$$\|u_h\|_K + {h_K}^{1/2}\|u_h^+\|_{\partial_- K} + {h_K}^{1/2}\|u_h^-\|_{\partial_+ K} \le C {h_K}^{1/2}\|u_h^-\|_{\partial_- K},\ K \in \mathcal{T}, \tag{3.3}$$

$$\|\gamma\cdot\nabla u_h\|_K \le C\left\{\|u_h\|_K + h_K^{-1/2}\|[u_h]\|_{\partial_- K}\right\},\ K \in \mathcal{T}_1, \tag{3.4}$$

$$\|\gamma\cdot\nabla u_h\|_K \le C\left\{h_K^{-\alpha/2}\|\sqrt{\mu}u_h\|_K + h_K^{-1/2}\|[u_h]\|_{\partial_- K}\right\},\ K \in \mathcal{T}_2. \tag{3.5}$$

$\mathcal{T}_1 \cup \mathcal{T}_2$. From now on we denote $u_h = u_{h|K} \in P_r(K)$. Let

$$B_K(u_h, v) = \int_K (\gamma \cdot \nabla u_h + \mu u_h) v dx - \int_{\partial_- K} u_h^+ v^+ \gamma \cdot n ds. \tag{3.6}$$

To prove (3.3), we choose $v = u_h + \delta h_K \gamma \cdot \nabla u_h$, where $\delta < 1$ is determined below. We note, by integration by parts, that

$$\int_K u_h \gamma \cdot \nabla u_h dx = \frac{1}{2} \int_{\partial K} u_h^2 \gamma \cdot n ds. \tag{3.7}$$

Since $\delta < 1$, we easily see, by (3.1) and (3.7), that

$$\|v\|_K^2 \le (1 + C\delta + C\delta^2) \|u_h\|_K^2. \tag{3.8}$$

We have from (3.6) that

$$\begin{aligned} B_K(u_h, v) = & \int_K \mu u_h^2 dx + \delta h_K \int_K (\gamma \cdot \nabla u_h)^2 dx + \frac{1}{2} \int_{\partial K} u_h^2 |\gamma \cdot n| ds \\ & + \delta h_K \int_K \mu u_h \gamma \cdot \nabla u_h dx - \delta h_K \int_{\partial_- K} u_h^+ (\gamma \cdot \nabla u_h)^+ \gamma \cdot n ds \\ \ge & \, \delta h_K \|\gamma \cdot \nabla u_h\|_K^2 + \frac{1}{2} \|u_h\|_{\partial K}^2 \\ & + \delta h_K \int_K \mu u_h \gamma \cdot \nabla u_h dx - \delta h_K \int_{\partial_- K} u_h^+ (\gamma \cdot \nabla u_h)^+ \gamma \cdot n ds. \end{aligned} \tag{3.9}$$

If $K \in \mathcal{T}_1$ and $h^\alpha < 1/\sqrt{\overline{\mu}}$, then we see, from (3.9), that

$$B_K(u_h, v) \ge \frac{\delta}{4} \{1 - C_1 \delta - C_1 h_K \overline{\mu}\} \Big\{ h_K \|\gamma \cdot \nabla u_h\|_K^2 + \|u_h\|_{\partial K}^2 \Big\}. \tag{3.10}$$

Choose $\delta = \min\big\{1, 1/(2C_1)\big\}$. We then obtain that if $h_K \le 1/(4C_1 \overline{\mu})$,

$$B_K(u_h, v) \ge C^{-1} \Big\{ h_K^{-1} \|u_h\|_K^2 + \|u_h\|_{\partial K}^2 \Big\}. \tag{3.11}$$

On the other hand, by (2.3) and (3.8), we have

$$\begin{aligned} B_K(u_h, v) = \int_{\partial_- K} u_h^- v^+ |\gamma \cdot n| ds & \le C h_K^{-1/2} \|u_h^-\|_{\partial_- K} \|v\|_K \\ & \le C h_K^{-1/2} \|u_h^-\|_{\partial_- K} \|u_h\|_K. \end{aligned} \tag{3.12}$$

Combining (3.11) and (3.12), we obtain (3.3) for $K \in \mathcal{T}_1$.

If $K \in \mathcal{T}_2$, then we obtain, by (3.1) and Young's inequality, that

$$\begin{aligned} \int_K \mu u_h \gamma \cdot \nabla u_h dx & \le 4\lambda h_K^{-2\alpha} \|u_h\|_K^2 + \frac{1}{4} \|\gamma \cdot \nabla u_h\|_K^2 \\ & \le 4\lambda h_K^{1-2\alpha} \{h_K \|\gamma \cdot \nabla u_h\|_K^2 + \|u_h\|_{\partial K}^2\} + \frac{1}{4} \|\gamma \cdot \nabla u_h\|_K^2 \\ & \le 4\lambda h_K^{-\alpha} \{h_K \|\gamma \cdot \nabla u_h\|_K^2 + \|u_h\|_{\partial K}^2\} + \frac{1}{4} \|\gamma \cdot \nabla u_h\|_K^2 \end{aligned} \tag{3.13}$$

and that

$$\int_{\partial_- K} u_h^+(\gamma\cdot\nabla u_h)^+|\gamma\cdot n|ds \le \frac{1}{4}\|\gamma\cdot\nabla u_h\|_K^2 + 4h_K^{-1}\|u_h\|_{\partial K}^2. \tag{3.14}$$

Thus, combining (3.9) and (3.13)–(3.14), we see that

$$B_K(u_h,v)\ge \delta\left\{\frac{1}{2}-4\lambda h_K^{1-\alpha}\right\}h_K\|\gamma\cdot\nabla u_h\|_K^2 + \left\{\frac{1}{2}-4\delta\lambda h_K^{1-\alpha}-4\delta\right\}\|u_h\|_{\partial K}^2.$$

Now noting that $h_K^{1-\alpha}\lambda < \frac{1}{16}$, take $\delta \le \frac{1}{9}$. We then have, by (3.1), that

$$\begin{aligned} B_K(u_h,v) &\ge \frac{\delta}{4}\left\{h_K\|\gamma\cdot\nabla u_h\|_K^2 + \|u_h\|_{\partial K}^2\right\} \\ &\ge \frac{\delta}{4}C\left\{h_K^{-1}\|u_h\|_K^2 + \|u_h\|_{\partial K}^2\right\}. \end{aligned} \tag{3.15}$$

Combining (3.12) and (3.15), and by Young's inequality, we obtain (3.3) for $K \in \mathcal{T}_2$.

To prove (3.5), let $K \in \mathcal{T}_2$. By taking $v = \gamma\cdot\nabla u_h$, we see from (2.3) that

$$\int_K(\gamma\cdot\nabla u_h + \mu u_h)\gamma\cdot\nabla u_h dx = \int_{\partial_- K}[u_h](\gamma\cdot\nabla u_h)^+\gamma\cdot n ds$$

or

$$\|\gamma\cdot\nabla u_h\|_K^2 + \int_K \mu u_h\gamma\cdot\nabla u_h dx \le \|[u_h]\|_{\partial_- K}\|\gamma\cdot\nabla u_h\|_{\partial_- K}.$$

Thus, by Young's inequality, we have that, if $h^\alpha < 1/\overline{\mu}$,

$$\begin{aligned} \frac{1}{2}\|\gamma\cdot\nabla u_h\|_K^2 &\le C\left\{\|\mu u_h\|_K^2 + h_K^{-1/2}\|[u_h]\|_{\partial_- K}\|\gamma\cdot\nabla u_h\|_K\right\} \\ &\le C\left\{h_K^{-\alpha}\|\sqrt{\mu}u_h\|_K^2 + h_K^{-1/2}\|[u_h]\|_{\partial_- K}\|\gamma\cdot\nabla u_h\|_K\right\} \end{aligned} \tag{3.16}$$

or

$$\|\gamma\cdot\nabla u_h\|_K \le C\left\{h_K^{-\alpha/2}\|\sqrt{\mu}u_h\|_K + h_K^{-1/2}\|[u_h]\|_{\partial_- K}\right\}. \tag{3.17}$$

This completes the proof of (3.5). Similarly, one can prove (3.4) and we shall omit the proof . □

Now, let $\widetilde{\chi}$ denote the locally defined L^2-projection of χ into W_h for each $\chi \in L^2(\Omega)$. That is, $\widetilde{\chi}$ is defined by

$$(\chi - \widetilde{\chi}, v)_K = 0 \ \forall\ v \in P_r(K), \quad K \in \mathcal{T}. \tag{3.18}$$

Then we shall need the following approximation properties in what follows [19]. For $2 \le q \le \infty$,

$$\begin{aligned} &||\chi-\widetilde{\chi}||_K \le Ch_K^{r+1}|\chi|_{H^{r+1}(K)}, \\ &||\chi-\widetilde{\chi}||_{\partial K} \le Ch_K^{r+1/2}|\chi|_{H^{r+1}(K)}, \\ &||\chi-\widetilde{\chi}||_{L^q(K)} \le Ch_K^l||\chi||_{W^{l,q}(K)},\ \ 0 \le l \le r+1, \\ &\qquad\qquad \text{if } \chi \in L^2(\Omega)\cap W^{l,q}(K), \\ &||\chi-\widetilde{\chi}||_{L^q(\partial K)} \le Ch_K^{l-1/2}||\chi||_{W^{l,q}(K)},\ \ 1/2 \le l \le r+1, \\ &\qquad\qquad \text{if } \chi \in L^2(\Omega)\cap W^{l,q}(K). \end{aligned} \tag{3.19}$$

To establish the global stability, we define some notations. Let Γ_h be the set of all interior edges and Γ be the set of the boundary edges. That is,

$$\Gamma_h = \cup_K \partial_- K \backslash \Gamma_- = \cup_K \partial_+ K \backslash \Gamma_+, \qquad \Gamma = \Gamma_- \cup \Gamma_+,$$

where $\Gamma_+ = \{x \in \partial\Omega : n(x) \cdot \gamma > 0\}$.

We now define

$$\begin{aligned} |||v|||^2 &= \|v\|_\Omega^2 + \|\sqrt{\mu} v\|_\Omega^2 + \sum_{K \in \mathcal{T}} h_K \|\gamma \cdot \nabla v\|_K^2 \\ &\quad + \|[v]\|_{\Gamma_h}^2 + \|v^+\|_{\Gamma_-}^2 + \|v^-\|_{\Gamma_+}^2. \end{aligned} \tag{3.20}$$

For the (strong) global stability analysis, we first show the weak stability with the $L^2(\Omega)$-norm. In the following lemma, we need an angle condition on K_{n0}^+ to treat the nonlocal birth process (2.5).

LEMMA 3.3. [illegible] $(0, t^{n-1})$ [illegible] K_{n0}^+ [illegible] $\pi/4$ [illegible] $r \geq 0$ [illegible] C [illegible]

$$\|u_h\|_\Omega \leq C \|u_0\|_{\Gamma_-^1}, \tag{3.21}$$

$$\|u_h\|_{\Gamma_-^2} \leq C \|u_0\|_{\Gamma_-^1}. \tag{3.22}$$

The idea of the proof is similar to the one of the following theorem and we postpone the proof to the next theorem.

If $r \leq 1$, then the weak stability is established without the angle condition on K_{n0}^+. The proof is given by using the nonnegativity of u_h and it is given in the appendix.

LEMMA 3.4. [illegible] $r \leq 1$ [illegible] C [illegible]

$$\|u_h\|_\Omega \leq C \|u_0\|_{\Gamma_-^1},$$

$$\|u_h\|_{\Gamma_-^2} \leq C \|u_0\|_{\Gamma_-^1}.$$

Using the weak stability results, we now prove that u_h is globally stable with the norm $|||\cdot|||$.

THEOREM 3.5. [illegible] W_h [illegible] (2.2) [illegible] $r \geq 0$ [illegible] 3.3 [illegible] 3.4 [illegible] h_0 [illegible] κ [illegible] K [illegible] $h_0^{1-\alpha}\lambda < 1$ [illegible] $h < h_0$ [illegible] (2.6) [illegible]

$$|||u_h||| \leq C \|u_0\|_{\Gamma_-^1},$$

[illegible] $C(a_\dagger, T)$ [illegible] h [illegible] λ [illegible]. The discontinuous Galerkin method (2.6) is written as

$$B(u_h, v) = l(u_h; v), \tag{3.23}$$

where

$$\begin{aligned} B(u_h, v) &= \sum_{K \in \mathcal{T}} \int_K (\gamma \cdot \nabla u_h + \mu u_h) v dx - \sum_{K \in \mathcal{T}} \int_{\partial_- K \backslash \Gamma_-} [u_h] v^+ \gamma \cdot n ds \\ &\quad - \int_{\Gamma_-} u_h^+ v^+ \gamma \cdot n ds, \\ l(u_h; v) &= - \int_{\Gamma_-^1} \widetilde{u_0} v^+ \gamma \cdot n ds - \int_{\Gamma_-^2} u_h(0,t) v^+ \gamma \cdot n ds \end{aligned}$$

with $u_h(0,t)$ given by (2.5).

Following [13], we consider $\psi(a) = \exp(-\delta a)$, where $\delta = \ln 2/(a_\dagger + 1)$. Then, $\gamma \cdot \nabla\psi = -\delta\psi$, $\|\psi\|_{L^\infty(\Omega)} = 1, |\psi| > 1/2$. We now choose $v = \widetilde{\psi u_h}$. We see that

$$B(u_h, \widetilde{\psi u_h}) = B(u_h, \psi u_h) - B(u_h, \psi u_h - \widetilde{\psi u_h}).$$

On the other hand, we easily see, by integration by parts, that

$$\int_K (\gamma \cdot \nabla u_h)\psi u_h dx = \frac{1}{2}\left\{\int_{\partial K} \psi u_h^2 \gamma \cdot n ds + \delta \int_K \psi u_h^2 dx\right\}.$$

Thus, we have that

$$\begin{aligned} B(u_h, \psi u_h) =& \frac{1}{2}\delta \sum_{K\in\mathcal{T}} \int_K \psi u_h^2 dx + \sum_{K\in\mathcal{T}} \int_K \psi\mu u_h^2 dx + \frac{1}{2}\sum_{K\in\mathcal{T}} \int_{\partial K} \psi u_h^2 \gamma \cdot n ds \\ &- \sum_{K\in\mathcal{T}} \int_{\partial_- K\setminus\Gamma_-} [u_h](\psi u_h)^+ \gamma \cdot n ds - \int_{\Gamma_-} u_h^+ (\psi u_h)^+ \gamma \cdot n ds \\ =& \frac{1}{2}\delta \sum_{K\in\mathcal{T}} \int_K \psi u_h^2 dx + \sum_{K\in\mathcal{T}} \int_K \psi\mu u_h^2 dx - \frac{1}{2}\sum_{K\in\mathcal{T}} \int_{\partial_- K\setminus\Gamma_-} \psi [u_h]^2 \gamma \cdot n ds \\ &+ \frac{1}{2}\sum_{K\in\mathcal{T}} \int_{\partial_- K\setminus\Gamma_-} \psi (u_h^-)^2 \gamma \cdot n ds \\ &+ \frac{1}{2}\sum_{K\in\mathcal{T}} \int_{\partial_+ K} \psi (u_h^-)^2 \gamma \cdot n ds - \frac{1}{2}\int_{\Gamma_-} \psi (u_h^+)^2 \gamma \cdot n ds. \end{aligned} \tag{3.24}$$

Since $\partial_- K\setminus\Gamma_-$ is a part of $\partial_+ K'$ for some $K' \in \mathcal{T}$ and the sign of the outer normal of $\partial_- K\setminus\Gamma_-$ is opposite of the one of $\partial_+ K'$, we have that

$$\sum_{K\in\mathcal{T}} \int_{\partial_- K\setminus\Gamma_-} \psi (u_h^-)^2 \gamma \cdot n ds + \sum_{K\in\mathcal{T}} \int_{\partial_+ K} \psi (u_h^-)^2 \gamma \cdot n ds = \int_{\Gamma_+} \psi (u_h^-)^2 \gamma \cdot n ds.$$

Thus we have, from (3.24), that

$$\begin{aligned} B(u_h, \psi u_h) \geq& \frac{1}{4}\delta \|u_h\|_\Omega^2 + \frac{1}{2}\|\sqrt{\mu} u_h\|_\Omega^2 - \frac{1}{4}\sum_{K\in\mathcal{T}} \int_{\partial_- K\setminus\Gamma_-} [u_h]^2 \gamma \cdot n ds \\ &+ \frac{1}{4}\int_{\Gamma_+} \psi (u_h^-)^2 \gamma \cdot n ds - \frac{1}{4}\int_{\Gamma_-} (u_h^+)^2 \gamma \cdot n ds \\ \geq& \frac{1}{4}\delta \|u_h\|_\Omega^2 + \frac{1}{2}\|\sqrt{\mu} u_h\|_\Omega^2 + \frac{1}{4}\|[u_h]\|_{\Gamma_h}^2 + \frac{1}{4}\|u_h^+\|_{\Gamma_-}^2 + \frac{1}{4}\|u_h^-\|_{\Gamma_+}^2. \end{aligned} \tag{3.25}$$

Noting that $\|\psi\|_{W^{l,\infty}(K)} \leq C\delta^l$, $\|u_h\|_{H^l(K)} \leq Ch_K^{-l}\|u_h\|_K$, $|u_h|_{H^{r+1}(K)} = 0$, we have, by Leibniz's rule and (3.19), the following properties of the local projection. If $\delta h \leq 1$, then

$$\begin{aligned} &\|\psi u_h - \widetilde{\psi u_h}\|_K + h_K^{1/2}\|\psi u_h - \widetilde{\psi u_h}\|_{\partial K} \leq Ch_K^{r+1}|\psi u_h|_{H^{r+1}(K)} \\ &= Ch_K^{r+1}\sum_{l=0}^{r+1} \|\psi\|_{W^{l,\infty}(K)}|u_h|_{H^{r+1-l}(K)} \\ &= Ch_K^{r+1}\sum_{l=1}^{r+1} \|\psi\|_{W^{l,\infty}(K)}|u_h|_{H^{r+1-l}(K)} \end{aligned} \tag{3.26}$$

$$\leq Ch_K^{r+1}\sum_{l=1}^{r+1}\delta^l h_K^{l-(r+1)}\|u_h\|_K$$
$$\leq C\delta h\sum_{l=0}^{r}\delta^l h_K^l \delta h_K\|u_h\|_K$$
$$\leq C(r+1)\delta h_K\|u_h\|_K.$$

We also have, by (3.2) and (3.19), that

$$\begin{aligned}\|\psi u_h-\widetilde{\psi u_h}\|_{L^\infty(K)}+h_K^{1/2}\|\psi u_h-\widetilde{\psi u_h}\|_{L^\infty(\partial K)}&\leq Ch_K^{r+1}|\psi u_h|_{W^{r+1,\infty}(K)}\\ &\leq C(r+1)\delta h_K\|u_h\|_{L^\infty(K)}\\ &\leq C(r+1)\delta\|u_h\|_{L^2(K)}.\end{aligned}$$

Since $\int_K(\psi u_h-\widetilde{\psi u_h})w dx=0\ \forall\ w\in P_r(K)$, we see that

$$\int_K(\psi u_h-\widetilde{\psi u_h})\gamma\cdot\nabla u_h dx=0. \tag{3.27}$$

We thus have, by Hölder's inequality, that

$$\begin{aligned}B(u_h,\psi u_h-\widetilde{\psi u_h})=&\sum_{K\in\mathcal{T}}\int_K\mu u_h(\psi u_h-\widetilde{\psi u_h})dx\\ &-\sum_{K\in\mathcal{T}}\int_{\partial_- K\setminus\Gamma_-}[u_h](\psi u_h-\widetilde{\psi u_h})^+\gamma\cdot n ds\\ &-\int_{\Gamma_-}u_h^+(\psi u_h-\widetilde{\psi u_h})^+\gamma\cdot n ds\\ \leq&\frac{1}{4}\|\sqrt{\mu}u_h\|_\Omega^2+C\sum_{K\in\mathcal{T}_1}h_K^2\|\psi u_h-\widetilde{\psi u_h}\|_{L^\infty(K)}^2\\ &+C\lambda\sum_{K\in\mathcal{T}_2}h_K^{2-\alpha}\|\psi u_h-\widetilde{\psi u_h}\|_{L^\infty(K)}^2\\ &+\frac{1}{8}\|[u_h]\|_{\Gamma_h}^2+8\sum_{K\in\mathcal{T}}\|\psi u_h-\widetilde{\psi u_h}\|_{\partial_- K}^2+\frac{1}{8}\|u_h^+\|_{\Gamma_-}^2\\ \leq&\frac{1}{4}\|\sqrt{\mu}u_h\|_\Omega^2+C\delta\sum_{K\in\mathcal{T}_1}h_K^2\|u_h\|_K^2+C\lambda\delta\sum_{K\in\mathcal{T}_2}h_K^{2-\alpha}\|u_h\|_K^2\\ &+\frac{1}{8}\|[u_h]\|_{\Gamma_h}^2+8\delta\sum_{K\in\mathcal{T}}h_K\|u_h\|_K^2+\frac{1}{8}\|u_h^+\|_{\Gamma_-}^2.\end{aligned} \tag{3.28}$$

Combining (3.25) and (3.28), we then have, if $0<\lambda h<\frac{1}{16}$,

$$\begin{aligned}B(u_h,\widetilde{\psi u_h})\geq&\frac{1}{16}\delta\|u_h\|_\Omega^2+\frac{1}{4}\|\sqrt{\mu}u_h\|_\Omega^2\\ &+\frac{1}{8}\|[u_h]\|_{\Gamma_h}^2+\frac{1}{8}\|u_h^+\|_{\Gamma_-}^2+\frac{1}{8}\|u_h^-\|_{\Gamma_+}^2.\end{aligned} \tag{3.29}$$

We also see, by Lemma 3.3, that

$$
\begin{aligned}
B(u_h, \widetilde{\psi u_h}) &= -\int_{\Gamma_-^1} \widetilde{u_0}\widetilde{\psi u_h}^+ \gamma \cdot n ds - \int_{\Gamma_-^2} u_h(0,t)\widetilde{\psi u_h}^+ \gamma \cdot n ds \\
&\le \|\widetilde{u_0}\|_{\Gamma_-^1} \|\widetilde{\psi u_h}^+\|_{\Gamma_-^1} + \|u_h(0,t)\|_{\Gamma_-^2} \|\widetilde{\psi u_h}^+\|_{\Gamma_-^2} \\
&\le \left\{ \|\widetilde{u_0}\|_{\Gamma_-^1} + \|u_h(0,t)\|_{\Gamma_-^2} \right\} \left\{ \|u_h^+\|_{\Gamma_-} + \|u_h^-\|_{\Gamma_+} \right\} \\
&\le C\|\widetilde{u_0}\|_{\Gamma_-^1} \left\{ \|u_h^+\|_{\Gamma_-} + \|u_h^-\|_{\Gamma_+} \right\}.
\end{aligned} \tag{3.30}
$$

On the other hand, we note from (3.4)–(3.5) that

$$
\sum_{K\in\mathcal{T}} h_K \|\gamma\cdot\nabla u_h\|_K^2 \le C \left\{ \sum_{K\in\mathcal{T}_1} h_K \|u_h\|_K^2 + \sum_{K\in\mathcal{T}_2} \|\sqrt{\mu} u_h\|_K^2 + \sum_{K\in\mathcal{T}} \|[u_h]\|_{\partial_- K}^2 \right\}. \tag{3.31}
$$

Thus, from (3.20) and Lemma 3.3, and combining (3.29)–(3.31), we obtain that

$$
\begin{aligned}
|||u_h|||^2 &\le C \left\{ \sum_{K\in\mathcal{T}_1} \|u_h\|_K^2 + \sum_{K\in\mathcal{T}_2} \|\sqrt{\mu} u_h\|_K^2 + \|[u_h]\|_{\Gamma_h}^2 + \|u_h^+\|_{\Gamma_-}^2 \right\} \\
&\le C\|u_0\|_{\Gamma_-^1} \left\{ \|u_h^+\|_{\Gamma_-} + \|u_h^-\|_{\Gamma_+} \right\}
\end{aligned} \tag{3.32}
$$

or

$$
|||u_h||| \le C\|u_0\|_{\Gamma_-^1}.
$$

This completes the proof. □

3.3. Choose

$$
v(x) = \begin{cases} \widetilde{\psi u_h}(x) & \text{if } x \in K \text{ and } K \in \mathcal{T}\backslash\{K_{n0}^+\}_{n=1}^N, \\ 0 & \text{otherwise.} \end{cases} \tag{3.33}
$$

We then see that

$$
B(u_h, v) = B_0(u_h, \widetilde{\psi u_h}) - B_0(u_h, \psi u_h - \widetilde{\psi u_h}), \tag{3.34}
$$

where

$$
\begin{aligned}
B_0(u_h, w) = &\sum_{K\in\mathcal{T}\backslash\{K_{n0}^+\}_{n=1}^N} \int_K (\gamma\cdot\nabla u_h + \mu u_h) w dx \\
&- \sum_{K\in\mathcal{T}\backslash\{K_{n0}^+\}_{n=1}^N} \int_{\partial_- K\backslash\Gamma_-} [u_h] w^+ \gamma\cdot n ds - \int_{\Gamma_-^1} u_h^+ w^+ \gamma\cdot n ds.
\end{aligned}
$$

In a similar way to (3.24)–(3.25), we see, by integration by parts, that

$$
\begin{aligned}
B_0(u_h, \psi u_h) \ge &\frac{1}{4}\delta \sum_{K\in\mathcal{T}\backslash\{K_{n0}^+\}_{n=1}^N} \|u_h\|_K^2 + \frac{1}{2} \sum_{K\in\mathcal{T}\backslash\{K_{n0}^+\}_{n=1}^N} \|\sqrt{\mu} u_h\|_K^2 \\
&+ \frac{1}{4} \sum_{K\in\mathcal{T}\backslash\{K_{n0}^+\}_{n=1}^N} \|[u_h]\|_{\partial_- K\backslash\Gamma_-}^2 + \frac{1}{4}\|u_h^+\|_{\Gamma_-^1}^2 + \frac{1}{4}\|u_h^-\|_{\Gamma_+^1}^2.
\end{aligned} \tag{3.35}
$$

In a similar way to (3.28), we also see that

$$B_0(u_h, \psi u_h - \widetilde{\psi u_h}) \le \frac{1}{4} \sum_{K\in\mathcal{T}\setminus\{K^+_{n0}\}_{n=1}^N} \|\sqrt{\mu} u_h\|^2_K + \frac{1}{8}\delta \sum_{K\in\mathcal{T}\setminus\{K^+_{n0}\}_{n=1}^N} \|u_h\|^2_K$$
$$+ \frac{1}{8} \sum_{K\in\mathcal{T}\setminus\{K^+_{n0}\}_{n=1}^N} \|[u_h]\|^2_{\partial_- K\setminus\Gamma_-} + \frac{1}{8}\|u_h^+\|^2_{\Gamma^1_-}. \tag{3.36}$$

Combining (3.35)–(3.36), we have that

$$B_0(u_h, \widetilde{\psi u_h}) \ge \frac{1}{8}\delta \sum_{K\in\mathcal{T}\setminus\{K^+_{n0}\}_{n=1}^N} \|u_h\|^2_K$$
$$+ \frac{1}{8} \sum_{K\in\mathcal{T}\setminus\{K^+_{n0}\}_{n=1}^N} \|[u_h]\|^2_{\partial_- K} + \frac{1}{8}\|u_h^+\|^2_{\Gamma^1_-} + \frac{1}{8}\|u_h^-\|^2_{\Gamma_+}. \tag{3.37}$$

On the other hand, we have, by the choice of v and (3.34), that

$$\begin{aligned} B(u_h, v) &= l(u_h; v) \\ &= -\int_{\Gamma^1_-} \widetilde{u_0} v^+ \gamma\cdot n ds - \int_{\Gamma^2_-} u_h^- v^+ \gamma\cdot n ds \\ &= -\int_{\Gamma^1_-} \widetilde{u_0}\widetilde{\psi u_h}^+ \gamma\cdot n ds \\ &\le \|u_0\|_{\Gamma^1_-}\|u_h^+\|_{\Gamma^1_-}. \end{aligned} \tag{3.38}$$

Thus, we obtain by (3.37)–(3.38) that

$$\sum_{K\in\mathcal{T}\setminus\{K^+_{n0}\}_{n=1}^N} \|u_h\|^2_K + \sum_{K\in\mathcal{T}\setminus\{K^+_{n0}\}_{n=1}^N} \|[u_h]\|^2_{\partial_- K} + \frac{1}{8}\|u_h^+\|^2_{\Gamma^1_-} + \frac{1}{8}\|u_h^-\|^2_{\Gamma_+}$$
$$\le C\|u_0\|^2_{\Gamma^1_-}. \tag{3.39}$$

We now have, by (2.5) and (3.3), and by the angle condition on K^+_{n0}, that

$$\begin{aligned} \|u_h\|^2_{K^+_{n0}} &\le h_{K^+_{n0}}\|u_h^-\|^2_{\Gamma^{2,n}_-} \\ &\le C h_{K^+_{n0}} \sum_{K\in\mathcal{T}^n} \|u_h\|^2_K. \end{aligned} \tag{3.40}$$

Summing over $n = 1, \dots, N$, we see from (3.40) that

$$\sum_{n=1}^N \|u_h\|^2_{K^+_{n0}} \le C \sum_{K\in\mathcal{T}} h_{K^+_{n0}} \|u_h\|^2_K. \tag{3.41}$$

Adding (3.39) and (3.41), we have, for sufficiently small $h_0 > 0$, that

$$\|u_h\|_\Omega \le C\|u_0\|_{\Gamma^1_-},$$

which proves (3.21). Thus, we have that

$$\|u_h\|_{\Gamma^{2,n}_-} \le C\|u_0\|_{\Gamma^1_-},$$

which shows (3.22). This completes the proof. □

4. L^2 error analysis. Convergence rates of the approximate solution obviously depend on the regularity of the solution to the problem. In this section, for the error estimate we let $\mathcal{T}_{22} = \{K \in \mathcal{T} : u \notin H^{r+1}(K)\}$.

We also consider the following extension of the projection $\widetilde{u}$ on Γ_-^2:

$$\widetilde{u}(0,t) = \int_0^{a_\dagger} \beta(a)\widetilde{u}(a,t)da. \tag{4.1}$$

To derive an error bound, we adopt the following notation: $e = u_h - u$, $\theta = u_h - \tilde{u}$, $-\rho = \tilde{u} - u$.

We now note from Hölder's inequality and (3.19) that if $K \in \mathcal{T}_{22}$, then

$$\begin{aligned} \|\rho\|_K &\le Ch_K^{1/p}\|\rho\|_{L^{2q}(K)} \\ &\le Ch_K^{1/p+l}\|u\|_{W^{l,2q}(K)} \\ &\le Ch_K^{l+1-1/q}\|u\|_{W^{l,2q}(K)} \end{aligned} \tag{4.2}$$

and

$$\|\rho\|_{\partial K} \le Ch_K^{l+1/2-1/q}\|u\|_{W^{l,2q}(K)}, \tag{4.3}$$

where $1/p + 1/q = 1$, $p, q \ge 1$, and $1/2 \le l \le r+1$. We also see from (1.2) and (2.5) that

$$\begin{aligned} \|\rho\|_{\Gamma_-^2}^2 &\le C\sum_{K\in\mathcal{T}} \|\rho\|_{L^2(K)}^2 \\ &\le C\Bigg\{ \sum_{K\in\mathcal{T}\setminus\mathcal{T}_{22}} h_K^{2r+2}\|u\|_{H^{r+1}(K)}^2 + \sum_{K\in\mathcal{T}_{22}} h_K^{2l+2-2/q}\|u\|_{W^{l,2q}(K)}^2 \Bigg\}, \end{aligned} \tag{4.4}$$

where $q \ge 1$ and $0 \le l \le r+1$. Combining (3.19) and (4.2)–(4.4), we easily obtain the following lemma.

LEMMA 4.1. W_h (2.2 $r \ge 0$ u $H^{r+1}(K)$ $K \in \mathcal{T}\setminus\mathcal{T}_{22}$ $W^{l,2q}(K)$ $K \in \mathcal{T}_{22}$ $1/2 \le l \le r+1$ $q \ge 1$ $C > 0$ λ h

$$|||\rho||| \le C\Bigg\{ \sum_{K\in\mathcal{T}\setminus\mathcal{T}_{22}} h_K^{r+1/2}\|u\|_{H^{r+1}(K)} + \sum_{K\in\mathcal{T}_{22}} h_K^{l+1/2-1/q}\|u\|_{W^{l,2q}(K)} \Bigg\}. \tag{4.5}$$

We are now ready to prove the main theorem of this section concerning the error estimates for the solution to (2.3)–(2.5).

THEOREM 4.2. W_h (2.2) $r \ge 0$ u $H^{r+1}(K)$ $K \in \mathcal{T}\setminus\mathcal{T}_{22}$ $W^{l,2q}(K)$ $K \in \mathcal{T}_{22}$ $1/2 \le l \le r+1$ $q \ge 1$ h_0 $(h_0\lambda < 1/16)$ κ r $h < h_0$

$$\begin{aligned} |||u - u_h|||^2 \le C\Bigg\{ &\sum_{K\in\mathcal{T}\setminus\mathcal{T}_{22}} h_K^{2r+1}\|u\|_{H^{r+1}(K)}^2 + \sum_{K\in\mathcal{T}_{22}} h_K^{2l+1-2/q}\|u\|_{W^{l,2q}(K)}^2 \\ &+ \sum_{K\in\mathcal{T}} h_K^{2r+2}\|u_0\|_{H^{r+1}(\partial_- K\cap\Gamma_-^1)}^2 \Bigg\}, \end{aligned}$$

$C(a_\dagger, T)$ λ h

. We have the following error equation: $\forall\, v \in W_h$,

$$B(\theta, v) = B(\rho, v) - \int_{\Gamma_-^2} \theta^- v^+ \gamma \cdot n ds + \int_{\Gamma_-^2} \rho^- v^+ \gamma \cdot n ds + \int_{\Gamma_-^1} \rho_0 v^+ \gamma \cdot n ds, \tag{4.6}$$

where $\rho_0 = u_0(a) - \widetilde{u_0}(a)$. We now choose $v = \widetilde{\psi\theta}$. We note that (3.29) also holds for u_h replaced by θ. Thus, we have that

$$B(\theta, \widetilde{\psi\theta}) \geq C\Big\{ \|\theta\|_\Omega^2 + \|\sqrt{\mu}\theta\|_\Omega^2 + \|[\theta]\|_{\Gamma_h}^2 + \|\theta^+\|_{\Gamma_-}^2 + \|\theta^-\|_{\Gamma_+}^2 \Big\}. \tag{4.7}$$

To estimate the right-hand side of (4.6), we first rewrite $B(\rho, \widetilde{\psi\theta})$. Since $\int_K \rho\gamma \cdot \nabla(\widetilde{\psi\theta})dx \equiv 0$, we see, by integration by parts, that

$$\begin{aligned} B(\rho, \widetilde{\psi\theta}) &= \sum_{K\in\mathcal{T}} \int_K (\gamma \cdot \nabla\rho + \mu\rho)\widetilde{\psi\theta} dx - \sum_{K\in\mathcal{T}} \int_{\partial_- K \setminus \Gamma_-} [\rho] \widetilde{\psi\theta}^+ \gamma \cdot n ds - \int_{\Gamma_-} \rho^+ \widetilde{\psi\theta}^+ \gamma \cdot n ds \\ &= \sum_{K\in\mathcal{T}} \int_K \mu\rho\widetilde{\psi\theta} dx + \sum_{K\in\mathcal{T}} \int_{\partial_- K \setminus \Gamma_-} \rho^- [\widetilde{\psi\theta}] \gamma \cdot n ds + \int_{\Gamma_+} \rho^- \widetilde{\psi\theta}^- \gamma \cdot n ds. \end{aligned} \tag{4.8}$$

If $K \in \mathcal{T}_2$, then, by Hölder's inequality and (3.1), we see that

$$\|\sqrt{\mu}\rho\|_K^2 \leq C\|\mu\|_{L^1(K)}\|\rho\|_{L^\infty(K)}^2 \leq Ch_K^{2-\alpha}\|\rho\|_{L^\infty(K)}^2 \leq Ch_K^{-\alpha}\|\rho\|_K^2. \tag{4.9}$$

We thus obtain by (3.19), (4.2)–(4.4), (4.8), and (4.9) that

$$\begin{aligned} B(\theta, \widetilde{\psi\theta}) &= B(\rho, \widetilde{\psi\theta}) - \int_{\Gamma_-^2} \theta^- \widetilde{\psi\theta}^+ ds + \int_{\Gamma_-^2} \rho^- \widetilde{\psi\theta}^+ + \int_{\Gamma_-^1} \rho_0 \widetilde{\psi\theta}^+ \gamma \cdot n ds \\ &\leq C\Big\{ \sum_{K\in\mathcal{T}_1} \|\rho\|_K + \sum_{K\in\mathcal{T}_2} h_K^{-\alpha/2}\|\rho\|_K + \|\rho^-\|_{\Gamma_h} + \|\rho^-\|_{\Gamma_+} + \|\theta^-\|_{\Gamma_-^2} + \|\rho^-\|_{\Gamma_-^2} \\ &\qquad + \|\rho_0\|_{\Gamma_-^1} \Big\} \Big\{ \|\theta\|_\Omega + \sum_{K\in\mathcal{T}_2} \|\sqrt{\mu}\theta\|_K + \|[\theta]\|_{\Gamma_h} + \|\theta^+\|_{\Gamma_-} + \|\theta^-\|_{\Gamma_+} \Big\} \end{aligned} \tag{4.10}$$

$$\begin{aligned} &\leq C\Big\{ \sum_{K\in\mathcal{T}\setminus\mathcal{T}_{22}} h_K^{r+1/2}\|u\|_{H^{r+1}(K)} + \sum_{K\in\mathcal{T}_{22}} h_K^{l+1/2-1/q}\|u\|_{W^{l,2q}(K)} \\ &\qquad + \sum_{K\in\mathcal{T}} h_K^{r+1}\|u_0\|_{H^{r+1}(\partial_- K\cap\Gamma_-^1)} + \|\theta^-\|_{\Gamma_-^2} \Big\} \\ &\qquad \times \Big\{ \|\theta\|_\Omega + \sum_{K\in\mathcal{T}_2} \|\sqrt{\mu}\theta\|_K + \|[\theta]\|_{\Gamma_h} + \|\theta^+\|_{\Gamma_-} + \|\theta^-\|_{\Gamma_+} \Big\}, \end{aligned}$$

where $q \geq 1$ and $0 < l \leq r+1$. Thus, combining (4.7) and (4.10), we have that

$$\begin{aligned} &\|\theta\|_\Omega + \|\sqrt{\mu}\theta\|_\Omega + \|[\theta]\|_{\Gamma_h} + \|\theta^+\|_{\Gamma_-} + \|\theta^-\|_{\Gamma_+} \\ &\leq C\Big\{ \sum_{K\in\mathcal{T}\setminus\mathcal{T}_{22}} h_K^{r+1/2}\|u\|_{H^{r+1}(K)} + \sum_{K\in\mathcal{T}_{22}} h_K^{l+1/2-1/q}\|u\|_{W^{l,2q}(K)} \\ &\qquad + \sum_{K\in\mathcal{T}} h_K^{r+1}\|u_0\|_{\partial_- K\cap\Gamma_-^1} + \|\theta^-\|_{\Gamma_-^2} \Big\}, \end{aligned}$$

where $0 < l \le r+1$, $q \ge 1$. We here note that Lemma 3.3 holds with u_h replaced by θ. Thus we see that

$$\begin{aligned}\|\theta\|_\Omega + \|\sqrt{\mu}\theta\|_\Omega + \|[\theta]\|_{\Gamma_h} + \|\theta^+\|_{\Gamma_-} + \|\theta^-\|_{\Gamma_+} \\ \le C\Big\{ \sum_{K\in\mathcal{T}\setminus\mathcal{T}_{22}} h_K^{r+1/2}\|u\|_{H^{r+1}(K)} + \sum_{K\in\mathcal{T}_{22}} h_K^{l+1/2-1/q}\|u\|_{W^{l,2q}(K)} \\ + \sum_{K\in\mathcal{T}} h_K^{r+1}\|u_0\|_{H^{r+1}(\partial_- K\cap\Gamma_-^1)}\Big\},\end{aligned} \tag{4.11}$$

where $0 < l \le r+1$, $q \ge 1$. Now, to estimate the term $\|\gamma\cdot\nabla\theta\|_K^2$, we first note the following local error equation:

$$\int_K \{\gamma\cdot\nabla e + \mu e\} v dx = -\int_{\partial_- K} [e] v^+ \gamma\cdot n ds,$$

or, by taking $v = \gamma\cdot\nabla\theta$,

$$\begin{aligned}\int_K \{\gamma\cdot\nabla\theta + \mu\theta\}\gamma\cdot\nabla\theta dx = \int_K \{\gamma\cdot\nabla\rho + \mu\rho\}\gamma\cdot\nabla\theta dx \\ + \int_{\partial_- K} [\rho](\gamma\cdot\nabla\theta)^+\gamma\cdot n ds - \int_{\partial_- K}[\theta](\gamma\cdot\nabla\theta)^+\gamma\cdot n ds.\end{aligned} \tag{4.12}$$

We now easily see that

$$\int_K \{\gamma\cdot\nabla\theta + \mu\theta\}\gamma\cdot\nabla\theta dx \ge \frac{7}{8}\|\gamma\cdot\nabla\theta\|_K^2 - 8h_K^{-1}\|\sqrt{\mu}\theta\|_K^2. \tag{4.13}$$

We also see by Young's inequality that

$$\begin{aligned}\int_K \{\gamma\cdot\nabla\rho + \mu\rho\}\gamma\cdot\nabla\theta dx + \int_{\partial_- K}[\rho](\gamma\cdot\nabla\theta)^+\gamma\cdot n ds - \int_{\partial_- K}[\theta](\gamma\cdot\nabla\theta)^+\gamma\cdot n ds \\ \le \|\gamma\cdot\nabla\rho\|_K\|\gamma\cdot\nabla\theta\|_K + Ch_K^{-1}\|\rho\|_K\|\gamma\cdot\nabla\theta\|_K \\ + h_K^{-1/2}\|[\rho]\|_{\partial_- K}\|\gamma\cdot\nabla\theta\|_K + h_K^{-1/2}\|[\theta]\|_{\partial_- K}\|\gamma\cdot\nabla\theta\|_K \\ \le \frac{1}{2}\|\gamma\cdot\nabla\theta\|_K^2 + 8Ch_K^{-1}\|[\theta]\|_{\partial_- K}^2 + 8\|\gamma\cdot\nabla\rho\|_K^2 \\ + 8Ch_K^{-2}\|\rho\|_K^2 + 8h_K^{-1}\|[\rho]\|_{\partial_- K}^2.\end{aligned} \tag{4.14}$$

Combining (4.12)–(4.14), we obtain that

$$\|\gamma\cdot\nabla\theta\|_K^2 \le C\Big\{h_K^{-1}\|\sqrt{\mu}\theta\|_K^2 + h_K^{-1}\|[\theta]\|_{\partial_- K}^2 + h_K^{-2}\|\rho\|_K^2 + \|\gamma\cdot\nabla\rho\|_K^2 + h_K^{-1}\|[\rho]\|_{\partial_- K}^2\Big\}$$

or

$$\begin{aligned}\sum_{K\in\mathcal{T}} h_K\|\gamma\cdot\nabla\theta\|_K^2 \le C\Big\{\|\sqrt{\mu}\theta\|_\Omega^2 + \sum_{K\in\mathcal{T}}\|[\theta]\|_{\partial_- K}^2 + \sum_{K\in\mathcal{T}} h_K^{-1}\|\rho\|_K^2 \\ + \sum_{K\in\mathcal{T}} h_K\|\gamma\cdot\nabla\rho\|_K^2 + \sum_{K\in\mathcal{T}}\|[\rho]\|_{\partial_- K}^2\Big\}.\end{aligned} \tag{4.15}$$

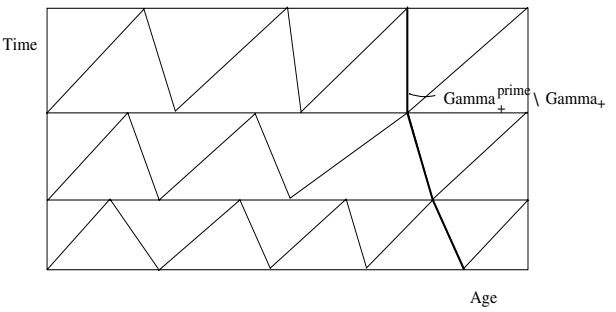

FIG. 4.1. *A sample triangulation.*

We thus have by Lemma 4.1, (3.20), (4.11), and (4.15) that

$$|||\theta|||^2 \le C\Big\{ \sum_{K\in\mathcal{T}\setminus\mathcal{T}_{22}} h_K^{2r+1}\|u\|^2_{H^{r+1}(K)} + \sum_{K\in\mathcal{T}_{22}} h_K^{2l+1-2/q}\|u\|^2_{W^{l,2q}(K)} + \sum_{K\in\mathcal{T}} h_K^{2r+2}\|u_0\|^2_{H^{r+1}(\partial_- K\cap\Gamma^1_-)}\Big\}. \tag{4.16}$$

This completes the proof. □

Let $\Omega' = \{x \in K : K \in \mathcal{T}\setminus\mathcal{T}_{22}\}$ be the regular region in Ω and let $\Gamma'_+ = \{x \in \partial\Omega' : n(x)\cdot\gamma > 0\}$ denote the outflow boundary of $\partial\Omega'$. Since u is not regular only in a and u_h is computed marching in time, we may assume that $\Gamma'_+\setminus\Gamma_+$ is geometrically conforming and $\overline{\partial\Omega'}\cap\Omega$ is a part of the outflow boundary $\partial\Omega'$ as in Figure 4.1, if necessary with a grid modification (calling it again $\mathcal{T}$). By following the proof of Theorem 4.2, we then obtain an optimal error estimate in order and in regularity away from the maximum age.

COROLLARY 4.3. [illegible] W_h [illegible] (2.2) [illegible] $r \ge 0$ [illegible] h_0 $(h_0\lambda < 1/16)$ [illegible] κ [illegible] r [illegible] $h < h_0$, [illegible]

$$\begin{aligned}
&\sum_{K\in\mathcal{T}\setminus\mathcal{T}_{22}} \|u-u_h\|^2_K + \sum_{K\in\mathcal{T}\setminus\mathcal{T}_{22}} \|\sqrt{\mu}(u-u_h)\|^2_K + \sum_{K\in\mathcal{T}\setminus\mathcal{T}_{22}} h_K\|\gamma\cdot\nabla(u-u_h)\|^2_K \\
&\quad + \sum_{K\in\mathcal{T}\setminus\mathcal{T}_{22}} \|[u-u_h]\|^2_{\partial_- K\setminus\Gamma_-} + \sum_{K\in\mathcal{T}\setminus\mathcal{T}_{22}} \|(u-u_h)^+\|^2_{\partial_- K\cap\Gamma_-} \\
&\quad + \sum_{K\in\mathcal{T}\setminus\mathcal{T}_{22}} \|(u-u_h)^-\|^2_{\partial_+ K\cap\Gamma_+} \\
&\le C\Big\{ \sum_{K\in\mathcal{T}\setminus\mathcal{T}_{22}} h_K^{2r+1}\|u\|^2_{H^{r+1}(K)} + \sum_{K\in\mathcal{T}\setminus\mathcal{T}_{22}} h_K^{2r+2}\|u_0\|^2_{H^{r+1}(\partial_- K\cap\Gamma^1_-)}\Big\},
\end{aligned}$$

[illegible] $C(a_\dagger, T)$ [illegible] λ [illegible] h [illegible] $q \ge 1$ $0 \le l \le r+1$.

[illegible]. Take the locally defined test function

$$v(x) = \begin{cases} \widetilde{\psi\theta}(x) & \text{if } x \in K \text{ and } K \in \mathcal{T}\setminus\mathcal{T}_{22}, \\ 0 & \text{otherwise,} \end{cases}$$

and follow the proof of Theorem 4.2 to obtain the desired results. □

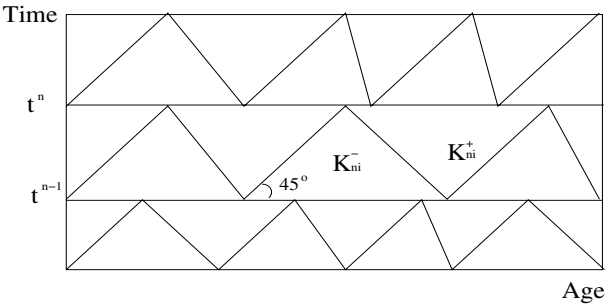

FIG. 5.1. *A sample triangulation.*

4.4. From Theorem 4.2 we easily see that

$$\sum_{K\in\mathcal{T}_{22}} \|u-u_h\|_K^2 \le C\Big\{ \sum_{K\in\mathcal{T}\setminus\mathcal{T}_{22}} h_K^{2r+1+\alpha}\|u\|_{H^{r+1}(K)}^2 + \sum_{K\in\mathcal{T}_{22}} h_K^{2l+1+\alpha-2/q}\|u\|_{W^{l,2q}(K)}^2 + \sum_{K\in\mathcal{T}} h_K^{2r+2}\|u_0\|_{H^{r+1}(\partial_- K\cap\Gamma_-^1)}^2 \Big\}.$$

5. Nonnegativity. In this section, we investigate the nonnegativity of the solution to (2.5)–(2.6). Nonnegativity of the solution is important; it is not only biologically meaningful but also it is essential to analyze long-time behavior of the solution. Throughout this section, we assume the followings on the triangulation $\mathcal{T}$:

(T2) On K_{ni}^-, the interior angle of the left vertex lying on $t = t^{n-1}$ is equal to $\pi/4$, as seen in Figure 5.1.

Under (T2), the age and time advance together along the characteristics and the discrete solution preserves the behavior of the solution to the model problem. Assumption (T2) can be viewed as an analogue of the CFL condition for the finite difference method applied to the hyperbolic equation (1.1)–(1.3). We here note that when the discontinuous Galerkin method is applied to a general linear hyperbolic problem, the same type of triangulation as (T2) is required to obtain a nonnegative solution. Furthermore, on actual computation, for the treatment of the nonlocal boundary condition of (2.3)–(2.5), one may do the following (Step 1)–(Step 3) while $1 \le n \le N$:

(Step 1) On $K \in \mathcal{T}^n\setminus\{K_{n0}^+\}$, compute u_h by (2.3)–(2.4).

(Step 2) On K_{n0}^+, compute

$$P_0 u_h(0,t) = \int_{t-t^{n-1}}^{a_\dagger} \beta(a)u_h(a,t)da$$

and let $Pu_h(a,t)$ be the solution to (2.3) with $u_h^-(0,t) = P_0u_h(0,t)$, and then compute

$$u_h^-(0,t) = \int_0^{t-t^{n-1}} \beta(a)Pu_h(a,t)da + \int_{t-t^{n-1}}^{a_\dagger} \beta(a)u_h(a,t)da.$$

(Step 3) On K_{n0}^+, compute u_h by (2.3) with $u_h^-(0,t)$ given by (Step 2).

We now notice that the triangle K satisfying (T2) is one of the cases of Figure 5.2.

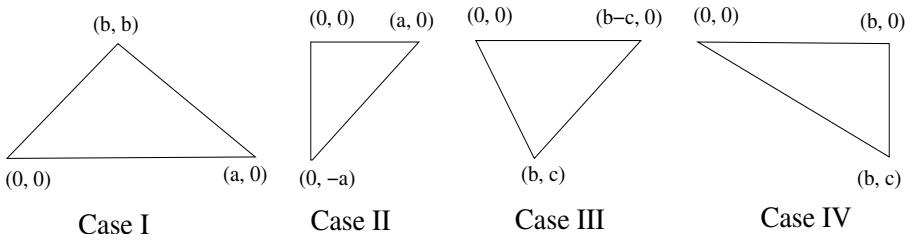

FIG. 5.2. *Sample triangles.*

LEMMA 5.1. [illegible] $r \le 1$ [illegible] u_h^- [illegible] $\partial_- K$ [illegible] K [illegible] 5.2 [illegible] u_h [illegible] K [illegible]. If we consider the mass lumping, then the term involving μ appears only through the diagonal. Without loss of generality we may thus assume that $\mu \equiv 0$. Let φ_i, $i = 1, 2, 3$, be the nodal basis on K and ψ_i, $i = 1, 2$, be the nodal basis on $\partial_- K$. Then $\psi_i = \varphi_{j_i}^+$ for some $j_i = 1, 2, 3$, $j_1 \neq j_2$, and $u_h^- = \alpha_1 \varphi_{j_1}^+ + \alpha_2 \varphi_{j_2}^+$, $\alpha_i \ge 0$, $i = 1, 2$. Let $u_h = U^1 \varphi_1 + U^2 \varphi_2 + U^3 \varphi_3$. Then by taking $v = \varphi_j$, $j = 1, 2, 3$, in (2.3) we see that

$$\int_K \gamma \cdot \nabla u_h \varphi_j dx - \int_{\partial_- K} u_h \varphi_j^+ \gamma \cdot n ds = - \int_{\partial_- K} u_h \varphi_j^+ \gamma \cdot n ds, \quad j = 1, 2, 3 \tag{5.1}$$

or, in matrix form, that $AU = B$, where $U = (U^1, U^2, U^3)^T$ and A and B are one of the following cases:

$$A = \begin{bmatrix} 1 & 1 & 1 \\ 0 & 2 & 1 \\ -1 & 0 & 1 \end{bmatrix}, \quad B = \begin{bmatrix} 2\alpha_1 + \alpha_2 \\ \alpha_1 + 2\alpha_2 \\ 0 \end{bmatrix} \quad \text{for Case I,}$$

$$A = \begin{bmatrix} 2 & -1 & 2 \\ 0 & -1 & 1 \\ 1 & -1 & 3 \end{bmatrix}, \quad B = \begin{bmatrix} 2\alpha_1 + \alpha_2 \\ 0 \\ \alpha_1 + 2\alpha_2 \end{bmatrix} \quad \text{for Case II,}$$

$$A = \begin{bmatrix} 2b & -\sqrt{b^2 + c^2} & b + \sqrt{b^2 + c^2} \\ 0 & -1 & 1 \\ b & -\sqrt{b^2 + c^2} & 2b + \sqrt{b^2 + c^2} \end{bmatrix}, \quad B = \begin{bmatrix} b(2\alpha_1 + \alpha_2) \\ 0 \\ b(\alpha_1 + 2\alpha_2) \end{bmatrix} \quad \text{for Case III,}$$

$$A = \begin{bmatrix} 2b(b-c) - c\sqrt{b^2 + c^2} & (c-b)\sqrt{b^2 + c^2} & b(b-c) + b\sqrt{b^2 + c^2} \\ -c & c - b & b \\ b(b-c) - c\sqrt{b^2 + c^2} & (c-b)\sqrt{b^2 + c^2} & 2b(b-c) + b\sqrt{b^2 + c^2} \end{bmatrix},$$

$$B = \begin{bmatrix} b(b-c)(2\alpha_1 + \alpha_2) \\ 0 \\ b(b-c)(\alpha_1 + 2\alpha_2) \end{bmatrix} \quad \text{for Case IV.}$$

For Cases I–IV, we easily see that $(U^1, U^2, U^3) \ge 0$. □

We now prove that the solution to (2.3)–(2.5) is nonnegative.

THEOREM 5.2. [illegible] $r \le 1$ [illegible] (2.3)–(2.5) u_h [illegible]

[illegible]. We easily see, by (2.3), that u_h on K_{ni}^-, $i \ge 1$ is nonnegative. We then see, by Lemma 5.1, that u_h on K_{ni}^+, $i \ge 1$, is nonnegative. We now have that $u_h^-(0,t)$ is nonnegative. Thus, in turn, we obtain that u_h is nonnegative on K_{n0}^+. □

6. Numerical results. In this section we present some numerical results. In the tests, we have computed twice the approximate solution and evaluated the errors twice, once with step size h and once with step size $h/2$. We estimated the errors in ℓ_2 and ℓ_∞ norms; the errors are denoted by, respectively, E_h^i and $E_{h/2}^i$, $i = 2$ or ∞. Then we computed the rate of convergence using the usual formula

$$r_h^i = \frac{\ln(E_h^i/E_{h/2}^i)}{\ln 2}, \quad i = 2 \text{ or } \infty.$$

In all the tests, we have used the piecewise linear polynomial space as an approximate space.

EXAMPLE 6.1. [illegible] (1.1)–(1.3) [illegible] $a_\dagger = 1$ $\beta(a) = 20a(1-a)$ $\mu(a) = 10exp(-100(1-a))$ $u_0(a)$ [illegible] $u(a,t) = \omega_0 exp(-\int_0^a \mu(\xi)\,d\xi - \alpha^* a)exp(\alpha^* t)$ [illegible] $\alpha^* \approx 2.78576939$ [illegible] $\omega_0 \approx 2.969447356$.

We took $u_0(a) = \omega_0 exp(\alpha^* t)$ as the initial data. We note that the compatibility condition at (0,0) is satisfied, which guarantees the continuity of the solution $u(a,t)$.

The results are presented in Table 6.1. From the table, we see that the effective rate of convergence is order two, which is a half order better than the expected one from the theoretical results (when the data are smooth and bounded).

In the next example we consider the case that the mortality function μ is unbounded.

EXAMPLE 6.2. [illegible] (1.1)–(1.3) [illegible] $a_\dagger = 1$ $\beta(a) = e$ $\mu(a) = \frac{1}{1-a}$, [illegible] $u_0(a) = (1-a)e^{-a}$

The results are shown to Table 6.2.

TABLE 6.3
Convergence estimates for Example 6.3.

h	E_h^∞	r_h^∞	E_h^2	r_h^2
1/8	0.0138519	0.73817	0.00358679	1.37705
1/16	0.0084722	0.70927	0.00132874	1.43263
1/32	0.0052516	0.68997	0.00049648	1.42024
1/64	0.0032805	0.678867	0.00019142	1.37499
1/128	0.0020576	0.672908	0.00007704	1.31307

When the mortality μ is unbounded and the other data are smooth, we obtain the convergent rate of the order of 3/2, which is in agreement with the theoretical results.

In the next example we consider the case that the solution $u \in H^1(\Omega)$ but $u \notin H^2(\Omega)$.

EXAMPLE 6.3. [illegible] (1.1)–(1.3) [illegible] $a_\dagger = 1$ $\beta(a) = 1/\int_0^1 (1-a)^{2/3} e^{-a} da$ $\mu(a) = \frac{2/3}{1-a}$, [illegible] $u_0(a) = (1-a)^{2/3} e^{-a}$

The exact solution is $u(a,t) = e^t(1-a)^{2/3}e^{-a}$. The results are shown to Table 6.3.

In Example 6.1, the mortality function is bounded and the solution is smooth and we obtain the convergence order of h^{r+1}. In Example 6.2, the mortality function is unbounded and the solution is smooth. In that case, we see from the theorem that the convergence rate is dominated by $h^{r+1/2}$ and our numerical example shows in agreement with the theorem. In Example 6.3, the mortality function is unbounded and the solution is not smooth. The results show that the solution of the discontinuous Galerkin method is stable and they indicate an $\mathcal{O}(h^{l+1/2})$ rate of convergence, which is the expected result from the theoretical estimate.

7. Conclusions. We have proposed a discontinuous Galerkin method to approximate the possibly nonsmooth solution to the model of population dynamics with unbounded mortality and nonlocal birth process. Due to the nonlocal birth process, some (reasonable) assumptions on the triangulation were made to obtain a stable approximate solution, which can be viewed as an analogue of the CFL condition for the finite difference method applied to (1.1)–(1.3). Regularity of the solution depends on the growth rate of the mortality function near the maximum age. In [15], it was shown that if $\alpha > 1$, or $\alpha = 1$ and $\lambda \geq 1$, then the solution is regular enough so that a collocation method can be used to approximate the solution to (1.1)–(1.3). In the present paper, we have considered the case that $0 < \alpha < 1$ and $\lambda > 0$. In such a case, the solution of the model is not regular. Discontinuous Galerkin finite element methods were proposed to approximate the solution. It was seen that the convergence rates were affected by the regularity of the solution rather than by the unboundedness itself of the coefficient of the differential equation. We conclude from the modeling point of view that it is important to choose an appropriate form of the mortality function (accordingly, an appropriate numerical method) for numerical simulations to be reliable and efficient, which are an important tool in indicating what possible dynamical properties solutions of equations have.

Finally, concerning the regularity of the solution to the problem, one may obtain by following [15] that, near the maximum age,

$$u \in H^1 \text{ but } u \notin H^2 \text{ if } 0 < \alpha < 1/2,$$
$$u \in H^1 \text{ but } u \notin H^2 \text{ if } \alpha = 1 \text{ and } 1/2 < \lambda < 1,$$

$u \notin H^1$ if $\alpha = 1$ and $0 < \lambda \le 1/2$,
$u \in W^{1,q}$ if $0 < \alpha < 1/q$ with $q \ge 1$.

8. Appendix.

3.4. We take $v = u_h$ in (2.3) and we see that

$$\int_K (\gamma \cdot \nabla u_h + \mu u_h) u_h dx - \int_{\partial_- K} (u_h^+)^2 \gamma \cdot n ds = - \int_{\partial_- K} u_h^- u_h^+ \gamma \cdot n ds. \tag{8.1}$$

By summing over all K in $\mathcal{T}$ and by integration by parts we see that

$$\begin{aligned} &\frac{1}{2}\Big\{ \sum_{K\in\mathcal{T}} \int_{\partial_+ K} (u_h^-)^2 \gamma \cdot n ds + \sum_{K\in\mathcal{T}} \int_{\partial_- K} (u_h^+)^2 \gamma \cdot n ds \Big\} + \sum_{K\in\mathcal{T}} \int_K \mu (u_h)^2 dx \\ &\quad - \sum_{K\in\mathcal{T}} \int_{\partial_- K} (u_h^+)^2 \gamma \cdot n ds = - \sum_{K\in\mathcal{T}} \int_{\partial_- K} u_h^- u_h^+ \gamma \cdot n ds. \end{aligned} \tag{8.2}$$

Since $\partial_- K \cap \Gamma_h$ is a part of $\partial_+ K'$ for some $K' \in \mathcal{T}$ and the sign of the outer normal of $\partial_- K \cap \Gamma_h$ is opposite of the one of $\partial_+ K'$, we have from (8.2) that

$$\begin{aligned} &-\frac{1}{2} \int_{\Gamma_h} [u_h]^2 \gamma \cdot n ds + \frac{1}{2\sqrt{2}} \int_0^{a_\dagger} u_h^2(a, t^n) da + \frac{1}{2\sqrt{2}} \int_0^{t^n} u_h^2(a_\dagger, t) dt \\ &\quad + \frac{1}{2\sqrt{2}} \int_0^{t^n} (u_h^+)^2(0,t) dt + \frac{1}{2\sqrt{2}} \int_0^{a_\dagger} (u_h^+)^2(a,0) da + \sum_{K\in\mathcal{T}} \int_K \mu u_h^2 dx \\ &\quad = \frac{1}{\sqrt{2}} \int_0^{t^n} u_h^-(0,t) u_h^+(0,t) dt + \frac{1}{\sqrt{2}} \int_0^{a_\dagger} \widetilde{u_0}(a) u_h^+(a,0) da. \end{aligned} \tag{8.3}$$

We see by Hölder's inequality that the right-hand side of (8.3) is bounded by

$$\begin{aligned} &2\sqrt{2} \int_0^{t^n} (u_h^-)^2(0,t) dt + \frac{1}{4\sqrt{2}} \int_0^{t^n} (u_h^+)^2(0,t) dt \\ &\quad + 2\sqrt{2} \int_0^{a_\dagger} (u_h^-)^2(a,0) da + \frac{1}{4\sqrt{2}} \int_0^{a_\dagger} (u_h^+)^2(a,0) da. \end{aligned} \tag{8.4}$$

Combining (8.3) and (8.4) we see that

$$\int_0^{a_\dagger} u_h^2(a, t^n) da \le 8 \|u_0\|^2 + 8 a_\dagger \overline{\beta} \int_0^{t^n} \int_0^{a_\dagger} u_h^2(a,t) da dt. \tag{8.5}$$

Let

$$w(t) = \int_0^{a_\dagger} u_h^2(a,t) da.$$

Then we see from (8.5) that

$$w(t^n) \le 8 \|u_0\|^2 + 8 a_\dagger \overline{\beta} \int_0^{t^n} w(t) dt. \tag{8.6}$$

Now let

$$\zeta^n = \begin{cases} \int_{t^{n-1}}^{t^n} w(t) dt, & n = 1, \dots, N, \\ 0, & n = 0. \end{cases} \tag{8.7}$$

Since $w(t)$ is quadratic on $[t^{n-1}, t^n]$, we then see that

$$\begin{aligned}\zeta^n &= \int_{t^{n-1}}^{t^n} w(t)dt \\ &= \frac{1}{3}(t^n - t^{n-1})\Big\{w(t^{n-1}) + 4w\big(\{t^{n-1}+t^n\}/2\big) + w(t^n)\Big\} \\ &\le h\{w(t^{n-1}) + w(t^n)\} \\ &\le h\Big\{16\|u_0\|^2 + 16a_\dagger\overline{\beta}\int_0^{t^{n-1}} w(t)dt + 8a_\dagger\overline{\beta}\int_{t^{n-1}}^{t^n} w(t)dt\Big\}.\end{aligned}$$

Now noting that

$$\sum_{m=1}^{n-1}\zeta^m = \int_0^{t^{n-1}} w(t)dt, \tag{8.8}$$

we have that

$$\zeta^n \le \frac{16h}{1-8a_\dagger\overline{\beta}h}\Big\{\|u_0\|^2 + a_\dagger\overline{\beta}\sum_{m=1}^{n-1}\zeta^m\Big\}. \tag{8.9}$$

Then, by Gronwall's inequality, we obtain that

$$\zeta^n \le C\exp^{CT} h\|u_0\|^2. \tag{8.10}$$

Therefore by (8.8) we see that

$$\int_0^T w(t)dt = \sum_{m=1}^{N}\zeta^m \le C\exp^{CT}\|u_0\|^2 \tag{8.11}$$

or that

$$\|u_h\|_\Omega \le C\exp^{CT}\|u_0\|, \tag{8.12}$$

where C is independent of h. This completes the proof. □

DELAUNAY DECOUPLING METHOD FOR PARALLEL GUARANTEED QUALITY PLANAR MESH REFINEMENT*

LEONIDAS LINARDAKIS† AND NIKOS CHRISOCHOIDES†

Abstract. Creating in parallel guaranteed quality large unstructured meshes is a challenging problem. Parallel mesh generation procedures decompose the original mesh generation problem into smaller subproblems that can be solved in parallel. The subproblems can be treated as either completely or partially coupled, or they can be treated as completely decoupled. In this paper we present a parallel guaranteed quality Delaunay method for 2-dimensional domains which is based on the complete decoupling of the subproblems. As a result the method eliminates the communication and the synchronization during the meshing of the subproblems. Moreover, it achieves 100% code reuse of existing, fine-tuned, and well-tested sequential mesh generators. The approach we describe in this paper presents for the first time an effective way to create in parallel guaranteed quality meshes with billions of elements in a few hundreds of seconds, and at the same time demonstrates that these meshes can be generated in an efficient and scalable way. Our performance data indicate superlinear speedups.

1. Parallel Delaunay mesh generation.

Parallel mesh generation methods decompose the original meshing problem into smaller subproblems that can be solved (i.e., meshed) in parallel. The requirements for the parallel and distributed solution of the subproblems are (1) —distributed meshes should retain the same level of quality of elements as the sequentially generated ones, (2) , and (3) , in order to leverage the ever-evolving basic sequential meshing techniques and software.

In [20, 25] parallel mesh generation methods for distributed memory computers or clusters of workstations (CoWs) are classified in terms of the and the the artificial boundary surfaces (interfaces) of the subproblems are meshed. Specifically, existing parallel methods are classified into three categories: (i) methods, which first mesh (either in parallel [34] or sequentially [41]) the interfaces of the subproblems and then mesh in parallel the individual subproblems; (ii) methods, which first solve the meshing problem in each of the subproblems in parallel and then mesh the interfaces [20] so that the global mesh is conforming; (iii) methods, which simultaneously mesh and improve the quality of the interfaces[1] as they mesh the individual subproblems [19, 13, 17, 36].

[1]The improvement of the interfaces is measured in terms of the surface-to-volume ratio.

In this paper we present an a priori method that contributes to the state-of-the-art parallel mesh generation in the following three ways: (1) it guarantees the same level of quality of the mesh with the sequentially generated ones, (2) it eliminates communication and synchronization during the meshing of the subproblems and achieves superlinear speedups with respect to the best (to our knowledge) sequential guaranteed quality mesh generator, Triangle [43], and (3) achieves 100% code reuse, providing the ability to use the best sequential Delaunay mesh generators with no modifications. This is the first method (to the best of our knowledge) that eliminates communication and synchronization, and at the same time is based on a 100% code reuse of sequential codes. It is the only, so far, parallel guaranteed quality method that can achieve superlinear speedups, when compared to the best sequential mesh generation codes, and the first to create over 1 billion (B) elements. The decoupling method we propose can also be used for sequential mesh generation, in order to create larger meshes in less time on one processor.

In [24] Galtier and George present a parallel projective Delaunay meshing (P^2DM) method which guarantees the quality of the elements and eliminates communication and synchronization, but, depending on the geometry, it might suffer from setbacks which affect its efficiency. The setbacks are in the form of discarding completely the triangulation because the separators are not always Delaunay admissible as new points are inserted. The problem of computing Delaunay admissible separators in the context of parallel Delaunay mesh refinement is solved in this paper successfully for 2-dimensional domains.

A 2-dimensional divide-and-conquer Delaunay triangulation (DCDT) algorithm and its parallel implementation are presented in [6]. The DCDT is based on finding a Delaunay path, through a projection to a paraboloid, that separates the initial set into two equal-sized subsets. Although this is an elegant and efficient procedure for Delaunay triangulation, it cannot be used for parallel mesh generation and refinement, which require new point insertion in the mesh without significant extensions like the ones presented in [29], which introduce communication.

SMGP parallel guaranteed quality Delaunay mesh (PGQDM) generation methods appeared in [36] and in [18]. The PGQDM is communication intensive, and despite the fact that it tolerates (masks) up to 90% of communication, its speedup is about 6 for 16 processors [18]. The second SMGP method, the constrained Delaunay mesh (PCDM) generation [13], is based on constrained Delaunay triangulation [10]. It substantially reduces the communication and eliminates synchronization, but the speedup is still 5.75 for 8 processors [13]. The PCDM implementation, as the PGQDM, does not reuse existing sequential Delaunay mesh generators, due to additional care for cavities that are constrained by internal boundaries.

The method we present here requires high-quality domain decompositions that (1) satisfy certain geometric constraints [44] regarding the angles and (2) do not introduce significant constraints that will affect the efficiency of the mesh generator and the quality of the final mesh. In this paper we propose a novel domain decomposition method for 2-dimensional geometries based on the medial axis of the domain. This method satisfies (1) and (2) above, but it has the disadvantage of being difficult to extend to 3 dimensions.

In the rest of the paper, we present in section 3 the medial axis domain decomposition method. In section 4 we proceed to decouple the mesh generation process of the individual subdomains, by defining and preprocessing a zone around the internal boundaries of the subdomains. Contrary to past work [34, 24], we prove that the preprocessing of the zone completely decouples the subdomains. Finally, in section 7 we

present the complete parallel mesh generation procedure, and in section 9 we provide experimental results that demonstrate the efficiency of our method.

2. The domain decomposition problem. Guaranteed quality mesh generation algorithms [11, 12, 40] and software [44, 43] generate elements with good aspect ratio and good angles. These algorithms require that the initial boundary angles be within certain good bounds. For example, Ruppert's algorithm [40] requires boundary angles (the angles formed by the boundary edges) no less than 60° in order to guarantee the termination. Since the separators are treated as external boundary, the domain decomposition should create separators that meet the requirements of the mesh generation algorithm. Therefore, the constructed separator should form angles no less than a given bound Φ_o, which is determined by the sequential mesh generation procedure that will be used to mesh the individual subdomains.

The domain decomposition is used in parallel mesh generation to explore data-parallelism, as in many other areas of scientific computing. The three fundamental issues in data-parallel computations are [illegible]. The parallel mesh generation method we propose eliminates communication and synchronization, using a proper decoupling (see section 4) of the subdomains. However, we achieve the decoupling at the cost of some over-refinement, which is analogous to the size of the separators of the subdomains. Therefore, one of our objectives in the domain decomposition step is to minimize the size of the separators relative to the area of the subdomains. Then the over-refinement we introduce is insignificant (see section 11).

The third important issue that affects parallel program performance is the good balance of the workload among the processors. The equidistribution of processors' workload is achieved by over-decomposing [5] the domain, i.e., $N \gg P$, where N is the number of subdomains and P is the number of processors. The created subdomains are distributed on the processors using an a priori estimation of the workload, based on the area of the subdomains. This static, ab initio distribution approach gives good results for uniform cluster environments (see section 8). However, a dynamic load-balancing approach can be adopted using general purpose runtime systems, like the ones presented in [2, 35], to migrate at runtime subdomains from overloaded processors to ones that have completed their work. The area criterion for estimating the work load appears to be a good measure in the case of our method, for the following reason: the decomposition procedure, as we will see, creates "good" angles and small separators, and the created subdomains tend to have similar shapes after the over-decomposition of the domain; since the geometries are similar, the work of the mesher is approximately proportional to the area of the subdomains. The above intuition is confirmed by the results in section 8.

In summary, the domain decomposition criteria for parallel mesh generation are the following.

C1. Create good angles, i.e., angles no smaller than a given tolerance Φ_o. The value of Φ_o is determined by the sequential, guaranteed quality, mesh generation algorithm.

C2. The subdomains should have approximately equal size (areawise).

C3. The size of the separator should be relatively small, i.e., minimize the ratio $\max\{|\mathcal{H}|/|\Omega_i|\}$, where $|\mathcal{H}|$ is the length of the separator and $|\Omega_i|$ is the area of the subdomains.

The first condition is essential, since it is the one that guarantees the termination of the mesh generation procedure and at the same time prevents the creation of new

features that will lower the quality of the final mesh. Criteria 2 and 3 are not required, but are desired for the efficiency of the parallel computations.

The domain decomposition that we propose here is independent of the decoupling procedure described in section 4, and it can be used in other parallel mesh generation methods, like PCDM, that require good quality domain decompositions.

3. Medial axis domain decomposition method. The medial axis domain decomposition (MADD) method we propose is based on an approximation of the medial axis (MA) of the domain. The MA was introduced by Blum [7] as a way to depict the shape of an object and has been studied extensively during the last two decades [9, 8, 14, 33, 42, 48]. In the context of mesh generation the medial axis has been used in [1, 23, 26, 39, 45]. The existing domain decomposition methods aim mostly to solve the load-balancing problem and to minimize the communication [21, 30, 46]. For the first time in parallel mesh generation the medial axis was proposed as a domain decomposition technique in [15].

One of the contributions of this paper is that, in addition to the load-balancing goal, the MA is used to guarantee domain decompositions with separators which form good angles between them and the external boundary. Like existing methods our decomposition method also aims for separators whose size is small relatively to the areas of the subdomains.

In the rest of the paper we define as a domain Ω the closure of an open connected bounded set in $\mathbf{R}^2$, and the boundary $\partial\Omega$ is defined by a planar straight line graph (PSLG), which forms a set of (nonintersecting) line segments connecting pairs of points. A circle $C \subseteq \Omega$ is said to be maximal in Ω, if there is no other circle $C' \subseteq \Omega$ such that $C \subsetneq C'$. The closure of the locus of the circumcenters of all maximal circles in Ω is called the [illegible] Ω and will be denoted by $\mathrm{MA}(\Omega)$. The intersection of a boundary of Ω and a maximal circle C is not empty. The points $C \cap \partial\Omega$, where a maximal circle C intersects the boundary, are called [illegible] of c, where c is the center of C. Every point $c \in \mathrm{MA}(\Omega) \setminus \partial\Omega$ has at least two contact points.

The domain decomposition method we propose is based on the following simple geometric property.

LEMMA 3.1. [illegible] $c \in MA(\Omega)$ [illegible] cb [illegible] $\partial\Omega$ [illegible] b [illegible] $\pi/2$

[illegible]. We prove the lemma in the general case when Ω has a piecewise C^1 boundary. Suppose that the proposition is not true. Then there is a point $c \in MA(\Omega)$ of the medial axis and a contact point $b \in \partial\Omega$ of c, such that cb forms an angle $\phi < \pi/2$ with the boundary at b (see Figure 3.1). Take c to be the origin of the axes and cb to define the y axis. Without loss of generality, we assume that ϕ is formed by the tangent from the right. Let $(x(s), y(s))$ be locally the normal parametric representation of the curve, with $b = (x(0), y(0)) = (0, y(0))$ and $x(s) \geq 0$. We have $y(0) > 0$. Since $\phi < \pi/2$, we have $y'(0) < 0$. Let $R(s) = x^2(s) + y^2(s)$ be the square of the distance between c and the points of the curve. Because b is a contact point of c, it must be $R(s) \geq R(0) = |cb|^2$. We have $R'(0) = 2y(0)y'(0) < 0$. This means that locally $R(s) < R(0)$, which is a contradiction. □

The medial axis of Ω can be approximated by Voronoi points of a discretization of the domain [9, 8]. We make use of the property of Lemma 3.1 to construct separators that consist of linear segments which connect the Voronoi points to the boundary. The approximation of the $\mathrm{MA}(\Omega)$ is achieved in two steps: (1) discretization of the boundary, and (2) computation of a boundary conforming Delaunay triangulation using the points from step (1). The circumcenters of the Delaunay triangles are the

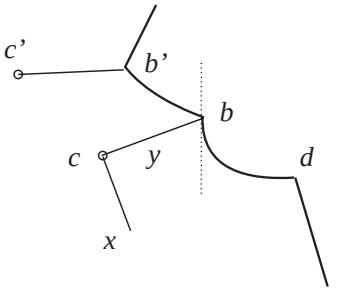

FIG. 3.1. *The angle cbd cannot be less than* 90°*, where c is a point of the medial axis and b its contact point. In some cases the angle is greater that* 90°*, as in the case* $c'b'$.

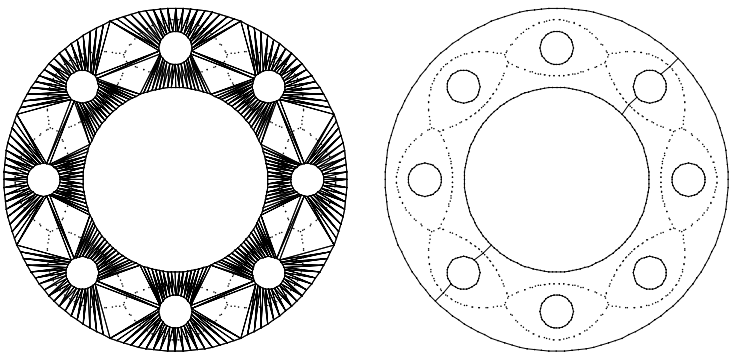

FIG. 3.2. *Left: The Delaunay triangulation of the pipe intersection. The circumcenters of the triangles approximate the medial axis. Right: The circumcenters are the Voronoi points. The separator is formed by selecting a subset of the Voronoi points and connecting them with the boundary.*

Voronoi points of the boundary vertices. The separators will be formed by connecting these circumcenters to the vertices of the Delaunay triangles. Figure 3.2 depicts the boundary conforming mesh of the cross section of a rocket (left), and the media axis approximation and a 2-way separator for the same geometry (right).

The level of the discretization of the boundary determines the quality of the approximation of the medial axis. However, our goal is not to approximate accurately the medial axis, but to obtain good angles from the separator. Therefore our criteria for the discretization of the domain will be determined from the quality of the angles formed between the separators and the boundary $\partial\Omega$. We achieve our goal by defining a new set of triangles (see Figure 3.3).

DEFINITION 3.2. $\mathcal{D}$ D $\partial\Omega$ $t \in \mathcal{D}$ junction triangle,

1. c
2. D
3. t $\geq \Phi_o$

The first criterion is set only for the simplicity of the MADD algorithm (see section 3.1.2) in order to avoid negative weights and guarantee that at least two angles between the segments are good. The second criterion prevents a decomposition that will create very small subdomains. The third criterion guarantees the quality of the angles. Let $a_1a_2a_3$ be the vertices of t. Then the third criterion demands the existence of at

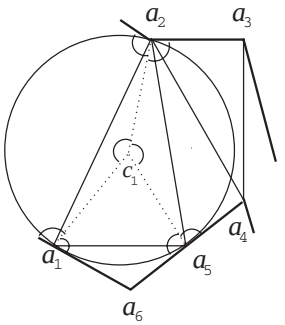

FIG. 3.3. *Triangle $a_1a_2a_5$ is a junction triangle, while $a_1a_5a_6$ has two edges on the boundary and $a_2a_4a_5$ does not include its cicrcumcenter, so they are not junction triangles.*

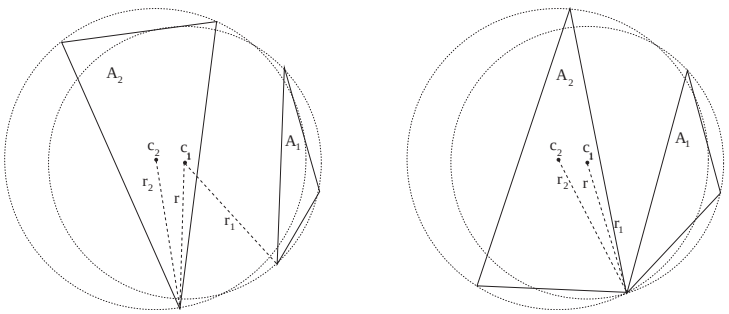

FIG. 3.4. *On the left, the two Delaunay triangles, A_1, A_2, do not have common vertices. On the right, the triangles share one common vertex; the case of two common vertices reduces to these.*

least one pair of segments a_ica_j, where c is the circumcenter of $a_1a_2a_3$, so that all the angles formed with these segments are greater than or equal to Φ_o. Such pairs a_ica_j are called , and they will be the candidates to form a complete separator. A complete separator decomposes a domain into two connected subdomains.

Let m be the number of holes of Ω. The level of refinement D we require for $\partial\Omega$ has to satisfy the following two conditions.

(i) In the Delaunay triangulation $\mathcal{D}$ of D there are at least $m+1$ junction triangles.

(ii) Every segment on the boundary D has an empty diametral circle.

The first condition in Definition 3.2 requires the existence of at least $m+1$ junction triangles. This ensures, as we will see in section 3.2, that there is at least one complete separator formed by partial separators. The second condition guarantees that all the segments of D will appear as edges in $\mathcal{D}$. It also guarantees that all the circumcenters of the triangles of $\mathcal{D}$ are contained in Ω [44]. This in turn guarantees the existence of at least one triangle that includes its circumcenter (see Lemma 3.4).

LEMMA 3.3. A_1, A_2 c_1 A_1 A_2 c_2 A_2 r_1 r_2 A_1 A_2 $r_1 < r_2$

. Let r be the smaller distance of c_1 from the vertices of A_2; see Figure 3.4. Then $r \geq r_1$. So we have $r_2 > r$, and consequently $r_2 > r_1$. □

LEMMA 3.4. D $\mathcal{D}$ D

. We know that, when the boundary segments have empty diametral circles, all the circumcenters of the triangles of $\mathcal{D}$ are in $\mathcal{D}$ [44]. We assume that the points are in general position; i.e., there are no cocircular points. We will prove the lemma by contradiction.

Suppose that the lemma is not true. Then for every triangle A_i there is another triangle $A_{i+1} \neq A_i$, such that the circumcenter c_i of A_i is included in A_{i+1}. Let r_i be the radius of the circumcircle of A_i. Since we assumed that no triangle includes its circumcenter, the sequence $\langle A_i \rangle$ is infinite. On the other hand, the set $\{t_i\}$ of all triangles in D is finite, so the sequence $\langle A_i \rangle$ includes an element t_k twice. Then $A_l = A_m = t_k$ for some $l < k$. From the previous lemma we have $r_l < r_{l+1} < \cdots < r_m$, which contradicts the fact that r_l and r_m are the radii of the same circle, and thus equal. So the lemma must hold. □

The discretization of the boundary is determined by the number of junction triangles we want to create, which in turn is determined by the geometry of the domain Ω. As we increase the refinement, the Voronoi points approximate the points of the medial axis and the formed angles with the boundary tend to be close to $\pi/2$. If we construct more junction triangles, and thus more partial separators, we have more choices to form a better separator, in terms of the quality of the angles, the size of the separator, and the balance of the areas of the subdomains. In our experiments a rather small refinement (less than 700 additional points for the 2-dimensional geometries we tried so far) gives satisfying results. Again this of course depends on the geometry, and a way to predefine the refinement level of the boundary of the domain is a subject of further research.

3.1. The MADD algorithm. The MADD algorithm uses as a starting point the approximation of the medial axis by the Delaunay triangulation $\mathcal{D}$, as described in the previous section. The complete separator is formed by partial separators, i.e., segments inserted in junction triangles of $\mathcal{D}$; these segments connect the circumcenter of the triangles to two of their vertices. Figure 3.2 (right) depicts a complete separator for a 2-way decomposition of the pipe.

The partial separators connect two points of the boundary, since $\mathcal{D}$ is a boundary conforming triangulation. The properties of junction triangles permit the construction of good angles between the partial separators and the external boundary of the geometry. The MADD algorithm will select to insert a set of partial separators that will guarantee the decomposition of the domain into two subdomains. The selection of the partial separators is based on the minimization of the ratio of the size of the separators to the areas of the subdomains.

The MADD algorithm maps the Delaunay triangulation $\mathcal{D}$ into a graph $G_{\mathcal{D}}$ which encapsulates the required information about the candidate partial separators. This information includes (1) the topology of $\mathcal{D}$, which is used to guarantee that the inserted partial separators form a complete separator and (2) the length of the partial separators and the area of the subdomains that will be created, which is used to optimize the ratio of the length of separators to the subdomains area. After $G_{\mathcal{D}}$ is constructed, the graph is contracted, so that only the junction triangles of $\mathcal{D}$ are represented. Then the contracted graph is partitioned; the graph partitioning can be obtained by using any of the well-known algorithms [32, 4, 27, 28, 30, 47] that decompose a connected graph into two connected subgraphs and minimize the ratio of the cut cost to the weights of the subgraphs. Finally the graph partition is translated into insertions of partial separators, which result into a 2-way decomposition. In summary the key steps of the algorithm are the following:

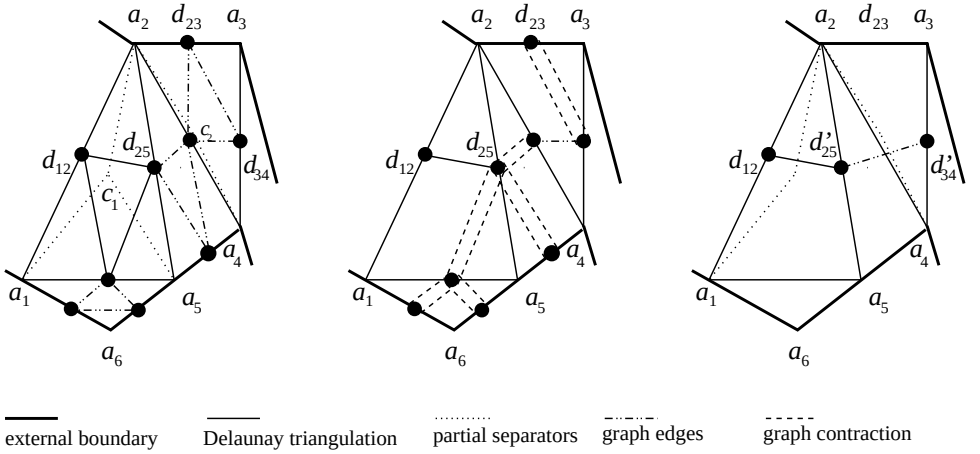

FIG. 3.5. *An example of creating the MADD graph. Left: a part of the Delaunay triangulation and the creation of the corresponding initial graph $G_{\mathcal{D}}$. Middle: the procedure of contracting the graph by combining the nodes of $G_{\mathcal{D}}$. The nodes connected by dashed lines are combined. Right: the final graph $G'_{\mathcal{D}}$ that corresponds to this part.*

1. Create a graph $G_{\mathcal{D}}$ from the Delaunay triangulation $\mathcal{D}$.
2. Contract $G_{\mathcal{D}}$ into the graph $G'_{\mathcal{D}}$, so that only the partial separators in the junction triangles are represented as edges of $G'_{\mathcal{D}}$.
3. Partition the graph $G'_{\mathcal{D}}$, optimizing the cut cost to subgraph weight ratio.
4. Translate the cuts of the previous partition into partial separators.

3.1.1. Construction of the graph $G_{\mathcal{D}}$. In this step the Delaunay triangulation $\mathcal{D}$ is represented as a weighted graph, the dual graph of the edges of the triangles. Two nodes of the graph are adjacent if their corresponding edges belong to the same triangle. The length of the radius of the circumcircle of this triangle will be the weight of the graph edge. The weights of the nodes are set to zero in this step, and they will be computed in the graph construction step (see section 3.1.2).

Figure 3.5 (left) depicts the step for constructing the graph $G_{\mathcal{D}}$. One graph node is created for each edge of the triangulation, and two nodes are connected if they belong to the same triangle. Let d_{ij} be the node corresponding to the edge a_ia_j. The weight of the edge connecting d_{ij}, d_{jk} is the length $|c_la_j|$, where c_l is the circumcenter of the triangle. For example, the edge that connects d_{12} and d_{25} has weight the length $|c_1a_2|$. The above procedure is described by the following algorithm.

ALGORITHM 1.

1. **for** all the edges a_ia_j in $\mathcal{D}$ **do**
2. Add node d_{ij} to the graph $G_{\mathcal{D}}$, with zero weight
3. **endfor**
4. **for** all triangles $t \in \mathcal{D}$ **do**
5. **for** the three pairs (a_ia_j, a_ja_k) of edges of t **do**
6. Create a graph edge between the corresponding nodes d_{ij}, d_{jk}, with weight the length of the circumradius of t
7. **endfor**
8. **endfor**

3.1.2. Graph contraction. In this step the graph $G_{\mathcal{D}}$ produced from the previous step is contracted into a new graph $G'_{\mathcal{D}}$, so that only the edges of junction triangles are represented as nodes in $G'_{\mathcal{D}}$. The nodes of $G_{\mathcal{D}}$ that correspond to edges of nonjunction triangles of $\mathcal{D}$ are contracted in $G'_{\mathcal{D}}$.

In order to contract the graph $G_{\mathcal{D}}$, first we iterate through all the triangles that are not junction triangles. The nodes of $G_{\mathcal{D}}$ that correspond to the three edges of a nonjunction triangle are combined into a single node and the new node replaces the initial nodes in the external graph edges, while the edges between the three initial nodes are deleted. The weight of the new node is the sum of the weights of the initial ones, plus the area of the triangle.

The remaining nodes correspond to the edges of junction triangles. Junction triangles contain candidate partial separators, whose number may vary from one to three. From the three possible partial separators we keep the one that forms the greater minimum angle. Since in junction triangles there is at least one partial separator that forms angles no less than Φ_o, the selected partial separator forms angles $\geq \Phi_o$. We establish this partial separator by combining the two of the three nodes that correspond to edges of the triangle. Let $a_1a_2a_3$ be a junction triangle and c its circumcenter. Let d_{ij} be the corresponding node to the edge a_ia_j, then the weight of the node d_{ij} is updated by adding the weight of the area included by the triangle ca_ia_j. Let a_jca_k be the partial separator that forms the greater minimum angle. Then the nodes d_{ji} and d_{ki} are contracted into a single node, where a_i is the remaining vertex. The procedure is illustrated by the following example.

Figure 3.5 (center) illustrates the procedure of contracting the graph. The bold lines indicate the external boundary. The triangles are part of the boundary conforming Delaunay triangulation of the domain. As above, we denote by d_{ij} the graph node that corresponds to the segment a_ia_j. We demonstrate four different cases.

I. The triangle $a_1a_5a_6$ has two edges on the boundary, so it is not a junction triangle, and the three corresponding nodes are combined in one. The edges connecting the new node d'_{15} are the external ones, i.e., the edges that connect d_{15} to d_{12} and d_{15} to d_{25}. The weight of d'_{15} is equal to the area of the triangle $a_1a_5a_6$.

II. The triangle $a_2a_4a_5$ does not include its circumcenter and so it is not a junction triangle. We follow the same procedure as in Case I. The nodes d_{25}, d_{24}, d_{45} are contracted into a new node d'_{25}. The new node has weight equal to the area of the triangle $a_2a_4a_5$ and is connected to the nodes $d_{12}, d'_{15}, d_{23}, d_{34}$.

III. The triangle $a_1a_2a_5$ is a junction triangle. The areas of the triangles formed by its circumcenter c_1 and its corners are added to the weight of the corresponding nodes. For example, the area $|a_2c_1a_1|$ is added to the node d_{12}, similarly the areas $|a_2a_5c_1|$ and $|a_1c_1a_5|$ are added to the nodes d'_{25} and d'_{15}, respectively. Suppose that the partial separator $a_1c_1a_2$ is the one that forms the greater minimum angle. Then the nodes d'_{15} and d'_{25} are contracted into a new node d'_{25} with its weight to be equal to the sum weights of the two previous nodes. The graph edge connecting the nodes d'_{15} and d'_{25} is deleted, while the two other graph edges are contracted into one edge connecting d'_{25} to d_{12}; the new edged weight is equal to the sum of the two previous edge weights, which is equal to the length of the partial separator $a_1c_1a_2$.

IV. The triangle $a_2a_3a_4$ is also a junction triangle. As for the previous triangle, first we add the areas of the triangles formed by the circumcenter c_2 and the vertices. The areas $|a_2c_2a_4|$, $|a_2c_2a_3|$, and $|a_3c_2a_4|$ are added to the weight of the nodes d'_{25}, d'_{23}, and d'_{34}, respectively. However, suppose in this case that the angle θ, formed by the segment c_2a_3 and the external boundary segment a_3b, is less than Φ_o.

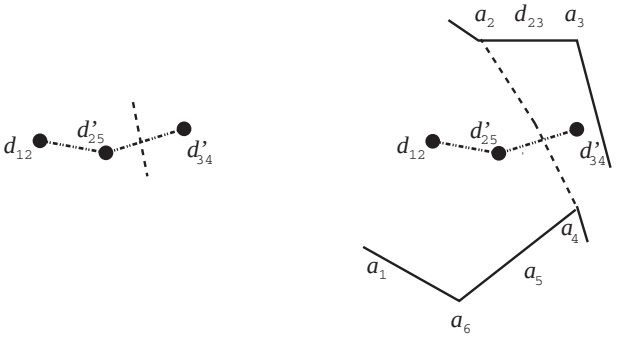

FIG. 3.6. *A partition of the graph and the corresponding separator, on the right, depicted with dashed lines.*

Then the two partial separators that include this segment are rejected and we keep the separator $a_2c_2a_4$, which is the one that forms the greater minimum angle. The nodes d_{23} and d_{34} are combined into the node d'_{34}. The new node is connected to d'_{25} by an edge with weight equal to the sum of the two previous edge weights, which is the length of the partial separator $a_2c_2a_4$. Figure 3.5 (right) shows the final graph.

The above procedure is described by the following algorithm.

ALGORITHM 2.

1. **for** all nonjunction triangles $t \in \mathcal{D}$ **do**
2. Combine the three nodes that correspond to the edges of t, generating a new node d'
3. Add the area of t to the weight of d'
4. **endfor**
5. **for** all junction triangles $t \in \mathcal{D}$ **do**
6. Let c be circumcenter of t
7. **for** all edges a_ia_j of t **do**
8. Add the area of the triangle a_ica_j to the weight of the corresponding node d_{ij}
9. **endfor**
10. Find the partial separator a_ica_j in t forming a max min angle
11. Combine the nodes d_{ik} and d_{jk}, where a_k is the remaining vertex
12. **endfor**

3.1.3. The construction of the separator. After contracting the graph, the constructed graph $G'_{\mathcal{D}}$ is partitioned. The number of the edges of the graph is less than or equal to the number of junction triangles; thus the size of the graph partitioning problem is significantly smaller than the elementwise dual graph of the boundary conforming Delaunay triangulation $\mathcal{D}$. Graph partitioning can be very expensive and has been an active area for several years [32, 4, 27, 28, 30, 47]. Any of the algorithms that give a partition of the graph into two connected subgraphs, with good cut cost to subgraph weight ratio, can be used as the graph partitioner for $G'_{\mathcal{D}}$. For algorithms that give nonconnected subgraphs, a check step must take place (see section 10).

After partitioning $G'_{\mathcal{D}}$, the final step of the MADD is to construct the separator of the geometry. From the previous step we have a partition of the graph $G'_{\mathcal{D}}$ into two connected subgraphs. This partition will give a corresponding separator for the geometry. Each edge of the graph corresponds to a partial separator of the form a_ica_j,

where c is a circumcenter of a junction triangle and a_i, a_j are two of its vertices. For every graph edge that is cut by the partition we will insert the related partial separator in the geometry. In our example above (see Figure 3.6) the partial separator $a_2c_2a_4$ is created in the case that the graph partitioner chooses to cut the edge e_2.

The construction of the separator is described in the following algorithm.

ALGORITHM 3.

1. **for** all triangles $t \in \mathcal{D}$ **do**
2. **if** one of the edges a_ia_j of t belongs to a different subgraph from the other two edges **then**
3. Insert the partial separator a_ica_j, where c is the circumcenter of t
4. **endif**
5. **endfor**

The algorithm traverses the list of all triangles and identifies those triangles whose edges correspond to disconnected nodes after the graph partition. In these triangles the partial separators are inserted, separating the edges that do not belong to the same subgraph. In Figure 3.6 the partial separator $a_2c_2a_4$ separates the edge a_2a_4 from the edges a_2a_3 and a_3a_4. The set of all these inserted partial separators establishes a (complete) separator for the domain, as we will see in section 3.2.

The ratio of the cost of the cut to the weight of the subgraphs is translated to the ratio of the total length of the separator to the area of the subdomains. Provided that the graph partitioner gives a good cut cost to subgraph weight ratio, the ratio of length of the separator to the area of the subdomains is also good. This way we obtain separators of relatively small size, and the areas of the subdomains are balanced. Moreover, since all the partial separators, by the construction of $G'_{\mathcal{D}}$, form good angles, the constructed separator forms good angles. In summary, the constructed separator meets the decomposition criteria C1–C3 in section 2.

3.2. Proof of correctness. In this subsection we prove that the MADD algorithm decomposes the domain Ω into two connected subdomains. We recall that the domain Ω is the closure of an open connected bounded set and the boundary $\partial\Omega$ is a PSLG that formed a set of linear segments which do not intersect. A separator $\mathcal{H} \subseteq \Omega$ is a finite set of simple paths (a continuous 1-1 map $h : [0,1] \to \Omega$) that do not intersect and define a decomposition A_1, A_2 of Ω in the following way: A_1 and A_2 are connected sets, with $A_1 \cup A_2 = \Omega$, and $U \cap \mathcal{H} \neq \emptyset$ for every path $U \subset \Omega$ which connects a point of A_1 to a point of A_2.

LEMMA 3.5. [illegible] m [illegible] Ω [illegible] n [illegible] $n > m$ [illegible] Ω [illegible]. We will prove the lemma by induction on m. If $m = 0$, then $n \geq 1$, and there is at least one partial separator. In this case, every partial separator is a separator for Ω, since every simple path $f : [a,b] \to \Omega$, with $f(a), f(b) \in \partial\Omega$ and $f(a,b) \subset \Omega^\circ$, is a separator for Ω.

Suppose the lemma is true for $m = q$, we will prove it is true for $m = q+1$. We have that $n > q+1$. If for a partial separator acb, where $a, b \in \partial\Omega$, we have that both a and b do not belong to the boundary of a hole; then acb forms a separator, as in the case $m = 0$. In the case that one of the points a, b belongs to the boundary of a hole O, then by inserting the partial separator acb we eliminate O. The new domain has q holes and $n - 1 > q$ junction triangles. Thus, by the inductive hypothesis, it can be decomposed by partial separators. Therefore there is a separator formed by partial separators, when the conditions of the lemma are satisfied. ∎

THEOREM 3.6. [illegible] Let $e_i, i = 1, \ldots, n$, be the edges of the contracted graph $G'_{\mathcal{D}}$ created by MADD. Each of these edges corresponds to a partial separator $h_i, i = 1, \ldots, n$. We will show that every decomposition of the graph $G'_{\mathcal{D}}$ corresponds to a decomposition of Ω formed by partial separators, and vice versa.

Let $E = \{e_i, i \in I\}$ be the set of edges that the graph partitioner cuts, creating two subgraphs G_1, G_2. Let $\mathcal{H} = \{h_i, i \in I\}$ be the set of partial separators that correspond to these edges. Finally, let $A_1, A_2 \subset \Omega$ be the two corresponding areas to the subgraphs G_1, G_2. Obviously $A_1 \cup A_2 = \Omega$. From the construction of the graph we have that the connected subgraphs correspond to path-connected areas of Ω. Assuming that the graph partitioner decomposes $G'_{\mathcal{D}}$ into two connected subgraphs, then G_1, G_2 are connected, and so A_1, A_2 are also connected. Every path $U \subset \Omega$ from a point of A_1 to a point of A_2 corresponds to a path U' in $G'_{\mathcal{D}}$ and forms a node of G_1 to a node of G_2. Since the edges E separate G_1 from G_2, we have $U' \cap E \neq \emptyset$. Let $e_j \in U' \cap E$. Then we have $U \cap h_j \neq \emptyset$, and the path U intersects $\mathcal{H}$. Thus $\mathcal{H}$ is a separator for Ω. Working backwards we see that a separator for Ω corresponds to a partition of the graph. The existence of such a separator is proved in Lemma 3.5, and this completes the proof. □

The algorithm always terminates, but the existence of a separator, according to the above theorem, depends on the number of junction triangles that we construct. If this number is greater than the genus of the domain, then a separator exists; there are cases though where fewer junction triangles are sufficient, depending on their position (for example, if none of their edges are on a hole). On the other hand, in order to achieve a better quality of the formed angles, as well as a better decomposition in terms of load-balancing, we would like to have as many junction triangles as possible, since this will increase the number of choices for partial separators. The number of junction triangles depends on the boundary refinement we will use, and two major parameters come into play: (a) the number of subdomains we wish to create, which largely depends on the size of the mesh we want to create; (b) the geometry of the domain. It is hard to define what a difficult geometry would be to decompose, since geometries that look complicated may form areas where "natural" cuts can be made, while geometries that look simple may lack these natural cuts. Small features of the geometry, which usually present a problem in the mesh generation, are not a problem for the decomposition, because they can be discarded (for example, they will form no junction triangles). In our experiments a small refinement (700 additional points) of the boundary produces enough junction triangles to form good separators (with an angle bound of $\Phi_o = 60°$); see Figure 10.1. Still an open problem, though, is a theory that would predefine the level of refinement (depending on the geometry) that would guarantee the creation of enough junction triangles and provide a good separator.

3.3. *N*-way decomposition. So far we have described the MADD procedure for a 2-way decomposition. In the following section we will describe a decoupling procedure which is applied on multiple subdomains and decouples the mesh generation procedure for all the given subdomains. In order to create more than two subdomains we can apply the MADD in a divide and conquer way (see Figure 3.7). When a 2-way separator is created, it is discretized and then every subdomain is decomposed independently. The resulting decomposition shows good adaptivity to the geometry. This approach requires one to recalculate the Delaunay triangulation of the subdomains. We can do that by just inserting the segments of the separator in the existing triangu-

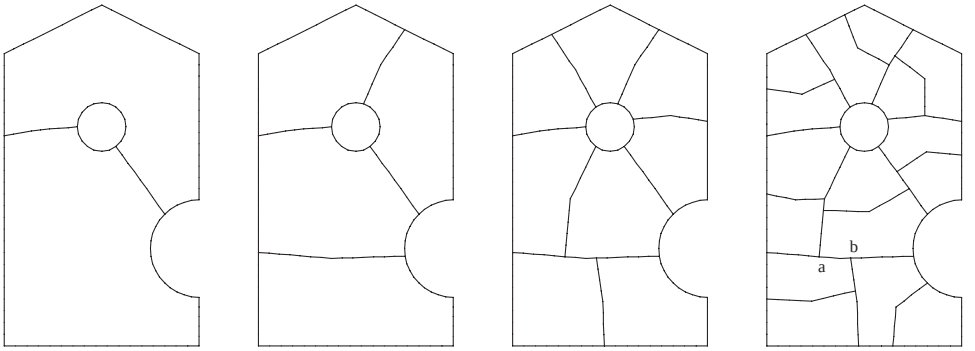

FIG. 3.7. *N-way partitions, where* $N = 2, 4, 8, 16$*, by the MADD divide and conquer method. METIS* [31] *was used as the graph partitioner and Triangle* [43] *produced the Delaunay triangulation.*

lation. These segments should be refined, and possibly the edges of the boundary also, so that the empty diametral circle property of the boundary, including the separators, is maintained.

Since every subdomain is decomposed independently, the discretization of the separators, which form the internal boundary, should be permanent. In practice, the size of the segments created by the discretization of the domain is much larger than the ones created by the mesh generation procedure. Here we should take into account that the level of decomposition is proportional to the size of the mesh we want to create. Thus, in the general case, the discretization does not create actual artificial constraints to the mesh. Figure 3.7 depicts that no new artifacts are introduced, given that segments like *ab* will be refined further.

In our method we refine even further the internal boundaries in order to decouple the subdomains, and our results show that the size and the quality of the mesh are not affected. For a more detailed experimental analysis see section 11.

An advantage of the divide and conquer approach is that it is easy to implement in parallel. In our implementation we have followed a parallel MADD divide and conquer strategy to create multiple subdomains. The method is described in detail in section 7.

4. The decoupling zone. The separators and the subdomains created by the MADD procedure have good quality in terms of the shape and size. Our goal though is to be able to create Delaunay meshes independently for each subdomain, and the previous procedure cannot guarantee this. In order to create the mesh independently in each subdomain we have to ensure that the final mesh will be Delaunay conforming. In the context of parallel Delaunay triangulation, a Delaunay conforming separator can be found using a projective method, presented in [6]. A study of conditions for a priori conformity for constrained Delaunay triangulations is presented in [37]. A method for independent mesh generation in each subdomain using a projective separator is presented in [24], but it does not always guarantee a priori Delaunay conformity.

In order to ensure the Delaunay conformity in the mesh generation context we will refine the separators using conditions derived from the mesh refining algorithm. A special "zone" around the segments of the separators (see Figure 4.1) will guarantee that the mesh generation procedure can be applied independently on each subdomain, giving a Delaunay conforming mesh for the whole domain, formed by the union of all the submeshes.

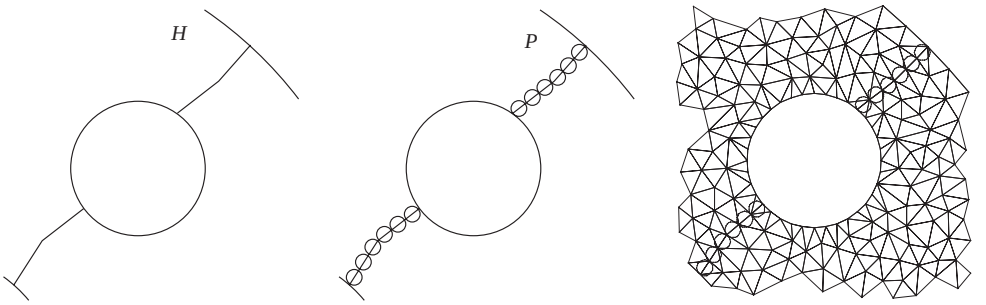

FIG. 4.1. *A fraction of the pipe intersection.* Left: *Part of the separators $\mathcal{H}$ inserted by MADD.* Middle: *Refining $\mathcal{H}$ gives a decoupling path $\mathcal{P}$; the decoupling zone $\mathcal{Z}_\mathcal{P}$ is depicted.* Right: *Ruppert's algorithm was applied on the subdomains with an element area restriction; $\mathcal{Z}_\mathcal{P}$ is empty and $\mathcal{P}$ is invariant. The final mesh is Delaunay conforming.*

Let $\mathcal{M}$ be a Delaunay mesh generation procedure. Let $D = \partial\Omega$ be a PSLG, where Ω is a domain as described in the previous section. Let $\mathcal{P}$ be a set of piecewise linear separators that decompose the domain Ω in n subdomains Ω_i and let $D_i = \partial\Omega_i$ be the boundaries of the subdomains.

DEFINITION 4.1.

$\mathcal{P}$ decoupling zone of $\mathcal{P}$ $\mathcal{Z}_\mathcal{P}$

DEFINITION 4.2. $\mathcal{P}$ decoupling path $\mathcal{M}$ $\mathcal{M}$ Ω_i $i = 1, \ldots, n$ $\mathcal{Z}_\mathcal{P}$

PROPOSITION 4.3. M_i $\mathcal{M}$ Ω_i $\mathcal{P}$ $\mathcal{M}$ $\cup M_i$

. Let M be the Delaunay triangulation of the vertices $V_M = \cup V_{M_i}$ of $\cup M_i$. We will prove that $M = \cup M_i$, by showing that the set of edges S of M are identical to the set of edges $\cup S_i$ of $\cup M_i$, thus the two triangulations are the same and $\cup M_i$ is a conforming Delaunay triangulation.

First we observe that $\mathcal{P}$ is a subset of both S and $\cup S_i$, because its decoupling zone is empty. For any edge $ab \in S$ there are two cases. (i) Both end points a, b belong to the same subdomain M_j, $a, b \in V_{M_j}$. (ii) $a \in M_i$ and $b \in M_j \setminus M_i$.

(i). Suppose $a, b \in V_{M_j}$. From the local Delaunay property, there is an empty circumcircle C of ab which does not include any points in V_M. Because $V_{M_j} \subseteq V_M$, C must be empty in the set V_{M_j}. Thus $ab \in S_j$ and $ab \in \cup S_i$.

(ii). We will show that this case cannot occur, there is no edge $ab \in S$ such that $a \in M_i$ and $b \in M_j \setminus M_i$. Suppose we have such an edge ab. Then $ab \subset D$ and since the subdomains M_i and M_j are separated by $\mathcal{P}$, a and b are separated by $\mathcal{P}$. So $ab \cap \mathcal{P} \neq \emptyset$. On the other hand, we have $\mathcal{P} \subseteq S$, which means that two edges of the triangulation M intersect. This contradicts the definition of a triangulation [23].

