Motivated by these difficulties, quasi-Newton RSQP (QN-RSQP) methods have been developed that replace $\mathbf{W}_z$ by a quasi-Newton approximation, which drops the convergence rate from quadratic to superlinear. The QN-RSQP method is summarized in Algorithm 3. In addition, the second derivative terms are dropped from the right-hand sides of the decision and adjoint steps, at the expense of a reduction from one-step to two-step superlinear convergence [8]. An important advantage of this variant of quasi-Newton method is that only two linearized forward/adjoint problems need to be solved at each iteration, as opposed to the m forward solves required by N-RSQP for constructing $\mathbf{A}_s^{-1}\mathbf{A}_d$ in $\mathbf{W}_z$ [19]. Furthermore, no second derivatives are required. Under assumptions on the existence and uniqueness of a local minimum, one can show that the combination of a sufficiently accurate line search and an appropriate quasi-Newton update guarantees a descent search direction and thus a globally convergent algorithm [12].

Algorithm 3. Quasi-Newton RSQP.

1: Choose $\mathbf{x}_s$, $\mathbf{x}_d$, $\boldsymbol{\lambda}$, $\mathbf{B}_z$
2: **loop**
3: Evaluate $\mathbf{c}$, $\mathbf{g}$, $\mathbf{A}$
4: $\mathbf{g}_z = \mathbf{g}_d + \mathbf{A}_d^T\boldsymbol{\lambda}$
5: **if** $\|\mathbf{g}_z\| \leq$ tol and $\|\mathbf{c}\| \leq$ tol **then**
6: Converged
7: **end if**
8: $\mathbf{B}_z\mathbf{p}_d = -\mathbf{g}_z$ solve for $\mathbf{p}_d$ (**Decision step**)
9: $\mathbf{A}_s\mathbf{p}_s = -\mathbf{A}_d\mathbf{p}_d - \mathbf{c}$ solve for $\mathbf{p}_s$ (**State step**)
10: $\mathbf{A}_s^T\boldsymbol{\lambda}_+ = -\mathbf{g}_s$ solve for $\boldsymbol{\lambda}_+$ (**Adjoint Step**)
11: $\mathbf{x}_+ = \mathbf{x} + \mathbf{p}_x$
12: Update $\mathbf{B}_z$
13: **end loop**

QN-RSQP has been parallelized efficiently for moderate numbers of decision variables [29]; the parallelism is fine-grained across the state and adjoint fields. Unfortunately, the number of iterations taken by quasi-Newton methods often increases as the number of decision variables grows,[4] rendering large-scale problems intractable. Additional processors will not help since the bottleneck is in the iteration dimension.

On the other hand, convergence of the nonlinear iterations of N-RSQP method can be independent of the number of decision variables m, particularly when these variables are mesh related. But unless an optimal $\mathbf{W}_z$ preconditioner can be used, the large number of forward/adjoint solves per iteration preclude its use, particularly on a parallel machine, where iterative methods for the forward problem must be used.

[4]For example, for the limiting case of a quadratic programming problem, the popular BFGS quasi-Newton method is equivalent to conjugate gradients, which scales with the square root of the condition number of the reduced Hessian.

However, there is a way to exploit the fast convergence of the Newton method and avoid solving the PDEs exactly, and this method is proposed in the next section. The basic idea is to solve the full space system (2.4) simultaneously for states, adjoints, and decision variables but invoke QN-RSQP as a preconditioner. Since it is just a preconditioner, we can avoid exact solution of the linearized state and adjoint equations in favor of applications of state and adjoint preconditioners.

3. LNKS method. The KKT optimality conditions (2.4) define a system of nonlinear equations. The Jacobian $\mathbf{K}$ of this system is termed the [illegible]. A Newton step on the optimality conditions is given by

$$\begin{bmatrix} \mathbf{W} & \mathbf{A}^T \\ \mathbf{A} & \mathbf{0} \end{bmatrix} \begin{Bmatrix} \mathbf{p}_x \\ \mathbf{p}_\lambda \end{Bmatrix} = - \begin{Bmatrix} \mathbf{g} + \mathbf{A}^T \boldsymbol{\lambda} \\ \mathbf{c} \end{Bmatrix} \quad (\text{or } \mathbf{K}\mathbf{v} = -\mathbf{h}), \tag{3.1}$$

where $\mathbf{p}_x$ and $\mathbf{p}_\lambda$ are the updates of $\mathbf{x}$ and $\boldsymbol{\lambda}$ from current to next iterations. Assuming sufficient smoothness, and that the initial guess is sufficiently close to a solution, Newton steps obtained by the above system will converge quadratically to a solution of the KKT system [17]. Thus, the forward solves required for reduced methods can be avoided by remaining in the full space of state and decision variables, since it is the reduction onto the decision space that necessitates the solves with $\mathbf{A}_s^{-1}$. Nevertheless, the full space approach presents difficulties too: a descent direction is not guaranteed, second derivatives are required, and the KKT system itself can be difficult to solve. The size of the KKT matrix is more than twice that of the forward problem, and it is expected to be very ill-conditioned. Ill-conditioning results not only from the ill-conditioning of the forward problem, but also from the different scales between first and second derivatives submatrices. Moreover, the system is indefinite; mixing negative and positive eigenvalues is known to slow down Krylov solvers. Therefore, a good preconditioner is essential to make the method efficient, and that is the main focus of Part I of this two-part article.

The LNKS method we present here uses a proper Newton method to solve the KKT optimality conditions. To compute the Newton step we solve the KKT system using an appropriate Krylov method. At the core of the algorithm lies the preconditioner $\mathbf{P}$ for the Krylov method, which in our case is an [illegible] version of the QN-RSQP algorithm. An outline of the local LNKS algorithm is given by Algorithm 4. In part II, we discuss and analyze globalization and inexactness aspects of LNKS.

Algorithm 4. Lagrange–Newton–Krylov–Schur.

1: Choose $\mathbf{x}$, $\boldsymbol{\lambda}$
2: **loop**
3: Check for convergence
4: Compute $\mathbf{c}$, $\mathbf{g}$, $\mathbf{A}$, $\mathbf{W}$
5: Solve $\mathbf{P}^{-1}\mathbf{K}\mathbf{v} = -\mathbf{P}^{-1}\mathbf{h}$
6: Update $\mathbf{x}_+ = \mathbf{x} + \mathbf{p}_x$
7: Update $\boldsymbol{\lambda}_+ = \boldsymbol{\lambda} + \mathbf{p}_\lambda$
8: **end loop**

This algorithm will produce the same steps taken by N-RSQP (in exact arithmetic, with exact solves and without globalization). It is easier to see how RSQP can be used to precondition LNKS if we rewrite the Newton step (3.1) in a block-partitioned

form:

$$\begin{bmatrix} \mathbf{W}_{ss} & \mathbf{W}_{sd} & \mathbf{A}_s^T \\ \mathbf{W}_{ds} & \mathbf{W}_{dd} & \mathbf{A}_d^T \\ \mathbf{A}_s & \mathbf{A}_d & \mathbf{0} \end{bmatrix} \begin{Bmatrix} \mathbf{p}_s \\ \mathbf{p}_d \\ \mathbf{p}_\lambda \end{Bmatrix} = - \begin{Bmatrix} \mathbf{g}_s + \mathbf{A}_s^T \boldsymbol{\lambda} \\ \mathbf{g}_d + \mathbf{A}_d^T \boldsymbol{\lambda} \\ \mathbf{c} \end{Bmatrix}. \tag{3.2}$$

RSQP is equivalent to a block-row elimination; given $\mathbf{p}_d$, solve the last block of equations for $\mathbf{p}_s$, then solve the first to find $\mathbf{p}_\lambda$, and finally solve the middle one for $\mathbf{p}_d$, the search direction for the decision variables. Therefore RSQP can be written as a particular block factorization of the KKT matrix:

$$\mathbf{K} = \begin{bmatrix} \mathbf{W}_{ss}\mathbf{A}_s^{-1} & \mathbf{0} & \mathbf{I} \\ \mathbf{W}_{ds}\mathbf{A}_s^{-1} & \mathbf{I} & \mathbf{A}_d^T\mathbf{A}_s^{-T} \\ \mathbf{I} & \mathbf{0} & \mathbf{0} \end{bmatrix} \begin{bmatrix} \mathbf{A}_s & \mathbf{A}_d & \mathbf{0} \\ \mathbf{0} & \mathbf{W}_z & \mathbf{0} \\ \mathbf{0} & \mathbf{W}_{sd} - \mathbf{W}_{ss}\mathbf{A}_s^{-1}\mathbf{A}_d & \mathbf{A}_s^T \end{bmatrix}. \tag{3.3}$$

Note that these factors are permutable to block triangular form (and therefore this is equivalent to a block-LU factorization) and that $\mathbf{W}_z$ is the Schur complement for $\mathbf{p}_d$.

This block factorization suggests a preconditioner created by replacing the reduced Hessian $\mathbf{W}_z$ with an approximation $\mathbf{B}_z$, for example a quasi-Newton approximation. However, we still require four forward solves per Krylov iteration. One way to restore the two solves per iteration of QN-RSQP is to, in addition, drop second-order information from the preconditioner, just as one does when going from N-RSQP to QN-RSQP. A further simplification of the preconditioner is to replace the exact forward operator $\mathbf{A}_s$ by an approximation $\tilde{\mathbf{A}}_s$, which could be any appropriate forward problem preconditioner. With these changes, $\tilde{\ }$ forward solves need to be performed at each inner (Krylov) iteration. Thus, the work per inner iteration becomes linear in the state and adjoint variable dimension (e.g., when $\tilde{\mathbf{A}}_s$ is a constant-fill domain decomposition approximation). Furthermore, when $\mathbf{B}_z$ is based on a limited-memory quasi-Newton update, the work per inner iteration is also linear in the decision variable dimension. Since all of the steps involved in an inner iteration not only require linear work but are also readily parallelized at the fine-grained level, we conclude that each inner (Krylov) iteration will execute with high parallel efficiency and scalability.

Scalability of the entire method additionally requires mesh-independence of both inner and outer iterations. Newton methods (unlike quasi-Newton) are often characterized by a number of iterations that is independent of problem size [1]. With an "optimal" forward preconditioner and a good $\mathbf{B}_z$ approximation, we can expect that the number of inner iterations is also insensitive to the problem size. Scalability with respect to both state and decision variables would then result. Several KKT preconditioning variations on this theme are discussed in the next subsection, and some choices for the reduced Hessian preconditioner $\mathbf{B}_z$ are presented in the following subsection.

3.1. Preconditioning variants for the KKT system. Below we present several preconditioners for the KKT matrix. They are based on the block-factorization of the KKT matrix (3.3) and are therefore indefinite matrices. To examine separately the effects of discarding the Hessian terms and approximating the forward solver, we define four different variations. The subscript denotes the number of the forward PDE solves per Krylov iteration, and a tilde mark on (top of) the preconditioner symbol means that a forward or adjoint solve is replaced by a single application of its preconditioner.

• Preconditioner $\mathbf{P}_4$ replaces $\mathbf{W}_z$ by $\mathbf{B}_z$ and retains the four exact linearized PDE solves per iteration. The preconditioner is

$$\mathbf{P}_4 = \begin{bmatrix} \mathbf{W}_{ss}\mathbf{A}_s^{-1} & \mathbf{0} & \mathbf{I} \\ \mathbf{W}_{ds}\mathbf{A}_s^{-1} & \mathbf{I} & \mathbf{A}_d^T\mathbf{A}_s^{-T} \\ \mathbf{I} & \mathbf{0} & \mathbf{0} \end{bmatrix} \begin{bmatrix} \mathbf{A}_s & \mathbf{A}_d & \mathbf{0} \\ \mathbf{0} & \mathbf{B}_z & \mathbf{0} \\ \mathbf{0} & \mathbf{W}_y & \mathbf{A}_s^T \end{bmatrix}, \tag{3.4}$$

and the preconditioned KKT matrix is

$$\mathbf{P}_4^{-1}\mathbf{K} = \begin{bmatrix} \mathbf{I} & \mathbf{0} & \mathbf{0} \\ \mathbf{0} & \mathbf{W}_z\mathbf{B}_z^{-1} & \mathbf{0} \\ \mathbf{0} & \mathbf{0} & \mathbf{I} \end{bmatrix}. \tag{3.5}$$

• Preconditioner $\mathbf{P}_2$ replaces $\mathbf{W}_z$ by $\mathbf{B}_z$ and discards all other Hessian terms, resulting in two exact linearized PDE solves per iteration. The preconditioner is

$$\mathbf{P}_2 = \begin{bmatrix} \mathbf{0} & \mathbf{0} & \mathbf{I} \\ \mathbf{0} & \mathbf{I} & \mathbf{A}_d^T\mathbf{A}_s^{-T} \\ \mathbf{I} & \mathbf{0} & \mathbf{0} \end{bmatrix} \begin{bmatrix} \mathbf{A}_s & \mathbf{A}_d & \mathbf{0} \\ \mathbf{0} & \mathbf{B}_z & \mathbf{0} \\ \mathbf{0} & \mathbf{0} & \mathbf{A}_s^T \end{bmatrix}, \tag{3.6}$$

and the preconditioned KKT matrix is

$$\mathbf{P}_2^{-1}\mathbf{K} = \begin{bmatrix} \mathbf{I} & \mathbf{0} & \mathbf{0} \\ \mathbf{W}_y^T\mathbf{A}_s^{-1} & \mathbf{W}_z\mathbf{B}_z^{-1} & \mathbf{0} \\ \mathbf{W}_{ss}\mathbf{A}_s^{-1} & \mathbf{W}_y\mathbf{B}_z^{-1} & \mathbf{I} \end{bmatrix}. \tag{3.7}$$

Note that the spectrum of the preconditioned KKT matrix is unaffected by dropping the second derivative terms.

• Preconditioner $\tilde{\mathbf{P}}_4$ replaces $\mathbf{W}_z$ by $\mathbf{B}_z$ and $\mathbf{A}_s$ by $\tilde{\mathbf{A}}_s$, and retains all other Hessian terms, resulting in four preconditioner applications but no forward/adjoint solves. The preconditioner is

$$\tilde{\mathbf{P}}_4 = \begin{bmatrix} \mathbf{W}_{ss}\tilde{\mathbf{A}}_s^{-1} & \mathbf{0} & \mathbf{I} \\ \mathbf{W}_{ds}\tilde{\mathbf{A}}_s^{-1} & \mathbf{I} & \mathbf{A}_d^T\tilde{\mathbf{A}}_s^{-T} \\ \mathbf{I} & \mathbf{0} & \mathbf{0} \end{bmatrix} \begin{bmatrix} \tilde{\mathbf{A}}_s & \mathbf{A}_d & \mathbf{0} \\ \mathbf{0} & \mathbf{B}_z & \mathbf{0} \\ \mathbf{0} & \tilde{\mathbf{W}}_y & \tilde{\mathbf{A}}_s^T \end{bmatrix}, \tag{3.8}$$

and the preconditioned KKT matrix is

$$\tilde{\mathbf{P}}_4^{-1}\mathbf{K} = \begin{bmatrix} \mathbf{I}_s & \mathbf{0} & \mathbf{0} \\ \mathbf{0} & \mathbf{W}_z\mathbf{B}_z^{-1} & \mathbf{0} \\ \mathbf{0} & \mathbf{0} & \mathbf{I}_s^T \end{bmatrix} + \begin{bmatrix} \mathbf{0} & \mathcal{O}(\mathbf{E}_s) & \mathbf{0} \\ \mathcal{O}(\mathbf{E}_s) & \mathcal{O}(\mathbf{E}_s) & \mathcal{O}(\mathbf{E}_s) \\ \mathcal{O}(\mathbf{E}_s) & \mathcal{O}(\mathbf{E}_s) & \mathbf{0} \end{bmatrix}, \tag{3.9}$$

where $\mathbf{E}_s := \mathbf{A}_s^{-1} - \tilde{\mathbf{A}}_s^{-1}$ and $\mathbf{I}_s := \mathbf{A}_s\tilde{\mathbf{A}}_s^{-1}$. The "cross-Hessian" $\tilde{\mathbf{W}}_y$ is given by (2.7) with the exception that the exact PDE solve $\mathbf{A}_s^{-1}$ is replaced by a preconditioner application $\tilde{\mathbf{A}}_s^{-1}$ in the definition of $\mathbf{Z}$. Clearly, $\mathbf{E}_s = \mathbf{0}$ and $\mathbf{I}_s = \mathbf{I}$ for exact forward PDE solves.

• Preconditioner $\tilde{\mathbf{P}}_2$ replaces $\mathbf{W}_z$ by $\mathbf{B}_z$ and $\mathbf{A}_s$ by $\tilde{\mathbf{A}}_s$, and drops all other Hessian terms, resulting in two preconditioner applications and no forward/adjoint solves. The preconditioner is

$$\tilde{\mathbf{P}}_2 = \begin{bmatrix} \mathbf{0} & \mathbf{0} & \mathbf{I} \\ \mathbf{0} & \mathbf{I} & \mathbf{A}_d^T\tilde{\mathbf{A}}_s^{-T} \\ \mathbf{I} & \mathbf{0} & \mathbf{0} \end{bmatrix} \begin{bmatrix} \tilde{\mathbf{A}}_s & \mathbf{A}_d & \mathbf{0} \\ \mathbf{0} & \mathbf{B}_z & \mathbf{0} \\ \mathbf{0} & \mathbf{0} & \tilde{\mathbf{A}}_s^T \end{bmatrix}, \tag{3.10}$$

and the preconditioned KKT matrix is

$$\tilde{\mathbf{P}}_2^{-1}\mathbf{K} = \begin{bmatrix} \mathbf{I}_s & \mathbf{0} & \mathbf{0} \\ \tilde{\mathbf{W}}_y^T & \mathbf{W}_z\mathbf{B}_z^{-1} & \mathbf{0} \\ \mathbf{W}_{ss}\tilde{\mathbf{A}}_s^{-1} & \tilde{\mathbf{W}}_y^T & \mathbf{I}_s^T \end{bmatrix} + \begin{bmatrix} \mathbf{0} & \mathcal{O}(\mathbf{E}_s) & \mathbf{0} \\ \mathbf{0} & \mathcal{O}(\mathbf{E}_s) & \mathcal{O}(\mathbf{E}_s) \\ \mathbf{0} & \mathbf{0} & \mathbf{0} \end{bmatrix}. \tag{3.11}$$

We review some basic properties of the Krylov methods that will allow us to understand the effectiveness of the preconditioners. The performance of a Krylov method depends highly on the preconditioned operator spectrum [22, 38]. In most Krylov methods the number of iterations required to obtain the solution is at most equal to the number of distinct eigenvalues (in exact arithmetic). When solving $\mathbf{Kv} = -\mathbf{h}$ such methods satisfy the following relation for the residual at the ith iteration:

$$\mathbf{r}_i = \text{span}\left\{\mathbf{r}_0 + \mathbf{K}\mathbf{r}_0 + \mathbf{K}^2\mathbf{r}_0 + \cdots + \mathbf{K}^i\mathbf{r}_0\right\} = \psi(\mathbf{K})\mathbf{r}_0, \quad \psi \in \mathcal{P}_i.$$

Here $\mathbf{v}_0$ is the initial guess, $\mathbf{r}$ is defined as $\mathbf{r} = \mathbf{h} + \mathbf{K}\mathbf{v}$, $\mathbf{r}_0 = \mathbf{h} + \mathbf{K}\mathbf{v}_0$, and $\mathcal{P}_i$ is the space of monic polynomials of degree at most i. Minimum residual methods like MINRES and GMRES determine a polynomial ψ so that[5]

$$\|\mathbf{r}_i\| = \min_{\psi \in \mathcal{P}_i} \|\psi(\mathbf{K})\mathbf{r}_0\|.$$

If $\mathbf{K}$ is diagonalizable (with spectrum $\mathcal{S}(\mathbf{K})$ and $\mathbf{X}$ the matrix or its eigenvectors), then[6]

$$\frac{\|\mathbf{r}_i\|}{\|\mathbf{r}_0\|} \leq \text{cond}(\mathbf{X}) \min_{\lambda \in \mathcal{S}(\mathbf{K})} |\psi(\lambda)|. \tag{3.12}$$

Additionally, if the spectrum lies on the positive real axis, it can be shown that

$$\frac{\|\mathbf{r}_i\|}{\|\mathbf{r}_0\|} \leq \text{cond}(\mathbf{X}) \frac{\lambda_{\max}}{\lambda_{\min}}. \tag{3.13}$$

From (3.12) we can see why clustering the eigenvalues is important. Indeed, if the eigenvalues are clustered, then the solution polynomial in the right-hand side of (3.12) can be approximated by the zeros of a low-degree polynomial (resulting in fewer Krylov iterations). When $\mathbf{K}$ is normal (unitarily diagonalizable) then $\text{cond}(\mathbf{X}) = 1$; in this case the estimates (3.12) and (3.13) are known to be sharp [22].

The preconditioned KKT matrix $\mathbf{P}_4^{-1}\mathbf{K}$ is a block-diagonal matrix with two unit eigenvalues and the m eigenvalues of the preconditioned reduced Hessian. It is immediate that GMRES takes $\mathcal{O}(\text{cond}(\mathbf{B}_z^{-1}\mathbf{W}_z))$ or at most $m + 2$ steps to converge for preconditioner $\mathbf{P}_4$. This is similar to the complexity estimates for a Krylov-based solution of the $\mathbf{B}_z$-preconditioned reduced Hessian in N-RSQP. Preconditioner $\mathbf{P}_2$ has the same effect on the spectrum of the KKT matrix, but the preconditioned KKT system is no longer a normal operator. Yet, if $\mathbf{P}_2^{-1}\mathbf{K}$ is diagonalizable and its eigenvector matrix well conditioned, relation (3.13) is still a good indicator of the effectiveness of the preconditioner.

A more efficient approach, of course, is to replace the exact forward operators $\mathbf{A}_s$ by their forward preconditioners $\tilde{\mathbf{A}}_s$, as in $\tilde{\mathbf{P}}_4$ or $\tilde{\mathbf{P}}_2$. In this case, the preconditioned KKT matrix assumes a more complicated structure. We write $\tilde{\mathbf{P}}_4^{-1}\mathbf{K}$ as the sum

[5] Throughout this paper we use the vector 2-norm for norms and condition numbers.

[6] Here λ is temporary overloaded to denote an eigenvalue of $\mathbf{K}$.

of two matrices; the second matrix in this sum includes terms that approach $\mathbf{0}$ as the forward preconditioner improves. The spectrum of the first matrix in (3.9) is given by $\mathcal{S}_n = \mathcal{S}(\mathbf{B}_z^{-1}\mathbf{W}_z) \cup \mathcal{S}(\tilde{\mathbf{A}}_s^{-1}\mathbf{A}_s)$. If $\tilde{\mathbf{A}}_s^{-1}\mathbf{A}_s$ is normal, then by the Bauer–Fike theorem [21] the eigenvalues are not sensitive to small KKT matrix perturbations and $\mathcal{S}(\tilde{\mathbf{P}}_4^{-1}\mathbf{K}) \cong \mathcal{S}_n$. Hence, a good preconditioner for the forward problem would bring the spectrum of $\tilde{\mathbf{P}}_4^{-1}\mathbf{K}$ close to the spectrum of $\mathbf{P}_4^{-1}\mathbf{K}$. Thus, we would expect a similar iteration count to N-RSQP, but at a much reduced cost per iteration—since the PDE solves would be replaced by preconditioner applications. For preconditioner $\tilde{\mathbf{P}}_2$, the left matrix in preconditioner (3.11) is not normal and may have ill-conditioned eigenvalues. In our numerical experiments, however, the number of Krylov iterations was unaffected by switching from $\tilde{\mathbf{P}}_4$ to $\tilde{\mathbf{P}}_2$.

Finally, we comment on our choice of a Krylov method for solving the symmetric indefinite KKT system (3.3) that has been preconditioned with any of the four preconditioners described above. The most popular method for large symmetric indefinite systems is the MINRES method. However, MINRES requires positive definite preconditioners, and the KKT preconditioners defined above are indefinite. Indefinite preconditioners are allowed in the quasi-minimum residual (QMR) method [18]. The version commonly used is the transpose-free QMR algorithm, which is designed for general nonsymmetric problems and requires two matrix-vector multiplications per Krylov iteration. In our implementation we use another variant, described in [18], that exploits symmetry and uses only one matrix-vector multiplication per iteration.

3.2. Preconditioners for the reduced Hessian. A very important component of the LNKS preconditioners is an approximation to the inverse of the reduced Hessian. In the preceding sections we suggested that a quasi-Newton approximation be used in place of the exact reduced Hessian $\mathbf{W}_z$, in the spirit of using QN-RSQP as a preconditioner. Below, we elaborate upon this choice and describe a two-step stationary iterative preconditioner that we use either stand-alone or to initialize the quasi-Newton preconditioner.

Limited memory quasi-Newton updates. Quasi-Newton methods are popular methods for approximating the reduced Hessian matrix in constrained optimization. Thus, they are natural candidates to precondition the exact reduced Hessian. In particular, we use the Broyden–Fletcher–Goldberg–Shanno (BFGS) update [32, section 8.1]. At each outer iteration we compute

$$\mathbf{s} = \mathbf{p}_d^{(+)} - \mathbf{p}_d,$$
$$\mathbf{y} = \mathbf{g}_z^{(+)} - \mathbf{g}_z$$

and update the approximation to the inverse of the reduced Hessian by

$$\mathbf{B}_+^{-1} = (I - \omega \mathbf{y}\mathbf{s}^T)^T \mathbf{B}^{-1} (I - \omega \mathbf{y}\mathbf{s}^T) + \omega \mathbf{s}\mathbf{s}^T, \qquad \omega = \frac{1}{\mathbf{y}^T\mathbf{s}}. \tag{3.14}$$

If we encounter an iterate that has $\mathbf{y}^T\mathbf{s} \leq \kappa\|\mathbf{y}\|$ we skip the update. $\mathbf{B}^{-1}$ is dense; thus for large decision-space problems, storing or operating with this matrix can be expensive or even impossible. Furthermore, applying the dense $\mathbf{B}^{-1}$ to a vector in parallel involves significant all-to-all communication and may be too expensive for problems that require large numbers of processors. Thus, we have chosen a limited memory variant of BFGS (L-BFGS), which uses a limited number of vectors to approximate the inverse of the reduced Hessian. When updating we do not compute (3.14) but instead we simply store $\mathbf{s}$ and $\mathbf{y}$. Then the action of $\mathbf{B}^{-1}$ on a vector $\mathbf{x}$ is given in

ALGORITHM 5. LIMITED MEMORY BFGS.

$\mathbf{q} = \mathbf{x}$, and $l =$ number of stored vectors
for $i = k-1, k-2, \ldots, k-l$ **do**
  $\alpha_i = \omega_i \mathbf{s}_i^T \mathbf{q}$
  $\mathbf{q} = \mathbf{q} - \alpha_i \mathbf{y}_i$
end for
$\mathbf{z} = \mathbf{B}_{z,0}^{-1} \mathbf{q}$
for $i = k-l, k-l+1, \ldots, k-1$ **do**
  $\beta = \omega_i \mathbf{y}_i^T \mathbf{z}$
  $\mathbf{z} = \mathbf{z} + \mathbf{s}_i(\alpha_i - \beta)$
end for

Algorithm 5. Analysis and details of the convergence properties of this algorithm can be found in [32, sections 9.1–9.2]. We generate the initial inverse reduced Hessian approximation, $\mathbf{B}_{z,0}$, using the stationary iterative preconditioner presented below.

Two-step stationary method. As an initialization for the L-BFGS approximation above, which can also be used as a stand-alone preconditioner, we turn to stationary iterative methods. Such methods provide us with a constant preconditioner as required by most Krylov methods, while effecting an approximate solution of the reduced Hessian system. To guarantee convergence, the most popular methods (such as Jacobi and SOR) require the iteration matrix to have spectral radius less than one, which is difficult to guarantee in the general case. Furthermore, most stationary iterative methods require some kind of splitting, which is not convenient for matrix-free treatment of operators like the reduced Hessian. A method that does not have the above restrictions is a two-step stationary iterative method, first presented by Frankel in 1950 [3, section 5.2]. The method is suitable for positive-definite matrices but requires an accurate estimate of the minimum and maximum eigenvalues. The preconditioner based on this method can be arbitrarily effective, depending on the number of iterations L it is carried to. If $\lambda_1 \leq \lambda_m$ are estimates for the extreme eigenvalues of $\tilde{\mathbf{W}}_z$, then the application of the preconditioner to a vector $\mathbf{d}_{\text{in}}$ is given by Algorithm 6. Step 4 requires the action of the reduced Hessian on a vector. To avoid exact forward solves, we use the approximate reduced Hessian $\tilde{\mathbf{W}}_z$ instead of $\mathbf{W}_z$. We obtain $\tilde{\mathbf{W}}_z$ from (2.11) if we replace the linearized forward PDE operators $\mathbf{A}_s^{-1}$ and $\mathbf{A}_s^{-T}$ with their preconditioners $\tilde{\mathbf{A}}_s^{-1}$ and $\tilde{\mathbf{A}}_s^{-T}$. Like CG, the method's convergence rate depends on the square root of the condition number of the (approximate) reduced Hessian. It parallelizes well because it does not require any inner products, and because in our context the matrix-vector products require just two forward preconditioner applications. To obtain estimates of the extremal eigenvalues, we use a few iterations of the Lanczos method (once per Newton iteration).

Other possibilities for reduced Hessian preconditioning. In addition to the quasi-Newton and two-step stationary iterative preconditioners we use, there are several other possibilities, which we comment on below.

- [illegible]. Incomplete factorizations are popular and robust preconditioners, but an assembled matrix (modulo some exceptions for structured grids) is required. Not only is the reduced Hessian usually prohibitive to assemble (for large-scale PDE optimization problems), but it is in general dense and thus impossible to store for a large number of decision variables. An incomplete factorization would be feasible only if the exact solves are replaced by the forward preconditioner and if some kind of sparsity is enforced (perhaps via element-by-element computations and

ALGORITHM 6. TWO-STEP STATIONARY ITERATIVE REDUCED SPACE PRECONDITIONER.

1: $\rho = \frac{1-\lambda_1/\lambda_n}{1+\lambda_1/\lambda_n}$, $\alpha = \frac{2}{1+(1-\rho^2)^{1/2}}$, $\beta_0 = \frac{1}{\lambda_1+\lambda_n}$, $\beta = \frac{2\alpha}{\lambda_1+\lambda_n}$,
2: $\mathbf{r} = -\mathbf{d}_{\text{in}}$, $\mathbf{d}_0 = \mathbf{0}$, $\mathbf{d}_1 = \beta_0\mathbf{r}$
3: **for** $i = 1 \cdots L$ **do**
4: $\quad \mathbf{r} = \tilde{\mathbf{W}}_z\mathbf{d}_1 - \mathbf{d}_{\text{in}}$
5: $\quad \mathbf{d} = \alpha\mathbf{d}_1 + (1-\alpha)\mathbf{d}_0 - \beta\mathbf{r}$
6: $\quad \mathbf{d}_0 = \mathbf{d}_1$, $\mathbf{d}_1 = \mathbf{d}$
7: **end for**

threshold-ILU methods).

• [illegible]. SPAI techniques are attractive since they require just matrix-vector multiplications and a given sparsity pattern. In [14] an analysis for CFD-related Schur complements shows that this method is promising.

• [illegible]. In [31] two different reduced Hessian preconditioners are presented, one based on a state-Schur complement factorization and the second on power series expansions. It is assumed that a (nonsingular approximation) $\tilde{\mathbf{W}}^{-1}$ is available. The basic component of these preconditioners is the application of $\mathbf{Z}^T\tilde{\mathbf{W}}^{-1}\mathbf{Z}$ on a vector. We did not test this method because in our problems $\mathbf{W}$ has thousands of zero eigenvalues and it is not clear how to construct an approximation to $\mathbf{W}^{-1}$. If $\mathbf{W}_{dd}$ is nonsingular, then a block-Jacobi-ILU technique could be used to approximate $\mathbf{W}_z^{-1}$ with $\mathbf{W}_{dd}^{-1}$ (or an approximation $\tilde{\mathbf{W}}_{dd}^{-1}$).

• [illegible]. Another option is to take a few CG iterations in the reduced space at each preconditioner application. Since we want to avoid solving the forward problem exactly, we replace $\mathbf{A}_s^{-1}$ with $\tilde{\mathbf{A}}_s^{-1}$ in (2.11). We experimented with this approach but found that full convergence of CG was needed to avoid loss of orthogonality for the Krylov vectors. This slowed down the method significantly. We have experimented also with flexible GMRES for the KKT solver, but the nice properties of a symmetric Krylov solver are lost and the algorithm was slow to converge.

• [illegible]. For PDE-constrained optimization problems one may be able to derive an approximate representation of the infinite-dimensional reduced Hessian. A discretization of this expression can then be used to precondition the reduced Hessian, e.g., [2].

Notwithstanding the above alternatives, we feel the choice of a limited memory quasi-Newton approximation, initialized by Frankel's two-step stationary iterative method, strikes the best balance between effectiveness, generality, and parallel scalability. In the next section we present numerical experiments that demonstrate the effectiveness of the stationary preconditioner. To isolate the effects of the (inner) Krylov–Schur solver on LNKS, we study problems with linear constraints and quadratic objective functions. For this class of problems, the KKT system is linear, Newton's method trivially requires just one step to converge, and globalization is not an issue. In part II of this article, we discuss how the limited memory quasi-Newton scheme can be used to safeguard the Newton step.

4. Numerical results. The LNKS method has been tested on two Stokes optimal flow control problems that give rise to quadratic programming problems. Both problems include the three-dimensional (3D) Stokes equations as PDE constraints, and Dirichlet boundary conditions on some portion of the boundary as decision variables. They differ in the choice of objective function: the first is a matching velocity

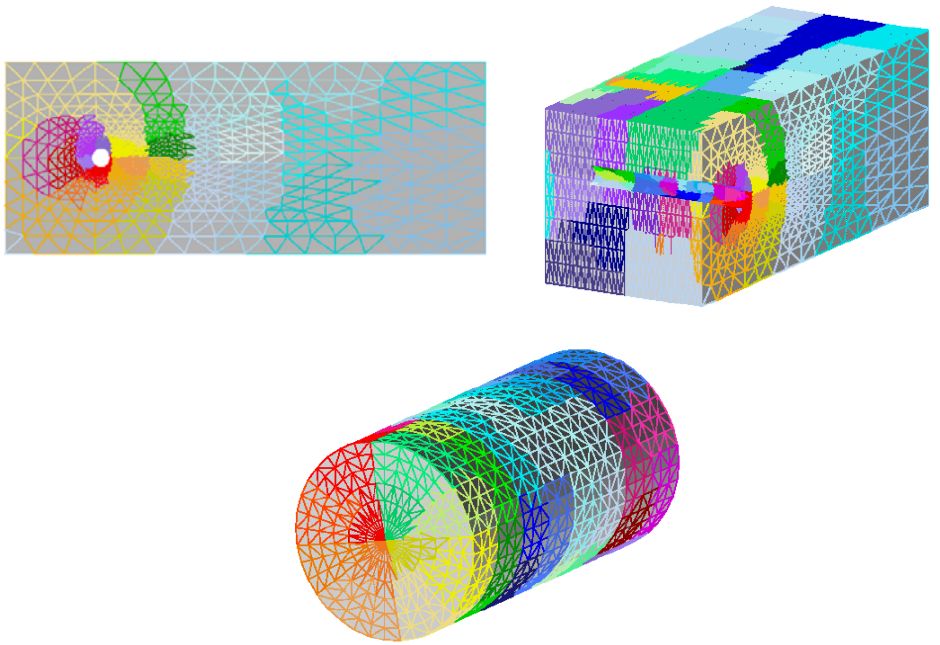

FIG. 1. *This figure depicts the (partitioned) computational meshes used in our numerical experiments. We have solved two different optimal flow control problems: that of Poiseuille flow in a pipe (bottom) and that of a flow around a cylinder embedded inside a rectangular duct (top). Both flows are interior flow problems with nonslip conditions everywhere except the outflow boundary. In the case of the Poiseuille flow the decision variables are the boundary conditions on the circumferential walls of the pipe. In the cylinder problem the decision variables are the downstream cylinder surface boundary conditions.*

problem for a Poiseuille flow, and the second is an energy dissipation minimization problem for a flow around a cylinder. Below, we define the two test problems, discuss a forward preconditioner (which as we have seen plays a key role in the effectiveness of the KKT preconditioner), and provide numerical results for both problems.

4.1. Optimal control of Stokes flows. An optimal flow control problem can be stated as follows:

$$\min_{\boldsymbol{u},\boldsymbol{u}_d,p} \mathcal{J}(\boldsymbol{u},\boldsymbol{u}_d,p) \tag{4.1}$$

$$\begin{aligned} \text{subject to} \quad & -\nu\nabla\cdot(\nabla\boldsymbol{u}+\nabla\boldsymbol{u}^T)+\nabla p=\boldsymbol{b} \text{ in } \Omega, \\ & \nabla\cdot\boldsymbol{u}=0 \quad \text{in } \Omega, \\ & \boldsymbol{u}=\boldsymbol{u}^* \quad \text{on } \Gamma_u, \\ & \boldsymbol{u}=\boldsymbol{u}_d \quad \text{on } \Gamma_d, \\ & -p\,\boldsymbol{n}+\nu(\nabla\boldsymbol{u}+\nabla\boldsymbol{u}^T)\boldsymbol{n}=\boldsymbol{0} \quad \text{on } \Gamma_N. \end{aligned} \tag{4.2}$$

Here, $\boldsymbol{u}$ is the fluid velocity, p the pressure, ν a nondimensional viscosity, $\boldsymbol{b}$ a body force, and $\boldsymbol{n}$ the outward unit normal vector on the boundary. The first problem is a velocity matching optimal control problem. A quadratic velocity profile is prescribed on the inflow boundary Γ_u, and we specify a traction-free outflow boundary Γ_N. The velocities $\boldsymbol{u}_d$, defined on Γ_d, are the decision variables. In this example, $\boldsymbol{u}^*$ is taken as a Poiseuille flow inside a pipe, and the decision variables correspond to boundary velocities on the circumferential surface of the pipe (Figure 1). The objective functional

is given by

$$\mathcal{J}(\boldsymbol{u}, \boldsymbol{u}_d, p) = \frac{1}{2}\int_\Omega (\boldsymbol{u}^* - \boldsymbol{u})^2 d\Omega + \frac{\rho}{2}\int_{\Gamma_d} \boldsymbol{u}_d^2 d\Omega,$$

where ρ penalizes the "cost" of the controls. Notice that the size of ρ effects the condition number of the reduced Hessian. Here we keep ρ constant and equal to 1.

In the second problem we control the flow around a cylinder that is anchored inside a rectangular duct. A quadratic velocity profile is used as an inflow Dirichlet condition and we prescribe a traction-free outflow. The decision variables are defined to be the velocities on the downstream portion of the cylinder surface. In this problem the objective functional is given by

$$\mathcal{J}(\boldsymbol{u}, \boldsymbol{u}_d, p) = \frac{1}{2}\int_\Omega |\nabla \boldsymbol{u} + \nabla \boldsymbol{u}^T|^2 d\Omega + \frac{\rho}{2}\int_{\Gamma_d} \boldsymbol{u}_d^2 d\Omega.$$

In this problem we also choose $\rho = 1$.

The Stokes equations are discretized by the Galerkin finite element method, using tetrahedral Taylor–Hood elements [23]. We implemented the reduced-space algorithm as well as the LNKS method with the four different preconditioners. Our code is based on the PETSc library [4, 5, 6] and makes use of PETSc parallel domain-decomposition preconditioners for the approximate forward solves. We use the symmetric QMR for both the KKT and Stokes linear systems. The two flow control problems have quadratic objective functions and linear constraints and thus Newton's method takes only one iteration to converge. Hence, it is not possible to build a quasi-Newton approximation (as described above) to use within the KKT preconditioner (but see [30] for other options). Instead, we use the two-step stationary algorithm to precondition the reduced Hessian.

4.2. The Stokes forward preconditioner. It is evident that one of the two major components of the LNKS method is the forward solver preconditioner (the choice of which is, of course, problem-dependent). The Stokes problem, in algebraic form, is given by

$$\begin{bmatrix} \mathbf{V} & \mathbf{P}^T \\ \mathbf{P} & \mathbf{0} \end{bmatrix} \begin{Bmatrix} \mathbf{u} \\ \mathbf{p} \end{Bmatrix} = \begin{Bmatrix} \mathbf{b}_u \\ \mathbf{b}_p \end{Bmatrix}. \tag{4.3}$$

In our earlier numerical experiments (results are reported in [9, 10]) we used the following preconditioner:

$$\begin{bmatrix} \mathbf{V}^{-1} & \mathbf{0} \\ \mathbf{0} & \mathbf{M}^{-1} \end{bmatrix}. \tag{4.4}$$

PETSc's block-Jacobi preconditioners with local ILU(0) were used to provide a domain decomposition approximation of $\mathbf{V}^{-1}$ and $\mathbf{M}^{-1}$, which are the discrete Laplacian and discrete pressure "mass" matrices, respectively. We found the performance of this preconditioner somewhat unsatisfactory, especially when it was part of the KKT preconditioner. For this reason we have switched to a preconditioner that is based on the following exact factorization of the inverse of (4.3),

$$\begin{bmatrix} \mathbf{I} & -\mathbf{V}^{-1}\mathbf{P}^T \\ \mathbf{0} & \mathbf{I} \end{bmatrix} \begin{bmatrix} \mathbf{V}^{-1} & \mathbf{0} \\ \mathbf{0} & \mathbf{S}^{-1} \end{bmatrix} \begin{bmatrix} \mathbf{I} & \mathbf{0} \\ -\mathbf{P}\mathbf{V}^{-1} & \mathbf{I} \end{bmatrix}, \tag{4.5}$$

where $\mathbf{S} := -\mathbf{P}\mathbf{V}^{-1}\mathbf{P}^T$ is the Schur complement for the pressure. Based on this factorization, the Stokes preconditioner is defined by replacing the exact solves $\mathbf{V}^{-1}$ with domain decomposition approximations $\tilde{\mathbf{V}}^{-1}$. For the pressure Schur complement block, we use the two-step stationary method described in Algorithm 6. Performance statistics are presented in Table 4.1. We can see that the factorization-based preconditioner reduces significantly solution times compared to the earlier block-Jacobi variant. Nevertheless, the efficiency of the new preconditioner is still mesh-dependent. It is known that block-Jacobi-ILU preconditioners require work that is superlinear in problem size. This can be overcome with an additive Schwarz domain-decomposition preconditioner, with generous overlap and a coarse grid component [13].

4.3. Numerical results for Poiseuille optimal flow control problem. Results for the Poiseuille flow control problem are presented in Table 4.2. We have solved for five different problem sizes on up to 256 processors in order to assess the performance and scalability of the LNKS algorithm. Our first and most important finding is that the fastest variant is LNKS-II (which uses $\tilde{\mathbf{P}}_2$ as a preconditioner; i.e., it performs two approximate forward solves per KKT iteration), which is approximately 30 [illegible] faster than QN-RSQP. Another observation is that LNKS-I (which uses $\mathbf{P}_2$, i.e., two exact forward solves), despite its discarding second-order terms and approximating the reduced Hessian, is very effective in reducing the number of iterations—note the difference in KKT iterations between LNK (unpreconditioned) and LNKS-I for each problem instance. Indeed, the mesh-independence of LNKS-I iterations suggests that the two-step stationary preconditioner is very effective for the reduced Hessian,[7] and that if a forward preconditioner that is spectrally equivalent to the forward operator is available, one can expect mesh-independence for the entire KKT preconditioner. Even if a suboptimal forward preconditioner is used (witnessed

[7] Also, the weak increase in quasi-Newton iterations suggests that the reduced Hessian for this problem is well-conditioned.

TABLE 4.2

Performance of LNKS and comparisons with QN-RSQP for the Poiseuille flow problem as a function of increasing number of state and decision variables and number of processors. Here, QN-RSQP *is quasi-Newton reduced-space SQP;* LNK *is the full-space Lagrange–Newton–Krylov method with no preconditioning for the KKT system;* LNKS-I *uses* $\mathbf{P}_2$ *KKT preconditioner—which requires two Stokes solves—combined with the two-step stationary preconditioner for the reduced Hessian* (3) *iterations);* LNKS-II *uses the* $\tilde{\mathbf{P}}_2$ *preconditioner with the same reduced Hessian preconditioner;* LNKS-III *is the same as* LNKS-II *except that no reduced Hessian preconditioning is used, i.e.,* $\mathbf{B}_z = \mathbf{I}$*;* QN iter *reports the number of quasi-Newton iterations (the number of outer iterations for the LNKS variants is just one, since this is a quadratic optimization problem);* KKT iter *is the number of Krylov (symmetric QMR) iterations for the KKT system to converge; finally* time *is wall-clock time in seconds on a Cray T3E-900. Both QN-RSQP and LNKS methods are converged so that* $\|\mathbf{c}\|/\|\mathbf{c}_0\| \leq 1 \times 10^{-6}$ *and* $\|\mathbf{g}\|/\|\mathbf{g}_0\| \leq 1 \times 10^{-6}$ *in all cases but the unpreconditioned KKT case, in which the Krylov method was terminated when the number of iterations exceeded* 500,000.

	LNKS-III	—	2,830	3,735

by the growth in KKT iterations with increasing problem size for LNKS-II), one can trade off increasing KKT iterations for reduced work per iteration to realize a significant reduction in overall work. For example, in the largest problem size case, we give up a factor of 24 in KKT iterations, but we gain a factor of 4.5 in execution time.

The number of unpreconditioned KKT iterations illustrates the severe ill-conditioning of the KKT matrix (even for a problem as simple as controlling a Poiseuille flow). The comparison between LNKS-I and QN-RSQP simply illustrates the better convergence properties of a true Newton, as opposed to quasi-Newton, method. The comparison between LNKS-II and LNKS-III reveals the significance of a good preconditioner for the reduced space. When the two-step preconditioner is used, LNKS runs approximately twice as quickly as with no preconditioning (and requires four times fewer iterations).

The scalability of LNKS is studied by tracking the execution time for LNKS as

TABLE 4.3

*Isogranular scalability results for LNKS-*I. PEs *is the number of processors;* max Mflop/s/PE *is the per-processor maximum (across PEs) sustained Mflop/s;* Mflop/s/PE *is the average sustained Mflop/s per processor. A comparison between the second and third columns is an indication of load imbalance. Implementation efficiency* (η_i) *is based on Mflop rate; optimization work efficiency* (η_a) *is based on number of optimization iterations; forward solver work efficiency* (η_f) *is based on the number of forward solver Krylov iterations* psc3 *(Table* 4.1*); overall efficiency* (η) *is based on execution time;* (η') *is an estimate of the overall efficiency given by* $\eta' = \eta_f \times \eta_i \times \eta_a$.

PEs	Max Mflop/s/PE	Mflop/s/PE	η_i	η_a	η_f	η	η'
16	76.5	52.0	1.00	1.00	1.00	1.00	1.00
32	74.8	51.1	0.98	1.04	0.71	0.84	0.72
64	74.9	49.2	0.96	0.93	0.48	0.41	0.43
128	71.2	47.8	0.91	0.93	0.31	0.26	0.26
256	69.8	45.1	0.87	0.84	0.26	0.18	0.19

the problem size and number of processors increase proportionately. The problem size per processor is held (relatively) constant, and execution time increases from about 8 minutes for 16 processors (65K states, 7K decisions) to about 30 minutes for 256 processors (960K states, 40K decisions). One may conclude that the method is not scalable. However, a glance at the KKT iterations column reveals that the number of optimization iterations when using the LNKS-I variant (so that the effect of inexact forward problem solves is factored out) is largely independent of problem size, and thus the work efficiency of LNKS should be very high. Furthermore, the Mflop rate drops (probably due to a poorer-quality mesh partition) only slowly as the problem size increases, suggesting good implementation efficiency. What, then, accounts for the increase in execution time?

Table 4.3 provides the answer. Following [25], the overall parallel efficiency η (based on execution time) has been decomposed into an implementation efficiency η_i (based on Mflop/s and which represents costs like latency, load imbalance, and interprocessor communication), and a work efficiency η_a (based on the number of optimization iterations), and the forward solver work efficiency η_f (based on Table 4.1). Whereas the optimization algorithm and the implementation are reasonably scalable (84% and 87% efficiency over a 16-fold increase in number of processors), the forward solver's parallel efficiency drops to near 26% for the largest problem size. The last column, η', gives an estimate of what the overall efficiency would be if we did not use the time measurement but instead set $\eta' = \eta_i * \eta_a * \eta_f$. The agreement between the last two columns makes apparent that the overall efficiency of the algorithm depends greatly upon the forward solver, which is essentially a question of forward preconditioning. The parallel inefficiency of the forward preconditioner can be addressed by switching to a more scalable approximation than the one we are currently using (nonoverlapping local ILU(0) block-Jacobi). With a better forward preconditioner, we anticipate good overall scalability.

Timings and flop measurements were performed by using PETSc logging routines, which were validated with native performance analyzers on the T3E and Origin platforms. At first glance CPU performance appears to be mediocre—less than 10% of the peak machine performance. Recall, however, that unstructured grid computations are not cache coherent and therefore the bottleneck is in memory bandwidth and not in the CPU flop rate.

. . . . 1. We do not advocate the use of exact forward solves within the LNKS context. If one can afford exact solves, then one should iterate in the reduced space.

If both exact forward solves and Hessian terms are retained, then 4 solves per KKT–Krylov iteration are required; iterating with N-RSQP requires only 2 solves per $\mathbf{W}_z$-Krylov iteration. Even when the Hessian terms are dropped (which is equivalent to retaining only $\mathbf{g}_z$ on the right-hand side of the decision equation (in Algorithm 2)), the positive definiteness of the reduced Hessian permits the use of CG in the reduced space, which seems more natural (in conjunction with a good reduced Hessian preconditioner) than iterating in the full space.

On the other hand, an order-of-magnitude argument can be used (assuming $\mathbf{A}_s$ is symmetric) to illustrate why it should be advantageous to stay in the full space when approximate solves are used. If the condition number of the preconditioned reduced Hessian is given by μ_m/μ_1 and the condition number of the preconditioned forward operator is given by λ_n/λ_1, the complexity for inverting the exact reduced Hessian is $\mathcal{O}(\sqrt{\mu_m/\mu_1} \times \sqrt{\lambda_n/\lambda_1} \times N)$, since the number of expected iterations is $\mathcal{O}(\sqrt{\mu_m/\mu_1})$ and for each iteration we need to solve the forward problem. (Recall that N is the number of states plus the number of decision variables.) Using the fact that (3.9) is block-diagonal we see that the complexity for inverting the preconditioned KKT system is given by $\mathcal{O}(\sqrt{\max(\mu_m, \lambda_n)/\min(\mu_1, \lambda_1)} \times N)$. If, in addition, the spectra of the preconditioned forward and reduced Hessian operators overlap, then a reduced method has an effective condition number that is approximately the square of the KKT system's condition number. (It is exactly equal to the square of the condition number of the reduced Hessian, if $\lambda_n = \mu_m$ and $\lambda_1 = \mu_1$.)

. . . 2. We have tested the four different preconditioners for the LNKS algorithm. Here we report results only for preconditioners $\mathbf{P}_2$ and $\tilde{\mathbf{P}}_2$. In our numerical experiments preconditioners $\mathbf{P}_4$ and $\mathbf{P}_2$ took approximately the same number of KKT iterations to converge. Since $\mathbf{P}_2$ requires two solves fewer, it is twice as fast as $\mathbf{P}_4$ and for this reason we report results only for $\mathbf{P}_2$. The same trend is evident when comparing the preconditioners $\tilde{\mathbf{P}}_4$ and $\tilde{\mathbf{P}}_2$ although the difference is less pronounced.

Numerical results for cylinder optimal flow control problem. In order to further test the KKT solver we performed additional numerical experiments for the flow around a cylinder. Figure 2 compares the controlled and the uncontrolled flow. Optimization drives the downstream surface of the cylinder to become a sink for the flow. As we can see in Figure 2, the locally controlled flow (around the cylinder) appears to be more irregular than the uncontrolled one. Yet the overall dissipation is reduced. The results can be explained if we consider the dissipation function as the sum along both the upstream and the downstream part of the duct. Flow suction results in reduced mass flow (i.e., velocity) on the downstream portion of the duct and thus minimizes dissipation losses.

Table 4.4 presents scalability results for this problem. We observe similar performance to the Poiseuille flow. Using exact second derivatives accelerates the algorithm by a factor of two. Switching to the inexact preconditioners makes the method another 6 (or more) times faster. For the 256 processor problem (941,685 states and 11,817 controls) quasi-Newton RSQP required 38 hours, whereas the LNKS algorithm with the $\tilde{\mathbf{P}}_2$ preconditioner required only 3 hours, almost 13 times faster. Notice that the fastest LNKS variant for this example (LNKS-III) does not precondition in the reduced space. Although LNKS-II takes fewer iterations to converge, the cost per KKT Krylov iteration is increased due to load imbalance—the Poiseuille flow problem has more uniform distribution of decision variables across processors.

The CPU performance has dropped compared to the Poiseuille flow results, but not significantly, as we can see in Table 4.5. The overall efficiency appears to be gov-

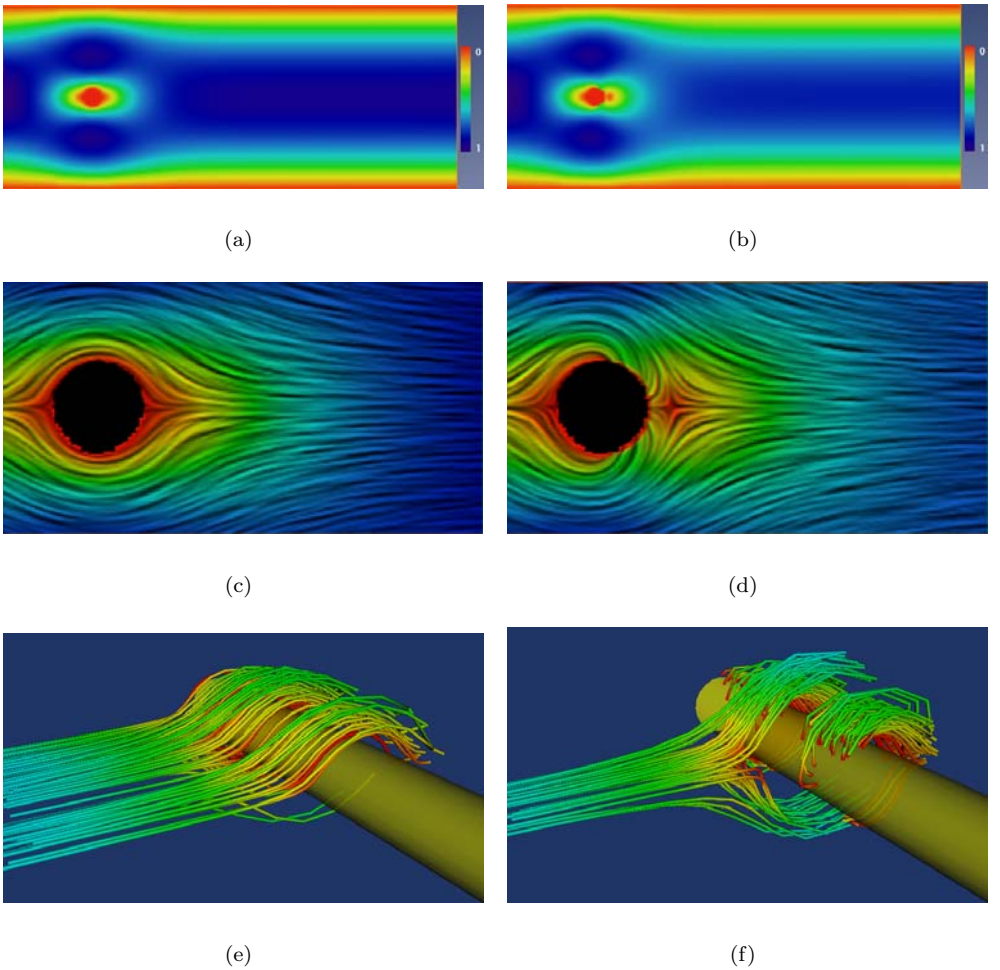

FIG. 2. *Optimal boundary control problem of a steady incompressible Stokes flow around a cylinder. The objective is to minimize the energy dissipation. The controls are injection points (velocity Dirichlet boundary conditions) on the downstream portion of the cylinder surface. The left column is the uncontrolled flow and the right column is the controlled one. Images* (a) *and* (b) *depict a color map of the velocity magnitude on a cross section at the middle of the duct. Comparing image* (a) *with* (b) *notice the lighter gray throughout the downstream region. This indicates smaller velocities and thus reduced dissipation. Images* (c) *and* (d) *show a closeup snapshot of the flow around the cylinder. The suction Dirichlet conditions (set by the optimizer) are clearly visible. Finally, the last two images show stream tubes of the flow around the cylinder. Although the flow appears to be more irregular (locally) for the controlled flow, overall the dissipation is reduced.*

erned by the forward problem preconditioner; however, there is a slight disagreement between the last two columns. An explanation can be found in η_a, which drops faster than in the Poiseuille flow case. The reason is that the faster LNKS variant for the cylinder example does not precondition in the reduced space.

Our performance analyses are based on isogranular scaling. More common are fixed-problem size scalability analyses. Although these kinds of tests are very good indicators of the performance of an algorithm, they do not capture the important issue

TABLE 4.4

Performance and scalability of the LNKS algorithm for the control of a 3D flow around a cylinder. Here the objective function is the energy dissipation and the constraints are the Stokes equations. QN-RSQP *is quasi-Newton reduced-space SQP;* LNK *is the full-space Lagrange–Newton–Krylov method with no preconditioning;* LNKS-I *uses the* $\mathbf{P}_2$ *preconditioner combined with the two-step stationary preconditioner for the reduced Hessian;* LNKS-II *uses the* $\tilde{\mathbf{P}}_2$ *preconditioner with the same reduced Hessian preconditioning;* LNKS-III *is the same as LNKS-*II *but the reduced Hessian is not preconditioned;* time *is wall-clock time in seconds on a T3E-*900*. of the dependence of number of Krylov iterations on the number of unknowns (mesh size). For completeness, we present a standard fixed-problem-size scalability analysis for the (117,048 states, 2,925 controls) cylinder problem for 4 different partitions and across two different platforms: a T3E-900 and an Origin 2000. Our experiments showed Origin to have superior performance, which is surprising since the T3E has a much faster interconnect. The fact that the Origin has bigger cache size is a possible explanation. Another observation is that the effectiveness of the LNKS algorithm degrades with the number of processors. The overall efficiency drops to 71% for the T3E and to 83% for the Origin. The work efficiency remains constant but part of it is hidden in η because the time per preconditioner application increases. Recall that the condition number of a linear system preconditioned with block-Jacobi is approximately $\mathcal{O}((pn)^{1/6})$ and therefore the flop count increases with the number of processors p. Our forward solver implementation uses such a preconditioner and this is why we observe the decrease in overall efficiency. We have not conducted any measurements on latency and bandwidth dependencies on the number of processors. The inferior performance of the T3E is somewhat surprising but this would probably

TABLE 4.5

Isogranular scalability results for LNKS-III ($\tilde{\mathbf{P}}_2$ KKT preconditioner with no preconditioning for the reduced Hessian). The Mflop rates given are sustained Mflop per processor; the first column is maximum across processors and the second column lists the average rate. The difference is an indication of imbalance. Efficiency (η_i) is based on Mflop rate; work efficiency (η_a) is based on number of optimization iterations; forward solver work efficiency (η_f) is based on Table 4.1; overall efficiency (η) is based on execution time; η' is an estimate of the overall efficiency given by $\eta' = \eta_f \times \eta_i \times \eta_a$.

change had we increased the number of processors further.[8]

4.4. LNKS parallel scalability. In this section, we provide arguments for verifying the scalability of the LNKS method, with respect to increasing problem size and number of processors. For scalability, we require that the work increases near-linearly with problem size (work scalability) and that it parallelizes well. Let us examine the major components.

Formation of the KKT matrix-vector product. For PDE-constrained optimization, the Hessian of the Lagrangian function and the Jacobian of the constraints are usually sparse with structure dictated by the mesh (particularly when the decision variables are mesh-related). Thus, formation of the matrix-vector product at each QMR iteration is linear in both state and decision variables, and parallelizes well due to a high computation-to-communication ratio and minimal sequential bottlenecks characteristic of parallel matvecs for PDE-type problems.

[8] At the time these experiments were performed, the 256 partition on the Origin was not available.

Application of the KKT preconditioner. The main work involved is application of the PDE preconditioner $\tilde{\mathbf{A}}_s$ and its transpose, and "inversion" of an approximation to the reduced Hessian, $\mathbf{B}_z$. We can often make use of scalable, parallel PDE preconditioners that require $\mathcal{O}(n)$ work to apply (as in various domain decomposition preconditioners or multigrid for elliptic problems). The stationary preconditioner for the reduced Hessian involves only matrix-vector multiplications and Jacobian preconditioner applications, and therefore requires linear work and parallelizes well. The same can be said about the limited-memory quasi-Newton update. Therefore, we conclude that application of the KKT preconditioner requires linear work and parallelizes well.

The Krylov (inner) iteration. As argued above, with an "optimal" state preconditioner and a good $\mathbf{B}_z$ approximation, we can expect that the number of inner (Krylov) iterations will be relatively insensitive to the problem size.

The Lagrange–Newton (outer) iteration. The number of outer (Newton) iterations is often independent of problem size for PDE-type problems, and the PDE-constrained optimization problems we have solved exhibit this type of behavior as well. For an extended discussion and results from numerical experiments on the outer iteration we refer the reader to part II of this article [11].

This combination of linear work per Krylov iteration, weak dependence of Krylov iterations on problem size, and independence of Lagrange–Newton iterations on problem size suggests a method that scales well with increasing problem size and number of processors.

5. Conclusions. The main new idea offered by the LNKS algorithm for PDE-constrained optimization problems is the use of a reduced space quasi-Newton method, not as a driver, but rather as a preconditioner for the KKT system. The preconditioning exploits the PDE structure of the constraints by permitting approximate PDE solves at each KKT iteration along with preconditioning of the reduced Hessian. We argue that in order to achieve algorithmic scalability, a bona fide Newton method is necessary. LNKS requires second derivatives (but only in the form of matrix-vector multiplications, which allows for a directionally differenced approximation) and the adjoint operator of the forward problem, beyond the information required by a (forward sensitivity-based) quasi-Newton RSQP method. The most important result is that the problem of devising a good preconditioner for the KKT system is reduced to that of finding a good preconditioner for the forward PDE operator and the reduced Hessian operator.

The problems we have chosen to investigate are relatively simple, yet provide a reasonable testbed for algorithmic tuning and experimentation. The results obtained thus far are very encouraging: the full space LNKS method with reduced space preconditioning is by a factor of 10–30 faster than a popular reduced space method. We expect that other problems will exhibit similar behavior. The method can be parallelized efficiently, and work efficiency can be achieved provided a good forward preconditioner is available. Scalability then results from the combination of these two.

In part II, we extend our discussion to nonlinear PDE constraints and examine issues of robustness and globalization of the LNKS method.

Acknowledgments. We thank the PETSc development group at Argonne National Lab for making this work possible. We also thank Jonathan Shewchuk for providing the meshing and partitioning routines Pyramid and Slice. Finally, we thank David Keyes, David Young, and the other members of the TAOS project—Roscoe Bartlett, Larry Biegler, and Andreas Wächter—for their useful comments.

PARALLEL LAGRANGE–NEWTON–KRYLOV–SCHUR METHODS FOR PDE-CONSTRAINED OPTIMIZATION. PART II: THE LAGRANGE–NEWTON SOLVER AND ITS APPLICATION TO OPTIMAL CONTROL OF STEADY VISCOUS FLOWS*

GEORGE BIROS† AND OMAR GHATTAS‡

Abstract. In part I of this article, we proposed a Lagrange–Newton–Krylov–Schur (LNKS) method for the solution of optimization problems that are constrained by partial differential equations. LNKS uses Krylov iterations to solve the linearized Karush–Kuhn–Tucker system of optimality conditions in the full space of states, adjoints, and decision variables, but invokes a preconditioner inspired by reduced space sequential quadratic programming (SQP) methods. The discussion in part I focused on the (inner, linear) Krylov solver and preconditioner. In part II, we discuss the (outer, nonlinear) Lagrange–Newton solver and address globalization, robustness, and efficiency issues, including line search methods, safeguarding Newton with quasi-Newton steps, parameter continuation, and inexact Newton ideas. We test the full LNKS method on several large-scale three-dimensional configurations of a problem of optimal boundary control of incompressible Navier–Stokes flow with a dissipation objective functional. Results of numerical experiments on up to 256 Cray T3E-900 processors demonstrate very good scalability of the new method. Moreover, LNKS is an order of magnitude faster than quasi-Newton reduced SQP, and we are able to solve previously intractable problems of up to 800,000 state and 5,000 decision variables at about 5 times the cost of a single forward flow solution.

1. Introduction.

In part I of this two-part article [3] we proposed a Newton–Krylov method for solution of the optimality system stemming from the optimization of systems governed by partial differential equations (PDEs). We concentrated our discussion on the inner iteration: the solution of the linear system associated with a Newton step on the Karush–Kuhn–Tucker (KKT) optimality conditions. The algorithm is based on a Krylov solver combined with a family of Schur-type preconditioners that are equivalent to an approximate quasi-Newton reduced SQP (QN-RSQP) step. We termed the method [illegible] (LNKS), a concatenation of [illegible] for the outer iteration and [illegible] for the inner iteration. We also provided theoretical and numerical evidence that these preconditioners work very well by considering several linearly-constrained quadratic optimization problems, namely those involving boundary control of Stokes flows with flow-matching

and dissipation-type objectives.

In part II, we present algorithmic components of the LNKS method related to the (outer) Lagrange–Newton solver, including such globalization strategies as line search, quasi-Newton safeguarding, and parameter continuation, and inexactness in the inner linear solver and its interaction with the line search. We assess performance of the LNKS method on several more stringent test problems that contain many features of the most challenging PDE-constrained optimization problems: three-dimensional unstructured meshes, multicomponent coupling, large problem size, nonlinearity, and ill-conditioning. The underlying problem class is optimal control of a viscous incompressible fluid by boundary velocities, which is of both theoretical and industrial interest.

Following part I, we refer to the unknown PDE field quantities as the [illegible]; the PDE constraints as the [illegible]; solution of the PDE constraints as the [illegible]; the inverse, design, or control variables as the [illegible]; and the problem of determining the optimal values of the inverse, design, or control variables as the [illegible].

The paper is organized as follows. In section 2 we briefly review the problem formulation. We then discuss algorithmic issues related to Lagrange–Newton methods and in particular globalization methodologies. We give details on three globalization techniques to enhance robustness in the LNKS method: line search, safeguarding LNKS steps with (approximate) QN-RSQP steps, and continuation. We also discuss inexact Newton methods and how they interact with a merit function line search. In section 3 we present the full globalized LNKS algorithm. Section 4 formulates the optimal control problem for the Navier–Stokes equations and presents results for a Poiseuille flow, a flow around a cylinder, and a flow around a Boeing 707 wing.

[illegible]. We use boldface characters to denote vector-valued functions and vector-valued function spaces. We use roman characters to denote discretized quantities and italics for their continuous counterparts. For example, $\boldsymbol{u}$ will be the continuous velocity field and $\mathbf{u}$ will be its discretization. Greek letters are overloaded and whether we refer to the discretization or the continuous fields should be clear from context. We also use + as a subscript or superscript to denote variable updates within an iterative algorithm.

2. Globalization and inexactness of the LNKS method. In this section we consider strategies for globalizing the Newton iteration at the heart of the LNKS method, as well as opportunities for introducing inexactness in the solution for a Newton step. Let us revisit the constrained optimization problem formulation,

$$\min_{\mathbf{x}\in\mathbb{R}^N} f(\mathbf{x}) \quad \text{subject to } \mathbf{c}(\mathbf{x}) = \mathbf{0}, \tag{2.1}$$

where $\mathbf{x} \in \mathbb{R}^N$ are the optimization variables, $f : \mathbb{R}^N \to \mathbb{R}$ is the objective function, and $\mathbf{c} : \mathbb{R}^N \to \mathbb{R}^n$ are the constraints. In our context these constraints are discretizations of the state equations. The Lagrangian,

$$\mathcal{L}(\mathbf{x}, \boldsymbol{\lambda}) := f(\mathbf{x}) + \boldsymbol{\lambda}^T \mathbf{c}(\mathbf{x}), \tag{2.2}$$

is used to transform the constrained optimization problem into a system of nonlinear equations, the first-order optimality conditions:

$$\begin{Bmatrix} \partial_x \mathcal{L} \\ \partial_\lambda \mathcal{L} \end{Bmatrix} (\mathbf{x}, \boldsymbol{\lambda}) = \begin{Bmatrix} \mathbf{g}(\mathbf{x}) + \mathbf{A}(\mathbf{x})^T \boldsymbol{\lambda} \\ \mathbf{c}(\mathbf{x}) \end{Bmatrix} = \mathbf{0} \quad (\text{or } \mathbf{h}(\mathbf{q}) = \mathbf{0}), \tag{2.3}$$

where $\mathbf{q} := \{\mathbf{x}, \boldsymbol{\lambda}\}^T$ represents the optimization variables and Lagrange multipliers. As in part I, $\mathbf{g}$ is the gradient of the objective function, $\mathbf{A}$ the Jacobian of the constraints, and $\mathbf{W}$ the Hessian of the Lagrangian. Consistent with part I, we think of $\mathbf{x}$, $\mathbf{g}$, $\mathbf{A}$, and $\mathbf{W}$ as being partitioned into state (indicated by an s subscript) and decision variable (d subscript) components. We use Newton's method to solve for $\mathbf{x}$ and $\boldsymbol{\lambda}$. A Newton step on the optimality conditions is given by

$$\begin{bmatrix} \mathbf{W} & \mathbf{A}^T \\ \mathbf{A} & \mathbf{0} \end{bmatrix} \begin{Bmatrix} \mathbf{p}_x \\ \mathbf{p}_\lambda \end{Bmatrix} = - \begin{Bmatrix} \mathbf{g} + \mathbf{A}^T \boldsymbol{\lambda} \\ \mathbf{c} \end{Bmatrix} \quad (\text{or } \mathbf{K}\mathbf{v} = -\mathbf{h}), \tag{2.4}$$

where $\mathbf{p}_x$ and $\mathbf{p}_\lambda$ are the updates of $\mathbf{x}$ and $\boldsymbol{\lambda}$ from the current to the next iteration. In part I we reviewed a popular algorithm for solving for a KKT point, RSQP and in particular its quasi-Newton variant (Algorithm 3 in part I). Although RSQP is efficient and robust, it often does not scale very well with the number of decision variables. It avoids solving (2.4) directly by reduction onto the decision space and in doing so requires repeated solution of linearized forward and adjoint problems. Thus, it can be very inefficient for large-scale PDE-constrained optimization. We argued that a better approach would be to remain in the full space of states, decisions, and multipliers by using a Krylov method to solve (2.4). For most problems, however, the KKT matrix is notoriously ill-conditioned. Motivated by this, part I proposed a family of efficient preconditioners. The key idea was to use an approximate RSQP method as a preconditioner. We showed that RSQP can be viewed as a block-LU factorization in which the reduced Hessian $\mathbf{W}_z$ is the Schur complement for the decision variables. It has the property that the only systems that have to be solved involve the reduced Hessian and the Jacobian of the state equations (and its transpose). Therefore, by using a limited memory quasi-Newton approximation of the reduced Hessian, and by replacing the linearized PDE solves by applications of their preconditioners, we obtain a method that requires no PDE solves within a Krylov iteration, yet maintains Newton convergence in the outer iteration. A sketch of the LNKS method for solving the KKT system (2.4) is given by Algorithm 1, in which $\mathbf{P}^{-1}$ is an application of the approximate RSQP preconditioner.

Algorithm 1. Lagrange–Newton–Krylov–Schur (LNKS).

1: Choose $\mathbf{x}$, $\boldsymbol{\lambda}$
2: **loop**
3: Check for convergence
4: Compute $\mathbf{c}$, $\mathbf{g}$, $\mathbf{A}$, $\mathbf{W}$
5: Solve $\mathbf{P}^{-1}\mathbf{K}\mathbf{v} = \mathbf{P}^{-1}\mathbf{h}$ (Newton step)
6: Update $\mathbf{x} = \mathbf{x} + \mathbf{p}_x$
7: Update $\boldsymbol{\lambda} = \boldsymbol{\lambda} + \mathbf{p}_\lambda$
8: **end loop**

Nevertheless, there are two issues that should be addressed before we can claim a fast and robust general-purpose algorithm. The first is whether the LNKS algorithm can be made convergent for any initial guess $(\mathbf{x}_0, \boldsymbol{\lambda}_0)$, and the second is whether we can utilize inexactness in the inner iterations to further accelerate LNKS. Within this framework we examine line search algorithms, reverting to a QN-RSQP step when a LNKS steps fails to make progress, continuation, and inexact Newton methods.

2.1. Line search methods. Algorithm 1 is only locally convergent. Popular methods to globalize Newton's method include line search and trust region

algorithms. Details can be found in [21]. Trust region methods, especially in combination with RSQP and inexact Newton methods, have been extended successfully to PDE-constrained optimization [14, 17, 19]. Global convergence proofs for these methods can be found in [5]. Trust region methods are often based on the Steihaug modification of the conjugate gradient (CG) algorithm [24]. However, this approach works well only with positive definite systems. It is not obvious how to use trust regions with an indefinite Krylov solver (which is required for the KKT system) and thus we have opted for a line search algorithm to help globalize LNKS.

An important component of a line search algorithm is the choice of a merit function: a scalar function (of the optimization variables) that monitors the progress of the algorithm. In contrast with unconstrained optimization, the choice of a merit function is not straightforward, since we are trying to balance minimization of the objective function with feasibility of the constraints. Two common choices are the l_1 merit function,

$$\phi(\mathbf{x}) := f + \rho_\phi \|\mathbf{c}\|_1, \tag{2.5}$$

and the augmented Lagrangian merit function,

$$\phi(\mathbf{x}, \boldsymbol{\lambda}) := f + \mathbf{c}^T \boldsymbol{\lambda} + \frac{\rho_\phi}{2} \mathbf{c}^T \mathbf{c}. \tag{2.6}$$

The scalar ρ_ϕ is the [illegible]—a weight chosen to balance minimization of the objective function with minimization of the residuals of the constraints. Both functions are "exact" provided the penalty parameter is large enough. By [illegible] we mean that if $\mathbf{x}^*$ is a minimizer for (2.1), then it is also an (unconstrained) minimizer for the merit function. A crucial property of a merit function is that it should accept unit step lengths close to a solution in order to allow full Newton steps and thus quadratic convergence. The l_1 merit function suffers from the "Maratos" effect; that is, sometimes it rejects good steps and slows down the algorithm. The augmented Lagrangian merit function does not exhibit such behavior but its drawback is that it requires accurate estimates of the Lagrange multipliers.

The outline of a general line search method is given in Algorithm 2. To simplify notation we use $\phi(\alpha)$ for $\phi(\mathbf{q} + \alpha\mathbf{v})$ and $\phi(0)$ for $\phi(\mathbf{q})$, and likewise for the derivative $\nabla\phi$. The algorithm used to compute the search direction $\mathbf{v}$ is intentionally left unspecified. All that matter to ensure global convergence are the properties of the merit function and the properties of $\mathbf{v}$. Step 3 in Algorithm 2 lists three conditions on $\mathbf{v}$: descent direction, sufficient angle, and sufficient step length size [9]. The condition in step 4 is often called the Armijo condition. If ϕ is bounded and has a minimum, and if $\mathbf{v}$ is bounded, Algorithm 2 is guaranteed to converge to a local minimum [20]. We use a simple backtracking line search, with a factor α of 0.5. The search is bounded so that $\alpha_{\min} \leq \alpha \leq 1$. As mentioned before, the choice of the penalty parameter has a great effect on the performance of the algorithm.

For a step computed by quasi-Newton RSQP (Algorithm 3 of part I), the update for the l_1-merit function is relatively straightforward. The directional derivative for a search direction $\mathbf{p}_x$ is given by

$$\nabla\phi^T \mathbf{p}_x = \mathbf{g}^T \mathbf{p}_x - \rho_\phi \|\mathbf{c}\|_1. \tag{2.7}$$

If $\mathbf{W}_z$ is positive definite, it can be shown that by setting

$$\rho_\phi = \|\boldsymbol{\lambda}\|_\infty + \delta, \quad \delta > 0, \tag{2.8}$$

ALGORITHM 2. LINE SEARCH.

1: Choose $\mathbf{q}$, $\delta_A > 0$ and κ_1, κ_2 arbitrary constants (strictly positive)
2: **while** Not converged **do**
3: Compute search direction $\mathbf{v}$ so that
$\mathbf{v}^T \nabla\phi(0) < 0$
$|\mathbf{v}^T \nabla\phi(0)| \geq \kappa_1 \|\mathbf{v}\| \, \|\nabla\phi(0)\|$ angle condition
$\|\mathbf{v}\| \geq \kappa_2 \|\nabla\phi(0)\|$ length condition
4: Compute α such that $\phi(\alpha) \leq \phi(0) + \alpha\delta_A \mathbf{v}^T \nabla\phi(0)$ Armijo condition
5: Set $\mathbf{q} = \mathbf{q} + \alpha\mathbf{v}$
6: **end while**

we obtain a descent direction. In our numerical experiments we have used the l_1-merit function with QN-RSQP and the augmented Lagrangian with LNKS. The l_1-merit function performed reasonably well. However, we did observe the Maratos effect. To overcome this obstacle we have implemented a second-order correction, in which an extra normal step toward feasibility is taken [21, p. 570].

When an augmented Lagrangian merit function is used, the penalty parameter should be chosen differently. The directional derivative of the augmented Lagrangian merit function is given by

$$\nabla\phi^T \mathbf{v} = (\mathbf{g} + \mathbf{A}^T \boldsymbol{\lambda} + \rho_\phi \mathbf{A}^T \mathbf{c})^T \mathbf{p}_x + \mathbf{c}^T \mathbf{p}_\lambda. \tag{2.9}$$

Lagrange multipliers slightly complicate the algorithm since we have to compute $\mathbf{p}_\lambda$. $\boldsymbol{\lambda}$ may be considered a function of $\mathbf{x}$ [4, 8] or an independent variable [5, 23] or may be simply ignored by setting $\mathbf{p}_\lambda = 0$ [25]. In LNKS we solve for $\boldsymbol{\lambda}$ simultaneously with $\mathbf{x}$ and it is natural to use the step $\mathbf{p}_\lambda$. On the other hand, RSQP uses $\boldsymbol{\lambda} = -\mathbf{A}_s^{-T} \mathbf{g}_s$ and it seems natural to consider $\boldsymbol{\lambda}$ a function of $\mathbf{x}$. In this case the last term in (2.9) is given by

$$\mathbf{c}^T \mathbf{p}_\lambda = \mathbf{c}^T (\partial_x \boldsymbol{\lambda}) \mathbf{p}_x,$$

where

$$\partial_x \boldsymbol{\lambda} := -\mathbf{A}_s^{-T} [\mathbf{W}_{ss} \ \mathbf{W}_{sd}].$$

(However, this formula cannot be used with the QN-RSQP method of Algorithm 3, part I, since second derivatives are not computed.) If we set

$$\rho_\phi = \frac{(\mathbf{g} + \mathbf{A}^T \boldsymbol{\lambda}) \mathbf{p}_x + \mathbf{c}^T \mathbf{p}_\lambda + \delta}{\mathbf{c}^T \mathbf{A} \mathbf{p}_x}, \quad \delta > 0, \tag{2.10}$$

we obtain a descent direction.

2.2. Combining QN-RSQP with LNKS. For iterates far from the solution, relying solely on a line search algorithm to globalize LNKS is not sufficient, since the Newton step is likely to be of poor quality. Usually global convergence can be shown if the reduced (and not full) Hessian $\mathbf{W}_z$ is positive definite. If $\mathbf{W}_z$ is positive definite (and assuming the system (2.4) is solved exactly), then the resulting step $\mathbf{v}$ satisfies the Armijo sufficient decrease criterion. Far from the minimum, however, $\mathbf{W}_z$ can be singular or indefinite. On the other hand, certain quasi-Newton methods, like BFGS, are preferable for iterates far from the solution since they can guarantee positive definiteness. For this reason (and for preconditioning purposes) LNKS does maintain a BFGS approximation for $\mathbf{W}_z$: if a computed Newton search direction fails to satisfy the Armijo criterion, we discard it and revert to a QN-RSQP step.

2.3. Continuation. One of the standard assumptions in global convergence proofs is the full rank of the constraint Jacobian for all iterates. In LNKS, this translates to the nonsingularity of the state Jacobian $\mathbf{A}_s$, i.e., the PDE state operator. For highly nonlinear PDEs such as the Navier–Stokes equations, this can be an unrealistic assumption. Even if $\mathbf{A}_s$ is nonsingular, severe ill-conditioning may cause both QN-RSQP and LNKS algorithms to stall. Indeed, in our numerical experiments, the most difficult computation (for iterates far from the solution) was converging the $\mathbf{A}_s$-related linear solves. Krylov solvers often reached their maximum iteration counts without a significant decrease in the linear system residual. As a result, the iterates were of poor quality and the algorithm stagnated as it was impossible to compute a search direction, be it from QN-RSQP or LNKS.

One remedy for this problem is parameter continuation. This idea (in its simplest form) works when we can express the nonlinearity of the problem as a function of a single scalar parameter. Continuation is suitable for problems in which the underlying PDE has a parameter that scales (and thus determines the effects of) nonlinear terms. Examples of such parameters are the Reynolds number for viscous flow, the Mach number for compressible flow, the Weissenberg number for viscoelastic flow, load magnitude for buckling problems, and the Hartman number in magnetohydrodynamics. In problems where such a parameter cannot be found, an alternative approach is to use a pseudotransient continuation scheme [18], a homotopy method [1], or mesh-size continuation.

Continuation allows uphill steps to be taken (unlike monotone line search methods) and generates good initial guesses, not only for the optimization variables, but also for the penalty parameter in the merit function. An important feature of the continuation algorithm is that under certain conditions it globalizes trivially.[1] If the continuation step places the next iterate outside the attraction basin of the Newton method, then we simply reduce the continuation step size. In principle, the method globalizes LNKS without the need to use line search or some other globalization strategy. Nevertheless, taking a large number of continuation steps significantly slows down the algorithm. Experience from our numerical experiments suggests that the best strategy for globalizing LNKS is a combination of line searching, reverting to quasi-Newton steps, and continuation.

2.4. Inexact Newton method. Before we discuss the inexact Newton method in the context of LNKS, we briefly summarize a few results for a general nonlinear system of equations. Assume we want to solve $\mathbf{h}(\mathbf{q}) = \mathbf{0}$. Further assume the following: (1) $\mathbf{h}$ and $\mathbf{K} := \partial_q \mathbf{h}$ are sufficiently smooth in a neighborhood of a solution $\mathbf{q}^*$; (2) at each iteration an inexact Newton method computes a step $\mathbf{v}$ that satisfies

$$\|\mathbf{K}\mathbf{v} + \mathbf{h}\| \leq \eta_N \|\mathbf{h}\|, \tag{2.11}$$

where η_N is often called the [illegible]. It can be shown that if $\eta_N < 1$, then $\mathbf{q} \to \mathbf{q}^*$ linearly; if $\eta_N \to 0$, then $\mathbf{q} \to \mathbf{q}^*$ superlinearly; and if $\eta_N = \mathcal{O}(\|\mathbf{h}\|)$, then we recover the quadratic convergence rate of an exact Newton method. The forcing term is usually given by

$$\eta_N = \frac{\|\mathbf{h}_{(+)} - \mathbf{h} - \mathbf{K}\mathbf{v}\|}{\|\mathbf{h}\|}. \tag{2.12}$$

Other alternatives exist (for details see [7]).

[1] This is true only when the initial problem is a well-posed quadratic programming problem (like Stokes) and all iterates on the continuation path are far from turning and bifurcation points.

The extension of inexact Newton methods to unconstrained optimization problems is relatively easy. The extension becomes more complicated for problems with constraints. In [14] global convergence proofs are given for a trust region RSQP-based algorithm, but to our knowledge such an approach has not been extended to full space algorithms. Close to a KKT point the theory for Newton's method applies and one can use the analysis presented in [6] to show that the inexact version of the LNKS algorithm converges. However, the line search we are using is not based on the residual of the KKT equations but instead on the merit function discussed in the previous session. It is not obvious that an inexact Newton step (which simply reduces $\|\mathbf{h}\|$) will satisfy the merit function criteria. [illegible] Our analysis is based on the augmented Lagrangian merit function.[2] We assume that, locally, $\mathbf{A}$ and $\mathbf{K}$ are nonsingular and uniformly bounded. We define $\kappa_1 := \max \|\mathbf{K}^{-1}(\mathbf{q})\|$ for $\mathbf{q}$ in the neighborhood of the solution $\mathbf{q}^*$. We also define $\mathbf{v}$ as the exact solution of the (linearized) KKT system so that

$$\mathbf{K}\mathbf{v} + \mathbf{h} = \mathbf{0}, \tag{2.13}$$

and $\tilde{\mathbf{v}}$ the approximate solution so that

$$\mathbf{K}\tilde{\mathbf{v}} + \mathbf{h} = \mathbf{r}. \tag{2.14}$$

We also have $\|\mathbf{r}\| = \eta\|\mathbf{h}\|$, $0 < \eta \leq \eta_N$, from the inexact Newton stopping criterion (2.11). By (2.3) we get that $\|\mathbf{h}\|^2 = \|\mathbf{g} + \mathbf{A}^T\boldsymbol{\lambda}\|^2 + \|\mathbf{c}\|^2$ and since $\mathbf{A}$ is uniformly bounded, there is constant κ_2 such that

$$\|\mathbf{A}^T\mathbf{c}\| \leq \kappa_2\|\mathbf{h}\|. \tag{2.15}$$

Besides the assumptions on $\mathbf{K}$ and $\mathbf{A}$ we also assume the following: (1) ρ_ϕ is sufficiently large so that the merit function is exact and $\|\nabla\phi\| \geq \kappa_3\|\mathbf{h}\|$ for some constant κ_3; (2) $\mathbf{v}$ is a descent direction and satisfies the angle and length conditions as well as the Armijo condition. From the latter it is immediate that $\mathbf{v}$ satisfies the Cauchy fraction condition:[3]

$$|\nabla\phi^T\mathbf{v}| \geq 2\kappa_4\|\nabla\phi\|^2. \tag{2.16}$$

We will show that if η is small enough, then the approximate step $\tilde{\mathbf{v}}$ satisfies the Cauchy fraction, angle, and length conditions. Then, we will use a theorem from [20] to conclude that the Armijo condition is satisfied with unit step lengths. Therefore if $\eta = \mathcal{O}(\|\mathbf{h}\|)$, quadratic convergence is preserved.

From (2.13) and (2.14) we have

$$\nabla\phi^T\tilde{\mathbf{v}} = \nabla\phi^T\mathbf{v} + \nabla\phi^T\mathbf{K}^{-1}\mathbf{r},$$

and thus by (2.16) we get

$$|\nabla\phi^T\tilde{\mathbf{v}}| \geq 2\kappa_4\|\nabla\phi\|^2 - |\nabla\phi^T\mathbf{K}^{-1}\mathbf{r}|.$$

Therefore, to satisfy the Cauchy fraction condition

$$|\nabla\phi^T\tilde{\mathbf{v}}| \geq \kappa_4\|\nabla\phi\|^2, \tag{2.17}$$

[2] For brevity we drop the subscript from ϕ_L and just use the symbol ϕ for the augmented Lagrangian merit function.

[3] The Cauchy step is a steepest descent step for the merit function.

we need to show that

$$|\nabla\phi^T\mathbf{K}^{-1}\mathbf{r}| \le \kappa_4\|\nabla\phi\|^2. \tag{2.18}$$

The gradient of the merit function is given by

$$\nabla\phi = \mathbf{h} + \rho_\phi \begin{Bmatrix} \mathbf{A}^T\mathbf{c} \\ \mathbf{0} \end{Bmatrix},$$

and thus

$$\begin{aligned} |\nabla\phi^T\mathbf{K}^{-1}\mathbf{r}| &= \left|\mathbf{h}^T\mathbf{K}^{-1}\mathbf{r} + \rho_\phi \begin{Bmatrix} \mathbf{A}^T\mathbf{c} \\ \mathbf{0} \end{Bmatrix}^T \mathbf{K}^{-1}\mathbf{r}\right| \\ &\le \kappa_1(\|\mathbf{h}\|\,\|\mathbf{r}\| + \rho_\phi\|\mathbf{A}^T\mathbf{c}\|\,\|\mathbf{r}\|) \\ &\le \kappa_1\eta(\|\mathbf{h}\|^2 + \rho_\phi\|\mathbf{A}^T\mathbf{c}\|\,\|\mathbf{h}\|) \\ &\le \kappa_1\eta(1+\rho_\phi\kappa_2)\|\mathbf{h}\|^2 \\ &\le \kappa_1\eta(1+\rho_\phi\kappa_2)\frac{\|\nabla\phi\|^2}{\kappa_3^2}. \end{aligned}$$

If

$$\eta \le \frac{\kappa_4\ \kappa_3^2}{\kappa_1(1+\rho_\phi\kappa_2)}, \tag{2.19}$$

then (2.18) holds. If we choose a superlinearly convergent inexact Newton variant, then

$$\eta \le \eta_N \to 0,$$

and therefore, close to the solution (2.19) holds. We also have that

$$\begin{aligned} \tilde{\mathbf{v}} &= \mathbf{K}^{-1}(\mathbf{r}-\mathbf{h}), \\ \|\tilde{\mathbf{v}}\| &\le \kappa_1(1+\eta)\|\mathbf{h}\|, \\ \|\tilde{\mathbf{v}}\| &\le \kappa_1(1+\eta)\frac{\|\nabla\phi\|}{\kappa_3}, \\ \|\tilde{\mathbf{v}}\| &\le \kappa_5\|\nabla\phi\|. \end{aligned} \tag{2.20}$$

By combining (2.20) and (2.17) we get

$$|\nabla\phi^T\tilde{\mathbf{v}}| \ge \kappa_4\|\nabla\phi\|^2 \ge \kappa_4\kappa_5\|\nabla\phi\|\,\|\tilde{\mathbf{v}}\|$$

and

$$\|\nabla\phi\|\,\|\tilde{\mathbf{v}}\| \ge \kappa_6|\nabla\phi^T\tilde{\mathbf{v}}| \ge \kappa_6\kappa_4\|\nabla\phi\|^2 \Longrightarrow \|\tilde{\mathbf{v}}\| \ge \kappa_7\|\nabla\phi\|.$$

That is, the length and angle conditions are satisfied. It can be shown [20, Theorem 10.6] that there is an α, bounded below, so that the Armijo condition holds true. Thus by choosing δ_A small enough, the Armijo condition is satisfied with unit step length. Hence the quadratic convergence rate associated with Newton's method is observed; i.e., the inexactness does not interfere with the merit function. In addition it can be shown that the augmented Lagrangian merit function allows unit step length near the solution (see [8, 23] and the references therein). Finally, notice that convergence does not require that $\eta_N \to 0$; it only requires that η_N is small enough. This is in contrast with inexact reduced space methods which require the tolerances to become tighter as the iterates approach the solution [14].

2.5. The globalized inexact LNKS algorithm. In this section we present the complete LNKS method incorporating the globalization and inexactness strategies discussed above, and give a high-level description of implementation details and specific heuristics used to accelerate convergence. The basic steps of our method are given in Algorithm 3.

ALGORITHM 3. GLOBALIZED LNKS.

1: Choose $\mathbf{x}_s$, $\mathbf{x}_d$, ρ_ϕ, δ_A, set $\mathrm{Re} = \mathrm{Re}_{start}$, $\mathrm{tol} = \mathrm{tol}_0$
2: $\mathbf{A}_s^T\boldsymbol{\lambda} + \mathbf{g}_s \approx \mathbf{0}$ solve inexactly for $\boldsymbol{\lambda}$
3: **while** $\mathrm{Re} \neq \mathrm{Re}_{target}$ **do**
4: **loop**
5: Evaluate f, $\mathbf{c}$, $\mathbf{g}$, $\mathbf{A}$, $\mathbf{W}$
6: $\mathbf{g}_z = \mathbf{g}_d + \mathbf{A}_d^T\boldsymbol{\lambda}$
7: Check convergence: $\|\mathbf{h}\| \leq \mathrm{tol}$
8: $\mathbf{P}^{-1}\mathbf{K}\mathbf{v} + \mathbf{P}^{-1}\mathbf{h} \approx \mathbf{0}$ solve inexactly for $\mathbf{v}$
9: Compute ρ_ϕ such that $\nabla\phi^T(0)\mathbf{v} \leq 0$
10: Compute α s.t. $\phi(\alpha) \leq \phi(0) + \delta_A\alpha(\nabla\phi^T(0)\mathbf{v})$
11: **if** Line search failed **then**
12: Compute α s.t. $\|\mathbf{h}(\alpha)\| < (1 - \delta_A\alpha\,(\mathbf{v}^T\,\mathbf{K}\,\mathbf{h}(0)))$ Armijo for KKT residual
13: **end if**
14: **if** LNKS step failed **then**
15: $\mathbf{B}_z\mathbf{p}_d = -\mathbf{g}_z$ solve inexactly for $\mathbf{p}_d$
16: $\mathbf{A}_s\mathbf{p}_s + \mathbf{A}_d\mathbf{p}_d + \mathbf{c} \approx \mathbf{0}$ solve inexactly for $\mathbf{p}_s$
17: $\mathbf{A}_s^T\boldsymbol{\lambda}_+ + \mathbf{g}_s \approx \mathbf{0}$ solve inexactly for $\boldsymbol{\lambda}_+$
18: Compute α s.t. $\phi(\alpha) \leq \phi(0) + \delta_A\alpha(\nabla\phi^T(0)\mathbf{v})$
19: **if** Line search on QN-RSQP step failed **then**
20: Reduce Re and go to step 5.
21: **end if**
22: **end if**
23: $\boldsymbol{\lambda}_+ = \boldsymbol{\lambda} + \mathbf{p}_\lambda$ (only for LNKS step)
24: $\mathbf{x}_+ = \mathbf{x} + \mathbf{p}_x$
25: **end loop**
26: $\mathrm{Re} = \mathrm{Re} + \Delta\,\mathrm{Re}$
27: Tighten tol
28: **end while**

The algorithm uses a three-level iteration.

- In the [illegible] (lines 3–28) the continuation parameter is gradually increased until the target value is reached.
- The [illegible] (lines 4–25) corresponds to the Lagrange–Newton solver for the KKT optimality system for a fixed continuation number.
- The [illegible] (line 8 for LNKS, and lines 15–17 for QN-RSQP) refers to the solution of the linearized KKT system.

The outer iteration consists of two core branches: the computation of the LNKS search direction and the computation of a search direction with the limited-memory BFGS QN-RSQP method. The default branch is the LNKS step. If this step fails to satisfy the line search conditions, we switch to QN-RSQP. If the QN-RSQP search direction fails to satisfy the line search criteria as well, then we reduce the continuation parameter Re and return to the beginning of the continuation loop (line 3).

There are several possible instantiations of this framework. Below, we give some

additional implementation details on our algorithmic choices.

• The linear solves in lines 8, 16, and 17 are performed inexactly. We follow [7] in choosing the forcing term. For the LNKS step (line 8) we use $\|\mathbf{h}\|$ as the residual that drives the Newton solver; for the QN-RSQP step (lines 15–18) we use $\|\mathbf{c}\|$ and $\|\mathbf{g}_z\|$.

• We allow for nonmonotone line searches. If the LNKS step (line 8) is rejected by the merit function line search (line 10) we do not switch immediately to QN-RSQP. Instead we do a line search on the KKT residual (line 12) and if the step is accepted we use it to update the variables for the next iteration. However, we do store information ($\boldsymbol{\lambda}$ and $\mathbf{x}$, the merit function value and gradient) for the iterate for which the LNKS step failed, and we insist that a subsequent iterate satisfies the conditions of the merit line search (evaluated at the failure point) after a fixed number of iterations. Typically, we permit two iterations before we demand reduction of the merit function. If the Armijo criterion is still violated, we backtrack to the original point of failure and switch to a QN-RSQP method (lines 15–18).

• We use various heuristics to bound the penalty parameter and possibly reduce it. A new penalty parameter ρ_ϕ^+ is computed using the LNKS step and formula (2.10). If $\rho_\phi^+ > 4\rho_\phi$ we update the penalty parameter and switch to QN-RSQP. If $\rho_\phi^+ < \rho_\phi/4$ we [illegible] the penalty parameter and set $\rho_\phi^+ = 0.5\rho_\phi$. We also reduce the penalty parameter if there is a successful search on the KKT residual (step 12).

• A Lanczos algorithm can be used to (approximately) check the second-order optimality conditions. If an extremal eigenvalue of $\tilde{\mathbf{W}}_z$ is negative, then we abandon the full space and revert to a QN-RSQP step. The eigenvalue computation is frozen through a single continuation step, but if a negative direction is detected, they are recomputed at each SQP iteration.

• In line 6 we use the adjoint variables to update the reduced gradient. This is equivalent to $\mathbf{g}_z = \mathbf{g}_d - \mathbf{A}_d^T \mathbf{A}_s^{-T} \mathbf{g}_s$ if $\boldsymbol{\lambda}$ is computed by solving exactly $\mathbf{A}_s^T \boldsymbol{\lambda} + \mathbf{g}_s = \mathbf{0}$. When $\boldsymbol{\lambda}$ is taken from the LNKS step computation, it includes second-order terms (which tend to zero as we approach a stationary point). This introduces error in the computation of $\mathbf{g}_z$. When $\boldsymbol{\lambda}$ is taken from QN-RSQP it introduces additional error since we never solve the linear systems exactly.

• Typical values for the parameters are $\rho_\phi = 0.5$, $\delta_A = 10^{-4}$, and tol $= 10^{-5}\|\mathbf{h}_0\|$ (following [6]). Here $\mathbf{h}_0$ is the value of the KKT residual at the first iteration of each outer loop.

We have shown how it is possible to augment the basic LNKS method with line search and continuation, safeguard it with QN-RSQP steps, and further accelerate it with inexact Newton. We have shown that inexactness does not interfere with the line search algorithm, and we have described the globalized algorithm and various heuristics that are observed to improve performance.

In the next section we study an optimal control problem for the steady incompressible Navier–Stokes equations. We cite results on the existence and uniqueness of solutions and make comparisons between the discrete and continuous forms of the optimality conditions.

3. Formulation of an optimal control problem. We turn our attention to the formulation and well-posedness of a specific optimization problem: the Dirichlet control of the steady incompressible Navier–Stokes equations. We present the continuous form of the KKT optimality conditions and we cite convergence results for finite element approximations from [15] and [16]. A survey and articles on this topic can be found in [11]. More on the Navier–Stokes equations can be found in [10, 13].

We study problems in which we specify both Dirichlet and Neumann boundary conditions. The controls are restricted to be of Dirichlet type only, but the theory is similar for distributed and Neumann controls [15].

3.1. Continuous optimality conditions. We use the velocity-pressure $(\boldsymbol{u}, p)$ form of the incompressible steady Navier–Stokes equations. We begin by writing the following strong form of the flow equations:

$$\begin{aligned} -\nu\nabla\cdot(\nabla\boldsymbol{u}+\nabla\boldsymbol{u}^T)+(\nabla\boldsymbol{u})\boldsymbol{u}+\nabla p &= \boldsymbol{b} \quad \text{in } \Omega,\\ \nabla\cdot\boldsymbol{u} &= 0 \quad \text{in } \Omega,\\ \boldsymbol{u} &= \boldsymbol{u}_g \quad \text{on } \Gamma_u,\\ \boldsymbol{u} &= \boldsymbol{u}_d \quad \text{on } \Gamma_d,\\ -p\boldsymbol{n}+\nu(\nabla\boldsymbol{u}+\nabla\boldsymbol{u}^T)\boldsymbol{n} &= \boldsymbol{0} \quad \text{on } \Gamma_N. \end{aligned} \tag{3.1}$$

Here $\nu = 1/\mathrm{Re}$ and the decision variables are the control velocities $\mathbf{u}_d$ on Γ_d. For a forward solve we need not distinguish between Γ_d and Γ_u. In the optimization problem, however, $\boldsymbol{u}_d$ is not known. We will present a mixed formulation that treats the tractions on the Dirichlet boundary Γ_d as additional unknown variables. The traction variables play the role of Lagrange multipliers (not to be confused with the Lagrange multipliers of the optimal control problem) and are used to enforce the Dirichlet boundary conditions [2].

By $L^2(\Omega)$ we denote the space of scalar functions that are square-integrable in Ω, and by $\boldsymbol{H}^1(\Omega)$ we denote the space of vector functions whose first derivatives are in $\boldsymbol{L}^2(\Omega)$. $\boldsymbol{H}^{1/2}(\Gamma)$ is the trace space (the restriction on Γ) of functions belonging to $\boldsymbol{H}^1(\Omega)$. Finally $\boldsymbol{H}^{-k}(D)$ is the set of bounded linear functionals on functions belonging to $\boldsymbol{H}^k(D)$, where D is some smooth domain in $\mathbb{R}^3$. We also define $\boldsymbol{V} := \{\boldsymbol{v} \in \boldsymbol{H}^1(\Omega) : \boldsymbol{v}|_{\Gamma_u} = \boldsymbol{0}\}$. We define the following bilinear and trilinear forms associated with the Navier–Stokes equations:

$$\begin{aligned} a(\boldsymbol{u},\boldsymbol{v}) &:= \int_\Omega (\nabla\boldsymbol{u}+\nabla\boldsymbol{u}^T)\cdot(\nabla\boldsymbol{v}+\nabla\boldsymbol{v}^T)\,d\Omega \quad \forall \boldsymbol{u},\boldsymbol{v}\in\boldsymbol{H}^1(\Omega),\\ c(\boldsymbol{w},\boldsymbol{u},\boldsymbol{v}) &:= \int_\Omega (\nabla\boldsymbol{u})\boldsymbol{w}\cdot\boldsymbol{v}\,d\Omega \quad \forall \boldsymbol{u},\boldsymbol{v},\boldsymbol{w}\in\boldsymbol{H}^1(\Omega),\\ b(q,\boldsymbol{v}) &:= \int_\Omega -q\nabla\cdot\boldsymbol{v}\,d\Omega \quad \forall q\in L^2,\ \boldsymbol{v}\in\boldsymbol{H}^1(\Omega). \end{aligned}$$

We also use the notation $(\boldsymbol{x},\boldsymbol{y})_D$ for $\int_D \boldsymbol{x}\cdot\boldsymbol{y}\,dD$.

In the weak formulation of (3.1) we seek $\boldsymbol{u} \in \boldsymbol{H}^1(\Omega)$, $p \in L^2(\Omega)$, and $\boldsymbol{\sigma} \in H^{-1/2}(\Gamma_d)$ such that

$$\begin{aligned} \nu a(\boldsymbol{u},\boldsymbol{v}) + c(\boldsymbol{u},\boldsymbol{u},\boldsymbol{v}) + b(p,\boldsymbol{v}) - (\boldsymbol{\sigma},\boldsymbol{v})_{\Gamma_d} &= (\boldsymbol{f},\boldsymbol{v})_\Omega \quad && \forall \boldsymbol{v}\in\boldsymbol{V},\\ b(q,\boldsymbol{u}) &= 0 && \forall q\in L^2(\Omega),\\ -(\boldsymbol{t},\boldsymbol{u})_{\Gamma_d} &= -(\boldsymbol{t},\boldsymbol{u}_d)_{\Gamma_d} && \forall \boldsymbol{t}\in\boldsymbol{H}^{-1/2}(\Gamma_d). \end{aligned} \tag{3.2}$$

We also define $\boldsymbol{d}$ to be the decision field (so that $\boldsymbol{u}_d = \boldsymbol{d}$). Based on the above formulation we proceed in defining the Lagrangian function for the optimization problem. The objective function is given by

$$\mathcal{J}(\boldsymbol{u},\boldsymbol{d}) := \frac{\nu}{2}a(\boldsymbol{u},\boldsymbol{u}) + \frac{\rho}{2}(\boldsymbol{d},\boldsymbol{d})_{\Gamma_d}, \tag{3.3}$$

and (the weak form of) the constraints are given by (3.2). We define the Lagrangian function $\mathcal{L}$ by

$$\begin{aligned}\mathcal{L}(\boldsymbol{u},p,\boldsymbol{d},\boldsymbol{\sigma},\boldsymbol{\lambda},\mu,\boldsymbol{\tau}) &:= \mathcal{J}(\boldsymbol{u},\boldsymbol{d})\\ &+ \nu a(\boldsymbol{u},\boldsymbol{\lambda}) + c(\boldsymbol{u},\boldsymbol{u},\boldsymbol{\lambda}) - (\boldsymbol{\sigma},\boldsymbol{\lambda})_{\Gamma_d} - (\boldsymbol{f},\boldsymbol{\lambda})_\Omega + b(p,\boldsymbol{\lambda})\\ &+ b(\mu,\boldsymbol{u}) - (\boldsymbol{\tau},\boldsymbol{u}-\boldsymbol{d})_{\Gamma_d}\\ &\quad \forall \boldsymbol{u}\in \boldsymbol{H}^1(\Omega),\quad p\in L^2(\Omega),\quad \boldsymbol{\sigma}\in \boldsymbol{H}^{-1/2}(\Gamma_d),\quad \boldsymbol{d}\in \boldsymbol{H}^{1/2}(\Gamma_d),\\ &\quad \forall \boldsymbol{\lambda}\in \boldsymbol{V},\quad \mu\in L^2(\Omega),\quad \boldsymbol{\tau}\in \boldsymbol{H}^{-1/2}(\Gamma_d).\end{aligned} \tag{3.4}$$

Here $\boldsymbol{\lambda}$, μ, $\boldsymbol{\tau}$ are the Lagrange multipliers for the state variables $\boldsymbol{u}$, p, $\boldsymbol{\sigma}$. By taking variations with respect to the Lagrange multipliers we obtain (3.2) augmented with $\boldsymbol{u}_d = \boldsymbol{d}$ on Γ_d. Taking variations with respect to the states $\boldsymbol{u}$, p, $\boldsymbol{\sigma}$ we obtain the weak form of the adjoint equations

$$\begin{aligned}&\nu a(\boldsymbol{v},\boldsymbol{\lambda}) + c(\boldsymbol{v},\boldsymbol{u},\boldsymbol{\lambda}) + c(\boldsymbol{u},\boldsymbol{v},\boldsymbol{\lambda}) + b(\mu,\boldsymbol{v}) + (\boldsymbol{\tau},\boldsymbol{v})_{\Gamma_d} = -\nu a(\boldsymbol{u},\boldsymbol{v}) \quad \forall \boldsymbol{v}\in \boldsymbol{V},\\ &b(q,\boldsymbol{\lambda}) = 0 \quad \forall q\in L^2(\Omega),\\ &(\boldsymbol{t},\boldsymbol{\lambda})_{\Gamma_d} = 0 \quad \forall \boldsymbol{t}\in \boldsymbol{H}^{-1/2}(\Gamma_d).\end{aligned} \tag{3.5}$$

Finally, by taking variations with respect to $\boldsymbol{d}$ we obtain the decision equation

$$\rho(\boldsymbol{d},\boldsymbol{r})_{\Gamma_d} + (\boldsymbol{\tau},\boldsymbol{r})_{\Gamma_d} = 0 \quad \forall \boldsymbol{r}\in \boldsymbol{H}^{1/2}(\Gamma_d). \tag{3.6}$$

Equations (3.2), (3.5), (3.6) are the weak form of the first-order optimality conditions. Extensive discussion on the existence of a solution and the existence of the Lagrange multipliers can be found in [15, 16]. In [15] the existence of a local minimum for the optimization problem and the existence of Lagrange multipliers that satisfy the first-order optimality conditions are asserted.[4] Furthermore, uniqueness is shown for sufficiently small data. Note that in the absence of a Neumann condition ($\Gamma_N = \emptyset$) the controls have to satisfy the incompressibility condition $(\boldsymbol{d}\cdot\boldsymbol{n})_{\Gamma_d} = 0$.

The strong form of the adjoint and decision equations can be obtained by using the following integration by parts formulas:

$$\begin{aligned}a(\boldsymbol{u},\boldsymbol{v}) &= -(\boldsymbol{v},\Delta\boldsymbol{u})_\Omega + ((\nabla\boldsymbol{u})\boldsymbol{n},\boldsymbol{v})_\Gamma,\\ c(\boldsymbol{u},\boldsymbol{v},\boldsymbol{\lambda}) &= -c(\boldsymbol{u},\boldsymbol{\lambda},\boldsymbol{v}) - ((\nabla\cdot\boldsymbol{u})\boldsymbol{\lambda},\boldsymbol{v})_\Omega + ((\boldsymbol{u}\cdot\boldsymbol{n})\boldsymbol{\lambda},\boldsymbol{v})_\Gamma,\\ b(\mu,\boldsymbol{v}) &= (\nabla\mu,\boldsymbol{v})_\Omega - (\mu\boldsymbol{n},\boldsymbol{v})_\Gamma.\end{aligned}$$

Upon sufficient smoothness we arrive at the strong form of the optimality conditions. Equation (3.1) is the strong form of the constraints. The strong form of the adjoint equations is given by

$$\begin{aligned}-\nu\nabla\cdot(\nabla\boldsymbol{\lambda}+\nabla\boldsymbol{\lambda}^T) + (\nabla\boldsymbol{u})^T\boldsymbol{\lambda} - (\nabla\boldsymbol{\lambda})\boldsymbol{u} + \nabla\mu &= \nu\nabla\cdot(\nabla\boldsymbol{u}+\nabla\boldsymbol{u}^T) \quad \text{in } \Omega,\\ \nabla\cdot\boldsymbol{\lambda} &= 0 \quad \text{in } \Omega,\\ \boldsymbol{\lambda} &= \boldsymbol{0} \quad \text{on } \Gamma_u,\\ \boldsymbol{\lambda} &= \boldsymbol{0} \quad \text{on } \Gamma_d,\\ -\mu\boldsymbol{n} + \nu(\nabla\boldsymbol{\lambda}+\nabla\boldsymbol{\lambda}^T)\boldsymbol{n} + (\boldsymbol{u}\cdot\boldsymbol{n})\boldsymbol{\lambda} &= -\nu(\nabla\boldsymbol{u}+\nabla\boldsymbol{u}^T)\boldsymbol{n} \quad \text{on } \Gamma_N,\end{aligned} \tag{3.7}$$

[4] The objective functional used in [15] is different from ours. An $\boldsymbol{L}^4$ functional is used for the matching problems and an $\boldsymbol{H}^{\frac{1}{2}}_{\Gamma_d}$ is used for the penalization of $\boldsymbol{u}_d$—resulting in a surface Laplacian equation for the decision variables.

and (equation for $\boldsymbol{\tau}$)

$$\nu(\nabla\boldsymbol{\lambda} + \nabla\boldsymbol{\lambda}^T)\boldsymbol{n} + \nu(\nabla\boldsymbol{u} + \nabla\boldsymbol{u}^T)\boldsymbol{n} - \boldsymbol{\tau} = \boldsymbol{0} \quad \text{on } \Gamma_d. \tag{3.8}$$

We may also determine that the strong form of the decision equation is given by

$$\boldsymbol{\tau} = \rho\boldsymbol{d} \quad \text{on } \Gamma_d. \tag{3.9}$$

In [15] estimates are given for the convergence rates of the finite element approximations to the exact solutions for the optimal control of steady viscous flow. For the case of boundary velocity control, the basic result is that if the exact solutions are smooth enough, then provided the Taylor–Hood element is used (for both adjoints and states), the solution error satisfies the following estimates:

$$\begin{aligned} \|\boldsymbol{u} - \boldsymbol{u}_h\|_0 &\le \mathcal{O}(h^3), \\ \|p - p_h\|_0 &\le \mathcal{O}(h^2), \\ \|\boldsymbol{\lambda} - \boldsymbol{\lambda}_h\|_0 &\le \mathcal{O}(h^3), \\ \|\mu - \mu_h\|_0 &\le \mathcal{O}(h^2). \end{aligned} \tag{3.10}$$

Here h is the maximum element size, and $\|\cdot\|_0$ is the $L^2(\Omega)$ norm.

3.2. Discrete and discretized optimality conditions. In our implementation we have not discretized the continuous forms of the optimality conditions. Instead we have discretized the objective function and the Navier–Stokes equations and then used this discretization to form the optimality conditions. In general, discretization and differentiation (to obtain optimality conditions) do not commute. That is, if $\boldsymbol{A}$ is the infinite-dimensional (linearized) forward operator and $\boldsymbol{A}^*$ is its adjoint, then in general

$$(\boldsymbol{A}^*)_h \neq (\boldsymbol{A}_h)^T,$$

where the subscript h indicates discretization. We will show that for Galerkin approximation of the steady incompressible Navier–Stokes optimal control problem, discretization and differentiation do commute.

For the discretized equations we use the following notation:

$$\begin{aligned} a(\boldsymbol{u}_h, \boldsymbol{v}_h) + c(\boldsymbol{u}_h, \boldsymbol{u}_h, \boldsymbol{v}_h) &\dashrightarrow \mathbf{U}(\mathbf{u})\mathbf{u}, \\ a(\boldsymbol{u}_h, \boldsymbol{v}_h) + c(\boldsymbol{p}_h, \boldsymbol{u}_h, \boldsymbol{v}_h) + c(\boldsymbol{u}_h, \boldsymbol{p}_h, \boldsymbol{v}_h) &\dashrightarrow \mathbf{V}(\mathbf{u})\mathbf{p}, \\ a(\boldsymbol{u}_h, \boldsymbol{v}_h) &\dashrightarrow \mathbf{Q}\mathbf{u}, \\ b(q_h, \boldsymbol{u}_h) &\dashrightarrow \mathbf{P}\mathbf{u}, \\ (\boldsymbol{t}_h, \boldsymbol{u}_h)_{\Gamma_d} &\dashrightarrow \mathbf{T}\mathbf{u}, \\ (d_h, r_h)_{\Gamma_d} &\dashrightarrow \mathbf{M}\mathbf{d}. \end{aligned}$$

The discretized form of the Navier–Stokes equations (3.2) is then given by

$$\begin{aligned} \mathbf{U}(\mathbf{u})\mathbf{u} + \mathbf{P}^T\mathbf{p} + \mathbf{T}^T\boldsymbol{\sigma} &= \mathbf{f}_1, \\ \mathbf{P}\mathbf{u} &= \mathbf{f}_2, \\ \mathbf{T}\mathbf{u} &= \mathbf{T}\mathbf{d}. \end{aligned} \tag{3.11}$$

The discrete Lagrangian function is given by

$$\begin{aligned}\frac{1}{2}\mathbf{u}^T\mathbf{Q}\mathbf{u}+\frac{\rho}{2}\mathbf{d}^T\mathbf{M}\mathbf{d}+\boldsymbol{\lambda}^T\{\mathbf{U}(\mathbf{u})\mathbf{u}+\mathbf{P}^T\mathbf{p}+\mathbf{T}^T\boldsymbol{\sigma}-\mathbf{f}_1\}\\ +\boldsymbol{\mu}^T\{\mathbf{P}\mathbf{u}-\mathbf{f}_2\}+\boldsymbol{\tau}^T\{\mathbf{T}\mathbf{u}+\mathbf{T}\mathbf{d}\}=\mathbf{0}.\end{aligned} \tag{3.12}$$

By taking derivatives with respect to the discrete Lagrange multiplier vectors $(\boldsymbol{\lambda},\boldsymbol{\mu},\boldsymbol{\tau})$, we recover the state equations (3.11). By taking derivatives with respect to the discrete state variables $(\mathbf{u},\mathbf{p},\boldsymbol{\sigma})$, we obtain the discrete adjoint equations

$$\begin{aligned}\mathbf{V}^T(\mathbf{u})\boldsymbol{\lambda}+\mathbf{P}^T\boldsymbol{\mu}+\mathbf{T}^T\boldsymbol{\tau}&=-\mathbf{Q}\mathbf{u},\\ \mathbf{P}\boldsymbol{\lambda}&=\mathbf{0},\\ \mathbf{T}\boldsymbol{\lambda}&=\mathbf{0}.\end{aligned} \tag{3.13}$$

These equations correspond to the discretization of (3.5) provided that $\mathbf{V}^T\boldsymbol{\lambda}$ is the discretization of $a(\boldsymbol{\lambda},\boldsymbol{u})+c(\boldsymbol{v},\boldsymbol{u},\boldsymbol{\lambda})+c(\boldsymbol{u},\boldsymbol{v},\boldsymbol{\lambda})$. The bilinear form $a(\cdot,\cdot)$ is symmetric so we omit it from our discussion. If ϕ denotes the basis function for $\boldsymbol{u}$, ψ_v for $\boldsymbol{v}$, and ψ_λ for $\boldsymbol{\lambda}$, then the (3×3)-block elements for the linearized state and adjoint are

$$\int_\Omega \mathbf{I}\,(\nabla\phi\cdot\boldsymbol{u})\psi_v+(\nabla\boldsymbol{u})\phi\psi_v\;d\Omega \quad \text{state element matrix,}$$

$$\int_\Omega \mathbf{I}\,(\nabla\psi_v\cdot\boldsymbol{u})\psi_\lambda+(\nabla\boldsymbol{u})^T\psi_\lambda\psi_v\;d\Omega \quad \text{adjoint element matrix.}$$

Therefore, the transpose of the discretized (linearized) state equations coincides with the discretization of the adjoint equations, i.e.,

$$(\boldsymbol{A}^*)_h=(\boldsymbol{A}_h)^T.$$

One needs to be careful to use the weak form given by (3.5). If (3.7) were used without employing the reverse integration by parts on the term $c(\boldsymbol{u},\boldsymbol{v},\boldsymbol{\lambda})$, this would result in a discretization which is incompatible with the discrete optimization problem (which is what is presented to the optimization algorithm). It would result in an nonsymmetric KKT matrix and would possibly prevent the optimizer from converging to a KKT point. A Petrov–Galerkin formulation would also be incompatible.

In our formulation we do not solve explicitly for $\boldsymbol{\sigma}$ and $\boldsymbol{\tau}$. We approximate both tractions and velocity traces in $\boldsymbol{H}^1(\Gamma_d)$; in this case the stresses can be eliminated. For a discussion on choice of $H^1(\Gamma_d)$ for the stresses see [12]. The resulting equations are equivalent to the formulations described in this section. We use a standard Galerkin approximation scheme (no upwinding) with Taylor–Hood elements to approximate the velocities, the pressures, and their adjoints.

We conclude this section with a remark on continuation. To solve a Navier–Stokes control problem with large Reynolds number, some kind of continuation scheme is usually needed. We first solve a Stokes-flow optimal control problem ($\mathrm{Re}_0=0$) and then we progressively increase the Reynolds number by $\mathrm{Re}_{(+)}=\mathrm{Re}+\Delta\,\mathrm{Re}$. One could set $\mathbf{u}_{(+)}=\mathbf{u}+(\partial_{\mathrm{Re}}\mathbf{u})\Delta\,\mathrm{Re}$, where $\partial_{\mathrm{Re}}\mathbf{u}$ can be easily computed through a linearized forward solve. Since we consider only steady flows, we follow [10] and use a fixed $\Delta\,\mathrm{Re}$, and simply set $\mathbf{u}_{(+)}=\mathbf{u}$; i.e., the initial guess at the new Reynolds number is the solution from the previous optimization step. Additionally, quasi-Newton information is carried forward to the next Reynolds number.

4. Numerical results. In this section we investigate the accuracy, performance, and scalability of the LNKS method via four numerical examples. Numerical approximation and parallel implementation details are described in section 4.1 of part I of

this article. First we examine the finite element approximation convergence rates with a problem that has a closed form solution. Then we revisit the Poiseuille flow problem of part I and use it to study the effectiveness of the limited-memory BFGS method as a preconditioner for the reduced Hessian. In both cases we solve for the boundary conditions that reproduce the exact solution by minimizing a matching velocity functional.

We then consider the more challenging problem of the control of a flow around a cylinder. The objective function to be minimized is the rate of energy dissipation functional. We use this problem to study the LNKS line search algorithm, the effectiveness of the Krylov–Schur preconditioner for highly nonlinear problems, and the heuristics we introduced in section 2. The last test problem is the optimal control of a flow around a wing.

4.1. Finite element approximation error. In this section we use a model problem to verify the convergence rate estimates given in the previous section. The velocity and pressure are given by

$$\boldsymbol{u}^*(x,y,z) = \{1-(x^2+y^2)^2, x, -y\}^T, \qquad p^*(x,y,z) = x^2+y^2-z^2,$$

which satisfy the Navier–Stokes equations. We restrict this solution to a cylindrical domain and choose a part of its boundary as the control domain Γ_d. We define the velocity on the circumferential walls to be the decision variables. On Γ/Γ_d we set $\boldsymbol{u} = \boldsymbol{u}^*$. The objective function is given by

$$\mathcal{J}(\boldsymbol{u}, \boldsymbol{u}_d, p) = \frac{1}{2}\int_\Omega (\boldsymbol{u}^* - \boldsymbol{u})^2 \, d\Omega.$$

Since the boundary conditions for $(\boldsymbol{u}, p)$ on Γ/Γ_d are compatible with $(\boldsymbol{u}^*, p^*)$, the values for the objective function and the Lagrange multipliers are equal to zero at the minimum.

Table 4.1 gives convergence rates for the state variables and the Lagrange multipliers. The results are in good agreement with the theoretical predictions. The convergence rate for the velocities and their adjoints is approximately 2.92 (comparing errors between the first and second rows) and 2.96 (comparing errors between the second and third rows). For the pressures and their adjoints the convergence rate is 1.96 and 1.97, respectively.

TABLE 4.1

Convergence rate of the finite element approximation for a matching velocity problem. Here $\mathbf{n}$ *is the number of elements and* h *is the cube root of the volume of the maximum inscribed sphere inside a tetrahedron of the finite element mesh. Near-optimal convergent rates can be observed for the state and adjoint variables.*

$\mathbf{n}$	h	$\|\boldsymbol{u}^* - \boldsymbol{u}_h\|_0$	$\|p^* - p_h\|_0$	$\|\boldsymbol{\lambda}^* - \boldsymbol{\lambda}_h\|_0$	$\|\mu^* - \mu_h\|_0$
124,639	0.80	1.34×10^{-4}	2.01×10^{-5}	3.88×10^{-4}	1.76×10^{-5}
298,305	0.53	4.40×10^{-5}	9.00×10^{-6}	1.19×10^{-4}	7.90×10^{-6}
586,133	0.40	1.70×10^{-5}	5.20×10^{-6}	5.00×10^{-5}	4.50×10^{-6}

4.2. Poiseuille flow. The Poiseuille flow is a stable solution of the Navier–Stokes equations for small Reynolds numbers. We use this example to study the effectiveness of the limited-memory BFGS method as a preconditioner for the reduced Hessian. Since the optimization problem is nonlinear, LNKS takes several iterations

and curvature information can be built up. Quasi-Newton theory predicts that $\mathbf{B}_z$ approaches $\mathbf{W}_z$ as the iterates get closer to the solution. Therefore, we expect the effectiveness of the preconditioner to improve as the optimization algorithm progresses. We store 30 vectors for the limited-memory BFGS preconditioner.

For this set of tests we fix the size and granularity of the problem. The target Reynolds number is 500. We start at Reynolds number 100 and use a continuation step $\Delta\,\mathrm{Re} = 200$. Continuation is used to initialize the state and control variables, but only to carry BFGS information forward to the next Reynolds number.

The forward problem preconditioner is based on a block factorization

$$\begin{bmatrix} \mathbf{I} & -\mathbf{V}^{-1}\mathbf{P}^T \\ \mathbf{0} & \mathbf{I} \end{bmatrix} \begin{bmatrix} \mathbf{V}^{-1} & \mathbf{0} \\ \mathbf{0} & \mathbf{S}^{-1} \end{bmatrix} \begin{bmatrix} \mathbf{I} & \mathbf{0} \\ -\mathbf{P}\mathbf{V}^{-1} & \mathbf{I} \end{bmatrix},$$

where $\mathbf{S} := -\mathbf{P}\mathbf{V}^{-1}\mathbf{P}^T$ is the Schur complement for the pressure. Based on this factorization, the preconditioner is defined by replacing the exact solves $\mathbf{V}^{-1}$ with domain decomposition approximations $\tilde{\mathbf{V}}^{-1}$. To "invert" the pressure Schur complement $\mathbf{S}$ we use several iterations of the two-step stationary method described in part I (section 3.2).

In QN-RSQP we use QMR for the linearized Navier–Stokes solves, preconditioned with an overlapping additive Schwarz method with ILU(1) in each subdomain.[5] Results for a problem with 21,000 state and 3,900 design variables on 4 processors and for a sequence of three Reynolds numbers are presented in Table 4.2. The number of KKT iterations in LNKS-I reveals the efficacy of the BFGS preconditioner. This number drops from an average 48 iterations to 38. The effect of BFGS in LNKS-II is hidden since the KKT iterations are dominated by the ill-conditioning of the forward and adjoint operators (in LNKS-I these solves are exact in each iteration). Overall, we can observe that LNKS reduces significantly the execution time relative to QN-RSQP.

The Newton solver performed well, requiring just 3 iterations to converge. In these problems we did not use inexact Newton criteria to terminate the KKT solves early; instead they were fully converged at each iteration. No line search was used in the LNKS variants; we used the l_1-merit function for the QN-RSQP.

It is rather surprising that the quasi-Newton approximation works well as a preconditioner within the Newton method, whereas it stagnates when used alone to drive the QN-RSQP method. One explanation could be that the QN-RSQP method in these tests suffered the Maratos effect. In our subsequent tests we switched to a second-order correction method [21, p. 570].

4.3. Flow around a cylinder. All the problems examined so far were useful in verifying certain aspects of the LNKS method, but they are linear or mildly nonlinear. In order to test LNKS further we consider a highly nonlinear problem: that of flow around a cylinder with a dissipation-type objective function. The cylinder is anchored inside a rectangular duct, much like a wind tunnel. A quadratic velocity profile is used as an inflow Dirichlet condition and we prescribe a traction-free outflow. The decision variables are defined to be the velocities on the downstream portion of the cylinder surface. We have investigated flows in the laminar steady-state regime. For exterior problems the transition Reynolds number is 40 but for the duct problem we expect higher Reynolds numbers due to the dissipation from the duct walls.

Figures 1 and 2 illustrate optimal solutions for different Reynolds numbers. LNKS eliminates the recirculation region and secondary flows downstream of the cylinder. In

[5] For definitions of ILU(0) and ILU(1) see [22].

TABLE 4.2

*Work efficiency of the proposed preconditioners for a Poiseuille flow matching problem for fixed size and fixed granularity as a function of the Reynolds number. Recall that LNKS does not use any preconditioner for the KKT system, LNKS-*I *uses a KKT preconditioner that involves two linearized exact forward/adjoint solves per iteration, and LINKS-*II *uses a KKT preconditioner that involves just the application of the forward problem preconditioner.* Re *is the Reynolds number;* N/QN *denotes the number of outer iterations. The number of iterations for the KKT system is averaged across the optimization iterations. The problem has* 21,000 *state equations and* 3,900 *control variables; results are for* 4 *processors of the T3E-*900*. Wall-clock time is in hours.*

	LNKS-II	3	4,300	9×10^{-6}	1.4
500	QN-RSQP	289	—	1×10^{-4}	7.3
	LNK	3	213,000	9×10^{-6}	9.0
	LNKS-I	3	38	9×10^{-6}	3.0
	LNKS-II	3	4,410	9×10^{-6}	1.4

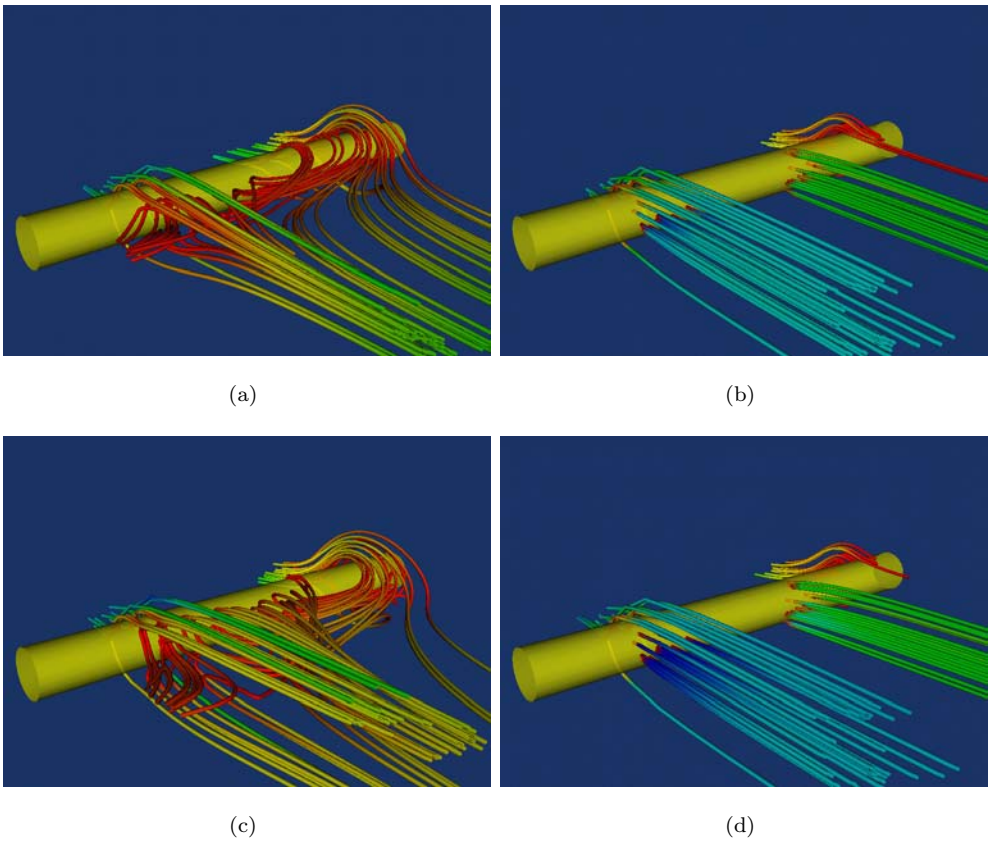
order to avoid the excessive suction that we observed in the Stokes case, we imposed Dirichlet boundary conditions on the outflow of the domain. The incompressibility condition prevents the optimizer from driving the flow inside the cylinder.[6]

Our experiments on the Stokes optimal control problem demonstrated the dependence of the performance of the Krylov–Schur iteration on the forward problem preconditioner. Thus before we discuss results on the LNKS algorithm we cite representative performance for the Navier–Stokes forward solver. We use an inexact Newton's method combined with the preconditioner we presented in part I. A block-Jacobi ILU(0) preconditioner is used for the velocity block as well as for the pressure mass matrix (scaled by 1/Re); the latter is used to precondition the pressure Schur complement block. ILU(1) would have been a better choice, but memory limitations prevented us from doing so.[7]

Table 4.3 gives statistics for three different Reynolds numbers and for three different problem sizes. We report the (aggregate) number or Krylov iterations required to converge the Newton solver, the number of Newton iterations, and the total execution time. For these runs we did not use continuation, but we did use an inexact Newton method. The time for a forward solve has increased almost sixfold in comparison with the linear Stokes solver (part I, Table 4.1). However the time , . Newton iteration is roughly the same as that taken in the linear Stokes case. For example, in the 128 processor problem and for Reynolds number 30, the average (Krylov) iteration count is 1005, whereas in the linear case it is 882. Similarly, the average time per Newton

[6]When Dirichlet conditions are specified everywhere on Γ, then $\int_\Gamma \boldsymbol{u} \cdot \boldsymbol{n}\, d\Gamma$ should be zero. The constraint should be imposed either explicitly or implicitly by using a proper function space. In our implementation we use a penalty approach by modifying the objective function.

[7]Our matrix storage includes the state Jacobian, the Hessian of the constraints, and the Hessian of the objective—substantially more than required for the forward solver. PSC's T3E-900 (which hosted the majority of our computations) has just 128 MB of memory per processor.



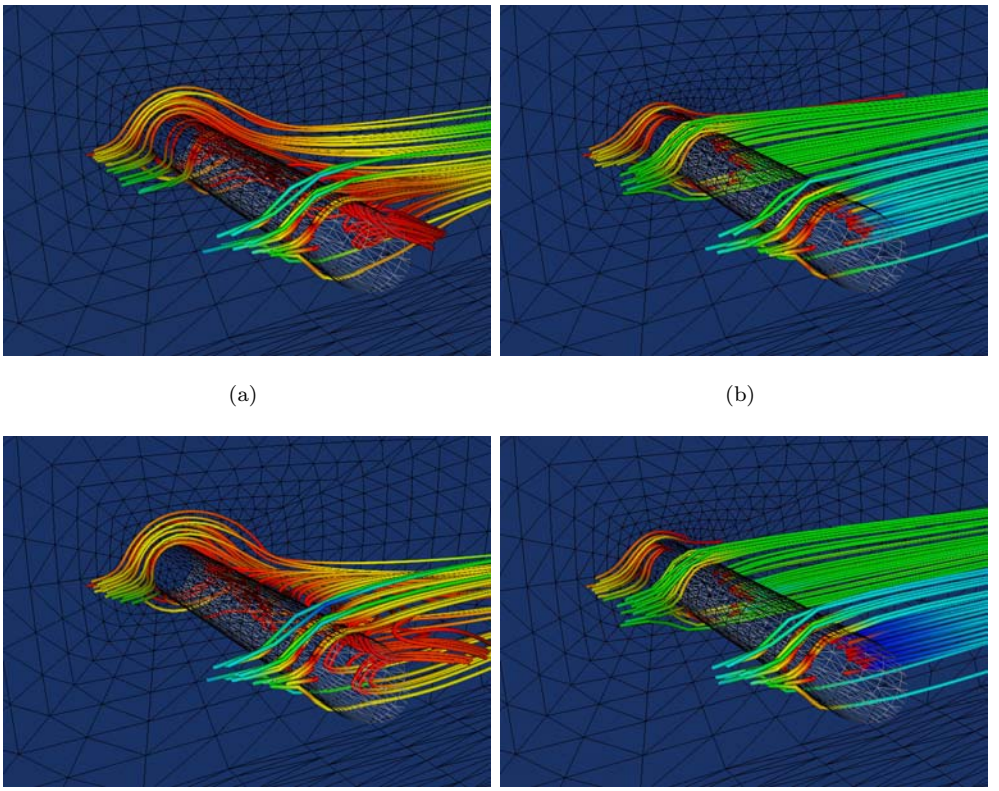


FIG. 1. *The top row depicts stream tubes of the flow for Reynolds number* 20 *and the bottom row for Reynolds number* 40. *The left column depicts the uncontrolled flow. The right column depicts the controlled flow. These images illustrate the flow pattern on the downstream side of the cylinder.*

step is 401 seconds. The time for the Stokes solver is little higher, 421 seconds.[8] We conclude that the forward preconditioner performs reasonably well.

Table 4.4 shows results for 32, 64, and 128 processors of a T3E-900 for increasing problem sizes. Results for two different preconditioning variants of LNKS are presented: the exact (LNKS-I) and inexact (LNKS-II) version of the Schur preconditioner. The globalized LNKS algorithm is compared with QN-RSQP. In LNKS-II-TR we activate the inexact Newton method. In this example we have used continuation to warm start the $\mathrm{Re} = 60$ problem. The reduced Hessian preconditioner is a combination of the BFGS and two-step preconditioners (as we described in part I, section 3.2). In the line search we use the augmented Lagrangian merit function.

Based on the overall wall-clock time reported in the rightmost column of Table 4.4, we observe that for this problem, QN-RSQP was able to converge, but only several days of wall-clock time. LNKS-I, although faster, does not reduce the required time significantly. LNKS-II, which avoids the exact forward/adjoint solves, is much

[8]The reason for this is related to the scaling between the velocity and pressure block of the forward problem. Increasing the Reynolds number improves this scaling and thus improves the eigenvalue distribution. Of course this is true up to certain Reynolds number. For higher values the Jacobian becomes highly nonsymmetric and ill-conditioned.

128	615,981	6,284	5	2,612	8,036	8	3,214	7,847	7	3,136

better—4 to 5 times faster than QN-RSQP. Even more dramatic is the acceleration achieved by using the inexact version of LNKS, i.e., LNKS-II-TR. The inexactness did not interfere at any point with the merit function and in all cases we observed quadratic convergence. Overall, LNKS-II-TR runs more than 10 times faster than

QN-RSQP (5.1 hours compared to 57.3 hours). This is consistent with the performance improvements we observed for the Stokes flow control problem.

Despite the high degree of nonlinearity of the external cylinder flow problem, the augmented Lagrangian globalization performed robustly and we did not have problems converging the optimality equations. In this example, the QN-RSQP safeguard was never activated due to detection of a negative curvature direction. Finally, it is worth noting that the optimization solution is found at a cost of 5 [illegible] — remarkable considering that there are thousands of control variables.

4.4. Flow around a Boeing 707 wing. For our last test we solved for the optimal flow control around a Boeing 707 wing. In this problem the control variables

TABLE 4.5

In this table we present results for the wing flow problem, which has 710,023 *state and* 4,984 *decision variables. The runs were performed on* 128 *processors on a T3E-900. Here* Re *is the Reynolds number;* iter *is the aggregate number of Lagrange–Newton iterations—the number in parentheses is the number of iterations in the last continuation step;* time *is the overall time in hours;* qn *is the number of QN-RSQP steps taken as a safeguard for Newton (the number in parentheses reports the number times a negative curvature was detected);* minc *is the number of nonmonotone line search iterations—in parentheses is the number of times this heuristic failed. The globalized LNKS-*II*-TR algorithm is used. The Lagrange–Newton solver was stopped after* 50 *iterations. In the last column* $\mathrm{Re} \times \Delta f$ *gives the reduction of the objective function (with the respect the uncontrolled flow). "no cont" means that continuation was not activated.*

Re	Iter	Time	qn	Minc	$\|\mathbf{g} + \mathbf{A}^T\boldsymbol{\lambda}\|$	$\|\mathbf{c}\|$	$\mathrm{Re} \times \Delta f$
100 no cont	19	4.06	2	4	9×10^{-6}	9×10^{-6}	4.065

are the velocities (Dirichlet conditions) on the downstream half of the wing. The Reynolds number (based on the length of the wing root) was varied from 100 to 500, and the angle of attack was fixed at 12.5 degrees. The problem size is characterized by 710,023 state variables and 4,984 control variables.

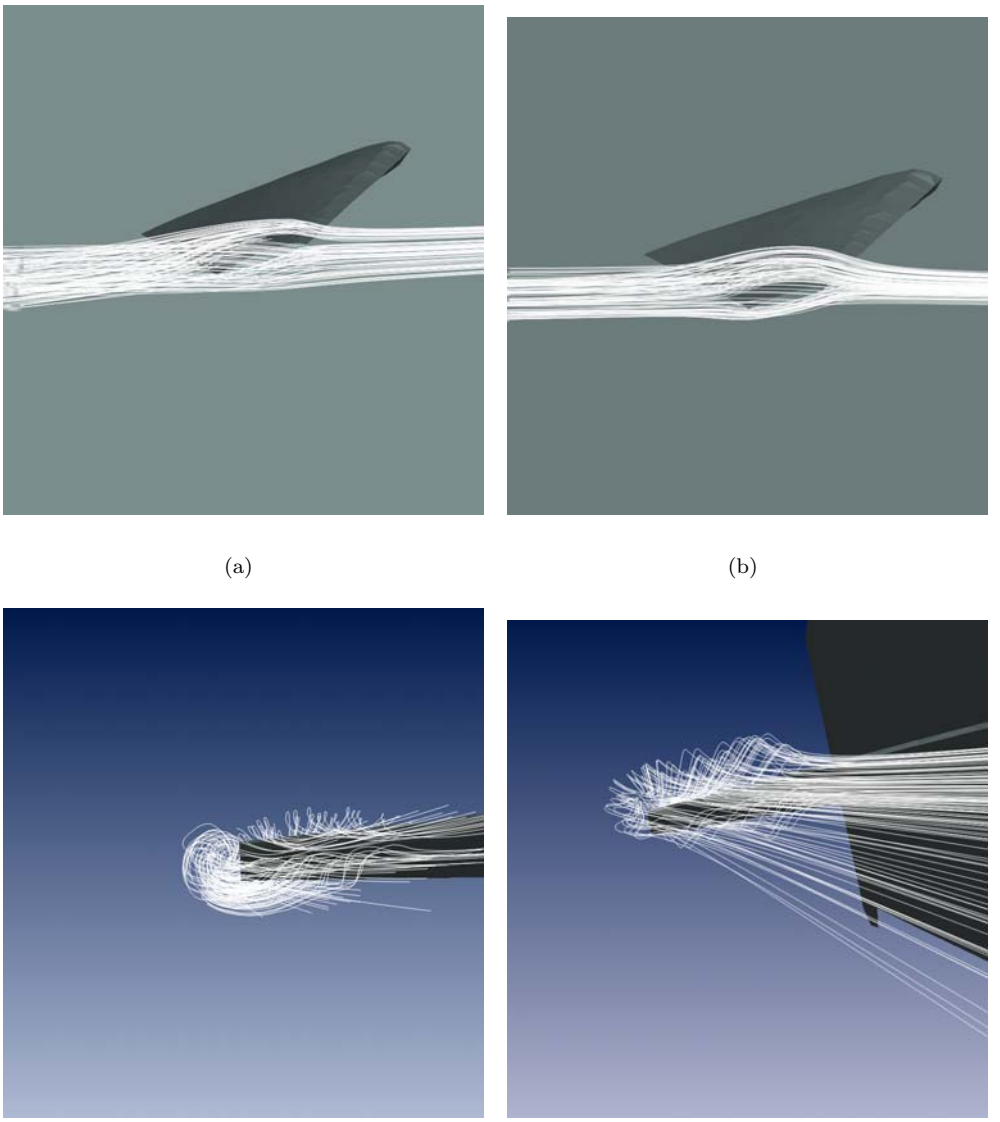
Table 4.5 summarizes the results from this set of experiments. The main purpose of this analysis is to compare continuation with the other globalization techniques. In addition we employ the double inexactness idea; that is, we solve inexactly in both the continuation loop and the Lagrange–Newton loop. It is apparent that the use of continuation is crucial in this problem. Without it, and for Reynolds numbers larger than 300, LNKS was forced to terminate early (we set the Lagrange–Newton iteration bound to 50). In the last row (Re = 500) and when we did not use continuation, LNKS ends up switching to a QN-RSQP step 42 times out of a total of 50 iterations; a negative curvature direction was detected 5 times. As a result LNKS was terminated without satisfying the convergence criteria. Furthermore, the small reduction in the objective function and the residuals (last three columns) indicate small progress at each optimization step. Note that in these examples we did not activate backtracking in the continuation parameter.

It could be argued that a reason the algorithm stagnated was the early termination of the Krylov–Schur solver due to inexactness. We did not conduct exhaustive experiments to confirm or reject this. However, our experience on numerous problems suggests that it is the ill-conditioning and nonlinearity of these problems that leads to stagnation and not the inexactness. In our tests (systematic or during debugging and development) it was never the case that a run with exact solves converged in reasonable time, and the inexact version did not. On the contrary, inexactness significantly reduced execution times.

On the other hand, when we used continuation (consisting of relatively large steps on the Reynolds number), the algorithm converged successfully after 39 Lagrange–Newton iterations. Reverting to QN-RSQP was required just once. In the minc

column of Table 4.5 we monitor the nonmonotone line search criterion. Recall that if the merit function line search on the LNKS step fails, we perform a line search with a different merit—the KKT residual (i.e., the first-order optimality conditions). If the step gets accepted, via backtracking, we use it as an update direction. Eventually, we insist that the (augmented Lagrangian) merit gets reduced. This strategy was successful 20 times and failed only twice.[9]

Finally we conclude with some comments on the physics of this problem. Figures 3 and 4 depict snapshots of the uncontrolled and controlled flow for Reynolds number 500. The wing-tip vortices are eliminated by optimization. But at what cost? Figure 5 shows a snapshot of the (scaled) control variables—the velocity boundary conditions. The image illustrates that optimization has created a perforated wing, which means a significant reduction in lift (the plane will never leave the ground!). Changing the problem to include a penalty on reduction in lift would remedy the difficulty; this example demonstrates the importance of including all relevant desired goals in the objective, lest optimization defeat them.



5. Conclusions. In this second part of our two-part article on the LNKS method for PDE-constrained optimization, we have presented the algorithmic components of the (outer) Lagrange–Newton solver, including such globalization strategies as line search, quasi-Newton safeguarding, and parameter continuation, and inexactness in the inner linear solver and its interaction with the line search. We studied the application of the LNKS method to a set of challenging viscous flow optimal boundary control problems that included such compounding factors as three-dimensional unstructured meshes, multicomponent coupling, large problem size, nonlinearity, and ill-conditioning. Our experiments demonstrate the efficacy and scalability of the LNKS method. The Krylov–Schur preconditioner maintained its effectiveness, the Lagrange–Newton solver exhibited mesh-independent convergence, and inexact Newton steps dramatically accelerated the method. A combination of line searching, quasi-Newton safeguarding, and continuation ensured global convergence.

The results reveal at least an order of magnitude improvement in solution time over popular quasi-Newton RSQP methods, rendering tractable some three-dimensional problems with close to a million state variables and several thousand control variables on parallel computers. Indeed, the optimum is often found in a , ,, multiple of the cost of a single simulation.

The LNKS method is more suitable for steady PDE constraints. Although the method is in principle applicable to time-dependent problems, it is not recommended for three-dimensional unsteady problems: because LNKS sees the entire space-time domain, it requires large memory for the state and adjoint variables. Moreover, the opportunities for economizing by hiding the nonlinear and linear forward iterations behind the optimization iterations are limited, since the nonlinear systems at each time step are usually mildly nonlinear and well-conditioned (for time-accurate integration). We are investigating various ways to address this issue. Another important extension of LNKS is the treatment of inequality constraints via interior point methods.

OPTIMIZING THE EVALUATION OF FINITE ELEMENT MATRICES*

ROBERT C. KIRBY†, MATTHEW KNEPLEY‡, ANDERS LOGG§, AND L. RIDGWAY SCOTT¶

Abstract. Assembling stiffness matrices represents a significant cost in many finite element computations. We address the question of optimizing the evaluation of these matrices. By finding redundant computations, we are able to significantly reduce the cost of building local stiffness matrices for the Laplace operator and for the trilinear form for Navier–Stokes operators. For the Laplace operator in two space dimensions, we have developed a heuristic graph algorithm that searches for such redundancies and generates code for computing the local stiffness matrices. Up to cubics, we are able to build the stiffness matrix on any triangle in less than one multiply-add pair per entry. Up to sixth degree, we can do it in less than about two pairs. Preliminary low-degree results for Poisson and Navier-Stokes operators in three dimensions are also promising.

Key words. finite element, compiler, variational form

1. Introduction.

It has often been observed that the formation of the matrices arising from finite element methods over unstructured meshes takes a substantial amount of time and is one of the primary disadvantages of finite elements over finite differences. Here, we will show that the standard algorithm for computing finite element matrices by integration formulae is far from optimal and will present a technique that can generate algorithms with considerably fewer operations even than well-known precomputation techniques.

From fairly simple examples with Lagrangian finite elements, we will present a novel optimization problem and present heuristics for the automatic solution of this problem. We demonstrate that the stiffness matrix for the Laplace operator can be computed in about one multiply-add pair per entry in two dimensions up to cubics, and about two multiply-add pairs up to degree 6. Low-order examples in three dimensions suggest similar possibilities, which we intend to explore in the future. More important, the techniques are not limited to linear problems—in fact, we show the potential for significant optimizations for the nonlinear term in the Navier–Stokes equations. These results seem to have lower flop counts than even the best quadrature rules for simplices.

Our long-term goal is to develop a "form compiler" for finite element methods. Such a compiler will map high-level descriptions of the variational problem and finite element spaces into low-level code for building the algebraic systems. Currently, the Sundance project [21, 20] and the DOLFIN project [10] are developing run-time C++ systems for the assembly variational forms. Recent work in the PETSc project [18] is leading to compilation of variational forms into C code for building local matrices. Our work here complements these ideas by suggesting compiler optimizations for such codes that would greatly enhance the run-time performance of the matrix assembly.

Automating tedious but essential tasks has proven remarkably successful in many areas of scientific computing. Automatic differentiation of numerical code has allowed complex algorithms to be used reliably [5]. Indeed the family of automatic differentiation tools [1] that automatically produce efficient gradient, adjoint, and Hessian algorithms for existing code has been invaluable in enabling optimal control calculations and Newton-based nonlinear solvers.

2. Matrix evaluation by assembly. Finite element matrices are assembled by summing the constituent parts over each element in the mesh. This is facilitated through the use of a numbering scheme called the local-to-global index. This index, $\iota(e, \lambda)$, relates the local (or element) node number, $\lambda \in \mathcal{L}$, on a particular element, indexed by e, to its position in the global node ordering [4]. This local-to-global indexing works for Lagrangian finite elements, but requires generalizations for other families of elements. While this generalization is required for assembly, our techniques for optimizing the computation over each element can still be applied in those situations.

We may write a finite element function f in the form

$$\sum_e \sum_{\lambda \in \mathcal{L}} f_{\iota(e,\lambda)} \phi^e_\lambda, \tag{2.1}$$

where f_i denotes the "nodal value" of the finite element function at the ith node in the global numbering scheme and $\{\phi^e_\lambda \,:\, \lambda \in \mathcal{L}\}$ denotes the set of basis functions on the element domain T_e. By definition, the element basis functions, ϕ^e_λ, are extended by zero outside T_e. In many important cases, we can relate all of the "element" basis functions ϕ^e_λ to a fixed set of basis functions on a "reference" element, $\mathcal{T}$, via some mapping of $\mathcal{T}$ to T_e. This mapping could involve changing both the "x" values and the "ϕ" values in a coordinated way, as with the Piola transform [2], or it could be one whose Jacobian is nonconstant, as with tensor-product elements or isoparametric elements [4]. But for a simple example, we assume that we have an affine mapping, $\xi \to J\xi + x_e$, of $\mathcal{T}$ to T_e:

$$\phi^e_\lambda(x) = \phi_\lambda \left(J^{-1}(x - x_e) \right).$$

The inverse mapping $x \to \xi = J^{-1}(x - x_e)$ has as its Jacobian

$$J^{-1}_{mj} = \frac{\partial \xi_m}{\partial x_j},$$

and this is the quantity which appears in the evaluation of the bilinear forms. Of course, $\det J = 1/\det J^{-1}$.

The assembly algorithm utilizes the decomposition of a variational form as a sum over "element" forms

$$a(v, w) = \sum_e a_e(v, w),$$

where the "element" bilinear form for Laplace's equation is defined (and evaluated) via

$$
\begin{aligned}
a_e(v,w) &:= \int_{T_e} \nabla v(x)\cdot\nabla w(x)\,dx \\
&= \int_{\mathcal{T}} \sum_{j=1}^{d} \frac{\partial}{\partial x_j} v(J\xi + x_e) \\
&\quad \frac{\partial}{\partial x_j} w(J\xi + x_e)\det(J)\,d\xi \\
&= \int_{\mathcal{T}} \sum_{j,m,m'=1}^{d} \frac{\partial \xi_m}{\partial x_j}\frac{\partial}{\partial \xi_m}\left(\sum_{\lambda\in\mathcal{L}} v_{\iota(e,\lambda)}\phi_\lambda(\xi)\right) \\
&\quad \times \frac{\partial \xi_{m'}}{\partial x_j}\frac{\partial}{\partial \xi_{m'}}\left(\sum_{\mu\in\mathcal{L}} w_{\iota(e,\mu)}\phi_\mu(\xi)\right)\det(J)\,d\xi \\
&= \begin{pmatrix} v_{\iota(e,1)} \\ \cdot \\ \cdot \\ v_{\iota(e,|\mathcal{L}|)} \end{pmatrix}^t \mathbf{K}^e \begin{pmatrix} w_{\iota(e,1)} \\ \cdot \\ \cdot \\ w_{\iota(e,|\mathcal{L}|)} \end{pmatrix}.
\end{aligned} \tag{2.2}
$$

Here, the [illegible], $\mathbf{K}^e$, is given by

$$
\begin{aligned}
K^e_{\lambda,\mu} &:= \sum_{j,m,m'=1}^{d} \frac{\partial \xi_m}{\partial x_j}\frac{\partial \xi_{m'}}{\partial x_j}\det(J)\int_{\mathcal{T}} \frac{\partial}{\partial \xi_m}\phi_\lambda(\xi)\frac{\partial}{\partial \xi_{m'}}\phi_\mu(\xi)\,d\xi \\
&= \sum_{j,m,m'=1}^{d} \frac{\partial \xi_m}{\partial x_j}\frac{\partial \xi_{m'}}{\partial x_j}\det(J) K_{\lambda,\mu,m,m'} \\
&= \sum_{m,m'=1}^{d} G^e_{m,m'} K_{\lambda,\mu,m,m'},
\end{aligned} \tag{2.3}
$$

where

$$
K_{\lambda,\mu,m,m'} = \int_{\mathcal{T}} \frac{\partial}{\partial \xi_m}\phi_\lambda(\xi)\frac{\partial}{\partial \xi_{m'}}\phi_\mu(\xi)\,d\xi \tag{2.4}
$$

and

$$
G^e_{m,m'} := \det(J)\sum_{j=1}^{d} \frac{\partial \xi_m}{\partial x_j}\frac{\partial \xi_{m'}}{\partial x_j} \tag{2.5}
$$

for $\lambda,\mu\in\mathcal{L}$ and $m,m' = 1,\ldots,d$.

The matrix associated with a bilinear form is

$$
A_{ij} := a(\phi_i,\phi_j) = \sum_e a_e(\phi_i,\phi_j) \tag{2.6}
$$

for all i,j, where ϕ_i denotes a global basis function. We can compute this again by assembly.

First, set all the entries of A to zero. Then loop over all elements e and local element numbers λ and μ and compute

$$A_{\iota(e,\lambda),\iota(e,\mu)} += K^e_{\lambda,\mu} = \sum_{m,m'} G^e_{m,m'} K_{\lambda,\mu,m,m'}, \tag{2.7}$$

where $G^e_{m,m'}$ are defined in (2.5). One can imagine trying to optimize the computation of each

$$K^e_{\lambda,\mu} = \sum_{m,m'} G^e_{m,m'} K_{\lambda,\mu,m,m'}, \tag{2.8}$$

but each such term must be computed separately. We consider this optimization in section 3.

3. Computing the Laplacian stiffness matrix with general elements. The tensor $K_{\lambda,\mu,m,n}$ can be presented as an $|\mathcal{L}| \times |\mathcal{L}|$ matrix of $d \times d$ matrices, as presented in Table 3.1 for the case of quadratics in two dimension. The entries of resulting matrix K^e can be viewed as the dot (or Frobenius) product of the entries of K and G^e. That is,

$$K^e_{\lambda,\mu} = \mathbf{K}_{\lambda,\mu} : G^e. \tag{3.1}$$

The key point is that certain dependencies among the entries of K can be used to significantly reduce the complexity of building each K^e. For example, the four 2×2 matrices in the upper-left corner of Table 3.1 have only one nonzero entry, and six others in K are zero. There are significant redundancies among the rest. For example, $\mathbf{K}_{3,1} = -4\mathbf{K}_{4,1}$, so once $\mathbf{K}_{4,1} : G^e$ is computed, $\mathbf{K}_{3,1} : G^e$ may be computed by only one additional operation.

By taking advantage of these simplifications, we see that each K^e for quadratics in two dimensions can be computed with at most 18 floating point operations (see section 3.2) instead of 288 floating point operations using the straightforward definition, an improvement of a factor of 16 in computational complexity.

The tensor $K_{\lambda,\mu,m,n}$ for the case of linears in three dimensions is presented in Table 3.2. Each K^e can be computed by computing the three row sums of G^e, the three column sums, and the sum of one of these sums. We also have to negate all of the column and row sums, leading to a total of 20 floating point operations instead of 288 floating point operations using the straightforward definition, an improvement of a factor of nearly 15 in computational complexity. Using symmetry of G^e (row sums equal column sums) we can reduce the computation to only 10 floating point operations, leading to an improvement of nearly 29.

We leave it as an exercise to work out the reductions in computation that can be done for the case of linears in two dimensions.

3.1. Algorithms for determining reductions. Obtaining reductions in computation can be done systematically as follows. It may be useful to work in rational arithmetic and keep track of whether terms are exactly zero and determine common divisors. However, floating point representations may be sufficient in many cases. We can start by noting which submatrices are zero, which ones have only one nonzero element, and so forth. Next, we find arithmetic relationships among the submatrices, as follows.

Determining whether

$$\mathbf{K}_{\lambda,\mu} = c\mathbf{K}_{\lambda',mu'} \tag{3.2}$$

-1	0	0	0	-1	0	0	0	-1	1	1	1

requires just simple linear algebra. We think of these as vectors in d^2-dimensional space and just compute the angle between the vectors. If this angle is zero, then (3.2) holds. Again, if we assume that we are working in rational arithmetic, then c could be determined as a rational number.

Similarly, a third vector can be written in terms of two others by considering its projection on the first two. That is,

$$\mathbf{K}_{\lambda,\mu} = c_1 \mathbf{K}_{\lambda^1,\mu^1} + c_2 \mathbf{K}_{\lambda^2,\mu^2} \tag{3.3}$$

if and only if the projection of $\mathbf{K}_{\lambda,\mu}$ onto the plane spanned by $\mathbf{K}_{\lambda^1,\mu^1}$ and $\mathbf{K}_{\lambda^2,\mu^2}$ is equal to $\mathbf{K}_{\lambda,\mu}$.

Higher-order relationships can be determined similarly by linear algebra as well. Note that any $d^2 + 1$ entries $\mathbf{K}_{\lambda,\mu}$ will be linearly dependent, since they are in d^2-dimensional space. Thus we might only expect lower-order dependencies to be useful in reducing the computational complexity.

We can then form graphs that represent the computation of K^e in (3.1). The graphs have d^2 nodes representing G^e as inputs and $|\mathcal{L}| \times |\mathcal{L}|$ nodes representing the entries of K^e as outputs. Internal edges and nodes represent computations and temporary storage. The inputs to a given computation come directly from G^e or indirectly from other internal nodes in the graph.

The computation represented in (2.7) would correspond to a dense graph in which each of the input nodes is connected directly to all $|\mathcal{L}| \times |\mathcal{L}|$ output nodes. It will be possible to attempt to reduce the complexity of the computation by finding sparse

graphs that represent equivalent computations.

We can generate interesting graphs by analyzing the entries of $\mathbf{K}_{\lambda,\mu}$ for relationships as described above. It would appear useful to consider

- entries $\mathbf{K}_{\lambda,\mu}$ which have only one nonzero element,
- entries $\mathbf{K}_{\lambda,\mu}$ which have $2 \leq k \ll d^2$ nonzero elements,
- entries $\mathbf{K}_{\lambda,\mu}$ which are scalar multiples of other elements,
- entries $\mathbf{K}_{\lambda,\mu}$ which are linear combinations of other elements,

and so forth. For each graph representing the computation of K^e, we have a precise count of the number of floating point operations, and we can simply minimize the total number over all graphs generated by the above heuristics. Our examples indicate that computational simplifications consisting of an order of magnitude or more can be achieved.

We have developed a code called `FErari` (Finite Element ReARrangements of Integrals or Finite Element Rearrangement to Automatically Reduce Instructions) to carry out such optimizations automatically. We describe this in detail in section 4.3. This code linearizes the graph representation discussed above, taking a particular evaluation path that is based on heuristics chosen to approximate optimal evaluation. We have used it to show that for classes of elements, significant improvements in computational efficiency are available.

3.2. Computing K for quadratics. Here we give a detailed algorithm for computing K for quadratics. Thus we have

(3.4)
$$6 * K^e = \begin{pmatrix} 3G_{11} & -G_{12} & \gamma_{11} & \gamma_0 & 4G_{12} & 0 \\ -G_{21} & 3G_{22} & \gamma_{22} & 0 & 4G_{21} & \gamma_1 \\ \gamma_{11} & \gamma_{22} & 3(\gamma_{11}+\gamma_{22}) & \gamma_0 & 0 & \gamma_1 \\ \gamma_0 & 0 & \gamma_0 & \gamma_2 & -\gamma_3 - 8G_{22} & \gamma_3 \\ 4G_{21} & 4G_{12} & 0 & -\gamma_3 - 8G_{22} & \gamma_2 & -\gamma_3 - 8G_{11} \\ 0 & \gamma_1 & \gamma_1 & \gamma_3 & -\gamma_3 - 8G_{11} & \gamma_2 \end{pmatrix},$$

where the G_{ij}'s are the inputs and the intermediate quantities γ_i are defined and computed from

(3.5)
$$\begin{aligned} \gamma_0 &= -4\gamma_{11}, \\ \gamma_1 &= -4\gamma_{22}, \\ \gamma_2 &= 4G_{1221} + 8G_{1122} = \gamma_3 + 8\gamma_{12} = 8(G_{12} + \gamma_{12}), \\ \gamma_3 &= 4G_{1221} = 4\gamma_{21} = 8G_{12}, \end{aligned}$$

where we use the notation $G_{ijk\ell} := G_{ij} + G_{k\ell}$, and finally, the γ_{ij}'s are

(3.6)
$$\begin{pmatrix} \gamma_{11} = G_{11} + G_{12} = G_{1112} & \gamma_{12} = G_{11} + G_{22} = G_{1122} \\ \gamma_{21} = G_{12} + G_{21} = G_{1221} & \gamma_{22} = G_{12} + G_{22} = G_{1222} \end{pmatrix}.$$

Let us distinguish different types of operations. The above formulas involve (a) negation, (b) multiplication of integers and floating point numbers, and (c) additions of floating point numbers. Since the order of addition is arbitrary, we may assume that the operations (c) are commutative (although changing the order of evaluation may change the result). Thus we have $G_{1222} = G_{2212}$ and so forth. The symmetry of G implies that $G_{1112} = G_{1121}$ and $G_{2122} = G_{1222}$. The symmetry of G implies that K^e is also symmetric, by inspection, as it must be from the definition.

The computation of the entries of K^e proceeds as follows. The computations in (3.6) are done first and require only four (c) operations, or three (c) operations and one (b) operation ($\gamma_{21} = 2G_{12}$). Next, the γ_i's are computed via (3.5), requiring four (b) operations and one (c) operation. Finally, the matrix K^e is completed, via three (a) operations, seven (b) operations, and three (c) operations. This makes a total of three (a) operations, twelve (b) operations, and three (c) operations. Thus only 18 operations are required to evaluate K^e, compared with 288 operations via the formula (2.8).

It is clear that there may be other algorithms with the same amount of work (or less) since there are many ways to decompose some of the submatrices in terms of others. Finding (or proving) the absolute minimum may be difficult. Moreover, the metric for minimization should be run time, not some arbitrary way of counting operations. Thus the right way to utilize the ideas we are presenting may be to identify sets of ways to evaluate finite element matrices. These could then be tested on different systems (architectures plus compilers) to see which is the best. It is amusing that it takes fewer operations to compute K^e than it does to write it down, so it may be that memory traffic should be considered in an optimization algorithm that seems to be the most efficient algorithm.

4. Evaluation of general multilinear forms. General multilinear forms can appear in finite element calculations. As an example of a trilinear form, we consider that arising from the first-order term in the Navier–Stokes equations. Though additional issues arise over bilinear forms, many techniques carry over to give efficient algorithms.

The local version of the form is defined by

$$
\begin{aligned}
c_e(\mathbf{u};\mathbf{v},\mathbf{w}) &:= \int_{T_e} \mathbf{u}\cdot\nabla\mathbf{v}(x)\cdot\mathbf{w}(x)\,dx \\
&= \int_{T_e} \sum_{j,k=1}^{d} u_j(x)\frac{\partial}{\partial x_j}v_k(x)w_k(x)\,dx \\
&= \int_{\mathcal{T}} \sum_{j,k=1}^{d} u_j(J\xi+x_e)\frac{\partial}{\partial x_j}v_k(J\xi+x_e)w_k(J\xi+x_e)\det(J)\,d\xi \\
&= \int_{\mathcal{T}} \sum_{j,k,m=1}^{d} \left(\sum_{\lambda\in\mathcal{L}} u_j^{\iota(e,\lambda)}\phi_\lambda(\xi)\right)\frac{\partial\xi_m}{\partial x_j}\left(\sum_{\mu\in\mathcal{L}} v_k^{\iota(e,\mu)}\frac{\partial}{\partial\xi_m}\phi_\mu(\xi)\right) \qquad (4.1)\\
&\quad\times\left(\sum_{\rho\in\mathcal{L}} w_k^{\iota(e,\rho)}\phi_\rho(\xi)\right)\det(J)\,d\xi \\
&= \sum_{j,k,m=1}^{d}\sum_{\lambda,\mu,\rho\in\mathcal{L}} u_j^{\iota(e,\lambda)}\frac{\partial\xi_m}{\partial x_j}v_k^{\iota(e,\mu)}w_k^{\iota(e,\rho)}\det(J) \\
&\quad\times\int_{\mathcal{T}}\phi_\lambda(\xi)\frac{\partial}{\partial\xi_m}\phi_\mu(\xi)\phi_\rho(\xi)\,d\xi.
\end{aligned}
$$

Thus we have found that

$$\begin{aligned} c_e(\mathbf{u},\mathbf{v},\mathbf{w}) &= \sum_{j,k=1}^{d} \sum_{\lambda,\mu,\rho\in\mathcal{L}} u_j^{\iota(e,\lambda)} v_k^{\iota(e,\mu)} w_k^{\iota(e,\rho)} \\ &\quad \times \sum_{m=1}^{d} \frac{\partial \xi_m}{\partial x_j} \det(J) \int_{\mathcal{T}} \phi_\lambda(\xi) \frac{\partial}{\partial \xi_m} \phi_\mu(\xi) \phi_\rho(\xi)\, d\xi \\ &= \sum_{j,k=1}^{d} \sum_{\lambda,\mu,\rho\in\mathcal{L}} u_j^{\iota(e,\lambda)} v_k^{\iota(e,\mu)} w_k^{\iota(e,\rho)} \sum_{m=1}^{d} \frac{\partial \xi_m}{\partial x_j} \det(J) N_{\lambda,\mu,\rho,m}, \end{aligned} \tag{4.2}$$

where

$$N_{\lambda,\mu,\rho,m} := \int_{\mathcal{T}} \phi_\lambda(\xi) \frac{\partial}{\partial \xi_m} \phi_\mu(\xi) \phi_\rho(\xi)\, d\xi. \tag{4.3}$$

To summarize, we have

$$\begin{aligned} c_e(\mathbf{u},\mathbf{v},\mathbf{w}) &= \sum_{j,k=1}^{d} \sum_{\lambda,\mu,\rho\in\mathcal{L}} u_j^{\iota(e,\lambda)} v_k^{\iota(e,\mu)} w_k^{\iota(e,\rho)} N^e_{\lambda,\mu,\rho,j} \\ &= \sum_{k=1}^{d} \sum_{\mu,\rho\in\mathcal{L}} v_k^{\iota(e,\mu)} w_k^{\iota(e,\rho)} \sum_{j=1}^{d} \sum_{\lambda\in\mathcal{L}} u_j^{\iota(e,\lambda)} N^e_{\lambda,\mu,\rho,j}, \end{aligned} \tag{4.4}$$

where the element coefficients $N^e_{\lambda,\mu,\rho,j}$ are defined by

$$N^e_{\lambda,\mu,\rho,j} := \sum_{m=1}^{d} \frac{\partial \xi_m}{\partial x_j} \det(J) N_{\lambda,\mu,\rho,m}. =: \sum_{m=1}^{d} \widetilde{G}_{mj} N_{\lambda,\mu,\rho,m}, \tag{4.5}$$

where $\widetilde{G}_m j := \frac{\partial \xi_m}{\partial x_j} \det(J)$. Recall that J is the Jacobian above, and J^{-1} is its inverse, and

$$\left(J^{-1}\right)_{m,j} = \frac{\partial \xi_m}{\partial x_j}.$$

Note that both $N_{\lambda,\mu,\rho,(\cdot)}$ and $N^e_{\lambda,\mu,\rho,(\cdot)}$ can be thought of as d-vectors. Moreover

$$N^e_{\lambda,\mu,\rho,(\cdot)} = \det(J) N_{\lambda,\mu,\rho,(\cdot)} J^{-1}.$$

Also note that $N_{\lambda,\mu,\rho,(\cdot)} = N_{\rho,\mu,\lambda,(\cdot)}$, so that considerable storage reduction could be made if desired.

The matrix C defined by $C_{ij} = c(\mathbf{u}, \phi_i, \phi_j)$ can be computed using the assembly algorithm as follows. First, note that C can be written as a matrix of dimension $|\mathcal{L}| \times |\mathcal{L}|$ with entries that are $d \times d$ diagonal blocks. In particular, let I_d denote the $d \times d$ identity matrix. Now set C to zero, loop over all elements, and update the matrix by

$$\begin{aligned} C_{\iota(e,\mu),\iota(e,\rho)} +&= I_d \sum_{j=1}^{d} \sum_{\lambda\in\mathcal{L}} u_j^{\iota(e,\lambda)} N^e_{\lambda,\mu,\rho,j} \\ &= I_d \sum_{m,j=1}^{d} \widetilde{G}_{mj} \left(\sum_{\lambda\in\mathcal{L}} u_j^{\iota(e,\lambda)} N_{\lambda,\mu,\rho,m} \right) \\ &= I_d \sum_{m,\lambda\in\mathcal{L}} \gamma_{m\lambda} N_{\lambda,\mu,\rho,m} \end{aligned} \tag{4.6}$$

for all μ and ρ, where

$$\gamma_{m\lambda} = \sum_{j=1}^{d} \widetilde{G}_{mj} u_j^{\iota(e,\lambda)}. \tag{4.7}$$

It thus appears that the computation of C can be viewed as similar in form to (3.1), and similar optimization techniques applied. In fact, we can introduce the notation $K^{e,u}$, where

$$K^{e,u}_{\mu,\rho} = \sum_{m,\lambda\in\mathcal{L}} \gamma_{m\lambda} N_{\lambda,\mu,\rho,m}. \tag{4.8}$$

Then the update of C is done in the obvious way with $K^{e,u}$.

4.1. Trilinear forms with piecewise linears. For simplicity, we may consider the piecewise linear case. Here, the standard mixed formulations are not inf-sup stable, but the trilinear form is still an essential part of the well-known family of stabilized methods [8, 11] that do admit equal-order piecewise linear discretizations. Moreover, our techniques could as well be used with the nonconforming linear element [6], which does admit an inf-sup condition when paired with piecewise constant pressures.

In the piecewise linear case, (4.3) simplifies to

$$N_{\lambda,\mu,\rho,m} := \frac{\partial \phi_\mu}{\partial \xi_m} \int_{\mathcal{T}} \phi_\lambda(\xi)\phi_\rho(\xi)\, d\xi. \tag{4.9}$$

We can think of $N_{\lambda,\mu,\rho,m}$ defined from two matrices $N_{\lambda,\mu,\rho,m} = D_{\mu,m}F_{\lambda,\rho}$, where

$$D_{\mu,m} := \frac{\partial \phi_\mu}{\partial \xi_m} = \begin{pmatrix} 1 & 0 \\ 0 & 1 \\ 1 & 1 \end{pmatrix} (d=2) \quad \text{and} \quad \begin{pmatrix} 1 & 0 & 0 \\ 0 & 1 & 0 \\ 0 & 0 & 1 \\ 1 & 1 & 1 \end{pmatrix} (d=3) \tag{4.10}$$

and

$$F_{\lambda,\rho} := \int_{\mathcal{T}} \phi_\lambda(\xi)\phi_\rho(\xi)\, d\xi. \tag{4.11}$$

The latter matrix is easy to determine. In the piecewise linear case, we can compute integrals of products using the quadrature rule that is based on edge midpoints (with equal weights given by the area of the simplex divided by the number of edges). Thus the weights are $\omega = 1/6$ for $d = 2$ and $\omega = 1/24$ for $d = 3$. Each of the values $\phi_\lambda(\xi)$ is either $\frac{1}{2}$ or zero, and the products are equal to $\frac{1}{4}$ or zero. For the diagonal terms $\lambda = \rho$, the product is nonzero on d edges, so $F_{\lambda,\lambda} = 1/12$ for $d = 2$ and $1/32$ for $d = 3$. If $\lambda \neq \rho$, then the product $\phi_\lambda(\xi)\phi_\rho(\xi)$ is nonzero for exactly one edge (the one connecting the corresponding vertices), so $F_{\lambda,\rho} = 1/24$ for $d = 2$ and $1/96$ for $d = 3$. Thus we can describe the matrices F in general as having d on the diagonals, 1 on the off-diagonals, and scaled by $1/24$ for $d = 2$ and $1/96$ for $d = 3$. Thus

$$\begin{aligned} F &= \frac{1}{4(d+1)!} \begin{pmatrix} d & 1 & \cdots & 1 \\ 1 & d & \cdots & 1 \\ \cdot & \cdot & \cdots & \cdot \\ 1 & 1 & \cdots & d \end{pmatrix} \\ &= \frac{d-1}{4(d+1)!} I_{d+1} + \frac{1}{4(d+1)!} \begin{pmatrix} 1 & 1 & \cdots & 1 \\ 1 & 1 & \cdots & 1 \\ \cdot & \cdot & \cdots & \cdot \\ 1 & 1 & \cdots & 1 \end{pmatrix} \end{aligned} \tag{4.12}$$

TABLE 4.1

0	0	0	0	0	0	0	0	1	1	1	3	1	1	1	3

for $d = 2$ or 3, where I_d denotes the $d \times d$ identity matrix. Note that for a given d, the matrices in (4.12) are $d+1 \times d+1$ in dimension.

The tensor N for linears in three dimensions is presented in Table 4.1. We see now a new ingredient for computing the entries of $K^{e,u}$ from the matrix $\gamma_{m,\lambda}$. Define $\gamma_m = \sum_{\lambda=1}^{4} \gamma_{m,\lambda}$ for $m = 1, 2, 3$, and then $\tilde{\gamma}_{m,\lambda} = 2\gamma_{m,\lambda} + \gamma_m$ for $m = 1, 2, 3$ and $\lambda = 1, 2, 3, 4$. Then

$$K^{e,u} = \begin{pmatrix} \tilde{\gamma}_{11} & \tilde{\gamma}_{21} & \tilde{\gamma}_{31} & \tilde{\gamma}_{11} + \tilde{\gamma}_{21} + \tilde{\gamma}_{31} \\ \tilde{\gamma}_{12} & \tilde{\gamma}_{22} & \tilde{\gamma}_{32} & \tilde{\gamma}_{12} + \tilde{\gamma}_{22} + \tilde{\gamma}_{32} \\ \tilde{\gamma}_{13} & \tilde{\gamma}_{23} & \tilde{\gamma}_{33} & \tilde{\gamma}_{13} + \tilde{\gamma}_{23} + \tilde{\gamma}_{33} \\ \tilde{\gamma}_{14} & \tilde{\gamma}_{24} & \tilde{\gamma}_{34} & \tilde{\gamma}_{14} + \tilde{\gamma}_{24} + \tilde{\gamma}_{34} \end{pmatrix}. \tag{4.13}$$

However, note that the γ_m's are not computations that would have appeared directly in the formulation of $K^{e,u}$ but are intermediary terms that we have defined for convenience and efficiency. This requires 39 operations, instead of 384 operations using (4.8).

4.2. Algorithmic implications. The example in section 4 provides guidance for the general case. First of all, we see that the "vector" space of the evaluation problem (4.8) can be arbitrary in size. In the case of the trilinear form in Navier–Stokes equations considered there, the dimension is the spatial dimension times the dimension of the approximation (finite element) space. High-order finite element approximations [14] could lead to very high-dimensional problems. Thus we need to think about looking for a relationship among the "computational vectors" in high-dimensional spaces, e.g., up to several hundred in extreme cases. The example in section 4.1 is the lowest order case in three space dimensions, and it requires a twelve-dimensional space for the complexity analysis.

Second, it will not be sufficient just to look for simple combinations to determine optimal algorithms, as discussed in section 3.1. The example in section 4.1 shows that we need to think of this as an approximation problem. We need to look for vectors (matrices) which closely approximate a set of vectors that we need to compute. The vectors $\mathbf{V}_1 = (1, 1, 1, 1, 0, \ldots, 0)$, $\mathbf{V}_2 = (0, 0, 0, 0, 1, 1, 1, 1, 0, 0, 0, 0)$, $\mathbf{V}_3 = (0, \ldots, 0, 1, 1, 1, 1)$ are each edit-distance one from four vectors we need to compute. The quantities γ_m represent the computations (dot-product) with $\mathbf{V}_m$. The quantities $\tilde{\gamma}_{m\lambda}$ are simple perturbations of γ which require only two operations to evaluate. A simple rescaling can reduce this to one operation.

TABLE 4.2
Summary of results for FErari on triangular Lagrange elements.

Order	Entries	Base MAPs	FErari MAPs
1	6	24	7
2	21	84	15
3	55	220	45
4	120	480	176
5	231	924	443
6	406	1624	867

Edit distance is a useful measure for approximating the computational complexity distance, since it provides an upper-bound on the number of computations it takes to get from one vector to another. Thus we need to add this type of optimization to the techniques listed in section 3.1.

4.3. The FErari system. The algorithms discussed in sections 3.1 and 4.2 have been implemented in a prototype system which we call FErari (Finite Element ReARrangements of Integrals or Finite Element Rearrangement to Automatically Reduce Instructions). We have used it to build optimized code for the local stiffness matrices for the Laplace operator using Lagrange polynomials of up to degree six. While there is no perfect metric to predict efficiency of implementations due to differences in architecture, we have taken a simple model to measure improvement due to FErari. A particular algorithm could be tuned by hand, common divisors in rational arithmetic could be sought, and more care could be taken to order the operations to maximize register usage. Before discussing the implementation of FErari more precisely, we point to Table 4.2 to see the levels of optimization detected. In the table, "Entries" refers to the number of entries in the upper triangle of the (symmetric) matrix. "Base MAPs" refers to the number of multiply-add pairs if we were not to detect dependencies at all, and "FErari MAPs" is the number of multiply-add pairs in the generated algorithm. Although we gain only about a factor of two for the higher-order cases, we are automatically generating algorithms with fewer multiply-add pairs than entries for linears, quadratics, and cubics.

FErari builds a graph of dependencies among the tensors $\mathbf{K}_{\lambda,\mu}$ in several stages. We now describe each of these stages, what reductions they produce in assembling K^e, and how much they cost to perform. We start by building the tensors $\{\mathbf{K}_{\lambda,\mu}\}$ for $1 \leq \lambda \leq \dim P_k$ and $\lambda \leq \mu \leq \dim P_k$ using FIAT (FInite element Automatic Tabulator) [15]. In discussing algorithmic complexity of our heuristics below, we shall let n be the size of this set. Throughout, we are typically using "greedy" algorithms that quit when they find a dependency. Also, the order in which these stages are performed matters, as if a dependency for a tensor found at one stage, will not mark it again later.

As we saw earlier, sometimes $\mathbf{K}_{\lambda,\mu} = 0$. In this case, $(K^e)_{\lambda,\mu} = 0$ as well for any e, so these entries cost nothing to build. Searching for uniformly zero tensors can be done in n operations. While we found that three tensors vanish for quadratics and cubics, none do for degrees four through six.

TABLE 4.3
Results of FErari on Lagrange elements of degrees 1 *through* 6.

Order	Entries	Zero	Eq	Eq t	1 Entry	Col	Ed1	Ed2	LC	Default	Cost
1	6	0	0	0	3	0	2	0	1	0	7
2	21	3	2	3	4	2	5	1	1	0	15
3	55	3	17	0	5	8	12	5	5	0	45
4	120	0	23	0	7	2	25	30	25	8	176
5	231	0	18	0	13	5	41	71	45	38	443
6	406	0	27	0	17	7	59	139	61	96	867

Next, if two tensors $\mathbf{K}_{\lambda,\mu}$ and $\mathbf{K}_{\lambda',\mu'}$ are equal, then their dot product into G^e will also be equal. So, we mark $\mathbf{K}_{\lambda',\mu'}$ as depending on $\mathbf{K}_{\lambda,\mu}$. Naively, searching through the nonzero tensors is an $O(n^2)$ process, but can be reduced to $O(n\log(n))$ operations by inserting the tensors into a binary tree using lexicographic ordering of the entries of the tensors. The fourth column of Table 4.3 titled "Eq" shows the number of such dependencies that FErari found.

As a variation on this theme, if $\mathbf{K}_{\lambda,\mu} = (\mathbf{K}_{\lambda',\mu'})^t$, then $\mathbf{K}_{\lambda,\mu} : G^e = (\mathbf{K}_{\lambda',\mu'} : G^e)$ since G^e is symmetric. Hence, once $(K^e)_{\lambda,\mu}$ is computed, $(K^e)_{\lambda',\mu'}$ is free. We may also search for these dependencies among nonzero tensors that are not already marked as equal to another tensor in $O(n\log(n))$ time by building a binary tree. In this case, we compare by lexicographically ordering the components of the symmetric part of each tensor (recall the symmetric part of K is $\frac{K+K^t}{2}$). Equality of symmetric parts is necessary but not sufficient for two matrices to be transposes of each other. So, if our insertion into the binary tree reveals an entry with the same symmetric part, we then perform an additional check to see if the two are indeed transposes. Unfortunately, we found such dependencies only for quadratics, where we found three. This is indicated in the fifth column of Table 4.3, titled "Eq t."

So far, we have focused on finding and marking tensors that can be dotted into G^e with no work (perhaps once some other dot product has been performed). Now, we turn to ways of finding tensors whose dot product with G^e can be computed cheaply. The first such way is to find unmarked tensors $\mathbf{K}_{\lambda,\mu}$ with only one nonzero entry. This may be trivially performed in $O(n)$ time. The sixth column of Table 4.3, titled "1 Entry," shows the number of such tensors for each polynomial degree.

If there is a constant α such that $\mathbf{K}_{\lambda',\mu'} = \alpha\mathbf{K}_{\lambda,\mu}$, then $\mathbf{K}_{\lambda',\mu'} : G^e = \alpha\mathbf{K}_{\lambda,\mu} : G^e$ and hence may be computed in a single multiply. Moreover, colinearity among the remaining tensors may be found in $O(n\log(n))$ time by a binary tree and lexicographic ordering of an appropriate normalization. To this end, we divide each (nonzero) tensor by its Frobenius norm and ensure that its first nonzero entry is positive. If insertion into the binary tree gives equality under this comparison, then we mark the tensors as colinear. The numbers of such dependencies found for each degree is seen in the "Col" column of Table 4.3.

Next, we seek tensors that are close together in edit distance, differing only in one or two entries. Then, the difference between the dot products can be computed cheaply. For each unmarked tensor, we look for a marked tensor that is edit-distance one away. We iterate this process until no more dependencies are found, then search for dependencies among the remainders. We repeat this process for things that are edit-distance two apart. In general, this process seems to be $O(n^2)$. Table 4.3 has two columns, titled "Ed1" and "Ed2," showing the number of tensors we were able to mark in such a way.

```

        K[2,2] = 0.5 * G[3]
        K[0,1] = K[1,0]
        K[0,2] = K[2,0]
        K[1,2] = K[2,1]
        return K
```

FIG. 4.1. *Generated code for computing the stiffness matrix for linear basis functions.*

If a tensor is a linear combination of two other tensors, then its dot product can be computed in two multiply-add pairs. This is an expensive search to perform ($O(n^3)$), since we have to search through pairs of tensors for each unmarked tensor. However, we do seem to find quite a few linear combinations, as seen in the "LC" column of Table 4.3. Any remaining tensors are marked as "Default" in which case they are computed by the standard four multiply-add pairs.

After building the graph of dependencies, we topologically sort the vertices. This gives an ordering for which, if vertex u depends on vertex v, then v occurs before u, an essential feature for generating code. We currently generate Python code for ease in debugging and integrating with the rest of our computational system, but we could just as easily generate C or Fortran. In fact, in the future we hope to generate not only particular code, but abstract syntax as in PETSc 3.0.

One interesting feature of the generated code is that it is completely unrolled—no loops are done. This leads to relatively large functions, but sets up the code to a point where the compiler really only needs to handle register allocation. In Figure 4.1, we present the generated code for computing linears.

4.4. Code verification. In general,the question of verifying a code's correctness is difficult. In this case, we have taken an existing Poisson solver and replaced the function to evaluate the local stiffness matrix with FErari-generated code. The correct convergence rates are still observed, and the stiffness matrices and computed solutions agree to machine precision. However, in the future, we hope to generate optimized code for new, complicated forms where we do not have an existing verified implementation, and the general question of verifying such codes is beyond the scope of this present work.

5. Computing a matrix via quadrature. The computations in equations (2.6)–(2.7) can be computed via quadrature as

$$
\begin{aligned}
A_{\iota(e,\lambda),\iota(e,\mu)} +&= \sum_{\xi\in\Xi} \omega_\xi \nabla\phi_\lambda(\xi)\cdot(\mathbf{G}^e\nabla\phi_\mu(\xi)) \\
&= \sum_{\xi\in\Xi} \omega_\xi \sum_{m,n=1}^{d} \phi_{\lambda,m}(\xi) G^e_{m,n}\phi_{\mu,n}(\xi) \\
&= \sum_{m,n=1}^{d} G^e_{m,n} \sum_{\xi\in\Xi} \omega_\xi \phi_{\lambda,m}(\xi)\phi_{\mu,n}(\xi) \\
&= \sum_{m,n=1}^{d} G^e_{m,n} K_{\lambda,\mu,m,n},
\end{aligned}
\tag{5.1}
$$

where the coefficients $K_{\lambda,\mu,m,n}$ are analogous to those defined in (2.3), but here they are defined by quadrature:

$$
K_{\lambda,\mu,m,n} = \sum_{\xi\in\Xi} \omega_\xi \phi_{\lambda,m}(\xi)\phi_{\mu,n}(\xi). \tag{5.2}
$$

(The coefficients are exactly those of (2.3) if the quadrature is exact.)

The right strategy for computing a matrix via quadrature would thus appear to be to compute the coefficients $K_{\lambda,\mu,m,n}$ first using (5.2), and then proceeding as before. However, there is a different strategy associated with quadrature when we want only to compute the [illegible] of the linear operator associated with the matrix and not the matrix itself (cf. [16]).

6. Other approaches. We have presented one approach to optimize the computation of finite element matrices. Other approaches have been suggested for optimizing code for scientific computation. The problem that we are solving can be represented as a sparse-matrix-times-full-matrix multiply, $\mathcal{K}\mathcal{G}$, where the dimensions of $\mathcal{K}$ are, for example, $|\mathcal{L}|^2 \times d^2$ for Laplace's equation in d dimensions using a (local) finite element space $\mathcal{L}$. For the nonlinear term in Navier–Stokes equations, the dimensions of $\mathcal{K}$ become $|\mathcal{L}|^2 \times d|\mathcal{L}|$. The first dimension of $\mathcal{G}$ of course matches the second of $\mathcal{K}$, but the second dimension of $\mathcal{G}$ is equal to the number of elements in the mesh. Thus it is worthwhile to do significant precomputation on $\mathcal{K}$.

At a low level, ATLAS [26] works with operations such as loop unrolling, cache blocking, etc. This type of optimization would not find the reductions in computation that FErari does, since the latter identifies more complex algebraic structures. In this sense, our work is more closely aligned with that of FLAME [7] which works with operations such as rank updates, triangular solves, etc. The BeBOP group has also worked on related issues in sparse matrix computation [22, 24, 23, 25, 12]. Our work could be described as utilizing a sparsity structure in a matrix representation, and it can be written as multiplying a sparse matrix times a very large set of (relatively small) vectors (the columns of $\mathcal{G}$). This is the reverse of the case considered in the SPARSITY system [13], where multiplying a sparse matrix times a small number of large vectors is considered.

Clearly the ideas we present here could be coupled with these approaches to generate improved code. The novelty of our work resides in the precomputation that is applied to evaluate the action of $\mathcal{K}$. In this way, it resembles the reorganization of computation done for evaluation of polynomials or matrix multiply [17].

7. Timing results. We performed several experiments for the Poisson problem with piecewise linear and piecewise quadratic elements. We set up a series of meshes using the mesh library in DOLFIN [10]. These meshes contained between 2048 and

524288 triangles. We timed computation of local stiffness matrices by several techniques; inserting them into a sparse PETSc matrix [3], multiplying the matrix onto a vector, and solving the linear system. All times were observed to be linear in the number of triangles, so we report all data as time per million triangles. All computations were performed on a Linux workstation with a 3 GHz Pentium 4 processor with 2 GB of RAM. All our code was compiled using `gcc` with "−O3" optimization.

Our goal is to assess the efficacy and relevance of our proposed optimizations. Solver technology has been steadily improving over the last several decades, with multigrid and other optimal strategies being found for wider classes of problems. When such efficient solvers are available, the cost of assembling the matrices (both computing local stiffness matrices and inserting them into the global matrix) is much more important. This is especially true in geometric multigrid methods in which a stiffness matrix can be built on each of a sequence of nested meshes, but only a few iterations are required for convergence. To factor out the choice of solver, we concentrate first on the relative costs of building local stiffness matrices, inserting them into the global matrix, and applying the matrix to a vector.

We used four strategies for computing the local stiffness matrices: numerical quadrature, tensor contractions (four flops per entry), tensor contractions with zeros omitted (this code was generated by the FEniCS form compiler [19]), and the FErari-optimized code translated into C. For both linear and quadratic elements, the cost of building all of the local stiffness matrices and inserting them into the global sparse matrix was comparable (after storage had been preallocated). In both situations, computing the matrix-vector product is an order of magnitude faster than computing the local matrices and inserting them into the global matrix. These costs, all measured as seconds to process one million triangles, are given in Table 7.1 and plotted in Figure 7.1 using log scale for time.

We may draw several conclusions from this. First, precomputing the reference tensors leads to a large performance gain over numerical quadrature. Beyond this, additional benefits are included by omitting the zeros, and more still by doing the FErari optimizations. We seem to have optimized the local computation to the point where it is constrained by read-write to cache rather than by floating point optimization. Second, these optimizations reveal a new bottleneck: matrix insertion. This motivates either studying whether we may improve the performance of insertion into the global sparse matrix or else implementing matrix-free methods.

While the FErari optimizations are highly successful for building the matrices, there is still quite a bit of solver overhead to contend with. We used GMRES (boundary conditions were imposed in a way that broke symmetry) preconditioned by the BoomerAMG method of HYPRE [9]. For both linear and quadratic elements, the Krylov solver converged with only three iterations. However, the cost of building and applying the AMG preconditioner is very large. Using numerical quadrature, building local stiffness matrices accounted for between five and nine percent of the total run time (building the local-to-global mapping, computing geometry tensors, computing local stiffness matrices, sorting and inserting local matrices into the global matrix, creating and applying the AMG preconditioner, and computing the Krylov iterations). Keeping everything else constant and switching to the FErari optimized code, building local stiffness matrices took less than one percent of the total time. Geometric multigrid algorithms tend to be much more efficient, and we conjecture that the cost of building local matrices would be even more important in this case.

TABLE 7.1

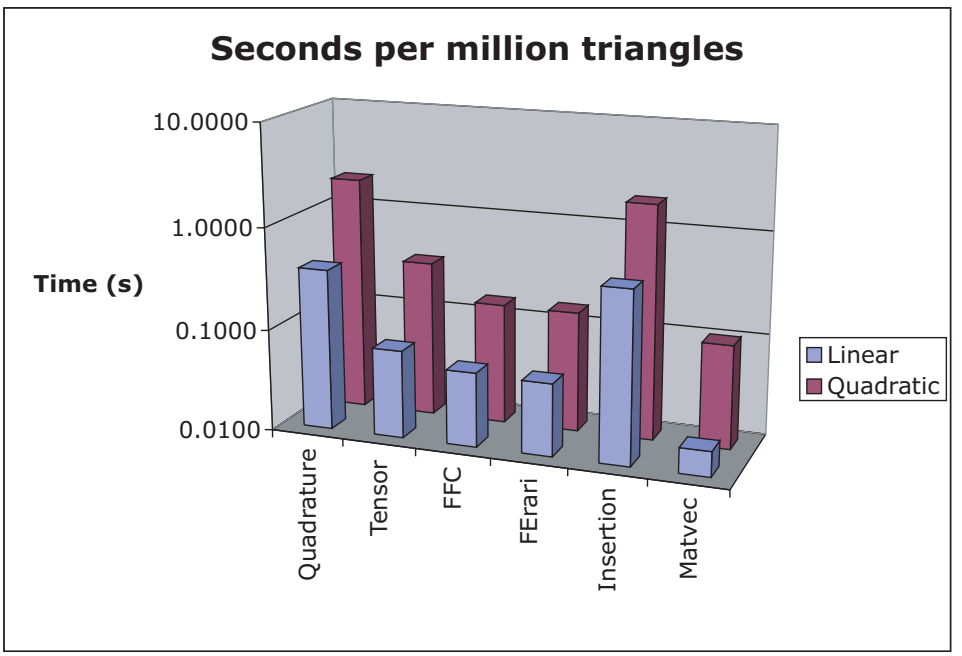

FIG. 7.1. *Seconds to process one million triangles: local stiffness matrices, global matrix insertion, and matrix-vector product.*

8. Conclusions. The determination of local element matrices involves a novel problem in computational complexity. There is a mapping from (small) geometry matrices to "difference stencils" that must be computed. We have demonstrated the potential speed-up available with simple low-order methods. We have suggested by examples that it may be possible to automate this to some degree by solving abstract graph optimization problems.

Acknowledgments. We thank the FEniCS team, and Todd Dupont, Johan Hoffman, and Claes Johnson in particular, for substantial suggestions regarding this paper.

EFFICIENT NUMERICAL CONTINUATION AND STABILITY ANALYSIS OF SPATIOTEMPORAL QUADRATIC OPTICAL SOLITONS*

D. J. B. LLOYD† AND A. R. CHAMPNEYS†

Abstract. A numerical method is set out which efficiently computes stationary (z-independent) two- and three-dimensional spatiotemporal solitons in second-harmonic-generating media. The method relies on a Chebyshev decomposition with an infinite mapping, bunching the collocation points near the soliton core. Known results for the type-I interaction are extended and a stability boundary is found by two-parameter continuation as defined by the Vakhitov–Kolokolov criteria. The validity of this criterion is demonstrated in (2+1) dimensions by simulation and direct calculation of the linear spectrum. The method has wider applicability for general soliton-bearing equations in (2+1) and (3+1) dimensions.

Key words. continuation, optical soliton, second harmonic generation, type-I interaction

1. Introduction.

Optical spatiotemporal solitons in second-harmonic-generating media have received much attention due to the possibility of creating fully localized, self-supporting objects which freely propagate in a nonlinear medium [15]. Unlike Kerr media, second-harmonic-generating media have no wave collapse in (2+1) and (3+1) dimensions in quadratic (χ^2) media and have been observed experimentally; see Liu et al. [20, 19]. The equations governing the evolution of these quadratic solitons are nonintegrable so that analytical closed form stable solutions do not exist. For a review of solitons due to quadratic nonlinearities see [6].

Malomed et al. [23] studied general stationary, nonradially symmetric solitons found in the type-I interaction second harmonic generation (SHG) case. Their approach was to first construct a Gaussian variational approximation of solitons in (2+1) and (3+1) dimensions and analytically find an approximate stability boundary. They then carried out numerical simulations of the full z-dependent equations to ascertain the accuracy of the approximate stability boundary. Since this Gaussian approximation amounts to a one-mode Galerkin truncation, the stability boundary was found to be "rather fuzzy". Part of the problem is that the accuracy of this approximation deteriorates with increasing dimensionality due to the approximation "cutting off" the tails of the soliton.

A more thorough analysis of stationary solitons in type-I interaction was carried out by Mihalache et al. [24] who considered the numerical boundary value problem (BVP) for the stationary light bullets. Existence and stability of "elliptic" solitons was explored in (2+1) and (3+1) dimensions with and without "walk-off" [24, 25]. Later, Beckwitt et al. [2] and Towers, Malomed, and Wise [33] explored the region where the second harmonic dispersion is normal via solving the initial value problem

starting from an initial Gaussian pulse. They also showed analytically that solitons with small oscillating tails at infinity, known as "quasi solitons", should exist in this region, though they were unable to find any numerically. One of the key problems with both numerical approaches is the high computational effort required to solve the equations with either finite difference or Fourier spectral methods. In both cases supercomputers were required to reduce the computational time.

The object of this work is to provide an [illegible] and [illegible] numerical method for calculating stationary spatiotemporal solitons, not necessarily just in the SHG equations, but also in other soliton bearing-equations in (2+1) and (3+1) dimensions. There are several benefits with using our method. First, we can easily move through parameter space and between (2+1) and (3+1) dimensions, assuming radial symmetry in (3+1) dimensions. Second, we can accurately compute light bullets with a mesh on the order of tens of modes rather than hundreds, greatly reducing the computational effort. Third, this approach also allows us to embed the method in a numerical continuation environment, e.g., AUTO [12], to compute branches of the solutions. Fourth, and perhaps most crucial, using criteria such as that due to Vakhitov and Kolokolov, which define soliton instabilities [30], one can then append the stability criterion to the numerical continuation problem. The Vakhitov–Kolokolov (VK) condition states that solitons will become unstable if the gradient of the energy of the solution (Q), as the effective propagation constant (κ) varies, becomes negative (i.e., $\partial_\kappa Q < 0$). A stability boundary of the solutions corresponds to when the gradient is zero (i.e., $\partial_\kappa Q = 0$). In a continuation environment this corresponds to a fold in the energy of the solution as the effective propagation constant is varied. Thus we can trace out stability boundaries automatically and accurately with the kind of computational effort that takes minutes on a Pentium 4, 2 GHz microprocessor.

Finally, criteria such as the VK conditions are necessary only for stability. The sufficiency of this condition can also be checked by computation of the spectrum linearized about the localized solution; see Mihalache et al. [24] for confirmation of the validity of the VK criteria in (2+1) and (3+1) dimensions. We demonstrate that an adaptation of our Chebyshev method can be used to calculate the linear spectrum. The description in terms of only tens of modes helps make such computations feasible.

The paper is organized in the following way. In section 2 we set out the problem. The numerical scheme for the computation of stationary solitons and their stability is stated in section 3. Our results for the type-I SHG interaction equations are presented in section 4. Section 5 draws conclusions and suggests avenues for future work.

2. Problem statement. We are interested in stationary (z-independent) soliton solutions to the scaled equations describing copropagation of the fundamental harmonic (FH) and second harmonic (SH) field in a quadratic optical medium,

$$\begin{aligned} iu_z + \nabla_\rho^2 u + u_{\tau\tau} - u + v\overline{u} &= 0, \\ 2iv_z + \nabla_\rho^2 v + \delta v_{\tau\tau} - \gamma v + \frac{1}{2}u^2 &= 0 \end{aligned} \tag{2.1}$$

(see [14] for their derivation and physical meaning).

Here $u = \sqrt{2}\Phi_1 e^{-iz/z_0} z_0 \omega_1^2 \chi^{(2)}/(k_1 c^2)$ and $v = \Phi_2 e^{-2iz/z_0} z_0 \omega_1^2 \chi^{(2)}/(k_1 c^2)$, $\Phi_{1,2}$ are complex electric-field envelopes at the frequencies ω_1 and $2\omega_1$, and $k_1 \equiv k(\omega_1)$ is the FH carrier wave number. The normalized propagation distance and reduced time are $\xi = z/z_0$ and $\tau = (t - z/\nu_g)/t_0$, respectively, with ν_g and t_0 being the group velocity and time scale at the FH. $z_0 = 2t_0^2/k_1''$, where k_1'' is the group velocity dispersion (GVD) coefficient at the FH, and the nondimensional transverse radial

coordinate is $\rho = \sqrt{x^2+y^2}/r_0$, where $r_0^2 = (z_0/2k_1)$. The diffraction operator, $\nabla_\rho^2 \equiv \partial^2/\partial\rho^2 + [(D-1)/\rho]\partial/\partial\rho$, where $D+1 = 2$ or 3 is the spatial dimension, acts on the transverse spatial coordinate(s) (we shall assume cylindrical symmetry in (3+1) dimensions). The phase mismatch between the harmonics $\gamma = 4+2z_0[2k(\omega_1)-k(2\omega_1)]$ and the ratio of the SH and FH GVD coefficients is $\delta = k_2''/k_1''$.

Under the substitution, $u(z,\rho,\tau) = u(\rho,\tau)e^{i\kappa z}$, $v(z,\rho,\tau) = v(\rho,\tau)e^{2i\kappa z}$, where κ is the effective propagation constant, we seek stationary, z-independent soliton solutions defined on the infinite domain, $-\infty < \rho < \infty$ and $-\infty < \tau < \infty$, given by the following equations for the , functions u and v:

$$
\begin{aligned}
u_{\rho\rho} + (d-1)\rho^{-1}u_\rho + u_{\tau\tau} - (1+\kappa)u + vu = 0,\\
v_{\rho\rho} + (d-1)\rho^{-1}v_\rho + \delta v_{\tau\tau} - (\gamma+4\kappa)v + \frac{1}{2}u^2 = 0.
\end{aligned}
\tag{2.2}
$$

Equations (2.2) are known to support localized solutions, known as solitary waves, that are able to survive strong perturbations and remain intact after collisions with other solitary waves [5]. Exact solitary wave solutions to (2.1) are not available, except in special degenerate limits, since the equations are nonintegrable and so numerical methods provide the only way to accurately calculate the solutions. Since the solitary waves seen in (2.1) have similar soliton shapes to solutions of integrable systems, we shall follow the physics convention and use the word "soliton" interchangeably with solitary wave.

We are seeking physical localized solutions of (2.1) which correspond to the solutions that decay (exponentially) to zero at infinity. We can see from the linearization of (2.2) at infinity that exponentially decaying solutions in both harmonics forming the soliton exist if the effective propagation constant $\kappa > \max(-1, -\gamma/4)$ and the GVD ratio coefficient $\delta \geq 0$. This last constraint corresponds to anomalous or zero dispersion in the SH. So we compute on a "large" domain and apply zero Dirichlet boundary conditions at the far-field edge of the domain. For the case when the GVD is normal at the SH ($\delta < 0$), both Beckwitt et al. [2] and Towers, Malomed, and Wise [33] showed analytically there should be a nonvanishing, oscillating tails in the SH v as $\tau \to \infty$.

3. Numerical approach. Our numerical method is based on setting up the BVP of (2.2) and using numerical continuation software, e.g., AUTO [12], to explore the parameter space of solitons. In particular, AUTO software implements the robust technique of pseudo-arclength continuation (see Keller [16]) for systems of nonlinear ODEs by solving the BVP using orthogonal collocation; see [1]. In order to use such software we need to discretize (2.2) to form an ODE system and apply appropriate boundary conditions. The numerical continuation software will then solve the BVP ODE system as an equation parameter is varied. To use such software one must provide an equations file defining the right-hand side of a first-order ODE system as well as specifying in which equation parameters one wants to continue. The AUTO manual and a tutorial on AUTO can be found in [11].

Two problems need to be tackled for this approach to work. The first is to efficiently discretize the problem in either the ρ or τ coordinate. A straight Fourier or finite-difference discretization scheme, though possible, has been found to require a large number of modes, and hence a huge amount of computing power is required to solve the resulting ODE system (both [33] and [24] cite the use of supercomputers). The reason for the inefficiency is due to interpolation points being equispaced, so a , , number of these points is required to interpolate the solution near the edge of

the computational domain where the soliton is zero. A more efficient approach is to reduce the number of interpolation points near the edge of the domain and move them to the center of the stationary soliton, where they can increase the accuracy of the method. To do this we use an adapted mesh to the localized soliton problem. Effectively, we map the spatial coordinate to a new scaled space and equidistribute. A similar approach to homoclinic orbits in 1 dimension was proposed by Liu, Moore, and Russell [17]. Another property of these solitons is that they are smooth and infinitely differentiable. For these types of problems, spectral methods provide [illegible] (unlike finite difference which provides only algebraic accuracy) and so only tens of modes should be required to accurately interpolate the soliton. The second problem is to find good solution data at certain fixed D, δ, γ parameters for the numerical continuation code to get started.

We shall tackle both of these problems in the next two subsections. In the third subsection we describe how we can adapt our numerical method to compute the stability of the solitons using the VK criteria and computation of the linear spectrum.

3.1. Numerical continuation. Using an adapted mesh to solve soliton-bearing equations is not a new idea. Boyd [3] talks about rational Chebyshev functions and other possible spectral functions for soliton equations including Hermite, Whittaker cardinal, and Fourier domain truncation functions. The biggest advantage with using Fourier and Chebyshev bases is that their functions and their corresponding collocation points have simple representations as well as the existence of a fast transform between the physical and spectral domains. Boyd [4] shows how the Chebyshev polynomials are just Fourier cosine functions in disguise and how a mapping can be used to adapt the mesh to the localized problem while still maintaining spectral accuracy.

There are three approaches one can take to implement the rational Chebyshev method: the discrete Fourier transform (DFT), the fast Fourier transform (FFT), and collocation differentiation matrices [34]. We have implemented all three methods and have found that they all produce the same results at roughly the same speed for truncations on the order of tens of modes. However, we have found that the collocation differentiation matrices approach is the most simple to program, and hence is the method of choice in practice. Henceforth, we describe only that method applied to (2.2). Note that the approach is quite general and is easily extended to other systems.

For the problem at hand, we choose to discretize in the τ coordinate since we wish to explore the $\delta = 0$ region and discretizing in ρ would make the problem singular at $\delta = 0$. To discretize in τ we expand u and v, such that

$$\begin{aligned} u_i &= u(\rho, \tau_i = f(x_i)), \\ v_i &= v(\rho, \tau_i = f(x_i)), \quad i = 0, \ldots, N, \end{aligned} \tag{3.1}$$

where $x \in [-1, 1]$ is the computational Chebyshev coordinate, N is the number of interpolation points, and f is a function that maps $[-1, 1]$ to the infinite domain $[-\infty, \infty]$. There two standard choices for such a mapping [4, 7] are the algebraic map

$$f(x) = L\frac{x}{\sqrt{1 - x^2}}, \tag{3.2}$$

and the exponential map

$$f(x) = L\tanh^{-1}x. \tag{3.3}$$

The constant L sets the length scale of the map and it can vary anywhere between 0 and $+\infty$, with the collocation points being more "bunched" near the origin for small

L. In general, if the solitons decay exponentially, then the exponential map will be the most efficient but it is also the most sensitive to changes in the mapping constant L; see Boyd [4]. Some experimentation of various length scales and number of collocation points is required to find a reasonable mapping. We shall stick with the exponential map in this paper since we shall mostly be exploring a parameter region where soliton tails decay exponentially.

Differentiation in τ is carried out using the chain rule for Chebyshev differentiation matrices [34] so that

$$(u_{\tau\tau})_i = \left[\left(\frac{\partial^2 f^{-1}(\tau_i)}{\partial \tau^2} D_N^{(1)} + \left[\frac{\partial f^{-1}(\tau_i)}{\partial \tau} \right]^2 D_N^{(2)} \right) u(\rho, x_i), \quad i = 0, \ldots, N \right],$$

$$\equiv A_N u(\rho, x_i), \quad i = 0, \ldots, N, \tag{3.4}$$

where $f^{-1}(\tau)$ is the inverse of the infinite mapping (3.3), $A_N = \partial^2 f^{-1}(\tau_i)/\partial \tau^2 D_N^{(1)} + [\partial f^{-1}(\tau_i)/\partial \tau]^2 D_N^{(2)}$ is an $(N+1) \times (N+1)$ matrix carrying out the differentiation in τ composed by the Chebyshev differentiation matrices $D_N^{(1)}$, where

$$(D_N)_{00} = \frac{2N^2+1}{6}, \qquad (D_N)_{NN} = -\frac{2N^2+1}{6},$$

$$(D_N)_{jj} = \frac{-x_j}{2(1-x_j^2)}, \qquad j = 1, \ldots, N-1,$$

$$(D_N)_{ij} = \frac{c_i}{c_j} \frac{(-1)^{i+j}}{(x_i - x_j)}, \qquad i \neq j, \ i, j = 0, \ldots, N,$$

and

$$c_i = \begin{cases} 2 & \text{when } i = 0 \text{ or } N, \\ 1 & \text{otherwise,} \end{cases}$$

and $D_N^{(2)} = D_N^{(1)} \circ D_N^{(1)}$. Finally, retaining a system of first-order ODEs in the ρ coordinate we have the BVP formulation

$$\begin{aligned} (u_\rho)_i &= w_i, \\ (w_\rho)_i &= -\frac{(d-1)}{\rho} w_i - (u_{\tau\tau})_i + (1+\kappa) u_i - (u_i v_i), \\ (v_\rho)_i &= y_i, \\ (y_\rho)_i &= -\frac{(d-1)}{\rho} y_i - \delta (v_{\tau\tau})_i + (\gamma + 4\kappa) v_i - \frac{1}{2}(u_i)^2, \\ \dot{\rho} &= 1. \end{aligned} \tag{3.5}$$

The numerical experiments in [23, 24, 25, 33] suggest that stable soliton solutions are even in both ρ and τ, respecting the reflectional symmetry of the equations $\rho \to -\rho$ and $\tau \to -\tau$. So we compute on the first quadrant and we rewrite the differentiation matrix A_N taking advantage of this symmetry.

We apply Neumann boundary conditions on u and v (i.e., $w_i = y_i = 0$) at both ends of the domain since we wish to preserve symmetry at the origin and any linear

boundary conditions at the far-field end of the domain are known to exponentially converge to the solution if we take a large enough truncation of the domain, say P, such that u and v decay to zero numerically; see [13]. So for the BVP equations (3.5), we imposed the boundary conditions

$$\begin{aligned} (w)_i &= 0, \\ (y)_i &= 0 \end{aligned} \tag{3.6}$$

for $i = 0, \ldots, N$ at $\rho = 0$ and $\rho = P$.

3.2. Initial solution. The problem (3.5) and boundary conditions (3.6) are set up well for continuation of one-parameter families of solutions. First we need a starting solution at one particular parameter value.

To acquire good starting data we assume that $\delta = 1$, $\kappa = 0$ at which parameter values (2.2) are radially symmetric. These symmetric solutions can be obtained from the reduced equations

$$\begin{aligned} u_{rr} + \frac{d}{r}u_r - u + uv &= 0, \\ v_{rr} + \frac{d}{r}v_r - \gamma v + \frac{1}{2}u^2 &= 0, \end{aligned} \tag{3.7}$$

where $r = \sqrt{\rho^2 + \tau^2}$ is the radial coordinate. Taking $d = 0$ and $\gamma = 1$, (3.7) have an exact soliton solution [5], of the form

$$\begin{aligned} u(r) &= \frac{3\sqrt{2}}{2}\mathrm{sech}^2\left(\frac{r}{2}\right), \\ v(r) &= \frac{3}{2}\mathrm{sech}^2\left(\frac{r}{2}\right). \end{aligned} \tag{3.8}$$

We can set up a simple continuation problem of solutions to (3.7), up to $d = 1$; see Champneys, Kuznetsov, and Sandstede [8]. Once we have our new solution for $d = 1$ we need to appropriately separate the data for the full continuation problem. Data for u and v are straightforward and the data for the first derivatives w and y are found by applying the chain rule to yield

$$w = u_\rho = \frac{\rho}{r}\frac{du(r)}{dr},$$

$$y = v_\rho = \frac{\rho}{r}\frac{dv(r)}{dr},$$

where $du(r)/dr$ is the numerical continuation, computed derivative. Finally, the data need to be interpolated to the Chebyshev grid in τ.

3.3. Computation of stability. Since we can now solve the BVP (3.5) to find the solitons, it would be useful to know whether the solitons found are stable or not. A standard approach to check the stability of stationary solitons is to use the VK criterion; see Skryabin [30]. This VK criterion is a nonrigorous, necessary condition stating that solitons in Hamiltonian systems may be stable if $\partial_\kappa Q < 0$, where Q is the energy of the system and κ is the effective propagation constant. The energy for problem (2.2) is defined in (2+1) dimensions as the integral $Q = \int_{-\infty}^{\infty}\int_{-\infty}^{\infty}(|u|^2 + 4|v|^2)d\tau d\rho$ and in (3+1) dimensions, $Q = 2\pi\int_{-\infty}^{\infty}\int_{0}^{\infty}(|u|^2 + 4|v|^2)\rho d\tau d\rho$.

Integration with respect to τ is carried out by changing to Chebyshev coordinates to obtain the integral (in (2+1) dimensions)

$$Q = \int_{-\infty}^{\infty}\int_{-1}^{1} (|u(\rho,\tau)|^2 + 4|v(\rho,\tau)|^2) \left[\frac{\partial f^{-1}(\tau)}{\partial \tau}\right]^{-1} dx d\rho. \tag{3.9}$$

Noting that the internal integral is of the form $\int_{-1}^{1} p(x)dx$ and can be computed efficiently via a Clenshaw–Curtis quadrature [34], we can append the BVP (3.5) and boundary conditions (3.6), with an integral condition

$$Q - q = 0, \tag{3.10}$$

where Q is the energy of the system and q is a "free" continuation parameter. This free parameter is introduced into the BVP and takes the value of Q as the system is solved for a set of equation parameters. The parameter q does not fix to a value of Q and is allowed to freely vary. Using parameter continuation in both κ and q, we can find where $\partial Q_\kappa = 0$. This particular point presents a fold in the solution branch, where we think of q as the bifurcation parameter and κ as part of the solution. Standard path-following techniques exist to follow fold points as another parameter, either γ or δ, is varied (see [29]) and hence trace out the VK stability criterion in two physical parameters.

Since the VK criterion is found as the compatibility condition arising in the leading (zero) order asymptotic expansion of the linear eigenvalue problem governing the stability of the soliton (see [30]), the stability boundary defines only a necessary region for stability. Hence, we need to check its validity. In order to do this, we have implemented the above Chebyshev discretization scheme in both the ρ and τ coordinates, with a fourth-order Runge–Kutta scheme (see [4, 7, 34] for temporal discretizations) to simulate the full z-dependent equations (2.1) as well as calculating the linear spectrum directly. The data from the numerical continuation software are interpolated to a new mesh for use as an initial condition. For $\delta < 0$ the end points of u and v in the τ direction are set to zero to stop Runge interpolation errors. All solutions shown have been interpolated onto a finer equispaced grid. It should be noted that the Runge–Kutta method is suitable only for solutions which do not have large changes in the z-derivatives since the PDEs are numerically stiff.

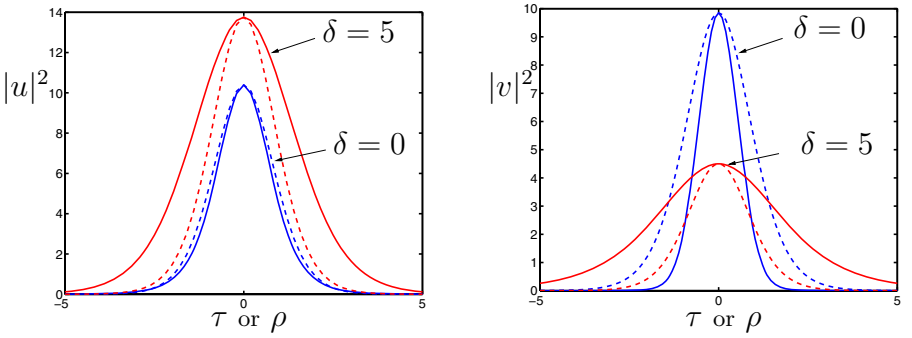
In order to calculate the linear spectrum of the PDEs (2.1) about the stationary soliton, we perturb the stationary soliton such that

$$\begin{aligned} u(\rho,\tau,z) &= u_s(\rho,\tau,z) + e^{\lambda z}(\tilde{u}_r(\rho,\tau) + i\tilde{u}_i(\rho,\tau)),\\ v(\rho,\tau,z) &= v_s(\rho,\tau,z) + e^{\lambda z}(\tilde{v}_r(\rho,\tau) + i\tilde{v}_i(\rho,\tau)), \end{aligned} \tag{3.11}$$

where $u_s = u(\rho,\tau)e^{\kappa z i}, v_s = v(\rho,\tau)e^{2\kappa z i}$ is the stationary soliton and $|\tilde{u}|, |\tilde{v}| \ll 1$ are small perturbations in the FH and SH, respectively. Substituting the ansatz (3.11) in the PDEs (2.1) and retaining terms of first order in $\tilde{u}$ and $\tilde{v}$, we obtain the linear eigenvalue problem; see Buryak [5]. To carry out the two-dimensional differentiation we have used Kronecker products with either Chebyshev or Fourier collocation matrices; see [34] for application of the Kronecker product to the two-dimensional Laplace equation. Taking advantage of reflectional symmetry in (2.1) we can reduce the size of the eigenvalue problem and hence make the problem tractable without resorting to special matrix linear algebra techniques.

4. Results.

4.1. Implementation details. We have used the numerical continuation package AUTO [12] in our computations; see [10, 22, 35] for other possible continuation software.



We have found that for a mesh of 11 points and $L = 6$ in the τ coordinate and $NTST = 10$, $NCOL = 4$ in AUTO, in the ρ coordinate, we have an error 10^{-4} in the maximum amplitude of u and v for $\delta = 1, \gamma = 1, \kappa = 0$ compared to AUTO computed ODEs (3.7) with $NTST = 50$ and $NCOL = 4$. For a mesh of 21 points ($L = 6$) the error decreases to 10^{-6}. The stability boundaries computed on the two meshes differ quantitatively at the third decimal place, though qualitatively they do not change; see Figures 4.2(a) and 4.2(c). Standard AUTO tolerances are used, see [12]. On a Pentium 4, 2 GHz microprocessor, computation of the stability boundaries, as in Figure 4.2(a), takes roughly 30 minutes depending on the size of the branch being computed. For numerical and interpolation reasons the infinite domain is truncated to $[-50, 50]$.

Since we are using small grids on the order of 11×11 modes, we have implemented the Runge–Kutta scheme simulating the full z-dependent equations (2.1) and the linear stability analysis in MATLAB. We have found that using an 11×11 grid the computation of the eigenvalues takes less than a minute on a 2 GHz PC and going up to a 21×21 grid takes less than five minutes. Taking advantage of symmetry is important here to minimize the size of the linear eigenvalue problem in MATLAB since the matrix grows like $4N^2$. Typical mesh sizes are for the Fourier method 20×20 points over $[0, 15]^2$ and the Chebyshev method 11×11 points with $L = 6$. Again the AUTO computed solution is interpolated to the new mesh. Any other mesh sizes will be stated where used.

4.2. Continuation and stability boundaries for $\delta \geq 0$ in (2+1) dimensions. Embedding the above continuation scheme into AUTO, we have explored the parameter region of the stationary solitons solutions to (2.1), as well as produced VK stability boundaries for various mismatch parameters.

For $\delta \neq 1$ the solitons are known to be "elliptic" in shape; see [24], where ellipticity is defined as the ratio of the soliton's temporal width to the transverse spatial width. In Figure 4.1, we see cross-sections of the computed light bullets for $\delta = 0$ and $\delta = 5$, along the spatial (ρ) and temporal (τ) coordinate. The continuous lines show the cross-section of the soliton along the temporal coordinate with the dashed lines showing the cross-section along the spatial coordinate. From Figure 4.1, for $\delta = 5$, the dashed line occurs below the solid line, in both harmonics, showing expansion along the temporal coordinate relative to the transverse coordinate, whereas for $\delta = 0$ we observe the opposite: the dashed line occurs above the solid line showing contraction along the temporal coordinate.

The VK stability plots δ versus κ are shown in Figure 4.2. Consider first Figure 4.2(a). The region of stable solitons can be found in the top right-hand corner of the figure with the unstable region directly below. The stability boundary described by the VK criterion is shown as a line separating the stable and unstable regions. Beneath the unstable region we have drawn the line showing the existence boundary of the solitons governed by the bound $\kappa > \max\{-\gamma/4, -1\}$ such that the tails in both harmonics decay exponentially. The region for the possible existence of quasi solitons is shown as $\delta < 0$. A "dip" in the stability boundary can be observed for mismatch parameters, $\gamma < 4$, close to $\delta = 0$ in (2+1) dimensions. Qualitatively similar behavior has been found by Malomed et al. [23] using a Gaussian approximation, albeit with

(a) (b)

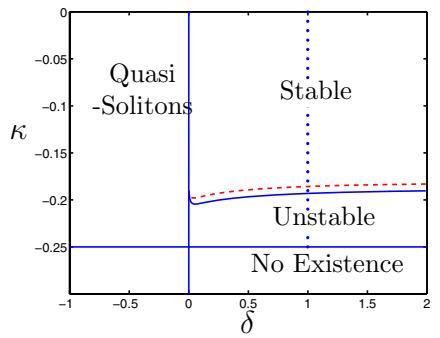


FIG. 4.1. *Spatial and temporal sections of the light bullets along* $\rho = 0$ *(solid line) and* $\tau = 0$ *(dashed line), respectively, for* $\gamma = 1$, $\kappa = 0$ *in* $(2+1)$ *dimensions and* $\delta = 0$ *and* $\delta = 5$. *The FH is shown in* (a) *and the SH is shown is* (b).

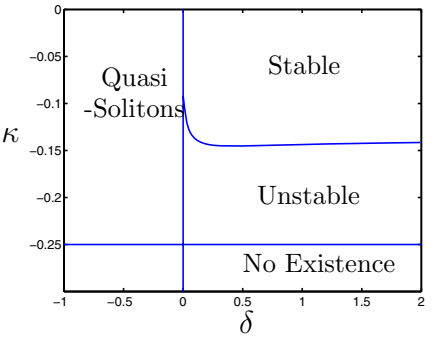
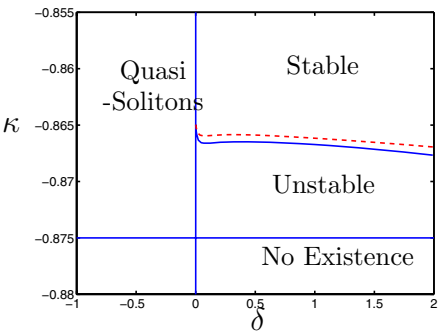
gross quantitative differences. As γ is increased towards 4, the stability boundary is found to uniformly approach the line $\kappa = -1$ ($\delta > 0$), such that for $\gamma \geq 4$ all solitons are found to be stable; see Figure 4.2(e), numerically confirming and extending the result found by Pelinovsky, Buryak, and Kivshar [28] and Steblina et al. [32]. For all γ between 0 and 4 the stability boundary is found to have similar qualitative shapes (results not depicted).

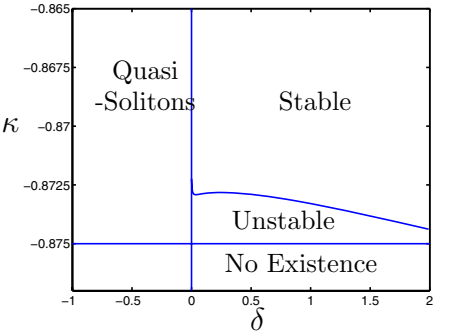


We can test the accuracy of the VK criteria by carrying out the linear stability analysis about the AUTO computed solitons using our Chebyshev method. In Figure 4.2(a) we have drawn a dotted line taking a cross-section through the VK stability boundary at $\gamma = 1$ and $\delta = 1$. In Figure 4.3 we depict the maximum computed positive eigenvalue for $\gamma = 1$ and $\delta = 1$ in (2+1) dimensions for a range of κ values. The VK stability boundary for these parameters occurs at $\kappa \approx -0.19$, shown in Figure 4.3 as a vertical dashed line. Using both the Chebyshev method and the Fourier method with a coarse mesh, described in section 3.3, we see that the VK criterion gives an overestimate for the stability region of the light bullets. Close to the stability boundary, both the Chebyshev method and the Fourier method give similar results. Under higher resolution, the Chebyshev method shows the solitons losing stability closer to the VK boundary. These results suggest (but do not prove) that in fact the VK criterion provides a sharp stability boundary.

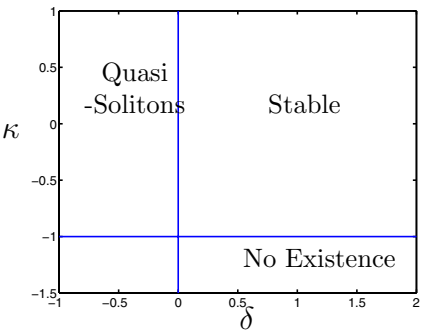
Figure 4.4(a) shows an evolution plot of the intensity of the SH of a stable stationary soliton along the line $\rho = 0$. Just past the stability boundary at $\delta = 1$ and $\kappa = -0.2$ we see from Figure 4.4(d) that the evolution of the stationary soliton, at this point, eventually becomes unstable after a long distance.



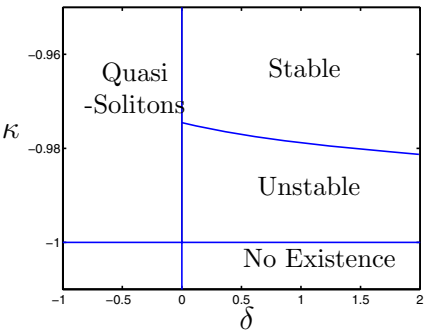
4.3. The region $\delta < 0$ in (2+1) dimensions. For $\delta < 0$, Towers, Malomed, and Wise [33] showed that no true solitons exist in this parameter region. Instead one should be able to find solutions that do not decay at infinity but have oscillatory tails; these solutions are known as quasi solitons [18]. Using our numerical method we find (for small negative δ values), solitons with oscillating tails; see Figure 4.5 with the corresponding evolution plot shown in Figure 4.4(b) showing the quasi soliton eventually becoming unstable. We have found, numerically, that one need not go



(a) $\gamma = 1, D = 2$



(b) $\gamma = 1, D = 3$



(c) $\gamma = 3.5, D = 2$

(d) $\gamma = 3.5, D = 3$

(e) $\gamma = 5, D = 2$

(f) $\gamma = 5, D = 3$

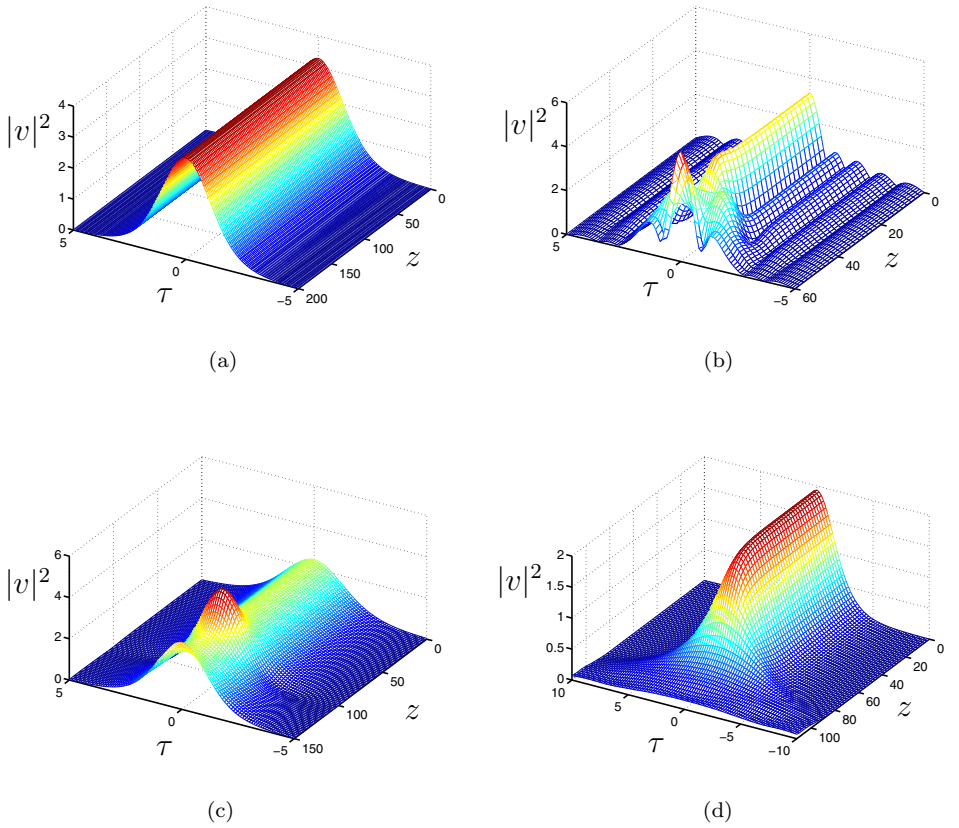
far into the quasi-soliton ($\delta < 0$) region to hit an existence boundary; e.g., in (2+1) dimensions, $\kappa = -0.15$ and $\gamma = 1$, the threshold for existence of such quasi solitons appears to be $0 > \delta \geq -0.042$. This may explain why Malomed et al. [23] found numerically stable quasi solitons for small negative δ, but no stable solitons far out into this region: they had stepped outside the existence boundary. As $\delta \to -0.042$ the fundamental harmonic tends to zero and the oscillations in the SH grow.

If either γ or κ is increased the existence region appears to increase in size with some of these quasi solitons found to be numerically stable; see Figure 4.6. Computation of quasi solitons using the Chebyshev basis on the infinite interval is known to poorly approximate solitons with oscillatory tails regardless of the number of modes used; see the discussion in Chapter 9 of Boyd [3]. The reason for the poor approximation of the oscillating tails is due to the Chebyshev method implicitly imposing zero boundary conditions at the ends of the domain, hence "cutting off" the oscillating tails. However, the numerical solution is known to provide an acceptable approximation of the core of the soliton, but questions of stability depend crucially on details of the tails and so cannot be answered with any certainty. As solitons become unstable in their tails this numerical method may falsely impose (in)stability where none may exist. This "cutting off" of the tails becomes more pronounced as either γ or κ is increased. In [26] it was shown that for small equations in (1+1) dimensions quasi solitons are always unstable albeit with a small unstable eigenvalue. We conjecture that this property is also true for quasi solitons in higher dimensions. Therefore, any numerical results on existence and stability of quasi solitons using a Chebyshev discretization method would be at best speculative. Hence, in Figure 4.3 for the region $\delta < 0$, any possibility of existence is labeled "quasi solitons."

Several amendments to the Chebyshev method on the infinite domain have been suggested (see Boyd [3]) but the computation of quasi solitons remains a challenging problem and has been solved only in (1+1) dimensions; see Champneys, Vanden-Broek, and Lord [9]. On should also stress that quasi solitons have questionable



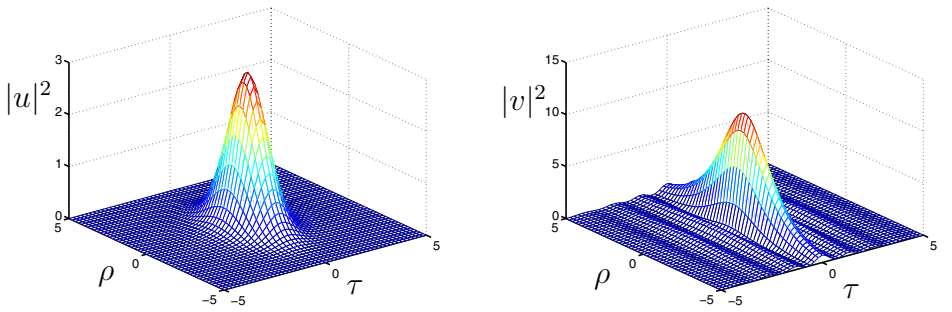


FIG. 4.4. *Evolution plots of* $|v(z,0,\tau)|^2$ *starting from initial data computed from numerical continuation for* $\gamma = 1$ *and* (a) *stable soliton* $\delta = 1$ *and* $\kappa = -0.15$, (b) *unstable quasi soliton* $\delta = -0.04$ *and* $\kappa = -0.15$, (c) *unstable soliton on stability boundary* $\delta = 1$ *and* $\kappa = -0.2$, (d) *unstable soliton* $\delta = 1$ *and* $\kappa = -0.225$

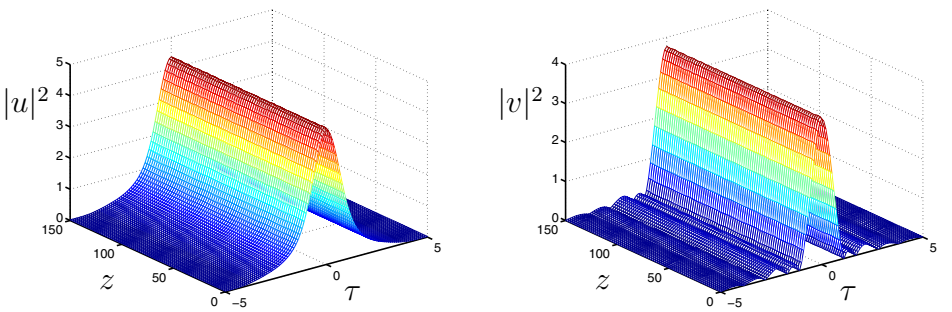
physical validity since they require sources and sinks of energy at infinity. At best their existence represents parameter regimes where finite-time, almost localized structures may be expected to be observed in an experiment.



4.4. Stability boundaries in (3+1) dimensions. If we assume radial symmetry in (3+1) dimensions, we can reduce the equations to an effective (2+1) dimension with the addition of a $(1/\rho)d/d\rho$ term. This allows us to use our method and compute VK stability boundaries in (3+1) dimensions. (We shall not attempt to verify the VK criteria in (3+1) dimensions since results are already known; see Mihalache et al. [24].) The results here are to show the full three-parameter shape of the stability boundary.

In (2+1) dimensions it is known that solitons cannot be unstable for $\gamma \geq 4$, but in (3+1) dimensions it is possible to find unstable regions for this parameter space; see Figure 4.2(f). This unstable region decreases in size until $\gamma = 4$ where all solitons are found to be stable. As we pass through $\gamma = 4$ we see the existence of a new unstable region. This region is always larger than the one found in (2+1) dimensions for equivalent parameters; see Figures 4.2(a) and 4.2(b).

5. Conclusion. In this paper we have set out an efficient numerical method for finding stationary soliton solutions for the type-I SHG equations in (2+1) and (3+1) dimensions. The method described uses an adapted mesh applied to the localized soliton problem and Chebyshev differentiation matrices to carry out either the spatial or temporal differentiation. This adapted mesh method allows us to reduce the size of the discretized problem enabling the use of numerical continuation software. Using the VK criterion we can trace out stability boundaries for various equation parameters in (2+1) and (3+1) dimensions. We have also found, numerically, quasi solitons when the dispersion at the SH is normal. Known results for the ellipticity of the light bullets for various dispersion coefficients at the SH and validity of the VK criteria are confirmed, and extended to three-parameter plots in δ, κ, γ.

We have used our discretization scheme to test the validity of the VK stability criteria in (2+1) dimensions via numerical simulation of the full z-dependent equations,

as well as direct computation of the linear spectrum about the stationary soliton. Confirmation of the VK stability criteria in (3+1) dimensions can be found in [24].

Our results in (2+1) dimensions confirm the findings of Mihalache et al. [24] and Skryabin and Firth [31], yet in addition we have been able to provide a full two-parameter plot of the stability region and indeed to show how this region shrinks when we vary a third parameter.

Our numerical method can be extended to a wide range of soliton-bearing equations including dissipative systems, though for dissipative systems the VK criterion is no longer valid and so stability boundaries would have to be calculated another way. Group velocity mismatch between the FH and SH could also be accommodated with our numerical method by moving into a traveling frame of reference (see Mihalache et al. [25]), but in this case the questions describing the soliton shape would be complex. For continuation purposes one must deal with the extra symmetry generated by the complex phase shift since the Jacobian of the symmetry will be singular. To form a well-posed BVP one could either explicitly decouple the complex phase (see Luce [21]) or use phase minimization techniques; see Munoz-Aimaraz et al. [27]. Future work will concentrate on the type-II interaction, SHG equations (see [5]) where far less is known about the structure of the solutions in (2+1) and (3+1) dimensions.

Acknowledgments. The authors would like to thank John P. Boyd, Boris A. Malomed and Dumitru Mihalache for their useful remarks. The authors would also like to thank Richard R. Kerswell for initially suggesting the numerical discretisation.

COMBINING FAST MULTIPOLE TECHNIQUES AND AN APPROXIMATE INVERSE PRECONDITIONER FOR LARGE ELECTROMAGNETISM CALCULATIONS*

B. CARPENTIERI†, I. S. DUFF‡, L. GIRAUD§, AND G. SYLVAND¶

Abstract. The boundary element method has become a popular tool for the solution of Maxwell's equations in electromagnetism. From a linear algebra point of view, this leads to the solution of large dense complex linear systems, where the unknowns are associated with the edges of the mesh defined on the surface of the illuminated object. In this paper, we address the iterative solution of these linear systems via preconditioned Krylov solvers. Our primary focus is on the design of an efficient parallelizable preconditioner. In that respect, we consider an approximate inverse method based on the Frobenius-norm minimization. The preconditioner is constructed from a sparse approximation of the dense coefficient matrix, and the patterns both for the preconditioner and for the coefficient matrix are computed a priori using geometric information from the mesh. We describe how such a preconditioner can be naturally implemented in a parallel code that implements the multipole technique for the matrix-vector product calculation. We investigate the numerical scalability of our preconditioner on realistic industrial test problems and show that it exhibits some limitations on very large problems of size close to one million unknowns. To improve its robustness on those large problems we propose an embedded iterative scheme that combines nested GMRES solvers with different fast multipole computations. We show through extensive numerical experiments that this new scheme is extremely robust at affordable memory and CPU costs for the solution of very large and challenging problems.

Key words. sparse approximate inverse preconditioner, large dense complex systems, Maxwell equations, boundary elements, fast multipole technique, frequency domain, electric field integral equations, parallel computing, large calculations

1. Introduction.

The analysis of wave propagation phenomena is gaining an increasing interest in recent years in the simulation of many challenging industrial processes, including the prediction of the Radar Cross Section (RCS) of arbitrarily shaped 3D objects such as aircraft, the study of electromagnetic compatibility of electrical devices with their environment, the design of antennae and absorbing materials, and many others. All these simulations are very demanding in terms of computer resources and require fast and efficient numerical methods to compute an approximate solution of Maxwell's equations. Using the equivalence principle, Maxwell's equations

can be recast in the form of four integral equations that relate the electric and magnetic fields to the equivalent electric and magnetic currents on the surface of the object.

Among integral formulations, the electric field integral equation (EFIE) is the most general for electromagnetic scattering problems, as it can handle fairly general geometries, and thus is widely used in industrial simulations. The EFIE provides a first-kind integral equation, which is well known to be ill-conditioned and gives rise to linear systems that are challenging to solve by iterative methods. The discretization is performed on the surface of the object and gives rise to a linear system

$$Ax = b, \tag{1.1}$$

where the matrix A is an $n \times n$, dense, complex, symmetric, non-Hermitian matrix. For many years, direct solution methods have been the methods of choice for solving systems (1.1) because they are reliable and predictable in terms of both accuracy and computing costs. However, for the solution of large-scale problems, direct methods are infeasible even on large parallel platforms because they require the unaffordable storage of n^2 single or double precision complex entries of the coefficient matrix and $\mathcal{O}(n^3)$ floating-point operations to compute the factorization. The use of preconditioned Krylov solvers can be an alternative to direct solution methods, provided we have fast matrix-free matrix-vector products and robust preconditioners. Research efforts have recently concentrated on fast methods for performing matrix-vector products with $\mathcal{O}(n \log(n))$ computational complexity, including strategies for parallel distributed memory implementations. These methods, generally referred to as [illegible], were introduced originally in the context of the study of particle simulations and can be used effectively in boundary element applications.

In this paper, we focus on the design of a parallelizable preconditioner to be used in conjunction with a parallel distributed fast multipole technique that implements the matrix-vector calculation. We consider an approximate inverse preconditioner based on Frobenius-norm minimization with a pattern prescribed in advance. In section 2, we describe the implementation of the preconditioner within an out-of-core parallel code that implements the fast multipole method (FMM) for the matrix-vector product. We investigate the numerical scalability of the preconditioner on a set of industrial problems of increasing size and show that it becomes less effective when the problem size becomes very large. To overcome this weakness, we propose in section 3 an embedded iterative scheme based on the GMRES method that aims at improving the robustness of the preconditioner on large applications. We illustrate the numerical efficiency and the cost effectiveness of the proposed scheme on systems of up to one million unknowns arising from challenging problems from the electromagnetism community.

2. Preconditioning boundary integral equations. For large meshes with many surface details, the density of the discretization mesh is nonuniform, and the matrix generated by the method of moments can become ill-conditioned. The convergence of Krylov methods depends to a large extent on the eigenvalue distribution of the coefficient matrix. In Figure 2.1, we plot the eigenvalue distribution in the complex plane of the matrix associated with a satellite geometry. This distribution is representative of the general trend; it can be seen that the eigenvalues of the system are very scattered; many of them have a large negative real part and no clustering appears. Such a distribution is not at all favorable for the rapid convergence of Krylov methods. One goal of preconditioning is to improve this distribution by grouping the

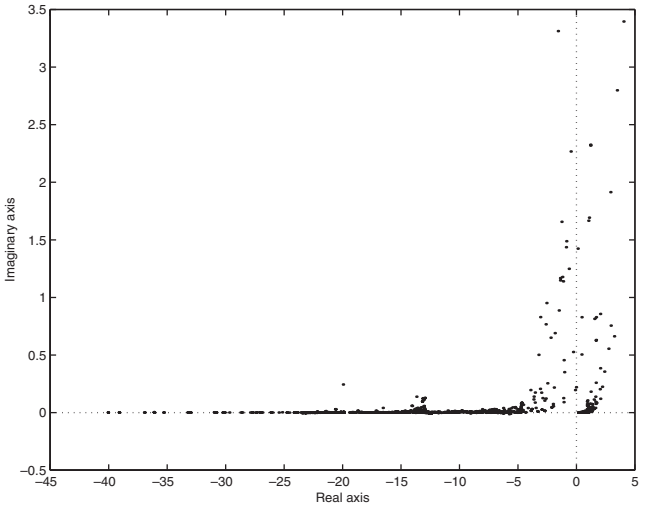

FIG. 2.1. *Eigenvalue distribution in the complex plane of the coefficient matrix for a scattering problem from a satellite that is representative of the general trend.*

eigenvalues into a few small clusters.

The design of robust preconditioners for boundary integral equations can be challenging. Simple preconditioners like the diagonal of A, diagonal blocks, or a band can be effective only when the coefficient matrix has some degree of diagonal dominance arising from the integral formulation [30]. Block diagonal preconditioners are generally more robust than their pointwise counterparts but may require matrix permutations or renumbering of the grid points to cluster the large entries close to the diagonal. Incomplete factorizations have been successfully used on nonsymmetric dense systems in [28] and hybrid integral formulations in [24], but for the EFIE the triangular factors computed by the factorization are often very ill-conditioned due to the indefiniteness of A. This makes the triangular solves highly unstable and the preconditioner useless. In [5], we used a small diagonal shift applied to A before computing the factorization with the intention of moving the eigenvalues along the imaginary axis. This might avoid a possible eigenvalue cluster close to zero and can help the computation of more stable factors in some cases. However, this shift is not easy to tune and there is no way to predict its effect.

Approximate inverse methods are generally less prone to instabilities on indefinite systems, and several preconditioners of this type have been proposed in electromagnetism (see for instance [1, 3, 4, 6, 23, 27, 35]). Owing to the rapid decay of the discrete Green's function, the location of the large entries in the inverse matrix exhibits some structure. In addition, only a few of its entries have relatively large magnitude. This means that a very sparse matrix is likely to retain the most relevant contributions to the exact inverse. This remarkable property can be effectively exploited in the design of robust approximate inverses as preconditioners for electromagnetism applications.

2.1. Frobenius-norm minimization preconditioner. In this section, we describe an approximate inverse preconditioner based on Frobenius-norm minimization. The original idea, due to Benson and Frederickson [2, 15], is to compute the sparse approximate inverse as the matrix M which minimizes $\|I - MA\|_F$ (or $\|I - AM\|_F$ for right preconditioning) subject to certain sparsity constraints. The Frobenius norm

is usually chosen since it allows for the decoupling of the minimization problems into n independent linear least-squares problems, one for each column of M, when preconditioning from the right (or row of M, when preconditioning from the left). The independence of these least-squares problems follows immediately from the identity

$$\|I - AM\|_F^2 = \sum_{j=1}^{n} \|e_j - Am_{\bullet j}\|_2^2, \tag{2.1}$$

where e_j is the jth canonical unit vector, $m_{\bullet j}$ is the column vector representing the jth column of M, and n the dimension of the square matrices. In the case of left preconditioning, because A is symmetric, the analogous relation

$$\|I - MA\|_F^2 = \|I - AM^T\|_F^2 = \sum_{j=1}^{n} \|e_j - Am_{j\bullet}\|_2^2 \tag{2.2}$$

holds, where $m_{j\bullet}$ is the column vector representing the jth row of M. Clearly, there is considerable scope for parallelism in this approach. The main issue is the selection of the sparsity pattern of M, that is, the set of indices

$$S = \{(i,j) \subseteq [1,n]^2 \text{ such that } m_{ij} = 0\}. \tag{2.3}$$

The idea is to keep M reasonably sparse while trying to capture the "large" entries of the inverse, which are expected to contribute the most to the quality of the preconditioner. Two different approaches can be followed for this purpose: an adaptive technique that dynamically tries to identify the best structure for M, and a static technique, where the pattern of M is prescribed a priori based on some heuristics. Adaptive methods usually start with a simple initial guess, like a diagonal matrix, and then improve the pattern until a criterion of the form $\|Am_{\bullet j} - e_j\|_2 < \varepsilon$ (for each j) is satisfied for a given $\varepsilon > 0$ or until a maximum number of nonzeros in $m_{\bullet j}$ is reached. If the norm is larger than ε and the number of nonzeros used is less than a fixed maximum, the pattern is enlarged according to some heuristics and the jth column of the approximate inverse is recomputed. The process is repeated until the required accuracy or storage limit is met (see [7, 21]).

Adaptive strategies can solve fairly general and hard problems but tend to be very expensive. The use of effective static pattern selection strategies can greatly reduce the amount of work in terms of CPU time and can substantially improve the overall setup process. When the coefficient matrix has a special structure or special properties, efforts have been made to find a pattern that can retain the entries of A^{-1} having large modulus [10, 11, 12, 32]. If A is row diagonally dominant, then the entries in the inverse decay columnwise and vice versa [32]. On boundary integral equations the discrete Green's function decays rapidly far from the diagonal, and the inverse of A may have a very similar structure to that of A. The discrete Green's function can be considered as a row or as a column of the exact inverse depicted on the physical computational grid. In this case a good pattern for the preconditioner can be computed in advance using graph information from $\tilde{A}$, a sparse approximation of the coefficient matrix constructed by dropping all the entries lower than a prescribed global threshold [1, 4, 22]. When fast methods are used for the matrix-vector products, all the entries of A are not available and the pattern can be formed by exploiting the near-field part of the matrix that is explicitly computed and available in the FMM [23].

Since we work in an integral equation context, relevant information for the construction of the pattern of M can be extracted from the mesh. When the object

geometries are smooth, only the neighboring edges (in the mesh topology sense) in the mesh can have a strong interaction with each other, while faraway connections are generally much weaker. Thus an effective pattern for the jth column of the approximate inverse can be computed by selecting in the mesh edge j and its qth level nearest neighbors. Three levels generally provide a good pattern for constructing an effective sparse approximate inverse. Using more levels increases the computational cost but does not improve the quality of the preconditioner substantially [4]. When the object geometries are not smooth or have disconnected parts, faraway edges in the mesh can have a strong interaction and be strongly coupled in the inverse matrix. In this case, a more robust pattern for the preconditioner can be computed using geometrical information, that is, selecting for each edge all those edges within a sufficiently large geometric neighborhood. In [4] we compared pattern selection strategies based on both algebraic and mesh information on a large set of problems and found that those exploiting geometric information are the most effective in capturing the large entries of the inverse.

In order to preserve sparsity, $\mathcal{O}(1)$ nonzero locations are computed in the pattern of the column $m_{\bullet j}$ of M. This makes each QR least-squares solution for each column of M from (2.1) cost $\mathcal{O}(n)$, and the overall construction of M costs approximately $\mathcal{O}(n^2)$ arithmetic operations. This cost can be significantly reduced if the preconditioner is computed using as input a sparse approximation $\tilde{A}$ of the dense coefficient matrix A. On general problems, this approach can cause a severe deterioration of the quality of the preconditioner. In an integral equation context, it is likely to be more effective because the boundary element method generally introduces a very localized strong coupling among the edges in the underlying mesh. It means that a very sparse matrix can still retain the most relevant contributions from the singular integrals that give rise to dense matrices. If the sparsity pattern S of M is known in advance, the nonzero structure for the jth column of M is automatically determined and defined as

$$J = \{i \in [1, n] \text{ such that } (i, j) \in S\}.$$

The least-squares solution involves only the columns of $\tilde{A}$ indexed by J; we indicate this subset by $\tilde{A}(:, J)$. When $\tilde{A}$ is sparse, many rows in $\tilde{A}(:, J)$ are usually null, not affecting the solution of the least-squares problems (2.1). Thus if I is the set of indices corresponding to the nonzero rows in $\tilde{A}(:, J)$, and if we define $\hat{A} = \tilde{A}(I, J)$, $\hat{m}_j = m_j(J)$, and $\hat{e}_j = e_j(J)$, the actual "reduced" least-squares problems are

$$\min \|\hat{e}_j - \hat{A}\hat{m}_j\|_2, \qquad j = 1, \ldots, n. \tag{2.4}$$

Usually problems (2.4) have much smaller size than problems (2.1) and can be efficiently solved by a dense QR factorization. In [1] the same nonzero sparsity pattern is selected for both $\tilde{A}$ and M; in that case, especially when the pattern is very sparse, the computed preconditioner may be poor on some geometries. Selecting more entries in $\tilde{A}$ than in M can provide a more robust preconditioner, and the additional cost in terms of CPU time is negligible because of the complexity of the QR factorization [4]. Increasing the number of rows q_I, that is, the number of entries of $\tilde{A}$, affects the CPU time far less than increasing the density of the preconditioner, that is, the number of columns p_J in the least-squares problems. This is because each least-squares solution costs $\mathcal{O}(q_I p_J^2)$.

2.2. Implementation of the preconditioner in the FMM context. The FMM, introduced by Greengard and Rokhlin in [20], provides an algorithm for computing approximate matrix-vector products for electromagnetic scattering problems.

The method is fast in the sense that the computation of one matrix-vector product costs $\mathcal{O}(n \log n)$ arithmetic operations instead of the usual $\mathcal{O}(n^2)$ operations. It requires storage only of the near-field part of the matrix, that is, of $\mathcal{O}(n \log n)$ instead of $\mathcal{O}(n^2)$ entries. These properties mean that using iterative solvers for the solution of large problems becomes feasible.

The basic idea of the algorithm is to compute interactions among degrees of freedom in the mesh at different levels of accuracy depending on their physical distance. Single and multilevel variants of the FMM exist. The 3D object is first entirely enclosed in a large cube that is subdivided into eight cubes. Each cube is recursively divided until the size is small compared with the wavelength. In the hierarchical multilevel algorithm, the box-wise partitioning of the obstacle is carried out until the size of the smallest box is generally half of a wavelength, and tree-structured data is used at all levels. In particular, only nonempty cubes are indexed and recorded in the data structure. The resulting tree is called the [illegible] (see Figure 2.2) and its leaves are referred to as [illegible]. The oct-tree provides a hierarchical representation of the computational domain partitioned by boxes: each cube has up to eight children and one parent in the oct-tree, except for the largest cube which encloses the whole domain. Obviously, the leaf boxes have no children. Multipole coefficients are computed for all cubes starting from the lowest level of the oct-tree, that is, from the leaf boxes, and then recursively for each parent cube by summing together multipole coefficients of its children. For each observation cube, an interaction list is defined which consists of those cubes that are not neighbors of the cube itself but whose parent is a neighbor of the cube's parent (see Figure 2.3 for a 2D representation). The interactions of degrees of freedom within neighboring boxes are computed exactly, while the interactions between cubes that are in the interaction list are computed using the FMM. All the other interactions are computed hierarchically on a coarser level by traversing the oct-tree. Both the computational cost and the memory requirement of the algorithm are of order $\mathcal{O}(n \log n)$. Further information on the algorithmic steps and recent theoretical investigations of the FMM can be found in [8, 9, 31]; also see [17, 19, 36] for discussions on parallel implementation issues.

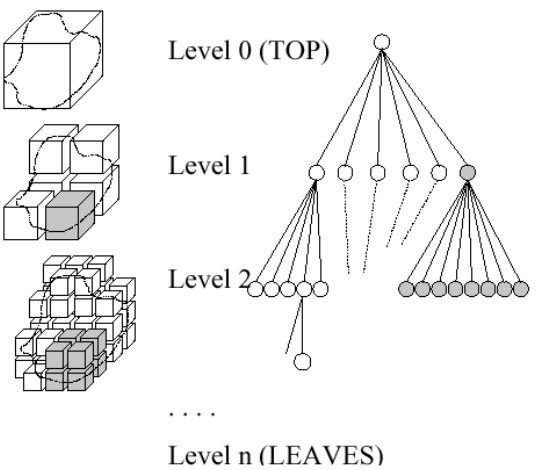

FIG. 2.2. *The oct-tree in the FMM algorithm. The maximum number of children is eight. The actual number corresponds to the subset that intersects the object.*

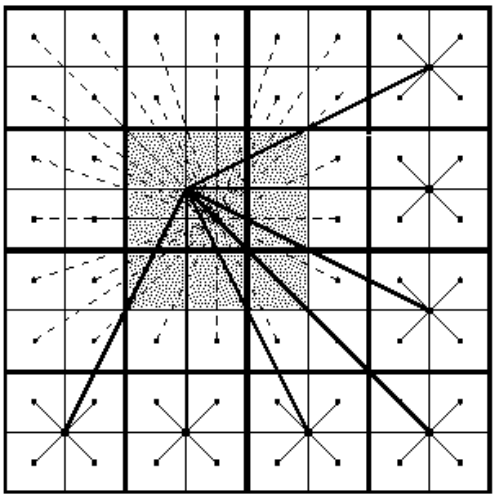

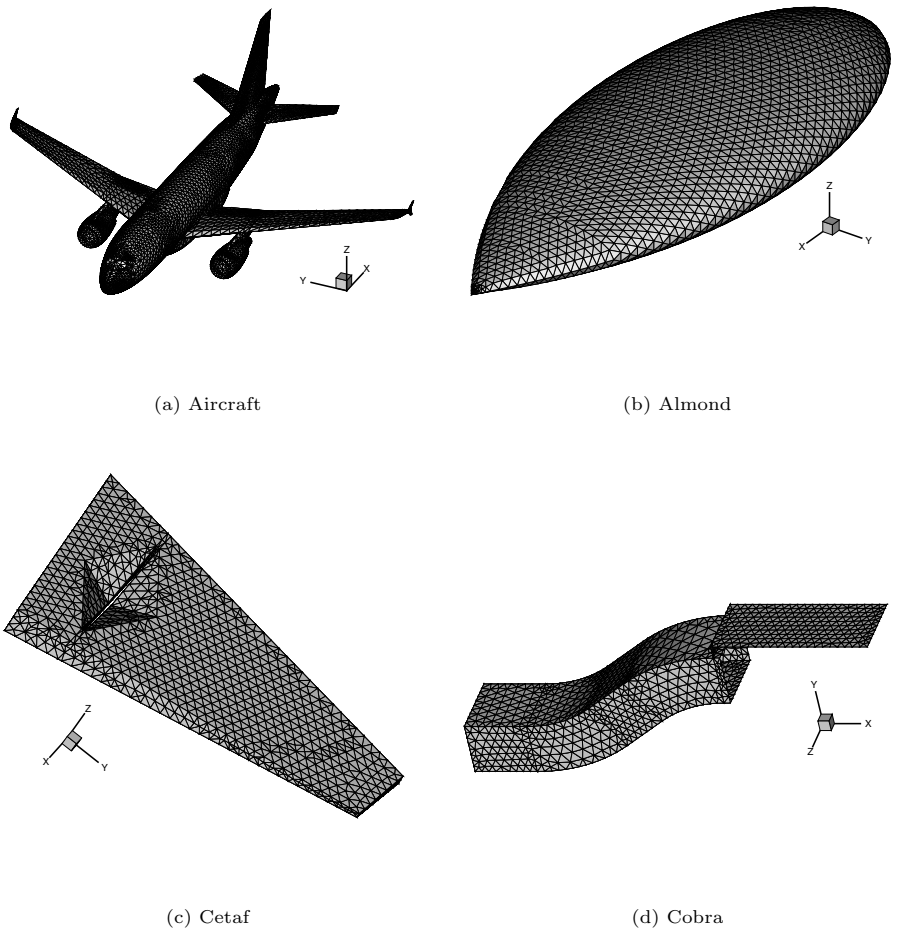

FIG. 2.3. *Interactions in the multilevel FMM. The interactions for the gray boxes are computed directly. We denote by dashed lines the interaction list for the observation box that consists of those cubes that are not neighbors of the cube itself but whose parent is a neighbor of the cube's parent. The interactions of the cubes in the list are computed using the FMM. All the other interactions are computed hierarchically on a coarser level, denoted by solid lines.*

The box-wise decomposition of the domain required by the FMM naturally leads to an a priori pattern selection strategy for M and $\tilde{A}$ using geometric information, that is on the spatial distribution of its degrees of freedom. We will adopt the following criterion: the nonzero structure of the column of the preconditioner associated with a given edge is defined by retaining all the edges within its leaf box and those in one level of neighboring boxes, and the structure for the sparse approximation of the dense coefficient matrix is defined by retaining the entries associated with edges included in the given leaf box as well as those belonging to the two levels of neighbors. The approximate inverse has a sparse block structure; each block is dense and is associated with one leaf box. Indeed the least-squares problems corresponding to edges within the same box are identical because they are defined using the same nonzero structure and the same set of entries of A. It means that we need only compute one QR factorization per leaf box. In our implementation we use two different oct-trees, and thus two different partitionings, to assemble the approximate inverse and for the approximate multipole coefficient matrix. The size of the smallest boxes in the partitioning associated with the preconditioner is a user-defined parameter that can be tuned to control the number of nonzeros computed per column, that is, the density of the preconditioner. According to our criterion, the larger the size of the leaf boxes, the larger the geometric neighborhood that determines the sparsity structure of the columns of the preconditioner. Parallelism can be exploited by assigning disjoint subsets of leaf boxes to different processors and performing the least-squares solutions independently on each processor. We refer to [31] for a complete description of the parallel code that we use.

2.3. Numerical scalability of the preconditioner. In this section, we study the numerical scalability of the Frobenius-norm minimization preconditioner. The optimal behavior would be to get frequency independent numerical behavior that

would result in convergence independent of the problem size. We show results on the following geometries:

- an industrial civil aircraft from a European company (see Figure 2.4(a)), a real-life model problem in an industrial context;
- an almond (see Figure 2.4(b)) that is also a typical test case in electromagnetic simulations;
- a Cetaf (see Figure 2.4(c)), a typical test case in electromagnetic simulations;
- a Cobra (see Figure 2.4(d)), a complex geometry that represents an air intake.

(a) Aircraft (b) Almond

(c) Cetaf (d) Cobra

FIG. 2.4. *Mesh associated with test examples.*

In all the numerical experiments, the surface of the object is always discretized using 10 points per wavelength; larger discretizations are obtained by increasing the frequency of the illuminating wave. In all the experiments, we consider a right preconditioned GMRES method [26] and the threshold for the stopping criterion is set to 10^{-3} on the normwise backward error $\frac{||r||}{||b||}$, where r denotes the residual and b the right-hand side of the linear system. This tolerance is accurate for engineering

purposes, as it enables the correct construction of the radar cross section of the object. The initial guess is the zero vector. All the runs have been performed in single precision on eight processors of a Compaq Alpha server. The Compaq Alpha server is a cluster of symmetric multiprocessors. Each node consists of four DEC Alpha processors (EV 6, 1.3 GFlops peak) that share 512 MB of memory. On that computer, the temporary disk space that can be used by the out-of-core solver is around 189 GB. Among all the possible right-hand sides for each geometry, we have selected those that are the most difficult to solve in order to better illustrate the robustness and the efficiency of our preconditioner.

In Table 1, we show the numerical behavior of the preconditioner observed on the four geometries when the size of the problems is increased. In this table "d" means day, "h" hour, and "m" minute. We see that the numerical behavior of the preconditioner does not scale well with the size of the problems, expecially GMRES(120) on the Cetaf, and there is no convergence on the largest aircraft problems. For GMRES(∞) the increase in the iteration count is less significant, even though on the Cetaf and the aircraft convergence cannot be obtained because we exceed either the memory limits of our computer or the time limit allocated to a single run. From a timing point of view, we see that the solution time of full GMRES is strongly affected by the orthogonalization involved in the Arnoldi procedure. On the Cetaf problem discretized with 531900 points, the number of iterations of GMRES(120) is twice as large with

respect to full GMRES, but GMRES(120) is about twice as cheap. Provided we get convergence, the use of a large restart often reduces the solution time even though it significantly deteriorates the convergence. On the Cetaf geometry, the solution time for the GMRES method increases superlinearly for small and medium problems, but nearly quadratically for large problems. On the largest test case, discretized with one million unknowns, unrestarted GMRES does not converge after 750 iterations requiring more than nine hours of computation on 32 processors. The aircraft is very difficult to solve because the mesh has many surface details and the discretization matrices become ill-conditioned. On small and medium problems, the number of GMRES iterations increases with the problem size, and the solution time increases superlinearly. On the largest test case, discretized with one million unknowns, full GMRES exceeds the memory limit on 64 processors. In this case, the use of large restarts (120 in this table) does not enable convergence within 2000 iterations except on a small mesh of size 94704.

We see in Table 1 that our strategy for adjusting the leaf box dimension for increasing frequencies causes the density of the sparse approximate inverse to decrease for increasing problem size. The number of unknowns per box remains constant, but the number of boxes increases, leading to a decrease in density and to poorer preconditioners. In Table 2, we investigate the influence of the density on the quality of the preconditioner on the Cobra using GMRES with a large restart (120). We adopt the same criterion described in section 2 to define the sparsity patterns, but we increase the size of the leaf boxes in the oct-tree associated with the preconditioner. The best trade-off between cost and performance is obtained for a radius of around 0.12 wavelengths, the default value set in the code. If the preconditioner is used to solve systems with the same coefficient matrix and multiple right-hand sides, it might be worth computing more nonzeros if we have sufficient disk space, because the construction cost can be quickly amortized. However, significantly enlarging the density of the preconditioner is not feasible on the largest problems because we would exceed the memory and disk capacity of our computer. As mentioned already, our main focus is on linear systems arising from EFIE. The advantages of this formulation are numerous; in particular, it does not require any hypothesis on the geometry of the objects. We should nevertheless mention that for closed geometries the CFIE (combined field integral equation) can also be used. The linear systems arising from the CFIE formulation are much easier to solve. For instance the solution of the problem associated with the aircraft with 213084 degrees of freedom requires only 129 iterations of unpreconditioned full GMRES, and 22 iterations of preconditioned full GMRES. Furthermore, preconditioned full GMRES converges in 24 iterations on the aircraft with more than a million degrees of freedom. Because the linear systems arising from the CFIE are not challenging from a linear algebra point of view, we do not consider them further in this paper.

Finally, in Table 3, we show the parallel scalability of the implementation of the FMM code [31]. We solve problems of increasing size on a larger number of processors, keeping the number of unknowns per processor constant. It can be seen that the construction of the preconditioner scales perfectly. This is a benefit from keeping the size of the leaf box constant. Its use requires some communication but it still scales reasonably well. The scalability of the matrix-vector product is also satisfactory, as the increase in the elapsed time is due not only to the amount of data exchanges but also to the $\log(n)$ effect of its computational complexity.

TABLE 2
Number of matrix-vector products and elapsed time to build the preconditioner and to solve the problem using GMRES(120) on a Cobra problem of size 179460, varying the parameters controlling the density of the preconditioner. The runs were performed on eight processors of the Compaq machine.

3. Improving the preconditioner robustness using embedded iterations. The numerical results shown in the previous section indicate that the Frobenius-norm minimization preconditioner tends to become less effective when the problem size increases, especially on difficult problems. By its nature the sparse approximate inverse is inherently local because each degree of freedom is coupled to only a very few neighbors. Because the exact inverse is dense the compact support used to define the preconditioner may not allow an exchange of global information and on large problems the lack of a global approximation may have a severe impact on the convergence. In our implementation, the overall number of computed nonzeros decreases for increasing values of the frequency. When the preconditioner becomes very sparse, information related to the far-field is completely lost. In this case, some suitable mechanism has to be introduced to recover global information for the numerical behavior of the discrete Green's function.

In this section, we describe an embedded iterative scheme, combined with multipole techniques, that is designed to meet the goals of robustness, scalability, and parallelism of the iterative solver. The basic idea is to carry out a few steps of an inner Krylov method for the preconditioning operation. The overall algorithm results in the inner-outer scheme depicted in Figure 3.1. The outer solver must be able to work with variable preconditioners. Amongst various possibilities, we mention FGMRES [25] and GMRES$\star$ [33, p. 91]; this latter reduces to GMRESR [34] when the inner solver is GMRES. The efficiency of the proposed algorithm relies on two main factors: the inner solver has to be preconditioned so that the residual in the inner iterations can be significantly reduced in a few steps, and the matrix-vector

products within the inner and the outer solvers can be carried out with a different accuracy. The motivation that naturally leads us to consider inner-outer schemes is to try to balance the locality of the preconditioner with the use of the multipole approach. Experiments conducted in [18] with inner-outer schemes combined with multipole techniques on the potential equation were not entirely successful. In that case, no preconditioner was used in the inner solver. The desirable feature of using different accuracies for the matrix-vector products is enabled by the use of the FMM. In our scheme, a highly accurate FMM is used within the outer solver, as it governs the final accuracy of the computed solution. A less accurate FMM is used within the inner solver, as it is a preconditioner for the outer scheme; in this respect the inner iterations attempt only to give a rough approximation of the solution and consequently do not require an accurate matrix-vector calculation. In fact, we solve a nearby system for the preconditioning operation that enables us to save considerable computational effort during the iterative process, as the less accurate matrix-vector calculation requires about half of the computing time of the accurate one. In Table 4, we show the average elapsed time in seconds observed on eight processors for a matrix-vector product using the FMM with different accuracy levels.

Outer solver $\longrightarrow$ FGMRES, GMRES$\star$

Do k $= 1, 2, \ldots$
- Matrix-vector product: FMM with high accuracy
- Preconditioning: **Inner solver** (GMRES, TFQMR, $\ldots$)

  Do i $= 1, 2, \ldots$
  - Matrix-vector product: FMM with low accuracy
  - Preconditioning: M_{Frob}

  End Do

End Do

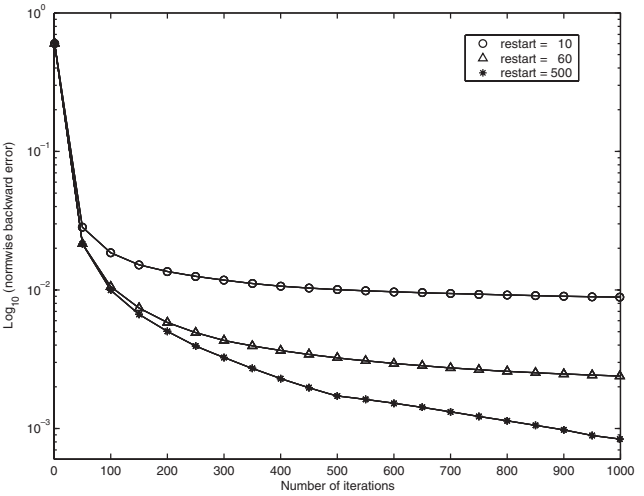

FIG. 3.2. *Convergence history of GMRES for different values of restarts on an aircraft discretized with* 94704 *points.*

3.1. Numerical results. In this section, we conduct experiments using the FGMRES method as the outer solver with an inner GMRES iteration preconditioned with the Frobenius-norm minimization method described in section 2. It is possible to vary the accuracy of the inner solver as the solution converges. However, in this paper, we present preconditioning results for a constant number of inner GMRES iterations. For the inner scheme we do not restart and perform only a prescribed number of full GMRES iterations or equivalently one step of restarted GMRES with the same prescribed restart. For the GMRES and FGMRES methods, we consider the implementations described in [14] and [13], respectively. The convergence history of GMRES depicted in Figure 3.2 for different values of the restart gives us some clues as to the numerical behavior of the proposed scheme. The residual of GMRES tends to decrease very rapidly in the first few iterations independently of the restarts, then decreases much more slowly, and finally tends to stagnate to a value that depends on the restart; the larger the restart, the lower the stagnation value. It suggests that a few steps in the inner solver could be very effective for obtaining a significant reduction of the initial residual. A different convergence behavior was observed when using other Krylov methods as an inner solver, for example, the TFQMR solver [3]. In this case, the residual at the beginning of the convergence is nearly constant or decreases very slowly. The use of TFQMR as an inner solver is ineffective.

In Table 5, we describe the results of experiments on an aircraft with 213084 degrees of freedom using different combinations of restarts for the inner and outer solvers. If the number of inner steps is too small, the preconditioning operation is poor and the convergence slows down, while too large restarts of GMRES tend to increase the overall computational cost but do not cause further reduction of the normwise backward error at the beginning of convergence. The choice of the restart for the outer solver depends to a large extent on the available memory of the target machine and the difficulty of the problem at hand, an issue that is also related to the illuminating direction of the incident wave that defines the right-hand side. Among the various possibilities, we select FGMRES(30) and GMRES(60) on the aircraft and

TABLE 5

Global elapsed time and total number of matrix-vector products required to converge on an aircraft with 213084 *points varying the inner restart parameter. The runs have been performed on eight processors of the Compaq machine.*

Restart FGMRES	Restart GMRES	# total inner mat-vec	# total outer mat-vec	Times
30	40	1960	51	4h 58m
30	50	1900	40	4h 53m
30	60	1920	34	4h 55m
30	70	2030	30	5h 13m
30	80	2240	29	5h 50m

the Cetaf problem, and FGMRES(15) and GMRES(30) on the Cobra and the Almond. These combinations are a good trade-off.

In Table 6 we show the results of experiments on the same geometries that we considered in section 2. We show the number of inner and outer matrix-vector products and the elapsed time needed to achieve convergence using a tolerance of 10^{-3} on eight processors of the Compaq machine. For comparison purposes, we show again in this table the results obtained with the restarted GMRES method. The comparison between the two solvers made in the tables is fair because GMRES has exactly the same storage requirements as the combination FGMRES/GMRES. In fact, for the same restart value, the storage requirements for the FGMRES algorithm are twice that for the standard GMRES algorithm, because it also stores the preconditioned vectors of the Krylov basis. It can be seen that the combination FGMRES/GMRES remarkably enhances the robustness of the preconditioner especially on large problems. The increase in the number of outer iterations is fairly modest except on the largest aircraft test cases. Nevertheless, the scheme is the only one that enables us to get the solution of this challenging problem since classical restarted GMRES does not converge and full GMRES exceeds the memory of our computer. Similarly, on the Cetaf discretized with one million points, the embedded scheme enables us to get convergence in 22 outer iterations, whereas GMRES(120) does not converge in 2000 iterations. The savings in time is also noticeable. The gain ranges from two to four depending on the geometry and tends to become larger when the problem size increases. On the Cobra and the Almond test cases, the embedded solver reduces not only the solution time but also the memory used, as FGMRES(15)/GMRES(30) is faster than GMRES(120) (see Table 1).

Similarly to what has been observed with GMRES, using a full FGMRES in the outer loop enables us to reduce the number of outer iterations but often results in a longer solution time. In Table 7 we show results obtained with full FGMRES and compare this with the full GMRES method. It can also be seen that the savings in time due to the use of the inner-outer scheme with respect to GMRES is also strongly related to the reduction in the number of dot product calculations since there are far fewer basis vectors to be orthogonalized. This gain is particularly visible on the aircraft test example with 213084 unknowns. The time spent in the FMM is longer for the FGMRES/GMRES solver, about 3 hours and 47 minutes (i.e., $33\times11.8+1920\times6.9$; see Tables 7 and 4), and it is about 3 hours and 11 minutes for GMRES. In that example, the embedded scheme is about 2 hours faster than regular GMRES. In this latter case, we have to orthogonalize up to 973 basis vectors while in the inner-outer scheme we do not have to orthogonalize a basis larger than 60. This is another illustration that the orthogonalization procedure is extremly time consuming.

In Figure 3.3 we show the typical convergence history of the FGMRES/GMRES and GMRES solvers on a large Cetaf problem discretized with 264156 points. We depict the convergence curve as a function of the elapsed time. It can be seen that the embedded solver clearly outperforms the single GMRES scheme. The FGMRES/GMRES solver continues to succeed in reducing the residual norm while GMRES converges slowly. Similar behavior is also reported for simpler model examples in [29].

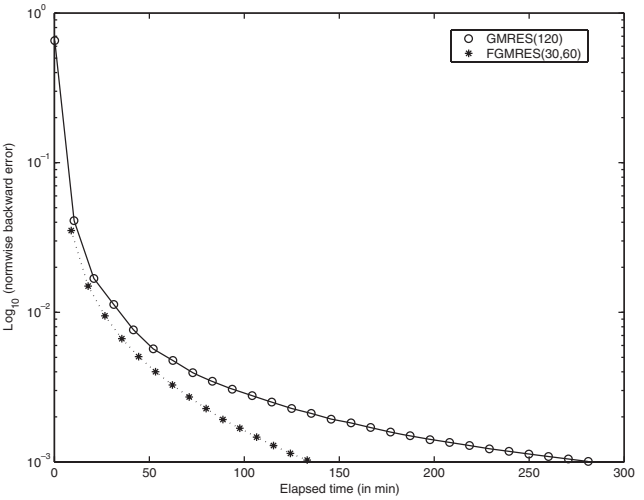

FIG. 3.3. *Convergence history as a function of elapsed time of GMRES versus FGMRES on the Cetaf problem discretized with* 264156 *points.*

For all the numerical experiments reported so far, we consider a discretization using ten points per wavelength. In that context, we vary the size of the linear system by varying the frequency of the illuminating wave and we consider objects with a fixed dimension expressed in meters. Consequently, each linear system corresponds to the simulation of a different physical phenomenon. In contrast, in Table 8 we solve the same physical phenomenon. We vary the size of the linear systems by varying the number of points per wavelength, keeping the frequency of the illuminating wave constant as well as the dimension of the object. In that table, λ denotes the wavelength and h the average mesh size. Because the leaf boxes used to build the preconditioner have a size that is a fraction of λ, the preconditioner becomes denser as the problem size increases. This observation partially explains the fact that the number of iterations of GMRES(60) slightly decreases when the the size of the linear system increases. This is an opposite behavior to what we observed in Table 6, where the density of the preconditioner decreases when the size of the problem is increased. We also observe that the behavior of FGMRES(15)/GMRES(30) is not affected by the mesh refinement.

4. Conclusions. In this paper we have described an effective and inherently parallel approximate inverse preconditioner, based on a Frobenius-norm minimization preconditioner, that can easily be implemented in an FMM code. We have studied the numerical scalability of our method for the solution of very large and dense linear systems of equations arising from real-life appplications in electromagnetism. The locality of the preconditioner on large problems can be significantly improved by embedding it within inner-outer solvers. We have described an embedded iterative scheme based on the GMRES method, implemented in a multipole context with different levels of accuracy for the matrix-vector products in the inner and outer loops. We have shown that the combination FGMRES/GMRES can effectively enhance the robustness of the preconditioner and reduce significantly the computational cost and the storage requirements for the solution of large problems. One could apply this idea recursively and embed several FGMRES schemes with decreasing FMM accuracy down to the

TABLE 8

lowest accuracy in the innermost GMRES. However, in our work, we consider only a two-level scheme. Most of the experiments shown in this paper require a huge amount of computation and storage, and they often reach the limits of our target machine in terms of memory and disk storage. To give an idea of how large these simulations are, the solution of systems with one million unknowns using a direct method would require 8 Tbytes of storage and 37 years of computation on one processor of the target computer (assuming the computation runs at peak performance). Such simulations are nowadays feasible thanks to the use of iterative methods and can be integrated in the design processes where the bottleneck moves from the simulation to the pre- and postprocessing of the results, as the tools are not yet available to easily manipulate meshes with millions of degrees of freedom. Finally we mention that the techniques described in this paper have recently been applied succesfully to large simulations in computational acoustics and extended to the computation of monostatic radar cross sections [16].

Acknowledgments. We would like to thank Guillaume Alléon from EADS-CCR for providing us with some test examples considered in this paper. We would also like to acknowledge the computing support provided by the CINES (Centre Informatique National de l'Enseignement Supérieur) and the CEA (Commissariat à l'Énergie Atomique) that enabled us to access their computing facilities.

MULTIDIMENSIONAL EXPONENTIAL TIMESTEPPING WITH BOUNDARY TEST*

KALVIS M. JANSONS† AND G. D. LYTHE‡

Abstract. Exponential timestepping algorithms are efficient for exit-time problems because a boundary test can be performed at the end of each timestep, giving high-order convergence in numerical evaluation of mean exit times. Successive time increments are independent random variables with an exponential distribution. We show how to perform exact timestepping for Brownian motion in more than one dimension and consider hitting times of curved surfaces. Taking as examples the exit times from a circle, from a ball, from an ellipse, and from the region bounded by the two lines of a hyperbola, we report the results of numerical experiments performed with the algorithms developed in this work.

1. Introduction.

One numerical realization of a stochastic process is a series of values generated successively. Under standard algorithms [1], the values correspond to times separated by a fixed, or at least deterministic, duration Δt. Under exponential timestepping [2], the times corresponding to numerical values are instead separated by independent realizations of a random variable $\boldsymbol{\delta t}$, where

$$\mathcal{P}[\boldsymbol{\delta t} > t] = \exp(-\lambda t) \tag{1.1}$$

and λ is a constant. Thus $\langle \boldsymbol{\delta t} \rangle = \lambda^{-1}$, where angled brackets denote mean over realizations. Random variables are set in boldface.

The increment of Brownian motion in one dimension with diffusivity D over a fixed time interval Δt is a Gaussian random variable with mean zero and variance $2D\Delta t$. Thus exact numerical updates require realizations of Gaussian random variables. If the time interval is not fixed but distributed according to (1.1), the increment of Brownian motion has a symmetric exponential distribution [2]. Exact updates under exponential timestepping therefore require realizations of random variables with an exponential distribution, which are easily generated as $-\log \mathbf{u}$, where $\mathbf{u}$ is distributed uniformly on $(0, 1)$. In this work, we construct the exact update for Brownian motion in n dimensions by separating the increment into a modulus and an angle.

The particular numerical problem we focus on in this paper is the measurement of exit or passage times, where the quantity of interest is the first time that a stochastic process attains a given value or exits a region [3, 4, 5, 6, 7, 8]. A numerical scheme for such a task has three components. The first component is an algorithm for updating the stochastic process so that realizations can be generated. The second is a criterion for deciding when the path hits the boundary, bringing the realization to an end. The

third is a relationship between the mean number of numerical timesteps per realization and the mean exit time.

The simplest criterion for bringing a realization to an end is that the process be outside the region at the end of a timestep. Numerical schemes using this criterion overestimate the mean exit time because of the strictly positive probability that an excursion is made outside the region during a timestep that starts and ends inside the region [2, 9, 10, 11, 12, 13, 14, 15]. To counteract this systematic error, a boundary test can be performed after each timestep, in which with probability p_i the realization is brought to an end, where p_i is an estimate for the conditional probability, given the starting and ending positions of a timestep, that an excursion out of the region has been made during the timestep [2, 10, 11, 12, 13, 14, 15]. Such tests have been shown to reduce the systematic error in mean exit times from being proportional to $\Delta t^{1/2}$ to being proportional to Δt when Δt is fixed [13]. Under exponential timestepping, the corresponding improvement is from an error proportional to $\langle \boldsymbol{\delta t} \rangle^{1/2}$, i.e., to the square root of the mean duration of a timestep, to an error proportional to $\langle \boldsymbol{\delta t} \rangle$ [2]. Alternatively, under the walk-on-spheres method, a path is constructed as a sequence of jumps from ball centers to ball surfaces and an absorption layer is defined close to the boundary [16, 17]. Realizations are brought to an end when they enter the layer.

The advantage of exponential timestepping is that expressions for the density of increments and for the conditional hitting probabilities required to devise boundary tests have a simple form. They are the Laplace transform of the corresponding quantities under fixed-duration timesteps and can be derived intuitively using the equivalence between the end of an exponential timestep and a mark on the path made by an independent Poisson point process with constant rate. In this work, we devise boundary tests under exponential timestepping in more than one dimension. Flat boundaries are equivalent to the one-dimensional case and thus can be dealt with exactly. Approximate boundary tests for smooth boundaries are derived and are valid when the radius of curvature is much larger than typical displacements in one timestep.

Armed with a criterion for bringing realizations to a stop, we generate large numbers of them and estimate the mean exit time from the mean number of timesteps per realization. In the case of timesteps of fixed duration Δt, the elapsed time until the [illegible] of the timestep at which the boundary was deemed hit is known exactly. The time [illegible] at which the boundary is hit is not known and must be estimated to obtain a mean exit time accurate to better than Δt [18]. In the case of exponential timestepping, the duration of any one timestep is not generated or known. Despite this apparent complication, evaluation of the mean exit time is straightforward under exponential timestepping because an update can be thought of as a jump to the next mark on the Brownian path made by an independent Poisson point process with rate λ (Figure 1.1). If N is the mean number of marks [illegible] a random time $\mathbf{H}$ that is independent of the marking process, then

$$\langle \mathbf{H} \rangle = \lambda N, \tag{1.2}$$

whatever the distribution of $\mathbf{H}$. Suppose there are M realizations and the boundary is deemed to have been hit during the n_jth timestep of realization j. The numerical estimate of the mean exit time is $M^{-1} \sum_{j=1}^{M} (n_j - 1)$.

Section 2 is a summary of basic results in one dimension and multiple dimensions. In section 3, we consider hitting times of curved boundaries. Exponential timestepping methods in n dimensions are described in section 4. Section 5 contains the results

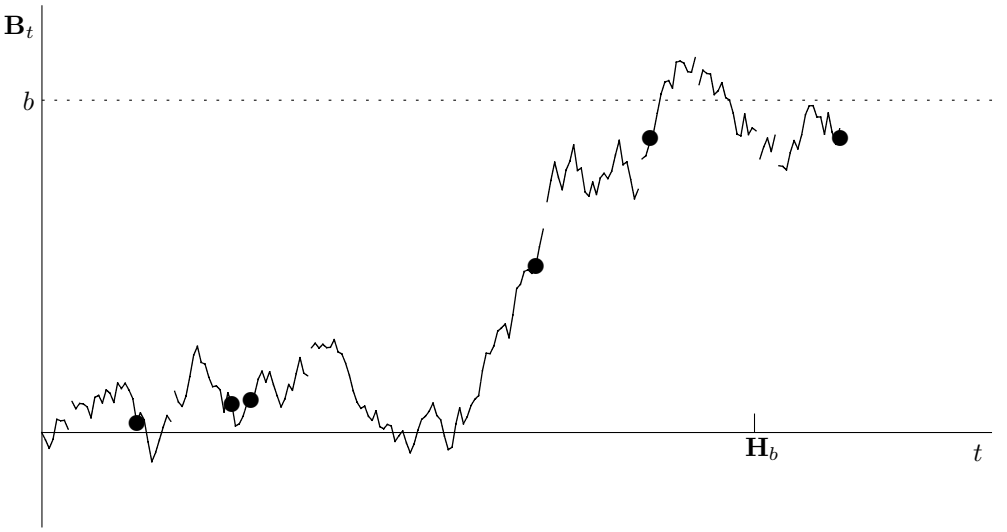

FIG. 1.1. *One realization is depicted. Exponential timesteps are jumps from one black point to the next. The values of the process at these times, but not the times themselves, are generated. The aim is to estimate the mean of* $\mathbf{H}_b$ *from many realizations.*

of numerical experiments with the new algorithms described here and with the Euler algorithm.

2. Basic results and notation. An n-dimensional Brownian motion $\mathbf{B}$ with diffusivity D has Cartesian components that are independent Brownian motions with diffusivity D. $\mathbf{B}_0 = 0$ and the probability density function of $\mathbf{B}_t$ for any fixed $t > 0$ is

$$p^{(n)}(x,t) = (4\pi Dt)^{-n/2} \exp\left(-|x|^2/4Dt\right), \tag{2.1}$$

where $x = (x_1, x_2, \ldots, x_n)$ and $|x|^2 = \sum_{i=1}^n x_i^2$. Consider an exponential timestep, started at 0, with mean duration λ^{-1}. The density of $\mathbf{B}_{\boldsymbol{\delta t}}$ is [23]

$$\begin{aligned} p_\nu^{(n)}(x) &= \int_0^\infty \lambda \exp(-\lambda t) p^{(n)}(x,t)\, \mathrm{d}t \\ &= \frac{\nu^n}{2\pi} \left(2\pi\nu|x|\right)^{1-n/2} K_{n/2-1}\left(\nu|x|\right), \end{aligned} \tag{2.2}$$

where K_m is the modified Bessel function of the second kind of order m and

$$\nu = (\lambda/D)^{1/2}. \tag{2.3}$$

In one dimension, let $\mathbf{H}_b = \inf\{t > 0 : \mathbf{B}_t = b\}$ and let $u(t) = \frac{\mathrm{d}}{\mathrm{d}t}\mathcal{P}[\mathbf{H}_b < t]$. Then [3, 7, 2]

$$u(t) = |b| \left(4\pi Dt^3\right)^{-1/2} \exp(-b^2/4Dt). \tag{2.4}$$

The probability that $\mathbf{H}_b < \boldsymbol{\delta t}$ is given by

$$\mathcal{P}[\mathbf{H}_b < \boldsymbol{\delta t}] = \mathrm{e}^{-\nu|b|}. \tag{2.5}$$

If the value at the end of the timestep is known, we have the following conditional probability:

$$\mathcal{P}[\mathbf{H}_b < \boldsymbol{\delta t}\,|\mathbf{B}_{\boldsymbol{\delta t}} = z\,] = \mathrm{e}^{-2\nu|b-\tilde{z}|}, \tag{2.6}$$

where $\tilde{z}$ is the closer of 0 and z to b. The one-dimensional results (2.5) and (2.6) hold for flat surfaces in any number of dimensions. For curved surfaces it remains true that the probability of hitting a surface during a timestep is significant when the starting or ending value is within a layer of width ν^{-1} of the surface.

2.1. Hitting circles and spheres. Exact results are also known for exit times from n-dimensional balls. Let

$$\mathbf{h}_R^{(n)}(r) = \inf\{t > 0 : |\mathbf{B}_t| = R \,|\, |\mathbf{B}_0| = r\,\}, \tag{2.7}$$

the first time $t > 0$ that $|\mathbf{B}_t| = R$, starting from $|\mathbf{B}_0| = r$. Then [8, 19]

$$\mathcal{P}[\mathbf{h}_R^{(n)}(r) < \boldsymbol{\delta t}] = \begin{cases} \left(\dfrac{r}{R}\right)^{1-n/2} \dfrac{I_{n/2-1}(\nu r)}{I_{n/2-1}(\nu R)}, & r < R, \\ \left(\dfrac{r}{R}\right)^{1-n/2} \dfrac{K_{n/2-1}(\nu r)}{K_{n/2-1}(\nu R)}, & r \geq R, \end{cases} \tag{2.8}$$

where I_m is the modified Bessel function of the second kind of order m.

Now consider the density of increments of the modulus of Brownian motion in n dimensions. Define

$$b^{(n)}(r, r_0) = \frac{\mathrm{d}}{\mathrm{d}r}\mathcal{P}[|\mathbf{B}_{\boldsymbol{\delta t}}| < r \,|\, |\mathbf{B}_0| = r_0\,]. \tag{2.9}$$

Then [19]

$$b^{(n)}(r, r_0) = \begin{cases} \nu^2 r^{n/2} r_0^{-n/2+1} I_{n/2-1}(\nu r_0) K_{n/2-1}(\nu r), & r_0 < r, \\ \nu^2 r^{n/2} r_0^{-n/2+1} K_{n/2-1}(\nu r_0) I_{n/2-1}(\nu r), & r_0 \geq r. \end{cases} \tag{2.10}$$

An advantage of the exponential duration of a timestep is that many conditional probabilities factorize. In particular, using (2.8) and (2.10) gives

$$\begin{aligned} \mathcal{P}[\mathbf{h}_R^{(n)}(r_0) < \boldsymbol{\delta t}\,|\,|\mathbf{B}_{\boldsymbol{\delta t}}| = r_1\,] &= \mathcal{P}[\mathbf{h}_R^{(n)}(r_0) < \boldsymbol{\delta t}] \left(b^{(n)}(r_1, r_0)\right)^{-1} b^{(n)}(r_1, R) \\ &= \begin{cases} \dfrac{I_{n/2-1}(\nu(r_0 \vee r_1))}{I_{n/2-1}(\nu R)} \dfrac{K_{n/2-1}(\nu R)}{K_{n/2-1}(\nu(r_0 \vee r_1))}, & (r_0 \vee r_1) < R, \\ \dfrac{I_{n/2-1}(\nu R)}{I_{n/2-1}(\nu(r_0 \wedge r_1))} \dfrac{K_{n/2-1}(\nu(r_0 \wedge r_1))}{K_{n/2-1}(\nu R)}, & (r_1 \wedge r_0) \geq R, \end{cases} \end{aligned} \tag{2.11}$$

where $(a \vee b) = \max(a, b)$ and $(a \wedge b) = \min(a, b)$.

It is illuminating to compare these results to (2.5) and (2.6). Taking the limit of (2.8) as $\nu R \to \infty$ with $S = \nu(R - r)$ fixed gives

$$\mathcal{P}[\mathbf{h}_R^{(n)}(r) < \boldsymbol{\delta t}] = \mathrm{e}^{-|S|}\left(1 - \frac{1}{2}(n-1)(\nu R)^{-1} S + \mathcal{O}((\nu R)^{-2})\right). \tag{2.12}$$

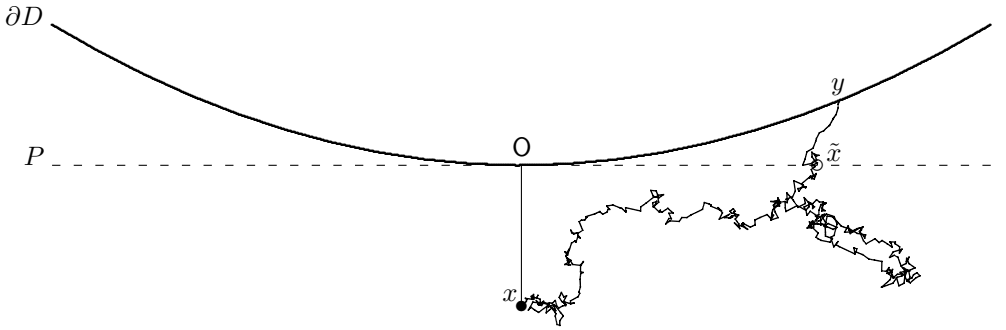

FIG. 3.1. *The initial position x is marked with a filled circle. Before hitting the curved surface ∂D, the path of the stochastic process hits the surface P, tangent to the point on ∂D closest to x. The distance from x to O is denoted by s.*

In (2.11), let r be the closer of r_0 and r_1 to R. In the same limit,

(2.13)
$$\mathcal{P}[\mathbf{h}_R^{(n)}(r_0) < \boldsymbol{\delta t} \,|\, |\mathbf{B}_{\boldsymbol{\delta t}}| = r_1\,] = \exp(-2|S|)\left(1 - \frac{n^2-4n+3}{(2\nu R)^2}S + \mathcal{O}((\nu R)^3)\right).$$

3. Curved boundaries. Consider a timestep started at a point x in a concave domain in $\mathbb{R}^n$ with boundary ∂D (Figure 3.1). We place O, the origin of coordinates in $\mathbb{R}^n$, at the point on ∂D nearest to x; define the x_n direction to be along the line $x\mathsf{O}$; and let s denote the distance from x to O. Let P be the $(n-1)$-dimensional surface tangent to ∂D at O. Let $\mathbf{H}_P^{(n)}(x)$ be the first hitting time of P,

$$\mathbf{H}_P^{(n)}(x) = \inf\{t > 0 : \mathbf{B}_t \in P \,|\mathbf{B}_0 = x\}. \tag{3.1}$$

We denote the value of $\mathbf{B}$ at the time $\mathbf{H}_P^{(n)}(x)$ by $\tilde{x}$ and write $\tilde{x} = (\tilde{x}^\perp, 0)$ where $\tilde{x}^\perp = (\tilde{x}_1, \tilde{x}_2, \ldots, \tilde{x}_{n-1})$.

Independent of n, we have

$$\mathcal{P}[\mathbf{H}_P^{(n)}(x) < \boldsymbol{\delta t}] = \mathrm{e}^{-\nu s}. \tag{3.2}$$

Consider the subset of paths for which $\mathbf{H}_P^{(n)}(x) < \boldsymbol{\delta t}$. For an event Θ, let

$$\mathcal{S}[\Theta] = \mathcal{P}[\Theta \,|\, \mathbf{H}_P^{(n)}(x) < \boldsymbol{\delta t}] = \frac{\mathcal{P}[\Theta, \mathbf{H}_P^{(n)}(x) < \boldsymbol{\delta t}]}{\mathcal{P}[\mathbf{H}_P^{(n)}(x) < \boldsymbol{\delta t}]}. \tag{3.3}$$

Let $q_P(x^\perp)$ be the density of arrival positions on the surface P, i.e.,

$$q_P(x^\perp) = \frac{\partial}{\partial x_1}\frac{\partial}{\partial x_2}\cdots\frac{\partial}{\partial x_{n-1}}\mathcal{S}[\tilde{x}_1 < x_1, \tilde{x}_2 < x_2, \ldots, \tilde{x}_{n-1} < x_{n-1}]. \tag{3.4}$$

The density of arrival times on P, conditioned on being earlier than $\boldsymbol{\delta t}$, is

$$u_\nu(t) = \frac{\mathrm{d}}{\mathrm{d}t}\mathcal{S}[\mathbf{H}_P^{(n)}(x) < t]. \tag{3.5}$$

Using (2.4), we find that

$$u_\nu(t) = s\exp(\nu s)\left(2\pi t^3\right)^{-1/2}\exp\left(-s^2/2t - \nu^2 t/2\right). \tag{3.6}$$

An expression for $q_P(x^\perp)$ is obtained by integrating $u_\nu(t)$ over the density of an $(n-1)$-dimensional Brownian motion. Explicitly,

$$q_P(x^\perp) = \int_0^\infty u_\nu(t)(2\pi t)^{-(n-1)/2}\exp\left(\frac{-|x^\perp|^2}{2t}\right)\mathrm{d}t \tag{3.7}$$

$$= 2s\exp(\nu s)\left(\frac{\nu}{2\pi}\right)^{n/2}\left(s^2+|x^\perp|^2\right)^{-n/4}K_{n/2}\left(\nu(s^2+|x^\perp|^2)^{1/2}\right). \tag{3.8}$$

Note that, for $1 \le i \le n-1$,

$$\int x_i^2 q_P(x^\perp)\,\mathrm{d}x^\perp = \int_{-\infty}^{\infty} x^2(s^2+x^2)^{-1/4}K_1(\nu(s^2+x^2)^{1/2})\mathrm{d}x = \frac{s}{\nu}. \tag{3.9}$$

Timesteps during which the boundary is hit typically have $\nu s = \mathcal{O}(1)$. Thus the typical spread of hitting points on P is such that $\tilde{x}_i = \mathcal{O}(\nu^{-1})$.

Now we consider the probability of hitting the curved boundary ∂D. Similarly to (3.1), let

$$\mathbf{H}_{\partial D}^{(n)}(x) = \inf\{t>0 : \mathbf{B}_t \in \partial D\,|\mathbf{B}_0 = x\}. \tag{3.10}$$

For the geometry chosen for Figure 3.1, $\mathcal{P}[\mathbf{H}_{\partial D}^{(n)}(x) < \boldsymbol{\delta t}] < \mathcal{P}[\mathbf{H}_{P}^{(n)}(x) < \boldsymbol{\delta t}]$. We invoke the following "memoryless" property of exponential timesteps: [illegible] ∂D [illegible] $\tilde{x} \in P$ [illegible] ∂D [illegible] $\tilde{x}$. Thus

$$\mathcal{P}[\mathbf{H}_{\partial D}^{(n)}(x) < \boldsymbol{\delta t}] = \mathrm{e}^{-\nu s}\int q_P(\tilde{x}^\perp)\mathcal{P}[\mathbf{H}_{\partial D}^{(n)}(\tilde{x}) < \boldsymbol{\delta t}]\,\mathrm{d}\tilde{x}^\perp. \tag{3.11}$$

When the boundary is flat, the integral in (3.11) is unity and we regain (3.2). As $\nu \to \infty$ with νs fixed, a smooth surface appears almost flat on the scale of typical displacements in one timestep and there is a small correction to (3.2).

Given a point y on ∂D, let $y = (y^\perp, y_n)$, where $y^\perp = (y_1, y_2, \ldots, y_{n-1})$. The directions of the axes are chosen so that the surface ∂D is parametrized as $y_n = y_n(y^\perp)$, where $y_n(y^\perp)$ has the Taylor series [21]

$$y_n(y^\perp) = \frac{1}{2}\left(\kappa_1 y_1^2 + \kappa_2 y_2^2 + \cdots + \kappa_{n-1}y_{n-1}^2\right) + \cdots. \tag{3.12}$$

Let $\kappa = \max_i \kappa_i$. The statement that ν is sufficiently large so that the maximum radius of curvature of ∂D is smaller than typical displacements in one timestep is equivalent to taking $\kappa/\nu \ll 1$.

The probability (3.2) is the lowest-order estimate of $\mathcal{P}[\mathbf{H}_{\partial D}^{(n)}(x) < \boldsymbol{\delta t}]$, the probability of hitting a curved boundary ∂D before the end of a timestep started at x. At next order, $\mathcal{P}[\mathbf{H}_{\partial D}^{(n)}(\tilde{x}) < \boldsymbol{\delta t}]$ in (3.11) is approximated by the probability of hitting the tangent plane through the point on ∂D closest to $\tilde{x}$ [22]. That is,

$$\mathcal{P}[\mathbf{H}_{\partial D}^{(n)}(\tilde{x}) < \boldsymbol{\delta t}] \to \exp(-\nu h(x^\perp)), \tag{3.13}$$

where $h(\tilde{x}^{\perp})$ is the distance from $\tilde{x} = (\tilde{x}^{\perp}, 0)$ to ∂D. Taking $\nu s = \mathcal{O}(1)$ and using (3.9), we can expand the exponential as follows:

$$\exp\left(-\nu h(x^{\perp})\right) = 1 - \frac{1}{2}\nu\left(\kappa_1 x_1^2 + \kappa_2 x_2^2 + \cdots + \kappa_{n-1} x_{n-1}^2\right) + \mathcal{O}\left(\left(\frac{\kappa}{\nu}\right)^2\right). \tag{3.14}$$

Thus, as $\kappa/\nu \to 0$ with νs fixed,

$$\mathcal{P}[\mathbf{H}_{\partial D}^{(n)}(x) < \boldsymbol{\delta t}] = \mathrm{e}^{-\nu s}\left(1 - \frac{1}{2}s(\kappa_1 + \kappa_2 + \cdots + \kappa_{n-1}) + \mathcal{O}\left(\left(\frac{\kappa}{\nu}\right)^2\right)\right). \tag{3.15}$$

A similar argument can be used to show that (3.15) holds when $\kappa_i < 0$.

For the boundary test, we need [illegible], given the end point of a timestep. Let

$$c(x, x') = \mathcal{P}[\mathbf{H}_{\partial D}^{(n)}(x) < \boldsymbol{\delta t} | \mathbf{B}_{\boldsymbol{\delta t}} = x']. \tag{3.16}$$

Because of the exponential distribution of $\boldsymbol{\delta t}$, any one path can be considered as starting afresh at the boundary and the conditional probability can be written as the product

$$c(x, x') = \mathcal{P}[\mathbf{H}_{\partial D}^{(n)}(x) < \boldsymbol{\delta t}]\left(p_{\nu}^{(n)}(x' - x)\right)^{-1} p_{\nu}^{*}(x, x'), \tag{3.17}$$

where $p_{\nu}^{(n)}(x)$ is given by (2.2),

$$p_{\nu}^{*}(x, x') = \int p_{\nu}^{(n)}(x' - y) q_{\partial D}(y^{\perp}) \mathrm{d}y^{\perp}, \tag{3.18}$$

and $q_{\partial D}(y^{\perp})$ is the density of arrival positions on ∂D, defined in the same way as (3.4). In one dimension, $p_{\nu}^{*}(x, x')$ is the density at x' after an exponential timestep started at the boundary and is independent of x. In more than one dimension, $p_{\nu}^{*}(x, x')$ is the density at x' resulting from the ensemble of realizations with initial conditions distributed according to the density of arrival positions on ∂D, which depends on x. Analysis of the conditional hitting probability (3.17) is the basis for boundary tests of arbitrary accuracy.

4. Exponential timestepping. In this section, we describe the update algorithm and alternative boundary test criteria that we have implemented for exponential timestepping in n dimensions. The Cartesian components of the increment of an n-dimensional Brownian motion over a time interval of fixed length are independent Gaussian random variables. Under exponential timestepping, the Cartesian coordinates of the increment are no longer independent. However, the fact that the distance traveled is independent of the direction traveled permits a simple algorithm to be developed.

4.1. Multidimensional increments. The density of the distance traveled after an exponentially distributed time is obtained from (2.9) by letting $r_0 \to 0$, which gives

$$b^{(n)}(r, 0) = 2^{1-n/2}\nu(\nu r)^{n/2} K_{n/2-1}(\nu r)/\Gamma(n/2). \tag{4.1}$$

To carry out an exact update for Brownian motion in n dimensions, we generate an increment whose modulus is $\nu^{-1}\mathbf{a}^{(n)}$, where

$$\frac{\mathrm{d}}{\mathrm{d}x}\mathcal{P}[\mathbf{a}^{(n)} < x] = 2^{1-n/2} x^{n/2} K_{n/2-1}(x)/\Gamma\left(\frac{n}{2}\right). \tag{4.2}$$

We construct realizations of the random variable $\mathbf{a}^{(n)}$ as

$$\mathbf{a}^{(n)} = \left(\mathbf{h}_1^2 + \mathbf{h}_2^2\right)^{1/2} \left(\mathbf{g}_1^2 + \mathbf{g}_2^2 + \cdots + \mathbf{g}_n^2\right)^{1/2}, \tag{4.3}$$

where $\mathbf{h}_1, \mathbf{h}_2$, and $\mathbf{g}_1, \mathbf{g}_2, \ldots, \mathbf{g}_n$ are independent Gaussian random variables with zero mean and unit variance [24]. The factor $(\mathbf{h}_1^2 + \mathbf{h}_2^2)^{1/2}$ is conveniently generated as $(-2\log \mathbf{u})^{1/2}$, where $\mathbf{u}$ is distributed uniformly on $(0, 1)$ [25].

The direction of the increment is independent of the modulus and uniformly distributed on the surface of the unit n-dimensional ball. Let $\mathbf{v}_1$ and $\mathbf{v}_2$ be independent and uniformly distributed between -1 and 1. For all pairs such that $\mathbf{v}_1^2 + \mathbf{v}_2^2 < 1$, let $\mathbf{x} = (\mathbf{v}_1^2 - \mathbf{v}_2^2)/(\mathbf{v}_1^2 + \mathbf{v}_2^2)$ and $\mathbf{y} = 2\mathbf{v}_1\mathbf{v}_2/(\mathbf{v}_1^2 + \mathbf{v}_2^2)$. Then $(\mathbf{x}, \mathbf{y})$ is uniformly distributed on the unit circle [26]. A uniform distribution on the unit sphere is produced by choosing $\mathbf{z}$ uniformly in $(-1, 1)$; then $\mathbf{x}$ and $\mathbf{y}$ uniformly on a circle with radius $\left(1 - \mathbf{z}^2\right)^{1/2}$. In dimension $n > 3$, two possible methods are as follows. First, a vector whose n components are independent mean-zero Gaussian random variables with equal variance has density that depends only on its magnitude. Normalizing to unit magnitude produces a uniform distribution on the n-dimensional sphere. Alternatively, for n not much above 3, one may sample from a uniform distribution in the n-cube that contains the unit ball, reject those outside the ball, then renormalize to unit magnitude.

4.2. Boundary tests. A boundary test is performed after each update of the process to take account of the probability that the boundary has been hit during the timestep. The boundary is deemed to have been hit the first time that

$$C_{\mathrm{num}}(s, s') > \mathbf{v}, \tag{4.4}$$

where $C_{\mathrm{num}}(s, s')$ is the approximation of (4.7) used in the numerical method and $\mathbf{v}$ is drawn, independently at each timestep, from a uniform distribution on $(0, 1)$.

The full information available for the boundary test is the value of the process at the start of the timestep, x, and the value at the end, x' (Figure 4.1). However, the conditional probability,

$$\mathcal{P}[\mathbf{H}_P^{(n)}(x) < \boldsymbol{\delta t} | \mathbf{B}_{\boldsymbol{\delta t}} = x'] = \exp\left(-2\nu(s \wedge s')\right), \tag{4.5}$$

is exact for the flat surface P, even though it makes no use of the information contained in the directions parallel to P. It can be obtained from (3.17) by integrating over $x^{\perp}$ and $(x')^{\perp}$. We call a boundary test using (4.5) the [illegible]. For numerical timesteps of fixed length Δt, the flat boundary approximation has been called a "half-space" approximation in [15]. The corresponding [illegible] is

$$C_{\mathrm{Euler}}(s, s') = \exp\left(2ss'\Delta t^{-1}\right). \tag{4.6}$$

We seek corrections to (4.5) by analyzing the conditional hitting probability in the form

$$\bar{c}(s, s') = \mathcal{P}[\mathbf{H}_{\partial D}^{(n)}(x) < \boldsymbol{\delta t} | x_n' = -s']. \tag{4.7}$$

This is a simplification of (3.16) because the conditional hitting probability is analyzed as a function of $s \in \mathbb{R}$ and $s' \in \mathbb{R}$, rather than as a function of $x \in \mathbb{R}^n$ and $x' \in \mathbb{R}^n$. We also need only the properties of the surface at its point nearest x.

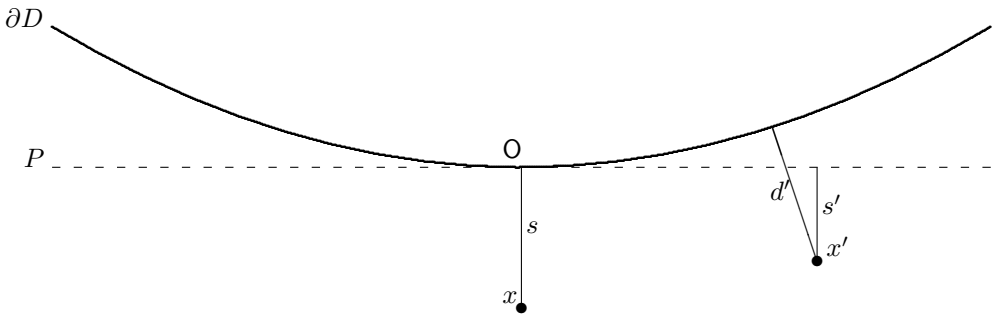

FIG. 4.1. *The position at the start of a timestep is x and the position at the end of the timestep is x'. The distance from x to ∂D is d and the distance from x' to ∂D is d'. The distance from x to P is $s = d$ and the distance from x' to P is $s' \neq d'$.*

Assuming that the surface ∂D can be parametrized as in (3.12), (4.7) is

$$\begin{aligned}(4.8)\quad \bar{c}(s,s') &= \mathcal{P}[\mathbf{H}_{\partial D}^{(n)}(x) < \boldsymbol{\delta t}] \left(p_\nu^{(1)}(s-s')\right)^{-1} \int p_\nu^{(1)}(y_n(y^\perp)+s') q_{\partial D}(y^\perp)\mathrm{d}y^\perp \\ &= \mathcal{P}[\mathbf{H}_{\partial D}^{(n)}(x) < \boldsymbol{\delta t}] \exp\left(\nu|s'-s| - \nu s'\right) \int \exp\left(-\nu y_n(y^\perp)\right) q_{\partial D}(y^\perp)\mathrm{d}y^\perp.\end{aligned}$$

Note that, if all κ_i in (3.12) are zero, then $y_n(y^\perp) = 0$ and (4.8) reduces to (4.5). The first factor in (4.8) was evaluated in (3.15). Now, similarly to (3.14),

$$(4.9)\qquad \exp\left(-\nu y_n(x^\perp)\right) = 1 - \frac{1}{2}\nu\left(\kappa_1 y_1^2 + \kappa_2 y_2^2 + \cdots + \kappa_{n-1} y_{n-1}^2\right) + \mathcal{O}\left(\left(\frac{\kappa}{\nu}\right)^2\right),$$

where $y_i = \mathcal{O}(\nu^{-1})$. With (3.12) we find

$$\begin{aligned}\int \exp\left(-\nu y_n(x^\perp)\right) q_{\partial D}(x^\perp)\mathrm{d}x^\perp &= 1 - \frac{1}{2}s(\kappa_1 + \kappa_2 + \cdots + \kappa_{n-1}) \\ &\quad + \mathcal{O}\left(\left(\frac{\kappa}{\nu}\right)^2\right). \qquad (4.10)\end{aligned}$$

Using (3.15) and (4.10) in (4.8) we find the [illegible], with errors proportional to $(\kappa/\nu)^2$:

$$(4.11)\qquad C_{\mathrm{cc}}(s,s') = \exp(-2\nu((s \wedge s') \vee 0))(1 - s(\kappa_1 + \kappa_2 + \cdots + \kappa_{n-1})).$$

We also implement a [illegible] boundary test, invariant under interchange of the start and end points of the timestep,

$$(4.12)\qquad C_{\mathrm{sym}} = \exp(-2\nu(d \wedge d')).$$

An extra complication arises when measuring the exit time from a nonconcave domain. In that case ∂D may be reached before P. If x' is between ∂D and P, then the boundary is deemed hit; the conditional hitting probability (4.4) needed for the boundary test is that restricted to those paths with x' inside the domain. Consider the conditional hitting probability as a function of s' for a given s. As $s' \to \infty$, we regain

(4.11). On the other hand, as $s' \to 0$, the curvature is not seen by the subset of paths that remain inside the domain, and so the limit is (4.5). In our numerical experiments with exit from domains such that $\kappa_i < 0$ for some i, we use the [illegible] given by

$$C_{\rm cv}(s,s') = \exp(-2\nu(s\wedge s'))\,(1-(s\wedge s')(\kappa_1+\kappa_2+\cdots+\kappa_{n-1})). \tag{4.13}$$

5. Numerical experiments. We restrict ourselves to Brownian motion, where the update is exact under both Euler and exponential timestepping, but a systematic error in the numerical mean exit time may arise from the numerical decision as to when the boundary is deemed to have been hit. Simple use of a boundary test gives an error in the mean exit time proportional to λ^{-1}, the mean duration of a timestep [2]. In this work we are able to obtain high-order convergence of the mean exit time under exponential timestepping.

We begin with exits from circles and spheres, where the problem can be transformed into a one-dimensional problem (although the transformed process is no longer driftless). In the case of an exit from a circle of radius R, the exact conditional hitting probability involves special functions that can be expanded in powers of $(\nu R)^{-1}$ in a form convenient for numerical implementation. The more terms that are included in the expansion, the higher is the order of the numerical method. In the case of exit from a sphere, the special functions reduce to a simple form that can be used to produce numerical estimates of the mean exit time [illegible]

We also study exit from the interior of an ellipse and from the region bounded by the two lines of a hyperbola. These examples illustrate the two cases of locally convex and locally concave domains with smooth boundaries that could be found in applications, and have the advantage that exact analytical results are available for comparison with numerics.

Numerical results are plotted as a function of the parameter λ^{-1}, the mean duration of a timestep. The same horizontal axis is used to display results obtained using the Euler method, where the duration of a timestep, Δt, is fixed and equal to λ^{-1}. We choose $D = \frac{1}{2}$ in all numerical experiments, which typically consist of 10^{10} realizations.

The programs used in the numerical experiments reported in this section are available at http://randomideas.org.

5.1. Exits from circles and spheres. We consider the problem of the numerical estimation of the mean exit time from an n-dimensional ball. The mean exit time with initial condition $x \in \mathbb{R}^n$ is denoted by $\langle \mathbf{h}_R^{(n)}(x)\rangle$ and given by

$$\left\langle \mathbf{h}_R^{(n)}(x)\right\rangle = \frac{R^2-|x|^2}{n}. \tag{5.1}$$

Figure 5.1 was obtained using the naive method of evaluating a mean exit time; i.e., each realization is continued without a boundary test until the first time that a value is generated at a distance greater than R from the origin. The difference between the mean time recorded and (5.1) is proportional to $\langle \boldsymbol{\delta t}\rangle^{1/2}$.

In Figure 5.2, we show the error in the mean exit time from a circle using various boundary tests and timestepping methods. The results labeled "Euler" are obtained using the Euler update and the boundary test (4.6). The results labeled "simple" and "corrected" are obtained using exponential timestepping and boundary tests based on (2.13). When only the leading term in (2.13) is used, we obtain errors proportional

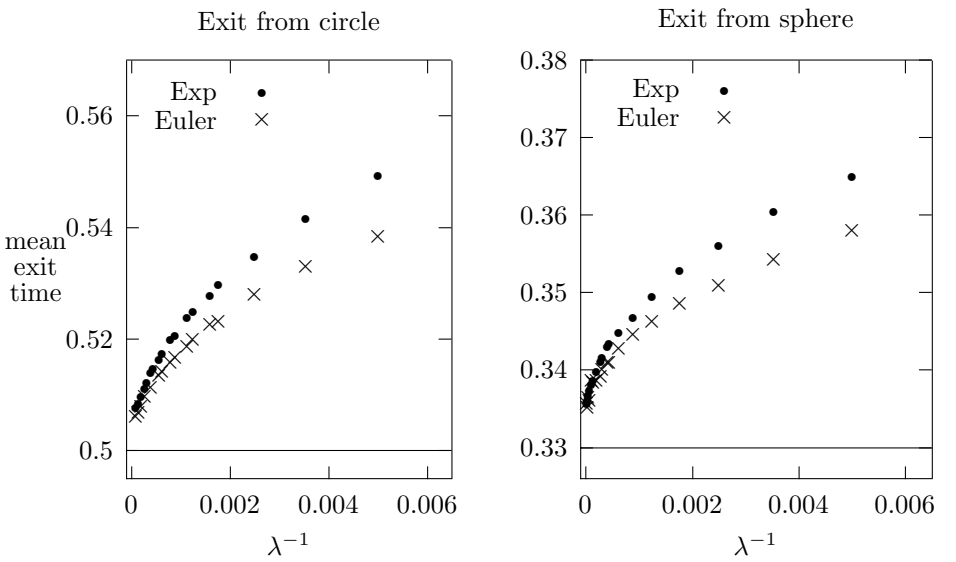

FIG. 5.1. *Measuring the mean exit time without a boundary test. Exit from a circle (left) and sphere (right) with unit radius, starting from the origin. Although the updates of the process are exact, the mean exit time is overestimated by an amount proportional to the square root of the mean duration of a timestep. The horizontal axis is the mean duration of a timestep in the case of exponential timestepping and the (fixed) length Δt of a timestep in the case of the Euler method. Statistical errors are smaller than the plotted symbols.*

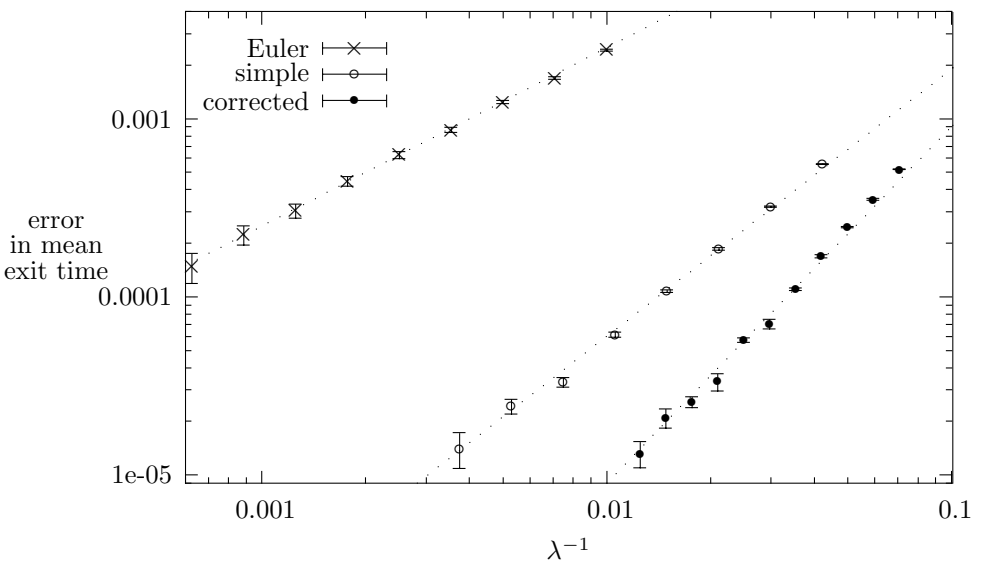

FIG. 5.2. *Error in numerical mean exit time, using boundary correction (logarithmic scales). Exit from a circle with radius $R = 1$, starting from the origin. Statistical errors are indicated by error bars. The dotted lines are error $= 0.25\langle \boldsymbol{\delta t} \rangle$, error $= 0.06\langle \boldsymbol{\delta t} \rangle^{3/2}$, and error $= 0.10\langle \boldsymbol{\delta t} \rangle^{2}$.*

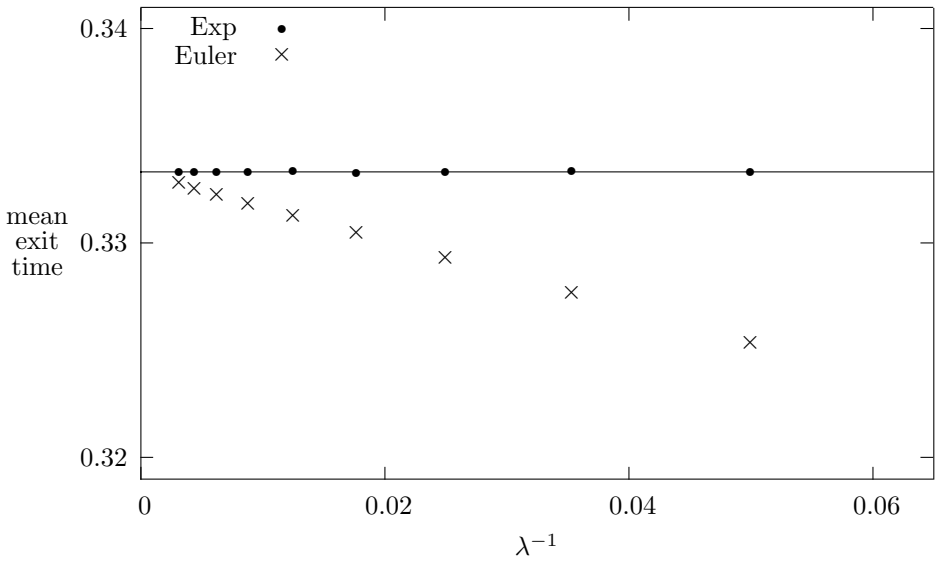

FIG. 5.3. *Error in numerical mean exit time, using boundary correction. Exit from a sphere with radius $R = 1$, starting from the origin. The solid line is the exact result* (5.1)*. The systematic error is zero for the exponential method with boundary test. Statistical errors are smaller than the plotted symbols.*

to $\langle \boldsymbol{\delta t} \rangle^{3/2}$. When the next term in (2.13) is included, we find errors proportional to $\langle \boldsymbol{\delta t} \rangle^{2}$. The size of the statistical errors is independent of λ, but on a logarithmic scale they appear large when the systematic error is small.

When $n = 3$, we find the convenient exact form

$$\mathcal{P}[\mathbf{h}_R^{(3)}(r_0) < \boldsymbol{\delta t} \,|\, |\mathbf{B}_{\boldsymbol{\delta t}}| = r_1] = \mathrm{e}^{-\nu|R-r|} \frac{\sinh \nu(r \vee R)}{\sinh \nu(r \wedge R)}, \tag{5.2}$$

where r is the closer of r_0 and r_1 to R. The mean exit time from a sphere is obtained [illegible] λ under exponential timestepping. In Figure 5.3 the mean exit time is plotted against λ^{-1}. Results obtained using exponential timestepping with (5.2) are shown as small filled circles and results obtained using the Euler method with (4.6) as crosses.

5.2. Exit from an ellipse. As an example of a convex domain, we consider the interior of an ellipse, i.e., the set of points $(x_1, x_2) \in \mathbb{R}^2$ satisfying

$$a x_1^2 + b x_2^2 < 1, \tag{5.3}$$

where a and b are positive constants. Let $\mathbf{H}_{a,b}(x_1, x_2)$ be the first time that a Brownian motion, started at (x_1, x_2), exits the interior of the ellipse. Then $\langle \mathbf{H}_{a,b}(x_1, x_2) \rangle = T(x_1, x_2)$, where

$$\frac{1}{2}\left(\frac{\partial^2}{\partial x_1^2} + \frac{\partial^2}{\partial x_2^2}\right) T(x_1, x_2) = -1, \qquad T(x_1, x_2) = 0 \quad \text{when} \quad a x_1^2 + b x_2^2 = 1. \tag{5.4}$$

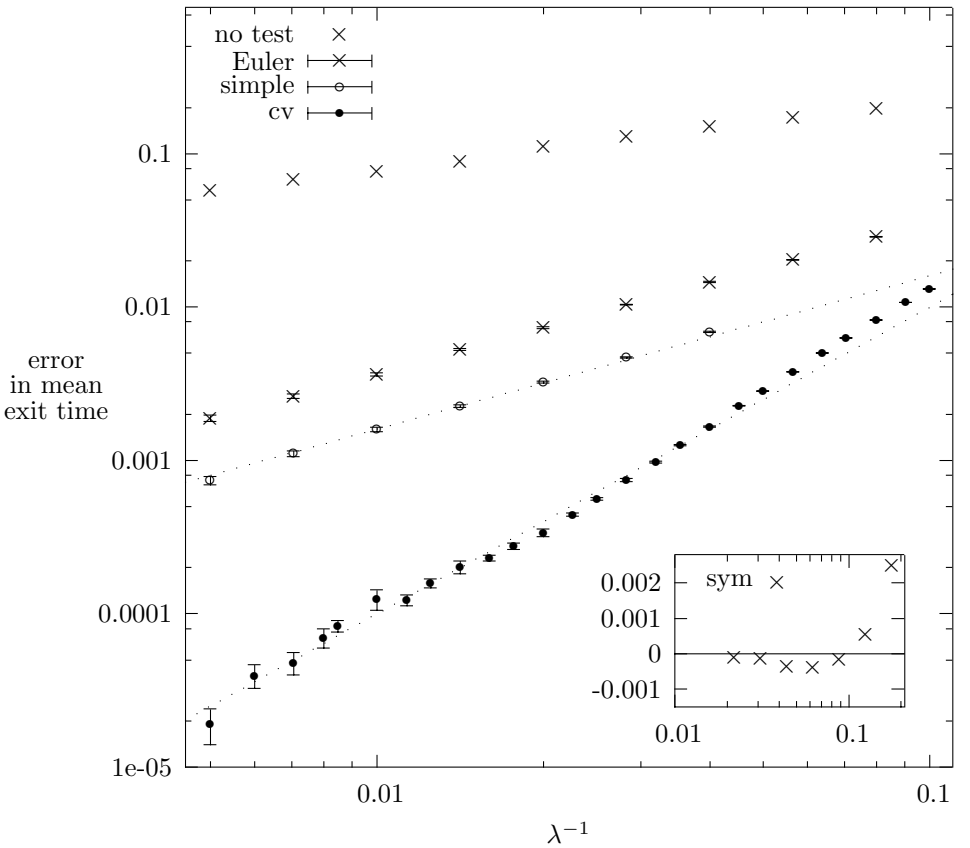

FIG. 5.4. *Error in numerical mean exit time (logarithmic scales). Exit from an ellipse, described by* (5.3) *with* $a = 1/4$ *and* $b = 1$. *The crosses are results using the Euler method, with no boundary test (crosses) and with the boundary test* (4.6) *(crosses with error bars). The results labeled "simple" were obtained using the boundary test,* (4.5); *those labeled "cv" were obtained using the curvature-corrected convex boundary test,* (4.13). *The dotted lines are error* $= 0.16\langle \boldsymbol{\delta t} \rangle^1$ *and error* $= 1.5\langle \boldsymbol{\delta t} \rangle^2$. *The inset displays the difference between the numerical and exact mean exit times using the symmetric boundary test* (4.12).

The solution of (5.4) is

$$T(x_1, x_2) = \left(1 - ax_1^2 - bx_2^2\right)/(a+b). \tag{5.5}$$

In our numerical experiments, the update is the same as that used for studying exits from circles. The boundary is deemed hit if the end point of a timestep is outside the ellipse or if the boundary test is satisfied. To evaluate the conditional probabilities for the boundary test, the closest point on the ellipse to the starting point of each timestep is found by Newton iteration.

In Figure 5.4, we display results obtained using five different methods: the standard Euler method with no boundary test and with the boundary test (4.6), and exponential timestepping with the boundary tests (4.5), (4.13), and (4.12). With (4.5) we find a systematic error in the mean exit time proportional to $\langle \boldsymbol{\delta t} \rangle^1$; with (4.13) we find a systematic error proportional to $\langle \boldsymbol{\delta t} \rangle^2$. Using (4.12) produces an error that passes through 0 at a finite value of λ (inset).

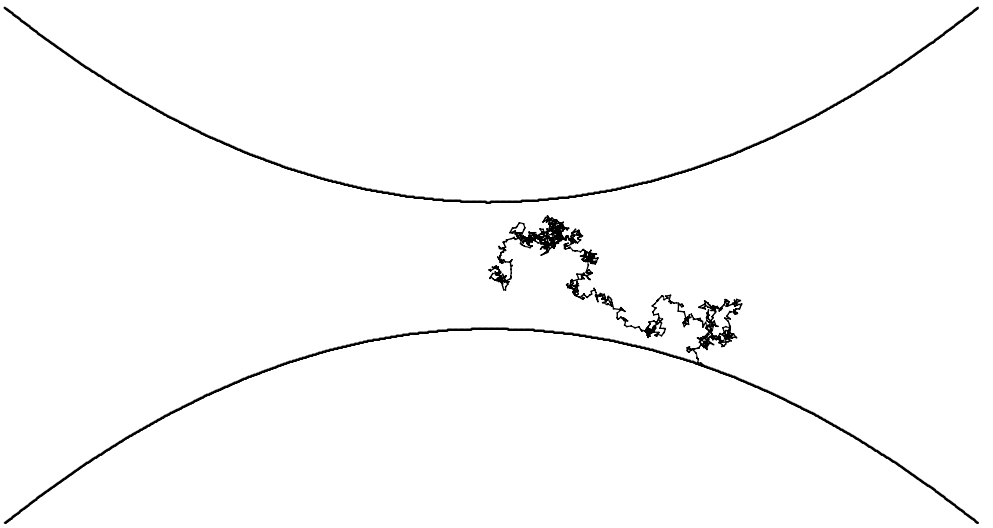

FIG. 5.5. *We measure the mean exit time from concave regions bounded by the two lines of a hyperbola. The figure shows one realization.*

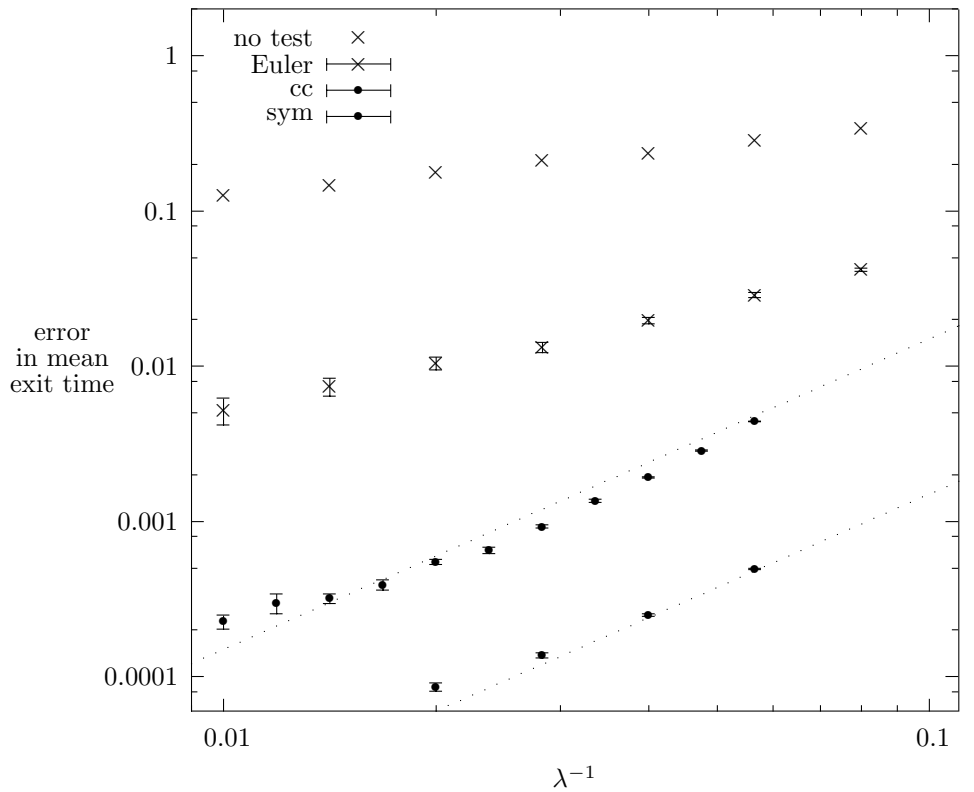

FIG. 5.6. *Error in numerical mean exit time, using boundary correction (logarithmic scales). Exit from a two-dimensional concave region. The hyperbola is described by* (5.3) *with* $a = -1/16$ *and* $b = 1$. *The dotted lines are error* $= 1.5\langle \boldsymbol{\delta t} \rangle^2$ *and error* $= 0.15\langle \boldsymbol{\delta t} \rangle^2$.

5.3. Exit from a region bounded by the two lines of a hyperbola. Consider a hyperbola, defined as the set of points $(x_1, x_2) \in \mathbb{R}^2$ satisfying

$$ax_1^2 + bx_2^2 = 1, \tag{5.6}$$

where $a < 0$ and $b > 0$. The mean exit time from the concave region between the two lines of the hyperbola, depicted in Figure 5.5, is also given by (5.5).

The numerical runs whose results are displayed in Figure 5.6 were performed using the symmetric boundary test (4.12) and the curvature-corrected boundary test (4.11). Statistical errors are large because many paths make long excursions before reaching a boundary. Both boundary tests used produce a systematic error proportional to $\langle \boldsymbol{\delta t} \rangle^2$. The symmetric boundary test is the most efficient for this concave region; the phenomenon of change of sign of the error at a finite value of λ, seen in the ellipsoidal region studied in section 5.2, is not found.

6. Conclusion. An exact numerical procedure has been described for the update of Brownian motion in n dimensions under exponential timestepping. The modulus of an increment is generated as a combination of simple random variables and the angle is uniformly distributed on the surface of the n-dimensional ball.

To evaluate a mean exit time, numerous numerical realizations are generated, each proceeding by updating the process, then performing a test for the possibility of a boundary having been reached in the time interval. A realization is brought to an end when the boundary is deemed hit. Under exponential timestepping, numerical orders of convergence greater than 1 are attainable because of the simple relationship that holds between the mean number of timesteps per realization and the mean exit time. Numerical evidence is presented for convergence proportional to the square of the mean duration of a timestep. An analytical demonstration that this is indeed the case will be the subject of future research.

Taking as examples the exit times from circles, spheres, ellipses, and regions bounded by the two lines of a hyperbola, we report the results of numerical experiments performed with the algorithms developed in this work. The mean exit time from a circle of radius R can be evaluated to arbitrary accuracy by expanding the conditional hitting probability in powers of $(\nu R)^{-1}$. The mean exit time from a sphere is evaluated without systematic error.

The simple boundary test for general smooth surfaces under exponential timestepping uses the minimum of the distance from the starting point and the ending point to the tangent plane through the point on the boundary closest to the starting point. We were able to obtain second-order convergence, i.e., an error proportional to the square of the mean duration of a timestep, using a boundary test that includes a term proportional to κ/ν, where κ is the curvature of the boundary measured at the point on the boundary closest to the starting point. Still higher orders of convergence are attainable if boundary tests including further terms in (3.12) can be derived.

We have considered concave and convex smooth boundaries. Analysis of hitting times of hyperbolae may prove useful in devising algorithms to deal with regions with corners because a suitable choice of parameters gives a geometry approximating that found near a corner with an acute angle. Exponential timestepping has been implemented for processes other than Brownian motion in one dimension [14]. The best way to generalize to multiple dimensions may be to use an approximation by mixing two processes with constant drifts at each timestep. Other areas for future development are algorithms capable of dealing with several close boundaries simultaneously, and boundary tests in three-dimensional regions that take as their starting point the simple exact solution for the conditional hitting probability of a sphere.

IMPLICIT SCHEMES FOR THE FOKKER–PLANCK–LANDAU EQUATION*

MOHAMMED LEMOU† AND LUC MIEUSSENS†

Abstract. We propose time implicit schemes to solve the homogeneous Fokker–Planck–Landau equation in both the isotropic and 3-dimensional geometries. These schemes have properties of conservation and entropy. Moreover, they allow for large time steps, making them faster than the usual explicit schemes. To solve the involved linear systems, we prove that the use of Krylov-like solvers preserves the conservation properties. We show in particular that the conjugate gradient method can be used. Numerical tests are performed for the isotropic case and demonstrate an important gain in terms of CPU time, with the same accuracy as explicit schemes. This work is a first step to the development of fast implicit schemes to solve a class of inhomogeneous kinetic equations.

Key words. kinetic equation, Fokker–Planck–Landau equation, implicit schemes, conservative schemes, Krylov methods

1. Introduction.

The Fokker–Planck–Landau (FPL) is a kinetic collisional model used to describe a system of particles in plasma physics (see [17] for instance). The particles are described through a distribution function $f(t,x,v)$ depending on time t, particle position $x \in \mathbb{R}^d$, and their velocity $v \in \mathbb{R}^d$ $(d = 2, 3)$. In this paper we are concerned with the homogeneous case where $f(t,x,v)$ does not depend on x. The model is written in the so-called Landau form

$$\partial_t f(t,v) = Q(f)(v) = \nabla \cdot \int_{\mathbb{R}^d} \Phi(v - v_*) \left(f(v_*) \nabla f(v) - f(v) \nabla f(v_*) \right) dv_*, \tag{1}$$

where $\Phi(w)$ is the following $d \times d$ matrix:

$$\Phi(w) = C|w|^{\gamma+2} S(w) = C|w|^{\gamma+2} \left(I_d - \frac{w \otimes w}{|w|^2} \right).$$

In this expression, C is a positive constant and γ is a parameter leading to the standard classification in hard potentials ($\gamma > 0$), Maxwellian potential ($\gamma = 0$), and soft potentials ($\gamma < 0$). This last case includes the most physically interesting case, the Coulombian case ($\gamma = -3$). The $d \times d$ matrix $S(w)$ is simply the orthogonal projection onto the plane orthogonal to w. For all $w \neq 0$, $\Phi(w)$ is a positive matrix whose null-space is

$$\operatorname{Ker} \Phi(w) = \mathbb{R} w.$$

Throughout this paper, when there is no confusion, the values of any function f under the integral signs will be denoted by f for $f(v)$ and by f_* for $f(v_*)$. Additionally,

it is also useful to write the FPL collision operator in the so-called "Log form":

$$Q(f)(v) = \nabla \cdot \int_{\mathbb{R}^d} \Phi(v - v_*) f f_* \left(\nabla \log f - \nabla \log f_*\right) \, dv_*. \tag{2}$$

This collision operator $Q(f)$ satisfies the following weak formulation:

$$\int_{\mathbb{R}^d} Q(f)\phi dv = -\frac{1}{2} \int_{\mathbb{R}^d} \int_{\mathbb{R}^d} \Phi(v - v_*) f f_* \left(\nabla \log f - \nabla \log f_*\right) \cdot \left(\nabla \phi - \nabla \phi_*\right) dv dv_* \tag{3}$$

for all distribution functions f and all test functions ϕ. From this formulation, one can immediately derive the following conservation and entropy properties:

(i) The only functions $\phi(v)$ such that

$$\int_{\mathbb{R}^d} Q(f)\phi \, dv = 0 \qquad \forall f$$

are linear combinations of $1, v, |v|^2$. In particular, total mass, momentum, and energy are conserved.

(ii) The entropy dissipation inequality

$$\int_{\mathbb{R}^d} Q(f) \log(f) \, dv \leq 0 \qquad \forall f > 0.$$

This also gives the well known H-theorem, saying that the functional $H(f) = \int_{\mathbb{R}^d} f \log(f) \, dv$ is a time nonincreasing function. Furthermore, this inequality becomes an equality if and only if f is a Maxwellian

$$f_{eq}(v) = \frac{\rho}{(2\pi T)^{\frac{d}{2}}} \exp\left(-\frac{|v - u|^2}{2T}\right), \tag{4}$$

where ρ, u, and T are velocity independent parameters. This is formally equivalent to saying that f is an equilibrium function, that is, $Q(f) = 0$.

Recently, numerous works have been concerned with constructing discretizations of the collision operator that obey the above physical properties of conservation and entropy. The first scheme in this direction was established in [8]. Unfortunately, it turned out to be very expensive in terms of CPU time. Later, various fast algorithms have been constructed to reduce this cost (see [6, 15, 4, 1]). Numerical experiments usually show that the exact preservation of properties (i) and (ii) is crucial to design efficient numerical schemes. In particular, a small error on conservation properties (i) may result in a substantial error on the equilibrium state and may generate some instabilities. On the other hand, nonconservative schemes have to be sufficiently accurate to reduce this error. This task can be achieved by refining the velocity grid (which is expensive) or by using spectral schemes as in [18, 19].

In all these works, the time discretization problem has not been completely solved. Indeed the schemes used are explicit in time, such as the usual Euler explicit scheme

$$f^{n+1} = f^n + \Delta t Q(f^n) \tag{5}$$

or higher order versions (explicit Runge–Kutta methods). It is known that such schemes induce a strong parabolic CFL condition of the form $\Delta t \leq C \Delta v^2$, Δt and Δv being the time and velocity steps. This condition is due to the diffusive nature

of the FPL operator and has been rigorously established in [4] for the isotropic case (that is, where the distribution function only depends on the modulus of the velocity). Therefore, to reach a given simulation time, a large number of iterations n_{it} is required. For instance, in the isotropic case, we have $n_{it} = N^2$, N being the dimension of the approximation space. In that case, even with fast evaluations of the collision operator in $O(N)$ or $O(N \log N)$ (as proposed in the previous works), these explicit schemes require a total simulation cost of the order of $n_{it}O(N) = O(N^3)$ or $O(N^3 \log N)$. However, according to some recent works, it is possible to use explicit schemes with slightly larger time steps. For instance, in [10] a high order explicit scheme with a large stability interval has been used. But the gain obtained with this method remains relatively small: the time step can be taken 5 to 10 times as large as that of the Euler method (5), and the total CPU time is divided by a factor of 4 only.

Consequently, it is attractive to use time implicit schemes, since it is known that they can be free of restrictive time step conditions. This consists of replacing $Q(f^n)$ in (5) by an approximation that also depends on f^{n+1}. Then the problem is how to construct such implicit schemes in order to satisfy the following two requirements:

- the properties (i) and (ii) must be preserved;
- the total computational cost must be smaller than that of the explicit scheme with almost the same accuracy.

Many works in plasma physics area use implicit schemes to solve the FPL equation (for instance, see [12, 13] and the references therein). However, the problem of exact preservation of (i) and (ii) is generally not addressed. Moreover, the total complexity of these algorithms is not optimal. We note that, beyond the fact that implicit schemes usually induce an additional computational cost (nonsparse matrix inversion), they may also affect the properties of conservation and entropy. In [9] for instance, Epperlein has proposed an implicit scheme which is conservative, whereas its total numerical complexity is comparable to the usual explicit resolution. This has been clearly shown in [5]. A recent work by Chacón et al. [7] uses a fast linear solver to reduce the cost of their implicit scheme. However, their approach does not exactly respect the conservation and entropy properties. In fact, whereas they claim that their scheme preserves the energy, they also point out that the solvers and the velocity boundary conditions that they used in practice affect the conservation properties.

In this paper we develop a strategy leading to exact conservative implicit schemes with a reduced computational cost. One of our schemes also satisfies the entropy property. Iterative Krylov solvers are used to efficiently solve the linear systems generated by the implicit schemes. This strategy is also proved to be conservative, even if the linear systems are only solved approximately, and an important gain in terms of computational cost is obtained. All the schemes developed in this work concern both the 2- and 3-dimensional cases as well as the isotropic FPL equation.

We point out that our method is based on the Landau form (1) or the Log form (2) of the FPL equation. Hence it can be used with various potentials and easily be extended to quantum and relativistic cases. This does not seem to be possible if one uses the so-called Rosenbluth form of the classical FPL equation, as done in [7]. Note also that our schemes can easily be used in the resolution of inhomogeneous problems via standard splitting techniques.

The outline of this paper is as follows. In the next section we focus on the time discretization only and present the different implicit schemes. In section 3, the velocity variable is also discretized, leading to completely discrete implicit schemes. All these schemes require the resolution of large and nonsparse linear systems. This is

addressed in section 4 where fast linear solvers are proposed. In section 5, we discuss the numerical complexity of our algorithms and present various numerical tests in the isotropic case. The validation of the present strategy for the 3-dimensional case needs further investigations to solve the linear systems. Therefore the numerical tests for the 3-dimensional geometries are deferred to a forthcoming paper. We finally mention that a part of this work has been summarized in a previous note [16].

2. Implicit schemes. In this section, we focus on the time discretization only. Suitable discretizations in the velocity variable will be developed in section 3. Below, we present different strategies to construct linear time implicit schemes that have properties of conservation and entropy.

2.1. Contracted implicit scheme. We first note that the FPL operator (1) can be rewritten in the following diffusive form:

$$Q(f) = \nabla \cdot (D(f)\nabla f + F(f)f), \tag{6}$$

where $D(f) = \int_{\mathbb{R}^d} \Phi(v - v_*) f(v_*)\, dv_*$, and $F(f) = \int_{\mathbb{R}^d} \Phi(v - v_*)\nabla f(v_*)\, dv_*$. This shows in particular that the CFL condition resulting from the use of time explicit schemes is due to the diffusive term $\nabla \cdot (D(f)\nabla f)$ in (6). Therefore the first idea is to make ∇f implicit in this last expression. On the other hand, the conservation and entropy properties are a consequence of the symmetry property (between v and v_*) of the collision operator. To preserve this symmetry, the friction coefficient $F(f)$ has to be implicit too. This leads to the following contracted implicit scheme:

$$\frac{f^{n+1} - f^n}{\Delta t} = q^c(f^n, f^{n+1}), \quad \text{with} \tag{7}$$

$$q^c(f, g) = \nabla \cdot \int_{\mathbb{R}^d} \Phi(v - v_*)\, (f_*\nabla g - f\nabla g_*)\, dv_*. \tag{8}$$

Note that this operator q^c is not the linearization of Q around f. The linearized operator around f is in fact

$$\begin{aligned} q(f, g) &= \nabla \cdot \int_{\mathbb{R}^d} \Phi(v - v_*)\, (f_*\nabla g - f\nabla g_* + g_*\nabla f - g\nabla f_*)\, dv_* \\ &= q^c(f, g) + q^c(g, f). \end{aligned} \tag{9}$$

Therefore, the contracted scheme (7) is not the usual linearized implicit scheme as used by Epperlein in [9]. The operator q^c is contracted in the sense that we only keep the terms that are necessary to ensure the symmetry between v and v_* in the linearized operator q.

PROPOSITION 2.1.

(i) [illegible] q^c [illegible]

$$\int_{\mathbb{R}^d} q^c(f, g)\phi dv = -\frac{1}{2}\int_{\mathbb{R}^d}\int_{\mathbb{R}^d} \Phi(v - v_*)\, (f_*\nabla g - f\nabla g_*) \cdot (\nabla\phi - \nabla\phi_*)\, dv dv_* \tag{10}$$

(ii) [illegible] ϕ [illegible] (7, 8) [illegible]

$$\forall n, \quad \int_{\mathbb{R}^d} \left(1, v, \frac{1}{2}|v|^2\right)^T f^n\, dv = \int_{\mathbb{R}^d} \left(1, v, \frac{1}{2}|v|^2\right)^T f^0\, dv.$$

(iii) [illegible]. The weak form is classically obtained using integration by parts and the permutation of the variables v and v_*. The conservation property is a direct consequence of the weak form: $\nabla\phi - \nabla\phi_*$ is zero for $\phi = 1$ and v and is in $\operatorname{Ker}\Phi(v - v_*)$ for $\phi = \frac{1}{2}|v|^2$. Finally, a simple Taylor expansion and the consistency relation $q^c(f, f) = Q(f)$ give the time order of the contracted scheme. ∎

2.2. A θ-scheme. The present approach first consists of a time integration of (1) using the standard θ-scheme

$$\frac{f^{n+1} - f^n}{\Delta t} = (1 - \theta)Q(f^n) + \theta Q(f^{n+1}). \tag{11}$$

Then we linearize $Q(f^{n+1})$ around f^n:

$$Q(f^{n+1}) = Q(f^n) + DQ(f^n)(f^{n+1} - f^n), \tag{12}$$

where $DQ(f)(g) = q(f, g)$ is given by formula (9). With this linearization, the θ-scheme (11) turns to

$$\frac{f^{n+1} - f^n}{\Delta t} = \theta q(f^n, f^{n+1}) + \left(\frac{1}{2} - \theta\right) q(f^n, f^n) \tag{13}$$

for any $\theta \in \mathbb{R}$.

If we introduce the classical symmetrized bilinear operator $q_s(f, g) = \frac{1}{2}q(f, g)$, then the previous scheme can be written as a convex combination:

$$\frac{f^{n+1} - f^n}{\Delta t} = 2\theta q_s(f^n, f^{n+1}) + (1 - 2\theta)q_s(f^n, f^n).$$

Note that the contracted scheme (7) is not a θ-scheme and that the linearized implicit scheme used by Epperlein in [9] is obtained for $\theta = 1$. Now we give the main properties of this scheme.

PROPOSITION 2.2.

(i) [illegible] θ [illegible] (13) [illegible]

$$\forall n, \quad \int_{\mathbb{R}^d} \left(1, v, \frac{1}{2}|v|^2\right)^T f^n \, dv = \int_{\mathbb{R}^d} \left(1, v, \frac{1}{2}|v|^2\right)^T f^0 \, dv.$$

(ii) [illegible] θ [illegible] $\theta = \frac{1}{2}$ [illegible]. The same arguments as for Proposition 2.1 give the results. ∎

However, we are not able to prove any entropy property for both the contracted and the θ-scheme, except in the isotropic case for the contracted scheme (see [16]). Therefore, we propose another strategy that uses the Log form (2) of the FPL collision operator. This leads to conservative and entropic schemes that are detailed in the next section.

2.3. Log implicit schemes. The first step is to make implicit only the log terms in the Log form (2) of the collision operator. This gives the following nonlinear implicit scheme:

$$\frac{f^{n+1} - f^n}{\Delta t} = q^{\log}(f^n, f^{n+1}) = \nabla \cdot \int_{\mathbb{R}^d} \Phi(v - v_*) f^n f_*^n \left(\nabla \log f^{n+1} - \nabla \log f_*^{n+1}\right) dv_*. \tag{14}$$

PROPOSITION 2.3.

(i) $q^{\log}$

$$\int_{\mathbb{R}^d} q^{\log}(f,g)\phi dv = -\frac{1}{2}\int_{\mathbb{R}^d}\int_{\mathbb{R}^d} \Phi(v-v_*) f f_* \left(\nabla \log g - \nabla \log g_*\right)\cdot\left(\nabla\phi - \nabla\phi_*\right) dv dv_* \tag{15}$$

(ii) ϕ (14)

$$\forall n, \quad \int_{\mathbb{R}^d} \left(1, v, \frac{1}{2}|v|^2\right)^T f^n\, dv = \int_{\mathbb{R}^d} \left(1, v, \frac{1}{2}|v|^2\right)^T f^0\, dv.$$

(iii) $q^{\log}$

$$\int_{\mathbb{R}^d} q^{\log}(f,g)\log g\, dv \le 0.$$

(iv) $H_n = \int_{\mathbb{R}^d} f^n \log f^n\, dv$

. Property (i) is again obtained by classical arguments as in the proof of Proposition 2.1. Properties (ii) and (iii) are direct consequences of (i). To prove (iv), we first compute the entropy variation:

$$H(f^{n+1}) - H(f^n) = \int_{\mathbb{R}^d} (f^{n+1} - f^n)\log f^{n+1}\, dv + \int_{\mathbb{R}^d} f^n \log\frac{f^{n+1}}{f^n}\, dv.$$

Using (14) and (iii) shows that the first integral is nonpositive. Moreover, it is classical to use a convexity inequality to prove that the second integral is also nonpositive. This completes the proof of (iv). ∎

However, $q^{\log}(f^n, f^{n+1})$ is nonlinear with respect to f^{n+1} which makes it difficult to use. In the second step, we propose the following linearization around f^n. We write

$$\log f^{n+1} \approx \log f^n + \frac{f^{n+1} - f^n}{f^n},$$

which is inserted in (14) to obtain the following log-linear implicit scheme:

$$\frac{f^{n+1} - f^n}{\Delta t} = Q(f^n) + q^l(f^n, f^{n+1}), \tag{16}$$

with

$$q^l(f,g) = \nabla\cdot\int_{\mathbb{R}^d} \Phi(v-v_*) f f_* \left(\nabla\left(\frac{g}{f}\right) - \nabla\left(\frac{g}{f}\right)_*\right) dv_*. \tag{17}$$

Note that $q^l(f,g) = q^l(f, g-f)$ which clearly shows that the scheme is consistent.

Proposition 2.4.

(i) q^l

$$\int_{\mathbb{R}^d} q^l(f,g)\phi dv = -\frac{1}{2}\int_{\mathbb{R}^d}\int_{\mathbb{R}^d} \Phi(v-v_*) f f_* \left(\nabla\left(\frac{g}{f}\right) - \nabla\left(\frac{g}{f}\right)_*\right)\cdot\left(\nabla\phi - \nabla\phi_*\right) dv dv_*. \tag{18}$$

(ii) [illegible] (16, 17) [illegible]

$$\forall n, \quad \int_{\mathbb{R}^d} \left(1, v, \frac{1}{2}|v|^2\right)^T f^n \, dv = \int_{\mathbb{R}^d} \left(1, v, \frac{1}{2}|v|^2\right)^T f^0 \, dv.$$

(iii) [illegible] (16, 17) [illegible]

$$\int_{\mathbb{R}^d} (Q(f) + q^l(f,g)) \left(\log f + \frac{g}{f}\right) dv \le 0.$$

(iv) [illegible] $H_n = \int_{\mathbb{R}^d} f^n \log f^n \, dv$ [illegible]

$$\inf_{n \in \mathbb{N}, v \in \mathbb{R}^d} \left(\frac{f^{n+1}}{f^n}\right) \ge \frac{1}{2}. \tag{19}$$

(v) [illegible] f [illegible] $g \mapsto q^l(f,g)$ [illegible]

$$\langle q^l(f,g), h\rangle_{\frac{1}{f}} := \int_{\mathbb{R}^d} q^l(f,g) h \, \frac{dv}{f} = \langle q^l(f,h), g\rangle_{\frac{1}{f}}, \qquad \langle q^l(f,g), g\rangle_{\frac{1}{f}} \le 0$$

[illegible] g [illegible] h

[illegible]. Again, we use an integration by parts and the symmetry between v and v_* in (17) to obtain (i). Using (3) and (i), we obtain the following weak formulation:

$$\int_{\mathbb{R}^d} (Q(f) + q^l(f,g))\phi \, dv = \int_{\mathbb{R}^d}\int_{\mathbb{R}^d} \Phi(v - v_*) f f_* \left[\nabla \left(\log f + \frac{g}{f}\right) - \nabla \left(\log f + \frac{g}{f}\right)_*\right] [\nabla\phi - \nabla\phi_*] \, dv dv_*.$$

This gives (ii) with $\phi(v) = 1, v, \frac{1}{2}|v|^2$ and (iii) with $\phi(v) = \log f + \frac{g}{f}$. Now we prove (iv): first a simple calculation shows that the entropy variation is

$$H(f^{n+1}) - H(f^n) = \int_{\mathbb{R}^d} (f^{n+1} - f^n) \left(\log f^n + \frac{f^{n+1}}{f^n}\right) dv + \int_{\mathbb{R}^d} B(f^n, f^{n+1}) \, dv, \tag{20}$$

where

$$B(f^n, f^{n+1}) = f^n \left(\frac{f^{n+1}}{f^n} \log \frac{f^{n+1}}{f^n} - \left(\frac{f^{n+1}}{f^n}\right)^2 + \frac{f^{n+1}}{f^n}\right).$$

From relation (16), the first integral of (20) is

$$\int_{\mathbb{R}^d} (f^{n+1} - f^n) \left(\log f^n + \frac{f^{n+1}}{f^n}\right) dv = \Delta t \int_{\mathbb{R}^d} (Q(f^n) + q^l(f^n, f^{n+1})) \left(\log f^n + \frac{f^{n+1}}{f^n}\right) dv,$$

which is nonpositive thanks to (iii).

To study the second integral of (20), we set $\theta(X) = X\log X - X^2 + X$ for $X \in \mathbb{R}^+$, which is concave on $[\frac{1}{2}, +\infty)$. Therefore, if $\frac{f^{n+1}}{f^n} \geq \frac{1}{2}$ we can use the Jensen inequality to get

$$\int_{\mathbb{R}^d} B(f^n, f^{n+1})\,dv = \int_{\mathbb{R}^d} f^n \theta\left(\frac{f^{n+1}}{f^n}\right) dv \leq \theta\left(\frac{\int_{\mathbb{R}^d} f^{n+1}\,dv}{\int_{\mathbb{R}^d} f^n\,dv}\right) \int_{\mathbb{R}^d} f^n\,dv = \theta(1)\int_{\mathbb{R}^d} f^n\,dv = 0.$$

Consequently, the two integrals of the RHS of (20) are nonpositive under assumption (19) of the proposition, which completes the proof of (iv).

For property (v), we use weak formulation (18) with $\phi = \frac{h}{f}$:

$$\langle q^l(f,g), h\rangle_{\frac{1}{f}} = -\frac{1}{2}\int_{\mathbb{R}^d}\int_{\mathbb{R}^d} \Phi(v-v_*) f f_* \left(\nabla\left(\frac{g}{f}\right) - \nabla\left(\frac{g}{f}\right)_*\right)\cdot\left(\nabla\left(\frac{h}{f}\right) - \nabla\left(\frac{h}{f}\right)_*\right) dv dv_*,$$

which is clearly a symmetric formula with respect to g and h. Moreover, taking $h = g$ in the previous relation gives the last inequality of (v). ∎

Remark 2.1. The condition (19) of the proposition is reasonable, since in practice the ratio $\frac{f^{n+1}}{f^n}$ should be close to 1. However, to get a weaker condition, one could consider the following modified scheme:

$$\frac{f^{n+1} - f^n}{\Delta t} = Q(f^n) + A q^l(f^n, f^{n+1}),$$

where A is a free positive parameter. This scheme is still consistent and condition (19) becomes

$$\inf_{n\in\mathbb{N}, v\in\mathbb{R}^d}\left(\frac{f^{n+1}}{f^n}\right) \geq \frac{1}{2A}.$$

The last property of the proposition is of practical importance since in that case, the conjugate gradient (CG) method could be used in the inversion process of the linear system (see details in section 4). However, the weight $\frac{1}{f^n}$, which is used to construct an inner product in the CG algorithm, should be positive at any time. Unfortunately, we cannot prove that this property is satisfied. We point out that the two first schemes (contracted and θ-schemes) do not have the self-adjointness property. Therefore, we propose modified versions of the θ and log-linear schemes in which the linear operators are self-adjoint at any time (in particular, the positivity of the weight is guaranteed at any time).

2.4. Equilibrium linearized implicit schemes. We write implicit terms $q(f^n, f^{n+1})$ and $q^l(f^n, f^{n+1})$ of schemes (13) and (16), (17) under the following perturbation form: $q(f^n, f^{n+1} - f^n) + q(f^n, f^n)$ and $q^l(f^n, f^{n+1} - f^n)$. The idea is to replace the first argument f^n of the perturbative terms $q(f^n, f^{n+1} - f^n)$ and $q^l(f^n, f^{n+1} - f^n)$ by its associate Maxwellian equilibrium f_{eq} of the form (4) that has the same mass, momentum, and energy as f^n:

$$q(f^n, f^{n+1} - f^n) \approx q(f_{eq}, f^{n+1} - f^n) \quad \text{and} \quad q^l(f^n, f^{n+1} - f^n) \approx q^l(f_{eq}, f^{n+1} - f^n).$$

TABLE 1
Properties of the different implicit schemes.

	Time order	Conservation	Entropy	H-theorem	Linear operator
contracted scheme (7-8)	1	yes	?	?	?
θ-scheme (11)	2 if $\theta = \frac{1}{2}$, 1 if not	yes	?	?	?
log-linear scheme (16-17)	1	yes	yes	yes	nonpositive self-adjoint
eq. θ-scheme (21)	1	yes	?	?	nonpositive self-adjoint
eq. log-linear scheme (22)	1	yes	?	?	nonpositive self-adjoint

This leads to the following schemes:

- Equilibrium θ-scheme:

$$\frac{f^{n+1} - f^n}{\Delta t} = Q(f^n) + \theta q(f_{eq}, f^{n+1} - f^n). \tag{21}$$

  Because f_{eq} is a Maxwellian, it is well known that the linear operator $g \mapsto q(f_{eq}, g)$ is nonpositive self-adjoint for the weight $\frac{1}{f_{eq}} > 0$. Moreover, this scheme is conservative.

- Equilibrium log linear scheme:

$$\frac{f^{n+1} - f^n}{\Delta t} = Q(f^n) + q^l(f_{eq}, f^{n+1} - f^n). \tag{22}$$

  Because f_{eq} is positive, from property (v) of Proposition 2.4, the linear operator $g \mapsto q^l(f_{eq}, g)$ is nonpositive self-adjoint for the weight $\frac{1}{f_{eq}}$. Moreover, this scheme is conservative.

We mention that the use of equilibrium approximation has already been exploited in other contexts. We refer, for instance, to [11] where equilibrium is used to truncate the so-called Wild sums, and also to the standard BGK model of the Boltzmann equation [2].

REMARK 2.2. Schemes (21), (22) are not obtained by a linearization of $Q(f^{n+1})$ near the equilibrium f_{eq}.

2.5. Summary. We summarize in Table 1 the properties of the previous implicit linear schemes: time order, conservation of mass and energy, the entropy dissipation property of the approximated collision operator, the decreasing of the entropy functional (H-theorem), and the properties of the linear operators $g \mapsto q(f, g), q^c(f, g), q^l(f, g), q(f_{eq}, g)$, and $q^l(f_{eq}, g)$.

2.6. A remark about an unconditionally positive implicit scheme. In this section, we introduce an alternative idea to make linear the nonlinear implicit scheme (14). To that purpose, we modify the approximation of the time derivative in the following way:

$$\partial_t f(n\Delta t) = (f \partial_t \log f)(n\Delta t) \approx f^n \frac{\log f^{n+1} - \log f^n}{\Delta t}.$$

According to this approximation, the nonlinear log scheme (14) is modified into

$$f^n \frac{\log f^{n+1} - \log f^n}{\Delta t} = q^{\log}(f^n, f^{n+1}). \tag{23}$$

This is still nonlinear in f^{n+1}, but it is linear in $F^{n+1} = \log f^{n+1}$ and can be easily solved. Then $f^{n+1} = \exp(F^{n+1})$ is unconditionally positive.

However, it is shown in the following proposition that this scheme cannot preserve the mass $\int f^n\,dv$.

PROPOSITION 2.5.

(i) [illegible] (23) [illegible] $f_0 > 0$ [illegible] $f_n > 0$ [illegible] n

(ii) [illegible] f^n [illegible]

$$\int f^{n+1}\,dv > \int f^n\,dv.$$

[illegible] n_0 [illegible] f^{n_0} [illegible] $n \geq n_0$ [illegible] $\int f^n\,dv$ [illegible]

[illegible]. By construction, the proof of (i) is straightforward. Now we prove (ii): first, integrating (23) with respect to v gives the following relation:

$$\int f^n \log\left(\frac{f^{n+1}}{f^n}\right) dv = 0. \tag{24}$$

Now using the Jensen inequality yields

$$\int f^n \log\left(\frac{f^{n+1}}{f^n}\right) dv \leq \log\left(\frac{\int f^{n+1}\,dv}{\int f^n\,dv}\right) \int f^n\,dv.$$

Since f^n is positive, the previous inequality gives

$$\log\left(\frac{\int f^{n+1}\,dv}{\int f^n\,dv}\right) \geq 0$$

which is equivalent to $\int f^{n+1}\,dv \geq \int f^n\,dv$.

To prove that this last inequality is strict, we assume the contrary, that is $\int f^{n+1}\,dv = \int f^n\,dv$, and use the Czisar–Kullback inequality to obtain

$$\int f^n \log\left(\frac{f^{n+1}}{f^n}\right) dv \leq -\frac{1}{4(\int f^n\,dv)^2} \|f^{n+1} - f^n\|_{L^1}^2.$$

Using (24) then gives $f^{n+1} = f^n$. Then we replace f^{n+1} by f^n in scheme (23) and this gives $q^{\log}(f^n, f^n) = Q(f^n) = 0$. Thus f^n is a Maxwellian, which is impossible due to the assumption of the proposition. Consequently, $\int f^{n+1}\,dv > \int f^n\,dv$. ∎

Despite its simplicity and its positivity property, this scheme does not provide attractive numerical results. This is probably due to the fact that it does not satisfy the conservation properties.

3. Implicit schemes and velocity discretization of the FPL equation: the isotropic case. The previous schemes can naturally be discretized in the velocity variable using standard conservative and entropic discretizations [8, 6, 15, 4, 1]. In this section, we illustrate this assertion with a simple velocity discretization of the FPL equation in the isotropic case.

The isotropic FPL model is (1) in which the distribution function f only depends on time t and on the particle kinetic energy $\varepsilon = |v|^2$. In this case, the FPL equation is written as

$$\partial_t f(t,\varepsilon) = Q(f) = \frac{1}{\sqrt{\varepsilon}} \frac{\partial}{\partial \varepsilon} \int_0^{+\infty} K(\varepsilon, \varepsilon_*) \left(f(\varepsilon_*)\partial_\varepsilon f(\varepsilon) - f(\varepsilon)\partial_\varepsilon f(\varepsilon_*)\right) d\varepsilon_*, \tag{25}$$

with $K(\varepsilon,\varepsilon_*)=\frac{16}{3}\pi\inf(\varepsilon^{3/2},\varepsilon_*^{3/2})$ for Coulombian interactions, and $K(\varepsilon,\varepsilon_*)=\frac{16}{3}\pi\varepsilon^{3/2}\varepsilon_*^{3/2}$ for Maxwellian interactions.

For any distribution function f, the collision operator $Q(f)$ satisfies the following weak formulation:

(26)
$$\int_0^{+\infty} Q(f)\phi(\varepsilon)\sqrt{\varepsilon}\,d\varepsilon = -\frac{1}{2}\int_0^{+\infty}\int_0^{+\infty} K(\varepsilon,\varepsilon_*)\left(f_*\partial_\varepsilon f - f\partial_\varepsilon f_*\right)\left(\partial_\varepsilon\phi-\partial_\varepsilon\phi_*\right)\,d\varepsilon d\varepsilon_*,$$

ϕ being any test function. From this formulation, one can immediately derive the following conservation and entropy properties:

$$\int_0^{+\infty}(1,\varepsilon)^T Q(f)\sqrt{\varepsilon}\,d\varepsilon = 0, \qquad \int_0^{+\infty} Q(f)\log(f)\sqrt{\varepsilon}\,d\varepsilon \le 0.$$

3.1. A conservative and entropic discretization of the isotropic FPL equation. We briefly recall here the discretization used by Berezin, Khudic, and Pekker [3] (also studied by Buet and Cordier [5]). The energy domain is replaced by a regular energy grid of step $\Delta\varepsilon$ and of nodes $\varepsilon_i=(i-1)\Delta\varepsilon$, with $i=1$ to N. The case of an irregular discretization is also considered at the end of this section. Here, the length of the grid is $e=(N-1)\Delta\varepsilon$. Any function f of ε is approximated on the grid by values $(f_i)_{i=1}^N$ supposed to be approximations of $(f(\varepsilon_i))_{i=1}^N$.

Integrals on $\mathbb{R}^+$ with respect to the measure $\sqrt{\varepsilon}d\varepsilon$ are approximated by the following weighted trapezoidal quadrature formula:

$$\int_0^{+\infty}\phi(\varepsilon)\sqrt{\varepsilon}\,d\varepsilon \approx \sum_{i=1}^N \phi(\varepsilon_i)\omega_i,$$

where $\omega_1=\frac{1}{2}\int_{\varepsilon_1}^{\varepsilon_2}\sqrt{\varepsilon}\,d\varepsilon$, $\omega_i=\int_{\varepsilon_{i-1}}^{\varepsilon_{i+1}}\sqrt{\varepsilon}\,d\varepsilon$ for $i=2$ to $N-1$, and $\omega_{N-1}=\frac{1}{2}\int_{\varepsilon_{N-1}}^{\varepsilon_N}\sqrt{\varepsilon}\,d\varepsilon$.

A simple discretization of (25) is

$$\partial_t f = Q(f),$$

where $Q(f)$ now is an N-vector of components

$$Q_i(f) = -\frac{1}{\omega_i}(D^*\mathcal{F})_i, \quad i=1:N. \tag{27}$$

The operator D^* is defined by $(D^*f)_i=f_{i-1}-f_i$, and the vector $\mathcal{F}$ is defined by

$$\mathcal{F}_i = \sum_{j=1}^{N-1} K_{ij}\big(f_j(Df)_i - f_i(Df)_j\big), \quad i=1:N-1, \tag{28}$$

and $\mathcal{F}_0=\mathcal{F}_N=0$. The finite difference operator D is the formal adjoint of D^* defined by $(Df)_i=f_{i+1}-f_i$.

This discretization is constructed so that the discrete collision operator satisfies the following weak formulation:

$$\sum_{i=1}^N Q_i(f)\phi_i\omega_i = -\frac{1}{2}\sum_{i=1}^{N-1}\sum_{j=1}^{N-1} K_{ij}\big(f_j(Df)_i - f_i(Df)_j\big)\big((D\phi)_i-(D\phi)_j\big).$$

This implies that conservation and entropy properties are preserved (see the proof in [5]). Namely, we have

$$\sum_{i=1}^{N} Q_i(f)(1, \sqrt{\varepsilon_i})^T \omega_i = 0, \quad \sum_{i=1}^{N} Q_i(f)(\log f_i)\, \omega_i \leq 0.$$

Another discretization is deduced from the log form of (25) similarly to (2) (see [3]). In that case the discrete collision operator has the same form as (27) but the vector $\mathcal{F}$ now is

$$\mathcal{F}_i = \sum_{j=1}^{N-1} K_{ij} f_i f_j \big((D \log f)_i - (D \log f)_j \big), \quad i = 1 : N-1,$$

and $\mathcal{F}_0 = \mathcal{F}_N = 0$. This scheme has the same properties as the nonlog scheme.

The main drawback of a regular discretization is the fact that the resolution is not accurate near $\varepsilon = 0$, while there are too many points for large ε. Therefore, it is interesting to consider an irregular discretization with the energy step $\Delta\varepsilon_i = \varepsilon_{i+1} - \varepsilon_i$ as in [4]. Following the same procedure as for the regular case, we obtain this discrete collision operator

$$Q_i(f) = \frac{1}{\omega_i}(\mathcal{F}_i - \mathcal{F}_{i-1}) \qquad i = 1 : N, \tag{29}$$

with

$$\mathcal{F}_i = \sum_{j=1}^{N-1} K_{ij} \big(f_j (Df)_i - f_i (Df)_j \big) \Delta\varepsilon_j, \quad i = 1 : N-1,$$

and $\mathcal{F}_0 = \mathcal{F}_N = 0$. Here D is the following finite difference operator $(Df)_i = \frac{f_{i+1} - f_i}{\Delta\varepsilon_i}$, for $i = 1 : N-1$. This approximation is conservative, but the associated equilibrium states are only approximations of the Maxwellians, i.e.,

$$(f_{eq})_i = \beta \prod_{j=1}^{i} (1 + \alpha \Delta\varepsilon_j),$$

β and α being some constants. Maxwellian equilibrium states can be obtained by using the conservative and entropic approximation of [4], which is based on the log form.

Consequently, we have a discrete collision operator that possesses all desired properties (both in log and Landau forms). Our implicit schemes can now be derived exactly as in the continuous case, as is illustrated in the next section.

3.2. Implicit schemes. In this section, we give completely discretized implicit schemes (in both time and velocity). For the sake of simplicity we only present the case of a regular discretization. The case of an irregular grid can be treated in the same way.

The different implicit schemes are given by (7, 13, 16, 21, 22), where the discrete collision operators are the N-vectors defined as follows:

- contracted scheme: $q_i^c(f, g) = -\frac{1}{\omega_i}(D^* \mathcal{F}^c(f, g))_i$ for $i = 1 : N$, where the flux $\mathcal{F}^c$ is

$$\mathcal{F}_i^c(f, g) = \sum_{j=1}^{N-1} K_{ij} \big(f_j (Dg)_i - f_i (Dg)_j \big), \quad i = 1 : N-1.$$

- θ-scheme: $q_i(f,g) = q_i^c(f,g) + q_i^c(g,f)$, $i = 1 : N$.
- log-linear scheme: $q_i^l(f,g) = -\frac{1}{\omega_i}(D^*\mathcal{F}^l(f,g))_i$ for $i = 1 : N$, where the flux $\mathcal{F}^l$ is

$$\mathcal{F}_i^l(f,g) = \sum_{j=1}^{N-1} K_{ij} f_i f_j \left[\left(D\left(\frac{g}{f}\right)\right)_i - \left(D\left(\frac{g}{f}\right)\right)_j \right], \quad i = 1 : N-1.$$

For all these definitions, numerical fluxes are zero for $i = 0$ and $i = N$, and D and D^* are the finite difference operators defined in section 3.1. Following the same strategy as in the continuous case, we can write the discrete versions of equilibrium schemes (21) and (22). In that case, the discrete equilibrium is the discrete Maxwellian $f_{eq,i} = \exp(\alpha + \beta\varepsilon_i)$ whose coefficients α and β are computed so as f_{eq} has the same discrete mass and energy as f.

It is now an easy matter to prove that these discrete collision operators satisfy weak formulations similar to those satisfied by the continuous model. Hence the discrete analogous properties of Propositions 2.1, 2.2, and 2.4 are satisfied by all these discrete schemes.

4. Linear solvers. In this section, we present a strategy to solve the linear implicit schemes (7, 13, 16, 21, 22), the unknown being f^{n+1}. The present method obeys the conservation properties as soon as the approximation of the collision operator Q is conservative. Here we deal with both the FPL equation (1) with $d = 2$ or 3 and the isotropic case (25). In this section, these models only differ by the dimension of the integration domain: $d = 2$ or 3 for (1), and $d = 1$ for (25).

We first assume that the collision operator is discretized with N velocity points and write the schemes (7, 13, 16) in the following matrix-forms:

contracted scheme (7)	$L^c(f^n)f^{n+1} = f^n,$
θ-scheme (13)	$L_\theta(f^n)f^{n+1} = f^n + \Delta t(1-2\theta)Q(f^n),$
log-linear scheme (16)	$L^l(f^n)f^{n+1} = f^n + \Delta t Q(f^n),$

where $L^c(f)$, $L_\theta(f)$, and $L^l(f)$ are the $N \times N$-matrices defined by

$$L^c(f)g = g - \Delta t\, q^c(f,g), \tag{30}$$

$$L_\theta(f)g = g - \Delta t\, \theta q(f,g), \tag{31}$$

$$L^l(f)g = g - \Delta t\, q^l(f,g) \tag{32}$$

for every vector g in $\mathbb{R}^N$.

We can also consider the following equivalent (and more convenient) δ-form:

$$L^c(f^n)\delta f^n = \Delta t Q(f^n), \tag{33}$$

$$L_\theta(f^n)\delta f^n = \Delta t Q(f^n), \tag{34}$$

$$L^l(f^n)\delta f^n = \Delta t Q(f^n), \tag{35}$$

where $\delta f^n = f^{n+1} - f^n$. Equilibrium implicit schemes (21) and (22) are defined in δ-form by

$$L_\theta(f_{eq})\delta f^n = \Delta t Q(f^n), \tag{36}$$

$$L^l(f_{eq})\delta f^n = \Delta t Q(f^n). \tag{37}$$

Before going to the resolution of these linear systems, we give some of their important algebraic properties.

PROPOSITION 4.1.

- $\Delta t > 0$ $f > 0$ $L^l(f)$ $\frac{1}{f}$
- $\Delta t > 0$ $\theta \in [0,1]$ f_{eq} $L_\theta(f_{eq})$ $\frac{1}{f_{eq}}$
- $f > 0$ $L^c(f)$ $L_\theta(f)$ Δt

. We do not give the proof of this proposition, since it is a direct consequence of the discrete versions of the properties of q^c, q, and q^l given in Propositions 2.1, 2.2, and 2.4. □

These linear systems are nonsparse, with generally large dimension. For a numerical resolution, one can mainly investigate three classes of methods: direct (as LU), iterative nonstationary (as Krylov methods), iterative stationary (as relaxation methods).

Direct methods have been used by Epperlein [9] for the isotropic FPL equation with LU factorization. However, it is clear that such solvers are not usable in multidimensional cases. The complexity of the algorithms is $O(N^3)$, and the memory storage for the matrices is $O(N^2)$. Even in the one-dimensional case as an isotropic equation, the total complexity for a given simulation time is asymptotically the same as the simple explicit scheme (see section 5.1).

Consequently, it is clear that iterative methods must be considered. At this stage, we want to point out a crucial fact: since iterative methods generally construct an approximate solution to the linear system, Indeed, it is questionable to construct perfectly conservative schemes if that property is destroyed by the linear solvers.

To make this point more precise, we define the $(d+2) \times N$ matrix M that associates to every vector $f \in \mathbb{R}^N$ its corresponding $(d+2)$-vector of moments Mf , an approximation of $\int_{\mathbb{R}^d}(1, v, \frac{1}{2}|v|^2)^T f\, dv$). For instance, we can set $Mf = \sum_{i=1}^N (1, v_i, \frac{1}{2}|v_i|^2)^T f_i\, \Delta v^d$ for a regular discretization and $d = 2$ or 3. For the isotropic case, a possible definition is $Mf = \sum_{i=1}^N (1, \varepsilon_i)^T f_i \sqrt{\varepsilon_i} \Delta\varepsilon$. Since we assume the discrete collision operator Q to be conservative, the following relations are satisfied for every f and g in $\mathbb{R}^N$:

$$Mq^c(f,g) = 0, \qquad Mq(f,g) = 0, \quad \text{and} \quad Mq^l(f,g) = 0.$$

This implies the following relations for the matrices (30), (31), (32):

$$ML^c(f) = M, \qquad ML_\theta(f) = M, \quad \text{and} \quad ML^l(f) = M.$$

Multiplying by M the δ-forms (33)–(37) of our implicit schemes is another way to check the conservation property $Mf^{n+1} = Mf^n$.

Consequently, the implicit schemes written under the δ-forms (33)–(37) are of the same type as the following general linear system in $\mathbb{R}^N$:

$$Ax = b,$$

where the $N \times N$-matrix A and N-vector b satisfy

$$MA = M \text{ and } Mb = 0. \tag{38}$$

Then we consider the following problem: find an iterative solver such that if we start with an initial vector $x^{(0)}$ satisfying $Mx^{(0)} = 0$, then any iterate $x^{(k)}$ also satisfies $Mx^{(k)} = 0$. Such solvers will be called [illegible]. They guarantee that the implicit scheme is still conservative even if convergence to the exact solution of the linear system is not achieved.

In what follows, we prove that Krylov subspace methods are conservative iterative linear solvers. In our study, these methods can be set in the following general frame (see [20] for an introduction to Krylov solvers).

ALGORITHM 4.1.

1. [illegible] $x^{(0)}$ [illegible] $Mx^{(0)} = 0$ [illegible] $r^{(0)} = b - Ax^{(0)}$.
2. [illegible] $k = 1$ [illegible] K [illegible] $x^{(k)}$ [illegible] $x^{(0)} + \mathcal{K}_k$ [illegible]

$$\mathcal{K}_k = \{r^{(0)}, Ar^{(0)}, \dots, A^{k-1}r^{(0)}\}.$$

The different versions of Krylov methods arise from different choices of $x^{(k)}$ in $\mathcal{K}_k$. We now prove the following proposition.

PROPOSITION 4.2. [illegible] 4.1 [illegible] $Mx^{(k)} = 0$ [illegible] k [illegible]. Using conservation property on the initial vector $x^{(0)}$ and property (38) yields

$$Mr^{(0)} = M(b - Ax^{(0)}) = 0 - Mx^{(0)} = 0,$$

and therefore $MA^p r^{(0)} = MAA^{p-1}r^{(0)} = MA^{p-1}r^{(0)} = \cdots = Mr^{(0)} = 0$ for every $p \geq 1$. Consequently, we have $M\mathcal{K}_k = \{0\}$, and necessarily $x^{(k)} \in x^{(0)} + \mathcal{K}_k$ implies $Mx^{(k)} = 0$. □

It is remarkable that this conservation property holds even if the linear system is not exactly solved. Another advantage of these methods is well known: they are "matrix-free," i.e., the matrix A only appears in matrix-vector products Ay in the solver. Thus we do not need to form and store the matrix A. Moreover in our case, if the quantities $q^c(f,g)$, $q(f,g)$, and $q^l(f,g)$ can be computed in $O(N)$ operations, then this is also possible for products Ay in Krylov solvers, since $A = L^c(f^n), L_\theta(f^n)$, or $L^l(f^n)$ which are given by (30), (31), (32).

Finally, we would emphasize the fact that all iterative solvers are not necessarily conservative. For instance, consider the general class of stationary methods, such as Jacobi, Gauss–Seidel, or relaxation methods. These methods consist of the splitting matrix A into $A = E - F$, and can be written as the following algorithm.

ALGORITHM 4.2.

1. [illegible] $x^{(0)}$ [illegible] $Mx^{(0)} = 0$ [illegible] $r^{(0)} = b - Ax^{(0)}$.
2. [illegible] $k = 0$ [illegible] K [illegible] $Ex^{(k+1)} = b + Fx^{(k)}$

In this case, we only have $MEx^{(k+1)} = 0 + MFx^{(k)} = M(E-A)x^{(k)} = MEx^{(k)} - Mx^{(k)}$. Even if we assume $Mx^{(k)} = 0$, there is no reason to have $Mx^{(k+1)} = 0$. For instance, with Jacobi method, matrix E is the diagonal part of A, and we do not have any information about the value of ME.

Among the above Krylov methods, we mainly use the GMRES and the CG methods. The CG method is used to solve linear systems whose matrices are positive definite self-adjoint. As stated in Proposition 4.1, this is the case for the log-linear and equilibrium log-linear schemes (16), (22) and the equilibrium θ-scheme (21). This is a real advantage, since the CG method is one of the most efficient Krylov solvers (in terms of CPU cost and memory storage). For the other schemes, we simply use the GMRES method.

TABLE 2
Complexity of explicit and linear implicit schemes for $d = 1, 2, 3$.

	$d = 1$	$d = 2$	$d = 3$
explicit	$O(N^3)$	$O(N^2)$	$O(N^{5/3})$
implicit	$KO(N)$	$KO(N)$	$KO(N)$

5. Complexity and numerical tests.

5.1. Complexity of the algorithms. In this section, we assume that for an arbitrary number of dimensions $d \geq 1$, the number of operations for computing $q^c(f,g), q(f,g)$, and $q^l(f,g)$ is $O(N)$. This is true for $d = 1$ in the case of isotropic equation with Coulomb or Maxwell potential (see [5]). For $d \geq 2$, cost reductions to $O(N \log N)$ can be obtained through rapid algorithms as multipole methods [15] and spectral methods [18]. The cost $O(N)$ could be reached by an extension of isotropic wavelet methods [1] to the multidimensional case. We also assume that the velocity domain is discretized with a step Δv or $\Delta\varepsilon = \frac{1}{n}$ in each direction and a total number of points of $N = n^d$. For a problem with a time scale τ, we want to compare the complexity of the usual Euler explicit scheme (5) and our linear implicit schemes for a given simulation time T.

For the explicit scheme, one iteration requires only one evaluation of $Q(f)$, which costs $O(N)$. Assume that the CFL condition imposes a time step $\Delta t = O(\frac{1}{n^2})$ (this seems to be true from numerical experiments and has been proved in the isotropic case [4]). Then the number of iterations is $\frac{T}{\Delta t} = O(n^2)$. Consequently, the total complexity is $O(N^{1+2/d})$.

For linear implicit schemes with Krylov solvers, the cost of one Krylov iteration is $O(N)$ (since only evaluations of $q^c(f,g)$, $q(f,g)$, and $q^l(f,g)$ are needed). We assume that K iterations of the Krylov solver are necessary to get a correct approximation of the time iterate. Thus the cost of one time iteration is $KO(N)$. Finally, if the time step can be set to τ, the number of time iterations is $\frac{T}{\tau}$, and therefore, the total complexity is $KO(N)$.

In Table 2, we give a comparison of these complexities for $d = 1, 2, 3$. We can see that for $d = 1$, there is an important gain even if $K = N$. For $d = 2$, there is still a gain if $K \ll N$. If $K = O(N)$, the explicit and implicit schemes have the same asymptotic cost $O(N^2)$. For $d = 3$, we have a significant gain only if $K \ll N^{2/3}$. Therefore, the efficiency of the implicit schemes decreases as the dimension increases. Consequently, the reduction of the number K of Krylov iterations becomes necessary in multidimensional cases. This could be done by using adapted preconditioning techniques. As noted by [7], such techniques can render K virtually independent of N. In that case, our implicit schemes would always be advantageous as compared to the explicit scheme. This is the subject of a future work.

5.2. Numerical tests. In order to check the properties of the implicit schemes that we introduced in this work, we present various numerical tests with both the Maxwellian and Coulombian potentials.

Maxwellian potential: comparison with an exact solution. First, in the case of Maxwellian potential, it is proved in [14] that

$$f(t,\varepsilon) = \frac{\rho}{(2\pi T)^{3/2}} \exp\left(-\frac{\varepsilon}{2T}\right)\left(1 + \frac{11}{120}\left(\left(\frac{\varepsilon}{T}\right)^2 - 10\frac{\varepsilon}{T} + 15\right)\exp(-8\rho t)\right)$$

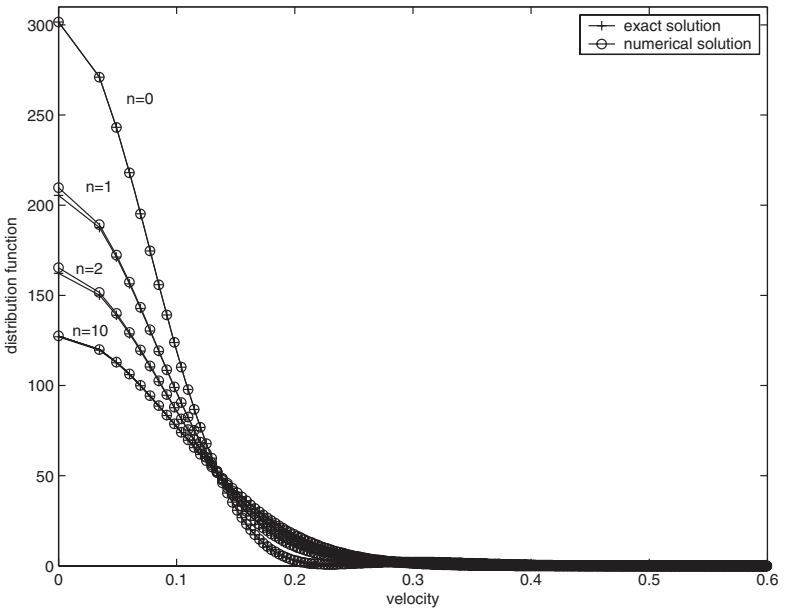

FIG. 1. *Exact solution and implicit scheme for Maxwellian potential: distribution function at different time steps.*

is an exact solution of (25). Then, in Figures 1 and 2, we compare the numerical solution obtained with the second-order θ-scheme (13) to this exact solution. The energy domain is $[0, 2]$ discretized with 500 points. The parameters of the exact solution are $\rho = 2$ and $T = 0.01$. The time step used with the implicit scheme is about 300 times the time step required by an explicit computation. In Figure 1, we plot f as a function of $v = \sqrt{\varepsilon}$ at different time steps. We observe that the numerical solution is very close to the exact one, and the equilibrium is reached in only ten iterations. This corresponds to a final physical time equal to $t_{\max} = 10$. This shows that the dynamics described by the exact FPL equation can efficiently be simulated with a much larger time step than those of usual explicit schemes. This is also clear in Figure 2 where the kinetic entropy is plotted. The slight difference that can be observed in the stationary regime is due to the velocity discretization itself. In fact, the discrete Maxwellian is different from the exact one.

Coulombian potential: regular energy discretization. The second test case uses Coulombian potential with the so-called Rosenbluth initial data:

$$f^0(\varepsilon) = 0.01 \exp(-10((\sqrt{\varepsilon} - 0.3)/0.3)^2).$$

In Figure 3, we plot the kinetic entropy obtained by the explicit scheme (5) with time step Δt_{exp}, which is the largest step ensuring the stability of the scheme. This entropy is compared with that obtained by the contracted implicit scheme (7). For this last scheme, we take a time step $\Delta t_{imp} = 50\Delta t_{exp}$. We use a regular energy discretization of $[0, 2]$ with $N = 100$ points. Tolerance for CG algorithm is 10^{-6}. The dynamics is well described by the implicit scheme even if the time step is much larger. However, the gain in terms of CPU time is not obtained unless the number of energy points is sufficiently large. Indeed, the implicit scheme is really advantageous for $N \geq 500$ only. This is clearly shown in Figure 4 where the CPU time versus N is plotted for

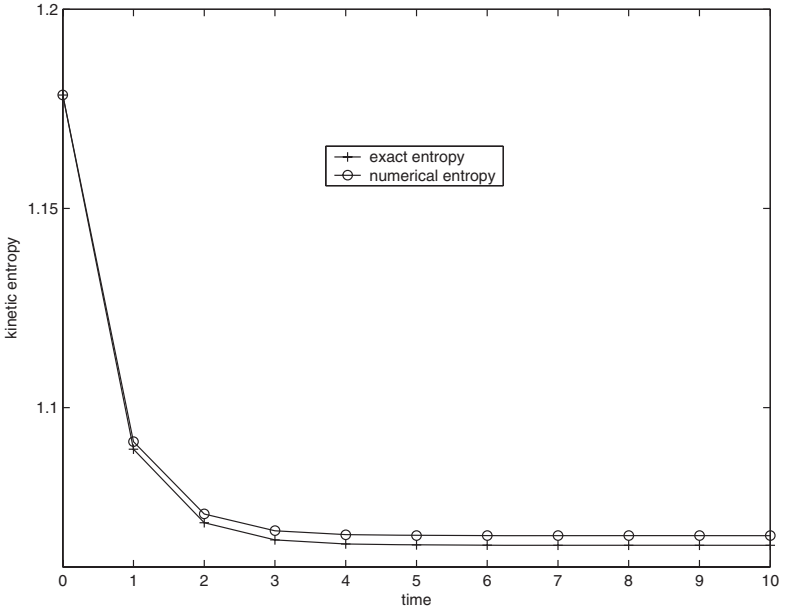

FIG. 2. *Exact solution and implicit scheme for Maxwellian potential: entropy.*

explicit and implicit schemes. According to what we explained in section 5.1, the CPU time of the explicit scheme behaves as $O(N^3)$. A contrario, the implicit scheme only requires $O(KN)$ operations, where K is the number of iterations in the Krylov procedure. It is known that $K \leq N$, and we observe that on this test case, K is much smaller than N. The test in Figure 4 confirms that the numerical complexity of the implicit scheme behaves like $O(N^2)$. Indeed, for $N \geq 500$, the slope of the curve is 1.95 for the implicit scheme whereas it is 2.8 for the explicit scheme.

Coulombian potential: irregular energy discretization. The use of irregular discretizations could be necessary when one is only interested in the dynamic of a localized region in the velocity space for instance or, in general, when using adaptive meshes. In such cases, one can expect a more important gain when using implicit schemes, since the time step of the explicit scheme is constrained by the smallest step size of the irregular mesh.

To illustrate this fact, we perform the previous Rosenbluth test case using an irregular energy discretization where the discrete energy points are $\varepsilon_i = 2(\frac{i}{N})^3$ for $i = 1$ to N. Here we use the equilibrium θ-scheme (11) with $\theta = 1$ and plot on Figure 5 the CPU time versus N for explicit and implicit schemes. We observe that for $N = 50$ points, the implicit scheme is 1.5 times faster than the explicit scheme. The CPU time is further reduced for larger N: it is divided by a factor 6 for $N = 100$ points and by a factor 33 for $N = 200$.

To go further in this direction, we mention that in most cases, the evaluation of the collision operator is very expensive (the present isotropic case is very particular). Example are 3-dimensional geometries with classical or relativistic particles. In these cases, the arguments of the kernel K cannot be separated in a simple way, and the use of fast evaluation algorithms is not as efficient as in the isotropic case. Consequently, in such situations it is attractive to reduce the number of time iterations by using implicit

schemes. To illustrate this fact, we consider the isotropic case in which we do not use any fast algorithms: we directly compute the collision operator with formula like (27), (28), which costs $O(N^2)$ operations. Of course, this is just used as a prototype of the previously mentioned realistic situations. In the case of the previous irregular grid with the same initial data, we obtain that for $N = 50$ points, the same implicit scheme is 2 times faster than the explicit scheme. The CPU time is further reduced

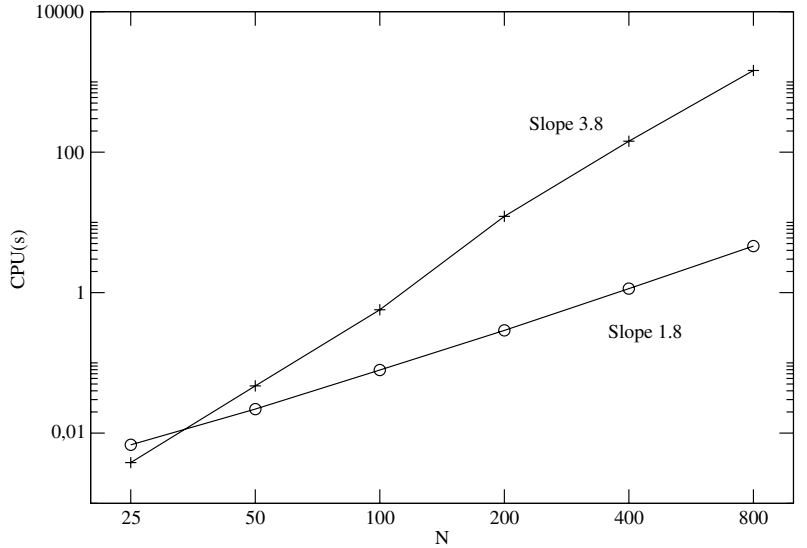

FIG. 5. *CPU cost of explicit* (+) *and equilibrium* θ*-scheme* (11) *with* $\theta = 1$ (o) *versus the number* N *of energy points in a logarithmic scale* (*Coulombian potential*). *Tolerance for CG is* 10^{-6}, *time step in implicit scheme is* 3. *Irregular energy grid is used.*

for $N = 100$ since it is divided by a factor 10.

Comparison of the different implicit schemes. For the same initial data, we compare the different implicit schemes studied in this work to the explicit one: contracted (7), θ-scheme (13), log-linear implicit scheme (16), equilibrium θ-scheme (21), equilibrium log-linear scheme (22). In Figure 6 we plot the fourth order moment $\int f(\varepsilon)\varepsilon^2\sqrt{\varepsilon}\,d\varepsilon$ as a function of time. We only compare first order (in time) schemes with $\Delta t_{imp} = 50\Delta t_{exp}$ and $N = 100$ on a regular grid. We observe that the equilibrium θ-scheme with $\theta = 1$ is the most accurate in this case. Despite its good mathematical properties, the log-linear scheme is not sufficiently accurate. This is probably due to the linearization of the log function.

In Figure 7, we compare our second order (in time) θ-scheme (with $\theta = 0.5$) to a second order explicit scheme (Runge–Kutta scheme). We use the same parameters as in Figure 6 and can see that the two results are in a very good agreement.

Conservation properties. Finally, we point out that all the schemes proposed in this paper are perfectly conservative, up to the machine error. For instance, on the second test case the variation amplitude of density and energy during the time evolution is about 10^{-16}, as for the explicit scheme. This confirms that the approximate resolution of the linear systems does not affect the conservation properties.

6. Conclusion. We have constructed various linear implicit schemes to solve the homogeneous FPL equation. It has been shown that these schemes possess important properties of conservation and entropy. Moreover, numerical tests in the isotropic case have shown a significant gain in terms of CPU time with the same accuracy when compared with usual explicit schemes.

As we pointed out in the introduction, our strategy applies to multidimensional collision operators, but still some details must be investigated in that case. Indeed, the involved linear systems are much larger, and suitable preconditioners are required. We

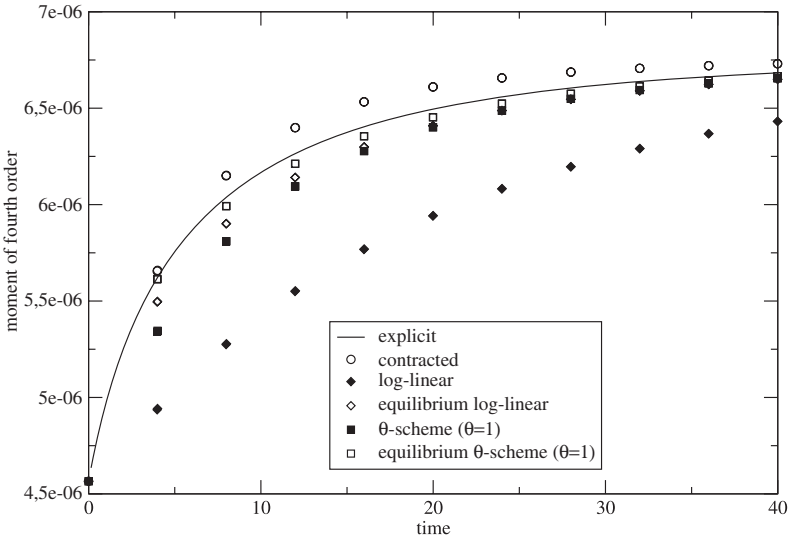

FIG. 6. *Fourth order moment for different implicit schemes.*

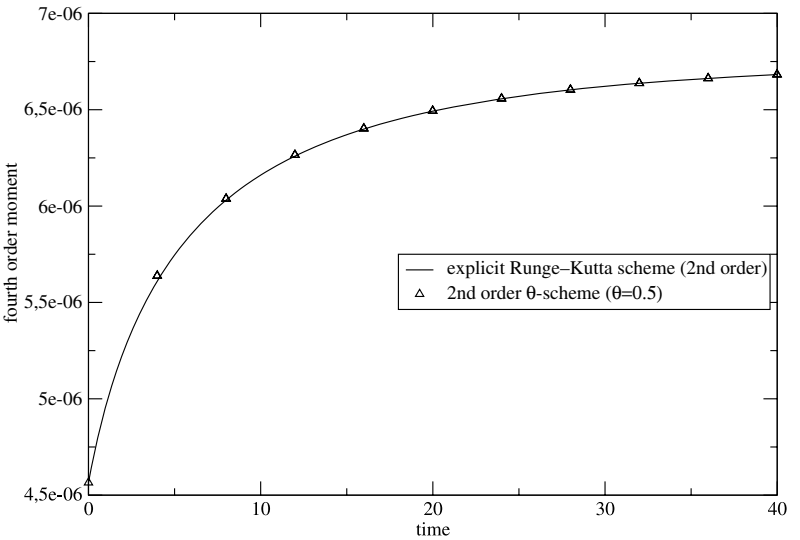

FIG. 7. *Fourth order moment for second order (in time) schemes.*

recall that in a Krylov method with a good preconditioner, the number of iterations is independent of N. Thus the complexity of our implicit schemes could be reduced to $O(N)$ only. Moreover, the rapid matrix-vector product that has been used in the isotropic case cannot be applied to the multidimensional cases. Therefore, to get a fast implicit solver in several dimensions, other acceleration techniques are required. We believe that this can be done using multipole or wavelet techniques [15, 1].

Note that for the inhomogeneous (space dependent) case, our implicit schemes should be more efficient. Indeed, in many inhomogeneous situations the transition phase is rapid and does not need to be accurately described. In such cases, our

implicit schemes allow one to directly reach the hydrodynamic behavior with a few time steps.

Finally, the extension of our strategy to other collision operators (including the relativistic and quantum effects for instance) is the subject of a future work.

A MULTIGRID METHOD FOR A FOURTH-ORDER DIFFUSION EQUATION WITH APPLICATION TO IMAGE PROCESSING*

STEFAN HENN†

Abstract. In this paper we are concerned with the efficient solution of the elliptic system $(\alpha L + I)u = f$, where L is the biharmonic operator supplemented by higher-order boundary conditions. This is a core task in image processing arising from the minimization of rotation invariant energy functionals.

For the purpose of numerical solution we approximate the partial differential equation by finite differences. In order to obtain efficient and robust solution methods we discuss how the system can be treated efficiently by multigrid methods. Finally, experimental results are reported that demonstrate the effectiveness of the multigrid approach.

Key words. multigrid methods, nonlinear diffusion equation, biharmonic equation, finite differences, image processing

1. Introduction.

In recent years there has been an increasing number of papers devoted to the application of partial differential equations (PDEs) in image processing, such as image restoration, segmentation, optical flow computation, and image registration. A good survey of these applications is given in [2, 8, 26] and the references therein. The behavior of image processing problems is often governed by parabolic initial value problems, frequently arising from the minimization of some energy functional. A principle task of scientific computing is the efficient numerical solution of these equations.

In this paper we are concerned with the solution of fourth-order diffusion equations given by the PDE:

$$\left.\begin{array}{rl} \frac{\partial u_i(x,y,t)}{\partial t} + \epsilon(t)\Delta^2 u_i(x,y,t) = d(u(x,y,t)) & \text{on } \Omega \times (0,T) \\ u_i(x,y,0) = z_i(x,y) & \text{on } \Omega \end{array}\right\} \tag{1.1}$$

supplemented by the boundary conditions

$$\left.\begin{array}{l} B_1[u_i(x,y,t)] = \frac{\partial}{\partial n}\Delta u_i(x,y,t) + (1-\sigma)K[u_i(x,y,t)] = 0 \\ B_2[u_i(x,y,t)] = \sigma\Delta u_i(x,y,t) + (1-\sigma)\frac{\partial^2 u_i(x,y,t)}{\partial n^2} = 0 \end{array}\right\} \text{on } \partial\Omega \times (0,T) \tag{1.2}$$

with the outward normal direction $n = (n_x, n_y)$, the tangential direction s, and the operator

$$K[u_i(x,y,t)] := \frac{\partial}{\partial s}\left[\frac{\partial^2 u_i(x,y,t)}{\partial x \partial y}(n_x^2 - n_y^2) + \left(\frac{\partial^2 u_i(x,y,t)}{\partial y^2} - \frac{\partial^2 u_i(x,y,t)}{\partial x^2}\right) n_x n_y\right]$$

for $i = 1, \ldots, m$. Here, the initial condition $z(x,y) = (z_1(x,y), \ldots, z_m(x,y))^t$ represents vector-valued input data, which can be, for instance, a single image ($m = 1$),

an initial motion estimation ($m = 2$), or an initial displacement field ($m = 2$). The behavior of the input data is governed by the so-called data term d. For instance, in the case of image denoising, the data term is given by

$$d(u(x, y, t)) = -2(u(x, y, t) - z(x, y)),$$

where u is to be recovered from the noisy data z; see, e.g., [6, 7, 22, 27]. In the case of two-dimensional mono-modal image registration the data term is given by $d(u(x, y, t)) =$

$$-\nabla T(x - u_1(x, y, t), y - u_2(x, y, t)) \cdot \big(T(x - u_1(x, y, t), y - u_2(x, y, t)) - R(x, y)\big),$$

where $u(x, y, t) = (u_1(x, y, t),\, u_2(x, y, t))^t$ is a displacement vector that should transform one image T, called the template, into another image R, called the reference; see, e.g., see [19]. Although the focus of our research is on image registration problems, for ease of presentation we assume in the following that $z(x, y)$ and $u(x, y)$ are single two-dimensional functions. The solution $u(x, y, t)$ of (1.1) represents the family of scaled versions of $z(x, y)$. The parameter $\epsilon(t) > 0$ for all $t \in (0, T)$ can be regarded as a scale parameter, which captures information at multiple spatial scales of $u(x, y, t)$. Alternatively, we can regard $z(x, y)$ as a thin plate with free edges under the action of a force d during the time t. Here, ϵ and the Poisson coefficient $\sigma \in [0, 1)$ reflect the plate material properties. We choose σ so that the changes in the plate are maximal, i.e., $\sigma = 0$. The diffusion time t is an artificial evolution parameter and Ω is a convex and polygonal domain. In image processing problems Ω will simply be the unit square $[0, 1]^2 \subset \mathbb{R}^2$.

Fourth-order PDEs in digital image processing have also been used in [12] for image registration. Here, the so-called curvature approach uses homogeneous Neumann boundary conditions for u and Δu, i.e., $\frac{\partial u}{\partial n} = 0$ and $\frac{\partial \Delta u}{\partial n} = 0$. The main difference between the two approaches is that the proposed approach is invariant under planar rotation while the curvature approach is not.

Since in the curvature approach no coupling of the boundary conditions is presented, the biharmonic system can be fully decoupled into two Poisson equations. Thus in this case fast Poisson solvers such as fast Fourier transformation (FFT) (see [25]) or straightforward multigrid methods [23] can be used to compute a solution. Unfortunately, for the boundary conditions (1.2) the situation is more sophisticated since the PDEs are coupled via the boundary conditions.

The paper is organized as follows. In section 2, we introduce the fully discrete semi-implicit time discretization of (1.1). Then we discuss the scale-space decomposition of a solution as presented in the companion paper [20] for image registration, and afterwards we consider computational aspects for solving (1.1). Employing semi-implicit time discretization, we are facing in each time step a stationary problem given by an elliptic PDE. The spatial discretization of the stationary problem by finite differences on the unit square is introduced in section 3.

This paper mainly addresses the issue of developing a fast numerical method for solving (1.1). Therefore in section 4, we construct a multigrid method for the fast iterative solution of the resulting linear systems that arise from applying the finite difference method. Numerical examples verify optimal multigrid complexity, i.e., the amount of work is proportional to the number of unknowns. In the fifth section we present a real image registration example that demonstrates the principle and reliability of the biharmonic diffusion approach considered. The last section is devoted to some conclusions and final remarks.

2. Preliminaries. In this section, we first describe the discretization of (1.1) in time, describe the scale-space properties of the equation, and give some preliminary computational considerations.

2.1. Semi-implicit time discretization. In order to avoid the CFL condition for explicit time discretization methods, which couples the length of the time step and the spatial discretization, we opt for an implicit time discretization scheme.

A full implicit scheme for (1.1) usually leads us to solve a nonlinear equation. Fast solution methods for the resulting nonlinear PDE require nonlinear full approximation storage (FAS) multigrid methods (as described, e.g., in [19]) for the image registration problem. However, in this paper, we choose a semi-implicit time discretization scheme which leads us to solve a linear PDE in each time step.

This is at least due to three factors. First, it is often hard to get FAS to work on new problems. Second, the evaluation of the data term d is often needed within the FAS and is usually expensive, especially for image processing problems. Third, in contrast to explicit schemes, the limitation of τ for the implicit scheme is not a delicate problem as far as stability is concerned. But if the problem arises from the minimization of an energy functional, a limitation is required in order to maintain the energy diminishing property during the iteration. In this case suitable choice rules for τ are given in [20].

However, using an implicit scheme for the stiff biharmonic term, an explicit scheme for the remaining data term, and first-order discretization in time leads to the following semi-implicit time discretization scheme:

$$\left.\begin{aligned} \tfrac{u^{(k+1)}-u^{(k)}}{\tau} &= -\epsilon_k \Delta^2 u^{(k+1)}(x,y) + d(u^{(k)}(x,y)) \quad \text{for} \quad (x,y) \in \Omega, \\ B_1[u^{(k+1)}(x,y)] &= B_2[u^{(k+1)}(x,y)] = 0 \qquad\quad \text{for} \quad (x,y) \in \partial\Omega, \end{aligned}\right\}, \tag{2.1}$$

where $\tau > 0$ is the length of the time step.

Let $L = (\Delta^2, B_1, B_2)$; then $Lu = f$ may be interpreted physically as the equation of a plate with free edges subject to a load f. Using L, (2.1) can be written by the linear elliptic system

$$\big(I + \tau\epsilon_k L\big)u^{(k+1)}(x,y) = f(\tau, u^{(k)}(x,y)), \quad (x,y) \in \Omega, \tag{2.2}$$

with right-hand side

$$f(\tau, u^{(k)}(x,y)) = u^{(k)}(x,y) + \tau d(u^{(k)}(x,y)),$$

which depends on τ, the approximation of the previous time step $u^{(k)}$, and the data term d. In order to give a variational formulation of problem (2.2), we introduce the symmetric bilinear form

$$b(u,v) = \epsilon\tau l(u,v) + (u,v) = \big\langle (\epsilon\tau L + I)u, v\big\rangle, \tag{2.3}$$

with the inner product $(u,v) = \int_\Omega uv dx$ and associated norm $||u|| = (u,u)^{1/2}$ for the Lebesgue space of square integrable functions on Ω. In the following, we use the symbol B to refer to the linear bounded operator related to the bilinear form b, and $||\cdot||_B$ stands for the energy norm induced by $b(\cdot,\cdot)$. The bilinear form l

$$l(u,v) = \int_\Omega \Delta u \Delta v + (1-\sigma)\left\{2\frac{\partial^2 u}{\partial x \partial y}\frac{\partial^2 v}{\partial x \partial y} - \left(\frac{\partial^2 u}{\partial x^2}\frac{\partial^2 v}{\partial y^2} + \frac{\partial^2 v}{\partial x^2}\frac{\partial^2 u}{\partial y^2}\right)\right\} d\Omega$$

is for $\sigma \in [0,1)$ symmetric and positive semidefinite on $H^2(\Omega)$ and symmetric positive definite on

$$\left\{ v \in H^2(\Omega), \int_\Omega v dx = \int_\Omega x v dx = \int_\Omega y v dx = 0 \right\} \subset H^2(\Omega).$$

Since ϵ and τ are positive the bilinear form $b(\cdot,\cdot)$ is coercive and bounded on $H^2(\Omega)$. Consequently the Lax–Milgram theorem can be used to prove the existence and uniqueness of the variational equation

$$b(u,v) = \langle f, v \rangle \quad \text{for all} \quad v \in H^2(\Omega) \tag{2.4}$$

for any functional $f \in V'$, the dual space of $H^2(\Omega)$.

2.2. Multiscale decomposition of u. In order to analyze multiscale properties of a weak solution $u \in H^2(\Omega)$ of (2.4), we consider

$$u = \sum_{i=1}^{\infty} \lambda_i^{-1} \langle f, \phi_i \rangle \phi_i.$$

The orthonormal system $\Phi = \{\phi_i\}_{i=1}^{\infty}$ is given by the set of eigenvectors of B. For the countable set of eigenvalues $\{\lambda_i\}_{i=1}^{\infty}$ of B, it holds that

$$1 = \lambda_1 = \lambda_2 = \lambda_3 < \lambda_4 \le \lambda_5 \le \cdots \le \lim_{j\to\infty} \lambda_j = \infty, \text{ with } \quad \lambda_j = 1 + \epsilon\tau\sigma_j, \tag{2.5}$$

with eigenvalues $0 = \sigma_1 = \sigma_2 = \sigma_3 < \sigma_4 \le \sigma_5 \le \cdots \le \lim_{j\to\infty} \sigma_j = \infty$ of L.

For the corresponding orthogonal system $[\phi_1^n, \ldots, \phi_n^n]$ of eigenfunctions of a n-dimensional subspace V_n of $H^2(\Omega)$ with corresponding positive eigenvalues $(1+\epsilon\tau\sigma_i)^{-1}$, the solution is given by

$$u_h = \sum_{i=1}^{n} \frac{1}{1+\epsilon\tau\sigma_i} \langle \phi_i^n, f_h \rangle \phi_i^n. \tag{2.6}$$

Note that this is the Galerkin approximation for the orthonormal system Φ. The ellipticity of the bilinear form b implies that the eigenvalue λ_i belonging to an eigenfunction ϕ_i of L depends only on the frequency of the eigenfunction and becomes larger the higher this frequency. Thus, the eigenspace (λ_i, ϕ_i) of the operator B can be regarded as a sequence of spatial scales; see [20]. Here, the coarsest scale is given by the affine-linear functions corresponding to the eigenvalues $\lambda_1 = \lambda_2 = \lambda_3 = 1$.

As a consequence of these considerations iteration (1.1) is embedded into a so-called scale-space framework, which efficiently treats different scales of u; see [20]. Here, the iteration starts with a large initial scale parameter, i.e., $\epsilon_0 \gg 0$. During the iteration the parameter is reduced by $\epsilon_k := \gamma^k \epsilon_0$ with some decay rate $\gamma \in (0,1)$, and the solution incorporates an increasing number of finer scaled functions.

2.3. Computational considerations. The kernel of the operator L is a linear subspace of $H^2(\Omega)$ given by

$$\ker(L) = \left\{ k \ : \ k = \sum_{i=1}^{3} s_i \phi_i, \quad \phi_i \in \{1, x, y\}, \ s_i \in \mathbb{R} \right\}.$$

Every element $u \in H^2(\Omega)$ can be uniquely decomposed into the sum $u = k + w$, where $k \in \ker(L)$ and $w \in \ker^{\perp}(L)$. Consequently, $H^2(\Omega)$ is the orthogonal sum of $\ker(L)$ and $\ker^{\perp}(L)$, i.e.,

$$H^2(\Omega) = \ker^{\perp}(L) \oplus \ker(L),$$

and numerical solution of (2.1) requires a different treatment reflecting the different character of the problem for these components. It is well known that the performance of multigrid solution methods for linear discrete variational problems crucially depends on the ellipticity of the underlying bilinear form. For ϵ large, the bilinear form $b(\cdot,\cdot)$ has a very small ellipticity constant. Nevertheless, if we archive an integrability condition good multigrid performance (independent of ϵ) can be obtained (see section 4). For $\epsilon \to \infty$ the solution is restricted to $\ker(L)$. Here the bilinear form agrees with the $L_2(\Omega)$ inner product. In this case the solution is given by $u = \sum_{j=1}^{3} s_j \phi_j$, where the s_j are given by the unique solution of the following linear 3×3 system:

$$\sum_{j=1}^{3} (\phi_j, \phi_i) s_j = (f, \phi_i), \ \phi_i \in \ker(L) \quad \text{for } i = 1, 2, 3.$$

On the other hand, for small ϵ the bilinear form $b(\cdot,\cdot)$ has a proper elliptic character on $\ker^{\perp}(L)$. Thus the use of standard multigrid schemes for the PDE (2.1) is possible.

3. The finite difference method for the biharmonic diffusion equation. This section concerns the problem of discretization and approximation of the PDE (2.1) on the unit square $\Omega = [0,1]^2$. We choose the finite difference method, which is widely used in image processing. This is a natural approach here, due to the fact that digital images are typically encoded by uniformly distributed picture elements (pixels).

3.1. Discretization. We use the regular grid

$$G_h = \big\{ x \in \mathbb{R}^2 : x = (ih_x, jh_y), \quad i, j = -\infty, \ldots, \infty \big\}$$

and get $\Omega_h = G_h \cap \Omega$ with $(N_x + 1) \times (N_y + 1)$ grid points

$$g^h_{i,j} = (x_i, y_j) = (ih_x, jh_y) \in \Omega, \ 0 \le i \le N_x, \ 0 \le j \le N_y.$$

The pixel width h_x and pixel height h_y are given by $(h_x, h_y) = (N_x^{-1}, N_y^{-1})$. In the following we assume that $h = hx = hy$ (resp., $N = N_x = N_y$) and denote by u_h a grid function defined by $u_h(i,j) = u(g^h_{i,j})$.

3.2. Operator splitting. Various approaches for the numerical solution of the biharmonic equation have been considered in the literature. For example, the well-known 13-point approximation with truncation error of order h^2 is given by

$$\begin{aligned}\frac{1}{h^2}\Big(&20u_h(i,j) - 8\big(u_h(i+1,j) + u_h(i-1,j) + u_h(i,j+1) + u_h(i,j-1)\big)\\ &+ 2\big(u_h(i+1,j+1) + u_h(i-1,j-1) + u_h(i-1,j+1) + u_h(i+1,j-1)\big)\\ &+ u_h(i+2,j) + u_h(i-2,j) + u_h(i,j+2) + u_h(i,j-2)\Big) = f_h(i,j),\end{aligned}$$

which needs to be modified at the grid points near the boundary; see [14]. Unfortunately, even conventional iterative methods such as Jacobi or Gauss–Seidel either

converge very slowly or diverge; also, the smoothing factor of the lexicographical Gauss–Seidel relaxation is not satisfactory and leads to poor multigrid efficiency [24]. Moreover, direct solvers for the resulting systems of linear equations can only be used for moderate grid size h [10].

The scalar biharmonic equation $\Delta\Delta u = f$ can be more efficiently solved as a system of two Poisson equations (see [9]):

$$\begin{pmatrix} \Delta & 0 \\ -I & \Delta \end{pmatrix} \begin{pmatrix} v(x,y) \\ u(x,y) \end{pmatrix} = \begin{pmatrix} f(x,y) \\ 0 \end{pmatrix}. \tag{3.1}$$

This approach has been used by many authors [1, 4, 5, 11, 15, 18]. In the case of simply supported edges, with boundary conditions $u(x,y) = v(x,y) = 0$, the biharmonic system is fully decoupled and can be solved efficiently with the same amount of work as solving two Poisson equations with Dirichlet boundary conditions.

Dirichlet boundary conditions for the biharmonic equation $u(x,y) = \frac{\partial u(x,y)}{\partial n} = 0$ lead to a system with undefined boundary conditions for the new variable $v(x,y)$. Consequently, the effectiveness of standard multigrid solvers near the boundary is much less than for interior points. Plenty of multigrid approaches for the biharmonic Dirichlet problem have been investigated to treat the slowness; see, e.g., [1, 4, 5, 18]. Due to the splitting (3.1), the elliptic system (2.1) can be written as

$$\Delta u(x,y) - v(x,y) = 0 \quad \text{and} \quad \alpha\Delta v(x,y) + u(x,y) = f(x,y)$$

for all $(x,y) \in \Omega$ and boundary conditions given as

$$\sigma v(x,y) + (1-\sigma)\frac{\partial^2 u(x,y)}{\partial n^2} = 0 \quad \text{and} \quad \frac{\partial v(x,y)}{\partial n} + (1-\sigma)K[u(x,y)] = 0$$

for all $(x,y) \in \partial\Omega$. By using $\Delta u = \frac{\partial^2 u}{\partial n^2} + \frac{\partial^2 u}{\partial s^2}$ and setting $\alpha := \tau\epsilon_k$ and $\sigma = 0$, the solution of (2.2) consists of solving the two Poisson-like equations

$$\begin{cases} \alpha\Delta v(x,y) + u(x,y) = f(x,y) & \text{for } (x,y) \in \Omega, \\ \frac{\partial v(x,y)}{\partial n} + K[u(x,y)] = 0 & \text{for } (x,y) \in \partial\Omega \end{cases} \tag{3.2}$$

and

$$\begin{cases} \Delta u(x,y) - v(x,y) = 0 & \text{for } (x,y) \in \Omega, \\ \frac{\partial^2 u(x,y)}{\partial n^2} = v(x,y) - \frac{\partial^2 u(x,y)}{\partial s^2} = 0 & \text{for } (x,y) \in \partial\Omega, \end{cases} \tag{3.3}$$

which are coupled via $u(x,y)$ and $v(x,y)$. We have to solve the following system:

$$\begin{pmatrix} L_v & I+K \\ -I & L_u \end{pmatrix} \begin{pmatrix} v(x,y) \\ u(x,y) \end{pmatrix} = \begin{pmatrix} f(x,y) \\ 0 \end{pmatrix}, \tag{3.4}$$

where I denotes the identity on Ω and

$$L_v v(x,y) = \begin{cases} \alpha\Delta v(x,y) & \text{on } \Omega, \\ \frac{\partial v(x,y)}{\partial n} & \text{on } \partial\Omega \end{cases} \quad \text{as well as} \quad L_u u(x,y) = \begin{cases} \Delta u(x,y) & \text{on } \Omega, \\ \frac{\partial^2 u(x,y)}{\partial s^2} & \text{on } \partial\Omega. \end{cases}$$

3.3. Approximation of the system. Let $D^+_{x,h}$, $D^+_{y,h}$ be the finite forward difference, $D^-_{x,h}$, $D^-_{y,h}$ be the finite backward difference, and $D^s_{x,h}$, $D^s_{y,h}$ be the finite symmetric discretization approximation at the grid points $g^h_{i,j}$ of $\frac{\partial}{\partial x}$ and $\frac{\partial}{\partial y}$, respectively. The second derivative $\frac{\partial^2}{\partial x^2}$ is discretized as the operator $D^+_{x,h}D^-_{x,h}$ and Δ by standard five-point approximation denoted by $\Delta_h := D^+_{x,h}D^-_{x,h} + D^+_{y,h}D^-_{y,h}$. Then the discretized (3.1) is given by

$$\begin{aligned} \alpha\Delta_h v_h(x,y) + u_h(x,y) &= f_h(x,y), \\ \Delta_h u_h(x,y) - v_h(x,y) &= 0 \end{aligned} \tag{3.5}$$

on Ω.

3.4. Approximation of the boundary conditions. In order to apply the finite difference method at the boundary of (2.2), we first consider the solution u of the plate equation with free boundary conditions $Lu = f$ on the unit square. It is well known that u has the regularity $u \in H^2(\Omega) \cap H^3(\Omega)$ and satisfies $||u||_3 \le c||f||_{-1}$. In the case $f \in L_2(\Omega)$, a weak solution of

$$l(u,v) = (f,v) \quad \text{for all } v \in H^2(\Omega)$$

is also a strong solution on each $\Omega' \subset \Omega$ with a small distance of $\partial\Omega'$ from the corner points of Ω. We refer to [3, 13] and references therein for more discussions on well-posedness, regularities, and restrictions for biharmonic problems on polygonal domains.

3.4.1. Finite difference discretization of L_u. A suitable discretization at the boundary of (3.3) can be found by approximating the boundary $\partial\Omega$ near the corner points by sufficiently smooth functions; see Figure 1.

In the following we denote this modified domain by Ω'. In order to solve the PDE numerically by a finite difference discretization approach, we map the nearest point on $\partial\Omega'$ to the corresponding corner point of Ω_h. If the distance between these two

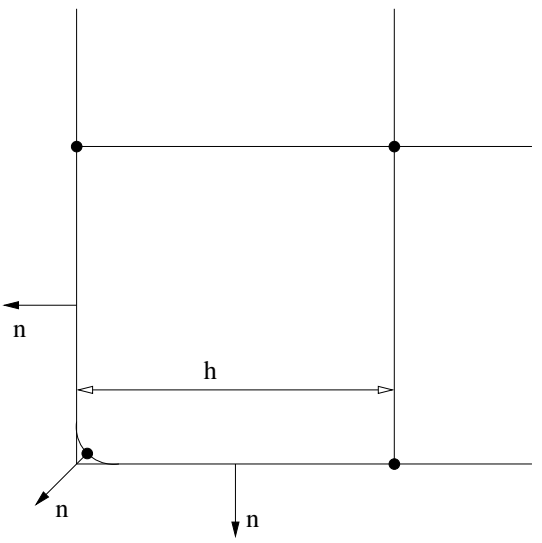

FIG. 1. *Discretization at the corner.*

points is small (in comparison to the mesh size h), the rates of convergence of the multigrid algorithm (presented in section 4) are conserved. This approach leads to the following normal directions in the corner points of Ω_h:

$$n = \frac{1}{\sqrt{2}} \begin{cases} (1,-1)^t & \text{at} \quad (N,0), \\ (-1,1)^t & \text{at} \quad (0,N) \end{cases} \quad \text{and} \quad n = \frac{1}{\sqrt{2}} \begin{cases} -(1,1)^t & \text{at} \quad (0,0), \\ (1,1)^t & \text{at} \quad (N,N). \end{cases} \tag{3.6}$$

Using this modification we get the following result.

PROPOSITION 3.1. [illegible] (3.3) [illegible]

$$v(x,y) = \begin{cases} \frac{\partial^2 u(x,y)}{\partial x^2} & \text{on} \quad \Gamma_S, \Gamma_N, \\ \frac{\partial^2 u(x,y)}{\partial y^2} & \text{on} \quad \Gamma_W, \Gamma_E \end{cases} \qquad v(x,y) = \begin{cases} 2\frac{\partial^2 u(x,y)}{\partial x \partial y} & \text{on} \quad (0,N),(N,0), \\ -2\frac{\partial^2 u(x,y)}{\partial x \partial y} & \text{on} \quad (0,0),(N,N), \end{cases}$$

[illegible] Γ_S Γ_N Γ_W [illegible] Γ_E [illegible]. By using

$$\frac{\partial^2 u(x,y)}{\partial s^2} = \left(n_y^2 \frac{\partial^2 u(x,y)}{\partial x^2} + n_x^2 \frac{\partial^2 u(x,y)}{\partial y^2} - 2 n_x n_y \frac{\partial^2 u(x,y)}{\partial x \partial y} \right)$$

the assumption for Γ_S, Γ_N, Γ_W, and Γ_E follows directly. For the corner points we get, because of (3.6),

$$\frac{\partial^2 u(x,y)}{\partial s^2} = \begin{cases} \frac{1}{2}\left(\frac{\partial^2 u(x,y)}{\partial x^2} + \frac{\partial^2 u(x,y)}{\partial y^2} \right) - \frac{\partial^2 u(x,y)}{\partial x \partial y} & \text{on } (0,N),(N,0), \\ \frac{1}{2}\left(\frac{\partial^2 u(x,y)}{\partial x^2} + \frac{\partial^2 u(x,y)}{\partial y^2} \right) + \frac{\partial^2 u(x,y)}{\partial x \partial y} & \text{on } (0,0),(N,N). \end{cases}$$

Inserting this into the boundary condition $v(x,y) - \frac{\partial^2 u(x,y)}{\partial s^2} = 0$, we get the assumption, due to $\Delta u(x,y) = v(x,y)$. □

By this result we are now in the position to discretize L_u by finite differences.

PROPOSITION 3.2. [illegible] Ω [illegible] (3.3)

(a) [illegible] $D^+_{x,h} D^-_{x,h}$ [illegible] $\frac{\partial}{\partial x^2}$ [illegible] $D^+_{y,h} D^-_{y,h}$ [illegible] $\frac{\partial}{\partial y^2}$ [illegible]

$$v(x,y) = \frac{\partial^2 u}{\partial s^2}(x,y) \quad \text{on} \quad \partial\Omega$$

[illegible]

$$v_h(i,j) = \frac{1}{h^2}\big(u_h(i,j-1) - 2u_h(i,j) + u_h(i,j+1)\big) \tag{3.7}$$

[illegible] $(i,j) \in \Gamma_{W,O}$ [illegible]

$$v_h(i,j) = \frac{1}{h^2}\big(u_h(i-1,j) - 2u_h(i,j) + u_h(i+1,j)\big) \tag{3.8}$$

[illegible] $(i,j) \in \Gamma_{N,S}$

(b) [illegible]

$$\frac{\partial^2}{\partial x \partial y} : \frac{h^{-2}}{2} \begin{bmatrix} 0 & -1 & 1 \\ -1 & 2 & -1 \\ 1 & -1 & 0 \end{bmatrix} \tag{3.9}$$

[illegible] $\frac{\partial^2 u(x,y)}{\partial x \partial y}$ [illegible] $(0,N)$ [illegible] $(N,0)$ [illegible]

$$v_h(N,0) = \frac{1}{h^2}\big(u_h(N-1,0) + u_h(N,1) - u_h(N-1,1) - u_h(N,0)\big)$$

[illegible]

$$v_h(0,N) = \frac{1}{h^2}\big(u_h(0,N-1) + u_h(1,N) - u_h(1,N-1) - u_h(0,N)\big).$$

(c) [illegible]

$$\frac{\partial^2}{\partial x \partial y} : \frac{h^{-2}}{2}\begin{bmatrix} -1 & 1 & 0 \\ 1 & -2 & 1 \\ 0 & 1 & -1 \end{bmatrix} \tag{3.10}$$

[illegible] $\frac{\partial^2 u(x,y)}{\partial x \partial y}$ [illegible] $(0,0)$ [illegible] (N,N) [illegible]

$$v_h(0,0) = \frac{1}{h^2}\big(u_h(1,0) + u_h(0,1) - u_h(1,1) - u_h(0,0)\big)$$

[illegible]

$$v_h(N,N) = \frac{1}{h^2}\big(u_h(N-1,N) + u_h(N,N-1) - u_h(N-1,N-1) - u_h(N,N)\big).$$

[illegible]

(a) The proof of this part is straightforward.

(b) By using (3.9) to approximate $\frac{\partial^2 u(x,y)}{\partial x \partial y}$ on $(N,0)$, we get

$$v_h(N,0) - \frac{1}{h^2}\begin{bmatrix} 0 & -1 & 1 \\ -1 & 2 & -1 \\ 1 & -1 & 0 \end{bmatrix} u_h(N,0) = 0.$$

By adding equation $\frac{\partial^2 u(x,y)}{\partial n^2} = 0$ at $(N,1)$ and $(N-1,0)$, we get, by using $D^+_{x,h}D^-_{x,h}$ and $D^+_{y,h}D^-_{y,h}$ to approximate $\frac{\partial^2 u(x,y)}{\partial n^2}$,

$$v_h(N,1) - \frac{1}{h^2}\begin{bmatrix} -2 & 1 & 0 \\ 1 & 2 & -1 \\ 0 & -1 & 0 \end{bmatrix} u_h = 0.$$

By adding $\Delta_h u_h(N,0) - v_h(N,0) = 0$ to this equation, we get

$$v_h(N,0) - \frac{1}{h^2}\begin{bmatrix} -1 & 1 & 0 \\ 1 & -1 & 0 \\ 0 & 0 & 0 \end{bmatrix} u_h(N,0) = 0.$$

By the same approach we get the approximation for $(0,N)$.

(c) By using (3.10) to approximate u_{xy} we get the approximations on $(0,0)$ and (N,N), respectively. □

3.4.2. Finite difference discretization of L_v. The boundary value problem (3.2) can be seen as a Poisson equation with Neumann boundary conditions perturbed by the operator K. In order to discretize the equation, we follow the approach given in [17] with second-order approximations for the derivates in outward normal direction. The proof of the following result is straightforward.

PROPOSITION 3.3. [illegible] Ω [illegible] K [illegible]

$$K[u(x,y)] = \begin{cases} -\frac{\partial^3 u(x,y)}{\partial x^2 \partial y} & \text{[illegible]} \ \Gamma_S, \\ \frac{\partial^3 u(x,y)}{\partial x^2 \partial y} & \text{[illegible]} \ \Gamma_N \end{cases} \qquad K[u(x,y)] = \begin{cases} -\frac{\partial^3 u(x,y)}{\partial x \partial y^2} & \text{[illegible]} \ \Gamma_W, \\ \frac{\partial^3 u(x,y)}{\partial x \partial y^2} & \text{[illegible]} \ \Gamma_E. \end{cases}$$

Using Proposition 3.3 leads to the following discretization of K on the unit square.

PROPOSITION 3.4. [illegible] $D^+_{x,h}$ $D^-_{x,h}$ [illegible] $\frac{\partial}{\partial x}$ [illegible] $D^+_{y,h}D^-_{y,h}$ [illegible] $\frac{\partial^2}{\partial y^2}$ [illegible]

(a) [illegible] K [illegible] Γ_W

$$K_h^W := -D^+_{y,h}D^-_{y,h}D^+_{x,h} = \frac{1}{h^3}\begin{bmatrix} 0 & 1 & -1 \\ 0 & -2 & 2 \\ 0 & 1 & -1 \end{bmatrix}. \tag{3.11}$$

(b) [illegible] K [illegible] Γ_E

$$K_h^E := D^+_{y,h}D^-_{y,h}D^-_{x,h} = \frac{1}{h^3}\begin{bmatrix} -1 & 1 & 0 \\ 2 & -2 & 0 \\ -1 & 1 & 0 \end{bmatrix}. \tag{3.12}$$

[illegible] $D^+_{y,h}$ $D^-_{y,h}$ [illegible] $\frac{\partial}{\partial y}$ [illegible] $D^+_{x,h}D^-_{x,h}$ [illegible] $\frac{\partial^2}{\partial x^2}$ [illegible]

(c) [illegible] K [illegible] Γ_S

$$K_h^S := -D^+_{x,h}D^-_{x,h}D^+_{y,h} = \frac{1}{h^3}\begin{bmatrix} -1 & 2 & -1 \\ 1 & -2 & 1 \\ 0 & 0 & 0 \end{bmatrix}. \tag{3.13}$$

(d) [illegible] K [illegible] Γ_N

$$K_h^N := D^+_{x,h}D^-_{x,h}D^-_{y,h} = \frac{1}{h^3}\begin{bmatrix} 0 & 0 & 0 \\ 1 & -2 & 1 \\ -1 & 2 & -1 \end{bmatrix}. \tag{3.14}$$

In order to discretize the derivatives of v normal to the boundary, a set of virtual v-points outside of Ω (so-called ghost points) are introduced parallel to the boundary and one mesh size from it, i.e., lines of points $v(-h, y)$, $v(1+h, y)$, $v(x, -h)$, and $v(x, 1+h)$. The virtual v-points are eliminated by imposing at boundary points the discrete versions of the differential equation and the boundary equations simultaneously. For example, we get the following discretization at the left boundary when we use the central difference D^s between the virtual points and the first interior v-points.

PROPOSITION 3.5. [illegible] K_h^W [illegible] (3.11) [illegible] [illegible] (3.2) Γ_W [illegible]

$$\frac{\alpha}{h^2}\begin{bmatrix} 0 & 1 & 0 \\ 0 & -4 & 2 \\ 0 & 1 & 0 \end{bmatrix} v_h(0,j) = f_h(0,j) - \frac{2\alpha}{h}K_h^W[u(0,j)] - u(0,j)$$

[illegible] $(0, j)$ Γ_W

Similarly, we get finite difference discretizations for the corner points. For example, we get the following discretization at point $(0,0)$.

PROPOSITION 3.6. K_h^W K Γ_W K_h^S K Γ_S (3.2) $x=(0,0)$

(3.15)
$$\frac{2\alpha}{h^2}\big(v_h(1,0)+v_h(0,1)-2v_h(0,0)\big)=f_h(x)-\frac{2\alpha}{h}\big(K_h^S[u(x)]+K_h^W[u(x)]\big)-u(x).$$

(3.11) (3.13) K_h^S K_h^W $(0,0)$ (3.2):

$$\frac{\alpha}{h^2}\Big(4\big(v_h(0,1)+v_h(1,0)\big)-6v_h(0,0)\Big)$$
$$=f_h(0,0)-\frac{2\alpha}{h}\left(\frac{1}{h^3}\big(u(0,2)-2u(0,1)+2u(0,0)-2u(1,0)+u(2,0)\big)\right)+u(0,0).$$

This yields

$$K_h^S+K_h^W=\frac{1}{h^3}\left(\begin{bmatrix}-1&2&-1\\1&-2&1\\0&0&0\end{bmatrix}+\begin{bmatrix}0&1&-1\\0&-2&2\\0&1&-1\end{bmatrix}\right)=\frac{1}{h^3}\begin{bmatrix}-1&3&-2\\1&-4&3\\0&1&-1\end{bmatrix}.$$

Since $\Delta u-v=0$ at $\partial\Omega$, we have

$$\begin{aligned}(K_h^S+K_h^W)u_h&=(K_h^S+K_h^W)u_h+\frac{1}{h}(-\Delta_h u_h(0,0)+v_h(0,0))\\&\quad+\frac{1}{h}(\Delta_h u_h(0,1)-v_h(0,1))+\frac{1}{h}(\Delta_h u_h(1,0)-v_h(1,0))\\&=\frac{1}{h^3}\Big(u_h(0,2)-2u_h(0,1)+2u_h(0,0)-2u_h(1,0)+u_h(2,0)\Big)\\&\quad+\frac{1}{h}\Big(v_h(0,0)-v_h(0,1)-v_h(1,0)\Big).\end{aligned}$$

Substituting this into (3.15) leads to the result. □

3.5. The discretization matrix. The connection between the discrete operator L_h and its discretization matrix A_h is given by the following theorem. The proof is straightforward and omitted here.

THEOREM 3.1. 3.1–3.6 (3.4) $2\cdot(N+1)^2$

$$\begin{pmatrix}L_{v,h}&I_h+K_h\\-I_h&L_{u,h}\end{pmatrix}\begin{pmatrix}v_h\\u_h\end{pmatrix}=\begin{pmatrix}f_h\\0\end{pmatrix}. \tag{3.16}$$

L

$$L_h=\begin{pmatrix}L_{v,h}&K_h\\-I_h&L_{u,h}\end{pmatrix}.$$

Notice that the matrices $L_{v,h}$, K_h, and $L_{u,h}$ are neither symmetric nor diagonally dominant. It is easy to see that the kernel of L_h is given by

$$\ker(L_h) = \left\{ \alpha_1 \begin{pmatrix} 0 \\ \phi_1^h \end{pmatrix} + \alpha_2 \begin{pmatrix} 0 \\ \phi_2^h \end{pmatrix} + \alpha_3 \begin{pmatrix} 0 \\ \phi_3^h \end{pmatrix}, \quad \alpha_1, \alpha_2, \alpha_3 \in \mathbb{R} \right\}.$$

Here, we identify by ϕ_1^h, ϕ_x^h, ϕ_y^h the vectors (in rowwise ordering) corresponding to the approximation on Ω_h of the two-dimensional functions 1, x, and y.

4. Multigrid treatment of the biharmonic diffusion equation. The aim of this section is to discuss the multigrid treatment of the system (3.4). The computational problem of solving a linear system arising from the discretization of a differential operator is well studied. Good introductions to multigrid computational methods are given, for instance, in [16, 21, 24]. Here, however, there are complications since the resulting discretization matrix is not at all diagonally dominant and consequently conventional iterative methods such as Jacobi or Gauss–Seidel diverge.

4.1. The multigrid scheme. The basic multigrid schemes are the V-cycle and the W-cycle, obtained by solving the coarse grid problem by one (i.e., $\gamma = 1$ in Algorithm 1) or two (i.e., $\gamma = 2$ in Algorithm 1) recursive applications of the multigrid scheme. The so-called F-cycle is given for $\gamma = -1$ in Algorithm 1.

Algorithm 1.

```
function MGS(l, u_l, f_l, γ)
    if l = 0 then
        u_0 ← A_0^{-1} f_0
    else
        for g = 1, ..., |γ| do
            u_l ← S_l(u_l, f_l, ν_1)                          ▷ Presmoothing
            u_{l-1} ← 0
            if γ = −1 then
                u_{l-1} ← MGS(l − 1, u_{l-1}, I_l^{l-1}(f_l − A_l u_l), γ)
            end if
            MGS(l − 1, u_{l-1}, I_l^{l-1}(f_l − A_l u_l), |γ|)
            u_l ← S_l(u_l + I_{l-1}^l u_{l-1}, f_l, ν_2)      ▷ Postsmoothing
        end for
    end if
end function
```

In any multigrid cycle there are two types of intergrid communication. The operators

$$I_l^{l-1} : G_l \to G_{l-1} \quad \text{and} \quad I_{l-1}^l : G_{l-1} \to G_l$$

designate the canonical intergrid transfers, where G_l denotes a grid with mesh size $2^l h$. The fine-to-coarse transfer (restriction) produces an approximation of the fine-grid residual on a coarse-grid G_{l-1}. The coarse-to-fine transfer (prolongation) interpolates the coarse-grid correction to the next finer grid. In our multigrid implementation, we used full weighting for restriction and bilinear interpolation, i.e.,

$$I_{l-1}^l = \frac{1}{16} \begin{bmatrix} 1 & 2 & 1 \\ 2 & 4 & 2 \\ 1 & 2 & 1 \end{bmatrix}_l^{l-1}, \quad I_{l-1}^l = \frac{1}{8} \begin{bmatrix} 1 & 1 \\ 2 & 2 \\ 1 & 1 \end{bmatrix}_l^{l-1}, \quad I_{l-1}^l = \frac{1}{4} \begin{bmatrix} 1 & 1 \\ 1 & 1 \end{bmatrix}_l^{l-1}$$

for the inner, edge, and corner points. On all grids the discretization is done in the same way as on the finest grid.

4.2. Boundary relaxation. An important part of multigrid schemes for the solution of discretized elliptic boundary value problems is relaxation. Although the smoothing factors of the Gauss–Seidel relaxation with lexicographical order of the grid points for the biharmonic operator are identical to the factors for Poisson's equation (see [24]), it is well known that finite difference multigrid solvers for the biharmonic operator are very sensitive to the boundary conditions associated with the problem. For instance, the convergence rates for multigrid schemes, by applying a point relaxation for the discretization of the boundary as proposed in section 3, are much slower than predicted for the interior points; see Figure 2.

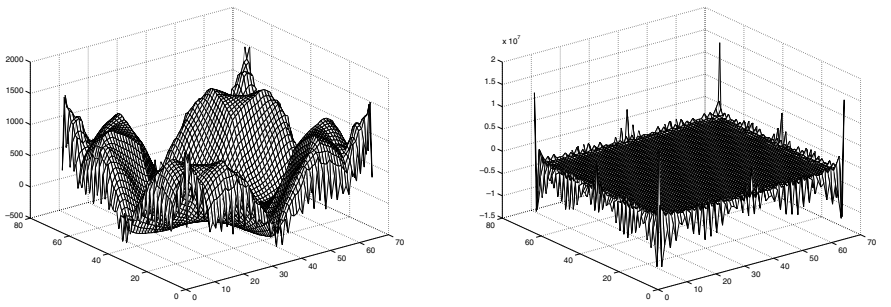

FIG. 2. *Defect after some multigrid $W(1,2)$-cycle by using Gauss–Seidel iteration without special boundary treatment.*

The reason is that the finite difference discretization is not diagonally dominant due to the equations at the boundary. Thus standard relaxations lack the smoothing property and must lose their efficiency. This is a fundamental observation for any local relaxation scheme for nondiagonally dominant operators. Consequently, a special treatment of the equations corresponding to the boundary points is necessary to attain full multigrid efficiency. It has been shown by Brandt in [4] for the biharmonic Dirichlet problem that the multigrid efficiency predicted by local mode analysis for the interior smoothing rates can be obtained by a special treatment of the boundary. Following this idea we use the following steps for a relaxation step S_l:

(1) For $\Gamma \in \{\Gamma_O, \Gamma_N, \Gamma_W, \Gamma_S\}$: A simultaneous relaxation of all boundary points $(i,j) \in \Gamma$ and the points near the boundary is performed. This means that all unknowns on Γ (including the corner points) and all points of the next q lines/columns (see Figure 3) are updated collectively.

(2) Simultaneous point relaxation is performed at interior points, meaning that new values $u^{new}(i,j)$ and $v^{new}(i,j)$ for $1 \le i \le N-1$, $1 \le j \le N-1$ are computed for each time the point (i,j) is relaxed. For instance, the Gauss–Seidel relaxation with lexicographical order of the grid points leads us to solve the 2×2 system

$$\begin{pmatrix} -4 & \alpha \\ 1 & -4 \end{pmatrix} \begin{pmatrix} u^{new}(i,j) \\ v^{new}(i,j) \end{pmatrix} = \begin{pmatrix} f(i,j) - \Sigma_u(i,j) \\ -\Sigma_v(i,j) \end{pmatrix}$$

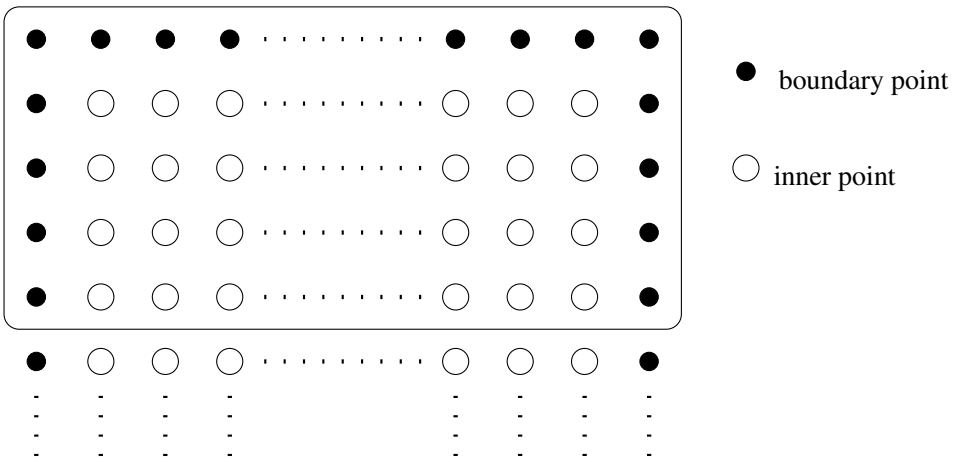

FIG. 3. *Collective line relaxation near upper boundary* Γ_N.

for all $1 \le i \le N-1$, $1 \le j \le N-1$, where

$$\Sigma_u(i,j) = u^{new}(i-1,j) + u^{new}(i,j-1) + u^{old}(i+1,j) + u^{old}(i,j+1)$$

and

$$\Sigma_v(i,j) = v^{new}(i-1,j) + v^{new}(i,j-1) + v^{old}(i+1,j) + v^{old}(i,j+1).$$

The treatment of the boundary points (1) leads to tridiagonal matrices, which can be solved effectively by an amount of work proportional to the number N of all grid points $\mathcal{O}(N)$.

4.3. Multigrid convergence. We apply the proposed multigrid method to the discretization presented in section 3 using the damped Jacobi relaxation with an underrelaxation parameter $\omega = 0.8$ to carry out the relaxation in the interior of Ω. For boundary treatment we solve five lines/columns collectively as outlined in the previous section. On the coarsest grid (with 5×5 grid points due to the boundary relaxation) we solve the problem exactly by using a direct Gaussian elimination scheme.

The asymptotic convergence rates are measured by the geometric average defect factor over k iterations, given by

$$\hat{q}^{(k)} := \sqrt[k]{\frac{||d_h^k||}{||d_h^0||}}.$$

We solve the linear system (3.4) for $\epsilon = \tau = 1$ (i.e., $\alpha = 1$) using a zero initial guess and a right-hand side f with random entries (chosen from a uniform distribution on the interval $[0, 100]$) for different mesh sizes h_l. In Table 4.1 the multigrid convergence of the $W(1,2)$-cycle (meaning 1 pre- and 2 postsmoothing steps) for different step sizes of the finest grid are presented.

Here, the convergence rates of our multigrid implementation are approximately 0.195 and independent of the grid size h_l. These rates can be improved by using a $W(3,0)$-cycle ($\hat{q}^{(10)} = 0.180$) or if the number of smoothing steps is increased; see

TABLE 4.1
The average defect reduction factor over 10 iterations $\hat{q}^{(10)}$ for a $W(1,2)$-cycle.

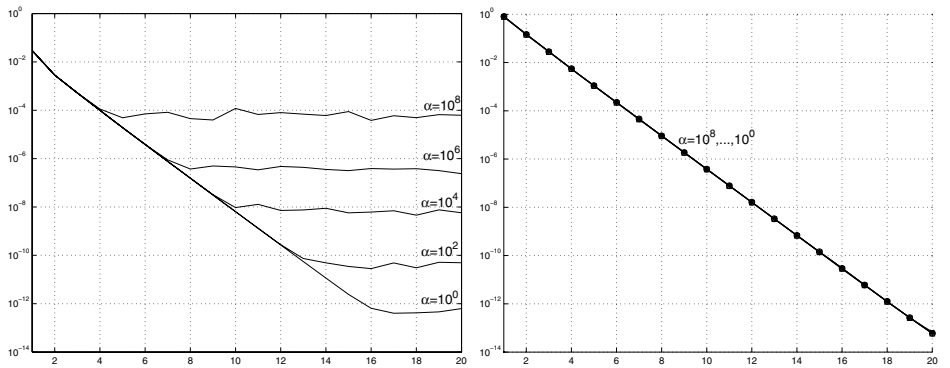
$\hat{q}^{(10)}$	0.607	0.330	0.303	0.314	0.186	0.129

Table 4.2. Moreover, it can be seen that the presented $W(\nu_1, \nu_2)$-cycle convergence factors are roughly the same as predicted by the local Fourier analysis (LFA); cf. [24, p. 305].

By using V-cycle we observe no convergence (n.c.) by using only one smoothing step and a convergence factor of the $V(1,1)$ of 0.681; see Table 4.3.

This behavior of the multigrid V-cycle has been also observed for the biharmonic Dirichlet problem; see [24]. This effect is caused by the boundary conditions, since in the case of simply supported edges (see section 3.2) we obtain good convergence factors for the same multigrid scheme in the interior of Ω.



In Table 4.4 the convergence rates for F-cycles are presented. It turns out that the F-cycle is a good compromise between the V-cycle and the W-cycle, since the F-cycle has only slightly higher computational costs than the V-cycle but convergence properties similar to those of the W-cycle.

In Table 4.5 we present the L_2-norm of the defects ($d_{h_l}^{(k)} = f_{h_l} - A_{h_l} u_{h_l}^{(k)}$) for the numerical solution $u_{h_l}^{(k)}$ after the kth multigrid iteration with mesh size h_l on the finest grid. In order to illustrate the asymptotic convergence of the multigrid cycle, we reduce the L_2-norm of the defect to less than 10^{-08}. It can be seen that the multigrid solver converges to this accuracy after approximately eleven multigrid iterations—independently of the grid size h_l. This indicates optimal multigrid convergence.

Of course, in image processing applications it is usually not necessary to reduce the defect down to an accuracy of 10^{-8}. Here, we typically apply 1–3 multigrid iterations per time step.

TABLE 4.5

(a) (4.1) violated (b) (4.1) fulfilled

FIG. 4. *Behavior of the defects (during the multigrid iteration) for different parameter α. The discrete L_2 norm of the defect is plotted in a logarithmic scale along the y-axis w.r.t. the kth multigrid iteration ($F(0,3)$-cycles) at the abscissa.*

In the following we want to discuss the influence of the parameter α on the convergence speed of the multigrid algorithm. In Figure 4(a) the L_2 norm of the defect is plotted in a logarithmic scale along the y-axis w.r.t. the kth multigrid iteration (x-axis) by using different parameters α. Here, we observe a rapid convergence of the proposed multigrid scheme during the first multigrid iteration steps. After a few steps the defect reduction stagnates. The reason is (see section 2.3) that the system for large α converges more and more to the singular system $Lu = f$, which could not be solved uniquely if the integrability condition

$$\langle f, \phi_l^* \rangle = 0 \quad \text{for all} \quad \phi_l^* \in \ker(L^T) \tag{4.1}$$

is violated. In this case the errors in $\ker^{\perp}(L)$ will be reduced efficiently in a few steps by the multigrid iteration, but the errors in $\ker(L)$ will not be reduced by the multigrid iteration. This error becomes greater the larger the parameter α.

There are many approaches to overcome this problem, e.g., solving an augmented system; see [16]. In order to solve the time-dependent problem (1.1), the elliptic system has to be solved many times with changing right-hand side f. In this case it is attractive to compute the kernel of L^T once (and to save the kernel for later use) with an arbitrarily high precision and to enforce the integrability condition for

each time step. If the integrability condition is satisfied, good multigrid convergence (independent of α) is observed; see Figure 4(b).

5. Image registration application. In order to demonstrate the principle and reliability of the proposed approach we present experimental results for mono-modal image registration; cf. [19]. The goal of image registration is to determine a displacement vector $u(x,y) = (u_1(x,y),\, u_2(x,y))^t$ (whose components are functions of the variables $x = (x,\, y)^t$) in such a way that $u(x,y)$ transforms the so-called template image T, into another image R, called the reference, so that

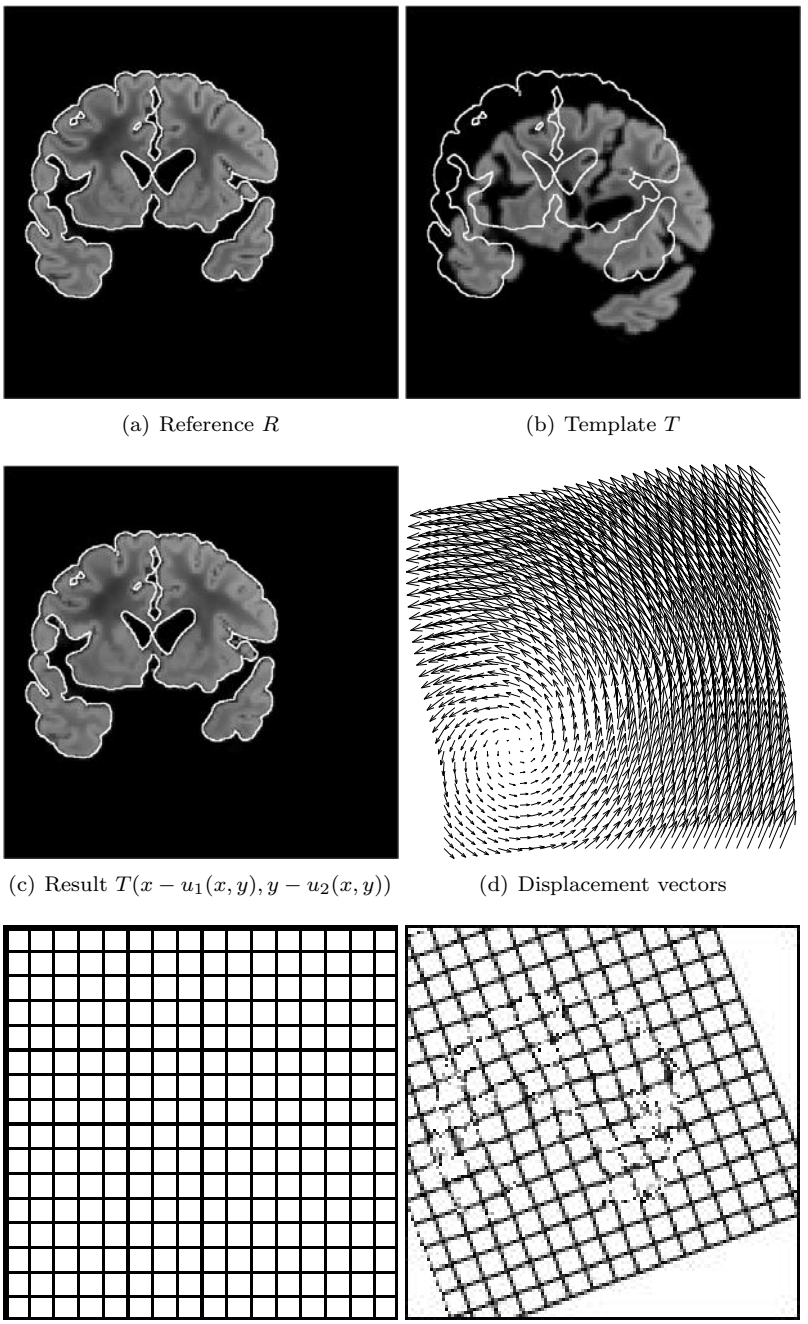
$$R(x,y) = T(x - u_1(x,y), y - u_2(x,y)). \tag{5.1}$$

This is a common criterion. It is used in the case where the images are recorded with the same imaging machinery. As described in [20], this leads us to solve the system

$$\frac{\partial u_i(x,y,t)}{\partial t} + \epsilon(t)\Delta^2 u_i(x,y,t) = -\nabla T(x - u_1(x,y,t), y - u_2(x,y,t)) \\ \big(T(x - u_1(x,y,t), y - u_2(x,y,t)) - R(x,y)\big)$$

on $\Omega \times (0,T)$,

$$B_1[u_i(x,y,t)] = B_2[u_i(x,y,t)] = 0 \quad \text{on } \partial\Omega \times (0,T),$$



and $u_i(x,y,0) = z_i(x,y)$ on Ω for $i = 1,2$. Here, the biharmonic diffusion approach unifies existing image registration approaches, which are normally classified due to the underlying transformations into either affine-linear or nonlinear approaches.

Figure 5 shows a typical example of a brain data set with a standard brain from a human brain atlas (different individuals). Here, the MRI image in Figure 5(a) is assumed to be the deformed template T and should be matched onto the corresponding reference MRI image (Figure 5(b)). Figure 5(c) shows the calculated result $T(x - u(x,t))$. All images are displayed with superimposed contour of the reference image. For this example, we use $\epsilon(0) = 10^6$ and $\tau = 0.015$. It is suitable to start the image registration with $z_1(x,y) = z_2(x,y) = 0$, which corresponds to the identity map. We use 100 time steps. During the iteration we decrease ϵ and τ as described in [20]. For each time step we chose two multigrid $F(2,1)$-cycles to determine the displacements as described in section 4. For images consisting of 256×256 picture elements, our algorithm takes (with a nonoptimized C implementation) approximately one minute on a 2GHz PC with 2GB of RAM.

6. Conclusion and remarks. In this paper we have introduced an efficient multigrid scheme for solving the biharmonic diffusion equation arising in image processing problems. We use a semi-implicit time discretization. The resulting stationary problem is given by a biharmonic operator with higher-order boundary conditions. For spatial discretization, we use the finite difference method.

Operator splitting leads us to solve two Poisson-like equations, which are coupled via the boundary conditions. We have shown via practical examples that the asymptotic convergence behavior, predicted by local mode analysis, can be attained by performing collective relaxation sweeps of some lines near the boundaries. Here, the results for V-cycle schemes are less remarkable, but F- and W-cycles are able to restore these rates.

There are a number of potential extensions of our work. First, in this paper we have only shown two-dimensional results; the extension to three-dimensional problems is our aim for future research. Second, in order to speed up the computations,

(a) Reference R (b) Template T

(c) Result $T(x - u_1(x, y), y - u_2(x, y))$ (d) Displacement vectors

(e) Uniform grid (f) Deformed grid

FIG. 5. (a) *Template image* T. (b) *Reference image* R. (c) *Template deformed by the solution of biharmonic diffusion approach.* (d) *Plot of displacement vectors as arrows with components* (u_1, u_2) *at the points* (x, y). (e) *Uniform grid.* (f) *Uniform grid deformed by the solution.*

the multiscale nature of the biharmonic diffusion equation suggests a treatment on different spatial grids. These approaches are similar to the full multigrid scheme and are described in [19].

APPROXIMATION OF HYPERBOLIC MODELS FOR CHEMOSENSITIVE MOVEMENT*

FRANCIS FILBET† AND CHI-WANG SHU‡

Abstract. Numerical methods with different orders of accuracy are proposed to approximate hyperbolic models for chemosensitive movements. On the one hand, first- and second-order well-balanced finite volume schemes are presented. This approach provides exact conservation of the steady state solutions. On the other hand, a high-order finite difference weighted essentially nonoscillatory (WENO) scheme is constructed and the well-balanced reconstruction is adapted to this scheme to exactly preserve steady states and to retain high-order accuracy. Numerical simulations are performed to verify accuracy and the well-balanced property of the proposed schemes and to observe the formation of networks in the hyperbolic models similar to those observed in the experiments.

Key words. chemotaxis, hyperbolic systems, finite volume methods, finite difference methods, weighted essentially nonoscillatory schemes, well-balanced schemes

1. Introduction.

Chemosensitive movement is a process by which cells change their direction when reacting to the presence of a chemical substance, approaching chemically favorable environments, and avoiding unfavorable environments. In the biological literature there is a distinction between chemotaxis and chemokinesis. Chemokinesis describes nondirected bias in the movement behavior, which indirectly leads to an oriented movement of the population, whereas chemotaxis denotes a directed orientation toward or away from a chemical stimulus. However, from a modeling viewpoint this distinction is not necessary and we will summarize all these orientation effects in a chemosensitive movement.

In a simple situation, where we consider only cells and one chemical substance (the chemo-attractant), a model for the space and time evolution of the density $n = n(t,x)$ of cells and the chemical concentration $c = c(t,x)$ at time t and position $x \in \Omega \subset \mathbb{R}^d$ has been introduced by Patlak [19] and Keller and Segel [13]. This model assumes that the propagation of cells is performed via a diffusion process and reads

$$\frac{\partial n}{\partial t} - \operatorname{div}\left(\nabla n - n\,\chi'(c)\,\nabla c\right) = 0, \tag{1}$$

where $\chi'(c) \geq 0$ denotes the chemotactic sensitivity and the chemical concentration c is given either by the following parabolic equation describing the diffusion of the chemo-attractant created by the cells themselves:

$$\frac{\partial c}{\partial t} - D_c\,\Delta c = n - c, \tag{2}$$

with $D_c \geq 0$ denoting the motility (ability of the cell to move), or in the angiogenesis case, simply by

$$\frac{\partial c}{\partial t} = -c\, n. \tag{3}$$

However, this approach is not always sufficiently precise to describe the evolution of bacteria movements. Indeed, experiments show that bacteria such as [illegible] move along straight lines, suddenly stop to choose a new direction, and then continue moving in the new direction. This phenomenon, called run and tumble, can be modeled by a stochastic process called the velocity-jump process [10, 25]. A kinetic transport model for describing this velocity-jump process has been introduced in [18]. In fact, parabolic chemotaxis equations, such as the Patlak–Keller–Segel (PKS) model (1)–(2), have been obtained as the diffusion limit of this kinetic model, thus allowing the determination of the motility D_c and the chemotactic sensitivity χ' [10, 17]. A more recent tendency has been to use hyperbolic equations, which respect finite propagation speeds and are based on the individual movement patterns of the cells; see for instance [3, 4, 11, 21].

In this paper, we propose accurate numerical methods to approximate hyperbolic chemotaxis models. Our approach relies on finite volume schemes and finite difference schemes with high-order weighted essentially nonoscillatory (WENO) reconstructions and allows us to exactly preserve a particular class of steady state solutions.

The outline of this paper is as follows. In section 2, we present a hyperbolic system previously proposed in [21] to describe the early stages of the formation of blood vessels. In section 3, we first propose a first-order well-balanced (i.e., preserving exactly certain steady state solutions) finite volume scheme and then extend it to second-order accuracy. In section 4, we design a high-order well-balanced finite difference WENO scheme. Finally, in section 5 we perform numerical simulations of the nonlinear hyperbolic models of chemotaxis to verify accuracy and the well-balanced property of the proposed finite volume and high-order WENO finite difference schemes and to observe the formation of networks in the hyperbolic models similar to those observed in the experiments [4, 5, 21].

2. A hyperbolic model for chemotaxis. In this paper, we consider numerical approximations of a hyperbolic model introduced in [5, 21], in which the cell density $n(t,x)$ and the population flux $n\,u(t,x)$ are solutions of the hyperbolic system

$$\begin{cases} \dfrac{\partial n}{\partial t} + \operatorname{div}(n\,u) = 0, \\ \dfrac{\partial (n\,u)}{\partial t} + \operatorname{div}(n\ u \otimes u + P(n)) = n\,\chi'(c)\,\nabla c - \sigma\, n\ u, \end{cases} \tag{4}$$

where $P(n)$ is the pressure and σ is the friction coefficient. The evolution of the chemical concentration $c(t,x)$ is still given by (2).

This model is used to describe vasculogenesis (early formation of blood vessels) [5, 21] and can be recovered from a hydrodynamic scaling of a kinetic model [4]. Finite time blowup was proved in [14] for spherically symmetric solutions to the hyperbolic system (4) coupled with a Poisson-type equation to c,

$$-\Delta c = n.$$

Indeed, the Euler–Poisson system is widely studied in plasma physics and astrophysics to model star evolution and it is more expected that shock-type structures arise here,

which could explain why the singularities are not pointwise blow-up typical to the solution of the parabolic model (1) but are more like line concentrations (high concentrations along a line or curve). Such singularities are indeed observed in the numerical simulations in section 5 (formation of networks) and seem to be compatible with the experiments on endothelial cells [5, 21]. Moreover, the hyperbolic model (2), (4) admits an entropy inequality when $\chi(c) = c$, $P(n) = n$, and $D_c = 1$,

$$\frac{\partial \eta}{\partial t} + \operatorname{div} G = -\sigma n u^2 - \left(\frac{\partial c}{\partial t}\right)^2 \leq 0,$$

where

$$\begin{aligned} \eta(t,x) &= \eta_h(n, n\,u) - nc + \frac{1}{2}\left(c^2 + \left(\frac{\partial c}{\partial x}\right)^2\right), \\ G(t,x) &= G_h(n, n\,u) - nuc - \frac{\partial c}{\partial t}\,\frac{\partial c}{\partial x}, \end{aligned} \tag{5}$$

and (η_h, G_h) corresponds to the entropy pair for the homogeneous problem without the source term,

$$\eta_h(n, n\,u) = n(\log\, n - 1) + \frac{1}{2}\,n\,u^2, \qquad G_h(n, n\,u) = n\,u\left(\log n + \frac{1}{2}\,u^2\right). \tag{6}$$

Finally, we conclude this section with some remarks on the connection between the hyperbolic chemotaxis model (2)–(4) and the parabolic chemotaxis system (1)–(2). We first notice that, when $P(n) = n\,Id$, it is possible to recover (1) as the strong friction limit of (4), i.e., when σ goes to infinity. Moreover, the hyperbolic system (4) admits several types of steady state solutions, but the steady state solutions with a zero population flux ($nu = 0$) are particularly important since they are the same as those of the PKS model (1)–(2). Indeed, such steady state solutions satisfy

$$n\,\chi'(c)\,\nabla c - \nabla n = 0, \tag{7}$$

which is the equation satisfied by stationary solutions to the diffusive model for chemotaxis [17, 18].

In what follows, we restrict our attention to the one-dimensional case with $P(n) = n$:

$$\begin{cases} \dfrac{\partial n}{\partial t} + \dfrac{\partial (n\,u)}{\partial x} = 0, \\ \dfrac{\partial (n\ u)}{\partial t} + \dfrac{\partial}{\partial x}\left(n\ u^2 + n\right) = n\,\chi'(c)\dfrac{\partial c}{\partial x} - \sigma\ n\ u. \end{cases} \tag{8}$$

For future reference, we denote by U the unknown, by $F(U)$ the flux function, and by $S(U)$ the source term, which for the nonlinear system (8) are given by

$$U = \begin{pmatrix} n \\ n\,u \end{pmatrix}, \qquad F(U) = \begin{pmatrix} n\,u \\ n\,u^2 + n \end{pmatrix}, \qquad S(U) = \begin{pmatrix} 0 \\ n\,\chi'(c)\frac{\partial c}{\partial x} - \sigma\ n\ u \end{pmatrix}. \tag{9}$$

3. Finite volume approximations. Let us denote by $(x_{i-1/2})_{i\in\mathbb{Z}}$ a mesh of $\mathbb{R}$ and $x_i = (x_{i-1/2} + x_{i+1/2})/2$. Finite volume schemes for hyperbolic systems use an upwinding of the fluxes and in the semidiscrete case they provide a discretized version of (8) under the form

$$\Delta x_i \frac{d}{dt} U_i(t) + F_{i+1/2} - F_{i-1/2} = \Delta x_i \, S_i \tag{10}$$

where Δx_i denotes the mesh size $\Delta x_i = x_{i+1/2} - x_{i-1/2}$, and the discrete unknown $U_i(t)$ is

$$U_i(t) = \begin{pmatrix} n_i(t) \\ n_i(t)\, u_i(t) \end{pmatrix},$$

which represents an approximation to the cell-average of U in the cell $(x_{i-1/2}, x_{i+1/2})$. $F_{i+1/2}$ is an approximation of the flux at the point $x_{i+1/2}$ and S_i is an approximation of the cell-average of the source term $S(U)$ in the cell $(x_{i-1/2}, x_{i+1/2})$.

3.1. A first-order well-balanced scheme. In a basic first-order accurate scheme, the fluxes are classically computed as

$$F_{i+1/2} = \mathcal{F}(U_i(t), U_{i+1}(t)), \tag{11}$$

where the numerical flux $\mathcal{F}(U_i, U_{i+1})$ is computed via an approximation of the Riemann problem. We assume that the numerical flux $\mathcal{F}$ satisfies the following assumptions:

1. It is consistent with the physical flux:

$$\mathcal{F}(U, U) = F(U). \tag{12}$$

2. It preserves the nonnegativity of the density $n_i(t)$ for the homogeneous problem, namely, (8) without the source terms. That is, the scheme

$$\Delta x_i \frac{d}{dt} U_i(t) + F_{i+1/2} - F_{i-1/2} = 0, \tag{13}$$

where the numerical flux $F_{i+1/2}$ is defined by (11), maintains $n_i(t) \geq 0$ if $n_i(0) \geq 0$.

3. The scheme (13) with the numerical flux $F_{i+1/2}$ defined by (11) satisfies a cell entropy inequality for the entropy pair (6) for the homogeneous problem. According to [2], this means that we can find a numerical entropy flux $\mathcal{G}_h$ such that

$$\begin{aligned} &G_h(U_{i+1}) + \nabla_U \eta_h(U_{i+1}) \left(\mathcal{F}(U_i, U_{i+1}) - F(U_{i+1})\right) \\ &\qquad \leq \mathcal{G}_h(U_i, U_{i+1}) \leq G_h(U_i) + \nabla_U \eta_h(U_i) \left(\mathcal{F}(U_i, U_{i+1}) - F(U_i)\right), \end{aligned} \tag{14}$$

where $\nabla_U \eta_h$ is the derivative of η_h with respect to $U = \binom{n}{nu}$.

Since the appearance of [7, 8], it has been known that cell-centered evaluations of the source term in a nonconservative hyperbolic system will generally not be able to preserve steady state solutions. In our case a particular class of steady state solutions, namely, the solution to (7), is given by

$$\log(n_i) - \chi(c_i) = \textit{constant}, \qquad u_i = 0 \qquad \forall\, i. \tag{15}$$

These steady state solutions play an important role in the modeling of chemosensitive movement because they also correspond to the steady state solutions of the parabolic equation (1), which describes the long time behavior of cells under the influence of the chemo-attractant c when the solutions do not blow up. Thus we would like to preserve these steady state solutions exactly at the discrete level.

Our approach follows the ideas of [1] for the shallow water equations (see also [6]). We propose a finite volume scheme according to (10) with flux functions

$$F_{i+1/2} = \mathcal{F}(U^-_{i+1/2}, U^+_{i+1/2}), \qquad U^\pm_{i+1/2} = \begin{pmatrix} n^\pm_{i+1/2} \\ n^\pm_{i+1/2}\, u^\pm_{i+1/2} \end{pmatrix}, \tag{16}$$

where the interface values $U^-_{i+1/2}$ and $U^+_{i+1/2}$ are locally reconstructed from U_i and U_{i+1}. The purpose of the reconstruction is not to increase the order of accuracy as usual, but to achieve a well-balanced property for the steady state solution (15). The source term is discretized by

$$S_i = \begin{pmatrix} 0 \\ \frac{1}{\Delta x_i}\left(n^-_{i+1/2} - n^+_{i-1/2}\right) \end{pmatrix} - \sigma \begin{pmatrix} 0 \\ n_i\, u_i \end{pmatrix}. \tag{17}$$

This ansatz is motivated by a balancing requirement. Indeed, when the population flux $n\,u$ is zero, the cell density n satisfies the balance of the momentum and the source term, i.e.,

$$\frac{\partial n}{\partial x} = n\,\chi'(c)\frac{\partial c}{\partial x}.$$

Integrating over $(x_{i-1/2}, x_{i+1/2})$, we obtain an approximation to the source term,

$$\frac{1}{\Delta x_i}\int_{x_{i-1/2}}^{x_{i+1/2}} n\,\chi'(c)\frac{\partial c}{\partial x}\,dx = \frac{1}{\Delta x_i}\left(n^-_{i+1/2} - n^+_{i-1/2}\right).$$

Therefore, when the velocity u is small, we are able to locally represent the cell-averaged source term as the discrete gradient of the momentum flux. This motivates the source term discretization (17). We will show later that this discretization is consistent with the source term in (8) also for solutions far away from these steady state solutions. It will be shown later that the steady state (15) is maintained exactly if, for such a state, we have

$$n^-_{i+1/2} = n^+_{i+1/2}, \qquad u^-_{i+1/2} = u^+_{i+1/2} = 0. \tag{18}$$

To achieve this, we choose

$$n^-_{i+1/2} = n_i\, e^{\chi_{i+1/2} - \chi(c_i)}, \qquad u^-_{i+1/2} = u_i \tag{19}$$

and

$$n^+_{i+1/2} = n_{i+1}\, e^{\chi_{i+1/2} - \chi(c_{i+1})}, \qquad u^+_{i+1/2} = u_{i+1}, \tag{20}$$

which lead to (18) for an arbitrary choice of $\chi_{i+1/2}$ when the steady state (15) is achieved. The evaluation of the interface value $\chi_{i+1/2}$ has to be such that the scheme is consistent and stable. We have chosen

$$\chi_{i+1/2} = \max\left(\chi(c_i), \chi(c_{i+1})\right) \tag{21}$$

in our numerical experiments. Another possible choice could be

$$\chi_{i+1/2} = \frac{1}{2}\left(\chi(c_i) + \chi(c_{i+1})\right).$$

To summarize, our first-order well-balanced finite volume scheme (10) is defined with the flux and reconstructions given by (16) and (19)–(20). The source term is given by (17), or equivalently, by

$$S_i = S^-_{i+1/2} + S^+_{i-1/2} - \sigma \begin{pmatrix} 0 \\ n_i u_i \end{pmatrix}, \tag{22}$$

with

$$S^-_{i+1/2} = \frac{1}{\Delta x_i}\begin{pmatrix} 0 \\ n^-_{i+1/2} - n_i \end{pmatrix}, \qquad S^+_{i-1/2} = \frac{1}{\Delta x_i}\begin{pmatrix} 0 \\ n_i - n^+_{i-1/2} \end{pmatrix}. \tag{23}$$

We may rewrite the scheme in a nonconservative form as in [2],

$$\Delta x_i \frac{d}{dt} U_i(t) + \mathcal{F}_l(U_i, U_{i+1}, c_i, c_{i+1}) - \mathcal{F}_r(U_{i-1}, U_i, c_{i-1}, c_i) = -\Delta x_i\, \sigma \begin{pmatrix} 0 \\ n_i u_i \end{pmatrix},$$

with the left and right numerical fluxes defined by

$$\begin{aligned} \mathcal{F}_l(U_i, U_{i+1}, c_i, c_{i+1}) &= F_{i+1/2} - \Delta x_i\, S^-_{i+1/2}, \\ \mathcal{F}_r(U_i, U_{i+1}, c_i, c_{i+1}) &= F_{i+1/2} + \Delta x_i\, S^+_{i+1/2}. \end{aligned} \tag{24}$$

Finally, the chemical concentration c is obtained by approximating (2) with a finite volume scheme,

$$\frac{dc_i}{dt} = \frac{D_c}{\Delta x_i}\left(\frac{c_{i+1} - c_i}{\Delta x_{i+1/2}} - \frac{c_i - c_{i-1}}{\Delta x_{i-1/2}}\right) + n_i - c_i, \tag{25}$$

where $\Delta x_{i+1/2} = x_{i+1} - x_i$.

We do not consider the influence of boundary conditions and will assume a periodic boundary condition. However, the numerical methods can be applied to general boundary conditions, as demonstrated in the numerical examples in section 5.

We have the following results for the scheme (10) defined above.

THEOREM 1. [illegible] (10) [illegible] (16), (17), (19), [illegible] (20)

(i) [illegible] $n_i(t)$.

(ii) [illegible] (15).

(iii) [illegible] (8).

(iv) [illegible] (5) [illegible] $\chi(c_i) = c_i$ [illegible] c_i [illegible] (25)

$$\Delta x_i \frac{\partial \eta_i}{\partial t} + G_{i+1/2} - G_{i-1/2} \le 0,$$

[illegible]

$$\eta_i = n_i\left(\log(n_i) - 1 + \frac{u_i^2}{2} - c_i\right) + \frac{1}{2}\left(c_i^2 + \frac{1}{\Delta x_i}\frac{(c_{i+1} - c_i)^2}{\Delta x_{i+1/2}}\right)$$

[illegible] $G_{i+1/2}$

. The ODE system (10) admits a unique smooth (in time) solution since the flux function is smooth enough. By this smoothness of the numerical solution in time, the flux $\mathcal{F}(U_l, U_r) = (\mathcal{F}_1, \mathcal{F}_2)(U_l, U_r)$ to the homogeneous problem (for example, the Lax–Friedrichs flux (41) to be used later) preserves the nonnegativity of n_i if and only if the first component of the flux $\mathcal{F}_1$ satisfies

$$\mathcal{F}_1((n_i = 0, u_i), (n_{i+1}, u_{i+1})) - \mathcal{F}_1((n_{i-1}, u_{i-1}), (n_i = 0, u_i)) \le 0 \quad \forall\, (u_j, n_j)_j. \tag{26}$$

Therefore, for our reconstruction (19)–(20), we need to check that, when $n_i = 0$,

$$\mathcal{F}_1(U^-_{i+1/2}, U^+_{i+1/2}) - \mathcal{F}_1(U^-_{i-1/2}, U^+_{i-1/2}) \le 0 \quad \forall\, u_{i-1}, u_i, u_{i+1}, n_{i-1}, n_{i+1}.$$

But, when $n_i = 0$, the reconstruction (19)–(20) gives that $n^+_{i-1/2} = n^-_{i+1/2} = 0$; hence,

$$\begin{aligned}
&\mathcal{F}_1(U^-_{i+1/2}, U^+_{i+1/2}) = \mathcal{F}_1((0, u_i), (n^+_{i+1/2}, u_{i+1})) \quad \forall\, (u_j, n^+_{j+1/2}, n^-_{j-1/2})_j,\\
&\mathcal{F}_1(U^-_{i-1/2}, U^+_{i-1/2}) = \mathcal{F}_1((n^-_{i-1/2}, u_{i-1}), (0, u_i)) \quad \forall\, (u_j, n^+_{j+1/2}, n^-_{j-1/2})_j.
\end{aligned}$$

Then from (26), we conclude that the scheme preserves nonnegativity of the density n_i.

To prove (ii), we assume the steady state (15) holds and would like to show

$$F_{i+1/2} - F_{i-1/2} = \Delta x_i\, S_i. \tag{27}$$

By the reconstruction of $n^+_{i+1/2}$ and $n^-_{i+1/2}$ given in (19)–(20), when (15) holds, we have

$$n^-_{i+1/2} = n^+_{i+1/2} = A\, e^{\chi_{i+1/2}}, \qquad u^-_{i+1/2} = u^+_{i+1/2} = 0,$$

where $A = n_i\, e^{-\chi(c_i)} = n_{i+1}\, e^{-\chi(c_{i+1})}$. On the one hand, the source term is given by

$$\Delta x_i\, S_i = \begin{pmatrix} 0 \\ n^-_{i+1/2} - n^+_{i-1/2} \end{pmatrix} = A \begin{pmatrix} 0 \\ e^{\chi_{i+1/2}} - e^{\chi_{i-1/2}} \end{pmatrix}. \tag{28}$$

On the other hand, by the consistency of the flux $\mathcal{F}$, we have

$$\begin{aligned}
F_{i+1/2} &= \mathcal{F}((A\, e^{\chi_{i+1/2}}, 0), (A\, e^{\chi_{i+1/2}}, 0))\\
&= F((A\, e^{\chi_{i+1/2}}, 0))\\
&= \begin{pmatrix} 0 \\ A\, e^{\chi_{i+1/2}} \end{pmatrix}.
\end{aligned} \tag{29}$$

Combining (28) and (29), we have proven (27).

To prove statement (iii), we apply the criterion in [1] and need to check two properties related to the consistency with the exact flux F and the consistency with the source term. The consistency with the exact flux is

$$\mathcal{F}_l(U, U, c, c) = \mathcal{F}_r(U, U, c, c) = F(U).$$

It is obviously satisfied since in this case $\chi_{i+1/2} = \chi(c)$, and therefore $n^+_{i+1/2} = n^-_{i+1/2} = n$. For the consistency with the source term, the criterion becomes

$$\mathcal{F}_r(U_l, U_r, c_l, c_r) - \mathcal{F}_l(U_l, U_r, c_l, c_r) = \begin{pmatrix} 0 \\ n\, \chi'(c)\, (c_r - c_l) + o(c_r - c_l) \end{pmatrix}, \tag{30}$$

as $U_r, U_l \to U = (n, u)$ and $c_r, c_l \to c$. In our case,

$$\mathcal{F}_r(U_l, U_r, c_l, c_r) - \mathcal{F}_l(U_l, U_r, c_l, c_r) = \begin{pmatrix} 0 \\ n_l\, e^{\chi_0 - \chi(c_l)} - n_l \end{pmatrix} - \begin{pmatrix} 0 \\ n_r\, e^{\chi_0 - \chi(c_r)} - n_r \end{pmatrix},$$

where $\chi_0 = \max(\chi(c_l), \chi(c_r))$. Now assume that $\chi_0 = \chi(c_l)$; then

$$\mathcal{F}_r(U_l, U_r, c_l, c_r) - \mathcal{F}_l(U_l, U_r, c_l, c_r) = \begin{pmatrix} 0 \\ n_r\, e^{-\chi(c_r)} \left(e^{\chi(c_r)} - e^{\chi(c_l)}\right) \end{pmatrix}$$

and we have

$$n_r\, e^{-\chi(c_r)} \left(e^{\chi(c_r)} - e^{\chi(c_l)}\right) = n\, e^{-\chi(c)} \left(e^{\chi(c_r)} - e^{\chi(c_l)}\right) + o(c_r - c_l),$$

which is consistent with the source term (30) since

$$n\, e^{-\chi(c)}\, \nabla e^{\chi(c)} = n\, \chi'(c)\, \nabla c.$$

The same argument applies when $\chi_0 = \chi(c_r)$, and we conclude that (30) always holds, which proves (iii).

In order to prove (iv), we proceed as in the continuous case and split the time derivative of the entropy into two pieces assuming $\chi(c) = c$,

$$\frac{\partial \eta_i}{\partial t} = \left(\frac{\partial \eta_{h,i}}{\partial t} - c_i \frac{\partial n_i}{\partial t}\right) + \left(-n_i \frac{\partial c_i}{\partial t} + \frac{1}{2}\left(\frac{\partial c_i^2}{\partial t} + \frac{1}{\Delta x_i} \frac{\partial}{\partial t} \frac{(c_{i+1} - c_i)^2}{\Delta x_{i+1/2}}\right)\right)$$

and we show that

$$\Delta x_i \left(\frac{\partial \eta_{h,i}}{\partial t} - c_i \frac{\partial n_i}{\partial t}\right) + G^1_{i+1/2} - G^1_{i-1/2} \le 0 \tag{31}$$

and

$$\Delta x_i \left(-n_i \frac{\partial c_i}{\partial t} + \frac{1}{2}\left(\frac{\partial c_i^2}{\partial t} + \frac{1}{\Delta x_i} \frac{\partial}{\partial t} \frac{(c_{i+1} - c_i)^2}{\Delta x_{i+1/2}}\right)\right) + G^2_{i+1/2} - G^2_{i-1/2} \le 0. \tag{32}$$

To prove (31), we first take notice of the assumption that the original numerical flux $\mathcal{F}$ satisfies a semidiscrete entropy inequality; hence (14) holds. Then, we set

$$G^1_{i+1/2} = \mathcal{G}_h(U^-_{i+1/2}, U^+_{i+1/2}) - \mathcal{F}_1(U^-_{i+1/2}, U^+_{i+1/2})\, c_{i+1/2}$$

and compute

$$\begin{aligned} G^1_{i+1/2} - G^1_{i-1/2} = {} & \mathcal{G}_h(U^-_{i+1/2}, U^+_{i+1/2}) - \mathcal{G}_h(U^-_{i-1/2}, U^+_{i-1/2}) \\ & - \mathcal{F}_1(U^-_{i+1/2}, U^+_{i+1/2})\, c_{i+1/2} + \mathcal{F}_1(U^-_{i-1/2}, U^+_{i-1/2})\, c_{i-1/2}. \end{aligned}$$

Using the two inequalities in (14), we get

$$\begin{aligned} G^1_{i+1/2} - G^1_{i-1/2} \le {} & G_h(U^-_{i+1/2}) + \nabla_U \eta_h(U^-_{i+1/2}) \left(\mathcal{F}(U^-_{i+1/2}, U^+_{i+1/2}) - F(U^-_{i+1/2})\right) \\ & - G_h(U^+_{i-1/2}) - \nabla_U \eta_h(U^+_{i-1/2}) \left(\mathcal{F}(U^-_{i-1/2}, U^+_{i-1/2}) - F(U^+_{i-1/2})\right) \\ & - \mathcal{F}_1(U^-_{i+1/2}, U^+_{i+1/2})\, c_{i+1/2} + \mathcal{F}_1(U^-_{i-1/2}, U^+_{i-1/2})\, c_{i-1/2}. \end{aligned}$$

This inequality can be rewritten as

$$\begin{aligned} G^1_{i+1/2} - G^1_{i-1/2} \leq & \left(\log(n^-_{i+1/2}) - \frac{1}{2}u_i^2 - c_{i+1/2}\right) \mathcal{F}_1(U^-_{i+1/2}, U^+_{i+1/2}) \\ & - \left(\log(n^+_{i-1/2}) - \frac{1}{2}u_i^2 - c_{i-1/2}\right) \mathcal{F}_1(U^-_{i-1/2}, U^+_{i-1/2}) \\ & + u_i \left(\mathcal{F}_2(U^-_{i+1/2}, U^+_{i+1/2}) - \mathcal{F}_2(U^-_{i-1/2}, U^+_{i-1/2}) + n^+_{i-1/2} - n^-_{i+1/2}\right). \end{aligned}$$

Now, by the definition of $n^-_{i+1/2}$, $n^+_{i-1/2}$, and S_i, we obtain

$$\begin{aligned} G^1_{i+1/2} - G^1_{i-1/2} \leq & \left(\log(n_i) - c_i - \frac{1}{2}u_i^2\right) \left(\mathcal{F}_1(U^-_{i+1/2}, U^+_{i+1/2}) - \mathcal{F}_1(U^-_{i-1/2}, U^+_{i-1/2})\right) \\ & + u_i \left(\mathcal{F}_2(U^-_{i+1/2}, U^+_{i+1/2}) - \mathcal{F}_2(U^-_{i-1/2}, U^+_{i-1/2}) \right. \\ & \left. + n^+_{i-1/2} - n^-_{i+1/2} + \sigma\, \Delta x_i n_i u_i\right) \\ \leq & -\Delta x_i\, \nabla_U \eta_h(U_i)\, \frac{dU_i}{dt} + \Delta x_i\, c_i\, \frac{dn_i}{dt}. \end{aligned}$$

We conclude that (31) holds.

To prove (32), we use the approximation (25) to the parabolic equation (2),

$$\begin{aligned} -n_i\, \frac{dc_i}{dt} &= -\left(\frac{dc_i}{dt} - \frac{1}{\Delta x_i}\left(\frac{c_{i+1}-c_i}{\Delta x_{i+1/2}} - \frac{c_i - c_{i-1}}{\Delta x_{i-1/2}}\right) + c_i\right) \frac{dc_i}{dt}, \\ &= -\left(\frac{dc_i}{dt}\right)^2 - \frac{1}{2}\,\frac{dc_i^2}{dt} + \frac{1}{\Delta x_i}\left(\frac{c_{i+1}-c_i}{\Delta x_{i+1/2}} - \frac{c_i - c_{i-1}}{\Delta x_{i-1/2}}\right) \frac{dc_i}{dt}. \end{aligned}$$

Using the equality

$$\begin{aligned} (c_{i+1}-c_i)\, \frac{d}{dt}\left(\frac{c_{i+1}-c_i}{\Delta x_{i+1/2}}\right) = & -\left(\frac{c_{i+1}-c_i}{\Delta x_{i+1/2}} - \frac{c_i - c_{i-1}}{\Delta x_{i-1/2}}\right) \frac{dc_i}{dt} \\ & + \left(\frac{c_{i+1}-c_i}{\Delta x_{i+1/2}}\, \frac{dc_{i+1}}{dt} - \frac{c_i - c_{i-1}}{\Delta x_{i-1/2}}\, \frac{dc_i}{dt}\right), \end{aligned}$$

we get

$$\frac{1}{2}\left(\frac{d}{dt}\frac{(c_{i+1}-c_i)^2}{\Delta x_{i+1/2}} + \Delta x_i \frac{dc_i^2}{dt}\right) - \Delta x_i\, n_i\, \frac{dc_i}{dt} + G^2_{i+1/2} - G^2_{i-1/2} \leq 0,$$

with

$$G^2_{i+1/2} = -\frac{c_{i+1}-c_i}{\Delta x_{i+1/2}}\, \frac{dc_{i+1}}{dt}.$$

Finally, gathering (31) and (32), we prove the result with $G_{i+1/2} = G^1_{i+1/2} + G^2_{i+1/2}$. ∎

. . . . 1. When using the time-space fully discrete scheme

$$U_i^{k+1}-U_i^{k+1}+\frac{\Delta t}{\Delta x_i}\left(\mathcal{F}_l(U_i^k,U_{i+1}^k,c_i^k,c_{i+1}^k)-\mathcal{F}_r(U_{i-1}^k,U_i^k,c_{i-1}^k,c_i^k)\right)=-\Delta t\,\sigma\begin{pmatrix}0\\ n_i^k u_i^k\end{pmatrix},$$

the consistency and the well-balanced property are still valid. The stability is guaranteed under a CFL condition,

$$\sigma(U_i,U_{i+1})\Delta t\le \min(\Delta x_i,\Delta x_{i+1}),$$

where $\sigma(U_i,U_{i+1})\ge 0$ is a numerical speed at the interface (see [1, 2] for a detailed proof). Moreover, if we use a time explicit scheme to (25), we get a more restrictive condition on the time step

$$\Delta t\le \frac{\Delta x_i}{2}\,\min(\Delta x_{i-1/2},\Delta x_{i+1/2}).$$

3.2. Extension to a second-order approximation. Now we describe the extension to second-order accuracy. To this aim we reconstruct values at both sides of the interface. These new values are obtained in three steps: prediction of the gradients in each cell, linear extrapolation, and a limiting procedure to preserve nonnegativity. First, we compute two second-order accurate interface values $U_{i,r}$ and $U_{i+1,l}$ at the point $x_{i+1/2}$ from linear reconstructions in cells $(x_{i-1/2},x_{i+1/2})$ and $(x_{i+1/2},x_{i+3/2})$, respectively, following the three steps mentioned above. We remark that second-order accuracy is achievable only away from the vacuum $n_i=0$, since in the cell where $n_i=0$ the reconstructed linear function is flat to maintain the nonnegativity of n. Using the same reconstruction procedure, we also compute two interface values for the chemoattractant $e^{\chi(c)}$ at the point $x_{i+1/2}$, denoted by $(e^{\chi(c)})_{i,r}$ and $(e^{\chi(c)})_{i+1,l}$. Once these second-order reconstructed values are known, we further apply the reconstruction in the previous section to achieve well balancedness. This gives the second-order well-balanced scheme (10) with the flux defined by

$$F_{i+1/2}=\mathcal{F}(U^-_{i+1/2},U^+_{i+1/2})$$

and

$$U^-_{i+1/2}=\begin{pmatrix} n^-_{i+1/2}\\ n^-_{i+1/2}\,u_{i,r}\end{pmatrix},\qquad U^+_{i+1/2}=\begin{pmatrix} n^+_{i+1/2}\\ n^+_{i+1/2}\,u_{i+1,l}\end{pmatrix},\tag{33}$$

where $n^-_{i+1/2}$ and $n^+_{i+1/2}$ are given by

$$n^-_{i+1/2}=n_{i,r}\,\frac{(e^{\chi(c)})_{i+1/2}}{(e^{\chi(c)})_{i,r}},\qquad n^+_{i+1/2}=n_{i+1,l}\,\frac{(e^{\chi(c)})_{i+1/2}}{(e^{\chi(c)})_{i+1,l}},\tag{34}$$

with

$$(e^{\chi(c)})_{i+1/2}=\max\left((e^{\chi(c)})_{i,r},(e^{\chi(c)})_{i+1,l}\right).\tag{35}$$

The source term is computed as before at the interface,

$$S_i=S^-_{i+1/2}+S^c_i+S^+_{i-1/2},\tag{36}$$

with

$$S^-_{i+1/2} = \frac{1}{\Delta x_i}\begin{pmatrix} 0 \\ n^-_{i+1/2} - n_{i,r} \end{pmatrix}, \qquad S^+_{i-1/2} = \frac{1}{\Delta x_i}\begin{pmatrix} 0 \\ n_{i,l} - n^+_{i-1/2} \end{pmatrix} \tag{37}$$

and

$$S^c_i = \frac{1}{\Delta x_i}\begin{pmatrix} 0 \\ \frac{1}{2}\left(\frac{n_{i,r}}{(e^{\chi(c)})_{i,r}} + \frac{n_{i,l}}{(e^{\chi(c)})_{i,l}}\right)\left((e^{\chi(c)})_{i,r} - (e^{\chi(c)})_{i,l}\right) \end{pmatrix} - \sigma\begin{pmatrix} 0 \\ n_i u_i \end{pmatrix}. \tag{38}$$

Using the definitions of the left and right numerical fluxes $\mathcal{F}_l$ and $\mathcal{F}_r$ in (24), a compact formulation of the scheme is

$$\Delta x_i \frac{d}{dt} U_i(t) + \mathcal{F}_l(U_{i,r}, U_{i+1,l}, c_{i,r}, c_{i+1,l}) - \mathcal{F}_r(U_{i-1,r}, U_{i,l}, c_{i-1,r}, c_{i,l}) = \Delta x_i\, S^c_i$$

and we prove the following result.

THEOREM 2. [illegible] $\mathcal{F}$ (11) [illegible] (12) [illegible] $n_i(t)$ [illegible] (13). [illegible] n [illegible] n [illegible] (33)–(38)

(i) [illegible] $n_i(t)$.

(ii) [illegible] (15).

(iii) [illegible] (8).

[illegible]. We first prove (i). Assume that $n_i = 0$, which means that it is a local minimum of n. Since the linear reconstruction uses slope limiters to preserve nonnegativity of n, the reconstructed linear function in this cell is flat and we have $n_{i,r} = n_{i,l} = n_i = 0$ and $n^-_{i+1/2} = n^+_{i-1/2} = 0$. Therefore, we can apply the strategy of the proof of Theorem 1 to show the scheme preserves nonnegativity of $n_i(t)$.

To show that the steady state (15) is exactly maintained, we have to prove (27) when $n_i = A\, e^{\chi(c_i)}$ and $u_i = 0$ for all i with a constant A. To this aim, we observe that since the reconstruction procedure for n is the same as that for $e^{\chi(c)}$, we have

$$\frac{n_{i,r}}{(e^{\chi(c)})_{i,r}} = \frac{n_{i,l}}{(e^{\chi(c)})_{i,l}} = A \quad \forall\, i. \tag{39}$$

Of course we also have $u_{i,r} = u_{i,l} = 0$. On the one hand, we have

$$n^-_{i+1/2} = n^+_{i+1/2} = A\,(e^{\chi(c)})_{i+1/2},$$

which gives, by the consistency of the numerical flux,

$$F_{i+1/2} = \mathcal{F}(U^-_{i+1/2}, U^+_{i+1/2}) = F((A\,(e^{\chi(c)})_{i+1/2}, 0)) = \begin{pmatrix} 0 \\ A\,(e^{\chi(c)})_{i+1/2} \end{pmatrix}. \tag{40}$$

On the other hand, from (36) and (39) we also get

$$S_i = \frac{1}{\Delta x_i}\begin{pmatrix} 0 \\ n^-_{i+1/2} - n^+_{i-1/2} \end{pmatrix} = \frac{A}{\Delta x_i}\begin{pmatrix} 0 \\ (e^{\chi(c)})_{i+1/2} - (e^{\chi(c)})_{i-1/2} \end{pmatrix}.$$

Together with the expression (40), we have proved that the steady state (15) is exactly maintained at the discrete level.

To prove consistency, we apply the same technique as that in the proof of Theorem 1, whereas the second-order accuracy is easily obtained by observing that the well-balanced scheme is only a second-order perturbation of the second-order reconstruction. Moreover, the source term S_i^c is a second-order approximation of the source term $n\,e^{-\chi(c)}\,\nabla(e^{\chi(c(x))})$. □

It seems to be difficult to extend this method to higher than second-order accurate finite volume schemes because the well-balanced requirement induces constraints on the approximation of the source term. Moreover, in dimensions higher than one, finite volume schemes higher than second-order accurate are much more expensive in terms of computational cost than finite difference schemes. Therefore, in the next section we apply the well-balanced reconstruction to a high-order Lax–Friedrichs flux splitting finite difference WENO scheme, which does not have such an inconvenience.

4. Finite difference approximation. In this section we first briefly review some of the basics of the high-order finite difference approximation and the WENO reconstruction; for more details, see [12, 22]. We then adapt the well-balanced reconstruction to high-order finite difference WENO schemes. In this section we assume the mesh is uniform with mesh size Δx.

4.1. High-order finite difference WENO approximation for hyperbolic systems. A conservative finite difference spatial discretization to a hyperbolic system such as (4) approximates the derivative by a kth-order accurate conservative difference

$$\left.\frac{\partial F(U)}{\partial x}\right|_{x=x_i} = \frac{1}{\Delta x}\left(\hat{F}_{i+1/2} - \hat{F}_{i-1/2}\right) + O(\Delta x^k),$$

where $\hat{F}_{i+1/2}$ is the numerical flux, which typically is a Lipschitz continuous function of several neighboring values of $U = (n, nu)$. For the details of the numerical reconstruction of the flux $\hat{F}_{i+1/2}$ from the point values of $F(U)$, we refer to [12, 22]. Notice that the finite difference methods have the same format for one or more space dimensions, which is a major advantage in terms of accuracy and computational cost in dimensions higher than one.

In many applications the numerical flux $\hat{F}_{i+1/2}$ is obtained by the Lax–Friedrichs flux splitting

$$F^{\pm}(U) = \frac{1}{2}(F(U) \pm \alpha\, U), \qquad \alpha = \max_{m,U} |\lambda_m(U)|, \tag{41}$$

where $(\lambda_m(U))_m$ are the eigenvalues of the Jacobian $F'(U)$ and the maximum is taken over the relevant range of U. We will adopt this flux splitting in our scheme. The WENO procedure is used to reconstruct the numerical flux functions for $F^+(U)$ and $F^-(U)$ separately via upwinding.

For schemes higher than second-order accurate, the procedure should be carried out in local characteristic fields to avoid spurious oscillations. Thus one would first find an average $U_{i+1/2}$ of U_i and U_{i+1} (e.g., the Roe average [20], which exists for many physical systems), and then compute the left and right eigenvectors of the Jacobian $F'(U_{i+1/2})$ and put them into the rows of $R^{-1}_{i+1/2}$ and the columns of $R_{i+1/2}$, respectively, such that

$$R^{-1}_{i+1/2}\, F'(U_{i+1/2})\, R_{i+1/2} = \Lambda_{i+1/2},$$

where $\Lambda_{i+1/2}$ is a diagonal matrix containing the real eigenvalues of $F'(U_{i+1/2})$. One then transforms all the quantities needed for evaluating the numerical flux $\hat{F}_{i+1/2}$ to the local characteristic fields by left multiplying them with $R^{-1}_{i+1/2}$, and then computes the numerical fluxes by the scalar procedure in each characteristic field. Finally, the flux in the original physical space is obtained by left multiplying by $R_{i+1/2}$ the numerical flux obtained in the local characteristic fields.

We refer to [12, 22] for more details on WENO schemes and conservative finite difference methods.

4.2. A well-balanced reconstruction. In this section, we describe the strategy for obtaining a kth-order well-balanced finite difference WENO scheme for arbitrary k. From the previous description, we have constructed a numerical flux using the characteristic Lax–Friedrichs flux splitting and obtained a kth-order approximation of the flux $\hat{F}_{i+1/2}$ via WENO reconstruction. Then, we have

$$\hat{F}_{i+1/2} = \hat{F}^{+}_{i+1/2} + \hat{F}^{-}_{i+1/2},$$

with

$$\hat{F}^{+}_{i+1/2} = R_{i+1/2}\left(R^{-1}_{i+1/2}\left(\,F(U) \,+\, \alpha\, U\,\right)\right)_{i,r}, \tag{42}$$

$$\hat{F}^{-}_{i+1/2} = R_{i+1/2}\left(R^{-1}_{i+1/2}\left(\,F(U) \,-\, \alpha\, U\,\right)\right)_{i+1,l}, \tag{43}$$

where $(\cdot)_{i,r}$ and $(\cdot)_{i+1,l}$ denote high-order WENO reconstructions at the cell boundary $x_{i+1/2}$ from the cells $(x_{i-1/2}, x_{i+1/2})$ and $(x_{i+1/2}, x_{i+3/2})$, respectively.

We now modify the numerical flux $\hat{F}^{\pm}_{i+1/2}$ to achieve the well-balanced property. The well-balanced finite difference scheme approximating (8) has the form

$$\Delta x \frac{d}{dt} U_i(t) + F_{i+1/2} - F_{i-1/2} = n_i\, e^{-\chi(c_i)} \begin{pmatrix} 0 \\ S_{i+1/2} - S_{i-1/2} \end{pmatrix} - \sigma \begin{pmatrix} 0 \\ n_i\, u_i \end{pmatrix}, \tag{44}$$

where $S_{i+1/2} - S_{i-1/2}$ is a conservative finite difference approximation to $\Delta x\, \partial_x e^{\chi(c)}$. Indeed, from the points values $S_i = e^{\chi(c_i)}$, we can reconstruct two kth-order accurate WENO or ENO [24] fluxes $S_{i+1/2}$, one from the interval $(x_{i-1/2}, x_{i+1/2})$ denoted by $S_{i,r}$ (the same reconstruction procedure used for computing $\hat{F}^{+}_{i+1/2}$), and the other from the interval $(x_{i+1/2}, x_{i+3/2})$ denoted by $S_{i+1,l}$ (the same reconstruction procedure used for computing $\hat{F}^{-}_{i+1/2}$). Finally, we choose, for instance,

$$S_{i+1/2} = \max\left(S_{i,r}, S_{i+1,l}\right). \tag{45}$$

Now, the numerical flux $F_{i+1/2}$ for the well-balanced scheme (44) is constructed from the following perturbation from the classical WENO flux $\hat{F}_{i+1/2}$:

$$F^{+}_{i+1/2} = \hat{F}^{+}_{i+1/2}\, \frac{S_{i+1/2}}{S_{i,r}}, \qquad F^{-}_{i+1/2} = \hat{F}^{-}_{i+1/2}\, \frac{S_{i+1/2}}{S_{i+1,l}}. \tag{46}$$

For this algorithm, we prove the following result.

THEOREM 3. [illegible] (8). [illegible] (44)–(46)

(i) [illegible] (15) [illegible] ε [illegible] $\varepsilon = 10^{-6}$ [12];

(ii) [illegible] (8).

[illegible]. We first prove (i). Assume that the steady state (15) is achieved,

$$n_i = A\, e^{\chi(c_i)}, \quad u_i = 0 \quad \forall\, i.$$

Then, for such a discrete solution $U_i = (n_i, u_i)$ the Lax–Friedrichs flux splitting is computed as

$$R^{-1}_{i+1/2} = \begin{pmatrix} 1 & 1 \\ -1 & 1 \end{pmatrix}, \qquad R_{i+1/2} = \begin{pmatrix} 1/2 & -1/2 \\ 1/2 & 1/2 \end{pmatrix},$$

which do not vary with i. This leads to

$$\Big(R^{-1}_{i+1/2}\,(\,F(U) + \alpha\, U\,)\Big)_{i,r} = \left(n \begin{pmatrix} 1+\alpha \\ 1-\alpha \end{pmatrix}\right)_{i,r},$$

$$\Big(R^{-1}_{i+1/2}\,(\,F(U) - \alpha\, U\,)\Big)_{i+1,l} = \left(n \begin{pmatrix} 1-\alpha \\ 1+\alpha \end{pmatrix}\right)_{i+1,l}.$$

Now we use the property of the ENO reconstruction [24] that for any constant λ,

$$(\lambda\, n)_{i,r} = \lambda\,(n)_{i,r}, \qquad (\lambda\, n)_{i+1,l} = \lambda\,(n)_{i+1,l}, \tag{47}$$

whereas for the WENO reconstruction,

$$(\lambda\, n)_{i,r} = \lambda\,(n)_{i,r} + O(\varepsilon), \qquad (\lambda\, n)_{i+1,l} = \lambda\,(n)_{i+1,l} + O(\varepsilon),$$

where ε is the small parameter used in the smooth indicator to avoid having the denominator become zero and typically takes the value $\varepsilon = 10^{-6}$ [12]. From now on we will use (47) in the analysis. Then, we get

$$\Big(R^{-1}_{i+1/2}\,(\,F(U) + \alpha\, U\,)\Big)_{i,r} = \begin{pmatrix} 1+\alpha \\ 1-\alpha \end{pmatrix} n_{i,r},$$

$$\Big(R^{-1}_{i+1/2}\,(\,F(U) - \alpha\, U\,)\Big)_{i+1,l} = \begin{pmatrix} 1-\alpha \\ 1+\alpha \end{pmatrix} n_{i+1,l}.$$

When the steady state (15) is achieved, the classical finite difference flux is given by

$$\hat{F}^{+}_{i+1/2} = n_{i,r} \begin{pmatrix} \alpha \\ 1 \end{pmatrix}, \qquad \hat{F}^{-}_{i+1/2} = n_{i+1,l} \begin{pmatrix} -\alpha \\ 1 \end{pmatrix}.$$

On the one hand, when the steady state (15) is reached, we know that

$$n_i = A\, e^{\chi(c_i)} \quad \forall\, i,$$

and since the reconstruction procedures for n and $e^{\chi(c)}$ are identical (using WENO or ENO reconstruction), we have

$$\hat{F}^{+}_{i+1/2} = A \begin{pmatrix} \alpha \\ 1 \end{pmatrix} S_{i,r}, \qquad \hat{F}^{-}_{i+1/2} = A \begin{pmatrix} -\alpha \\ 1 \end{pmatrix} S_{i+1,l}.$$

Then, by the definition of $F^{\pm}_{i+1/2}$ in (46), we get

$$F_{i+1/2} = A \begin{pmatrix} 0 \\ 1 \end{pmatrix} S_{i+1/2}.$$

On the other hand, by the construction of the source term (44),

$$S_i = n_i\, e^{-\chi(c_i)} \begin{pmatrix} 0 \\ 1 \end{pmatrix} \left(S_{i+1/2} - S_{i-1/2}\right).$$

When the steady state (15) is reached, we have $n_i\, e^{-\chi(c_i)} = A$ for all i; hence,

$$S_i = A \begin{pmatrix} 0 \\ 1 \end{pmatrix} (S_{i+1/2} - S_{i-1/2}),$$

which exactly satisfies the balance with the flux difference $F_{i+1/2} - F_{i-1/2}$.