Since case (ii) cannot occur, we conclude from case (i) that $S \subseteq \cup S_i$. The two triangulations M and $\cup M_i$ must have the same number of edges, so we have $S = \cup S_i$, and thus $M = \cup M_i$. This proves the proposition. ∎

PROPOSITION 4.4. $\mathcal{M}$ $\mathcal{P}$ $\mathcal{M}$

. Suppose that during the procedure $\mathcal{M}$ an edge $s \in \mathcal{P}$ is destroyed. That means that the diametral circle C_s of s includes some point. Since $\mathcal{M}$ does not

remove points, C_s will not be empty after the termination of $\mathcal{M}$. This contradicts the definition of the decoupling path. □

Proposition 4.3 proves that, provided that we have constructed a decoupling path, the subdomains can be meshed independently and the final mesh will be Delaunay conforming. Our next step will be to construct a decoupling path from the separators created by MADD.

The decoupling path is defined with respect to a mesh generation procedure and, in many cases [11, 40], the stopping conditions of the mesh generation algorithm allow us to compute the length of the edges of the separators, so that these edges will form a decoupling path. Then we only have to refine the segments of the separators, acquiring this predefined length.

5. Ruppert's algorithm. For the mesh procedure we will consider Ruppert's algorithm [40]. This is a mesh refinement algorithm for 2 dimensions that guarantees the quality of the elements. It creates an initial triangulation and follows an incremental approach to refine the mesh. Triangles which have circumradius to shortest edge ratio greater than $\sqrt{2}$ are split, by inserting points in their circumcenters and constructing a new Delaunay triangulation. If a point to be inserted encroaches the diametral circle of a boundary edge, then, instead of inserting this point, the boundary edge is split in half. The algorithm maintains the Delaunay property after the insertion of each point. In order to guarantee the termination of this procedure the boundary angles should be at least 60°.

Let D be a PSLG, as defined above. An entity is either a vertex or a segment of the boundary; two entities are incident when they share a common point. The [illegible] of D is defined as the minimum distance between two nonincident entities [44];[2] it will be denoted by $\mathrm{lfs}_{\min}(D)$.

The following proposition holds [44].

PROPOSITION 5.1. [illegible] D [illegible] 60°. [illegible] D [illegible] $\sqrt{2}$ [illegible] $\mathrm{lfs}_{\min}(D)$

The only requirement for Ruppert's algorithm is that the boundary angles must be at least 60°. Provided that our initial boundary D satisfies this criterion, we can apply MADD to decompose Ω using an angle bound $\Phi_o = 60°$. So, both the constructed separators and the external boundaries form angles $\geq 60°$. Consequently the created subdomains are acceptable for this mesh generation algorithm.

6. The construction of the decoupling path. Let $D = \partial\Omega$ be the boundary of the domain Ω, and $\mathcal{H}$ the set of separators in Ω created by the MADD method using an angle bound of $\Phi_o = 60°$. Let $D_i = \partial\Omega_i$ be the boundaries of the created subdomains and $D_{\mathcal{H}} = D \cup \mathcal{H}$.

In order to construct a decoupling path $\mathcal{P}$ from the separators $\mathcal{H}$ we will refine $\mathcal{H}$ by inserting points along its edges, obtaining a desirable segment length. The calculation of this length is based on a parameter k. Let $L = \min\{|s|/\ s \text{ is a segment of } \mathcal{H}\}$.

[2]For a PSLG domain the minimum local feature size will be the minimum distance between two vertices, or a vertex and a segment [44]. In our implementation we use a simple brute force approach, checking all the distances. This approach is satisfactory for relatively simple domains with few initial vertices. For more complicated geometries better algorithms should be used, similar to the ones for finding the two closest pair of a set of points (see [38]), which have $\boldsymbol{O}(n \log n)$ complexity.

Let k be a real constant parameter, such that

$$0 < k \leq \min(\mathrm{lfs}_{\min}(D_{\mathcal{H}}), L/4). \tag{6.1}$$

The parameter k will be calculated from the conditions of the algorithm, so that it can be guaranteed that no edge will be created with length less than k.

The following lemma describes the refining procedure of $\mathcal{H}$.

LEMMA 6.1. [illegible] $\mathcal{H}$ [illegible] $\nu \in \mathbf{N}$ [illegible] $\nu - 1$ [illegible] b_i [illegible] $\frac{2}{\sqrt{3}}k \leq |b_i b_{i+1}| < 2k$ [illegible] b_i, b_{i+1}

[illegible]. Let l be the length of the segment s; there is $\nu \in \mathbf{N}$ such that $2(\nu-1)k \leq l < 2\nu k$. Then, by dividing the s into ν equal subsegments, we have for the length l' of the subsegments: $\frac{2(\nu-1)}{\nu}k \leq l' < 2k$. For $\nu \geq 3$, we have $\frac{2(\nu-1)}{\nu} > \frac{2}{\sqrt{3}}$, and this proves the lemma. □

Let $\mathcal{P}$ be the separators $\mathcal{H}$ after we have inserted the points b_i, as described in the previous lemma, and let $D_{\mathcal{P}} = D \cup \mathcal{P}$. The following lemmata hold.

LEMMA 6.2. [illegible] b_i, b_{i+1} [illegible] s [illegible] $\mathcal{H}$ [illegible] $b_i b_{i+1}$ [illegible]

[illegible]. The diametral circle C of $b_i b_{i+1}$ is contained in the diametral circle of s, which by the MADD construction does not include any of the points of $D_{\mathcal{H}}$.

The remaining points to be examined are the inserted points b_j. We have that all the angles are greater than 60° and, from Lemma 6.1, no created segment is less than half of any other created segment. Consequently, C cannot contain a point b_j created by the refining procedure. □

LEMMA 6.3. [illegible] $\mathrm{lfs}_{\min}(D_{\mathcal{P}}) \geq k$.

[illegible]. We have from relation (6.1) that $\mathrm{lfs}_{\min}(D_{\mathcal{H}}) \geq k$. We will examine the distances created by the inserted points.

Let b_i be a point inserted in a segment s of $\mathcal{H}$. For the distance d of b_i from a nonincident to s segment we have $d \geq \mathrm{lfs}_{\min}(D_{\mathcal{H}}) \geq k$. The same holds for the distance d' from points that are not incident to s, because we have $d' \geq d \geq k$.

For the distance d between b_i and an incident segment we have $d \geq \sin 60° \cdot \frac{2}{\sqrt{3}}k = k$. Finally, the distance between b_i and a point that belongs to an incident segment is greater than the distance d of the previous relation, and this completes the proof. □

The previous lemma demonstrates the property that will be used to prove that $\mathcal{P}$ is a decoupling path. Our next step will be to calculate the parameter k.

Ruppert's algorithm can be applied using either the quality criterion for the circumradius to shortest edge ratio, or by adding a criterion for the maximum area of the created elements. We will calculate k for these two cases separately. We will prove that $\mathcal{P}$ is a decoupling path for the two cases: (I) when Ruppert's algorithm is applied with only the quality criterion of the circumradius to shortest edge ratio; (II) when it is applied with an additional criterion for the maximum triangle area.

6.1. Case I: The ratio criterion. In this case we are interested only in the circumradius to shortest edge ratio. Since k gives a bound for the size of the created segments, we would like k to be as big as possible and at the same time satisfy relation (6.1). Proposition 5.1 and Lemma 6.3 indicate that we can define $k = \min\{\mathrm{lfs}_{\min}(D_{\mathcal{H}}), L/4\}$.

PROPOSITION 6.4. [illegible] $k = \min\{\mathrm{lfs}_{\min}(D_{\mathcal{H}}), L/4\}$ [illegible] $\mathcal{P}$ [illegible] 6.1. [illegible] $\mathcal{P}$ [illegible]

. According to Proposition 5.1, Ruppert's algorithm when applied to a subdomain D_i, will not create segments less than $\text{lfs}_{\min}(D_i)$. We will show ad absurdo that the decoupling zone $\mathcal{Z}_\mathcal{P}$ is empty after the termination of the algorithm.

Suppose that $\mathcal{Z}_\mathcal{P}$ is not empty after the mesh procedure and some points have been inserted in it. That means that some boundary segments of $\mathcal{P}$ have been encroached and thus have been split in half. From Lemma 6.1 the length of the segments of $\mathcal{P}$ is less than $2k$ and by splitting them the created segments will have length less than k. This contradicts Proposition 5.1 because, from Lemma 6.3, we have $\text{lfs}_{\min}(D_i) \geq \text{lfs}_{\min}(D_\mathcal{P}) \geq k$.

Thus the decoupling zone $\mathcal{Z}_\mathcal{P}$ is empty after applying Ruppert's algorithm, and $\mathcal{P}$ is a decoupling path with respect to this algorithm. □

COROLLARY 6.5. $\mathcal{P}$.

. Ruppert's algorithm does not remove points and maintains the Delaunay property after inserting a point. The corollary is a direct consequence of the previous proposition and of Proposition 4.4. □

Proposition 6.4 states that we can process the subdomains independently, using Ruppert's algorithm, and the final mesh will be Delaunay conforming and of guaranteed quality. Next we will examine the case where we have an additional condition for the area of the triangles.

6.2. Case II: The ratio and maximum area criteria. In this case, besides the circumradius to shortest edge ratio condition, we have an additional criterion for the maximum triangle area. In many cases we want to construct Delaunay meshes, not only with good quality of angles, but also of a desired maximum size. Let A be a bound to the maximum triangle area, then all the triangles of the final mesh will have an area at most A. To achieve this, the mesh generation algorithm will split the triangles in two cases: (a) because of the bad circumradius to shortest edge ratio; (b) because the area of the triangle is greater than A.

We will calculate k so that the previous results will remain valid.

LEMMA 6.6. l A $\sqrt{2}$ $l > \sqrt{\frac{A}{\sqrt{2}}}$.

. Let r be the circumradius of the triangle. Then $\frac{r}{l} \leq \sqrt{2}$ and $A < r \cdot l$. So, $A < r \cdot l \leq \frac{l^2}{\sqrt{2}} \Rightarrow l > \sqrt{\frac{A}{\sqrt{2}}}$. □

We want to define k in such a way that the mesh generation procedure will not create edges smaller than k. The previous lemma indicates that we should have $k \leq \frac{1}{2}\sqrt{\frac{A}{\sqrt{2}}}$. We will take $k = \min\{\text{lfs}_{\min}(D_\mathcal{H}),\ L/4,\ \frac{1}{2}\sqrt{\frac{A}{\sqrt{2}}}\}$. Then Lemma 6.3 holds, and we have the following theorem.

THEOREM 6.7. $k = \min\{\text{lfs}_{\min}(D_\mathcal{H}),\ L/4,\ \frac{1}{2}\sqrt{\frac{A}{\sqrt{2}}}\}$ 6.1, $\mathcal{P}$ $\mathcal{P}$ $\sqrt{2}$ A

. There are two cases for splitting a triangle: (a) because of its circumradius to shortest edge ratio or (b) because of its area.

When Ruppert's algorithm splits a triangle because of its circumradius to shortest edge ratio it does not create edges smaller than $\text{lfs}_{\min}(D_\mathcal{P}) \geq k$. If a triangle is split because of its size, then from Lemma 6.6 we have that the smaller created edge will be no less than $\frac{1}{2}\sqrt{\frac{A}{\sqrt{2}}} \geq k$. In both cases no edge smaller than k will be created.

It is easy to see now that the decoupling zone $\mathcal{Z}_{\mathcal{P}}$ will be empty, after Ruppert's algorithm has been applied on the subdomains D_i with the additional condition of a maximum triangle area A. If this was not so, then some edge of $\mathcal{P}$ would be encroached and split. From Lemma 6.1 the new edges will be smaller than k, which is a contradiction. □

In summary, the procedure of preprocessing the separators created by MADD, as described in Lemma 6.1, creates a decoupling path with respect to Ruppert's algorithm, in both cases of the quality and the size criteria. In the first case, the construction is based on the minimum local feature size, while in the second the maximum area of the triangles is taken into account.

The size optimality (times a constant) of the mesh produced by Ruppert's algorithm, when only the angle criterion is used, is based on the local feature size [40, 44]. The size optimality, combined with the angle quality, provides the basis of the adaptivity to the geometry, that the Delaunay mesh displays. On the other hand, the insertion of separators by itself changes the geometry to be meshed, and the uniform refinement of the separators alternates the local feature size of the geometry. After applying the decoupling procedure, the size optimality of the mesh is not any more guaranteed. The use of the local feature size, instead of the global minimum, in creating the decoupling path, would improve the gradation and mesh size, especially when there are big differences in the local feature size. In cases, though, where the geometry is very simple but h-refinement is important [22], we would like to limit the area of the triangles, and in these cases the optimality of the mesh size is not based on the local feature size. The meshes produced using the area restriction are usually much larger, and thus more prompt for parallel processing. The experiments that we ran show that the over-refinement imposed by the decoupling procedure is insignificant (see section 11) when the area criterion is used.

The creation of the decoupling path allows us to generate Delaunay meshes, independently for each subdomain, with good angle quality and of the desired size. The final mesh, formed by the union of the submeshes, is Delaunay conforming. As a result, this procedure decouples the domain and enables us to parallelize the mesh generation procedure, while eliminating the communication between the processors.

7. The parallel Delaunay decoupling procedure. The procedure for the parallel mesh generation consists of two steps.

1. [illegible]: In this step the domain is decomposed using the divide and conquer MADD method.
2. [illegible]: This step is performed independently for each subdomain and includes two substeps.
   (a) The decoupling of the subdomains by refining the interfaces, as described in section 6.
   (b) The mesh generation on the subdomains. In this step the sequential mesh generator is used as a library and is applied independently on each subdomain.

During the PMADD phase the domain is over-decomposed (i.e., we create $N \gg P$ subdomains, where P is the number of processors), in order to achieve good load balancing (see section 8). The PMADD method is implemented using a master/worker model. Processor 0 is used as the master processor, while all the processors, including processor 0, are used as worker processors. The master processor maintains a sorted list of the areas assigned to each processor. In each iteration of the PMADD procedure a decomposition request is sent from the master processor to the processors assigned

with larger total areas. The processors that receive such requests decompose their larger subdomain into two subdomains using MADD. One of the two new subdomains is sent to a processor with small total assigned area. The procedure is repeated until all N subdomains are created. Observe that the MADD is sequential and it includes a Delaunay triangulation procedure. The resulting triangulations are discarded, since they cannot be used in the next phase. The decomposition gradually creates simple geometries (see Figure 10.1) so that the cost to triangulate them is small. Nevertheless, the cost of the initial Delaunay triangulation remains but is small related to the cost of creating big meshes.

The area of the subdomains is used to estimate the workload for the mesh procedure (see section 8). The goals of the PMADD is to minimize the larger area and to distribute the subdomains uniformly to the processors. Once the PMADD phase is finished, no data movement takes place. This is an approximate criterion for the load balance, other means [2] for dynamic load balancing can be used.

After the requested number of subdomains have been created, the master processor sends requests to all processors to mesh the subdomains assigned to them. Each processor iterates through its subdomains and performs two steps.

(a) It refines the interfaces, where the separators created by the MADD are refined by inserting vertices, as described in the decoupling procedure in section 6, according to the given mesh quality criteria. The parameter k, that determines the refinement of the separators, is computed before the mesh generation phase begins, and is used to refine the internal boundaries of all the subdomains, independently for each subdomain. Although each interface is refined independently for the two subdomains where it belongs, the result is conforming, because the same parameter k is used, the same orientation for the interfaces, and of course the same algorithm.

(b) The mesh generation procedure is applied on the subdomains independently. The sequential mesh generator is used as is, in the form of a library. The interfaces, since they are refined from the decoupling procedure, will not be further refined form the mesh generation procedure and they will remain unchanged, as proved in section 4. So, no communication is required, and the created meshes are Delaunay conforming.

The procedure terminates when all the meshes for subdomains have been created. The parallel procedure is described next.

ALGORITHM 4.

Master processor:

1. Read the definition of the domain Ω
2. Initialize and maintain a sorted list of the areas of the subdomains
3. **while** the current number of subdomains is less than N **do**
4. **send** decompose requests to processors that are assigned large area of subdomains
5. **receive** replies about decoupling and area information
6. **endwhile**
7. **send** requests to processors to mesh their subdomains
8. **receive** replies **until** all processors completed meshing
9. **send** requests for termination

Worker processors:

10. **while** not terminate **do**
11. **receive** request from Master and/or other workers
12. **if** request is to decompose **then**
13. Apply MADD on the largest subdomain

```
14.            send reply to Master
15.            send a new subdomain to other processor
16.          endif
17.          if request is to receive a subdomain then
18.            Add the new subdomain to this worker's mesh-queue
19.            send reply to Master
20.          endif
21.          if request is to start meshing then
22.            for each assigned subdomain do
23.                Refine the separators according to the decouple procedure
24.                Apply the sequential mesh generator on the subdomain
25.            endfor
26.            send completion message to master
27.          endif
28.      endwhile
```

During the PMADD phase, the first P subdomains are created in $\lg(P)$ iterations. The total number of iterations for the parallel MADD phase is $\frac{N-P}{P/2} + \lg(P) = 2(M-1) + \lg(P)$, where M is the average number of the final subdomains per processor. Typical values for M in our experiments vary between 12 and 20. The procedure is using in average $\frac{N-1}{2(M-1)+\lg(P)} = \frac{PM-1}{2(M-1)+\lg(P)}$ processors per iteration.

This divide and conquer approach is not optimal, but the cost is very small (see section 12) with respect to the cost for the mesh generation. On the other hand, it achieves a good load balance among the processors, which is a more significant factor for the total performance of the parallel mesh generation (see section 12.2). In the next section we present in detail the load balance attained using the parallel MADD.

8. Load balancing. Our experiments show that more than 99% of the total time is spent in the meshing phase (see section 12), which does not suffer from communication or synchronization cost. Thus, the workload balance among the processors is the main parameter that affects the performance of the method. The load-balancing problem for mesh refinement is a difficult problem, because of the unpredictable computational behavior of the meshing procedure. The problem becomes more approachable by the use of the PMADD for over-decomposing the domain. The resulting subdomains have similar geometric shapes, and their area is proved to be a good measure for estimating the workload for the mesh generator.

Our experimental data show, for the geometries we tested so far, that the parallel MADD procedure creates subdomains with similar "good" shape (see Figure 10.1), when the number N of subdomains is large. Figure 8.1 shows that, as we increase N and thus decrease the area of the subdomains, the meshing time converges, with very small differences between subdomains of similar size. This result demonstrates that the area of the subdomain can be used to estimate the workload of the mesher for this subdomain. Of course this depends on the geometry of the original domain, which is one of the parameters that determine the level of required decomposition. An adaptive to the geometry approach for the PMADD would optimize the results, and this is a subject of future work.

The load balance among the processors is achieved by balancing the total area of the subdomains assigned to each processor. The first effort to create subdomains with similar sizes takes place during the graph partition. This result, though, is not guaranteed, and the obtained subdomains can have differences in size. By over-decomposing we have the ability to distribute the subdomains, so that each processor

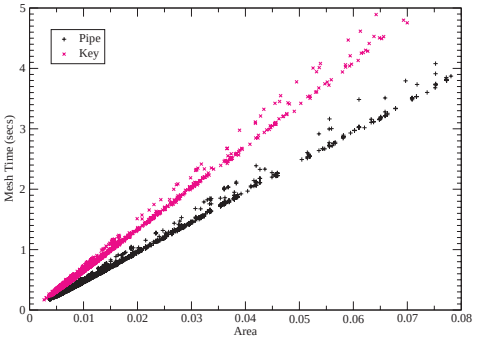

FIG. 8.1. *Mesh time for different sizes of subdomains of the key and the pipe geometry.*

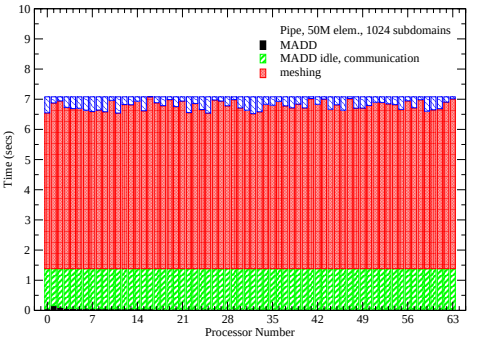

FIG. 8.2. *The work balance for* 64 *processors,* 50 *M elements.*

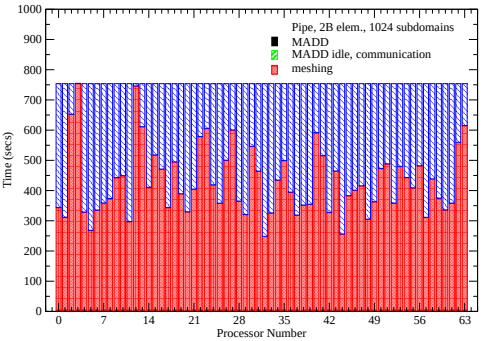

FIG. 8.3. *The work balance for* 64 *processors,* 2 *B elements,* 1024 *subdomains for the pipe.*

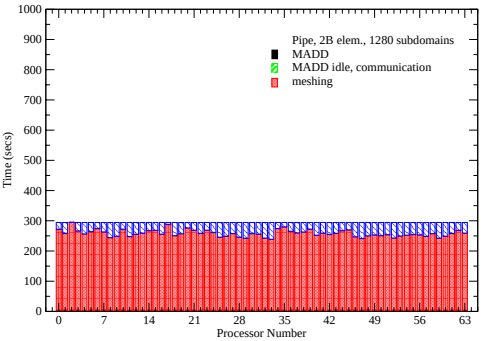

FIG. 8.4. *The work balance for* 64 *processors,* 2 *B elements,* 1280 *subdomains for the pipe.*

is assigned approximately the same total size. Moreover, the random distribution of the subdomains gives a more uniform assignment of subdomains that differ from the average in terms of size and geometry. The results of this simple approach are good. Figure 8.2 depicts the load balance among 64 processors for the pipe geometry, for 1024 subdomains and 50 M mesh size. This picture is typical in most cases. However, we have observed that the load balance depends not only on the geometry and the size of the subdomain but also on the size of the created mesh.

Figure 8.3 shows the load balance for the same decomposition of the pipe, as in Figure 8.2, this time for a mesh size of 2 billion elements. We see that the good load balance of Figure 8.2 is destroyed. The reason for this is that the time for creating larger meshes is much more sensitive to area and geometry differences. The answer to this problem is to increase N. In this way we improve two parameters: (i) the size of the mesh for each subdomain is decreased, and thus the time to create it is less sensitive to the differences, and (ii) a more uniform assignment of the subdomains can be accomplished. Figure 8.4 shows the balance for the same mesh size, 2 billion elements, by decomposing it into 1280 subdomains. This small increase of the number of subdomains gives an impressive improvement, the load balance is satisfactory and the total time is decreased to less than half; the reasons are described in sections 11

and 12.1.

The previous example shows that the load balance is sensitive to the size of the final mesh. The level of the required decomposition depends not only on the geometry and the number of processors, but mainly on the size of the final mesh. Let E be an estimation for the final size of the mesh in millions of elements. From our experiments we found that, for our setup, the number of subdomains should be at least $N = \frac{E}{1.6}$. This means that on average 1.6 M elements will be created for each subdomain. A higher decomposition has, of course, higher time cost, but this cost is insignificant against the gain, Figures 8.3 and 8.4, as well as the results in the next section demonstrate it.

9. Performance evaluation. We evaluate the parallel Delaunay decoupling (PDD) method with respect to three requirements listed in the introduction: (1) stability, (2) parallel efficiency, and (3) code reuse. Our experimental data indicate that the PDD method is stable; i.e., the elements of the distributed mesh retain the same good quality of angles as the elements generated by the Triangle (see Figures 11.3 and 12.3 (right)); at the same time it is very efficient as our fixed and scaled speedup data (see Figures 12.2 and 12.3 (left)) indicate. Finally it is based on 100% code reuse; i.e., existing sequential libraries like METIS and Triangle are used without any modifications for the parallel mesh generation.

10. Experimental setup. We have used two model domains (see Figure 10.1), with relatively simple geometries:[3] The , a cross section of a rocket from a NASA model problem where the peripheral pipes are used to cool the main cylinder in the center that contains combustion gases, and the , a domain provided with Triangle. We ran three sets of experiments: (1) to observe the behavior of the MADD and decoupling method in sequential execution for small meshes, 4–5 million (M) elements, (2) to calculate the fixed speedup for fixed size meshes of the order of 40–50 M elements, and (3) to compute the scaled speedup for meshes whose size range from 12 M to 2 billion (B) elements.

The programming language for our implementation was C++ and DMCS [3] was used as the communication substrate. The Triangle [43] library was used for the mesh generation procedure as well as for the creation of the Delaunay triangulation during the MADD procedure. The parameters passed to Triangle for the mesh generation were two: (a) for the quality of the elements (Ruppert's algorithm is used to achieve circumradius to shortest edge ration less then $\sqrt{2}$) and (b) for the maximum area of the generated elements. Also, METIS [31] was used for the graph partitioning step in the MADD procedure. The cases where METIS returned nonconnected subgraphs were recognized and discarded. All the libraries were used without modifications, minimizing the cost for the parallel implementation and achieving 100% code reuse.

The experiments ran on SciClone, a high-performance computing environment in the College of William and Mary. SciClone is a heterogeneous cluster of Sun workstations which use the Solaris 7 operating system. For our experiments we have used a subcluster of 32 dual-CPU Sun Ultra 60 workstations 360 MHz, with 512 MB memory and 18.2 GB local disk. Networking was provided by a 36-port 3Com Fast Ethernet switch (100Mb/s).

[3]The complexity of the geometry will challenge the PMADD and in particular the Delaunay triangulation procedure. Provided the efficiency of *Triangle*, this shouldn't be a problem. The mesh refinement procedure will be applied on the created subdomains, which have simple geometries. However, for three dimensional cases the complexity of the geometry is a much more serious issue.

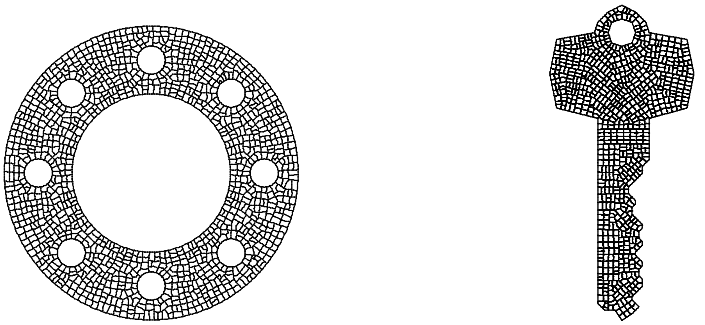

FIG. 10.1. *Left: The Pipe domain divided into* 1200 *subdomains. Right: The Key domain divided into* 768 *subdomains.*

11. Sequential experiments. We ran a set of sequential experiments in order to compare the sequential Delaunay decoupling method, where we over-decompose the domain, with Triangle, the best known publicly available sequential guaranteed quality Delaunay mesh generation code for 2-dimensional domains. In these experiments we examine the affects of the decoupling procedure with respect to the performance of the mesh procedure, the size of the final mesh, which indicates that the over-refinement we introduce is insignificant, and the quality of the elements in terms of the angle distribution. The size of the meshes we created is limited by the size (5.5 M) we were able to generate with Triangle due to memory limitations. However, using the

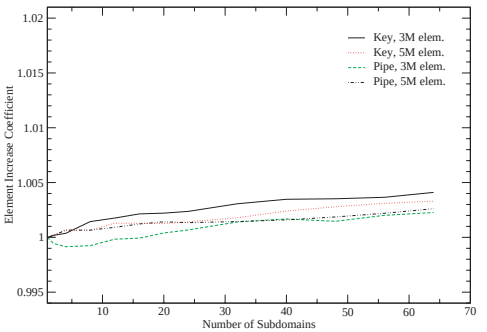

FIG. 11.1. *The increase of number of elements for decoupling into different number of subdomains.*

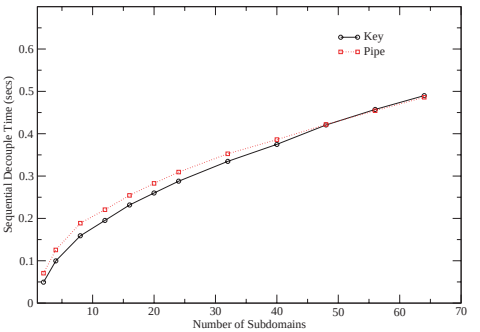

FIG. 11.2. *The time for the sequential MADD.*

Delaunay decoupling method we were able to generate more than 30 M on a single processor.

Figure 11.1 shows the ratio of the size of the decoupled meshes over the size of the nondecoupled mesh, which is a measure of the over-refinement we introduce when we decouple the domains.

Similarly, Table 11.1 presents the number of elements for different levels of decoupling. The over-refinement is insignificant; it is less than 0.4%, despite the intense over-decomposition (less than 90 K elements per subdomain).

The overhead of the sequential MADD method is approximately linear with respect to the number of subdomains; see Figure 11.2. This overhead is small compared to the mesh generation time. The total execution time using the sequential decoupling

TABLE 11.1

Total time	59.263	41.342	41.046	40.370	40.352	40.147

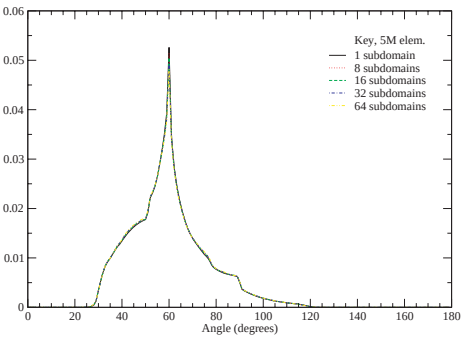

FIG. 11.3. *The angle distribution for different number of subdomains.*

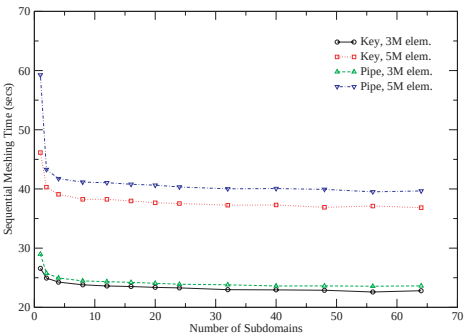

FIG. 11.4. *The time for sequential meshing after decoupling into subdomains. The times do not include the mesh merging procedure.*

procedure is decreased up to 68% of the time it takes for Triangle to generate a mesh with the same quality (Figure 11.4). As the size of the mesh increases, the performance of the decoupling procedure compared to Triangle is improving even further, because the size of the working set for each subdomain is smaller and the Delaunay mesh algorithm used in Triangle has a nonlinear time complexity [43].

The quality of the elements produced after the decoupling of the domain into subdomains is evaluated by comparing the distribution of angles. We compare the angles of the elements from both the nondecoupled mesh generated by Triangle and the decoupled ones generated by our method. Figure 11.3 shows that the distribution is the same. The above results hold as we scale the mesh size in our parallel experiments.

In summary, the decoupling method demonstrates merits even for sequential mesh generation. The gains in the performance from the better memory utilization cover the small overheads due to decoupling and over-refinement, while the element quality is independent of the decoupling, which shows that our method is stable regarding the quality of the mesh.

12. Parallel experiments. We performed two sets of experiments in order to calculate the fixed and scaled speedup using 8, 16, 32, and 64 processors. With 64 processors we were able to generate 2.1 billion (B) high quality elements for the Pipe in less than 3.5 minutes, while using Triangle [43] on a single workstation we were able to generate 5.5 million (M) elements in about one minute (see Tables 11.1 and 12.2).

In the rest of the section we present performance data for both the parallel medial axis domain decomposition (PMADD) method and the parallel mesh generation. The

PMADD procedure is evaluated in terms of its total parallel execution time which includes some communication and idle time and the maximum computation time spent on a single processor. The parallel mesh generation phase does not require communication and its performance is measured in terms of maximum and average computation time of processors. The ratio of these two numbers is used to measure the load imbalance of the parallel meshing phase.

Finally, we evaluate the scalability of the method in terms of two performance criteria: (1) the , , , , that it takes for one element to be created on a single processor, over all the processors and elements that are created, and (2) the , , cost (due to decomposition and parallelism) for each processor we use. Both criteria indicate that the parallel mesh generation method we present here is scalable and that we can generate billions of elements with insignificant overhead (see Table 12.2).

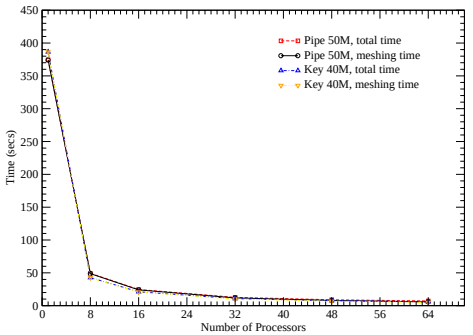

FIG. 12.1. *The performance for fixed size mesh.*

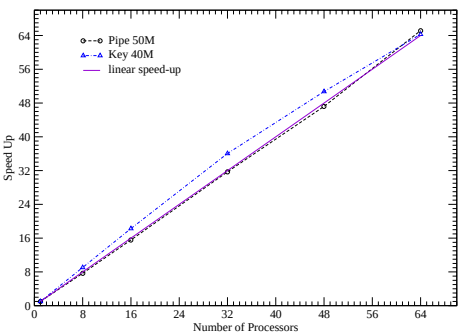

FIG. 12.2. *The speedup for fixed size mesh.*

12.1. Fixed size mesh experiments. In the fixed size set of parallel experiments we used a mesh of 40 M elements for the Key domain and 50 M for the cross section of the Pipe. For the Key domain we created 12 subdomains for each processor while for the Pipe we created 16 subdomains. The maximum triangle area is fixed throughout the experiments for each domain.

The results are presented in Table 12.1. The data again indicate an unimportant increase in the number of elements for the different levels of over-decomposition, which

shows that the over-refinement we introduce is insignificant. The total execution time and the computation time for the actual mesh generation are depicted in Figure 12.1. These times are very close, because the PMADD overhead cost is very small. This cost is neutralized by the effect of over-decomposition, which, along with the good load balancing and zero communication during the parallel meshing, leads to superlinear speedup; see Figure 12.2. The speedup is calculated against the total time it takes to create the mesh on one processor, as is presented in Table 12.1.

12.2. Scaled size mesh experiments. A more practical way to evaluate the scalability and true performance of a parallel algorithm and software is to scale the size of the problem in proportion to the number of processors used. In the following experimental data we use the same level of decomposition for every configuration of processors, i.e., we keep the average number of subdomains per processor constant, and thus we eliminate the effect of over-decomposition in the resulting performance data. Theoretically we should be able to achieve the same creation time per element per processor for all the parallel configurations independently of the number of processors used. However, this is not feasible for the following two reasons: (1) the decomposition overhead, which increases very slowly but nevertheless there is an increase in the overhead as the number of processors increases and (2) load imbalances due to unpredictable and variable computation of the mesh generation kernel.

Table 12.2 shows some performance indicators for the two model problems we use, the Key and the Pipe geometry. In the experiments for the Key model we created 12 subdomains per processor and generated on average 1.6 M elements per subdomain, i.e., a total of 20 M per processor. For the Pipe model we created 20 subdomains per processor and generated on average 1.6 M elements per subdomain, i.e., a total of 32 M per processor. Small differences exist in the size of the mesh because our stopping criteria are based on the quality and size of elements, and thus the mesh size cannot be exactly predefined. It is clear from Table 12.2 that for larger processor configurations, like 64 processors, 99.5% of the total execution time is spent in the meshing phase by the Triangle. This suggests that for realistic problems the PMADD overhead is about 0.5% of the total execution time.

We observe that, while the maximum PMADD time on one processor remains almost constant, the time for PMADD phase increases as the number of processors increases. This is in agreement with the analysis in section 7. As the number of processors increases, the number of PMADD iterations increases, although the number of the subdomains per processor is constant. In each PMADD iteration all the processors finish the decomposition before the next iteration begins. This synchronization imposes an additional cost in the PMADD time. Moreover, the communication during this phase increases, as the number of processors increases. Fortunately, the communication and synchronization cost is less than 0.02 s per processor. In comparison with the total execution time this cost is very small.

The load imbalance is measured by the ratio of the maximum meshing time on one processor and the average meshing time for all the processors. In Table 12.2 we observe that the load balance for the Pipe is very good, 1.14 for 64 processors, while for the Key it is a satisfactory 1.25. The load balance is based on over-decomposing the domain and equi-distributing the areas, and although it depends on the size of the mesh as we saw in section 8, it also depends on the geometry and the number of the processors. Further improvement in the load balance can be achieved by using parallel runtime software systems that address load-balancing problems, as the one presented in [2].

TABLE 12.2

Performance data for the Key and the Pipe geometry. The meshing time includes the time of the decoupling procedure (MADD). The MADD phase includes the load balance estimation procedure and the distribution of the subdomains to the processors. The imbalance is measured as ratio of the max meshing processor time over the average. All times are in seconds except for the time/(elem./procs) which is in microsecs.

Additional cost /procs	0%	1.6%	0.6%	0.5%	0.3%	0.4%

An important measure for evaluating the efficiency of a parallel meshing method is the (total) time spent for creating one element on one processor. Let $T^{(P)}$ be the total time running on P processors in order to create a mesh of size $S^{(P)}$. Then the time per element per processor is $T_e^{(P)} = \frac{T^{(P)} \cdot P}{S^{(P)}}$. This measure eliminates the differences in the mesh size, providing a more objective view of the scaled performance. We see in Table 12.2 that this time is almost constant, and thus the method is scalable. The slight increase of this time is mainly due to the imbalance increase, while the contribution of the overhead time cost is very small. This is evident in Figure 12.3, where the imbalance is depicted on the top and the scaled speedup on the bottom. The scaled speedup for P processors is measured as $U_P = \frac{T_e^s \cdot P}{T_e^{(P)}}$, where T_e^s is the time to create sequentially one element for a nondecomposed mesh of size 5 M. We again observe the superlinear speedup for the same reasons as in the fixed size experiments. In this figure the direct impact of the imbalance to the speedup is obvious.

Another measure for evaluating the scalability is the additional time cost for each processor that we use, relative to the total time when running on one processor. The additional cost C_P per processor, when using P processors, is computed as $C_P = \frac{T_e^{(P)} - T_e^{(1)}}{T_e^{(1)} \cdot P}$. Taking into account that the mesh size $S^{(P)}$ is approximately proportional to the number of processors P, we have $C_P \simeq \frac{T^{(P)} - T^{(1)}}{T^{(1)} \cdot P}$. We can consider the quantity $T^{(1)}$ as the ideal time for creating on P processors a mesh of size $S^{(P)} \simeq P \cdot S^{(1)}$, since the effect of over-decomposition is eliminated. In this way the additional cost C_P measures the distance from the ideal speedup, distributed to the number of processors used.

The time $T_e^{(P)}$ is increasing as P increases; the reasons were explained above.

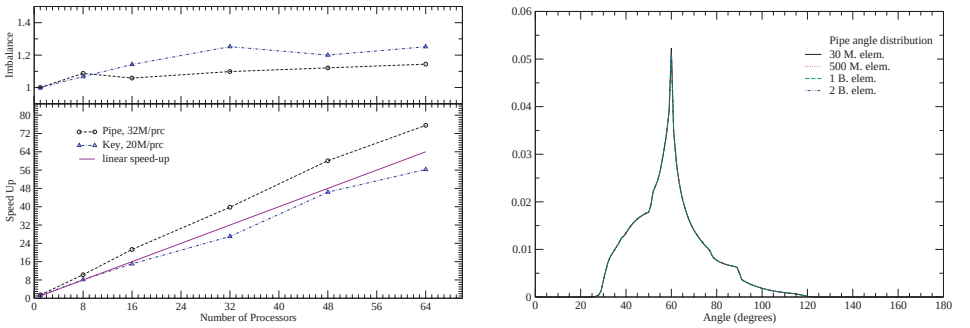

FIG. 12.3. *Left: At top is the imbalance and at bottom the speedup for the scaled experiments. The speedup is measured against the sequential creation of* 5 *M elements and is based on the overall time it takes for one element to be created. Observe the direct impact of the imbalance to the speedup. Right: The angle distribution for scaled mesh sizes of the Pipe.*

This increase, though, is small for the Key and even smaller for the Pipe domain. It is interesting to observe that the additional cost C_P tends to decrease as P increases. Although we have to pay a (small) cost in the performance for each additional processor we use, this cost tends to decrease, when measured in scale. This result underlines the scalability of the method.

Finally, we should compare the quality of the elements of scaled meshes that the decoupling procedure produces. In Figure 12.3 (right) is depicted the distribution of the angles of the elements, for meshes varying from 30 M triangles to 2.1 B. The quality is obviously the same.

13. Conclusions and future work. We presented a decoupling procedure for parallel Delaunay guaranteed quality mesh generation on distributed memory machines for 2-dimensional domains. The method eliminates the communication during the mesh generation and maintains the size and the quality of the final mesh. It also shows good speedup and scalability, making it suitable for creating very large meshes on distributed memory machines. A major advantage of our method is that a commercial, off-the-shelf and state-of-the-art, sequential mesher, like Triangle [43], can be used as a library, without any modification, achieving 100% code reuse. The method can be used at the same time for sequential mesh generation, in order to create larger meshes in less time using one processor. Because of the zero communication and the scalability for large meshes, this method seems to be suitable for Grid computing applications [16].

Future work for 2-dimensional geometries includes the extension of our approach for optimizing over-refinement of the interfaces, using the local feature size rather than $\text{lfs}_{\min}$. This will address the mesh gradation and improve the mesh-size optimality criterion.

Another problem is to determine the required level of the medial axis approximation that guarantees the creation of a minimum number of junction triangles, in order to produce separators that satisfy our geometric constraints.

It is also interesting to see how this approach can be applied in three dimensions for surface and volume parallel guaranteed quality mesh generation. The main issue in 3-dimensional domains is the creation of suitable domain decompositions, similar to the one we are able to create for the 2-dimensional cases.

Acknowledgment. The authors would like the thank the reviewers for their time in reviewing this paper and for their very useful suggestions.

ALTERNATIVE WEIGHTED DROPPING STRATEGIES FOR ILUTP*

JAN MAYER†

Abstract. This paper presents a weighted dropping strategy for the matrix L of the incomplete LU preconditioner with pivoting and dropping based on a dual threshold strategy (ILUTP). Preconditioners using this strategy often perform better than the standard ILUTP preconditioner for some difficult matrices. For matrices that are relatively easy to precondition, the results are similar. The implementation and setup times are somewhat longer than the ILUTP preconditioner employing the standard dropping strategy.

Key words. incomplete LU factorization, ILU, preconditioning, ILU with threshold, ILUT, ILUTP, iterative methods, sparse linear systems

1. Introduction.

In this paper, we present a new method for dropping elements in the rows of the matrix L of the ILUTP preconditioner of a matrix A based on assigning weights to the elements of the row of L being calculated. The ILUT preconditioner, first introduced in [11], is based on an incomplete LU factorization of A with dropping being implemented using a dual threshold strategy in order to ensure sparsity. If the Gaussian elimination is performed with column pivoting, we obtain the ILUTP preconditioner found in [14], for which we present the weighted dropping strategy.

Different dropping strategies for ILU-type preconditioners have recently received more attention. An approach based on monitoring the growth of inverse factors (i.e., of L^{-1} and U^{-1}) can be found in [2]. A similar approach for an ILU-type preconditioner based on Crout's formulation called ILUC can be found in [9]. It is better for some matrices than the standard ILUT preconditioner but not as flexible as the ILUTP preconditioner because it does not permit pivoting.

Our approach is based instead on approximating the error made by dropping a single element in the LU factorization. For matrices for which the standard ILUTP preconditioner already yields satisfactory results (in other words, for matrices for which the standard ILUTP preconditioner can be chosen to be fairly sparse and the iterative method converges well), the performance of the new dropping method is at times slightly worse than the standard method. On the other hand, for the more difficult matrices considered here for which ILUTP preconditioners require more fill-in in order to work, the weighted dropping strategy often performs better, although this appears to depend somewhat on the application from which the matrix arises. Hence, the standard strategy should be preferred whenever it appears likely that ILUTP will work with little fill-in, whereas the weighted strategy is an option when ILUTP is expected to require fill-in with a factor of approximately 1.5 or more. As the setup times for the weighted strategy are somewhat longer, using it is only worthwhile if this is compensated by a reduction in the iterations (or the iteration time).

Unfortunately, a similar dropping strategy for U is not available despite being possible theoretically. It is possible to implement the strategy for L because the ILUTP preconditioner is calculated by rows. Implementing a similar strategy for U would, however, require the preconditioner to be calculated by columns. In this sense, it is certainly possible to use such a strategy for U at the expense of not being able to use it for L. Implementing both, however, seems to be impossible.

For ILUC, on the other hand, L is calculated by columns and U by rows, so for this preconditioner it is theoretically possible to calculate the weights needed for both L and U. Using this approach, all the elements of a column of L being calculated (or a row of U) are assigned the same weight; in other words, the column of L (or row of U) is just scaled. Hence, using a dropping rule based on the relative sizes of elements yields the same results as a dropping rule without weights. However, a dropping rule using the absolute sizes of the elements yielded poor results. Thus, the weighted strategy does not appear to be suitable for ILUC.

Although the weighted strategies can be used with ILUT-based and ILUC-based multilevel preconditioners as implemented in pARMS (see [15]) or ILUPACK (see [3], [4], and [5]) without any modification, preliminary testing indicates that using the weighted strategy makes almost no difference in the quality of the resulting preconditioner. Hence, at this time, using weighted dropping in this situation does not appear to be advisable, but further investigation in this area may be worthwhile.

In the next section, we review the basic ideas concerning the ILUTP preconditioner. Then we present the theoretical justification for the weighted dropping strategy. Doing this rigorously appears to be possible only for dropping a single element, but this does provide a heuristic for dropping several elements at a time. We conclude this paper by presenting extensive numerical results that underline the observations alluded to before, i.e., that the weighted dropping strategy improves the ILUTP preconditioner for some difficult matrices.

2. The ILUTP preconditioner. The ILUTP preconditioner is calculated by an incomplete LU factorization using column pivoting. A simpler version without pivoting is called the ILUT preconditioner, which we describe first.

For a given matrix $A \in \mathbb{R}^{n\times n}$, the ILUT preconditioner is calculated by performing an LU factorization of A in such a manner that in the ith step ($i = 1, \ldots, n$) the ith row of both L and U are calculated completely and by dropping certain elements of these rows in order to ensure sparsity. The following algorithmic description is due to [14, p. 312]. For details, particularly on implementation issues, consult [4], [6], [11], and [12].

ALGORITHM (ILUT).

```
1.  for i = 1..n
2.      w := a_i                                  (a_i is the ith row of A)
3.      for k = 1..i − 1 and w_k ≠ 0
4.          w_k = w_k/a_kk
5.          Apply a dropping rule to w_k.
6.          if w_k ≠ 0 then
7.              w = w − w_k ∗ u_k                 (u_k is the kth row of U)
8.          end if
9.      end for k
10.     Apply a dropping rule to w.
11.     for j = 1..i − 1 : l_ij = w_j
12.     for j = i..n : u_ij = w_j
```

13. $w = 0$
14. end for i

Dropping in the ith step is usually done by a dual strategy based on two parameters $p \in \mathbb{N}$, which indicates the maximal number of elements in each row of L and U, and $\tau \in \mathbb{R}$, which gives a threshold for fill-in. Let w^L and w^U be the vectors consisting of the elements of w corresponding to L and U, respectively; i.e., w^L consists of the first $i-1$ elements of w and w^U consists of the remaining ones. For the standard dropping strategy, first all nonzero elements w_i^L of w^L satisfying $|w_i^L| < \tau$ are set to zero in line 5. Then all nonzero elements of w^U satisfying $|w_i^U| < \tau \cdot ||w^U||$ are set to zero in line 10. Finally, if there are still more than p elements in either w^L or w^U, then only the largest p elements by absolute value of w^L and w^U, respectively, are kept. For lack of a better name, we call this dropping strategy S0.

By choosing the largest element by absolute value as the pivot in each row and permuting the columns of A appropriately in the algorithm above, we obtain the ILUTP preconditioner. Often, elements are permuted only if their relative sizes exceed another parameter, the permutation tolerance. Based on the empirical results presented in [6], which indicate that pivoting yields somewhat better results, and the fact that our focus lies on fairly difficult matrices, we will always perform pivoting and not go into the details of implementing a permutation tolerance.

Although preprocessing is, strictly speaking, not part of the incomplete LU factorization, generally it improves the resulting preconditioner considerably and should be used; see [1].

3. New weighted dropping strategies. Let $L = (l_{ij})$, U and A be matrices such that $LU = A$, and $\hat{L}$ be the matrix obtained by dropping l_{ij} from L, i.e., by setting $l_{ij} = 0$. The error in the maximum norm made by using the factorization $\hat{L}U$ instead of LU is

$$||A - \hat{L}U||_\infty = ||LU - \hat{L}U||_\infty = ||(L - \hat{L})U||_\infty.$$

Because $L - \hat{L}$ is a matrix containing only zeros except for l_{ij}, the matrix $(L - \hat{L})U$ is a matrix having only zeros, except for the ith row, which contains $l_{ij} \cdot u_j$, u_j being the jth row of U. Hence, we have

$$||A - \hat{L}U||_\infty = |l_{ij}| \cdot ||u_j||_1.$$

Thus, if we wish to drop a single element from L such that the error obtained in the factorization above is minimal, we will need to drop the element l_{ij} such that $|l_{ij}| \cdot ||u_j||_1$ is minimal. Although these considerations are only accurate for dropping a single element, we do obtain heuristically that we should drop those elements l_{ij} for which $|l_{ij}| \cdot ||u_j||_1$ is smallest. In other words, the elements of the jth column of L should be weighted by the norm of the jth row of U. A similar consideration for dropping elements of U would indicate that the elements of the ith row of U should be weighted by the ith column of L. Because the ILUT preconditioner is calculated by rows, dropping elements in U using this approach is not possible in this case and we will not pursue it further. Finally, these considerations carry over to the ILUTP preconditioner as well without any modifications. For simplicity, we will just describe the implementation for the ILUT preconditioner.

As ILUT preconditioners are calculated by rows, in the ith step the first $i-1$ rows of L and U and the vectors w, w^L, and w^U are available. Let v^L be the vector of weighted elements, i.e., $v_j^L = w_j^L \cdot ||u_j||_1$. Using a double threshold strategy in

different ways, it is possible to construct several similar, but different, preconditioners. Simply replacing w^L of the standard dropping rule in line 5 of the algorithm by a weighted version may be the most straightforward approach, but the resulting preconditioner is generally poor. This is probably due to the fact that the elements dropped are important for the calculations in line 7, i.e., for calculating subsequent elements of L and U, even though the heuristic considerations above indicate that they are not important for the preconditioner itself. Hence, we would expect that using a weighted dropping rule in line 10 would be more successful and indeed this has been the case. We obtain a preconditioner with a weighted dropping strategy, which we call W0, if we use the standard strategy as described above and additionally drop the elements w_i^L with index i in line 10 of the algorithm for which $|v_i^L| < \tau \cdot ||v^L||$. If w^L still contains more than p elements, we keep only those p elements for which $|v_i^L|$ is largest. Note that the standard strategy performs no dropping in line 10 based on the threshold τ. However, it keeps only those p elements of w^L for which $|w_i^L|$ is largest. Here we need to point out that usually p is set to be very large, and thus only the threshold τ is responsible for dropping elements. These preconditioners tend to be better and the setup times are usually somewhat better, as the selection of the p largest elements (by absolute value) of a vector can be avoided. Consequently, for most practical purposes, the aspect of (weighted) dropping based on the parameter p is not particularly relevant. In any case, the weighted dropping rule described above leads to the idea that the standard dropping rule could be supplemented by additional dropping in L in line 10 based on τ. The corresponding dropping rule would be to drop those elements w_i^L of w^L for which $|w_i^L| < \tau \cdot ||w^L||$. Unlike W0, this strategy is not very effective for reasons which are not quite clear and we will not pursue it further.

Until now, we have used the same parameter τ for dropping in line 5 and line 10 of the algorithm. Dropping in L twice with the same parameter as for W0 may result in a preconditioner that is quite sparse and hence poor, so it may be advantageous to use different values for τ in lines 5 and 10. Using $0.1 \cdot \tau$ instead of τ in line 5 of W0, we obtain W1. Similarly, we obtain S1 if we use the standard strategy and drop with $0.1 \cdot \tau$ in line 5 and with τ in line 10. Both S1 and W1 use a denser w^L in the calculations of line 7, so their setup times are longer than for S0 and W0, but the resulting preconditioners are somewhat better. Nevertheless, these gains are usually not so significant as to justify longer setup times, in particular as W0 effects similar improvements. We summarize the use of τ in these dropping rules in Table 1. As mentioned before, the standard dropping rules S0 as well as S1 keep only the largest p elements by absolute value of w^L and w^U, whereas the weighted dropping rules W0 and W1 keep only those p elements whose weights are largest by absolute value.

TABLE 1

The use of τ in the dropping rules for L of ILUTP. The element w_i^L of w^L with index i is dropped if either of the conditions above is true.

Preconditioner	Dropping rule in line 5	Dropping rule in line 10
S0	$\|w_i^L\| < \tau$	none
S1	$\|w_i^L\| < 0.1 \cdot \tau$	$\|w_i^L\| < \tau \cdot \|\|w^L\|\|$
W0	$\|w_i^L\| < \tau$	$\|v_i^L\| < \tau \cdot \|\|v^L\|\|$
W1	$\|w_i^L\| < 0.1 \cdot \tau$	$\|v_i^L\| < \tau \cdot \|\|v^L\|\|$

4. Numerical results. We examined 163 matrices arising from different applications which we obtained from the University of Florida Sparse Matrix Collection [7] and the Matrix Market [10]. We tested these matrices using ILUPACK [4] implemention of SPARSKIT [12] using the standard routine for the ILUTP preconditioner as it is distributed, except that we used 1.0 as the permutation tolerance; i.e., we always pivoted. The preconditioners S1, W0, and W1 were constructed by minor modifications of the ILUTP preconditioner which this software provided. For testing these preconditioners, we used the routines implemented by ILUPACK as follows: If the matrix provided a right-hand side, then it was used. Otherwise, the right-hand side was constructed so that the exact solution of the resulting linear system is a vector consisting of all 1's. Next, the rows and columns were scaled and reordered using the PQ method (see [13]) as implemented by ILUPACK. Although other reordering methods also worked quite well, for example reverse Cuthill–McKee (see [8]), PQ seemed to yield the best overall results despite the fact that it was designed to be used with multilevel preconditioners. Hence, we report only on results for the PQ-reordering. Finally, GMRES(30) was used to attempt to solve the linear system. If the relative residual was decreased by a factor of $\sqrt{\text{eps}} \approx 3 \times 10^{-10}$ in at most 500 iterations, then the iteration was considered to be successful. The calculations were performed by an Athlon-XP 2.6 MHz CPU.

4.1. Summary of results for all matrices. All matrices were tested with $p = n$, n being the dimension of the matrix, and for various values of τ. Although we tested other combinations of p and τ, we restrict our attention to $p = n$ as the results are similar and $p = n$ is the default value of ILUPACK. Indeed, this usually yielded the best results. Hence, the preconditioners depended de facto only on the parameter τ. A notable disadvantage of this approach, particularly in large practical applications, is, however, that the memory requirement of the preconditioner is not known in advance, which can result in the calculation of the preconditioner terminating because of insufficient memory. This is remedied somewhat by ILUPACK requiring the user to provide an estimate of the required memory in advance. In any case, for each matrix and preconditioner we tested at least 20 different values of τ.

We attempted to choose the largest value of τ in order to obtain the sparsest preconditioner possible and the largest such that no more than 30 and 10 iterations, respectively, were needed to calculate the solution. Let γ_I be the least amount of fill-in that is needed to obtain the required reduction of the residual in no more than I iterations. Hence, for each preconditioner, we recorded $\gamma_{\min} = \gamma_{500}$, γ_{30}, and γ_{10}. Recall that the fill-in γ is defined to be the ratio of the sum of nonzero elements of L and U to those of A, the matrix tested. Although recording the various values for the fill-in seems to suggest that we were primarily interested in constructing preconditioners which are as sparse as possible, this is not the case. In other words, the new dropping strategies often enable sparser preconditioners, but usually they also require fewer iterations to calculate a solution than the standard preconditioner having the same fill-in. In any case, we chose to restrict our attention to this parameter because it appears to be most objective. Simply comparing the performance of preconditioners for a fixed τ is unsatisfactory, as for a given τ the weighted preconditioners, especially W0, are generally sparser but may require more iterations, and thus the comparison is often not very meaningful. On the other hand, comparing the number of required iterations for preconditioners for a fixed γ is difficult, as sensible values for γ depend highly on the matrix, making any choice for γ subjective. Additionally, if one preconditioner is better than another based on the fill-in required to obtain a

certain number of iterations, then this preconditioner is usually better based on another criterion: the number of iterations needed for a fixed γ. Hence, only recording the minimal fill-in needed to obtain no more than I iterations seems to be sufficient.

We report on the computation times only as part of the more extensive results for selected matrices. The additional time required to implement the weighted dropping is roughly proportional to the average number of elements in the row of L. Hence, if the original matrix is quite sparse and the fill-in required by the preconditioner is not too high, then weighted dropping results only in a small increase of setup times. On the other hand, if the preconditioner needs to be fairly dense, then implementing weighted dropping can require a considerable amount of extra time. For W0, this increase almost never exceeds a factor of about 1.5 and is often much lower. For S1 and W1, the setup times are usually increased by a factor of less than 2. Nevertheless, this time can generally only be amortized if the preconditioner is used to solve several systems or if the iteration times are reduced significantly by using one of the new strategies.

Before going into detail, we give an overview of the matrices tested. The first group, which we call hb58, consists of matrices of the Harwell-Boeing collection having size larger than 500. It has previously been used as a standard testing set; see [13]. As this set includes matrices from a wide range of applications, it generally gives a good overview of the quality of a preconditioner. In our particular case, the results for the various preconditioners are fairly similar, which is probably due to the fact that the differences between the preconditioners in question appear to be more significant for large matrices and the matrices in hb58 are fairly small. Next, we tested a set of 31 matrices arising from applications in chemical engineering, which we refer to as chem. The set pde consists of 19 matrices arising from partial differential equations, fidap consists of the 42 matrices from the fidap set having at least dimension 500, and sim consists of 13 matrices from circuit and device simulation problems. A list of the matrices tested can be found in Table 2.

We do not report on results comparing these preconditioners to multilevel preconditioners because extensive results comparing these preconditioners to ILUTP can be found on the homepage of ILUSTAB [3]. For that matter, these preconditioners go in a somewhat different direction. Although they are more robust than these ILUTP-based preconditioners and can often be constructed to be significantly sparser, which makes them very attractive alternatives to ILUTP, they often require significantly longer setup times, frequently much more than the additional work the strategies presented here require. Hence, if one of the ILUTP-type preconditioners presented here performs well for a given matrix (or is expected to perform well), then using a multilevel preconditioner, which may be considerably more expensive, is not necessary unless severe memory restrictions are an issue.

Before giving detailed results for selected matrices, we will summarize our results for all matrices and preconditioners tested in Tables 3, 4, and 5. In this summary, we also denoted "NC" for "no convergence" if γ of the preconditioners tested required a fill-in γ of more than 8 to solve the system in the prescribed number of iterations. In this case, the ILUTP-type preconditioners tested do not appear to be suitable for this matrix. If just one preconditioner succeeded with fill-in less than 8, we used one of the other classifications. We indicate that a preconditioner is "infinitely" better than another if calculating the solution in the prescribed number of iterations was possible for one preconditioner but not the other. In this case, we allowed γ to become very large to ensure that we record only significant failures of one strategy in this category. In other words, if for one preconditioner we achieved the required number of iterations for a particular amount of fill-in, we attempted to find a suitable γ for the others and

A first quick glance at these results suggests that the weighted dropping strategy is no improvement over the standard one. A more careful inspection of the raw data, however, reveals that the standard strategy is often better than the weighted strategy whenever the preconditioner is particularly sparse, often even sparser than the original matrix. Not surprisingly, this suggests that using additional dropping for a preconditioner which is already quite sparse is not a good idea. In practice, this does not really pose a problem: for these matrices, preconditioning is easy and ILUTP with the standard dropping strategy does the job satisfactorily, so there is usually no need to find a better preconditioner. Furthermore, because these preconditioners are

quite sparse, the standard strategy is significantly better only in a relative sense. In an absolute sense, the difference between the respective γ's for both strategies is often quite small, usually no more than 0.2. Hence, using a new strategy even when the standard strategy works better does not result in significantly worse results. In any case, it is generally best simply not to use a strategy other than the standard strategy for preconditioners constructed to be quite sparse. As a rule of thumb, the standard strategy should be used if τ is larger than approximately 10^{-2}. For these reasons, the results presented in the second set of tables (Tables 6, 7, and 8) are more interesting because here the results are restricted to matrices for which we have $\gamma \geq 1.5$ for S0.

TABLE 8

The results recorded in these tables seem to indicate the following:

- The strategies W0, S1, and W1 are often better than S0 for harder matrices. W0 already improves ILUTP, but W1 even more so. However, this comes at the cost of even higher setup times, and therefore it is probably better to use W0 than W1 as a general rule. Although S1 can improve ILUTP as much as W1, it is worse than S0 more often. Considering that the setup times for S1 and W1 are almost equal, W1 should be preferred. It appears that dropping fewer elements prior to calculation and some afterwards may be worthwhile if weighted dropping is performed (as for W1), but much less so if standard dropping is used (as for S1).
- As fewer elements are dropped, the differences between the various dropping strategies become less significant. This is not surprising as all dropping strategies applied to a given vector will yield more similar results if fewer elements are dropped.
- Weighted dropping appears to work particularly well for the matrices in the sets fidap and sim. The set hb58 contains a significant number of matrices which are fairly easy to precondition; hence for most matrices either strategy works well. For the harder ones, however, W0 is better, and S0 is better for the easier ones. For the set chem there are no significant differences, although for some matrices arising from chemical engineering problems, in particular the west matrices (which are recorded as part of hb58), W0 works quite well. Finally, for pde the standard strategy appears to be somewhat better. However, this set is characterized by a particularly large number of failures, suggesting that a different preconditioner should be used.

Next, we summarize the results of the specific matrices listed in Table 9 characterizing the observations mentioned in Table 10. Here, N refers to the dimension of the matrix, NNZ to the number of nonzero elements, and $\delta = \frac{\text{NNZ}}{\text{N}}$ is the average number of elements per row or column. These matrices were chosen to give an overview of the differences in performance. Hence, these results do not include matrices

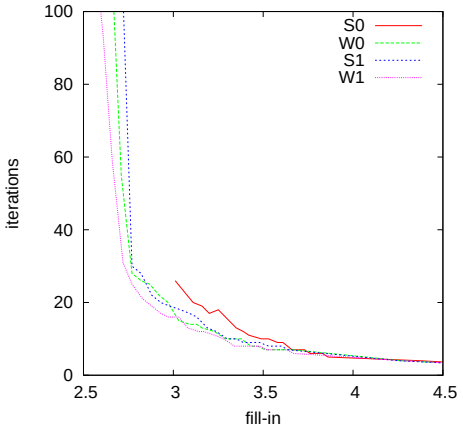
for which the strategies produce similar results and underrepresent matrices for which S0 performs worse than the other strategies.

Finally, we present timing results in Table 11 for these matrices. For these results, we tested different values of τ in order to obtain similar values for γ for each preconditioner. We attempted to choose γ in order to obtain a fairly sparse preconditioner. All timing results are recorded in seconds. A result of "NM" (not measurable) indicates that the times measured were too short to be considered accurate, usually 0.01 seconds or less. As mentioned before, if a preconditioner is fairly sparse, then implementing the weighted strategy adds little to the setup time. Whenever the preconditioner is fairly dense (i.e., $\gamma \cdot \frac{\text{NNZ}}{\text{N}}$ fairly large), the weighted dropping strategy can increase the setup time significantly. In this case, using the weighted preconditioner is only worthwhile if the iteration times decrease sufficiently or if it is used for several systems.



We conclude with a few graphical results in Figure 1 illustrating the improvements that can be obtained by using the weighted dropping strategies. These underline that

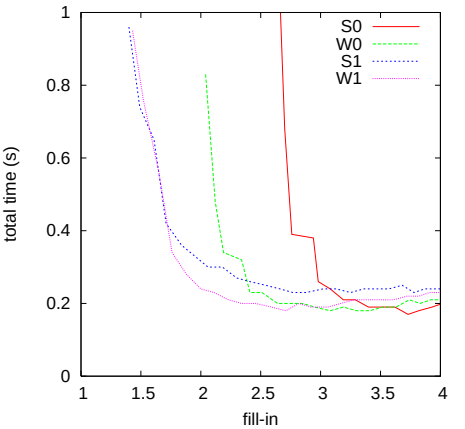
the preconditioners using weighted dropping strategies can often be constructed to be sparser than their standard counterparts and that, if a particularly sparse preconditioner is required, the iterations needed will be lower for a weighted preconditioner, but the total time to solve a system usually cannot be reduced if fill-in is chosen optimally with regard to reducing the total time. On the other hand, as the number of iterations is often reduced more effectively by a weighted strategy, the total times will usually be less if several systems are solved.



5. Conclusion. The weighted dropping strategy W0 presented in this paper is an alternative to the standard dropping method S0 usually employed in calculating the ILUTP preconditioner. W0 often yields a better preconditioner, especially for more difficult matrices. For matrices which are easy to precondition, results are often worse, so care must be taken when choosing to implement the weighted strategy. The setup times for the preconditioner are generally somewhat longer, but this additional time is often compensated for by shorter iteration times, making this strategy particularly worthwhile if the same linear system is solved for several different right-hand sides. On the other hand, the setup times for the other strategies S1 and W1 are significantly longer, making them attractive alternatives to S0 and W0 only in exceptional cases.

PRECONDITIONING LANCZOS APPROXIMATIONS TO THE MATRIX EXPONENTIAL*

JASPER VAN DEN ESHOF† AND MARLIS HOCHBRUCK†

Abstract. The Lanczos method is an iterative procedure to compute an orthogonal basis for the Krylov subspace generated by a symmetric matrix A and a starting vector v. An interesting application of this method is the computation of the matrix exponential $\exp(-\tau A)v$. This vector plays an important role in the solution of parabolic equations where A results from some form of discretization of an elliptic operator. In the present paper we will argue that for these applications the convergence behavior of this method can be unsatisfactory. We will propose a modified method that resolves this by a simple preconditioned transformation at the cost of an inner-outer iteration. A priori error bounds are presented that are independent of the norm of A. This shows that the worst case convergence speed is independent of the mesh width in the spatial discretization of the elliptic operator. We discuss, furthermore, a posteriori error estimation and the tuning of the coupling between the inner and outer iteration. We conclude with several numerical experiments with the proposed method.

Key words. matrix exponential, iterative methods, restricted rational approximation, matrix-free time integration methods, preconditioning

DOI. 10.1137/040605461

1. Introduction.

Using the matrix exponential operator in the numerical solution of large time-dependent problems has been an extensive area of research in the last few years. A key aspect of such exponential integrators is that they require the evaluation or approximation of the product of the exponential of the Jacobian with a vector. In this paper we consider the approximation of

$$y(\tau) = \exp(-\tau A)v, \qquad \|v\| = 1, \tag{1.1}$$

where A results from a finite difference or finite element discretization of an elliptic partial differential operator.

In 1978, Moler and van Loan [24] published their famous paper discussing nineteen dubious ways to compute the exponential of a matrix. Since then, Krylov subspace methods have been an important development towards tackling the problem (1.1) when the matrix A is very large and sparse. Hence the updated paper [23] mentions Krylov subspace methods as the "twentieth" method. For matrices A that stem from a self-adjoint elliptic partial differential equation, it has been shown [7, 8, 13] that Krylov approximations to $y(\tau)$ always yield superlinear error reduction with the superlinear decay starting after the number of steps exceeds $\|A\|^{1/2}$. Unfortunately, numerical experiments typically show that these error bounds are fairly sharp for these applications. This means that the computational complexity grows like $n^{1+1/d}$ for a uniform discretization of an elliptic operator on a d-dimensional cube with n spatial grid points. The aim of this paper is to present an algorithm which allows us to compute the approximation with $\mathcal{O}(n)$ operations. Speeding up the Lanczos process is

*Received by the editors March 22, 2004; accepted for publication (in revised form) January 11, 2005; published electronically January 27, 2006. This work was supported by the Deutsche Forschungsgemeinschaft.

achieved by a preconditioned operation. The emphasis in this paper is on the computation of the vector in (1.1), and we will not discuss details of the spatial discretization resulting in the matrix A. For ease of presentation, throughout this paper we assume that A is symmetric and positive semidefinite, although most of the techniques apply to discretizations of sectorial operators as well. The demand that the matrix is positive definite is not an essential restriction since indefinite matrices can easily be handled by shifting the matrix and multiplying the result with a suitable factor.

The paper is organized as follows. In section 2 we discuss the motivation for this work. The central idea in this paper is to transform the spectrum in such a way that convergence is much faster. This leads to a new method, which is proposed in section 3, consisting of an inner and outer iteration. The convergence behavior of the new method is treated in section 3.1, and termination strategies are the subject of section 4. In section 5 we discuss the tuning of the coupling between the inner and outer iteration in such a way that the overall procedure is as efficient as possible. We conclude by giving some examples of typical numerical experiments in section 6.

We have learned recently that the method proposed in this paper has been studied earlier by Moret and Novati in [25]. In that work the authors derive the method from a different point of view and consider the more general problem of approximating the matrix exponential of sectorial operators. Unfortunately, this makes it much more challenging to give insight into the behavior and properties of the method. In that sense the results in this paper supplement the work in [25] since we consider Hermitian matrices, which allows us to give a more thorough discussion. Moreover, the central question in the present paper is on how to include a preconditioner efficiently into Lanczos approximation methods for the matrix exponential, whereas in [25] the linear systems are solved with a direct method.

2. Motivation. When approximating the vector $y(\tau)$ in (1.1) for high dimensional matrices A, it becomes essential to exploit the sparsity of the matrix and the fact that only the action on a given vector is required. A standard idea is to use a polynomial approximation to the exponential function. In most cases this approach can be divided into two parts. First, there is the construction of a basis for the m-dimensional Krylov subspace. This part can often be summarized by the following matrix formulation:

$$AV_m = V_m T_m + \beta_m v_{m+1} e_m^*, \quad \text{where} \quad V_m e_1 = v. \tag{2.1}$$

The matrix T_m is upper Hessenberg, and the vector e_j denotes the jth column of the identity matrix. The second ingredient is the approximation to the product of the matrix exponential, and the vector v and is usually given by

$$y(\tau) \approx y_m(\tau) = V_m \exp(-\tau T_m) e_1. \tag{2.2}$$

Different choices for T_m lead to different polynomial approximations. The simplest choice is when T_m is defined by

$$T_m e_j = e_{j+1} \quad \text{for } j < m \quad \text{and} \quad T_m e_m = 0.$$

In this case the polynomial approximation (2.2) coincides with the standard Taylor series expansion of the matrix exponential [23, section 3]. Other attempts have been based on Chebyshev polynomials, e.g., [38], or, in the non-Hermitian case, on Faber polynomials in the complex plane, e.g., [29].

In this paper we focus on methods where (2.1) is constructed by means of the Lanczos method in which case the columns of the matrix V_m form an orthogonal basis for the Krylov subspace. The resulting method has been discussed by several authors and analyzed in various papers; see, for instance, [6, 7, 8, 10, 13, 33, 42] and [23] for a more extensive bibliography. We will refer to the vector $y_m(\tau)$ in this case as the [illegible] approximation. The advantage here is that these Lanczos approximations have a potential for exploiting the discrete nature of the spectrum of A: By interpolating the exponential in eigenvalues of A, the required degree of the polynomial approximation can be much smaller than for Chebyshev approximations where, for example, a uniform approximation is constructed on an interval containing the spectrum of A. Moreover, no a priori knowledge is required about the spectral radius of the method.

Unfortunately, when A is a discrete representation of the elliptic operator, Lanczos approximations can have two distinct drawbacks. First of all, the Lanczos method often is unsuccessful in exploiting the discrete character of the spectrum, as mentioned above. One example is when A is the usual finite difference/element discretization of a one-dimensional Poisson operator with Dirichlet boundary conditions. In this case, the eigenvalues of A coincide with the roots of a shifted and scaled Chebyshev polynomial and the Lanczos method cannot identify any eigenvalue of A quickly, e.g., [21, section 4.1]. This explains why we often observe for parabolic problems that Lanczos approximations do not require significantly fewer multiplications with the matrix than use of a polynomial approximation based on Chebyshev polynomials, whereas they do have some overhead cost compared to this method. A related issue is that convergence analysis shows that the required number of steps is proportional to $\|A\|^{1/2}$. This means that the number of operations grows faster than linearly in the number n of spatial grid points. This should be compared with the solution of an elliptic problem which can be accomplished in $\mathcal{O}(n)$ flops using multigrid techniques.

An extension of the Lanczos approximation is to somehow precondition the iterative procedure as is done when solving linear systems. This is the aim of this paper. Other attempts in this direction have been made in [4]. The main idea there is to choose a matrix $M \approx A$ (the preconditioner) for which $\exp(-\tau M)v$ is cheap to compute and to combine this with a generalized Runge–Kutta method for the solution of the differential equation for the defect. It should also be mentioned that for the solution of parabolic partial differential equations, the idea of preconditioning the time-differencing is not new. Two important developments in this area are parabolic multigrid methods [12] and methods based on waveform relaxation, e.g., [15].

3. Preconditioning Lanczos approximations. The exponential function is a quickly decaying function. This implies that the vector $\exp(-\tau A)v$ is mostly determined by the smallest eigenvalues and their corresponding invariant subspaces. Recall again that the Lanczos method does not necessarily utilize this since the first eigenvalues (and their eigenvectors) are difficult to find. This suggests that we should transform the spectrum in such a way that the Lanczos method can quickly find these eigenpairs. The simplest idea is to apply the Lanczos method to the matrix $(I+\gamma A)^{-1}$ (with $\gamma > 0$) which emphasizes the eigenvalues of importance. The Lanczos relation for the spectrally transformed matrix reads

$$(3.1) \quad (I+\gamma A)^{-1} V_m = V_m T_m + \beta_m v_{m+1} e_m^*, \quad \text{where} \quad V_m e_1 = v \text{ and } V_m^* V_m = I.$$

We define the function

$$f_\gamma^\tau(t) = \exp((1-t^{-1})\tau/\gamma) \quad \text{for } t \in (0,1], \quad f_\gamma^\tau(0) = 0,$$

and note that $f_\gamma^\tau((I+\gamma A)^{-1}) = \exp(-\tau A)$. As an approximation to $y(\tau)$ we use

$$y_m(\tau) = V_m f_\gamma^\tau(T_m)e_1 = V_m \exp(-\tau \widetilde{T}_m)e_1, \quad \widetilde{T}_m = \frac{1}{\gamma}(T_m^{-1} - I).$$

It is well known that the Lanczos method usually quickly finds approximations to the eigenvalues that are in some sense nicely separated from the other eigenvalues in the spectrum. A quantitative measure that expresses this separation is the ratio between the eigenvalue spread and gap. For the invariant subspace that corresponds to the smallest eigenvalue, this quantity is given by

$$\frac{\lambda_n - \lambda_1}{\lambda_2 - \lambda_1}, \tag{3.2}$$

where λ_1, λ_2, and λ_n denote, respectively, the smallest, second smallest, and largest eigenvalue of A. This quantity appears in upper bounds on the convergence speed of the Lanczos method for finding eigenpairs; see, e.g., [17]. On the other hand, for the transformed system the ratio of the eigenvalue spread and gap of the invariant subspace corresponding to the smallest (positive) eigenvalue of the transformed system is bounded by

$$\frac{(1+\gamma\lambda_1)^{-1} - (1+\gamma\lambda_n)^{-1}}{(1+\gamma\lambda_1)^{-1} - (1+\gamma\lambda_2)^{-1}} \leq \frac{(1+\gamma\lambda_1)^{-1}}{(1+\gamma\lambda_1)^{-1} - (1+\gamma\lambda_2)^{-1}} = \frac{1+\gamma\lambda_2}{\gamma(\lambda_2 - \lambda_1)}.$$

The first expression follows directly from (3.2) by plugging in the transformed eigenvalues. When A stems from an appropriate discretization of an elliptic operator, then the eigenvalues λ_1 and λ_2 approach the eigenvalues of the elliptic operator when the accuracy of the spatial discretization increases. As a consequence this ratio does not become arbitrarily large when the size of the matrix A increases as a result of decreasing the mesh width in the spatial discretization. For example, for the already mentioned one-dimensional Poisson operator with Dirichlet boundary conditions the spread/gap ratio for the smallest invariant subspace of the continuous operator is unbounded since the spread of the spectrum is infinite. On the other hand, the spread/gap ratio for the transformed spectrum can be bounded by $(1+\gamma 4\pi^2)/(3\gamma\pi^2)$.

The practical importance of these observations is that a good approximation to the leading invariant subspaces can in turn speed up the convergence of the method in a way that is analogous to what is often witnessed for the conjugate gradient method [41]. Our hope is that, due to the spectral transformation, the Lanczos method is more effectively able to exploit the discrete nature of an important part of the spectrum.

Finally, we mention that in our [illegible] Lanczos method we have to invert a fairly standard elliptic operator in every step. This can be done efficiently by very effective preconditioned methods that can be found in the literature. This is exploited in our numerical experiments in section 6. The idea of this paper is to incorporate preconditioning in the Lanczos method by using it to accomplish a spectral transformation that results in more favorable convergence speed at the cost of an inner-outer iteration. We will further investigate this in the coming sections.

3.1. A priori error estimation. The Lanczos approximations are given by

$$V_m f_\gamma^\tau(T_m)e_1 = p((I+\gamma A)^{-1})v = (I+\gamma A)^{-(m-1)}q(A)v, \quad p, q \in \Pi_{m-1}.$$

The space Π_{m-1} is the space of all polynomials of degree $m-1$ or less. Our method can be alternatively characterized as constructing iterates from the class of [illegible]

rational approximations defined by

$$\mathcal{R}_i^j = \left\{ p(t)(1+\gamma t)^{-i} \,|\, p \in \Pi_j \right\}.$$

This shows that the Lanczos approximations now are matrix rational approximations to $\exp(-\tau t)$ with all poles fixed at $-1/\gamma$. In the present section we will exploit this viewpoint to get more insight into the impact of our spectral transformation on the convergence speed, and we will neglect the discrete nature of the spectrum. We define

$$E_i^j(\gamma) := \inf_{r \in \mathcal{R}_i^j} \sup_{t \geq 0} |r(t) - \exp(-t)|. \tag{3.3}$$

We can now easily derive the following result.

LEMMA 3.1. [illegible] $A - \mu I$ [illegible]

$$\|V_m f_\gamma^\tau(T_m) e_1 - \exp(-\tau A) v\| \leq 2 \exp(-\tau\mu) E_{m-1}^{m-1}(\widetilde{\gamma}) \quad [illegible] \quad \widetilde{\gamma} = \frac{\gamma}{\tau(1+\gamma\mu)}.$$

[illegible]. The eigenvalues of A are all larger than μ, and as a direct consequence of [33, Lemma 4.1] we have that

$$\begin{aligned}
\|V_m f_\gamma^\tau(T_m) e_1 - \exp(-\tau A) v\| &\leq 2 \inf_{p \in \Pi_{m-1}} \sup_{t \in (0, (1+\gamma\mu)^{-1}]} |f_\gamma^\tau(t) - p(t)| \\
&= 2 \inf_{p \in \Pi_{m-1}} \sup_{t \in (0,1]} \left| f_\gamma^\tau\left(\frac{t}{1+\gamma\mu}\right) - p(t) \right| \\
&= 2 \inf_{p \in \Pi_{m-1}} \sup_{t \in (0,1]} \left| \exp(-\mu\tau) \exp\left(\left(1 - \frac{1}{t}\right) \frac{\tau(1+\gamma\mu)}{\gamma} \right) - p(t) \right| \\
&= 2 \exp(-\mu\tau) E_{m-1}^{m-1}(\widetilde{\gamma}). \qquad \square
\end{aligned}$$

It is important to stress that this error estimate is independent of the norm of A and only the first (smallest) eigenvalue of A plays a modest role in the form of μ. We also see that the restriction of A to positive semidefinite matrices is too stringent since reasonable upper bounds are obtained if the spectrum is bounded from below by a modest constant.

A priori error bounds for the proposed method can be obtained by estimating $E_{m-1}^{m-1}(\widetilde{\gamma})$. A good choice for $\widetilde{\gamma}$ automatically leads to a good choice for γ (if τ and a reasonable estimate for μ are known). Therefore we want to derive upper bounds to (3.3) where we, without loss of generality, assume that $\tau = 1$ and $\mu = 0$, which leads to $\widetilde{\gamma} = \gamma$. Our attempts for bounding this quantity have resulted in upper bounds which are too pessimistic. However, some insight can be obtained by considering the asymptotic situation for $m \to \infty$. The use of the class $\mathcal{R}_j^{j-1}$ to approximate $\exp(-t)$ for $t \in [0, \infty)$ is discussed by Saff, Schönhage, and Varga [34]. The authors' analysis implies that the best shift is given by $\gamma = 1/j$, which was shown to lead to geometric convergence with an asymptotic decay rate between $1/5.828$ and $1/2$. This result was later sharpened by Andersson [1], who showed the following result.

THEOREM 3.2 (Andersson [1]). [illegible] γ [illegible] $\sqrt{2}/j$ [illegible]

$$\lim_{j \to \infty} \left(E_j^j(\sqrt{2}/j) \right)^{1/j} = \frac{1}{\sqrt{2}+1}.$$

Hence, the value of γ should ideally be chosen to be inversely proportional to the number of Lanczos steps. Our shift-and-invert strategy requires a fixed a priori chosen value of γ. In this case we cannot expect linear convergence. Based on work in [34] we can show the following result.

THEOREM 3.3. [illegible] $0 < \gamma < 1$ [illegible]

$$\left(E_j^{j-1}(\gamma)\right)^{1/\sqrt{j}} \leq \kappa_j, \quad \text{[illegible]} \quad \lim_{j\to\infty} \kappa_j = \exp\left(-\sqrt{\frac{2(1-\gamma)}{\gamma}}\right).$$

[illegible]. Equations (3.4) and (3.14) in [34] are

$$E_j^{j-1}(\gamma) \leq \sqrt{2}\rho_{j-1}(1/\gamma), \tag{3.4}$$

where

$$\rho_{j-1}(1/\gamma)^2 < \frac{1}{2}\exp(1/\gamma)\int_0^\infty \exp(-s/\gamma)\left(\frac{s}{s+1}\right)^{2j-2}\omega_j(s)ds$$

and

$$\omega_j(t) = \frac{(j+1)(2j+1)t^2}{(1+2t)(1+t)} + \frac{(4j+5)t^4}{(1+2t)^2(1+t)} + \frac{4t^6}{(1+2t)^3(1+t)}.$$

We have

$$\omega_j(t) \leq \frac{t^2}{(1+t)^2}\overline{\omega_j}(t), \qquad \overline{\omega_j}(t) := (j+1)(2j+1) + \frac{4j+5}{4}t + \frac{1}{2}t^2.$$

Using the identity $\exp(-s/\gamma) = \exp(-s/\gamma + s)\exp(-s)$ and the mean value theorem we obtain

$$\begin{aligned}\rho_{j-1}(1/\gamma)^2 &< \frac{1}{2}\max_{t\geq 0}\left\{\exp\left(\frac{1-t}{\gamma}+t\right)\left(\frac{t}{t+1}\right)^{2j}\right\}\int_0^\infty \exp(-s)\overline{\omega_j}(s)ds \\ &\leq \max_{t\geq 0}\exp(\psi_j(t))\left(j^2+2j+\frac{13}{8}\right) \\ &\leq 5j^2\max_{t\geq 0}\exp(\psi_j(t))\end{aligned}$$

with

$$\psi_j(t) = \frac{1}{\gamma}(1-t) + t + 2j(\log(t) - \log(t+1)).$$

We find that

$$\max_{t\geq 0}\psi_j(t) = \frac{1}{2\gamma}\left(3 - D_j - \gamma + 4j\gamma\log\left(-\frac{\gamma - 1 + D_j}{\gamma - 1 - D_j}\right)\right) =: \overline{\psi_j},$$

with $D_j = \sqrt{(1-\gamma)(8j\gamma - \gamma + 1)}$ (the maximum is attained at $t = \frac{1}{2}(-1 + \frac{D_j}{1-\gamma})$).

Taking the limit of $\overline{\psi_j}/\sqrt{j}$ for $j \to \infty$ and using (3.4) provides the desired result. □

In our context we are interested in approximations where the degree is modest. In the absence of insightful analytical estimates, we have decided to give numerical

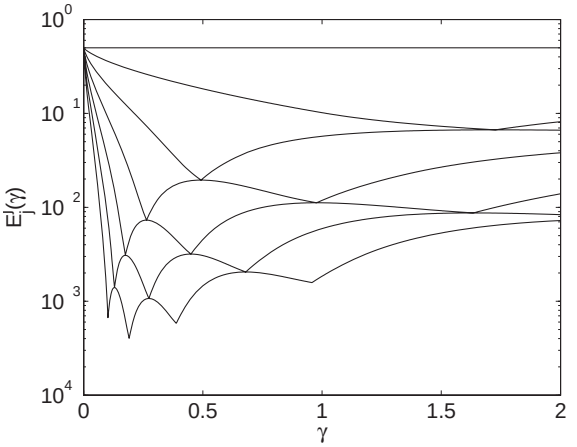

FIG. 3.1. $E_j^j(\gamma)$ *as a function of* γ *for* $j = 0, \ldots, 6$.

TABLE 3.1
Numerical approximations to the optimal value of γ, γ_{opt}, *and the corresponding value* $E_j^j(\gamma_{opt})$.

approximations to the values of $E_{m-1}^{m-1}(\gamma)$ and, more interestingly, the location of the optimal value of γ, that is, the value that minimizes $E_{m-1}^{m-1}(\gamma)$. These results can be obtained using the Remez method, e.g., [31, section 1.3], by constructing the optimal polynomial approximation to $f_\gamma^1(t)$ on the interval $[0, 1]$. See the proof of Lemma 3.1 for more details.

In Figure 3.1 we have plotted $E_{m-1}^{m-1}(\gamma)$ as a function of γ for seven different values of m. This shows a very interesting pattern that is summarized by the following observation.

CONJECTURE 3.1. [illegible] $E_{j-1}^{j-1}(\gamma)$ [illegible] $j = \{2, 3, \ldots\}$ [illegible] $j - 1$ [illegible] [illegible] $E_j^j(\gamma)$ [illegible] $E_{j-1}^{j-1}(\gamma)$ [illegible] $E_j^j(\gamma)$

If the curve $E_j^j(\gamma)$ has a local minimum, this appears to coincide with the fact that the error curve for the polynomial approximation at this point seems to have one additional alternation point. In Table 3.1 the optimal value of γ and the corresponding error have been reported. We used a straightforward search algorithm for this in combination with Remez approximations.

As mentioned previously we must choose our shift γ before we start our iterative procedure. Changing it during the process is too expensive. Although this appears

to be a drawback from a theoretical point of view, in practice this is no problem since the required precision is known beforehand. For instance, if one is interested in a precision of about 10^{-5} one can consider Table 3.1 and decide to choose $\gamma = 0.119\tau$, since this γ minimizes our upper bound from Lemma 3.1.

3.2. Discussion. One might wonder if there is anything to gain by using different real shifts in the Lanczos method, that is, if it pays to construct an approximation from the class

$$\widetilde{\mathcal{R}}_i^j = \left\{ p(t) \prod_{i=1}^{i} (1 + \gamma_i t)^{-1} \,|\, p \in \Pi_j \right\}, \quad \text{where } \gamma_i \in \mathbb{R}.$$

Using different shifts in a Lanczos method can be facilitated by rational Krylov methods [32]. Interestingly enough, it was conjectured in two independent papers [19, 22] that the optimal approximation from $\widetilde{\mathcal{R}}_i^j$ is also contained in $\mathcal{R}_i^j$. This conjecture was later shown to be true [2, Theorem 1]. If one is willing to work with quadratic factors, or linear factors with complex shift, one can consider using Chebyshev rational approximations. A comparison for solving linear parabolic equations between the Crank–Nicolson method and using a Chebyshev rational approximation can be found in [5].

Using optimal restricted rational approximations on the negative real axis to approximate the exponential function for solving semidiscretized parabolic differential equations is discussed in [34, p. 319]. The authors emphasize the computational advantages when only shifted systems with constant real shifts have to be solved. Many other rational approximations, for example, Chebyshev rational approximations and the diagonal elements of the Padé table, cannot be factored into linear factors with real coefficients. Restricted rational approximations to the matrix exponential of Padé type have been used by Nørsett and Trickett [26, 27, 28]; see also the paper by Van Iseghem [43]. These rational approximations play an important role in the development of so-called semi-implicit diagonal Runge–Kutta methods, which are attractive since in one step of the method only systems have to be inverted with a constant real shift. In [16] explicit expressions for the restricted rational approximations are derived that interpolate the exponential function in an equispaced mesh. It is shown by a numerical example that rational interpolations are better suited for approximating the matrix exponential than restricted Padé approximations when A originates from a Poisson operator. The main difference between all these techniques and the method considered in this paper is that the use of the Lanczos method allows us to exploit the favorable eigenvalue spectrum of the transformed matrix as discussed previously. This will become clear when we discuss numerical examples in section 6.

The proposed method in this paper is also related to the work on Krylov subspaces in [9], where the authors are interested in Krylov subspaces for A extended by a Krylov subspace generated by A^{-1}. They show that these subspaces have a superior approximation quality (although they consider a different function class). One essential difference is that, in the present paper, we work with shifted inverses and, considering the results in the previous section, we mention that this is pivotal. Also, the a priori error bounds presented in [9] depend on the condition number of the matrix A. Finally, a difference is that we are interested in preconditioned solvers for the solution of linear systems. We will discuss this further in section 5.

4. A posteriori error estimation. In this section we consider strategies for terminating the shift-and-invert Lanczos process as soon as $y_m(\tau)$ is within a predefined

distance to the sought-after vector. To this purpose we first derive an explicit expression for the error. In practice this relation cannot be evaluated exactly. Subsequently we will discuss a few ideas to come to practical error estimators.

By rewriting (3.1) we find that

$$V_m T_m^{-1} = (I + \gamma A)V_m + \beta_m \widetilde{v}_{m+1} z_m^*, \quad \widetilde{v}_{m+1} = (I + \gamma A)v_{m+1}, \quad z_m = T_m^{-1} e_m.$$

Hence, we obtain the following relation:

$$AV_m = V_m \widetilde{T}_m - \frac{\beta_m}{\gamma} \widetilde{v}_{m+1} z_m^*, \quad \widetilde{T}_m = \frac{1}{\gamma}(T_m^{-1} - I). \tag{4.1}$$

Using this relation we see that our approximation satisfies

$$\begin{aligned} y_m'(t) &= -V_m \widetilde{T}_m \exp(-t\widetilde{T}_m) e_1 = -A y_m(t) + g_m(t), \\ g_m(t) &= -\frac{\beta_m}{\gamma} \widetilde{v}_{m+1} z_m^* \exp(-t\widetilde{T}_m) e_1, \end{aligned}$$

with $y_m(0) = v$, whereas the exact solution fulfills

$$y'(t) = -Ay(t), \qquad y(0) = v.$$

We define $e_m(t) = y_m(t) - y(t)$ and get

$$e_m'(t) = -Ae_m(t) + g_m(t), \quad e_m(0) = 0. \tag{4.2}$$

Finally, an explicit expression for the error follows by writing down the solution of this ODE using variation of constants, which yields

$$\begin{aligned} e_m(\tau) &= \int_0^\tau \exp(-(\tau - t)A) g_m(t)\, \mathrm{d}t \\ &= -\frac{\beta_m}{\gamma} \int_0^\tau \exp(-(\tau - t)A) \widetilde{v}_{m+1} z_m^* \exp(-t\widetilde{T}_m) e_1\, \mathrm{d}t \end{aligned} \tag{4.3}$$

or, equivalently,

$$e_m(\tau) = -\frac{\beta_m}{\gamma} X_m v_{m+1}, \tag{4.4}$$

where

$$X_m := \int_0^\tau e_m^* (I + \gamma \widetilde{T}_m) \exp(-t\widetilde{T}_m) e_1 \exp(-(\tau - t)A)(I + \gamma A)\, \mathrm{d}t. \tag{4.5}$$

Hence, the error is determined by the norm of the operator X_m. Unfortunately, the precise size of the error is hard to assess through (4.3) since this quantity is difficult to evaluate. In the remainder of this section we focus on practical error estimators.

We substitute

$$\exp(-(\tau - t)A) = I - (\tau - t)A + \frac{1}{2}(\tau - t)^2 A^2 + \cdots$$

in (4.3) and obtain

$$e_m(\tau) = -\frac{\beta_m}{\gamma} \int_0^\tau \left(I - (\tau - t)A + \frac{1}{2}(\tau - t)^2 A^2 + \cdots \right) \widetilde{v}_{m+1} z_m^* \exp(-t\widetilde{T}_m) e_1\, \mathrm{d}t.$$

By defining the functions

$$\phi_j(-\tau A) = \frac{1}{(j-1)!}\int_0^\tau (\tau - t)^{j-1}\exp(-tA)\,\mathrm{d}t, \tag{4.6}$$

we get the following result.

LEMMA 4.1. [illegible] $e_m(\tau)$ [illegible]

$$e_m(\tau) = -\frac{\beta_m}{\gamma}\sum_{j=0}^{\infty} z_m^* \phi_{j+1}(-\tau\widetilde{T}_m)e_1(-A)^j(I+\gamma A)v_{m+1}. \tag{4.7}$$

By partial integration it can be shown that the ϕ-functions can be computed by means of a simple recursion. This series is similar to the one given in [33] for standard Lanczos approximations. A practical error estimator follows by taking only the first summand of the series:

$$\|e_m(\tau)\| \approx \frac{\beta_m}{\gamma}|z_m^*\phi_1(-\tau\widetilde{T}_m)e_1|\,\|(I+\gamma A)v_{m+1}\|. \tag{4.8}$$

More advanced strategies can be taken as in the software package [35] for the standard Lanczos approximation which is based on the analogous expansion in [33]. We will not follow this direction.

Our derivation of (4.7) immediately suggests alternative approximations to the error by using more advanced approximations than the Taylor series expansion, e.g., using Chebyshev series, or again by Lanczos approximations. We can substitute, for instance, into (4.3) the following approximation:

$$(I+\gamma A)\exp(-(\tau-t)A)v_{m+1} \approx V_{m+j}(I+\gamma\widetilde{T}_{m+j})\exp(-(\tau-t)\widetilde{T}_{m+j})e_{m+1}.$$

The obvious advantage of this approximation is that the error estimator only requires information that is already computed in the Lanczos process, so there is no additional work necessary. Not surprisingly, it is very easy to see that with this substitution the norm of (4.3) is equal to $\|y_{m+j}(\tau) - y_m(\tau)\|$.

Estimating the error by the difference of two (consecutive) approximations is straightforward and simple; however, it has some less appealing properties. For example, stagnation of the process leads to excessively optimistic error estimates. In our practical experience with the presented method, no problems were encountered if γ is sensibly chosen and therefore convergence is fast enough. A different problem occurs in the first few steps where we see that $\|y_m(\tau)\| \ll \|y(\tau)\|$, which can be explained by the fact that the eigenvalues of $\widetilde{T}_m$ are far from the smallest eigenvalue of A. Numerical experience shows that an effective upper bound for the [illegible] error in step m is given by

$$\delta_m = \frac{\|y_m(\tau) - y_{m-j}(\tau)\|}{\|y_m(\tau)\|}.$$

With this assumption we have that $\|y(\tau)\| \lesssim \delta_m\|y(\tau)\| + \|y_m(\tau)\|$ and we correct the error estimator as follows:

$$\|e_m(\tau)\| \lesssim \frac{\delta_m}{1-\delta_m}\|y_m(\tau)\|. \tag{4.9}$$

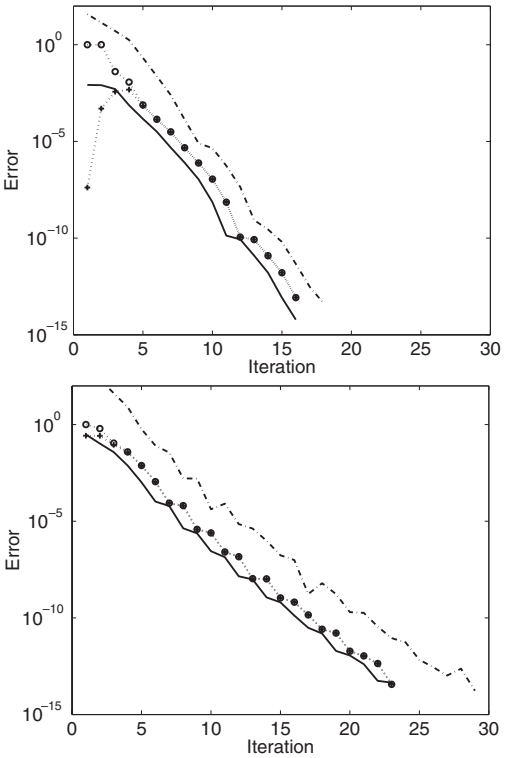

FIG. 4.1. *Error of the shift-and-invert Lanczos approximation (solid) and the error estimators* (4.8) *(dash-dot),* (4.9) *(o), and the difference of two iterates (+). In both pictures* $\gamma = \tau/10$. *Top picture:* $\tau = 1/5$*; bottom picture:* $\tau = 1/100$.

A trivial upper bound is $\|e_m(\tau)\| \leq 1 + \|y_m(\tau)\|$. In our experiments, we take the minimum of this bound and (4.9) as an error estimator to circumvent very large error estimates in the first steps. Furthermore, in all our experiments we have taken j to be equal to one.

The corrected estimator (4.9) turns out to be very effective in experiments and we will now demonstrate this with a simple example. The matrix A is a central finite difference discretization with 30 grid points in both directions of the Poisson operator on the unit square with homogeneous Dirichlet boundary conditions. Figure 4.1 illustrates that for $\tau = 1/5$ estimating the error by the difference of two iterates can lead to overly optimistic estimates in the start. This behavior is corrected by (4.9). Typically we see that the estimator starts in the neighborhood of one and after a few iterations it quickly decreases as more information on the norm of the error becomes available. We remark that these two figures demonstrate some interesting properties of the convergence of the proposed method; we will discuss this in detail in section 6.

5. Tuning the inner-outer iteration. We want to compute an approximation $y_m(\tau)$ which is at an absolute distance of about ϵ from the true vector. In step j of the shift-and-invert Lanczos process we have to solve a linear system involving an elliptic operator. If this is accomplished using an iterative solver, we have to prescribe

a constant η_j that determines the precision for this inner solve, that is,

$$\|r_j\| \le \eta_j \quad \text{with} \quad r_j = v_j - (I + \gamma A)c_j. \tag{5.1}$$

The vector c_j is the approximate solution of the linear system. In this section we look in more detail at the influence of these inaccuracies on the Lanczos approximation. Numerical experiments show that the sensitivity towards these errors in the Lanczos process is similar to that witnessed in other applications of the Lanczos method where matrix-vector products are perturbed. A precise error analysis, however, turns out to be very challenging, and we restrict ourselves to more heuristical arguments here.

The errors in the solution of the linear systems in (5.1) result in a perturbed Lanczos relation (3.1) which after some manipulation can be recast as a perturbed form of (4.1):

$$AV_m = V_m \widetilde{T}_m - \frac{\beta_m}{\gamma} \widetilde{v}_{m+1} z_m^* - \frac{1}{\gamma} F_m T_m^{-1}. \tag{5.2}$$

Here, the jth column of the matrix F_m equals the residual of the linear system that is solved in the jth step of the Lanczos process; in other words, we have $F_m e_j = r_j$. We warn the reader that the tridiagonal matrix T_m and the matrix V_m in this relation are different from the tridiagonal matrix generated by the Lanczos method in the error-free case. For instance, there is no guarantee that the matrix V_m is orthogonal. Another source of errors is rounding errors resulting from the use of floating point arithmetic. Since these errors are typically many orders of magnitude smaller than the approximation errors introduced in the solution of the shifted systems, we will neglect rounding errors. Using the relation (5.2) and reasoning along the same lines as in the previous section, we find the following bound for the error:

$$\|e_m(\tau)\| \le \frac{\beta_m}{\gamma} \|X_m v_{m+1}\| + \frac{1}{\gamma} \left\| \int_0^\tau \exp(-(\tau - t)A) F_m T_m^{-1} \exp(-t\widetilde{T}_m) e_1 \, \mathrm{d}t \right\|.$$

The matrix X_m is again as defined in (4.5). If we assume that $\eta_j = \epsilon$, and therefore $\|r_j\| \le \epsilon$, then a crude estimate for the second quantity is given by

$$\frac{1}{\gamma} \left\| \int_0^\tau \exp(-(\tau - t)A) F_m T_m^{-1} \exp(-t\widetilde{T}_m) e_1 \, \mathrm{d}t \right\| \le \|T_m^{-1} e_1\| \frac{\sqrt{m}\tau}{\gamma} \epsilon.$$

Here we have used the Cauchy–Schwarz inequality. This shows that

$$\|e_m(\tau)\| \le \frac{\beta_m}{\gamma} \|X_m v_{m+1}\| + \|(I + \gamma \widetilde{T}_m) e_1\| \frac{\sqrt{m}\tau}{\gamma} \epsilon. \tag{5.3}$$

We see that in the first few iterations the first term is the dominating quantity and, in fact, determines the convergence behavior of the perturbed method. Standard practice would be to view the first term in (5.3) as the error computed by an exact Lanczos process on a nearby matrix. This is a common approach in the analysis of perturbed Lanczos methods; see, for instance, [6]. Unfortunately, this idea does not easily carry over to the method of the present paper since the matrix X_m defined by (4.5) depends not only on the tridiagonal matrix T_m but also on the original matrix A.

As an alternative we focus on the expansion in Lemma 4.1 and in particular the quantities $z_m^* \phi_{j+1}(-\tau \widetilde{T}_m) e_1$ as a function of the iteration number m. We assume that for all m, the eigenvalues of T_m are contained in an interval $(0, \alpha]$. In practice the

positive definiteness of the tridiagonal matrix T_m can be guaranteed by using a version of the Lanczos method based on coupled recurrences in combination with solving the linear systems by the conjugate gradient method. Bounds on the eigenvalues of the tridiagonal matrix T_m generated by a perturbed Lanczos process can be found in [30]. For every polynomial $p \in \Pi_{m-2}$, we have

$$\begin{aligned} |z_m^* \phi_{j+1}(-\tau \widetilde{T}_m) e_1| &= |e_m^* (T_m^{-1} \phi_{j+1}(-\tau \widetilde{T}_m) e_1 - p(T_m)) e_1| \\ &\leq \inf_{p \in \Pi_{m-2}} \sup_{t \in (0,\alpha]} |\tfrac{1}{t} \phi_{j+1}(\tfrac{\tau}{\gamma}(1 - \tfrac{1}{t})) - p(t)|. \end{aligned}$$

This suggests that the coefficients in the expansion (4.8) decrease as a function of m with our assumption on the eigenvalues of the tridiagonal matrices. This argument confirms the observation that the vector $\|X_m v_{m+1}\|$ gets many orders of magnitude smaller than ϵ before it stagnates. As a consequence, this means that in the end the attainable precision of the method is essentially bounded by the second term in (5.3), and we have argued that the method can achieve a final precision of $\mathcal{O}(\epsilon)$ when all linear systems are solved with a fixed residual precision of ϵ.

There are some recent research efforts in the analysis of the effect of approximate matrix-vector products on Krylov subspace methods, e.g., [3, 11, 36, 39]. These works show that when solving linear systems or computing eigenvectors by means of a Krylov subspace method, accurate approximations to the matrix-vector product are necessary in the first iterations, but this precision can be relaxed as the method converges. It is interesting to see if such strategies can be extended to the current context where inexact matrix-vector products result from the errors in the solution of the shifted systems.

A key issue of the analysis in [11, 36, 39] is that the computed vector in the approximation subspace has a decreasing pattern. Suppose that after m steps of the error-free method we have computed an approximation that is sufficiently accurate, i.e., $\|y_m(\tau) - y(\tau)\| \leq \epsilon$. We have the following for the component of the solution in the direction of the vector $v_j = V_m e_j$:

$$\begin{aligned} |v_j^* y_m(\tau)| &\leq |v_j^*(y_m(\tau) - y(\tau))| + |v_j^* y(\tau)| \\ &\leq \epsilon + \|(I - V_{j-1} V_{j-1}^*) y(\tau)\| \leq \epsilon + \|e_{j-1}(\tau)\|. \end{aligned}$$

In the last step we have assumed that the iterate from step $j-1$ is approximately equal to the optimal approximation from the $(j-1)$th Krylov subspace. Intuitively, this shows that the errors in the Lanczos process in the first steps have a relatively large impact since the solution lies mainly in the direction of the first Lanczos vectors. For this reason, we propose the following strategy for controlling the tolerances of the linear systems:

$$\eta_j = \frac{\epsilon}{\|e_{j-1}(\tau)\| + \epsilon}. \tag{5.4}$$

Practical strategies result from replacing $\|e_{j-1}(\tau)\|$ in (5.4) with a suitable upper bound as discussed in the previous section, for instance, (4.9). Following nomenclature from [3] we will refer to (5.4) as a [illegible] strategy for the remainder of this paper. In the current context such a strategy turns out to be much harder to analyze than for linear systems due to the nonlinear character. Nevertheless, this strategy worked very satisfactorily in all our numerical experiments. We will give an example of this in section 6.1.

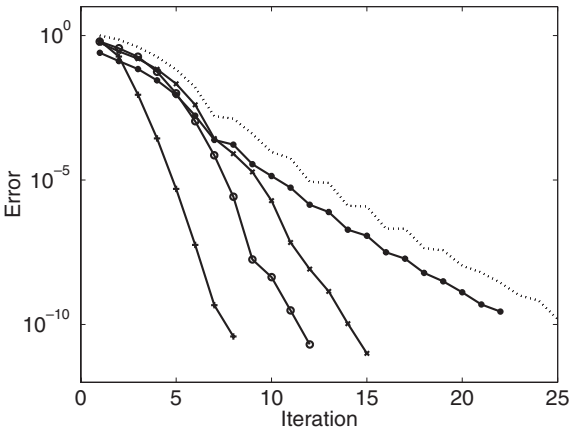

FIG. 6.1. *Error as a function of the number of iterations for* $\tau = 1/2$ *(+),* $\tau = 1/20$ *(o),* $\tau = 1/50$ *(×),* $\tau = 1/2000$ *(•), and the upper bound from Lemma* 3.1 *(dotted).*

6. Numerical experiments. In this section we discuss some numerical experiments that are typical of our experiences with the presented method. All experiments are conducted in MATLAB. The purpose of our first experiment is to illustrate properties of the convergence behavior of the new method. The matrix A results from a simple central finite difference discretization of the one-dimensional Poisson operator with periodic boundary conditions. Although this matrix is of little practical importance, it leads to representative results and, more importantly, it allows us to compute the true solution with a fast Fourier transform for comparison purposes. Moreover, the smallest eigenvalue of this matrix is zero, which means that the norms of the true solutions are not very sensitive to the choice of τ. The dimension of the matrix is 10^5 and in all experiments in this section we take $\gamma = \tau/10$. This latter choice is not necessarily optimal. However, using this fixed strategy in all experiments shows that the method is not very sensitive towards a very precise choice for γ. Notice that the traditional Lanczos approximation is not an option here since upper bounds suggest, and experiments often show, that for one-dimensional elliptic operators convergence starts after the number of iteration steps is almost equal to the number of spatial grid points. The results of our numerical experiments are reported in Figure 6.1, where we have included as a reference the upper bound from Lemma 3.1.

Interestingly, the number of Lanczos iterations increases when τ becomes smaller. An explanation lies in the fact that for larger values of τ a relatively small portion of the eigenvalues essentially determines the final vector. Due to the nice separation of these eigenvalues, as discussed in section 3, Krylov subspaces quickly come to contain approximations to the corresponding invariant subspaces and therefore only a few iteration steps are required. When τ decreases, loosely speaking, more and more eigenvalues determine the final result and a more uniform approximation is more effective then. This shows that the Lanczos approximation indeed takes advantage of the nice eigenvalue distribution of the transformed system, and it shows that convergence might be much faster than is expected from treating the problem as a uniform approximation problem on an unbounded interval as we did in our upper bounds in section 3.1.

6.1. The impact of errors in the solution of the linear systems. In the remainder of this section we take as a model equation the parabolic partial differential equation in two spatial dimensions:

$$\frac{\partial}{\partial t}u(t,x,y) = \mathcal{L}u(t,x,y), \quad (x,y) \in \Omega = (0,1)^2, \quad 0 \le t \le \tau, \tag{6.1}$$

subject to the initial condition

$$u(0,x,y) = u_0(x,y).$$

The operator $\mathcal{L}$ is a self-adjoint linear second-order elliptic operator,

$$\mathcal{L} = \frac{\partial}{\partial x}a(x,y)\frac{\partial}{\partial x} + \frac{\partial}{\partial y}b(x,y)\frac{\partial}{\partial y} + c(x,y), \tag{6.2}$$

with time-independent boundary conditions. The matrix A originates from discretizing the operator $\mathcal{L}$ using central finite differences on a square grid.

We investigate the impact of errors in the solution of the shifted systems (the inner iteration) on the final accuracy of the overall method. Therefore we have experimented with two choices of η_j in (5.1): taking $\eta_j = \epsilon$ (fixed) and the relaxation strategy given by (5.4) in section 5. For the latter strategy we have replaced the norm of the error by the approximation given by (4.9). Moreover, the Lanczos process was terminated as soon as this quantity dropped below ϵ. The matrix A stems from discretizing the operator $\mathcal{L}$ in (6.2) with

$$a(x,y) = 1 + y - x, \quad b(x,y) = 1 + x + x^2, \quad c(x,y) = 0,$$

and homogenous Dirichlet boundary conditions on the western and eastern boundaries and a homogenous Neumann boundary condition on the northern and southern boundaries of the domain. For the discretization of the operator we have used 40 grid points in both directions, which still allows us to compute the true solution with a dense method for comparison purposes. We are interested in a precision of $\epsilon = 10^{-6}$.

The results of our numerical experiments are summarized in Table 6.1. The shifted linear systems are solved with the conjugate gradient method (CG) preconditioned by a standard incomplete LU preconditioner. In the next section we use more advanced and effective preconditioners. As a measure for the total amount of work we have reported the total number of applications of the ILU preconditioner in the inner iterations and the number of outer iterations. Moreover, we have included the error of the computed approximation at termination as well as the error estimated at this point by (4.9).

TABLE 6.1
Numerical results for $\gamma = \tau/10$.

	Fixed			Relaxed		
τ	In./out.	Error	Estimate	In./out.	Error	Estimate
1	228/5	$3.8 \cdot 10^{-8}$	$3.9 \cdot 10^{-7}$	152/5	$3.7 \cdot 10^{-8}$	$4.0 \cdot 10^{-7}$
1/5	348/10	$6.5 \cdot 10^{-8}$	$3.1 \cdot 10^{-7}$	230/10	$1.9 \cdot 10^{-7}$	$3.1 \cdot 10^{-7}$
1/10	326/12	$2.3 \cdot 10^{-7}$	$8.9 \cdot 10^{-8}$	202/12	$5.7 \cdot 10^{-7}$	$9.6 \cdot 10^{-8}$
1/50	182/13	$8.2 \cdot 10^{-7}$	$7.0 \cdot 10^{-7}$	114/13	$8.9 \cdot 10^{-7}$	$7.0 \cdot 10^{-7}$
1/100	140/14	$1.2 \cdot 10^{-6}$	$2.3 \cdot 10^{-7}$	82/14	$1.3 \cdot 10^{-6}$	$2.1 \cdot 10^{-7}$

The table shows that in all cases we achieve the required precision of about 10^{-6}. The use of a relaxation strategy as opposed to using a fixed precision for the inner

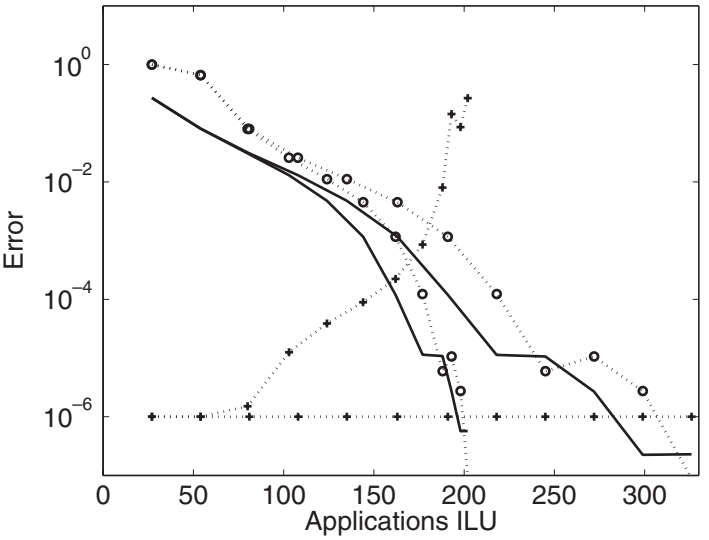

FIG. 6.2. *Error (solid), tolerance η_j (+), and error estimator (o) as a function of the total number of applications of the ILU preconditioner for $\eta_j = \epsilon$ and η_j as in* (5.4) *for $\tau = 1/10$. See also Table* 6.1.

iterations has no influence on the total number of Lanczos (outer) iterations. The amount of work in the inversions of the linear systems, measured as the total number of applications of the ILU preconditioner, is reduced by about 30 to 40 percent. This is comparable with reductions that are seen in applications of inexact Krylov methods in other areas; for a more detailed discussion see [40, section 3]. For the purpose of illustration we have included in Figures 6.2 and 6.3 a visual representation of the results for $\tau = 1/10$ and $\tau = 1/100$ for both strategies.

Again, we have that the number of Lanczos iterations increases when τ becomes smaller, as in the previous example. This is a combination of the fast convergence of the method for modest values of τ and, furthermore, is partially explained by the small norm of the true solution. On the other hand, we see that the number of CG steps per outer iteration decreases for smaller values of τ. This is a result of our choice $\gamma = \tau/10$, which makes the matrix more and more diagonally dominant when τ becomes smaller. For comparison purposes we mention that solving a linear system with this matrix and right-hand side to a precision of 10^{-6} requires 49 steps of the GMRES method preconditioned by an incomplete LU decomposition, a factor 4 less than for computing the exponential with $\tau = 1/10$.

From Figures 6.2 and 6.3 it seems that the convergence of the method stagnates now and then for one iteration. A possible explanation is that the Lanczos approximation mimics a property of the optimal uniform approximation. This is related to the observation in Conjecture 3.1 and can also be seen in Figure 3.1. Since for smaller values of τ the Lanczos method constructs a more and more uniform approximation on an interval, this might explain why these plateaus occur more often for small values of τ; see Figures 6.2, 6.3, and 4.1. We notice that in this experiment the error estimator (4.9) is a little too optimistic in the neighborhood of 10^{-5} for $\tau = 1/10$, which is caused by the temporary stagnation of the method at that point. Although such underestimation is not large and, in our experience, seldomly occurs, it can be resolved by switching to $j = 2$ in (4.9).

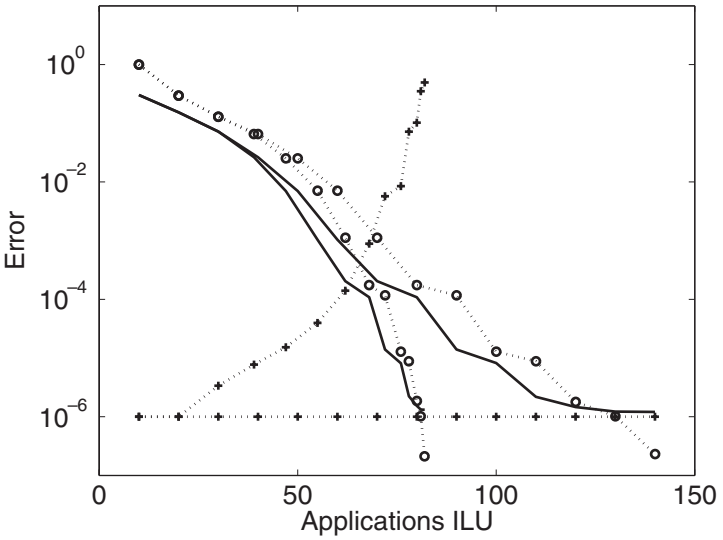

FIG. 6.3. *Error (solid), tolerance η_j (+), and error estimator (o) as a function of the total number of applications of the ILU preconditioner for $\eta_j = \epsilon$ and η_j as in* (5.4) *for $\tau = 1/100$. See also Table* 6.1.

6.2. The influence of mesh refinement. In our next experiment we explore the impact of the number of spatial grid points on the method. In order to be able to handle large matrices we have used the SAMG algebraic multigrid package [37] for solving the shifted systems. This package is written in Fortran and we have interfaced it with MATLAB. For ease of illustration we have taken the standard Poisson operator on a square grid with Dirichlet boundary conditions, i.e., $a(x, y) = b(x, y) = 1$ and $c(x, y) = 0$ in (6.2). We aim at a precision of $\epsilon = 10^{-8}$. In Table 6.2 we have reported the total number of cycles done in the inner iterations and the number of Lanczos iterations necessary to reduce the error estimator below 10^{-8} for different combinations of n (number of spatial grid points) and τ. Again we have used two strategies for choosing η_j: $\eta_j = \epsilon$ and η_j as in (5.4) with the norm of the error replaced by the estimator (4.9). The matrices were unfortunately too large to check if the obtained solution fulfills our accuracy requirement by comparing it against the outcome of a dense method. Instead, we have verified the results via another sparse method set to a smaller tolerance. In all cases the computed vectors have an error that is at most of the order of the required precision.

The table shows that increasing the accuracy in the spatial discretization has no dramatic influence on the total number of Lanczos iterations. For example, for $\tau = 1$, in all tests we needed four steps. This shows that even in situations where convergence is heavily based on exploiting the eigenvalue spectrum, the convergence is grid independent. This is expected since the upper estimate of the spread/gap ratio does not depend on the norm of A. When τ is decreased we see again that more steps of the Lanczos method are required. The computational advantage of a relaxation strategy is modest for a large value of τ. The reason is that in this situation the upper bound is around one in the first iterations and then very quickly drops in the final two iterations. For smaller values of τ the gain is comparable to that for the example in the previous section. We warn the reader that the SAMG package detects diagonal

TABLE 6.2
Total number of cycles/number of Lanczos iterations as a function of τ and the size of the matrix.

n	32^2	64^2	128^2	256^2	512^2	1024^2
			Fixed			
$\tau = 1$	20/4	24/4	24/4	27/4	28/4	28/4
$\tau = 1/10$	65/13	70/13	78/13	78/13	90/13	91/13
$\tau = 1/100$	104/15	48/16	89/18	90/18	108/18	108/18
$\tau = 1/1000$	23/8	52/11	123/14	64/16	76/16	80/16
			Relaxed			
$\tau = 1$	18/4	21/4	21/4	23/4	24/4	24/4
$\tau = 1/10$	43/13	48/13	52/13	53/13	58/13	60/13
$\tau = 1/100$	62/15	32/16	48/18	55/18	61/18	64/18
$\tau = 1/1000$	15/8	30/11	66/14	39/16	42/16	48/16

dominance of a matrix and automatically switches to a different solution strategy if this is more appropriate. This means that one cannot straightforwardly compare the total number of cycles for different combinations of τ and n.

7. Summary and outlook. The aim of this paper is to generalize the concept of preconditioning for linear systems to the computation of the product of the matrix exponential and a vector. The idea explored is to apply the Lanczos process to a shifted and inverted matrix that better emphasizes the important eigenvalues. This results in an inner-outer iteration scheme where the solution of the shifted systems can be accomplished by preconditioned solvers. The worst case convergence behavior of the method can be bounded in terms of a rational approximation problem on the positive real axis. However, convergence speeds observed in practice are often much higher than these bounds suggest. This is due to the fact that the spectral transformation facilitates the exploitation of the discrete nature of the spectrum of the matrix. We have argued and demonstrated that the method shows convergence speeds independent of the norm of the matrix and, if an appropriate method is used for the solution of the linear systems, we can compute the sought-after vector in a time proportional to the number of spatial grid points. Furthermore, we have proposed an empirical strategy for choosing the tolerances for the errors in the solution of the shifted linear systems. This strategy can reduce the amount of work in the solution of the shifted systems by up to 40 percent compared with using a fixed tolerance on the error.

For the sake of clarity, in this paper we have restricted our attention to the computation of the exponential function. However, the same approach seems to carry over successfully to the computation of the matrix functions related to (4.6) that play, besides the exponential function, an important role in exponentially based integrators; e.g., see [14, 18, 20]. Also, we have assumed throughout this paper that the matrix is symmetric positive semidefinite. It is clear how our work can be extended to deal with so-called sectorial operators as well. Much of the theory and heuristics here are expected to hold in this case too. For example, it has been shown that there is a sequence of approximations from the classes $\mathcal{R}_m^{m-1}$ that converges geometrically to $\exp(-t)$ in a sector symmetrically around the real axes; see [34].

In our future work we plan to investigate other ideas for incorporating preconditioning in the computation of the matrix exponential. This is particularly important in applications where the matrix is skew-symmetric and, therefore, has purely imaginary eigenvalues. In this case it is not possible to exploit the rapid decay of the exponential functions, and a different approach is required.

Acknowledgments. We would like to thank Klaus Stüben and Tanja Clees of the GMD for providing us with the SAMG package and for their assistance in using the package. The authors appreciate the useful suggestions and comments of the referees that improved the presentation of this paper. We are thankful to Paolo Novati and Igor Moret for providing us with copy of a preliminary version of [25]. Our gratitude goes to our colleague Jörg Niehoff for helpful discussions.

PARTITIONS OF A SIMPLEX LEADING TO ACCURATE SPECTRAL (FINITE) VOLUME RECONSTRUCTION*

QIAN-YONG CHEN†

Abstract. In this paper, we present several systematic techniques, based on the Voronoi diagram and its variants, to partition a one- and two-dimensional simplex. The Fekete points are used as input to generate the Voronoi diagram, as they concentrate near the edges and are almost optimal for polynomial interpolation in a simplex.

Spectral (finite) volume reconstructions on the resultant partitions have small Lebesgue constants. When using the Dubiner basis, the reconstruction matrix is well conditioned. Moreover, the total number of edges of the partitions (the total work when being used in spectral volume methods) is shown to be at most twice the minimum number of edges of all partitions for reconstructions of the same order accuracy. These suggest that the obtained partitions are well suited for spectral volume methods and other numerical methods which rely on reconstructions from cell averages.

Key words. spectral volume method, Voronoi diagram, Lebesgue constant, finite volume reconstruction

DOI. 10.1137/030601387

1. Introduction.

In [4], Wang proposed a new finite volume method, called the spectral volume method, for hyperbolic conservation laws. The spectral volume method has several good properties: it is high-order accurate, conservative, geometrically flexible, and computationally efficient. (A comparison with the discontinuous Galerkin methods is given in [5].) In the spectral volume method, a volume or a cell (named spectral volume) is partitioned into nonoverlapping subcells called control volumes. Then cell-averaged solutions on the control volumes are used to perform high-order reconstructions, i.e., spectral volume reconstructions. The spectral volume reconstruction is different from the reconstruction procedure of previous finite volume methods, which employs cell-averaged solutions on neighbor cells to perform the reconstruction.

The spectral volume reconstruction is basically an approximation problem. Given a smooth function and an approximation space, the accuracy of the spectral volume reconstructions only depends on the partition of the spectral volume. Not all partitions produce good results. For example, uniform partitions [6] yield bad results for high-order reconstructions because of the Runge phenomenon. As far as we know, no systematic technique has been developed to partition an m-dimensional simplex, $S^m \subset R^m$, except that in [6] Wang gave a few partitions for up to the fourth-order reconstruction on a standard equilateral triangle. It is difficult to directly build good high-order partitions because there are too many parameters, such as the position of points, the number of edges for each subcell, and the topology of the subcells. Of course, one can compute the so-called L^2 optimal partitions as in [7]. But even for the one-dimensional case, the L^2 optimal partitions are not as satisfactory as the correspondents for the interpolation [8].

However, another approximation problem on a simplex, the interpolation based on node values, has been extensively studied in the past (see [9] and the references therein). Some almost optimal nodal sets for polynomial interpolation on a two-dimensional simplex are given in [7, 9, 10]. In this paper, we develop several systematic techniques, based on the well-known Voronoi diagram and its variants with those optimal nodal sets as the input, to generate partitions of a one- and two-dimensional simplex. Using these techniques, we obtained partitions for up to the 14th order polynomial reconstruction on an equilateral triangle.

The remainder of the paper is organized as follows. In section 2, we restate the spectral volume reconstruction problem on a two-dimensional simplex. The Lebesgue constant is introduced as one measurement of the quality of spectral volume reconstructions. Section 3 describes the systematic techniques to partition a one- and two-dimensional simplex. Finally, we summarize the paper and make some concluding remarks in section 4.

2. Spectral volume reconstruction. In this section, we define the spectral volume reconstruction problem on an equilateral triangle, S^2. Some issues related to the quality of spectral volume reconstructions are also addressed.

The spectral volume reconstruction is a key element of the recently proposed spectral volume method [4, 6], in which a target cell is divided into nonoverlapping subcells. The cell-averaged solutions on the subcells are then used to reconstruct an approximate solution on the target cell. The number of subcells is the same as the dimension of the approximation space. In general, the approximation space can consist of any functions. Here, we focus on the space of polynomials of degree up to n, denoted as P_2^n. The dimension of this approximation space is

$$N_n^2 = \dim P_2^n = \binom{2+n}{2}. \tag{1}$$

$N = N_n^2$ and $P^n = P_2^n$ will be used to simplify the notations if there is no confusion.

The spectral volume reconstruction problem can be formally stated as follows.

Spectral Volume Reconstruction Problem on S^2. [illegible] $u(x,y)$ [illegible] S^2 [illegible] $u \in C^0(S^2)$ [illegible]

1. [illegible] Π_n [illegible] S^2

$$S^2 = C_1 \cup \cdots \cup C_N,$$

[illegible] $\{C_1, \ldots, C_N\}$ [illegible] N [illegible]

2. [illegible] $I_{\Pi_n} u :\in P^n$ [illegible]

$$\int_{C_i} (I_{\Pi_n} u)\, dV = \int_{C_i} u(x,y) dV, \qquad i = 1, \ldots, N; \tag{2}$$

[illegible] u [illegible] $I_{\Pi_n} u$ [illegible]

The projection, $I_{\Pi_n} u$, can be computed once the partition Π_n is known. Express $I_{\Pi_n} u$ as a series sum of a complete basis of P^n, $\{p_1(x,y), \ldots, p_N(x,y)\}$:

$$I_{\Pi_n} u = \sum_{i=1}^{N} a_i\, p_i(x,y). \tag{3}$$

Denote $\bar{u}_i$ as the average of $u(x,y)$ over the subcell C_i, i.e.,

$$\bar{u}_i = \frac{1}{V_i}\int_{C_i} u(x,y)\, dV, \qquad i = 1,\ldots,N, \tag{4}$$

where V_i is the area of C_i. Plug (3) and (4) into (2), and rewrite the new equation in a matrix form

$$A\, a \;=\; \bar{u}, \tag{5}$$

where $\bar{u} = (\bar{u}_1,\ldots,\bar{u}_N)^T$, $a = (a_1,\ldots,a_N)^T$, and the reconstruction matrix A takes the form

$$A = \begin{pmatrix} \frac{1}{V_1}\int_{C_1} p_1(x,y)dV & \cdots & \frac{1}{V_1}\int_{C_1} p_N(x,y)dV \\ \cdots & \cdots & \cdots \\ \frac{1}{V_N}\int_{C_N} p_1(x,y)dV & \cdots & \frac{1}{V_N}\int_{C_N} p_N(x,y)dV \end{pmatrix}. \tag{6}$$

When the partition is nonsingular, i.e., the matrix A is nonsingular, we solve (5) and substitute the solution a back into (3) to obtain

$$I_{\Pi_n} u = \sum_{i=1}^{N} \bar{u}_i\, L_i(x,y), \tag{7}$$

where the cardinal basis functions $L = (L_1(x,y),\ldots,L_N(x,y))$ are given as

$$L = (p_1(x,y),\ldots,p_N(x,y))\; A^{-1}. \tag{8}$$

Then we equip the space P^n and $C^0(S^2)$ with an L^∞ norm (supremum-norm, denoted as $\|\cdot\|$) and the induced functional norm

$$\|I_{\Pi_n}\| \;=\; \sup_{\|u\|\neq 0} \frac{\|I_{\Pi_n} u\|}{\|u\|}.$$

Since $|\bar{u_i}| \le \|u\|$ for $i = 1,\ldots,N$, one can show that

$$\|I_{\Pi_n}\| = \max_{(x,y)\in S^2} \sum_{i=1}^{N} |L_i(x,y)|. \tag{9}$$

2.1. Error of spectral volume reconstruction. One measurement of the quality of spectral volume reconstruction is the error. Similar to that of polynomial interpolation, the error of spectral volume reconstruction is bounded from below as

$$\|u - u^*\| \le \|u - I_{\Pi_n} u\|, \tag{10}$$

where u^* is the optimal approximating polynomial whose existence is guaranteed by the continuity of $u(x,y)$ [1]. Although it is difficult to determine such optimal approximation for general functions, its existence enables us to evaluate the quality of other approximations. From the linearity of the projection operator I_{Π_n} and the fact that $I_{\Pi_n} f = f\ \forall f \in P^n(S^2)$, one can verify that

$$\|u - I_{\Pi_n} u\| \le (1 + \Lambda(\Pi_n))\, \|u - u^*\|, \tag{11}$$

where

$$\Lambda(\Pi_n) = \|I_{\Pi_n}\| = \max_{(x,y)\in S^2} \sum_{i=1}^{N} |L_i(x,y)| \tag{12}$$

is called the Lebesgue constant of the operator I_{Π_n}.

From the manner of computing $I_{\Pi_n} u$ as previously described, one can show that the Lebesgue constant only depends on the partition Π_n when the approximation space is fixed.

LEMMA 1. [illegible]

[illegible]. From the definition of the Lebesgue constant (cf. (12)), it is enough to show that the same cardinal basis functions will be obtained for two different basis sets of the approximation space.

Choose another basis set, $(q_1(x,y),\ldots,q_N(x,y)) = (p_1(x,y),\ldots,p_N(x,y))\cdot T$, where T is a constant nonsingular matrix. According to (6), the new reconstruction matrix is

$$\tilde{A} = A \cdot T.$$

Therefore the new cardinal basis is

$$\tilde{L} = (q_1,\ldots,q_N)\cdot\left(\tilde{A}\right)^{-1} = (p_1,\ldots,p_N)\cdot T\cdot T^{-1}A^{-1} = L,$$

which proves the lemma. □

According to (11) and (10), the magnitude of the Lebesgue constant reflects how close the spectral volume reconstruction is to the optimal polynomial approximation. Therefore, spectral volume reconstructions with small Lebesgue constant are preferred. For simplicity, we consider only partitions with subcells being convex polygons with straight edges. However, this might keep us from obtaining spectral volume reconstructions with Lebesgue constant as small as those of polynomial interpolation in [10] and [9].

Another important issue is the work load when the spectral volume reconstruction procedure is used in solving partial differential equations. As shown in [6, 4], the work load is roughly proportional to the total number of edges of the partition. Hence the optimal partition should have a minimum number of edges and lead to the smallest Lebesgue constant. If one wants to optimize the partition, one needs to minimize both the number of edges and the Lebesgue constant at the same time, which apparently is not an easy task. We made no such effort in this paper.

We also want to emphasize that it is necessary that the reconstruction matrix A is well conditioned for high-order spectral volume reconstructions because of the finite precision of computers. For polynomial interpolation on a triangle, this is usually achieved by choosing the Dubiner basis [2] instead of the notorious monomials, provided the nodal set is good.

3. Partitions from Voronoi diagram and its variants. In this section, we describe a few systematic techniques to partition a one- and two-dimensional simplex by using the Voronoi diagram and its variants.

3.1. The Voronoi diagram and its variants. The following definition is a generalization of the two-dimensional Voronoi diagram [3, 11].

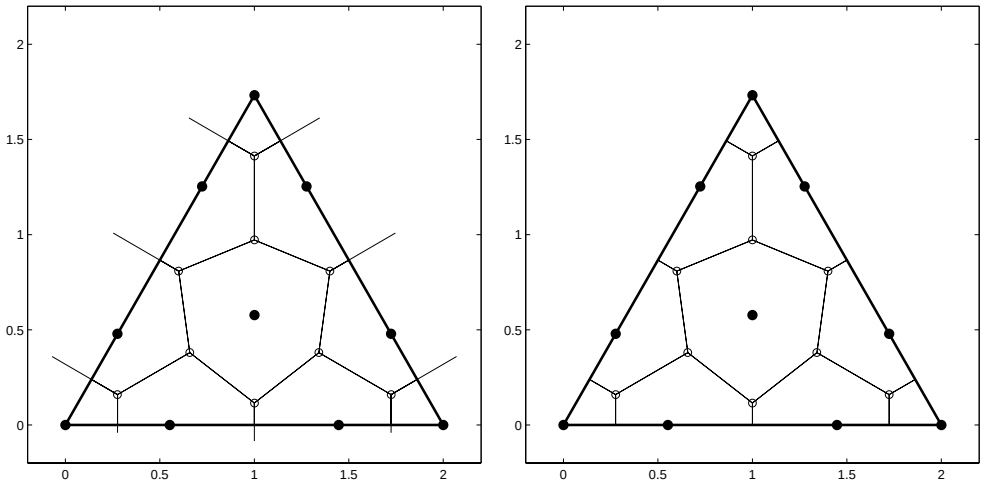

FIG. 1. *Partition of a triangle from the Voronoi diagram of given points on the triangle. On the left graph, the dark dots are the input points, the circles are the Voronoi vertices, and the thin solid lines are the Voronoi edges. The right graph displays the partition.*

DEFINITION 2 (Voronoi diagram). N $S = \{p_1, \ldots, p_N\}$ R^m R^m N $\{V_1, \ldots, V_N\}$ $p_i \in V_i$ $i = 1, \ldots, N$ V_i R^m p_i S.

$$V_i = \{x \in R^m \ : \ |x - p_i| \leq |x - q|, \forall q \in S - p_i\}, \tag{13}$$

$|x-y|$ x y

All Voronoi cells and faces form a cell complex whose vertices and edges are called and . The unbounded edges are also called . When the input points, $\{p_1, \ldots, p_N\}$, are in the plane ($m = 2$), we can bound the number of the Voronoi vertices and Voronoi edges by the following theorem [3, 11].

THEOREM 3. $N \geq 3$ N $2N-5$ $3N-6$

When the input points are on a triangle, it is straightforward to generate a partition of the triangle from the Voronoi diagram, e.g., Figure 1. Thus, we can partition a triangle by choosing the input points and computing the Voronoi diagram. Furthermore, each Voronoi vertex (the circles in Figure 1) is the circumcenter of one triangle with vertices being three input points. One can get a few variants of the Voronoi diagram, and thus different partitions, by replacing each Voronoi vertex (circumcenter) with the corresponding incenter, centroid, or any other point related to that triangle. We recall that for a triangle the circumcenter is the center of its circumcircle, the incenter is the center of its incircle, and the centroid is the intersection of the triangle's three triangle medians.

3.2. Partitions of S^1. S^1 is simply a line segment. Without loss of generality, let $S^1 = [-1, 1]$. One can generate a partition from any given input points set as follows. Suppose $-1 = x_0 < x_1 < \cdots < x_n = 1$ are the input points. Take $y_0 = x_0, y_{n+1} = x_n$ and $y_i = (x_i + x_{i-1})/2, i = 1, \ldots, n$. The points $\{y_i\}$ then

define a partition: $V_i = [y_i, y_{i+1}], i = 0, \ldots, n$. A different points set will yield a different partition. Table 1 includes the Lebesgue constants corresponding to the Legendre–Gauss–Lobatto (LGL) and Chebyshev–Gauss–Lobatto (CGL) quadrature points. Note that the LGL points are actually the Fekete points in the interval [12]. Λ^{LGL} and Λ^{CGL} represent the Lebesgue constants of polynomial interpolation with the LGL and CGL points. $\Lambda_{\mathrm{V}}^{\mathrm{LGL}}$ and $\Lambda_{\mathrm{V}}^{\mathrm{CGL}}$ represent the Lebesgue constants for the reconstruction on the partitions with LGL and CGL points being the input. $\Lambda_{\mathrm{V}}^{\mathrm{Eq}}$ denotes the Lebesgue constant for spectral volume reconstruction on the uniform mesh; i.e., all subcells have the same size.

Note that the Lebesgue constants of spectral volume reconstruction on the partitions from both LGL and CGL points are less than twice those of polynomial interpolation, which are very close to the Lebesgue constants of the optimal nodal set [9]. In summary,

$$\Lambda_{\mathrm{V}}^{\mathrm{Eq}} > \Lambda_{\mathrm{V}}^{\mathrm{LGL}} > \Lambda_{\mathrm{V}}^{\mathrm{CGL}} > \Lambda^{\mathrm{CGL}} > \Lambda^{\mathrm{LGL}}. \tag{14}$$

3.3. Partitions of S^2. We study only the standard equilateral triangle S^2 (cf. Figure 1) because any other triangle can be obtained from a linear transformation of this triangle. The linear transformation will not change the Lebesgue constant of spectral volume reconstruction, which will be shown below.

LEMMA 4. [illegible] S^2 [illegible] $\Pi_n = \{C_1, \ldots, C_N\}$ [illegible] $\tilde{S}$ [illegible] $\xi - \eta$ [illegible] $\tilde{S}$ $\tilde{\Pi}_n = \{\tilde{C}_1, \ldots, \tilde{C}_N\}$ [illegible] S^2 [illegible] $\tilde{S}$ [illegible] Π_n [illegible] $\tilde{S}$ [illegible] S^2 [illegible]. Denote $\tilde{V}_i$ as the area of subcell $\tilde{C}_i$. Use $\tilde{A}$ and $\tilde{L}$ to represent the reconstruction matrix and cardinal basis set on $\tilde{S}$. For S^2, the same notation will be used as in section 2.

From the definition of the Lebesgue constant, it suffices to show that

$$\tilde{L}(\xi,\eta) = L(x,y) \qquad \forall (\xi,\eta) \in \tilde{S} \text{ or } (x,y) \in S^2.$$

According to (8),

$$\begin{cases} L(x,y) = (p_1(x,y),\ldots,p_N(x,y))\, A^{-1}, \\ \tilde{L}(\xi,\eta) = (p_1(\xi,\eta),\ldots,p_N(\xi,\eta))\, \tilde{A}^{-1}. \end{cases}$$

Since the transformation $(\xi,\eta) \leftarrow (x,y)$ is linear, there exists a constant matrix T such that

$$(p_1(\xi,\eta),\ldots,p_N(\xi,\eta)) = (p_1(x,y),\ldots,p_N(x,y)) \cdot T. \tag{15}$$

T is also nonsingular as the transformation is nonsingular. (The nonsingularity of T can be proved by evaluating (15) at N distinct points.)

Plug (15) into the reconstruction matrix

$$\tilde{A} = \begin{pmatrix} \frac{1}{\tilde{V}_1}\int_{\tilde{C}_1} \tilde{p}_1(\xi,\eta)d\tilde{V} & \cdots & \frac{1}{\tilde{V}_1}\int_{\tilde{C}_1} \tilde{p}_N(\xi,\eta)d\tilde{V} \\ \cdots & \cdots & \cdots \\ \frac{1}{\tilde{V}_N}\int_{\tilde{C}_N} \tilde{p}_1(\xi,\eta)d\tilde{V} & \cdots & \frac{1}{\tilde{V}_N}\int_{\tilde{C}_N} \tilde{p}_N(\xi,\eta)d\tilde{V} \end{pmatrix}$$

to obtain

$$\tilde{A} = A \cdot T.$$

Hence,

$$\begin{aligned} \tilde{L}(\xi,\eta) &= (p_1(\xi,\eta),\ldots,p_n(\xi,\eta))\, \tilde{A}^{-1} \\ &= (p_1(x,y),\ldots,p_N(x,y)) \cdot T \cdot (A \cdot T)^{-1} = L(x,y). \end{aligned}$$ □

The first kind of partitions, denoted as $\Pi^{\mathrm{F}}_{\mathrm{out}}$, are from the Voronoi diagram[1] of the two-dimensional Fekete points [10] on the triangle. As previously mentioned, each Voronoi vertex is the circumcenter of one triangle with vertices being three input points. Therefore, there might be some Voronoi vertices which are outside the big equilateral triangle. When this happens, the partition is not as obvious as shown in Figure 1. But as demonstrated in Figure 2, we can obtain a partition by replacing each outside Voronoi vertex with the intersection point of the corresponding Voronoi ray and the edge of the big equilateral triangle. With this strategy, we generate partitions up to 14th order (Figure 3). The Lebesgue constants of spectral volume reconstruction are listed in Table 2. The number of distinct edges is bounded as follows.

THEOREM 5. [illegible] $\Pi^{\mathrm{F}}_{\mathrm{out}}$ [illegible]. For the nth order partition $\Pi^{\mathrm{F}}_{\mathrm{out}}$, according to Theorem 3, the Voronoi diagram contributes at most $(3N-6)$ to the total number of edges, where $N = \binom{2+n}{2}$ (cf. (1)) is the total number of input points on the triangle. In addition, there are

[1]Fortune's code is used to compute the two-dimensional Voronoi diagram.

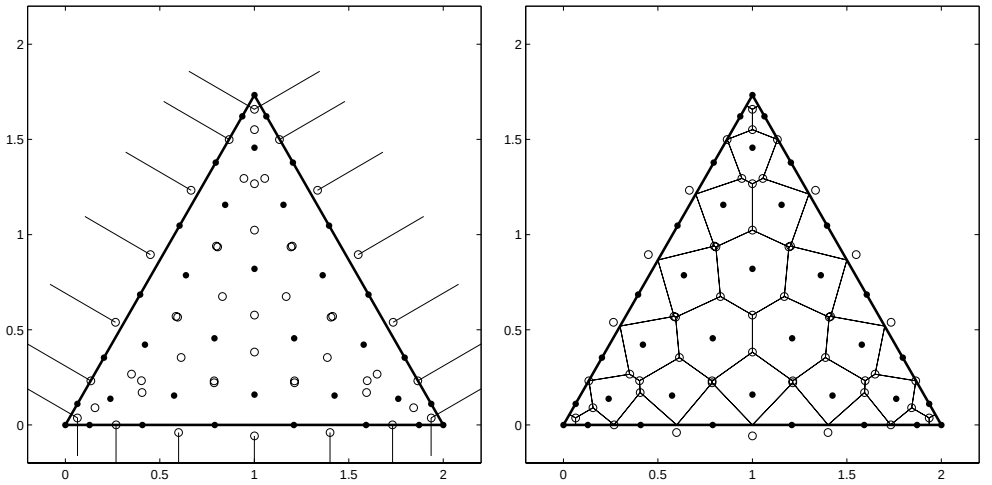

FIG. 2. *The seventh order partition from the Voronoi diagram of given Fekete points. On the left graph, the thin solid lines are the Voronoi rays; the circles are the Voronoi vertices. The right graph is the partition. The outside Voronoi vertices are also plotted for clarity.*

14	120	15.9693	87.1305	61.5641	36.1131	1090.979

$3(n+1)$ edges which lie on the edges of the big equilateral triangle. Thus, the total number of edges of the nth partition $\Pi^{\mathrm{F}}_{\mathrm{out}}$ is at most

$$3N - 6 + 3(n+1) = \frac{3}{2}(n^2 + 5n). \tag{16}$$

Consider an arbitrary partition leading to an nth-order spectral volume reconstruction. Denote X as the number of edges of the partition which are on the edges of the big equilateral triangle, and Y as the number of remaining edges (called , since they are inside the big equilateral triangle). Clearly, $X = 3(n+1)$. Since an nth-order reconstruction needs N polygons, each of which has at least three edges, one can show that

$$X + 2Y \geq 3N,$$

where the coefficient before Y is due to the fact that each inside edge belongs to two polygons. Thus, the minimum number of distinct edges for any nth-order partition satisfies

$$X + Y \geq X + \frac{3N - X}{2} = 3(n+1) + \frac{3N - 3(n+1)}{2} = \frac{3}{4}(n^2 + 5n + 4).$$

Comparing the above equation with (16) proves the theorem. □

However, this simple usage of the Voronoi diagram does not yield very small Lebesgue constants, as shown in Figure 7, for high-order spectral volume reconstructions.

We derive the second kind of partitions (denoted as $\Pi^{\mathrm{F}}_{\mathrm{in}}$) from one variant of the Voronoi diagram in which each Voronoi vertex is replaced by the corresponding incenter. By doing that, the structure of the partitions is more similar to the structure of the input points in the sense of layered structures and concentration near the edges (see Figures 3 and 4). This is due to the fact that the incenter of a triangle is always inside the triangle. We believe that the layered structure and the concentration near the edges of the subcells are crucial for the partition to produce small Lebesgue

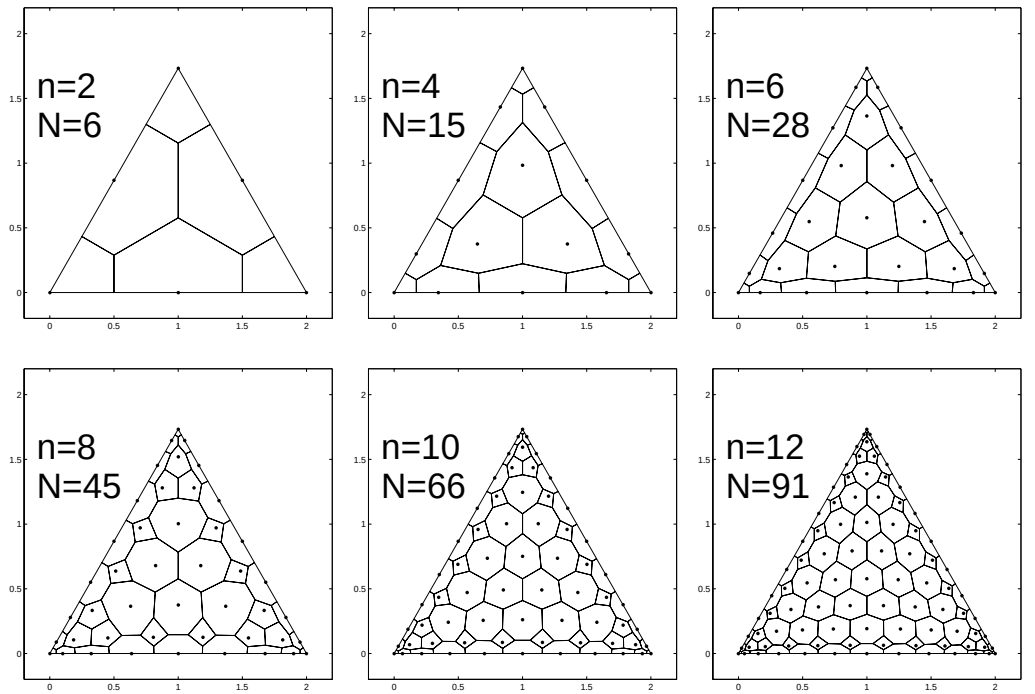

FIG. 4. *Partition* $\Pi^{\mathrm{F}}_{\mathrm{in}}$. *n: order of spectral volume reconstruction; N: number of subcells; ".": input Fekete points on the triangle.*

constants. As expected, the partition $\Pi^{\mathrm{F}}_{\mathrm{in}}$ produces smaller Lebesgue constants than $\Pi^{\mathrm{F}}_{\mathrm{out}}$ for most cases of the spectral volume reconstructions of order up to 14 (Table 2).

Unfortunately, as shown in Figure 7, there is a sudden increase in the Lebesgue constants of the 8th or higher order $\Pi^{\mathrm{F}}_{\mathrm{in}}$ partitions. By examining Figure 4 more carefully, we notice that the layered structure is a bit "distorted" in the place close to the edges of the big triangle. The distortion is responsible for the sudden increase of the Lebesgue constants.

The Fekete points set itself has a very nice structure (Figure 5), based on which we come up with the third kind of partitions, denoted as $\Pi^{\mathrm{F}}_{\mathrm{mass}}$. There are three steps to build the partition, which are demonstrated in Figure 5. At first, we concatenate the input points layer by layer (see the left graph of Figure 5). Then we construct a triangular mesh as shown in the middle graph of Figure 5. Finally, for each input point inside the big triangle, we construct a polygon by connecting the centroids (or any other points) of the small triangles that share the input point (see the right graph of Figure 5). When an input point is on the edge of the big triangle, one can construct a polygon containing it by using two more points on the edges of the big equilateral triangle. Some examples of the partitions are displayed in Figure 6. We also tried to use the incenter instead of centroid of those small triangles. It leads to almost the same Lebesgue constants as the centroid does.

The same upper bound holds for the number of edges of the partitions $\Pi^{\mathrm{F}}_{\mathrm{in}}$ and $\Pi^{\mathrm{F}}_{\mathrm{mass}}$.

THEOREM 6. [illegible] $\Pi^{\mathrm{F}}_{\mathrm{in}}$ [illegible] $\Pi^{\mathrm{F}}_{\mathrm{mass}}$ [illegible]

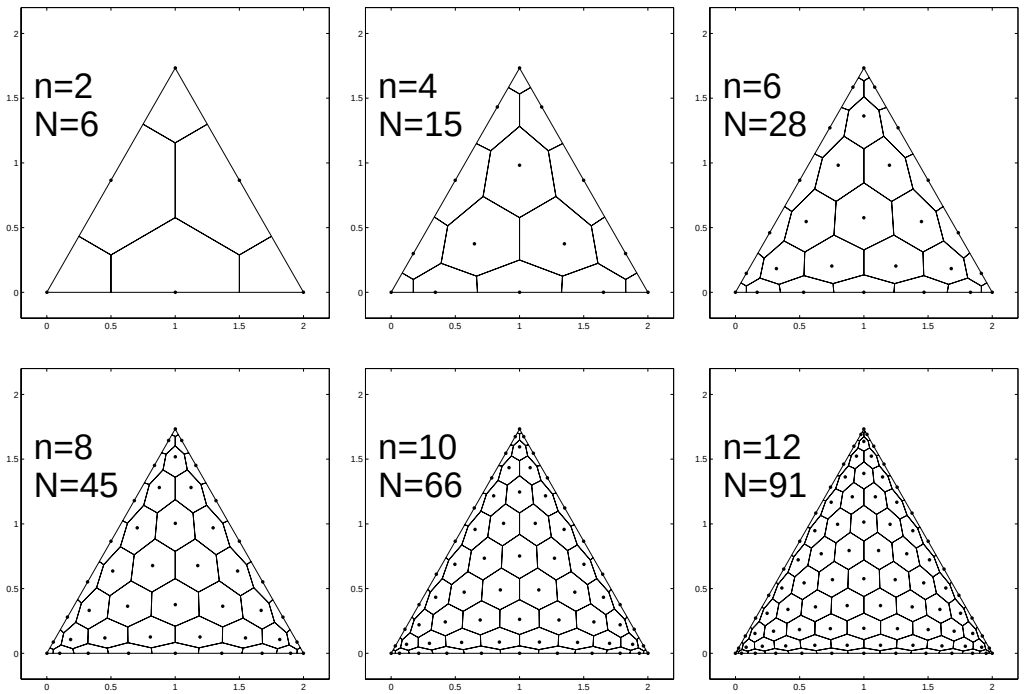

FIG. 6. *Partition* $\Pi^{\mathrm{F}}_{\mathrm{mass}}$. *n: order of spectral volume reconstruction; N: number of subcells; ".": input Fekete points on the triangle.*

The proof is omitted as it is basically the same as that of Theorem 5.

For comparison, we also compute the Lebesgue constants of the partition $\Pi^{\mathrm{Eq}}_{\mathrm{V}}$, which is from the Voronoi diagram of equispaced (in the area coordinate system) points on the equilateral triangle. The Lebesgue constants for all partitions are listed in Table 2. Table 3 contains the 2-norm condition numbers of the reconstruction matrix when the Dubiner basis is used. Figure 7 displays the ratios of the Lebesgue constants from the above partitions to those of the polynomial interpolations based on the Fekete points.

4. Conclusions. We have developed several systematic techniques to partition a one- and two-dimensional simplex by using the well-known Voronoi diagram and its variants. The resulting partitions have layered structure and the subcells concentrate near the edges. These two properties are found to be crucial for the partitions which lead to spectral volume reconstructions with small Lebesgue constants.

The spectral volume reconstructions on those partitions have small Lebesgue constants, one of which is roughly twice the Lebesgue constant of the same order interpolation based on the almost optimal nodal sets. The total number of edges (the total work when being used in the spectral volume method) of the partitions is shown to be at most twice the minimum number of edges of all partitions for the reconstructions of the same order accuracy. When using the Dubiner basis, the spectral volume reconstruction matrix is very well conditioned. All of these suggest that the partitions are a good choice for the spectral volume methods and other numerical methods which rely on reconstructions from cell averages.

Acknowledgments. The author thanks Prof. Franco P. Preparata for many helpful suggestions and greatly appreciates the guidance and support of Prof. David Gottlieb and Prof. Jan S. Hesthaven. The author would also like to thank Prof. Z. J. Wang; this project arose from his seminar.

A NOVEL MULTIGRID BASED PRECONDITIONER FOR HETEROGENEOUS HELMHOLTZ PROBLEMS*

Y. A. ERLANGGA†, C. W. OOSTERLEE†, AND C. VUIK†

Abstract. An iterative solution method, in the form of a preconditioner for a Krylov subspace method, is presented for the Helmholtz equation. The preconditioner is based on a Helmholtz-type differential operator with a complex term. A multigrid iteration is used for approximately inverting the preconditioner. The choice of multigrid components for the corresponding preconditioning matrix with a complex diagonal is validated with Fourier analysis. Multigrid analysis results are verified by numerical experiments. High wavenumber Helmholtz problems in heterogeneous media are solved indicating the performance of the preconditioner.

Key words. Helmholtz equation, nonconstant high wavenumber, complex multigrid preconditioner, Fourier analysis

DOI. 10.1137/040615195

1. Introduction.

In this paper we present a novel preconditioner for high wavenumber Helmholtz problems in heterogeneous media. The preconditioner is based on the Helmholtz operator, where an imaginary term is added. This preconditioner can be handled by multigrid. This is somewhat surprising as multigrid, without enhancements, has convergence troubles for the original Helmholtz operator at high wavenumbers.

A part of this paper is therefore reserved for the analysis of the multigrid method for Helmholtz problems with a complex zeroth order term. This is done, for constant wavenumbers, by means of Fourier analysis. The preconditioned system leads to a favorably clustered spectrum for a Krylov subspace convergence acceleration. As the preconditioner is not based on a regular splitting of the original Helmholtz problem, it must be used in the setting of Krylov subspace methods. The particular example presented can be viewed as a generalization of the work by Bayliss, Goldstein, and Turkel [3] from the 1980s, where the Laplacian was used as a preconditioner for Helmholtz problems. This work has been generalized by Laird and Giles [17], proposing a Helmholtz preconditioner with a $+$ sign in front of the Helmholtz term. In [13] we have proposed a preconditioner with a purely imaginary shift added to the Laplacian. The method here is an improvement of that method.

In this paper we benefit from Fourier analysis in several ways. First of all, for idealized (homogeneous boundary conditions, constant coefficients) versions of the preconditioned system it is possible to visualize its spectrum for different values of the wavenumber, as Fourier analysis provides all eigenvalues. Second, for analyzing multigrid algorithms quantitatively, Fourier smoothing, two-, and three-grid analysis [6, 7, 23, 24, 30] are the tools of choice.

TABLE 1
Number of grid points employed, related to the wavenumber, so that $kh = 0.625$.

k	40	50	80	100	150	200	500	600
h	1/64	1/80	1/128	1/160	1/240	1/320	1/800	1/960

The outline of this paper is as follows. In section 2 the Helmholtz problem is introduced and the convergence difficulties of multigrid for this equation are detailed. The new preconditioner is introduced in section 3, where multigrid components for Helmholtz problems with a complex term (smoothing, operator-dependent prolongation) are presented. Fourier analysis to obtain quantitative performance estimates of components and methods is performed in section 4. Numerical experiments on two-dimensional high wavenumber heterogeneous Helmholtz problems are presented in section 5.

2. Helmholtz equation, standard multigrid. Consider the Helmholtz equation for a wave problem in a heterogeneous medium

$$\mathcal{A}\phi := -\partial_{xx}\phi - \partial_{yy}\phi - (1-\alpha i)k^2(x,y)\phi = g(x,y) \quad \text{in } \Omega \subset \mathbb{R}^2. \tag{1}$$

Here, $\phi = \phi(x,y)$ represents the solution, usually a pressure field, and g represents the source term. The medium is barely attenuative if $0 \le \alpha << 1$, with α indicating the fraction of damping in the medium ($i = \sqrt{-1}$, the imaginary unit). In geophysical applications, which are our main interest, this damping can be set up to 5% ($\alpha = 0.05$). The wavenumber $k = \omega_f/c$ is space-dependent because of a spatially dependent speed of sound $c(x,y)$ in a heterogeneous medium. With $\omega_f := 2\pi f$ the angular frequency (f is the frequency), wavelength ℓ is defined by $\ell = c/f$. The number of wavelengths in a domain of size L equals L/ℓ. n_w, the number of points per wavelength, is typically chosen to be 10–12 points. Wavenumber k can be large.

The dimensionless wavenumber $\overline{k}$ on a nondimensional $[0,1]^2$ domain is defined by $\overline{k} = 2\pi f L/c$. A dimensionless discretization step reads $h = \ell/(n_w L)$, and therefore for the angular frequency one finds $\omega_f = 2\pi/(n_w h) = 2\pi L/\ell$. With domain size $L = 1$, an accuracy requirement for second order discretizations is that $kh \le \pi/5 (\approx 0.63)$ for $n_w = 10$ points per wavelength, and $kh \le 0.53$ with $n_w = 12$ points per wavelength. In Table 1, the number of grid points used for several wavenumbers k is displayed. For each combination we have $kh = 0.625$. These mesh refinements assume a linear connection between k and h. However, in order to avoid a reduction of accuracy for a second order scheme due to the so-called [illegible] [26, 14] k^2h^3 should be set constant. As for an iterative solution method, keeping kh constant is more severe; we stay with kh as in Table 1. In this paper we emphasize the iterative solution rather than the accuracy of the discretization.

Typically, boundary conditions at the boundary $\Gamma = \partial\Omega$ are in the form of first- or second-order absorbing boundary conditions or of a perfectly matched layer (PML). We use approximate radiation (or nonreflecting) boundary conditions at an artificial boundary. The well-known second-order radiation boundary condition [12], to avoid unphysical reflections at boundaries, reads

$$\mathcal{A}_\Gamma\phi := \frac{\partial\phi}{\partial\nu} - ik\phi - \frac{i}{2k}\frac{\partial^2\phi}{\partial\tau^2} = 0 \quad \text{on } \Gamma, \tag{2}$$

with ν the outward normal direction to the boundary and τ pointing in the tangential direction. At the cornerpoints the suggestions in [2] to avoid corner reflections

have been adopted. Whereas these conditions are commonly applied for problems in homogeneous media, they are less obvious for inhomogeneous media with discontinuous wavenumbers at the boundaries. The reason is that these discontinuities may act as unphysical scatterers at the boundaries. This can be avoided by appropriately increasing damping, modeled by the imaginary part in (2). Another natural approach with an inhomogeneous medium at the boundaries may be the use of the PML.

If a discretization is applied to (1) and (2), a linear system of the form

$$A\boldsymbol{\phi} = \boldsymbol{g}, \qquad A \in \mathbb{C}^{N\times N}, \qquad \boldsymbol{\phi}, \boldsymbol{g} \in \mathbb{C}^N, \tag{3}$$

is obtained, where N is the number of unknowns in the computational domain Ω_h. Matrix A has complex components due to the discrete boundary operator (2) and the damping term in (1). A is in general symmetric with eigenvalues in the left and right half-plane, non-Hermitian, and, because of the accuracy requirements, also large for high wavenumbers. However, A is also sparse; its sparsity pattern depends on the discretization method used.

We consider here, in stencil notation, the well-known $O(h^2)$ 5-point discretization stencil:

$$A_h \stackrel{\wedge}{=} \frac{1}{h^2}\begin{bmatrix} & -1 & \\ -1 & 4-(kh)^2(1-\alpha i) & -1 \\ & -1 & \end{bmatrix}. \tag{4}$$

We use matrix and stencil notation simultaneously: Matrix A (3) relates to the discretization of (1), (2), and discrete operator A_h (4) relates to the discretization of (1). The discrete solution is represented by $\boldsymbol{\phi}$ and ϕ_h, respectively. The eigenvalues (for constant k-problems with homogeneous Dirichlet boundary conditions)

$$\begin{aligned} \lambda_h^{\ell,m} &= \widetilde{\lambda}_h^{\ell,m} - k^2(1-\alpha i) \\ &\equiv \frac{2}{h^2}(2-\cos\ell\pi h - \cos m\pi h) - k^2(1-\alpha i) \quad (\ell, m = 1, 2, \ldots, \sqrt{N}-1) \end{aligned} \tag{5}$$

are not equal to zero as long as $k^2(1-\alpha i)$ is not equal to any of the eigenvalues of the corresponding discrete Laplacian $\widetilde{\lambda}_h^{\ell,m}$. Otherwise, the matrix is singular, and its null-space is spanned by the eigenfunctions

$$v_h^{\ell,m} = \sin\ell\pi x \sin m\pi y, \tag{6}$$

with ℓ, m for which $\lambda_h^{\ell,m} = 0$.

2.1. Multigrid convergence for the Helmholtz equation. Textbook multigrid methods are typically set up so that a smoothing method reduces high frequency components of an error between the numerical approximation and the exact discrete solution, and a coarse grid correction handles the low frequency error components. Whereas such methods are easily defined for elliptic Poisson-like equations, this is not the case for the Helmholtz equation without any damping in (1), $\alpha = 0$. Depending on the particular value of k^2, this equation gives rise to both smoothing and coarse grid correction difficulties. The matrix has eigenvalues in only the right half-plane as long as k^2 is less than the smallest eigenvalue of the Laplacian, $\widetilde{\lambda}_h^{1,1}$. For $k^2 > \widetilde{\lambda}_h^{1,1}$, the matrix does not have only positive eigenvalues. Pointwise Jacobi iteration with underrelaxation does not [illegible] in that case, but since its smoothing properties are

satisfactory, the multigrid convergence will deteriorate only gradually for increasing k^2. By the time k^2 approaches the 6th eigenvalue $\widetilde{\lambda}_h^{\ell,m}$ ($k^2 \approx 150$), the standard multigrid method diverges. The Jacobi relaxation now diverges for smooth eigenfrequencies $v_h^{\ell,m}$ with $\widetilde{\lambda}_h^{\ell,m} < k^2$. Consequently, the multigrid method will still converge as long as the coarsest level used is fine enough to represent these smooth eigenfrequencies sufficiently. So, the coarsest level chosen limits the convergence. When k^2 gets larger more variables need to be represented on the coarsest level for standard multigrid convergence. Eventually, this does not result in an $\mathcal{O}(N)$ iterative method.

In addition to this feature, the Helmholtz equation also brings a multigrid coarse grid correction difficulty. Eigenvalues close to the origin may undergo a sign change after discretization on a coarser grid. If a sign change occurs, the coarse grid solution does not give a convergence acceleration to the finer grid problem but gives a severe convergence degradation (or even divergence) instead. In [11] this phenomenon is analyzed and a remedy for the coarse grid correction related to these problematic eigenvalues is proposed. The efficient treatment in [11] is that the multigrid method is combined with Krylov subspace iteration methods. GMRES is proposed as a smoother and as a cure for the problematic coarse grid correction.

Standard multigrid will also fail for k^2-values very close to eigenvalues. In that case subspace correction techniques should be employed [9].

An advanced multigrid based solution method for the Helmholtz equation is the wave-ray multigrid method [8]. The method has been adapted for a first-order system least-squares version of the Helmholtz equation in [18]. Wave-ray multigrid has been developed for Helmholtz problems with constant or smoothly varying wavenumbers. A thorough overview for the numerical solution of the Helmholtz equation is presented in [25].

3. Shifted Laplacian preconditioner. To solve (3), iterative methods based on the Krylov subspace are of interest. In particular, we choose preconditioned Bi-CGSTAB. In [13], Bi-CGSTAB is preferred over other Krylov subspace methods as the convergence for Helmholtz problems is reported typically faster than that of GMRES. We have also tested advanced versions such as Bi-CGSTAB(2) [22] and GMRESR [28], but Bi-CGSTAB remains the method of choice, especially for the Helmholtz equation without damping ($\alpha = 0$). A preconditioner $M \in \mathbb{C}^{N\times N}$ for A is developed such that the preconditioned system

$$AM^{-1}\boldsymbol{\psi} = \boldsymbol{g}, \qquad \boldsymbol{\psi} = M\boldsymbol{\phi}, \tag{7}$$

has better spectral properties than the original system. The preconditioner M proposed here is based on the following operator:

$$\mathcal{M} \equiv -\partial_{xx} - \partial_{yy} - (\beta_1 - \beta_2 i)k^2(x,y), \qquad \beta_1, \beta_2 \in \mathbb{R}, \tag{8}$$

with (β_1, β_2) parameters that can be chosen freely and with i the imaginary unit. Boundary conditions are set identical to those for the original Helmholtz problem (2).

A large imaginary value for the "wavenumber" physically corresponds to adding some form of damping for preconditioning. In the time domain the heat equation is sometimes used as the preconditioner for the Laplacian. Also the Jacobi iteration for the Laplacian can be interpreted as a time stepping procedure for the heat equation. For the wave equation such an iteration is a less common approach. A large imaginary Helmholtz term can be seen as a time-dependent term that is transformed to Fourier space.

If one is interested in only the interior problem without any damping term and real-valued boundary conditions, the original problem would be real-valued. Introducing a complex shift then introduces complex arithmetic into a real problem. Besides the extra work, it necessitates possibly different iterative solvers. Here, however, we are interested in geophysics applications with outgoing waves.

The basic choice in this paper is $(\beta_1, \beta_2) = (1, 1)$. Tuning of multigrid components is especially necessary for $\beta_2 < 1$, for example, for $\beta_2 = 0.5$, to be presented below. In [13] we have proposed a positive [illegible] shift $(\beta_1, \beta_2) = (0, 1)$ to the Laplacian for a satisfactory convergence. Preconditioner (8) is an improvement of this preconditioner with $\beta_1 = 1$.

We perform Fourier analysis to visualize the effect of the choice of (β_1, β_2) in the preconditioner on the clustering of the eigenvalues of the preconditioned system. For this we consider operator (7) with homogeneous Dirichlet boundary conditions, wavenumber k constant, and a discrete version of Helmholtz operator (1), A_h, and of preconditioner (8), M_h. This particular choice of the boundary conditions especially simplifies the analysis. For radiation boundary conditions the Helmholtz operator is nonnormal. Hence eigenvalue analysis alone would not be sufficient for analyzing preconditioned Krylov subspace methods. Here, we perform the analysis as a first indication of what we can expect from the solver to be developed and concentrate on the eigenvalues.

For both A_h and M_h we choose the 5-point stencil, as in (4). The components (6) are eigenfunctions of these discrete operators with constant coefficients. With these eigenfunctions $A_h M_h^{-1}$ is diagonalizable and the eigenvalues are easily determined. In the first tests we do not include damping in A_h, $\alpha = 0$ in (1), (4).

Figure 1 presents spectra of $A_h M_h^{-1}$ for $(\beta_1, \beta_2) = (0, 0)$ (Laplacian preconditioner), $(\beta_1, \beta_2) = (-1, 0)$ (Laird preconditioner [17]), $(\beta_1, \beta_2) = (0, 1)$ (preconditioner from [13]), $(\beta_1, \beta_2) = (1, 1)$ (basic parameter choice), $(\beta_1, \beta_2) = (1, 0.5)$, and $(\beta_1, \beta_2) = (1, 0.3)$ (more advanced parameters). The results are for $k = 40$ ($k^2 = 1600$) and $h = 1/64$. Similar eigenvalue distributions are observed for finer grids.

From the spectra presented with the new preconditioner, the lower pictures of Figure 1 are favorable as their real parts vary between 0 and 1. The Laplacian preconditioner in Figure 1(a) exhibits large isolated eigenvalues; for the Laird preconditioner the eigenvalues in Figure 1(b) are distributed between -1 and 1 on the real axis. The preconditioners with complex Helmholtz terms give rise to a curved spectrum. Whereas the real part of the spectrum in Figure 1(c) still includes a part of the negative real axis, this is not the case for the (β_1, β_2)-preconditioners with $\beta_1 = 1$. The difference between Figures 1(d), 1(e), and 1(f) is that, with a smaller value of β_2, fewer outliers close to the origin are observed. This is favorable for the convergence of the preconditioned Krylov method. The approximate inversion of the preconditioner itself by multigrid, however, will be shown to be harder for smaller values of β_2. In Figure 2 the spectra for $k = 100 (k^2 = 10^4)$ are presented on a grid with $h = 1/160$ for $\beta_1 = 1$ and β_2 varying between 1 and 0.3. The spectra are very similar to those in Figure 1. More eigenvalues lie, however, in the vicinity of the origin due to the higher wavenumber and the correspondingly finer grid. Figure 3 presents the distribution of eigenvalues for the case that 5% damping ($\alpha = 0.05$) is set in $\mathcal{A}$. Parameters in the preconditioner are $(\beta_1, \beta_2) = (1, 0.5)$. Again the 5-point stencil as in (4) is used for discretization. Figure 3(a) presents the spectrum for $k = 40, h = 1/64$, and Figure 3(b) presents the spectrum for $k = 100, h = 1/160$. An interesting observation is that now the eigenvalues move away from the origin into the right half-plane. This

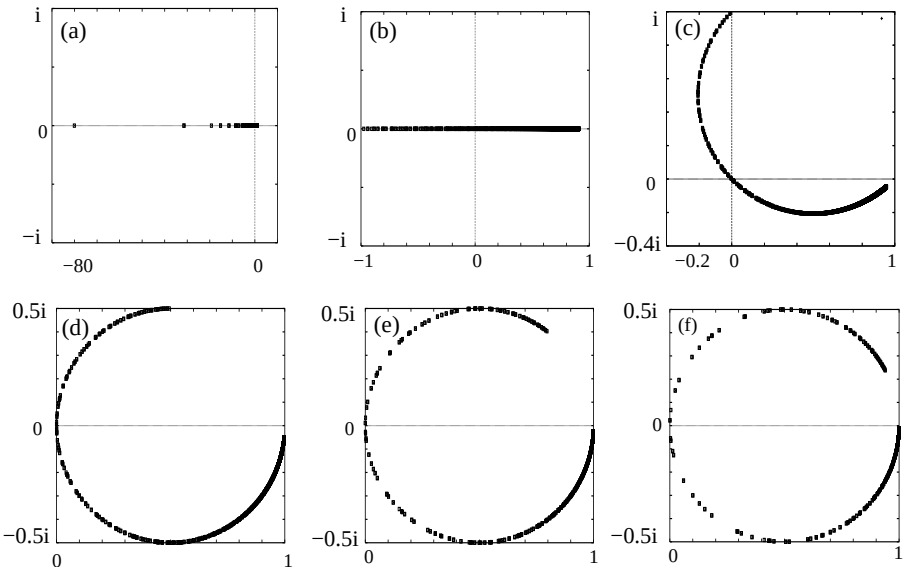

FIG. 1. *Spectral pictures of* $A_h M_h^{-1}$ *with* $\alpha = 0$ *and different values of* (β_1, β_2) *in* (8). (a) $(\beta_1, \beta_2) = (0, 0)$, (b) $(-1, 0)$, (c) $(0, 1)$, (d) $(1, 1)$, (e) $(1, 0.5)$, *and* (f) $(1, 0.3)$.

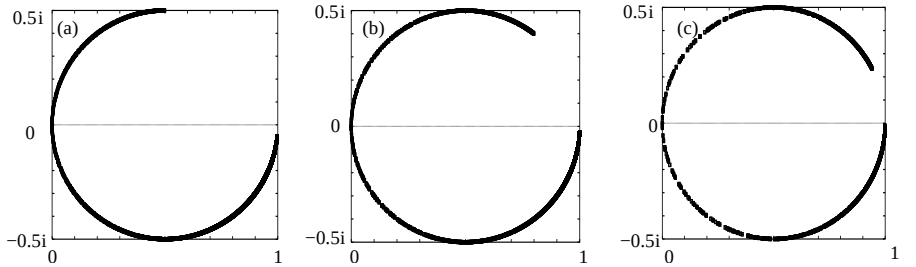

FIG. 2. *Spectral pictures of* $A_h M_h^{-1}$ *for* $k = 100$, $h = 1/160$, *and* $\alpha = 0$; (a) $(\beta_1, \beta_2) = (1, 1)$, (b) $(\beta_1, \beta_2) = (1, 0.5)$, *and* (c) $(\beta_1, \beta_2) = (1, 0.3)$.

is beneficial for iterative solution methods. From the spectra in Figure 3 it is expected that the Bi-CGSTAB (and GMRES) convergence in the case of damping will be considerably faster than for the undamped case.

4. Multigrid for the preconditioner.

4.1. Multigrid components. Geometric multigrid converges satisfactorily for the Helmholtz operator (8) for certain choices of β_1 and β_2 (assumed in [15], see also [16]). In this section, we detail the multigrid components that can be specified for approximately inverting a discrete version of $\mathcal{M}$ in (8). We consider a 5-point discretization and denote the equation for the preconditioner by $M_h \phi_h = \psi_h$. Standard multigrid coarsening, i.e., doubling the mesh size h in every direction, is chosen.

For smoothing the pointwise Jacobi relaxation with underrelaxation (ω-JAC) is chosen. This smoother is well parallelizable, which is an important aspect for our research (w.r.t. a generalization to three dimensions). In principle, one can choose the underrelaxation parameter $\omega \in \mathbb{C}$, but the Fourier analysis indicates that there is no real benefit for the problems considered. So, we choose $\omega \in \mathbb{R}$.

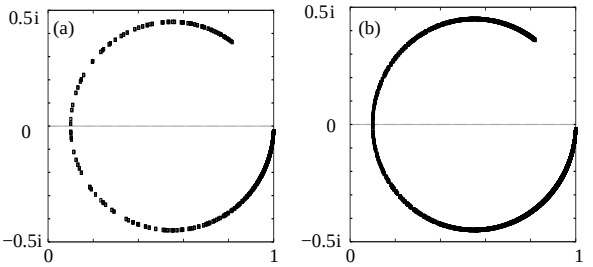

FIG. 3. *Spectral pictures of AM^{-1} with 5 % damping in A and $(\beta_1, \beta_2) = (1, 0.5)$; (a) $k = 40, h = 1/64$ and (b) $k = 100, h = 1/160$.*

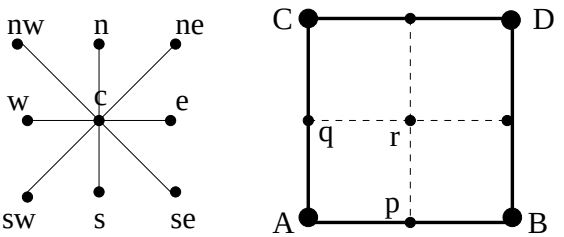

FIG. 4. *Left: Nine point stencil with numbering. Right: Coarse grid cell and four fine cells, (Coarse grid indices designated by capital letters and fine grid indices designated by lower case letters).*

The coarse grid correction components are also based on established operators. For the discrete coarse grid operators $M_{2h}, M_{4h}, \ldots$, the Galerkin coarse grid operator is used:

$$M_{2h} := R_h^{2h} M_h P_{2h}^h, \quad M_{4h} := R_{2h}^{4h} M_{2h} P_{4h}^{2h}, \quad \text{etc.}$$

In the Fourier analysis to follow, this discretization will be compared to a direct coarse grid discretization of (1). The Galerkin coarse grid discretization is a natural choice for heterogeneous problems. Also with boundary conditions containing first and second derivatives, it is convenient to choose the Galerkin coarse grid discretization as it defines the appropriate coarse grid boundary stencils automatically. The transfer operators used in building the coarse grid operators are the same as those used for transferring coarse and fine grid quantities to fine and coarse grids, respectively. The prolongation operator considered is an operator-dependent interpolation based on de Zeeuw's transfer operators [31]. Originally, this prolongation was set up for general (possibly unsymmetric) real-valued matrices with a splitting of matrix M into a symmetric and an antisymmetric part, $M_s = \frac{1}{2}(M + M^T)$, $M_t = M - M_s$ in [31]. However, since the discretization here leads to a complex symmetric matrix, the prolongation is adapted and briefly explained for such matrices with nine diagonals. The numbering in a stencil for the explanation of the prolongation is as shown in Figure 4 (left side). The right side of Figure 4 shows one coarse and four fine grid cells with indices for the explanation of the interpolation weights. Capital letters denote coarse grid points and lower case letters denote fine grid points. Operator element m_p^w, for example, denotes the west element of operator M_h at point p on the fine grid. The corrections from the coarse to the fine grid are obtained by interpolation among nearest coarse grid neighbors. The operator-dependent interpolation weights,

w, to determine the fine grid correction quantities e_h are derived with the following formulas.

- For fine grid points p in Figure 4, $e_{h,p} = w_A e_{H,A} + w_B e_{H,B}$.
  $w_A = \min(1, \max(0, w_w))$; $w_B = \min(1, \max(0, w_e))$,

where

$$d_w = \max(|m_p^{sw} + m_p^w + m_p^{nw}|, |m_p^{sw}|, |m_p^{nw}|), \tag{9}$$

$$d_e = \max(|m_p^{se} + m_p^s + m_p^{ne}|, |m_p^{se}|, |m_p^{ne}|), \tag{10}$$

$$w_w = \frac{d_w}{d_w + d_e}, \qquad w_e = \frac{d_e}{d_w + d_e}. \tag{11}$$

- For fine grid points q in Figure 4, $e_{h,q} = w_A e_{H,A} + w_C e_{H,C}$.
  $w_A = \min(1, \max(0, w_s))$; $w_C = \min(1, \max(0, w_n))$,

with

$$d_n = \max(|m_q^{nw} + m_q^n + m_q^{ne}|, |m_q^{nw}|, |m_q^{ne}|), \tag{12}$$

$$d_s = \max(|m_q^{sw} + m_q^s + m_q^{se}|, |m_q^{sw}|, |m_q^{se}|), \tag{13}$$

$$w_s = \frac{d_s}{d_s + d_n}, \qquad w_n = \frac{d_n}{d_s + d_n}. \tag{14}$$

On the remaining points the prolongation is defined as follows:

$$\text{On fine grid points that are also coarse points, } e_h(A) = e_{2h}(A). \tag{15}$$

$$\text{On points } r,\ e_h(r) \text{ is determined so that } \quad M_h P_{2h}^h e_{2h} = 0 \text{ at } r. \tag{16}$$

The interpolation weights are the same as in [31] but are specially tailored to the symmetric complex Helmholtz equation, i.e., the unsymmetric components in [31] have been removed. $|.|$ denotes the modulus, in this case, leading to real-valued interpolation weights. As for symmetric problems with jumping coefficients, the prolongation operator by de Zeeuw [31] is very similar to the original operator-dependent prolongation in [1]. In [1], for d_w, for example, the lumped sum of three elements, $m_p^{sw} + m_p^w + m_p^{nw}$, is chosen. For satisfactory convergence it is, however, important to consider the [illegible] of the operator elements, as in (9), (10), (12), and (13), in the definition of the interpolation weights. This prolongation is also valid at boundaries.

The full weighting operator is employed as the restriction operator. So, we do not choose the adjoint of the prolongation operator, which is commonly used but is not absolutely necessary, as already stated in [1] (an example where the restriction is not the adjoint of the prolongation operator has been given in [10]). We choose the combination of a full weighting restriction and the operator-dependent interpolation, as it brings a robust convergence for a variety of Helmholtz problems with constant and nonconstant coefficients. For constant coefficients and mildly varying wavenumbers, bilinear interpolation also gives very satisfactory convergence results, but for strongly varying coefficients, as in the Marmousi problem discussed in section 5.3, a robust and efficient convergence on different grid sizes and for many frequencies is observed for the combination of the transfer operators chosen.

4.2. Fourier analysis. Fourier smoothing and two-grid analysis, two classical multigrid analysis tools, have been used for quantitative estimates of the smoothing properties and of the other multigrid components in a two-grid method [5, 6, 7, 23, 24]. Consider a discretization of (7), (8), $M_h \phi_h = \psi_h$, where ϕ_h represents the exact discrete solution. The error $w_h^l = \phi_h^l - \phi_h$ after the lth iteration is transformed by a

cycle as

$$w_h^{l+1} = T_h^{2h}\, w_h^l, \qquad T_h^{2h} = S_h^{\nu_2} K_h^{2h} S_h^{\nu_1}, \qquad K_h^{2h} = I_h - P_{2h}^h (M_{2h})^{-1} R_h^{2h} M_h. \tag{17}$$

M_h, M_{2h} correspond to discretizations of (8) on the h-, $2h$-grid, S_h is the smoothing operator on the fine grid, and I_h is the identity operator. ν_l $(l = 1, 2)$ represents the number of pre- and postsmoothing steps, and R_h^{2h} and P_{2h}^h denote the restriction and prolongation operator, respectively. In the analysis we assume an equidistant grid with $\sqrt{N}$ points in each direction. The $O(h^2)$-discrete complex Helmholtz operator from (8) with constant wavenumber and Dirichlet boundary conditions belongs to the class of symmetric stencils. For these stencils it is possible to apply Fourier analysis on the basis of discrete sine-eigenfunctions $v_h^{\ell,m}$, $\ell, m = 1, \ldots, \sqrt{N} - 1$ (6), instead of the local Fourier analysis with exponential functions. For problems with symmetric stencils and homogeneous Dirichlet boundary conditions, this analysis can predict h-dependent convergence factors. From the discussion of multigrid methods for the original Helmholtz equation, it seems necessary to gain insight into the h-dependency of the multigrid methods developed also for the complex Helmholtz operator. (The definition of the operator-dependent prolongation and the Galerkin coarse grid stencils in section 4.1 also leads to symmetric operators that can be analyzed within this framework.)

For the pointwise Jacobi smoother, the $v_h^{\ell,m}$ (6) are also eigenfunctions of the smoothing operator. This is not true for the two-grid iteration operator T_h^{2h}. However, 4-dimensional linearly independent spaces, the

$$E_h^{\ell,m} = \left[v_h^{\ell,m},\ v_h^{\sqrt{N}-\ell,\sqrt{N}-m},\ -v_h^{\sqrt{N}-\ell,m},\ -v_h^{\ell,\sqrt{N}-m} \right] \quad \text{for} \quad \ell, m = 1, \ldots, \tfrac{\sqrt{N}}{2} \tag{18}$$

are invariant under these operators. One can show [23, 24] that

$$\begin{aligned} &M_h : \operatorname{span}[v_h^{\ell,m}] \to \operatorname{span}[v_h^{\ell,m}], \quad (M_{2h})^{-1} : \operatorname{span}[v_{2h}^{\ell,m}] \to \operatorname{span}[v_{2h}^{\ell,m}], \\ &S_h : \operatorname{span}[v_h^{\ell,m}] \to \operatorname{span}[v_h^{\ell,m}], \\ &R_h^{2h} : E_h^{\ell,m} \to \operatorname{span}[v_{2h}^{\ell,m}], \quad P_{2h}^h : \operatorname{span}[v_{2h}^{\ell,m}] \to E_h^{\ell,m}, \end{aligned}$$

and $T_h^{2h} : E_h^{\ell,m} \to E_h^{\ell,m}$ $(\ell, m = 1, \ldots, \frac{\sqrt{N}}{2})$. Therefore, the representation of T_h^{2h} with respect to $E_h^{\ell,m}$ leads to a block-diagonal matrix, $\widetilde{T}_h^{2h}$,

$$T_h^{2h} \triangleq \left[\widehat{T}_h^{2h}(\ell, m) \right]_{\ell,m=1,\ldots,\frac{\sqrt{N}}{2}} =: \widetilde{T}_h^{2h} \ . \tag{19}$$

Here the blocks $\widehat{T}_h^{2h}(\ell, m)$ are 4×4 matrices if $\ell, m < \frac{\sqrt{N}}{2}$, and are 2×2 (1×1) matrices if either $\ell = \frac{\sqrt{N}}{2}$ or $m = \frac{\sqrt{N}}{2}$ $(\ell = \frac{\sqrt{N}}{2}$ and $m = \frac{\sqrt{N}}{2})$. The two-grid convergence factor is defined as

$$\rho_{2g} := \max_{1 \le \ell, m \le \frac{\sqrt{N}}{2}} \rho\Big(\widehat{T}_h^{2h}(\ell, m) \Big) \ . \tag{20}$$

Thus, the spectral radii of at most 4×4 matrices $\widehat{T}_h^{2h}(\ell, m)$ have to be determined, and their maximum with respect to ℓ and m has to be found.

The definition of the smoothing factor μ is closely related. The smoothing factor measures the reduction of high frequency error components by an iterative method.

It is based on a coarse grid correction operator that annihilates the low frequency error components completely and keeps the high frequency components unchanged. K_h^{2h} is replaced by a projection operator Q_h^{2h} mapping onto the space of high frequencies, i.e., a block-diagonal matrix with $\widehat{Q}_h^{2h}$ at most 4×4-diagonal blocks defined by $\mathrm{diag}(0,1,1,1)$. So, μ is computed as ρ_{2g} (20) with $\widehat{K}_h^{2h}$ in $\widehat{T}_h^{2h}$ replaced by $\widehat{Q}_h^{2h}$.

Recently, three-grid Fourier analysis was proposed in [30]. An issue that can be analyzed in some more detail with a third grid is the coarse grid correction. If a large difference occurs between the two-grid and the three-grid convergence factors, ρ_{2g} and ρ_{3g}, this is an indication for a problematic coarse grid correction. For the complex Helmholtz preconditioner it is important to analyze the coarse grid correction carefully. The error transformation by a three-grid cycle is given by

$$\begin{aligned} & w_h^{l+1} = T_h^{4h}\, w_h^l \quad \text{with} \\ T_h^{4h} = S_h^{\nu_2} K_h^{4h} S_h^{\nu_1} \quad & \text{and} \quad K_h^{4h} = I_h - P_{2h}^h (I_{2h} - (T_{2h}^{4h})^\gamma)(M_{2h})^{-1} R_h^{2h} M_h. \end{aligned} \tag{21}$$

Here T_{2h}^{4h}, defined by (17), reads $T_{2h}^{4h} = S_{2h}^{\nu_2}(I_{2h} - P_{4h}^{2h}(M_{4h})^{-1}R_{4h}^{2h})S_{2h}^{\nu_1}$. M_{4h} corresponds to $4h$-grid discretization of (8); S_{2h} is the smoothing operator, and I_{2h} is the identity on the $2h$-grid; and R_{2h}^{4h} and P_{4h}^{2h} are transfer operators between the different grids. The $2h$-equation is solved approximately in a three-grid cycle (21) by performing γ two-grid iterations T_{2h}^{4h} with zero initial approximation; see also [23, 30].

The three-grid analysis is a recursive application of the two-grid analysis. Four frequencies are coupled not only in the transition from the h- to the $2h$-grid but also in the transition from the $2h$- to the $4h$-grid. Thus the three-grid error transformation operator couples 16 Fourier frequencies. As a consequence, T_h^{4h} is unitarily equivalent to a block-diagonal matrix $\widetilde{T}_h^{4h}$ with at most 16×16 blocks, $\widehat{T}_h^{4h}(\ell, m)$. The block matrices are composed of the Fourier symbols from the two-grid analysis, which is due to the recursive application of the two-grid analysis. One may compute the three-grid factor ρ_{3g} as the supremum of the spectral radii from the 16×16 block matrices, $\widehat{T}_h^{4h}(\ell, m)$.

For more details about the three-grid analysis, we refer to [30]. Three-grid Fourier analysis software, based on the exponential functions, is freely available; see http://www.mgnet.org/mgnet-codes-wienands.html.

4.3. Fourier analysis and multigrid results. We first compare the numerical multigrid convergence with asymptotic convergence factors $\mu, \rho_{2g}, \rho_{3g}$ from Fourier analysis. For this, we consider here solely the preconditioner $\mathcal{M}$ (8). (The behavior of the complete solution method will be considered in the next section.) Wavenumber k is taken as a constant here and a square domain with an equidistant grid is used. The second-order boundary conditions (2) are set in the numerical experiments to mimic reality.

An interesting aspect is that almost identical convergence factors are obtained, both from the analysis and from the actual experiments, for constant values of kh. They are set as in Table 1. The results are validated from $k = 40$ up to $k = 600$, the highest wavenumber tested is ($k^2 = 3.6 \times 10^5$). During testing the following abbreviations are used: "ω-JAC" is the Jacobi smoother with underrelaxation, "Galerkin" is the Galerkin coarse grid discretization, and "direct" is a direct coarse grid discretization of the PDE. "Direct" has not been implemented in the numerical code, but it can be used in the analysis framework.

Multigrid coarsening is continued until fewer than 10×10 points are processed on the coarsest grid. The number of levels is h- and therefore also k-dependent, as

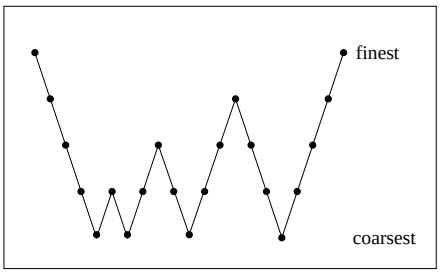

FIG. 5. *An F-cycle for five grids.*

TABLE 2

Comparison of asymptotic convergence from Fourier analysis with numerical multigrid convergence, $(\beta_1, \beta_2) = (0, 1)$. μ *is the smoothing factor;* ρ_{2g}, ρ_{3g} *are the two- and three-grid convergence factors from Fourier analysis; and* ρ_h *is the numerical multigrid convergence factor. The smoother is* ω*-JAC with* $\omega = 0.8$.

(ν_1, ν_2)	μ	ρ_{2g}	ρ_{3g}, $\gamma = 2$	ρ_h, F-cycle
(1,0)	0.60	0.60	0.60	0.58
(1,1)	0.36	0.36	0.36	0.34

kh is kept constant on the finest grid, and varies between 5 and 9 grids.

The F-cycle (see Figure 5) is always used in the numerical tests; the V-cycle's performance was generally too poor; and the W-cycle is considered too expensive on the very fine grids processed at high wavenumbers. The F-cycle often shows the robustness of the W-cycle at the efficiency of the V-cycle. In the three-grid analysis, $\gamma = 2$, the W-cycle analysis is used.

. . . . The Fourier analysis applied directly to the Helmholtz equation (1) with $\alpha = 0$ and the specified mesh sizes gives a satisfactory smoothing factor, but the two- and three-grid analysis convergence factors and also the actual multigrid results show a strong divergence, as expected.

. . . . $(\beta_1, \beta_2) = (0, 1)$ We start with $(\beta_1, \beta_2) = (0, 1)$, as in [13]. This case is not of the highest interest as a preconditioner, as the Bi-CGSTAB convergence for the corresponding preconditioned system is worse than with $\beta_1 = 1$ (shown in the next section). This case $(\beta_1, \beta_2) = (0, 1)$ serves as a reference for the comparison between Fourier analysis and numerical convergence. The underrelaxation parameter ω is set to $\omega = 0.8$, as this is the optimal choice for the Laplacian [24]. The agreement between the smoothing two- and three-grid Fourier analysis results with one and two smoothing iterations and the numerical convergence is excellent, presented in Table 2. The results obtained are very similar to the convergence factors for the Laplacian with ω-JAC.

. . . . For the case $(\beta_1, \beta_2) = (0, 1)$, one can adopt the well-known multigrid components: direct PDE coarse grid discretization and red-black Gauss–Seidel relaxation. This gives $\rho_{3g} = 0.16$ for $\gamma = 1$ and $\rho_{3g} = 0.08$ for $\gamma = 2$ with two smoothing iterations, very similar to the Laplacian situation. Red-black Gauss–Seidel relaxation is, however, not as robust as the ω-JAC relaxation for the $\beta_1 = 1$ cases. Furthermore, the cost in CPU time on a Linux PC of one red-black Gauss–Seidel iteration is about twice that of a Jacobi iteration.

. . . . $(\beta_1, \beta_2) = (1, 1)$ The second test is for $(\beta_1, \beta_2) = (1, 1)$. In this test we employ ω-JAC smoothing with $\omega = 0.7$ in an F(1,1)-cycle ($\nu_1 = \nu_2 = 1$). It is necessary to adapt the relaxation parameter ω for satisfactory numerical convergence. The

TABLE 3

Comparison of convergence $(\beta_1, \beta_2) = (1, 1)$ with Fourier analysis convergence ($\gamma = 1$), ω-JAC, $\omega = 0.7$, and $F(1,1)$-cycle. Coarse grid discretizations are compared. (The direct discretization has not been implemented).

TABLE 4

Fourier analysis convergence factors compared to multigrid convergence $(\beta_1, \beta_2) = (1, 0.5)$. The smoother is ω-JAC with $\omega = 0.5$. (The direct discretization has not been implemented).

Coarse discr.	μ	ρ_{2g}	ρ_{3g}, $\gamma = 2$	ρ_h, F(1,1)
Galerkin	0.60	0.60	0.60	0.61
Direct	0.60	0.60	0.60	-

performance of the ω-JAC smoother is not sensitive with respect to choosing somewhat smaller values of ω. We compare the Galerkin discretization with the direct coarse grid PDE discretization. Analysis results with two smoothing iterations are shown in Table 3, and they are compared to the numerical F(1,1) multigrid convergence.

Convergence factors well below 0.5 are obtained with the F(1,1)-cycle and ω-JAC relaxation with $\omega = 0.7$. The Fourier analysis results with the Galerkin coarse grid discretization are very similar to those obtained with a direct coarse grid PDE discretization.

$(\beta_1, \beta_2) = (1, 0.5)$ The preconditioner of choice in this paper is based on the parameters $(\beta_1, \beta_2) = (1, 0.5)$. For this parameter set it is possible to define a converging multigrid iteration by means of an F(1,1)-cycle, ω-JAC relaxation with $\omega = 0.5$, and a Galerkin coarse grid discretization. The underrelaxation parameter needs to be adapted for a robust convergence for a variety of heterogeneous Helmholtz problems. For values $\beta_2 < 0.5$ it is very difficult to define a satisfactory converging multigrid F(1,1)-cycle with the components at hand. They are therefore not considered.

Table 4 compares the Galerkin with the direct PDE coarse grid discretization. Also here, the operator-dependent interpolation and full weighting restriction are chosen, and two smoothing iterations are applied. The smoothing factors and two- and three-grid factors are very similar, which is an indication for the proper choice of coarse grid correction components for the problems under investigation. The numerical convergence with the F(1,1)-cycle is again very similar to the Fourier results.

In the following three remarks, we explain the satisfactory convergence of a standard multigrid method for the complex Helmholtz equation and $\beta_1 = 1$ with some heuristic arguments. The remarks show that, when β_2 is chosen small but such that the multigrid method still converges, the coarse grid stencils do not represent the fine grid problem well. In particular, the main diagonal operator elements in (22) on different coarse grids are smaller than the off-diagonal elements. This will be the reason why the V-cycle does not perform as well as the F-cycle and why damped Jacobi relaxation is a more robust smoother than red-black Gauss–Seidel relaxation for the case $\beta_2 = 0.5$.

The Fourier symbol of ω-JAC for the complex Helmholtz equation reads

TABLE 5
Smoothing factors μ_h for ω-JAC on different coarse grids and various (β_1, β_2)-values.

(β_1, β_2)	ω in ω-JAC	h			
		1/64	1/32	1/16	1/8
$(1, 0)$	0.7	0.47	0.75	2.31	0.18
$(0, 1)$	0.8	0.36	0.32	0.13	0.05
$(1, 1)$	0.7	0.47	0.56	0.35	0.13

$$S_h = 1 - \frac{\omega}{4 - (\beta_1 - \beta_2 i)(hk)^2} \left(4 - (\beta_1 - \beta_2 i)(hk)^2 - 2\cos \ell\pi h - 2\cos m\pi h\right),$$
$$\ell, m = 1, \ldots, \sqrt{N} - 1.$$

We consider the case $k = 40, h = 1/64$ and take ω as in the previous experiments. Table 5 presents smoothing factors on four consecutive grids for $(\beta_1, \beta_2) = (1, 0)$ (the original Helmholtz equation) and for $(\beta_1, \beta_2) = (0, 1), (1, 1)$, and $(1, 0.5)$. For simplicity, a direct PDE discretization on the coarse grids has been used. From Table 5, one confirms that for $h = 1/16, \omega$-JAC diverges for the original Helmholtz operator (also found with other relaxation parameters). This is in accordance with the remarks in [9, 11] that smoothing problems do not occur on the very fine or the very coarse grids but do occur on the intermediate grids. Furthermore, it can be observed that the $(\beta_1, \beta_2) = (0, 1)$-preconditioner resembles a Laplacian-type situation, with excellent smoothing factors on all grids. The preconditioners with $\beta_1 = 1, \beta_2 \neq 0$ give smoothing factors less than one on every grid. The (1,1)-preconditioner exhibits better smoothing factors than the set $(\beta_1, \beta_2) = (1, 0.5)$, which represents a limit case for which smoothing factors are still below one.

Some insight into the coarse grid correction can be gained from the so-called "simplified coarse grid analysis" or first-differential-approximation analysis [7, 9, 24]. As in [11] we apply this analysis for a one-dimensional (1D) Helmholtz operator. Assuming that transfer operators do not have any effect on the lowest frequencies, the quantity $1 - \lambda_h^\ell / \lambda_{2h}^{2\ell}$ (ℓ small) gives some insight into the relation between the discrete fine and coarse grid operators. This quantity should be close to zero and is an indication of the suitability of a coarse grid operator in a multigrid method. For the original 1D Helmholtz equation and $\alpha = 0$ (no damping), this quantity reads [11]

$$1 - \lambda_h^\ell / \lambda_{2h}^{2\ell} = \frac{\sin^4(\ell h\pi/2)}{\sin^2(\ell h\pi/2)\cos^2(\ell h\pi/2) - (kh/2)^2}, \qquad \ell = 1, \ldots, N.$$

It may give rise to a problematic coarse grid correction in the range where

$$\sin^2(\ell h\pi/2)\cos^2(\ell h\pi/2) \approx (kh/2)^2$$

and ℓ is associated with a smooth mode. For a 1D version of the [illegible] Helmholtz operator, this quantity reads

$$1 - \lambda_h^\ell / \lambda_{2h}^{2\ell} = \frac{\sin^4(\ell h\pi/2)}{\sin^2(\ell h\pi/2)\cos^2(\ell h\pi/2) - (kh/2)^2(\beta_1 - \beta_2 i)}$$
$$= \frac{\sin^4(\ell h\pi/2)\left(\sin^2(\ell h\pi/2)\cos^2(\ell h\pi/2) - (kh/2)^2(\beta_1 + \beta_2 i)\right)}{\left(\sin^2(\ell h\pi/2)\cos^2(\ell h\pi/2) - (kh/2)^2\beta_1\right)^2 + (kh/2)^2\beta_2^2},$$
$$\ell = 1, \ldots, N.$$

This expression for the complex Helmholtz operator is close to zero for the (β_1, β_2)-sets under consideration: the denominator does not reach zero, and the numerator contains the term $\sin^4 \ell h\pi/2$ which is very small for smooth eigenmodes.

When a Galerkin coarse grid discretization is used, it is difficult to gain insight into the coarse grid correction, as the coarse grid stencil elements are constructed with nontrivial formulas. Therefore, we discuss here for the case $(\beta_1, \beta_2) = (1, 0.5)$ two coarse grid discretizations. With $h = 1/64, k = 40$, $\alpha = 0$ in (4), we obtain by direct PDE discretization similar coarse grid stencils as the fine grid stencil with grid sizes $2h$ or $4h$, respectively. In that case, only the central stencil element contains an imaginary contribution. When the Galerkin coarse grid operator is employed, the imaginary part is distributed over all entries. With operator-dependent interpolation and full weighting restriction we find

$$A_{2h} \triangleq \begin{bmatrix} -282.9 + 15.3i & -665.8 + 80.6i & -282.9 + 15.3i \\ -665.8 + 80.6i & 2164.5 + 461.2i & -665.8 + 80.6i \\ -282.9 + 15.3i & -665.8 + 80.6i & -282.9 + 15.3i \end{bmatrix},$$

$$A_{4h} \triangleq \begin{bmatrix} -129.5 + 43.0i & -290.1 + 135.0i & -129.5 + 43.0i \\ -290.1 + 135.0i & -101.4 + 483.2i & -290.1 + 135.0i \\ -129.5 + 43.0i & -290.1 + 135.0i & -129.5 + 43.0i \end{bmatrix}. \tag{22}$$

The h-ellipticity measures are 0.28 and 0.18, indicating the suitability of the stencils for pointwise smoothing [7, 24]. For the direct PDE discretization, the h-ellipticity measures are 0.13 and 0.45 for the $2h$- and $4h$-discretizations, respectively. The fact that these qualitative measures are not close to zero means that pointwise smoothers can be constructed for these stencils. From these complicated coarse grid stencils it is, however, difficult to judge between the different smoothers, relaxation parameters, etc., but the three-grid Fourier analysis helps to some extent. We obtain very satisfactory multigrid convergence with simple multigrid components, although the coarse grid discretization (22) seems awkward. At least it does not spoil the h-independent multigrid convergence. One merely needs to choose the underrelaxation parameter in the smoother with some care.

4.4. Multigrid for the preconditioner. One multigrid iteration is taken for approximating the inverse of the operator in (8). After some experimentation it was found that it is sufficient to employ a multigrid iteration with a convergence factor $\rho_h \approx 0.6$ for the preconditioner. To some extend this can also be observed qualitatively from spectral pictures obtained by Fourier analysis (again, constant k, Dirichlet boundary conditions). Starting with a regular splitting of M_h,

$$C_h \phi_h^{l+1} = (C_h - M_h)\phi_h^l + \psi_h, \quad \text{or} \quad \phi_h^{l+1} = (I_h - C_h^{-1} M_h)\phi_h^l + C_h^{-1}\psi_h. \tag{23}$$

This splitting is considered to represent a multigrid iteration, with iteration matrix $(I_h - C_h^{-1}M_h)$ and C_h^{-1} an [illegible] of M_h^{-1}. T_h^{2h} in (17) represents the two-grid version of a multigrid iteration matrix. Therefore, we equate $T_h^{2h} = I_h - C_h^{-1}M_h$. Matrix $\widetilde{T}_h^{2h}$ in (19) is a block matrix related to T_h^{2h}: $\widetilde{T}_h^{2h} = U_h T_h^{2h} U_h^{-1}$, where U_h is a unitary matrix with four consecutive rows defined by the orthogonal eigenvectors related to (6). U_h transforms the two-grid iteration matrix into the block-diagonal matrix $\widetilde{T}_h^{2h}$. Clearly,

$$\widetilde{T}_h^{2h} = I_h - U_h C_h^{-1} M_h U_h^{-1}, \text{ and}$$
$$U_h C_h^{-1} M_h U_h^{-1} = U_h C_h^{-1} U_h^{-1} U_h M_h U_h^{-1} =: \widetilde{C}_h^{-1} \widetilde{M}_h$$

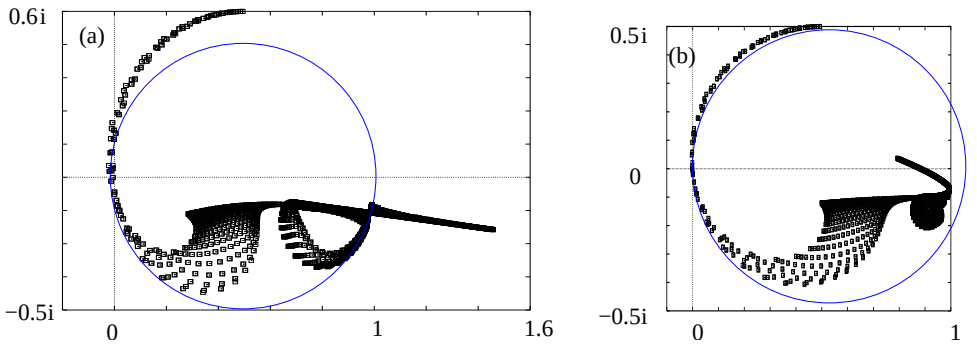

FIG. 6. *Spectral pictures of the preconditioned system with one two-grid iteration used for preconditioning* $(\beta_1, \beta_2) = (1, 1)$, $k = 40, h = 1/64$*:* (a) *one* ω*-JAC relaxation and* (b) *two* ω*-JAC relaxations,* $\omega = 0.7$*. (The eigenvalues with the exact inversion lie at the circles.)*

is in block-diagonal form. We have $\widetilde{C}_h^{-1}\widetilde{M}_h\widetilde{M}_h^{-1} = (I_h - \widetilde{T}_h^{2h})\widetilde{M}_h^{-1}$. So, the expression for the block-diagonal form $\widetilde{A}_h\widetilde{C}_h^{-1}$ ($\widetilde{C}_h^{-1}$ is the approximation of $\widetilde{M}_h^{-1}$) from (7) reads

$$\widetilde{A}_h\widetilde{C}_h^{-1} = \widetilde{A}_h(I_h - \widetilde{T}_h^{2h})\widetilde{M}_h^{-1}. \tag{24}$$

As all the symbols of the operators in the right-hand side of (24) can be formed easily with Fourier two-grid analysis, the corresponding eigenvalues can be visualized for various multigrid cycles. These spectra can be compared to those in Figure 1, where operator M_h from (8) is inverted exactly. Figure 6, for example, presents the spectrum of the $(\beta_1, \beta_2) = (1, 1)$-preconditioned system where a two-grid iteration is used for preconditioning for wavenumber $k = 40$ ($h = 1/64$). Figure 6(a) shows the spectrum for one ω-JAC ($\omega = 0.7$) smoothing iteration for which $\rho_{2g} \approx 0.7$, whereas Figure 6(b) shows the two-grid spectral picture with two ω-JAC smoothing iterations, $\nu_1 + \nu_2 = 2$, operator-dependent interpolation, full weighting restriction, and Galerkin coarse grid discretization ($\rho_{2g} = 0.45$). Figure 6(b) shows a spectrum that coincides well with the spectrum related to the exact inversion in Figure 1(d), whereas in Figure 6(a) eigenvalues are also outside the circle obtained with the exact inversion.

Figure 7 presents the spectra with a two-grid iteration for the $(\beta_1, \beta_2) = (1, 0.5)$-preconditioner and Galerkin coarsening, with ω-JAC relaxation ($\omega = 0.5$). Figure 7(a) is for $\nu = 1$; Figure 7(b) is for $\nu = 2$. Also for this approximate inversion of the preconditioner the spectrum obtained in Figure 7(b) compares well with the exact inversion in Figure 1(e), indicating that one multigrid iteration with two ω-JAC smoothing steps may be sufficient for approximating M_h^{-1}.

Indeed, a numerical comparison between inverting the preconditioner by several multigrid iterations versus by only one multigrid iteration did not lead to substantially different numbers of Krylov subspace iterations for solving the Helmholtz problem.

5. Applications. In this section the overall solution method, preconditioned Bi-CGSTAB for the indefinite heterogeneous Helmholtz problems (1) with the complex Helmholtz (β_1, β_2)-preconditioner, is evaluated. One multigrid F(1,1)-cycle is used for approximately inverting the preconditioner equation with the complex Helmholtz operator. Three problems of increasing difficulty are discussed.

5.1. Constant wavenumber. For constant wavenumbers k the Bi-CGSTAB convergence for the Helmholtz equation with the three preconditioners is presented.

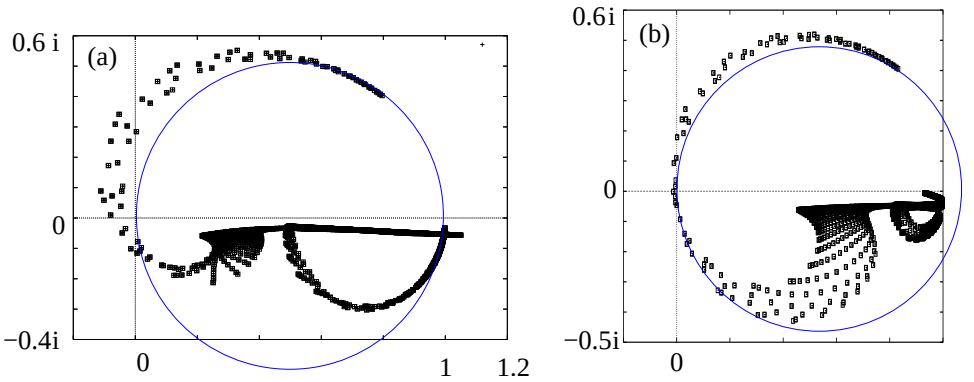

FIG. 7. *Spectral pictures of preconditioned system with one two-grid iteration used for preconditioning* $(\beta_1, \beta_2) = (1, 0.5)$*,* $k = 40, h = 1/64$*:* (a) *one* ω*-JAC relaxation and* (b) *two* ω*-JAC relaxations,* $\omega = 0.5$*. (The eigenvalues with exact inversion lie at the circles.)*

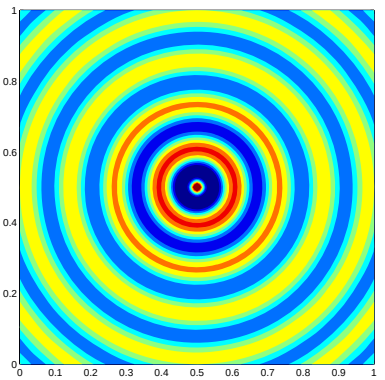

FIG. 8. *Numerical solution at* $k = 50$ *for the model problem with* k *constant.*

We consider a square domain $\Omega = (0, 1)^2$. A point source is located at the center of the domain. The solution satisfies the second-order conditions (2). In these experiments the finest grid size for each wavenumber is as shown in Table 1. The numerical solution corresponding to $k = 50$ is presented in Figure 8. Unphysical reflections at the boundaries are not present due to the boundary treatment.

A zero initial guess has been used during the computations. The Bi-CGSTAB iteration is terminated as soon as the initial residual is reduced by 7 orders of magnitude. Note that each Bi-CGSTAB iteration involves two preconditioning steps.

For all three preconditioners, $(\beta_1, \beta_2) = (0, 1), (1, 1)$, and $(1, 0.5)$, the method chosen to approximately invert the preconditioner consists of one multigrid F(1,1)-cycle with ω-JAC, operator-dependent interpolation plus full weighting as the transfer operators, and a Galerkin coarse grid discretization. The only difference is the value of the underrelaxation parameter in ω-JAC, which is $\omega = 0.8$ for $(\beta_1, \beta_2) = (0, 1)$, $\omega = 0.7$ for $(\beta_1, \beta_2) = (1, 1)$, and $\omega = 0.5$ for $(\beta_1, \beta_2) = (1, 0.5)$. The results for different values of k and $(\beta_1, \beta_2) = (0, 1)$ are presented in the upper part of Table 6. In the middle part of Table 6, the Bi-CGSTAB convergence with the $(\beta_1, \beta_2) = (1, 1)$-preconditioner is presented. In the lower lines of Table 6 the $(\beta_1, \beta_2) = (1, 0.5)$-preconditioner is employed. Next to the results for the Helmholtz equation without

TABLE 6

Number of preconditioned Bi-CGSTAB iterations and CPU time in seconds (in parentheses) to reduce the initial residual by 7 orders. Damping parameter α is varied in the Helmholtz problem.

	5 % damping	44 (11.9)	64 (115)	66 (165)

any damping ($\alpha = 0$), we also show the convergence with 2.5% ($\alpha = 0.025$) and 5% ($\alpha = 0.05$) damping. The number of Bi-CGSTAB iterations are presented as well as the CPU time on a Pentium 4 PC with 2.4 Ghz and 2 Gb RAM. From the results in Table 6 we conclude that the preferred methods among the choices are the preconditioners with $\beta_1 = 1$. This was already expected from the spectra in Figure 1. Fastest convergence is obtained for $(\beta_1, \beta_2) = (1, 0.5)$. The components of the multigrid iteration for this preconditioner have been validated with the help of the Fourier analysis.

Table 6 shows that the Bi-CGSTAB convergence with some damping in the Helmholtz problem is considerably faster than for $\alpha = 0$. This was already expected from the spectra in Figure 3. Furthermore, the number of iterations in the case of damping grows only slowly for increasing wavenumbers, especially for the $(\beta_1, \beta_2) = (1, 0.5)$-preconditioner.

The difference between the two preconditioners with $\beta_1 = 1$ is more pronounced if we compute higher wavenumbers. The Bi-CGSTAB convergence and CPU time for the higher wavenumbers, without and with damping in the Helmholtz problem, are presented in Table 7. Also for the higher wavenumbers damping in the Helmholtz problem by means of $\alpha \neq 0$ improves the convergence significantly. Very satisfactory convergence is found for high wavenumbers on fine grids.

5.2. The wedge model. A problem of intermediate difficulty is the wedge model. It is used to evaluate the preconditioner's behavior for a simple heterogeneous medium. The problem is adopted from [19]. The domain is defined to be a rectangle of dimension $600 \times 1000\ m^2$. The second-order boundary conditions (2) are set, and a point source is located at the center of the upper surface (which is assigned

(a) (b) (c)

FIG. 9. *Wedge problem:* (a) *Problem geometry with velocity profile indicated,* (b) *real part of numerical solution at* 30 *Hz, and* (c) *real part of numerical solution at* 50 *Hz.*

to be $y = 0$) with frequency, $f = \overline{k}c/(2\pi)L$, varying from 10 to 60 Hz (where c is the speed of sound). The corresponding values of the local dimensionless wavenumbers $\overline{k}$ vary between 20 (smallest for 10 Hz) and 240 (biggest for 60 Hz). For the problem at 10 Hz approximately 18 points per wavelength are used. Figure 9(a) presents the domain, the wedge, and the variation of c in the medium. The variation of c is due to the different local properties of the medium. The real part of the numerical solution for the wedge problem at 30 Hz and 50 Hz is plotted in Figures 9(b) and 9(c).

In the preconditioner (8) wavenumber $k(x, y)$ is chosen as in the original problem. Also the boundary conditions in the preconditioner are as for the original problem. The number of Bi-CGSTAB iterations with one multigrid iteration for the preconditioner with $(\beta_1, \beta_2) = (0, 1), (1, 1)$, and $(1, 0.5)$ are displayed in Table 8 for frequencies ranging from 10 to 60 Hz on corresponding grid sizes. Results with and without damping in the Helmholtz problem are presented. The only difference in the multigrid methods for the preconditioner is the value of the relaxation parameter: for $(\beta_1, \beta_2) = (0, 1)$ $\omega = 0.8$, for $(\beta_1, \beta_2) = (1, 1)$ $\omega = 0.7$, and for $(\beta_1, \beta_2) = (1, 0.5)$ $\omega = 0.5$. A zero initial guess has been used as a starting approximation. The convergence results for $(\beta_1, \beta_2) = (1, 0.5)$ are best, also without any damping in the original problem. The convergence with the (1,0.5)-preconditioner is about 1.5 times faster than with the (1,1)-preconditioner and about 3 times faster than with the (0,1)-preconditioner. The Bi-CGSTAB convergence for the wedge problem for $\alpha = 0$ and different frequencies are also visualized for $(\beta_1, \beta_2) = (1, 0.5)$ in Figure 10.

5.3. The Marmousi problem. This example is a part of the full Marmousi problem which mimics subsurface geology [4]; see also [19]. The domain is rectangular with a dimension of $6000 \times 1600\ m^2$. A point source is placed at the center of the upper surface. The values for the speed of sound c are irregularly structured throughout the

domain; see Figure 11(a). The minimum number of points per wavelength equals 17. The frequency is varied between 1 and 30 Hz.

Preconditioning consists of one multigrid iteration for the complex Helmholtz equation with the multigrid components prescribed. The underrelaxation parameter in ω-JAC is varied as usual depending on (β_1, β_2). In the preconditioner again the wavenumbers $k(x, y)$ are as in the original problem. Also the boundary conditions are as in the original problem. Table 9 presents the number of Bi-CGSTAB iterations to solve the indefinite Helmholtz–Marmousi problem with the CPU times required shown

		2.5%	67 (34.1)	55 (28.2)	32 (17.0)
		5.0%	64 (32.5)	53 (27.3)	31 (16.5)
10	751 × 201	0.0%	180 (89.2)	84 (42.4)	47 (24.2)
		2.5%	119 (59.4)	59 (30.1)	33 (17.5)
		5.0%	96 (48.3)	48 (24.8)	28 (15.0)
20	1501 × 401	0.0%	414 (832.3)	168 (308.7)	104 (212.1)
		2.5%	203 (410.8)	88 (179.9)	55 (115.3)
		5.0%	145 (294.7)	64 (133.4)	37 (79.3)
30	2001 × 534	0.0%	458 (1724.8)	211 (799.4)	136 (519.4)
		2.5%	197 (745.6)	94 (361.1)	58 (226.8)
		5.0%	119 (455.3)	61 (238.4)	38 (151.9)

in parentheses. Results are presented for $\alpha = 0, 0.025$, and 0.05. A zero initial guess has been used. The $(\beta_1, \beta_2) = (1, 0.5)$-preconditioner shows a satisfactory and robust convergence for this problem with irregularly varying wavenumbers. For $\alpha = 0.05$ the number of iterations increases only very slowly for increasing frequencies. With the $(\beta_1, \beta_2) = (1, 0.5)$-preconditioner the CPU time is reduced by a factor of 3 compared to the performance of the $(\beta_1, \beta_2) = (0, 1)$-preconditioner for the challenging problems. The difference with the $(\beta_1, \beta_2) = (1, 1)$ is less pronounced but still significant.

The real parts of the solutions at 20 Hz for $\alpha = 0$ and $\alpha = 0.025$ are presented in Figures 11(b) and 11(c). The effect of damping of the solution is significant, as can be deduced from these global pictures. However, in the actual geophysics applications, some damping is present. Figure 11(c) may therefore be a more realistic solution for the real application. An adaptation of the solution method presented to a variant

of the Helmholtz problem in which the damping parameter α is varying [illegible] is an easy generalization in our preconditioner.

6. Conclusions. In this paper a complex Helmholtz preconditioner has been proposed for handling indefinite Helmholtz problems in heterogeneous media. In the preconditioner we advocate the use of a Helmholtz operator with a negative real term, as in the original Helmholtz problem, plus a positive imaginary Helmholtz part. Multigrid is proposed for approximately inverting the complex Helmholtz operator in the preconditioner. As the original Helmholtz problems are defined on square domains with structured grids (a common choice for many geophysical applications), a geometric multigrid method based on cartesian grids can be defined for the complex Helmholtz preconditioner. Extension of the geometric multigrid to the complex Helmholtz operator is straightforward. We can employ very similar multigrid components as those for the Laplacian, with some variation of the underrelaxation parameter in the point-wise Jacobi smoother, and an operator-dependent prolongation operator to deal with highly varying wavenumbers. These components are validated by Fourier analysis tools. The smallest size of the β_2-parameter in front of the imaginary Helmholtz term in the preconditioner, for which the multigrid method can be successfully employed, has been determined. After a parameter study all parameters appearing in the method are fixed (i.e., $\beta_1 = 1, \beta_2 = 0.5, \omega = 0.5$ in ω-JAC).

Bi-CGSTAB, preconditioned with a multigrid iteration for the complex Helmholtz operator, proves to be an efficient and robust iterative solution method to solve heterogeneous high wavenumber Helmholtz problems. The applications ranged from constant wavenumber to irregular heterogeneity structures in a medium. The multigrid components have been chosen such that the solution method is well parallelizable. The method proposed and the corresponding analysis are easily generalized to three dimensions. This is currently being done.

Acknowledgments. The use of Roman Wienands freely available Fourier analysis software *LFA00_scalar* and the particular version *RFA00_scalar* has been extremely helpful and is gratefully acknowledged.