Now let us prove (ii); i.e., the numerical scheme is a kth-order approximation to (8). The source term can be written in the form

$$n\,\chi'(c)\frac{\partial c}{\partial x} = n\, e^{-\chi(c)}\, \frac{\partial}{\partial x} e^{\chi(c)}$$

and clearly the right-hand side of (44) is a kth-order approximation to this source term when the flux $S_{i+1/2}$ is defined by (45), since both $S_{i,r}$ and $S_{i+1,l}$ are kth-order fluxes computed by WENO reconstruction. Also, it is obvious that $F^{\pm}_{i+1/2}$ is only a kth-order perturbation of the original kth-order accurate WENO flux $\hat{F}^{\pm}_{i+1/2}$, since the difference between $S_{i,r}$ and $S_{i+1,l}$ is at the level of truncation error for the kth-order WENO reconstruction. This demonstrates that the scheme (44) is kth-order accurate. ∎

5. Numerical simulations.

5.1. Accuracy test in one dimension. In this example, we consider the one-dimensional hyperbolic system (8) with $\chi'(c) = \frac{1}{1+c}$,

$$\begin{cases} \dfrac{\partial n}{\partial t} + \dfrac{\partial (nu)}{\partial x} = 0, \\ \dfrac{\partial (nu)}{\partial t} + \dfrac{\partial}{\partial x}\left(nu^2 + n\right) = \dfrac{n}{1+c}\,\dfrac{\partial c}{\partial x} - \sigma\, nu. \end{cases} \tag{48}$$

We take periodic boundary conditions, $\sigma = 1$, $t \in [0, T_{end}]$, with $T_{end} = 1$ and smooth initial data

$$n(0,x) = 1 \,+\, 0.2\,\cos(\pi\, x), \quad u(0,x) = 0, \quad x \in [-1,1],$$

whereas the chemo-attractant c is fixed to

$$c(x) = \exp(-16\, x^2), \quad x \in [-1,1].$$

This system does not admit an explicit solution, but to evaluate the error and the order of accuracy we first compute an accurate approximation using the fifth-order accurate classical WENO scheme with 1600 points and compare different numerical solutions with this reference solution. To show the advantage of the well-balanced

TABLE 1
Comparison of L^1 errors and numerical orders of accuracy for the classical WENO scheme and well-balanced WENO scheme with fourth-order Runge–Kutta time discretization.

TABLE 2
Comparison of L^1 errors and numerical orders of accuracy for a second-order finite volume scheme and well-balanced finite volume scheme with second-order Runge–Kutta time discretization.

Number of points	Finite volume		Well-balanced finite volume	
	L^1 error	order	L^1 error	order
50	1.13E-02		8.01E-03	
100	2.94E-03	1.94	2.30E-03	1.80
200	7.74E-04	1.92	6.01E-04	1.94
400	2.01E-04	1.94	1.58E-04	1.93

algorithm, we compare a fifth-order WENO finite difference scheme with and without the well-balanced reconstruction (presented in section 4) coupled with a fourth-order Runge–Kutta scheme for the time discretization.

In Table 1, we present the L^1 errors and numerical orders of accuracy obtained from both schemes. We observe that both methods achieve orders of accuracy above four and the well-balanced approach not only preserves the high-order accuracy, but also in this case allows us to reduce the error even if the solution is far from the equilibrium. We also give in Table 2 the L^1 errors and numerical orders of accuracy for the second-order finite volume monotone upstream-centered scheme for conservation laws (MUSCL) [16], namely, a linear reconstruction based on the usual minmod limiters,

$$\operatorname{minmod}(a,b) = \frac{sign(a) + sign(b)}{2} \min(|a|,|b|),$$

the Lax–Friedrichs monotone numerical flux, and the second-order TVD time discretization [23], with and without the well-balanced reconstruction presented in section 3. Second order is well achieved but the numerical errors are large compared to those obtained from the WENO scheme on the same mesh.

To test the steady state conservation, we consider the steady state solution

$$n_0(x) = (1 + c(x))/10, \quad u(0,x) = 0, \tag{49}$$

where c is given by

$$c_0(x) = \begin{cases} 1 & \text{if } |x| \le 1/2, \\ 0.125 & \text{else.} \end{cases} \tag{50}$$

We compute the numerical solution using the WENO scheme with and without the well-balanced reconstruction and observe that the density n and the population flux nu are exactly conserved up to the round-off error with the well-balanced reconstruction, whereas spurious oscillations are generated when a centered approximation of

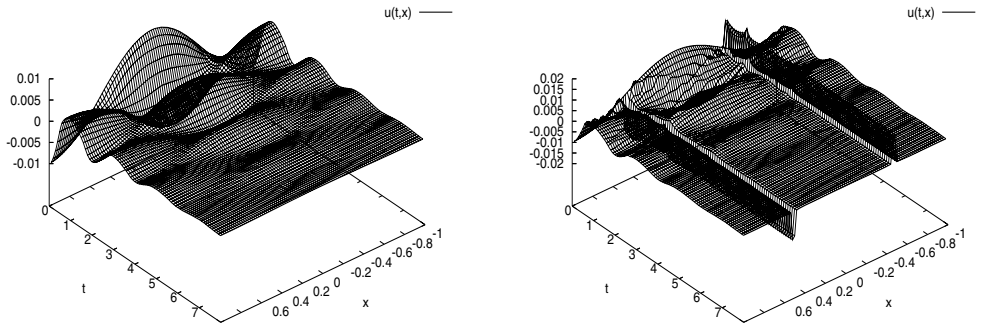

FIG. 1. *Accuracy test for well-balanced steady state resolution: time evolution of the population flux $n(t,x)\ u(t,x)$. Left: WENO scheme with the well-balanced reconstruction. Right: WENO schemes with a centered approximation of the source term.*

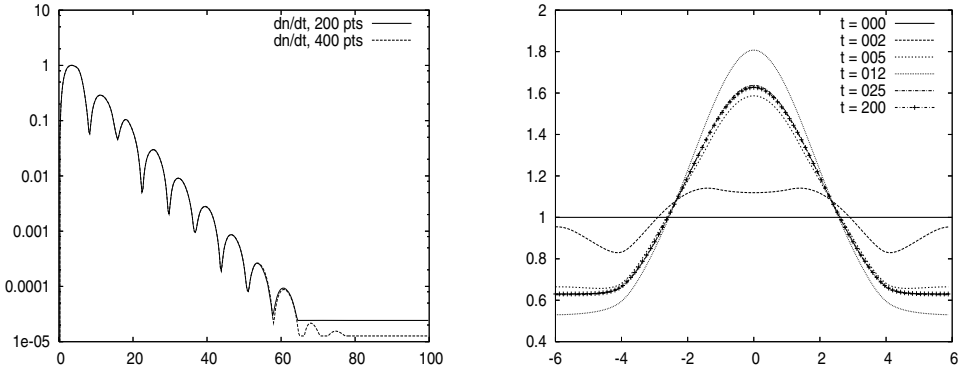
the source term is used. In Figure 1, we also present the numerical results obtained for a perturbation of the steady state: $n(t=0,x)$ and $c(t=0,x)$ are given by (49)–(50) and

$$u(t,x) = 0.01\,\cos(\pi x), \quad x \in [-1,1].$$

Then, some spurious oscillations appear in the population flux close to the discontinuities of the source term c when a centered approximation to the source term is used.

5.2. Convergence to the equilibrium in one dimension. Now we perform numerical simulations using the well-balanced fifth-order WENO finite difference scheme to observe the long time behavior of the solution to the hyperbolic model (48) with $\sigma = 0.25$ and $x \in [-6,6]$ with periodic boundary conditions, with the chemo-attractant c being the solution of the parabolic equation



$$\begin{cases} \dfrac{\partial c}{\partial t} - \dfrac{1}{10}\dfrac{\partial^2 c}{\partial x^2} = \alpha\, n - c, \\ \\ c(t,-6) = c(t,6) = 0, \end{cases}$$

and α a given compactly supported function

$$\alpha(x) = \begin{cases} (16-x^2)/16 & \text{if } |x| \le 4, \\ 0 & \text{else.} \end{cases}$$

The initial density is chosen as a constant density $n = 1$, whereas the initial population flux $n\ u$ and chemo-attractant c are equal to zero.

To observe the convergence to an equilibrium state we plot in Figure 2 the evolution of the L^1 norm of the time derivative of the cell density $\partial_t n$. We also plot the evolution of the cell density on different time intervals and at the final time ($t = 200$) when the steady state is reached. Clearly, the curves at $t = 25$ and $t = 200$ are overlapping, indicating that the numerical solution has already converged to steady state by visual inspection at $t = 25$.

FIG. 2. *Convergence to equilibrium.* (a) *Time evolution of the* L^1 *norm of the time derivative of the cell density* $\partial_t n(t,x)$. (b) *Time evolution of the cell density* $n(t,x)$ *for* $t = 0$, 2, 5, 12, 25, *and* 200.

5.3. Chemosensitive movement in two dimensions. In the previous two numerical examples, we have shown the efficiency of the finite difference WENO method for treating the convergence to steady states and the evolution of the cell density. Now we present numerical simulations obtained with the well-balanced fifth-order (in space) finite difference method to show that the hyperbolic models can give a good description of cell motion.

We consider the system in two space dimension,

$$\begin{cases} \dfrac{\partial n}{\partial t} + \operatorname{div}(nu) = 0, \\ \dfrac{\partial (nu)}{\partial t} + \operatorname{div}\left(nu \otimes u + n\right) = n\,\nabla c - \sigma\, nu, \end{cases}$$

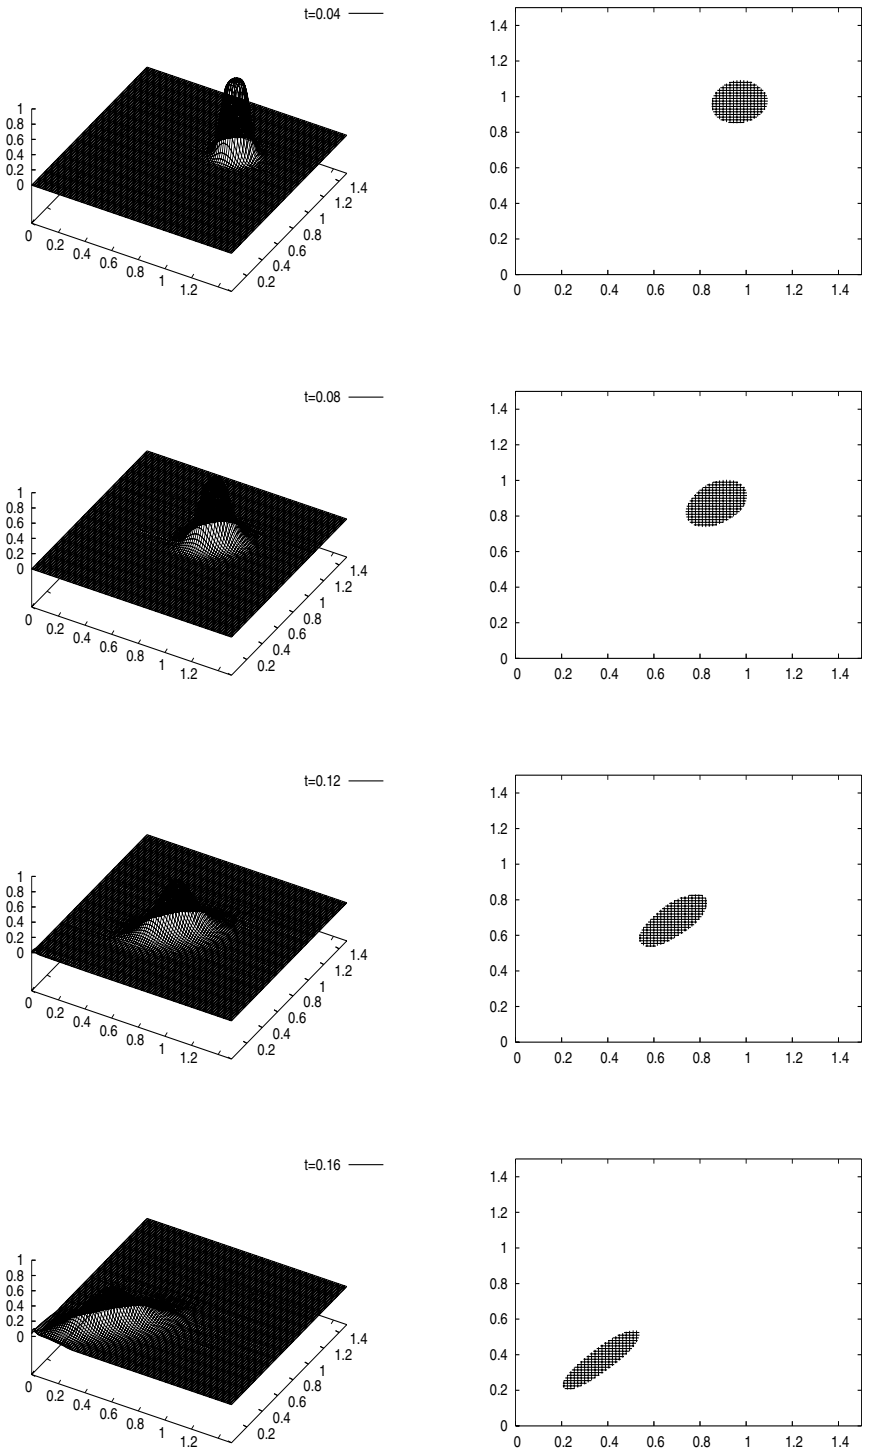
where $\sigma = 0$ and the chemo-attractant c is fixed and concentrated at the origin (0,0),

$$c(x) = 400\, \exp(-x^2)/\pi, \quad x \in [0,2]^2.$$

We then consider two cell concentrations located far from the high concentration regions of the chemo-attractant. In Figure 3, we represent the evolution of cells, which move and stretch to the highest concentration region of the chemo-attractant. This simple test illustrates the attractive effect of the chemo-attractant gradient on the population flux nu and on the cell density n.

5.4. Formation of networks. As in [21, 5], we perform numerical simulations of the hyperbolic model (4) coupled with (2) on a square box of length $L = 20$ with periodic boundary conditions. For good accuracy, we use the well-balanced fifth-order WENO scheme described in the previous section to approximate the solution of (4) and a fourth-order finite difference scheme to approximate the solution of the parabolic equation (2),

$$\frac{dc_i}{dt} = D_c\, \frac{(-c_{i+2} + 16c_{i+1} - 30c_i + 16c_{i-1} - c_{i-2})}{12\Delta x^2} + n_i - c_i.$$



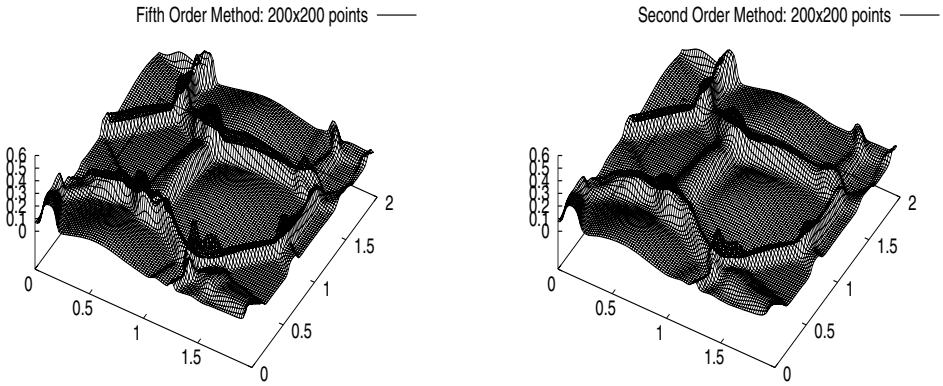


FIG. 3. *Chemosensitive movement: Time evolution of the cell density* $n(t,x)$ *at time* $t = 0.04$, 0.08, 0.12, *and* 0.16.

(a) (b)

FIG. 4. *Formation of network: comparison of numerical results between* (a) *the fifth-order WENO method and* (b) *the second-order finite volume scheme with* 200^2 *grid points.*

These results can be compared with those obtained in [4, 5] for the formation of networks: high cell concentrations are generated and linked together by line concentrations.

In (2) we take the diffusion rate $D_c = 1/10$ and also in (4) choose the pressure to be

$$P(n) = \beta\, n,$$

where $\beta = 1/4$ is the mean cell radius, $\chi'(c) = 1$, and the friction is $\sigma = 1/10$.

Now, the initial datum $n(0)$ is chosen by throwing cells randomly inside the box, with zero population flux $nu(0) = 0$ and zero concentration $c(0) = 0$ initially. More precisely, for $(x, y) \in (0, L)^2$, we choose

$$n(0, x, y) = \frac{1}{(2\,\pi\sigma)^2} \sum_{i=1}^{N} \exp\left(\frac{-\left((x - x_i)^2 + (y - y_i)^2\right)}{2\,\sigma^2} \right),$$

where $(x_i, y_i)_{1 \le i \le N}$ are uniformly distributed random variables in the box $(0, L)^2$, each Gaussian bump of width σ representing a single cell. Thus N denotes the total number of cells.

We first present a comparison between the fifth-order finite difference scheme and the second-order finite volume method to show the advantage of the high-order method. In Figure 4, we give the cell density on the square $[0, 2] \times [0, 2]$ at time $t = 0.31$ obtained with 200^2 points using the two methods. We can observe that the network is formed for both methods, but the numerical diffusion of the second-order finite volume scheme is more noticeable. We also present the cell density at time $t = 0.31$ and $x = -1.24$ for different meshes: 200^2 and 400^2 grid points for the fifth-order method, and 200^2, 400^2, and 800^2 points for the second-order method, in Figure 5. Clearly, the fifth-order WENO scheme gives results that converge faster and are more accurate than the finite volume scheme used in [4]. Even with 800^2 points, the numerical solution obtained with the second-order scheme still does not

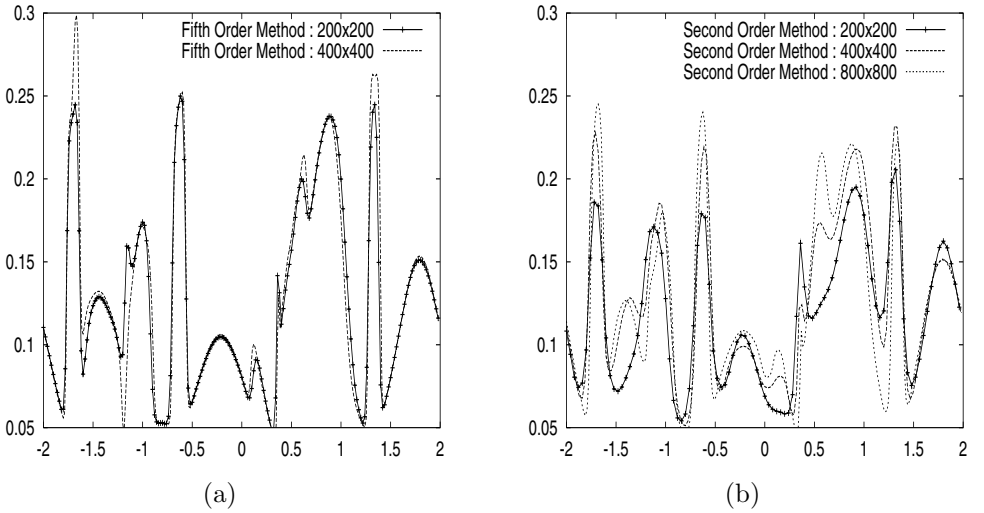

FIG. 5. *Formation of network: comparison of numerical results between* (a) *the fifth-order WENO method with* 200^2 *and* 400^2 *grid points and* (b) *the second-order finite volume scheme with* 200^2, 400^2, *and* 800^2 *grid points. Density cut at* $x = -1.24$.

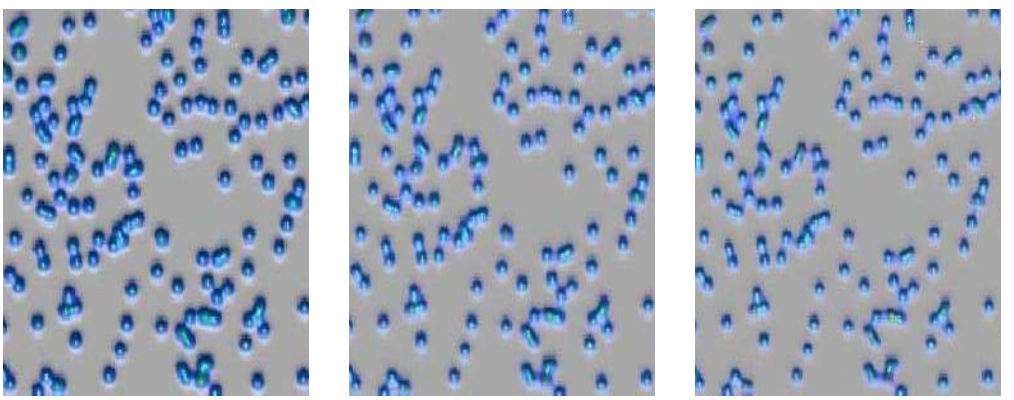

FIG. 6. *Formation of network: time evolution* ($t = 0.20$, 0.26, *and* 0.33) *of the cell density with* $N = 400$.

seem to be of the quality of the solution obtained with the fifth-order one using only 200^2 points, in terms of capturing the complicated features in the solution.

Finally, we present different numerical simulations when the initial total cell density N varies. Figures 6 and 7 represent a zoom of the cell density evolution for different initial concentrations ($N = 400$, 800, and 1200). On the one hand, in Figure 6 we observe the formation of high concentration regions but the number of cells is not large enough to generate a network. Indeed, a local density (representing several cells) does not interact with the surrounding densities; then local high concentrations are produced without any link to other cell densities. On the other hand, in Figure 7, cells are first uniformly located and then move to generate high concentration regions which are linked together by chords representing cells which are stretching. Finally, a network is formed as observed in the experiments [4, 21]. We cannot interpret the

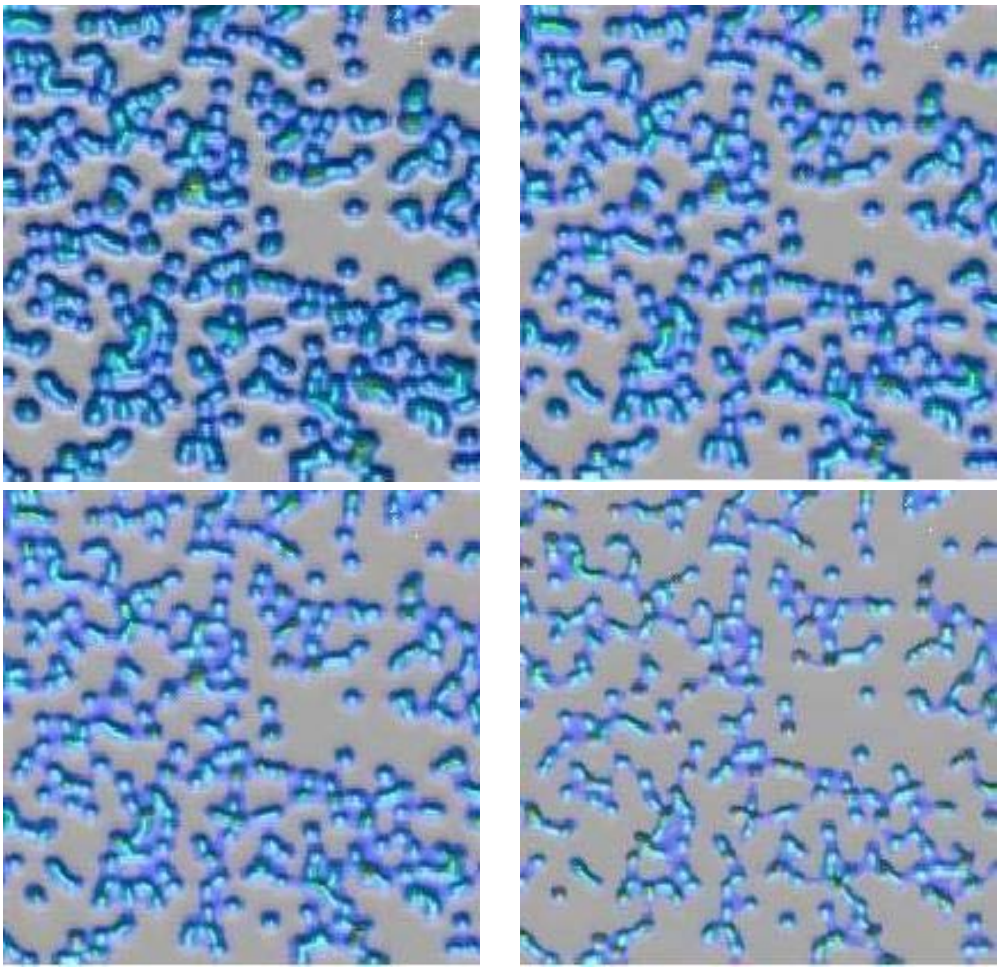

FIG. 7. *Formation of network: time evolution* ($t = 0.17$, 0.22, 0.26, *and* 0.42) *of the cell density with* $N = 800$.

results for longer time because the numerical solution blows up (cell concentrations become larger and larger), as is expected from theoretical results on other models (Euler–Poisson [14] or parabolic system PKS [9, 15]). But, the transient regime seems to be well described by the hyperbolic model. In this last example, we do not gain any advantage by using the well-balanced algorithm since the solution does not converge to a steady state, but even in this case the method works well.

AN ALGEBRAIC SUBSTRUCTURING METHOD FOR LARGE-SCALE EIGENVALUE CALCULATION*

CHAO YANG†, WEIGUO GAO‡, ZHAOJUN BAI§, XIAOYE S. LI†, LIE-QUAN LEE¶, PARRY HUSBANDS†, AND ESMOND NG†

Abstract. This paper is concerned with solving large-scale eigenvalue problems by algebraic substructuring. Algebraic substructuring refers to the process of applying matrix reordering and partitioning algorithms to divide a large sparse matrix into smaller submatrices from which a subset of spectral components are extracted and combined to form approximate solutions to the original problem. Through an algebraic analysis, we identify critical conditions under which a simple version of algebraic substructuring works well. This particular version of substructuring is identical to the component mode synthesis (CMS) method (see [R. R. Craig and M. C. C. Bampton, *Coupling of substructures for dynamic analysis*, AIAA J., 6 (1968), pp. 1313–1319] and [W. C. Hurty, *Vibrations of structure systems by component-mode synthesis*, J. Engrg. Mech., 86 (1960), pp. 51–69]) when the matrix reordering is based on a geometric partitioning of the computational domain. We observe an interesting connection between the accuracy of an approximate eigenpair obtained through substructuring and the distribution of the components of eigenvectors of a canonical matrix pencil congruent to the original problem. A priori error bounds for the smallest eigenpair approximation are developed. This development leads to a simple heuristic for choosing spectral components (modes) from each substructure. The effectiveness of such a heuristic is demonstrated with numerical examples. We show that algebraic substructuring can be effectively used to solve a generalized eigenvalue problem arising from the finite element analysis of an accelerator structure.

1. Introduction.

Substructuring is a commonly used technique for studying the static or dynamic properties of large engineering structures [11, 12, 23, 17]. The basic idea of substructuring is analogous to the concept of domain decomposition, which is widely used in the numerical solution of partial differential equations [28, 25]. By dividing a large structure model or computational domain into a few smaller components (substructures), one can often obtain an approximate solution to the original problem from a linear combination of solutions to similar problems defined on the

substructures. Because solving problems on each substructure requires far less computational power than what would be required to solve the entire problem as a whole, substructuring can lead to a significant reduction in the computational time required to carry out a large-scale simulation and analysis.

The automated multilevel substructuring (AMLS) method [5, 6, 7, 18] is an extension of a substructuring method called [illegible] (CMS) [11, 17] originally developed in the 1960s. Recent studies have shown that AMLS can be used successfully in the vibration and acoustic analysis of large-scale finite element models of automobile bodies [18, 21]. The frequency response analysis performed in these studies requires computing several thousand eigenvalues and eigenvectors associated with a large-scale symmetric generalized eigenvalue problem. The timing results reported in [18, 21] indicate that AMLS is significantly faster than conventional Lanczos-based approaches [22, 16].

It is important to note that the accuracy achieved by a substructuring method such as AMLS is typically lower than that achieved by the standard Lanczos algorithm. However, in many applications, the level of accuracy required for an approximate solution to an algebraic problem is no more than what is provided by the finite element scheme used to discretize the original continuous problem. Thus, the use of substructuring is easily justified as long as the error associated with the substructuring approximation does not exceed that produced by the finite element discretization.

Asymptotic analysis is performed in [8, 9] to assess the level of accuracy attainable by the CMS method. The analysis is based on the standard finite element theory and properties of the partial differential equation governing the evolution of the structure. The recent work described in [7] provides a high-level mathematical description of the AMLS in a continuous variational setting. However, neither of these studies provides a satisfactory algebraic explanation on why substructuring works well in practice.

Our focus in this paper is on examining substructuring methods for solving large-scale eigenvalue problems from a purely algebraic point of view. We use the term [illegible] to refer to the process of applying matrix reordering and partitioning algorithms (such as the [illegible] algorithm [15]) to divide a large sparse matrix into smaller submatrices from which a subset of spectral components are extracted and combined to form an approximate solution to the original eigenvalue problem. Through algebraic manipulation, we identify the critical conditions under which a simple version of algebraic substructuring works well. This particular version of substructuring is identical to the CMS method when the matrix reordering is based on the geometric partitioning of the computational domain. We observe an interesting connection between the accuracy of an approximate eigenpair obtained through substructuring and the distribution of components of eigenvectors associated with a canonical matrix pencil congruent to the original problem. An error estimate for the approximation to the smallest eigenpair is developed. The estimate leads to a simple heuristic for choosing spectral components (modes) from each substructure. The effectiveness of such a heuristic is demonstrated with numerical examples. Our analysis is related to but different from the recent work by Bekas and Saad [4], who view algebraic substructuring as an approximation to the spectral Schur complement method [1, 2, 10].

Our interest in algebraic substructuring is motivated in part by an application arising from the simulation of the electromagnetic field associated with the next generation particle accelerator design [20]. We will show through a numerical example that algebraic substructuring can be used effectively to compute the cavity resonance frequencies and the electromagnetic field generated by a linear particle accelerator

model.

Our presentation is organized as follows. In section 2, we give a brief overview of the algorithmic ingredients of a simple algebraic substructuring method. The accuracy of the approximate eigenpairs is analyzed in section 3. Our analysis of algebraic substructuring is confirmed by numerical examples presented in section 4.

Throughout this paper, uppercase and lowercase Latin letters denote matrices and vectors, respectively, while lowercase Greek letters denote scalars. An $n \times n$ identity matrix will be denoted by I_n. The jth column of the identity matrix is denoted by e_j. The transpose of a matrix A is denoted by A^T. We use $\|x\|$ to denote the standard 2-norm of x and use $\|x\|_M$ to denote the M-norm defined by $\|x\|_M = \sqrt{x^T M x}$. We will use $\angle_M(x, y)$ to denote the M inner product induced acute angle (M-angle for short) between x and y. This angle can be computed from

$$\cos \angle_M(x, y) = \frac{x^T M y}{\|x\|_M \|y\|_M}.$$

Similarly, we use $\angle_M(x, \mathcal{S})$ to denote the M-angle between a vector x and a subspace $\mathcal{S}$. This angle can be computed from

$$\cos \angle_M(x, \mathcal{S}) = \frac{\|Q^T M x\|_2}{\|x\|_M}, \tag{1}$$

where Q is an M-orthonormal basis of the subspace $\mathcal{S}$; i.e., $\mathcal{S} = \text{span}\{S\}$ and $Q^T M Q = I$.

A matrix pencil (K, M) is said to be [illegible] if both K and M are symmetric and M is positive definite. A matrix pencil (K, M) is said to be [illegible] to another pencil (A, B) if there exists a nonsingular matrix P such that $A = P^T K P$ and $B = P^T M P$.

2. Algebraic substructuring. In this section, we briefly describe a single-level algebraic substructuring algorithm. Our description does not use any information regarding the geometry or the physical structure on which the original problem is defined.

We are concerned with solving the generalized algebraic eigenvalue problem

$$Kx = \lambda M x, \tag{2}$$

where K is symmetric and M is symmetric positive definite. We assume both K and M are sparse. They may or may not have the same sparsity pattern. Suppose the rows and columns of K and M have been permuted so that these matrices can be partitioned as

$$K = \begin{array}{c} \\ n_1 \\ n_2 \\ n_3 \end{array} \begin{array}{c} \begin{array}{ccc} n_1 & n_2 & n_3 \end{array} \\ \begin{pmatrix} K_{11} & & K_{13} \\ & K_{22} & K_{23} \\ K_{13}^T & K_{23}^T & K_{33} \end{pmatrix} \end{array} \quad \text{and} \quad M = \begin{array}{c} \\ n_1 \\ n_2 \\ n_3 \end{array} \begin{array}{c} \begin{array}{ccc} n_1 & n_2 & n_3 \end{array} \\ \begin{pmatrix} M_{11} & & M_{13} \\ & M_{22} & M_{23} \\ M_{13}^T & M_{23}^T & M_{33} \end{pmatrix} \end{array}, \tag{3}$$

where the labels n_1, n_2, and n_3 are inserted into the top and left borders of the partitioned matrices to indicate the dimension of each submatrix block. The permutation can be accomplished by applying a matrix ordering and partitioning algorithm, such as the nested dissection algorithm [15], to the matrix $|K| + |M|$.

The pencils (K_{11}, M_{11}) and (K_{22}, M_{22}) now define two algebraic substructures that are connected by the third block rows and columns of K and M, which we will refer to collectively as the [illegible] block. We assume that n_3 is much smaller than n_1 and n_2.

A single-level algebraic substructuring algorithm proceeds by performing a block factorization

$$K = LDL^T, \tag{4}$$

where

$$L = \begin{pmatrix} I_{n_1} & & \\ & I_{n_2} & \\ K_{13}^T K_{11}^{-1} & K_{23}^T K_{22}^{-1} & I_{n_3} \end{pmatrix} \quad \text{and} \quad D = \begin{pmatrix} K_{11} & & \\ & K_{22} & \\ & & \widehat{K}_{33} \end{pmatrix}.$$

The last diagonal block of D, often known as the [illegible], is defined by

$$\widehat{K}_{33} = K_{33} - K_{13}^T K_{11}^{-1} K_{13} - K_{23}^T K_{22}^{-1} K_{23}.$$

The inverse of the lower triangular factor L defines a congruence transformation that, when applied to the matrix pencil (K, M), yields a new matrix pencil $(\widehat{K}, \widehat{M})$:

$$\widehat{K} = L^{-1} K L^{-T} = D \quad \text{and} \quad \widehat{M} = L^{-1} M L^{-T} = \begin{pmatrix} M_{11} & & \widehat{M}_{13} \\ & M_{22} & \widehat{M}_{23} \\ \widehat{M}_{13}^T & \widehat{M}_{23}^T & \widehat{M}_{33} \end{pmatrix}. \tag{5}$$

The off-diagonal blocks of $\widehat{M}$ satisfy

$$\widehat{M}_{i3} = M_{i3} - M_{ii} K_{ii}^{-1} K_{i3} \quad \text{for} \quad i = 1, 2.$$

The last diagonal block of $\widehat{M}$ satisfies

$$\widehat{M}_{33} = M_{33} - \sum_{i=1}^{2} (K_{i3}^T K_{ii}^{-1} M_{i3} + M_{i3}^T K_{ii}^{-1} K_{i3} - K_{i3}^T K_{ii}^{-1} M_{ii} K_{ii}^{-1} K_{i3}).$$

The pencil $(\widehat{K}, \widehat{M})$ is often called the [illegible] form [11] in structural engineering. Note that the eigenvalues of $(\widehat{K}, \widehat{M})$ are identical to those of (K, M), and the corresponding eigenvectors $\widehat{x}$ are related to the eigenvectors of the original problem (2) through $\widehat{x} = L^T x$.

The substructuring algorithm constructs a subspace in the form of

$$S = \begin{array}{c} \\ n_1 \\ n_2 \\ n_3 \end{array} \begin{array}{c} \begin{array}{ccc} k_1 & k_2 & n_3 \end{array} \\ \begin{pmatrix} S_1 & & \\ & S_2 & \\ & & I_{n_3} \end{pmatrix} \end{array}, \tag{6}$$

where S_1 and S_2 consist of k_1 and k_2 selected eigenvectors of (K_{11}, M_{11}) and (K_{22}, M_{22}), respectively. These eigenvectors will be referred to as [illegible] in the discussion that follows. Note that k_1 and k_2 are typically much smaller than n_1 and n_2, respectively.

The approximation to the desired eigenvalues and eigenvectors of the pencil $(\widehat{K}, \widehat{M})$ is obtained by projecting the pencil $(\widehat{K}, \widehat{M})$ onto the subspace spanned by S; i.e., we seek θ and $q \in \mathbb{R}^{k_1+k_2+n_3}$ such that

$$(S^T \widehat{K} S)q = \theta(S^T \widehat{M} S)q. \tag{7}$$

It follows from the standard Rayleigh–Ritz theory [24, p. 213] that θ serves as an approximation to an eigenvalue of (K, M), and the vector formed by $z = L^{-T}Sq$ is the approximation to the corresponding eigenvector.

A summary of the single-level algebraic substructuring algorithm described in this section is provided below.

ALGORITHM. Single-level algebraic substructuring.

Input: A matrix pencil (K, M), where $K = K^T$ and $M = M^T > 0$;
Output: $\theta_j \in \mathbb{R}$ and $z_j \in \mathbb{R}^n$, $(j = 1, 2, \ldots, k)$ such that $Kz_j \approx \theta_j M z_j$.

1. Order K and M to be in the form of (3);
2. Perform block factorization $K = LDL^T$;
3. Compute a subset of eigenpairs of the substructures (K_{11}, M_{11}) and (K_{22}, M_{22}). The eigenvectors of each substructure form the columns of S_1 and S_2, respectively;
4. Project the matrix pencil (K, M) into subspace spanned by columns of $Z = L^{-T}S$, where S is defined by (6);
5. Compute k desired eigenpairs (θ_j, q_j) from $(Z^T K Z, Z^T M Z)$, and set $z_j = Zq_j$ $(j = 1, 2, \ldots, k)$; apply the inverse of the permutation used in step 1 to z_j to restore the original order of the solution.

A few remarks are in order.

- Note that the most expensive computational task associated with this algorithm is the block factorization $K = LDL^T$ and the congruence transformation of M required for projecting M into the subspace spanned by $Z = L^{-T}S$. These computational tasks must be carried out with care in order to reduce memory requirements and floating point operations. However, it is beyond the scope of this paper to discuss these important implementation issues.
- Since $k_1 \ll n_1$ and $k_2 \ll n_2$, step 3 of the algorithm can be carried out by using a shift-invert Lanczos algorithm to obtain a small number of desired eigenpairs from each substructure. The cost of this computation is generally small compared to the rest of the computation, especially when this algorithm is extended to a multilevel scheme.
- Similarly, because n_3 is typically much smaller than n_1 and n_2, the dimension of the projected problem (7) is significantly smaller than that of the original problem. Thus, the cost of solving (7) is also small compared to step 2 of the algorithm.
- Decisions must be made on how to select eigenvectors from each substructure. The selection should be made in such a way that the subspace spanned by the columns of Z retains a sufficient amount of spectral information from (K, M). The process of choosing appropriate eigenvectors from each substructure will be referred to as [illegible]. We will postpone the discussion on this key aspect of the algebraic substructuring algorithm until the next section.

The algebraic substructuring algorithm we presented above becomes identical to the CMS method [11, 17] when the permutation of the pencil in (3) is derived from a

geometric partitioning of the computational domain. The algorithm can be extended in two ways. First, the matrix reordering and partitioning scheme used to create the block structure of (3) can be applied recursively to (K_{11}, M_{11}) and (K_{22}, M_{22}), respectively, to produce a multilevel division of (K, M) into smaller submatrices. The reduced computational cost associated with finding selected eigenpairs from these even smaller submatrices further improves the efficiency of the algorithm. Second, one may replace I_{n_3} in (6) with a subset of eigenvectors of the interface pencil $(\widehat{K}_{33}, \widehat{M}_{33})$. This modification will further reduce the computational cost associated with solving the projected eigenvalue problem (7). A combination of these two extensions yields the AMLS algorithm presented in [18, 7]. However, we will limit the scope of our presentation to a single-level substructuring algorithm.

3. Accuracy and error estimation. Algebraic substructuring allows one to break a large-scale eigenvalue problem into a set of smaller subproblems that are easier to solve. The algorithm would be less attractive to use if one had to compute all eigenvalues and eigenvectors of each subproblem. Fortunately, such a calculation is not necessary, as we will show in this section. In practice, only a small subset of the eigenvectors of (K_{11}, M_{11}) and (K_{22}, M_{22}) is needed to assemble the projection subspace spanned by the columns of the matrix S in (6). To simplify the analysis, we will work with the matrix pencil $(\widehat{K}, \widehat{M})$, where $\widehat{K}$ and $\widehat{M}$ are defined as in (5). As we noted earlier, $(\widehat{K}, \widehat{M})$ and (K, M) have the same set of eigenvalues. If $\widehat{x}$ is an eigenvector of $(\widehat{K}, \widehat{M})$, then $x = L^{-T}\widehat{x}$ is an eigenvector of (K, M), where L is the transformation defined in (4).

Let $(\mu_j^{(i)}, v_j^{(i)})$ be the jth eigenpair of the ith subproblem, i.e.,

$$K_{ii} v_j^{(i)} = \mu_j^{(i)} M_{ii} v_j^{(i)},$$

where $v_j^{(i)}$ is M_{ii}-orthonormal, i.e.,

$$(v_j^{(i)})^T M_{ii} v_k^{(i)} = \begin{cases} 1, & j = k, \\ 0, & \text{otherwise.} \end{cases}$$

To simplify our discussion, we assume that $\mu_j^{(i)}$ has been ordered such that

$$\mu_1^{(i)} \le \mu_2^{(i)} \le \cdots \le \mu_{n_i}^{(i)}. \tag{8}$$

Let us define $V_i = (v_1^{(i)} v_2^{(i)}, \ldots, v_{n_i}^{(i)})$, $V = \mathrm{diag}(V_1, V_2, I_{n_3})$ and $\Lambda_i = \mathrm{diag}(\mu_1^{(i)}, \mu_2^{(i)}, \ldots, \mu_{n_i}^{(i)})$. An eigenvector of $(\widehat{K}, \widehat{M})$, say $\widehat{x}$, can be expressed as a linear combination of columns of V. That is,

$$\widehat{x} = Vy = \begin{pmatrix} V_1 & & \\ & V_2 & \\ & & I_{n_3} \end{pmatrix} \begin{pmatrix} y_1 \\ y_2 \\ y_3 \end{pmatrix}, \tag{9}$$

where $y = (y_1^T, y_2^T, y_3^T)^T$ is an eigenvector of the generalized eigenvalue problem

$$\begin{pmatrix} \Lambda_1 & & \\ & \Lambda_2 & \\ & & \widehat{K}_{33} \end{pmatrix} \begin{pmatrix} y_1 \\ y_2 \\ y_3 \end{pmatrix} = \lambda \begin{pmatrix} I_{n_1} & & G_{13} \\ & I_{n_2} & G_{23} \\ G_{13}^T & G_{13}^T & \widehat{M}_{33} \end{pmatrix} \begin{pmatrix} y_1 \\ y_2 \\ y_3 \end{pmatrix}, \tag{10}$$

where $G_{13} = V_1^T \widehat{M}_{13}$ and $G_{23} = V_2^T \widehat{M}_{23}$. Note the matrix pencil defined by (10) can be obtained by applying V^T from the left to $\widehat{K}\widehat{x} = \lambda \widehat{M}\widehat{x}$ and expressing $\widehat{x}$ by $\widehat{x} = Vy$. This pencil is clearly congruent to the pencils $(\widehat{K}, \widehat{M})$ and (K, M). Thus they share the same set of eigenvalues. We will refer to (10) as a [illegible] of the generalized eigenvalue problem (2).

If $\widehat{x}$ can be well approximated by a linear combination of the columns of S, as suggested by the description of the algorithm in section 2, then the vectors y_1 and y_2 must contain only a few large entries. All other components of y_1 and y_2 are likely to be small and negligible. In this section, we seek to formalize this key concept by developing a priori error bounds for the approximations to the smallest eigenvalue of $(\widehat{K}, \widehat{M})$ and the corresponding eigenvector. As we will see below, these bounds can be expressed in terms of the small components of y_1 and y_2.

Suppose $\Lambda_i - \lambda I_{n_i}$ is nonsingular, for $i = 1, 2$. It follows from the first two block rows of the canonical eigenproblem (10) that

$$y_i = \lambda(\Lambda_i - \lambda I)^{-1} G_{i3} y_3. \tag{11}$$

Consequently, we can express the jth element of y_i by

$$e_j^T y_i = \frac{\lambda}{\mu_j^{(i)} - \lambda} g_j^{(i)} = \frac{1}{\mu_j^{(i)}/\lambda - 1} g_j^{(i)}, \tag{12}$$

where $g_j^{(i)} = e_j^T G_{i3} y_3$. It is easy to see from (12) that, when $|\mu_j^{(i)}/\lambda| \approx 1$, $|e_j^T y_i|$ will be relatively large, provided $|g_j^{(i)}|$ is bounded from below. On the other hand, if $\mu_j^{(i)}$ is far away from λ, and if $|g_j^{(i)}|$ is bounded from above, $|e_j^T y_i|$ will be relatively small. Thus, if λ is surrounded by a few eigenvalues of (K_{ii}, M_{ii}), and if S_i contains only the eigenvectors associated with these eigenvalues, one would expect to obtain an accurate approximation to λ by solving the projected problem (7).

To make the above statements more precise, we introduce some additional notation. Let us define

$$\rho_k(\omega) = \left| \frac{\lambda_k}{\omega - \lambda_k} \right|, \tag{13}$$

where λ_k is the kth eigenvalue of (K, M). If $|g_j^{(i)}| \in [\gamma_1, \gamma_2]$ for some modest-size constants $\gamma_1 < \gamma_2$, then $\rho_k(\mu_j^{(i)})$ provides a reliable measure for $|e_j^T y_i|$.

It is easy to verify that

$$\rho_k(\mu_{j+1}^{(i)}) \le \rho_k(\mu_j^{(i)}) \quad \text{for } \mu_j^{(i)} > \lambda_k$$

and

$$\rho_k(\mu_j^{(i)}) \le \rho_k(\mu_{j+1}^{(i)}) \quad \text{for } \mu_{j+1}^{(i)} < \lambda_k.$$

These inequalities suggest that $\rho_k(\mu_j^{(i)})$, and therefore $|e_j^T y_i|$, is relatively large when $\mu_j^{(i)}$ is sufficiently close to λ_k.

Let us now focus on the special case in which $k = 1$, i.e., the case associated with the smallest eigenvalue. Because (K_{ii}, M_{ii}) represents the restriction of the pencil $(\widehat{K}, \widehat{M})$ to a subspace, all of its eigenvalues satisfy

$$\lambda_1 \le \mu_j^{(i)} \le \lambda_n.$$

Consequently, the inequality

$$\rho_1(\mu_1^{(i)}) \geq \rho_1(\mu_2^{(i)}) \geq \cdots \geq \rho_1(\mu_{n_1}^{(i)}) \tag{14}$$

holds. Suppose $k_i < n_i$ is the smallest integer such that $\rho_1(\mu_{k_i+1}^{(i)}) \leq \tau$ for some $\tau \ll 1$; then we can assert, under the assumption

$$|g_j^{(i)}| \leq \gamma, \quad \text{for some small constant } \gamma,$$

that $|e_j^T y_i|$ is relatively small for all $j > k_i$. This assertion follows directly from (14) and the observation made in (12). Hence, if our goal is to seek an accurate approximation to λ_1 by projecting $(\widehat{K}, \widehat{M})$ into a subspace $\mathcal{S}$ spanned by the columns of

$$S = \begin{array}{c} \\ n_1 \\ n_2 \\ n_3 \end{array} \begin{array}{c} \begin{array}{ccc} k_1 & k_2 & n_3 \end{array} \\ \begin{pmatrix} S_1 & & \\ & S_2 & \\ & & I_{n_3} \end{pmatrix} \end{array}, \tag{15}$$

it is natural to set S_i to include only the leading k_i columns of V_i.

Given this choice of subspace, it remains to be shown how much accuracy one can expect from the approximate eigenvalue and eigenvector obtained by applying the Rayleigh–Ritz procedure to S. To simplify our discussion, let us assume that λ_1 is simple. Suppose θ_1 is the smallest eigenvalue of the projected problem

$$(S^T \widehat{K} S)q = \theta(S^T \widehat{M} S)q,$$

and q_1 is the corresponding eigenvector. We will now quantify the accuracy of the [illegible] (θ_1, u_1), where $u_1 = Sq_1$, by providing a priori error bounds for both $\theta_1 - \lambda_1$ and $\angle_{\widehat{M}}(\widehat{x}_1, u_1)$ in terms of small elements of y_1 and y_2. Note that $\angle_{\widehat{M}}(\widehat{x}_1, u_1)$ is the $\widehat{M}$-angle (between $\widehat{x}$ and u_1) defined in section 1.

To develop these error bounds, we use the following theorem, which is a generalization of a similar theorem associated with a standard symmetric eigenvalue problem [26, 27].

THEOREM 3.1. [illegible] $K, M \in \mathbb{R}^{n \times n}$ [illegible] M [illegible] (K, M) (λ_i, x_i) [illegible]

$$\lambda_1 < \lambda_2 \leq \cdots \leq \lambda_n.$$

[illegible] (θ_i, u_i) $i = 1, 2, \ldots, k$ [illegible] k [illegible] $\mathcal{S}$ [illegible]

$$\theta_1 \leq \theta_2 \leq \cdots \leq \theta_k,$$

[illegible]

$$\theta_1 - \lambda_1 \leq (\lambda_n - \lambda_1) \sin^2 \angle_M(x_1, \mathcal{S}), \tag{16}$$

$$\sin \angle_M(u_1, x_1) \leq \sqrt{\frac{\lambda_n - \lambda_1}{\lambda_2 - \lambda_1}} \sin \angle_M(x_1, \mathcal{S}), \tag{17}$$

[illegible] $\angle_M(u_1, x_1)$ [illegible] M [illegible] x_1 [illegible] u_1 [illegible] $\angle_M(x_1, \mathcal{S})$ [illegible] M [illegible] x_1 [illegible] $\mathcal{S}$

The proof of Theorem 3.1 is included in [30]. The theorem suggests that the accuracy of the desired Ritz pair is determined largely by the $\widehat{M}$-angle between the exact eigenvector $\widehat{x}_1$ and the subspace $\mathcal{S}$ from which the Ritz pair is extracted. We now focus on seeking a bound for $\sin\angle_{\widehat{M}}(\widehat{x}_1, \mathcal{S})$. The following theorem, which is a generalization of a similar theorem in [29, p. 250], provides a useful characterization for $\sin\angle_{\widehat{M}}(\widehat{x}_1, \mathcal{S})$.

THEOREM 3.2. [illegible] $\|x\|_M = 1$ [illegible] $\mathcal{S}$ [illegible]

$$\sin\angle_M(x, \mathcal{S}) = \min_{w \in \mathcal{S}} \|x - w\|_M.$$

Theorem 3.2 suggests that we can provide a bound for $\sin\angle_{\widehat{M}}(\widehat{x}_1, \mathcal{S})$ by measuring the distance between $\widehat{x}_1$ and a particular choice of a vector $w \in \mathcal{S}$ that is "close" to $\widehat{x}_1$ in the $\widehat{M}$-norm.

Our choice of such a vector $w \in \mathcal{S}$ is made as follows. We define $\hat{y}_i$ $(i = 1, 2)$ by

$$e_j^T \widehat{y}_i = \begin{cases} e_j^T y_i & \text{for } j \le k_i, \\ 0 & \text{for } k_i < j \le n_i, \end{cases} \tag{18}$$

where y_i satisfies

$$\begin{pmatrix} \Lambda_1 & & \\ & \Lambda_2 & \\ & & \widehat{K}_{33} \end{pmatrix} \begin{pmatrix} y_1 \\ y_2 \\ y_3 \end{pmatrix} = \lambda_1 \begin{pmatrix} I_{n_1} & & G_{13} \\ & I_{n_2} & G_{23} \\ G_{13}^T & G_{23}^T & \widehat{M}_{33} \end{pmatrix} \begin{pmatrix} y_1 \\ y_2 \\ y_3 \end{pmatrix}. \tag{19}$$

It is easy to verify that

$$w = \begin{pmatrix} V_1 & & \\ & V_2 & \\ & & I \end{pmatrix} \begin{pmatrix} \widehat{y}_1 \\ \widehat{y}_2 \\ y_3 \end{pmatrix} \in \mathcal{S} = \operatorname{span}\{S\}.$$

For this particular choice of w, we can easily show that

$$\widehat{x}_1 - w = \begin{pmatrix} V_1 & & \\ & V_2 & \\ & & I \end{pmatrix} \begin{pmatrix} h_1 \\ h_2 \\ 0 \end{pmatrix},$$

where $h_i = y_i - \widehat{y}_i$ for $i = 1, 2$. Consequently, we have

$$\|\widehat{x}_1 - w\|_{\widehat{M}}^2 = \begin{pmatrix} h_1^T & h_2^T & 0 \end{pmatrix} \begin{pmatrix} I & & G_{13} \\ & I & G_{23} \\ G_{13}^T & G_{23}^T & \widehat{M}_{33} \end{pmatrix} \begin{pmatrix} h_1 \\ h_2 \\ 0 \end{pmatrix} = h_1^T h_1 + h_2^T h_2.$$

Hence, we can now conclude that

$$\sin\angle_{\widehat{M}}(\widehat{x}_1, \mathcal{S}) = \min_{w \in \mathcal{S}} \|\widehat{x}_1 - w\|_{\widehat{M}} \le \sqrt{h_1^T h_1 + h_2^T h_2}. \tag{20}$$

Note that the vector w is essentially obtained from (9) by truncating components associated with the trailing $n_i - k_i$ elements of y_i. These elements are typically small, and they form the nonzero entries of h_i.

Combining (16) and (17) with (20), we obtain the following result.

THEOREM 3.3. [illegible] $\widehat{K}$ [illegible] $\widehat{M}$ [illegible] (5) [illegible] $(\lambda_i, \widehat{x}_i)$ $(i = 1, 2, \ldots, n)$ [illegible] $(\widehat{K}, \widehat{M})$ [illegible] $\lambda_1 < \lambda_2 \le \cdots \le \lambda_n$

(θ_i, u_i) $(i = 1, 2, \ldots, k)$ k $\mathcal{S}$ S (15) $\theta_1 \le \theta_2 \le \cdots \le \theta_k$

$$\theta_1 - \lambda_1 \le (\lambda_n - \lambda_1)(h_1^T h_1 + h_2^T h_2), \tag{21}$$

$$\sin \angle_{\widehat{M}}(u_1, \hat{x}_1) \le \sqrt{\frac{\lambda_n - \lambda_1}{\lambda_2 - \lambda_1}} \sqrt{h_1^T h_1 + h_2^T h_2}, \tag{22}$$

$h_i = y_i - \widehat{y}_i$ y_i $\widehat{y}_i$ $(i = 1, 2)$ (19) (18)

Theorem 3.3 indicates that the accuracy of (θ_1, u_1) is proportional to the size of $h_1^T h_1 + h_2^T h_2$, a quantity that provides a cumulative measure of the "truncated" components in (9). Similar a priori error estimates can be made for other Ritz pairs by utilizing a generalization of Theorems 4.5 and 4.6 in [26, pp. 135–136] which are developed for standard eigenvalue problems. However, to keep our presentation concise, we will not pursue this type of error estimate.

To end this section, we provide an estimate for $h_1^T h_1 + h_2^T h_2$ that is independent of the number of nonzero elements in h_1 and h_2. Note that the nonzero elements of h_i are those elements of y_i associated with

$$\rho_1(\mu_j^{(i)}) < \tau < 1.$$

If $|g_j^{(i)}| \le \gamma$ for some moderate-size constant γ, then it follows from (12) that each individual element of h_i is either zero or tiny. Moreover, since $\rho_1(\mu_j^{(i)})$ decreases rapidly as $\mu_j^{(i)}$ increases, we can establish a bound for $h_i^T h_i$ in terms of τ under some mild conditions.

To simplify our notation, we will drop the superscript of $\mu_j^{(i)}$ in the following. Suppose the eigenvalues μ_j of (K_{ii}, M_{ii}) are distinct and that

$$\min_{j \ge k_i}(\mu_{j+1} - \mu_j) \ge \delta$$

for some constant $\delta > 0$. Then it is easy to show that

$$\begin{aligned} h_i^T h_i &= \sum_{j=k_i+1}^{n_i} (e_j^T h_i)(e_j^T h_i) = \sum_{j=k_i+1}^{n_i} \rho_1^2(\mu_j)(e_j^T G_{i3} y_3)^2 \\ &\le \left[\sum_{j=k_i+1}^{n_i} \rho_1^2(\mu_j) \right] \gamma^2 \le \gamma^2 \left[\rho_1^2(\mu_{k_i+1}) + \frac{1}{\delta} \int_{\mu_{k_i+1}}^{\mu_{n_i}} \rho_1^2(\omega) d\omega \right] \\ &= \gamma^2 \left[\frac{\lambda_1}{\mu_{k_i+1} - \lambda_1} \rho_1(\mu_{k_i+1}) + \frac{\lambda_1}{\delta} \left(\frac{\lambda_1}{\mu_{k_i+1} - \lambda_1} - \frac{\lambda_1}{\mu_{n_i} - \lambda_1} \right) \right] \\ &\le \gamma^2 \lambda_1 \left[\frac{1}{\Delta_i} + \frac{1}{\delta} \right] \tau, \end{aligned} \tag{23}$$

where $\Delta_i = \mu_{k_i+1} - \lambda_1$. By combining (23) with inequalities (21)–(22) and setting $\Delta = \min\{\Delta_1, \Delta_2, \delta\}$. we obtain

$$\frac{\theta_1 - \lambda_1}{\lambda_1} \le (\lambda_n - \lambda_1)(\alpha\tau), \tag{24}$$

$$\sin \angle_{\widehat{M}}(\hat{x}_1, u_1) \le \sqrt{\lambda_1 \left(\frac{\lambda_n - \lambda_1}{\lambda_2 - \lambda_1} \right)} \sqrt{\alpha\tau}, \tag{25}$$

where $\alpha = 4\gamma^2/\Delta$.

We should mention that the presence of multiple (or tightly clustered) eigenvalues of (K_{ii}, M_{ii}) does not alter the qualitative measure of the bounds established in (24) and (25). In that case, we can simply replace the definition of δ with the minimum distances between two adjacent eigenvalue clusters and multiply the bounds by the largest multiplicity of the eigenvalues of (K_{ii}, M_{ii}).

Our assumption that $|g_j^{(i)}|$ is bounded by a moderate constant γ can be justified by noting that

$$(y_1^T\ y_2^T\ y_3^T) \begin{pmatrix} I & & G_{13} \\ & I & G_{23} \\ G_{13}^T & G_{23}^T & \widehat{M}_{33} \end{pmatrix} \begin{pmatrix} y_1 \\ y_2 \\ y_3 \end{pmatrix} = 1 \tag{26}$$

and by the fact that M is positive definite. Since

$$\begin{pmatrix} I & & G_{13} \\ & I & G_{23} \\ G_{13}^T & G_{23}^T & \widehat{M}_{33} \end{pmatrix} = \begin{pmatrix} I & & \\ & I & \\ G_{13}^T & & I \end{pmatrix} \begin{pmatrix} I & & \\ & I & G_{23} \\ & G_{23}^T & \widehat{M}_{33} - G_{13}^T G_{13} \end{pmatrix} \begin{pmatrix} I & & G_{13} \\ & I & \\ & & I \end{pmatrix},$$

it follows from (26) that

$$\|y_1 + G_{13} y_3\| \leq 1.$$

Hence, the jth component of $y_1 + G_{13} y_3$ must satisfy

$$|e_j^T y_1 + g_j^{(1)}| \leq 1. \tag{27}$$

It then follows from (27) and (12) that

$$|g_j^{(1)}| \leq 1 + |e_j^T y_1| = 1 + \rho_1(\mu_j^{(1)}) |g_j^{(1)}|.$$

Consequently,

$$|g_j^{(1)}| \leq \frac{1}{1 - \rho(\mu_j^{(1)})} \quad \text{when} \quad \rho(\mu_j^{(1)}) < 1.$$

Thus, if $\rho_1(\mu_j^{(1)}) \ll 1$, then $|g_j^{(1)}|$ is clearly bounded by a small constant. A similar argument can be used to show that $|g_j^{(2)}|$ is bounded by a small constant also.

We should also emphasize that (24) and (25) merely provide a qualitative estimate of the error in the Ritz pair (θ_1, u_1) in terms of the threshold τ that may be used as a heuristic in practice to determine which spectral components of a substructure should be included in the subspace $\mathcal{S}$ defined in (15). This result was verified independently in the recent work by Elssel and Voss [14]. They derived a bound on the relative accuracy of the approximate eigenvalue in a more general setting by making using of the minmax principle for a rational eigenvalue problem.

4. Numerical experiments. We present two numerical examples in this section to illustrate the effectiveness of the single-level algebraic substructuring algorithm presented in section 2. These examples also confirm the analysis carried out in section 3. All experiments are performed in MATLAB. The desired eigenpairs of all pencils are computed by using the MATLAB `eigs` function. For illustration, we computed more eigenvalues and eigenvectors of each subproblem than we actually need in the following experiments. In practice, one would only need to compute a selected number of eigenpairs of (K_{ii}, M_{ii}) incrementally.

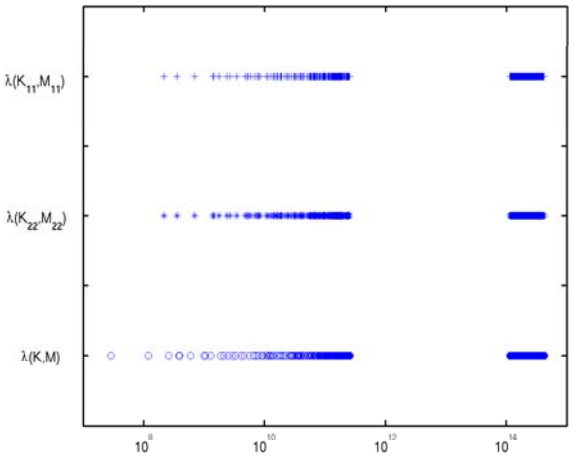

FIG. 1. *The spectra of the pencils* (K_{11}, M_{11}), (K_{22}, M_{22}), *and* (K, M) *associated with the structural dynamics example.*

4.1. Example 1. Structural dynamics. The matrices used in this example, BCSSTK09 and BCSSTM09, are part of the Harwell–Boeing sparse matrix collection [13]. These matrices originated from a dynamic analysis of a clamped plate. The dimensions of these matrices are $n = 1083$. We used METIS [19] to dissect the matrix into two main substructures coupled by a small separator (interface block). The two substructures of the reordered K are identical. The dimension of each substructure is $n_1 = n_2 = 513$. The separator contains only 57 rows and columns. The mass matrix M is diagonal in this example. Applying the same reordering to M does not change its structure.

The spectra of the original matrix pencil (K, M) and the substructure pencils (K_{ii}, M_{ii}) $(i = 1, 2)$ are shown in Figure 1. There is a large gap between the 361st and the 362nd eigenvalues of (K, M). Similar gaps are present in the spectra of (K_{ii}, M_{ii}). In this example, the eigenvalues of interest are the ones on the left side of the spectrum. Naturally, we would select the eigenvectors associated with the smallest eigenvalues of (K_{ii}, M_{ii}) to construct the subspace (6) required in step 5 of the single-level algebraic substructuring algorithm.

To determine how many eigenvectors of (K_{ii}, M_{ii}) we should include in the subspace represented by (6), we examine the ρ-factor defined in (13). It follows from the discussion in section 3 that one may develop a selection scheme by setting a threshold value τ for ρ_1; i.e., one can choose substructure modes that satisfy

$$\rho_1(\mu_j^{(i)}) > \tau$$

for some small τ. However, since the computation of ρ_1 requires the knowledge of the exact λ_1, which we do not have in advance, a more practical scheme is perhaps to compute an approximate ρ-factor by replacing λ_1 in (13) with an approximate eigenvalue σ.

We use $\sigma = \min(\mu_1^{(1)}, \mu_1^{(2)})/2$ in all of our experiments and define

$$\widehat{\rho}_1(\omega) = \left| \frac{\sigma}{\omega - \sigma} \right|. \tag{28}$$

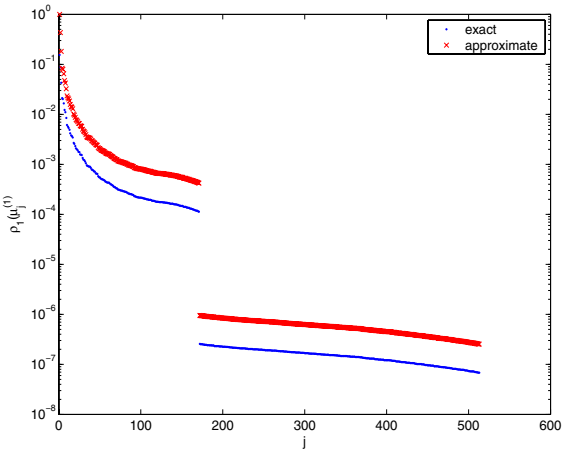

FIG. 2. *The exact (marked by* x*'s) and the approximate (marked by dots) ρ-factors associated with the first substructure of the structural dynamics problem. The exact ρ-factor is defined by* (13)*, and the approximate ρ-factor is defined by* (28)*.*

In Figure 2, we plot both $\rho_1(\mu_j^{(1)})$ and $\widehat{\rho}_1(\mu_j^{(1)})$. (The two substructures in this problem are identical.) The figure clearly shows that there is essentially no qualitative difference between $\rho_1(\mu_j^{(1)})$ and $\widehat{\rho}_1(\mu_j^{(1)})$. Both decrease rapidly as $\mu_j^{(1)}$ increases. There is a clear gap between $\rho_1(\mu_{171}^{(1)})$ and $\rho_1(\mu_{172}^{(1)})$. A similar gap is observed between $\widehat{\rho}_1(\mu_{171}^{(1)})$ and $\widehat{\rho}_1(\mu_{172}^{(1)})$. These gaps reflect the gaps observed in the spectrum of (K_{11}, M_{11}).

Several choices of τ values (listed in Table 1) have been made. The analysis performed in section 3 indicates that, the smaller the value of τ, the more accurate the smallest Ritz pair should be. This prediction is confirmed in Figure 3, where we plot the relative errors of the smallest 50 Ritz values extracted from three subspaces constructed by using these different choices of τ values. Notice that with the choice of $\tau = 10^{-4}$, which corresponds to selecting the leading 171 eigenvectors from each substructure to form the matrix S_i required in (15), θ_1 exhibits roughly 10 digits of accuracy.

TABLE 1

The effect of τ on the number of selected modes associated with the structural dynamics problem, the relative accuracy of the smallest Ritz value, and the relative error bound defined by (21)*.*

τ	k_i	$(\theta_1 - \lambda_1)/\lambda_1$	Relative error bound
10^{-2}	18	1.4×10^{-4}	3.4×10^{0}
10^{-3}	84	2.0×10^{-6}	6.4×10^{-3}
10^{-4}	171	1.2×10^{-12}	4.2×10^{-12}

Even though our error estimate presented in section 3 is targeted only at (θ_1, u_1), Figure 3 shows that the improvement in the accuracy of other Ritz values is also proportional to the decrease of τ.

In this example, the least upper bound for the elements of $g^{(i)}$ used in (12) is roughly $\gamma = 0.28$. Hence, $\rho_1(\mu_j^{(i)})$ provides a reliable upper bound for the magnitude of $e_j^T y_i$ $(i = 1, 2)$, where $(y_1^T, y_2^T, y_3^T)^T$ is the eigenvector associated with the smallest

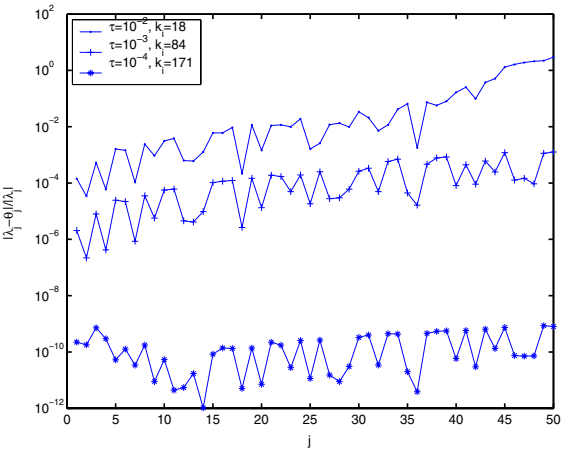

FIG. 3. *The relative error of the smallest* 50 *Ritz values extracted from three subspaces constructed by using different choices of the* ρ*-factor thresholds* (τ *values) for the structural dynamics problem.*

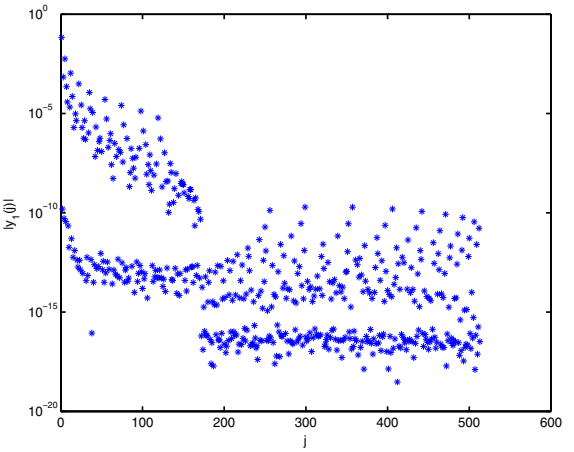

FIG. 4. *The magnitude of* $e_j^T y_1$*, where* $(y_1^T, y_2^T, y_3^T)^T$ *is the eigenvector corresponding to the smallest eigenvalue of the canonical problem* (10) *associated with the structural dynamics example.*

eigenvalue (λ_1) of the canonical eigenvalue problem (10).

Judging from the small magnitude of $\rho_1(\mu_j^{(i)})$ for $j > 171$, which is less than 10^{-6}, we predict the magnitude of $e_j^T y_i$, $i = 1, 2$, to be tiny for $j > 171$. This is indeed the case, as is demonstrated in Figure 4, where we plot $|e_j^T y_1|$ (The plot for y_2 is identical.) We observe that $|e_j^T y_1| < 2 \times 10^{-10}$ for all $j > k_1 = 171$. This observation, when used in conjunction with Theorem 3.3, provides a clear explanation for the high accuracy of θ_1 displayed in Figure 3.

Table 1 further illustrates the connections between the mode selection threshold τ, the number of modes selected from each substructure (k_i), the relative accuracy of θ_1, and the error estimates established in Theorem 3.3. Note that the relative error bound listed in the last column of Table 1, which is calculated directly from the right-hand side of (21), tends to be somewhat pessimistic. However, it does provide

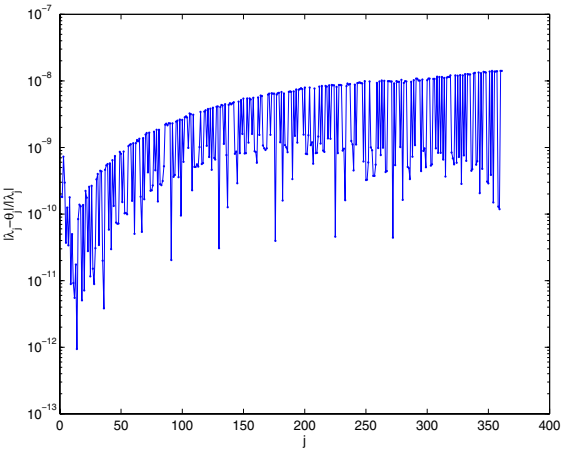

FIG. 5. *The relative error of the smallest* 361 *approximate eigenvalues associated with the structural dynamics problem.*

a qualitative estimate for the relative accuracy of θ_1.

It is interesting to see from Figure 4 that, among the first 171 elements of both y_1 and y_2, many have magnitudes less than 10^{-10}. This observation suggests that one may potentially reduce the dimension of the subspace (6) by excluding eigenvectors of (K_{ii}, M_{ii}) that are associated with these small entries from S_i. We will pursue this idea further in a follow-up paper on mode selection strategies.

We will end this example by pointing out that the large gap between the leading 361 eigenvalues of (K, M) and the rest of the spectrum is a highly favorable feature of this problem. This gap, which also manifests itself in the ρ-factor plots displayed in Figure 2, allows an algebraic substructuring algorithm to easily construct a subspace that contains accurate approximations to the leading 361 eigenvalues of (K, M). Figure 5 shows that, by setting $k_i = 171$, the leading 361 Ritz values extracted from the subspace $\mathcal{S}$ spanned by columns of (15) all have at least 7 digits of accuracy.

4.2. Example 2. Short traveling wave accelerating structure. We show in this example that algebraic substructuring can be used to compute approximate cavity resonance frequencies and the electromagnetic field associated with a small accelerator structure. The matrix pencil used in this example is obtained from a finite element model of a five-cell traveling wave accelerating structure. The three-dimensional geometry of the model is shown in Figure 6. The model contains three cavity cells and two couplers. The dimension of the pencil (K, M) is $n = 1898$. The stiffness matrix K has 336 zero rows and columns. These zero rows and columns are produced by a particular hierarchical vector finite element discretization scheme. Because the null space of K has a special structure, it can be effectively deflated in the algebraic substructuring algorithm. The details of the deflation scheme can be found in [30, 3].

In order to deflate the null space of (K, M) associated with these zero rows and columns, which has no physical significance, we perform the following two-stage matrix reordering:

- A single-level dissection is applied to $|K| + |M|$ first using the METIS [19] software. The dissection produces two substructures of sizes $n_1 = 995$ and $n_2 = 887$, respectively. These substructures are connected by a small separa-

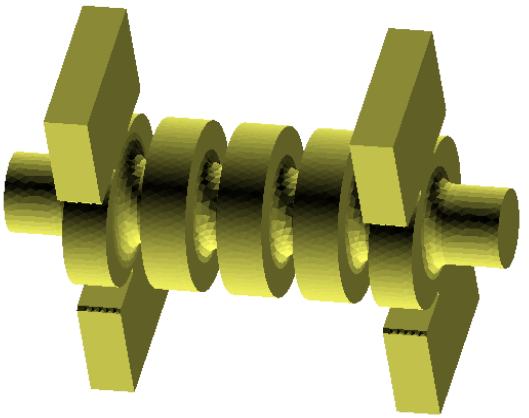

FIG. 6. *The finite element model corresponding to a five-cell traveling wave accelerating structure.*

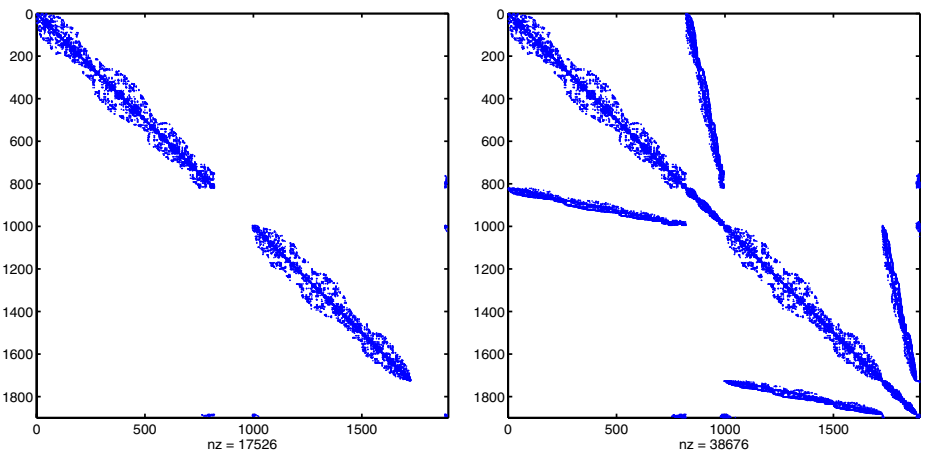

FIG. 7. *The nonzero pattern of the permuted stiffness matrix K (left) and the mass matrix M (right) associated with the traveling wave accelerating structure.*

tor (an interface block) which contains only 16 rows and columns. The K_{11} block of the permuted K contains 175 zero rows and columns, the K_{22} block contains 157 zero rows and columns, and the K_{33} block contains 6 zero rows and columns.

- The nonzero rows and columns of K_{11}, K_{22}, and K_{33} are permuted to the leading blocks of these submatrices. The matrix M is permuted accordingly.

The nonzero patterns of the permuted K and M are displayed in Figure 7. The distribution of the nonzero eigenvalues of (K, M) is shown in Figure 8. We are interested in the smallest nonzero eigenvalues, which appear to be relatively well separated from the large end of the spectrum. In addition to the spectrum of (K, M), we also plot the spectra of (K_{ii}, M_{ii}) $(i = 1, 2)$ in Figure 8. Notice that the spectra of both substructures show a distribution pattern similar to that of (K, M).

In Figure 9 we plot the $\widehat{\rho}$-factors associated with the smallest eigenvalue of the deflated problem. We observe that the $\widehat{\rho}$-factors associated with this example decrease

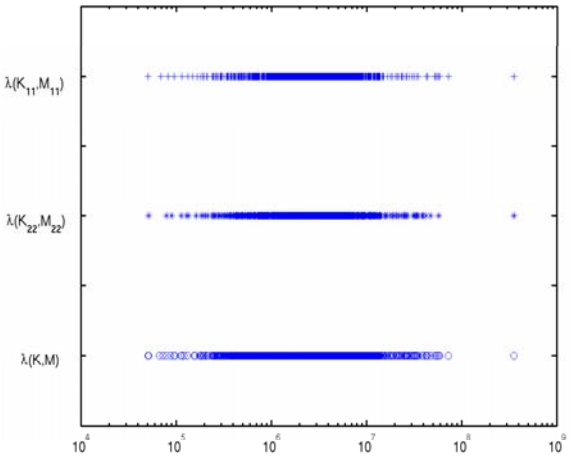

FIG. 8. *The spectra of the pencils* (K_{11}, M_{11}), (K_{22}, M_{22}), *and* (K, M) *associated with the traveling wave accelerating structure.*

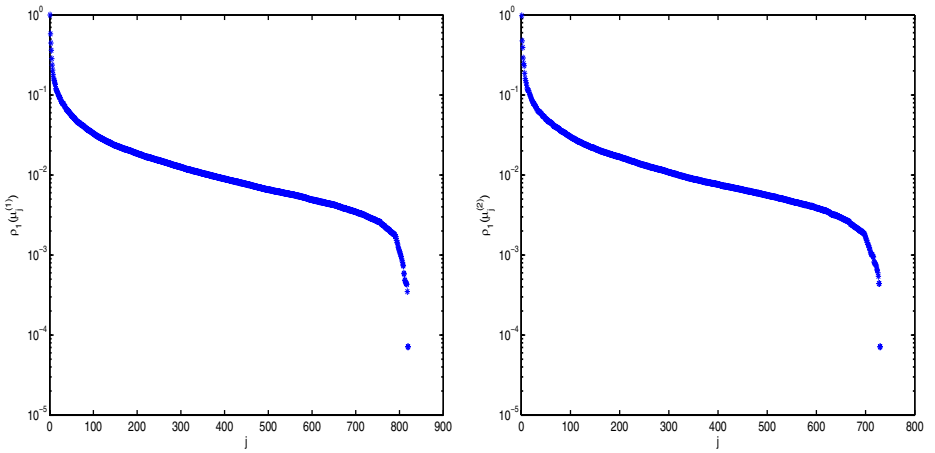

FIG. 9. *The approximate* ρ*-factors associated with each substructure of the traveling wave accelerating structure.*

at a somewhat slower rate. Three different choices of τ values were used as the thresholds ($\tau = 0.1, 0.05, 0.01$) for selecting substructure modes. The relative accuracy of the 50 smallest nonzero Ritz values extracted from the subspaces constructed with these choices of τ values is displayed in Figure 10.

We observe that with $\tau = 0.1$, θ_1 has roughly four digits of accuracy, which is quite sufficient for this particular discretized model. If we decrease τ down to 0.01, most of the smallest 50 nonzero Ritz values have at least four digits of accuracy.

The least upper bound for $|g_j^{(i)}|$ used in (12) is $\gamma = 0.02$. Thus the ρ-factor gives an overestimate of $|e_j^T y_i|$ in this case. In Figure 11, we plot $|e_j^T y_1|$ and $|e_j^T y_2|$, where $(y_1^T, y_2^T, y_3^T)^T$ is the eigenvector associated with the smallest nonzero eigenvalue of (10). For simplicity, we excluded the values of $|e_j^T y_1|$ and $|e_j^T y_2|$ corresponding to the null space of (K_{11}, M_{11}) and (K_{22}, M_{22}), which have been deflated from our calculations (see section 4). We observe that $|e_j^T y_i|$ is much smaller compared to

TABLE 2

The effect of τ *on the number of selected modes associated with the traveling wave accelerating structure, the relative accuracy of the smallest Ritz value, and the relative error bound defined by* (21).

τ	k_1	k_2	$(\theta_1 - \lambda_1)/\lambda_1$	Relative error bound
0.1	18	19	1.4×10^{-4}	1.7×10^{-3}
0.05	51	56	1.2×10^{-5}	2.6×10^{-4}
0.01	325	361	2.4×10^{-8}	2.5×10^{-6}

$\widehat{\rho}_1(\mu_j^{(i)})$, and it decays much faster than the $\widehat{\rho}$-factor also.

We conclude this example by listing in Table 2 the mode selection threshold τ,

the number of modes selected from each substructure (k_i), the relative accuracy of θ_1, and the error estimate computed directly from the right-hand side of (21).

5. Concluding remarks. A purely algebraic analysis of a single-level substructuring algorithm for large-scale eigenvalue calculation is developed in this paper. By applying a sequence of special congruence transformations to (K, M), we transform the original generalized eigenvalue (2) into a canonical problem (10) with a simpler structure. We observed that the desired eigenvector y of the canonical problem (10) often contains only a few large entries. The magnitude of these entries ultimately determines which eigenvectors (modes) of each substructure should be included in the subspace (6), from which approximations to the eigenpairs of (K, M) are extracted. All other substructure modes can essentially be truncated from (9) without sacrificing the required level of accuracy in our approximation. We provided an explicit a priori error estimate for the smallest Ritz pair in terms of the small components of y that are truncated from (9). We also suggested a practical way to estimate the magnitude of each component of y by exploiting its relationship with the "ρ-factor" defined in (13). This estimation leads to a practical way to select substructure modes by specifying a threshold value τ for the ρ-factor. We showed that the accuracy of the smallest Ritz pair is proportional to the size of τ under some mild conditions. A number of numerical examples are provided to confirm our theoretical analysis. Moreover, we demonstrated that an algebraic substructuring algorithm can be an effective tool for computing cavity resonance frequencies and the electromagnetic field generated by a linear accelerator structure.

Our analysis of a simple algebraic substructuring algorithm can be extended to a multilevel setting. Our error estimate can be made for nonextreme Ritz pairs as well. These topics will be pursued in our future research. Another interesting area that would require further research is the development of a better strategy for selecting substructuring modes.

Our presentation has focused on the theoretical aspects of the algebraic substructuring algorithm. Implementation details and comparsion of a multilevel algebraic substructuring algorithm with other methods for large-scale eigenvalue computation will be reported elsewhere.

Acknowledgments. We would like to thank the anonymous referees for their careful reading and helpful comments.

GAUSSIAN-TYPE QUADRATURE RULES FOR MÜNTZ SYSTEMS*

GRADIMIR V. MILOVANOVIĆ† AND ALEKSANDAR S. CVETKOVIĆ

Abstract. A method for constructing the generalized Gaussian quadrature rules for Müntz polynomials on $(0,1)$ is given. Such quadratures possess several properties of the classical Gaussian formulae (for polynomial systems), such as positivity of the weights, rapid convergence, etc. They can be applied to the wide class of functions, including smooth functions, as well as functions with end-point singularities, such as those in boundary-contact value problems, integral equations with singular kernels, complex analysis, potential theory, etc. The constructive method is based on an application of orthogonal Müntz polynomials introduced by Badalyan [*Akad. Nauk Armyan. SSR. Izv. Fiz.-Mat. Estest. Tehn. Nauk*, 8 (1955), pp. 1–28; 9 (1956), pp. 3–22 (Russian; Armenian summary)] and studied intensively by Borwein, Erdélyi, and Zhang [*Trans. Amer. Math. Soc.*, 342 (1994), pp. 523–542], as well as by Milovanović on a numerical procedure for evaluation of such polynomials with high precision [*Müntz orthogonal polynomials and their numerical evaluation*, in Applications and Computation of Orthogonal Polynomials, Internat. Ser. Numer. Math. 131, W. Gautschi, G. H. Golub, and G. Opfer, eds., Birkhäuser, Basel, 1999, pp. 179–194]. The method is numerically stable. Some numerical examples are included.

1. Introduction.

Gauss's famous method of approximate integration from 1814 can be extended in a natural way to nonpolynomial functions, taking a system of linearly independent functions

$$\{P_0(x), P_1(x), P_2(x), \ldots\} \qquad (x \in [a,b]), \tag{1.1}$$

usually chosen to be complete in some suitable space of functions (cf. Gautschi [6], Karlin and Studden [12], Harris and Evans [11], Ma, Rokhlin, and Wandzura [13]). If $d\sigma(x)$ is a given nonnegative measure on $[a,b]$ and the quadrature rule

$$\int_a^b f(x)d\sigma(x) = \sum_{k=1}^{n} A_k f(x_k) + R_n(f) \tag{1.2}$$

is such that it integrates exactly the first $2n$ functions in (1.1), we call rule (1.2) [illegible] (1.1). The existence and uniqueness of a Gaussian quadrature rule (1.2) with respect to the system (1.1), or, for brevity, a [illegible], is always guaranteed if the first $2n$ functions of this system constitute a Chebyshev system on $[a,b]$. Then, all the weights $A_1, \ldots, A_n$ in (1.2) are positive. In terms of moment spaces, the Gaussian rule corresponds to the unique [illegible] of the measure $d\sigma(x)$ (see Karlin and Studden [12]).

†Department of Mathematics, Faculty of Electronic Engineering, University of Niš, P. O. Box 73, 18000 Niš, Serbia (grade@ni.ac.yu, aca@elfak.ni.ac.yu).

The generalized Gaussian quadratures for Müntz systems goes back to Stieltjes's paper [22] of 1884. Taking $P_k(x) = x^{\lambda_k}$ on $[a,b] = [0,1]$, where $0 \le \lambda_0 < \lambda_1 < \cdots$, he showed the existence of Gaussian formulae. In his short note he considered also Gauss–Radau formulae.

A numerical algorithm for constructing the generalized Gaussian quadratures was recently investigated by Ma, Rokhlin, and Wandzura [13]. They take a Chebyshev system of functions $\{P_0, P_1, \dots, P_{2n-1}\}$ on $[a,b]$ with the following properties:

(1) $P_k \in C^1[a,b]$ $(k = 0,1,\dots,2n-1)$;

(2) the determinants

$$\begin{vmatrix} P_0(x_1) & \cdots & P_0(x_n) & P_0'(x_1) & \cdots & P_0'(x_n) \\ P_1(x_1) & & P_1(x_n) & P_1'(x_1) & & P_1'(x_n) \\ \vdots & & & & & \\ P_{2n-1}(x_1) & & P_{2n-1}(x_n) & P_{2n-1}'(x_1) & & P_{2n-1}'(x_n) \end{vmatrix}$$

are nonzero for any set of n points $x_1, \dots, x_n \in [a,b]$ ($x_i \ne x_j$ for $i \ne j$).

Such a system will be referred to as an [illegible].

The procedure given in [13] requires the construction of the functions

$$\xi_i(x) = \sum_{j=1}^{2n} \alpha_{ij} P_{j-1}(x), \qquad \eta_i(x) = \sum_{j=1}^{2n} \beta_{ij} P_{j-1}(x) \qquad (i = 1,\dots,n) \tag{1.3}$$

such that

$$\begin{cases} \xi_i(x_k) = 0, \\ \xi_i'(x_k) = \delta_{ik}, \end{cases} \qquad \begin{cases} \eta_i(x_k) = \delta_{ik}, \\ \eta_i'(x_k) = 0, \end{cases} \tag{1.4}$$

for all $i = 1,\dots,n$ and all $k = 1,\dots,n$. The algorithm is ill conditioned (see [13, Remark 6.2]). In order to obtain the double precision results (REAL*8), the authors performed the computations in extended precision (Q-arithmetic, i.e., REAL*16) for generating Gaussian quadratures up to order 20, and in MATHEMATICA (120-digit operations) for generating Gaussian quadratures of higher orders ($n \le 40$). In particular, they considered the following important cases of EH systems:

$$\left\{1, \log x, x, x\log x, \dots, x^{n-1}, x^{n-1}\log x\right\} \tag{1.5}$$

and

$$\left\{1, x^s, x, x^{s+1}, \dots, x^{n-1}, x^{s+n-1}\right\} \tag{1.6}$$

for $s = 1/3$, $s = -1/3$, $s = -2/3$. The case (1.5) was also considered by Andronov [1] in order to solve certain boundary-contact value problems.

For a given sequence of real numbers $\Lambda = \{\lambda_0, \lambda_1, \lambda_2, \dots\}$ given in nondecreasing order, i.e., $\lambda_k \le \lambda_{k+1}$, $k \in \mathbb{N}_0$, in this paper we consider Müntz polynomials as linear combinations of the Müntz system

$$\left\{x^{\lambda_0}, x^{\lambda_1}, \dots, x^{\lambda_n}\right\}.$$

By $M_n(\Lambda)$ we denote the set of all such polynomials, i.e.,

$$M_n(\Lambda) = \operatorname{span}\left\{x^{\lambda_0}, x^{\lambda_1}, \dots, x^{\lambda_n}\right\},$$

where the linear span is over the real numbers.

Here, we present an alternatively numerical method for constructing the generalized Gaussian quadratures for Müntz polynomials

$$\int_0^1 f(x)d\sigma(x) = \sum_{k=1}^{n} A_k f(x_k) + R_n(f), \tag{1.7}$$

which are exact for each $f \in M_{2n-1}(\Lambda)$. Our method is rather stable and simpler than the previous one. It performs calculations in double precision arithmetic to get double precision results.

As is well known (see [14], [28]), the Gaussian quadrature rule is unique, provided the measure σ has a nonnegative absolutely continuous part and has finitely many atoms on $[0,1]$. Such quadratures possess several properties of the classical Gaussian formulae (for polynomial systems), such as positivity of the weights, rapid convergence, etc. They can be applied to the wide class of functions, including smooth functions, as well as functions with end-point singularities, such as those in boundary-contact value problems (see [1]), integral equations, complex analysis, potential theory, and several other fields (see [13]).

This paper is organized as follows. Section 2 is devoted to some properties of orthogonal Müntz polynomials on $(0,1)$ and their connection with orthogonal rational functions, including numerical evaluation of such generalized polynomials. A numerical method for constructing the quadrature rules (1.7) is presented in section 3. Finally, in section 4 we give numerical results.

2. Orthogonal Müntz–Legendre polynomials. We are interested in the class of Müntz polynomials introduced by Badalyan [2], and we refer to it as Müntz–Legendre polynomials.

Let a complex sequence $\Lambda = \{\lambda_0, \lambda_1, \lambda_2, \ldots\}$ be such that $\operatorname{Re}(\lambda_k) > -1/2$ for every $k \in \mathbb{N}_0$ and let $\Lambda_n = \{\lambda_0, \lambda_1, \ldots, \lambda_n\}$. If Γ is a simple contour surrounding all the zeros of the denominator in the rational function

$$W_n(s) = \prod_{k=0}^{n-1} \frac{s + \bar{\lambda}_k + 1}{s - \lambda_k} \cdot \frac{1}{s - \lambda_n} \qquad (n \in \mathbb{N}_0), \tag{2.1}$$

then the Müntz–Legendre polynomials are defined by (see [2], [3], [4], [15], [25])

$$P_n(x) = P_n(x; \Lambda_n) = \frac{1}{2\pi i} \oint_\Gamma W_n(s) x^s \, ds. \tag{2.2}$$

In the case $n = 0$, an empty product in (2.1) should be taken to be equal to 1.

If $\lambda_k \neq \lambda_j$ $(k \neq j)$, by the Cauchy residue theorem, these generalized polynomials can be expressed in a power form as

$$P_n(x) = \sum_{k=0}^{n} C_{nk} x^{\lambda_k}. \tag{2.3}$$

If there exists a pair with the property $\lambda_k = \lambda_j$, $k \neq j$, an application of Cauchy residue theorem produces terms with log function included. For example, we consider the important special case, where

$$\lambda_{2k} = \lambda_{2k+1} = k \qquad (k = 0, 1, \ldots).$$

Namely, we take $\lambda_{2k} = k$ and $\lambda_{2k+1} = k + \varepsilon$ $(k = 0, 1, \ldots)$, where ε decreases to zero. The corresponding limit process leads to orthogonal Müntz polynomials with logarithmic terms. Then, (2.1) becomes

$$W_n(s) = \begin{cases} \displaystyle\prod_{\nu=0}^{m-1} \Big(\frac{s+\nu+1}{s-\nu}\Big)^2 \frac{1}{s-m} & \text{when } n = 2m, \\ \displaystyle\prod_{\nu=0}^{m} \Big(\frac{s+\nu+1}{s-\nu}\Big)^2 \frac{1}{s+m+1} & \text{when } n = 2m+1. \end{cases}$$

Applying the Cauchy residue theorem to the integral in (2.2), with this rational function, we obtain the following representation for the corresponding Müntz polynomials:

$$P_n(x) = R_n(x) + S_n(x) \log x \qquad (n = 0, 1, \ldots), \tag{2.4}$$

where $R_n(x)$ and $S_n(x)$ are algebraic polynomials of degree $[n/2]$ and $[(n-1)/2]$, respectively, i.e.,

$$R_n(x) = \sum_{\nu=0}^{[n/2]} a_\nu^{(n)} x^\nu, \qquad S_n(x) = \sum_{\nu=0}^{[(n-1)/2]} b_\nu^{(n)} x^\nu.$$

Notice that $P_n(1) = R_n(1) = 1$. A general expression for the polynomial P_n, $n \in \mathbb{N}_0$, was given in [17]. These Müntz polynomials can be used in the proof of the irrationality of $\zeta(3)$ and of other familiar numbers (see [4, pp. 372–381] and [27]).

In the special case when $\lambda_0 = \lambda_1 = \cdots = \lambda$, (2.2) gives

$$P_n(x; \Lambda_n) = x^\lambda L_n(-(\lambda + \bar{\lambda} + 1) \log x), \tag{2.5}$$

where $L_n(x)$ is the Laguerre polynomial orthogonal with respect to e^{-x} on $[0, \infty)$ and such that $L_n(0) = 1$ (cf. [5, p. 145]).

THEOREM 2.1. [illegible] (2.2) [illegible]

$$(P_n, P_m) = \int_0^1 P_n(x)\overline{P_m(x)}\, dx = \frac{\delta_{nm}}{\lambda_n + \bar{\lambda}_n + 1}. \tag{2.6}$$

According to this theorem we can construct orthonormal sequence of Müntz–Legendre polynomials, denoted by $p_n(x) := p_n(x; \Lambda) = (\lambda_n + \bar{\lambda}_n + 1)^{1/2} P_n(x)$, $n \in \mathbb{N}_0$.

For a general nondecreasing sequence Λ, the case when some of λ_k, $k \in \mathbb{N}_0$, are the same, it is complicated to express the basis functions in a closed form. For example, if all λ_k, $k \in \mathbb{N}_0$, are different, we have that the system of basis functions is given by $\{x^{\lambda_0}, x^{\lambda_1}, \ldots\}$. In the case $\lambda_k = \lambda_{k+1} = k$, $k \in \mathbb{N}_0$, we have that the system of basis functions is given by $\{1, \log x, x, x \log x, \ldots\}$. To make notation simple, we use the notation x^Λ to denote the set of basis functions for the general nondecreasing sequence Λ. Also, we introduce the notation x^{Λ_n} for the first n functions in the system x^Λ.

Putting $\lambda_k + \beta/2$ instead of λ_k, $k = 0, 1, \ldots$, in the sequence Λ, we can define a kind of Müntz–Jacobi polynomials $P_n^{(\beta)}(x)$ by

$$P_n^{(\beta)}(x) = \frac{x^{-\beta/2}}{2\pi i} \oint_\Gamma W_n^{(\beta)}(s) x^s\, ds, \tag{2.7}$$

where

$$W_n^{(\beta)}(s) = \prod_{k=0}^{n-1} \frac{s + \bar{\lambda}_k + \beta/2 + 1}{s - \lambda_k - \beta/2} \cdot \frac{1}{s - \lambda_n - \beta/2}.$$

Then the following result holds.

THEOREM 2.2. [illegible] $\beta \in \mathbb{R}$ [illegible] $\operatorname{Re}\lambda_k > -(\beta+1)/2$ [illegible] $k \in \mathbb{N}_0$ [illegible]

$$(P_n^{(\beta)}, P_m^{(\beta)}) = \int_0^1 P_n^{(\beta)}(x)\overline{P_m^{(\beta)}(x)}\, x^\beta\, dx = \frac{\delta_{nm}}{\lambda_n + \bar{\lambda}_n + \beta + 1}.$$

Let $P_n(\cdot;\Lambda)$, $n \in \mathbb{N}_0$, denote the Müntz–Legendre polynomials for a nondecreasing sequence $\Lambda = \{\lambda_0, \lambda_1, \lambda_2, \ldots\}$. Then it is very easy to verify that $P_n^{(\beta)}(x) = x^{-\beta/2}P_n(x;\Lambda+\beta/2)$, where $P_n(\cdot;\Lambda+\beta/2)$ are really Müntz–Legendre polynomials orthogonal with respect to the Legendre measure. This means that an orthogonality with respect to x^β is obtained straightforwardly from Theorem 2.1.

Also, some recurrence relations exist for Müntz–Legendre polynomials, e.g.,

$$xP_n'(x) - xP_{n-1}'(x) = \lambda_n P_n(x) + (1 + \bar{\lambda}_{n-1})P_{n-1}(x) \tag{2.8}$$

and

$$P_n(x) = P_{n-1}(x) - (\lambda_n + \bar{\lambda}_{n-1} + 1)x^{\lambda_n}\int_x^1 t^{-\lambda_n - 1}P_{n-1}(t)\, dt \qquad (x \in (0,1]).$$

It is easy to prove that

$$P_n(1) = 1 \qquad \text{and} \qquad P_n'(1) = \lambda_n + \sum_{k=0}^{n-1}(\lambda_k + \bar{\lambda}_k + 1).$$

Taking $x = e^{-t}$, the Müntz–Legendre polynomials can be expressed in terms of a Laplace transform. Namely, we can prove the following (cf. [17]).

THEOREM 2.3. [illegible] $W_n(s)$ [illegible] (2.1) [illegible]

$$G_n(s) = -W_n(-s) = \prod_{k=0}^{n-1} \frac{s - (\bar{\lambda}_k + 1)}{s + \lambda_k} \cdot \frac{1}{s + \lambda_n},$$

[illegible] $P_n(e^{-t})$ [illegible] $G_n(s)$ [illegible]

$$P_n(e^{-t}) = \mathcal{L}^{-1}[G_n(s)].$$

In the proof of this result we can take, for example, $\alpha > 1/2$, and then prove that

$$P_n(e^{-t}) = \frac{1}{2\pi i}\int_{\alpha - i\infty}^{\alpha + i\infty} G_n(s)e^{st}\, ds.$$

An interesting question is connected with the zero distribution of the Müntz–Legendre polynomials for a real sequence Λ. A nice proof of the following result was given in [3].

THEOREM 2.4. [illegible] $\lambda_\nu > -1/2$ $(\nu = 0, 1, \ldots)$ [illegible] $P_n(x;\Lambda_n)$ [illegible] n [illegible] $(0,1)$ [illegible]

$$P_{n-1}(x;\Lambda_{n-1}) \qquad\qquad P_n(x;\Lambda_n)$$

[illegible] $(0,1)$ [illegible]

3. Numerical construction of the generalized Gaussian quadrature rule. Applying the theory of orthogonality for Müntz systems and using a method for evaluating orthogonal Müntz polynomials, in this section we present the method for the numerical construction of the generalized Gaussian quadrature rule for Müntz systems given by (1.7), i.e.,

$$\int_0^1 f(x)d\sigma(x) = \sum_{k=1}^{n} A_k f(x_k) + R_n(f), \tag{3.1}$$

being exact for each $f \in M_{2n-1}(\Lambda)$. The presented method is rather stable and performs calculations in double precision arithmetic to obtain double precision results.

Let $\Lambda = \{\lambda_0, \lambda_1, \lambda_2, \ldots\}$ be nondecreasing real sequence such that $\lambda_\nu > -1/2$ for every $\nu \in \mathbb{N}_0$. The orthogonal Müntz–Legendre system $\{P_0, P_1, \ldots, P_{2n-1}\}$, defined by (2.2), is an EH system. It can be recognized as a linear span of the system of basis functions x^Λ, which is an EH system.

In what follows, by $P_n(x) := P_n(x;\Lambda)$ we denote Müntz–Legendre polynomials given by (2.2), constructed for the nondecreasing real sequence $\Lambda = \{\lambda_0, \lambda_1, \ldots\}$. By σ we denote a positive measure supported on the interval $[0,1]$. The use of orthogonal Müntz–Legendre polynomials in our procedure is very important. Our construction is quite different not only from the procedure for the classical Gaussian integration formulae with an algebraic degree of precision but also from the corresponding algorithm given in [13].

In the polynomial case the well-known Golub and Welsch procedure [9] is applied when the quadrature nodes x_k are eigenvalues of the three-diagonal Jacobi matrix, i.e., the zeros of the (algebraic) polynomial $P_n(x)$ orthogonal with respect to the measure $d\sigma(x)$, and weights A_k are expressed in terms of first component of the normalized eigenvectors corresponding to the eigenvalues x_k, respectively (cf. the routine GAUSS in the package ORTHPOL given by Gautschi [7]).

The algorithm in [13] for finding nodes and weights in (3.1) needs the construction of the functions ξ_i and η_i, $i = 1, \ldots, n$, defined by (1.3) and (1.4). The nodes $x_1, \ldots, x_n$ are Gaussian if and only if (see [13, Theorem 4.1])

$$\int_0^1 \xi_i(x)\, d\sigma(x) = \sum_{j=1}^{2n} \alpha_{ij} \int_0^1 P_{j-1}(x)\, d\sigma(x) = 0, \quad i = 1, \ldots, n.$$

In this case, the Gaussian weights are given by

$$A_i = \int_0^1 \eta_i(x)\, d\sigma(x) = \sum_{j=1}^{2n} \beta_{ij} \int_0^1 P_{j-1}(x)\, d\sigma(x), \quad i = 1, \ldots, n.$$

Our algorithm can be summarized in the following steps.

We start with the initial system of nonlinear equations given by

$$\sum_{k=1}^{n} A_k P_\nu(x_k) = \mu_\nu = \int_0^1 P_\nu(x)\, d\sigma, \quad \nu = 0, 1, \ldots, 2n-1. \tag{3.2}$$

Note that the vector of moments μ_ν becomes quite simple, provided $d\sigma(x) = x^{\lambda_0} dx$. In this special case, according to the orthogonality condition of the Müntz–Legendre polynomials (see (2.6)), we have

$$\mu_\nu = \frac{\delta_{\nu,0}}{2\lambda_0 + 1}, \quad \nu \in \mathbb{N}_0.$$

We rewrite the system of equations (3.2) in the form

$$U_n \boldsymbol{A} - \boldsymbol{c} = \boldsymbol{0}, \quad V_n \boldsymbol{A} - \boldsymbol{d} = \boldsymbol{0},$$

where $\boldsymbol{A} = [A_1\ A_2\ \cdots\ A_n]^T$, $\boldsymbol{c} = [\mu_0\ \mu_1\ \cdots\ \mu_{n-1}]^T$, and $\boldsymbol{d} = [\mu_n\ \mu_{n+1}\ \cdots\ \mu_{2n-1}]^T$, and we apply the Newton–Kantorovich method in order to solve it.

Let $\Delta \boldsymbol{A} = \boldsymbol{A} - \hat{\boldsymbol{A}}$ and $\Delta \boldsymbol{x} = \boldsymbol{x} - \hat{\boldsymbol{x}}$, where $\hat{\boldsymbol{A}}$ and $\hat{\boldsymbol{x}}$ are the unique solutions of the starting nonlinear system. Then we can formulate the Newton–Kantorovich method as

$$U_n \Delta \boldsymbol{A} + Y_n \Delta \boldsymbol{x} = U_n \boldsymbol{A} - \boldsymbol{c},$$

$$V_n \Delta \boldsymbol{A} + Z_n \Delta \boldsymbol{x} = V_n \boldsymbol{A} - \boldsymbol{d},$$

or, equivalently,

$$W_n \begin{bmatrix} \Delta \boldsymbol{A} \\ \Delta \boldsymbol{x} \end{bmatrix} = \begin{bmatrix} U_n \boldsymbol{A} - \boldsymbol{c} \\ V_n \boldsymbol{A} - \boldsymbol{d} \end{bmatrix}, \tag{3.3}$$

where

$$W_n = \begin{bmatrix} U_n & Y_n \\ V_n & Z_n \end{bmatrix}, \qquad \boldsymbol{x} = \begin{bmatrix} x_1 & x_2 & \cdots & x_n \end{bmatrix}^T, \tag{3.4}$$

$$U_n = U_n(\boldsymbol{x}) = \begin{bmatrix} P_0(x_1) & P_0(x_2) & \cdots & P_0(x_n) \\ P_1(x_1) & P_1(x_2) & & P_1(x_n) \\ \vdots & & & \\ P_{n-1}(x_1) & P_{n-1}(x_2) & & P_{n-1}(x_n) \end{bmatrix},$$

$$V_n = V_n(\boldsymbol{x}) = \begin{bmatrix} P_n(x_1) & P_n(x_2) & \cdots & P_n(x_n) \\ P_{n+1}(x_1) & P_{n+1}(x_2) & & P_{n+1}(x_n) \\ \vdots & & & \\ P_{2n-1}(x_1) & P_{2n-1}(x_2) & & P_{2n-1}(x_n) \end{bmatrix},$$

$$Y_n = Y_n(\boldsymbol{x}) = \begin{bmatrix} A_1 P_0'(x_1) & A_2 P_0'(x_2) & \cdots & A_n P_0'(x_n) \\ A_1 P_1'(x_1) & A_2 P_1'(x_2) & & A_n P_1'(x_n) \\ \vdots & & & \\ A_1 P_{n-1}'(x_1) & A_2 P_{n-1}'(x_2) & & A_n P_{n-1}'(x_n) \end{bmatrix},$$

$$Z_n = Z_n(\boldsymbol{x}) = \begin{bmatrix} A_1 P_n'(x_1) & A_2 P_n'(x_2) & \cdots & A_n P_n'(x_n) \\ A_1 P_{n+1}'(x_1) & A_2 P_{n+1}'(x_2) & & A_n P_{n+1}'(x_n) \\ \vdots & & & \\ A_1 P_{2n-1}'(x_1) & A_2 P_{2n-1}'(x_2) & & A_n P_{2n-1}'(x_n) \end{bmatrix}.$$

Now, our iterative process becomes

$$\hat{\boldsymbol{x}} = \boldsymbol{x} - \left[V_n U_n^{-1} Y_n - Z_n\right]^{-1} (\boldsymbol{d} - V_n U_n^{-1} \boldsymbol{c}),$$

$$\hat{\boldsymbol{A}} = U_n^{-1} \left[Y_n (\boldsymbol{x} - \hat{\boldsymbol{x}}) + \boldsymbol{c}\right]. \tag{3.5}$$

We can prove that our method for this construction is convergent. The basic theorem on the convergence of the Newton–Kantorovich method can be summarized as follows: Suppose we are given some differentiable function $\boldsymbol{f} : \mathbb{R}^m \mapsto \mathbb{R}^m$, $m \in \mathbb{N}$, with the property that at the solution of $\boldsymbol{f}(\boldsymbol{x}) = 0$, we have that $|J(\boldsymbol{x})| \neq 0$, i.e., the Jacobian of $\boldsymbol{f}$ at the solution is not singular. Then, there exists some $\varepsilon > 0$, such that for any $\boldsymbol{y}_0$, with the property $||\boldsymbol{y}_0 - \boldsymbol{x}|| < \varepsilon$, we have that the sequence $\boldsymbol{y}_k$, $k \in \mathbb{N}$, defined by

$$\boldsymbol{y}_{k+1} = \boldsymbol{y}_k - (J(\boldsymbol{y}_k))^{-1}\boldsymbol{f}(\boldsymbol{y}_k), \quad k \in \mathbb{N}_0,$$

tends to $\boldsymbol{x}$ with a quadratic speed.

LEMMA 3.1. [illegible] (3.5) [illegible]. The Jacobian for the starting nonlinear system can be easily calculated in the form

$$J(\hat{\boldsymbol{x}}, \hat{\boldsymbol{A}}) = W_n.$$

It is easy to see that the determinant $|W_n|$ can be written as

$$|W_n| = \left(\prod_{k=1}^{n} A_k\right) \begin{vmatrix} P_0(x_1) & \cdots & P_0(x_n) & P_0'(x_1) & \cdots & P_0'(x_n) \\ P_1(x_1) & & P_1(x_n) & P_1'(x_1) & & P_1'(x_n) \\ \vdots & & & & & \\ P_{2n-1}(x_1) & & P_{2n-1}(x_n) & P_{2n-1}'(x_1) & & P_{2n-1}'(x_n) \end{vmatrix}.$$

Since our system of functions is EH and the weights A_k, $k = 1, \ldots, n$, are positive, this determinant cannot be zero, and thus the Jacobian has full rank. Also, since the system of functions x^Λ is Chebyshev, the matrix U_n is invertible. It is enough to apply the theorem on the matrix inversion in the block form presented in [18, p. 205] (see also [10, p. 13] and [26, p. 201]) to finish the proof. □

The standard problem with the Newton–Kantorovich method is a problem of determining starting values. One way to ensure the convergence, for $d\sigma(x) = x^{\lambda_0}dx$, is based on the continuation of the classical Gaussian quadrature rule.

LEMMA 3.2. [illegible] $\Lambda = \{\lambda_k \mid k \in \mathbb{N}_0\}$ $\lambda_k > -1/2$ $k \in \mathbb{N}_0$ [illegible] $A_k := A_k(\alpha)$ $x_k := x_k(\alpha)$ $\alpha \in [0, 1]$ [illegible]

$$\sum_{k=1}^{n} A_k P_\nu^\alpha(x_k) = \frac{\delta_{\nu,0}}{2\alpha\lambda_0 + 1}, \quad \nu = 0, 1, \ldots, 2n-1,$$

[illegible]

$$P_\nu^\alpha(x) := P_\nu(x; (1-\alpha)\mathbb{N}_0 + \alpha\Lambda) = \frac{1}{2\pi i}\oint_\Gamma G_\nu(s, \alpha, \Lambda)x^s\, ds$$

[illegible]

$$G_\nu(s, \alpha, \Lambda) = \prod_{k=0}^{\nu-1} \frac{s + (1-\alpha)k + \alpha\lambda_k + 1}{s - (1-\alpha)k - \alpha\lambda_k} \frac{1}{s - (1-\alpha)\nu - \alpha\lambda_\nu},$$

[illegible]

. It is easy to verify that the function

$$\boldsymbol{F}(\boldsymbol{x},\boldsymbol{A},\alpha)=\begin{bmatrix}\sum\limits_{k=1}^{n}A_kP_0^{\alpha}(x_k)\\ \vdots\\ \sum\limits_{k=1}^{n}A_kP_{2n-1}^{\alpha}(x_k)\end{bmatrix}$$

has derivatives in x_k, A_k, $k=1,\dots,n$, and α for $0<x_1<x_2<\cdots<x_n<1$, $A_k>0$, $k=1,\dots,n$, and $\alpha\in(0,1)$. We have

$$\partial_{x_j}\left(\sum_{k=1}^{n}A_kP_\nu^{\alpha}(x_k)\right)=A_j(P_\nu^{\alpha})'(x_j),\quad \nu=0,1,\dots,2n-1,\quad j=1,\dots,n,$$

$$\partial_{A_j}\left(\sum_{k=1}^{n}A_kP_\nu^{\alpha}(x_k)\right)=P_\nu^{\alpha}(x_j),\quad \nu=0,1,\dots,2n-1,\quad j=1,\dots,n,$$

$$\partial_{\alpha}\left(\sum_{k=1}^{n}A_kP_\nu^{\alpha}(x_k)\right)=\frac{1}{2\pi i}\oint_{\Gamma}\partial_{\alpha}\left\{\big(G_\nu(s,\alpha,\Lambda)\big)\left(\sum_{k=1}^{n}A_kx_k^s\right)\right\}ds.$$

Since for every $\alpha\in[0,1]$, there exists the unique solution of

$$\boldsymbol{F}(\boldsymbol{A},\boldsymbol{x},\alpha)=\frac{\boldsymbol{e}_0}{2\alpha\lambda_0+1} \tag{3.6}$$

in $\boldsymbol{A}$ and $\boldsymbol{x}$, we can define the functions $A_k:=A_k(\alpha)$, $x_k:=x_k(\alpha)$, $k=1,\dots,n$. Here, $\boldsymbol{e}_0$ is the fist coordinate vector, i.e., $\boldsymbol{e}_0=[1\ 0\ \cdots\ 0]^T$.

Using the system of equations (3.6), we can calculate derivatives with respect to α in the form

$$\partial_{\alpha}\boldsymbol{F}+\sum_{k=1}^{n}\left(\partial_{x_k}\boldsymbol{F}\frac{dx_k}{d\alpha}+\partial_{A_k}\boldsymbol{F}\frac{dA_k}{d\alpha}\right)=-\frac{2\lambda_0}{(2\alpha\lambda_0+1)^2}\boldsymbol{e}_0.$$

Now, from here we get

$$W_n\begin{bmatrix}\dfrac{dA_1}{d\alpha}\\ \vdots\\ \dfrac{dx_n}{d\alpha}\end{bmatrix}=-\frac{2\lambda_0}{(2\alpha\lambda_0+1)^2}\boldsymbol{e}_0-\partial_{\alpha}\boldsymbol{F},$$

where the matrix W_n is the same as in (3.4), formed with P_ν replaced by P_ν^{α}. Since the matrix W_n is invertible, it is easy to conclude that the functions $A_k:=A_k(\alpha)$, $x_k:=x_k(\alpha)$, $k=1,\dots,n$, are differentiable. □

Since the functions $A_k(\alpha)$ and $x_k(\alpha)$, $k=1,\dots,n$, are continuous in $\alpha\in[0,1]$, we start with $\alpha=0$ and construct the classical Gaussian quadrature rule with parameters $A_k(0)$ and $x_k(0)$. Now, if we increase α by a small amount, we can use the obtained values for $A_k(0)$ and $x_k(0)$ as starting values for $A_k(\alpha)$ and $x_k(\alpha)$ in the Newton–Kantorovich method. Again, we can increase α by a small amount and try to solve the system with starting values obtained from the previous step. We repeat the procedure until $\alpha=1$ is reached.

There is still another possibility of continuation. Namely, we have the following lemma.

LEMMA 3.3. [illegible] $\boldsymbol{\mu} = [\mu_0\ \mu_1\ \cdots\ \mu_{2n-1}]^T$ [illegible] (3.2) [illegible] $A_k := A_k(\boldsymbol{\mu})$ [illegible] $x_k := x_k(\boldsymbol{\mu})$ $k = 1, \ldots, n$ [illegible] (3.2) [illegible]. Note that by the fact that there exists a unique solution to the system of equations (3.2), we have that A_k and x_k are single valued functions. Since the Jacobi matrix W_n is invertible at any solution, according to the inverse function theorem, we have that x_k and A_k, $k = 1, \ldots, n$, are continuous in $\boldsymbol{\mu}$. □

Using this lemma and the following idea we can construct the generalized Gaussian quadrature rule for some measure σ. Denote moments for the measure $x^{\lambda_0}dx$ by $\delta_{\nu,0}/(2\lambda_0+1)$, $\nu = 0, 1, \ldots, 2n-1$. By $\boldsymbol{\mu}$ integrals as in (3.2), we can introduce the moments

$$\hat{\mu}_\nu = (1-\alpha)\frac{\delta_{\nu,0}}{2\lambda_0+1} + \alpha\mu_\nu, \quad \nu = 0, 1, \ldots, 2n-1, \quad \alpha \in [0,1]. \tag{3.7}$$

Then x_k and A_k, $k = 1, \ldots, n$, are continuous functions of $\alpha \in [0,1]$. Thus, we increase α by a small amount and solve the systems of nonlinear equations (3.2) in order to achieve $\alpha = 1$ starting with $\alpha = 0$.

According to the previous two lemmas, we can construct the solution using the following steps:

- First, using Lemma 3.2, starting from the classical Gauss–Legendre quadrature rule, we construct the generalized quadrature rule for the $x^{\lambda_0}dx$ measure and any given system Λ.
- Once the generalized quadrature rule is constructed for the $x^{\lambda_0}dx$ measure, we introduce the moments, as given in (3.7), to construct the generalized quadrature rule for the targeting measure σ, with the moment vector $\boldsymbol{\mu}$.

We next address numerical properties of the nonlinear system of equations (3.2). For example, we have to give the algorithm to calculate the values of the polynomials P_ν, $\nu = 0, 1, \ldots, 2n-1$, at the points x_k, $k = 1, \ldots, n$. This is already solved (see [17]), and we address it in subsection 3.3. For derivatives $P_k'(x)$ we can use the recurrence relation (2.8), i.e.,

$$xP_n'(x) - xP_{n-1}'(x) = \lambda_n P_n(x) + (1+\bar{\lambda}_{n-1})P_{n-1}(x).$$

It is easy to verify that our method depends strongly on the condition number of the matrix U_n. In fact, assuming the Newton–Kantorovich method is converging, it is easy to verify that the weights $\boldsymbol{A}$ are the solution of the system of linear equations

$$U_n\boldsymbol{A} = \frac{\boldsymbol{e}_0}{2\lambda_0+1},$$

where the matrix $U_n = [P_\nu(x_k)]_{\nu,k=1}^n$ is calculated at the solution for the nodes x_k, $k = 1, \ldots, n$. Hence, the precision in constructed weights A_k, $k = 1, \ldots, n$, can be determined according to the condition number of the matrix U_n. Note that the precision in the constructed nodes x_k, $k = 1, \ldots, n$, is also determined by the precision in the constructed weights A_k. To present this simple fact, we consider our system of equations for the Newton–Kantorovich method (3.5). We have

$$\begin{aligned}\hat{x} &= x - (V_nU_n^{-1}Y_n - Z_n)^{-1}(\boldsymbol{d} - V_nU_n^{-1}\boldsymbol{c}) \\ &= x - (V_nU_n^{-1}Y_n - Z_n)^{-1}(\boldsymbol{d} - V_n\bar{\boldsymbol{A}}) = x - (V_nU_n^{-1}Y_n - Z_n)^{-1}(\boldsymbol{d} - \bar{\boldsymbol{d}}),\end{aligned}$$

where

$$\bar{\boldsymbol{d}} = V_n \bar{\boldsymbol{A}}$$

is a vector of the calculated moments $[\bar{\mu}_n \cdots \bar{\mu}_{2n-1}]^T$ with weights $\bar{\boldsymbol{A}}$. Obviously we have $\boldsymbol{d} \neq \bar{\boldsymbol{d}}$, which has as a consequence that nodes $\boldsymbol{x}$ are constructed with an error originating from the fact that weights cannot be constructed without an error.

3.1. Condition number of U_n. The algorithm strongly depends on the condition number of the matrix U_n. Assuming all nodes $\boldsymbol{x}$ are known, it is obvious that we can calculate the weights $\boldsymbol{A}$ as $U_n^{-1}\boldsymbol{c}$. Although it is hard to give precise results about the condition number of U_n, for some special cases linked with polynomials, we can give some theoretical results concerning the condition number of this matrix.

We define the condition number of a matrix B to be $||B||||B^{-1}||$, where, as it is known, any matrix norm will do. Following [8, p. 64], we restrict our attention to the Frobenius norm, i.e., $||\,[b_{i,j}]_{i,j=1}^{n}\,|| = (\sum_i \sum_j b_{i,j}^2)^{1/2}$. We consider the slightly modified matrix U_n, i.e., we put the normalized version of Müntz–Legendre polynomials into the system of nonlinear equations (3.2) so that we have

$$\sum_{k=1}^{n} A_k p_\nu(x_k) = \frac{\mu_\nu}{||P_\nu||} = \int_0^1 p_\nu(x)d\sigma(x), \quad \nu = 0, 1, \ldots, 2n-1.$$

This has as a consequence that in matrices U_n, V_n, Y_n, and Z_n, P_ν is replaced with p_ν, $\nu = 0, 1, \ldots, 2n-1$, and vectors $\boldsymbol{d}$ and $\boldsymbol{c}$ are filled with the sequence of moments $\mu_\nu/||P_\nu||$, $\nu \in \mathbb{N}_0$. This renormalization of the system does not change anything, as is explained in [8, pp. 65–66].

In this case, we can express

$$||U_n||^2 = \sum_{k=1}^{n} \sum_{\nu=0}^{n-1} p_\nu(x_k)^2.$$

In order to get the inverse matrix, we define Müntz–Lagrange polynomials as

$$\ell_k(x) = \sum_{\nu=0}^{n-1} \alpha_k^\nu p_\nu(x), \quad k = 1, \ldots, n,$$

with the property

$$\ell_k(x_\nu) = \delta_{k,\nu}, \quad k, \nu = 1, \ldots, n.$$

The Müntz–Lagrange polynomials ℓ_k, $k = 1, \ldots, n$, are defined correctly since p_ν, $\nu = 0, 1, \ldots, n-1$, makes a Chebyshev system. Also, it is easy to prove that $\operatorname{span}\{\ell_k \mid k = 1, \ldots, n\}$ is exactly the same as $\operatorname{span}\{p_\nu \mid \nu = 0, 1, \ldots, n-1\}$.

Now, we can identify the matrix U_n^{-1} as the matrix $[\alpha_k^\nu]_{\nu=0,1,\ldots,n-1,k=1,\ldots,n}$, and then we can calculate the norm of the matrix U_n^{-1} in the form

$$||U_n^{-1}||^2 = \sum_{\nu=0}^{n-1} \sum_{k=1}^{n} (\alpha_k^\nu)^2.$$

Using the simple identity

$$\int_0^1 \ell_k(x)^2 dx = \int_0^1 \left\{ \sum_{\nu=0}^{n-1} \alpha_k^\nu p_\nu(x) \sum_{\mu=0}^{n-1} \alpha_k^\mu p_\mu(x) \right\} dx = \sum_{\nu=0}^{n-1} (\alpha_k^\nu)^2,$$

we get

$$||U_n^{-1}||^2 = \int_0^1 \left(\sum_{k=1}^{n} \ell_k(x)^2 \right) dx.$$

In total we express the condition number of the matrix U_n as

$$||U_n||||U_n^{-1}|| = \left(\sum_{k=1}^{n} \sum_{\nu=0}^{n-1} p_\nu(x_k)^2 \right)^{1/2} \left(\int_0^1 \left(\sum_{k=1}^{n} \ell_k(x)^2 \right) dx \right)^{1/2}.$$

It is not easy to give some estimates of this number; hence, we are going to discuss two cases connected to the orthogonal polynomials. The first is for $\Lambda = \{k \mid k \in \mathbb{N}_0\}$, where our Müntz–Legendre polynomials are really Legendre polynomials. The second case is for $\Lambda = \{0 \mid k \in \mathbb{N}_0\}$, where our Müntz–Legendre polynomials are Laguerre polynomials in $-\log x$, as given in (2.5). As experiments show, the behavior for the general nondecreasing sequence Λ can be understood using these two special cases. Hence, we discuss these two cases.

According to the fact that in these cases Müntz–Lagrange polynomials can be expressed in the form

$$\ell_\nu(x) = \frac{p_n(x)}{(x - x_\nu) p_n'(x_\nu)}, \quad \nu = 1, \ldots, n,$$

for the Legendre case, and as

$$\ell_\nu(x) = \frac{p_n(x)}{(-\log x - x_\nu) p_n'(x_\nu)}, \quad \nu = 1, \ldots, n,$$

in the Laguerre case, we have an orthogonality of the Müntz–Lagrange polynomials, i.e.,

$$\int_0^1 \ell_\nu(x) \ell_k(x) dx = ||\ell_k||^2 \delta_{\nu,k}, \quad \nu, k = 1, \ldots, n.$$

Then, according to the fact that $1 = \sum_\nu \ell_\nu(x)$, and using the mentioned orthogonality, we find

$$\int_0^1 \left(\sum_{\nu=1}^{n} \ell_\nu(x)^2 \right) dx = \int_0^1 \left(\sum_{\nu=1}^{n} \ell_\nu(x) \sum_{k=1}^{n} \ell_k(x) \right) dx = \int_0^1 \left(\sum_{\nu=1}^{n} \ell_\nu(x) \right)^2 dx = 1,$$

so that $||U_n^{-1}|| = 1$.

Using the Shohat formula (see [19], [23]), we can express the norm $||U_n||$ in the form

$$||U_n||^2 = \sum_{k=1}^{n} \frac{1}{w_k},$$

where we denoted by w_k, $k = 1, \ldots, n$, the weights in the classical Gaussian quadrature rule associated with the sequence of polynomials p_ν, $\nu \in \mathbb{N}_0$. Using the Markov inequality (see [24, p. 50])

$$\sum_{k=\nu+1}^{n} w_k \leq \int_{x_\nu}^{+\infty} d\mu(x), \quad \nu = 1, \ldots, n-1,$$

we have, for the Laguerre measure, $\exp(x_{n-1}) \le (w_n)^{-1}$, which means that in the Laguerre case we have $||U_n|| \ge \exp(\sqrt{n}/2)$, where we have used an estimate for zeros of Laguerre polynomials given in [24, p. 129]. Hence, for the sequence $\Lambda = \{0 \mid k \in \mathbb{N}_0\}$, the condition number of the matrix U_n grows exponentially with n.

In what follows, for two sequences A_n and B_n we write $A_n \sim B_n$ if and only if there exist two positive constants C_1 and C_2 such that $C_1 \le |A_n/B_n| \le C_2$.

Now, for the Legendre measure we use the following asymptotic estimate $w_k \sim \pi(1-x_k^2)^{1/2}/n$, $k = 1, \dots, n$, given in [21, p. 85] (see also Szegő [24, p. 253]), to get

$$||U_n||^2 = \sum_{k=1}^{n} \frac{1}{w_k} \sim \frac{n}{\pi} \sum_{k=1}^{n} (1-x_k^2)^{-1/2}.$$

Using the estimate for the zeros $x_k = -\cos\theta_k$, $k = 1, \dots, n$, of the Legendre polynomials (see [24, p. 125])

$$\frac{k-1/2}{n+1/2} < \theta_k < \frac{k}{n+1/2}, \quad k = 1, \dots, n,$$

and Jordan inequality $2\theta/\pi < \sin\theta < \theta$, $\theta \in (0, \pi/2)$, we have simply

$$||U_n||^2 \sim \frac{n}{\pi} \sum_{k=1}^{n} \frac{1}{\sin\theta_k} \sim \frac{2n}{\pi} \sum_{k=1}^{[n/2]} \frac{1}{\sin\theta_k} \sim n \sum_{k=1}^{[n/2]} \frac{1}{\theta_k} \sim n\left(n+\frac{1}{2}\right) \sum_{k=1}^{[n/2]} \frac{1}{k} \sim n^2 \log n,$$

so that, for the Legendre case, i.e., $\Lambda = \{k \mid k \in \mathbb{N}_0\}$, we have that the condition number of the matrix U_n grows like $n \log^{1/2} n$.

LEMMA 3.4. , $\Lambda = \{k \mid k \in \mathbb{N}_0\}$, . . $||U_n||||U_n^{-1}|| \sim n \log^{1/2} n$, $\Lambda = \{0 \mid k \in \mathbb{N}_0\}$, . . $||U_n||||U_n^{-1}|| \sim \exp(\sqrt{n}/2)$

This lemma shows that in the cases when a nondecreasing sequence Λ is close to the Legendre case, we should expect the condition number of U_n to grow relatively slowly with respect to n. In the opposite case for the almost constant sequence Λ, we should expect the condition number to grow rather rapidly with respect to n. This behavior is going to be illustrated in the last section.

3.2. Construction for the nonintegrable basis. In what follows we discuss the construction of the generalized Gaussian quadrature rule in the case when a nondecreasing sequence Λ is such that for some λ_k we have $2\lambda_k \le -1$. It is easy to verify that in this case we cannot construct the sequence of Müntz–Legendre polynomials orthogonal with respect to the Legendre measure since the functions $x^{\lambda_k} x^{\lambda_k}$, for which $2\lambda_k \le -1$, are not integrable with respect to the Legendre measure.

What we can do is use Müntz polynomials given by (2.7), which are orthogonal with respect to the measure $x^\beta dx$, where β is chosen such that we have $2\lambda_k + \beta > -1$, $k \in \mathbb{N}_0$. If we introduce a new nondecreasing sequence $\Lambda + \beta/2$, we can construct the sequence of Müntz polynomials $P_n(\cdot; \Lambda + \beta/2)$, $n \in \mathbb{N}_0$, generated by $\Lambda + \beta/2$, orthogonal with respect to Legendre measure, and then, using the previously described method, we are able to solve the system of equations

$$\sum_{k=1}^{n} A_k P_\nu\left(x_k; \Lambda + \frac{\beta}{2}\right) = \frac{\delta_{\nu,0}}{2\lambda_0 + \beta + 1} = \int_0^1 x^{\lambda_0 + \beta/2} P_\nu\left(x; \Lambda + \frac{\beta}{2}\right) dx, \; 0 \le \nu \le 2n-1.$$

Then, if we rewrite the system in the form

$$\sum_{k=1}^{n}\left(A_k x_k^{\beta/2}\right)\left(x_k^{-\beta/2}P_\nu\left(x_k;\Lambda+\frac{\beta}{2}\right)\right)$$
$$=\frac{1}{2\lambda_0+\beta+1}\delta_{\nu,0}=\int_0^1 x^{\lambda_0+\beta}\left(x^{-\beta/2}P_\nu\left(x;\Lambda+\frac{\beta}{2}\right)\right)dx,\quad \nu=0,1,\ldots,2n-1,$$

and if we choose

$$A_k^*=A_k x_k^{\beta/2},\quad x_k^*=x_k,\quad k=1,\ldots,n,$$

it can be verified that the quadrature rule

$$\sum_{k=1}^{n}A_k^* f(x_k^*)$$

is exact in the linear span of $x^{\Lambda_{2n-1}}$ with respect to the measure $x^{\lambda_0+\beta}dx$. Thus, we have the following result.

LEMMA 3.5. $\Lambda+\beta/2\quad\beta\in\mathbb{R}$ $x_k\quad A_k\quad k=1,\ldots,n$ (3.2) $x^{\lambda_0+\beta/2}dx$ (3.2) $x^{\lambda_0+\beta}dx$ $x^{\Lambda_{2n-1}}$

$$x_k^*=x_k,\quad A_k^*=A_k x_k^{\beta/2},\quad k=1,\ldots,n.$$

A consequence of this simple observation is the possibility of using the described algorithm for the construction of the generalized Gaussian quadrature rule, for example, for the set of functions

$$x^{k-2/3},\quad x^k,\quad k=0,1,\ldots,2n-1.$$

Some numerical values for this case are presented in the last section.

3.3. Numerical computation of Müntz–Legendre polynomials. A direct evaluation of Müntz polynomials $P_n(x)$ in the power form (2.3) can be a big problem in finite arithmetic, especially when n is a large number and x is close to 1. These problems have been addressed in [17].

In this subsection we give a stable numerical method for evaluating the values of the Müntz–Legendre polynomials defined by (2.1) and (2.2), i.e.,

$$P_n(x)=\frac{1}{2\pi i}\oint_\Gamma W_n(s)x^s\,ds,\qquad W_n(s)=\prod_{\nu=0}^{n-1}\frac{s+\bar{\lambda}_\nu+1}{s-\lambda_\nu}\cdot\frac{1}{s-\lambda_n}. \tag{3.8}$$

For a detailed discussion, see [17].

Our method is based on a direct evaluation of the contour integral in (3.8). At first we take the contour $\Gamma=\Gamma_R=C_R\cup L_R$ (see Figure 3.1 (left)). As we can see, C_R is a semicircle with the center at $\sigma<-1/2$, its radius R is such that all poles of $W_n(s)$ are inside the contour Γ_R, and L_R is a part of the straight line $s=\sigma+it$, $-R\le t\le R$. (Notice that the function $W_n(s)$ in Figure 3.1 has only real poles.)

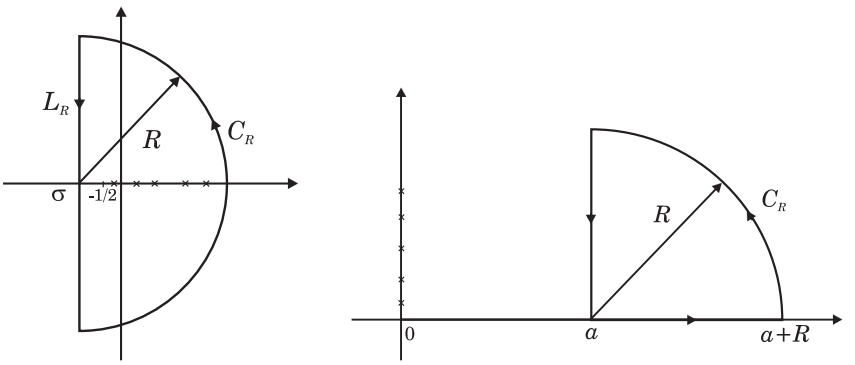

FIG. 3.1. *The contour of integration for the integral in* (3.1) (*left*) *and for the integral* $L_2(f_n(\cdot;\omega))$ (*right*).

We have a simple lemma.

LEMMA 3.6. $\int_{C_R} W_n(s)x^s\,ds \to 0$ $R \to +\infty$

Thus, when $R \to +\infty$, an integration along the contour Γ_R reduces to the integration over the line L_R, so that

$$P_n(x) = \frac{x^\sigma}{2\pi i}\int_{-\infty}^{+\infty} f_n(t;\omega)e^{it}\,dt,$$

where $\omega = \log(1/x) > 0$ and

$$f_n(t;\omega) = \prod_{\nu=0}^{n-1} \frac{t + i(\sigma + \bar{\lambda}_\nu + 1)\omega}{t + i(\sigma - \lambda_\nu)\omega} \cdot \frac{1}{t + i(\sigma - \lambda_n)\omega}. \tag{3.9}$$

This gives the following result.

THEOREM 3.7. $\sigma < -1/2$ $\omega = \log(1/x)$ $f_n(t;\omega)$ (3.9)

$$\varphi_n(t;\omega) = \frac{1}{2i}\Big(f_n(t;\omega)e^{it} + f_n(-t;\omega)e^{-it}\Big). \tag{3.10}$$

$$P_n(x) = \frac{x^\sigma}{\pi}\int_0^{+\infty} \varphi_n(t;\omega)\,dt. \tag{3.11}$$

In what follows we consider the case when the sequence Λ is real. An important corollary of Theorem 3.7 is the following result.

THEOREM 3.8. $\Lambda = \{\lambda_0, \lambda_1, \lambda_2, \ldots\}$ $\lambda_\nu > -1/2$ $k \in \mathbb{N}_0$ $f_n(t;\omega)$ (3.9) $\omega = \log(1/x)$ $\sigma < -1/2$

$$P_n(x) = \frac{x^\sigma}{\pi}\mathrm{Im}\left\{\int_0^{+\infty} f_n(t;\omega)e^{it}\,dt\right\}. \tag{3.12}$$

In this case we have $f_n(-t;\omega) = \overline{f_n(t;\omega)}$, then (3.10) becomes $\varphi_n(t;\omega) = \mathrm{Im}\{f_n(t;\omega)e^{it}\}$, and (3.11) gives (3.12). The poles of $f_n(t;\omega)$ are then purely imaginary, $i(\lambda_\nu - \sigma)\omega$, $\nu = 0, 1, \ldots, n$, and located on the positive part of the imaginary axes, because of $\lambda_\nu > \sigma$ and $\omega = \log(1/x) > 0$.

In order to calculate the integral in (3.12) (or in (3.11)) we use an idea from complex integration (see [16, Thm. 2.2]). We select a positive number $a = m\pi$ ($m \in \mathbb{N}$) and put

$$\int_0^{+\infty} f_n(t;\omega)e^{it}\,dt = \int_0^{a} f_n(t;\omega)e^{it}\,dt + \int_a^{+\infty} f_n(t;\omega)e^{it}\,dt$$
$$= L_1(f_n(\cdot;\omega)) + L_2(f_n(\cdot;\omega)).$$

Here,

$$L_1(f_n(\cdot;\omega)) = \int_0^{a=m\pi} f_n(t;\omega)e^{it}\,dt = \sum_{k=1}^{m}\int_{(k-1)\pi}^{k\pi} f_n(t;\omega)e^{it}\,dt,$$

i.e.,

$$L_1(f_n(\cdot;\omega)) = \pi\int_0^1 \left[\sum_{k=1}^{m} f_n\big(\pi(\xi+k-1);\omega\big)e^{i\pi(\xi+k-1)}\right] d\xi, \tag{3.13}$$

and $L_2(f_n(\cdot;\omega)) = \int_a^{+\infty} f_n(t;\omega)e^{it}\,dt$.

Since $f_n(z;\omega)$ is a holomorphic function in the region $D = \big\{z \in \mathbb{C} \mid \operatorname{Re} z \geq a > 0,\ \operatorname{Im} z \geq 0\big\}$ and $|f_n(z;\omega)| \leq A/|z|$ when $|z| \to +\infty$, for some positive constant A, we can prove

$$L_2(f_n(\cdot;\omega)) = ie^{ia}\int_0^{+\infty} f_n(a+iy;\omega)e^{-y}\,dy. \tag{3.14}$$

For $a = m\pi$, (3.14) becomes

$$L_2(f_n(\cdot;\omega)) = (-1)^m\int_0^{+\infty} \psi_n(y;\omega)e^{-y}\,dy, \tag{3.15}$$

where

$$\psi_n(y;\omega) = if_n(a+iy;\omega) = \prod_{\nu=0}^{n-1}\frac{y+(\sigma+\lambda_\nu+1)\omega-ia}{y+(\sigma-\lambda_\nu)\omega-ia}\cdot\frac{1}{y+(\sigma-\lambda_n)\omega-ia}.$$

THEOREM 3.9. [illegible] 3.8 [illegible]

$$P_n(x) = \frac{x^\sigma}{\pi}\operatorname{Im}\Big\{L_1(f_n(\cdot;\omega)) + L_2(f_n(\cdot;\omega))\Big\},$$

[illegible] $L_1(f_n(\cdot;\omega))$ [illegible] $L_2(f_n(\cdot;\omega))$ [illegible] (3.13) [illegible] (3.15) [illegible]

In the numerical implementation we use the Gauss–Legendre rule on $(0,1)$ and the Gauss–Laguerre rule for calculating $L_1(f_n(\cdot;\omega))$ and $L_2(f_n(\cdot;\omega))$, respectively. A convenient choice for the parameter σ is $\lambda_{\min} - \pi/\omega$, where $\lambda_{\min} = \min\{\lambda_0, \lambda_1, \ldots\}$.

4. Numerical examples. In this section we present some numerical examples. Here we want to emphasize that in all examples, as starting values for the Newton–Kantorovich method (3.2), we used the zeros of the Müntz–Legendre polynomial P_n. According to Theorem 2.4 there are exactly n different zeros of P_n in the interval $(0,1)$.

TABLE 4.1

Nodes and weights in the generalized Gaussian quadrature rule for $\lambda_{2k} = k$ and $\lambda_{2k+1} = k+1/3$, $k \in \mathbb{N}_0$ (left) and $\lambda_{2k} = \lambda_{2k+1} = k$, $k \in \mathbb{N}_0$ (right) for 30 points.

The first example is concerned with $\lambda_{2k} = k$ and $\lambda_{2k+1} = k + 1/3$, $k \in \mathbb{N}$. Using the demonstrated algorithm we are able to safely construct generalized Gaussian quadrature rules with 30 points. The corresponding results are presented in Table 4.1 (left). Numbers in parentheses indicate decimal exponents. The presented precision is achieved in six iterations. Figure 4.1 (left) presents the condition number of the matrix U_n as a function of the number of nodes n in the generalized Gaussian quadrature rule (1.7). As we can see, the condition number grows as n^2, which makes the

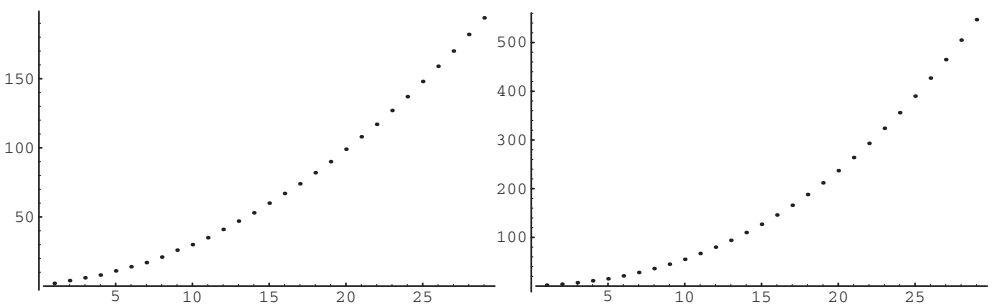

FIG. 4.1. *The condition number of the matrices U_n (left) and $V_n U_n^{-1} Y_n - Z_n$ (right) for $n = 2(1)30$ and $\lambda_{2k} = k$, $\lambda_{2k+1} = k + 1/3$, $k \in \mathbb{N}_0$.*

construction possible. The condition number of the matrix $V_n U_n^{-1} Y_n - Z_n$ is given in Figure 4.1 (right). The presented condition number of the matrix U_n suggests that we should be ready to lose certain digits of precision with which we are working. Actually, experiments show that the presented algorithm, in double precision arithmetic (REAL*8), gives exact results with 14 significant digits. Thus, the results presented in Table 4.1 (left) have all digits exact.

Another example is presented in Table 4.1 (right) that is the generalized Gaussian quadrature rule for the sequence $\lambda_{2k} = \lambda_{2k+1} = k$, $k \in \mathbb{N}_0$, or for the system of functions x^k, $x^k \log x$, $k \in \mathbb{N}_0$. In this case, the condition numbers of U_n, as well as of $V_n U_n^{-1} Y_n - Z_n$ (see Figure 4.2), are growing faster than in the previous example. The same behavior we encounter in the example for $\lambda_{3k} = \lambda_{3k+1} = \lambda_{3k+2} = k$, $k \in \mathbb{N}_0$, given in Table 4.2, with condition numbers presented in Figure 4.3. In the latter case, the condition numbers are bigger. This behavior can be understand according to Lemma 3.4. In these two cases the Λ sequence is quite different from the Λ sequence in the Legendre case. It turns out that, using the presented algorithm in double precision arithmetic (REAL*8), we can safely calculate 14 digits.

In the final example we present an application of our algorithm to a computation of the generalized Gaussian quadrature formula (1.7) in the case when the basis functions are nonintegrable. Consider the system of functions $x^{k-2/3}\ x^k$, $k \in \mathbb{N}_0$. For this system of functions our algorithm cannot be applied directly, since the sequence

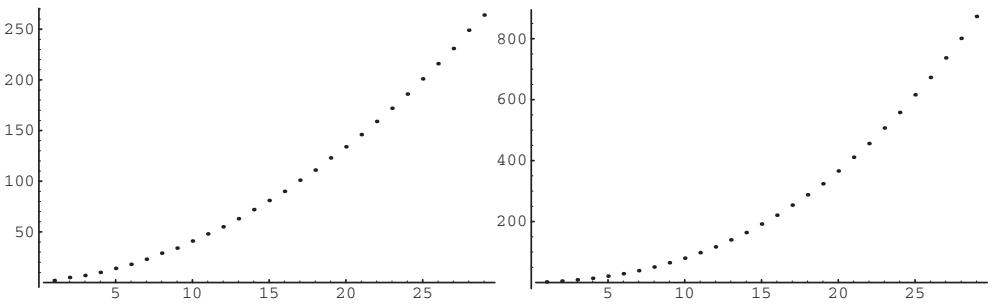

FIG. 4.2. *The condition number of the matrices* U_n *and* $V_n U_n^{-1} Y_n - Z_n$ *for* $n = 2(1)30$ *and* $\lambda_{2k} = \lambda_{2k+1} = k$, $k \in \mathbb{N}_0$.

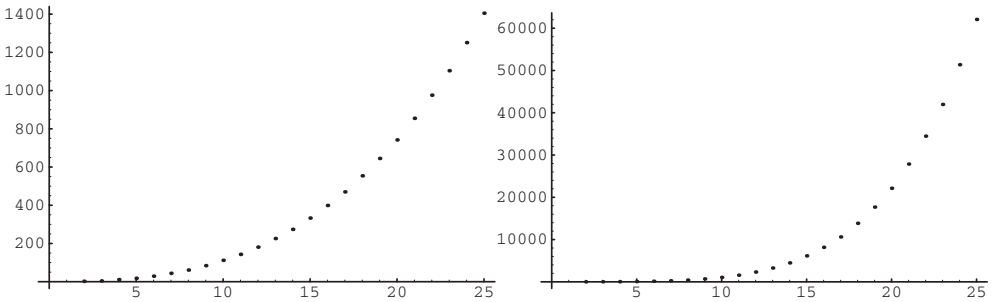

FIG. 4.3. *The condition number of the matrices* U_n *and* $V_n U_n^{-1} Y_n - Z_n$ *for* $n = 2(1)30$ *and* $\lambda_{3k} = \lambda_{3k+1} = \lambda_{3k+2} = k$, $k \in \mathbb{N}_0$.

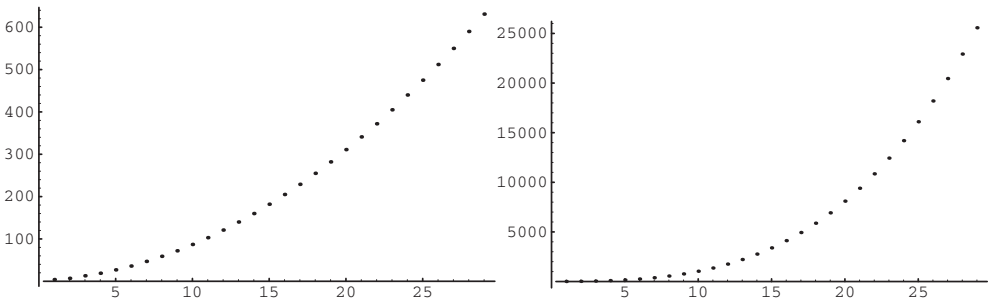

FIG. 4.4. *The condition number of the matrices* U_n *and* $V_n U_n^{-1} Y_n - Z_n$ *for* $n = 2(1)30$ *and* $\lambda_{2k} = k - 2/3$, $\lambda_{2k+1} = k$, $k \in \mathbb{N}_0$.

$\lambda_{2k} = k - 2/3$, $\lambda_{2k+1} = k$, $k \in \mathbb{N}_0$, does not satisfy the condition $\mathrm{Re}\,(\lambda_k) > -1/2$ and orthogonal Müntz–Legendre polynomials do not exist. However, we can apply Lemma 3.5. For example, we can choose $\beta = 2/3$ and apply our algorithm for constructing the generalized Gaussian quadrature rule (1.7) for the sequence $\lambda_{2k} = k - 1/3$, $\lambda_{2k+1} = k + 1/3$, $k \in \mathbb{N}_0$. Using Lemma 3.5, once our algorithm is applied, we can construct the generalized Gaussian quadrature rule for the system of functions $x^{k-2/3}$, x^k, $k \in \mathbb{N}_0$, with respect to the Legendre measure. The results for $n = 30$ nodes in the generalized Gaussian quadrature rule (1.7) are presented in Table 4.2 (right). The corresponding condition numbers are given in Figure 4.4.

TABLE 4.3

Relative errors for the classical Gauss–Legendre quadrature, with $n = 100(100)600$ *points, in evaluation of* (4.1).

n	100	200	300	400	500	600
r. err	1.2(−3)	3.0(−4)	1.3(−4)	7.4(−5)	4.7(−5)	3.3(−5)

TABLE 4.4

Relative errors for the generalized Gaussian quadrature rule, with $n = 5$, 10, *and* 15 *nodes, in evaluation of* (4.1), *for the sequence* $\lambda_{2k} = \lambda_{2k+1} = k$, $k \in \mathbb{N}_0$.

n	5	10	15
r. err	9.0(−7)	1.3(−15)	m.p.

At the end of this section we present an application of the derived quadrature formulae. We consider the integral

$$\int_0^1 J_0(x)(1+\log x)dx = -0.05310803758951187304684861869781 72\ldots, \tag{4.1}$$

where $J_0(x)$ is the Bessel function. Table 4.3 lists relative errors for the classical Gauss–Legendre quadrature rule, shifted to the interval $(0,1)$, applied to the previous integral. This is an example of the well-known saturation phenomenon (see [20]). However, using the generalized Gaussian quadrature rule derived for the sequence $\lambda_{2k} = \lambda_{2k+1} = k$, $k \in \mathbb{N}_0$, the machine precision (m.p. $\approx 2.26(-16)$) can be achieved with 15 nodes, as presented in Table 4.4.

A SEMI-IMPLICIT RELAXATION SCHEME FOR MODELING TWO-PHASE FLOW IN A PIPELINE*

MICHAËL BAUDIN†, FRÉDÉRIC COQUEL‡, AND QUANG-HUY TRAN†

Abstract. This work is devoted to the numerical approximation of the solutions to the system of conservation laws which arises in the modeling of two-phase flows in pipelines. The PDEs are closed by two highly nonlinear algebraic relations, namely, a pressure law and a hydrodynamic law. We have previously proposed an explicit relaxation scheme which allows us to cope with these nonlinearities. But the system considered has eigenvalues which are of very different orders of magnitude, which prevents the explicit scheme from being effective, since the time step has to be very small. In order to solve this effectiveness problem, we now proceed to construct a scheme which is explicit with respect to the small eigenvalues and linearly implicit with respect to the large eigenvalues. Numerical evidences are provided.

Key words. two-phase flows, relaxation scheme, semi-implicit, Riemann solvers

DOI. 10.1137/030601624

Introduction. We are interested in the simulation of two-phase flows in petroleum pipelines by a specific kind of models called [illegible] [13]. The peculiarity of such a model lies in the existence of two algebraic closure laws, that is, a thermodynamic law and a hydrodynamic law. The complexity of these closure laws makes classical numerical schemes such as Godunov or Roe schemes very difficult to use. Our feeling is that only a "rough" scheme would be able to successfully meet the challenge of nonlinearities.

An essential property of our system is that it possesses fast characteristic speeds (acoustic waves) and slow ones (kinematic waves). From the engineer's standpoint, however, the most interesting phenomena to be observed are those associated with kinematic waves, since these reflect mass transportation. With such a purpose in mind, an explicit scheme appears not to be suitable, not only because the time required for the simulation would be prohibitive due to the large characteristic speeds, but also because a small time step would induce too much dissipation on kinematic waves.

Inspired by [9], Faille and Heintzé have proposed in [6] a VFRoe-type scheme which is sufficiently rough (diffusive) to handle very stiff industrial cases. The scheme is linearly implicit with respect to the large eigenvalues and explicit with respect to the small eigenvalues [6]. Then this semi-implicit scheme will combine (i) accuracy on kinematic waves and (ii) CPU-time reduction insofar as the CFL limitation only applies to small eigenvalues.

But this scheme also suffers from a few drawbacks. For one, it is still CPU-time consuming because it needs to numerically assess the eigenvalues of the Jacobian matrix of the system. For another, these eigenvalues are not necessarily real; that is,

the system is not always hyperbolic. As a matter of fact, it is observed [2] that the system is hyperbolic only if the slip between the phases is not too large.

Since Xin and Jin's pioneering work [14] on relaxation schemes, several ideas have been put forward in order to improve the original relaxation procedure. For instance, Evje and Fjelde [5] attempted to achieve a more accurate approximation by splitting the flux into a convective part and a pressure part, thus reducing the stability condition on the relaxation coefficient. In [1], the authors have taken another road to construct an explicit relaxation scheme. The idea was to partially relax the most "prominent" nonlinearities of the system, namely, the hydrodynamic and thermodynamic closure laws. Those nonlinearities are first spotted by means of a Lagrangian change of coordinates. Then, these are relaxed. Finally, the equations are brought back to the Eulerian frame. The resulting relaxation system is automatically hyperbolic and has all its fields linearly degenerated. This scheme is less CPU-time consuming than the VFRoe-type because the most algorithmically complex step is the computation of only two relaxation coefficients. Moreover, the most interesting aspect of this relaxation procedure is that these coefficients can be optimally adjusted [1] in order to satisfy physical properties such as the positivity of the density and, most of all, the maximum principle on the gas mass fraction.

The goal of this paper is to work out a semi-implicit version of the explicit scheme [1] via some mathematically sound extension procedures. In essence, the extension is possible and sound because of the linear degeneracy property of the relaxation system.

The paper is organized as follows. In section 1, we introduce the two-phase flow model together with the boundary conditions and the characteristics of this model. In section 2, we develop the second-order explicit relaxation scheme with the computation of new relaxation coefficients and boundary conditions. In section 3, we present the semi-implicit scheme and section 4 is devoted to the numerical results.

1. Two-phase flow model.

1.1. Equations. In the flow, the gas (resp., liquid) is characterized by its density ρ_{G} (resp., ρ_{L}), its velocity v_{G} (resp., v_{L}), and its surface fraction $R_{\mathrm{G}} \in [0,1]$ (resp., $R_{\mathrm{L}} \in [0,1]$) with the property $R_{\mathrm{L}} + R_{\mathrm{G}} = 1$. The model is governed by the following system of conservation laws:

$$\left\{\begin{array}{lll} \partial_t(\rho_{\mathrm{L}} R_{\mathrm{L}}) & + \partial_x(\rho_{\mathrm{L}} R_{\mathrm{L}} v_{\mathrm{L}}) & = 0, \\ \partial_t(\rho_{\mathrm{G}} R_{\mathrm{G}}) & + \partial_x(\rho_{\mathrm{G}} R_{\mathrm{G}} v_{\mathrm{G}}) & = 0, \\ \partial_t(\rho_{\mathrm{L}} R_{\mathrm{L}} v_{\mathrm{L}} + \rho_{\mathrm{G}} R_{\mathrm{G}} v_{\mathrm{G}}) & + \partial_x(\rho_{\mathrm{L}} R_{\mathrm{G}} v_{\mathrm{L}}^2 + \rho_{\mathrm{G}} R_{\mathrm{G}} v_{\mathrm{G}}^2 + p) & = S(\mathbf{w}) \end{array}\right. \tag{1.1}$$

for $x \in \mathbb{R}$ and $t \geq 0$. The unknowns are $\mathbf{w} := (\rho_{\mathrm{L}} R_{\mathrm{L}}, \rho_{\mathrm{G}} R_{\mathrm{G}}, \rho_{\mathrm{L}} R_{\mathrm{L}} v_{\mathrm{L}} + \rho_{\mathrm{G}} R_{\mathrm{G}} v_{\mathrm{G}})$. Here the source term S includes gravity and wall friction terms which are given functions of the unknowns. We will consider a perfect gas and a compressible liquid with the state equations

$$\rho_{\mathrm{G}} = p/a_{\mathrm{G}}^2, \quad \rho_{\mathrm{L}} = \rho_{\mathrm{L}}^0 + (p - p^0)/a_{\mathrm{L}}^2, \tag{1.2}$$

where p^0 is the atmospheric pressure, ρ_{L}^0 is the liquid density for $p = p^0$, and a_{G} (resp., a_{L}) is the sound speed in the gas (resp., the liquid). Sometimes, we will use the noncompressible liquid state equation $\rho_{\mathrm{L}} = \rho_{\mathrm{L}}^0$. Anyhow, the pressure law can be put in the general form $p = p(\mathbf{w}_1, \mathbf{w}_2)$ and is a smooth function. We consider a general algebraic hydrodynamic law of the type

$$v_{\mathrm{L}} - v_{\mathrm{G}} = \Phi(\mathbf{w}), \quad \text{for } \mathbf{w} \in (\mathbb{R}^+)^2 \times \mathbb{R}, \tag{1.3}$$

in order to close (1.1). In (1.3), the mapping Φ is assumed to be smooth enough. In practical situations, Φ turns out to be nonlinear in the unknown $\mathbf{w}$ [2, 15].

1.2. Boundary and initial conditions. At the inlet of the pipe ($x = 0$), the mass flow rates are given as functions of time, i.e.,

$$(\rho_\alpha R_\alpha v_\alpha)(0,\ t) = q_\alpha^0(t),\ t \geq 0,\ \alpha = \mathrm{L}, \mathrm{G},$$

and at the outlet of the pipe ($x = L$) the pressure is a given function of time, i.e.,

$$p(L,\ t) = p^L(t), \quad t \geq 0.$$

We will treat cases in which the flow is induced only by variations of the boundary conditions: in such experiments, the initial condition is the steady state, computed by the values of the boundary conditions at time $t = 0$.

1.3. Characteristics of the model. There is no analytical expression for the physical flux of the considered system, except for very simple hydrodynamic laws. Therefore the eigenvalues of the system (1.1) are not known in full generality. However, in most common situations, i.e., for usual values of $\mathbf{w}$, the system is hyperbolic and has three real eigenvalues $\lambda_1 < \lambda_2 < \lambda_3$, with $\lambda_1 < 0$ and $\lambda_3 > 0$.

Typically, $|\lambda_{1,3}| \gg |\lambda_2|$ and the large eigenvalues are 10–100 times bigger than the small eigenvalue. The extreme eigenvalues $\lambda_{1,3}$ correspond to the acoustic waves that we do not really care about, while the middle eigenvalue λ_2, which has a variable sign, corresponds to the kinematic waves that we wish to capture accurately.

2. Explicit relaxation scheme. Most computational details of this section are given in [1] and only the main results will be reported here.

2.1. The relaxation model. Let us consider the total density of the mixing $\rho = \rho_\mathrm{L} R_\mathrm{L} + \rho_\mathrm{G} R_\mathrm{G}$, the total momentum $\rho v = \rho_\mathrm{L} R_\mathrm{L} v_\mathrm{L} + \rho_\mathrm{G} R_\mathrm{G} v_\mathrm{G}$, and ρY, where Y denotes the gas mass fraction $Y = \frac{\rho_\mathrm{G} R_\mathrm{G}}{\rho}$ (so that $1 - Y = \frac{\rho_\mathrm{L} R_\mathrm{L}}{\rho}$). The natural phase space associated with such variables then reads

$$\Omega = \left\{ \mathbf{u} = (\rho,\ \rho v,\ \rho Y) \in \mathbb{R}^3;\ \rho > 0,\ v \in \mathbb{R},\ Y \in [0, 1] \right\}.$$

With some little abuse, both the pressure law p and the hydrodynamic closure Φ will keep their previous notations when expressed in terms of the new variable $\mathbf{u}$. In order to simplify the notations, let us introduce the two functions

$$\sigma(\mathbf{u}) = \rho Y(1 - Y)\Phi(\mathbf{u}), \quad P(\mathbf{u}) = p(\mathbf{u}) + \rho Y(1 - Y)\Phi(\mathbf{u})^2 \tag{2.1}$$

of the unknown $\mathbf{u}$. Weak solutions of the system (1.1)–(1.3) equivalently obey the conservative system

$$\left\{ \begin{array}{lllll} \partial_t(\rho) & + & \partial_x(\rho v) & = & 0, \\ \partial_t(\rho v) & + & \partial_x(\rho v^2 + P(\mathbf{u})) & = & S(\mathbf{u}), \\ \partial_t(\rho Y) & + & \partial_x(\rho Y v - \sigma(\mathbf{u})) & = & 0. \end{array} \right. \tag{2.2}$$

To determine the main nonlinearities of the equilibrium system (2.2), we proceed to a Lagrangian change of coordinates. Let us set $\tau = 1/\rho$, and define the Lagrangian mass coordinate by $dy = \rho dx - \rho v dt$. The Lagrangian set of variables is $\mathbf{z} = (\tau, v, Y)$. For the sake of simplicity and with some abuse in the notations, nonlinear functions

(like the pressure or the hydrodynamic law) will be given the same notation when expressed in both types of variables. The system (2.2) then rewrites as

$$\left\{\begin{array}{lll} \partial_t \tau & - \partial_y v & = 0, \\ \partial_t v & + \partial_y P(\mathbf{z}) & = S(\mathbf{z}), \\ \partial_t Y & - \partial_y \sigma(\mathbf{z}) & = 0. \end{array}\right. \tag{2.3}$$

We introduce two new state variables Σ and Π which are intended to coincide, respectively, with $\sigma(\mathbf{z})$ and $P(\mathbf{z})$ in the limit of an infinite relaxation parameter λ. We propose as a relaxation model the system

$$\left\{\begin{array}{lll} \partial_t \tau & - \partial_y v & = 0, \\ \partial_t v & + \partial_y \Pi & = S(\mathbf{u}), \\ \partial_t \Pi & + a^2 \partial_y v & = \lambda(P(\mathbf{u}) - \Pi), \\ \partial_t Y & - \partial_y \Sigma & = 0, \\ \partial_t \Sigma & - b^2 \partial_y Y & = \lambda(\sigma(\mathbf{u}) - \Sigma), \end{array}\right. \tag{2.4}$$

where a and b are two real positive parameters, the so-called relaxation coefficients to be properly prescribed to protect the relaxation procedure from instabilities in the regime $\lambda \to \infty$ (see [1] and the references therein). Returning back to Eulerian coordinates, we end up with

$$\left\{\begin{array}{lll} \partial_t \rho & + \partial_x (\rho v) & = 0, \\ \partial_t (\rho v) & + \partial_x (\rho v^2 + \Pi) & = S(\mathbf{u}), \\ \partial_t (\rho \Pi) & + \partial_x (\rho \Pi v + a^2 v) & = \lambda\rho(P(\mathbf{u}) - \Pi), \\ \partial_t (\rho Y) & + \partial_x (\rho Y v - \Sigma) & = 0, \\ \partial_t (\rho \Sigma) & + \partial_x (\rho \Sigma v - b^2 Y) & = \lambda\rho(\sigma(\mathbf{u}) - \Sigma). \end{array}\right. \tag{2.5}$$

The above relaxation system will be given hereafter the convenient abstract form

$$\partial_t \mathbf{v} + \partial_x \mathcal{G}(\mathbf{v}) = \lambda \mathcal{R}(\mathbf{v}) + \mathcal{S}(\mathbf{v}), \quad \text{for } t > 0,\ x \in \mathbb{R}, \tag{2.6}$$

in which the flux function $\mathcal{G}$ receives a clear definition and

$$\mathcal{R}(\mathbf{v}) = (0,\ 0,\ \lambda\rho\,(P(\mathbf{u}) - \Pi)\,,\ 0,\ \lambda\rho\,(\sigma(\mathbf{u}) - \Sigma))^T\,, \tag{2.7}$$

$$\mathcal{S}(\mathbf{v}) = (0,\ S(\mathbf{u}),\ 0,\ 0,\ 0)^T\,. \tag{2.8}$$

The associated admissible state space $\mathcal{V}$ reads

$$\begin{aligned} \mathcal{V} = \big\{ \mathbf{v} = (\rho,\ \rho v,\ \rho\Pi,\ \rho Y,\ \rho\Sigma)^T \in \mathbb{R}^5; \\ \rho > 0,\ v \in \mathbb{R},\ \Pi \in \mathbb{R},\ Y \in [0,1],\ \Sigma \in \mathbb{R} \big\}\,. \end{aligned} \tag{2.9}$$

The following lemma has been proven in [1].

LEMMA 2.1. (a, b) $\mathbf{v} \in \mathcal{V}$ (2.5)

$$v,\ v \pm a\tau,\ v \pm b\tau,$$

(2.5) $\mathcal{V}$

2.2. First-order explicit scheme. The pipeline is made of cells, denoted by $(M_i)_{i=1,I}$. Let x_i be the center of the cell and Δx its length. We also denote $x_{i+1/2} = (x_i + x_{i+1})/2$ the interface between two cells, $x_{1/2} = 0$ the inlet boundary interface, and $x_{I+1/2} = L$ the outlet boundary interface. Let $\Delta t^n = t^{n+1} - t^n$ be the time step. Let $\mathbf{u}_i^n \approx \mathbf{u}(x_i, t^n)$ be the discrete unknown. On the grounds of the relaxation model (2.5), we suggest the two-step procedure below to advance in time the approximate solution.

1. In order to prescribe the initial data $\mathbf{v}_i^n \simeq \mathbf{v}(x_i, t^n)$, we advocate the equilibrium condition by setting

$$\Pi_i^n := P(\mathbf{u}_i^n), \qquad \Sigma_i^n := \sigma(\mathbf{u}_i^n). \tag{2.10}$$

2. Choosing $\lambda = 0$, we solve the Cauchy problem $\partial_t \mathbf{v} + \partial_x \mathcal{G}(\mathbf{v}) = \mathcal{S}(\mathbf{v})$, $\mathbf{v}(0,x) = \mathbf{v}(t^n, x)$ for small time $t \in [0, \Delta t^n]$. This strategy leads to the finite volume scheme

$$\frac{\mathbf{v}_i^{n+1} - \mathbf{v}_i^n}{\Delta t^n} + \frac{\mathbf{H}_{i+1/2}^{n+1/2} - \mathbf{H}_{i-1/2}^{n+1/2}}{\Delta x} = \mathcal{S}(\mathbf{v}_i^n) \tag{2.11}$$

with $\mathbf{H}_{i+1/2}^{n+1/2}$ the numerical flux based on the Godunov scheme. We designate by $\mathbf{v_L} = \mathbf{v}_i^n$ and $\mathbf{v_R} = \mathbf{v}_{i+1}^n$ the left and right states of the Riemann problem and $\mathbf{v}^\star(\mathbf{v_L}, \mathbf{v_R})$ the value of the solution of this Riemann problem at $x = x_{i+1/2}$. The Godunov numerical flux is

$$\mathbf{H}_{i+1/2}^{n+1/2} = \mathbf{H}^{\mathrm{God}}(\mathbf{v_L}, \mathbf{v_R}) = \mathcal{G}(\mathbf{v}^\star(\mathbf{v_L}, \mathbf{v_R})). \tag{2.12}$$

The explicit computations for $\mathbf{v}^\star$ are given in Proposition 2.2 at the end of this section. For a proof of this proposition, see [1]. Let us underline the fact that the linear degeneracy of all fields allows for very simple expressions. For any quantity φ, we introduce the average $\overline{\varphi} = (\varphi_{\mathbf{L}} + \varphi_{\mathbf{R}})/2$ and the midjump $\langle\varphi\rangle = (\varphi_{\mathbf{L}} - \varphi_{\mathbf{R}})/2$ between the two states $\mathbf{v_L}$ and $\mathbf{v_R}$.

PROPOSITION 2.2. (a,b) (2.5)

$$\mathbf{v}(x,\,0) = \begin{cases} \mathbf{v_L} & x < 0, \\ \mathbf{v_R} & x > 0 \end{cases} \tag{2.13}$$

$$\mathbf{v}(x,t) = \begin{cases} \mathbf{v_L} = \mathbf{v}_0 & \dfrac{x}{t} < \mu_1, \\ \mathbf{v}_j & \mu_j < \dfrac{x}{t} < \mu_{j+1}, \quad 1 \le j \le 4, \\ \mathbf{v_R} = \mathbf{v}_5 & \dfrac{x}{t} > \mu_5. \end{cases} \tag{2.14}$$

$$\begin{aligned} \tau_{\mathbf{L}}^\star &= \tau_{\mathbf{L}} - \frac{\langle v\rangle}{a} + \frac{\langle\Pi\rangle}{a^2}, & \tau_{\mathbf{R}}^\star &= \tau_{\mathbf{R}} - \frac{\langle v\rangle}{a} - \frac{\langle\Pi\rangle}{a^2}, \\ v^\star &= \overline{v} + \frac{\langle\Pi\rangle}{a}, & \Pi^\star &= \overline{\Pi} + a\langle v\rangle, \\ Y^\star &= \overline{Y} - \frac{\langle\Sigma\rangle}{b}, & \Sigma^\star &= \overline{\Sigma} - b\langle Y\rangle. \end{aligned} \tag{2.15}$$

a $\tau^\star_{\mathbf{L}}$ $\tau^\star_{\mathbf{R}}$, (2.15)
(2.29)
$a > b$

$$\underbrace{v_{\mathbf{L}} - a\tau_{\mathbf{L}}}_{\mu_1(\mathbf{v_L})} \le v^\star - b\tau^\star_{\mathbf{L}} \le v^\star \le v^\star + b\tau^\star_{\mathbf{R}} \le \underbrace{v_{\mathbf{R}} + a\tau_{\mathbf{R}}}_{\mu_5(\mathbf{v_R})}, \tag{2.16}$$

$$\mathbf{v}_1 = \begin{pmatrix} \rho^\star_{\mathbf{L}} \\ \rho^\star_{\mathbf{L}} v^\star \\ \rho^\star_{\mathbf{L}} \Pi^\star \\ \rho^\star_{\mathbf{L}} Y_{\mathbf{L}} \\ \rho^\star_{\mathbf{L}} \Sigma_{\mathbf{L}} \end{pmatrix}, \ \mathbf{v}_2 = \begin{pmatrix} \rho^\star_{\mathbf{L}} \\ \rho^\star_{\mathbf{L}} v^\star \\ \rho^\star_{\mathbf{L}} \Pi^\star \\ \rho^\star_{\mathbf{L}} Y^\star \\ \rho^\star_{\mathbf{L}} \Sigma^\star \end{pmatrix}, \ \mathbf{v}_3 = \begin{pmatrix} \rho^\star_{\mathbf{R}} \\ \rho^\star_{\mathbf{R}} v^\star \\ \rho^\star_{\mathbf{R}} \Pi^\star \\ \rho^\star_{\mathbf{R}} Y^\star \\ \rho^\star_{\mathbf{R}} \Sigma^\star \end{pmatrix}, \ \mathbf{v}_4 = \begin{pmatrix} \rho^\star_{\mathbf{R}} \\ \rho^\star_{\mathbf{R}} v^\star \\ \rho^\star_{\mathbf{R}} \Pi^\star \\ \rho^\star_{\mathbf{R}} Y_{\mathbf{R}} \\ \rho^\star_{\mathbf{R}} \Sigma_{\mathbf{R}} \end{pmatrix}.$$

2.3. Relaxation coefficients. We present in this section the computation of the relaxation coefficients a and b. Our approach is based on the Chapman–Enskog expansions

$$\Pi = P + \lambda^{-1}\Pi_1 + \mathcal{O}(\lambda^{-2}), \tag{2.17}$$

$$\Sigma = \sigma + \lambda^{-1}\Sigma_1 + \mathcal{O}(\lambda^{-2}). \tag{2.18}$$

In order to get a first estimate for the relaxation coefficients (a, b), we decided to weaken the procedure introduced in [1]. This amounts to thinking of the Lagrangian relaxation system (2.4) as being made of two "uncoupled" subsystems: the first one, in (τ, v, Π), consists of the first three equations and is called the subsystem; the second one, in (Y, Σ), consists of the last two equations and is called the subsystem.

According to this decoupling strategy, we temporarily assume that the mappings P and σ depend only on the equilibrium variables involved in their respective subsystems, i.e., (τ, v) for P and Y for σ. This yields a first estimate $(a^\flat, b^\flat)$, which is then given a fairly simple correction $(a^\sharp, b^\sharp)$ so as to enforce—in the framework of general P and σ laws—two central stability properties, that is, the positivity of the density and the maximum principle on the mass fraction.

2.3.1. Two stability theorems. Let us consider the first subsystem

$$\begin{cases} \partial_t \tau - \partial_y v = 0, \\ \partial_t v + \partial_y \Pi = 0, \\ \partial_t \Pi + a^2 \partial_y v = \lambda(P - \Pi). \end{cases} \tag{2.19}$$

THEOREM 2.3. $P = P(\tau, v)$ (2.19)

$$\partial_t \mathbf{w}^1 + \Gamma^1(\mathbf{w}^1)\partial_y \mathbf{w}^1 = \lambda^{-1}\partial_y \left[\Delta_a(\mathbf{w}^1)\partial_y \mathbf{w}^1\right], \tag{2.20}$$

$\mathbf{w}^1 = (\tau, v)^T$

$$\Delta_a(\mathbf{w}^1) = \begin{pmatrix} 0 & 0 \\ E & a^2 - A \end{pmatrix} \quad E = -P_v P_\tau, \ \ A = -P_\tau + P_v^2. \tag{2.21}$$

2.3. Substituting (2.17) into (2.19), we end up with the first-order asymptotic system

$$\left\{ \begin{array}{l} \partial_t \tau - \partial_y v = 0, \\ \partial_t v + \partial_y P = -\lambda^{-1} \partial_y \Pi_1, \end{array} \right. \tag{2.22}$$

where the first-order corrector Π_1 reads $\Pi_1 = -(\partial_t P + a^2 \partial_y v)$. Let us express the time derivative Π_1 by means of space derivatives. To do this, we start from the hypothesis $P = P(\tau, v)$ in order to have the identity $\partial_t P = (P_\tau \quad P_v)\, \partial_t \mathbf{w}^1$. Second, the equilibrium system (2.3) gives $\partial_t \mathbf{w}^1 = \partial_y (v \quad -P)^T$. Third, we differentiate P using the classical chain rule, which yields

$$\partial_y (v \quad -P)^T = \begin{pmatrix} 0 & 1 \\ -P_\tau & -P_v \end{pmatrix} \partial_y \mathbf{w}^1. \tag{2.23}$$

Finally, the combination of the last three identities leads to $-\Pi_1 = \partial_t P + a^2 \partial_y \mathbf{w}^1 = \begin{pmatrix} E & a^2 - A \end{pmatrix} \partial_y \mathbf{w}^1$, which completes the proof. ∎

Let us consider the second subsystem

$$\left\{ \begin{array}{l} \partial_t Y - \partial_y \Sigma = 0, \\ \partial_t \Sigma - b^2\, \partial_y Y = \lambda(\sigma - \Sigma). \end{array} \right. \tag{2.24}$$

THEOREM 2.4. $\sigma = \sigma(Y)$ (2.24)

$$\partial_t Y - \partial_y \sigma = \lambda^{-1} \partial_y \left[\Delta_b(Y) \partial_y Y \right], \tag{2.25}$$

$$\Delta_b(Y) = b^2 - B \qquad B = \sigma_Y^2. \tag{2.26}$$

2.4. Substituting (2.18) into (2.24), we obtain

$$\partial_t Y - \partial_y \sigma = \lambda^{-1} \partial_y \Sigma_1, \tag{2.27}$$

where the first-order corrector Σ_1 reads $\Sigma_1 = -(\partial_t v - b^2 \partial_y Y)$. The hypothesis and the equilibrium system (2.3) give easily $\partial_t \sigma = B \partial_y Y$. This implies $-\Sigma_1 = (B - b^2) \partial_y Y$, which completes the proof. ∎

Then, requiring that the second-order operator of the asymptotic systems (2.22) and (2.25) be dissipative (so as to heuristically ensure stability), we are led to the following conditions.

COROLLARY 2.5. $\Delta_a(w)$ $\Delta_b(Y)$ $a^2 - A \geq 0$ $b^2 - B \geq 0$

REMARK 2.6. P σ $a > b$ a b

2.3.2. Practical computation of the relaxation coefficients. We present in this section the computation of the relaxation coefficients a and b for general pressure and slip laws. We consider a local pair $(a_{i+1/2},\, b_{i+1/2})$ on each interface $x_{i+1/2}$ in order to minimize the numerical dissipation. The relaxation coefficients are designed in order to ensure the following.

1. The stability of the first-order asymptotic equilibrium system thanks to the Chapman–Enskog expansion. On the grounds of Corollary 2.5, we opt for the following first estimates:

$$\begin{aligned} a^{\flat}_{i+1/2} &= \sqrt{\max(A(\mathbf{u}_i), A(\mathbf{u}_{i+1}))}, \qquad A(\mathbf{u}) = -P_\tau(\mathbf{u}) + P_v^2(\mathbf{u}), \\ b^{\flat}_{i+1/2} &= \sqrt{\max(B(\mathbf{u}_i), B(\mathbf{u}_{i+1}))}, \qquad B(\mathbf{u}) = \sigma_Y^2(\mathbf{u}). \end{aligned} \tag{2.28}$$

2. The positivity of the density and the mass fractions. As explained in [1], we have to correct the above first estimates in order to comply with two additional but fundamental physical properties: the positivity of the density and, above all, the maximum principle on the gas mass fraction, i.e., $Y_i^n \in [0, 1]$. This is done by setting [1]

(2.29)

$$a^{\sharp}_{i+1/2} = \frac{(v_i - v_{i+1}) + \sqrt{(v_i - v_{i+1})^2 + 8\max(\tau_i, \tau_{i+1})|\Pi_i - \Pi_{i+1}|}}{4\min(\tau_i, \tau_{i+1})},$$

$$b^{\sharp}_{i+1/2} = \frac{|\rho_i\Phi(\mathbf{u}_i) + \rho_{i+1}\Phi(\mathbf{u}_{i+1})|}{2} + \frac{|\rho_i\Phi(\mathbf{u}_i) - \rho_{i+1}\Phi(\mathbf{u}_{i+1})|}{2}$$

and by finally requiring that

$$a_{i+1/2} \geq \max(a^{\flat}_{i+1/2}, a^{\sharp}_{i+1/2}) \quad \text{and} \quad b_{i+1/2} \geq \max(b^{\flat}_{i+1/2}, b^{\sharp}_{i+1/2}). \tag{2.30}$$

The lower bounds (2.29) to be met by the relaxation coefficients have been proven to be almost optimal in [1]: a failure to satisfy those conditions generally results in a violation of our positivity requirements. Again, the bounds are valid for general pressure and slip laws.

The above strategy, simpler than the one in [1], has been discovered in a pragmatic way, considering a numerical experiment (a contact discontinuity) with real-life slip laws in which the old fashion [1] led to overestimated coefficients $b_{i+1/2}$. The resulting numerical solutions were very dissipated and therefore unacceptable, as shown in Appendix A, which the reader is referred to for more details. The new procedure for deriving the relaxation coefficients significantly lowers the numerical dissipation while still achieving stability properties.

2.4. Second order in space. The scheme is extended to second-order accuracy in space by using the classical MUSCL (monotonic upstream scheme for conservation laws) technique [11, 12]. The limited slopes are those of the "physical variable" (p, Y, v) rather than those of the conservative variable $\mathbf{u}$ [6, 7].

2.5. Second order in time. We use the following Runge–Kutta second-order procedure. Let us suppose that we denote $\mathbb{L}$ the explicit operator, which is second order in space, first order in time so that $\mathbf{u}^{n+1} = \mathbb{L}(\mathbf{u}^n)$. Then the explicit second order both in space and time is

$$\mathbf{u}^{(1)} = \mathbb{L}(\mathbf{u}^n), \quad \mathbf{u}^{(2)} = \mathbb{L}(\mathbf{u}^{(1)}), \quad \mathbf{u}^{n+1} = \frac{1}{2}(\mathbf{u}^n + \mathbf{u}^{(2)}). \tag{2.31}$$

2.6. Time step. The time step of the relaxation explicit scheme is limited by the CFL condition

$$\frac{\Delta t^n}{\Delta x} \max_{i=1,I} |V_i^n| \leq \mu, \tag{2.32}$$

where $\mu = 0.5$ is the CFL and V_i^n is a characteristic speed given—under the natural ordering (2.16)—by

$$V_i^n = \max(|v_{i-1/2}^{\mathbf{R}} + a_{i-1/2}\tau_{i-1/2}^{\mathbf{R}}|,\ |v_{i+1/2}^{\mathbf{L}} - a_{i+1/2}\tau_{i+1/2}^{\mathbf{L}}|). \tag{2.33}$$

This condition enables us to obtain a sequence of noninteracting Riemann problems located at each cell interface $x_{i+1/2}$.

2.7. Treatment of boundary conditions. In order to take the boundary conditions into account, we introduce two ghost cells: $\mathbf{u}_0^n$ at the inlet of the pipe and $\mathbf{u}_{I+1}^n$ at the outlet. The computation of these two states must be explicit, due to the specific implementation of the linearly implicit scheme.

It is well known that the number of scalar physical conditions to specify on the boundaries is equal to the number of entering characteristics [2]. We have already noticed that our system is conditionally hyperbolic and, for most cases, admits three real eigenvalues $\lambda_1 < \lambda_2 < \lambda_3$, with $\lambda_1 < 0$ and $\lambda_3 > 0$. Moreover, [illegible] at the inlet, $\lambda_2 \geq 0$. Since our system is of dimension 3, this justifies the two physical conditions (q_{L} and q_{G}) at the inlet and just one physical condition (the pressure) at the outlet.

2.7.1. Inlet ($x = 0$). We compute the state $\mathbf{v}_0^n$ in order to satisfy the five following conditions. First, the relaxation state $\mathbf{v}_0^n$ is at equilibrium, which leads to the two identities (2.10). Second, we specify the total mass flow rate (which corresponds to the first component ρv) and the gas mass flow rate (which corresponds to the fourth component $\rho Y v - \Sigma$) which leads to the two identities

$$\mathbf{H}^1(\mathbf{v}_0^n,\ \mathbf{v}_1^n) = q_{\mathrm{L}}^0(t^n) + q_{\mathrm{G}}(t^n), \quad \mathbf{H}^4(\mathbf{v}_0^n,\ \mathbf{v}_1^n) = q_{\mathrm{G}}^0(t^n). \tag{2.34}$$

Third, let us introduce ℓ_1, the left eigenvector corresponding to the first eigenvalue of $\nabla\mathcal{G}(\mathbf{u}_1^n)$. We then specify the characteristic projection

$$\ell_1.\mathbf{v}_0^n = \ell_1.\mathbf{v}_1^n. \tag{2.35}$$

The nonlinear system made up of the five equations (2.10), (2.34), and (2.35) is solved by a classical nonlinear solver (for instance, Newton's method).

2.7.2. Outlet ($x = L$). We compute the state $\mathbf{v}_{I+1}^n$ in order to satisfy the five following conditions. First, the relaxation state $\mathbf{v}_{I+1}^n$ is at equilibrium, which leads to the two identities (2.10). Second, we specify the pressure, which leads to the identity

$$p(\mathbf{u}_{I+1}^n) = p^L(t^n). \tag{2.36}$$

Third, we could have chosen, as at the inlet, two characteristic projections based on the left eigenvectors corresponding to the fourth and fifth eigenvalues of $\nabla\mathcal{G}(\mathbf{u}_I^n)$. But the experience (based on numerous numerical experiments) shows that it suffices to write the identities

$$Y_{I+1}^n = Y_I^n, \quad v_{I+1}^n = v_I^n. \tag{2.37}$$

The nonlinear system made up of the five equations (2.10), (2.36), and (2.37) is solved exactly.

The no-return condition. On offshore petroleum installations, the mixture coming out of a vertical pipe ("riser") usually falls into a separator whose goal is to separate the liquid and gas phases. This is why we would like to enforce the additional condition: the liquid flow rate on the outlet must remain positive. Note that this condition is independent of the change of sign of whatever eigenvalue. The numerical treatment that we have chosen is therefore the following. After having computed the ghost state $\mathbf{v}_{I+1}^n$ satisfying the previous conditions, we compute the numerical flux on the last interface $\mathbf{H}_{I+1/2} = \mathbf{H}(\mathbf{v}_{I+1}^n,\, \mathbf{v}_{I+1}^n)$. We then modify the first component of the flux by

$$\overline{\mathbf{H}}_{I+1/2}^1 = \begin{cases} \mathbf{H}_{I+1/2}^3 & \text{if} \quad \mathbf{H}_{I+1/2}^1 - \mathbf{H}_{I+1/2}^3 \leq 0, \\ \mathbf{H}_{I+1/2}^1 & \text{otherwise.} \end{cases} \tag{2.38}$$

This type of boundary condition is analyzed in [8].

3. Semi-implicit relaxation scheme.

3.1. First-order linearly implicit scheme.

3.1.1. The linear system. Let us consider the five-equation relaxation hyperbolic system (2.4)

$$\partial_t \mathbf{v} + \partial_x \mathcal{G}(\mathbf{v}) = \mathcal{S}(\mathbf{v}). \tag{3.1}$$

In the previous section, we have constructed the explicit scheme

$$\mathbf{v}_i^{n+1} = \mathbf{v}_i^n - \frac{\Delta t^n}{\Delta x} \left(\mathbf{H}(\mathbf{v}_i^n,\, \mathbf{v}_{i+1}^n) - \mathbf{H}(\mathbf{v}_{i-1}^n,\, \mathbf{v}_i^n) \right) + \Delta t^n\, \mathcal{S}(\mathbf{v}_i^n), \tag{3.2}$$

where the right-hand side contains only the approximate solution at time t^n. Such a time discretization implies that the time step will be sufficiently small. A classical technique to get rid of this limitation is to use the implicit time discretization

$$\mathbf{v}_i^{n+1} = \mathbf{v}_i^n - \frac{\Delta t^n}{\Delta x} \left(\mathbf{H}\left(\mathbf{v}_i^{n+1},\, \mathbf{v}_{i+1}^{n+1}\right) - \mathbf{H}\left(\mathbf{v}_{i-1}^{n+1},\, \mathbf{v}_i^{n+1}\right) \right) + \Delta t^n\, \mathcal{S}\left(\mathbf{v}_i^{n+1}\right), \tag{3.3}$$

where the computation of the approximate solution at time t^{n+1} is based on the inversion of a nonlinear problem. This inversion is expensive in terms of CPU time. On the other hand, numerical experiments show that the scheme is stable with just one Newton iteration with a far less restrictive CFL condition. Therefore we choose this strategy which gives a [illegible] scheme for which the flux $\mathbf{H}$ and the source term $\mathcal{S}$ are approximated by the first-order Taylor expansions

$$\mathbf{H}\left(\mathbf{v}_i^{n+1},\, \mathbf{v}_{i+1}^{n+1}\right) \approx \mathbf{H}\left(\mathbf{v}_i^n,\, \mathbf{v}_{i+1}^n\right) + \partial_1 \mathbf{H}\, \delta \mathbf{v}_i + \partial_2 \mathbf{H}\, \delta \mathbf{v}_{i+1}, \tag{3.4}$$

$$\mathcal{S}\left(\mathbf{v}_i^{n+1}\right) \approx \mathcal{S}\left(\mathbf{v}_i^n\right) + \nabla \mathcal{S}_i\, \delta \mathbf{v}_i, \tag{3.5}$$

where $\delta \mathbf{v}_i = \mathbf{v}_i^{n+1} - \mathbf{v}_i^n$; the partial derivatives of $\mathbf{H}$, which are designated by $\partial_1 \mathbf{H}$ and $\partial_2 \mathbf{H}$, are evaluated at $(\mathbf{v}_i^n,\, \mathbf{v}_{i+1}^n)$; and the Jacobian matrix $\mathcal{S}$ is evaluated at $\mathbf{v}_i^n$. Let us denote

$$\alpha_i = \frac{\Delta t^n}{\Delta x} \partial_1 \mathbf{H}(\mathbf{v}_i^n,\, \mathbf{v}_{i+1}^n) \quad \text{and} \quad \gamma_{i+1} = \frac{\Delta t^n}{\Delta x} \partial_2 \mathbf{H}(\mathbf{v}_i^n,\, \mathbf{v}_{i+1}^n) \tag{3.6}$$

the partial derivatives of $\mathbf{H}$. Plugging (3.4) and (3.5) into (3.3), one obtains the numerical scheme

$$\begin{aligned}\mathbf{v}_i^{n+1} = \mathbf{v}_i^n - \frac{\Delta t^n}{\Delta x}\left(\mathbf{H}(\mathbf{v}_i^n,\ \mathbf{v}_{i+1}^n) - \mathbf{H}(\mathbf{v}_{i-1}^n,\ \mathbf{v}_i^n)\right) + \Delta t^n\ \mathcal{S}(\mathbf{v}_i^n)\\ - (\alpha_i\delta\mathbf{v}_i + \gamma_{i+1}\delta\mathbf{v}_{i+1}) + (\alpha_{i-1}\delta\mathbf{v}_{i-1} + \gamma_i\delta\mathbf{v}_i) + \Delta t^n\ \nabla\mathcal{S}_i\ \delta\mathbf{v}_i.\end{aligned} \tag{3.7}$$

The first three terms of the right-hand side of (3.7) correspond to the explicit scheme. This is why the linearly implicit scheme is classically split into three steps.

1. In the physical step, one computes a "predictor" using the explicit scheme

$$\mathbf{v}_i^\sharp = \mathbf{v}_i^n - \frac{\Delta t^n}{\Delta x}\left(\mathbf{H}(\mathbf{v}_i^n, \mathbf{v}_{i+1}^n) - \mathbf{H}(\mathbf{v}_{i-1}^n, \mathbf{v}_i^n)\right) + \Delta t^n\ \mathcal{S}(\mathbf{v}_i^n). \tag{3.8}$$

2. In the mathematical step, one solves the linear equation in $\delta\mathbf{v}$,

$$-\alpha_{i-1}\delta\mathbf{v}_{i-1} + \beta_i\delta\mathbf{v}_i + \gamma_{i+1}\delta\mathbf{v}_{i+1} = \mathbf{v}_i^\sharp - \mathbf{v}_i^n, \tag{3.9}$$

   where β_i is the matrix $\beta_i = \mathbb{I} + \alpha_i - \gamma_i - \Delta t^n\ \nabla\mathcal{S}_i$ with $\mathbb{I}$ the 5×5 identity matrix. The mathematical step involves a nonsymmetric tridiagonal by block matrix which is solved by a classical linear solver.
3. Now we can update the conservative variable of the cell i by

$$\mathbf{v}_i^{n+1} = \mathbf{v}_i^n + \delta\mathbf{v}_i. \tag{3.10}$$

Now, the remaining question is: how to construct the matrices α and γ? It is easy [6] to compute these matrices from the definition (3.6) when the explicit scheme is a Roe-type scheme. The main objective of the next section is therefore to put the relaxation explicit scheme under Roe's form. Afterwards, we will give the explicit computations of the matrices α and γ for the linearly implicit relaxation scheme.

3.1.2. Roe's form of the explicit relaxation scheme. We consider the Riemann problem for the relaxation system (2.5) with $\lambda = 0$, no source terms, and the left and right states $\mathbf{v}^{\mathbf{L}} = \mathbf{v}_0$ and $\mathbf{v}^{\mathbf{R}} = \mathbf{v}_5$. Let $(\mathbf{v}_j)_{j=1,4}$ be the intermediate states and $(\mu_j)_{j=1,5}$ the eigenvalues defined in Proposition 2.2. It is interesting to compare the following results with the one obtained by Godlewski and Raviart [10, Chap. III, section 3.4] while considering the gas dynamic system and rewriting Godunov's method in terms of a Roe-type linearization. Such a rewriting is based on a shock curve decomposition and is possible when the solution of the Riemann problem is only made of discontinuities (see also Dubois and Mehlmann [4]).

LEMMA 3.1. [illegible]

$$\mathbf{v}_j - \mathbf{v}_{j-1} = \delta_j r_j, \quad j = 1, 5, \tag{3.11}$$

[illegible] δ_j [illegible]

$$\begin{aligned}&\delta_1 = \rho_{\mathbf{L}}^\star - \rho_{\mathbf{L}}, && \delta_2 = \rho_{\mathbf{L}}^\star(Y^\star - Y_{\mathbf{L}}), && \delta_3 = \rho_{\mathbf{R}}^\star - \rho_{\mathbf{L}}^\star,\\ &\delta_4 = \rho_{\mathbf{R}}^\star(Y_{\mathbf{R}} - Y^\star), && \delta_5 = \rho_{\mathbf{R}} - \rho_{\mathbf{R}}^\star,\end{aligned}$$

$R = (r_j)_{j=1,5}$ [illegible]

$$R = \begin{pmatrix} 1 & 0 & 1 & 0 & 1 \\ v_{\mathbf{L}} - a\tau_{\mathbf{L}} & 0 & v^\star & 0 & v_{\mathbf{R}} + a\tau_{\mathbf{R}} \\ \Pi_{\mathbf{L}} + a^2\tau_{\mathbf{L}} & 0 & \Pi^\star & 0 & \Pi_{\mathbf{R}} + a^2\tau_{\mathbf{R}} \\ Y_{\mathbf{L}} & 1 & Y^\star & 1 & Y_{\mathbf{R}} \\ \Sigma_{\mathbf{L}} & b & \Sigma^\star & -b & \Sigma_{\mathbf{R}} \end{pmatrix}. \tag{3.12}$$

With this lemma, it is easy to construct Roe's matrix.

PROPOSITION 3.2. [illegible] A^{Roe} [illegible] $A^{\mathrm{Roe}}(\mathbf{v^L}, \mathbf{v^R}) = R\Lambda L$ [illegible] $\Lambda = \mathrm{Diag}(\mu_j)_{j=1,5}$ [illegible] (2.16) R [illegible] (3.12) [illegible] $L = R^{-1}$ [illegible] A^{Roe} [illegible]

The right eigenvectors of A^{Roe} are obviously the vectors $(r_j)_{j=1,5}$, since

$$A^{\mathrm{Roe}} r_j = \mu_j r_j, \quad j = 1, 5. \tag{3.13}$$

Let us notice that for $\mathbf{v^L} \neq \mathbf{v^R}$, the Roe matrix $A^{\mathrm{Roe}}(\mathbf{v^L}, \mathbf{v^R})$ is not the value of the Jacobian of the relaxed flux $\mathcal{G}$ at an "average" state. We define the absolute value of the Roe matrix by $|A^{\mathrm{Roe}}(\mathbf{v^L}, \mathbf{v^R})| = R|\Lambda|L$. The Roe matrix allows us to construct Roe's numerical scheme and to conclude, thanks to the forthcoming theorem.

THEOREM 3.3. [illegible]

$$\mathbf{H}^{\mathrm{Roe}}(\mathbf{v^L}, \mathbf{v^R}) = \frac{1}{2}\left(\mathcal{G}(\mathbf{v^L}) + \mathcal{G}(\mathbf{v^R})\right) - \frac{1}{2}|A^{\mathrm{Roe}}(\mathbf{v^L}, \mathbf{v^R})|(\mathbf{v^R} - \mathbf{v^L}) \tag{3.14}$$

[illegible]

$$\mathbf{H}^{\mathrm{Roe}}(\mathbf{v^L}, \mathbf{v^R}) = \mathbf{H}^{\mathrm{God}}(\mathbf{v^L}, \mathbf{v^R}), \tag{3.15}$$

[illegible] $\mathbf{H}^{\mathrm{God}}$ [illegible] (2.12)

Such a scheme can be constructed when all the fields of the relaxation system are linearly degenerated, which is our case, or when the solution of the Riemann problem is only made up of shocks.

[illegible] 3.1. The main ideas involved in the following computations are the use of the Rankine–Hugoniot condition and the conservation of an appropriate Riemann invariant. The proof of the lemma is composed of the proof of the five equalities (3.11), as each of these requires a specific treatment.

In a first step, we show that $\mathbf{v}_1 - \mathbf{v}_0 = \delta_1 r_1$. By definition,

$$\begin{aligned} \mathbf{v}_1 - \mathbf{v}_0 = (&\rho^\star_{\mathbf{L}} - \rho_{\mathbf{L}},\ \rho^\star_{\mathbf{L}} v^\star - \rho_{\mathbf{L}} v_{\mathbf{L}},\ \rho^\star_{\mathbf{L}} \Pi^\star - \rho_{\mathbf{L}} \Pi_{\mathbf{L}}, \\ &(\rho^\star_{\mathbf{L}} - \rho_{\mathbf{L}}) Y_{\mathbf{L}},\ (\rho^\star_{\mathbf{L}} - \rho_{\mathbf{L}}) \Sigma_{\mathbf{L}})^T. \end{aligned} \tag{3.16}$$

First, the Rankine–Hugoniot condition applied on the Eulerian equation $\partial_t \rho + \partial_x(\rho v) = 0$ with the first discontinuity gives

$$\rho^\star_{\mathbf{L}} v^\star - \rho_{\mathbf{L}} v_{\mathbf{L}} = (v_{\mathbf{L}} - a\tau_{\mathbf{L}})(\rho^\star_{\mathbf{L}} - \rho_{\mathbf{L}}). \tag{3.17}$$

Second, in Lagrangian coordinates, $\mathcal{I} = \Pi + a^2\tau$ is a Riemann invariant for the characteristic speed 0, i.e., $\partial_t \mathcal{I} = 0$. This is a straightforward consequence of the two Lagrangian conservation laws $\partial_t \tau - \partial_y v = 0$ and $\partial_t \Pi + a^2 \partial_y v = 0$. Back in Eulerian

coordinates, $\mathcal{I}$ is a Riemann invariant for the characteristic speed v. A direct application is $\Pi^\star + a^2\tau_{\mathbf{L}}^\star = \Pi_{\mathbf{L}} + a^2\tau_{\mathbf{L}}$, which implies $\rho_{\mathbf{L}}^\star\left(\Pi^\star + a^2\tau_{\mathbf{L}}^\star\right) - \rho_{\mathbf{L}}\left(\Pi_{\mathbf{L}} + a^2\tau_{\mathbf{L}}\right) = \left(\rho_{\mathbf{L}}^\star - \rho_{\mathbf{L}}\right)\left(\Pi_{\mathbf{L}} + a^2\tau_{\mathbf{L}}\right)$. The expansion of the left-hand side of the last equality gives

$$\rho_{\mathbf{L}}^\star\Pi^\star - \rho_{\mathbf{L}}\Pi_{\mathbf{L}} = \left(\rho_{\mathbf{L}}^\star - \rho_{\mathbf{L}}\right)\left(\Pi_{\mathbf{L}} + a^2\tau_{\mathbf{L}}\right) \tag{3.18}$$

because $\rho_{\mathbf{L}}^\star \times (a^2\tau_{\mathbf{L}}^\star) - \rho_{\mathbf{L}} \times (a^2\tau_{\mathbf{L}}) = 0$. Substituting equalities (3.17) and (3.18) into the jump (3.16) and using the definitions of δ_1 and r_1 gives $\mathbf{v}_1 - \mathbf{v}_0 = \delta_1 r_1$.

In a second step, the definition of the intermediate states gives

$$\mathbf{v}_2 - \mathbf{v}_1 = \left[0,\ ,\ 0,\ 0,\ \rho_{\mathbf{L}}^\star\left(Y^\star - Y_{\mathbf{L}}\right),\ \rho_{\mathbf{L}}^\star\left(\Sigma^\star - \Sigma_{\mathbf{L}}\right)\right]^T. \tag{3.19}$$

Here, we use the Lagrangian equation $\partial_t Y - \partial_y \Sigma = 0$. We then apply the Rankine–Hugoniot condition with the second discontinuity, which gives $-(\Sigma^\star - \Sigma_{\mathbf{L}}) = -b\,(Y^\star - Y_{\mathbf{L}})$. Multiplying each side by $\rho_{\mathbf{L}}^\star$, one easily obtains

$$\rho_{\mathbf{L}}^\star(\Sigma^\star - \Sigma_{\mathbf{L}}) = b\,\rho_{\mathbf{L}}^\star(Y^\star - Y_{\mathbf{L}}). \tag{3.20}$$

Substituting the equality (3.20) into the jump (3.19) and using the definitions of δ_2 and r_2 gives $\mathbf{v}_2 - \mathbf{v}_1 = \delta_2 r_2$.

In a third step, the definitions of δ_3 and r_3 give directly $\mathbf{v}_3 - \mathbf{v}_2 = \delta_3 r_3$. Similarly, one can prove that $\mathbf{v}_4 - \mathbf{v}_3 = \delta_4 r_4$ and $\mathbf{v}_5 - \mathbf{v}_4 = \delta_5 r_5$, which completes the proof. ∎

3.2. We must show that the matrix A^{Roe} satisfies the three Roe conditions. This will be done by using the definition of this matrix and some easy computations, as we are going to see.

1. By definition, the matrix $A^{\mathrm{Roe}}(\mathbf{v}^{\mathbf{L}}, \mathbf{v}^{\mathbf{R}})$ is diagonalizable with real eigenvalues $(\mu_j)_{j=1,5}$. Its right (resp., left) eigenvectors are $(r_j)_{j=1,5}$, the columns of R (resp., $(l_j)_{j=1,5}$, the lines of L). The five right eigenvectors form a basis of $\mathbb{R}^5$.
2. An easy but tedious calculation enables us to check that $A^{\mathrm{Roe}}(\mathbf{v}, \mathbf{v}) = \nabla\mathcal{G}(\mathbf{v})$.
3. Let us now prove that $A^{\mathrm{Roe}}(\mathbf{v}^{\mathbf{L}}, \mathbf{v}^{\mathbf{R}})(\mathbf{v}^{\mathbf{R}} - \mathbf{v}^{\mathbf{L}}) = \mathcal{G}(\mathbf{v}^{\mathbf{R}}) - \mathcal{G}(\mathbf{v}^{\mathbf{L}})$. First, one can notice that, by definition (3.11), $\mathbf{v}^{\mathbf{L}} - \mathbf{v}^{\mathbf{R}} = \sum_{j=1,5}(\mathbf{v}_j - \mathbf{v}_{j-1}) = \sum_{j=1,5}\delta_j r_j$. It is therefore easy to see that, thanks to (3.13) and (3.11),

$$A^{\mathrm{Roe}}(\mathbf{v}^{\mathbf{L}},\ \mathbf{v}^{\mathbf{R}})(\mathbf{v}^{\mathbf{L}} - \mathbf{v}^{\mathbf{R}}) = \sum_{j=1,5}\delta_j\mu_j r_j = \sum_{j=1,5}\mu_j(\mathbf{v}_j - \mathbf{v}_{j-1}).$$

On the other hand, the Rankine–Hugoniot condition gives the jump through the jth discontinuity as

$$\mathcal{G}(\mathbf{v}_j) - \mathcal{G}(\mathbf{v}_{j-1}) = \mu_j(\mathbf{v}_j - \mathbf{v}_{j-1}), \quad j = 1, \ldots, 5. \tag{3.21}$$

It follows that

$$A^{\mathrm{Roe}}(\mathbf{v}^{\mathbf{L}},\ \mathbf{v}^{\mathbf{R}})(\mathbf{v}^{\mathbf{L}} - \mathbf{v}^{\mathbf{R}}) = \sum_{j=1,5}\mathcal{G}(\mathbf{v}_j) - \mathcal{G}(\mathbf{v}_{j-1}) = \mathcal{G}(\mathbf{v}^{\mathbf{L}}) - \mathcal{G}(\mathbf{v}^{\mathbf{R}}),$$

which is the desired result. ∎

3.3. We use the two equalities [11, Chap. 3, Lemma 4.3]

$$\frac{2}{\Delta x}\int_0^{\Delta x/2}\mathbf{v}\left(\frac{x}{\Delta t^n}\right)dx = \mathbf{v}_5 - 2\frac{\Delta t^n}{\Delta x}\left(\mathcal{G}(\mathbf{v}_5) - \mathbf{H}(\mathbf{v}_0,\ \mathbf{v}_5)\right), \tag{3.22}$$

$$\frac{2}{\Delta x}\int_{-\Delta x/2}^{0}\mathbf{v}\left(\frac{x}{\Delta t^n}\right)dx = \mathbf{v}_0 - 2\frac{\Delta t^n}{\Delta x}\left(\mathbf{H}(\mathbf{v}_0,\ \mathbf{v}_5) - \mathcal{G}(\mathbf{v}_0)\right), \tag{3.23}$$

with Δt^n satisfying the CFL condition (2.32). One denotes $\mu_j^+ = \max(\mu_j, 0)$ and $\mu_j^- = \min(\mu_j, 0)$ for $j = 1, 5$. The main idea of the proof is to compute explicitly the left-hand sides of (3.22)–(3.23) and to obtain two distinct expressions for the Godunov numerical flux. As the CFL condition is satisfied, we are sure that $\mu_5^+ \Delta t \leq \frac{\Delta x}{2}$ and $\mu_1^- \Delta t \geq -\frac{\Delta x}{2}$, which justify such computations. The half-sum of these equalities will give a flux involving the eigenvalues and eigenvectors of the Roe matrix, and that will easily be transformed into the Roe numerical flux (3.14).

We want to compute the left-hand side of (3.22) by integrating the solution of the Riemann problem on the first domain $[0, \Delta x/2] \times [0, \Delta t^n]$ so as to get

$$\begin{aligned}\int_0^{\Delta x/2} \mathbf{v}\left(\frac{x}{\Delta t^n}\right) dx = \mathbf{v}_0 \mu_1^+ \Delta t^n + \mathbf{v}_1(\mu_2^+ - \mu_1^+)\Delta t^n + \cdots \\ + \mathbf{v}_4(\mu_5^+ - \mu_4^+)\Delta t^n + \mathbf{v}_5\left(\frac{\Delta x}{2} - \mu_5^+ \Delta t^n\right).\end{aligned} \tag{3.24}$$

This process leads to

$$\frac{2}{\Delta x}\int_0^{\Delta x/2} \mathbf{v}\left(\frac{x}{\Delta t^n}\right) dx = 2\frac{\Delta t^n}{\Delta x}\sum_{j=1,5}(\mathbf{v}_{j-1} - \mathbf{v}_j)\mu_j^+ + \mathbf{v}_5.$$

By comparison with (3.22), we infer that

$$\mathbf{H}(\mathbf{v}_0,\ \mathbf{v}_5) = \mathcal{G}(\mathbf{v}_5) - \sum_{j=1,5}(\mathbf{v}_j - \mathbf{v}_{j-1})\mu_j^+. \tag{3.25}$$

Similarly, we compute the left-hand side of (3.23) by integrating the solution of the Riemann problem on the second domain $[-\Delta x/2, 0] \times [0, \Delta t^n]$ to get

$$\mathbf{H}(\mathbf{v}_0, \mathbf{v}_5) = \mathcal{G}(\mathbf{v}_0) + \sum_{j=1,5}(\mathbf{v}_j - \mathbf{v}_{j-1})\mu_j^-. \tag{3.26}$$

The equality $|\mu| = \mu^+ - \mu^-$ combined with the half-sum of (3.25) and (3.26) gives

$$\mathbf{H}(\mathbf{v}_0, \mathbf{v}_5) = \frac{1}{2}(\mathcal{G}(\mathbf{v}_0) + \mathcal{G}(\mathbf{v}_5)) - \frac{1}{2}\sum_{j=1,5}|\mu_j|(\mathbf{v}_j - \mathbf{v}_{j-1}). \tag{3.27}$$

But we have already noticed that $\mathbf{v}_5 - \mathbf{v}_0 = \sum_{j=1,5}\delta_j r_j$ and therefore

$$\begin{aligned}|A^{\mathrm{Roe}}(\mathbf{v}_0, \mathbf{v}_5)|(\mathbf{v}_5 - \mathbf{v}_0) &= \sum_{j=1,5}\delta_j R|\Lambda|L r_j = \sum_{j=1,5}\delta_j|\mu_j|r_j \\ &= \sum_{j=1,5}|\mu_j|(\mathbf{v}_j - \mathbf{v}_{j-1}),\end{aligned}$$

which yields the equality (3.15). □

3.1.3. The first-order linearly implicit relaxation scheme. We are now in a position to compute the partial derivatives of the numerical flux defined by (3.14). They are obtained by assuming that Roe's matrix is constant. We obtain the matrices α and γ as

$$\alpha_i \approx \frac{\Delta t^n}{2\Delta x}\left(A^{\mathbf{L}} + |A^{\mathrm{Roe}}|\right), \quad \gamma_{i+1} \approx \frac{\Delta t^n}{2\Delta x}\left(A^{\mathbf{R}} - |A^{\mathrm{Roe}}|\right), \tag{3.28}$$

where $A^{\mathbf{L},\mathbf{R}} = \nabla\mathcal{G}(\mathbf{v}^{\mathbf{L},\mathbf{R}})$ and $A^{\mathrm{Roe}} = A^{\mathrm{Roe}}(\mathbf{v}^{\mathbf{L}}, \mathbf{v}^{\mathbf{R}})$.

The first-order linearly implicit relaxation scheme consists, at each time step, in solving the linear system $\mathbb{A}\,\delta\mathbf{v} = b$. The matrix $\mathbb{A}$ is a tridiagonal by block matrix with each block of size 5×5; the resulting matrix is a band matrix with nine extradiagonal terms.

We have already shown the interior lines (3.8)–(3.9), but we have not described the first and the last lines, which are related to the boundary conditions. For the states $\mathbf{v}_0$ and $\mathbf{v}_{I+1}$, we specify $\delta\mathbf{v}_0 = 0$ and $\delta\mathbf{v}_{I+1} = 0$.

3.2. First-order semi-implicit relaxation scheme. The relaxation scheme is constructed so as to be

- linearly implicit with respect to the fast acoustic waves of speed $v \pm a\tau$,
- explicit with respect to the slow kinematic waves of speed v and the associated relaxation waves of speed $v \pm b\tau$.

Accordingly, when one computes the partial derivatives of the numerical flux, only the terms associated with the largest eigenvalues are kept. We take the diagonal matrix $\tilde{\Lambda} = \mathrm{Diag}(v_{\mathbf{L}} - a\tau_{\mathbf{L}},\, 0,\, 0,\, 0,\, v_{\mathbf{R}} + a\tau_{\mathbf{R}})$ which modifies Roe's matrix by $\tilde{A}^{\mathrm{Roe}} = R\tilde{\Lambda}L$ with the same matrices R and L as previously. Like Roe's matrix, the eigenvalues of the Jacobian matrices are modified in the same way by $\tilde{A}^{\mathbf{L},\mathbf{R}} = R^{\mathbf{L},\mathbf{R}}\tilde{\Lambda}^{\mathbf{L},\mathbf{R}}L^{\mathbf{L},\mathbf{R}}$. The matrices α and β are then computed with (3.28) and the previous modified matrices.

3.2.1. Time step of the semi-implicit relaxation scheme. At each time step, one computes two auxiliary time steps.

1. The explicit time step is

$$\Delta t^{\mathrm{Void}} = \mu^{\mathrm{Void}}\frac{\Delta x}{\max_{i=1,I}|V_i^{\mathrm{Void}}|},$$

   with $\mu^{\mathrm{Void}} = 0.5$ and $|V_i^{\mathrm{Void}}| = \max\left(|v^\star|,\, |v^\star - b\tau_{\mathbf{L}}^\star|,\, |v^\star + b\tau_{\mathbf{R}}^\star|\right)$.
2. The linearly implicit time step is

$$\Delta t^{\mathrm{Press}} = \mu^{\mathrm{Press}}\frac{\Delta x_i}{\max_{i=1,I}|V_i^{\mathrm{Press}}|},$$

   with $\mu^{\mathrm{Press}} = 20$ and $|V_i^{\mathrm{Press}}| = \max\left(|v_{\mathbf{L}} - a\tau_{\mathbf{L}}|,\, |v_{\mathbf{L}} + a\tau_{\mathbf{R}}|\right)$.

The selected time step is $\Delta t^n = \min\left(\Delta t^{\mathrm{Void}}, \Delta t^{\mathrm{Press}}\right)$. The CFL number $\mu^{\mathrm{Press}} = 20$, experimentally determined, turns out to be a good compromise between a small CPU time and an acceptable amount of smearing out for the numerical solution.

3.2.2. Implicit projection. We follow the ideas of Chalons [3]. The use of a linearly implicit scheme implies that the projection step is giving steady states that are not accurate. The solution is to link the evolutions of the relaxed variables associated with an implicit field to the evolutions of the equilibrium variables. In our case, the only relaxed variable associated with an implicit field is $\rho\Pi$; the relaxation variable $\rho\Sigma$ is associated with the eigenvalues $v \pm b\tau$, which are explicit. We therefore write the implicit projection equation

$$\delta(\rho\Pi)_i = \left(\frac{\partial\mathcal{I}}{\partial\rho}\right)_i^n \delta\rho_i + \left(\frac{\partial\mathcal{I}}{\partial(\rho Y)}\right)_i^n \delta(\rho Y)_i + \left(\frac{\partial\mathcal{I}}{\partial(\rho v)}\right)_i^n \delta(\rho v)_i,$$

with $\mathcal{I}(\mathbf{u}) = \rho P(\mathbf{u})$. The partial derivatives of $\mathcal{I}$ are computed on $\mathbf{u}_i^n$. The previous identity gives an equation that replaces the fifth line of (3.9), i.e., modifies the linear

system to be solved in the mathematical step. It enables us to reduce the size of each block from 5×5 to 4×4 and therefore reduce the size of the global linear system.

Numerical experiments show that not only are the steady solutions more accurate [3], but even transient solutions are more accurate.

REMARK 3.4.

1.

2.

3.

3.3. Second-order semi-implicit scheme. The slope limiters used to build the second-order explicit scheme lead to a nondifferentiable expression. That is why we choose a simplified version in which we do not differentiate the nonlinear operator involved in the second-order correction. In the physical step, we first compute the second-order correction of the states $\mathbf{u_{L,R}}$ and evaluate the numerical flux. In the mathematical step, we solve the first-order linear system, but the derivatives are computed with the corrected states $\mathbf{u_{L,R}}$.

In order to have a second order in time scheme, we use again the Runge–Kutta 2 procedure. Since the scheme is only semi-implicit, the order 2 in time is only achieved on the explicit waves and the linearly implicit waves are solved with order 1 in time.

4. Numerical results. In this section, we show the numerical results of the semi-implicit relaxation scheme: shock tube test (without boundary conditions) and real-life cases (with boundary conditions). The first two test-cases are Riemann problems. The length of the domain is 100 meters and the discontinuity between the two initial constant states is located at $x = 50$ m. The last two test-cases are real-life problems in which the solution is driven by the changes of the boundary conditions.

4.1. Experiment 1: No-slip law. The details of this test-case are shown in Table 4.1 and the results are displayed in Figure 4.1. We see that the second-order correction leads to a more accurate scheme.

4.2. Experiment 2: Zuber–Findlay law. The details of this test-case are shown in Table 4.2 and the results are displayed in Figure 4.2. We used the VFRoeTACITE scheme described in [6] with the same CFL numbers. The two schemes are semi-implicit second-order schemes. The numerical results exhibit a good agreement between the two schemes.

4.3. Experiment 3: No-slip law. The details of this test-case are shown in Table 4.3 and the results are given in Figure 4.3. This is the simplest real-life problem we can imagine: we just double the inlet gas flow rate. There are no one-phase states. The numerical results show a good agreement between the two schemes.

4.4. Experiment 4: Zuber–Findlay-like law. The details of this test-case are shown in Table 4.4 and the results are given in Figure 4.4.

Length of the pipe	$L = 10000$ m, horizontal
Cell size	$\Delta x = 200$ m
Diameter	0.146 m
Inlet condition on gas flow rate	0.2 to 0.4 kg/s
Inlet condition on liquid flow rate	20 kg/s
Outlet condition on pressure	10^6 Pa

In this test-case [6], the inlet gas flow rate is decreased from 0.114 to 0 kg/s. As the mass flow rates are small, the decrease in the inlet gas mass flow rate gives rise to negative oil velocities in the upper part of the pipeline. Therefore a void fraction between a "single-phase gas" state and a "two-phase" state propagates from the outlet down the pipe. Simultaneously, the change in the inlet gas mass flow rates induces another void fraction front which propagates from the inlet up the pipe. These two fronts meet around $x = 47$ m at time $t = 260$ s to form a unique discontinuity wave which propagates towards the outlet. At time $t = 200$ s, this discontinuity wave reaches the outlet, and the pipe turns to a single-phase liquid steady state.

This test-case is quite stiff. During the simulation, the scheme must handle two-phase states, liquid state and gas state. Moreover, the discontinuity propagating at the end on the simulation is between two one-phase states. The classical VFRoe scheme is not rough enough to handle this case and that is why the authors of [6] introduced more numerical diffusion in their VFRoe-TACITE scheme. The numerical

results show a good agreement between the two schemes.

5. Conclusion. A second-order semi-implicit relaxation scheme has been obtained as soon as we have succeeded in expressing the explicit scheme in Roe's form, that is to say, in computing the Roe matrix. The semi-implicit relaxation scheme is then explicit for the slow waves and linearly implicit for the fast waves and enables us to reduce the CPU time as well as to be more accurate on slow waves. Numerical experiments show a good agreement with the exact solution on shock tube tests and with a VFRoe-type scheme on more realistic problems.

There are a great number of prospects and open issues to this work: extension to the multicomponent case and to the energy equation, investigation into the link between the relaxation coefficients and the implicit projection, boundary conditions that are consistent with positivity properties for the inner scheme, and so on.

Appendix A. Additional benchmarks. In this appendix, we provide a few more critical numerical experiments so the reader can have a broader grasp of various aspects of the explicit and semi-implicit schemes.

A.1. Old vs. new relaxation coefficients. In [1], the relaxation coefficients a and b were assessed in a "coupled" way. In this paper, these are derived from the formulae detailed in section 2.3, based on a rough "decoupling" strategy. We wish to compare the performance of the explicit relaxation scheme based on the conditions of [1], called "old" (a, b), and the performance of the explicit relaxation scheme based on the conditions of section 2.3, called "new" (a, b).

Figure A.1 plots the pressure, the velocity, the gas mass fraction, and the density at the final time for a test-case consisting merely of a transport of the mass-fraction. First-order explicit approximations are considered. It can be seen that the "old" coefficients give rise to a slightly more smoothed out front. The difference between the two ways of computing (a, b) is hardly noticeable here, because in both cases b is very small, and the difference brought about by $a_{\text{new}} < a_{\text{old}}$ essentially lies in acoustic waves, which do not exist here. The discrepancy is much more impressive in Figure A.2, where we plot the results for a similar test-case with the Zuber–Findlay slip law. Here, $b_{\text{new}} \ll b_{\text{old}}$, which accounts for the excessively smeared out front in the curves associated with the old coefficients. This example highlights the great benefit of the new procedure for adjusting the relaxation coefficients.

A.2. CFL ratio for the semi-implicit scheme. In order to get a better understanding of the basic properties of the semi-implicit scheme regarding accuracy and stability properties, we plot in Figure A.3 a comparison of three first-order schemes, namely,

1. the explicit scheme with CFL = 0.5,
2. the semi-implicit scheme with CFL = 20 (CFL corresponding to fast waves),
3. the semi-implicit scheme with CFL = 0.5 (CFL based on fast wave),

for a Riemann problem consisting of a single transport of the slow wave. Note that since the Zuber–Findlay closure law is used, the pressure p is not preserved at the contact jump (which would be the case for a no-slip closure law).

It turns out that scheme 1 has the same amount of diffusion as scheme 3 and gives results better than scheme 2 at the pressure jump. Nevertheless, both are less sharp than scheme 2 as far as the mass-fraction is concerned. It is a well-known fact for an explicit scheme that the larger the CFL is, the less the computed solution is smeared out. It is thus tempting to take the "largest" μ^{Void} possible. However, we are limited by the fact that a large CFL ratio introduces errors via the implicit part

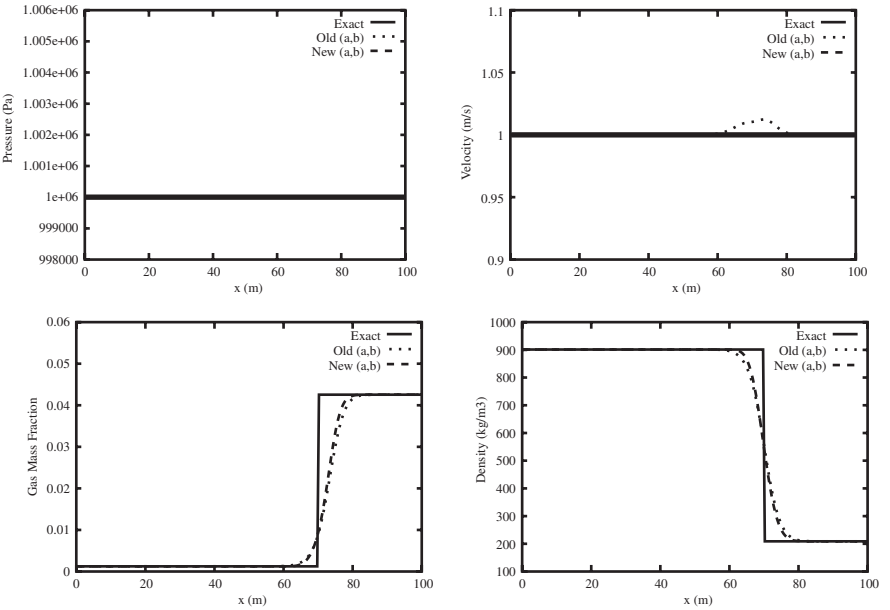

FIG. A.1. *Results for old and new relaxation coefficients with the no-slip law.*

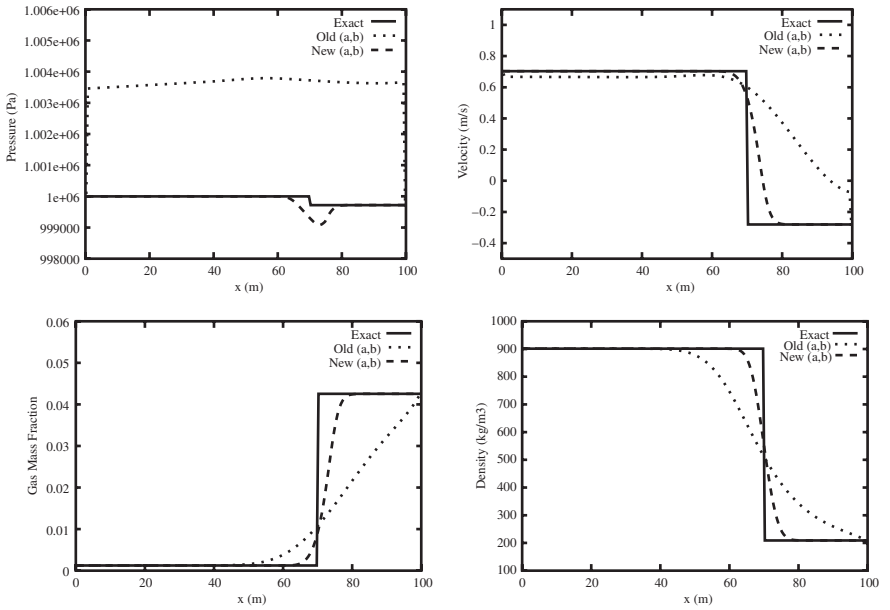

FIG. A.2. *Results for old and new relaxation coefficients with the Zuber–Findlay law.*

of the scheme (since only one Newton iteration is carried out). In this respect, the CFL number $\mu^{\text{Press}} = 20$ appears to be a good experimental compromise.

The fact that we do not observe any obvious difference between the three curves is due to the nature of the experiment at issue, in which only a slow wave is involved. The semiexplicit scheme has been purportedly designed to achieve good accuracy

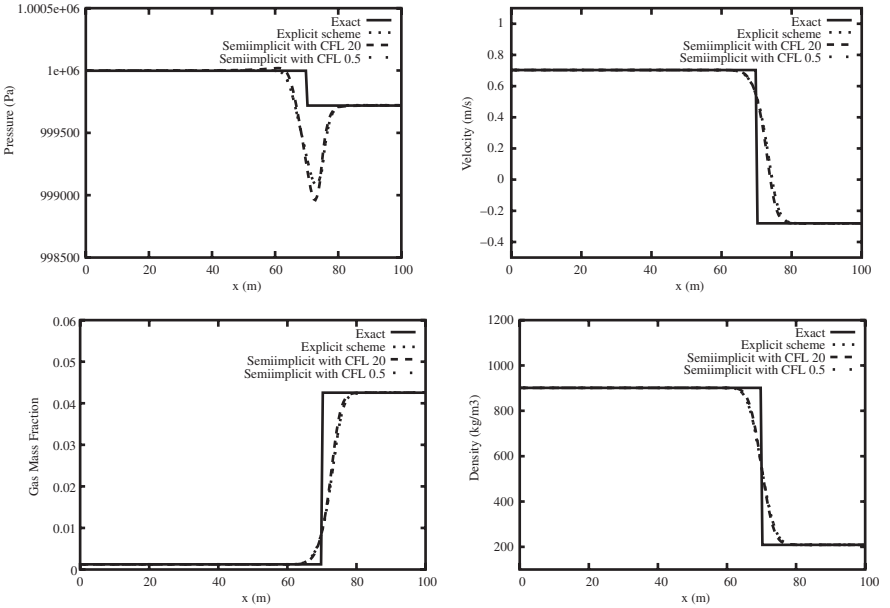

FIG. A.3. *Various first-order schemes, Zuber–Findlay law.*

for these slow waves. Had we considered a case with many types of waves, as in Experiment 3, we would have seen a relatively poor performance of the semi-implicit scheme on acoustic waves. Therefore, Figure A.3 should be interpreted as good news, insofar as it confirms our claim that the new semi-implicit scheme is able to achieve high accuracy on slow waves while saving a lot of computational time.

Acknowledgments. The authors wish to thank I. Faille and F. Willien for the numerous helpful discussions we had. We are also grateful to the anonymous reviewer who suggested several improvements to the original text.

ANALYSIS OF HALF-QUADRATIC MINIMIZATION METHODS FOR SIGNAL AND IMAGE RECOVERY*

MILA NIKOLOVA† AND MICHAEL K. NG‡

Abstract. We address the minimization of regularized convex cost functions which are customarily used for edge-preserving restoration and reconstruction of signals and images. In order to accelerate computation, the *multiplicative* and the *additive* half-quadratic reformulation of the original cost-function have been pioneered in Geman and Reynolds [*IEEE Trans. Pattern Anal. Machine Intelligence*, 14 (1992), pp. 367–383] and Geman and Yang [*IEEE Trans. Image Process.*, 4 (1995), pp. 932–946]. The alternate minimization of the resultant (augmented) cost-functions has a simple explicit form. The goal of this paper is to provide a systematic analysis of the convergence rate achieved by these methods. For the multiplicative and additive half-quadratic regularizations, we determine their upper bounds for their root-convergence factors. The bound for the multiplicative form is seen to be always smaller than the bound for the additive form. Experiments show that the number of iterations required for convergence for the multiplicative form is always less than that for the additive form. However, the computational cost of each iteration is much higher for the multiplicative form than for the additive form. The global assessment is that minimization using the additive form of half-quadratic regularization is faster than using the multiplicative form. When the additive form is applicable, it is hence recommended. Extensive experiments demonstrate that in our MATLAB implementation, both methods are substantially faster (in terms of computational times) than the standard MATLAB OPTIMIZATION TOOLBOX routines used in our comparison study.

1. Introduction.

This work addresses a wide class of problems where a sought vector $\hat{x} \in R^p$ (e.g., an image or a signal) is estimated based on degraded data $y \in \mathbb{R}^q$ by minimizing a cost function $J : \mathbb{R}^p \to \mathbb{R}$ which combines a quadratic data-fidelity term and a regularization term Φ, weighted by a parameter $\beta > 0$:

$$\hat{x} = \min_{x \in \mathbb{R}^p} J(x), \tag{1.1}$$

$$J(x) = \|Ax - y\|^2 + \beta\Phi(x). \tag{1.2}$$

In a statistical framework, this data-fidelity term assumes that data y are obtained from the original x by a linear transform, modeled by $A \in \mathbb{R}^{q \times p}$, and that they are contaminated by white Gaussian noise. Such data-fidelity terms are popular in denoising, in deblurring, and in numerous inverse problems such as seismic imaging,

nondestructive evaluation, and X-ray tomography [1, 12, 28, 29, 31]. We focus on regularization terms Φ of the form

$$\Phi(x) = \sum_{i=1}^{r} \phi(g_i^T x), \tag{1.3}$$

where $g_i^T : \mathbb{R}^p \to \mathbb{R}$, for $i = 1, \ldots, r$, are linear operators. Typically, $\{g_i^T x\}$ are first- or second-order differences between neighboring samples in x. For example, if x is a one-dimensional signal, usually $g_i^T x = x_i - x_{i+1}$, for $i = 1, \ldots, p-1$. Let G denote the $r \times p$ matrix whose ith row is g_i^T, for $i = 1, \ldots, r$. Some basic requirements are

$$\phi \not\equiv 0 \quad \text{and} \quad \ker(A^T A) \cap \ker(G^T G) = \{0\}. \tag{1.4}$$

We focus on convex, [illegible] potential functions $\phi : \mathbb{R} \to \mathbb{R}$ in (1.3), because they give rise to image and signal estimates of high quality, involving edges and homogeneous regions. Examples of such functions are [4, 5, 8, 17, 22]

$$\phi(t) = |t|^\alpha, \ 1 < \alpha \leq 2, \tag{1.5}$$

$$\phi(t) = \sqrt{\alpha + t^2}, \tag{1.6}$$

$$\phi(t) = \log(\cosh(\alpha t)), \tag{1.7}$$

$$\phi(t) = |t|/\alpha - \log\left(1 + |t|/\alpha\right), \tag{1.8}$$

$$\phi(t) = \begin{cases} t^2/2 & \text{if} \quad |t| \leq \alpha, \\ \alpha|t| - \alpha^2/2 & \text{if} \quad |t| > \alpha, \end{cases} \tag{1.9}$$

where $\alpha > 0$ is a parameter. We will systematically consider that ϕ is convex, even, and $\mathcal{C}^2$ and that

$$A^T A \ \text{ is invertible} \quad \text{and/or} \quad \phi''(t) > 0 \ \ \forall t \in \mathbb{R}. \tag{1.10}$$

Remark 1. [illegible] (1.10) [illegible] (1.4) [illegible] $y \in \mathbb{R}^p$ [illegible] J [illegible]

However, the minimizers $\hat{x}$ of cost-functions J involving edge-preserving regularization are nonlinear with respect to y and their computation is costly, especially when A has many nonzero entries and/or A is ill-conditioned. In order to cope with the computation, [illegible] reformulation of J was pioneered, in two different ways, in [13, 14]. The idea is to construct an [illegible] $\mathcal{J} : \mathbb{R}^p \times \mathbb{R}^r \to \mathbb{R}$ which involves an auxiliary variable $b \in \mathbb{R}^r$,

$$\mathcal{J}(x, b) = \|Ax - y\|^2 + \beta \sum_{i=1}^{r} \left(\, Q(g_i^T x, \ b_i) + \psi(b_i) \, \right), \tag{1.11}$$

where $Q(., s) : \mathbb{R} \to \mathbb{R}$ is quadratic for any $s \in \mathbb{R}$ and $\psi : \mathbb{R} \to \mathbb{R}$ satisfies

$$\phi(t) = \min_{s \in \mathbb{R}} \{Q(t, \ s) + \psi(s)\} \quad \forall t \in \mathbb{R}. \tag{1.12}$$

Such a [illegible] potential function ψ is determined using the theory of convex conjugacy [18, 27]. Condition (1.12) ensures that

$$J(x) = \min_{b \in \mathbb{R}^r} \mathcal{J}(x, b) \quad \forall x \in \mathbb{R}^p. \tag{1.13}$$

The regularization term involved in $\mathcal{J}$ is half-quadratic, and hence the name of the method. The minimizer $(\hat{x}, \hat{b})$ of $\mathcal{J}$ is calculated using [illegible]. Let the solution at iteration $(k-1)$ read $(x^{(k-1)}, b^{(k-1)})$. At iteration k we calculate

$$b^{(k)} \text{ such that } \mathcal{J}(x^{(k-1)}, b^{(k)}) \leq \mathcal{J}(x^{(k-1)}, b) \quad \forall b \in \mathbb{R}^r, \tag{1.14}$$

$$x^{(k)} \text{ such that } \mathcal{J}(x^{(k)}, b^{(k)}) \leq \mathcal{J}(x, b^{(k)}) \quad \forall x \in \mathbb{R}^p. \tag{1.15}$$

This amounts to finding $b^{(k)}$ and $x^{(k)}$ according to

$$\begin{aligned} b^{(k)} &= \left[\sigma(g_i^T x^{(k-1)})\right]_{i=1}^r, \\ x^{(k)} &= \chi(b^{(k)}), \end{aligned} \tag{1.16}$$

where $\sigma : \mathbb{R} \to \mathbb{R}$ and $\chi : \mathbb{R}^r \to \mathbb{R}^p$ are minimizer functions which are defined in sections 2 and 3. For every $t \in \mathbb{R}$, the scalar $\sigma(t)$ is such that

$$Q(t, \sigma(t)) + \psi(\sigma(t)) \leq Q(t, s) + \psi(s) \quad \forall s \in \mathbb{R}. \tag{1.17}$$

For every $b \in \mathbb{R}^r$, the vector $\chi(b) \in \mathbb{R}^p$ is such that

$$\|A\chi(b) - y\|^2 + \beta \sum_{i=1}^r Q(g_i^T \chi(b),\ b_i) \leq \|Ax - y\|^2 + \beta \sum_{i=1}^r Q(g_i^T x,\ b_i)\ \forall x \in \mathbb{R}^p. \tag{1.18}$$

The key points are that each component $b_i^{(k)}$ is calculated using a scalar function σ and that $x^{(k)}$ is calculated using an affine function of y, namely χ. Moreover, both functions σ and χ have an explicit form. Thus $b^{(k)}$ and $x^{(k)}$ are easy to compute and allow J to be decreased.

REMARK 2. [illegible] (1.14)–(1.15) [illegible] $k \in \mathbb{N}$ [illegible]

$$\mathcal{J}(x^{(k+1)}, b^{(k+1)}) \leq \mathcal{J}(x^{(k)}, b^{(k+1)}) \leq \mathcal{J}(x^{(k)}, b^{(k)}). \tag{1.19}$$

[illegible] $\mathcal{J}$ [illegible]

$$\{\ldots, \mathcal{J}(x^{(k)}, b^{(k)}), \mathcal{J}(x^{(k)}, b^{(k+1)}), \mathcal{J}(x^{(k+1)}, b^{(k+1)}), \ldots\}$$

[illegible] $k \to \infty$ [illegible] $J(x^{(k+1)}) \leq J(x^{(k)})$ [illegible] k [illegible] $\{J(x^{(k)})\}$ [illegible]

By extending the notion of line-variable [15], Geman and Reynolds [13] first considered quadratic terms of the [illegible],

$$Q(t, s) = \frac{1}{2} t^2 s \quad \text{for} \quad t \in \mathbb{R}, \quad s \in \mathbb{R}_+. \tag{1.20}$$

Later, Geman and Yang proposed in [14] the [illegible] for Q,

$$Q(t, s) = (t - s)^2 \quad \text{for} \quad t \in \mathbb{R}, \quad s \in \mathbb{R}. \tag{1.21}$$

In [13, 14], half-quadratic regularization was used to simplify simulated annealing minimization in cases when ϕ is nonconvex and A has many nonzero entries. These fruitful ideas have been pursued and deepened by many authors. The multiplicative form (1.20) was considered in [7, 8, 11, 19, 21, 30]. The additive form (1.21) seems to have suggested a narrower interest. It was considered in [3, 7, 10, 19]. In [10],

the auxiliary variable is introduced in a nonconvex data-fidelity term. Extensions of the multiplicative form to interacting line variables b were proposed in [30, 19]. The convergence of the alternate minimization (1.14)–(1.15) of $\mathcal{J}$ towards the sought minimizer $\hat{x}$ of the original J for the multiplicative form is considered in [8, 11, 19] and for the additive form in [3] in a continuous setting.

In [3, 7, 10, 13, 14], the numerical results have shown that minimization using half-quadratic (HQ) regularization can speed up computation compared with the steepest descent method. However, the convergence rate of HQ minimization methods has never been analyzed in a systematic way. The effectiveness of the two HQ formulations (1.20) and (1.21) has never been compared theoretically. The main objective of this paper is to characterize the speed of convergence and estimate the bound on the convergence rate relevant to each form of HQ regularization and to compare it with standard minimization methods. We show that minimization using HQ regularization amounts to finding the fixed point $\hat{x}$ of a mapping $F : \mathbb{R}^p \to \mathbb{R}^p$ of the form

$$F(x) = x - (\mathcal{H}(x))^{-1} DJ(x),$$

where $\mathcal{H}(x) \in \mathbb{R}^{p\times p}$ performs a pertinent correction of the steepest descent direction $-DJ(x)$. We analyze the contraction properties of the mapping F corresponding to the multiplicative and the additive forms of HQ regularization. In order to compare the iterations corresponding to these two forms, we focus on the root-convergence factor [9, 26], namely

$$C(F,\hat{x}) = \sup\left\{ \limsup_{k\to\infty} \left\| x^{(k)} - \hat{x} \right\|^{\frac{1}{k}} \;:\; x^{(0)} \in \mathbb{R}^p \right\}. \tag{1.22}$$

Let us emphasize that $C(F,\hat{x})$ characterizes the convergence speed for any norm used to measure the residual $\|x^{(k)} - \hat{x}\|$; see, e.g., [26]. Using the linear convergence theorem [26, p. 301], there are conditions ensuring that

$$C(F,\hat{x}) = \text{Spectral Radius}(DF(\hat{x})).$$

For each form we determine an upper bound of the spectral radius of DF at $\hat{x}$ which is shown to be strictly smaller than 1. The bound for the multiplicative form is revealed to be smaller than the bound for the additive form. This result suggests that the multiplicative form (1.20) needs fewer iterations to find the minimum than the additive form (1.21). However, the cost per iteration is much smaller for the additive form than for the multiplicative form. By combining these two factors, we demonstrate that minimization using the additive form is faster than using the multiplicative form. When the additive form is applicable, it is more attractive. We also propose a fast method to effectively recover signals and images using regularization with the Huber function ϕ—cf. (1.9)—and a nonsmooth augmented cost-function $\mathcal{J}$. Furthermore, we discuss different ways to improve the computational cost of HQ minimization. Extensive experiments based on the MATLAB computing environment demonstrate that the additive form achieves minimization faster than the multiplicative form, and that both forms in our MATLAB implementation substantially outperform in terms of computational times the routines in the MATLAB Optimization Toolbox. (These results must be qualified by the observation that MATLAB run times for the same operations can vary by orders of magnitude depending on the particular coding used.)

Organization of the paper. Section 2 is dedicated to the speed of convergence of the multiplicative form. In section 3, we study the speed of convergence relevant

to the additive form. The convergence properties of the two forms, multiplicative and additive, are compared in section 4. Section 5 summarizes the experimental results. Concluding remarks are presented in section 6.

Notations. When necessary, a vector $x \in \mathbb{R}^p$ is also written as $[x_i]_{i=1}^p$. Given $x \in \mathbb{R}^p$, $\mathrm{diag}(x) \equiv \mathrm{diag}\left([x_i]_{i=1}^p\right)$ is the diagonal $p \times p$ matrix whose diagonal elements are the entries of x. For a function $f : \mathbb{R} \to \mathbb{R}$, $f'(t^-)$ and $f'(t^+)$ are its left-side and right-side derivatives at t, respectively. By $\lim_{t \searrow 0} f(t)$ we mean the limit of f when t converges to 0 by positive values. The symbol $\mathbb{R}_+$ addresses the nonnegative reals and $\mathbb{R}_+^*$ the positive reals. If $f : \mathbb{R}^p \times \mathbb{R}^q \to \mathbb{R}$ depends on two variables, $D_j^k f$ is its kth differential with respect to the jth variable. The Euclidean norm of a vector $u \in \mathbb{R}^p$ is denoted $\|u\|$. If H is a $p \times p$ real matrix, its largest-in-magnitude eigenvalue is denoted by $\rho(H)$. Furthermore, $|\!|\!|H|\!|\!| = \sqrt{\rho(H^T H)}$, which is in fact the largest singular value of H. We write $H \succ 0$ if H is symmetric and positive definite. The symbol I stands for identity matrix and $\mathbb{1}$ for a vector whose entries are equal to 1. Given $x \in \mathbb{R}^p$ and $\delta > 0$, we denote $B(x, \delta) = \{u \in \mathbb{R}^p : \|x - u\| \leq \delta\}$. Furthermore, $S = \{x \in \mathbb{R}^p : \|x\| = 1\}$. We also systematically denote

$$\nu^2 = \min\left\{\mu \in \mathbb{R}_+ : \mu \text{ is an eigenvalue of } A^T A\right\},$$

where A is the matrix involved in (1.2).

2. Multiplicative form of half-quadratic regularization.

2.1. Preliminary facts.

Based on previous papers, we suppose that

$$\begin{array}{ll} \text{(a)} & t \to \phi(t) \ \text{ is convex on } \ \mathbb{R}, \\ \text{(b)} & t \to \phi(\sqrt{t}) \ \text{ is concave on } \ \mathbb{R}_+, \\ \text{(c)} & \phi(t) = \phi(-t) \ \forall t \in \mathbb{R}, \\ \text{(d)} & \phi \ \text{ is } \ \mathcal{C}^1 \text{ on } \mathbb{R}, \\ \text{(e)} & \phi'(0^+) > 0, \\ \text{(f)} & \lim\limits_{t \to \infty} \phi(t)/t^2 = 0. \end{array} \tag{2.1}$$

The dual function ψ is convex and reads

$$\psi(s) = \sup_{t \in \mathbb{R}} \left\{ -\frac{1}{2} s t^2 + \phi(t) \right\}. \tag{2.2}$$

As required in (1.12), we have reciprocally (cf. section 7.1 in the appendix)

$$\phi(t) = \inf_{s \in \mathbb{R}} \left\{ \frac{1}{2} s t^2 + \psi(s) \right\}. \tag{2.3}$$

The relation between ϕ and ψ under different assumptions on ϕ were analyzed in [8, 13, 19]. Using (1.11) and (1.20), the augmented cost-function $\mathcal{J}$ reads

$$\begin{aligned} \mathcal{J}(x, b) &= \|Ax - y\|^2 + \beta \sum_{i=1}^{r} \left(\frac{b_i}{2} \, (g_i^T x)^2 + \psi(b_i) \right) \\ &= \|Ax - y\|^2 + \frac{\beta}{2} (Gx)^T \mathrm{diag}(b) \, Gx + \beta \sum_{i=1}^{r} \psi(b_i). \end{aligned} \tag{2.4}$$

The minimizer function σ, defined by (1.17), admits an explicit form which was first determined in [8]:

$$\sigma(t) = \begin{cases} \phi''(0^+) & \text{if} \quad t = 0, \\ \dfrac{\phi'(t)}{t} & \text{if} \quad t \neq 0. \end{cases} \tag{2.5}$$

For its proof under (2.1), see section 7.1 in the appendix. The expression of σ for several functions ϕ is given in Table 4.1. It is useful to notice its main properties.

REMARK 3. [illegible] ϕ [illegible] (2.1)

1. [illegible] $t \to \sigma(t)$ [illegible] $\mathbb{R}_+$ [illegible] (b) [illegible] $t \to \frac{d}{dt}\phi(\sqrt{t}) = \phi'(\sqrt{t})/(2\sqrt{t}) = \sigma(\sqrt{t})/2$ [illegible] $\mathbb{R}_+$
2. [illegible] (a), (c), [illegible] (e), [illegible] $t > 0$ [illegible] $\phi'(t) > 0$ [illegible] $\sigma(t) > 0$ [illegible] $t \in \mathbb{R}$ [illegible]

$$\sigma(t) \in \big(\, 0, \phi''(0^+) \,\big] \quad \forall t \in \mathbb{R}. \tag{2.6}$$

Hence, we can consider b in (2.4) only on $(0, \phi''(0^+)\,]^r$. For any b fixed, the minimizer function χ, introduced in (1.18), is determined by solving with respect to x the equation $D_1\mathcal{J}(x, b) = 0$, that is, $H(b)x = 2A^T y$, where

$$H(b) = 2A^T A + \beta G^T \mathrm{diag}(b) G. \tag{2.7}$$

LEMMA 2.1. [illegible] $H : \mathbb{R}^r \to \mathbb{R}^{p\times p}$ [illegible] (2.7) [illegible] (1.4) [illegible] $\zeta > 0$ [illegible] $\lambda_\zeta > 0$ [illegible] $b \in [\zeta, \infty)^r$ [illegible] $H(b)$ [illegible] λ_ζ [illegible]. Given $\zeta > 0$, let λ_ζ be the smallest eigenvalue of $H(\zeta \mathbb{1})$ and $u_0 \in S$ be the corresponding eigenvector. Clearly, $\lambda_\zeta \geq 0$. We have

$$u_0^T H(\zeta \mathbb{1}) u_0 = \lambda_\zeta = 2\|Au_0\|^2 + \beta\zeta\|Gu_0\|^2.$$

If $u_0 \in \ker(A^T A)$, then (1.4) guarantees that $\|Gu_0\|^2 > 0$. By (1.4) again, if $u_0 \in \ker(G^T G)$, we have $\|Au_0\|^2 > 0$. In all cases, $\lambda_\zeta > 0$. Furthermore, for any $b \in [\zeta, \infty)^r$ and $u \in S$,

$$u^T H(b) u = 2\|Au\|^2 + \beta \sum_{i=1}^{r} b_i (g_i^T u)^2 \geq 2\|Au\|^2 + \beta\zeta\|Gu\|^2 = u^T H(\zeta \mathbb{1}) u \geq \lambda_\zeta.$$

Hence we have the conclusion. □

If (1.4) and (1.10) hold, for every $b \in (0, \infty)^r$ fixed, $H(b)$ is invertible and χ reads

$$\chi(b) = (H(b))^{-1} 2A^T y. \tag{2.8}$$

Although $\mathcal{J}(x, .)$ and $\mathcal{J}(., b)$ are convex functions, $(x, b) \to \mathcal{J}(x, b)$ is generally nonconvex.[1] The convergence of $\{x^{(k)}\}$ in the alternate minimization sequence

[1] For $x \in \mathbb{R}$, $y \in \mathbb{R}$, $A = 1$, and $g_1 = 1$, we have $J(x) = (x - y)^2 + \beta\phi(x)$, and hence $\mathcal{J}(x, b) = (x - y)^2 + \frac{\beta}{2} b x^2 + \beta\psi(b)$. Consider that ψ is twice differentiable on $\mathbb{R}_+^*$. The second differential of $\mathcal{J}$ at an arbitrary (x, b) reads

$$D^2\mathcal{J}(x, b) = \begin{bmatrix} 2 + \beta b & \beta x \\ \beta x & \beta\psi''(b) \end{bmatrix}.$$

$D^2\mathcal{J}(x, b)$ is not positive definite for all $(x, b) \in \mathbb{R} \times \mathbb{R}_+^*$ since for any $b > 0$ and $|x| > (2/\beta + b)\psi''(b)$ we have $\det D^2\mathcal{J}(x, b) < 0$.

$\{(x^{(k)}, b^{(k)})\}$ towards the minimizer $\hat{x}$ of J was initially proven in [8] under strong assumptions on ϕ and later in [19] under conditions similar to (2.1). Convergence towards local minimizers of a nonconvex J was addressed in [11]. It is easy to see that under our assumptions, the sequence $\{(x^{(k)}\}$ is convergent.

LEMMA 2.2. [illegible] J [illegible] (1.2)–(1.3) [illegible] (1.4) [illegible] (2.1) [illegible] $\mathcal{J}$ [illegible] (2.2)–(2.4) [illegible] $\{(x^{(k)}, b^{(k)})\}$ [illegible] (1.14)–(1.15) [illegible]

$$\|x^{(k)} - x^{(k+1)}\| \to 0 \quad k \to \infty.$$

[illegible] Since the function $\mathcal{J}(., b)$ is quadratic, for any $k \in \mathbb{N}$ we can write that

$$\mathcal{J}(x^{(k-1)}, b^{(k)}) - \mathcal{J}(x^{(k)}, b^{(k)}) = D_1\mathcal{J}(x^{(k)}, b^{(k)}) \left(x^{(k-1)} - x^{(k)}\right) + \frac{1}{2} \left(x^{(k-1)} - x^{(k)}\right)^T H(b^{(k)}) \left(x^{(k-1)} - x^{(k)}\right),$$

where the matrix $H(b^{(k)})$ reads as in (2.7). Since $x^{(k)}$ minimizes $\mathcal{J}(., b^{(k)})$, we have $D_1\mathcal{J}(x^{(k)}, b^{(k)}) = 0$. Then

$$\mathcal{J}(x^{(k-1)}, b^{(k)}) - \mathcal{J}(x^{(k)}, b^{(k)}) = \frac{1}{2} \left(x^{(k-1)} - x^{(k)}\right)^T H(b^{(k)}) \left(x^{(k-1)} - x^{(k)}\right). \tag{2.9}$$

The rest of the proof uses the following simple observation.

REMARK 4. [illegible] (1.4) [illegible] ϕ [illegible] J [illegible] 0 [illegible] $\lim_{\|x\| \to \infty} J(x) = \infty$ [illegible] 2 [illegible] $\{J(x^{(k)})\}$ [illegible] $\delta \in (0, \infty)$ [illegible]

$$x^{(k)} \in B(0, \delta) \quad \forall k \in \mathbb{N}. \tag{2.10}$$

For this $\delta > 0$, put

$$\zeta = \sigma(\delta \, |||G|||); \tag{2.11}$$

then $\zeta > 0$ by Remark 3 condition 2. Then we have

$$\begin{aligned} x \in B(0, \delta) \quad &\Rightarrow \quad |g_i^T x| \le \delta \, |||G||| \qquad \forall i \in \{1, \dots, r\}, \\ &\Rightarrow \quad \sigma(g_i^T x) \ge \zeta > 0 \qquad \forall i \in \{1, \dots, r\}, \end{aligned} \tag{2.12}$$

where the second implication comes from Remark 3 condition 1. Since $b_i^{(k)} = \sigma(g_i^T x^{(k-1)})$ for all i and k, combining (2.10) and (2.12) yields

$$b_i^{(k)} \ge \zeta > 0 \quad \forall i \in \{1, \dots, r\}, \quad \forall k \in \mathbb{N}. \tag{2.13}$$

Let $\lambda_\zeta > 0$ be the constant exhibited in Lemma 2.1 relevant to ζ. Then (2.9) yields

$$\mathcal{J}(x^{(k-1)}, b^{(k)}) - \mathcal{J}(x^{(k)}, b^{(k)}) \ge \frac{\lambda_\zeta}{2} \left\|x^{(k-1)} - x^{(k)}\right\|^2 \quad \forall k \in \mathbb{N}.$$

By Remark 2, $\mathcal{J}(x^{(k-1)}, b^{(k)}) - \mathcal{J}(x^{(k)}, b^{(k)}) \to 0$ as $k \to \infty$, and hence we have the conclusion. □

2.2. Convergence analysis. We will assume that in addition to (2.1),

$$\phi \text{ is } \mathcal{C}^2 \text{ on } \mathbb{R} \text{ and } \mathcal{C}^3 \text{ near zero.} \tag{2.14}$$

REMARK 5. ϕ (2.1) (2.14) σ (2.5) $\mathcal{C}^1$ $\mathbb{R}$ $\sigma'(0) = 0$ $t \in \mathbb{R} \setminus \{0\}$

$$\sigma'(t) = \frac{\phi''(t)t - \phi'(t)}{t^2} \tag{2.15}$$

$t \to 0$

$$\lim_{t\to 0} \sigma'(t) = \lim_{t\to 0} \frac{\frac{d}{dt}\left(\phi''(t)t - \phi'(t)\right)}{\frac{d}{dt}\left(t^2\right)} = \lim_{t\to 0} \frac{\phi'''(t)}{2} = 0.$$

Notice that $\phi'''(0) = 0$ because ϕ is even and $\mathcal{C}^3$ near zero.

THEOREM 2.3. J (1.2)–(1.3) (1.4) (1.10) ϕ (2.1) (2.14) $\{(x^{(k)}, b^{(k)})\}$ (1.16) σ χ (2.5) (2.7)–(2.8)

(i) $k \in \mathbb{N}$

$$x^{(k)} = F(x^{(k-1)}), \tag{2.16}$$

$F : \mathbb{R}^p \to \mathbb{R}^p$ $\mathcal{C}^1$ $B(0,\delta)$ $\delta \in (0,\infty)$

$$F(x) = x - (\mathcal{H}(x))^{-1} DJ(x), \tag{2.17}$$

$$\mathcal{H}(x) = 2A^TA + \beta G^T \operatorname{diag}\left(\left[\sigma(g_i^T x)\right]_{i=1}^r\right) G \succ 0, \tag{2.18}$$

DJ J (1.2)–(1.3).

(ii) $k \to \infty$ $\{x^{(k)}\}$ $\hat{x}$ J.

(iii) DF $\hat{x}$

$$\rho\left(DF(\hat{x})\right) \le K \max_{1\le i\le r} \mathcal{R}(|g_i^T\hat{x}|) \le K \sup_{0\le t\le \mu} \mathcal{R}(t) < 1, \tag{2.19}$$

$\mu = \max_{1\le i\le r} |g_i^T\hat{x}|$ $K \in [0,1]$ $\mathcal{R} : \mathbb{R}_+ \to [0,1]$

$$K = \frac{\beta\phi''(0)\left\|\!\left|G\right|\!\right\|^2}{2\nu^2 + \beta\phi''(0)\left\|\!\left|G\right|\!\right\|^2}, \tag{2.20}$$

$$\mathcal{R}(t) = 1 - \frac{\phi''(t)}{\sigma(t)}. \tag{2.21}$$

The shape of $\mathcal{R}$ for different functions ϕ can be seen in Table 4.2 and Figures 4.1 and 4.2. Notice that $\mathcal{R}$ is monotone increasing provided that ϕ'' is monotone decreasing on $\mathbb{R}_+$ and that the latter is true for all potential functions cited in (1.6)–(1.9).