THE METHOD OF FUNDAMENTAL SOLUTIONS FOR STATIONARY HEAT CONDUCTION PROBLEMS IN ROTATIONALLY SYMMETRIC DOMAINS*

YIORGOS-SOKRATIS SMYRLIS† AND ANDREAS KARAGEORGHIS†

Abstract. We propose an efficient boundary collocation method for the solution of certain two- and three-dimensional problems of steady-state heat conduction in isotropic bimaterials. In particular, in two dimensions we consider the case where a circular region composed of one material is coated with an annular region of another material. In three dimensions, we examine the corresponding case for axisymmetric domains. The proposed method involves the use of a domain decomposition technique in conjunction with a matrix decomposition algorithm. The circulant structure of the matrices appearing in this method is exploited by using fast Fourier transforms. The method is tested numerically on several problems.

Key words. heat conduction in layered materials, method of fundamental solutions, Laplace equation, axisymmetric domains

1. Introduction.

We consider steady-state heat conduction in an isotropic bimaterial. The bimaterial is decomposed into two subdomains $\mathfrak{O}_1$ and $\mathfrak{O}_2$, with boundaries $\partial\mathfrak{O}_1$ and $\partial\mathfrak{O}_2$, respectively, which are separated by an interface $\mathcal{S} = \partial\mathfrak{O}_1$. The two materials in $\mathfrak{O}_1$ and $\mathfrak{O}_2$ are characterized by the thermal conductivity constants k_1 and k_2, respectively. The temperature distribution in each subdomain satisfies the Laplace equation. On the interface $\mathcal{S}$ we have continuity of the temperature

$$u_1 = u_2$$

and continuity of the flux

$$k_1 \frac{\partial u_1}{\partial n} = k_2 \frac{\partial u_2}{\partial n},$$

where $\partial/\partial n$ denotes the normal derivative in the outward direction to $\mathfrak{O}_1$ on the interface. Examples and details about the modeling of such problems may be found in [18, 24].

The aim of this study is to develop efficient algorithms for the numerical solution of such problems in the case when $\overline{\mathfrak{O}}_1 \subset \mathfrak{O}_2$ and both domains are axisymmetric about the same axis. In two dimensions this means that we consider the case where one material occupies a circular region and another material occupies a concentric annular region surrounding it. In three dimensions, we examine the case where one material occupies an axisymmetric region and is coated by another material occupying a region which is axisymmetric about the same axis.

This work was supported by University of Cyprus grant 8037-3/312-21005 21014. Part of the second author's work was undertaken while the author was a visiting professor in the Department of Mathematical and Computer Sciences, Colorado School of Mines, Golden, CO 80401.

The numerical method that we use is the method of fundamental solutions (MFS) which is a boundary collocation meshless technique. In recent years, the MFS has become very popular, primarily because of the ease with which it can be implemented. It belongs to the family of Trefftz-type methods (see [4]), and details about its implementation and its various applications can be found in the survey articles [6, 7, 11] and the books [10, 14].

We use a domain decomposition approach and a matrix decomposition algorithm. The domain is decomposed in a natural way into two subdomains, each containing a different material. Domain decomposition MFS applications can be found in [1], where heat conduction in layered materials is considered, and in [2, 9], where linear elasticity problems are studied. In the current work, in both the two- and the three-dimensional cases, the MFS discretization leads to the solution of linear systems whose coefficient matrices have [illegible] structures which can be exploited by using fast Fourier transforms (FFTs). The circulant and/or block circulant structure of the matrices appearing when the MFS is applied to axisymmetric problems has been exploited in [8, 22]. The idea of exploiting the FFTs to solve axisymmetric integral equations was introduced in [12]; see also [16]. The circulant structure of the coefficient matrices also arises from the application of other boundary methods such as the boundary element method (BEM), and this has been exploited in the past (see, e.g., [3, 15]). Details of applying a multiregion BEM approach to heat conduction problems in layered materials are presented in [19].

This paper is organized as follows. In section 2, we present the MFS formulation in the two-dimensional case. In section 3, we present the MFS formulation in the three-dimensional case. In section 4, we test numerically the proposed algorithms. Finally, in section 5, we give some concluding remarks.

2. The two-dimensional case.

2.1. The problem.

We consider the bimaterial problem in $\mathbb{R}^2$,

$$\Delta u_1 = 0 \quad \text{in} \quad B_{\varrho_1}, \tag{2.1a}$$

$$\Delta u_2 = 0 \quad \text{in} \quad A_{\varrho_1,\varrho_2}, \tag{2.1b}$$

subject to the boundary condition

$$u_2 = f \quad \text{on} \quad S_{\varrho_2} \tag{2.1c}$$

and the interface conditions

$$u_1 = u_2 \quad \text{and} \tag{2.1d}$$

$$k_1 \frac{\partial u_1}{\partial n} = k_2 \frac{\partial u_2}{\partial n} \quad \text{on} \quad S_{\varrho_1}. \tag{2.1e}$$

Here,

$$B_\varrho = \{\boldsymbol{x} : |\boldsymbol{x}| < \varrho\}, \quad S_\varrho = \{\boldsymbol{x} : |\boldsymbol{x}| = \varrho\},$$

and

$$A_{\varrho_1,\varrho_2} = \{\boldsymbol{x} \in \mathbb{R}^2 : \varrho_1 < |\boldsymbol{x}| < \varrho_2\}.$$

The coefficients k_1, k_2 in (2.1e) are the thermal conductivity constants. Δ denotes the Laplacian and f is a given function. The boundary of A_{ϱ_1,ϱ_2} is $\partial A_{\varrho_1,\varrho_2} = S_{\varrho_1} \cup S_{\varrho_2}$. In (2.1e), $\partial/\partial n$ denotes the normal derivative in the outward direction to B_{ϱ_1} on S_{ϱ_1}.

2.2. MFS formulation. We treat the two subdomains separately: in B_{ϱ_1} we approximate u_1 at a point P by

$$u_1^N(\boldsymbol{c}, \boldsymbol{Q}; P) \;=\; \sum_{\nu=1}^{N} c_\nu \varphi(P, Q_\nu),$$

and in A_{ϱ_1,ϱ_2} we approximate u_2 at a point P by

$$u_2^N(\boldsymbol{d}, \boldsymbol{e}, \boldsymbol{S}, \boldsymbol{T}; P) \;=\; \sum_{\nu=1}^{N} d_\nu \varphi(P, S_\nu) + \sum_{\nu=1}^{N} e_\nu \varphi(P, T_\nu),$$

where the $2N$-dimensional vectors $\boldsymbol{Q}$, $\boldsymbol{S}$, and $\boldsymbol{T}$ contain the coordinates of the [illegible]. In particular, the singularities described by $\boldsymbol{Q}$ lie outside $\overline{B}_{\varrho_1}$, whereas the singularities described by $\boldsymbol{S}$ and $\boldsymbol{T}$ lie outside the annulus $\overline{A}_{\varrho_1,\varrho_2}$.

The function $\varphi(P, Q)$ is a fundamental solution of the Laplacian Δ, i.e.,

$$-\Delta\, \varphi(\cdot, Q) \;=\; \delta_Q, \tag{2.2}$$

where δ_Q is the Dirac unit mass at Q. Equation (2.2) is satisfied in the sense of distributions. In particular, we take

$$\varphi(P, Q) \;=\; -\frac{1}{2\pi} \log |P - Q|,$$

with $|P - Q|$ denoting the distance between the points P and Q. The vectors $\boldsymbol{c} = (c_1, \ldots, c_N)$, $\boldsymbol{d} = (d_1, \ldots, d_N)$, and $\boldsymbol{e} = (e_1, \ldots, e_N)$ contain the coefficients of the fundamental solutions.

Specifically, the singularities $\boldsymbol{Q} = (Q_1, \ldots, Q_N)$ are placed on the circle of radius R_1, i.e., $S_{R_1} = \{\boldsymbol{x} : |\boldsymbol{x}| = R_1\}$, where $R_1 > \varrho_1$, at the points

$$Q_j \;=\; (R_1 \cos \vartheta_j, R_1 \sin \vartheta_j), \quad \vartheta_j = \frac{2\pi(j - 1 + \alpha)}{N}, \quad j = 1, \ldots, N,$$

and the singularities $\boldsymbol{S} = (S_1, \ldots, S_N)$ and $\boldsymbol{T} = (T_1, \ldots, T_N)$ are placed on the circles $S_{R_2} = \{\boldsymbol{x} : |\boldsymbol{x}| = R_2\}$, and $S_{R_3} = \{\boldsymbol{x} : |\boldsymbol{x}| = R_3\}$, respectively, with $R_2 < \varrho_1 < \varrho_2 < R_3$, at the points

$$S_j \;=\; (R_2 \cos \psi_j, R_2 \sin \psi_j), \quad T_j \;=\; (R_3 \cos \psi_j, R_3 \sin \psi_j), \quad \psi_j = \frac{2\pi(j - 1 + \beta)}{N},$$

$j = 1, \ldots, N$. The parameters α and β, where $\alpha, \beta \in [-\frac{1}{2}, \frac{1}{2}]$, describe rotations of the singularities. It has been observed that such rotations improve the approximation significantly, especially when the singularities are close to the boundary. (See [20, 21, 23, 25]).

Two sets of equally spaced collocation (or observation) points $\boldsymbol{P}^1 = (P_1^1, \ldots, P_N^1)$ and $\boldsymbol{P}^2 = (P_1^2, \ldots, P_N^2)$ are taken on the circles S_{ϱ_1} and S_{ϱ_2}, respectively:

$$P_j^1 \;=\; (\varrho_1 \cos \chi_j, \varrho_1 \sin \chi_j), \quad P_j^2 \;=\; (\varrho_2 \cos \chi_j, \varrho_2 \sin \chi_j), \quad \chi_j = \frac{2\pi(j - 1)}{N},$$

where $j = 1, \dots, N$. The vectors of coefficients $\boldsymbol{c}$, $\boldsymbol{d}$, and $\boldsymbol{e}$ are determined from the collocation equations

$$u_1^N(\boldsymbol{c}, \boldsymbol{Q}; P_j^1) = u_2^N(\boldsymbol{d}, \boldsymbol{e}, \boldsymbol{S}, \boldsymbol{T}; P_j^1), \tag{2.3a}$$

$$k_1 \frac{\partial}{\partial n} u_1^N(\boldsymbol{c}, \boldsymbol{Q}; P_j^1) = k_2 \frac{\partial}{\partial n} u_2^N(\boldsymbol{d}, \boldsymbol{e}, \boldsymbol{S}, \boldsymbol{T}; P_j^1), \tag{2.3b}$$

$$u_2^N(\boldsymbol{d}, \boldsymbol{e}, \boldsymbol{S}, \boldsymbol{T}; P_j^2) = f(P_j^2), \tag{2.3c}$$

$j = 1, \dots, N$. Clearly, (2.3a), (2.3b), and (2.3c) correspond to (2.1d), (2.1e), and (2.1c), respectively. These yield the $3N \times 3N$ system

$$H \left(\begin{array}{c} \boldsymbol{c} \\ \hline \boldsymbol{d} \\ \hline \boldsymbol{e} \end{array} \right) = \left(\begin{array}{c} 0 \\ \hline 0 \\ \hline \boldsymbol{f} \end{array} \right), \tag{2.4}$$

where

$$H = \left(\begin{array}{c|c|c} \mathcal{A}(\boldsymbol{P}^1, \boldsymbol{Q}) & -\mathcal{A}(\boldsymbol{P}^1, \boldsymbol{S}) & -\mathcal{A}(\boldsymbol{P}^1, \boldsymbol{T}) \\ \hline k_1 \mathcal{B}(\boldsymbol{P}^1, \boldsymbol{Q}) & -k_2 \mathcal{B}(\boldsymbol{P}^1, \boldsymbol{S}) & -k_2 \mathcal{B}(\boldsymbol{P}^1, \boldsymbol{T}) \\ \hline 0 & \mathcal{A}(\boldsymbol{P}^2, \boldsymbol{S}) & \mathcal{A}(\boldsymbol{P}^2, \boldsymbol{T}) \end{array} \right) = \left(\begin{array}{c|c|c} H_{11} & H_{12} & H_{13} \\ \hline H_{21} & H_{22} & H_{23} \\ \hline H_{31} & H_{32} & H_{33} \end{array} \right)$$

and $\boldsymbol{f} = \big(f(P_1^2), \dots, f(P_N^2)\big)$, with

$$\big(\mathcal{A}(\boldsymbol{V}, \boldsymbol{W})\big)_{\mu\nu} = -\frac{1}{2\pi} \log |V_\mu - W_\nu| \quad \text{and}$$
$$\big(\mathcal{B}(\boldsymbol{V}, \boldsymbol{W})\big)_{\mu\nu} = -\frac{\partial}{\partial n_{V_\mu}} \frac{1}{2\pi} \log |V_\mu - W_\nu|$$

for $\boldsymbol{V} = \big(V_1, \dots, V_N\big)$, $\boldsymbol{W} = \big(W_1, \dots, W_N\big)$, and $\mu, \nu = 1, \dots, N$.

2.3. Matrix decomposition algorithm. All the blocks H_{ij}, $i, j = 1, 2, 3$, of the coefficient matrix H in system (2.4) are [illegible]. A square matrix G is circulant (see [5]) if it has the form

$$G = \begin{pmatrix} g_1 & g_2 & \cdots & g_N \\ g_N & g_1 & \cdots & g_{N-1} \\ \cdots & \cdots & \cdots & \cdots \\ g_2 & g_3 & \cdots & g_1 \end{pmatrix} \tag{2.5}$$

and is denoted by $G = \operatorname{circ}(g_1, g_2, \dots, g_N)$. Circulant matrices are diagonalizable by

$$G = U^* D U,$$

where

$$D = \operatorname{diag}\big(\lambda_1, \dots, \lambda_N\big)$$

is a diagonal matrix whose diagonal elements are the eigenvalues of the matrix G, given by (see [5])

$$\lambda_j = \sum_{\ell=1}^{N} \omega^{(j-1)(\ell-1)} g_\ell \tag{2.6}$$

and

$$U^* = \frac{1}{\sqrt{N}} \begin{pmatrix} 1 & 1 & 1 & \cdots & 1 \\ 1 & \omega & \omega^2 & \cdots & \omega^{N-1} \\ 1 & \omega^2 & \omega^4 & \cdots & \omega^{2N-2} \\ \cdots & \cdots & \cdots & \cdots & \cdots \\ 1 & \omega^{N-1} & \omega^{2(N-1)} & \cdots & \omega^{(N-1)(N-1)} \end{pmatrix}, \tag{2.7}$$

with $\omega = \mathrm{e}^{\frac{2\pi \mathrm{i}}{N}}$. The matrix U^*, known as the Fourier matrix, is unitary.

It is obvious from (2.6) that the λ_j can be obtained from the g_ℓ via discrete Fourier transforms. The blocks $H_{ij},\ i,j = 1,2,3$, of the system matrix H can therefore be diagonalized by the Fourier matrix so that (2.4) may be written as

$$\big(I_3 \otimes U\big) H \big(I_3 \otimes U^*\big)\big(I_3 \otimes U\big) \left(\begin{array}{c} \boldsymbol{c} \\ \hline \boldsymbol{d} \\ \hline \boldsymbol{e} \end{array}\right) = \big(I_3 \otimes U\big) \left(\begin{array}{c} 0 \\ \hline 0 \\ \hline \boldsymbol{f} \end{array}\right), \tag{2.8}$$

where I_3 is the 3×3 identity matrix and $\otimes$ is the [illegible].[1]

Thus system (2.8) can be written as

$$\left(\begin{array}{c|c|c} D_{11} & D_{12} & D_{13} \\ \hline D_{21} & D_{22} & D_{23} \\ \hline D_{31} & D_{32} & D_{33} \end{array}\right) \left(\begin{array}{c} \hat{\boldsymbol{c}} \\ \hline \hat{\boldsymbol{d}} \\ \hline \hat{\boldsymbol{e}} \end{array}\right) = \left(\begin{array}{c} 0 \\ \hline 0 \\ \hline \hat{\boldsymbol{f}} \end{array}\right), \tag{2.9}$$

where

$$\hat{\boldsymbol{c}} = U\boldsymbol{c},\ \ \hat{\boldsymbol{d}} = U\boldsymbol{d},\ \ \hat{\boldsymbol{e}} = U\boldsymbol{e},\ \ \hat{\boldsymbol{f}} = U\boldsymbol{f},$$

and

$$D_{ij} = UH_{ij}U^* = \operatorname{diag}\big(\lambda_{ij}^1, \ldots, \lambda_{ij}^N\big), \quad i,j = 1,2,3.$$

The elements λ_{ij}^ℓ can be computed from (2.6), with the appropriate choice of g_ℓ's.

Thus the linear system (2.9) reduces to N independent 3×3 systems:

$$\begin{pmatrix} \lambda_{11}^\ell & \lambda_{12}^\ell & \lambda_{13}^\ell \\ \lambda_{21}^\ell & \lambda_{22}^\ell & \lambda_{23}^\ell \\ \lambda_{31}^\ell & \lambda_{32}^\ell & \lambda_{33}^\ell \end{pmatrix} \begin{pmatrix} \hat{c}_\ell \\ \hat{d}_\ell \\ \hat{e}_\ell \end{pmatrix} = \begin{pmatrix} 0 \\ 0 \\ \hat{f}_\ell \end{pmatrix}, \qquad \ell = 1, \ldots, N. \tag{2.10}$$

Finally, system (2.4) can be solved efficiently using the following algorithm:

[1] The tensor (or Kronecker) product of the $m \times n$ matrix V and the $\ell \times k$ matrix W is the $m\,\ell \times n\,k$ matrix

$$V \otimes W = \begin{pmatrix} v_{11}\,W & v_{12}\,W & \cdots & v_{1n}\,W \\ v_{21}\,W & v_{22}\,W & \cdots & v_{2n}\,W \\ \cdots & \cdots & \cdots & \cdots \\ v_{m1}\,W & v_{m2}\,W & \cdots & v_{mn}\,W \end{pmatrix}.$$

Basic properties are (i) $V \otimes (W \otimes Z) = (V \otimes W) \otimes Z$, (ii) $(V_1 \otimes W_1)\,(V_2 \otimes W_2) = (V_1 V_2) \otimes (W_1 W_2)$, and (iii) $V \otimes (W + Z) = V \otimes W + V \otimes Z$. A comprehensive list of properties of the tensor product can be found in [5, pp. 22–23] or [17, pp. 597–598].

Step 1: Compute $\hat{\boldsymbol{f}} = U\boldsymbol{f}$.
Step 2: Evaluate the (diagonal) elements the diagonal matrices $D_{\mu\nu}$, $\mu, \nu = 1, 2, 3$, using formula (2.6).
Step 3: Solve the N systems of order 3 in (2.10) to determine the vectors $\hat{\boldsymbol{c}}$, $\hat{\boldsymbol{d}}$, and $\hat{\boldsymbol{e}}$.
Step 4: Compute the vectors $\boldsymbol{c} = U^*\hat{\boldsymbol{c}}$, $\boldsymbol{d} = U^*\hat{\boldsymbol{d}}$, and $\boldsymbol{e} = U^*\hat{\boldsymbol{e}}$.

(i) In Steps 1 and 4, because of the form of the matrices U and U^*, the operations can be carried out via FFTs at a cost of $\mathcal{O}(N \log N)$ operations.

(ii) FFTs can also be used for the evaluation of the diagonal matrices in Step 2 at a cost of $\mathcal{O}(N \log N)$.

(iii) In Step 3, we need to solve N complex linear systems of order 3 which can be done at a cost of $\mathcal{O}(N)$ operations.

3. The three-dimensional case.

3.1. The problem. We consider the bimaterial problem in $\mathbb{R}^3$,

$$\Delta u_1 = 0 \quad \text{in} \quad \Omega_1, \tag{3.1a}$$

$$\Delta u_2 = 0 \quad \text{in} \quad \Omega_2 \setminus \overline{\Omega}_1, \tag{3.1b}$$

where $\overline{\Omega}_1 \subset \Omega_2$, subject to the boundary condition

$$u_2 = f \quad \text{on} \quad \partial\Omega_2 \tag{3.1c}$$

and the interface conditions

$$u_1 = u_2 \quad \text{and} \tag{3.1d}$$

$$k_1 \frac{\partial u_1}{\partial n} = k_2 \frac{\partial u_2}{\partial n} \quad \text{on} \quad \partial\Omega_1. \tag{3.1e}$$

The regions $\Omega_1, \Omega_2 \subset \mathbb{R}^3$ are axisymmetric, which means that they are formed by rotating regions $\Omega_1', \Omega_2' \subset \mathbb{R}^2$ ($\Omega_1' \subset \Omega_2'$), respectively, about the z-axis.

3.2. MFS formulation. As in the two-dimensional case, we treat the two subdomains separately: in Ω_1 we approximate u_1 at a point P by

$$u_1^{M,N}(\boldsymbol{c}, \boldsymbol{Q}; P) = \sum_{\mu=1}^{M} \sum_{\nu=1}^{N} c_{\mu,\nu}\, \Phi(P, Q_{\mu,\nu})$$

and in $\Omega_2 \setminus \overline{\Omega}_1$, u_2 at a point P is approximated by

$$u_2^{M,N}(\boldsymbol{d}, \boldsymbol{e}, \boldsymbol{S}, \boldsymbol{T}; P) = \sum_{\mu=1}^{M} \sum_{\nu=1}^{N} d_{\mu,\nu} \Phi(P, S_{\mu,\nu}) + \sum_{\mu=1}^{M} \sum_{\nu=1}^{N} e_{\mu,\nu} \Phi(P, T_{\mu,\nu}).$$

Here

$$\begin{aligned} \boldsymbol{c} &= (c_{11}, c_{12}, \ldots, c_{1N}, \ldots, c_{M1}, \ldots, c_{MN})^T, \\ \boldsymbol{d} &= (d_{11}, d_{12}, \ldots, d_{1N}, \ldots, d_{M1}, \ldots, d_{MN})^T, \\ \boldsymbol{e} &= (e_{11}, e_{12}, \ldots, e_{1N}, \ldots, e_{M1}, \ldots, e_{MN})^T, \end{aligned}$$

and $\boldsymbol{Q}$, $\boldsymbol{S}$, $\boldsymbol{T}$ are $3MN$-vectors containing the coordinates of the singularities $Q_{\mu,\nu}$, $S_{\mu,\nu}$, $T_{\mu,\nu}$, $\mu = 1,\dots,M$, $\nu = 1,\dots,N$. The singularities described by $\boldsymbol{Q}$ lie outside $\overline{\Omega}_1$, whereas the singularities described by $\boldsymbol{S}$ and $\boldsymbol{T}$ lie outside $\overline{\Omega}_2 \setminus \Omega_1$. More specifically, the singularities $\boldsymbol{S}$ lie in Ω_1 and the singularities $\boldsymbol{T}$ lie outside $\overline{\Omega}_2$.

The function $\Phi(P,Q)$ is a fundamental solution of Laplace's equation in $\mathbb{R}^3$ given by

$$\Phi(P,Q) = \frac{1}{4\pi\,|P-Q|}$$

with $|P-Q|$, as before, denoting the distance between the points P and Q.

Two sets of MN collocation points $\{P^1_{m,n}\}^{M,N}_{m=1,n=1}$ and $\{P^2_{m,n}\}^{M,N}_{m=1,n=1}$ are chosen on $\partial\Omega_1$ and $\partial\Omega_2$, respectively, in the following way.

We first choose N points on each of the boundaries $\partial\Omega_1'$ and $\partial\Omega_2'$. These are described by their cartesian coordinates $\left(r_n^{P^1}, z_n^{P^1}\right)$, $n = 1,\dots,N$, and $\left(r_n^{P^2}, z_n^{P^2}\right)$, $n = 1,\dots,N$, in Ω_1' and Ω_2', respectively. Here $r_n^{P^i}$ denotes the horizontal distance from the axis of rotation, and $z_n^{P^i}$ denotes the z-coordinate. The points on $\partial\Omega_i$, $i = 1,2$, are taken to be

$$x_{P^i_{m,n}} = r_n^{P^i}\cos\varphi_m,\quad y_{P^i_{m,n}} = r_n^{P^i}\sin\varphi_m,\quad z_{P^i_{m,n}} = z_n^{P^i}, \tag{3.2}$$

where $\varphi_m = \frac{2(m-1)\pi}{M}, m = 1,\dots,M$.

Similarly, we choose three sets of MN singularities $\{Q_{\mu,\nu}\}^{M,N}_{\mu=1,\nu=1}$, $\{S_{\mu,\nu}\}^{M,N}_{\mu=1,\nu=1}$, and $\{T_{\mu,\nu}\}^{M,N}_{\mu=1,\nu=1}$ given by

$$\begin{aligned}
x_{Q_{\mu,\nu}} &= r_\nu^Q\cos\psi_\mu, \quad y_{Q_{\mu,\nu}} = r_\nu^Q\sin\psi_\mu, \quad z_{Q_{\mu,\nu}} = z_\nu^Q,\\
x_{S_{\mu,\nu}} &= r_\nu^S\cos\chi_\mu, \quad y_{S_{\mu,\nu}} = r_\nu^S\sin\chi_\mu, \quad z_{S_{\mu,\nu}} = z_\nu^S,\\
x_{T_{\mu,\nu}} &= r_\nu^T\cos\chi_\mu, \quad y_{T_{\mu,\nu}} = r_\nu^T\sin\chi_\mu, \quad z_{T_{\mu,\nu}} = z_\nu^T,
\end{aligned} \tag{3.3}$$

where

$$\psi_\mu = \frac{2(\mu-1+\alpha)\pi}{M}, \qquad \chi_\mu = \frac{2(\mu-1+\beta)\pi}{M}, \qquad \mu = 1,\dots,M.$$

The parameters $\alpha,\beta \in [-\frac{1}{2},\frac{1}{2}]$ prescribe the rotations of the singularities in the azimuthal direction.

The coefficients $\boldsymbol{c}$, $\boldsymbol{d}$, and $\boldsymbol{e}$ are determined so that the interface and boundary conditions are satisfied at the boundary points $\{P^1_{m,n}\}^{M,N}_{m=1,n=1}$ and $\{P^2_{m,n}\}^{M,N}_{m=1,n=1}$, respectively,

$$u_1^{M,N}\left(\boldsymbol{c},\boldsymbol{Q};P^1_{mn}\right) - u_2^{M,N}\left(\boldsymbol{d},\boldsymbol{e},\boldsymbol{S},\boldsymbol{T};P^1_{mn}\right) = 0,$$

$$k_1\frac{\partial}{\partial n}u_1^{M,N}\left(\boldsymbol{c},\boldsymbol{Q};P^1_{mn}\right) - k_2\frac{\partial}{\partial n}u_2^{M,N}\left(\boldsymbol{d},\boldsymbol{e},\boldsymbol{S},\boldsymbol{T};P^1_{mn}\right) = 0,$$

$$u_2^{M,N}(\boldsymbol{d},\boldsymbol{e},\boldsymbol{S},\boldsymbol{T};P^2_{m,n}) = f(P^2_{m,n}),$$

$m = 1,\dots,M$, $n = 1,\dots,N$. These equations yield a $3MN \times 3MN$ linear system of the form

$$H\left(\begin{array}{c}\boldsymbol{c}\\ \hline \boldsymbol{d}\\ \hline \boldsymbol{e}\end{array}\right) = \left(\begin{array}{c}0\\ \hline 0\\ \hline \boldsymbol{f}\end{array}\right), \tag{3.4}$$

where

$$H = \left(\begin{array}{c|c|c} \mathcal{A}(\boldsymbol{P}^1,\boldsymbol{Q}) & -\mathcal{A}(\boldsymbol{P}^1,\boldsymbol{S}) & -\mathcal{A}(\boldsymbol{P}^1,\boldsymbol{T}) \\ \hline k_1\mathcal{B}(\boldsymbol{P}^1,\boldsymbol{Q}) & -k_2\mathcal{B}(\boldsymbol{P}^1,\boldsymbol{S}) & -k_2\mathcal{B}(\boldsymbol{P}^1,\boldsymbol{T}) \\ \hline 0 & \mathcal{A}(\boldsymbol{P}^2,\boldsymbol{S}) & \mathcal{A}(\boldsymbol{P}^2,\boldsymbol{T}) \end{array}\right) = \left(\begin{array}{c|c|c} H_{11} & H_{12} & H_{13} \\ \hline H_{21} & H_{22} & H_{23} \\ \hline H_{31} & H_{32} & H_{33} \end{array}\right).$$

Here $\boldsymbol{f} = \big(f_{mn}\big)_{m=1,n=1}^{M,N}$ and the $MN \times MN$ matrices are given by

$$\big(\mathcal{A}(\boldsymbol{V},\boldsymbol{W})\big)_{(m-1)N+n,(\mu-1)N+\nu} = \frac{1}{4\pi|V_{m,n} - W_{\mu,\nu}|},$$

$$\big(\mathcal{B}(\boldsymbol{V},\boldsymbol{W})\big)_{(m-1)N+n,(\mu-1)N+\nu} = \frac{\partial}{\partial n_{V_{m,n}}}\left\{\frac{1}{4\pi|V_{m,n} - W_{\mu,\nu}|}\right\}$$

for

$$\boldsymbol{V} = (V_{11}, V_{12}, \ldots, V_{1N}, \ldots, V_{M1}, \ldots, V_{MN})^T,$$
$$\boldsymbol{W} = (W_{11}, W_{12}, \ldots, W_{1N}, \ldots, W_{M1}, \ldots, W_{MN})^T$$

and $m, \mu = 1, \ldots, M$ and $n, \nu = 1, \ldots, N$.

3.3. Matrix decomposition algorithm. Each of the nine blocks H_{ij}, $i, j = 1, 2, 3$, of the coefficient matrix H in (3.4) has a [illegible] structure [8, 22] of the form

$$H_{ij} = \left(\begin{array}{c|c|c|c} H_{ij}^1 & H_{ij}^2 & \cdots & H_{ij}^M \\ \hline H_{ij}^M & H_{ij}^1 & \cdots & H_{ij}^{M-1} \\ \hline \vdots & \vdots & \ddots & \vdots \\ \hline H_{ij}^2 & H_{ij}^3 & \cdots & H_{ij}^1 \end{array}\right),$$

where the matrices H_{ij}^ℓ, $\ell = 1, \ldots, M$, $i, j = 1, 2, 3$, are $N \times N$ matrices defined by

$$\big(H_{11}^\ell\big)_{n,\nu} = \frac{1}{4\pi|P_{1,n}^1 - Q_{\ell,\nu}|}, \quad \big(H_{12}^\ell\big)_{n,\nu} = -\frac{1}{4\pi|P_{1,n}^1 - S_{\ell,\nu}|},$$

$$\big(H_{13}^\ell\big)_{n,\nu} = -\frac{1}{4\pi|P_{1,n}^1 - T_{\ell,\nu}|}, \quad \big(H_{21}^\ell\big)_{n,\nu} = k_1\frac{\partial}{\partial n_{P_{1,n}^1}}\left\{\frac{1}{4\pi|P_{1,n}^1 - Q_{\ell,\nu}|}\right\},$$

$$\big(H_{22}^\ell\big)_{n,\nu} = -k_2\frac{\partial}{\partial n_{P_{1,n}^1}}\left\{\frac{1}{4\pi|P_{1,n}^1 - S_{\ell,\nu}|}\right\}, \quad \big(H_{23}^\ell\big)_{n,\nu} = -k_2\frac{\partial}{\partial n_{P_{1,n}^1}}\left\{\frac{1}{4\pi|P_{1,n}^1 - T_{\ell,\nu}|}\right\},$$

$$\big(H_{31}^\ell\big)_{n,\nu} = 0, \quad \big(H_{32}^\ell\big)_{n,\nu} = \frac{1}{4\pi|P_{1,n}^2 - S_{\ell,\nu}|}, \quad \big(H_{33}^\ell\big)_{n,\nu} = \frac{1}{4\pi|P_{1,n}^2 - T_{\ell,\nu}|},$$

$n, \nu = 1, \ldots, N$. Because of the block circulant structure of the matrices H_{ij}, following a technique similar to the ones employed in [8, 22], for every $i, j = 1, 2, 3$, we have that

$$H_{ij} = \sum_{\ell=1}^{N} \mathcal{P}^{\ell-1} \otimes H_{ij}^\ell,$$

where the matrix $\mathcal{P}$ is the $M \times M$ permutation matrix $\mathcal{P} = \mathrm{circ}(0, 1, 0, \ldots, 0)$ and $\mathcal{P}^0 = I_M$. Thus

$$H = \left(\begin{array}{c|c|c} H_{11} & H_{12} & H_{13} \\ \hline H_{21} & H_{22} & H_{23} \\ \hline H_{31} & H_{32} & H_{33} \end{array}\right)$$

$$= \left(\begin{array}{c|c|c} \sum_{\ell=1}^{M} \mathcal{P}^{\ell-1} \otimes H_{11}^{\ell} & \sum_{\ell=1}^{M} \mathcal{P}^{\ell-1} \otimes H_{12}^{\ell} & \sum_{\ell=1}^{M} \mathcal{P}^{\ell-1} \otimes H_{13}^{\ell} \\ \hline \sum_{\ell=1}^{M} \mathcal{P}^{\ell-1} \otimes H_{21}^{\ell} & \sum_{\ell=1}^{M} \mathcal{P}^{\ell-1} \otimes H_{22}^{\ell} & \sum_{\ell=1}^{M} \mathcal{P}^{\ell-1} \otimes H_{23}^{\ell} \\ \hline \sum_{\ell=1}^{M} \mathcal{P}^{\ell-1} \otimes H_{31}^{\ell} & \sum_{\ell=1}^{M} \mathcal{P}^{\ell-1} \otimes H_{32}^{\ell} & \sum_{\ell=1}^{M} \mathcal{P}^{\ell-1} \otimes H_{33}^{\ell} \end{array}\right)$$

$$= \sum_{\ell=1}^{M} \left(\begin{array}{c|c|c} \mathcal{P}^{\ell-1} \otimes H_{11}^{\ell} & \mathcal{P}^{\ell-1} \otimes H_{12}^{\ell} & \mathcal{P}^{\ell-1} \otimes H_{13}^{\ell} \\ \hline \mathcal{P}^{\ell-1} \otimes H_{21}^{\ell} & \mathcal{P}^{\ell-1} \otimes H_{22}^{\ell} & \mathcal{P}^{\ell-1} \otimes H_{23}^{\ell} \\ \hline \mathcal{P}^{\ell-1} \otimes H_{31}^{\ell} & \mathcal{P}^{\ell-1} \otimes H_{32}^{\ell} & \mathcal{P}^{\ell-1} \otimes H_{33}^{\ell} \end{array}\right). \tag{3.5}$$

From [5], the matrices $\mathcal{P}^{\ell}$ can be diagonalized as

$$\mathcal{P}^{\ell} = U^* E^{\ell} U,$$

where U is defined from (2.7) and $E = \mathrm{diag}\big(1, \omega, \omega^2, \ldots, \omega^{M-1}\big)$, with $\omega = \mathrm{e}^{2\pi \mathrm{i}/M}$. Premultiplying system (3.4) by

$$\left(\begin{array}{c|c|c} U & 0 & 0 \\ \hline 0 & U & 0 \\ \hline 0 & 0 & U \end{array}\right) \otimes I_N = I_3 \otimes U \otimes I_N$$

yields

$$\big(I_3 \otimes U \otimes I_N\big)\, H\, \big(I_3 \otimes U^* \otimes I_N\big)\big(I_3 \otimes U \otimes I_N\big) \left(\begin{array}{c} \boldsymbol{c} \\ \hline \boldsymbol{d} \\ \hline \boldsymbol{e} \end{array}\right) = \big(I_3 \otimes U \otimes I_N\big) \left(\begin{array}{c} 0 \\ \hline 0 \\ \hline \boldsymbol{f} \end{array}\right)$$

(using the fact that $\big(I_3 \otimes U^* \otimes I_N\big)\big(I_3 \otimes U \otimes I_N\big) = I_{3MN}$) or

$$\tilde{H} \left(\begin{array}{c} \tilde{\boldsymbol{c}} \\ \hline \tilde{\boldsymbol{d}} \\ \hline \tilde{\boldsymbol{e}} \end{array}\right) = \left(\begin{array}{c} 0 \\ \hline 0 \\ \hline \tilde{\boldsymbol{f}} \end{array}\right), \tag{3.6}$$

where

$$\tilde{H} = \big(I_3 \otimes U \otimes I_N\big)\, H\, \big(I_3 \otimes U^* \otimes I_N\big)$$

and

$$\tilde{\boldsymbol{c}} = \big(U \otimes I_N\big)\, \boldsymbol{c}, \quad \tilde{\boldsymbol{d}} = \big(U \otimes I_N\big)\, \boldsymbol{d}, \quad \tilde{\boldsymbol{e}} = \big(U \otimes I_N\big)\, \boldsymbol{e}, \quad \tilde{\boldsymbol{f}} = \big(U \otimes I_N\big)\, \boldsymbol{f}.$$

From (3.5)

$$\tilde{H} = \sum_{\ell=1}^{M} \big(I_3 \otimes U \otimes I_N\big) \left(\begin{array}{c|c|c} \mathcal{P}^{\ell-1} \otimes H_{11}^{\ell} & \mathcal{P}^{\ell-1} \otimes H_{12}^{\ell} & \mathcal{P}^{\ell-1} \otimes H_{13}^{\ell} \\ \hline \mathcal{P}^{\ell-1} \otimes H_{21}^{\ell} & \mathcal{P}^{\ell-1} \otimes H_{22}^{\ell} & \mathcal{P}^{\ell-1} \otimes H_{23}^{\ell} \\ \hline \mathcal{P}^{\ell-1} \otimes H_{31}^{\ell} & \mathcal{P}^{\ell-1} \otimes H_{32}^{\ell} & \mathcal{P}^{\ell-1} \otimes H_{33}^{\ell} \end{array}\right) \big(I_3 \otimes U^* \otimes I_N\big),$$

and using the fact that

$$\big(U \otimes I_N\big)\big(\mathcal{P}^{\ell-1} \otimes H_{ij}^{\ell}\big)\big(U^* \otimes I_N\big) \;=\; E^{\ell-1} \otimes H_{ij}^{\ell},$$

we obtain

$$\tilde{H} = \sum_{\ell=1}^{M} \left(\begin{array}{c|c|c} E^{\ell\,-1} \otimes H_{11}^{\ell} & E^{\ell\,-1} \otimes H_{12}^{\ell} & E^{\ell\,-1} \otimes H_{13}^{\ell} \\ \hline E^{\ell\,-1} \otimes H_{21}^{\ell} & E^{\ell\,-1} \otimes H_{22}^{\ell} & E^{\ell\,-1} \otimes H_{23}^{\ell} \\ \hline E^{\ell\,-1} \otimes H_{31}^{\ell} & E^{\ell\,-1} \otimes H_{32}^{\ell} & E^{\ell\,-1} \otimes H_{33}^{\ell} \end{array}\right).$$

Thus, system (3.6) can be written as

$$\sum_{\ell=1}^{M} \left(\begin{array}{c|c|c} E^{\ell\,-1} \otimes H_{11}^{\ell} & E^{\ell\,-1} \otimes H_{12}^{\ell} & E^{\ell\,-1} \otimes H_{13}^{\ell} \\ \hline E^{\ell\,-1} \otimes H_{21}^{\ell} & E^{\ell\,-1} \otimes H_{22}^{\ell} & E^{\ell\,-1} \otimes H_{23}^{\ell} \\ \hline E^{\ell\,-1} \otimes H_{31}^{\ell} & E^{\ell\,-1} \otimes H_{32}^{\ell} & E^{\ell\,-1} \otimes H_{33}^{\ell} \end{array}\right) \left(\begin{array}{c} \tilde{\boldsymbol{c}} \\ \hline \tilde{\boldsymbol{d}} \\ \hline \tilde{\boldsymbol{e}} \end{array}\right) = \left(\begin{array}{c} 0 \\ \hline 0 \\ \hline \tilde{\boldsymbol{f}} \end{array}\right).$$

Since the matrix E is diagonal, each block $E^{\ell-1} \otimes H_{ij}^{\ell}$ is block diagonal, i.e.,

$$E^{\ell-1} \otimes H_{ij}^{\ell} \;=\; \operatorname{diag}\big(H_{ij}^{\ell}, \omega^{\ell-1} H_{ij}^{\ell}, \ldots, \omega^{(\ell-1)(M-1)} H_{ij}^{\ell}\big),$$

as are the blocks of the matrix $\tilde{H}$:

$$\begin{aligned} \sum_{\ell=1}^{M} E^{\ell-1} \otimes H_{ij}^{\ell} &= \operatorname{diag}\left(\sum_{\ell=1}^{M} H_{ij}^{\ell}, \sum_{\ell=1}^{M} \omega^{\ell-1} H_{ij}^{\ell}, \ldots, \sum_{\ell=1}^{M} \omega^{(\ell-1)(M-1)} H_{ij}^{\ell} \right) \\ &= \operatorname{diag}\big(\tilde{H}_{ij}^{1}, \tilde{H}_{ij}^{2}, \ldots, \tilde{H}_{ij}^{M}\big), \end{aligned}$$

where

$$\tilde{H}_{ij}^{m} \;=\; \sum_{\ell=1}^{M} \omega^{(\ell-1)(m-1)} H_{ij}^{\ell}, \quad m = 1, \ldots, M, \quad i, j = 1, 2, 3. \tag{3.7}$$

System (3.4) thus reduces to the M independent $3N \times 3N$ systems:

$$\left(\begin{array}{c|c|c} \tilde{H}_{11}^{m} & \tilde{H}_{12}^{m} & \tilde{H}_{13}^{m} \\ \hline \tilde{H}_{21}^{m} & \tilde{H}_{22}^{m} & \tilde{H}_{23}^{m} \\ \hline \tilde{H}_{31}^{m} & \tilde{H}_{32}^{m} & \tilde{H}_{33}^{m} \end{array}\right) \left(\begin{array}{c} \tilde{\boldsymbol{c}}_m \\ \hline \tilde{\boldsymbol{d}}_m \\ \hline \tilde{\boldsymbol{e}}_m \end{array}\right) = \left(\begin{array}{c} 0 \\ \hline 0 \\ \hline \tilde{\boldsymbol{f}}_m \end{array}\right), \quad m = 1, \ldots, M, \tag{3.8}$$

where

$$\begin{aligned} \tilde{\boldsymbol{c}}_m &= \big(\tilde{c}_{m1}, \tilde{c}_{m2}, \cdots, \tilde{c}_{mN}\big)^T, \quad \tilde{\boldsymbol{d}}_m = \big(\tilde{d}_{m1}, \tilde{d}_{m2}, \cdots, \tilde{d}_{mN}\big)^T, \\ \tilde{\boldsymbol{e}}_m &= \big(\tilde{e}_{m1}, \tilde{e}_{m2}, \cdots, \tilde{e}_{mN}\big)^T, \quad \tilde{\boldsymbol{f}}_m = \big(\tilde{f}_{m1}, \tilde{f}_{m2}, \cdots, \tilde{f}_{mN}\big)^T. \end{aligned}$$

Once $\tilde{\boldsymbol{c}}$, $\tilde{\boldsymbol{d}}$, and $\tilde{\boldsymbol{e}}$ are computed, the vectors $\boldsymbol{c}$, $\boldsymbol{d}$, and $\boldsymbol{e}$ can be calculated from

$$\boldsymbol{c} = \big(U^* \otimes I_N\big)\, \tilde{\boldsymbol{c}}, \quad \boldsymbol{d} = \big(U^* \otimes I_N\big)\, \tilde{\boldsymbol{d}}, \quad \boldsymbol{e} = \big(U^* \otimes I_N\big)\, \tilde{\boldsymbol{e}}. \tag{3.9}$$

System (3.8) can thus be solved efficiently using the following algorithm:

Step 1: Compute $\tilde{\boldsymbol{f}} = (U \otimes I_N)\, \boldsymbol{f}$.

Step 2: Construct the matrices $\tilde{H}_{ij}^{m}$, $i, j = 1, 2, 3$, $m = 1, \ldots, M$, from formula (3.7).

Step 3: Solve the M systems of order $3N$ in (3.8).
Step 4: Compute $\boldsymbol{c}$, $\boldsymbol{d}$, and $\boldsymbol{e}$ from (3.9).

(i) In Steps 1 and 4, because of the form of the matrices U and U^*, the operations can be carried out via FFTs and inverse FFTs at a cost of $\mathcal{O}(NM\log M)$.

(ii) In Step 2, for each $r,s=1,\ldots,N$, we need to perform an M-dimensional inverse FFT, in order to compute the entries $(\tilde{H}_{ij}^1)_{rs},\ldots,(\tilde{H}_{ij}^M)_{rs}$. This can be done at a cost of $\mathcal{O}(N^2\,M\log M)$.

(iii) In Step 3, we need to solve M complex linear systems of order $3N$. This can be done using an LU-factorization with partial pivoting at a cost of $\mathcal{O}(MN^3)$ operations.

4. Numerical experiments.

4.1. Two-dimensional case. In this subsection, we test numerically the algorithms proposed in section 2 in the case of problem (2.1). Since both the exact solutions u_1, u_2 and approximate solutions u_1^N, u_2^N are harmonic in $\mathfrak{O}_1=B_{\varrho_1}$ and $\mathfrak{O}_2=A_{\varrho_1,\varrho_2}$, respectively, the maximum principle applies to their difference, and thus

$$\sup_{\boldsymbol{x}\in\mathfrak{O}_j}|u_j^N(\boldsymbol{x})-u_j(\boldsymbol{x})| \;=\; \sup_{\boldsymbol{x}\in\partial\mathfrak{O}_j}|u_j^N(\boldsymbol{x})-u_j(\boldsymbol{x})|, \qquad j=1,2.$$

In all of our experiments, we calculated the maximum relative error of the problem

$$E \;=\; \max\{E_1,E_2\}, \tag{4.1a}$$

where

$$E_j \;=\; \frac{\sup_{\boldsymbol{x}\in\partial\mathfrak{O}_j}\left|u_j^N(\boldsymbol{x})-u_j(\boldsymbol{x})\right|}{\sup_{\boldsymbol{x}\in\partial\mathfrak{O}_j}\left|u_j(\boldsymbol{x})\right|}, \qquad j=1,2. \tag{4.1b}$$

The maximum relative error was calculated on uniform grids on the boundaries of the two regions, namely, at the points $\{V_\ell^j\}_{\ell=1,\ldots,L}^{j=1,2}$ given by

$$V_\ell^j \;=\; \big(\varrho_j\cos\vartheta_\ell,\varrho_j\sin\vartheta_\ell\big), \qquad \vartheta_\ell=\frac{2\pi}{L}(\ell-1).$$

In most experiments, the parameter L was taken to be equal to 1001.

In our numerical experiments we took the boundary data in (2.1c) to represent Fourier frequencies, namely, $f=\varrho_2^m\,\mathrm{e}^{\mathrm{i}m\vartheta}$, where m is a nonnegative integer. The exact solution of this problem, for $m>0$, is of the form

$$u_1(r,\vartheta) \;=\; A\,r^m\,\mathrm{e}^{\mathrm{i}m\vartheta}, \quad u_2(r,\vartheta) \;=\; B\,r^m\,\mathrm{e}^{\mathrm{i}m\vartheta}+\Gamma\,r^{-m}\,\mathrm{e}^{\mathrm{i}m\vartheta},$$

where A, B, and Γ can be uniquely determined from (2.1c)–(2.1e),

$$A=\frac{2k_2\,\varrho_2^{2m}}{k_1(\varrho_2^{2m}-\varrho_1^{2m})+k_2(\varrho_1^{2m}+\varrho_2^{2m})},$$

$$B=\frac{\varrho_2^{2m}(k_1+k_2)}{k_1(\varrho_2^{2m}-\varrho_1^{2m})+k_2(\varrho_1^{2m}+\varrho_2^{2m})},$$

$$\Gamma=\frac{k_2-k_1}{k_1(\varrho_2^{2m}-\varrho_1^{2m})+k_2(\varrho_1^{2m}+\varrho_2^{2m})}.$$

When $m=0$, the solution is $u_1=u_2=1$. We also chose $\varrho_1=1$, $\varrho_2=3$, $k_2/k_1=2$.

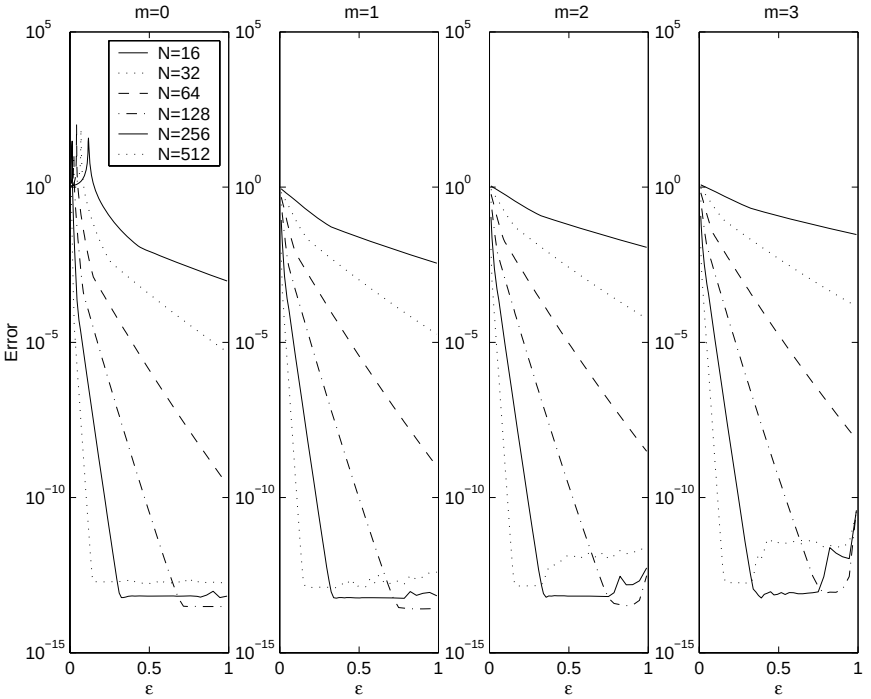

FIG. 1. *Semilog-plot of the error versus* ε *in Example* 1 *for different values of* N *when* $f = \varrho_2^m \mathrm{e}^{\mathrm{i}m\vartheta}$, $m = 0,\ 1,\ 2,\ 3$.

The FFT operations were performed using the NAG[2] routines `C06FPF`, `C06FQF`, and `C06FRF`. All numerical experiments were carried out on an IBM RS6000 (375 MHz) workstation.

Figure 1. We present the logarithm of E, as defined by (4.1a) and (4.1b), versus the distance ε of the three circles S_{R_j}, $j = 1, 2, 3$ describing the pseudoboundaries from the corresponding boundaries, S_{ϱ_1} and S_{ϱ_2}. That is,

$$R_1 = \varrho_1 + \varepsilon, \quad R_2 = \varrho_1 - \varepsilon, \quad R_3 = \varrho_2 + \varepsilon.$$

Here we consider the unrotated case, i.e., $\alpha = \beta = 0$. We consider the cases $m = 0, 1, 2, 3$ with $N = 16, 32, 64, 128, 256$ and 512.

We observe that, for a fixed m and a fixed N, as $\varepsilon \in (0, 1)$ grows, the accuracy improves exponentially fast. Further, for fixed ε and fixed m, the error decays exponentially as N grows. Also, for fixed N and ε, as m increases, the error increases.

The cusps in the case $m = 0$ occur because the coefficient matrix in (2.10), when $\ell = 1$, becomes singular for the values of ε where the cusps occur. When $\ell \neq 1$, no such singularity was observed. Since only the solution of system (2.10) for $\ell = m + 1$ contributes to the MFS solution corresponding to m, this phenomenon is not observed for $m \neq 0$. The analyses of similar observations, in the case of the Dirichlet problem in the disk and the annulus, are reported in [23, 25], respectively.

Note that as N and ε increase, the errors become close to machine accuracy.

[2]Numerical Analysis Group (NAG) Library Mark 20, NAG Ltd, Wilkinson House, Jordan Hill Road, Oxford, UK, 2001.

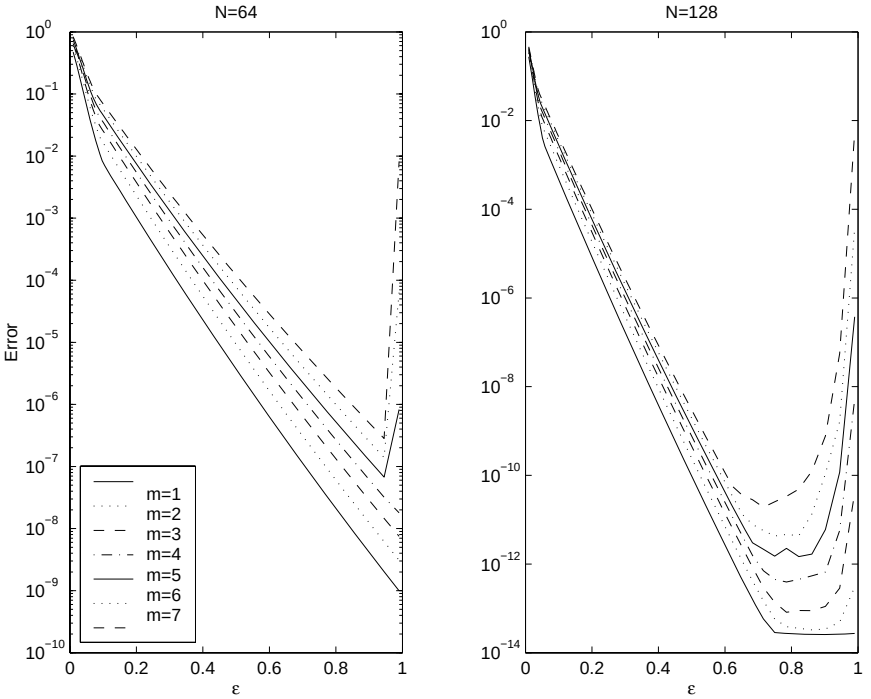

FIG. 2. *Semilog-plot of the error versus* ε *in Example* 1 *for different values of* m *when* $f = \varrho_2^m \mathrm{e}^{\mathrm{i}m\vartheta}$ *and* $N = 64, 128$.

Figure 2. In this case we show the dependence of the logarithm of E on ε for $m = 1, \ldots, 7$, for the cases $N = 64, 128$.

We observe that in both cases, as m increases, the accuracy of the approximation deteriorates. Similar phenomena were observed in previous studies, in particular, in [13, 23, 25]. In [23], in the case of the Dirichlet problem in a disk of radius ϱ, with the singularities placed on a circle of radius R, it is shown that the error behaves like

$$E = \mathcal{O}\left(\left(\frac{\varrho}{R}\right)^{N-2m}\right).$$

Further, we observe that for large m there is a deterioration of the accuracy for $\varepsilon \approx 1$. This is due to ill-conditioning resulting from the fact that the radius of S_{R_2} is close to zero.

Figure 3. We present the dependence of the error on the angular parameters α and β, when $m = 1$, $\varepsilon = .005, .01, .02, .04, .08, .16$. The two subplots correspond to the cases $N = 64$ and $N = 128$. For simplicity we took $\alpha = \beta$. Because of symmetry we need to consider only $\alpha \in [0, \frac{1}{2}]$.

We observe that, for the values of ε presented, as ε increases, the error E is optimized for $\alpha \approx \frac{1}{4}$. However, the improvement in the accuracy of the MFS approximation is more visible for smaller values of ε. In particular, for $\varepsilon = .005$, the accuracy of the approximation improves by a factor of ten at $\alpha \approx .1$, which is where the minimum is reached. Further, for larger values of ε the improvement due to rotation is negligible. These phenomena were also observed in previous studies [20, 21].

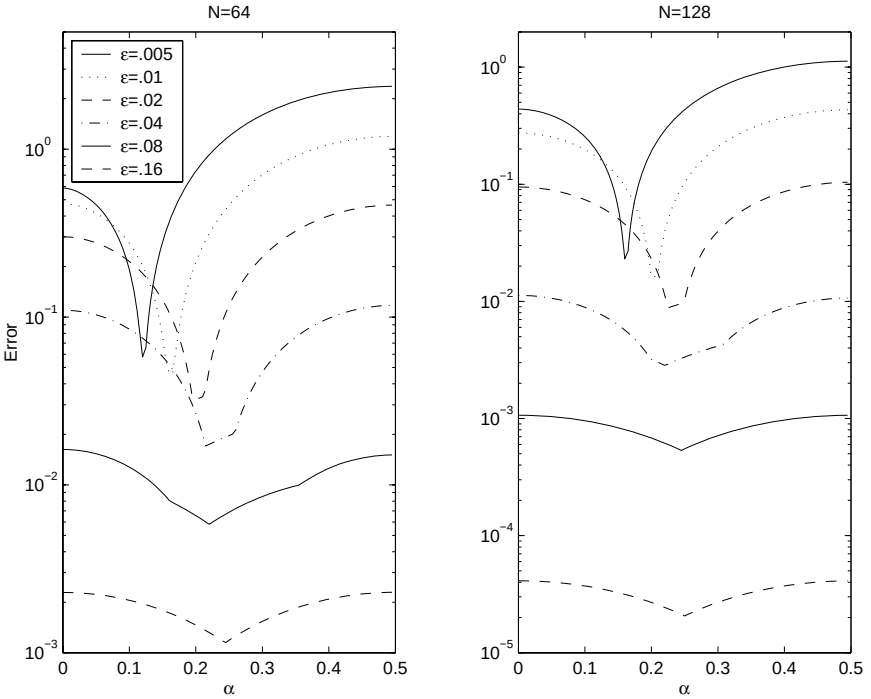

FIG. 3. *Semilog-plot of the error versus the angular parameter α when $f = \varrho_2 e^{\mathrm{i}\vartheta}$ for various values of ε and $N = 64, 128$. The parameter β is taken to be equal to α.*

4.2. Three-dimensional case. In this subsection we test numerically the algorithm proposed in section 3 for (3.1e). In the three-dimensional case it is difficult to construct an exact solution for (3.1e), and therefore, in order to test the convergence of the algorithm, we examine, as an estimate of the error, the supremum norm of the differences $u_i^{M,N} - u_i^{2M,2N}$, $i = 1, 2$, for various values of M and N. Since these differences are harmonic, from the maximum principle, it is sufficient to consider them on the boundaries $\partial\Omega_i$, $i = 1, 2$. We therefore calculate

$$E^{M,N} = \max\left\{E_1^{M,N}, E_2^{M,N}\right\}, \tag{4.2a}$$

where

$$E_1^{M,N} = \sup_{x\in\partial\Omega_1} \left|u_1^{M,N}(\boldsymbol{x}) - u_1^{2M,2N}(\boldsymbol{x})\right|, \tag{4.2b}$$

$$E_2^{M,N} = \sup_{x\in\partial\Omega_1\cup\partial\Omega_2} \left|u_2^{M,N}(\boldsymbol{x}) - u_2^{2M,2N}(\boldsymbol{x})\right|. \tag{4.2c}$$

This quantity was calculated on prescribed grids on the boundaries of the two regions which will be specified for each case.

We consider two examples of boundary data in (3.1c), namely,

1. $f = \cosh(.03x)\cosh(.04y)\cos(.05z)$.
2. $f = (9.5 - x^2 - y^2 - z^2)^{-1}$.

In all numerical experiments performed in this study, we took $k_2/k_1 = 2$.

4.2.1. Spherical domains. We consider the case where Ω_1 and Ω_2 are the spheres of radii ϱ_1 and ϱ_2 ($\varrho_1 < \varrho_2$), respectively, that is,

$$\Omega_j = \{(x,y,z) \in \mathbb{R}^3 : x^2 + y^2 + z^2 < \varrho_j^2\}, \quad j = 1, 2.$$

The singularities $\{Q_{\mu,\nu}\}_{\mu=1,\nu=1}^{M,N}$, $\{S_{\mu,\nu}\}_{\mu=1,\nu=1}^{M,N}$, and $\{T_{\mu,\nu}\}_{\mu=1,\nu=1}^{M,N}$ are placed on the spherical surfaces $\partial\Omega_Q$, $\partial\Omega_S$, and $\partial\Omega_T$, centered at the origin, of radii R_Q, R_S, and R_T, respectively, with $R_S < \varrho_1 < R_T$ and $\varrho_2 < R_Q$. The coordinates of the singularities are given by (3.3) with

$$\begin{aligned} r_\nu^Q &= R_Q \sin\vartheta_\nu, \;\; z_\nu^Q = R_Q \cos\vartheta_\nu, \\ r_\nu^S &= R_S \sin\vartheta_\nu, \;\; z_\nu^S = R_S \cos\vartheta_\nu, \\ r_\nu^T &= R_T \sin\vartheta_\nu, \;\; z_\nu^T = R_T \cos\vartheta_\nu, \end{aligned}$$

where $\vartheta_\nu = \frac{\nu\pi}{N+1}$, $\nu = 1, \ldots, N$. The collocation points $\{P_{m,n}^i\}_{m=1,n=1}^{M,N}$ on the boundaries $\partial\Omega_i$, $i = 1, 2$, are given by

$$x_{P_{m,n}^i} = \varrho_i \sin\vartheta_n \cos\varphi_m, \quad y_{P_{m,n}} = \varrho_i \sin\vartheta_n \sin\varphi_m, \quad z_{P_{m,n}^i} = \varrho_i \cos\vartheta_n. \tag{4.3}$$

Note that we avoid the points corresponding to $\vartheta_j = 0$ and $\vartheta_j = \pi$ as they remain invariant under rotation in the φ-direction and would lead to singular matrices.

The error was calculated at the points

$$V_{k,\ell}^i = \varrho_i(\sin\Theta_\ell \cos\Phi_k, \sin\Theta_\ell \sin\Phi_k, \cos\Theta_\ell), \quad i = 1, 2,$$

where $\Theta_\ell = \frac{\pi\ell}{L+1}$ and $\Phi_k = \frac{2\pi(k-1)}{L}$, $k, \ell = 1, \ldots, L$. In most numerical experiments L was taken to be equal to 31.

In our numerical experiments, we considered the case of the spheres of radii 1 and 3, respectively.

Figure 4. We present the logarithm of error, as defined by (4.2c), versus the distance ε of the three spherical surfaces $\partial\Omega_Q$, $\partial\Omega_S$, and $\partial\Omega_T$ from the corresponding boundaries $\partial\Omega_1$, $\partial\Omega_2$. That is,

$$R_Q = \varrho_1 + \varepsilon, \quad R_S = \varrho_1 - \varepsilon, \quad R_T = \varrho_2 + \varepsilon.$$

We consider both Examples 1 and 2 in the unrotated case, i.e., $\alpha = \beta = 0$. We took $M = N = 12, 16, 24, 32, 48$. From this figure we observe that, for both examples, as ε varies on the interval $(10^{-2}, 1)$, the error decreases exponentially fast. Also, the rate of convergence is more rapid as N grows.

Figure 5. We present the dependence of the error on the angular parameters α and β. For simplicity, we considered the case when $\alpha = \beta$. Because of symmetry we need to consider only the case $\alpha \in [0, \frac{1}{2}]$ and examine the behavior of the error for $M = N = 16, 24, 32, 48$ and fixed ε.

We observe that for small ε an optimal value was reached at about $\alpha \approx \frac{1}{4}$. This behavior can be seen in Figure 5 in the case $\varepsilon = \frac{1}{10}$ for both Examples 1 and 2. For larger values of ε, the minimum is no longer visible. Similar phenomena have been observed in previous studies [20, 23].

Figure 6. In Figure 6 we present the logarithm of an estimate of the condition number in the L^∞-norm of the coefficient matrix in system (3.8) for $m = 1$ versus ε, for $N = 8, 12, 16, 24, 32$, and 48. As can be seen from this figure, the conditioning of the matrix deteriorates considerably as ε increases. The estimate of the condition number was calculated using the NAG pair `F07ARF-F07AUF`. The behavior of the condition number of the matrices in the cases $m = 2, 3, \ldots M$ is very similar.

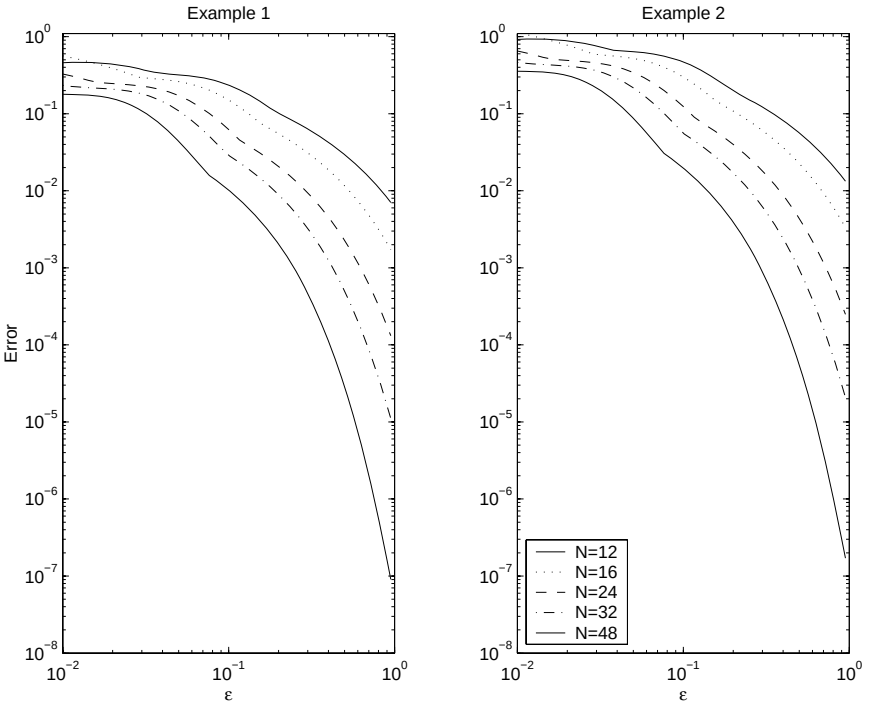

FIG. 4. *Loglog-plot of the error versus ε in Examples* 1 *and* 2 *in the case where Ω_1 and Ω_2 are spheres.*

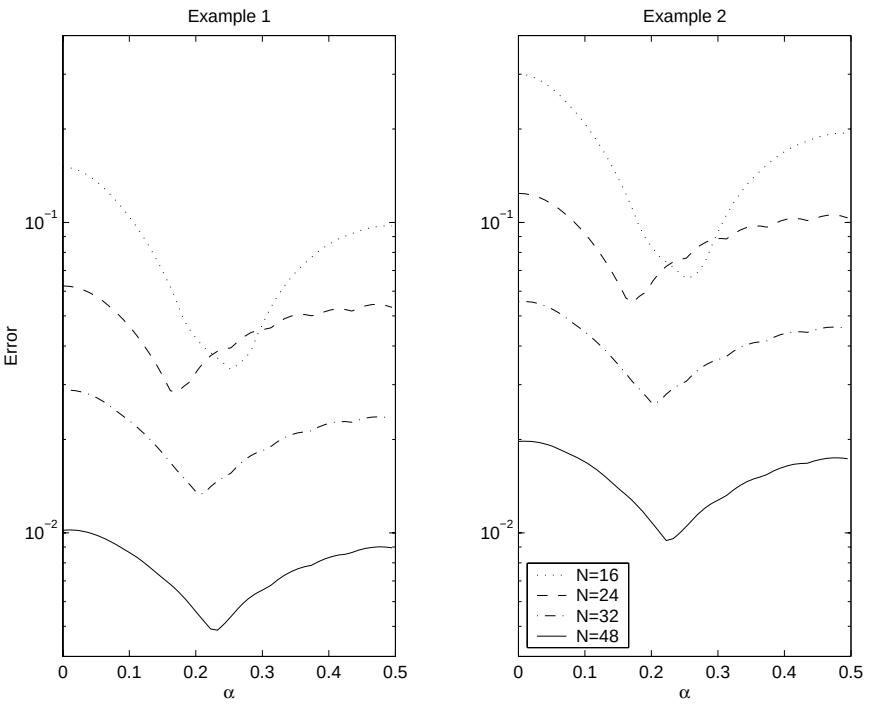

FIG. 5. *Spherical domains: Semilog-plot of the error versus the angular parameter α in Examples* 1 *and* 2 *for $\varepsilon = 1/10$. The parameter β is taken to be equal to α.*

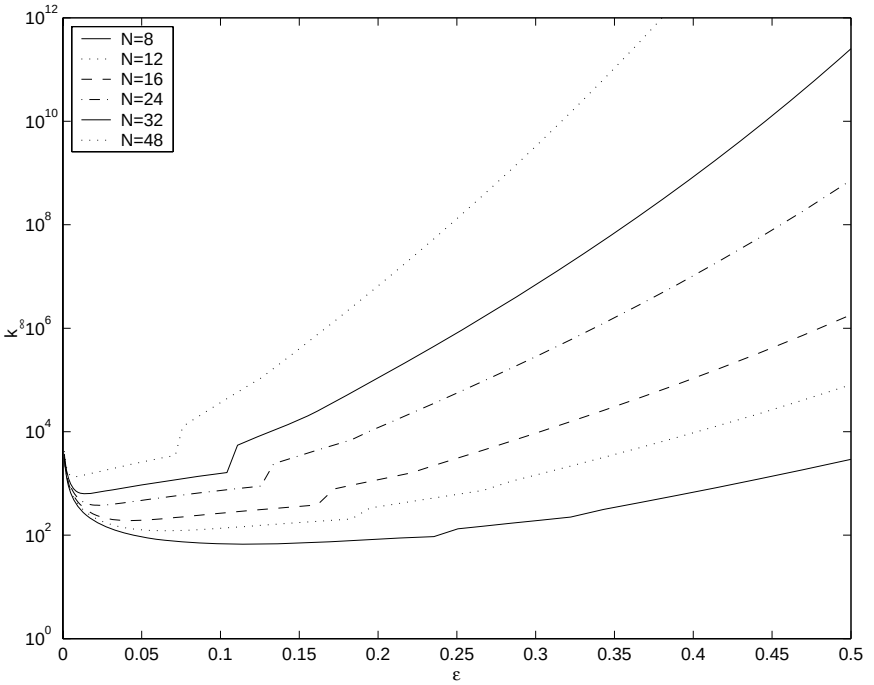

FIG. 6. *Spherical domains: Semilog-plot of the condition number κ_∞ of the matrix in the system* (3.8) *versus* ε.

4.2.2. Cylinder inside a sphere. We consider the case when Ω_1 is the cylinder

$$\Omega_1 = \left\{(x,y,z) \in \mathbb{R}^3 \,:\, x^2+y^2 < \varrho_1^2,\ |z| < h\right\}$$

and Ω_2 is the sphere

$$\Omega_2 = \left\{(x,y,z) \in \mathbb{R}^3 \,:\, x^2+y^2+z^2 < \varrho_2^2\right\}$$

where $\varrho_1^2 + h^2 < \varrho_2^2$. The boundary points $P^2_{\mu,\nu}$ are chosen as in (4.3). The points $P^1_{\mu,\nu}$ are given by (3.2), where $(r_n^{P^1}, z_n^{P^1}) \in \mathbb{R}^2$ are uniformly distributed on the three sides of the rectangle $[0,\varrho_1]\times[-h,h]$ which is the generator of the cylinder.

The singularities $Q_{\mu,\nu}$ and $S_{\mu,\nu}$ are placed on cylinders similar to Ω_1, both at a distance ε from $\partial\Omega_1$. The singularities $T_{\mu,\nu}$ are placed on a sphere of radius R_T, where $R_T - \varrho_2 = \varepsilon > 0$.

In our numerical experiments, we took $h = 1$, $\varrho_1 = 1$, and $\varrho_2 = 3$.

Figure 7. We present the logarithm of the error as defined by (4.2c) versus ε. We apply the method to Example 1 in the unrotated case, and we varied ε in the interval $(10^{-2}, 1)$. We took $M = N = 8, 12, 16, 24, 32, 48$. From this figure, we observe that as ε increases, the error decreases exponentially fast up to about $\varepsilon \approx \frac{1}{2}$. For larger values of ε, the quality of the approximation deteriorates rapidly. For this geometry, the approximation is considerably less accurate than the corresponding approximation in the case of the spherical domains. This is due to the presence of the edges in the cylindrical subdomain. Further, the error in the approximation for this geometry starts deteriorating for smaller values of ε than for the spherical domains.

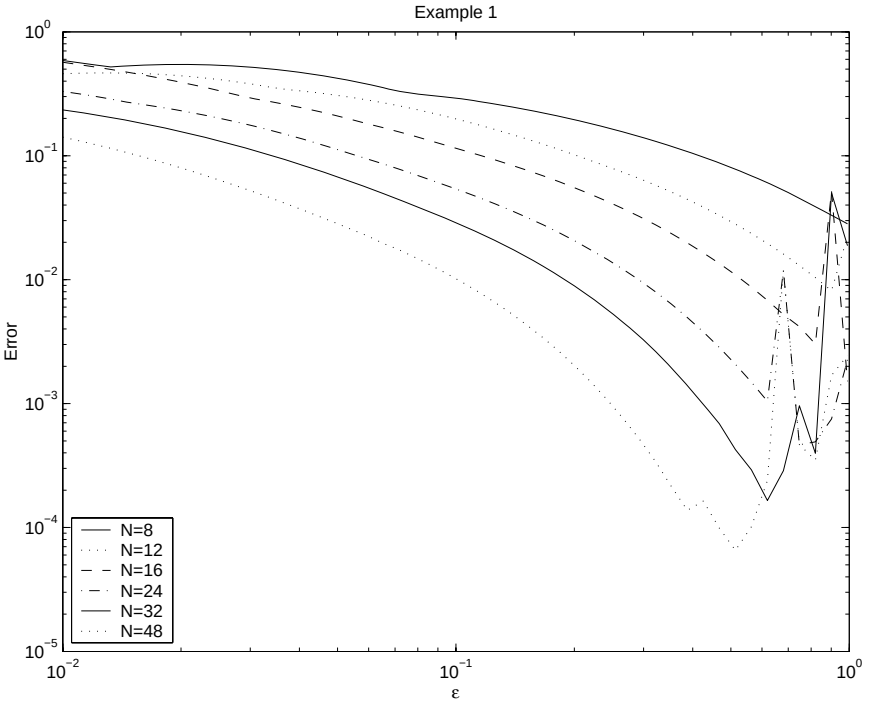

FIG. 7. *Cylinder inside a sphere: Loglog-plot of the error versus ε in Example* 1.

Figure 8. We present the dependence of the error on the angular parameters α and β in Example 1. For simplicity, again, we considered the case when $\alpha = \beta$, and because of symmetry we examined $\alpha \in [0, \frac{1}{2}]$. In the first subplot we took $\varepsilon = \frac{1}{10}$ and $M = N = 16, 24, 32, 48$. As observed previously, there is a tendency for the optimum to be reached at $\alpha = \frac{1}{4}$ and fixed ε. We observed that for small ε an optimal value was reached at about $\alpha \approx \frac{1}{4}$.

In the second subplot we present the corresponding results for $\varepsilon = \frac{1}{2}$. As expected, the accuracy is higher, and similar phenomena to those seen in the first subplot are observed.

5. Concluding remarks. In this paper, we apply a meshless boundary collocation method for the solution of certain heat conduction problems in layered materials in two and three dimensions. In two dimensions, we consider materials in concentric regions whereas in three dimensions we consider axisymmetric domains possessing the same axis of symmetry. We employ a domain decomposition technique which leads to systems whose coefficient matrices exhibit block circulant structures. Matrix decomposition methods in conjunction with the use of FFTs enable us to construct efficient algorithms for the numerical solution of these problems.

The algorithms developed in this study could be easily extended to the solution of bimaterial problems in the same geometries in two and three dimensions but governed by different differential equations such as the Helmholtz equation, the biharmonic equation, or the Cauchy–Navier equations of elasticity, in two and three dimensions. Further, this method is not restricted to dealing with bimaterial problems but could also be applied to multilayered materials in corresponding axisymmetric domains in two and three dimensions.

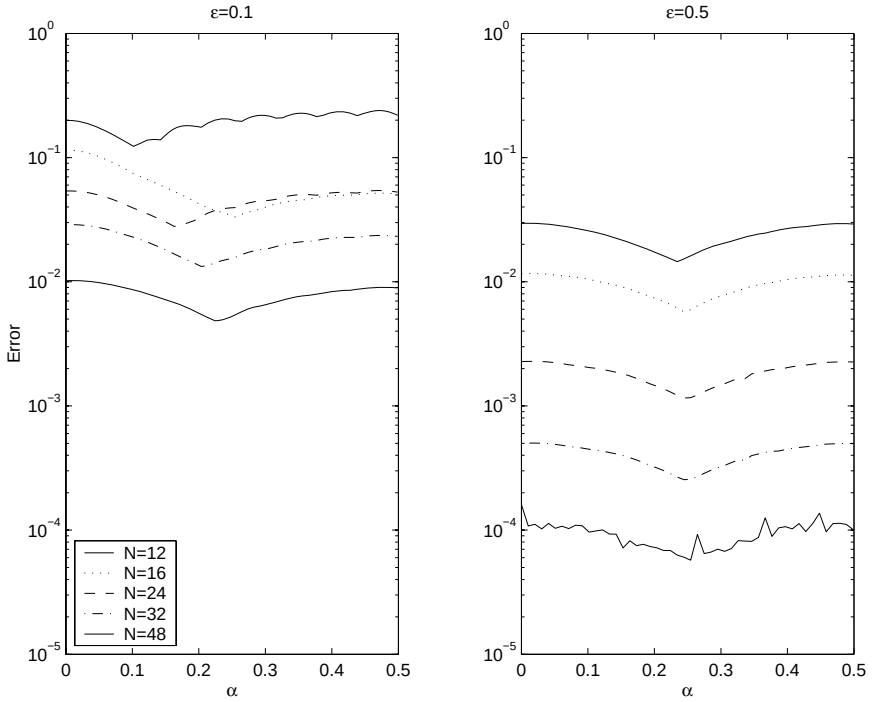

FIG. 8. *Cylinder inside a sphere: Semilog-plot of the error versus the angular parameter* α *for* $\varepsilon = 1/10,\ 1/2$. *The parameter* β *is taken to be equal to* α.

Finally, the block circulant structure of the matrices arising in these problems is preserved for other boundary method discretizations. The current algorithm could thus be used when, for example, the BEM is applied to the type of problems examined in this work.

Acknowledgments. The authors wish to thank Professors John R. Berger, Graeme Fairweather, and Paul A. Martin of the Colorado School of Mines for their helpful suggestions.

SPECIAL ISSUE: 2004 COPPER MOUNTAIN CONFERENCE

The biennial Copper Mountain Conference on Iterative Methods was held March 28–April 2, 2004, in Copper Mountain, Colorado. In addition to the traditional management services provided by Front Range Scientific Computations, Inc., Howard Elman (University of Maryland) and Panayot Vassilevski (Center for Applied Scientific Computing at LLNL) served as co-chairs representing the conference's new organizing institutions. The Conference gratefully acknowledges support from all three major national labs—Los Alamos, Lawrence Livermore, and Sandia—as well as support from the Department of Energy, IBM, and the National Science Foundation.

Traditionally, the Copper Mountain Conference is organized in cooperation with the Society for Industrial and Applied Mathematics (SIAM). This special issue was open to the public and was advertised in advance on the web sites of both the [illegible] (SISC) and the Copper Mountain Conference.

There were 35 manuscripts submitted; 15 found their place in this special issue. It is the guest editor-in-chief's opinion that these papers reflect state-of-the-art trends in iterative methods, among them parallel-block preconditioning, various improved versions of GMRES (block, relaxed, and flexible), approximate factorization preconditioners for saddle-point problems, and iterative methods exploiting deflation. But above all, this special issue clearly demonstrates the strong impact of multigrid/multilevel methods as the unique optimal-order iterative methods in various areas of applications. It also demonstrates the search for optimal-order methods or preconditioners on the basis of multilevel ideas in variety of nontraditional areas.

I would like to thank the guest editorial board—Loyce Adams, Xiao-Chuan Cai, Iain Duff, Roland Freund, Anne Greenbaum, Tim Kelley, David Keyes, Tom Manteuffel, Steve McCormick, Ray Tuminaro, Henk van der Vorst, Olof Widlund, and Carol Woodward of the conference program committee—as well as Raymond Chan of the SISC editorial board and the many anonymous referees for their hard work to help meet the strict deadlines.

I would also like to thank the SIAM staff for their constant support and efforts to bring this issue to life. Of course, this issue would not have been possible without the authors' contributions. Some of these submissions also appeared in the student paper competition, a unique event at the Copper Mountain conferences that has proven to be a very successful forum for presenting the latest results in the field. We have had increasingly strong participation from very talented recent Ph.D. holders and current Ph.D. students in this competition.

We thank all the authors for their valuable contributions and hope that this special issue will stimulate further progress in this exciting area of research.

A NEW BLOCK PARALLEL SOR METHOD AND ITS ANALYSIS*

DEXUAN XIE†

Abstract. As the development of the PSOR method (a point parallel SOR method by mesh domain partitioning proposed in [*SIAM J. Sci. Comput.*, 20 (1999), pp. 2261–2281], this paper introduces a new mesh domain partition and ordering (the multitype partition and ordering), and proposes a new block parallel SOR (BPSOR) method for numerically solving 2-dimensional (2D) or three-dimensional (3D) elliptic boundary problems. A general mathematical analysis shows that the BPSOR method can have the same asymptotic convergence rate as the corresponding sequential block SOR method if the coefficient matrix of the block linear system is "consistently ordered." It also shows that the original sequential ordering can be maintained in the parallel implementation of the BPSOR method so that the BPSOR method can be effectively applied to solve complex elliptic boundary problems. Furthermore, three particular multitype orderings are proposed based on strip and block mesh partitions, which lead to three effective BPSOR methods for solving the five-point like linear systems (in two dimensions) and the seven-point like linear systems (in three dimensions). In addition, it is shown that the PSOR method can be generated from BPSOR if each block equation is solved approximately by only one point SOR iteration. Thus, the PSOR method is well defined without involving any interprocessor data communication operations, and extended to solving three-dimensional (3D) problems. Finally, numerical results are presented which confirm the theoretical results and show that BPSOR has a good parallel performance on a parallel MIMD computer.

1. Introduction.

The successive overrelaxation (SOR) method [28] is an important classic iterative method for solving large-scale sparse linear systems arising from a finite element or finite difference discretization of the elliptic boundary problem. It is also widely used to produce efficient preconditioners [10, 14, 28] and robust smoothers [10, 22, 25, 27]. Due to the efficiency and simplicity in implementation, the SOR method is often used in scientific computing. For example, in protein simulations, three widely used biomolecular simulation packages, CHARMM [5], DelPha [19], and UHBD [7], include the SOR method as the default solver for the linearized Poisson–Boltzmann equation (an elliptic Dirichlet boundary problem with discontinuous coefficients), which models the electrostatic potential energy of a solvate protein system through treating the solvent and the protein as two different continuum dielectric materials [6, 13, 20]. However, the SOR method using the natural ordering is sequential. It must be parallelized to be implemented on a parallel computer.

Various parallel SOR methods have been developed by using multicolor ordering schemes and domain decomposition techniques [1, 2, 4, 8, 9, 12, 15, 16, 17, 18, 23, 24, 26, 28]. Usually, a parallel SOR method defined by multicolor techniques can have a faster convergence rate but may be more difficult to apply for solving complex elliptic boundary problems than a parallel SOR method constructed from a domain decomposition. To improve the convergence rate of a domain decomposition algorithm, a novel mesh partition strategy was proposed in [26] which led to an efficient parallel

SOR method called the PSOR method. The PSOR method was shown to retain the convergence rate of the sequential SOR method [26]. However, the PSOR method was only considered as a point iterative algorithm for solving 2-dimensional (2D) elliptic boundary value problems, and its definition involved a usage of interprocessor data communication operations.

As the development of the PSOR method, this paper proposes a new domain decomposition scheme called the multitype partition. The idea of the multitype partition can be briefly described as follows: the mesh domain Ω_h is first divided into p subdomains, $\{\Omega_{h\mu}\}_{\mu=1}^{p}$, and then the mesh points of each subdomain are grouped into t types, $\{\Omega_{h,\mu}^{i}\}_{i=1}^{t}$, such that each type is coupled only with different adjacent types and at least one of the adjacent types is located in a neighboring subdomain. Here p is the number of processors, and t is less than or equal to the number of neighboring subdomains. The multitype ordering is then defined by numbering the tp type subdomains $\{\Omega_{h,\mu}^{i}\}$ from $\mu = 1$ to p for $i = 1$ to t, while the original ordering is kept within each type subdomain.

This paper then proposes a new block parallel SOR (BPSOR) method by using the multitype partition. A general mathematical analysis shows that the BPSOR method can have the same convergence rate as the corresponding sequential block SOR method if the coefficient matrix of the block linear system is "consistently ordered." (Note that a consistently ordered matrix in this paper usually refers to the blocks of the matrix being consistently ordered. See Definition 9-2.2 in [11] for details.) This paper also introduces three particular multitype partitions based on strip and block mesh partitioning for solving 5-point like (in two dimensions) and 7-point like (in three dimensions) finite difference equations. The three corresponding BPSOR methods are shown, separately, to have the same convergence rate as the corresponding sequential block SOR method.

Two matrix forms of the BPSOR iterative expression are obtained in this paper. One is formulated in the original sequential ordering, and the other in the multitype ordering. With the matrix form formulated by the multitype ordering, the BPSOR method is shown to be equivalent to the normal block SOR method for solving the reordered block linear system by the multitype ordering. Hence, the BPSOR method can be analyzed in the framework of the classic SOR theory [28]. On the other hand, with the matrix form formulated by the original sequential ordering, the BPSOR method is shown to be an iterative method for solving the original block linear system. This implies that the BPSOR method can be implemented easily in parallel on an MIMD parallel computer without any reordering scheme of the unknowns.

In addition, this paper shows that the point PSOR method can be defined as an inexact BPSOR method in which each block equation is solved approximately by only one point sequential SOR iteration. As an inexact BPSOR method, the PSOR method is now well defined without involving any interprocessor data communication operations and extended to solving 3-dimensional (3D) problems. Since the BPSOR theory is developed based on the work of PSOR in [26], some notation and analysis techniques from [26] are kept in this paper for consistency.

Numerical experiments were made on a parallel MIMD computer, the SGI (Silicon Graphics, Inc.) Origin 2000 at the University of Wisconsin-Milwaukee, which has 16 R12000 400 MHz processors. The test model problem is a 7-point finite difference approximation to the Poisson equation on a unit cubic domain. The parallel program is written in FORTRAN 77 and MPI [3]. Each block equation was solved either by the sparse LDL^T subroutine from the SGI's Scientific Computing Software Library or

simply by the sequential point SOR method. Numerical results confirm that BPSOR has the same convergence rate as the corresponding sequential block SOR method. They also show that BPSOR has good parallel performances. For examples, speedups around 13 to 16 were obtained on the sixteen processors of the SGI Origin 2000 for solving the model problem with $h = 1/65$ and $1/129$. Moreover, numerical results show that BPSOR can significantly improve the convergence rate and parallel performance of the point PSOR method. For example, BPSOR is found to take about 16 times fewer iterations and about 16 times less interprocessor communication time than the point PSOR method for the model problem with grid size $h = 1/65$ on eight processors. Here the number of iterations is determined by an iteration termination rule. Even with the point SOR method as a solver of each block equation, test results show that the total CPU time of BPSOR can be less than that of PSOR. Clearly, the total CPU time of BPSOR can be further reduced if each block equation of BPSOR is solved by a more efficient iterative algorithm (such as the multigrid method).

It is possible to generate efficient parallel preconditioners and robust parallel smoothers from the BPSOR method through a proper selection of a local solver, a mesh domain partition, and an accuracy of local solutions. Also, the multitype ordering can be extended to parallelize the sequential Schwartz multiplicative domain decomposition method [21]. Such research topics will be investigated in the sequential papers.

The remainder of the paper is organized as follows. Section 2 introduces the multitype partition and the BPSOR method. Section 3 analyzes the BPSOR method. Section 4 defines three particular and useful BPSOR methods based on strip and block partitionings. Numerical results are presented in section 5.

2. The multitype partition and the BPSOR method.

2.1. The block linear system by the multitype partition. Consider a large-scale system of linear equations that arises from a finite element or finite difference approximation to a 2D or 3D elliptic Dirichlet boundary problem. Let the mesh domain Ω_h be a set of grid points on which the unknowns of the linear system are defined with a grid size of h. To solve the linear system in parallel on p processors of a multiprocessor computer, the mesh domain Ω_h is divided into p disjoint subdomains $\Omega_{h,\mu}$ with $\mu = 1, 2, \ldots, p$ such that

$$\Omega_h = \Omega_{h,1} \cup \Omega_{h,2} \cup \cdots \cup \Omega_{h,p} \quad \text{and} \quad \Omega_{h,\mu} \cap \Omega_{h,\nu} = \emptyset \quad \text{for } \mu \neq \nu. \tag{2.1}$$

Based on domain decomposition (2.1), the linear system can be formulated into p block linear equations:

$$\sum_{\nu=1}^{p} A_{\mu\nu}\mathcal{U}_\nu = \mathcal{F}_\mu, \quad \mu = 1, 2, \ldots, p, \tag{2.2}$$

where $\mathcal{U}_\nu$ is the vector of unknowns defined on Ω_ν, $\mathcal{F}_\mu$ is a given right-hand side vector on $\Omega_{h,\mu}$, $A_{\mu\mu}$ is a nonsingular matrix defined on $\Omega_{h,\mu}$, and $A_{\mu\nu}$ denotes the matrix that indicates the connection of Ω_μ with Ω_ν. If the matrix $A_{\mu\nu}$ with $\mu \neq \nu$ contains at least one nonzero entry, Ω_μ is said to be connected to Ω_ν. Two subdomains are referred to as two neighboring subdomains if they are connected and the intersection of their closures is nonempty. It is assumed that the matrix $A_{\mu\nu}$ with $\mu \neq \nu$ is nonzero if and only if Ω_μ and Ω_ν are two neighboring subdomains.

According to the connection information of each subdomain with its neighboring subdomains, the grid points of each subdomain can be grouped into t different types

such that each type is connected only to its different adjacent types, and at least one of the adjacent types is located in a neighboring subdomain. Here the number t is less than or equal to the number of neighboring subdomains, and two types are called two adjacent types only if they are connected and have a nonempty closure intersection. If $\Omega_{h,\mu}^i$ denotes the ith type of the μth subdomain, then the multitype partition of the mesh domain Ω_h is defined by

$$\Omega_{h,\mu} = \Omega_{h,\mu}^1 \cup \Omega_{h,\mu}^2 \cup \cdots \cup \Omega_{h,\mu}^t \quad \text{and} \quad \Omega_{h,\mu}^i \cap \Omega_{h,\mu}^j = \emptyset \quad \text{for } i \neq j \tag{2.3}$$

for $\mu = 1, 2, \ldots, p$.

Based on the multitype partition (2.3), a system of tp block linear equations is formulated as

$$\sum_{\nu=1}^{p} \sum_{j=1}^{t} A_{\mu\nu}^{ij} \mathcal{U}_\nu^j = \mathcal{F}_\mu^i, \quad i = 1, 2, \ldots, t \text{ and } \mu = 1, 2, \ldots, p, \tag{2.4}$$

where $\mathcal{U}_\mu^i$ and $\mathcal{F}_\mu^i$ denote the vectors defined on $\Omega_{h,\mu}^i$, $A_{\mu\mu}^{ii}$ is a nonsingular matrix defined on $\Omega_{h,\mu}^i$, and $A_{\mu\nu}^{ij}$ denotes the matrix that indicates the connections of $\Omega_{h,\mu}^i$ with $\Omega_{h,\nu}^j$. In the multitype partition, the submatrix $A_{\mu\nu}^{ij}$ with $\mu \neq \nu$ and $i \neq j$ is nonzero only if $\Omega_{h,\mu}^i$ and $\Omega_{h,\nu}^j$ are two adjacent types. Specifically, $A_{\mu\nu}^{ij} = 0$ for all $i \leq j$ if $\mu < \nu$ and for all $i \geq j$ if $\mu > \nu$ so that the block linear system of (2.4) can be simplified as

$$\sum_{j=1}^{t} A_{\mu\mu}^{ij} \mathcal{U}_\mu^j + \sum_{\nu=\mu+1}^{p} \sum_{j=1}^{i-1} A_{\mu\nu}^{ij} \mathcal{U}_\nu^j + \sum_{\nu=1}^{\mu-1} \sum_{j=i+1}^{t} A_{\mu\nu}^{ij} \mathcal{U}_\nu^j = \mathcal{F}_\mu^i, \tag{2.5}$$

where $\mu = 1, 2, \ldots, p$ and $i = 1, 2, \ldots, t$. Many submatrices $A_{\mu\nu}^{ij}$ in (2.5) may still be zero, but they are retained in (2.5) to include various multitype partitions.

The linear system can be expressed in a matrix equation if a global ordering of the unknowns is given. A natural way to order the tp-type subdomains $\{\Omega_{h,\mu}^i\}$ is to order them from $i = 1$ to t for each value of μ from 1 to p. Such a global ordering will be referred to as the natural ordering.

In the natural ordering, the block linear system (2.5) can be expressed in the matrix form

$$Au = f, \tag{2.6}$$

where u and f are two collective vectors defined by

$$u = \begin{pmatrix} \mathcal{U}_1 \\ \mathcal{U}_2 \\ \vdots \\ \mathcal{U}_p \end{pmatrix} \text{ with } \mathcal{U}_\mu = \begin{pmatrix} \mathcal{U}_\mu^1 \\ \mathcal{U}_\mu^2 \\ \vdots \\ \mathcal{U}_\mu^t \end{pmatrix}, \; f = \begin{pmatrix} \mathcal{F}_1 \\ \mathcal{F}_2 \\ \vdots \\ \mathcal{F}_p \end{pmatrix} \text{ with } \mathcal{F}_\mu = \begin{pmatrix} \mathcal{F}_\mu^1 \\ \mathcal{F}_\mu^2 \\ \vdots \\ \mathcal{F}_\mu^t \end{pmatrix}, \tag{2.7}$$

and A is a $tp \times tp$ partitioned block matrix defined by

$$A = \begin{bmatrix} A_{11} & A_{12} & \cdots & A_{1p} \\ A_{21} & A_{22} & \cdots & A_{2p} \\ \vdots & \vdots & \ddots & \vdots \\ A_{p1} & A_{p2} & \cdots & A_{pp} \end{bmatrix} \text{ with } A_{\mu\mu} = \begin{bmatrix} A_{\mu\mu}^{11} & A_{\mu\mu}^{12} & \cdots & A_{\mu\mu}^{1t} \\ A_{\mu\mu}^{21} & A_{\mu\mu}^{22} & \cdots & A_{\mu\mu}^{2t} \\ \vdots & \vdots & \ddots & \vdots \\ A_{\mu\mu}^{t1} & A_{\mu\mu}^{t2} & \cdots & A_{\mu\mu}^{tt} \end{bmatrix}, \tag{2.8}$$

and

$$A_{\mu\nu} = \begin{cases} \begin{bmatrix} 0 & 0 & \cdots & 0 \\ A_{\mu\nu}^{21} & 0 & \cdots & 0 \\ \vdots & \ddots & \ddots & \vdots \\ A_{\mu\nu}^{t1} & \cdots & A_{\mu\nu}^{t,t-1} & 0 \end{bmatrix} & \text{for } \mu < \nu, \\ \begin{bmatrix} 0 & A_{\mu\nu}^{12} & \cdots & A_{\mu\nu}^{1t} \\ 0 & 0 & \ddots & \vdots \\ \vdots & \vdots & \ddots & A_{\mu\nu}^{t-1,t} \\ 0 & 0 & \cdots & 0 \end{bmatrix} & \text{for } \mu > \nu. \end{cases} \tag{2.9}$$

Here the block matrix A is assumed to be sparse, symmetric positive definite, or consistently ordered.

2.2. The sequential block SOR method by the *t*-type partition. Let the block matrix A be split into the form

$$A = D - L - U, \tag{2.10}$$

where L and U are the two strictly block lower- and upper-triangular matrices, respectively, and D is the block diagonal matrix. They are defined as

$$D = \operatorname{diag}(D_1, D_2, \ldots, D_p) \text{ with } D_\mu = \operatorname{diag}(A_{\mu\mu}^{11}, A_{\mu\mu}^{22}, \ldots, A_{\mu\mu}^{tt}), \tag{2.11}$$

$$L = -\begin{bmatrix} L_1 & 0 & \cdots & 0 \\ A_{21} & L_2 & \ddots & \vdots \\ \vdots & \ddots & \ddots & 0 \\ A_{p1} & \cdots & A_{p(p-1)} & L_p \end{bmatrix}, \quad U = -\begin{bmatrix} U_1 & A_{12} & \cdots & A_{1p} \\ 0 & \ddots & \ddots & \vdots \\ \vdots & \ddots & U_{p-1} & A_{(p-1)p} \\ 0 & \cdots & 0 & U_p \end{bmatrix},$$

where the abbreviation $\operatorname{diag}(\alpha_1, \alpha_2, \ldots, \alpha_m)$ denotes the diagonal matrix with the diagonal elements $\alpha_1, \alpha_2, \ldots, \alpha_m$, and

$$L_\mu = \begin{bmatrix} 0 & 0 & \cdots & 0 \\ A_{\mu\mu}^{21} & 0 & \cdots & 0 \\ \vdots & \ddots & \ddots & \vdots \\ A_{\mu\mu}^{t1} & \cdots & A_{\mu\mu}^{t,t-1} & 0 \end{bmatrix}, \quad U_\mu = \begin{bmatrix} 0 & A_{\mu\mu}^{12} & \cdots & A_{\mu\mu}^{1t} \\ \vdots & \ddots & \ddots & \vdots \\ 0 & \cdots & 0 & A_{\mu\mu}^{t-1,t} \\ 0 & \cdots & 0 & 0 \end{bmatrix}. \tag{2.12}$$

In terms of the above matrices, the block SOR method by the t-type partition is defined by

$$u^{(k+1)} = M_{SOR} u^{(k)} + \omega[D - \omega L]^{-1} f, \tag{2.13}$$

where $u^{(k)}$ is a block vector in the form

$$u^{(k)} = \begin{pmatrix} \mathcal{U}_1^{(k)} \\ \mathcal{U}_2^{(k)} \\ \vdots \\ \mathcal{U}_p^{(k)} \end{pmatrix} \quad \text{with} \quad \mathcal{U}_\mu^{(k)} = \begin{pmatrix} \mathcal{U}_\mu^{1,(k)} \\ \mathcal{U}_\mu^{2,(k)} \\ \vdots \\ \mathcal{U}_\mu^{t,(k)} \end{pmatrix} \quad \text{for } \mu = 1, 2, \ldots, p, \tag{2.14}$$

$\mathcal{U}_\mu^{i,(k)}$ is the kth iterate on $\Omega_{h,\mu}^i$, and M_{SOR} is the SOR iteration matrix defined by

$$M_{SOR} = [D - \omega L]^{-1}[(1-\omega)D + \omega U]. \tag{2.15}$$

See [28] for the details on the analysis of the SOR method.

However, the block SOR method is a sequential iterative method. In fact, on each type subdomain, Ω_μ^i, the component expression of the block SOR method (2.13) can be written as

$$\begin{aligned}\mathcal{U}_\mu^{i,(k+1)} = \omega(A_{\mu\mu}^{ii})^{-1}\Bigg[\mathcal{F}_\mu^i - \sum_{j=1}^{i-1} A_{\mu\mu}^{ij}\mathcal{U}_\mu^{j,(k+1)} - \sum_{j=i+1}^{t} A_{\mu\mu}^{ij}\mathcal{U}_\mu^{j,(k)} \\ - \sum_{\nu=\mu+1}^{p}\sum_{j=1}^{i-1} A_{\mu\nu}^{ij}\mathcal{U}_\nu^{j,(k)} - \sum_{\nu=1}^{\mu-1}\sum_{j=i+1}^{t} A_{\mu\nu}^{ij}\mathcal{U}_\nu^{j,(k+1)}\Bigg] + (1-\omega)\mathcal{U}_\mu^{i,(k)},\end{aligned} \tag{2.16}$$

where $i = 1, 2, \ldots, t$, $\mu = 1, 2, \ldots, p$, and $k = 0, 1, 2, \ldots$. From (2.16) it can be seen that the current new iterate $\mathcal{U}_\mu^{i,(k+1)}$ depends on the previous new iterates $\{\mathcal{U}_\nu^{j,(k+1)}\}_{\nu=1}^{\mu-1}$, which are located on other subdomains, $\{\Omega_{h,\nu}\}_{\nu=1}^{\mu-1}$. Thus, the block SOR method by the multitype partition is sequential in terms of subdomains $\{\Omega_{h,\nu}\}_{\nu=1}^{p}$.

2.3. The BPSOR method. However, the sequential block SOR method by the multitype partition can be easily parallelized by using the multitype ordering, which orders the subdomains $\{\Omega_{h,\mu}^i\}$ from $\mu = 1$ to p for each value of i from 1 to t. In detail, the subdomains $\{\Omega_{h,\mu}^1\}_{\mu=1}^p$ of type 1 is first ordered from $\mu = 1$ to p, then the subdomains $\{\Omega_{h,\mu}^2\}_{\mu=1}^p$ of type 2, and so on, through the subdomains $\{\Omega_{h,\mu}^t\}_{\mu=1}^p$ of type t. Within each type subdomain, the original natural ordering of mesh points is maintained so that each block equation of (2.5) is kept. The multitype ordering with t types will be simply referred to as the t-type ordering.

In the t-type ordering, the iterates $\mathcal{U}_\nu^{j,(k+1)}$ with $j = 1, 2, \ldots, i-1$ and $\nu = \mu, \mu+1, \ldots, p$ will be computed before the calculation of $\{\mathcal{U}_\mu^{i,(k+1)}\}_{\mu=1}^p$. Hence, the p iterates $\{\mathcal{U}_\mu^{i,(k+1)}\}_{\mu=1}^p$ can be defined by

$$\begin{aligned}\mathcal{U}_\mu^{i,(k+1)} = \omega(A_{\mu\mu}^{ii})^{-1}\Bigg[\mathcal{F}_\mu^i - \sum_{\nu=\mu}^{p}\sum_{j=1}^{i-1} A_{\mu\nu}^{ij}\mathcal{U}_\nu^{j,(k+1)} - \sum_{\nu=1}^{\mu}\sum_{j=i+1}^{t} A_{\mu\nu}^{ij}\mathcal{U}_\nu^{j,(k)}\Bigg] \\ + (1-\omega)\mathcal{U}_\mu^{i,(k)} \quad \text{for} \quad \mu = 1, 2, \ldots, p, \quad i = 1, 2, \ldots, t.\end{aligned} \tag{2.17}$$

Here $k = 0, 1, 2, \ldots$, $\mathcal{U}_\nu^{j,(0)}$ is a given initial guess, and $\omega \in (0, 2)$. Since all the iterates on the right-hand side of the above equations are given or computed in the previous steps, the iterative expressions of $\{\mathcal{U}_\mu^{i,(k+1)}\}_{\mu=1}^p$ in (2.17) are completely independent. In addition, these p iterates are defined on p different subdomains, $\{\Omega_{h,\mu}\}_{\mu=1}^p$, respectively. Hence, when each subdomain is assigned to one processor, they can be calculated in parallel on p processors. Therefore, the iterative method defined by (2.17) is a parallel scheme based on the domain decomposition (2.1). For clarity, it will be called the block parallel SOR (BPSOR) method.

A parallel implementation scheme of BPSOR is described in Algorithm 1. Here processor μ contains both subdomain Ω_μ and its ghost boundary, which is a set of the mesh points of the neighboring subdomains that are connected to Ω_μ for $\mu = 1, 2, \ldots, p$.

ALGORITHM 1 (for parallel implementation of BPSOR). u_μ^i $\mathcal{U}_\mu^{i,(k)}$ $\mathcal{U}_\mu^{i,(0)}$ $\mu = 1$ p

1. $u_\mu^i := \mathcal{U}_\mu^{i,(0)}$ $i = 1, 2, \ldots, t$ $k = 1$
2. $\{u_\mu^i\}_{i=1}^t$ i $i = 1, 2, \ldots, t$
   (a) $A_{\mu\mu}^{ii} v_\mu^i = f_\mu^i$ v_μ^i f_μ^i

$$f_\mu^i := \mathcal{F}_\mu^i - \sum_{j=1}^{i-1} \sum_{\nu=\mu}^{p} A_{\mu\nu}^{ij} u_\nu^j - \sum_{j=i+1}^{t} \sum_{\nu=1}^{\mu} A_{\mu\nu}^{ij} u_\nu^j.$$

   (b) $u_\mu^i := \omega v_\mu^i + (1-\omega) u_\mu^i$.
   (c) u_μ^i (i)
3. $k := k + 1$ 2

3. The analysis of the BPSOR method.

3.1. BPSOR as an iterative method using the natural ordering. From Algorithm 1 it can be seen that the BPSOR iterates $\{\mathcal{U}_\mu^{i,(k)}\}$ are calculated from $i = 1$ to t within each processor. Thus, the pt BPSOR iterates $\{\mathcal{U}_\mu^{i,(k)}\}$ can be formulated as a block vector in the natural ordering.

THEOREM 3.1. $\{\mathcal{U}_\mu^{i,(k)}\}$ (2.17) $u^{(k)}$ (2.14)

$$u^{(k+1)} = M_{BPSOR} u^{(k)} + \omega [D - \omega(B + M)]^{-1} f \quad k = 0, 1, 2, \ldots, \tag{3.1}$$

$\omega \in (0, 2)$, M_{BPSOR}

$$M_{BPSOR} = [D - \omega(B + M)]^{-1} [(1 - \omega) D + \omega(C + N)], \tag{3.2}$$

D (2.11) B C

$$B = -\operatorname{diag}(L_1, L_2, \ldots, L_p) \qquad C = -\operatorname{diag}(U_1, U_2, \ldots, U_p), \tag{3.3}$$

M N

$$N = L - B \qquad M = U - C. \tag{3.4}$$

L, U, L_μ U_μ (2.11) (2.12) . With (3.4), the matrices L and U can be expressed by

$$L = N + B \quad \text{and} \quad U = M + C. \tag{3.5}$$

Thus, the regular splitting (2.10) becomes

$$A = D - B - C - M - N. \tag{3.6}$$

An iterative method using the natural ordering means the one for solving the linear system $Au = f$ given in (2.6). With the splitting formula (3.6), an iterative sequence $\{u^{(k)}\}$ using the natural ordering can be defined by

$$Du^{(k+1)} = (B + M)u^{(k+1)} + f + (C + N)u^{(k)}, \quad k = 0, 1, 2, \ldots.$$

Introducing the relaxation parameter ω into the above iterative sequence gives

$$Du^{(k+1)} = \omega[(B + M)u^{(k+1)} + f + (C + N)u^{(k)}] + (1 - \omega)u^{(k)}. \tag{3.7}$$

Solving the above equation for $u^{(k+1)}$ yields the matrix iterative expression (3.1). Expanding the matrix expression (3.1) into the block component expressions in terms of $\{\mathcal{U}_\mu^{i,(k)}\}$ yields the BPSOR iterative expressions in (2.17). Thus, the block iterative sequence defined by (3.7) is exactly the BPSOR method (2.17). Hence, the expression (3.1) is also the matrix iterative expression of the BPSOR method. Therefore, the BPSOR method can be regarded as an iterative method using the natural ordering. This completes the proof of the theorem.

Because of (3.5), the BPSOR iterative expression (3.1) can be changed to the sequential block SOR iterative expression (2.13) by simply switching the positions of N and M. Such a matrix-switch operation is completed in step (c) of Algorithm 1. In this sense, BPSOR can be regarded as a parallel version of the block SOR method (2.13), which is generated from a novel usage of interprocessor communication operations. □

3.2. BPSOR as the block SOR using the multitype ordering. Let P be a permutation matrix defined by $\hat{u} = Pu$ for u in the form (2.7), and $\hat{u}$ in the following form:

$$\hat{u} = \begin{pmatrix} \hat{\mathcal{U}}_1 \\ \hat{\mathcal{U}}_2 \\ \vdots \\ \hat{\mathcal{U}}_t \end{pmatrix} \text{ with } \quad \hat{\mathcal{U}}_i = \begin{pmatrix} \mathcal{U}_1^i \\ \mathcal{U}_2^i \\ \vdots \\ \mathcal{U}_p^i \end{pmatrix} \text{ for } 1 \le i \le t. \tag{3.8}$$

Obviously, by the t-type ordering, the block linear system $Au = f$ in (2.6) can be reordered into an equivalent block linear system. In terms of P, the reordered linear system can be expressed as

$$\hat{A}\hat{u} = \hat{f}, \tag{3.9}$$

where $\hat{A} = PAP^T$, $\hat{u} = Pu$, and $\hat{f} = Pf$. The matrix form of $\hat{A}$ can be found as

$$\hat{A} = \begin{bmatrix} \hat{A}_{11} & \hat{A}_{12} & \cdots & \hat{A}_{1t} \\ \hat{A}_{21} & \hat{A}_{22} & \cdots & \hat{A}_{2t} \\ \vdots & \ddots & \ddots & \vdots \\ \hat{A}_{t1} & \cdots & \hat{A}_{t,t-1} & \hat{A}_{tt} \end{bmatrix} \tag{3.10}$$

with $\hat{A}_{ij}$ being defined by

$$\hat{A}_{ij} = \begin{cases} \operatorname{diag}(A_{11}^{ii}, A_{22}^{ii}, \ldots, A_{pp}^{ii}) & \text{for} \quad i = j, \\ \begin{bmatrix} A_{11}^{ij} & A_{12}^{ij} & \cdots & A_{1p}^{ij} \\ 0 & A_{22}^{ij} & \cdots & A_{2p}^{ij} \\ \vdots & \ddots & \ddots & \vdots \\ 0 & \cdots & 0 & A_{pp}^{ij} \end{bmatrix} & \text{for} \quad i > j, \\ \begin{bmatrix} A_{11}^{ij} & 0 & \cdots & 0 \\ A_{21}^{ij} & A_{22}^{ij} & \ddots & \vdots \\ \vdots & \vdots & \ddots & 0 \\ A_{p1}^{ij} & A_{p2}^{ij} & \cdots & A_{pp}^{ij} \end{bmatrix} & \text{for} \quad i < j. \end{cases} \tag{3.11}$$

THEOREM 3.2. $\{\mathcal{U}_{\mu}^{i,(k)}\}$ (2.17) $\hat{u}^{(k)}$ (3.8) (2.17)

$$\hat{u}^{(k+1)} = \hat{M}_{SOR}\hat{u}^{(k)} + \omega(\hat{D} - \omega\hat{L})^{-1}\hat{f}, \tag{3.12}$$

$\hat{M}_{SOR}$

$$\hat{M}_{SOR} = (\hat{D} - \omega\hat{L})^{-1}[(1-\omega)\hat{D} + \omega\hat{U}], \tag{3.13}$$

$\hat{D}, \hat{L}$ $\hat{U}$

$$\hat{A} = \hat{D} - \hat{L} - \hat{U}, \tag{3.14}$$

$\hat{A}$ (3.10)

. By the splitting of $\hat{A}$ in (3.14), it is easy to find that the block SOR method using the multitype ordering has the matrix iterative expression (3.12). In terms of $\mathcal{U}_{\mu}^{i,(k)}$, the block component expressions of the matrix form (3.12) turn out to be the same as the iterative expressions of the BPSOR method in (2.17). Hence, the BPSOR method is equivalent to the block SOR method using the multitype ordering for solving the reordered linear system (3.9). This completes the proof of the theorem. □

3.3. The relationship between the two iteration matrices. Two matrix iterative expressions, (3.1) and (3.12), have been formulated for the BPSOR method by the natural ordering and the t-type ordering. The expression of (3.1) indicates that the BPSOR method can be easily implemented in parallel since the original natural ordering is maintained. From the expression of (3.12) it implies that the BPSOR method can be analyzed under the framework of the classic SOR theory [28].

THEOREM 3.3. M_{BPSOR} $\hat{M}_{SOR}$ (3.2) (3.13) P (3.8)

$$\hat{M}_{SOR} = PM_{BPSOR}P^T. \tag{3.15}$$

. The key step in proving (3.15) is to show the following two identities:

$$\hat{L} = P(B+M)P^T \quad \text{and} \quad \hat{U} = P(C+N)P^T. \tag{3.16}$$

The proof of the first one is given below.

By multiplying both sides of expression (3.1) by P, (3.1) can be rewritten as

$$\begin{aligned}\hat{u}^{(k+1)} = {} & [\hat{D} - \omega P(B+M)P^T]^{-1}[(1-\omega)\hat{D} + \omega P(C+N)P^T]\hat{u}^{(k)} \\ & + \omega[\hat{D} - \omega P(B+M)P^T]^{-1}\hat{f},\end{aligned} \tag{3.17}$$

where the identities $P^TP = I$, $Pu^{(k)} = \hat{u}^{(k)}$, $Pf = \hat{f}$, and $PDP^T = \hat{D}$ have been used. The following two expressions of $\hat{u}^{(1)}$ are then produced from (3.17) and (3.12) by setting $\hat{u}^{(0)} = 0$:

$$\hat{u}^{(1)} = \omega[\hat{D} - \omega P(B+M)P^T]^{-1}\hat{f} \quad \text{and} \quad \hat{u}^{(1)} = \omega[\hat{D} - \omega\hat{L}]^{-1}\hat{f}.$$

Combining them as one identity yields

$$[\hat{D} - \omega P(B+M)P^T]^{-1}\hat{f} = [\hat{D} - \omega\hat{L}]^{-1}\hat{f}.$$

Since $\hat{f}$ is arbitrary, the above identity follows as $[\hat{D} - \omega P(B+M)P^T]^{-1} = [\hat{D} - \omega\hat{L}]^{-1}$. Simplifying it gives $\hat{L} = P(B+M)P^T$.

To prove the second identity of (3.16), substituting $P(B+M)P^T$ by $\hat{L}$ in (3.17) gives

$$\hat{u}^{(k+1)} = [\hat{D} - \omega\hat{L}]^{-1}[(1-\omega)\hat{D} + \omega P(C+N)P^T]\hat{u}^{(k)} + \omega[\hat{D} - \omega\hat{L}]^{-1}\hat{f}.$$

Combining the above expression with (3.12) yields

$$[(1-\omega)\hat{D} + \omega P(C+N)P^T]\hat{u}^{(k)} = [(1-\omega)\hat{D} + \omega U]\hat{u}^{(k)} \quad \text{for all } k \geq 0.$$

Since the above identity holds for any vector of $\hat{u}^{(k)}$, it implies that

$$(1-\omega)\hat{D} + \omega P(C+N)P^T = (1-\omega)\hat{D} + \omega U.$$

Simplifying again gives that $\hat{U} = P(C+N)P^T$.

Finally, with (3.16) and $\hat{D} = PDP^T$,

$$\begin{aligned}\hat{M}_{SOR} &= (\hat{D} - \omega\hat{L})^{-1}[(1-\omega)\hat{D} + \omega\hat{U}] \\ &= (PDP^T - \omega P(B+M)P^T)^{-1}[(1-\omega)PDP^T + \omega P(C+N)P^T] \\ &= P(D - \omega(B+M))^{-1}[(1-\omega)D + \omega(C+N)]P^T = PM_{BPSOR}P^T.\end{aligned} \tag{3.18}$$

This completes the proof of Theorem 3.3. □

3.4. Convergence of the BPSOR method. The main convergence results of the BPSOR method are presented in the following theorem.

THEOREM 3.4. $M_J, M_{SOR},$ M_{BPSOR}

A (2.8)

$u^{(k)}$ $u^* = A^{-1}f$ $k \to \infty$

ω $0 < \omega < 2$

A M_J $\rho(M_J) < 1$

$$\rho(M_{BPSOR}(\omega)) = \rho(M_{SOR}(\omega)) \tag{3.19}$$

$$= \begin{cases} \frac{1}{4}\left[\omega\rho(M_J) + \sqrt{\omega^2\rho(M_J)^2 - 4(\omega-1)}\right]^2 & 0 < \omega \le \omega_b, \\ \omega - 1 & \omega_b \le \omega < 2, \end{cases} \tag{3.20}$$

$$\omega_b = \frac{2}{1 + \sqrt{1 - \rho(M_J)^2}}. \tag{3.21}$$

$\rho(\cdot)$ M_{SOR} M_{BPSOR} (2.15)

(3.2) $M_J = L + U$ L U (2.11)

Since the reordered matrix $\hat{A}$ defined in (3.10) satisfies $\hat{A} = PAP^T$ and A is symmetric positive definite, then $\hat{A}$ is symmetric positive definite. Also, from Theorem 4.1 in [26] it follows that $\hat{A}$ is consistently ordered if A is consistently ordered. Moreover, in Theorem 3.2, the BPSOR method has been shown to be equivalent to the block SOR method for solving the reordered linear system (3.9). Hence, from the classic SOR theory [28] it can be shown that the BPSOR iterates $\hat{u}^{(k)}$ converge to the exact solution $\hat{u}^*$ if and only if the relaxation parameter ω satisfies $0 < \omega < 2$, and both the spectral radius $\rho(\hat{M}_{SOR})$ and the optimal relaxation value $\hat{\omega}_b$ can be expressed as

$$\rho(\hat{M}_{SOR}) = \begin{cases} \frac{1}{4}\left[\omega\rho(\hat{M}_J) + \sqrt{\omega^2\rho(\hat{M}_J)^2 - 4(\omega-1)}\right]^2, & 0 < \omega \le \hat{\omega}_b, \\ \omega - 1, & \hat{\omega}_b \le \omega < 2, \end{cases} \tag{3.22}$$

and

$$\hat{\omega}_b = \frac{2}{1 + \sqrt{1 - \rho(\hat{M}_J)^2}}, \tag{3.23}$$

where $\hat{M}_J = \hat{L} + \hat{U}$ is the Jacobi iteration matrix of the reordered linear system (3.9), and $\hat{u}^* = Pu^*$ with u^* being the exact solution of the original linear system (2.6).

On the other hand, from the classic SOR theory [28] it follows that $\rho(M_{SOR})$ and ω_b have the same expressions as given in (3.20) and (3.21). That $\hat{M}_J = PM_JP^T$ follows easily from (3.16). Thus, $\rho(\hat{M}_J) = \rho(M_J)$. As a result, the expressions (3.22) and (3.23) become the same as the expressions (3.20) and (3.21), resulting in $\rho(\hat{M}_{SOR}) = \rho(M_{SOR})$ for $0 < \omega < 2$. Furthermore, from (3.15) it follows that $\rho(M_{BPSOR}) = \rho(\hat{M}_{SOR})$. Consequently,

$$\rho(M_{BPSOR}) = \rho(\hat{M}_{SOR}) = \rho(M_{SOR}).$$

Finally, the BPSOR iterate $u^{(k)} = P^T\hat{u}^{(k)} \to P^T\hat{u}^* = u^*$ as $k \to \infty$. This completes the proof. □

Two different iterative methods are said to have the same asymptotic rate of convergence if they have the same spectral radius [28]. Hence, (3.19) implies that the BPSOR method has the same asymptotic rate of convergence as the corresponding sequential block SOR method.

3.5. The point PSOR method as an inexact BPSOR scheme. To reduce the computing cost, the block equations of the BPSOR method can be solved approximately by an iterative method. Different iterative solvers with different approximation accuracies lead to different inexact BPSOR methods. In particular, the point PSOR method proposed in [26] can be regarded as an inexact BPSOR method in which each block equation is solved by only one point SOR iteration.

To show the above claim, let $\{\mathcal{U}_\mu^{i,(k)}\}$ be a sequence of the inexact BPSOR iterates in which each block equation is solved by only one point SOR iteration. Then, $\mathcal{U}_\mu^{i,(k+1)}$ is defined by

$$\mathcal{U}_\mu^{i,(k+1)} = \omega(D_\mu^i)^{-1}[f_\mu^i + L_\mu^i \mathcal{U}_\mu^{i,(k+1)} + U_\mu^i \mathcal{U}_\mu^{i,(k)}] + (1-\omega)\mathcal{U}_\mu^{i,(k)}, \tag{3.24}$$

where D_μ^i, L_μ^i, and U_μ^i denote the diagonal, strictly lower-triangular, and strictly upper-triangular matrices satisfying $A_{\mu\mu}^{ii} = D_\mu^i - L_\mu^i - U_\mu^i$, f_μ^i is a vector defined by

$$f_\mu^i = \mathcal{F}_\mu^i - \sum_{\nu=\mu}^{p}\sum_{j=1}^{i-1} A_{\mu\nu}^{ij}\mathcal{U}_\nu^{j,(k+1)} - \sum_{\nu=1}^{\mu}\sum_{j=i+1}^{t} A_{\mu\nu}^{ij}\mathcal{U}_\nu^{j,(k)},$$

$\mu = 1, 2, \ldots, p$, and $i = 1, 2, \ldots, t$. In terms of $A_{\mu\nu}$, $\mathcal{U}_\mu^{(k)}$, L_μ, and U_μ, in (2.9), (2.14), and (2.12), the block vector $f_\mu = ((f_\mu^1)^T, (f_\mu^2)^T, \ldots, (f_\mu^t)^T)^T$ can be expressed as

$$f_\mu = \mathcal{F}_\mu - \sum_{\nu=\mu+1}^{p} A_{\mu\nu}\mathcal{U}_\nu^{(k+1)} - L_\mu\mathcal{U}_\mu^{(k+1)} - \sum_{\nu=1}^{\mu-1} A_{\mu\nu}\mathcal{U}_\nu^{(k)} - U_\mu\mathcal{U}_\mu^{(k)}. \tag{3.25}$$

By using (3.25) and the three block diagonal matrices, $\tilde{D}_\mu = \mathrm{diag}(D_\mu^1, D_\mu^2, \ldots, D_\mu^t)$, $\tilde{B}_\mu = \mathrm{diag}(L_\mu^1, L_\mu^2, \ldots, L_\mu^t)$, and $\tilde{C}_\mu = \mathrm{diag}(U_\mu^1, U_\mu^2, \ldots, U_\mu^t)$, the t expressions of $\{\mathcal{U}_\mu^{i,(k+1)}\}_{i=1}^t$ in (3.24) can be formulated as one vector form:

$$\begin{aligned}\mathcal{U}_\mu^{(k+1)} = \omega(D_\mu)^{-1}\Bigg[&\mathcal{F}_\mu + (\tilde{B}_\mu + L_\mu)\mathcal{U}_\mu^{(k+1)} + (\tilde{C}_\mu + U_\mu)\mathcal{U}_\mu^{i,(k)} \\ &- \sum_{\nu=\mu+1}^{p} A_{\mu\nu}\mathcal{U}_\nu^{(k+1)} - \sum_{\nu=1}^{\mu-1} A_{\mu\nu}\mathcal{U}_\nu^{(k)}\Bigg] + (1-\omega)\mathcal{U}_\mu^{(k)}.\end{aligned} \tag{3.26}$$

Further, define three block diagonal matrices as

$$\tilde{D} = \mathrm{diag}(\tilde{D}_1, \tilde{D}_2, \ldots, \tilde{D}_p),\ \tilde{B} = \mathrm{diag}(\tilde{L}_1, \tilde{L}_2, \ldots, \tilde{L}_p),\ \tilde{C} = \mathrm{diag}(\tilde{U}_1, \tilde{U}_2, \ldots, \tilde{U}_p),$$

where $\tilde{L}_\mu = \tilde{B}_\mu + L_\mu$ and $\tilde{U}_\mu = \tilde{C}_\mu + U_\mu$, which are the strictly lower- and upper-triangular matrices satisfying $A_{\mu\mu} = \tilde{D}_\mu - \tilde{L}_\mu - \tilde{U}_\mu$. By using them, the p expressions in (3.26) can be written as the matrix form

$$u^{(k+1)} = \omega\tilde{D}^{-1}[f + (\tilde{B} + M)u^{(k+1)} + (\tilde{C} + N)u^{(k)}] + (1-\omega)u^{(k)},$$

where the matrices M and N are given in (3.4). Solving the above equation for $u^{(k+1)}$ yields the matrix iterative expression of the inexact BPSOR method:

$$\begin{aligned}u^{(k+1)} = &[\tilde{D} - \omega(\tilde{B} + M)]^{-1}[(1-\omega)\tilde{D} + \omega(\tilde{C} + N)]u^{(k)} \\ &+ \omega[\tilde{D} - \omega(\tilde{B} + M)]^{-1}f.\end{aligned} \tag{3.27}$$

On the other hand, from [26] it is known that the point PSOR method has the same matrix expression as the one above. Hence, the inexact BPSOR method is exactly the point PSOR method defined in [26].

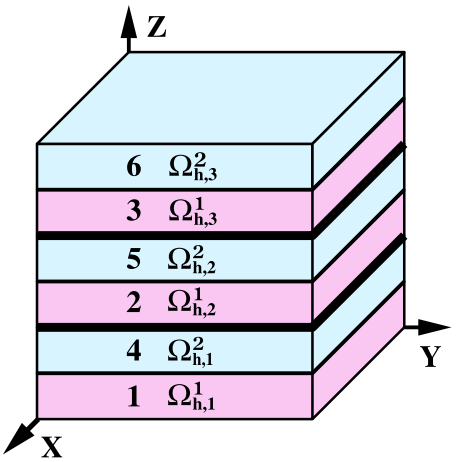

FIG. 4.1. *The 2-type partition based on a 3-strip partitioning of a cubic domain ($p = 3$ and $t = 2$). Each strip contains two types, $\Omega^1_{h,\mu}$ and $\Omega^2_{h,\mu}$ for $\mu = 1, 2, 3$, which are numbered in the 2-type ordering.*

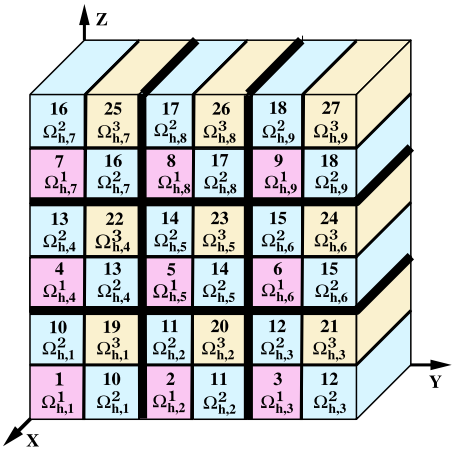

FIG. 4.2. *The 3-type partition based on a 2D 9-block partitioning of a cubic domain ($p = 9$ and $t = 3$). Each block contains three types, $\Omega^1_{h,\mu}$, $\Omega^2_{h,\mu}$, and $\Omega^3_{h,\mu}$ for $\mu = 1, 2, \ldots, 9$, which are numbered in the 3-type ordering.*

4. Three BPSOR methods based on strip and block partitionings.

4.1. The 2-type BPSOR method by strip partitioning. The 2-type BPSOR method is the BPSOR method by the 2-type partition based on a strip partition of the mesh domain Ω_h. For finite element and finite difference equations, the mesh-domain Ω_h is partitioned into p strips along one direction of the space such that each interior strip has only two coupled neighboring strips. Thus, each strip $\Omega_{h,\mu}$ contains only two types, $\Omega^1_{h,\mu}$ and $\Omega^2_{h,\mu}$. An illustration of the 2-type partition and ordering is given in Figure 4.1. Here a cubic domain is partitioned into three strips ($p = 3$), the two types are colored in two different colors, and each type is numbered in the 2-type ordering.

In the case of the 2-type partition ($t = 2$), the block matrix A in (2.8) becomes a tridiagonal block matrix with $A_{ij} = 0$ for $|i - j| \geq 2$. The nonzero off-diagonal submatrices of each row have the following forms:

$$A_{\mu,\mu+1} = \begin{bmatrix} 0 & 0 \\ A^{21}_{\mu,\mu+1} & 0 \end{bmatrix} \quad \text{and} \quad A_{\mu+1,\mu} = \begin{bmatrix} 0 & A^{12}_{\mu+1,\mu} \\ 0 & 0 \end{bmatrix}. \tag{4.1}$$

By setting $A^{12}_{1,0} = A^{21}_{p,p+1} = 0$, the BPSOR method by the strip partitioning can be expressed as

$$\begin{aligned} \mathcal{U}^{1,(k+1)}_\mu &= \omega(A^{11}_{\mu\mu})^{-1}[\mathcal{F}^1_\mu - A^{12}_{\mu,\mu-1}\mathcal{U}^{2,(k)}_{\mu-1} - A^{12}_{\mu,\mu}\mathcal{U}^{2,(k)}_\mu] \\ &\quad + (1-\omega)\mathcal{U}^{1,(k)}_\mu, \quad \mu = 1, 2, \ldots, p \quad \text{for Type 1,} \end{aligned} \tag{4.2}$$

$$\begin{aligned} \mathcal{U}^{2,(k+1)}_\mu &= \omega(A^{22}_{\mu\mu})^{-1}[\mathcal{F}^2_\mu - A^{21}_{\mu,\mu}\mathcal{U}^{1,(k+1)}_\mu - A^{21}_{\mu,\mu+1}\mathcal{U}^{1,(k+1)}_{\mu+1}] \\ &\quad + (1-\omega)\mathcal{U}^{2,(k)}_\mu, \quad \mu = 1, 2, \ldots, p \quad \text{for Type 2.} \end{aligned} \tag{4.3}$$

Obviously, the p iterative expressions of (4.2) are completely independent; so are the p iterative expressions of (4.3). Hence, the 2-type BPSOR method is a parallel iterative scheme by the strip partitioning.

In the 2-type ordering, the reordered matrix $\hat{A}$ of (3.10) becomes a 2×2 block matrix in the form

$$\hat{A} = \begin{bmatrix} \hat{A}_{11} & \hat{A}_{12} \\ \hat{A}_{21} & \hat{A}_{22} \end{bmatrix},$$

where $\hat{A}_{11} = \text{diag}(A_{11}^{11}, A_{22}^{11}, \ldots, A_{pp}^{11})$, $\hat{A}_{22} = \text{diag}(A_{11}^{22}, A_{22}^{22}, \ldots, A_{pp}^{22})$,

$$\hat{A}_{12} = \begin{bmatrix} A_{11}^{12} & & & \\ A_{21}^{12} & A_{22}^{12} & & \\ & \ddots & \ddots & \\ & & A_{p,p-1}^{12} & A_{pp}^{21} \end{bmatrix}, \text{ and } \hat{A}_{21} = \begin{bmatrix} A_{11}^{21} & A_{12}^{21} & & \\ & A_{22}^{21} & \ddots & \\ & & \ddots & A_{p-1,p}^{21} \\ & & & A_{pp}^{21} \end{bmatrix}.$$

Obviously, the above $\hat{A}$ is consistently ordered since it is a form of block red-black matrix [11]. Hence, the 2-type BPSOR method has the same convergence rate as the corresponding block SOR method.

4.2. The 3-type BPSOR method by 2D block partitioning. The 3-type BPSOR method is the BPSOR method by the 3-type partition based on the 2D block partitioning. For a linear system that arises from a 5-point-like or 7-point-like finite difference approximation to a 2D or 3D elliptic boundary problem, the mesh domain Ω_h is partitioned into p blocks $\Omega_{h,\mu}$ along two dimensions of the space such that each interior block is only connected to the four neighboring blocks from the left, right, top, and bottom sides. Each block is then divided into three types $\Omega_{h,\mu}^1, \Omega_{h,\mu}^2$, and $\Omega_{h,\mu}^3$ for $\mu = 1, 2, \ldots, p$. An illustration of the 3-type partition is given in Figure 4.2. Here a cubic domain is partitioned into nine blocks along the y-axis and z-axis directions, and the types labeled as $\Omega_{h,\mu}^i$ for $\mu = 1, 2, \ldots, 9$ and $i = 1, 2, 3$ are numbered in the 3-type ordering. Note that each second type $\Omega_{h,\mu}^2$ consists of two small blocks since the iterates defined on these two small blocks can be calculated simultaneously without affecting the definition of BPSOR.

In the case of the 3-type partition, the block matrix A given in (2.8) becomes a 5-diagonal block matrix such that the BPSOR method defined in (2.17) can be simplified as

$$\begin{aligned}
\mathcal{U}_\mu^{1,(k+1)} &= \omega(A_{\mu\mu}^{11})^{-1}[\mathcal{F}_\mu^1 - A_{\mu\mu}^{12}\mathcal{U}_\mu^{2,(k)} - A_{\mu,\mu-1}^{12}\mathcal{U}_{\mu-1}^{2,(k)} - A_{\mu,\mu-m}^{12}\mathcal{U}_{\mu-m}^{2,(k)}] \\
&\quad + (1-\omega)\mathcal{U}_\mu^{1,(k)}, \quad \mu = 1, 2, \ldots, p, \quad \text{for Type 1,} \\
\mathcal{U}_\mu^{2,(k+1)} &= \omega(A_{\mu\mu}^{22})^{-1}[\mathcal{F}_\mu^2 - A_{\mu\mu}^{21}\mathcal{U}_\mu^{1,(k+1)} - A_{\mu\mu}^{23}\mathcal{U}_\mu^{3,(k)} - A_{\mu,\mu-1}^{23}\mathcal{U}_{\mu-1}^{3,(k)} \\
&\quad - A_{\mu,\mu+1}^{21}\mathcal{U}_{\mu+1}^{1,(k+1)} - A_{\mu,\mu+m}^{21}\mathcal{U}_{\mu+m}^{1,(k+1)} - A_{\mu,\mu-m}^{23}\mathcal{U}_{\mu-m}^{3,(k)}] \\
&\quad + (1-\omega)\mathcal{U}_\mu^{2,(k)}, \quad \mu = 1, 2, \ldots, p, \quad \text{for Type 2,} \\
\mathcal{U}_\mu^{3,(k+1)} &= \omega(A_{\mu\mu}^{33})^{-1}[\mathcal{F}_\mu^3 - A_{\mu\mu}^{32}\mathcal{U}_\mu^{2,(k+1)} - A_{\mu,\mu+1}^{32}\mathcal{U}_{\mu+1}^{2,(k+1)} - A_{\mu,\mu+m}^{32}\mathcal{U}_{\mu+m}^{2,(k+1)}] \\
&\quad + (1-\omega)\mathcal{U}_\mu^{3,(k)}, \quad \mu = 1, 2, \ldots, p, \quad \text{for Type 3,}
\end{aligned} \tag{4.4}$$

where $A_{\mu j}^{12} = A_{\mu j}^{23} = 0$ for $j \leq 0$ and $A_{\mu k}^{21} = A_{\mu k}^{32} = 0$ for $k \geq p$. Obviously, the p expressions of each type in (4.4) are completely independent. Hence, the 3-type BPSOR method is a parallel scheme by the 2D block partitioning.

Under the 3-type ordering, the reordered matrix $\hat{A}$ of (3.10) becomes a 3×3 block matrix in the form

$$\hat{A} = \begin{bmatrix} \hat{A}_{11} & \hat{A}_{12} & 0 \\ \hat{A}_{21} & \hat{A}_{22} & \hat{A}_{23} \\ 0 & \hat{A}_{32} & \hat{A}_{33} \end{bmatrix}, \tag{4.5}$$

where $\hat{A}_{ii} = \mathrm{diag}(A^{ii}_{11}, A^{ii}_{22}, \ldots, A^{ii}_{pp})$ for $i = 1, 2, 3$, $\hat{A}_{12}$, $\hat{A}_{23}, \hat{A}_{21}$, and $\hat{A}_{32}$ have nonzero entries only on the main diagonal, the second off-diagonal, and the mth off-diagonal. That is, $\hat{A}_{12}$ and $\hat{A}_{23}$ have the forms

$$\hat{A}_{12} = \begin{bmatrix} A^{12}_{11} & & & & & \\ A^{12}_{21} & A^{12}_{22} & & & & \\ A^{12}_{m+1,1} & \ddots & \ddots & & & \\ & \ddots & A^{12}_{p-1,p-2} & A^{12}_{p-1,p-1} & & \\ & & A^{12}_{p,p-m} & A^{12}_{p,p-1} & A^{12}_{pp} & \end{bmatrix},$$

$$\hat{A}_{23} = \begin{bmatrix} A^{23}_{11} & & & & & \\ A^{23}_{21} & A^{23}_{22} & & & & \\ A^{23}_{m+1,1} & \ddots & \ddots & & & \\ & \ddots & A^{23}_{p-1,p-2} & A^{23}_{p-1,p-1} & & \\ & & A^{23}_{p,p-m} & A^{23}_{p,p-1} & A^{23}_{pp} & \end{bmatrix};$$

$\hat{A}_{21} = \hat{A}^T_{12}$ and $\hat{A}_{32} = \hat{A}^T_{23}$ if A is symmetric.

By the definition of the consistently ordered matrix as the one given in Definition 9-2.2 of [11], it can be shown that the reordered matrix $\hat{A}$ in (4.5) is consistently ordered. In fact, the index set $S = \{1, 2, \ldots, 3p\}$ since $\hat{A}$ for a $3p\times 3p$ block matrix of $\hat{A}$ has the partition $S = S_1 \cup S_2 \cup S_3$, where $S_1 = \{1, 2, \ldots, p\}$, $S_2 = \{p+1, p+2, \ldots, 2p\}$, and $S_3 = \{2p + 1, 2p + 2, \ldots, 3p\}$, which satisfies the definition of the consistently ordered matrix [11, 28]. That is, if the (i, j)th entry of $\hat{A}$ is nonzero and $i \in S_k$, then $j \in S_{k+1}$ for $j > i$ and $j \in S_{k-1}$ if $j < i$.

Since $\hat{A}$ is consistently ordered, from the classic SOR theory it follows that the 3-type BPSOR method has the same convergence rate as the corresponding block SOR method.

4.3. The 6-type BPSOR method by the 3D block partitioning. The 6-type BPSOR method is the BPSOR method by the 6-type partition based on the 3D block partitioning. For the linear system arising from a 7-point-like finite difference approximation to a 3D elliptic boundary problem, a 3D mesh domain is partitioned into p blocks along the three dimensions of the space such that each block is only connected to its six neighboring blocks that come from the left, right, bottom, top, back, and front sides. Each block is then divided into six types Ω^i_μ with $i = 1, 2, \ldots, 6$ and $\mu = 1, 2, \ldots, p$ as illustrated in Figure 4.3. An example of the 6-type partition is given in Figure 4.4. Here a cubic domain is partitioned into eight blocks along the x-, y-, and z-axis directions. To view the labels and ordering numbers of each type, this 6-type partition is cut into four portions along the x-axis direction so that the 48 types $\Omega^i_{h,\mu}$ with $\mu = 1, 2, \ldots, 8$ and $i = 1, 2, \ldots, 6$ of this 6-type partition can be displayed in the four plots of Figure 4.5.

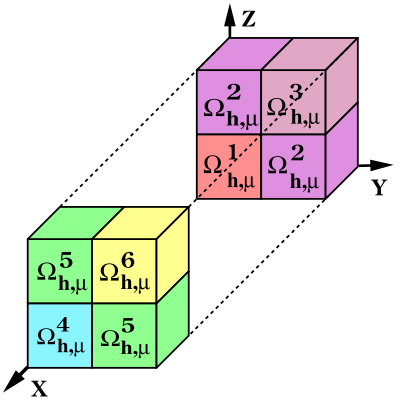

FIG. 4.3. *The six types of each block for the* 6*-type partition in Figure* 4.4*. The six types are labeled as* $\Omega^i_{h,\mu}$ *for* $i = 1, 2, \ldots, 6$*, and the front three types have been pushed away from the back three types to display the labels.*

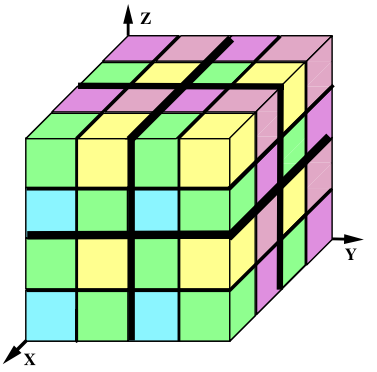

FIG. 4.4. *The* 6*-type partition based on a* $2 \times 2 \times 2$ *block partitioning of a cubic domain. The six types of each block are illustrated in Figure* 4.3*. See Figure* 4.5 *for the* 6*-type ordering.*

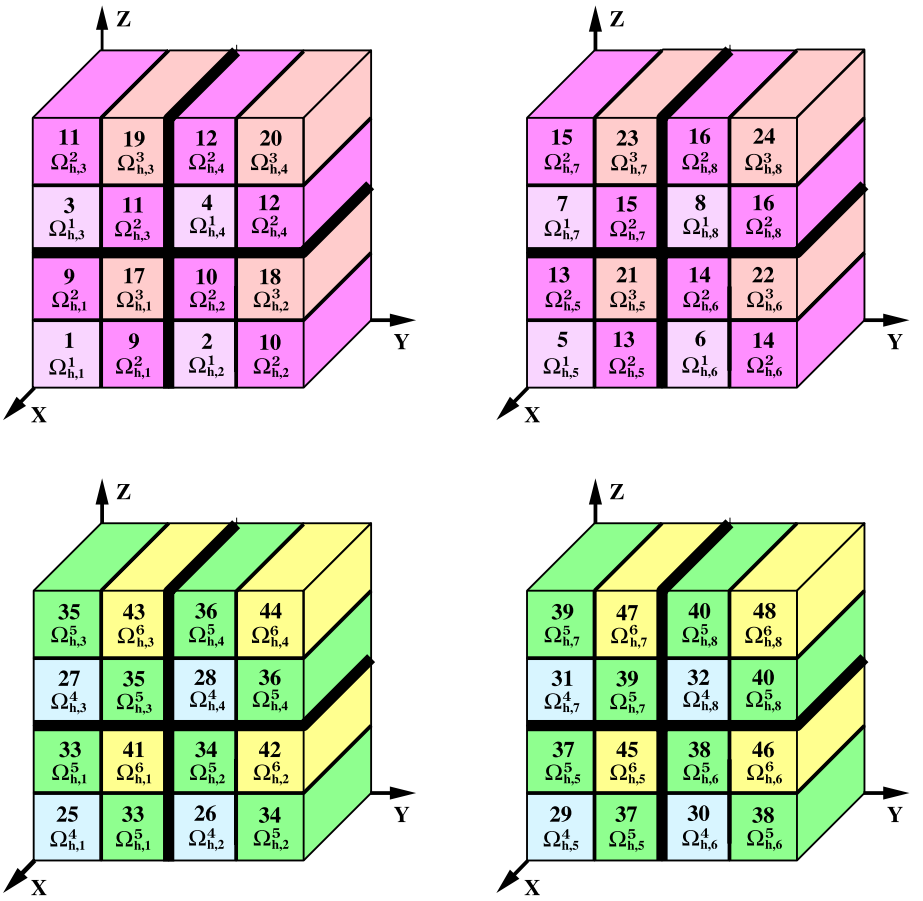

FIG. 4.5. *The* 6*-type ordering and the* 48 *types* $\Omega^i_{h,\mu}$ *with* $\mu = 1, 2, \ldots, 8$ *and* $i = 1, 2, \ldots, 6$ *of the* 6*-type partition in Figure* 4.4*. Here the* 6*-type partition consists of four type layers, which are drawn separately in the four plots to display the label and ordering number of each type.*

In the case of the 6-type partition, the block matrix A in (2.8) is reduced to a seven diagonal block matrix so that the iterative expression of the 6-type BPSOR method can be obtained directly from the general expression (2.17). In the 6-type ordering, the reordered matrix $\hat{A}$ in (3.10) is consistently ordered. In fact, since $\hat{A}$ is a $6p \times 6p$ block matrix, the index set $S = \{1, 2, \ldots, 6p\}$ is considered. It can be found that S has the following partition:

$$S = S_1 \cup S_2 \cup S_3 \cup S_4,$$

where $S_1 = \{1, 2, \ldots, p\}$, $S_2 = \{p+1, p+2, \ldots, 2p, 3p+1, 3p+2, \ldots, 4p\}$, $S_3 = \{2p+1, 2p+2, \ldots, 3p, 4p+1, 4p+2, \ldots, 5p\}$, and $S_4 = \{5p+1, 5p+2, \ldots, 6p\}$. It then can be shown that the partition of S satisfies the definition of a consistently ordered matrix. Since $\hat{A}$ is a consistently ordered matrix, the classic SOR theory follows that the 6-type BPSOR method has the same convergence rate as the corresponding sequential block SOR method.

5. Numerical results. Numerical experiments were made on the SGI Origin 2000 at the University of Wisconsin-Milwaukee, which contains 16 R12000 processors. A linear system for numerical tests comes from a 7-point finite difference approximation to a 3D Poisson boundary value problem on the unit cubic domain with a boundary value of zero. The mesh domain Ω_h consists of the interior mesh points (x_i, y_j, z_k) with $x_i = (i-1)h$, $y_j = (j-1)h$, and $z_k = (k-1)h$ for $i, j, k = 2, 3, \ldots, n$. Here $h = 1/n$. By setting $u_{i,j,k}$ as the numerical approximation to the Poisson solution at mesh point (x_i, y_j, z_k), the linear system is defined as

$$\begin{aligned} 6u_{i,j,k} - u_{i+1,j,k} - u_{i-1,j,k} - u_{i,j+1,k} - u_{i,j-1,k} \\ - u_{i,j,k-1} - u_{i,j,k+1} = h^2 f_{i,j,k}, \end{aligned} \tag{5.1}$$

where $i, j, k = 2, 3, \ldots, n$, $f_{i,j,k}$ denotes the value of the right-hand side function at mesh point (x_i, y_j, z_k), and the boundary values are $u_{i1} = u_{i,n+1} = u_{1i} = u_{n+1,i} = 0$ for $1 \le i \le n+1$. In numerical tests, $f_{i,j,k}$ was set as one.

The parallel program was written in FORTRAN 77 and MPI (the Message Passing Interface) [3]. The program was compiled by using the optimization level $O2$. The CPU time was measured by the MPI function MPI_Wtime, which returns the wall time in seconds. The sequential SOR program in FORTRAN 77 was implemented on one processor of the computer. Its CPU time was measured by the F77 function $etime()$. The iteration termination rule is given by

$$\|f - Au^{(k)}\| < 10^{-6}, \tag{5.2}$$

where $u^{(k)}$ denotes the kth iterate for solving the linear system $Au = f$.

5.1. Solution of each block linear equation. Each BPSOR iteration requires us to solve tp block equations, $A^{ii}_{\mu\mu} v^i_\mu = f^i_\mu$ for $i = 1, 2, \ldots, t$ and $\mu = 1, 2, \ldots, p$. Since each block equation is located within one processor, it can be solved accurately by a sequential direct method or approximately by a sequential iterative method. In this numerical test, the sequential point SOR method, and the sparse LDL^T method from the SGI's Scientific Computing Software Library were used to solve block equations. Here a point SOR iterate $v^{i,(k)}_\mu$ was accepted as an approximate solution of block equation $A^{ii}_{\mu\mu} v^i_\mu = f^i_\mu$ when it met the termination rule: $\|f^i_\mu - A^{ii}_{\mu\mu} v^{i,(k)}_\mu\| \le 10^{-8}$ for all $i = 1, 2, \ldots, t$, $\mu = 1, 2, \ldots, p$. For simplicity, the point SOR method

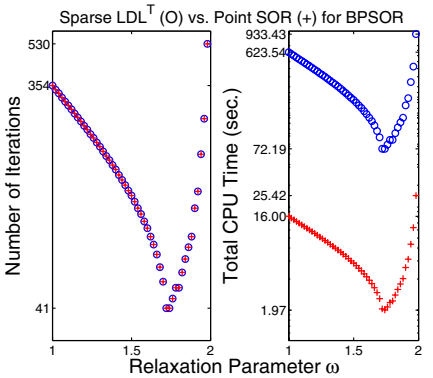

FIG. 5.1. *Comparisons of the convergence and performance of the BPSOR method using the LDL^T direct solver for each block equation with that using the sequential point SOR iterative solver for each block equation. The tests were made on eight processors for the model problem* (5.1) *with* $h = 1/65$.

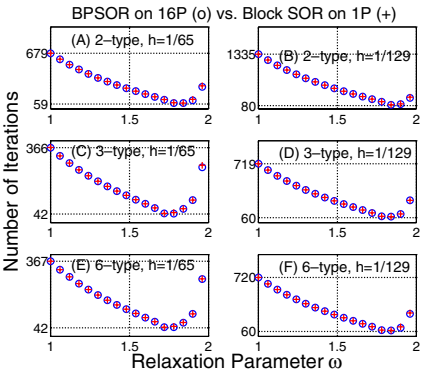

FIG. 5.2. *Comparisons of the convergence rates of the three particular BPSOR methods defined by the* 2*-type,* 3*-type, and* 6*-type partitions on 16 processors with that of the three corresponding sequential block SOR methods on one processor for solving the model problem* (5.1) *with* $h = 1/65$ *and* $h = 1/129$.

used $\omega = 1.54$ (which may not be optimal) for solving all the block equations. The BPSOR method was carried out on eight processors based on an 8-strip partition along the z-axis direction. The numerical results were plotted in Figure 5.1. They show that with the point SOR method, the BPSOR method can have almost the same number of iterations determined by (5.2) as that with the sparse LDL^T direct solver, while can take much less CPU time (about 40 times less in this test).

5.2. Convergence comparisons. Figure 5.2 compares the total numbers of iterations of the three particular BPSOR methods defined by the 2-type, 3-type, and 6-type partitions with that of the three corresponding sequential block SOR methods for solving the model problem (5.1) with $h = 1/65$ and $h = 1/129$, respectively. The BPSOR methods were implemented on the sixteen processors of the SGI Origin 2000. The total number of iterations was determined by the termination rule (5.2). The 2-type, 3-type, and 6-type partitions were constructed based on the strip partitioning of order $1 \times 1 \times 16$, the 2D-block partitioning of $1 \times 4 \times 4$, and the 3D-block partitioning of $2 \times 2 \times 4$, respectively. The size of each block equation was selected to be almost the same. Each block equation was solved approximately by the sequential point SOR method with $\omega = 1.54$ for the 2-type case and $\omega = 1.7$ for the 3-type and 6-type cases. From Figure 5.2 it can be seen that all the three BPSOR methods have almost the same numbers of iterations as the three corresponding sequential block SOR methods. This confirms the conclusion of Theorem 3.4; i.e., the BPSOR method has the same asymptotic rate of convergence as the corresponding sequential block SOR method.

5.3. Parallel performances of BPSOR. Figure 5.3 displays the CPU time data of the above BPSOR and block SOR methods and the speedups of the three BPSOR methods as functions of relaxation parameter ω between 1 and 1.98. The interprocessor data communication time spent by BPSOR were also reported in the figure as dashed lines. Here for each value the speedup was calculated as the ratio of the total CPU time of the sequential block SOR method on one processor to that of the BPSOR method on sixteen processors. From Figure 5.3 it can be seen that all the

The dotted lines *indicate the interprocessor communication times. The speedups of the BPSOR methods are also presented.*

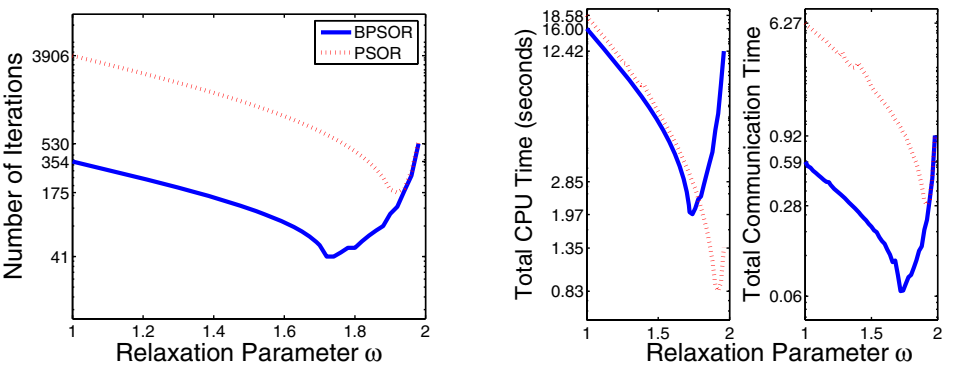

FIG. 5.4. *Performance comparisons of BPSOR with PSOR on eight processors of the SGI Origin 2000 based on an* 8*-strips partition of the cubic mesh domain with* $h = 1/65$.

three BPSOR methods have the speedups between 12 to 16 on the sixteen processors of the SGI Origin 2000, which indicate that the BPSOR methods have good parallel performances.

5.4. Parallel performance comparisons with PSOR. The parallel performance of the BPSOR method was compared with that of the point PSOR method in Figure 5.4. Both BPSOR and PSOR were defined on the same 8-strip partition along the z-axis, and implemented on eight processors of the SGI Origin 2000. The first plot of Figure 5.4 shows that BPSOR took about 10 to 16 times fewer iterations than PSOR from $\omega = 1$ to $\omega = 1.76$ to satisfy the termination rule (5.2), confirming that BPSOR has a much faster rate of convergence than the point PSOR method. As a result, as displayed in the third plot of Figure 5.4, the BPSOR method took about 10 to 16 times less CPU time in interprocessor data communications than the point PSOR method. The second plot of Figure 5.4 also shows that BPSOR took up to 53 percent less total CPU time than PSOR for the values of ω from 1 to 1.76. Furthermore, the first plot shows that the convergence rate of BPSOR is less sensitive

to the value selection of ω than that of the point PSOR method. Obviously, the total performance of BPSOR can be further improved significantly when a more efficient sequential iterative method (such as the multigrid method [22]) is used to solve each block equation.

PARALLEL ALGEBRAIC MULTIGRIDS FOR STRUCTURAL MECHANICS*

MARIAN BREZINA†, CHARLES TONG‡, AND RICHARD BECKER§

Abstract. This paper presents the results of a comparison of three parallel algebraic multigrid (AMG) preconditioners for structural mechanics applications. In particular, we are interested in investigating both the scalability and robustness of the preconditioners. Numerical results are given for a range of structural mechanics problems with various degrees of difficulty, and they show that algebraic multigrid methods can be applied successfully even to difficult problems in structural mechanics.

Key words. algebraic multigrid, preconditioning, parallel computing

1. Introduction.

Krylov methods with algebraic multigrid preconditioners have been demonstrated to offer fast convergence rates as well as good parallel efficiency for the iterative solution of linear systems arising from discretizations of many elliptic partial differential equations. Two classes of algebraic multigrid (AMG) methods have gained popularity: the classical AMG method, originally conceived in [5] and developed practically by Ruge and Stüben (RS) [22], and smoothed aggregation (SA) multigrid proposed by Vaněk, Mandel, and Brezina [28, 26]. In addition, improvements to SA have been made to handle more difficult problems such as Maxwell's equations [4]. In this paper we investigate another improvement to SA to handle difficult problems in structural mechanics. This improvement involves locally enriching the prolongation operator using low energy eigenvectors of subdomains in a finite element framework. The idea of enriching the coarse space was already recognized in [28] in conjunction with treatment of high-order equations and was later expanded into an adaptive procedure similar to the one presented here by Brezina, Heberton, and Vaněk in [7] as a general principle to eliminate convergence problems due to local irregularities of the finite element discretization. The latter method was, however, limited to two levels. Our implementation generalizes this coarse-space enriching approach to multilevel, replacing the subdomain smoothers with more efficient multilevel

procedure that allows for further coarsening. We call this method GSA, an acronym for generalized smoothed aggregation.

Parallelization issues for AMG preconditioners are also considered in this paper. The application of AMG involves two phases: the setup phase and the solution phase. A typical setup phase consists of coarse grid selection, construction of prolongation operators, and creation of coarse grid matrices. The original coarse grid selection procedures in both RS and SA are sequential in nature. Efforts to parallelize the coarsening step have been reported in [24, 16, 18, 15]. The construction of coarse grid matrices using triple matrix products can be parallelized in a straightforward manner, but perfect scalability is difficult to achieve. Scalability issues in the solution phase are associated mainly with the parallel smoothers, and with solution of the coarse grid problem. In this paper we discuss some of these parallelization issues in detail and make recommendations giving different options.

This paper is organized as follows. In section 2, we give an introduction of the three AMG methods in question. Section 3 is dedicated to expounding the GSA methods and providing theoretical motivation for the method. Section 4 describes in more detail the parallel aspects of the setup and solution phases. Numerical experiments will be presented in section 5, followed by a few afterthoughts in section 6.

2. A brief review of AMG. AMG methods can be used as independent linear solvers for solving linear systems of the form

$$Ax = b, \tag{2.1}$$

where $A \in \Re^{n\times n}$ is a positive definite matrix and $x, b \in \Re^n$. In practice, they are often used as preconditioners in preconditioned conjugate gradient and/or generalized minimal residual methods. A typical V-cycle AMG is given as follows (by calling $\mathrm{MG}(A_0, b, u, 0)$).

ALGORITHM $\mathrm{MG}(A_k, b_k, u_k, k)$.

1. If level k is the coarsest level, $u_k = A_k^{-1} b_k$, return
2. $u_k = S_k(A_k, b_k, u_k)$ /* presmoothing */
3. $r_k = b_k - A_k u_k$ /* residual calculation */
4. $b_{k+1} = R_k * r_k$ /* restriction */
5. $v_{k+1} = 0$
6. $\mathrm{MG}(A_{k+1}, b_{k+1}, v_{k+1}, k+1)$
7. $u_k = u_k + P_k v_{k+1}$ /* coarse grid correction */
8. $u_k = S_k(A_k, b_k, u_k)$ /* post-smoothing. */

Here S_k, R_k, and P_k are the smoothing, restriction, and prolongation operators, respectively.

Application of AMG methods consists of distinct setup and iteration phases. In the setup phase, the transfer operators P_k, R_k are created based on the operator A_k, and the multigrid smoothing operators S_k are set up. Once P_k becomes available, the restriction operator, R_k, is typically defined as $R_k = P_k^T$, and the coarse problem operator is constructed using the Galerkin formula, $A_{k+1} = R_k A_k P_k$. The hybrid Gauss–Seidel smoother [29] is chosen for our numerical study, and its performance aspects will be discussed later.

The main idea of multigrid is based on the complementary roles of the multigrid smoothing and coarse grid correction procedures. In order to have a well-convergent multigrid, the solution error not eliminated well by smoothing must be eliminated well by coarse grid correction. As the prolongation operators define the coarse spaces, they play a critical role in transmitting and eliminating the error modes between

different grid levels. In the following subsections we briefly describe two different ways of selecting the coarse variables and the corresponding prolongation operators.

2.1. The classical AMG. Setting up the coarse grid structure in the classical algebraic multigrid [22] (RS) is guided by two principles.

P1: Errors not efficiently reduced by smoothing must be approximated well by the range of interpolation, and

P2: the coarse grid correction must efficiently eliminate fine grid error in the range of interpolation.

For problems with the M-matrix property P1 is satisfied by a two-pass coarse grid selection and the RS interpolation formula [22], while construction of coarse problems using the Galerkin formula allows P2 to be satisfied.

A typical setup phase for RS is as follows [11].

RS Setup Phase.

1. Set k = 0.
2. Partition the level k set of points Ω^k into disjoint sets C^k and F^k.
   (a) Set $\Omega^{k+1} = C^k$.
   (b) Define interpolation P_k.
3. Set $R_k = P_k^T$ and $A_{k+1} = R_k A_k P_k$.
4. If Ω_{k+1} is small enough, stop. Otherwise, set $k = k + 1$ and go to step 2.

Step 2 begins by forming a set of dependencies for each point i (a point can be a single unknown in the scalar case or a set of unknowns in the system case) in the current grid level defined by

$$S_i = \{j \neq i : -a_{ij} \leq \alpha \max_{k \neq i}(-a_{ik})\}, \tag{2.2}$$

where α is the strength threshold for pruning weak couplings between variables. All points in the domain are chosen either as coarse or fine points. A set of interpolation points C_i is then selected for every fine point i. Since errors are more effectively smoothed in the direction of influence, a suitable criterion for selecting C_i is $C_i = S_i \cap C$ (C is the set of all C points.)

Two criteria for choosing the F and C sets are as follows.

P3: For each $i \in F$, each $j \in S_i$ is either in C or $S_j \cap C_i \neq \emptyset$, and

P4: C is a maximal set with the property that if i and j are both coarse points, then $j \notin S_i$ and $i \notin S_j$.

Criterion P3 says that if i is a fine point, then the points influencing i must either be coarse points or must share a common coarse point with i. P4 is enforced to keep the coarse grid as small as possible. Since it may not be possible to satisfy both criteria simultaneously, a common practice is to enforce P3, guided by P4. This commonly takes the form of a two-pass coarse selection, which proceeds by first choosing a maximal independent set of coarse points, followed by patching up the C set to satisfy P3.

Once the coarse set C has been determined, the interpolation formula is prescribed as

$$(P_k u_{k+1})_i = \begin{cases} (u_{k+1})_l & \text{if } i \in C \text{ and } i \text{ and } l \text{ are the same point,} \\ \sum_{j \in C_i} \omega_{ij} (u_{k+1})_j & \text{if } i \in F. \end{cases}$$

Details of computing the quantities ω_{ij} can be found in [22].

Note that the RS method was originally developed for problems with M-matrix property, so the problems considered in this paper are outside its theoretical scope. However, the method has been successfully applied to a variety of problems violating the M-matrix property, and we demonstrate that it can, with some success, be applied to the problems under our consideration.

2.2. The SA multigrid. The coarse grid construction for SA differs from that of RS in that, instead of choosing the coarse set as a subset of the current grid nodes (a node can be a single unknown in the scalar case or a set of unknowns in the system case), each fine node is assigned to a unique aggregate. Each aggregate thus corresponds to one or more equations in the coarse grid operator. The first coarsening step is thus to form a collection of mutually disjoint aggregates covering all the fine nodes (however, the equations corresponding to the essential boundary conditions are usually left out). The goal is to have uniformly shaped aggregates. The optimal aggregate size for the standard method has a diameter three, i.e., three nodes along the diameter (small aggregates may result in higher overall complexity, but very large aggregates may result in poor convergence rates unless a nonstandard prolongator smoother is applied; cf. [27]). A basic aggregation procedure proceeds as follows [28, 24].

SA STEP (GIVEN A GRAPH REPRESENTING THE NODE CONNECTIVITY).
Phase 1: Form initial set of aggregates: for $i = 1$ to n,
  a. If node i has been aggregated or it is adjacent to an aggregated node, go to the next node.
  b. Otherwise, select it as a root node, and define a new aggregate as node i plus all its strongly coupled neighbors.
Phase 2: Put unaggregated nodes into existing aggregates: for $i = 1$ to n,
  a. If node i has been aggregated, go to the next node.
  b. Otherwise, put it in the aggregate to which one of its neighbors belongs.

Actual implementation can add complexity to this aggregation algorithm. For example, more phases may be needed if aggregate size control is incorporated. Also, different criteria for choosing host aggregates in phase 2 may be prescribed to enhance performance.

The aggregation step is followed by forming the tentative prolongation operator $\tilde{P}_k$, the formula of which, in the simplest case of piecewise constant interpolation, is given as

$$(\tilde{P}_k u_{k+1})_i = \begin{cases} (u_{k+1})_j & \text{if } i \in \text{aggregate}_j, \\ 0 & \text{otherwise.} \end{cases} \tag{2.3}$$

For construction of the tentative prolongation in more general cases we refer to [28]. For solving systems of partial differential equations, aggregation is typically performed on the nodes in the computational grid. Three-dimensional elasticity problems, for example, have three unknowns per node corresponding to displacements in the three orthogonal directions. Thus, in the case of structured hexahedral mesh, each aggregate would ideally contain 27 nodes or 81 unknowns. In addition, instead of using piecewise constant interpolation for each aggregate, rigid body modes or near null space vectors can be provided for defining $\tilde{P}_k$. The number of coarse grid equations for each aggregate is then the number of null space vectors provided. For three-dimensional elasticity, six rigid body modes can be computed from the nodal coordinates which are readily available from most applications.

More robust prolongators can be constructed by smoothing the tentative prolongators. For example, applying a damped Jacobi smoother gives

$$P_k = (I - \omega D_k^{-1} A_k)\tilde{P}_k, \tag{2.4}$$

where D_k is the diagonal of A_k, and ω is the damping factor related to the maximum eigenvalue of the scaled matrix $D_k^{-1}A_k$. Convergence theory [26] proves that this prolongation smoother is needed to guarantee convergence rates only mildly dependent on the grid size.

3. Generalized smoothed aggregation. For many applications, the knowledge of a small number of near-kernel components suffices to construct a robust smoothed aggregation solver. However, for difficult problems, it may be beneficial or indeed necessary to generalize the method.

To motivate the GSA method, we first recall the theoretical convergence estimate derived in [27]. Throughout this section we drop the level indices in the notation for the multigrid operators when there is no danger of ambiguity. Let n and m denote the dimensions of the Euclidean spaces associated with the fine and coarse spaces, respectively. We further define $A_S = S^2 A$, where S denotes the prolongator smoother. Then for the two-level smoothed aggregation method employing a presmoother with a linear part given by S and a post-smoother with linear part given by

$$S' = I - \frac{\hat{\omega}}{\varrho(A_S)} A_S, \tag{3.1}$$

the following result holds (cf. [27]).

THEOREM 3.1. C_{apx}

1. Q $\Re^n$ $\text{Range}(\hat{P})$

$$\|(I-Q)u\|^2 \le \frac{C_{\text{apx}}^2}{\bar{\varrho}(A_S)} \|u\|_A^2 \quad \forall u \in \Re^n; \tag{3.2}$$

2. S A $\varrho(S) \le 1$

e_i i $P = S\hat{P}$ $e_i^S = Se_i$

$$\|e_i^S\|_A^2 \le (1-C)^i \|e_0\|_A^2,$$

$$C = \frac{C_{\text{apx}}^{-2}\hat{\omega}(2-\hat{\omega})}{1 + C_{\text{apx}}^{-2}\hat{\omega}(2-\hat{\omega})}, \quad \hat{\omega} \quad (3.1).$$

As assumption 2 of Theorem 3.1 is usually easy to satisfy, our attention is focused on minimizing the constant C_{apx} in (3.2). We note that the left-hand side of (3.2) depends only on the tentative prolongator, while the prolongator smoother is present only in the form of a bound on the spectral radius of A_S in the denominator of the right-hand side.

The smoothed aggregation method thus possesses two mechanisms for ensuring good convergence properties. One strategy leading to improved constant C_{apx} relies on developing more powerful prolongator smoothers S, thus forcing $\varrho(S^2A) \ll \varrho(A)$. This

approach had been investigated in [27], where a two-level method with convergence properties independent of the size of the coarse grid was developed.

Another way to improve C_{apx} is based on appropriately enriching the range of the tentative prolongator $\hat{P}$, thus minimizing the left-hand side in (3.2). This approach can, naturally, be combined with the improvement of S for a compound benefit. Note, however, that in forming the prolongator $P = S\hat{P}$ to be used in the final method, all columns of $\hat{P}$ must be multiplied by S. Hence, the effect of using an improved S is global in nature. The corresponding smoothing of the coarse space basis functions is thus appropriate for correcting global convergence phenomena tied to the differential equation solved, and the use of nonstandard prolongator smoothers may thus be an overkill if slow convergence of the method is rooted in local phenomena. In contrast, due to the disjoint nature of the aggregate decomposition, the enrichment of the range of $\hat{P}$ can be carried out locally one aggregate at a time.

As the emphasis of this paper is on parallel implementation, we are seeking a procedure which would modify the iterative solver locally in the problematic regions. We will thus focus on local enrichment of the range of the tentative prolongator $\hat{P}$ and refer the interested reader to [27] for details on construction of S.

We will consider a decomposition of our computational domain, Ω, into J nonoverlapping subdomains, Ω_i,

$$\Omega = \bigcup_{i=1}^{J} \bar{\Omega}_i, \quad \Omega_i \cap \Omega_j = \emptyset \text{ if } i \neq j. \tag{3.3}$$

We assume that each $\bar{\Omega}_i$ is a connected cluster of elements. Denote by n_i the number of degrees of freedom in $\bar{\Omega}_i$, by A_i the $n_i \times n_i$ local stiffness matrix corresponding to $\bar{\Omega}_i$, and by N_i the zero-one matrix mapping the degrees of freedom associated with $\bar{\Omega}_i$ into the set of global degrees of freedom in matrix A. Obviously, the stiffness matrix A can be assembled from the local stiffness matrices A_i by

$$A = \sum_{i=1}^{J} N_i A_i N_i^T. \tag{3.4}$$

We will utilize a system of large nodal aggregates $\{\mathcal{A}_i\}_{i=1}^{J}$ forming a disjoint covering of the set of all nodes such that all nodes in $\mathcal{A}_i$ lie in $\bar{\Omega}_i$. Such aggregates are easily formed by assigning all the nodes in $\bar{\Omega}_i$ to $\mathcal{A}_i$ and distributing any nodes shared by more than one $\bar{\Omega}_i$ to exactly one of the corresponding aggregates at will.

To formalize this distribution of nodes, for each subdomain $\bar{\Omega}_i$ with number of degrees of freedom n_i, we define a zero-one diagonal matrix I_i of dimension n_i as

$$(I_i)_{dd} = \begin{cases} 1 & \text{if degree of freedom } d \text{ corresponds to a node in } \mathcal{A}_i, \\ 0 & \text{otherwise.} \end{cases} \tag{3.5}$$

We further define for each subdomain $\bar{\Omega}_i$ a set of vectors $\{w_j^{(i)}\}_{j=1}^{m_i}$, $w_j^{(i)} \in \text{Range}(I_i)$, and denote by W_i the $n_i \times m_i$ matrix consisting of orthogonal columns $\{w_j^{(i)}\}_{j=1}^{m_i}$. The tentative prolongator $\hat{P} : \Re^m \mapsto \Re^n$, which is able to represent exactly all functions in $\{w_j^{(i)}\}_{j=1}^{m_i}$ over $\mathcal{A}_i$, can then be defined by

$$\hat{P}x = \sum_{i=1}^{J} N_i W_i x^{(i)}, \tag{3.6}$$

where $x^{(i)}$ denotes the segment of coarse degrees of freedom associated with aggregate $\mathcal{A}_i$.

Theorem 3.1 guarantees that the rate of convergence of the two-level method is bounded by $1 - \frac{C_{\text{apx}}^{-2}}{1+C_{\text{apx}}^{-2}}$ under the assumption that there exists $v \in \Re^m$ such that

$$\|u - \hat{P}v\|_{l^2(\bar{\Omega})}^2 \leq \frac{C_{\text{apx}}^2}{\varrho(S^2A)}\|u\|_A^2 \quad \forall u \in \Re^n. \tag{3.7}$$

Using the sparsity structure of $\hat{P}$ stemming from disjointness of the aggregates, we can write, for any $u \in \Re^n$,

$$\|u - \hat{P}v\|_{l^2(\bar{\Omega})}^2 = \sum_{i=1}^{J} \|u - \hat{P}_{*,i}v_i\|_{l^2(\mathcal{A}_i)}^2,$$

where $\|\cdot\|_{l^2(\mathcal{A}_i)}$ denotes the restriction of the Euclidean norm to the set of degrees of freedom corresponding to the node in the aggregate $\mathcal{A}_i$, and $\hat{P}_{*,i}$ denotes the supercolumn of $\hat{P}$ corresponding to aggregate $\mathcal{A}_i$. Similarly, using (3.4), we write

$$\|u\|_A^2 = \sum_{i=1}^{J} \langle A_i N_i^T u, N_i^T u\rangle.$$

Thus, in order to satisfy (3.7) it suffices to satisfy over all aggregates $\mathcal{A}_i$ the inequality

$$\|u - \hat{P}v\|_{l^2(\mathcal{A}_i)}^2 \leq \frac{C_{\text{apx}}^2}{\varrho(S^2A)}\langle A_i N_i^T u, N_i^T u\rangle \quad \forall u \in \Re^n. \tag{3.8}$$

Assuming a fixed prolongator smoother S, the satisfaction of (3.8) depends solely on the selection of columns of $\hat{P}$. We are thus led to constructing $\hat{P}$ so that

$$\inf_{v_i \in \Re^{m_i}} \|u - \hat{P}_{*,i}v_i\| = \langle (I - Q_i)u, u\rangle_{l^2(\mathcal{A}_i)} \leq \Lambda_i \|u\|_{A_i}^2 \quad \forall u \in \Re^n, \tag{3.9}$$

where $Q_i = W_i(W_i^T W_i)^{-1}W_i^T$ is the $\Re^{n_i}$-orthogonal projection onto the Range(W_i). Equation (3.9) can be reformulated as a generalized eigenvalue problem for $I_i(I-Q_i)I_i$ preconditioned by A_i. The constant Λ_i in (3.9) can be decreased by finding the largest eigenvalue of the generalized eigenvalue problem and adding the corresponding eigenvector to the range of Q_i. This amounts to introducing new columns corresponding to aggregate $\mathcal{A}_i$ into the tentative prolongator $\hat{P}$. This procedure can be repeated until (3.9) is eventually satisfied with a uniform constant $\Lambda \geq \Lambda_i$ for all $i = 1, \ldots, J$.

To reduce cost associated with the solution of the local generalized eigenvalue problem, we instead solve the local eigenvalue problem for A_i. The following lemma [7] justifies this reduction in cost.

LEMMA 3.2. $w_j^{(i)} = I_i\hat{w}_j^{(i)}$ $\hat{w}_j^{(i)}$ A_i A_i $\frac{1}{\Lambda} > 0$

$$\langle I_i(I - Q_i)I_i u, u\rangle_{\Re^{n_i}} \leq \Lambda \|u\|_{A_i}^2 \quad \forall u \in \Re^{n_i}.$$

Note that we only compute the near null space vectors for the subproblems corresponding to subdomains Ω_i created by the domain partitioner (computing the near

null space vectors for the global matrix would be prohibitively expensive). The setup cost is still relatively high, but it can be performed in parallel with no interprocessor communication. To keep cost down, the size of each subdomain is limited to a few thousand nodes.

The coarse-space enriching technique we have thus far described in this section is based on the two-level method proposed in [7], which utilizes aggregates $\mathcal{A}_i$, where each aggregate consists of all the nodes in the subdomain Ω_i. This necessitates the use of special prolongator smoothers and special multigrid relaxation procedure in order to guarantee good convergence. Here we are interested in providing a multilevel generalization. Our current GSA method differs from that in [7] in that a standard aggregation coarsening will be applied on each $\bar{\Omega}_i$. Thus the nodes of Ω_i are subaggregated into a number of small, standard-sized aggregates, $\mathcal{N}_i = \bigcup \mathcal{A}_{ij}$, where $\mathcal{N}_i$ denotes the set of unique nodes corresponding to subdomain $\bar{\Omega}_i$. The eigenmodes of A_i are then restricted to these smaller aggregates, $\mathcal{A}_{ij}$, and the tentative prolongator used in the current GSA can be written as

$$\tilde{P}x = \sum_{i=1}^{J} \sum_{j=1}^{\mu_i} \hat{N}_{ij} W_{ij} x^{(ij)}, \tag{3.10}$$

where W_{ij} denotes restriction of W_i to $\mathcal{A}_{ij}$ and $\hat{N}_{ij}$ is a zero-one matrix mapping the degrees of freedom in $\mathcal{A}_{ij}$ into the set of global degrees of freedom. $x^{(ij)}$ denotes the segment of coarse degrees of freedom associated with aggregate $\mathcal{A}_{ij}$.

As the computation of eigenmodes on each subdomain is performed independently, we do not allow aggregation across the subdomain boundary in order to facilitate alignment. Consequently, the number of unknowns on the coarsest grid is at least $J \times \nu$, where J is the number of subdomains and ν is the desired number of null space vectors. When both J and ν are large, the coarsest problem can become too large for direct solution.

Since the set of coarse grid basis functions generated by $\tilde{P}$ is a refinement of that generated by $\hat{P}$, we trivially obtain

$$\sum_{j=1}^{\mu_i} \min_{x^{(ij)}} \|u - \tilde{P}x^{(ij)}\|^2_{l^2(\mathcal{A}_{ij})} \leq \min_{x^{(i)}} \|u - \hat{P}x^{(i)}\|^2_{l^2(\mathcal{A}_i)} \leq \Lambda \|u\|^2_{A_i}.$$

Thus the standard convergence theory for the smoothed aggregation method [26] can be used to guarantee convergence of the resulting method. As a result of using the standard aggregates, $\tilde{P}$ can approximate well not only the computed set of eigenmodes, $\{w_j^{(i)}\}_{j=1}^{m_i}$ but also a much richer subspace consisting of any modes with locally similar character. This can reduce the number of eigenmodes that need to be computed. Another benefit of using GSA, compared to the method of [7], is the reduced amount of interprocessor communication. The method of [7] was primarily intended for a serial environment. Its multigrid relaxation is based on polynomial smoothing, which makes it suitable for parallel implementation. But its use of the more powerful prolongation smoothing, required to achieve optimal convergence rates, results in larger cross-processor overlap in its coarse-level basis functions. This leads to increased communication necessary in setting up the coarse-level matrices. In contrast, GSA, with its use of the standard prolongation smoother, reduces communication and is certain to result in higher flop rates in a massively parallel environment.

For completeness, we include a summary of the GSA multilevel coarsening procedure below. Let l denote the level index ($l = 0$ corresponds to the finest grid).

Furthermore, let us denote by $\mathcal{N}_i^l$ the set of unique nodes on level l which is associated with subdomain $\bar{\Omega}_i$, and by μ_i^l its number. Symbol $\mathcal{A}_j^l$ denotes the aggregates on level l. Given a decomposition of the domain (3.3) and the corresponding subdomain matrices, A_i, GSA coarsening proceeds as follows:

1. Initialize one large aggregate, $\mathcal{A}_i^0 = \mathcal{N}_i$, per subdomain $\bar{\Omega}_i, i = 1, \ldots, J$, distributing any shared nodes so that the resulting $\mathcal{N}_i$ are mutually disjoint. Set $\mu_i^0 = card(\mathcal{N}_i), i = 1, \ldots, J$.
2. For each local matrix $A_i, i = 1, \ldots, J$, compute a set of m_i eigenmodes, W_i^k, smaller than Λ. Set $l = 0$.
3. Perform standard SA aggregation independently over each $\mathcal{N}_i^l$ to produce $\{\mathcal{A}_{ij}^l\}$ such that $\mathcal{N}_i^l = \bigcup_j \mathcal{A}_{ij}^l$. Split W_i^l into segments, W_{ij}^l, corresponding to aggregates.
4. Construct operator $\tilde{P}_l$ as in (3.10). Simultaneously, compute W_i^{l+1}, the coarse-level representations of W_i^l such that $W_i^l = \tilde{P} W_i^{l+1}$.
5. Construct smoothed prolongator, $P_l = (I - \omega D_l^{-1} A_l)\tilde{P}_l$.
6. Construct coarse-level operator, $A_{l+1} = P_l^T A_l P_l$
7. If $l + 1$ is the coarsest level, stop.
   Otherwise, set $\mathcal{N}_i$ to be the set consisting of global numbers indexing the aggregates on level l, $\mu_i^{l+1} = card(\{\mathcal{A}_{ij}^l\})$, set $l = l + 1$, and go to step 3.

The construction of $\tilde{P}$ in step 4 (and in (3.10)) is modified in practice by orthogonalizing the columns of W_{ij}^l over the local aggregates $\mathcal{A}_{ij}^l$. Such modification does not change the range of the constructed tentative prolongator but produces better-conditioned coarse-level matrices (cf. [28]). Also, it can be conveniently combined with the computation of the coarse-level representation W_i^{l+1} (cf. [26]).

We note that a coarse-space enrichment similar to the one described here has been used in the context of classical AMG in the AMGe class of methods [6, 10] and also by Mandel [20, 21] in the context of two-level domain decomposition suitable for p-version finite elements. Reference [13] describes a coarse-space enrichment for a nonsmoothed aggregation method using very small element agglomerates, under the assumption that the local element matrices are available. The recently introduced class of adaptive smoothed aggregation methods (αSA; cf. [8]) approaches local coarse-space enrichment by run-time evaluation of the error components of the iteration and subsequent incorporation of these modes into its multigrid transfer and coarse operators.

4. Parallel implementation issues. The original coarse-grid selection algorithms for both RS and SA are inherently sequential. In the solution phase, the primary factor for parallel efficiency is the use of parallel and robust smoothers. This section briefly reviews efforts pertaining to these two issues.

4.1. Parallel coarsenings for RS AM. Several parallel coarsening algorithms have been proposed and tested successfully: the parallel RS coarsening [14], the Cleary–Luby–Jones–Plassmann (CLJP) coarsening [11], and the hybrid (or Falgout) coarsening. The parallel RS coarsening first performs independent local coarsening within each processor, followed by coarsening on the processor boundaries. The CLJP coarsening is a form of a parallel maximal independent set algorithm [17, 19] modified to enforce the coarsening criteria. The hybrid coarsening uses the RS coarsening interior to the processors and CLJP coarsening on the boundaries. The relative performance of these algorithms varies dependent on the applications. Since the CLJP algorithm generally gives better results for unstructured grid problems, it is used in

our numerical experiments. For other strategies which have been proved successful in parallelizing RS-based multigrid methods we refer the reader to [18, 15].

4.2. Parallel coarsenings for SA AMG. Reference [24] describes three parallel aggregation algorithms. The coupled aggregation scheme proceeds by having each processor first separating all nodes assigned to it into the interior and border nodes. Border nodes are those which share a grid edge with a nodes on another processor. Subsequently, this scheme aggregates the border nodes before aggregating the interior nodes. This scheme has the disadvantage that some processors may have to wait until other processors have completed aggregating their border nodes. The worst-case scenario would require a wait time proportional to $P^{1/3}$, where P is the number of processors. However, the scheme can give significantly better aggregates than the other approaches considered.

The second parallel aggregation scheme is based on maximally independent set (MIS). In brief, the widely studied parallel MIS algorithms can be applied to the square of the matrix representing grid connectivities. This scheme has the disadvantage that it requires computing the square of a matrix.

The third scheme, which is our choice in our numerical studies, is called the decoupled aggregation scheme. This scheme lets each processor form its set of aggregates independently of one another. It is very simple to implement and it generally gives good performance. However, its performance depends a great deal on the quality of the domain partitioner. Furthermore, not allowing the aggregate to cross the processor boundaries can result in slightly higher overall grid complexity (the total number of grid nodes in the grid hierarchy) and larger coarsest grid size when the number of processors is large. We remedy the latter by triggering a processor aggregation step (forming processor connectivity graph and grouping processors into aggregates) when the coarsest grid is too large.

4.3. Parallel smoothers. Smoothers play a critical role in the AMG solution phase. On sequential computers, Gauss–Seidel (GS) is usually the smoother of choice. On massively parallel computers, however, the choice of smoother is less clear. The GS smoother can be modified for higher degree of parallelism by combining it with the Jacobi smoother. By preserving the sequential nature of GS within each processor and exploiting the parallel nature of Jacobi across processor boundaries, a hybrid GS-Jacobi smoother has been demonstrated to be quite effective on a small number of processors. For massive parallelism, it may suffer from slow convergence rates. Another approach is to improve GS's parallelism by using multicoloring [1]. A limitation of this approach is that there needs to be sufficient number of unknowns on each processor, and it is thus not an effective smoother on the coarse grids. Other efforts include the use of polynomial smoothers [2] and Krylov smoothers preconditioned with Jacobi, block Jacobi, or overlapped Schwarz, all with limited success.

In our numerical experiments, we use a variant of the hybrid GS-Jacobi smoother given in [29]. The idea is to recover fast convergence rates by using underrelaxation in GS and/or damped Jacobi across processors. The relaxation parameters can be computed by a few conjugate gradient iterations.

5. Test problems from structural mechanics. The test problems are taken from the ALE3D [3] code developed at the Lawrence Livermore National Laboratory. The implicit integration algorithm in ALE3D for solid materials is based on an updated Lagrangian displacement-based formulation. A set of nonlinear equations is solved for equilibrium using the state and configuration at the end of a time step.

During the time integration, nonlinearities arise because of the material response and configuration changes.

The basic equations are the momentum equations derived by starting with the local dynamic equilibrium relation in a form suitable for a solid body

$$\begin{aligned} \rho \mathbf{u}_{tt} &= \nabla \cdot \boldsymbol{\sigma} + \rho \mathbf{b}, \\ \mathbf{n} \cdot \boldsymbol{\sigma} &= \mathbf{g}, \end{aligned} \tag{5.1}$$

where $\mathbf{u}$ is the displacement vector, $\boldsymbol{\sigma}$ is the stress tensor, $\mathbf{b}$ is the body force vector per unit mass, ρ is the density, and $\mathbf{g}$ is the surface traction. Applying the weak form and then integrating by parts yield

$$\int_V \rho \mathbf{u}_{tt} \cdot \delta \mathbf{u} dV + \int_V \boldsymbol{\sigma} : (\nabla \delta \mathbf{u})^T dV - \int_S \mathbf{n} \cdot \boldsymbol{\sigma} \cdot \delta \mathbf{u} dS - \int_V \rho \mathbf{b} \cdot \delta \mathbf{u} dV = 0, \tag{5.2}$$

where the colon signifies a double inner product, V is the volume, and S is the surface of the body. Time integration is performed by using the full Newton–Raphson iteration scheme represented by

$$\frac{dP}{d\mathbf{u}} \cdot d\mathbf{u} = -P, \tag{5.3}$$

where P is the left-hand side of (5.2) and (A being the surface area)

$$dP = \int_V \left[d\boldsymbol{\sigma} - (\nabla d\mathbf{u})^T \cdot \boldsymbol{\sigma} + (\nabla \cdot d\mathbf{u}) \boldsymbol{\sigma} \right] : (\nabla \delta \mathbf{u})^T dV \tag{5.4}$$

$$\begin{aligned} &- \int_S \left[\frac{d\mathbf{g}}{d\mathbf{u}} \cdot d\mathbf{u} + \frac{1}{A} \mathbf{g} \frac{dA}{d\mathbf{u}} \cdot d\mathbf{u} \right] \cdot \delta \mathbf{u} dS \\ &- \int_V \rho \left[\frac{d\mathbf{b}}{d\mathbf{u}} \right] \cdot d\mathbf{u} + \int_V \rho \left[\frac{d\mathbf{u}_{tt}}{d\mathbf{u}} \right] \cdot \delta \mathbf{u} dV. \end{aligned} \tag{5.5}$$

This displacement-based Jacobian equation is solved with the finite element method using linear elements on a hexahedral mesh. At each time step, corrections are added to the previous estimate of the nodal displacements. The nodal displacements are then used to calculate displacement gradients and strain increment tensors that are passed to the constitutive model.

The constitutive relation we use cannot be written simply in terms of stresses and elastic properties. It also depends on current loading. For a forward gradient stress integration, the material stiffness would take the form

$$C_{ijkl} = L_{ijkl} - \frac{L_{ijrs} P_{rs} P_{tu} L_{tukl}}{h + P_{rs} L_{rstu} P_{tu}}, \quad i, j, k, l, r, s, t, u = 1, \ldots, 3, \tag{5.6}$$

where L is the standard fourth order elasticity tensor, P is the derivative of the yield surface with respect to the stress tensor, and h is the material strain hardening.

5.1. The spherical shell problem. The domain for the first problem is an octant of a spherical shell depicted in Figure 1. The shell has three layers having steel on the outside and inside layers and polycarbonate in the middle. Both elasticity and plasticity are present in the constitutive model. The forcing function is the small amount of energy injected into the polycarbonate layer, causing the polycarbonate to expand against the inner and outer layers. Equation (5.6) can be simplified to $C = L$ in this case, as there is no plasticity.

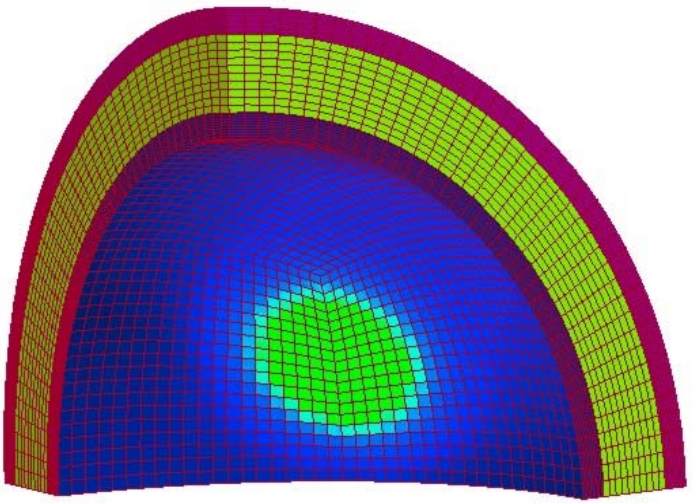

FIG. 1. *The spherical shell problem.*

5.2. The crystal plasticity problem. This test problem (called Tbar and shown in Figure 2) uses a crystal plasticity constitutive model given by

$$C_{ijkl} = L_{ijkl} - \sum_{a=1}^{12} \sum_{b=1}^{12} L_{ijmn} Q^a_{mn} R^b_{rs} L_{rskl}, \tag{5.7}$$

where Q^a and R^b are each second order tensors for each of the 12 slip systems. As a result, the global stiffness matrix is slightly nonsymmetric. Boundary conditions for this test problem are forces applied at one end in the direction of the bar length and the other end is tied down to prohibit displacement in the direction of the bar length.

5.3. The bifurcation problem. This test problem (called Rbar and shown in Figure 3) involves bifurcation which occurs when the force required to stretch the perfectly uniform rod reaches a peak. The load is the axial stress times the cross sectional area. During deformation, the stress first increases linearly with strain as an elastic material. When stretched to a stress level known as the yield point, dislocation mechanisms in the metal allow rearrangement of the atoms and result in permanent deformation of the material. This is plastic flow. During plastic flow the rate of change of stress with strain is typically 2 to 3 orders of magnitude less than during the initial elastic deformation. This rate typically decreases continuously during deformation. Also, during plastic flow the volume of the material is roughly constant leading to a measurable decrease in the bar diameter as it is stretched.

Since the load is the stress times the cross-sectional area, the load rate is comprised of two terms containing the increasing stress rate and the decreasing area rate. For most metals the area rate contribution overtakes the stress rate contribution in the strain range from 5% to 30% extension. This is the peak load and corresponds to the Considère [12] condition. Up to the peak load, energy considerations require that the bar deform uniformly. At the peak load the incremental energy increase applied

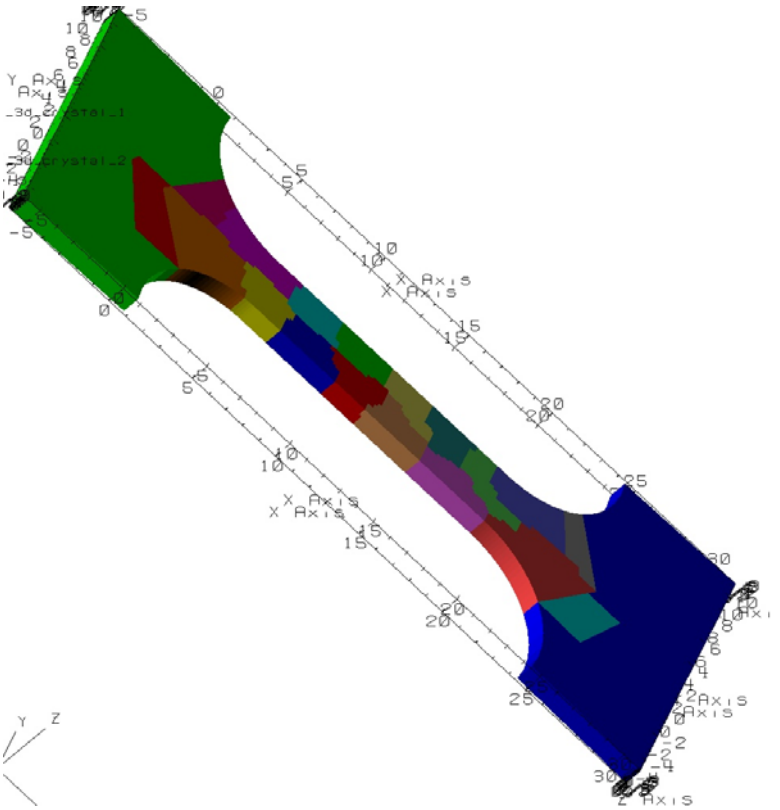

FIG. 2. *The Tbar problem (subdomains in different colors).*

to extend the bar is the same whether it continues stretching uniformly or some nonuniform strain rate pattern emerges. If a nonuniform strain rate pattern emerges, it is not unique.

It is the behavior at this instance of nonunique solution that is challenging to the solver. If everything is geometrically perfect and the low order digits are all the same, the bar can continue to deform uniformly. This has occasionally been seen with direct solvers. If the numerical perturbations are not negligible, a nonuniform deformation pattern will emerge, triggered by the numerical imperfections. The energy increase and the load at the nodes of the finite element mesh are nearly the same regardless of the mode selected.

In the physical experiments, the real materials are not perfect and the effects of the grip ends holding the specimen generally force a nonuniform deformation pattern whereby the diameter reduces faster in one location. The second order work terms at the Considère point are such that these localized deformation modes are favored over continued uniform deformation. Once the localized modes begin, the bar is energetically favored to continue deforming in the localized mode. This eventually leads to what is known as a necking behavior and fracture of the bar (see Figure 4).

6. Numerical experiments. The numerical experiments are run on two IBM SP2 computers (to be called SP2-White and SP2-Blue from this point on) at the Lawrence Livermore National Laboratory. The SP2-White computer has more than

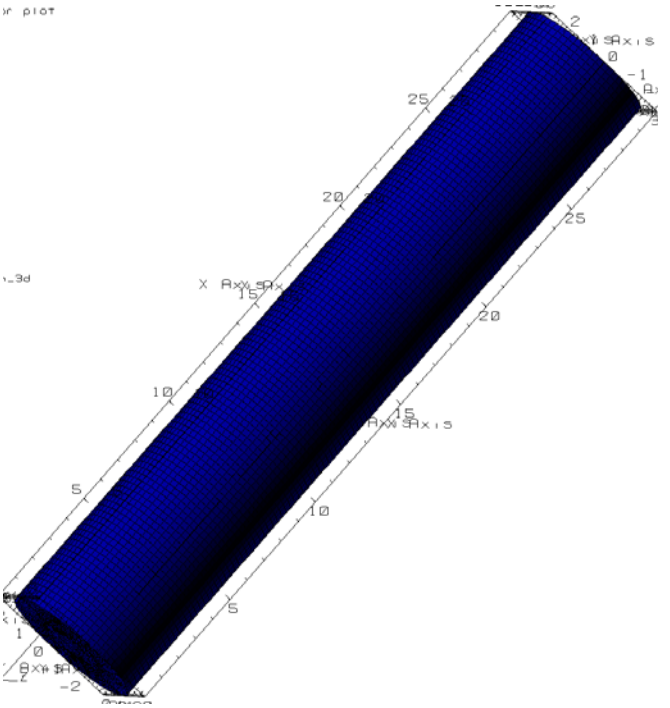

FIG. 3. *The Rbar problem (cylindrical computational domain).*

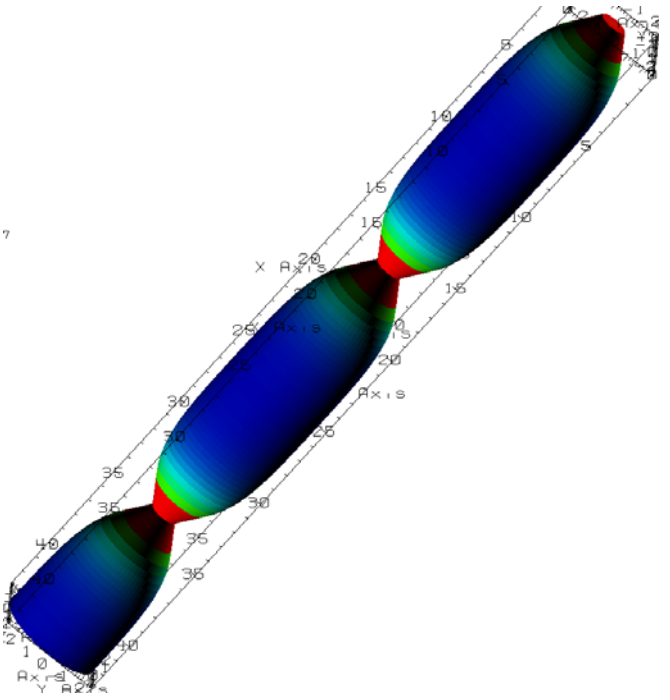

FIG. 4. *The Rbar problem (a deformation configuration).*

500 nodes with 16 gigabyte of main memory per node. Each node has 16 Power3 processors running at 375 MHz each. The SP2-Blue computer has 264 nodes with 4 PowerPC 604e processors and 1.5 gigabytes of memory per node. Due to the scarce availability of large number of processors (1000 or more) and the large disk space requirement for storing the finite element meshes, our numerical experiments are limited to a maximum of 512 processors. For the spherical shell problem, some performance data were collected for RS and SA on 4000 SP2-White processors. The largest run for RS is about 300 millions unknowns which consumes 200 iterations and 2000 seconds for each solve. For SA we were able to successfully run an even larger problem (610 million unknowns, which takes about 500 iterations and 1500 seconds) due to its lower memory requirements.

For both RS and SA, we prescribe one sweep of hybrid SSOR-Jacobi for both pre-smoothing and post-smoothing. For RS, we choose different strength thresholds for best results on different test problems. For SA, the strength threshold is 0.0 and no prolongation smoothing is used for all test problems. In addition, the near null space vectors (the 6 rigid body modes) are computed from the nodal coordinates from our finite element package. For GSA, additional near null space information is calculated from the element stiffness matrices.

6.1. Scalability study for the spherical shell problem. We study the parallel performance of the spherical shell problem on the SP2-White computer using the conjugate gradient method with RS and SA as preconditioners. Each processor has about 100K unknowns, yielding more than 51 million unknowns on 512 processors. The entire simulation takes about 10 linear solves, and the timing results are the averages of all linear solves. Convergence criterion for the conjugate gradient is 10^{-6}. The best strength threshold for RS is around 0.9–0.99 for this problem. We use 0.95 in our experiment. With this threshold the grid and operator complexities (grid complexity is the ratio of the total number of rows in all A_k's with respect to A_0 while the operator complexity is the ratio of the total number of nonzeros in all A_k's with respect to the number of nonzeros in A_0) are approximately 2.1 and 2.5, respectively. The corresponding grid and operator complexities for SA are 1.08 and 1.15, respectively. The timing results and iteration counts are shown in Figures 5 and 6.

These results show that SA is reasonably scalable (that is, the total solution time grows slowly with the number of processors given the same problem size per processor), while RS appears to be somewhat less scalable due mainly to the faster convergence rate deterioration with larger problem size (but RS gives much better solution times than SA when the number of processors is small). For SA, we observe a substantial increase in the solution time going from $P = 128$ to $P = 256$ even though the iteration counts stay about the same. After eliminating the cause attributing to load imbalance, we conclude that the performance deterioration is probably due to higher memory access conflicts for larger test problems.

6.2. Scalability/robustness study for the Tbar problem. Numerical experiments for the Tbar problem are performed on the SP2-Blue computer. Each processor has about 30K unknowns, yielding a total of more than 14 million unknowns for 512 processors. The generalized minimal residual (GMRES [23]) method with a restart size of 200 is used for this problem due to nonsymmetry. The prescribed convergence criterion is 10^{-8}. We use 0.9 as strength threshold for RS. With this threshold the grid and operator complexities are about 2.1 and 3.4, respectively, for all processor configurations. The grid and operator complexities for SA are 1.09

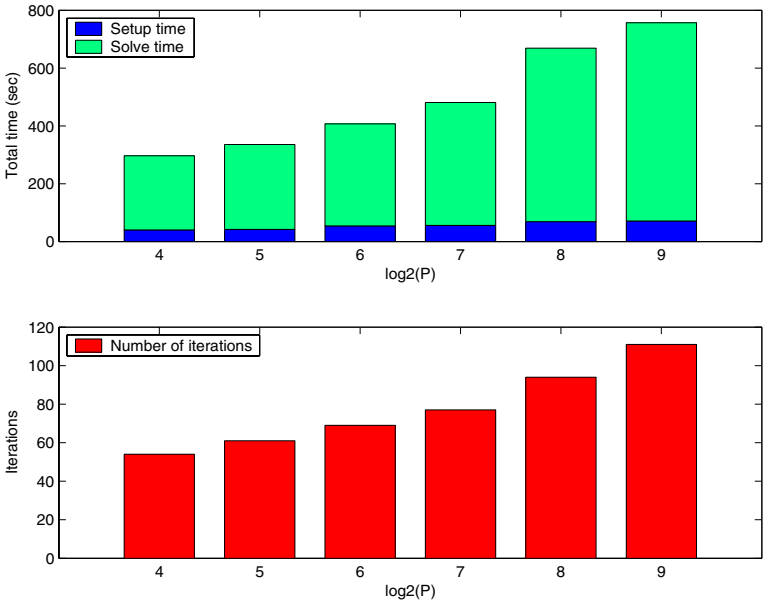

FIG. 5. *Spherical shell problem using RS preconditioner.*

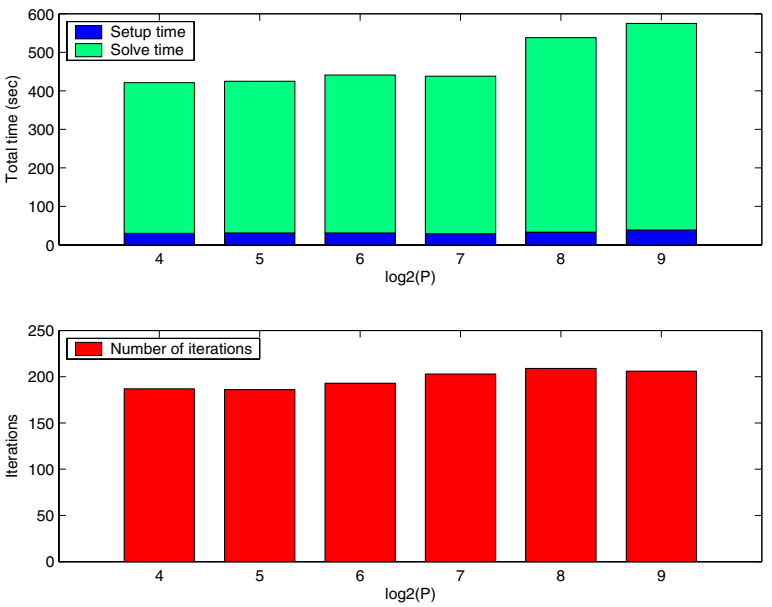

FIG. 6. *Spherical shell problem using SA preconditioner.*

and 1.13, respectively. The numerical results given in Figures 7 and 8 are for the first linear solve. We observe that starting from the second linear solve RS fails to converge (stagnation occurs when the relative residual norm drops to about 10^{-2}), while SA takes many more iterations. We demonstrate in Figures 9 and 10 that GSA helps to improve the robustness of SA.

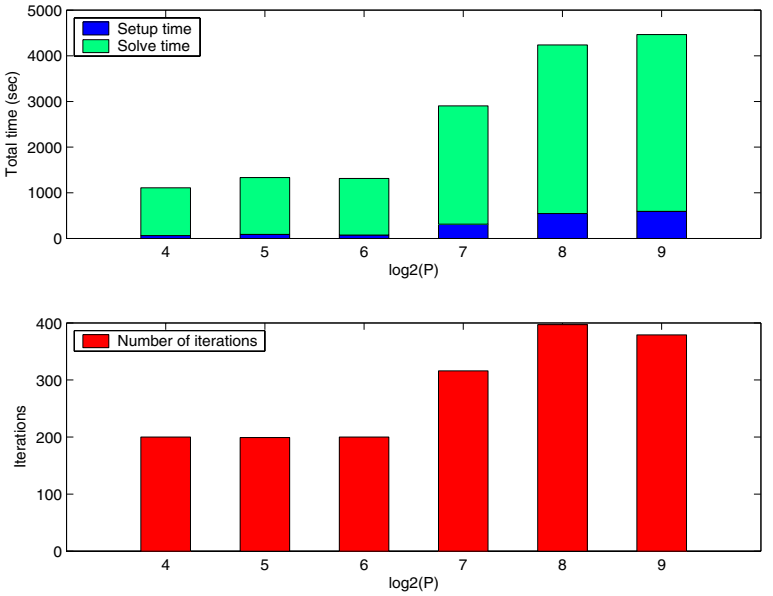

FIG. 7. *Tbar problem using RS preconditioner.*

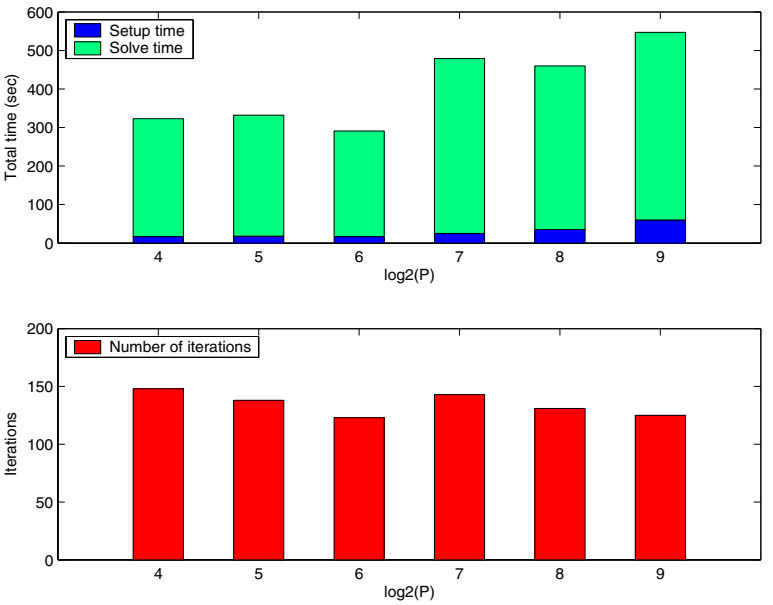

FIG. 8. *Tbar problem using SA preconditioner.*

From Figures 7 and 8, we observe that RS takes many more iterations than SA to converge even for the first linear solve. From examining the convergence history (not shown here) we further notice that the iteration count for RS would have been reduced by a factor of 4 if the convergence criterion is raised to 10^{-6}. We conclude that, for low accuracy runs, RS and SA give comparable performance. Similarly, the

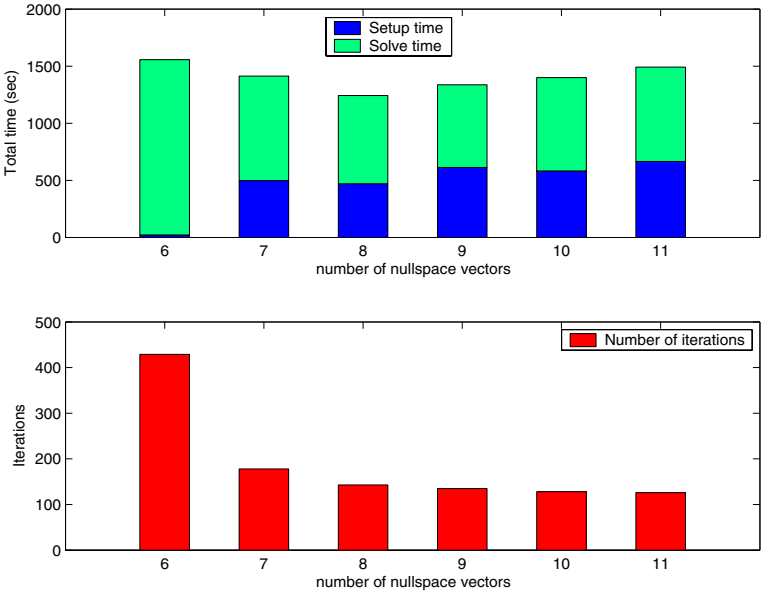

FIG. 9. *Tbar problem using GSA preconditioner.*

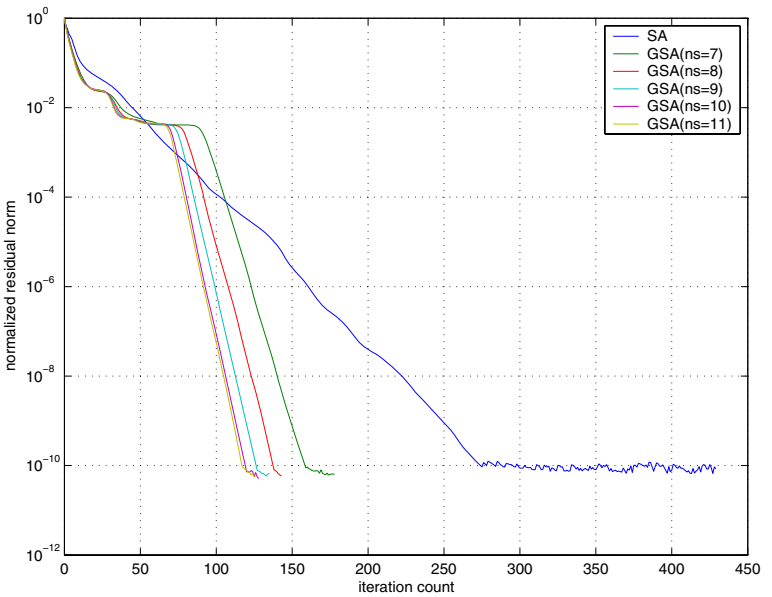

FIG. 10. *Convergence history of Tbar problem using GSA preconditioner.*

residual norm curves in Figure 10 shows that SA would have been competitive with GSA for low accuracy runs. For higher accuracy runs and in later time steps when the effect of crystal plasticity becomes more prominent, GSA performs the best.

6.3. Robustness study for the Rbar problem. For the Rbar problem, our focus is on the robustness of the preconditioners. Since similar scalability behaviors

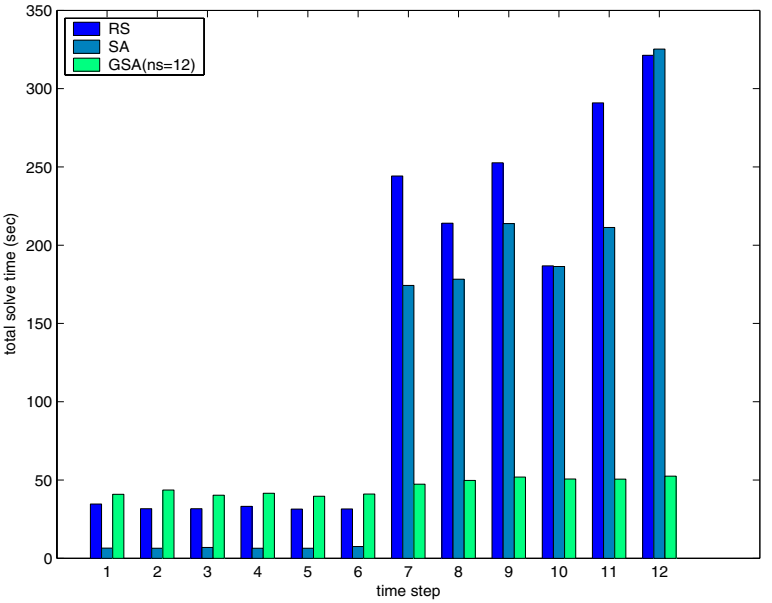

FIG. 11. *Rbar problem with all three preconditioners.*

(as the spherical shell and Tbar problems) are observed here, we deliberately omit the scalability results. The concern for solver robustness stems from the observation that convergence deteriorates rapidly in later time steps when nonuniform deformation occurs. To illustrate the relative performance of the different solvers, we use a test problem with 380K unknowns running on 64 processors of the SP2-Blue computer. Again, we use GMRES(m) with $m = 100$ and convergence criterion 10^{-8}. To reduce the eigendecomposition time in GSA, 128 subdomains are used, with each subdomain having roughly about 3000 unknowns. The number of grid levels and near null space vectors for GSA are 3 and 12 (ns=12), respectively, yielding the coarsest grid size of about 1500.

Timing results for all three AMGs are given in Figure 11 up to the 12th time step. Each time step involves 3 to 6 linear solves, and the data given here are the averages. We observe that in the first 6 time steps when the problem is still well-behaved, SA without enriching the prolongation operator is adequate. Beyond the 12th time step, both RS and SA fail to converge, but GSA continues to march on in time with acceptable convergence rates, as depicted in Figure 12. We observe from Figure 12 that a large fraction of the setup time is in the eigendecomposition. We comment that this setup time can be improved by noting that the first 6 near null space vectors are already available and only 6 additional ones are to be computed. In the current implementation, we have not taken advantage of this fact.

7. Summary and conclusion. In this paper we demonstrate the feasibility of using AMG for solving large-scale structural mechanics problems on massively parallel processors.

For difficult structural mechanics problems, the smoothing and coarsening procedures used by the standard AMG methods may fail to satisfactorily capture all significant low energy modes of the error. Although the standard SA can guarantee approximation of a general set of functions, it requires that these functions be known

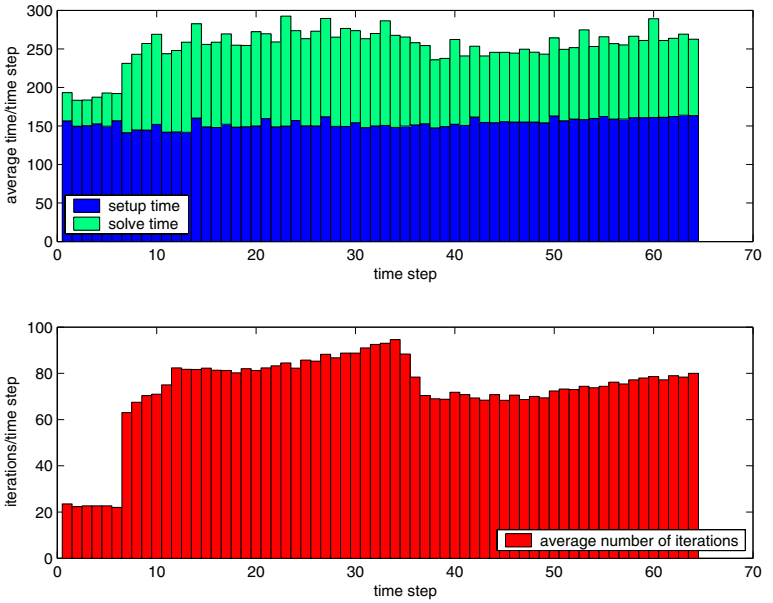

FIG. 12. *Rbar problem using GSA preconditioner.*

before its setup procedure commences. The RS coarsening faces an additional hurdle: even if the set of low energy modes were a priori known, an approximation of a general set of functions is an open problem for RS interpolation. Local prolongation enriching methods such as GSA help to alleviate these problems. Superior convergence has been observed for GSA compared to the RS and SA. Some shortcomings of GSA are the expensive eigendecomposition in the preprocessing step and the potentially large coarsest grid problem. Faster eigensolvers and faster parallel direct solvers are critical for this class of efficient and robust multigrid solvers. Future effort should focus on improving efficiency by reducing memory traffic.

APPROXIMATE FACTORIZATION CONSTRAINT PRECONDITIONERS FOR SADDLE-POINT MATRICES*

H. S. DOLLAR† AND A. J. WATHEN†

Abstract. We consider the application of the conjugate gradient method to the solution of large, symmetric indefinite linear systems. Special emphasis is put on the use of constraint preconditioners and a new factorization that can reduce the number of flops required by the preconditioning step. Results concerning the eigenvalues of the preconditioned matrix and its minimum polynomial are given. Numerical experiments validate these conclusions.

Key words. preconditioning, indefinite linear systems, Krylov subspace methods, conjugate gradient method

AMS subject classifications. 65F10, 65F50

DOI. 10.1137/04060768X

1. Introduction.

There are many areas where we wish to solve matrix systems of the form

$$\underbrace{\begin{bmatrix} A & B^T \\ B & 0 \end{bmatrix}}_{\mathcal{A}} \begin{bmatrix} x \\ y \end{bmatrix} = \underbrace{\begin{bmatrix} c \\ d \end{bmatrix}}_{b}, \tag{1.1}$$

where $A \in \mathbb{R}^{n\times n}$ is symmetric and $B \in \mathbb{R}^{m\times n}$. We shall assume that $0 < m \leq n$, B is of full rank, and A is positive definite in the nullspace of B. The symmetric matrix $\mathcal{A}$ is indefinite (i.e., it has both positive and negative eigenvalues.) Such systems may arise in convex quadratic programming problems [13] and saddle-point systems (see [2] and [10, Chapters 7, 9]), as well as many other areas.

Solution of systems of equations of the form (1.1) can be achieved by a number of methods. For large, sparse or structured matrices iterative methods are an attractive option. In particular, Krylov subspace methods apply techniques that involve orthogonal projections onto subspaces of the form

$$\mathcal{K}(\mathcal{A}, b) \equiv \text{span}\{b, \mathcal{A}b, \mathcal{A}^2b, \ldots, \mathcal{A}^{n-1}b, \ldots\}.$$

The conjugate gradient method (CG), minimum residual method (MINRES), and generalized minimal residual method (GMRES) are all common iterative Krylov subspace methods. The CG method is used for symmetric, positive definite matrices, MINRES for symmetric and possibly indefinite matrices, and GMRES for unsymmetric matrices [12].

MINRES and GMRES will find the solution of the linear system (1.1) within $n + m$ iterations in exact arithmetic, but CG may fail because of the indefiniteness of the system. GMRES is just an expensive way to implement MINRES when $\mathcal{A}$ is symmetric as here. For very large systems this upper bound on the number of

†Oxford University Computing Laboratory, Numerical Analysis Group, Wolfson Building, Parks Road, Oxford, OX1 3QD, UK (hsd@comlab.ox.ac.uk, wathen@comlab.ox.ac.uk). The work of the first author was supported by an EPSRC Doctoral Training Account.

iterations is not helpful and such methods would generally not be employed unless many fewer iterations were required in practice; it is often advantageous to use a preconditioner $\mathcal{P}$ with such iterative methods. The preconditioner should reduce the number of iterations required for convergence but not significantly increase the amount of computation required at each iteration [12, Chapter 13].

Keller, Gould, and Wathen [8] investigated the use of a preconditioner of the form

$$\mathcal{P} = \begin{bmatrix} G & B^T \\ B & 0 \end{bmatrix}, \tag{1.2}$$

where G approximates but is not the same as A. They were able to prove various results about the eigenvalues and eigenvectors for the preconditioned systems $\mathcal{P}^{-1}\mathcal{A}$, where $\mathcal{A}$ and $\mathcal{P}$ are defined in (1.1) and (1.2), respectively; $\mathcal{P}$ is called a [illegible]

The system (1.1) is symmetric and indefinite, implying that we are unable to apply the CG method directly in a robust way since it might fail [3, section 6.3]. Gould, Hribar, and Nocedal [7] show how the CG method can still be used when solving quadratic programming problems provided a preconditioner of the form (1.2) is employed. We extend their method to the general problem of solving systems of the form (1.1) where a constraint preconditioner of the form (1.2) is also used in sections 2 and 3. In section 4 we introduce a new factorization for the preconditioner $\mathcal{P}$. This previously unpublished factorization was recently developed by Wil Schilders (Tech. Univ. Eindhoven/Philips) [11]. We shall refer to this as the Schilders factorization. In section 5 we give numerical examples to demonstrate the effectiveness of the use of this method. A related but different factorization is the variable-reduction method [4, Chapter 5].

2. CG method for the reduced system. We wish to solve the system (1.1) to find $[x^{*T}y^{*T}]^T$. Let Z be an $n \times (n-m)$ matrix spanning the nullspace of B; then $BZ = 0$. The columns of B^T together with the columns of Z span $\mathbb{R}^n$ and any solution x^* of linear equations $Bx = d$ can be written as

$$x^* = B^T x^*_{_B} + Z x^*_{_Z}. \tag{2.1}$$

Substituting this into (1.1) gives

$$\begin{bmatrix} A & B^T \\ B & 0 \end{bmatrix} \begin{bmatrix} B^T x^*_{_B} + Z x^*_{_Z} \\ y^* \end{bmatrix} = \begin{bmatrix} c \\ d \end{bmatrix}. \tag{2.2}$$

Let us split the matrix $\mathcal{A}$ into a block 3×3 structure where each corner block is of dimension $m \times m$. We can also expand the vector $[x^{*T}y^{*T}]^T$ into a matrix-vector product, $\mathcal{H}\rho^*$. Let $Z = [Z_1^T Z_2^T]^T$. Expression (2.2) then becomes

$$\begin{bmatrix} A_{1,1} & A_{1,2} & B_1^T \\ A_{2,1} & A_{2,2} & B_2^T \\ B_1 & B_2 & 0 \end{bmatrix} \underbrace{\begin{bmatrix} B_1^T & Z_1 & 0 \\ B_2^T & Z_2 & 0 \\ 0 & 0 & I \end{bmatrix}}_{\mathcal{H}} \underbrace{\begin{bmatrix} x^*_{_B} \\ x^*_{_Z} \\ y^* \end{bmatrix}}_{\rho^*} = \begin{bmatrix} c_1 \\ c_2 \\ d \end{bmatrix}. \tag{2.3}$$

To maintain symmetry of our system we premultiply (2.3) by $\mathcal{H}^T$. Multiplying the matrix expression $\mathcal{H}^T\mathcal{A}\mathcal{H}$ and simplifying, we obtain the linear system

$$\begin{bmatrix} BAB^T & BAZ & BB^T \\ Z^TAB^T & Z^TAZ & 0 \\ BB^T & 0 & 0 \end{bmatrix} \begin{bmatrix} x^*_{_B} \\ x^*_{_Z} \\ y^* \end{bmatrix} = \begin{bmatrix} Bc \\ Z^Tc \\ d \end{bmatrix}. \tag{2.4}$$

We observe that an $m \times m$ system determines x_B^*:

$$BB^T x_B^* = d. \tag{2.5}$$

Since B is of full rank, BB^T is symmetric, positive definite. We could therefore solve this system using the Cholesky factorization of BB^T if the dimension of the system is small enough [5, p. 143]. From (2.4), having found x_B^*, we can find x_Z^* by solving

$$A_{ZZ} x_Z^* = -c_Z, \tag{2.6}$$

where

$$A_{ZZ} = Z^T A Z, \qquad c_Z = Z^T (A B^T x_B^* - c).$$

The matrix A is symmetric, positive definite in the nullspace of B; hence $Z^T A Z$ is symmetric, positive definite. Anticipating our technique, we can apply the CG method to compute an approximate solution to the system (2.6). Substituting this into (2.1) will give us an approximate solution for x^*. Using (2.4) with (2.1) we obtain a system that can be solved to give an approximate solution for y^*:

$$BB^T y^* = B(c - Ax^*). \tag{2.7}$$

If we used a Cholesky factorization to find x_B^*, then this same factorization could be employed to solve (2.7).