. Let $\delta > 0$ be the radius exhibited in Remark 4 and let ζ be defined as in (2.11). The first step of iteration k is to calculate

$$b_i^{(k)} = \sigma(g_i^T x^{(k-1)}) \quad \forall i \in \{1,\dots,r\}. \tag{2.22}$$

Noticing that $b^{(k)}$ satisfies (2.13), the matrix $H(b^{(k)})$ defined by (2.7) is invertible (cf. Lemma 2.1). The second step of iteration k is to calculate $x^{(k)}$ using (2.8):

$$x^{(k)} = \left(H(b^{(k)})\right)^{-1} 2A^T y = \left(2A^T A + \beta G^T \mathrm{diag}(b^{(k)}) G\right)^{-1} 2A^T y. \tag{2.23}$$

Introducing (2.22) into (2.23) yields

$$x^{(k)} = F(x^{(k-1)}),$$

where $F : \mathbb{R}^p \to \mathbb{R}^p$ reads

$$F(x) = (\mathcal{H}(x))^{-1} 2A^T y, \tag{2.24}$$

and $\mathcal{H}$ is as given in (2.18). From (1.2)–(1.3),

$$DJ(x) = 2A^T Ax + \beta G^T \left[\phi'(g_i^T x)\right]_{i=1}^r - 2A^T y. \tag{2.25}$$

By (2.5), for every $i \in \{1, \ldots, r\}$ we can write

$$\phi'(g_i^T x) = \sigma(g_i^T x)\, g_i^T x.$$

Then (2.25) yields

$$\begin{aligned} 2A^T y &= 2A^T Ax + \beta G^T \mathrm{diag}\left(\left[\sigma(g_i^T x)\right]_{i=1}^r\right) Gx - DJ(x) \\ &= \mathcal{H}(x)\, x - DJ(x). \end{aligned}$$

Inserting this expression into (2.24) yields (2.17).

Let us fix $\delta > 0$ arbitrarily. Then define ζ according to (2.11). Based on Lemma 2.1, $b \to (H(b))^{-1}$ is $\mathcal{C}^1$ on $[\zeta, \phi''(0)\,]^r$ since $b \to H(b)$ is $\mathcal{C}^\infty$ and

$$D(H(b))^{-1} = -(H(b))^{-1} DH(b) (H(b))^{-1}$$

is continuous. Using (2.12) we have $[\sigma(g_i^T x)]_{i=1}^r \in [\zeta, \phi''(0)\,]^r$ for all $x \in B(0, \delta)$ and, since σ is $\mathcal{C}^1$ on $\mathbb{R}$ (see Remark 5), it follows that

$$x \to (\mathcal{H}(x))^{-1} = \left(H\left([\sigma(g_i^T x)]_{i=1}^r\right)\right)^{-1}$$

is $\mathcal{C}^1$ on $B(0, \delta)$. Combining the latter with the fact that J is $\mathcal{C}^2$ shows that F is $\mathcal{C}^1$ on $B(0, \delta)$. The proof of (i) is complete.

By Lemma 2.2, the sequence $\{x^{(k)}\}$ converges; let $\hat{x}$ denote its limit as $k \to \infty$. Since F is continuous, considering (2.16) for $k \to \infty$ yields

$$\hat{x} = F(\hat{x}). \tag{2.26}$$

Introducing this into (2.17) shows that $(\mathcal{H}(\hat{x}))^{-1} DJ(\hat{x}) = 0$ and consequently that $DJ(\hat{x}) = 0$. Since J has a unique minimizer (cf. Remark 1), it follows that J reaches its minimum at $\hat{x}$. Hence we prove (ii).

Next, we determine DF at an arbitrary x. Using (2.24),

$$\mathcal{H}(x) F(x) = 2A^T y \quad \forall x \in B(0, \delta).$$

Differentiating both sides of this equation with respect to x yields

$$D\mathcal{H}(x)F(x) + \mathcal{H}(x)DF(x) = 0 \quad \forall x \in B(0,\delta). \tag{2.27}$$

Then $DF(x) = -(\mathcal{H}(x))^{-1} D\mathcal{H}(x)F(x)$, where

$$\begin{aligned} D\mathcal{H}(x)F(x) &= \lim_{\epsilon\to 0} \frac{\mathcal{H}(x+\epsilon F(x)) - \mathcal{H}(x)}{\epsilon} = \beta G^T \mathrm{diag}\left(\left[\sigma'(g_i^T x)\; g_i^T F(x)\right]_{i=1}^r\right) G \\ &= -\beta G^T \mathrm{diag}\left(\left[\,\left|\sigma'(g_i^T x)\; g_i^T x\right|\,\right]_{i=1}^r\right) G \\ &\quad -\beta G^T \mathrm{diag}\left(\left[\sigma'(g_i^T x)\; g_i^T (x - F(x))\right]_{i=1}^r\right) G, \end{aligned}$$

where we use the fact that $\sigma'(t)t \le 0$ for all $t \in \mathbb{R}$. It follows that

$$DF(x) = M(x) + E(x), \tag{2.28}$$

where

$$M(x) = (\mathcal{H}(x))^{-1}\, \beta G^T \mathrm{diag}\left(\left[\;\left|\;\sigma'(g_i^T x)\; g_i^T x\;\right|\;\right]_{i=1}^r\right) G, \tag{2.29}$$

$$E(x) = (\mathcal{H}(x))^{-1}\, \beta G^T \mathrm{diag}\left(\left[\sigma'(g_i^T x)\; g_i^T\, (x - F(x))\right]_{i=1}^r\right) G. \tag{2.30}$$

The eigenvalues of $M(x)$, for $x \in \mathbb{R}^p$, are considered next.

LEMMA 2.4. [illegible] 2.3 [illegible] $M : \mathbb{R}^p \to \mathbb{R}^{p\times p}$ [illegible] (2.29) [illegible]

$$\rho(M(x)) \le K \max_{1\le i\le r} \mathcal{R}(|g_i^T x|) \quad \forall x \in \mathbb{R}^p, \tag{2.31}$$

[illegible] K [illegible] $\mathcal{R}$ [illegible] (2.20) [illegible] (2.21) [illegible]

2.4. Let us first focus on the function $\mathcal{R}$ defined in (2.21). Clearly, $\mathcal{R}(t) \le 1$ for all $t \in \mathbb{R}_+$ since $\phi''(t) \ge 0$ and $\sigma(t) > 0$ for all $t \in \mathbb{R}$. Using (2.5), (2.6), and (2.15), for any $t \ge 0$ we can write

$$\mathcal{R}(t) = \frac{1}{\sigma(t)}\left(\frac{\phi'(t)}{t} - \phi''(t)\right) = \frac{-\sigma'(t)\, t}{\sigma(t)}, \tag{2.32}$$

where in particular $\mathcal{R}(0) = 0$. For all $t \in \mathbb{R}_+$, Remark 3 condition 1 says that $\sigma'(t) \le 0$, and hence $\mathcal{R}(t) \ge 0$. This allows us to write down that

$$\mathcal{R}(|t|) = \frac{|\sigma'(t)t|}{\sigma(t)} \quad \forall t \in \mathbb{R}. \tag{2.33}$$

Given $x \in \mathbb{R}^p$, let $\lambda \in \mathbb{C}$ be the largest-in-magnitude eigenvector of $M(x)$. Let $u \in \mathbb{C}^p$ be such that $\|u\| = 1$ and $M(x)\; u = \lambda\; u$. Using the expression for M, we obtain

$$\beta(Gu)^T \mathrm{diag}\left(\left[\;\left|\sigma'(g_i^T x)\; g_i^T x\right|\;\right]_{i=1}^r\right) Gu = \lambda\; u^T\; \mathcal{H}(x)\; u \ge 0. \tag{2.34}$$

The last inequality comes from the fact that $G^T \mathrm{diag}\left(\left[\;\left|\sigma'(g_i^T x)\; g_i^T x\right|\;\right]_{i=1}^r\right) G$ is semi-positive definite and that $\mathcal{H}(x)$ is positive definite. It implies that λ is real with $\lambda \ge 0$

and that $u \in S$. If $\lambda = 0$, then (2.31) is satisfied. In the following, consider that $\lambda > 0$. Inserting (2.18) into (2.34) yields

$$\beta(Gu)^T \operatorname{diag}\Big(\big[\ |\sigma'(g_i^T x)\ g_i^T x| - \lambda\sigma(g_i^T x)\ \big]_{i=1}^r \Big)\, Gu = 2\lambda\|Au\|^2 \geq 2\lambda\nu^2 \geq 0.$$

Using (2.33), this is equivalent to

$$\beta \sum_{i=1}^r \sigma(g_i^T x)\left(\mathcal{R}(g_i^T x) - \lambda\right)\ \left(g_i^T u\right)^2 = 2\lambda\|Au\|^2 \geq 2\lambda\nu^2 \geq 0. \tag{2.35}$$

Let $j \in \{1, \ldots, r\}$ be such that

$$\sigma(g_j^T x)\left(\mathcal{R}(g_j^T x) - \lambda\right) \geq \sigma(g_i^T x)\left(\mathcal{R}(g_i^T x) - \lambda\right) \quad \forall i \in \{1, \ldots, r\}.$$

From (2.35) we find that $\sigma(g_j^T x)\left(\mathcal{R}(g_j^T x) - \lambda\right) \geq 0$. Using (2.35) yet again,

$$\beta\sigma(g_j^T x)\left(\mathcal{R}(g_j^T x) - \lambda\right)\|\!|G|\!\|^2 \geq \beta\sigma(g_j^T x)\left(\mathcal{R}(g_j^T x) - \lambda\right)\|Gu\|^2 \geq 2\lambda\nu^2.$$

Since $\sigma(t) \leq \phi''(0)$ for all $t \in \mathbb{R}$ (cf. Remark 3 condition 2), we obtain

$$\mathcal{R}(|g_j^T x|) - \lambda \geq \frac{2\lambda\nu^2}{\beta\phi''(0)\,\|\!|G|\!\|^2}.$$

It follows that

$$\lambda \leq K\mathcal{R}(|g_j^T x|) \leq K \max_{1\leq i\leq r} \mathcal{R}(|g_i^T x|),$$

where $K \leq 1$ is the constant given in (2.20). □

We pursue the proof of the theorem. From (2.26) it follows that $E(\hat{x}) = 0$, and hence

$$DF(\hat{x}) = M(\hat{x}). \tag{2.36}$$

On the other hand, the function $\mathcal{R}$ is continuous on $\mathbb{R}_+$ with $\mathcal{R}(0) = 0$. The first two inequalities in (2.19) are an immediate consequence of (2.36) and Lemma 2.4. If $\phi''(t) > 0$, for all $t \in \mathbb{R}$, (2.6) and (2.21) show that $\mathcal{R}(t) < 1$, for all $t \in \mathbb{R}_+$, and hence

$$\sup_{0\leq t\leq\mu} \mathcal{R}(t) < 1,$$

since $[0, \mu]$ is compact. Thus, the assumption in (1.10) ensures that

$$K < 1 \quad \text{and/or} \quad \sup_{0\leq t\leq\mu} \mathcal{R}(t) < 1,$$

and hence (2.19). □

REMARK 6. F (2.28) DF M E $\|\!|E(x^{(k)})|\!\|$ $\|x^{(k)} - F(x^{(k)})\|$ $x^{(k)}$ $\hat{x}$ $\rho\left(DF(x^{(k)})\right) > 1$ $\|\!|E(x^{(k)}|\!\|$ M DF $\hat{x}$ (2.19) $\eta > 0$

$$\sup_{x\in B(\hat{x},\eta)} \rho\left(DF(x)\right) < 1.$$

$k_0 \in \mathbb{N}$

$$x^{(k)} \in B(\hat{x}, \eta) \quad \forall k \geq k_0.$$

F $B(\hat{x}, \eta)$ $\hat{x}$

The assumption in (2.14) that ϕ is $\mathcal{C}^3$ near zero is only technical. The proof is easy to extend to functions ϕ which are $\mathcal{C}^2$ and have $\phi''(0^+)$ finite. Even if σ is nondifferentiable at zero, its side derivatives there are then finite. Noticing that the function $t \to \sigma(t)t$ is continuous, the analysis of M in Lemma 2.4 remains unchanged. An example of a function ϕ with σ nonsmooth at zero is $\phi(t) = |t|/\alpha - \log(1 + |t|/\alpha)$ since we have $\sigma'(0^+) = \alpha = -\sigma'(0^-)$. Extending the proof to functions ϕ as discussed above would considerably complicate the presentation.

COROLLARY 2.5. 2.3 $C(F, \hat{x})$ (1.22)

$$C(F, \hat{x}) \leq K \max_{1 \leq i \leq r} \mathcal{R}(|g_i^T \hat{x}|) \leq K \sup_{0 \leq t \leq \mu} \mathcal{R}(t) < 1,$$

$||.||$ (1.22)

It is easy to check that F satisfies all conditions required in the linear convergence theorem [26, p. 301]. By the latter theorem, $C(F, \hat{x}) = \rho(DF(\hat{x}))$. The result follows from Theorem 2.3. □

3. Additive form of half-quadratic regularization.

3.1. Preliminary facts.

This form is considered under the following conditions:

$$\begin{array}{ll} \text{(a)} & \phi \text{ is convex,} \\ \text{(b)} & c > 0 \text{ is such that } t \to ct^2/2 - \phi(t) \text{ is convex,} \\ \text{(c)} & \phi(t) = \phi(-t) \quad \forall t \in \mathbb{R}, \\ \text{(d)} & \phi \text{ is continuous on } \mathbb{R}, \\ \text{(e)} & \lim_{|t| \to \infty} \phi(t)/t^2 < c/2. \end{array} \tag{3.1}$$

By (a)–(b), ϕ is differentiable.[2] The dual function ψ is given by

$$\psi(s) = \sup_{t \in R} \left\{ -\frac{1}{2} \left(t\sqrt{c} - \frac{s}{\sqrt{c}} \right)^2 + \phi(t) \right\}, \tag{3.2}$$

where $c > 0$ is as specified in (3.1). Under (3.1), ψ is convex and the requirement in (1.12) is satisfied since

$$\phi(t) = \inf_{s \in R} \left\{ \frac{1}{2} \left(t\sqrt{c} - \frac{s}{\sqrt{c}} \right)^2 + \psi(s) \right\}. \tag{3.3}$$

The connections between ϕ and ψ under different assumptions on ϕ were considered in [3, 10, 14, 19]. For completeness, these are sketched in section 7.2 in the appendix.

[2] By (a), $\phi'(t^-) \leq \phi'(t^+)$ for all t. If for some t the latter inequality is strict, (b) cannot be satisfied for any c. If follows that $\phi'(t^-) = \phi'(t^+) = \phi'(t)$. For example, if we apply (3.2) to $\phi(t) = |t|$ with $c = 1$, we get $\psi(s) = |s| + 1/2$. Then (3.3) yields $\min_s \left(\psi(s) + (s-t)^2/2\right) \neq \phi(t)$.

According to (1.11) and (1.21), $\mathcal{J}$ reads

$$\begin{aligned} \mathcal{J}(x,b) &= \|Ax-y\|^2 + \beta \sum_{i=1}^{r} \left(\frac{1}{2} \left(\sqrt{c}\, g_i^T x - \frac{1}{\sqrt{c}}\, b_i \right)^2 + \psi(b_i) \right) \\ &= \|Ax-y\|^2 + \frac{\beta}{2} \left\| \sqrt{c}\, Gx - \frac{1}{\sqrt{c}}\, b \right\|^2 + \beta \sum_{i=1}^{r} \psi(b_i). \end{aligned} \tag{3.4}$$

The expression of σ for several functions ϕ is presented in Table 4.1. The minimizer function σ defined by (1.17) admits an explicit form [7, 10, 3] and its derivation is recalled in section 7.2 in the appendix:

$$\sigma(t) = ct - \phi'(t). \tag{3.5}$$

If (1.4) holds, the minimizer function χ defined by (1.18) reads

$$\chi(b) = \mathcal{H}^{-1} \left(2A^T y + \beta G^T b \right), \tag{3.6}$$

where

$$\mathcal{H} = 2A^T A + \beta c\, G^T G \succ 0 \tag{3.7}$$

is invertible thanks to (1.4).

As exhibited in [19], $\mathcal{J}$ is convex on $\mathbb{R}^p \times \mathbb{R}^r$, and hence the convergence of alternate minimization towards the minimizer $\hat{x}$ of J. Convergence when x and y are defined on a bounded domain of $\mathbb{R}^2$—in the context of image restoration—was established in [3] under appropriate assumptions on ϕ.

3.2. Convergence analysis. The analysis here is developed in a similar fashion as for the multiplicative form.

THEOREM 3.1. [illegible] J [illegible] (1.2)–(1.3) [illegible] (1.4) [illegible] (1.10) [illegible] ϕ [illegible] $\mathcal{C}^2$ [illegible] $\mathbb{R}$ [illegible] (3.1) [illegible] $\{(x^{(k)}, b^{(k)})\}$ [illegible] (1.16) [illegible] σ [illegible] χ [illegible] (3.5) [illegible] (3.6)–(3.7) [illegible]

(i) [illegible] $k \in \mathbb{N}$ [illegible]

$$x^{(k)} = F(x^{(k-1)}), \tag{3.8}$$

[illegible] $F : \mathbb{R}^p \to \mathbb{R}^p$ [illegible] $\mathcal{C}^1$ [illegible]

$$F(x) = x - \mathcal{H}^{-1} DJ(x), \tag{3.9}$$

$$\mathcal{H} = 2A^T A + \beta c G^T G \succ 0; \tag{3.10}$$

(ii) [illegible] $x \in \mathbb{R}^p$

$$\rho\left(DF(x)\right) \leq K \max_{1 \leq i \leq r} \mathcal{R}(|g_i^T x|) \leq K \sup_{0 \leq t \leq \mu} \mathcal{R}(t) < 1, \tag{3.11}$$

[illegible] $\mu = \max_{1 \leq i \leq r} |g_i^T x|$ $K \in [0,1]$ [illegible] $\mathcal{R} : \mathbb{R}_+ \to [0,1]$ [illegible]

$$K = \frac{\beta c \left\| G \right\|^2}{2\nu^2 + \beta c \left\| G \right\|^2}, \tag{3.12}$$

$$\mathcal{R}(t) = 1 - \frac{\phi''(t)}{c}; \tag{3.13}$$

(iii) [illegible] $k \to \infty$ $\{x^{(k)}\}$ [illegible] $\hat{x}$ [illegible] J

The function $\mathcal{R}$ for several potential functions ϕ is presented in Table 4.2 and Figures 4.1 and 4.2. For all potential functions cited in (1.6)–(1.9), ϕ'' is monotone decreasing on $\mathbb{R}_+$, and hence $\mathcal{R}$ is monotone increasing on $\mathbb{R}_+$.

[illegible] Given $x^{(k-1)}$, iterate $b^{(k)}$ is calculated using (3.5):

$$b^{(k)} = \left[\sigma(g_i^T x^{(k-1)})\right]_{i=1}^r = cGx^{(k-1)} - \left[\phi'(g_i^T x^{(k-1)})\right]_{i=1}^r. \tag{3.14}$$

Next, $x^{(k)}$ is calculated using (3.6)–(3.7):

$$x^{(k)} = \mathcal{H}^{-1}(2A^T y + \beta G^T b^{(k)}).$$

Inserting (3.14) into the expression given above yields

$$x^{(k)} = F(x^{(k-1)}), \tag{3.15}$$

where $F : \mathbb{R}^p \to \mathbb{R}^p$ reads

$$F(x) = \mathcal{H}^{-1}\left(2A^T y + \beta c G^T G x - \beta G^T \left[\phi'(g_i^T x)\right]_{i=1}^r\right). \tag{3.16}$$

The expression for DJ given in (2.25) yields

$$\begin{aligned} 2A^T y &= 2A^T A x + \beta G^T \left[\phi'(g_i^T x)\right]_{i=1}^r - DJ(x) \\ &= \mathcal{H}x - \beta c G^T G x + \beta G^T \left[\phi'(g_i^T x)\right]_{i=1}^r - DJ(x). \end{aligned}$$

Introducing this into (3.16) leads to $F(x) = \mathcal{H}^{-1}\left(\mathcal{H}x - DJ(x)\right)$, and hence to (3.9). Since J is $\mathcal{C}^2$, it is straightforward that F is $\mathcal{C}^1$ on $\mathbb{R}^p$. The proof of (i) is complete.

The differential of F at an arbitrary $x \in \mathbb{R}^p$ reads

$$\begin{aligned} DF(x) &= I - \mathcal{H}^{-1}\left(2A^T A + \beta G^T \operatorname{diag}\left(\left[\phi''(g_i^T x)\right]_{i=1}^r\right) G\right) \\ &= \beta c \mathcal{H}^{-1} G^T \operatorname{diag}\left(\left[\mathcal{R}(g_i^T x)\right]_{i=1}^r\right) G, \end{aligned} \tag{3.17}$$

where $\mathcal{R}$ was introduced in (3.13). The eigenvalues of $DF(x)$, for any $x \in \mathbb{R}^p$, are analyzed below.

LEMMA 3.2. [illegible] 3.1 [illegible]

$$\rho(DF(x)) \le K \max_{1 \le i \le r} \mathcal{R}(|g_i^T x|) \quad \forall x \in \mathbb{R}^p, \tag{3.18}$$

[illegible] K [illegible] $\mathcal{R}$ [illegible] (3.12) [illegible] (3.13) [illegible]

3.2. Consider first the function $\mathcal{R}$ introduced in (3.13). Since ϕ is $\mathcal{C}^2$, the constant c in (3.1)(b) satisfies

$$\phi''(t) \le c \quad \forall t \in \mathbb{R}, \tag{3.19}$$

and hence $0 \le \mathcal{R}(t) \le 1$ for all $t \in \mathbb{R}$.

For $x \in \mathbb{R}^p$, let $\lambda \in \mathbb{C}$ be the largest-in-magnitude eigenvector of $DF(x)$. Let $u \in \mathbb{C}^p$ be such that $\|u\| = 1$ and $DF(x)u = \lambda u$. Then using (3.17) we get

$$\beta c (Gu)^T \operatorname{diag}\left(\left[\mathcal{R}(g_i^T x)\right]_{i=1}^r\right) Gu = \lambda u^T \mathcal{H} u \ge 0. \tag{3.20}$$

The last inequality above comes from the facts that $\mathcal{H}$ is positive definite and that $G^T \operatorname{diag}\left(\left[\mathcal{R}(g_i^T x)\right]_{i=1}^r\right) G$ is semipositive definite. It shows that $\lambda \geq 0$ and that $u \in S$. If $\lambda = 0$, then (3.18) is satisfied. In the following we consider that $\lambda > 0$. Introducing (3.10) into (3.20) yields

$$\beta c \sum_{i=1}^{r} \left(\mathcal{R}(g_i^T x) - \lambda\right) \left(g_i^T u\right)^2 = 2\lambda \|Au\|^2 \geq 2\lambda \nu^2 \geq 0. \tag{3.21}$$

Let $j \in \{1, \ldots, r\}$ be such that

$$\mathcal{R}(g_j^T x) - \lambda \geq \mathcal{R}(g_i^T x) - \lambda \quad \forall i \in \{1, \ldots, r\}.$$

Then (3.21) shows that $\mathcal{R}(g_j^T x) - \lambda \geq 0$ and we can write down that

$$\beta c \left(\mathcal{R}(g_j^T x) - \lambda\right) \|\!|G|\!\|^2 \geq \beta c \left(\mathcal{R}(g_j^T x) - \lambda\right) \|Gu\|^2 \geq 2\lambda \|Au\|^2 \geq 2\lambda \nu^2.$$

It follows that

$$\lambda \leq \frac{\beta c \|\!|G|\!\|^2}{2\nu^2 + \beta c \|\!|G|\!\|^2} \mathcal{R}(|g_j^T x|) \leq K \max_{1 \leq i \leq r} \mathcal{R}(|g_i^T x|).$$

The lemma is proved. □

We pursue the proof of the theorem. If $\phi''(t) > 0$ for all $t \in \mathbb{R}$, noticing that $\mathcal{R}$ is continuous on $\mathbb{R}$ and that $[0, \mu]$ is compact, (3.13) and (3.19) show that $\sup_{0 \leq t \leq \mu} \mathcal{R}(t) < 1$. By the assumption given in (1.10) we have

$$K < 1 \quad \text{and/or} \quad \sup_{0 \leq t \leq \mu} \mathcal{R}(t) < 1.$$

Combining this with Lemma 3.2 proves (ii).

Let $\delta \in (0, \infty)$ be the radius exhibited in Remark 4. Define $\eta = \delta \|\!|G|\!\|$; then

$$|g_i^T x| \leq \eta \quad \forall i \in \{1, \ldots, r\}, \ \forall x \in B(0, \delta).$$

Using Lemma 3.2 yet again,

$$\sup_{x \in B(0,\delta)} \rho(DF(x)) \leq K \sup_{x \in B(0,\delta)} \max_{1 \leq i \leq r} \mathcal{R}(|g_i^T x|) \leq K \sup_{0 \leq t \leq \eta} \mathcal{R}(t) < 1. \tag{3.22}$$

It follows that the sequence $\{x^{(k)}\}$ converges; let $\lim_{k \to \infty} x^{(k)} = \hat{x}$. Since F is continuous, letting $k \to \infty$ in (3.8) shows that $\hat{x} = F(\hat{x})$. Introducing the latter result into (3.9) shows that $DJ(\hat{x}) = 0$. Since J has a unique minimizer (Remark 1), it follows that J reaches its minimum at $\hat{x}$. Hence we prove (iii). □

COROLLARY 3.3. [illegible] 3.1 [illegible] $C(F, \hat{x})$ [illegible] (1.22) [illegible]

$$C(F, \hat{x}) \leq K \max_{1 \leq i \leq r} \mathcal{R}(|g_i^T \hat{x}|) \leq K \sup_{0 \leq t \leq \mu} \mathcal{R}(t) < 1,$$

[illegible] $\|.\|$ [illegible] (1.22)

[illegible]. It is easy to see that the linear convergence theorem [26] can be applied, which shows that $C(F, \hat{x}) = \rho(DF(\hat{x}))$. The result follows from Theorem 3.1. □

REMARK 7 (the optimal value of c). (3.19) $c \geq \sup_{t\in\mathbb{R}} \phi''(t)$ ψ (3.2) (3.12) (3.13) K $\mathcal{R}(t)$ $t \in \mathbb{R}$ c c c

$$c = \sup_{t\in\mathbb{R}} \phi''(t). \tag{3.23}$$

Noticing that edge-preserving functions ϕ satisfy $\phi''(0) = \sup_{t\in\mathbb{R}} \phi''(t)$, (3.23) becomes

$$c = \phi''(0). \tag{3.24}$$

This recommendation is corroborated by the experiments in section 5.

3.3. Fast additive form based on nonsmooth dual function. We now concentrate on the Huber potential function ϕ:

$$\phi(t) = \begin{cases} \frac{1}{2}t^2 & \text{if} \quad |t| \leq \alpha, \\ \alpha|t| - \frac{1}{2}\alpha^2 & \text{if} \quad |t| > \alpha. \end{cases} \tag{3.25}$$

This potential function is edge preserving, since it is affine beyond α. Unlike total variation regularization $\phi(t) = |t|$ which yields a stair-casing effect, the quadratic part of ϕ in (3.25) near 0 allows smoothly varying regions in $\hat{x}$ to be restored [25]. Homogeneous regions in $\hat{x}$ correspond with $|g_i^T \hat{x}| \leq \alpha$ while edges correspond with $|g_i^T \hat{x}| > \alpha$.

REMARK 8. $A^T A$ $y \in \mathbb{R}^q$ J $\hat{x}$ $D^2 J$ $\hat{x}$ J $A^T A$ ϕ'' $-\alpha$ α $A^T A$ $y \in \mathbb{R}^q$ $\hat{x}$ $|g_i^T \hat{x}| = \alpha$ i $\mathbb{R}^q$ y J $\mathcal{C}^\infty$ $\hat{x}$ $A^T A$

From (3.25) we have $\max_{t\in\mathbb{R}}\{\phi''(t^-), \phi''(t^+)\} = 1$. For $c > 1$, the dual ψ reads

$$\psi(s) = \begin{cases} \dfrac{s^2}{(2c(c-1))} & \text{if} \quad |s| \leq (c-1)\alpha, \\ \dfrac{\alpha|s|}{c - \alpha^2(c-1)/(2c)} & \text{if} \quad |s| > (c-1)\alpha. \end{cases}$$

Previous papers [7, 19] recommend taking $c > 1$ in order to ensure that ψ is $\mathcal{C}^1$. Using (3.5), the minimizer function σ is

$$\sigma(t) = \begin{cases} (c-1)t & \text{if} \quad |t| \leq \alpha, \\ ct - \alpha \operatorname{sign}(t) & \text{if} \quad |t| > \alpha. \end{cases} \tag{3.26}$$

Instead, for $c = 1$, we get

$$\psi(s) = \alpha|s|. \tag{3.27}$$

It is easy to check[3] that applying (3.3) leads to ϕ as given in (3.25). The function σ now takes a particularly simple form:

$$\sigma(t) = \begin{cases} 0 & \text{if} \quad |t| \le \alpha, \\ t - \alpha \ \text{sign}(t) & \text{if} \quad |t| > \alpha. \end{cases} \tag{3.28}$$

The computation of each $b_i^{(k)} = \sigma(g_i^T x^{(k)})$ using (3.28) is much easier than using (3.26). Typically we have $|g_i^T x^{(k)}| \le \alpha$ for most of the indexes $i \in \{1, \dots, r\}$ since most of the pixels are in homogeneous regions. The relevant $b_i^{(k)}$ are set to zero after verifying that $|g_i^T x^{(k)}| \le \alpha$: thus, they need no calculation.

The augmented cost-function $\mathcal{J}$ now reads

$$\mathcal{J}(x, s) = \|Ax - y\|^2 + \beta \sum_{i=1}^{r} \left(\frac{1}{2}(g_i^T x - s_i)^2 + |s_i| \right). \tag{3.29}$$

The convergence of alternate minimization is easily deduced from Theorem 1.4, p. 73 in [16]. Furthermore, Theorem 3.1 can be extended to potential functions ϕ which satisfy (3.1) and which at several points α_i have $\phi''(\alpha_i^-)$ and $\phi''(\alpha_i^+)$ different but finite. Instead of DF, the subdifferential of F must be considered in (3.17). The inequalities presented in the proof of Theorem 3.1 remain basically the same.

4. Theoretical comparisons of two forms.

The expressions for σ and $\mathcal{R}$ for both forms are displayed in Tables 4.1 and 4.2.

4.1. Extension to alternative regularization terms. In some image processing applications, the regularization term Φ in (1.2) reads [2]

$$\Phi(x) = \sum_{i=1}^{p} \phi(\|G_i x\|), \tag{4.1}$$

where every $G_i x$ is a vector approximating the gradient of x at pixel i. We wish to know whether the resultant J can be minimized using HQ regularization methods. According to (1.11)–(1.12), an auxiliary variable b_i is associated with each $\|G_i x\|$.

- In the multiplicative form of HQ regularization, the augmented cost-function $\mathcal{J}$ is similar to (2.4):

$$\mathcal{J}(x, b) = \|Ax - y\|^2 + \beta \sum_{i=1}^{p} \left(\frac{b_i}{2} \ \|G_i x\|^2 + \psi(b_i) \right).$$

  Notice that $\mathcal{J}(x, .)$ is separable and the minimization over b is given by p scalar minimizer functions σ of the form (2.5). Since the function $\mathcal{J}(., b)$ is quadratic, the minimizer function χ, defined in (1.18), is linear in y and has an explicit form similar to (2.7)–(2.8). Minimization using the multiplicative form of HQ regularization is straightforward.

---

[3] Given $t \in \mathbb{R}$, define $h_t : \mathbb{R} \to \mathbb{R}$ by $h_t(s) = (s - t)^2/2 + \alpha|s|$. The function h_t reaches its minimum at $\hat{s} \in \mathbb{R}$ if and only if [18]

$$\begin{array}{lll} \hat{s} = 0 & \Rightarrow & h_t'(0^-) \le 0 \le h_t'(0^+), \quad \text{i.e.,} \quad -t - \alpha \le 0 \le -t + \alpha; \\ \hat{s} \neq 0 & \Rightarrow & h_t'(\hat{s}) = 0, \quad \text{i.e.,} \quad \hat{s} - t + \alpha \text{sign}(\hat{s}) = 0. \end{array}$$

It is easily deduced that

$$\begin{array}{lllll} |t| \le \alpha & \Rightarrow & \hat{s} = 0 & \Rightarrow & \inf_s h_t(\hat{s}) = t^2/2, \\ |t| > \alpha & \Rightarrow & \hat{s} = t - \alpha \text{sign(t)} & \Rightarrow & \inf_s h_t(\hat{s}) = \alpha|t| - \alpha^2/2. \end{array}$$

In other words, $\inf_{s \in R} \left((s - t)^2/2 + \alpha|s| \right) = \phi(t)$ where ϕ is given in (3.25).

TABLE 4.1
Minimizer function σ relevant to multiplicative and additive form of HQ regularization (cf. (2.5) and (3.5)) for different potential functions ϕ.

Potential function	Multiplicative form	Additive form
$\phi(t) = \lvert t\rvert^{\alpha}, \quad \alpha \in (1,2]$	$\sigma(t) = \alpha\lvert t\rvert^{\alpha-2}$	not applicable
$\phi(t) = \sqrt{\alpha + t^2}$	$\sigma(t) = \dfrac{1}{\sqrt{\alpha + t^2}}$	$\sigma(t) = ct - \dfrac{t}{\sqrt{\alpha + t^2}}$
$\phi(t) = \dfrac{\lvert t\rvert}{\alpha} - \log\left(1 + \dfrac{\lvert t\rvert}{\alpha}\right)$	$\sigma(t) = \dfrac{1}{\alpha(\alpha + \lvert t\rvert)}$	$\sigma(t) = ct - \dfrac{t}{\alpha(\alpha + \lvert t\rvert)}$
$\phi(t) = \begin{cases} \dfrac{t^2}{2}, & \lvert t\rvert \le \alpha \\ \alpha\lvert t\rvert - \dfrac{\alpha^2}{2}, & \lvert t\rvert > \alpha \end{cases}$	$\sigma(t) = \begin{cases} 1, & \lvert t\rvert \le \alpha \\ \dfrac{\alpha}{\lvert t\rvert}, & \lvert t\rvert > \alpha \end{cases}$	$\sigma(t) = \begin{cases} (c-1)t, & \lvert t\rvert \le \alpha \\ ct - \alpha\,\mathrm{sign(t)}, & \lvert t\rvert > \alpha \end{cases}$
$\phi(t) = \log(\cosh(\alpha t))$	$\sigma(t) = \alpha\dfrac{\tanh(\alpha t)}{t}$	$\sigma(t) = ct - \alpha\tanh(\alpha t)$

- In the additive form of HQ regularization, $\mathcal{J}$ reads

$$\mathcal{J}(x,b) = \|Ax - y\|^2 + \beta \sum_{i=1}^{p} \left(\frac{1}{2}\left(\|G_i x\| - b_i\right)^2 + \psi(b_i) \right),$$

  where for simplicity we take $c = 1$. Now the function $\mathcal{J}(.,b)$ is nonquadratic since it is nonsmooth. The minimizer function χ defined by (1.18) is nonlinear in y and is difficult to calculate numerically. There is no advantage to consider minimization using the additive form of HQ regularization when Φ is of the form (4.1).

4.2. The bound on convergence rate. The minimization of a J of the form (1.2)–(1.3) using either the multiplicative or the additive form of HQ regularization amounts to constructing a sequence of iterates $\{x^{(k)}\}$ as

$$x^{(k)} = F(x^{(k-1)}), \tag{4.2}$$

where $F : \mathbb{R}^p \to \mathbb{R}^p$ is of the form

$$F(x) = x - (\mathcal{H}(x))^{-1} DJ(x).$$

The matrix $\mathcal{H}(x)$ here provides a correction of the steepest descent direction $-DJ(x)$. Recall that the classical Newton method corresponds to $\mathcal{H}(x) = D^2J(x)$, where

$$D^2J(x) = 2A^TA + \beta G^T \mathrm{diag}\left(\left[\phi''(g_i^T x)\right]_{i=1}^{r} \right) G. \tag{4.3}$$

In the multiplicative form, the matrix $\mathcal{H}(x)$ given in (2.18) differs from $D^2J(x)$ only in that the entries of the diagonal matrix above are $\sigma(g_i^T x) = \phi'(g_i^T x)/g_i^T x$. Since $\sigma(t) \approx \phi''(t)$ if $t \approx 0$, the entries relevant to small differences $|g_i^T x|$ are almost the

same for $\mathcal{H}$ and for D^2J. For $|g_i^T x|$ large, $\phi''(g_i^T x) \approx 0$ because ϕ is edge preserving; such entries heavily deteriorate the conditioning of D^2J. On the other hand, (2.21) shows that $\sigma(t) > \phi''(t)$ if $t \neq 0$. In fact, $\sigma(g_i^T x)$ remains larger than $\phi''(g_i^T x)$ for large differences $|g_i^T x|$, thus preventing $\mathcal{H}(x)$ from being as ill-conditioned as $D^2J(x)$.

In the additive form, $\mathcal{H}$ is constant for all x; cf. (3.10). If we choose $c = \phi''(0)$, as recommended in (3.24), then $\mathcal{H} \approx D^2J(\mathbb{1})$. Here again, the entries of the diagonal matrix in (4.3) relevant to small differences $|g_i^T x| \approx 0$ are the same for D^2J and $\mathcal{H}$.

The calculation of $x^{(k)}$, as given by (4.2), can also be put into the form

$$x^{(k)} = F^k(x^{(0)}), \quad \text{where} \quad F^k = \underbrace{F \circ \cdots \circ F}_{k \text{ times}}.$$

In the multiplicative form of HQ regularization, F is not necessarily a contraction except in the vicinity of the minimizer $\hat{x}$—see Remark 6. We can expect that in early iterations the decrease of J is relatively slow. In the additive form of HQ regularization, Theorem 3.1 and Lemma 3.2 show that F is a contraction.

By (2.19) and (3.11), the convergence rate relevant to the multiplicative and the additive forms of HQ regularization is upper bounded by a term of the form

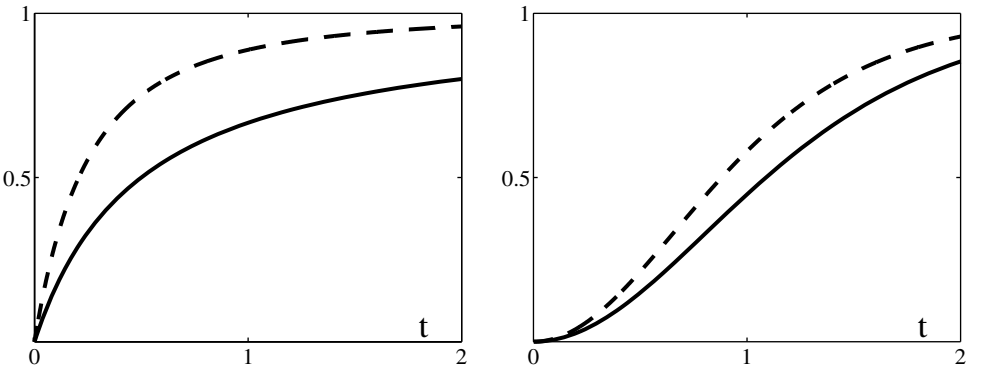
$$K \sup_{|t| \leq \mu} \mathcal{R}(t). \tag{4.4}$$

If in the additive form we choose $c = \phi''(0)$, as recommended in (3.24), then the constant K is the same for both forms; cf. (2.20) and (3.12). We notice that K decreases when ν^2 increases, which means that convergence is faster if $A^T A$ is well-conditioned. For $A^T A$ singular, $K = 1$. Furthermore, comparing (2.21) and (3.13) shows that the function $\mathcal{R}$ has a similar expression for both the multiplicative and the additive forms of HQ regularization. Moreover, for all edge-preserving functions ϕ used in practice $\mathcal{R}$ is monotone increasing on $\mathbb{R}_+$ since ϕ'' is monotone decreasing on $\mathbb{R}_+$. In the multiplicative form, using that $\mathcal{R}(t) \geq 0$ for all $t \in \mathbb{R}_+$ and Remark 3, we find that

$$\phi''(t) \leq \sigma(t) \leq \phi''(0) \quad \forall t \in \mathbb{R}.$$

These inequalities are strict in the usual situation when $t \to \phi(\sqrt{t})$ is strictly concave and $\phi''(t) > 0$ for all $t \in \mathbb{R}$. In such a case, (2.21) and (3.13) lead to

$$\underset{\text{multipl. form}}{\mathcal{R}(t)} < \underset{\text{additive form}}{\mathcal{R}(t)} \qquad \forall t \in \mathbb{R} \setminus \{0\},$$



with $\mathcal{R}(0) = 0$ for both forms. Table 4.2 and Figures 4.1 and 4.2 illustrate this result. This suggests that the multiplicative form needs fewer iterations than the additive form in order to reach the minimizer $\hat{x}$. This is corroborated by the experiments presented in section 5. In Figure 4.2, we show $\mathcal{R}$ corresponding to $\phi(t) = \sqrt{\alpha + t^2}$, for $\alpha = 0.5$ and $\alpha = 0.05$. It is worth noticing that for both forms, $\mathcal{R}$ decreases when α increases, hence convergence is faster if α is larger. The constant $\mu \in (0, \infty)$ in (4.4) is determined essentially by the magnitude of the differences $|g_i^T x|$. Since $\mathcal{R}$ is monotone increasing on $\mathbb{R}_+$, convergence is slower if $\hat{x}$ involves large differences.

4.3. Computational cost. In both the multiplicative and the additive forms of HQ regularization, the calculation of $b^{(k)}$ has basically the same complexity. In the multiplicative form, the new iterate $x^{(k)}$ is the solution of a linear system

$$\mathcal{H}(b^{(k)})x = 2A^T y, \tag{4.5}$$

TABLE 4.2
The convergence factor $\mathcal{R}$ for multiplicative and additive HQ regularization; cf. (2.21) *and* (3.13).

Potential function	$\mathcal{R}$ for the multiplicative form	$\mathcal{R}$ for the additive form
$\phi(t) = \sqrt{\alpha + t^2}$	$\dfrac{t^2}{\alpha + t^2}$	$1 - \dfrac{\alpha}{c(\alpha + t^2)\sqrt{\alpha + t^2}}$
$\phi(t) = \lvert t\rvert/\alpha - \log(1 + \lvert t\rvert/\alpha)$	$\dfrac{t}{\alpha + t}$	$1 - \dfrac{1}{c(\alpha + t)^2}$
$\phi(t) = \begin{cases} \dfrac{t^2}{2}, & \lvert t\rvert \le \alpha \\ \alpha\lvert t\rvert - \dfrac{\alpha^2}{2}, & \lvert t\rvert > \alpha \end{cases}$	$\begin{cases} 0, & t \le \alpha \\ 1, & t > \alpha \end{cases}$	$\begin{cases} 1 - \dfrac{1}{c}, & t \le \alpha \\ 1, & t > \alpha \end{cases}$
$\phi(t) = \log(\cosh(\alpha t))$	$1 - \dfrac{\alpha t}{\sinh(\alpha t)\cosh(\alpha t)}$	$1 - \dfrac{\alpha^2(1 - \tanh^2(\alpha t))}{c}$

$\phi(t) = \dfrac{|t|}{\alpha} - \log\left(1 + \dfrac{|t|}{\alpha}\right)$, $\alpha = 0.5$. $\phi(t) = \log(\cosh(\alpha t))$ for $\alpha = 1$.

FIG. 4.1. *The shape of $\mathcal{R}$ for multiplicative (solid lines) and for additive (dotted lines) form of HQ regularization corresponding to different functions ϕ. In the additive form, $c = \phi''(0)$.*

where $\mathcal{H}(b^{(k)})$ is given in (2.7). We note that the matrix $\mathcal{H}(b^{(k)})$ is changing, but the right-hand side is fixed at each iteration. This system must be solved at each iteration. When p is small, (4.5) can be solved using Gaussian elimination. The complexity is then $O(p^3)$. In signal and image deblurring, A is a Toeplitz matrix. However, $\mathcal{H}(b^{(k)})$ is not necessarily Toeplitz: no benefit can be made from the special structure of A. When p is large, the conjugate gradient method can be used to solve (4.5). Although invertible, the matrix $\mathcal{H}(b^{(k)})$ can be ill-conditioned and/or there are a number of clusters in the small eigenvalues of the Hessian matrix. Solving (4.5) then needs a large number of iterations.

In the additive form, $x^{(k)}$ is the solution of

$$\mathcal{H}\, x = 2A^T y + \beta G^T b^{(k)}, \tag{4.6}$$

where $\mathcal{H}$ is given in (3.7). Now $\mathcal{H}$ is fixed, but the right-hand side is changing at each iteration. If p is small, we can compute $\mathcal{H}^{-1}$ before starting iterations and

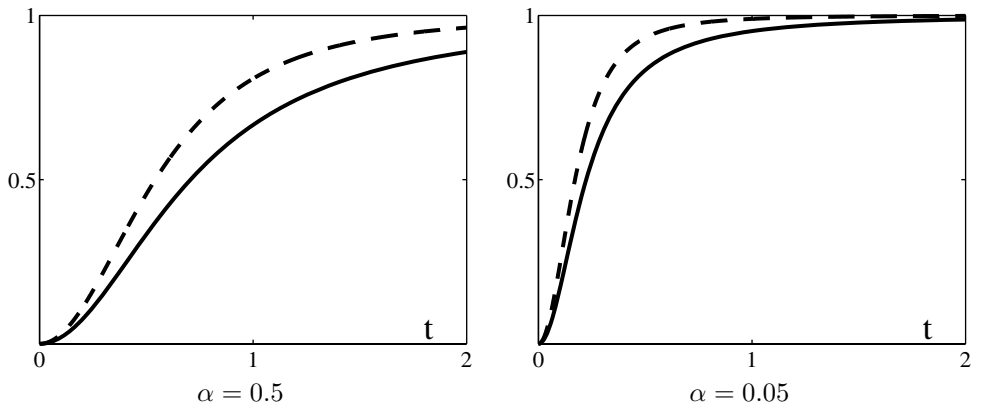


FIG. 4.2. *The shape of $\mathcal{R}$ as a function of α for $\phi(t) = \sqrt{\alpha + t^2}$. Multiplicative form (solid lines) and additive form (dotted lines) for $c = \phi''(0)$.*

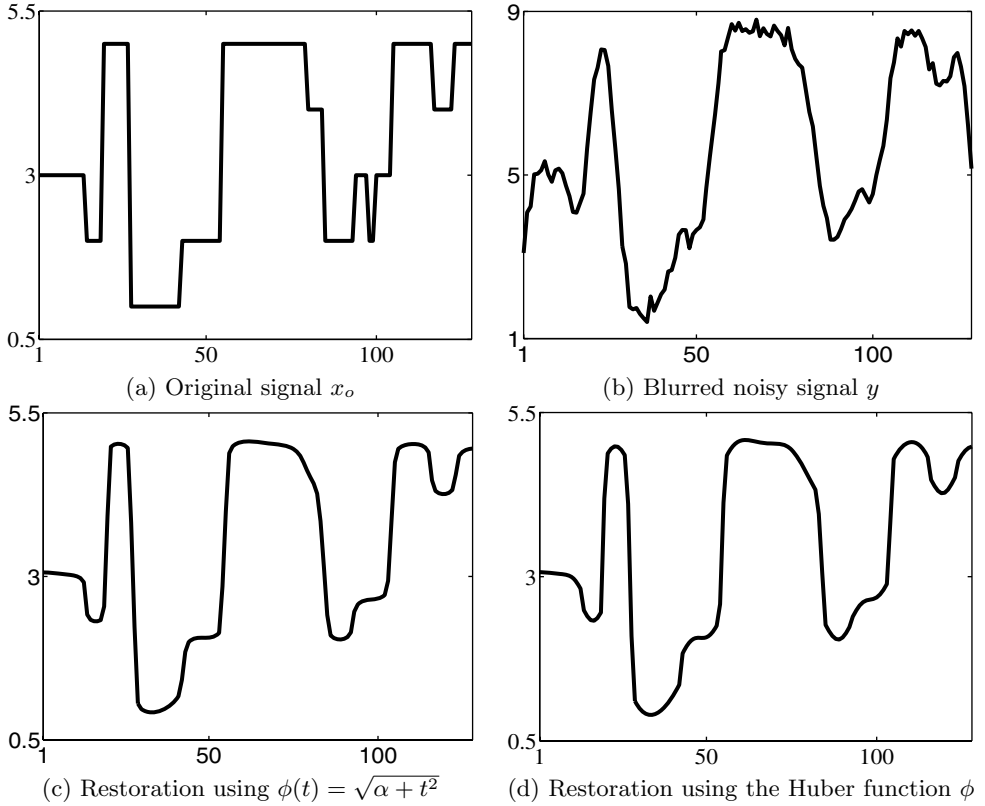
then, at each iteration, $x^{(k)} = \mathcal{H}^{-1}\left(2A^T y + \beta G^T b^{(k)}\right)$. A stable way to solve (4.6) is to first compute the Cholesky factorization of $\mathcal{H}$ and then solve the corresponding triangular systems at each iteration. The factorization requires $O(p^3)$ operations, but the complexity of solving a triangular system is only $O(p^2)$. Observe that if A is a Toeplitz matrix, $\mathcal{H}$ is a Toeplitz-like matrix [20, 6] as well. We note that $A^T A$ is a Toeplitz-like matrix and G is the discretization matrix of the first-order or the second-order differential operator. There are many direct or iterative Toeplitz solvers with costs ranging from $O(p \log p)$ to $O(p^2)$ [20, 6]. When p is large, the conjugate gradient method can be used to solve (4.6) at each iteration. Convergence can be improved using preconditioning techniques. When A is a Toeplitz-type or block-Toeplitz-Toeplitz-block-type matrix, transform-based preconditioning techniques have been proven to be very successful [24]. For example, if A is a blurring matrix generated by a symmetric point spread function, $\mathcal{H}$ can be diagonalized by a fast transform matrix; then (4.6) is solved by using three fast transforms in $O(p \log p)$ operations [24].

In conclusion, the computational cost of each iteration for the additive form of HQ regularization is smaller than for the multiplicative form. Moreover, it can substantially be improved using fast solvers and preconditioning.



5. Numerical results.

5.1. One-dimensional signal. Our goals are first to compare the convergence properties of the two forms of HQ regularization and second to compare them with standard minimization methods. All the computations are done in MATLAB 6.0. The MATLAB optimization routines are compared with our written MATLAB codes. Their computational times are reported in the tables in this section.

We give average results based on the restoration of 1000 generated original 128-length signals from blurred noisy data. If x_o is such an original signal, observed data read $y = Ax_o + n$, where

$$A_{i,j} = \gamma e^{-0.1(i-j)^2}, \quad i, j = 1, 2, \ldots, p,$$

γ is a normalization constant such that $\sum_{i=1}^{p} A_{i,1} = 1$, and n is white Gaussian noise yielding a signal-to-noise ratio (SNR) of 40dB. In Figure 5.1(a) we show an example of a randomly generated original signal x_o and in Figure 5.1(b) data y generated as explained above. For all minimization methods, the stopping criterion is

(a) Original signal x_o (b) Blurred noisy signal y

(c) Restoration using $\phi(t) = \sqrt{\alpha + t^2}$ (d) Restoration using the Huber function ϕ

FIG. 5.1. *Example of restoration of a randomly generated original signal* (a) *from blurred noisy data* (b). *Restored signals:* (c) $\phi(t) = \sqrt{\alpha + t^2}$, *and* $\alpha = 0.001$, $\beta = 0.8$; (d) $\phi(t) = t^2/2$ *if* $|t| \leq \alpha$, $\phi(t) = \alpha|t| - \alpha^2/2$ *if* $|t| > \alpha$, *where* $\alpha = 0.1$, $\beta = 10$.

$||x^{(k)} - x^{(k-1)}||_2 < 1 \times 10^{-4}/||x_o||$, while the maximum iteration number is 1000. For the restoration of each signal, we minimize cost-functions J defined using different potential functions ϕ and different sets of parameters (α, β). Figures 5.1(c) and (d) show two restorations obtained from the data in Figure 5.1(b). Each cost-function J is minimized using the multiplicative form of HQ regularization, the additive form of HQ regularization where $c = \phi''(0)$, as well as using MATLAB optimization routines "fminunc.m." In the latter optimization procedure, we use quasi-Newton updating schemes "bfgs" or "dfp," the line search algorithm "cubicpoly," as well as the steepest descent scheme "steepdesc." Tables 5.1–5.5 summarize the average number of iterations (the first row of each set of parameters) and the average computational times in seconds (the second row of each set of parameters) for each minimization method. Below we briefly comment on the obtained results.

- The multiplicative form of HQ regularization allows us to minimize J using a smaller number of iterations than the additive form of HQ regularization.
- The overall computational times used by the additive form are less than those used by the multiplicative form.
- The performance of MATLAB optimization routines are poorer than those of both forms of HQ regularization in our MATLAB implementation. These results must be qualified by the observation that MATLAB run times for the

same operations can vary by orders of magnitude depending on the particular coding used. This result may show that HQ regularization is a powerful tool for the minimization of cost functions of the form (1.2)–(1.3).

- We have computed the condition numbers of the matrices $\mathcal{H}(b^{(k)})$ and $\mathcal{H}$ arising from the multiplicative form and the additive form of HQ regularization, respectively. As expected, the condition number of $\mathcal{H}(b^{(k)})$ is always larger

where γ is a normalization constant, and

$$A_{i,j} = \gamma_{i,j} e^{-0.1(i-j)^2}, \quad i, j = 1, 2, \ldots, p,$$

where $\gamma_{i,j} \in [0, 1]$ are random numbers. In the former case A is banded and in the latter A is not Toeplitz. All observations stated above have been corroborated.

We focused on the role of the constant c involved in the definition of ψ in the additive form of HQ regularization—see (3.1) and (3.2). The results presented in Figure 5.2 show that the convergence rate depends linearly on the value of c. This nicely corroborates our Remark 7 on the optimal choice for c.

5.2. Two-dimensional images. The original image and the data, degraded by blur and noise, are shown in Figure 5.3. We consider spatial-invariant blurring, in which case A is a Toeplitz-like matrix [23]. In the regularization term, G is the discretization matrix of the first-order differentiation operator. The matrix $\mathcal{H}$ in the additive form can be diagonalized by the discrete cosine transform matrix. Thus the

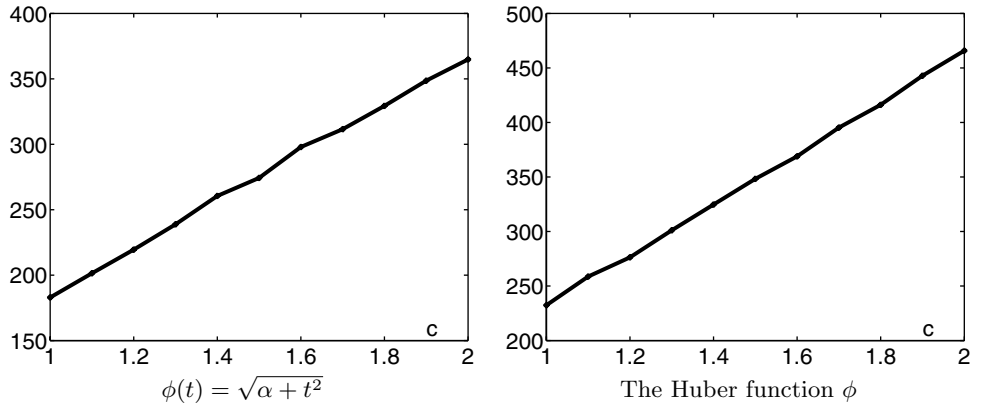

FIG. 5.2. *Average number of iterations as a function of the values of c in the additive form: (left)* $\phi(t) = \sqrt{\alpha + t^2}$ *(*$\alpha = 0.001$*); (right)* $\phi(t) = t^2/2$ *if* $|t| \leq \alpha$ *and* $\phi(t) = \alpha|t| - \alpha^2/2$ *if* $|t| > \alpha$ *(*$\alpha = 0.1$*).*

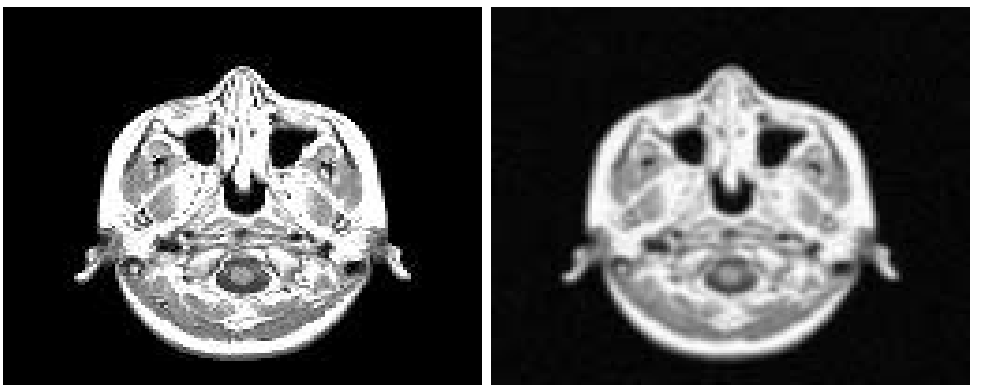

FIG. 5.3. *Original image (left) and blurred and noisy image (right).*

computational complexity to solve (4.6) at each iteration is $O(p^2 \log p)$ operations for a p-by-p image. In the multiplicative form, the matrix $\mathcal{H}(b)$ cannot be diagonalized efficiently. At each iteration, we solve (4.5) using conjugate gradient methods. The computational complexity is $O(p^2 \log p)$ per iteration.

The restored images using the Huber potential function are displayed in Figure 5.4 for the additive and the multiplicative forms with $\alpha = \beta = 1$. The stopping criterion of the HQ regularization iterations is $||x^{(k)} - x^{(k-1)}||_2 < 1 \times 10^{-3}\|y\|_2$. For the inner conjugate gradient iterations, we set the stopping criterion such that the $\mathcal{H}(b)$-norm of the solution error $||x^{(k)} - x_j^{(k)}||_{\mathcal{H}(b)}$ is less than 1×10^{-4}, where $x^{(k)}$ is the solution of the linear system (4.5) and $x_j^{(k)}$ is the jth iterate of the conjugate gradient iteration [6]. Visually, two restored images using the additive and the multiplicative form are almost the same. From Table 5.7, we see that the multiplicative form is more effective than the additive form in terms of the number of iterations, the objective function values, and the relative errors. However, the differences are not significant. The computational times required by using the additive form are significantly less than those using the multiplicative form.

6. Concluding remarks. We showed that the minimization of J using both the multiplicative and the additive form of HQ regularization amounts to finding the fixed point of a mapping involving a pertinent correction of the steepest descent direction. We presented a theoretical analysis of the convergence rate for each one of these minimization methods. More precisely, for both forms we derived an upper bound on the root-convergence factor. The bound for the multiplicative form was found to be smaller than the bound for the additive form. Our experimental results

show that minimization using the multiplicative form needs fewer iterations than the additive form, but that it requires a higher computation time. When applicable, the additive form is more attractive to use than the multiplicative form. Extensive experiments demonstrate that in our MATLAB implementation, minimization using HQ regularization is substantially faster (in terms of computational times) than standard routines, such as those in the MATLAB Optimization Toolbox. These results must be qualified by the observation that MATLAB run times for the same operations can vary by orders of magnitude depending on the particular coding used.

7. Appendix. From the theory of convex conjugated functions [27, 18], given $f : \mathbb{R} \to \mathbb{R}$, its conjugated function g is defined by $g(s) = \sup_{t\in\mathbb{R}}\{st - f(t)\}$ and is convex on $\mathbb{R}$. If f is continuous, convex and $f \not\equiv \infty$ on $\mathbb{R}$, we have reciprocally $\sup_{s\in\mathbb{R}}\{st - g(s)\} = f(t)$.

7.1. Functions ψ and σ for the multiplicative form. We suppose that ϕ satisfies all conditions given in (2.1). Define $\theta : \mathbb{R} \to \mathbb{R}$ as

$$\theta(t) = \begin{cases} \phi(\sqrt{t}) & \text{if} \quad t \geq 0, \\ -\infty & \text{if} \quad t < 0. \end{cases} \tag{7.1}$$

By (2.1)(b), the function $-\theta$ is convex on $\mathbb{R}$. Using convex conjugacy, if

$$\psi(s) = \sup_{t\in\mathbb{R}_+} \{\ h(t,s)\ \}, \quad \text{where} \quad h(t,s) = \left(-\frac{1}{2}s\right) t - (-\theta(t)), \tag{7.2}$$

we have reciprocally

$$\theta(t) = \inf_{s\in\mathbb{R}_+^*} \left\{\frac{1}{2}st + \psi(s)\right\}, \tag{7.3}$$

where the infimum is taken over $\mathbb{R}_+^*$ because $\psi(s) = +\infty$ if $s \leq 0$. Since $t \in \mathbb{R}_+$ in (7.2) and (7.3), we can write t^2 in place of t. Using that $\theta(t^2) = \phi(t)$, these expressions yield (2.2) and (2.3), respectively.

Since for any $s > 0$ the function $t \to h(t,s)$ is concave on $\mathbb{R}_+$ by (2.1)(b) and satisfies $\lim_{t\to\infty} h(t,s) = -\infty$ by (2.1)(f), it follows that $h(.,s)$ reaches its supremum for a finite $t \in [0,\infty)$. We determine σ by exhibiting all the pairs $(\hat{t},\hat{s})$ for which the supremum in (7.2) is reached, i.e., $\psi(\hat{s}) = h(\hat{t},\hat{s})$.

- For any $\hat{s} \geq 2\theta'(0^+)$, the function $h(.,\hat{s})$ reaches its maximum at $\hat{t} = 0$ since $\lim_{t\searrow 0} D_1h(t,\hat{s}) \leq 0$ shows that $h(.,\hat{s})$ is decreasing on the right side of zero.
- Consider that $\hat{s} \in (0, 2\theta'(0^+))$. Since $\lim_{t\searrow 0} D_1h(t,\hat{s}) > 0$, the function $h(.,\hat{s})$ increases on the right of zero. The supremum in (7.2) is then reached for a $\hat{t} \in (0,\infty)$ such that $D_1h(\hat{t},\hat{s}) = 0$, hence $\hat{s} = 2\theta'(\hat{t}) = \phi'(\sqrt{\hat{t}})/\sqrt{\hat{t}}$.

Using $\theta(t^2) = \phi(t)$ again shows that σ is as given in (2.5).

7.2. Functions ψ and σ for the additive form. We assume that ϕ satisfies (3.1). Using (3.1)(b), convex conjugacy shows that if

$$\psi(s) + \frac{1}{2c}s^2 = \sup_{t\in\mathbb{R}} \{\ h(t,s)\ \}, \quad \text{where} \quad h(t,s) = ts - \left(\frac{c}{2}t^2 - \phi(t)\right), \tag{7.4}$$

we have reciprocally

$$\frac{c}{2}t^2 - \phi(t) = \sup_{s\in\mathbb{R}} \left(ts - \left(\psi(s) + \frac{1}{2c}s^2\right)\ \right).$$

The equation in (7.4) is equivalent to (3.2) while the latter is equivalent to (3.3). Here again, the function σ is obtained by determining all the pairs $(\hat{t}, \hat{s})$ which achieve the supremum in (7.4). Using (3.1)(b) and (3.1)(e), for any $s \in \mathbb{R}$, the function $h(., s)$ is concave and satisfies $\lim_{|t|\to\infty} h(t, s) = -\infty$. It follows that for any $\hat{s}$, the supremum in (7.4) is reached for a finite $\hat{t}$. Since h is differentiable, any such $\hat{t}$ satisfies $D_1 h(\hat{t}, \hat{s}) = 0$. Hence $\hat{s} = \sigma(\hat{t})$ if σ reads as in (3.5).

A NONLINEAR GALERKIN SCHEME INVOLVING VECTOR AND TENSOR SPHERICAL HARMONICS FOR SOLVING THE INCOMPRESSIBLE NAVIER–STOKES EQUATION ON THE SPHERE*

M. J. FENGLER† AND W. FREEDEN†

Abstract. This work is concerned with a nonlinear Galerkin method for solving the incompressible Navier–Stokes equation on the sphere. It extends the work of [A. Debussche, T. Dubois, and R. Temam, *Theoret. Comput. Fluid Dyn.,* 7 (1995), pp. 279–315; M. Marion and R. Temam, *SIAM J. Numer. Anal.,* 26 (1989), pp. 1139–1157; J. Shen and R. Temam, *Proceedings of the International Conference on Nonlinear Evolution Partial Differential Equations*, AMS, Providence, RI, 1997, pp. 363–376] from one-dimensional or toroidal domains to the spherical geometry. In the first part, the method based on type 3 vector spherical harmonics is introduced and convergence is indicated. Further it is shown that the occurring coupling terms involving three vector spherical harmonics can be expressed algebraically in terms of Wigner-3j coefficients. To improve the numerical efficiency and economy we introduce an FFT-based pseudospectral algorithm for computing the Fourier coefficients of the nonlinear advection term. The resulting method scales with $O(N^3)$ if N denotes the maximal spherical harmonic degree. The latter is demonstrated in an extensive numerical example.

Key words. incompressible spherical Navier–Stokes equation, nonlinear Galerkin scheme, vector spherical harmonics, pseudospectral algorithm, transform method

1. Motivation.

Spectral methods are well known for solving different types of partial differential equations such as Laplace, Helmholtz, and heat or wave equations, but also for nonlinear equations such as the Burger, shallow water, or full Navier–Stokes equation or even more complex coupled partial differential equations, e.g., those known from dynamo theory, magnetohydrodynamics, or meteorology (cf. [1, 2, 3, 9, 12, 15, 20, 21, 22, 25]). Spectral methods are usually implemented in Galerkin schemes, which are applied to, for example, complex flows but in simple geometries, e.g., a two-dimensional rectangular, periodic cell. These geometries provide an easy access to fast basis transforms by exploiting the periodicity of the basis functions, leading to FFT-based algorithms. Moreover, recent publications due to Temam et al. [7, 17, 23, 24] extend the idea of linear Galerkin approximations to nonlinear Galerkin methods. The key idea is that nonlinear expressions such as the nonlinear advection term can be treated more efficiently and also more economically than in a linear Galerkin ansatz. Nonlinear Galerkin methods are able to capture the flow behavior with fewer test functions than are needed within a linear Galerkin approach.

This article deals with a formulation of a nonlinear Galerkin method for solving the Navier–Stokes equations on the sphere involving vector and tensor spherical harmonics. The method itself is mainly motivated by the work of Marion and Temam [17], who have given a proof of convergence within a general Hilbert space concept. In

detail, this work extends the results of [7, 23] from one-dimensional and toroidal domains to the spherical geometry, which is, for example, of great interest in meteorology and oceanography. Moreover, special emphasis is given on a fast computation of the nonlinear advection. Importantly, the techniques introduced later on differ from that used in the torus geometry due to the loss of periodicity in latitudinal direction. The idea is based on the so-called [illegible] or [illegible] originally introduced by Orszag [20]; see also the related works of [2, 12, 25]. However, the main difference between [2, 12, 20, 25] and this work is that the new method proposed below follows intrinsically a vectorial and tensorial formulation of the advection term. Thus, we are concerned with the fast transformation of (physically meaningful) vectorial and tensorial spherical harmonics which are not reduced (componentwise) to scalar ones. In doing so, we can easily separate the involved vector fields into poloidal and toroidal parts. This is important since we are interested here in flows, which are free of surface divergences. Finally, it should be noted that the term [illegible] is often used in meteorology to denote an exact variant of the so-called [illegible], while the latter is then meant to be approximative (see, for instance, [20, 25]). However, throughout this work we follow the standard textbook of Boyd [3] and use the term [illegible] synonymously; i.e., we use this method as an exact replacement of an algebraic evaluation of the advection term. In that sense, the term [illegible] is understood to denote the general idea behind, which is applied to many other special functions and geometries, e.g., Chebyshev polynomials on finite intervals (see [3] and the references therein).

The layout of the paper is as follows: First, we introduce reference function spaces. Within this framework various estimates are derived to show that the theorem of convergence as proposed by [17] can be applied. Second, we discuss the occurring coupling terms in the nonlinear Galerkin scheme, in particular, the nonlinear advection term. To improve the algorithmic efficiency, we extend the techniques known for pseudospectral algorithms to toroidal vector and tensor fields. Finally, we numerically illustrate our method for an extensive example, which involves the rotational Coriolis terms, the nonlinear advection, the viscosity, and the time-dependent flow driving forces.

2. Preliminaries. In what follows we adopt the nomenclature proposed by Freeden, Gervens, and Schreiner [11]:

$\mathbb{R}^3$	Three-dimensional Euclidean space
x, y, z	Elements of $\mathbb{R}^3$
$x \cdot y$	Scalar product of vectors $x, y \in \mathbb{R}^3$
$x \wedge y$	Vector product of vectors $x, y \in \mathbb{R}^3$
$x \otimes y$	Tensor product of vectors $x, y \in \mathbb{R}^3$
$\varepsilon^i, i = 1, 2, 3$	Canonical orthonormal basis in $\mathbb{R}^3$
∇	Gradient in $\mathbb{R}^3$
Δ	Laplacian in $\mathbb{R}^3$
r, t, ϕ	Polar coordinates in $\mathbb{R}^3$
Ω	Unit sphere in $\mathbb{R}^3$
ξ, η	Elements of the unit sphere $\Omega \subset \mathbb{R}^3$
$\varepsilon^r, \varepsilon^\phi, \varepsilon^t$	Moving orthonormal triad on Ω
∇^*	Surface gradient on Ω
L^*	Surface curl gradient on Ω
$\nabla^* \cdot$	Surface divergence on Ω
$L^* \cdot$	Surface curl on Ω
Δ^*	Scalar Beltrami operator on Ω
$\mathbf{\Delta}^*$	Vectorial Beltrami operator on Ω

$C^{(k)}_{\mathbb{K}}(\Omega), L^p_{\mathbb{K}}(\Omega)$ (respectively, $c^{(k)}_{\mathbb{K}}(\Omega), l^p_{\mathbb{K}}(\Omega)$) denote the following classes of scalar-valued (respectively, vector-valued) functions on Ω (with $\mathbb{K} = \mathbb{R}$ or $\mathbb{C}$):

$C^{(k)}_{\mathbb{K}}(\Omega)$	Class of scalar functions $F : \Omega \to \mathbb{K}$ possessing k continuous derivatives on Ω
$L^p_{\mathbb{K}}(\Omega)$	Class of scalar functions $F : \Omega \to \mathbb{K}$ which are measurable and for which $\|F\|_{L^p(\Omega)} = (\int_\Omega \|F(\xi)\|^p dS(\xi))^{1/p} < \infty$ (dS is the surface element)
$c^{(k)}_{\mathbb{K}}(\Omega)$	Class of vector functions $f : \Omega \to \mathbb{K}^3$ possessing k continuous derivatives on Ω
$l^p_{\mathbb{K}}(\Omega)$	Class of vector functions $f : \Omega \to \mathbb{K}^3$ which are measurable and for which $\|f\|_{l^p(\Omega)} = (\int_\Omega \|f(\xi)\|^p dS(\xi))^{1/p} < \infty$

We denote by $Y_{n,k}$ the complex scalar spherical harmonics as introduced by Edmonds [8]. Moreover, we denote by $y^{(i)}_{n,k}(\xi)$ vector spherical harmonics for $n = 0_i, \ldots; k = -n, \ldots, n$ and $i = 1, 2, 3$ with $0_1 = 0$ and $0_2 = 0_3 = 1$. To be more specific, we let

$$\begin{aligned} y^{(1)}_{n,k}(\xi) &= \xi Y_{n,k}(\xi), \\ y^{(2)}_{n,k}(\xi) &= \frac{1}{\sqrt{n(n+1)}} \nabla^*_\xi Y_{n,k}(\xi), \\ y^{(3)}_{n,k}(\xi) &= \frac{1}{\sqrt{n(n+1)}} L^*_\xi Y_{n,k}(\xi) \end{aligned}$$

for $n = 0_i, \ldots; k = -n, \ldots, n$. Finally, the scalar spherical harmonics can be used to introduce tensor spherical harmonics by

(2.1)

$$\begin{aligned} \mathbf{y}^{(1,1)}_{n,k}(\xi) &= \xi \otimes \xi Y_{n,k}(\xi), \\ \mathbf{y}^{(1,2)}_{n,k}(\xi) &= \frac{1}{\sqrt{n(n+1)}} \xi \otimes \nabla^*_\xi Y_{n,k}(\xi), & \mathbf{y}^{(1,3)}_{n,k}(\xi) &= \frac{1}{\sqrt{n(n+1)}} \xi \otimes L^*_\xi Y_{n,k}(\xi), \\ \mathbf{y}^{(2,1)}_{n,k}(\xi) &= \frac{1}{\sqrt{n(n+1)}} \nabla^*_\xi Y_{n,k}(\xi) \otimes \xi, & \mathbf{y}^{(2,2)}_{n,k}(\xi) &= \frac{1}{\sqrt{n(n+1)}} \nabla^*_\xi \otimes \nabla^*_\xi Y_{n,k}(\xi), \\ \mathbf{y}^{(2,3)}_{n,k}(\xi) &= \frac{1}{\sqrt{n(n+1)}} \nabla^*_\xi \otimes L^*_\xi Y_{n,k}(\xi), & \mathbf{y}^{(3,1)}_{n,k}(\xi) &= \frac{1}{\sqrt{n(n+1)}} L^*_\xi Y_{n,k}(\xi) \otimes \xi, \\ \mathbf{y}^{(3,2)}_{n,k}(\xi) &= \frac{1}{\sqrt{n(n+1)}} L^*_\xi \otimes \nabla^*_\xi Y_{n,k}(\xi), & \mathbf{y}^{(3,3)}_{n,k}(\xi) &= \frac{1}{\sqrt{n(n+1)}} L^*_\xi \otimes L^*_\xi Y_{n,k}(\xi) \end{aligned}$$

for $n = 0_{i,j}, \ldots; k = -n, \ldots, n$ with

$$0_{i,j} = \begin{cases} 0 & \text{if } (i,j) = (1,1), \\ 1 & \text{else.} \end{cases}$$

Furthermore, in analogy to [11], we introduce the function spaces

$$\begin{aligned} \mathrm{Harm}_{p,\ldots,q}(\Omega) &= \mathrm{span}_{n=p,\ldots,q;k=-n,\ldots,n}\{Y_{n,k}\}, \\ \mathrm{harm}^{(i)}_{p,\ldots,q}(\Omega) &= \mathrm{span}_{n=p,\ldots,q;k=-n,\ldots,n}\{y^{(i)}_{n,k}\}, \quad i = 1, 2, 3, \\ l^2_{(i)}(\Omega) &= \overline{\mathrm{harm}^{(i)}_{0_i,\ldots,\infty}(\Omega)}^{\|\cdot\|_{l^2(\Omega)}}. \end{aligned}$$

From now on, we simply let $H = l^2_{(3)}(\Omega)$ if no confusion is likely to arise.

Finally, we introduce certain Sobolev spaces:

$$\mathcal{H}(\{A_n\};\Omega) = \left\{ F \in L^2(\Omega) | \sum_{n=0}^{\infty} \sum_{k=-n}^{n} \langle F, Y_{n,k}\rangle^2_{L^2(\Omega)} A_n^2 < \infty \right\},$$

$$h^{(i)}(\{A_n\};\Omega) = \left\{ f \in l^2(\Omega) | \sum_{n=0_i}^{\infty} \sum_{k=-n}^{n} \langle f, y^{(i)}_{n,k}\rangle^2_{l^2(\Omega)} A_n^2 < \infty \right\},$$

$$h(\{A_n\};\Omega) = h^{(1)}(\{A_n\};\Omega) \oplus h^{(2)}(\{A_n\};\Omega) \oplus h^{(3)}(\{A_n\};\Omega)$$

for sequences $\{A_n\}$ with $A_n \in \mathbb{R}$ for all n.

Following the terminology of [17], we let $A = -\boldsymbol{\Delta}^*$; i.e., A is the negative vectorial Beltrami operator. This basic dissipative operator A is a linear self-adjoint unbounded operator in H with domain of definition $D(A)$ dense in H (see [11]). Moreover, we know from [11] that A is positive and that A^{-1} is compact. Thus, one can define powers A^s of A for $s \in \mathbb{R}$; A^s maps $D(A^s)$ into H and $D(A^s)$ is a Sobolev space when endowed with the norm $\|A^s \cdot \|_{l^2_{(\Omega)}}$. We set $\mathcal{V} = D(A^{1/2})$ and denote by

$$\|\cdot\|_{\mathcal{V}} = \|(-\boldsymbol{\Delta}^*)^{1/2} \cdot \|_{l^2(\Omega)}$$

the norm on $\mathcal{V}$. Hence, we find by [11] the relation

$$\mathcal{V} = h^{(3)}(\{\sqrt{n(n+1)}\};\Omega).$$

Thus we arrive at

$$A : H \supset D(A) \to H, \qquad u \mapsto Au = -\boldsymbol{\Delta}^* u. \tag{2.2}$$

Moreover, we define the bilinear advection operator B by

$$B : \mathcal{V} \times \mathcal{V} \to \mathcal{V}', \qquad (u,v) \mapsto ((u \cdot \nabla^*)v)\,, \tag{2.3}$$

where $\mathcal{V}'$ is understood to be the dual space of $\mathcal{V}$. The Coriolis operator C is defined by

$$C : H \to H, \qquad u \mapsto 2\omega \wedge u, \tag{2.4}$$

where ω denotes the rotational axis pointing in direction of ε^3. By $b(u,v,w) = \langle B(u,v), w\rangle_{\mathcal{V}',\mathcal{V}}$ we denote the trilinear form defined by

$$b(u,v,w) = \int_\Omega ((u \cdot \nabla^*)v) \cdot w \; dS \tag{2.5}$$

for all $u, v, w \in \mathcal{V}$. Finally, we introduce the space

$$L^2_\Omega(0,T;\mathcal{V}) = \left\{ f(t) \in \mathcal{V} : [0,T] \to \mathbb{R}^3 \,\middle|\, \left(\int_0^T |f(t)|^2 \, dt \right)^{1/2} < \infty \right\}.$$

The Navier–Stokes equations. Throughout this work we denote by u the fluid velocity, by T the temperature, by p the pressure, by g the apparent gravity, and by ρ the fluid's density. Additional flow driving terms are given by f, whereas friction

and dissipation are induced by a viscous term $\nu\boldsymbol{\Delta}^*$. In the sense of meteorology, we introduce Q as the total heating rate per unit mass, c_v as the specific heat at constant volume, and c_R as the gas constant per unit mass. From [18, 19] we recapitulate the set of forecasting equations for a pure tangential, atmospherical stream as follows:

$$\frac{\partial u}{\partial t} = -(u \cdot \nabla^*)u - 2\omega \wedge u - 1/\rho\nabla^* p - \nabla^* g + \nu\boldsymbol{\Delta}^* u + f, \tag{2.6}$$

$$c_v \frac{\partial T}{\partial t} = -c_v(u \cdot \nabla^*)T - \frac{p}{\rho}\nabla^* \cdot u + Q, \tag{2.7}$$

$$\frac{\partial \rho}{\partial t} = -(u \cdot \nabla^*)\rho - \rho\nabla^* \cdot u, \tag{2.8}$$

$$p = \rho c_R T, \tag{2.9}$$

$$u(0) = u_0, \qquad p(0) = p_0, \qquad T(0) = T_0, \qquad \rho(0) = \rho_0. \tag{2.10}$$

We restrict ourselves to pure tangential [illegible] flows on a sphere. This leads us to $\nabla^* \cdot u = 0$ and $\rho = \text{const.}$, which simplifies (2.6)–(2.10). To be more specific, in our Galerkin approach, the pressure and gravity terms drop out in a weak formulation. Namely, let ϕ be a smooth toroidal vector-valued function; then

$$\langle \nabla^* p(t), \phi \rangle_{l^2(\Omega)} = 0$$

(by standard theorems; see, for example, [11]). The latter decouples the system (2.6)–(2.10) such that we have to consider "only" (in the weak sense) the equations

$$\begin{aligned} \frac{\partial u}{\partial t} &= -(u \cdot \nabla^*)u - 2\omega \wedge u + \nu\boldsymbol{\Delta}^* u + f, \\ \nabla^* \cdot u &= 0, \\ u(0) &= u_0. \end{aligned} \tag{2.11}$$

In the formulation used above, we can write (2.11) as follows:

$$\frac{\partial u}{\partial t} + \nu Au + B(u, u) + Cu - f = 0, \tag{2.12}$$

where f is understood to be projected onto $l^2_{(3)}(\Omega)$.

Existence and uniqueness. For the Navier–Stokes equations on the 2-sphere Il'in [13] and Il'in and Filatov [14] have verified existence and uniqueness of a generalized (weak) solution, provided that $f \in L^2_\Omega(0, T; \mathcal{V}')$ and $u_0 \in H$. Moreover, they have proven that the solution is continuous and a member of class $L^2_\Omega(0, T; \mathcal{V})$.

3. Operator estimates. This section is concerned with some operator estimates involving (2.12). Based on these results we are able to assure the convergence of the nonlinear Galerkin method. As a matter of fact, we present the estimates for the spherical case the same way as [17]. It should be noted that $l^2(\Omega)$ is written instead of $l^2_{\mathbb{R}}(\Omega)$ if no confusion is likely to arise.

First some results are borrowed from [14].

LEMMA 3.1 (antisymmetry of the trilinear form). [illegible] $u, v, w \in \mathcal{V}$ [illegible] b [illegible] (2.5) [illegible]

$$b(u, v, w) = -b(u, w, v).$$

LEMMA 3.2. [illegible] $u \in \mathcal{V}$

$$\|u\|_{l^4(\Omega)} \le c_1 \|u\|_{l^2(\Omega)}^{1/2} \|u\|_{\mathcal{V}}^{1/2}. \tag{3.1}$$

From [10] we have the following important embedding theorem.

LEMMA 3.3 (embedding $\mathcal{V}$). [illegible] $2 \le p \le 4$ [illegible]

(i) $\mathcal{H}(\{n(n+1)\};\Omega) \subset \mathcal{H}(\{\sqrt{n(n+1)}\};\Omega) \subset L^p(\Omega) \subset L^2(\Omega)$
(ii) $h(\{n(n+1)\};\Omega) \subset h(\{\sqrt{n(n+1)}\};\Omega) \subset l^p(\Omega) \subset l^2(\Omega)$
(iii) $h^{(3)}(\{n(n+1)\};\Omega) \subset h^{(3)}(\{\sqrt{n(n+1)}\};\Omega) \subset l^p_{(3)}(\Omega) \subset l^2_{(3)}(\Omega)$
(iv) $\mathcal{V} \subset l^p_{(3)}(\Omega) \subset l^2_{(3)}(\Omega)$

Consequently, we can deduce a corollary relating the norms of the involved Sobolev spaces and $l^2(\Omega)$.

COROLLARY 3.4. [illegible] u [illegible] $h^{(3)}(\{n(n+1)\};\Omega)$ [illegible]

$$\|u\|_{l^2(\Omega)} \le \|u\|_{\mathcal{V}} \le \|u\|_{h^{(3)}(\{n(n+1)\};\Omega)}.$$

Based on these results we are able to deduce the following estimates.

ESTIMATE 3.5 (estimating the trilinear form). [illegible] b [illegible] $u, v, w \in \mathcal{V}$ [illegible]

(i)

$$|b(u,v,w)| \le c_1 \|u\|_{\mathcal{V}} \|v\|_{\mathcal{V}} \|w\|_{\mathcal{V}},$$

(ii)

$$|b(u,v,w)| \le c_2 \|u\|_{l^2(\Omega)}^{1/2} \|u\|_{\mathcal{V}}^{1/2} \|v\|_{\mathcal{V}} \|w\|_{l^2(\Omega)}^{1/2} \|w\|_{\mathcal{V}}^{1/2}. \tag{3.2}$$

[illegible]. The first statement has already been proven in [14]. The second statement can be derived by expanding the trilinear form in its Cartesian components: By keeping in mind that u, v, w are tangential vector fields, we find

$$b(u,v,w) = \int_\Omega [(u \cdot \nabla^*)v] \cdot w \, dS = \int_\Omega [(u \cdot \nabla)v] \cdot w \, dS. \tag{3.3}$$

Since ∇ is the gradient in $\mathbb{R}^3$, we are able to expand (3.3) componentwise in Cartesian coordinates, i.e., $v_i = \varepsilon^i \cdot v$ and $\nabla_i = \varepsilon^i \cdot \nabla$, such that

$$b(u,v,w) = \int_\Omega \sum_{i=1}^3 \sum_{j=1}^3 u_i (\nabla_i v_j) w_j \, dS.$$

By applying Cauchy–Schwarz twice we estimate the absolute value of b by

$$\begin{aligned} |b(u,v,w)| &\le \sum_{i=1}^3 \sum_{j=1}^3 \int_\Omega |u_i (\nabla_i v_j) w_j| \, dS \le \sum_{i=1}^3 \sum_{j=1}^3 \|u_i\|_{L^4(\Omega)} \|\nabla_i v_j\|_{L^2(\Omega)} \|w_j\|_{L^4(\Omega)} \\ &\le \left(\sum_{i=1}^3 \|u_i\|_{L^4(\Omega)} \right)^{1/2} \left[\sum_{j=1}^3 \left(\sum_{i=1}^3 \|\nabla_i v_j\|_{L^2(\Omega)} \right)^{1/2} \|w_j\|_{L^4(\Omega)} \right] \\ &\le \left(\sum_{i=1}^3 \|u_i\|_{L^4(\Omega)} \right)^{1/2} \left(\sum_{i=1}^3 \sum_{j=1}^3 \|\nabla_i v_j\|_{L^2(\Omega)} \right)^{1/2} \left(\sum_{j=1}^3 \|w_j\|_{L^4(\Omega)} \right)^{1/2}. \end{aligned} \tag{3.4}$$

Now the first and third sums can be estimated by the aid of (3.1)

$$\|u_i\|^2_{L^4(\Omega)} = \|u_i\varepsilon_i\|^2_{l^4(\Omega)} \le \|u\|^2_{l^4(\Omega)} \le c_1^2\|u\|_{l^2(\Omega)}\|u\|_{\mathcal{V}}.$$

This leads us to

$$\left(\sum_{i=1}^{3}\|u_i\|^2_{L^4(\Omega)}\right)^{1/2} \le \sqrt{3}c_1\|u\|^{1/2}_{l^2(\Omega)}\|u\|^{1/2}_{\mathcal{V}}. \tag{3.5}$$

Observing the estimate

$$\begin{aligned}\sum_{i=1}^{3}\sum_{j=1}^{3}\|\nabla_i v_j\|^2_{L^2(\Omega)} &= \sum_{i=1}^{3}\sum_{j=1}^{3}\int_\Omega \nabla_i v_j\nabla_i v_j\,dS = -\sum_{i=1}^{3}\sum_{j=1}^{3}\int_\Omega v_j(\nabla_i)^2 v_j\,dS\\ &= -\sum_{i=1}^{3}\int_\Omega v\cdot(\nabla_i)^2 v\,dS = -\int_\Omega v\cdot\Delta v\,dS\\ &= -\int_\Omega v\cdot\Delta^* v\,dS = \|v\|^2_{\mathcal{V}}\end{aligned}$$

we finally get the desired result. □

In the following we are concerned with the well-known Poincaré inequality on the sphere.

ESTIMATE 3.6 (Poincaré inequality). [illegible] $u \in \mathcal{V}$ [illegible]

$$\|u\|_{l^2(\Omega)} \le \frac{1}{\sqrt{2}}\|u\|_{\mathcal{V}}.$$

[illegible] Let us expand u in type 3 vector spherical harmonics such that $u = \sum_{n=1}^{\infty} u^{(3)}_{n,k}y^{(3)}_{n,k}$. Then $\|u\|^2_{\mathcal{V}}$ reads as

$$\|u\|^2_{\mathcal{V}} = \sum_{n=1}^{\infty} n(n+1)\left(u^{(3)}_{n,k}\right)^2.$$

Since $n(n+1) \ge 2$ for all $n \ge 1$ we get the desired result. □

ESTIMATE 3.7 (estimating the Coriolis term). [illegible] $u \in \mathcal{V}$ [illegible] $\omega \in \mathbb{R}^3$

$$\|Cu\|_{l^2(\Omega)} \le \sqrt{2}|\omega|\|u\|_{\mathcal{V}}.$$

[illegible] First we see that

$$\|Cu\|_{l^2(\Omega)} \le 2\|\omega\wedge u\|_{l^2(\Omega)} = 2\left[\int_\Omega(\omega\wedge u)^2\,dS\right]^{1/2}.$$

Applying the Lagrange identity we obtain

$$\begin{aligned}2\left[\int_\Omega(\omega\wedge u)^2\,dS\right]^{1/2} &= 2\left[\int_\Omega(\omega\cdot\omega)(u\cdot u)-(u\cdot\omega)(\omega\cdot u)\,dS\right]^{1/2}\\ &\le 2\left[\int_\Omega|\omega|^2(u\cdot u)\,dS\right]^{1/2}\\ &= 2|\omega|\|u\|_{l^2(\Omega)}.\end{aligned}$$

By aid of the Poincaré inequality from Estimate 3.6 we have

$$2|\omega|\|u\|_{l^2(\Omega)} \leq \sqrt{2}|\omega|\|u\|_{\mathcal{V}},$$

which proves our estimate. □

ESTIMATE 3.8 (positive definiteness of $\nu A + C$). A [illegible] (2.2) [illegible] C [illegible] (2.4) [illegible] $\nu \in \mathbb{R}^+$ [illegible] $u \in \mathcal{V}$,

$$\int_\Omega [(\nu A + C)u] \cdot u \; dS \geq \nu \|u\|_{\mathcal{V}}^2.$$

[illegible]. Let us drop for a moment the operator νA. We expand u in type 3 vector spherical harmonics such that $u = \sum_{n=1}^{\infty} \sum_{k=-n}^{n} u_{n,k}^{(3)} y_{n,k}^{(3)}$ in the sense of $l^2(\Omega)$. Then, we get for the Coriolis operator the following identity:

$$\int_\Omega Cu \cdot u \; dS = 2 \int_\Omega (\omega \wedge u) \cdot u \; dS = 0.$$

By using the linearity of the integral operator, we are able to deduce that

$$\int_\Omega [(\nu A + C)u] \cdot u \; dS = \int_\Omega \nu Au \cdot u \; dS = \nu \|u\|_{\mathcal{V}}^2.$$

This guarantees Estimate 3.8. □

Finally we are concerned with some estimates for the nonlinear advection operator B.

ESTIMATE 3.9 (estimating the advection operator). [illegible] B [illegible] (2.3) [illegible]

(i) [illegible] $v \in D(A), u \in \mathcal{V}$ [illegible]

$$\|B(u,v)\|_{l^2(\Omega)} \leq c_2 \|u\|_{l^2(\Omega)}^{1/2} \|u\|_{\mathcal{V}}^{1/2} \|v\|_{\mathcal{V}}^{1/2} \|Av\|_{l^2(\Omega)}^{1/2}. \tag{3.6}$$

(ii) [illegible] $u \in D(A)$ [illegible]

$$\|B(u,u)\|_{l^2(\Omega)} \leq c_2 \|u\|_{l^2(\Omega)}^{1/2} \|u\|_{\mathcal{V}} \|Au\|_{l^2(\Omega)}^{1/2}.$$

(iii) [illegible] $v \in D(A), u \in \mathcal{V}$ [illegible]

$$\|B(u,v)\|_{\mathcal{V}'} \leq c_2 \|u\|_{l^2(\Omega)}^{1/2} \|u\|_{\mathcal{V}}^{1/2} \|v\|_{\mathcal{V}}^{1/2} \|v\|_{l^2(\Omega)}^{1/2}.$$

(iv) [illegible] $u, v \in D(A)$ [illegible]

$$\|B(u,v)\|_{\mathcal{V}'} \leq c_2 \|u\|_{l^2(\Omega)}^{1/2} \|u\|_{\mathcal{V}} \|v\|_{\mathcal{V}}^{1/2}.$$

(v) [illegible] $u, v \in D(A)$ [illegible]

$$\|B(u,v)\|_{l^2(\Omega)} \leq c_2 \|u\|_{l^2(\Omega)}^{1/2} \|u\|_{\mathcal{V}} \|v\|_{\mathcal{V}}^{1/2}.$$

(vi) [illegible] $u, v \in D(A)$ [illegible]

$$\|B(u,v)\|_{l^2(\Omega)} \leq c_2 \|u\|_{\mathcal{V}}^{1/2} \|Au\|_{l^2(\Omega)}^{1/2} \|v\|_{\mathcal{V}}.$$

Before entering into detailed steps for the proof of these five estimates, we need a preliminary result.

LEMMA 3.10. [illegible] $v \in h^{(3)}(\{A_n\};\Omega) \subset l^2_{(3)}(\Omega)$ [illegible] $\{A_n\}$ [illegible]

$$\|v \cdot \varepsilon_i\|_{\mathcal{H}(\{A_n\};\Omega)} \le \|v\|_{h(\{A_n\};\Omega)}$$

[illegible] $= 1, 2, 3$

[illegible] It is clear that $\|v \cdot \varepsilon_i\|_{L^2(\Omega)} \le \|v\|_{l^2(\Omega)}$. As $y^{(3)}_{n,k} \in \oplus^3_{i=1}\mathrm{Harm}_n(\Omega)\,\varepsilon_i$ for all $k = -n, \dots, n$ (see [11]). Since $v \in l^2_{(3)}(\Omega)$ we are able to verify that

$$\sum_{k=-n}^{n} \left\langle v, y^{(3)}_{n,k} \right\rangle_{l^2(\Omega)} y^{(3)}_{n,k} = \sum_{i=1}^{3} \sum_{k=-n}^{n} \langle v, Y_{n,k}\varepsilon_i \rangle_{l^2(\Omega)}\, Y_{n,k}\varepsilon_i.$$

From the right-hand side we get an estimate for the Fourier coefficients of the component functions $v_i, i = 1, 2, 3$,

$$\sum_{k=-n}^{n} |(v \cdot \varepsilon_i)^\wedge(n,k)|^2 \le \sum_{i=1}^{3} \sum_{k=-n}^{n} |(v \cdot \varepsilon_i)^\wedge(n,k)|^2 = \sum_{k=-n}^{n} |v^{(3)}(n,k)|^2.$$

By similar arguments we obtain

$$A_n^2 \sum_{k=-n}^{n} |(v \cdot \varepsilon_i)^\wedge(n,k)|^2 \le A_n^2 \sum_{k=-n}^{n} |v^{(3)}(n,k)|^2$$
$$\|v \cdot \varepsilon_i\|_{\mathcal{H}(\{A_n\};\Omega)} \le \|v\|_{h(\{A_n\};\Omega)}. \qquad \square$$

Lemmas 3.3 and 3.10 enable us to establish the proof of Estimate 3.9.

[illegible] (i) The first estimate can be derived from (3.4) and (3.5):

$$|b(u,v,w)| \le \left(\sum_{i=1}^{3} \|u_i\|_{L^4(\Omega)}\right)^{1/2} \left(\sum_{i=1}^{3}\sum_{j=1}^{3} \|\nabla_i v_j\|_{L^2(\Omega)}\right)^{1/2} \left(\sum_{j=1}^{3} \|w_j\|_{L^4(\Omega)}\right)^{1/2}$$

$$\le \left(\sum_{i=1}^{3}\sum_{j=1}^{3} \|\nabla_i v_j\|_{L^2(\Omega)}\right)^{1/2} \sqrt{3}c_1 \|u\|^{1/2}_{l^2(\Omega)} \|u\|^{1/2}_{\mathcal{V}} \|w\|_{l^2(\Omega)}. \tag{3.7}$$

It remains to look at the first term. Due to our assumption we have $v \in D(A) \subset h(\{n(n+1)\};\Omega)$. Thus, $\nabla_i v_j \in \mathcal{H}(\{\sqrt{n(n+1)}\};\Omega) \subset L^4(\Omega) \subset L^2(\Omega)$ by the aid of Lemma 3.3. This yields $\|\nabla_i v_j\|_{L^2(\Omega)} \le \|\nabla_i v_j\|_{L^4(\Omega)}$. We observe

$$\|\nabla_i v_j\|^4_{L^4(\Omega)} = \|(\varepsilon_i \cdot \nabla) v_j\|^4_{L^4(\Omega)} \le \|\nabla v_j\|^4_{l^4(\Omega)} \le c_1^4 \|\nabla v_j\|^2_{l^2(\Omega)} \|\nabla v_j\|^2_{\mathcal{V}}. \tag{3.8}$$

The term on the right-hand side of (3.8) can be further simplified by

$$\|\nabla v_j\|^4_{l^4(\Omega)} \le c_1^4 \|\nabla^* v_j\|^2_{l^2(\Omega)} \|\nabla^* v_j\|^2_{\mathcal{V}} = c_1^4 \|v_j\|^2_{\mathcal{V}} \|\Delta^* v_j\|^2_{L^2(\Omega)}.$$

By using the auxiliary Lemma 3.10 we get

$$\|\nabla_i v_j\|^4_{L^4(\Omega)} \le c_1^4 \|v\|^2_{\mathcal{V}} \|\Delta^* v\|^2_{l^2(\Omega)} = c_1^4 \|v\|^2_{\mathcal{V}} \|Av\|^2_{l^2(\Omega)}.$$

Taking the fourth root of both sides of the equation yields

$$\|\nabla_i v_j\|_{L^4(\Omega)} \le c_1 \|v\|^{1/2}_{\mathcal{V}} \|Av\|^{1/2}_{l^2(\Omega)}.$$

By plugging the last result into (3.7) we find

$$|b(u,v,w)| \le 3\sqrt{3}c_1^2 \|u\|_{l^2(\Omega)}^{1/2} \|u\|_{\mathcal{V}}^{1/2} \|v\|_{\mathcal{V}}^{1/2} \|Av\|_{l^2(\Omega)}^{1/2} \|w\|_{l^2(\Omega)}.$$

Finally we can conclude the first estimate for the advection operator B:

$$\begin{aligned}\|B(u,v)\|_{l^2(\Omega)} &= \sup_{w\in H} \frac{\langle B(u,v),w\rangle_{l^2(\Omega)}}{\|w\|_{l^2(\Omega)}} = \sup_{w\in H} \frac{|b(u,v,w)|}{\|w\|_{l^2(\Omega)}} \\ &\le 3\sqrt{3}c_1^2 \|u\|_{l^2(\Omega)}^{1/2} \|u\|_{\mathcal{V}}^{1/2} \|v\|_{\mathcal{V}}^{1/2} \|Av\|_{l^2(\Omega)}^{1/2}.\end{aligned}$$

(ii) The second estimate follows from the first one by setting $v = u$.

(iii) To verify the third estimate we use the estimate from (3.2)

$$|b(u,v,w)| \le c_2 \|u\|_{l^2(\Omega)}^{1/2} \|u\|_{\mathcal{V}}^{1/2} \|v\|_{\mathcal{V}} \|w\|_{l^2(\Omega)}^{1/2} \|w\|_{\mathcal{V}}^{1/2} \tag{3.9}$$

and use the antisymmetry relation for the trilinear form b from Lemma 3.1, i.e., $b(u,v,w) = -b(u,w,v)$, to deduce that

$$|b(u,v,w)| \le c_2 \|u\|_{l^2(\Omega)}^{1/2} \|u\|_{\mathcal{V}}^{1/2} \|w\|_{\mathcal{V}} \|v\|_{l^2(\Omega)}^{1/2} \|v\|_{\mathcal{V}}^{1/2}.$$

By keeping in mind the Riesz–Fischer representation theorem we may regard for all $u \in \mathcal{V}$ and $v \in D(A)$ the value $B(u,v)$ as a representation of a linear functional in $\mathcal{V}'$. Thus we can estimate the norm of this functional by

$$\begin{aligned}\|B(u,v)\|_{\mathcal{V}'} &= \sup_{w\in\mathcal{V}} \frac{|\langle B(u,v),w\rangle_{l^2(\Omega)}|}{\|w\|_{\mathcal{V}}} = \sup_{w\in\mathcal{V}} \frac{|b(u,v,w)|}{\|w\|_{\mathcal{V}}} \\ &\le c_2 \|u\|_{l^2(\Omega)}^{1/2} \|u\|_{\mathcal{V}}^{1/2} \|v\|_{l^2(\Omega)}^{1/2} \|v\|_{\mathcal{V}}^{1/2},\end{aligned}$$

which finally proves the third estimate.

(iv) The proof of this estimate follows directly from relation (iii) and (3.9), i.e.,

$$\|B(u,v)\|_{\mathcal{V}'} = \sup_{\|w\|_{\mathcal{V}}=1} |b(u,v,w)| \le \sup_{\|w\|_{\mathcal{V}}=1} c_2 \|u\|_{l^2(\Omega)}^{1/2} \|u\|_{\mathcal{V}}^{1/2} \|v\|_{\mathcal{V}} \|w\|_{l^2(\Omega)}^{1/2} \|w\|_{\mathcal{V}}^{1/2}.$$

Since $\|w\|_{l^2(\Omega)} \le \|w\|_{\mathcal{V}}$ from the Poincaré inequality we finally arrive at

$$\|B(u,v)\|_{\mathcal{V}'} \le c_2 \|u\|_{l^2(\Omega)}^{1/2} \|u\|_{\mathcal{V}}^{1/2} \|v\|_{\mathcal{V}}.$$

(v) The fifth estimate can easily be obtained from (iv) by applying again the Riesz–Fischer representation theorem. This theorem yields the identity $\|B(u,v)\|_{\mathcal{V}'} = \|B(u,v)\|_{\mathcal{V}}$. From $\|B(u,v)\|_{l^2(\Omega)} \le \|B(u,v)\|_{\mathcal{V}}$ we get the desired result.

(vi) The last estimate can be derived by using again (3.2). The Poincaré inequality yields

$$\begin{aligned}\|B(u,v)\|_{l^2(\Omega)} \le \|B(u,v)\|_{\mathcal{V}} &= \|B(u,v)\|_{\mathcal{V}'} \\ &\le \sup_{\|w\|_{\mathcal{V}}=1} c_2 \|u\|_{l^2(\Omega)}^{1/2} \|u\|_{\mathcal{V}}^{1/2} \|v\|_{\mathcal{V}} \|w\|_{l^2(\Omega)}^{1/2} \|w\|_{\mathcal{V}}^{1/2} \\ &\le \sup_{\|w\|_{\mathcal{V}}=1} c_2 \|u\|_{l^2(\Omega)}^{1/2} \|u\|_{\mathcal{V}}^{1/2} \|v\|_{\mathcal{V}} \|w\|_{\mathcal{V}} \\ &\le c_2 \|u\|_{l^2(\Omega)}^{1/2} \|u\|_{\mathcal{V}}^{1/2} \|v\|_{\mathcal{V}}.\end{aligned}$$

Since we required $u \in D(A) \subset h^{(3)}(\{n(n+1)\};\Omega)$, we obtain the result by Corollary 3.4:

$$\|B(u,v)\|_{l^2(\Omega)} \le c_2 \|u\|_{h^{(3)}(\{n(n+1)\};\Omega)}^{1/2} \|u\|_{\mathcal{V}}^{1/2} \|v\|_{\mathcal{V}} = c_2 \|Au\|_{l^2(\Omega)}^{1/2} \|u\|_{\mathcal{V}}^{1/2} \|v\|_{\mathcal{V}}. \qquad \square$$

4. The nonlinear Galerkin method on the sphere. The implementation of the Galerkin method is based on the set of eigenvectors $\{y^{(3)}_{n,k}\}$, $n = 1, \ldots; k = -n, \ldots, n$, of the operator A with eigenvalues $0 < n(n+1), n = 1, 2, \ldots$. Further, for $m \in \mathbb{N}$, we consider the spaces $\mathrm{harm}^{(3)}_{1,\ldots,m}(\Omega)$ and $\mathrm{harm}^{(3)}_{m+1,\ldots,2m}(\Omega)$, respectively. Moreover, let $P_{1,\ldots,m}$ be the orthogonal projection operator $P_{1,\ldots,m} : l^2(\Omega) \to \mathrm{harm}^{(3)}_{1,\ldots,m}(\Omega)$, respectively, $P_{m+1,\ldots,2m}$ the projector on $\mathrm{harm}^{(3)}_{m+1,\ldots,2m}(\Omega)$.

Assume that u_0 is of class H, and let u be the solution of (2.12) with the initial condition $u(0) = u_0$. For every integer m, we are now looking for an approximation u_m of the form

$$u_m : \mathbb{R}^+_0 \to \mathrm{harm}^{(3)}_{1,\ldots,m}(\Omega), \qquad u_m(t) = \sum_{n=1}^{m} \sum_{k=-n}^{n} u^m_{n,k}(t) y^{(3)}_{n,k}. \tag{4.1}$$

The function u_m is determined by the resolution of a system involving another unknown function z_m given by

$$z_m : \mathbb{R}^+_0 \to \mathrm{harm}^{(3)}_{m+1,\ldots,2m}(\Omega), \qquad z_m(t) = \sum_{n=m+1}^{2m} \sum_{k=-n}^{n} z^m_{n,k}(t) y^{(3)}_{n,k}. \tag{4.2}$$

The pair (u_m, z_m) is expected to fulfill the equations

$$\begin{aligned} \frac{\partial}{\partial t}\langle u_m, v\rangle_{l^2(\Omega)} + \nu\langle Au_m, v\rangle_{l^2(\Omega)} + \langle Cu_m, v\rangle_{l^2(\Omega)} + b(u_m, u_m, v) \\ + b(z_m, u_m, v) + b(u_m, z_m, v) = \langle f, v\rangle_{l^2(\Omega)}, \end{aligned} \tag{4.3}$$

$$\nu\langle Az_m, \tilde{v}\rangle_{l^2(\Omega)} + \langle Cz_m, \tilde{v}\rangle_{l^2(\Omega)} + b(u_m, u_m, \tilde{v}) = \langle f, \tilde{v}\rangle_{l^2(\Omega)} \tag{4.4}$$

for all $v \in \mathrm{harm}^{(3)}_{1,\ldots,m}(\Omega)$ and $\tilde{v} \in \mathrm{harm}^{(3)}_{m+1,\ldots,2m}(\Omega)$ together with

$$u_m(0) = P_{1,\ldots,m} u_0. \tag{4.5}$$

Our purpose is to show that systems (4.3) and (4.4) are equivalent to an ordinary differential equation in terms of u_m.

Observing that $P_{m+1,\ldots,2m} A z_m = A z_m$, (4.4) is indeed linear in z_m and hence can be written as

$$(\nu A + P_{m+1,\ldots,2m} C) z_m = P_{m+1,\ldots,2m}(f - B(u_m, u_m)). \tag{4.6}$$

By virtue of Estimate 3.8, [17] guarantees the invertibility of the projected operator $P_{m+1,\ldots,2m}(\nu A + C)$ on $\mathrm{harm}^{(3)}_{m+1,\ldots,2m}(\Omega)$. Therefore, we have z_m explicitly given in terms of u_m by

$$z_m = (\nu A + P_{m+1,\ldots,2m} C)^{-1} P_{m+1,\ldots,2m}(f - B(u_m, u_m)). \tag{4.7}$$

Then, systems (4.3) and (4.4) are equivalent to the ordinary differential system

$$\frac{\partial u_m}{\partial t} + \nu A u_m + P_{1,\ldots,m}(Cu_m + B(u_m, u_m) + B(z_m, u_m) + B(u_m, z_m)) = P_{1,\ldots,m} f \tag{4.8}$$

with z_m given by (4.7).

Note that the system (4.8) with $z_m = 0$ yields exactly as a byproduct of the linear Galerkin method on the sphere.

Existence and uniqueness of a solution u_m to the system (4.8) equipped with the initial value from (4.5) defined on a maximal interval $[0, T_{\max})$ follows from standard theorems on ordinary differential equations. In fact, it is known that $T_{\max} = +\infty$ (see, for example, [17]). Based on all results stated above, we can study now the limit $m \to +\infty$.

THEOREM 4.1 (main convergence theorem). [illegible] 3.1 [illegible] 3.5 3.7 3.9 [illegible] u_m [illegible] (4.8) [illegible] (4.5) [illegible] $m \to +\infty$ [illegible] (2.12) [illegible] $u(0) = u_0$ [illegible] $u_0 \in H$ [illegible]

(4.9)
- $u_m \to u$ [illegible] $L^2(0,T;\mathcal{V})$ [illegible] $L^p(0,T;H)$ [illegible] $T > 0$ [illegible] $1 \le p < \infty$;
- $u_m \to u$ [illegible] $L^\infty(\mathbb{R}^+;H)$ [illegible]

The proof can be found in [17] for a general Hilbert space concept. It outlines the intuition that on the one hand z_m is small compared to u_m, but on the other hand that, at each given time, $z_m(t)$ is a minor correction to $u_m(t)$. Moreover, it turns out that on long intervals of times, z_m modifies u_m in a nonnegligible way.

5. Implementation of the nonlinear Galerkin scheme. Referring to (4.3) and (4.4) we formulate here an algorithm based on an Euler method for the sake of clarity. However, it should be outlined that we use in our numerical implementation an explicit Runge–Kutta-4(5) method.

ALGORITHM 5.1 (nonlinear Galerkin scheme (Euler variant)).
Purpose: Compute an approximation $u_m(t)$, $t \in [t_0, T]$, for some $T > t$ based on an Euler scheme. Let u_0 be the initial value, i.e., $u_0 = u(t_0) \in H$. Moreover, let $t_i = t_0 + ih$ be the time-step with some time-stepping size $h > 0$.

while $t_i \le T$
Compute $z_m = z_m(t_i)$ from $u_m = u_m(t_i)$ and $f = f(t_i)$ by solving the linear system

(5.1)
$$\nu \left\langle Az_m, y^{(3)}_{n,j} \right\rangle_{l^2(\Omega)} + \left\langle Cz_m, y^{(3)}_{n,j} \right\rangle_{l^2(\Omega)} + \left\langle B(u_m, u_m), y^{(3)}_{n,j} \right\rangle_{l^2(\Omega)} = \left\langle f, y^{(3)}_{n,j} \right\rangle_{l^2(\Omega)}$$

for $n = m+1, \dots, 2m; j = -n, \dots, n$. Compute $k = \sum_{n=1}^{m} \sum_{j=-n}^{n} k^{(3)}_{n,j} y^{(3)}_{n,j}$ by solving the linear system for the Fourier coefficients

$$\left\langle k, y^{(3)}_{n,j} \right\rangle_{l^2(\Omega)} = \left\langle f, y^{(3)}_{n,j} \right\rangle_{l^2(\Omega)} - \nu \left\langle Au_m, y^{(3)}_{n,j} \right\rangle_{l^2(\Omega)} - \left\langle Cu_m, y^{(3)}_{n,j} \right\rangle_{l^2(\Omega)} \tag{5.2}$$

$$- \left\langle B(u_m, u_m), y^{(3)}_{n,j} \right\rangle_{l^2(\Omega)} - \left\langle B(z_m, u_m), y^{(3)}_{n,j} \right\rangle_{l^2(\Omega)} - \left\langle B(u_m, z_m), y^{(3)}_{n,j} \right\rangle_{l^2(\Omega)} \tag{5.3}$$

for $n = 1, \dots, m; j = -n, \dots, n$. Continue with the next step

$$u_m(t_{i+1}) = u_m(t_i) + hk$$

end while

The above algorithm requires the computation of coupling integrals, which are of special interest in the case of the Coriolis term and nonlinear advection. In [10] we find the following theorems, which are very cumbersome to establish by the use of Wigner-3j, -6j, and -9j symbols.

THEOREM 5.2 (calculation of the Coriolis term). [illegible] $k,l,n,j \in \mathbb{N}$ [illegible] $k>0$ $r>0$ $n>0$ [illegible] $\omega = |\omega|\varepsilon^3$ [illegible]

$$\int_\Omega \left(\omega \wedge y_{k,l}^{(3)}(\eta)\right) \cdot y_{n,j}^{(3)*}(\eta)\, dS(\eta) = |\omega| i \frac{-l}{n(n+1)} \delta_{k,n}\delta_{l,j}. \tag{5.4}$$

THEOREM 5.3 (calculation of the advection term). [illegible] $k,l,n,j,r,s \in \mathbb{N}$ [illegible] $k>0, r>0$ [illegible] $n>0$ [illegible]

$$\int_\Omega \left[\left(y_{k,l}^{(3)}(\eta)\cdot\nabla_\eta^*\right) y_{r,s}^{(3)}(\eta)\right] \cdot y_{n,j}^{(3)*}(\eta)\, dS(\eta) = T(n,j,r,s,k,l), \tag{5.5}$$

[illegible]

$$\begin{aligned} T(n,j,r,s,k,l) = (-1)^{j+1} i \frac{1}{\sqrt{4\pi}} & \frac{n(n+1)+r(r+1)-k(k+1)}{4\sqrt{r(r+1)n(n+1)k(k+1)}} \\ & \times \begin{pmatrix} r & n & k \\ s & -j & l \end{pmatrix} \sqrt{(2r+1)(2n+1)(2k+1)} \begin{pmatrix} r-1 & n & k \\ 0 & 0 & 0 \end{pmatrix} \\ & \times \sqrt{(n+k+r+1)(k+r-n)(n-k+r)(n+k-r+1)}. \end{aligned}$$

COROLLARY 5.4. [illegible] $3j$ [illegible] (5.5) [illegible]

$$\int_\Omega \left[\left(y_{k,l}^{(3)}(\eta)\cdot\nabla_\eta^*\right) y_{r,s}^{(3)}(\eta)\right] \cdot y_{n,j}^{(3)*}(\eta)\, dS(\eta) = 0,$$

[illegible]

(i) $k > r+n$ [illegible] $k < |r-n|$
(ii) $s+l-j \neq 0$
(iii) $r+n+k$ [illegible]

Now we consider the nonlinear part in (5.1) in more detail by dropping for a moment all other terms. Expanding u in terms of type 3 vector spherical harmonics, we are able to express the Fourier coefficients of z in connection with (5.5) by

$$\tilde{z}_{n,j} = \sum_{r=1}^{N} \sum_{s=-r}^{r} \sum_{k=1}^{N} \sum_{l=-k}^{k} u_{r,s}^{(3)} u_{k,l}^{(3)} T(n,j,r,s,k,l) \tag{5.6}$$

for $n = N+1,\dots,2N; |j| \le n$. Since our considered velocity field of the flow is real-valued, we can restrict the computation to all j with $0 \le j \le n$ and obtain all remaining coefficients for negative orders by antisymmetry. To estimate the number of operations required to compute the coefficients $\tilde{z}_{n,j}$, we assume that the quantity

T has been tabulated beforehand. By exploiting the Wigner-3j selection rule from Corollary 5.4(iii), we have a total of

$$\sum_{n=N+1}^{2N}(n+1)\sum_{r=1}^{N}(2r+1)^2 \approx 2N^5$$

complex × complex × real multiplications, each of them equivalent to six real multiplications. Selection rules for 3j-coefficients with zero bottom row require $r-1+n+k$ to be even, reducing the number of terms in (5.6) by a factor of 2. Thus, the number of real multiplications is about $6N^5$. For each six real multiplications, (5.6) involves two real additions; and thus a total of about $2N^5$ additions.

Since values of N greater than 100 occur in practice (for example, in meteorology, the European Center for Medium-Range Weather Forecast (ECMWF) uses $N=511$; see [22]), it is important to reduce the preceding estimate for the number of operations. Furthermore, the preceding estimate assumes that the coupling integrals have been tabulated in an a priori step. Although Wigner selection rules and symmetries greatly reduce the storage required, the number of storage locations scale like $O(N^5)$.

To improve the scaling for the evaluation of nonlinear terms, several authors [2, 6, 12, 20, 15, 25] introduced FFT techniques to evaluate these so-called vector-coupled sums. The first seems to be Orszag [20] in 1970, whereas James [15] extended Orszag's method to his tensor calculus in 1974. For a detailed overview of pseudospectral methods the reader is referred to Corey and Tromp [6] and the references therein.

5.1. Fast pseudospectral method (FPSM). The extension of Orszag's method to spherical vector and tensor fields can be found by James [15] for his tensor calculus. Unfortunately, his rank-k-tensor approach differs in its basis representation from our philosophy: We like to separate any vector and tensor field into physically meaningful parts, e.g., into tangential and radial components, or to be more specific, into surface gradient and surface curl (toroidal) contributions.

Thus, this section is dedicated to the rapid evaluation of the nonlinear advection term $(u\cdot\nabla^*)u = (\nabla^*\otimes u)^T u$ involving the framework of vectorial and tensorial harmonics. The main advantage of our methods proposed in the following is that they are based on [illegible] integration in the Gauss–Legendre transform (GLT) rather than on solving linear systems as proposed by James [15]. For a detailed description of the vectorial and tensorial variants, algorithms, and examples see [10]. The techniques introduced here allow us to evaluate and reconstruct the advection term in the order $O(N^3)$ instead of the estimate $O(N^5)$ explained above.

Idea. Before formulating the algorithm we sketch for brevity the idea of pseudospectral methods in the vectorial type 3 case. Obviously the evaluation and reconstruction of real type 3 vector fields $u_N^{(3)} \in \mathrm{harm}^{(3)}_{1,\dots,N}(\Omega)$ can be written out as follows:

$$u_N^{(3)} = \sum_{n=1}^{N}\sum_{k=-n}^{n} u_{n,k}^{(3)} y_{n,k}^{(3)}, \tag{5.7}$$

where

$$y_{n,k}^{(3)}(t,\phi) = \frac{(-1)^k}{\sqrt{n(n+1)}}\left[\frac{ik}{\sqrt{1-t^2}}c_{n,k}P_n^k(t)e^{ik\phi}\varepsilon^t - \sqrt{1-t^2}c_{n,k}P_n^{k'}(t)e^{ik\phi}\varepsilon^\phi\right]$$

for $n = 1, \ldots, N; k = 0, \ldots, N$. Thereby, $P_n^{k'}(t)$ denotes the first derivative of $P_n^k(t)$ with respect to t, and in what follows $P_n^{k''}(t)$ will denote the second derivative. Usually, the coefficients $c_{n,k}$ are chosen such that the spherical harmonics are orthonormal with respect to $\langle \cdot, \cdot \rangle_{L^2(\Omega)}$; see, for example, [8]. The negative orders can be obtained by

$$y_{n,-k}^{(3)}(t,\phi) = (-1)^k \left(y_{n,k}^{(3)}(t,\phi) \right)^*, \quad k = 1, \ldots, N.$$

Before entering details of our extended pseudospectral method, we should outline that the occurring singularities at the poles are of removable type [8]. Moreover, we do not expect computational problems, since we use in a latitudinal direction an open Gauss–Legendre quadrature (i.e., the poles do not belong to our integration nodes). The latter fact allows us to handle the terms belonging to ε^ϕ, respectively, ε^t, separately. Since both do not depend on the summations, the problem of reconstructing $u_N^{(3)}$ on the same tensor product grid as introduced above separates outside the poles into two subproblems such that

$$u_N^{(3)} = {}^{\varepsilon^t}u^{(3)}\varepsilon^t + {}^{\varepsilon^\phi}u^{(3)}\varepsilon^\phi.$$

Further, we introduce a vectorial expansion and a corresponding scalar reduction between backward and forward transform. Then, the [illegible] for type 3 vector fields works as follows.

Pseudospectral algorithm for type 3 vector fields. Pseudospectral transforms are essentially based on the [illegible] notation provided by (5.7) by interchanging the summation for n and k. Moreover, we set $y_{0,0}^{(3)} = 0$ and its "Fourier coefficient" $u_{0,0}^{(3)} = 0$ to benefit in a clear algorithmic structure. This introduced [illegible] saves us the analogy to the scalar pseudospectral algorithm (see, for example, [6]). To evaluate $u_N^{(3)} = {}^{\varepsilon^t}u^{(3)}\varepsilon^t + {}^{\varepsilon^\phi}u^{(3)}\varepsilon^\phi$ on the Gauss–Legendre grid [6], we have to compute the quantities

$${}^{\varepsilon^t}u_{*,k}^{(3)}(t_j) = \sum_{n=\max\{|k|,1\}}^{N} u_{n,k}^{(3)} \frac{(-1)^k}{\sqrt{n(n+1)}} \frac{ik}{\sqrt{1-t_j^2}} c_{n,k} P_n^k(t_j),$$

$j = 1, \ldots, N+1; k = 0, \ldots, N$, and

$${}^{\varepsilon^\phi}u_{*,k}^{(3)}(t_j) = \sum_{n=\max\{|k|,1\}}^{N} u_{n,k}^{(3)} \frac{-(-1)^k}{\sqrt{n(n+1)}} \sqrt{1-t_j^2}\, c_{n,k} P_n^{k'}(t_j),$$

$j = 1, \ldots, N+1; k = 0, \ldots, N$.

Since $u_N^{(3)}$ is real, we store ${}^{\varepsilon^t}u_{*,k}^{(3)}(t_j) = ({}^{\varepsilon^t}u_{*,k}^{(3)}(t_j))^*$ in decreasing order $k = N, \ldots, 1$ columnwise. To evaluate finally ${}^{\varepsilon^t}u^{(3)}$ on the Gauss–Legendre grid, we apply an inverse FFT in longitudinal direction (rowwise) and expand by ε^t. The same procedure for ${}^{\varepsilon^\phi}u_{*,k}^{(3)}$, which is associated with ε^ϕ, allows us to reconstruct $u_N^{(3)}(t_j, \phi_i) = {}^{\varepsilon^t}u^{(3)}(t_j, \phi_i)\varepsilon^t + {}^{\varepsilon^\phi}u^{(3)}(t_j, \phi_i)\varepsilon^\phi, j = 1, \ldots, N+1; i = 1, \ldots, 2N+1$.

Conversely, we can determine the Fourier coefficients of $u_N^{(3)}$ by integration: Assume $u_N^{(3)}$ to be real-valued in $\mathrm{harm}_{1,\ldots,N}^{(3)}(\Omega)$, to be given on the grid introduced above. By applying Fubini's theorem, we are able to deduce for the Fourier coefficients $u_{n,k}^{(3)}$

that

(5.8)

$$
\begin{aligned}
u_{n,k}^{(3)} &= \int_{\Omega} u^{(3)}(\eta)\cdot y_{n,k}^{(3)*}(\eta)\; dS(\eta)\\
&= \int_{-1}^{1}\Bigg[\underbrace{\frac{1}{2\pi}\int_0^{2\pi}\left(u^{(3)}(t,\phi)\cdot\varepsilon^{t}\right)e^{-ik\phi}d\phi}_{={}^{\varepsilon^t}u_{*,k}^{(3)}(t)}\Bigg]\frac{(-1)^k}{\sqrt{n(n+1)}}\frac{-ik}{\sqrt{1-t^2}}c_{n,k}P_n^k(t)\,dt\\
&\quad+\int_{-1}^{1}\Bigg[\underbrace{\frac{1}{2\pi}\int_0^{2\pi}\left(u^{(3)}(t,\phi)\cdot\varepsilon^{\phi}\right)e^{-ik\phi}d\phi}_{={}^{\varepsilon^\phi}u_{*,k}^{(3)}(t)}\Bigg]\frac{-(-1)^k}{\sqrt{n(n+1)}}\sqrt{1-t^2}c_{n,k}P_n^{k'}(t)\,dt\\
&= \int_{-1}^{1}{}^{\varepsilon^t}u_{*,k}^{(3)}(t)\frac{(-1)^k}{\sqrt{n(n+1)}}\frac{-ik}{\sqrt{1-t^2}}c_{n,k}P_n^k(t)\,dt\\
&\quad+\int_{-1}^{1}{}^{\varepsilon^\phi}u_{*,k}^{(3)}(t)\frac{-(-1)^k}{\sqrt{n(n+1)}}\sqrt{1-t^2}c_{n,k}P_n^{k'}(t)\,dt.
\end{aligned}
$$

Thus, we can apply an FFT in longitudinal direction to evaluate ${}^{\varepsilon^t}u_{*,k}^{(3)}(t_j), j=1,\dots,N+1$, and ${}^{\varepsilon^\phi}u_{*,k}^{(3)}(t_j), j=1,\dots,N+1$, and an exact integration to evaluate for $n=1,\dots,N; k=0,\dots,N$,

$$
{}^{\varepsilon^t}u_{n,k}^{(3)} = \sum_{j=1}^{N+1} w_j\,{}^{\varepsilon^t}u_{*,k}^{(3)}(t_j)\frac{(-1)^k}{\sqrt{n(n+1)}}\frac{-ik}{\sqrt{1-t_j^2}}c_{n,k}P_n^k(t_j) \tag{5.9}
$$

and

$$
{}^{\varepsilon^\phi}u_{n,k}^{(3)} = \sum_{j=1}^{N+1} w_j\,{}^{\varepsilon^\phi}u_{*,k}^{(3)}(t_j)\frac{-(-1)^k}{\sqrt{n(n+1)}}\sqrt{1-t_j^2}c_{n,k}P_n^{k'}(t_j)
$$

such that

$$
u_{n,k}^{(3)} = {}^{\varepsilon^t}u_{n,k}^{(3)} + {}^{\varepsilon^\phi}u_{n,k}^{(3)}.
$$

Since $u_N^{(3)}$ is real, $u_{n,-k}^{(3)}$ is given by

$$
u_{n,-k}^{(3)} = (-1)^k u_{n,k}^{(3)*}, \quad k=1,\dots,N.
$$

The same strategy can be performed analogously for tensor fields (see [10]). The idea for a fast evaluation of the nonlinear advection is to reconstruct $\nabla^*\otimes u$ and u on the exact integration grid and then to compute in the space domain $(\nabla^*\otimes u)^T u$. Consequently, we transform into the Fourier domain to obtain the corresponding coefficients. In addition, it should be noted that this method also allows the exact separation of vector fields of mixed types, since we apply a polynomially exact integration. This last point is of special importance for the advection.

Before entering into the details of our algorithm we introduce the following abbreviations: For $n=1,\dots,N; k=0,\dots,N$ we define

$$
{}^{\varepsilon^t}d_{n,k}^{(3)}(t) = \frac{(-1)^k}{\sqrt{n(n+1)}}\frac{ik}{\sqrt{1-t^2}}c_{n,k}P_n^k(t), \tag{5.10}
$$

$$
{}^{\varepsilon^\phi}d_{n,k}^{(3)}(t) = -\frac{(-1)^k}{\sqrt{n(n+1)}}\sqrt{1-t^2}c_{n,k}P_n^{k'}(t), \tag{5.11}
$$

where the upper left index reflects the association of these terms to ε^t, respectively, ε^ϕ. For structural simplicity we let ${}^{\varepsilon^t}d^{(3)}_{0,0}(t) = 0$ and ${}^{\varepsilon^\phi}d^{(3)}_{0,0}(t) = 0$ corresponding to the "Fourier coefficient" $u^{(3)}_{0,0} = 0$ operating in the following as a [illegible]. From the idea explained above, it is advisable to have a closer look at the reconstruction of $\nabla^* \otimes u^{(3)} = \mathbf{u}^{(2,3)}$ tensor fields. These tensor fields can be written as

$$\begin{aligned}\mathbf{u}^{(2,3)}(\eta) &= \sum_{n=1}^{N}\sum_{k=-n}^{n} u^{(2,3)}_{n,k}(\nabla^*_\eta \otimes y^{(3)}_{n,k})(\eta)\\ &= \sum_{k=-N}^{N}\sum_{n=\max\{|k|,1\}}^{N} u^{(2,3)}_{n,k}(\nabla^*_\eta \otimes y^{(3)}_{n,k})(\eta).\end{aligned}$$

From (2.1) we have $\mathbf{y}^{(2,3)}_{n,k}(\eta) = (\nabla^*_\eta \otimes y^{(3)}_{n,k})(\eta)$. By some minor calculation we derive a representation of $\mathbf{y}^{(2,3)}_{n,k}$ that allows us again to separate scalar latitudinal and longitudinal terms:

(5.12)

$$\begin{aligned}\mathbf{y}^{(2,3)}_{n,k}(t,\phi) = e^{ik\phi}\Bigg\{ &\\ &\left[\frac{-ik(-1)^k}{\sqrt{n(n+1)}}c_{n,k}P^{k'}_n(t) - \frac{t}{1-t^2}\frac{ik}{\sqrt{n(n+1)}}(-1)^k c_{n,k}P^k_n(t)\right]\varepsilon^\phi\otimes\varepsilon^\phi\\ &+\left[\frac{-k^2}{1-t^2}\frac{1}{\sqrt{n(n+1)}}(-1)^k c_{n,k}P^k_n(t)\right]\varepsilon^\phi\otimes\varepsilon^t\\ &+\left[\frac{t}{\sqrt{n(n+1)}}(-1)^k c_{n,k}P^{k'}_n(t) - \frac{1-t^2}{\sqrt{n(n+1)}}(-1)^k c_{n,k}P^{k''}_n(t)\right]\varepsilon^t\otimes\varepsilon^\phi\\ &+\left[\frac{ik}{\sqrt{n(n+1)}}(-1)^k c_{n,k}P^k_n(t)\right]\varepsilon^t\otimes\frac{\partial}{\partial t}\varepsilon^t\\ &+\left[\frac{-1}{\sqrt{n(n+1)}}(-1)^k c_{n,k}P^{k'}_n(t)\right]\varepsilon^\phi\otimes\frac{\partial}{\partial\phi}\varepsilon^\phi\\ &+\left[\frac{t}{1-t^2}\frac{ik}{\sqrt{n(n+1)}}(-1)^k c_{n,k}P^k_n(t) + \frac{ik}{\sqrt{n(n+1)}}(-1)^k c_{n,k}P^{k'}_n(t)\right]\varepsilon^t\otimes\varepsilon^t\Bigg\}\end{aligned}$$

for $n = 1,\dots,N; k = 0,\dots,N$. The negative orders can be obtained by observing

$$\mathbf{y}^{(2,3)}_{n,-k} = (-1)^k\left(\mathbf{y}^{(2,3)}_{n,k}\right)^*.$$

It turns out that the problem of reconstructing $\mathbf{u}^{(2,3)}$ on the same tensor product grid as introduced above separates into six subproblems, namely,

$$\begin{aligned}\mathbf{u}^{(2,3)} = {}& {}^{\varepsilon^\phi\otimes\varepsilon^\phi}u^{(2,3)}\varepsilon^\phi\otimes\varepsilon^\phi + {}^{\varepsilon^\phi\otimes\varepsilon^t}u^{(2,3)}\varepsilon^\phi\otimes\varepsilon^t + {}^{\varepsilon^t\otimes\varepsilon^\phi}u^{(2,3)}\varepsilon^t\otimes\varepsilon^\phi\\ &+ {}^{\varepsilon^t\otimes\frac{\partial}{\partial t}\varepsilon^t}u^{(2,3)}\varepsilon^t\otimes\frac{\partial}{\partial t}\varepsilon^t + {}^{\varepsilon^\phi\otimes\frac{\partial}{\partial\phi}\varepsilon^\phi}u^{(2,3)}\varepsilon^\phi\otimes\frac{\partial}{\partial\phi}\varepsilon^\phi + {}^{\varepsilon^t\otimes\varepsilon^t}u^{(2,3)}\varepsilon^t\otimes\varepsilon^t.\end{aligned}$$

According to this partition we introduce the following six functions (in analogy to the [illegible] known from quantum mechanics [5]):

(5.13)

$$
\begin{aligned}
{}^{\varepsilon^\phi\otimes\varepsilon^\phi}d_{n,k}^{(2,3)}(t) &= \frac{-ik(-1)^k}{\sqrt{n(n+1)}}c_{n,k}P_n^{k'}(t) - \frac{t}{1-t^2}\frac{ik}{\sqrt{n(n+1)}}(-1)^k c_{n,k}P_n^k(t),\\
{}^{\varepsilon^\phi\otimes\varepsilon^t}d_{n,k}^{(2,3)}(t) &= \frac{-k^2}{1-t^2}\frac{1}{\sqrt{n(n+1)}}(-1)^k c_{n,k}P_n^k(t),\\
{}^{\varepsilon^t\otimes\varepsilon^\phi}d_{n,k}^{(2,3)}(t) &= \frac{t}{\sqrt{n(n+1)}}(-1)^k c_{n,k}P_n^{k'}(t) - \frac{1-t^2}{\sqrt{n(n+1)}}(-1)^k c_{n,k}P_n^{k''}(t),\\
{}^{\varepsilon^t\otimes\frac{\partial}{\partial t}\varepsilon^t}d_{n,k}^{(2,3)}(t) &= \frac{ik}{\sqrt{n(n+1)}}(-1)^k c_{n,k}P_n^k(t),\\
{}^{\varepsilon^\phi\otimes\frac{\partial}{\partial\phi}\varepsilon^\phi}d_{n,k}^{(2,3)}(t) &= \frac{-1}{\sqrt{n(n+1)}}(-1)^k c_{n,k}P_n^{k'}(t),\\
{}^{\varepsilon^t\otimes\varepsilon^t}d_{n,k}^{(2,3)}(t) &= \frac{t}{1-t^2}\frac{ik}{\sqrt{n(n+1)}}(-1)^k c_{n,k}P_n^k(t) + \frac{ik}{\sqrt{n(n+1)}}(-1)^k c_{n,k}P_n^{k'}(t)
\end{aligned}
$$

for $n = 1,\dots,N; k = 0,\dots,N$. Note that the upper left index reflects the association of these terms to the corresponding tensors.

To save us a clear matrix-vector notation, we again introduce dummy elements, viz.,

$$
\begin{aligned}
{}^{\varepsilon^\phi\otimes\varepsilon^\phi}d_{0,0}^{(2,3)}(t) &= 0, & {}^{\varepsilon^\phi\otimes\varepsilon^t}d_{0,0}^{(2,3)}(t) &= 0,\\
{}^{\varepsilon^t\otimes\varepsilon^\phi}d_{0,0}^{(2,3)}(t) &= 0, & {}^{\varepsilon^t\otimes\frac{\partial}{\partial t}\varepsilon^t}d_{0,0}^{(2,3)}(t) &= 0,\\
{}^{\varepsilon^\phi\otimes\frac{\partial}{\partial\phi}\varepsilon^\phi}d_{0,0}^{(2,3)}(t) &= 0, & {}^{\varepsilon^t\otimes\varepsilon^t}d_{0,0}^{(2,3)}(t) &= 0,\\
u_{0,0}^{(2,3)} &= 0.
\end{aligned}
$$

Then, except for the vectorial expansion, the backward transform into the space domain works in analogy to the type 3 vector spherical harmonic case. Accordingly, the vectorial expansion is substituted by the corresponding tensorial expansion.

ALGORITHM 5.5 (FSPM for the nonlinear advection term).
Purpose: The algorithm computes the Fourier coefficients $v_{n,k}^{(3)}$ corresponding to $v = (u\cdot\nabla^*)u = (\nabla^*\otimes u)^T u$. In the first part of this algorithm we evaluate the tensorial term $[(\nabla_\eta^*\otimes u)(\eta)]^T$ and then the vectorial term $u(\eta)$ of the integrand.

We use in the following the Gauss–Legendre integration grid: The grid points (t_j,ϕ_i) are given by $\phi_i = 2\pi(i-1)/(4N+1), i = 1,\dots,4N+1$, and $t_j, j = 1,\dots,2N+1$, where the latter denote the Gauss–Legendre integration nodes with corresponding weights $w_j, j = 1,\dots,2N+1$. This grid yields a cubature rule which allows polynomial exact integration up to degree $2(2N+1)-1 = 4N+1$.

1. [illegible] $(\nabla^*\otimes u)$ [illegible]

(i) Compute the quantities ${}^{\varepsilon^\phi\otimes\varepsilon^\phi}u_{*,k}^{(2,3)}(t_j) = \sum_{n=|k|}^N u_{n,k}^{(3)}\,{}^{\varepsilon^\phi\otimes\varepsilon^\phi}d_{n,k}^{(2,3)}(t_j)$ for $k = 0,\dots,N; j = 1,\dots,2N+1$. This can be achieved by applying an inverse GLT. Assume that the $N+1$ (rectangular) Gauss–Legendre matrices have been tabulated

beforehand. Equipped with them, perform matrix-vector products between

$$ {}^{\varepsilon^\phi\otimes\varepsilon^\phi}D_k^{(2,3)} = \begin{pmatrix} {}^{\varepsilon^\phi\otimes\varepsilon^\phi}d_{k,k}^{(2,3)}(t_1) & {}^{\varepsilon^\phi\otimes\varepsilon^\phi}d_{k+1,k}^{(2,3)}(t_1) & \dots & {}^{\varepsilon^\phi\otimes\varepsilon^\phi}d_{N,k}^{(2,3)}(t_1) \\ {}^{\varepsilon^\phi\otimes\varepsilon^\phi}d_{k,k}^{(2,3)}(t_2) & {}^{\varepsilon^\phi\otimes\varepsilon^\phi}d_{k+1,k}^{(2,3)}(t_2) & \dots & {}^{\varepsilon^\phi\otimes\varepsilon^\phi}d_{N,k}^{(2,3)}(t_2) \\ \vdots & \vdots & & \vdots \\ {}^{\varepsilon^\phi\otimes\varepsilon^\phi}d_{k,k}^{(2,3)}(t_{2N+1}) & {}^{\varepsilon^\phi\otimes\varepsilon^\phi}d_{k+1,k}^{(2,3)}(t_{2N+1}) & \dots & {}^{\varepsilon^\phi\otimes\varepsilon^\phi}d_{N,k}^{(2,3)}(t_{2N+1}) \end{pmatrix} \text{ and} $$

$$ u_{*,k} = \begin{pmatrix} u_{k,k}^{(3)} & u_{k+1,k}^{(3)} & \dots & u_{N,k}^{(3)} \end{pmatrix}^T \tag{5.14} $$

to obtain the vectors

$$ {}^{\varepsilon^\phi\otimes\varepsilon^\phi}D_k^{(2,3)}u_{*,k} = {}^{\varepsilon^\phi\otimes\varepsilon^\phi}u_{*,k}^{(2,3)} \tag{5.15} $$

for $k = 0, \dots, N$. Assume that the column vectors ${}^{\varepsilon^\phi\otimes\varepsilon^\phi}u_{*,k}^{(2,3)}, k = 0, \dots, N$, are stored in the first $N+1$ columns of a $(2N+1) \times (4N+1)$ matrix. Compute ${}^{\varepsilon^\phi\otimes\varepsilon^\phi}u_{*,k}^{(2,3)}$ for the negative orders by

$$ {}^{\varepsilon^\phi\otimes\varepsilon^\phi}u_{*,-k}^{(2,3)}(t_j) = \left({}^{\varepsilon^\phi\otimes\varepsilon^\phi}u_{*,k}^{(2,3)}(t_j) \right)^*, \quad k = 1, \dots, N; j = 1, \dots, 2N+1. $$

Then, store these vectors in descending order in the columns of this matrix starting from the rightmost with order -1. The remaining columns are filled up with zeros:

$$ \left({}^{\varepsilon^\phi\otimes\varepsilon^\phi}u_{*,0}^{(2,3)} \quad \dots \; {}^{\varepsilon^\phi\otimes\varepsilon^\phi}u_{*,N}^{(2,3)} \quad 0 \quad \dots \quad 0 \quad {}^{\varepsilon^\phi\otimes\varepsilon^\phi}u_{*,-N}^{(2,3)} \quad \dots \quad {}^{\varepsilon^\phi\otimes\varepsilon^\phi}u_{*,-1}^{(2,3)} \right). $$

(ii) Apply rowwise an inverse FFT and obtain immediately the grid values ${}^{\varepsilon^\phi\otimes\varepsilon^\phi}u^{(2,3)}(t_j, \phi_i), j = 1, \dots, 2N+1; i = 1, \dots, 4N+1$.

2. Repeat the last step analogously for

$$ {}^{\varepsilon^\phi\otimes\varepsilon^t}d_{n,k}^{(2,3)}, \; {}^{\varepsilon^t\otimes\varepsilon^\phi}d_{n,k}^{(2,3)}, \; {}^{\varepsilon^t\otimes\frac{\partial}{\partial t}\varepsilon^t}d_{n,k}^{(2,3)}, \; {}^{\varepsilon^\phi\otimes\frac{\partial}{\partial\phi}\varepsilon^\phi}d_{n,k}^{(2,3)}, \; {}^{\varepsilon^t\otimes\varepsilon^t}d_{n,k}^{(2,3)} $$

to obtain the quantities ${}^{\varepsilon^\phi\otimes\varepsilon^t}u^{(2,3)}$, ${}^{\varepsilon^t\otimes\varepsilon^\phi}u^{(2,3)}$, ${}^{\varepsilon^t\otimes\frac{\partial}{\partial t}\varepsilon^t}u^{(2,3)}$, ${}^{\varepsilon^\phi\otimes\frac{\partial}{\partial\phi}\varepsilon^\phi}u^{(2,3)}$, and ${}^{\varepsilon^t\otimes\varepsilon^t}u^{(2,3)}$ evaluated on the grid $\{t_j, \phi_i\}, j = 1, \dots, 2N+1; i = 1, \dots, 4N+1$.

3. [illegible] Compute the desired tensor on the grid by

$$ \begin{aligned} \mathbf{u}^{(2,3)}(t_j, \phi_i) = {} & [\, {}^{\varepsilon^\phi\otimes\varepsilon^\phi}u^{(2,3)}\varepsilon^\phi \otimes \varepsilon^\phi](t_j, \phi_i) + [\, {}^{\varepsilon^\phi\otimes\varepsilon^t}u^{(2,3)}\varepsilon^\phi \otimes \varepsilon^t](t_j, \phi_i) \\ & + [\, {}^{\varepsilon^t\otimes\varepsilon^\phi}u^{(2,3)}\varepsilon^t \otimes \varepsilon^\phi](t_j, \phi_i) + [\, {}^{\varepsilon^t\otimes\frac{\partial}{\partial t}\varepsilon^t}u^{(2,3)}\varepsilon^t \otimes \varepsilon^{\frac{\partial}{\partial t}}] \\ & + [\, {}^{\varepsilon^\phi\otimes\frac{\partial}{\partial\phi}\varepsilon^\phi}u^{(2,3)}\varepsilon^\phi \otimes {}^{\frac{\partial}{\partial\phi}}\varepsilon^\phi](t_j, \phi_i) + [\, {}^{\varepsilon^t\otimes\varepsilon^t}u^{(2,3)}\varepsilon^t \otimes \varepsilon^t](t_j, \phi_i) \end{aligned} $$

for $j = 1, \dots, 2N+1; i = 1, \dots, 4N+1$.

4. [illegible]

(i) Compute the quantities ${}^{\varepsilon^t}u_{*,k}^{(3)}(t_j) = \sum_{n=|k|}^N u_{n,k}\, {}^{\varepsilon^t}d_{n,k}^{(3)}(t_j)$ for $k = 0, \dots, N$; $j = 1, \dots, 2N+1$. This can be achieved by applying an inverse GLT. Assume that the $N+1$ (rectangular) Gauss–Legendre matrices have been tabulated beforehand. Analogously to (5.15) we perform matrix-vector products between

$$ {}^{\varepsilon^t}D_k^{(3)} = \begin{pmatrix} {}^{\varepsilon^t}d_{k,k}^{(3)}(t_1) & {}^{\varepsilon^t}d_{k+1,k}^{(3)}(t_1) & \dots & {}^{\varepsilon^t}d_{N,k}^{(3)}(t_1) \\ {}^{\varepsilon^t}d_{k,k}^{(3)}(t_2) & {}^{\varepsilon^t}d_{k+1,k}^{(3)}(t_2) & \dots & {}^{\varepsilon^t}d_{N,k}^{(3)}(t_2) \\ \vdots & \vdots & & \vdots \\ {}^{\varepsilon^t}d_{k,k}^{(3)}(t_{2N+1}) & {}^{\varepsilon^t}d_{k+1,k}^{(3)}(t_{2N+1}) & \dots & {}^{\varepsilon^t}d_{N,k}^{(3)}(t_{2N+1}) \end{pmatrix} $$

and $u_{*,k}$ from (5.14) to obtain the vectors

$$ {}^{\varepsilon^t}D_k^{(3)} u_{*,k} = {}^{\varepsilon^t}u_{*,k}^{(3)} \tag{5.16} $$

for $k = 0, \ldots, N$. Assume that the column vectors ${}^{\varepsilon^t}u_{*,k}^{(3)}, k = 0, \ldots, N$ are stored in the first $N+1$ columns of a $(2N+1) \times (4N+1)$ matrix. Compute ${}^{\varepsilon^t}u_{*,k}^{(3)}$ for the negative orders by

$$ {}^{\varepsilon^t}u_{*,-k}^{(3)}(t_j) = \Big({}^{\varepsilon^t}u_{*,k}^{(3)}(t_j) \Big)^*, \quad k = 1, \ldots, N; j = 1, \ldots, 2N+1. $$

Then, store these vectors in descending order in the columns of this matrix starting from the rightmost with order -1. The remaining columns are filled up with zeros:

$$ \Big({}^{\varepsilon^t}u_{*,0}^{(3)} \quad \ldots \quad {}^{\varepsilon^t}u_{*,N}^{(3)} \quad 0 \quad \ldots \quad 0 \quad {}^{\varepsilon^t}u_{*,-N}^{(3)} \quad \ldots \quad {}^{\varepsilon^t}u_{*,-1}^{(3)} \Big). $$

(ii) Apply rowwise an inverse FFT and obtain immediately the grid values ${}^{\varepsilon^t}u^{(3)}(t_j, \phi_i), j = 1, \ldots, 2N+1; i = 1, \ldots, 4N+1$.

5. Repeat the last step analogously for ${}^{\varepsilon^\phi}d_{n,k}^{(3)}(t)$ to obtain the quantities ${}^{\varepsilon^\phi}u^{(3)}(t_j, \phi_i)$ evaluated on the grid $\{(t_j, \phi_i)\}, j = 1, \ldots, 2N+1; i = 1, \ldots, 4N+1$.

6. [illegible] Compute the desired vector field on the grid by

$$ u(t_j, \phi_i) = [\,{}^{\varepsilon^t}u^{(3)} \varepsilon^t](t_j, \phi_i) + [\,{}^{\varepsilon^\phi}u^{(3)} \varepsilon^\phi](t_j, \phi_i) $$

for $j = 1, \ldots, 2N+1; i = 1, \ldots, 4N+1$.

7. [illegible] $(\nabla \otimes u)^T u$ [illegible] Compute on the grid the vector field v:

$$ v(t_j, \phi_i) = \big[(\mathbf{u}^{(2,3)})^T u\big](t_j, \phi_i), j = 1, \ldots, 2N+1; i = 1, \ldots, 4N+1. $$

8. [illegible] Form the inner product with $\varepsilon^t(t_j, \phi_i), j = 1, \ldots, N+1; i = 1, \ldots, 2N+1$, which projects the vector field on its ${}^{\varepsilon^t}v$ content. Analogously, we obtain the projection on its ${}^{\varepsilon^\phi}v$ content. It should be remarked that v is a vector field of mixed type, namely, of types 2 and 3. By using implicitly a polynomial exact integration against $y_{n,k}^{(3)}$ we are able to separate the desired type 3 part.

9. [illegible] To transform into the Fourier domain, we apply rowwise a forward FFT to determine the quantities ${}^{\varepsilon^t}v_{*,k}(t_j), j = 1, \ldots, 2N+1; k = 0, \ldots, 2N$. This corresponds to the first $2N+1$ column vectors ${}^{\varepsilon^t}v_{*,k}$.

We conclude the algorithm by applying the forward GLT by computing the $2N+1$ matrix-vector products between

$$ {}^{\varepsilon^t}\widetilde{D}_k^{(3)} = \frac{2\pi}{4N+1} \begin{pmatrix} w_1\, {}^{\varepsilon^t}d_{k,k}^{(3)}(t_1) & w_2\, {}^{\varepsilon^t}d_{k,k}^{(3)}(t_2) & \ldots & w_n\, {}^{\varepsilon^t}d_{k,k}^{(3)}(t_{2N+1}) \\ w_1\, {}^{\varepsilon^t}d_{k+1,k}^{(3)}(t_1) & w_2\, {}^{\varepsilon^t}d_{k+1,k}^{(3)}(t_2) & \ldots & w_n\, {}^{\varepsilon^t}d_{k+1,k}^{(3)}(t_{2N+1}) \\ \vdots & \vdots & & \vdots \\ w_1\, {}^{\varepsilon^t}d_{2N,k}^{(3)}(t_1) & w_2\, {}^{\varepsilon^t}d_{2N,k}^{(3)}(t_2) & \ldots & w_n\, {}^{\varepsilon^t}d_{2N,k}^{(3)}(t_{2N+1}) \end{pmatrix} $$

and ${}^{\varepsilon^t}v_{*,k}$ to obtain the the Fourier coefficients corresponding to ε^t,

$$ {}^{\varepsilon^t}\widetilde{D}_k^{(3)} \begin{pmatrix} {}^{\varepsilon^t}v_{*,k}(t_1) \\ {}^{\varepsilon^t}v_{*,k}(t_2) \\ \vdots \\ {}^{\varepsilon^t}v_{*,k}(t_{2N+1}) \end{pmatrix} = \begin{pmatrix} {}^{\varepsilon^t}v_{k,k} \\ {}^{\varepsilon^t}v_{k+1,k} \\ \vdots \\ {}^{\varepsilon^t}v_{2N,k} \end{pmatrix} \tag{5.17} $$

for $k = 0, \ldots, 2N$. Analogously, we find ${}^{\varepsilon^\phi}v_{n,k}, n = 0, \ldots, 2N; k = 0, \ldots, n$, such that we finally get the type 3 Fourier coefficients of v by

$$v^{(3)}_{n,k} = {}^{\varepsilon^t}v_{n,k} + {}^{\varepsilon^\phi}v_{n,k}, \qquad n = 0, \ldots, 2N; k = 0, \ldots, n,$$

and with

$$v^{(3)}_{n,-k} = (-1)^k \left(v^{(3)}_{n,k}\right)^*, \qquad k = 1, \ldots, n,$$

the negative orders, since v is real.

Algorithmic effort. We have to perform six GLTs to reconstruct the tensor on the grid and two GLTs for the velocity field u. Beyond that, we have for the transform back into the Fourier domain two additional GLTs, which yields finally for the storage of the a priori calculated GLT matrices

$$(6+2)\sum_{k=0}^{N}(2N+1)(N-k+1) + 2\sum_{k=0}^{2N}(2N+1)(2N-k+1) \approx 16N^3. \tag{5.18}$$

The algorithmic effort scales analogously with $O(N^3)$. Namely, the $N+1$, respectively, $2N+1$, matrix-vector products in (5.15), (5.16), and (5.17) cost

$$(6+2)\sum_{k=0}^{N}(2N+1)(N-k+1) + 2\sum_{k=0}^{2N}(2N+1)(2N-k+1) \approx 16N^3$$

real $\times$ complex multiplications, each of which is equivalent to two real multiplications. Additionally, we have twice as many complex–complex additions, which are equivalent to two real additions. Thus, the GLT leads us to about $32N^3$ real multiplications, and about $64N^3$ real additions. In between, the complex FFTs (not necessarily complex: one could also use complex-to-real and real-to-complex FFTs) each require about $8N \log_2 N$ real multiplications, and $12N \log_2 N$ real additions. Thus all FFTs require $(6+2+2)(2N+1)8N \log_2 N \approx 160N^2 \log_2 N$ multiplications and $(6+2+2)(2N+1)12N \log_2 N \approx 240N^2 \log_2 N$ additions. Keeping in mind that we have $\approx 8N^2$ grid points, the vectorial and tensorial expansion, the remaining matrix-vector product in the space domain, and then the scalar reduction (see step 8 in Algorithm 5.5) requires approximately

$$8N^2(6 \cdot 9 + 2 \cdot 3 + 9 + 2 \cdot 3) \approx 600N^2$$

complex $\times$ complex multiplications, which is equivalent to $2400N^2$ real multiplications and $1200N^2$ real additions. Obviously, the algorithm profits from the semilinear scaling of the FFTs. Thus, the whole procedure is dominated by the GLT and scales with $O(N^3)$, while the break-even point is approximately at $N = 12$. Since we use in our simulations (also with respect to applications in meteorology) much larger basis sets, we obtain, for example, at $N = 100$ a speedup factor of 500!

6. Numerical results. In this section we report numerical results obtained by using the nonlinear Galerkin method. To demonstrate the efficiency of our method, we study an example that is motivated by [7] for a toroidal domain, i.e., the two-dimensional periodic case. However, we study here an extension of [7] to the rotating sphere by involving a Coriolis term and, moreover, time-dependent flow driving forces. Finally, we compare the nonlinear Galerkin method with the linear one, which can be obtained by setting $z_m = 0$.

Description of the computations. The initial condition $u_0 = u_0/\|u_0\|_{l^\Omega}$ with $u_0 = \sum_{n=1}^{20} \sum_{k=-n}^{n} u_{n,k}^{(3)} y_{n,k}^{(3)}$ is computed from a given spectrum given by

$$u_{n,k}^{(3)} = \frac{2}{n + (\sqrt{\nu} n)^5} e^{i\theta_k} \qquad \text{for} \quad n = 1, \dots, 20; k = 0, \dots, n,$$

where $\theta_0 = 0$, and $\theta_k, k = 1, \dots, n$, is generated by a random function. The negative orders are obtained by $u_{n,-k} = (-1)^k u_{n,k}^*$. The viscosity ν is set to $\nu = 10^{-4}$. This example is chosen in analogy to [7]. Obviously, the initial spectrum decays like n^{-1}. As Figure 6.1 shows, the flow has no organized structures and visible vortices. Moreover, the flow is driven by some time-dependent (decaying) external force f, given by

$$f(t, \eta) = \gamma(t) y_{3,0}^{(3)}(\eta), \qquad \eta \in \Omega,$$

with

$$\gamma(t) = \begin{cases} 1 & \text{for } t \in [0, 10] \\ \cos(\pi/5t) e^{-(t-10)/5} & \text{for } t \in (10, 60]. \end{cases}$$

In order to describe all the scales of motion, the spherical harmonics degree k_N must be chosen so that an associated (spherical grid) size $2\pi/N$ is smaller than the dissipative (Kraichnan) scale l_η; in terms of the spherical harmonic degree it means $k_N > k_\eta$. We recall that under the dissipative scales the motion is damped by viscosity. In fact, the total number of degrees of freedom needed to describe the motion, from dissipative scales to large scales containing eddies, can be estimated by the ratio $(k_\eta/k_N)^2$ (see, for example, [7]).

This quantity is related to the dimension of the attractor of the Navier–Stokes equations

$$\left(\frac{k_\eta}{k_N}\right)^2 \approx \mathrm{Re},$$

where Re is the integral scale Reynolds number. The Reynolds number can be defined by

$$\mathrm{Re} = \frac{LU}{\nu},$$

where U denotes the [illegible] velocity of the flow, and $L = 1/k_N$ the integral length scale defined by

$$L = \frac{U}{\sqrt{2}\eta^{1/3}}$$

with $\eta = \nu \|\Delta^* u\|_{l^2(\Omega)}^2 / |\Omega|$. Then $L \approx 0.7$ and $U \approx 0.3$, so that $\mathrm{Re} \approx 2100$. The dissipative wave number can be estimated by $k_\eta^2 = \mathrm{Re} \cdot k_N^2$ such that $k_\eta \approx 50$. Finally we take the angular velocity $|\omega| = 2.0$ such that the Rossby number relating the advection and Coriolis term reads as follows:

$$R_o = \frac{U}{L|\omega|} \approx 0.2.$$

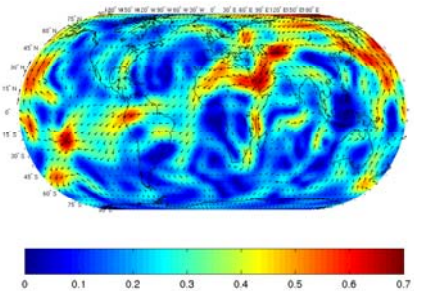

FIG. 6.1. *Initial flow velocity at* $t = 0$.

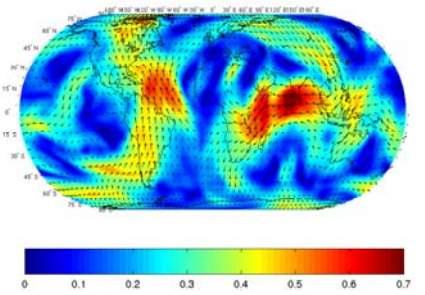

FIG. 6.2. *Flow at* $t = 5$.

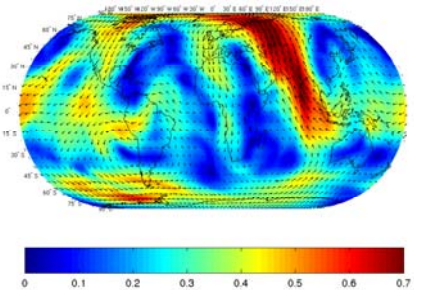

FIG. 6.3. *Flow velocity at* $t = 10$.

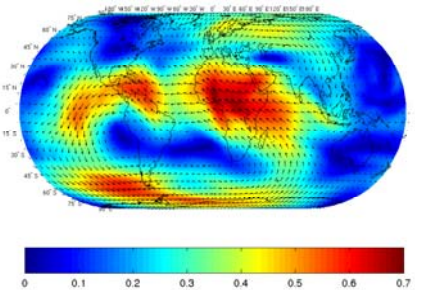

FIG. 6.4. *Flow velocity at* $t = 20$.

Obviously, this Rossby number is not much smaller than 1, which indicates that the Coriolis term is in the same order as the advection term. In order to be sure to resolve all the scales of the considered flow, we set the truncation level to a spherical harmonic degree of 100. According to (4.1) and (4.2) this truncation level corresponds to $m = 50$. In detail, the low-frequency approximation u_{50} is represented by spherical harmonics up to degree 50, whereas the high-frequency approximation z_{50} covers the terms up to degree 100. The results for the flow velocity of our simulation is plotted in Figures 6.1–6.8.

Now, it appears that the dissipation wave number k_η is of order 42 and varies slightly between 40 and 45 during the computation. Hence, the previous estimate based on the dimension of the attractor matches the computational results. We also remark that if, at $t = 0$, the small scales corresponding to a spherical harmonic degree larger than 20 are set to zero, then a dissipation range appears very quickly, as we can see in Figure 6.9 at $t = 5$. The enstrophy transfer from the large scales to the small ones acts on the smallest scales after a few iterations. Figure 6.10, illustrating $\|z_{50}\|_{l^2(\Omega)}$, indicates that this transition period is very short. After this period, the smaller scales are damped by viscosity until an equilibrium between viscous and nonlinear terms appears. Thenceforward, we can see that $\|z_{50}\|_{l^2(\Omega)}$ develops completely independently of $\|u_{50}\|_{l^2(\Omega)}$; see Figure 6.10. The $l^2(\Omega)$-norm of the Galerkin approximation u_{50} depends also on the forcing term f which varies over time. This dependency is illustrated in Figure 6.10, which shows also $\gamma(t)$. It is interesting to note that at $t \approx 30$ the viscous term dominates the external force f, and the energy decays.

As Figures 6.1–6.8 show the small random structures of the flow at the initial time disappear quickly; fusions of these very small structures lead to larger ones. So,

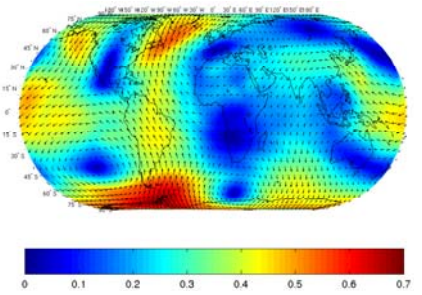

FIG. 6.5. *Flow velocity at* $t = 30$.

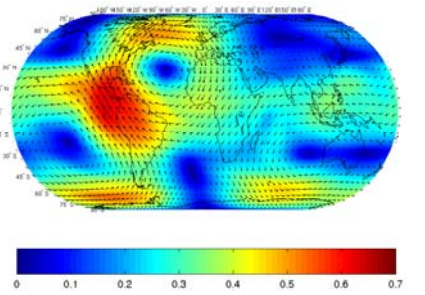

FIG. 6.6. *Flow velocity at* $t = 40$.

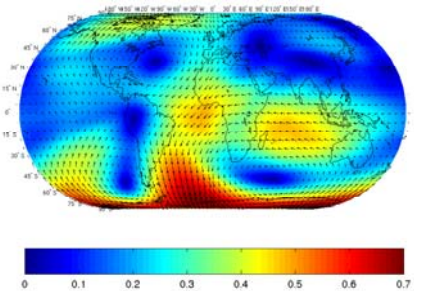

FIG. 6.7. *Flow velocity at* $t = 50$.

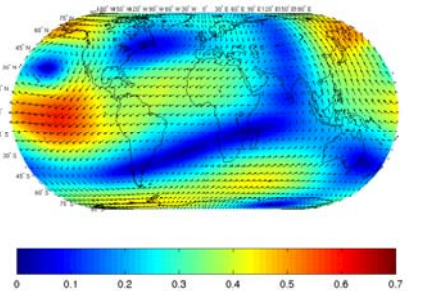

FIG. 6.8. *Flow velocity at* $t = 60$.

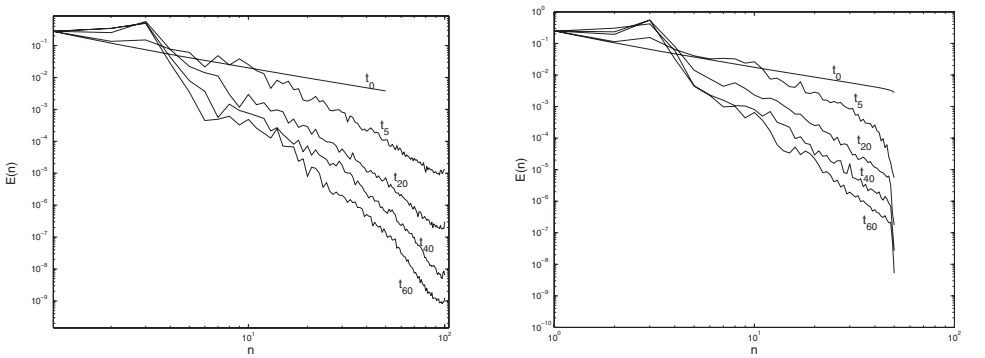

FIG. 6.9. *Comparison of the energy spectrum* $E(n)$ *for the linear (left) and for the nonlinear (right) Galerkin method with truncation level* $N = 100$ *at different time-steps.*

after a transient period, the flow is mainly constituted by large structures.

This can also be studied by looking at the energy spectrum; see Figure 6.9. The energy spectrum is given by

$$E(n) = \sum_{k=-n}^{n} |u_{n,k}^{(3)}|^2,$$

showing the energy contained in each degree averaged over all orders. It is interesting to note that after a short transient time an initial range is appearing. And we note that more and more energy is transferred into the low-frequency parts of the flow

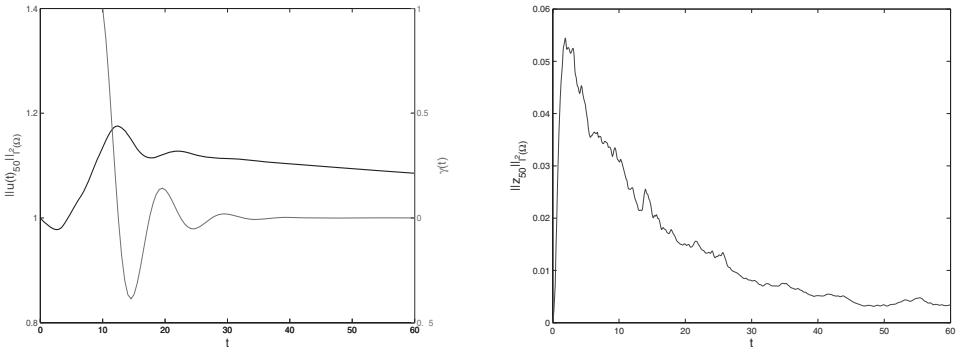

FIG. 6.10. *Time evolution of* $\|u_{50}(t)\|_{l^2(\Omega)}$ *and* $\gamma(t)$ *(left) and of* $\|z_{50}(t)\|_{l^2(\Omega)}$ *(right).*

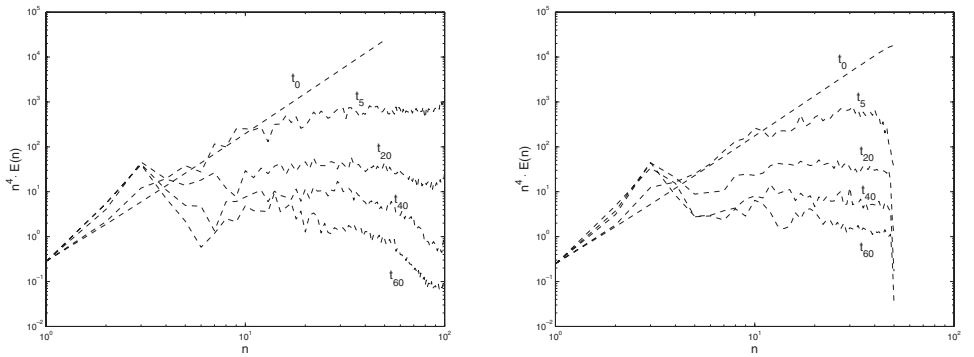

FIG. 6.11. *Comparison of the decay of the energy spectrum* $E(n)$ *of the linear Galerkin method (left) and the nonlinear Galerkin method (right) with truncation level* $N = 100$ *at different time-steps. We observe an* n^{-4}*-decay in both energy spectra after some eddy-turnover times.*

(large eddies). Moreover, let us study the energy decay of the Fourier modes from Figure 6.11. From this illustration we observe an approximate n^{-4}-decay that was also reported by Temam [7] for a flow in a two-dimensional, periodic geometry, i.e., on a torus. Evidently, the decay of energy is more rapid than the n^{-3}-decay predicted by Kraichnan's phenomenological theory of turbulence [16]. But our results are in agreement with the ones obtained by Brachet et al. [4] and Orszag [21], who show that an n^{-3}-energy spectrum can only be obtained when the Reynolds number is much larger, e.g., of the order of 2.5×10^4 (see [21]).

The time-step is chosen according to accuracy and stability considerations. To ensure the stability, the time-step h must satisfy a CFL condition like

$$hN\|u\|_{l^\infty(\Omega)} < 1. \tag{6.1}$$

Having tracked the $l^\infty(\Omega)$-norm of u on a grid, $\|u\|_{l^\infty(\Omega)}$ reached a maximum of 0.72 satisfying (6.1). Since we used a Runge–Kutta solver of fourth order for the time-integration, a time-step of 10^{-3} allows most of the spectrum to be recovered. Thus, the global accuracy is then of order 10^{-12}.

With the characteristic length scale L and velocity U, we define a characteristic

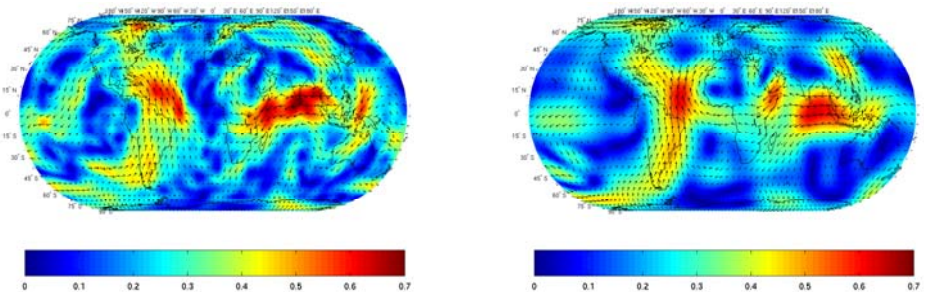

FIG. 6.12. *Comparison of the velocity structures obtained with the linear Galerkin method (left) and the nonlinear Galerkin method (right) at truncation level* $N = 30$ *and time* $t = 5$.

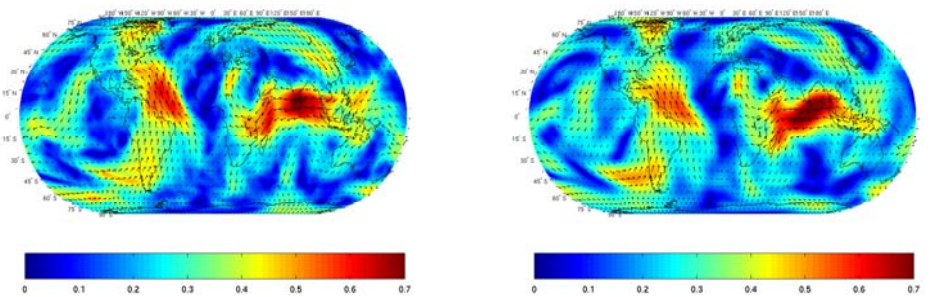

FIG. 6.13. *Comparison of the velocity structures obtained with the linear Galerkin method (left) and the nonlinear Galerkin method (right) at truncation level* $N = 50$ *and time* $t = 5$.

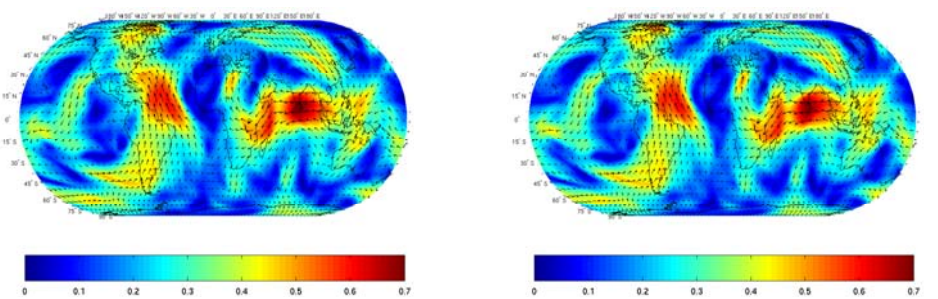

FIG. 6.14. *Comparison of the velocity structures obtained with the linear Galerkin method (left) and the nonlinear Galerkin method (right) at truncation level* $N = 100$ *and time* $t = 5$.

time unit by the ratio

$$\tau = \frac{L}{U},$$

which is called eddy-turnover time. This quantity is of order 2.33 for the flow considered. We have let the flow evolve over 6×10^4 iterations, i.e., on the time interval $[0, 60]$, which corresponds to more than 25 time units. The code has been implemented in Fortran 90 using Intel's Fortran compiler and the Math Kernel Library (MKL) to perform the FFTs and BLAS calls. The computation required more than 120 hours of CPU time on a Pentium 4 (3.2 GHz) processor, not counting all the preliminary tests needed to develop and improve the algorithm.

Mesh refinement and comparison to the linear Galerkin method. The strength of the nonlinear Galerkin method is to represent the considered flow with fewer degrees of freedoms than required by a linear Galerkin scheme. This is observed by obtaining similar results for the same problem in less time. In detail, we compare at a fixed time $t = 5$ and at different truncation levels $N = \{30, 50, 100\}$ the linear and nonlinear schemes in Figures 6.12–6.14. In the case of the linear Galerkin method the [illegible] N denotes that all scales of motion up to degree N are resolved. The mesh refinement indicates for both schemes that they are stable: In detail, we see in Figure 6.12 that the linear Galerkin method shows some high-frequency flicker that is induced by higher frequency scales of u_0 that are not resolved. This flicker becomes less for $N = 50$ and disappears when the truncation level is increased to $N = 100$; see Figures 6.13 and 6.14. Moreover, it should be outlined that the nonlinear method is about 20% faster than the linear Galerkin method (for the same resolution). Finally, a closer look at the tails of the energy spectrum in Figures 6.9 and 6.11 shows a small increase in the Fourier coefficients in the case of the linear method. This effect is known as [illegible] and is induced by aliasing effects; see Figure 6.13 and, for example, Boyd [3]. In Figure 6.14 we observe a rapid decrease in the tails of the energy spectrum. This effect is inherent to nonlinear Galerkin methods and is known as [illegible], which stabilizes the whole solution procedure (see [3, 7]).

Concluding remarks. In this work we introduced a nonlinear Galerkin method which was applied to the inhomogenous, incompressible Navier–Stokes equation on the sphere. The arising coupling terms were expressed by Wigner-3j symbols known from quantum mechanics. To increase the efficiency, we extended the idea of FFT-based pseudospectral algorithms to the rapid evaluation of the considered type 3 vector and tensor fields. This allowed us to compute in each time-step the coupling integrals of the nonlinear advection term at once, yielding finally an $O(N^3)$ method. Finally, we demonstrated the algorithm in an extensive numerical example including the Coriolis term. At last, we like to point the reader's attention to the segmentation of the energy spectrum in Figure 6.9. While the inertial range shows a power-law spectrum, the dissipative range shows an exponential decay. This result fits excellently into the phenomenological theory of turbulence by Kraichnan [16] and differs from the linear Galerkin method. In the latter case the energy spectrum does not show a distinct segmentation into an inertial and dissipative range (for more illustrations, see [7, 10]). A challenge for the future is to extend the algorithm to the full set of equations noted in (2.6)–(2.9) in the compressible case.

A COMPARISON OF TROUBLED-CELL INDICATORS FOR RUNGE–KUTTA DISCONTINUOUS GALERKIN METHODS USING WEIGHTED ESSENTIALLY NONOSCILLATORY LIMITERS*

JIANXIAN QIU† AND CHI-WANG SHU‡

Abstract. In [*SIAM J. Sci. Comput.*, 26 (2005), pp. 907–929], we initiated the study of using WENO (weighted essentially nonoscillatory) methodology as limiters for the RKDG (Runge–Kutta discontinuous Galerkin) methods. The idea is to first identify "troubled cells," namely, those cells where limiting might be needed, then to abandon all moments in those cells except the cell averages and reconstruct those moments from the information of neighboring cells using a WENO methodology. This technique works quite well in our one- and two-dimensional test problems [*SIAM J. Sci. Comput.*, 26 (2005), pp. 907–929] and in the follow-up work where more compact Hermite WENO methodology is used in the troubled cells. In these works we used the classical minmod-type TVB (total variation bounded) limiters to identify the troubled cells; that is, whenever the minmod limiter attempts to change the slope, the cell is declared to be a troubled cell. This troubled-cell indicator has a TVB parameter M to tune and may identify more cells than necessary as troubled cells when M is not chosen adequately, making the method costlier than necessary. In this paper we systematically investigate and compare a few different limiter strategies as troubled-cell indicators with an objective of obtaining the most efficient and reliable troubled-cell indicators to save computational cost.

Key words. Runge–Kutta discontinuous Galerkin method, limiters, weighted essentially nonoscillatory finite volume scheme, high-order accuracy

1. Introduction.

In [13], we initiated the study of using weighted essentially nonoscillatory (WENO) methodology as limiters for the Runge–Kutta discontinuous Galerkin (RKDG) methods. The idea is to first identify "troubled cells," namely, those cells where limiting might be needed, then to abandon all moments in those cells except the cell averages and reconstruct those moments from the information of neighboring cells using a WENO methodology. This technique works quite well in our one- and two-dimensional test problems [13] and in the follow-up work [14] and [15], where more compact Hermite WENO methodology was used in the troubled cells. In these earlier works we adopted the classical minmod-type total variation bounded (TVB) limiters as in [5, 3, 7] to identify the troubled cells; that is, whenever the minmod limiter attempts to change the slope, the cell is declared to be a troubled cell. This troubled-cell indicator has a TVB parameter M to tune. When M is taken too small, more cells than necessary may be identified as troubled cells. Even though

the WENO reconstruction procedure used in these cells will not degrade the order of accuracy of the original RKDG scheme, the extra work done for these WENO reconstructions in such wrongly identified troubled cells increases the cost of the algorithm. On the other hand, when M is taken too large, some of the real troubled cells may not be identified, resulting in oscillations or even instability for the method. In this paper we systematically investigate and compare a few different limiter strategies as troubled-cell indicators with an objective of trying to obtain the most efficient and reliable troubled-cell indicators to save the computational cost.

The first discontinuous Galerkin (DG) method was introduced in 1973 by Reed and Hill [16] in the framework of neutron transport (steady-state linear hyperbolic equations). A major development of the DG method was carried out by Cockburn et al. in a series of papers [6, 5, 4, 3, 7], in which they established a framework to easily solve , , , time-dependent hyperbolic conservation laws,

$$\begin{cases} u_t + \nabla \cdot f(u) = 0, \\ u(x,0) = u_0(x), \end{cases} \tag{1.1}$$

using explicit, nonlinearly stable high-order Runge–Kutta time discretizations [20] and DG discretization in space with exact or approximate Riemann solvers as interface fluxes and TVB limiter [18] to achieve nonoscillatory properties for strong shocks. These schemes are termed RKDG methods.

An important component of RKDG methods for solving conservation laws (1.1) with strong shocks in the solutions is a nonlinear limiter, which is applied to detect discontinuities and control spurious oscillations near such discontinuities. Many such limiters have been used in the literature on RKDG methods. For example, we mention the minmod-type TVB limiter [6, 5, 4, 3, 7], which is a slope limiter using a technique borrowed from the finite volume methodology; the moment-based limiter [1] and an improved moment limiter [2], which are specifically designed for DG methods and work on the moments of the numerical solution. These limiters tend to degrade accuracy when mistakenly used in smooth regions of the solution. More recently, a strategy was designed in [12], based on a strong superconvergence at the outflow boundary of each element in smooth regions for the discontinuous Galerkin method, to detect discontinuities and to lower the order of accuracy in the approximation there to avoid spurious oscillations near such discontinuities when solving hyperbolic systems of conservation laws. There are also many limiters developed in the finite volume and finite difference literature, such as the various flux limiters [23], the monotonicity-preserving (MP) limiters [22], modifications of MP limiters [17], and a discontinuity detecting method [9] used to sharpen contact discontinuities in ENO schemes.

In [13], we initiated a study of using WENO methodology as limiters for RKDG methods. We have adopted the following framework.

, , 1. First we identify the "troubled cells," namely, those cells which might need the limiting procedure.

, , 2. Then we replace the solution polynomials in those troubled cells by reconstructed polynomials using WENO methodology which maintain the original cell averages (conservation), have the same orders of accuracy as before, but are less oscillatory.

This technique works quite well in our one- and two-dimensional test problems in [13] and in the follow-up work [14] and [15], where a more compact Hermite WENO methodology was used in the troubled cells. The emphasis of all these works is on Step 2, where different WENO reconstruction strategies are considered. Step 1 is

dealt with by the classical minmod-type TVB limiters as in [5, 3, 7] to identify the troubled cells. It is realized that the TVB parameter M must be chosen carefully in order to reach a nonoscillatory result with the minimal number of troubled cells. However, Step 1 is not investigated in detail in [13, 14, 15].

We do want to point out a fact, which was also highlighted in [13, 14, 15], that since the WENO reconstruction procedure in Step 2 maintains the high-order accuracy of the original RKDG scheme, it is less crucial for Step 1 to identify exactly the troubled cells. If more troubled cells are identified than necessary, the order of accuracy will not degrade, although the computational cost will increase.

In this paper we concentrate on Step 1 in the procedure above, and investigate systematically a few discontinuity detecting methods as troubled-cell indicators. We also test a new discontinuity detecting method based on the subcell resolution idea of Harten [9]. For Step 2 in the procedure above, we simply use the regular WENO reconstruction procedure developed in [13]. We review and describe the details of a few discontinuity detecting methods in section 2, and present extensive numerical results in section 3 to compare their performance as troubled-cell indicators. Concluding remarks are given in section 4.

2. Review and implementation of discontinuity detecting methods. In this section we review a few discontinuity detecting methods to identify troubled cells. We also develop a new discontinuity detecting method based on the subcell resolution method of Harten [9].

We start with the description in the one-dimensional case and use the notation in [5]; however, we emphasize that the procedure described below does not depend on the specific basis chosen for the polynomials and works also in multidimensions. We would like to solve the one-dimensional scalar conservation law:

$$\begin{cases} u_t + f(u)_x = 0, \\ u(x,0) = u_0(x). \end{cases} \tag{2.1}$$

The computational domain is divided into N cells with boundary points $0 = x_{\frac{1}{2}} < x_{\frac{3}{2}} < \cdots < x_{N+\frac{1}{2}} = L$. The points x_i are the centers of the cells $I_i = [x_{i-\frac{1}{2}}, x_{i+\frac{1}{2}}]$, and we denote the cell sizes by $\Delta x_i = x_{i+\frac{1}{2}} - x_{i-\frac{1}{2}}$ and the maximum cell size by $h = \max_i \Delta x_i$. The solution as well as the test function space are given by $V_h^k = \{p : p|_{I_i} \in P^k(I_i)\}$, where $P^k(I_i)$ is the space of polynomials of degree $\le k$ on the cell I_i. We adopt a local orthogonal basis over I_i $\{v_l^{(i)}(x),\ l = 0, 1, \ldots, k\}$, namely, the scaled Legendre polynomials:

$$v_0^{(i)}(x) = 1, \qquad v_1^{(i)}(x) = \frac{x - x_i}{\Delta x_i/2}, \qquad v_2^{(i)}(x) = \left(\frac{x - x_i}{\Delta x_i/2}\right)^2 - \frac{1}{3}, \ldots .$$

Then the numerical solution $u^h(x,t)$ in the space V_h^k can be written as

$$u^h(x,t) = \sum_{l=0}^{k} u_i^{(l)}(t) v_l^{(i)}(x) \qquad \text{for } x \in I_i, \tag{2.2}$$

and the degrees of freedom $u_i^{(l)}(t)$ are the moments defined by

$$u_i^{(l)}(t) = \frac{1}{a_l} \int_{I_i} u^h(x,t) v_l^{(i)}(x)\, dx, \qquad l = 0, 1, \ldots, k,$$

where $a_l = \int_{I_i} (v_l^{(i)}(x))^2 dx$ are the normalization constants since the basis is not orthonormal. In order to determine the approximate solution, we evolve the degrees of freedom $u_i^{(l)}$:

$$\frac{d}{dt}u_i^{(l)} + \frac{1}{a_l}\left(- \int_{I_i} f(u^h(x,t)) \frac{d}{dx} v_l^{(i)}(x)\, dx + \hat{f}(u^-_{i+1/2}, u^+_{i+1/2}) v_l^{(i)}(x_{i+1/2}) \right. \tag{2.3}$$
$$\left. - \hat{f}(u^-_{i-1/2}, u^+_{i-1/2}) v_l^{(i)}(x_{i-1/2}) \right) = 0, \qquad l = 0, 1, \ldots, k,$$

where $u^{\pm}_{i+1/2} = u^h(x^{\pm}_{i+1/2}, t)$ are the left and right limits of the discontinuous solution u^h at the cell interface $x_{i+1/2}$, and $\hat{f}(u^-, u^+)$ is a monotone flux (nondecreasing in the first argument and nonincreasing in the second argument) for the scalar case and an exact or approximate Riemann solver for the system case. The semidiscrete scheme (2.3) is discretized in time by a nonlinearly stable Runge–Kutta time discretization, e.g., the third-order version [20]. The integral term in (2.3) can be computed either exactly or by a suitable numerical quadrature accurate to at least $O(h^{k+l+2})$.

We will now review a few discontinuity detecting methods to identify troubled cells. Numerical examples to compare them will be given in the next section.

1. [illegible] [5]. Denote

$$u^-_{i+1/2} = u_i^{(0)} + \tilde{u}_i, \qquad u^+_{i-1/2} = u_i^{(0)} - \tilde{\tilde{u}}_i.$$

From (2.2) we can see that

$$\tilde{u}_i = \sum_{l=1}^{k} u_i^{(l)} v_l^{(i)}(x_{i+1/2}), \qquad \tilde{\tilde{u}}_i = -\sum_{l=1}^{k} u_i^{(l)} v_l^{(i)}(x_{i-1/2}).$$

These are modified either by the standard minmod limiter [8]

$$\tilde{u}_i^{(mod)} = m(\tilde{u}_i, \Delta_+ u_i^{(0)}, \Delta_- u_i^{(0)}), \qquad \tilde{\tilde{u}}_i^{(mod)} = m(\tilde{\tilde{u}}_i, \Delta_+ u_i^{(0)}, \Delta_- u_i^{(0)}),$$

where the minmod function m is given by

(2.4)
$$m(a_1, a_2, \ldots, a_n) = \begin{cases} s \cdot \min_{1 \le j \le n} |a_j| & \text{if } \operatorname{sign}(a_1) = \operatorname{sign}(a_2) = \cdots = \operatorname{sign}(a_n) = s, \\ 0 & \text{otherwise,} \end{cases}$$

or by the TVB-modified minmod function [18]

$$\tilde{m}(a_1, a_2, \ldots, a_n) = \begin{cases} a_1 & \text{if } |a_1| \le Mh^2, \\ m(a_1, a_2, \ldots, a_n) & \text{otherwise,} \end{cases} \tag{2.5}$$

where $M > 0$ is a constant. The choice of M depends on the solution of the problem. For scalar problems it is possible to estimate M by the initial condition as in [5] (M is proportional to the second derivative of the initial condition at smooth extrema); however, it is more difficult to estimate M for the system case. If M is chosen too small, more cells than necessary will be identified as troubled cells, thereby increasing the computational cost; however, if M is chosen too large, spurious oscillations may appear.

2. [illegible] [1]. We will denote this limiter as the BDF limiter in this paper. The moment-based limiter in [1] is given by

$$u_i^{(l),mod} = \frac{1}{2l-1}\, m\left((2l-1)u_i^{(l)}, u_{i+1}^{(l-1)} - u_i^{(l-1)}, u_i^{(l-1)} - u_{i-1}^{(l-1)}\right), \tag{2.6}$$

where m is again the minmod function (2.4). This limiter is applied adaptively. First, the highest-order moment $u^{(k)}$ is limited. Then the limiter is applied to successively lower-order moments when the next higher-order moment on the interval has been changed by the limiting. For our purpose, when the BDF limiter (2.6) is enacted (returns other than the first argument) for the highest-order moment, the cell is declared as a troubled cell and marked for further reconstruction.

3. [illegible] [2]. We will denote this modified moment limiter as the BSB limiter in this paper. For our purpose as a troubled-cell indicator, if both (2.6) and

$$\hat{u}_i^{(l),mod} = \frac{1}{2l-1} m\Big((2l-1)u_i^{(l)}, u_{i+1/2}^{(l-1)+} - u_i^{(l-1)}, u_i^{(l-1)} - u_{i-1/2}^{(l-1)-}\Big) \tag{2.7}$$

are enacted for the highest-order moment $u^{(k)}$, where

$$u_{i+1/2}^{(l-1)+} = u_{i+1}^{(l-1)} - (2l-1)u_{i+1}^{(l)}, \qquad u_{i-1/2}^{(l-1)-} = u_{i-1}^{(l-1)} + (2l-1)u_{i-1}^{(l)},$$

that is, if both $u_i^{(k),mod} \neq u_i^{(k)}$ and $\hat{u}_i^{(k),mod} \neq u_i^{(k)}$, then the cell is identified as a troubled cell, marked for further reconstruction.

4. [illegible] [22]. In [22], Suresh and Huynh designed a limiter to preserve accuracy near smooth extrema, which works well with Runge–Kutta time stepping for a class of high-order MP schemes. The interface values in these schemes are obtained by limiting a higher-order polynomial reconstruction. The key idea in that work is to distinguish between a smooth local extremum and a genuine $O(1)$ discontinuity.

For our purpose as a troubled-cell indicator, the MP limiter can be described as follows. First a median function is defined as

$$\text{median}(x, y, z) = x + m(y - x, z - x), \tag{2.8}$$

where m is again the minmod function (2.4). If

$$u_{i+1/2}^{-} \neq \text{median}(u_{i+1/2}^{-}, u_{i+1/2}^{\min}, u_{i+1/2}^{\max}), \tag{2.9}$$

where

$$u_{i+1/2}^{\min} = \max\Big[\min(u_i^{(0)}, u_{i+1}^{(0)}, u_{i+1/2}^{MD}), \min(u_i^{(0)}, u_{i+1/2}^{UL}, u_{i+1/2}^{LC})\Big],$$
$$u_{i+1/2}^{\max} = \min\Big[\max(u_i^{(0)}, u_{i+1}^{(0)}, u_{i+1/2}^{MD}), \max(u_i^{(0)}, u_{i+1/2}^{UL}, u_{i+1/2}^{LC})\Big],$$

and

$$d_i = u_{i+1}^{(0)} - 2u_i^{(0)} + u_{i-1}^{(0)}, \quad d_{i+1/2}^{M4X} = m(4d_i - d_{i+1}, 4d_{i+1} - d_i, d_i, d_{i+1}, d_{i-1}, d_{i+2}),$$
$$u_{i+1/2}^{MD} = \frac{1}{2}\left(u_i^{(0)} + u_{i+1}^{(0)} - d_{i+1/2}^{M4X}\right), \quad u_{i+1/2}^{UL} = u_i^{(0)} + \alpha\Big(u_i^{(0)} - u_{i-1}^{(0)}\Big),$$
$$u_{i+1/2}^{LC} = u_i^{(0)} + \frac{1}{2}\left(u_i^{(0)} - u_{i-1}^{(0)}\right) + \frac{\beta}{3} d_{i-1/2}^{M4X},$$

or if $u^+_{i-1/2}$ satisfies a similar (symmetric) condition, then the cell is identified as a troubled cell, marked for further reconstruction. We take the parameters $\alpha = 2$ and $\beta = 4$ in the numerical tests in the next section, as suggested in [22].

5. [illegible] [17]. We will denote this modified MP limiter as the MMP limiter in this paper. In [17], Rider and Margolin presented a simple modification of the standard MP limiter in [22]. These modified MP limiters relax the relatively stringent condition of preserving monotonicity, while enforcing less-restrictive conditions. For our purpose as a troubled-cell indicator, the MMP limiter can be described as follows:

$$\phi = \min(1, \Delta\overline{u}^{\min}/\Delta_{\min}u), \tag{2.10}$$

where

$$\Delta\overline{u}^{\min} = u_i^{(0)} - \min\Big(u_{i-1}^{(0)}, u_i^{(0)}, u_{i+1}^{(0)}\Big), \quad \Delta_{\min}u = u_i^{(0)} - \min\big(u^+_{i-1/2}, u^-_{i+1/2}\big).$$

When $\phi \neq 1$, the limiter enacts and the cell is identified as a troubled cell, marked for further reconstruction.

6. [illegible] [12]. We will denote the troubled-cell indicator based on this technique as the KXRCF indicator in this paper.

The strategy in [12] is based on a strong superconvergence at the outflow boundary of each element in smooth regions for the DG method to detect discontinuities and to lower the order of accuracy in the approximation there to avoid spurious oscillations near such discontinuities when solving hyperbolic systems of conservation laws.

For our purpose as a troubled-cell indicator, the KXRCF indicator can be described as follows. Partition the boundary of a cell I_i into two portions ∂I_i^- and ∂I_i^+, where the flow is into ($\vec{v}\cdot\vec{n} < 0$) and out of ($\vec{v}\cdot\vec{n} > 0$) I_i, respectively. The discontinuity detector in [12] is defined as

$$\mathcal{I}_i = \frac{\left|\displaystyle\int_{\partial I_i^-} (u^h|_{I_i} - u^h|_{I_{n_i}})\, ds\right|}{h^{(k+1)/2}\left|\partial I_i^-\right| \|u^h|_{I_i}\|}. \tag{2.11}$$

Here we choose h as the radius of the circumscribed circle in the element I_i, I_{n_i} is the neighbor of I_i on the side of ∂I_i^-, and the norm is based on the maximum norm taken at the integration quadrature points in two dimensions and based on an element average in one dimension. If $\mathcal{I}_i > 1$, the cell I_i is identified as a troubled cell, marked for further reconstruction.

7. [illegible] [9]. We will denote this indicator as the Harten indicator in this paper.

In [9], Harten introduced the notion of subcell resolution, which is based on the observation that, unlike point values, cell averages of a discontinuous piecewise-smooth function contain information about the exact location of a discontinuity within the cell. For our purpose as a troubled-cell indicator, the Harten indicator can be described as follows.

Let

$$F_i(z) = \frac{1}{\Delta x}\left\{\int_{x_{i-1/2}}^{z} u^h(x,t)|_{I_{i-1}}dx + \int_{z}^{x_{i+1/2}} u^h(x,t)|_{I_{i+1}}dx\right\} - u_i^{(0)},$$

where $u^h(x,t)|_{I_{i-1}}$ denotes the approximate solution u^h defined in the cell I_{i-1}, extended into cell I_i, and likewise $u^h(x,t)|_{I_{i+1}}$ is the approximate solution u^h defined in the cell I_{i+1}, extended into cell I_i. When

$$F_i(x_{i-1/2}) \cdot F_i(x_{i+1/2}) \le 0,$$

I_i is suspected of having a discontinuity of $u^h(x,t)$ in its interior. However, this could also be a smooth extremum of the solution. To exclude the latter case, Harten [9] has a criterion comparing a minmod function of the first divided differences. We modify this criterion in the context of the RKDG method as follows. We compare the kth moment $u_i^{(k)}$, which has the same magnitude of the kth derivative of $u^h(x,t)$ modulo constant with that of the neighbors. Thus, if

(2.12)
$$F_i(x_{i-1/2}) \cdot F_i(x_{i+1/2}) \le 0 \quad \text{and} \quad |u_i^{(k)}| > \alpha |u_{i-1}^{(k)}|, \quad |u_i^{(k)}| > \alpha |u_{i+1}^{(k)}|,$$

then the cell I_i is identified as a troubled cell, marked for further reconstruction. We take the constant $\alpha = 1.5$ in the numerical tests in the next section.

Once the troubled cells are identified with one of the previous seven methods, we would reconstruct the polynomial solution in this cell, while retaining its cell average using the WENO methodology [13]. We refer to [13] for the details of this reconstruction and will not repeat them here. For the case of hyperbolic systems, to identify the troubled cells, we could use either a componentwise indicator or a characteristic one. The former works on each component of the solution and identifies a troubled cell when any component of the solution is flagging this cell as a troubled cell. The latter works in the local characteristic direction to do this identification. The componentwise indicator is less expensive to implement but may identify more cells as troubled cells, thereby increasing the cost on the reconstruction in these cells. In this paper we will only show results using the componentwise indicator. We have also implemented the characteristic indicator and have obtained qualitatively similar comparison results. For both the one-dimensional and two-dimensional Euler equations, we use only the components of density and energy as indicator variables. We emphasize that the componentwise strategy is used only to identity troubled cells. Once these cells are identified, the WENO reconstructions in them are performed in local characteristic directions. We again refer to [13] and [19] for more details of the reconstruction.

3. Numerical results. In this section we perform extensive numerical experiments to compare the seven different troubled-cell indicators outlined in the previous section when used on the RKDG methods with the WENO reconstruction limiters. The comparison is concentrated on whether the results are oscillatory and on the percentage of cells flagged as troubled cells. We only plot cell averages of the solution in the graphs. The notation TVB-1, TVB-2, and TVB-3 refer to the minmod TVB limiter with the TVB constants $M = 0.01$, $M = 10$, and $M = 100$, respectively.

' . ,' 3.1 We solve the following one-dimensional nonlinear system of Euler equations:

$$u_t + f(u)_x = 0 \tag{3.1}$$

with

$$u = (\rho, \rho v, E)^T, \qquad f(u) = (\rho v, \rho v^2 + p, v(E+p))^T.$$

	Harten	3.31	7.50		0.51	2.00		1.54	5.25	

Here ρ is the density, v is the velocity, E is the total energy, p is the pressure, related to the total energy by $E = \frac{p}{\gamma-1} + \frac{1}{2}\rho v^2$ with $\gamma = 1.4$.

We use the following Riemann initial condition for the Sod problem:

$$(\rho, v, p) = (1, 0, 1) \text{ for } x \le 0, \qquad (\rho, v, p) = (0.125, 0, 0.1) \text{ for } x > 0.$$

Average (over time steps) and maximum percentages of cells being flagged as troubled cells and the quality of the approximation with respect to spurious oscillations, for the different troubled-cell indicators, are summarized in Table 3.1 for $t = 2.0$ using $N = 200$ and $N = 400$ uniform cells. The quality of the approximation is marked in the column "Osc" with "Y" indicating the result is oscillatory (there exist overshoots or undershoots with a size more than 2% of the range of the exact or reference solution), "L" indicating the result is slightly oscillatory (there exist overshoots or undershoots with a size between 0.5% and 2% of the range of the exact or reference solution), or blank indicating the result is nonoscillatory (there are no overshoots or undershoots with a size more than 0.5% of the range of the exact or reference solution). We observe from Table 3.1 that the winners for this example, in terms of having smaller percentages of troubled cells, are the TVB-2, KXRCF, and Harten indicators. We can also observe that the percentage of troubled cells decreases with a mesh refinement in almost all the cases, which is a very desirable property for troubled-cell indicators.

In Figures 3.1–3.3, we plot the computed densities ρ at $t = 2.0$ against the exact solution by the RKDG method with WENO limiters using the TVB-2, KXRCF, and Harten troubled-cell indicators with $N = 200$ uniform cells for $k = 1$, 2, and 3 (second-, third-, and fourth-order RKDG). We can observe that the results for all the cases keep sharp discontinuities and are mostly oscillation-free.

' . ,' 3.2 We repeat the numerical experiments of the previous example using the following Riemann initial condition for the Lax problem:

$$(\rho, v, p) = (0.445, 0.698, 3.528) \text{ for } x \le 0, \qquad (\rho, v, p) = (0.5, 0, 0.571) \text{ for } x > 0.$$

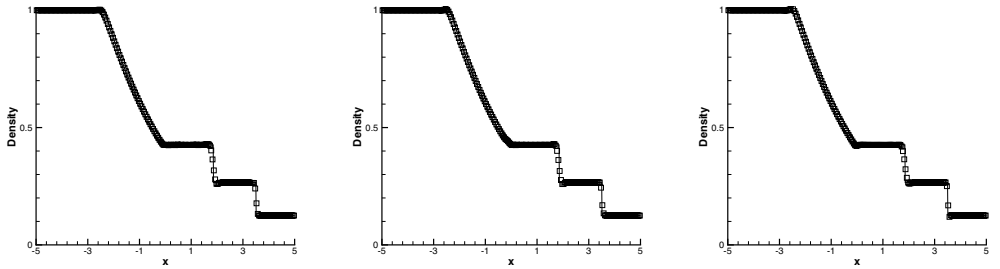

FIG. 3.1. *Sod problem, $t = 2.0$. RKDG with WENO limiters using different troubled-cell indicators: TVB-2 (left), KXRCF (middle), and Harten (right); $k = 1$, 200 cells. Density: solid line, the exact solution; squares, numerical solution.*

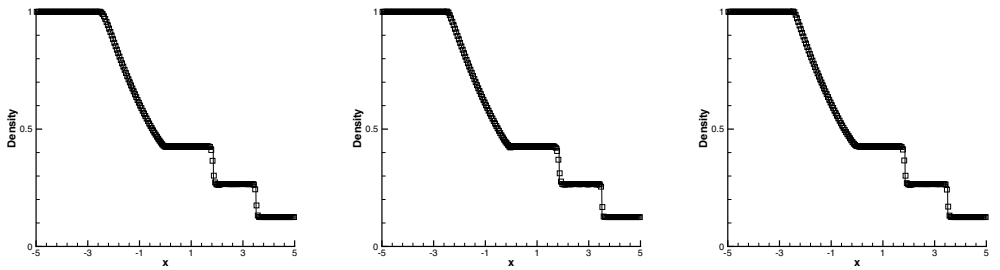

FIG. 3.2. *Sod problem, $t = 2.0$. RKDG with WENO limiters using different troubled-cell indicators: TVB-2 (left), KXRCF (middle), and Harten (right); $k = 2$, 200 cells. Density: solid line, the exact solution; squares, numerical solution.*

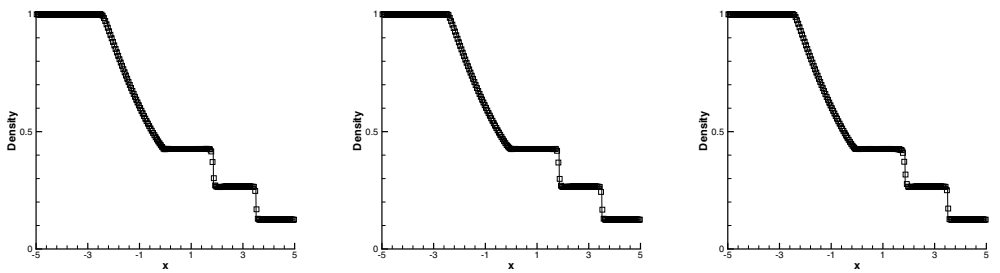

FIG. 3.3. *Sod problem, $t = 2.0$. RKDG with WENO limiters using different troubled-cell indicators: TVB-2 (left), KXRCF (middle), and Harten (right); $k = 3$, 200 cells. Density: solid line, the exact solution; squares, numerical solution.*

This is a more demanding test case in terms of controlling spurious oscillations. Results similar to those in the previous example, at $t = 1.3$, are given in Table 3.2 and in Figures 3.4–3.6. We can observe a similar pattern as in the previous example, except that more cases involving the TVB-2, MMP, KXRCF, and Harten troubled-cell indicators are marked as "slightly oscillatory" or even "oscillatory."

3.3 A higher-order scheme would show its advantage when the solution contains both shocks and complex smooth regions. A typical example for this is the problem of shock interaction with entropy waves [21]. We solve the Euler equations (3.1) with a moving Mach = 3 shock interacting with sine waves in density, i.e., initially

$$(\rho, v, p) = (3.857143, 2.629369, 10.333333) \text{ for } x < -4,$$
$$(\rho, v, p) = (1 + \varepsilon \sin(5x), 0, 1) \text{ for } x \geq -4.$$

Here we take $\varepsilon = 0.2$. The computed density ρ is plotted at $t = 1.8$ against the reference "exact" solution, computed using a fifth-order WENO scheme [11] using 2000 grid points.

Results similar to the previous two examples, at $t = 1.8$, are given in Table 3.3 and in Figures 3.7–3.9. We can observe a similar pattern as in the previous examples; namely, the winners for this example, in terms of having smaller percentages of troubled cells, are the TVB-3, KXRCF, and Harten indicators. Notice that some cases with the MMP troubled-cell indicator are marked as "slightly oscillatory." Because

the TVB-3 and KXRCF troubled-cell indicators identify a smaller percentage of troubled cells than the Harten indicator for this problem, the resolution of the detailed structures in the solution behind the shock is better for the results using the TVB-3 and KXRCF indicators than that using the Harten indicator. This also indicates that the original RKDG method does a better job than the WENO reconstruction in

keeping the resolution for such structures, so we should keep the number of troubled cells, hence the reconstruction, to a minimum under the nonoscillatory constraint. This will be beneficial both in saving computational costs for the reconstruction and in obtaining better resolutions from the original RKDG method.

EXAMPLE 3.4 We consider the interaction of blast waves of the Euler equation (3.1) with the initial condition:

$$(\rho, v, p) = (1, 0, 1000) \text{ for } 0 \le x < 0.1,$$
$$(\rho, v, p) = (1, 0, 0.01) \text{ for } 0.1 \le x < 0.9,$$
$$(\rho, v, p) = (1, 0, 100) \text{ for } 0.9 \le x.$$

A reflecting boundary condition is applied to both ends; see [24, 10]. The computed density ρ is plotted at $t = 0.038$ against the reference "exact" solution, which is a converged solution computed by the fifth-order finite difference WENO scheme [11] with 2000 grid points.

Results similar to the previous examples, at $t = 0.038$, are given in Table 3.4 and in Figures 3.10–3.12. We can observe a similar pattern as in the previous examples; namely, the winners for this example, in terms of having smaller percentages of troubled cells, are still the TVB-3, KXRCF, and Harten indicators. For this problem, only a few cases with the MMP troubled-cell indicators are marked as "slightly oscillatory." Unlike in the previous example, in this example the Harten indicator identifies a smaller percentage of troubled cells than the TVB-3 and KXRCF indicators. As a result, the resolution is better for the results using the Harten indicator than that using the TVB-3 and KXRCF indicators, especially for the $k = 1$ (second-order) case.

EXAMPLE 3.5 Double Mach reflection. This problem is originally from [24]. The computational domain for this problem is $[0, 4] \times [0, 1]$. The reflecting wall lies at the bottom, starting from $x = \frac{1}{6}$. Initially a right-moving Mach 10 shock is positioned at $x = \frac{1}{6}, y = 0$ and makes a 60° angle with the x-axis. For the bottom boundary, the exact postshock condition is imposed for the part from $x = 0$ to $x = \frac{1}{6}$ and a reflective

boundary condition is used for the rest. At the top boundary, the flow values are set to describe the exact motion of a Mach 10 shock. We compute the solution up to $t = 0.2$. In Table 3.5 we document the percentage of cells declared to be troubled cells for different orders of accuracy with the TVB-3, KXRCF, and Harten indicators to identify troubled cells. We can see that in most cases only a small percentage

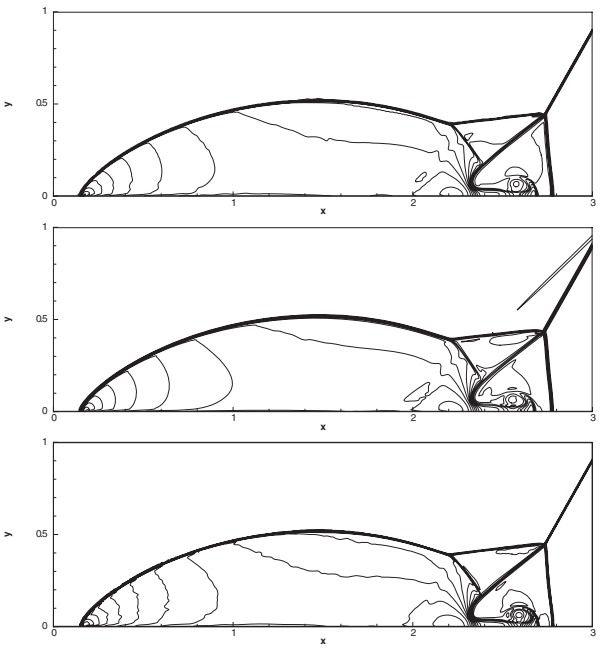

FIG. 3.13. *Double Mach reflection problem, $t = 0.2$. RKDG with WENO limiters using different troubled-cell indicators: TVB-3 (top), KXRCF (middle), and Harten (bottom); $k = 1$, 960×240 cells. Thirty equally spaced density contours from 1.5 to 22.7.*

of cells are declared as troubled cells. For this problem, the TVB-3 indicator seems to be better (in terms of producing a smaller percentage of troubled cells) than the KXRCF indicator, which in turn is better than the Harten indicator. Four uniform meshes, with 120×30, 240×60, 480×120, and 960×240 uniform cells, and three different orders of accuracy for the RKDG with WENO limiters, from $k = 1$ to $k = 3$ (second- to fourth-order), are used in the numerical experiments. To save space, we plot only the simulation results on the most refined mesh with 960×240 cells with the TVB-3, KXRCF, and Harten indicators to identify troubled cells in Figures 3.13,

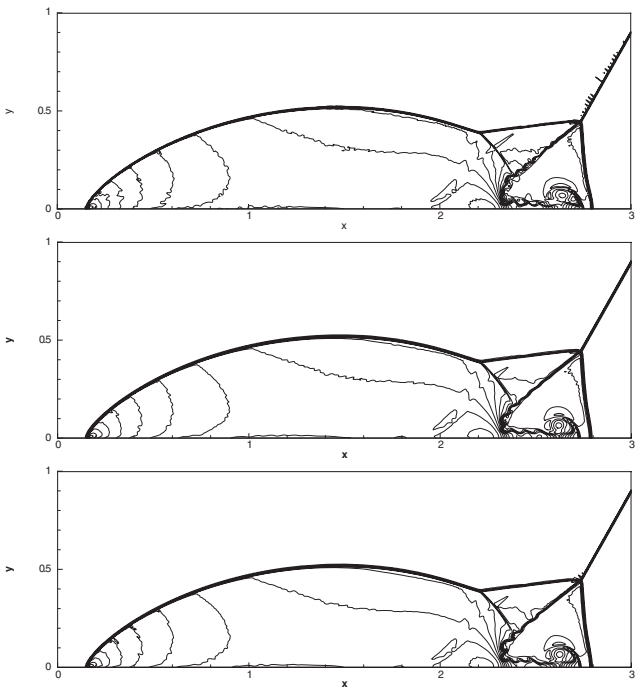

FIG. 3.17. *Double Mach reflection problem,* $t = 0.2$. *RKDG with WENO limiters using different troubled-cell indicators: TVB-*3 (*top*), *KXRCF* (*middle*), *and Harten (bottom);* $k = 3$, 960×240 *cells. Thirty equally spaced density contours from* 1.5 *to* 22.7.

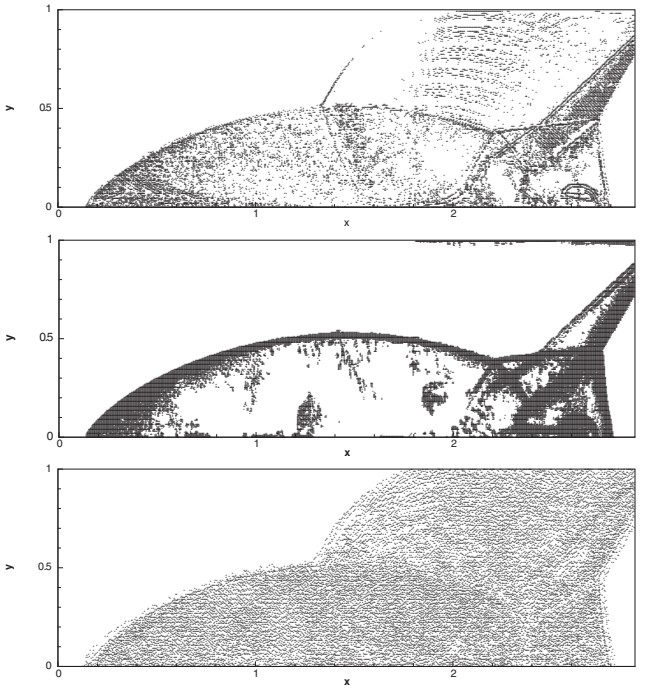

FIG. 3.18. *Double Mach reflection problem. Cells which are identified as troubled cells at* $t = 0.2$. *RKDG with WENO limiters using different troubled-cell indicators: TVB-*3 (*top*), *KXRCF* (*middle*), *and Harten* (*bottom*); $k = 3$, 960×240 *cells.*

3.15, and 3.17. All the figures are showing 30 equally spaced density contours from 1.5 to 22.7. The troubled cells identified by the TVB-3, KXRCF, and Harten indicators at the last time step are shown in Figures 3.14, 3.16, and 3.18, respectively. It is intriguing to see, in Figures 3.13–3.18, that raising the order of approximation from second- to fourth-order (from $k = 1$ to $k = 3$) leads to an increase in the number of troubled cells. Also, the extent to which the three troubled-cell indicators give the correct identification of the troubled cells affects not only the number but also the distribution of the troubled cells within the computational domain, as k increases from 1 to 3.

4. Concluding remarks. In this paper we have systematically studied and compared a few different troubled-cell indicators for the RKDG methods using WENO methodology as limiters. Extensive one- and two-dimensional simulations on the hyperbolic systems of Euler equations indicate that the minmod-based TVB indicator (when the TVB constant M is suitably chosen), the KXRCF indicator by Krivodonova et al. [12], and an indicator based on Harten's subcell resolution idea [9] are better than other choices in all the test cases. Among these three there is no clear winner: any one of them would work better in some examples but not in all examples. All three of them should be suitable candidates for applications of the RKDG methods using WENO reconstructions.

DETERMINING ANALYTICITY FOR PARAMETER OPTIMIZATION OF THE GEGENBAUER RECONSTRUCTION METHOD*

A. GELB† AND Z. JACKIEWICZ†

Abstract. The Gegenbauer reconstruction method effectively eliminates the Gibbs phenomenon and restores exponential accuracy to the approximations of piecewise smooth functions. Recent investigations show that its success depends upon choosing parameters in such a way that the regularization and the truncation error estimates are equally considered. This paper shows that the underlying analyticity of the function in smooth regions plays a critical role in the regularization error estimate. Hence we develop a technique that first analyzes the behavior of the function in its regions of smoothness and then applies this knowledge to refine the regularization error estimate. Such refinement yields better parameter choices for the Gegenbauer reconstruction method, and is confirmed both by better accuracy and more robustness in the approximation of piecewise smooth functions.

Key words. Fourier pseudospectral approximation, Gegenbauer reconstruction, exponential convergence

DOI. 10.1137/040603814

1. Introduction.

The Gegenbauer reconstruction method, originally developed in [14], effectively eliminates the Gibbs phenomenon from the spectral approximation of a piecewise smooth function while maintaining its exponential convergence properties, even up to the discontinuities of the function. Since its conception, investigators have considered various aspects of the Gegenbauer reconstruction method, including construction from Fourier and other spectral expansion coefficients (e.g., Chebyshev and Legendre) in one and two dimensions as well as on spheres. Recent advancements of the Gegenbauer reconstruction method include an adaptation to noisy environments [2], avoidance of round-off error [7], parameter optimization techniques [7] and [15], and an alternative implementation by the inverse method [17]. All have contributed to making the Gegenbauer reconstruction method a viable option in both high and low resolution environments for multidimensional and multiscale problems, even in the presence of noise. Additionally, the Gegenbauer reconstruction method has been successfully employed in numerous scientific applications, including medical image reconstruction (e.g., [1], [10]) and as a postprocessing technique for conservation laws (e.g., [8], [16]). A good overview of the development and application of the Gegenbauer reconstruction method can be found in [11], [12], and [13], and the references therein.

The success of the Gegenbauer reconstruction method hinges on the underlying analytic behavior of the piecewise smooth function $f(x)$ in the regions between known discontinuities. In particular, the approximation of the regularization error of the

Gegenbauer reconstruction method has been guided by an assumption of smoothness, first described in [14] as follows.

ASSUMPTION 1.1. Let $f(x)$ be an analytic but nonperiodic function on $[-1,1]$. There exist constants $\rho \geq 1$ and $C(\rho)$ such that for every $k \geq 0$,

$$\max_{-1\leq x\leq 1} \left| \frac{d^k f(x)}{dx^k} \right| \leq C(\rho) \frac{k!}{\rho^k}.$$

The authors proceed to explain that this is a standard assumption for analytic functions where ρ is the distance from $[-1,1]$ to the nearest singularity of $f(x)$ in the complex plane. Note that for $x \in [a,b]$ the assumption can be easily modified.

Later in [12] the regularization error is validated for functions under the following assumption.

ASSUMPTION 1.2. There exist a constant $0 \leq r_0 < 1$ and an analytic extension of $f(x)$ onto the elliptic domain

$$D = \left\{ z : z = \frac{1}{2}\left(r\, e^{i\theta} + \frac{1}{r}\, e^{-i\theta} \right), \quad 0 \leq \theta \leq 2\pi, \quad r_0 \leq r < 1 \right\}. \tag{1.1}$$

Once again this assumption is satisfied by all analytic functions defined on $[-1,1]$ and can easily be modified for $f(x)$ on general $[a,b]$.

Despite the fact that the smoothness of $f(x)$ is generally unknown, the Gegenbauer reconstruction method was shown to yield exponential convergence in most cases [14]. However, the accuracy of the method was seemingly function dependent, and varied with the particular parameters used in its construction.

A parameter optimization technique was first suggested for the Fourier-based Gegenbauer reconstruction method in [7], where an "average case scenario" $\rho = 1$ in Assumption 1.1 was used to estimate the regularization error, since the underlying analyticity of the function in smooth regions was unknown. Later in [15] the procedure was refined for the Chebyshev case, where Assumption 1.2 was also considered. Here it was assumed that the smoothness of $f(x)$ was known explicitly, or equivalently that the values ρ and r_0 were somehow predetermined. As discussed in [15], such knowledge yields significant improvement to the sharpness of the regularization error estimate, which in turn produces a more refined technique for choosing optimal parameters for the reconstruction. It was shown that in some cases the reconstruction was dramatically improved, in particular when $\rho \neq 1$. It is therefore of critical interest to assess the analyticity of the underlying function for reconstruction, since such knowledge will serve to both refine and automate the parameter optimization techniques introduced in [7] and [15]. Specifically, we seek to accurately determine the smoothness parameters ρ and r_0 in Assumptions 1.1 and 1.2. Once this is accomplished, the parameters for the Gegenbauer reconstruction method can be determined accordingly. The Gegenbauer reconstruction method can then be directly applied in any region of smoothness without further consideration of the behavior of the function.

Our paper is organized in the following way. In section 2, the Gegenbauer reconstruction method based on Fourier coefficients is briefly reviewed. A general parameter optimization technique is described in section 3, and a new method for evaluating the analyticity of $f(x)$ is introduced in section 4. Numerical examples for the completely automated procedure are provided in section 5. For ease of presentation, we restrict our discussion throughout this paper to the reconstruction of a smooth nonperiodic function $f(x)$ on $[-1,1]$ from its Fourier coefficients, and note that although some

additional complications involving edge detection will arise for piecewise smooth functions, the techniques discussed here for the specific purpose of reconstruction remain the same.

2. Review of the Gegenbauer reconstruction method. Consider an analytic but nonperiodic function $f(x)$ defined on the interval $[-1,1]$. The Fourier partial sum,

$$f_N(x) = \sum_{n=-N}^{N} \widehat{f}_n e^{in\pi x}, \tag{2.1}$$

with Fourier coefficients $\widehat{f}_n$ defined by

$$\widehat{f}_n = \frac{1}{2}\int_{-1}^{1} f(x)e^{-in\pi x}dx, \tag{2.2}$$

shows $O(1)$ spurious oscillations near the boundaries ± 1. Additionally, the convergence of $f_N(x)$ to $f(x)$ on $[-1,1]$ is reduced to first order. This behavior is the well-known Gibbs phenomenon, and many techniques have been developed to reduce or eliminate its effects. The Gegenbauer reconstruction method, first introduced in [14], uses information from the first $2N+1$ Fourier coefficients (2.2) to completely resolve the Gibbs phenomenon and yields exponential convergence to $f(x)$ in the uniform norm on $[-1,1]$. Here we briefly describe the method and refer the reader to [14], [11], [12], and [13] for more complete details.

Denote by C_l^λ the Gegenbauer polynomials [3], [5], i.e., the polynomials which are orthonormal with respect to the inner product,

$$\langle C_k^\lambda, C_l^\lambda \rangle = \frac{1}{h_l^\lambda}\int_{-1}^{1}(1-x^2)^{\lambda-\frac{1}{2}} C_k^\lambda(x) C_l^\lambda(x)\,dx,$$

where for $\lambda > 0$ the scaling factor h_l^λ is defined by

$$h_l^\lambda = \sqrt{\pi}\, C_l^\lambda(1)\frac{\Gamma(\lambda+\frac{1}{2})}{\Gamma(\lambda)(l+\lambda)}, \quad C_l^\lambda(1) = \frac{\Gamma(l+2\lambda)}{l!\,\Gamma(2\lambda)}.$$

The Gegenbauer reconstruction method consists of approximating the function $f(x)$ by computing the truncated approximate Gegenbauer series

$$f_g^{m,\lambda}(x) = \sum_{l=0}^{m} \widehat{g}^\lambda(l) C_l^\lambda(x), \tag{2.3}$$

where the coefficients $\widehat{g}^\lambda(l)$ are given by

$$\widehat{g}^\lambda(l) = \frac{1}{h_l^\lambda}\int_{-1}^{1}(1-x^2)^{\lambda-\frac{1}{2}} f_N(x) C_l^\lambda(x)dx. \tag{2.4}$$

As first shown in [14], the coefficients (2.4) provide an exponentially accurate approximation to the exact Gegenbauer coefficients, defined by

$$\widehat{f}^\lambda(l) = \frac{1}{h_l^\lambda}\int_{-1}^{1}(1-x^2)^{\lambda-\frac{1}{2}} f(x) C_l^\lambda(x)dx, \tag{2.5}$$

provided that $\lambda, m \sim N$; that is, they scale like N. In fact, if λ and m are proportional to N, i.e.,

$$\lambda = \alpha N, \quad m = \beta N, \tag{2.6}$$

then

$$\max_{-1\le x\le 1} \left| f(x) - f_g^{m,\lambda}(x) \right| \le A\Big(q_T^N + q_R^N\Big), \tag{2.7}$$

where A is a polynomial in N, q_T corresponds to the truncation error

$$TE = \max_{-1\le x\le 1} \left| \sum_{l=0}^{m} \Big(\widehat{f}^{\lambda}(l) - \widehat{g}^{\lambda}(l)\Big) C_l^{\lambda}(x) \right|, \tag{2.8}$$

and q_R corresponds to the regularization error

$$RE = \max_{-1\le x\le 1} \left| f(x) - \sum_{l=0}^{m} \widehat{f}^{\lambda}(l) C_l^{\lambda}(x) \right|. \tag{2.9}$$

Both q_T and q_R are constants less than one. Although it was shown that in general $\lambda, m \sim N$ will yield exponential convergence [14], the parameter choices (2.6) lead to the convenient analysis of (2.8) and (2.9) and are furthermore shown in [7] to produce greater theoretical accuracy than other parameter alternatives.

It was shown in [14] that the constant q_T for (2.6) takes the form

$$q_T = \frac{(\beta + 2\,\alpha)^{\beta+2\,\alpha}}{(2\pi e)^{\alpha}\alpha^{\alpha}\beta^{\beta}}. \tag{2.10}$$

As discussed in the introduction, the constant q_R, representing the regularization error, can be defined in different ways depending on the smoothness of $f(x)$ on $[-1, 1]$. If we consider the latter case given in Assumption 1.2, then q_R is defined as [12]

$$q_R = q_R^1 = \left(\frac{(1+2\gamma)^{\frac{1+2\gamma}{2}}}{(2\gamma)^{\gamma}}\, r_0 \right)^{\beta}, \qquad \gamma = \frac{\lambda}{m}. \tag{2.11}$$

The parameters defined in (2.6) yield

$$q_R^1 = \frac{(\beta + 2\alpha)^{\frac{\beta+2\alpha}{2}} r_0^{\beta}}{(2\alpha)^{\alpha}\beta^{\frac{\beta}{2}}}. \tag{2.12}$$

On the other hand, Assumption 1.1 gives the ratio q_R as [14]

$$q_R = q_R^2 = \left(\frac{(1+2\gamma)^{1+2\gamma}}{\rho\, 2^{1+2\gamma}\, \gamma^{\gamma}\, (1+\gamma)^{1+\gamma}} \right)^{\beta}, \qquad \gamma = \frac{\lambda}{m}, \tag{2.13}$$

which, assuming (2.6), reduces to

$$q_R^2 = \frac{(\beta + 2\alpha)^{\beta+2\alpha}}{2^{\beta+2\alpha}\alpha^{\alpha}(\alpha+\beta)^{\alpha+\beta}\rho^{\beta}}. \tag{2.14}$$

In section 3 we propose a parameter optimization technique based on the minimization of the ratio (2.10) corresponding to the truncation error assuming that it is equal to the respective ratios (2.12) and (2.14) corresponding to the regularization errors. We note that although the original theoretical discussion [14] is based on the continuous Fourier coefficients (2.2), all of our numerical experiments are conducted utilizing the corresponding pseudospectral Fourier coefficients

$$\widetilde{f}_n = \frac{1}{2Nc_n} \sum_{j=0}^{2N} f(x_j) e^{-in\pi x_j}, \tag{2.15}$$

based on equally spaced grid points x_j, $j = 0, 1, \ldots, 2N$. Here $c_n = \frac{1}{2}$ for $n = -N$ or $n = N$, and $c_n = 1$ otherwise.

3. Determining optimal parameters. Although it was shown in [14] that the parameter choices $\lambda = \alpha N$ and $m = \beta N$ appearing in (2.6) yield exponential convergence of $f_g^{m,\lambda}(x)$ to $f(x)$ for a large class of functions, the accuracy of the approximation, and even the convergence itself, can depend critically on the choices of these parameters. For instance, numerical experiments in [14] for the reconstruction of analytic nonperiodic functions from Fourier coefficients indicated that choosing the parameters $\alpha = \beta = 0.4$ typically led to more accurate results than for $\alpha = \beta = 0.25$, provided that no round-off error was present. It was additionally shown that for fixed $\beta \le \frac{\pi}{4}$, the ratio q_T defined by (2.10) attains its minimum for

$$\alpha = \frac{1}{4}\Big(\pi - 2\beta + \sqrt{\pi(\pi - 4\beta)}\Big). \tag{3.1}$$

The resulting experiments conducted with $\beta = 0.25$ and α chosen according to (3.1) demonstrated very fast convergence for functions having no regularization error. However, for more general functions in which both the truncation and regularization errors are present, the convergence rate was not improved. This was further analyzed in [7] where a systematic approach was designed to select m and λ to yield exponential convergence for both the truncation and regularization errors. A similar technique was later developed for the Chebyshev–Gegenbauer reconstruction method in [15], where it was additionally assumed that the underlying "smoothness" behavior of $f(x)$ in regions between the discontinuities was known, i.e., the values of ρ and r_0 in Assumptions 1.1 and 1.2 were given. It was also shown that if the parameters m and λ were characterized by (2.6), then the contribution of A to the error bound on the right-hand side of (2.7) was negligible since A is only a polynomial in N. Hence the optimization technique presented in [15] is a function only of the parameters α and β, and is independent of N. We will follow this approach here.

The strategy for choosing α and β in (2.6) is simple. As in [7] and [15], it is based on balancing the truncation (2.10) and regularization errors (2.12) or (2.14). Specifically, we set $q_T = q_R^1$ or $q_T = q_R^2$, depending on the underlying smoothness of the function. The optimal parameters are then determined by the minimization of q_T.

We realize that this optimization is valid only for relatively small N or sparse data sets. Round-off error greatly impacts the ability of the computed Gegenbauer coefficients to decay at the rate needed to balance the large growth of the Gegenbauer polynomials. Here we proceed with the discussion without consideration of round-off error, and note that some numerical results may be more affected by round-off error than by lack of analytical convergence. In such cases it was shown in [7] that

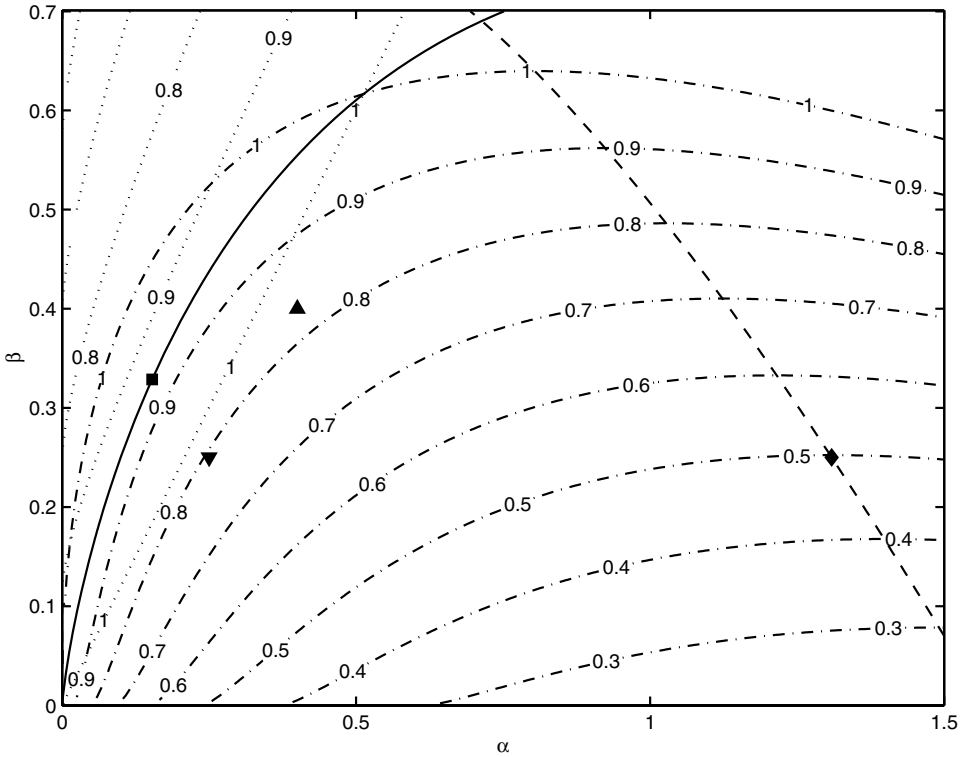

FIG. 3.1. *Contour plots of q_T (dash-dotted lines), q_R^1 (dotted lines), the curve $q_T = q_R^1$ for $r_0 = \sqrt{2}-1$ (solid line), and the curve defined by* (3.1) *(dashed line). Specific point values for α and β include $\alpha = \beta = 0.25$ (downward triangle), $\alpha = \beta = 0.4$ (upward triangle), $\beta = 0.25$ and $\alpha = 1.31$ computed by* (3.1) *(diamond), and the points obtained using our strategy based on minimization of* (3.2) *(square).*

rather than forcing the relationship (2.6) of m and λ with N, it is better to determine maximum admissible values for m and λ such that the Gegenbauer reconstruction is only minimally affected by round-off error. All admissible combinations m and λ are then considered in the computation of (2.7), and the smallest value of (2.7) yields the "optimal" admissible pair of m and λ. Details are discussed in [7]. However, the underlying smoothness of a function still plays a critical role in determining suitable parameters even when round-off error becomes relevant in the reconstruction.

To illustrate the parameter optimization technique derived here, Figure 3.1 displays the contours of q_T (dash-dotted lines), q_R^1 (dotted lines), and the curve $q_T = q_R^1$ for the given value $r_0 = \sqrt{2} - 1$ (solid line). For comparison with the previous parameter selection strategies, Figure 3.1 also displays the curve defined by (3.1) (dashed line).

Figure 3.2 displays the corresponding contour plots of q_R^2 for the "average case scenario," i.e., with $\rho = 1$ which, as discussed in [12] and [15], corresponds to $r_0 = \sqrt{2}-1$ assuming that the singularity of $f(x)$ closest to the interval $[-1, 1]$ is located on the imaginary axis. Both figures display the values for α and β originally suggested in [14] to illustrate the relationship of the parameters to the truncation and regularization errors. Here we point out that the strategy proposed in this paper takes into account both the regularization and truncation errors obtained from the Gegenbauer recon-

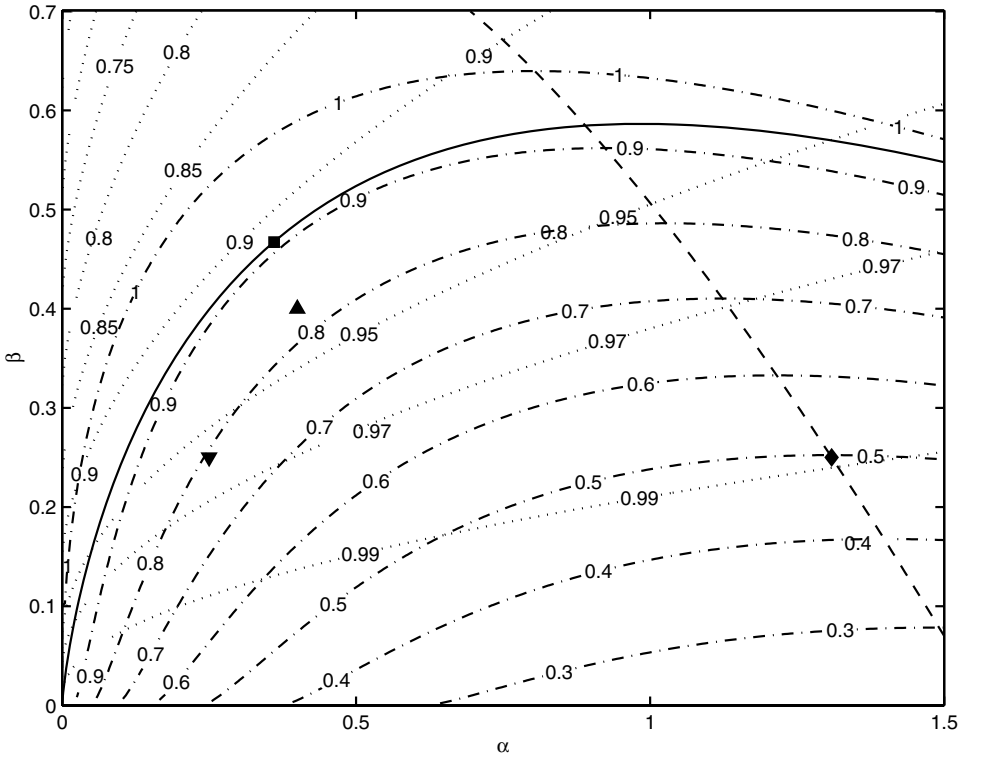

FIG. 3.2. *Contour plots of q_T (dash–dotted lines), q_R^2 (dotted lines), the curve $q_T = q_R^2$ for $\rho = 1$ (solid line), and the curve defined by* (3.1) *(dashed line). Specific point values for α and β include $\alpha = \beta = 0.25$ (downward triangle), $\alpha = \beta = 0.4$ (upward triangle), $\beta = 0.25$ and $\alpha = 1.31$ computed by* (3.1) *(diamond), and the points obtained using our strategy based on minimization of* (3.2) *(square).*

struction method. These values are obtained numerically by minimizing the objective functions

$$\phi^l(\alpha, \beta) = q_T + C\Big(q_T - q_R^l\Big)^2, \quad l = 1, 2, \tag{3.2}$$

where C is a positive penalty constant which was chosen as $C = 1000$. The resulting values for $q_T = q_R^1$ with $r_0 = \sqrt{2} - 1$ are $\alpha = 0.176$, $\beta = 0.343$, while the same algorithm for $q_T = q_R^2$ with $\rho = 1$ yields $\alpha = 0.370$, $\beta = 0.401$.

Figures 3.3 and 3.4 depict the optimal choices for α and β obtained by minimizing (3.2) for $0 \le r_0 \le 1$ and $\rho \ge 1$ (upper graphs) together with the corresponding values of $q_T = q_R^l$, $l = 1, 2$ (lower graphs). The thin lines plotted in Figure 3.4 illustrate the values of α and β obtained by using (2.14) for $\rho < 1$. Once ρ is less than about 0.5, the resulting estimates are meaningless since $q_T = q_R^2$ is complex.

There are several things to note here:

1. The optimization strategy (3.2) used here assumes knowledge of the smoothness parameters ρ and r_0. This information is not inherently known, and hence in section 4 we develop a technique to approximate these values to allow a more refined strategy for determining optimal parameters α and β.

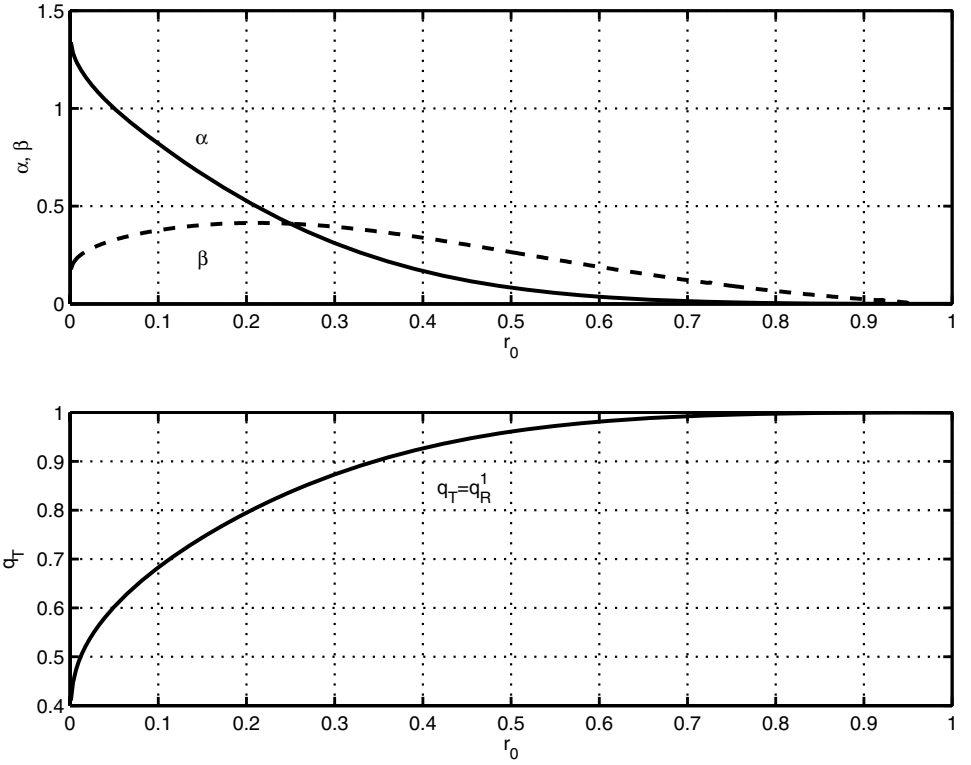

FIG. 3.3. *Parameters α and β versus r_0 (upper graph) and $q_T = q_R^1$ versus r_0 (lower graph).*

2. We reiterate that the optimal strategy (3.2) does not consider round-off errors in its minimization. As discussed previously in [7], the Gegenbauer reconstruction method is numerically inhibited by large values of $m = \beta N$ and $\lambda = \alpha N$, due to the lack of numerical convergence of the Gegenbauer coefficients (2.4). For instance, the values for α shown in Figure 3.4 would be unreasonable for $N > 32$ (conservatively), and in general, the numerically computed Gegenbauer coefficients cease to decay at the required exponential rate for even moderate values of α and β.
3. Although the algorithm is derived for smooth functions in $[-1, 1]$, it can be easily modified to optimize parameter choices for any smooth region $[a, b]$.

To compare the strategy based on minimizing $\phi^1(\alpha, \beta)$ or $\phi^2(\alpha, \beta)$, Figure 3.5 exhibits the equations $q_T = q_R^1$ and $q_T = q_R^2$ versus r_0 under the assumption that the closest singularity of $f(x)$ to $[-1, 1]$ is on the imaginary axis. As explained in [15] (see also [12]), the relationship between r_0 and ρ is then given by

$$\rho = \frac{1}{2}\Big(\frac{1}{r_0} - r_0\Big) \quad \text{or} \quad r_0 = \sqrt{1+\rho^2} - \rho. \tag{3.3}$$

Figure 3.5 indicates that if both strategies for determining α and β are applicable, then minimizing $\phi^2(\alpha, \beta)$ will yield smaller analytical truncation and regularization

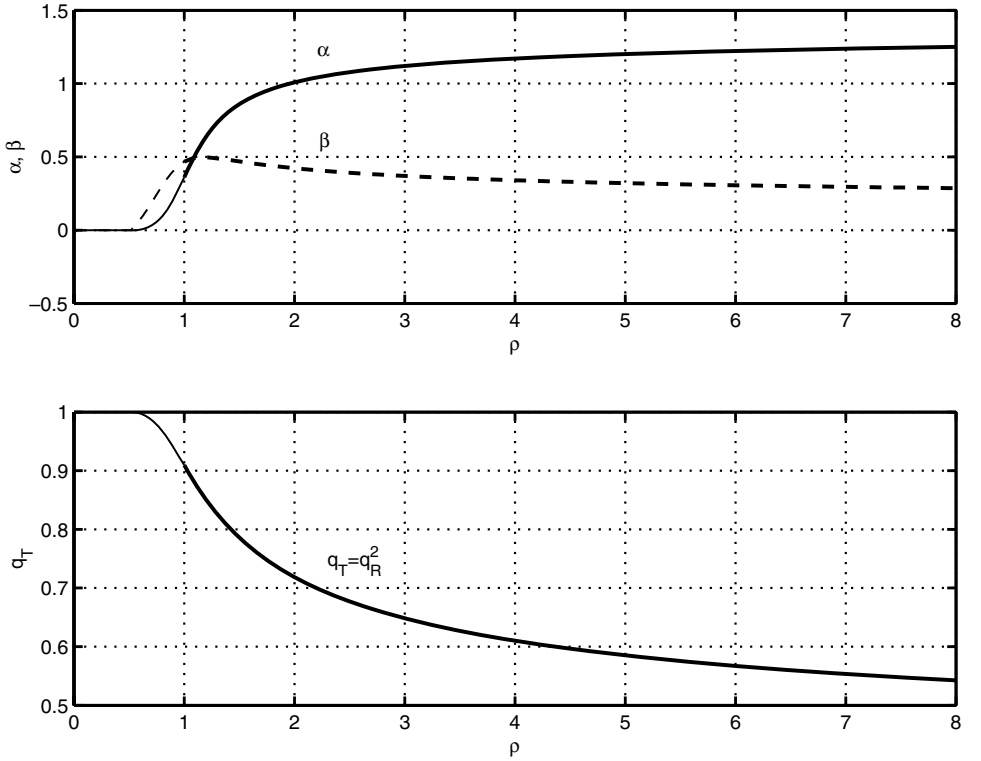

FIG. 3.4. *Parameters α and β versus ρ (upper graph) and $q_T = q_R^2$ versus ρ (lower graph).*

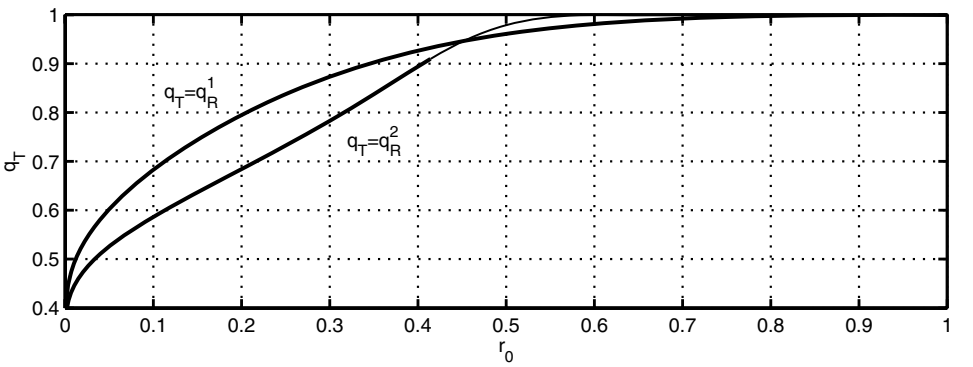

FIG. 3.5. *Ratios $q_T = q_R^1$ and $q_T = q_R^2$ versus r_0.*

errors than minimizing $\phi^1(\alpha, \beta)$, concurring with previous results described for the Chebyshev case in [15]. Figures 3.1 and 3.2 suggest the same conclusion. However, as apparent from the top of Figure 3.4 and prior remarks, minimizing $\phi^2(\alpha, \beta)$ for $\rho \geq 2$ $(0 \leq r_0 \leq \sqrt{5} - 2)$ can potentially yield large round-off errors in the Gegenbauer reconstruction case. In fact, the strategy can be inhibited by round-off error even when $\rho < 2$ $(r_0 > \sqrt{5} - 2)$ for $\lambda = \alpha N$ as N increases. In this case, the top of Figure 3.3 suggests that the strategy based on minimizing $\phi^1(\alpha, \beta)$, although not

theoretically optimal, will yield better results as N increases. Additionally, note the thin line in Figure 3.5 corresponding to $\rho < 1$ or equivalently $r_0 > \sqrt{2} - 1$. In this case, $\rho < 0.5$ ($r_0 > 0.618$) produces complex values for $q_T = q_R^2$ and subsequently yields useless estimates.

Due to the various factors discussed above, we will employ the parameters α and β determined by minimizing $\phi^1(\alpha, \beta)$ in our numerical experiments discussed in section 5.

4. Determination of smoothness parameters. As discussed in section 3, the notion of smoothness plays an important role in determining the optimal parameters α and β for the Gegenbauer reconstruction method. Specifically we wish to determine the analyticity of the underlying function based on the parameters ρ and r_0 described in Assumptions 1.1 and 1.2. These values are unknown in advance and must be approximated from the $2N+1$ Fourier coefficients (2.2) or pseudospectral coefficients (2.15). This is an inherently difficult problem, since the Fourier approximation (2.1) is contaminated by Gibbs oscillations and cannot be expected to produce reliable results for determining factors ρ or r_0.

As shown in [9], another way for assessing smoothness of a function is from its Chebyshev coefficients, namely

$$\limsup_{k\to\infty} |a_k|^{1/k} = r_0, \tag{4.1}$$

where a_k, $k = 0, 1, \ldots$, are the Chebyshev coefficients of the function $f(x)$. This suggests that determining the smoothness parameters ρ and r_0 is equivalent to evaluating the decay rate of the Chebyshev coefficients a_k as $k \to \infty$. Clearly (4.1) cannot be used directly since the exact function $f(x)$ is not known. However, it is possible to compute an approximation to the Chebyshev coefficients $a_k^{(N)}$ based on the partial sum $f_N(x)$ in (2.1). Unfortunately, due to the poor convergence properties of $f_N(\mathrm{x})$, we cannot expect that

$$r_0^{(N)} := \limsup_{k\to\infty} \left| a_k^{(N)} \right|^{1/k} \tag{4.2}$$

will give a reliable estimate of r_0. Hence we seek a function approximation $\widetilde{f}_N(x)$ whose Chebyshev coefficients characterize the original function $f(x)$, such that

$$\widetilde{r}_0^{(N)} := \limsup_{k\to\infty} \left| \widetilde{a}_k^{(N)} \right|^{1/k} \to r_0, \tag{4.3}$$

where $\widetilde{a}_k^{(N)}$, $k = 0, 1, \ldots, K$, are the computed Chebyshev coefficients of $\widetilde{f}_N(x)$.

One possibility is to compute $\widetilde{f}_N(x) = f_g^{m,\lambda}(x)$ in (2.3) based on the assumed value of $\rho = 1$, as in [7]. This approximation converges exponentially to $f(x)$ when $\rho \neq 1$ (although not optimally), yet the computed Chebyshev coefficients $\widetilde{a}_k^{(N)}$ will not yield the correct r_0 in (4.3). This is due to the fact that $f_g^{m,\lambda}$ is a polynomial yielding $r_0 = \infty$ irrespective of m and λ.

A second alternative is to exploit the Bernoulli reconstruction method, [4] and [6], to approximate a function that is characterized by the same analyticity of $f(x)$ once the discontinuities have been removed. To be more specific, in this approach we define

$$\widetilde{f}_N(x) := f_N(x) - \frac{\sigma_N}{2}\Big(s_N(x) - s(x)\Big), \tag{4.4}$$

where $s_N(x)$ is the Fourier partial sum of the function

$$s(x) = x, \quad -1 \le x \le 1,$$

and σ_N is an approximation to the exact jump $\sigma = f(1) - f(-1)$ of the function $f(x)$. This approximation can be computed from the formula [18]

$$\sigma_N = \frac{\pi}{2\mu_1}\Big(f_N(\xi_N) - f_N(\bar{\xi}_N)\Big), \tag{4.5}$$

where

$$\mu_1 = \int_0^\pi \frac{\sin t}{t}\, dt \approx 1.852, \quad \xi_N = \frac{2N-1}{2N}, \quad \text{and} \quad \bar{\xi}_N = \frac{1-2N}{2N}.$$

It can be verified that

$$\widetilde{f}_N(x) - f(x) = g_N(x) - g(x) + \frac{\sigma - \sigma_N}{2}\Big(s_N(x) - s(x)\Big), \tag{4.6}$$

where

$$g(x) = f(x) - \frac{\sigma}{2}\, s(x) \quad \text{and} \quad g_N(x) = f_N(x) - \frac{\sigma}{2}\, s_N(x).$$

The function $g(x)$ is periodic and continuous on $[-1, 1]$ and as a result $g_N(x)$ is linearly convergent to $g(x)$ in the uniform norm. Since σ_N is also linearly convergent to σ, [18], it follows from (4.6) that $\widetilde{f}_N(x)$ is linearly convergent to $f(x)$. Therefore, (4.4) can be viewed as a preliminary resolution of the Gibbs phenomenon. More precisely, since $\widetilde{f}_N(x)$ was obtained by subtracting the oscillatory behavior of $f_N(x)$ we can expect that $\widetilde{f}_N(x)$ and $f(x)$ share similar smoothness characteristics on the interval $[-1, 1]$ described by the parameters ρ or r_0. Hence we expect that the Chebyshev coefficients $\widetilde{a}_k^{(N)}$, $k = 0, 1, \ldots, K$, for $K \approx N$, of the function $\widetilde{f}_N(x)$ will provide an accurate and reliable estimate of r_0 in (4.1). To illustrate that this is indeed the case, Figure 4.1 exhibits the approximations of r_0, $r_0^{(N)}$, and $\widetilde{r}_0^{(N)}$ versus ρ for the family of functions

$$f(x) = \frac{e^x}{x^2 + \rho^2}, \quad -1 \le x \le 1. \tag{4.7}$$

In this case, $f(x)$ has singularities on the imaginary axis at $x = \pm i\rho$ and the relationship between r_0 and ρ is given by (3.3). The approximations to r_0 are computed from the respective formulae

$$r_0 \approx \min\Big\{|a_k|^{1/k} : \ k_0 \le k \le K\Big\}, \tag{4.8}$$

$$r_0^{(N)} \approx \min\Big\{\Big|a_k^{(N)}\Big|^{1/k} : \ k_0 \le k \le K\Big\}, \tag{4.9}$$

and

$$\widetilde{r}_0^{(N)} \approx \min\Big\{\Big|\widetilde{a}_k^{(N)}\Big|^{1/k} : \ k_0 \le k \le K\Big\}, \tag{4.10}$$

which are less susceptible to round-off errors than the approximations based on (4.1), (4.2), and (4.3). Here, k_0 is a small positive integer chosen to eliminate the influence

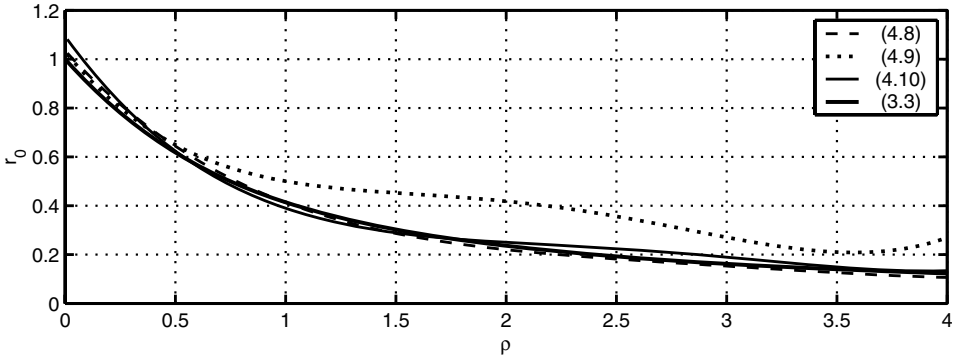

FIG. 4.1. r_0, $r_0^{(N)}$, *and* $\widetilde{r}_0^{(N)}$ *given by* (4.8), (4.9), *and* (4.10) *for* $K = N = 20$ *and* r_0 *given by* (3.3) *versus* ρ *for the function* (4.7).

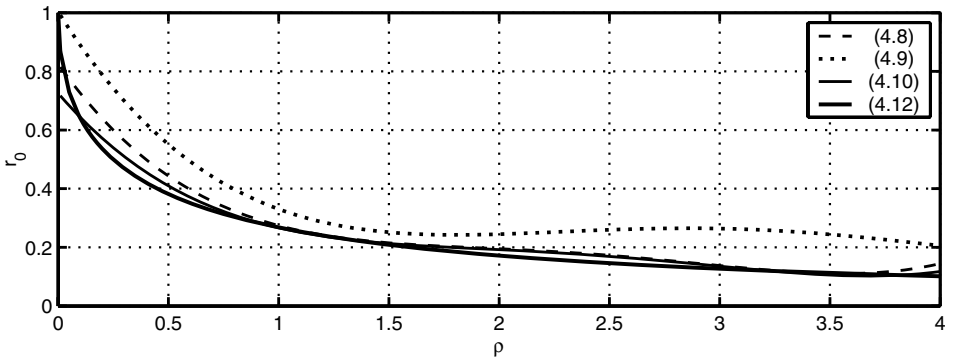

FIG. 4.2. r_0, $r_0^{(N)}$, *and* $\widetilde{r}_0^{(N)}$ *given by* (4.8), (4.9), *and* (4.10) *for* $K = N = 20$ *and* r_0 *given by* (4.12) *versus* ρ *for the function* (4.11).

of the first few Chebyshev coefficients on the estimate of r_0 and $K < N$. The exact value of r_0 given in (3.3) for $f(x)$ given in (4.7) is also plotted in Figure 4.1 by a thick solid line. It is evident that the approximation for $\widetilde{r}_0^N$, (4.10), converges to the desired value r_0. Figure 4.2 displays the approximations r_0, $r_0^{(N)}$, and $\widetilde{r}_0^{(N)}$ versus ρ for the family of functions

$$f(x) = \frac{e^x}{x^2 - (1+\rho)^2}, \quad -1 \le x \le 1, \tag{4.11}$$

which have singularities on the real axis at $x = \pm(1+\rho)$. In this case the relationship of r_0 and ρ is given by (see [12] and [15])

$$\rho = \frac{(r_0 - 1)^2}{2\, r_0} \quad \text{or} \quad r_0 = 1 + \rho - \sqrt{\rho^2 + 2\rho}. \tag{4.12}$$

As exhibited in Figure 4.2, the value of $\widetilde{r}_0^{(N)}$ computed by (4.10) yields an accurate comparison to (4.12), plotted by the thick solid line. The success of the smoothness predictor (4.10) will be further illustrated in section 5.

It is important to consider the following:

1. Recall that when the closest singularity of $f(x)$ to $[-1,1]$ is on the imaginary axis, then the relationship between r_0 and ρ is given by (3.3). This is further indication that parameter optimization based on Assumption 1.2, or equivalently the minimization of $\phi^1(\alpha,\beta)$ in (3.2), is more convenient since the computation of r_0 is possible without a priori knowledge of the position of the closest singularities. To determine ρ for $\phi^2(\alpha,\beta)$, it would first be necessary to determine where these singularities are in the complex plane.
2. Observe in Figures 4.1 and 4.2 that r_0 is approximated for $K = 20$. Although theoretically the estimate of r_0 should improve as $K \to \infty$, numerical implementation indicates that round-off error will affect the results for large K. Furthermore, reasonable estimates are already obtained for $K = 20$ yielding better computational efficiency for the evaluation of the approximation to the parameter r_0.
3. As explained in [6], the approximation (4.4) to $g(x)$ can be of higher order. It is likely that the smoothness parameter $\widetilde{r}_0^{(N)}$ resulting from a higher-order approximation of $g(x)$ will better match r_0 determined from (4.10). However, numerical experiments suggest that the first-order approximation is good enough in resolving (4.3), and we will therefore confine ourselves to this approximation.
4. The method described is developed exclusively for one-dimensional problems. Future investigations will address smoothness assessment for higher-dimensional functions.

5. Numerical examples. In this section we demonstrate the effectiveness of using the optimal parameters α and β which is determined by minimizing $\phi^1(\alpha,\beta)$ in (3.2). Recall that this optimization is inherently dependent on the smoothness parameter, r_0, (4.8), which is approximated by (4.10). As will become apparent, the strategy for selecting the Gegenbauer reconstruction parameters α and β is ideal for sparse data sets, that is, small N. For higher resolution, round-off error prohibits the Gegenbauer reconstruction method from converging for large m and λ, so other parameter alternatives must be considered. We experimented with the functions defined by (4.7) and (4.11), which have singularities on imaginary and real axis. For these respective functions, Tables 5.1 and 5.2 compare the exact values of r_0 given by (3.3) and (4.12) to the values $\widetilde{r}_0^{(N)}$, (4.10). Also displayed are the optimized parameters α and β corresponding to $\widetilde{r}_0^{(N)}$, which are computed by the least squares minimization method described in section 3. Finally, the last column shows the minimum balanced values of $q_T = q_R^1$ which indicate the speed of theoretical exponential convergence of the resulting Gegenbauer reconstruction.

TABLE 5.1
Parameters r_0, $\widetilde{r}_0^{(N)}$ for $K = N = 20$, α, β, and $q_T = q_R^1$ for $\rho = 0.25$, 0.5, 1, 2, and 4 corresponding to the function (4.7).

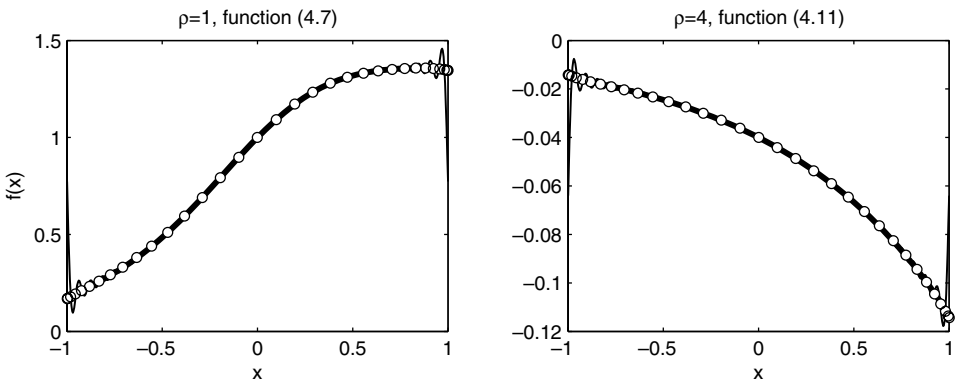

FIG. 5.1. *A comparison of the Gegenbauer (denoted by circles) and Fourier partial sum reconstructions (thin lines) for* (a) (4.7) *with $\rho = 1$ and* (b) (4.11) *with $\rho = 4$. Original functions are plotted by thick lines. Here $N = 32$, with α and β chosen from option* 4.

In the numerical experiments that follow, we consider the following four options for choosing the Gegenbauer parameters α and β:

- Option 1: $\beta = 0.25$ and $\alpha = 1.31$ computed from (3.1).
- Option 2: $\alpha = \beta = 0.25$, as suggested in [14].
- Option 3: $\alpha = \beta = 0.4$, also suggested in [14].
- Option 4: α and β computed by the minimization of $\phi^1(\alpha, \beta)$ in (3.2).

These values (corresponding to option 4) are listed in Table 5.1 for the function (4.7) and in Table 5.2 for the function (4.11) for specific values of the parameter ρ.

Figure 5.1 compares the Gegenbauer and Fourier partial sum reconstruction of (4.7) for $\rho = 1$ and (4.11) for $\rho = 4$ based on the parameters chosen by option 4. In each case we used $N = 32$. The results for the Gegenbauer reconstruction, using the parameters suggested by our strategy are clearly Gibbs-free and convergent.

The truncation (2.10) and regularization (2.12) errors can be viewed as competitive. Specifically, we observe that while the overall error converges for $\lambda, m \sim N$, the results of q_T get worse as m increases, and similarly q_R^1 (and q_R^2) will not decay as quickly for large λ. This behavior, illustrated in Figures 5.2 and 5.3, demonstrates why parameter optimization based on the analyticity of the underlying function is critical for the spectral convergence of the Gegenbauer reconstruction method, and why option 4 sometimes yields the only convergent approximation. The values of α and β corresponding to option 4 and specific values of the parameter ρ are indicated on Figures 5.2 and 5.3 by white diamonds. This is further punctuated by the example

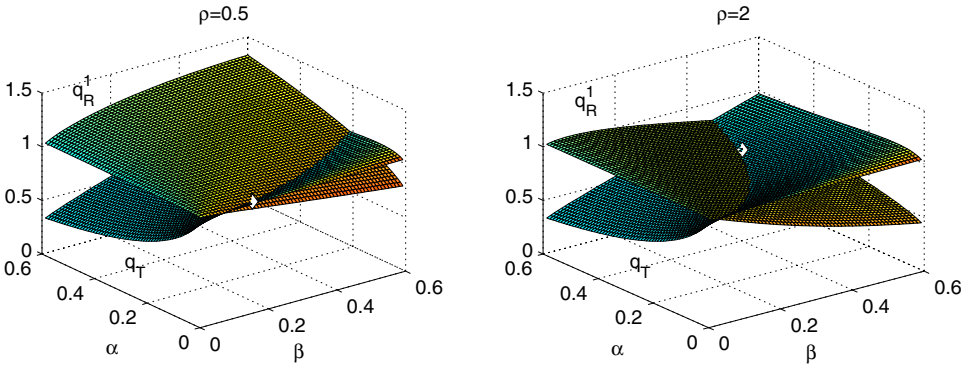

FIG. 5.2. *A comparison of the "competing" regularization and truncation errors for the function* (4.7) *with* (a) $\rho = 0.5$ *and* (b) $\rho = 2$.

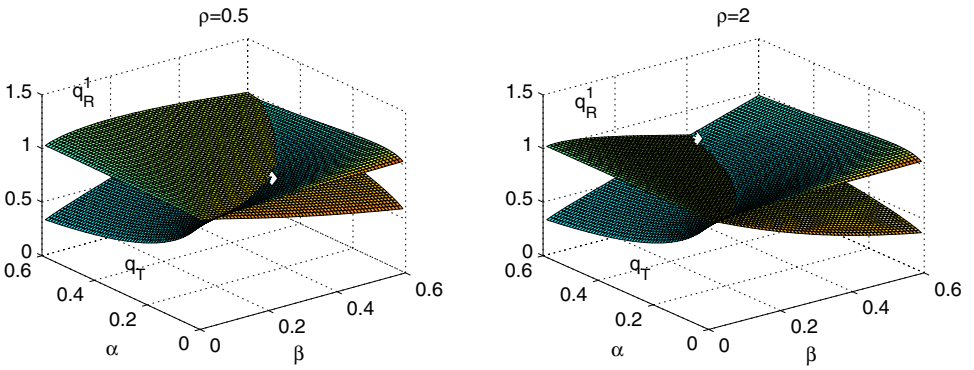

FIG. 5.3. *A comparison of the "competing" regularization and truncation errors for the function* (4.11) *with* (a) $\rho = 0.5$ *and* (b) $\rho = 2$.

given in (4.7) for $\rho \leq 0.5$. The Gegenbauer method is not convergent when α and β are chosen according to option 1, option 2, or option 3. Convergence is only observed when option 4 is used to pick the Gegenbauer parameters. Even in this case, as indicated by the ratio $q_T = q_R^1$ in Table 5.1, the convergence is quite slow and manifests itself only for large values of N. For example, for both $\rho = 0.25$ and $\rho = 0.5$, we require $N \geq 100$ for reasonable convergence and for $\rho = 0.5$, $q_T = q_R^1$ only for values close to 1. On the other hand, when $\rho = 1$, 2, or 4, all of the parameter choosing options lead to exponential convergence. The fastest rate corresponds to option 4. Figure 5.4 (left) illustrates a comparison of the convergence rates of the Gegenbauer reconstruction method utilizing different strategies for determining α and β for the example in (4.7) with $\rho = 1$. A least squares fit of these errors is also provided. As displayed in Table 5.1, when $\rho = 2$ the values of α and β determined by option 2 and by option 4 are quite similar, leading to similar convergence rates for these two choices of α and β.

Similar conclusions are also valid for the example given in (4.11), although in this case we observe exponential convergence for all choices of α and β and all values of ρ listed in Table 5.2. The parameters chosen by option 4 yield the fastest rate of

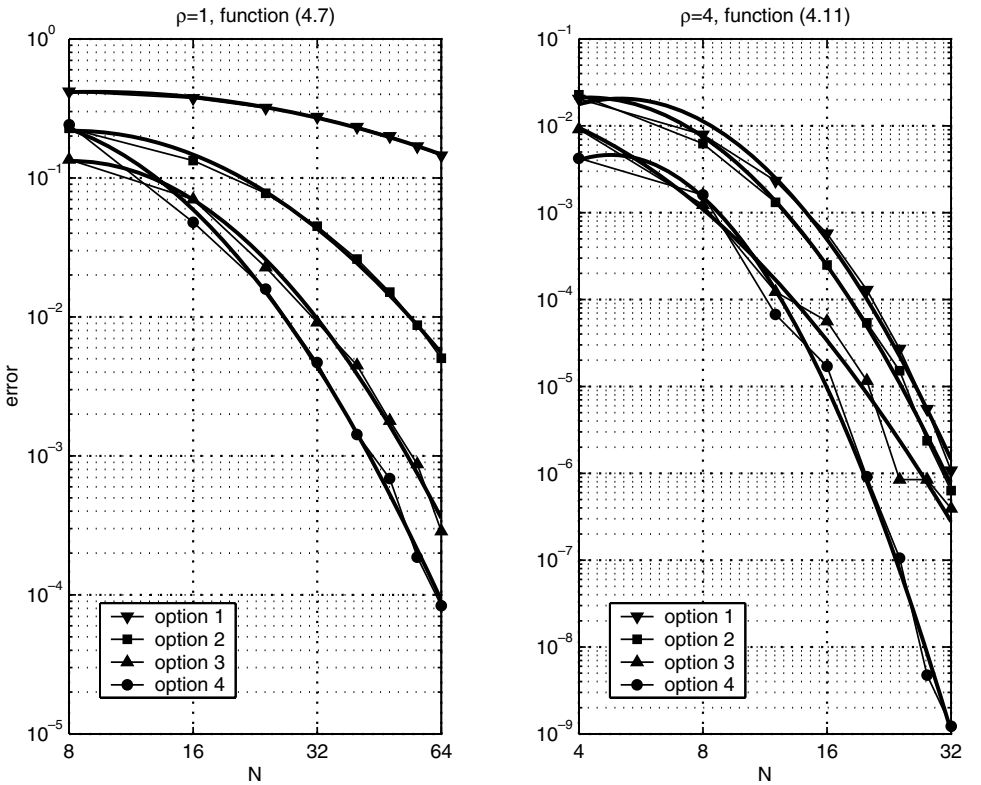

FIG. 5.4. *Errors of the Gegenbauer reconstruction methods for $\rho = 1$ and function* (4.7) *(left graph) and for $\rho = 4$ and the function* (4.11) *(right graph) versus N for different values of the parameters α and β. Least squares fits of these errors are also plotted by thick solid lines.*

convergence with the most pronounced improvement occurring for large values of ρ. For illustration, the errors of the resulting Gegenbauer reconstruction corresponding to $\rho = 4$ and α and β chosen according to option 1, option 2, option 3, and option 4 are displayed in Figure 5.4 (right) along with the least squares fits of these errors.

We note that the results are shown for relatively sparse data sets, or small N. As N and subsequently $\lambda = \alpha N$ and $m = \beta N$ increase, round-off error prohibits the convergence of the numerical Gegenbauer coefficients (2.4), and the overall convergence of the Gegenbauer reconstruction method will start to deteriorate. In fact it is possible to observe the beginning of round-off error effects in Figure 5.4 (right), where option 3 for $N = 28$ and $N = 32$ yields errors that do not signify exponential convergence. The continuation of these numerical experiments for larger N would yield round-off error for all options, and eventually the Gegenbauer reconstruction method would fail to converge at all. This problem can be alleviated by restricting the parameters m and λ by some upper bound where the effects of round-off errors can be controlled. These topics are discussed further in the recent paper [7].

6. Concluding remarks. The efficient resolution of a discontinuous function f from its first $2N + 1$ Fourier coefficients by the Gegenbauer reconstruction method requires the determination of the parameters $\lambda = \alpha N$ and $m = \beta N$ of the Gegenbauer polynomials C_l^λ, and coefficients $\widehat{g}^\lambda(l)$, $l = 0, 1, \ldots, m$. These parameters deter-

mine the speed of exponential convergence of the resulting reconstruction. However, they depend on the smoothness characteristics of the function f and are usually not known in advance. In this paper we have developed a new technique to estimate these smoothness characteristics of the function f from the Fourier partial sum $f_N(x)$. The smoothness of the function f can be characterized by a parameter r_0 which corresponds to the "size" of the ellipse for which the function f has analytic continuation. Our technique of assessing r_0 is based on using the information provided by the Chebyshev coefficients $a_k^{(N)}$ corresponding to the partial Fourier sum $f_N(x)$ and utilizes the fundamental formula $\limsup_{k\to\infty}|a_k|^{1/k} = r_0$, where a_k are Chebyshev coefficients of f, as discussed in [9]. The approximation method for the smoothness parameter r_0 described in this paper is suitable for one-dimensional problems, but due to its construction, we anticipate additional complexities in higher dimensions. Future work will address these issues. Once r_0 is computed, the optimal parameters α and β are then determined by minimizing the objective function (3.2) which assumes that the convergence rates corresponding to the regularization and truncation errors of the Gegenbauer reconstruction are asymptotically equal. The effectiveness of this technique for sparse data sets is demonstrated by numerical experiments for discontinuous functions which have singularities on the real or imaginary axis. In the case of large data sets, the smoothness indicator can be combined with other error estimates to alleviate the effects of round-off errors.

The results given here and other recent investigations suggest that the Gegenbauer reconstruction method may be beneficial for a wide variety of problems, particularly in imaging applications, especially if it continues to produce evidence of satisfactory performance in noisy environments. This will be the topic of future investigations, as will smoothness parameter approximation in higher dimensions.

MULTILEVEL ILU WITH REORDERINGS FOR DIAGONAL DOMINANCE*

YOUSEF SAAD†

Abstract. This paper presents a preconditioning method based on combining two-sided permutations with a multilevel approach. The nonsymmetric permutation exploits a greedy strategy to put large entries of the matrix in the diagonal of the upper leading submatrix. The method can be regarded as a complete pivoting version of the incomplete LU factorization. This leads to an effective incomplete factorization preconditioner for general nonsymmetric, irregularly structured, sparse linear systems.

Key words. incomplete LU factorization, ILUT, multilevel ILU preconditioner, Krylov subspace methods, multielimination, complete pivoting

1. Introduction.

In recent years, preconditioned Krylov subspace methods have made good progress toward their acceptance as general purpose techniques for solving irregularly structured sparse linear systems. One may distinguish between two categories of linear systems that are tackled by such methods. First is the class of linear systems which originate from the discretization of partial differential equations. Initially, preconditioned Krylov methods were only attempted on problems of elliptic type, for which a good body of theory existed. Because of their success, these methods have increasingly been employed on systems arising from various flow problems, Stokes and Navier–Stokes equations, Maxwell's equations, Helmholtz equations, and other types of models which lead to indefinite linear systems. The second category of linear systems includes problems which arise from applications which are not governed by partial differential equations (PDEs). An archetype of this class of problems is one that originated from power networks (see, e.g., [21, 18]) and which can be considered in some ways to be at the origin of irregularly structured sparse matrix problems as we know them today. Nowadays, these problems are considered small and are often best handled by sparse direct solvers. However, there are somewhat related problems in circuit simulation [13, 38], which cause difficulties to linear solvers. One may ask whether the distinction between these two classes of problems is important for a given system solver. For direct solvers, the origin of the problem has no direct impact on the solution algorithm, except that its "geometric" nature can influence complexity. The geometry of the underlying graph may matter more than whether or not the problem is likely to be highly indefinite, as it may have a major impact on fill-in. In general, however, the prevailing consensus so far has been that iterative methods are not as successful for this second class of methods as they have been for the PDE-based problems. As the sizes of the linear systems are becoming larger and more challenging, this issue has resurfaced recently and a few methods have been developed to increase the range of applicability of iterative methods. The work of Olschowka and Neumaier

[33] in particular showed that it is possible to essentially perform "static" pivoting prior to Gaussian elimination. Otherwise stated, it is possible to permute the rows of a matrix in such a way that in many cases pivoting becomes unnecessary during the elimination process. Olschowka and Neumaier indicated that this could be helpful in an incomplete LU factorization as well. The work by Duff and Koster described in [23, 24] followed this idea further by developing efficient codes and showing that the method can be quite effective in some cases. Other articles have since tested the idea on various problems and reported excellent success; see, for example, [3, 38].

This paper proposes a reordering method that is similar in spirit to the one described in [23, 24]. While both methods are based on improving diagonal dominance the one presented in this paper is essentially "dynamic" instead of "static." It proceeds by levels whereby each level corresponds to a block which has been extracted from the original matrix by permuting its rows and columns in a nonsymmetric way.

2. The quest for robust ILUs. Several distinct paths have been taken to improve the robustness of preconditioners for irregularly structured linear systems. The first [1] is to add partial pivoting to the incomplete LU factorization with threshold (ILUT); see [35]. The standard ILUT technique often fails for irregularly structured matrices. Partial column pivoting can be added to ILUT, and this yields the ILUTP algorithm [35]. Pivoting does help but there is no guarantee that a factorization will even be produced in some cases. One of the most common cases of failure results from the appearance of zero rows during factorization caused by the combination of permutations and dropping. However, ILUTP can work rather well if substantial fill-in is allowed—but the cost of the factorization may become prohibitive.

The second class of methods, which became popular in recent years, avoids ILU factorizations altogether and utilizes instead one of several methods to compute an approximation to the inverse of A directly; see, e.g., [5, 7, 8, 15, 27, 29]. Initially, these "approximate inverse methods" have been primarily developed for their parallelism. However, they are often viewed as robust alternatives to ILU factorization preconditioners; see, e.g., comments in [4, 6]. Though the factors produced by these methods do not suffer from the instability which plagues incomplete factorizations, they tend to require more memory and to cost more to build.

A third approach is to use a form of preordering whose goal is to move large entries of the matrix to the diagonal. In this method, the matrix is ordered on one side (e.g., rows only). Then pivoting is obviated during Gaussian elimination [24, 23]. The combination of ILU-type preconditioners with such a reordering strategy has been shown to be quite effective [3, 24, 23, 38].

The last class of methods we will mention has been developed following the work by Bollhöfer [9] which addresses the problem of rigorous dropping in ILU-type methods. These methods are founded on the intimate relationships between ILU factorizations and approximate inverse techniques [10]. Small terms are usually dropped in ILU either by considering their location (positional dropping) or their magnitude (threshold dropping) in some relative sense. The first approach works well for regularly structured problems arising from PDEs, but it is not designed for the more general case. The second is generally applicable but the greedy criterion on which it is based focuses on making LU close to A instead of making the preconditioned matrix close to the identity. It is often observed that the resulting factors are very ill-conditioned, and this leads to poor performance. A better strategy was defined in

[1] The order is not chronological.

[9] which exploits condition number estimators for dropping terms whose removal is least likely to be detrimental to the preconditioner. This strategy was combined with a Crout implementation of ILU in [31].

In contrast with similar existing strategies, the method discussed in this paper does not attempt to fill the whole diagonal of the original matrix with large entries. Instead, a more progressive, multilevel approach is taken whereby the unknowns associated with the upper leading submatrix are eliminated and the process is repeated on the reduced system. An alternative view of the process is that of a block complete pivoting ILU. Viewed from this angle, the process consists of finding two permutations P and Q such that

$$PAQ^T = \begin{pmatrix} B & F \\ E & C \end{pmatrix},$$

in which the B matrix has large diagonal entries. The unknowns associated with the B block can now be "safely" eliminated and the process repeated on the reduced system. Preconditioning techniques developed in this paper obtain approximate factorizations derived from this strategy. The method can also be regarded as a nonsymmetric version of the algebraic recursive multilevel solver (ARMS), which uses symmetric permutations (i.e., $P = Q$). Numerical experiments indicate a marked improvement in robustness over using symmetric permutations.

Note that in the ideal case, B would be of the same size as A. One can think, for example, of an algorithm that would yield a B matrix that is diagonal and contains most of the large entries of the matrix A. However, forcing B to be diagonal could severely limit its size in general, resulting in an expensive option.

We now briefly discuss practical issues surrounding pivoting for incomplete factorization. When a row version of delayed-update Gaussian elimination (the so-called IKJ version; see [26, p. 99]) is used, it is relatively easy to incorporate column pivoting. Since the pivoting is local, i.e., it is oblivious to the rows below the working (kth) row, dropping may lead to undesired results in later steps during the ILU factorization. For example, we already mentioned the common occurrence of zero rows during the process, especially when low levels of fill are used. When it works, the resulting LU factorization is capable of solving more problems in general, but the loss of structure due to pivoting results in a much more expensive algorithm, especially in terms of memory usage.

Incorporating partial pivoting in the more common rank-one update variant (the so-called KIJ variant) or other forms of incomplete LU factorizations does not seem to have been undertaken. However, the more interesting question one might ask is whether or not a form of complete pivoting is practical in the context of ILU. Searching for the largest entry in the working submatrix at each step seems to be exceedingly expensive and impractical. On the other hand, if this were possible, it would potentially enable the dropping of more terms. This is because the resulting factors are more likely to be stable (the norms of their inverses are not too large), and this will cause a milder effect on the terms dropped; see, for example, [9, 11]. A simplified argument of this fact is as follows. Let $A = LU + E$ where E represents the matrix of the terms that have been dropped from the factorization. Then the split-preconditioned matrix is such that

$$L^{-1}AU^{-1} = I + L^{-1}EU^{-1} .$$

This shows that the larger $\|L^{-1}\|$ and $\|U^{-1}\|$, the smaller the dropped terms must be in order to obtain a preconditioned matrix that is not too far from the identity.

To cope with the issue of cost, the method presented in this paper essentially resorts to a block pivoting approach that performs only an approximate version of complete pivoting.

3. Multilevel ILU preconditioners. A common method used to obtain a preconditioner is via a block ILU factorization, which involves an approximate Gaussian elimination process based on separating the original unknowns into a "coarse" and a "fine" set. These terms are borrowed from the algebraic multigrid (AMG) literature. In the class of preconditioners developed in [14, 37, 1, 36] the idea of independent sets or "group-independent" sets [25, 32, 30, 17, 34] is exploited to define this partition. Block independent set orderings permute the original linear system $Ax = b$ into the form

$$\begin{pmatrix} B & F \\ E & C \end{pmatrix} \begin{pmatrix} u \\ y \end{pmatrix} = \begin{pmatrix} f \\ g \end{pmatrix}, \tag{1}$$

in which the submatrix B is block diagonal. The ILUM [34] factorization utilizes standard independent set orderings which result in a matrix B that is diagonal. In this situation, it is easy to eliminate the u variable to obtain a system with only the y variable. The coefficient matrix for this "reduced system" is the Schur complement $S = C - EB^{-1}F$ which is still sparse, in general.[2] This idea was used recursively, applying dropping to S to limit fill-in and reordering the resulting reduced system into the above form via independent sets. This is repeated for a few levels until the system is small enough or a maximum number of levels is reached. Then the system is solved by some other standard means, such as a direct solver or an ILUT-GMRES combination.

3.1. Two-sided permutations. The algorithms described in this paper do not require B to have any particular structure. Instead, the rows and columns of A are permuted using two different permutations P (rows) and Q (columns), which will transform A into the form

$$PAQ^T = \begin{pmatrix} B & F \\ E & C \end{pmatrix}, \tag{2}$$

in which the matrix B has the property of being [illegible], in a way that is yet to be specified.

At the lth level of the procedure, the coefficient matrix is reordered as in (2) and the following block factorization is computed "approximately" (subscripts corresponding to level numbers are introduced):

$$P_l A_l Q_l^T = \begin{pmatrix} B_l & F_l \\ E_l & C_l \end{pmatrix} \approx \begin{pmatrix} L_l & 0 \\ E_l U_l^{-1} & I \end{pmatrix} \times \begin{pmatrix} U_l & L_l^{-1} F_l \\ 0 & A_{l+1} \end{pmatrix}, \tag{3}$$

where

$$B_l \approx L_l U_l, \tag{4}$$

$$A_{l+1} \approx C_l - (E_l U_l^{-1})(L_l^{-1} F_l)\ . \tag{5}$$

[2] For example, when B is diagonal, E has no more than nz_E nonzero elements per row, and F has no more than nz_F nonzero elements per row, then $EB^{-1}F$ will have no more than $nz_E \times nz_F$ nonzero entries per row.

When described with the help of recursivity, the procedure consists essentially of three steps. First, an ordering of the matrix in the form (2) is obtained and applied. Then, an ILU factorization $B_l \approx L_l U_l$ for B_l is computed. Finally, approximations to the matrices $L_l^{-1}F_l$, $E_l U_l^{-1}$, and then A_{l+1} are obtained. The process is repeated recursively on the matrix A_{l+1} until a selected number of levels is reached. At the last level, a simple ILUT factorization, typically with pivoting and very high fill-in levels, can be applied.

The A_is will no longer remain sparse in general, since B is no longer assumed to be diagonal or block-diagonal. Sparsity is regained by dropping small terms in various ways in the construction of L_l, U_l, $L_l^{-1}F_l, E_l U_l^{-1}$, and A_{l+1}. Note that the matrices $E_l U_l^{-1}, L_l^{-1}F_l$ or their approximations

$$G_l \approx E_l U_l^{-1}\ , \qquad W_l \approx L_l^{-1}F_l, \tag{6}$$

which are used to obtain the Schur complement via (5), need not be saved. They are computed only for the purpose of obtaining an approximation to A_{l+1}. Once this is accomplished, they are discarded to save storage. Subsequent operations with $L_l^{-1}F_l$ and $E_l U_l^{-1}$ are performed using U_l, L_l, and the blocks E_l and F_l.

The rationale of the orderings that will be proposed next is that it is critical to have an accurate and well-conditioned B block in the multilevel factorization discussed above. Alternatively, we can also think in terms of complete pivoting. Assume for a moment that B is a 1×1 block. Then, clearly one can think of selecting the permutations P and Q in such a way as to move the best possible pivot from the matrix to location $(1,1)$. The first row can then be eliminated and the process could be repeated for the remaining $(n-1) \times (n-1)$ matrix. Unfortunately, this procedure is too costly because of the search required to find the best pivot at each step. A more effective alternative is to select the best k pivots at the same time, so B now becomes a block of size k. The next section discusses a few heuristics which use diagonal dominance as a criterion for selecting the B block.

3.2. The block complete pivoting viewpoint. We begin by introducing the notation and terminology used in describing the algorithms. A pair of permutations (P, Q) is completely defined from the corresponding two permutations $\{p_1, p_2, \ldots, p_n\}$ $\{q_1, q_2, \ldots, q_n\}$ of the set $\{1, 2, \ldots, n\}$. Since we use partial permutations (which define the block B), we define a matching set $\mathcal{M}$ as a set of n_M pairs (p_i, q_i) where $n_M \leq n$ and

$$1 \leq p_i, q_i \leq n \text{ for } i = 1, \ldots, n_M \quad \text{and} \quad p_i \neq p_j \text{ for } i \neq j, \quad q_i \neq q_j \text{ for } i \neq j. \tag{7}$$

Note that the case when $n_M = n$ corresponds precisely to a (full) permutation pair (P, Q). A partial matching set can be completed into a complete matching set by simply scanning the set of p_is and adding entries from the set $\{1, 2, \ldots, n\}$ which are missing, and then repeating the process for the q_is. The function returning the number of nonzero entries in a row or column is denoted by $nz(.)$. Thus, for example, $nz(a_{i,:})$ is the number of nonzero elements in the ith row of A and $nz(a_{:,j})$ is the number of nonzero elements in the jth column of A.

For lack of a better name we will refer to the class of reordering algorithms to be described in this section as "ddPQ" orderings (P and Q stand for the permutations used and "dd" indicates that the ideal permutation would yield a diagonally dominant B block). These are heuristic methods which consist of two stages. In a first stage, candidate entries a_{ij} are "preselected" as possible diagonal entries. This procedure will

also order the candidate entries that are selected by using a certain measure which will attempt to use a criterion of diagonal dominance and the number of nonzero entries. The second stage scans these candidate entries in the order given by the preselection stage and decides on accepting or rejecting the entry into the $\mathcal{M}$ set.

The simplest preselection algorithm is based on using the ratios

$$\frac{|a_{ij}|}{\|a_{i,:}\|_1}.$$

A criterion using ratios of this type for the diagonal entries ($i = j$) was also used in an early version of ARMS [36] for filtering equations that are least diagonal dominant in a symmetric permutation setting. Let $j(i)$ be a column index of the largest (in absolute value) entry of row i ($|a_{i,j(i)}| \geq |a_{ij}|$ for all j). The ratio

$$\frac{|a_{i,j(i)}|}{\|a_{i,:}\|_1} \tag{8}$$

can be viewed as a measure of rowwise diagonal dominance of row i if the term $(i, j(i))$ is permuted as a diagonal entry. The selection of $a_{i,j(i)}$ as a diagonal term would result in a (weakly) diagonally dominant row if the above ratio is $\geq 1/2$. In practice, we can screen out all entries for which these ratios are no greater than a certain threshold τ.

In a second step, the preselection algorithm will rank all the pairs $(i, j(i))$ in preparation for the next phase of matching, where the permutations P and Q are actually built. The ranking will simply yield a good order in which to scan the list of pairs when determining which ones are valid or best to keep. The simplest possibility is to sort the selected pairs $(i, j(i))$ by decreasing value of the ratios (8). This would favor diagonally dominant rows to be scanned first. However, this ranking does not take sparsity into account. For example, a dense row may be selected because of a high diagonal dominance ratio, and this will yield a full Schur complement matrix. To remedy this, we multiply the above ratios by a quantity that will encourage sparser rows to be selected first. Several such measures were tested and they lead to similar results. The measure

$$\frac{|a_{i,j(i)}|}{\|a_{i,:}\|_1} \times \frac{1}{nz(a_{i,:})} \tag{9}$$

gives higher priority to rows with good diagonal dominance characteristics which are at the same time sparse. Other possibilities tested incorporated the value $nz(a_{:,j(i)})$ or both the values $nz(a_{:,j(i)})$ and $nz(a_{i,:})$. The following algorithm uses the ratios (9).

ALGORITHM 3.1. PRESELECTION

1 $\mathcal{D} = \emptyset$
2 For $i = 1, \ldots, n$
3 Compute $t_i = \|a_{i,:}\|_1$ and $j(i) = argmax_k |a_{ik}|$
4 If $|a_{i,j(i)}| > \tau\, t_i$ then $(i, j(i)) \in \mathcal{D}$
5
6 For each $(i, j(i)) \in \mathcal{D}$
7 Compute $w_i = \frac{|a_{i,j(i)}|}{\|a_{i,:}\|_1} \times \frac{1}{nz(a_{i,:})}$
8
9 Sort $\mathcal{D}$ according to decreasing values of w_i. Thus, $\mathcal{D} = \{(i_1, j_1), (i_2, j_2), \ldots, (i_{n_D}, j_{n_D})\}$ where $w_{i_1} \geq w_{i_2} \geq \cdots \geq w_{i_{n_D}}$

In order to avoid situations in which the preselection algorithm returns with an empty set, we scale the threshold τ relative to the largest of these ratios. Thus, given an input parameter τ_0, the actual threshold τ used in the algorithm is

$$\tau = \tau_0 \times \max_i \left[\frac{|a_{i,j(i)}|}{\|a_{i,:}\|_1} \right] . \tag{10}$$

This ensures that the worst rows on a relative basis will be rejected. The parameter τ_0 should be between 0 and 1 and typical values are in the range 0.1–0.3. If τ_0 is strictly less than one, then at least one row will be preselected.

The algorithm begins by computing the required norms, and then in line 4 it prescreens the rows by keeping only those that do show enough diagonal dominance (relative to other rows). This initial rejection of poor candidate rows will reduce the cost of the next phase, which involves a sort (line 9). As discussed above, in order to reduce fill-in the diagonal dominance ratios are modified. They are divided by the number of nonzero elements in row i (see line 7). The last stage of the algorithm sorts the entries in $\mathcal{D}$ in descending order of the resulting ratios.

The above algorithm selects good candidates for diagonal entries according to a simple diagonal dominance criterion. To complete the process we now need to select pairs to keep in $\mathcal{M}$. We could, for example, scan all pairs returned by Algorithm 3.1 and keep all the pairs as long as they do not violate the requirement in the definition (7). Clearly, the list should be traversed in the same order in which it is provided by Algorithm 3.1. Therefore, the simplest strategy is a greedy technique which scans the set $\mathcal{D}$ and accepts any pair (p_i, q_i) such that neither p_i nor q_i have already been included in a pair of $\mathcal{M}$.

ALGORITHM 3.2. GREEDY MATCHING SET SELECTION

0 $\mathcal{D}$ $count = 0$
1 $\mathcal{M} = \emptyset$ $P(i) = Q(i) = -1$ $i = 1, \ldots, n$
2 $k = 1, \ldots, n_D$
3 (i_k, j_k) k $\mathcal{D}$
4 $(Q(j_k) == -1$
5 (i_k, j_k) $\mathcal{M}$ $count = count + 1$
6 $P(i_k) = count$; $Q(j_k) = count$.
7
8

Note that normally we would also require that $P(i_k) == -1$ in line 4, but this is unnecessary since there is only one (i_k, j_k) selected for each row and therefore $P(i_k)$ can be assigned a positive value only once. At the completion of the algorithm, the matching set is the set of all pairs (i, j) such that $P(i)$ and $Q(j)$ are both nonnegative. Note also that $P(:)$ represents an incomplete reverse permutation array. If completed it would simply be the "old-to-new" usual mapping for the row permutations. Similarly, the Q array represents an incomplete "old-to-new" mapping for the columns. The only remaining step now is to complete these two permutations. This is achieved by a simple greedy procedure such as the following, applied here to P.

```
1. For i = 1 : n Do:
2.       if (P(i) < 0)
3.                 count = count + 1
4.                 P(i) = count;
5.       EndIf
6. EndFor
```

Note that, initially, *count* must have the value returned by the matching algorithm. The same procedure as above is applied to complete the permutation Q. We will refer to this procedure as the "greedy completion" algorithm. It should be mentioned that this simple procedure will allow zero entries to be introduced in the diagonal of the C block. This is not a problem, for two reasons. First, it is the Schur complement matrix that counts and when it is built, fill-ins are likely to be introduced into its diagonal. Second, this block will be further permuted anyway, either by the recursive application of the process to the new level created or, if the last level is reached, by column pivoting in the ILUTP procedure or the full Gaussian elimination, when solving the system.

This process is illustrated in Figure 1. In the 8×8 matrix shown on the left of the figure, the circled entries are the ones preselected by the algorithm, with the numbers in the circles indicating the ranks attributed by the sorting step in Line 9 of the algorithm. The entries shown in shaded squares are the other nonzero elements of the matrix.

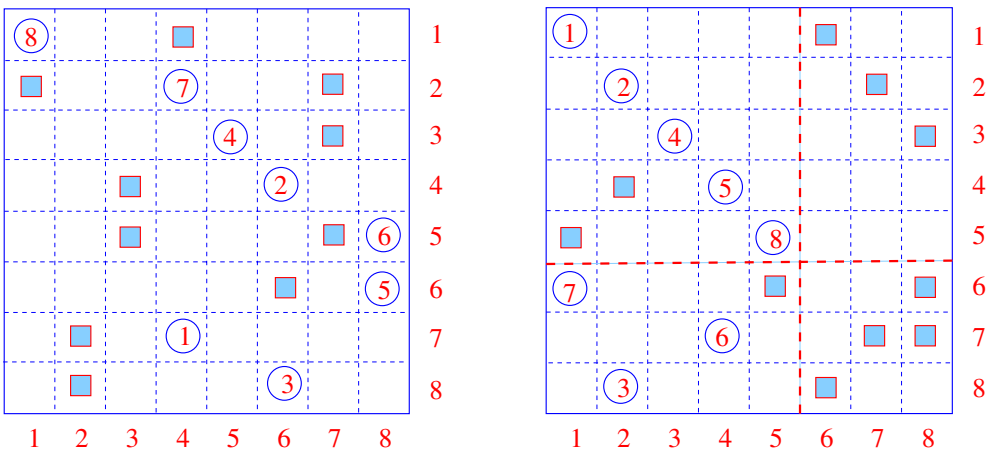

FIG. 1. *An* 8×8 *matrix after the preselection algorithm (left) and the result of the nonsymmetric permutation obtained from the greedy matching procedure. Circled numbers are selected entries and the numbers are the ranks attributed by the preselection algorithm (right).*

Observe that, by its nature, the algorithm clearly selects at most one entry per row. However, there may be more than one selected entry per column. If the greedy matching algorithm is applied, it will end up accepting 5 pairs, and the status of the arrays P, Q at the end is as follows:

P	5	-1	3	2	-1	4	1	-1
Q	5	-1	-1	1	3	2	-1	4

These are then completed by "greedy completion" into

P	5	6	3	2	7	4	1	8
Q	5	6	7	1	3	2	8	4

Once the permutation is found, the matrix is reordered into the form (2). The thick dashed lines in the matrix on the right side of the figure correspond to the partitioning in the right-hand side of (2). Note that there is no particular structure associated with the block B. In the next block-elimination step, equations from 1

to 5 (first level) of the permuted matrix are eliminated and dropping is applied to the resulting 3×3 Schur complement matrix. This means that we compute the factorization (3). This entails computing the ILU factorization of B (4), and then computing an approximation to the Schur complement, as shown in (5). If desired, the process can now be repeated on the next level, i.e., on the Schur complement matrix A_{l+1}.

The outer (Gaussian) elimination procedure stops whenever either a maximum number of levels is exceeded or the Schur complement becomes small enough. Assume that for the above example it is decided that only one level is performed. Then it only remains to solve this last (3×3) linear system. In our code, this is done with a pivoting ILUTP procedure, typically with very little dropping (as dictated by a parameter). For all purposes, one can think of this as an accurate solve with Gaussian elimination with column pivoting. ILUTP is selected for the cases when the last block is not small enough, in order to provide more options to the procedure. Note that one can easily obtain a singular Schur complement matrix S after dropping is applied. If no dropping is applied, then it is well known that S will be nonsingular as long as the original matrix and B are both nonsingular. An important point here is that the permutations P, Q that are sought at a given level do not have to take into consideration the quality of the resulting Schur complement A_{l+1}. This matrix will be dealt with at the next level.

Of course, if the original matrix is strongly diagonally dominant, then the process will retain many rows in the first one or two levels, so the algorithm will require very few levels. In general, the algorithm requires a small number of levels, unless τ_0 is close to one.

If B were to be a diagonal matrix, then the elimination process could be viewed as a multielimination algorithm with complete pivoting. Instead of selecting one pivot at a time, the algorithm selects the largest possible number of pivots allowed by a greedy approach, in which the selection criterion attempts to compromise between a diagonal dominance requirement and the number of nonzero entries in the rows.

Note that one alternative to Algorithm 3.2 is to use the MC21 procedure, which performs a maximal transversal for bipartite matching; see, e.g., [23, 21, 20, 19]. This algorithm, whose goal is to find a maximal set of matching pairs, is not expensive and is easy to implement. One major difference from Algorithm 3.2 is that MC21 does not take into account numerical values or any weights assigned to entries. It only finds a row (or column) permutation P such that PA has nonzero entries on the diagonal.

Another observation is that the procedure will fail when a row or column of the Schur complement is zero. It turns out that this rarely happens in practice. Recall that if B is nonsingular and A is nonsingular, then S is nonsingular, so the situation will not happen in this ideal case. The only risk is to make S singular because of dropping, but this is rare with standard threshold-based dropping procedures.

3.3. Diagonal scaling. Scaling the rows and columns of a general sparse matrix prior to attempting to compute its ILU factorization is critical to the success of the preconditioner. The effect of row and column scaling on the quality of the preconditioner is not too well understood, however. When scaling, e.g., the rows of a nondiagonally dominant matrix by, say, their infinity norms, the effect may not necessarily be beneficial to the accelerator. This may be due to the fact that scaling affects the degree of nonnormality. Diagonally or nearly diagonally dominant matrices do not seem to be affected as much by row/column scaling.

Our research code ARMS-C (C for complete pivoting) offers some options for

scaling the matrices obtained at each level and the last level. If requested, rows of the interlevel matrices A_i are first scaled by their 1-norms. Then, if requested, columns of the resulting matrix are also scaled by their 1-norms. In particular, vectors must be allocated to save the scaling factors for the left and right scaling at each level. Though this strategy works well in many cases, experiments reveal that it is not always the best. As was already mentioned, we have found that the use of scaling may yield a poorer preconditioner than without any scaling at all (see the numerical tests section), though this situation is somewhat uncommon. There are also cases when it is best to start scaling the columns first and then the rows, or scaling rows only or columns only. The issue of scaling in the context of preconditioners is a topic of great importance, and one that has not been given enough attention in the literature. Scaling will be revisited in the numerical experiments section.

4. Matching heuristics. We now examine a few alternatives to the greedy approach of Algorithm 3.2. It may be desirable, for example, to seek to enforce some form of diagonal dominance in the B part of (1). Having a B matrix in a form that leads to easy solutions may also be appealing. We have tested a good number of strategies but show only three here in addition to the greedy technique of Algorithm 3.2.

It is worthwhile to first examine carefully the problem of enforcing diagonal dominance in B. The strategy of Algorithm 3.2 is not guaranteed to produce a B matrix that is diagonally dominant, in general. The ideal situation would be to find permutations P, Q so that the B block in (2) is exactly diagonally dominant, as well as of large size. Note that we are restricting the diagonal dominance requirement to the rows of B, not those of A; i.e., entries in F do not matter. We can state that the problem is to find a matching set satisfying (7) such that the corresponding B matrix, which is defined as

$$\{a_{p(i),q(j)}\}_{i,j=1,\ldots,n_M},$$

is diagonally dominant. As can be easily grasped, this is a difficult problem since its requirement is a global one: the diagonal dominance requirement involves the matching set as a whole.

One possibility for obtaining a diagonally dominant B is simply not to accept any rows that are not diagonally dominant as rows of A in the preselection algorithm. Taking $\tau = 0.5$ in Algorithm 3.1 forces candidate rows scanned in line 4 of the algorithm to be diagonally dominant. Since the corresponding B rows have fewer (nondiagonal) entries than the same row of A, then a fortiori the corresponding row in B will be diagonally dominant. However, this does not work in general simply because in many cases, A may not even have one single row that is diagonally dominant. The sufficient condition used in this strategy is too restrictive. It should be mentioned that in our codes, the scalar τ is determined on a relative basis by a formula such as (10).

Enforcing diagonal dominance in B is easily achieved by restricting B to be triangular. This strategy is presented first in spite of its main limitation, which is that it tends to produce a B block that is small. It will also serve as an introduction to the other matching strategies, which relax the triangularity restriction.

4.1. Matching for a triangular diagonally dominant B. To obtain a lower triangular matrix, it suffices to mark all column indices of a selected row i so that they will become ineligible for inclusion in the later steps. In addition, before adding $(i, j(i))$ to the set $\mathcal{M}$, we need to verify that the row is diagonally dominant. This gives the following modification of Algorithm 3.2.

ALGORITHM 4.1. REORDERING FOR A TRIANGULAR B BLOCK

1 $\mathcal{M} = \emptyset$. $P(i) = Q(i) = -1$, $i = 1, \ldots, n$. $count = 0$.
2 For $i = 1, \ldots, n_D$
3 If $Q(j(i)) != -1$
4 Compute $t_B = \sum_{k \in S_B(i)} |a_{ik}|$ where $S_B(i) = \{k |\ k \in adj(A,i).$
$Q(k) \geq 0\}$
5 If $t_B \leq |a_{i,j(i)}|$
6 Add $(i, j(i))$ to $\mathcal{M}$ (a) $count = count + 1$. (b) $P(i) = Q(j(i)) = count$.
7 For $k = 1, \ldots, ks$ if $adj(A,i)$ and $Q(k) == -1$
8 Set $Q(k) = -2$
9 EndIf
10 EndFor

The set $S_B(i)$ introduced in line 4 represents the set of column indices that have already been accepted into B prior to step i. These will represent the indices of the nonzero entries of row $P(i)$ of the strict lower triangular matrix after permutation. Thus, step 4 computes the sum of the absolute values of all entries in the strict lower part of the matrix that would become B after reordering. The next line tests if the corresponding row is (weakly) diagonally dominant. If it is, then the candidate pair $(i, j(i))$ is accepted (line 6) and all column indices in the row which are not yet assigned are assigned the value -2, so that these columns will not be selected in future steps. This ensures that B will be lower triangular. A negative value that is different from -1 is used to allow proper completion by the greedy completion algorithm.

4.2. Matching for an augmented triangular B. Forcing B to be triangular may be restrictive. It leads to a B block that is typically much smaller than with the greedy approach of Algorithm 3.2, resulting in a higher number of levels and a more expensive factorization in the end. The algorithm described next can be viewed as a less restrictive version of Algorithm 4.1 whereby some entries are allowed in the upper triangular part of B so long as diagonal dominance is preserved.

At each ith step, the modified algorithm begins by computing the quantity

$$t = |a_{i,j(i)}| - \sum_{k \in S_B(i)} |a_{ik}| .$$

Recall that $S_B(i)$ is simply the set of indices that correspond to the lower triangular part of row $P(i)$ of the matrix B. Similarly, we denote by $S_F(i)$ the set of column indices that have been rejected prior to step i. We set $n_B(i) = |S_B(i)|$ and, similarly, $n_F(i) = |S_F(i)|$. Thus, there are at most $nz(a_{i,:}) - n_B(i) - n_F(i)$ entries which have not yet been tagged as members of B or F. If t is negative, then this row cannot be diagonally dominant since the lower part of B is already not diagonally dominant. In this case the algorithm will skip to the next candidate pair. If, on the other hand, t is positive, then we may accept entries to the right of the diagonal entry of B. In this case, the algorithm will proceed to accept entries that are not larger than

$$\frac{t}{nz(a_{i,:}) - n_B(i) - n_F(i))},$$

where $n_B(i)$ is the number of entries of the row being examined that are already in B, and, similarly, $n_F(i)$ is the number of entries that are already in F. All other column entries are rejected; i.e., they are tagged as part of F.

ALGORITHM 4.2. AUGMENTED TRIANGULAR B

1 $\mathcal{M} = \emptyset$. $P(i) = Q(i) = -1$, $i = 1, \ldots, n$. $count = 0$
2 $i = 1, \ldots, n_D$
3 $Q(j(i)) \; != \; -1$
4 $S_B(i) = \{k |\; k \in adj(A, i); Q(k) \geq 0\}$
5 $S_F(i) = \{k |\; k \in adj(A, i); Q(k) == -2\}$.
6 $t_B = \sum_{k \in S_B(i)} |a_{ik}| \quad n_B = |S_B(i)|$ $n_F = |S_F(i)|$
7 $t_B \leq |a_{i,j(i)}|$
8 $(i, j(i))$ $\mathcal{M}$ (a) $count = count + 1$.
(b) $P(i) = Q(j(i)) = count$.
9 $\gamma = (|a_{i,j(i)}| - t_B)/(nz(a_{i,:}) - nB - nF)$
10 k, $adj(A, i)$ $Q(k) == -1$
11 $|a_{ik}| > \gamma$ $Q(k) = -2$
12
13
14
15 $\mathcal{M}$

The resulting rows of B will be row diagonally dominant.

PROPOSITION 4.1. P, Q 4.2 B (2)

Recall that $S_B(i)$ is the subset of column indices that have been accepted into B prior to step i and $S_F(i)$ is the set of rejected columns prior to step i. Define $S'_B(i)$ to be the set of all column indices that have been accepted into B of step i and $S_a(i)$ to be the set of entries that have been accepted at step i. So $S'_B(i) = S_B(i) \cup S_a(i)$. Let $n_a = |S_a(i)|$ and note $n_a + n_B(i) + n_F(i) \leq nz(a_{i,:})$, i.e., $n_a \leq nz(a_{i,:}) - n_B(i) - n_F(i)$. Then

$$\begin{aligned} |a_{i,j(i)}| - \sum_{k \in S'_B(i)} |a_{ik}| &= |a_{i,j(i)}| - \sum_{k \in S_B(i)} |a_{ik}| - \sum_{k \in S_a(i)} |a_{ik}| \\ &= t - \sum_{k \in S_a} |a_{ik}| \\ &\geq t - n_a \times \frac{t}{nz(a_{i,:}) - n_B(i) - n_F(i)} \\ &\geq 0. \qquad \square \end{aligned}$$

A variation on this procedure consists essentially of adjusting the average γ computed in line 9 as new entries are accepted. The sum t_B as well as the number n_B are changed each time a new entry is accepted into B. This allows the acceptance of more entries. An algorithm of this type is described next.

4.3. Matching based on dynamic averages. This technique assigns a "dynamic" measure of diagonal dominance of a row when considered as a row of B at a given step. Each step of the algorithm examines the selected pairs $i, j(i)$ from $\mathcal{D}$. It begins by computing $\rho_i = |a_{i,j(i)}|$, which is the entry of the row with largest magnitude. The row is then scanned to determine how much room is left for accepting new entries into B. This is done as follows. Prior to step i the algorithm has accepted a number of entries already. These will show up in the lower triangular part after reordering. The indicator ρ_i will be adjusted by subtracting from it the absolute values of all these entries. It will be updated similarly every time a column is accepted into

the B part. Some columns have also been rejected and these will show up in the F part after reordering. The columns that are left are potential candidates for being accepted in the B part. The algorithm will reject columns among these based on a criterion similar to the one in the previous algorithm.

When a row is scanned, an entry $|a_{ik}|$ is tested against the current value of ρ_i divided by the number of entries that may still potentially be candidates for being accepted in B. If it is less, then it is accepted into B and ρ_i is decreased accordingly. If the test is not satisfied the column k is marked as not accepted. The counter of the number of entries in the row that are not in B is also decremented.

ALGORITHM 4.3. AUGMENTED TRIANGULAR B WITH DYNAMIC AVERAGES

1 $\mathcal{M} = \emptyset$ $P(i) = Q(i) = -1$ $i = 1, \ldots, n$ $count = 0$
2 $i = 1, \ldots, n_D$
3 $Q(j(i)) \; != \; -1$ $(i, j(i)$
4 $S_B(i) = \{k |\; k \in adj(A, i); Q(k) \geq 0\}$
5 $S_F(i) = \{k |\; k \in adj(A, i); Q(k) == -2\}.$
6 $\rho = |a_{i,j(i)}| - \sum_{k \in S_B(i)} |a_{ik}|$
7 $nz = |adj(A, i)| - |S_B(i)| - |S_F(i)|$
8 $(\rho < 0)$ $(i, j(i))$
9 $(i, j(i))$ $\mathcal{M}$ (a) $count = count + 1$. (b) $P(i) = Q(j(i)) = count$.
10 $j \in Adj(i)$ $Q(j) == -1$
11 $(nz * |a_{i,j}| > \rho)$
12 $Q(j) = -2$ j
13 j
14 $\rho = \rho - |a_{i,j}|$ ρ
15
16 $nz = nz - 1$ nz
17
18
19 $\mathcal{M}$

We now briefly discuss the main steps of the algorithm. The variable ρ can be viewed as a diagonal dominance indicator for the running row, as a row of B. As long as it is nonnegative then the current row remains diagonally dominant. Lines 4 to 7 compute the value of ρ at the start, which is the max value $|a_{i,j(i)}|$ minus the absolute values of the entries $a_{i,j}$ for which the column j is already a row of B. The number of columns that are still "undecided," i.e., that are neither in B nor in F, is also computed (line 7) and it is called nz. If the computed initial value of ρ is negative then clearly row i must be rejected as is done in line 8. Otherwise the pair $(i, j(i))$ is added to $\mathcal{M}$ by updating P, Q, and the counter *count* as is done in line 9. The loop in lines 10–17 scans row i a second time. Each column j that is still undecided ($Q(j) == -1$) is examined. If $|a_{ij}| > \rho/nz$, then the column is tagged as rejected ($Q(j) == -2$). Otherwise it is accepted (so far), and the B-diagonal dominance indicator ρ is updated accordingly. In either case, the number of undecided columns is reduced by one. It is clear that acceptance into B is only tentative since a column that is accepted at this step may be rejected later.

As can be easily established, the algorithm produces a matrix B that is row (weakly) diagonally dominant.

PROPOSITION 4.2. P, Q 4.3 B (2)

. Throughout step i of the algorithm, the variable ρ represents the absolute

value of the difference between $a_{i,j(i)}$ and the entries a_{ij} that are accepted into the B part, i.e., those for which $Q(j)$ will wind up positive after step $i-1$. After line 8, the B part of row i is diagonally dominant since $\rho \geq 0$. When a column is not tagged with -2, then it can potentially become part of B. Consider now the row at the completion of the next loop (lines 10–17). At each step when a column is not rejected (lines 13–15), a new ρ is computed, $\rho_{new} = \rho - |a_{ij}|$, and the new total potential entries in the B part of the row is also updated as $nz_{new} = nz - 1$. We have

$$\rho_{new} = \rho - |a_{ij}| \geq nz|a_{ij}| - |a_{ij}| = nz_{new}|a_{ij}|,$$

which shows that ρ will remain nonnegative throughout the step. In the end there will be fewer entries that are finally accepted (as some columns will be rejected in later steps). Therefore the resulting row of B will remain diagonally dominant. ∎

5. Cost analysis of multilevel nonsymmetric orderings. The first concern when considering the use of the algorithms described above is likely to be in regards to cost, specifically the cost of obtaining the pair of permutations. Obtaining the permutations may be expensive with a poor implementation or a poor choice of parameters.

Consider the preselection algorithm first and let nnz_l be the number of nonzero elements in A_l. At each level there are nnz_l potential candidates to become diagonal entries. The parameter τ allows the elimination of a large fraction of them with the goal of reducing the cost. The algorithm starts by obtaining the largest entry in each row at the cost of nnz_l. In the second phase of the algorithm, weight factors are computed for each of the n_D entries of $\mathcal{D}$ at the cost of $O(n_D)$. Finally, the entries in $\mathcal{D}$ are sorted according to these weights, at the cost of $O(n_D \log n_D)$. Since we do not have an idea of the size of n_D, we need to make an assumption which will enable us to obtain an estimate. We will assume that from one level to the next the size n_l of the matrix A_l is reduced by a constant ratio K. In other words, referring to the splitting (3), we assume that

$$size(A_l)/size(A_{l+1}) \approx K > 1 \ .$$

On average this is a fairly representative model. It is clear that K will depend on τ as well as on the structure of the matrix, its number of nonzero elements per row, etc. At each level the size of $\mathcal{D}$ is a fraction of n_l, the matrix size at level l. Since we limit the fill-in in each row (see the parameters used in the experiments), the number nnz_l of nonzero entries in A_l is a multiple of n_l (in worse situations it can possibly be as high as $n_l \log n_l$, but this does not affect the end result). With this the cost at each level becomes

$$O(nnz_l) + O(n_D \log n_D) \leq \beta n_l + \gamma n_l \log n_l \sim \gamma n_l \log n_l \ .$$

If we have p levels the total cost will be of the form

$$\begin{aligned} T(n) &= \gamma \left[n \log n + \frac{n}{K} \log \frac{n}{K} + \frac{n}{K^2} \log \frac{n}{K^2} + \cdots + \frac{n}{K^p} \log \frac{n}{K^p} \right] \\ &= \gamma \sum_{i=0}^{p} \left[\frac{n}{K^i} \log \frac{n}{K^i} \right] \\ &= \gamma \sum_{i=0}^{p} \left[\frac{n \log n}{K^i} - i \frac{n \log K}{K^i} \right] \end{aligned}$$

$$= \gamma \left[\frac{K - K^{-p}}{K-1} \; n \log n - n \log(K) \; \sum_{i=0}^{p} \frac{i}{K^i} \right] .$$

A close look at the second term in the final expression reveals that it is of order n, since the sum of i/K^i is bounded by a constant which depends only on K (and not p). In the end,

$$T(n) \approx \gamma \frac{K}{K-1} \; n \log n \; .$$

As can be seen, when K is close to one, the algorithm will do poorly, reflecting the fact that the diagonal dominance criterion does not reject enough rows at each level. The analysis indicates that the overall cost for obtaining the permutation is dominated by the sorting step in the preselection phase. In fact, it is clear that an exact sort is not necessary and could easily be replaced by an inexact and less expensive sort. For example, it is possible to reduce the cost of the sorting step by grouping the ratios into a small number of nearby representatives and resorting to a bucket sort. This would lead to a cost of $O(n)$.

The cost of the matching algorithm (for example, Algorithm 4.2) is easier to estimate using a similar model. Once again, the main assumption is that nnz_l is a small multiple, say α, of n_l—due to the dropping strategy. Thus, on average each row of A_l has α nonzero elements. In this case the cost of the ith step of Algorithm 4.2 is $O(n_D) \times \alpha$, with $n_D \approx n_l/K$. Adding these costs for each level will yield

$$n\alpha \left[\frac{1}{K} + \frac{1}{K^2} + \cdots + \frac{1}{K^p} \right] \approx \frac{n\alpha}{K-1},$$

a cost which is linear in n and which shows a similar degradation as for the preselection algorithm, when K is close to one.

6. Numerical tests. We have implemented a version of the algorithm described in earlier sections by using the ARMS framework [36]. We refer to the resulting algorithm as ARMS-C. The goal of the experiments in this section is to illustrate the performance of the ARMS-C strategy as well as to give an idea of its cost and the effect of some parameters. The experiments in section 6.2 and 6.3 were performed on one processor of an IBM/SP computer. The processor is a 375 MHz Power3 (Winterhawk) node with 4 GB of memory. All other experiments were performed on a Linux platform with two 1.7 Xeon GHz processors, a 256 KB cache, and 1 GB of main memory.

6.1. Comparing matching strategies. We begin this section with a comparison of a few matching strategies. In the following experiments, we use only one preselection technique, namely, the one described by Algorithm 3.1. We run a number of strategies and attempt to solve a sequence of linear systems from the Harwell-Boeing collection [22]. The linear systems are obtained from all those matrices from the RUA (real unsymmetric assembled) collection whose size is 500 or higher. There are 58 matrices that satisfy this criterion and their names are listed in Table 1 along with their sizes. If one (or several) right-hand side(s) is (are) provided, then the system with this (the first) right-hand side is solved. Otherwise an artificial right-hand side is taken, which is formed by taking $b = A * e$, where e is the vector of all ones. The iteration is stopped whenever the residual norm has been reduced by 8 orders of magnitude. This does not necessarily mean that the solution that is computed is accurate, because the

matrices involved may be highly ill-conditioned. Since right-preconditioning is used, the tests are on the actual residuals not the preconditioned ones.

In spite of their rather small sizes, some of the matrices in this list cause difficulties to iterative solvers. It is, for example, not easy to find an iterative procedure which solves all the systems with the same input parameters. Most of the matrices are irregularly structured, and some have a very irregular pattern. The next plots show a comparison of the performance of GMRES preconditioned with ARMS-C with various matching strategies. We compare four methods:

- the greedy strategy of Algorithm 3.2,
- the triangular B algorithm described by Algorithm 4.1,
- the augmented triangular B technique described by Algorithm 4.2,
- the algorithm of dynamic averages described by Algorithm 4.3.

The parameters used for the experiment are listed below.

		Drop tolerance				Fill-max			
$nlev_{max}$	tol_{DD}	LU-B	GW	S	LU-S	LU-B	GW	S	LU-S
100	0.1	0.001	0.01	0.001	0.01	10	10	10	5

In the table, $nlev_{max}$ is the maximum number of levels allowed and tol_{DD} is the tolerance τ_0 used in the preselection algorithm; see (10). The next 4 parameters define the dropping factors for the factorization algorithms. The drop tolerance for LU-B is the one used in the ILUT factorization [35] of the B block, while the one denoted by GW is used when computing the matrices G_l and W_l defined by (6) at each level. The drop tolerance used to compute S from G_l and W_l is given next. Finally, the drop tolerance for the ILU factorization at the last level is given. The incomplete factorization with column pivoting (ILUTP) is used for this. The next set of columns define the upper limit for fill-ins for each of these computations in the same order. Note that these numbers are the multiples of the average number of nonzero elements, i.e., at the lth level the actual amount of nonzero entries allowed in each row is $fill_{max} * nnz(A_l)/n$. Another parameter not shown here is the cut-off dimension for the last level, which is set to 100. This means that no further levels are sought when the dimension of the Schur complement is ≤ 100 or when the maximum number of levels allowed is reached. We ran ARMS-C with different matching strategies with the [illegible] 58 [illegible].

The incomplete factorizations were computable in all cases. However, the iteration

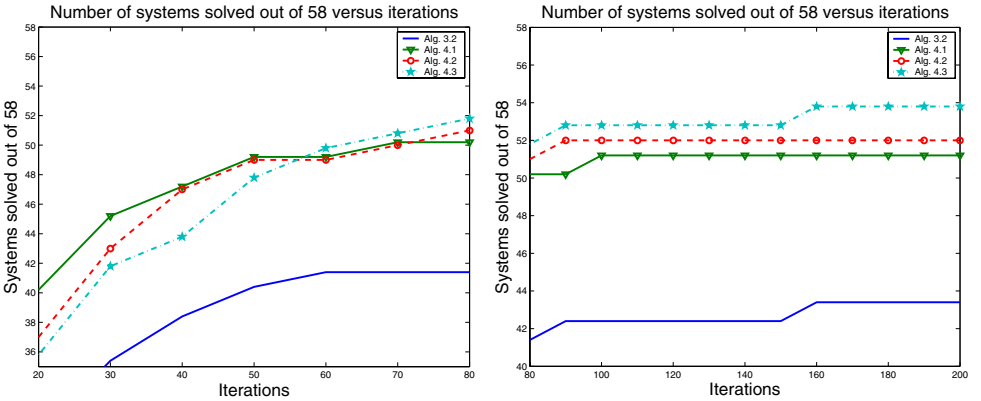

FIG. 2. *Experiment with* 58 *HB matrices showing the number of converged systems among* 58*, versus iteration count.*

TABLE 2
Some statistics on the tests with the 58 *HB matrices.*

Method	Average fill-fact	Average iter. count	Successful iterations
ILUTP	2.71	12.12	43
Alg. 3.2	1.61	20.58	43
Alg. 4.1	1.87	15.00	51
Alg. 4.2	1.63	17.23	52
Alg. 4.3	1.65	22.11	54

phase was not successful in all cases. An iteration was labeled as a failure when the residual norm was not reduced by 8 orders of magnitude in fewer than 200 GMRES steps. We used GMRES with a restart of 100. This was done in order to measure the quality of the preconditioner alone as distinct from that of the accelerator.

The results are divided into two plots for better clarity. The left side of Figure 2 shows the number of successful solves requiring iteration counts of 80 or less and the right side those requiring more than 80 steps. For better visibility, the curves have been slightly shifted in order to avoid superposition. As can be observed, the strategy of Algorithm 4.3 handles harder problems quite well (right side of figure) while Algorithm 4.1 yields faster convergence on easier problems (left side of figure).

A standard preconditioner which is often used for comparison purposes is ILUTP [35]. When a good amount of fill-in is allowed, the preconditioner can be fairly robust. However, it does not perform well for matrices with highly irregular patterns and when not enough fill-in is allowed. For comparison purposes, we ran ILUTP-GMRES under similar conditions on the 58 problems. Specifically, we selected a drop tolerance of 0.01 and a fill-in limit of $3 * nnz(A)/n$, which means that each row of the factors L and U has at most 3 times the number of nonzero elements per row of A. To give an idea of the overall performance, we show in Table 2 the average fill-factor and average iteration count for each [illegible] for all methods, including ILUTP. The fill-factor reflects the memory requirement of the preconditioner and is defined as the ratio of the number of nonzero elements of the resulting preconditioner over that of the original matrix.

It is interesting to note that ILUTP required far more fill-in to solve the same number of problems (43) as the worst performer among the ARMS-C algorithms. The

average iteration counts are not indicative of robustness. Since the fill-in is rather high, the iteration counts for the easy problems are usually very small numbers for the (fewer) successful runs of ILUTP, which leads to a low average among the 43 successful cases. This is in contrast with the ARMS-C strategies which solve more of the harder problems but, as can be expected, at the cost of a larger number of GMRES steps on average.

ILUTP was able to solve some of the problems for which it failed in the above test. However, this was achieved at the cost of much more memory.

6.2. Effect of the filtering parameter τ_0. We vary the parameter τ_0 used in the preselection algorithm and compare the iteration number and the times to compute the factorization for a system associated with the matrix `twotone` from the University of Florida Sparse Matrix Collection [16]. This matrix is known to cause difficulties to standard ILUT and ILUTP preconditioners. The parameters used for the test are given in the following table.

		Drop tolerance				Fill-max			
$nlev_{max}$	tol_{DD}	LU-B	GW	S	LU-S	LU-B	GW	S	LU-S
200	varies	0.001	0.0001	0.001	0.01	10	10	10	5

Algorithm 4.3 was used to obtain the P, Q permutations.

For this matrix the ARMS-C procedure requires unusually small values for the drop tolerances before the preconditioner starts yielding a converging iteration. On the other hand, and somewhat surprisingly, the resulting fill-factor is not too large, and convergence can be obtained for fill-factors below 2. This phenomenon is not observed too often and is likely related to the structure of the problem. ILUTP did not yield convergence for this problem, even for a fairly large fill-factor.

As τ_0 increases from 0.0 to 0.4, one can observe a steady improvement in the convergence of the algorithm while the fill-factor remains almost the same. Therefore a better quality factorization is being computed with about the same amount of fill. Then the iteration count sees a sizable decrease, reaching the smallest number of 27 when $\tau_0 = 0.7$. At this point the maximum number of levels, which has been set to 200, is reached and the fill-factor increases. Eventually, the iteration starts to deteriorate slowly, reaching 38 when $\tau_0 = 0.9$. For a small value of τ_0 more entries are initially preselected. For example, when $\tau_0 = 0$ all the largest entries in each row are candidates. They are then sorted using a measure which mixes diagonal dominance with the number of nonzero entries. The resulting algorithm is more tolerant of nondiagonal dominance. Selecting a larger τ_0 sets a stricter condition for accepting an entry as a candidate. Excluding more rows in this way results in more robust, often faster, convergence, but this increases the number of levels as can be seen in Table 3. In fact the number of levels shown in the table for $\tau_0 \geq 0.7$ is the limit allowed.

One may wonder why the iteration time is not proportional to the amount of fill of the factorization and the iteration count. For example, when between $\tau_0 = 0.8$ and $\tau_0 = 0.9$, the iteration time jumps 78% while the iteration count increases only 20%. This is likely due to the fact that the last Schur complement is much larger for the latter case.

6.3. Effect of the number of levels. One important consideration when using ARMS-C is the number of levels. At one extreme when only one level is used, ARMS-C will yield the ILUTP factorization. Indeed, the procedure considers the matrix at the top level to be the Schur complement matrix and uses ILUTP to factor it. Large Schur complements are likely to lead to expensive factorizations. The current

TABLE 3
Performance of ARMS-C for various values of τ_0 for the `twotone` *matrix.*

τ_0	filf	lev	iter	setup sec	iters sec
0.00	1.75	91	81	5.96e+01	6.84e+01
0.10	1.79	90	74	6.05e+01	6.24e+01
0.20	1.75	97	87	5.90e+01	7.45e+01
0.30	1.78	117	71	7.01e+01	6.19e+01
0.40	1.80	145	47	8.70e+01	4.29e+01
0.50	1.89	193	34	1.18e+02	3.60e+01
0.60	1.91	200	28	1.46e+02	3.41e+01
0.70	1.95	200	27	1.64e+02	4.14e+01
0.80	1.95	200	29	1.72e+02	5.45e+01
0.90	1.91	200	35	2.34e+02	9.73e+01

code uses as a parameter the maximum number of levels and the smallest allowable Schur complement, which is usually set to 100, i.e., as soon as a matrix A_{l+1} in (3) reaches a size of 100 or smaller the procedure stops generating more levels. In the next experiment we explore this with a goal of demonstrating the beneficial effect of a multilevel approach in contrast with one that is based on one or very few levels.

The matrix used in this test arises from the simulation of a two-dimensional flow in a driven cavity and is available from the Matrix Market[3] under the name `E40R0100` in the collection DRIVCAV. Its size is $n = 17,922$ and it has $nnz = 567,467$ nonzero entries. The Reynolds number for the example is 100. The parameters used for the experiment are listed below.

		Drop tolerance				Fill-max			
$nlev_{max}$	tol_{DD}	LU-B	GW	S	LU-S	LU-B	GW	S	LU-S
varies	0.2	0.01	0.05	0.05	0.01	6	6	6	6

The stopping criterion is as before, namely the norm of the residual should be reduced by 8 orders of magnitude. The case $nlev_{max} = 0$ corresponds to ILUTP—with the drop tolerance 0.01 and a max fill-in of $6 \times nz/n$. Figure 3 shows the number of GMRES iterations as well as the resulting fill-factor when the number of levels varies from zero to 30. Note that for this case only 27 levels were required before the Schur complement matrix reached the smallest allowable size of 100, so the case $nlev_{max} = 30$ was never reached. The plot shows a fairly regular decrease in the fill-factor as the number of levels increases. At the same time, the iteration count increases and then levels off at around 75.

A different perspective on this experiment would be to vary the parameter τ_0 as was done in the previous section and let the number of levels be as large as required. With the set of parameters used in the previous experiment, the maximum number of levels for the matrix `E40R0100` was 27. In order to obtain larger numbers of levels, we tightened the drop tolerance slightly by halving the two drop tolerance values of 0.05 used for the G, W matrices and the Schur complement to 0.025. The parameter τ_0 is varied from 0.0 to 0.7 in increments of 0.05. The plot on the right of Figure 3 shows the result. Essentially, the fill-factor remains in a rather narrow band (1.93 2.23) while the iteration count changes, but not substantially. The additional axis shows the number of levels required for each case. These numbers are much bigger than the ones obtained with a drop tolerance of 0.05. This last experiment, as well as the one in section 6.2 and others not reported here, suggests that it is best not

[3] `http://math.nist.gov/MatrixMarket/`

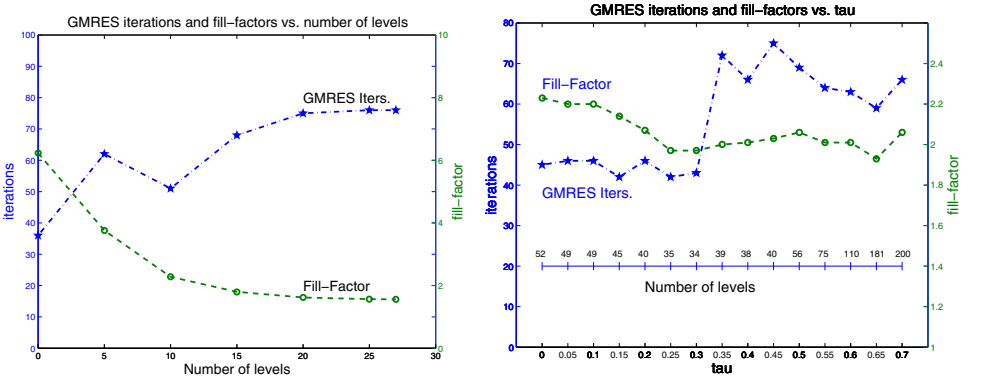

FIG. 3. *Iteration and fill-factor for the driven cavity problem, versus the number of levels (left side) and τ_0 parameter (right side). The right plot uses a slightly different set of parameters.*

to limit the number of levels to a too small number. Limiting the number of levels in this way may lead to a large last Schur complement matrix which is then poorly handled by the ILUTP approach.

6.4. Solution of KKT problems and a comparison. The ARMS-C procedure can be applied to solve saddle-point problems such as those arising from the incompressible Navier–Stokes equations or from Karush–Kuhn–Tucker (KKT) optimality conditions in nonlinear programming. In [28] Haws and Meyer focus on KKT problems and compare a few methods for solving them. Such problems are symmetric and highly indefinite, but one of the methods tested in [28] is to ignore symmetry and use ILUT as a preconditioner on a reordered system. The reordering used is MC64, the one-sided reordering developed in [23, 24, 33] whose goal is to put large entries on the diagonal. Two sets of problems are tested in [28]. We only consider the first set corresponding to the results reported in Table I of that paper.

TABLE 4
Results for solving five KKT problems with ARMS-C.

Matrix	n	nnz	nnz_{pre}	lev	Iters.	Setup sec.	Iter sec.
stiff4	8496	41318	73332	4	49	0.09	0.39
stiff5	33410	177256	341363	6	112	0.48	6.73
mass04	8496	56818	61799	2	7	0.07	0.04
mass05	33410	241012	259026	5	41	0.35	1.53
mass06	33794	257220	302009	6	20	0.47	0.73

Table 4 shows the same statistics as those of Table I in [28] plus the number of levels (lev) required for each case for a similar approach which ignores symmetry and solves the problems by an ARMS-C/GMRES combination. In the table, n and nnz are the size and number of nonzero entries of the matrix, nnz_{pre} is the number of nonzero entries required for the preconditioner, and the rest of the data is self-explanatory. The parameters used for the experiment are listed below.

		Drop tolerance				Fill-max			
$nlev_{max}$	tol_{DD}	LU-B	GW	S	LU-S	LU-B	GW	S	LU-S
100	0.25	0.05	0.01	0.01	0.01	4	4	4	4

The right-hand side, initial guess, and convergence criterion are identical with those

of [28]. As with earlier tests we do not attempt in any way to tune the parameters for each separate case. These were selected to yield a comparable number of nonzero elements for the preconditioners as in [28]. In fact, all five problems tested here are relatively easy to solve with the ARMS-C procedure in the sense that almost any parameter selection would yield convergence. This is not the case for some matrices (see, e.g., section 6.2).

TABLE 5
Results for solving the five KKT systems of Table 4 *with ILUT-MC*64*, as reported in* [28]. *Note that the times are not directly comparable with those of Table* 4.

Matrix	nnz_{pre}	Iters.	Setup sec.	Iter. sec
stiff4	77 118	28	0.129	0.786
stiff5	341417	135	0.575	15.48
mass04	68875	3	0.126	0.186
mass05	323299	32	0.705	3.902
mass06	394821	30	0.806	4.038

As a comparison we reproduce in Table 5 the statistics for the MC64-ILUT combination from [28]. As can be seen for similar fill-in, the number of iterations obtained in each case are comparable. Note that the accelerator used in [28] is BCGSTAB instead of GMRES. Execution times are not easily comparable as they depend on many factors in addition to the raw speed of the processors used. The processor used in [28] is an AMD Duron 800 MHz processor, which is slower than the Xeon 1.7 GHz on which this experiment has been conducted. On the other hand the codes in [28] were optimized with the use of ATLAS BLAS. In addition, the algorithms in [28] are coded in FORTRAN whereas the ARMS-C code is coded mostly in C. The ARMS-C codes have not been optimized in any way. All that can be said is that by taking into account the speeds of the processors, the times obtained in these experiments are within a comparable range.

Note that the MC64-ILUT procedure was not the best overall method reported in [28]. However, the point of this experiment is not to show that the method discussed in this paper can compete with specialized solvers tailored to a given application or structure. It is only to show that the method can perform reasonably well as a general-purpose solver, in that it can handle KKT problems as easily as a problem arising from the discretization of PDEs.

6.5. Tests with larger matrices. Apart from the test in section 6.2 with the matrix `twotone`, the linear systems of the earlier numerical tests are all relatively small. In this section we report on some tests performed with larger, more realistic matrices arising from applications which are known to cause difficulties to iterative solvers. We selected 10 matrices, most of which have already been used as test problems in the literature. The first 5 matrices were taken from [38]. They are the largest linear systems in size taken from [38] if the matrix `pre2` therein is ignored. For the system `pre2` no method among those reported in [38] worked, and a similar conclusion was reached with ARMS-C. These 5 matrices, which originate from device simulation, are available from the `Schenk` sets of the University of Florida collection [16]. Along with these matrices, we also selected the two largest matrices from [2], namely the matrix `circ2a` and the matrix `scircuit`. The matrix `scircuit` can also be obtained from the set `Hamm` of the University of Florida collection, while the larger matrix `circ2a` was sent to us by Achim Basermann [2]. Finally, we added the 2 largest matrices (`wang1, wang2`) from the `Wang` set of the University of Florida collection, and

TABLE 6
General information on 10 *test matrices.*

wang3.rua	26064	177168	Device simulation (UFL, Wang set)
wang4.rua	26068	177196	Device simulation (UFL, Wang set)

the largest matrix (`circuit_4`) from the set `Bomhoff` of the same collection. These examples are all from circuit simulation. Some general information on all 10 matrices is shown in Table 6.

We tested ARMS-C, based on the ddPQ ordering given by Algorithm 4.3 on all 10 matrices with the following parameter settings.

		Drop tolerance				Fill-max			
$nlev_{max}$	tol_{DD}	LU-B	GW	S	LU-S	LU-B	GW	S	LU-S
40	0.1	0.01	0.01	0.01	1.e-05	3	3	3	20

The parameters for the ILUTP preconditioner for the last level essentially lead to a direct solve. Another parameter not shown here is the cut-off dimension for the last level, which is set to 300. No further levels are sought when the dimension of the Schur complement is ≤ 300 or when the maximum number of levels allowed (40) is reached.

We ran two tests with the GMRES accelerator, one with a restart dimension of 60, the other with a restart dimension of 100. Note that memory is allocated dynamically for the basis vectors required by GMRES(k). In both cases, the iteration was stopped whenever either a maximum number of iterations of 300 was reached or the initial residual was reduced by 10^{-8}. The times are in seconds on the 1.7 GHz Xeon processor mentioned earlier. The iteration times are repeated for the case when GMRES(60) and GMRES(100) take the same number of iterations (these correspond to the exact same operations and should be the same under ideal conditions). Results are shown in Table 7.

TABLE 8
Solution of the system `scircuit` *when no scaling is used, using two different sets of parameters.*

	Fill factor	Levels	Set-up time	GMRES(60) Its.	GMRES(60) Time	GMRES(100) Its.	GMRES(100) Time
Same parameters	0.89	4	1.81e+00	400	9.13e+01	297	8.79e+01
Drop-tol = 0.001	1.00	5	1.89e+00	98	2.23e+01	82	2.27e+01

Of all the matrices tested, only `scircuit` failed to reduce the residual by 8 orders of magnitude in 300 steps with the set of parameters selected above. In 300 steps the residual norm was reduced by $\approx 1.8 \times 10^{-07}$ by GMRES(100) and by 3.13×10^{-7} by GMRES(60). This particular matrix is a good representative of those situations mentioned earlier in which row/column scaling does not necessarily help. If the exact same parameters are used but no row or column scaling is performed (set by parameters in ARMS-C), then, as is shown in Table 8, GMRES(100) does succeed in reducing the residual norm by 8 orders of magnitude in 297 steps, while GMRES(60) also achieves the same result in 400 steps. Table 8 also shows an additional test for the same matrix when no scaling is used. Here the drop tolerance parameters labeled "LU-B," "GW," and "S," which were set to 0.01 in this experiment, are changed to 0.001. The resulting convergence is much faster. It should be noted that convergence is also achieved with these values of the drop tolerance for the situation when row/column scaling is used, although it is much slower.

Observe that the fill-factors, the memory required for the preconditioner normalized by that required for the original matrix A, are generally quite modest. It is less than 1 in 7 of the 10 cases. Not seen in the reported results is a peculiar behavior of the solver with the matrix `circuit_4` as well as with the matrix `circ2a`. In contrast with most other systems, results with `circuit_4` were exceedingly sensitive to parameters and even to the initial guess (which is always a random vector).

Regarding the matrix `circ2a`, it can be observed in the table that the time to compute the preconditioner appears to be abnormally high relative to the other test cases. This matrix is the largest in size among the 10 tested, but it is not the largest in terms of the number of nonzero entries. The first reaction to this might be that the algorithms have some hidden cost associated with the size n rather than the nonzero entries. A test with the matrix `pre2` mentioned earlier disproved this. This matrix is of size $n = 659,033$ and has $nz = 5,959,282$ nonzero entries. Yet the same parameters produced the factorization in almost an order of magnitude less time (24.2 seconds to be exact) on the same platform. The fill-factor was 0.99, which was even higher than that for `circ2a`. We examined the sizes and numbers of nonzero entries of the matrices obtained at each level. The method stopped prematurely with a C block of size zero yielding the previous level (third one, in this case) as the last level. This level had a size of 4,679, which is somewhat large. Indeed, no fill-minimizing ordering is performed prior to factoring the last Schur complement, because in most cases the last Schur complement is a small matrix of size a few hundreds at most. However, further examination revealed that, quite remarkably, this last Schur complement is a diagonal matrix. This explains why the algorithm stopped prematurely. In the end, we reached the only plausible explanation that some intermediate matrices that were generated were quite dense before they were sparsified by dropping. Selecting a different filter parameter τ_0 can force a larger number of levels and reduce the set-up substantially in this case. For example, with $\tau_0 = 0.7$, 18 levels were used, with a fill-factor of 0.77, quite close to the previous case. The set-up time was reduced to

43 seconds. The number of GMRES steps was also reduced from 18 to 12 (but the iteration time increased slightly to 12.1 seconds due to the larger number of levels).

6.6. Available software and other tests. The algorithms described in this paper are part of a recent package, called ILUPACK, developed primarily by Matthias Bollhöfer [11]. The package is available from Bollhöfer's web-site; see [12]. It offers a large selection of preconditioners, many of which utilize the inverse-based dropping technique mentioned in the introduction; see also [9]. Along with software, the site offers a repository of statistics on a sizable number of numerical experiments with various methods. These experiments show, in particular, a number of comparisons with the similar MC64 strategy.

7. Conclusion. We conclude with a few remarks and observations regarding the performance of ARMS-C and on issues remaining to be examined. Our first observation is that the method seems to perform well as a general purpose alternative to a direct solver. Though the algorithms do not compete with the robustness of direct solvers, they can often tackle problems that were inaccessible to iterative solvers so far at a small fraction of the memory and computational costs required by direct solvers. Note also that the methods perform in a similar way for problems with a very poor structure as for systems which arise from discretized PDEs. There are, however, a number of questions that remain to be answered and issues to be examined for a better understanding of the general approach proposed in this paper.

One of the primary concerns with a strategy such as the one described in this paper is the large number of tunable parameters available. With such variety it may indeed be difficult to find the best fit for a given linear system. However, in a software package, one may simply fix most of these parameters without causing serious harm to performance. The primary candidates for this "hard-wiring" are the maximum number of levels allowed (along with the minimum size of the Schur complement before switching to ILUTP) and the diagonal dominance filtration parameter τ_0. Indeed, when the better matching algorithms are used (Algorithm 4.3 or 4.2) performance does not vary too much with these parameters for [illegible] problems. The other parameters left are those that control fill-in, i.e., the accuracy of the factorization. Although our research code provides separate fill-in parameters for various parts of the factorization at a given level, these can be taken to be the same as was done in most of our experiments. The drop tolerance and fill-in parameters can be fixed to provide a very accurate factorization for the last level Schur complement matrix. In the end all that remains to select are the drop tolerances and the max fill-in allowed for the interlevel matrices (those for LU-B and GW in the various tables). This would not be too different from the parameters required by ILUT [35].

We observed that fill-in does not necessarily improve the quality of the factorization. In fact the contrary is often seen. While the same observation can be made for ILUT, we note that it is not as common. This behavior underscores the difficulty in predicting the effect of dropping small terms in the factors on the conditioning of the preconditioned system. The dropping strategies which were tested utilize a simple threshold criterion, but it is clear that one based on estimating the condition number of the factors [9] would be ideal in this situation.

A diagonal dominance criterion was selected as a means of building a good B block because it is easy to apply and ensures large diagonal entries in a relative sense to the 1-norm of the row. However, one can ask if it is possible to find a more elaborate criterion—for example, one that takes into account the "stability" of the resulting factors. A related subquestion is the problem of selecting the parameter

τ. The choice made in this paper uses a relative measure which keeps the best rows according to a rule based on a parameter input by the user. There remains to find a rigorous way to select the parameter τ.

Another important issue that deserves further investigation is that of scaling. As was reported, the performance of the preconditioners is significantly affected by scaling. Yet it still remains difficult to devise scaling strategies whose effects on the preconditioner are well understood and predictable.

Finally, our current codes do not attempt to reduce fill-in by means other than dropping. A simple strategy which can be employed is to use fill-reducing (symmetric) orderings on the B matrices after they have been generated.

Acknowledgments. The code ARMS-C discussed in the experiments has been adapted from ARMS [36], a C code which was developed jointly with Brian Suchomel. I am grateful to Matthias Bollhöfer for numerous insightful discussions on the topic of this paper. The numerical experiments would not have been possible without the availability of a sizable collection of test matrices. I would like to thank John Haws for providing the matrices used in section 6.4, Achim Basermann for sending us his circuit simulation matrices, and Olaf Schenk for making available the large device and circuit matrices discussed in section 6.5. Special thanks to Tim Davis for making these and other linear systems available in his excellent repository of test matrices. Finally, I am grateful to the referees for their numerous suggestions which helped improve the quality of this paper.

MULTIDIMENSIONAL INTEGRAL INVERSION, WITH APPLICATIONS IN SHAPE RECONSTRUCTION*

ANNIE CUYT†, GENE GOLUB‡, PEYMAN MILANFAR§, AND BRIGITTE VERDONK†

Abstract. In shape reconstruction, the celebrated Fourier slice theorem plays an essential role. It allows one to reconstruct the shape of a quite general object from the knowledge of its Radon transform [S. Helgason, *The Radon Transform*, Birkhäuser Boston, Boston, 1980]—in other words from the knowledge of projections of the object. In case the object is a polygon [G. H. Golub, P. Milanfar, and J. Varah, *SIAM J. Sci. Comput.*, 21 (1999), pp. 1222–1243], or when it defines a quadrature domain in the complex plane [B. Gustafsson, C. He, P. Milanfar, and M. Putinar, *Inverse Problems*, 16 (2000), pp. 1053–1070], its shape can also be reconstructed from the knowledge of its moments. Essential tools in the solution of the latter inverse problem are quadrature rules and formal orthogonal polynomials.

In this paper we show how shape reconstruction from the knowledge of moments can also be realized in the case of general compact objects, not only in two but also in higher dimensions. To this end we use a less-known homogeneous Padé slice property. Again integral transforms—in our case the multivariate Stieltjes transform and univariate Markov transform—formal orthogonal polynomials in the form of Padé denominators, and multidimensional integration formulas or cubature rules play an essential role.

We emphasize that the new technique is applicable in all higher dimensions and illustrate it through the reconstruction of several two- and three-dimensional objects.

Key words. shape, multidimensional, inverse problem, moment problem

1. Problem statement.

The problem of reconstructing a function and/or its domain given its moments is encountered in many areas. Several applications from diverse areas such as probability and statistics [10], signal processing [18], computed tomography [16, 17], and inverse potential theory [4, 19] (magnetic and gravitational anomaly detection) can be cited, to name just a few. We can expound on some of these applications in a bit more detail. Consider the following diverse set of examples:

- A region of the plane can be regarded as the domain of a probability density function. In this case, the problem is that of reconstructing this density function and/or approximating its domain from measurements of its moments [10].
- Tomographic (line integral) measurements of a body can be converted into moments from which an approximation to its density and boundary can be extracted [17].
- Measurements of exterior gravitational field induced by a body of uniform mass can be turned into moment measurement, from which the shape of the region may be reconstructed [19].
- Measurements of an exterior magnetic field induced by a body of uniform

magnetization can yield measurement of the moments of the region from which the shape of the region may be determined [19].

- Measurements of thermal radiation made outside a uniformly hot region can yield moment information, which can subsequently be inverted to give the shape of the region [19].

In fact, aside from the general case where the density inside the body may not be uniform, the set of inverse problems for uniform density regions related to general elliptical equations can all be cast as moment problems which fall within the scope of application of the results of this paper.

Although the reconstruction of a shape from its Radon transform is well understood, the reconstruction of a shape from its moments is a problem that has only partially been solved. For instance, when the object is a polygon [11], or when it defines a quadrature domain in the complex plane [12], it has been proved that its shape can be exactly reconstructed from the knowledge of its moments. Both results deal with particular two-dimensional shapes. For general n-dimensional shapes no inversion algorithm departing from the moments is known. In order to explain the type of result we are looking for, we briefly repeat the inversion formula based on a shape's projections provided by the Radon transform.

The Radon transform $R_{\vec{\xi}}(f)$ of a square-integrable n-variate function $f(\vec{x})$ with $\vec{x} = (x_1, \ldots, x_n)$ is defined as (for ease of notation we drop the dependence of f in the notation)

$$R_{\vec{\xi}}(u) = \int_{\mathbb{R}^n} f(\vec{x})\ \delta(\vec{\xi}\vec{x} - u)\ d\vec{x}$$

with $||\vec{\xi}|| = 1$ and $\vec{\xi} \cdot \vec{x} = u$ an $(n-1)$-dimensional manifold orthogonal to $\vec{\xi}$. When $n = 2$, $\vec{\xi}$ is fully determined by an angle θ and is given by

$$R_\theta(u) = \int_{-\infty}^{+\infty} \int_{-\infty}^{+\infty} f(t,s)\, \delta(t\cos\theta + s\sin\theta - u)\, dt\, ds.$$

For $n = 3$, $\vec{\xi}$ is determined by angles θ and ϕ and

$$R_{\theta,\phi}(u) = \int_{\mathbb{R}^3} f(t,s,v)\, \delta(t\cos\phi\cos\theta + s\cos\phi\sin\theta + v\sin\phi - u)\, dt\, ds\, dv.$$

Making use of the celebrated Fourier slice theorem, one obtains, for instance, that the one-dimensional Fourier transform of $R_\theta(u)$,

$$\mathcal{F}_1(R_\theta)(z) = \int_{-\infty}^{+\infty} R_\theta(u) \exp(-2\pi \mathrm{i} z u)\, du,$$

equals the two-dimensional Fourier transform of the function f restricted to the straight line $(z\cos\theta, z\sin\theta)$:

$$\begin{aligned} \mathcal{F}_2(f)(z\cos\theta, z\sin\theta) &= \int_{-\infty}^{+\infty} \int_{-\infty}^{+\infty} f(t,s) \exp\left(-2\pi \mathrm{i} z(t\cos\theta + s\sin\theta)\right)\, dt\ ds \\ &= \mathcal{F}_1(R_\theta)(z). \end{aligned} \tag{1}$$

When $f(t,s)$ is the characteristic function of a compact set A in the complex plane, then (1) allows one to reconstruct A, departing from the Radon transform $R_\theta(u)$, by

taking the inverse two-dimensional Fourier transform of $\mathcal{F}_1(R_\theta)$. In higher dimensions the procedure is completely analogous [14].

Our aim is to establish a similar type of relationship, making use of moment information instead of projections. To this end we need to introduce a few tools.

2. Univariate Markov transform and Padé approximant. A Markov function $g(z)$ is defined to be a function with an integral representation of the form

(2)
$$g(z) = \int_a^b \frac{f(u)}{1+zu}\, du, \quad -\infty < a \le 0 \le b < +\infty, \quad z \notin]-\infty, -1/b] \cup [-1/a, +\infty[,$$

where $f(u)$ is nontrivial and positive and the moments

$$c_i = \int_a^b u^i f(u)\, du, \qquad i = 0, 1, \ldots, \tag{3}$$

are finite. The function g is called the Markov transform of f and is also denoted by $g = \mathcal{M}_1(f)$. A Markov series is defined to be a series of the form

$$\sum_{i=0}^{\infty} (-1)^i c_i z^i \tag{4}$$

which is derived by a formal expansion of (2). It is well known that the one-dimensional Markov moment problem is determinate.

Given a series of the form (4), one can construct Padé approximants of this series as follows. With the moments c_i introduced in (3), one computes coefficients $a_0, \ldots, a_{m+k}$ and $b_0, \ldots, b_m$ such that for

$$p_{m+k,m}(z) = \sum_{i=0}^{m+k} a_i z^i,$$
$$q_{m+k,m}(z) = \sum_{i=0}^{m} b_i z^i,$$

the series expansion of $(gq_{m+k,m} - p_{m+k,m})(z)$ satisfies

$$\sum_{i=0}^{\infty} d_i z^i = \left(\sum_{i=0}^{\infty} (-1)^i c_i z^i \right) q_{m+k,m}(z) - p_{m+k,m}(z) = O(z^{2m+k+1}). \tag{5}$$

In other words, the $2m+k+2$ coefficients $a_0, \ldots, a_{m+k}$ and $b_0, \ldots, b_m$ are determined from the $2m+k+1$ conditions $d_0 = 0, \ldots, d_{2m+k} = 0$ and an additional normalization condition. The irreducible form of $p_{m+k,m}(z)/q_{m+k,m}(z)$ is denoted by $r_{m+k,m}(z)$ and is called the $(m+k, m)$ Padé approximant. It is usually normalized by putting the constant term in the denominator equal to 1.

The following property plays a crucial role in our novel shape reconstruction technique.

THEOREM 1 (see [1, p. 228]). [illegible] (2) [illegible] $\{r_{m+k,m}(z)\}_{m \in \mathbb{N}}$ [illegible] $k \ge -1$ [illegible] (2) [illegible] $z \notin]-\infty, -1/b] \cup [-1/a, +\infty[$ [illegible]

$$\limsup_{m \to \infty} |g(z) - r_{m+k,m}(z)|^{1/m} \le \left| \frac{\sqrt{1/z+b} - \sqrt{1/z+a}}{\sqrt{1/z+b} + \sqrt{1/z+a}} \right|.$$

3. Multivariate Stieltjes transform and homogeneous Padé approximant. Padé approximants have been generalized to higher dimensions by several authors in different ways. For an overview and comparison of these definitions the reader is referred to [8]. For our purpose the definition given in [7, 6] is most useful. Without loss of generality, we repeat it only for bivariate functions, but it can be defined in any number of variables.

A bivariate Stieltjes function $g(v,w)$ is defined by the integral representation

$$g(v,w) = \int_0^\infty \int_0^\infty \frac{f(t,s)}{1+(vt+ws)}\, dt\, ds \tag{6}$$

with finite real-valued moments

$$c_{ij} = \int_0^\infty \int_0^\infty t^i s^j f(t,s)\, dt\, ds.$$

A formal expansion of (6) provides a bivariate Stieltjes series

$$\sum_{i,j=0}^{\infty} \binom{i+j}{i} (-1)^{i+j} c_{ij} v^i w^j. \tag{7}$$

The function g is also called the bivariate Stieltjes transform of f and is denoted by $g = \mathcal{S}_2(f)$.

Given the moments c_{ij}, one can compute the $(m+k,m)$ homogeneous bivariate Padé approximant of (7) as follows. First we introduce the homogeneous expressions

$$\begin{aligned} A_\ell(v,w) &= \sum_{i+j=\ell} a_{ij} v^i w^j, \\ B_\ell(v,w) &= \sum_{i+j=\ell} b_{ij} v^i w^j \end{aligned}$$

to define the polynomials

$$\begin{aligned} p_{m+k,m}(v,w) &= \sum_{\ell=(m+k)m}^{(m+k)(m+1)} A_\ell(v,w), \\ q_{m+k,m}(v,w) &= \sum_{\ell=(m+k)m}^{(m+k+1)m} B_\ell(v,w). \end{aligned}$$

Second we write down the homogeneous accuracy-through-order conditions

$$\begin{aligned} C_\ell(v,w) &= \sum_{i+j=\ell} \binom{\ell}{i} c_{ij} v^i w^j, \\ \sum_{i,j=0}^{\infty} d_{ij} v^i w^j &= \left(\sum_{\ell=0}^{\infty} (-1)^\ell C_\ell(v,w) \right) q_{m+k,m}(v,w) - p_{m+k,m}(v,w) \\ &= O\left(v^i w^j, i+j \geq (m+k+2)m + k + 1\right). \end{aligned} \tag{8}$$

It has been shown [7, pp. 60–61] that a nontrivial solution of these conditions can always be computed. Moreover, all solutions $p_{m+k,m}(v,w)/q_{m+k,m}(v,w)$ deliver the

same unique irreducible form $r_{m+k,m}(v,w)$, which is called the homogeneous Padé approximant of (7). A proper normalization of $r_{m+k,m}(v,w)$ can still be chosen but differs most of the time from the univariate normalization $q_{m+k,m}(0)=1$ since the denominator of $r_{m+k,m}(v,w)$ need not start with a constant term. It starts with a homogeneous expression in v and w of as low degree as possible. This homogeneous generalization of the Padé approximant is the only one to satisfy the following powerful slice theorem. Although it was pointed out soon after the introduction of homogeneous Padé approximants, its full impact was only understood recently [9, 3]. For the sake of the reader we also repeat the short proof.

Let us define the slice function:

$$g_\theta(z) = g(z\cos\theta, z\sin\theta), \quad -\pi/2 < \theta \le \pi/2, \tag{9}$$
$$= \int_0^\infty \int_0^\infty \frac{f(t,s)}{1+(t\cos\theta + s\sin\theta)z}\, dt\, ds.$$

We denote the univariate $(m+k,m)$ Padé approximant of $g_\theta(z)$ as defined in (5) by $r^{(g_\theta)}_{m+k,m}(z)$.

THEOREM 2 (see [15, 5]). [illegible] $r_{m+k,m}(v,w)$ [illegible] $g(v,w)$ [illegible]

$$r_{m+k,m}(z\cos\theta, z\sin\theta) = r^{(g_\theta)}_{m+k,m}(z), \qquad -\pi/2 < \theta \le \pi/2.$$

[illegible]. The univariate rational function of the variable z, parameterized by θ,

$$\begin{aligned} r_{m+k,m}(z\cos\theta, z\sin\theta) &= \frac{\sum_{\ell=(m+k)m}^{(m+k)(m+1)} \left(\sum_{i+j=\ell} a_{ij}\cos^i\theta\sin^j\theta\right) z^\ell}{\sum_{\ell=(m+k+1)m}^{(m+k+1)m} \left(\sum_{i+j=\ell} b_{ij}\cos^i\theta\sin^j\theta\right) z^\ell} \\ &= \frac{\sum_{\ell=0}^{m+k} \left(\sum_{i+j=(m+k)m+\ell} a_{ij}\cos^i\theta\sin^j\theta\right) z^\ell}{\sum_{\ell=0}^{m} \left(\sum_{i+j=(m+k)m+\ell} b_{ij}\cos^i\theta\sin^j\theta\right) z^\ell} \\ &=: \frac{p^{(\theta)}_{m+k,m}(z)}{q^{(\theta)}_{m+k,m}(z)}, \end{aligned}$$

satisfies

$$\left(\sum_{\ell=0}^{\infty} (-1)^\ell C_\ell(\cos\theta,\sin\theta) z^\ell\right) q^{(\theta)}_{m+k,m}(z) - p^{(\theta)}_{m+k,m}(z)$$
$$= g_\theta(z) q^{(\theta)}_{m+k,m}(z) - p^{(\theta)}_{m+k,m}(z) = O(z^{2m+k+1})$$

with d_{2m+k+1} in (5) being a homogeneous expression in $\cos\theta$ and $\sin\theta$. Because of the unicity of the Padé approximant, $r^{(g_\theta)}_{m+k,m}(z)$ must equal the irreducible form of

$$\frac{p^{(\theta)}_{m+k,m}(z)}{q^{(\theta)}_{m+k,m}(z)}, \tag{10}$$

which completes the proof. □

In other words, restricting the homogeneous Padé approximant to the slice

$$S_\theta = \{(z\cos\theta, z\sin\theta) \mid z \in \mathbb{R}\} \tag{11}$$

is equivalent to computing the univariate Padé approximant of the slice function $g_\theta(z)$. After analyzing the behavior of the homogeneous Padé approximant on the slices S_θ, let us have another look at the slice function $g_\theta(z)$ itself.

Let the square-integrable function $f(t,s)$ be defined in a compact region A of the first quadrant $t \geq 0,\ s \geq 0$ of the plane. According to a fundamental property of the Radon transform $R_\theta(u)$ of $f(t,s)$ [14], the following relation holds for any square-integrable function $F(u)$:

$$\int_{-\infty}^{+\infty} R_\theta(u)F(u)\,du = \int_0^\infty \int_0^\infty f(t,s)F(t\cos\theta + s\sin\theta)\,dt\,ds. \tag{12}$$

If we take $F(u) = 1/(1+zu)$, then

$$\int_{-\infty}^{+\infty} \frac{R_\theta(u)}{1+zu}\,du = \int_0^\infty \int_0^\infty \frac{f(t,s)}{1+(t\cos\theta + s\sin\theta)z}\,dt\,ds = g_\theta(z). \tag{13}$$

Consequently, if $f(t,s)$ is zero outside a compact subset A of the first quadrant, then $g_\theta(z)$ is a Markov function, because $R_\theta(u)$ is zero outside a compact support. In addition Theorem 1 applies.

4. Connection and new results. Making use of the homogeneous Padé slice property and the fact that the slice function $g_\theta(z)$ is a Markov function with f in (2) equal to the Radon transform of $f(t,s)$, it is now easy to obtain the following result for the bivariate Stieltjes transform $g(v,w)$ defined by (6).

THEOREM 3. [illegible] $f(t,s)$ [illegible] (6) [illegible] $A \subset \{(t,s) : 0 \leq t^2+s^2 \leq 1\} \cap \{(t,s) : t \geq 0, s \geq 0\}$ [illegible] S_θ [illegible] (11) [illegible] $k \geq -1$ [illegible] $-\pi/2 < \theta \leq \pi/2$ [illegible] $\{r_{m+k,m}(z\cos\theta, z\sin\theta)\}_{m\in\mathbb{N}}$ [illegible] $g(z\cos\theta, z\sin\theta)$ [illegible] $|z| < 1$ [illegible] (6) [illegible]

$$\limsup_{m\to\infty} |g(z\cos\theta, z\sin\theta) - r_{m+k,m}(z\cos\theta, z\sin\theta)|^{1/m} \leq \left|\frac{\sqrt{1/z+1}-\sqrt{1/z-1}}{\sqrt{1/z+1}+\sqrt{1/z-1}}\right|. \tag{14}$$

[illegible]. Since $f(t,s)$ is zero outside A and by means of the celebrated Fourier slice formula (12), we know that

$$\begin{aligned}\mathcal{S}_2(f)(z\cos\theta, z\sin\theta) = g(z\cos\theta, z\sin\theta) &= \int\int_A \frac{f(t,s)}{1+(t\cos\theta+s\sin\theta)z}\,dt\,ds \\ &= \int_{a(\theta)}^{b(\theta)} \frac{R_\theta(u)}{1+zu}\,du = \mathcal{M}_1(R_\theta)(z)\end{aligned}$$

with $-1 \leq a(\theta) \leq b(\theta) \leq 1$. Combining Theorems 1 and 2 delivers

$$\int_{a(\theta)}^{b(\theta)} \frac{R_\theta(u)}{1+zu}\,du = \lim_{m\to\infty} r^{(g_\theta)}_{m+k,m}(z) = \lim_{m\to\infty} r_{m+k,m}(z\cos\theta, z\sin\theta)$$

for $-1/b(\theta) < z < -1/a(\theta)$ with $|1/b(\theta)| \geq 1$ and $|1/a(\theta)| \geq 1$. The rate of convergence easily follows from Theorem 2. □

When the compact support A intersects all four quadrants, the theorem still holds. The current formulation is just one way of scaling the problem, without loss of generality.

To the authors' knowledge, at the time of this writing, no inverse Stieltjes transform exists for the transform defined by (6). Hence the function $f(t,s)$ must be solved for from the relationship

$$\mathcal{S}_2(f)(z\cos\theta, z\sin\theta) = \mathcal{M}_1(R_\theta)(z) = \lim_{m\to\infty} r_{m+k,m}(z\cos\theta, z\sin\theta), \tag{15}$$

which is an identity of the same type as (1). Note that the switch from Cartesian to polar coordinates is only required to make the transition from the Stieltjes transform to the Markov and Radon transform. More generally,

$$\mathcal{S}_2(f)(v,w) = \lim_{m\to\infty} r_{m+k,m}(v,w),$$

where $(v,w) = (z\cos\theta, z\sin\theta)$ with $-\pi/2 < \theta \leq \pi/2$. In the new reconstruction algorithm, this Markov and Radon transform shall not be computed explicitly. We only want to make use of moment information. We summarize the computations described so far and complete the reconstruction of $f(t,s)$ by solving (15).

5. Shape reconstruction algorithm. From the preceding theory we now summarize the bivariate reconstruction algorithm, with the higher-dimensional case being completely similar. Given the moments

$$c_{ij} = \int_0^\infty \int_0^\infty f(t,s)\, t^i s^j \, dt\, ds \tag{16}$$

we compute, for some $k \geq -1$ and consecutive m, the homogeneous bivariate Padé approximant $r_{m+k,m}(v,w)$ as a function of the Cartesian coordinates v and w. A fast algorithm for the computation of the multivariate Padé approximant is given in [2]. The computation of $r_{m+k,m}(v,w)$ requires knowledge of the moments c_{ij} appearing in the expressions $C_\ell(v,w)$ given in (8) for $\ell = 0,\ldots,2m+k$, or in other words the first $(2m+k+1)(2m+k+2)/2$ moments c_{ij}.

In the reconstructions, shape often means compact set A in $\mathbb{R}^2$ (or $\mathbb{R}^3$) and then $f(t,s)$ equals the characteristic function δ_A. In that case

$$c_{ij} = \int\int_A t^i s^j \, dt\, ds.$$

Theorem 3 guarantees that the approximants $r_{m+k,m}(v,w)$ converge rapidly on each slice S_θ to $g(v,w)$ restricted to that slice. A typical value for m is between 3 and 7, and hence one needs with $k=-1$ on average between 21 and 105 moments. Moreover, the moments are not required very accurately. For a rough estimate of a shape as in Figure 2, moments with 2 to 3 significant digits (a relative error bounded by 5×10^{-2} or 5×10^{-3}) are sufficient.

The Padé approximant is then evaluated in a discrete number of points (v_j,w_j) inside the unit disc to approximate

$$g(v_j,w_j) \approx r_{m+k,m}(v_j,w_j).$$

The latter constitutes the right-hand side of (17). To speed up the convergence of the Padé approximants $r_{m+k,m}$ the points (v_j,w_j) can be taken in a disc of radius $r<1$: Padé approximants converge more rapidly in the neighborhood of the origin. At the same time, for each point (v_j,w_j) the value $g(v_j,w_j)$ can be approximated to high accuracy by a cubature formula,

$$\sum_{i=1}^{L} \frac{\omega_i}{1+t_i v_j + s_i w_j} f(t_i,s_i), \quad j=0,1,\ldots,$$

with weights ω_i and nodes (t_i, s_i). The inverse problem of computing $f(t_i, s_i)$ from

$$\sum_{i=1}^{L} \frac{\omega_i}{1 + t_i v_j + s_i w_j} f(t_i, s_i) \approx g(v_j, w_j) = \lim_{m \to \infty} r_{m+k,m}(v_j, w_j) \tag{17}$$

is a (structured) system of linear equations. When applying a quadrature method directly to (16), it is clear that a few dozen moments are not sufficient to retrieve the value of $f(t, s)$ with the accuracy shown in the illustrations below ($h = k = 2^{-5}$ gives a resolution of about 3200 pixels in the unit disk and $h = k = 2^{-6}$ a resolution of almost 13,000 pixels)! The current technique allows one to write down as many equations as required, by adding evaluations of the Padé approximant in points (v_j, w_j), without increasing the number of required moments c_{ij}.

The linear problem (17) is in general ill-conditioned, and therefore a regularization technique must be applied. In all of the following examples we have found the technique known as truncated SVD [13] to do an excellent job. After regularization, we solve (17) for $f(t_i, s_i)$ and identify an approximation for the shape A with

$$A \approx \{(t_i, s_i) \mid f(t_i, s_i) \geq 0.5\}.$$

The threshold 0.5 is chosen because for the original shape $f(t, s) = 1$ inside A and $f(t, s) = 0$ outside A.

Since the homogeneous Padé approximant can be defined analogously in higher dimensions, the procedure for three-dimensional shape reconstruction is entirely similar. In this case, we are given the moments

$$c_{ijk} = \int_0^\infty \int_0^\infty \int_0^\infty f(t, s, v)\, t^i s^j v^k \, dt \, ds \, dv. \tag{18}$$

Here Theorems 2 and 3 hold on the slices

$$S_{\theta,\phi} = \{(z \cos\phi \cos\theta, z \cos\phi \sin\theta, z \sin\phi) \mid z \in \mathbb{R}\},$$

and the three-dimensional version of (13) is

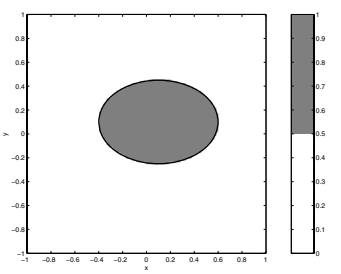
$$\begin{aligned} \int_{-\infty}^{+\infty} \frac{R_{\theta,\phi}(u)}{1 + zu} du &= \int_0^\infty \int_0^\infty \int_0^\infty \frac{f(t, s, v)}{1 + (t \cos\phi \cos\theta + s \cos\phi \sin\theta + v \sin\phi) z} \, dt \, ds \, dv \\ &= \lim_{m \to \infty} r_{m+k,m}(z \cos\phi \cos\theta, z \cos\phi \sin\theta, z \sin\phi). \end{aligned} \tag{19}$$

The homogeneous Padé approximant $r_{m+k,m}(w, x, y)$ of the Stieltjes transform

$$\int_0^\infty \int_0^\infty \int_0^\infty \frac{f(t, s, v)}{1 + (tw + sx + vy)} \, dt \, ds \, dv \tag{20}$$

is now constructed from the trivariate Stieltjes series representation

$$\sum_{i,j,k=0}^{\infty} (-1)^{i+j+k} \binom{i+j}{i} \binom{i+j+k}{i+j} c_{ijk} w^i x^j y^k$$



for (20). Note that the vector $(\cos\phi \cos\theta, \cos\phi \sin\theta, \sin\phi)$ generating the one-dimensional slice $S_{\theta,\phi}$ belongs to the three-dimensional unit sphere.

6. Numerical examples. For each example we give the cubature parameters h and k used in formula (21) or h, k, and ℓ used in (22) and the distance Δ between the coordinates of the points (v_j, w_j) used in the formulation of (17). For these evaluation points we construct a uniform grid (the distance Δ in the x- and y-directions is kept equal) that we intersect with the disc of radius r. All points in the intersection are selected. We also list the denominator degree m of the Padé approximant (the numerator degree is $m-1$), the radius r of the disc in which the points (v_j, w_j) are chosen, and the relative accuracy ϵ of the moments (here $2^{-4}, 2^{-11}, 2^{-14}$, and 2^{-24} stand for, respectively, 2, 4, 5, and 8 significant digits). Even when $r < 1$, the shape A is allowed to cover the entire unit disk. Note that the resolution of the reconstruction is expressed by h and k or h, k, and ℓ, not by Δ.

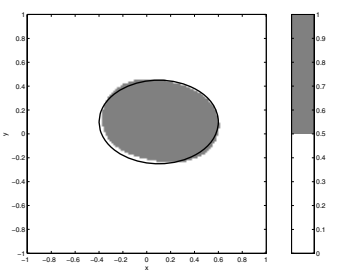
6.1. Reconstruction of two-dimensional shapes. We take for $f(t,s)$ in Theorem 3 the characteristic function of a compact set A contained in the unit disc and use the simple compound 4-point Gauss-Legendre product rule [20, pp. 230–231] for the approximation of $g(v_j, w_j)$ in (17):

$$
\begin{aligned}
\int_a^{a+h}\int_b^{b+k} \frac{f(t,s)}{1+tv_j+sw_j}dt\,ds &\approx \frac{hk}{4}\sum_{i=1}^{4}\frac{f(t_i,s_i)}{1+t_iv_j+s_iw_j},\\
(t_1,s_1) &= \left(a+\frac{3-\sqrt{3}}{6}h,\ b+\frac{3-\sqrt{3}}{6}k\right),\\
(t_2,s_2) &= \left(a+\frac{3-\sqrt{3}}{6}h,\ b+\frac{3+\sqrt{3}}{6}k\right),\\
(t_3,s_3) &= \left(a+\frac{3+\sqrt{3}}{6}h,\ b+\frac{3-\sqrt{3}}{6}k\right),\\
(t_4,s_4) &= \left(a+\frac{3+\sqrt{3}}{6}h,\ b+\frac{3+\sqrt{3}}{6}k\right).
\end{aligned}
\tag{21}
$$

We reconstruct several shapes, such as a simple convex shape like the ellipse in Figures 1 and 2, the more difficult nonconvex lemniscates in Figures 3 and 4, and the bone-like Figure 5 containing a hole. In each of the illustrations we delimit the original shape in black and show the reconstructed area in gray. The black contour is given only for comparison. Note that the shape's boundary is unknown in real-life situations where only the shape's moments are known up to some order and accuracy. For the reconstruction of the two-dimensional shapes we choose h and k in (21) equal to $h = k = 2^{-5}$.

$A = \{(t,s) \mid ((t-0.1)/0.5)^2 + ((s-0.1)/0.35)^2 = 1\}$

FIG. 1.
$m = 7, r = 1.00, \epsilon = 2^{-24}, \Delta = 2^{-4}$.



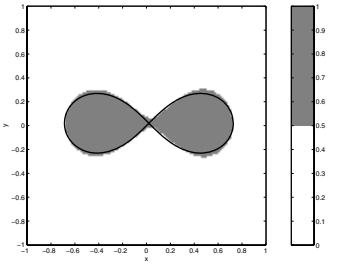


FIG. 2.
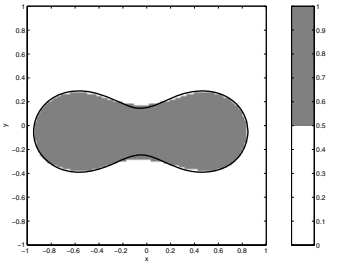
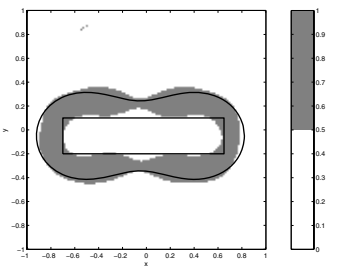
$m = 5, r = 0.15, \epsilon = 2^{-4}, \Delta = 2^{-6}$.

$$A = \{(t,s) \mid \left((t-t_0)^2 + (s-s_0)^2 + \alpha^2\right)^2 - 4\alpha^2(t-0.1)^2 = \beta^4\}$$

FIG. 3. $t_0 = s_0 = 0.02, \alpha = \beta = 0.5,$ $m = 9, r = 0.12, \epsilon = 2^{-11}, \Delta = 2^{-6}.$





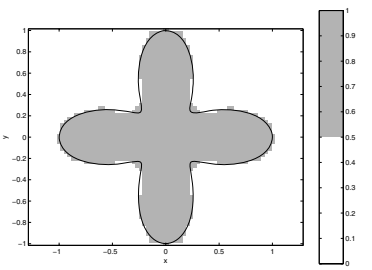


FIG. 4. $t_0 = s_0 = -0.05, \alpha = 0.62, \beta = 0.65,$ $m = 9, r = 0.30, \epsilon = 2^{-14}, \Delta = 2^{-5}.$

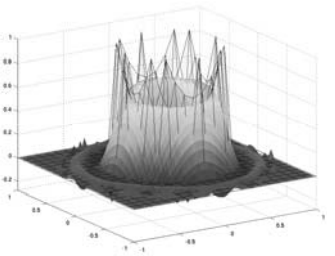
$$A = \{(t,s) \mid \left(t^2 + s^2 + 0.4225\right)^2 - 1.69t^2 = 0.2401\} \setminus \{(t,s) \mid |t| < 0.8, |s| < 0.1\}$$

FIG. 5. $m = 9, r = 0.50, \epsilon = 2^{-24}, \Delta = 2^{-4}.$

Finally, a difficult two-dimensional shape is presented in Figure 6. Here, for a change, $h = k = 2^{-4}$ and the evaluation points (v_j, w_j) are placed on a radial grid, while the moments are computed to almost full double precision.

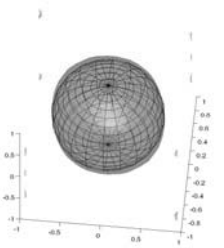


$$A = \{(t,s) \mid t = (\cos(4\tau) + 2)\cos(\tau)/3, s = (\cos(4\tau) + 2)\sin(\tau)/3\}$$

FIG. 6. $m = 10, r = 0.5, \Delta \approx 1/12.$

6.2. Reconstruction of particular three-dimensional shapes. Since Theorem 3 also applies to more general functions $f(t,s)$ than characteristic functions, particular three-dimensional shapes as in Figure 7, namely, with one flat side, can also be reconstructed by means of the two-dimensional integral inversion technique. Here the positive function $f(t,s)$ defines the top surface of the three-dimensional shape while the bottom surface is the domain of f in the (t,s)-plane. Further, the object is cylindrical. The reconstruction of the crater-like object is obtained by plotting the reconstruction of $f(t,s)$ as a function of t and s. The plot is overlaid with a mesh depicting the exact function $f(t,s)$.

In this example we have also increased the sizes of h and k to 2^{-4}, while keeping the number of points (v_j, w_j) rather moderate.



Three-dimensional object with surface $f(t,s) = t^2 + s^2$ *for* $t^2 + s^2 \leq 0.25$.
FIG. 7. $m = 8, r = 0.5, \epsilon = 2^{-11}, \Delta = 2^{-4}$.

6.3. Reconstruction of three-dimensional shapes. A more general three-dimensional shape, such as the ball in Figure 8, can be reconstructed through the solution of the three-dimensional analogue of (17) for its characteristic function $f(t,s,v)$. Here we use the compound 8-point Gauss–Legendre product cubature formula given in [20, pp. 230–231]:

$$\int_a^{a+h}\int_b^{b+k}\int_c^{c+\ell} \frac{f(t,s,v)}{1+tw+sx+vy}dt\,ds\,dv \approx \frac{hk\ell}{8}\sum_{i=1}^{8}\frac{f(t_i,s_i,v_i)}{1+t_iw_j+s_ix_j+v_iy_j},$$

$$(t_i,s_i,v_i) = \left(a+\frac{3\pm\sqrt{3}}{6}h, b+\frac{3\pm\sqrt{3}}{6}k, c+\frac{3\pm\sqrt{3}}{6}\ell\right). \tag{22}$$

Reconstruction of the ball $t^2 + s^2 + v^2 \leq 0.49$.
FIG. 8. $m = 6, h = k = \ell = 2^{-2}, \Delta = 2^{-4}$.

7. Conclusion. The new technique is able to deal with very general shapes: nonconvex such as in Figures 3 and 4, shapes with nonconnected boundary such as in Figure 5, and last but not least higher-dimensional objects such as in Figures 7 and 8. In Figure 7 we illustrate that the technique can also be used for more general functions $f(t,s)$ than characteristic functions.

By carrying out a lot of numerical experiments, we have come to the conclusion that the numerical quality of the output delivered by an implementation of the mathematical property formulated in Theorem 3 seems to depend on a number of elements. Let us formulate a conclusion and some numerical advice.

When the accuracy in the moment information decreases, then it is recommended to reduce the radius r of the ball from which the points (v_j, w_j) (in two dimensions) or (w_j, x_j, y_j) (in three dimensions) are selected. This shrinking of the region for the evaluation points improves the quality of the Padé approximant. We refer the reader to Figures 1 and 2 for a clear illustration. With moments known up to 7

significant digits, a perfect reconstruction is possible with $r = 1$, with a moderate number of moments. With moments known only up to 2 significant digits, a good quality reconstruction is possible when selecting the (v_j, w_j) inside a disc with far smaller radius. Fortunately, the lack of quality of the moments does not have to be compensated for by their quantity. Note that in Figure 2 even fewer moments are used than in Figure 1: $m = 5$ versus $m = 7$.

The quality of the reconstruction improves when the shape's center of gravity is positioned near the origin. To illustrate this we increase the values of t_0 and s_0 in Figure 3 to $t_0 = s_0 = 0.1$, without altering the other parameters. The reconstruction technique then delivers Figure 9. The same observation is made in [11], the reason for this being that the conditioning of the problem improves.

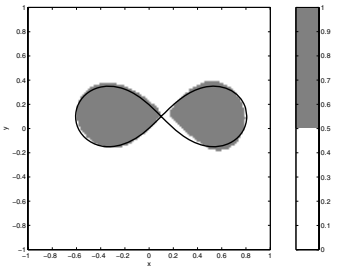


FIG. 9. $m = 9, r = 0.12, \epsilon = 2^{-11}, \Delta = 2^{-6}$.

Increasing the degree of the Padé denominator has little or no influence on the reconstruction. This is due to the fact that the Padé approximants converge quite rapidly. Their relative error drops quickly below the relative error on the moments. As a rule of thumb one can bound the relative error of the Padé approximant $r_{m-1,m}$ in the proposed reconstruction technique by 10^{-m-1}.

A WEIGHTED ESSENTIALLY NONOSCILLATORY, LARGE TIME-STEP SCHEME FOR HAMILTON–JACOBI EQUATIONS*

E. CARLINI†, R. FERRETTI‡, AND G. RUSSO§

Abstract. We investigate the application of weighted essentially nonoscillatory (WENO) reconstructions to a class of semi-Lagrangian schemes for first order time-dependent Hamilton–Jacobi equations. In particular, we derive a general form of the scheme, study sufficient conditions for its convergence with high-order reconstructions, and perform numerical tests to study its efficiency. In addition, we prove that the weights of the WENO interpolants are positive for any order.

Key words. semi-Lagrangian schemes, Hamilton–Jacobi equations, WENO methods

1. Introduction.

In this paper we treat a class of high-order, large time-step Godunov schemes for time-dependent Hamilton–Jacobi equation of first order. Although several extensions are possible, we will focus on the model problem

$$\begin{cases} v_t + H(\nabla v) = 0 & \text{in } \mathbb{R}^N \times \mathbb{R}, \\ v(x,0) = v_0(x) & \text{in } \mathbb{R}^N \end{cases} \tag{1.1}$$

and assume that the function H is smooth and strictly convex.

Many approximation schemes have been proposed for (1.1), but only a relatively recent part of the existing literature is devoted to high-order schemes. Within this rapidly growing research line, we quote the pioneering works by Osher and Sethian [23], Osher and Shu [24], Abgrall [1], [2] and, among more recent contributions, Lin and Tadmor [20], and Bryson and Levy [6]. Weighted essentially nonoscillatory (WENO) schemes were introduced by Liu, Osher, and Chan in [22], extensively studied and improved in [18], [16], and applied to Hamilton–Jacobi (HJ) equations in Jiang and Peng [17], Zhang and Shu [29], and Bryson and Levy [7].

On the other hand, large time-step, characteristics-based schemes for hyperbolic PDEs have been first proposed by Courant, Isaacson, and Rees in [8] (see also [19]). At the moment, they have gained a considerable popularity in the Numerical Weather Prediction community (where they are also known as [illegible]; see the review paper [27]). In the field of HJ equations, such schemes have been first applied to stationary Bellman equations related to optimal control problems (see [10] and the review [9]) and later to time-dependent equations for which the schemes under consideration might be seen (see [11], [12], [28]) as discrete counterparts of the Lax–Hopf–Oleinik representation formula.

It is well known that solutions of (1.1) should be understood in the viscosity sense (see [21], [4], [5]), which does not require v to be everywhere differentiable. Moreover, singularities in the gradient ∇v usually bring important information in HJ equations (as an example, in dynamic programming equations, singularities are typically associated to switching curves for the optimal control). Therefore, it would be crucial for the scheme to be accurate in smooth regions, while retaining low numerical dissipation and a nonoscillatory behavior in the neighborhood of singularities.

A further argument leads us to consider the use of WENO reconstructions in SL schemes. In fact, the scheme performs at any node and any time step a minimization which involves several computations of the numerical reconstruction. Its efficiency is, therefore, critical. Piecewise smooth functions can be effectively reconstructed using ENO or WENO methods (see [14], [15], [25]). Both techniques tend to choose interpolation points on the smooth side of the function; however, ENO schemes compute twice the required number of divided differences: at each step (that is, at any increase of the polynomial degree) the choice between the two new interpolation points is made according to the magnitude of the two divided differences obtained with the two candidate stencils (see [25]). On the other hand, in WENO schemes this process is performed by weighting the different polynomials, and this allows information from both sides to be used whenever possible.

The paper is organized as follows. Section 2 reviews the construction and basic convergence theory of SL schemes for (1.1), section 3 presents a general framework for the implementation of WENO interpolation as required by the SL scheme, with the explicit form of the schemes of order 2/3 and 3/5. In section 4 we prove positivity of the linear and nonlinear weights for any order of the polynomial and give their explicit form for evenly spaced nodes. In section 5 we derive from the positivity of the weights a sufficient condition for the convergence of the scheme, whereas section 6 is devoted to numerical tests.

2. Construction of the scheme and basic convergence theory. As it has been already pointed out, the SL schemes for HJ equations might be interpreted (see [11]) as discrete versions of the Lax–Hopf–Oleinik representation formula for the solution, which reads

$$v(x,t) = \inf_{\alpha\in\mathbb{R}^N} \{tH^*(\alpha) + v_0(x+\alpha t)\} \tag{2.1}$$

(where $H^*(\alpha)$ is the Legendre transform of $H(p)$). The general form of the scheme is a discretization of (2.1) on a single time step, namely,

$$v_j^{n+1} = \min_{a\in\mathbb{R}^N} \left(\Delta t H^*(a) + I[V^n](x_j + a\Delta t)\right), \tag{2.2}$$

where $V^n = \{v_j^n\}_{j\in\mathbb{Z}}$, $I[V^n](x)$ is a numerical reconstruction of the approximate solution at time $t_n = n\Delta t$ for any $x \in \mathbb{R}^N$, and v_j^{n+1} approximates $v(x_j, t_{n+1})$. If the reconstruction $I[V^n]$ is of degree r, then the consistency error of the scheme is estimated by

$$E_{\Delta t,\Delta x} \le C\frac{\Delta x^r}{\Delta t} \tag{2.3}$$

(note that in this situation, the best accuracy of the scheme would, in principle, be achieved by performing a single time step). If the Hamiltonian H depends also on x, then the representation formula (2.1) takes a more general form (see [4]) and in the

consistency analysis, there arises a further error term related to the approximation of characteristics (see [11] for a complete analysis). More precisely, if characteristics are approximated with order p, the full consistency estimate reads

$$E_{\Delta t,\Delta x} \le C_1 \Delta t^p + C_2 \frac{\Delta x^r}{\Delta t}. \tag{2.4}$$

In this case, both the term Δt^p and the need for a global minimum search in (2.2) make it unfeasible to perform a single time step when approximating the solution at a fixed time T. Note that according to (2.4), the scheme is consistent provided $\Delta x^r = o(\Delta t)$ and that the highest consistency rate is achieved for

$$\Delta t \sim \Delta x^{\frac{r}{p+1}}.$$

We briefly review here the convergence theory developed in [13] for the scheme (2.2). Assume that (1.1) is posed on $\mathbb{R}$ and discretized on an infinite uniform grid with nodes $x_j = j\Delta x$ ($j = 0, \pm 1, \pm 2, \ldots$). Also assume that the Hamiltonian function H is a $W^{2,\infty}$ function and that

$$H''(p) \ge m_H > 0. \tag{2.5}$$

The key assumption is that for any Lipschitz continuous function $v(x)$, once defined the sequence $V = \{v_j\}_j = \{v(x_j)\}_j$, the interpolation operator $I[V]$ satisfies, for some constant $C < 1$,

$$I[V](x_k) = v(x_k)\ , \quad |I[V](x) - I_1[V](x)| \le C \max_{x_k \in U(x)} |v_{k+1} - 2v_k + v_{k-1}|, \tag{2.6}$$

where by $I_1[V]$ we denote the P_1, i.e., piecewise linear, interpolation on the sequence V, and by $U(x) = (x - h_-\Delta x, x + h_+\Delta x)$ the stencil of the reconstruction $I[V](x)$. For example, a quadratic Lagrange reconstruction can be performed taking one node on the left and two nodes on the right of the point x (in this case, $h_- = 1$, $h_+ = 2$), or two nodes on the left and one on the right (and in this case, $h_- = 2$, $h_+ = 1$). In a second order ENO reconstruction (see [25]), both cases are possible depending on the solution (and thus, $h_- = h_+ = 2$). A third order Lagrange reconstruction is typically performed using two nodes on the left and two on the right, so that $h_- = h_+ = 2$. In the third order ENO case, $h_- = h_+ = 3$ and so forth. It is proved in [13] that condition (2.6) is satisfied for Lagrange and ENO reconstructions up to the fifth order if the reconstruction stencil includes the interval $[x_j, x_{j+1}]$.

Under such assumptions it is possible (see [13]) to prove the following.

THEOREM 2.1. [illegible] (2.2) [illegible] (1.1) [illegible] $N = 1$ [illegible] (2.5), (2.6) [illegible] $\Delta x = O(\Delta t^2)$ [illegible] v_0 [illegible] $V^n = \{v_j^n\}_j$ [illegible] v_j^n [illegible] (2.2)) [illegible]

$$\|I[V^n] - v(n\Delta t)\|_\infty \to 0$$

[illegible] v [illegible] (1.1) [illegible] $0 \le n \le T/\Delta t$ [illegible] $\Delta t \to 0$

3. A general form of WENO interpolation. Although the construction of a WENO interpolation is a well-established matter, we will give here some details of the procedure, since it is usually treated and used in a different framework. In this section, we will [illegible] assume a uniform mesh spacing.

To construct a WENO interpolation of degree $2n-1$ on the interval $[x_j, x_{j+1}]$, we start from the Lagrange polynomial built on the stencil $S = \{x_{j-n+1}, \dots, x_{j+n}\}$ and written in the form

$$Q(x) = \sum_{k=1}^{n} C_k(x) P_k(x), \tag{3.1}$$

where the "linear weights" C_k are polynomials of degree $n-1$ and the P_k are polynomials of degree n interpolating V on the stencil $S_k = \{x_{j-n+k}, \dots, x_{j+k}\}$, $k = 1, \dots, n$ (note that all the stencils S_k overlap on the interval $[x_j, x_{j+1}]$, and that the dependence on j has been dropped in this general expression). The nonlinear weights are then constructed so as to obtain an approximation of the highest degree if suitable smoothness indicators β_k give the same result on all stencils. This leads us to define

$$\alpha_k(x) = \frac{C_k(x)}{(\beta_k + \varepsilon)^2} \tag{3.2}$$

(with ε a properly small parameter, usually of the order of 10^{-6}), and then the nonlinear weights as

$$w_k(x) = \frac{\alpha_k(x)}{\sum_l \alpha_l(x)}, \tag{3.3}$$

where, following [25], the smoothness indicators are typically computed as

$$\beta_k = \sum_{l=1}^{n} \int_{x_j}^{x_{j+1}} \Delta x^{2l-1} (P_k^{(l)})^2 \, dx. \tag{3.4}$$

In the section on numerical tests we shall consider some different expressions for the smoothness indicators, such as the one proposed in [17], which does not depend on the first derivative of the function.

Last, the WENO interpolation reads

$$I[V](x) = \sum_{k=1}^{n} w_k(x) P_k(x). \tag{3.5}$$

Note that usually one is interested in computing the reconstruction in specific points in the cell. In this case the polynomials C_k take some specific value.

Let us now turn back to the linear weights C_k, which have not been given a precise expression. Due to (3.1) and to the definition of the polynomials P_k, the C_k are characterized by the fact that $Q(x)$ should be the interpolating polynomial of $V(x)$ on the stencil S. Since P_k interpolates V on the stencil S_k, it would be natural to require that C_k should vanish at the nodes outside S_k, and that in the nodes of S the nonzero weights should have unit sum. In this way, if P_k is the polynomial that interpolates the function on S_k, then (3.1) is the polynomial that interpolates V on S.

Taking into account that the number of nodes belonging to S but not to S_k is precisely n, we thus infer that the linear weights must necessarily have the form

$$C_k(x) = \gamma_k \prod_{x_l \in S \setminus S_k} (x - x_l) = \gamma_k \tilde{C}_k(x) \tag{3.6}$$

with γ_k to be determined in order to have unit sum. Note that the conditions

$$\sum_{k=1}^{n} C_k(x_i) = 1 \tag{3.7}$$

for each $x_i \in S$ apparently constitute a set of $2n$ equations in n unknowns. Actually, the correct perspective to look at these conditions is the following. The left-hand side of (3.7) is a polynomial of degree $n-1$ (computed at x_i), and on the right-hand side we have the polynomial $p(x) \equiv 1$. Therefore, imposing that the two polynomials coincide on more than $n-1$ points is equivalent to impose that they are identical. Now, it is easy to show that the monic polynomials $\tilde{C}_k$, $k = 1, \ldots, n$, are independent and form a basis of the space $\mathbb{P}_{n-1}$ of polynomials of degree $n-1$. Condition

$$\sum_{k=1}^{n} C_k(x) = 1 \quad \forall x \in \mathbb{R} \tag{3.8}$$

uniquely determines the constants γ_k as a polynomial identity.

Condition (3.8) can be conveniently satisfied by imposing it on a suitable set of points. Consider first the node x_{j-n+1}. Then, using (3.6) into (3.1), we note that, among all the linear weights computed at x_{j-n+1}, the only nonzero weight is C_1, so that

$$Q(x_{j-n+1}) = C_1(x_{j-n+1})P_1(x_{j-n+1}) = C_1(x_{j-n+1})v_{j-n+1} \tag{3.9}$$

and this implies that $C_1(x_{j-n+1}) = 1$ and allows us to compute γ_1. On the other hand, in the following node x_{j-n+2}, the nonzero weights are C_1 and C_2, and with a similar argument we obtain the condition

$$\begin{aligned} Q(x_{j-n+2}) &= C_1(x_{j-n+2})P_1(x_{j-n+2}) + C_2(x_{j-n+2})P_2(x_{j-n+2}) \\ &= [C_1(x_{j-n+2}) + C_2(x_{j-n+2})]v_{j-n+2}, \end{aligned} \tag{3.10}$$

which implies that $C_1(x_{j-n+2}) + C_2(x_{j-n+2}) = 1$, whence γ_2 can be computed. Following this guideline, we finally obtain the set of conditions

$$\sum_{i=1}^{k} C_i(x_{j-n+k}) = 1 \quad (k = 1, \ldots, n), \tag{3.11}$$

that is, more explicitly,

$$\sum_{i=1}^{k} \gamma_i \prod_{x_l \in S \setminus S_i} (x_{j-n+k} - x_l) = 1 \quad (k = 1, \ldots, n), \tag{3.12}$$

which is a linear triangular system in the unknowns γ_i.

Although the construction outlined in this section does not require a constant space step, the problem of giving an explicit expression to the coefficients γ_i is considerably easier in the case of constant Δx. This case will be treated in detail in section 4, along with the study of sign for the linear weights. In the next subsections we give two examples of this construction (on a uniform mesh), including the expressions for the smoothness indicators (3.4). The resulting schemes will be used in the section on numerical tests.

3.1. Second–third order WENO interpolation. To construct a third order interpolation we start from two polynomials of second degree, so that

$$I[V^n](x) = w_L P_L(x) + w_R P_R(x), \tag{3.13}$$

where $P_L(x)$ and $P_R(x)$ are second order polynomials constructed, respectively, on the nodes x_{j-1}, x_j, x_{j+1} and on the nodes x_j, x_{j+1}, x_{j+2}. The two linear weights C_L and C_R are first degree polynomials in x, and according to the general theory outlined so far, they read

$$C_L = \frac{x_{j+2} - x}{3\Delta x}, \quad C_R = \frac{x - x_{j-1}}{3\Delta x}, \tag{3.14}$$

and the expressions of α_L, α_R, w_L, and w_R may be easily recovered from the general form.

According to (3.4), the smoothness indicators have the explicit expressions

$$\beta_L = \frac{13}{12}v_{j-1}^2 + \frac{16}{3}v_j^2 + \frac{25}{12}v_{j+1}^2 - \frac{13}{3}v_{j-1}v_j + \frac{7}{6}v_{j-1}v_{j+1} - \frac{19}{3}v_j v_{j+1}, \tag{3.15}$$

$$\beta_R = \frac{13}{12}v_{j+2}^2 + \frac{16}{3}v_{j+1}^2 + \frac{25}{12}v_j^2 - \frac{13}{3}v_{j+2}v_{j+1} + \frac{7}{6}v_{j+2}v_j - \frac{19}{3}v_j v_{j+1}. \tag{3.16}$$

3.2. Third–fifth order WENO interpolation. To construct a fifth order interpolation we start from three polynomials of third degree:

$$I[V^n](x) = w_L P_L(x) + w_C P_C(x) + w_R P_R(x), \tag{3.17}$$

where the third order polynomials $P_L(x)$, $P_C(x)$, and $P_R(x)$ are constructed, respectively, on $x_{j-2}, x_{j-1}, x_j, x_{j+1}$, on $x_{j-1}, x_j, x_{j+1}, x_{j+2}$, and on $x_j, x_{j+1}, x_{j+2}, x_{j+3}$. The weights C_L, C_C, and C_R are second degree polynomials in x, and have the form

$$\begin{aligned} C_L &= \frac{(x - x_{j+2})(x - x_{j+3})}{20\Delta x^2}, \quad C_C = \frac{(x - x_{j-2})(x - x_{j+3})}{10\Delta x^2}, \\ C_R &= \frac{(x - x_{j-2})(x - x_{j-1})}{20\Delta x^2}, \end{aligned} \tag{3.18}$$

while the smoothness indicators β_C and β_R have the expressions

$$\begin{aligned} \beta_C = {} & \frac{61}{45}v_{j-1}^2 + \frac{331}{30}v_j^2 + \frac{331}{30}v_{j+1}^2 + \frac{61}{45}v_{j+2}^2 - \frac{141}{20}v_{j-1}v_j + \frac{179}{30}v_{j-1}v_{j+1} \\ & + \frac{293}{180}v_{j-1}v_{j+2} - \frac{1259}{60}v_j v_{j+1} + \frac{179}{30}v_j v_{j+2} - \frac{141}{20}v_{j+1}v_{j+2}, \end{aligned} \tag{3.19}$$

$$\begin{aligned} \beta_R = {} & \frac{407}{90}v_j^2 + \frac{721}{30}v_{j+1}^2 + \frac{248}{15}v_{j+2}^2 + \frac{61}{45}v_{j+3}^2 - \frac{1193}{60}v_j v_{j+1} + \frac{439}{30}v_j v_{j+2} \\ & - \frac{683}{180}v_j v_{j+3} - \frac{2309}{60}v_{j+1}v_{j+2} + \frac{309}{30}v_{j+1}v_{j+3} - \frac{553}{60}v_{j+2}v_{j+3}, \end{aligned} \tag{3.20}$$

and β_L can be obtained using the same set of coefficients of β_R in a symmetric way (that is, replacing the indices $j-2, \dots, j+3$ with $j+3, \dots, j-2$).

It is interesting to check that, due to their structure, the linear weights are always positive in the interval $[x_j, x_{j+1}]$ for $n = 2, 3$. This also means that pointwise the linear combination (3.5) is in fact a convex combination, and this has important consequences at the level of convergence analysis. We will prove in the next section that this property holds for linear weights up to an arbitrary order.

4. On the positivity of the weights in WENO reconstruction. We prove in this section that the positivity result for the weights in WENO interpolation, obtained in the previous section by direct computation up to third–fifth order, actually holds in general. In addition, we give an explicit expression for the linear weights in the case of evenly spaced nodes.

It is worth pointing out that this result of positive sign for the linear and nonlinear weights is not in contrast with the well-known situation in which the weights may change sign (see [26]). In fact, this latter situation may occur in the case of reconstructions based on cell averages instead of pointwise values such as the interpolation procedure above.

We first give a general proof of positivity for the linear weights $C_k(x)$.

THEOREM 4.1. $\{x_i\}$ $\mathbb{R}$ $Q(x)$ $f(x)$ $S = \{x_{j-n+1}, \dots, x_{j+n}\}$ (3.1) $C_k(x)$ $(k = 1, \dots, n)$ $x \in (x_j, x_{j+1})$ $\sum_k C_k(x) \equiv 1$

Let us denote by $Q^{(l,m)}(x)$ (with $j - n + 1 \le l \le j < j + 1 \le m \le j + n$ and $m - l \ge n$) the interpolating polynomial constructed on the stencil $\{x_l, \dots, x_m\}$, so that

$$Q(x) = Q^{(j-n+1,j+n)}(x) \tag{4.1}$$

and, moreover,

$$P_k(x) = Q^{(j-n+k,j+k)}(x). \tag{4.2}$$

We will also write a generic $Q^{(l,m)}(x)$ as

$$Q^{(l,m)}(x) = \sum_k C_k^{(l,m)}(x) P_k(x), \tag{4.3}$$

where the summation may be extended to all $k = 1, \dots, n$ by setting $C_k^{(l,m)} = 0$ whenever the stencil of P_k is not included in $\{x_l, \dots, x_m\}$. Therefore, the final linear weights will be

$$C_k(x) = C_k^{(j-n+1,j+n)}(x). \tag{4.4}$$

We proceed by induction on the degree of $Q^{(l,m)}$, given by $i = \deg Q^{(l,m)} = m - l$, starting with $i = n$ up to $i = 2n - 1$. First we prove that the claim of the theorem extends to all polynomials $Q^{(l,m)}(x)$ defined in (4.3). The claim is obviously true for $Q^{(j-n+k,j+k)}(x)$ by (4.2). In this case the coefficients $C_k^{(l,m)} = 1$, $C_s^{(l,m)} \equiv 0$, $s \ne k$. Then, we assume the claim is true for the set of linear weights $C_k^{(l,m)}(x)$ of a generic $Q^{(l,m)}(x)$ such that $m - l = i$ and add a node to the right (adding a node to the left leads to an analogous computation). By inductive assumption we have, for any l and m such that $l \le j < j + 1 \le m$ and $m - l = i$, that (4.3) holds with $C_k^{(l,m)}(x) \ge 0$. On the other hand, by elementary interpolation theory arguments (Neville's recursive form of the interpolating polynomial),

$$Q^{(l,m+1)}(x) = \frac{x_{m+1} - x}{x_{m+1} - x_l} Q^{(l,m)}(x) + \frac{x - x_l}{x_{m+1} - x_l} Q^{(l+1,m+1)}(x). \tag{4.5}$$

Note that $\deg Q^{(l,m)} = \deg Q^{(l+1,m+1)} = i$, and that both fractions which multiply $Q^{(l,m)}(x)$ and $Q^{(l+1,m+1)}(x)$ are positive as long as $x \in (x_j, x_{j+1})$. Therefore, using

(4.3) into (4.5), we get

$$Q^{(l,m+1)}(x) = \sum_k \left[\frac{x_{m+1} - x}{x_{m+1} - x_l} C_k^{(l,m)}(x) + \frac{x - x_l}{x_{m+1} - x_l} C_k^{(l+1,m+1)}(x) \right] P_k(x). \tag{4.6}$$

The term in square brackets is $C_k^{(l,m+1)}(x)$ and it is immediate to check that it is nonnegative. Iterating this argument up to $Q^{(j-n+1,j+n)}(x)$ completes the proof of nonnegativity for all the linear weights $C_k(x)$.

Last, setting $f(x) \equiv 1$, we also have $Q(x) \equiv 1$ and, for any k, $P_k(x) \equiv 1$. Plugging these identities into (3.1) we obtain $\sum_k C_k(x) \equiv 1$. □

We turn now to the problem of giving an explicit expression to the linear weights in the situation of evenly spaced nodes. The expression of the weights for the linear scheme is

$$C_k = \gamma_k \prod_{x_l \in S \setminus S_k} (x - x_l).$$

First observe that the polynomial $C_k(x)$ does not change sign in the interval $[x_j, x_{j+1}]$. More precisely, the sign of it, in this interval, is given by $\text{sign}(\gamma_k)(-1)^{n+k}$. Therefore,

$$C_k(x) > 0 \quad \forall x \in [x_j, x_{j+1}] \quad \forall k, n \quad \Leftrightarrow \quad \text{sign}\gamma_k = (-1)^{n+k}. \tag{4.7}$$

For simplicity, set $j = n$ in the definition of the stencil S, so that $S = \{x_1, \ldots, x_{2n}\}$. Let us introduce the integer stencils

$$\tilde{S} = S/\Delta x, \quad \tilde{S}_k = S_k/\Delta x.$$

Then the polynomials C_k can be written as

$$C_k(\Delta x \xi) = \tilde{\gamma}_k \prod_{l \in \tilde{S} \setminus \tilde{S}_k} (\xi - l),$$

where $\tilde{\gamma}_k = \gamma_k \Delta x^{n-1}$. The nondimensional constants $\tilde{\gamma}_k$ satisfy the condition

$$\sum_{i=1}^{k} \tilde{\gamma}_i \prod_{\substack{l=1 \\ l \notin (i,\ldots,i+n)}}^{2n} (i - l) = 1.$$

Introducing now the matrix

$$a_{ki} = \frac{\prod_{l=1}^{2n}(k-l)}{\prod_{l=i}^{i+n}(k-l)} = \frac{(k-1)!(2n-k)!}{(n+i-k)!(k-i)!}(-1)^{n+i}, \tag{4.8}$$

the system can be written as

$$\sum_{i=1}^{k} a_{ki} \tilde{\gamma}_i = 1.$$

Let $\mu_i \equiv (-1)^{n+i}\tilde{\gamma}_i$. Then, such constants satisfy the triangular system

$$\sum_{i=1}^{k} |a_{ki}| \mu_i = 1, \tag{4.9}$$

and according to (4.7) $C_i(x) > 0$, $x \in [x_n, x_{n+1}]$ if and only if $\mu_i > 0$.

The solution to system (4.9) can be explicitly given. In fact, we will prove now that

$$\mu_i = \frac{n!(n-1)!}{(n-i)!(i-1)!(2n-1)!} \quad (i = 1, \dots, n). \tag{4.10}$$

Actually, plugging (4.10) and (4.8) into (4.9) we obtain the set of conditions that we want to check:

$$\sum_{i=1}^{k} \frac{(k-1)!(2n-k)!n!(n-1)!}{(n+i-k)!(k-i)!(n-i)!(i-1)!(2n-1)!} = 1.$$

These relations can be rearranged in the form

$$\frac{(k-1)!(2n-k)!}{(2n-1)!} \sum_{i=1}^{k} \binom{n}{k-i} \binom{n-1}{i-1} = 1,$$

and, hence, rewriting the first term and shifting the summation index as $j = i - 1$,

$$\sum_{j=0}^{k-1} \binom{n}{k-1-j} \binom{n-1}{j} = \binom{2n-1}{k-1},$$

which is in turn a special case of the identity[1] (see [3])

$$\sum_{j=0}^{N} \binom{n}{N-j} \binom{m}{j} = \binom{n+m}{N}$$

with $N = k - 1$ and $m = n - 1$.

We also prove here that the μ_i are inverse of integers. In fact, note first that by (4.10), $\mu_i = \mu_{n-i+1}$, so that it suffices to prove the claim for $i \le (n+1)/2$. Then, we rewrite the μ_i as

$$\mu_i = \begin{cases} \dfrac{n!}{(2n-1)!} & \text{if } i = 1, \\ \dfrac{(n-i+1)\cdots(n-1)n(n-1)!}{(i-1)!(2n-1)!} & \text{if } i > 1. \end{cases} \tag{4.11}$$

While the claim is obvious if $i = 1$, if $i > 1$, we derive from (4.11)

$$\mu_i = \frac{(2n-2i+2)\cdots(2n-2)}{2^{i-1}(i-1)!(n+1)\cdots(2n-1)}.$$

Now, if $i \le (n+1)/2$, then $2n-2i+2 \ge n+1$ and, therefore, any term of the product $(2n-2i+2)\cdots(2n-2)$ can be simplified with a term of the product $(n+1)\cdots(2n-1)$. This completes the proof of the claim.

We report in Table 1 the value of $1/\mu_i$ for values of n up to $n = 8$.

[1] We thank professor Corrado Falcolini for bringing this result to our attention.

5. A sufficient condition for convergence. We briefly check here that the convergence theory developed in [13] may be applied to the scheme under consideration. To this end, we work in the framework of Theorem 2.1 and prove the following.

THEOREM 5.1. [illegible] $V = \{v_j\}_j = \{v(x_j)\}_j$ [illegible] $v(x)$ [illegible] $I[V]$ [illegible] (3.5) [illegible] (2.6) [illegible] $n \le 5$

[illegible] First, the condition

$$I[V](x_k) = v(x_k) \tag{5.1}$$

is clearly satisfied since (3.5) is built as an interpolation. Concerning the second part of (2.6), namely,

$$|I[V](x) - I_1[V](x)| \le C \max_{x_k \in U(x)} |v_{k+1} - 2v_k + v_{k-1}| \tag{5.2}$$

with $C < 1$, this condition is satisfied for all the polynomials $P_k(x)$ if $n \le 5$, as proved in [13], since all the stencils S_k include the interval $[x_j, x_{j+1}]$. Although the structure under consideration for $I[V]$ is not globally polynomial, it is easy to see from (3.2), (3.3) that once x is given, since all the linear weights C_k are nonnegative by Theorem 4.1, then the right-hand side of (3.5) is in fact a convex combination of the polynomials P_k. Therefore,

$$\min_k P_k(x) \le I[V](x) \le \max_k P_k(x) \tag{5.3}$$

and, therefore, the constant C appearing in (2.6) is the same as obtained in [13] for polynomials of degree n. That is, (2.6) is satisfied with $C < 1$ up to WENO interpolations of fifth–ninth order. □

[illegible] The positivity of the linear weights, obtained in the framework of WENO reconstructions, also allows to prove a further result related to Lagrange reconstructions. Actually, the bound (5.3) does not require $I[V]$ to be in the form (3.5), but it also applies to the form (3.1). Therefore, (2.6) is also satisfied for Lagrange reconstructions up to the ninth order, at least if the reconstruction stencil is symmetrical, which corresponds to odd orders of interpolation. Moreover, in the case of even (up to the eighth) orders, an analogous result can be obtained. More precisely, if a sixth order interpolation is performed using the nodes $x_{j-3}, \dots, x_{j+3}$, the linear weights have the expressions

$$C_1(x) = \frac{(x - x_{j+2})(x - x_{j+3})}{30\Delta x^2},$$

$$C_2(x) = -\frac{(x - x_{j-3})(x - x_{j+3})}{15\Delta x^2},$$

$$C_3(x) = \frac{(x - x_{j-3})(x - x_{j-2})}{30\Delta x^2},$$

whereas if an eighth order interpolation is performed using the nodes $x_{j-4}, \ldots, x_{j+4}$, the linear weights read

$$C_1(x) = -\frac{(x - x_{j+2})(x - x_{j+3})(x - x_{j+4})}{336\Delta x^3},$$

$$C_2(x) = \frac{(x - x_{j-4})(x - x_{j+3})(x - x_{j+4})}{112\Delta x^3},$$

$$C_3(x) = -\frac{(x - x_{j-4})(x - x_{j-3})(x - x_{j+4})}{112\Delta x^3},$$

$$C_4(x) = \frac{(x - x_{j-4})(x - x_{j-3})(x - x_{j-2})}{336\Delta x^3}.$$

Again, a direct computation shows that $C_k(x) > 0$ for $x \in [x_j, \ldots, x_{j+1}]$, so that (5.3) (and hence (2.6)) still holds.

6. Numerical tests. In this section we present the results of several numerical tests in which we compare the WENO scheme described with P_1, P_2, cubic Lagrange, and third order ENO schemes. The WENO schemes considered are of second–third order and third–fifth order, and the two-dimensional reconstruction has been implemented by a tensor product of one-dimensional interpolations. The minimization step has been performed by bisection in the one-dimensional case, and by the Powell-like routine `PRAXIS` (taken from the NETLIB repository at ftp.netlib.org) in the two-dimensional examples. In order to evaluate the accuracy of the reconstruction, the tolerance in the minimization phase has been set to an order of magnitude far lower than the truncation error, although this may have somewhat slowed down the scheme. The upwinding along characteristics has been performed by means of a plain Euler method as in (2.2) (in the situation of H depending on the gradient alone, this choice has the best accuracy anyway).

Errors have been expressed in terms of the relative discrete L^∞ norm, defined as

$$\epsilon_{\infty,rel} = \frac{\max_j |v_j - v(x_j)|}{\max_j |v_j|}.$$

The computation of relative discrete L^1 norm of the errors has given similar indications and is therefore omitted.

Unless otherwise stated, figures showing approximate solutions have been obtained with the WENO 2/3 scheme.

In addition to the usual choice (3.4) as proposed by Shu, which has been denoted by S in the tables, some different possibility has been considered for the smoothness indicator. An indicator based on the second derivative alone, that is,

$$\beta_k = \int_{x_j}^{x_{j+1}} \Delta x^3 (P_k'')^2 dx, \tag{6.1}$$

has been denoted by D2 in the tables, whereas an indicator which only takes into account the highest order derivative, namely,

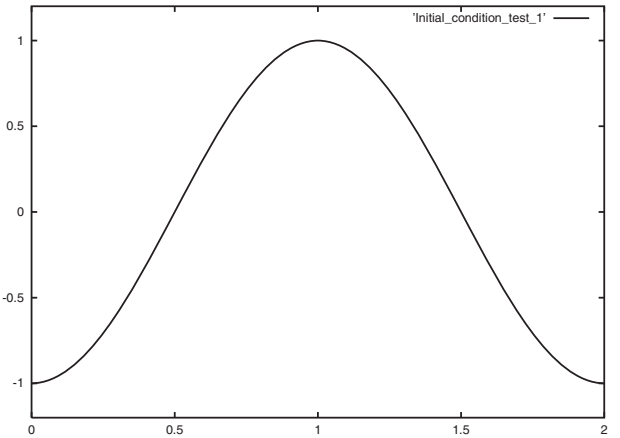
$$\beta_k = \int_{x_j}^{x_{j+1}} \Delta x^{2n-1} (P_k^{(n)})^2 dx, \tag{6.2}$$

has been implemented—it clearly coincides with the indicator D2 for the second–third order scheme, and has been denoted by D3 for the third–fifth order scheme. Last, as proposed by Jiang and Peng (see [17]), a smoothness indicator which takes into account all derivatives but the first, that is,

$$\beta_k = \sum_{l=2}^{n} \int_{x_j}^{x_{j+1}} \Delta x^{2l-1} (P_k^{(l)})^2 dx, \tag{6.3}$$

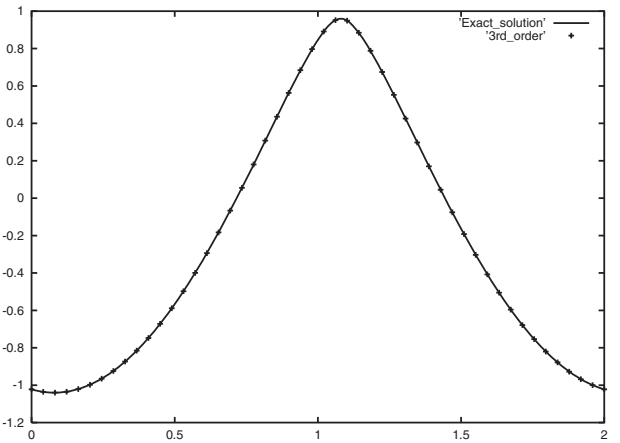
has been implemented for the third-fifth order scheme and denoted by D2+D3. Although the creation of singularities in HJ equations is at the level of the gradient, and therefore it could seem natural to drop first derivatives in the smoothness indicator, nevertheless, we will show that the use of the full expression (3.4) seems to be the most robust choice, although it might not be the most accurate one in any situation. We have summarized in Table 7 a comparison of the WENO schemes (with various smoothness indicators) with P_1, P_2, cubic, and third order ENO implementations of (2.2) on all numerical tests, in the standard setting of a 50×50 grid (50 nodes for test 1), and after the onset of the singularity for tests 1, 2, and 4.

Test 1: One-dimensional periodic solution. This test (also considered in [6], [20], [17]) deals with the HJ equation



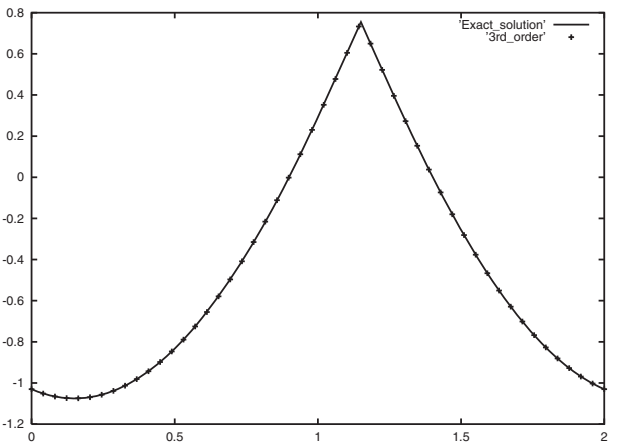
$$\begin{cases} v_t(x,t) + \frac{1}{2}(v_x(x,t)+1)^2 = 0, \\ v(x,0) = v_0(x) = -\cos(\pi x), \end{cases} \tag{6.4}$$

considered in $[0,2]$, with periodic boundary conditions. The approximate solution is computed before the singularity, at $T = 0.8/\pi^2$, with 4 time steps, and after the singularity, at $T = 1.5/\pi^2$, with 5 time steps. Plots of exact versus approximate solutions are shown in Figure 1 and relative errors obtained with the Shu smoothness indicator are compared in Tables 2–3.



Note that according to the consistency estimate (2.3), the convergence rates should be $p = 4$ for the WENO3 scheme and $p = 6$ for the WENO5 scheme, since the time step has been kept constant. Roughly speaking, this behavior is confirmed by numerical tests, although with a slight decrease in the convergence rate after the onset of the singularity. However, note that even in this latter case the computation of the approximate solution is highly accurate. If the exact solution v is semiconcave (roughly speaking, this means that it can be written as the sum of a concave and a $W^{2,\infty}$ function), this fact can be heuristically explained as follows. At a time step n and for a given node x_j, the reconstruction is performed at an "upwind" point which in the Lax–Hopf formula would be a minimum of the function

$$F_{n,j}(a) = \Delta t H^*(a) + v(t_{n-1}, x_j + a\Delta t).$$



Now, the function to be minimized contains two terms. The first is smooth, due to the assumptions on H, whereas the second is semiconcave. Their sum is therefore semiconcave and it is known (see [4]) that minima of semiconcave functions can occur only at points where the function is at least differentiable. Although the scheme in

200	2.01×10^{-8}	5.5	1.89×10^{-9}	5.2

fact uses a discretization of the function $F_{n,j}$, this analysis seems to give a convincing explanation of numerical results.

In the summarizing Table 7 we note that the performance of the third order schemes is similar and that there is an apparent loss of accuracy in the D2 version of the WENO3 scheme, as well as in the D2+D3 version of the WENO5 scheme.

Test 2: Generation of a two-dimensional singularity. This test refers to the HJ equation

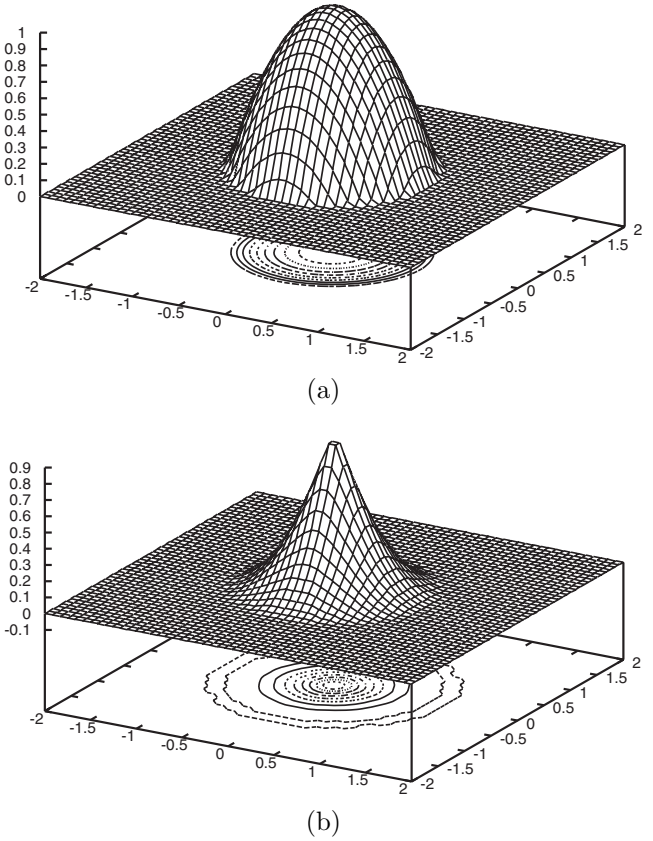
$$\begin{cases} v_t(x,t) + \frac{1}{2}|\nabla v(x,t)|^2 = 0, \\ v(x,0) = v_0(x) = \max(0, 1 - |x|^2). \end{cases} \tag{6.5}$$

The problem is considered in $[-2,2]^2$. For any positive time, the solution of this test problem has discontinuous second derivatives along the circle $|x| = 1$ and generates a further singularity in the gradient at the origin for $t \geq 1/2$.

The exact solution of (6.5) can be explicitly computed and for $t \geq 1/2$ reads

$$v(t,x) = \begin{cases} \frac{(|x|-1)^2}{2t} & \text{if } |x| \leq 1, \\ 0 & \text{if } |x| \geq 1. \end{cases}$$

The solution, computed with $\Delta t = 0.1$, is shown in Figure 2 at $t = 0$ and $t = 0.5$. Table 4 shows execution times (on a SUN E 420 R platform) at $t = T = 0.5$ for different reconstructions and different smoothness indicators, on a 50×50 grid. The errors reported in Table 7 show that the solution is computed with nearly the same accuracy by all the schemes, and the use of nonoscillatory interpolation does not seem to give any advantage (this is related to the lack of uniform semiconcavity of the solution; see the above discussion of this point). We point out, in any case, that the singularity in the gradient is well resolved, and that the scheme does not introduce instabilities. However, looking at Figure 3, in which we zoom the solution close to the x_1-x_2 plane for the third order linear, ENO, and WENO schemes, we may see



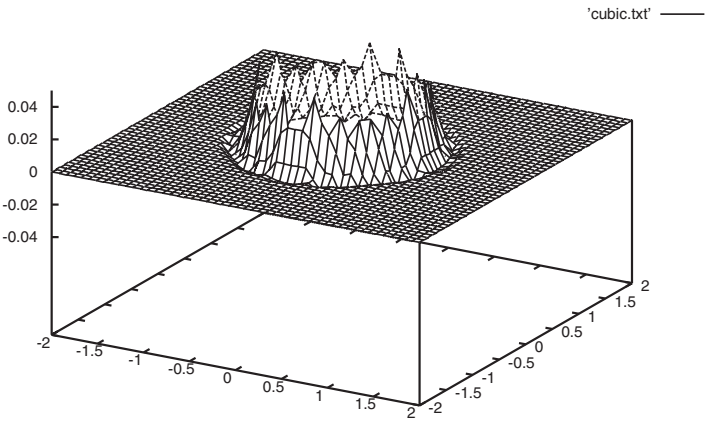


FIG. 2. *Approximate solution for test* 2. (a) *Initial condition.* (b) *Solution at* $t = 0.5$.

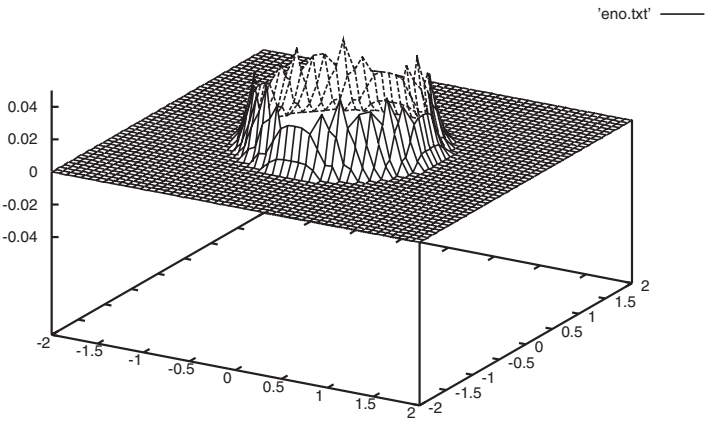

TABLE 4
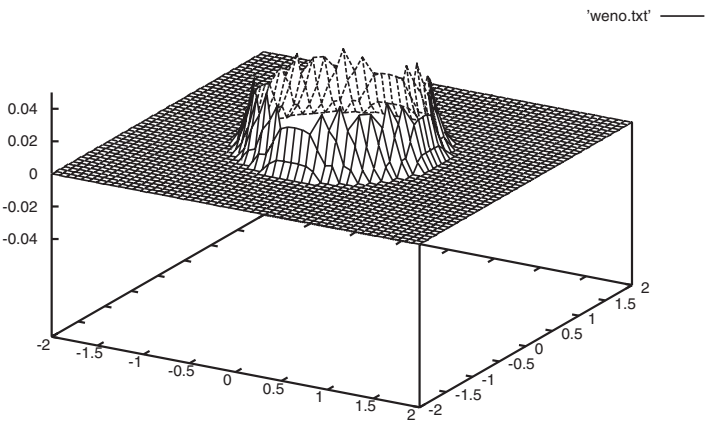
Comparison of CPU times for different schemes on test 2.

Scheme	CPU
P_1	34s
P_2	41s
cubic	52s
ENO 3	3m36s
WENO 2/3 S	1m43s
WENO 2/3 D2	1m55s
WENO 3/5 S	3m55s
WENO 3/5 D2	3m55s
WENO 3/5 D3	4m02s
WENO 3/5 D2+D3	4m05s



that the plain cubic reconstruction, as expected, introduces a zone of undershoot in the neighborhood of the circle $|x| = 1$, where a discontinuity in the second derivative appears. This artifact is avoided by nonoscillatory schemes, among which, however, the WENO scheme performs apparently better in terms of CPU time. Also, the behavior of the scheme is remarkably isotropic, as shown in the scatter plot of Figure 4,

(a)

(b)

(c)

FIG. 3. *Zoom of the approximate solutions for test* 2. (a) *Linear third order scheme.* (b) *Third order ENO scheme.* (c) *Third order WENO scheme.*

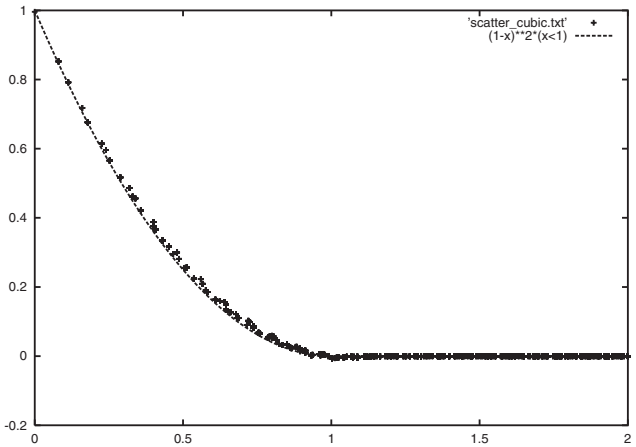


FIG. 4. *Scatter plot of the approximate solution for test* 2.

in which at any node the numerical solution is plotted as a function of $|x|$ for the cubic Lagrange reconstruction (ENO and WENO reconstructions give similar results).

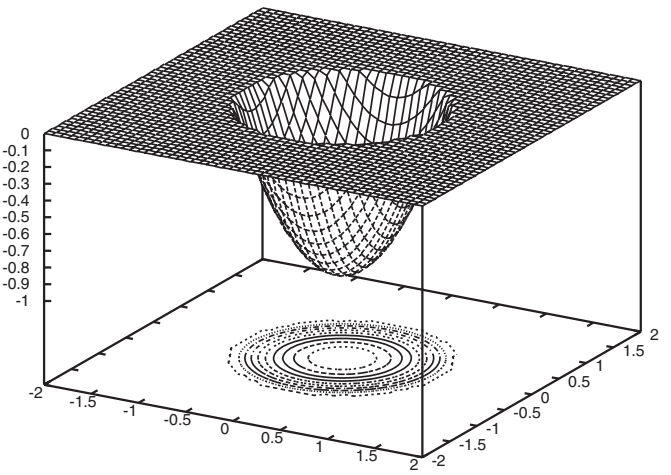
Test 3: Uniformly semiconcave solution. This test refers again to the HJ equation

$$\begin{cases} v_t(x,t) + \frac{1}{2}|\nabla v(x,t)|^2 = 0, \\ v(x,0) = v_0(x) = \min(0, |x|^2 - 1), \end{cases} \tag{6.6}$$

considered in $[-2,2]^2$, in which the initial condition v_0 has been changed to a semiconcave function.

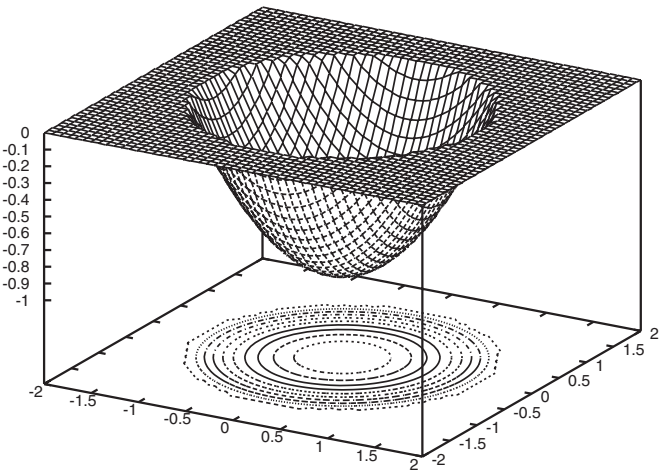
The exact solution of (6.6) is now uniformly semiconcave for any positive time; more precisely, it has the explicit form

$$v(t,x) = \begin{cases} \frac{|x|^2}{2t+1} - 1 & \text{if} |x| \le 2t+1, \\ 0 & \text{if} |x| \ge 2t+1. \end{cases}$$



The approximate solution is shown in Figure 5 at $t = 0$ and $t = 0.5$ with a 50×50 nodes computational grid. Table 7 reports a strong reduction of the error with respect to the previous test. This shows that in the case of semiconcave solutions, numerical schemes can take advantage of higher consistency rates, although the piecewise quadratic structure of the solution is too simple to be really discriminating in this respect. Among different smoothness indicators, the best accuracy is achieved by D2+D3 indicator, whereas other choices yield similar results.

Test 4: Two-dimensional periodic solution. This test (taken again from [6], [17], [20]) deals with the HJ equation



$$\begin{cases} v_t(x,t) + \frac{(v_{x_1}(x,t) + v_{x_2}(x,t)+1)^2}{2} = 0, \\ v(x,0) = v_0(x) = -\cos\frac{\pi(x_1+x_2)}{2}, \end{cases} \tag{6.7}$$

considered in $[-2,2]^2$, with doubly periodic boundary conditions.

In this situation, the structure of the solution is more complex, and we have tested the various schemes in terms of convergence rate using computational meshes

(a)

(b)

FIG. 5. *Approximate solutions for test* 3. (a) *Initial condition.* (b) *Solution at* $t = 0.5$.

of 25×25, 50×50, 100×100, and 200×200 nodes. The approximate solution has been computed before the singularity, at $T = 0.8/\pi^2$, with 4 time steps, and after the singularity, at $T = 1.5/\pi^2$, with 5 time steps. The Euler method has been used to approximate characteristics and reconstruction has been performed by the WENO Shu version. Relative errors are reported in Tables 5–6, whereas Figure 6 shows the approximate solution plotted at $t = 0$ and $t = T = 1.5/\pi^2$.

Error tables confirm the theoretical convergence rate of the schemes in the presence of a smooth solution, whereas, after the singularity, convergence rate of the WENO5 scheme is heavily underestimated by the theory (we suppose this might be due to particular circumstances of the test).

The comparison among the different schemes, in Table 7, shows (at fixed 50×50 grid and after the singularity) similar performances except for a loss in accuracy of the WENO3 D2 scheme. At this level the fifth order scheme has no better performance,

TABLE 5

WENO 3/5 D2+D3	6.17×10^{-5}	2.68×10^{-2}	8.73×10^{-5}	1.78×10^{-4}

although looking at Table 5 we see that it would have a great improvement passing from 50 to 100 nodes.

Conclusions. We have built a class of WENO large time-step schemes based on an SL formulation. Under suitable assumptions, convergence of the schemes can be proved up to the ninth order. Theoretical consistency analysis is generally confirmed by numerical experiments, even when singular solutions are taken into account. Among all the smoothness indicators considered, there has been now and then a considerably better or worse accuracy for some of them. The original Shu indicator, however, seems to be a robust and accurate choice in all the cases tested.

While this work has been focused on the special case of (1.1), this class of schemes can be immediately adapted (see the appendix in [4]) to treat dynamic programming equations of the Bellman type

$$v + \max_{a \in A} \{ -b(x,a) \cdot Dv - f(x,a) \} = 0 \tag{6.8}$$

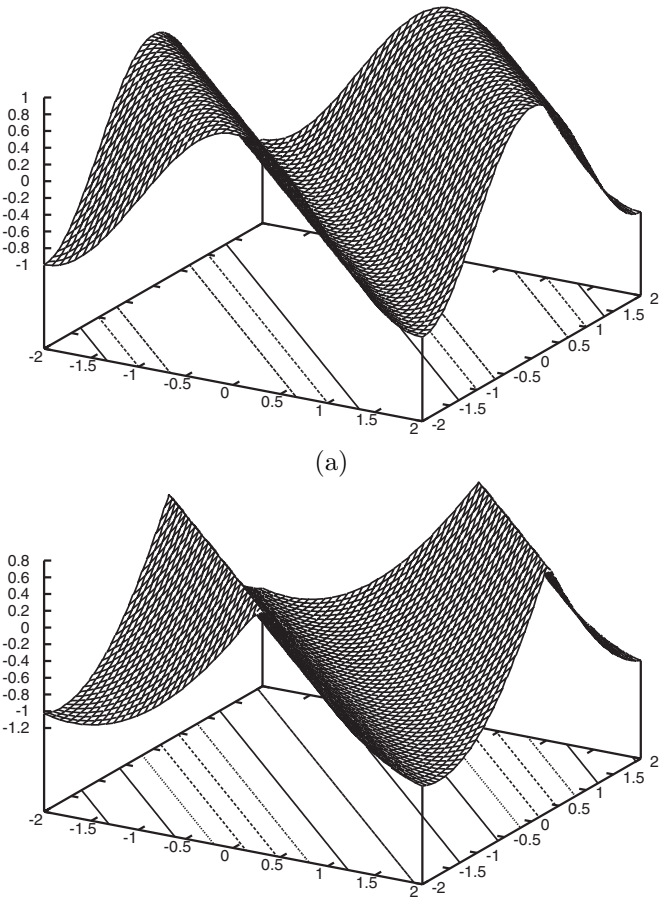

FIG. 6. *Approximate solutions for test* 4. (a) *Initial condition.* (b) *Solution at* $t = 1.5/\pi^2$.

(which leads to a convex Hamiltonian and includes (1.1) as a special case) or, in even greater generality, of the nonconvex Isaacs type

$$v + \min_{a_2 \in A_2} \max_{a_1 \in A_1} \{ -b(x, a_1, a_2) \cdot Dv - f(x, a_1, a_2) \} = 0, \tag{6.9}$$

although in such settings no complete theory exists on the high-order case.

The advantage of WENO over ENO reconstructions is apparent in terms of CPU time, while the accuracy in both cases seems to be comparable with the accuracy of linear Lagrange reconstructions. WENO techniques can be valuable, however, when special information associated to singularities (e.g., switching curves for dynamic programming equations) requires a nonoscillatory behavior of the approximation scheme.

COMPONENT-AVERAGED ROW PROJECTIONS: A ROBUST, BLOCK-PARALLEL SCHEME FOR SPARSE LINEAR SYSTEMS*

DAN GORDON† AND RACHEL GORDON‡

Abstract. A new method for the parallel solution of large sparse linear systems is introduced. It proceeds by dividing the equations into blocks and operating in block-parallel iterative mode; i.e., all the blocks are processed in parallel, and the partial results are "merged" to form the next iterate. The new scheme performs Kaczmarz row projections within the blocks and merges the results by certain *component-averaging* operations—hence it is called component-averaged row projections, or CARP. The system matrix can be general, nonsymmetric, and ill-conditioned, and the division into blocks is unrestricted. For partial differential equations (PDEs), if the blocks are domain-based, then only variables at the boundaries between domains are averaged, thereby minimizing data transfer between processors. CARP is very robust; its application to test cases of linear systems derived from PDEs shows that it converges in difficult cases where state-of-the-art methods fail. It is also very memory efficient and exhibits an almost linear speedup ratio, with efficiency greater than unity in some cases. A formal proof of convergence is presented: It is shown that the component-averaging operations are equivalent to row projections in a certain superspace, so the convergence properties of CARP are identical to those of Kaczmarz's algorithm in the superspace. CARP and its convergence proof also apply to the consistent convex feasibility problem.

1. Introduction.

Iterative methods for solving large sparse linear systems of equations are advantageous over the classical direct solvers, especially for huge systems. Methods of parallelizing iterative algorithms [20, 29] divide the equations into blocks and usually fall into one of two modes of operation. In the block-sequential (also called block-iterative) mode, the blocks are processed sequentially, but the computations on each block's equations are done in parallel. Examples of block-sequential methods are found in [1, 6, 10]. In the second mode of operation, sometimes referred to as block-parallel, the blocks are assigned to different processors to be processed in parallel, and the results from all the blocks are then combined in some manner to produce the next iterate. Typical examples of block-parallel schemes are parallel versions of Bi-CGSTAB [35], RGMRES [30], conjugate gradient (CG), and CG-squared (CGS) [31]; other examples include those in [2, 4, 9, 12, 13].

Kaczmarz's row projection method (KACZ) [23] was one of the first iterative methods used for large nonsymmetric systems. Its main advantages are robustness, guaranteed convergence on consistent systems, and cyclic convergence on inconsistent systems [8, 16, 32]. KACZ was also independently discovered in the context of image reconstruction from projections, where it is called ART (algebraic reconstruction technique) [21]. Kaczmarz's algorithm, by its nature and mathematical definition, is inherently sequential since, at each iterative step, the current iterate is projected

onto the hyperplane defined by the next equation. In the context of partial differential equations (PDEs), current approaches to parallelizing KACZ have taken the block-sequential approach by replacing row projections with block projections and processing the blocks sequentially; see [6, 7, 24].

In this paper we present a block-parallel method of parallelizing Kaczmarz's algorithm for PDEs without block projections. Our approach stems from domain-decomposition considerations: After partitioning the domain into subdomains and assigning subdomains to processors, each processor is assigned the block of equations whose central node lies in its subdomain(s). Starting from some initial estimate, each processor performs a sequence of row projections on the hyperplanes defined by its block's equations, as in KACZ, and the results from the various blocks are then "merged" together to form the next iterate. The merge operation takes variables, which belong to two or more blocks, and replaces their different values (in the different domains) by their average. Thus, only variables bordering subdomain boundaries are averaged, so communication between processors is limited. Domain boundaries can even overlap, which means that the blocks of equations need not be disjoint.

We call this algorithm [illegible], or CARP. The principle of component-averaging also appeared, in a different form, in the CAV and BICAV algorithms of Censor, Gordon, and Gordon in [11, 10]. The main idea there was to utilize the sparsity of the system matrix of image-reconstruction problems. Note that the "string-averaging" algorithm [9, 12] also performs block-parallel row projections, but the resulting vectors of the separate blocks are combined by taking their regular (weighted) average.

CARP is completely general and places no restriction on the system matrix or the selection of the blocks. A formal proof of convergence is presented. It relies on a novel result which shows that the averaging operations are equivalent to row projections in a certain superspace. From this, it follows that the convergence properties of CARP are identical to those of Kaczmarz's algorithm in the superspace, and that CARP can also be used for nonsquare systems. CARP and its convergence proof, which uses a result of Aharoni and Censor [1], are also valid for the consistent case of the convex feasibility problem.

CARP provides a very robust parallel iterative method for solving large sparse linear systems derived from PDEs. It converges in difficult cases where state-of-the-art parallel versions of RGMRES, CGS, and Bi-CGSTAB fail. Since CARP is a linear iterative method, its convergence rate is theoretically limited; see [20, sec. 3.2.5]. Hence, it is not as efficient as some of the nonlinear methods to which it is compared in this paper. However, some of the nonlinear methods fail to converge on several of the test cases. In terms of its parallel behavior, CARP exhibits an almost linear speedup ratio, as well as efficiency greater than unity on some of the test cases.

CARP is memory efficient, compared to block-based projection methods such as those in [2, 3, 6, 7] or Krylov-based methods, since each processor operates on its equations one at a time. The memory requirement for each processor is just the submatrix of its local equation coefficients and the local part of the iterated solution vector; there is no need to store any other data related to a domain's submatrices, as in other methods. Furthermore, for many problems, there is no need even to store the equation coefficients since they can be calculated "on the fly" as needed. Another advantage is that there is no need to preprocess the system matrix, so CARP is suitable for quasi-linearization methods for nonlinear problems, in which the system matrix is modified repeatedly.

The rest of the paper is organized as follows. Section 2 places our work in relation

to previous work. Section 3 presents the mathematical background, the formulation of CARP, the convergence proofs, and some extensions. Section 4 presents numerical results comparing the new approach with state-of-the-art parallel techniques, and section 5 concludes with a discussion and future research directions.

2. Relation to previous work. Block projection methods (see Elfving [17]) use block projections instead of the row projections of KACZ [23] or Cimmino's algorithm [14]. Hence, such methods require computation and storage of data related to the inverses of submatrices. This data consists of Cholesky factors of the normal equation matrices or the LU factors of the augmented system matrices. As mentioned, this gives CARP an advantage with regard to memory and applicability to nonlinear systems.

Bramley and Sameh [6], following Kamath and Sameh [24], parallelized block KACZ with CG-acceleration under five partitioning schemes on regular grids. The method was very robust, but there was no clear-cut "best" partitioning scheme: The RP9 scheme produced the fastest runtime results on most of the test problems, but it requires inverse submatrix data, and it is unsuitable for unstructured grids. The RP27 scheme does not need submatrix data, but it performed best on only one problem and it is suitable only for structured grids. The cube-4 scheme is adaptable to unstructured grids, but it also uses data related to submatrix inverses, and its runtime is the worst or second worst of the schemes tested.

In [7], the above approach was extended to include also CG-acceleration of block-Cimmino and a new projection method called V-RP. These methods, using the RP9 scheme from [6], were compared with RGMRES and CGNE, both with and without preconditioning. Arioli et al. [2] studied parallel CG-acceleration of block-Cimmino for different block partitionings. Their study was restricted to block-tridiagonal systems, though their technique may be applicable to other cases. This method also requires data related to submatrix inverses, with the above disadvantages. In [3], this research was extended to include block-Lanczos acceleration, which improved the runtime performance (over the CG-acceleration) for some ill-conditioned systems.

Three of the most successful and commonly used parallel techniques for large sparse nonsymmetric systems are RGMRES [29], CGS [31], and Bi-CGSTAB [35]. These methods, which can be used with or without preconditioners, often converge faster than the (linear) projection methods. However, they are not as robust as row projection methods and fail in some difficult cases.

As mentioned, the convergence proof of CARP relies on extending the Euclidean space into a certain superspace. Pierra [27, 28] introduced the concept of extending the Euclidean space into a product space, and this idea was used by Combettes [15] to prove the convergence of Cimmino's algorithm. In the product space extension, each coordinate is "extended" to a fixed number of coordinates in the superspace. Our technique of a superspace extension is a generalization of the product space concept, allowing extensions of only some of the coordinates, as well as different-sized extensions for different coordinates.

3. Mathematical development.

3.1. Background, motivation, and presentation of CARP. Consider the following system of m linear equations in n variables:

$$\sum_{j=1}^{n} x_j a_j^i \;=\; b_i \;\text{ for }\; 1 \le i \le m, \quad \text{or, in matrix form: } \; Ax \;=\; b. \tag{1}$$

In KACZ, each iterate is projected onto a hyperplane (defined by one of the equations) in a cyclic manner. KACZ has been studied very extensively, both theoretically and experimentally. Its convergence with relaxation parameters, for consistent systems, has been shown by Herman, Lent, and Lutz [22] and by Trummer [33]. Tanabe [32] proved that when the system is inconsistent, it converges [illegible]; i.e., for each hyperplane, the sequence of projections on that hyperplane converges to a limit. See also [8] for further results in that direction.

Throughout the rest of the paper we assume that every column of A is nonzero. Such a column, if it exists, can be removed as a preliminary step since it corresponds in effect to coefficients of a "fictitious" variable, i.e., one whose value can be arbitrary. For $1 \le i \le m$, we denote by a^i the ith row vector of the matrix A in (1) and by $\langle u, v \rangle$ the dot product of two vectors u, v. KACZ can be described as follows: Starting from an arbitrary point x^0 in the n-dimensional Euclidean space, the kth iterate x^k is projected toward the next hyperplane, and the hyperplanes are chosen in cyclic order. To simplify our notation, we denote by $i(k)$ the kth index taken cyclically from 1 to n, i.e., $i(k) = (k \bmod m) + 1$. The regular KACZ algorithm (with relaxation parameters) is the following.

ALGORITHM 1 (KACZ).

Initialization: $x^0 \in \mathbb{R}^n$ [illegible]

Iterative step: [illegible] x^k [illegible]

$$x^{k+1} = x^k + \lambda_k \frac{b_{i(k)} - \langle a^{i(k)}, x^k \rangle}{\|a^{i(k)}\|^2} a^{i(k)} . \tag{2}$$

If we assume that the equations are normalized, i.e., for $1 \le i \le n$, the ith equation is divided by $\|a^i\|$, then (2) can be replaced by

$$x^{k+1} = x^k + \lambda_k \left(b_{i(k)} - \langle a^{i(k)}, x^k \rangle \right) a^{i(k)} . \tag{3}$$

It is easy to see that the sequence of points produced by KACZ is identical to the one obtained by first normalizing the equations and replacing (2) by (3).

The motivation for CARP was to parallelize KACZ for PDEs using domain decomposition, but without using block projections with their inherent limitations. This led to a block-parallel method in which the domain is divided into subdomains (possibly overlapping), which can be assigned to different processors. Each processor is assigned the block of those equations whose central node lies in its subdomain(s). Starting from some initial estimate, the following two main steps are repeated until convergence: In the first step, consecutively executed row projections are performed in every block (as in KACZ) on all the equations of the block; in fact, more than one sweep can be carried out. In the second step, every variable shared by two or more blocks is replaced by the average of its values in the separate blocks. Thus, only variables bordering a neighboring domain are averaged. The above approach is formalized as follows.

The equations of the linear system (1) are divided into blocks, $B_1, \ldots, B_t$, which are not necessarily disjoint. For each $1 \le j \le n$, denote by I_j the index set of the blocks which contain an equation with a nonzero coefficient of x_j; i.e., $I_j = \{1 \le q \le t \mid x_j$ has a nonzero coefficient in some equation of $B_q\}$. Let $s_j = |I_j|$ (the size of I_j). The following definition explains and formalizes the merge operation of CARP.

DEFINITION 1. [illegible] $B = \{B_1, \ldots, B_t\}$ [illegible] B [illegible] $\mathrm{CA}_B : (\mathbb{R}^n)^t \to (\mathbb{R}^n)$ [illegible]

$x^1, \ldots, x^t \in \mathbb{R}^n$ ... $\mathrm{CA}_B(x^1, \ldots, x^t)$ ... $\mathbb{R}^n$ ... j ...

$$\mathrm{CA}_B(x^1, \ldots, x^t)_j \;=\; \frac{1}{s_j} \sum_{q \in I_j} x_j^q \;,$$

... x_j^q ... j ... x^q ... $1 \le q \le t$

We can now present the CARP algorithm. In the following, given a block of equations B_q and a point $x \in \mathbb{R}^n$, we use the term "KACZ sweep" to refer to the operation of successively projecting x onto the hyperplanes defined by the equations of B_q, as in KACZ (Algorithm 1); this is formalized as follows.

DEFINITION 2. ... B_q $1 \le q \le t$ ... (1)
... $\{i_1, \ldots, i_r\}$ ... B_q ... $x \in \mathbb{R}^n$ ...
... $\mathrm{KSWP}(B_q, x) : \mathbb{R}^n \to \mathbb{R}^n$ ... $x^0 = x$ ... $0 \le j < r$ ...

$$x^{j+1} \;=\; x^j \;+\; \lambda_j \frac{b_{i_j} - \langle a^{i_j}, x^j \rangle}{\|a^{i_j}\|^2} a^{i_j} \;,$$

... λ_j ... $\mathrm{KSWP}(B_q, x) = x^r$

ALGORITHM 2 (CARP).
Initialization: $x^0 = (x_1^0, \ldots, x_n^0) \in \mathbb{R}^n$ ...
Iterative step: ... x^k, ...
1. ... $1 \le q \le t$, ... B_q. ... $1 \le q \le t$, ... $\bar{x}^q$. ... $p_k \ge 1$, $\bar{x}^q = \mathrm{KSWP}^{p_k}(B_q, x^k)$.
2. $x^{k+1} = \mathrm{CA}_B(\bar{x}^1, \ldots, \bar{x}^t)$.

Appendix A provides a detailed implementation of CARP, allowing separate processors for the different blocks.

3.2. Convergence proofs. The proof of convergence of CARP proceeds along the following lines. We first transform the system (1) into a system of equations in some superspace $\mathbb{R}^s$of $\mathbb{R}^n$. In $\mathbb{R}^s$, the equations belonging to different blocks do not share any common variables, so the parallel processing of the separate blocks is equivalent to regular sweeps of KACZ in $\mathbb{R}^s$. We then prove a general ..., according to which, operations of component averaging are equivalent to certain row projections. From this it follows that CARP is just KACZ in $\mathbb{R}^s$.

Assume w.l.o.g. that for some $1 \le r \le n$ the variables $x_1, \ldots, x_r$ are exactly the ones shared by two or more blocks, i.e., $s_1, \ldots, s_r \ge 2$ and $s_{r+1} = \cdots = s_n = 1$. Denote $s = \sum_{j=1}^n s_j$, and consider the space $\mathbb{R}^s$. In order to simplify our notation, we will use y instead of x for vectors and components of $\mathbb{R}^s$, and index vectors of $\mathbb{R}^s$ as follows:

$$y \;=\; \Big(\underbrace{y_{1,1}, \ldots, y_{1,s_1}}_{s_1 \text{ elements}}, \;\cdots\;, \underbrace{y_{r,1}, \ldots, y_{r,s_r}}_{s_r \text{ elements}}, \; \underbrace{y_{r+1}, \ldots, y_n}_{n-r \text{ elements}} \Big) \,.$$

We now define the following ... $E : \mathbb{R}^n \to \mathbb{R}^s$:

$$E(x_1, \ldots, x_n) \;=\; (y_{1,1}, \ldots, y_{1,s_1}, \;\cdots\;, y_{r,1}, \ldots, y_{r,s_r}, \; y_{r+1}, \ldots, y_n) \,,$$

where $y_{j,1} = \cdots = y_{j,s_j} = x_j$ for $1 \le j \le r$ and $y_j = x_j$ for $r < j \le n$.

Each I_j (the index set of the blocks which contain a nonzero coefficient of x_j) has s_j elements, so it can be represented as $I_j = \{q_{j,1}, q_{j,2}, \ldots, q_{j,s_j}\}$. For every $1 \le j \le n$ and $1 \le \ell \le s_j$, variables of the form $y_{j,\ell}$ will be used to "represent" the "copy" of x_j in the block $B_{q_{j,\ell}}$, as follows: For $1 \le j \le r$ and $1 \le \ell \le s_j$, replace x_j by $y_{j,\ell}$ in block $B_{q_{j,\ell}}$. For $1 \le j \le r$, replace x_j by y_j in all the equations.

Let $B'_1, \ldots, B'_t$ denote the blocks of equations obtained from $B_1, \ldots, B_t$, respectively, by the above replacements. Clearly, in the new blocks, there are no variables belonging to two or more blocks, even if there were shared equations in the original blocks. Denote $B' = \bigcup_{q=1}^{t} B'_q$; this set of equations is defined in the space $\mathbb{R}^s$. We now present an alternative formulation of CARP in which the basic operations are performed in $\mathbb{R}^s$.

ALGORITHM 3 (alternate CARP).

Initialization:

1. $x^0 = (x_1^0, \ldots, x_n^0) \in \mathbb{R}^n$ [illegible]
2. $y^0 = E(x^0)$ [illegible] $\mathbb{R}^s$
3. [illegible] B'

Iterative step: [illegible] y^k

1. [illegible] $1 \le q \le t$ [illegible] B'_q [illegible] B'_q [illegible] $p_k \ge 1$ [illegible] $\bar{y}^q = \mathrm{KSWP}^{p_k}(B'_q, y^k)$
2. (a) [illegible] $1 \le j \le r$ [illegible]

$$y_{j,1}^{k+1} = \cdots = y_{j,s_j}^{k+1} = \frac{1}{s_j}\left(\sum_{\ell=1}^{s_j} \bar{y}_{j,\ell}^{\,q_{j,\ell}}\right).$$

(b) [illegible] $r < j \le n$ $I_j = \{q_{j,1}\}$ [illegible] $y_j^{k+1} = \bar{y}_j^{q_{j,1}}$

(c) [illegible] $y^{k+1} = \left(y_{1,1}^{k+1}, \ldots, y_{1,s_1}^{k+1}, \ldots, y_{r,1}^{k+1}, \ldots, y_{r,s_r}^{k+1}, y_{r+1}^{k+1}, \ldots, y_n^{k+1}\right)$

Final step [illegible] K [illegible] $x^* = (x_1^*, \ldots, x_n^*)$ [illegible]

$$x_j^* = \begin{cases} y_{j,1}^K & \text{[illegible] } 1 \le j \le r, \\ y_j^K & \text{[illegible] } r < j \le n. \end{cases}$$

We can see that other than the initial and final steps, the entire algorithm can be executed iteratively or in parallel in $\mathbb{R}^s$, since the blocks B'_q do not contain any common variables. It follows that iterative step 1 is one (or more) KACZ sweeps on the equations of B'. Furthermore, it is clear that the result (after some K iterative steps) of this alternative form of CARP is the same as that of the regular CARP, assuming that the same relaxation parameters and repetition factors (λ_k and p_k) are used.

The following lemma will be used to show that the averaging operations in iterative step 2 are row projections in $\mathbb{R}^s$.

LEMMA 1 (the averaging lemma). [illegible] $1 \le m \le n$ $y^0 = (y_1^0, \ldots, y_n^0) \in \mathbb{R}^n$ [illegible] $y^1 = (y_1^1, \ldots, y_n^1) \in \mathbb{R}^n$ [illegible] $y_i^1 = (y_1^0 + \cdots + y_m^0)/m$ [illegible] $1 \le i \le m$ [illegible] $y_i^1 = y_i^0$ [illegible] $m < i \le n$ [illegible] y^1 [illegible] y^0 [illegible] $m - 1$ [illegible] $\mathbb{R}^n$ [illegible] KACZ [illegible]. The proof proceeds by induction on m. For $m = 1$, there is nothing to prove. For $m = 2$, project y^0 onto the plane defined by the equation $-y_1 + y_2 = 0$. The vector of coefficients is $a = (-1, 1, 0, \ldots, 0)$, the square of its norm is $\|a\|^2 = 2$,

and the projection $y' = (y'_1, y'_2, \dots)$ is

$$\begin{aligned} y' &= y^0 \; - \; \frac{1}{2}\langle y^0, a\rangle a \\ &= (y^0_1, y^0_2, \dots) \; - \; \frac{1}{2}(-y^0_1 + y^0_2)(-1, 1, 0, \dots, 0) \\ &= \left(\frac{1}{2}(y^0_1 + y^0_2),\; \frac{1}{2}(y^0_1 + y^0_2),\; y^0_3,\; y^0_4, \dots\right). \end{aligned}$$

In other words, for $m = 2$, we obtained $y'_1 = y'_2 = (y^0_1 + y^0_2)/2$ (and left the other components unchanged) by performing one orthogonal projection on a suitable hyperplane.

We assume that the statement is true for m, and prove it for $m + 1$: Let $y^0 = (y^0_1, \dots, y^0_n)$. Project y^0 onto the hyperplane defined by the equation $-y_1 - y_2 - \cdots - y_m + my_{m+1} = 0$. The vector of coefficients is $a = (-1, \dots, -1, m, 0, \dots, 0)$ and the square of its norm is $\|a\|^2 = m + m^2 = m(m + 1)$. The projection is the point $y' = (y'_1, \dots, y'_n)$ defined by

$$\begin{aligned} y' &= y^0 \; - \; \frac{\langle y^0, a\rangle}{m(m+1)}\, a \\ &= (y^0_1, \dots, y^0_n) \; - \; \frac{-y^0_1 - \cdots - y^0_m + my^0_{m+1}}{m(m+1)}\; (-1, \dots, -1, m, 0, \dots, 0)\,. \end{aligned}$$

For each $1 \le i \le m$, we have

$$y'_i \;=\; y^0_i \;-\; \frac{1}{m(m+1)}\left(\sum_{j=1}^{m} y^0_j \;-\; my^0_{m+1}\right),$$

and the $(m + 1)$st coefficient is

$$\begin{aligned} y'_{m+1} &= y^0_{m+1} \;+\; \frac{y^0_1 + \cdots + y^0_m - my^0_{m+1}}{m(m+1)}\, m \\ &= \frac{1}{m+1}\left(y^0_1 + \cdots + y^0_m\right) \;+\; \left(1 - \frac{m}{m+1}\right) y^0_{m+1} \\ &= \frac{1}{m+1}\left(y^0_1 + \cdots + y^0_m\right) \;+\; \frac{m+1-m}{m+1}\, y^0_{m+1} \\ &= \frac{1}{m+1}\left(y^0_1 + \cdots + y^0_m + y^0_{m+1}\right). \end{aligned}$$

In other words, y'_{m+1} already has the required value. For $m + 1 < i \le n$, y^0_i is unchanged, i.e., $y'_i = y^0_i$. To set the other variables to the same value, we rely on the induction hypothesis, according to which we can set

$$y''_1 \;=\; \cdots \;=\; y''_m \;=\; \frac{1}{m}\left(y'_1 + \cdots + y'_m\right)$$

by using $m - 1$ orthogonal projections on hyperplanes of $\mathbb{R}^n$. Note also that by the induction hypothesis, all the other variables will remain unchanged, i.e., $y''_i = y'_i$ for $m + 1 \le i \le n$.

For each $1 \le k \le m$, we have

$$\begin{aligned}
y_k'' &= \frac{1}{m}\sum_{i=1}^{m} y_i' \\
&= \frac{1}{m}\sum_{i=1}^{m}\left[y_i^0 \;-\; \frac{1}{m(m+1)}\left(\sum_{j=1}^{m} y_j^0 \;-\; m y_{m+1}^0\right)\right] \\
&= \frac{1}{m}\sum_{i=1}^{m} y_i^0 \;-\; \frac{1}{m^2(m+1)}\sum_{i=1}^{m}\left[\sum_{j=1}^{m} y_j^0 \;-\; m y_{m+1}^0\right] \\
&= \frac{1}{m}\sum_{i=1}^{m} y_i^0 \;-\; \frac{m}{m^2(m+1)}\left(\sum_{j=1}^{m} y_j^0 \;-\; m y_{m+1}^0\right) \\
&= \frac{1}{m}\sum_{i=1}^{m} y_i^0 \;-\; \frac{1}{m(m+1)}\sum_{j=1}^{m} y_j^0 \;+\; \frac{1}{m+1}\, y_{m+1}^0 \\
&= \left(\frac{1}{m} - \frac{1}{m(m+1)}\right)\sum_{i=1}^{m} y_i^0 \;+\; \frac{1}{m+1}\, y_{m+1}^0 \\
&= \frac{1}{m+1}\sum_{i=1}^{m} y_i^0 \;+\; \frac{1}{m+1}\, y_{m+1}^0 \\
&= \frac{1}{m+1}\sum_{i=1}^{m+1} y_i^0 \,.
\end{aligned}$$

This proves the induction hypothesis and the lemma. □

We shall refer to the equations required by CARP for part 2 of its iterative step as the "averaging" equations. We also denote by B'' the system of equations consisting of B' together with all the averaging equations. As a consequence of the averaging lemma, we have the following.

THEOREM 1. [illegible] (1) [illegible] B'' [illegible] (1) [illegible] λ_k [illegible] $\epsilon < \lambda_k < 2-\epsilon$ [illegible] ϵ [illegible] p_k [illegible] (1) [illegible] 1. [illegible] 2. [illegible] B'' [illegible]. Assume that the system (1) is consistent. It follows immediately that the set of equations of B' is also consistent. In B', each of the original variables x_j belonging to two or more blocks is replaced by a set of variables of the form $y_{j,1}, \ldots, y_{j,s_j}$, so the equations of B', together with the set of equations $\{y_{j,1} = y_{j,2}, \ldots, y_{j,s_{j-1}} = y_{j,s_j} \mid 1 \le j \le r\}$, form a consistent set of equations. Note now that the averaging equations are mathematically equivalent to the above set of equations. Hence, the system B'' (consisting of B' together with the averaging equations) forms a consistent system of linear equations in $\mathbb{R}^s$.

Furthermore, note that the number of averaging equations is exactly equal to $s-n$, which is the number of additional coordinates we get in going from $\mathbb{R}^n$ to $\mathbb{R}^s$. This means that the number of additional equations (in going from B' to B'') is exactly equal to the number of additional variables. In particular, if the system matrix of (1) is square, then the system matrix of B'' is also square. We refer now to the results of Aharoni and Censor [1], according to which KACZ converges on a consistent system even if the projections are not performed cyclically; all that is required is that each equation should be used infinitely often. This allows us to perform, in iterative step 1 of CARP, any positive number of internal sweeps in each block. See subsection 3.4 for details of the results of [1].

Assume now that the system (1) is inconsistent. Tanabe [32] shows that KACZ converges cyclically when there are no relaxation parameters (i.e., $\lambda = 1$). The extension of this result to cyclic relaxation parameters follows from Eggermont, Herman, and Lent [16, Thm. 3.1], from which our result for inconsistent systems follows. ∎

Note that when the averaging operations are considered as row projections, they require a relaxation parameter $\lambda = 1$. Theorem 1 allows us to use $\lambda \neq 1$ for the other equations, in an inconsistent system, provided the projections follow a cyclic pattern and the relaxation parameter associated with every equation is fixed.

The generality of [1, Thm. 1], in the consistent case, allows us to modify the blocks, the number of inner iterations, and the relaxation parameters during the course of CARP, provided the conditions for [1, Thm. 1] are observed. This could be useful in a setting in which the number of processors can vary during the course of a computation.

3.3. CARP1: Blocks of one equation. A special case of CARP, which we call CARP1, occurs when every equation is taken as a separate block. In this case, s_j is simply the number of equations in which x_j has a nonzero coefficient, and the iterative step of CARP1 is given by the equation

$$x_j^{k+1} \;=\; x_j^k \;+\; \frac{\lambda_k}{s_j} \sum_{i=1}^{m} \frac{b_i - \langle a^i, x^k \rangle}{\|a^i\|_2^2} a_j^i \;. \tag{4}$$

CARP1 can be implemented on a multiprocessor system in block-parallel mode, though the implementation blocks are not necessarily single equations—they are simply (disjoint) blocks of equations assigned to different processors for the sake of runtime efficiency. Furthermore, the implementation blocks of CARP1 are not intrinsic to the algorithm as in the general CARP. This implementation is detailed in Appendix B.

Equation (4) is similar to the well-known Cimmino algorithm [14], whose iterative step is

$$x_j^{k+1} \;=\; x_j^k \;+\; \frac{\lambda_k}{m} \sum_{i=1}^{m} \frac{b_i - \langle a^i, x^k \rangle}{\|a^i\|_2^2} a_j^i \;. \tag{5}$$

Cimmino's algorithm was the initial motivational step leading to the CAV algorithm [11]: It was observed that when system (1) is sparse, then in the sum of (5) only a "small" number of elements are nonzero, but the sum is divided by the "large" m. This led to an attempt to replace m by s_j, resulting in the iterative step of [11, eq. 1.9], which is identical to (4). Note that even though CARP1 already appeared in [11] (without any specific name), no proof of convergence was given there; naturally,

the convergence properties of CARP1 follow from Theorem 1.[1]

In [11], CARP1 was examined on test cases of image reconstruction from projections. Its initial rate of convergence was identical to that of CAV, but the images obtained were somewhat inferior to those obtained with CAV. Similar comparative results were obtained in [10] with BICAV (a block-sequential version of CAV) and a block-sequential version of CARP1.

CAV made use of sparsity-oriented weights, but differently from CARP: With s_j defined as for CARP1, we define a [illegible] $w_i = 1/(\sum_{j=1}^{n} s_j (a_j^i)^2)$ for $1 \le i \le m$. The iterative step of CAV is given by

$$x^{k+1} = x^k + \lambda_k \sum_{i=1}^{m} w_i \left(b_i - \langle a^i, x^k \rangle\right) a^i \,. \tag{6}$$

Hence, the projections in CAV are orthogonal to the hyperplanes and weighted by w_i (in addition to λ_k). CAV and CARP1 are identical only when all the s_j's are equal.

Note that in CARP1, as given by (4), x^{k+1} can be viewed as the average of certain projections of x^k, but these projections are [illegible], in general, orthogonal to the hyperplanes: Assume for simplicity that the equations are normalized and that $\lambda_k = 1$; then from (4) we get

$$x_j^{k+1} = \frac{1}{m} \sum_{i=1}^{m} \left[x_j^k + \frac{m}{s_j} \left(b_i - \langle a^i, x^k \rangle\right) a_j^i \right] \,. \tag{7}$$

It follows that x^{k+1} is the average of a set of vectors p^i, $1 \le i \le m$, where the jth component of p^i is the summand of (7). If we consider p^i to be a projection of x^k in some direction "toward" the hyperplane defined by the ith equation, then the [illegible] of this projection is $p^i - x^k$. However, from (7), we see that the jth component of this direction vector is $m(bi - \langle a^i, x^k \rangle) a_j^i / s_j$, so the direction vector is not colinear with a^i (unless all the s_j's are equal). Hence, p^i is not, in general, an orthogonal projection of x^k in the direction of the ith hyperplane.

3.4. Applicability of CARP to the convex feasibility problem. Aharoni and Censor [1] proved a general theorem regarding orthogonal projections onto convex sets. This result, together with the averaging lemma, led to the proof of Theorem 1. We shall show that Theorem 1 also applies to the consistent case of the convex feasibility problem (CFP), from which it follows that CARP is also applicable to the CFP.

Some preliminary definitions are needed: Let $I = \{1, 2, \ldots, m\}$ be a set of integers. A function $w : I \to \mathbb{R}$ is called a [illegible] if $w(i) \ge 0$ for all $i \in I$ and $\sum_{i \in I} w(i) = 1$. An infinite sequence of weight functions $\{w_k\}_{k \ge 0}$ is called [illegible] if for every $i \in I$, $w_k(i) > 0$ infinitely often; i.e., the inequality holds for infinitely many values of k.

Let $\{Q_i \mid i \in I\}$ be a finite family of closed convex sets in $\mathbb{R}^n$ such that $Q = \bigcap_{i \in I} Q_i \ne \emptyset$, and let $P_i : \mathbb{R}^n \to Q_i$ be defined as the [illegible] onto Q_i; i.e., for $x \in \mathbb{R}^n$, $P_i(x) = \arg\min\{\|x - y\| \mid y \in Q_i\}$. Now, given a weight function w, we define $P_w : \mathbb{R}^n \to \mathbb{R}^n$ by $P_w(x) = \sum_{i \in I} w(i) P_i(x)$.

[1] While revising this paper, the authors learned that Censor, Elfving, and Herman independently proved that CARP1, with weights, converges for both consistent and inconsistent systems.

Consider now the [illegible] (BIP) algorithm [1, Alg. 1], which starts from an arbitrary point $x^0 \in \mathbb{R}^n$ and whose iterative step is given by

$$x^{k+1} \;=\; x^k \;+\; \lambda_k \left(P_{w_k}(x^k) - x^k \right), \tag{8}$$

where $\{w_k\}_{k\geq 0}$ is a fair sequence of weight functions and $\{\lambda_k\}_{k\geq 0}$ is a sequence of user-determined relaxation parameters. We can see from (6) and (8) that when the convex sets Q_i are hyperplanes, then CAV and BIP have the same form, though the sparsity weights of CAV do not necessarily satisfy the conditions for the weights of BIP.

In [1, Thm. 1], it is shown that if for some $\epsilon > 0$, $\epsilon < \lambda_k < 2 - \epsilon$ for all k, then the sequence of points $\{x^k\}_{k\geq 0}$ generated by the BIP algorithm converges to a point $x^* \in \widehat{Q}$, where $\widehat{Q} = \bigcap_{i\in \widehat{I}} Q_i$ and $\widehat{I} = \{i \in I \mid \sum_{k=0}^{\ell} w_k(i) \;\underset{\ell\to\infty}{\Longrightarrow}\; \infty\}$. (If $\widehat{I} = \emptyset$, then $\widehat{Q}$ is defined as $\mathbb{R}^n$.) The choices of blocks and weight functions determine the behavior of BIP—from sequential to block-sequential and to simultaneous; see [1] for details.

To apply CARP to the CFP, we divide the set of projections (onto the convex sets) into blocks, which need not be disjoint. Starting from an arbitrary initial point, we perform, for each block of projections, a sequence of orthogonal projections onto the convex sets of the block. This is done in parallel on all the blocks. The results from the separate blocks are then merged by component-averaging, as in the CARP algorithm for linear equations, to form the next iterate. The variables that are averaged are only those which are affected by projections belonging to two or more blocks.

The convergence proof for the consistent case is the same as in Theorem 1. This follows from the simple observation that, in the superspace, the hyperplanes defined by the averaging equations are also convex sets. It is easily seen that if the original convex sets have a nonempty intersection, then in the superspace, the convex sets and the hyperplanes defined by the averaging equations also have a nonempty intersection.

4. Numerical results and discussion. Tests were run on two different types of parallel machines: A shared memory SGI origin 2000, and a distributed machine—a PC cluster running under Linux. The PC cluster consists of 16 single Pentium IV, 2.8GHz processors with 1GB memory each, connected with a dedicated 1Gb/sec. ethernet switch. Results were obtained on both machines on six test problems from the literature. The problems were run on the SGI and the PC cluster with 1, 2, 4, 8, and 16 processors, and also with 32 and 64 processors on the SGI machine. This section describes the test problems, the nonsymmetric solvers to which CARP was compared, numerical considerations and implementation, the stopping tests, and the numerical results and discussion.

4.1. The test problems. We examined six PDE problems proposed by Bramley and Sameh [7]. These problems were collected from a variety of sources [18, 24, 25, 26] and were later used as test problems in several other works [2, 3]. The problems are typical of many fields, such as computational fluid dynamics (CFD), heat transfer, and structural mechanics, and are commonly used in a wide variety of industrial and engineering applications.

Each problem has an assigned analytic solution which is used to determine the boundary conditions. Furthermore, the analytic solution enables the calculation of the norm of the error. In the following, we use the common notation $\Delta u = u_{xx}+u_{yy}+u_{zz}$. Our test problems and their predetermined solutions are the following.

1. $\Delta u + 1000 u_x = F$.
2. $\Delta u + 1000 \exp(xyz)(u_x + u_y - u_z) = F$.

3. $\Delta u + 100xu_x - yu_y + zu_z + 100(x+y+z)u/xyz = F$.
4. $\Delta u - 10^5 x^2(u_x + u_y + u_z) = F$.
5. $\Delta u - 1000(1+x^2)u_x + 100(u_y + u_z) = F$.
6. $\Delta u - 1000\,[(1-2x)u_x + (1-2y)u_y + (1-2z)u_z] = F$.

The analytical (preassigned) solutions for the above problems are the following:
Problem 1: $u(x,y,z) = xyz(1-x)(1-y)(1-z)$.
Problem 2: $u(x,y,z) = x+y+z$.
Problems 3–6: $u(x,y,z) = \exp(xyz)\sin(\pi x)\sin(\pi y)\sin(\pi z)$.
The expression for the right-hand-side function F in all six problems is computed analytically for each case, using the preassigned solution.

The test problems were solved on the unit cube domain ($[0,1]\times[0,1]\times[0,1]$) using a seven-point centered difference scheme. The equations were discretized using the same number of grid points in each direction. Results are shown for problems of size $40\times40\times40 = 64{,}000$ equations and of size $80\times80\times80 = 512{,}000$ equations.

4.2. Parallel methods used for comparison. The common wisdom today is that there is no "best" solver for ,, problems. Each class or type of problem has its own most effective solver. Since we propose CARP as a general-purpose solver, we chose to compare it with other general-purpose, state-of-the-art methods, even though better solvers exist for each particular problem. Our methods of choice were three parallel Krylov-based iterative nonsymmetric solvers: RGMRES [30], CGS [31], and Bi-CGSTAB [35]. Each of these methods was used by itself and with the following preconditioners: ILUT, Jacobi, Neumann, and least-squares. We also tried the symmetric Gauss–Seidel preconditioner, but it failed completely in all cases. The comparisons used the AZTEC software library [34], which is designed for the parallel solution of large sparse linear systems of equations.

RGMRES(k) was run with Krylov subspace size $k = 10$; larger values of k do not improve the robustness of RGMRES(k) until k becomes a significant fraction of the problem size (with a large increase of the required storage). The Jacobi, Neumann, and least-squares polynomial preconditioners were run with AZTEC's default polynomial order parameter of 3.

The ILUT preconditioner [29] depends on two parameters which strongly affect its behavior: the ,, , (the value below which elements are taken as zero), and the ,, , which controls the maximum number of nonzeros allowed in each column/row of the incomplete LU factors. Similarly to the other preconditioners, we used the default AZTEC values for ILUT's parameters: drop tolerance = 0 and fill-in = 1.0 (i.e., no additional elements). These default values produced excellent results, so we found no need to experiment with them. Moreover, a thorough study of ILUT should also consider recent improvements, such as reorderings, scalings, and multilevel extensions, all of which go beyond the scope of the present study. Note that ILUT is essentially sequential, and its parallel implementation in AZTEC is based on using it separately on the submatrices of the subdomains.

4.3. Implementation details. In order to implement CARP efficiently on the given problems, we used the domain-decomposition approach and mapped different domains to different processors. Although other approaches are feasible in theory, this approach limits interprocessor communications because only variables bordering a neighboring domain need to be averaged (and hence exchanged between processors).

Both AZTEC and our implementation of CARP used the message passing interface (MPI) library for exchanging messages between the processors. We used SGI's proprietary implementation of MPI on the SGI machine and the public domain

MPICH routines on the PC cluster. CARP was implemented with the MPI Cartesian topology routines for interprocessor communications; these routines are designed for six-way nearest neighbor communications for domain-based data.

Numerical PDE approximations on three-dimensional grids (structured and unstructured) exhibit spatial locality, since each equation centered about a grid point involves only its neighboring grid points. This feature enables domain-decomposition approaches to parallel solvers, in which the coefficient matrix is distributed among the processors with local indexing of submatrices. Besides the memory savings, this allows efficient basic matrix-vector operations. For structured three-dimensional grids, the resulting coefficient matrix is a seven-point stencil matrix.

Our implementation of the data structures used by CARP is similar to that of AZTEC. It is aimed at facilitating the implementation of the communication tasks and gaining efficiency during the iterative procedure. In a preprocessing stage, the following information is saved in each processor:

1. a list of neighboring processors with which it communicates,
2. a list of local nodes that are coupled with external nodes,
3. local representation of the submatrix used by each processor.

The local submatrix in each processor was stored in the sparse matrix format called the "distributed modified sparse row" (DMSR) format; see [34]. This format, which is a generalization of the MSR format [29], stores only the nonzero elements of the coefficient matrix.

In CARP, one can perform any finite number of inner KACZ iterations inside a block before averaging the boundary values that are common to neighboring blocks. Such inner iterations are fast relative to the outer iterations since they do not use interprocessor communications. This allows us to choose the number of inner iterations so as to minimize the overall computation time. Naturally, this choice depends on the specific problem and the machine architecture. Note that when implementing CARP, the residual can be computed efficiently as part of the iterative procedure; see (3).

4.4. Stopping tests. There are several stopping criteria which one may apply to iterative systems. Our stopping criterion was to use the L_2 norm of the residual: $||b - Ax||_2 < \tau$, where τ is a preassigned tolerance. Since this stopping criterion depends on the scaling of the equations, we first normalized the equations by dividing each equation by the norm of its coefficient vector. For problems 1, 2, 4, 5, and 6, τ was defined by setting $\tau^2 = 10^{-11}$ ($\tau \approx 3.16 \times 10^{-5}$). For problem 3, τ was taken as $\tau = 2.3 \times 10^{-3}$. The reason for this difference is that in problem 3, CARP converged well until this residual value was reached, and then continued to converge too slowly to be practically significant. All the other methods failed to converge on problem 3.

In order to limit the time taken by the methods implemented in AZTEC, the maximum number of iterations was set to 5000. The AZTEC library has several other built-in stopping criteria: numerical breakdown, numerical loss of precision, and numerical ill-conditioning.

4.5. Results and discussion.

4.5.1. Main results. In all our runs the initial estimate x^0 was taken as the zero vector. Table 1 presents a summary of the convergence status of all the methods and preconditioners that were examined, for the six test problems, for 512,000 equations on 16 processors. In the case of convergence failure, it also indicates the reason for the failure. The results shown in the table are also valid for four processors with 64,000 and 512,000 equations, unless noted otherwise.

TABLE 1
Convergence status of the six problems on 16 *processors with* 512,000 *equations.*

Method	Problem number					
	1	2	3	4	5	6
CARP	**conv**	**conv**	**conv**	**conv**	**conv**	**conv**
RGMRES	**conv**	**conv**	stgn	**conv**	**conv**	**conv**

Bi-CGSTAB + Neum.	**conv**[3]	nbdn	nbdn	nbdn	nbdn	nbdn
Bi-CGSTAB + LSQ	nbdn	nbdn	nbdn	nbdn	nbdn	nbdn

Notation: **conv** – convergence, divg – divergence, mxit – max. iter. reached, nbdn – num. breakdown, stgn – stagnation.

Notes: Status also valid for 4 proc. with 64,000 and 512,000 eqns., unless noted: [1] **conv** with 64,000 eqns. [2] divg with 64,000 eqns. [3] nbdn with 64,000 eqns. [4] nbdn with 512,000 eqns. [5] stgn with 64,000 eqns. [6] stgn with 512,000 eqns.

Table 1 demonstrates the robustness of CARP—it converged in all cases, including problem 3, in which all the other methods failed. However, it should be noted that in problem 3, the residual decreased very slowly after it was reduced to 3×10^{-3}. Of the other methods tested, RGMRES is generally the most successful; it converged by itself (and with some of the preconditioners) in all the problems except problem 3.

Figures 1–6 present a comparison of the (L_2 norm of the) residual versus the execution time for the six test problems, for 64,000 equations, as obtained on the SGI machine with four processors. For each problem, results are presented for all the methods that converged (except for problems 1 and 2 with CGS and CGS+LSQ, which converged extremely slowly). The CARP results are for the optimal relaxation parameters. These figures indicate that there is no "best" solver for all cases; however, RGMRES, either by itself or with ILUT, is among the fastest methods, while ILUT is the most successful preconditioner.

We also tried out the following parallel methods:

- CARP1 performed poorly in all cases except number 3.
- CAV [11], although successful in problems of image reconstruction from projections, performed poorly in all cases except number 3, where it was identical to CARP1.
- String averaging [9, 12] also performs block-parallel row projections, but, as mentioned in the introduction, the results are merged by taking the weighted average of the separate results. This method performed poorly in all six problems, indicating the effectiveness of componentwise averaging in CARP.

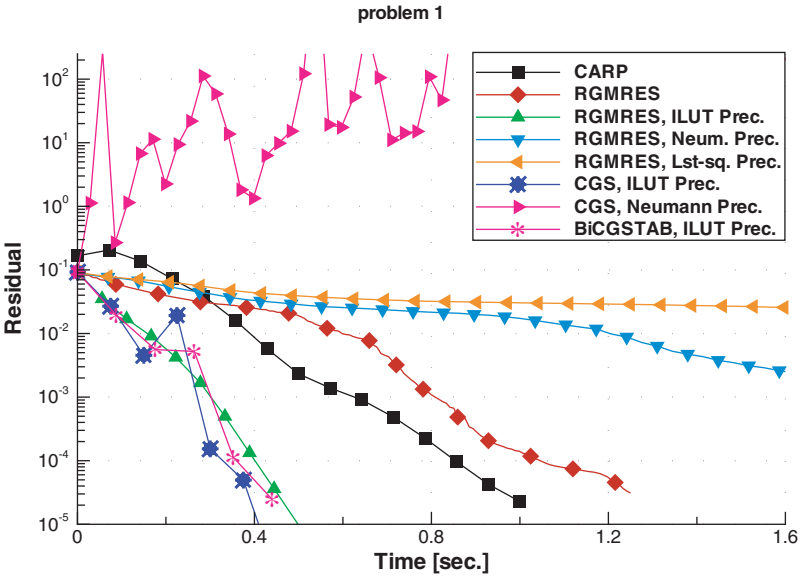

FIG. 1. *Execution times for problem* 1.

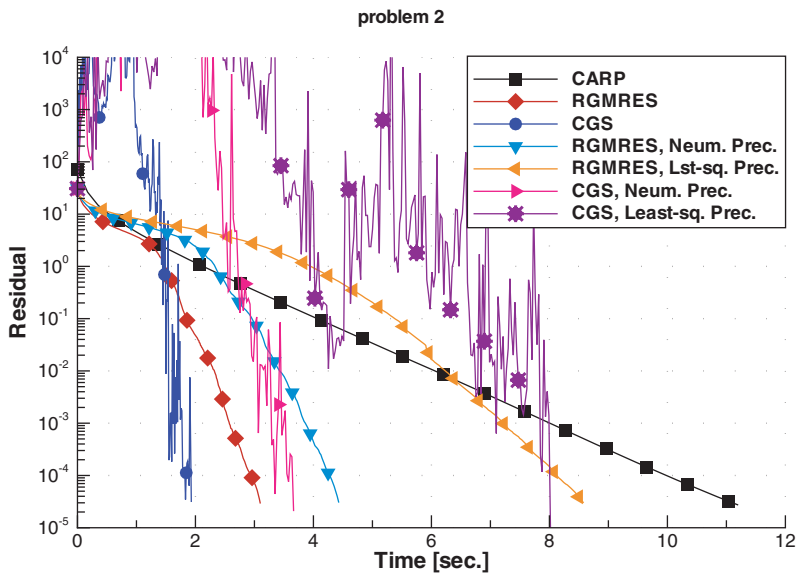

FIG. 2. *Execution times for problem* 2.

The convergence graphs for problem 3 compare CARP, CARP1, KACZ, and CAV. It can be seen that CARP's initial rate of convergence is very fast compared to the others, until a residual of approximately 10^{-2} is reached. From then on, CARP1, KACZ, and CAV exhibit a better rate of convergence. From this we can surmise that a hybrid algorithm, consisting initially of CARP and then CARP1 or KACZ or CAV, will function in this problem better than any single method. Problem 3 is hard

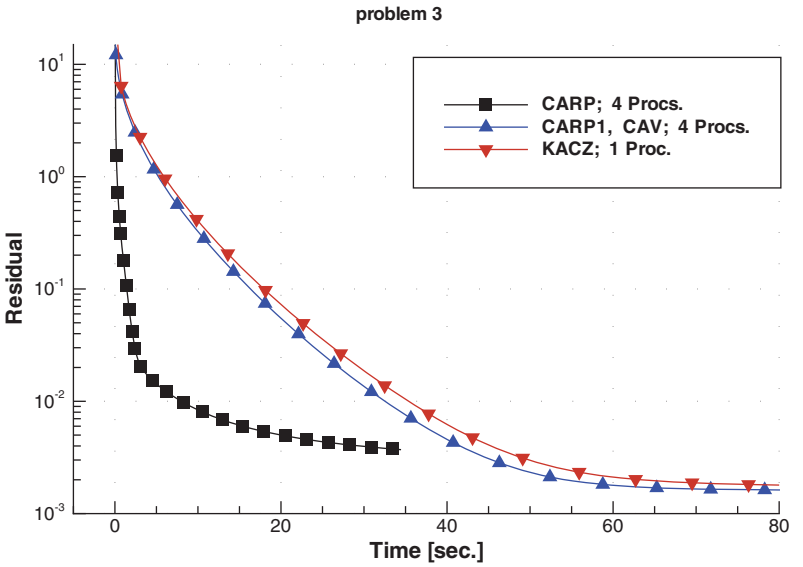

FIG. 3. *Execution times for problem* 3.

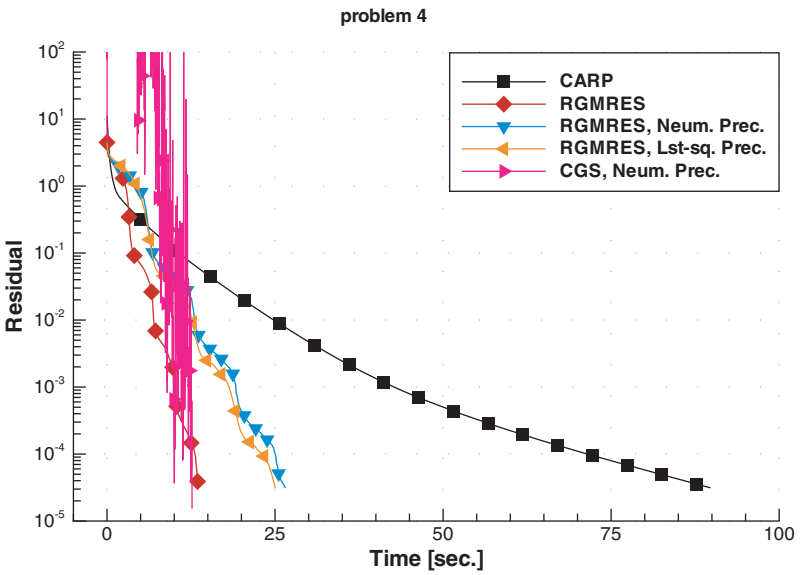

FIG. 4. *Execution times for problem* 4.

for solvers such as GMRES because it is indefinite, with eigenvalues surrounding the origin. It is well known that the eigenvalue distribution and the conditioning of the matrix of eigenvectors are more important for the convergence of GMRES than the conditioning of the system matrix. See also [2, 6, 7].

Tables 2 and 3 present various convergence measures obtained with CARP for 64,000 and 512,000 equations. Denoting by u and x the true solution and current

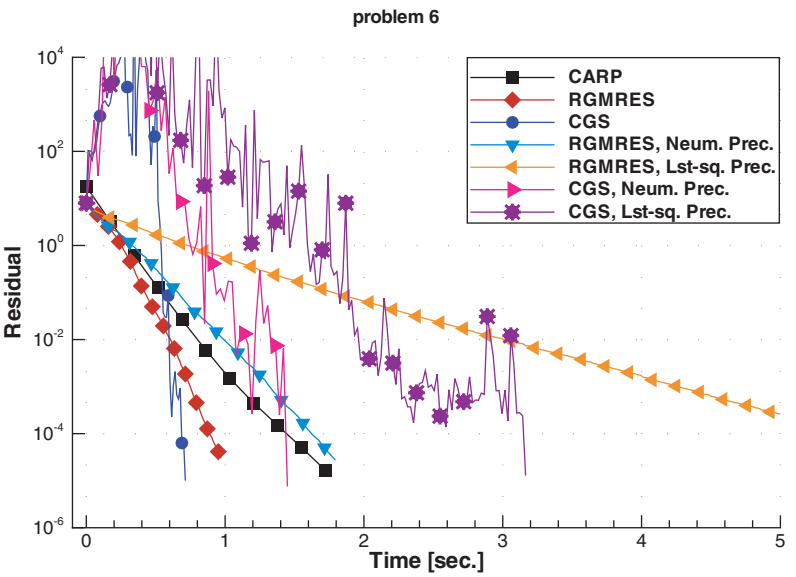

FIG. 6. *Execution times for problem* 6.

estimate, respectively, we computed the following convergence measures:

- The L_2 norm of the residual: $\text{RES}_2 = \|b - Ax\|_2$.
- The relative (or scaled) L_2 norm of the residual: $\text{REL-RES}_2 = \|b - Ax\|_2 / \|b\|_2$ (the initial estimate is taken as zero).
- The L_∞ norm of the residual: $\text{RES}_\infty = \|b - Ax\|_\infty$.
- The relative L_2 norm of the error: $\text{REL-ERR}_2 = \|u - x\|_2 / \|u\|_2$.
- The L_∞ norm of the error: $\text{ERR}_\infty = \|u - x\|_\infty$.

TABLE 2
Various convergence measures for four processors with 64,000 *equations.*

Problem:	1	2	3	4	5	6
RES_2	2.28E-5	2.72E-5	2.70E-3	3.13E-5	1.85E-5	1.66E-5
REL-RES_2	1.37E-4	3.78E-7	8.71E-5	2.87E-6	1.63E-6	9.29E-7
RES_∞	2.28E-6	1.81E-6	1.68E-4	1.21E-6	1.96E-6	1.98E-6
REL-ERR_2	8.19E-5	7.82E-7	8.30E-3	1.72E-3	1.16E-3	9.39E-4
ERR_∞	9.60E-6	2.24E-5	5.60E-2	7.80E-3	1.38E-3	2.19E-3

TABLE 3
Various convergence measures for four processors with 512,000 *equations.*

Problem:	1	2	3	4	5	6
RES_2	2.64E-5	2.93E-5	2.70E-3	3.16E-5	3.08E-5	2.80E-5
REL-RES_2	1.34E-4	2.10E-7	1.47E-4	2.06E-6	2.16E-6	1.37E-6
RES_∞	1.23E-6	1.98E-6	6.51E-5	1.09E-6	1.15E-6	1.36E-6
REL-ERR_2	9.56E-5	6.83E-7	8.93E-3	3.96E-4	2.96E-4	2.40E-4
ERR_∞	9.93E-6	2.74E-5	6.98E-2	2.05E-3	3.33E-4	3.05E-4

As can be seen from these tables, there is a wide variance between the measures achieved for the different problems, even though the convergence criterion for all of them (except problem 3) was taken as a fixed value for RES_2. For example, the achieved values of REL-RES_2 and REL-ERR_2 for problem 2 are much better than for the other problems. Also, REL-RES_2 for problem 3 is similar to that of problem 1, even though they differ greatly in RES_2. The consequence of the above is that there can be no absolute convergence criterion suitable for all cases.

Figures 7 and 8 present the speedup graphs of CARP for problems 1–6 with 512,000 equations, on the PC cluster and the SGI machine, respectively. The figures also include the plot corresponding to an efficiency of 1. It can be seen that all plots exhibit an almost linear behavior, and in some cases, the efficiency is greater than 1. This "super speedup" phenomenon is well known; it is due to the fact that in some cases, the total number of iterations required by CARP decreases as the number of blocks increases. A secondary contributing factor could be due to better utilization of memory cache when a problem of a certain size is divided among more processors.

4.5.2. Parametric studies.

Relaxation parameter $\boldsymbol{\lambda}$. Although the general theory allows us to vary λ during the iterative process, we chose a fixed value in our tests. Varying the value of λ during the iterations is a topic for further study. CARP's rate of convergence depends strongly on the choice of λ, and there is an optimal value for λ for each case, which we determined by numerical experimentation. This optimal value depends mainly on the problem being solved, and to a small extent, on the number of equations and the number of processors. Table 4 presents the optimal (fixed) relaxation parameters used for CARP, for the six test problems, with four processors.

Partitioning scheme. The initial strategy for choosing the partitioning scheme is to minimize the number of shared variables, but depending on the problem at hand, other partitioning schemes may yield better runtime results. The runtime and number of iterations required for convergence of CARP depend, for some problems, on the domain decomposition. Problems 1 and 5 are symmetric with respect to y and z but asymmetric with respect to x. Thus, a decomposition of the computational domain

TABLE 4
Optimal relaxation parameter λ for CARP, for problems 1–6, with four processors.

Problem:	1	2	3	4	5	6
64,000 eqs.	1.90	1.90	1.60	1.50	1.85	1.35
512,000 eqs.	1.94	1.75	1.60	1.40	1.90	1.50

into four subdomains using a $4\times1\times1$ division in the x, y, z directions, respectively, requires considerably more iterations than a decomposition into $1\times4\times1$ or $1\times1\times4$ subdomains.

Inner iterations. Table 5 shows comparisons of the time and number of iterations required for convergence with one and four inner iterations, with different subdivisions, for problems 1 and 5 with 64,000 equations. In Tables 5 and 6, the number of iterations is the number of outer iterations, i.e., not counting the inner ones. The advantage of the $1\times4\times1$ and $1\times1\times4$ schemes over the $4\times1\times1$ scheme can be attributed to the fact that in the first two schemes, a relatively large number of "almost" parallel row vectors are placed in the same subdomain. Table 5 also shows that in some cases, one inner iteration is better than four, and in other cases, the opposite is true. For symmetric problems, there is no direction preference. The domain should be divided into (approximately) the same number of subdivisions in all directions to minimize the number of boundary nodes and reduce the communication time.

TABLE 5
Time and number of iterations required for different subdivision schemes for problems 1 *and* 5 *with* 64,000 *equations.*

Subdivision scheme	Problem 1				Problem 5			
	1 inner it.		4 inner it.		1 inner it.		4 inner it.	
	time	# it.	time	# it.	time	# it.	time	# it.
$4\times1\times1$	3.26	400	12.35	640	8.95	1050	17.11	880
$1\times4\times1$	**0.99**	**140**	1.28	70	3.42	480	**1.96**	**110**
$1\times1\times4$	**0.99**	**140**	1.28	70	3.56	500	2.07	110

Figures 9 and 10 present a more detailed view of the dependence of the number of iterations (required for convergence) on the relaxation parameter λ and the partitioning scheme for problems 1 and 6, respectively, for 512,000 equations. In both figures, the number of inner iterations was one, unless noted otherwise. Note in particular the shape of the graph for problem 1: It decreases linearly until the minimum and then "shoots" upward superlinearly. Figure 10 is typical for problems 2–6.

Table 6 summarizes the optimal values of the following parameters for the six problems, with 512,000 equations: the number of (outer) iterations, the relaxation parameter λ, the number of inner iterations, and the partitioning scheme.

Communication time. Table 7 provides the communication time required by CARP on problem 1 with 512,000 equations for the SGI machine and Linux cluster. This table emphasizes how the partitioning scheme affects the time required for communications: The $1\times1\times16$ scheme requires some 96,000 transfer edges (between adjacent grid points divided by a boundary), while the $1\times4\times4$ scheme requires only about 38,000 transfer edges. Also, the net computation time (total time minus communication time) for each machine is almost independent of the partitioning scheme. It follows that most of the time difference for this case is due to the communications overhead.

5. Conclusions and further research. CARP is a new block-parallel method for solving large sparse nonsymmetric, general linear systems of equations on parallel machines. It uses single-row projections within each block, as in Kaczmarz's algorithm [23], followed by merging of the block results using certain component-averaging operations. CARP is also applicable in principle to nonsquare systems,

converges cyclically on inconsistent systems, and is applicable to the consistent case of the convex feasibility problem. A formal proof of convergence shows that CARP is equivalent to Kaczmarz's algorithm in a certain superspace. The new method is robust, memory efficient, and simple to program. It is also suitable for quasi-linearization approaches for nonlinear systems since there is no need to compute and store data related to submatrix inverses after every update of the system matrix.

CARP was compared with other state-of-the-art nonsymmetric solvers, with and without preconditioners, on six well-known test problems and on two different types of parallel machines. Test runs indicate that it is extremely robust compared to these methods, but since CARP is a linear method, its runtime, compared to nonlinear methods, is somewhat limited on some of the problems. On the other hand, CARP exhibits a linear speedup ratio, with efficiency sometimes greater than unity. These results indicate that CARP deserves a place in any robust iterative solution package for parallel machines.

One should note that the optimal performance of CARP depends on the choice of the relaxation parameter and the number of inner iterations in each block, and these are not known a priori. However, the rate of convergence behaves as a simple function of the relaxation parameters (just one local extremum). Hence, an adaptive search scheme can handle this problem: The processors are set to work for a small number of iterations on different values of these parameters, and the initial rates of convergence are compared; the search space is then narrowed by using the most promising parameter values.

Currently, work is in progress to speed up CARP's runtime efficiency by incorporating CG acceleration schemes, with very good results [19]. This is done by applying the techniques of [5] to the Kaczmarz scheme in the superspace. Another potential avenue of research would be to replace Kaczmarz in each block by other solution methods, such as CGNR or CGNE, on the block's submatrix. The solutions from the blocks can then be merged as in CARP. Such a scheme would require a different convergence proof. Another potential for speedup could be the implementation of communication hiding, i.e., information transmission between processors done in parallel with computations. Future research on CARP will also study its applicability to other areas of scientific computing.

Appendix A. Implementation details for CARP.

1. The equations of (1) are divided into blocks $B_1, \ldots, B_t$, which are not necessarily disjoint. A processor P_q is assigned to B_q for $1 \le q \le t$.
2. The (normalized) system (1) and the s_j's are sent to the processors, but each processor retains only the equations belonging to its block. For $1 \le q \le t$, denote $J_q = \{j \mid \text{in some equation of } B_q, \text{ the coefficient of } x_j \neq 0\}$. Processor P_q retains only those s_j's for which $j \in J_q$.
3. Every processor P_q, for every $j \in J_q$, determines if it is the "main owner" of x_j. For every j, there should be exactly one main owner of x_j, even if x_j has nonzero coefficients in several blocks. The main owner of x_j will need access to and from any other processor P_r for which $j \in J_r$.
4. The initial estimate $x^0 = (x_1^0, \ldots, x_n^0)$ is sent to the processors, but each processor P_q holds only the variables x_j^0 for $j \in J_q$.
5. Every processor P_q, for $1 \le q \le t$, sets the iteration index $k = 1$ and repeats the following steps until convergence:
   (a) Perform some finite number of KACZ sweeps on the equations of B_q and denote the result by $\bar{x}^q$; i.e., for some $p_k \ge 1$, $\bar{x}^q = \mathrm{KSWP}^{p_k}(B_q, x^k)$.
   (b) For every $j \in J_q$: If P_q is not the main owner of x_j, send $\bar{x}_j^q$ to the main owner of x_j; if P_q is the main owner of x_j, receive the values $\bar{x}_j^r$ from all other processors P_r for which $j \in J_r$.
   (c) For every $j \in J_q$, if P_q is the main owner of x_j, compute the jth component of the next iterate:

$$x_j^{k+1} = \begin{cases} \bar{x}_j^q & \text{if } s_j = 1, \\ \dfrac{1}{s_j} \displaystyle\sum_{j \in J_r} \bar{x}_j^r & \text{if } s_j > 1. \end{cases}$$

   Note that the sum includes the case $j \in J_q$.
   (d) For every $j \in J_q$, if P_q is the main owner of x_j, send x_j^{k+1} to all other processors P_r for which $j \in J_r$.
   (e) Advance the iteration index k by 1.

6. The last iterate is sent by the processors to the master processor.

Appendix B. Block-parallel implementation of CARP1.

1. The equations of (1) are partitioned into disjoint blocks by partitioning the index set $\{1, 2, \ldots, m\}$ into disjoint sets $I_1, \ldots, I_t$. A processor P_q is assigned to the equations of I_q for $1 \le q \le t$.
2. The (normalized) system (1) and the s_j's are sent to the processors, but each processor retains only the equations belonging to its block. For $1 \le q \le t$, denote $J_q = \{j \mid \text{in some equation of } I_q, \text{ the coefficient of } x_j \neq 0\}$. Processor P_q retains only those s_j's for which $j \in J_q$.
3. Every processor P_q, for every $j \in J_q$, determines if it is the "main owner" of x_j. For every j, there should be exactly one main owner of x_j, even if x_j has nonzero coefficients in several blocks. The main owner of x_j will need access to and from any other processor P_r for which $j \in J_r$.
4. The initial estimate $x^0 = (x_1^0, \ldots, x_n^0)$ is sent to the processors, but each processor P_q holds only the variables x_j^0 for $j \in J_q$.
5. Every processor sets the iteration index $k = 0$.
6. Every processor P_q, for $1 \le q \le t$, repeats the following steps until convergence:
   (a) For every $j \in J_q$, compute the value
   $$d_{q,j} \;=\; \sum_{i \in I_q} \left(b_i - \langle a^i, x^k \rangle\right) a_j^i \;.$$
   (b) For every $j \in J_q$: If P_q is not the main owner of x_j, send $d_{q,j}$ to the main owner of x_j; if P_q is the main owner of x_j, receive the values $d_{r,j}$ from all other processors P_r for which $j \in J_r$.
   (c) For every $j \in J_q$, if P_q is the main owner of x_j, compute the jth component of the next iterate:
   $$x_j^{k+1} \;=\; x_j^k \;+\; \frac{\lambda_k}{s_j} \sum_{j \in J_r} d_{r,j} \;.$$
   Note that the sum includes the case $j \in J_q$.
   (d) For every $j \in J_q$, if P_q is the main owner of x_j, send x_j^{k+1} to all other processors P_r for which $j \in J_r$.
   (e) Advance the iteration index k by 1.
7. The last iterate is sent by the processors to the master processor.

HIGH-ORDER COLLOCATION METHODS FOR DIFFERENTIAL EQUATIONS WITH RANDOM INPUTS*

DONGBIN XIU† AND JAN S. HESTHAVEN‡

Abstract. Recently there has been a growing interest in designing efficient methods for the solution of ordinary/partial differential equations with random inputs. To this end, stochastic Galerkin methods appear to be superior to other nonsampling methods and, in many cases, to several sampling methods. However, when the governing equations take complicated forms, numerical implementations of stochastic Galerkin methods can become nontrivial and care is needed to design robust and efficient solvers for the resulting equations. On the other hand, the traditional sampling methods, e.g., Monte Carlo methods, are straightforward to implement, but they do not offer convergence as fast as stochastic Galerkin methods. In this paper, a high-order stochastic collocation approach is proposed. Similar to stochastic Galerkin methods, the collocation methods take advantage of an assumption of smoothness of the solution in random space to achieve fast convergence. However, the numerical implementation of stochastic collocation is trivial, as it requires only repetitive runs of an existing deterministic solver, similar to Monte Carlo methods. The computational cost of the collocation methods depends on the choice of the collocation points, and we present several feasible constructions. One particular choice, based on sparse grids, depends weakly on the dimensionality of the random space and is more suitable for highly accurate computations of practical applications with large dimensional random inputs. Numerical examples are presented to demonstrate the accuracy and efficiency of the stochastic collocation methods.

Key words. collocation methods, stochastic inputs, differential equations, uncertainty quantification

1. Introduction.

This paper is devoted to numerical solutions of differential equations with random inputs. The source of random inputs includes uncertainty in system parameters, boundary/initial conditions, etc. Such kinds of uncertainty are ubiquitous in engineering applications and are often modeled as random processes. The classical approach is to model the random inputs as some idealized processes which typically are white noises, e.g., Wiener processes, Poisson processes, etc., and has led to elegant mathematical analysis and numerical methods by using stochastic calculus, e.g., Ito or Strantonovich calculus. The resulting differential equations are termed "stochastic ordinary/partial differential equations" (SODE/SPDE) (see, for example, [18, 25, 28, 43]). Recently, there has been a growing interest in studying problems with more correlated random inputs ("colored noises") and, in case of random parameters, fully correlated random processes, i.e., random variables. In this context, the classical stochastic calculus does not readily apply and other approaches are required.

The traditional approach for differential equations with random inputs is the Monte Carlo method, which generates ensembles of random realizations for the prescribed random inputs and utilizes repetitive deterministic solvers for each realization. Monte Carlo methods have been applied to many applications and their implementations are straightforward. Although the convergence rate—the ensemble mean of a brute-force Monte Carlo method with K realizations converges asymptotically at a rate $1/\sqrt{K}$—is relatively slow, it is (formally) independent of the dimensionality of the random space, i.e., independent of the number of random variables used to characterize the random inputs (e.g., [13]). To accelerate convergence, several techniques have been developed, for example, Latin hypercube sampling, [34, 48], the quasi-Monte Carlo (QMC) method, [14, 39, 40], and the Markov chain Monte Carlo method (MCMC) [16, 22, 36]. These methods can improve the efficiency of the brute-force Monte Carlo method. However, additional restrictions are imposed based on their specific designs and their applicability is limited.

Another class of methods is the nonsampling methods, where no repetitive deterministic solvers are employed. Methods along this line of approach include perturbation methods [27] and second-moment analysis [31, 32]. These methods do not result in convergent series of expansion and their applicability is restricted to systems with relatively small random inputs and outputs. Such a condition is difficult to satisfy, especially for nonlinear problems where small random inputs may induce large random outputs (e.g., [56]). Stochastic Galerkin methods, whose convergence can be established for problems with relatively large magnitude of random inputs/outputs, have been developed. The stochastic Galerkin methods are generalizations of the Wiener–Hermite polynomial chaos expansion, which was developed in [51] and has been applied to various problems in mechanics [21]. The generalizations, also called generalized polynomial chaos, employ non-Hermite polynomials to improve efficiency for a wider class of problems and include global polynomial expansions based on hypergeometrical polynomials [53, 52, 54], piecewise polynomial expansions [2, 12], and wavelet basis expansions [29, 30]. In general, these methods exhibit fast convergence rates with increasing order of the expansions, provided that solutions are sufficiently smooth in the random space. However, the resulting set of [illegible] equations is often coupled and care is needed to design efficient and robust solver. (See [52, 55] for examples of diffusion equations.) The form of the resulting equations can become very complicated if the underlying differential equations have nontrivial and nonlinear forms. (See [7, 37, 57] for examples of hyperbolic systems.)

In this paper, we propose a class of stochastic collocation methods that combines the strength of Monte Carlo methods and stochastic Galerkin methods. By taking advantage of the existing theory on multivariate polynomial interpolations (e.g., [5, 6]), the stochastic collocation methods achieve fast convergence when the solutions possess sufficient smoothness in random space, similar to stochastic Galerkin methods. On the other hand, the implementations of stochastic collocation methods are straightforward as they only require solutions of the corresponding [illegible] problems at each interpolation point, similar to Monte Carlo methods at each sampling point. Such properties make stochastic collocation methods good alternatives to Monte Carlo methods and stochastic Galerkin methods. The core issue is the construction of the set of interpolation points, and it is nontrivial in multidimensional random spaces. For such a cases, point sets based on tensor products of one-dimensional quadrature points [37, 53] are not suitable, as the number of points grows too fast with increasing dimensions. Therefore, we investigate and propose two other choices. One is based on Stroud's cubature points [49] and the other on sparse grids from the Smolyak

algorithm [46]. The former approach is of relatively low-order accuracy but results in highly efficient algorithms, especially for problems with large dimensional random inputs. The latter offers true high-order accuracy with convergence rate depending weakly on dimensionality. Both methods are more efficient than brute-force Monte Carlo methods in a large range of random dimensionality. Compared to stochastic Galerkin methods, the collocation methods generally result in a larger number of equations than a typical Galerkin method; however, these equations are easier to solve as they are completely decoupled and require only repetitive runs of a deterministic solver. Such a property makes the collocation methods more attractive for problems with complicated governing equations.

This paper is organized as follows. In section 2 we present the mathematical framework of stochastic differential equations—the functional spaces and the strong and weak forms are formulated in section 2.1 and we briefly review the Monte Carlo methods and stochastic Galerkin methods in section 2.2. The stochastic collocation methods are discussed in section 3, where the construction of collocation points is discussed in detail. More technical details and numerical examples are presented in sections 4 and 5, and we conclude the paper in section 6.

2. Random differential equations. Let $(\Omega, \mathcal{A}, \mathcal{P})$ be a complete probability space, where Ω is the event space, $\mathcal{A} \subset 2^\Omega$ the σ-algebra, and $\mathcal{P}$ the probability measure. Consider a d-dimensional bounded domain $D \subset \mathbb{R}^d$ $(d = 1, 2, 3)$ with boundary ∂D, and we study the following problem: find a stochastic function, $u \equiv u(\omega, x) : \Omega \times \bar{D} \to \mathbb{R}$, such that for $\mathcal{P}$-almost everywhere $\omega \in \Omega$, the following equation holds:

$$\mathcal{L}(\omega, x; u) = f(\omega, x), \qquad x \in D, \tag{2.1}$$

subject to the boundary condition

$$\mathcal{B}(\omega, x; u) = g(\omega, x), \qquad x \in \partial D, \tag{2.2}$$

where $x = (x_1, \ldots, x_d)$ are the coordinates in $\mathbb{R}^d$, $\mathcal{L}$ is a (linear/nonlinear) differential operator, and $\mathcal{B}$ is a boundary operator. The operator $\mathcal{B}$ can take various forms on different boundary segments, e.g., $\mathcal{B} \equiv \mathbb{I}$ on Dirichlet segments (where $\mathbb{I}$ is the identity operator) and $\mathcal{B} \equiv n \cdot \nabla$ on Neumann segments (where n is the outward unit normal vector). In the most general settings, the operators $\mathcal{L}$ and $\mathcal{B}$, as well as the driving terms f and g, can all have random components. Finally, we assume that the boundary ∂D is sufficiently regular and the driving terms f and g are properly posed, such that (2.1)–(2.2) is well-posed $\mathcal{P}$-a.e. $\omega \in \Omega$. (With a slight abuse of notation, (2.1)–(2.2) can incorporate time-dependent problems, if we consider D to be in an $(\mathbb{R}^{d+1})$-dimensional space, with the extra dimension designated to time.)