Let us consider the practical application of the CG method to the system (2.6). As we noted in section 1, the use of preconditioning can improve the rate of convergence of the CG iteration. Let us assume that a preconditioner W_{ZZ} is given, where W_{ZZ} is a symmetric, positive definite matrix of dimension $n - m$. Let us consider the class of preconditioners of the form $W_{ZZ} = Z^T G Z$, where G is a symmetric matrix such that $Z^T G Z$ is positive definite. The preconditioned CG method can then be applied to the $(n - m)$-dimensional reduced system $A_{ZZ} x_Z^* = -c_Z$ (see [7, Algorithm 2.1]).

3. CG method for the full system. Explicit use of Algorithm 2.1 from [7] would require knowledge of Z and solution of systems involving W_{ZZ}. The algorithm may, however, be written to make explicit use of the constraint preconditioner without the need for Z at all. Let us define the scaled projection matrix

$$P = Z(Z^T G Z)^{-1} Z^T. \tag{3.1}$$

We will later see that P is independent of the choice of nullspace basis Z.

ALGORITHM 3.1 (preconditioned CG in expanded form). [illegible] x [illegible] $Bx = d$ [illegible] $r = Ax - c$ $g = Pr$ [illegible] $p = -g$ [illegible]

$$\begin{aligned} x &\leftarrow x + \alpha p, \quad \alpha = r^T g / p^T A p, \\ r^+ &= r + \alpha A p, \\ g^+ &= P r^+, \\ p &\leftarrow -g^+ + \beta p, \quad \beta = (r^+)^T g^+ / r^T g, \\ g &\leftarrow g^+, \qquad r \leftarrow r^+. \end{aligned}$$

Note the definition of g^+ via the projection step $g^+ = Pr^+$. Following the terminology of [7], the vector g^+ will be called the [illegible]. It is defined to

be in the nullspace of B. We now wish to be able to apply the projection operator $Z(Z^TGZ)^{-1}Z^T$ without a representation of the nullspace basis Z. If G is nonsingular, then P can be expressed as

$$P = G^{-1}(I - B^T(BG^{-1}B^T)^{-1}BG^{-1}). \tag{3.2}$$

We can find g^+ by solving the system

$$\begin{bmatrix} G & B^T \\ B & 0 \end{bmatrix} \begin{bmatrix} g^+ \\ v^+ \end{bmatrix} = \begin{bmatrix} r^+ \\ 0 \end{bmatrix} \tag{3.3}$$

whenever $z^TGz \neq 0$ for all nonzero z for which $Bz = 0$ [4, section 5.4.1]. The idea in Algorithm 3.2 below is to replace the projection step with the solution of (3.3) to define the same g^+: this is why a constraint preconditioner of the form (1.2) is needed. A preconditioner which is not of constraint form would not suffice.

Discrepancy in the magnitudes of g^+ and r^+ can cause numerical difficulties for which Gould, Hribar, and Nocedal [7] suggest using a residual update strategy that redefines r^+ so that its norm is closer to that of g^+. This dramatically reduces the roundoff errors in the projection operation in practice.

ALGORITHM 3.2 (preconditioned CG with residual update (PCG)).

$$\begin{bmatrix} G & B^T \\ B & 0 \end{bmatrix} \begin{bmatrix} g \\ v \end{bmatrix} = \begin{bmatrix} r \\ 0 \end{bmatrix},$$

$y = v$ $r \leftarrow r - B^Ty$

$g^+ = Pr^+$ (3.3)

$r \leftarrow r^+$ $r \leftarrow r^+ - B^Tv^+$

The key point is that Algorithm 3.2 does not require the computation of any nullspace basis but is a CG procedure for a symmetric, positive definite system which yields the solution of the indefinite system (1.1).

We would therefore like to be able to solve the systems of the form (3.3) efficiently. If we were to use Gaussian elimination to solve this system then, in general, the number of flops required would be $\mathcal{O}((n+m)^3)$ [5, p. 98]. Although this may be reduced depending on the sparsity, it could be impractical for large systems. In the following section we introduce a different factorization for matrices of the form $\mathcal{P}$ in (1.2). If $2m \leq n$, then we can use this factorization to solve (3.3) in $\mathcal{O}((n-m)^3)$ flops. If $2m > n$, then the number of flops required is $\mathcal{O}(m^3)$.

4. Schilders' factorization for preconditioning step. The preconditioning step of solving (3.3) in Algorithm 3.2 involves a constraint preconditioner of the same form of $\mathcal{P}$ given in (1.2). Let us split $\mathcal{P}$ into a block 3×3 structure as we did for the matrix $\mathcal{A}$ in (2.3). Suppose we choose matrices $L_1 \in \mathbb{R}^{m\times m}$ and $L_2 \in \mathbb{R}^{(n-m)\times(n-m)}$ such that L_2 is nonsingular and assume that B_1 is nonsingular; then we can factorize $\mathcal{P}$ in the following manner:

$$\mathcal{P} = \underbrace{\begin{bmatrix} {B_1}^T & 0 & L_1 \\ {B_2}^T & {L_2} & E \\ 0 & 0 & I \end{bmatrix}}_{\mathcal{P}_1} \underbrace{\begin{bmatrix} D_1 & 0 & I \\ 0 & D_2 & 0 \\ I & 0 & 0 \end{bmatrix}}_{\mathcal{P}_2} \underbrace{\begin{bmatrix} B_1 & B_2 & 0 \\ 0 & {L_2}^T & 0 \\ {L_1}^T & E^T & I \end{bmatrix}}_{\mathcal{P}_3}, \tag{4.1}$$

where

$$D_1 = {B_1}^{-T} G_{1,1} {B_1}^{-1} - {L_1}^T {B_1}^{-1} - {B_1}^{-T} L_1, \tag{4.2}$$

$$D_2 = {L_2}^{-1} (G_{2,2} - {B_2}^T D_1 B_2 - E B_2 - {B_2}^T E^T) {L_2}^{-T}, \tag{4.3}$$

$$E = G_{2,1} {B_1}^{-1} - {B_2}^T D_1 - {B_2}^T {L_1}^T {B_1}^{-1}. \tag{4.4}$$

We should emphasize that ensuring that B_1 is nonsingular by permutation of columns, if necessary, is an important and nontrivial practical issue.

Equations (4.2), (4.3), and (4.4) are such that we can choose the matrix G and use this to define D_1, D_2, and E, or we could choose matrices D_1, D_2, and E that then define the matrix G. If we choose to use the second option, then we need to make sure that G satisfies several criteria set out in sections 2 and 3. These are

- G is nonsingular, and
- $Z^T G Z$ is symmetric, positive definite.

Since $\mathcal{P}_1 (= \mathcal{P}_3^T)$ is nonsingular, G will certainly satisfy these criteria if $\mathcal{P}_2$ is symmetric, positive definite. This is equivalent to the simple condition that D_2 is symmetric, positive definite.

In using the factorization (4.1) to solve (3.3), we take $L_2 = I$ for simplicity. We then need to calculate the `lu` factorization of $B_1 \in \mathbb{R}^{m \times m}$ and the Cholesky factorization of $D_2 \in \mathbb{R}^{(n-m) \times (n-m)}$ once and then use these factored forms in each iteration. Note that we need only choose D_2 to be symmetric, positive definite, so we can effectively choose how much work is involved in the factorization of D_2: the choice $D_2 = I$ will give a less effective preconditioner but renders this Cholesky factorization trivial. If i iterations are carried out in Algorithm 3.2, then there are $i + 1$ solves carried out using the factorization (4.1). For general B, D_1, D_2, E, L_1, and L_2, the total number of flops required by PCG is given by

$$no.\quad flops. \sim \frac{2}{3}(2(n-m)^3 + m^3) + 2(i+1)(13m^2 + 3n^2).$$

However, if D_2 and L_2 are diagonal, then the number of flops required reduces to

$$no.\quad flops. \sim \frac{2}{3} m^3 + 4m(i+1)(5m + 3n).$$

We would like to balance this reduction in the number of flops with the possible increase in the number of iterations carried out.

Keller, Gould, and Wathen give a bound on the dimension of the Krylov subspace $\mathcal{K}(\mathcal{P}^{-1}\mathcal{A}, b)$. Proof of the following theorem can be found in [8].

THEOREM 4.1. [illegible] $\mathcal{A} \in \mathbb{R}^{(n+m)\times(n+m)}$ [illegible]

$$\mathcal{A} = \begin{bmatrix} A & B^T \\ B & 0 \end{bmatrix},$$

[illegible] $A \in \mathbb{R}^{n \times n}$ [illegible] $B \in \mathbb{R}^{m \times n}$ [illegible] Z [illegible] $n \times (n-m)$ [illegible] B [illegible] $\mathcal{A}$ [illegible]

$$\mathcal{P} = \begin{bmatrix} G & B^T \\ B & 0 \end{bmatrix},$$

[illegible] $G \in \mathbb{R}^{n \times n}$ [illegible] $G \neq A$ [illegible] $B \in \mathbb{R}^{m \times n}$ [illegible]

- $\mathcal{P}^{-1}\mathcal{A}$
  1. 1 $2m$
  2. $n-m$ λ $Z^TAZx_z = \lambda Z^TGZx_z$
- $\mathcal{K}(\mathcal{P}^{-1}\mathcal{A}, b)$ $n-m+2$

Let us consider what happens if $G_{1,1} = A_{1,1}$, $G_{1,2} = {G_{2,1}}^T = A_{1,2}$, and we choose some matrix D_2 which is symmetric, positive definite. Equation (4.3) can be rearranged to give an explicit expression for $G_{2,2}$: this is given in Theorem 4.2. We assume that $G_{2,2} \neq A_{2,2}$. By choosing D_2 and using the factorization (4.1) to solve (3.3), we will never have to explicitly form the matrix $\mathcal{P}$.

Theorem 4.1 reveals that the preconditioned system $\mathcal{P}^{-1}\mathcal{A}$ has an eigenvalue at 1 with multiplicity $2m$, and $n-m$ eigenvalues which are defined by the generalized eigenvalue problem $Z^TAZx_z = \lambda Z^TGZx_z$. Noting that B_1 is nonsingular, we observe that $Z = [-{B_2}^T{B_1}^{-T} \;\; I]^T{L_2}^{-T}$ is an $n \times (n-m)$ basis for the nullspace of B. Using the above values of $G_{1,1}$, $G_{1,2}$, $G_{2,1}$, and $G_{2,2}$, it is straightforward to show that the $n-m$ eigenvalues can be defined by

$$\widehat{D}_2 x_z = \lambda D_2 x_z, \tag{4.5}$$

where

$$\widehat{D}_2 = {L_2}^{-1}(A_{2,2} - {B_2}^T D_1 B_2 - EB_2 - {B_2}^T E^T){L_2}^{-T}. \tag{4.6}$$

In the optimization community, $\widehat{D}_2$ is called the reduced Hessian.

Note that both D_2 and $\widehat{D}_2$ are symmetric, positive definite, so the eigenvalues are all real. Using the preconditioning matrix $\mathcal{P}$ with $G = [A_{1,1} \;\; A_{1,2};\; A_{2,1} \;\; G_{2,2}]$, we can improve on the Krylov subspace dimension given in Theorem 4.1.

THEOREM 4.2. $\mathcal{A} \in \mathbb{R}^{(n+m)\times(n+m)}$

$$\mathcal{A} = \begin{bmatrix} A & B^T \\ B & 0 \end{bmatrix},$$

$A \in \mathbb{R}^{n\times n}$ $B \in \mathbb{R}^{m\times n}$ m $A = [A_{1,1} \;\; A_{1,2};\; A_{2,1} \;\; A_{2,2}]$ $B = [B_1 \;\; B_2]$ $A_{1,1}, B_1 \in \mathbb{R}^{m\times m}$ $A_{1,2} \in \mathbb{R}^{m\times(n-m)}$ $A_{2,1}, B_2 \in \mathbb{R}^{(n-m)\times m}$ $A_{2,2} \in \mathbb{R}^{(n-m)\times(n-m)}$ $m < n$ $\mathcal{A}$ $L_1 \in \mathbb{R}^{m\times m}$ $L_2, D_2 \in \mathbb{R}^{(n-m)\times(n-m)}$ L_2 D_2 $\mathcal{A}$

$$\mathcal{P} = \begin{bmatrix} A_{1,1} & A_{1,2} & B_1^T \\ A_{2,1} & G_{2,2} & B_2^T \\ B_1 & B_2 & 0 \end{bmatrix},$$

$$G_{2,2} = L_2 D_2 {L_2}^T - {B_2}^T {B_1}^{-T} A_{1,1} {B_1}^{-1} B_2 + A_{2,1} {B_1}^{-1} B_2 + {B_2}^T {B_1}^{-T} A_{1,2};$$

$\mathcal{K}(\mathcal{P}^{-1}\mathcal{A}, b)$ $n-m+1$

. By assumption, B_1 is nonsingular so we can use Schilders' factorization (4.1) to express both $\mathcal{A}$ and $\mathcal{P}$. Using these factorizations we can express $\mathcal{P}^{-1}\mathcal{A}$ as

$$\mathcal{P}^{-1}\mathcal{A} = \begin{bmatrix} I & \Theta & 0 \\ 0 & {L_2}^{-T} {D_2}^{-1} \widehat{D}_2 {L_2}^T & 0 \\ 0 & \Upsilon & I \end{bmatrix}, \tag{4.7}$$

where D_1, $\widehat{D}_2$, and E are given by (4.2), (4.6), and (4.4), respectively, and

$$\Theta = {B_1}^{-1} B_2 (I - {L_2}^{-T} {D_2}^{-1} \widehat{D}_2 {L_2}^T), \tag{4.8}$$

$$\Upsilon = (E^T - {L_1}^T {B_1}^{-1} B_2)(I - {L_2}^{-T} {D_2}^{-1} \widehat{D}_2 {L_2}^T). \tag{4.9}$$

From the eigenvalues of the preconditioned system, it is evident that the characteristic polynomial of the preconditioned system is of the form

$$(\mathcal{P}^{-1}\mathcal{A} - I)^{2m} \prod_{i=1}^{n-m} (\mathcal{P}^{-1}\mathcal{A} - \lambda_i I).$$

To prove the upper bound on the dimension of the Krylov subspace we need to show that the degree of the minimum polynomial is less than or equal to $n - m + 1$. Expanding the polynomial $\prod_{i=1}^{n-m}(\mathcal{P}^{-1}\mathcal{A} - \lambda_i I)$ of degree $n - m$, we obtain a matrix of the form

$$\begin{bmatrix} \prod_{i=1}^{n-m}(1-\lambda_i) I & f_{n-m}(\Theta) & 0 \\ 0 & \prod_{i=1}^{n-m}(S - \lambda_i I) & 0 \\ 0 & f_{n-m}(\Upsilon) & \prod_{i=1}^{n-m}(1-\lambda_i) I \end{bmatrix}, \tag{4.10}$$

where $S = {L_2}^{-T} {D_2}^{-1} \widehat{D}_2 {L_2}^T$ and $f_{n-m}(\cdot)$ is defined by the recursive formula

$$f_{n-m}(\Gamma) = \Gamma \prod_{i=1}^{n-m-1} (1-\lambda_i) I + f_{n-m-1}(\Gamma)(S - \lambda_{n-m} I)$$

with base case $f_1(\Gamma) = \Gamma$. Now let us premultiply the matrix (4.10) by $\mathcal{P}^{-1}\mathcal{A} - I$ to give

$$\begin{bmatrix} 0 & \Theta \prod_{i=1}^{n-m}(S - \lambda_i I) & 0 \\ 0 & (S - I) \prod_{i=1}^{n-m}(S - \lambda_i I) & 0 \\ 0 & \Upsilon \prod_{i=1}^{n-m}(S - \lambda_i I) & 0 \end{bmatrix}. \tag{4.11}$$

We note that the $(1,2)$, $(2,2)$, and $(3,2)$ entries are in fact zero, since the λ_i $(i = 1, \ldots, n-m)$ are eigenvalues of S, which is similar to a symmetric matrix and thus diagonalizable. Hence, the degree of the minimum polynomial of $\mathcal{P}^{-1}\mathcal{A}$ is less than or equal to $n - m + 1$. ∎

If at least one of the eigenvalues defined by (4.5) has multiplicity greater than one, then we can sharpen this bound.

THEOREM 4.3. [illegible] $\mathcal{A}$ [illegible] $\mathcal{P}$ [illegible] 4.2 [illegible] $\alpha \in \mathbb{R}$ [illegible] $1 \le j < n - m$ [illegible] (4.5) [illegible]

$$\begin{aligned} \lambda_i &\neq \alpha, \quad i = 1, \ldots, j, \\ \lambda_i &= \alpha \quad i = j+1, \ldots, n-m; \end{aligned}$$

[illegible] $\mathcal{K}(\mathcal{P}^{-1}\mathcal{A}, b)$ [illegible] $j + 2$ [illegible]. Following the proof of Theorem 4.2 we can show that

$$\prod_{i=1}^{j+1} (\mathcal{P}^{-1}\mathcal{A} - \lambda_i I) = \begin{bmatrix} \prod_{i=1}^{j+1}(1-\lambda_i) I & f_{j+1}(\Theta) & 0 \\ 0 & \prod_{i=1}^{j+1}(S - \lambda_i I) & 0 \\ 0 & f_{j+1}(\Upsilon) & \prod_{i=1}^{j+1}(1-\lambda_i) I \end{bmatrix}, \tag{4.12}$$

where Θ, Υ, S, and $f_{j+1}(\cdot)$ are as defined previously. Now let us premultiply the matrix (4.12) by $\mathcal{P}^{-1}\mathcal{A} - I$ to give

$$\begin{bmatrix} 0 & \Theta \prod_{i=1}^{j+1}(S-\lambda_i I) & 0 \\ 0 & (S-I)\prod_{i=1}^{j+1}(S-\lambda_i I) & 0 \\ 0 & \Upsilon \prod_{i=1}^{j+1}(S-\lambda_i I) & 0 \end{bmatrix}. \tag{4.13}$$

As in the proof of Theorem 4.2, we note that the $(1,2)$, $(2,2)$, and $(3,2)$ entries are in fact zero. Hence, the degree of the minimum polynomial of $\mathcal{P}^{-1}\mathcal{A}$ is less than or equal to $j+2$. ∎

THEOREM 4.4. [illegible] $\mathcal{A}$ [illegible] $\mathcal{P}$ [illegible] 4.2 [illegible] $A_{2,2}$ [illegible] $D_2 = L_2^{-1}A_{2,2}L_2^{-T}$ [illegible] $\mathcal{K}(\mathcal{P}^{-1}\mathcal{A}, b)$ [illegible] $\min(2m+2, n-m+1)$ [illegible]. Let us expand the difference $\widehat{D_2} - D_2$:

$$\begin{aligned} \widehat{D_2} - D_2 &= L_2^{-1}(A_{2,2} + B_2^T B_1^{-T} A_{1,1} B_1^{-1} B_2 - A_{2,1}B_1^{-1}B_2 - B_2^T B_1^{-T} A_{1,2})L_2^{-T} \\ &\quad - L_2^{-1} A_{2,2} L_2^{-T} \\ &= L_2^{-1}(B_2^T B_1^{-T}(A_{1,1}B_1^{-1}B_2 - A_{1,2}) - A_{2,1}B_1^{-1}B_2)L_2^{-T}. \end{aligned}$$

Now,

$$\begin{aligned} rank(\widehat{D_2} - D_2) &\le \min\,[\min[rank(B_2), \min[rank(A_{1,1}), rank(B_2)] + rank(A_{1,2})] \\ &\quad + \min[rank(A_{2,1}), rank(B_2)], n-m] \\ &\le \min(2m, n-m). \end{aligned}$$

Since D_2 is, by assumption, positive definite, we may write $D_2 = WW^T$ for some nonsingular W. Thus

$$W^{-1}\widehat{D_2}W^{-T} = I + W^{-1}L_2^{-1}(B_2^T B_1^{-T}(A_{1,1}B_1^{-1}B_2 - A_{1,2}) - A_{2,1}B_1^{-1}B_2)L_2^{-T}W^{-T}$$

differs from the identity matrix by a matrix of rank at most $\min(2m, n-m)$, and hence there are at most $\min(2m, n-m)$ nonunit eigenvalues defined by the generalized eigenvalue problem (4.5). We can therefore arrange the eigenvalues such that there exists $1 \le j \le \min(2m, n-m)$ and

$$\begin{aligned} \lambda_i &\ne 1, \quad i = 1, \ldots, j, \\ \lambda_i &= 1, \quad i = j+1, \ldots, n-m. \end{aligned}$$

From Theorems 4.2 and 4.3 we conclude that the dimension of the Krylov subspace $\mathcal{K}(\mathcal{P}^{-1}\mathcal{A}, b)$ is at most $\min(2m+2, n-m+1)$. ∎

5. Numerical examples. We apply Algorithm 3.2 to solve a selection of problems from the CUTEr collection [6], and also a set of Stokes saddle-point problems generated using the `ifiss` incompressible flow software associated with the book [2]. Any simple bounds in the CUTEr problems are removed to create a problem of the form

$$\begin{aligned} &\min_x f(x) = \tfrac{1}{2}x^T A x + s^T x \\ &\quad \text{subject to } Bx = t. \end{aligned}$$

For both sets of problems, the matrix $A \in \mathbb{R}^{n\times n}$ is symmetric and $B \in \mathbb{R}^{m\times n}$ is the full row rank matrix of linear constraints; A is positive definite in the nullspace

of B (in fact on the whole space for the Stokes problems), and vectors x, s, and t have appropriate dimensions. A permuted `lu` factorization of B^T is used to find a permutation matrix, M, such that the first m columns of BM are linearly independent [5, Chapter 3]. We then set $B \leftarrow BM$, $A \leftarrow M^T AM$, $s \leftarrow M^T s$, and $x \leftarrow M^T x$. The assumption about the nonsingularity of B_1 will now hold.

The dimensions of the problems and number of nonzeros in the associated matrices A and B are given in Table 5.1. Tables 5.2–5.6 show the results of using Algorithm 3.2 with different preconditioners and a low tolerance. The results of using the preconditioner $\mathcal{P} = [I\ B^T; B\ 0]$ are shown in Table 5.2. This preconditioner is of the general form considered in [8] (see also [9]). Another possible choice for G is to use the diagonal entries of A [1]. The results of using this preconditioner are shown in Table 5.3. In Tables 5.4 and 5.5 we use preconditioners of the form considered in Theorems 4.2 and 4.4, respectively. The final preconditioner that we try will generally reproduce less of the matrix A in G than the previous two do, but we hope that this will be compensated by the iterations being "cheaper" to apply. The results are given in Table 5.6.

We compare the number of iterations and the amount of CPU time taken when we use an `lu` factorization of the preconditioner $\mathcal{P}$, and when we use the Schilders' factorization for $\mathcal{P}$. In both cases, we carry out the factorization once and then use the factored forms in each iteration. When producing Schilders' factorization, we set $L_1 = 0$ and $L_2 = I$. At present, we have not carried out substantial research into how we should choose the values of L_1 and L_2. In an attempt to maintain sparsity, an approximate minimum degree preordering strategy is applied before carrying out any `lu` factorizations. Threshold pivoting is also used during the `lu` factorization stages: the default threshold value in MATLAB is used.

The number of iterations carried out is given in the column headed "Its." We also measure the CPU time taken in carrying out the factorization of the preconditioners (FTime) and the CPU time then taken by Algorithm 3.2 when using these factored forms (ITime). The time spent finding an initial x which satisfies $Bx = d$ is excluded from the value given in Itime. The total CPU time used to solve the problem is given by "Total." Each problem is solved ten times and the mean of the CPU times recorded. The minimum values of $\frac{1}{2}x^T Ax + s^T x$ calculated are also compared for all the problems, although this is not immediately applicable to the Stokes problems. The number of digits of agreement in these values are given in "Digits." We observe that for the majority of the CUTEr problems, the differences in rounding errors of the two factorization methods do not greatly affect the calculated minimum values. We note that for some of the Stokes problems at least one of the solutions is rather inaccurate, though we have no easy way of finding out which! An important factor in how well a certain factorization will perform is its sparsity; in particular, the number of nonzeros in the `lu` factors of $\mathcal{P}$, and the number of nonzeros in the factors of D_2. These values are also given for each of our preconditioners, and the total amount of storage required for the various blocks required. Note that the matrices D_1 and E should not be generated when using Schilders' factorization.

The diagonal form of D_2 used in the examples of Table 5.4 produces a significant

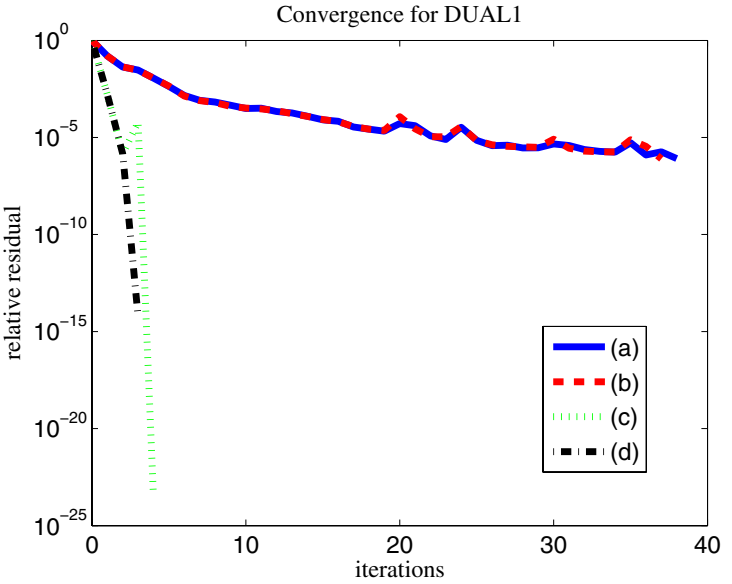

FIG. 5.1. *Convergence of relative residuals $r^T g$ with the different preconditioning strategies from Table* 5.7 *for the problem DUAL*1.

drop in the CPU times when we use the Schilders' factorization instead of the `lu` factorization of $\mathcal{P}$. However, this choice of D_2 is not so practical because we have to form the matrix $\widehat{D}_2$, as defined in (4.6), and then use the diagonal. If $A_{2,2}$ is positive definite and sparse enough for us to consider factorizing it, then we can set $D_2 = A_{2,2}$ with $G_{1,1} = A_{1,1}$ and $G_{1,2} = G_{2,1}^T = A_{1,2}$. From Theorem 4.4 we know that the dimension of the Krylov subspace $\mathcal{K}(\mathcal{P}^{-1}\mathcal{A}, b)$ is at most $\min(n-m+1, 2m+2)$. The results of using such a preconditioner are shown in Table 5.5. In particular, note the four DUAL* problems. For each of these $m = 1$, so the upper bound on the dimension of the Krylov subspace $\mathcal{K}(\mathcal{P}^{-1}\mathcal{A}, b)$ is at most 4. Our results support this claim.

All tests were performed on a dual Intel Xeon 3.20GHz machine with hyper-threading and 2GB of RAM. It was running Fedora Core 2 (Linux kernel 2.6.8) and all programs were written in MATLAB 7.0. We terminate the iteration when the value of $r^T g$ is reduced by at least a factor of 10^{-2}. If no result is given for a problem, then the machine we used ran out of memory during the factorization stage. This is indicated by — in the results tables. Consider the test problem CONT-300. We were unable to solve it by choosing G explicitly, as in Tables 5.2 and 5.3, and then factoring it because of the machine running out of memory. However, when we used Schilders' factorization with $D_2 = A_{2,2}$, our algorithm successfully terminated, as in Tables 5.5 and 5.6. We were also able to factor $\mathcal{P}$ with an `lu` factorization for $G_{1,1} = 0$, $G_{1,2} = G_{2,1}^T = 0$, and $D_2 = A_{2,2}$, but the factorization time was over 300 times larger than using Schilders' factorization, resulting in the total CPU time being at least 38 times larger.

It is clear that, for the majority of the problems, factoring $\mathcal{P}$ with an `lu` factorization is preferable when we choose G as in Tables 5.2 and 5.3. However, it is generally preferable to use Schilders' factorization for the other choices of preconditioner, as we would expect. Table 5.7 shows results for the factorization of preference with four of the preconditioners that we have considered. The iteration process is terminated

when $r^T g$ has been reduced by a factor of 10^{-6}. The number of iterations required and the total CPU time is recorded. We observe that Schilders' factorization with $G_{1,1} = 0$, $G_{1,2} = 0$, and $D_2 = A_{2,2}$ is preferable, or of equal preference, for twelve out of the seventeen CUTEr test problems. However, setting $G = \mathrm{diag}(A)$ and then carrying out an `lu` factorization is better for the Stokes problems tested because the number of iterations required is greatly reduced. The convergence of the relative residuals of $r^T g$ are plotted in Figure 5.1 for the problem DUAL1. The line labeled "(c)" corresponds to a preconditioner which satisfies the assumptions of Theorem 4.4. The plot supports this theorem.

6. Conclusion. In this paper, we have discussed the use of the PCG method for solving indefinite linear systems. We have investigated the use of a new factorization for constraint preconditioners and shown how this can be used in incomplete forms to decrease the number of flops required overall by the preconditioned iterative method. We obtained an upper bound on the number of iterations required to solve systems of the form (1.1) by means of appropriate Krylov subspace methods by using a minimum polynomial argument.

We have provided computational evidence that the PCG method works well for nontrivial quadratic programming problems; however, it would not be the method of choice for the Stokes saddle-point problems tested. Indeed, problem-based preconditioned iterative methods which have optimal computational complexity exist for these problems (see [2, Chapter 6]).

In some cases, the use of Schilders' factorization to define a preconditioner can speed up the solution time by a factor of 5 compared to using the `lu` factorization of a preconditioner for which G has been chosen. For larger dimensional problems, we have shown an example where Schilders' factorization approach enables fast solution but the `lu` factorization with popular choices of preconditioner fails because of memory costs.

The cost of finding m linearly independent columns in the matrix B via a permuted `lu` factorization is often higher than we would like. We plan to investigate different strategies for this in the future, and how these may change the number of iterations required to solve the problems.

Acknowledgments. The authors would like to thank Nick Gould and Wil Schilders for their helpful input during the early stages of this research.

ADAPTIVE MULTISCALE REDISTRIBUTION FOR VECTOR QUANTIZATION*

YAIR KOREN† AND IRAD YAVNEH†

Abstract. Vector quantization is a classical problem that appears in many fields. Unfortunately, the quantization problem is generally nonconvex, and therefore affords many local minima. The main problem is finding an initial approximation which is close to a "good" local minimum. Once such an approximation is found, the Lloyd–Max method may be used to reach a local minimum near it. In recent years, much improvement has been made with respect to reducing the computational costs of quantization algorithms, whereas the task of finding better initial approximations received somewhat less attention. We present a novel multiscale iterative scheme for the quantization problem. The scheme is based on redistributing the representation levels among aggregates of decision regions at changing scales. The rule governing the redistribution relies on the so-called point density function and on the number of representation levels in each aggregate. Our method focuses on achieving better local minima than those achieved by other contemporary methods such as LBG. When quantizing signals with sparse and patchy histograms, as may occur in color images, for example, the improvement in distortion relative to LBG may be arbitrarily large.

Key words. quantization, Lloyd–Max, LBG, point density

DOI. 10.1137/040607769

1. Introduction.

Quantization [11, 13] is the process of representing continuum with only a finite number of representatives or representing an initially rich amount of discrete data with a lesser amount of representatives. Rounding off real numbers to the nearest integer is a simple form of scalar quantization. Representing color images with a lesser amount of colors is an example of vector quantization.

In general, many digital signal processing problems require some form of quantization. In particular, as the world moves toward an increased use of digital media, the digital processing of sound, images, and video involves an increasing amount of quantization. Some problems that would benefit from better quantization algorithms are analogue-to-digital conversion, sampling in general, and compression [16, 15].

Quantization and Voronoi tessellations are closely related and have a variety of applications to more than just signal processing and telecommunication. For example, distribution of resources and clustering algorithms [14, 19, 18] are, in essence, quantization algorithms that are used in various fields such as statistical analysis, pattern recognition, learning theory, computer graphics, and combinatorial chemistry [5]. A review on Voronoi tessellations as well as additional applications, such as quadrature rules, finite difference schemes, statistics, cellular biology, and the cellular behavior of animals [17], can be found in [7].

1.1. Formal definition.

Stating the problem more formally, let Ω be some input domain and let $p : \Omega \to \mathbb{R}$ be the probability density function of some random process over Ω. Let n be a known positive integer. A quantizer $q : \Omega \to \Omega$ is defined

*Received by the editors May 5, 2004; accepted for publication (in revised form) December 21, 2004; published electronically February 3, 2006. This research was supported by the Israeli Science Foundation under grant 48/02 and by the Israeli Ministry of Science.

†Department of Computer Science, Technion—Israel Institute of Technology, Haifa 32000, Israel (yair_k@cs.technion.ac.il, irad@cs.technion.ac.il).

by n representation levels $R = \{\vec{r}_i\}_{i=1}^n$ and n decision regions $\{D_i\}_{i=1}^n$, where for all $i, r_i \in D_i$, and $\cup_i D_i = \Omega$. That is, $q(\Omega)$ is a piecewise constant approximation of Ω, where all $\vec{x} \in D_i$ are represented by $\vec{r}_i$. An optimal quantizer achieves minimal distortion, defined as the expectation of the quantization error raised to some power t,

$$\mathcal{D}(q) = E[\|\vec{x} - q(\vec{x})\|_2^t] = \sum_{i=1}^{n} \int_{D_i} \|\vec{x} - \vec{r}_i\|_2^t \, p(\vec{x}) \, d\vec{x}. \tag{1.1}$$

Here, $\|\cdot\|_2$ is the L_2 norm. In the discrete case, where $p(\vec{x})$ is nonzero at only a finite number of points $\{\vec{x}_i\}_{i=1}^N$, a similar functional is minimized:

$$\mathcal{D}(q) = E[\|\vec{x} - q(\vec{x})\|_2^t] = \sum_{i=1}^{n} \left\{ \sum_{\vec{x}_j \in D_i} \|\vec{x}_j - \vec{r}_i\|_2^t p(\vec{x}_j) \right\}. \tag{1.2}$$

Henceforth, we permit $p(\vec{x})$ to be any nonnegative function, not necessarily a distribution density function of unit mass. We also set $t = 2$, yielding the ubiquitous mean square error (MSE) measure. In the theoretical background section we show that our algorithms are equally applicable for any t.

1.2. Previous work. In recent years, many methods have been presented that reduce the complexity of finding a solution, e.g., solving multiple 1-D problems [1], recursively splitting the domain in two [25, 16, 30], and accelerating known algorithms [32, 27]. These methods are usually greedy and/or heuristic and involve a complexity/distortion tradeoff. That is, lower complexity algorithms generally arrive at solutions with higher distortion. Wu [31] generalizes the algorithms described in [25, 16, 30] and attempts to arrive at a good local minimum by making an observation about a constant number of consecutive splits and by using dynamic programming.

1.3. The Lloyd–Max iterative process. Necessary conditions for a minimum of (1.1) are

$$\begin{aligned} \frac{\partial}{\partial \vec{r}_i} \mathcal{D}(q) &= 0, \qquad 1 \le i \le n, \\ \frac{\partial}{\partial D_i} \mathcal{D}(q) &= 0, \qquad 1 \le i \le n. \end{aligned} \tag{1.3}$$

When $t = 2$, these conditions yield

$$\begin{aligned} \vec{r}_i &= \frac{\int_{D_i} \vec{x} p(\vec{x}) d\vec{x}}{\int_{D_i} p(\vec{x}) d\vec{x}}, \qquad 1 \le i \le n, \\ D_i &= \mathcal{V}(\vec{r}_i), \qquad\qquad 1 \le i \le n. \end{aligned} \tag{1.4}$$

Here, $\mathcal{V}(\vec{r}_i)$ is the Voronoi cell corresponding to $\vec{r}_i$, i.e., the set of all points in Ω that are closer to $\vec{r}_i$ than to any other representation level $\vec{r}_j$, $j \neq i$. Lloyd [22] and Max [24] independently developed (1.4) and proposed "ping-ponging" back and forth

between the two optimality equations,

$$D_i^\ell = \mathcal{V}((\vec{r}_i)^\ell), \qquad \ell = 0, 1, 2, \ldots, \tag{1.5}$$

$$(\vec{r}_i)^{\ell+1} = \frac{\int_{D_i^\ell} \vec{x} p(\vec{x}) d\vec{x}}{\int_{D_i^\ell} p(\vec{x}) d\vec{x}}, \qquad \ell = 0, 1, 2, \ldots, \tag{1.6}$$

that is, optimizing the D_i's according to the $\vec{r}_i$'s (computing the Voronoi cells of the $\vec{r}_i$'s) followed by optimizing the $\vec{r}_i$'s according to the new D_i's (computing the centers of mass of the D_i's), and so on. $\vec{r}^0$ is an initial guess at the solution. This process converges monotonically to a solution that satisfies (1.4) (see [22]).

When applying Lloyd–Max iterations (1.5), (1.6) in the discrete case (1.2) one need not actually compute the Voronoi diagram, which takes $\theta(n \log n + n^{\lceil k/2 \rceil})$ operations for a k-dimensional domain Ω. For high dimensions it is both sufficient and efficient to determine, for each $\vec{x} \in \Omega$, which representation level $\vec{r}_i$ is closest to $\vec{x}$. The naive method of inspecting all n possibilities for each $\vec{x} \in \Omega$ and choosing the closest one takes $O(kNn)$ operations, where $N = |\{\vec{x} : p(\vec{x}) \neq 0\}|$. If a k-d tree [9] is used to find best matches, then the expected computation time of a Lloyd–Max iteration is $O(kN \log n)$.

For scalar quantization ($k = 1$), Fleischer showed that a sufficient condition for a unique minimum of the distortion is that $\log(p(x))$ be concave [8]. For vector quantization, we are unaware of a similar result.

Since the Lloyd–Max iterative process requires an initial guess at the solution in order to start iterating, many heuristic methods, such as k-means [23] and Linde–Buzo–Gray (LBG) [21], have been proposed to find a good initial approximation. The LBG algorithm [21] is a "grid refinement" type of process that starts by finding a solution (using the generalized Lloyd algorithm) for two $\vec{r}_i$'s and then splitting each $\vec{r}_i$ into two new $\vec{r}_i$'s. This process is repeated recursively until the number of $\vec{r}_i$'s equals n. The generalized Lloyd algorithm is the iterative process (1.5), (1.6) with the reduction in distortion used as a stopping criterion. That is, the process is stopped at the iteration in which the ratio between the current distortion and the previous iteration's distortion exceeds some threshold. In what follows, we shall compare our method with LBG.

A multigrid [4, 29] approach for scalar (1-D) quantization was presented in [20]. Our approach was basically a multigrid full approximation scheme algorithm [3] with the Lloyd–Max iteration (1.5), (1.6) used as relaxation. The benefits are three-fold. First, much faster convergence is achieved. The convergence rates of our method seem independent of the number of representation levels sought. In contrast, both Lloyd–Max and LBG converge at a rate that is quadratically dependent on the number of representation levels. Second, the speed up alleviates the need for a convergence/stopping criterion such as the one used for LBG. This is because reaching machine accuracy requires only several iterations when using our method. Third, our method sometimes arrives at better minima than other methods.

The vector quantization problem is generally nonconvex and therefore affords multiple local minima [12]. Figure 1.1 depicts several local minima for the simple case, where $p(x, y) \equiv 1$ and four representation levels are sought. We consider the acceleration of convergence less important than converging to a solution of lower distortion. This paper presents methods for both scalar and vector quantization to overcome the multiple local minima problem. Our methods arrive at solutions of lower distortion and do so in less time compared to competing algorithms.

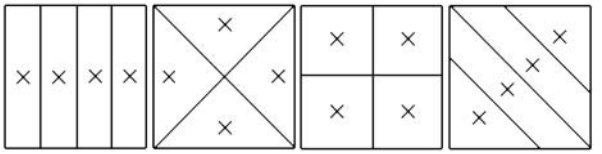

FIG. 1.1. *Multiple local minima for $p(x, y) \equiv 1$. These are all local minima, as the Lloyd–Max criteria* (1.4) *are satisfied. That is, the representation levels are the centers of mass of the decision regions and the decision regions are the Voronoi diagram of the representation levels.*

This paper is organized as follows. Section 2 presents the theoretical background upon which our algorithms are built. Section 3 provides a detailed description of our proposed adaptive multiscale redistribution (AMR) algorithms for vector quantization. Section 4 includes results of our vector quantization algorithms and a comparison with LBG. Section 5 presents a conclusion and further discussion.

2. Theoretical background. Much theoretical research and analysis have been conducted on the problem of quantization [2, 22, 33, 26, 10, 28]. In this section, in order to maintain a self-contained presentation, we recount Gersho's theoretical results concerning optimality criteria for vector quantizers [10]. The optimality criteria are valid for general values of t in the distortion definition (1.1). Therefore, the algorithms derived in the following section are also valid for any t. Gersho's results are true in the large n limit. Nevertheless, our algorithms, which are based on Gersho's results, perform extremely well for small n as well. Examples are presented in section 4.

In his dissertation [33], Zador proves that the [illegible] structure of an asymptotically optimal quantizer can be that of an optimal quantizer for a uniform distribution. Therefore, we henceforth assume that $p(\vec{x})$ is uniform, whereas in what follows we shall apply the optimality criteria derived in this section to nonuniform $p(\vec{x})$ as well.

In 1979, Gersho [10] made the now widely accepted conjecture that, for a uniform distribution $p(\vec{x})$ in any dimension k, the optimal decision regions are all congruent to some k-dimensional convex polytope (precluding the decision regions touching the boundaries of Ω). The Voronoi diagram in this case is referred to as a [illegible] of the k-dimensional domain Ω. Gersho's conjecture has been proven for one (see [6, p. 59]) and two [28] dimensions, where the appropriate tessellation-generating polytopes are the section and the regular hexagon, respectively.

Henceforth, we assume that Gersho's conjecture is correct. Under this assumption, an analysis of the distortion of lattice quantizers is within reach. The class of admissible polytopes in $\mathbb{R}^k$, denoted H_k, is defined as follows. A convex polytope H is admissible, i.e., in H_k, if it generates a tessellation of $\mathbb{R}^k$ that is a Voronoi diagram with respect to the centers of mass of the polytopes comprising this tessellation.

The [illegible] of a polytope H is defined as

$$I(H) = \int_H \|\vec{x} - \mathtt{com}(H)\|^t \, d\vec{x} \Big/ V(H)^{1+t/k}, \tag{2.1}$$

where $V(H)$ is the volume of H and $\mathtt{com}(H)$ is the center of mass of H, or more formally, the point y in H that minimizes $\int_H \|x - y\|^t dx$. Note that $I(\alpha H) = I(H)$ for all $\alpha > 0$, where $\alpha H = \{\alpha\vec{x} : \vec{x} \in H\}$. Intuitively, the normalized inertia measures the quality of a polytope's shape, disregarding size, with respect to distortion minimization.

An optimal polytope, H^*, is an admissible polytope that minimizes the normalized inertia, i.e.,

$$I(H^*) = \inf_{H \in H_k} I(H). \tag{2.2}$$

Given a quantizer q_n having n representation levels, a piecewise constant [illegible] [22] for q_n is defined as

$$\lambda_n(\vec{x}) = (nV(D_i))^{-1} = \frac{1}{n \int_{D_i} d\vec{y}}, \tag{2.3}$$

where D_i is the decision region containing $\vec{x}$, and $V(D_i)$ is D_i's volume. $\lambda_n(\vec{x})\Delta V(\vec{x})$ approximates the fraction of representation levels in the volume element $\Delta V(\vec{x})$. As n approaches infinity, $\lambda_n(\vec{x})$ approximates closely a continuous density function, denoted $\lambda(\vec{x})$. $\lambda(\vec{x})$ has unit mass, i.e., $\int_\Omega \lambda(\vec{x})d\vec{x} = 1$, since $\int_{D_i} \lambda_n(\vec{x})d\vec{x} = 1/n$ for any i and n. Integrating $\lambda(\vec{x})$ over a set $S \in \Omega$ yields the fraction of representation levels in S, whereas integrating $\lambda_n(\vec{x})$ over S approximates this fraction. That is,

$$\frac{|\{\vec{r}_i \,:\, \vec{r}_i \in S\}|}{n} \approx \int_S \lambda_n(\vec{x})d\vec{x}. \tag{2.4}$$

When the number of representation levels is large we may assume that $p(\vec{x}) \approx p(\vec{r}_i)$ for all $\vec{x} \in D_i$; that is, we may assume that the distribution is approximately uniform inside each decision region. Under this assumption, the probability may be removed from under the integral in the distortion definition (1.1), yielding

$$\mathcal{D}(q_n) = \sum_{i=1}^{n} p(\vec{r}_i) \int_{D_i} \|\vec{x} - \vec{r}_i\|^t \, d\vec{x}. \tag{2.5}$$

Plugging in the normalized inertia, we obtain

$$\mathcal{D}(q_n) = \sum_{i=1}^{n} p(\vec{r}_i) \, I(H^*) \, [V(D_i)]^{1+\frac{t}{k}}, \tag{2.6}$$

since, under Gersho's conjecture, the minimal distortion is achieved by decision regions that are similar to H^*. According to (2.3), $V(D_i)$ may be expressed by $\lambda_n(\vec{x})$:

$$\mathcal{D}(q_n) = n^{-(t/k)} I(H^*) \sum_{i=1}^{n} p(\vec{r}_i) \, [\lambda_n(\vec{r}_i)]^{-(t/k)} \, V(D_i). \tag{2.7}$$

As n approaches infinity, the above sum is approximated by the integral

$$\mathcal{D}(q_n) \approx n^{-(t/k)} I(H^*) \int_\Omega \frac{p(\vec{x})}{[\lambda(\vec{x})]^{t/k}} d\vec{x}. \tag{2.8}$$

Equation (2.8) is an approximation of the distortion that is independent of the representation levels and the decision regions. In fact, the only unknown in (2.8) is $\lambda(\vec{x})$. Therefore, the minimal distortion is achieved by optimally choosing $\lambda(\vec{x})$, i.e., by minimizing the integral.

Observe that, by Hölder's inequality,

$$\int_\Omega \left\{ \left[p\left(\vec{x}\right) \lambda(\vec{x})^{-(t/k)} \right]^{\frac{1}{1+t/k}} \right\} \left\{ \lambda(\vec{x})^{\frac{t/k}{1+t/k}} \right\} d\vec{x} \tag{2.9}$$

$$\leq \left\{ \int_\Omega p\left(\vec{x}\right) \lambda(\vec{x})^{-(t/k)} d\vec{x} \right\}^{\frac{1}{1+t/k}} \left\{ \int_\Omega \lambda\left(\vec{x}\right) d\vec{x} \right\}^{\frac{t/k}{1+t/k}},$$

with equality if and only if the right-hand side integrands are proportional, i.e., if and only if $p(\vec{x})[\lambda(\vec{x})]^{-(t/k)} \propto \lambda(\vec{x})$.

As $\lambda(\vec{x})$ has unit mass, we obtain from (2.9)

$$\int_\Omega \frac{p(\vec{x})}{\left[\lambda\left(\vec{x}\right)\right]^{t/k}} d\vec{x} \geq \left\{ \int_\Omega \left[p\left(\vec{x}\right)\right]^{\frac{1}{1+t/k}} d\vec{x} \right\}^{1+t/k}. \tag{2.10}$$

The left-hand side of (2.10) is evidently minimized when equal to the right-hand side. By (2.8), (2.9), and (2.10) the distortion is therefore minimized if and only if

$$\lambda(x) \propto [p(x)]^{k/(k+t)}. \tag{2.11}$$

In what follows we construct algorithms based on the two following corollaries, appearing in Gersho's paper [10].

COROLLARY 2.1. [illegible]

$$\int_S \lambda(\vec{x}) d\vec{x} \approx \frac{\int_S p^{\frac{k}{k+t}}(\vec{x}) d\vec{x}}{\int_\Omega p^{\frac{k}{k+t}}\left(\vec{x}\right) d\vec{x}} \tag{2.12}$$

[illegible] S [illegible] Ω [illegible]. This is a direct result of the previous derivations. The right-hand side denominator assures unit volume for $\lambda(\vec{x})$. □

COROLLARY 2.2. [illegible] q [illegible] (1.1) [illegible]. Using (2.3) and (2.11), one may express both $p(\vec{r}_i)$ and $V(D_i)$ by $\lambda(\vec{x})$ in (2.7). This yields the stated result, as each term in the sum in (2.7) is reduced to the same constant, namely, $1/n$ times the proportion constant from (2.11) □

The property indicated by Corollary 2.2 was observed for $k = 1$ by Panter and Dite [26] and for $k = 2$ by Toth [28].

3. Adaptive multiscale redistribution algorithms. We now exploit the theoretical results described above within a novel AMR algorithm. We begin by defining three methods for building a quantizer. Our ultimate quantization algorithm involves concatenating these three methods.

The first method is an extremely quick way of attaining a good initial set of n representation levels. This method heavily relies on (2.12) and achieves a distortion that usually is nearly as low as our final result. The complexity of obtaining this initial guess is proportional to $\log(n)$ Lloyd–Max relaxations, where n is the number of representation levels sought. Stopping this iterative initial guess phase after two to three iterations usually results in a good initial approximation, which may be even better than LBG's final result. From our tests, LBG [21] also seems to require $O(\log(n))$ iterations in order to arrive at an initial guess, but LBG's guess is usually not as good as the one provided by our method, as shall be demonstrated in section 4. In

addition, stopping LBG before $O(\log(n))$ Lloyd–Max iterations have been performed usually results in a poor initial approximation.

The second method is used to improve an initial guess. The improvement is based on Corollary 2.2 and is performed by moving representation levels from low distortion areas to areas with higher distortion.

The last method is simply applying Lloyd–Max iterations (1.5), (1.6) to the best approximation found to date, thus reaching a local minimum of the quantization distortion. We propose a quantization algorithm that is made up of these three steps. First, find an initial guess. Second, improve the initial guess. Third, relax until a local minimum has been reached.

3.1. The general approach. In both acquiring an initial guess and improving it, we use the following AMR approach. A hierarchy of scales is defined. Scale m, denoted R^m, is a partition of the set of representation levels R into m disjoint aggregates. That is,

$$R^m = \{R_j^m\}_{j=1}^m, \; R = \bigcup_j R_j^m. \tag{3.1}$$

At any scale m, all m aggregates are approximately equal in size. At the finest scale, each aggregate is made up of a single representation level, that is, $m = n$. When passing from scale m to scale $m/2$ (the next coarser scale), the m aggregates are grouped in pairs to form approximately $m/2$ new aggregates. This set of $m/2$ new aggregates is scale $m/2$. The coarsest scale consists of two aggregates.

At each scale, we determine the poorest aggregate, that is, the aggregate that would benefit the most from an additional representation level. In a similar manner, we determine the richest aggregate, that is, the aggregate that would suffer the least from giving up a representation level. Then we transfer a representation level from the richest aggregate to the poorest aggregate.

3.2. Acquiring an initial guess. For the purpose of acquiring an initial guess we exploit our knowledge of the optimal point density function (2.12). Let

$$D(R_j^m) = \bigcup_{\vec{r}_i \in R_j^m} D_i, \tag{3.2}$$

that is, $D(R_j^m)$ is the union of the decision regions of all the representation levels in R_j^m. For each aggregate R_j^m of the m aggregates in R^m, (2.12) suggests the fractional number of representation levels that an optimal quantizer allocates to the region $D(R_j^m)$. Subtracting this amount (multiplied by n) from the actual number of representation levels in $D(R_j^m)$, we arrive at the , , $\mathcal{W}_j^m$, of aggregate R_j^m. More formally,

$$\mathcal{W}_j^m = |R_j^m| - n \left\{ \frac{\int_{D(R_j^m)} p^{\frac{k}{k+2}}(\vec{x}) d\vec{x}}{\int_\Omega p^{\frac{k}{k+2}}(\vec{x})\, d\vec{x}} \right\}. \tag{3.3}$$

According to this definition, the wealth of an aggregate of decision regions is simply the excess of representation levels it currently contains. We call aggregates whose wealth is above zero , aggregates and aggregates whose wealth is below zero , aggregates.

Our algorithm for obtaining an initial guess is as follows. We initialize R^n by randomly choosing n representation levels uniformly in Ω. We use this uniform initial approximation for two reasons. First, it is extremely cheap to compute. Second, and more important, the $Obtain-Guess$ algorithm transfers representation levels to places in Ω that already contain other representation levels. Therefore, a uniform initial approximation gives an equal chance for all areas in Ω to receive representation levels. Next, we call the following recursive function with R^n as input (note that $n = |R^n|$).

ALGORITHM.
$R^m \leftarrow Obtain-Guess(p(\vec{x}), R^m)$.

1. Perform a single Lloyd–Max relaxation.
2. Calculate $\mathcal{W}^m = \{\mathcal{W}_i^m\}_{i=1}^m$.
3. Let $\mathcal{W}_{max}^m$ denote $\max(\mathcal{W}^m)$ and $\mathcal{W}_{min}^m$ denote $\min(\mathcal{W}^m)$.
4. *WHILE* $\mathcal{W}_{max}^m - \mathcal{W}_{min}^m > 1$, *DO*:
   (a) $\vec{r}_j \leftarrow Select-Source(R_{max}^m)$.
   (b) $\vec{t} \leftarrow Select-Destination(R_{min}^m)$.
   (c) Transfer $\vec{r}_j$ from R_{max}^m to R_{min}^m at location $\vec{t}$.
   (d) $\mathcal{W}_{min}^m \leftarrow \mathcal{W}_{min}^m + 1$, $\mathcal{W}_{max}^m \leftarrow \mathcal{W}_{max}^m - 1$.
5. $R^{m/2} \leftarrow Match(R^m)$.
6. *IF* $R^{m/2} = R^m$
   (a) *RETURN* R^m.
7. *ELSE*,
   (a) Recursively call $Obtain-Guess(p(\vec{x}), R^{m/2})$.

Throughout the $Obtain-Guess$ algorithm, subscripts *max* and *min* refer to aggregates of maximal and minimal wealth, respectively. Note that the decision regions are not recalculated after the transition of representation levels, but only within the Lloyd–Max relaxation occurring at step 1 of $Obtain-Guess$. This single Lloyd–Max relaxation at each scale is performed to improve the solution. In addition, this relaxation is needed for the calculation of $\mathcal{W}_i^m$, as this calculation requires knowing the decision regions. The output of the $Obtain-Guess$ algorithm is the set of representation levels yielding the lowest distortion achieved.

Note that $Obtain-Guess$ is an adaptive multiscale redistribution of the representation levels. The goal of this redistribution is to have the quantizer's point density function obey (2.12) as best as possible. Since checking (2.12) for all possible sets S is intractable, we do so only for various unions of decision regions. The following lemma shows how each transition of a representation level at step 4(c) of $Obtain-Guess$ makes the point density function of the quantizer more coherent with (2.12).

LEMMA 3.1. [illegible] $\mathcal{W}_{max}^m - \mathcal{W}_{min}^m > 1$ [illegible] 4 [illegible] $Obtain-Guess$ [illegible] 4(c) [illegible] $Obtain-Guess$ [illegible] $\sum_i |\mathcal{W}_i^m|$ [illegible]. We shall prove that $|\mathcal{W}_{max}^m - 1| + |\mathcal{W}_{min}^m + 1| < |\mathcal{W}_{max}^m| + |\mathcal{W}_{min}^m|$. Assume that $0 \le \mathcal{W}_{max}^m < 1$ and $-1 < \mathcal{W}_{min}^m \le 0$. When this is not true, the result is trivial. Note that $\mathcal{W}_{max}^m \ge 0$ and $\mathcal{W}_{min}^m \le 0$ always hold. $|\mathcal{W}_{max}^m - 1| = 1 - \mathcal{W}_{max}^m < -\mathcal{W}_{min}^m = |\mathcal{W}_{min}^m|$. The first equality is implied by $\mathcal{W}_{max}^m < 1$ and the inequality by $\mathcal{W}_{max}^m - \mathcal{W}_{min}^m > 1$. In a similar manner, $|\mathcal{W}_{min}^m + 1| = 1 + \mathcal{W}_{min}^m < \mathcal{W}_{max}^m = |\mathcal{W}_{max}^m|$, where the first equality is implied by $\mathcal{W}_{min}^m > -1$ and the inequality by $\mathcal{W}_{max}^m - \mathcal{W}_{min}^m > 1$. □

The selection of a representation level in the richest aggregate, at step 4(a) of $Obtain - Guess$, is described next.

ALGORITHM.
$\vec{r}_i \leftarrow Select - Source(R_j^m)$.

1. *IF* $\left|R_j^m\right| > 1$
   (a) *IF* $R_j^m = R_s^{2m}$ for some $1 \le s \le 2m$,
      i. Recursively call $Select - Source(R_s^{2m})$.
   (b) *ELSE*,
      i. $R_j^m = R_u^{2m} \cup R_v^{2m}$ for some $1 \le u, v \le 2m$.
      Let R_ℓ^{2m} be the aggregate that achieves $\max\{\mathcal{W}_u^{2m}, \mathcal{W}_v^{2m}\}$.
      ii. Recursively call $Select - Source(R_\ell^{2m})$.
2. *ELSE*,
   (a) *RETURN* the single $\vec{r}_i \in R_j^m$.

Less formally, we wish to remove the representation level in R_j^m that belongs to the richest aggregate [illegible]. We traverse the scales from the present scale to the finer scales. At each scale m we deal with a single aggregate R_j^m. R_j^m is usually made up of two $2m$-scale aggregates (the actual matching is performed by $Match$). We choose the richer aggregate of the two and continue recursively. When we reach an aggregate containing a single representation level, we choose it as the representation level to remove.

The selection of a destination in the poorest aggregate, at step 4(b) of $Obtain - Guess$, is described next.

ALGORITHM.
$\vec{t} \leftarrow Select - Destination(R_j^m)$.

1. *IF* $\left|R_j^m\right| > 2$
   (a) *IF* $R_j^m = R_s^{2m}$ for some $1 \le s \le 2m$,
      i. Recursively call $Select - Destination(R_s^{2m})$.
   (b) *ELSE*,
      i. $R_j^m = R_u^{2m} \cup R_v^{2m}$ for some $1 \le u, v \le 2m$.
      Let R_ℓ^{2m} be the aggregate that achieves $\min\{\mathcal{W}_u^{2m}, \mathcal{W}_v^{2m}\}$.
      ii. Recursively call $Select - Source(R_\ell^{2m})$.
2. *ELSE*,
   (a) *RETURN* the mean of the set R_j^m.

Less formally, we wish to insert a representation level at a location that belongs to the poorest aggregate [illegible]. In a manner similar to $Select - Source$, we traverse the scales from the present scale to the finer scales. This time, at each scale m we choose the poorest aggregate of the two that make up R_j^m and continue recursively. When we reach an aggregate containing just two representation levels, we choose the destination as the midpoint between the two levels.

The coarser scales are required to take care of the situations in which many small aggregates are moderately poor and many other small aggregates are moderately rich. In this case, as the wealth function (3.3) is linear, the grouping of several somewhat poor aggregates should form a larger aggregate that is poor enough to warrant an additional representation level. In a similar fashion, the grouping of several somewhat rich aggregates should form a larger aggregate that is rich enough to allow a

representation level to be removed. In the appendix, we demonstrate the importance of wrapping the redistribution in a multiscale framework.

In light of the above, the matching between pairs of aggregates that is performed at step 5 of $Obtain - Guess$ and is designed to produce larger aggregates should only match aggregates that are either both rich or both poor. In addition we prefer to match aggregates that are close to each other. This is because adding a new representation level to an aggregate made up of two distant regions only increases the wealth of the region that accepts the representation level. This accepting region may not even be one of the two distant ones, in which case the transition is clearly not the right course of action. If the accepting region is one of the two distant ones and indeed the transfer is beneficial, then it should have been performed at a finer scale, where each of the two regions was a separate aggregate.

We define the distance between two aggregates as the distance between the mean of the representation levels in each aggregate, i.e.,

$$\|R_i^m, R_j^m\| = \left\| \frac{\sum_{\vec{r}_i \in R_i^m} (\vec{r}_i)}{|R_i^m|} - \frac{\sum_{\vec{r}_j \in R_j^m} (\vec{r}_j)}{|R_j^m|} \right\|_2 . \tag{3.4}$$

More formally, the matching algorithm is defined as follows.

ALGORITHM.
$R^{m/2} \leftarrow Match(R^m)$.

1. Initialize $R^{m/2} = \phi$.
2. Sort the aggregates in R^m according to $|\mathcal{W}_i^m|$.
3. Traverse the sorted list, *FOR EACH* aggregate R_j^m, *DO*:
   (a) Denote by Δ the set of unmatched aggregates, R_k^m, that satisfy $\text{sign}(\mathcal{W}_k^m) = \text{sign}(\mathcal{W}_j^m)$.
   (b) *IF* $\Delta = \phi$
      i. Add R_j^m to $R^{m/2}$ and mark R_j^m as matched.
   (c) *ELSE*,
      i. Find $R_i^m = \underset{R_k^m \in \Delta}{\text{argmin}} \|R_k^m, R_j^m\|$.
      ii. Add $R_j^m \cup R_i^m$ to $R^{m/2}$ and mark both R_j^m and R_i^m as matched.
4. *RETURN* $R^{m/2}$.

Using k-d trees [9] to compute $\text{argmin} \|R_k^m, R_j^m\|$ in step 3(c)(i) of $Match$, the expected complexity of the matching algorithm is $O(km \log m)$, where m is the number of aggregates. Note that this is asymptotically much less than the $O(kN \log n)$ required for a Lloyd–Max relaxation (recall that N is the number of points, $\vec{x}$, for which $p(\vec{x}) > 0$).

We apply $Obtain - Guess$ several times until no representation levels are transferred at any scale. Each call to $Obtain - Guess$ applies $O(\log(n))$ Lloyd–Max relaxations that are the bulk of its time complexity. In practice we have applied this method to many examples. We have found that about 2–3 calls to $Obtain - Guess$ generate a "steady" initial guess, i.e., one that is not affected by another call to $Obtain - Guess$.

From our tests, the distortion of the initial guess thus obtained may be quite close to the final distortion achieved by concatenating our three methods. Whether or not the subsequent gain justifies the additional work is both application and user

dependent. For example, video compression may be performed off-line and the additional computational cost may therefore by acceptable in return for an even mild improvement in the resulting compressed file size. On the other hand, real time applications do not have the luxury of long processing time even if the improvement in the resulting distortion is significant. We expect those who need a good solution and require a fast algorithm to be quite satisfied with the initial guess and not apply the following two phases. On the other hand, those who require the best solution possible and/or are willing to accept a somewhat slower process are encouraged to apply the entire three phase process. For $p(\vec{x})$ that are sparse and patchy (e.g., color images), the ratio between the distortion achieved by AMR (either the single phase algorithm or the three phase algorithm) and the distortion achieved by LBG may be arbitrarily small, as shall be demonstrated in section 4.

3.3. Improving an initial guess. Improving a guess requires more leniency than acquiring an initial guess. The harsh demand that $\max(\mathcal{W}^m) - \min(\mathcal{W}^m) > 1$ (step 4 of $Obtain-Guess$) in order to perform a transition is relaxed by $\max(\mathcal{W}^m) - \min(\mathcal{W}^m) > T$ for some positive threshold T. In all of our tests, we have used $T = 1/2$. In addition we redefine an aggregate's wealth. This time the definition is based on Corollary 2.2,

$$\mathcal{W}_j^m = 1 - \frac{average\ distortion\ at\ aggregate\ j}{average\ distortion\ in\ \Omega}, \tag{3.5}$$

where "*average distortion*" is the average distortion per representation level.

ALGORITHM.
$R^m \leftarrow Improve-Guess(R^m, T, \nu)$.

1. Perform a single Lloyd–Max relaxation.
2. *WHILE* the distortion of R^m, $\mathcal{D}(R^m)$, decreases, *DO:*
   (a) Calculate $\mathcal{W}^m = \{\mathcal{W}_i^m\}_{i=1}^m$.
   (b) *IF* $\max(\mathcal{W}^m) - \min(\mathcal{W}^m) > T$,
      i. Move 1 representation level from the richest aggregate to the poorest aggregate, using $Select-Source$ and $Select-Destination$. Denote by $\tilde{R}^m$ the set of aggregates after the transition.
      ii. $\tilde{R}^m \leftarrow Beat-Target-Distortion(\tilde{R}^m, \mathcal{D}(R^m), \nu)$.
      iii. *IF* the distortion has not improved,
         A. discard the new $\tilde{R}^m$ and keep R^m.
      iv. *ELSE*,
         A. $R^m \leftarrow \tilde{R}^m$.
3. Form a set of new aggregates: $R^{m/2} \leftarrow Match(R^m)$.
4. *IF* $R^{m/2} = R^m$
   (a) *RETURN* R^m.
5. *ELSE*,
   (a) Recursively call $Improve-Guess(R^{m/2}, T, \nu)$.

According to Corollary 2.2, an optimal quantizer obeys $\mathcal{W}_j^m = 0$ for all $1 \le j \le m \le n$. This definition still permits us to call aggregates whose wealth is above zero [illegible] aggregates and call aggregates whose wealth is below zero [illegible] aggregates.

Our improvement method uses the above distortion-based wealth definition (3.5). From our tests, the distortion-based wealth definition (3.5) leads to better results. On the other hand, a meaningful threshold for the initial guess phase (step 4 in

$Obtain-Guess$), such as the one that Lemma 3.1 provides for (3.3), is more difficult to come by for (3.5). This is why we use the point density–based wealth definition (3.3) with threshold $T = 1$ when acquiring an initial guess.

$Beat-Target-Distortion$ applies Lloyd–Max relaxations to $\tilde{R}^m$, attempting to achieve a distortion lower than $\mathcal{D}(R^m)$. After each relaxation, the function tries to assess if ν additional relaxations are likely to reduce the distortion enough. This assessment is made by assuming that each additional Lloyd–Max relaxation will reduce the distortion by the actual reduction achieved via the previous Lloyd–Max relaxation.

The linear extrapolation we use to forecast the distortion reduction has the following property. It is optimistic in the early stages, at which time a more accurate approximation may halt the process prematurely, whereas in the later stages, as the distortion reduction rate reduces, it becomes more accurate. If the target distortion is beaten, then $Beat-Target-Distortion$ applies ν additional Lloyd–Max relaxations and the result is returned. The additional ν relaxations are performed to allow the new solution to realize its potential. More formally, we have the following algorithm.

ALGORITHM.
$R^m \leftarrow Beat-Target-Distortion(R^m, \mathcal{D}, \nu)$.

1. *DO*: {
   (a) Denote the current distortion $\mathcal{D}^{old} = \mathcal{D}(R^m)$.
   (b) Perform a Lloyd–Max relaxation on R^m.
   (c) Denote the new distortion by $\mathcal{D}^{new} = \mathcal{D}(R^m)$.
   (d) *IF* $\mathcal{D}^{new} < \mathcal{D}$
      i. Apply ν additional Lloyd–Max relaxations to R^m and return the result.

   } *WHILE* $\mathcal{D}^{new} - \nu|\mathcal{D}^{new} - \mathcal{D}^{old}| < \mathcal{D}$.
2. *RETURN* R^m.

When a representation level is added or removed (step 2(b)(i) of $Improve-Guess$), a Lloyd–Max iteration (1.5), (1.6) propagates this change only to the neighbors of this representation level. Assuming that the representation levels are spread uniformly in the domain Ω, we see that it would take approximately $n^{1/k}$ Lloyd–Max iterations to propagate this change throughout all of the representation levels. For this reason, we used $\nu = \lceil n^{1/k} \rceil$ throughout our tests. For the threshold T, we used $T = 1/2$.

Coarse scale changes may upset the balance achieved at the finer scales. Therefore, it may be beneficial to call $Improve-Guess$ several times. Before calling $Improve-Guess$ an additional time, ν may be raised and T lowered. In our examples we always called $Improve-Guess$ two to three times, while T and ν were never changed.

The AMR process can be stopped at any time. In our tests, no matter when the process was stopped, the results were better than those achieved by LBG after the same amount of time.

4. Vector quantization results. Many digital signal processing applications involve some form of quantization. As an example, color images may be compressed by representing them with only a fraction of their initial amount of colors. The histograms of color images are usually sparse and patchy, as Figure 4.1 illustrates. Close inspection of Figure 4.1 reveals that the image's histogram is concentrated around seven patches. Six of the patches are fairly close to one another and represent the brighter areas in the image, e.g., sky, lawn, and walls and roof of the house. The seventh patch is quite distant from the rest and represents the darker areas in the

image, e.g., the house's window shutters, the bushes surrounding the house, and the shadows of the car and the utility pole. We demonstrate our algorithms on discrete 2-D data using the discrete distortion definition (1.2) with $t = 2$. Let

$$p_{ij} = \begin{cases} 5 & i, j \in \{1, 1, 2, \ldots, 150\}, \\ 3 & i, j \in \{201, 201, 202, \ldots, 256\}, \\ 0 & otherwise. \end{cases} \tag{4.1}$$

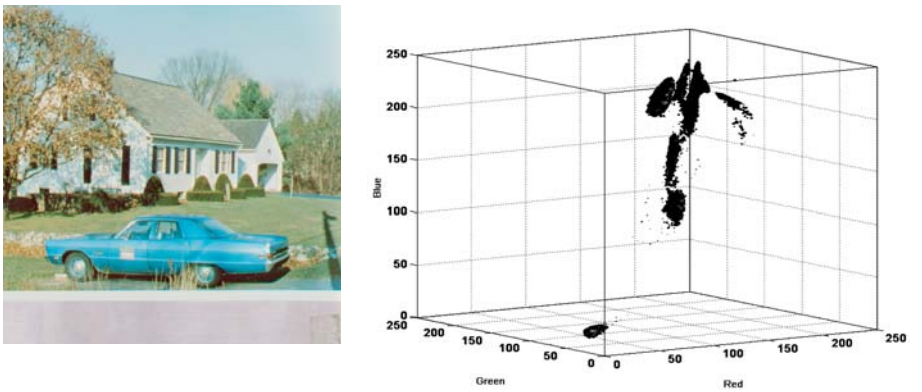

FIG. 4.1. *Left: House and car,* 512×512 *color image. Right: An isosurface of the image's histogram* $p(\vec{x})$.

p_{ij} is a simple probability density function comprised of only two patches (see Figure 4.2). Nevertheless, this p_{ij} is quite similar to probability density functions of real color images, such as the one depicted in Figure 4.1. Therefore, we consider the results exhibited in this section for the above 2-D naive p_{ij} as evidence of our methods' abilities to quantize real multidimensional signals.

From p_{ij}'s structure alone we can deduce that most of the representation levels should be allocated to the larger patch. The fact that the patches are square is completely unimportant; we have defined p_{ij} in this way solely for simplicity.

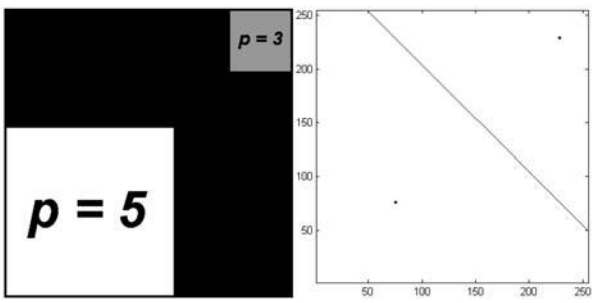

FIG. 4.2. *Left:* p_{ij}. *Right: Globally optimal solution for* $n = 2$ *produced by both LBG and AMR.*

We applied both LBG and AMR to this problem. Each algorithm execution in this section is performed independently of the others, that is, each execution starts from scratch. LBG was used with threshold $1 - 10^{-2}$, that is, Lloyd–Max iterations were

performed at each scale until the ratio of successive distortions ($\mathcal{D}^{new}/\mathcal{D}^{old}$) exceeded $1-10^{-2}$. On the finest scale, we have taken as LBG's initial guess the solution at the iteration in which the ratio of successive distortions exceeded this $1-10^{-2}$ threshold. Thereafter, Lloyd–Max relaxations were performed until the solution reached machine accuracy, that is, until no further improvement could be made. At the stages in which the representation levels are split, LBG adds a new representation level next to each existing one. Our implementation of LBG inserts the new representation levels in a random direction and at a random short distance relative to each of the existing representation levels. An implementation in which the new representation levels are inserted at a constant direction and distance from the existing ones would permit the building of simple probability density functions, for which LBG performs quite poorly.

For $n = 2$ both LBG and our method produce the same solution, namely, one representation level in each patch (see Figure 4.2). Figure 4.3 displays the solutions achieved by AMR and LBG for $n = 4, 8, 16, 32$, and 64. Figure 4.3 implies that LBG cannot always remedy errors made at coarse scales and that coarse scale solutions are not always good initial approximations for the finer scales, an assumption implicitly made by LBG. At the stage when $n = 2$, LBG decided to allocate one representation level to each patch. From that moment on, no representation levels could move from patch to patch since, for any representation level, the center of mass of its decision region is always located within its patch.

TABLE 4.1

256	21	153	157	$2.03 \cdot 10^6$	$2.00 \cdot 10^6$	62	135	$3.49 \cdot 10^6$	$3.31 \cdot 10^6$	1.72	1.66

Table 4.1 compares AMR to LBG. The table displays the running times as well as the distortion values of the solutions attained by AMR and LBG for various n's. The running time is measured in Lloyd–Max iterations to obtain an implementation-independent comparison. Note that the computational cost of both AMR and LBG is dominated by that of the Lloyd–Max relaxations. The last column of Table 4.1 displays the ratio between the AMR distortion and the LBG distortion. It can be seen that, in this example, the first phase of the AMR algorithm (obtaining a guess) already yields a distortion that is close to the final result achieved by applying all three phases. It can also be seen that the complexity of AMR's first phase is $O(\log n)$

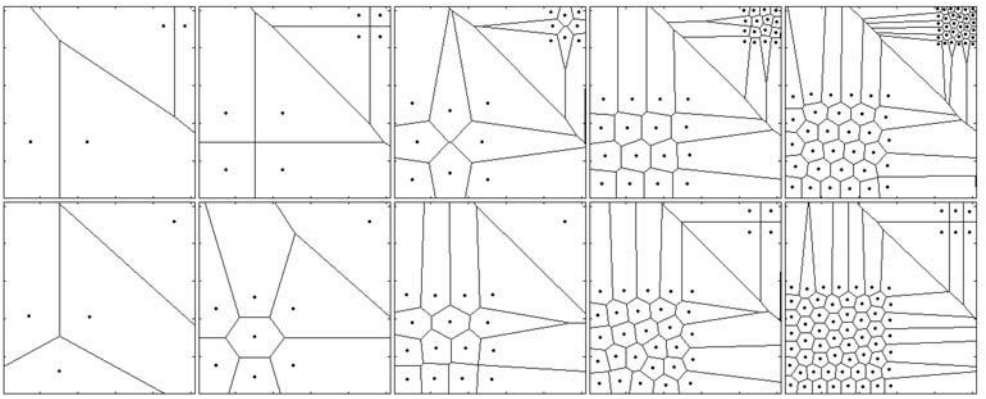

FIG. 4.3. *Quantization results of AMR and LBG applied to the p_{ij} that is defined by* (4.1) *and depicted in Figure* 4.2 *with* $n = 4, 8, 16, 32,$ *and* 64. *Top five plots: LBG. Bottom five plots: AMR.*

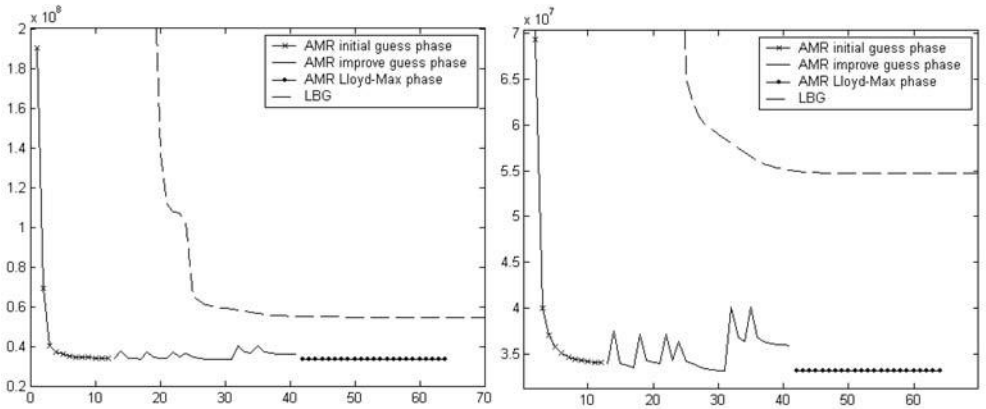

FIG. 4.4. *Distortion versus iterations for the AMR and LBG methods applied to p_{ij} that is defined in* (4.1) *and depicted in Figure* 4.2, *with* $n = 16$. *Note the different scale in each plot. Left: overall look at both processes. LBG's graph is dashed whereas AMR's three phases are solid with x-marks, solid without marks, and solid with point-marks, respectively. Right: close-up plot of the final distortion values.*

Lloyd–Max iterations, as multiplying n by 2 results in only a constant increase in the number of Lloyd–Max iterations.

From Figure 4.3 it is obvious that raising the LBG distortion improvement threshold for any $n > 2$ would not be beneficial. Raising the threshold would yield a solution with lower-valued distortion at each of the coarse scales. LBG implicitly assumes that coarse scale solutions are good initial guesses for the finer scales. Figure 4.3 demonstrates that, for example, when moving from $n = 2$ to $n = 4$, this is not necessarily the case.

In contrast to LBG, where the coarse scales lead us astray, AMR uses the coarse scales effectively to improve the fine scale solution. This is done by correcting errors at the coarse scales that were unrecognizable at the finer scales.

Figure 4.4 displays the distortion versus Lloyd–Max iterations for both LBG and

AMR when $n = 16$. The left-hand plot is an overall view of both processes. At its first stage, AMR begins with a uniform guess and redistributes the representation levels between the patches using the point density–based wealth function (3.3). Note the substantial drop in distortion achieved by the first three iterations. LBG falls short of this result even when run to completion. The phenomenon of 2–3 AMR iterations yielding lower distortion than tens or even hundreds of LBG iterations is quite common when quantizing sparse and patchy data. In general, for this kind of data, AMR may provide better solutions at a fraction of the computation time required by LBG, as LBG's solution at any time before $O(\log(n))$ Lloyd–Max iterations have been performed is quite poor. At its second phase, AMR tries to improve the solution by using (3.5). The purpose of this improvement stage is to traverse other feasible solutions that may have been overlooked at the first phase. Indeed, several improvements are found. Finally, the best solution to date is brought to a local minimum by application of Lloyd–Max iterations (1.5), (1.6). That is, Lloyd–Max iterations are performed until no further improvement is possible. The right-hand plot displays a close-up view of the processes when approaching the local minimum.

Our multiscale improvement method, $Improve-Guess$, was carried out until the first time that no transitions of representation levels were beneficial at any scale.

Table 4.1 demonstrates how the AMR solution may be significantly better than the LBG solution. We now show that the LBG solution may be arbitrarily bad.

OBSERVATION 1. [illegible] ℓ [illegible] $p(\vec{x})$ [illegible] $p(\vec{x})$ [illegible] ℓ [illegible]. Consider a patchy $p(\vec{x})$. Let $p(\vec{x})$ be nonzero at only $\ell+1$ disjoint patches $\{\Omega_i\}_{i=1}^{\ell+1}$. One patch covers a considerable part of the domain Ω and the other ℓ patches cover an arbitrarily small part of Ω. Assume that $p(\vec{x})$ is constant within each patch and that $\int_{\Omega_i} p(\vec{x})dx$ is equal for all $1 \le i \le \ell+1$. That is, all patches have the same mass. Figure 4.5 is an example of such a $p(\vec{x})$ with eight patches that is defined formally in (4.2).

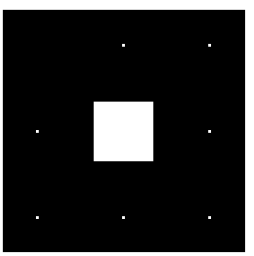

FIG. 4.5. *$p(x, y)$ with eight patches of different sizes but same mass, defined formally in* (4.2).

At the scale $n = \ell+1$, LBG's solution is, at best, comprised of one representation level per patch, which is the optimal solution. For larger n, LBG doubles each representation level. The Lloyd–Max relaxations do not permit representation levels to move from patch to patch, as the center of mass of any decision region always resides within the single patch covered by this region. Therefore, for any $n > \ell$, LBG places approximately $n/(\ell+1)$ representation levels in each patch. Assuming that the ℓ small patches are impulse functions (multiplied by the constant patch mass), the distortion that they contribute is zero once one or more representation levels are allocated to each of them. Therefore, for $n > \ell$, the optimal solution has $n-\ell$ representation levels

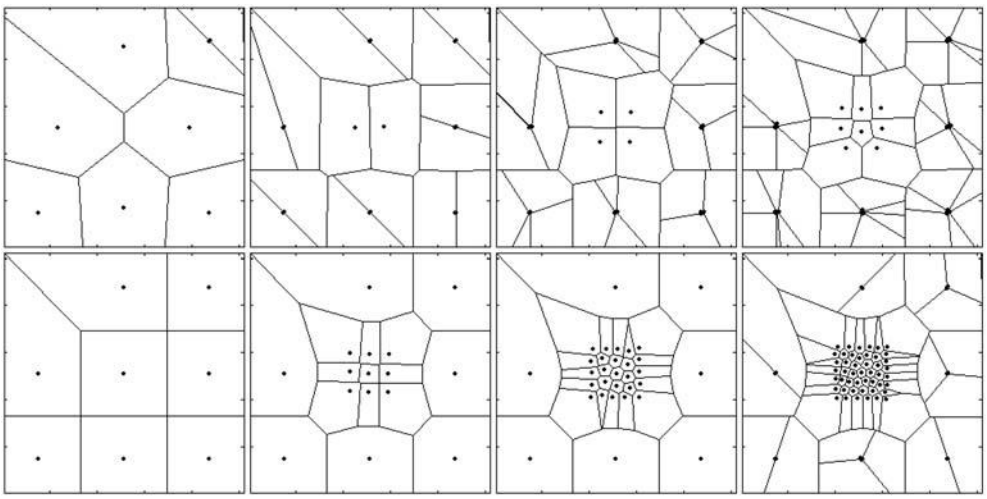

FIG. 4.6. *Quantization results of AMR and LBG on the eight-patch* $p(\vec{x})$ *defined by* (4.2) *and depicted in Figure* 4.5 *with* $n = 8, 16, 32,$ *and* 64. *Top four plots: LBG. Bottom four plots: AMR.*

in the large patch S, whereas LBG has only $n/(\ell+1)$ representation levels there.

It can be shown that, for the large patch, the distortion is roughly proportional to the inverse of the number of representation levels. This implies that the LBG solution is approximately ℓ times worse than the optimal solution.

More generally, for a d-dimensional problem, it can be shown that the distortion of the large patch is proportional to $n^{-2/d}$. Therefore, for a d-dimensional domain, one should choose a $p(\vec{x})$ with $(\ell+1)^{d/2}$ patches ($\ell+1$ in the 2-D case) to realize the stated result. □

Note that even when the ℓ smaller patches are not impulse functions, the optimal solution behaves similarly; that is, the great majority of representation levels are allocated to the larger patch. This is due to the quadratic penalty for input points that are far from their representative (1.1).

To demonstrate that Observation 1 is applicable in practice, consider the probability density function depicted in Figure 4.5. This $p(\vec{x})$ is comprised of one large patch and seven small ones, all of which have the same mass. $p(\vec{x})$ is formally defined as

$$p(x,y) = \begin{cases} 1 & (x,y) \in \{97,98,\ldots,158,159\} \times \{97,98,\ldots,158,159\}, \\ 441 & (x,y) \in \{36,37,38\} \times \{127,128,129\}, \\ 441 & (x,y) \in \{36,37,38\} \times \{218,219,220\}, \\ 441 & (x,y) \in \{127,128,129\} \times \{36,37,38\}, \\ 441 & (x,y) \in \{127,128,129\} \times \{218,219,220\}, \\ 441 & (x,y) \in \{218,219,220\} \times \{36,37,38\}, \\ 441 & (x,y) \in \{218,219,220\} \times \{127,128,129\}, \\ 441 & (x,y) \in \{218,219,220\} \times \{218,219,220\}, \\ 0 & \textit{otherwise}. \end{cases} \tag{4.2}$$

Figure 4.6 presents the quantization results of AMR and LBG on this $p(\vec{x})$ when $n = 8, 16, 32,$ and 64. Note the differences in the number of representation levels per patch for various n in the LBG results. These differences are due to the aforementioned randomized implementation and the independence of each execution. Table 4.2

demonstrates how the AMR solution for this $p(\vec{x})$ is generally between four and six times better than the LBG solution for various n. In general, the larger the number of patches and the smaller the area that each of the smaller patches covers, the worse the LBG solution becomes relative to the optimal solution and the AMR solution. Note that the computation time of the LBG algorithm in this example is quite fast. This is because the Lloyd–Max relaxations mainly affect the representation levels in the large patch. As the Lloyd–Max process's convergence rate is highly dependent on the number of representation levels, and as only a fraction of the original number of representation levels n are active, the LBG algorithm converges faster than for a more general $p(\vec{x})$. The gain of AMR over LBG is not as high as predicted by Observation 1 only because the patches are not impulse functions.

TABLE 4.2

Results of LBG and AMR applied to the eight-patch $p(\vec{x})$ defined by (4.2) *and depicted in Figure* 4.5. *This table's structure is identical to that of Table* 4.1.

5. Conclusions and further discussion. With respect to the multiple local minima problem, we have demonstrated an adaptive multiscale redistribution (AMR) strategy based on the point density function and distortion attributes of an optimal quantizer.[1] This strategy is nonlocal and may determine from a local glance that the solution is not globally optimal, an attribute not shared by the Lloyd–Max method. Our strategy includes a fast method for obtaining an initial guess, as well as a method for improving a guess and bringing it to a local minimum. This strategy may beat LBG by an arbitrary factor, and it may be substantially faster than LBG.

In a previous paper [20] we have presented a multigrid acceleration of the 1-D Lloyd–Max iterative process. That is, given an initial guess, a local minimum near it may be reached at a complexity equivalent to just a few Lloyd–Max iterations. Using the AMR methods for the scalar case may be very powerful. This is because, at the guess improvement stage, we may replace every application of Lloyd–Max iterations (step 2(b)(i) of $Improve-Guess$) with our monotonically convergent multigrid solver [20]. Doing so implies that we need not guess if a transition of a representation level is worthwhile. Instead, we can use our multigrid method to arrive at a local minimum and compare its distortion with the best distortion to date.

An interesting question is whether or not an acceleration scheme similar to that of the scalar quantization problem exists for vector quantization. We believe that a standard multigrid approach, such as the one in [20], cannot work since the problem does not behave "elliptically." A small change in the solution at some point may cause a large change in the solution at some other distant point. For this reason, the Lloyd–Max relaxations do not smooth the distortion/residual, which is a basic demand of multigrid schemes.

We believe that the ideas proposed in this paper may be applied to other interesting representation problems, for example, representing a k-dimensional manifold $S(\vec{x})$ by n points. From these n points, given some interpolation scheme, one can

[1] Implementations are available at http://www.cs.technion.ac.il/~irad/Quantization/index.htm.

compute an approximating manifold $S'(\vec{x})$. The objective is to minimize

$$\int \|S(\vec{x}) - S'(\vec{x})\|^2 d\vec{x}. \tag{5.1}$$

With suitable adaptations, our proposed methods may also be able to deal with other image processing problems such as halftoning, where the average color value of the halftoned image should equal the average color value of the original image at all scales. These problems are currently being researched.

Appendix. The importance of *multiscale* redistribution. Performing redistribution on the finest scale alone yields noteworthy results. Nevertheless, wrapping the redistribution operation within a multiscale framework yields a noticeably better performance, as the following observation implies.

OBSERVATION 2.

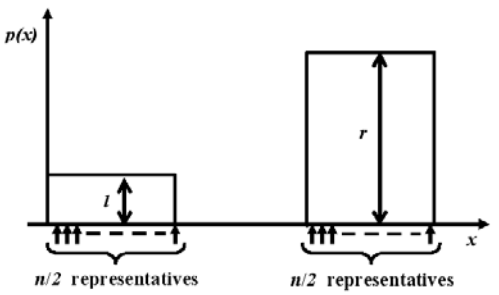

FIG. A.1. *Probability density function $p(x)$ with two patches.*

. Consider the probability density function

$$p(x) = \begin{cases} l : 0 \le x \le 1/3, \\ r : 2/3 \le x \le 1, \\ 0 : otherwise. \end{cases} \tag{A.1}$$

For simplicity, we choose a 1-D $p(x)$. Similar examples exist for any dimension. Assume that $n/2$ representation levels are allocated to each of the two patches of $p(x)$. This configuration is depicted in Figure A.1. For any l and r, uniformly distributing the representation levels in each patch yields a local minimum of the distortion. For any such local minimum, in each patch separately, the wealth of any two decision regions is equal since $p(x)$ is constant. Denote by $\mathcal{W}_l$ and $\mathcal{W}_r$ the wealth of any decision region in the left and right patches, respectively. Evidently, there exist values of l and r such that $\mathcal{W}_l = T/2 - \epsilon$ and $\mathcal{W}_r = -T/2 + \epsilon$, where T is either the chosen threshold in the $Improve - Guess$ algorithm or $T = 1$ for the $Obtain - Guess$ algorithm. Recall that representation levels are redistributed if and only if $\mathcal{W}_l - \mathcal{W}_r > T$. At the finest scale, no redistribution occurs since $\mathcal{W}_l - \mathcal{W}_r = T - 2\epsilon$. At the second finest scale, where Ω is partitioned into, say, $n/2$ aggregates of decision regions, $\mathcal{W}_l = T - 2\epsilon$ and $\mathcal{W}_r = -T + 2\epsilon$, which implies $\mathcal{W}_l - \mathcal{W}_r > T$ for small enough ϵ, and therefore redistribution occurs. In fact, $n/4$ representation levels are transferred from

the left patch of $p(x)$ to the right patch at this scale. For general scale m, where Ω is partitioned into m aggregates of decision regions after approximately $\log_2(m)$ aggregations, the proof is similar. There exist values of l and r such that, at the finest scale, $\mathcal{W}_l = T/(n/m) - \epsilon$ and $\mathcal{W}_r = -T/(n/m) + \epsilon$. All scales finer than m fail to comply with the redistribution criterion $\mathcal{W}_l - \mathcal{W}_r > T$. However, at scale m, for small enough ϵ, the criterion is satisfied and redistribution occurs because the wealth per m-scale aggregate, which consists of n/m representation levels, is equal to n/m times the fine scale wealth. In fact, approximately $m/2$ representation levels are transferred from the left patch of $p(x)$ to the right patch at this scale. □

A MULTILEVEL METHOD FOR IMAGE REGISTRATION*

ELDAD HABER† AND JAN MODERSITZKI†

Abstract. In this paper we introduce a new framework for image registration. Our formulation is based on consistent discretization of the optimization problem coupled with a multigrid solution of the linear system which evolves in a Gauss–Newton iteration. We show that our discretization is h-elliptic independent of parameter choice, and therefore a simple multigrid implementation can be used. To overcome potential large nonlinearities and to further speed up computation, we use a multilevel continuation technique. We demonstrate the efficiency of our method on a realistic highly nonlinear registration problem.

Key words. image registration, multigrid, multilevel, optimization

DOI. 10.1137/040608106

1. Introduction and problem setup. Image registration is one of today's challenging image processing problems. Given a so-called reference R and a so-called template image T, the basic idea is to find a transformation such that a transformed version of the template image becomes to the reference image. Image registration has to be applied whenever images resulting from different times, devices, and/or perspectives need to be compared or integrated; see, e.g., [6, 19] and references therein.

The computation of nonrigid image registration has two main building blocks. The first one is a distance measure $\mathcal{D}$ quantifying distance or similarity of images, and the second one is a regularizer $\mathcal{S}$ which rules out nonreasonable solutions. Note that image registration is an ill-posed problem; see, e.g., [19]. Therefore, regularization is inevitable. A common treatment of the registration problem is based on the following variational approach: Find a transformation $\boldsymbol{u}$ minimizing the joint energy

$$\mathcal{J}^{\alpha}[\boldsymbol{u}] := \mathcal{D}(R, T(\boldsymbol{u})) + \alpha \mathcal{S}(\boldsymbol{u}). \tag{1}$$

Here, $\alpha > 0$ is a regularization parameter that compromises similarity and regularity.

The formulation (1) is common to many ill-posed inverse problems where the data fitting term $\mathcal{D}$ is balanced with a regularization term using the regularization parameter α. Many authors have dealt with the optimal choice of α, using a variety of approaches; see, for example, [14, 24]. If the difference between the images is associated with random noise, then standard methods that are based on the statistics of the noise, such as generalized cross validation (GCV) [9] or χ^2 [21], can be used. However, in image registration the difference between two images (at least in most medical applications) is not associated with random noise. In fact, the difference may be highly structured, and only a trained professional (e.g., a radiologist) could determine the exact amount of regularization needed. Therefore, we prefer to provide a sequence of registered image pairs for various α's and leave the final choice of an optimal α to a trained professional.

In general, the optimization problem (1) cannot be solved analytically. Thus, numerical schemes and appropriate discretizations are required. Typically, a discretization leads to a finite dimensional nonlinear problem, where the number of unknowns can be large. For example, the discrete registration problem for two $128 \times 128 \times 64$ MRI scans results in a nonlinear system of equations in about $3 \cdot 10^6$ unknowns. Thus, highly efficient algorithms are required in order to perform the registration in a reasonable amount of time. This applies, in particular, if one is interested not only in a solution for a fixed α but in a sequence of solutions for a variety of different α's. Furthermore, since we want our codes to run in a clinical setting, we require only modest computational hardware.

There are two main approaches for the discretization of the registration problem (1). In the first, the [illegible] approach, one forms the objective function and then differentiates to obtain the continuous Euler–Lagrange equations, which are finally discretized and solved numerically; see, e.g., [7, 15, 19]. The second approach is the [illegible] approach. Here, one directly discretizes the problem and then solves a finite (but typically high) dimensional optimization problem; see, e.g., [13]. The advantage of the latter approach is that standard optimization methods can be used. We prefer the discretize-optimize approach; however, in order to take advantage of efficient optimization techniques, all parts of the discrete problem need to be continuously differentiable. We discuss the implications and advantages of this necessity in the paper.

To gain additional computational efficiency and obtain a scalable algorithm, one can either use a full approximation multigrid scheme (FAS) or a multilevel Newton-type scheme with an efficient solver for the linearized systems of equations. In this paper we propose a multilevel inexact Gauss–Newton scheme combined with a multigrid solver for a computation of a numerical solution of (1). Although no proof exists, the latter approach has an efficiency similar to that of FAS [23, p. 154], but it is much more modular. Particularly, the linear solver is decoupled from the optimization strategy. Therefore, the code can be modified easily to deal with any differentiable distance measure and/or regularizer. However, for the sake of simplicity, we focus on the so-called [illegible] (SSD) as a distance measure $\mathcal{D}$ and the elastic potential as a regularizer $\mathcal{S}$:

$$\mathcal{D}[\boldsymbol{u}] = \frac{1}{2}\int_\Omega (T(\boldsymbol{x}+\boldsymbol{u}(\boldsymbol{x})) - R(\boldsymbol{x}))^2 \, d\boldsymbol{x}, \tag{2a}$$

$$\begin{aligned}\mathcal{S}[\boldsymbol{u}] &= \int_\Omega \langle \mathcal{B}\boldsymbol{u}, \mathcal{B}\boldsymbol{u}\rangle \, d\boldsymbol{x} \\ &:= \frac{1}{2}\left\| \begin{pmatrix} \sqrt{\lambda+\mu}\,\nabla\cdot & & \\ \sqrt{\mu}\,\nabla & & \\ & \ddots & \\ & & \sqrt{\mu}\,\nabla \end{pmatrix} \begin{pmatrix} \boldsymbol{u}_1 \\ \vdots \\ \boldsymbol{u}_d \end{pmatrix} \right\|^2_{L_2(\Omega)} \\ &= \int_\Omega \frac{\lambda+\mu}{2} \| \nabla\cdot \boldsymbol{u}\|^2 + \frac{\mu}{2}\sum_{i=1}^{d} \| \nabla \boldsymbol{u}_i\|^2 \, d\boldsymbol{x},\end{aligned} \tag{2b}$$

where $\Omega = (0,1)^d$ is the registration domain and λ and μ are the Lamé constants.

Our discretization is based on the weak form of the problem (1) which naturally leads to staggered grid discretization. To the best of our knowledge, staggered grid discretization was introduced into imaging in [13]. In this paper, we prove the h-ellipticity of the discretization for the elastic potential, independent of the problem parameters. As has already been shown in [13], this discretization is also stable for pointwise volume preserving constraints.

Our work relates to the work of Henn and Witsch [15], Clarenz, Droske, and Rumpf [7], and Kalmoun and Rüde [18]. In [15], an FAS based on the discretized optimality conditions for the continuous problem is presented. In [7], a diffusive rather than an elastic regularizer is used. A d-linear interpolation scheme is used to compute the deformed template in [7, 15, 18]. Therefore, the objective function is not continuously differentiable, and this may lead to failure of standard optimization techniques. In [18] a multigrid method is developed for the related optical flow problem but with the diffusive regularizer.

This paper is organized as follows. In section 2, we discuss the discretization of the registration problem (1). Our optimization approach, which is based on a Gauss–Newton-type scheme (cf., e.g., [20]), is discussed in section 3. In section 4, we propose a multigrid method for a solution of the linearized problems. Using a local mode analysis we show that our discretization is particularly amenable to multigrid methods and suggest appropriate multigrid treatment. In section 5, we combine our nonlinear iteration with a multilevel continuation method. Finally, in section 6, we present numerical examples that demonstrate the effectiveness of our algorithm.

2. Discretization. Choosing a stable discretization method for a system of partial differential equations with mixed derivatives is a delicate matter. Here, we use staggered grids (cf. Figure 1), which are very common for stable discretizations of fluid flow (see, e.g., [8]) and electromagnetics (see, e.g., [11, 27]), where operators such as the gradient, curl, and divergence are discretized. It is also well known that staggered grids are tightly connected to mixed finite element methods which are commonly used for elasticity [3].

In this section we briefly summarize the discretization we use. Further discussion and details are given in [13].

2.1. Discretizing $\boldsymbol{u}$. We assume that our discrete images have $m_1 \times \cdots \times m_d$ pixels, where $d = 2, 3$ is the image dimensionality. For ease of presentation, we also assume that each pixel is square or cubic, where each side has length h. In our description we allow for half-step indices. As usual in image processing, we identify pixels/voxels with cell centered grid points $x_{j,k,\ell}$, which are therefore labeled with full integer indices. Given a pixel/voxel $x_{j,k,\ell}$, their faces are numbered with a half index, $x_{j\pm\frac{1}{2},k,\ell}$, $x_{j,k\pm\frac{1}{2},\ell}$, and $x_{j,k,\ell\pm\frac{1}{2}}$, and we discretize the ith component u^i of $\boldsymbol{u}$ on the ith face for every pixel/voxel. With some abuse of notation, we denote the discrete analogue of the continuous vector field by $\boldsymbol{u} = (u^1, \ldots, u^d)^\top$, where u^i denotes the grid function which is approximated on the face staggered grid.

If needed, the derivatives $\partial_j u^k$ are approximated by the short (central) differences,

$$\partial_j u^k \approx \partial_j^h u^k := \frac{1}{h}\Big(u^k_{\ldots,i_j+\frac{1}{2},\ldots} - u^k_{\ldots,i_j-\frac{1}{2},\ldots}\Big). \tag{3}$$

Note that no boundary conditions are needed to approximate derivatives in the normal directions ($\partial_j u^j$). For the tangential directions ($\partial_j u^k$, $j \neq k$) we imposed Neumann boundary conditions.

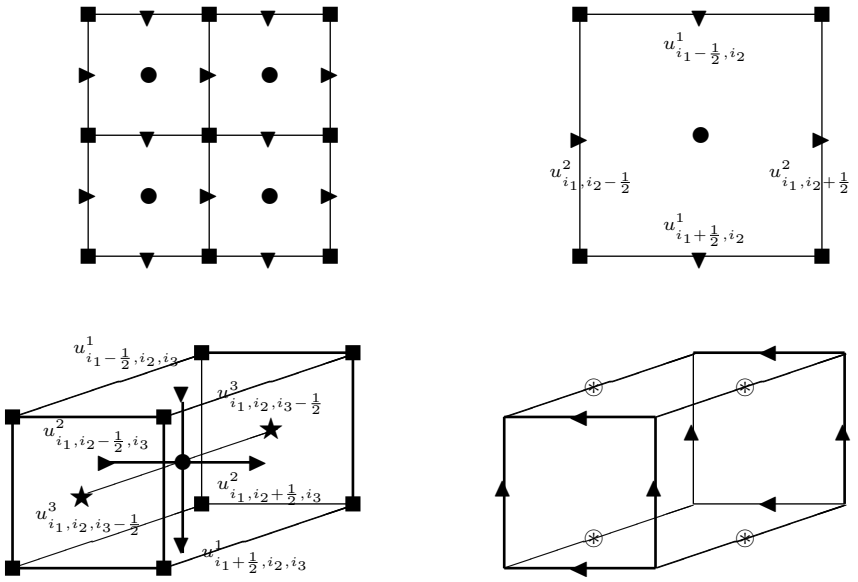

FIG. 1. *Staggered grids for dimensions $d = 2, 3$, nodal ■, cell centered •, face staggered grids (▼ in x_1-, ► in x_2-, and ★ in x_3-direction), and edge staggered grids (▲ in x_1-, ◄ in x_2-, and ⊛ in x_3-direction). Top left: $d = 2$, four pixels. Top right: $d = 2$ pixel (i_1, i_2) with grids. Bottom left: $d = 3$, voxel (i_1, i_2, i_3) with face staggered grids and positions of u^1, u^2, u^3. Bottom right: $d = 3$, edge staggered grids.*

2.2. Discretizing $\mathcal{S}$. Since many regularizers are phrased in terms of the more complex differential operators gradient ∇ and divergence $\nabla\cdot$, we introduce the notation ∇^h_j and $\nabla^h\cdot$ for the discrete analogues,

$$\nabla^h_j\, u^j = (\partial^h_1 u^j, \dots, \partial^h_d u^j)^\top \quad \text{and} \quad \nabla^h \cdot \boldsymbol{u} = \sum \partial^h_j u^j. \tag{4}$$

Using these discrete analogues the elastic potential $\mathcal{S}$ (2b) is discretized as

$$\mathcal{S}^h(\boldsymbol{u}) = \|\boldsymbol{B}\boldsymbol{u}\|_2^2 := \frac{\lambda+\mu}{2}\| \nabla^h \cdot \boldsymbol{u}\|^2 + \frac{\mu}{2}\sum_{i=1}^{d} \| \nabla^h_j \boldsymbol{u}_i\|^2. \tag{5}$$

In the course of the registration process we require derivatives. Upon differentiation of the regularizer we obtain the Navier–Lamé operator

$$\mathcal{S}^h_{\boldsymbol{u}}(\boldsymbol{u}) = (\lambda+\mu)(\nabla^h\cdot)^\top \nabla^h \cdot \boldsymbol{u} - \mu\Delta_h \boldsymbol{u} =: \boldsymbol{A}\boldsymbol{u}, \tag{6}$$

where Δ_h is the usual seven points discrete vector Laplacian. Note that the approach in [7] is diffusion based (i.e., setting $\lambda = -\mu$ in (2b) and (5)), such that coupling terms vanishes. In contrast to [15], where the strong form given by the product $\mathcal{B}^*\mathcal{B}$ is discretized, we discretize $\mathcal{B}$ and build the discrete product $\boldsymbol{A} := \boldsymbol{B}^\top \boldsymbol{B}$. A discretization of the product $\mathcal{S}^h_{\boldsymbol{u}} \approx \mathcal{B}^*\mathcal{B}$ may not be directly linked to a discrete objective function of the form $\int(\mathcal{B}\boldsymbol{u})^2 d\boldsymbol{x}$. Thus our discretization is a mimetic discretization (see [16]).

The advantage of this approach is that the derivative $\mathcal{S}_{\boldsymbol{u}}^h$ is automatically the derivative of the discrete function $\mathcal{S}^h$. Moreover, boundary conditions are naturally related to those of the operator $\mathcal{B}$.

2.3. Discretizing T and R. If we require a continuously differentiable objective function, we need a continuous image model. For noisy images we use a smoothing B-spline to approximate the images where the smoothing parameter is chosen using the GCV [9, 22]. For data interpolation using B-splines see [25]. Since the grid is regular, we can quickly evaluate the spline coefficients using a cosine transform. The continuous smooth approximation is denoted by T^{spline}.

We are looking for a fast and efficient optimization scheme, and therefore differentiability does play a key role. Thus, as previously discussed in [22], although computationally superior, d-linear image approximations cannot be used, since they are not continuously differentiable. In our implementation we use a cubic B-spline approximation. For further discussion on the effects of higher or lower order B-spline interpolation on the quality of the registration we refer to [22].

Given the staggered grid representation of $\boldsymbol{u}$ we use averaging operators P_j for the transfer to the cell centered positions, and we set

$$\begin{aligned}(P_j u^j)_{\dots,i_j,\dots} &= \frac{1}{2}\Big(u^j_{\dots,i_j+\frac{1}{2},\dots} + u^j_{\dots,i_j-\frac{1}{2},\dots}\Big)\\ T(\boldsymbol{u}) &:= T^{\text{spline}}(x^1 + P_1 u^1, \dots, x^d + P_d u^d);\end{aligned}$$

see [13] for details. We denote the Jacobian of T by

$$T_{\boldsymbol{u}} := \frac{\partial T}{\partial \boldsymbol{u}}(\boldsymbol{u}) = (\operatorname{diag}(P_1^\top \partial_1 T), \dots, \operatorname{diag}(P_d^\top \partial_d T)), \tag{7}$$

where the partial derivatives $\partial_j T$ are evaluated at the spatial positions $(x^1 + P_1 u^1, \dots, x^d + P_d u^d)$. Note that, using a spline approximation for T, $T_{\boldsymbol{u}}$ is a sparse matrix with only four nonzero diagonals.

2.4. Discretizing $\mathcal{D}$. Our discretization of SSD (2a) is straightforward:

$$\boldsymbol{D}(\boldsymbol{u}) := \frac{1}{2}\|T(\boldsymbol{u}) - R\|_2^2 \quad \text{and thus} \quad \boldsymbol{D}_{\boldsymbol{u}}(\boldsymbol{u}) = T_{\boldsymbol{u}}(\boldsymbol{u})^\top (T(\boldsymbol{u}) - R).$$

3. Optimization. The discretized analogue of the image registration problem (1) for fixed α reads as follows:

$$\text{find} \quad \boldsymbol{u} \quad \text{such that} \quad \boldsymbol{J}^\alpha(\boldsymbol{u}) := \boldsymbol{D}(\boldsymbol{u}) + \alpha \boldsymbol{S}(\boldsymbol{u}) = \min. \tag{8}$$

To solve this problem numerically we use an inexact Gauss–Newton method; cf., e.g., [20].

Starting with the initial guess $\boldsymbol{u}$, at each step we compute the gradient $\boldsymbol{J}_{\boldsymbol{u}}^\alpha$ of (8)

$$\boldsymbol{J}_{\boldsymbol{u}}^\alpha = T_{\boldsymbol{u}}(\boldsymbol{u})^\top (T(\boldsymbol{x} + \boldsymbol{u}) - R(\boldsymbol{x})) + \alpha \boldsymbol{A}\boldsymbol{u} \tag{9}$$

and approximately solve the system of linear equations

$$\boldsymbol{H}\delta_{\boldsymbol{u}} = -\boldsymbol{J}_{\boldsymbol{u}}^\alpha, \tag{10}$$

using a multigrid technique which is described in section 4. Here $\boldsymbol{H}$ is an approximation to the Hessian,

$$\boldsymbol{H} = \boldsymbol{M} + \alpha \boldsymbol{A}, \tag{11}$$

and $\boldsymbol{M}$ is an approximation to $T_{\boldsymbol{u}}(\boldsymbol{u})^\top T_{\boldsymbol{u}}(\boldsymbol{u})$. For example, for $d = 3$, we have

$$T_{\boldsymbol{u}}(\boldsymbol{u})^\top T_{\boldsymbol{u}}(\boldsymbol{u}) = \begin{pmatrix} (\partial_1 T)^2 & (\partial_1 T)(\partial_2 T) & (\partial_1 T)(\partial_3 T) \\ (\partial_1 T)(\partial_2 T) & (\partial_2 T)^2 & (\partial_2 T)(\partial_3 T) \\ (\partial_1 T)(\partial_3 T) & (\partial_2 T)(\partial_3 T) & (\partial_3 T)^2 \end{pmatrix}.$$

Although from an optimization standpoint it is better to use the matrix $\boldsymbol{M} = T_{\boldsymbol{u}}(\boldsymbol{u})^\top T_{\boldsymbol{u}}(\boldsymbol{u})$, the usage of this matrix results in a more complicated multigrid solver. As discussed in [18] a simple restriction cannot be used effectively, and an operator-induced interpolation is needed. Such interpolation requires more memory and is slower overall than the simple geometric multigrid scheme. In order to have a simple multigrid scheme, which uses less storage, we approximated this matrix by

$$\boldsymbol{M} = \begin{pmatrix} (\partial_1 T)^2 & 0 & 0 \\ 0 & (\partial_2 T)^2 & 0 \\ 0 & 0 & (\partial_3 T)^2 \end{pmatrix}.$$

Such a choice leads to linear convergence of the optimization scheme even if the problem has a low residual. Nevertheless, it is similar to other Newton multigrid methods [23], since each iteration can be done quickly; then our approach tends to be faster than the full Gauss–Newton approach.