2.1. Strong and weak forms. To solve (2.1)–(2.2) numerically, we need to reduce the infinite-dimensional probability space to a finite-dimensional space. This can be accomplished by characterizing the probability space by a finite number of random variables. Such a procedure, termed the "finite-dimensional noise assumption" in [2], is often achieved via a certain type of decomposition which can approximate the target random process with desired accuracy. One of the choices is the Karhunen–Loève type expansion [33], which is based on the spectral decomposition of the covariance function of the input random process. Following a decomposition and assuming that the random inputs can be characterized by N random variables, we can rewrite the

random inputs in abstract form, e.g.,

$$\mathcal{L}(\omega, x; u) = \mathcal{L}(Y^1(\omega), \dots, Y^N(\omega), x; u), \qquad f(\omega, x) = f(Y^1(\omega), \dots, Y^N(\omega), x), \tag{2.3}$$

where $\{Y^i\}_{i=1}^N$ are real random variables with zero mean value and unit variance. Hence, following the Doob–Dynkin lemma [43], the solution of (2.1)–(2.2) can be described by the same set of random variables $\{Y^i(\omega)\}_{i=1}^N$, i.e.,

$$u(\omega, x) = u(Y^1(\omega), \dots, Y^N(\omega), x). \tag{2.4}$$

By characterizing the probability space with N random variables, we have effectively reduced the infinite-dimensional probability space to a N-dimensional space.

From a mathematical and computational point of view, it is most convenient to further assume that these random variables are mutually independent, and subsequently, we can define the corresponding Hilbert functional spaces via simple tensor product rules. However, such an assumption could potentially introduce more errors in approximating the input random processes (in addition to the errors induced by truncating the infinite series during a decomposition procedure such as the Karhunen–Loève expansion). For example, for non-Gaussian processes, the Karhunen–Loève expansion yields a set of [illegible] random variables that are not necessarily mutually independent. To transform them into independent random variables, a (nonlinear) transformation is needed and its numerical construction can be nontrivial. In fact, a mathematically rigorous transformation exists by using merely the definition of joint cumulative density function (CDF) [44]. However, such a transformation is of little practical use as it requires the knowledge of all the joint CDFs of the underlying random process.

In this paper, we take the customary approach (see, for example, [2, 30, 52]) of assuming that the random inputs are already characterized by a set of mutually independent random variables with satisfactory accuracy. We emphasize that how to (numerically) achieve this, i.e., to represent [illegible] via the Karhunen–Loève decomposition or any other representation and to ensure that the random variables involved are independent, falls into the topic of numerical representation of non-Gaussian processes. It remains an active research area (e.g., [23, 45, 58]) and is beyond the scope of this paper. We also remark that it is possible to construct multidimensional functional spaces based on finite number of [illegible] random variables [47]. However, such a construction does not, in its current form, allow straightforward numerical implementations.

Let us now assume that $\{Y^i\}_{i=1}^N$ are independent random variables with probability density functions $\rho_i : \Gamma^i \to \mathbb{R}^+$ and their images $\Gamma^i \equiv Y^i(\Omega)$ are bounded intervals in $\mathbb{R}$ for $i = 1, \dots, N$. Then

$$\rho(y) = \prod_{i=1}^N \rho_i(Y^i) \qquad \forall y \in \Gamma \tag{2.5}$$

is the joint probability density of $y = (Y^1, \dots, Y^N)$ with the support

$$\Gamma \equiv \prod_{i=1}^N \Gamma^i \subset \mathbb{R}^N. \tag{2.6}$$

This allows us to rewrite (2.1)–(2.2) as an $(N+d)$-dimensional differential equation in the strong form

$$\mathcal{L}(y,x;u) = f(y,x), \qquad (y,x) \in \Gamma \times D, \tag{2.7}$$

subject to the boundary condition

$$\mathcal{B}(y,x;u) = g(y,x), \qquad (y,x) \in \Gamma \times \partial D, \tag{2.8}$$

where N is the dimensionality of the random space Γ and d is the dimensionality of the physical space D.

Similar to the weak formulations in deterministic problems, we often seek to solve (2.7)–(2.8) in a weak form. For example, we can define a (finite-dimensional) subspace $V_\Gamma \subset L^2_\rho(\Gamma)$, the space of all square integrable function in Γ with respect to the measure $\rho(y)dy$, and seek $u_V(y,x) \in V_\Gamma(y)$, such that

$$\int_\Gamma \rho(y)\mathcal{L}(y,x;u_V)\, v(y)dy = \int_\Gamma \rho(y) f(y,x) v(y)dy \qquad \forall v(y) \in V_\Gamma, x \in D, \tag{2.9}$$

$$\int_\Gamma \rho(y)\mathcal{B}(y,x,u_V) v(y)dy = \int_\Gamma \rho(y) g(y,x) v(y)dy \qquad \forall v(y) \in V_\Gamma, x \in \partial D. \tag{2.10}$$

The resulting problem (2.9)–(2.10) thus becomes a deterministic problem in the physical domain D and can be solved by a standard discretization technique, e.g., finite elements, finite volume.

2.2. Existing numerical methods. Several numerical methods can be applied to problem (2.7)–(2.8), or (2.9)–(2.10). Here we briefly review two of the more popular methods—Monte Carlo methods and stochastic Galerkin methods—whose strengths complement each other.

2.2.1. Monte Carlo methods. Monte Carlo simulation is one of the most developed methods for solving stochastic differential equations. Although the convergence rate is relatively slow—a typical Monte Carlo simulation consisting of K realizations converges asymptotically as $1/\sqrt{K}$ [13]—it is independent of the number of random variables $\{Y^i(\omega)\}_{i=1}^N$. The procedure of applying a Monte Carlo method to problem (2.7)–(2.8) takes the following steps:

1. For a prescribed number of realizations K, generate independent and identically distributed (i.i.d.) random variables $\{Y_j^i\}_{i=1}^N \equiv \{Y^i(\omega_j)\}_{i=1}^N$, for $j = 1, \ldots, K$;
2. For each $j = 1, \ldots, K$, solve a deterministic problem (2.7)–(2.8) with $y_j = (Y_j^1, \ldots, Y_j^N)$ and obtain solution $u_j \equiv u(y_j, x)$, i.e., solve $\mathcal{L}(y_j, x; u_j) = f(y_j, x)$ in D, subject to $\mathcal{B}(y_j, x; u_j) = g(y_j, x)$ on ∂D;
3. Postprocess the results to evaluate the solution statistics, e.g., $\langle u \rangle \equiv \mathbb{E}[u] = \frac{1}{M}\sum_{j=1}^M u_j$.

Here $\mathbb{E}[u] = \int_\Gamma \rho(y)u(y)dy$ is the expectation. Note that for each realization $j = 1, \ldots, K$, step 2 is a deterministic problem and can be solved by any suitable scheme.

2.2.2. Stochastic Galerkin methods. Stochastic Galerkin methods deal with the weak form (2.9)–(2.10), and they offer fast convergence when the solution is sufficiently smooth in the random space. Forms of stochastic Galerkin methods differ in the construction of the subspace V_Γ in (2.9). Here we briefly review the construction

based on global orthogonal polynomial expansions. Let us define one-dimensional subspaces for $L^2_{\rho_i}(\Gamma^i)$,

$$W^{i,p_i} \equiv \left\{ v : \Gamma^i \to \mathbb{R} : v \in \text{span}\left\{\phi_m(Y^i)\right\}_{m=0}^{p_i} \right\}, \qquad i = 1, \dots, N, \tag{2.11}$$

where $\{\phi_m(Y^i)\}$ are a set of orthogonal polynomials satisfying the orthogonality conditions

$$\int_{\Gamma_i} \rho_i(Y^i)\phi_m(Y^i)\phi_n(Y^i)dY^i = h_m^2 \delta_{mn}, \tag{2.12}$$

with normalization factors $h_m^2 = \int_{\Gamma_i} \rho_i \phi_m^2 dY^i$. The type of the orthogonal polynomials $\{\phi_m(Y^i)\}$ in (2.12) is determined by $\rho_i(Y^i)$, the probability density function of $Y^i(\omega)$, for $i = 1, \dots, N$. For example, uniform distributions are better approximated by Legendre polynomials, and Hermite polynomials are more appropriate for Gaussian distributions. (See [53, 52] for a detailed list of correspondences.) We remark that such a correspondence is not mandatory, so long as $\{\phi_m(Y^i)\}$ forms a complete basis.

The corresponding N-dimensional subspace V_Γ for Γ can be defined as

$$W_N^p \equiv \bigotimes_{|\mathbf{p}| \le p} W^{i,p_i}, \tag{2.13}$$

where the tensor product is over all possible combinations of the multi-index $\mathbf{p} = (p_1, \dots, p_N) \in \mathbb{N}_0^N$ satisfying $|\mathbf{p}| = \sum_{i=1}^N p_i \le p$. Thus, W_N^p is the space of N-variate orthogonal polynomials of total degree at most p, and the number of basis functions in (2.13) is $\dim(W_N^p) = \binom{N+p}{N}$. Hereafter, we will refer to W_N^p as a complete polynomial space. Such spaces are often employed in the (generalized) polynomial chaos expansions [21, 52, 54].

Another construction of V_Γ is based on the tensor products of the one-dimensional polynomial spaces with fixed highest polynomial orders in N dimensions, i.e.,

$$Z_N^p = \bigotimes_{i=1}^N W^{i,p_i}, \quad \max_i p_i = p. \tag{2.14}$$

Such a space will be denoted as tensor polynomial space hereafter. They are employed in [2, 15], and the number of basis functions in Z_N^p is $\dim(Z_N^p) = (p+1)^N$.

If the same one-dimensional subspaces (2.11) are employed, then $W_N^p \subset Z_N^p$. The numbers of basis functions in both spaces depend on the number of dimensions N and the polynomial orders p, and they grow fast with increasing N and p. In particular, the total number of terms can grow exponentially fast with increasing order p when $N \gg 1$ (curse-of-dimensionality). We also remark that when $N \gg 1$ and p is moderate (e.g. $p \le 10$), $\dim(W_N^p) \ll \dim(Z_N^p)$.

For low to moderate value of N, stochastic Galerkin methods are preferred because their high accuracy and fast convergence; for large value of $N \gg 1$, the rapidly growing number of basis functions effectively reduces its efficiency. In this case, the Monte Carlo method is preferred. However, if a highly accurate stochastic solution is desired, then stochastic Galerkin methods can be more efficient even for relatively large value of N (e.g., [2]).

3. Stochastic collocation methods. In this section, we present high-order collocation methods for (2.1)–(2.2). The objective is to combine the strength of the two existing approaches: the high resolution of stochastic Galerkin methods resulting from polynomial approximations in random spaces, and the ease of implementation of Monte Carlo methods by sampling at discrete points in random spaces.

3.1. Formulation. The construction of high-order stochastic collocation methods is based on polynomial interpolations in the multidimensional random space. Let us denote by $y = (Y^1, \ldots, Y^N)$ any point in the random space $\Gamma \subset \mathbb{R}^N$, by Π_N the space of all N-variate polynomials with real coefficients, and by Π_N^p the subspace of polynomials of total degree at most p. (Note that the space W_N^p defined in (2.13) is a subset of Π_N^p.) When derivatives are not interpolated, the [illegible] can be stated in the following form.

DEFINITION 3.1 (Lagrange interpolation). [illegible] $y_1, \ldots, y_M$ [illegible] $b_1, \ldots, b_M$ [illegible] $V_I \in \Pi_N$ [illegible] $l \in V_I$ [illegible]

$$l(y_j) = b_j, \qquad j = 1, \ldots, M. \tag{3.1}$$

The points $y_1, \ldots, y_M$ are called interpolation [illegible], and V_I is the [illegible].

DEFINITION 3.2 (poisedness). [illegible] 3.1, [illegible] $y_1, \ldots, y_M \in \mathbb{R}^N$ [illegible] V_I [illegible] $b_1, \ldots, b_M \in \mathbb{R}$ [illegible] $f \in V_I$ [illegible] $f(y_j) = b_j$ $j = 1, \ldots, M$ [illegible] M [illegible] $\mathbb{R}^N$ [illegible] V_I [illegible] V_I [illegible] M

There is a well-developed and extensive classical theory of univariate Lagrange polynomial interpolation. However, the multivariate case is more difficult. In particular, the Haar spaces exist in abundance for $N = 1$ but not for $N > 1$. In fact, in this case there are no Haar spaces of dimension greater than one—the so-called loss-of-Haar. (For more details and the refinement of this statement, see [11, 35].) Thus, research has focused on the [illegible] of points $\{y_i\}_{i=1}^M$ such that one achieves a good approximation by a Lagrange interpolation.

Let $\Theta_N = \{y_i\}_{i=1}^M \in \Gamma$ be a set of (prescribed) nodes such that the Lagrange interpolation (3.1) in the N-dimensional random space Γ is poised in a corresponding interpolation space V_I. (For sufficient conditions on the distribution of the nodes to ensure a unique interpolation, see [8].) Subsequently, Lagrange interpolation of a smooth function, $f : \mathbb{R}^N \to \mathbb{R}$, can now be viewed as follows: find a polynomial $\mathcal{I}(f) \in V_I$ such that $\mathcal{I}(f)(y_i) = f(y_i)$, $\forall i = 1, \ldots, M$.

The polynomial approximation $\mathcal{I}(f)$ can be expressed by using the Lagrange interpolation polynomials, i.e.,

$$\mathcal{I}(f)(y) = \sum_{k=1}^{M} f(y_k) L_k(y), \tag{3.2}$$

where

$$L_i(y) \in V_I, \quad L_i(y_j) = \delta_{ij}, \quad 1 \le i, j \le M, \tag{3.3}$$

are the Lagrange polynomials.

We equip the space V_I with the supremum-norm $\|\cdot\|$ and introduce

$$\|\mathcal{I}\| = \sup_{f \neq 0} \frac{\|\mathcal{I}f\|_\infty}{\|f\|_\infty}. \tag{3.4}$$

The Lebesgue theorem states that the interpolation error is uniformly bounded as

$$\|f(y) - f^*(y)\|_\infty \le \|f(y) - \mathcal{I}f(y)\|_\infty \le (1+\Lambda)\,\|f(y) - f^*(y)\|_\infty, \tag{3.5}$$

where $f^*(y)$ is the best approximating polynomial, and $\Lambda = \|\mathcal{I}\| = \max_{y\in\Gamma} \sum_{k=1}^{K} |L_i(y)|$ is the Lebesgue constant. We remark that the determination of $f^*(y)$ is an unsolved problem for arbitrary $(N > 1)$-dimensional spaces, and the estimation of the Lebesgue constant, which depends on the particular choice of nodal sets Θ_N, is a nontrivial task even for $N = 1$.

By denoting

$$\hat{u}(y) \equiv \mathcal{I}u(y) = \sum_{k=1}^{M} u(y_k) L_k(y), \tag{3.6}$$

the collocation procedure to solve the stochastic elliptic equation (2.7) is

$$R\left(\hat{u}(y)\right)\big|_{y_k} = 0 \qquad \forall k = 1, \dots, M, \tag{3.7}$$

where $R(u) = \mathcal{L}(u) - f$ is the residual of (2.7). By using the property of Lagrange interpolation (3.3), we immediately obtain: for $k = 1, \dots, M$,

$$\mathcal{L}(y_k, x; u) = f(y_k, x), \qquad x \in D, \tag{3.8}$$

with boundary condition

$$\mathcal{B}(y_k, x; u) = g(y_k, x), \qquad x \in \partial D. \tag{3.9}$$

Thus, the stochastic collocation method is equivalent to solving M deterministic problems (3.8)–(3.9), the deterministic counterpart of problem (2.7)–(2.8), at each nodal point $y_k, k = 1, \dots, M$ in a given nodal set Θ_N. Note that the problem (3.8)–(3.9) for each k is naturally , and existing deterministic solvers can be readily applied. This is in direct contrast to the stochastic Galerkin approaches, where the resulting expanded equations are, in general, coupled.

Once the numerical solutions of (3.8)–(3.9) are obtained at all collocation points, the statistics of the random solution can be evaluated, e.g.,

$$\mathbb{E}(\hat{u})(x) = \sum_{k=1}^{M} u(y_k, x) \int_\Gamma L_k(y)\rho(y)dy. \tag{3.10}$$

The evaluations of such expectations require explicit knowledge of the Lagrange interpolation polynomials $\{L_k(y)\}$. For a given nodal set Θ_N, the polynomials can be determined numerically by inverting a Vandermonde-type matrix. (The matrix is invertible under the assumption that the Lagrange interpolation is poised on Θ_N.) In multivariate cases, such a procedure can be cumbersome, but can be accomplished once and for all at the preprocessing stage.

An alternative is to choose the set Θ_N to be a cubature point set. Recall that a cubature rule approximates an integral by

$$\int_\Gamma f(y)dy \simeq \sum_{i=1}^{M} f(y_i) w_i, \tag{3.11}$$

where $\{w_i\}$ are the weights. It is called "of order s" if the approximation is exact for all $f \in \Pi_N^r, r \leq s$, and not exact for at least one $f \in \Pi_N^{s+1}$. When we choose the interpolation point set Θ_N to be the same as a cubature point set, the evaluation of (3.10) is reduced to

$$\mathbb{E}(\hat{u})(x) = \sum_{k=1}^{M} u(y_k, x) w_k. \tag{3.12}$$

It should be noted that the use of cubature formula to evaluate the solution statistics will introduce extra errors whenever the integrals defining these statistics, e.g., (3.10) for mean solution, cannot be evaluated exactly by an s-order cubature.

Construction of cubature formulas has long been an active and challenging research area, and we refer interested readers to [10, 9] for extensive reviews.

3.2. Choices of collocation points. The computational complexity of the stochastic collocation methods (3.8)–(3.9) is M times that of a deterministic problem, where M is the total number of collocation points. Thus, we need to choose a nodal set Θ_N with fewest possible number of points under a prescribed accuracy requirement. In this section, we present several choices of such collocation points. The main focus here is on multidimensional random spaces, i.e., $\Gamma \subset \mathbb{R}^N$ with $N > 1$. Without loss of generality, we assume that the bounded support of the random variables Y^i is $\Gamma^i = [-1, 1]$ for $i = 1, \ldots, N$ and subsequently the bounded random space Γ is a N-hypercube, i.e., $\Gamma = [-1, 1]^N$. (Note that random variables with bounded support in $[a, b]$ can always be mapped to $[-1, 1]$, and any domain $\Gamma^* = \prod_{i=1}^N [a^i, b^i]$ to $[-1, 1]^N$.)

3.2.1. Tensor products of one-dimensional nodal sets. A natural choice of the nodal set is the tensor product of one-dimensional sets. In interpolating smooth functions $f : [-1, 1]^N \to \mathbb{R}$, much is known about good interpolation formulas for $N = 1$, i.e., for every direction $i = 1, \ldots, N$, we can construct a good one-dimensional interpolation

$$\mathcal{U}^i(f) = \sum_{k=1}^{m_i} f(Y_k^i) \cdot a_k^i \tag{3.13}$$

based on nodal sets

$$\Theta_1^i = (Y_1^i, \ldots, Y_{m_i}^i) \subset [-1, 1], \tag{3.14}$$

where $a_k^i \equiv a_k(Y^i) \in C([-1, 1])$. We assume that a sequence of formulas (3.13) is given. In the multivariate case $N > 1$, the tensor product formulas are

$$\mathcal{I}(f) \equiv \left(\mathcal{U}^{i_1} \otimes \cdots \otimes \mathcal{U}^{i_N}\right)(f) = \sum_{k_1=1}^{m_{i_1}} \cdots \sum_{k_N=1}^{m_{i_N}} f(Y_{k_1}^{i_1}, \ldots, Y_{k_N}^{i_N}) \cdot (a_{k_1}^{i_1} \otimes \cdots \otimes a_{k_N}^{i_N}). \tag{3.15}$$

Clearly, the above product formula needs $M = m_{i_1} \cdots m_{i_N}$ nodal points. If we choose to use the same interpolating function (3.13) in each dimension with the same number of points, i.e., $m_{i_1} = \cdots = m_{i_N} \equiv m$, the total number of points is $M = m^N$. This number grows quickly in high dimensions $N \gg 1$—even for a poor approximation with two points ($m = 2$) in each dimension, $M = 2^N \gg 1$ for $N \gg 1$.

The tensor product interpolation is easy to construct—the interpolation points and space are obtained by tensor products of the univariate ones. The Lagrange formula are easily extended to this case, as can be found in [4, 24]. However, because of the rapidly growing number of interpolation nodes in high dimensions, we will not consider this approach extensively in this paper.

3.2.2. Sparse grids. In this section we propose to solve the stochastic collocation problem (3.8)–(3.9) on a [illegible] constructed by the Smolyak algorithm. The Smolyak algorithm is a linear combination of product formulas, and the linear combination is chosen in such a way that an interpolation property for $N = 1$ is preserved for $N > 1$. Only products with a relatively small number of points are used and the resulting nodal set has significantly less number of nodes compared to the tensor product rule (3.15). Much research has been devoted to the Smolyak algorithm since its introduction in [46]; see, e.g., [3, 41, 42].

Starting with the one-dimensional interpolation formula (3.13), the Smolyak algorithm is given by (see [50])

$$\mathcal{I}(f) \equiv A(q,N) = \sum_{q-N+1 \le |\mathbf{i}| \le q} (-1)^{q-|\mathbf{i}|_1} \cdot \binom{N-1}{q-|\mathbf{i}|} \cdot \left(\mathcal{U}^{i_1} \otimes \cdots \otimes \mathcal{U}^{i_N}\right), \tag{3.16}$$

where $\mathbf{i} = (i_1, \ldots, i_N) \in \mathbb{N}^N$. To compute $A(q,N)$, we only need to evaluate function on the "sparse grid"

$$\Theta_N \equiv \mathcal{H}(q,N) = \bigcup_{q-N+1 \le |\mathbf{i}| \le q} (\Theta_1^{i_1} \times \cdots \times \Theta_1^{i_N}). \tag{3.17}$$

In this paper, we choose to use Smolyak formulas that are based on one-dimensional polynomial interpolation at the extrema of the Chebyshev polynomials. (Other choices, such as the Gauss quadrature points, can be considered as well.) For any choice of $m_i > 1$, these nodes are given by

$$Y_j^i = -\cos\frac{\pi \cdot (j-1)}{m_i - 1}, \qquad j = 1 \ldots, m_i. \tag{3.18}$$

In addition, we define $Y_1^i = 0$ if $m_i = 1$. The functions a_j^i in (3.13) are characterized by the requirement that $\mathcal{U}^i$ reproduce all polynomials of degree less than m_i. We also choose $m_1 = 1$ and $m_i = 2^{i-1}$ for $i > 1$. By doing so, the one-dimensional nodal sets Θ_1^i are nested, i.e., $\Theta_1^i \subset \Theta_1^{i+1}$, and subsequently $\mathcal{H}(q,N) \subset \mathcal{H}(q+1,N)$.

It has been shown that if we set $q = N + k$, then $A(N+k,N)$ is exact for all polynomials in Π_N^k [42], and the total number of nodes for $N \gg 1$ is [41]

$$M \equiv \dim(A(N+k,N)) \sim \frac{2^k}{k!} N^k, \qquad k \text{ fixed}, N \gg 1. \tag{3.19}$$

On the other hand, $\dim(\Pi_N^k) = \binom{N+k}{N} \sim N^k/k!$ for $N \gg 1$. Thus, $A(N+k,N)$ uses about 2^k times as many points as the degree-of-freedom of Π_N^k. Since this factor is [illegible] of N, the algorithm may be regarded as optimal. Formula (3.19) also indicates that the number of nodes from the Smolyak sparse grid is larger than the number of expansion terms of a stochastic Galerkin method in the complete polynomial space W_N^k. Hereafter, we will refer k in $A(N+k,N)$ as the "level" of the Smolyak construction.

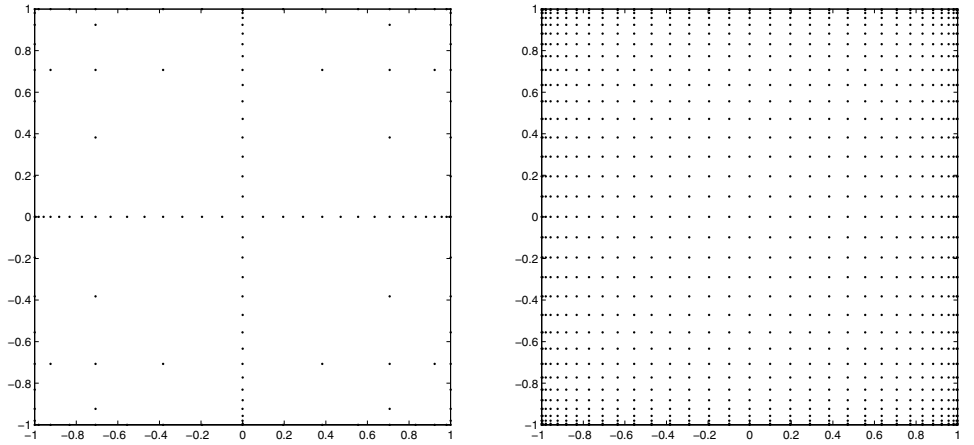

FIG. 3.1. *Two-dimensional ($N = 2$) interpolation nodes based on the extrema of Chebyshev polynomials* (3.18). *Left: sparse grid $\mathcal{H}(N+k, N)$ from Smolyak algorithm, $k = 5$. Total number of points is* 145. *Right: tensor product algorithm* (3.15) *from the same one-dimensional nodes. Total number of nodes is* $1,089$.

TABLE 3.1

The degrees-of-freedom of the Smolyak sparse grid ($\mathcal{H}(N + k, N) = \dim(A(N + k, N))$), the complete polynomial space W_N^k, and the tensor polynomial space Z_N^k, for various dimensions N and order k.

N	k	$\mathcal{H}(N + k, N)$	$\dim(W_N^k)$	$\dim(Z_N^k)$
2	1	5	3	4
	2	13	6	9
	3	29	10	16
	4	65	15	25
10	1	21	11	$1,024$
	2	221	66	$59,049$
	3	$1,581$	286	$1,048,576$
20	1	41	21	$1,048,576$
	2	841	231	$\approx 3.5 \times 10^9$
50	1	101	51	$\approx 1.1 \times 10^{16}$
	2	$5,101$	$1,326$	$\approx 7.2 \times 10^{23}$

In Figure 3.1, we show the two-dimensional ($N = 2$) interpolation nodes by the sparse grid $\mathcal{H}(N + k, N)$ described above, with $k = 5$. For comparison, the two-dimensional tensor product grid based on the same one-dimensional nodes are shown on the right of Figure 3.1, and we observe that the sparse grid has significantly fewer nodes.

In Table 3.1 we list the number of nodes of the Smolyak sparse grid $\mathcal{H}(N+k, N) = \dim(A(N + k, N))$, the degrees-of-freedom of the complete polynomial space W_N^k (2.13), and the tensor polynomial space Z_N^k (2.14). (As shown in [42], the interpolation by $A(N + k, N)$ is exact in a polynomial space richer than W_N^k but not as rich as Z_N^k.) It can be seen that as N grows, the number of nodes from the Smolyak sparse grid is significantly less than $\dim(Z_N^k)$. Also, the relation (3.19) can be observed. This indicates that only at low dimensions, e.g., $N < 5$, should the tensor product construction of interpolation nodes be considered.

The interpolation error in a space $F_N^l = \{f : [-1, 1]^N \to \mathbb{R} \mid \partial^{|\mathbf{m}|} f \text{ continues}, m_i \leq l, \forall i\}$, where $\mathbf{m} \in \mathbb{N}_0^N$ and $\partial^{|\mathbf{m}|}$ is the usual N-variate partial derivative of order $|\mathbf{m}|$,

is (cf. [3])

$$\|\mathbb{I}_N - A(q,N)\|_\infty \le C_{N,l}\cdot M^{-l}\cdot(\log M)^{(l+2)(N-1)+1}, \tag{3.20}$$

where $\mathbb{I}_N$ is the identity operator in a N-dimensional space and $M = \dim(\mathcal{H}(q,N)$ is the number of interpolation points.

Another intriguing property of the sparse grid constructed above is that it is also the nodes of a good cubature formula (3.11). Thus, we can efficiently evaluate the solution statistics in a similar way of (3.12). For analysis on integration error estimates of Smolyak sparse grid for multivariate integrals, see [41].

3.2.3. Stroud's cubature of degrees 2 and 3. For the N-hypercube spaces $[-1,1]^N$ considered in this paper, Stroud constructed a set of cubature points with $(N+1)$-point that is accurate for multiple integrals of polynomials of degree 2, and a set of degree 3 with $2N$-point [49]. The degree 2 formula, termed the Stroud-2 method hereafter, consists of points $\{y_k\}_{k=0}^N$ such that

$$Y_k^{2r-1} = \sqrt{\frac{2}{3}}\cos\frac{2rk\pi}{N+1}, \qquad Y_k^{2r} = \sqrt{\frac{2}{3}}\sin\frac{2rk\pi}{N+1}, \quad r = 1,2,\ldots,[N/2], \tag{3.21}$$

where $[N/2]$ is the greatest integer not exceeding $N/2$, and if N is odd $Y_k^N = (-1)^k/\sqrt{3}$. The degree 3 formula, which will be called as Stroud-3 method, has the points $\{y_k\}_{k=1}^{2N}$ such that

$$Y_k^{2r-1} = \sqrt{\frac{2}{3}}\cos\frac{(2r-1)k\pi}{N}, \qquad Y_k^{2r} = \sqrt{\frac{2}{3}}\sin\frac{(2r-1)k\pi}{N}, \quad r = 1,2,\ldots,[N/2], \tag{3.22}$$

and if N is odd $Y_k^N = (-1)^k/\sqrt{3}$.

It was proved in [38] that the Stroud-2 and -3 methods employ the minimal number of points for their corresponding [illegible] accuracy. However, to the authors' knowledge, no theory exists on the approximation properties of the Lagrange interpolations constructed on these nodes. It is expected that the interpolation errors will be lower than degree 2 and 3 for the Stroud-2 and -3 method, respectively.

In this paper, we will employ the Stroud-2 and -3 nodes for stochastic collocation methods. For relatively low-order accuracy requirement in the solution statistics (expectations), the Stroud methods are highly efficient especially in high-dimensional spaces ($N \gg 1$) because the numbers of nodal points are minimal. However, the accuracy cannot be improved any further and no error estimates can be obtained.

4. Applications to stochastic elliptic equations. In this section we use a stochastic elliptic problem to illustrate the applications of stochastic collocation methods. In particular, we consider for $\mathcal{P}$-a.e. $\omega \in \Omega$,

$$\begin{aligned} -\nabla\cdot(a(\omega,x)\nabla u(\omega,x)) &= f(\omega,x), && \text{in } D,\\ u(\omega,x) &= 0, && \text{on } \partial D, \end{aligned} \tag{4.1}$$

where $a, f : \Omega\times D \to \mathbb{R}$ are known stochastic functions. Standard assumptions are made on the regularity of the input functions so that (4.1) is well-posed, e.g., $a \in L^\infty(\Omega, D)$ is strictly positive.

Again let us assume that the random input functions can be characterized by N independent random variables $\{Y^i(\omega)\}_{i=1}^N$, whose images are bounded intervals

and define an N-dimensional random space $\Gamma \subset \mathbb{R}^N$. Without loss of generality, let $\Gamma = [-1,1]^N$. Problem (4.1) can be then expressed in the strong form,

$$\begin{aligned} -\nabla \cdot (a(y,x)\nabla u(y,x)) &= f(y,x) \quad \forall (y,x) \in \Gamma \times D, \\ u(y,x) &= 0 \qquad \forall (y,x) \in \Gamma \times \partial D, \end{aligned} \tag{4.2}$$

and weak variational form: find $u \in L^2_\rho(\Gamma) \otimes H^1_0(D)$ such that

$$\mathcal{K}_\rho(u,v;\kappa) = \mathcal{I}_\rho(f,v) \quad \forall v \in L^2_\rho(\Gamma) \otimes H^1_0(D), \tag{4.3}$$

where

$$\mathcal{I}_\rho(v,w) = \int_\Gamma \rho(y) \int_D v(y,x) w(y,x) dx dy$$

and

$$\mathcal{K}_\rho(v,w;\kappa) = \int_\Gamma \rho(y) \int_D a(y,x) \nabla v(y,x) \cdot \nabla w(y,x) dx dy.$$

4.1. Formulations and error estimates. A stochastic collocation method, combined with a finite element method (FEM) in the physical space $D \subset \mathbb{R}^d$, takes the following form: for a given set of collocation nodes $\Theta_N = \{y_k\}_{k=1}^M$ on which the Lagrange interpolation is poised in an interpolation space $V_I \subset L^2_\rho(\Gamma)$, and a piecewise (continuous) FEM mesh $X^h_d \in H^1_0(D)$ (where $h > 0$ is its mesh spacing parameter) that satisfies all the standard requirements on a FEM mesh, find as follows: for $k = 1, \ldots, M$, $u^h_k(x) \equiv u^h(y_k, x) \in X^h_d$, such that

$$\int_D a(y_k,x) \nabla u^h_k(x) \cdot \nabla \chi(x) dx = \int_D f(y_k,x) \chi(x) dx \qquad \forall \chi \in X^h_d. \tag{4.4}$$

The final numerical solution takes the form

$$\hat{u}_h(y,x) = \sum_{k=1}^M u^h_k(x) L_k(y). \tag{4.5}$$

To study error estimates, let us define an error in term of the deterministic energy error, i.e.,

$$\mathcal{E}_G \equiv \left(\mathbb{E} \int_D a(\nabla(u - \hat{u}_h))^2 dx \right)^{1/2}. \tag{4.6}$$

We can show that

$$\begin{aligned} \mathcal{E}_G &= \left(\int_\Gamma \rho(y) \int_D a(y,x) (\nabla(u - \hat{u}_h))^2 dx dy \right)^{1/2} \\ &\le \left(\|\rho a\|_{L^\infty(\Gamma \times D)} \right)^{1/2} \min_{v \in V_I \otimes X^d_h} \|u - v\|_{L^2_\rho(\Gamma) \otimes H^1_0(D)} \\ &\le \left(\|\rho a\|_{L^\infty(\Gamma \times D)} \right)^{1/2} (\mathcal{E}_D + \mathcal{E}_\Gamma), \end{aligned} \tag{4.7}$$

where $\mathcal{E}_D = \min_{v \in L^2_\rho(\Gamma) \otimes X^d_h} \|u - v\|_{L^2_\rho(\Gamma) \otimes H^1_0(D)}$ is the standard $H^1_0(D)$ FEM approximation error, and $\mathcal{E}_\Gamma$ is the $L^2_\rho(\Gamma)$ approximation error in the random space satisfying

$$\mathcal{E}_\Gamma = \min_{v \in V_I \otimes H^1_0(D)} \|u - v\|_{L^2_\rho(\Gamma) \otimes H^1_0(D)} \le \|u - \mathcal{I}(u)\|_{L^2_\rho(\Gamma) \otimes H^1_0(D)} \le \|u - \mathcal{I}(u)\|_\infty = \mathcal{E}_I. \tag{4.8}$$

The last term is the interpolation error, which can be bounded by the Lebesgue theorem (3.5). For the interpolation by Smolyak sparse grid, this error is (3.20). We hence have the following proposition.

PROPOSITION 4.1 (separation of error estimates). (4.6)

$$\mathcal{E}_G \le C(\mathcal{E}_D + \mathcal{E}_I), \tag{4.9}$$

$\mathcal{E}_D$ $H_0^1(D)$ D $\mathcal{E}_I$ Γ C D Γ

4.2. Numerical results. Numerical implementations of stochastic Galerkin methods are not considered here as they have been considered in many earlier publications. For Galerkin methods in tensor polynomial spaces, see [12, 1, 2, 15]; in complete polynomial spaces, see [19, 20, 21, 52, 54, 55]. Here we focus on numerical examples of stochastic collocation methods and consider the following problem in one spatial dimension ($d = 1$) and $N > 1$ random dimensions:

$$\frac{d}{dx}\left[a(y,x)\frac{du}{dx}(y,x)\right] = 0, \qquad (y,x) \in \Gamma \times (0,1), \tag{4.10}$$

with boundary conditions

$$u(y,0) = 0, \qquad u(y,1) = 1, \qquad y \in \Gamma.$$

The use of one-dimensional physical space D allows us to focus on the properties of the stochastic collocation methods associated with the random space Γ. Extensions to two- and three-dimensional physical spaces are straightforward. We assume that the random diffusivity has the form

$$a(y,x) = 1 + \sigma \sum_{k=1}^{N} \frac{1}{k^2\pi^2} \cos(2\pi k x) Y^k(\omega), \tag{4.11}$$

where $Y^k(\omega) \in [-1,1], k = 1, \ldots, N$, are independent uniformly distributed random variables. The form of (4.11) is similar to those obtained from a Karhunen–Loève expansion with eigenvalues delaying as $1/k^4$. Here we employ (4.11) to eliminate the errors associated with a numerical Karhunen–Loève solver and to keep the random diffusivity strictly positive as $N \to \infty$. The series in (4.11) converge as $N \to \infty$ and we have

$$\mathbb{E}(a(y,x)) = 1, \qquad 1 - \frac{\sigma}{6} < a(y,x) < 1 + \frac{\sigma}{6}.$$

The spatial discretization is done on a p-type spectral element with high-order modal expansions. The basis functions $\psi(\xi)$ in a standard interval $\xi \in (-1,1)$ are defined as

$$\psi_p(\xi) = \begin{cases} \frac{1-\xi}{2}, & p = 0, \\ \frac{1-\xi}{2}\frac{1+\xi}{2} P_{p-1}^{1,1}(\xi), & 0 < p < P, \\ \frac{1+\xi}{2}, & p = P, \end{cases} \tag{4.12}$$

where $P_p^{\alpha,\beta}(\xi)$ is the Jacobi polynomial of order p with parameters $\alpha, \beta > -1$. For more details of such a basis, see [26]. In all the following computations, the spatial

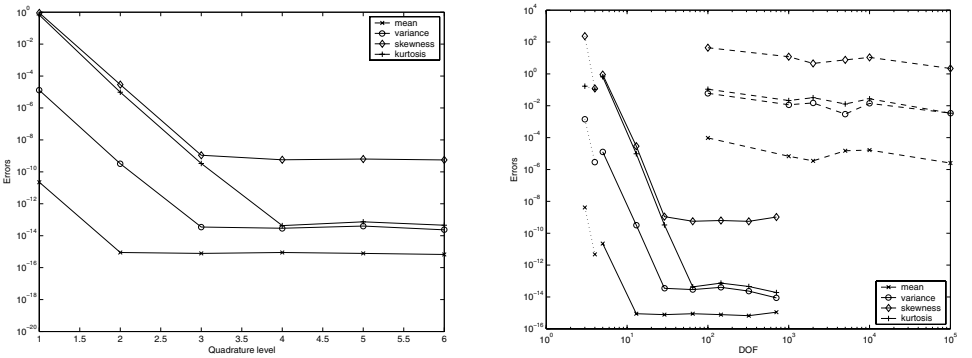

FIG. 4.1. *Convergence of errors in moments with two-dimensional random input ($N = 2$). Left: convergence with respect to level of approximation k of Smolyak formula $A(N + k, N)$; Right: convergence with respect to number of quadratures of different methods, Smolyak sparse grid (solid lines), Stroud's cubature (dotted lines), and Monte Carlo simulation (dashed lines).*

discretizations are conducted with sufficiently high-order basis such that the spatial errors are subdominant.

The exact solution to this problem is

$$u_e(y, x) = c_1 \int \frac{1}{a(y, x)} dx + c_2,$$

where the two constants c_1, c_2 are determined by the boundary conditions. However, the closed form expression for the exact solution is not readily available.

4.2.1. Low-dimensional random inputs: Accuracy. In this section, a low-dimensional random input is assumed. In particular, we choose $N = 2$. The "exact" solution is obtained by using the Smolyak sparse grid with level 8, i.e., $A(N+8, N) = A(10, 2)$.

In Figure 4.1, the errors in the first four moments of the solution are shown. On the left, the error of the Smolyak collocation method is shown. We observe that as the approximation level k of $A(N + k, N)$ increases, the errors converge exponentially fast before reaching saturate levels.

On the right of Figure 4.1, the error convergence of a few different methods is shown with respect to the degree-of-freedom, i.e., the total number of interpolation points. It can be seen that the Smolyak method has the best accuracy; the Stroud-2 and -3 methods approximate the lower moments (mean and variance) well, with considerable less degrees-of-freedom (only three and four points for the Stroud-2 and -3 method, respectively). On the other hand, the standard Monte Carlo method has the expected $O(\mathrm{DOF}^{-1/2})$ convergence.

4.2.2. Moderate-dimensional random inputs. Here we choose a moderately high-dimensional random space with $N = 8$. Figure 4.2 shows the error convergence with respect to degrees-of-freedom for different methods. Again, the Stroud-3 method offers solutions with accuracy comparable to the Smolyak method at level one ($k = 1$ for $A(N + k, N)$), and with fewer nodes. In this case, both the Stroud method and Smolyak method are more efficient than Monte Carlo methods. We also observe that there is no clear sign of accuracy improvement in kurtosis, when comparing the Stroud-3 and Stroud-2 methods. (See also the results in Figure 4.1.) The reason is

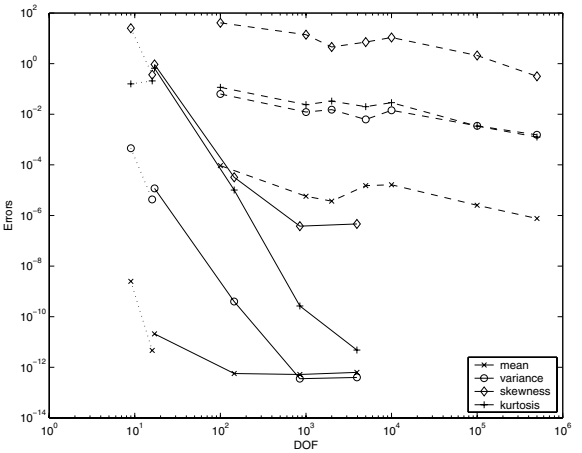

FIG. 4.2. *Convergence of errors in moments with eight-dimensional random input ($N = 8$). Smolyak sparse grid $A(N + k, N), k \leq 4$ (solid lines), Stroud's cubature (dotted lines), and Monte Carlo simulation (dashed lines).*

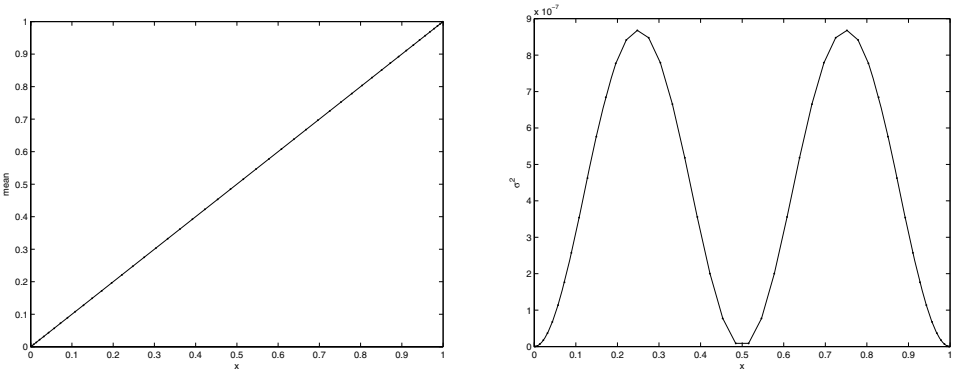

FIG. 4.3. *Stochastic solution of* (4.10) *with* 50*-dimensional ($N = 50$) random input. Left: mean solution. Right: variance.*

TABLE 4.1

Solutions at high-dimensional random input ($N = 50$), with Stroud-2 and -3 method, Smolyak method $A(N+k, N)$, and Monte Carlo method. Degrees-of-freedom for polynomial spaces: for $k = 1$, $\dim(W_N^k) = 51$, $\dim(Z_N^k) \approx 1.1 \times 10^{16}$; for $k = 2$, $\dim(W_N^k) = 1,326$, $\dim(Z_N^k) \approx 7.2 \times 10^{23}$.

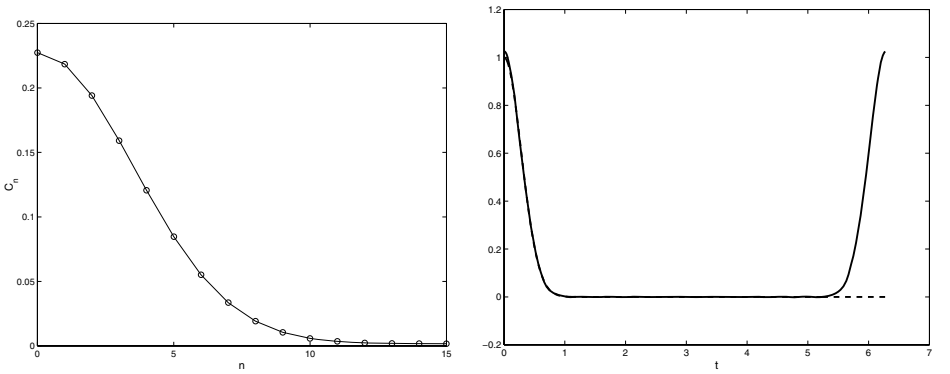
Methods	DOF	$\max \sigma_u^2(x)$
Stroud 2	51	8.67914(−7)
Stroud 3	100	8.67916(−7)
Smolyak ($k = 1$)	101	8.67925(−7)
Smolyak ($k = 2$)	5101	8.67919(−7)
MCS	100	8.16677(−7)
MCS	5000	8.73434(−7)

that kurtosis is the fourth moment of the solution and neither of the Stroud's methods is precise beyond third-order polynomials.

4.2.3. High-dimensional random inputs: Efficiency. In this section, we focus on problem (4.10) with high-dimensional random input, $N = 50$. In Figure 4.3, the solution profiles of mean and variance are shown. The maximums of variance are tabulated in Table 4.1. It can be seen that the Stroud-2, -3 method and Smolyak method with $k = 2$ agree with each other well. With similar numbers of degrees-of-freedom, Monte Carlo methods show noticeable differences. In this particular case, both the Stroud methods (Stroud-2 and Stroud-3) and the Smolyak method ($k = 1$ and $k = 2$) are superior to the Monte Carlo method, and the Stroud-2 method is to be preferred, as it gives sufficiently accurate results (in variance) with only 51 nodes. The collocation points based on tensor products and Galerkin methods in tensor polynomial spaces Z_N^k are clearly not practical, as $\dim(Z_N^k) \approx 7.2 \times 10^{23}$. The Galerkin methods in the complete polynomial spaces have number of expansion terms of 51 and 1,326 for $k = 1, 2$, respectively. The choice between a Galerkin method and a Smolyak collocation method in this case will depend on users, i.e., whether to use a deterministic solver more times or to design a solver for a coupled system of equations with less terms.

5. Time dependent problem: An illustrative example. Although the stochastic collocation algorithm is discussed in the context of boundary value problems, it is straightforward to apply it to time-dependent problems. Let us consider a damped motion of a particle in a bistable potential in the presence of a noisy periodic forcing. In particular, we consider for $\omega \in \Omega$

$$\frac{dx}{dt}(t,\omega) = x - x^3 + f(t,\omega), \qquad x(0,\omega) = x_0, \tag{5.1}$$



where $f(t,\omega)$ is a 2π-periodic random process with zero mean value and a 2π-periodic covariance function, i.e., $\mathbb{E}[f(t,\omega)] = 0$, and $\mathbb{E}[f(t_1,\omega)f(t_2,\omega)] = \sigma_f^2 C_f(|t_1 - t_2|)$, where σ_f^2 is the variance and $C_f(t) = C_f(t + 2\pi)$. We remark that with proper noisy input on top of a periodic driving force, the system (5.1) can exhibit complicated behavior such as stochastic resonance. (See, for example, [17].) However, the purpose of this example is on computational aspects of the algorithm, and we will restrict ourselves to cases with relatively simple dynamical behavior.

To model the periodic random process $f(t,\omega)$, we use a Fourier-type expansion

$$\hat{f}(t,\omega) = \sum_{n=-K}^{K} f_n(\omega) e^{-int} \tag{5.2}$$

for its characterization by a finite number of random variables. Here, the coefficients $f_n(\omega) = f_n^r(\omega) + i f_n^i(\omega)$ are complex random variables. It is straightforward to show that if f_n^r and f_n^i are statistically independent for all n and have zero mean and variance of $C_n/4$, where $C_n = \frac{1}{\pi}\int_0^{2\pi} C_f(t)\cos(nt)dt$ are the coefficients of the Fourier cosine series of the 2π-periodic covariance function C_f, then the random field $\hat{f}(t,\omega)$ given by (5.2) approximates the prescribed 2π-periodic covariance function $C_{\hat{f}} \to C_f$ as $K \to \infty$. Let $y(\omega) = (f_0^r, f_1^r, f_1^i, \ldots, f_K^r, f_K^i)$, then $\hat{f}(t,\omega) \equiv \hat{f}(t, y(\omega))$ has $(2K+1)$ random dimensions. (Note f_0^i does not take effect in (5.2).) Obviously, $\hat{f}(t, y(\omega))$ is an approximation of $f(t,\omega)$, as (5.2) is a finite-term summation. In practice, we choose the number of expansion terms so that the contributions from the truncated terms are sufficiently small.

In this numerical example, we choose a 2π-periodic covariance function C_f by extending the standard Gaussian covariance function $C_G(t) = \exp(-t^2/b^2)$ to the

(a) (b)

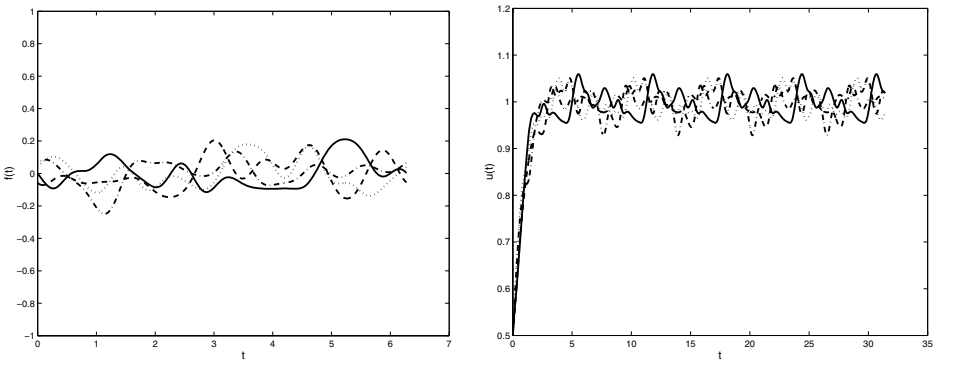


FIG. 5.1. *Construction of a 2π-periodic covariance function C_f.* (a) *Decay of Fourier cosine coefficients $C_n, n = 0, 1, \ldots$;* (b) *reconstructed periodic covariance function (solid line) by extending the regular Gaussian covariance function (dashed line) $C_G(t) = \exp(t^2/b^2)$ with correlation length $b = 0.4$.*

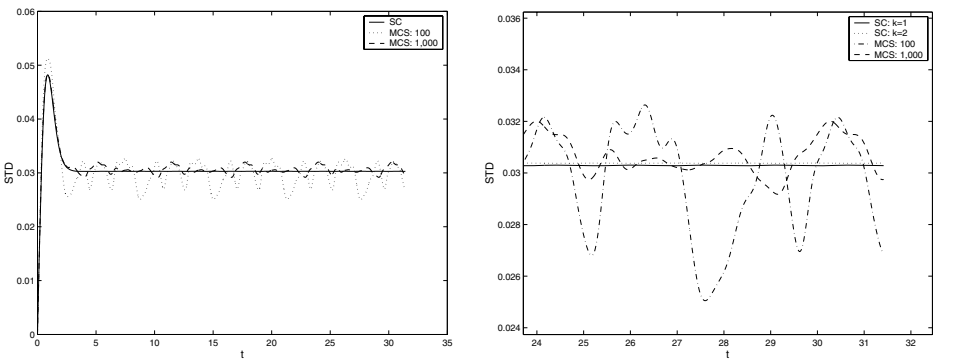
periodic domain $(0, 2\pi)$, where b is the correlation length. Hereafter we choose a moderately short correlation length $b = 0.4$. In Figure 5.1(a), the decay of the Fourier cosine coefficient of C_f is shown. Due to the relatively fast decay of these coefficients, we choose to use $K = 10$ in the truncated series (5.2). Thus, $\hat{f}(t, y)$ has $N = 2K+1 = 21$ random dimensions. The constructed covariance function $C_{\hat{f}}(t)$ is shown in Figure 5.1(b), along with the standard nonperiodic Gaussian covariance function C_G, which we extended to the periodic domain.

Figure 5.2(a) shows four (arbitrarily chosen) realizations of $\hat{f}(t, y)$, constructed by $N = 21(K = 10)$ dimensions with correlation length $b = 0.4$ and $\sigma = 0.1$. Corresponding to these four realizations of forcing, the four realizations of solution to (5.1), with initial condition $x_0 = 0.5$, are shown in Figure 5.2(b). In this case, all realizations are attracted to one of the stable wells ($x = 1$) and oscillate nonlinearly around it. Subsequently, $\mathbb{E}[u(t)] \to 1$ and $\mathbb{E}[u^2(t)] \to \sigma_u^2 = \text{const.}$ as $t \to \infty$. The computational results of the evolution of the standard deviation $\sigma_u(t)$ is shown in Figure 5.3. Stochastic collocation based on the Smolyak grid $A(N + k, N)$ is conducted for $k = 1$ and $k = 2$. With $N = 21$, $A(N+1, N)$ has 43 points and $A(N+2, N)$ has 925 points. The results of standard deviation with $k = 2$ shows little visual difference compared to $k = 1$, and is regarded as the well-resolved solution. Results by Monte Carlo simulation are also shown in Figure 5.3. We observe the numerical oscillations resulted from the statistical errors, and the reduction of such errors from 100 realizations to 1,000 realizations is rather modest.



Problem (5.1) can also be solved via a stochastic Galerkin method. In the stochastic Galerkin method, we expand the solution as $u(t, y) = \sum_{i=1}^{M} u_i(t)\Phi_i(y)$, where $\{\Phi_i(y)\}$ is the multidimensional orthogonal basis defined in (2.13). The resulting equations for the expansion coefficients take the form

(5.3)
$$\frac{du_m}{dt}(t) = x_m - \frac{1}{\langle \Phi_m^2 \rangle} \sum_{i=1}^{M} \sum_{j=1}^{M} \sum_{k=1}^{M} x_i x_j x_k \langle \Phi_i \Phi_j \Phi_k \Phi_m \rangle + f_m(t), \qquad m = 1, \ldots, M,$$

(a) (b)

FIG. 5.2. *Realizations of problem* (5.1). (a) *Four realizations of the periodic random forcing* $\hat{f}(t, y(\omega))$*;* (b) *four realizations of the solution* $u(t, y(\omega))$ *corresponding to the four realizations of forcing on the left.*

where $\{f_i(t)\}$ are the expansion coefficients for the random forcing term. Solution of each of the M number of equations requires a M^3 triple summations and storage (or on-the-fly evaluations) of the constants $\langle \Phi_i \Phi_j \Phi_k \Phi_m \rangle$ of the size M^4. In the case here, when $N = 21$, $M = 22$ for first-order expansion, and $M = 252$ for second-order expansion. Neither the storage nor computing of these is negligible.

6. Summary. A class of high-order collocation methods is proposed in this paper. The method is a forge of several known mathematical and numerical components, e.g., sampling method, cubature formula/sparse grid, and collocational method. Its formulation is similar to that of a Monte Carlo method, where a deterministic equation is solved repetitively at each discrete point in the random space. However, in collocation methods the distribution of collocation points is fixed deterministically a priori and is determined through the aid of existing theory of multivariate polynomial inter-

polation (or integration). Furthermore, by constructing the appropriate polynomial interpolations, stochastic collocation methods can achieve fast convergence (exponential convergence under sufficient smoothness conditions), similar to stochastic Galerkin methods. Thus, the stochastic collocation methods can be regarded as high-order "deterministic sampling methods." Also, when the interpolation error of certain collocation nodes is known, as in the case of the Smolyak sparse grid, we can obtain error estimates in strong form (e.g., the error estimate in (4.7)), whereas in cubature sampling or statistical sampling methods the interpolation errors are usually not known.

Several choices of the collocation nodal sets were investigated. It was found that the sparse grid based on Smolyak algorithm offers high accuracy and fast convergence, with a weak dependence on the number of random dimensions. An alternative, based on the Stroud-2 and -3 cubature, is optimal at lower orders. However, their accuracy is fixed and cannot be improved. Numerical experiments were conducted on an elliptic equation with random inputs, and we demonstrate that the error estimate can be effectively separated into two parts: one for the standard spatial discretization error and one for the interpolation error in random space. It was found that for random dimensions as high as 50, the stochastic collocation methods (including both Stroud's methods and Smolyak methods) are more efficient than brute-force Monte Carlo methods. With low accuracy, the Stroud-3 method is preferred to the Smolyak method with degree one ($k = 1$). On the other hand, the implementation of a collocation method is "embarrassingly" trivial, when compared to a stochastic Galerkin method which requires a specialized solver for the resulting coupled set of equations. However, the high-order collocation method based on Smolyak sparse grid has more degrees-of-freedom than Galerkin methods in complete polynomial spaces. An example of a time dependent nonlinear ODE is also presented. The collocation method exhibits good convergence and accuracy for a 21-dimensional random input. This problem has a cubic nonlinearity, and a stochastic Galerkin approach, albeit with less expansion terms compared to the sparse grid collocation method, would incur nonnegligible extra computation cost due to the nonlinearity. The choice between a collocation method and a Galerkin method is problem dependent, and the advantage of collocation methods will be more noticeable for problems with more complicated forms of governing equations. A complete comparison between collocation and Galerkin methods depends on many factors, including detailed error estimates (particularly, in this paper we did not study the aliasing error by collocation methods) and assessment of the algorithm efficiency for a Galerkin method (for solving the coupled set of equations). This is our ongoing research.

A SECOND ORDER ACCURATE EMBEDDED BOUNDARY METHOD FOR THE WAVE EQUATION WITH DIRICHLET DATA*

HEINZ-OTTO KREISS† AND N. ANDERS PETERSSON‡

Abstract. The accuracy of Cartesian embedded boundary methods for the second order wave equation in general two-dimensional domains subject to Dirichlet boundary conditions is analyzed. Based on the analysis, we develop a numerical method where both the solution and its gradient are second order accurate. We avoid the small-cell stiffness problem without sacrificing the second order accuracy by adding a small artificial term to the Dirichlet boundary condition. Long-time stability of the method is obtained by adding a small fourth order dissipative term. Several numerical examples are provided to demonstrate the accuracy and stability of the method. The method is also used to solve the two-dimensional TM_z problem for Maxwell's equations posed as a second order wave equation for the electric field coupled to ordinary differential equations for the magnetic field.

Key words. wave equation, stability, accuracy, embedded boundary

1. Introduction.

Consider the Dirichlet problem for the second order wave equation in a two-dimensional domain Ω with boundary Γ:

$$u_{tt} = \Delta u + F(\boldsymbol{x}, t), \quad \boldsymbol{x} \in \Omega, \quad t \geq 0, \tag{1}$$

$$u(\boldsymbol{x}, t) = f(\boldsymbol{x}, t), \quad \boldsymbol{x} \in \Gamma, \quad t \geq 0, \tag{2}$$

$$u(\boldsymbol{x}, 0) = u_0(\boldsymbol{x}), \quad \boldsymbol{x} \in \Omega, \tag{3}$$

$$u_t(\boldsymbol{x}, 0) = u_1(\boldsymbol{x}), \quad \boldsymbol{x} \in \Omega. \tag{4}$$

In this paper we continue the approach started in [1] and [2] and develop a numerical method that directly discretizes the second order wave equation. This approach is motivated by wave propagation problems from applications such as seismology, acoustics, and general relativity, where the underlying differential equations are systems of second order hyperbolic partial differential equations. For every second order hyperbolic system, there is an equivalent but larger first order hyperbolic system. For example, two-dimensional acoustic wave propagation is governed by a scalar second order wave equation for the pressure or by a system of three first order hyperbolic equations for the two velocity components and the pressure. Hence, the obvious advantage of the second order formulation is that the size of the system is reduced. Both continuous formulations need one boundary condition to form a well-posed initial-boundary value problem, which means that two extrapolation boundary conditions must be supplied to close the discretized first order system. This can be done, but one has to be careful not to introduce instabilities [3]. Furthermore, if the solution is not properly resolved

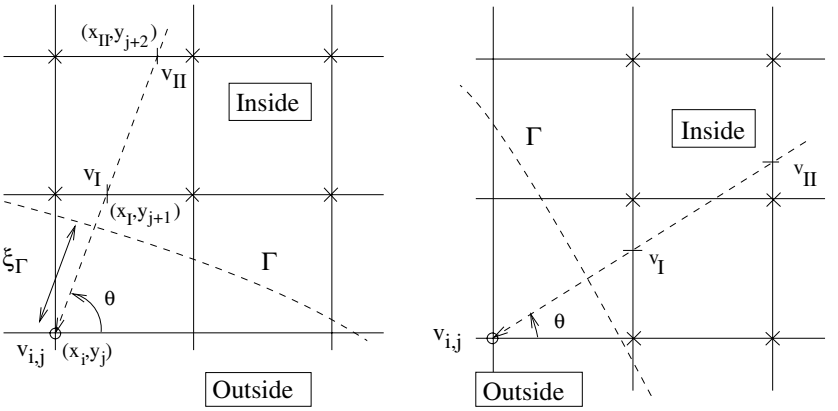

FIG. 1. *The points used for discretizing the Dirichlet boundary condition for the cases of horizontal interpolation (left) and vertical interpolation (right).*

on the grid, the discretized first order system allows for spurious waves that travel in the wrong direction [4]. The latter two problems can be circumvented by using a staggered grid (which amounts to nothing else but solving the original second order problem in disguise). However, when the boundary is not aligned with the grid, it is hard to find an accurate and stable staggered grid discretization of the boundary conditions. In contrast, the second order formulation does not need extrapolation boundary conditions and, as we have shown in [1], a node based discretization of the second order formulation avoids the difficulties with spurious waves traveling in the wrong direction. The subject of the present paper is to derive a stable second order accurate discretization of the wave equation subject to Dirichlet boundary conditions on boundaries that are not aligned with the grid.

A Cartesian embedded boundary approach will be used to solve the above problem numerically. We cover the domain Ω by a regular Cartesian grid with points $\boldsymbol{x}_{i,j} = (ih, jh)^T$, where i, j are integers and h is the grid size. The boundary is allowed to intersect the grid in an arbitrary manner; see Figure 1. Centered finite differences are used to discretize the wave equation in both space and time and the boundary condition is approximated using straightforward interpolation. However, the details of how the boundary condition is discretized are important since they determine the accuracy and stability of the numerical method. In the current paper, we discretize the Dirichlet boundary condition such that both the solution and its gradient become second order accurate. Furthermore, we add an artificial term to the discrete boundary condition that removes the stiffness due to small cells cut by the boundary without sacrificing the second order accuracy of the method. As a result, we can use an explicit time-integration method where the time step essentially equals that of a periodic domain. Stability of the method is obtained by using a small fourth order stabilizing term of the form $h^3 A^T A u_t$, where A is the matrix representation of the discrete Laplace operator satisfying the discrete boundary condition [2].

The embedded boundary technique for discretizing partial differential equations dates back to the first order technique by Weller and Shortley [5] and the higher order generalizations of Collatz [6]. More recently, several embedded boundary methods have been presented for various types of partial differential equations. For example, Pember et al. [7] used a Cartesian grid method for solving the time-dependent equa-

tions of gas dynamics. For the one- and two-dimensional Euler equations, Berger, Helzel, and LeVeque [8] developed a Cartesian "h-box" method which aims at avoiding the small-cell time step restriction without sacrificing accuracy. Zhang and LeVeque [9] solved the acoustic wave equation with discontinuous coefficients written as a first order system. A staggered grid method was used by Ditkowski, Dridi, and Hesthaven [10] for solving Maxwell's equations on a Cartesian grid. The methods described in these papers all solve first order systems (in time). For Poisson's equation with Dirichlet boundary conditions, Johansen and Colella [11] derived an embedded boundary technique based on the finite volume method combined with multigrid. More recently, Li and Greengard [12] developed a method for the scalar second order wave equation in two space dimensions, which combines a free-space Green's function evolution formula with an integral equation technique to satisfy Dirichlet or Neumann boundary conditions.

We have previously developed a Cartesian embedded boundary method for solving the wave equation subject to Dirichlet conditions [1]. That numerical method produces a solution that is second order accurate in max-norm, but the gradient of the solution is only first order accurate. Having accurate gradients is important in applications such as the elastic wave equation, where the stresses depend on the gradient of the displacement and the boundary condition on a free surface is expressed in terms of the stresses. As a step toward solving the elastic wave equation, we will here consider Maxwell's equations written as a second order wave equation for the electric field. In this application it is important to compute the gradient of the electric field to second order accuracy, since the time derivative of the magnetic field depends on the curl of the electric field.

There are two reasons why difference methods that use the embedded boundary discretization technique have problems calculating gradients with full accuracy:

1. Even if the initial data are fully compatible with the boundary condition for the analytic problem, the spatial discretization can destroy the compatibility on the truncation error level, which can degrade the rate of convergence for the gradient. This problem occurs already in one space dimension, and in section 2 we will discuss how it can be avoided by using a "smooth start" procedure, where we change variables

$$u(\boldsymbol{x},t) = \tilde{u}(\boldsymbol{x},t) + (u_0(\boldsymbol{x}) + t u_1(\boldsymbol{x}))e^{-t^2} \tag{5}$$

   and numerically solve the problem for $\tilde{u}$. Since the new variable $\tilde{u}$ satisfies a modified wave equation subject to homogeneous initial conditions, there will be no incompatibilities on the truncation error level for the solution or its first time derivative.
2. Because the boundary is embedded in a regular Cartesian grid, the truncation error in the boundary condition can oscillate wildly between consecutive grid points along the boundary. This problem occurs in two or more space dimensions and can again degrade the rate of convergence for the gradient. In section 3, we first analyze this problem for Poisson's equation and then show that the wave equation behaves in the same way as long as the truncation error is smooth in time and compatible with the initial conditions. The analysis shows that due to the highly oscillatory truncation error, the Dirichlet boundary condition must be discretized using a third order accurate formula to obtain a second order accurate gradient of the solution. The analysis also shows that a second order truncation error that varies smoothly along the

boundary also results in a second order accurate gradient.

Guided by these results, we develop a new Cartesian embedded boundary method for the Dirichlet problem which we outline now. Let $v_{i,j}(t)$ denote the semidiscrete approximation of $u(x_i, y_j, t)$. A second order approximation of the Laplacian of u is given by

$$\Delta_h v_{i,j} =: \frac{1}{h^2}(v_{i+1,j} + v_{i-1,j} + v_{i,j+1} + v_{i,j-1} - 4v_{i,j}). \tag{6}$$

To be able to evaluate $\Delta_h v_{i,j}$ at all grid points inside Ω, we use ghost points just outside the domain; see Figure 1. Let x_I, x_{II} be the intersections between the normal going through $\boldsymbol{x}_{i,j}$ and the grid lines $y = y_{j+1}$ and $y = y_{j+2}$, respectively. Denote by ξ_I, $\xi_{II} = 2\xi_I$ the distances between $\boldsymbol{x}_{i,j}$ and (x_I, y_{j+1}), (x_{II}, y_{j+2}), respectively. To aid in the approximation of the Dirichlet condition, we construct a Lagrange interpolant between three points along the normal: $(0, v_{i,j})$, (ξ_I, v_I), (ξ_{II}, v_{II}),

$$Lv =: g_0(\xi_\Gamma)v_{i,j} + g_I(\xi_\Gamma)v_I + g_{II}(\xi_\Gamma)v_{II}, \tag{7}$$

where the coefficients are given by

$$g_0(\xi) = \frac{(\xi_I - \xi)(2\xi_I - \xi)}{2\xi_I^2}, \quad g_I(\xi) = \frac{\xi(2\xi_I - \xi)}{\xi_I^2}, \quad g_{II}(\xi) = \frac{\xi(\xi - \xi_I)}{2\xi_I^2}. \tag{8}$$

To approximate v_I and v_{II}, we interpolate along the horizontal grid lines y_{j+1} and y_{j+2}:

$$v_I = d_1 v_{i,j+1} + d_2 v_{i+1,j+1} + d_3 v_{i+2,j+1}, \tag{9}$$

$$v_{II} = d_4 v_{i,j+2} + d_5 v_{i+1,j+2} + d_6 v_{i+2,j+2}, \tag{10}$$

where $d_k = \mathcal{O}(1)$ are the quadratic Lagrange interpolation coefficients. The interpolant $Lu(t)$ is a third order approximation of the boundary value, i.e., $Lu(t) = u(\boldsymbol{x}_{i,j}^\Gamma, t) + \mathcal{O}(h^3)$, where $\boldsymbol{x}_{i,j}^\Gamma$ is the intersection point between the boundary and the normal going through the ghost point $\boldsymbol{x}_{i,j}$.

The interpolation formulas for v_I and v_{II}, (9)–(10), hold when the angle θ between the normal and the x-axis satisfies $\pi/4 \le \theta \le \pi/2$. When $0 \le \theta \le \pi/4$, the horizontal interpolations are replaced by corresponding interpolations in the vertical direction; see Figure 1. Despite the sudden switching between horizontal and vertical interpolation at $\theta = \pi/4$, the interpolation formulas for v_I and v_{II} are Lipschitz continuous in θ. Approaching the limit from above, the coefficients in the horizontal interpolation formulas (9)–(10) tend to $d_2 = d_6 = 1$, $d_1 = d_3 = d_4 = d_5 = 0$. Geometrically, this corresponds to the normal intersecting the mesh along the diagonal, so $v_I = v_{i+1,j+1}$ and $v_{II} = v_{i+2,j+2}$. The same limit is found with the corresponding vertical interpolation formulas as $\theta \to \pi/4$ from below. The Lipschitz continuity also holds at $\theta = \pi/2$, where the horizontal interpolation switches from using points to the right of the ghost point to using points to the left of it. At $\theta = \pi/2$, both the left and the right interpolation formulas use $v_I = v_{i,j+1}$ and $v_{II} = v_{i,j+2}$. The same argument shows Lipschitz continuity at $\theta = 0$, where the vertical interpolation switches from using points above the ghost point to using points below it. The formulas in the other three quadrants are simply obtained by reflections in index space, leading to a total of 8 different cases to treat all possible directions of the boundary.

When the normal is close to vertical (or horizontal), the boundary can intersect the grid such that ξ_Γ is arbitrarily close to ξ_I; i.e., $g_0(\xi_\Gamma)$ can be arbitrarily close to

zero. The limit $\xi_\Gamma = \xi_I$ corresponds to v_I being on the boundary and coinciding with a grid point, in which case one could eliminate the ghost point from the computation and simply use $v_I = f$ as a discrete boundary condition. This could be achieved for one ghost point by shifting the mesh appropriately. But for a general two-dimensional domain discretized on a fine grid, there can be thousands of ghost points and it is not possible to move the mesh to ensure that ξ_Γ stays bounded away from ξ_I for all ghost points simultaneously. Hence, it is important that the discretization of the boundary condition works for arbitrarily small $g_0(\xi_\Gamma)$.

If (7) were used to approximate the boundary condition, i.e., $Lv(t) = f(\boldsymbol{x}_{i,j}^\Gamma, t)$, we would need to divide by $g_0(\xi_\Gamma)$ to solve for the ghost point value using

$$v_{i,j} = \frac{1}{g_0(\xi_\Gamma)} \left(f(\boldsymbol{x}_{i,j}^\Gamma, t) - g_I(\xi_\Gamma) v_I - g_{II}(\xi_\Gamma) v_{II} \right). \tag{11}$$

The ghost point value is used to evaluate the discrete Laplacian (6), and as we demonstrate for the one-dimensional case in Appendix A, (11) would make the time-stepping of (1) very stiff as $g_0 \to 0$. This phenomenon is known as the small-cell stiffness problem. To mitigate the stiffness, we add an artificial term to the interpolant (7) and instead consider

$$B_h v(t) =: g_0(\xi_\Gamma) v_{i,j} + g_I(\xi_\Gamma) v_I + g_{II}(\xi_\Gamma) v_{II} + \gamma(v_{i,j} - 2v_I + v_{II}) = f(\boldsymbol{x}_{i,j}^\Gamma, t), \tag{12}$$

where the constant $\gamma > 0$. The artificial term is an undivided second difference in the normal direction, and thus it inflicts an $\mathcal{O}(h^2)$ error in the boundary condition approximation. When the direction of the normal changes smoothly along the boundary, the error due to the artificial term also varies smoothly along the boundary. This is precisely the situation analyzed in section 3, since the truncation error in the boundary condition is composed of a highly oscillatory $\mathcal{O}(h^3)$ part and a smooth $\mathcal{O}(h^2)$ component. The accuracy of both the solution and its discrete gradient should therefore be $\mathcal{O}(h^2)$.

Because of the artificial term in the boundary condition, the coefficient in front of the ghost point $v_{i,j}$ is bounded uniformly away from zero, since

$$\gamma \le g_0(\xi_\Gamma) + \gamma < 1 + \gamma.$$

As a result, the small-cell stiffness problem is removed. By estimating the spectrum for the one-dimensional wave equation, we find that the eigenvalue with the largest magnitude is independent of small cells near the boundary when $\gamma \ge 0.25$; see Appendix A. Numerical computations indicate that $0.2 \le \gamma \le 0.5$ works well in practice; i.e., it is big enough to allow the time step to be chosen independently of the small cells near the boundary but small enough to prevent the artificial term from dominating the error in the numerical solution.

We can use the boundary condition (12) to eliminate all ghost points in the discrete Laplacian (6). For example, at the point $(i, j+1)$ in the left part of Figure 1 we get

$$\begin{aligned} \Delta_h v_{i,j+1} = {} & \frac{1}{h^2}(v_{i+1,j+1} + v_{i-1,j+1} + v_{i,j+2} - 4v_{i,j+1}) \\ & - \frac{(g_I - 2\gamma)}{h^2(g_0 + \gamma)}(d_1 v_{i,j+1} + d_2 v_{i+1,j+1} + d_3 v_{i+2,j+1}) \\ & - \frac{(g_{II} + \gamma)}{h^2(g_0 + \gamma)}(d_4 v_{i,j+2} + d_5 v_{i+1,j+2} + d_6 v_{i+2,j+2}) + \frac{f(\boldsymbol{x}_{i,j}^\Gamma, t)}{h^2(g_0 + \gamma)}, \end{aligned} \tag{13}$$

assuming that (i,j) is the only nearest neighbor of $(i,j+1)$ that is outside of Ω. (If additional points are outside, other formulas of the type (12) would be used to eliminate those points as well.) The expression (13) defines the discrete boundary forcing function $\boldsymbol{b}$ at point $(i,j+1)$:

$$\boldsymbol{b}_{i,j+1}(t) = \frac{f(\boldsymbol{x}^{\Gamma}_{i,j}, t)}{h^2(g_0+\gamma)}. \tag{14}$$

In the interior of Ω, i.e., for points $\boldsymbol{x}_{i,j}$ where $\boldsymbol{x}_{i\pm1,j}$ and $\boldsymbol{x}_{i,j\pm1}$ are all inside Ω, $\boldsymbol{b}^n_{i,j} = 0$.

After all ghost points have been eliminated, the discrete approximation of the Laplacian of u (for functions satisfying the boundary condition $u = f(\boldsymbol{x}^{\Gamma}, t)$) can be written in matrix form

$$\Delta u(\boldsymbol{x}, t) \approx A\boldsymbol{v}(t) + \boldsymbol{b}(t). \tag{15}$$

Here the array $\boldsymbol{v}$ contains the solution at all grid points inside Ω. Using this notation, the semidiscrete approximation of (1)–(4) becomes

$$\boldsymbol{v}_{tt} = A\boldsymbol{v} + \boldsymbol{b}(t) + \boldsymbol{F}(t), \quad t \geq 0, \tag{16}$$

$$\boldsymbol{v}(0) = u_0(\boldsymbol{x}), \qquad \boldsymbol{x} \in \Omega, \tag{17}$$

$$\boldsymbol{v}_t(0) = u_1(\boldsymbol{x}), \qquad \boldsymbol{x} \in \Omega, \tag{18}$$

where $\boldsymbol{F}_{i,j}(t) = F(\boldsymbol{x}_{i,j}, t)$ for all $\boldsymbol{x}_{i,j} \in \Omega$.

We discretize the second order time derivative in (16) using a centered finite difference formula on the regular grid $t_n = nk$, $n = 0, 1, 2, \ldots$, where $k > 0$ is the time step. Let $\boldsymbol{v}^n = \boldsymbol{v}(t_n)$ and $\boldsymbol{b}^n = \boldsymbol{b}(t_n)$. Because of the discretized form of the Dirichlet boundary condition, the matrix A in (16) will not be symmetric. To avoid the resulting mild instability which was analyzed for the Neumann problem in [2], we use the discrete stabilization operator $h^3 A^T[A(\boldsymbol{v}^n - \boldsymbol{v}^{n-1})/k + d\boldsymbol{b}/dt(t_n)]$, which was proposed in the same paper. Note the time derivative of the boundary forcing is included within the brackets to make that expression a consistent approximation of Δu_t, for functions satisfying the boundary condition $u_t = f_t(\boldsymbol{x}^{\Gamma}, t)$. Also note that the discrete stabilization operator can be applied all the way up to the boundary. Away from the boundary, it is equivalent to $h^3\Delta_h^2(\boldsymbol{v}^n - \boldsymbol{v}^{n-1})/k$, which is a very efficient damping term for highly oscillatory instabilities. For the case with inhomogeneous boundary conditions and internal forcing, the proposed scheme becomes

$$\frac{\boldsymbol{v}^{n+1} - 2\boldsymbol{v}^n + \boldsymbol{v}^{n-1}}{k^2} = A\boldsymbol{v}^n + \boldsymbol{b}^n + \boldsymbol{F}(t_n) - \alpha h^3 A^T \left((A\boldsymbol{v}^n - A\boldsymbol{v}^{n-1})/k + \frac{d\boldsymbol{b}}{dt}(t_n) \right). \tag{19}$$

The numerical experiments in section 4 indicate that $\alpha = \mathcal{O}(10^{-3})$ suffices to stabilize the scheme for long time computations. We note that the sparse structure of A can be used to efficiently evaluate both $A\boldsymbol{v}$ and $A^T\boldsymbol{v}$ without the need to store the matrix explicitly; see [2]. Also note that this scheme bears many similarities with our method for the Neumann problem [2]. In particular, both methods use the same set of grid points for discretizing the boundary condition and the same type of stabilization term. Hence, the two methods can be combined in a straightforward manner to solve problems with mixed Neumann–Dirichlet conditions.

The remainder of the paper is organized as follows. The influence of incompatibilities between initial and boundary data on the truncation error level is analyzed in section 2 and the effect of highly oscillatory truncation errors in the boundary condition is studied in section 3. Two-dimensional numerical experiments are performed in section 4. We first construct a smooth solution against which the error in the numerical solution can be evaluated. The accuracy of the scheme and effects of the smooth start technique are evaluated in section 4.1. In section 4.2 we test the method by solving the TM_z problem for Maxwell's equations, i.e., the case when the electric field only has a component in the z-direction and the magnetic field has no component in the z-direction. The TM_z problem can be formulated as a scalar wave equation for the electric field in the (x, y) plane, subject to a Dirichlet boundary condition. The wave equation for the electric field is coupled to ODEs for the magnetic field that are integrated in time as the electric field is evolved. This is a good test of the scheme, since the accuracy of the magnetic field is determined by the accuracy of the curl of the electric field. Numerical experiments are performed for a circular domain where the numerical solution is compared to an analytic solution, as well as for more complex domains. Concluding remarks are presented in section 5.

2. Smooth start. We start by considering the one-dimensional half-plane problem

$$u_{tt} = u_{xx} + F(x,t), \quad a \le x < \infty, \quad t \ge 0, \tag{20}$$

with initial data

$$u(x,0) = u_0(x), \quad u_t(x,0) = u_1(x) \tag{21}$$

and the boundary condition

$$u(a,t) = f(t). \tag{22}$$

We henceforth assume that all data belong to C^∞. Therefore also the solution is smooth, provided compatibility conditions are satisfied. In the one-dimensional setting, these are

$$\begin{aligned}
u(a,0) &= u_0(a) = f(0),\\
u_t(a,0) &= u_1(a) = f_t(0),\\
u_{tt}(a,0) &= u_{0xx}(a) + F(a,0) = f_{tt}(0),\\
u_{ttt}(a,0) &= u_{1xx}(a) + F_t(a,0) = f_{ttt}(0),\\
u_{tttt}(a,0) &= u_{0xxxx}(a) + F_{xx}(a,0) + F_{tt}(a,0) = f_{tttt}(0),\\
u_{ttttt}(a,0) &= u_{1xxxx}(a) + F_{xxt}(a,0) + F_{ttt}(a,0) = f_{ttttt}(0),\\
&\vdots
\end{aligned} \tag{23}$$

We introduce a grid

$$x_\nu = \nu h, \quad \nu = 0, 1, 2, \ldots, \tag{24}$$

where $h > 0$ is the grid size. When the boundary is aligned with the grid, e.g., $a = 0$, a second order centered finite difference approximation of (20)–(22) yields the expected second order convergence of the numerical solution and its gradient. However, we are

interested in the case when the boundary is not aligned with the grid. We therefore take $a = (1-\beta)h$, $0 < \beta < 1$, so that the boundary falls between x_0 and x_1. Hence, the grid point x_0 is outside the domain but will be used as a ghost point to aid in the difference approximation. Let $v(x_j, t)$ be a grid function approximating $u(x_j, t)$. The one-dimensional counterpart of the boundary condition (12) is

$$B_h^{(1)} v(t) =: c_0(\beta)v(x_0,t) + c_1(\beta)v(x_1,t) + c_2(\beta)v(x_2,t) + \gamma(v(x_0,t) - 2v(x_1,t) + v(x_2,t)) = f(t), \quad \gamma > 0, \tag{25}$$

where the coefficients satisfy

$$c_0(\beta) = \frac{1}{2}\beta(1+\beta), \quad c_1(\beta) = (1-\beta)(1+\beta), \quad c_2(\beta) = -\frac{1}{2}\beta(1-\beta). \tag{26}$$

Similar to the two-dimensional case, we remove the stiffness in the time integration by taking $\gamma > 0$ such that the coefficient in front of $v(x_0, t)$ is bounded away from zero for $0 \le \beta \le 1$.

The semidiscrete difference approximation of (20)–(22) when the boundary is not aligned with the grid becomes

$$v_{tt}(x_\nu, t) = D_+^x D_-^x v(x_\nu, t) + F(x_\nu, t), \quad \nu = 1, 2, \ldots, \tag{27}$$

$$v(x_\nu, 0) = u_0(x_\nu), \quad v_t(x_\nu, 0) = u_1(x_\nu), \quad \nu = 1, 2, \ldots, \tag{28}$$

$$B_h^{(1)} v(t) = f(t), \tag{29}$$

where $D_+^x v(x_\nu, t) = (v(x_{\nu+1}, t) - v(x_\nu, t))/h$ is the usual forward divided difference operator in the x-direction and $D_-^x v(x_\nu, t) = D_+^x v(x_{\nu-1}, t)$. For later use, we also define the centered operator $D_0^x v(x_\nu, t) = (v(x_{\nu+1}, t) - v(x_{\nu-1}, t))/(2h)$. Using Taylor series expansions, we see that the error $e(x_\nu, t) = u(x_\nu, t) - v(x_\nu, t)$ satisfies

$$e_{tt}(x_\nu, t) = D_+^x D_-^x e(x_\nu, t) - \frac{h^2}{12} u_{xxxx}(x_\nu, t) + \mathcal{O}(h^4), \quad \nu = 1, 2, \ldots, \tag{30}$$

$$e(x_\nu, 0) = e_t(x_\nu, 0) = 0, \quad \nu = 1, 2, \ldots, \tag{31}$$

$$B_h^{(1)} e(t) = \gamma h^2 u_{xx}(a, t) + h^3 (C + \gamma\beta) u_{xxx}(a, t) + \mathcal{O}(h^4). \tag{32}$$

Since the data are $\mathcal{O}(h^2)$, $|e(\cdot, t)|_\infty = \mathcal{O}(h^2)$. To derive an estimate for the gradient of e, we first derive an equation for $w = e_{tt}$. By taking two time derivatives of the differential equation (30) and the boundary condition (32), we get

$$w_{tt}(x_\nu, t) = D_+^x D_-^x w(x_\nu, t) - \frac{h^2}{12} u_{xxxxtt}(x_\nu, t) + \mathcal{O}(h^4), \quad \nu = 1, 2, \ldots,$$

$$B_h^{(1)} w(t) = \gamma h^2 u_{xxtt}(a, t) + h^3 (C + \gamma\beta) u_{xxxtt}(a, t) + \mathcal{O}(h^4).$$

To derive initial data for w, we can apply the differential equation (30) to the initial data (31). However, this only applies away from the boundary. For $\nu \ge 2$ we have

$$w(x_\nu, 0) = -\frac{h^2}{12} u_{xxxx}(x_\nu, 0) + \mathcal{O}(h^4), \quad \nu = 2, 3, \ldots,$$

$$w_t(x_\nu, 0) = -\frac{h^2}{12} u_{xxxxt}(x_\nu, 0) + \mathcal{O}(h^4), \quad \nu = 2, 3, \ldots .$$

To evaluate the initial data at the first interior point x_1, we must first apply the boundary condition (32) to define $e(x_0, 0)$:

$$B_h^{(1)} e(0) =: (c_0 + \gamma)e(x_0, 0) + (c_1 - 2\gamma)e(x_1, 0) + (c_2 + \gamma)e(x_2, 0) \\ = \gamma h^2 u_{xx}(a, 0) + h^3(C + \gamma\beta)u_{xxx}(a, 0) + \mathcal{O}(h^4).$$

Since $e(x_1, 0) = e(x_2, 0) = 0$, $D_+^x D_-^x e(x_1, 0) = e(x_0, 0)/h^2$. Therefore, (30) gives us

$$w(x_1, 0) = e_{tt}(x_1, 0) = \frac{\gamma}{c_0 + \gamma} u_{xx}(a, 0) + \frac{h(C + \gamma\beta)}{c_0 + \gamma} u_{xxx}(a, 0) + \mathcal{O}(h^2).$$

By taking the time derivative of the boundary condition, the same procedure can be used to obtain

$$w_t(x_1, 0) = e_{ttt}(x_1, 0) = \frac{\gamma}{c_0 + \gamma} u_{xxt}(a, 0) + \frac{h(C + \gamma\beta)}{c_0 + \gamma} u_{xxxt}(a, 0) + \mathcal{O}(h^2).$$

Hence, in general the forcing in the initial data is $\mathcal{O}(1)$ at the first interior point, which makes $|w(\cdot, t)|_\infty = \mathcal{O}(1)$. Consequently, $|D_+^x D_-^x e(\cdot, t)|_\infty = \mathcal{O}(1)$ and we can not obtain the desired estimate for the gradient of e.

The situation is much better in the case with homogeneous initial data, $u_0(x) = u_1(x) = 0$. Now all spatial derivatives of u and u_t are initially zero, so the initial data for w are

$$w(x_\nu, 0) = w_t(x_\nu, 0) = 0, \quad \nu = 1, 2, \ldots .$$

Hence the forcing for w is $\mathcal{O}(h^2)$. Therefore, we can derive an estimate for $|e_{tt}(\cdot, t)|_\infty = |w(\cdot, t)|_\infty = \mathcal{O}(h^2)$ and

$$|D_+^x D_-^x e(\cdot, t)|_\infty \le |w(\cdot, t)|_\infty + \frac{h^2}{12} |u_{xxxx}(\cdot, t)|_\infty = \mathcal{O}(h^2).$$

Since $|D_+^x e(\cdot, t)|_\infty$ can be estimated in terms of e and $D_+^x D_-^x e$ using a discrete Sobolev inequality (see, e.g., [13]), we have

$$|D_+^x e|_\infty = \mathcal{O}(h^2).$$

A problem with general, but compatible, initial data can be reformulated into a problem with homogeneous initial data by changing variables according to (5). If the original variable u satisfies (1)–(4), the variable $\tilde{u}$ satisfies the modified problem

$$\tilde{u}_{tt} = \Delta\tilde{u} + \tilde{F}(\boldsymbol{x}, t), \quad \boldsymbol{x} \in \Omega, \quad t \ge 0, \tag{33}$$

$$\tilde{u}(\boldsymbol{x}, t) = \tilde{f}(\boldsymbol{x}, t), \quad \boldsymbol{x} \in \Gamma, \quad t \ge 0, \tag{34}$$

$$\tilde{u}(\boldsymbol{x}, 0) = 0, \quad \boldsymbol{x} \in \Omega, \tag{35}$$

$$\tilde{u}_t(\boldsymbol{x}, 0) = 0, \quad \boldsymbol{x} \in \Omega, \tag{36}$$

where the modified internal forcing function is

$$\tilde{F}(\boldsymbol{x}, t) = F(\boldsymbol{x}, t) + \left[\Delta u_0(\boldsymbol{x}) + t\Delta u_1(\boldsymbol{x}) + (2 - 4t^2)u_0(\boldsymbol{x}) + (6t - 4t^3)u_1(\boldsymbol{x})\right] e^{-t^2}$$

and the boundary forcing becomes

$$\tilde{f}(\boldsymbol{x}, t) = f(\boldsymbol{x}, t) - [u_0(\boldsymbol{x}) + tu_1(\boldsymbol{x})]e^{-t^2}, \quad \boldsymbol{x} \in \Gamma.$$

To solve the problem for $u(\boldsymbol{x},t)$, we first compute $\tilde{u}(\boldsymbol{x},t)$ numerically and then add in $(u_0(\boldsymbol{x})+tu_1(\boldsymbol{x}))e^{-t^2}$ to obtain the solution of the original problem. By doing so, we obtain a second order accurate solution where the gradient and second derivative of the numerical solution are also second order accurate.

To verify the above theory, we solve the embedded boundary problem (27)–(29) numerically. Now we consider the bounded domain

$$a \le x \le b$$

and add a boundary condition at $x=b$,

$$u(b,t) = f_2(t).$$

The interior grid points are $q_0 \le \nu \le q_1$ such that $a+\beta h = x_{q_0}$ and $x_{q_1}+\beta_2 h = b$, $0<\beta_2<1$. We take initial data, interior forcing function, and boundary forcing functions such that the analytic problem is solved by $u(x,t)=\sin(2x-t+\pi/4)$, i.e.,

$$\begin{aligned} F(x_\nu,t) &= 3\sin(2x_\nu - t + \pi/4),\\ f(t) &= \sin(2a-t+\pi/4),\\ f_2(t) &= \sin(2b-t+\pi/4),\\ u_0(x_\nu) &= \sin(2x_\nu+\pi/4), \quad u_1(x_\nu) = -\cos(2x_\nu+\pi/4). \end{aligned}$$

We introduce a grid in time $t_n = nk$, $k>0$ and discretize time derivatives by centered differences. We set $h=2\pi/N$, where N is a positive integer, so that $x_N = 2\pi$. The boundary condition at $x=a$ is discretized by (25), shifted to involve the points (q_0-1, q_0, q_0+1). The boundary condition at $x=b$ is discretized using a corresponding formula involving the points (q_1-1, q_1, q_1+1) with β_2 replacing β. We arrive at the following explicit time integration scheme:

$$\begin{aligned} D_+^t D_-^t v(x_\nu,t_n) &= D_+^x D_-^x v(x_\nu,t_n) + F(x_\nu,t_n), \quad \nu = q_0, q_0+1,\dots,q_1,\\ v(x_\nu,0) &= u_0(x_\nu), \quad \nu = q_0, q_0+1,\dots,q_1,\\ v(x_\nu,-k) &= u_0(x_\nu) - ku_1(x_\nu) + \frac{k^2}{2}\left(u_{0xx}(x_\nu,0)+F(x_\nu,0)\right)\\ &\qquad -\frac{k^3}{6}\left(u_{1xx}(x_\nu,0)+F_t(x_\nu,0)\right), \quad \nu = q_0, q_0+1,\dots,q_1,\\ B_h^{(a)} v(t_n) &= f(t_n), \quad B_h^{(b)} v(t_n) = f_2(t_n). \end{aligned} \tag{37}$$

One can show that the above scheme is stable for $k/h<1$ when $\gamma \ge 0.25$; see [1] and Appendix A. Numerical computations (see Table 1) indicate that the solution is second order accurate, but the gradient is only a little better than first order accurate and the second derivative has an $\mathcal{O}(1)$ error. However, by using the smooth start procedure, i.e., changing variables according to (5) and numerically solving (33)–(36), second order accuracy is also obtained for the gradient and the second derivative; see Table 2.

We have also observed that the convergence of the gradient improves when the initial data is inhomogeneous, but the interior and boundary forcing functions are homogeneous, $F(x,t)=0$, $f(t)=0$. From the compatibility relations (23), we see that all even spatial derivatives of u and u_t are zero at $x=a$, $t=0$. In particular, $u_{xx}(a,0)=0$ and $u_{xxt}(a,0)=0$, so the leading order terms in the initial data for w become one order smaller in h. Hence, $w(x_1,0)=\mathcal{O}(h)$ and $w_t(x_1,0)=\mathcal{O}(h)$,

TABLE 1

Direct start: Error in the computed solution when the boundary is embedded between grid points. The errors are reported at time $t = 6.333$, the domain is $0.37 \le x \le 5.1$, $\gamma = 0.2$, and $k/h = 0.9$.

N	$\|u - v\|_\infty$	$\|\frac{\partial u}{\partial x} - D_0^x v\|_\infty$	$\|\frac{\partial^2 u}{\partial x^2} - D_+^x D_-^x v\|_\infty$	β	β_2
200	1.22×10^{-3}	9.36×10^{-3}	1.88×10^{0}	0.222	0.338
400	2.53×10^{-4}	3.13×10^{-3}	3.59×10^{-1}	0.445	0.676
800	6.29×10^{-5}	1.26×10^{-3}	2.98×10^{-1}	0.890	0.352

TABLE 2

Smooth start: Error in the computed solution when the boundary is embedded between grid points. The errors are reported at time $t = 6.333$, the domain is $0.37 \le x \le 5.1$, $\gamma = 0.2$, and $k/h = 0.9$.

N	$\|u - v\|_\infty$	$\|\frac{\partial u}{\partial x} - D_0^x v\|_\infty$	$\|\frac{\partial^2 u}{\partial x^2} - D_+^x D_-^x v\|_\infty$	β	β_2
200	8.90×10^{-4}	1.14×10^{-3}	1.02×10^{-3}	0.222	0.338
400	2.22×10^{-4}	2.86×10^{-4}	2.56×10^{-4}	0.445	0.676
800	5.55×10^{-5}	7.09×10^{-5}	6.38×10^{-5}	0.890	0.352

and we get $|w(\cdot,t)|_\infty = \mathcal{O}(h)$. Hence, $|e(\cdot,t)|_\infty = \mathcal{O}(h^2)$ but $|D_+^x D_-^x e(\cdot,t)|_\infty = \mathcal{O}(h)$. Numerical experiments suggest that the solution and its gradient are second order accurate but the second derivative is only first order accurate. Naturally, the error in the second derivative can be made second order accurate also in this case by using smooth start.

There are also cases when the smooth start procedure is not necessary. This occurs, for example, when the boundary data are homogeneous, $f(t) = 0$, and the internal forcing and initial data have compact support in the interior of Ω.

3. An analytic model of the Dirichlet problem. In this section we first consider Poisson's equation

$$u_{xx} + u_{yy} = F(x,y) \tag{38}$$

on the half-plane $y - 2x \le 0$ with Dirichlet boundary conditions

$$u(x,y) = f(x,y) \quad \text{for} \quad y = 2x. \tag{39}$$

We want to solve the problem numerically, use the same Cartesian grid as before, and approximate (38) by the second order approximation

$$\Delta_h v(x_m, y_l) = F_h(x_m, y_l)$$

in all interior points. Here F_h is the restriction of F to the grid.

The grid is not aligned with the boundary. Along the boundary only every second point is on the grid. A second order accurate approximation of (39) is, for example, given by

$$v(lh, 2lh) = f(lh, 2lh), \tag{40}$$

$$\frac{1}{2}\left\{v\big((l-1)h, (2l-1)h\big) + v\big(lh, (2l-1)h\big)\right\} = f\left(\left(l - \frac{1}{2}\right)h, (2l-1)h\right) \tag{41}$$

for $l = 0, \pm 1, \pm 2, \ldots$. We write (40)–(41) formally as

$$B_h v = f_h.$$

To obtain an error estimate we assume that the solution of (38)–(39) is smooth. (This is, for example, the case if F, f are smooth and decay rapidly as $|x| + |y| \to \infty$; cf. [14].) The usual truncation error analysis gives us, for the error $e = v - u$ on the grid,

$$\Delta_h e = h^2 G \quad \text{in the interior,} \tag{42}$$

$$B_h e = h^2 g \quad \text{on the boundary.} \tag{43}$$

Here G is the restriction of a smooth function to the grid but g is, in general, not smooth. The boundary condition (41) implies that g oscillates between 0 and $u_{xx} + \mathcal{O}(h^2)$ from grid point to grid point. This rapid change is typical for embedded boundary difference approximations in general domains.

If we want only to estimate e, this is tolerable because one can prove, using the discrete maximum principle, that the error is $\mathcal{O}(h^2)$. However, if we also want to calculate the gradient, then the error degrades, in general, to $\mathcal{O}(h)$. This degradation does not depend on G. If $G \neq 0$, we solve an auxiliary problem

$$\Delta_h e_1 = h^2 G \quad \text{in the interior,} \tag{44}$$

$$B_h e_1 = 0 \quad \text{on the boundary.} \tag{45}$$

The problem (44)–(45) is a second order accurate approximation of

$$\Delta u_1 = h^2 G \quad \text{in the interior,}$$
$$u_1 = 0 \quad \text{on the boundary.}$$

The function u_1 and its gradient are of order $\mathcal{O}(h^2)$. Since $e_1 - u_1 = \mathcal{O}(h^4)$ on the grid, the discrete gradient of e_1 is $\mathcal{O}(h^2)$. Subtracting the solution of (44)–(45) from the solution of (42)–(43) shows that we can assume that $G \equiv 0$; i.e., we discuss

$$\Delta_h e = 0 \quad \text{in the interior,} \tag{46}$$

$$B_h e = h^2 g \quad \text{on the boundary.} \tag{47}$$

To gain insight into the effects of highly oscillatory boundary data, we analyze a modified equation model of (46)–(47). A more sophisticated analysis, where the discrete nature of the problem is taken into account, will be presented elsewhere. The problem (46)–(47) is a second order accurate approximation of

$$\Delta e = 0, \quad y - 2x \leq 0, \tag{48}$$

$$e = h^2 g, \quad y = 2x, \tag{49}$$

and we proceed by studying the properties of its solution, in particular when g is highly oscillatory. To simplify the notation, we rotate the coordinate system and introduce the new independent variables

$$\xi = (2x - y)/\sqrt{5}, \tag{50}$$

$$\eta = (x + 2y)/\sqrt{5}. \tag{51}$$

The boundary is aligned with $\xi = 0$ and we consider the half-plane problem for $\xi \geq 0$. We assume that all functions are 2π-periodic in η. Fourier transforming (48)–(49) in η gives us

$$\hat{e}_{\xi\xi} - \omega^2 \hat{e} = 0, \quad \omega \text{ integer},$$
$$\hat{e}(0,\omega) = h^2 \hat{g}(\omega).$$

Since we are mainly interested in highly oscillatory g, we always assume that $\hat{g}(0) = 0$. Then the unique solution in L_2 is given by

$$e = h^2 \sum_{\omega \neq 0} e^{-|\omega|\xi + i\omega\eta} \hat{g}(\omega), \tag{52}$$

and we have

$$e_\xi = -h^2 \sum_{\omega \neq 0} |\omega| e^{-|\omega|\xi + i\omega\eta} \hat{g}(\omega).$$

We make the following observations:

(1) If the boundary data are smooth, i.e., $\hat{g}(\omega)$ decays rapidly, then the solution is also smooth up to the boundary.

(2) If we only know that $g \in L_2$, then we obtain, for every fixed ξ,

$$\begin{aligned}\|e_\xi(\xi,\cdot)\|^2 &= \int_{-\pi}^{\pi} |e_\xi(\xi,\eta)|^2 d\eta = \sum_{\omega \neq 0} |\omega|^2 e^{-2|\omega|\xi} |h^2 \hat{g}(\omega)|^2 \\ &= \frac{1}{\xi^2} \sum_{\omega \neq 0} |\xi\omega|^2 e^{-2|\omega|\xi} |h^2 \hat{g}(\omega)|^2 \leq \frac{\text{const.}}{\xi^2} \sum_{\omega \neq 0} e^{-|\omega|\xi} |h^2 \hat{g}(\omega)|^2.\end{aligned}$$

Thus the solution becomes smooth away from the boundary layer at $\xi = 0$.

(3) If the boundary data are highly oscillatory, i.e.,

$$g(\eta) = \sum_{|\omega| \geq 1/h} e^{i\omega\eta} \hat{g}(\omega), \quad 0 < h \ll 1,$$

we obtain

$$\begin{aligned}\|e_\xi(\xi,\cdot)\|^2 &\leq \frac{\text{const.}}{\xi^2} \sum_{|\omega| \geq 1/h} e^{-|\omega|\xi} |h^2 \hat{g}(\omega)|^2 \\ &\leq \frac{\text{const.}}{\xi^2} e^{-\xi/h} \sum_{|\omega| \geq 1/h} e^{-(|\omega| - 1/h)\xi} |h^2 \hat{g}(\omega)|^2;\end{aligned}$$

i.e., the thickness of the boundary layer is $\mathcal{O}(h)$.

(4) The highest frequency on a grid is $|\omega h| = \pi$. Hence, if $\hat{g}(\omega) = 0$ for $|\omega| > \pi/h$, then

$$\|e_\xi(\xi,\cdot)\|^2 = \frac{1}{h^2} \sum_{|\omega h| \leq \pi} |\omega h|^2 e^{-2|\omega|\xi} |h^2 \hat{g}(\omega)|^2 \leq \pi^2 \sum_{|\omega h| \leq \pi} e^{-2|\omega|\xi} |h\hat{g}(\omega)|^2.$$

Thus the gradient is of the order $\mathcal{O}(h)$.

We would like to point out that these estimates correspond to Schauder-type interior regularity estimates; see, e.g., Chapters 4 and 6 of [14].

To summarize our results for the Dirichlet problem for Poisson's equation, the gradient is only of the order $\mathcal{O}(h^2)$ if the boundary data $h^2 g(\eta)$ are the restriction of a smooth function. For highly oscillatory $g(\eta)$, the gradient will be $\mathcal{O}(h)$. We can also use a third order accurate approximation of the boundary condition. Then the solution is of the order $\mathcal{O}(h^3)$ and the discrete gradient is of the order $\mathcal{O}(h^2)$, even if the boundary data are highly oscillatory. Since the problem is linear, we also get a discrete gradient of the order $\mathcal{O}(h^2)$ when the boundary data consist of a smooth $\mathcal{O}(h^2)$ term together with a highly oscillatory $\mathcal{O}(h^3)$ component.

3.1. The wave equation. We next consider the wave equation (1)–(4) on the half-plane $y - 2x \le 0$. We use the same grid and the same spatial discretization as for Poisson's equation, and study the following semidiscrete approximation:

$$\begin{aligned} v_{tt}(x_m, y_l, t) &= \Delta_h v(x_m, y_l, t) + F_h(x_m, y_l, t), \qquad y_l - 2x_m < 0,\ t \ge 0, \\ B_h v(t) &= f_h(t) \qquad\qquad \text{on the boundary},\ t \ge 0, \\ v(x_m, y_l, 0) &= u_0(x_m, y_l), \qquad\qquad y_l - 2x_m < 0, \\ v_t(x_m, y_l, 0) &= u_1(x_m, y_l), \qquad\qquad y_l - 2x_m < 0. \end{aligned}$$

Again we are interested in the accuracy of the solution and its gradient. We assume that F, u_0, and u_1 are smooth functions that can be expanded smoothly to the entire plane such that they decay rapidly as $|x| + |y| \to \infty$. Therefore, we can assume that

$$F \equiv u_0 \equiv u_1 \equiv 0. \tag{53}$$

Otherwise, we would first solve the continuous and semidiscrete Cauchy problems which we would then subtract from u and v, respectively. The gradient of the solution of the semidiscrete Cauchy problem has full accuracy since it satisfies the same equation as the solution itself (with different data). Thus we consider

$$\begin{aligned} u_{tt} &= \Delta u, \qquad\qquad y - 2x \le 0, \quad t \ge 0, \\ u(x, y, t) &= f(x, y, t), \qquad y - 2x = 0, \quad t \ge 0, \\ u(x, y, 0) &= u_t(x, y, 0) = 0, \qquad y - 2x \le 0. \end{aligned}$$

If $f(x, 2x, 0) \ne 0$, then the boundary data are not compatible with the initial data. If we want the solution to have p bounded time derivatives, we need

$$\partial^j f(x, y, t)/\partial t^j \big|_{t=0} = 0, \quad j = 0, 1, 2, \ldots, p-1, \quad y = 2x. \tag{54}$$

The corresponding difference approximation is

$$\begin{aligned} v_{tt}(x_m, y_l, t) &= \Delta_h v(x_m, y_l, t), \qquad y_l - 2x_m < 0,\ t \ge 0, \\ B_h v(t) &= f_h(t) \qquad\qquad \text{on the boundary},\ t \ge 0, \\ v(x_m, y_l, 0) &= v_t(x_m, y_l, 0) = 0, \qquad y_l - 2x_m < 0. \end{aligned}$$

We want to obtain an estimate for the error $e = v - u$ on the grid, and by using the same truncation error technique as for Poisson's equation, we get the following discrete error equation:

$$\begin{aligned} e_{tt}(x_m, y_l, t) &= \Delta_h e(x_m, y_l, t), \qquad y_l - 2x_m < 0,\ t \ge 0, \\ B_h e(t) &= h^2 g_h(t) \qquad\qquad \text{on the boundary},\ t \ge 0, \\ e(x_m, y_l, 0) &= e_t(x_m, y_l, 0) = 0, \qquad y_l - 2x_m < 0, \end{aligned}$$

where g_h is highly oscillatory in space but smooth in time (because the interpolation formulas do not depend on time). We proceed as for Poisson's equation and study the continuous modified equation model of the discrete error equation:

$$\begin{aligned} e_{tt} &= \Delta e, && y - 2x < 0,\ t \geq 0, \\ e &= h^2 g, && y - 2x = 0,\ t \geq 0, \\ e(x, y, 0) &= e_t(x, y, 0) = 0, && y - 2x < 0. \end{aligned}$$

By rotating the coordinate system according to (50)–(51), we align the boundary with $\xi = 0$ and arrive at a half-plane problem for $\xi \geq 0$, $-\infty < \eta < \infty$. Up to now, we have assumed a second order accurate discretization of the boundary condition, but the same arguments also apply to a higher order boundary discretization. We therefore take $\phi = h^2 g$ and study the half-plane problem

$$\begin{aligned} e_{tt} &= \Delta e, \\ e(0, \eta, t) &= \phi(\eta, t), \\ e(\xi, \eta, 0) &= e_t(\xi, \eta, 0) = 0. \end{aligned} \tag{55}$$

We assume that all data are 2π-periodic functions in η, Fourier transform the problem in the η-direction, and obtain

$$\begin{aligned} \hat{e}_{tt} &= \hat{e}_{\xi\xi} - \omega^2 \hat{e}, \\ \hat{e}(0, \omega, t) &= \hat{\phi}(\omega, t), \\ \hat{e}(\xi, \omega, 0) &= \hat{e}_t(\xi, \omega, 0) = 0, \end{aligned} \tag{56}$$

with

$$\partial^j \hat{\phi}(\omega, t)/\partial t^j \big|_{t=0} = 0, \quad j = 0, 1, 2, \ldots, p-1.$$

Because of the compatibility assumption (54), the solution will be smooth in time. If the boundary data are smooth in η, i.e., the Fourier coefficients $\hat{\phi}(\omega, t)$ decay rapidly for large ω, the solution will also be smooth in space. However, as we have seen before, the truncation error in the boundary condition is highly oscillatory in space, and we proceed by studying large $|\omega|$.

When $|\omega| \gg 1$, we solve (56) by iteration. For $j = 1, 2, \ldots$, let

$$\begin{aligned} \hat{e}^{(j)}_{\xi\xi} - \omega^2 \hat{e}^{(j)} &= \hat{e}^{(j-1)}_{tt}, \\ \hat{e}^{(j)}(0, \omega, t) &= \hat{\phi}(\omega, t). \end{aligned}$$

We take $\hat{e}^{(0)} = 0$, so $\hat{e}^{(1)}$ satisfies

$$\begin{aligned} \hat{e}^{(1)}_{\xi\xi} - \omega^2 \hat{e}^{(1)} &= 0, \\ \hat{e}^{(1)}(0, \omega, t) &= \hat{\phi}(\omega, t). \end{aligned}$$

The only bounded solution is $\hat{e}^{(1)}(\xi, \omega, t) = \hat{\phi}(\omega, t) e^{-|\omega|\xi}$. The problem for $\hat{e}^{(2)}$ becomes

$$\begin{aligned} \hat{e}^{(2)}_{\xi\xi} - \omega^2 \hat{e}^{(2)} &= \hat{\phi}_{tt}(\omega, t) e^{-|\omega|\xi}, \\ \hat{e}^{(2)}(0, \omega, t) &= \hat{\phi}(\omega, t), \end{aligned}$$

which is solved by

$$\hat{e}^{(2)} = \hat{e}^{(1)} - \frac{1}{2\omega^2}\hat{\phi}_{tt}|\omega|\xi e^{-|\omega|\xi}.$$

Note that $\alpha e^{-\alpha} \leq$ const. for $\alpha \geq 0$. Hence, for $|\omega| \gg 1$ the solution of (56) is

$$\hat{e}(\xi,\omega,t) = \hat{\phi}e^{-|\omega|\xi} - \frac{1}{2\omega^2}\hat{\phi}_{tt}|\omega|\xi e^{-|\omega|\xi} + \mathcal{O}\left(\frac{1}{\omega^4}\right).$$

As long as ϕ_{tt} is of the same order as ϕ, the gradient satisfies

$$\hat{e}_\xi(\xi,\omega,t) = \hat{e}^{(1)}_\xi(\xi,\omega,t)\left(1 + \mathcal{O}\left(\frac{1}{\omega^2}\right)\right).$$

Therefore, the properties of the gradient of $\hat{e}$ can be reduced to the properties of $\hat{e}^{(1)}$, which was studied in the previous section. Hence, for boundary data $\phi(\xi,t)$ which are highly oscillatory in space but smooth in time, the gradient of e only becomes large in a boundary layer near $\xi = 0$, while the solution remains smooth in the interior of the domain. This means that if the boundary approximation is third order accurate with a highly oscillatory truncation error, i.e., $\phi = h^3 g$, the gradient of the solution will be third order accurate except near the boundary $\xi = 0$, where it will be second order accurate.

Note that the time-smoothness assumption is essential because ϕ_{tt} appears as forcing for $\hat{e}^{(2)}$ and the number of time derivatives in the forcing will increase by two for each iteration. However, this is not only a technicality due to our way of constructing the solution. The error in the solution is studied numerically in the next section, and it can clearly be seen that the error in the gradient becomes large throughout the domain when the truncation error is not smooth in time; cf. Figure 2. This illustrates a major difference in the behavior of hyperbolic and elliptic problems. For elliptic problems, a high frequency boundary error will lead to a solution error that is unsmooth only in a boundary layer. In contrast, for hyperbolic problems, a boundary error which is highly oscillatory in both space and time will make the solution error highly oscillatory throughout the domain. The unsmooth solution error will be confined to a boundary layer only if the boundary error is smooth in time.

4. Numerical experiments. In this section we numerically solve (1)–(4) with the scheme described above. We denote the CFL-number by CFL $\equiv k/h$. Note that for a two-dimensional periodic domain our time-integration scheme (19) is stable for CFL $\leq 1/\sqrt{2} \approx 0.71$. Also note that all errors reported below are measured in max-norm over all grid points inside Ω.

We start the time integration at $n = 0$ and take $v^0_{i,j} = u_0(x_i, y_j)$. We need to use a fourth order accurate approximation of $u(x_i, y_j, -k)$ for $v^{-1}_{i,j}$. This is achieved by using the differential equation to approximate the second and third time derivatives,

(57)
$$v^{-1}_{i,j} = u_0(x_i,y_j) - ku_1(x_i,y_j) + \frac{k^2}{2}\left(D^x_+D^x_- + D^y_+D^y_-\right)u_0(x_i,y_j) + \frac{k^2}{2}F(\boldsymbol{x}_{i,j},0) - \frac{k^3}{6}\left(D^x_+D^x_- + D^y_+D^y_-\right)u_1(x_i,y_j) - \frac{k^3}{6}F_t(\boldsymbol{x}_{i,j},0).$$

Note that when the smooth start procedure is employed, the initial data are homogeneous, and thus the above formula simplifies to

$$\tilde{v}_{i,j}^{-1} = \frac{k^2}{2}\tilde{F}(\boldsymbol{x}_{i,j}, 0) - \frac{k^3}{6}\tilde{F}_t(\boldsymbol{x}_{i,j}, 0),$$

where the modified forcing initially satisfies

$$\tilde{F}(\boldsymbol{x}, 0) = F(\boldsymbol{x}, 0) + 2u_0(\boldsymbol{x}) + \Delta u_0(\boldsymbol{x}), \quad \tilde{F}_t(\boldsymbol{x}, 0) = F_t(\boldsymbol{x}, 0) + 6u_1(\boldsymbol{x}) + \Delta u_1(\boldsymbol{x}).$$

To use the smooth start procedure, we need to evaluate Δu_k, $k = 0, 1$, at all interior grid points. When $u_0(x, y)$ and $u_1(x, y)$ are complicated analytic expressions of x and y, an appealing alternative is to approximate Δu_k by finite differences. Numerical experiments indicate that a centered second or fourth order accurate difference approximation of Δu_k, $k = 0, 1$, can replace analytic expressions without any noticeable degradation of the computed solutions, as long as u_0 and u_1 are well resolved on the grid. However, to define all values in the five- or seven-point formula for the centered difference approximation of the Laplacian, this approach works only if u_0 and u_1 can be evaluated at all interior grid points as well as one or two grid points outside the boundary, respectively.

4.1. Trigonometric exact solution. To evaluate the accuracy of the method and the properties of the smooth start technique, we begin by considering the case when the exact solution is known. Given a smooth function $U(\boldsymbol{x}, t)$, this is accomplished by constructing balancing interior and boundary forcing functions $F(\boldsymbol{x}, t) = U_{tt}(\boldsymbol{x}, t) - \Delta U(\boldsymbol{x}, t)$ and $f(\boldsymbol{x}_\Gamma, t) = U(\boldsymbol{x}_\Gamma, t)$, respectively. The initial data are obtained by setting $u_0(\boldsymbol{x}) = U(\boldsymbol{x}, 0)$, $u_1(\boldsymbol{x}) = U_t(\boldsymbol{x}, 0)$. The continuous problem is then discretized and the error in the discrete solution can be obtained by taking the difference between the numerical and analytic solutions at each grid point.

We choose the exact solution to be the trigonometric traveling wave

$$U(x, y, t) = \sin(\omega(x - t)) \sin(\omega y), \quad \omega = 2\pi. \tag{58}$$

The domain Ω is taken to be an ellipse centered at the origin with semiaxes $x_s = 1$ and $y_s = 0.75$. The Cartesian grid covers the rectangle $-1.04 \le x \le 1.04$, $-0.78 \le y \le 0.78$, the grid size is $h = 2.08/(N - 1)$, and CFL $= 0.5$. To assess the accuracy of the scheme we run the computations until time $t = 2.0$. Note that no damping is necessary for these short runs ($\alpha = 0$). In Table 3, we present a grid refinement study for the scheme (19) started directly (from inhomogeneous initial data) and smoothly, respectively. In both cases, the solution itself converges as $\mathcal{O}(h^2)$, but the gradient and Laplacian are second order accurate only when smooth start is being used. (The second order formulas $D_0^x v_{i,j}$ and $D_0^y v_{i,j}$ are used to approximate the discrete gradient, and the component of the gradient with the largest error is reported. The Laplacian is approximated by $\Delta_h v_{i,j}$.) Note that when the computation is started directly, the error in the gradient is only a little better than first order accurate and the error in the Laplacian is $\mathcal{O}(1)$. This agrees with our observations for the one-dimensional case; cf. Table 1.

To more clearly see the impact of the smooth start procedure on the solution, in Figure 2 we plot the error in the solution at time $t = 2.0$, with direct and smooth start. Clearly, the smooth start procedure efficiently removes the high frequency errors present in the computation using direct start.

TABLE 3

Grid refinement study showing the errors in the computed solutions at $t = 2.0$ when the exact solution is the trigonometric function (58)*, with direct and smooth start.*

	Direct start			Smooth start		
N	$\|u_{\text{err}}\|_\infty$	$\|\nabla u_{\text{err}}\|_\infty$	$\|\Delta u_{\text{err}}\|_\infty$	$\|u_{\text{err}}\|_\infty$	$\|\nabla u_{\text{err}}\|_\infty$	$\|\Delta u_{\text{err}}\|_\infty$
201	$2.23 \cdot 10^{-3}$	$3.48 \cdot 10^{-2}$	14.3	$1.39 \cdot 10^{-3}$	$8.60 \cdot 10^{-3}$	$7.25 \cdot 10^{-2}$
401	$5.38 \cdot 10^{-4}$	$1.27 \cdot 10^{-2}$	9.86	$3.43 \cdot 10^{-4}$	$2.15 \cdot 10^{-3}$	$1.83 \cdot 10^{-2}$

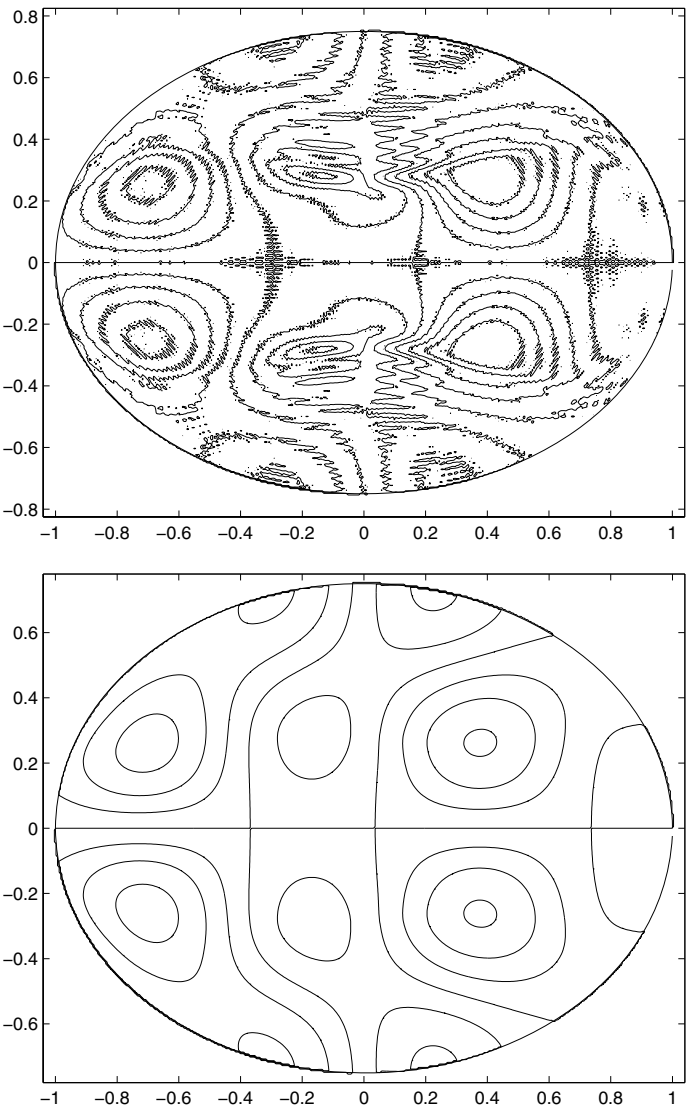

FIG. 2. *Error in the solution at time $t = 2.0$, with direct start (top) and smooth start (bottom). In both cases, the grid size was $h = 2.08/400$ ($N = 401$) and CFL $= 0.5$. Contours are equally spaced in $[-4 \cdot 10^{-4}, 4 \cdot 10^{-4}]$ with step size 10^{-4}.*

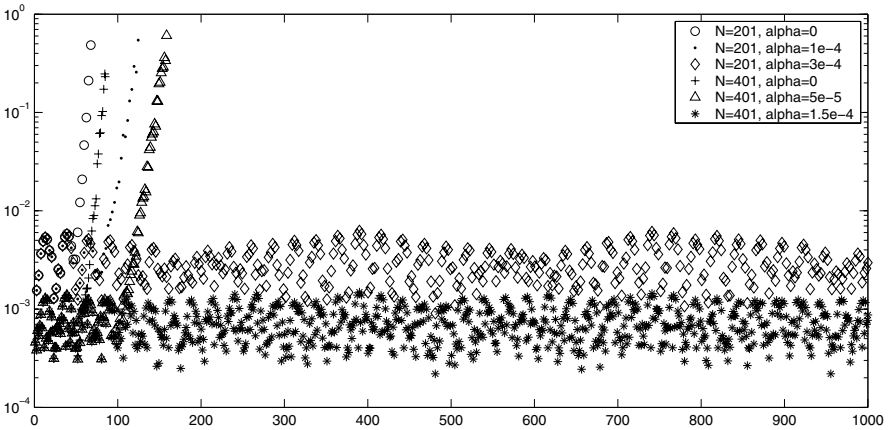

FIG. 3. *Max error in the solution as a function of time for different damping coefficients α and grid sizes N. For $N = 401$, time 1000 was reached after taking 384,615 time steps.*

Next we investigate the long-time properties of the time-integration scheme. In Figure 3 we report the error in the solution for different values of the damping coefficient α and for grid sizes $N = 201$ and $N = 401$. The domain is the same ellipse as before, CFL $= 0.5$, and smooth start is enabled. Damping is clearly needed to reach time 1000, corresponding to $384,615$ time steps on the finer grid, and we need to take $\alpha = 3 \cdot 10^{-4}$ to stabilize the scheme for the coarse grid. However, for the finer grid it suffices with $\alpha = 1.5 \cdot 10^{-4}$. This suggests that $\alpha = h\tilde{\alpha}$; i.e., the damping term can be of the order $\mathcal{O}(h^4)$. Note that there is no apparent increase in the error after long times, which indicates that the damping is very mild and that the scheme is appropriate for long time computations.

4.2. The TM$_z$ problem. We proceed by testing our method on the TM$_z$ problem for Maxwell's equations, i.e., the two-dimensional case where

$$\boldsymbol{H} = H^{(x)}(x, y, t)\boldsymbol{e}_x + H^{(y)}(x, y, t)\boldsymbol{e}_y$$

and $\boldsymbol{E} = E^{(z)}(x, y, t)\boldsymbol{e}_z$. By scaling the dependent variables and time, Maxwell's equations describing a homogeneous, lossless material without charges simplify to (cf. [15])

$$\frac{\partial H^{(x)}}{\partial t} = -\frac{\partial E^{(z)}}{\partial y}, \tag{59}$$

$$\frac{\partial H^{(y)}}{\partial t} = \frac{\partial E^{(z)}}{\partial x} \qquad \text{in } \Omega, \quad t \geq 0, \tag{60}$$

$$\frac{\partial E^{(z)}}{\partial t} = \frac{\partial H^{(y)}}{\partial x} - \frac{\partial H^{(x)}}{\partial y}, \tag{61}$$

subject to the constraint

$$\frac{\partial H^{(x)}}{\partial x} + \frac{\partial H^{(y)}}{\partial y} = 0 \quad \text{in } \Omega, \quad t \geq 0. \tag{62}$$

By cross-differentiation,

$$\frac{\partial^2 E^{(z)}}{\partial t^2} = \frac{\partial^2 E^{(z)}}{\partial x^2} + \frac{\partial^2 E^{(z)}}{\partial y^2} \quad \text{in } \Omega, \quad t \geq 0. \tag{63}$$

The perfectly electric conducting (PEC) boundary condition $\boldsymbol{n} \times \boldsymbol{E} = 0$, where $\boldsymbol{n} = n^{(x)}\boldsymbol{e}_x + n^{(y)}\boldsymbol{e}_y$ is the outward normal of the boundary, becomes

$$(\boldsymbol{e}_x n^{(y)} - \boldsymbol{e}_y n^{(x)}) E^{(z)} = 0 \quad \text{on } \Gamma,$$

i.e.,

$$E^{(z)} = 0 \quad \text{on } \Gamma. \tag{64}$$

Instead of directly solving the first order system (59)–(61), we solve the second order equation (63) subject to the Dirichlet boundary condition (64). Once $E^{(z)}$ is computed, the equations for $H^{(x)}$ and $H^{(y)}$, (59) and (60), reduce to ordinary differential equations at each point in Ω.

On the discrete side, (59) and (60) are integrated in time using the second order Adams–Bashforth method:

$$H_{i,j}^{(x)}(t_{n+1}) = H_{i,j}^{(x)}(t_n) - \frac{k}{2}\left(3D_0^y E_{i,j}^{(z)}(t_n) - D_0^y E_{i,j}^{(z)}(t_{n-1})\right), \tag{65}$$

$$H_{i,j}^{(y)}(t_{n+1}) = H_{i,j}^{(y)}(t_n) + \frac{k}{2}\left(3D_0^x E_{i,j}^{(z)}(t_n) - D_0^x E_{i,j}^{(z)}(t_{n-1})\right). \tag{66}$$

As a result, the following second order accurate centered approximation of the divergence constraint (62) satisfies

$$D_0^x H_{i,j}^{(x)}(t_n) + D_0^y H_{i,j}^{(y)}(t_n) = D_0^x H_{i,j}^{(x)}(0) + D_0^y H_{i,j}^{(y)}(0), \quad t_n > 0.$$

Hence, if the discrete divergence is initially zero, it will remain so for all subsequent times.

We use the scheme (19) together with the smooth start procedure to evolve (63). This is a good test of the numerical accuracy of $E^{(z)}$, since $H^{(x)}$ and $H^{(y)}$ depend on the gradient of $E^{(z)}$. Initial conditions for (59)–(61) are $H^{(x)}(\boldsymbol{x}, 0)$, $H^{(y)}(\boldsymbol{x}, 0)$, and $E^{(z)}(\boldsymbol{x}, 0)$. The second order formulation (63) also needs the time derivative of $E^{(z)}$ at $t = 0$. This follows from (61):

$$E_t^{(z)}(\boldsymbol{x}, 0) = H_x^{(y)}(\boldsymbol{x}, 0) - H_y^{(x)}(\boldsymbol{x}, 0).$$

Furthermore, to start the Adams–Bashforth scheme (65)–(66), we need an accurate approximation of $E^{(z)}(\boldsymbol{x}_{i,j}, -k)$:

$$E^{(z)}(\boldsymbol{x}_{i,j}, -k) = E^{(z)}(\boldsymbol{x}_{i,j}, 0) - kE_t^{(z)}(\boldsymbol{x}_{i,j}, 0) + \frac{k^2}{2}\Delta_h E^{(z)}(\boldsymbol{x}_{i,j}, 0).$$

When Ω is a unit circular disc, Maxwell's equations can be solved analytically using separation of variables using polar coordinates (ρ, θ):

$$x(\rho, \theta) = \rho \cos\theta,$$
$$y(\rho, \theta) = \rho \sin\theta.$$

TABLE 4
Error in the computed solution of the TM_z problem for the mode $m = 3$, $n = 1$ at time $t = 2.0$.

N	$\|E^{(z)}_{\text{error}}\|_\infty$	$\|H^{(x)}_{\text{error}}\|_\infty$	$\|H^{(y)}_{\text{error}}\|_\infty$	$\|E^{(z)}_{x\,\text{error}}\|_\infty$	$\|E^{(z)}_{y\,\text{error}}\|_\infty$	$\|\Delta E^{(z)}_{\text{error}}\|_\infty$
Direct start						
201	$1.03 \cdot 10^{-3}$	$1.47 \cdot 10^{-3}$	$1.98 \cdot 10^{-3}$	$1.32 \cdot 10^{-2}$	$1.63 \cdot 10^{-2}$	$8.52 \cdot 10^{0}$
401	$2.53 \cdot 10^{-4}$	$3.54 \cdot 10^{-4}$	$4.90 \cdot 10^{-4}$	$3.99 \cdot 10^{-3}$	$4.77 \cdot 10^{-3}$	$4.02 \cdot 10^{0}$
Smooth start						
201	$1.59 \cdot 10^{-3}$	$3.93 \cdot 10^{-3}$	$3.28 \cdot 10^{-3}$	$2.61 \cdot 10^{-3}$	$5.53 \cdot 10^{-3}$	$4.22 \cdot 10^{-2}$
401	$3.95 \cdot 10^{-4}$	$1.08 \cdot 10^{-3}$	$8.41 \cdot 10^{-4}$	$6.58 \cdot 10^{-4}$	$1.54 \cdot 10^{-3}$	$1.06 \cdot 10^{-2}$

We can alternatively express $\boldsymbol{H}$ in terms of its Cartesian or polar components, related by

$$H^{(x)} = H^{(\rho)} \cos\theta - H^{(\theta)} \sin\theta,$$
$$H^{(y)} = H^{(\rho)} \sin\theta + H^{(\theta)} \cos\theta.$$

Let $J_m(\xi)$ denote the Bessel function of the first kind of order m ($m = 0, 1, 2, \dots$) and let $\mathcal{X}_{mn}$ be the nth zero of J_m ($n = 1, 2, 3, \dots$), i.e., $J_m(\mathcal{X}_{mn}) = 0$, $0 < \mathcal{X}_{m1} < \mathcal{X}_{m2} < \cdots$. In terms of polar coordinates and components, the TM_z problem is solved by (cf. [15])

$$E^{(z)}_{mn}(\rho, \theta) = \mathcal{X}_{mn} J_m(\mathcal{X}_{mn}\rho) \cos(m\theta) \cos(\mathcal{X}_{mn} t), \tag{67}$$

$$H^{(\rho)}_{mn}(\rho, \theta) = \frac{m}{\rho} J_m(\mathcal{X}_{mn}\rho) \sin(m\theta) \sin(\mathcal{X}_{mn} t), \tag{68}$$

$$H^{(\theta)}_{mn}(\rho, \theta) = \mathcal{X}_{mn} J'_m(\mathcal{X}_{mn}\rho) \cos(m\theta) \sin(\mathcal{X}_{mn} t). \tag{69}$$

Since the equations are linear, any linear combination of the above solution is also a solution.

We evaluate the numerical scheme by solving the TM_z problem on a unit circular disc and compare the numerical solution to the exact analytic solution (67)–(69). We consider the case $m = 3$, $n = 1$, where $\mathcal{X}_{31} \approx 6.3801618959$. The problem is discretized on a computational grid with grid size $h = 2.08/(N - 1)$ and CFL $= 0.5$. In this computation, the coefficient of the artificial term in the Dirichlet boundary condition is $\gamma = 0.2$. No stabilization is necessary for these short time computations, and we set $\alpha = 0$. In Table 4 we compare the errors when the computation is started directly (from inhomogeneous initial data) and smoothly. In both cases, the errors in $E^{(z)}$, $H^{(x)}$, $H^{(y)}$, $E^{(z)}_x$, and $E^{(z)}_y$ are all $\mathcal{O}(h^2)$. However, the errors in $\Delta E^{(z)}$ reveal a highly oscillatory component in $E^{(z)}$ when the computation is started directly. Since $\partial \boldsymbol{H}/\partial t$ depends on the gradient of $E^{(z)}$, it is surprising that the errors in $\boldsymbol{H}$ are smaller when the computation is started directly, since the errors in the gradient of $E^{(z)}$ are smaller when the smooth start procedure is used.

In terms of our scaled variables, the total field energy within Ω is

$$E_{\text{field}}(t) = \int_\Omega \boldsymbol{E} \cdot \boldsymbol{E} + \boldsymbol{H} \cdot \boldsymbol{H} \, d\Omega. \tag{70}$$

Maxwell's equations (59)–(61) subject to a homogeneous PEC boundary condition (64) imply $E_{\text{field}}(t) = E_{\text{field}}(0)$, $t > 0$. Since our scheme uses damping to ensure

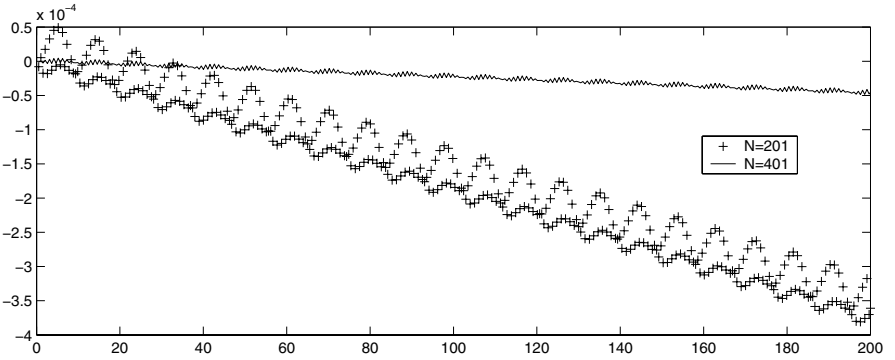

FIG. 4. *The error in the relative energy* $E_{\text{field}}(t)/E_{\text{field}}(0)$ *as a function of time for a circular domain for the mode* $m = 3$, $n = 1$ *of* (67)–(69).

stability, it is of interest to evaluate how well the energy (70) is conserved by the numerical approximation.

To evaluate (70), we need to integrate a grid function defined on the embedded boundary grid. Let $g(\boldsymbol{x})$ be a smooth function defined in Ω and take

$$g_{i,j} = \begin{cases} g(\boldsymbol{x}_{i,j}), & \boldsymbol{x}_{i,j} \in \Omega, \\ \text{extrap}(g)_{i,j}, & \boldsymbol{x}_{i,j} \notin \Omega,\ \boldsymbol{x}_{i\pm1,j} \in \Omega \text{ or } \boldsymbol{x}_{i,j\pm1} \in \Omega, \\ 0, & \text{otherwise}, \end{cases}$$

where $\text{extrap}(g)_{i,j}$ is defined by linear extrapolation from the interior points. We approximate the integral by a sum of grid cell averages of g:

$$\int_\Omega g(\boldsymbol{x})\, d\Omega \approx \sum_{i,j} C_{i+1/2,j+1/2} \frac{g_{i,j} + g_{i+1,j} + g_{i,j+1} + g_{i+1,j+1}}{4}. \tag{71}$$

For interior cells where all four grid vertices are inside Ω, the cell area is $C_{i+1/2,j+1/2} = h^2$. When all four grid vertices are outside Ω, the cell area is $C_{i+1/2,j+1/2} = 0$. For cells cut by the boundary, we first compute the intersections between the boundary and the four grid lines x_i, x_{i+1}, y_j, y_{j+1}. To estimate the cell area, the cell boundary is approximated by a linear segment between each intersection point. This procedure together with the linear extrapolation to define $\text{extrap}(g)$ in points just outside the boundary has been verified to give a second order accurate quadrature formula.

In Figure 4 we plot the error in the relative energy $E_{\text{field}}(t)/E_{\text{field}}(0)$ as a function of time for a circular domain. As before, we study the mode $m = 3$, $n = 1$ and use the same parameters as before. For these long time computations, the stabilization term is necessary and we set $\alpha = 10^{-3}$. As can be expected, the conservation error is $\mathcal{O}(h^2)$ and grows approximately linearly in time. For the fine mesh, the relative energy is conserved to within $5 \cdot 10^{-5}$ at time $t = 200$, and we conclude that the effect of the stabilization term is very small.

Next we study the evolution of a pulse centered at $(x, y) = (x_F, y_F)$ in a more complicated region where the boundary is represented by a cubic spline; see Figure 5. We start the computation from a localized perturbation in $E^{(z)}$ near (x_F, y_F):

$$E^{(z)}(x, y, 0) = \phi(\sqrt{(x - x_F)^2 + (y - y_F)^2}).$$

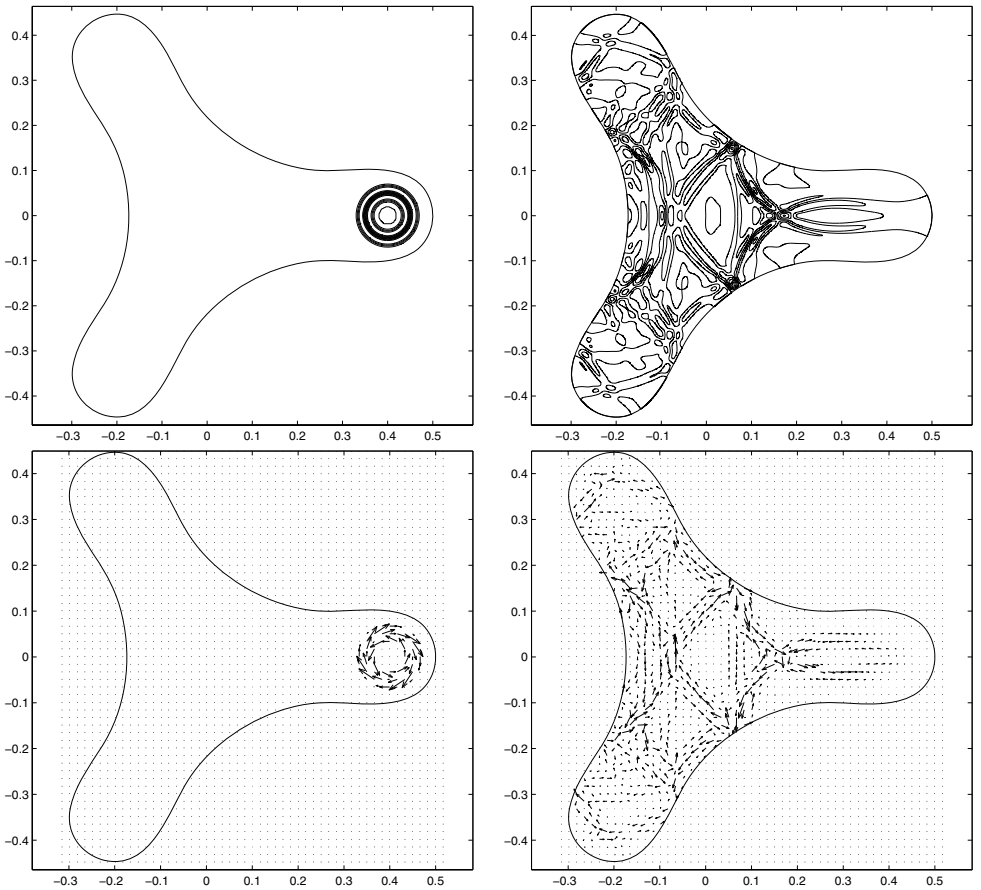

FIG. 5. *The evolution of* $E^{(z)}$ *(top) and* $\boldsymbol{H}$ *(bottom) in the problem for the grid refinement test. The left-hand figures show initial data and the right-hand figures show the solution at time* $t = 0.8$*. The solutions are shown on the finest grid with* 1601×1790 *grid points. Contours are spaced equally in* $[-1.0, 1.0]$ *with step size* 0.2*. Every* 32*nd grid point is used in the vector plots in the bottom row.*

To make the perturbation propagate (essentially) radially outward from (x_F, y_F), we take

$$\frac{\partial E^{(z)}}{\partial t}(x, y, 0) = -\phi'(\sqrt{(x - x_F)^2 + (y - y_F)^2}).$$

However, to start the computation we must specify compatible initial data for $\boldsymbol{H}$. Let $\psi(x, y)$ be a scalar field. The initial $\boldsymbol{H}$ field will be divergence free if

$$H^{(x)}(x, y, 0) = -\frac{\partial \psi}{\partial y}, \tag{72}$$

$$H^{(y)}(x, y, 0) = \frac{\partial \psi}{\partial x}. \tag{73}$$

Note that (61) yields

$$\frac{\partial E^{(z)}}{\partial t}(x, y, 0) = \Delta \psi.$$

Hence, we can find the initial data for $(E^{(x)}, E^{(y)})$ by solving the Poisson problem

$$\Delta\psi = -\phi' \tag{74}$$

and inserting the gradient of ψ in (72)–(73). In special cases, this can be done analytically. Introduce polar coordinates (ρ, θ) centered around the point (x_F, y_F),

$$\begin{aligned} x &= x_F + \rho\cos\theta, \\ y &= y_F + \rho\sin\theta, \end{aligned}$$

and let ϕ be independent of θ, i.e., $\phi = \phi(\rho)$. The solution of (74) is then

$$\psi_\rho(\rho) = -\phi(\rho) + \frac{1}{\rho}\int_0^\rho \phi(\rho')\,d\rho', \tag{75}$$

and since ψ is independent of θ, $\psi_x = (x - x_F)\psi_\rho/\rho$ and $\psi_y = (y - y_F)\psi_\rho/\rho$. If we take

$$\phi(\rho) = \begin{cases} 0, & \rho < r_0, \\ P\left(\frac{\rho - r_0}{r_1 - r_0}\right), & r_0 \le \rho \le r_1, \\ 0, & r > r_1, \end{cases} \qquad P(\xi) = a\xi^5(1-\xi)^5(\xi - 1/2),$$

we have $\int_0^1 P(\xi)\,d\xi = 0$, and thus $\psi_\rho(\rho)$ has compact support in $r_0 \le \rho \le r_1$.

In the computation shown in Figure 5, we used $x_F = 0.4$, $y_F = 0$, $r_0 = 0.02$, and $r_1 = 0.08$ to give the initial data compact support inside Ω, and set $a = 10938.8$, which normalizes the initial data to $-1 \le E^{(z)}(x, y, 0) \le 1$. Since the initial data have compact support, the smooth start procedure was not necessary in this computation. No exact solution is known for this problem and we resort to a grid refinement study to access the accuracy of the computed solution. Three calculations were performed where the grid size was $h = 5.193 \cdot 10^{-4}$, $2h$, and $4h$, respectively. The corresponding grids had 1601×1790, 801×896, and 401×448 grid points, respectively. In this computation, we used $\alpha = 10^{-3}$, $\gamma = 0.25$, and CFL $= 0.5$. Let $(E_h^{(z)}, H_h^{(x)}, H_h^{(y)})$ be the discrete solutions corresponding to grid size h. If the discrete solution is resolved on the grid, we expect it to satisfy

$$E_h^{(z)}(x_i, y_j, t_n) = E^{(z)}(x_i, y_j, t_n) + h^2 R(x_i, y_j, t_n) + \mathcal{O}(h^3)$$

and similar expressions for $H_h^{(x)}$ and $H_h^{(y)}$. Hence,

$$\frac{\|E_h^{(z)} - E_{4h}^{(z)}\|_\infty}{\|E_h^{(z)} - E_{2h}^{(z)}\|_\infty} \to 5, \quad h \to 0,$$

and corresponding expressions for $H_h^{(x)}$ and $H_h^{(y)}$. In Table 5, we report the calculated convergence rates at time $t = 0.8$. The calculated rates are near the asymptotic value of 5, which indicates that the solution is second order accurate. The relatively large difference between the solution on the fine and coarse grids indicates that the solution on that grid is not very accurate, despite being in the asymptotic range.

For completeness, we give the (x, y)-coordinates of the 21 node points in the periodic interpolating cubic spline: $(-0.0384, -0.2665)$; $(0.25, -0.1)$; $(0.4, -0.1)$; $(0.4707, -0.0707)$; $(0.5, 0.0)$; $(0.4707, 0.0707)$; $(0.4, 0.1)$; $(0.25, 0.1)$; $(-0.0384, 0.2665)$; $(-0.1134, 0.3964)$; $(-0.1741, 0.443)$; $(-0.25, 0.433)$; $(-0.2966, 0.3722)$; $(-0.2866, 0.2964)$; $(-0.2116, 0.1665)$; $(-0.2116, -0.1665)$; $(-0.2866, -0.2964)$; $(-0.2966, -0.3722)$; $(-0.25, -0.433)$; $(-0.1741, -0.443)$; and $(-0.1134, -0.3964)$.

TABLE 5
Convergence of the discrete solution.

	$X = E^{(z)}$	$X = H^{(x)}$	$X = H^{(y)}$
$\|X_h - X_{4h}\|_\infty$	0.3636	0.3552	0.2491
$\|X_h - X_{2h}\|_\infty$	0.0744	0.0621	0.0622
Ratio	4.89	5.24	4.00

5. Conclusions. We have developed a Cartesian embedded boundary method for the second order wave equation in general two-dimensional domains subject to Dirichlet boundary conditions, where both the solution and its gradient are second order accurate. By adding a small artificial term to the discrete boundary condition, we avoid the small-cell stiffness problem and can use an explicit time-integration method where the time step essentially equals that of a periodic domain.

Work is under way to solve Maxwell's equations written as a system of second order wave equations by combining the current method with our previous method for the Neumann problem [2]. Future developments include treatment of discontinuous wave propagation speeds, unbounded domains (far field boundaries), and generalizations to three space dimensions.

Appendix A. Estimating γ in the Dirichlet boundary condition.

Consider the semidiscrete one-dimensional wave equation (27)–(29). After eliminating the ghost point v_0, we can write the system in matrix form as follows:

$$\boldsymbol{v}_{tt} = A\boldsymbol{v} + \boldsymbol{F} + \boldsymbol{b}, \quad \boldsymbol{v} = (v_1, v_2, v_3, \dots)^T.$$

As before, $\boldsymbol{F}$ and $\boldsymbol{b}$ are the interior and boundary forcing terms, respectively. The tridiagonal matrix A satisfies

$$A = \frac{1}{h^2}\begin{pmatrix} -2 - \frac{c_1 - 2\gamma}{c_0 + \gamma} & 1 - \frac{c_2 + \gamma}{c_0 + \gamma} & 0 & 0 & \cdots \\ 1 & -2 & 1 & 0 & \cdots \\ 0 & 1 & -2 & 1 & \\ \vdots & & \ddots & \ddots & \ddots \end{pmatrix}.$$

Let the eigenvalues of A be λ_j. Since A can be symmetrized by a diagonal matrix, all eigenvalues of A are real valued. For all rows except the first, the Gershgorin circles (see, e.g., [16]) for the matrix $h^2 A$ are

$$\Lambda_j = \{z : |z + 2| \le 2\}, \quad j \ge 2,$$

that is, a circle in the complex z-plane with radius 2 centered at $z = -2$. The circle corresponding to the first row is

$$\Lambda_1 = \left\{ z : \left| z + 2 + \frac{c_1 - 2\gamma}{c_0 + \gamma} \right| \le 1 - \frac{c_2 + \gamma}{c_0 + \gamma} \right\}.$$

Since all eigenvalues of A are real, the circles correspond to intervals on the real axis, and the Gershgorin circle theorem says that all eigenvalues of A are located in the union of these intervals.

We begin by demonstrating the small-cell stiffness when $\gamma = 0$ and $\beta \to 0$. In this case, the Gershgorin circle from the first row in A is disjoint from the remaining circles when $0 \le \beta < (\sqrt{3}-1)/2$. For such β, there must be one eigenvalue of A that lies within the interval

$$-3 - \frac{c_1 - c_2}{c_0} \le h^2\lambda_1 \le -1 - \frac{c_1 + c_2}{c_0},$$

and we conclude that $h^2\lambda_1 \to -\infty$ as $\beta \to 0$. As a result, the CFL condition for the explicit time integration scheme (37) becomes $k/h \to 0$ as $\beta \to 0$; see [1].

Next, we want to estimate the eigenvalue with the largest magnitude for $\gamma > 0$. The interval corresponding to all circles except the first is $-4 \le \Re(z) \le 0$ and the interval from Λ_1 is

$$-3 - \frac{c_1 - c_2 - 3\gamma}{c_0 + \gamma} \le \Re(z) \le -1 + \frac{\gamma - c_1 - c_2}{c_0 + \gamma}.$$

Hence, we study how large

$$q(\beta, \gamma) = \frac{c_1(\beta) - c_2(\beta) - 3\gamma}{c_0(\beta) + \gamma}$$

can be for $0 \le \beta \le 1$, $\gamma > 0$. The coefficients in q are given by (26). When $\gamma \le 0.25$, the maximum of q is attained at $\beta = 0$ and satisfies

$$\max_{0 \le \beta \le 1} q(\beta, \gamma) = q(0, \gamma) = \frac{1 - 3\gamma}{\gamma}, \quad \gamma \le 0.25. \tag{76}$$

For $\gamma > 0.25$, $\max q(\beta, \gamma) < q(0, 0.25)$. Hence, to obtain the same lower bound from the first Gershgorin circle as from the rest, we require $\max q \le 1$ and (76) gives $\gamma \ge 0.25$. The upper bound from Λ_1 is always less than zero for $0 \le \beta \le 1$. Hence, all eigenvalues of A satisfy the estimate

$$-4 \le h^2\lambda_j \le 0 \quad \text{for } \gamma \ge 0.25,$$

and the CFL condition for the explicit time integration scheme (37) becomes $k/h < 1$, see [1].

A COMPARATIVE STUDY OF LAGRANGIAN METHODS USING AXISYMMETRIC AND DEFORMING BLOBS*

LOUIS F. ROSSI†

Abstract. This paper presents results from a head-to-head comparison of two Lagrangian methods for solutions to the two-dimensional, incompressible convection-diffusion equations. The first Lagrangian method is an axisymmetric core spreading method using Gaussian basis functions. The second method uses deforming elliptical Gaussian basis functions. Previous results show that the first method has second-order spatial accuracy and the second method has fourth-order spatial accuracy. However, the deforming basis functions require more computational effort per element, so this paper examines computational performance as well as overall accuracy. The test problem is the deformation and diffusion of ellipsoidal distribution of scalar with an underlying flow field that has closed circular streamlines. The test suite includes moderate, high, and infinite Péclet number problems. The results indicate that the performance tradeoff for the sample flow calculation occur at modest problem sizes and that the fourth-order method offers distinct advantages as a general approach for challenging problems.

Key words. convection-diffusion, particle methods, computational fluid dynamics, deforming blobs

DOI. 10.1137/030600679

1. Introduction.

Lagrangian schemes for solving convection-diffusion equations are naturally adaptive in the sense that information about the computed field closely follows physical path lines. These schemes are a natural reduction from vortex methods for Navier–Stokes and other nonlinear schemes and differ only in the sense that the velocity is specified rather than determined from the computed field. Since these methods express the computed field as a linear combination of basis functions, sometimes called blobs, that move with the local flow velocity, one can argue that computational resources are dedicated only where the computed field is substantial and nowhere else. To boost the efficiency of Lagrangian methods, many investigators have explored anisotropic and dynamically deforming computational elements as a way to use fewer elements in complex flow geometries. For instance, Marshall and Grant [12], Meiburg [14], and Teng [22] have specified anisotropic vortex elements to develop more efficient means of capturing boundary layers and mixing layers. Furthermore, it makes sense that improvements to the accuracy of moving, localized basis functions should come through local corrections in the shape of the basis function. Leonard [11], Moeleker and Leonard [15], Rossi [19], and Teng [23, 24] have developed methods that permit the computational elements to deform dynamically based on linearized deviations in the flow velocity. All these papers report improved accuracy, though not necessarily an order of spatial convergence beyond the anticipated second order and not necessarily improved computational performance. Since anisotropic and deforming basis functions require more computational resources than simple anisotropic elements, one would hope that the more sophisticated scheme will have substantial improvements

in accuracy to justify the additional cost. To the contrary, Moeleker and Leonard [15] report that the increased computational effort over calculations with axisymmetric elements for the convection-diffusion equations does not justify the cost of using dynamically deforming elements. Recently, Rossi determined that this general category of method, when used with velocity and velocity derivative data evaluated at the basis function centroid, has second-order spatial correctness so that the deforming method and axisymmetric methods have the same order of convergence. However, this same analysis indicates that a curvature correction to the velocity field coupled with the adaptive deformations achieves fourth-order spatial accuracy [20]. Tests using deforming methods with and without the correction conclusively show that the theoretical convergence rates are indicative of the method's actual convergence rate and that the method using curvature corrections outperforms the same method without the corrections. What remains to be studied is whether it is better to use the more expedient axisymmetric elements or the more accurate but computationally intensive deforming basis functions for reasonably challenging problems. This paper makes a head-to-head comparison between Lagrangian methods with axisymmetric blobs and high-order deforming blobs to understand flow-dependent performance tradeoffs between the efficiency and accuracy of the two techniques when solving problems that are challenging on current desktop machines.

This paper focuses on solutions to the two-dimensional, incompressible, convection-diffusion equations,

$$\partial_t \rho + (\vec{u} \cdot \nabla)\rho = \frac{1}{\mathrm{Pe}} \nabla^2 \rho, \tag{1.1a}$$

$$\nabla \cdot \vec{u} = 0, \tag{1.1b}$$

on the unbounded plane where ρ is a passive scalar quantity that moves and diffuses with the flow. The $\vec{u}$ is a known fluid velocity field and Pe is the Péclet number, a dimensionless quantity expressing the ratio of convective to diffusive effects in the flow. Both the method using axisymmetric blobs and the method using deforming blobs are known as [illegible] because the width of each computational element grows with time to capture the diffusive term. Core-spreading methods are known to be inconsistent except when $\mathrm{Pe} = \infty$ because the growth of the core is governed by the Péclet number (or Reynolds number for vortex methods) and cannot be reduced below a nontrivial value. C. Greengard discusses the matter in some detail in [4]. Regarding practical issues when computing flows, Kida [6], Kida and Nakajima [7], and Kida, Nakajima, and Suemitsu [8] have since shown that there are important applications where these spatial errors are considerably smaller than other sources of numerical errors, so meaningful calculations can be performed with these inconsistent techniques. Essentially, the inconsistent formulation is useful for applications where the timescale of interest is much smaller than the growth in core size. If one strives for consistency, there are a number of ways to check the growth of core widths, including remeshing onto a regular array elements (see [2] for a survey) as well as adaptive refinement and merging [17, 18], but this is secondary to considerations of the accuracy and performance of the underlying method.

This comparative study has two goals. First, we will determine roughly where the high spatial order method outperforms the low-order method. It worth knowing whether or not the method has concrete advantages over lower-order but more efficient methods for reasonable applications on current computing platforms. Second, we use this study to highlight quantitative and qualitative differences in the convergent behavior of the two methods. While both methods are inconsistent methods,

using deforming elements extends the range of applicability before one must apply corrections to the method. In other words, both algorithms are naturally adaptive in the sense that computational effort is expended only where the field is nontrivial, but the scheme using deforming elements is more adaptive than the method using rigid elements in a concrete sense that will be explored in section 4.

These goals are similar but not identical to Legras and Dritschel's comparison of contour surgery and pseudospectral methods [10]. Both Legras and Dritschel's study and this work represent an effort to understand the strengths and weaknesses of a new method by comparing it to an established method. This study has a more intense focus on the computational performance and efficiency of the methods in addition to their convergence toward an exact solution. In Legras and Dritschel's study, they examine a complex flow with the two numerical schemes and compare the results to one another. In this paper, we test two similar Lagrangian methods on a flow problem using three different Péclet numbers by comparing approximate solutions to a highly resolved reference solution. Where the Lagrangian methods are general algorithms, the reference solution is calculated using a spectral scheme that is customized for this particular problem geometry. Legras and Dritschel's study compares quantities such as contour moments and area increments to measure the relative proximity of solutions. This paper will present the root-mean-squared distances (L_2) between the two methods that are being tested and the reference solution. Legras and Dritschel use two levels of refinement, coarse and fine. This paper examines solutions over different flow parameters at six distinct resolutions to establish convergence properties and performance trends.

This paper is organized as follows. This section (section 1) describes the background of the problem and provides a review of relevant works by other investigators. In section 2, we present the two methods under examination and discuss the time integration scheme used by both. In section 3, we define the fluid flow problems in the test suite and the practicalities of the error measurements used in this paper. The results of these tests are in section 4. Finally, section 5 contains summary remarks and future directions in this work.

2. The semidiscrete systems and temporal integration. This study compares two methods, one using spreading Gaussian blobs and the other using deforming elliptical Gaussian blobs. As noted before, both methods are inconsistent when $\mathrm{Pe} < \infty$ but can be corrected with adaptive refinement or remeshing. The spreading term arises when we capture the diffusive term in the same discrete dynamical system used to capture the convective terms in (1.1). Some popular alternatives for capturing the diffusive term include field redistribution and random walks, but these suffer from a lack of adaptivity in the former and low efficiency and accuracy in the latter. Both require operator splitting with the associated splitting errors. The advantages of core-spreading methods are that they are fully deterministic and naturally adaptive and the particle dynamics capture the underlying partial differential equation without splitting the operator.

In this paper, we define $\widehat{\rho}$ to be the approximation using a linear combination of moving basis functions:

$$\widehat{\rho} = \sum_{i=0}^{N} \gamma_i \phi(\vec{x} - \vec{x}_i, \dots). \tag{2.1}$$

The shape of the basis function is determined by ϕ and most often is chosen to be axisymmetric. For instance, if one is trying to solve the Navier–Stokes equations

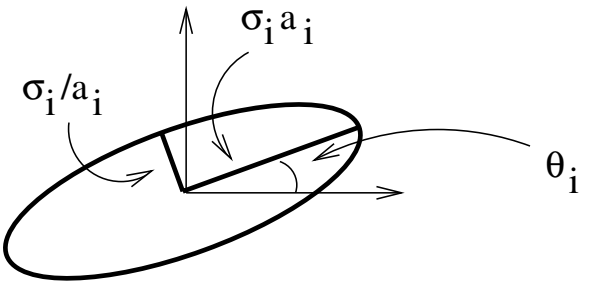

FIG. 2.1. *A schematic diagram of an elliptical Gaussian basis function as defined in* (2.3a). *The ellipse is representative of a single level set.*

where $\vec{u}$ and ρ are related via a Biot–Savart integral, then radial symmetry makes the velocity integration much simpler. The first of the two methods, which we shall refer to as the axisymmetric blob method, is the simplest available core-spreading method:

$$\phi(\vec{x},t;\vec{x}_i,\sigma_i) = \frac{1}{4\pi\sigma_i^2}\exp\left[-\frac{|\vec{x}-\vec{x}_i|^2}{4\sigma_i^2}\right], \tag{2.2a}$$

$$\frac{d\vec{x}_i}{dt} = \widehat{u}_i, \tag{2.2b}$$

$$\frac{d\sigma_i^2}{dt} = \frac{1}{\mathrm{Pe}}, \tag{2.2c}$$

where $\vec{x} = \left[\begin{smallmatrix} x \\ y \end{smallmatrix}\right]$. This method can use centroid velocity data ($\widehat{u}_i = \vec{u}(\vec{x}_i)$) with no penalty to its spatial accuracy. We shall refer to the second method in this study as the deforming blob method:

$$\phi(\vec{x};\vec{x}_i,\sigma_i,a_i,\theta_i) = \frac{1}{4\pi\sigma_i^2}\exp\left\{-\frac{|A_{\theta_i,a_i}(\vec{x}-\vec{x}_i)|^2}{4\sigma_i^2}\right\}, \tag{2.3a}$$

$$\frac{d}{dt}\vec{x}_i = \widehat{u}_i, \tag{2.3b}$$

$$\frac{d}{dt}(\sigma_i^2) = \frac{1}{2\mathrm{Pe}}(a_i^2 + a_i^{-2}), \tag{2.3c}$$

$$\frac{d}{dt}(a_i^2) = 2[d_{11}(c_i^2 - s_i^2) + (d_{12}+d_{21})s_ic_i]a_i^2 + \frac{1}{2\sigma^2\mathrm{Pe}}(1-a_i^4), \tag{2.3d}$$

$$\frac{d}{dt}\theta_i = \frac{d_{21}-d_{12}}{2} + \left[\frac{d_{21}+d_{12}}{2}(s_i^2-c_i^2) + 2d_{11}s_ic_i\right]\frac{(a_i^{-2}+a_i^2)}{(a_i^{-2}-a_i^2)}, \tag{2.3e}$$

where d_{ij} are the constituent elements of $D\vec{u}$, the matrix of partial derivatives of the velocity field $\vec{u}$, $c_i = \cos(\theta_i)$, $s_i = \sin(\theta_i)$, and

$$A_{\theta,a} = \begin{bmatrix} \cos\theta/a & \sin\theta/a \\ -a\sin\theta & a\cos\theta \end{bmatrix}. \tag{2.4}$$

So, in addition to the usual parameters, these basis functions have an orientation (θ_i) and an aspect ratio (a_i^2) as shown in Figure 2.1. The system (2.3) is larger and more complex than (2.2), and so there is a computational penalty for using the deforming blob method. Also, to have fourth-order spatial accuracy [20], the velocity field is

adjusted away from centroid velocity data as

$$\widehat{u}_i = \vec{u}(\vec{x}_i) + \sigma_i^2 \left(\vec{u}_{xx}(\vec{x}_i) M_{xx} + 2\vec{u}_{xy}(\vec{x}_i) M_{xy} + \vec{u}_{yy}(\vec{x}_i) M_{yy} \right), \tag{2.5}$$

where

$$M_{xx} = c_i^2 a_i^2 + s_i^2 / a_i^2, \tag{2.6a}$$

$$M_{xy} = c_i s_i (a_i^2 - a_i^{-2}), \tag{2.6b}$$

$$M_{yy} = c_i^2 / a_i^2 + s_i^2 a_i^2. \tag{2.6c}$$

There are no known advantages to curvature corrections in $D\vec{u}$ when using this method, though this was explored somewhat in [20].

When we approximate solutions to (1.1) using one of these schemes, we must choose a temporal integrator. For a problem where the velocity field is known and easy to compute, a Runge–Kutta method might be appropriate. However, there are many nonlinear problems where Lagrangian methods would be desirable, and in these cases, the velocity field might be expensive to compute. For instance, in vortex methods, the velocity field depends upon $\widehat{\rho}$ though a Biot–Savart integral. This is the most expensive part of the computation, even if one is using fast summation. To be general and open to the reality of extended applications, we perform the study with an explicit multistep integrator.

We use a third-order Adams–Bashforth multistep integrator for the trajectories in this comparative study. Also, we use a composite scheme because the deformation of the elements can occur on a timescale that is much faster than changes in the flow field. The deformation of each element occurs on half-steps because we would like to remain flexible and achieve second-order accuracy if the velocity were to depend upon ρ (even though it does not in this paper). Thus, the time-stepping algorithm is as follows:

1. Integrate either (2.2b) for the axisymmetric blob method or (2.3b) for the deforming blob method to move particles forward one-half a time step using an explicit stepper. Evaluate the velocity field.
2. Integrate (2.2c) for the axisymmetric blob method or (2.3c)–(2.3e) for the deforming blob method to deform basis functions for a full timestep. (2.2c) [illegible] Evaluate the velocity field.[1]
3. Integrate (2.2b) or (2.3b) to move particles forward one more half time step. Evaluate the velocity field.
4. To continue, return to step 1.

It can be shown that this simple splitting technique is second-order correct in time though it would be worthwhile to investigate whether or not there is a high-order multistep method for the entire system. The algorithm is implemented in a modular program, and the codes are identical except for the evolution equations governing the computational elements. That is, input/output, the looping structures, and all other routine tasks are absolutely identical in both codes.

[1] In the case of (2.3c)–(2.3e), an adaptive fourth-order Runge–Kutta algorithm is used with half-stepping for error control. We experimented with an adaptive Cash–Karp error control algorithm as outlined in [16] but found this to be less efficient than a simple half-stepping for this particular application.

3. The test problem. To examine the performance of the two methods, each will approximate the solution of (1.1) with an underlying differentially rotating flow given by the stream function

$$\psi = \frac{\pi}{4} r^2 + \delta(r^2 + c_1 r^4 + c_2 r^6), \tag{3.1a}$$

$$\vec{u} = \begin{bmatrix} \frac{\partial \psi}{\partial y} \\ -\frac{\partial \psi}{\partial x} \end{bmatrix}, \tag{3.1b}$$

where $\delta = 3/10$, $c_1 = -7/6$, and $c_2 = 1/10$ on an unbounded domain. This is the same flow field used in [20], but these tests will use different initial data. Where we applied axisymmetric initial data in previous work so that an exact solution could be used for convergence studies, in this study we will use a normalized, anisotropic distribution of scalar,

$$\rho(\vec{x}, 0) = \frac{32}{\pi} e^{-32\left(x^2/8 + 8y^2\right)}, \tag{3.2}$$

so that, in the absence of dissipation, fine filaments will be generated after a small number of rotations as seen in Figure 3.1. We select this sample problem because one uses Lagrangian methods when the quantity of interest, ρ, occupies a fraction of the computational domain at any given time during the simulation. While axisymmetric structures are useful for a convergence study, it is unlikely anyone would choose a Lagrangian method if the computed field was expected to fill the domain of interest. Instead, a performance measurement should involve a distribution that is more typical for the method being tested.

With this flow structure, the turnover time near the origin is about 3 but the turnover time near the edge of the structure is roughly $\frac{9}{2}$. The computation is performed until $T = 9$ so that the inside of the initial distribution is twisted a full revolution relative to the edges as seen in Figure 3.1. To test the two Lagrangian methods, the calculation is performed with $\mathrm{Pe} = 10^4$, $\mathrm{Pe} = 10^5$, and $\mathrm{Pe} = \infty$. The initial data for both methods is identical. Since the initial data has infinite support, we initially arrange computational elements over the domain

$$8(x^2/8 + 8y^2) \leq 1, \tag{3.3}$$

beyond which ρ has decayed to less than 2% of its initial maximum value. The strength of each element is determined using an exact deregularization procedure, as discussed in [21], so that the growth of spatial errors in solving (1.1) are much greater than the growth of initial errors. Isotropic particles are arranged on the domain (3.3) in a regular square lattice of width $\frac{\sigma_0}{2}$, where σ_0 is the initial core width for the trial simulation. Both methods were tested in trials with initial core widths of 8×10^{-4}, 4×10^{-4}, 2×10^{-4}, 10^{-4}, 5×10^{-5}, and 2.5×10^{-5}.

A high resolution spectral calculation will serve as a reference ("exact") solution for the convergence study. The spectral code is implemented in Matlab using scripts from Trefethen's monograph [25]. The spectral code takes advantage of the fact that we know the domain of interest a priori, so we can compute spatial derivatives spectrally on the unit disk (see Chapter 11 of the monograph) using Chebyshev interpolation in the radial direction and trigonometric interpolation in the azimuthal direction. The spectral code used in this paper modifies Trefethen's MATLAB program to take advantage of sparsity in the two-dimensional differentiation matrix.

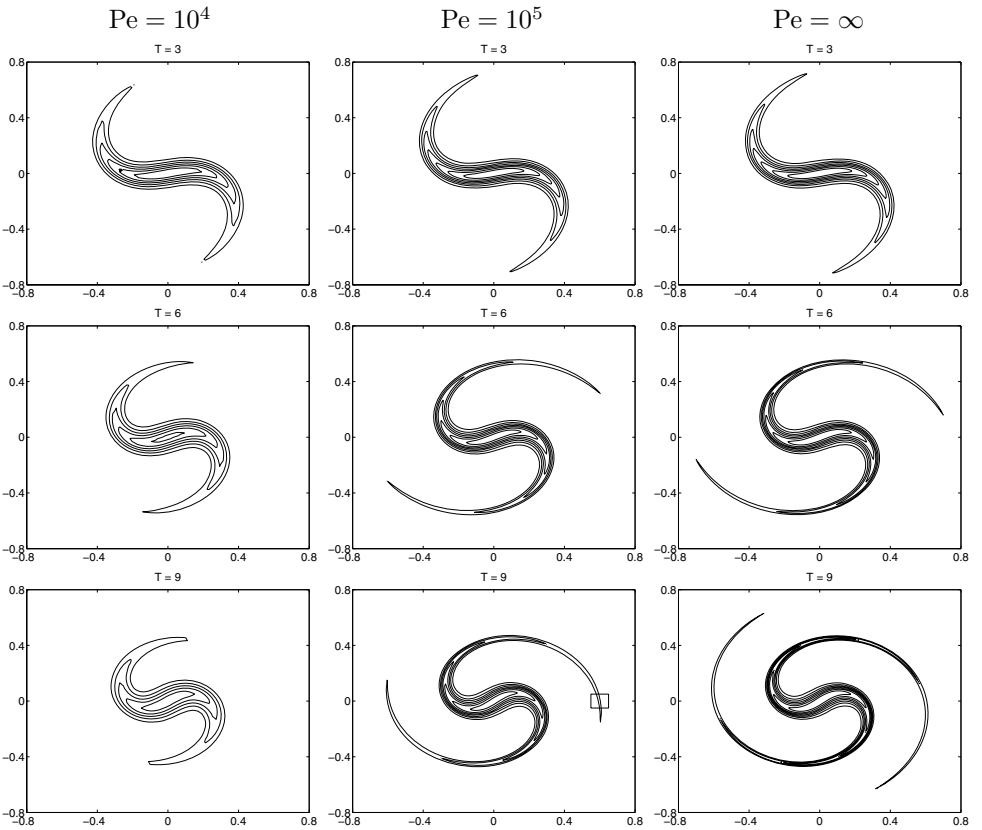

FIG. 3.1. *Solutions for* $\mathrm{Pe} = 10^4$ *(left),* $\mathrm{Pe} = 10^5$ *(center), and* $\mathrm{Pe} = \infty$ *(right). The contour increment is* 4 *units of* ρ *per division. The differential rotation of the underlying flow intensifies gradients while diffusion suppresses gradients. The long, slender filaments at high Péclet number pose a challenge to any numerical method. The area of detail indicated at the bottom center is expanded in Figure* 4.2.

Time-stepping is performed using third-order Adams–Bashforth with timesteps of either 10^{-3} or 6×10^{-5} for $\mathrm{Pe} = 10^4$ and 10^5, respectively, depending upon the stability requirements of the spectral differentiation matrix. Refinement studies indicate that all computations are temporally resolved. While the purpose of this paper is to examine the trade-offs between the axisymmetric blob method and the deforming blob method, it is worthwhile to discuss three notable distinctions between the spectral reference solution and the Lagrangian solutions.

- The most important difference is that we should achieve spectral accuracy in space from the spectral code since the exact solution is smooth for all finite time. That is, we expect the spatial accuracy to scale like C^{-N}, where N is the number of modes used in the computation. The Lagrangian methods are second order $O(\sigma^2)$ and fourth order $O(\sigma^4)$ in space, respectively. However, for very high Péclet numbers, the scalar filaments can become quite sharp, and the resulting large gradients make the spectral convergence rate very slow.
- The spectral code is designed to take advantage of the simple geometry of the test problem, whereas the Lagrangian code is general and is applicable

to any flow geometry. For instance, if we were to superpose a straining flow such as $\psi_2 = Cxy$ into the flow field, we could directly apply the same Lagrangian code, whereas the spectral code would need to be modified for a new computational domain.

- The spectral method operates on a finite domain where $\widehat{\rho} = 0$ at $r = 1$ in polar coordinates, whereas the Lagrangian code operates on an unbounded domain and the choice of basis function automatically satisfies $\widehat{\rho} \to 0$ as $r \to \infty$. Since (3.2) decays rapidly and the Péclet number is high, solutions from either method can be compared to one another.

Solutions to all calculations are compared on a uniform grid that is sufficiently fine to resolve differences down to four decimal places. For $\mathrm{Pe} = 10^4$, a 100×100 mesh is sufficient, but for $\mathrm{Pe} = 10^5$ and $\mathrm{Pe} = \infty$, a 400×400 mesh is used. For the Lagrangian computations, $\widehat{\rho}$ is computed directly at each mesh point. For the spectral reference solution, we acquire regularly spaced data using the corresponding spectral projection. To measure the difference between two solutions, u and v, we use an l_2 approximation to the L_2 norm:

$$\|u - v\|_2 = \sqrt{\sum_{i,j} (u_{i,j} - v_{i,j})^2 \Delta x \Delta y}, \tag{3.4}$$

where the sum is over all mesh points and Δx and Δy are, respectively, the width and height of the regular adjoint grid cells. Thus, the error in a test calculation is the l_2 difference between the test solution and the reference solution.

4. Results. It is no surprise that both Lagrangian methods achieve the predicted spatial convergence rate as seen in Figure 4.1 and reported in [20] because only the flow parameters and initial data have been changed. Examining (2.2) and (2.3), we see that the core sizes for the deforming elements will always be at least as large as those of the axisymmetric system. In Figure 4.1, we see that for the same initial widths, the deforming elements grow substantially larger. Yet, despite having wider elements, the deforming blob scheme realizes better results because elements conform to the local flow geometry as seen in Figure 4.2. If one extrapolates to a hypothetical situation where the initial widths are zero, one can see that the final state will correspond to the deforming blob method having wider elements but a more accurate solution. In other words, while both techniques are inconsistent if left uncorrected by remeshing or adaptive refinement techniques, the deforming blob method suffers less for it.

To measure the performance of both methods, the overall precision of the computation can be seen as a function of computational effort expended to achieve the resulting accuracy. The problem size, computational time, and overall accuracy of each computation are shown in Table 4.1. Typically, the deforming elements require between five and six times the computational effort of an axisymmetric blob because there are more degrees of freedom and the evolution of σ^2 is coupled to a^2 so neither can be solved analytically as is the case for the axisymmetric elements. In Figure 4.1, we see that the tradeoff between complexity and accuracy occurs even at small problem sizes of about 10,000 (axisymmetric) elements at $\mathrm{Pe} = 10^4$, and the improvements are realized at increasingly large problem sizes as we increase the Péclet number. This does not correspond to a loss of performance at large Pe because accurate solutions to larger Pe flow will require a larger number of computational elements to resolve it. Since it is not unusual for high-performance Lagrangian computations to use millions of computational elements, these results indicate that the use of deforming elements

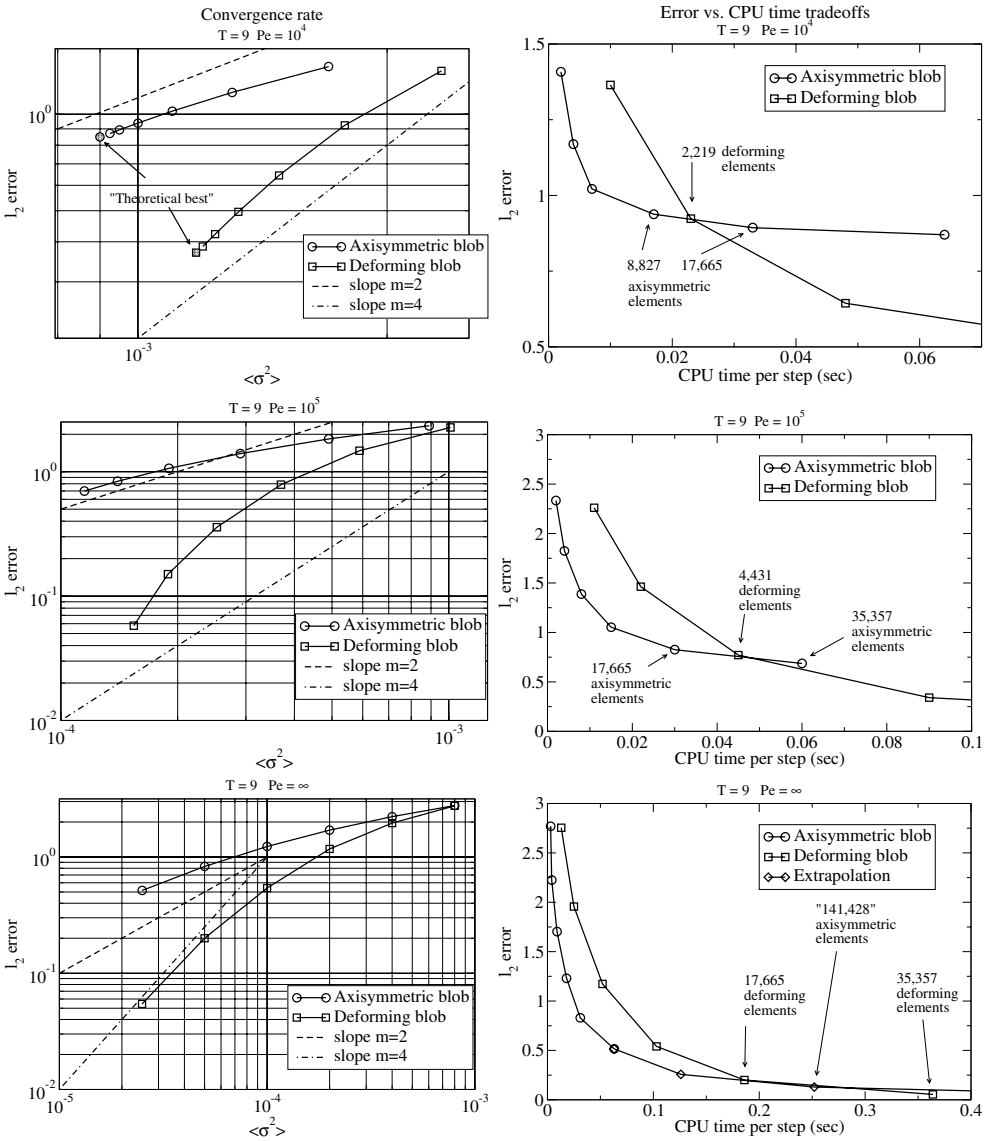

FIG. 4.1. *Convergence rates using logarithmic scales (left) and performance data (right) for test problems using the axisymmetric blob and deforming blob methods. Theoretical convergence rates are achieved for both Lagrangian methods, and the deforming blob method works better. In the absence of remeshing or adaptive refinement, both methods are inconsistent, meaning that* $\langle \sigma^2 \rangle$ *has a lower bound. The "theoretical best" value is extrapolated back to a position where initial core widths would be zero for the* $\mathrm{Pe} = 10^4$ *calculation. By examining the accuracy gained as a function of ticks of the CPU clock, we can measure the tradeoff between the simpler low-order method and the more complex high-order method. One can see that the tradeoff depends upon the Péclet number.*

would benefit many investigations, should lead to significant improvements in accuracy, and will make aggressive calculations more accessible with modest computational resources.

As a final note, it is also meaningful to report upon the spectral method used to generate reference solutions. Though the references themselves are not the focal point

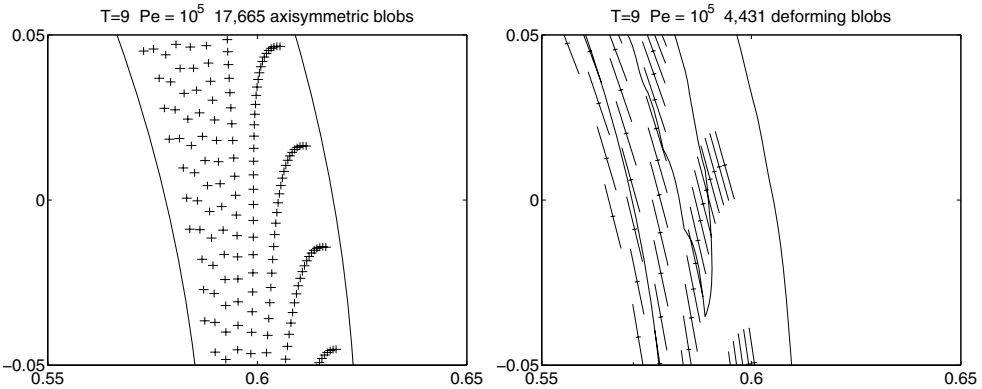

FIG. 4.2. *Sample particle positions using the axisymmetric (left) and deforming blob methods (right). Particle positions are indicated by oriented X's whose arms correspond to* $\sigma a/10$ *and* $\sigma/a/10$. *Scalar concentrations are indicated by the solid contour line. The area of detail is indicated in Figure* 3.1 *in the bottom center figure. The axisymmetric calculation uses more blobs to achieve slightly less accurate results than the deforming computation on the right. The deforming elements are more than twice as wide, but they naturally conform to the geometry of the computed field.*

TABLE 4.1

Table of computation times and accuracy of the methods used in this paper. N is the total number of computational elements. CPU is the total computational time in minutes required to run the full simulation from start to finish, including overhead costs associated with initializations, startup procedures for multistep methods, etc. Accuracy is the l_2 *error associated with the computation at various Péclet numbers.*

	Axisymmetric blob method				Deforming blob method			
N	CPU	l_2 error			CPU	l_2 error		
	(min)	$\mathrm{Pe} = 10^{-4}$	10^{-5}	∞	(min)	$\mathrm{Pe} = 10^{-4}$	10^{-5}	∞

of the paper, the efforts required to generate them merit some attention. At $\mathrm{Pe} = 10^4$, the spectral computation ran with about 100 modes azimuthally and radially in less than two hours to produce a reference solution that was well below the theoretical best solution that could be obtained with either Lagrangian method. Like the Lagrangian methods that were being tested, the spectral algorithm struggled with computations at $\mathrm{Pe} = 10^5$ and $\mathrm{Pe} = \infty$. The spectral reference solution at $\mathrm{Pe} = 10^5$ required more than 250 modes azimuthally and radially and needed roughly 28 days of CPU time. Part of the problem is that the spatial resolution required a small time step of 6×10^{-5} for the time-stepping to be stable. Before being critical about this performance, one should consider that the Lagrangian method could never reach this accuracy at all without remeshing or refinement. Also, a crafty spectral guru would know of some tricks to save memory and clock cycles or do a better job of avoiding stability boundaries. For instance, one might remap the domain to allocate more resolution away from the outer boundary and possibly dedicate more nodes closer to the filaments (see [9] for an example). When $\mathrm{Pe} = \infty$, the Lagrangian methods are consistent, and the standard spectral scheme is prohibitively expensive in both memory and time. The deforming

Lagrangian method was used to generate its own reference solution. Even with close to 150,000 particles, it ran in three and a half hours and so was the natural choice for generating a reference solution.

5. Conclusions. A number of common themes emerge from this quantitative comparison of low- and high-order Lagrangian methods. The general conclusion is that there are significant performance advantages in using the deforming blob method over the axisymmetric blob method for problems of general interest that are accessible with currently available computing devices. The more specific findings are as follows.

- The performance tradeoff depends upon the Péclet number of the problem, so the tradeoffs occur at larger problem sizes when diffusion is less dominant. The other side of this result is that one might be better off using methods with axisymmetric blobs if the resolution requirements are low.
- While both the axisymmetric and deforming blob methods are inconsistent unless one applies a correction method, the deforming blob method has a better limiting accuracy. Therefore, one can argue that the range of applicability of the deforming blob method is greater than the axisymmetric blob method, and the deforming blob method requires fewer corrections if one desires consistency.
- Both Lagrangian methods compare very favorably to the reference spectral scheme at high Péclet numbers, and this really highlights the advantage of natural adaptivity in Lagrangian schemes. As a general tool for fluid flows, the Lagrangian algorithm dedicates resources more effectively where the field is substantial. This is not intended to criticize the use of spectral methods for high Péclet number flows but rather to point out that it might require some a priori knowledge of the solution to tune the spectral scheme. The results in this paper suggest that these Lagrangian methods are high quality general tools for flow problems where the field of interest occupies a fraction of the domain of interest.

This study was designed around a problem where the exact solution can be approximated to a high degree of precision by a standard spectral method, but the problem itself is only one of many possibilities one might try. This particular problem focuses on a flow with a large sustained deformation rate. In the final analysis, we see a significant performance tradeoff where fourth-order errors are important. Since the velocity curvature governs the fourth-order corrections (2.5), (2.6), one infers that the performance advantages will be most pronounced in flows where velocity curvatures are large.

These results point toward closely related projects. To go beyond the convection-diffusion equations, one might solve the nonlinear vorticity equations where ρ would represent the vorticity of a fluid flow, but one must extract the velocity field from $\widehat{\rho}$. Some progress in this area has already been made by determining a fourth-order asymptotic expression for the Biot–Savart integral of an elliptical Gaussian [19]. Naturally, approximating the velocity field of an elliptical Gaussian is more computationally expensive than the exact evaluation for an axisymmetric Gaussian. However, in practical calculations, one uses fast summation algorithms which reduce the computational complexity by separating near and far field velocity contributions. For examples of different adaptive summation methods, see [1, 3, 5, 13]. Anisotropic elements in the far field introduce no added complexity or computational effort, so contributions from the far field would not differ significantly for axisymmetric and nonaxisymmetric blobs. However, direct interactions in the near field would be more

costly for anisotropic elements than for isotropic elements.

Along different lines, one might examine the three-dimensional convection-diffusion equations using deforming ellipsoidal Gaussian blobs. Many of the ideas and techniques in this paper and in [20] would apply. Finally, most of the work on remeshing and adaptive refinement has focused on axisymmetric elements. Generalizations to these techniques for highly anisotropic blobs should be explored to make methods like these fully consistent in flow calculations with finite diffusivity.

Acknowledgments. The author would like to thank Prof. Toby Driscoll at the University of Delaware for his helpful advice on the practicalities of implementing the spectral code used in this paper, and the referees for their thoughtful comments and suggestions.

AUTHORITY RANKINGS FROM HITS, PAGERANK, AND SALSA: EXISTENCE, UNIQUENESS, AND EFFECT OF INITIALIZATION*

AYMAN FARAHAT†, THOMAS LOFARO‡, JOEL C. MILLER§, GREGORY RAE¶, AND LESLEY A. WARD¶

Abstract. Algorithms such as Kleinberg's HITS algorithm, the PageRank algorithm of Brin and Page, and the SALSA algorithm of Lempel and Moran use the link structure of a network of web pages to assign weights to each page in the network. The weights can then be used to rank the pages as authoritative sources. These algorithms share a common underpinning; they find a dominant eigenvector of a nonnegative matrix that describes the link structure of the given network and use the entries of this eigenvector as the page weights. We use this commonality to give a unified treatment, proving the existence of the required eigenvector for the PageRank, HITS, and SALSA algorithms, the uniqueness of the PageRank eigenvector, and the convergence of the algorithms to these eigenvectors. However, we show that the HITS and SALSA eigenvectors need not be unique. We examine how the initialization of the algorithms affects the final weightings produced. We give examples of networks that lead the HITS and SALSA algorithms to return nonunique or nonintuitive rankings. We characterize all such networks in terms of the connectivity of the related HITS authority graph. We propose a modification, Exponentiated Input to HITS, to the adjacency matrix input to the HITS algorithm. We prove that Exponentiated Input to HITS returns a unique ranking, provided that the network is weakly connected. Our examples also show that SALSA can give inconsistent hub and authority weights, due to nonuniqueness. We also mention a small modification to the SALSA initialization which makes the hub and authority weights consistent.

1. Introduction.

The rapid growth of the World Wide Web has created a need for search tools. In the past, search engines ranked pages by using word frequency or similar measures. Recently, new algorithms have been created that greatly improve rankings, using the network structure of the web. Two prominent ranking algorithms are PageRank [3] (the underlying method of the search engine) and HITS [9, 15] (Hypertext Induced Topic Search). A third algorithm, SALSA [17] (Stochastic Approach for Link Structure Analysis), combines ideas from PageRank and HITS. Some search tools, such as HITS, first use conventional information-retrieval techniques to identify a subnetwork of pages relevant to a particular query, and then order the results so that the most relevant web pages are presented near the top of the list. Others, such as PageRank, rank the whole web on an absolute scale and then select

those pages relevant to the query, preserving the order.

The common thread running through these methods is linear algebra. For each method, the ranking vector is the dominant eigenvector of some matrix describing the network. How this matrix is defined differs in each method. However, this commonality allows us to establish theorems (see section 3) providing conditions for each method which ensure the convergence of the algorithm, existence of solutions, and uniqueness of solutions. These results also apply to any other methods that reduce to the computation of a dominant eigenvector.

Introducing the HITS algorithm in [15, p. 613], Kleinberg writes:

> For the sake of simplicity, we will make the following technical assumption ... $|\lambda_1(M)| > |\lambda_2(M)|$ [that is, the dominant eigenvalue is simple]. ... When the assumption does not hold, the analysis becomes less clean, but it is not affected in any substantial way.

This idea has been repeated in (among others) [2, 5, 6, 11, 18, 25]. See, for example, this passage from [6, p. 5]:

> iteration will converge to the principal eigenvector for any "nondegenerate" choice of initial vector — ... for example, for any vector all of whose entries are positive. This says that the hub and authority weights we compute are truly an [illegible] feature of the collection of linked pages, not an artifact of our choice of initial weights or the tuning of arbitrary parameters. [Italics in the original.]

In this paper we take up the question of the choice of initial weights. We examine the dependence of the results of the algorithms on changes in initialization. The key point is that the dominant eigenvalue of the appropriate matrix need not be simple. When it is simple, the convergence asserted above for HITS is valid. However, when the dominant eigenvalue is repeated, the ranking vector could be any nonnegative vector in the multidimensional dominant eigenspace. (This occurs for HITS in our example in Figure 4.1, section 4.) In particular, the ranking vector may not be unique, but may depend on the initial seed vector.

Even when the dominant eigenvalue is simple, HITS can return inappropriate zero weights (Figure 4.3, section 4).

We show that the HITS and SALSA algorithms are "badly behaved" on certain networks, meaning that (i) they can return ranking vectors that are not unique but depend on the initial seed vector or (ii) HITS can return ranking vectors that inappropriately assign zero weights to parts of the network. In some cases, this behavior can cause SALSA to return hub and authority weights that are inconsistent.

We characterize all networks where HITS and SALSA are badly behaved in terms of the connectivity of a certain related graph (our [illegible], Definition 4.3). We propose a modification, [illegible], of the adjacency matrix input to the HITS algorithm; our new input matrix adds information about longer paths in the network. We prove that with Exponentiated Input, the HITS algorithm returns a unique eigenvector, without inappropriate zero weights, as long as the network is weakly connected.

Here is an outline of the paper. In section 2, we review four eigenvector ranking algorithms, namely, the PageRank, HITS, and SALSA algorithms, along with our Exponentiated Input modification to the adjacency matrix input to the HITS algorithm. For each algorithm, we identify the nonnegative matrix that describes the structure of the network being considered.

In section 3, we review the Perron–Frobenius theorems which deal with the properties of dominant eigenvalues and eigenvectors of nonnegative matrices. We present existence and (where applicable) uniqueness results for the dominant eigenvectors the ranking algorithms find. In particular, we show that Exponentiated Input to HITS does return a unique ranking (independent of the initialization), without inappropriate zero weights, when the network graph is weakly connected.

In section 4, we give examples of simple networks for which the HITS and SALSA algorithms return nonunique dominant eigenvectors and for which HITS assigns inappropriate zero weights to significant parts of the network. We say that an algorithm is [illegible] on a network if it has either of these two features. We give a characterization of all networks for which HITS and SALSA are badly behaved in terms of the connectivity of our HITS authority graph G' (Definition 4.3), which is an undirected graph related to the directed graph representing the network.

For our example in section 4, Figure 4.1, SALSA returns authority and hub vectors which are inconsistent. In section 4.3 we suggest a modification to the SALSA initialization which makes the vectors consistent.

In section 5 we discuss related issues, including stability of the algorithms, sample networks for which the dominant and second eigenvalues are arbitrarily close for Exponentiated Input to HITS, and other possible modifications of the adjacency matrix input to HITS. Section 6 considers related work, and section 7 gives our conclusions.

2. Eigenvector-based ranking algorithms. To prepare our review of the eigenvector-based ranking algorithms (or [illegible]) PageRank, HITS, Exponentiated Input to HITS, and SALSA, we give some definitions.

The network of web pages and links defines a directed graph G, with the web pages defining the nodes $1, \ldots, n$ and the links defining the edges. This graph is described by an $n \times n$ [illegible] A, where $a_{ij} = 1$ if there is a link from page i to page j and $a_{ij} = 0$ otherwise. We use the following standard definitions from graph theory.

DEFINITION 2.1. [illegible] indegree (outdegree) [illegible] i [illegible] G [illegible] ([illegible]) i

DEFINITION 2.2. [illegible] G weakly connected [illegible]

The notion of dominant eigenvectors and eigenvalues is central to the descriptions of the algorithms in terms of linear algebra.

DEFINITION 2.3. [illegible] dominant eigenvector [illegible] ([illegible]) dominant [illegible] largest [illegible]

We note that some authors use the term [illegible] in a slightly different sense. Also, in [15] the term [illegible] indicates an eigenvector whose eigenvalue is simple and of [illegible] largest modulus.

With our definitions, we can describe the four linear link analysis algorithms.

2.1. PageRank. The PageRank method, developed by Brin and Page [3], is a random walk with random resets on G. This process describes a Markov chain. Let W be the transition probability matrix describing the Markov chain without reset, so that the (i, j)-entry in W gives the probability of following a link on page i to page j. Assuming all links are equally likely, W is derived from A by

$$w_{ij} = \frac{a_{ij}}{\sum_{k=1}^{n} a_{ik}}. \tag{2.1}$$

If at least one node has zero outdegree, then the Markov chain is absorbing, and a modification to W is needed. For instance, PageRank temporarily removes the links to all such nodes, then replaces them after the ranking is calculated [23].

The random reset part of PageRank is described by a probability $\varepsilon < 1$, which determines whether we restart, and a (positive) uniform transition probability matrix U having $u_{ij} = 1/n$ for all i and j. (Positive, nonuniform choices for U are also possible.) Combining these two elements we conclude that the PageRank algorithm is described by the stochastic matrix

$$P = \varepsilon U + (1 - \varepsilon)W. \tag{2.2}$$

With probability ε we randomly choose a new page. Otherwise we follow one of the directed edges from our present node.

The relationship between Markov chains such as this and linear algebra is well understood (see Gantmacher [8], for example). The stationary distribution of this Markov chain is simply the dominant eigenvector of the matrix P^T (the transpose of P). We return to this point in section 3.

2.2. HITS. The HITS algorithm was developed by Kleinberg [15] and is now a part of the CLEVER Searching project of the IBM Almaden Research Center [13]. Similar ideas are used in the Teoma search engine, subsequently acquired by Ask Jeeves [24]. The premise of the algorithm is that a web page serves two purposes: to provide information on a topic and to provide links to other pages giving information on a topic. This gives rise to two ways of categorizing a web page. First, we consider a web page to be an [illegible] on a subject if it provides good information about the subject. Second, we consider the web page to be a [illegible] if it provides links to good authorities on the subject. The HITS algorithm is an iterative algorithm developed to quantify each page's value as an authority and as a hub.

The HITS algorithm is not applied to the graph representing the whole web, but rather to a subgraph, typically of 1000–5000 nodes, derived from traditional text matching of the query terms in the search topic.

We again consider the directed graph G. Each node i is given an initial authority weight $a_0(i)$ and hub weight $h_0(i)$, although the initial authority weights are not used by the algorithm as presented in [15, p. 612]. To begin the algorithm, these nodes are uniformly weighted. The original paper [15, p. 614] states "one can compute weights ... starting from any initial [weights]." We will later discuss complications that can arise if the initial weighting is changed or if the algorithm starts from the initial authority weights instead of the initial hub weights.

The algorithm proceeds iteratively, until values from successive iterations are within a specified error, as follows.

1. In the kth iteration, node i is assigned a new authority weight $a_k(i)$ equal to the sum of $h_{k-1}(j)$, where the sum runs over each node j which points to node i. This is repeated for all nodes in G.

2. The new hub weight $h_k(i)$ is the sum of $a_k(j)$, where the sum runs over the nodes j to which node i points. This is repeated for all nodes in G. Note that the hub weights are computed from the [illegible] authority weights, which in turn were computed from the [illegible] hub weights.

3. Still in the kth iteration, after new weights are computed for all nodes, the weights are normalized so that $\sum_i a_k(i)^2 = \sum_i h_k(i)^2 = 1$.

To construct a linear algebra formulation of this method, we create a vector $\vec{a}_k$ of

the authority weights at iteration k and another vector $\vec{h}_k$ of the hub weights, where

$$\vec{a}_k = [a_k(1), a_k(2), \ldots, a_k(n)]^T, \tag{2.3}$$

$$\vec{h}_k = [h_k(1), h_k(2), \ldots, h_k(n)]^T. \tag{2.4}$$

A uniform initialization gives

$$\vec{a}_0 = [1/\sqrt{n},\ 1/\sqrt{n},\ \ldots,\ 1/\sqrt{n}]^T, \tag{2.5}$$

$$\vec{h}_0 = [1/\sqrt{n},\ 1/\sqrt{n},\ \ldots,\ 1/\sqrt{n}]^T \tag{2.6}$$

up to normalization. When A is the adjacency matrix of the directed graph G, the algorithm becomes

$$\vec{a}_k = \phi_k A^T \vec{h}_{k-1}, \qquad \vec{h}_k = \psi_k A \vec{a}_k, \tag{2.7}$$

where ϕ_k and ψ_k are the normalization constants chosen such that the sum of the squares of the authority weights, as well as that of the hub weights, is 1 in the kth iteration.

Combining the formulas in (2.7), we reach

$$\vec{a}_k = \phi_k \psi_{k-1} A^T A \vec{a}_{k-1} \qquad \text{for } k > 1; \tag{2.8}$$

$$\vec{h}_k = \psi_k \phi_k A A^T \vec{h}_{k-1} \qquad \text{for } k > 0. \tag{2.9}$$

When this method converges, the resulting authority and hub vectors satisfy

$$\vec{a}^* = \frac{1}{\lambda^*} A^T A \vec{a}^*, \qquad \vec{h}^* = \frac{1}{\lambda^*} A A^T \vec{h}^*. \tag{2.10}$$

In other words, the authority vector $\vec{a}^*$ is an eigenvector of $A^T A$, and the hub vector $\vec{h}^*$ is an eigenvector of AA^T. It is simple to show (see section 3.2) that these eigenvectors are, as in the case of PageRank, dominant eigenvectors corresponding to the dominant eigenvalue λ^*. To avoid confusion, it should be noted that throughout this paper, we do not concern ourselves with the eigenvalues of A, but just those of $A^T A$ and AA^T.

2.3. Exponentiated Input to HITS. In [20], we showed that certain network topologies caused the standard HITS algorithm to return either nonunique or non-intuitive results (see section 4). We developed the Exponentiated Input method to address these limitations. HITS's direct dependence on the adjacency matrix A restricts it, in a given iteration step, to considering only paths of length 1. That is, to determine the hub score of a page, at each iteration HITS looks only at the authority scores of adjacent pages. We replace A by a new matrix with information about longer paths.

To consider paths of length greater than 1, we note that given an adjacency matrix A, the number of paths of length m from node i to node j is given by the (i, j)-entry of A^m. We want to consider paths of length 1 to be more important than paths of length 2, 3, and so on. To accomplish this we use the new matrix

$$A + A^2/2! + A^3/3! + \cdots + A^m/m! + \cdots = e^A - I. \tag{2.11}$$

This series converges, since each entry in the mth term of the series can be bounded by $n^m/m!$. While the original adjacency matrix A is binary, $e^A - I$ need not be.

Using this new "exponentiated" matrix $e^A - I$, the HITS algorithm with exponentiated input can be expressed in linear algebra terms as follows. We initialize the authority and hub vectors so that $a_0(i) > 0$ and $h_0(i) > 0$ for all i, and $\sum_i a_0(i)^2 = \sum_i h_0(i)^2 = 1$. (Again, the uniform initialization $a_0(i) = h_0(i) = 1/\sqrt{n}$ is one possibility, and again, $\vec{a}_0$ is never used.) For $k \geq 1$, we [illegible] A [illegible] $e^A - I$, so that we define

$$\vec{a}_k = \phi_k (e^A - I)^T \vec{h}_{k-1}, \qquad \vec{h}_k = \psi_k (e^A - I)\vec{a}_k \tag{2.12}$$

for $k > 0$, with normalization constants ϕ_k, ψ_k. We will show that the sequence $\{\vec{a}_k\}$ approaches the eigenspace of the largest eigenvalue of $(e^A - I)^T(e^A - I)$, and that the sequence $\{\vec{h}_k\}$ approaches the eigenspace of the largest eigenvalue of $(e^A - I)(e^A - I)^T$.

We prove in sections 3.2 and 3.3 that given a weakly connected input graph, the Exponentiated Input modification of HITS prevents the possibilities of (i) returning nonunique rankings that depend on the initialization and (ii) returning inappropriate zero weights. Other matrices such as $A + A^2/2$ or $I + A$ rather than $e^A - I$ would also exclude these possibilities; again, so long as G is weakly connected.

2.4. SALSA. The SALSA (stochastic approach for link structure analysis) algorithm, developed by Lempel and Moran [17], combines the random walk idea of PageRank with the hub/authority idea of HITS. Given a graph G, a bipartite undirected graph H is constructed by building the subset V_a of all the nodes with positive indegree (the potential authorities), and the subset V_h of all the nodes with positive outdegree (the potential hubs). After renumbering, the elements of V_a and V_h become the nodes of H. Since some nodes may have both positive indegree and outdegree, the number m of nodes of H satisfies $m \leq 2n$, where n is the number of nodes of G. The (undirected) edges of H are defined from G as follows: if G has a link from i to j, then we put an edge between the nodes corresponding to i in V_h and j in V_a. The algorithm corresponds to a two-step random walk on the graph H.

If we pick a node in V_a and randomly follow an edge, we traverse to a node in V_h. A second step returns us to V_a. Thus a pair of two-step random walks, one starting in V_a and the other in V_h, can be used to determine the hub and authority vectors. As in the PageRank scheme, each random walk is a Markov chain with a corresponding transition probability matrix. As before, let A be the adjacency matrix of G. Let W_r be the matrix generated from A by dividing each entry of A by its row sum. Similarly define W_c to be generated by dividing each entry of A by its column sum. We arrive at $\vec{a}_k = W_c^T W_r \vec{a}_{k-1}$ and $\vec{h}_k = W_r W_c^T \vec{h}_{k-1}$. Note that the sequence $\vec{a}_k$ depends on the initialization $\vec{a}_0$, and $\vec{h}_k$ depends on the initialization $\vec{h}_0$. This contrasts with HITS, where both sequences depend on $\vec{h}_0$, and leads to subtle differences in the behavior of the two algorithms. In particular the SALSA limits $\vec{a}$ and $\vec{h}$ may not satisfy $\vec{a} = W_c^T \vec{h}$.

A significant advantage of SALSA is that the weightings can be computed explicitly without the iterative process described here [17]. Although the initial paper provides an explicit calculation only in the case of uniform initial weights, this quick method of calculating the weightings can be easily generalized to accommodate nonuniform initial weights.

3. Existence and convergence. Each of the algorithms presented in section 2 reduces to computing the dominant eigenvector of some matrix that describes the connectivity of the given graph. In this section, we discuss the graph properties that ensure the existence and uniqueness of these eigenvectors. If the dominant eigenvalue is repeated, it will have a full eigenspace, and a unique ranking does not exist.

Therefore, perhaps unexpectedly, the ranking returned by an algorithm depends on the initialization used to start the algorithm. We discuss this in greater detail in section 4.

3.1. The Perron–Frobenius theorems. We begin by presenting the necessary theorems concerning dominant eigenvalues and eigenvectors of nonnegative matrices. These theorems describe why the ranking vectors of the above methods exist and when the rankings are unique. In addition, the different hypotheses allow us to describe shortcomings of HITS and SALSA (see section 4). The following definitions and theorems (including proofs) can be found in Gantmacher [8].

DEFINITION 3.1. M positive M nonnegative M

DEFINITION 3.2. M matrix permutation σ_{ij} (i,j) i j i j

A matrix permutation applied to the adjacency matrix of a graph corresponds to a relabeling of the nodes. We use the notation $\circ$ for composition of matrix permutations.

DEFINITION 3.3. M reducible $\sigma = \sigma_{i_1,j_1} \circ \cdots \circ \sigma_{i_m,j_m}$

$$\sigma(M) = \begin{pmatrix} M_1 & 0 \\ M_2 & M_3 \end{pmatrix}, \tag{3.1}$$

M_1 M_3 0 M irreducible

A graph is said to be strongly connected if every node can be reached from every other node following the direction of the edges. It can be shown that a graph whose (weighted) adjacency matrix is M is strongly connected if and only if the matrix is irreducible. This is commonly used as an equivalent definition of irreducibility.

The following three theorems concern the existence and multiplicity of a dominant real eigenvalue and the properties of its corresponding eigenvector. For our results, it is particularly important whether or not the dominant eigenvalue is simple. The first theorem, due to Perron, has the most restrictive hypothesis.

THEOREM 3.4. M r r

Frobenius generalized Perron's result to irreducible nonnegative matrices. The conclusions are naturally weaker in the sense that there may be other eigenvalues having the same modulus as r. However, the dominant real eigenvalue has multiplicity 1.

THEOREM 3.5. M r r r

Finally, if we remove the irreducibility hypothesis, even less can be said. (Consider, for instance, the identity matrix, whose dominant eigenvalue is of course not simple.) However, the dominant real eigenvalue r does exist, is nonnegative, and has a nonnegative eigenvector.

THEOREM 3.6. M r r r

We give a lemma that will help to show that for HITS, the nonnegative eigenvalue found using the above theorems is in fact larger in modulus than all other eigenvalues.

LEMMA 3.7. B B^TB .

. The eigenvalues are real and have full eigenspaces because $M = B^TB$ is symmetric. To show that they are nonnegative, we must show that $x^TMx \geq 0$ for any vector x [16]. This is straightforward: $x^TMx = x^TB^TBx = |Bx|^2 \geq 0$. ∎

3.2. Existence and uniqueness of ranking vectors. In this section, we present existence and uniqueness results for positive or nonnegative dominant eigenvectors of the associated matrices for the four algorithms. In section 3.3, we address convergence to these eigenvectors. Theorems similar to those below can be found in the original papers, but the results on uniqueness (or lack thereof) in Theorems 3.9 and 3.10 seem to have been largely overlooked.

THEOREM 3.8 (PageRank). G A ε (2.2) U .

Here, by the phrase , we mean that the PageRank matrix P for G has an eigenvector (which we call the PageRank vector) corresponding to a positive eigenvalue that is at least as large as the modulus of every other eigenvalue of P, and similarly for the HITS, SALSA, and Exponentiated Input to HITS hub and authority vectors in Theorems 3.9, 3.10, and 3.11 below.

3.8. The result follows immediately from Theorem 3.4. If $\varepsilon > 0$ and U is a positive matrix, then the matrix P of (2.2) is positive, and hence P^T has a simple dominant eigenvalue, which is positive, with a unique eigenvector having positive entries. Convergence of the PageRank algorithm to this eigenvector follows from the theory of Markov chains. See, for instance, [19, p. 490]. ∎

THEOREM 3.9 (HITS). G A

. AA^T and A^TA are nonnegative. Theorem 3.6 gives the result. ∎

THEOREM 3.10 (SALSA). G A

. The matrices $W_c^TW_r$ and $W_rW_c^T$ defined in section 2.4 are nonnegative. Theorem 3.6 gives the result. ∎

We have proved that the eigenvector exists for HITS and SALSA. As we show in section 4, it may not be unique, since the dominant eigenvalue may be repeated (although all other eigenvalues are smaller in modulus, by Lemma 3.7 for HITS and by the theory of Markov chains for SALSA as shown in [17]). However, for Exponentiated Input to HITS, the eigenvector is unique, as we now show.

THEOREM 3.11 (Exponentiated Input to HITS). G A G G

. We prove this result by showing that the authority matrix $(e^A - I)^T(e^A - I)$ has a simple dominant eigenvalue whose eigenvector is positive exactly on those nodes whose indegree is positive. The proof for the hub matrix is analogous.

Without loss of generality, we assume that G has n nodes, t of which have indegree equal to zero, and that those nodes with indegree zero are labeled $n-t+1,\dots,n$. Then the adjacency matrix is given by

$$A = \begin{pmatrix} \widetilde{A} & 0 \\ \widetilde{B} & 0 \end{pmatrix}, \tag{3.2}$$

where $\widetilde{A}$ is $(n-t)\times(n-t)$ and the matrix $\widetilde{B}$ is $t\times(n-t)$. The last t columns of

$$e^A - I = A + A^2/2! + \cdots + A^m/m! + \cdots \tag{3.3}$$

have only zero entries. Therefore

$$(e^A - I)^T(e^A - I) = \begin{pmatrix} C & 0 \\ 0 & 0 \end{pmatrix}, \tag{3.4}$$

where $C = (e^{\widetilde{A}} - I)^T(e^{\widetilde{A}} - I)$. Moreover, the characteristic polynomial of $(e^A - I)^T(e^A - I)$ is $\lambda^t p_C(\lambda)$ where $p_C(\lambda)$ is the characteristic polynomial of C. Hence if C has a simple, dominant, positive eigenvalue, then the same is true for $(e^A - I)^T(e^A - I)$. Further, if the corresponding eigenvector of C is positive, then the corresponding eigenvector of $(e^A - I)^T(e^A - I)$ is the same vector, padded with 0 entries for all the zero indegree nodes. Lemma 3.7 shows that the eigenvalues of C are real and nonnegative. We need to show that C is irreducible so that Theorem 3.5 applies.

Let G' be the graph whose (weighted) adjacency matrix is given by C. This graph G' is the analogue, for Exponentiated Input to HITS, of our HITS authority graph; see section 4.2 and especially Definition 4.3. Note that G' can be considered an undirected graph because C is symmetric. C is irreducible if and only if G' is connected. We seek to show that G' is connected.

The (i,j)-entry of C is nonzero if and only if there is a node k such that the original graph G has a path from k to i and a path from k to j. From this we conclude that all vertices that can be reached from a node k following the links in G must be in the same component of G'. Further, if k has nonzero indegree, it follows that k is in that component of G' as well.

Let us assume that G' is disconnected. Then it can be separated into two components H_1 and H_2 (which may themselves be disconnected). It must be true that there is no link between H_1 and H_2 in G. Since G is weakly connected, there must be a node (with zero indegree) that links to some node l in H_1 and to another node m in H_2. However, that would lead to a connection between these nodes (l and m) in G', contradicting the assumption that G' is disconnected.

Thus G' is connected and C is irreducible. This completes the proof. □

A close inspection of the proof shows that if the more easily computable matrix $A + A^2/2$ were used instead of $e^A - I$, then the result would still hold. The main observation needed is that all nodes that can be reached from a given node i following edges in G are still in the same component of G'. This is because a link from i to j and a link from j to k in G will imply a link between j and k in G'. Consequently the proof above still applies.

Alternatively we could use $I + A$, as the graph G' contains the graph G (ignoring direction) as a subgraph. Consequently, if G is weakly connected, then G' is connected. Since G' is connected, the same arguments then show that the algorithm converges uniquely. The graph G' will be discussed in more detail later.

3.3. Convergence of the ranking algorithms. All of the methods described in section 2 reduce to the computation of a dominant eigenvector. However, PageRank and SALSA compute this eigenvector using a Markov chain method, while HITS and Exponentiated Input to HITS are formulated in terms of summing the weights of linked nodes at each step.

A probability transition matrix is [illegible] if some power of the matrix is positive. Moreover, a regular transition matrix has a unique dominant eigenvector that (after scaling) gives the stationary distribution of the associated Markov chain.

The transition matrix P of the PageRank method is positive, and hence regular, if the random reset parameter $\varepsilon > 0$. The ergodic theorem guarantees that the random walk process that PageRank uses converges to the stationary vector of the transition matrix. Therefore PageRank converges to a unique ranking vector.

SALSA also uses this approach. However, because SALSA does not incorporate random reset, the graph structure affects whether the ranking vector is unique. In particular, if the bipartite graph H is not connected, then the authority and hub vectors are not unique. The original SALSA paper showed, using the ergodic theorem, that each component of the graph has a simple dominant eigenvalue which is equal to one. Each component will converge on its own, and the final result will depend on how much weight each component is given in the initialization.

The HITS and Exponentiated Input to HITS methods differ only in their input matrices, and so the proof of convergence is identical for both methods. We offer a heuristic proof, followed by a short rigorous proof.

It is sufficient to consider the convergence of the hub vector $\vec{h}_k$. Let $\lambda_1 \geq \lambda_2 \geq \cdots \geq \lambda_n \geq 0$ be the eigenvalues of AA^T. Because AA^T is symmetric, each eigenvalue has a full eigenspace and the eigenvectors can be chosen to form an orthogonal basis for $\mathbf{R}^n$.

We can express $\vec{h}$ as a linear combination of the eigenvectors $\vec{v}_1, \ldots, \vec{v}_n$. So $\vec{h}_1 = \alpha_1\vec{v}_1 + \cdots + \alpha_n\vec{v}_n$, where $\alpha_i = \vec{h}_1 \cdot \vec{v}_i / \|\vec{v}_i\|^2$. Then $\vec{h}_2 = \lambda_1\alpha_1\vec{v}_1 + \cdots + \lambda_n\alpha_n\vec{v}_n$. Suppose $\lambda_1 = \lambda_2 = \cdots = \lambda_r \neq \lambda_{r+1}$. We can rewrite $\vec{h}_2$ as $\lambda_1(\alpha_1\vec{v}_1 + \cdots + \alpha_r\vec{v}_r) + \lambda_{r+1}\alpha_{r+1}\vec{v}_{r+1} + \cdots + \lambda_n\alpha_n\vec{v}_n$. Iterating, we obtain

$$\vec{h}_{k+1} = \xi_k \left(\lambda_1^k [\alpha_1\vec{v}_1 + \cdots + \alpha_r\vec{v}_r] + \sum_{i=r+1}^{n} \lambda_i^k \alpha_i \vec{v}_i \right), \tag{3.5}$$

where $\xi_k = \psi_k\phi_k\xi_{k-1}$ is the normalization constant. As k increases, the λ_1^k term dominates. Thus, $\vec{h}_k \to c\,(\alpha_1\vec{v}_1 + \cdots + \alpha_r\vec{v}_r)$. A closer analysis shows that $\psi_k\phi_k \to \lambda_1$, which gives a numerical test for convergence.

We now offer a rigorous proof of convergence.

THEOREM 3.12. [illegible] $\vec{a}_k$ [illegible]
[illegible] A^TA [illegible] $\vec{h}_k$ [illegible]
[illegible] AA^T [illegible]
$(e^A - I)^T(e^A - I)$ [illegible] $(e^A - I)(e^A - I)^T$

The HITS algorithm computes all future hub and authority vectors, $\vec{h}_k$ and $\vec{a}_k$, $k \geq 1$, from the initial [illegible] vector $\vec{h}_0$; it does not use the initial authority vector $\vec{a}_0$ (section 2.2). A fine point is that if instead the HITS algorithm were implemented so that it made use of the initial [illegible] vector and ignored the initial hub vector, then the resulting authority vectors $\vec{a}_k$ could converge to a [illegible] vector. Figure 4.1 gives

an example where this would happen. Theorem 4.4 provides a sufficient condition for HITS to converge to the same authority vector, regardless of whether HITS makes use of $\vec{h}_0$ or $\vec{a}_0$. If G' is weakly connected, Theorem 3.11 proves that Exponentiated Input to HITS also enjoys that uniqueness property.

3.12. The eigenvalues of AA^T are real and nonnegative. It follows that while the eigenvalue of largest modulus may be repeated, all other eigenvalues have strictly smaller modulus. Since AA^T is symmetric, the eigenspaces are orthogonal. In the dominant eigenspace, we can use Gram–Schmidt orthonormalization to choose orthogonal vectors such that one of them is nonnegative. Because $\vec{h}_0$ is positive, its dot product with this nonnegative vector is positive, and thus $\vec{h}_0$ has a nontrivial component in the eigenspace of the dominant eigenvalue. This ensures that the algorithm converges to an eigenvector of the largest eigenvalue [10, pp. 351–353]. By the construction of the HITS algorithm, the limit cannot have negative entries. Note that although the algorithm converges, it could converge to any nonnegative, normalized vector in the eigenspace of the dominant eigenvalue λ_1, depending on the initial choice $\vec{h}_0$ of the hub weights.

The same argument applies to the HITS authority vector and to the authority and hub vectors for the Exponentiated Input to HITS algorithm. □

We note that one could apply the PageRank idea of adding a matrix εU, where $\varepsilon > 0$ and U is a positive matrix, to the matrices AA^T and A^TA for HITS, $W_rW_c^T$ and $W_c^TW_r$ for SALSA, and $(e^A - I)(e^A - I)^T$ and $(e^A - I)^T(e^A - I)$ for Exponentiated Input to HITS. (For the last-mentioned algorithm, this would be needed only when G is not weakly connected and so the dominant eigenvalue is not already known to be simple.) Since the resulting perturbed matrices are positive, Theorem 3.4 then guarantees the existence and uniqueness of a dominant eigenvector for each perturbed matrix. One could then use perturbation analysis to study the stability of the resulting eigenvector and how close this eigenvector is to the dominant eigenspace of the original unperturbed matrix—in particular, how close the resulting authority vector is to the possible authority vectors given by the original matrix.

4. Limitations of the HITS and SALSA algorithms. In the previous section, we presented conditions for the existence and uniqueness of ranking vectors. The weakest conclusions were for the HITS and SALSA algorithms. In this section we explore in more detail the limitations of these two methods. The key questions here are whether the largest eigenvalue of A^TA for HITS, or of $W_c^TW_r$ for SALSA, is simple or repeated and whether its eigenvector has inappropriate zero entries.

4.1. Examples. We begin by considering a few simple examples that illustrate some limitations of the HITS and SALSA algorithms.

We first demonstrate the problem of repeated largest eigenvalue as the initialization changes. Examples of networks with repeated largest eigenvalue for HITS have appeared in [20] and independently in [2, section 5] (where they were considered in the context of finding communities). The initial SALSA paper [17] mentioned the possibility of a repeated dominant eigenvalue but did not investigate changes in the initialization.

With the uniform initialization $\vec{h}_0 = [1/\sqrt{n}, 1/\sqrt{n}, \ldots, 1/\sqrt{n}]^T$ for the hub vector, the HITS algorithm applied to the network in Figure 4.1 yields $\vec{a} = [2/\sqrt{5}, 1/2\sqrt{5}, 1/2\sqrt{5}, 1/2\sqrt{5}, 1/2\sqrt{5}, 0]^T$ and $\vec{h} = [0, 1/\sqrt{5}, 1/\sqrt{5}, 1/\sqrt{5}, 1/\sqrt{5}, 1/\sqrt{5}]^T$. This means that vertex 6 is no better a hub than vertices 2, 3, 4, and 5. In contrast, if the chain of $\vec{h}_i$ and $\vec{a}_i$ were to start from a uniformly initialized $\vec{a}_0$ rather than $\vec{h}_0$, we would find

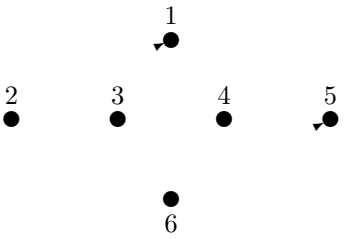

FIG. 4.1. *A network with repeated largest eigenvalue for A^TA. The HITS algorithm with standard input yields different authority vectors for different initial seed vectors, and the SALSA algorithm with standard input gives inconsistent authority and hub vectors.*

that $\vec{a} = [1/\sqrt{5}, 1/\sqrt{5}, 1/\sqrt{5}, 1/\sqrt{5}, 1/\sqrt{5}, 0]^T$ and $\vec{h} = [0, 1/2\sqrt{5}, 1/2\sqrt{5}, 1/2\sqrt{5}, 1/2\sqrt{5}, 2/\sqrt{5}]^T$ so that vertex 1 is now no better an authority than vertices 2, 3, 4, and 5.

More generally, choosing different (positive) initial seed vectors for the HITS algorithm, the final authority vector for the network in Figure 4.1 can be

$$\vec{a} = [\alpha, \beta, \beta, \beta, \beta, 0]^T \tag{4.1}$$

for any positive numbers α and β such that $\alpha^2 + 4\beta^2 = 1$. In other words, the possible outcomes for $\vec{a}$ can be , normalized, nonnegative vector in the two-dimensional eigenspace of the dominant eigenvalue for A^TA except $[1, 0, 0, 0, 0, 0]^T$ and $[0, 1/2, 1/2, 1/2, 1/2, 0]^T$.

Similar behavior occurs when the SALSA algorithm is applied to the same network (in Figure 4.1). The rankings from SALSA result from the limits of two different chains which do not interact. Each of these chains will converge, but their limits will be unrelated.

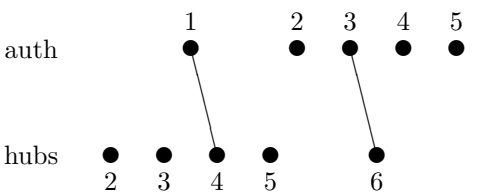

FIG. 4.2. *The SALSA graph H associated with Figure* 4.1.

The random walk performed by the SALSA algorithm is confined to whichever component of Figure 4.2 it begins in. Using the standard uniform initialization, we find that $\vec{a} = [1/5, 1/5, 1/5, 1/5, 1/5, 0]^T$ and $\vec{h} = [0, 1/5, 1/5, 1/5, 1/5, 1/5]^T$, so that all nodes with nonzero outdegree are equally good hubs and all nodes with nonzero indegree are equally good authorities.

These two weightings are inconsistent. Because the premise of HITS and SALSA is that good hubs point to good authorities, if four out of five equally good hubs all point to one node and no others, then we expect that node to be a better authority than any of the four nodes pointed to by the fifth hub. In other words, we expect that $\vec{a} = W_c^T \vec{h}$ and $\vec{h} = W_r \vec{a}$. The fact that this is not the case results from the repeated eigenvalue of $W_c^T W_r$. For arbitrary positive initial vectors, the final authority vector can be any vector of the form shown in (4.1) such that $\alpha, \beta > 0$ and $\alpha + 4\beta = 1$.

The reason for the inconsistency is that the initial hub vector assigns the first

component four times as much weight as the second component. In contrast, the authority vector assigns the second component four times as much weight as the first.

For both HITS and SALSA, there are some graphs that give rise to repeated eigenvalues. The output of all these graphs is sensitive to the initial vector chosen. A second problem, inappropriate zero weights, can arise in HITS regardless of the output's dependence on or independence of the initial vector.

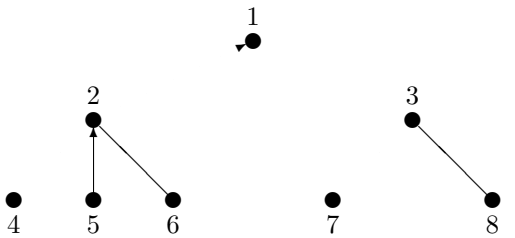

FIG. 4.3. *A tree with simple largest eigenvalue for A^TA.*

Consider the graph in Figure 4.3. If we remove vertex 5 from the graph, obtaining the two-level binary tree, then the characteristic polynomial of A^TA is $(\lambda-2)^3\lambda^4$ and so A^TA has a repeated dominant eigenvalue leading to nonunique behavior. However, the inclusion of vertex 5 creates a significantly different situation. Now A^TA has a simple dominant eigenvalue 3 and repeated eigenvalues of 2 and 0.

In this case, as long as the initial seed vector is positive, the output of HITS is

$$\vec{a} = [0,\ 1,\ 0,\ 0,\ 0,\ 0,\ 0,\ 0]^T, \tag{4.2}$$

$$\vec{h} = [0,\ 0,\ 0,\ 1/\sqrt{3},\ 1/\sqrt{3},\ 1/\sqrt{3},\ 0,\ 0]^T. \tag{4.3}$$

This means that node 2 gets authority weight 1, while all other nodes get authority weight 0. The majority of the graph is deemed to be completely unimportant. However, we would expect that node 1 should be a better authority than any other node, because it is accessible from every node. Meanwhile, node 3 should be only slightly less important than node 2, since there is only one more node pointing to node 2.

For the same graph (Figure 4.3), SALSA once more has repeated eigenvalues and nonunique rankings. In this case, if we use the uniform initialization, we again have inconsistent results: $\vec{a} \neq W_c^T\vec{h}$. In most cases where the SALSA algorithm has repeated eigenvalues, the uniform initialization will result in this inconsistency between the authority and hub vectors. The following definition introduces terminology to describe these behaviors.

DEFINITION 4.1. badly behaved

4.2. Characterization of badly behaved graphs. Theorem 4.2 in this section gives a linear algebra interpretation of what it means for the HITS and SALSA algorithms to be badly behaved on a graph. We also characterize (Theorems 4.4 and 4.5) the graphs for which the HITS and SALSA algorithms are badly behaved.

THEOREM 4.2.

1. AA^T
2. AA^T (A^TA)

. Assume that condition 1 of Theorem 4.2 holds; that is, AA^T has a repeated dominant eigenvalue.

Let the seed vector given to the HITS algorithm be $\vec{h}_0$. Each iteration preserves the direction while changing the magnitude of the component in each eigenspace. Once the nondominant eigenvectors are effectively scaled to zero, the final result is the (normalized) component of $\vec{h}_0$ in the eigenspace of the dominant eigenvalue. Since the eigenvalue is repeated, there are many possibilities for this component. Conversely, if there are multiple possible outcomes depending on the seed vector, then the component in the eigenspace of the dominant eigenvalue is not unique, and so the eigenspace is multidimensional.

Now assume that condition 2 of Theorem 4.2 holds; that is, the dominant eigenvector has a 0 in entry i, corresponding to a node i with positive outdegree. As the iterates converge to the dominant eigenvector, the hub weight of node i converges to 0.

Conversely, if the hub weight of node i converges to 0, then the corresponding entry from the dominant eigenvector must be 0. □

In fact, if the dominant eigenvalue is repeated, the eigenspace is spanned by several nonnegative eigenvectors that satisfy condition 2.

Next we characterize the set of graphs on which the HITS algorithm is badly behaved, and describe some results about its behavior on these graphs.

DEFINITION 4.3. G $1, \ldots, n$ HITS authority graph G' G' G ( ) G' $\{i,j\} \in E(G')$ $k \in G$ (k,i) (k,j) G

This graph G' was first described in [20]. Shortly thereafter, it was independently described in [2] in the context of stability (see section 5.1).

We give some intuition for why the HITS authority graph G' is important for understanding the behavior of the HITS algorithm on G. Under the HITS algorithm, the authority weight of i has an impact on the hub weight of k because (k,i) is an edge of G. Similarly, the hub weight of k affects the authority weight of j. Thus, the edge $\{i,j\}$ represents a relation in two iterations of the algorithm between the authority weights of nodes i and j.

If we start the HITS algorithm with node i having authority weight 1 and all other nodes having authority weight 0, then after two iterations, all nodes joined to i in G' will have nonzero weight. After four iterations, all nodes that can be reached in at most two steps in G' will have nonzero weight. Continuing, all nodes that are in the same component as i will get nonzero weight, but the weight will not leak into any other components.

If we allow repeated edges $\{i,j\}$ in G' whenever there are multiple nodes pointing to i and j in G, and if we allow a loop at i in G' for each k pointing to i in G, then the adjacency matrix of G' is A^TA (up to deletion of zero rows and columns in A^TA). Using appropriate matrix permutations, this matrix can be made block diagonal with each block corresponding to a different component of G'. Therefore, the eigenvectors (and eigenvalues) of A^TA can be partitioned into disjoint subsets corresponding to the connected components of the HITS authority graph G'. (Note that allowing repeated edges and loops does not change the connectivity of G'.) This leads to our theorem characterizing the cases where HITS is badly behaved.

THEOREM 4.4. G G'

. The "only if" direction of the proof follows from Theorem 3.5 along with Lemma 3.7. If HITS is badly behaved, then the matrix $\widetilde{C}$ defined below must be reducible, and therefore G' is disconnected.

Assume that there are t nodes with positive indegree. Defining $C = A^T A$ and labeling the nodes so that those with 0 indegree have the highest index, we can rewrite C as

$$C = \begin{pmatrix} \widetilde{C} & 0 \\ 0 & 0 \end{pmatrix}, \tag{4.4}$$

where $\widetilde{C}$ is $t \times t$. We are interested in the dominant eigenvalue and eigenvector of $\widetilde{C}$.

If the dominant eigenvalue is not simple, or the eigenvector has zero entries for nodes with nonzero indegree, then $\widetilde{C}$ must be reducible. However, as noted in the proof of Theorem 3.11 above, $\widetilde{C}$ is reducible if and only if G' is disconnected.

To prove the "if" direction, it suffices to show that for each component there is a nonnegative eigenvector that is positive exactly on that component. Since the matrix is symmetric, all eigenvectors of different eigenvalues are orthogonal. If there exists a unique dominant eigenvector, it is nonnegative, and thus it cannot be orthogonal to all of these. In fact, it must be one of these. Using this and Theorem 4.2, it follows that the HITS algorithm is badly behaved.

(Another way to see this is, for G' with more than one connected component, to relabel the vertices of G' with the vertices of the first component first, then those of the second component, and so on. The matrix $\widetilde{C}$ becomes block diagonal. Each eigenvector of $\widetilde{C}$ arises as an eigenvector of one of the blocks, padded with zeroes "outside that block." Thus any unique dominant eigenvector $\vec{v}$ of $\widetilde{C}$ is of this special form. But then $\vec{v}$ has zero entries everywhere "outside that block," and in particular in those positions corresponding to vertices in other components of G'. But these vertices have positive indegree in G. Thus the HITS algorithm on G is badly behaved.) □

There is a strong connection between the HITS authority graph G' and the SALSA bipartite graph H. In particular, each edge of G' corresponds to a "vee" in H. More specifically, if there is an edge $\{i, j\}$ in G', then there exists a node k that links to both i and j. This means that on the graph H there is a hub node corresponding to k that has an edge to both i and j. It follows immediately that G' is disconnected if and only if H is disconnected. This proves the following.

THEOREM 4.5. . G G' .

This theorem can also be proven easily from the results of section 6.1 of [17]. It is not mentioned in [17] that multiple components can lead to inconsistent hub and authority rankings.

We do not know how likely it is in practice for the HITS authority graph G' corresponding to a particular query to be disconnected.

4.3. Modification to the SALSA initialization. The results of this section show that the inconsistency encountered with SALSA is due to the SALSA graph being disconnected. In particular, when we uniformly initialize the authority and hub vectors, the total authority weight given to a component may differ from the total hub weight given to that component. In all such cases, the final authority vector will be inconsistent with the hub vector.

This suggests the following modified initialization. To each component C_i we assign a component weight equal to $|C_i|/|H|$, the proportion of the nodes in the SALSA graph H which are in C_i. Note that $|C_i|$ counts nodes in both the authority and the

hub subsets, V_a and V_h, of H. When we initialize the authority weights in component C_i, we ensure that their sum equals the component weight, and similarly we initialize the hub weights. Then the final hub and authority weights will be consistent.

Although this correction will ensure that the weightings given are consistent, it does not guarantee that the weightings are meaningful in terms of the application. If some components are a priori more important than others because of extra information, then that should be considered when assigning the component weights.

When applied to Figure 4.1, this initialization results in $\vec{a} = [1/2, 1/8, 1/8, 1/8, 1/8, 0]^T$ and $\vec{h} = [0, 1/8, 1/8, 1/8, 1/8, 1/2]^T$. This contrasts with the results of the standard initialization, which were that all of the nonzero weights were 1/5.

5. Related issues. In this section, we discuss the stability of HITS to changes in the network structure; two scenarios involving closely clustered top eigenvalues; and a different modification, [illegible], of the adjacency matrix.

5.1. Stability. Recent work in [21, 22] studied the stability of HITS and other algorithms under small changes in the network structure. We can view the network perturbation as a continuous change in the adjacency matrix. An added link can be given weight t and a deleted link can be given weight $1-t$ as t goes from 0 to 1. Thus we move from an original network to the modified network by a continuous process.

If the first two eigenvectors switch, this corresponds to their associated eigenvalues switching order. In order for this to happen, the eigenvalues must be equal at some value t_0. Consider the network structure at that value. The only restriction on the value of the link weights in our proof of Theorem 4.4 was that they be positive. This theorem gives a necessary condition for the dominant eigenvalue to be repeated.

The authors of [21, 22] found examples of real networks on which small changes in the link structure appeared to cause the sort of switch in eigenvalues described above. This suggests that the HITS authority graph G' may have been disconnected to have caused that effect, or nearly so to have caused a similar effect.

More generally, small changes to a matrix tend to result in large changes to eigenvectors only when eigenvalues are close. We would expect the leading eigenvalues to be close together when G' is less tightly connected. This implies a close relationship between the connectivity of G' and the stability of HITS.

Similar results are obtained in [2]. The authors of [2] also describe the HITS authority graph, and focus their attention on cases where it is connected (their "authority-connected graphs").

5.2. Arbitrarily close eigenvalues. Although we have shown that for Exponentiated Input to HITS the largest eigenvalue of $(e^A - I)^T(e^A - I)$ is not repeated, a potential problem arises when the second largest eigenvalue is very close to the largest. The number of iterations needed for convergence increases without bound as the eigenvalues get close to one another. The following examples illustrate two scenarios where this problem appears to occur.

[illegible] 5.1. We begin by describing a family of graphs where numerical experiments suggest that the dominant and second eigenvalues can be made arbitrarily close. These graphs are of the [illegible]" form shown in Figure 5.1. The graph has a root vertex from which two identical branches begin. Each branch consists of m consecutive nodes of outdegree 1; we call $l = m - 1$ the [illegible] of the graph. The last node in this sequence has outdegree b, producing a [illegible]" at the end of each branch. We call b the [illegible] of the graph.

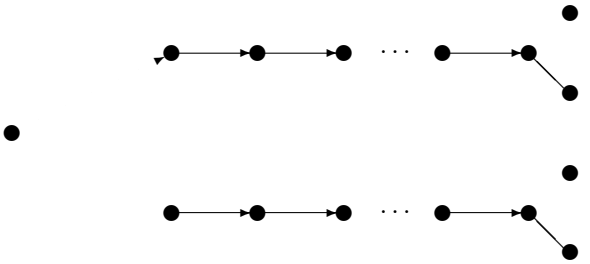

FIG. 5.1. *Broom tree with brush width* $b = 2$ *and large handle length* l.

The ratio between the second largest eigenvalue and the dominant eigenvalue of $(e^A - I)^T(e^A - I)$ is called the [illegible] of the graph. Using a program written in MATLAB [14] we fixed the brush width and let the handle length increase from $l = 5$ to $l = 50$. For each value of l we computed the corresponding eigenvalue ratio. When the brush width is held at $b = 1$ we obtain a family of brooms for which the eigenvalue ratio increases monotonically from 0.7796 at $l = 5$ to 0.9277 at $l = 50$. Fixing the brush width at $b = 2$ and letting l increase produces a dramatically faster convergence of the gap ratio from 0.9524 at $l = 5$ to 1.000 at $l = 50$ (all calculations rounded to 4 significant digits). Figure 5.2 shows the graph of handle length versus eigenvalue ratio for $b = 1, 2, 3$.

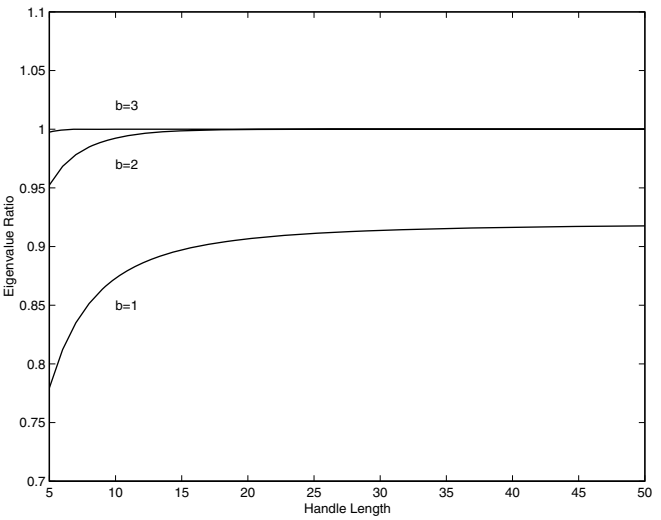

FIG. 5.2. *Ratio between second and dominant eigenvalues appears to approach one as* $l \to \infty$.

One can consider many different modifications to the adjacency matrix A input to HITS, beyond our Exponentiated Input $e^A - I$. In the example above we fixed the modification of A, and varied the graph, in order to get an eigenvalue ratio close to one. We now give an example showing that we can vary the modification of A for a fixed graph and thus obtain an eigenvalue ratio close to one.

[illegible] 5.2. Consider the two-level binary tree (delete vertex 5 from the graph shown in section 4.1, Figure 4.3). Here the standard HITS algorithm is badly behaved because the graph has a repeated dominant eigenvalue. Consider a modification of A where paths of length 2 are counted with value ε. Let $\widetilde{A} = A + \varepsilon A^2$. With this $\widetilde{A}$,

we can prove that the dominant eigenvalue will be simple for any weakly connected graph. Then the input to the HITS algorithm corresponds to finding eigenvectors of

$$\widetilde{A}^T\widetilde{A} = \begin{bmatrix} 2+4\varepsilon^2 & 2\varepsilon & 2\varepsilon & \cdots & 0 \\ 2\varepsilon & 2 & 0 & & \\ 2\varepsilon & 0 & 2 & & \\ \vdots & & & \ddots & \\ 0 & & & & 0 \end{bmatrix}, \tag{5.1}$$

where all omitted entries are 0. As $\varepsilon \to 0$, Gershgorin's disk theorem [12, p. 344] shows that the three largest eigenvalues of $\widetilde{A}^T\widetilde{A}$ become arbitrarily close.

To sum up, the examples in this subsection indicate that the top few eigenvalues, either of $(e^A - I)^T(e^A - I)$ or of $\widetilde{A}^T\widetilde{A}$, may be very close to each other, even if they are not equal in modulus.

5.3. Usage Weighted Input to HITS. A different type of modification to the adjacency matrix is possible when web server logs are available for a given network. In [20], we proposed [illegible], in which we initialize the matrix to zero, and then increment the (i, j)-entry every time a user travels from node i to node j. (The resulting input matrix need not mirror the network, since users may ignore some hyperlinks and may navigate directly between pages that are not hyperlinked.) In each iteration the most frequently followed links play the largest role in determining new authority weights. The effect is similar to that of lifting by gradient ascent [7] but does not require direct querying of users. Similar approaches have recently been advocated by [26], [27].

6. Related work. Kleinberg's HITS algorithm is presented in [15] and discussed in more detail in [9]. Several authors have extended the HITS algorithm using textual analysis. In their paper [1] on topic distillation in hyperlinked environments, Bharat and Henzinger combine the connectivity analysis of the HITS algorithm with content analysis. They identify three limitations of the HITS algorithm: (i) mutually reinforcing relationships between hosts; (ii) automatically generated links that do not reflect a human assessment of the value of pages; and (iii) nonrelevant documents leading to topic drift. They propose modifications to the HITS algorithm, using content analysis, that address these limitations. For instance, they address the common problem of topic drift by introducing the [illegible] of a node, which measures the similarity of the node to a query document. Relevance weights are then used to prune nonrelevant nodes and to regulate the influence of a node according to its relevance, specifically by multiplying the vectors of hub and authority weights componentwise by the vector of relevance weights. Both the limitations and the solutions are different from those considered in the present paper; in particular we do not use content analysis.

The ARC or [illegible] system [5], for compiling a list of authoritative web documents on a given topic, also augments the HITS algorithm with content analysis. Specifically, the ARC system multiplies the weight assigned to an [illegible] link to a given node by a positive factor that increases with the amount of topic-related text occurring around the [illegible] link. These ideas are developed further in the paper [4] on spectral filtering. Here nodes may be web pages or even smaller units, allowing a finer analysis of the link topology and in particular inhibiting topic drift. In [4], the HITS algorithm is also modified to address several other idiosyncratic features of the web. The adjacency matrix is replaced by an [illegible] in which

the entry a_{ij} represents the strength of the affinity between nodes i and j. The value of a_{ij} is a sum of three components, one of which quantifies the occurrence of query terms in text near the hyperlink to node j.

The paper [7] on customized authority lists modifies the HITS algorithm by [illegible] of authority weights. The idea is to incorporate user feedback to adjust the authority weights to reflect an individual user's evaluation of authoritativeness.

Borodin et al. [2] discuss other related theoretical aspects of authority and hub algorithms including both HITS and SALSA. They provide two mechanisms for determining when different algorithms provide similar rankings and then use this framework to compare several ranking algorithms. The stability of ranking algorithms to graph modifications is also discussed in detail. These ideas are similar in spirit to those in [21, 22].

Our work differs from [4, 5] in that we do not use textual analysis and from [7] in that we do not require direct querying of users. Our Exponentiated Input work differs from the other work discussed here in that the adjacency matrix is modified to take into account paths of length greater than one. Our work differs from [2, 21, 22] in that we are not concerned with the stability of the result to changes in the network structure. We are interested in networks for which the results of the ranking algorithm are sensitive to changes in the initialization.

The use of links in ranking documents and finding authoritative sources is similar to the techniques of citation analysis in bibliometrics. See also [4, 7] for fuller surveys of the literature.

7. Conclusions and further work. We have given a unified treatment of the existence and uniqueness of ranking vectors generated by four link analysis algorithms, and of convergence of the algorithms. We have shown that the HITS and SALSA algorithms behave unexpectedly on some graphs. In particular, their output can depend on the initial seed vector; the output of HITS can depend on whether the implementation uses the initial authority vector or the initial hub vector; HITS can inappropriately assign zero weights to parts of a graph; and the authority and hub vectors produced by SALSA can be inconsistent. The PageRank algorithm does not display this behavior; nor does Exponentiated Input to HITS if the graph is weakly connected.

It is important to understand when this unexpected behavior occurs. We have characterized the graphs for which HITS and SALSA are badly behaved; for this we presented a general method that extends ideas in [2, 17]. This method can be easily applied to other algorithms and can help motivate modifications that eliminate the bad behavior. In this light, we have introduced a new modification of the HITS algorithm, namely Exponentiated Input to HITS, which eliminates bad behavior as long as the network is weakly connected. We have also proposed a change to the initialization of SALSA which eliminates inconsistency in hub and authority weights.

The idea of Exponentiated Input can be extended to SALSA by changing the input matrix A with similar results. The following natural extension leads to a similar algorithm. Consider a web surfer surfing for n time steps. At each step, she either remains where she is, with probability $(n-1)/n$, or she follows a link at random, with probability $1/n$. After n time steps the expected number of links followed is 1. The surfer then follows links backward in a similar manner for n time steps. Taking the limit as $n \to \infty$, the algorithm reduces to finding the dominant eigenvector of $e^{W_r} e^{W_c^T}$.

The choice of scaling factors (for paths of each length) used in constructing the Exponentiated Input matrix would be interesting to study. This is especially true because calculating powers of a large matrix is computationally expensive. At present

we have no principled way to decide which scaling factors are most appropriate for a given application.

While the results of this paper are concerned with existence and uniqueness and with the dependence of rankings on initialization, we have discussed how the methods applied here may relate to other important ideas of link analysis. In particular, the HITS authority graph G' can be used to explore both stability and community issues addressed in other works.

Acknowledgment. We are grateful for the detailed comments provided by two anonymous reviewers.

ANALYSIS OF BOX SCHEMES FOR REACTIVE FLOW PROBLEMS*

S. L. MITCHELL†, K. W. MORTON‡, AND A. SPENCE‡

Abstract. Key properties of the box scheme are shown to be advantageous for reactive flow problems. Unconditional stability and compact conservation are shown by a detailed modified equation analysis to enable the scheme to reflect exactly the "reduced speed," enhanced diffusion, and dispersion which are typical of such "hyperbolic conservation laws with relaxation." A novel modified equation analysis is also used to show how the spurious checkerboard mode behaves and can be controlled. Numerical experiments for some nonlinear one-dimensional problems and a two-dimensional problem demonstrate that the behavior of the scheme deduced from a simple model problem has general validity.

Key words. box scheme, reactive flow problems, modified equation analysis

DOI. 10.1137/030601910

1. Introduction.

Our objectives in this paper are twofold. First, we wish to develop effective numerical methods for the differential equations which arise in the transport of reacting substances by groundwater flow of the general form

$$\mathbf{u}_t + \operatorname{div} \mathcal{F}(\mathbf{u}) = \mathbf{R}(\mathbf{u}), \quad \mathbf{u}(\mathbf{x}, t) : \mathbb{R}^d \times \mathbb{R}^+ \to \mathbb{R}^p, \tag{1.1}$$

where the fluxes $\mathcal{F}$ represent the groundwater transport and the terms $\mathbf{R}$ on the right represent the chemical reactions. In typical problems the reaction rates vary widely, and some may be on a time scale much shorter than the advection velocities occurring in the transport terms. The result is the phenomenon of "reduced speed" whereby the transport occurs at a speed very much lower than the advection velocity; this precludes the use of simple explicit numerical schemes for modeling the transport.

Such situations are common in other applications, such as river-flow modeling. And there the standard numerical remedy is to use the box scheme, often called the Preissmann box scheme; see [6] and [15]. The name of the scheme derives from its construction by integrating the differential equation over a box in $(\mathbf{x}, t)$-space, applying the divergence theorem to the differential terms, and approximating all the integrals by quadrature formulae based on values at the corners of the box. This gives a very compact difference scheme on a uniform mesh (or a finite volume scheme on a general mesh) which has natural conservation properties. It is also implicit and unconditionally stable. For it to be fully effective, two steps are necessary. First, an efficient marching scheme is needed to solve the implicit system of equations by sweeping out from the given initial and boundary conditions. Second, the time step needs to be chosen so that the dominant flow of "information" corresponds roughly to a main diagonal of the discretization box. Then the remaining disadvantage of the scheme is the presence of spurious oscillations in the numerical solution, which have to be controlled in some way.

Thus our second objective is to explore the properties of the box scheme and show how it may best be used for the problems under consideration. In the next section we begin with the study of a linear model problem in one space dimension in order to introduce most of the key ideas. We show by an asymptotic analysis how the reaction terms lead to the reduced speed, and we also introduce diffusion and dispersion into the simple model. In section 3 we consider the box scheme for this problem—its stability by an energy method and its modified equation analysis. For smooth approximations it reproduces the reduced speed, diffusion, and dispersion of the differential equation, with the last achieved by choosing the time step so that the CFL number based on the reduced speed is set to unity; a novel modified equation analysis of the spurious oscillatory modes shows how they move at a completely different speed and how they can be damped by applying a general θ-weighting to the advective terms with $\theta = \frac{1}{2} + \mathcal{O}(\Delta t)$. To demonstrate that these key properties extend to more general problems, in section 4 the method is applied to one-dimensional problems with nonlinear reaction terms and in section 5 to a two-dimensional problem with an incompressible flow field and a nonuniform mesh.

To conclude this introduction, we should point out that the standard schemes in widespread use for modeling reactive transport in groundwater flow make use of operator-splitting techniques—see, for example, [8], [19], [7], [24], [2], [3], and [1]. That is, one solves alternately the equilibrium equation system $\mathbf{R}(\mathbf{u}) = 0$ and the transport equation. There are several disadvantages of such a procedure, as has been pointed out in [3] and [7]. These include the fact that the transport can occur at the incorrect speed unless the reaction rates are sufficiently fast, an $\mathcal{O}(\Delta t)$ error arises due to the splitting, and stability constraints determined by the velocity of the transport equation are possible. Nonetheless, splitting schemes are computationally attractive and form the basis for several software packages, notably PARSIM [1] and MINTRAN [19].

2. A linear model in one space dimension. The simplest model that displays the key features we wish to study is for a single chemical component being transported through rock by steady groundwater flow and reacting with the rock. Let c be the concentration of the chemical in the water, s the concentration in the rock, λ the rate of adsorption into the rock, μ the rate of desorption from the rock into the water, and V the groundwater flow velocity. Then we have the following pair of equations, with λ, μ, and V all positive,

$$\frac{\partial c}{\partial t} + V\frac{\partial c}{\partial x} = \mu s - \lambda c, \tag{2.1}$$

$$\frac{\partial s}{\partial t} = \lambda c - \mu s, \tag{2.2}$$

to hold on $(x, t) \in [0, \infty) \times [0, \infty)$.

In a typical problem the concentrations are zero initially, but then there is a release of the chemical at one point over a short period of time, followed by its dispersal through the rock. Thus we shall take as initial and boundary conditions

$$c(x, 0) = s(x, 0) = 0 \text{ for } x \geq 0, \quad c(0, t) = h(t), \text{ given, for } t > 0; \tag{2.3}$$

then $s(0, t)$ is found from integrating (2.2) with respect to t.

The general behavior of this system is easy to deduce. At each point in the rock the concentration s is obtained by integrating (2.2), while the concentration c

is advected to the right with velocity V but decays through the term $-\lambda c$ and is augmented by μs. For this linear model the result can be expressed in the form of two integral equations which can be solved by the use of Laplace transforms—see [16] and [14] for details. Examples of the resulting (exact) solution are shown in Figure 1, which can be used to judge the accuracy of our numerical methods; note that, in common with the usual practice in this field, we plot the solution against time at a given point in space. Key features of the solutions obtained for different values of λ and μ are the speed of propagation of the initial pulse and its change of form. Some of these features can be deduced by simple, generally applicable, asymptotic analysis, the validity of which can again be checked for this model problem against the Laplace transform solution.

2.1. Asymptotic analysis. For large values of λ and μ, one may apply the analysis of [13] (see also [4]) for [illegible]. These are defined as systems of the form (1.1) in which there exists a constant matrix Q with rank $r < p$ such that $Q\mathbf{R}(\mathbf{u}) = 0$ and $\mathbf{R} = \epsilon^{-1}\tilde{\mathbf{R}}$, where ϵ is a small parameter. Then this defines an [illegible] given by the mapping $\mathcal{M} : \mathbf{v} \in \mathbb{R}^r \to \mathbf{u}^e \in \mathbb{R}^p$, on which $\tilde{\mathbf{R}}(\mathbf{u}^e) = 0$. In one space dimension, where we write (1.1) as $\mathbf{u}_t + \mathbf{f}_x = \mathbf{R}$ with $\mathbf{f} : \mathbb{R}^p \to \mathbb{R}^p$, we can define a new flux $\mathbf{g} : \mathbb{R}^r \to \mathbb{R}^r$ by $\mathbf{g}(\mathbf{v}) = Q\mathbf{f}(\mathcal{M}\mathbf{v})$; thence, by operating on the equation with the constant matrix Q, we obtain an [illegible]

$$\frac{\partial \mathbf{v}}{\partial t} + \frac{\partial \mathbf{g}(\mathbf{v})}{\partial x} = 0, \tag{2.4}$$

whose solution provides a lowest order approximation to $\mathbf{u}$ as $\epsilon \to 0$.

For the linear model (2.1), (2.2), the equilibrium manifold is given by $\lambda c = \mu s$ with Q the row vector $(1, 1)$. Hence we add the two equations to give

$$s_t + c_t + V c_x = 0, \tag{2.5}$$

which is an important equation in its own right. Then, substituting for s in this equation gives the equilibrium model

$$c_t + \frac{\mu V}{\lambda + \mu} c_x = 0, \tag{2.6}$$

which shows how the reduced speed $V' = \mu V/(\lambda + \mu)$ comes into play in the limit of large λ and μ. Strictly speaking, in the sense of [13], the equilibrium model should be written in terms of $c + s$, but for this linear problem c, s, and $c + s$ all satisfy (2.6) so we use the simpler form.

Further levels of approximation are obtained by expanding the mapping $\mathcal{M}$ in powers of the small parameter, the reciprocals of λ and μ in the present case. From differentiating (2.2) we obtain

$$s_t = (\lambda/\mu)c_t - (1/\mu)s_{tt}, \tag{2.7}$$

and then to the lowest order we can derive the approximation

$$s_{tt} = (\lambda/\mu)c_{tt} - (1/\mu)s_{ttt} \sim (\lambda/\mu)V'^2 c_{xx}. \tag{2.8}$$

Substitution back into the conservation equation (2.5) then gives

$$c_t + \frac{\mu V}{\lambda + \mu} c_x = \frac{\lambda \mu V^2}{(\lambda + \mu)^3} c_{xx}, \tag{2.9}$$

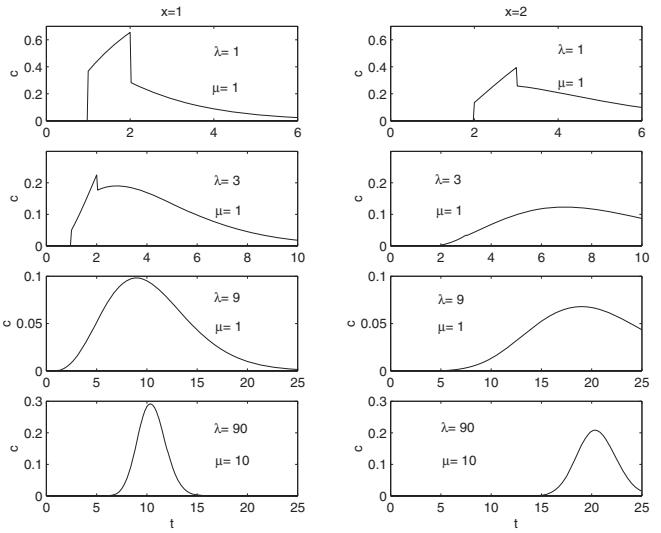

FIG. 1. *The Laplace transform solution* c *at* $x = 1$ *and* $x = 2$ *for* $V = 1$ *for various values of* (λ, μ). *The boundary condition is a square pulse of height and width* 1.

commonly called the [illegible]. Continuing to one order higher introduces a dispersion term to give

$$c_t + \frac{\mu V}{\lambda + \mu} c_x = \frac{\lambda \mu V^2}{(\lambda + \mu)^3} c_{xx} - \frac{\lambda \mu (\lambda - \mu) V^3}{(\lambda + \mu)^5} c_{xxx}. \tag{2.10}$$

From the plots in Figure 1 we can clearly see the effect not only of the reduced speed but also of the diffusion term in the improved model (2.9) and the dispersion term in (2.10). In the four cases shown we have $V = 1$ and the values of λ and μ are $(1, 1)$, $(3, 1)$, $(9, 1)$, and $(90, 10)$. These give values of the reduced velocity $V' = \mu V/(\lambda + \mu)$ equal to $1/2$, $1/4$, $1/10$, and $1/10$, respectively. In Table 2.1 these are compared with estimates of the actual speed of the initial pulse deduced from the solutions in the figures. Note too how the solutions are smoothed and damped, particularly in the last two cases, and in the table the values of the diffusion and dispersion coefficients in the improved equilibrium models are also given.