The deformation is updated by $\boldsymbol{u} \leftarrow \boldsymbol{u} + \gamma\delta_{\boldsymbol{u}}$, where γ is chosen according to an Armijo line search, and the process is repeated until convergence, i.e., $\|\boldsymbol{u} - \boldsymbol{u}_{\text{old}}\| \leq \text{tol}$. The algorithm is summarized in Algorithm 1.

ALGORITHM 1. Gauss–Newton method for image registration:
$\boldsymbol{u} \leftarrow \text{GNIR}(\alpha, \boldsymbol{u})$;

```
while true do
  compute J_u^α and H;
  approximately solve H δ_u = −J_u^α;
  if ‖δ_u‖ < tol then
    break;
  end if
  using a line search set u ← u + γδ_u
end while
```

3.1. Continuation in α. As discussed in the introduction, the optimal value of the regularization parameter α is in general unknown a priori. In order to estimate a reasonable α, we follow the strategy suggested in [12]. Starting with a large α_0, we compute a sequence of solutions $\boldsymbol{u}^{\alpha_j}$, where $\alpha_{j+1} < \alpha_j$. This sequence can be viewed as a continuation with respect to the regularization parameter α.

For a large regularization parameter the registration problem is almost quadratic, and therefore its solution requires only a few iterations using a Newton-type optimization technique. Let $j = 0$; starting with α_j, we compute $d_j := \boldsymbol{D}(\boldsymbol{u}^{\alpha_j})$ and expect at least the solution $\boldsymbol{u}^{\alpha_0}$ to under-fit the data. We use $\boldsymbol{u}^{\alpha_j}$ as an excellent starting guess for the computation of the solution of the registration problem for α_{j+1}. We stop if a solution $\boldsymbol{u}^{\alpha_j}$ becomes too irregular. Regularity has to be monitored by a trained professional. Technically, the regularity parameter of our code is given by c. The algorithm is summarized in Algorithm 2.

ALGORITHM 2. Continuation in α: $[\boldsymbol{u}, \alpha] \leftarrow \text{continuation}(\boldsymbol{u}, \alpha, c)$

```
set u_0 ← u, choose η < 1;
while true do
  solve (1) using Alg. 1: u ← GNIR(α, u);
  if D(u) < c then
    break;
  end if
  relax the regularization parameter: α ← ηα;
end while
```

4. A multigrid solution of the linear systems. The challenging part within the nonlinear optimization is the solution of the linear systems. Each system can be very large and is strongly coupled, but it has a few characteristics which are particularly amenable to multigrid methods. We now discuss a multigrid method for the solution of the linear system. General comments on smoothing, prolongation, restriction, and coarse grid solution are given in [23].

4.1. *h*-ellipticity. To show that the discrete equations (10) are amenable to multigrid methods, we first analyze them by local Fourier analysis (LFA) and show that the system is h-elliptic. It is well known (see, e.g., [23, p. 121–129]) that h-ellipticity is crucial for any multigrid method to be effective. For simplicity, we perform the analysis in two dimensions, but it can be directly generalized into three dimensions.

Recall that the Hessian for the unconstrained optimization problem reads as

$$\boldsymbol{H} = \alpha \boldsymbol{A} + \boldsymbol{M},$$

where $\boldsymbol{M}$ is a nonnegative diagonal matrix. An LFA with freezing coefficients takes the worst-case scenario into account, i.e., $\boldsymbol{M} = \boldsymbol{0}$. Therefore, we need to study the matrix $\boldsymbol{A}$ alone, which is a discretization of the Navier–Lamé operator

$$\begin{aligned}\mathcal{A} = \mathcal{B}^*\mathcal{B} &:= -\mu\Delta - (\lambda+\mu)\nabla\nabla\cdot \\ &= \begin{pmatrix} (2\mu+\lambda)\partial_{x_1,x_1} + \mu\partial_{x_2,x_2} & (\lambda+\mu)\partial_{x_1,x_2} \\ (\lambda+\mu)\partial_{x_1,x_2} & \mu\partial_{x_1,x_1} + (2\mu+\lambda)\partial_{x_2,x_2} \end{pmatrix},\end{aligned}$$

where the so-called Lamé constants λ and μ reflect material properties. Staggered grid discretization leads to the following four stencils for the four parts of the operator (see [23, p. 302] for notation):

$$\left.\begin{aligned} S^{1,1} &= \begin{pmatrix} 0 & -a & 0 \\ -b & 2(a+b) & -b \\ 0 & -a & 0 \end{pmatrix}, & S^{1,2} &= c\begin{pmatrix} 1 & -1 \\ -1 & 1 \end{pmatrix}, \\ S^{2,1} &= (S^{1,2})^\top, & S^{2,2} &= (S^{1,1})^\top, \end{aligned}\right\} \tag{12}$$

abbreviating $a = (2\mu+\lambda)$, $b = \mu$, and $c = \lambda+\mu$.

Applying the discretized operators $\boldsymbol{A}_h$ to a grid function $\chi(\boldsymbol{x}, \boldsymbol{\theta}) = e^{\frac{i}{h}\boldsymbol{\theta}^\top \boldsymbol{x}}$, we obtain the symbols of our discretized operators:

$$\widetilde{A}_h(\boldsymbol{\theta}) = \begin{pmatrix} 2aw_1 + 2bw_2 & -4c\sin\frac{\theta_1}{2}\sin\frac{\theta_2}{2} \\ -4c\sin\frac{\theta_1}{2}\sin\frac{\theta_2}{2} & 2bw_1 + 2aw_2 \end{pmatrix},$$

where $w_j := 1 - \cos\theta_j = 2\sin^2\frac{\theta_j}{2}$. Its determinant is given by

$$\begin{aligned} d(\boldsymbol{\theta}) = \widetilde{d}(\boldsymbol{w}) &= 4abw_1^2 + 4abw_2^2 + 4(a^2+b^2)w_1w_2 - 4c^2w_1w_2 \\ &= 4ab(w_1+w_2)^2. \end{aligned} \tag{13}$$

THEOREM 4.1. [illegible] (12)

$$E_h(\boldsymbol{A}_h) = \frac{1}{4},$$

[illegible] independent [illegible] Following [23, section 8.3.2],

$$E_h(\boldsymbol{A}_h) := \frac{\min\{|\det \widetilde{A}_h| :\ \theta \in T^{\text{high}}\}}{\max\{|\det \widetilde{A}_h| :\ -\pi < \theta_j \le \pi\}}.$$

From (13), we see that the min and max are independent of λ and μ:

$$\begin{aligned} \max\{d(\boldsymbol{\theta}) :\ -\pi < \theta_j \le \pi\} &= \max\{\widetilde{d}(\boldsymbol{w}) :\ 0 \le w_j \le 1\} \\ &= \widetilde{d}(1,1) = 16ab = 16\mu(2\mu+\lambda), \\ \min\{d(\boldsymbol{\theta}) :\ \theta \in T^{\text{high}}\} &= \min\left\{\widetilde{d}(\boldsymbol{w}) :\ \frac{1}{2} \le |w_j| \le 1\right\} \\ &= \widetilde{d}\left(\frac{1}{2},\frac{1}{2}\right) = 4ab = 4\mu(2\mu+\lambda). \qquad \square \end{aligned}$$

[illegible] 4.2. The above theorem is remarkable because as the ratio λ/μ becomes larger, the system becomes more ill-conditioned. Nevertheless, the theorem suggests that an appropriate multigrid implementation works well regardless of that ratio. Note also that other iterative techniques (such as conjugate gradient) are very sensitive to this ratio while our multigrid method is not.

4.2. Smoothing. The h-ellipticity of our discretization (independent of choices of the Lamé constants λ and μ) guaranties that, for example, a Kaczmarz relaxation has smoothing properties. Here we have implemented a damped Jacobi smoother with damping parameter of 2/3. Since we want our code to run on modest computational architecture and use only a small amount of memory, our implementation does not generate the matrix and only matrix vector products are calculated.

4.3. Prolongation and restriction. To fulfill the relation between the order of the differential operator and the sum of the orders of prolongation and restriction, we use linear interpolation for prolongation and its transpose for the restriction. This is similar to prolongation and restriction used in computational fluid dynamics. For an elaborate discussion on these operations on a staggered grid see [26, p. 253].

4.4. Coarse grid operator. Although it is possible to use a Galerkin coarse grid operator for building the coarse grid system $\boldsymbol{A}_H$, a straightforward implementation requires either additional memory or additional computations. For problems with uniform and structured grids, one can use rediscretization to get a faster implementation. However, since rediscretization cannot be applied to the diagonal matrix $\boldsymbol{M}_h$, we choose the following approach leading to a diagonal $\boldsymbol{M}_H$. In the first stage we

extract the diagonal entries of $\boldsymbol{M}_h$; this corresponds to a vector with the same dimensions of $\boldsymbol{u}_h$. Second, we generate the diagonal matrix $\boldsymbol{M}_H$ by restricting this vector using the same restriction operator designed for $\boldsymbol{u}_h$, and set the diagonal elements of $\boldsymbol{M}_H$ to the restricted values.

4.5. Multigrid cycles. The above components are linked together to a V- or a W-cycle. In our implementation we use only a single V-cycle for each nonlinear iteration. As we show in the numerical experiments, a $V(3,1)$-cycle is very effective and decreases the residual in one or two orders of magnitude.

5. Multilevel continuation. Image registration can be highly nonlinear, and therefore, one may require many iterations to achieve a solution. An important method to save computational work and to deal with nonlinearities is to use a multilevel continuation. Multilevel continuation is well established for optimization problems and systems of nonlinear equations; see, e.g., [1, 2]. However, in image registration it has an additional advantage. Similar to [10, 4], we use the multilevel approach to efficiently identify the relevant range of α's. Thus, our multilevel approach uses continuation in both the grid and the regularization parameter. Note that even for approaches where the images may not be smooth, the desired solution $\boldsymbol{u}^\alpha$ is smooth. Therefore, multilevel methods provide an effective tool for the continuation problem.

Given an initial upper bound C for the image distance, using a secant method, we compute a parameter α_C, such that

$$\mathcal{D}(\boldsymbol{u}^{\alpha_C}) \approx C. \tag{14}$$

After α_C is computed, we use Algorithm 2 on the fine grid to obtain a sequence of solution $\boldsymbol{u}^\alpha$, where $c \leq \mathcal{D}(\boldsymbol{u}^\alpha) \leq C$. We summarize the multilevel algorithm in Algorithm 3.

ALGORITHM 3. Multilevel image registration: $\boldsymbol{u} \leftarrow \text{MLIR}$

```
choose u on the coarsest grid;
while true do
  solve the registration problem u = GNIR(u, α); cf. Alg. 1;
  if |D(u) − C| ≥ tol then
    adjust α using a secant method;
  end if
  if on finest grid then
    return;
  end if
  prolongate u to the finer grid: u ← prolongate(u);
end while
```

6. Numerical examples. In this section we perform numerical experiments that demonstrate the effectiveness of our algorithm. We present a registration of three-dimensional MRI scans of a human knee (images provided by Thomas Netsch, Philips Medical Systems, Hamburg, Germany). The problem is known to be hard because large nonlinear deformations are needed in order to perform the registration; see also [17].

As is apparent from Figure 2, the reference shows the knee in an almost straight position, and the template shows the knee in a bent position. The deformation is thus

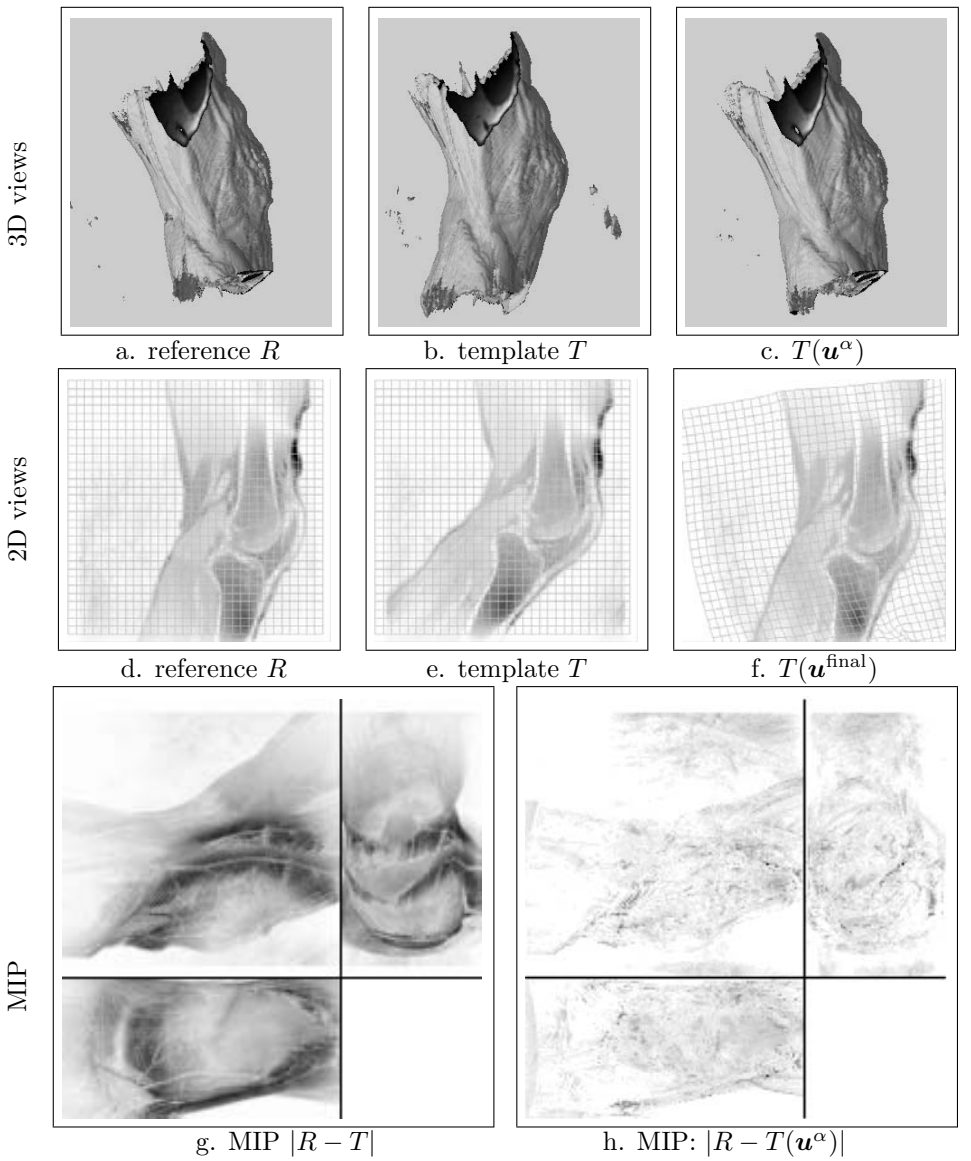

FIG. 2. *Registration results for two* $128\times128\times64$ *MRI scans of a human knee; three-dimensional views of* R (a), T (b), *and* $T(\boldsymbol{u}^{\alpha})$ (c)*; the generic slice* 40 *with grid for* R (d), T (e), *and* $T(\boldsymbol{u}^{\alpha})$ (f)*; maximum intensity projections for* $|R-T|$ (g) *and* $|R-T(\boldsymbol{u}^{\alpha})|$ (h).

expected to be highly nonlinear. To clarify the example, we divide this section into two parts. In the first part we go over the computational details, while in the second we discuss the results from an imaging point of view.

As common to many other registration algorithms we use a two-phase registration (see [19]). In the first phase a multilevel linear preregistration is done, followed by a second-phase multilevel nonlinear registration. The linear registration managed to reduce the image distance to 50.1%, and the rest was done using our nonlinear registration.

TABLE 1
Reductions in the SSD (compared with the initial SSD in %), and iterations (in #) for a decreasing α (image size $128 \times 128 \times 64$).

α	Iter	SSD
$8.5 \cdot 10^{-4}$	1	15.6%
$4.2 \cdot 10^{-4}$	1	12.2%
$2.1 \cdot 10^{-4}$	2	10.9%
$1.0 \cdot 10^{-4}$	2	10.1%

All computations are performed using MATLAB 6.1 on a 2.2GHz laptop with 1GB of RAM. The overall time for a registration ($\alpha = 10^{-3}$) was about 118 minutes, including the computation for the B-spline coefficients ($\approx$ 11 minutes). Since the signal-to-noise ratio in the images is high, for the computation of the B-spline we assume that the images do not contain any noise (thus the B-splines interpolate the images). In our computations, about one third of the time is needed for the linear part, and about two thirds is needed for the nonlinear part. Within the nonlinear part, 66% are needed for the computation of $T(\boldsymbol{u})$ and $T_{\boldsymbol{u}}(\boldsymbol{u})$, and 24% are needed to solve the linear system. An overview with respect to levels is presented in Table 2.

6.1. Computational details. We present three types of experiments. In our first example, we run the algorithm precisely as described in this paper (Algorithm 3); i.e., starting on the coarse grid we compute an initial α and adjust it by using the continuation techniques described in section 5. In order to present comparable multigrid convergence rates, we also present results for fixed values of α in our second example. Finally, in the third set of experiments we test the sensitivity of our multigrid algorithm to the elasticity parameters λ and μ. Although all image registration algorithms known to us fix this ratio at roughly 1, we experiment with a high ratio which challenges our multigrid method.

6.1.1. Continuation in grid and $\boldsymbol{\alpha}$. In our first numerical experiment we set $\mu = \lambda = 1$ and the constant C in Algorithm 3 to 0.2. Using Algorithm 3 we solve the problem, and this yields α which is $1.71 \cdot 10^{-3}$ (performance and results for $\alpha = 1.71 \cdot 10^{-3}$ and $\alpha = 10^{-3}$ are indistinguishable).

We then follow Algorithm 2, gradually reducing the regularization parameter to 10^{-4} by solving the problem for 4 different α's. For each regularization parameter we use the solution for the previous α as described in Algorithm 2. The number of iterations for each α and the SSD is recorded in Table 1. We observe both the images and the distorted grid for each solution. We stop the iteration at $1.0 \cdot 10^{-4}$ because we observe that the grid is highly distorted. The solution converges quickly (1 or 2 steps) for each new regularization parameter when starting from the solution of the previous regularization parameter. This demonstrates the importance of continuation in α for the robustness of the algorithm.

6.1.2. Sensitivity of the algorithm to the regularization parameter. In our second experiment we test the effect of different regularization parameters on the efficiency of our algorithm. We run our code with the (fixed) regularization parameters $\alpha = 10^{-2}, 10^{-3}, 10^{-4}$. The results of these experiment are documented in Table 2.

As common to many inverse problems, convergence of the optimization algorithm slows down as the regularization parameter decreases (see [12]). This implies that starting with an arbitrary guess on the fine grid may result in many more expensive iterations. Nevertheless, using a multilevel continuation approach, we are able to

TABLE 2
Reductions in the SSD (compared with the initial SSD in %), and iterations (in #) for the multilevel elastic registration; image size is $n^3/2$.

Level	n	Iterations			SSD		
		$\alpha = 10^{-4}$	$\alpha = 10^{-3}$	$\alpha = 10^{-2}$	$\alpha = 10^{-4}$	$\alpha = 10^{-3}$	$\alpha = 10^{-2}$
5	8	21	13	10	26.1%	17.2%	11.3%
4	16	18	16	12	25.9%	17.8%	10.9%
3	32	12	9	7	25.5%	17.9%	10.7%
2	64	9	8	6	25.3%	17.2%	10.2%
1	128	7	6	5	25.3%	17.2%	10.1%

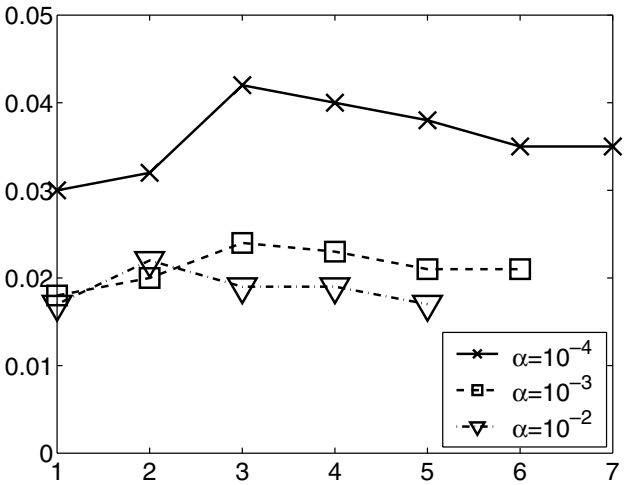

FIG. 3. *Convergence rate for each linear iteration versus iteration for $\alpha = 10^{-2}, 10^{-3}, 10^{-4}$; see also Table 2.*

quickly converge on the finest grid because we have a good starting guess which is obtained on coarser grids. This demonstrates the importance of multilevel continuation.

To observe the effectiveness of our multigrid algorithm solver we record the reduction of the residual for each of the linearized Gauss–Newton iterations on the finest grid. Note that for each iteration we have a different approximation to the Hessian characterized by the different $\boldsymbol{M}$'s. In our experiment, the multigrid solver was very effective, and after only a single $V(3,1)$-cycle our residual is decreased by approximately two orders of magnitudes. The convergence history is plotted in Figure 3.

The convergence properties of the linear iteration was only mildly influenced by the decreasing regularization parameter. This observation is similar to other multigrid methods for inverse problems [5].

6.1.3. Sensitivity of the algorithm to the ratio μ/λ. In the previous experiments, common to many other image registration algorithms [15], we used the ratio $\mu/\lambda = 1$. However, as Theorem 1 shows, the h-ellipticity of our discretized system is 0.25 independent of this choice, which implies in particular that the multigrid iteration should not be affected by this ratio. To put this theory to a test, we vary the ratio μ/λ, starting at 10 to 10^{-3}. Note that for the latter, the regularization operator is close to $\| \nabla \cdot \boldsymbol{u}\|^2$, which is the incompressible limit. However, we emphasize that

TABLE 3
Number of iterations and average residual reduction for different ratios μ/λ.

Ratio	10^1	10^0	10^{-1}	10^{-2}	10^{-3}
Iterations	18	17	16	16	17
Reduction	$2.3 \cdot 10^{-2}$	$2.1 \cdot 10^{-2}$	$2.4 \cdot 10^{-2}$	$2.8 \cdot 10^{-2}$	$2.9 \cdot 10^{-2}$

such a large ratio is meaningless for the purpose of image registration since it results in very irregular grids. From an imaging point of view, only the ratio $\mu/\lambda = 1$ leads to a reasonable displacement (judging by eye inspection). Our experiments are done solely to test our multigrid method.

For these experiments we set $\alpha = 10^{-3}$, and in order to have a long enough iteration history, we run the inversion process on the fine grid alone. For each nonlinear (Gauss–Newton) iteration we perform a single V(3,1)-cycle. For each cycle we record the reduction of the residual. At the end of each registration process we average the reduction of the residuals and record it as the [illegible]. The results of these experiments are summarized in Table 3.

In accordance with the theory, our experiments demonstrate that the multigrid method is in fact not very sensitive the ratio μ/λ. In fact, although the condition number for the system which results from $\mu/\lambda = 10^{-3}$ is roughly 10^3 times the condition number of the system which results from $\mu/\lambda = 1$, the reduction in the residuals (and therefore the convergence) is very minimally influenced. Note that this property is unique to multigrid methods, and a naively preconditioned conjugate gradient method would not have had such properties.

6.2. Qualitative analysis of the images. In Figure 2 we show the results for $\alpha = 10^{-3}$. As is apparent from Figure 2(c), the overall registration is reasonable. We also analyze the results in terms of a pairwise comparison of image slices. A two-dimensional view of the generic slice 40 of a total of 64 is shown in Figure 2(d), (e), (f). We add a regular grid to R and T and the deformed grid to $T(\boldsymbol{u}^\alpha)$. Though highly nonlinear, the deformation appears to be sufficiently smooth, as can be seen from the deformed grid. Finally, Figure 2 also shows maximum intensity projections of the distances $|R - T|$ and $|R - T(\boldsymbol{u}^\alpha)|$, respectively.

Running our scheme with a regularization parameter $\alpha = 10^{-2}$ leads to visually indistinguishable results but to a much higher distance (reduction to 25.3% instead of 17.2% for $\alpha = 10^{-3}$). On the other hand, choosing $\alpha \leq 10^{-4}$ results in nonphysical deformations which are visible on the deformed grid. Therefore, it is easy to derive a lower bound for α. However, choosing an "optimal" regularization parameter α is a delicate matter since it requires a quantification of "physically meaningful." We do not believe in an automatic detection and therefore leave the final choice to an expert.

7. Summary. In this paper we have developed a multilevel registration scheme for image registration based on a variational formulation. The scheme is based on a multilevel inexact Gauss–Newton scheme with a multigrid solver for the linearized systems. We make extensive use of numerical optimization techniques and therefore pay special attention to differentiability issues. We use smoothing B-splines to compute the solution to the forward problem and staggered grids to discretize the transformation. We prove that the discretization is h-elliptic and therefore is amenable to multigrid methods. The numerical experiments support our theoretical prediction and show that we can solve large scale problems using computational tools like MATLAB.

ON IMPROVING LINEAR SOLVER PERFORMANCE: A BLOCK VARIANT OF GMRES*

A. H. BAKER†, J. M. DENNIS‡, AND E. R. JESSUP§

Abstract. The increasing gap between processor performance and memory access time warrants the re-examination of data movement in iterative linear solver algorithms. For this reason, we explore and establish the feasibility of modifying a standard iterative linear solver algorithm in a manner that reduces the movement of data through memory. In particular, we present an alternative to the restarted GMRES algorithm for solving a single right-hand side linear system $Ax = b$ based on solving the block linear system $AX = B$. Algorithm performance, i.e., time to solution, is improved by using the matrix A in operations on groups of vectors. Experimental results demonstrate the importance of implementation choices on data movement as well as the effectiveness of the new method on a variety of problems from different application areas.

Key words. GMRES, block GMRES, iterative methods, Krylov subspace, memory access costs

1. Introduction.

We consider the solution of a large sparse system of linear equations:

$$Ax = b, \tag{1}$$

where $A \in \mathbb{R}^{n\times n}$ and $x, b \in \mathbb{R}^n$. Iterative methods are often chosen to solve such linear systems, and when A is nonsymmetric, the GMRES (generalized minimum residual) [38] method is a common choice. Because linear systems are ubiquitous in science and engineering applications, improving the robustness of linear solvers continues to be of interest.

The two main costs associated with an iterative linear solver algorithm are the floating-point operations and the cost of moving data through memory, and performance may be improved by reducing either of these costs. Our focus is on achieving a balance between improving the efficiency of an iterative linear solver from a memory-usage standpoint while maintaining favorable numerical properties. In particular, the goal of this work is to demonstrate the feasibility of improving the performance

of a common iterative linear solver (restarted GMRES), and likewise other iterative solvers, via a combination of a memory-efficient implementation and algorithmic modifications that reduce data movement.

In this paper, we report on our investigation into a memory-efficient iterative linear solver and describe the resulting new block method. We emphasize the implementation of the new method, numerous numerical test results, and evaluation of performance based on the tracking of data movement through parts of the memory hierarchy. In section 2 we discuss related background information. We outline our approach for improving restarted GMRES performance in section 3. Section 4 introduces our new block method. We discuss implications of implementation decisions on data movement and present computational results for a variety of problems in section 5. Finally, we give concluding remarks in section 6.

2. Background. Though the cost of a numerical linear algebra algorithm has traditionally been measured in terms of the floating-point operations required, a more memory-centric approach has long been advocated (e.g., see [19, 16, 23]). It is well known that matrix algorithm performance continues to be limited by the gap between microprocessor performance and memory access time (e.g., see [16, 45, 28, 26, 20, 1]). The discrepancy between DRAM (dynamic random access memory) access time and microprocessor speeds has increased by nearly 50% per year [35]. As a result, the percentage of overall application time spent waiting for data from main memory has increased [35]. The situation is compounded by advances in algorithm development that have decreased the total number of floating-point operations required by many algorithms [20]. Therefore, the number of floating-point operations required by an algorithm is not necessarily an accurate predictor of algorithm performance for a large matrix algebra problem [20]. In fact, performance bounds based on sustainable memory bandwidth (such as the STREAM [27] benchmark) are thought to predict algorithm performance most accurately [20, 1]. In particular, when solving a linear system, efficient data reuse (i.e., reducing data movement) is crucial to reducing an algorithm's memory costs [23, 16, 19].

Krylov subspace methods such as GMRES are based on an iteration loop that accesses the coefficient matrix A once per loop and performs a sparse matrix-vector multiply. Thus, a desirable modification in terms of reducing data movement is to perform more than one matrix-vector product for a single memory access of A. This optimization is natural when solving several linear systems with the same coefficient matrix A but different right-hand sides. Such linear systems can be written as a single block linear system

$$AX = B, \tag{2}$$

where $A \in \mathbb{R}^{n \times n}$, $X, B \in \mathbb{R}^{n \times s}$, and the columns of B are the different right-hand sides. By solving the block linear system (as opposed to solving s systems individually), A now operates on a group of vectors (, , ,) instead of a single vector at each iteration. The matrix A is accessed from memory fewer times than it would be if each system were solved individually.

O'Leary first introduced block iterative solvers for block linear systems with symmetric A with the block conjugate gradient (BCG) and other related algorithms in [34]. For nonsymmetric A, a block version of the GMRES algorithm (BGMRES) is first described in [43], and detailed descriptions can also be found in [39, 40, 37]. BGMRES is essentially identical to GMRES, except that operations are performed with multivectors instead of single vectors. As with GMRES, the resources required by BGMRES

may be impractical since storage and computational requirements increase with each iteration. In this case, a restarted version of BGMRES (BGMRES(m)) is commonly used in practice.

Several variants of the BGMRES method have been developed for both multiple and single right-hand side systems. For multiple right-hand side systems, a hybrid block GMRES method is presented in [39] that often solves the block system faster than solving each single system individually due in part to fewer memory accesses. In addition, block methods that augment the approximation space with eigenvector approximations are given in [22, 29]. These methods are particularly useful for matrices that are sufficiently close to normal and have a few particular eigenvalues that inhibit convergence.

Of primary interest to us is the use of a block method on a block linear system to solve a single right-hand side system. This strategy is briefly noted as a possibility in [34] for BCG algorithms. To our knowledge, the first mention of using block GMRES to solve a single right-hand side system occurs in [9]. In this work, Chapman and Saad suggest that convergence may be improved for $Ax = b$ by using a block method with approximate eigenvectors or random vectors for the additional right-hand side vectors, particularly when convergence is hampered by a few small eigenvalues.

Also of note is a block variant of GMRES for single right-hand sides systems in [25]. This method is mathematically equivalent to standard GMRES and is implemented as an s-step method (matrix A performs s consecutive matrix-vector multiplies at each iteration). The primary drawback is loss of accuracy with increasing block size (s). As with most blocked algorithms, the implementation allows for the use of level 3 BLAS (basic linear algebra subprograms) [14], and codes based on these routines often achieve good performance because they minimize data movement (e.g., see [13, 14, 20]).

3. Approach. Our approach to reducing data movement in restarted GMRES (GMRES(m)) is to modify the algorithm such that more than one matrix-vector product occurs for a single memory access of A. To this end, we investigate an alternative for solving a single right-hand side system as in (1) based on solving a corresponding block linear system as in (2). This algorithmic change requires the selection of additional starting vectors and right-hand sides.

Algorithmic changes that reduce memory access costs should not degrade the numerical properties of the original algorithm. Therefore, our goal in choosing appropriate families of additional right-hand sides and starting vectors was to select vectors that would accelerate convergence to the single right-hand side solution. For this reason, we looked to existing Krylov subspace method acceleration techniques.

It is well known that subspace information is lost in GMRES(m) due to restarting, and a number of acceleration methods attempt to in some sense compensate for this loss (e.g., see [30, 31, 42, 12, 9, 4]). Our block method derives from the LGMRES method [4], an augmented Krylov subspace method with appealing convergence properties. In particular, the extra right-hand sides used in the block method are the same as used to augment the standard GMRES approximation space in LGMRES.

In addition, beyond the algorithmic modifications required for a block formulation of GMRES(m), close attention to implementation techniques is essential for a memory-efficient, sparse linear solver. The compressed storage formats used for sparse matrices generally result in irregular patterns of memory referencing (e.g., see [18, 15]), and many approaches to improving the performance of the sparse matrix-vector multiply have been investigated (e.g., see [41, 36, 44, 19, 8, 23]). In our new

block method, we reduce the cost of the additional matrix-vector operations in each iteration loop via an efficient matrix-multivector multiply routine discussed in [20, 21] that improves the performance of [illegible] sparse matrix-vector multiplies. This approach allows the multiplication of a [illegible] of size four (i.e., a group of four vectors) by a matrix at about 1.5 times the cost of calculating a single matrix-vector product. We discuss this type of matrix-multivector multiply routine and associated routines in section 5.1.

4. A new block algorithm. In this section, we first briefly review the LGMRES method, of which the new algorithm is an extension. We then describe the new algorithm and its implementation and discuss additional considerations.

4.1. The LGMRES method. Consider GMRES(m) when solving (1). Restart parameter m denotes a fixed maximum dimension for the Krylov subspace. If convergence has not occurred at the end of m iterations, the algorithm restarts. We refer to the group of m iterations between successive restarts as a cycle. We denote the restart number with a subscript: x_i is the approximate solution after i cycles or $m \cdot i$ total iterations, and r_i is the corresponding residual ($r_i = b - Ax_i$). The minimum residual property requires that GMRES(m) find $x_{i+1} \in x_i + K_m(A, r_i)$ such that $r_{i+1} \perp AK_m(A, r_i)$ (e.g., see [37]), where $K_i(A, r_i) \equiv span\{r_i, Ar_i, \ldots, A^{i-1}r_i\}$ denotes an i-dimensional Krylov subspace.

Let $\hat{x}$ be the true solution to (1). We denote the true error after the ith restart cycle by e_i, where $e_i \equiv \hat{x} - x_i$. Then the vector

$$z_i \equiv x_i - x_{i-1} \tag{3}$$

is an approximation to that error after i restart cycles, where $z_i \equiv 0$ for $i < 1$.

An error approximation is a natural choice of vector with which to augment the next approximation space $\mathcal{K}_m(A, r_i)$, since augmenting with the true error would solve the problem exactly (e.g., see [17]). Furthermore, because $z_i \in \mathcal{K}_m(A, r_{i-1})$, it in some sense represents the space $\mathcal{K}_m(A, r_{i-1})$ generated and discarded in the previous cycle. Therefore, the LGMRES method accelerates convergence by appending k vectors that approximate the error from previous restart cycles to the standard Krylov approximation space at the end of each restart cycle. In particular, after $i+1$ restart cycles, LGMRES(m, k) finds an approximate solution to (1) in the following way:

$$x_{i+1} = x_i + q_{i+1}^{m-1}(A)r_i + \sum_{j=i-k+1}^{i} \alpha_{ij} z_j,$$

where polynomial q_{i+1}^{m-1} and α_{ij} are chosen such that $\|r_{i+1}\|_2$ is minimized.

4.2. The new algorithm: B-LGMRES. The augmentation scheme used by LGMRES(m, k) is easily extended to a block method by using the k previous error approximations z_j to build additional Krylov subspaces. We refer to this block extension as B-LGMRES(m, k), for "block" LGMRES. Conceptually, we view one restart cycle (i) of B-LGMRES(m, k) as a cycle of block GMRES on the system $AX_{i+1} = B$, where B contains the right-hand side of (1) and the k most recent error approximations z_j, $j = (i-k+1) : i$. In other words, $B = [b, z_i, \ldots, z_{i-k+1}]$. The initial guess at restart cycle i, X_i, is then written as $X_i = [x_i, 0, \ldots, 0]$, where the approximate solution to our single right-hand side system, x_i, is placed in the first column and the remaining columns are set to zero. X and B are size $n \times (k+1)$ or $n \times s$, where $s \equiv k+1$ indicates the block size.

After $i+1$ restart cycles, the B-LGMRES$(m,\ k)$ approximation space consists of the traditional Krylov portion built by repeated application of A to the current residual r_i together with Krylov spaces resulting from the application of A to previous error approximations. Therefore, we write the B-LGMRES$(m,\ k)$ approximation as

$$x_{i+1} = x_i + q_{i+1}^{m-1}(A)r_i + \sum_{j=i-k+1}^{i} \alpha_{ij}^{m-1}(A)z_j, \tag{4}$$

where the degree $m-1$ polynomials α_{ij}^{m-1} and q_{i+1}^{m-1} are chosen such that $\|r_{i+1}\|_2$ is minimized. Recall that $z_i \in \mathcal{K}_m(A, r_{i-1})$ and that $Az_i = r_{i-1} - r_i$ from (3). Therefore, by choosing z_i as an additional right-hand side, the standard approximation space is augmented with part of the information generated in the previous approximation space.

Using (3), we now rewrite B-LGMRES$(m,\ k)$ in (4) in the following way:

$$z_{i+1} = q_{i+1}^{m-1}(A)r_i + \sum_{j=i-k+1}^{i} \alpha_{ij}^{m-1}(A)z_j.$$

In the above form, as shown for the LGMRES method in [4], this block method resembles a truncated polynomial-preconditioned full conjugate gradient method with variable preconditioning. In this analogy, the polynomial preconditioner is q_{i+1}^{m-1}, and it changes at each iteration (i). In addition, the error approximation vectors z_j are analogous to conjugate gradient direction vectors (e.g., see [2]), and now these direction vectors are weighted by polynomials in A (α_{ij}) instead of scalars. Furthermore, as in [4], it is easily shown that these direction vectors z_j are A^TA-orthogonal.

THEOREM 1 (orthogonality of the error approximations). [illegible] $z_j \equiv x_j - x_{j-1}$ [illegible] A^TA [illegible]. We define subspaces $\mathcal{M}_{i+1}$ and $\mathcal{M}_i$ as

$$\mathcal{M}_{i+1} \equiv \mathcal{K}_m(A, r_i) + \sum_{j=i-k+1}^{i} \mathcal{K}_m(A, z_j),$$

$$\mathcal{M}_i \equiv \mathcal{K}_m(A, r_{i-1}) + \sum_{j=i-k}^{i-1} \mathcal{K}_m(A, z_j).$$

By construction, $r_i \perp A\mathcal{M}_i$ and $r_{i+1} \perp A\mathcal{M}_{i+1}$. From (3), $r_i - r_{i+1} = Az_{i+1} \Rightarrow Az_{i+1} \perp A(\mathcal{M}_i \cap \mathcal{M}_{i+1})$. Because $\{z_j\}_{j=(i-k+1):i} \subset \mathcal{M}_i \cap \mathcal{M}_{i+1}$, $z_{i+1} \perp_{A^TA} \{z_j\}_{j=(i-k+1):i}$. ∎

To provide additional insight into the B-LGMRES augmentation scheme, we briefly describe the B-LGMRES method in the framework presented in [9]. In [9], Chapman and Saad consider the addition of an arbitrary subspace, $\mathcal{W}$, to the standard Krylov approximation space of a minimum residual method, such as GMRES. This addition results in the augmented approximation space

$$\mathcal{M} = \mathcal{K} + \mathcal{W}, \tag{5}$$

where $\mathcal{K}$ is the standard Krylov subspace. A minimal residual method finds an approximate solution $\tilde{x} \in x_0 + \mathcal{M}$ such that the residual $\tilde{r}$ satisfies $\tilde{r} \perp A\mathcal{M}$, removing components of the initial residual r_0 in subspace $A\mathcal{M}$ via an orthogonal projection

1. $r_i = b - Ax_i$, $\beta = \|r_i\|_2$, $r_i = r_i/\beta$
2. $R_i = [r_i, z_i, \ldots, z_{i-k+1}]$
3. $R_i = V_1\hat{R}$ (QR factorization)
4. for $j = 1 : m$
5. $\quad U_j = AV_j$
6. $\quad$ for $l = 1 : j$
7. $\quad\quad H_{l,j} = V_l^T U_j$
8. $\quad\quad U_j = U_j - V_l H_{l,j}$
9. $\quad$ end

process. Following the discussion in [9], the minimization process over the augmented approximation space (5) is

$$\|\tilde{r}\|_2 = \min_{d,w} \|b - Ad - Aw\|_2,$$

where $d \in x_0 + \mathcal{K}$ and $w \in \mathcal{W}$. Chapman and Saad then show that if r_d results from minimizing $\|b - Ad\|_2$, where again $d \in x_0 + \mathcal{K}$, then

$$\|\tilde{r}\|_2 \le \|(I - P_{AW})r_d\|_2, \tag{6}$$

where P_{AW} is an orthogonal projector onto subspace $A\mathcal{W}$. In particular, for a cycle of B-LGMRES(m, k) with $k = 1$, we have that $\mathcal{K} = \mathcal{K}_m(A, r_i)$ and $\mathcal{W} = \mathcal{K}_m(A, z_i) = \mathcal{K}_m(A, e_i - e_{i-1})$. Therefore, from (6) we see that the addition of $\mathcal{W}$ in the B-LGMRES method results in the removal of components of r_d (the residual from the standard Krylov approximation space) from the subspace $A\mathcal{K}_m(A, e_i - e_{i-1})$ or, equivalently, the removal of components of the error from subspace $\mathcal{K}_m(A, e_i - e_{i-1})$.

4.3. Algorithm details. The implementation of B-LGMRES(m, k) is similar to that of BGMRES. For reference, one restart cycle (i) of B-LGMRES(m, k) is given in Figure 1. As with BGMRES, B-LGMRES(m, k) requires the application of s^2 rotations at each iteration to transform H_m into an upper triangular matrix (e.g., see [37]). Because B-LGMRES(m, k) solves $Ax = b$, as opposed to a block system, the least-squares solution step (line 13) varies from that of standard BGMRES; the triangular matrix $\hat{R}$ from the QR decomposition in line 3 does not need to be saved since only $\beta = \|r_i\|_2$ is needed, and only s rotations must be applied to the least-squares problem's right-hand side (βe_1) at each step.

Though we think of the error approximations z_j, $j = (i - k + 1) : i$ as additional right-hand side vectors, we do not form the block approximate solutions X_i. Instead we append the k most recent error approximations to the initial residual to form a block residual R_i, as seen in line 2 of Figure 1. We normalize the error approximations $(z_j/\|z_j\|_2)$ so that each column of the initial residual block R_i is of unit length. The m size $n \times s$ orthogonal block matrices V_j form the orthogonal $n \times m \cdot s$ matrix W_m, where $W_m = [V_1, V_2, \ldots, V_m]$. H_m is a size $(m + 1)s \times m \cdot s$ band-Hessenberg matrix with s subdiagonals, and the following standard relationship holds:

$$AW_m = W_{m+1}H_m.$$

TABLE 1
Algorithm specifications per restart cycle.

Method	Approx. space size	Length n vector storage	Accesses of A
GMRES(m)	m	$m+3$	m
LGMRES(m, k)	$m+k$	$m+3k+3$	m
B-LGMRES(m, k)	$m(k+1)$	$(m+2)k+m+3$	m

As with LGMRES, only i error approximations are available at the beginning of restart cycles with $i < k$. As a result, the creation of the initial residual block in line 2 of the B-LGMRES(m, k) algorithm must be modified for the first k cycles where $i < k$. (The first cycle is $i = 0$.) Recall that $z_j \equiv 0$ for $j < 1$, and when $z_j \equiv 0$, we say that z_j is an error approximation that is not available. In our implementation, we replace any $z_i, \ldots, z_{i-k+1}$ that is not available with a randomly generated vector of length n.

For the B-LGMRES(m, k) implementation given in Figure 1, the multivectors are of size s, where $s = k + 1$. For example, the orthogonal block matrices V_j in lines 3, 5, 8, 10, and 12 of Figure 1 are size s multivectors consisting of s vectors of length n. In addition, R_i in lines 2 and 3 and U_j in lines 5, 7, 8, and 10 are also multivectors. The matrix-multivector multiply occurs in line 5, and the importance of this aspect of the implementation is demonstrated in section 5.1.

One restart cycle, or m iterations, of B-LGMRES(m, k) requires m matrix-[illegible] multiplies, irrespective of the value of k. Therefore, matrix A is accessed from memory m times per cycle. For comparison, we list the approximation space size, the number of vectors of length n stored, and the number of matrix accesses per restart cycle in terms of parameters m and k for GMRES(m), LGMRES(m, k), and B-LGMRES(m, k) in Table 1.

B-LGMRES(m, k) is compatible with both left and right preconditioning. We denote the preconditioner by M^{-1}. For left preconditioning, the initial residual in line 1 of Figure 1 must be preconditioned as usual: $r_i = M^{-1}(b - Ax_i)$. Then we replace A with $M^{-1}A$ in line 5. To incorporate right preconditioning, we replace A with AM^{-1} in line 5. We define $\hat{z}_j \equiv M(x_j - x_{j-1}) = Mz_j$ and replace z with $\hat{z}$ everywhere in lines 2 and 14. While no explicit change is required for line 15 as given in Figure 1, note that, with right preconditioning, line 15 is equivalent to $x_{i+1} = x_i + M^{-1}\hat{z}_{i+1}$.

We note that in our implementation, no reorthogonalization was performed, and residual norms are computed recursively at each step within a restart cycle. Additionally, although deflation is often an important issue for block methods, it is not required for B-LGMRES because we are not solving a block linear system. The possibility of a breakdown due to rank deficiency for the initial residual block does exist, but we have not had any breakdowns in practice (a random vector may be substituted for z_i if a breakdown is detected).

5. Numerical experiments. In this section, we first give the specific details of our B-LGMRES implementation and demonstrate the advantages of some performance programming techniques. We then show the importance of reducing data movement to achieve an efficient implementation. Finally, we present promising experimental results from our efficient implementation of B-LGMRES on a variety of problems.

We implemented the B-LGMRES algorithm in C using a locally modified version

of PETSc 2.1.5 (Argonne National Laboratory's Portable, Extensible Toolkit for Scientific Computation) [6, 5]. All results provided in this paper were run on a single processor of a 16-processor Sun Enterprise-6500 server with 16 Gbytes RAM. This system consists of 400 Mhz Sun Ultra II processors, each with a 16 Kbyte L1 cache and a 4 Mbyte L2 cache. For reference, Table 2 lists multiple test problems from the University of Florida Sparse Matrix Collection [11], the Matrix Market Collection [33], and the PETSc test collection.

5.1. An efficient implementation. To specifically demonstrate the benefit of an efficient implementation, we implemented B-LGMRES in PETSc 2.1.5 both with and without what we refer to as a [illegible]. For the multivector optimization implementation, the [illegible] implementation, we followed the previously mentioned approach in [20, 21] for improving the performance of a matrix-multivector multiply routine by grouping computations on the same data. Consider the size s multivector V, where $V \equiv [v_1, v_2, \ldots, v_s]$ for vectors $v_1, v_2, \ldots, v_s \in \mathbb{R}^{n\times 1}$. By processing the s individual vectors as a group, the matrix-multivector multiply routine performs a greater number of floating-point operations for each access of a nonzero element of the coefficient matrix A and has the potential to reduce the amount of data moved through parts of the memory subsystem by a factor of s. The approach of grouping computations together affects more than just the matrix multiply routine; it pervades the implementation of the entire B-LGMRES algorithm. The second implementation, referred to as the [illegible] implementation, does not group multivector computations together and represents the best implementation possible with the tools available in PETSc. Both implementations were written so as to eliminate any copying of data from one data structure to another and represent best coding efforts.

Three primary sections of the B-LGMRES code are affected by the multivector optimization: the matrix-vector multiply (MatMult), the modified Gram–Schmidt orthogonalization (MGS), and the application of the preconditioner (Prec), if required. For the MV implementation for our set of test problems, the percentage of time spent in each of the three primary sections varies from 18% to 83% for MatMult, 6% to 55%

for MGS, and 31% to 53% for Prec. Because the Prec section of code shows similar characteristics to the MatMult section, we only discuss the MatMult and MGS sections of code. In addition, note that we concentrate on a multivector of size $s = 2$, which corresponds to B-LGMRES(m, k) with $k = 1$. We show in section 5.3 that size $k = 1$ is generally optimal for the algorithm. However, because our results are applicable to improving the performance of general block linear solvers as well, we also discuss the advantages of a larger block size.

For the remainder of this section, we detail the MV implementation, explain how it differs from the non-MV implementation in terms of data movement, and compare the performance of the two implementations. Because algorithmic changes in a numerical code affect data movement between main memory and cache and between levels of cache, the size of the data structures determines the part of the memory most affected by the multivector optimizations. Therefore, for each we discuss the [illegible], which is the size in Mbytes of data loaded through the memory hierarchy for each operation. Note that for a typical memory hierarchy, L1 caches typically have access times of two to three clock cycles, L2 cache access times are generally 5–15 times slower, and main memory access times are generally at least 100 times slower still (e.g., see [44, 32, 7]).

The MatMult section of the code corresponds to the matrix-vector multiply in line 5 of Figure 1. For the non-MV implementation, successive calls are made to a matrix-vector multiply routine for each individual vector $v_1, v_2, \ldots, v_s$ in multivector V_j. In contrast, for the MV implementation, we store the multivectors in a format referred to as [illegible] in the PETSc 2.1.5 manual [5] and use the associated PETSc matrix-multivector multiply routine. This multicomponent format is a row-wise storage format that stores V as a vector of length $n \cdot s$ in which the components of the s vectors are interlaced. In other words, multivector elements separated by stride s belong to a single vector: $v_1 = [V(0); V(s); V(2s); \ldots; V(ns - s)]$. The working set size for the MatMult section, $WS_{MatMult}$, is approximately equal to the storage required for matrix A. Therefore, for compressed sparse row storage, $WS_{MatMult} = sizeof(double) * nnz + sizeof(int) * (n + nnz)$, where the function $sizeof()$ returns the size of its argument in bytes. If $WS_{MatMult}$ is significantly larger than the L2 cache size, then successive calls to a matrix-vector multiply routine repeatedly read matrix A from main memory through both levels of cache. For $WS_{MatMult}$ smaller than the L2 cache size but larger than L1, portions of matrix A may remain in L2 cache for successive matrix-vector multiplies.

The MGS section (lines 6–10 in Figure 1) often contributes significantly to the overall cost of the B-LGMRES algorithm and is dominated by the PETSc routines [illegible] and [illegible], which are the vector dot product and axpy routines, respectively. For the MV implementation, we wrote multivector versions of these two routines, referred to as [illegible] and [illegible], in a manner that limits movement of data. For example, in the non-MV implementation, determining the dot product of two size s multivectors, which are themselves $n \times s$ matrices, results in an $s \times s$ matrix. Computing that matrix requires s^2 successive calls to VecDot and $2 \cdot n \cdot s^2$ data values to be read from the memory hierarchy. In contrast, one call to VecStrideDot provides the same functionality, but only $2 \cdot n \cdot s$ data values are read because computations on related data are fused together. Therefore, if $WS_{MGS} \equiv sizeof(double) \cdot 2 \cdot n \cdot s$ is greater than either the L1 or L2 cache size, the multivector optimization affects data movement in the MGS section of code.

Both VecStrideAXPY and VecStrideDot were written using loop temporaries and loop unrolling to aid compiler optimization. The use of loop temporaries allows a

compiler to identify data reuse more easily at the register level. Loop unrolling further helps register reuse and allows different iterations of the loop to occur simultaneously. In our MV implementation we unroll the inner loop s times, where s is the block size. We chose to write our own VecStrideAXPY and VecStrideDot routines instead of using the level 3 BLAS DGEMM routine [14] due to the performance advantage of a hand-coded implementation. The timings to perform a multivector AXPY and dot product are given in Tables 3 and 4, respectively, for $s = 2$. The version of DGEMM labeled "src" is compiled from source code and the version labeled "opt" is the vendor supplied optimized library. Timings are given in μsec for a subset of the test problems with a range of matrix orders. For both routines, the MV and non-MV implementations are superior to DGEMM, and the hand-tuned MV implementations are the clear winners. Our MV implementations outperform DGEMM because the loops are unrolled to the specific block sizes. Because the MGS section can consume a large percentage of total execution time, the simple optimizations described can have as significant an impact on overall execution time of the solver as the use of the optimized matrix-multivector multiply routine.

As previously explained, we store the multivectors row-wise in our MV implementation. Alternatively, one might wonder whether column-wise ordering is a viable option as column-wise ordering better facilitates algorithmic needs such as deflation and requires less reorganization of data. Therefore, in Table 5, we give results for the MatMult routine on block sizes $s = 2$ and $s = 4$. MV-row and MV-col indicate row-wise and column-wise variations of the MV implementation. In addition to four problems from our test set, row 5 in Table 5 lists an additional problem, poisson3Db, from the UF collection (n= 85623 and nnz = 2374949) that has a large bandwidth. Our experiments indicate that the use of the column-wise storage format for multivectors on large problems with a large matrix bandwidth causes TLB misses, as suggested in [24]. (The TLB is a cache of translations between the real and virtual addresses of recently referenced pages of memory. A TLB miss incurs two loads to memory: one to load the address translation and a second to load the actual operand.) To illustrate the impact of TLB misses, line 6 of Table 5 lists the results for the poisson3Db problem with reverse Cuthill–McKee (RCM) [10] reordering. The

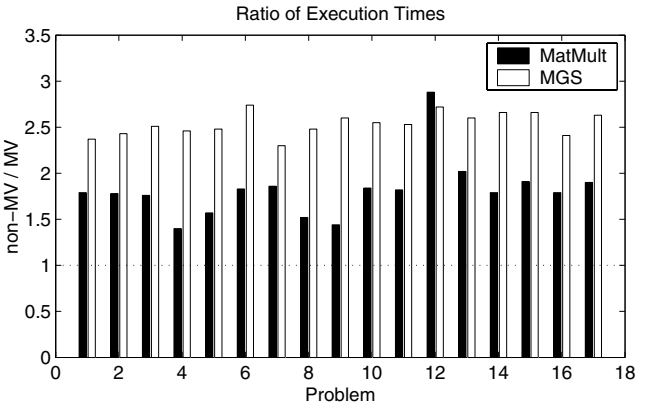

FIG. 2. *A comparison of execution time for the MatMult and MGS sections with the non-MV implementation of B-LGMRES(*15,1*) versus the MV implementation for ten restart cycles for the* 17 *test problems.*

RCM reordering reduces the matrix bandwidth and significantly decreases execution time for the column-wise multivector storage format. A large bandwidth does not impact the row-wise storage as much because consecutive accesses of the multivector elements correspond to data items that are stored contiguously. All further numerical experiments in this manuscript use the row-wise MV implementation.

We now compare the execution times for the non-MV and MV implementations on both the MatMult and MGS sections of code in Figure 2. The x-axis corresponds to the numbered test problems in Table 2, and the y-axis is the execution time for the non-MV implementation divided by the execution time for the MV implementation. A value greater than one indicates that the execution time for MV is less than that for non-MV. For the MatMult section, the MV implementation reduces the execution time by a factor of 1.4 to 2.7 over the non-MV implementation, and it is an open question what impact matrix density (or even nonzero structure) has on the effectiveness of the multivector optimizations. For the MGS section, the execution time shows an even greater improvement on average: the MV implementation of MGS reduces execution time by a factor of 2.3 to 2.7 over the non-MV implementation. As for the execution time for the entire B-LGMRES code, the MV implementation is close to twice as fast on average as the non-MV implementation with multivectors of size $s = 2$, and the performance improvement is independent of problem size (n) and number of nonzeros (nnz) for our test set in Table 2.

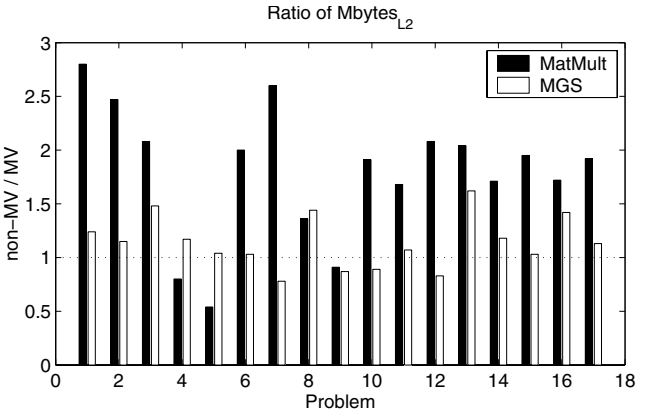

FIG. 3. *A comparison of data movement from main memory to L2 cache in the MatMult and MGS sections for the non-MV implementation of B-LGMRES(*15,1*) versus the MV implementation for ten restart cycles for the* 17 *test problems.*

Additionally, we remark that we modified our local installation of PETSc to include multivector versions of the PETSc routines and . VecMAXPY adds a scaled sum of vectors to a vector, which is used when solving the least-squares problem. MatSolve performs a forward and back solve for use with the ILU preconditioner.

5.2. Impact of data movement on execution time. We now explain reductions in execution time due to the multivector optimization using data from hardware performance counters that monitor data movement. We focus on two counters that measure the megabytes of data moved between main memory and L2 cache, denoted by $Mbytes_{L2}$, and between the L2 and L1 caches, denoted by $Mbytes_{L1}$.

We first examine data movement between main memory and the L2 cache in Figure 3. The y-axis in this figure indicates the ratio of $Mbytes_{L2}$ for non-MV to MV for both the MatMult and MGS sections. Because $s = 2$, we expected a factor of two reduction in $Mbytes_{L2}$ for the MV implementations for test problems with a working set size significantly larger than the L2 cache. For the MatMult section, problems 6 and 11–17 have $WS_{MatMult}$ larger than the 4 Mbytes L2 cache size. These problems all have ratios from 1.75 to 2.0, which correlate well with the factor of two reductions in execution time for those problems seen in Figure 2. For the MGS section, only problem 16 has WS_{MGS} greater than the L2 cache size, and this problem shows a ratio of 1.4, which does not correlate well with the factor of 2.4 improvement in execution time shown in Figure 2. Furthermore, the results in Figure 3 are inconsistent with those in Figure 2 in other ways: several problems appear to show an increase in $Mbytes_{L2}$ for the MGS and MatMult sections for the MV implementation. In fact, for these problems the amounts of data moved are quite small for both implementations and the apparent increases are likely the result of measurement error. Nonetheless, the MV implementation is faster than the non-MV one. These inconsistencies indicate that a reduction in $Mbytes_{L2}$ does not accurately predict a reduction in execution time for MGS for most of the test problems.

We now consider data movement between the L1 and L2 caches. Figure 4 shows the ratio of $Mbytes_{L1}$ for the non-MV to MV implementation. For the MatMult section, we expected test problems with $WS_{MatMult} \gg sizeof(L1\ cache)$ to show a

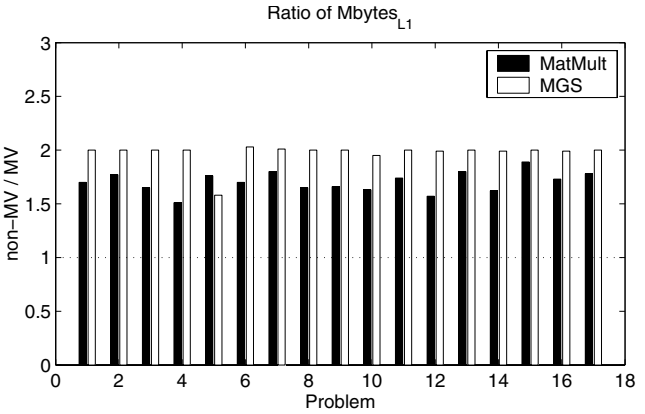

FIG. 4. *A comparison of data movement from L2 cache to L1 cache in the MatMult and MGS sections for the non-MV implementation of B-LGMRES(*15,1*) versus the MV implementation for ten restart cycles for the* 17 *test problems.*

reduction in $Mbytes_{L1}$. Test problem 1 has the smallest $WS_{MatMult}$ at 978 Kbytes, which is significantly larger than the 16 Kbyte L1 cache. Thus, Figure 4 shows that for all of the test problems the ratios of data moved do in fact range from 1.5 to 1.9. Similarly for the MGS section, problem 12 has the smallest WS_{MGS} at 241 Kbytes, which is also significantly larger than the L1 cache. Consequently, all of the test problems have ratios that range from 1.6 to 2.0. The reduction in $Mbytes_{L1}$ is thus consistent with the reduction in execution time seen in Figure 2 for both sections of code.

Therefore, from Figures 3 and 4 one can infer that the reduction in execution time due to the MV implementation correlates to the reduction in $Mbytes_{L1}$ for our test problems (see [3] for more details). The importance of optimizations that reduce movement of data between levels of cache was unexpected in that emphasis is traditionally placed on reducing data movement between cache and main memory, which is of most concern to large problems. For much larger test problems, where both $WS_{MatMult}$ and WS_{MGS} are much larger than the L2 cache size, for example, we expect that the reduction $Mbytes_{L2}$ would more strongly correlate to execution time. However, our results indicate that data movement is not just an issue for very large problems. In fact, the results presented in this section demonstrate that reformulating an iterative solver to use multivectors enables an efficient implementation that can reduce data movement for problems of any size. Furthermore, these multivector optimizations would benefit larger block sizes and other types of block methods, including those that solve systems with multiple right-hand sides.

5.3. Comparison with other methods. In this section, we demonstrate the potential of the B-LGMRES method both with and without preconditioning by presenting experimental results for the test problems in Table 2. If a right-hand side was not provided, we generated a random right-hand side. For all problems, the initial guess was a zero vector. For each problem we report wall clock time for the linear solve only; we do not time any I/O or the setup of the preconditioner. For the preconditioned problems, we use either ILU(p) or ILUTP($droptol$, $permtol$, $lfil$) (e.g., see [37]). The timings reported are averages from five runs and have standard deviations of at most two percent. All tests are run until the relative residual norm is

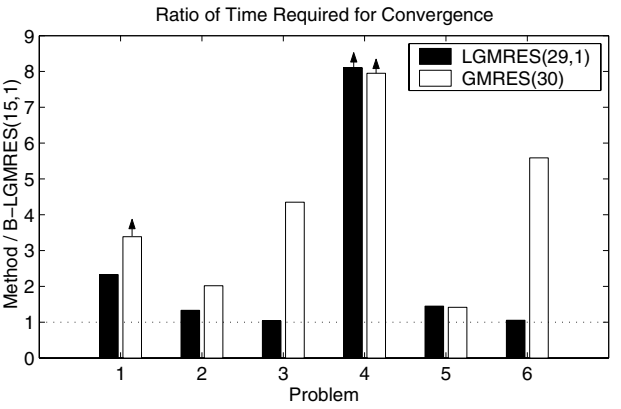

FIG. 5. *A comparison of the time required for convergence for nonpreconditioned test problems* 1–6 *with GMRES(*30*) and LGMRES(*29, 1*) versus B-LGMRES(*15, 1*).*

less than the convergence tolerance $\zeta = 10^{-9}$, i.e., when $\|r_i\|_2/\|r_0\|_2 \leq \zeta$. However, if a method does not converge in 1000 restart cycles, then the execution time reported reflects the time for 1000 cycles and we say that the method does not converge.

We evaluate the performance of B-LGMRES(m, k) for a particular problem by comparing its time to converge to that of GMRES(m) and LGMRES(m, k) with equal-sized approximation spaces. We use the GMRES(m) implementation available in PETSc 2.1.5 and the PETSc implementation of LGMRES(m, k) described in [4]. For GMRES(m), we chose restart parameter $m = 30$ because it is a common choice for GMRES(m) and is the default in PETSc. We required that the approximation spaces for both LGMRES(m, k) and B-LGMRES(m, k) be of size 30 as well. Furthermore, we wanted to evaluate the performance of LGMRES(m, k) and B-LGMRES(m, k) using the same number of error approximation vectors, i.e., the same k, for each. In choosing a value of k, we note that for LGMRES(m, k), $k \leq 3$ is typically optimal, and variations in algorithm performance are small for $k \leq 3$ (see [4]). Note that for a fixed approximation space size, increasing k for B-LGMRES(m, k) decreases the powers of A represented in the approximating subspace. For this set of test problems, preliminary testing showed that using $k > 2$ was typically not beneficial and $k = 1$ was generally optimal. (For an approximation space larger than 30, we expect that using $k > 1$ would be an advantage more often.) As a result, we chose $k = 1$ for the experiments presented here, and this choice together with the constraint of a size 30 approximation space determined parameter m for each method as in Table 1. Note the approximation space for B-LGMRES(15, 1) at restart cycle $i+1$ is given by $\mathcal{K}_{15}(A, r_i)+\mathcal{K}_{15}(A, z_i)$ and that for LGMRES(29, 1) is given by $\mathcal{K}_{29}(A, r_i)+span\{z_i\}$.

We first present results for the nonpreconditioned test problems. Figure 5 compares the time required for convergence for B-LGMRES(15, 1) to both LGMRES(29, 1) and GMRES(30) for the test problems given in Table 2. The y-axis is the time required for convergence for either LGMRES(29, 1) or GMRES(30) divided by the time required for convergence for B-LGMRES(15, 1). Therefore, bars extending above one indicate faster convergence for B-LGMRES(15, 1). For all of these problems, B-LGMRES(15, 1) converges. However, arrows above the bars in Figure 5 indicate that GMRES(30) did not converge in 1000 restart cycles for problem 1 and both LGMRES(29, 1) and GMRES(30) did not converge for problem 4. Again, the time

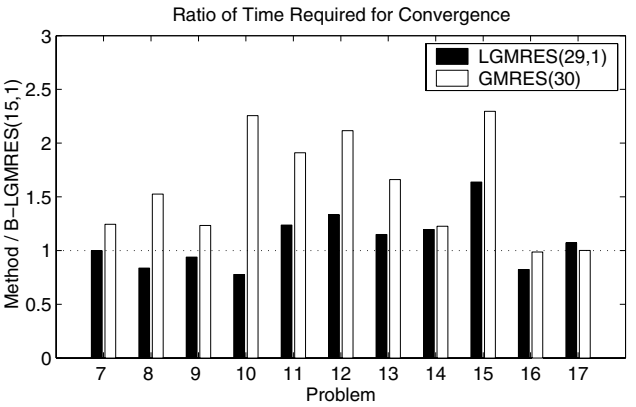

FIG. 6. *A comparison of the time required for convergence for preconditioned test problems* 7–17 *with GMRES(*30*) and LGMRES(*29, 1*) versus B-LGMRES(*15, 1*).*

for 1000 restart cycles is reported for methods that do not converge, resulting in an understated ratio of improvement for B-LGMRES(15, 1) for the bars with arrows. B-LGMRES(15, 1) converges in less time than GMRES(30) for all problems, and improvements over LGMRES(29, 1) are more modest since LGMRES is typically also an improvement over GMRES(m) [4].

We now do the same performance evaluation for B-LGMRES(m, k) on preconditioned problems, problems 7–17, in Figure 6. We use left preconditioning, and determination of convergence is based on the preconditioned residual norm as usual. As in Figure 5, the bars extending above one favor B-LGMRES(15, 1). The time required for convergence for B-LGMRES(15, 1) is less than that for GMRES(30) for problems 7–15 and about the same as GMRES(30) for problems 16 and 17. However, performance gains are not as dramatic as those without preconditioning due to lower iteration counts. For large problems, though, even a small improvement in iteration count translates into a nontrivial time savings. The comparison of B-LGMRES(15, 1) to LGMRES(29, 1) is not as straightforward. The LGMRES method is quite effective for these test problems, and as a result, predicting which algorithm will "win" for a particular test problem is an open question. As an example, we tested problem memplus both without and with preconditioning, problems 3 and 8, respectively. For this problem, B-LGMRES(15, 1) converges in slightly less time than LGMRES(29, 1) when no preconditioner is used, but LGMRES(29, 1) is faster with preconditioning.

For all of the test problems in Table 2, we found that the time to solution of the restarted methods correlates well with the number of accesses of A, as opposed to the number of matrix-vector multiplies. In particular, Figure 7 illustrates that the number of accesses of A largely determines execution time. Therefore, the method that converges in the least amount of time for a particular problem in Figures 5 and 6 is generally that with the smallest number of iterations. However, it is important to acknowledge that the efficient implementation of B-LGMRES(15, 1) makes the preceding statement possible because each iteration of B-LGMRES(15, 1) requires two matrix-vector multiplies; a poor implementation of B-LGMRES(15, 1) could potentially cost twice as much per iteration as GMRES(30).

Because our machine has sufficient resources, full GMRES is a viable option. Therefore, we also compared the time to solution of B-LGMRES(15, 1) to full GMRES for each of the 17 test problems. B-LGMRES converges in significantly less time than

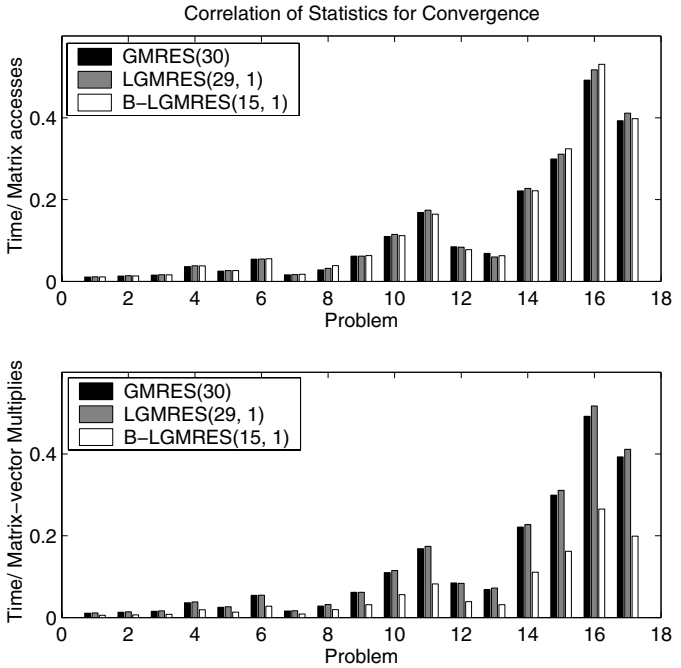

FIG. 7. *The upper panel shows the ratios of time required for convergence to number of accesses of A for GMRES (*30*), LGMRES(*29, 1*), and B-LGMRES(*15, 1*) on the* 17 *test problems. The lower panel shows the ratios of time required for convergence to number of matrix-vector multiplies.*

GMRES on all but four problems: 7, 10, 13, and 15. There was no correlation between problem size and method in terms of time required for convergence for these test problems. See [3] for more details.

For the problems presented here, the time to solution of B-LGMRES(m, k) is typically an improvement over that of GMRES(m), as shown in Figures 5 and 6. The additional right-hand side vector(s) in B-LGMRES inhibit the tendency of restarted GMRES to form similar polynomials at every other restart cycle (see [4]), thus improving convergence. As with the LGMRES method, B-LGMRES acts as an accelerator, but in general does not help with stalling. In other words, B-LGMRES(m, k) has a total approximation space size of $m \cdot (k+1)$ and typically does not help problems that stall for GMRES($m \cdot (k+1)$), though we have found a few exceptions. For problems that stall, full GMRES or Morgan's GMRES-DR method [31] can be good options. Although a thorough understanding of the convergence behavior of B-LGMRES is an open question that warrants further investigation, the experimental results presented in this section demonstrate that solving a single right-hand side system via a block system is a viable means of improving the time to solution of an iterative method such as GMRES(m). In particular, achieving a balance between maintaining or improving an iterative linear solver algorithm's numerical properties and reducing data movement is possible.

6. Concluding remarks. In this paper, we explore the feasibility of modifying restarted GMRES to reduce data movement. We show that for iterative linear solvers, the time to solution is largely dependent on the number of accesses of A from memory as opposed to the total number of matrix-vector multiplies. Therefore, mod-

ifications that reduce data movement are a particularly effective means of improving performance. Furthermore, our results indicate that using available performance programming techniques to drive algorithm development can be effective and that careful attention to implementation details can be quite beneficial. For example, hand-tuned routines can outperform subroutines such as DGEMM for certain matrix sizes, and an efficient implementation of a block version of an iterative method may be only marginally more expensive per access of coefficient matrix A than a nonblock version. A unique aspect of this study is the thorough investigation of data movement through the memory hierarchy. Typically the impact of memory performance on an iterative linear solver is not studied in this detail.

Our investigation led to a block variant of the GMRES method that solves a linear system with a single right-hand side. This new method, B-LGMRES, results from choosing error approximation vectors as additional right-hand side vectors. This choice mimics a truncated polynomial-preconditioned conjugate gradient method. In our experiments, B-LGMRES performed best with a block size of two for an approximation space of dimension 30. For larger approximation space sizes and larger problems, a larger block size may prove more beneficial. We find that predicting the algorithm's performance is nontrivial due to its dependence on many factors: problem size (number of nonzeros and matrix order), restart parameter, block size, matrix properties, preconditioner choices, and machine characteristics. Furthermore, other right-hand side vectors may be more appropriate for particular problem classes. Given the potential performance gains from larger block sizes described in section 5.1, our implementation of B-LGMRES can serve as a template for other block methods.

Nevertheless, the substantial improvement in performance due to reduced data movement is sufficient enticement toward pursuing block methods for single right-hand side problems. Given the increasing gap between processor performance and memory access time, re-examining popular linear solver algorithms is particularly important to achieving respectable performance on modern architectures.

MULTILEVEL PRECONDITIONERS CONSTRUCTED FROM INVERSE-BASED ILUs*

MATTHIAS BOLLHÖFER† AND YOUSEF SAAD‡

Abstract. This paper analyzes dropping strategies in a multilevel incomplete LU decomposition context and presents a few strategies for obtaining related ILUs with enhanced robustness. The analysis shows that the incomplete LU factorization resulting from dropping small entries in Gaussian elimination produces a good preconditioner when the inverses of these factors have norms that are not too large. As a consequence a few strategies are developed whose goal is to achieve this feature. A number of "templates" for enabling implementations of these factorizations are presented. Numerical experiments show that the resulting ILUs offer a good compromise between robustness and efficiency.

Key words. incomplete LU decompositions, ILU, preconditioning, multilevel ILU, approximate inverse, algebraic multilevel method, iterative solver

1. Introduction.

In recent years, research on "black-box" techniques for solving sparse linear systems of equations has accelerated due to two factors. First, linear systems are becoming ever more difficult to solve due to their bigger sizes. In spite of recent progress in parallel direct solvers [8, 21, 13], practitioners are looking at cheaper alternatives. The second factor is that preconditioning methods have also made some tangible progress in improving robustness. Iterative methods based on preconditioned Krylov subspace techniques are increasingly viewed as attractive alternatives to direct solvers, both for structured problems, such as those arising from discretized partial differential equations (PDEs), and for systems arising from applications areas which yield highly unstructured systems and for which iterative methods were viewed as ineffective in the past.

One essential improvement for the use of Krylov subspace solvers consists of preconditioning methods [18], in particular methods based on incomplete LU decompositions [17]. One of the first attempts at using Krylov subspace methods as a general purpose black-box solver was by Simon [22], who used standard (symmetric) reordering techniques from direct solution methods to preprocess matrices prior to applying level-of-fill ILU. More recent work which employs nonsymmetric reordering strategies [10, 2] indicates that systems arising from a wide range of applications can be successfully solved by this approach in conjunction with ILUs.

Aside from this progress, there still remains a drawback of incomplete LU decompositions, which is that they are sensitive to parameters such as drop tolerances or certain static reordering strategies. Progress has been made in improving the stability of ILUs by taking into account the inverse triangular factors [5, 3, 14]. Also,

combining incomplete LU decompositions in a hierarchical fashion with preordering pivoting strategies [19] helps in improving stability of the preconditioner.

In this paper we will discuss the rationale for a new multilevel strategy which mainly focuses on keeping the inverse triangular factors bounded. This is justified by an analysis that indicates that stability can be enhanced by this approach.

2. Impact of dropping on the preconditioned system. This section analyzes how a perturbation introduced by dropping small terms while computing incomplete LU decompositions affects the preconditioned system. This analysis will help design incomplete LU factorization preconditioners with improved robustness.

2.1. The inverse error for a single level. We start with a partial factorization of our matrix that is terminated after k steps. We assume that the initial $n \times n$ nonsingular matrix A is rearranged as

$$P^\top A Q = \begin{pmatrix} B & F \\ E & C \end{pmatrix},$$

where the leading matrix B is nonsingular and of size $k \times k$ and where P and Q are suitably chosen permutation matrices. Suppose that this matrix is approximately factored as

$$\begin{pmatrix} B & F \\ E & C \end{pmatrix} = \begin{pmatrix} \tilde{L}_B & 0 \\ \tilde{L}_E & I \end{pmatrix} \begin{pmatrix} \tilde{D}_B & 0 \\ 0 & \tilde{S} \end{pmatrix} \begin{pmatrix} \tilde{U}_B & \tilde{U}_F \\ 0 & I \end{pmatrix} + \mathcal{E}_k \equiv \tilde{\mathcal{L}}_k \tilde{\mathcal{D}}_k \tilde{\mathcal{U}}_k + \mathcal{E}_k. \tag{2.1}$$

Here, $\tilde{L}_B$ and $\tilde{U}_B^\top$ are unit lower triangular and $\tilde{D}_B$ is diagonal. The matrix $\tilde{S}$ is an approximation to the Schur complement $S = C - EB^{-1}F$. Assume for simplicity that we do not encounter zero pivots. We note that in principle one could generalize the following analysis using pivoting. To keep the analysis simple we assume that no pivoting is necessary for this partial incomplete factorization.

At any given step $l = 1, \ldots, k$, entries of $\tilde{\mathcal{L}}_l$ and $\tilde{\mathcal{U}}_l^\top$ may be dropped in some positions (m, l), where $m > l$. We represent these dropped values by an $n \times n$ matrix

$$\mathcal{V}_l = \left(\begin{array}{ccc|ccc} v_1 & \cdots & v_l & 0 & \cdots & 0 \end{array} \right) = \left(\begin{array}{c|c} \begin{array}{c} 0 \\ \diagdown \\ 0 \end{array} & 0 \\ \hline 0 & 0 \end{array} \right) \tag{2.2}$$

for $\tilde{\mathcal{L}}_l$ and

$$\mathcal{W}_l = \begin{pmatrix} w_1^\top \\ \vdots \\ w_l^\top \\ \hline 0 \\ \vdots \\ 0 \end{pmatrix} = \left(\begin{array}{cc} \begin{array}{c} 0 \\ \diagdown \\ 0 \end{array} & \square \\ \hline 0 & 0 \end{array} \right) \tag{2.3}$$

for $\tilde{\mathcal{U}}_l$. The elimination process adds one row/column at every step l.

Depending on how the approximate Schur complement $\tilde{S}$ is defined, a different error matrix $\mathcal{E}_k$ will be obtained. We will only distinguish between two choices.

S- : This corresponds to the "simple" approximate Schur complement defined by

$$\tilde{S} = C - \tilde{L}_E \tilde{D}_B \tilde{U}_F. \tag{2.4}$$

T- : This corresponds to the more expensive Schur complement proposed in [23] and defined by

$$\tilde{T} = \begin{pmatrix} -\tilde{L}_E \tilde{L}_B^{-1} & I \end{pmatrix} P^\top A Q \begin{pmatrix} -\tilde{U}_B^{-1} \tilde{U}_F \\ I \end{pmatrix}. \tag{2.5}$$

Note that the T-version of the Schur complement results from applying the inverse factors $\tilde{\mathcal{L}}_k^{-1}$ to the left and $\tilde{\mathcal{U}}_k^{-1}$ to the right to $P^\top A Q$ and taking the lower right block. Obtaining $\tilde{T}$ does not really require inverting $\tilde{L}_B$ and $\tilde{U}_B$. It can be computed by updating $\tilde{T}$ by a low-rank matrix at each step $l = 1, \ldots, k$.

The next result shows how the error matrix $\mathcal{E}_k$ can be characterized for the two choices of the approximate Schur complement.

LEMMA 2.1. (2.4)

$$\mathcal{E}_k = \mathcal{V}_k \tilde{\mathcal{D}}_k + \tilde{\mathcal{D}}_k \mathcal{W}_k, \tag{2.6}$$

(2.5)

$$\mathcal{E}_k = \mathcal{V}_k \tilde{\mathcal{D}}_k \tilde{\mathcal{U}}_k + \tilde{\mathcal{L}}_k \tilde{\mathcal{D}}_k \mathcal{W}_k. \tag{2.7}$$

. We will show this by induction. Initially at step $l = 0$ there is no error present and we set $\mathcal{V}_0 = \mathcal{W}_0 = 0$ and $\tilde{\mathcal{L}}_0 = \tilde{\mathcal{U}}_0 = I$.

Now going from step $l-1$ to step l ($l \leqslant k$) we have

$$P^\top A Q = \tilde{\mathcal{L}}_{l-1} \tilde{\mathcal{D}}_{l-1} \tilde{\mathcal{U}}_{l-1} + \mathcal{E}_{l-1}.$$

To distinguish between step $l-1$ and l we add a subscript l to all matrices. We partition the approximate Schur complement $\tilde{S}_{l-1}$ from $\tilde{\mathcal{D}}_{l-1}$ as

$$\tilde{S}_{l-1} = \begin{pmatrix} \beta & f^\top \\ e & \hat{C} \end{pmatrix}.$$

At step l we get

$$\tilde{\mathcal{L}}_l = \tilde{\mathcal{L}}_{l-1} \left(I + [y - v]\, e_l^\top \right),$$

where

$$y = \begin{pmatrix} 0 \\ 0 \\ \beta^{-1} e \end{pmatrix} \begin{matrix} \leftarrow \text{size} = l-1, \\ \leftarrow \text{size} = 1, \\ \leftarrow \text{size} = n-l \end{matrix}$$

is the leading column of the approximate Schur complement divided by the diagonal entry and

$$v = \begin{pmatrix} 0 \\ 0 \\ \beta^{-1} \varepsilon_e \end{pmatrix}$$

denotes the vector of those entries from y that are dropped at step l. For the U-part, we similarly obtain

$$\tilde{\mathcal{U}}_l = (I + e_l(z-w)^\top)\tilde{\mathcal{U}}_{l-1},$$

where

$$z^\top = \begin{pmatrix} 0 & 0 & f^\top/\beta \end{pmatrix}$$

and

$$w^\top = \begin{pmatrix} 0 & 0 & \varepsilon_f^\top/\beta \end{pmatrix}$$

denotes the vector of those entries from z being dropped.

We now consider the S-version and T-version separately, beginning with the S-version. For the S-version the next approximate Schur complement $\tilde{S}_l$ is set as

$$\tilde{S}_l = \hat{C} - (e-\varepsilon_e)\beta^{-1}(f-\varepsilon_f)^\top.$$

It follows that

$$\begin{aligned}
&\tilde{\mathcal{L}}_l\tilde{\mathcal{D}}_l\tilde{\mathcal{U}}_l \\
&= \begin{pmatrix} L_{B,l-1} & 0 \\ L_{E,l-1} & \begin{pmatrix} 1 & 0 \\ \frac{e-\varepsilon_e}{\beta} & I \end{pmatrix} \end{pmatrix} \begin{pmatrix} D_{B,l-1} & 0 & 0 \\ 0 & \beta & 0 \\ 0 & 0 & \tilde{S}_l \end{pmatrix} \begin{pmatrix} U_{B,l-1} & U_{F,l-1} \\ 0 & \begin{pmatrix} 1 & \frac{(f-\varepsilon_f)^\top}{\beta} \\ 0 & I \end{pmatrix} \end{pmatrix} \\
&= \begin{pmatrix} L_{B,l-1} & 0 \\ L_{E,l-1} & I \end{pmatrix} \begin{pmatrix} D_{B,l-1} & 0 & 0 \\ 0 & \beta & (f-\varepsilon_f)^\top \\ 0 & e-\varepsilon_e & \hat{C} \end{pmatrix} \begin{pmatrix} U_{B,l-1} & U_{F,l-1} \\ 0 & I \end{pmatrix} \\
&= \tilde{\mathcal{L}}_{l-1}\tilde{\mathcal{D}}_{l-1}\tilde{\mathcal{U}}_{l-1} - v\beta e_l^\top - e_l\beta w^\top.
\end{aligned}$$

By induction we already have

$$\tilde{\mathcal{L}}_{l-1}\tilde{\mathcal{D}}_{l-1}\tilde{\mathcal{U}}_{l-1} = P^\top AQ - \mathcal{E}_{l-1} = P^\top AQ - \mathcal{V}_{l-1}\tilde{\mathcal{D}}_{l-1} - \tilde{\mathcal{D}}_{l-1}\mathcal{W}_{l-1},$$

and by definition we have $v = \mathcal{V}_l e_l$ and $w^\top = e_l^\top \mathcal{W}_l$. The leading $l \times l$ part of $\tilde{\mathcal{D}}_l$ is diagonal and the (l,l) entry is just β. Thus we obtain

$$\tilde{\mathcal{L}}_l\tilde{\mathcal{D}}_l\tilde{\mathcal{U}}_l = P^\top AQ - \mathcal{V}_{l-1}\tilde{\mathcal{D}}_{l-1} - \tilde{\mathcal{D}}_{l-1}\mathcal{W}_{l-1} - v\beta e_l^\top - e_l\beta w^\top = P^\top AQ - \mathcal{V}_l\tilde{\mathcal{D}}_l - \tilde{\mathcal{D}}_l\mathcal{W}_l,$$

which shows (2.6).

We now consider the T-version. In contrast with the S-version, for the T-version we get for $\tilde{T}_l$

$$\tilde{T}_l = \left(-(e-\varepsilon_e)\frac{1}{\beta},\ I\right)\tilde{S}_{l-1}\begin{pmatrix} -(f-\varepsilon_f)^\top\frac{1}{\beta} \\ I \end{pmatrix} = \hat{C} - e\frac{1}{\beta}f^\top + \varepsilon_e\frac{1}{\beta}\varepsilon_f^\top.$$

From this it follows that

$$\begin{aligned}
\tilde{\mathcal{L}}_l^{-1}P^\top AQ\tilde{\mathcal{U}}_l^{-1} &= \tilde{\mathcal{L}}_l^{-1}\left(\tilde{\mathcal{L}}_{l-1}\tilde{\mathcal{D}}_{l-1}\tilde{\mathcal{U}}_{l-1} + \mathcal{E}_{l-1}\right)\tilde{\mathcal{U}}_l^{-1} \\
&= (I-(y-v)e_l^\top)\tilde{\mathcal{D}}_{l-1}(I-e_l(z-w)^\top) \\
&\quad +\tilde{\mathcal{L}}_l^{-1}\mathcal{V}_{l-1}\tilde{\mathcal{D}}_{l-1}(I-e_l(z-w)^\top) \\
&\quad +(I-(y-v)e_l^\top)\tilde{\mathcal{D}}_{l-1}\mathcal{W}_{l-1}\tilde{\mathcal{U}}_l^{-1} \\
&= \tilde{\mathcal{D}}_l + v\beta e_l^\top + e_l\beta w^\top \\
&\quad +\tilde{\mathcal{L}}_l^{-1}\mathcal{V}_{l-1}\tilde{\mathcal{D}}_{l-1} \\
&\quad +\tilde{\mathcal{D}}_{l-1}\mathcal{W}_{l-1}\tilde{\mathcal{U}}_l^{-1}.
\end{aligned}$$

For the last equation we used the definition of $\tilde{\mathcal{D}}_l$ and, in particular, that of $\tilde{T}_l$. Also note that only the leading $l-1$ columns of $\mathcal{V}_{l-1}\tilde{\mathcal{D}}_{l-1}$ are nonzero (analogously, $e_l^\top \tilde{\mathcal{D}}_{l-1}\mathcal{W}_{l-1} = 0$).

It is easy to verify that $v\beta e_l^\top = \tilde{\mathcal{L}}_l^{-1} v\beta e_l^\top$ since the leading l entries of v are zero. A similar argument can be made for $e_l\beta w^\top$. Altogether we have

$$\tilde{\mathcal{L}}_l^{-1} P^\top A Q \tilde{\mathcal{U}}_l^{-1} = \tilde{\mathcal{D}}_l + \tilde{\mathcal{L}}_l^{-1}\mathcal{V}_l\tilde{\mathcal{D}}_l + \tilde{\mathcal{D}}_l\mathcal{W}_l\tilde{\mathcal{U}}_l^{-1},$$

since $v\beta e_l^\top$ and $e_l\beta w^\top$ are the l column/row of $\mathcal{V}_l\tilde{\mathcal{D}}_l$ and $\tilde{\mathcal{D}}_l\mathcal{W}_l$. This completes the proof. ∎

A corollary of the representation of the error is obtained when we consider the inverse error

$$\mathcal{F}_k = \tilde{\mathcal{L}}_k^{-1}\mathcal{E}_k\tilde{\mathcal{U}}_k^{-1}. \tag{2.8}$$

COROLLARY 2.2. [illegible] 2.1

$$\mathcal{F}_k = \tilde{\mathcal{L}}_k^{-1}\mathcal{V}_k\tilde{\mathcal{D}}_k\tilde{\mathcal{U}}_k^{-1} + \tilde{\mathcal{L}}_k^{-1}\tilde{\mathcal{D}}_k\mathcal{W}_k\tilde{\mathcal{U}}_k^{-1}, \tag{2.9}$$

[illegible]

$$\mathcal{F}_k = \tilde{\mathcal{L}}_k^{-1}\mathcal{V}_k\tilde{\mathcal{D}}_k + \tilde{\mathcal{D}}_k\mathcal{W}_k\tilde{\mathcal{U}}_k^{-1}. \tag{2.10}$$

An important consequence of Corollary 2.2 is that the inverse triangular factors $\tilde{\mathcal{L}}_k^{-1}$ and $\tilde{\mathcal{U}}_k^{-1}$ amplify the size of the entries being dropped during the incomplete LU decomposition. For the S-version this impact is likely to be stronger since both inverse factors contribute to the error at the same time.

An interesting observation can be made when taking a detailed look at the patterns of the inverse errors. To do this, partition $\mathcal{V}_k$ and $\mathcal{W}_k$ as

$$\mathcal{V}_k = \begin{pmatrix} V_B & 0 \\ V_E & 0 \end{pmatrix} \equiv \begin{pmatrix} \overset{0}{\blacktriangle} & 0 \\ \underset{0}{\blacksquare} & 0 \end{pmatrix}, \tag{2.11}$$

$$\mathcal{W}_k = \begin{pmatrix} W_B & W_F \\ 0 & 0 \end{pmatrix} \equiv \begin{pmatrix} \overset{0}{\blacktriangle} & \blacksquare \\ \underset{0}{} & 0 \end{pmatrix}. \tag{2.12}$$

Then the inverse error of the S-version can be sketched with a pattern

$$\mathcal{F}_k = \underbrace{\begin{pmatrix} \overset{0}{\blacktriangle} \\ \underset{0}{\blacksquare} \end{pmatrix}\begin{pmatrix} \blacktriangle & \blacksquare \end{pmatrix}}_{(\tilde{\mathcal{L}}_k^{-1}\mathcal{V}_k\tilde{\mathcal{D}}_k)\cdot\tilde{\mathcal{U}}_k^{-1}} + \underbrace{\begin{pmatrix} \blacksquare \\ \blacksquare \end{pmatrix}\begin{pmatrix} \overset{0}{\blacktriangle} & \blacksquare \end{pmatrix}}_{\tilde{\mathcal{L}}_k^{-1}\cdot(\mathcal{V}_k\tilde{\mathcal{D}}_k\tilde{\mathcal{U}}_k^{-1})},$$

which shows that the error produced by dropping in the lower triangular part also contributes to the upper triangular part and vice versa. However, this is different for the T-version. Here we have

$$\mathcal{F}_k = \underbrace{\begin{pmatrix} \overset{0}{\blacktriangle} & 0 \\ \underset{0}{\blacksquare} & 0 \end{pmatrix}}_{\tilde{\mathcal{L}}_k^{-1}\mathcal{V}_k\tilde{\mathcal{D}}_k} + \underbrace{\begin{pmatrix} \overset{0}{\blacktriangle} & \blacksquare \\ 0 & 0 \end{pmatrix}}_{\tilde{\mathcal{D}}_k\mathcal{W}_k\tilde{\mathcal{U}}_k^{-1}},$$

showing that dropping in the lower/upper triangular part produces errors in these parts only, and by the definition of the approximate Schur complement there clearly will be no perturbation in the lower right block. Note also that for the T-version, there are no errors in the (2,2) block, which is not surprising since the Schur complement is computed exactly from applying the inverses of the (inexact) factors $\mathcal{L}_k$ and $\mathcal{U}_k$ to $P^\top AQ$.

Let $\tilde{d}_1, \ldots, \tilde{d}_k$ be the leading k diagonal entries of $\tilde{\mathcal{D}}_k$. If we keep in mind that the entries being dropped at step l are the entries in column l of $\mathcal{V}_l$ and $\mathcal{W}_l^\top$, then we can see that for the S-version we have

$$\mathcal{F}_k = \sum_{l \leqslant k} \left(\tilde{\mathcal{L}}_k^{-1} v_l \tilde{d}_l e_l^\top \tilde{\mathcal{U}}_k^{-1} + \tilde{\mathcal{L}}_k^{-1} e_l \tilde{d}_l w_l^\top \tilde{\mathcal{U}}_k^{-1} \right) \tag{2.13}$$

and, analogously for the T-version,

$$\mathcal{F}_k = \sum_{l \leqslant k} \left(\tilde{\mathcal{L}}_k^{-1} v_l \tilde{d}_l e_l^\top + e_l \tilde{d}_l w_l^\top \tilde{\mathcal{U}}_k^{-1} \right). \tag{2.14}$$

Equation (2.13) implies that the perturbation introduced at step l of the incomplete LU decomposition is given by

$$\tilde{\mathcal{L}}_k^{-1} v_l \tilde{d}_l e_l^\top \tilde{\mathcal{U}}_k^{-1}$$

from the L-part and

$$\tilde{\mathcal{L}}_k^{-1} e_l \tilde{d}_l w_l^\top \tilde{\mathcal{U}}_k^{-1}$$

from the U-part. For the T-version one can skip one of the inverse factors, as can be seen from (2.14). This indicates that it is wise to incorporate the norm $\|\tilde{\mathcal{L}}_k^{-1}\|$ into the dropping strategy at step l when entries of $\mathcal{L}_l$ are being dropped. In principle one should also include the norm $\|\tilde{\mathcal{U}}_k^{-1}\|$ in the S-version case when dropping in $\mathcal{L}_k$. Similar arguments apply when dropping in $\mathcal{U}_k$.

Unless we control the growth of $\tilde{\mathcal{L}}_k^{-1}$ and $\tilde{\mathcal{U}}_k^{-1}$ and keep their norm below a constant κ, the error introduced by dropping at step l can be arbitrarily amplified by the inverse factors.

COROLLARY 2.3. [illegible] $\|L_l^{-1}\| \leqslant \kappa$ [illegible] $\|U_l^{-1}\| \leqslant \kappa$ [illegible] $l = 1, \ldots, k$ [illegible] $\kappa > 0$ [illegible] $\tilde{d}_l$ [illegible] l

1. [illegible] $\tilde{s}_{lj}$ [illegible] $\tilde{s}_{il}$ [illegible] $i, j > l$ [illegible] l [illegible] $\tilde{s}_{lj}$ $\tilde{s}_{il}$ [illegible]

$$\kappa^2 |\tilde{s}_{lj}| \leqslant \varepsilon |\tilde{d}_l|, \ \kappa^2 |\tilde{s}_{il}| \leqslant \varepsilon |\tilde{d}_l|;$$

[illegible]

$$\mathcal{F}_k = \sum_{l=1}^{k} \mathcal{F}_{L,l} + \sum_{l=1}^{k} \mathcal{F}_{U,l},$$

[illegible] $F_{L,l}$ [illegible] $F_{U,l}$ [illegible] 1 [illegible] $\varepsilon |\tilde{d}_l|$

2. [illegible] $\tilde{t}_{lj}$ [illegible] $\tilde{t}_{il}$ [illegible] $i,j > l$ [illegible] l [illegible] $i,j > l$ $\tilde{t}_{lj}$ [illegible] $\tilde{t}_{il}$ [illegible]

$$\kappa|\tilde{t}_{lj}| \leqslant \varepsilon|\tilde{d}_l|, \ \kappa|\tilde{t}_{il}| \leqslant \varepsilon|\tilde{d}_l|;$$

[illegible]

$$\mathcal{F}_k = \mathcal{F}_{L,k}\tilde{\mathcal{D}}_k + \tilde{\mathcal{D}}_k\mathcal{F}_{U,k},$$

[illegible]

$$\max_{i,j} e_i^\top |\mathcal{F}_{L,k}| e_j \leqslant \varepsilon, \qquad \max_{i,j} e_i^\top |\mathcal{F}_{U,k}| e_j \leqslant \varepsilon.$$

[illegible]. The results follow immediately from the assumptions and (2.13) for the S-version case and (2.14) for the T-version case. □

2.2. The multilevel framework. Multilevel ILU procedures do not usually proceed until $k = n$; stop at a certain step k and postpone factoring the remaining part to the next level. Thus, one can write at a given level η

$$P^\top A_\eta Q = \begin{pmatrix} B & F \\ E & C \end{pmatrix} = \begin{pmatrix} \tilde{L}_B & 0 \\ \tilde{L}_E & I \end{pmatrix} \begin{pmatrix} \tilde{D}_B & 0 \\ 0 & \tilde{S} \end{pmatrix} \begin{pmatrix} \tilde{U}_B & \tilde{U}_F \\ 0 & I \end{pmatrix} + \mathcal{E}_k \rightarrow A_{\eta+1} = \tilde{S}.$$

Postponing the factorization of $A_{\eta+1} \equiv S$ may be mandatory because the prescribed bound may otherwise be exceeded. When considering the next level matrix $A_{\eta+1}$, specific techniques, such are nonsymmetric permutations, can be invoked to ensure that the factorization at this level is more accurate and reliable. The simple version of the Schur complement is often preferred since it leads to less fill-in than the T-version. However, the stability analysis seen above has shown that this version is much more sensitive to perturbations. On the other hand, the T-version gains from its higher robustness, but it will suffer from the fact that it is more expensive to compute and it may have significantly more fill-in.

A natural way of combining the S-version and the T-version in a multilevel framework could be to approximate B only using the S-version. This could still give a good approximation as long as B is, say, close to being diagonal dominant. But for the next level which requires the remaining Schur complement, one could switch to the T-version. This leads to the M-version.

M-[illegible]: Define the approximate Schur complement via

$$\tilde{M} = \begin{pmatrix} -\tilde{L}_E\tilde{L}_B^{-1} & I \end{pmatrix} P^\top A Q \begin{pmatrix} -\tilde{U}_B^{-1}\tilde{U}_F \\ I \end{pmatrix} \tag{2.15}$$

at step k and via the S-version prior to step k.

The motivation for this variant is that in a multilevel approach, it sometimes is possible to ensure that the factors of the B block are nicely bounded. In this situation it pays to compute the Schur complement more accurately, and the T-version may be ideal for this.

COROLLARY 2.4. [illegible] LU [illegible] $l = 1, \ldots, k$ [illegible] k [illegible]

$$\Pi = \begin{pmatrix} 0 & 0 \\ 0 & I \end{pmatrix}.$$

(2.16)
$$\begin{aligned}\mathcal{F}_k = &\left(\tilde{\mathcal{L}}_k^{-1}\mathcal{V}_k\tilde{\mathcal{D}}_k\tilde{\mathcal{U}}_k^{-1} + \tilde{\mathcal{L}}_k^{-1}\tilde{\mathcal{D}}_k\mathcal{W}_k\tilde{\mathcal{U}}_k^{-1}\right)\\ &-\Pi\left(\tilde{\mathcal{L}}_k^{-1}\mathcal{V}_k\tilde{\mathcal{D}}_k\tilde{\mathcal{U}}_k^{-1} + \tilde{\mathcal{L}}_k^{-1}\tilde{\mathcal{D}}_k\mathcal{W}_k\tilde{\mathcal{U}}_k^{-1}\right)\Pi.\end{aligned}$$

. Since we compute until step k the incomplete LU decomposition via the S-version, we will have until that step

$$\mathcal{E}_k = \mathcal{V}_k\tilde{\mathcal{D}}_k + \tilde{\mathcal{D}}_k\mathcal{W}_k.$$

As we now switch to the T-version, it means that we precisely have

$$\tilde{M} = \begin{pmatrix} 0 & I \end{pmatrix}\tilde{\mathcal{L}}_k^{-1}(P^\top AQ)\tilde{\mathcal{U}}_k^{-1}\begin{pmatrix} 0 \\ I \end{pmatrix} \Rightarrow \begin{pmatrix} 0 & I \end{pmatrix}\mathcal{F}_k\begin{pmatrix} 0 \\ I \end{pmatrix} = 0.$$

This means that there will be no error in the lower right block. ∎

The inverse error that has been computed so far is based on the assumption that the approximate factorization from (2.1) is used with either the S-version or the T-version as approximate Schur complement. Since we would like to use this ILU in a multilevel context, we do not have to keep the factors $\tilde{L}_E$ and $\tilde{U}_F$. Instead we can substitute them with $E\tilde{U}_B^{-1}\tilde{D}_B^{-1}$ and $\tilde{D}_B^{-1}\tilde{L}_B^{-1}F$. Keeping in mind that we will not compute these factors explicitly but only solve systems with them, this leads to the approximate factorization

(2.17)
$$\begin{pmatrix} B & F \\ E & C \end{pmatrix} = \underbrace{\begin{pmatrix} \tilde{L}_B & 0 \\ E\tilde{U}_B^{-1}\tilde{D}_B^{-1} & I \end{pmatrix}}_{\tilde{L}_k}\underbrace{\begin{pmatrix} \tilde{D}_B & 0 \\ 0 & \tilde{S} \end{pmatrix}}_{\tilde{D}_k}\underbrace{\begin{pmatrix} \tilde{U}_B & \tilde{D}_B^{-1}\tilde{L}_B^{-1}F \\ 0 & I \end{pmatrix}}_{\tilde{U}_k} + \mathcal{E}_k.$$

In this case one can easily see that the error and the inverse error only show up in the B-part and the C-part.

THEOREM 2.5. *LU* (2.17) $\mathcal{V}_k$ $\mathcal{W}_k$ (2.11)–(2.12)

1.
$$\mathcal{F}_k = \tilde{\mathcal{L}}_k^{-1}\begin{pmatrix} V_B\tilde{D}_B + \tilde{D}_BW_B & 0 \\ 0 & 0 \end{pmatrix}\tilde{\mathcal{U}}_k^{-1}.$$

2.
$$\begin{aligned}\mathcal{F}_k = &\quad \tilde{\mathcal{L}}_k^{-1}\begin{pmatrix} V_B\tilde{D}_B + \tilde{D}_BW_B & 0 \\ 0 & 0 \end{pmatrix}\tilde{\mathcal{U}}_k^{-1}\\ &-\Pi\tilde{\mathcal{L}}_k^{-1}\begin{pmatrix} V_B\tilde{D}_B + \tilde{D}_BW_B & 0 \\ 0 & 0 \end{pmatrix}\tilde{\mathcal{U}}_k^{-1}\Pi,\end{aligned}$$

Π 2.4

. From (2.17) one can immediately see that

$$\mathcal{E}_k = \begin{pmatrix} * & 0 \\ 0 & * \end{pmatrix}.$$

Then the assertion follows immediately from Corollaries 2.2 and 2.4. ∎

In principle, for the T-version the same approach leads to analogous bounds which are more complicated. But one essential property will be lost: Entries dropped in the lower triangular part would only contribute to the perturbation in this part (similar for the upper triangular part).

2.3. The inverse error contribution from lower levels. In the multilevel context the best we can achieve is to find permutation matrices P_C and Q_C for the approximate Schur complement $\tilde{S}$ such that

$$\left.\begin{array}{c} P_C^\top \tilde{S} Q_C \\ P_C^\top \tilde{M} Q_C \\ P_C^\top \tilde{T} Q_C \end{array}\right\} = L_C D_C U_C + \mathcal{E}_C,$$

where D_C is diagonal and $\|L_C^{-1}\|, \|U_C^{-1}\| \leqslant \kappa$ with a reasonable small inverse error $\mathcal{F}_C = L_C^{-1} \mathcal{E}_C U_C^{-1}$. In this case we finally end up with an approximate factorization:

$$\begin{aligned} &\begin{pmatrix} I & 0 \\ 0 & L_C^{-1} P_C^\top \end{pmatrix} \mathcal{L}_k^{-1} P^\top A Q \mathcal{U}_k^{-1} \begin{pmatrix} I & 0 \\ 0 & Q_C U_C^{-1} \end{pmatrix} \\ &= \begin{pmatrix} D_B & 0 \\ 0 & D_C \end{pmatrix} + \begin{pmatrix} I & 0 \\ 0 & L_C^{-1} P_C^\top \end{pmatrix} \mathcal{F}_k \begin{pmatrix} I & 0 \\ 0 & Q_C U_C^{-1} \end{pmatrix} + \begin{pmatrix} I & 0 \\ 0 & \mathcal{F}_C \end{pmatrix}. \end{aligned}$$

This result indicates that the inverse error might be amplified by the additional inverse factors L_C^{-1} and U_C^{-1} from the lower levels. Although this is an extremal case and we expect this to rarely happen in practice, this suggests again that it is strongly advisable to also keep the inverse factors L_C^{-1} and U_C^{-1} bounded.

2.4. Perturbation of the approximate Schur complement. The results discussed so far dealt with perturbations introduced by dropping compared with the diagonal part and the remaining approximate Schur complement

$$\tilde{\mathcal{D}}_k = \begin{pmatrix} \tilde{D}_B & 0 \\ 0 & \tilde{X} \end{pmatrix},$$

where $\tilde{X}$ is one of $\tilde{S}$, $\tilde{M}$, or $\tilde{T}$. Nothing has been said so far about the error between the approximate Schur complements $\tilde{S}$, $\tilde{M}$, and $\tilde{T}$ and the exact Schur complement $S = C - EB^{-1}F$. This information is of great importance since the approximate Schur complement will be used as the input matrix for the next level. The perturbation results deal only with the approximate Schur complement, and as long as the inverse triangular factors are kept bounded it is likely that the errors are small. But in a relative sense even small perturbations may have a serious impact on the preconditioned system if the diagonal entries of $\mathcal{D}_k$ become small in absolute value. This may be a property of the underlying original system. But this may in particular happen if the approximate Schur complement becomes ill conditioned.

For this reason we will investigate the error introduced to the approximate Schur complement by computing the incomplete LU factorization. An incomplete LU decomposition results in an approximate factorization from (2.1) of the type

$$A = \tilde{\mathcal{L}}_k \tilde{\mathcal{D}}_k \tilde{\mathcal{U}}_k + \mathcal{E}_k,$$

where it is assumed that no pivoting is necessary to ensure that $\|\tilde{\mathcal{L}}_k\|, \|\tilde{\mathcal{U}}_k\| \leqslant \kappa$. Suppose that we can also exactly factor A as

$$A = \mathcal{L}_k \mathcal{D}_k \mathcal{U}_k,$$

where

$$\mathcal{L}_k = \begin{pmatrix} L_B & 0 \\ L_E & I \end{pmatrix}, \quad \mathcal{U}_k = \begin{pmatrix} U_B & U_F \\ 0 & I \end{pmatrix}, \quad \mathcal{D}_k = \begin{pmatrix} D_B & 0 \\ 0 & S \end{pmatrix},$$

and $L_B, U_B^\top$ are unit lower triangular; D_B is diagonal, and S is the exact Schur complement.

Comparing the exact Schur complement and the approximate Schur complements we find that

$$\tilde{\mathcal{L}}_k^{-1}\mathcal{L}_k\mathcal{D}_k\mathcal{U}_k\tilde{\mathcal{U}}_k^{-1} = \tilde{\mathcal{D}}_k + \mathcal{F}_k.$$

Looking only at the lower right block yields

$$\left.\begin{matrix}\tilde{S}\\ \tilde{M}\\ \tilde{T}\end{matrix}\right\} = S - \tilde{L}_E\tilde{L}_B^{-1}(L_B - \tilde{L}_B)D_B(U_B - \tilde{U}_B)\tilde{U}_B^{-1}\tilde{U}_F - (0,I)\mathcal{F}_k\begin{pmatrix}0\\ I\end{pmatrix}. \tag{2.18}$$

From this equation we can see that the error between the exact and approximate Schur complements is driven by

1. the previous error $L_B - \tilde{L}_B$ and $U_B - \tilde{U}_B$ between both factorizations,
2. the inverse error $(0,I)\mathcal{F}_k\left(\begin{smallmatrix}0\\ I\end{smallmatrix}\right)$ produced by dropping and the choice of the approximate Schur complement, and
3. the norm of the inverse triangular factors $\tilde{\mathcal{L}}_k^{-1}$ and $\tilde{\mathcal{U}}_k^{-1}$ ($\|\tilde{L}_E\tilde{L}_B^{-1}\|, \|\tilde{U}_B^{-1}\tilde{U}_F\| \leqslant \kappa$).

Suppose that the error from previous steps is bounded by ε. If we ensure that at step k entries are dropped such that $\|(0,I)\mathcal{F}_K\left(\begin{smallmatrix}0\\ I\end{smallmatrix}\right)\| \leqslant \varepsilon$ and that $\varepsilon^2\kappa^2 \leqslant \varepsilon$, then the remaining error in (2.18) will reveal the same order ε. We will summarize this observation in a theorem.

Denote the entries of the approximate Schur complements $\tilde{S}^{(l)}, \tilde{T}^{(l)}$ after $l = 1, \ldots, k$ steps of incomplete Gaussian elimination by $\tilde{s}_{ij}^{(l)}$ ($\tilde{t}_{ij}^{(l)}$, respectively). To simplify the analysis we assume that

$$\Gamma \geqslant |\tilde{s}_{ll}^{(m)}|, |\tilde{t}_{ll}^{(m)}| \geqslant \gamma, \tag{2.19}$$

$m = 0, \ldots, k$, $l = 1, \ldots, k$. For the leading k diagonal entries this means that they are approximately of the same order. Initially this can be achieved by scaling and reordering, which will in fact be done in the section on numerical examples.