TABLE 2.1

	$(\lambda, \mu) = (1, 1)$	$(\lambda, \mu) = (3, 1)$	$(\lambda, \mu) = (9, 1)$	$(\lambda, \mu) = (90, 10)$
Observed speed	1.00	0.31	0.11	0.10
Reduced speed	0.50	0.25	0.10	0.10
Max observed c	0.394	0.123	0.068	0.208
$c_{\max}$ (from (2.12))	0.200	0.115	0.067	0.210
Diffusion coefficient	0.125	0.047	0.009	9×10^{-4}
Dispersion coefficient	0	0.006	7.2×10^{-4}	7.2×10^{-6}

We have already referred to the similarity of the present problems to those encountered in river modeling. In a classic paper [11], [12], Lighthill and Whitham carried out an asymptotic analysis of flood waves in which they derived an expression

for the maximum flood height as well as the speed of the wave. If we differentiate (2.1) with respect to t and add to it μ times the conservation equation (2.5), we can eliminate s and obtain the following second order equation for c:

$$c_{tt} + Vc_{tx} + (\lambda + \mu)c_t + \mu V c_x = 0. \tag{2.11}$$

Following the procedure used in [11], [12], and [22] we can apply a Laplace transform to this equation, with the initial and boundary conditions given in (2.3), and obtain an expression for the solution in terms of a contour integral. Then the solution near the dynamic wave-front can be deduced from the behavior of the integrand for large values of the transform variable. In particular, we find that the maximum occurs where $x = V't$ and for large values of $\lambda + \mu$ is given by

$$c_{\max} \sim \frac{1}{2}\left(\frac{(\lambda+\mu)^3}{\pi\lambda\mu t}\right)^{\frac{1}{2}}. \tag{2.12}$$

Values of this expression are also compared with the observed maxima for the four exact solutions in Table 2.1.

3. The box scheme for the linear model. The box scheme became a popular method for approximating the St. Venant equations of river flow through the work of Preissmann and his colleagues [6]. The scheme is also associated with the name of Keller, who applied it to parabolic problems [10] and to two-point boundary value problems [9]. It was also analyzed in the early paper [18] and very recently in [15]. It can be identified as the valuable cell-vertex finite volume method for approximating the Euler equations (and also the Navier–Stokes equations) of steady transonic aerodynamics (see, for example, [5]), and its multisymplectic structure has been recognized and has led to its application to the KdV equation [23]. When applied to these cases, a valuable feature of the scheme, which follows from the derivation outlined in the introduction, is the accurate and compact discretization that it yields on a nonuniform quadrilateral mesh. However, we shall concentrate here on its finite difference formulation on a uniform rectangular mesh, because we can demonstrate that its asymptotic behavior closely mirrors that of the differential system as outlined in the previous section. We shall also begin by using the simple trapezoidal rule weighting in time, although we shall show later, as is well known, that the more general θ-weighting is important in controlling the spurious checkerboard mode.

Suppose we have a uniform mesh over the rectangle $0 \le t \le T$, $0 \le x \le L$, with time step $\Delta t = T/N$ and spatial step $\Delta x = L/J$ for a given N and J. Let U_j^n denote the numerical approximation of u at $(x_j, t^n) := (j\Delta x, n\Delta t)$ for $j = 0, 1, \ldots, J$ and $n = 0, 1, \ldots, N$. On the mesh we define the finite difference operators

$$\delta_x U_{j+\frac{1}{2}}^{n+\frac{1}{2}} = U_{j+1}^{n+\frac{1}{2}} - U_j^{n+\frac{1}{2}}, \quad \mu_x U_{j+\frac{1}{2}}^{n+\frac{1}{2}} = \tfrac{1}{2}\left(U_{j+1}^{n+\frac{1}{2}} + U_j^{n+\frac{1}{2}}\right) \tag{3.1}$$

and, similarly, δ_t and μ_t. Then the box scheme consistently uses the operator $\mu_x\delta_t$ to approximate ∂_t and, similarly, $\mu_t\delta_x$ to approximate ∂_x in a partial differential equation (PDE). If we apply this scheme to the conservation law (2.6), we obtain

$$\mu_x\delta_t C_{j+\frac{1}{2}}^{n+\frac{1}{2}} + \mu_x\delta_t S_{j+\frac{1}{2}}^{n+\frac{1}{2}} + p\mu_t\delta_x C_{j+\frac{1}{2}}^{n+\frac{1}{2}} = 0, \text{ where } p = V\Delta t/\Delta x \tag{3.2}$$

and p denotes the CFL number. This is a very compact scheme which uses four neighboring values of the unknowns, and it is actually , , , as it involves two points

at the new time level. However, for appropriate initial and boundary conditions such as those given in (2.3), the discrete equations can be solved by marching away from a boundary. To complete the approximation we have to discretize the reaction equation (2.2), which is an ordinary differential equation in time, to which we apply the one-dimensional box scheme (i.e., the trapezoidal rule) to obtain

$$\delta_t S_j^{n+\frac{1}{2}} = \mu_t\big(\lambda' C_j^{n+\frac{1}{2}} - \mu' S_j^{n+\frac{1}{2}}\big), \tag{3.3}$$

where $\lambda' := \lambda\Delta t$ and $\mu' := \mu\Delta t$. Note that this equation needs no boundary condition as its application for $j = 0$ integrates the boundary data for c up the t-axis.

Equations (3.2) and (3.3) can be written out as

$$\begin{aligned}&(1+p)C_{j+1}^{n+1} + (1-p)C_j^{n+1} - (1-p)C_{j+1}^n - (1+p)C_j^n\\ &\quad + \big(S_{j+1}^{n+1} - S_{j+1}^n\big) + \big(S_j^{n+1} - S_j^n\big) = 0,\end{aligned} \tag{3.4}$$

$$S_{j+1}^{n+1} = \frac{\frac{1}{2}\lambda'}{1+\frac{1}{2}\mu'}\big(C_{j+1}^{n+1} + C_{j+1}^n\big) + \left(\frac{1-\frac{1}{2}\mu'}{1+\frac{1}{2}\mu'}\right) S_{j+1}^n, \tag{3.5}$$

and they are applied for $j = 0, \ldots, (J-1)$ and $n = 0, \ldots, (N-1)$. This is an explicit scheme when the conditions of (2.3) are used: from (3.5), S_{j+1}^{n+1} can be substituted into (3.4) to obtain an explicit formula to solve for C_{j+1}^{n+1}, by marching away from the boundary.

3.1. Stability analysis. The box scheme is centered in x and t and the trapezoidal scheme is centered in t, so all the odd order terms in a local truncation error analysis cancel and the scheme is second order accurate. Moreover, a Fourier analysis of the method shows that it is Lax–Richtmyer stable for all Δx and Δt. (See [14] for details.) Unfortunately, the scheme suffers from the notorious checkerboard mode $(-1)^{j+n}$. This is clearly a solution of (3.2), and when the reaction equation approximation (3.3) is space-averaged (a form we shall sometimes use in the analysis below), it is a solution of that too. Thus it is clearly a spurious solution of the complete system. However, applying the unaveraged (3.3) along the t-axis provides special boundary data which minimizes its effect, so that it is then mainly initiated by nonsmooth boundary data for c.

A more illuminating analysis of stability is provided by an energy analysis. We consider first the differential equations (2.1) and (2.2): multiplying (2.1) by c and (2.2) by s and integrating in x over $(0, \infty)$ gives

$$\frac{\mathrm{d}}{\mathrm{d}t}\int_0^\infty \frac{1}{2}c^2\,\mathrm{d}x + V\int_0^\infty \frac{\mathrm{d}}{\mathrm{d}x}\left(\frac{1}{2}c^2\right)\mathrm{d}x = -\int_0^\infty c(\lambda c - \mu s)\,\mathrm{d}x, \tag{3.6}$$

$$\frac{\mathrm{d}}{\mathrm{d}t}\int_0^\infty \frac{1}{2}s^2\,\mathrm{d}x = \int_0^\infty s(\lambda c - \mu s)\,\mathrm{d}x. \tag{3.7}$$

We assume the boundary data is zero for $t > t^*$ and $c(x,t) \to 0$ as $x \to \infty$ for all finite t, so the second integral in (3.6) is then zero; hence if we multiply (3.6) and (3.7) by λ and μ, respectively, and add the results, we deduce that for $t > t^*$

$$\frac{\mathrm{d}}{\mathrm{d}t}\int_0^\infty \frac{1}{2}\left(\lambda c^2 + \mu s^2\right)\,\mathrm{d}x = -\int_0^\infty (\lambda c - \mu s)^2\,\mathrm{d}x \le 0. \tag{3.8}$$

To obtain a similar result for the box scheme we first introduce $R := \lambda C - \mu S$. Then we rewrite the box scheme of (3.2) and (3.3) by substituting for S in the first

and applying the space average to the second to obtain

$$\mu_x\big[C^{n+1}_{j+\frac12}-C^n_{j+\frac12}\big]+\tfrac12 p\delta_x\big[C^{n+1}_{j+\frac12}+C^n_{j+\frac12}\big]=-\tfrac12\Delta t\mu_x\big[R^{n+1}_{j+\frac12}+R^n_{j+\frac12}\big], \tag{3.9}$$

$$\mu_x\big[S^{n+1}_{j+\frac12}-S^n_{j+\frac12}\big]=\tfrac12\Delta t\mu_x\big[R^{n+1}_{j+\frac12}+R^n_{j+\frac12}\big]. \tag{3.10}$$

For convenience, we introduce the notation $\bar C^n := \mu_x C^n_{j+1/2}$, etc. and $\langle \bar C^n, \bar S^n\rangle_2$ for a typical l^2 inner product. To emulate the procedure carried out in the continuous case, we multiply (3.9) and (3.10) by $\bar C^{n+1}+\bar C^n$ and $\bar S^{n+1}+\bar S^n$, respectively, and sum over the mesh. Then from the identity $\langle \mu_x W, \delta_x W\rangle_2 \equiv \frac12(W_J^2-W_0^2)$, and assuming that $t^n > t^*$ so that $C^n_0=0$, we obtain

$$\begin{aligned}\|\bar C^{n+1}\|_2^2-\|\bar C^n\|_2^2+\tfrac12 V\Delta t\big[C^{n+1}_J+C^n_J\big]^2&=-\tfrac12\Delta t\langle \bar C^{n+1}+\bar C^n,\bar R^{n+1}+\bar R^n\rangle_2\\ \|\bar S^{n+1}\|_2^2-\|\bar S^n\|_2^2&=\tfrac12\Delta t\langle \bar S^{n+1}+\bar S^n,\bar R^{n+1}+\bar R^n\rangle_2.\end{aligned}$$

Multiplying the first expression by λ and the second by μ, and adding gives

$$\begin{aligned}&\lambda\|\bar C^{n+1}\|_2^2+\mu\|\bar S^{n+1}\|_2^2-\big[\lambda\|\bar C^n\|_2^2+\mu\|\bar S^n\|_2^2\big]\\ &\qquad=-\tfrac12\Delta t\|\bar R^{n+1}+\bar R^n\|_2^2-\tfrac12 V\Delta t\big[C^{n+1}_J+C^n_J\big]^2\le 0.\end{aligned} \tag{3.11}$$

Hence we have established the strong stability of the [illegible] $\mu_x C$ and $\mu_x S$.

However, this does not cover the spurious mode $(-1)^{j+n}$ oscillations. We could treat these by mapping between the cell averages and the nodal values, which we can do since we have prescribed the boundary value, setting it to zero for $t^n > t^*$: every nodal value can then be obtained from the averages by a recurrence ($C^n_1 = 2\bar C^n_{1/2}$, $C^n_2 = 2(\bar C^n_{3/2}-\bar C^n_{1/2})$, etc.), which defines an oscillation matrix, from the l^2 norm of which we deduce that $\|C^n\|_2 \le \sqrt{2J(J+1)}\|\bar C^n\|_2$. Hence there is a potential linear growth which is consistent with the well-known phenomenon that imposing inappropriate boundary conditions may cause a linear growth in the oscillatory mode [17]. It is more useful, though, to consider these modes by means of a modified equation analysis; by this means we can also show how they can be damped by introducing a θ-weighting in the time averaging for the spatial derivative. This is done next.

3.2. Modified equation analysis. The use of a modified equation analysis is a well-known technique for understanding the properties of a finite difference approximation of a given PDE. Ignoring the highest frequencies, the analysis yields an asymptotic series of PDEs that can provide a more accurate representation of the behavior of the solution of the difference scheme. Such an analysis can be especially helpful in giving a qualitative understanding of features like diffusion and dispersion in a numerical scheme (see [21] and [15]).

The finite difference operators defined by (3.1) can be expanded in terms of differential operators using Taylor series expansions, i.e.,

$$\delta_x = \Delta x\big[1+\tfrac{1}{24}\Delta x^2\partial_x^2+\mathcal{O}(\Delta x^4)\big]\partial_x,\quad \mu_x = 1+\tfrac18\Delta x^2\partial_x^2+\mathcal{O}(\Delta x^4), \tag{3.12}$$

with similar expansions for δ_t and μ_t. Subsequently, we shall use the notation "..." to mean either $\mathcal{O}(\Delta x^4)$ or $\mathcal{O}(\Delta t^4)$. Strictly speaking, we need to replace the discrete variables by suitable prolongations (for example, using Fourier expansions or high order polynomials) before we can apply the differential operators to them, but we shall not make that distinction in our notation here.

If we define the operators

$$\mathcal{D}_x := \frac{\delta_x \mu_x^{-1}}{\Delta x}, \quad \mathcal{D}_t := \frac{\delta_t \mu_t^{-1}}{\Delta t}, \tag{3.13}$$

then we readily obtain

$$\mathcal{D}_x = \left(1 - \tfrac{1}{12}\Delta x^2 \partial_x^2 + \ldots\right) \partial_x, \tag{3.14}$$

while for the corresponding expansion for $\mathcal{D}_t$ it is convenient to invert the difference operator bracket to obtain

$$\partial_t = \left(1 + \tfrac{1}{12}\Delta t^2 \partial_t^2 + \ldots\right) \mathcal{D}_t. \tag{3.15}$$

Moreover, we can rewrite (3.2) and (3.3) as

$$\mathcal{D}_t C + \mathcal{D}_t S + V \mathcal{D}_x C = 0, \quad (\mathcal{D}_t + \mu) S = \lambda C. \tag{3.16}$$

Since all the operators commute, we can eliminate S to obtain a second order equation for C,

$$[\mathcal{D}_t^2 + (\lambda + \mu + V\mathcal{D}_x)\mathcal{D}_t + \mu V \mathcal{D}_x] C = 0 \tag{3.17}$$

(cf. (2.11)). Because the model is linear this equation also holds for S and for the total concentration $C + S$. It can also be interpreted as a quadratic for $\mathcal{D}_t$, with the two roots corresponding to two wave modes.

The solutions to the quadratic equation are functions of the operator $\mathcal{D}_x$: if we expand these as power series, it is easily seen that we get

$$\mathcal{D}_t = -\frac{\mu V}{\lambda + \mu}\mathcal{D}_x + \frac{\mu \lambda V^2}{(\lambda + \mu)^3}\mathcal{D}_x^2 - \frac{\mu\lambda(\lambda - \mu)V^3}{(\lambda + \mu)^5}\mathcal{D}_x^3 + \ldots \tag{3.18}$$

for the positive root, which corresponds to the main advected wave, and

$$\mathcal{D}_t = -(\lambda + \mu) - \frac{\lambda V}{\lambda + \mu}\mathcal{D}_x - \frac{\mu \lambda V^2}{(\lambda + \mu)^3}\mathcal{D}_x^2 + \frac{\mu\lambda(\lambda - \mu)V^3}{(\lambda + \mu)^5}\mathcal{D}_x^3 - \ldots \tag{3.19}$$

for the negative root, which corresponds to a damped wave which is also advected but with a different speed.

The correspondence of the leading terms in (3.18) to those in the improved equilibrium models (2.9) and (2.10) is very clear: it follows, of course, from the consistent way that the box scheme discretizes the differential equation, which is the basis of its multisymplectic properties already referred to. But now we can use the expansion in (3.14) for all the terms in $\mathcal{D}_x$. Moreover, we can apply the similar expansion in (3.15) to $\mathcal{D}_t$ on the left and obtain, after a straightforward calculation and applying the operators to C, the following expansion (to second order in Δx) for C_t:

$$\begin{aligned} C_t = &-\frac{\mu V}{\lambda + \mu} C_x + \frac{\mu \lambda V^2}{(\lambda + \mu)^3} C_{xx} \\ &- \frac{\mu V}{\lambda + \mu}\left(\frac{\lambda(\lambda - \mu)V^2}{(\lambda + \mu)^4} C_{xxx} + \frac{1}{12}\Delta t^2 C_{xtt} - \frac{1}{12}\Delta x^2 C_{xxx}\right) + \ldots . \end{aligned} \tag{3.20}$$

This is in the usual form found in the first stage of a conventional modified equation analysis, namely, with some higher order t-derivatives on the right-hand side;

these can then be eliminated in favor of x-derivatives by successive differentiation and substitution from this equation. Alternatively, we can use finite difference operator calculus to write $\mathcal{D}_t = (\frac{1}{2}\Delta t)^{-1}\tanh(\frac{1}{2}\Delta t\partial_t)$, take the inverse of this relation, and, from the Taylor expansion of $\tanh^{-1}$, obtain the relation

$$\partial_t = \left(1 + \tfrac{1}{12}\Delta t^2\mathcal{D}_t^2 + \ldots\right)\mathcal{D}_t, \tag{3.21}$$

into which we can substitute (3.18). Either procedure produces

$$\begin{aligned} C_t = &-V'C_x + \frac{\lambda\mu V^2}{(\lambda+\mu)^3}C_{xx} \\ &- V'\left(\frac{\lambda(\lambda-\mu)V^2}{(\lambda+\mu)^4} + \frac{1}{12}\left[V'^2\Delta t^2 - \Delta x^2\right]\right)C_{xxx} + \ldots, \end{aligned} \tag{3.22}$$

where $V' = V\mu/(\lambda+\mu)$ is the reduced speed. Similarly and to the same order, from (3.19) we obtain for the damped wave

$$\begin{aligned} C_t = &-(\lambda+\mu)\left(1 + \frac{1}{12}(\lambda+\mu)^2\Delta t^2\right)C - \bar{V}\left(1 + \frac{1}{4}(\lambda+\mu)^2\Delta t^2\right)C_x \\ &- \bar{V}\left(\frac{V'}{\lambda+\mu} + \frac{1}{4}(\lambda+\mu)V\Delta t^2\right)C_{xx} \\ &+ \bar{V}\left(\frac{V'(\bar{V}-V')}{(\lambda+\mu)^2} - \frac{1}{12}(V^2 + VV' + V'^2)\Delta t^2 + \frac{1}{12}\Delta x^2\right)C_{xxx}\ldots, \end{aligned} \tag{3.23}$$

where $\bar{V} = V\lambda/(\lambda+\mu)$ is the basic speed of this wave.

For the main advective wave, the lowest order discretization terms appear in the dispersive term—consistent with the second order accuracy. But the key point to note is that these become zero when the mesh ratio is based on the reduced speed, i.e., when $V'\Delta t = \Delta x$; the dispersive coefficient then reduces to that obtained in section 2.1 for the differential equation. The improved accuracy obtained with this choice is demonstrated in the numerical results given in section 3.5. Note, however, that for the damped wave the dominant effect of the discretization is to increase the damping, although it similarly affects the advective speed and the diffusion term.

The above modified equation analysis, with its emphasis on Taylor expansions of smooth solutions, is unsuitable for studying high frequency modes and in particular the checkerboard mode. The importance of this mode and some of the ways in which it can affect the result of using the box scheme are demonstrated in Figures 2, 3, and 4; there we see that it is greatly enhanced by discontinuous boundary data and that its behavior is markedly different for different values of λ and μ. In the next section we therefore present an extension of the above analysis to describe this behavior, pointing to some of the ways in which the mode may be controlled.

3.3. Separating the smooth and oscillatory numerical solution. Suppose we consider a Fourier mode $C_j = \mathrm{e}^{\mathrm{i}kj\Delta x}$ substituted into the box scheme. The Fourier symbols of the spatial difference operators μ_x and δ_x appearing in (3.2) are given by the relations

$$\mu_x C_{j+\frac{1}{2}} = (\cos\tfrac{1}{2}k\Delta x)C_{j+\frac{1}{2}}, \quad \delta_x C_{j+\frac{1}{2}} = (2\mathrm{i}\sin\tfrac{1}{2}k\Delta x)C_{j+\frac{1}{2}}; \tag{3.24}$$

for small values of $k\Delta x$, Taylor expansions of these symbols correspond to the expansions in (3.12) when the Fourier symbol $\mathrm{i}k$ of ∂_x is substituted in the latter. However,

the checkerboard mode has $k\Delta x = \pi$ and for modes near this frequency the symbol has a very different behavior. Indeed, if we write $k\Delta x = \pi + k'\Delta x$ where $k'\Delta x$ is small, then we get instead

$$\mu_x C_{j+\frac{1}{2}} = (-\sin\tfrac{1}{2}k'\Delta x)C_{j+\frac{1}{2}}, \quad \delta_x C_{j+\frac{1}{2}} = (2\mathrm{i}\cos\tfrac{1}{2}k'\Delta x)C_{j+\frac{1}{2}}. \tag{3.25}$$

These expressions can then be expanded in powers of $k'\Delta x$. Moreover, if we write $C_j = (-1)^j C_j^o$, we get from (3.25) and (3.24)

$$\mu_x C_{j+\frac{1}{2}} = -\sin\tfrac{1}{2}k'\Delta x(-1)^{j+\frac{1}{2}}C^o_{j+\frac{1}{2}} = (-1)^{j+1}\tfrac{1}{2}\delta_x C^o_{j+\frac{1}{2}}, \tag{3.26}$$

and similarly

$$\delta_x C_{j+\frac{1}{2}} = (-1)^{j+1}2\mu_x C^o_{j+\frac{1}{2}}. \tag{3.27}$$

These considerations prompt the following approach.

An arbitrary mesh function can be represented by an expansion in Fourier modes for which $|k\Delta x| \le \pi$. Suppose we split this range at $\pi/2$ for an expansion of both C and S before substitution in the box scheme. Suppose, moreover, that there is little interaction between the two sets of modes. Then the behavior of the smooth set of modes is described by the modified equation analysis of the previous subsection. Now we use the relations (3.26) and (3.27) and an assumption that C^o and S^o are smooth to develop a modified equation analysis of the oscillatory modes and, in particular, the checkerboard mode. Thus we write C_j^n as a sum of smooth and oscillatory components,

$$C_j^n \equiv (C^s)_j^n + (-1)^{j+n}(C^o)_j^n, \tag{3.28}$$

and treat S similarly. Then, with similar relations to (3.26) and (3.27) holding for the time difference operators, (3.2) and (3.3) become, for the oscillatory part, after cancellation of the factor $(-1)^{j+n}$,

$$\delta_x\mu_t(C^o + S^o) + p\delta_t\mu_x C^o \approx 0, \quad -2\mu_t S^o \approx -\tfrac{1}{2}\delta_t\left(\lambda' C^o - \mu' S^o\right). \tag{3.29}$$

We can write these in terms of the operators (3.13) to obtain

$$\mathcal{D}_x(C^o + S^o) + p_2\mathcal{D}_t C^o \approx 0, \quad 4S^o \approx \mathcal{D}_t\left(\lambda'' C^o - \mu'' S^o\right), \tag{3.30}$$

where $p_2 := V(\Delta t/\Delta x)^2$, $\lambda'' := \lambda\Delta t^2$, and $\mu'' := \mu\Delta t^2$.

As in the treatment of the smooth part in the previous subsection, we can eliminate S^o to obtain a second order equation for C^o,

$$\left[\mu'' p_2\mathcal{D}_t^2 + (4p_2 + (\lambda'' + \mu'')\mathcal{D}_x)\,\mathcal{D}_t + 4\mathcal{D}_x\right] C^o = 0. \tag{3.31}$$

Then we rewrite this so that it is precisely of the form of (3.17), namely,

$$\left[\mathcal{D}_t^2 + [(4/\mu'') + ((\lambda+\mu)/\mu p_2)\mathcal{D}_x]\mathcal{D}_t + (4/\mu'' p_2)\mathcal{D}_x\right] C^o = 0. \tag{3.32}$$

To simplify application to the present case of the result proved in section 3.2 for that equation, and also to allow for generalization of the analysis to the general weighted scheme in the next section, we restate the main derivation as a lemma; its proof consists of a straightforward manipulation, which we omit.

LEMMA 3.1. $\mathcal{D}_t$ $\mathcal{D}_x$
(3.13) U $\alpha > \beta$

$$\left[(\mathcal{D}_t+\alpha)(\mathcal{D}_t+\beta)+(a\mathcal{D}_t^2+b\mathcal{D}_t+c)\mathcal{D}_x\right]U=0. \tag{3.33}$$

U

(3.34)

$$D_t=\sum_{j=0}^{3}(-a\mathcal{D}_x)^j\left\{-\beta-\tfrac{1}{2}b\mathcal{D}_x+\tfrac{1}{2}(\alpha-\beta)[d\mathcal{D}_x+\tfrac{1}{2}(e-d^2)(1-d\mathcal{D}_x)\mathcal{D}_x^2]\right\}+\ldots,$$

$$d=[(\alpha+\beta)b-2(\alpha\beta a+c)]/(\alpha-\beta)^2,\quad e=(b^2-4ac)/(\alpha-\beta)^2;$$

α β

Hence, by comparing the coefficients in (3.32) with those in the lemma, we deduce that the main advected wave for the oscillatory mode C^o is described by the following expansion:

$$\begin{aligned}C_t^o=&-\frac{V}{p^2}C_x^o+\left(\frac{\lambda\Delta t^2V^2}{4p^4}\right)C_{xx}^o\\&-\frac{V}{p^2}\left(\frac{\lambda(\lambda-\mu)\Delta t^4V^2}{16p^4}+\frac{\Delta x^2}{12p^2}\left[1-p^2\right]\right)C_{xxx}^o+\ldots.\end{aligned} \tag{3.35}$$

The first coefficient here gives the speed at which the envelope of a set of checkerboard oscillations move. It is easy to check that this speed V/p^2 is in fact just the group velocity of the box scheme applied to the linear advection equation when one sets $k\Delta x=\pi$. Note that it is independent of λ and μ. Also, it is quite small for a reasonably large choice of CFL number. The second, damping coefficient is proportional to λ, and it depends on the mesh through a factor $\Delta x^4/\Delta t^2$. Note that for $\lambda=\mu$ the dispersion coefficient is positive for $p>1$ and negative for $p<1$. We shall see the effect of these terms in the numerical experiments presented in section 3.5.

3.4. The weighted box scheme. The traditional method of controlling the checkerboard mode is to introduce θ-weighting in the time integration (see [6]). In this section we describe this scheme and modify the analysis given above to cover this change. We confine the change to the transport equation and so obtain, instead of (3.2),

$$\mu_x\delta_tC_{j+\frac{1}{2}}^{n+\frac{1}{2}}+\mu_x\delta_tS_{j+\frac{1}{2}}^{n+\frac{1}{2}}+p\theta_t\delta_xC_{j+\frac{1}{2}}^{n+\frac{1}{2}}=0, \tag{3.36}$$

where we define the θ-averaging operator as

$$\theta_tC_j^{n+\frac{1}{2}}=\theta C_j^{n+1}+(1-\theta)C_j^n. \tag{3.37}$$

The scheme is second order accurate provided $\theta=\frac{1}{2}+O(\Delta t)$, and a Fourier analysis shows it is Lax–Richtymer stable for all Δx and Δt provided $\theta\geq\frac{1}{2}$; we shall therefore make this assumption in all that follows.

We first reconsider the energy analysis, making use of the identities and notation used earlier. As implied above, we continue to use the trapezoidal weighting for the source term; thus the equations become

$$\mu_x \delta_t C^{n+\frac{1}{2}} + p\theta_t \delta_x C^{n+\frac{1}{2}} = -\Delta t \mu_x \mu_t R^{n+\frac{1}{2}}, \tag{3.38}$$

$$\mu_x \delta_t S^{n+\frac{1}{2}} = \Delta t \mu_x \mu_t R^{n+\frac{1}{2}}, \tag{3.39}$$

where the discretization of the reaction equation has again been space-averaged.

Following the same procedure as before, we multiply (3.38) and (3.39) by $\theta_t \bar{C}^{n+1/2}$ and $\theta_t \bar{S}^{n+1/2}$, respectively, and then sum the resulting equations over j. The advection inner product collapses and, with the assumption that $t^n > t^*$, the boundary term at $j = 0$ vanishes and we obtain

$$\begin{aligned} &\theta \|\bar{C}^{n+1}\|_2^2 + (1-2\theta)\langle \bar{C}^{n+1}, \bar{C}^n\rangle_2 - (1-\theta)\|\bar{C}^n\|_2^2 \\ &\qquad + \tfrac{1}{2} V \Delta t \big[\theta_t C_J^{n+\frac{1}{2}}\big]^2 = -\Delta t \langle \theta_t \bar{C}^{n+\frac{1}{2}}, \mu_t \bar{R}^{n+\frac{1}{2}}\rangle_2, \end{aligned} \tag{3.40}$$

$$\begin{aligned} &\theta \|\bar{S}^{n+1}\|_2^2 + (1-2\theta)\langle \bar{S}^{n+1}, \bar{S}^n\rangle_2 - (1-\theta)\|\bar{S}^n\|_2^2 \\ &\qquad = \Delta t \langle \theta_t \bar{S}^{n+\frac{1}{2}}, \mu_t \bar{R}^{n+\frac{1}{2}}\rangle_2. \end{aligned} \tag{3.41}$$

Now from the Cauchy–Schwarz inequality we have, for $\theta \geq \frac{1}{2}$,

$$(2\theta - 1)\langle \bar{A}^{n+1}, \bar{A}^n\rangle_2 \leq \big(\theta - \tfrac{1}{2}\big)\big[\|\bar{A}^{n+1}\|_2^2 + \|\bar{A}^n\|_2^2\big].$$

Hence the terms on the left of (3.40) can be greatly simplified to give

$$\tfrac{1}{2}\|\bar{C}^{n+1}\|_2^2 - \tfrac{1}{2}\|\bar{C}^n\|_2^2 \leq -\Delta t \langle \theta_t \bar{C}^{n+\frac{1}{2}}, \mu_t \bar{R}^{n+\frac{1}{2}}\rangle_2. \tag{3.42}$$

Similarly, from (3.41), we get

$$\tfrac{1}{2}\|\bar{S}^{n+1}\|_2^2 - \tfrac{1}{2}\|\bar{S}^n\|_2^2 \leq \Delta t \langle \theta_t \bar{S}^{n+\frac{1}{2}}, \mu_t \bar{R}^{n+\frac{1}{2}}\rangle_2. \tag{3.43}$$

Combining these results as in (3.11) we obtain

$$\begin{aligned} &\lambda \|\bar{C}^{n+1}\|_2^2 + \mu \|\bar{S}^{n+1}\|_2^2 - \lambda \|\bar{C}^n\|_2^2 - \mu \|\bar{S}^n\|_2^2 \\ &\qquad \leq -\Delta t \big[\theta \|\bar{R}^{n+1}\|_2^2 + (1-\theta)\|\bar{R}^n\|_2^2 + \langle \bar{R}^{n+1}, \bar{R}^n\rangle_2\big]. \end{aligned} \tag{3.44}$$

Now we can rewrite the terms on the right by setting $\theta = \frac{1}{2}(1+\xi)$, and apply the Cauchy–Schwarz inequality again, to get

$$\begin{aligned} &\tfrac{1}{2}\big[(1+\xi)\|\bar{R}^{n+1}\|_2^2 + (1-\xi)\|\bar{R}^n\|_2^2 + 2\langle \bar{R}^{n+1}, \bar{R}^n\rangle_2\big] \\ &\qquad \geq \tfrac{1}{2}\xi\big[\|\bar{R}^{n+1}\|_2^2 - \|\bar{R}^n\|_2^2\big]. \end{aligned} \tag{3.45}$$

Substituting this result in (3.44) then yields the required stability of the cell averages, since we have $\xi \geq 0$, in terms of the energy $\lambda\|\bar{C}^n\|_2^2 + \mu\|\bar{S}^n\|_2^2 + \frac{1}{2}\xi\Delta t\|\bar{R}^n\|_2^2$. We should also note at this point how the weighting affects the propagation of the oscillatory mode into the interior from the boundary data—and hence the mapping from the cell averages to the nodal values. In applying a Godunov–Ryabenkii stability analysis, we can substitute a mode of the form $\alpha^n(-1)^j$ into (3.36); only the advection term contributes and yields the result $\alpha = 1 - 1/\theta$. So this mode is damped if $\theta > \frac{1}{2}$.

However, it is the modified equation analysis which gives the most information on the behavior of the weighted box scheme. The averaging operator θ_t can be written as

$$\theta_t = \mu_t + \big(\theta - \tfrac{1}{2}\big)\delta_t, \tag{3.46}$$

so we can introduce the operator

$$\mathcal{M}_t := \mu_t^{-1}\theta_t = 1 + \left(\theta - \tfrac{1}{2}\right)\Delta t\mathcal{D}_t. \tag{3.47}$$

The modified equation analysis can now proceed in exactly the same way as in sections 3.2 and 3.3, with the only changes being the replacement of $\mathcal{D}_x$ by $\mathcal{M}_t\mathcal{D}_x$ and the operator equations for both the smooth waves and the oscillatory waves being in the form covered by Lemma 3.1. For the main advected wave which previously led to the expansion in (3.22), it is a straightforward calculation to find that we get instead

$$\begin{aligned} C_t = &-V'C_x + V'^2\left\{\frac{\lambda}{\mu(\lambda+\mu)} + \left(\theta - \frac{1}{2}\right)\Delta t\right\}C_{xx} \\ &- V'\left\{\frac{\lambda(\lambda-\mu)V^2}{(\lambda+\mu)^4} + \frac{1}{12}\left[V'^2\Delta t^2 - \Delta x^2\right] + 3\frac{\lambda V'^2}{\mu(\lambda+\mu)}\left(\theta - \frac{1}{2}\right)\Delta t\right. \\ &\left. + V'^2\left(\theta - \frac{1}{2}\right)^2\Delta t^2\right\}C_{xxx} + \ldots. \end{aligned} \tag{3.48}$$

On comparing this with the unweighted case, we see that diffusion is enhanced for $\theta > \frac{1}{2}$ as expected, but the advection speed is unaffected; also there are extra terms in the dispersion, which will affect the choice of mesh ratio to minimize the numerical dispersion—note, however, that the term $\left(\theta - \frac{1}{2}\right)^2\Delta t^2$ is negligible if $\theta = \frac{1}{2} + O(\Delta t)$.

The most significant change is in the expansion for the main oscillatory wave, where the leading terms of (3.35) are replaced by

$$\begin{aligned} C_t^o = &-4\frac{\theta - \frac{1}{2}}{\Delta t}(1+\gamma)C^o \\ &- \frac{V}{p^2}\left(\frac{1 - (\lambda+\mu)(\theta - \frac{1}{2})\Delta t}{1 - \mu(\theta - \frac{1}{2})\Delta t}\right)(1+3\gamma)C_x^o + \ldots, \end{aligned} \tag{3.49}$$

where $\gamma = (4/3)(\theta - \frac{1}{2})^2$ and the factors involving this quantity arise from the transformation of an expansion for $\mathcal{D}_t$ into one for ∂_t. Thus even for $\theta = \frac{1}{2} + O(\Delta t)$, exponential damping of the oscillatory modes occurs, while the advective speed is little changed.

3.5. Numerical experiments. In all of the numerical experiments with the linear model problem that we present here, we have taken $V = 1.0$ and, in the early cases, we use the simple scheme with $\theta = \frac{1}{2}$. The plots are generally of the concentration C at a fixed point $x = 1$, as a function of t. Figure 2, in which we take $\Delta x = 0.025$, shows three results for the case of $(\lambda, \mu) = (1, 1)$: the bottom graph shows the smooth result obtained with Gaussian boundary data, while the top two show the corresponding results obtained with a square pulse boundary data (of unit height on the interval $(0, 1)$, which is our standard test data). The exact solution is shown as an unbroken line. These two plots show how devastating the checkerboard mode can be. The top plot is for the CFL number, $p = V\Delta t/\Delta x$, equal to 0.8 and shows the oscillations moving faster than the main pulse; the middle plot is with $p = 1.25$ and shows the oscillations moving more slowly, as predicted by the V^2/p velocity component in (3.35). In Figure 3 corresponding results are shown for the case $\lambda = 90$, $\mu = 10$, the top plot for square pulse data and the bottom plot for Gaussian data, both with $p = 0.8$. The middle plot has $p = 1.25$. The results are quite accurate and show the mollifying effect of increasing λ and μ. In Figure 4 this case is repeated with square pulse initial data, with $\Delta x = 0.04$, and varying values of the CFL number.

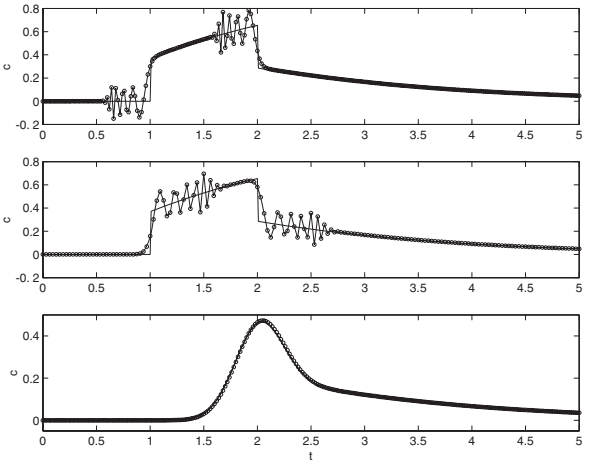

FIG. 2. *Solution c for $V = 1$ and $x = 1$: the thin unbroken line indicates the exact solution, the dots joined by an unbroken line indicate the box scheme. In all cases $(\lambda, \mu) = (1, 1)$, $\Delta x = 0.025$. The top plot has a square pulse initial data with CFL number $p = 0.8$, the middle plot has the same initial data with $p = 1.25$, and the bottom plot has Gaussian initial data with $p = 0.8$.*

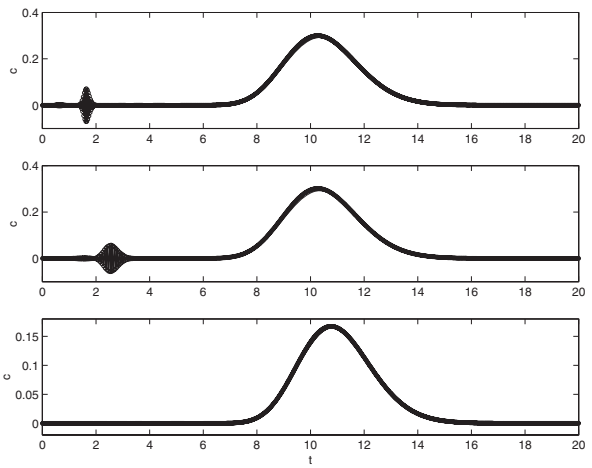

FIG. 3. *As for Figure 2 but with $(\lambda, \mu) = (90, 10)$.*

Choosing p to match the reduced speed (that is, $p = (\lambda + \mu)/\mu = 10$) eliminates the effects of the discretization in the dispersion term in (3.22). However, the best results are obtained by taking $p = 6.4103$, which is calculated to set the coefficient of the dispersion term in (3.22) to zero (which is possible in this model problem but unlikely to hold in applications). These results confirm the modified equation analysis of section 3.2 showing that the accuracy is improved by tuning p to match the reduced speed rather than the speed in the transport equation. They also show how the effect of the oscillations is reduced by such a choice. These experiments are repeated with $\theta = .51$ in Figure 4, showing how such a choice completely eliminates the oscillations, as predicted by the analysis in section 3.4. Finally, we show that the spurious oscillations move with speed V/p^2 independent of λ and μ as predicted by

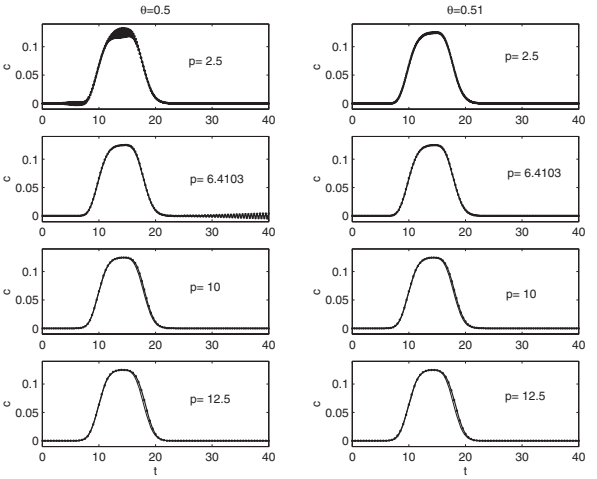

FIG. 4. *Solution c for $V = 1$ at $x = 1$: the thin unbroken line indicates the exact solution and the dotted line the box scheme solution. In all cases $\Delta x = 0.04$ $(\lambda, \mu) = (90, 10)$. The values of p are 2.5, 6.4103, 10, and 12.5. The left-hand column has $\theta = 0.5$ and the right-hand column has $\theta = 0.51$.*

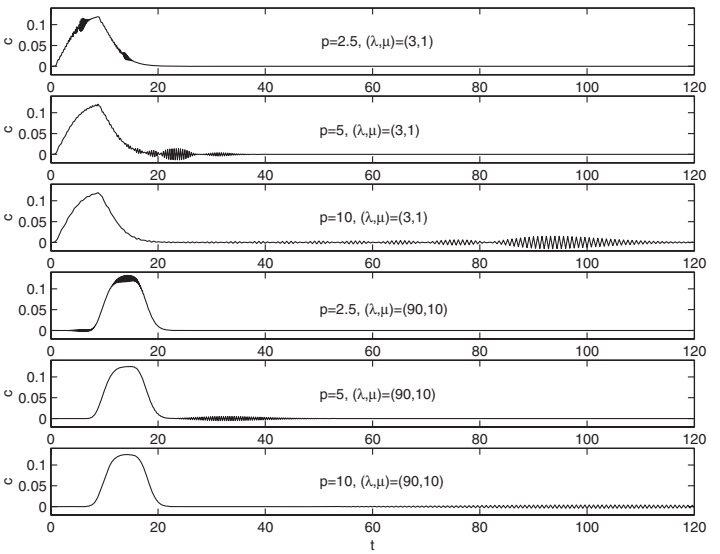

FIG. 5. *Solution c for $V = 1$ at $x = 1$ for $(\lambda, \mu) = (3, 1)$ and $(\lambda, \mu) = (90, 10)$, for three values of $p = \Delta t/\Delta x$: the thin line indicates the box scheme solution. It is easily seen that the spurious oscillations move with speed V/p^2.*

(3.35). This is easily observed in Figure 5 for $(\lambda, \mu) = (90, 10)$ and $(\lambda, \mu) = (3, 1)$, where the spurious oscillations exhibit the same qualitative behavior for the two sets of parameter values.

4. A nonlinear model in one space dimension. We now turn our attention to the following problem with a nonlinear reaction term:

$$c_t + Vc_x = r(c,s), \tag{4.1}$$

$$s_t = -r(c,s). \tag{4.2}$$

If $r(c,s) = -\lambda c + \mu s$, then we recover the linear problem discussed in section 2. Common nonlinear expressions are the Langmuir reaction (see [16], p. 166)

$$r(c,s) = -\lambda c(\mathcal{B} - s) + \mu s, \tag{4.3}$$

where $\mathcal{B}$ represents the maximum capacity for absorption, and thus the rate of absorption of c into the rock reduces as s increases, and the Freundlich reaction

$$r(c,s) = -\lambda c^{1+\beta} + \mu s, \tag{4.4}$$

where the first term on the right-hand side represents a $(1+\beta)$th-order reaction for the adsorption of c into the rock. Often $-1 < \beta < 0$, but we do not impose this restriction here.

Adding (4.1) and (4.2) gives the conservation equation

$$(c+s)_t + Vc_x = 0, \tag{4.5}$$

and, following [13], let us assume that the reaction term $r(c,s)$ in (4.1) and (4.2) can be written as $r(c,s) = (s - S(c))/\epsilon$ for some smooth $S(c)$ and some small parameter ϵ. Thus (4.2) is written as

$$s_t = \frac{1}{\epsilon}(S(c) - s), \tag{4.6}$$

and the equilibrium manifold (see the first paragraph in section 2.1) is $s = S(c)$.

The equilibrium model (see (2.4)) arises by replacing s in (4.5) by $S(c)$ to give the nonlinear conservation law

$$c_x + \frac{1}{V}(c + S(c))_t = 0, \tag{4.7}$$

where the roles of x and t are reversed in the application of standard theory of hyperbolic conservation laws. Consider this equation subject to Riemann boundary data

$$c(0,t) = \begin{cases} c_L, & t \le \tau, \\ c_R, & t > \tau, \end{cases} \tag{4.8}$$

for some $\tau \ge 0$. If $S''(c) > 0$, as is the case for the Freundlich nonlinearity for $\beta > 0$, and $c_L > c_R$, (4.7) develops a shock with speed

$$U_s := \frac{V(c_L - c_R)}{S(c_L) - S(c_R) + c_L - c_R}, \tag{4.9}$$

but if $c_L < c_R$, (4.7) describes a rarefaction wave. If $S''(c) < 0$, as is the case for the Langmuir nonlinearity, the two cases are interchanged. The improved equilibrium model is (cf. (2.9))

$$c_x + \frac{1}{V}(c + S(c))_t = \frac{\epsilon}{V}(S'(c)c_t)_t, \tag{4.10}$$

where we have replaced s_t in (4.5) using $s_t = (S(c))_t - \epsilon s_{tt}$ and have approximated s_{tt} using $s_{tt} \approx (S'(c)c_t)_t$. Here we see that if $S'(c) > 0$, as is the case in both our examples, then the right-hand side of (4.10) provides a "viscous damping" term that prevents shocks from forming. The numerical results presented in section 4.1 show that discontinuities are indeed gradually smoothed and damped.

As in the linear model, we use the predicted pulse speed to choose the time step; this can be done dynamically as the pulse develops. The shock speed U_s, given by (4.9), is our main guide in the case of a data pulse of height $|c_L - c_R|$; but note that as c_L tends to c_R this becomes the [illegible] $V' = V/(1 + S'(c))$, the characteristic speed of the equilibrium model (4.7) which in general differs from the shock speed. We note also that a traveling wave solution of (4.1), (4.2) propagates at the shock speed (cf. [22, pp. 101–102]).

4.1. Numerical results. Here we present numerical results for two examples with nonlinear reactions. We shall see that the weighted box scheme with appropriately chosen mesh ratio produces good results for the problems under consideration. A likely strategy in a practical situation would be to fix Δx and tune Δt based either on the shock speed, so that $U_s \Delta t/\Delta x \approx 1$, or on the reduced speed, so that $\frac{V}{1+S'(c)}\Delta t/\Delta x \approx 1$, for some appropriate choice of c. Here we carry out experiments with fixed Δt and Δx to fully understand the performance of the box scheme, and to compare the nonlinear case with the linear case discussed in section 3.5.

First, let us consider system (4.1), (4.2) with the Freundlich nonlinearity (4.4) where $\beta = 1$, i.e., $r(c, s) = -\lambda c^2 + \mu s$, and hence $S(c) = \lambda c^2/\mu$, the reduced speed is $\mu V/(\mu + 2\lambda c)$, but the shock speed is $\mu V/(\mu + \lambda|c_L - c_R|)$. We take the boundary condition

$$c(0,t) = \begin{cases} 1/3, & 0 \le t \le 1, \\ 0, & \text{otherwise}, \end{cases} \tag{4.11}$$

and since $S'' > 0$ we expect the "switch-off" discontinuity at $t = 1$ to lead to a steep front. Let $V = 1$, $(\lambda, \mu) = (90, 10)$, so the shock speed is $U_s = 0.25$, which suggests the choice $\Delta t = 4\Delta x$. In Figure 6 we present results for several values of $\Delta t/\Delta x$ at $x = 1$, and in Figure 7 we repeat the experiment using the weighted box scheme with $\theta = 0.52$. First, we see in Figure 6 that the spurious oscillations are strongly evident for all values of p shown here, and they move with speed V/p^2 as predicted for the linear theory by (3.35). However, the θ-weighting eliminates the spurious oscillations in all cases. As x increases the pulse diffuses, as indicated by (4.10), so for optimal results we should tune Δt using the reduced speed so that Δt would gradually reduce from the value $4\Delta x$ derived using the shock speed.

Next, let us consider system (4.1), (4.2) with the Langmuir nonlinearity (4.3) with $\mathcal{B} = 1$, i.e., $r(c, s) = -\lambda c(1 - s) + \mu s$, subject to the same boundary condition as the previous example. Now we have $S(c) = \lambda c/(\mu + \lambda c)$, the reduced speed is $V[1 + \lambda\mu(\mu + \lambda c)^{-2}]$, and the shock speed is $V[1 + \lambda\mu\{(\mu + \lambda c_R)(\mu + \lambda c_L)\}^{-1}] = 4/13$ for the data given in (4.11). Since $S''(c) < 0$ we expect the "switch-on" discontinuity at $t = 0$ to give the steep front and we choose Δt based on the shock speed so that $\Delta t = 3.25\Delta x$. Numerical results for the box scheme using $\Delta x = 1/30$ with both $\theta = 0.5$ (i.e., no weighting) and $\theta = 0.51$ are given in Figure 8. Again we see the significant effect of the spurious oscillations in the unweighted scheme, though for $p = \Delta t/\Delta x = 10/3$ rather good results are obtained. As expected, the introduction of a small amount of weighting produces much improved results for all values of p. As in the first example, we see that the spurious oscillations introduced by the discontinuity

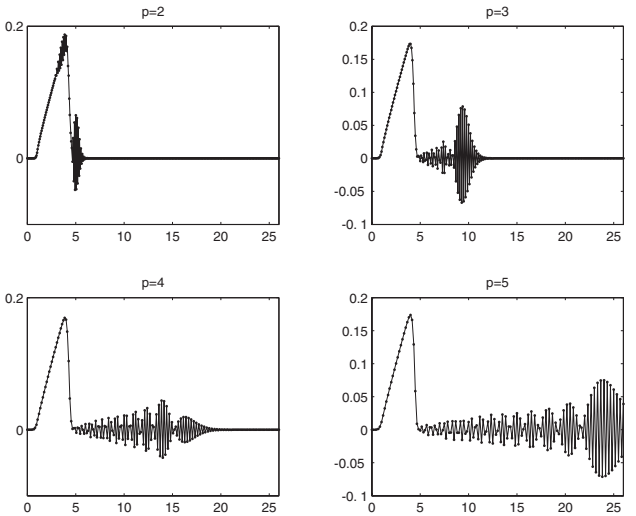

FIG. 6. *The box scheme with no θ-weighting is applied to* (4.1), (4.2) *with Freundlich nonlinearity* (4.4), *and with a square pulse boundary condition* (4.11). *Here* $\beta = 2$, $\lambda = 90$, $\mu = 10$, $V = 1$, $\Delta x = 1/30$, *and* $p := \Delta t/\Delta x$.

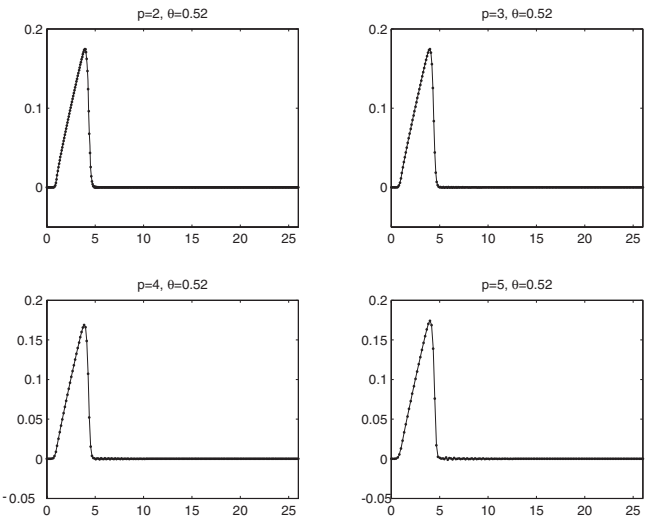

FIG. 7. *As for Figure* 6 *but with* $\theta = 0.52$.

at $x = 0$, $t = 1$ for $\theta = 0.5$ propagate with speed V/p^2, as indicated by (3.35) for the linear problem.

5. The box scheme for two-dimensional problems. Most practical problems are posed in two or three space dimensions with variable velocity profiles. We shall see that the theory of the box scheme in one dimension predicts well its behavior in two dimensions and that the weighted scheme successfully eliminates any spurious oscillations.

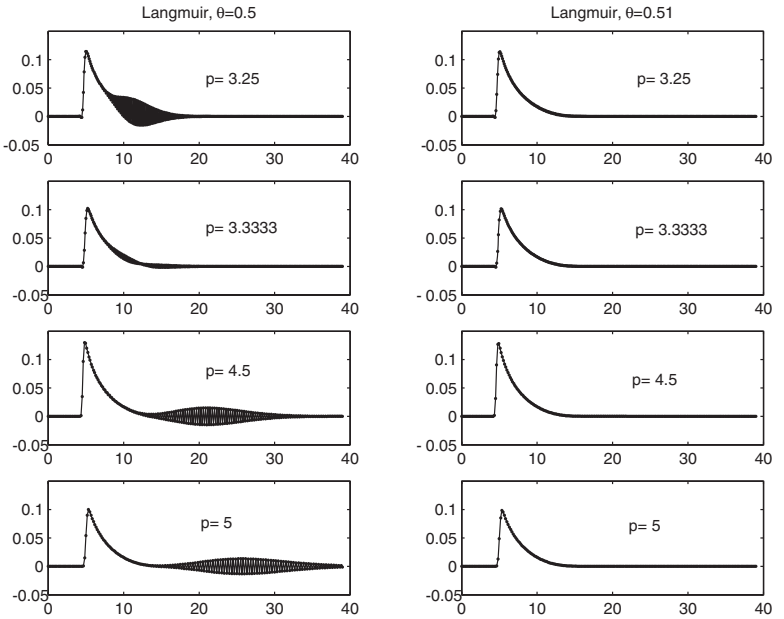

FIG. 8. *The box scheme with* $\theta = 0.5$ *and* 0.51 *is applied to* (4.1), (4.2) *with Langmuir nonlinearity* (4.3), *and with a square pulse boundary condition* (4.11). *Here* $\mathcal{B} = 1$, $(\lambda, \mu) = (90, 10)$, $V = 1$, $x = 1$, *and* $p := \Delta t/\Delta x$.

In [19] and [20] the authors consider the mobility of potentially toxic dissolved metals discharged from a mine tailings source into an aquifer in which the flow is incompressible (see Figure 2 in [20]). We simplify this situation by considering a single chemical pollutant with a reacting term as in the linear model problem. The system to be solved, in conservation form, is

$$c_t + s_t + (U(x,z)c)_x + (V(x,z)c)_z = 0, \tag{5.1}$$

$$s_t = \lambda c - \mu s, \tag{5.2}$$

in the domain $\mathcal{D} := 0.5 \le x \le 2.0$, $0.8 \le z \le 1.0$, for $t \ge 0$, with the incompressible flow field $(U(x,z), V(x,z))$ being given by

$$U(x,z) = \frac{2}{\pi \sinh\left(\frac{\pi Z}{2X}\right)} \cosh\left(\frac{\pi z}{2X}\right) \sin\left(\frac{\pi x}{2X}\right), \tag{5.3}$$

$$V(x,z) = \frac{-2}{\pi \sinh\left(\frac{\pi Z}{2X}\right)} \sinh\left(\frac{\pi z}{2X}\right) \cos\left(\frac{\pi x}{2X}\right). \tag{5.4}$$

(These expressions arise by solving $\nabla^2 \phi(x,z) = 0$ in $0 \le x \le X$, $0 \le z \le Z$, subject to the boundary conditions $\phi_z(x,0) = 0$, $\phi_z(x,Z) = -0.5$, $\phi_x(0,z) = 0$, $\phi(X,z) = 1$, using separation of variables and then taking the first terms in the expressions for $\phi_x(x,z)$ and $\phi_z(x,z)$ as the respective velocity components.)

The initial condition is

$$c(x,z,0) = s(x,z,0) = 0 \quad \text{for } (x,z) \in \mathcal{D}, \tag{5.5}$$

and the boundary condition is

$$c(x,Z,t)=\begin{cases} g(x), & 0\le t\le t^*,\\ 0, & t>t^*. \end{cases} \tag{5.6}$$

In our examples, $t^*=2$ and

$$g(x)=\begin{cases} 0, & x\le\tau,\\ \sin^2\left(\frac{\alpha\pi}{2}(x-\tau)\right), & \tau<x<\frac{1}{\alpha}+\tau,\\ 1, & \frac{1}{\alpha}+\tau\le x\le\beta-\frac{1}{\alpha}+\tau,\\ \sin^2\left(\frac{\alpha\pi}{2}(\beta+\tau-x)\right), & \beta-\frac{1}{\alpha}+\tau\le x\le\beta+\tau,\\ 0, & x>\beta+\tau. \end{cases} \tag{5.7}$$

Here α can be varied, with a small α giving a smooth pulse and a large α making the pulse more "squarelike." In our numerical experiments $\alpha=6$, $\beta=0.8$, and $\tau=0.6$.

In terms of difference operators, the box scheme applied to (5.1), (5.2) produces

$$\begin{aligned} &\frac{\mu_x\mu_z\delta_t}{\Delta t}C^{n+\frac12}_{i+\frac12,j+\frac12}+\frac{\mu_x\mu_z\delta_t}{\Delta t}S^{n+\frac12}_{i+\frac12,j+\frac12}\\ &\quad+\frac{\mu_z\mu_t\delta_x}{\Delta x}(U\ C)^{n+\frac12}_{i+\frac12,j+\frac12}+\frac{\mu_x\mu_t\delta_z}{\Delta z}(V\ C)^{n+\frac12}_{i+\frac12,j+\frac12}=0,\\ &\frac{\delta_t}{\Delta t}S^{n+\frac12}_{i+1,j+1}=\lambda\ \mu_t C^{n+\frac12}_{i+1,j+1}-\mu\ \mu_t S^{n+\frac12}_{i+1,j+1}. \end{aligned}$$

The box scheme is an implicit scheme, but in this linear problem, with the fluxes flowing in the same general direction in all the cells, an efficient explicit scheme is obtained by sweeping from the top left-hand corner. We use an averaged mesh in the x and z direction calculated as follows. Set

$$\hat U(x)=\frac{1}{0.2}\int_{0.8}^{1}U(x,z)\,\mathrm{d}z,\qquad \hat V(z)=\frac{1}{1.5}\int_{0.5}^{2}V(x,z)\,\mathrm{d}x$$

and choose variable step sizes Δx_{i+1} and Δz_{j+1} such that

$$\frac{\hat U(x_{i+1})+\hat U(x_i)}{2\Delta x_{i+1}}=\frac{\hat V(z_{j+1})+\hat V(z_j)}{2\Delta z_{j+1}}.$$

In our numerical experiments we take $\lambda=90$, $\mu=10$. We expect the solution to be close to that for the equilibrium model, and hence the solution speed is reduced by a factor of $\frac{\mu}{\lambda+\mu}$. Thus we expect the optimal choice for Δt to be given by

$$\Delta t=\frac{\lambda+\mu}{\mu}\frac{2\Delta x_{i+1}}{\hat U(x_{i+1})+\hat U(x_i)}=\frac{\lambda+\mu}{\mu}\frac{2\Delta z_{i+1}}{\hat V(x_{i+1})+\hat V(x_i)}.$$

If we introduce the quantity p given by

$$p=\frac{\hat U(x_{i+1})+\hat U(x_i)}{2}\frac{\Delta t}{\Delta x_{i+1}} \tag{5.8}$$

(cf. (3.2) for the one-dimensional problem), then to tune the mesh for optimal results we take p to be $\frac{\lambda+\mu}{\mu}$. Numerical results obtained using the box scheme with $p=\frac{\lambda+\mu}{\mu}=10$ are shown in Figure 9, and for the θ-weighted scheme in Figure 10. The unweighted scheme clearly shows the spurious mode moving at a different speed from the pulse, and the weighted scheme has again successfully removed the oscillations. To illustrate the behavior of the spurious oscillations, we show in Figures 11 and 12 the

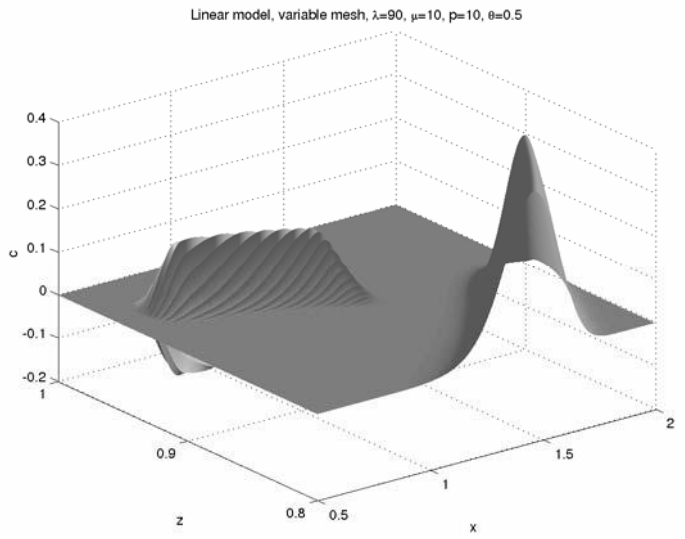

FIG. 9. *Box scheme applied to* (5.1), (5.2) *with* $\theta = 0.5$. *Here the solution pulse moves independently of the spurious oscillations.*

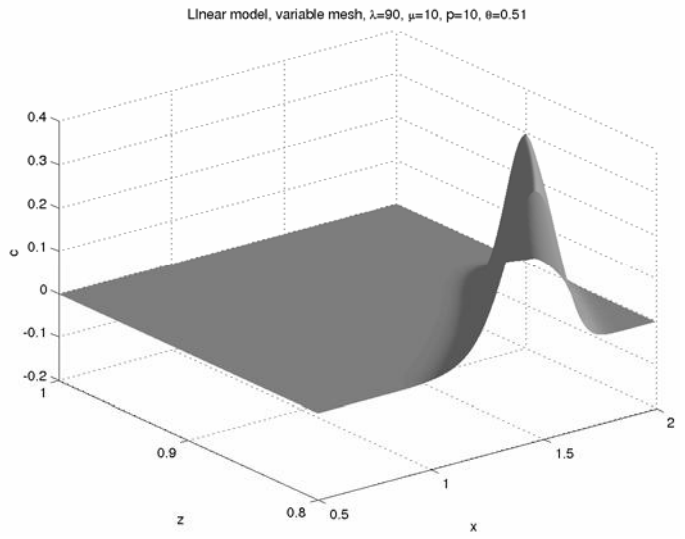

FIG. 10. *Box scheme applied to* (5.1), (5.2) *with* $\theta = 0.51$ *has removed the spurious oscillations.*

computed values of $c(1, 0.95, t)$ for $0 \leq t \leq 25$ for four values of p, namely, $p = 1.25$, 2.5, 5, and 10. Figure 11 shows the results from the unweighted box scheme. As p doubles we see the spurious oscillations move at a speed determined by the mesh and not the parameters in the differential equation. In fact, they move at a speed roughly like $1/p^2$, as predicted by (3.35) for one-dimensional problems (cf. also Figure 5). Figure 12 shows improved results obtained by the weighted box scheme with $\theta = 0.51$, and in particular the spurious oscillations have disappeared for the optimal value $p = 10$, as expected.

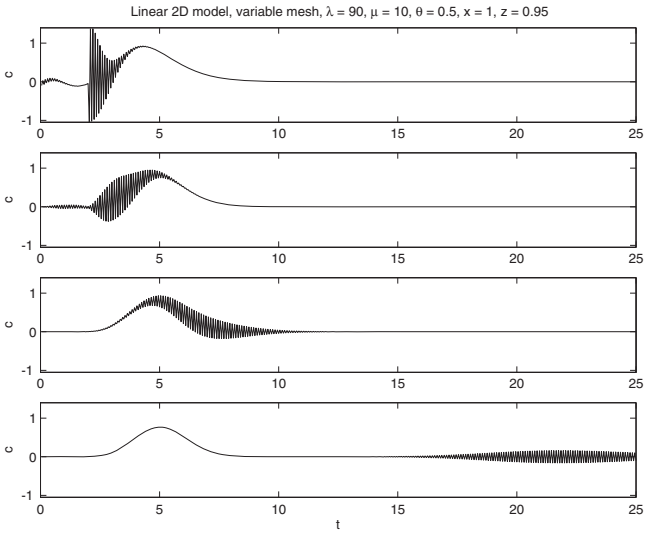

FIG. 11. *Plot of the computed value of* $c(1, 0.95, t)$ *for* $0 \le t \le 25$ *for* $\Delta t = 0.05$ *and* $p = 1.25, 2.5, 5, 10$*, respectively. The pulse of spurious oscillations moves like* p^{-2} *just as predicted in the one-dimensional theory.*

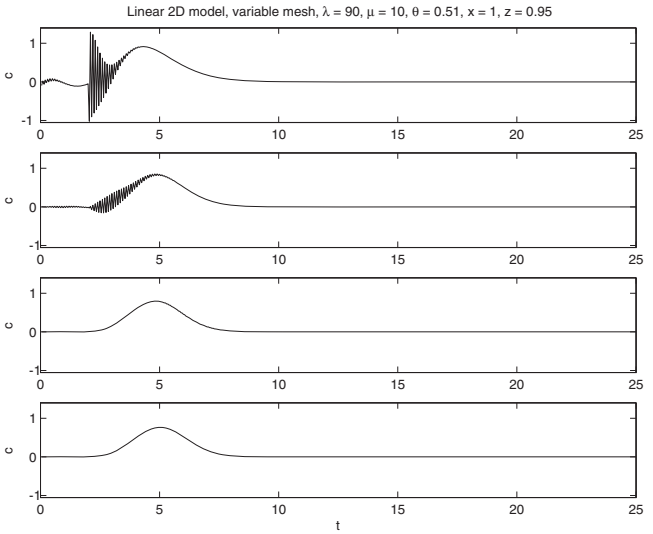

FIG. 12. *As for Figure* 11 *but with* $\theta = 0.51$*. The spurious oscillations have been greatly reduced and for* $p = 10$ *have disappeared.*

6. Conclusions. In this paper we discuss the application of the box scheme to hyperbolic conservation laws with reactive source terms. Our discussion centers initially on a model problem with linear reaction terms. First, we provide a straightforward asymptotic analysis that explains the phenomena of reduced speed, enhanced diffusion, and dispersion. An energy analysis for the box scheme shows the stability of cell averages but also indicates how the notorious checkerboard mode may grow linearly. A detailed modified equation analysis shows how to tune the mesh parameters

in the box scheme to capture the main advected wave with minimal dispersion. A novel modified equation analysis, based on separating smooth and oscillatory solutions, shows how the checkerboard mode moves at a nonphysical speed determined by the mesh parameters. The θ-weighted box scheme is also discussed and, in particular, the modified equation analysis clearly shows how the θ-weighting exponentially damps the checkerboard mode. We show how the deductions from the analysis for the linear problem apply to problems with nonlinear reactions; this has applications in other physically important problems, such as the St. Venant equations for open channel flow. Numerical results for linear and nonlinear reactions in one dimension and linear reactions in two dimensions illustrate the applicability of the theory, including the nonphysical speed of the checkerboard mode and the effectiveness of θ-weighting, across a variety of problems.

AVERAGING TECHNIQUES FOR THE EFFECTIVE NUMERICAL SOLUTION OF SYMM'S INTEGRAL EQUATION OF THE FIRST KIND*

CARSTEN CARSTENSEN† AND DIRK PRAETORIUS‡

Abstract. Averaging techniques for finite element error control, occasionally called *ZZ estimators* for the gradient recovery, enjoy a high popularity in engineering because of their striking simplicity and universality: One does not even require a PDE to apply the nonexpensive postprocessing routines. Recently, averaging techniques have been mathematically proved to be reliable and efficient for various applications of the finite element method. This paper establishes a class of averaging error estimators for boundary integral methods. Symm's integral equation of the first kind with a nonlocal single-layer integral operator serves as a model equation studied both theoretically and numerically. We introduce four new error estimators which are proven to be reliable and efficient up to terms of higher order. The higher-order terms depend on the regularity of the exact solution. Several numerical experiments illustrate the theoretical results and show that the [normally unknown] error is sharply estimated by the proposed estimators, i.e., error and estimators almost coincide.

Key words. integral equations, boundary element method, a posteriori error estimates, reliability, efficiency, adaptive algorithm

AMS subject classifications. 65N38, 65R20, 65N50

DOI. 10.1137/040609033

1. Introduction.

Reliable error control and efficient meshdesign in today's boundary element analysis are usually based on a posteriori error estimates. Let Ω be a bounded domain in $\mathbb{R}^d$, $d = 2, 3$, with Lipschitz boundary $\partial\Omega$, and let $\Gamma \subset \partial\Omega$ be an open surface. Suppose we are given the right-hand side f and an approximation u_h for the unknown exact solution u of the operator equation

$$Vu = f \qquad \text{in } \widetilde{H}^{-1/2}(\Gamma) \tag{1.1}$$

for the single-layer potential [ds_y denotes surface integration on $\Gamma \subseteq \mathbb{R}^d$ with respect to the variable y] defined by

$$(Vu)(x) = \int_\Gamma u(y)\kappa(x-y)\, ds_y \quad \text{for } x \in \Gamma \tag{1.2}$$

and interpreted in a weak sense for the kernel

$$\kappa(x) := \begin{cases} -\frac{1}{\pi}\log|x| & \text{for } d = 2, \\ \frac{1}{2\pi}|x|^{-1} & \text{for } d = 3. \end{cases} \tag{1.3}$$

A posteriori error estimators $\eta = \eta(u_h, f, \mathcal{T})$ are computable quantities in terms of the right-hand side f, a computed approximate solution u_h, and the given underlying

mesh $\mathcal{T} = \{\Gamma_1, \ldots, \Gamma_n\}$ which bound the exact error from below or above [so-called efficiency and reliability of η, resp.]. So far, for boundary element methods, the following four groups (i)–(iv) of a posteriori estimates have been introduced; see [CFa] for more details.

(i) Weighted residual error estimators in 2D, established in [C1, C2, C3, CES, CS1, CS2],

$$\eta_{R,j} := h_j^{\alpha} \, \|\partial R/\partial s\|_{L^2(\Gamma_j)} \tag{1.4}$$

with the derivative $\partial R/\partial s$ of the residual $R := f - Vu_h$ along Γ and $h_j := |\Gamma_j|$ the size of Γ_j. For the *hp*-method, see [CFS] and, recently, for 3D [CMS, CMPS].

(ii) Local double-integral seminorms in [F2, F3, CP1] with a double integration over overlapping domains $\omega_j := \Gamma_{j-1} \cup \Gamma_j$ in 2D and 3D,

$$\varrho_{F,j}^2 := \int_{\omega_j} \int_{\omega_j} \frac{|R(x) - R(y)|^2}{|x - y|^{1+2\alpha}} \, ds_x \, ds_y. \tag{1.5}$$

(iii) Based on an idea in the finite element literature [BR], Babuška–Rheinboldt-type error estimators are suggested in [F1], so far only for hypersingular integral equations.

(iv) Multilevel error estimators involve a hierarchy of grids and, usually, a disputable saturation assumption [MMS, MSW, CMPS].

Other suggested error estimators employ the notion of an influence index and strengthened Cauchy inequalities [R1, R2, WY, Y1, Y2], localize the outer integration in the Sobolev–Slobodeckij norm (1.5) of the residual $R := f - Vu_h$ [FHK], try to recover gradients [SW, SSW], or employ corrections with another integral equation [MPM, S, SSt].

The nonlocal character of the involved pseudodifferential operator V and the nonlocal Sobolev spaces [of functions on Γ] cause severe difficulties in the mathematical derivation of computable lower and upper error bounds for a discrete (known) approximation u_h to the (unknown) exact solution u. A comparison [F2, F3] shows that the Faermann error estimator $\eta_F := \big(\sum_{j=1}^n \eta_{F,j}^2\big)^{1/2}$ and its modification μ_F from [CP1] were the , , , proven reliable and efficient estimators for unstructured grids in the sense that

$$C_{\text{eff}} \|u - u_h\|_{\widetilde{H}^{-1/2}(\Gamma)} \le \eta_F \le \mu_F \le C_{\text{rel}} \, \|u - u_h\|_{\widetilde{H}^{-1/2}(\Gamma)} \tag{1.6}$$

for the energy norm $\|u - u_h\|_{\widetilde{H}^{-1/2}(\Gamma)}$ of the error in a Galerkin boundary element method.

In this paper we introduce a new class of error estimators η_M, μ_M, η_A, and μ_A for Symm's integral equation based on averaging techniques. For finite element methods it has recently been shown that any averaging technique yields in fact reliable error estimators [ZZ, CB, AC, CFu]. Our results in this paper establish this concept for the Galerkin boundary element method.

In the simplest case, let $\mathcal{T}_H$ be a given mesh with mesh size H, and let $\mathcal{T}_h$ be obtained by uniform refinements of $\mathcal{T}_H$. Let $u_h \in \mathcal{P}_0(\mathcal{T}_h)$ be a $\mathcal{T}_h$-piecewise constant Galerkin approximation of the exact solution $u \in \widetilde{H}^{-1/2}(\Gamma)$ of (1.1). If $\mathbb{G}_H : \widetilde{H}^{-1/2}(\Gamma) \to \mathcal{P}_1(\mathcal{T}_H)$ and $\mathcal{A}_H : \widetilde{H}^{-1/2}(\Gamma) \to \mathcal{P}_1(\mathcal{T}_H)$ denote the Galerkin projection, respectively, the L^2-projection onto the $\mathcal{T}_H$-piecewise affine [not necessarily continuous] functions and if the mesh size h is small enough compared with H, then the error estimator [with $|\!|\!| \cdot |\!|\!|$ the energy norm of section 2.2]

$$\eta_M := |\!|\!| u_h - \mathbb{G}_H u_h |\!|\!| := \langle V(u_h - \mathbb{G}_H u_h)\,; u_h - \mathbb{G}_H u_h\rangle^{1/2} \tag{1.7}$$

is always reliable and efficient up to terms of higher order; cf. Theorem 5.2. The higher-order terms depend only on the smoothness of the exact solution $u \in \widetilde{H}^{-1/2}$. For the lowest-order ansatz $u_h \in \mathcal{P}_0(\mathcal{T}_h)$ it suffices that u is $\mathcal{T}_h$-piecewise in $H^{1+\varepsilon}$ for some $\varepsilon > 0$ [in fact, Γ is therefore required to be piecewise smoother than only Lipschitz].

Since $\mathbb{G}_H$ is the best approximation operator with respect to the energy norm, there holds $|\!|\!| u_h - \mathbb{G}_H u_h |\!|\!| \le |\!|\!| u_h - \mathcal{A}_H u_h |\!|\!|$. In particular, the error estimator

$$\eta_A := |\!|\!| u_h - \mathcal{A}_H u_h |\!|\!| \tag{1.8}$$

is reliable. Theorem 5.6 states the efficiency of η_A provided H^1-stability of $\mathcal{A}_H$ [i.e., $\mathcal{A}_H$ is continuous as operator from $H^1(\Gamma)$ to $H^1(\Gamma)$]. By interpolation and inverse estimates we show that the error estimators

$$\mu_M := \|H^{1/2}(\mathbb{1} - \mathbb{G}_H)u_h\|_{L^2(\Gamma)} \quad \text{and} \quad \mu_A := \|H^{1/2}(\mathbb{1} - \mathcal{A}_H)u_h\|_{L^2(\Gamma)} \tag{1.9}$$

are equivalent to η_M and η_A, respectively, i.e.,

$$C_1^{-1}\mu_M \le \eta_M \le C_2\mu_M \quad \text{and} \quad C_1^{-1}\mu_A \le \eta_A \le C_2\mu_A \tag{1.10}$$

with constants C_1, C_2 that do not depend on the size or the number of the elements in $\mathcal{T}_h$ and $\mathcal{T}_H$; cf. Corollaries 5.4 and 5.5. Since the L^2 norm is local in the sense that $\|\cdot\|^2_{L^2(\Gamma)} = \sum_{\gamma\in\mathcal{T}_H} \|\cdot\|^2_{L^2(\gamma)}$, μ_M and μ_A can be employed for an indicator-based adaptive mesh refinement introduced in section 6.3 below.

The paper is organized as follows: section 2 recalls the definition of the Sobolev spaces $\widetilde{H}^\alpha(\Gamma)$ and $H^\alpha(\Gamma)$ of fractional order $-1 \le \alpha \le 1$. Section 3 displays preliminaries on the mesh geometry and finite elements. A local first-order approximation result for the L^2-projection in scales of $H^\alpha(\Gamma)$ is proven in section 4. Section 5 establishes the a posteriori error estimates and introduces four error estimators (1.7)–(1.9) based on averaging techniques. In section 6 we give implementational details following the spirit of [CP1]. Finally, section 7 reports on five experiments, from which conclusions are drawn in section 8.

2. Preliminaries on the functional analytic setting. This section aims to recall the definition of the fractional-order Sobolev spaces on open screens $\Gamma \subseteq \partial\Omega$, where Ω is a bounded Lipschitz domain in $\mathbb{R}^d$, $d = 2, 3$, with boundary $\partial\Omega$. We provide the interpolation results we are going to use in section 4 and recall the mapping properties of the single layer potential (1.2) in scales of Sobolev spaces $H^\alpha(\Gamma)$.

2.1. Fractional order Sobolev spaces and interpolation. For any (relatively) open set $\omega \subseteq \partial\Omega$ and $0 \le \alpha \le 1$, we define Sobolev spaces of fractional order by complex interpolation

$$\widetilde{H}^\alpha(\omega) = [L^2(\omega); H^1_0(\omega)]_\alpha \quad \text{and} \quad H^\alpha(\omega) = [L^2(\omega); H^1(\omega)]_\alpha, \tag{2.1}$$

where $[X_0; X_1]_\alpha$ denotes the complex interpolation of X_0 and $X_1 \subseteq X_0$ [BL, McL]. The norm $\|\cdot\|_{H^1(\omega)}$ is given by the surface gradient ∇ as $\|u\|^2_{H^1(\omega)} = \|u\|^2_{L^2(\omega)} + \|\nabla u\|^2_{L^2(\omega)}$, and $H^1(\omega)$ and $H^1_0(\omega)$ are defined as the completions of $\mathrm{Lip}(\omega)$ and $\{v \in \mathrm{Lip}(\omega) : v|_{\partial\omega} = 0\}$, respectively. Sobolev spaces with negative index are defined by duality,

$$H^{-\alpha}(\Gamma) := \widetilde{H}^\alpha(\Gamma)^* \quad \text{and} \quad \widetilde{H}^{-\alpha}(\Gamma) := H^\alpha(\Gamma)^* \tag{2.2}$$

with corresponding norms and duality brackets

$$\langle \cdot\,;\cdot \rangle \quad \text{in } \widetilde{H}^{-\alpha}(\Gamma) \times H^{\alpha}(\Gamma) \tag{2.3}$$

which extend the $L^2(\Gamma)$ scalar product.

2.1. Let X_0, X_1 be normed spaces with $X_1 \subseteq X_0$ and $0 \le \alpha \le 1$. Then, the norm of the interpolation space $X := [X_0; X_1]_\alpha$ satisfies

$$\|\cdot\|_{[X_0;X_1]_\alpha} \le \|\cdot\|_{X_0}^{1-\alpha} \|\cdot\|_{X_1}^{\alpha}. \tag{2.4}$$

Furthermore, let $Y := [Y_0; Y_1]_\alpha$ be the complex interpolation of normed spaces $Y_1 \subseteq Y_0$. If $T \in L(X_0; Y_0)$ can also be viewed as an operator $T \in L(X_1; Y_1)$, then $T : X \to Y$ is well defined and continuous and the corresponding operator norms satisfy

$$\|T\|_{L(X;Y)} \le \|T\|_{L(X_0;Y_0)}^{1-\alpha} \|T\|_{L(X_1;Y_1)}^{\alpha}. \qquad \square \tag{2.5}$$

LEMMA 2.1 (see [P, StS]). Let $\mathcal{T} = \{\Gamma_1, \ldots, \Gamma_n\}$ be a partition of Γ into relatively open pieces $\Gamma_1, \ldots, \Gamma_n$ of Γ, $0 \le \alpha \le 1$, and $u \in H^\alpha(\Gamma)$. Then $u|_{\Gamma_j} \in H^\alpha(\Gamma_j)$ for $j = 1, \ldots, n$ and

$$\sum_{j=1}^{n} \|u|_{\Gamma_j}\|_{H^\alpha(\Gamma_j)}^2 \le \|u\|_{H^\alpha(\Gamma)}^2. \qquad \square \tag{2.6}$$

2.2. (i) The constant factor 1 on the right-hand side of (2.6) [not displayed explicitly] holds for complex interpolation and needs to be replaced by an n-independent constant in case of real interpolation as well as in case of alternative definitions by extension or by Sobolev–Slobodeckij norms.

(ii) The converse inequality in (2.6) fails to hold in general [F2, F3].

2.2. Single-layer potential and energy norm. The single-layer potential (1.2) defines a continuous linear operator

$$V : \widetilde{H}^{\alpha-1}(\Gamma) \to H^{\alpha}(\Gamma) \tag{2.7}$$

for all $0 \le \alpha \le 1$ [Co, McL]. For $d = 3$, V always is an isomorphism [i.e., V is bijective and V and V^{-1} are continuous]. Moreover,

$$\langle\!\langle u\,; v \rangle\!\rangle := \langle Vu\,; v\rangle \quad \text{for } u, v \in \widetilde{H}^{-1/2}(\Gamma) \tag{2.8}$$

defines a scalar product on $\widetilde{H}^{-1/2}(\Gamma)$. For $d = 2$, V is bijective if the capacity of Γ is not 1, and (2.8) defines a scalar product on $\widetilde{H}^{-1/2}(\Gamma)$ provided the capacity is strictly less than 1 [e.g., Ω is contained in the open unit disk]; cf. [McL].

In what follows we assume for $d = 2$ that the capacity of Ω is strictly less than 1 so that all results of this paper hold for $d = 2$ and $d = 3$ simultaneously. The induced

$$|\!|\!| u |\!|\!| := \langle\!\langle u\,; u \rangle\!\rangle^{1/2} \tag{2.9}$$

is an equivalent norm on $\widetilde{H}^{-1/2}(\Gamma)$. According to the Lax–Milgram lemma, given $f \in H^{1/2}(\Gamma)$ there is a unique solution $u := V^{-1} f \in \widetilde{H}^{-1/2}(\Gamma)$ of (1.1).

3. Preliminaries on finite element approximation.

3.1. Galerkin discretization of $\widetilde{H}^{-1/2}(\Gamma)$. Let $\mathcal{T} = \{\Gamma_1, \dots, \Gamma_n\}$ be a triangulation of Γ. Each element Γ_j of the triangulation $\mathcal{T}$ is supposed to be a connected (affine) boundary piece for $d = 2$ and a (flat) triangle for $d = 3$, respectively. For $d = 3$, we assume that $\mathcal{T}$ is a regular triangulation: Two distinct and intersecting Γ_j and Γ_k share either a common edge or a vertex. The set of all nodes of the triangulation $\mathcal{T}$ is denoted with $\mathcal{N}$. Let $h \in L^\infty(\Gamma)$ denote the local mesh size $h|_{\Gamma_j} := h_j := \operatorname{diam}(\Gamma_j)$.

For an integer $p \geq 0$, $\mathcal{P}_p(\mathcal{T})$ denotes the space of all isoparametric polynomials of total degree $\leq p$ [defined on reference elements $\Gamma_{\mathrm{ref}} = [0,1]$ and $\Gamma_{\mathrm{ref}} = \operatorname{conv}\{(0,0),(0,1),(1,0)\}$ for $d = 2, 3$, resp.].

If $\mathcal{S}$ is a finite dimensional subspace of $\widetilde{H}^{-1/2}(\Gamma)$ [e.g., $\mathcal{S} = \mathcal{P}_p(\mathcal{T})$], the discrete Galerkin approximation $u_h \in \mathcal{S}$ is uniquely determined by the linear system of equations

$$\langle\!\langle u_h \,;\, v_h \rangle\!\rangle = \langle f \,;\, v_h \rangle \quad \text{for all } v_h \in \mathcal{S}. \tag{3.1}$$

The Galerkin projection $\mathbb{G} : \widetilde{H}^{-1/2}(\Gamma) \to \mathcal{S}$ defined by

$$\langle\!\langle \mathbb{G}u \,;\, v_h \rangle\!\rangle = \langle\!\langle u \,;\, v_h \rangle\!\rangle \quad \text{for all } v_h \in \mathcal{S}$$

is the orthogonal projection onto $\mathcal{S} \subseteq \widetilde{H}^{-1/2}(\Gamma)$ with respect to the energy norm.

3.2. Inverse estimate for the energy norm. Given $\mathcal{T}$ and $\mathcal{S} = \mathcal{P}_p(\mathcal{T})$, we assume that there is a mesh size independent constant $C_{\mathrm{inv}} > 0$ which depends only on Γ, p, and the shape of the elements of $\mathcal{T}$ such that, for all $v_h \in \mathcal{P}_p(\mathcal{T})$, there holds

$$\|v_h\|_{L^2(\Gamma)} \leq C_{\mathrm{inv}} |\!|\!| h^{-1/2} v_h |\!|\!|. \tag{3.2}$$

3.1. The estimate (3.2) is proven in [GHS, Theorem 3.6] for $p \in \mathbb{N}_0$ and Γ a 2D manifold in $\mathbb{R}^3$, but the arguments work for a 1D boundary as well. We stress that here, with a focus on adapted meshes, the mesh size enters the estimates. Well-established inverse estimates

$$\|v_h\|_{L^2(\Gamma)} \lesssim h_{\min}^{-1/2} |\!|\!| v_h |\!|\!| \qquad \text{for } v_h \in \mathcal{P}_p(\mathcal{T}) \tag{3.3}$$

involve the global quantity $h_{\min} := \min_{1 \leq j \leq n} h_j$.

3.3. Standard approximation estimate. Given a regular triangulation $\mathcal{T}$, real numbers $\alpha, m \in \mathbb{R}$ with $m \geq \alpha$, and an integer $p \geq 0$, define $\widehat{p} := \min\{p+1, m\} - \alpha$. Moreover, let $\mathcal{S}_p(\mathcal{T})$ denote either $\mathcal{P}_0(\mathcal{T})$ or $\mathcal{P}_p(\mathcal{T}) \cap \mathcal{C}(\Gamma)$ for $p = 0$ and $p > 0$, respectively. Define the $\mathcal{T}$-piecewise Sobolev space

$$H^m(\mathcal{T}) := \{u \in L^2(\Gamma) \,:\, u|_{\Gamma_j} \in H^m(\Gamma_j) \text{ for all } \Gamma_j \in \mathcal{T}\}$$

with norm $\|u\|^2_{H^m(\mathcal{T})} = \sum_{j=1}^n \|u|_{\Gamma_j}\|^2_{H^m(\Gamma_j)}$. Then, there is constant $C_3 > 0$ depending only on Γ, α, m, p, and the shape of the elements in $\mathcal{T}$ such that

$$\min_{v_h \in \mathcal{S}_p(\mathcal{T})} \|u - v_h\|_{H^\alpha(\Gamma)} \leq C_3 h_{\max}^{\widehat{p}} \, \|u\|_{H^m(\mathcal{T})} \tag{3.4}$$

for all $u \in H^\alpha(\Gamma) \cap H^m(\mathcal{T})$ and $h_{\max} := \max_{1 \leq j \leq n} h_j$; cf. [SaS].

3.4. Local first-order approximation operator. The following definitions adapt [CB] for fixed $0 \le \alpha \le 1$ to obtain an approximation operator:

$$\mathcal{J}_h : H^\alpha(\Gamma) \to \mathcal{P}_1(\mathcal{T}) \cap \mathcal{C}(\Gamma) \subseteq L^2(\Gamma). \tag{3.5}$$

For each node $z \in \mathcal{N}$ let $\varphi_z \in \mathcal{P}_1(\mathcal{T}) \cap \mathcal{C}(\Gamma)$ denote the nodal basis functions with $\varphi_z(z) = 1$ and $\varphi_z(\tilde{z}) = 0$ for $\tilde{z} \in \mathcal{N}\backslash\{z\}$. Note that $\{\varphi_z : z \in \mathcal{N}\}$ is a partition of unity. The support of φ_z is denoted with $\omega_z := \operatorname{supp}(\varphi_z)$ and has the diameter $h_z := \operatorname{diam}(\omega_z)$. For each $u \in L^1(\Gamma)$ define

$$\mathcal{J}_h(u) := \sum_{z\in\mathcal{N}} \lambda_z(u)\varphi_z \in \mathcal{P}_1(\mathcal{T}) \cap \mathcal{C}(\Gamma) \quad \text{with} \quad \lambda_z(u) := \frac{\int_{\omega_z} u\varphi_z\, ds}{\int_{\omega_z} \varphi_z\, ds} \quad \text{for } z \in \mathcal{N}. \tag{3.6}$$

LEMMA 3.1. [illegible] $C_4 > 0$ [illegible] Γ [illegible] [illegible] $z \in \mathcal{N}$ $0 \le \alpha \le 1$ [illegible] $u \in H^\alpha(\Gamma)$ [illegible]

$$\|(u - \lambda_z(u))\varphi_z\|_{L^2(\omega_z)} \le C_4 h_z^\alpha \|u\|_{H^\alpha(\omega_z)}. \tag{3.7}$$

[illegible]. We derive from [CB, Theorem 2.1] the existence of $C_4 > 0$ such that

$$\|(u - \lambda_z(u))\varphi_z\|_{L^2(\omega_z)} \le C_4 \min\{\|u\|_{L^2(\omega_z)}, h_z\|\nabla u\|_{L^2(\omega_z)}\}$$

for all $z \in \mathcal{N}$ and $u \in H^1(\Gamma)$. [The proof therein is formulated for a domain $\Gamma \subseteq \mathbb{R}^2$ but applies to the present situation.] For $\alpha = 0$ and $\alpha = 1$, the linear operator

$$T_\alpha : H^\alpha(\omega_z) \to L^2(\omega_z), u \mapsto (u - \lambda_z(u))\varphi_z$$

is well defined and continuous with operator norms $\|T_0\| \le C_4$ and $\|T_1\| \le C_4 h_z$, respectively. By interpolation, T_α is well defined and continuous with $\|T_\alpha\| \le C_4 h_z^\alpha$. This proves (3.7). □

4. Local first-order approximation property. An interpolation argument shows that the L^2-projection has a [illegible] first-order approximation property with respect to the energy norm [equivalent to the $\widetilde{H}^{-1/2}$norm].

DEFINITION 1. [illegible] $\mathcal{S}$ [illegible] $\mathcal{P}_p(\mathcal{T})$ $p \ge 0$ [illegible] $0 \le \alpha \le 1$ [illegible] [illegible] [illegible] $\mathcal{A} : L^2(\Gamma) \to \mathcal{S}$ [illegible] local first-order approximation property with respect to the $\widetilde{H}^{-\alpha}$-norm [illegible] $C_{\text{apx}} > 0$ [illegible] Γ α p [illegible] $\mathcal{T}$ [illegible]

$$\|(\mathbb{1} - \mathcal{A})v\|_{\widetilde{H}^{-\alpha}(\Gamma)} \le C_{\text{apx}} \|h^\alpha v\|_{L^2(\Gamma)} \quad \text{[illegible]} \quad v \in L^2(\Gamma). \tag{4.1}$$

[illegible] C_{apx} [illegible]

The following theorem shows that the L^2-projection has the first-order approximation property provided the space $\mathcal{S}$ is rich enough. It will be used first to prove reliability and efficiency of η_M in Theorem 5.1 and second to show reliability of μ_A and μ_M in Corollary 5.4.

THEOREM 4.1. [illegible] $\mathcal{S}$ [illegible] $\mathcal{P}_0(\mathcal{T})$ [illegible] $\mathcal{P}_1(\mathcal{T}) \cap \mathcal{C}(\Gamma)$ [illegible] L^2 [illegible] $\Pi : L^2(\Gamma) \to \mathcal{S}$ [illegible] $\mathcal{S}$ [illegible] (4.1)

The proof of Theorem 4.1 follows ideas from [CMPS, Theorem 4.1] and involves Lemmas 2.1 and 3.1. We shall consider the cases $\mathcal{P}_0(\mathcal{T}) \subseteq \mathcal{S}$ and $\mathcal{P}_1(\mathcal{T}) \cap \mathcal{C}(\Gamma) \subseteq \mathcal{S}$ separately.

Proof of Theorem 4.1 for $\mathcal{P}_1(\mathcal{T}) \cap \mathcal{C}(\Gamma) \subseteq \mathcal{S}$ Notice that, for $v \in L^2(\Gamma)$, orthogonality of the projection $(\mathbb{1} - \Pi)$ and $\varphi_z \in \mathcal{S}$ lead to

$$\langle (\mathbb{1} - \Pi)v \,;\, \varphi_z \rangle = 0 \quad \text{for all } z \in \mathcal{N}. \tag{4.2}$$

For $u \in H^\alpha(\Gamma)$, we have $u = \sum_{z\in\mathcal{N}} u\varphi_z$ and therefore $\varrho := (\mathbb{1} - \Pi)v$ satisfies

$$\begin{aligned} \langle \varrho \,;\, u \rangle &= \sum_{z\in\mathcal{N}} \langle \varrho \,;\, u\varphi_z \rangle = \sum_{z\in\mathcal{N}} \langle \varrho \,;\, (u - \lambda_z(u))\varphi_z \rangle \\ &\le \sum_{z\in\mathcal{N}} \|\varrho\|_{L^2(\omega_z)} \|(u - \lambda_z(u))\varphi_z\|_{L^2(\omega_z)}. \end{aligned} \tag{4.3}$$

The combination of (4.3) and (3.7) yields

$$\begin{aligned} \langle \varrho \,;\, u \rangle &\le C_4 \sum_{z\in\mathcal{N}} \|h_z^\alpha \varrho\|_{L^2(\omega_z)} \|u\|_{H^\alpha(\omega_z)} \\ &\le C_4 \left(\sum_{z\in\mathcal{N}} \|h_z^\alpha \varrho\|^2_{L^2(\omega_z)} \right)^{1/2} \left(\sum_{z\in\mathcal{N}} \|u\|^2_{H^\alpha(\omega_z)} \right)^{1/2}. \end{aligned} \tag{4.4}$$

A coloring argument in [CMS, section 3] and [CMPS, Theorem 4.1] shows that we can find a finite number of index sets $J_1, J_2, \ldots, J_M$ such that for each k the sets ω_z in $\{\omega_z \,:\, z \in J_k\}$ are pairwise disjoint. The number M depends on the overlap of the patches ω_z, $z \in \mathcal{N}$, and thus on the aspect ratios of the elements and on Γ. Lemma 2.1 can be applied for each set J_k and so yields eventually

$$\sum_{z\in\mathcal{N}} \|u\|^2_{H^\alpha(\omega_z)} \le M \, \|u\|^2_{H^\alpha(\Gamma)}. \tag{4.5}$$

With the constant $C_5 := \max\{h_z/h_T \,:\, z \in \mathcal{K}, T \in \mathcal{T} \text{ with } T \subseteq \omega_z\}$, there holds

$$\sum_{z\in\mathcal{N}} \|h_z^\alpha \varrho\|^2_{L^2(\omega_z)} \le C_5^{2\alpha} \sum_{z\in\mathcal{N}} \|h^\alpha \varrho\|^2_{L^2(\omega_z)} \le M C_5^{2\alpha} \, \|h^\alpha \varrho\|^2_{L^2(\Gamma)}. \tag{4.6}$$

The combination of (4.4), (4.6) yields

$$\|\varrho\|_{\widetilde{H}^{-\alpha}(\Gamma)} = \sup_{\substack{u\in H^\alpha(\Gamma) \\ u\neq 0}} \frac{\langle \varrho \,;\, u \rangle}{\|u\|_{H^\alpha(\Gamma)}} \le M \, C_4 C_5^\alpha \|h^\alpha \varrho\|_{L^2(\Gamma)}. \qquad \square \tag{4.7}$$

Proof of Theorem 4.1 for $\mathcal{P}_0(\mathcal{T}) \subseteq \mathcal{S}$ With $\Pi_0 : L^2(\Gamma) \to \mathcal{P}_0(\mathcal{T})$ the L^2-projection onto $\mathcal{P}_0(\mathcal{T})$, there holds for any $u \in H^1(\Gamma_j)$

$$\|(\mathbb{1}-\Pi)u\|_{L^2(\Gamma_j)} = \inf_{v_h\in\mathcal{S}} \|u - v_h\|_{L^2(\Gamma_j)} \le \inf_{v_h\in\mathcal{P}_0(\mathcal{T})} \|u - v_h\|_{L^2(\Gamma_j)} = \|(\mathbb{1}-\Pi_0)u\|_{L^2(\Gamma_j)}.$$

An application of the Poincaré inequality proves $\|(\mathbb{1}-\Pi_0)u\|_{L^2(\Gamma_j)} \le C_6 h_j \|\nabla u\|_{L^2(\Gamma_j)}$ with $C_6 = 1/\pi$. Hence, the operator $T_\alpha : H^\alpha(\Gamma_j) \to L^2(\Gamma_j), u \mapsto u - \Pi u$ has operator norm $||T_0|| = 1$ and $||T_1|| \le C_6 h_j$ for $\alpha = 0, 1$, respectively. With the interpolation estimate (2.5), we infer $||T_\alpha|| \le C_6^\alpha h_j^\alpha$ and therefore

$$\|(\mathbb{1} - \Pi)u\|_{L^2(\Gamma_j)} \le C_6^\alpha h_j^\alpha \|u\|_{H^\alpha(\Gamma_j)}, \quad \text{for } u \in H^\alpha(\Gamma_j). \tag{4.8}$$

Now, let $v \in L^2(\Gamma)$ and $u \in H^\alpha(\Gamma)$. The symmetry of orthogonal projections yields

$$\langle (\mathbb{1} - \Pi)v\,;u\rangle = \langle v\,;(\mathbb{1} - \Pi)u\rangle \le \sum_{j=1}^{n} \|v\|_{L^2(\Gamma_j)} \|(\mathbb{1} - \Pi)u\|_{L^2(\Gamma_j)}. \tag{4.9}$$

The combination of (4.8)-(4.9) with Lemma 2.1 concludes the proof,

$$\langle (\mathbb{1} - \Pi)v\,;u\rangle \le C_6^\alpha \sum_{j=1}^{n} \|h^\alpha v\|_{L^2(\Gamma_j)} \|u\|_{H^\alpha(\Gamma_j)} \le C_6^\alpha \|h^\alpha v\|_{L^2(\Gamma)} \|u\|_{H^\alpha(\Gamma)}. \qquad \square$$

COROLLARY 4.2. $\alpha = 1/2$ 4.1 $\mathbb{G} : \widetilde{H}^{-1/2}(\Gamma) \to \mathcal{S}$ $\mathcal{S}$. With the best approximation property $\|(\mathbb{1} - \mathbb{G})v\| \le \|(\mathbb{1} - \Pi)v\|$, for all $v \in L^2(\Gamma)$, the proof follows from the equivalence of $\|\cdot\|$ and the $\widetilde{H}^{-1/2}(\Gamma)$-norm. $\square$

The following elementary lemma sharpens the local first-order approximation property. It will be applied for Π and $\mathbb{G}$ to obtain reliability of μ_A and μ_M, respectively.

LEMMA 4.3. $\mathcal{A} : L^2(\Gamma) \to \mathcal{P}_p(\mathcal{T})$ [$\mathcal{A}^2 = \mathcal{A}$] $\mathcal{A}$ (4.1) $v \in L^2(\Gamma)$

$$\|(\mathbb{1} - \mathcal{A})v\|_{\widetilde{H}^{-\alpha}(\Gamma)} \le C_{\rm apx} \min\big\{\|h^\alpha v\|_{L^2(\Gamma)}, \|h^\alpha (\mathbb{1} - \mathcal{A})v\|_{L^2(\Gamma)}\big\}. \tag{4.10}$$

Since $(\mathbb{1} - \mathcal{A})$ is idempotent, we obtain from (4.1) for $w := (\mathbb{1} - \mathcal{A})v \in L^2(\Gamma)$

$$\|w\|_{\widetilde{H}^{-\alpha}(\Gamma)} = \|(\mathbb{1} - \mathcal{A})v\|_{\widetilde{H}^{-\alpha}(\Gamma)} = \|(\mathbb{1} - \mathcal{A})w\|_{\widetilde{H}^{-\alpha}(\Gamma)} \le C_{\rm apx}\, \|h^\alpha w\|_{L^2(\Gamma)}. \qquad \square$$

5. A posteriori error control by averaging techniques. This section aims to provide a new class of error estimators and states their reliability and efficiency of which. We need two discrete finite element spaces $\mathcal{S}_h$ and $\mathcal{S}_H$, where $\mathcal{S}_h$ belongs to a finer mesh $\mathcal{T}_h$ but lower polynomial degree as compared to $\mathcal{S}_H$.

5.1. Assumptions and notations. Fix two regular triangulations $\mathcal{T}_h = \{\Gamma_1, \ldots, \Gamma_n\}$ and $\mathcal{T}_H = \{\gamma_1, \ldots, \gamma_N\}$ with mesh sizes $h \ll H$ [cf. (5.4) for a precise statement]. For integers $0 \le p < q$, let $\mathcal{S}_h$ and $\mathcal{S}_H$ be subspaces of $\mathcal{P}_p(\mathcal{T}_h)$ and $\mathcal{P}_q(\mathcal{T}_H)$, respectively. With respect to Theorem 4.1 we suppose that $\mathcal{S}_h$ contains $\mathcal{P}_0(\mathcal{T}_h)$ or $\mathcal{P}_1(\mathcal{T}_h) \cap \mathcal{C}(\Gamma)$.

Let $u \in \widetilde{H}^{-1/2}(\Gamma)$ denote the unique solution of (1.1), and let $u_h \in \mathcal{S}_h$ be its Galerkin approximation with respect to $\mathcal{S} = \mathcal{S}_h$ in (3.1). The Galerkin projection

$$\mathbb{G}_H : \widetilde{H}^{-1/2}(\Gamma) \to \mathcal{S}_H \subseteq \widetilde{H}^{-1/2}(\Gamma) \tag{5.1}$$

onto $\mathcal{S}_H$ [i.e., the orthogonal projection onto $\mathcal{S}_H$ with respect to the energy norm] is compared with an [not necessarily linear or continuous] operator

$$\mathcal{A}_H : L^2(\Gamma) \to \mathcal{S}_H. \tag{5.2}$$

We consider the following four error estimators:

$$\begin{aligned} \eta_M &:= \|(\mathbb{1} - \mathbb{G}_H)u_h\|, & \mu_M &:= \|H^{1/2}(\mathbb{1} - \mathbb{G}_H)u_h\|_{L^2(\Gamma)}, \\ \eta_A &:= \|(\mathbb{1} - \mathcal{A}_H)u_h\|, & \mu_A &:= \|H^{1/2}(\mathbb{1} - \mathcal{A}_H)u_h\|_{L^2(\Gamma)}, \end{aligned} \tag{5.3}$$

i.e., we estimate the difference of the (low-order) discrete solution u_h on a finer mesh $\mathcal{T}_h$ and a higher-order approximation of which on a coarser mesh $\mathcal{T}_H$.

In what follows, we use the inverse estimate (3.2) for [subspaces of] $\mathcal{P}_p(\mathcal{T}_h)$, $\mathcal{P}_q(\mathcal{T}_h)$, and $\mathcal{P}_q(\mathcal{T}_H)$. To be precise, we therefore write, for instance, $C_{\rm inv}^{h,p} = C_{\rm inv}(\Gamma, p, \mathcal{T}_h)$. The analogous notation is used for the first-order approximation property of the L^2-projection [resp., Galerkin-projection] and we write, for instance, $C_{\rm apx}^{h,p}$. Let $\Pi_h : L^2(\Gamma) \to \mathcal{S}_h$ denote the L^2-projection onto $\mathcal{S}_h$, and let $C_{\rm apx}^{h,p} > 0$ be defined as in Theorem 4.1 with $\mathcal{S} = \mathcal{S}_h$. With the constant $C_{\rm inv}^{H,q} > 0$ in the inverse estimate (3.2) for $\mathcal{S}_H$, we assume

$$C_{\rm apx}^{h,p} C_{\rm inv}^{H,q} \max_{\gamma_j \in \mathcal{T}_H} (\|h\|_{L^\infty(\gamma_j)}/H_j)^{1/2} =: L < 1. \tag{5.4}$$

The analysis in the subsequent sections requires some additional regularity assumption on the exact solution, namely

$$u \in H^m(\mathcal{T}_H) \quad \text{for some } m > p + 1. \tag{5.5}$$

[illegible] 5.1. (i) The authors are aware that Assumption (5.5) is not reasonable for arbitrary Lipschitz screens Γ but requires some further (piecewise) smoothness of Γ so that $H^m(\mathcal{T}_H)$ is well defined [SaS].

(ii) Even for slit problems [HMS] with smooth right-hand side f in (1.1), the solution u does not satisfy (5.5).

5.2. The results. The main theorem in section 5.3 states the reliability and efficiency of η_M [up to terms of higher order]. The perhaps surprising result is that η_A is always reliable; cf. Corollary 5.3. The explicit estimator μ_A appears to be less costly compared with the other three since these involve the (approximate) computation of large full matrices; cf. section 8. The L^2-norm based estimators μ_M and μ_A immediately allow for local error indication for adaptive mesh-refining algorithms. Under weak additional assumptions [cf. section 5.4], we prove that η_M and μ_M, respectively, η_A and μ_A are equivalent, i.e., there are constants $C_7, C_8 > 0$ such that there holds

$$C_7\mu_M \le \eta_M \le C_8\mu_M \quad \text{and} \quad C_7\mu_A \le \eta_A \le C_8\mu_A.$$

In the case that $\mathcal{A}_H$ is the L^2-projection onto $\mathcal{S}_H$ and provided that $\mathcal{A}_H$ is H^1-stable, Theorem 5.6 states the efficiency of η_A and, in particular, of μ_A.

5.3. Reliability and efficiency of the error estimator η_M. The idea of the following argument goes back at least to an Oberwolfach conference in the eighties as the authors learned from L.B. Wahlbin, but it has not been applied to integral equations before.

THEOREM 5.1. [illegible] (5.4) [illegible]

$$|||u - u_h||| \le \frac{1}{1-L} |||(\mathbb{1} - \mathbb{G}_H)(u - u_h)|||. \tag{5.6}$$

[illegible]. Define $\widetilde{h} \in \mathcal{P}_0(\mathcal{T}_H)$ by $\widetilde{h}|_{\gamma_j} := \|h\|_{L^\infty(\gamma_j)}$ for each element $\gamma_j \in \mathcal{T}_H$. For the Galerkin error $e := u - u_h$, the approximation property of Π_h yields

$$|||(\mathbb{1} - \Pi_h)\mathbb{G}_H e||| \le C_{\rm apx}^{h,p} \|h^{1/2}\mathbb{G}_H e\|_{L^2(\Gamma)} \le C_{\rm apx}^{h,p} \|\widetilde{h}^{1/2}\mathbb{G}_H e\|_{L^2(\Gamma)}.$$

Now, we use the inverse estimate (3.2) for $H^{1/2}\mathbb{G}_H e \in \mathcal{P}_q(\mathcal{T}_H)$ and infer

$$\|\widetilde{h}^{1/2}\mathbb{G}_H e\|_{L^2(\Gamma)} \leq \|(\widetilde{h}/H)^{1/2}\|_{L^\infty(\Gamma)}\|H^{1/2}\mathbb{G}_H e\|_{L^2(\Gamma)} \leq C_{\mathrm{inv}}^{H,q}\|(\widetilde{h}/H)^{1/2}\|_{L^\infty(\Gamma)}|||\mathbb{G}_H e|||.$$

The combination with the best approximation property $|||\mathbb{G}_H e||| \leq |||e|||$ shows

$$|||(\mathbb{1} - \Pi_h)\mathbb{G}_H e||| \leq L|||e|||.$$

Using the Galerkin orthogonality and a Cauchy inequality, we obtain for $\Pi_h\mathbb{G}_H e \in \mathcal{S}_h$

$$\langle\!\langle e\,;\mathbb{G}_H e\rangle\!\rangle = \langle\!\langle e\,;\mathbb{G}_H e - \Pi_h\mathbb{G}_H e\rangle\!\rangle \leq |||e|||\,|||(\mathbb{1} - \Pi_h)\mathbb{G}_H e||| \leq L|||e|||^2.$$

Now, another Cauchy inequality leads to

$$|||e|||^2 = \langle\!\langle e\,;\mathbb{G}_H e\rangle\!\rangle + \langle\!\langle e\,;e - \mathbb{G}_H e\rangle\!\rangle \leq |||e|||\,\big(L|||e||| + |||(\mathbb{1} - \mathbb{G}_H)e|||\big).$$

This concludes the proof. □

5.2. The proof of Theorem 5.1 relies solely on the existence of an approximation operator $P_h : L^2(\Gamma) \to \mathcal{S}_h$ with $|||(\mathbb{1} - P_h)v_H||| \leq C_{\mathrm{apx}}\|h^{1/2}v_H\|_{L^2(\Gamma)}$ for all $v_H \in \mathcal{S}_H$. If Π_h is replaced by such an operator P_h, the richness assumption on $\mathcal{S}_h$ could be dropped.

5.3. Under the additional assumption $u \in L^2(\Gamma)$, $\mathbb{G}_H$ in Theorem 5.1 may be replaced by $\mathcal{A}_H$ since the proof only needs that $\mathcal{A}_H(u - u_h)$ is well defined. No further properties of $\mathbb{G}_H$ enter.

5.4. In contrast to residual-based techniques, we could not derive analogous results for collocation or qualocation schemes since the proof of Theorem 5.1 makes explicit use of the Galerkin orthogonality.

THEOREM 5.2. [illegible] (5.4) [illegible] (5.5) [illegible] η_M [illegible]

[illegible]

$$|||u - u_h||| \leq \frac{1}{1 - L}\big(\eta_M + |||(\mathbb{1} - \mathbb{G}_H)u|||\big) \tag{5.7}$$

[illegible] $0 < L < 1$ [illegible] 5.1 [illegible]

$$\eta_M \leq |||u - u_h||| + |||(\mathbb{1} - \mathbb{G}_H)u|||. \tag{5.8}$$

[illegible] $|||u - u_h|||$ [illegible] η_M [illegible] $|||(\mathbb{1} - \mathbb{G}_H)u|||$ [illegible]

[illegible]. According to (3.4), the error in the energy norm is of order

$$|||u - u_h||| = O(h_{\max}^{\widehat{p}}) \quad \text{with} \quad \widehat{p} := \min\{p+1, m\} + 1/2 = p + 3/2.$$

Furthermore, for smooth u we have

$$|||(\mathbb{1} - \mathbb{G}_H)u||| = O(H_{\max}^{\widehat{q}}) \quad \text{with} \quad \widehat{q} := \min\{q+1, m\} + 1/2 \geq \min\{p+2, m\} + 1/2.$$

Since $m > p + 1$, $|||(\mathbb{1} - \mathbb{G}_H)u|||$ is of higher order. Theorem 5.1 combined with a triangle inequality shows

$$|||u - u_h||| \leq \frac{1}{1 - L}\big(|||(\mathbb{1} - \mathbb{G}_H)u||| + |||(\mathbb{1} - \mathbb{G}_H)u_h|||\big)$$

and proves the reliability. A simple triangle inequality shows the efficiency

$$\eta_M \leq |||(\mathbb{1} - \mathbb{G}_H)(u - u_h)||| + |||(\mathbb{1} - \mathbb{G}_H)u|||,$$

since $(\mathbb{1} - \mathbb{G}_H)$ is an orthogonal projection with respect to the energy norm. □

5.4. Reliability of the error estimators η_A, μ_A, and μ_M. Replacing the best approximation operator $\mathbb{G}_H$ by another operator $\mathcal{A}_H$, we immediately obtain the following corollary.

COROLLARY 5.3. $\eta_M \le \eta_A$ (5.4) (5.5)
η_A □

This and an application of Lemma 4.3 proves the reliability of μ_A and μ_M.

COROLLARY 5.4. $\mathcal{A}_H : L^2(\Gamma) \to \mathcal{S}_H \subseteq L^2(\Gamma)$ (4.1)

$$\eta_A \le C_{\rm apx}^{H,q}\mu_A. \tag{5.9}$$

μ_M (5.4) (5.5)
$\mathcal{P}_0(\mathcal{T}_H) \subseteq \mathcal{S}_H$ $\mathcal{P}_1(\mathcal{T}_H) \cap \mathcal{C}(\Gamma) \subseteq \mathcal{S}_H$ □

An application of the inverse estimate (3.2) shows that μ_A is efficient if and only if η_A is efficient.

COROLLARY 5.5. $C_9 := \max_{\Gamma_j \in \mathcal{T}_h} (\|H\|_{L^\infty(\Gamma_j)}/h_j)^{1/2}$ $\mathcal{S}_H \subseteq \mathcal{P}_q(\mathcal{T}_h)$

$$\mu_A \le C_9 C_{\rm inv}^{h,q}\eta_A. \tag{5.10}$$

μ_M □

5.5. Note that the assumption $\mathcal{S}_H \subseteq \mathcal{P}_q(\mathcal{T}_h)$ is quite weak and, in particular, satisfied if $\mathcal{T}_h$ is obtained by refinements of $\mathcal{T}_H$.

5.5. Efficiency of η_A and μ_A for the L^2-projection. For the remaining part of this section, we suppose that the interpolation operator $\mathcal{A}_H = \Pi_H$ is just the L^2-projection onto $\mathcal{S}_H \subseteq H^1(\Gamma)$.

DEFINITION 2. L^2 $\mathcal{A}_H : L^2(\Gamma) \to \mathcal{S}_H$ $\mathcal{S}_H$ H^1-stable

$$\|\mathcal{A}_H v\|_{H^1(\Gamma)} \le C_{10}\|v\|_{H^1(\Gamma)} \quad v \in H^1(\Gamma), \tag{5.11}$$

$C_{10} > 0$ Γ, q $\mathcal{T}_H$

THEOREM 5.6. (5.4) (5.5) H^1 L^2 $\mathcal{A}_H : L^2(\Gamma) \to \mathcal{S}_H$ $\mathcal{S}_H$ η_A

. Define the operator $T_\alpha = (\mathbb{1} - \mathcal{A}_H) : H^\alpha(\Gamma) \to H^\alpha(\Gamma)$ which is linear and continuous for $\alpha = 0$ and $\alpha = 1$, respectively. Interpolation yields continuity of $T_{1/2}$ with operator norm $\|T_{1/2}\| \le \|T_1\|^{1/2}$ since $\|T_0\| = 1$. We consider the adjoint operator $T_{1/2}^* : \widetilde{H}^{-1/2}(\Gamma) \to \widetilde{H}^{-1/2}(\Gamma)$ defined formally by

$$\langle T_{1/2}^* w\,; v\rangle = \langle w\,; T_{1/2} v\rangle \quad \text{for } w \in \widetilde{H}^{-1/2}(\Gamma), v \in H^{1/2}(\Gamma). \tag{5.12}$$

Notice that, for $w \in L^2(\Gamma)$, we have $T_{1/2}^* w = T_{1/2} w$ according to the symmetry of the orthogonal projection T_0 and the L^2 scalar product on the right-hand side of (5.12) in case $w \in L^2(\Gamma)$. Since $T_{1/2}^*$ is continuous, let $C_{11} < \infty$ denote the operator norm of $T_{1/2}^*$ with respect to the energy norm. As above, a simple triangle inequality shows

$$\eta_A \le |\!|\!|(\mathbb{1} - \mathcal{A}_H)(u - u_h)|\!|\!| + |\!|\!|(\mathbb{1} - \mathcal{A}_H)u|\!|\!| \le C_{11}|\!|\!|u - u_h|\!|\!| + |\!|\!|(\mathbb{1} - \mathcal{A}_H)u|\!|\!|, \tag{5.13}$$

where we have used $u-u_h \in L^2(\Gamma)$ and $T^*_{1/2}(u-u_h) = (\mathbb{1}-\mathcal{A}_H)(u-u_h)$. Theorem 4.1 and a standard approximation result in L^2 yield

$$|||(\mathbb{1}-\mathcal{A}_H)u||| \le C_{\mathrm{apx}} H_{\max}^{1/2} \|(\mathbb{1}-\mathcal{A}_H)u\|_{L^2(\Gamma)} = O(H_{\max}^{\widehat{q}+1/2}) \quad \text{with} \quad \widehat{q} := \min\{q+1, m\}.$$

Therefore, the last term in (5.13) is of higher order; cf. the proof of Theorem 5.2. ∎

The efficiency of μ_A follows from the previous section.

COROLLARY 5.7. $\mathcal{P}_1(\mathcal{T}_H) \cap \mathcal{C}(\Gamma) \subseteq \mathcal{S}_H \subseteq \mathcal{P}_q(\mathcal{T}_h)$

$$\mu_A \le C_9 C_{\mathrm{inv}}^{h,q} \eta_A \qquad \eta_A \le C_{\mathrm{apx}}^{H,q} \mu_A, \tag{5.14}$$

μ_A 5.6 ∎

5.6. For special cases it is easy to derive the efficiency of η_A although $\mathcal{S}_H \not\subseteq H^1(\Gamma)$. For instance, assume $\mathcal{S}_h = \mathcal{P}_0(\mathcal{T}_h)$ and $\mathcal{S}_H = \mathcal{P}_1(\mathcal{T}_H) \subseteq \mathcal{P}_1(\mathcal{T}_h)$. Suppose that $\mathcal{A}_H$ is the L^2-projection onto $\mathcal{S}_H$ and Π_H is the L^2-projection onto $\mathcal{P}_1(\mathcal{T}_H) \cap \mathcal{C}(\Gamma)$. An application of the derived results shows

$$\eta_A \lesssim \|H^{1/2}(\mathbb{1}-\mathcal{A}_H)u_h\|_{L^2(\Gamma)} \le \|H^{1/2}(\mathbb{1}-\Pi_H)u_h\|_{L^2(\Gamma)} \lesssim |||u-u_h|||,$$

where $\lesssim$ denotes $\le$ up to a mesh size independent constant.

6. Numerical realization in two dimensions. For the numerical experiments, we choose $\mathcal{S}_h = \mathcal{P}_0(\mathcal{T}_h)$ and $\mathcal{S}_H = \mathcal{P}_1(\mathcal{T}_H)$. The finer mesh $\mathcal{T}_h$ is obtained from the coarser $\mathcal{T}_H$ by uniform refinements; cf. section 6.3 for details. This ensures $\mathcal{S}_H = \mathcal{P}_1(\mathcal{T}_H) \subseteq \mathcal{P}_1(\mathcal{T}_h)$. The approximation $u_h \in \mathcal{S}_h$ is then defined by $u_h|_{\Gamma_j} = \mathbf{x}_j$, where $\mathbf{x} \in \mathbb{R}^n$ is the solution of a linear system

$$\mathbf{A}\mathbf{x} = \mathbf{b}. \tag{6.1}$$

In all numerical experiments we consider the error estimators η_M, μ_M based on the Galerkin projection $\mathbb{G}_H$ and the error estimators η_A, μ_A based on the L^2-projection $\mathcal{A}_H = \Pi_H$.

6.1. Poisson problem and Symm's integral equation. In the numerical experiments we consider three examples where the right-hand side f in (1.1) comes from a Poisson problem

$$\Delta U = 0 \text{ in } \Omega \quad \text{and} \quad U = g \text{ on } \Gamma = \partial\Omega \tag{6.2}$$

with given Dirichlet data g on Γ [plus boundary conditions at infinity if Ω is unbounded]. This problem is equivalent to Symm's integral equation (1.1), where f takes the form $f = (K+\mathbb{1})g$ with the double-layer potential operator K, defined as Cauchy principal value by

$$(Kg)(x) := -\frac{1}{\pi} \int\!\!\!\!\!\!- _{\Gamma} g(y) \frac{(y-x)\cdot n(y)}{|x-y|^2}\, ds_y \quad \text{for } x \in \Gamma. \tag{6.3}$$

Then, the exact solution of (1.1) is just the normal derivative $u = \partial U/\partial n$ of U on the boundary Γ. Notice that Kg vanishes on Γ whenever Γ is a slit.

6.2. Computation of the discrete solution. The coefficients of the stiffness matrix $\mathbf{A} \in \mathbb{R}^{n\times n}_{sym}$ are computed by

$$\mathbf{A}_{jk} := \langle\!\langle \chi_j \,;\, \chi_k \rangle\!\rangle = -\frac{1}{\pi} \int_{\Gamma_j} \int_{\Gamma_k} \log|x-y| \, ds_y ds_x. \tag{6.4}$$

Here, χ_j denotes the characteristic function of the set $\Gamma_j \subseteq \mathbb{R}^2$ [i.e., $\chi_j(x) = 1$ if $x \in \Gamma_j$ and $\chi_j(x) = 0$ else]. The right-hand side $\mathbf{b} \in \mathbb{R}^n$ is given by

$$\mathbf{b}_j := \int_{\Gamma_j} f(x) \, ds_x \tag{6.5}$$

with f from (1.1). While $\mathbf{A}_{jk}$ can be computed analytically [Ma], the computation of $\mathbf{b}_j$ involves proper quadrature rules—in particular, if the right-hand side is induced by a Poisson problem; cf. [CP1, section 6].

6.3. Adaptive algorithm. All mesh refinements are performed with the following adaptive algorithm based on the refinement indicators $\mu_{M,j}$ or $\mu_{A,j}$ defined as follows: Given the coarse mesh $\mathcal{T}_H = \{\gamma_1, \dots, \Gamma_N\}$ and the L^2-projection $\Pi_H : \mathcal{P}_0(\mathcal{T}_h) \to \mathcal{P}_1(\mathcal{T}_H)$, we define

(6.6)

$$\mu_{M,j} := H_j^{1/2} \|(\mathbb{1} - \mathbb{G}_H) u_h\|_{L^2(\gamma_j)}, \quad \text{respectively,} \quad \mu_{A,j} := H_j^{1/2} \|(\mathbb{1} - \Pi_H) u_h\|_{L^2(\gamma_j)} \quad \text{for } j = 1, \dots, N,$$

i.e., $\mu_M = \big(\sum_{j=1}^N \mu_{M,j}^2\big)^{1/2}$ and $\mu_A = \big(\sum_{j=1}^N \mu_{A,j}^2\big)^{1/2}$, respectively.

ALGORITHM 6.1. [illegible] $\mathcal{T}_H^{(0)}$ $k = 0$ $\ell \in \mathbb{N}_{\geq 2}$ $0 \leq \theta \leq 1$

(i) [illegible] $\mathcal{T}_h^{(k)} = \{\Gamma_1, \dots, \Gamma_n\}$ [illegible] $\mathcal{T}_H^{(k)} = \{\gamma_1, \dots, \gamma_N\}$ [illegible] $\gamma_j \in \mathcal{T}_H^{(k)}$ [illegible] ℓ [illegible]

(ii) [illegible] $u_h^{(k)}$ [illegible] $\mathcal{T}_h^{(k)}$

(iii) [illegible] η_M η_A [illegible] $\mu_{M,j}$ $\mu_{A,j}$

(iv) [illegible] γ_j [illegible] $\mu_{M,j} \geq \theta \max\{\mu_{M,1}, \dots, \mu_{M,N}\}$ $\mu_{A,j} \geq \theta \max\{\mu_{A,1}, \dots, \mu_{A,N}\}$ [illegible]

(v) [illegible] $\gamma_j \in \mathcal{T}_H^{(k)}$ [illegible] $\mathcal{T}_H^{(k+1)}$ [illegible] (i)

7. Numerical experiments in two dimensions. This section reports on some numerical experiments to study the accuracy of the introduced error estimators and the performance of the proposed adaptive strategy. All computations are done with MATLAB. Example 7.1 corresponds to a Dirichlet problem with smooth solution such that the smoothness assumptions in section 5 are satisfied and guarantee reliability and efficiency of our error estimators. Examples 7.2–7.4 are taken from [CP1] and [ChS], respectively. They have been realized and studied in [CP1] for adaptive mesh-refinement with respect to the residual-based error estimator introduced by Faermann [F1, F2, F3]; cf. (7.3). Example 7.2 considers Symm's integral equation corresponding to a Dirichlet problem on the L-shaped domain. The exact solution is known and has a singularity at the reentrant corner. Therefore, adaptivity is necessary to retain the optimal convergence rate. Example 7.3 deals with a constant

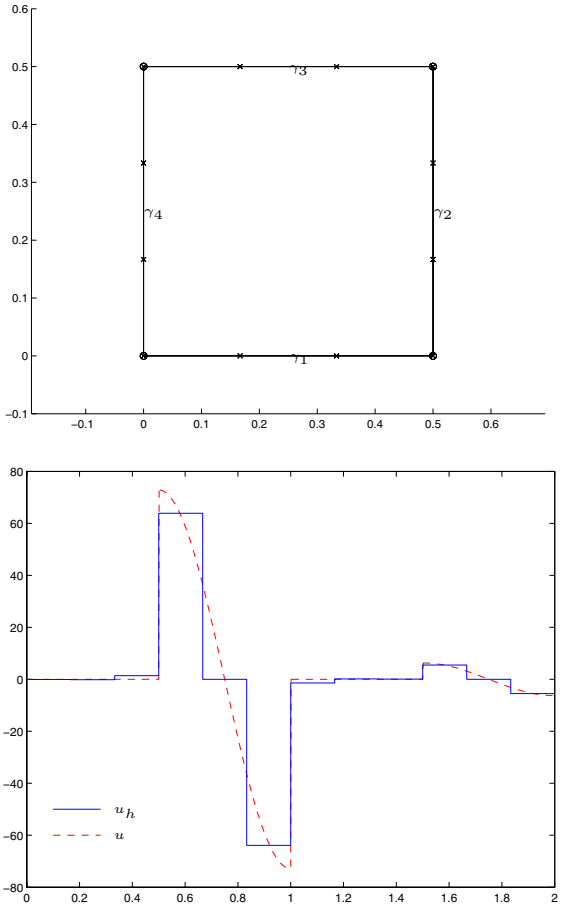

FIG. 1. *Initial coarse mesh* $\mathcal{T}_H^{(0)}$ *in Poisson problem* 7.1 *with* $N = 4$ *elements* [*nodes indicated by* o] (*top*) *and the corresponding refined mesh* $\mathcal{T}_h^{(0)}$ *for* $\ell = 3$ *in Algorithm* 6.1, *i.e.* $n = 12$ [*nodes indicated by* x]. *The related discrete solution* u_h *on* $\mathcal{T}_h^{(0)}$ (*bottom*) *is plotted over the arclength* $s = 0, \dots, 2$ *of* Γ. *The exact solution* u *from* (7.6) *is shown for comparison* (*bottom*); u *is piecewise smooth and jumps together with the outer normal in the corners of* Γ [*for arclength parameters* $s = 1/2, 1, 3/2,$ *and* 2].

right-hand side to exclude positive and negative effects due to quadrature errors. The exact solution is unknown. The sequence of discrete solutions shows singularities at the five rectangular corners of the L-shape. Example 7.4 taken from [ChS] considers a slit problem, where the known exact solution u lacks almost any smoothness, more precisely $u \notin L^2(\Gamma)$. Finally, Example 7.5 involves the approximation of a smooth boundary by a polygonal boundary. We approximate a smooth eigenfunction of the single-layer potential on the sphere with radius 1/2.

Preliminaries. Uniform and adaptive meshes as well as plots of discrete and exact solutions u_h and u are shown in Figures 1, 4, and 10 as functions of its arclength parametrization s, $0 \le s \le \text{length}(\Gamma) = 2$. Furthermore, errors and estimators are considered for the energy norm. Various numbers are provided in Tables 1, 2, and 3 and even more convergence results are visualized in Figures 2, 5–7, 9, 11, 13, and

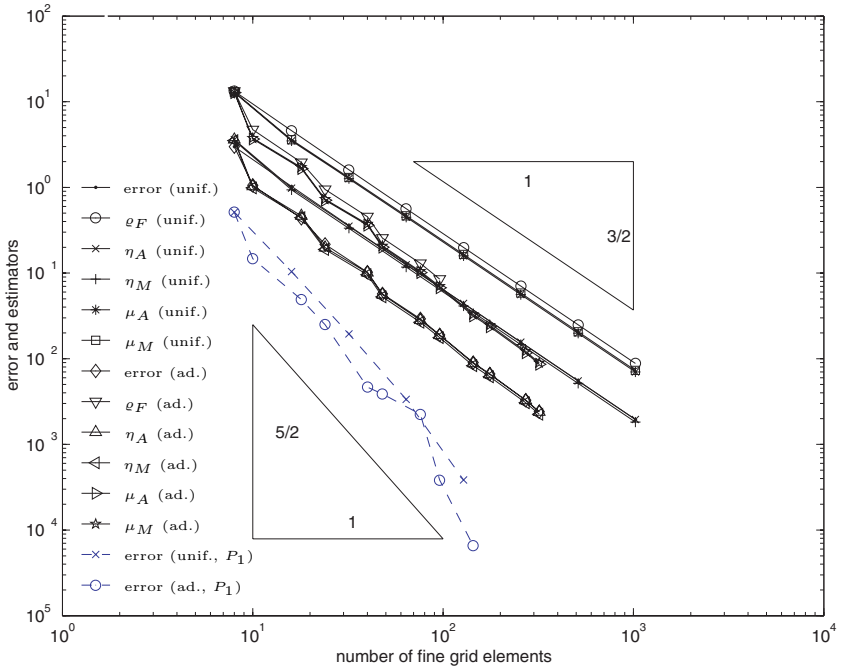

FIG. 2. *Error and error estimators η_M, η_A, μ_M, and μ_A for uniform* [*indicated by* unif.] *and μ_A-adaptive* [*indicated by* ad.] *mesh refinement in Poisson problem* 7.1 *and $\ell = 2$ in Algorithm* 6.1. *The $\mathcal{P}_0$ boundary element method leads to the optimal convergence rate $h^{3/2}$. For comparison, also the error for the $\mathcal{P}_1$ boundary element method* [*dashed lines*] *on the generated meshes* [*i.e., uniform, resp., μ_A-adaptive*] *is shown. As expected, one again observes the optimal experimental convergence rate $h^{5/2}$.*

16. Some adaptively generated meshes are shown in Figures 3, 12, and 14.

We compute the experimental convergence rate of the error

$$E^{(k)} := |||u - u_h^{(k)}||| = \big(|||u|||^2 - |||u_h^{(k)}|||^2\big)^{1/2} \tag{7.1}$$

by the formula

$$\kappa^{(k)} = \log(E^{(k-1)}/E^{(k)}) \,/\, \log(n^{(k)}/n^{(k-1)}). \tag{7.2}$$

Here, $n^{(k)} = \mathrm{card}(\mathcal{T}_h^{(k)})$ denotes the number of elements. The energy norm of the discrete solution u_h reads $|||u_h|||^2 = \mathbf{x}\cdot\mathbf{A}\mathbf{x}$ with the stiffness matrix $\mathbf{A}$ and the coefficient vector $\mathbf{x}$ introduced in section 6. The energy norm $|||u|||$ of the exact solution is either computed exactly or obtained by Aitkin's Δ^2 extrapolation of the sequence of values for discrete solutions on uniformly refined meshes.

For comparison, in Figures 2, 5–7, 11, 13, and 16 we also show the residual-based error estimator ϱ_F introduced by Faermann,

$$\varrho_F := \left(\sum_{j=1}^{n} \varrho_{F,j}^2\right)^{1/2}, \tag{7.3}$$

where the refinement indicators

$$\varrho_{F,j} := \int_{\Gamma_j \cup \Gamma_{j+1}} \int_{\Gamma_j \cup \Gamma_{j+1}} \frac{|r_h(x) - r_h(y)|^2}{|x-y|^2}\, ds_y ds_x \tag{7.4}$$

are local Sobolev–Slobodeckij seminorms of the residual $r_h := f - Vu_h \in H^{1/2}(\Gamma)$. This estimator is known to be reliable and efficient for the Galerkin method. Details on the numerical realization of these double boundary integrals are provided in [CP1]. Since the reliability and efficiency of this estimator depends in 2D on the local mesh ratio

$$\kappa(\mathcal{T}_h) = \max\{h_{T_j}/h_{T_k} \,:\, T_j, T_k \in \mathcal{T}_h \text{ neighbors}\}, \tag{7.5}$$

we extend the marking strategy in (iv) of Algorithm 6.1 to ensure that there holds $\kappa(\mathcal{T}_H) \le 2$, i.e., that the mesh size of two neighboring coarse elements varies at most by 2.

7.1. Poisson-problem with smooth solution. We consider problem (6.2) on the halved unit square $\Omega = [0, 1/2]^2$ with exact solution $U(x, y) = \sinh(2\pi\, x)\, \cos(2\pi\, y)$ and solve the corresponding Symm's integral equation $Vu = f$ with right-hand side $f = (K + 1)g$ and $g = U|_\Gamma$. Then, $u = \partial U/\partial n$ is smooth on each affine boundary piece,

$$u(x, y) = 2\pi \begin{pmatrix} \cosh(2\pi x)\, \cos(2\pi y) \\ -\sinh(2\pi x)\, \sin(2\pi y) \end{pmatrix} \cdot n(x, y) \tag{7.6}$$

with the outer normal $n(x, y)$ of Ω on $\Gamma = \partial\Omega$, and we expect to obtain optimal convergence rate $\mathcal{O}(n^{3/2})$ even for uniform mesh refinement. Notice that u vanishes on $[0, 1/2] \times \{0, 1/2\}$, i.e., on the lower and upper boundary of Ω.

Figure 1 shows the initial coarse mesh $\mathcal{T}_H^{(0)}$, the exact solution u from (7.6) plotted over the arclength $s = 0, \dots, 2$, and a discrete solution u_h corresponding to $\mathcal{T}_h^{(0)}$ with $\ell = 3$ in Algorithm 6.1. As can be seen, u vanishes on the parameter intervals $0 \le s \le 1/2$ and $1 \le s \le 3/2$. On the other two affine boundary pieces, u is smooth and jumps with the normal vector in the corners of Γ.

Figure 2 shows errors and error estimators for both uniform and μ_A-adaptive mesh refinement and $\ell = 2$ in Algorithm 6.1. All values are shown on a log-log scale so that the experimental convergence rates (7.2) of both the error and the estimators are visible as the slope of the corresponding curves. The error $E = |||u - u_h|||$ is computed via (7.1), where the energy norm of the exact solution is obtained by extrapolation, $|||u|||^2 = 162.1448097$. As is to be expected from the regularity of u, uniform mesh refinement leads to the optimal experimental convergence rate $h^{3/2}$. The curve for the error on adaptively generated meshes is parallel, but the absolute values are improved by a factor of 5. This improvement can be explained by the fact that the adaptive algorithm mainly resolves the strong growth of the function within the arclength parameter intervals $1/2 \le s \le 1$ and $3/2 \le s \le 2$, where u does not vanish; cf. Figure 1. The corresponding adaptive meshes are shown in Figure 3. For comparison, Figure 2 also shows the error for the $\mathcal{P}_1$ boundary element methods on the same meshes, since this term corresponds to the higher-order terms of our error estimates. As expected, the $\mathcal{P}_1$-error shows the optimal experimental convergence rate of $h^{5/2}$.

For both $\mathcal{P}_0$ and $\mathcal{P}_1$ boundary element methods, the error shows no preasymptotic behavior but converges with optimal convergence order from the very start. This is reflected by the error estimation of the $\mathcal{P}_0$ error $E = |||u - u_h|||$ by the error estimators η_M and η_A. The error is very sharply estimated: The values of both estimators almost coincide with the corresponding error value. This is also underlined by several numbers in Table 1: The quotients η_M/E, respectively, η_M/η_A converge to approximately 0.94 and 0.93 for both uniform and adaptive mesh refinement. The performance of the L^2-error estimators μ_M and μ_A is examined in Table 2. The error estimator μ_M and μ_A almost coincide. The quotient μ_M/μ_A stays bounded by approximately 1.04. The error is overestimated by a factor 3.5–3.7. For comparison, note that the Faermann error estimator ϱ_F overestimates the error by a factor 4.4, 4.5.

7.2. Poisson-problem on L-shaped domain. For a fixed parameter $\alpha > 0$ we consider Problem (6.2) on the L-shaped domain Ω shown in Figure 4 with exact solution

$$U(x) = r^\alpha \cos(\alpha\varphi) \quad \text{in polar coordinates} \quad x = r\,(\cos\varphi, \sin\varphi). \tag{7.7}$$

Then, the exact solution u of Symm's integral equation reads in polar coordinates

$$u(x) = (w \cdot n(x))\,\alpha r^{\alpha-1} \quad \text{with } w := \begin{pmatrix} \cos(\varphi)\cos(\alpha\varphi) + \sin(\varphi)\sin(\alpha\varphi) \\ \sin(\varphi)\cos(\alpha\varphi) - \cos(\varphi)\sin(\alpha\varphi) \end{pmatrix} \in \mathbb{R}^2. \tag{7.8}$$

For the numerical experiment we choose $\alpha = 2/3$. The Poisson problem then leads to $U \notin H^2(\Omega)$. Aitkin's Δ^2 method gives $|||u|||^2 = 0.4041161973$.

The initial coarse mesh $\mathcal{T}_H^{(0)}$ with $N = 8$ equisized elements and the corresponding discrete solution u_h for $\ell = 4$ in Algorithm 6.1 as well as the exact solution are shown in Figure 4. Here, u and u_h are shown as plots over the arc length. The singularity of u at $(0, 0)$ is visible at arc-length parameter $s = 0$ and $s = 2$ by periodicity.

To illustrate the performance of the proposed adaptive algorithm, we run Algorithm 6.1 with $\mathcal{T}_0$ from Figure 4, $\ell = 2, 3, 4$, and $\theta = 0, 1/2$. The values of the error and the error estimators are visualized in Figures 5–7 and 9. The error $E = \|\!|u - u_h|\!\|$ is computed via (7.1), where the energy norm of the exact solution is obtained by extrapolation with Aitkin's Δ^2 method, $\|\!|u|\!\|^2 = 0.4041161973$. For any choice of ℓ, the uniform mesh refinement, i.e., $\theta = 0$, leads to suboptimal convergence rate $2/3$ for the error caused by a corner singularity of u which can be predicted theoretically. The fact that the slope of the corresponding error estimators even is $2/3$ gives empirical evidence that the estimators are reliable and efficient although the solution lacks the regularity assumed in section 5. The error estimators η_M and η_A, respectively, μ_M and μ_A almost coincide. Due to numerical instabilities in computing the stiffness matrix for the $\mathcal{P}_1$ boundary element method, the error estimators μ_M, η_M, and η_A are only computed up to an error of $10^{-7/2}$. Up to this breakdown of the computation, the μ_M- and μ_A-adaptive meshes coincide. Thus, for large numbers n of fine grid elements, Figures 5–7 only show the error and the error estimators ϱ_F and μ_A.

The proposed adaptive mesh-refining strategy retains the optimal convergence rate $3/2$ expected for smooth solutions; cf. section 7.1. This observation is independent of the choice of ℓ in Algorithm 6.1. The larger ℓ, the better is the estimation of the error by the error estimators η_A and η_M which can be expected from the involved constant L in Theorems 5.1 and 5.2; cf. (5.4) for the definition. We always have $\eta_M \lesssim \|\!|u - u_h|\!\| \lesssim 1/(1 - L)\,\eta_M$, where $\lesssim$ denotes an inequality up to terms of higher order. By definition of our mesh strategy in Algorithm 6.1, there holds $\|h\|_{L^\infty(\gamma_j)}/H_j = 1/\ell$, whence $L \to 0$ for $\ell \to \infty$. On the other hand, ℓ should not be chosen too large since the asymptotic behavior of $h^{3/2}$ and $H^{5/2}$ then might not be visible for the number of elements considered. However, the effect is visible for $\ell = 2, 3, 4$ as well; cf. Figures 5–7. For $\ell = 2$, the curves of η_M, η_A, and E are getting closer for $H, h \to 0$, and it is expected that the curves almost coincide for larger values of n. For $\ell = 3$, the error and the error estimators η_M and η_A seem to coincide for $n \geq 200$. Finally, for $\ell = 4$, the error is sharply estimated by η_M and η_A even for lower degrees of freedom; cf. Figure 7.

Figure 8 shows the sequence of (μ_A-) adaptively generated meshes $\mathcal{T}_H$. We observe the expected mesh refinement towards the reentrant corner at the endpoints 0 and 2 and a moderate refinement elsewhere. The sequence of adaptive meshes for $\ell = 2, 3$ looks similar. Figure 9 shows the error and the error estimator μ_A for uniform and μ_A-adaptive mesh refinement and, for comparison, $\ell = 2, 3, 4$. Note that not only the slope of the errors for different choices of ℓ but even the absolute values coincide asymptotically.

Finally, Table 3 shows the calculated values of the error $E = \|\!|u - u_h|\!\|$, the error estimator, and the corresponding experimental convergence rate κ for uniform and μ_A-adaptive mesh refinement and $\ell = 4$. The values underline the given interpretation of the figures. For uniform mesh refinement, μ_A overestimates the error by a factor 2.75 independent of the number n of fine grid elements. For adaptively generated meshes, the quotient μ_A/E varies between 2.75 and 5 and seems to converge to a value about 3 for large n. This underlines the empirical efficiency and reliability of μ_A as is proven for smooth solutions in section 5. For the error estimators μ_M and μ_A, the quotient μ_M/μ_A is about 1 and both error estimators almost coincide. This underlines why both refinement strategies lead to the same adaptive mesh refinement.

7.3. Symm's integral equation with constant right-hand side. The boundary integral equation $V\phi = 1$ with constant right-hand side is considered for the L-

shaped domain Ω of Figure 4. To compute the error in the energy norm, we used the extrapolated value $\|\!|u|\!\|^2 = 2.40769127$ in (7.1). The exact solution u is unknown. Figure 10 shows discrete solutions u_h related to the initial mesh and an adaptively generated mesh [with $n = 32$ and $n = 656$ fine grid elements, resp.]. The discrete solutions show singularities at the five rectangular corners of the L-shape corresponding to the arc-length parameters $s = 1/4, 1/2, 1, 3/2$, and $7/4$. Figure 11 shows the errors and the error estimators for uniform and μ_A-adaptive mesh refinement and $\ell = 3, 4$ in Algorithm 6.1. As in Poisson problem 7.2, the error is sharply estimated by the error estimators η_M and η_A and the error estimators μ_M and μ_A coincide: The larger ℓ, the better is the error estimation. Again, the $\mathcal{P}_1$ boundary element stiffness matrix showed instabilities for the error $E \approx 10^{-7/2}$. The corresponding adaptive meshes are shown in Figure 12.

7.4. Exterior crack problem with nonsmooth solution. The fourth example from [ChS] represents a typical endpoint singularity for open curves and concerns the Poisson problem (6.2) exterior to a straight slit $\Gamma := [-1, 1] \times \{0\}$, $\Omega := \mathbb{R}^2 \backslash \Gamma$. For $g(x, 0) := -x$, the exact solution u of the corresponding Symm's integral equation reads

$$u(x, 0) = -x/\sqrt{1 - x^2} \quad \text{for } -1 < x < 1. \tag{7.9}$$

There holds $u \in H^\alpha(\Gamma)$ for all $\alpha < 0$, but $u \notin L^2(\Gamma)$ since u is singular at the tips of the domain, $u(x, 0) \to \pm\infty$ for $x \to \pm 1$. Since Kg vanishes on the straight slit Γ, Symm's integral equation (1.1) simplifies to

$$Vu = g \quad \text{on } \Gamma. \tag{7.10}$$

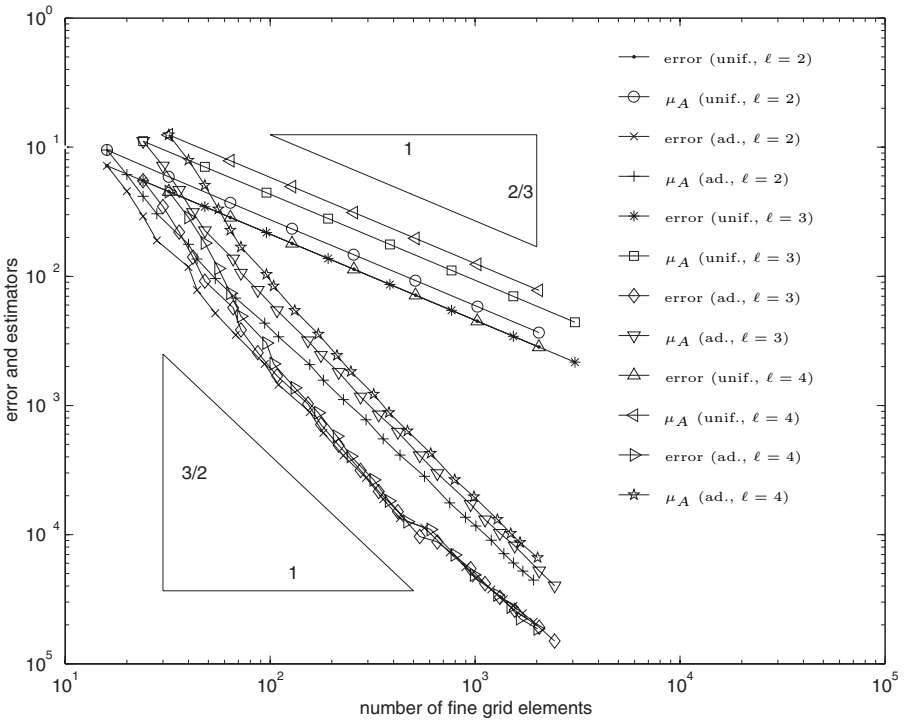

FIG. 9. *Comparison of error and error estimator μ_A in Poisson problem* 7.2 *for uniform and μ_A-adaptive mesh refinement and different choices of $\ell = 2, 3, 4$ in Algorithm* 6.1.

The energy norm of the exact solution can be computed exactly,

$$\|u\|^2 = \langle Vu\,;u\rangle = \int_{-1}^{1} \frac{x^2}{\sqrt{1-x^2}}\,dx = \frac{\pi}{2}.$$

Figure 13 shows the error and error estimators for $\ell = 3, 4$ and both uniform and adaptive mesh refinement. Some adaptively generated meshes are provided in Figure 14. As can be expected, we observe a high mesh refinement towards the ends ± 1 of the slit and coarse local mesh sizes inbetween.

7.5. Smooth eigenfunction of the single-layer potential. Finally, we consider an example on a smooth boundary with the discrete scheme involving the approximation of the boundary Γ by a piecewise-affine boundary Γ_h. Note that the error due to the boundary approximation is not included in the analysis given above.

We consider the sphere $\Gamma = \partial B(0, r)$ with radius $r < 1$. Then, for fixed $k \in \mathbb{Z}\backslash\{0\}$,

$$\phi(x) := \cos(kt) \quad \text{with } x = r\,(\cos t, \sin t) \tag{7.11}$$

is an eigenfunction of the single-layer potential V corresponding to the eigenvalue $\lambda = r/|k|$. For the numerical experiment, we used $r = 1/2$ and $k = 3$. Note that this example satisfies the smoothness assumptions of section 5. For the implementational realization, we approximate Γ by a (convex) polygonal Γ_H with vertices on the sphere. We therefore modify the adaptive Algorithm 6.1 as follows.

ALGORITHM 7.1. [illegible] $\mathcal{T}_H^{(0)}$ [illegible] $\mathcal{T}_H^{(0)}$ [illegible] $k = 0$ $\ell \in \mathbb{N}_{\geq 2}$ [illegible] $0 \leq \theta \leq 1$

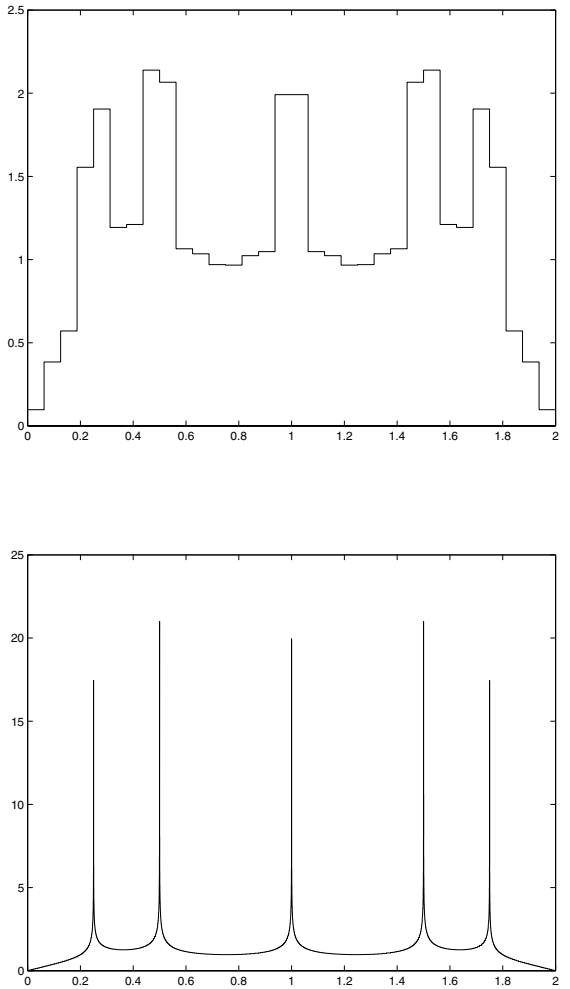

FIG. 10. *Discrete solution* u_h $(n = 32)$ *in Example* 7.3 *related to* $\ell = 4$ *and the initial mesh* $\mathcal{T}_H^{(0)}$ *with* $N = 8$ *elements shown in Figure* 4 (*top*) *and discrete solution* u_h $(n = 656)$ *related to* μ_A*-adaptive generated coarse mesh* $\mathcal{T}_H^{(10)}$ *with* $N = 164$ *elements* (*bottom*). *Note the different scalings on the y-axis of the plots.*

On the other hand, the larger ℓ, the larger is the preasymptotic range before the optimal convergence order* 3/2 *is visible for adaptive mesh refinement.*

FIG. 12. *Adaptive mesh refinement in Example 7.3 related to $\ell = 4$ and error estimator μ_A. Adaptive mesh refinement with respect to μ_M leads to the same meshes up to $\mathcal{T}_H^{(11)}$ [with $N = 64$ coarse grid elements] when the P1 boundary element method becomes unstable. The adaptively generated meshes are highly adapted towards the five rectangular corners of the L-shape, where the discrete solutions show singularities; cf. Figure* 10.

(vi) $\gamma_j \in \mathcal{T}_H^{(k)}$ $\mu_{M,j} \geq \theta \max\{\mu_{M,1},\dots,\mu_{M,N}\}$ $\mu_{A,j} \geq \theta \max\{\mu_{A,1},\dots,\mu_{A,N}\}$

(vii) $\gamma_j \in \mathcal{T}_H^{(k)}$ $\mathcal{T}_H^{(k+1)}$ (i)

To clarify the mesh organization, Figure 15 shows the initial coarse mesh with $N = 6$ elements and the refined meshes $\mathcal{T}_h^{(0)}$ and $\widetilde{\mathcal{T}}_h^{(0)}$ for $\ell = 3$ with $n = 18$ elements. Experimental results are shown in Figure 16 for $\ell = 4$ and both uniform and adaptive mesh refinement. As can be expected from the smoothness of u, the adaptive mesh refining strategy leads to almost uniform meshes. The experimental convergence orders for uniform and adaptive mesh refinement stay optimal. The curves of the error and error estimators almost coincide.

8. Conclusions. In this paper we introduced a new class of error estimators based on averaging techniques. We gave the analytical fundament that these error estimators estimate the (unknown) error $|||u - u_h|||$ both reliably and efficiently, under weak assumptions on the boundary elements used. The strongest assumption is a (piecewise) high regularity of the exact solution u. However, this regularity assumption might be nonsatisfied in practice. We introduced an adaptive algorithm which steers the mesh refinement with respect to the localized error estimators μ_M and μ_A, respectively. In the numerical experiments we treated examples with different regularity. In all experiments the introduced adaptive strategy retains the optimal convergence rate $\mathcal{O}(h^{3/2})$ and is therefore superior to uniform mesh refinement.

Finally, we highlight some of our computational and analytical results.

8.1. Error estimation with η_M, η_A and choice of ℓ. The numerical experiments underline the good performance of the introduced error estimators. The values of the error estimators η_M and η_A almostcoincide with the error $|||u-u_h|||$ provided ℓ is chose large enough. The explicit choice of ℓ is not discussed in this paper and is part of a generalized eigenvalue problem to compute $C_\Pi C_{\rm inv}^{H,q}$ in (5.4). For the numerical experiments treated, the choice of $\ell = 3, 4$ was sufficient to ensure that the error is sharply estimated by η_M and η_A. The efficiency and reliability constants, i.e.,

$$C_{\rm eff}^{-1}\eta \leq |||u - u_h||| \leq C_{\rm rel}\eta$$

for an error estimator η, are unknown except that we know $C_{\rm eff} = 1$ [up to higher order terms] for η_M. At least in the numerical experiments in section 7 we observed $C_{\rm eff}, C_{\rm rel} \to 1$ for $h \to 0$.

8.2. Adaptive mesh-refinement with respect to μ_M, μ_A. The examples 7.2–7.4 show that the proposed adaptive strategy can retain the optimal convergence rate $\mathcal{O}(h^{3/2})$ even for examples with nonsmooth exact solution. Poisson problem 7.2, also a benchmark for 2D finite element schemes, has exactly one corner singularity. Therefore the asymptotic convergence rates are visible from the beginning. This is not typical and so we addressed a generic example with smooth right-hand side, namely $f = 1$, which is [according to the authors' knowledge] not explicitly accompanied with an equivalent Poisson problem. Figure 11 shows a larger preasymptotic range for $N \leq 20$ and adaptive mesh refinement. The final Example 7.5 shows how the averaging based error estimation can be employed in combination with the approximation of a smooth boundary.

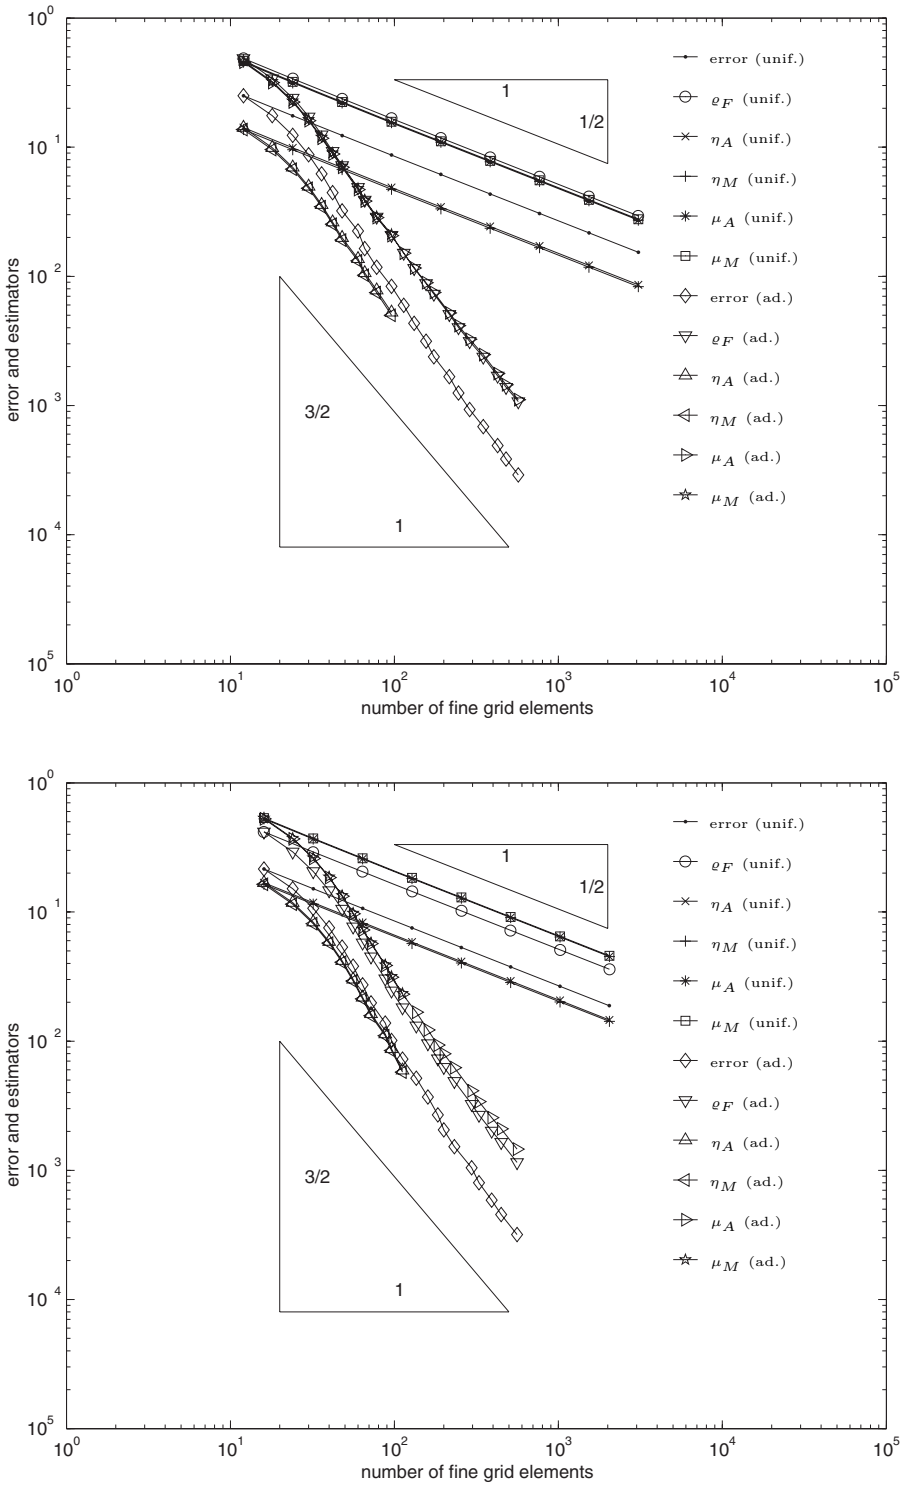

FIG. 13. *Error and error estimators* η_M, η_A, μ_M, *and* μ_A *for uniform* [*indicated by* unif.] *and* μ_A*-adaptive* [*indicated by* ad.] *mesh refinement in Example* 7.4 *and* $\ell = 3$ (*top*), *respectively,* $\ell = 4$ (*bottom*) *in Algorithm* 6.1.

8.3. Computational cost of the introduced error estimators. The naive computational cost for the estimators μ_M, η_M, η_A is quadratic in the number of unknowns since we have to compute the stiffness matrix for the $\mathcal{P}_1$ boundary element methods to compute $\mathbb{G}_H u_h$ for μ_M and η_M, respectively, $\|\mathbb{G}_H u_h\|$ and $\|\mathcal{A}_H u_h\|$ for η_M and η_A. This can be overcome by use of approximation techniques like panel clustering or $\mathcal{H}$-matrices which compute, store, and evaluate the stiffness matrix in almost linear complexity. Nevertheless, the computational cost for computing μ_A seems to be striking: The computation of μ_A for the L^2-projection $\mathcal{A}_H$ only needs the assembly of the usual L^2 mass matrix $\mathbf{M}$. This matrix is sparse and therefore assembled and stored in linear complexity. Moreover, the computation of $\mathcal{A}_H u_h$ involves the solution of $\mathbf{My} = \mathbf{c}$ for a given right-hand side $\mathbf{c}$, and the condition number of $\mathbf{M}$ is bounded, i.e., $\mathcal{O}(1)$ for $h \to 0$.

8.4. Applicability to 3D problems. We stress that the presented analysis works for 3D problems, i.e., 2D boundary pieces, as well. In the numerical experiments we restricted ourselves to 2D problems for ease of presentation, since the implementation of the boundary element schemes and even the data structures are much more involved for the 3D boundary element method.

8.5. Further developments and open problems. From an analytical point of view, Theorem 5.1 is the core result for providing the averaging error estimators. The proof is only based on the validity of a local inverse estimate; cf. section 3.2, and the existence of an appropriate (local) first order approximation operator. In a forthcoming paper, we will provide both the hypersingular integral equation as well [CP2, FP]. Is is expected that the ideas carry over to a quite general class of integral equations.

The analytical verification of the introduced error estimators needs high regularity assumptions on u. Since our numerical experiments indicate that these assumptions can be weakened, it would be desirable to have a refined analysis that covers these cases as well, i.e. which either avoids the regularity assumptions on u or explains the good performance of the indicator-based strategy analytically.

ADAPTIVE ALGEBRAIC MULTIGRID*

M. BREZINA†, R. FALGOUT‡, S. MACLACHLAN†,
T. MANTEUFFEL†, S. MCCORMICK†, AND J. RUGE†

Abstract. Efficient numerical simulation of physical processes is constrained by our ability to solve the resulting linear systems, prompting substantial research into the development of multiscale iterative methods capable of solving these linear systems with an optimal amount of effort. Overcoming the limitations of geometric multigrid methods to simple geometries and differential equations, algebraic multigrid methods construct the multigrid hierarchy based only on the given matrix. While this allows for efficient black-box solution of the linear systems associated with discretizations of many elliptic differential equations, it also results in a lack of robustness due to unsatisfied assumptions made on the near null spaces of these matrices. This paper introduces an extension to algebraic multigrid methods that removes the need to make such assumptions by utilizing an adaptive process. Emphasis is on the principles that guide the adaptivity and their application to algebraic multigrid solution of certain symmetric positive-definite linear systems.

Key words. iterative methods, algebraic multigrid (AMG), adaptive method

DOI. 10.1137/040614402

1. Introduction.

While the original development of algebraic multigrid (AMG) began over twenty years ago (cf. [8, 24]), the current high level of interest and research activity is fairly recent. This dramatic increase is largely due to the potential of these methods for solving very large problems arising from partial differential equations with irregular grids and varying coefficients. See, for example, [1, 3, 13, 28, 33].

By the term AMG, we mean the class of solvers based on multigrid principles that depend little or not at all on geometric information about the problem, but instead attempt to use basic concepts of "algebraic smoothness" to determine effective coarsening and/or relaxation processes. Solvers of this type typically assume some defining characteristic of algebraic smoothness, specifying error components that are not quickly eliminated by the relaxation that is being used. For example, all such components are assumed, in standard AMG (cf. [27] and section 2), to vary slowly along so-called strong connections in the matrix, or, in smoothed aggregation (SA; cf. [29]), to be represented locally by a few prototype vectors supplied by the user. While appropriate use of the characteristic of algebraic smoothness seems essential

for obtaining effective solvers, these additional assumptions limit the scope of applicability of the resulting methods. In many important cases, errors missed by standard relaxation processes can vary substantially along strong matrix connections, and, in many cases, even the concept of strength of connection is not well understood. Moreover, supplying a fully representative set of prototypical smooth components is not always easy nor possible in practice.

The principal aim of the adaptive approach developed here is to eliminate, or substantially reduce, this reliance on the additional assumptions usually present in related methods. The basic idea is to test the initial version of the given solver on the homogeneous problem, $A\mathbf{x} = \mathbf{0}$, to determine its performance and expose whatever types of errors it does not effectively reduce. The resulting prototypical errors that these tests produce are then used to improve the AMG process.

The concept of using a multigrid algorithm to improve itself is not new. Using prototypical algebraically smooth vectors in the coarsening process was first developed in the early stages of the AMG project of Brandt, McCormick, and Ruge (documented in [24]), where interpolation was defined to fit vectors obtained by relaxation on the homogeneous problem. In [8], a variation of this idea was used for recovering typical AMG convergence rates for a badly scaled scalar elliptic problem. While this initial approach was very basic and used only one prototype of algebraically smooth error, it contained many of the ingredients of the adaptive process described here. These concepts were developed further in [23, 26, 25, 27]. The concept of fitting eigenvectors corresponding to the smallest eigenvalues was advocated in [23] and [27], where an AMG algorithm determining these eigenvectors through Rayleigh quotient minimization was outlined. These vectors were, in turn, used to update the AMG interpolation and coarse-level operators. Adaptivity of linear solvers has a long history, including adaptive choice of the overrelaxation parameter in SOR [18] or the parameters in a Chebyshev iteration [21], and has seen renewed interest of late as a way to improve robustness of existing linear solvers, as in the work of Brandt [7] and Wagner and Wittum [32, 31].

In many ways, using algebraically smooth vectors in the definition of interpolation represents the next logical step in improving the interpolation operators used in robust geometric and algebraic multigrid methods. Alcouffe et al. introduced the concept of operator-induced interpolation in [2]. This improvement on the previously used geometric interpolation approach opened up a much larger class of problems to black-box multigrid solution.

In the present paper, we use an operator-induced interpolation approach as well, but also rely on an automatic process that supplies representative algebraically smooth components to ensure optimal performance. By integrating information regarding algebraically smooth vectors into the definition of interpolation, we develop multigrid schemes that are hopefully optimal for elliptic problems, where the discrete system is not necessarily in the form of an M-matrix. These operator- and relaxation-induced interpolation approaches can, if properly implemented, greatly enlarge the class of problems that admits optimal performance by a black-box multigrid technique.

We also introduce this form of adaptivity into AMG. While classical multigrid methods can be viewed as stationary iterative methods [4], the methods presented here are dynamic in their setup phase. In fact, we propose using the method itself to drive its own iterative improvement. A "bootstrap" AMG method that is similar to the approach developed here was recently proposed for the classical AMG setting by Brandt [7] and by Brandt and Ron [9].

Several other attempts have been made to allow the solver itself to determine from the discrete problem the information required to solve it successfully, without a priori assumptions on the form of the smooth error, including the methods of [11, 10, 14, 17]. All of these methods, however, have in common their requirement that the local finite element matrices of the problem be available, and they construct the multigrid transfer operators based on the algebraically smooth eigenvectors corresponding to local stiffness matrices assembled over element agglomerates. Although they can achieve encouraging convergence rates, their need to construct, store, and manipulate the coarse-level element information typically leads to increased storage requirements compared to those of classical AMG or standard SA. The methods described below attempt to achieve the good convergence properties of the element-based methods without requiring access to or manipulation of element information that may not even be available.

We refer to the approach developed here as adaptive because it involves self-testing to expose slowly converging error components and adaptation of the schemes' components to improve themselves. The acronym αMG is used to refer to the general class of multigrid methods of this type, to suggest their primal algebraic nature: we have in mind methods that use only the defining characteristic of algebraic smoothness and must use an automatic algebraic process to determine additional characteristics that enable effective determination of the full MG algorithm. The additional abbreviations αAMG and αSA, respectively, are used to refer to the specific AMG and SA versions of αMG.

In the next section, we give a brief description of standard AMG to set the stage for the development of αAMG in the following sections. Section 3 provides an introduction to the adaptive framework and develops some fundamental principles that guide our construction of the adaptive process. In section 4, we discuss details of the interpolation scheme used as well as some of its theoretical properties. Some important details of implementation are discussed in section 5, and numerical performance is illustrated in section 6.

2. Standard AMG. The key to the efficiency of any multigrid process lies in the complementarity of the relaxation and coarse-grid correction processes. For this reason, any discussion of the classical AMG algorithm begins with the defining property of algebraic smoothness that the residual is, on average, small after a few sweeps of relaxation: $(A\mathbf{e})_i \approx 0$ for each point i. Considering pointwise relaxation, such as Gauss–Seidel, and a symmetric positive-definite operator, such errors are typically associated with the small eigenvalues of the operator, and this is often what is meant when discussing algebraically smooth errors. Also central is the assumed property that such errors vary slowly along strong connections in the matrix. This additional assumption is generally applicable for discretizations of scalar elliptic PDEs, for which AMG was originally designed. Other problems, such as systems of PDEs, may require other assumptions on the nature of algebraically smooth errors. In any case, awareness of this assumption is important in analyzing the performance of AMG, particularly when this performance is poor.

To construct interpolation to approximate a general algebraically smooth error, $\mathbf{e}$, we use the premise of a small residual (that, for example, $\mathbf{e}^T A^2 \mathbf{e} \ll \rho(A)\mathbf{e}^T A\mathbf{e}$, where $\rho(A)$ is the spectral radius of A) to conclude that, for a given row, i, $(A\mathbf{e})_i \approx 0$ or

$$a_{ii}e_i \approx -\sum_{j\neq i} a_{ij}e_j. \tag{2.1}$$

Now, suppose that a coarse set of points that forms a subset of the fine degrees of freedom (DOFs) has been chosen (strategies for which are discussed below). Then, the fine-level DOFs can be represented as $\{1, 2, \ldots, N\} = C \cup F$, where C is the set of coarse-level points and F is the set of remaining fine-level points (so $C \cap F = \emptyset$). Since A is sparse, we introduce "neighborhood" notation: $N_i = \{j \neq i : a_{ij} \neq 0\}$, $C_i = C \cap N_i$, and $F_i = F \cap N_i$. Equation (2.1) can then be rewritten as

$$a_{ii}e_i \approx -\sum_{j \in C_i} a_{ij}e_j - \sum_{k \in F_i} a_{ik}e_k. \tag{2.2}$$

Were the last sum not present in (2.2), this expression could be used to define interpolation, because it would give the F-point value, e_i, approximately as a sum of the C_i-point values. The aim is therefore to "collapse" the connections from point i to points $k \in F_i$ onto the points $\{j \in C_i\} \cup \{i\}$. That is, we want to set a_{ik}, $k \in F_i$, to 0 while adjusting a_{ij}, for $j \in C_i$, and a_{ii} in some way to compensate for the inaccuracies this elimination introduces. The main assumption needed to collapse the stencil is that the values of algebraically smooth $\mathbf{e}$ at F_i points can be written in terms of its values at points in $C_i \cup \{i\}$:

$$e_k \approx \sum_{j \in C_i} \omega_{kj}^i e_j + \omega_{ki}^i e_i \qquad \text{for } k \in F_i. \tag{2.3}$$

We could then substitute this expression into the latter sum in (2.2) to obtain an expression for e_i in terms of $e_j, j \in C_i$, which is exactly the aim. Note that (2.3) is a special form of interpolation from $C_i \cup \{i\}$ to F_i. This special interpolation formula is used in reducing the stencil connections to determine the final interpolation formula, so this overall process is sometimes called "twice-removed" or "iterated" interpolation.

Now, in classical AMG algorithms, the $\{\omega_{kj}^i\}$ in (2.3) are determined from $\{a_{kj}\}$ based on the additional assumption that $\mathbf{e}$ is constant along strong connections. Thus, first we must ask the question as to whether the connection between i and k is important. To do this, we define the concept of strength of connection between two nodes. Considering the connections in the matrix to represent weights on the edges of the matrix graph (if $a_{ij} = 0$, there is no edge between nodes i and j), node i is said to strongly depend on node j if $-a_{ij} \geq \theta \max_{k \neq i}, \{-a_{ik}\}$. Likewise, node i strongly influences node j if $-a_{ji} \geq \theta \max_{k \neq j}, \{-a_{jk}\}$. Here, θ is a predetermined threshold value, $0 \leq \theta \leq 1$, often chosen to be 0.25.

Now, if k does not strongly influence i, then its value is not helpful in interpolation, as it is not a strong interpolation point. The set of such k is denoted F_i^w and referred to as the set of weak connections. These connections are not simply discarded; rather, their values are collapsed onto the diagonal. That is, $\omega_{kj}^i = 0$ for $j \neq i$, and $\omega_{ki}^i = 1$. Notice that this approach is, in fact, quite stable. If the classification of $k \in F_i$ misidentifies a strong influence as a weak one, it replaces the value e_k with e_i, which (because of the assumption about smooth error and strong connections) are, in fact, approximately equal.

The remaining $k \in F_i \setminus F_i^w \equiv F_i^s$ all strongly influence i. Adding the requirement that a node $k \in F_i^s$ be also strongly dependent on some $j \in C_i$, then we can hope to determine the value at point k based on the coarse-grid neighbors it has in common with i. Since the strength of k's connection to a point $j \in C_i$ is proportional to the matrix coefficient a_{kj}, the value e_k can be approximated by the average of these e_j

weighted by their coefficients. That is,

$$e_k = \frac{\sum_{j \in C_i} a_{kj} e_j}{\sum_{l \in C_i} a_{kl}}. \tag{2.4}$$

An important property of this intermediate interpolation formula is that it is an average; if $\mathbf{e}$ is constant for all $j \in C_i$, then it takes the same value at k. For problems such as the Laplacian, where the smoothest mode is the constant vector (up to boundary conditions), it is quite important to ensure the accuracy of interpolation for this mode.

Combining these approximations yields an overall interpolation formula for $i \in F$: $e_i = \sum_{j \in C_i} w_{ij} e_j$, with

$$w_{ij} = -\frac{a_{ij} + \sum_{k \in F_i^s} \left(\frac{a_{ik} a_{kj}}{\sum_{l \in C_i} a_{kl}} \right)}{a_{ii} + \sum_{m \in F_i^w} a_{im}}.$$

The effectiveness of this interpolation operator is now very dependent on the quality of the coarse-grid points selected. This is apparent from the assumption that each point $k \in F_i^s$ has a strong dependence on some $j \in C_i$. In addition, we need the coarse grid to satisfy an often contradictory condition that it must be small enough that there is a real benefit to coarsening. There are many options for choosing the coarse-grid points, such as the approach of [27], where the number of strongly connected neighbors of each point is considered. Also of interest is the recent work on compatible relaxation; cf. [16, 19]. We do not discuss the selection process further, except to say that it is of primary importance to the efficiency and success of an AMG: the coarse level must support accurate approximation of algebraically smooth error using only a small fraction of the fine-level points.

Once a set of coarse points, C, and an interpolation operator, P, have been chosen, we must still choose a restriction operator, R (for transferring the residuals to the coarse level), and a coarse-level operator, A_c (for defining the coarse-level correction equation). Assuming that A is a symmetric and positive-definite matrix, it is natural to define these operators by the so-called Galerkin conditions (cf. [27]):

$$R = P^T \qquad \text{and} \qquad A_c = RAP.$$

These definitions arise from minimization principles and are a result of choosing R and A_c so that the coarse-level correction minimizes the fine-level A-norm of the error over all such corrections.

AMG is a generalization of classical geometric multigrid. It is an efficient solver for many problems, including those involving discretizations on stretched or irregular grids, or discretizations of many problems with anisotropic or variable coefficients. There are, however, still many problems for which classical AMG is not effective, including problems with highly anisotropic or highly variable coefficients and those coming from the discretization of certain systems of PDEs such as linear elasticity. Simply put, the further the algebraically smooth components of a problem are from being locally constant, the more the performance of classical AMG suffers.

3. The adaptive AMG framework. The details of the αAMG and αSA [12] algorithms are quite intricate. We arrived upon them by careful consideration of the basic principles and methodologies of an adaptive algorithm. For this reason, our

discussion focuses on these basic principles before the particular details. We restrict our attention for the remainder of the paper to the case that the $N \times N$ matrix, $A = (a_{ij})$, is symmetric and positive-definite, although most of what is developed applies to more general cases. Our aim is to develop an AMG process to solve the matrix equation,

$$A\mathbf{x} = \mathbf{b},$$

without a priori knowledge of the character of algebraically smooth error.

3.1. The adaptive MG algorithm. An efficient multigrid process for solving $A\mathbf{x} = \mathbf{b}$ relies on the appropriate complementarity of relaxation and coarse-grid correction. Thus, we view the goal of the adaptive process as the development of a representative collection of vectors for which the chosen relaxation process is inefficient. In its most basic form, the adaptive process would be quite simple: relax on a significant number of vectors to expose slow-to-converge components (which act as prototypes of algebraically smooth error), and then choose interpolation to fit these vectors. Such an approach may, however, be quite inefficient and a multiscale viewpoint often proves more useful.

Suppose we know the matrix, A, but nothing more. Relaxation is then the only feasible way to expose algebraically smooth error components. However, with no further knowledge, there is no way of predicting, a priori, how many distinct components are needed to achieve good results. Experience (and, in the case of SA, theory [30]) has shown that, for discretizations of second-order scalar elliptic PDEs, a single component is sufficient, whereas six components may be needed for a problem such as three-dimensional (3D) linear elasticity. Thus, to arrive at an optimal solver with a minimal amount of work, it seems necessary to start with a single vector and introduce new prototypes as the evolving method proves inadequate.

The situation is then that we have a given matrix and seek to find a single algebraically smooth vector upon which to base interpolation. Relaxation alone can achieve this, simply by iteration on the homogeneous problem. However, it typically requires a huge number of relaxations to expose a global algebraically smooth vector, and so we seek to expose such components through multiscale development instead. We first relax only a few times, which should be sufficient to expose errors that are smooth enough to be handled on the first coarse grid. Smoother errors may be exposed by relaxation on the homogeneous problem on this coarse grid, particularly since the injected fine-grid prototype is a good initial guess for the algebraically smooth error we seek. The coarse-grid algebraically smooth error may then be used to create a still coarser grid in the usual multigrid fashion. Just a few steps of relaxation on the homogeneous problem on the finest grid quickly reduces a significant portion of a random initial guess, leaving error that can then be said to be locally algebraically smooth. If this prototype is used locally to define interpolation from some preselected coarse grid, then a coarse-grid problem that adequately represents the algebraically smooth error on the fine grid can be created. We can now iterate to an appropriate coarsest grid and interpolate a prototype of the smooth error to all grids. Proceeding recursively, this resembles a full approximation scheme (FAS; cf. [5]) multigrid process for the algebraically smooth component, rather than the usual correction scheme method.

In this manner, a good prototype of a single algebraically smooth component can be determined and the resulting solver tested by applying it to the homogeneous problem, $A\mathbf{x} = \mathbf{0}$, with a random initial guess. If the solver proves sufficient, then

the adaptive stage is complete. Inefficiency in the resulting solver indicates that relaxation and coarse-grid correction are not yet appropriately complementary, and that there are distinct algebraically smooth components that are not being well enough approximated on the coarser levels. Since these components are being reduced neither by relaxation nor coarse-grid correction, they can be exposed by an iteration as above, with the current solver taking the place of relaxation. This may be repeated until acceptable convergence rates are attained.

Thus, we sketch the adaptive procedure as follows.

ALGORITHM 1 (abstract adaptive process).

1. $k = 1$ $\mathbf{x}^{(1)}$ l $_l(\mathbf{x}^{(l)}, \mathbf{b}^{(l)})$ ν $A^{(l)}\mathbf{x}^{(l)} = \mathbf{b}^{(l)}$
2. $_k(\mathbf{x}^{(k)}, \mathbf{0})$
3. I_{k+1}^k $\mathbf{x}^{(k+1)} = (\mathbf{x}^{(k)})_c$ $\mathbf{x}^{(k)}$ $k+1$ $k = k+1$ 2
4. $k > 1$ $k = k-1$ $\mathbf{x}^{(k)} = I_{k+1}^k \mathbf{x}^{(k+1)}$ $_k(\mathbf{x}^{(k)}, \mathbf{0})$
5. $k = 1$ $\mathbf{x}^{(1)}$ l $_l(\mathbf{x}^{(l)}, \mathbf{b}^{(l)})$ ν $A^{(l)}\mathbf{x}^{(l)} = \mathbf{b}^{(l)}$ $_1(\mathbf{x}^{(1)}, \mathbf{0})$ 2

3.2. Principles. Perhaps the easiest way to understand the adaptive methodology is to begin with the principles upon which it is based. Here, we list the core ideas that motivate and provide a foundation for αMG, with the primary focus on the αAMG scheme. The pragmatic reader may prefer to defer reading this discussion until after section 4 or to see [12].

Algebraic smoothness. The concept of algebraic smoothness is of utmost importance in achieving an optimally efficient AMG method. Since we allow reduction of the error only through the processes of relaxation and coarse-grid correction, the algebraically smooth error (which, by definition, is slow to be resolved by relaxation) must be accurately corrected from the coarse grid. That is, interpolation must be very accurate for algebraically smooth components. In fact, a stronger requirement is imposed by the eigenvector approximation criterion that, for a given eigenvector, $\mathbf{u}$, of A, interpolation must reconstruct $\mathbf{u}$ to an accuracy proportional to its eigenvalue [6, 22].

The AMG methods considered here are based on some defining characteristic of what algebraic smoothness means. This definition generally amounts to articulating an algebraic property of the errors that the given (fixed) relaxation process cannot reduce effectively. For example, classical AMG is developed based on properties of a polynomial iterative method such as the Richardson iteration:

$$\tilde{\mathbf{x}} \leftarrow \tilde{\mathbf{x}} - \frac{1}{\|A\|}(A\tilde{\mathbf{x}} - \mathbf{b}).$$

For this iteration, the error, $\mathbf{e} = A^{-1}\mathbf{b} - \tilde{\mathbf{x}}$, converges slowly in the A-norm,

$$\|\mathbf{e}\|_A = \sqrt{\langle A\mathbf{e}, \mathbf{e}\rangle},$$

if and only if $\mathbf{e}$ yields a small generalized Rayleigh quotient:

$$RQ_A(\mathbf{e}) = \frac{\langle A\mathbf{e}, A\mathbf{e}\rangle}{\|A\|\langle A\mathbf{e}, \mathbf{e}\rangle}.$$

For this reason, the set of algebraically smooth vectors is often also referred to as the near null space of A; we use these two terms interchangeably, with the prevailing meaning to be that of vectors that the chosen relaxation scheme is slow to reduce. Proper use of this defining property of algebraic smoothness gives AMG its potential for optimal performance over a wide range of problems. It enables coarsening processes that rightfully depend on the matrix and hopefully capture the errors that relaxation cannot eliminate.

Most AMG methods, however, require additional assumptions regarding algebraically smooth error that allow them to capitalize on the special nature of the assumed algebraic smoothness. For example, classical AMG rests on two related main assumptions: that the constant vector, $\mathbf{1}$, must be interpolated exactly, and that algebraically smooth errors vary slowly along strong connections. While this enables effective treatment of many problems, it also restricts the class to which these algorithms apply. Many discrete systems exhibit algebraically smooth errors that vary dramatically across strong connections, and many others offer no clear understanding of what strength of connection even means. Also, as we discuss further in the next section, $\mathbf{1}$ is not necessarily a good representative of algebraically smooth error. A major goal of the adaptive process is to capitalize on the definition of algebraically smooth error without making additional specific assumptions about its character.

Prototypes. A central idea in the development of αAMG methods is the use of prototypes that serve as representatives of algebraically smooth error. In fact, prototypes are used in the development of nearly all multigrid methods, often implicitly. As mentioned above, for example, classical AMG uses $\mathbf{1}$ to build its matrix-based interpolation coefficients (see (2.4) and the discussion in section 2). αAMG differs in that it attempts to generate these prototypes automatically.

Given a set of these prototypes, it is important to recognize that they should only be used locally as representatives of algebraically smooth error. Otherwise, it would not be possible to achieve optimality. As an illustration of this point, consider the fact that the preconditioned conjugate gradient method can be interpreted as a two-level αMG method that uses the generated prototypes globally as representatives of slow-to-converge error components. (Here, the smoother plays the role of the preconditioner, and the coarse-grid corrections are the Krylov subspace projections; see [15] for details.) In general, errors left by relaxation consist of a large fraction of the spectrum of the matrix, so that coarsening must effectively approximate $O(N)$ components with varying degrees of accuracy. The goal in designing a multigrid interpolation operator is to achieve this approximation property by using only a small, $O(1)$, number of computed prototypes.

This use of a small number of prototypes to achieve approximation of a much larger space is a cornerstone of multigrid methods. It is essential, then, that each prototype be used effectively as a representative of many components with similar local character. Remember that the constant vector, $\mathbf{1}$, is used in classical AMG to define an interpolation whose range not only includes $\mathbf{1}$ but also approximates all smooth errors. This is analogous to how local basis functions are used in finite elements: piecewise polynomial basis functions are used locally not only because they can reconstruct their global counterparts, but also because they can approximate all smooth components of the solution of the PDE. The global prototype is a representative of many algebraically smooth components and thus is used locally to determine an interpolation operator that has many such smooth components in its range.

Self-testing. Computation of a rich supply of prototypes can be done by carefully testing the algorithm as it evolves. These self-tests should be done on a problem with known solution. The homogeneous problem, $A\mathbf{x} = \mathbf{0}$, is especially appropriate because it avoids trouble with machine representation when the approximation is very close to that solution. For our αMG schemes, we can test the current version of the algorithm on $A\mathbf{x} = \mathbf{0}$ by measuring the A-norm of the error of successive iterates. This test serves a dual role: it signals when the algorithm is performing well enough, and it produces a good prototype when it is not. Assuming that enough iterations are used, the prototype must be appropriate because it is algebraically smooth (relaxation is not eliminating it), yet poorly represented by whatever current coarsening process is being used (if any). This prototype can then be used in the underlying algorithm precisely where the additional smoothness assumptions were used. For classical AMG, this means that the prototype would provide information on the correct coefficients to use in eliminating the matrix connections to points that are only on the fine level.

While the homogeneous problem is important as a measure of performance because it has a known solution, other measures can be useful in monitoring the evolving behavior and improving the prototypes. This issue is most clearly exposed when a direct solver is used on the coarsest level, where solving the homogeneous problem seems paradoxical: why solve $A\mathbf{x} = \mathbf{0}$ when all you presumably get is $\mathbf{x} = \mathbf{0}$? At this point, a simple approach is to just accept the prototype computed on the next finer level so that the coarsest level is never really used in the adaptive process. This means that the prototype is never really improved there either. It may be better to enhance the coarsest-level prototype by using a more precise measure of smoothness. For our αMG schemes, we could choose to improve the prototype, $\mathbf{x}$, on the coarsest level by minimizing the generalized Rayleigh quotient, $RQ_A(\mathbf{x})$. The situation is more complicated in the case of multiple prototypes, however; in neither the scalar PDE case considered in section 4 nor the αSA method in [12] have we found any need for improving the coarsest-level prototype in this manner, so we choose not to address this issue further. The Rayleigh quotient can, however, be useful as a diagnostic tool in assessing how the adaptive process is behaving, as in [20].

Range of interpolation. The primary aim of coarsening in any multigrid process is to appropriately complement relaxation, allowing fast solution of the given system of equations. To accomplish this, all algebraically smooth errors must be approximated well by vectors in the range of interpolation. Within the adaptive process, such errors are represented only by the prototypes, and therefore the primary aim of this process is to develop an interpolation operator that accurately approximates the prototypes in such a way that good multigrid convergence is obtained by the resulting cycle.

Achieving the desired multigrid performance requires more than simply fitting the set of given prototypes exactly. Error in the direction of a single prototype can easily be corrected from a single coarse DOF, but this generally does not provide enough of an acceleration to the relaxation process to yield a scalable algorithm. Indeed, such an algorithm resembles a preconditioned conjugate gradient iteration [15] that would require many steps to converge for the matrices that typically arise from discretized PDEs. To develop an effective interpolation operator, it is necessary to consider each prototype as a [illegible] of a class of errors that relaxation is slow to reduce. Since pointwise relaxation is a local process, any error that has a similar character to the prototype, measured locally, is also expected to be slow to converge with relaxation. We look for all such errors to be approximated by the

range of interpolation and, thus, employ a localization (partition of unity) strategy in defining our multigrid interpolation operator. This strategy, unfortunately, is also generally not sufficient to achieve good multigrid performance: piecewise constant interpolation fits the prototypical constant vector exactly, and many locally similar errors well, yet leads to poor V-cycle performance for solving Laplace's equation [5]. Interpolation must also be chosen so that a variational coarse-grid correction is not distracted by non–algebraically smooth errors that are also in the range of interpolation. Classical AMG interpolation (as discussed in section 2) is known to attain all of these properties for typical scalar elliptic equations based on the single prototype of the constant vector, and we aim to mimic these properties here in the more general adaptive AMG setting.

Constructing interpolation in this way (described in detail in section 4) has important consequences. Not only is each prototype fit closely by the range of interpolation, but so are all locally similar vectors are as well. Thus, the range of interpolation includes many algebraically smooth vectors, including, if possible, many vectors that are significantly smoother (measured, for example, by their Rayleigh quotients) than the prototype used to construct interpolation in the first place. Given the lower cost of relaxation on the coarser grid, we look to improve the prototype through iteration on the homogeneous coarse-grid problem. Thus, we coarsen in the adaptive process, to quickly expose better prototypes of the fine-level algebraically smooth error. As the fine-level prototype is, itself, well represented on the coarse grid, the adaptive process attempts to improve the prototype directly on this level, instead of through a more cumbersome correction scheme. Success of this process rests on our ability to find components in the range of the constructed interpolation operator that are significantly smoother than the current prototype. Again, the keys to this success are in AMG's local operator-induced interpolation approach, which ensures that the range of P is rich in components that are locally similar to the prototypes, and the variational construction of the coarse-grid operators through the Galerkin condition [27], which allows iteration on the coarse grid to find a significantly smoother prototype than the one upon which interpolation was based (if such a vector exists).

Optimality. Multigrid methods are useful solution techniques because they exhibit optimal traits, such as $O(N)$ or $O(N \log N)$ scaling in both number of operations and storage. As such, any adaptive multigrid process should also retain this optimality. In particular, the adaptive process must not make requirements of the solver that compromise the optimality of the overall process and must itself scale optimally in operation count and storage.

Classical AMG controls complexity by its intricate way of determining the coarse points and its careful use of the matrix entries. The adaptive AMG approach assumes that a suitable coarsening process is available (such as compatible relaxation [7, 16, 19]), with the attendant assumption that there is sufficient reduction in grid sizes from fine to coarse levels. When fitting multiple prototypes, however, it is tempting to abandon the tight control on the stencil of interpolation (such as to the nonzero pattern of A_{fc}, the submatrix of A linking fine- to coarse-grid nodes, as is used in classical AMG) to allow for exact fitting of more prototypes. This must be done with utmost care, as each new nonzero entry in the interpolation operator can lead to new nonzero connections in the coarse-grid matrix. Care must also be taken to ensure that the stencil of interpolation is not too small: early experiments limited the size of C_i, the set of coarse-grid points from which the fine-grid point i is interpolated, to the number of prototypes being fit, which led to an extremely inefficient algorithm

because a single prototype could be used to define only one-sided interpolation, and so multiple prototypes were needed for good convergence even for second-order scalar PDEs.

Constructing a prototype set of minimal size is important to practical success and control over the complexity of the algorithm. While the same near null space may be well represented by a small number of very precise vectors or a larger number of less-resolved prototypes, the costs of the adaptive process and, possibly, the resulting method increase with the number of prototypes. For this reason, it is often more efficient to consider improvement of the existing prototype(s) than to add a new one. As each prototype emerges, we can consider improvement of its representation by running the setup cycle again, with the prototype as an initial guess for the algebraically smooth error. This either improves the prototype as a representative of the algebraically smooth components that are not well represented by the rest of the prototype set, or signals that the prototype is a strong representative of such components. In either case, valuable information about the adaptive process is gained, either through an improved prototype or through the knowledge that further improvement in the resulting algorithm must be gained through additional prototypes.

To ensure that the adaptive process is also optimal, adaptations are made whenever sufficient new information becomes known, but also only when the change is expected to improve the overall algorithm. For example, we develop the algebraically smooth prototype in a manner similar to the full approximation scheme, representing the prototype on all levels and looking for the algebraically smoothest component on each level. The prototype on a given level is discarded when it can be improved from a coarser grid, as we expect relaxation on coarser levels to better expose the algebraically smooth components that we seek. We do not, however, update interpolation or coarse-grid operators on the upward traverse of the setup V-cycle. Such an adaptation would be wasted because operators at higher levels also change as the cycle moves toward the finest grid. For this reason, while we allow for multiple V-cycles to be performed in the setup phase, the last cycle always terminates at the coarsest grid.

Termination of the adaptive process must also be properly implemented in order to maintain optimality. Experience has shown that improvement in the resulting multigrid process becomes less cost-effective with the number of setup phases and the total amount of relaxation in the adaptive step. A method with an acceptable convergence factor may be attained after even a single adaptive step, and a second adaptive step improves this factor by only a fraction of a percent. This may be addressed by reducing the amount of relaxation per adaptive step to a single sweep on each level and monitoring the convergence of the prototype vector between sweeps (for example, measuring its Rayleigh quotient). Unfortunately, the majority of the cost of an adaptive step is in the computation of interpolation and coarse-grid operators and not relaxation, so performing many adaptive steps is undesirable. For this reason, we choose a strategy attempting to minimize the number of setup cycles, motivated in [20], with enough relaxations in these cycles to quickly achieve convergence factors within a few percent of the apparent optimal performance.

4. Interpolation for adaptive AMG. Our goal in developing a new type of AMG method is to extend the applicability of classical AMG schemes. Thus, a primary concern is the generalization of the definition of interpolation in AMG. The guiding principles for this generalization come from basic properties of all multigrid algorithms:

- simple relaxation is inefficient for solving $A\mathbf{x} = \mathbf{b}$ on error components, $\mathbf{e}$, whose residuals, $A\mathbf{e}$, are small relative to $\mathbf{e}$ in some sense;
- efficient multigrid performance depends on effective complementarity of relaxation and coarsening so that they efficiently cooperate to eliminate all error components.

In this section, we propose a method for choosing interpolation that is appropriate in the case of M-matrices for which the algebraically smoothest mode is not close to the constant vector. As such, this interpolation may be viewed as an extension of the classical AMG interpolation [27]. In developing this new interpolation procedure, we consider the case of pure algebraic coarsening; however, for practical reasons, we choose to first implement the algorithm in the case of regular geometric coarsening. We do not address the important question of coarse-grid selection here, but expect that in a practical situation, the coarsening techniques of compatible relaxation [7, 16, 19] would be necessary in choosing an adequate coarse grid. The numerical results presented in section 6 are for this interpolation on geometrically chosen grids in the case of a scalar PDE.

4.1. Definition of interpolation. Since the success of our methods depends on the complementarity of relaxation and coarse-grid correction, a good starting point for defining interpolation is to consider a vector, $\mathbf{e}$, that is not quickly reduced by relaxation. Using a simple (pointwise) relaxation scheme, such as Gauss–Seidel, this also means that $A\mathbf{e} \approx \mathbf{0}$ or

$$a_{ii}e_i \approx -\sum_{j\in C_i} a_{ij}e_j - \sum_{k\in F_i} a_{ik}e_k, \tag{4.1}$$

where, as in (2.2), we assume a splitting of N_i into C_i and F_i. Again writing error e_k, $k \in F_i$, as

$$e_k \approx \sum_{j\in C_i} \omega_{kj}^i e_j + \omega_{ki}^i e_i$$

and using this expression in the second sum of (4.1) yields a general interpolation formula for point $i \in F$,

$$e_i = -\sum_{j\in C_i} \left(\frac{a_{ij} + \sum_{k\in F_i} a_{ik}\omega_{kj}^i}{a_{ii} + \sum_{k\in F_i} a_{ik}\omega_{ki}^i} \right) e_j. \tag{4.2}$$

The αAMG interpolation is different from that used in classical AMG [27] in that the $\{\omega_{kj}^i\}$ are chosen to depend on both the entries in A and a (computed) prototype, $\mathbf{x}^{(1)}$, that represents many algebraically smooth components. How this prototype is computed is the subject of section 5.

To be specific about the choice of $\{\omega_{kj}^i\}$, consider the idea of twice-removed interpolation [8]. Suppose we have a point, i, whose neighbors have been partitioned into the two sets, C_i and F_i. The problem of collapsing the $F - F$ connections is equivalent to that of determining a way to interpolate to point $k \in F_i$ from points $j \in C_i$ (or, more generally, $j \in C_i \cup \{i\}$). That is, we seek to write (as before)

$$e_k = \sum_{j\in C_i} \omega_{kj}^i e_j, \tag{4.3}$$

dropping the term $\omega_{ki}^i e_i$, under the assumption that k is as strongly connected to some point (or points) in C_i as it is to i. If there is a particular vector, $\mathbf{x}^{(1)}$, that we want to be in the range of interpolation, then we ask that (4.3) hold when $\mathbf{e}$ is replaced by $\mathbf{x}^{(1)}$. This constraint with one vector, $\mathbf{x}^{(1)}$, fixes one DOF of the possibly many for set $\{\omega_{kj}^i\}$, but leads to a unique F_i-interpolation formula if it is restricted to be of the form $D^{-1}A_{fc}$, where D is a diagonal matrix. (This choice is motivated by the discussion in [11].) The matrix D is determined by

$$d_{kk}^i x_k^{(1)} = -\sum_{j\in C_i} a_{kj} x_j^{(1)}$$

or

$$d_{kk}^i = \frac{-\sum_{j\in C_i} a_{kj} x_j^{(1)}}{x_k^{(1)}}. \tag{4.4}$$

Thus, choosing $\omega_{kj}^i = (d_{kk}^i)^{-1} a_{kj}$ in (4.3), the F_i-interpolation formula is

$$e_k = -\sum_{j\in C_i} \frac{a_{kj}}{d_{kk}^i} e_j.$$

Interpolation to $i \in F$, given by (4.2), then has the particular form

$$e_i = -\sum_{j\in C_i} \frac{1}{a_{ii}} \left(a_{ij} + \sum_{k\in F_i} a_{ik} \frac{a_{kj} x_k^{(1)}}{\sum_{j'\in C_i} a_{kj'} x_{j'}^{(1)}} \right) e_j. \tag{4.5}$$

Note that the interpolation operator, P, as a mapping from C to $F \cup C$, then has the form

$$P = \begin{bmatrix} W \\ I \end{bmatrix},$$

where W is the matrix of coefficients determined by (4.5).

This αAMG interpolation formula is a simple generalization of the classical AMG formula that allows for a sense of smoothness that may differ from what AMG conventionally uses. The primary assumption used in standard AMG to collapse $F - F$ connections is that the smoothest error component is constant [27]. Thus, classical AMG interpolation is recovered from the formula in (4.5) by choosing $\mathbf{x}^{(1)} \equiv \mathbf{1}$.

The iterated interpolation of (4.3) and (4.4) was chosen to exactly match the near null space approximation, $\mathbf{x}^{(1)}$. The final interpolation in (4.5), however, does not necessarily match this vector exactly. For a fine-grid point, i, the misfit is easily calculated as

$$x_i^{(1)} - (P\mathbf{x}_c^{(1)})_i = \frac{1}{a_{ii}} (A\mathbf{x}^{(1)})_i. \tag{4.6}$$

This is in accord with the classical AMG point of view that interpolation must be more accurate for errors that yield smaller residuals. In fact, it may be directly compared with the eigenvector approximation criterion, as described by Brandt [6, Theorem 4.1], which relies on the existence of a constant, C_0, bounded away from zero such that

$$C_0 \sum_i a_{ii} (e_i - (P\mathbf{e}_c)_i)^2 \le \mathbf{e}^T A \mathbf{e}$$

for all $\mathbf{e} \in \mathbb{R}^N$. Squaring (4.6), multiplying through by a_{ii}, and summing over both fine- and coarse-grid points, we have

$$\sum_i a_{ii}(x_i^{(1)} - (P\mathbf{x}_c^{(1)})_i)^2 \leq \sum_i \frac{1}{a_{ii}}(A\mathbf{x}^{(1)})_i^2 = (\mathbf{x}^{(1)})^T A \left(\operatorname{diag}\left(\frac{1}{a_{ii}}\right)\right) A\mathbf{x}^{(1)}$$
$$\leq \rho\left(A^{\frac{1}{2}}\left(\operatorname{diag}\left(\frac{1}{a_{ii}}\right)\right)A^{\frac{1}{2}}\right)(\mathbf{x}^{(1)})^T A\mathbf{x}^{(1)}.$$

For a diagonally dominant operator with constant diagonal, such as the finite-element Laplacian, $\rho(A^{\frac{1}{2}}(\operatorname{diag}(\frac{1}{a_{ii}}))A^{\frac{1}{2}})$ is easily bounded by 2, and so the constant, C_0, in Brandt's bound is not made unduly small due to the misfit in the interpolation of $\mathbf{x}^{(1)}$. While such a bound is only for the prototype, $\mathbf{x}^{(1)}$, and not for any arbitrary fine-grid vector (as required by the eigenvector approximation criteria), we consider $\mathbf{x}^{(1)}$ to be an appropriate prototype of the algebraically smooth error for which this bound is most difficult to achieve and, thus, indicative of a good interpolation scheme.

. . . . 1. While this paper considers methods involving just one prototype vector, $\mathbf{x}^{(1)}$, appropriate for scalar PDEs, these concepts can also be generalized to systems. Consider discretizing a system so that its DOFs are located on the same grid; i.e., there are d DOFs colocated at each node. Since we seek to generalize the ideas from the scalar case, we start by generalizing the notation: A_{kj} becomes the $d \times d$ matrix of connections between the DOFs located at nodes k and those located at node j, the diagonal entries of D (D_{kk}^i) become $d \times d$ matrices, and $\mathbf{x}^{(1)}$ becomes the matrix, $X^{(1)}$, composed of d columns of distinct prototypes. The restriction of $X^{(1)}$ to the d DOFs at node k is denoted by $X_k^{(1)}$. The analogue of (4.4) is then

$$D_{kk}^i = -\Big(\sum_{j \in C_i} A_{kj} X_j^{(1)}\Big)\big(X_k^{(1)}\big)^{-1}.$$

The F_i-interpolation formula for systems thus becomes

$$\mathbf{e}_k = -\sum_{j \in C_i} (D_{kk}^i)^{-1} A_{kj} \mathbf{e}_j,$$

which yields the final nodal interpolation formula

$$\mathbf{e}_i = -A_{ii}^{-1}\left(\sum_{j \in C_i}\left(A_{ij} + \sum_{k \in F_i} A_{ik}(D_{kk}^i)^{-1}A_{kj}\right)\right)\mathbf{e}_j.$$

4.2. Theoretical properties. One situation that can cause difficulty for classical AMG is when the matrix is rescaled. For example, if A is the discretization of a Poisson-like problem, then it is generally true that A applied to $\mathbf{1}$ yields a relatively small residual: $A\mathbf{1} \approx \mathbf{0}$. This means that constant vectors are indeed algebraically smooth, as classical AMG presumes. Rescaling A by multiplying it on both left and right (to preserve symmetry) by a positive diagonal matrix can dramatically change this property. Thus, if A is replaced by $\hat{A} = SAS$ for some positive diagonal matrix S, then $\hat{A}(S^{-1}\mathbf{1}) \approx 0$, and the new near null space component is actually $S^{-1}\mathbf{1}$. If the diagonal entries of S have significant variation in them, then $S^{-1}\mathbf{1}$ has a significantly different character than does $\mathbf{1}$. For classical AMG, this can cause a dramatic deterioration in convergence rates, although it can be prevented if the scaling is supplied to AMG so that the original matrix can essentially be recovered (as in [8]), but this is

not always possible in practice. Fortunately, as the following result shows, such scaling causes no problem for αAMG, provided the scaled prototype can be accurately computed.

THEOREM 4.1. [illegible] S [illegible] $\mathbf{x}^{(1)}$ $\hat{\mathbf{x}}^{(1)} = S^{-1}\mathbf{x}^{(1)}$ $\mathbf{b}$ [illegible] $\hat{\mathbf{b}} = S\mathbf{b}$ [illegible] α [illegible] $\hat{A}\hat{\mathbf{x}} = \hat{\mathbf{b}}$ [illegible] $\hat{\mathbf{x}}^{(1)}$ [illegible] $\hat{A}$ [illegible] α [illegible] $A\mathbf{x} = \mathbf{b}$ [illegible] $\mathbf{x}^{(1)}$ [illegible] A [illegible].

PROOF. Given a coarse-grid set, C, and the complementary fine-grid set, F, partition A and S to have the forms

$$A = \begin{bmatrix} A_{ff} & A_{fc} \\ A_{cf} & A_{cc} \end{bmatrix} \quad \text{and} \quad S = \begin{bmatrix} S_f & 0 \\ 0 & S_c \end{bmatrix},$$

so that

$$\hat{A} = \begin{bmatrix} S_f A_{ff} S_f & S_f A_{fc} S_c \\ S_c A_{cf} S_f & S_c A_{cc} S_c \end{bmatrix}.$$

The weights, $\hat{\omega}^i_{kj}$, for matrix $\hat{A}$ are given by

$$\begin{aligned} \hat{\omega}^i_{kj} &= \frac{\hat{a}_{kj}\hat{x}^{(1)}_k}{\sum_{j' \in C_i} \hat{a}_{kj'}\hat{x}^{(1)}_{j'}} \\ &= \frac{s_k a_{kj} s_j s_k^{-1} x^{(1)}_k}{\sum_{j' \in C_i} s_k a_{kj'} s_{j'} s_{j'}^{-1} x^{(1)}_{j'}} = s_k^{-1}\omega^i_{kj} s_j, \end{aligned}$$

where the weights, ω^i_{kj}, are chosen as for matrix A. Equation (4.5) then gives (with some algebra)

$$e_i = -\sum_{j \in C_i} s_i^{-1} \left(\frac{a_{ij} + \sum_{k \in F_i} a_{ik}\omega^i_{kj}}{a_{ii}} \right) s_j e_j, \qquad i \in F.$$

For $i \in C$, again simply take the value from the coarse grid and assign it as the value on the fine grid. Thus, the interpolation operator, $\hat{P}$, is of the form

$$\hat{P} = \begin{bmatrix} \hat{W} \\ I \end{bmatrix} = \begin{bmatrix} S_f^{-1} W S_c \\ I \end{bmatrix} = S^{-1} P S_c,$$

where P is the interpolation operator from the unscaled case. Further, considering the coarse-grid operator, $\hat{A}_c$, note that $\hat{A}_c = S_c P^T A P S_c = S_c A_c S_c$, where A_c is the coarse-grid operator from αAMG on A.

Thus, the coarse-grid operator for the scaled problem is simply the scaled version of the coarse-grid operator for the unscaled problem. Since standard relaxation techniques such as Gauss–Seidel or Jacobi (both pointwise and block forms) are scaling-invariant (that is, if A is scaled to SAS as above, initial guess $\mathbf{x}^{(0)}$ to $S^{-1}\mathbf{x}^{(0)}$, and initial right side $\mathbf{b}$ to $S\mathbf{b}$, then the approximation generated changes from $\mathbf{x}^{(1)}$ to $S^{-1}\mathbf{x}^{(1)}$), we see that the entire process is independent of any diagonal scaling. □

THEOREM 4.2. [illegible] 4.1 [illegible].

PROOF. The proof is identical in form to that for the scalar case and is, thus, omitted. □

5. Determining $\mathbf{x^{(1)}}$. Successful implementation of this interpolation scheme relies on having an appropriate prototype vector, $\mathbf{x}^{(1)}$ (or set of vectors, $X^{(1)}$). Since we rely on the complementarity of relaxation and coarsening, the best choice for $\mathbf{x}^{(1)}$ would be a representative of the vectors for which relaxation is inefficient. Thus, a straightforward method for generating this prototype would be to start with a vector that is hopefully rich in all components (i.e., all eigenvectors of symmetric A), relax on $A\mathbf{x} = \mathbf{b}$ for some $\mathbf{b}$, and then determine the error in the approximate solution after a sufficient number of relaxations.

We typically make use of relaxation schemes whose error-propagation matrices have the form $I - BA$. While, for general B, it is possible that the slow-to-converge modes of the relaxation iteration, $I - BA$, are not modes for which $A\mathbf{e} \approx \mathbf{0}$, in many practical situations they are. In particular, for the pointwise relaxation schemes considered here, the two descriptions of algebraically smooth error are equivalent. In fact, for many choices of B, the true near null space of A is accurately reflected in the vectors for which relaxation is inefficient. Knowledge of this space could be used as it is with standard AMG to determine an effective coarsening process. Our focus, however, is on the case where this knowledge is misleading, inadequate, or even unavailable. We thus concentrate on the case that a good prototype of errors that are slow to converge under the given relaxation scheme, $\mathbf{x}^{(1)}$, is not known.

Start with a vector generated randomly from a uniform distribution on $(0, 1)$. (Consideration of positive vectors is motivated by the case of scalar second-order operators, which tend to discretize as M-matrices and so have positive near null space vectors. A more general choice is appropriate when considering problems such as linear elasticity, but care must be taken because the definition of interpolation for αAMG presented here breaks down if $\sum_{j\in C_i} a_{kj} x_j^{(1)} = 0$ for any $i \in F$, $k \in F_i$.) Such a vector is, in general, not equally rich in all error components. However, in the scalar PDE case, it tends to be rich enough that a few relaxation sweeps on the homogeneous problem, $A\mathbf{x} = \mathbf{0}$, produce a good representative of the slow-to-converge components. Note that the homogeneous problem is advantageous to use here because the prototype is simply the error in approximating the exact solution, $\mathbf{x} = \mathbf{0}$. Thus, starting with a random initial guess and performing relaxation on $A\mathbf{x} = \mathbf{0}$ generates a prototype vector, $\mathbf{x}^{(1)}$, that represents the slow-to-converge components and that can then be used in the interpolation formula developed in section 4.1.

Unfortunately, generating the prototype by fine-grid relaxation alone is effective only in terms of the first coarse level and is, in general, quite inefficient in a multilevel setting. To produce a prototype that is smooth enough to represent the components associated with smoothness on very coarse levels, a multilevel scheme is needed. Here, we again measure smoothness by the eigenvector approximation criterion. Basing every interpolation operator on a single component, whose Rayleigh quotient is near the minimal eigenvalue on the finest grid, requires significant algebraic smoothness in that component, as the eigenvector corresponding to this eigenvalue must be interpolated with accuracy proportional to this small value. For coarser grids, such smoothness is much more efficiently represented by calculation on these grids. Thus, we start with a random guess on the fine level and perform a few (ν_0) relaxation sweeps there to generate a tentative $\mathbf{x}^{(1)}$. Using this current prototype, an interpolation operator is computed (as in section 4.1), and the coarse-level and restriction operators are formed using the Galerkin condition. We use injection of $\mathbf{x}^{(1)}$ (direct restriction of the values on the C-points) to form a coarse-level initial guess, relax ν_1 times, and recurse to the coarsest level. From this coarsest level, interpolate and relax ν_2 times on the vector

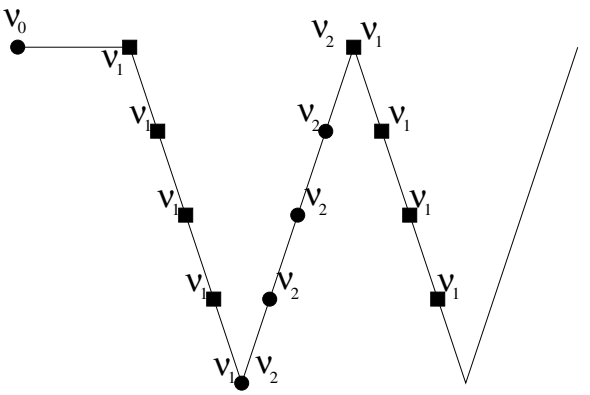

FIG. 5.1. *The setup scheme for determining* $x^{(1)}$.

all the way to the finest level, but do not recompute the coarse-level and grid-transfer operators.

The cycle can then be repeated, using the resulting vector as an overall initial guess in an attempt to further improve the prototype. This cycling strategy is illustrated in Figure 5.1, where boxes indicate stages where coarse-level operators are computed and circles indicate stages where only application of the current solver is necessary. Note that since the multigrid operators are computed only on the downward part of the cycle, no relaxation is necessary on the upward part of the final setup cycle. As is discussed in section 6, this procedure yields multigrid solvers with convergence factors bounded independently of mesh size (tested up to 1024×1024 grids) for many scalar problems.

One important benefit of generating the initial prototype vector in a multilevel fashion is the ability to implement a proper transition to simplicity in the algorithm. That is, since we begin by relaxing on a random vector (assumed to be rich in all components), it is easy to tell whether relaxation alone is sufficient to solve either the fine-grid problem or one of the generated coarse-level problems. If this is indeed the case, then no additional labor is needed in designing an algorithm because an efficient solver already exists.

For systems of PDEs and higher-order problems, an added wrinkle is the need to generate multiple prototype vectors. The cycling scheme described above can easily be generalized to account for multiple prototypes, by replacing the role of relaxation with the current solver. That is, once a single prototype is known, additional prototypes need to be generated that both are algebraically smooth and that represent distinct slow-to-converge components from the existing prototype. One way to generate such components is to apply the current solver to the homogeneous problem, in much the same way as we currently use relaxation to expose its own slow-to-converge components. Further investigation is necessary, however, to ensure that the generated prototypes represent a full set of algebraically smooth errors, without being redundant. This is the subject of current research.

6. Numerical results. To examine the feasibility of this approach, we implemented a solver for the special case of a rectangular grid in two dimensions with full coarsening. This restriction in generality has a notable effect on the range of problems that are able to be reasonably considered (anisotropy, for example, becomes

much more difficult to account for in this setting). However, examining problems without such difficulties, we feel that we can obtain a good initial indication of the performance of this approach. In particular, the aim here is to test the quality of the interpolation operator, not that of the coarsening procedure. Indeed, given current research into new coarsening techniques [7, 16, 19], it is difficult to say which coarsening method would be most appropriate for comparison.

We consider several measures of the effectiveness of the algorithm. Of primary importance is the total time to solution, given only the matrix equation, $A\mathbf{x} = \mathbf{b}$. Here, solving a problem is defined as reducing the residual by 10 orders of magnitude, and the wall-clock time to solution on a modern desktop workstation (2.66 GHz Intel Pentium 4) is measured. Another relevant measure is the asymptotic convergence factor of the resulting cycle. While setup costs may form a significant portion of the cost of solving a linear system with a single right-hand side, many problems require repeated solution with multiple right-hand sides (such as in implicit time stepping). In these cases, the (possibly large) setup cost can be amortized over the number of solutions, and the cost of only the solution stage is important. The asymptotic convergence factor reflects this cost, as a lower factor requires fewer iterations in the solution phase. We discard the usual AMG measures of grid and operator complexity because, in the structured coarsening framework considered here, these measures are constant for all fine-grid operators of the same mesh and stencil sizes.

As discussed in section 5, the setup may be performed in an iterative fashion. This is an appealing feature because, in practice, convergence of the prototype vector can be measured as an indicator of convergence of the method. This iteration is, however, quite expensive, as it involves computation of new interpolation and new Galerkin coarse-grid operators at each iteration. Testing indicates that it is usually significantly more efficient to perform more relaxation sweeps (i.e., increase ν_0 and ν_1) in a single setup cycle than it is to perform multiple setup cycles with fewer iterations per cycle to generate a single prototype [20]. Thus, in the results that follow, we first consider performing only a single setup cycle and track the number of relaxations (values of ν_0 and ν_1) necessary to achieve highly efficient solver performance. For the problems considered here, this calibrated AMG method is typically more efficient than the adaptive AMG method, whose results appear later. In the adaptive procedure, we fix the number of relaxations used in each setup phase and perform setup iterations until an acceptable solver is determined (measured by the error reduction in the solver). Here, we use the adaptive approach described in section 5 and Figure 5.1, where a single prototype is iteratively improved until the resulting solver is deemed to perform well.

We consider four PDEs as test problems, all discretized using bilinear finite elements on the unit square. Problem 1 is Laplace's equation with pure Dirichlet boundary conditions. Problem 2 is Laplace's equation with pure Neumann boundary conditions. Problems 3 and 4 are discretizations of

$$-\nabla \cdot \mathcal{K}(\mathbf{x}) \nabla p(\mathbf{x}) = 0,$$

with Dirichlet boundary conditions on the East and West boundaries and Neumann boundary conditions along the North and South boundaries. For Problem 3, $\mathcal{K}(\mathbf{x})$ is chosen as

$$\mathcal{K}(\mathbf{x}) = \begin{cases} 10^{-8}, & \mathbf{x} \in [\frac{1}{3}, \frac{2}{3}]^2, \\ 1, & \text{otherwise.} \end{cases}$$

For Problem 4, $\mathcal{K}(\mathbf{x})$ is assumed to be constant on each element and chosen to have value 10^{-8} on 20% of the elements (chosen randomly) and value 1 everywhere else.

A significant advantage of the αAMG method is its invariance to diagonal scaling, as shown in section 4.2. Thus, for each of these problems, we consider the results of such scaling. A common scaling is to make the diagonal entries of A all have value 1, using the diagonal matrix given by $s_{ii} = \frac{1}{\sqrt{a_{ii}}}$. For Problems 1–4 above, the problems with matrices thus scaled are referred to as Problems 1u–4u (where the u refers to the unit diagonal of the matrix). We also consider a more drastic scaling given by $s_{ii} = 10^{5r_i}$, where again r_i is chosen from a uniform distribution on $[0, 1]$ for each i. We call these Problems 1r–4r (where the r refers to the random scaling). Note that this scaling is dependent on the mesh size, and so it is expected that the overall work (measured relative to the cost of a fine-scale matrix-vector product), including both setup and solution phases, will grow as the mesh size is reduced.

6.1. AMG benchmarks. A baseline for these problems is established by considering the performance of standard AMG under the same assumptions (primarily that coarsening is performed geometrically). Since we expect the scalings employed to destroy any sense of strong connection in the matrix coefficients, we consider here a "strong-connection-only" version of AMG, equivalent to setting $\theta = 0$ in the definitions of strong influence and dependence in section 2. Wall-clock times and iteration counts are shown in Table 6.1, while convergence factors are shown in Table 6.2.

These results show that classical AMG interpolation gives a scalable solver for Problems 1, 2, and 3, coming directly from discretization. If, however, the discretization matrices are scaled, then there is a significant increase in the work needed for solution, especially noticeable as the problem grows (but also present with smaller fine grids). Improving on the results from these unscaled problems is difficult, so our aim should be to determine a balance where significant improvement on the results from the scaled problems is found, while not excessively increasing the cost of solution for problems such as 1, 2, and 3. The results for the unscaled Problem 4 are typical of the situation where, as h decreases, the problem becomes more difficult to solve due to the increase in the number of internal material interfaces.

6.2. Calibrated AMG results. For the adaptive AMG methodology, we consider several questions around the same problems. Experience has shown that a single

setup cycle is often most efficient if parameters ν_0 and ν_1 can be chosen such that this cycle yields an effective solver. How to best choose these parameters depends on our interests. For solving the matrix equation, $A\mathbf{x} = \mathbf{b}$, for a single vector, $\mathbf{b}$, we would like to choose ν_0 and ν_1 such that the total time to solution is smallest. This may mean sacrificing performance of the solver to save cost in the setup stage. For solving the matrix equation for many right-hand sides, the parameters should be chosen such that the solver performs optimally. Here, we primarily consider the latter situation, and demonstrate that doing so does not severely impact the time to solution for a single right-hand side.

We first present what might best be described as a calibrated AMG approach, reflecting that parameters ν_0 and ν_1 are chosen to calibrate the AMG performance, rather than a truly adaptive approach, where ν_0 and ν_1 remain fixed and setup is performed until an efficient solver is exposed. Thus, these results indicate the theoretical best performance of an adaptive AMG algorithm, with the minimal amount of total setup work, but do not represent a realistic adaptive algorithm, where adaptation is performed until a termination criterion is met. Such an algorithm is presented in the next section.

Our experiments were performed with the goal of (approximately) minimizing the asymptotic convergence factors of the resulting methods. To do this, we computed the asymptotic convergence factors for very large ν_0 and ν_1, corresponding to the optimal case where $\mathbf{x}^{(1)}$ is the slowest-to-converge mode of relaxation, then chose the smallest values for ν_0 and ν_1 such that the convergence factor of the resulting method was within 0.005 of the optimal factor when that factor was less than 0.1, and within 0.01 of the optimal factor otherwise. We found that, for Problems 1, 2, and 3, good asymptotic convergence factors could be achieved with relatively small values of ν_0 and ν_1. For Problem 4, the same performance as for standard AMG on the unscaled system can be recovered with small values of ν_0 and ν_1. Table 6.3 shows the time required for the setup phase for given values of these parameters and different grid sizes. As always happens when measuring computational performance, the timings are accurate only to within a few hundredths of a second, and so there is some variation in the timings of program stages that require the same number and ordering of operations.

Table 6.4 presents the asymptotic convergence factors for the methods resulting from the setup stages as outlined in Table 6.3. Note that, for the first three problems and for all grid sizes, αAMG achieves convergence factors bounded well below 1, with very small growth as the mesh size decreases. For Problem 4, we see growth like that

in the standard AMG results. Note also that scaling the matrices has no effect on our ability to determine an efficient solver for these problems.

Finally, in Table 6.5, we consider the total cost of solving $A\mathbf{x} = \mathbf{0}$ a single time, with random initial guess, using the near-optimal solver. Calibrated AMG did not (and could not be expected to) beat the overall performance of standard AMG on

the four unscaled problems. However, the setup costs of calibrated AMG were not significantly higher than those of AMG. On a 1024×1024 mesh, AMG setup required approximately 5 seconds of CPU, and so the adaptive setup needed between 30% and 240% more time, but tended to produce a better solver than classical AMG. For these reasons, the overall cost of calibrated AMG is close to that of standard AMG in the cases where standard AMG works well.

When standard AMG fails, there is no contest. Calibrated AMG was able to solve those problems that caused difficulty for standard AMG in a small fraction of the time. For the first three randomly scaled problems, the calibrated AMG setup time requires at most 12 seconds on the 1024×1024 grid, equivalent in cost to approximately 15 AMG V-cycles. However, the resulting convergence factors of at most 0.108 are much lower than the AMG convergence factors, the smallest of which was 0.992. Thus, after setup and a single cycle of the calibrated AMG approach, the error will be smaller than if the equivalent amount of work, 16 classical AMG cycles, was performed, which would reduce the error by a factor of approximately 0.879. Even for the fourth randomly scaled problem, where the setup cost is equivalent to approximately 20 AMG V-cycles, the error reduction after a single cycle will be significantly better than the equivalent in cost of 21 classical AMG cycles, which would yield a total reduction of approximately 0.900.

6.3. Adaptive AMG (αAMG) results. While the calibrated AMG approach yields solvers with optimal performance characteristics, its results are achieved at a significant cost of user time in tuning the setup parameters of ν_0 and ν_1. Details of this tuning process are documented in [20]. In practice, an adaptive approach may be used instead, moving the burden of calibration from the user to the solver itself.

In the αAMG approach, a small fixed number of relaxation sweeps are initially performed on the finest grid to locally expose algebraically smooth error. This error is used to create an interpolation operator and (through the Galerkin conditions) a coarse-grid problem. Relaxation is then performed on this grid, and the problem is further coarsened. After the initial multigrid hierarchy is created in this fashion, another identical setup cycle is performed with the current prototype as an initial guess. This is done to further improve the prototype as a representative of algebraically smooth error.

Alternately, we could look for a representative of the error missed by the multigrid cycle that results from the first setup cycle and use a prototype of this error to further improve interpolation and generate a more robust solver. Here, however, we consider problems similar to those for which classical AMG is effective. In particular, we consider those problems where the near null space can be represented by a single vector. The question of how to improve an existing AMG interpolation operator with information from a second prototype vector is not easily addressed. Instead, here we redefine the interpolation operator based on improving the prototype vector and not multiple distinct algebraically smooth components.

The results in Tables 6.6, 6.7, and 6.8 reflect performing 8 iterations of Gauss–Seidel relaxation on the homogeneous problem at each level of the setup phase. After each setup cycle, the resulting solver is tested by running 8 iterations of the solver on the homogeneous problem with a random initial guess. The fine-grid multigrid cycle is accepted when the error reduction factor (measured in the A-norm) of the last of these iterations is less than 0.4. Performing fewer iterations of relaxation on each level in the setup phase results in less exposure of slow-to-converge error and typically increases

the number of setup cycles needed. Considering the high cost in recomputation of the interpolation and coarse-grid operators, we prefer to avoid this. Performing more iterations of relaxation on the homogeneous problem on each level better exposes the error sought, but at the cost of potentially significant unnecessary computation. Another additional cost in the adaptive setup phase is that of the "test drive" that

performs 8 iterations of the current V-cycle on the homogeneous problem (to ensure adequate performance) after each setup cycle. Here, fewer iterations may give a poor indication of asymptotic cycle performance, while the cost of more iterations to better determine the true cycle performance is wasted if the cycle is to be further improved by another setup phase. Choosing the threshold for accepting the solver is less ambiguous, as setting a high threshold reduces the setup time but admits poor solvers, whereas setting the threshold to be small improves the solver but potentially requires more setup cycles.

Table 6.6 demonstrates the typical higher computational cost of the adaptive approach as compared to the calibrated approach. Some of this cost is certainly unavoidable. Fixing the number of iterations performed on the homogeneous problem undoubtedly results in some extraneous relaxations being performed, particularly on coarser grids, where few relaxation sweeps are "necessary." Likewise, the cost of testing the solver can be avoided only if we know, a priori, whether the solver will be acceptable. While these costs are significantly higher than those for calibrated AMG (as in Table 6.3), they do remain relatively low, still under one minute of CPU time for a 1024×1024 grid in all but the most difficult case.

Convergence factors for the adaptive AMG approach (Table 6.7) demonstrate its robustness. While the requirement for a successful setup was a single-step convergence factor less than 0.4 when measured after 8 iterations, we see that the asymptotic convergence factors are generally bounded by 0.4 as well. The asymptotic performance of the cycle for Problem 3r is relatively poor, but, in our tests, the first 15 steps of the resulting method reduced the residuals by factors better than 0.3 at each step. This example, however, does indicate that a more reliable performance indicator would be of use. Note that some of the factors are worse than the corresponding convergence factors for the calibrated AMG approach; they could also be improved at the cost of more expensive setup cycles. A constant convergence factor of 0.4 is still sufficient, however, to reduce the error by a factor of 10^{10} in 25 iterations.

The overall time to solution of the adaptive approach, as in Table 6.8, reflects the expected behavior. Iteration counts are low—at most 18 iterations are required for residual reduction by a factor of 10^{10}—and so the time to solution, ignoring the setup phase, is quite low. The increased setup costs due to multiple adaptations are reflected in the total time to solution. Comparing these results to the calibrated AMG approach is somewhat disappointing; however, in all cases, the solution was still obtained quickly, with total time for the αAMG approach within a factor of at most 8.5 (and often only 2) of the total time for the calibrated AMG results. Comparing this with the standard AMG results shows that the overall time to solution for the unscaled problems is higher than that for standard AMG, whereas, for the scaled problems, adaptive AMG always yields a quickly converging solver and so yields lower overall solution times in all cases where standard AMG performance suffered.

The calibrated and adaptive AMG results are very encouraging. For the scaled problems, there is a tremendous improvement in the amount of effort required for solution of the linear systems when compared to the results for standard AMG interpolation in Table 6.2. The solution phase of the algorithm scales well across all five grid sizes, and the actual costs are quite reasonable. It must be acknowledged, however, that once we account for the cost of the setup phase of our algorithm, classical AMG is still a slightly more efficient solver for the unscaled matrices when we consider solving with only a single right-hand side. Put simply, if the algebraically smoothest component of an elliptic PDE is known exactly, αAMG can do no better than design-

ing multigrid interpolation based on that component. Indeed, if this component is given as input to the adaptive AMG method for creating the multigrid hierarchy, we can solve the problem with the same cost as classical AMG on the unscaled problem, simply by using this prototype as $\mathbf{x}^{(1)}$ in (4.5), as discussed in section 4.2.

7. Conclusions. The adaptive multigrid strategies outlined here provide an opportunity for the recovery of classical multigrid performance in cases where the near null space components of the matrix are not locally constant. This can be done in both the case of a known nonconstant near null space component or of an unknown near null space component. The interpolation presented is a generalization of the classical Ruge–Stüben scheme, and, when coupled with the multilevel prototype of the near null space, it provides a scalable algorithm for matrix systems that the classical interpolation does not.

A TWO-GRID DISCRETIZATION SCHEME FOR SEMILINEAR ELLIPTIC EIGENVALUE PROBLEMS*

C.-S. CHIEN† AND B.-W. JENG†

Dedicated to Professor E. L. Allgower on the occasion of his seventieth birthday

Abstract. We present a two-grid finite element discretization scheme with a two-loop continuation algorithm for tracing solution branches of semilinear elliptic eigenvalue problems. First we use the predictor-corrector continuation method to compute an approximating point for the solution curve on the coarse grid. Then we use this approximating point as a predicted point for the solution curve on the fine grid. In the corrector step we solve the first and the second order approximations of the nonlinear PDE to obtain corrections for the state variable on the fine grid and the coarse grid, respectively. The continuation parameter is updated by computing the Rayleigh quotient on the fine space. To guarantee the approximating point we just obtained lies on the solution curve, we perform Newton's method. We repeat the process described above until the solution curve on the fine space is obtained. We show how the singular points, such as folds and bifurcation points, can be well approximated. Comprehensive numerical experiments show that the two-grid finite element discretization scheme with a two-loop continuation algorithm is efficient and robust for solving second order semilinear elliptic eigenvalue problems.

Key words. two-grid scheme, linear eigenvalue problems, nonlinear eigenvalue problems, continuation method, finite element method, singular points

1. Introduction.

During the 1980s, some researchers studied multigrid methods in the context of continuation methods for second order semilinear elliptic eigenvalue problems. See, e.g., Bank and Chan [3], Bolstad and Keller [4], Chan and Keller [5], Mittelmann and Weber [22], Ta'asan [26], and Weber [28, 29]. Other numerical studies of nonlinear elliptic eigenvalue problems can be found, e.g., in [12, 15, 20, 21].

Almost simultaneously, the mesh independence principle (MIP) for Newton's method was investigated by various researchers. See, e.g., Allgower and Böhmer [1] and the further references cited therein. The MIP means that the number of Newton iterations required in solving the discretized nonlinear differential equation is asymptotically independent of the asymptotic parameters such as the mesh size. In [30, 31] Xu studied two-grid discretization methods for semilinear elliptic boundary value problems based on finite element approximations. It is shown in [30] that one first uses a coarse space to produce a rough approximate solution. A fine grid correction is made on this approximate solution by solving a residual equation of the PDE. The desired solution on the fine space is obtained by performing a further coarse grid correction, which can improve the accuracy of the approximate solution.

Later, Xu and Zhou [32] proposed a two-grid discretization scheme for solving linear eigenvalue problems, including both PDEs and integral equations. If this procedure is implemented in the context of a finite element method, one needs to solve a generalized linear eigenvalue problem to obtain an eigenpair on a coarse space. Next,

one computes the desired eigenvector on the fine space. The corresponding eigenvalue is obtained by computing the Rayleigh quotient on the fine space. The eigenpairs can be computed up to the dimension of the coarse space.

In this paper, we will combine the ideas of these two schemes described in [30, 32] and develop a two-grid discretization scheme with a two-loop continuation algorithm for solving semilinear elliptic eigenvalue problems of the following form:

$$\begin{aligned} -\Delta u + \lambda f(u) &= 0 \qquad \text{in } \Omega = (0,1)^2, \\ u &= 0 \qquad \text{on } \partial\Omega, \end{aligned} \tag{1.1}$$

where $f(u)$ is a smooth function of u. For bifurcation problems further assumptions are necessary, e.g., f must satisfy $f(0) = 0$, $f'(0) \cdot f'''(0) \neq 0$. For simplicity we rewrite (1.1) as an operator form

$$F(u, \lambda) = 0, \tag{1.2}$$

where $F : B_1 \times \mathbb{R} \to B_2$ with $u \in B_1$, $\lambda \in \mathbb{R}$ is a smooth mapping, B_1 and B_2 are two real Banach spaces, and $\mathbb{R}$ is the real line. We call u the state variable and λ the parameter variable. To solve (1.2) numerically by the two-grid discretization scheme with a two-loop continuation method, we first discretize it, e.g., by a finite element method or a finite difference method on a coarse space. The predictor-corrector continuation method [2, 17] is then used to compute an approximating point on the coarse space.

Let $(u_{\tilde{h}}^{(i)}, \lambda_{\tilde{h}}^{(i)})$ be a point which has been accepted as an approximating point for the solution curve $\widetilde{c}$ on the coarse grid. We use this approximating point as a predicted point for the solution curve c on the fine grid. We solve the first order approximation of (1.2) on the fine grid to obtain a correction for the state variable $u_{\tilde{h}}^{(i)}$. To improve the accuracy of the state variable, we make a further correction on the coarse space by solving the second order approximation of (1.2), and thus obtain the state variable $u_h^{(i)}$ on the fine grid. In order to obtain an accurate parameter $\lambda_h^{(i)}$ corresponding to $u_h^{(i)}$, we compute the Rayleigh quotient as in [32]. To guarantee the approximating point is accurate enough on the fine grid, we use $(u_h^{(i)}, \lambda_h^{(i)})$ as an initial guess and perform Newton's method. This process constitutes the corrector step of the continuation algorithm on the fine space. Then we go back to the coarse grid to find the next approximating point $(u_{\tilde{h}}^{(i+1)}, \lambda_{\tilde{h}}^{(i+1)})$ for $\widetilde{c}$ by using the predictor-corrector continuation method. We repeat the process described above until the solution curve c on the fine space is traced.

Two main issues must be addressed here. First, are the solution branches obtained by implementing the two-grid discretization scheme accurate enough on the fine space? Next, are the singular points on the solution branches well approximated? The accuracy of the approximating solution curve is guaranteed by implementing the error estimators developed by Liu and Rheinboldt [19]. An alternative is to use the solution curve obtained by implementing, e.g., the multigrid-continuation algorithm [9] as the known data, and construct an interpolation polynomial for the approximating points obtained on the fine grid. The error bounds can be easily obtained. However, this process has to be implemented pointwise and is tedious. For simplicity we use sample checking on some interior nodes of the domain at each continuation step. In order to get better approximations of singular points in curve tracking, we perform Newton's method near the singular point after the two-grid solution is obtained. The effectiveness of this viewpoint has been verified by our numerical experiments.

This paper is organized as follows. In section 2 we briefly review the predictor-corrector continuation method. Section 3 describes a two-grid finite element discretization scheme for computing the first few eigenpairs of a second order linear elliptic eigenvalue problem. We indicate that the main work of this algorithm lies in solving symmetric positive definite linear systems with multiple right-hand sides. We propose to use the single seed method [25] or the preconditioned Lanczos method with iterative refinement [8] to solve the linear systems. In section 4 we derive the two-grid discretization schemes with two-loop continuation algorithms for semilinear elliptic eigenvalue problems. The two algorithms proposed in section 4 were implemented to trace solution curves of some test problems. These problems have been widely used as numerical examples in the literature of continuation methods [[3, 4, 5, 6, 7, 9, 14, 15, 19, 20, 21, 22, 26, 28, 29]. Our numerical results in section 5 show that the two-grid finite element discretization scheme is quite robust for second order semilinear elliptic eigenvalue problems. Finally, some concluding remarks are given in section 6.

2. A brief review of the predictor-corrector continuation method. To start with, we briefly review the predictor continuation method for tracing solution curves of semilinear elliptic eigenvalue problems. We refer to [2, 17] and the further references cited therein for a comprehensive study of numerical continuation methods.

We consider parameter-dependent problems of the form

$$F(x, \lambda) = 0, \tag{2.1}$$

where $F : \mathbb{R}^N \times \mathbb{R} \to \mathbb{R}^N$ is a continuously differentiable function of $x \in \mathbb{R}^N$ and $\lambda \in \mathbb{R}$. We denote the Jacobian of F by $DF = [D_x F, D_\lambda F]$ and a solution curve of (2.1) by

$$c = \{y(s) = (x(s), \lambda(s)) \mid F(y(s)) = 0, s \in I\}.$$

Here I is any interval in $\mathbb{R}$. Assume that a parameterization via arc length is available on c. We will trace the solution curve c by the predictor-corrector continuation methods. If the assumption that 0 is a regular value of F is not satisfied, then $F^{-1}(0)$ may contain bifurcation points and the augmented matrix of DF becomes singular there. On the other hand, if the solution curve c contains a simple fold, then the matrix $D_x F$ becomes singular there. In either case we have to solve nearly singular systems in numerical curve tracking if we are close to a fold or a bifurcation point. Differentiating (2.1) with respect to s, we obtain

$$DF(y(s)) \cdot \dot{y}(s) = 0, \tag{2.2}$$

where $\dot{y}(s) = (\dot{x}(s), \dot{\lambda}(s))^T$ denotes a tangent vector to c at $y(s)$ and $DF(y(s)) = (D_x F(y(s)), D_\lambda F(y(s)))$ is the $N \times (N+1)$ Jacobian matrix.

Let $y_i = (x_i, \lambda_i) \in \mathbb{R}^{N+1}$ be a point which has been accepted as an approximating point for c. A new point $z_{i+1,1}$ is predicted by the Euler predictor, i.e.,

$$z_{i+1,1} = y_i + \delta_i v_i. \tag{2.3}$$

Here $\delta_i > 0$ is the step length and v_i is the unit tangent vector at y_i, which is obtained by solving the linear system

$$A(y_i) \cdot v_i = \begin{bmatrix} 0 \\ 1 \end{bmatrix}, \tag{2.4}$$

where $A(y(s)) = \begin{bmatrix} DF(y(s)) \\ v_{i-1}^T \end{bmatrix}$ is the augmented Jacobian matrix and v_{i-1} is the unit tangent vector of the previous continuation step. To maintain orientation and control of the local curvature, we also require that

$$v_i^T \cdot v_{i-1} > 1 - \alpha > 0 \quad \text{for some } \alpha \in (0,1). \tag{2.5}$$

The accuracy of approximation to the solution curve must generally be improved via a corrector process. This may be done by choosing a hyperplane, which is orthogonal to $\dot{y}(s)$ at $z_{i+1,1}$ and performing Newton's iteration constrained to the hyperplane. The continuation algorithm described above will be used to trace solution curves on the coarse grid in section 4.

3. Two-grid discretization schemes for linear eigenvalue problems. A two-grid discretization scheme is proposed in [32] to approximate the first few eigenpairs of the following linear eigenvalue problem:

$$\begin{aligned} -\Delta u &= \lambda u \qquad \text{in } \Omega = (0,1)^2, \\ u &= 0 \qquad \text{on } \partial\Omega. \end{aligned} \tag{3.1}$$

Let $H^k(\Omega)$ be the Sobolev space endowed with Sobolev norm and $H_0^k(\Omega) = \{v \in H^k(\Omega) \mid v|_{\partial\Omega} = 0\}$. For $0 < h < \widetilde{h} < 1$, let $V_{\tilde{h}}(\Omega) \subset V_h(\Omega) \subset H_0^1(\Omega)$ be two finite element subspaces. The finite element approximation of (3.1) on the coarse space $V_{\tilde{h}}(\Omega)$ is to find $\lambda_{\tilde{h}} \in \mathbb{R}^1$, $u_{\tilde{h}} \in V_{\tilde{h}}(\Omega)$ with $\|\nabla u_{\tilde{h}}\|_{L^2} = 1$ such that

$$\int_\Omega \nabla u_{\tilde{h}} \cdot \nabla v = \lambda_{\tilde{h}} \int_\Omega u_{\tilde{h}} v \quad \text{holds } \forall v \in V_{\tilde{h}}(\Omega). \tag{3.2}$$

For simplicity, we denote $V_{\tilde{h}}(\Omega)$ and $V_h(\Omega)$ by $V_{\tilde{h}}$ and V_h, respectively. Note that the discrete version of (3.2) is a generalized symmetric eigenvalue problem

$$A_{\tilde{h}}\{u_{\tilde{h}}\} = \lambda_{\tilde{h}} B_{\tilde{h}}\{u_{\tilde{h}}\}, \tag{3.3}$$

where $A_{\tilde{h}}$ and $B_{\tilde{h}}$ are the coefficient matrices associated with $\int_\Omega \nabla u_{\tilde{h}} \cdot \nabla v$ and $\int_\Omega u_{\tilde{h}} v$, respectively, and $\{u_{\tilde{h}}\}$ is a vector whose entries are the values of $u_{\tilde{h}}$ at each coarse grid point. For simplicity in what follows we will omit the symbol "$\{\cdot\}$" in (3.4) and use $u_{\tilde{h}}$ to represent a vector in the Euclidean space as well. The Rayleigh quotient iteration (RQI) is widely used to solve generalized symmetric eigenvalue problems, where the preconditioned Lanczos method or the MINRES [23] can be used as a linear solver. See, e.g., [13] and the further references cited therein.

The accuracy of the approximate eigenvectors we obtained on the coarse grid can be improved by solving symmetric positive definite linear systems on the fine space. Suppose that we wish to compute the first k eigenpairs of (3.1). The main work of the two-grid scheme will involve solving linear systems with multiple right-hand sides of the form

$$AX = B \tag{3.4}$$

on the fine grid, where $A \in \mathbb{R}^{N\times N}$ is symmetric positive definite, $X = [x^{(1)}, \ldots, x^{(k)}] \in \mathbb{R}^{N\times k}$ is the matrix of unknowns, and $B = [b^{(1)}, \ldots, b^{(k)}] \in \mathbb{R}^{N\times k}$ is the matrix of right-hand sides. Smith, Peterson, and Mittra [25] developed a specific conjugate gradient (CG) algorithm, called the single seed method, for solving (3.4). Recently Chien and Chang [8] proposed to use the preconditioned Lanczos method with iterative refinement for solving (3.4). The numerical results reported therein show that

the two algorithms mentioned above are quite competitive for solving (3.4). We also let A_h and B_h be the coefficient matrices corresponding to $\int_\Omega \nabla u_h \cdot \nabla v$ and $\int_\Omega u_h v$ on the fine space, respectively. In order to improve the accuracy of the eigenpairs we obtained on the fine space V_h, we propose to perform the RQI again. The two-grid finite element scheme of Xu and Zhou [32] can be modified as follows.

ALGORITHM 3.1. A two-grid finite element discretization scheme for (3.1).

1. Use the RQI to find the first k eigenvalues $\lambda_{\tilde{h}}^1, \ldots, \lambda_{\tilde{h}}^k$ and the corresponding eigenfunctions $u_{\tilde{h}}^1, \ldots, u_{\tilde{h}}^k \in V_{\tilde{h}}$ with $\|\nabla u_{\tilde{h}}^1\|_{L^2} = \cdots = \|\nabla u_{\tilde{h}}^k\|_{L^2} = 1$ on the coarse space $V_{\tilde{h}}$: Solve
$$\int_\Omega \nabla u_{\tilde{h}}^i \cdot \nabla v = \lambda_{\tilde{h}}^i \int_\Omega \nabla u_{\tilde{h}}^i \nabla v \quad \forall v \in V_{\tilde{h}}, \quad i = 1, \ldots, k.$$
2. Use the single seed method or the preconditioned Lanczos method with iterative refinement to solve the s.p.d. linear systems with multiple right-hand sides on the fine space V_h: Find $u_h^i \in V_h$ such that
$$\int_\Omega \nabla u_h^i \cdot \nabla v = \lambda_{\tilde{h}}^i \int_\Omega u_{\tilde{h}}^i v \quad \forall v \in V_h, \quad i = 1, 2, \ldots, k.$$
3. Compute the Rayleigh quotient
$$\lambda_h^i = \frac{\|\nabla u_h^i\|_{L^2}^2}{\|u_h^i\|_{L^2}^2}, \quad i = 1, 2, \ldots, k.$$
4. Perform the RQI:
   (i) Normalize the approximate eigenvectors obtained in Step 2,
   $$u_0^i = \frac{u_h^i}{\|\nabla u_h^i\|_{L^2}}, \quad \text{and set} \quad \mu_0^i = \lambda_h^i, \quad i = 1, 2, \ldots, k.$$
   (ii) For $i = 1 : k$
   For $j = 0, 1, 2, \ldots$
   Solve $(A_h - \mu_j^i B_h) z_{j+1}^i = B_h u_j^i$ for z_{j+1}^i
   $$u_{j+1}^i = \frac{z_{j+1}^i}{\sqrt{(z_{j+1}^i)^T A_h z_{j+1}^i}}$$
   $$\mu_{j+1}^i = \frac{(u_{j+1}^i)^T A_h u_{j+1}^i}{(u_{j+1}^i)^T B_h u_{j+1}^i}$$
   End
   End

Let u_h be the approximate eigenvector obtained on the fine grid as in [32]. The following results hold:

$$\|\nabla(u - u_h)\| = O(h + \widetilde{h}^2) \quad \text{and} \quad |\lambda_h - \lambda| = O(h^2 + \widetilde{h}^4). \tag{3.5}$$

These estimates show that we can choose $\widetilde{h} = O(\sqrt{h})$. We refer to [32] for details.

It is straightforward to describe a two-grid centered difference discretization scheme corresponding to Algorithm 3.1. The only difference is that we use the block Lanczos method to compute the first k eigenpairs of (3.1) on the coarse grid. Recently, the authors have developed some two-grid centered difference discretization schemes for solving the Schrödinger eigenvalue problem [10] and the Schrödinger–Poisson system [11, 16, 24]. The details will be given elsewhere.

4. Two-grid continuation algorithms for nonlinear eigenvalue problems. In this section we will present some two-grid discretization schemes with two-loop continuation algorithms for tracing solution branches of (1.2). We consider the finite element approximation of (1.2) on the coarse space by finding an approximating point $(u_{\tilde{h}}, \lambda_{\tilde{h}}) \in V_{\tilde{h}} \times \mathbb{R}$ for the solution curve $\widetilde{c}$ such that

$$\langle F(u_{\tilde{h}}, \lambda_{\tilde{h}}), v\rangle = \langle \nabla u_{\tilde{h}}, \nabla v\rangle + \lambda_{\tilde{h}} \langle f(u_{\tilde{h}}), v\rangle = 0 \qquad \forall v \in V_{\tilde{h}}. \tag{4.1}$$

Let $(u, \lambda_{\tilde{h}})$ be an exact solution of (1.2). We fix the parameter $\lambda_{\tilde{h}}$ here in order to make a correction for the state variable $u_{\tilde{h}}$ on the fine space as in [30]. The linear approximation of the mapping $F(u, \lambda_{\tilde{h}})$ at $u_{\tilde{h}}$ is

$$F(u, \lambda_{\tilde{h}}) \approx F(u_{\tilde{h}}, \lambda_{\tilde{h}}) + D_u F(u_{\tilde{h}}, \lambda_{\tilde{h}})(u - u_{\tilde{h}}). \tag{4.2}$$

Setting $e = u - u_{\tilde{h}}$, (4.2) is equivalent to

$$D_u F(u_{\tilde{h}}, \lambda_{\tilde{h}})e \approx -F(u_{\tilde{h}}, \lambda_{\tilde{h}}),$$

where the Fréchet derivative $D_u F(u_{\tilde{h}}, \lambda_{\tilde{h}}) = -\Delta + \lambda_{\tilde{h}} f'(u_{\tilde{h}})$. The approximate solution $u_{\tilde{h}}$ can be corrected by solving the following equation:

$$\begin{aligned} -\Delta e + \lambda_{\tilde{h}} f'(u_{\tilde{h}})e &= \Delta u_{\tilde{h}} - \lambda_{\tilde{h}} f(u_{\tilde{h}}) && \text{in } \Omega = (0,1)^2, \\ e &= 0 && \text{on } \partial\Omega. \end{aligned} \tag{4.3}$$

Since $-\langle \nabla u_{\tilde{h}}, \nabla v\rangle - \lambda_{\tilde{h}} \langle f(u_{\tilde{h}}), v\rangle = 0$ for all $v \in V_{\tilde{h}}$, a finite element discretization of (4.3) on the coarse space $V_{\tilde{h}}$ produces only the trivial solution, and (4.3) must be solved on the fine space V_h. The finite element approximation of (4.3) is to find $e_h \in V_h$ such that

$$\langle \nabla e_h, \nabla v\rangle + \lambda_{\tilde{h}} \langle f'(u_{\tilde{h}})e_h, v\rangle = -\langle \nabla u_{\tilde{h}}, \nabla v\rangle - \lambda_{\tilde{h}} \langle f(u_{\tilde{h}}), v\rangle \qquad \forall v \in V_h.$$

For the further correction on the coarse space $V_{\tilde{h}}$, we use the quadratic approximation of $F(u, \lambda_{\tilde{h}})$ at $u_{\tilde{h}}$, i.e.,

$$F(u, \lambda_{\tilde{h}}) \approx F(u_{\tilde{h}}, \lambda_{\tilde{h}}) + D_u F(u_{\tilde{h}}, \lambda_{\tilde{h}})(u - u_{\tilde{h}}) + \frac{1}{2} D_{uu} F(u_{\tilde{h}}, \lambda_{\tilde{h}})(u - u_{\tilde{h}})^2.$$

Then

$$D_u F(u_{\tilde{h}}, \lambda_{\tilde{h}})(\widetilde{e} + e_h) \approx -F(u_{\tilde{h}}, \lambda_{\tilde{h}}) - \frac{1}{2} D_{uu} F(u_{\tilde{h}}, \lambda_{\tilde{h}})(\widetilde{e} + e_h)^2, \tag{4.4}$$

where $\widetilde{e} = u - u_{\tilde{h}} - e_h$. Note that $D_{uu} F(u_{\tilde{h}}, \lambda_{\tilde{h}})(\widetilde{e} + e_h)^2 = \lambda_{\tilde{h}} f''(u_{\tilde{h}})(\widetilde{e} + e_h)^2$. Equation (4.4) can be expressed as

$$-\Delta(\widetilde{e} + e_h) + \lambda_{\tilde{h}} f'(u_{\tilde{h}})(\widetilde{e} + e_h) \approx \Delta u_{\tilde{h}} - \lambda_{\tilde{h}} f(u_{\tilde{h}}) - \frac{1}{2} \lambda_{\tilde{h}} f''(u_{\tilde{h}})(\widetilde{e} + e_h)^2. \tag{4.5}$$

Since e_h is the approximate solution of (4.3), (4.5) becomes

$$-\Delta \widetilde{e} + \lambda_{\tilde{h}} f'(u_{\tilde{h}})\widetilde{e} \approx -\frac{1}{2} \lambda_{\tilde{h}} f''(u_{\tilde{h}})(\widetilde{e} + e_h)^2 \approx -\frac{1}{2} \lambda_{\tilde{h}} f''(u_{\tilde{h}}) e_h^2.$$

Thus the further coarse space correction is obtained by solving the following equation:

$$\begin{aligned} -\Delta \widetilde{e} + \lambda_{\tilde{h}} f'(u_{\tilde{h}})\widetilde{e} &= -\frac{1}{2} \lambda_{\tilde{h}} f''(u_{\tilde{h}}) e_h^2 && \text{in } \Omega = (0,1)^2, \\ \widetilde{e} &= 0 && \text{on } \partial\Omega. \end{aligned} \tag{4.6}$$

The finite element approximation of (4.6) is to find $e_{\tilde{h}} \in V_{\tilde{h}}$ such that

$$\langle \nabla e_{\tilde{h}}, \nabla v \rangle + \lambda_{\tilde{h}} \langle f'(u_{\tilde{h}}) e_{\tilde{h}}, v \rangle = -\frac{1}{2} \lambda_{\tilde{h}} \langle f''(u_{\tilde{h}}) e_{\tilde{h}}^2, v \rangle \qquad \forall v \in V_{\tilde{h}}. \tag{4.7}$$

In order to correct the parameter $\lambda_{\tilde{h}}$, we set $u_h = u_{\tilde{h}} + e_h + e_{\tilde{h}}$ and compute the Rayleigh quotient

$$\lambda_h = -\frac{\displaystyle\int_\Omega \nabla u_h \cdot \nabla u_h}{\displaystyle\int_\Omega f(u_h) u_h}.$$

From the discussion given above, we will describe a two-grid finite element discretization scheme with a two-loop continuation algorithm for solving second order semilinear elliptic eigenvalue problems. If $(u_{\tilde{h}}^{(i-1)}, \lambda_{\tilde{h}}^{(i-1)})$ has been accepted as an approximating point for $\widetilde{c}$ on the coarse space, then $(u_{\tilde{h}}^{(i)}, \lambda_{\tilde{h}}^{(i)})$ can be obtained by solving (1.2) with the predictor-corrector continuation method, which is called the outer-loop continuation. To obtain the corresponding approximating point $(u_h^{(i)}, \lambda_h^{(i)})$ for the solution curve c on the fine space, we use $(u_{\tilde{h}}^{(i)}, \lambda_{\tilde{h}}^{(i)})$ as a predicted point for the inner-loop continuation. In practice, we have to interpolate $u_{\tilde{h}}^{(i)}$ on the fine space. In the corrector step, we solve the first order approximation of $F(u, \lambda) = 0$ on the fine space to obtain a correction e_h for the state variable $u_{\tilde{h}}^{(i)}$. The linearization of (1.2) shows that this process is equivalent to performing one Newton iteration on the fine space; see [30]. To improve the accuracy of the state variable, we make a further correction on the coarse space by solving the second order approximation of (1.2), and thus obtain the state variable $u_h^{(i)}$ on the fine grid. We compute the Rayleigh quotient as in [32] for the corresponding $\lambda_h^{(i)}$. In order to guarantee that the approximating point is accurate enough, we use $(u_h^{(i)}, \lambda_h^{(i)})$ as an initial guess and perform Newton's method until it converges to the desired solution. Then we finish the corrector step of the inner continuation and go back to the coarse space to find the next approximating point for $\widetilde{c}$. We repeat this process until the solution curve c on the fine space is traced. We denote the restriction operator from the fine space to the coarse space by $I_h^{\tilde{h}}$ and the interpolation operator from the coarse space to the fine space by $I_{\tilde{h}}^h$. That is, $I_h^{\tilde{h}} : \mathbb{R}^{N^2} \to \mathbb{R}^{\widetilde{N}^2}$ and $I_{\tilde{h}}^h : \mathbb{R}^{\widetilde{N}^2} \to \mathbb{R}^{N^2}$.

ALGORITHM 4.1. A two-grid finite element discretization scheme with a two-loop continuation algorithm for tracing solution curves of (1.1).

Input:

$\varepsilon :=$ accuracy tolerance of approximating points for both solution curves $\widetilde{c}$ and c on the coarse and fine spaces, respectively

$i_{max} :=$ maximum number of continuation steps

$\left(u_{\tilde{h}}^{(0)}, \lambda_{\tilde{h}}^{(0)}\right) :=$ starting approximating point for $\widetilde{c}$

$i = 1$

1. **Outer continuation.**
   (i) Use the predictor-corrector continuation algorithm to find the approxi-

mating point $(u_{\tilde{h}}^{(i)}, \lambda_{\tilde{h}}^{(i)}) \in V_{\tilde{h}} \times \mathbb{R}$ for $\widetilde{c}$ such that

$$\int_\Omega \nabla u_{\tilde{h}}^{(i)} \cdot \nabla v + \lambda_{\tilde{h}}^{(i)} \int_\Omega f\left(u_{\tilde{h}}^{(i)}\right) v = 0 \quad \forall v \in V_{\tilde{h}}.$$

(ii) Compute the a posteriori error estimate for $(u_{\tilde{h}}^{(i)}, \lambda_{\tilde{h}}^{(i)})$.

2. **Inner continuation.**

(i) Predictor. Set $(I_{\tilde{h}}^h u_{\tilde{h}}^{(i)}, \lambda_{\tilde{h}}^{(i)})$ as the predicted point.

(ii) Corrector.

(a) Make a correction on the fine space V_h: Find $e_h \in V_h$ such that

$$\int_\Omega \nabla e_h \cdot \nabla v + \lambda_{\tilde{h}}^{(i)} \int_\Omega f'\left(u_{\tilde{h}}^{(i)}\right) e_h v = -\int_\Omega \nabla u_{\tilde{h}}^{(i)} \cdot \nabla v - \lambda_{\tilde{h}}^{(i)} \int_\Omega f\left(u_{\tilde{h}}^{(i)}\right) v \quad \forall v \in V_h.$$

(b) Make a further correction on the coarse space $V_{\tilde{h}}$: Find $e_{\tilde{h}} \in V_{\tilde{h}}$ such that

$$\int_\Omega \nabla e_{\tilde{h}} \cdot \nabla v + \lambda_{\tilde{h}}^{(i)} \int_\Omega f'(u_{\tilde{h}}^{(i)}) e_{\tilde{h}} v = -\frac{1}{2} \lambda_{\tilde{h}}^{(i)} \int_\Omega f''\left(u_{\tilde{h}}^{(i)}\right) e_h^2 v \quad \forall v \in V_{\tilde{h}}.$$

(c) Set $u_h^{(i)} = u_{\tilde{h}}^{(i)} + e_h + e_{\tilde{h}}$.

(d) Compute $\lambda_h^{(i)} = -\dfrac{\displaystyle\int_\Omega \nabla u_h^{(i)} \cdot \nabla u_h^{(i)}}{\displaystyle\int_\Omega f(u_h^{(i)}) u_h^{(i)}}$.

(e) If $\|F(u_h^{(i)}, \lambda_h^{(i)})\| > \varepsilon$, then
use $(u_h^{(i)}, \lambda_h^{(i)})$ as an initial guess and perform Newton's method. If Newton's method does not converge, then stop.
End if

(f) Compute an posteriori error estimate for the accepted approximating point.

3. If $i = i_{max}$, exit.
Else
set $i = i + 1$ and go to step 1.
End if

Next, we will describe a centered difference counterpart of Algorithm 4.1. Let $(u_{\tilde{h}}, \lambda_{\tilde{h}}) \in \mathbb{R}^{\widetilde{N}^2} \times \mathbb{R}$ be the centered-difference approximate solution of (1.1) on the coarse grid with uniform mesh size $\widetilde{h} = \frac{1}{\widetilde{N}+1}$, i.e.,

$$A_{\tilde{h}} u_{\tilde{h}} + \lambda_{\tilde{h}} f(u_{\tilde{h}}) = 0, \tag{4.8}$$

where $A_{\tilde{h}} \in \mathbb{R}^{\widetilde{N}^2 \times \widetilde{N}^2}$ is the coefficient matrix corresponding to the Laplace operator $-\Delta$ and $f(u_{\tilde{h}}) = [f((u_{\tilde{h}})_1), f((u_{\tilde{h}})_2), \ldots, f((u_{\tilde{h}})_{\widetilde{N}^2})]^T \in \mathbb{R}^{\widetilde{N}^2}$. Similar to the two-grid finite element discretization scheme, we correct $(u_{\tilde{h}}, \lambda_{\tilde{h}})$ by solving

$$\begin{aligned} -\Delta e + \lambda_{\tilde{h}} f'(u_{\tilde{h}}) e &= \Delta u_{\tilde{h}} - \lambda_{\tilde{h}} f(u_{\tilde{h}}) && \text{in } \Omega = (0,1)^2, \\ e &= 0 && \text{on } \partial\Omega \end{aligned} \tag{4.9}$$

on the fine grid with uniform mesh size $h = \frac{1}{N+1}$. Let

$$\begin{aligned} D_h &= \operatorname{diag}\left(f'((I_{\tilde{h}}^h u_{\tilde{h}})_1), f'((I_{\tilde{h}}^h u_{\tilde{h}})_2), \ldots, f'((I_{\tilde{h}}^h u_{\tilde{h}})_{N^2})\right) \in \mathbb{R}^{N^2 \times N^2}, \\ f(I_{\tilde{h}}^h u_{\tilde{h}}) &= \left[f((I_{\tilde{h}}^h u_{\tilde{h}})_1), f((I_{\tilde{h}}^h u_{\tilde{h}})_2), \ldots, f((I_{\tilde{h}}^h u_{\tilde{h}})_{N^2})\right]^T \in \mathbb{R}^{N^2}. \end{aligned} \tag{4.10}$$

The centered-difference analogue of (4.9) is of the form

$$(A_h + \lambda_{\tilde{h}} D_h) e_h = -A_h (I_{\tilde{h}}^h u_{\tilde{h}}) - \lambda_{\tilde{h}} f(I_{\tilde{h}}^h u_{\tilde{h}}). \tag{4.11}$$

Denote the solution of (4.11) by e_h. The further coarse grid correction is obtained by solving

$$\begin{aligned} -\Delta \widetilde{e} + \lambda_{\tilde{h}} f'(u_{\tilde{h}}) \widetilde{e} &= -\frac{1}{2} \lambda_{\tilde{h}} f''(u_{\tilde{h}}) e_{\tilde{h}}^2 \qquad \text{in } \Omega = (0,1)^2, \\ \widetilde{e} &= 0 \qquad \text{on } \partial\Omega \end{aligned} \tag{4.12}$$

on the coarse grid. Denote

$$\begin{aligned} D_{\tilde{h}} &= \operatorname{diag}\left(f'((u_{\tilde{h}})_1), f'((u_{\tilde{h}})_2), \ldots, f'((u_{\tilde{h}})_{\widetilde{N}^2})\right) \in \mathbb{R}^{\widetilde{N}^2 \times \widetilde{N}^2}, \\ E_{\tilde{h}} &= \operatorname{diag}\left((I_h^{\tilde{h}} e_h)_1, (I_h^{\tilde{h}} e_h)_2, \ldots, (I_h^{\tilde{h}} e_h)_{\widetilde{N}^2}\right) \in \mathbb{R}^{\widetilde{N}^2 \times \widetilde{N}^2}, \\ f''(u_{\tilde{h}}) &= \left[f''((u_{\tilde{h}})_1), f''((u_{\tilde{h}})_2), \ldots, f''((u_{\tilde{h}})_{\widetilde{N}^2})\right]^T \in \mathbb{R}^{\widetilde{N}^2}. \end{aligned} \tag{4.13}$$

The centered-difference counterpart of (4.12) is of the form

$$(A_{\tilde{h}} + \lambda_{\tilde{h}} D_{\tilde{h}}) e_{\tilde{h}} = -\frac{1}{2} \lambda_{\tilde{h}} E_{\tilde{h}}^2 f''(u_{\tilde{h}}). \tag{4.14}$$

Denote the solution of (4.14) by $e_{\tilde{h}}$. In order to obtain an accurate parameter λ_h on the fine grid, we set $u_h = I_{\tilde{h}}^h u_{\tilde{h}} + e_h + I_{\tilde{h}}^h e_{\tilde{h}}$ and compute the Rayleigh quotient

$$\lambda_h = -\frac{(u_h)^T A_h u_h}{(u_h)^T f(u_h)},$$

where $f(u_h) = [f((u_h)_1), f((u_h)_2), \ldots, f((u_h)_{N^2})]^T \in \mathbb{R}^{N^2}$. Therefore, we have the following result.

ALGORITHM 4.2. A two-grid centered-difference discretization scheme with a two-loop continuation algorithm for tracing solution curves of (1.1).

Input:

$\varepsilon :=$ accuracy tolerance of approximating points for both solution curves $\widetilde{c}$ and c on the coarse and fine spaces, respectively

$i_{max} :=$ maximum number of continuation steps

$(u_{\tilde{h}}^{(0)}, \lambda_{\tilde{h}}^{(0)}) :=$ accepted approximating point for $\widetilde{c}$

$i = 1$

1. **Outer continuation.**
   (i) Use the predictor-corrector continuation algorithm to find the approximating point $(u_{\tilde{h}}^{(i)}, \lambda_{\tilde{h}}^{(i)})$ for $\widetilde{c}$ on the coarse grid: Solve the nonlinear system

$$A_{\tilde{h}} u_{\tilde{h}}^{(i)} + \lambda_{\tilde{h}}^{(i)} f(u_{\tilde{h}}^{(i)}) = 0.$$

   (ii) Compute the a posteriori error estimate for $(u_{\tilde{h}}^{(i)}, \lambda_{\tilde{h}}^{(i)})$.

2. **Inner continuation.**
   (i) Predictor. Set $(I_{\tilde{h}}^{h} u_{\tilde{h}}^{(i)}, \lambda_{\tilde{h}}^{(i)})$ as the predicted point.
   (ii) Corrector.
      (a) Make a correction on the fine grid: Solve the linear system

$$\left(A_h + \lambda_{\tilde{h}}^{(i)} D_h\right) e_h = -A_h \left(I_{\tilde{h}}^{h} u_{\tilde{h}}^{(i)}\right) - \lambda_{\tilde{h}}^{(i)} f\left(I_{\tilde{h}}^{h} u_{\tilde{h}}^{(i)}\right).$$

      (b) Make a further correction on the coarse grid: Solve the linear system

$$\left(A_{\tilde{h}} + \lambda_{\tilde{h}}^{(i)} D_{\tilde{h}}\right) e_{\tilde{h}} = -\frac{1}{2} \lambda_{\tilde{h}}^{(i)} E_{\tilde{h}}^{2} f''\left(u_{\tilde{h}}^{(i)}\right).$$

      (c) Set $u_h^{(i)} = I_{\tilde{h}}^{h} u_{\tilde{h}}^{(i)} + e_h + I_{\tilde{h}}^{h} e_{\tilde{h}}$.
      (d) Compute $\lambda_h^{(i)} = -\dfrac{(u_h^{(i)})^T A_h u_h^{(i)}}{(u_h^{(i)})^T f(u_h^{(i)})}$.
      (e) If $\|F(u_h^{(i)}, \lambda_h^{(i)})\| > \varepsilon$, then
          use $(u_h^{(i)}, \lambda_h^{(i)})$ as an initial guess and perform Newton's method. If Newton's method does not converge, then stop.
          End if
      (f) Compute an posteriori error estimate for the accepted approximating point.
3. If $i = i_{max}$, exit.
   Else
      set $i = i + 1$ and go to step 1.
   End if

We remark here that Algorithms 4.1 and 4.2 provide a mechanism which guarantees the accuracy of the approximate solution curves and singular points we obtained if the algorithms converge. We explain this mechanism as follows.

(1) In steps 1 and 2 of Algorithm 4.1 we use the error estimators in [19] to compute an posteriori error estimate for the approximate solution $(u_h^{(i)}, \lambda_h^{(i)})$. For comparison the multigrid-continuation algorithm [9] was also implemented to trace solution branches of some test problems. More precisely, let $(v_h^{(i)}(x_0, y_0), \mu_h^{(i)})$ be the approximate solution at a point $(x_0, y_0) \in \Omega$ which is obtained by implementing the multigrid-continuation algorithm. We use the data $\{(v_h^{(j)}(x_0, y_0), \mu_h^{(j)})\}_{j=i-k}^{j=i+k}$ to construct an interpolation polynomial $P_{2k}(\mu)$ of degree $2k$. It was verified by our numerical experiments that the inequality $|u_h^{(i)}(x_0, y_0) - P_{2k}(\lambda_h^{(i)})| < 10^{-5}$ holds.
(2) The Newton iteration in step 2 of Algorithms 4.1 and 4.2 serves as a criterion to check how close the two-grid approximating point we obtained is to the solution curve on the fine grid. Moreover, if the Newton iteration converges at each continuation step, then the algorithms converge eventually. As well, it is evident that we can compute accurate singular points.

At this moment it does not seem adequate to us to give a rigorous proof for the convergence of Algorithm 4.1. However, our numerical results show that the algorithm is indeed robust and efficient and converges for various second order semilinear elliptic eigenvalue problems. Note that the PLTMGC [3] also uses a continuation procedure to follow the solution curve on the coarsest grid and a multigrid algorithm to refine the solution at selected points using an adaptive mesh refinement strategy. The

drawback of this strategy is that the approximating points on the solution curve without refinement would become poor approximations for the exact solution curve. See, e.g., Tables 2 and 5.

5. Numerical results. The algorithms described in sections 3 and 4 were implemented to compute the first few eigenpairs of (3.1) and to trace solution branches of various second order semilinear elliptic eigenvalue problems with Dirichlet boundary conditions, respectively. These problems have been widely used as test problems in the literature of continuation methods. Table 1 lists the numerical algorithms we have implemented during the past years. However, for consistency we will discuss only the numerical results concerning the implementations of Algorithms 4.1 and 4.2. The numerical results of implementing Methods 1 and 4 can be found in [6] and [9], respectively.

Equations (5.1)–(5.8) were discretized by the six-node triangular elements method. The domain Ω was divided into two families of triangles, $\mathcal{T}_{\tilde{h}} = \{\tau_{\tilde{h}}\}$ and $\mathcal{T}_h = \{\tau_h\}$, as shown in Figure 1. We chose $V_{\tilde{h}} \subset V_h \subset H_0^1$ as the quadratic spaces of piecewise continuous quadratic functions defined on $\mathcal{T}_{\tilde{h}}$ and $\mathcal{T}_h$, respectively. Here $\widetilde{h}$ and h denote the distance of two adjacent nodes on the coarse and fine grids, respectively. In Examples 1–6 we chose $\widetilde{h} = \frac{1}{16}$ and $h = \frac{1}{128}$, while in Examples 7–8, we set $\widetilde{h} = \frac{1}{16}$ and $h = \frac{1}{256}$. For the two-grid centered difference discretization scheme, $\widetilde{h}$ and h are defined in the same way. All of our computations were executed on an IBM xSeries 335 machine using FORTRAN 95 language with double precision arithmetic. The following notations are used in Tables 2–7.

NOMENCLATURE

ε	: accuracy tolerance in Newton corrector
tol	: stopping criterion for solving linear systems
$\|u_{\tilde{h}}\|_\infty$	: maximum norm of the approximate solution $u_{\tilde{h}}$
Error$(u_{\tilde{h}}, \lambda_{\tilde{h}})$	: the a posteriori error estimate for the approximate solution $(u_{\tilde{h}}, \lambda_{\tilde{h}})$
$\|u_h\|_\infty$	: maximum norm of the approximate solution u_h
Error(u_h, λ_h)	: the a posteriori error estimate for the approximate solution (u_h, λ_h)
Time	: total execution time (in seconds)
NCS	: number of the continuation steps

' . , 1.

$$\begin{aligned} \Delta u + \lambda e^u &= 0 \quad \text{in} \quad \Omega = (0,1)^2, \\ u &= 0 \quad \text{on} \quad \partial\Omega. \end{aligned} \tag{5.1}$$

Equation (5.1) is the well-known Gelfand–Bratu problem and is widely used as a test problem in the literature of continuation methods; see, e.g., [3, 5, 9, 14, 15, 19]. Our numerical experiments show that we have to choose a proper step size on the outer-loop continuation if Algorithm 4.2 was implemented to follow the solution curve of (5.1).

' . , 2.

$$\begin{aligned} \Delta u + \lambda \exp\left(\frac{u}{1+\alpha u}\right) &= 0 \quad \text{in} \quad \Omega = (0,1)^2, \\ u &= 0 \quad \text{on} \quad \partial\Omega. \end{aligned} \tag{5.2}$$

Equation (5.2) is the two-parameter Bratu problem [4].

$(\|u_h\|_\infty, \lambda_h)$	$(1.1561320, 22.4964732)$	$(2.9545366, 79.3873102)$

Equation (5.4) describes a model for the equilibrium of a set of point vortices or a guiding-center plasma in the domain Ω. See [28, 29].

' . ,' 5.

$$\begin{aligned} \Delta u + \lambda u - u^3 &= 0 \quad \text{in} \quad \Omega = (0,1)^2, \\ u &= 0 \quad \text{on} \quad \partial\Omega. \end{aligned} \tag{5.5}$$

See [29] for the numerical study of (5.5).

' . ,' 6.

$$\begin{aligned} \Delta u + \lambda \sin u &= 0 \quad \text{in} \quad \Omega = (0,1)^2, \\ u &= 0 \quad \text{on} \quad \partial\Omega. \end{aligned} \tag{5.6}$$

The numerical study of (5.6) can be found, e.g., in [20, 22] and some references cited in [20]. Both Algorithms 4.1 and 4.2 were used to trace the solution curve of (5.6) bifurcating at $(0, \lambda_{1,1}) \approx (0, 19.7392088)$. Our numerical result is shown in Table 2. Figure 1 displays the error estimates for the solution curves on both grids. By comparing our result with the multigrid solution we find that the maximum norm of u_h is correct up to six decimal digits. The total execution time of implementing Algorithm 4.1 and the multigrid-continuation algorithm is shown in Table 3.

' . ,' 7.

$$\begin{aligned} \Delta u + \lambda \sin u - u^4 &= 0 \quad \text{in} \quad \Omega = (0,1)^2, \\ u &= 0 \quad \text{on} \quad \partial\Omega. \end{aligned} \tag{5.7}$$

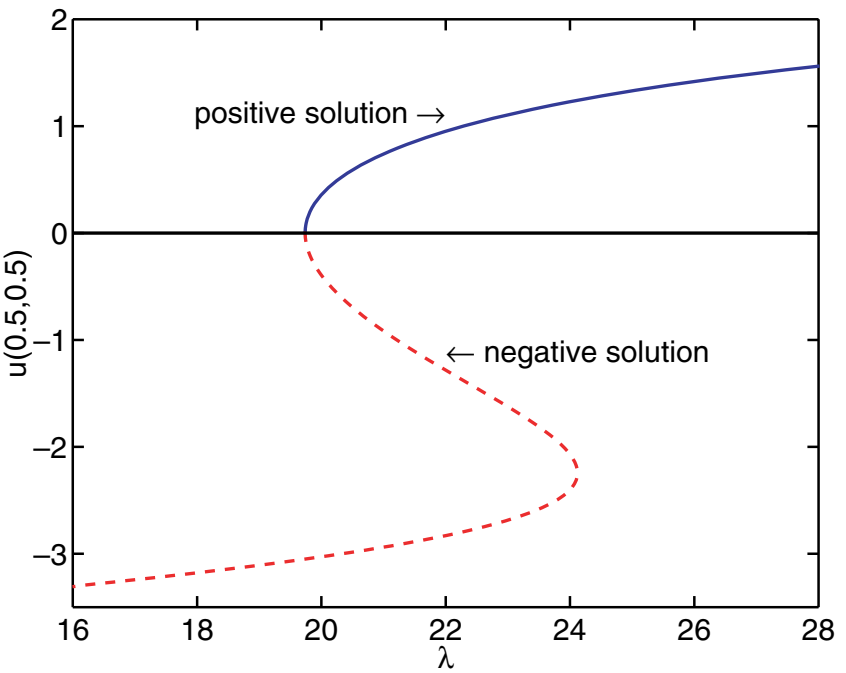

FIG. 2. *The solution curve of* (5.7) *bifurcating at* $(0, \lambda_{1,1})$.

Equation (5.7) was used as a test problem in [29]. Algorithms 4.1 and 4.2 were implemented to trace the solution curve of (5.7) with $\widetilde{h} = \frac{1}{16}$ and $h = \frac{1}{256}$. Table 4 lists some sample approximating points for the solution curve of (5.7). Figure 2 shows the solution curve.

8. Let Ω be a bounded regular domain in $\mathbb{R}^N$. In [18, Remark 1.7] Lions claimed that the equation

$$(5.8) \qquad \begin{aligned} -\Delta u - \lambda(u(1 - \sin u) + u^p) &= 0 \quad \text{in} \quad \Omega = (0,1)^N, \quad 1 < p < N^\star, \\ u &= 0 \quad \text{on} \quad \partial\Omega \end{aligned}$$

has exactly one fold on the $(\lambda, \|u\|_\infty)$ plane if $N = 2$. Here $N^* = \infty$ if $N = 1, 2$, and

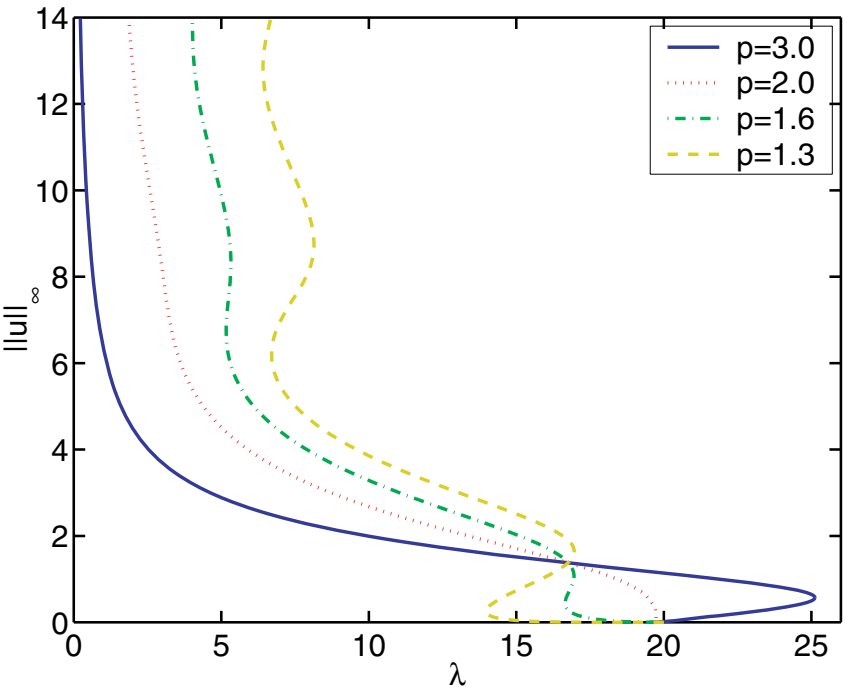

FIG. 3. *The solution curves of* (5.8) *with* $p = 1.3, 1.6, 2,$ *and* 3.

$N^* = (N+2)/(N-2)$ if $N \geq 3$. The numerical study of (5.8) can be found, e.g., in [21, 29], where only the case $p = 3$ was considered. Recently, Wang [27] showed that for the one-dimensional problem of (5.8) the number of folds on each solution curve varies with respect to the values of p. In particular, for $p = 1$ the solution curve has infinitely many folds. Therefore, it is getting tough to trace the solution curves of (5.8) as p is close to 1. A detailed numerical investigation of (5.8) for $N = 1, 2,$ and 3 can be found in [7]. We used Algorithm 4.1 to follow some solution curves of (5.8). Figure 3 shows the solution curves of (5.8) with $p = 1.3, 1.6, 2,$ and 3. Table 5 lists some sample approximating points for the solution curve of (5.8) with $p = 1.3$, where the first four folds are detected at $(\|u\|_\infty, \lambda) \approx (0.2523042, 13.9777120)$, $(1.6399861, 16.9622642)$, $(6.2075371, 6.7043602)$, and $(8.7675950, 8.1421997)$. For $p = 1.6$, the first four folds are detected at $(0.4404359, 16.6538055)$, $(1.0762562, 16.9532893)$, $(6.7520017, 5.1649507)$, and $(8.2972692, 5.3251472)$. For $p = 2.0$, there is no fold on the solution curve, while for $p = 3.0$ the only fold is detected at $(0.5650960, 25.1183419)$. We refer to [7] for a comparison.

Table 6 lists the performance results of Methods 1, 2, 3, and 4 on Examples 1, 2, 3, 4, 5, 6, 7, and 8.

9. The eigenvalues of (3.1) are

$$\lambda_{p,q} = (p^2 + q^2)\pi^2, \quad p, q = 1, 2, 3, \ldots.$$

Equation (3.1) was discretized via six-node triangular elements. We chose $\widetilde{h} = \frac{1}{8}$ on the coarse grid and $h = \frac{1}{128}$ on the fine grid. The coefficient matrices on the coarse grid and on the fine grid are of order 49×49 and 16129×16129, respectively. We used Algorithm 3.1 to find the first six eigenpairs of the discrete problem. Table 7 shows the numerical results.

TABLE 5

The solution curve of (5.8) *with* $p = 1.3$ *branching from* $(0, \lambda_{1,1}) \approx (0, 19.7392088)$, $\widetilde{h} = 1/16$, $h = 1/256$, $\varepsilon = 5 \times 10^{-8}$, $tol = 5 \times 10^{-10}$, *using Algorithm* 4.1.

6. Conclusions. In this paper, we present two-grid discretization schemes with two-loop continuation algorithms for tracing solution branches of second order semilinear elliptic eigenvalue problems. Of particular interest here are the computations of singular points such as folds and bifurcations. Based on the results of our numerical implementations, we wish to state some conclusions concerning the performance of the two schemes we propose. We will also compare the differences between the two-grid, the single grid, and the multigrid schemes for semilinear elliptic eigenvalue problems.

(1) In the two-grid schemes, two solution branches are numerically traced; one is on the coarse grid, and the other is on the fine grid. Therefore, we need to

perform two-loop continuation algorithms. Besides, the shape of approximating points computed on both grids looks like a saw. Tracing a solution branch on the coarse grid is quite inexpensive because the grid size is relatively small compared to the one on the fine grid. Moreover, the approximating points on the coarse grid serve as predicted points for computing approximating points on the fine space. This means that we don't have to solve linear systems for tangent vectors. Furthermore, it is unnecessary to use any step size control strategy on the inner-loop continuation. The purpose of multigrid method is to reduce the computational costs for solving linear systems on the finest grid. However, we have to solve additional linear systems on each level between the coarsest and finest grids. Both the single grid and most of the multigrid methods require step size strategy and the determination of tangent vectors on the fine grid except the PLTMGC.

(2) In the two-grid schemes, exploiting symmetry of the Laplace operator is manifest on both coarse and fine spaces. In the case of single grid or multigrid schemes, however, in order to exploit symmetry of the Laplacian, one either has to solve bordered linear systems by using the block elimination algorithm or choose a proper constraint vector to make the augmented matrices symmetric.

(3) From Table 3 we see that Algorithm 4.1 runs faster and more efficiently than the multigrid-continuation algorithm. We obtained similar results for Example 1 which are not shown here.

(4) Finally, our numerical results show that the two-grid centered difference discretization scheme may fail to converge near folds of semilinear elliptic eigenvalue problems. We suspect that it is probably the discretization error that makes this scheme less robust than the finite element one.

Acknowledgments. The authors would like to thank the two referees for their valuable comments that have improved the original version of this paper.

PARALLEL FULL SPACE SQP LAGRANGE–NEWTON–KRYLOV–SCHWARZ ALGORITHMS FOR PDE-CONSTRAINED OPTIMIZATION PROBLEMS*

ERNESTO E. PRUDENCIO†, RICHARD BYRD‡, AND XIAO-CHUAN CAI‡

Abstract. Optimization problems constrained by nonlinear partial differential equations have been the focus of intense research in scientific computing lately. Current methods for the parallel numerical solution of such problems involve sequential quadratic programming (SQP), with either reduced or full space approaches. In this paper we propose and investigate a class of parallel full space SQP Lagrange–Newton–Krylov–Schwarz (LNKSz) algorithms. In LNKSz, a Lagrangian functional is formed and differentiated to obtain a Karush–Kuhn–Tucker (KKT) system of nonlinear equations. An inexact Newton method with line search is then applied. At each Newton iteration the linearized KKT system is solved with a Schwarz preconditioned Krylov subspace method. We apply LNKSz to the parallel numerical solution of some boundary control problems of two-dimensional incompressible Navier–Stokes equations. Numerical results are reported for different combinations of Reynolds number, mesh size, and number of parallel processors. We also compare the application of the LNKSz method to flow control problems against the application of the Newton–Krylov–Schwarz (NKSz) method to flow simulation problems.

Key words. nonlinear partial differential equations constrained optimization, inexact Newton method, domain decomposition, Schwarz preconditioners, parallel computing, flow control, incompressible Navier–Stokes equations

1. Introduction.

In this paper we describe a general framework for solving optimization problems in interaction with nonlinear partial differential equations (PDEs). The focus is on how to adapt state-of-the-art PDE solvers to the requirements of optimization methods, while allowing for an efficient parallel implementation. Our method treats the differential equations as equality constraints. In order to demonstrate its effectiveness, the problem of optimizing fluid flows modeled by incompressible Navier–Stokes equations on two-dimensional domains is considered. Among optimization problems with constraints, those constrained by nonlinear PDEs are very challenging, both mathematically and computationally. Examples of such problems are inverse, optimal design, and optimal control problems. In inverse problems some parameters of the governing equations of the system behavior are not known and must be estimated by analysis of experimental system output data [3, 34, 45]. Optimal design problems usually refer to problems where the variable is the shape of a domain and one has to find the best shape that minimizes or maximizes an objective function

[35]. In optimal control problems one usually searches for the best feasible control variables, such as boundary values or external forces that minimize or maximize a certain system behavior, such as turbulence [4, 6, 10, 23, 43]. In this paper, we consider only boundary control problems, which refer to the control of the system through boundary conditions. In general, a control problem can be described as

$$\begin{cases} \text{Find controls } \mathbf{u} \in \mathbf{U} \text{ and states } \mathbf{s} \in \mathbf{S} \\ \text{such that } \mathcal{F}(\mathbf{s}, \mathbf{u}) \text{ is minimized,} \\ \text{subject to } \mathbf{C}(\mathbf{s}, \mathbf{u}) \geqslant \mathbf{0}. \end{cases}$$

Here $\mathbf{S}$ and $\mathbf{U}$ are called state and control spaces, respectively; the state variables $\mathbf{s}$ represent the state of the system being controlled; the control variables $\mathbf{u}$ represent the means one has to control the system; the objective or cost functional $\mathcal{F} : \mathbf{S} \times \mathbf{U} \to \mathbb{R}$ to be minimized (or maximized) represents the reason why one wants to control the system; and constraints $\mathbf{C}(\mathbf{s}, \mathbf{u}) \geqslant \mathbf{0}$ represent the system behavior and other constraints imposed on state and control variables.

In flow control problems [16, 26, 28, 29], typical state variables are velocity, pressure, temperature, and internal energy. Control variables might be defined on the boundary or inside the flow domain and can be the temperature, velocity, external force, etc. The objective can be, for instance, minimization of turbulence or maximization of mixing. The constraints are given by the physical equations that must be obeyed by the system being controlled, e.g., Navier–Stokes equations, and by eventual bounds on the state and control variables. The discipline of flow control comprises many other disciplines, e.g., fluid mechanics, nonlinear PDEs, optimization algorithms, discretization techniques, numerical methods, high-performance computing, control engineering, microelectromechanical systems, and nanoelectromechanical systems [7]. In addition, the control of fluid flows has many applications as well, e.g., internal combustion engines (efficiency and emissions), heat transfer, chemical reactors, and aerodynamic surfaces [40].

For finite dimensional equality constrained optimization problems there are two major families of techniques: reduced space sequential quadratic programming (SQP) methods and full space SQP methods. Reduced space methods have been the method of choice until recently since they require much less memory, even though many subiterations are needed to converge the outer iterations and the parallel scalability is less ideal. As more powerful computer systems with lots of memory and many processors become available, full space methods seem to be more appropriate due to their increased scalability. One such method, Lagrange–Newton–Krylov–Schur (LNKSr), was introduced in [8, 9], where four block factorization based preconditioners, as well as globalization techniques and heuristics, are proposed and tested. In this paper we replace the Schur-type preconditioner with an overlapping Schwarz method, which has a better asymptotic convergence rate and is easier to convert to a nonlinear preconditioner [13, 14, 31] for highly nonlinear problems.

The rest of the paper is organized as follows. Section 2 discusses the numerical solution of optimal control problems with equality constraints. Section 3, the core of this paper, presents the full space SQP [illegible] (LNKSz) method for the parallel numerical solution of such problems and also briefly describes some current methods that have already appeared in the literature. Section 4 presents some boundary flow control problems, which are then solved in section 5 with LNKSz. Numerical experiments are performed and analyzed for different combinations of Reynolds number, mesh size, and number of parallel processors. Final conclusions are given in section 6.

2. Optimal control with equality constraints. In this paper we focus on optimal control problems with equality constraints:

$$\left\{ \begin{array}{ll} \min\limits_{(\mathbf{s},\mathbf{u})\in\mathbf{S}\times\mathbf{U}} & \mathcal{F}(\mathbf{s},\mathbf{u}) \\ \text{subject to} & \mathbf{C}(\mathbf{s},\mathbf{u}) = \mathbf{0} \in \mathbf{Y}, \end{array} \right. \tag{2.1}$$

where $\mathbf{S}$, $\mathbf{U}$, and $\mathbf{Y}$ are normed spaces, $\mathcal{F} : \mathbf{S} \times \mathbf{U} \to \mathbb{R}$ is the objective function, $\mathbf{C} : \mathbf{S} \times \mathbf{U} \to \mathbf{Y}$ represents the constraints, and $\mathbf{C}(\cdot,\cdot) = \mathbf{0}$ is referred to as state equations or a forward problem. The Lagrangian functional $\mathcal{L} : \mathbf{S} \times \mathbf{U} \times \mathbf{Y}^* \to \mathbb{R}$ associated with (2.1) is defined by

$$\mathcal{L}(\mathbf{s},\mathbf{u},\boldsymbol{\lambda}) \equiv \mathcal{F}(\mathbf{s},\mathbf{u}) + \langle \boldsymbol{\lambda}, \mathbf{C}(\mathbf{s},\mathbf{u})\rangle_{\mathbf{Y}} \quad \forall\ (\mathbf{s},\mathbf{u},\boldsymbol{\lambda}) \in \mathbf{S} \times \mathbf{U} \times \mathbf{Y}^*, \tag{2.2}$$

where $\mathbf{Y}^*$ is the adjoint space of $\mathbf{Y}$, $\langle\cdot,\cdot\rangle_{\mathbf{Y}}$ denotes the duality pairing, and variables $\boldsymbol{\lambda}$ are called Lagrange multipliers or adjoint variables.

When the constraints are PDEs over a domain Ω, the discretization necessary for the solution of (2.1) can occur at two different points in the logical development of an algorithm. In the first case, the [illegible] (OTD) approach, one demonstrates that if $(\hat{\mathbf{s}},\hat{\mathbf{u}})$ is a (local) solution of (2.1), then there exist Lagrange multipliers $\hat{\boldsymbol{\lambda}}$ such that $(\hat{\mathbf{s}},\hat{\mathbf{u}},\hat{\boldsymbol{\lambda}})$ is a critical point of $\mathcal{L}$. So, under sufficient smoothness assumptions, one obtains, as necessary condition for a solution, a system of equations, called the Karush–Kuhn–Tucker (KKT) or optimality system, which is then discretized, generating a finite dimensional system of nonlinear equations [27, 32, 41].

In the second case, the [illegible] (DTO) approach, one begins by creating a mesh Ω_h of characteristic size $h > 0$ and then discretizing problem (2.1), obtaining a finite dimensional equality constrained optimization problem with $\mathbf{S} = \mathbb{R}^{n_{s,h}}$, $\mathbf{U} = \mathbb{R}^{n_{u,h}}$, and $\mathbf{Y} = \mathbb{R}^{m_h} = \mathbf{Y}^*$. Under sufficient smoothness conditions the KKT system becomes $\nabla\mathcal{L}_h(\hat{\mathbf{s}},\hat{\mathbf{u}},\hat{\boldsymbol{\lambda}}) = \mathbf{0} \in \mathbb{R}^{n_{s,h}+n_{u,h}+m_h}$. The theory for finite dimensional constrained optimization problems guarantees, under appropriate assumptions, the existence of such Lagrange multipliers $\hat{\boldsymbol{\lambda}}$. It should be pointed out that the discrete KKT systems from both approaches are [illegible] necessarily the same.

No approach, however, has a clear advantage over the other [26]. In both cases, the derivation of the Lagrangian w.r.t. state (control, Lagrange multiplier) variables results in the adjoint (control, state, respectively) equations. OTD usually demands the weak formulation of the state PDEs and allows the use of different meshes and techniques (e.g., boundary conditions for infinite domains, or shock-wave capturing schemes for the case of flows) for the state and adjoint equations. DTO, on the other hand, guarantees a consistency between the gradients of the objective function and of the Lagrangian functional and is also suited for the use of automatic differentiation.

From now on, we work only with the DTO approach. For simplicity, let us omit the symbols "h" and "$\hat{\ }$" and use the notation $N \equiv n_s + n_u + m$ and $\mathbf{X} \equiv (\mathbf{x},\boldsymbol{\lambda}) \equiv (\mathbf{s},\mathbf{u},\boldsymbol{\lambda}) \in \mathbb{R}^N$. The KKT system becomes

$$\mathbf{F}(\mathbf{X}) \equiv \begin{pmatrix} \nabla_{\mathbf{x}}\mathcal{L} \\ \nabla_{\boldsymbol{\lambda}}\mathcal{L} \end{pmatrix} = \begin{pmatrix} \nabla\mathcal{F} + \boldsymbol{\nabla}\mathbf{C}^T\boldsymbol{\lambda} \\ \mathbf{C}(\mathbf{s},\mathbf{u}) \end{pmatrix} = \begin{pmatrix} \nabla_{\mathbf{s}}\mathcal{F} + \boldsymbol{\nabla}_{\mathbf{s}}\mathbf{C}^T\boldsymbol{\lambda} \\ \nabla_{\mathbf{u}}\mathcal{F} + \boldsymbol{\nabla}_{\mathbf{u}}\mathbf{C}^T\boldsymbol{\lambda} \\ \mathbf{C}(\mathbf{s},\mathbf{u}) \end{pmatrix} = \mathbf{0}, \tag{2.3}$$

where $\mathbf{F} : \mathbb{R}^N \to \mathbb{R}^N$, $\nabla_{\mathbf{x}}\mathcal{L}$ denotes the gradient of $\mathcal{L}$ w.r.t. state and control variables, with similar meaning holding for $\nabla_{\boldsymbol{\lambda}}\mathcal{L}$, $\nabla_{\mathbf{s}}\mathcal{F}$, and $\nabla_{\mathbf{u}}\mathcal{F}$, while $\boldsymbol{\nabla}\mathbf{C}$ denotes the Jacobian of $\mathbf{C}$ and $\boldsymbol{\nabla}_{\mathbf{s}}\mathbf{C}$ and $\boldsymbol{\nabla}_{\mathbf{u}}\mathbf{C}$ denote the Jacobian of $\mathbf{C}$ w.r.t. state and control variables, respectively. In (2.3), we refer to $\boldsymbol{\nabla}_{\mathbf{s}}\mathbf{C}$ as the linearized forward operator.

System (2.3) can be solved with an inexact Newton method [21, 22]. Given an initial guess $\mathbf{X}^{(0)}$, at each iteration $k = 0, 1, 2, \ldots$, an approximate solution

$$\mathbf{p}^{(k)} \equiv \left(\mathbf{p}_{\mathbf{x}}^{(k)}, \mathbf{p}_{\boldsymbol{\lambda}}^{(k)}\right) \equiv \left(\mathbf{p}_{\mathbf{s}}^{(k)}, \mathbf{p}_{\mathbf{u}}^{(k)}, \mathbf{p}_{\boldsymbol{\lambda}}^{(k)}\right)$$

of the linearized KKT system

$$\mathbf{K}^{(k)}\ \mathbf{p}^{(k)} \ = \ -\mathbf{F}^{(k)} \tag{2.4}$$

is computed, where $\mathbf{K}^{(k)} = \boldsymbol{\nabla}\mathbf{F}(\mathbf{X}^{(k)})$ and $\mathbf{F}^{(k)} = \mathbf{F}(\mathbf{X}^{(k)})$. The KKT matrix $\mathbf{K}^{(k)}$ is the transpose of the Hessian of the Lagrangian $\mathcal{L}$, is symmetric indefinite under sufficient smoothness assumptions, and can be computed by a finite difference approximation. System (2.4) can also be written as (all terms should be understood as evaluated at $\mathbf{X}^{(k)}$)

$$\begin{bmatrix} \boldsymbol{\nabla}^2_{\mathbf{xx}}\mathcal{L}^{(k)} & \boldsymbol{\nabla}\mathbf{C}^{(k)^T} \\ \boldsymbol{\nabla}\mathbf{C}^{(k)} & \mathbf{0} \end{bmatrix} \begin{pmatrix} \mathbf{p}_{\mathbf{x}}^{(k)} \\ \mathbf{p}_{\boldsymbol{\lambda}}^{(k)} \end{pmatrix} = - \begin{pmatrix} \nabla_{\mathbf{x}}\mathcal{L}^{(k)} \\ \mathbf{C}^{(k)} \end{pmatrix}.$$

Thus, if $\boldsymbol{\nabla}\mathbf{C}^{(k)}$ has full rank and $\boldsymbol{\nabla}^2_{\mathbf{xx}}\mathcal{L}^{(k)}$ is positive definite in the tangent space of the constraints (i.e., $\mathbf{d}^T[\boldsymbol{\nabla}^2_{\mathbf{xx}}\mathcal{L}^{(k)}]\mathbf{d} > 0$ for all $\mathbf{d} \neq \mathbf{0}$ such that $[\boldsymbol{\nabla}\mathbf{C}^{(k)}]\mathbf{d} = \mathbf{0}$), then we can interpret $(\mathbf{p}_{\mathbf{x}}^{(k)}, \mathbf{p}_{\boldsymbol{\lambda}}^{(k)})$ as being the [illegible] solution and Lagrange multipliers of

$$\begin{cases} \min\limits_{\mathbf{p_x} \in \mathbf{S}\times\mathbf{U}} & \frac{1}{2}\mathbf{p}_{\mathbf{x}}^T[\boldsymbol{\nabla}^2_{\mathbf{xx}}\mathcal{L}^{(k)}]\mathbf{p}_{\mathbf{x}} + \nabla_{\mathbf{x}}\mathcal{L}^{(k)^T}\mathbf{p}_{\mathbf{x}} \\ \text{subject to} & \boldsymbol{\nabla}\mathbf{C}^{(k)}\mathbf{p}_{\mathbf{x}} + \mathbf{C}^{(k)} = \mathbf{0} \in \mathbf{Y}. \end{cases}$$

This interpretation justifies the use of the terminology [illegible] (SQP) for methods involving (2.4); see [36]. Alternatively, one can interpret $(\mathbf{p}_{\mathbf{x}}^{(k)}, \boldsymbol{\lambda}^{(k)} + \mathbf{p}_{\boldsymbol{\lambda}}^{(k)})$ as the solution and Lagrange multipliers for the quadratic programming (QP) using, in its objective function, $\nabla\mathcal{F}^{(k)}$ instead of $\nabla_{\mathbf{x}}\mathcal{L}^{(k)}$.

After approximately solving (2.4), one may use a globalization method such as [illegible] or [illegible] [44]. In this study we focus on a line search approach, where the next iterate is $\mathbf{X}^{(k+1)} = \mathbf{X}^{(k)} + \alpha^{(k)}\mathbf{p}^{(k)}$ and the step length $\alpha^{(k)}$ is selected by backtracking until the sufficient decrease condition

$$\phi(\mathbf{X}^{(k)} + \alpha^{(k)}\mathbf{p}^{(k)}) \leqslant \phi(\mathbf{X}^{(k)}) + \alpha^{(k)}c_1\nabla\phi(\mathbf{X}^{(k)})^T\mathbf{p}^{(k)} \tag{2.5}$$

is satisfied. Here ϕ is a merit function, and c_1 is a constant satisfying $0 < c_1 < 1/2$. For constrained optimization, merit functions such as l_1 or augmented Lagrangian [5, 33] are most commonly used. In contrast to the standard merit function $\|\mathbf{F}(\mathbf{X})\|_2^2/2$, which is commonly used for systems of nonlinear equations, these merit functions try to balance the sometimes conflicting goals of reducing the objective function and satisfying the constraints [36]. We use the augmented Lagrangian $\phi_{AL} : \mathbb{R}^N \to \mathbb{R}$ in our experiments in this paper. Given a penalty parameter $\rho > 0$, it is defined by

$$\phi_{AL}(\mathbf{X}; \rho) = \mathcal{L}(\mathbf{s}, \mathbf{u}, \boldsymbol{\lambda}) + \frac{\rho}{2}\ \|\mathbf{C}(\mathbf{s}, \mathbf{u})\|_2^2 \quad \forall\ \mathbf{X} = (\mathbf{s}, \mathbf{u}, \boldsymbol{\lambda}) \in \mathbf{S} \times \mathbf{U} \times \mathbf{Y}.$$

At iteration k, $\rho = \rho^{(k)}$ must be such that we obtain descent directions $\mathbf{p}^{(k)}$, i.e.,

$$(\nabla\phi_{AL}(\mathbf{X}^{(k)}; \rho^{(k)}))^T\mathbf{p}^{(k)} = (\nabla\mathcal{L}^{(k)})^T\mathbf{p}^{(k)} + \rho^{(k)}\ \mathbf{C}^{(k)^\mathbf{T}}[\boldsymbol{\nabla}\mathbf{C}^{(k)}]\mathbf{p}_{\mathbf{x}}^{(k)} < 0. \tag{2.6}$$

Since $\mathbf{C}^{(k)^{\mathbf{T}}}[\boldsymbol{\nabla}\mathbf{C}^{(k)}]\mathbf{p}_{\mathbf{x}}^{(k)} = -\|\mathbf{C}^{(k)}\|_2^2$ for an exact step, it is reasonable to expect

$$\mathbf{C}^{(k)^{\mathbf{T}}}[\boldsymbol{\nabla}\mathbf{C}^{(k)}]\mathbf{p}_{\mathbf{x}}^{(k)} < 0 \tag{2.7}$$

for approximate steps if $\mathbf{C}^{(k)} \neq \mathbf{0}$ and the tolerances for the Krylov subspace method are small enough and the preconditioner is good enough to guarantee that the Krylov subspace method does not stop by achieving the maximum allowed number of iterations. If (2.7) does not hold, we can continue the Krylov iterations, with eventual smaller tolerances, until it does. Once (2.7) holds, we then use a fairly common strategy where we demand that $\rho^{(k)}$ satisfy

$$(\nabla\phi_{AL}(\mathbf{X}^{(k)};\rho^{(k)}))^T\mathbf{p}^{(k)} \leqslant \frac{\rho^{(k)}}{2}\ \mathbf{C}^{(k)^{\mathbf{T}}}[\boldsymbol{\nabla}\mathbf{C}^{(k)}]\mathbf{p}_{\mathbf{x}}^{(k)},$$

that is,

$$\rho^{(k)} \geqslant \overline{\rho}^{(k)} = -2\frac{(\nabla\mathcal{L}^{(k)})^T\mathbf{p}^{(k)}}{\mathbf{C}^{(k)^{\mathbf{T}}}[\boldsymbol{\nabla}\mathbf{C}^{(k)}]\mathbf{p}_{\mathbf{x}}^{(k)}}.$$

We then choose

$$\rho^{(k)} = \max\{\overline{\rho}^{(k)}, \rho^{(k-1)}\},$$

where $\rho^{(-1)} > 0$ is a given positive value.

However, if $\mathbf{C}^{(k)} = \mathbf{0}$, then there is no way to guarantee a descent direction. This is a fundamental issue with line search methods. Some algorithms handle this by modifying the Hessian to make it positive definite on the null space of $\boldsymbol{\nabla}\mathbf{C}^{(k)}$, but for problems of the size we are considering there is no efficient way to check positive definiteness.

In all tests described in this paper, (2.7) held for every step generated, as long as we made the absolute Krylov tolerance small enough that at least one Krylov iteration was performed. In addition, it is worth noting that, in each run, the value of $\rho^{(k)}$ became fixed before 60% of the iterations had been made. Thus the heuristic merit parameter updating strategy described above appeared to work well for the examples of this paper.

3. Parallel full space SQP Lagrange–Newton–Krylov–Schwarz. In this section we briefly review some existing techniques and then present a new parallel algorithm based on a Newton method with line search and an overlapping Schwarz preconditioner for solving (2.1). The new algorithm will be referred to as the Lagrange–Newton–Krylov–Schwarz (LNKSz) algorithm. All these methods differentiate themselves by the way (2.4) is solved.

3.1. Brief review of existing methods. In this subsection we assume that the number of constraints is equal to the number of state variables, i.e.,

$$m = n_s, \tag{3.1}$$

in (2.1); that is, $\boldsymbol{\nabla}_{\mathbf{s}}\mathbf{C}$ is a square matrix of dimension m. Situation (3.1) usually happens after the discretization of PDE-constrained optimization problems that involve well-posed boundary value problems as constraints. To explain the existing techniques

[8, 9] we need the following block-LU factorization:

$$\mathbf{K}^{(k)} = \begin{bmatrix} \nabla^2_{\mathbf{ss}}\mathcal{L}\nabla_{\mathbf{s}}\mathbf{C}^{-1} & \mathbf{0} & \mathbf{I} \\ \nabla^2_{\mathbf{su}}\mathcal{L}\nabla_{\mathbf{s}}\mathbf{C}^{-1} & \mathbf{I} & \mathbf{L}^T \\ \mathbf{I} & \mathbf{0} & \mathbf{0} \end{bmatrix} \begin{bmatrix} \nabla_{\mathbf{s}}\mathbf{C} & \nabla_{\mathbf{u}}\mathbf{C} & \mathbf{0} \\ \mathbf{0} & \mathbf{H}_1 & \mathbf{0} \\ \mathbf{0} & \mathbf{H}_2 & \nabla_{\mathbf{s}}\mathbf{C}^T \end{bmatrix}, \tag{3.2}$$

where $\mathbf{H}_1 = \nabla^2_{\mathbf{uu}}\mathcal{L} - \mathbf{L}^T\mathbf{H}_2 - \nabla^2_{\mathbf{su}}\mathcal{L}\mathbf{L}$, $\mathbf{H}_2 = \nabla^2_{\mathbf{us}}\mathcal{L} - \nabla^2_{\mathbf{ss}}\mathcal{L}\mathbf{L}$, and $\mathbf{L} = \nabla_{\mathbf{s}}\mathbf{C}^{-1}\nabla_{\mathbf{u}}\mathbf{C}$. The matrix $\mathbf{H}_1$ is the Schur complement for $\mathbf{p}^{(k)}_{\mathbf{u}}$ and is called the reduced Hessian of the Lagrangian.

Full space SQP methods solve the entire system of linear equations (2.4) simultaneously, while reduced space SQP methods divide the problem into smaller ones, first solving for the n_u control variables only and then solving for state variables and Lagrange multipliers. Newton reduced space SQP (N-RSQP) methods basically correspond to the block-LU factorization (3.2). Quasi-Newton reduced space SQP (QN-RSQP) methods drop second order terms from the right-hand side of the equations in N-RSQP and also substitute $\mathbf{H}_1$ by quasi-Newton approximations, usually via BFGS [36].

Reduced methods have the advantage of requiring less memory. However, N-RSQP demands too many solutions of systems of m linear equations per outer iteration, while in QN-RSQP the number of outer iterations tends to increase too much as n_u grows. Full space methods try to overcome the lack of parallel scalability of reduced approaches, but they also present difficulties, not only because a descent direction is not guaranteed but also due to the linearized KKT system: it is more than twice the size of the forward problem, usually indefinite (a property known to slow down Krylov solvers), and very ill conditioned. One such method, Lagrange–Newton–Krylov–Schur (LNKSr), was presented in [8, 9], where four preconditioners based on the block factorization (3.2), as well as globalization techniques and heuristics (such as maintaining a BFGS approximation of $\mathbf{H}_1$ and using a QN-RSQP step in case the original LNKSr computed step fails), are proposed and tested. LNKSr attempts to transform the problem of finding a good preconditioner for the KKT matrix to the problem of finding a good preconditioner for the linearized forward operator.

3.2. Lagrange–Newton–Krylov–Schwarz. As mentioned earlier, the key element of a successful full space approach is the preconditioning of the Jacobian of the KKT system, which is indefinite and extremely ill conditioned. A good preconditioner has to be able to substantially reduce the condition number and, at the same time, provide good scalability so that the potential of massively parallel computers can be realized. The Schur complement preconditioner used in LNKSr is an [illegible] type of technique, in which a sequential block elimination step is needed to form the Schur complement w.r.t. the control variable. In contrast to operator-splitting, Schwarz-type preconditioners are [illegible] in the sense that all variables are treated equally and the partition is based completely on the physical domain Ω. Because there is no need to eliminate any variables from the system, there is one fewer sequential step in the preconditioning process. Another advantage of LNKSz method is that it does not demand assumption (3.1). With LNKSz we can, for instance, deal directly with full [30] boundary control problems, where an equation like (4.6) is explicitly added to the constraints.

Schwarz preconditioners can be used in one-level or multilevel approaches and, in each case, with a combination of additive and/or multiplicative algorithms [39, 42]. In this paper we deal only with one-level additive algorithms [20]. Let $\Omega \subset \mathbb{R}^2$ be a bounded open domain on which the control problem is defined. We consider only

simple box domains with uniform mesh of characteristic size h here. To obtain the overlapping partition, we first partition the domain into nonoverlapping subdomains Ω_j^0, $j = 1, \ldots, N_s$. Then we extend each subdomain Ω_j^0 to a larger subdomain Ω_j^δ, i.e., $\Omega_j^0 \subset \Omega_j^\delta$. Here $\delta > 0$ indicates the size of the overlap. Only simple box decomposition is considered in this paper; i.e., all the subdomains Ω_j^0 and Ω_j^δ are rectangular and made up of an integral number of fine mesh cells. For boundary subdomains, we simply cut off the part that is outside Ω. Let $H > 0$ denote the characteristic diameter of subdomains Ω_j. Let N, N_j^0, and N_j denote the number of degrees of freedom associated with Ω, Ω_j^0, and Ω_j^δ, respectively. Let $\mathbf{K}$ be an $N \times N$ matrix of a linear system that needs to be solved during the numerical solution process of the differential problem. Let d indicate the degree of freedom per mesh point. For simplicity let us assume that d is the same throughout the entire mesh. We define the $N_j \times N$ matrix $\mathbf{R}_j^\delta$ as follows: Its $d \times d$ block element $(\mathbf{R}_j^\delta)_{\ell_1,\ell_2}$ is either (a) an identity block if the integer indices $1 \leqslant \ell_1 \leqslant N_j/d$ and $1 \leqslant \ell_2 \leqslant N/d$ are related to the same mesh point and this mesh point belongs to $\Omega_j^{'}$ or (b) a zero block otherwise. The multiplication of $\mathbf{R}_j^\delta$ with an $N \times 1$ vector generates a smaller $N_j \times 1$ vector by discarding all components corresponding to mesh points outside $\Omega_j^{'}$. The $N_j \times N$ matrix $\mathbf{R}_j^0$ is similarly defined, with the difference that its application to an $N \times 1$ vector also zeros all those components corresponding to mesh points on $\Omega_j^{'} \setminus \Omega_j$. We denote by $\mathbf{K}_j$ the $N_j \times N_j$ subdomain matrix given by

$$\mathbf{K}_j = \mathbf{R}_j^\delta \ \mathbf{K} \ \left(\mathbf{R}_j^\delta\right)^T.$$

Let $\mathbf{B}_j^{-1}$ be either an inverse of $\mathbf{K}_j$ or a preconditioner for $\mathbf{K}_j$. The classical one-level additive Schwarz preconditioner $\mathbf{B}_{asm}^{-1}$ for $\mathbf{K}$ is defined as

$$\mathbf{B}_{asm}^{-1} = \sum_{j=1}^{N_s} \left(\mathbf{R}_j^\delta\right)^T \mathbf{B}_j{}^{-1} \mathbf{R}_j^\delta.$$

In addition to this standard additive Schwarz method (ASM) described above, we also consider the newly introduced restricted version (RAS) of the method [11, 15]. For some applications, the restricted version requires less communication time since one of the restriction or extension operations does not involve any overlap. The RAS preconditioner is defined as

$$\mathbf{B}_{ras}^{-1} = \sum_{j=1}^{N_s} \left(\mathbf{R}_j^\delta\right)^T \mathbf{B}_j{}^{-1} \mathbf{R}_j^0.$$

Some numerical comparisons of the ASM and RAS are presented later in the paper.

When the Schwarz preconditioner is applied to symmetric positive definite systems arising from the discretization of elliptical problems defined in $H_0^1(\Omega)$, the condition number κ of the preconditioned system satisfies $\kappa \leqslant C\,(1 + H/\delta)\,/H^2$, where C is independent of h, H, δ, and the shapes of Ω and Ω_j^δ [39]; that is, a Schwarz preconditioned Krylov subspace method is expected to have the following properties:

(3.3) The number of iterations grows approximately proportional to $1/H$;

(3.4) If δ is maintained proportional to H, the number of iterations is bounded independently of h and H/h (a parameter related to the number of degrees of freedom of each subproblem);

(3.5) The convergence gets better as δ is increased.

Theoretically, results (3.3)–(3.5) may not be applied immediately to Krylov subspace methods, e.g., GMRES [24, 38], for the solution of indefinite linearized KKT systems. Nonetheless, we carefully examine all the properties in our numerical experiments. In particular, let $\bar{l}$ be the average number of Schwarz preconditioned GMRES iterations per linearized KKT system. We look for the following scalability properties:

(3.6) For fixed h and δ, $\bar{l}$ increases as H decreases;

(3.7) For fixed H and δ, $\bar{l}$ is not very sensitive to the mesh refinement;

(3.8) For fixed h and H, $\bar{l}$ decreases as δ increases.

4. Boundary control of incompressible Navier–Stokes flows. In this section we discuss the boundary control of the two-dimensional steady-state incompressible Navier–Stokes equations in the velocity-vorticity formulation. The velocity is denoted by $\mathbf{v} = (v_1, v_2)$ and the vorticity by ω. Let Ω be an open and bounded polygonal domain in the plane, with $\Gamma = \partial\Omega$ its boundary and $\boldsymbol{\nu}$ the unit outward normal vector along Γ. Let $\mathbf{f}$ be a given external force defined in Ω. An example of a flow simulation problem consists of finding (v_1, v_2, ω) such that

$$
\left\{
\begin{array}{lcll}
-\Delta v_1 - \dfrac{\partial \omega}{\partial x_2} & = & 0 & \text{in } \Omega, \\
-\Delta v_2 + \dfrac{\partial \omega}{\partial x_1} & = & 0 & \text{in } \Omega, \\
-\Delta \omega + Re\ v_1 \dfrac{\partial \omega}{\partial x_1} + Re\ v_2 \dfrac{\partial \omega}{\partial x_2} - Re\ \text{curl}\ \mathbf{f} & = & 0 & \text{in } \Omega, \\
\mathbf{v} - \mathbf{v}_D & = & \mathbf{0} & \text{on } \Gamma, \\
\omega + \dfrac{\partial v_1}{\partial x_2} - \dfrac{\partial v_2}{\partial x_1} & = & 0 & \text{on } \Gamma,
\end{array}
\right. \tag{4.1}
$$

where Re is the Reynolds number, $\mathbf{v}_D$ is a prescribed boundary velocity satisfying $\int_\Gamma \mathbf{v}_D \cdot \boldsymbol{\nu}\, d\Gamma = 0$, and $\text{curl}\ \mathbf{f} = -\frac{\partial f_1}{\partial x_2} + \frac{\partial f_2}{\partial x_1}$. If $\mathbf{v} \in C^3(\Omega) \times C^3(\Omega)$, then [18]

$$
\omega + \frac{\partial v_1}{\partial x_2} - \frac{\partial v_2}{\partial x_1} = 0 \quad \text{in } \Omega \tag{4.2}
$$

and

$$
\nabla \cdot \mathbf{v} = 0 \quad \text{in } \Omega. \tag{4.3}
$$

These two equations show the consistency of the two-dimensional velocity-vorticity formulation of incompressible flows, since (4.2) is the formal definition of the vorticity and (4.3) is related to the physical law of mass conservation.

An example of a boundary control problem consists of finding $(v_1, v_2, \omega, u_1, u_2)$ such that the minimization

$$
\min_{(\mathbf{s},\mathbf{u}) \in \mathbf{S} \times \mathbf{U}} \mathcal{F}(\mathbf{s}, \mathbf{u}) = \frac{1}{2} \int_\Omega \omega^2\, d\Omega + \frac{c}{2} \int_{\Gamma_u} \|\mathbf{u}\|_2^2\, d\Gamma \tag{4.4}
$$

is achieved subject to the constraints

$$
(4.5)\quad \begin{cases}
-\Delta v_1 - \dfrac{\partial \omega}{\partial x_2} = 0 & \text{in } \Omega,\\
-\Delta v_2 + \dfrac{\partial \omega}{\partial x_1} = 0 & \text{in } \Omega,\\
-\Delta \omega + Re\ v_1 \dfrac{\partial \omega}{\partial x_1} + Re\ v_2 \dfrac{\partial \omega}{\partial x_2} - Re\ \text{curl}\ \mathbf{f} = 0 & \text{in } \Omega,\\
v_i - v_{D,i} = 0 & \text{on } \Gamma_{D,i}, \quad i = 1,2,\\
\dfrac{\partial v_i}{\partial \boldsymbol{\nu}} - v_{N,i} = 0 & \text{on } \Gamma_{N,i}, \quad i = 1,2,\\
\mathbf{v} - \mathbf{u} = \mathbf{0} & \text{on } \Gamma_u,\\
\omega + \dfrac{\partial v_1}{\partial x_2} - \dfrac{\partial v_2}{\partial x_1} = 0 & \text{on } \Gamma,\\
\displaystyle\int_\Gamma \mathbf{v}\cdot\boldsymbol{\nu}\, d\Gamma = 0, &
\end{cases}
$$

where, for $i = 1, 2$, $\Gamma = \Gamma_{D,i} \cup \Gamma_{N,i} \cup \Gamma_u$, $\Gamma_{D,i}$ ($\Gamma_{N,i}$) is the part of the boundary where the v_i velocity component is specified through a Dirichlet (Neumann) condition with a prescribed velocity $v_{D,i}$, and Γ_u is the part of the boundary where the velocity is specified through a Dirichlet condition with a control velocity $\mathbf{u}$. The positive constant parameter c is used to adjust the relative importance of the control norms in achieving the minimization, thus indirectly constraining the size of those norms. The physical objective behind problem (4.4)–(4.5) is the minimization of turbulence [1, 7, 30]. The last constraint, given by

$$
(4.6)\qquad \int_\Gamma \mathbf{v}\cdot\boldsymbol{\nu}\, d\Gamma = 0,
$$

is necessary for the consistency with the physical law of mass conservation. Therefore, the control $\mathbf{u} = (u_1, u_2)$ cannot be any control: it must belong to the space of functions satisfying (4.6). We denote problems like (4.4)–(4.5), where controls are allowed to assume nonzero normal values at the boundary, as [illegible] boundary control problems (BCPs) [30]. In these kinds of problems assumption (3.1) is not valid, due to the extra constraint (4.6). This fact also complicates the parallel finite differences approximation of Jacobian matrices, since one does not have only PDEs (i.e., equations with local behavior) anymore. The integral condition (3.1) couples nonneighboring mesh points. An alternative formulation, which compromises between the physical law of mass conservation and the complexity of parallel Jacobian approximations, eliminates the explicit constraint (4.6), thus making (3.1) valid, but adds to the objective function the term $\tilde{c}\left[\int_\Gamma \mathbf{v}\cdot\boldsymbol{\nu}\, d\Gamma\right]^2/2$, with $\tilde{c} \gg 1$ [9].

One can also deal with [illegible] BCPs, where the control is allowed to be just tangential to the boundary (i.e., $\mathbf{u}\cdot\boldsymbol{\nu} = 0$ on Γ_u) and the velocity $\mathbf{v}$ is assumed to satisfy $\int_{\Gamma\setminus\Gamma_u} \mathbf{v}\cdot\boldsymbol{\nu}\, d\Gamma = 0$. Thus, (3.1) is valid. Since tangential BCPs restrict even more the space where the control $\mathbf{u} = (u_1, u_2)$ can exist, one naturally expects better objective function values with full BCPs. In this paper we study only tangential boundary control problems.

5. Numerical experiments. In our numerical experiments we deal with two-dimensional rectangular domains $\Omega = (0, L_1) \times (0, L_2)$, $L_2 \leqslant L_1$. All notation related to the geometry of the computational domain is depicted in Figure 5.1. In particular,

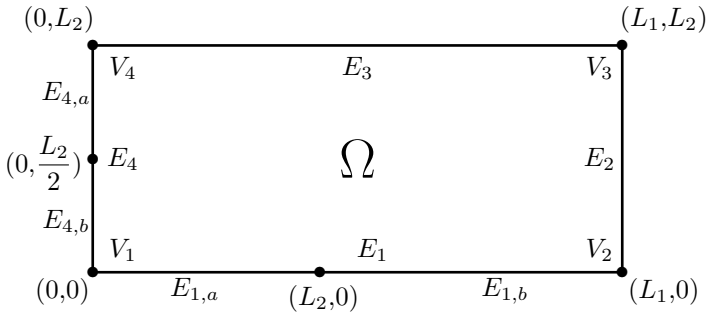

FIG. 5.1. *General rectangular domain* $\Omega = (0, L_1) \times (0, L_2)$*, with* $L_2 \leqslant L_1$*, involved in our numerical experiments.*

we define $E_{1,a} = \{(x_1, x_2) \in E_1 : 0 < x_1 \leqslant L_2\}$, $E_{1,b} = E_1 \setminus E_{1,a}$, $E_{4,a} = \{(x_1, x_2) \in E_4 : \dfrac{L_2}{2} \leqslant x_2 < L_2\}$, and $E_{4,b} = E_4 \setminus E_{4,a}$.

5.1. Flow problems. In order to simplify the implementation, we rewrite (4.4)–(4.5), defining the control $\mathbf{u}$ everywhere on Γ, but not necessarily allowing it to vary everywhere. We consider two flow problems: cavity flow and backward-facing step flow problems. In each case we describe a simulation problem and a tangential BCP. Also, we describe only the boundary conditions on the velocity and the constraints on the boundary controls, since all problems have in common the three differential equations in Ω and the boundary condition on ω that appear in (4.1). All control problems seek the minimization of the objective function (4.4) with $c = 10^{-2}$.

Lid-driven cavity flow. In this case, $L_1 = L_2 = 1$ and (see Figure 5.2(a))

$$\mathbf{f} = \left(-\sin^2(\pi x_1)\cos(\pi x_2)\sin^2(\pi x_2),\ \sin^2(\pi x_2)\cos(\pi x_1)\sin^2(\pi x_1)\right).$$

The simulation problem assumes slip rigid walls on Γ:

$$\begin{cases} \mathbf{v} \cdot \boldsymbol{\nu} &= 0 & \text{on } \Gamma, \\ \dfrac{\partial \mathbf{v}}{\partial \boldsymbol{\nu}} &= \mathbf{0} & \text{on } \Gamma. \end{cases} \tag{5.1}$$

The tangential BCP has $\Gamma_u = \Gamma$ and velocity and control constraints given by

$$\begin{cases} \mathbf{v} - \mathbf{u} &= \mathbf{0} & \text{on } \Gamma_u, \\ \mathbf{u} \cdot \boldsymbol{\nu} &= 0 & \text{on } \Gamma_u. \end{cases} \tag{5.2}$$

Backward-facing step flow. In this case, $L_1 = 6$, $L_2 = 1$, and $\mathbf{f} = \mathbf{0}$. We define $v_{\text{in}}(x_1, x_2) = 8(1 - x_2)(x_2 - \frac{1}{2})$ and $v_{\text{out}}(x_1, x_2) = x_2(1 - x_2)$. See Figures 5.3 and 5.6. The simulation problem has velocity boundary conditions given by

$$\begin{cases} v_1 &= 0 & \text{on } \{V_1\} \cup E_{1,b} \cup \overline{E}_3 \cup E_{4,b}, \\ v_1 &= v_{\text{in}} & \text{on } E_{4,a}, \\ v_1 &= v_{\text{out}} & \text{on } E_2, \\ \dfrac{\partial v_1}{\partial \boldsymbol{\nu}} &= 0 & \text{on } E_{1,a}, \\ v_2 &= 0 & \text{on } \Gamma \setminus E_{4,b}, \\ \dfrac{\partial v_2}{\partial \boldsymbol{\nu}} &= 0 & \text{on } E_{4,b}. \end{cases} \tag{5.3}$$

The tangential BCP has $\Gamma_u = E_{4,b} \cup \{V_1\} \cup E_{1,a}$ and velocity and control constraints given by

$$\text{(5.4)} \qquad \begin{cases} \mathbf{v} - \mathbf{u} &= \mathbf{0} & \text{on } \Gamma_u, \\ \mathbf{u} \cdot \boldsymbol{\nu} &= 0 & \text{on } \Gamma_u, \\ v_1 &= 0 & \text{on } E_{1,b} \cup \overline{E}_3, \\ v_1 &= v_{\text{in}} & \text{on } E_{4,a}, \\ v_1 &= v_{\text{out}} & \text{on } E_2, \\ v_2 &= 0 & \text{on } \Gamma \setminus \Gamma_u. \end{cases}$$

We run flow problems for $Re = 200$ and $Re = 300$. In this range of Reynolds numbers the flow is known to be steady and two-dimensional [30].

5.2. Details of numerical approaches. To discretize the flow problems, we use a five-point second order finite difference method on a uniform mesh.[1] All derivative terms of interior PDEs are discretized with a second order central difference scheme. The boundary condition $\omega + \partial v_1/\partial x_2 - \partial v_2/\partial x_1 = 0$ on Γ is also discretized with a second order approximation, using, however, only mesh points adjacent to the boundary, by applying (4.2) at these points also. This combination of second order approximation with only mesh points adjacent to the boundary is good for parallel performance reasons. We show how to achieve this combination for the boundary mesh points on edge E_1 and at corner V_1. Equations for the other boundary regions are similarly deduced. Let h denote the uniform mesh spacing. Given a mesh point, let subindices r, l, a, and b denote mesh points located, respectively, to the right of, to the left of, above, and below this given mesh point. The meanings for subindices ar, br, bl, al, rr, ll, aa, bb, etc. are straightforward. For mesh points located on edge E_1 we know that

$$w = -\frac{-3v_1 + 4v_{1,a} - v_{1,aa}}{2h} + \frac{v_{2,r} - v_{2,l}}{2h} + O(h^2),$$

$$w_a = -\frac{v_{1,aa} - v_1}{2h} + \frac{v_{2,ar} - v_{2,al}}{2h} + O(h^2).$$

Thus, taking the sum of the expressions, $v_{1,aa}$ is cancelled:

$$w + w_a + 2\frac{v_{1,a} - v_1}{h} - \frac{v_{2,ar} - v_{2,al}}{2h} - \frac{v_{2,r} - v_{2,l}}{2h} = O(h^2).$$

Using a similar technique, we obtain, for corner V_1,

$$w + w_a + w_r + w_{ar} + 2\frac{v_{1,a} - v_1}{h} + 2\frac{v_{1,ar} - v_{1,r}}{h} - 2\frac{v_{2,r} - v_2}{h} - 2\frac{v_{2,ar} - v_{2,a}}{h} = O(h^2).$$

To form an algebraic system of nonlinear equations from the finite difference equations, we need to order the unknowns and the corresponding functions. The unknowns are ordered mesh point by mesh point, in contrast to physical variable by physical variable as required by all SQP methods related to the matrix structure (3.2). At each mesh point the unknowns are ordered in the order of $v_1, v_2, \omega, u_1, u_2, \lambda_1, \lambda_2$, and λ_3. The mesh points are ordered subdomain by subdomain, for the purpose of

[1] Since our research focus in this paper is the iterative method LNKSz, we use a simple nonstaggered mesh. Another approach is to use staggered meshes in order to numerically better preserve the physical conditions (4.2) and (4.3) [18, 25, 37].

parallel processing. The ordering of the subdomains is not important since we use an additive method whose performance has nothing to do with the subdomain ordering. In order to avoid pivoting during the sparse LU method (used in our experiments), the corresponding functions are ordered as $\nabla_{\lambda_1}\mathcal{L}$,$\nabla_{\lambda_2}\mathcal{L}$,$\nabla_{\lambda_3}\mathcal{L}$, $\nabla_{u_1}\mathcal{L}$,$\nabla_{u_2}\mathcal{L}$, $\nabla_{v_1}\mathcal{L}$,$\nabla_{v_2}\mathcal{L}$, and $\nabla_{\omega}\mathcal{L}$. Because the orderings for the unknowns and for the function components are different, the Jacobian matrix becomes nonsymmetric and so we use GMRES.

Some of the numerical results obtained using LNKSz for tangential boundary flow control problems are compared with the corresponding simulation results obtained using NKSz [12]. Although NKSz has been well studied for flow simulation problems, little is known about its applicability and performance for solving KKT systems arising from flow control problems. The NKSz algorithm can be briefly described as follows:

$$
\left\{
\begin{array}{ll}
1. & \text{Initialize the iteration } k = 0 \text{ and } \mathbf{X}^{(0)} = \mathbf{0};\\
2. & \text{Decide whether to stop based on } \|\mathbf{F}(\mathbf{X}^{(k)})\|_2;\\
3. & \text{Approximately solve } \left[\boldsymbol{\nabla}\mathbf{F}(\mathbf{X}^{(k)})\right]\mathbf{p}^{(k)} = -\mathbf{F}(\mathbf{X}^{(k)}),\\
 & \text{using GMRES with a left Schwarz preconditioner;}\\
4. & \text{Perform line search } \mathbf{X}^{(k+1)} = \mathbf{X}^{(k)} + \alpha^{(k)}\mathbf{p}^{(k)}\\
 & \text{using the standard merit function } \|\mathbf{F}\|_2^2/2;\\
5. & \text{Set } k \leftarrow k+1; \text{ go to step 2.}
\end{array}
\right. \tag{5.5}
$$

LNKSz is very similar to NKSz, except that it uses an augmented Lagrangian merit function in step 4 of (5.5). Note that Reynolds continuation is not used in any of the algorithms.

In all experiments, the Jacobian matrix is constructed approximately using a multicolored central finite difference method with step size 10^{-5} [17]. In problem (4.4)–(4.5), since there is no variable with power greater than two, central finite difference approximations of the Jacobian are exact up to roundoff errors. To solve the Jacobian systems we use restarted GMRES with an absolute tolerance equal to 10^{-6}, a relative tolerance equal to 10^{-4}, a restart parameter equal to 90, and a maximum number of iterations equal to 5,000. The GMRES tolerances are checked over preconditioned residuals. Regarding the one-level additive Schwarz preconditioner, the number of subdomains is equal to the number of processors, and the extended subdomain problems have zero Dirichlet interior boundary conditions and are solved with sparse LU. The line search with the merit function defined in section 2 is performed with cubic backtracking, with $c_1 = 10^{-4}$ in (2.5) and a minimum allowed step length $\alpha^{(k)}$ equal to 10^{-6}. For augmented Lagrangian merit functions we follow the strategy explained in section 2 with $\rho^{(-1)}$=10. For Newton iterations we use an absolute stopping tolerance equal to 10^{-6} and a relative tolerance equal to 10^{-10} times the initial residual. The maximum allowed number of Newton iterations is 100.

5.3. Results of numerical experiments. All tests were performed on a cluster of Linux PCs, and our parallel object-oriented software was developed using the C++ programming language and the Portable, Extensible Toolkit for Scientific Computing (PETSc) library [2] from Argonne National Laboratory. Our main concern is the scalability of the algorithms in terms of the linear and nonlinear iteration numbers. Computing times are also reported, but they should not be taken as a reliable measure of the scalability of the algorithms because our network is relatively slow and is shared by other processes.

Results are grouped into tables according to a unique combination of problem type (simulation or control), Reynolds number Re, ASM type (standard or restricted), overlap δ, and merit function (standard or augmented Lagrangian). Each table presents

results for nine situations, related to three different sizes of meshes (parameter h) and three different numbers of processors (parameter H). For each case we report the following:

- the total number of Newton iterations: n;
- the average number of GMRES iterations per Newton iteration: $\bar{l}$;
- the total computing time in seconds spent on all Newton iterations: t_n;
- the average computing time, in seconds, per Newton iteration, spent on solving for the Newton steps: $\bar{t}_l$.

For each table we compare the behavior of $\bar{l}$ against (3.6)–(3.8). Predictions (3.6) and (3.7) can be checked by observing the values of $\bar{l}$ in a column (fixed h and δ) and in a row (fixed H and δ), respectively. Prediction (3.8) can be checked by observing the values of $\bar{l}$ at the same situation (fixed problem type, Re, ASM type, merit function, H, and h) in different tables (different δ). We also compare approximate values of

$$\|\omega\|_h^2 = \int_{\Omega_h} \omega^2 \, d\Omega_h. \tag{5.6}$$

We show some [illegible] results, defined as follows: the base computing time is obtained on 16 processors, and the parallel efficiencies E_n (related to t_n) and $\overline{E}_l$ (related to $\bar{t}_l$) are given by the expression

$$\frac{(\text{computing time } (t_n \text{ or } \bar{t}_l) \text{ using 16 processors}) \times 16}{(\text{computing time } (t_n \text{ or } \bar{t}_l) \text{ using } N_p \text{ processors}) \times N_p}. \tag{5.7}$$

5.3.1. Cavity flow problems. Table 5.1 presents results for the simulation problem (5.1) with $Re = 200$. The preconditioner is ASM with $\delta = 1/64$ and the standard merit function is used in the line search. The total number of Newton iterations does not change with the mesh size or the number of processors. The average number of Krylov iterations per Newton iteration changes as expected in predictions (3.6) and (3.7).

TABLE 5.1

Results for the cavity flow simulation problem with $Re = 200$, standard ASM with overlap $\delta = 1/64$ and standard merit function $\|\mathbf{F}\|_2^2/2$. n is the total number of Newton iterations, $\bar{l}$ is the average number of Krylov iterations per Newton iteration, t_n is the total time in seconds spent on all Newton iterations, and $\bar{t}_l$ is the average time in seconds, per Newton iteration, spent on solving for Newton steps. For the case of finest mesh, 256×256, the number of variables is 198,147 and $\|\omega\|_h^2 \approx 55.4$. See (5.6).

# Procs.	Mesh

of processors are not pronounced. We observe that $\bar{l}$ follows (3.8). With the same δ used on the simulation problem, we can see in Table 5.2 that the average number of GMRES iterations is now more sensitive to both h and, especially, H. Table 5.3 is

the one where $\bar{l}$ best follows both (3.6) and (3.7) and the computing times t_n and $\bar{t}_l$ for the finest mesh decrease with the increase in the number of processors. Table 5.4 shows that if δ gets too big, then the consequent decrease on $\bar{l}$ might not compensate for the increased time taken by sparse LU on the larger extended subdomains; that is, $\bar{t}_l$ increases. Comparing values of $\bar{t}_l$ in Tables 5.2 and 5.3 with the values in Table 5.1, we see that the average time spent on computing $\mathbf{p}^{(k)}$ can be more than 10 times longer in control problems than in simulation problems on the same mesh, instead of being around $8/3 \approx 3$ times longer, in accordance to the ratio between the number of variables per mesh point on control problems and on simulation problems.

As reported in subsection 5.2, we use a GMRES relative tolerance of 1.0×10^{-4}, a GMRES absolute tolerance of 1.0×10^{-6}, and a Newton absolute tolerance of 1.0×10^{-6}. Case "(*)" in Table 5.3, however, gives results for a Newton absolute tolerance of 1.2×10^{-6}. When a Newton absolute tolerance of 1.0×10^{-6} is used, although full steps are accepted in some iterations, the line search stalls once $||F||_2 \approx 1.14 \times 10^{-6}$. If we change the GMRES relative tolerance to 1.0×10^{-6} and the GMRES absolute tolerance to 1.0×10^{-13} (in order to obtain a more accurate Newton step), then we achieve $||F||_2 < 1.00 \times 10^{-6}$ with $n = 6$, $\bar{l} \approx 272$, $t_n \approx 9.38$, and $\bar{t}_l \approx 1.42$. Although we performed our tests with fixed GMRES tolerances, this experiment suggests that for more demanding Newton tolerances one might need to use decreasing GMRES tolerances as the outer loop proceeds, as expected by the theory for superlinear convergence of the inexact Newton method [19, 36].

In the next two tables, we change the preconditioner to RAS and everything else stays the same; i.e., these results are for the tangential BCP (5.2) with $Re = 200$ and we use an augmented Lagrangian merit function in the line search. We increase the overlap size in the RAS preconditioner as follows: Table 5.5 for $\delta = 1/32$ and Table 5.6 for $\delta = 1/16$. The average number of GMRES iterations continues to follow (3.8) but now it better follows (3.6) and (3.7). The computing times t_n and $\bar{t}_l$ for the finest mesh in Table 5.6 decrease with the increase in the number of processors. The average number of GMRES iterations is larger in Table 5.5 than in Table 5.3, but the saving in communications of RAS compensates for this increase so that $\bar{t}_l$ does not increase proportionally. By comparing finest mesh results on Tables 5.6 and 5.4 we see that RAS performs better than the standard ASM in terms of both $\bar{l}$ and $\bar{t}_l$, resulting in a smaller t_n.

Table 5.7 presents results for the tangential BCP (5.2) with $Re = 250$, restricted ASM with $\delta = 1/16$, and augmented Lagrangian merit function. We can see that, with a Reynolds number greater than that in the previous table, both nonlinear (n) and average linear ($\bar{l}$) complexities increase.

In order to determine if tighter fixed GMRES tolerances would improve the number of Newton iterations and thus, eventually, improve the total computing time, we rerun the tests of Table 5.7 with the same parameters, except for a GMRES relative tolerance of 1.0×10^{-6}, instead of 1.0×10^{-4}, and a GMRES absolute tolerance of 1.0×10^{-13}, instead of 1.0×10^{-6}. When compared to the results in Table 5.7, at least one Newton step is saved in all nine tests, but the increase in $\bar{l}$ (and consequently $\bar{t}_l$) makes t_n increase in all cases with 32 and 64 processors. In fact, t_n decreases just for the case of 256×256 mesh and 16 processors, from 1,090 seconds to 1,040 seconds. So, although there was some improvement in the number of Newton steps, it was usually not enough to compensate for the expected increase in linear complexity, resulting in a longer overall computing time t_n.

Next, in Table 5.8 we present some parallel efficiency results derived from data presented in previous tables.

TABLE 5.5

Results for the cavity tangential boundary flow control problem with $Re = 200$, restricted ASM with overlap $\delta = 1/32$, and augmented Lagrangian merit function. n is the total number of Newton iterations, $\bar{l}$ is the average number of Krylov iterations per Newton iteration, t_n is the total time in seconds spent on all Newton iterations, and $\bar{t}_l$ is the average time in seconds, per Newton iteration, spent on solving for Newton steps. For the case of finest mesh, 256×256, the number of variables is 528,392 and $\|\omega\|_h^2 \approx 32.5$. See (5.6).

Finally, we present a comparison of computed velocity fields for $Re = 200$. Figure 5.2(b) refers to the simulation problem (5.1), and Figures 5.2(c) and 5.2(d) refer to the tangential BCP (5.2). Recall that the objective of the tangential boundary control is to minimize the intensity of the velocity field in the vortex shown in Figure 5.2(b). Figure 5.2(d) shows that the tangential boundary control acts in the opposite direction

of the interior flow. The achieved minimization can be observed in two ways: by comparing Figure 5.2(c) against Figure 5.2(b) and by comparing the value $\|\omega\|_h^2 \approx 32.5$ in Tables 5.2–5.6 to the value $\|\omega\|_h^2 \approx 55.4$ in Table 5.1.

5.3.2. Backward-facing step flow problems. In this subsection we present results for the backward-facing step problem. Table 5.9 contains results for the simulation problem (5.3) with $Re = 200$. The standard merit function is used in the line search, and an overlap $\delta = 1/32$ is used in the ASM preconditioner. The total number of Newton iterations does not change with the mesh size or the number of processors. The average number of GMRES iterations does not seem to follow (3.6) and (3.7) as closely as in the case of cavity flow simulation problems. But $\bar{l}$ behaves better when RAS is employed.

TABLE 5.9

Results for the backward-facing step flow simulation problem with $Re = 200$, standard ASM with overlap $\delta = 1/32$, and standard merit function $\|\mathbf{F}\|_2^2/2$. n is the total number of Newton iterations, $\bar{l}$ is the average number of Krylov iterations per Newton iteration, t_n is the total time in seconds spent on all Newton iterations, and $\bar{t}_l$ is the average time in seconds, per Newton iteration, spent on solving for Newton steps. For the case of finest mesh, 768×128, the number of variables is 297,603 and $\|\omega\|_h^2 \approx 3.35$. See (5.6).

# Procs.	Mesh 192×32		Mesh 384×64		Mesh 768×128	
16	$n = 5$	$t_n \approx 1.35$	$n = 5$	$t_n \approx 6.49$	$n = 5$	$t_n \approx 37.2$
	$\bar{l} \approx 54$	$\bar{t}_l \approx 0.22$	$\bar{l} \approx 59$	$\bar{t}_l \approx 1.15$	$\bar{l} \approx 64$	$\bar{t}_l \approx 6.85$
32	$n = 5$	$t_n \approx 1.37$	$n = 5$	$t_n \approx 5.96$	$n = 5$	$t_n \approx 30.7$
	$\bar{l} \approx 92$	$\bar{t}_l \approx 0.22$	$\bar{l} \approx 109$	$\bar{t}_l \approx 1.09$	$\bar{l} \approx 121$	$\bar{t}_l \approx 5.82$
64	$n = 5$	$t_n \approx 0.96$	$n = 5$	$t_n \approx 3.35$	$n = 5$	$t_n \approx 13.6$
	$\bar{l} \approx 89$	$\bar{t}_l \approx 0.13$	$\bar{l} \approx 102$	$\bar{t}_l \approx 0.58$	$\bar{l} \approx 102$	$\bar{t}_l \approx 2.50$

Next, we consider the tangential BCP (5.4) with $Re = 200$ and an augmented Lagrangian merit function in the line search. In this case the standard ASM with $\delta = 1/32$ does not result in a good enough preconditioner for GMRES; i.e., the maximum allowed number (5,000) of Krylov iterations is eventually achieved without any tolerance being satisfied. Table 5.10 presents results for the standard ASM with $\delta = 1/16$. Interestingly, the total number of Newton iterations decreases as the mesh is refined, although the overall effort to find a solution increases. Comparing these results with Table 5.9, we can see that the average number of GMRES iterations is now much more sensitive to both h and H.

With $\delta > 1/16$ we expect a better convergence of LNKSz. But instead of applying the standard ASM with $\delta = 1/8$, we apply, in Table 5.11, RAS with $\delta = 1/8$, trying to balance more sparse LU time spent on bigger extended subdomains with less communication time spent on RAS. The number of Newton iterations continues to decrease as the mesh is refined. With an overlap δ four times as large as the one used on the simulation problem, the average number of GMRES iterations now follows (3.6) and (3.7) more closely. Comparing values of $\bar{t}_l$ in Tables 5.11 and 5.9, we see that the average time spent on computing $\mathbf{p}^{(k)}$ can be more than 20 times greater in control problems than in simulation problems with the same mesh, instead of being around $8/3 \approx 3$ times greater, in accordance to the ratio between the number of variables per mesh point on control problems and on simulation problems.

We now increase the Reynolds number to $Re = 300$, and the performance data for the tangential BCP (5.4) is provided in Table 5.12. We use the augmented Lagrangian merit function in the line search and $\delta = 1/8$ in RAS. With the increase in Re, both

and thus, eventually, improve the total computing time, we rerun the tests of Table 5.12 with the same parameters, except for a GMRES relative tolerance of 1.0×10^{-6} instead of 1.0×10^{-4}, and a GMRES absolute tolerance of 1.0×10^{-13} instead of 1.0×10^{-6}. When compared to the results in Table 5.12, one or two Newton steps are saved in just two of the nine tests, while the increase in $\bar{l}$ (and $\bar{t}_l$, consequently) makes t_n increase in all nine cases.

In Table 5.13 some parallel efficiency results derived from data presented in previous tables are given.

Finally, we look at the computed velocity fields for $Re = 200$. Figures 5.3–5.5 are for the simulation problem (5.3), and Figures 5.6–5.8 are for the tangential BCP

(5.4). The results are very similar to those of the cavity flow problem; more precisely speaking, Figures 5.4 and 5.8 show that the tangential boundary control acts in the opposite direction of the interior flow. The achieved minimization values can be measured either by comparing Figure 5.7 with Figure 5.4, or by comparing the value $\|\omega\|_h^2 \approx 3.28$ in Tables 5.10–5.11 with the value $\|\omega\|_h^2 \approx 3.35$ in Table 5.9.

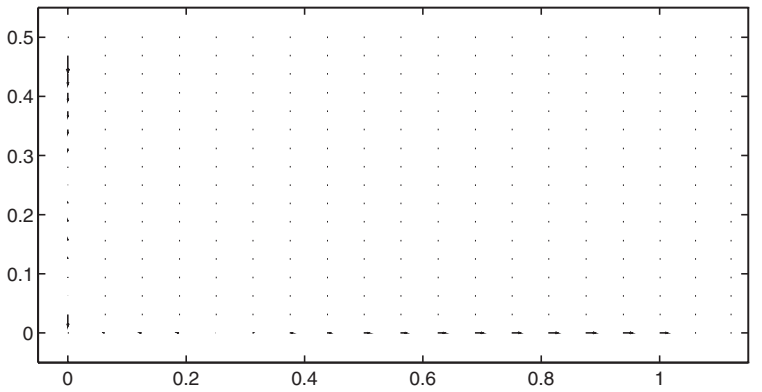

FIG. 5.8. *Highlight of the boundary velocity in the left bottom region of Figure* 5.6.

6. Conclusions. We have developed a general LNKSz algorithm for PDE constrained optimization problems and applied it to some tangential BCPs involving two-dimensional incompressible Navier–Stokes equations. In our numerical experiments the LNKSz algorithm, together with an augmented Lagrangian merit function, provides a fully parallel and robust solution method. The one-level additive Schwarz preconditioned GMRES, with a proper overlap, works well for the indefinite linearized KKT systems. A proper overlap for a control problem seems to be greater than a proper overlap for a simulation problem. More precisely, in our experiments the proper overlaps are two to four times greater in the control problems. For larger overlaps the restricted version of ASM seems to perform better than the standard ASM as a preconditioner for linearized KKT systems.

Our experiments also show that control problems are computationally more demanding, in terms of the total number of nonlinear iterations, the average number of linear iterations per Newton iteration, and the total computing time, than the corresponding simulation problems. The overall computational effort grows as Re increases, in terms of the number of both nonlinear and average linear iterations.

Acknowledgments. We would like to thank the PETSc team of Argonne National Laboratory for their help on using the PETSc library. We would also like to thank Professors G. Biros, O. Ghattas, S. Hou, and S. Ravindran, as well as two anonymous referees, for their useful comments.

ON OSCILLATIONS IN DISCONTINUOUS GALERKIN DISCRETIZATION SCHEMES FOR STEADY STATE PROBLEMS*

N. B. PETROVSKAYA†

Abstract. High order discontinuous Galerkin discretization schemes are considered for steady state problems. We discuss the issue of oscillations arising when Newton's method is employed to obtain a steady state solution. It will be demonstrated that flux approximation near flux extrema may produce spurious oscillations propagating over the domain of computation. The control over the numerical flux in the problem allows one to obtain nonoscillating convergent solutions.

Key words. discontinuous Galerkin, spurious oscillations, Newton's method

DOI. 10.1137/040603085

1. Introduction. In recent years a variety of discretization methods have been developed to solve complex problems of physics and engineering. One of them is a discontinuous Galerkin (DG) discretization scheme. Introduced in [11] and further developed by many authors (see [4] for the review of DG schemes), the DG method is a finite element scheme which uses piecewise polynomial approximation in space. The method also involves an approximate Riemann solver, since the approximate solution is discontinuous at grid interfaces.

The hyperbolic systems of conservation laws present a wide class of problems where the DG method can be successfully applied. The DG discretization scheme affords optimal orders of convergence for smooth problems by using high order approximating spaces. For the problems whose solutions have strong gradients and/or discontinuities, solution oscillations may occur when a high order DG scheme is used to discretize a conservation law. Since the nonphysical oscillations have a disastrous impact on the convergence of the approximate solution, a limiting procedure that eliminates the oscillations near discontinuities should be addressed. A number of authors have contributed to the issue of limiters for DG schemes in recent years (e.g., see [5], [6], [9]). It has been demonstrated many times that stabilization of the scheme by means of local limiters allows one to obtain accurate nonoscillating solutions to nonlinear hyperbolic problems.

The local limiters are not always helpful, however, when steady state solutions to conservation laws are considered. In practice, a time-dependent algorithm (e.g., a backward Euler integration) is used to approach a steady state solution. The time step is usually scaled as a function of the norm of the residual, so that the scheme with an infinitely large time step is equivalent to Newton's method. Thus it seems to be a reasonable strategy to solve time-dependent equations only at the early stages of computations. Once the basin of attraction has been approached, the Newton method may be exploited in order to provide a faster convergence rate. Meanwhile, our numerical experience shows that a transient solution may exhibit strong oscillations over

the entire domain of computation, if the Newton iteration method is used to solve a system of nonlinear equations obtained as a result of a high order DG discretization in space. Those oscillations may appear for a smooth solution as well as a discontinuous one, and their excitation does not depend on how close the initial guess for the Newton method is to the fixed point considered as a steady state solution for the problem. The spurious oscillations propagating over the domain cannot be eliminated by means of a standard limiting procedure [5], and their nature requires careful study.

In our work, we consider two nonlinear scalar equations in order to examine a high order DG discretization for steady state solutions. Simple enough, they nevertheless demonstrate the difficulties arising in the solution of steady state problems. In our first example the exact solution is smooth, while the solution to the second problem has a discontinuity. It will be shown that in both cases a standard high order DG discretization yields a divergent solution.

Based on our consideration, we conclude that a high order DG scheme is not able to recognize flux extrema that may result in a singular Jacobian when Newton's method is used to solve the problem. Moreover, a transient solution may generate nonphysical flux extrema which lead to a singular matrix as well. Thus, spurious solution oscillations occur in the problem due to incorrect flux approximation, so that a high order DG discretization requires flux control over each grid cell. We present a flux control procedure that allows one to obtain convergent solutions.

2. The problem statement. We consider an ordinary differential equation written for a function $u(x)$ in the conservative form

$$F_x(x,u)=0, \quad x\in\Omega=[0,1], \tag{1}$$

where $F(x,u(x))$ is a flux function. An appropriate boundary condition

$$\mathbf{B}u=0 \tag{2}$$

is provided for (1), where $\mathbf{B}$ denotes a boundary condition operator.

For numerical solution of the boundary-value problem (1), (2) we introduce the element partition G of the region, $G=\bigcup_{i=1}^{N} e_i$, $e_i=[x_i,x_{i+1}]$, $1\le i\le N$, where x_i is a nodal coordinate, and $h_i=x_{i+1}-x_i$ is a grid step size. We also use the notation x_i-0 and x_i+0 for the left and right limits at the point x_i.

Let $u(x)$ be the solution to the problem (1), (2). In order to find the approximate solution $u_h(x)$, a weak formulation of the problem is used. Multiplying (1) by test function $\phi_k(x)$, defined on the cell e_i for $k=0,1,\dots,K$ as

$$\phi_k(x)=\left(\frac{x-x_i}{h_i}\right)^k, \quad x\in e_i,$$

and integrating by parts over the cell e_i, we obtain

$$F(x_{i+1},u(x_{i+1}))\phi_k(x_{i+1})-F(x_i,u(x_i))\phi_k(x_i)-\int_{x_i}^{x_{i+1}}F(x,u)\frac{d\phi_k(x)}{dx}dx=0,$$
$$k=0,1,\dots,K. \tag{3}$$

We now replace the function $u(x)$ in (3) by the approximate solution $u_h(x)$. The DG discretization seeks for the approximation $u_h(x)$ to the solution $u(x)$ such that

$u_h(x)$ is a piecewise polynomial function over Ω. The approximate solution $u_h(x)$ is expanded on the cell e_i as

$$u_h(x) = \sum_{k=0}^{K} u_k \phi_k(x), \quad k = 0, 1, \ldots, K, \quad x \in e_i. \tag{4}$$

Since $u_h(x)$ is discontinuous at cell interfaces, (3) considered for the solution $u_h(x)$ requires us to define numerical flux $\tilde{F}(u_h)$. Suppose that the flux $\tilde{F}(u_h)$, which generally depends on the two values of the approximate solution at any grid point, is chosen for a given problem. Then the DG discretization scheme reads

$$\tilde{F}(u_h(x_{i+1}))\phi_k(x_{i+1}) - \tilde{F}(u_h(x_i))\phi_k(x_i) - \int_{x_i}^{x_{i+1}} F(x, u_h(x)) \frac{d\phi_k(x)}{dx} dx = 0, \tag{5}$$
$$k = 0, 1, \ldots, K.$$

For steady state problem (1), (2), the DG space discretization over the grid results in the following system of nonlinear equations:

$$\mathbf{R}(\mathbf{u}) = 0, \tag{6}$$

where the vector $\mathbf{R}(\mathbf{u})$ is the residual of the DG method given by (5) on each grid cell and $\mathbf{u}$ is the solution vector. We use Newton's iteration method to solve the nonlinear equations (6). Let $\mathbf{u}^n$ and $\mathbf{u}^{n+1}$ be the solution vector at the nth and $(n+1)$th solution iteration, respectively. Then the linearized system is

$$\mathbf{J}(\mathbf{u}^n)(\mathbf{u}^{n+1} - \mathbf{u}^n) = -\mathbf{R}(\mathbf{u}^n), \tag{7}$$

where the Jacobian matrix $\mathbf{J}(\mathbf{u}) = [\partial \mathbf{R}/\partial \mathbf{u}]$ and residual $\mathbf{R}(\mathbf{u})$ are taken from the nth iteration. The GMRES algorithm [12], [2] is used to solve numerically the algebraic system of linear equations obtained at each Newton iteration.

In the remainder of our paper we discuss oscillations appearing in solution (5), (7). One important observation about the DG scheme is that for the steady state problem (1), (2) the solution on the ith grid cell impacts on the solution on neighboring cells only by means of the numerical flux $\tilde{F}(u_h)$. Hence, the two possible ways of the excitation of oscillations at the nth Newton iteration are as follows.

1. The numerical flux required to define the DG discretization on the cell e_i is correct, but the approximate solution on the cell does not converge in a particular norm. That may happen, for instance, when a discontinuity presented in the cell is approximated by smooth function (4). The solution overshoots arising as a result of such approximation are local and do not affect the solution on other cells.
2. The numerical flux is not correct on the ith cell. The incorrect flux approximation produces solution oscillations that will propagate over the domain at the next Newton iterations and result in a divergent solution.

While local limiters can be successfully used to smooth the local solution overshoots, another approach is required to recognize and eliminate the spurious oscillations propagating over the grid. That approach will be discussed below.

3. The numerical flux in steady state problems. In this section, we address a numerical flux used in the formulation of the DG discretization. Usually, oscillations arising in the approximate solution are associated with solution discontinuities. Thus,

our aim is to verify the definition of the numerical flux and demonstrate that the oscillations may appear for a smooth solution as well as a discontinuous function.

We begin our consideration with a simple example of (1) that illustrates the problem. Let the flux $F(x,u)$ be

$$F(x,u) = p(x)f(u), \quad p(x) = \frac{1}{((x-x_0)(x-x_1))^2}, \quad f(u) = (u-A)^2. \tag{8}$$

The problem parameters x_0, x_1, and A and the boundary condition are chosen to provide a smooth solution to the problem

$$U(x) = A + C(x-x_0)(x-x_1), \quad x \in [0,1],$$

where C is a constant. Namely, we take $A = 1.0$, $C = -1.0$, $x_0 = -0.5$, and $x_1 = 1.5$, so that bifurcation points $x = x_0$ and $x = x_1$ lie outside the domain of computation. The boundary condition is

$$\int_0^1 u(x)dx = B, \tag{9}$$

where the value B is defined by integrating the exact solution with the parameters above.

The model problem (1), (8) is numerically solved by using the DG discretization approach. We choose the Engquist–Osher definition [10] to approximate the flux at grid interfaces. Let u_l and u_r be the left and right states at the interface x_i, respectively. The numerical flux reads

$$\tilde{F}^{EO}(u_l,u_r) = \int_0^{u_r} \min(F'(s),0)ds + \int_0^{u_l} \max(F'(s),0)ds + F(0). \tag{10}$$

For the problem (8), the flux has a single extremum point, $u = A$. Hence, the numerical flux (10) is as follows:

$$\tilde{f}(u_l,u_r) = \begin{cases} f(u_l), & u_l > A,\ u_r > A, \\ f(u_r), & u_l < A,\ u_r < A, \\ f(A), & u_l < A,\ u_r > A, \\ f(u_l) + f(u_r) - f(A), & u_l > A,\ u_r < A. \end{cases} \tag{11}$$

The numerical experience with the problem shows that the convergence of the Newton method depends strongly on the choice of initial guess. Consider a sine wave function

$$u_0(x,s_0) = \sin(2\pi x) + s_0,$$

where s_0 is a parameter. Let us consider $s_0^{\mathrm{I}} = 2.3$ and $s_0^{\mathrm{II}} = 1.8$. For the initial guess $u_0^{\mathrm{I}} = u_0(x, s_0^{\mathrm{I}})$, the flux $f(u)$ is a monotone function over the domain of definition $u_0 \in [u_{min}^{\mathrm{I}}, u_{max}^{\mathrm{I}}]$. For the function $u_0^{\mathrm{II}} = u_0(x, s_0^{\mathrm{II}})$, we have $u_{min}^{\mathrm{II}} < A$, $u_{max}^{\mathrm{II}} > A$, so that the flux approximation is required at the extremum point $u = A$ at the first Newton step.

Although the curves u_0^{I} and u_0^{II} are close to each other, i.e., $||u_0^{\mathrm{II}} - u_0^{\mathrm{I}}||_{L^\infty} = |s_0^{\mathrm{II}} - s_0^{\mathrm{I}}|$, $x \in [0,1]$, the convergence results are quite different for the two functions. Starting with the initial guess u_0^{I}, Newton's method rapidly converges to the approximate solution $u_h(x)$. The convergence results obtained on a sequence of uniform grids

confirm the consistency of the approximation (5), (11). In particular, the DG scheme with polynomial degree $K = 2$ provides a precise reconstruction of the quadratic function $U(x)$. Meanwhile, the choice of u_0^{II} as initial guess for the problem results in a divergent solution for any polynomial degree $K > 0$.

Let us look more closely at the numerical flux used in the problem. For a scalar flux function, the definition of the numerical flux is essentially based on the analysis of the flux derivative, the results of which depend on how the solution variation $u_r - u_l$ is determined. In the definition (10), the solution variation is assigned to the grid interface x_i, $u_l = u_h(x_i - 0)$, $u_r = u_h(x_i + 0)$. In other words, the definition (10) implies that the flux variation is due only to the solution variation at grid interfaces, i.e., $F(u) = \mathrm{const}$ within a grid cell. Evidently, this assumption will be correct if the approximate solution is constant over each cell. Meanwhile, for a high order DG discretization scheme the approximate solution varies in the domain $[x_i, x_{i+1}]$. The solution variation $\delta u_h = u_h(x_{i+1} - 0) - u_h(x_i + 0)$ may generate a flux extremum at the interior point of the cell e_i, while the flux remains a monotone function at both interfaces x_i and x_{i+1}. Below we compare flux approximation in a piecewise constant and a higher order DG discretization and demonstrate that for a high order scheme, considering a flux as a monotone function at the interfaces of the cell where the flux extremum is located may lead to incorrect DG approximation.

As an example of a high order DG scheme, let us consider a piecewise linear approximate solution

$$u_h(x) = u_0 + u_1\phi_1(x), \quad x \in e_i.$$

Since a DG discretization with polynomial degree K results in $K+1$ unknown solution values (degrees of freedom) per cell, two DG equations (5) per cell must be employed for a piecewise linear solution. Those equations are a discrete conservation law,

$$p(x_{i+1})\tilde{f}(u_l, u_r) - p(x_i)\tilde{f}(u_l, u_r) = 0, \tag{12}$$

and the momentum equation,

$$p(x_{i+1})\tilde{f}(u_l, u_r) - \frac{1}{h_i}\int_{x_i}^{x_{i+1}} p(x)f(u_h(x))dx = 0. \tag{13}$$

For the purpose of further discussion it is more convenient to define the DG discretization on a given cell in terms of the solution values rather than the solution derivatives in the expansion (4) (see [13] for more details). We now introduce the notation u_i^l and u_i^r for the left and right solution states at the interface x_i, respectively. Then the values u_i^r and u_{i+1}^l are defined by the piecewise linear function $u_h(x)$ on a given cell e_i. The evident transformation

$$u_i^r \equiv u_h(x_i + 0) = u_0, \quad u_{i+1}^l \equiv u_h(x_{i+1} - 0) = u_0 + u_1,$$

allows one to consider left and right solution states as unknown degrees of freedom for a piecewise linear solution.

The flux approximation in the DG equations at the first Newton step is illustrated in Figure 1 for a piecewise constant and a linear approximate solution. The flux function $f(u) = (u - A)^2$ is shown in the $(u, f(u))$-plane in Figure 1(a)–(b). The solution degrees of freedom are stationed at the u-axis, and the solution values required to approximate the flux at cell interfaces are displayed as black dots. The

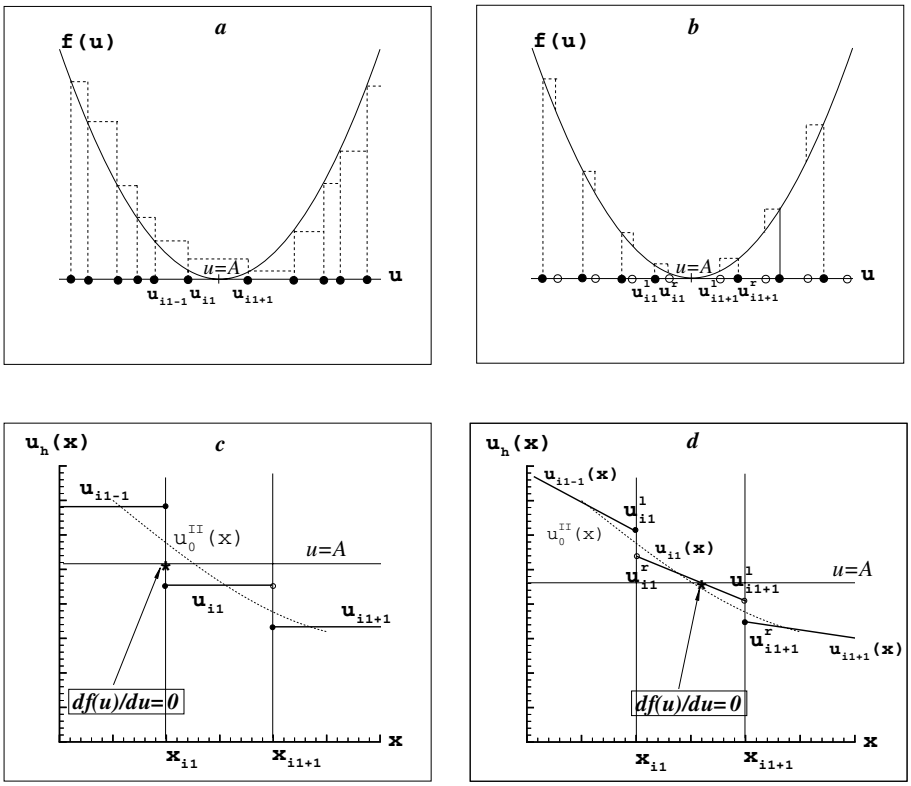

FIG. 1. (a)–(b) *The numerical flux near the extremum point for the problem* (1), (8). (a) *The numerical flux for the piecewise constant approximate solution. Both degrees of freedom are not involved in the flux approximation on the cell where the flux extremum is located.* (c)–(d) *The DG discretization in the* $(x, u_h(x))$*-plane.* (c) *Piecewise constant solution approximation captures the flux extremum.* (d) *Higher order solution approximation misses the extremum point inside the grid cell.*

corresponding values of the numerical flux (10) at grid interfaces are shown at the curve $f(u)$. In the figure, the flux approximation is presented in the vicinity of the cell e_{i1} : $u^r_{i1} > A$, $u^l_{i1+1} < A$. In other words, the initial guess is a decreasing function near the extremum point, and the solution states at the grid interfaces corresponding to greater values of u are shown at the left from the extremum point $u = A$.

The flux approximation for the piecewise constant approximate solution (one degree of freedom per cell) is presented in Figure 1(a). It can be seen from the figure that, according to the definition (10), a discrete conservation law (12) involves one unknown solution value per cell. In other words, the number of DG equations to be solved over the grid is equal to the number of unknown solution values, as all degrees of freedom are involved in the flux approximation.

Now we look at the flux approximation in a piecewise linear DG scheme shown in Figure 1(b). Let flux be a monotone function over a given cell e_i. Again the DG equation (12) requires one degree of freedom per cell to balance the monotone fluxes at the left and right cell interfaces. That degree of freedom is chosen to provide the upwind discretization; i.e., we take u^r_i for $df(u)/du < 0$ or u^l_{i+1} for $df(u)/du > 0$ to approximate the flux. A second degree of freedom on the cell is not involved in the

discrete conservation equation (12), and thus another equation is required to define the second unknown solution value on the cell. This equation appears as the momentum equation (13) in the DG scheme. Hence, there are two DG equations for two unknown solution values on any cell where the flux is a monotone function through the cell.

The situation is different, however, on the cell where the flux extremum is located at the interior point. Now both degrees of freedom on the cell are not involved in the flux approximation, as the definition of the numerical flux concerns only the solution on the adjacent cells. Namely, we have $u^l_{i1} > A$, $u^r_{i1} > A$ at the left cell interface, so that the upwind flux is $f(u^l_{i1})$. Meanwhile, $u^l_{i1+1} < A$, $u^r_{i1+1} < A$, and the numerical flux is $f(u^r_{i1+1})$ at the right cell interface.

The DG equations on the cell e_{i1} are illustrated in the $(x, u_h(x))$-plane in Figure 1(c)–(d) for a piecewise constant and a linear discretization, respectively. Again, the solution values required to define the flux at the interfaces of the cell e_{i1} are shown as black dots. It can be seen from the figure that for the piecewise constant DG discretization, displayed in Figure 1(c), the extremum point at the interface is taken into account in the definition of the numerical flux. The discrete conservation law reads

$$p(x_{i1+1})f(u^r_{i1+1}) - p(x_{i1})(f(u^l_{i1}) + f(u^r_{i1}) - f(A)) = 0.$$

For the linear approximate solution, shown in Figure 1(d), the "phantom" solution on the cell e_{i1} is not involved in the flux definition. The discrete conservation law is

$$p(x_{i1+1})f(u^r_{i1+1}) - p(x_{i1})f(u^l_{i1}) = 0, \tag{14}$$

where $u^l_{i1} = u_h(x_{i1} - 0)$ and $u^r_{i1+1} = u_h(x_{i1+1} + 0)$ are the solution unknowns on the adjacent cells.

Thus, we still need two equations to define the unknowns (u^r_{i1}, u^l_{i1+1}), while the DG discretization provides us with only one more equation that involves the unknowns on the cell e_{i1}. Let us also note that, by the definition of the numerical flux (10), the unknowns (u^r_{i1}, u^l_{i1+1}) on the cell e_{i1} are not required for the discretization on neighboring cells (see Figure 1(b)), and thus the number of DG equations to be solved over the grid is not equal to the number of unknown solution values for a piecewise linear solution. This indicates that the solution should be reduced to piecewise constant approximation on the cell e_{i1} in order to avoid the underdetermined system of equations over the grid. In other words, the number of degrees of freedom is excessive on the cell e_{i1}, and only one of them should be used for the discretization.

The same conclusion can be made in the case of a DG discretization with any polynomial degree $K > 0$. For instance, a piecewise quadratic approximation $K = 2$ results in three unknown values per cell. Instead of coefficients (u_0, u_1, u_2) in the expansion (4), these unknowns can be defined as u^r_i, u^l_{i+1}, and u^m_i, where $u^m_i = u_h(x_m)$, $x_m = 0.5(x_i + x_{i+1})$. Again, the discrete conservation law (12) on the cell e_{i1} does not require any of these degrees of freedom, as only the solution on adjacent cells is concerned, and thus we have two equations per cell to find three unknown values.

Consequently, solving the underdetermined system of equations arising as a result of a high order DG discretization leads to a singular Jacobian in the Newton method. For a piecewise linear solution, let us define a local Jacobian $\mathbf{j}_{k_1k_2} = [\partial R_{k_1}/\partial u_{k_2}]$ by linearizing the two DG equations on the cell e_{i1}. Here the local index $k_1 = 0, 1$ is related to the DG residual on the cell, while the local index $k_2 = 0, 1$ refers to the corresponding degree of freedom from the set (u^r_{i1}, u^l_{i1+1}). Then the first row in the 2×2-matrix $\mathbf{j}_{k_1k_2}$ has only zero entries, as we have $j_{00} \equiv \partial R_0/\partial u^r_{i1} = 0$ and

$j_{01} \equiv \partial R_0/\partial u^l_{i1+1} = 0$ for the residual R_0 defined by (14). Hence, the rank of the local Jacobian is $\mathrm{rank}(\mathbf{j}_{k_1k_2}) = 1 < \dim(\mathbf{j}_{k_1k_2}) = 2$, and by reordering the rows and columns we can obtain a zero column in the matrix $\mathbf{j}_{k_1k_2}$.

We now consider the matrix $\mathbf{j}_{k_1k_2}$ as the block J_{lm} of the Jacobian $\mathbf{J}$ of the linearized system (7). The global indices for the block entries are $l = k_1 + M_1$ and $m = k_2 + M_1$, where $M_1 = 2\,i1 - 1$. Since the definition (10) provides the exact flux splitting for the problem, we have the Jacobian entries $J_{lM1} = 0$, $J_{lM1+1} = 0$, $\forall l$: $l < M_1$ or $l > M_1 + 1$. On the other hand, it follows from the above consideration that the rows and columns of the Jacobian matrix can be reordered to provide

$$J_{lM_1} = 0, \quad l = M_1, M_1 + 1,$$

while we still have $J_{lM1} = 0$, $\forall l$: $l < M_1$ or $l > M_1 + 1$ in the reordered matrix. Hence, a zero column appears in the Jacobian of the system (7). The singular Jacobian leads to an incorrect transient solution (whose appearance depends strongly on the robustness of the GMRES solver used in the problem). That solution, in turn, will impact on the flux at the next Newton iterations, so that the oscillations will rapidly propagate over the domain resulting in the divergence of the method. Let us also notice that a similar analysis can be carried out for a DG discretization with any polynomial degree $K > 0$ to demonstrate that a singular Jacobian will appear in the problem, if the number of unknowns on the cell exceeds the number of equations.

The above results bring us to the conclusion that the nature of oscillations arising in the steady state problem (8), (9) is different from that appearing in approximate solution to hyperbolic conservation laws. In the latter case the oscillations arise near a solution discontinuity, and the approximation implies a well-defined numerical flux over the computational domain. Now the numerical flux $\tilde{f}(u)$ is not a correct approximation to the flux function $f(u)$ at the extremum point, while the solution remains a smooth monotone function near the flux extremum.

We are now going back to the problem (8). The above analysis reveals that a high order approximate solution should be reduced to a piecewise constant approximation near a flux extremum in order to avoid nonphysical oscillations in the problem. If the flux extremum generates a "phantom" solution on a given grid cell e_i (i.e., the number of unknowns exceeds the number of equations on the cell) at the nth Newton iteration, then we compute $\bar{u} = \frac{1}{h_i}\int_{x_i}^{x_{i+1}} u_h(x)dx$ and define the approximate solution on the cell e_i as $u_h(x) = \bar{u}$. The equations

$$\begin{gathered} p(x_{i+1})\tilde{f}(u_h) - p(x_i)\tilde{f}(u_h) = 0, \quad k = 0, \\ u_k = 0, \quad k = 1, \ldots, K, \end{gathered}$$

are then considered on the cell e_i to obtain the solution at the $(n+1)$th Newton iteration. A modified DG discretization allows one to obtain the convergent solution with the polynomial degree $K > 0$ for the function $u_0^{\mathrm{II}}(x)$ considered as the initial guess.

Finally, let us mention that the problem of flux approximation in a high order DG discretization cannot be completely solved by considering another numerical flux in a problem. The discussion in this section demonstrates that the number of degrees of freedom should be equal to the number of equations on each grid cell in a high order DG scheme. Hence, many of the upwind fluxes which provide exact flux splitting at the flux extremum point are hardly appropriate for a high order discretization, as they do not meet the requirement above. For instance, the Godunov flux is defined

as

$$\tilde{F}^G(u_l,u_r)=\begin{cases}\min\limits_{u_l\le u\le u_r} F(u) & \text{if } u_l\le u_r,\\ \max\limits_{u_l\le u\le u_r} F(u) & \text{otherwise}\end{cases}$$

for the left state u_l and right state u_r at a given grid interface. It can be seen from the flux definition that the Godunov flux presents us with the same problem as the Engquist–Osher flux (10). Since the discrete conservation law does not involve the solution near the extremum for a high order DG discretization, the number of unknowns exceeds the number of equations on the cell, where the extremum point is located. On the other hand, the space-centered fluxes, such as the local Lax–Friedrichs flux,

$$\tilde{F}^{LLF}(u_l,u_r)=\frac{1}{2}[F(u_l)+F(u_r)-C(u_r-u_l)],$$
$$C=\max_{min(u_l,u_r)\le s\le max(u_l,u_r)}|F'(s)|,$$

use both left and right solution states to approximate the flux, which makes the number of degrees of freedom equal to the number of equations on each grid cell. However, the space-centered fluxes cannot be considered a priori as a preferable choice for a high order DG discretization, as the issues of accuracy also should be taken into account. For instance, it is well known that the Lax–Friedrichs flux is more dissipative than upwind fluxes, and thus it may not be acceptable for a problem under consideration (e.g., see [14]). This makes the choice of a numerical flux in steady state problems a complicated task which requires further study and discussion.

4. The numerical flux for time-dependent problems. Approximate Riemann solvers have been successfully used many times in numerical solution of the hyperbolic systems of conservation laws (e.g., see [7] and the references therein). Thus, it is instructive to compare the results obtained for the steady state problem above with the convergence of a nonlinear solver for a time-dependent problem. The inviscid Burgers equation

$$\frac{\partial u}{\partial t}+u\frac{\partial u}{\partial x}=0 \tag{15}$$

is a well-known example of a nonlinear hyperbolic equation which provides us with a quadratic flux function $f(u)=\frac{u^2}{2}$ similar to that in (8). We solve (15) in the domain $x\in[0,1]$ due to a periodic boundary condition. The initial condition is taken from [3], where it has been chosen as a sine wave function,

$$u(x,0)=u_0(x)=\frac{1}{4}+\frac{1}{2}\sin(\pi(2x-1)).$$

The exact solution is smooth for any time $T<1/\pi$, while the shock appears at later times.

For numerical solution of the conservation law (15), a DG discretization in space is combined with a backward Euler time integration scheme which results in a system of nonlinear equations at each time step. This system is linearized in order to obtain the solution at the upper time level. Notice that the choice of the initial condition requires the flux approximation near the extremum point $u=0$. Nevertheless, the nonlinear solver provides a convergent solution at any time $T>0$. An approximate

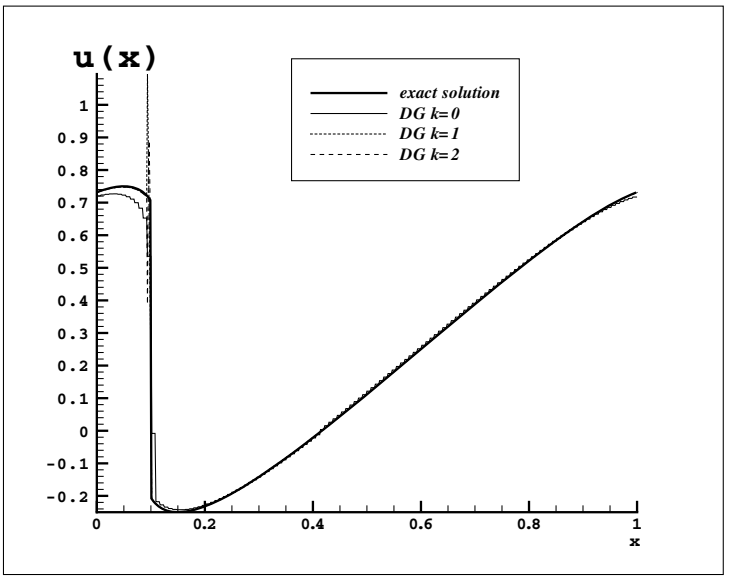

FIG. 2. *Exact and numerical solution to the Burgers equation. Smooth approximation to the solution generates local oscillations at the shock for the DG solution with polynomial degree $K > 0$. The solution overshoots can be eliminated by means of local limiters.*

solution at $T = 0.4$ is shown in Figure 2 for DG discretizations with polynomial degree $K \geq 0$ on a uniform grid of 128 cells. Let us notice that the DG $K = 1$ and $K = 2$ approximate solutions oscillate near the shock. However, those oscillations are local and can be eliminated by means of a limiting procedure [5].

The robustness of the nonlinear solver for the time-dependent problem (15) is readily explained based on the analysis of the Jacobian matrix. Consider the conservation law

$$\frac{\partial u}{\partial t} + F_x(x, u) = 0, \quad x \in \Omega. \tag{16}$$

The semidiscrete formulation of (16) on the cell e_i is

$$\int_{e_i} \frac{\partial u}{\partial t} \phi_k(x) dx + R_k^{DG}(\mathbf{u}) = 0, \quad k = 0, 1, \ldots, K,$$

where $R_k^{DG}(\mathbf{u})$ is the DG residual given by (5).

Let $\mathbf{u}^n$ and $\mathbf{u}^{n+1}$ be the solution vector over the grid at time t^n and $t^{n+1} = t^n + \Delta t$, respectively. After discretizing in time, the implicit scheme for the hyperbolic equation (16) reads

$$\mathbf{M}(\mathbf{u}^{n+1} - \mathbf{u}^n) = -\Delta t \mathbf{R}^{DG}(\mathbf{u}^{n+1}), \tag{17}$$

where positive diagonal matrix $\mathbf{M}$ is given by

$$M_{kl} = \int_{e_i} \phi_k(x) \phi_l(x) dx, \quad k, l = 0, 1, \ldots, K,$$

on each grid cell.

The linearization of the residual vector yields the system of equations

$$\mathbf{J}(\mathbf{u}^{n+1} - \mathbf{u}^n) = -\mathbf{R}(\mathbf{u}^n).$$

The Jacobian matrix is

$$\mathbf{J} = \frac{\mathbf{M}}{\Delta t} + \mathbf{J}^{DG},$$

where $\mathbf{J}^{DG}$ is the Jacobian of steady state problem (1), $\mathbf{J}^{DG} = [\partial \mathbf{R}^{DG}/\partial \mathbf{u}]$.

It can be seen from the above expression that the presence of mass matrix $\mathbf{M}$ in the discretization ensures diagonal entries in the Jacobian, even if matrix $\mathbf{J}^{DG}$ is singular. Hence, the time derivative can be considered as a stabilization term for high order DG discretizations.

5. The flux correction for steady state solutions. Lack of stabilization terms in steady state problems makes it difficult to use Newton's method for their numerical solution. On the one hand, it has been demonstrated in section 3 of the paper that an approximate Riemann solver may result in a singular matrix near the flux extremum. On the other hand, to obtain a convergent solution it is not sufficient to control the flux only near the extremum point. Below we demonstrate that a general case, unlike a simple model problem considered above, requires flux control on any grid cell.

Consider a scalar flux function $F(u)$. Any smooth function $F(u)$ that is not monotone in the domain of definition yields a multivalued solution $u(x)$ to the steady state equation (1). (From a geometric point of view, this means that the solution $F(x, u) = C$ to (1) intersects the curve $F(u)$ more than one time in the $(u, F(u))$-plane.) For the boundary-value problem (1), (2), the uniqueness of the solution is defined by a boundary condition.[1] However, a transient solution may experience jumps from one solution branch to another, until the basin of attraction is approached. Those local bifurcations may change the sign of the derivative dF/du and produce nonphysical flux extrema on the cell. As a result, a "phantom" solution appears on the cell, which, in turn, leads to incorrect flux approximation and a singular Jacobian in the problem.

The flux correction algorithm that we present in this section detects all flux extrema over the grid. It is important to notice here that one should distinguish between physical and nonphysical extrema in the problem. At the physical flux extremum, the solution should be reduced to piecewise constant approximation, as the number of degrees of freedom is not equal to the number of equations for a high order DG discretization. Nonphysical extrema appear in the regions where the flux should be a monotone function. In this case it is sufficient to render the flux monotone on a given cell, as the number of unknowns is equal to the number of equations on the cells where the flux is a monotone function.

The topic of the treatment of physical flux extrema has been covered in section 3. Below we discuss how to eliminate the nonphysical flux extrema in the problem. Let us denote the extremum points of the function $F(u)$ as $u_1, u_2, \ldots, u_{P-1}$. The domain of definition of the variable u can be partitioned as $\mathcal{D}_u = \bigcup_{p=0}^{P-1} [u_p, u_{p+1}]$, where u_0

[1] For a weak solution, additional constraints, such as the entropy condition (e.g., see [8]), are also required to provide the uniqueness of the solution.

and u_P are the boundary points of the domain. Consider the values $u(x_i - 0)$ and $u(x_{i+1} + 0)$, i.e., the approximate solution taken from the adjacent cells at the left and right interfaces of the cell e_i. Each of these values lies between two extremum (or boundary) points, $u(x_i - 0) \in [u_p, u_{p+1}]$, $u(x_{i+1} + 0) \in [u_q, u_{q+1}]$, where $0 \le p, q < P$. We now consider $u(x_i + 0)$ and $u(x_{i+1} - 0)$, which are the boundary values of the solution approximation in the cell e_i. Our goal is to detect nonphysical flux extrema within each grid cell. Instead of limiting the solution variation, we bound the flux variation in the cell in order to eliminate the flux oscillations.

Namely, we require that

$$u(x_i + 0) \in [u_p, u_{p+1}], \qquad u(x_{i+1} - 0) \in [u_q, u_{q+1}].$$

In other words, an approximate Riemann solver used in the problem must give the same choice of the numerical flux for the solution considered at $[u_l = u(x_i + 0), u_r = u(x_{i+1} - 0)]$ as for the interval $[u_l = u(x_i - 0), u_r = u(x_{i+1} + 0)]$.

From an algorithmic point of view, it is convenient to introduce the following formal description of our approach. Let us denote the left and right solution states at the interface x_i as u_{1i} and u_{2i}, respectively. Given numerical flux $\tilde{F}(u_h)$, we define $\mathbf{s}_i = (s_{1i}, s_{2i})^T$ at each grid interface x_i, $i = 1, \dots, N+1$, as follows:

$$\mathbf{s}_{li} = \begin{cases} 1 & \text{if } u_{li} \text{ is required to define } \tilde{F}(u_h), \quad l = 1, 2, \\ 0 & \text{otherwise.} \end{cases}$$

Once the state vector has been defined at each grid interface, the cell e_i can be described by the matrix $\mathbf{S}_i$,

$$\mathbf{S}_i = \begin{bmatrix} s_{1\,i} & s_{1\,i+1} \\ s_{2\,i} & s_{2\,i+1} \end{bmatrix},$$

where the columns of the matrix $\mathbf{S}_i$ are state vectors taken at the left and right cell interface, respectively.

The values $u(x_i - 0)$ and $u(x_{i+1} + 0)$ define the main diagonal of the matrix $\mathbf{S}_i$, while the $u(x_i + 0)$ and $u(x_{i+1} - 0)$ define the off-diagonal entries. Hence, the flux within the cell can be controlled by means of the matrix $\mathbf{S}_i$. In particular, it can be easily seen that zero off-diagonal entries of the matrix indicate the "phantom" solution, which yields incorrect flux approximation in the cell e_i.

Below we illustrate our approach with a nonlinear boundary-value problem known as the problem of mass flow in a convergent-divergent nozzle [1]. Let A(x) be the area of the nozzle, $A(x) = 1/2 + 2(x - 1/2)^2$, $0 \le x \le 1$, and let $u(x)$ be the velocity deviation.

The conservation law is

$$\frac{dF(x, u(x))}{dx} \equiv \frac{d(A(x)m(u))}{dx} = 0, \quad x \in [0, 1], \tag{18}$$

where the mass flux through the nozzle is given by

$$m(u) = \frac{1}{2}(1 - u^2). \tag{19}$$

The value $u_s = 0$ (sonic point) is a flux extremum point.

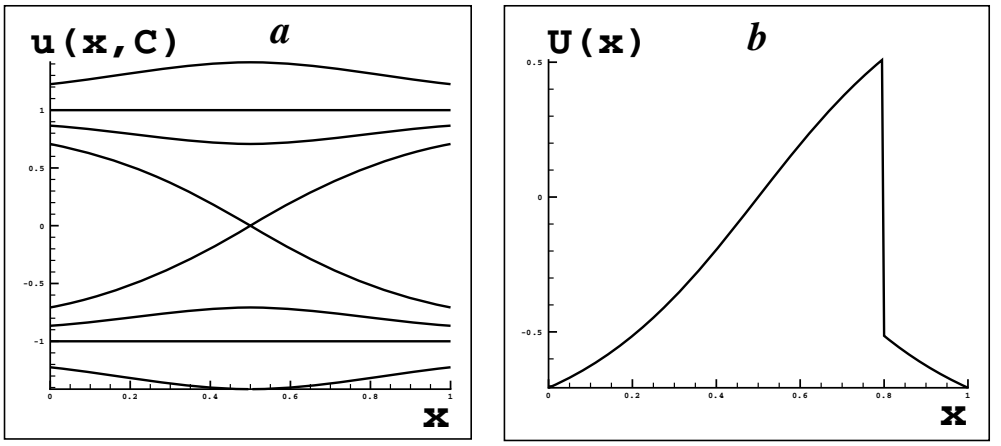

FIG. 3. *The nozzle problem.* (a) *The solution parametric field* $u(x, C)$. (b) *A discontinuous solution to the boundary-value problem* (18), (9).

A solution to the problem (18) is multivalued. The solutions are given by

$$u_{1,2}(x) = \pm\sqrt{1 - \frac{2C}{A(x)}},$$

where C is a constant. The solution parametric field $u(x, C)$ is shown in Figure 3(a). The value $x_s = 1/2$ is a solution extremum point for any $C \neq 0$ from the domain of the definition of C.

The value C is a controlling parameter for the problem. Let us choose $C = 1/4$, such that $u(x_s) = u_s$ and the point $P_s = (x_s, u_s)$ becomes the solution bifurcation point. Then the solution may be discontinuous at the point x_{sh}:

$$U(x) = \begin{cases} -\sqrt{(1 - 1/2A(x))}, & 0 \le x \le x_s \text{ or } x_{sh} + 0 \le x \le 1, \\ \sqrt{(1 - 1/2A(x))}, & x_s \le x \le x_{sh} - 0. \end{cases} \tag{20}$$

Equation (18) is solved due to the boundary condition (9) which determines the shock location x_{sh}. Integrating the solution over the domain $[0, 1]$ yields the following algebraic equation with respect to the variable x_{sh}:

$$I_1 + I_2(x_{sh}) + I_3(x_{sh}) = B,$$

where

$$I_1 = -\int_0^{x_s} \sqrt{1 - 1/2A(x)}dx, \quad I_2(x_{sh}) = \int_{x_s}^{x_{sh}} \sqrt{1 - 1/2A(x)}dx,$$

$$I_3(x_{sh}) = -\int_{x_{sh}}^{1} \sqrt{1 - 1/2A(x)}dx.$$

Solving this equation for a given value of B, the shock location can be defined. If we choose $B = -0.25$, then the shock will be located at $x_{sh} = 0.798074$. The discontinuous solution $U(x)$ is shown in Figure 3(b).

Consider the approximate solution $u_h(x)$ at the interface x_i. Given the left and right states at the interface, the Engquist–Osher numerical flux is similar to that in (11),

$$\tilde{m}(u_l,u_r)=\begin{cases} m(u_r), & u_l<0,\ u_r<0 \ \text{(subsonic case)},\\ m(u_l), & u_l>0,\ u_r>0 \ \text{(supersonic case)},\\ m(0), & u_l<0,\ u_r>0 \ \text{(sonic case)},\\ m(u_l)+m(u_r)-m(0), & u_l>0,\ u_r<0 \ \text{(shock case)}. \end{cases} \tag{21}$$

First, we use the standard DG approach to solve the boundary problem (18), (9). The problem is solved on a sequence of uniform grids. The initial guess on the first grid of eight nodes is chosen as $u_0(x)=\text{const}=-1.0$. The initial guess for the next finer grid is obtained by linear interpolation of the solution taken from a previous grid. The results with the standard DG discretization are that Newton's method fails to obtain a convergent solution for any polynomial degree $K>0$. Only a piecewise constant discretization reconstructs the discontinuous solution $U(x)$.

A DG discretization with polynomial degree $K>0$ yields a singular Jacobian on a shock cell. However, simple reduction to piecewise constant approximation near the shock is not successful in the problem and results in a divergent solution. A more thorough control of the numerical flux is required. For this purpose, we compute the matrix $\mathbf{S}_i$ on each grid cell e_i, $i=1,\dots,N$, at each Newton step. The definition (21) gives us the following formal classification of the matrix $\mathbf{S}_i$:

$$\mathbf{S}_i=\begin{bmatrix} 0 & s_{1\,i+1}\\ s_{2\,i} & 1 \end{bmatrix} \text{ (subsonic case)}, \quad \mathbf{S}_i=\begin{bmatrix} 1 & s_{1\,i+1}\\ s_{2\,i} & 0 \end{bmatrix} \text{ (supersonic case)},$$

$$\mathbf{S}_i=\begin{bmatrix} 0 & s_{1\,i+1}\\ s_{2\,i} & 0 \end{bmatrix} \text{ (sonic case)}, \qquad \mathbf{S}_i=\begin{bmatrix} 1 & s_{1\,i+1}\\ s_{2\,i} & 1 \end{bmatrix} \text{ (shock case)},$$

where $s_{1\,i+1}$ and $s_{2\,i}$ may take the value 0 or 1.

Based on the analysis of the state matrix $\mathbf{S}_i$, the correction algorithm, which eliminates nonphysical flux extrema for the problem (18), (9), is as follows.

1. [illegible] $u_h(x)$ [illegible] e_i, $i=1,\dots,N$ [illegible]
2. [illegible] $\mathbf{S}_i$ [illegible] e_i, $i=1,\dots,N$ [illegible] $\mathbf{S}_i$
3. [illegible] e_i [illegible]
   - 3.1 $s_{2i}\neq 1$, $s_{1\,i+1}\neq 0$ [illegible] $\mathbf{S}_i$
   - 3.2 $s_{2i}\neq 0$, $s_{1\,i+1}\neq 1$ [illegible] $\mathbf{S}_i$
   - 3.3 $s_{2i}=0$, $s_{1\,i+1}=0$ [illegible] $\mathbf{S}_i$ [illegible]
   - 3.4 $\mathbf{S}_i$ [illegible]
4. [illegible] e_i
$$u_h^{lin}(x)=u_{1i}+(u_{2\,i+1}-u_{1i})\phi_1(x).$$
5. [illegible] e_i [illegible] e_i
$$u_h^{c}(x)=\frac{1}{h_i}\int_{x_i}^{x_{i+1}} u_h^{lin}(x)dx.$$
6. [illegible] $u_h(x)$ [illegible]

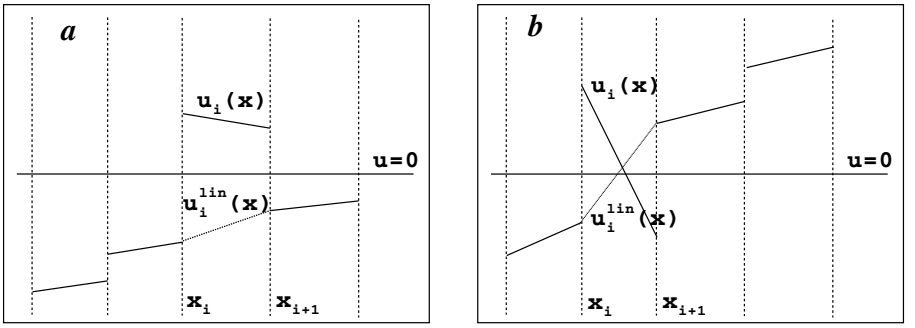

FIG. 4. *Examples of nonphysical flux extrema in the problem* (18), (9). (a) *The subsonic solution overshoot produces a sonic point and a shock at the cell interfaces.* (b) *The sonic solution overshoot produces a shock at the interior point of the cell and another sonic point at the cell interface.*

The above algorithm traces flux extrema over the grid for a transient solution at each Newton iteration. For the subsonic and supersonic cases, i.e., in the regions where the flux $m(u)$ is a monotone function, it is sufficient to control off-diagonal entries of $\mathbf{S}_i$ to ensure that there is no local bifurcation in the cell. We require that a transient solution generates the state matrix on the cell e_i as follows:

$$\mathbf{S}_i = \begin{bmatrix} 0 & 0 \\ 1 & 1 \end{bmatrix} \text{ (subsonic case)}, \quad \mathbf{S}_i = \begin{bmatrix} 1 & 1 \\ 0 & 0 \end{bmatrix} \text{ (supersonic case)}.$$

Let, for instance, the "subsonic" matrix be

$$\mathbf{S}_i = \begin{bmatrix} 0 & 1 \\ 0 & 1 \end{bmatrix}.$$

This matrix is related to the solution shown in Figure 4(a). The matrix $\mathbf{S}_i$ indicates that a local solution overshoot appears on the cell e_i. That overshoot produces two nonphysical flux extrema (a sonic point and a shock) which must be eliminated. For this purpose, we linearly interpolate a transient solution on the cell e_i between the points $u(x_i - 0)$ and $u(x_{i+1} + 0)$ (see Figure 4(a)).

For the sonic case, we must eliminate the state matrix

$$\mathbf{S}_i = \begin{bmatrix} 0 & 0 \\ 0 & 0 \end{bmatrix},$$

which indicates a "phantom" sonic solution. Again, the solution on the cell e_i will be linearly interpolated between the points $u(x_i - 0)$ and $u(x_{i+1} + 0)$ if a sonic cell yields the above matrix (see Figure 4(b)). The other "sonic" matrices are legal. The matrix $\mathbf{S}_i$, which has $s_{1\,i+1} = 1$ and $s_{2\,i} = 1$, corresponds to the sonic point inside the cell e_i, while the other two matrices indicate the sonic point at the interface.

As it has been earlier discussed, the linear solution interpolation between the points $u(x_i - 0)$ and $u(x_{i+1} + 0)$ is not sufficient for the shock. The interpolated solution eliminates nonphysical flux extrema on the cell, but it remains "phantom" in the presence of the shock. In other words, the number of degrees of freedom is not equal to the number of equations on the shock cell for the interpolated solution. Thus, in our algorithm we reduce the solution to piecewise constant approximation at the shock.

TABLE 1

The number N of Newton iterations required to converge on a given grid. N_c is the number of grid cells.

$N(K, N_c)$:	$N_c = 8$	$N_c = 16$	$N_c = 32$	$N_c = 48$	$N_c = 64$
K=0	9	5	4	3	4
K=1	9	5	5	4	4
K=2	10	5	5	4	4
K=3	10	5	4	4	4

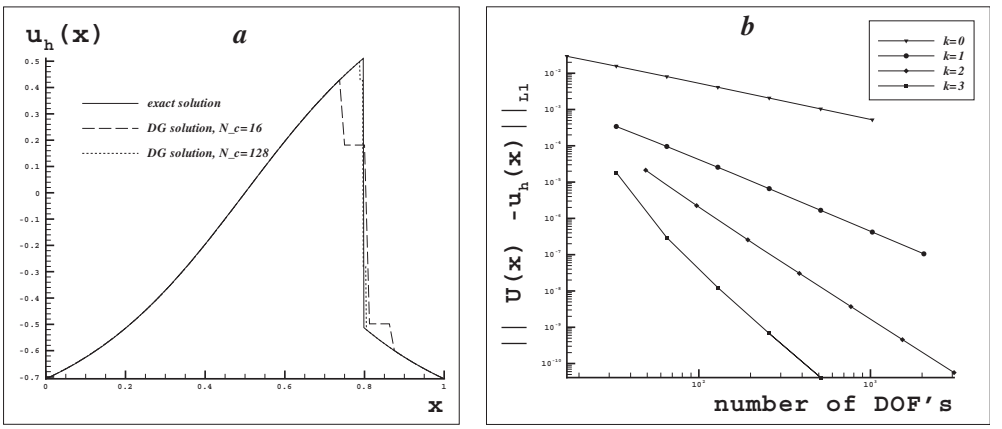

FIG. 5. *Numerical solution to the problem* (18), (9). (a) *An example of the DG solution (polynomial degree $K = 3$) on a coarse and a fine grid. N_c is the number of grid cells.* (b) *Convergence history for the DG solution with polynomial degree $K \geq 0$.*

The correction procedure allows one to obtain convergent solutions for DG $K > 0$ discretization schemes. Once the flux correction has been performed, the Newton method rapidly converges to the approximate solution. The number of Newton iterations required to converge on a given grid is displayed in Table 1 for the polynomial degree $K \geq 0$.

The approximate DG solution with polynomial degree $K = 3$ obtained by the flux correction is shown in Figure 5(a) on a coarse uniform grid of 16 cells and a fine grid of 128 cells. According to the correction algorithm, the shock is smeared over two adjacent grid cells, as an uncorrected solution has the shock at the grid interface at the final Newton step.

The convergence history on a sequence of uniform grids is plotted in Figure 5(b) for polynomial degree $K \geq 0$. The L_1-norm of the solution error,

$$||err||_{L_1} = \int_0^1 |U(x) - u_h(x)|dx,$$

is computed in regions where the solution is smooth (i.e., grid cells, which produce a shock state matrix, are not taken into account). The error norm is shown in the logarithmic scale. It can be seen from the convergence plots that the suggested algorithm keeps the order of approximation. The polynomial degree of the approximate solution is reduced only for a transient solution at the current Newton step. Once the solution is correct, the original polynomial degree will be restored on the cell at the next iterations. This approach allows one to obtain the optimal order of the convergence for high order DG discretizations.

6. Concluding remarks. We have considered high order DG schemes for steady state solutions. It has been shown that flux approximation near extremum points may generate spurious solution oscillations. Physical flux extrema require careful treatment to avoid a singular Jacobian in a steady state problem. Besides, false flux extrema may appear in a transient solution, when Newton's method is used to solve the problem. A high order DG discretization needs flux monitoring over each grid cell in order to eliminate nonphysical flux extrema.

The requirement of careful flux approximation makes Newton's method hardly appropriate for those steady state problems which do not have stabilization terms (e.g., diffusion and/or source terms) providing nonzero diagonal entries in the Jacobian. Although the flux control algorithm presented in the paper allows one to avoid a singular matrix in the one-dimensional case, it does not seem to always be efficient for multidimensional problems, where the construction of the state matrix on each grid cell becomes a complicated task.

The results of our paper confirm that a reasonable alternative to Newton's method is to use a time marching approach in order to obtain a steady state solution. It has been discussed in the paper that the time derivative can be considered as a stabilization term for high order DG schemes. However, an ill-conditioned Jacobian may appear at the end of the time stepping process when we approach "quasi-Newton" iterations. Thus, care should be taken of the flux approximation even in the case that a time stepping algorithm is used, and the issue of the numerical flux for high order DG discretizations requires further study when steady state problems are considered.

WAVELET GALERKIN SCHEMES FOR BOUNDARY INTEGRAL EQUATIONS—IMPLEMENTATION AND QUADRATURE*

HELMUT HARBRECHT† AND REINHOLD SCHNEIDER†

Abstract. In the present paper we consider the fully discrete wavelet Galerkin scheme for the fast solution of boundary integral equations in three dimensions. It produces approximate solutions within discretization error accuracy offered by the underlying Galerkin method at a computational expense that stays proportional to the number of unknowns. We focus on algorithmical details of the scheme, in particular on numerical integration of relevant matrix coefficients. We illustrate the proposed algorithm by numerical results.

Key words. boundary integral equations, biorthogonal wavelet bases, matrix compression, numerical integration

Introduction. Various problems in science and engineering can be formulated as boundary integral equations. In general, boundary integral equations are solved numerically by the boundary element method (BEM). For example, BEM is a favorable approach for the treatment of exterior boundary value problems. Nevertheless, traditional discretizations of integral equations suffer from a major disadvantage. The associated system matrices are densely populated. Therefore, the complexity for solving such equations is at least $\mathcal{O}(N_J^2)$, where N_J denotes the number of equations. This fact seriously restricts the maximal size of the linear equations.

Modern methods for the fast solution of BEM reduce the complexity to a suboptimal rate $\mathcal{O}(N_J \log^\alpha N_J)$ or even an optimal rate $\mathcal{O}(N_J)$. Prominent examples for such methods are the [16], the [18], $\mathcal{H}$ [17], or the [1, 6, 10, 11, 31]. In fact, a Galerkin discretization with wavelet bases results in quasi-sparse matrices; i.e., most matrix entries are negligible and can be treated as zero. Discarding these nonrelevant matrix entries is called matrix compression. As shown in [6, 31] only $\mathcal{O}(N_J)$ significant matrix entries remain.

Concerning boundary integral equations, a strong effort has been expended on the construction of appropriate wavelet bases on surfaces [8, 12, 13, 14, 20, 26]. In order to achieve the optimal complexity of the wavelet Galerkin scheme, wavelet bases are required which provide a sufficiently large number of vanishing moments. Our realization is based on biorthogonal spline wavelets derived from the multiresolution developed in [3]. These wavelets are advantageous since the regularity of the duals is known [33]. Moreover, the duals are compactly supported, which preserves the linear complexity of the fast wavelet transform also for its inverse. This is an important task for the coupling of the finite element method and BEM; cf. [21, 22]. Additionally,

in view of the discretization of operators of positive order, e.g., the hypersingular operator, globally continuous wavelets are available [2, 4, 12, 20]. We refer the reader to [23] for the details on the wavelet bases employed for our actual implementation of the wavelet Galerkin scheme.

In the present paper we describe algorithmical details of a fully discrete wavelet Galerkin scheme for the fast solution of boundary integral equations. Particularly, we realized the so-called second compression to achieve linear complexity [6, 31]. The efficient computation of the relevant matrix coefficients turned out to be the cornerstone for the successful application of the wavelet Galerkin method [20, 27, 31]. A fully discrete Galerkin scheme based on numerical quadrature is also required to treat nontrivial geometries. We expended much effort to realize an efficient quadrature strategy. Supposing that the given manifold is piecewise analytic, one applies an *hp*-quadrature scheme [20, 27, 31, 32] based on tensor product Gauss–Legendre quadrature formulas to arrive at an algorithm with asymptotically linear complexity without compromising the accuracy of the Galerkin scheme. However, a careful organization of the quadrature is indispensable to avoid wasteful and multiple calculations that affect the performance. We propose an element-based quadrature similar to the traditional single-scale Galerkin scheme. Especially we require only the quadrature routines of the traditional scheme to compute element-element interactions, except for the extension to different degrees of quadrature to deal with elements on different levels. The *h*-refinement is realized by replacing an element-element interaction by the element-element interactions related to the sons of the elements. Combined with a [illegible] to reuse previously computed element-element interactions (cf. sections 8 and 9) the work for quadrature decreases significantly. We emphasize that the proposed strategy greatly reduces the break-even point. By numerical experiments, considering the sphere and a nontrivial gearwheel, we confirm that we proceeded in developing a fast solver for the considered class of problems.

The outline of the present paper is as follows. First, in section 1, we introduce the class of problems under consideration. Then we provide the wavelet bases on manifolds in section 2 and recall the matrix compression in section 3. The next sections are concerned with implementational aspects: In section 4 a suitable data structure is introduced to handle a wide class of wavelets, in section 5 the numerical evaluation of distances is performed, in section 6 the compression pattern is set up, and in section 7 the computation of the compressed system matrix is reduced to the computation of certain element-element interactions which are investigated in section 8. Section 9 is concerned with the quadrature of element-element interactions which correspond mostly to nearly singular and singular integrals. We prove that, using our quadrature strategy, the compressed system matrix is computed within linear complexity. In section 10 we present numerical results employing both piecewise constant and bilinear wavelets.

We shall frequently write $a \lesssim b$ to express that a is bounded by a constant multiple of b, uniformly with respect to all parameters on which a and b may depend. Then $a \sim b$ means $a \lesssim b$ and $b \lesssim a$.

1. Problem formulation and preliminaries. We consider boundary integral equations on a closed boundary surface Γ of a three-dimensional domain $\Omega \subset \mathbb{R}^3$,

$$Au = f \quad \text{on } \Gamma, \tag{1.1}$$

where the boundary integral operator

$$Au(x) = \int_\Gamma k(x,y)u(y)d\Gamma_y$$

is assumed to be an operator of order $2q$, that is, $A : H^q(\Gamma) \to H^{-q}(\Gamma)$. The kernel functions under consideration are supposed to be piecewise smooth as functions in the variables x, y, apart from the diagonal $\{(x, y) \in \Gamma \times \Gamma : x = y\}$, and may have a singularity on the diagonal. Such kernels arise, for instance, by applying a boundary integral formulation to a second order elliptic problem. In general, they decay like a negative power of the distance of the arguments that depends on the operator order $2q$.

Throughout the remainder of this paper we shall assume that the boundary manifold Γ is given as a parametric surface consisting of smooth patches. More precisely, let $\square := [0,1]^2$ denote the unit square. The manifold $\Gamma \in \mathbb{R}^3$ is partitioned into a finite number of

$$\Gamma = \bigcup_{i=1}^{M} \Gamma_i, \qquad \Gamma_i = \gamma_i(\square), \qquad i = 1, 2, \ldots, M, \tag{1.2}$$

where each $\gamma_i : \square \to \Gamma_i$ defines a diffeomorphism of $\square$ onto Γ_i. The intersection $\Gamma_i \cap \Gamma_{i'}$, $i \neq i'$, of two different patches is supposed to be either empty or a common edge or vertex.

A mesh of level j on Γ is induced by dyadic subdivisions of depth j of the unit square into 4^j squares

$$\square_{j,k} := [2^{-j}k_1, 2^{-j}(k_1+1)] \times [2^{-j}k_2, 2^{-j}(k_2+1)] \subseteq \square,$$

where $k = (k_1, k_2)$ with $0 \le k_1, k_2 < 2^j$. This generates $4^j M$ (or elementary domains) $\Gamma_{i,j,k} := \gamma_i(\square_{j,k}) \subseteq \Gamma_i$, $i = 1, \ldots, M$.

In order to ensure that the collection of elements $\{\Gamma_{i,j,k}\}$ on the level j forms a regular mesh on Γ, the parametric representation is subjected to the following : A bijective, affine mapping $\Xi : \square \to \square$ exists such that for all $x = \gamma_i(s)$ on a common edge of Γ_i and $\Gamma_{i'}$ it holds that $\gamma_i(s) = (\gamma_{i'} \circ \Xi)(s)$. In other words, the diffeomorphisms γ_i and $\gamma_{i'}$ yield the same parametrization of the common edge except for orientation. This setting is frequently used and well understood in computer aided geometric design; cf. [24, 28], for example. A conforming mesh of a gearwheel is depicted in Figure 1.1.

Denoting the surface measure by $\kappa_i(s) := \|\partial_{s_1}\gamma_i(s) \times \partial_{s_2}\gamma_i(s)\|$, the canonical inner product in $L^2(\Gamma)$ is given by

$$\langle u, v \rangle := \int_\Gamma u(x)v(x)d\Gamma_x = \sum_{i=1}^{M} \int_\square u\big(\gamma_i(s)\big)v\big(\gamma_i(s)\big)\kappa_i(s)ds.$$

The associated Sobolev spaces are denoted by $H^t(\Gamma)$, endowed with the norms $\|\cdot\|_t$, where for $t < 0$ it is understood that $H^t(\Gamma) = (H^{-t}(\Gamma))'$. Of course, depending on the global smoothness of the surface, the range of permitted $t \in \mathbb{R}$ is limited to $t \in (-t_\Gamma, t_\Gamma)$.

In what follows it will be rather convenient to have access to the $\gamma_{i,j,k} : \square \to \Gamma_{i,j,k}$ given by

$$\gamma_{i,j,k}(s) := \gamma_i\big(2^{-j}\left[\begin{smallmatrix} k_1+s_1 \\ k_2+s_2 \end{smallmatrix}\right]\big), \qquad s = \left[\begin{smallmatrix} s_1 \\ s_2 \end{smallmatrix}\right] \in \square. \tag{1.3}$$

For $m \in \mathbb{N}$ we conclude that

$$\partial_{s_n}^m \gamma_{i,j,k}(s) = 2^{-jm}\,(\partial_{s_n}^m \gamma_i)\big(2^{-j}\left[\begin{smallmatrix} k_1+s_1 \\ k_2+s_2 \end{smallmatrix}\right]\big), \qquad n = 1, 2; \tag{1.4}$$

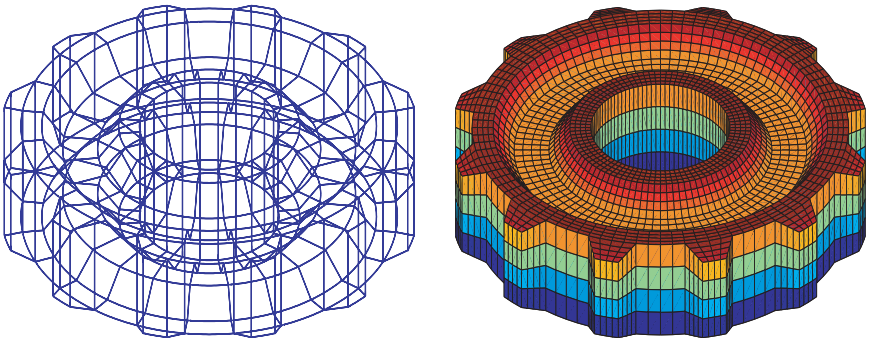

FIG. 1.1. *A gearwheel represented by* 336 *patches and the associated mesh on the level* 2.

in particular, the corresponding surface measure satisfies

$$\kappa_{i,j,k}(s) := \big\|\partial_{s_1}\gamma_{i,j,k}(s) \times \partial_{s_2}\gamma_{i,j,k}(s)\big\| = 2^{-2j}\kappa_i\big(2^{-j}\left[\begin{smallmatrix}k_1+s_1\\ k_2+s_2\end{smallmatrix}\right]\big). \tag{1.5}$$

We can now specify the kernel functions. To this end, we denote by $\alpha = (\alpha_1, \alpha_2)$ and $\beta = (\beta_1, \beta_2)$ multi-indices of dimension two and define $|\alpha| := \alpha_1 + \alpha_2$.

DEFINITION 1.1. [illegible] $k(x,y)$ [illegible] $2q$ [illegible]

$$k_{i,i'}(s,t) := k\big(\gamma_i(s), \gamma_{i'}(t)\big)\kappa_i(s)\kappa_{i'}(t), \qquad s,t \in \square, \qquad 1 \le i, i' \le M, \tag{1.6}$$

[illegible]

$$|\partial_s^\alpha \partial_t^\beta k_{i,i'}(s,t)| \le c_{\alpha,\beta}\|\gamma_i(s) - \gamma_{i'}(t)\|^{-(2+2q+|\alpha|+|\beta|)},$$

[illegible] $2 + 2q + |\alpha| + |\beta| > 0$

We emphasize that this definition requires patchwise smoothness but [illegible] global smoothness of the geometry. The surface itself needs to be only Lipschitz. Generally, under this assumption, the kernel of a boundary integral operator A of order $2q$ is a standard kernel of order $2q$. Hence, we may assume this property in what follows. We shall encounter further specifications in connection with numerical integration.

2. Biorthogonal wavelet bases. The nested trial spaces $V_j \subset V_{j+1}$ that we shall employ in the Galerkin scheme are the spaces of piecewise constant or bilinear functions on the given partition. These trial spaces have the [illegible] $d = 1$ and $d = 2$ in the case of the piecewise constants and bilinears, respectively; i.e., $\inf_{v_j \in V_j} \|v - v_j\|_0 \lesssim 2^{-jd}\|v\|_d$. They are spanned by so-called [illegible] $\Phi_j = \{\phi_{j,k} : k \in \Delta_j\}$ which can be specified as follows: On the level j, we find for each element $\Gamma_{i',j,k'}$ a piecewise constant scaling function $\phi_{j,k}$ with

$$\phi_{j,k}\big|_{\Gamma_{i',j,k'}} \equiv 2^j \tag{2.1}$$

and $\phi_{j,k}(x) = 0$ elsewhere. To describe the canonical piecewise bilinear scaling functions, we define four bilinear shape functions on the unit square:

$$\begin{aligned} p_1^\square(s) &:= (1-s_1)(1-s_2), & p_2^\square(s) &:= s_1(1-s_2),\\ p_3^\square(s) &:= s_1 s_2, & p_4^\square(s) &:= (1-s_1)s_2. \end{aligned} \tag{2.2}$$

Thus, $\phi_{j,k}$ is equal to 2^j in one node and equal to zero in the remaining nodes and, if its support contains an element $\Gamma_{i',j,k'}$, we find an $m \in \{1,2,3,4\}$ such that

$$\phi_{j,k}\big|_{\Gamma_{i',j,k'}}(x) = 2^j p_m^{\square}(s), \qquad x = \gamma_{i',j,k'}(s) \in \Gamma_{i',j,k'}. \tag{2.3}$$

Continuity is supposed on each patch, but along the interfaces of the patches we may consider double nodes or continuity. Notice that our definition yields the L^2-normalization $\|\phi_{j,k}\|_0 \sim 1$.

Associated with the [illegible] $\{V_j\}_{j\geq j_0}$ is always a [illegible] multiresolution sequence $\{\widetilde{V}_j\}_{j\geq j_0}$ which is generated by dual bases $\widetilde{\Phi}_j = \{\widetilde{\phi}_{j,k} : k \in \Delta_j\}$; i.e., one has $\langle \phi_{j,k}, \widetilde{\phi}_{j,k'}\rangle = \delta_{k,k'}$, $k,k' \in \Delta_j$. Here and below j_0 always stands for some fixed coarsest level of resolution that may depend on Γ. For the current type of boundary surfaces Γ the $\Phi_j, \widetilde{\Phi}_j$ are generated by first constructing dual pairs of single-scale bases on the interval $[0,1]$, using the dual components from [3] adapted to the interval [9]. Tensor products yield corresponding dual pairs on $\square$. Using the parametric liftings γ_i and gluing across patch boundaries leads to globally continuous single-scale bases $\Phi_j, \widetilde{\Phi}_j$ on Γ [2, 4, 13]. The dual spaces have approximation order $\widetilde{d} \geq d$ such that $d + \widetilde{d}$ is even.

Given the single-scale bases $\Phi_j, \widetilde{\Phi}_j$, one now can construct biorthogonal [illegible] $\Psi_j = \{\psi_{j,k} : k \in \nabla_j := \triangle_{j+1} \setminus \triangle_j\}$, $\widetilde{\Psi}_j = \{\widetilde{\psi}_{j,k} : k \in \nabla_j\}$, i.e., $\langle \psi_{j,k}, \widetilde{\psi}_{j',k'}\rangle = \delta_{(j,k),(j',k')}$, such that

$$\begin{aligned} W_j &:= \operatorname{span}\{\Psi_j\} \perp \widetilde{V}_j, \qquad & V_{j+1} &= V_j \oplus W_j, \\ \widetilde{W}_j &:= \operatorname{span}\{\widetilde{\Psi}_j\} \perp V_j, \qquad & \widetilde{V}_{j+1} &= \widetilde{V}_j \oplus \widetilde{W}_j, \end{aligned}$$

and $\operatorname{diam}\operatorname{supp}\psi_{j,k} \sim \operatorname{diam}\operatorname{supp}\widetilde{\psi}_{j,k} \sim 2^{-j}$ $(j \geq j_0)$; see, e.g., [2, 4, 12, 13] and [20, 23] for particularly useful local representations of important construction ingredients. We suppose these complement bases are normalized in $L^2(\Gamma)$.

A biorthogonal or [illegible] pair of wavelet bases is now obtained by taking the coarse single-scale basis and the union of the complement bases,

$$\Psi = \bigcup_{j\geq j_0-1} \Psi_j, \qquad \widetilde{\Psi} = \bigcup_{j\geq j_0-1} \widetilde{\Psi}_j,$$

where we have set for convenience $\Psi_{j_0-1} := \Phi_{j_0}$, $\widetilde{\Psi}_{j_0-1} := \widetilde{\Phi}_{j_0}$. Of course, in the infinite-dimensional case the notion of basis has to be made more specific. The key feature of the wavelet basis is now the fact that $\Psi, \widetilde{\Psi}$ are actually [illegible] in $L^2(\Gamma)$.

From biorthogonality and the fact that the dual spaces $\widetilde{V}_j$ have the approximation order $\widetilde{d}$ one infers [illegible] or the [illegible] of the primal wavelets

$$|\langle v, \psi_{j,k}\rangle| \lesssim 2^{-j(\widetilde{d}+1)} |v|_{W^{\widetilde{d},\infty}(\operatorname{supp}\psi_{j,k})}. \tag{2.4}$$

Here $|v|_{W^{\widetilde{d},\infty}(\Omega)} := \sup_{|\alpha|=\widetilde{d},\, x\in\Omega} |\partial^\alpha v(x)|$ denotes the seminorm in $W^{\widetilde{d},\infty}(\Omega)$. The fact that the concept of biorthogonality allows us to choose the order $\widetilde{d}$ of vanishing moments higher than the approximation order d is essential for deriving optimal compression strategies that could not be realized by orthonormal bases.

3. Matrix compression. We shall be concerned with the Galerkin method for the solution of the given boundary integral equation (1.1): Find $u_J \in V_J$ solving the variational problem

$$\langle Au_J, v_J \rangle = \langle f, v_J \rangle \quad \text{for all} \quad v_J \in V_J.$$

Traditionally this equation is discretized by the single-scale basis of V_J which yields a densely populated system matrix. Using instead wavelets with a sufficiently strong cancellation property (2.4), the system matrix becomes quasi-sparse and most matrix coefficients are negligible without compromising the order of convergence of the Galerkin scheme [6, 31].

But before we formulate this result, we introduce the following abbreviation:

$$\Omega_{j,k} := \operatorname{conv\,hull}(\operatorname{supp} \psi_{j,k}), \qquad \Omega'_{j,k} := \operatorname{sing\,supp} \psi_{j,k}. \tag{3.1}$$

Notice that the first expression denotes the convex hull of the support of a wavelet with respect to the Euclidean space $\mathbb{R}^3$. The second expression indicates the [illegible], i.e., that subset of Γ where the wavelet is not smooth.

THEOREM 3.1 (a priori compression). [illegible] $\Omega_{j,k}$ [illegible] $\Omega'_{j,k}$ [illegible] (3.1) [illegible] $\mathbf{A}_J$ [illegible] A [illegible]

$$[\mathbf{A}_J]_{(j,k),(j',k')} := \begin{cases} 0, & \operatorname{dist}(\Omega_{j,k}, \Omega_{j',k'}) > \mathcal{B}_{j,j'} \quad j, j' \geq j_0, \\ 0, & \operatorname{dist}(\Omega_{j,k}, \Omega_{j',k'}) \lesssim 2^{-\min\{j,j'\}} \\ & \operatorname{dist}(\Omega'_{j,k}, \Omega_{j',k'}) > \mathcal{B}'_{j,j'}, \quad j' > j \geq j_0 - 1, \\ & \operatorname{dist}(\Omega_{j,k}, \Omega'_{j',k'}) > \mathcal{B}'_{j,j'}, \quad j > j' \geq j_0 - 1, \\ \langle A\psi_{j',k'}, \psi_{j,k} \rangle & \text{[illegible]} \end{cases} \tag{3.2}$$

[illegible]

$$a, a' > 1, \qquad d < d' < \widetilde{d} + 2q, \tag{3.3}$$

[illegible] $\mathcal{B}_{j,j'}$ [illegible] $\mathcal{B}'_{j,j'}$ [illegible]

$$\begin{aligned} \mathcal{B}_{j,j'} &= a \ \max\left\{ 2^{-\min\{j,j'\}}, 2^{\frac{2J(d'-q)-(j+j')(d'+\tilde{d})}{2(\tilde{d}+q)}} \right\}, \\ \mathcal{B}'_{j,j'} &= a' \max\left\{ 2^{-\max\{j,j'\}}, 2^{\frac{2J(d'-q)-(j+j')d'-\max\{j,j'\}\tilde{d}}{\tilde{d}+2q}} \right\}. \end{aligned} \tag{3.4}$$

[illegible]

$$\|u - u_J\|_{2q-d} \lesssim 2^{-2J(d-q)} \|u\|_d \tag{3.5}$$

[illegible] u_J [illegible] u [illegible] Γ [illegible]

In [6, 20] we presented a general theorem which shows that the overall complexity of assembling the compressed system matrix can be kept of the order $\mathcal{O}(N_J)$, $N_J = \dim V_J$, even when a computational cost of logarithmic order is allowed for each entry. This theorem will be used later as the essential ingredient in proving that the quadrature strategy proposed in section 9 scales linearly.

THEOREM 3.2. $\mathbf{A}_J$ (3.2) $\mathcal{O}(N_J)$ $\alpha \geq 0$ $\mathcal{O}\big([2J-j-j']^4\big)$ $\langle A\psi_{j',k'}, \psi_{j,k}\rangle$

Numerical integration of relevant matrix coefficients has to be performed with sufficient accuracy. It turns out that the higher the level of resolution the lower the required accuracy. In accordance with [6, 20] we can formulate the following sufficient condition to retain the optimal order of convergence of the Galerkin scheme.

THEOREM 3.3. $\mathbf{A}_J$ 3.1 $\widetilde{\mathbf{A}}_J$

$$\big|[\mathbf{A}_J - \widetilde{\mathbf{A}}_J]_{(j,k),(j',k')}\big| \leq \varepsilon_{j,j'}$$

$\varepsilon_{j,j'}$

$$\varepsilon_{j,j'} \sim \min\Big\{2^{-|j-j'|}, 2^{-(2J-j-j')\frac{d'-q}{d+q}}\Big\} 2^{2Jq} 2^{-\delta(2J-j-j')} \tag{3.6}$$

$d' \in (d, \widetilde{d}+2q)$ (3.3) $\delta > d$ u_J (3.5) u Γ

If the order q of the boundary integral operator A is $\neq 0$, the compressed system matrix $\mathbf{A}_J$ becomes more and more ill conditioned when J increases. However, as a consequence of the norm equivalences of wavelet bases, the diagonally scaled system matrix has uniformly bounded spectral condition numbers, provided that the regularity $\widetilde{\gamma}$ of the dual wavelets satisfies $\widetilde{\gamma} > -q$ [5, 7, 10, 31]. Let us further remark that based on (3.6) an a posteriori compression is also available, which reduces again the number of nonzero coefficients; cf. [6, 20].

4. The data structure. In general the wavelet bases are not simply defined via tensor products of the univariate case. In particular, considering globally continuous wavelets, a single wavelet might be supported on several patches. This requires a suitable data structure to handle such wavelet bases.

4.1. The element tree. According to section 1 the elements $\Gamma_{i,j,k} = \gamma_i(\square_{j,k})$ are the images of the refined unit square under the parametric liftings γ_i. We introduce a hierarchical element tree with respect to "$\subseteq$" as follows. Starting with the M patches $\Gamma_i := \Gamma_{i,0,(0,0)}$ as the first generation, each element $\Gamma_{i,j,k}$ has the four sons $\Gamma_{i,j+1,k'} \subseteq \Gamma_{i,j,k}$, $k' \in \big\{(2k_1, 2k_2), (2k_1+1, 2k_2), (2k_1+1, 2k_2+1), (2k_1, 2k_2+1)\big\}$. Denoting by J the level of discretization, the tree consists of $J+1$ generations.

Notice that this element tree is given implicitly. The number of all elements is given by $N_\Gamma := \frac{M}{3}(4^{J+1}-1)$. Hence, we may utilize the bijective mapping

$$\lambda := \theta(i,j,k) = \frac{M}{3}(4^j - 1) + 4^j M i + 2^j k_2 + k_1 \tag{4.1}$$

to indicate the element $\Gamma_{i,j,k}$ uniquely by an integer $\lambda \in \{0, 1, \ldots, N_\Gamma - 1\}$. This numbering corresponds to indexing the element tree line-by-line. For the sake of brevity we frequently will write Γ_λ instead of $\Gamma_{i,j,k}$. Moreover, it is rather convenient to set $|\lambda| := j$.

4.2. The wavelet representation. The common way to perform the quadrature for, e.g., piecewise bilinear functions is element-based; that is, for all pairs of

elements one computes the element-element interactions of the associated shape functions and updates the system matrix correspondingly. Roughly speaking, a basis function is represented by in general four quadrilaterals (we call them the elements) and certain weights (namely equal to 2^j in the common vertex and zero elsewhere) of the shape functions associated with the vertices of these quadrilaterals. Since the wavelets of the level j are contained in V_{j+1}, we can represent the wavelet $\psi_{j,k}$ similarly by a set of elements $\Gamma_{i',j+1,k'} \subset \operatorname{supp} \psi_{j,k}$ and certain weight factors of the associated shape functions. This enables us to perform an element-based quadrature. It turns out that parts of the support of the wavelets are smooth even on the previous level, i.e., with respect to the elements $\Gamma_{i',j,k'}$; cf. [20, 23], for example. Therefore, we recommend a two level representation of the wavelets, which increases the performance of the wavelet Galerkin scheme enormously since fewer element-element interactions have to be evaluated.

More precisely, for each wavelet there exists a set $\mathcal{L}_{j,k}$ of elements $\Gamma_\lambda \in \operatorname{supp} \psi_{j,k}$, $|\lambda| \in \{j, j+1\}$, satisfying

$$\operatorname{supp} \psi_{j,k} = \bigcup_{\Gamma_\lambda \in \mathcal{L}_{j,k}} \Gamma_\lambda \subseteq \Omega_{j,k}, \qquad \Omega'_{j,k} \subseteq \bigcup_{\Gamma_\lambda \in \mathcal{L}_{j,k}} \partial\Gamma_\lambda \tag{4.2}$$

such that $\psi_{j,k} \circ \gamma_\lambda$ is either constant ($d = 1$),

$$\psi_{j,k}(x) \equiv 2^{|\lambda|} \omega_{j,k,\lambda}, \quad x = \gamma_\lambda(s), \quad s \in \square, \quad \Gamma_\lambda \in \mathcal{L}_{j,k}, \tag{4.3}$$

or piecewise bilinear ($d = 2$),

$$\psi_{j,k}(x) = 2^{|\lambda|} \sum_{m=1}^{4} \omega_{j,k,\lambda,m} p_m^{\square}(s), \quad x = \gamma_\lambda(s), \quad s \in \square, \quad \Gamma_\lambda \in \mathcal{L}_{j,k}, \tag{4.4}$$

with certain weights $\omega_{j,k,\lambda} \in \mathbb{R}$ and $\omega_{j,k,\lambda,m} \in \mathbb{R}$, respectively. This is illustrated in Figure 4.1 in the case of a piecewise bilinear wavelet.

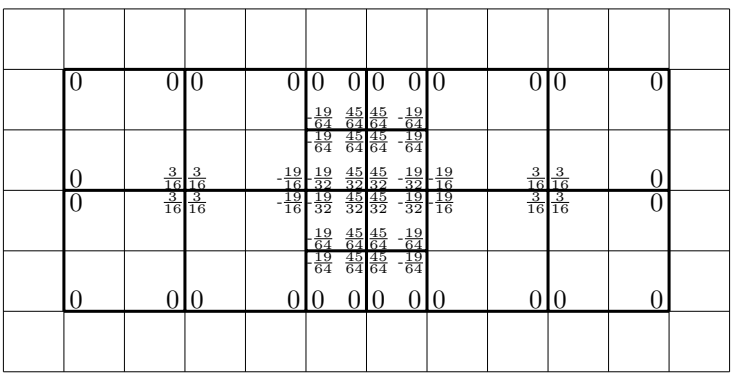

FIG. 4.1. *Element-based representation of a piecewise bilinear wavelet (four vanishing moments).*

Storing all weights is expensive, particularly for the piecewise bilinears. Since many wavelets correspond to identical masks, a suitable arrangement of the elements in the lists $\mathcal{L}_{j,k}$ induces identical lists of weights for such wavelets. Hence, we suggest storing only the different lists of weights. That way, the required memory is limited to $\mathcal{O}(1)$ since the number of different masks is independent of the level J.

Finally, in view of setting up the compression pattern, we introduce a wavelet tree defined with respect to the supports. Each wavelet has a certain number of sons with

$$\Omega_{j+1,\mathrm{son}} \subseteq \Omega_{j,\mathrm{father}} \qquad \text{if } \psi_{j+1,\mathrm{son}} \text{ is son of } \psi_{j,\mathrm{father}}. \tag{4.5}$$

We mention that the father-son relation might be described by fixed index operations independently of the geometry. However, the tree depends on the chosen wavelet construction.

5. Computing distances numerically. To determine the degrees of quadrature it is necessary to evaluate the distance between elements. Additionally, for the matrix compression, the distance between the supports of two wavelets, as well as the distance between the support of one wavelet and the singular support of another wavelet, has to be computed.

5.1. Computing distances between elements. For each element Γ_λ we determine a sphere $B(m_{\Gamma_\lambda}, r_{\Gamma_\lambda}) := \{x \in \mathbb{R}^3 : \|x - m_{\Gamma_\lambda}\| \le r_{\Gamma_\lambda}\}$ which encloses the element. Then, the distance between elements is approximated by

$$\begin{aligned} \operatorname{dist}(\Gamma_\lambda, \Gamma_{\lambda'}) &\ge \operatorname{dist}\big(B(m_{\Gamma_\lambda}, r_{\Gamma_\lambda}), B(m_{\Gamma_{\lambda'}}, r_{\Gamma_{\lambda'}})\big) \\ &= \max\{0, \|m_{\Gamma_\lambda} - m_{\Gamma_{\lambda'}}\| - r_{\Gamma_\lambda} - r_{\Gamma_{\lambda'}}\}. \end{aligned} \tag{5.1}$$

We start on the finest level $J = |\lambda|$ and compute the smallest sphere $B(m_{\Gamma_\lambda}, r_{\Gamma_\lambda})$ containing the four vertices of a given element Γ_λ. Assuming that J is sufficiently large, this sphere satisfies $\Gamma_\lambda \subseteq B(m_{\Gamma_\lambda}, r_{\Gamma_\lambda})$. Next, due to

$$\Gamma_\lambda = \bigcup_{\Gamma_{\lambda'} \text{ is son of } \Gamma_\lambda} \Gamma_{\lambda'},$$

the spheres to the elements on the lower levels are obtained recursively by determining the smallest spheres that contain the spheres of the associated sons. This ensures $\Gamma_\lambda \in B(m_{\Gamma_\lambda}, r_{\Gamma_\lambda})$ for all $|\lambda| \le J$ even if the surface Γ is strongly curved.

In the next subsection, the computation of the distance of the singular support and the support of wavelets is reduced to the computation of the distance $\operatorname{dist}(\Gamma_{i,j,k}, \partial\Gamma_{i',j',k'})$ $(j > j')$. Clearly, we find

$$\operatorname{dist}(\Gamma_{i,j,k}, \partial\Gamma_{i',j',k'}) = \operatorname{dist}(\Gamma_{i,j,k}, \Gamma_{i',j',k'}), \qquad i \ne i', \tag{5.2}$$

which is evaluated according to (5.1). Thus, it remains to consider $i = i'$. Since γ_i defines a diffeomorphism, we deduce $\operatorname{dist}(\Gamma_{i,j,k}, \partial\Gamma_{i,j',k'}) \sim \operatorname{dist}(\square_{j,k}, \partial\square_{j',k'})$; i.e. we might reduce our problem to the unit square. Observing that the ℓ^2-norm and the ℓ^∞-norm are equivalent in $\mathbb{R}^2$, the square $\square_{j,k}$ might be interpreted as the sphere $B(m_{\square_{j,k}}, r_{\square_{j,k}})$ with the midpoint $m_{\square_{j,k}} := \gamma_i\big(2^{-(j+1)}\left[\begin{smallmatrix}2k_1+1\\2k_2+1\end{smallmatrix}\right]\big)$ and the radius $r_{\square_{j,k}} := 2^{-(j+1)}$. Therefore, we conclude

$$\operatorname{dist}(\Gamma_{i,j,k}, \partial\Gamma_{i,j',k'}) \sim \big|\|m_{\square_{j,k}} - m_{\square_{j',k'}}\|_\infty - r_{\square_{j',k'}}\big| - r_{\square_{j,k}} \tag{5.3}$$

since either $\square_{j,k} \subseteq \square_{j',k'}$ or $\square^\circ_{j,k} \cap \square^\circ_{j',k'} = \emptyset$.

5.2. Computing distances between wavelets. Computing for each wavelet the sphere $B(m_{\psi_{j,k}}, r_{\psi_{j,k}})$ with

$$B(m_{\psi_{j,k}}, r_{\psi_{j,k}}) := \inf_{B(m,r)\in\mathbb{R}^3} \left\{ B(m,r) \supseteq \bigcup_{\Gamma_\lambda\in\mathcal{L}_{j,k}} B(m_{\Gamma_\lambda}, r_{\Gamma_\lambda}) \right\}, \tag{5.4}$$

we conclude from (4.2) that $\Omega_{j,k} \subseteq B(m_{\psi_{j,k}}, r_{\psi_{j,k}})$. Thus, the distance between the wavelets $\psi_{j,k}$ and $\psi_{j',k'}$ is computed analogously to (5.1) by

$$\operatorname{dist}(\Omega_{j,k}, \Omega_{j',k'}) \geq \max\{0, \|m_{\psi_{j,k}} - m_{\psi_{j',k'}}\| - r_{\psi_{j,k}} - r_{\psi_{j',k'}}\}. \tag{5.5}$$

. . . . Of course, it suffices to compute only appropriate approximations to the infimum in (5.4). Moreover, one can use also axis-parallel boxes instead of spheres, which offers the advantage of resolving the high aspect ratios of the wavelets. However, one obtains different distances when rotating the geometry.

Next, the computation of $\operatorname{dist}(\Omega_{j,k}, \Omega'_{j',k'})$ is performed by invoking $\mathcal{L}_{j,k}$ and $\mathcal{L}_{j',k'}$. One readily infers

$$\operatorname{dist}(\Omega_{j,k}, \Omega'_{j',k'}) \gtrsim \min_{\Gamma_\lambda\in\mathcal{L}_{j,k}} \min_{\Gamma_{\lambda'}\in\mathcal{L}_{j',k'}} \big\{ \operatorname{dist}(\Gamma_\lambda, \partial\Gamma_{\lambda'}) \big\},$$

which is evaluated by (5.2) and (5.3), respectively.

6. Setting up the compression pattern. Checking the distance criteria (3.2) for each matrix coefficient in order to assemble the compressed matrix would require $\mathcal{O}(N_J^2)$ function calls. To realize linear complexity, we exploit the tree structure with respect to the supports of the wavelets to predict negligible matrix coefficients. Recall that each son $\psi_{j+1,\text{son}}$ of the wavelet $\psi_{j,\text{father}}$ satisfies $\Omega_{j+1,\text{son}} \subseteq \Omega_{j,\text{father}}$. The following observation is an immediate consequence of the relations $\mathcal{B}_{j,j'} \geq \mathcal{B}_{j+1,j'} \geq \mathcal{B}_{j+1,j+1'}$ and $\mathcal{B}'_{j,j'} \geq \mathcal{B}'_{j+1,j'}$ for $j > j'$.

LEMMA 6.1. . . $\Omega_{j+1,\text{son}} \subseteq \Omega_{j,\text{father}}$ . . $\Omega_{j'+1,\text{son}'} \subseteq \Omega_{j',\text{father}'}$ . . . . . .

1. $\operatorname{dist}(\Omega_{j,\text{father}}, \Omega_{j',\text{father}'}) > \mathcal{B}_{j,j'}$ . . . $\operatorname{dist}(\Omega_{j+1,\text{son}}, \Omega_{j',\text{father}'}) > \mathcal{B}_{j+1,j'}$ . . . $\operatorname{dist}(\Omega_{j+1,\text{son}}, \Omega_{j'+1,\text{son}'}) > \mathcal{B}_{j+1,j+1'}$
2. . . . . $j > j'$ . . $\operatorname{dist}(\Omega_{j,\text{father}}, \Omega'_{j',\text{father}'}) > \mathcal{B}'_{j,j'}$ . . . . . $\operatorname{dist}(\Omega_{j+1,\text{son}}, \Omega'_{j',\text{father}'}) > \mathcal{B}'_{j+1,j'}$

Thanks to this lemma we have to check the distance criteria only for coefficients that stem from subdivisions of calculated coefficients on a coarser level. Obviously, the resulting procedure of checking the distance criteria is then of linear complexity.

7. Assembling the system matrix. This section is concerned with assembling the relevant matrix coefficients $\langle A\psi_{j',k'}, \psi_{j,k}\rangle$. For applying product Gauss quadrature rules it is necessary to split the wavelets into the smooth parts of their supports.

First, for piecewise constant wavelets we introduce the . . . . by

$$\alpha_{\lambda,\lambda'} := 2^{|\lambda|+|\lambda'|} \int_\square \int_\square k\big(\gamma_\lambda(s), \gamma_{\lambda'}(t)\big)\kappa_\lambda(s)\kappa_{\lambda'}(t)dtds. \tag{7.1}$$

Then, from the wavelet representation (4.3) we conclude

$$\langle A\psi_{j',k'}, \psi_{j,k}\rangle = \sum_{\Gamma_\lambda\in\mathcal{L}_{j,k}} \sum_{\Gamma_{\lambda'}\in\mathcal{L}_{j',k'}} \omega_{j,k,\lambda}\omega_{j',k',\lambda'}\alpha_{\lambda,\lambda'}. \tag{7.2}$$

For piecewise bilinear wavelets, the element-element interactions are given by

$$\beta_{(m,\lambda),(m',\lambda')} := 2^{|\lambda|+|\lambda'|}\int_{\square}\int_{\square} k\big(\gamma_\lambda(s),\gamma_{\lambda'}(t)\big)p_m^{\square}(s)p_{m'}^{\square}(t)\kappa_\lambda(s)\kappa_{\lambda'}(t)dtds. \tag{7.3}$$

Thus, the representation (4.4) yields the equation

$$\langle A\psi_{j',k'},\psi_{j,k}\rangle = \sum_{\Gamma_\lambda\in\mathcal{L}_{j,k}}\sum_{\Gamma_{\lambda'}\in\mathcal{L}_{j',k'}}\sum_{m,m'=1}^{4}\omega_{j,k,\lambda,m}\omega_{j',k',\lambda',m'}\beta_{(m,\lambda),(m',\lambda')}. \tag{7.4}$$

Consequently, the computation of the stiffness matrix is reduced to the computation of element-element interactions. Moreover, since the support of a wavelet on the level j is subdivided into finitely many elements of the levels j and $j+1$, it suffices to compute the element-element interactions $\alpha_{\lambda,\lambda'}$ and $\beta_{(m,\lambda),(m',\lambda')}$ with the precision $\varepsilon_{|\lambda|,|\lambda'|}$ according to (3.3).

8. On element-element interactions. As we have seen in the last section, the assembling of the compressed system matrix reduces to the computation of element-element interactions. Utilizing the mapping θ from (4.1), these element-element interactions are identified uniquely with coefficients of a (sparse) matrix $\mathbf{Q}_J$, where, in the case of piecewise bilinear wavelets, a single entry consists of 16 double values. The pattern of $\mathbf{Q}_J$ is structured similarly to the corresponding compressed system matrix; namely, it is symmetric and [illegible]. In particular, the symmetry of the pattern suggests computing the element-element interaction of Γ_λ with $\Gamma_{\lambda'}$ and that of $\Gamma_{\lambda'}$ with Γ_λ simultaneously since the application of our quadrature algorithm yields many identical function calls.

Nearly all element-element interactions of $\mathbf{Q}_J$ represent singular or nearly singular integrals. Hence, we often have to subdivide the associated domain of integration for quadrature. We realize this subdivision efficiently by the following [illegible] yielding again element-element interactions which can be [illegible] when assembling the compressed system matrix. Considering a given element Γ_{father} with index father $= (i,j,k)$, the indices of its sons are given by

$$\begin{aligned}
&\text{son}_1 := (i,j+1,(2k_1,2k_2)), && \text{son}_2 := (i,j+1,(2k_1+1,2k_2)),\\
&\text{son}_3 := (i,j+1,(2k_1,2k_2+1)), && \text{son}_4 := (i,j+1,(2k_1+1,2k_2+1)).
\end{aligned}$$

In the case of piecewise constants, by (7.1) one readily verifies the recycling formulas

$$\begin{aligned}
\alpha_{\text{father},\lambda} &= (\alpha_{\text{son}_1,\lambda}+\alpha_{\text{son}_2,\lambda}+\alpha_{\text{son}_3,\lambda}+\alpha_{\text{son}_4,\lambda})/2,\\
\alpha_{\lambda,\text{father}} &= (\alpha_{\lambda,\text{son}_1}+\alpha_{\lambda,\text{son}_2}+\alpha_{\lambda,\text{son}_3}+\alpha_{\lambda,\text{son}_4})/2.
\end{aligned} \tag{8.1}$$

Similar formulas can be derived in the case of piecewise bilinears; for example, we have

$$\begin{aligned}
\beta_{(1,\text{father}),(m,\lambda)} &= \beta_{(1,\text{son}_1),(m,\lambda)}/2\\
&\quad+(\beta_{(2,\text{son}_1),(m,\lambda)}+\beta_{(4,\text{son}_1),(m,\lambda)}+\beta_{(1,\text{son}_2),(m,\lambda)}+\beta_{(1,\text{son}_3),(m,\lambda)})/4\\
&\quad+(\beta_{(3,\text{son}_1),(m,\lambda)}+\beta_{(4,\text{son}_2),(m,\lambda)}+\beta_{(2,\text{son}_3),(m,\lambda)}+\beta_{(1,\text{son}_4),(m,\lambda)})/8,\\
\beta_{(m,\lambda),(1,\text{father})} &= \beta_{(m,\lambda),(1,\text{son}_1)}/2\\
&\quad+(\beta_{(m,\lambda),(2,\text{son}_1)}+\beta_{(m,\lambda),(4,\text{son}_1)}+\beta_{(m,\lambda),(1,\text{son}_2)}+\beta_{(m,\lambda),(1,\text{son}_3)})/4\\
&\quad+(\beta_{(m,\lambda),(3,\text{son}_1)}+\beta_{(m,\lambda),(4,\text{son}_2)}+\beta_{(m,\lambda),(2,\text{son}_3)}+\beta_{(m,\lambda),(1,\text{son}_4)})/8.
\end{aligned} \tag{8.2}$$

Since a finite number of element-element interactions has to be calculated per relevant matrix coefficient, the number of nonzero coefficients of $\mathbf{Q}_J$ is $\mathcal{O}(N_J)$. However, we recommend not storing $\mathbf{Q}_J$ completely since this is so expensive that the computable number of unknowns is crucially restricted. Instead, we propose an element-based assembling of the system matrix. For a fixed element Γ_λ one computes and stores all relevant element-element interactions $\alpha_{\lambda,\lambda'}$ and $\alpha_{\lambda',\lambda}$ with $|\lambda| \geq |\lambda'|$ by the quadrature algorithm introduced in the next section, and likewise for the piecewise bilinears. Then, after updating the system matrix, these values can be deleted. According to $\varepsilon_{j,j'} \leq \varepsilon_{j+1,j'} \leq \varepsilon_{j+1,j'+1}$ for all $j_0 - 1 \leq j \leq j' < J$ (cf. (3.6)), the element-element interactions just have to be computed successively by starting on the coarse grid. Clearly, the proposed strategy requires a rearrangement of the loops within the wavelet Galerkin scheme. However, the number of multiple calculations is reduced enormously, while the requirement of memory is not too high.

9. Numerical integration. As we have seen in the previous sections it suffices to compute element-element interactions with respect to the domain of integration $\square \times \square$. Based on tensor product Gauss–Legendre rules we construct an adaptive quadrature algorithm which converges exponentially. In combination with Theorem 3.2 we realize linear complexity for the computation of the compressed system matrix.

9.1. Error estimates on the reference domain. For a given function $f \in C([0,1])$, we set $I^{[0,1]}f := \int_0^1 f(s)\,ds$. The g-point Gauss–Legendre formula on $[0,1]$ $Q_g^{[0,1]}f := \sum_{i=1}^g \omega_{g,i} f\big(\xi_{g,i}\big)$ applied to $f \in C^{2g}(0,1)$ produces the error

$$\big|R_g^{[0,1]}f\big| := \big|I^{[0,1]}f - Q_g^{[0,1]}f\big| = \frac{2^{4n+1}(n!)^4}{[(2n)!]^3(2n+1)}\big|f^{(2g)}(\xi)\big|, \qquad 0 < \xi < 1;$$

cf. [19], for example. Employing Stirling's formula $n! \sim \sqrt{2\pi n} n^n e^{-n}$, we arrive at the estimate

$$\big|R_g^{[0,1]}f\big| \lesssim \frac{2^{-4g}}{(2g)!} \max_{s\in[0,1]} \big|f^{(2g)}(s)\big|. \tag{9.1}$$

For $f \in C(\square)$ we define $I^\square f := \big(I^{[0,1]} \otimes I^{[0,1]}\big)f = \int_\square f(s)\,ds$ with $s = \left[\begin{smallmatrix} s_1 \\ s_2 \end{smallmatrix}\right]$. Approximating $I^\square f$ by the product Gauss–Legendre quadrature formula

$$Q_g^\square f := \big(Q_g^{[0,1]} \otimes Q_g^{[0,1]}\big)f = \sum_{i,i'=1}^g \omega_{g,i}\omega_{g,i'} f\Big(\left[\begin{smallmatrix} \xi_{g,i} \\ \xi_{g,i'} \end{smallmatrix}\right]\Big), \tag{9.2}$$

we find the following error estimate.

LEMMA 9.1. [illegible] $f \in C^{2g}(\square)$ [illegible] $R_g^\square f := I^\square f - Q_g^\square f$ [illegible] (9.2) [illegible]

$$\big|R_g^\square f\big| \lesssim \frac{2^{-4g}}{(2g)!}\Big[\max_{s\in\square}\big|\partial_{s_1}^{2g} f(s)\big| + \max_{s\in\square}\big|\partial_{s_2}^{2g} f(s)\big|\Big]. \tag{9.3}$$

[illegible]. Invoking (9.1), the classical tensor product argument

$$\begin{aligned} R_g^\square f &= \Big[\big(I^{[0,1]} \otimes I^{[0,1]}\big) - \big(Q_g^{[0,1]} \otimes Q_g^{[0,1]}\big)\Big]f \\ &= \Big[\big(I^{[0,1]} \otimes I^{[0,1]}\big) - \big(I^{[0,1]} \otimes Q_g^{[0,1]}\big) + \big(I^{[0,1]} \otimes Q_g^{[0,1]}\big) - \big(Q_g^{[0,1]} \otimes Q_g^{[0,1]}\big)\Big]f \\ &= \Big[I^{[0,1]} \otimes \big(I^{[0,1]} - Q_g^{[0,1]}\big)\Big]f + \Big[\big(I^{[0,1]} - Q_g^{[0,1]}\big) \otimes Q_g^{[0,1]}\Big]f \end{aligned}$$

leads us to the desired estimate (9.3). ∎

Next, to a function $f(s,t) \in C(\square \times \square)$ we apply the four-dimensional product Gauss–Legendre quadrature formula

$$Q_{g,g'}^{\square\times\square} f := \big(Q_g^{\square} \otimes Q_{g'}^{\square}\big) f = \sum_{i,i'=1}^{g} \sum_{j,j'=1}^{g'} \omega_{g,i}\omega_{g,i'}\omega_{g',j}\omega_{g',j'} f\Big(\begin{bmatrix} \xi_{g,i} \\ \xi_{g,i'} \end{bmatrix}, \begin{bmatrix} \xi_{g',j} \\ \xi_{g',j'} \end{bmatrix}\Big) \tag{9.4}$$

in order to approximate the integral $I^{\square\times\square} f := \big(I^{\square} \otimes I^{\square}\big) f = \int_{\square}\int_{\square} f(s,t)\, dt\, ds$.

LEMMA 9.2. [illegible] $f(s,t) \in C^{2g}(\square) \times C^{2g'}(\square)$ [illegible] $R_{g,g'}^{\square\times\square} f := I^{\square\times\square} f - Q_{g,g'}^{\square\times\square} f$ [illegible] (9.4) [illegible]

$$\begin{aligned} \big|R_{g,g'}^{\square\times\square} f\big| \lesssim & \frac{2^{-4g}}{(2g)!}\Big[\max_{s,t\in\square}\big|\partial_{s_1}^{2g} f(s,t)\big| + \max_{s,t\in\square}\big|\partial_{s_2}^{2g} f(s,t)\big|\Big] \\ & + \frac{2^{-4g'}}{(2g')!}\Big[\max_{s,t\in\square}\big|\partial_{t_1}^{2g'} f(s,t)\big| + \max_{s,t\in\square}\big|\partial_{t_2}^{2g'} f(s,t)\big|\Big]. \end{aligned}$$

[illegible]. This lemma is proven analogously to the previous lemma. □

9.2. Basic estimates. We now assume that the diffeomorphisms γ_i are analytical on $\square$ for all $i \in \{1,2,\ldots,M\}$. Then, in general, a given boundary integral operator $A : H^q(\Gamma) \to H^{-q}(\Gamma)$ of order $2q$ satisfies the following definition.

DEFINITION 9.3. [illegible] $k(x,y)$ [illegible] $2q$ [illegible] (1.6) [illegible]

$$|\partial_s^\alpha \partial_t^\beta k_{i,i'}(s,t)| \lesssim \frac{(|\alpha|+|\beta|)!}{r^{|\alpha|+|\beta|}} \big\|\gamma_i(s) - \gamma_{i'}(t)\big\|^{-(2+2q+|\alpha|+|\beta|)}$$

[illegible] $r > 0$ [illegible] $2 + 2q + |\alpha| + |\beta| > 0$

Defining the local transported kernels

$$k_{\lambda,\lambda'}(s,t) := k\big(\gamma_\lambda(s), \gamma_{\lambda'}(t)\big)\kappa_\lambda(s)\kappa_{\lambda'}(t) dt ds$$

for $s,t \in \square$, we find the relation

$$I^{\square\times\square} k_{\lambda,\lambda'} = 2^{-(|\lambda|+|\lambda'|)} \alpha_{\lambda,\lambda'}. \tag{9.5}$$

LEMMA 9.4. [illegible] $k(x,y)$ [illegible] $2q$ [illegible] $\operatorname{dist}(\Gamma_\lambda, \Gamma_{\lambda'}) > 0$ [illegible] $Q_{g,g'}^{\square\times\square}$ [illegible] (9.4) [illegible] (9.5) [illegible]

$$\begin{aligned} \big|R_{g,g'}^{\square\times\square} k_{\lambda,\lambda'}\big| \lesssim 2^{-2(|\lambda|+|\lambda|')} & \Bigg[\left(\frac{2^{-|\lambda|}}{4r}\right)^{2g} \operatorname{dist}(\Gamma_\lambda, \Gamma_{\lambda'})^{-(2+2q+2g)} \\ & + \left(\frac{2^{-|\lambda'|}}{4r}\right)^{2g'} \operatorname{dist}(\Gamma_\lambda, \Gamma_{\lambda'})^{-(2+2q+2g')}\Bigg]. \end{aligned} \tag{9.6}$$

[illegible]. Since the kernel is analytically standard of order $2q$, (1.4) and (1.5) imply the estimate

$$|\partial_s^\alpha \partial_t^\beta k_{\lambda,\lambda'}(s,t)| \lesssim \frac{(|\alpha|+|\beta|)!}{r^{|\alpha|+|\beta|}} \frac{2^{-|\lambda|(|\alpha|+2)} 2^{-|\lambda'|(|\beta|+2)}}{\big\|\gamma_\lambda(s) - \gamma_{\lambda'}(t)\big\|^{2+2q+|\alpha|+|\beta|}}. \tag{9.7}$$

Hence, we find

$$\max_{s,t\in\square}\left|\partial_{s_n}^{2g}k_{\lambda,\lambda'}(s,t)\right| \lesssim 2^{-2(|\lambda|+|\lambda'|)}\ 2^{-2g|\lambda|}\ \frac{(2g)!}{r^{2g}}\ \min_{s,t\in\square}\left\|\gamma_\lambda(s)-\gamma_{\lambda'}(t)\right\|^{-(2+2q+2g)}$$
$$\lesssim 2^{-2(|\lambda|+|\lambda'|)}\ 2^{-2g|\lambda|}\ \frac{(2g)!}{r^{2g}}\ \operatorname{dist}(\Gamma_\lambda,\Gamma_{\lambda'})^{-(2+2q+2g)}$$

for $n=1,2$. Analogously one infers

$$\max_{s,t\in\square}\left|\partial_{t_n}^{2g'}k_{\lambda,\lambda'}(s,t)\right| \lesssim 2^{-2(|\lambda|+|\lambda'|)}\ 2^{-2g'|\lambda'|}\ \frac{(2g')!}{r^{2g'}}\ \operatorname{dist}(\Gamma_\lambda,\Gamma_{\lambda'})^{-(2+2q+2g')}.$$

The integrand $k_{\lambda,\lambda'}$ is nonsingular if $\operatorname{dist}(\Gamma_\lambda,\Gamma_{\lambda'})>0$. Therefore, we conclude the desired estimate by Lemma 9.2. ∎

In the case of piecewise bilinear wavelets, we have to compute in accordance with (7.3) the integrals

$$I^{\square\times\square}\left[k_{\lambda,\lambda'}(p_m^\square\otimes p_{m'}^\square)\right]=2^{-(|\lambda|+|\lambda'|)}\beta_{(m,\lambda),(m',\lambda')}. \tag{9.8}$$

Herein, $p_m^\square$, $p_{m'}^\square$ denote the bilinear polynomials on $\square$ defined by (2.2).

LEMMA 9.5. [illegible] $k(x,y)$ [illegible] $2q$ [illegible] $\operatorname{dist}(\Gamma_\lambda,\Gamma_{\lambda'})\gtrsim 2^{-\min\{|\lambda|,|\lambda'|\}}$ [illegible] $Q_{g,g'}^{\square\times\square}$ (9.4) [illegible] (9.8) [illegible]

$$\left|R_{g,g'}^{\square\times\square}\left[k_{\lambda,\lambda'}(p_m^\square\otimes p_{m'}^\square)\right]\right| \lesssim \left(\frac{2^{-|\lambda|}}{4r}\right)^{2g}\frac{2^{-2|\lambda|'-|\lambda|}}{\operatorname{dist}(\Gamma_\lambda,\Gamma_{\lambda'})^{1+2q+2g}}$$
$$+\left(\frac{2^{-|\lambda'|}}{4r}\right)^{2g'}\frac{2^{-2|\lambda|-|\lambda|'}}{\operatorname{dist}(\Gamma_\lambda,\Gamma_{\lambda'})^{1+2q+2g'}}. \tag{9.9}$$

[illegible]. The $(2g)$th partial derivative of $k_{\lambda,\lambda'}(s,t)p_m^\square(s)p_{m'}^\square(t)$ with respect to s_n, $n=1,2$, is given by

$$\partial_{s_n}^{2g}\left[k_{\lambda,\lambda'}(s,t)p_m^\square(s)p_{m'}^\square(t)\right]=\partial_{s_n}^{2g}k_{\lambda,\lambda'}(s,t)p_m^\square(s)p_{m'}^\square(t)$$
$$+\partial_{s_n}^{2g-1}k_{\lambda,\lambda'}(s,t)\partial_{s_n}p_m^\square(s)p_{m'}^\square(t).$$

Obviously, there holds $\left|p_m^\square(s)p_{m'}^\square(t)\right|\le 1$ and $\left|\frac{\partial p_m^\square(s)}{\partial s_n}p_{m'}^\square(t)\right|\le 1$ for all $s,t\in\square$ and $1\le m,m'\le 4$; cf. (2.2). Therefore, according to (9.7) we find the bound

$$\max_{s,t\in\square}\left|\partial_{s_n}^{2g}\left[k_{\lambda,\lambda'}(s,t)p_m^\square(s)p_{m'}^\square(t)\right]\right|$$
$$\lesssim 2^{-2g|\lambda|}\frac{(2g)!}{r^{2g}}\frac{2^{-2|\lambda|'-|\lambda|}}{\operatorname{dist}(\Gamma_\lambda,\Gamma_{\lambda'})^{1+2q+2g}}\cdot\underbrace{\left[\frac{2^{-|\lambda|}}{\operatorname{dist}(\Gamma_\lambda,\Gamma_{\lambda'})}+\frac{r}{2g}\right]}_{\lesssim 1\text{ since }\operatorname{dist}(\Gamma_\lambda,\Gamma_{\lambda'})\gtrsim 2^{-\min\{|\lambda|,|\lambda'|\}}}$$
$$\lesssim 2^{-2g|\lambda|}\frac{(2g)!}{r^{2g}}\frac{2^{-2|\lambda|'-|\lambda|}}{\operatorname{dist}(\Gamma_\lambda,\Gamma_{\lambda'})^{1+2q+2g}}.$$

Analogously one gets the corresponding result for the derivatives with respect to t_1 and t_2. Hence, (9.9) is valid according to Lemma 9.2. ∎

We now can formulate the following proposition, which is an immediate consequence of Lemmas 9.4 and 9.5.

PROPOSITION 9.6. $k(x,y)$ $2q$ ε Γ_λ $\Gamma_{\lambda'}$

$$\operatorname{dist}(\Gamma_\lambda,\Gamma_{\lambda'}) \geq 2^{-\min\{|\lambda|,|\lambda'|\}s}, \qquad s > \frac{1}{4r}. \tag{9.10}$$

$Q_{g,g'}^{\square\times\square}$ (9.4) $\alpha_{\lambda,\lambda'}$ $\beta_{(m,\lambda),(m',\lambda')}$ $\lesssim \varepsilon$

$$\begin{aligned} g &= \left\lceil -\tfrac{1}{2}\cdot\frac{|\lambda|+|\lambda'|+\log_2(\varepsilon)+(2+2q)\log_2(\operatorname{dist}(\Gamma_\lambda,\Gamma_{\lambda'}))}{|\lambda|+2+\log_2 r+\log_2(\operatorname{dist}(\Gamma_\lambda,\Gamma_{\lambda'}))}\right\rceil, \\ g' &= \left\lceil -\tfrac{1}{2}\cdot\frac{|\lambda|+|\lambda'|+\log_2(\varepsilon)+(2+2q)\log_2(\operatorname{dist}(\Gamma_\lambda,\Gamma_{\lambda'}))}{|\lambda'|+2+\log_2 r+\log_2(\operatorname{dist}(\Gamma_\lambda,\Gamma_{\lambda'}))}\right\rceil \end{aligned} \tag{9.11}$$

$$\begin{aligned} g &= \left\lceil -\tfrac{1}{2}\cdot\frac{|\lambda'|+\log_2\varepsilon+(1+2q)\log_2(\operatorname{dist}(\Gamma_\lambda,\Gamma_{\lambda'}))}{|\lambda|+2+\log_2 r+\log_2(\operatorname{dist}(\Gamma_\lambda,\Gamma_{\lambda'}))}\right\rceil, \\ g' &= \left\lceil -\tfrac{1}{2}\cdot\frac{|\lambda|+\log_2\varepsilon+(1+2q)\log_2(\operatorname{dist}(\Gamma_\lambda,\Gamma_{\lambda'}))}{|\lambda'|+2+\log_2 r+\log_2(\operatorname{dist}(\Gamma_\lambda,\Gamma_{\lambda'}))}\right\rceil \end{aligned} \tag{9.12}$$

Notice that the error of quadrature does not tend to zero when increasing g and g' if the elements violate the distance criterion (9.10). For such integrals we propose an adaptive quadrature strategy in the next subsection.

A special situation occurs if $|\lambda| = |\lambda'|$ and $\Gamma_\lambda \cap \Gamma_{\lambda'} \neq \emptyset$, i.e., if both elements are identical or share a common edge or vertex. Then, the domain of integration contains the singularity. We utilize the to transform the singular integrands on nonsingular ones; cf. [15, 29, 30]. It suffices to consider an error of quadrature which behaves as in (9.6) and (9.9), respectively, with $\operatorname{dist}(\Gamma_\lambda,\Gamma_{\lambda'}) := 2^{-|\lambda|}$. Consequently, we have to subdivide the domain of integration $[0,1]^4$ into 16^M equal sized cubes. Herein, M denotes the nonnegative integer $M := \max\{0, \lceil \log_2 s\rceil\}$ with s from (9.10). After rescaling the domains of integration to $[0,1]^4$, the application of the quadrature formula $Q_{g,g'}^{\square\times\square}$ with

$$g = g' = \left\lceil \frac{q|\lambda| - (\log_2\varepsilon)/2}{2+M+\log_2 r}\right\rceil \tag{9.13}$$

yields a quadrature error $\lesssim \varepsilon$.

A refined analysis shows that the choice (9.13) can be weakened. Indeed, in certain coordinates the degree of quadrature can be chosen smaller; see [30] for the details.

9.3. An adaptive quadrature strategy. We are now in the position to formulate the recursive adaptive algorithm. We prove in Lemma 9.8 that the algorithm computes the element-element interaction of Γ_λ and $\Gamma_{\lambda'}$ with the precision $\varepsilon_{|\lambda|,|\lambda'|}$. Without loss of generality we assume $|\lambda'| \geq |\lambda|$. An example of the subdivision of the elements is depicted in Figure 9.1.

1. If the elements Γ_λ and $\Gamma_{\lambda'}$ violate the distance criterion (9.10), then goto item 2 if $|\lambda'| > |\lambda|$ or goto item 3 if $|\lambda| = |\lambda'|$. Otherwise apply the product Gauss–Legendre quadrature formula $Q_{g,g'}^{\square\times\square}$ choosing g and g' associated with the precision $\varepsilon_{|\lambda|,|\lambda'|}$ as in Proposition 9.6.

2. $|\lambda'| > |\lambda|$ Replace the larger element Γ_λ by its four sons and compute the associated element-element interactions with precision $\varepsilon_{|\lambda|,|\lambda'|}$ according to item 1. The desired element-element interaction is calculated via the recycling formulas.
3. $|\lambda| = |\lambda'|$ If the domain of integration contains the singularity, then apply the Duffy trick. Else, replace both elements Γ_λ and $\Gamma_{\lambda'}$ by their sons and compute the associated element-element interactions with precision $\varepsilon_{|\lambda|,|\lambda'|}$ according to item 1. The desired element-element interaction is calculated via the recycling formulas.

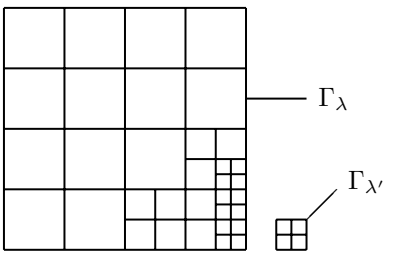

FIG. 9.1. *This subdivision of the elements* Γ_λ *and* $\Gamma_{\lambda'}$ *results if* $s = 3/2$.

Notice that the recycling is easily realized by inserting "return the previously computed element-element interaction if it exists" in item 1. The next lemma shows that the algorithm stops after at most $\mathcal{O}(||\lambda| - |\lambda'||)$ subdivision steps.

LEMMA 9.7. $\alpha_{\lambda,\lambda'}$ $\beta_{(m,\lambda),(m',\lambda')}$

1. $\mathcal{O}(||\lambda|-|\lambda'||)$ $\alpha_{\widehat{\lambda},\widehat{\lambda}'}$ $\beta_{(m,\widehat{\lambda}),(m',\widehat{\lambda}')}$ $|\widehat{\lambda}| \geq |\lambda|$ $|\widehat{\lambda}'| \geq |\lambda'|$
2. $|\lambda| \leq |\lambda'|$ $|\lambda| \leq |\widehat{\lambda}| \leq |\widehat{\lambda}'| \sim |\lambda'|$ $|\lambda'| \leq |\lambda|$
3. $|\widehat{\lambda}|$ $|\widehat{\lambda}'|$ $\alpha_{\widehat{\lambda},\widehat{\lambda}'}$ $\beta_{(m,\widehat{\lambda}),(m',\widehat{\lambda}')}$ $\mathcal{O}(1)$

. There is nothing to prove in the case of two elements Γ_λ and $\Gamma_{\lambda'}$ satisfying the distance criterion (9.10) or if the Duffy trick is applied. Hence, we consider first $|\lambda| = |\lambda'|$ and two disjoint elements Γ_λ and $\Gamma_{\lambda'}$ which violate the distance criterion (9.10). Since the mesh is quasi-uniform, a constant $c_\Gamma > 0$ exists such that $\operatorname{dist}(\Gamma_\lambda, \Gamma_{\lambda'}) \geq 2^{-|\lambda|} c_\Gamma$ for all pairs of elements with $\Gamma_\lambda \cap \Gamma_{\lambda'} = \emptyset$. Herein, c_Γ depends on only the manifold and its parametrization but not on $|\lambda|$ or J. The algorithm subdivides the desired element-element interaction into at most 16^M element-element interactions $\alpha_{\widehat{\lambda},\widehat{\lambda}'}$ or $\beta_{(m,\widehat{\lambda}),(m',\widehat{\lambda}')}$, where $|\lambda| \leq |\widehat{\lambda}| = |\widehat{\lambda}'| \leq |\lambda| + M$ and $M = \max\{0, \lceil \log_2(s/c_\Gamma) \rceil\}$.

Finally, we consider the case of two elements Γ_λ and $\Gamma_{\lambda'}$, $|\lambda| \neq |\lambda'|$, violating the distance criterion (9.10). Without loss of generality we assume $|\lambda| < |\lambda'|$. Moreover, we make use of the following observation. Due to $\operatorname{diam}(\Gamma_{\widehat{\lambda}}) \sim 2^{-|\widehat{\lambda}|}$, for a fixed level $|\widehat{\lambda}| \leq |\lambda'|$, only $\mathcal{O}(s^2)$ elements $\Gamma_{\widehat{\lambda}}$ exist with $\operatorname{dist}(\Gamma_{\widehat{\lambda}}, \Gamma_{\lambda'}) < s 2^{-|\widehat{\lambda}|}$. Consequently, our algorithm subdivides for all $|\lambda| < |\widehat{\lambda}| \leq |\lambda'|$ only $\mathcal{O}(s^2)$ element-element interactions while $\mathcal{O}(s^2)$ element-element interactions are evaluated since they satisfy the

distance criterion. The remaining $\mathcal{O}(s^2)$ element-element interactions associated with $|\widehat{\lambda}| = |\lambda|$ are subdivided into $\mathcal{O}(s^4)$ element-element interactions according to the aforementioned cases. □

We prove now that the proposed quadrature algorithm computes the desired element-element interaction with a precision that stays proportional to $\varepsilon_{|\lambda|,|\lambda'|}$.

LEMMA 9.8. [illegible] $\alpha_{\lambda,\lambda'}$ [illegible] $\beta_{(m,\lambda),(m',\lambda')}$ [illegible] $\varepsilon_{|\lambda|,|\lambda'|}$ [illegible]. Without loss of generality we assume $|\lambda| \le |\lambda'|$. According to Lemma 9.7, the computation of the desired element-element interaction is reduced to the computation of element-element interactions $\alpha_{\widehat{\lambda},\widehat{\lambda}'}$ or $\beta_{(m,\widehat{\lambda}),(m',\widehat{\lambda}')}$, where $|\lambda| \le |\widehat{\lambda}| \le |\widehat{\lambda}'| \sim |\lambda'|$. Hereby, for a fixed pair of levels $|\widehat{\lambda}|, |\widehat{\lambda}'|$, only $\mathcal{O}(1)$ element-element interactions are evaluated. Observing the damping factor $1/2$ in the recycling formulas (8.1) and (8.2), we might estimate the final quadrature error by $\sum_{|\widehat{\lambda}|=|\lambda|}^{|\lambda'|} \varepsilon_{|\lambda|,|\lambda'|} 2^{|\lambda|-|\widehat{\lambda}|} \lesssim \varepsilon_{|\lambda|,|\lambda'|}$. □

Consequently, by the above quadrature algorithm, the system matrix is computed consistent with Theorem 3.3. In combination with Theorem 3.2 we prove next that the proposed quadrature strategy in fact computes the compressed system matrix within linear complexity. This is achieved even without the recycling of previously computed element-element interactions. But we like to stress that the recycling accelerates the computation of the system matrix enormously.

THEOREM 9.9. [illegible] $\alpha_{\lambda,\lambda'}$ [illegible] $\beta_{(m,\lambda),(m',\lambda')}$ [illegible] $\varepsilon_{|\lambda|,|\lambda'|}$ [illegible] (3.6) [illegible] $\mathcal{O}\big([2J - |\lambda| - |\lambda'|]^4\big)$ [illegible]. (i) Throughout this proof we will abbreviate $j := |\lambda|$ and $j' := |\lambda'|$. We find $\frac{d'-q}{\widetilde{d}+q} < 1$ due to (3.3). Consequently, $\varepsilon_{j,j'}$ can be estimated by

$$\varepsilon_{j,j'} \sim \min\left\{2^{-|j-j'|}, 2^{-(2J-j-j')\frac{d'-q}{\widetilde{d}+q}}\right\} 2^{2Jq} 2^{-d'(2J-j-j')} \ge 2^{2Jq} 2^{-(d'+1)(2J-j-j')}.$$

Moreover, according to (9.4), the quadrature rule $Q_{g,g'}^{\square\times\square}$ applies $(gg')^2$ quadrature points. In view of Lemma 9.7 we may neglect the evaluation of the recycling formulas since this complexity scales linearly with the number $\mathcal{O}(|j-j'|)$ of computed element-element interactions and $|j-j'| \le 2J-j-j'$.

(ii) We estimate the degrees of quadrature to compute a single element-element interaction $\alpha_{\widehat{\lambda},\widehat{\lambda}'}$ or $\beta_{(m,\widehat{\lambda}),(m,\widehat{\lambda}')}$, which stems from our adaptive quadrature algorithm, with the precision $\varepsilon_{j,j'}$. Without loss of generality we assume $j' \ge j$, which implies $j' \sim \widehat{j}' := |\widehat{\lambda}'| \ge \widehat{j} := |\widehat{\lambda}| \ge j$ according to Lemma 9.7. Quadrature is applied if either the Duffy trick is employed or the distance criterion (9.10) is satisfied.

First, we treat the case that the Duffy trick is applied, which implies $\widehat{j} = \widehat{j}'$. We have to compute 16^M, $M = \max\{0, \lceil \log_2 s \rceil\}$, integrals with the degree of quadrature given by (9.13). The choice of M ensures $2 + M + \log_2 r = c > 0$, which leads to

$$g = g' \sim \tfrac{q\widehat{j} - (\log_2 \varepsilon_{j,j'})/2}{2+M+\log_2 r} \le \tfrac{1}{2c}[-2q(J-\widehat{j}) + (d'+1)(2J-j-j')].$$

Hence, we need $\mathcal{O}\big([2J-j-j']^4\big)$ quadrature points since

$$-2q(J-\widehat{j}) \lesssim \begin{cases} 1 & \text{if } q \ge 0, \\ -2q(2J-j-j') & \text{otherwise} \end{cases} \tag{9.14}$$

and $M \sim 1$ independently of J and $\widehat{j}$.

Next, let the distance criterion (9.10) be satisfied. Thus, there holds

$$\widehat{j} + 2 + \log_2 r + \log_2 \big(\operatorname{dist}(\Gamma_{\widehat{\lambda}}, \Gamma_{\widehat{\lambda}'})\big) \geq \widehat{j} + 2 + \log_2 r + \log_2(2^{-\widehat{j}} s) =: c > 0.$$

Inserting this inequality into (9.11) yields

$$\begin{aligned} g &\sim -\tfrac{1}{2} \cdot \tfrac{\widehat{j}+\widehat{j}'+\log_2(\varepsilon_{j,j'})+(2+2q)\log_2(\operatorname{dist}(\Gamma_{\widehat{\lambda}},\Gamma_{\widehat{\lambda}'}))}{\widehat{j}+2+\log_2 r+\log_2(\operatorname{dist}(\Gamma_{\widehat{\lambda}},\Gamma_{\widehat{\lambda}'}))} \\ &\leq -\tfrac{1}{2c}[\widehat{j} + \widehat{j}' + \log_2(\varepsilon_{j,j'}) + (2+2q)\log_2(2^{-\widehat{j}} s)] \\ &= \tfrac{1}{2c}[-2q(J-\widehat{j}) + \widehat{j} - \widehat{j}' + (d'+1)(2J-j-j') + (2+2q)\log_2(1/s)]. \end{aligned}$$

Inequality (9.14) and $\widehat{j} \leq \widehat{j}'$ imply $g \lesssim 2J - j - j'$. In complete analogy we estimate

$$\begin{aligned} g' &\sim -\tfrac{1}{2} \cdot \tfrac{\widehat{j}+\widehat{j}'+\log_2(\varepsilon_{j,j'})+(2+2q)\log_2(\operatorname{dist}(\Gamma_{\widehat{\lambda}},\Gamma_{\widehat{\lambda}'}))}{\widehat{j}'+2+\log_2 r+\log_2(\operatorname{dist}(\Gamma_{\widehat{\lambda}},\Gamma_{\widehat{\lambda}'}))} \\ &= -\tfrac{1}{2} \cdot \tfrac{\widehat{j}+\widehat{j}'+\log_2(\varepsilon_{j,j'})+(2+2q)\log_2(\operatorname{dist}(\Gamma_{\widehat{\lambda}},\Gamma_{\widehat{\lambda}'}))}{[\widehat{j}'-\widehat{j}]+[\widehat{j}+2+\log_2 r+\log_2(\operatorname{dist}(\Gamma_{\widehat{\lambda}},\Gamma_{\widehat{\lambda}'}))]} \lesssim \tfrac{1}{\widehat{j}'-\widehat{j}+c}(2J-j-j'). \end{aligned}$$

Consequently, $\mathcal{O}\big(\frac{1}{(\widehat{j}'-\widehat{j}+c_s)^2}[2J-j-j']^4\big)$ quadrature points are evaluated. One readily verifies that both estimates remain valid for the degrees of quadrature given by (9.12), i.e., in the case of piecewise bilinear functions.

(iii) According to Lemma 9.7 we have just to sum over $\widehat{j}$ with $j < \widehat{j} \leq j'$ to estimate the work of computing the desired element-element interaction. From

$$\sum_{\widehat{j}=j+1}^{j'} \frac{1}{(j'-\widehat{j}+c)^2} < \sum_{\widehat{j}=0}^{\infty} \frac{1}{(\widehat{j}+c)^2} < \frac{1}{c^2} + \sum_{\widehat{j}=1}^{\infty} \frac{1}{\widehat{j}^2} = \frac{1}{c^2} + \frac{\pi^2}{6} \lesssim 1$$

we derive indeed the desired complexity $\mathcal{O}\big([2J-j-j']^4\big)$. ∎

10. Numerical results. In order to confirm our analysis and to demonstrate the proposed method we shall present some numerical results in this section. We shall consider the Laplace equation $\Delta u = 0$ in Ω, where we employ first the unit sphere as domain Ω. It is well known that, denoting the spherical harmonics by Y_n^m, the functions of type $u(x) = \|x\|^2 Y_n^m(x/\|x\|)$ are solutions of the Laplace equation in the sphere. We will treat both the Dirichlet problem with data $f := u|_\Gamma = Y_2^0$ and the Neumann problem with data $g := \partial u/\partial n = 2Y_2^0$. Then, $u = \|x\|^2 Y_2^0(x/\|x\|)$ is the unique solution (modulo some constant in the case of the Neumann problem) of the interior Dirichlet and Neumann problem, respectively.

We solve both the interior Dirichlet and the interior Neumann problem by the indirect approach using the [illegible]

$$V : H^{-1/2}(\Gamma) \to H^{1/2}(\Gamma), \qquad (V\rho)(x) = \frac{1}{4\pi} \int_\Gamma \frac{1}{\|x-y\|} \rho(y) d\Gamma_y,$$

the [illegible] K and its adjoint $K^\star$,

$$K - 1/2 : L^2(\Gamma) \to L^2(\Gamma), \qquad (K\rho)(x) = \frac{1}{4\pi} \int_\Gamma \frac{\partial}{\partial n_y} \frac{1}{\|x-y\|} \rho(y) d\Gamma_y,$$

$$K^\star + 1/2 : L^2(\Gamma)/\mathbb{R} \to L^2(\Gamma)/\mathbb{R}, \qquad (K^\star\rho)(x) = \frac{1}{4\pi} \int_\Gamma \frac{\partial}{\partial n_x} \frac{1}{\|x-y\|} \rho(y) d\Gamma_y,$$

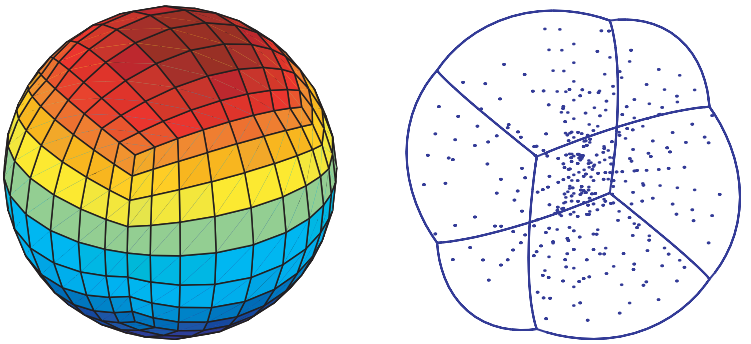

FIG. 10.1. *The mesh on the unit sphere ($j = 3$) and evaluation points of the solution.*

as well as the hypersingular operator

$$W : H^{1/2}(\Gamma)/\mathbb{R} \to H^{-1/2}(\Gamma)/\mathbb{R}, \qquad (W\rho)(x) = -\frac{1}{4\pi}\frac{\partial}{\partial n_x}\int_\Gamma \frac{\partial}{\partial n_y}\frac{1}{\|x-y\|}\rho(y)d\Gamma_y.$$

The indirect method yields a density ρ living on the boundary Γ which leads to the solution $u(x)$ by potential evaluation. More precisely, for the Dirichlet problem we derive the Fredholm integral equations of the first kind,

$$V\rho = f \text{ on } \Gamma, \qquad u(x) = (V\rho)(x) \text{ in } \Omega, \tag{10.1}$$

and of the second kind,

$$\left(K - \frac{1}{2}\right)\rho = f \text{ on } \Gamma, \qquad u(x) = (K\rho)(x) \text{ in } \Omega. \tag{10.2}$$

The Neumann problem is solved via the Fredholm integral equations of the first kind,

$$W\rho = g \text{ on } \Gamma, \qquad u(x) = (K\rho)(x) \text{ in } \Omega, \tag{10.3}$$

and of the second kind,

$$\left(K^\star + \frac{1}{2}\right)\rho = g \text{ on } \Gamma, \qquad u(x) = (V\rho)(x) \text{ in } \Omega. \tag{10.4}$$

The parametric representation of the sphere via six patches is derived by projecting the cube $[-1,1]^3$ onto the unit sphere; cf. Figure 10.1. We shall solve all these integral equations by piecewise constant and bilinear wavelets. Equations (10.1), (10.2), and (10.4) are discretized by piecewise constant wavelets with three vanishing moments as well as piecewise bilinear wavelets with double nodes along the interfaces and four vanishing moments. The discretization of (10.3) requires [illegible] piecewise bilinear wavelet bases since the energy space of the hypersingular operator is $H^{1/2}(\Gamma)/\mathbb{R}$. It suffices that the wavelets provide two vanishing moments. Since the kernel is hypersingular, we employ the identity $\langle W\rho, \mu\rangle = \langle V \operatorname{curl}_\Gamma \rho, \operatorname{curl}_\Gamma \mu\rangle$ (cf. [25]).

Since the spherical harmonics are eigenfunctions of all these boundary integral operators, the density ρ is a certain multiple of Y_2^0. Therefore, we are able to measure the $L^2(\Gamma)$-error of the density for which the error estimate $\|\rho - \rho_J\|_{L^2(\Gamma)} \lesssim 2^{-Jd}$

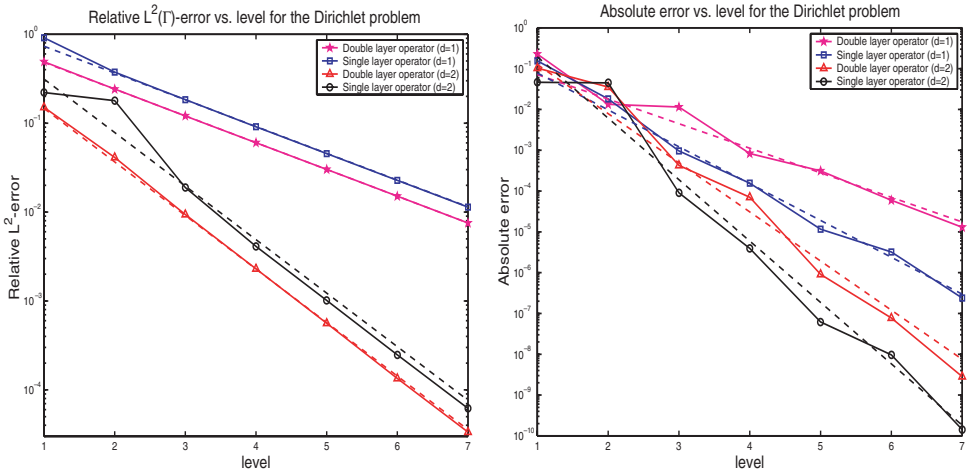

FIG. 10.2. *Dirichlet problem: errors of the density (left) and the potential evaluation (right).*

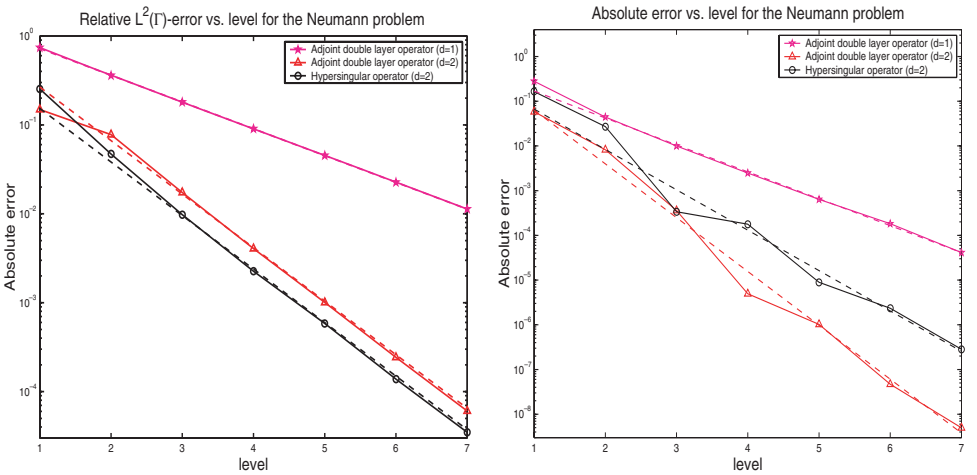

FIG. 10.3. *Neumann problem: errors of the density (left) and the potential evaluation (right).*

holds. In order to measure also the best possible order of convergence, we compute additionally the approximate solution u_J of the Laplace equation in a lot of points x_i distributed in the interior of the sphere as shown in the right plot of Figure 10.1. Depending on the approximation order d and the operator order $2q$, the optimal order of convergence (including the Aubin–Nitsche trick) of $u(x_i) - u_J(x_i)$ in a fixed evaluation point x_i is given by $|u(x_i) - u_J(x_i)| \lesssim 2^{-2J(d-q)}$; cf. [34]. However, the errors in a single point might oscillate extremely due to round-off errors. To be on safe ground we compute the ℓ^∞-norm of the measurements in all points. If this norm converges with the optimal order, we are sure that we achieve the optimal order of convergence. Instead of the ℓ^∞-norm we computed also the mean value and the ℓ^2-norm. But this has not changed the convergence behavior. The convincing results produced by our algorithm are presented in Figures 10.2 and 10.3 for the Dirichlet and the Neumann

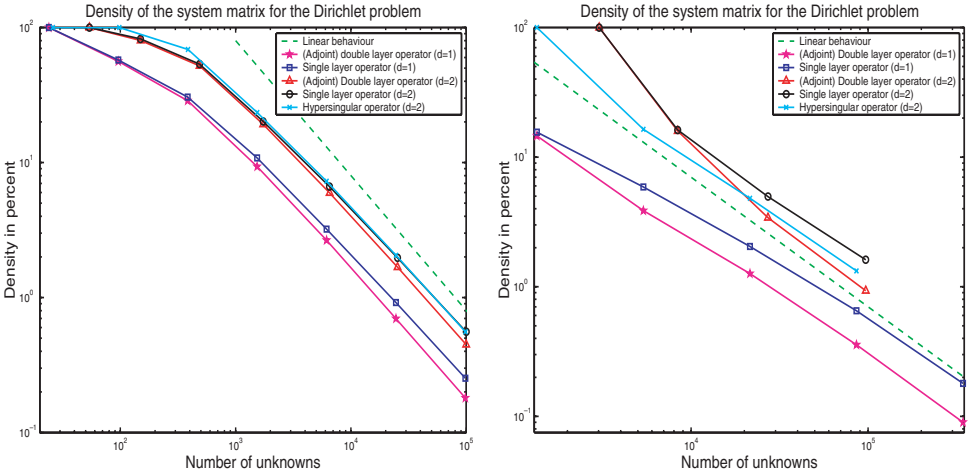

FIG. 10.4. *Compression rates for the sphere (left) and the gearwheel (right).*

problem, respectively. The left-hand plots are concerned with the relative $L^2(\Gamma)$-error of the density, while the right-hand plots show the absolute ℓ^∞-error of the potential evaluation. In all computations, the optimal orders of convergence, indicated by the dashed lines, are realized.

The density of the system matrix, measured by the ratio of relevant coefficients versus N_J^2, is visualized on the left-hand side of Figure 10.4. One figures out that the number of nonzero coefficients tends in fact to a linear behavior (dashed line).

In our second example we consider the gearwheel presented in Figure 1.1 as domain Ω and choose, as above, the Dirichlet or Neumann data of the harmonical function $u(x) = \langle x, [1,2,4]^T\rangle/\|x\|^3$, $x \notin \Omega$, as boundary conditions. Since in this case the density is unknown, we measure only the ℓ^∞-norm of the error of the solution with respect to about 8000 evaluation points x_i distributed inside the gearwheel. We emphasize that the density ρ exhibits strong singularities due to the presence of vertices and edges, even though the solution u is smooth. Hence, we cannot expect the same orders of convergence as on the sphere.

In Tables 10.1 and 10.2 we tabulated the results for the Dirichlet and the Neumann problem, respectively. The cpu-time refers to the computation of the approximate density, i.e., assembling and solving the linear system of equations by a CG or GMRES algorithm. The bracketed values correspond to the ratio of the error on the previous level to the actual error and reflect the order of convergence. The number of nonzero coefficients of the system matrix (density) is given in percent; see also Figure 10.4 for a visualization. The present example demonstrates that the wavelet Galerkin scheme remains applicable also in the case of complex geometries. It turns out that a piecewise bilinear discretization requires about twice the memory and five times the cpu-time of the corresponding piecewise constant discretization. However, the higher order yields a much higher accuracy. In Figure 10.5 we plot the absolute error versus the cpu-time. In the case of the Dirichlet problem (left-hand plot), one observes that the single layer operator discretized by piecewise bilinears yields the best performance. In the case of the Neumann problem (right-hand plot), the situation is not so clear. However, when extrapolating the graphs, the adjoint of the double layer operator discretized by piecewise bilinears seems to perform best.

All computations were performed by a standard workstation with 2 Gigabyte main memory. We never needed a degree of quadrature higher than 11. Moreover, we set $d' = \delta = 1.25$ if $d = 1$ and $d' = \delta = 2.25$ if $d = 2$, and $s = r = 1$. The parameter a was chosen equal to 1 for the sphere, which to our experience is a robust choice if all distances are scaled such that the largest patch has a diameter $\sqrt{2}$ that corresponds to the unit square. However, in our second example we increased this parameter to $a = 1.5$ to achieve an accuracy on the coarse grids that is comparable to that produced by the traditional Galerkin scheme. Finally, let us remark that we never subdivided elements living on the same levels, that is, $M = 0$. This choice does a good job if the constant c_Γ in the proof of Lemma 9.7 is sufficiently large, which is the case for both geometries. But we emphasize that M has to be increased if the geometry contains patches that meet in a very acute angle.

DISCONTINUOUS GALERKIN METHODS FOR A MODEL OF POPULATION DYNAMICS WITH UNBOUNDED MORTALITY*

MI-YOUNG KIM†

Abstract. Discontinuous Galerkin finite element methods in age-time domain are proposed to approximate a possibly nonsmooth solution to the model of population dynamics with unbounded mortality (coefficient) function. The strong stability is established and a priori L^2 error estimates are obtained. We show that the error estimates are optimal both in rate and in regularity away from the maximum age. Nonnegativity of the solution is also shown. The scheme is explicit and the solution is computed strip by strip marching in time. Several numerical examples are presented.

Key words. population dynamics, finite element method, discontinuous Galerkin method, error estimate, regularity of the solution

1. Introduction.

We consider the following linear initial-boundary value problem due to Lotka and McKendrick [9]:

$$\frac{\partial u}{\partial t} + \frac{\partial u}{\partial a} + \mu(a)u = 0, \quad 0 < a < a_\dagger, \quad t > 0, \tag{1.1}$$

$$u(0,t) = \int_0^{a_\dagger} \beta(a)u(a,t)da, \quad t > 0, \tag{1.2}$$

$$u(a,0) = u_0(a), \quad 0 \le a < a_\dagger. \tag{1.3}$$

Here, the function $u(a,t)$ denotes the age-specific density of individuals of age a at time t. The demographic parameters $\mu = \mu(a) \ge 0$ and $\beta = \beta(a) \ge 0$ are the age-specific mortality and natality rates, respectively. System (1.1)–(1.3) describes the evolution of the age density $u(a,t)$ of a population with a maximum age $a_\dagger < \infty$, whose growth is regulated by the vital rates $\beta(a)$ and $\mu(a)$, [8, 9, 21].

Throughout the paper we assume the following hypotheses [9]:

(H1) the nonnegative function u_0 belongs to $L^2[0, a_\dagger]$,
(H2) $\beta \in L^\infty[0, a_\dagger]$ and $0 \le \beta(a) \le \overline{\beta}$ for some positive constant $\overline{\beta}$,
(H3) $\mu(a) \ge 0$, $\mu \in L^1_{loc}[0, a_\dagger)$.

Under the assumptions (H1)–(H3), it is known [9] that problem (1.1)–(1.3) has a unique nonnegative solution, global in time.

Due to the finite maximum age $a_\dagger$, the mortality rate μ is unbounded near the maximum age [9]. Following [11], we assume the following general growth rates near $a_\dagger$:

(H4) There exist positive constants $a_* < a_\dagger$ and $\overline{\mu}$ such that $0 \le \mu(a) \le \overline{\mu}$ for $a \in [0, a_*]$,
(H5) $\mu(a) = \lambda/(a_\dagger - a)^\alpha$ on $(a_*, a_\dagger]$, for some $0 < \alpha < 1$, $\lambda > 0$.

In traditional models of population dynamics, the maximum age $a_\dagger$ is assumed to be infinite and the mortality function μ is typically assumed to be Lipschitz continuous, for the sake of convenience. However, the growing complexity of physiologically structured population model makes it increasingly unrealistic to model the problems in ecology, epidemiology, population genetics, and cell growth with an infinite maximum age and a Lipschitz continuous mortality function. On the other hand, for the last several decades there has been much investigation for solving models with an infinite maximum age and a Lipschitz continuous mortality function. Most of them involve uniform time and age discretization with the age step chosen to be equal to the time step. We refer to [1, 7, 10, 12, 14, 16, 17, 18] and the references cited therein for more details. Recently, in [2] Ayati used a moving age discretization that allows nonuniform age and time discretizations.

In this paper, we consider the case that the maximum age is finite and the mortality function is unbounded. In such a case, regularity of the solution depends on the growth rate of the mortality function and so does the proper choice of the numerical method to approximate the solution; if the solution is not regular, finite difference methods such as the method of characteristics are not desirable or may not be applicable to the problem [11]. In this paper, we for the first time propose a method which is able to treat the problem with unbounded coefficient function and nonsmooth solution. More precisely, we consider the case that $0 < \alpha < 1$, $\lambda > 0$ and thus that the solution does not belong to $C^1([0, a_\dagger] \times [0, T])$ [15]. Discontinuous Galerkin finite element methods are proposed to approximate the model. There are difficulties in the problem treating nonlocal birth process (1.2) and the unbounded mortality function. To resolve them, we find some condition on the triangulation, say, (T1) in section 2, which guarantees the strong stability and accordingly the optimal L^2 error estimates. With locally defined test functions we could then show the (weak) stability with the L^2 norm. Using this result, we finally obtain the strong stability. Our method is easy to implement; the resulting discrete system decouples the nonlocal birth process from the system and it is blockwise solvable. We note that the discontinuous Galerkin method applied in age-time discretization allows varying age and time stepping. Thanks to the variable time steps one can adaptively choose the time steps to assure robustness and efficiency. Advantages of independent age and time discretizations are fewer computations and less memory use when the dependence on age is weak relative to the dependence on time. Our scheme is especially effective in a large system including space variables; if the considered model is especially spatially heterogeneous, then it becomes a more than four-dimensional problem (including two or three space dimensions) and it is very important to use an efficient mesh in age-time domain. In fact, there are many situations, such as Proteus mirabilis swarm colony development, in which there are very rapid changes in space requiring very small time steps, although the age dependence is smooth (see, for example, [2, 6, 20]). Our numerical method will help form a systematic basis for a simulation theory for physiologically structured such as age or body, individual-based population models, together with space variables. On the other hand, for the last several decades, discontinuous Galerkin methods have been successfully applied to many problems. For the discontinuous Galerkin methods applied to general problems, we refer to [5] and the references cited therein.

In [2, 3], Ayati considered moving age discretization along the characteristic (leaving the time variable to be continuous). There, the mortality function was assumed to be bounded. Stability of the approximate solution to the problem was not discussed. Nonnegativity of the solution was not treated, either. Our approximation can be viewed as a generalization of them. Furthermore, our method is simpler to implement

without any transformation of the problem as opposed to the case in [2, 3]. We also show that our discrete solution is strongly stable. Nonnegativity of the solution is very important for the analysis of the long-time behavior as well as from a biological point of view. We find some condition on the triangulation to preserve the nonnegativity of the solution to (1.1)–(1.3), which reflect the important fact that age and time advance together. Such a condition is a generalization of the CFL condition which is obtained by applying the finite difference method to the problem. Concerning the error estimate, we show that the discrete solution converges at the rate of $r + 1/2$ away from the maximum age and it converges at the rate of $l + 1/2 + \alpha/2 - 1/q$, if $u \in W^{l,2q}$ near the maximum age, where r is the degree of the polynomial of the approximation space, $1/2 \le l \le r + 1$, and $q \ge 1$.

It is noted that for $\alpha > 1$ or $\alpha = 1$ and $\lambda \ge 1$, the solution belongs to $C^1([0, a_\dagger] \times [0, T])$ provided that the compatibility condition at the origin is satisfied with smooth data [15]. In that case, a collocation method would be a proper choice for the effective computation. However, if the solution does not belong to $C^1([0, a_\dagger] \times [0, T])$, then the collocation method does not run well [15].

The organization of the remainder of this article is as follows. In the next section, we present a discontinuous Galerkin method in the age-time domain to approximate the solution to (1.1)–(1.3). In section 3, we show the local and global stabilities of the discrete solutions. In section 4, we discuss convergence results of the scheme, in detail. In section 5, we investigate the nonnegativity of the solution on the special type of triangulation. In section 6, we present some numerical examples. Finally, in section 7, we give some concluding remarks.

2. Numerical method. In this section we introduce a discontinuous Galerkin method in the age-time domain $\Omega = (0, a_\dagger) \times (0, T)$ so that the resulting problem is considered as an advection-reaction equation in two "space" dimensions. Now, let $0 = t^0 < t^1 < t^2 < \cdots < t^N = T$ be the time step, let $\mathcal{T}$ be a triangulation of Ω which is defined strip by strip in time, and let $\mathcal{T}^n \subset \mathcal{T}$ be the triangulation on the strip $S^n := (0, a_\dagger) \times (t^{n-1}, t^n)$. Then, the triangulation $\mathcal{T}$ of Ω may be defined as

$$\mathcal{T} = \left\{K_{ni}^-, K_{ni}^+ : n = 1, 2, \cdots, i = 1, 2, \dots\right\} \cup \left\{K_{n0}^+\right\},$$

where K_{ni}^- is a triangle having two vertices on $t = t^{n-1}$ and K_{ni}^+ has its two vertices on $t = t^n$ as in Figure 2.1. We assume that $\mathcal{T}$ satisfies the following:

(T1) On K_{ni}^-, the interior angle of the left vertex lying on $t = t^{n-1}$ is less than or equal to $\pi/4$ and the interior angle of the right vertex lying on $t = t^{n-1}$ is less than or equal to $\pi/2$.

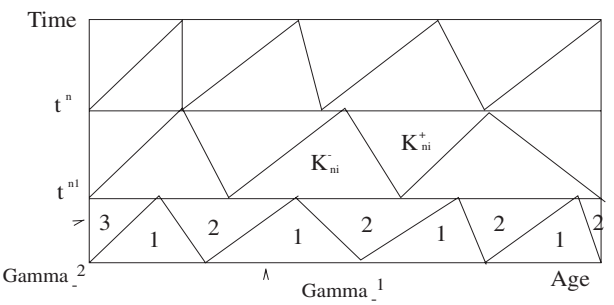

FIG. 2.1. *A sample triangulation.*

We here note that condition (T1) can be viewed as a generalization of the CFL condition which is obtained by applying the finite difference method to the linear hyperbolic problem.

Let $h = \max_{K\in\mathcal{T}} h_K$, where h_K denotes the diameter of $K \in \mathcal{T}$. We also assume that $\mathcal{T}$ is a regular family of triangulations in the sense that

$$\text{there exists a } \kappa > 0 \text{ such that } \frac{h}{h_{\min}} < \kappa, \quad h_{\min} = \min_{K\in\mathcal{T}} h_K. \tag{2.1}$$

Now, let Γ_- denote the inflow part of the boundary $\partial\Omega$: $\Gamma_- = \{x \in \partial\Omega : n(x)\cdot\gamma < 0\}$, where $\gamma = (1/\sqrt{2}, 1/\sqrt{2})$ is the unit vector of the convective direction and $n(x)$ is the outward unit normal to $\partial\Omega$ at x. Let $\Gamma_-^1 = \{(a,0) : 0 \le a \le a_\dagger\}$ and $\Gamma_-^2 = \{(0,t) : 0 \le t \le T\}$, and thus $\Gamma_- = \Gamma_-^1 \cup \Gamma_-^2$. Similarly, we denote $\partial_- K = \{x \in \partial K : n(x)\cdot\gamma < 0\}$ and $\partial_+ K = \{x \in \partial K : n(x)\cdot\gamma > 0\}$ for each $K \in \mathcal{T}$. Let $v^\pm(x) = \lim_{\epsilon\to 0} v(x \pm \epsilon\gamma)$ for $x \in (\cup_{K\in\mathcal{T}}\partial K)\backslash\partial\Omega$, and let $[v] = v^+ - v^-$.

A key mesh condition of our method is that the solution to (1.1)–(1.3) within each element K be uniquely determined by u on $\partial_- K$. The mesh will then be traversable in an explicit, element-by-element fashion, in the direction of increasing t, without violating any domain of dependence condition, as numbered in Figure 2.1. We here note that u on Γ_-^2 is not known in advance and u on K_{n0}^+ is determined in the end on each strip.

In what follows we use the space $L^p(\Omega)$ and the Sobolev spaces $W^{m,p}(\Omega)$ and $H^m(\Omega) = W^{m,2}(\Omega)$, $m \ge 1, 1 \le p \le \infty$ in their usual meaning for Ω a domain in R^2. $(\cdot,\cdot)$ denotes the inner product of $L^2(\Omega)$ and $(v,w)_{\Gamma_-} = \int_{\Gamma_-} vw|\gamma\cdot n|ds$, with analogous definition of $(\cdot,\cdot)_{\partial K}$. The norm in $L^p(\Omega)$ is denoted by $\|\cdot\|_{p,\Omega}$ if $p \ne 2$ and by $\|\cdot\|_\Omega$ if $p = 2$. Similarly, if Λ is a piecewise smooth curve or a union of such curves, $\|\cdot\|_{p,\Lambda}$ denotes the induced norm in $L^p(\Lambda)$, with the subindex p omitted if $p = 2$.

Let $P_r(K)$ denote the space of all polynomials of degree $\le r$ on K. Let W_h be the family of subspaces of $L^2(\Omega)$ given by

$$W_h = \{v \in L^2(\Omega) : v_{|K} \in P_r(K)\}. \tag{2.2}$$

Without loss of generality, we now write μ to represent $\frac{1}{\sqrt{2}}\mu$. Then, the discontinuous Galerkin method we shall analyze is given as follows. For each $K \in \mathcal{T}^n$, $1 \le n \le N$ and for given u_h^- on $\partial_- K$, find u_h on K such that $u_{h|K} \in P_r(K)$ and

$$\int_K (\gamma\cdot\nabla u_h + \mu u_h)v dx - \int_{\partial_- K} [u_h]v^+\gamma\cdot n ds = 0 \quad \forall\, v \in P_r(K) \tag{2.3}$$

with

$$u_h(a,0) = \widetilde{u_0}(a) \quad \text{if } (a,0) \in \Gamma_-^1, \tag{2.4}$$

$$u_h^-(0,t) = \int_0^{a_\dagger} \beta(a)u_h(a,t)da \quad \text{if } (0,t) \in \Gamma_-^2, \tag{2.5}$$

where $\widetilde{u_0}$ is the locally defined L^2-projection on Γ_-^1; see (3.18) for the definition of the locally defined L^2-projection. By summing over $K \in \mathcal{T}$ in (2.3) we obtain the following equivalent form of the discontinuous Galerkin method. Given r and $\mathcal{T}$, find

$u_h \in W_h$ such that for any $v \in W_h$,

$$\sum_{K\in\mathcal{T}} \int_K (\gamma\cdot\nabla u_h + \mu u_h) v dx - \sum_{K\in\mathcal{T}} \int_{\partial_- K\setminus\Gamma_-} [u_h] v^+ \gamma\cdot n ds - \int_{\Gamma_-} u_h^+ v^+ \gamma\cdot n ds = -\int_{\Gamma_-^1} u_0 v^+ \gamma\cdot n ds - \int_{\Gamma_-^2} u_h^- v^+ \gamma\cdot n ds, \tag{2.6}$$

where $u_h^-(0,t)$ is given by (2.5).

System (2.3)–(2.5) is solved successively for u_h on each strip S^n, $1 \le n \le N$. We here note that u_h is always computed successively by starting from $K \in \mathcal{T}^n$ in our triangulation satisfying $\partial_- K \subset \Gamma_-^1$. As will be seen in Theorem 3.2, u_h is uniquely determined by (2.3)–(2.5). We here notice that the scheme is very easy to implement; the coefficient matrices of the discrete system on each strip are block diagonal matrices and each block is an $\{(r+1)(r+2)/2\} \times \{(r+1)(r+2)/2\}$ matrix.

Below, we denote by C a positive constant which may take different values on different occurrences. The constant may depend on the above parameter κ and r but not on other parameters, unless indicated explicitly.

3. Stability. For the stability analysis, we decompose $\mathcal{T}$ into two parts. Let $\mathcal{T}_1 = \{K \in \mathcal{T} :\ a < a_* \ \forall\, (a,t) \in \overline{K}\}$ and $\mathcal{T}_2 = \mathcal{T}\setminus\mathcal{T}_1$. We then see that $\mu(a) \le \overline{\mu}$ on $K\ \forall\ K \in \mathcal{T}_1$.

We shall frequently use the following inequalities, which are obtained by a scaling argument and by the equivalence of norms in a finite dimensional space. For any $w \in P_r(K)$ and $K \in \mathcal{T}$,

$$C^{-1}\{h_K^{-1/2}\|w\|_K + \|w\|_{\partial K}\} \le \{h_K\|\gamma\cdot\nabla w\|^2 + \|w\|_{\partial K}^2\}^{1/2} \le C h_K^{-1/2}\|w\|_K, \tag{3.1}$$

where C depends only on κ and K.

We also use the relations among various norms on the finite element space [4].

LEMMA 3.1. K R^n (2.1) $P_r(K)$ $W^{l,p}(K)\cap W^{m,q}(K)$ $1 \le p \le \infty,\ 1 \le q \le \infty,$ $0 \le m \le l$ $C = C(K,r,l,p,q,\kappa)$ $v \in P_r(K)$

$$\|v\|_{W^{l,p}(K)} \le C h^{m-l+n/p-n/q}\|v\|_{W^{m,q}(K)}. \tag{3.2}$$

One can always solve (2.3)–(2.5) successively, triangle by triangle, with u_h^- given on $\partial_- K$ either by the previously computed values or by the boundary conditions. Thus, u_h is determined uniquely if (2.3)–(2.5) is uniquely solved in each $K \in \mathcal{T}$ for given u_h^-. In fact, since the scheme (2.3)–(2.5) is linear, the unique solvability is a direct consequence of the following local stability.

THEOREM 3.2. h_0 κ K $h_0^{1-\alpha}\lambda < 1/16$ $h_0^\alpha < \min\{1/\sqrt{\overline{\mu}},\ 1/\overline{\mu}\}$ $h < h_0$