THEOREM 2.6. [illegible] (2.19) [illegible] κ [illegible] ε [illegible] $\frac{1}{\kappa^2}$

1. [illegible] m $m = 1, \ldots, k$ [illegible] l_{im} u_{mj} $\tilde{\mathcal{L}}_m$ $\tilde{\mathcal{U}}_m$ [illegible]

$$|\tilde{l}_{im}|, |\tilde{u}_{mj}| \leqslant \frac{\varepsilon}{\kappa^2}.$$

[illegible] K [illegible] i, j [illegible]

$$|s_{ij} - \tilde{s}_{ij}| \leqslant K\varepsilon.$$

2. [illegible] K [illegible] i, j [illegible]

$$|s_{ij} - \tilde{m}_{ij}| \leqslant K(\kappa\varepsilon)^2.$$

3. [illegible] m $m = 1, \ldots, k$ [illegible] l_{im} [illegible] u_{mj} [illegible] $\tilde{\mathcal{L}}_m$ [illegible] $\tilde{\mathcal{U}}_m$ [illegible]

$$|\tilde{l}_{im}|, |\tilde{u}_{mj}| \leqslant \varepsilon.$$

[illegible] K [illegible] i, j [illegible]

$$|s_{ij} - \tilde{t}_{ij}| \leqslant K(\kappa\varepsilon)^2.$$

[illegible] Suppose that at step m we have

$$|s_{ij}^{(m)} - \tilde{s}_{ij}^{(m)}| \leqslant K\varepsilon$$

for the S- and M-versions, respectively, and $|s_{ij}^{(m)} - \tilde{t}_{ij}^{(m)}| \leqslant K\varepsilon$ for the T-version. Because of (2.19) it follows that there exists a further constant C such that

$$|l_{ij} - \tilde{l}_{ij}|, |u_{ji} - \tilde{u}_{ji}| \leqslant C\varepsilon, \qquad j = 1, \ldots, m, \quad i > j.$$

From (2.18) we obtain that after step $m+1$, the error $|s_{ij}^{(m+1)} - \tilde{s}_{ij}^{(m+1)}|$ and $|s_{ij}^{(m+1)} - \tilde{t}_{ij}^{(m+1)}|$ can be bounded by

$$\max |\tilde{L}_E \tilde{L}_B^{-1}(L_B - \tilde{L}_B) D_B (U_B - \tilde{U}_B)\tilde{U}_B^{-1}\tilde{U}_F| + \max \left| (0, I)\mathcal{F}_k \begin{pmatrix} 0 \\ I \end{pmatrix} \right|.$$

For the first part we obtain the bound

$$\max |\tilde{L}_E \tilde{L}_B^{-1}(L_B - \tilde{L}_B) D_B (U_B - \tilde{U}_B)\tilde{U}_B^{-1}\tilde{U}_F| \leqslant \Gamma\varepsilon^2\kappa^2.$$

Since $\varepsilon\kappa^2 < 1$, we see that

$$\max |\tilde{L}_E \tilde{L}_B^{-1}(L_B - \tilde{L}_B) D_B (U_B - \tilde{U}_B)\tilde{U}_B^{-1}\tilde{U}_F| \leqslant \Gamma\varepsilon.$$

Suppose we can show that the entries $|s_{ij}^{(m+1)} - \tilde{s}_{ij}^{(m+1)}|$ and $|s_{ij}^{(m+1)} - \tilde{t}_{ij}^{(m+1)}|$ are bounded by $K\varepsilon$. Then the same has to hold for the $(m+1)$ column of $\mathcal{L}_{m+1} - \tilde{\mathcal{L}}_{m+1}$ and $\mathcal{U}_{m+1}^\top - \tilde{\mathcal{U}}_{m+1}^\top$, since by hypothesis (2.19) the diagonal entries of the approximate Schur complement are uniformly bounded away from zero.

It remains to show that we can bound the error $|s_{ij}^{(m+1)} - \tilde{s}_{ij}^{(m+1)}|$, $|s_{ij}^{(m+1)} - \tilde{t}_{ij}^{(m+1)}|$ by $K\varepsilon$; i.e., we have to show that

$$\max |(0, I)\mathcal{F}_k \begin{pmatrix} 0 \\ I \end{pmatrix}| \leqslant L\varepsilon$$

for some constant L.

1. According to Theorem 2.5, for the S-version we will have

$$\mathcal{F}_{m+1} = \tilde{\mathcal{L}}_{m+1}^{-1} \begin{pmatrix} V_B \tilde{D}_B + \tilde{D}_B W_B & 0 \\ 0 & 0 \end{pmatrix} \tilde{\mathcal{U}}_{m+1}^{-1}.$$

Thus, if the entries in L_B and U_B in every step are dropped at most if they are less than ε/κ^2, then the inverse error is also bounded by a constant L times ε. From this it follows that the error $|s_{ij}^{(m+1)} - \tilde{s}_{ij}^{(m+1)}|$ remains below a constant times ε.

2. For step $1, \ldots, k$, the M-version and the S-version are the same. The difference between the M-version and the S-version is that after the final step k the remaining Schur complement is computed in a different way; i.e., the lower right block of the inverse error $\mathcal{F}_k$ vanishes.
3. For the T-version we note that by Corollary 2.2 the inverse error $\mathcal{F}_m$ is given by

$$\mathcal{F}_m = \tilde{\mathcal{L}}_m^{-1}\mathcal{V}_m\tilde{\mathcal{D}}_m + \tilde{\mathcal{D}}_m\mathcal{W}_m\tilde{\mathcal{U}}_m^{-1}.$$

That is, the entries that are dropped in $\tilde{\mathcal{L}}_m$ and $\tilde{\mathcal{U}}_m$ are only amplified by one inverse triangular factor. But by construction there is no inverse error in those positions, where the entries of the approximate Schur complement $\tilde{T}$ are located. Thus we don't have to divide by κ (or κ^2). Since $\varepsilon\kappa^2 < 1$, the error between the exact and the approximate Schur complements can be estimated by some constant K times ε. ∎

- For Theorem 2.6 it is essential to require that (2.19) be fulfilled. This is needed to ensure that the leading k diagonal entries of the approximate Schur complement are uniformly bounded away from zero, as well as to protect $\tilde{L}_E\tilde{L}_B^{-1}(L_B - \tilde{L}_B)D_B(U_B - \tilde{U}_B)\tilde{U}_B^{-1}\tilde{U}_F$ from being amplified by too large diagonal entries in D_B.
  This certainly indicates a strong need for preordering and scaling algorithms that properly prepare the leading block B. To safeguard this process, small diagonal pivots should be moved to the end. This is a side effect of keeping the inverse triangular factors below a bound κ, since $\kappa|s_{mm}^{(m)}| \geqslant \max_{i,j}\{|s_{im}^{(m)}|, |s_{mj}^{(m)}|\}$ is necessary to keep the inverse triangular factors below κ.
- From Theorem 2.6 we may conclude that the entries of $\tilde{\mathcal{L}}_k$ and $\tilde{\mathcal{U}}_k$ outside the leading $k \times k$ block are not needed at all. This is only true if the approximate Schur complement is not computed from these entries but by using $\tilde{\mathcal{L}}_k$, $\tilde{\mathcal{U}}_k$ from (2.17). Otherwise, using Corollary 2.2 we need to keep

$$\max|\mathcal{F}_{m+1}| = \max|\tilde{\mathcal{L}}_{m+1}^{-1}\mathcal{V}_{m+1}\tilde{\mathcal{D}}_{m+1}\tilde{\mathcal{U}}_{m+1}^{-1} + \tilde{\mathcal{L}}_{m+1}^{-1}\tilde{\mathcal{D}}_{m+1}\mathcal{W}_{m+1}\tilde{\mathcal{U}}_{m+1}^{-1}| \leqslant L\varepsilon,$$

which shows that even the entries in the E and F block need to be less than ε/κ^2.

3. Inverse-based multilevel ILUs. Corollary 2.2 suggests that, whenever possible, incomplete LU factorizations should be computed in such a way that the inverse triangular factors remain bounded. While keeping the entries of L and U small is straightforward, e.g., with the help of pivoting, making the same demand for the inverse matrices is more delicate. We have adopted a strategy to achieve these features, which is based on combining the following three ingredients.

1. A static preordering of the system that puts the original matrix A in the form

$$P^\top AQ = \begin{pmatrix} B & F \\ E & C \end{pmatrix},$$

where the leading block B is likely to have nicely bounded inverse triangular factors.
2. A partial incomplete LU factorization which approximately factors $P^\top AQ$ and uses pivoting to keep the inverse triangular factors below a given bound κ. The factorization is partial in that it only proceeds with the elimination of the unknowns corresponding to the B block. Details are given below.

3. A multilevel setting, possibly a recursive one, which completes the partial incomplete factorization of step 2. Indeed, this amounts to (recursively) repeating the previous two steps on the Schur complement system resulting from step 2.

A few clarifications are now given for steps 2 and 3. Step 2 starts with a new reordering $P^\top AQ \rightarrow \hat{P}^\top A\hat{Q}$ of A with a smaller leading block. This reordering consists of moving to the end rows and columns that are responsible for undesired large inverse factors. In other words, we obtain

$$\hat{P}^\top A\hat{Q} = \tilde{P}^\top (P^\top AQ)\tilde{Q} = \tilde{P}^\top \begin{pmatrix} B & F \\ E & C \end{pmatrix} \tilde{Q} = \left(\begin{array}{c|cc} B_{11} & B_{12} & F_1 \\ \hline B_{21} & B_{22} & F_2 \\ E_1 & E_2 & C \end{array}\right) \equiv \left(\begin{array}{c|c} \hat{B} & \hat{F} \\ \hline \hat{E} & \hat{C} \end{array}\right).$$

The incomplete factorization is then computed for

$$\hat{P}^\top A\hat{Q} = \left(\begin{array}{c|c} \hat{B} & \hat{F} \\ \hline \hat{E} & \hat{C} \end{array}\right) \approx \underbrace{\left(\begin{array}{c|c} L_{\hat{B}} & 0 \\ \hline L_{\hat{E}} & I \end{array}\right)}_{\mathcal{L}} \left(\begin{array}{c|c} D_{\hat{B}} & 0 \\ \hline 0 & S \end{array}\right) \underbrace{\left(\begin{array}{c|c} U_{\hat{B}} & U_{\hat{F}} \\ \hline 0 & I \end{array}\right)}_{\mathcal{U}}, \tag{3.1}$$

where $L_{\hat{B}}, U_{\hat{B}}^\top$ are unit lower triangular factors, $D_{\hat{B}}$ is diagonal, and S is the approximate Schur complement. The partial incomplete factorization is performed ensuring that the inverse triangular factors fulfill $\|\mathcal{L}^{-1}\|, \|\mathcal{U}^{-1}\| \leqslant \kappa$.

Further comments on these three pieces of the factorization are given next.

3.1. Template 1: Preorderings. Standard static ordering techniques can be used to give some desirable properties to the original matrix. Among these are all the graph-based routines to reduce fill-in and more recent approaches to improve diagonal dominance. A few popular examples of fill-reducing methods are the reverse Cuthill–McKee (RCM), the multiple minimum degree ordering (MMD), the nested dissection (ND), and the approximate minimum fill (AMF). See [11] for an overview of some of these reorderings and [16, 1] for the AMF ordering.

The nonsymmetric orderings used in MC64 [10] and in the ddPQ strategy [18] attempt to improve the diagonal dominance of the matrix in different ways. The objective is to rearrange the columns and/or the rows so that the diagonal part gets a maximum weight. In [10] scaling is part of this approach but fill reduction is performed by a static (symmetric) postordering of the resulting matrix. In contrast, ddPQ assumes that some scaling is done a priori and the reordering is performed as a compromise between diagonal dominance and fill. A more detailed description of MC64 is provided in section 4.

3.2. Template 2: Partial incomplete LU decomposition. A partial (I)LU of a partitioned matrix is a factorization of the matrix in the form of the right-hand side of (3.1). Any Gaussian elimination-based procedure can be adapted to yield a partial factorization. However, the most attractive method exploits the Crout version of Gaussian elimination; see [9, p. 50] and [14]. The Crout (sometimes referred to as the Crout–Doolittle) algorithm computes the kth column of L and the kth row of U at step k. A partial factorization consists of performing a number, say p, steps of this algorithm and then computing the Schur complement. There are several advantages of Crout versions of ILU, some of which are discussed in [14].

In the context of the partial ILU factorization needed for a multilevel scheme, diagonal pivoting is necessary. In fact pivoting is an integral part of the reordering

scheme. Diagonal pivoting relies on various estimates for the inverse triangular factors; see, e.g., [6, 12]. When the estimated norm of the inverse triangular factor exceeds the prescribed bounds, then the associated column and row are pushed to the end (see Figure 3.1). From the point of view of implementation, a diagonal pivoting strategy of this type can be easily added to the Crout factorization.

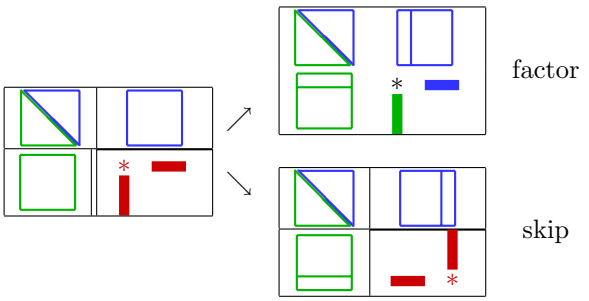

FIG. 3.1. *Diagonal pivoting in the Crout version.*

3.3. Template 3: The multilevel scheme. The next part of the preconditioner involves recursion by repeating the first two steps on the approximate Schur complement resulting from step 2. This leads naturally to a multilevel strategy. To solve a linear system using this multilevel ILU, we could simply proceed as in [20]. Based on the underlying approximate factorization

$$P^\top AQ = \begin{pmatrix} B & F \\ E & C \end{pmatrix} \approx \begin{pmatrix} I & 0 \\ EB^{-1} & I \end{pmatrix} \begin{pmatrix} B & 0 \\ 0 & \tilde{S}_C \end{pmatrix} \begin{pmatrix} I & B^{-1}F \\ 0 & I \end{pmatrix},$$

the associated preconditioner would require the application of

$$(P^\top AQ)^{-1} \approx \begin{pmatrix} \tilde{B}^{-1} & 0 \\ 0 & 0 \end{pmatrix} + \begin{pmatrix} -\tilde{B}^{-1}F \\ I \end{pmatrix} \tilde{S}_C^{-1} \begin{pmatrix} -E\tilde{B}^{-1} & I \end{pmatrix}. \tag{3.2}$$

Here $\tilde{B}$ is the approximation to B corresponding to an ILU of B, and a solve with $\tilde{S}_C$ in (3.2) corresponds to a recursive solve invoking the next "coarser" level.

4. Numerical tests. This section presents numerical experiments to test the inverse-based multilevel ILU approach. We begin by pointing out that the algorithms described in this paper are part of a recently released package called ILUPACK [4], which is available online. Along with the package, the ILUPACK website [4] also posts a rather exhaustive set of experiments with various publicly available test matrices. The numerical computations were performed on an IBM RISC 6000 with four Power 3-II processors (375 MHz). Sixty-four bit address length and up to 4 GB memory were used. All codes use optimization.

The discussion of the experiments centers around two main questions:

- How does the reliability depend on the drop tolerance? (sensitivity)
- How many problems (statistically) can be solved with an incomplete LU factorization (with or without multilevel) if we fix the number of nonzeros of L, U relative to the nonzeros of A?

We will compare three approaches:

1. ILUTP [17, 18] using a binary search tree;

2. inverse-based ILUTC [14], which computes a single ILU without pivoting and uses the inverse triangular factors within dropping;
3. inverse-based multilevel ILU as described in section 3, hereafter referred to as ILUPACK. According to the theory presented here we will use the S-version (SIMPLE version) and the M-version (DEFAULT version).

These methods are combined with several reordering strategies:

(a) AMF [1],
(b) MMD [11],
(c) RCM [11], and
(d) ddPQ, a strategy recently presented in [19], which we will also use for the multilevel strategy.

A recent algorithm called MC64 [10] that is designed to improve the diagonal dominance is also included in the numerical results for comparison and in order to see how MC64 can help improve performance. The MC64 algorithm computes a nonsymmetric permutation via a maximum weight matching based on the bipartite graph representation of the input matrix A. This is a well-known assignment problem in operations research and combinatorial analysis. In the solution of the assignment problem, a permutation matrix P and two vectors $u = (u_i)_{i=1,\dots,n}$ and $v = (v_i)_{i=1,\dots,n}$ are generated (so-called dual variables). $D_r = \text{diag}\,(u_1, \dots, u_n)$ and $D_c = \text{diag}\,(v_1, \dots, v_n)$ can be used to rescale the input matrix and P is used to reorder its columns. The matrix $D_r A D_c P$ resulting from these operations has diagonal entries which are one in modulus and off-diagonal entries which do not exceed one in modulus. Note that in our numerical experiments the time for MC64 is almost negligible relative to that of the incomplete LU factorization and the iterative solution process. This confirms earlier observations made in [2].

All codes that are used refer to their versions as they were implemented in ILUPACK [4]. As iterative solver restarted GMRES(30) [18] is used. The iteration is stopped whenever the residual is reduced by $\sqrt{\text{eps}} \approx 1.5 \cdot 10^{-8}$. The iterative process is deemed to have failed if more than 500 steps are required or a breakdown occurs.

For the inverse-based multilevel ILU we prescribe the bound κ for the inverse factors. However, dropping is not performed with respect to some drop tolerance divided by this bound κ, but by the estimated maximum norm $\tilde{\kappa}$ of L_k^{-1} and U_k^{-1} at step k of the algorithm, which may be less than κ. This is done because one cannot predict a priori whether this bound κ is ever attained, so using $\tilde{\kappa} = \max(\|L_k^{-1}\|, \|U_k^{-1}\|)$ is a good compromise. As mentioned earlier the inverse norms are estimated by essentially using the results of [6].

4.1. Sensitivity with respect to the drop tolerance. The first set of numerical experiments investigates how the success of the incomplete LU decomposition is affected by the choice of the drop tolerance. To measure this sensitivity to drop tolerance, we use 81 test problems from PDEs available at the Davis collection [7] and from the Matrix Market [15]. We chose several larger matrices (at least a few thousand unknowns) that were available at the time of the numerical tests.

Figures 4.1, 4.2, and 4.3 show the relative number (percentage) of problems solved using a specific ILU (ILUTP, inverse-based ILUTC, and inverse-based multilevel ILU) and one of the above orderings (AMF/MMD/RCM/PQ). We show the results for the S-version of the inverse-based multilevel ILU (referred to as ILUPACK) and $\kappa = 10$.

Figures 4.1, 4.2, and 4.3 show clearly that the multilevel ILU is the least sensitive to the given drop tolerance. Using MC64 [10] one could even improve the results further. However, we noticed that for this class of problems only slight improvements

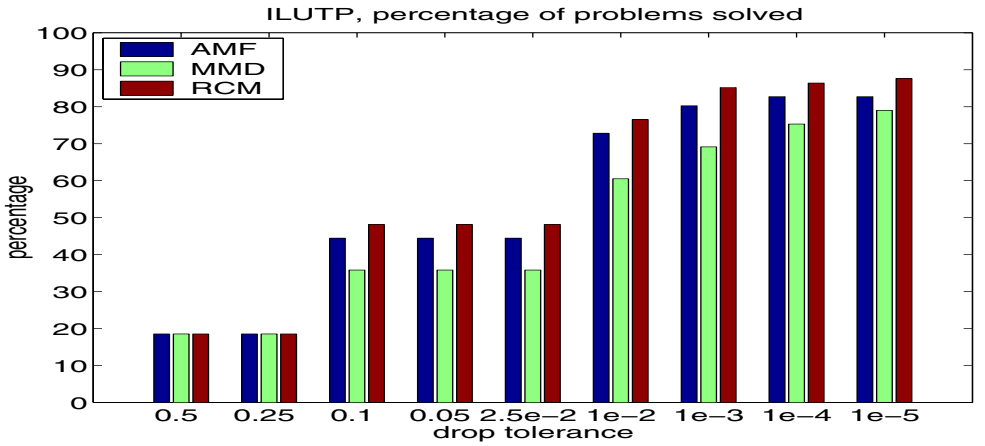

FIG. 4.1. *Numerical sensitivity of ILUTP (PDE problems).*

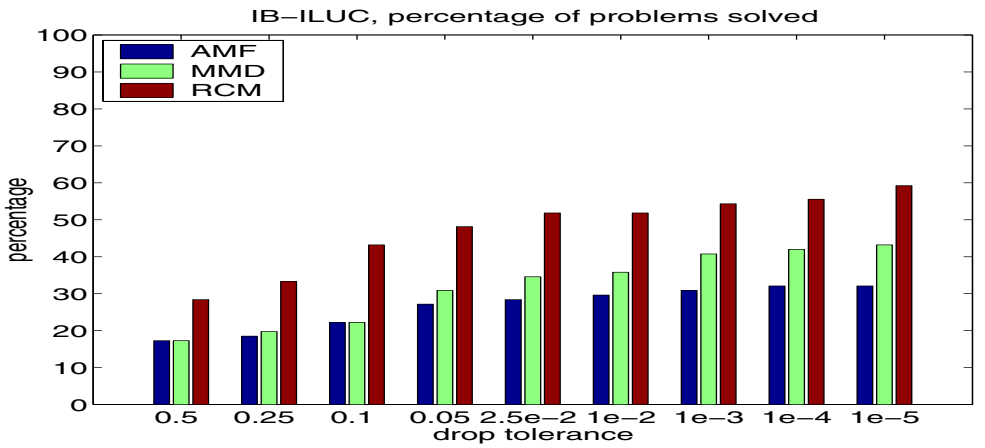

FIG. 4.2. *Numerical sensitivity of inverse-based ILUTC (PDE problems).*

were made. Note that matrices arising from PDEs are typically symmetrically structured and that orderings like AMF, MMD, and RCM, and ILUs such as ILUTC and the inverse-based multilevel ILU preserve symmetry.

4.2. Efficiency via fill-in. The above statistics regarding the dependence of the drop tolerance give only a partial idea of the efficiency of the methods. To get a more detailed view on the fill-in of the triangular factors resulting from the incomplete factorizations, we now study how the number of successfully solved systems is related to the fill-in resulting from the factorization. In a typical situation, an ILU which allows more fill-in is more accurate and should therefore yield faster convergence.

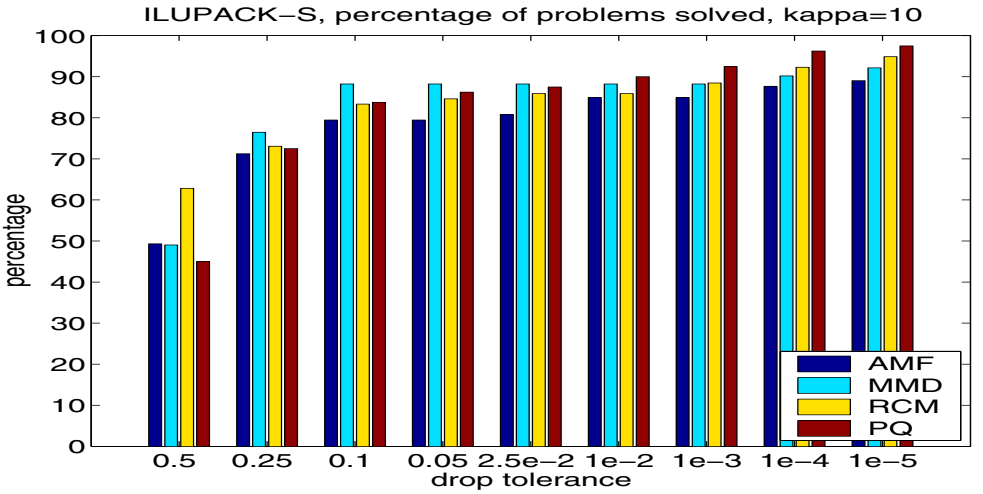

FIG. 4.3. *Numerical sensitivity of ILUPACK, S-version,* $\kappa = 10$ *(PDE problems).*

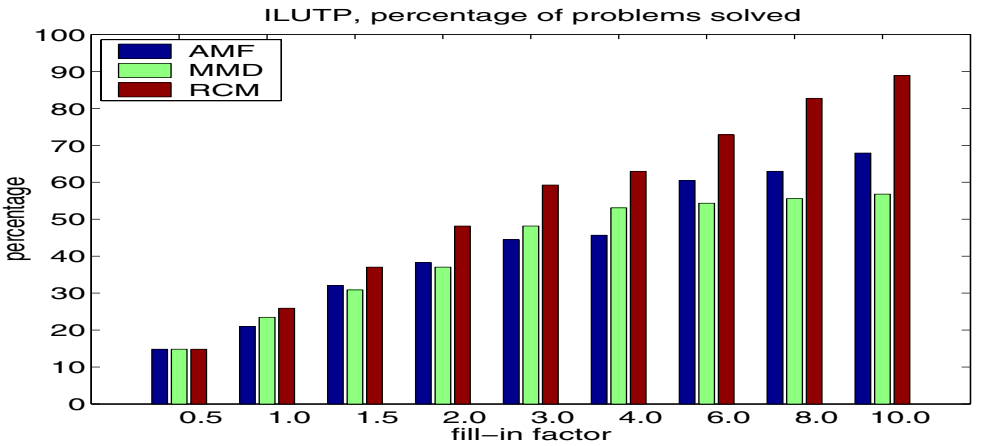

FIG. 4.4. *ILUTP, successful computation versus fill-in (PDE problems).*

The relevant results are in Figures 4.4, 4.5, and 4.6.

It turns out again that the fill-in of the triangular factor of the inverse-based multilevel ILU is the least related to the number of problems that could be solved. Better results can again be obtained by using MC64. Compared with the upcoming section 4.3 on unstructured problems, the improvements by MC64 here are not that impressive and show only a slight improvement.

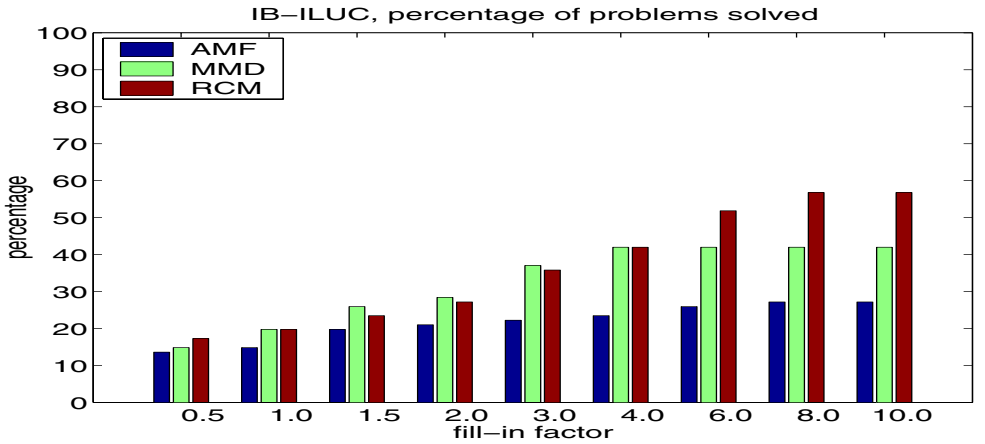

FIG. 4.5. *Inverse-based ILUTC, successful computation versus fill-in (PDE problems).*

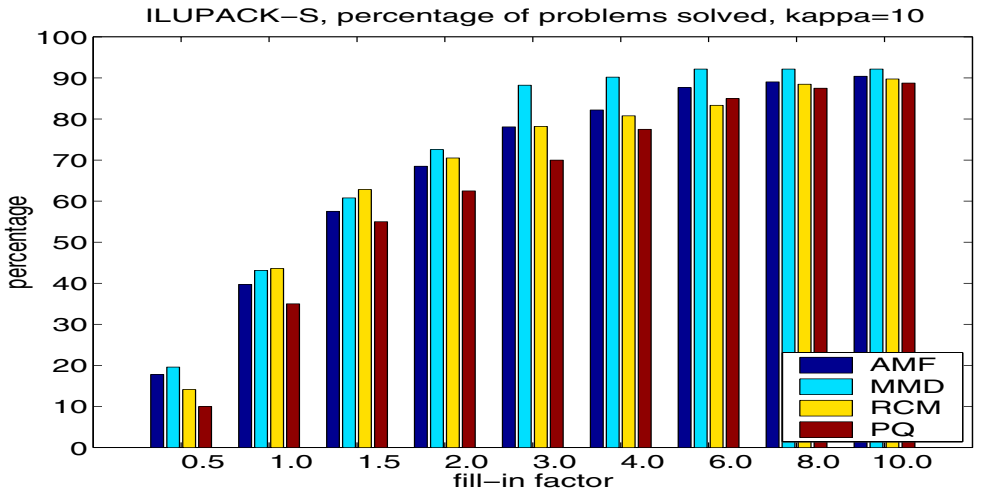

FIG. 4.6. *ILUPACK, S-version,* $\kappa = 10$*, successful computation versus fill-in (PDE problems).*

4.3. Unstructured problems. To give an idea of how the inverse-based multilevel ILU performs on highly unstructured problems we consider a set of 33 test problems from chemical engineering, available at [7]. These matrices are typically highly indefinite and pivoting, or an a priori nonsymmetric reordering, is often helpful. To show this we first present in Figures 4.7, 4.8, and 4.9 the statistics on the sensitivity with respect to the drop tolerance (analogous to the set of PDE problems) when the original matrices are considered.

It is important to mention that ILUPACK does not implement pure versions

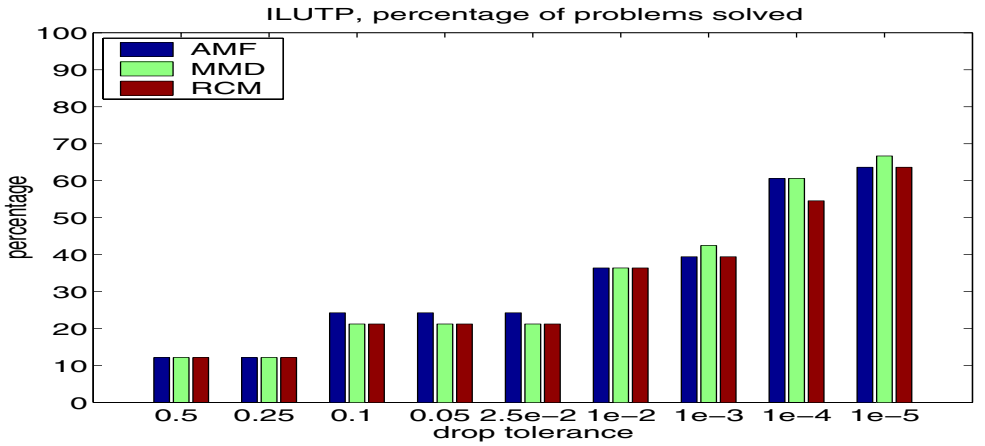

FIG. 4.7. *Numerical sensitivity of ILUTP (chemical engineering).*

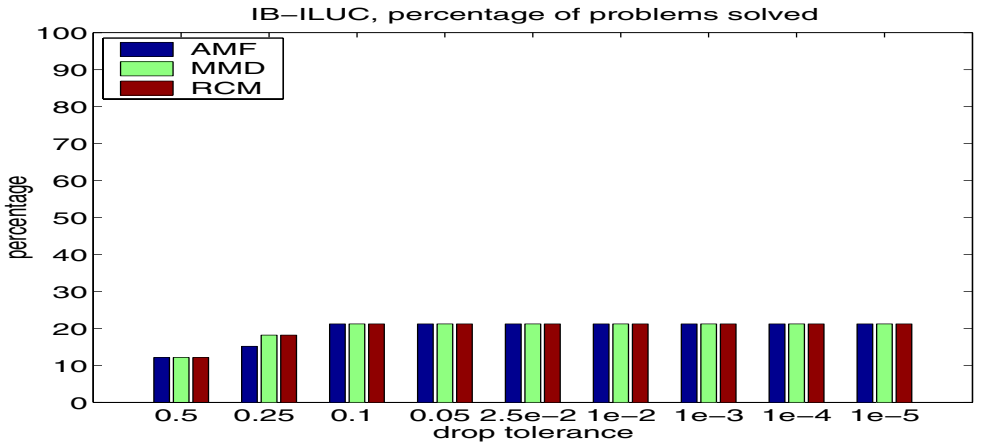

FIG. 4.8. *Numerical sensitivity of inverse-based ILUTC (chemical engineering).*

of the standard symmetric orderings like AMF, MMD, or RCM. Since these do not include any pivoting they are likely to fail on highly unstructured problems. The multilevel ILU in ILUPACK uses only diagonal pivoting, so it was configured so as to automatically switch to the ddPQ ordering when the other simple orderings (AMF, MMD, and RCM) fail to produce a sufficiently large leading diagonal block B. This explains why in Figures 4.7, 4.8, and 4.9 the orderings like AMF, MMD, and RCM perform quite well despite the high indefiniteness of the test problem class.

Due to the high indefiniteness of this problem class, MC64 dramatically improves the numerical performance. On the other hand, relative to ILUTP and ILUTC, the inverse-based multilevel ILU is only mildly affected by this reordering (cf. Figures

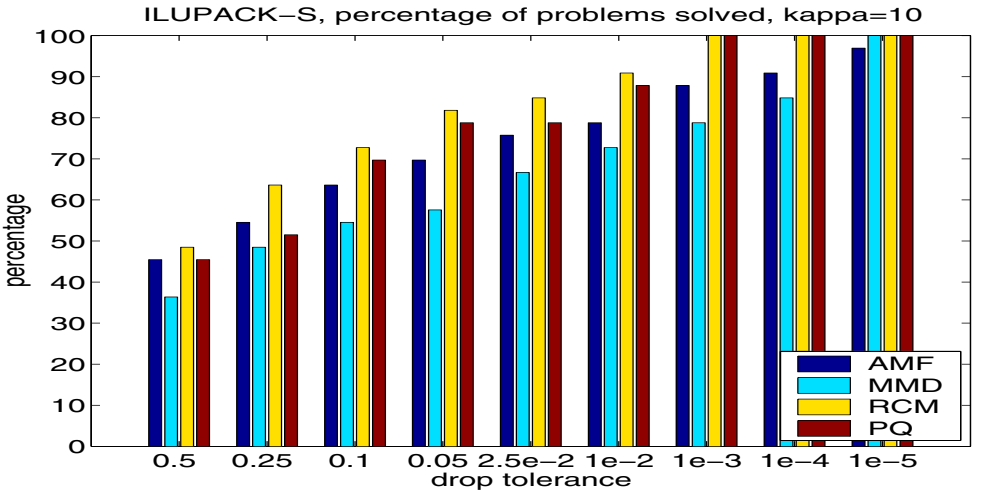

FIG. 4.9. *Numerical sensitivity of ILUPACK, S-version, $\kappa = 10$ (chemical engineering).*

4.10, 4.11, and 4.12).

We should point out again that ILUTC does not include any form of pivoting. This explains why it fails without MC64 for most problems but works very well after MC64 has been applied.

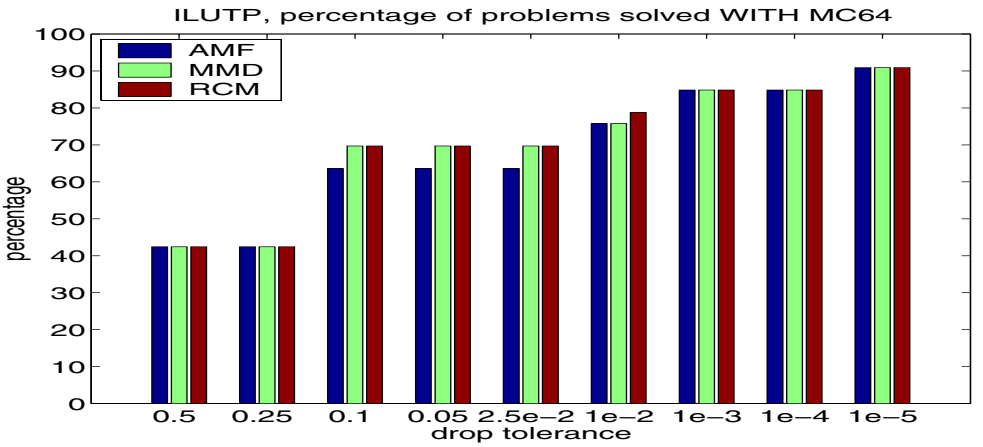

FIG. 4.10. *Numerical sensitivity of $ILUTP + MC64$ (chemical engineering).*

4.4. Variants of the inverse-based multilevel ILU. The previous results compare the new inverse-based multilevel ILU with existing ILU approaches in general terms. In this section we briefly comment on the impact of parameters such as the

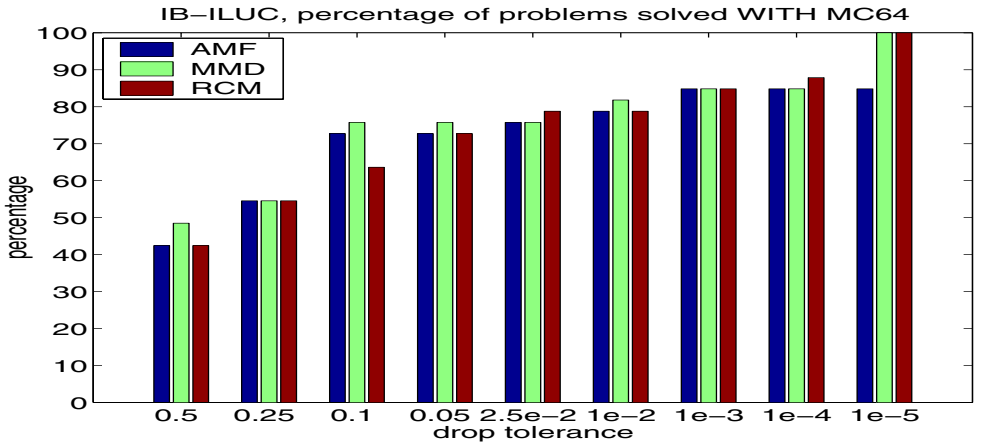

FIG. 4.11. *Numerical sensitivity of inverse-based ILUTC + MC64 (chemical engineering).*

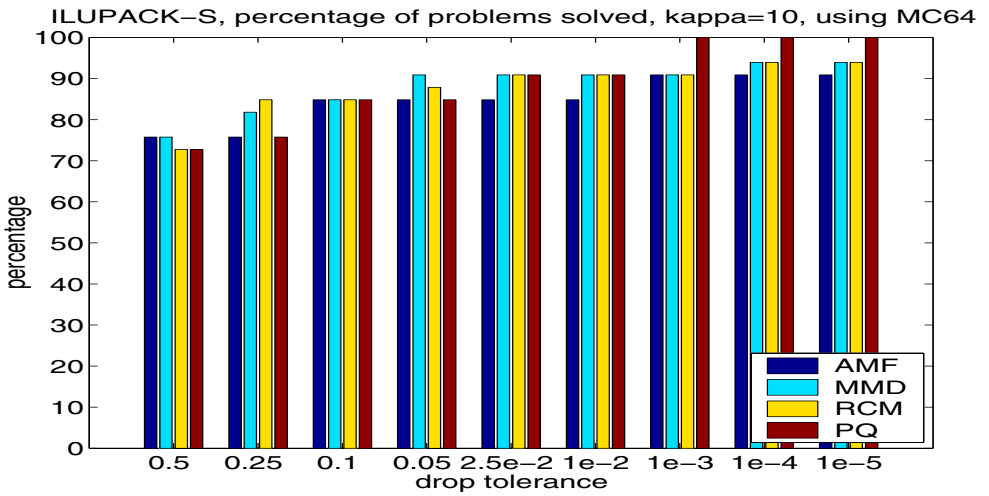

FIG. 4.12. *Numerical sensitivity of ILUPACK + MC64, S-version, $\kappa = 10$ (chemical engineering).*

bound κ for the inverse triangular factors, as well as the choice between the S-version and the M-version.

Recall that the norms of the inverse factors are kept below a threshold κ, which is a parameter of the algorithm. In our numerical tests we found that the influence of the prescribed bound κ on performance is relatively mild. This is caused by the use of the maximal norm of the estimates $\tilde{\kappa}$ for $\|L_k^{-1}\|$ and $\|U_k^{-1}\|$ as a substitute for κ. Clearly κ remains an upper bound, but since it is not clear whether this bound will

ever be reached by the inverse triangular factor, the estimate $\tilde{\kappa}$ seems to be a good compromise. Only $\tilde{\kappa}$ is used for dropping in conjunction with the drop tolerance.

The theory developed in earlier sections suggests that the M-version will be less sensitive to the drop tolerance since the corresponding approximate Schur complement is more accurate. However, this is likely to comes at a higher expense in terms of fill-in. By using a coarser approximation of the Schur complement, the S-version is likely to require smaller drop tolerances. This was confirmed in the numerical examples.

We now show, in a few tables, test examples where fixed parameters are used. For ILUTP and ILUTC a drop tolerance of $\varepsilon = 10^{-3}$ is used. For the inverse-based multilevel ILU, a significantly coarser drop tolerance $\varepsilon = 10^{-1}$ and $\kappa = 10$ are used. We examine some sample problems which arise in the numerical treatment of PDEs. Therefore, we use RCM as a fixed ordering. The results are summarized in Tables 1, 2, 3, and 4. The results show that ILUTP with RCM is fairly robust, but this robustness comes at an exceedingly high memory cost. On the other hand, the multilevel inverse-based ILU from ILUPACK consumes very little memory, though at least the S-version fails to solve two of the problems.

certainly argue that recent progress in the field has considerably shortened the gap between the two classes of methods. The ingredients in this progress came in large part from a better understanding of the impact of dropping on the inverse factors. As long as ILU techniques were only applied to easy problems arising from elliptic-type PDEs, little attention was paid to these inverses because their condition numbers are often within reasonable range. When the success of ILUs grew and their range of applicability expanded, it was realized that the classical ideas that were behind the development of ILU basically failed. Recent work [3] showed that it becomes critical in this situation to analyze the effect of dropping on the inverse factors, and a further analysis of this was given in section 2. In particular, it becomes critical to design the preconditioners in such a way that the perturbations of the inverse factors, caused by dropping, remain small. From a practical implementation viewpoint, this calls for a multilevel strategy which strives to yield bounded inverse factors of the B block corresponding to the "fine" level. Then, recursion can be invoked to deal with the Schur complement resulting from the fine-coarse partitioning.

A package based on three "templates" for implementing the basic ideas has been implemented and thoroughly tested. Numerical experiments indicate that this multilevel ILU can be a good alternative to direct solvers in most cases. They also show

that nonsymmetric reorderings, diagonal pivoting, and efficient Crout implementations can contribute to a better robustness and efficiency of the preconditioner. The code and a large set of experiments are available online; see [4].

Still lacking is a parallel implemention of the algorithms. While the algorithms have not been designed with parallelism in mind, many of the ideas are extensible to parallel environments, at a minimum via a domain decomposition viewpoint.

BLOCK PRECONDITIONERS BASED ON APPROXIMATE COMMUTATORS*

HOWARD ELMAN†, VICTORIA E. HOWLE‡, JOHN SHADID§, ROBERT SHUTTLEWORTH¶, AND RAY TUMINARO‡

Abstract. This paper introduces a strategy for automatically generating a block preconditioner for solving the incompressible Navier–Stokes equations. We consider the "pressure convection–diffusion preconditioners" proposed by Kay, Loghin, and Wathen [*SIAM J. Sci. Comput.*, 24 (2002), pp. 237–256] and Silvester, Elman, Kay, and Wathen [*J. Comput. Appl. Math.*, 128 (2001), pp. 261–279]. Numerous theoretical and numerical studies have demonstrated mesh independent convergence on several problems and the overall efficacy of this methodology. A drawback, however, is that it requires the construction of a convection–diffusion operator (denoted F_p) projected onto the discrete pressure space. This means that integration of this idea into a code that models incompressible flow requires a sophisticated understanding of the discretization and other implementation issues, something often held only by the developers of the model. As an alternative, we consider automatic ways of computing F_p based on purely algebraic considerations. The new methods are closely related to the "*BFBt* preconditioner" of Elman [*SIAM J. Sci. Comput.*, 20 (1999), pp. 1299–1316]. We use the fact that the preconditioner is derived from considerations of commutativity between the gradient and convection–diffusion operators, together with methods for computing sparse approximate inverses, to generate the required matrix F_p automatically. We demonstrate that with this strategy the favorable convergence properties of the preconditioning methodology are retained.

1. Introduction.

Recently, the development of efficient iterative methods for the fully implicit solution of the Navier–Stokes equations has seen considerable activity. In this paper, we consider a promising class of methods (denoted , , ,

solve linear systems associated with the incompressible Navier–Stokes equations

$$\begin{aligned} \alpha \mathbf{u}_t - \nu \nabla^2 \mathbf{u} + (\mathbf{u} \cdot \operatorname{grad}) \mathbf{u} + \operatorname{grad} p &= \mathbf{f} \\ -\operatorname{div} \mathbf{u} &= 0 \end{aligned} \quad \text{in } \Omega \subset \mathbb{R}^3, \tag{1.1}$$

where $\mathbf{u}$ are the velocities, p are the pressures, and $\mathbf{u}$ satisfies suitable boundary conditions on $\partial\Omega$. The value $\alpha = 0$ corresponds to the steady-state problem, and $\alpha = 1$ to the transient case. Linearization and stable discretization (discussed in section 2) yield systems of equations of the form

$$\begin{pmatrix} F & G \\ D & 0 \end{pmatrix} \begin{pmatrix} \mathbf{u} \\ p \end{pmatrix} = \begin{pmatrix} \mathbf{f} \\ g \end{pmatrix}, \tag{1.2}$$

where G and D are discrete gradient and (negative) divergence operators, respectively, and F contains all other terms coming from the linearized momentum equation and time derivatives. These systems, which are the focus of this paper, must be solved at each step of a nonlinear (Picard or Newton) iteration or at each time step.

The pressure convection–diffusion preconditioner is based on an approximate block factorization of (1.2). The key to attaining mesh independent convergence lies with the effective approximation of the inverse of the following operator:

$$S = DF^{-1}G. \tag{1.3}$$

S is the Schur complement of (1.2) and is obtained by algebraically eliminating the velocity equations. Most effective block preconditioners for (1.2) must approximate the inverse of the Schur complement in some fashion. The presence of the term F^{-1} between the rectangular operators D and G makes S prohibitively expensive to compute and almost completely dense. The pressure convection–diffusion preconditioner can be viewed as a way to approximate (1.3) by an expression in which the inverse term is moved (or commuted) so that it no longer appears between the two rectangular operators. This approximation takes the form

$$S \approx \hat{S} = DGF_p^{-1}, \tag{1.4}$$

where F_p is a discrete convection–diffusion operator defined on the discrete pressure space. This operator will be discussed in detail in section 2.

This idea requires the explicit construction of the matrix F_p. In all previous work on these schemes, this operator has been constructed using a discretization consistent with that used for the pressure term of the Navier–Stokes equations. For example, if linear finite elements are used to discretize the pressures in (1.1), then F_p is defined using the same basis. Although most codes used to model incompressible flow have the primary kernels needed for such a construction, this places a significant burden on a potential user of this methodology, something not found in standard algebraic preconditioners.

Our aim in this study is to rectify this situation, and to enable the preconditioning methodology derived from (1.4) to be available to users in "black-box" fashion requiring nothing more than a statement of the problem (1.2). This is achieved using the property of commutativity alluded to above. Specifically, we derive an approximate solution to the algebraic problem

$$GF_p \approx FG, \tag{1.5}$$

where F_p must be determined given G and F. This is accomplished by considering a least-squares approximation to (1.5). We show how this leads to a natural interpretation of the related "[illegible] algorithm" [6]. We also illustrate how the above commutator equation can be modified to incorporate diagonal scaling and how proper scaling is critical to obtaining satisfactory convergence rates. In one algebraic variant, sparse approximate inverse ideas are adapted to the above commutator strategy. We present this approach in section 4, where we give a specific algorithm based on the methods of Grote and Huckle [9]. In section 5, numerical results are given to illustrate the competitiveness of the automatically computed pressure convection–diffusion preconditioner with the original version of this approach [11, 16] (which requires the user to provide the matrix F_p) in terms of convergence speed.

2. The pressure convection–diffusion preconditioner. We are concerned with the incompressible form of the Navier–Stokes equations given by (1.1). Our focus is on solution algorithms for the systems of equations that arise after linearization of the system (1.1). We will restrict our attention to a Picard iteration for the nonlinear system, derived by lagging the convection coefficient in the quadratic term $(\mathbf{u} \cdot \text{grad})\,\mathbf{u}$. For the steady-state problem, this lagging procedure starts with some initial guess $\mathbf{u}^{(0)}$ (satisfying the discrete incompressibility constraint) for the velocities and then computes the kth Picard iterate for velocity and pressure by solving the

$$\begin{aligned} -\nu\nabla^2\mathbf{u}^{(k)} + (\mathbf{u}^{(k-1)} \cdot \text{grad})\,\mathbf{u}^{(k)} + \text{grad}\, p^{(k)} &= \mathbf{f}, \\ -\text{div}\,\mathbf{u}^{(k)} &= 0. \end{aligned} \tag{2.1}$$

For transient problems, a strategy of this type can be combined with an implicit time discretization; see [17, 18].

A stable finite difference, finite volume, or finite element discretization of (2.1) leads to a linear system of equations of the form (1.2) which must be solved at each step of the Picard iteration. For the steady problem, the matrix F has block diagonal form in which each individual diagonal block consists of a discretization of a convection–diffusion operator

$$-\nu\nabla^2 + (\mathbf{w} \cdot \text{grad})\,, \tag{2.2}$$

where $\mathbf{w} = \mathbf{u}^{(k-1)}$. For the transient problem, the blocks of F represent discretizations of an operator essentially of the form

$$\frac{1}{\Delta t} I - \nu\nabla^2 + (\mathbf{w} \cdot \text{grad})\,, \tag{2.3}$$

which arises from an implicit time discretization of the time-dependent convection–diffusion equation.

The strategy we employ for solving (1.1) is derived from the block factorization

$$\begin{pmatrix} F & G \\ D & 0 \end{pmatrix} = \begin{pmatrix} I & 0 \\ DF^{-1} & I \end{pmatrix} \begin{pmatrix} F & G \\ 0 & -S \end{pmatrix}, \tag{2.4}$$

where $S = DF^{-1}G$ is the Schur complement. This implies that

$$\begin{pmatrix} F & G \\ D & 0 \end{pmatrix} \begin{pmatrix} F & G \\ 0 & -S \end{pmatrix}^{-1} = \begin{pmatrix} I & 0 \\ DF^{-1} & I \end{pmatrix}, \tag{2.5}$$

which, in turn, suggests a preconditioning strategy for (1.1). If it were possible to use the matrix

$$\mathcal{Q} = \begin{pmatrix} F & G \\ 0 & -S \end{pmatrix} \tag{2.6}$$

as a right-oriented preconditioner, then the preconditioned operator would be the one given in (2.5). All the eigenvalues have the value 1, and it can be shown that this operator contains Jordan blocks of dimension at most 2, and consequently that at most two iterations of a preconditioned GMRES iteration would be needed to solve the system [12].

The key bottleneck in applying $\mathcal{Q}^{-1}$ is the action of the inverse Schur complement operator $(DF^{-1}G)^{-1}$. In practice, this must be replaced with an inexpensive approximation. If it were possible to find a matrix F_p that makes (1.5) an equality, then this would imply that

$$F^{-1}G = GF_p^{-1}, \tag{2.7}$$

which in turn would mean $S = \tilde{S}$ in (1.4). In general, (1.5) is an overdetermined system (with range(G) a proper subset of range(F)), so it is not possible to find such an F_p. Consequently, we have an approximation in (1.4). Using $\tilde{S} = (DG)F_p^{-1}$ within a preconditioning operation entails applying the action of the inverse, given by

$$\tilde{S}^{-1} = F_p(DG)^{-1}. \tag{2.8}$$

Note that DG is a scaled discrete Laplacian operator, so that working with (2.8) will require a Poisson solve followed by a matrix-vector product with F_p. For purposes of efficiency, the action of $(DG)^{-1}$ is often approximated by an inexact Poisson solver without any significant degradation in convergence. Thus, application of (2.8) is inexpensive.

A good approximation can be expected in (1.5) because of the nature of the differential operators associated with the matrices. In particular, suppose the convection–diffusion operator

$$(-\nu\nabla^2 + (\mathbf{w}\cdot\operatorname{grad}))_p \tag{2.9}$$

can be defined on the pressure space (where the subscript p indicates that the operator is acting on the pressure space). Consider the commutator with the gradient operator, as follows:

$$(-\nu\nabla^2 + (\mathbf{w}\cdot\operatorname{grad}))\operatorname{grad} - \operatorname{grad}(-\nu\nabla^2 + (\mathbf{w}\cdot\operatorname{grad}))_p\,. \tag{2.10}$$

If $\mathbf{w}$ is constant, then this expression would be zero on the interior of Ω, and it is also reasonable to expect it to be small for smooth $\mathbf{w}$. This suggests that if F_p is a discretization of (2.9), then the discrete commutator

$$FG - GF_p \tag{2.11}$$

will also be small. A similar statement would apply if time derivatives are present: as in (2.3), discretization in time would add terms essentially of the form $\frac{1}{\Delta t}I$ to both convection–diffusion operators in (2.10).

In [11, 16], F_p is obtained from discretization of the convection–diffusion operator of (2.9). In this paper, we develop an automated construction of F_p designed explicitly

to make the commutator (1.5) small. This removes the process of discretization from the design of the iterative solution algorithm and enables the preconditioning to adapt automatically to different discretizations without any intervention on the part of the designer of a Navier–Stokes code. One of the ideas for approximating (1.5) is to adapt methods for computing sparse approximate inverses to define sparse approximate commutators. This will be considered in section 4.

Before exploring sparse approximations, it is worthwhile to consider a classical normal equations solution to (1.5). In particular, suppose f_j, the jth column of F_p, is computed to solve the least-squares problem with respect to the Euclidean norm

$$\min \|Gf_j - [FG]_j\|_2 ,$$

where $[FG]_j$ represents the jth column of the matrix FG. This leads to the normal equations

$$(G^T G) f_j = G^T [FG]_j .$$

An equivalent formulation is that F_p minimizes the Frobenius norm of the error in the complete system

$$\min \|GF_p - FG\|_F . \tag{2.12}$$

Thus, the solution is

$$F_p = (G^T G)^{-1} G^T FG. \tag{2.13}$$

When $D = G^T$ (as is normally the case), the resulting Schur complement preconditioner becomes

$$(G^T G)^{-1} G^T FG (G^T G)^{-1}. \tag{2.14}$$

This corresponds exactly to the [illegible] preconditioner proposed in [6] and also in [15]. This method can be considered as an alternative to the pressure convection–diffusion preconditioner; it is of particular interest for Newton's method, for which (in contrast to Picard iteration) it is difficult to derive a discretization of (2.9) that will make (2.11) small. We should also point out that the original derivation of the [illegible] preconditioner is considerably different from the viewpoint given here. The notion of the normal equations solution to (1.5) is in our opinion more intuitive than the description given in [6] and provides additional insight into this preconditioner. From this perspective, however, the approximate solution of the commutator equation is certainly not a new idea, as it has already been done with the [illegible] preconditioner. In effect, we are proposing alternate solutions and modifications to (1.5) that may have better properties. These modifications will include the use of diagonal scaling in (2.12) as well as boundary condition adjustments. It will be shown how these simple improvements can significantly accelerate convergence. Note also that use of (2.14) will entail two Poisson solves in each invocation of the preconditioner; it will become apparent that sparse approximate inverses can be used to eliminate one of these two solves.

3. Diagonally scaled commutators. The construction of an algebraic commutator need not explicitly rely on the PDE analogue used to derive the pressure

convection–diffusion preconditioning. This implies that alternative relationships derived from commutators can be explored when developing Schur complement approximations. Consider, for example,

$$M_2^{-1} G F_p \approx M_2^{-1} F M_1^{-1} G, \tag{3.1}$$

where M_2 and M_1 are diagonal matrices. The operator M_2^{-1} can be thought of as a weight matrix that transforms (2.12) into a weighted least-squares problem. The introduction of M_1^{-1} can be viewed as a way to precondition F and G so that they are more amenable to commuting. After premultiplying (3.1) by $DF^{-1}M_2$, it is easy to show that the inverse Schur complement is now approximated by

$$(DF^{-1}G)^{-1} \approx F_p (DM_1^{-1}G)^{-1}, \tag{3.2}$$

where

$$F_p = (G^T M_2^{-2} G)^{-1} G^T M_2^{-2} F M_1^{-1} G \tag{3.3}$$

when the normal equations are used to produce an approximate solution to (3.1). The net effect of "preconditioning" the commutator equation in this way is that a new definition of F_p is given and the inverse discrete Poisson operator in (2.8) is now replaced by a discrete variable-coefficient diffusion operator (when M_1 is a diagonal matrix), which can still be effectively handled with solution methods such as multigrid. In this paper, we will primarily consider choices for M_1 and M_2 that are based on the diagonal of the velocity mass matrix. However, before exploring this, it is worthwhile to consider another choice for M_1 and M_2 that highlights connections between F_p solvers and the well-known SIMPLE method [13].

3.1. Diagonal scaling and SIMPLE. One interesting aspect of the diagonally scaled commutator equation is that it bridges the gap between pressure convection–diffusion solvers and traditional pressure-correction methods such as SIMPLE [13]. In particular, the original SIMPLE method is a numerical time marching procedure for incompressible flow in which the inverse Schur complement is approximated by $(D\,\mathrm{diag}(F)^{-1}G)^{-1}$, where $\mathrm{diag}(F)$ is the diagonal matrix whose entries are taken from the main diagonal of F. When $M_1 = \mathrm{diag}(F)$ and F_p is the identity matrix, the right side of (3.2) is identical to SIMPLE's approximation of the inverse Schur complement. In general, F_p will be close to the identity when $F\,\mathrm{diag}(F)^{-1}$ is close to the identity. This, in turn, occurs when the entries on the diagonal of F are much larger than the off-diagonal entries, as is often the case for time-dependent problems with small time steps. Thus, we can conclude that the Schur complement approximations for the diagonally scaled commutator and SIMPLE are basically the same in the small time-step scenario.

The true advantage of the F_p solvers occurs for larger time steps or steady-state problems. Let A denote the coefficient matrix of (1.2). Consider the new block preconditioner based on the factorization

$$\tilde{A} \equiv \begin{pmatrix} F & 0 \\ D & -D\,\mathrm{diag}(F)^{-1}G \end{pmatrix} \begin{pmatrix} I & \mathrm{diag}(F)^{-1}G \\ 0 & I \end{pmatrix} \begin{pmatrix} I & 0 \\ 0 & F_p^{-1} \end{pmatrix}. \tag{3.4}$$

This new preconditioner is similar to standard F_p methods with the exception that the underlying block decomposition is built on SIMPLE's approximate block factorization

as opposed to (2.4). It is well known that when F_p is the identity, the LU decomposition given by (3.4) corresponds to SIMPLE's underlying matrix factorization [14]. By multiplying out matrices, it is easy to show that

$$\tilde{A} = \begin{pmatrix} F & F\mathrm{diag}(F)^{-1}GF_p^{-1} \\ D & 0 \end{pmatrix}$$

and that the difference between $\tilde{A}$ and the discrete incompressible Navier–Stokes operator, A, of (1.2) is given by

$$A - \tilde{A} = \begin{pmatrix} 0 & (GF_p - F\mathrm{diag}(F)^{-1}G)F_p^{-1} \\ 0 & 0 \end{pmatrix}. \tag{3.5}$$

It follows once again that the SIMPLE method (where F_p is the identity) will perform well when $G - F\ \mathrm{diag}(F)^{-1}G$ is small, i.e., when F has relatively large diagonal entries. On the other hand, comparison of the structure of the nonzero block in the $(1,2)$ entry of (3.5) with (3.1), the "preconditioned commutator relation" using $M_1 = \mathrm{diag}(F)$ and $M_2 = I$, indicates that the error matrix $A - \tilde{A}$ will be small if the commutator is small, irrespective of the size of the diagonal of F.

3.2. Diagonal scaling and the mass matrix. Replacement of a differential commuting relationship with an algebraic commuting relationship assumes certain additional properties of the discrete operator. If, for example, a finite difference approach such as the marker-and-cell method [10] is used to discretize the Navier–Stokes equations, then the relation (2.11) looks very much like its continuous analogue (2.10), and heuristic justification for the validity of (2.11) comes from Taylor series arguments. On the other hand, for mixed finite element discretizations with different order elements, such as the stable Q_2–Q_1 (biquadratic velocity, bilinear pressure) element, the discrete commutator (2.11) will typically not be small. This does not present a problem when the required matrix F_p is obtained, as in [11, 16], by constructing a discrete convection–diffusion operator using the given pressure discretization (bilinear elements in the example noted above). However, it complicates the construction of F_p when a purely algebraic approach is used.

To gain insight into this matter, consider the differential operators

$$\mathcal{L}_1 u \equiv -u_{xx} \qquad \text{and} \qquad \mathcal{L}_2 u \equiv u_x$$

on the one-dimensional domain $0 \le x \le 1$, with periodic boundary conditions. Clearly, the differential operators formally commute. That is, $\mathcal{L}_1\mathcal{L}_2$ is equivalent to $\mathcal{L}_2\mathcal{L}_1$. Now let L_1 and L_2 be the discrete approximations to $\mathcal{L}_1$ and $\mathcal{L}_2$ obtained from piecewise linear nodal finite elements

$$\phi_i(x) = \begin{cases} \alpha_i \frac{x - x_{i-1}}{x_i - x_{i-1}}, & x_{i-1} \le x \le x_i, \\ \alpha_i \frac{x - x_{i+1}}{x_i - x_{i+1}}, & x_i \quad \le x \le x_{i+1}, \\ 0 & \text{otherwise} \end{cases}$$

and a Galerkin discretization. Here x_i denotes the location of the ith mesh point and α_i effectively scales each element in an arbitrary way. Standard nodal elements have $\alpha_i = 1$ for all i, and it can be shown that on uniform meshes

$$L_1^s L_2^s = L_2^s L_1^s,$$

where the superscript s indicates standard (or unscaled) nodal element discretization. The use of arbitrary scaling, however, effectively scales the corresponding discrete operators:

$$L_1 = D_\alpha L_1^s D_\alpha \qquad \text{and} \qquad L_2 = D_\alpha L_2^s D_\alpha,$$

where L_1 and L_2 denote discretizations generated with arbitrary scaling and D_α is the diagonal matrix with α_i in the (i,i)th entry. Although L_1 and L_2 do not commute for arbitrary scaling, we do have

$$L_1 D_\alpha^{-2} L_2 = L_2 D_\alpha^{-2} L_1, \tag{3.6}$$

that is, an appropriate scaling enables commutativity.

The example above is artificial, but an analogous strategy can be used to enhance performance in the setting we are concerned with. In particular, it is possible to choose a diagonal matrix M_1 so that a version of the commutator is small on some components of the pressure space. For the Q_2–Q_1 discretization, if M_1 is chosen to be $\mathrm{diag}(M)$, the diagonal matrix whose entries are those on the diagonal of the velocity mass matrix M, then $M_1^{-1}Gq$ is constant on grid points at the interior of Ω whenever the nodal vector q comes from a linear function. Moreover, for such q and this choice of M_1, if F_p is a discrete bilinear approximation to (2.9) with constant $\mathbf{w}$, then

$$(GF_p - FM_1^{-1}G)q = 0 \quad \text{in the interior of } \Omega.$$

Thus, we use this strategy for choosing M_1. Note that in the example leading to (3.6), the diagonal of the mass matrix is simply D_α^2, and thus this choice of M_1 is consistent with the motivating example.

We will derive an automated version of the pressure convection–diffusion preconditioner in the following section. We conclude here by presenting a variant of the [illegible] method based on this approach. Insertion of the normal equations solution to (3.1) into (3.2) yields the following approximation to the inverse Schur complement (assuming $D = G^T$):

$$(DF^{-1}G)^{-1} \approx (G^T M_2^{-2} G)^{-1} (G^T M_2^{-2} F M_1^{-1} G)\, (G^T M_1^{-1} G)^{-1}.$$

As noted above, M_1 is the diagonal of the velocity mass matrix. We take $M_2 = sqrt(M_1)$ to make the two variable-coefficient Poisson operators identical. The resulting preconditioner, with these choices for M_1 and M_2, will be referred to as the [illegible] method. It can also be shown that the matrix F_p obtained from the normal equations for (3.1) corresponds to a convection–diffusion operator in (2.9) for which the L_2-norm of the commutator (2.10), viewed as an operator on the (finite element) pressure space, is approximately minimized; see [8, Chapter 8] for details. As will be seen in section 5, the introduction of this diagonal scaling can have a dramatic impact on the overall convergence of the method.

4. Sparse approximate commutator (*SPAC*). One disadvantage of both the [illegible] and scaled [illegible] methods is that they require two Poisson-like solves during each invocation, as opposed to the single solve needed by the pressure convection–diffusion preconditioners. This implies that the application of the approximate inverse Schur complement is more costly for [illegible] methods than for pressure convection–diffusion methods.

To alleviate the burden of the additional solve required by [illegible] methods, we consider approximate solutions to (1.5) built on concepts from sparse approximate

inverses. The resulting method will still require only one invocation of the Poisson solver per iteration, although there is an additional setup cost associated with building the sparse approximate inverse. Since sparse approximate inverses are typically used to approximate the matrix inverse of a square matrix, an adaptation that is suitable for the rectangular matrix associated with the approximate commutator equation is considered. We begin by discussing standard sparse approximate inverses.

Sparse approximate inverses were originally developed as preconditioning operators for sparse matrices; they were designed to be easier to compute and use on parallel architectures than other preconditioners such as incomplete LU factorizations. Given a large, sparse matrix A, these methods produce a sparse matrix Q that approximates A^{-1}. The sparse approximate inverse is inherently parallel and intended to retain the convergence properties of an incomplete LU factorization. In addition, sparse approximate inverses are important for situations in which incomplete LU factorizations have difficulties, such as when the factorization encounters a zero pivot or produces unstable factors [5]. Let A represent a generic matrix of order n, and let I denote the identity matrix of order n. Typically, sparse approximate inverse techniques are based on producing a sparse matrix Q that minimizes the Frobenius norm of the residual matrix

$$\min_{Q} \|AQ - I\|_F, \tag{4.1}$$

which was first suggested by Benson and Frederickson [1, 2]. The residual matrix minimization reduces to n independent least-squares problems

$$\min_{q_j} \|Aq_j - e_j\|_2, \quad j = 1, \ldots, n, \tag{4.2}$$

where q_j is the jth column of Q and e_j is the jth unit vector, i.e., the jth column of I.

Note that our task is less difficult than that required for construction of sparse approximate inverses. The key obstacle in the latter setting is picking the proper sparsity pattern of Q to capture enough of A^{-1}, which is usually dense even when A is sparse. In our case, it is reasonable to expect that the matrix F_p needed in the discrete commutator equation is sparse (as we know this to be the case in standard pressure convection–diffusion preconditioning). Thus we have the simpler task of computing a sparse approximation to a sparse matrix.

There are several strategies for computing sparse approximate inverses (see, e.g., [3, section 5]). Many sparse approximate inverse methods (e.g., Chow [4]) require iterated applications of matrix-vector products of the form $Ar, A(Ar), \ldots$. The SPAI algorithm of Grote and Huckle [9] avoids this construction and is natural to apply in the present setting where a commutator is required for a rectangular matrix. We call this adaptation , (for sparse approximate commutator). Before discussing the adaptation of SPAI to commutators, it is important to note that approximate inverses based on square matrices can also be used by instead considering the normal equations

$$(G^T M_2^{-2} G) F_p = G^T M_2^{-2} F M_1^{-1} G.$$

In this case, one replaces (4.1) with

$$\min_{F_p} \|G^T M_2^{-2} G F_p - G^T M_2^{-2} F M_1^{-1} G\|_F^2,$$

which involves square matrices. We do not pursue this further but instead consider ideas for computing sparse matrices that directly address the commutator relationship.

[illegible] is based on replacing (4.1) with

$$\min_{F_p \text{ sparse}} \|\tilde{G}F_p - \tilde{F}\tilde{G}\|_F^2, \tag{4.3}$$

where $\tilde{G} = M_2^{-1}G$ and $\tilde{F} = M_2^{-1}FM_1^{-1}M_2$. This reduces to a set of n constrained least-squares problems as follows:

$$\min_{f_j \text{ sparse}} \|\tilde{G}f_j - b_j\|_2^2, \tag{4.4}$$

where b_j is the jth column of $\tilde{F}\tilde{G}$ and f_j is the jth column of F_p.

Our [illegible] algorithm follows the technique of Grote and Huckle [9]. We will use the following notation: given index sets $\mathcal{I}$, $\mathcal{J}$, let $\tilde{G}(\mathcal{I}, \mathcal{J})$ denote the submatrix of $\tilde{G}$ with entries $\tilde{g}_{ij}$, where $i \in \mathcal{I}$, $j \in \mathcal{J}$; by analogy with MATLAB, a colon (:) represents the complete index set $\{1, \ldots, n\}$. Similarly, for a vector v, $v(\mathcal{I})$ or $v(\mathcal{J})$ denotes the subvector of v with entries v_i or v_j, where $i \in \mathcal{I}$ and $j \in \mathcal{J}$. As in [9], we describe the algorithm for one column of F_p. We begin by getting an initial sparsity pattern. Let $\mathcal{B}$ be the set of indices of the nonzero rows in b_j, let $\mathcal{J}$ be the set of indices of nonzero columns of $\tilde{G}(\mathcal{B}, :)$, and let $\mathcal{I}$ be the set of indices of the nonzero rows of $\tilde{G}(:, \mathcal{J})$. The algorithm starts by solving the $n_1 \times n_2$ least-squares problem $\tilde{G}(\mathcal{I}, \mathcal{J})f_j(\mathcal{J}) = b_j(\mathcal{I})$, where $n_1 = |\mathcal{I}|$ and $n_2 = |\mathcal{J}|$. The vector f_j obtained by inserting $f_j(\mathcal{J})$ into the zero vector is the initial approximation to the jth column of F_p. We improve F_p by augmenting the sparsity structure to obtain a more effective commutator.

As in [9], we accomplish this by reducing the current error $\|\tilde{G}F_p - \tilde{F}\tilde{G}\|_F^2$, i.e., reducing $\|\tilde{G}f_j - b_j\|_2^2$ for each column $j = 1, \ldots, n$ of F_p. Let the residual $r = \tilde{G}f_j - b_j$. If $r = 0$, then f_j is exactly the jth column of the commutator and no improvement is possible. If $r \neq 0$, we augment the sets of indices $\mathcal{I}$ and $\mathcal{J}$ to reduce $\|r\|_2$. Let $\mathcal{R}$ be the set of indices of the nonzero elements of r, and let $\tilde{\mathcal{J}}$ be the set of new column indices that appear in $\mathcal{R}$ but not in $\mathcal{J}$. To determine the most profitable reduction in $\|r\|_2$, for each $k \in \tilde{\mathcal{J}}$ we solve the one-dimensional minimization problem

$$\min_{\mu_k} \|r + \mu_k \tilde{G}(:, \tilde{\mathcal{J}}(k))\|_2, \tag{4.5}$$

whose solution is given by

$$\mu_k = -\frac{(r^T \tilde{G}(:, \tilde{\mathcal{J}}(k)))^2}{\|\tilde{G}(:, \tilde{\mathcal{J}}(k))\|_2^2}, \tag{4.6}$$

where $\tilde{\mathcal{J}}(k)$ is the kth element of the index set $\tilde{\mathcal{J}}$. For each k, we compute $\rho_k = \|r + \mu_k \tilde{G}(:, \tilde{\mathcal{J}}(k))\|_2^2$, the square of the Euclidean norm of the new residual, using

$$\rho_k = \|r\|_2^2 - \frac{(r^T \tilde{G}(:, \tilde{\mathcal{J}}(k)))^2}{\|\tilde{G}(:, \tilde{\mathcal{J}}(k))\|_2^2}. \tag{4.7}$$

We reduce $\tilde{\mathcal{J}}$ to the set of indices with the lowest ρ_k. In particular, we delete from $\tilde{\mathcal{J}}$ the indices whose ρ values are greater than the median of the ρ_k. We improve $\mathcal{J}$

by augmenting it with $\tilde{\mathcal{J}}$, $\mathcal{J} = \mathcal{J} \cup \tilde{\mathcal{J}}$. $\mathcal{I}$ is updated to contain the indices of the nonzero rows of $\tilde{G}(:, \mathcal{J})$. We then repeat the solution of the least-squares problem $\tilde{G}(\mathcal{I}, \mathcal{J}) f_j(\mathcal{J}) = b_j(\mathcal{I})$, updating the elements of f_j indexed by $\mathcal{J}$ to produce an improved column of F_p. To reduce fill, we drop entries of f_j that are less than a given tolerance.

We stop improving $\mathcal{J}$ and the current column of the commutator F_p when we have achieved sufficient reduction in the error $\|\tilde{G}F_p - \tilde{F}\tilde{G}\|_F^2$. The entire algorithm is given below.

ALGORITHM 1.

- [illegible] b_j [illegible] $\tilde{F}\tilde{G}$
- [illegible] [illegible] $\mathcal{I}, \mathcal{J}$ [illegible] $\tilde{G}$
  - [illegible] $\mathcal{B} =$ [illegible] b_j
  - [illegible] $\mathcal{J} =$ [illegible] $\tilde{G}(\mathcal{B}, :)$
  - [illegible] $\mathcal{I} =$ [illegible] $\tilde{G}(:, \mathcal{J})$
- [illegible] $r_{norm} = 1$
- [illegible] $reduction = 1$
- [illegible] $reduction / r_{norm} > tol_1$ & $r_{norm} > tol_2$
  - [illegible] $\mathcal{J}_{prev} = \mathcal{J}$
  - [illegible] $\min \|\tilde{G}(\mathcal{I}, \mathcal{J}) f_j(\mathcal{J}) - b_j(\mathcal{I})\|_2^2$ [illegible] $f_j(\mathcal{J})$ [illegible] f_j [illegible] $\mathcal{J}$
  - [illegible] $r = \tilde{G} f_j - b_j$
  - [illegible] $r_{norm} = \|r\|_2$
  - [illegible] $\mathcal{R} =$ [illegible] r
  - [illegible] $\tilde{\mathcal{J}} =$ [illegible] $\tilde{G}$ [illegible] $\mathcal{R}$ [illegible] $\mathcal{J}$
  - [illegible] $k = 1, \ldots, |\tilde{\mathcal{J}}|$
    - [illegible] $\mu_k = (r^T \tilde{G}(:, \tilde{\mathcal{J}}(k)))^2 / (\tilde{G}(:, \tilde{\mathcal{J}}(k))^T \tilde{G}(:, \tilde{\mathcal{J}}(k)))$
    - [illegible] $\rho_k = \|r\|_2^2 - \mu_k$
  - [illegible] $reduction = \max_k \mu_k$
  - [illegible] $\mathcal{J}$ [illegible] $\tilde{\mathcal{J}}$ [illegible] ρ [illegible] $\tilde{\mathcal{J}}$ [illegible] ρ [illegible] ρ_k [illegible] $\mathcal{J}$ $\mathcal{J} \cup \tilde{\mathcal{J}}$
  - [illegible] $\mathcal{I}$ $\mathcal{I} =$ [illegible] $\tilde{G}(:, \mathcal{J})$
- [illegible] $f_j < drop_tol$ [illegible] $ind =$ [illegible]
- [illegible] $F_p(\mathcal{J}_{prev}(ind), j) = f_j(ind)$

The resulting [illegible] algorithm is almost identical to the method presented by Grote and Huckle. Therefore, its cost should be similar to this sparse approximate inverse algorithm. It is also important to keep in mind that the dimension of the Schur complement system is only a small fraction of the entire system (often about one quarter for three-dimensional problems) and that fairly sparse approximations can be used (as F_p in pressure convection–diffusion preconditioning is sparse). Thus, it is natural to expect that the cost to construct the [illegible] operator (relative to the cost of solving the entire saddle point system) is considerably less than the setup costs associated with standard sparse approximate inverses.

5. Results. Numerical experiments are presented for two benchmark problems in two dimensions: models of flow over a backward facing step and in a lid driven cavity application. The linear problems were generated by applying a Picard iteration to

the nonlinear system and stopping this iteration when the nonlinear residual satisfied

$$\left\| \begin{pmatrix} \mathbf{f} - \left(\mathbf{F}(\mathbf{u}^{(m)})\mathbf{u}^{(m)} + Gp^{(m)}\right) \\ g - D\mathbf{u}^{(m)} \end{pmatrix} \right\|_2 \leq 10^{-5} \left\| \begin{pmatrix} \mathbf{f} \\ g \end{pmatrix} \right\|_2, \tag{5.1}$$

where $\mathbf{F}(\mathbf{u})\mathbf{u}$ is the discretization of the nonlinear convection–diffusion operator, $-\nu\nabla^2\mathbf{u} + (\mathbf{u} \cdot \text{grad})\mathbf{u}$, and g comes from boundary data. At each Picard step m, the Oseen equations (1.2) are solved for a correction to the current iterate; the right-hand side of the linear system is the nonlinear residual given on the left of (5.1). The numbers reported correspond to the total number of GMRES iterations (without restarting) required to solve the saddle point system associated with the last Picard iteration, using various preconditioners. The linear iteration was stopped when the residual of the linear system (1.2) satisfied

$$\|\mathbf{r}^{(k)}\|_2 \leq 10^{-6}\|\mathbf{f}^{(m)}\|_2 \tag{5.2}$$

starting with a zero initial iterate, where $\mathbf{f}^{(m)}$ is the current nonlinear residual vector and $\mathbf{r}^{(k)}$ is the residual at the kth linear iteration. The performance of the iterative solvers was not sensitive to the particular Picard step, and these results are representative.

All the preconditioners are of the form given by (2.6) where an exact solver is used for all needed Poisson solves and convection–diffusion solves. The inverse Schur complement is the only aspect that is varied; preconditioners tested include an application-provided pressure convection–diffusion preconditioner (i.e., the method of [11, 16], denoted "F_p" in the tables), [illegible], scaled [illegible] (denoted [illegible]), [illegible] F_p without diagonal scaling, and [illegible] $-M\ F_p$ ([illegible] using the same diagonal scaling as scaled [illegible] to define $\tilde{F}$ and $\tilde{G}$). For the application-provided pressure convection–diffusion preconditioner, the matrix F_p is obtained from the convection–diffusion operator that determines F, discretized on the pressure space. Two discretizations were considered: the Q_2–Q_1 (biquadratic velocity/bilinear pressure) mixed finite element discretization [8] and the marker-and-cell (MAC) finite difference discretization [10]. The experiments were done in MATLAB. The Q_2–Q_1 discretization and all tests of iterative methods were performed using the Incompressible Flow Iterative Solution Software package IFISS [7] developed in conjunction with [8].

First, we compare methods on the backward facing step. In this example, a Poiseuille flow profile (steady horizontal flow in a channel driven by pressure difference between the two ends) is imposed on the inflow boundary ($x = -1; 0 \leq y \leq 1$), and a no-flow (zero velocity) condition is imposed on the walls. At the outflow boundary ($x = 5; -1 < y < 1$), the Neumann condition

$$\begin{aligned} \nu\tfrac{\partial u_x}{\partial x} - p &= 0, \\ \tfrac{\partial u_y}{\partial x} &= 0 \end{aligned} \tag{5.3}$$

is satisfied and automatically sets the mean outflow pressure to zero [8]. (Here the velocity vector is $\mathbf{u} = (u_x, u_y)^T$.) The Q_2–Q_1 discretization is performed on a uniform finite element grid, where the grid is set up so that the rectangle enclosing the step would contain a uniform $n \times 3n$ grid of velocity nodes of width $h = 2/n$. Figure 5.1 shows the velocity field and pressure field for a representative solution to a two-dimensional backward facing step problem with $n = 64$.

In Table 5.1 and Table 5.2, the number of GMRES iterations needed to satisfy the stopping criterion (5.2) are shown for a variety of Reynolds numbers $Re = 2/\nu$, where

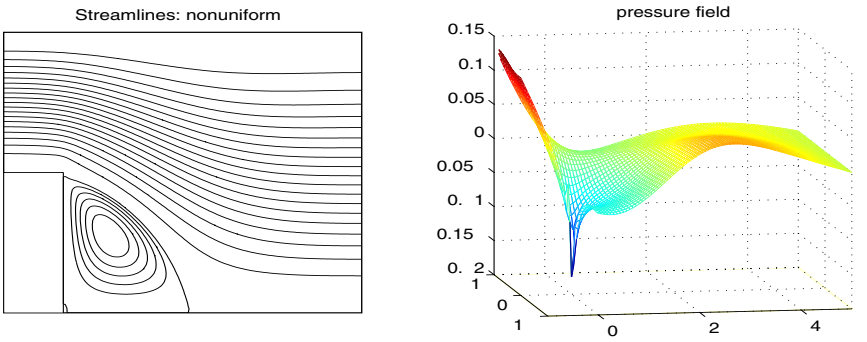

FIG. 5.1. *Streamline contours (left) and pressure plot (right) of a Q_2–Q_1 approximation to a backward facing step problem with parabolic inflow boundary conditions and natural outflow boundary conditions with $Re = 100$ on an underlying 64×192 grid.*

the viscosity ν is as in (1.1). For the [illegible]-generated F_p (both diagonally scaled and unscaled), we use the following drop tolerances in Algorithm 1: $drop_tol = 0.1, tol_1 = 0.01,$ and $tol_2 = 0.1$.

100	58	104	29	124	39
200	63	106	29	142	60

As the tables illustrate, the standard [illegible] method requires noticeably more iterations than the application-provided pressure convection–diffusion method. This type of behavior has been observed by others and has led to the perception that the [illegible] method is largely inferior to the pressure convection–diffusion method. However, inclusion of diagonal scaling improves the method so that it now significantly outperforms the pressure convection–diffusion method (often achieving a factor of two improvement in the number of iterations for higher Reynolds numbers). The tables further illustrate how the [illegible] method somewhat mirrors the behavior of [illegible]. In particular, the nonscaled version does not perform well while the scaled version is quite competitive with the application-provided pressure convection–diffusion preconditioner. It is also worth noting that these [illegible] iterations correspond to relatively large drop tolerances. We have performed additional experiments with smaller tolerances and have noticed only modest reductions in iteration counts. (See also some comments below on use of [illegible] tolerances.) It should be kept in mind that in the

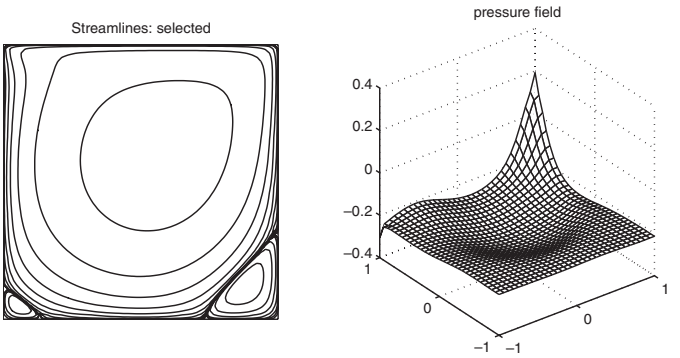

FIG. 5.2. *Exponentially spaced streamline contours (left) and pressure plot (right) of a Q_2–Q_1 approximation to a two-dimensional lid driven cavity problem with $Re = 500$ on a 64×64 grid.*

limit as the drop tolerance goes to zero, the [illegible] methods become identical to the [illegible] methods. Of course, in this limit the computation of the sparse approximate commutator would be quite costly compared to one using a large tolerance.

Next, we compare preconditioners on the lid driven cavity in two dimensions using a Q_2–Q_1 discretization. Specifically, we consider a square region with unit length sides. Velocities are zero on all edges except the top (lid), which has a driving velocity of one. The two-dimensional lid driven cavity is a well-known benchmark for fluids problems and contains many features of harder flows. Figure 5.2 shows a representative solution.

In Table 5.3 and Table 5.4, the numbers of iterations needed to reduce the initial residual by 10^6 are shown for a variety of Reynolds numbers $Re = 2/\nu$; the [illegible] drop tolerances are identical to those used for the backward facing step.

2000	106	154	85	192	105

In this case, the [illegible] results are better relative to the pressure convection–diffusion method than in the case of the backward facing step. Once again the use of diagonal scaling improves the [illegible] method so that it outperforms the pressure convection–diffusion method (though not as dramatically as in the backward facing step problem). Similar to the results for the backward facing step, [illegible] and [illegible]–*M* roughly mirror their [illegible] counterparts, and the scaled algebraic methods compare

quite well with results for the application-provided pressure convection–diffusion preconditioners. We believe that in the large Reynolds number case, lack of accuracy of the discrete convection–diffusion operators F and F_p hinders the effectiveness of the pressure convection–diffusion preconditioner; comparison of Tables 5.3 and 5.4 shows that performance of the pressure convection–diffusion preconditioner and of the scaled algebraic methods improves as the mesh is refined. This is in contrast to the backward facing step problem where all the preconditioners exhibit some iteration growth. We suspect that iteration growth on the backward facing step problem (for all the preconditioners) is associated with the boundary conditions of the F_p system. This will be explored in our final example.

Next, we verify that similar convergence behavior is exhibited for different discretizations. Specifically, iterations for a lid driven cavity problem with a MAC discretization are given in Table 5.5 and Table 5.6. (Here the problem is posed on $[0,1] \times [0,1]$ and $Re = 1/\nu$.) In this case, scaled versions of [illegible] and [illegible] are not considered, as all the velocity basis functions effectively have the same scaling. That is, the equivalent of the mass matrix for the MAC scheme has a constant diagonal and so the introduction of M_1 and M_2 does not change the method. In the last column of these tables ([illegible]), we consider a further modification to the matrix F_p produced by [illegible] so that the boundary conditions correspond to those in the application-provided version of F_p. In particular, for problems such as the lid driven cavity with enclosed flow, it is standard for the application-provided method to enforce Neumann boundary conditions when discretizing the convection–diffusion operator on the pressure space. For problems such as the backward facing step where both inflow and outflow conditions are present the situation is somewhat more complicated [8]. Unfortunately, the [illegible] preconditioner does not automatically reproduce the proper boundary conditions. This should not be surprising as the notion of commuting does not apply at the boundaries. This implies that the algebraic commuting equation is not satisfied near boundaries and therefore the computed F_p stencil at the boundaries may not be best. To mimic Neumann boundary conditions, the diagonal of the [illegible] F_p is modified so that the row sums are identically zero.

100	26	32	39	24
1000	57	53	65	54

Once again the results indicate that both the [illegible] and the [illegible] preconditioners are competitive with the application-provided pressure convection–diffusion preconditioner. Further, the inclusion of the boundary modification to [illegible]'s F_p

yields an additional reduction in the number of required iterations, with boundary-modified , performing better than the application-provided version of the pressure convection–diffusion method. More importantly, the , *bc* method appears to exhibit mesh independent convergence while mesh independence is less clear for the other two algebraic algorithms. Given this impact on convergence, further study of boundary conditions within these preconditioners needs to be explored.

We conclude this section with some observations on the costs, in CPU time, of the , preconditioning. It has been observed [4] that the setup cost may be significant when computing a sparse approximate inverse with a dynamically determined sparsity pattern. We have observed a similar phenomenon in computing , . As with standard sparse approximate inverses, the cost can be significantly reduced for the , algorithm if a predetermined sparsity pattern is employed. As we recall from section 4, the basic computational task involves the solution of the least-squares problem $\min \|\tilde{G}(\mathcal{I},\mathcal{J})f_j(\mathcal{J}) - b_j(\mathcal{I})\|_2^2$, where b_j is the jth column of $\tilde{F}\tilde{G}$ and f_j is the jth column of F_p to be computed. Instead of dynamically determining the index sets, $\mathcal{I}$ and $\mathcal{J}$, as in section 4, we can simply define $\mathcal{I}$ to be the set of nonzero row indices in b_j and $\mathcal{J}$ to be the set of nonzero column indices in $G(\mathcal{I},:)$. The least-squares problem is then solved , any additional computation to reduce the size of the residual commutator. This algorithm may not lead to as accurate a construction of the commutator, but it tends to perform almost as well and is significantly cheaper than the construction given in Algorithm 1.

Table 5.7 shows the iteration counts and timings using the simplified version of the , *bc* preconditioner for the driven cavity problem using a MAC discretization on a 128×128 grid. For the sake of comparison, timings for the application-provided pressure convection–diffusion preconditioner are also provided. These data were obtained in serial on a 3.20GHz Intel Xeon processor using the GMRES algorithm provided by MATLAB; the factors of F and G^TG used by the preconditioners were computed once and used throughout the iterations. The , *bc* iteration counts should be compared with those of Table 5.6. It is evident that this variant of the , preconditioner is competitive with that defined by Algorithm 1 (in terms of iteration counts), and the overhead associated with computing the preconditioner is small.

6. Conclusions. Variants of the pressure convection–diffusion preconditioning have been considered for the solution of the linear systems associated with the incompressible Navier–Stokes equations. Standard versions of this method require users to provide a discretization of a convection–diffusion equation over the pressure space. Although kernels needed for this discretization are available within most application codes, the additional burden of supplying this somewhat unnatural operator, denoted F_p, can be quite cumbersome. As an alternative, we have considered the use of an algebraic commuting relationship to determine the F_p operator automatically. We have shown that automatic techniques for generating F_p compete quite well

with application-provided pressure convection–diffusion methods in terms of convergence rates. These automatic methods are based on solving an algebraic commuting equation in a least-squares sense.

Two solution strategies to the commuting equation have been considered. The first centers on the normal equations and actually corresponds to a new interpretation of the [illegible] method. This new interpretation is somewhat more natural than that given in the original paper proposing the [illegible] method. Further, this new perspective leads to a diagonally scaled variant of the [illegible] preconditioner. This diagonal scaling is based on the diagonal of the mass matrix associated with the velocity equations and yields significantly improved convergence rates for the method. Overall, the diagonally scaled [illegible] method converges in a similar fashion to the application-provided pressure convection–diffusion method and actually outperforms it many times. It should, of course, be kept in mind that applying a [illegible] method is more costly than an application-provided pressure convection–diffusion method, because two Poisson solves and one convection–diffusion solve are required for each preconditioner invocation as opposed to only one Poisson solve and one convection–diffusion solve for the pressure convection–diffusion preconditioning. The significance of this extra Poisson solve is often quite modest, however, as the convection–diffusion system is much larger than the Poisson system and frequently dominates the run time.

The second solution strategy for the commuting equation builds on sparse approximate inverse techniques. Each column of F_p is built independent of every other column. The basic idea is to identify a sparsity pattern within each column and solve a local least-squares problem to minimize the error in the residual of the commuting equation. To some extent, this method can be viewed as an approximation of the [illegible] methods. The main advantage of the sparse approximate commutator, [illegible], computed in this way is that it requires one Poisson solve per preconditioner invocation similar to the application-provided pressure convection–diffusion methods. Thus, the cost per iteration should be nearly identical for the [illegible] and the application-provided pressure convection–diffusion methods. Numerical results have been given to illustrate how this method also competes quite effectively with application-provided pressure convection–diffusion preconditioners.

TOWARD AN h-INDEPENDENT ALGEBRAIC MULTIGRID METHOD FOR MAXWELL'S EQUATIONS*

JONATHAN J. HU†, RAYMOND S. TUMINARO†, PAVEL B. BOCHEV‡, CHRISTOPHER J. GARASI§, AND ALLEN C. ROBINSON¶

Abstract. We propose a new algebraic multigrid (AMG) method for solving the eddy current approximations to Maxwell's equations. This AMG method has its roots in an algorithm proposed by Reitzinger and Schöberl. The main focus in the Reitzinger and Schöberl method is to maintain null-space properties of the weak $\nabla \times \nabla \times$ operator on coarse grids. While these null-space properties are critical, they are not enough to guarantee h-independent convergence rates of the overall multigrid scheme. We present a new strategy for choosing intergrid transfers that not only maintains the important null-space properties on coarse grids but also yields significantly improved multigrid convergence rates. This improvement is related to those we explored in a previous paper, but is fundamentally simpler, easier to compute, and performs better with respect to both multigrid operator complexity and convergence rates. The new strategy builds on ideas in smoothed aggregation to improve the approximation property of an existing interpolation operator. By carefully choosing the smoothing operators, we show how it is sometimes possible to achieve h-independent convergence rates with a modest increase in multigrid operator complexity. Though this ideal case is not always possible, the overall algorithm performs significantly better than the original scheme in both iterations and run time. Finally, the Reitzinger and Schöberl method, as well as our previous smoothed method, are shown to be special cases of this new algorithm.

1. Introduction.

We consider the three-dimensional (3D) eddy current formulation of Maxwell's equations

$$\nabla \times \nabla \times \vec{E} + \sigma \vec{E} = \vec{f}, \tag{1.1}$$

with Neumann, Dirichlet, or periodic boundary conditions, where $\vec{E}$ is the unknown electric field to be computed, σ is the spatially varying electrical conductivity, and $\vec{f}$ is the known right-hand side. We assume that (1.1) is discretized with first-order edge elements on arbitrary unstructured meshes so that the following vector identity is preserved in a discrete sense:

$$\nabla \times (\nabla \phi) = 0. \tag{1.2}$$

This identity states that gradients of scalar functions lie within the kernel of the curl operator. The discrete version of (1.1) is denoted by

$$K_1^{(e)} e_1 = f_1, \tag{1.3}$$

where $K_1^{(e)} = S_1 + M_1$. S_1 is the discrete approximation to the weak form of the first term in (1.1), and M_1 is the discrete approximation to the weak form of the second term in (1.1). The discrete null-space analogue of (1.2) is represented by the rectangular matrix T_1. This matrix is a discrete gradient operator and is trivial to construct. In particular, each row of T_1 contains at most two nonzeros (± 1) and corresponds to an edge between two nodes in the associated nodal graph [5]. The following relationship holds:

$$S_1 T_1 = \Theta,$$

where Θ denotes the zero matrix. In this paper, we use the notation (*curl*, *curl*) to refer to S_1 as it emphasizes the character of the operator. Edge element discretizations of the eddy current formulation with the discrete null-space property have been investigated for both tetrahedral and hexahedral meshes. While the multigrid techniques described here are not restricted to hexahedral meshes, all of our experiments have been with hexahedral meshes, where it is assumed that the domain of interest can in fact be covered by such elements [4, 16].

The focus of this paper is the solution of the discrete linear system given in (1.3) and the special treatment required by the multigrid smoother and the multigrid grid transfers to address the large (*curl*, *curl*) kernel. Several groups have considered this problem. Hiptmair developed a geometric multigrid method with h-independent (or mesh-independent) convergence rates in [10]. Reitzinger and Schöberl [11] proposed an initial algebraic multigrid (AMG) method for Maxwell's equations that maintains a coarse grid notion of (1.2) but does not have mesh-independent convergence rates. We considered modifications to Reitzinger and Schöberl's strategy for choosing a prolongator in a previous paper [3]. The current paper proposes an improvement to the intergrid transfers that is related to those explored in [3]. The resulting method performs noticeably better than the previous method in terms of both multigrid cost per iteration and convergence. In addition, the new prolongator is much simpler to understand and implement and leads to nearly h-independent convergence of a multigrid W-cycle on some model problems.

2. Background. In this section, we give an overview of multigrid, as well as previous work in applying multigrid to Maxwell's equations.

2.1. Multigrid overview. Multigrid methods (e.g., [9, 12, 8]) are among the most efficient iterative algorithms for solving the linear system, $Ax = b$, associated with elliptic partial differential equations. The basic idea is to damp errors by utilizing multiple resolutions in the iterative scheme. High-energy (or oscillatory) components are effectively reduced through a simple smoothing procedure, while the low-energy (or smooth) components are tackled using an auxiliary lower resolution version of the problem (coarse grid). The idea is applied recursively on the next coarser level. An example multilevel iteration is given in Figure 2.1 to solve

$$A_1 u_1 = b_1. \tag{2.1}$$

The two operators needed to fully specify the multigrid method are the relaxation procedures, R_k, $k = 1, \ldots, N_{levels}$, and the grid transfers, P_k, $k = 2, \ldots, N_{levels}$.

```
// Solve A_k u_k = b_k
procedure multilevel(A_k, b_k, u_k, k)
    u_k = R_k(A_k, b_k, u_k);
    if (k ≠ N_levels)
        r_k = b_k − A_k u_k;
        A_{k+1} = P_{k+1}^T A_k P_{k+1};
        u_{k+1} = 0;
        multilevel(A_{k+1}, P_{k+1}^T r_k, u_{k+1}, k + 1);
        u_k = u_k + P_{k+1} u_{k+1};
        u_k = R_k(A_k, b_k, u_k);
```

FIG. 2.1. *Multigrid* V*-cycle consisting of* N_{levels} *grids to solve* $A_1 u_1 = b_1$.

Note that P_k is an interpolation operator that transfers grid information from level k to level $k-1$. The coarse grid discretization operator A_{k+1} $(k \geq 1)$ is specified by the Galerkin product

$$A_{k+1} = P_{k+1}^T A_k P_{k+1}. \tag{2.2}$$

The key to fast convergence is the complementary nature of these two operators. That is, errors not reduced by R_k must be well interpolated by P_k.

When grid transfers are defined using mesh and/or finite element information, this is generally termed geometric multigrid. While geometric multigrid methods often work well, they can be somewhat difficult to implement for highly unstructured meshes with irregular boundaries (especially on parallel machines). Further, they often rely on details of the specific simulation program. That is, applications are forced to develop their own version of geometric multigrid where they supply a mesh hierarchy and a means to move between grids. While potentially efficient, software development can be time consuming and the resulting multigrid code may not be well suited for other applications. In algebraic multigrid, however, only A_1 and b_1 are given, hence R_k and P_k must be deduced from purely algebraic principles. While constructing multigrid methods via algebraic concepts presents certain challenges, AMG can be used for several problem classes without requiring a major effort for each application. In this paper, we focus on a strategy to determine the P_k's based on algebraic principles. It is assumed that A_1 and b_1 are given.

2.2. Geometric multigrid for Maxwell's equations. A unique difficulty in solving Maxwell's equations arises from the kernel of the $(curl, curl)$ operator. This kernel includes the gradients of all differentiable scalar functions. Since the gradient of a smooth function is smooth and the gradient of an oscillatory function is oscillatory, it is clear that both smooth and oscillatory functions lie within the kernel. We denote the range space of operator A by $\mathcal{R}an(A)$. In the standard multigrid context, relaxation must damp oscillatory errors in $\mathcal{R}an(T_1)$ and $\mathcal{R}an(T_1^{\perp})$, and the coarse grid correction must approximate smooth errors in $\mathcal{R}an(T_1)$ and $\mathcal{R}an(T_1^{\perp})$. While the canonical coarse grid transfers of a geometric multigrid method sufficiently approximate smooth errors in $\mathcal{R}an(T_1)$ and $\mathcal{R}an(T_1^{\perp})$,[1] a special relaxation procedure must be used so that oscillatory errors in $\mathcal{R}an(T_1)$ are damped. This is because methods like Jacobi and Gauss–Seidel rely on oscillatory error components being well represented in the residual. When M_1 is small compared to S_1, however, errors in the kernel of the

(*curl*, *curl*) operator are not well represented. This can be seen by considering the following error decomposition:

$$
\begin{aligned}
&\epsilon = \epsilon_T + \epsilon_{T^\perp}, \qquad \epsilon_T \in \mathcal{R}an(T_1),\ \epsilon_{T^\perp} \in \mathcal{R}an(T_1^\perp),\ ||\epsilon_T|| \approx ||\epsilon_{T^\perp}||, \\
&r = (S_1 + M_1)(\epsilon_T + \epsilon_{T^\perp}) \\
&\quad = S_1 \epsilon_{T^\perp} + M_1(\epsilon_T + \epsilon_{T^\perp}) \\
&\quad \approx S_1 \epsilon_{T^\perp} \text{ when } ||S_1|| \gg ||M_1||.
\end{aligned} \tag{2.3}
$$

Hiptmair was essentially the first to propose a suitable relaxation procedure for (1.3), and this led to a geometric multigrid method with h-independent convergence rates [10]. This smoother is a specific instance of a more general idea termed distributed relaxation [7]. Specifically, a standard smoother is first applied to $K_1^{(e)}$. Then, a correction equation is formed and projected onto $\mathcal{R}an(T_1)$. Standard smoothing is applied to the projected equation, and the correction is added into the previous solution estimate. A summary of this smoother is given in Figure 2.2. It is important to note that a basis for the kernel of the (*curl*, *curl*) operator must be explicitly constructed on all levels within a multigrid scheme to apply this relaxation procedure. A related smoother was considered in [15] for mixed finite element problems, and alternative smoothers have been proposed in [2].

2.3. AMG for Maxwell's equations. While several good geometric multigrid options now exist, the situation is not nearly so clear for AMG methods. The first practical AMG method for solving Maxwell's equations was developed by Reitzinger and Schöberl [11]. The principal idea of the method is to maintain the representation of a discrete gradient and its relationship to the discrete (*curl*, *curl*) operator on coarse meshes. Reitzinger and Schöberl achieve this by creating two multigrid hierarchies. The primary hierarchy is a coarsening of the space where the problem (1.3) lies. The interpolation operator is given by $P_k^{(e)}$, and the coarse grid operator is given by the Galerkin product

$$K_{k+1}^{(e)} = (P_k^{(e)})^T K_k^{(e)} P_k^{(e)}.$$

This is the hierarchy that is used during the multigrid iterations. The other hierarchy serves an auxiliary role and is used only in the setup phase to construct the intergrid transfers $P_k^{(e)}$ for the primary hierarchy.

To construct the auxiliary hierarchy, Reitzinger and Schöberl discretize the partial differential equation

$$\int_\Omega \sigma u \cdot v + \int_\Omega \nabla u \cdot \nabla v \tag{2.4}$$

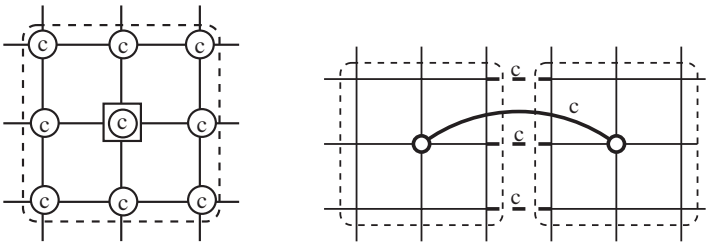
using nodal finite elements on the same mesh as (1.1). This yields a matrix $K_1^{(n)}$. The matrix T_1 is also needed for this AMG method. T_1 can be created directly from the mesh. This is done by adding one matrix row for each edge in $K_1^{(e)}$ with the two nonzero entries corresponding to nodal degrees of freedom associated with the mesh. It is also possible, however, to construct T_1 using the matrix graph of $K_1^{(n)}$ [5]. Specifically, each off-diagonal nonzero (i, j) in the upper triangular portion of $K_1^{(n)}$ corresponds to a row in T_1 containing a 1 and a -1 in columns i and j. This implies that one way to build a coarse grid discrete "gradient," T_2, is to apply an AMG procedure to $K_1^{(n)}$. This yields a prolongation operator, $P_k^{(n)}$, and a coarse grid discretization matrix, $K_2^{(n)} = (P_1^{(n)})^T K_1^{(n)} P_1^{(n)}$. The graph of $K_2^{(n)}$ can then be used to define a coarse grid discrete gradient.

The auxiliary nodal hierarchy can be viewed as an explicit coarsening of the (*curl*, *curl*) null space. The key question is now how to choose the interpolation, $P_1^{(e)}$, so that T_2 is precisely the null space of the coarse grid discrete (*curl*, *curl*) operator,

$$S_2 = (P_1^{(e)})^T S_1 P_1^{(e)}. \tag{2.5}$$

Reitzinger and Schöberl showed that the following commuting relationship is necessary and sufficient to maintain the null-space property on coarse grids:

$$P_k^{(e)} T_{k+1} = T_k P_k^{(n)}, \tag{2.6}$$



where T_k, $P_k^{(n)}$, and $P_k^{(e)}$ are the discrete gradient, nodal prolongator, and edge prolongator on the kth level. Specifically, assume that $S_k T_k = \Theta$ and that (2.6) holds. Then,

$$\begin{aligned} S_{k+1} T_{k+1} &= (P_k^{(e)})^T S_k P_k^{(e)} T_{k+1} \\ &= (P_k^{(e)})^T S_k T_k P_k^{(n)} \qquad \text{by (2.6)} \\ &= \Theta. \end{aligned}$$

Further discussions of the commuting property (2.6) are given in [11]. Thus, our computational task is reduced to producing a $P_k^{(e)}$ given T_k, T_{k+1}, and $P_k^{(n)}$ such that (2.6) holds. This will preserve the null space on coarse meshes and allow the distributed relaxation procedure to be applied. To do this effectively, however, a prolongation operator that maintains good approximation properties and leads to low multigrid operator complexities (cost per multigrid iteration) is necessary.

Reitzinger and Schöberl proposed a strategy for computing a $P_k^{(e)}$ that satisfies (2.6) and gives low multigrid operator complexities. Specifically, coarse nodes are first constructed by aggregating (or grouping) fine nodes together. $P_k^{(n)}$ is now defined as piecewise-constant interpolation from each coarse node to all of the fine nodes within its aggregate. A coarse nodal discretization is then defined using $P_k^{(n)}$, $K_k^{(n)}$, and the Galerkin product, (2.2). Coarse edges in the coarse nodal matrix simply link coarse nodes from adjacent aggregates. $P_k^{(e)}$ is then defined by injecting the value from each coarse edge to all the fine edges connecting the two adjacent aggregates associated with the coarse edge. We omit the details of the prolongator and refer the reader to [11, 3]. Figure 2.3 depicts a simple example for a single nodal basis function and a single edge basis function in the respective prolongators.

Reitzinger and Schöberl's paper properly identified the importance of (2.6). Their AMG method is easy to compute, maintains low multigrid operator complexity, and

(a) Node interpolation. (b) Edge interpolation.

is relatively insensitive to the electric conductivity. The main drawback, however, is that the prolongator has poor approximation properties, and so multigrid convergence rates suffer. In particular, h-independent AMG convergence rates typically rely on accurately approximating functions with smaller energy norm (i.e., algebraically smooth functions) on coarse meshes. Within smoothed aggregation, for example, the theory relies on bounding the energy of all the coarser grid basis functions independent of mesh spacing. This is not possible with piecewise-constant basis functions. The Reitzinger and Schöberl edge prolongation operators are built using piecewise-constant interpolation for the nodal space and actually are less accurate than piecewise-constant operators. In fact, when interpolating coarse grid edges, there are no contributions to fine grid edges that are contained completely within an aggregate. Contributions are made only to fine grid edges that connect the two aggregates defining the coarse grid edge. Thus, it is not possible to bound the energy of the coarse grid basis functions and so it is not surprising that the resulting method has convergence rates that are far from h-independent. Table 1 illustrates the growth in iterations as the mesh size increases for a model two-dimensional (2D) problem using a preconditioned conjugate gradient (CG) algorithm where a Reitzinger and Schöberl AMG method is used in a V(1,1) cycle.[2] The smoother consists of three steps: one symmetric Gauss–Seidel iteration on the entire system, one symmetric Gauss–Seidel iteration on the null-space projected equations, and a final symmetric Gauss–Seidel iteration on the entire system. It is clear for very large problems that this lack of scalability will be prohibitive.

[2]V(1,1) indicates that a V-cycle multigrid algorithm is used with 1 presmoothing sweep and 1 postsmoothing sweep on each level.

Therefore, the remainder of this paper describes a new prolongation operator that improves scalability.

3. An improved prolongation operator. Consider the new prolongation operator

$$\mathcal{P}_k^{(e)} = (I - \alpha D_{S,k}^{-1} S_k + \beta T_k D_{T,k}^{-1} T_k^T M_k) P_k^{(e)}, \tag{3.1}$$

where $P_k^{(e)}$ is the Reitzinger and Schöberl edge prolongator, S_k is the (*curl*, *curl*) term on the kth level, M_k is the mass term on the kth level, $D_{S,k}$ is the diagonal of S_k, $D_{T,k}$ is the diagonal of $T_k^T M_k T_k$, and α and β are damping parameters. It is easy to show that $\mathcal{P}_k^{(e)}$ still satisfies the commuting properties. Namely,

$$\begin{aligned}
\mathcal{P}_k^{(e)} T_{k+1} &= (I - \alpha D_{S,k}^{-1} S_k + \beta T_k D_{T,k}^{-1} T_k^T M_k) P_k^{(e)} T_{k+1} \\
&= (I - \alpha D_{S,k}^{-1} S_k + \beta T_k D_{T,k}^{-1} T_k^T M_k) T_k P_k^{(n)} \qquad \text{by (2.6)} \\
&= (I + \beta T_k D_{T,k}^{-1} T_k^T M_k) T_k P_k^{(n)} \qquad \text{using } S_k T_k = \Theta \\
&= T_k (I + \beta D_{T,k}^{-1} T_k^T M_k T_k) P_k^{(n)} \\
&= T_k \mathcal{P}_k^{(n)},
\end{aligned}$$

where

$$\mathcal{P}_k^{(n)} = (I + \beta D_{T,k}^{-1} T_k^T M_k T_k) P_k^{(n)}. \tag{3.2}$$

Thus, the commuting property is satisfied when the nodal prolongator is given by $\mathcal{P}_k^{(n)}$.

The new nodal prolongator (3.2) can be viewed as a *smoothed* version of the original piecewise-constant nodal interpolation operator. This terminology comes from the smoothed aggregation multigrid method [14, 13]. In smoothed aggregation multigrid, an original (or tentative) prolongator is developed. Then, a new prolongator, Q, is produced by lowering the energy of the tentative prolongator via the following damped Jacobi iteration:

$$Q = (I - \gamma D^{-1} A) Q_T, \tag{3.3}$$

where Q_T is a tentative prolongator, A is some fine grid discretization matrix, D is the diagonal of A, and γ is a damping parameter. When applied to a Poisson operator, the tentative prolongator corresponds to piecewise-constant interpolation. For this paper, it is important to understand that the smoothed prolongator has significantly better approximation properties than piecewise-constant interpolation and that the smoothing step is critical to obtaining h-independent multigrid convergence rates for the nodal problem [6, 13, 14].

In our context, it is reasonable to expect that a smoothed nodal prolongator *might* give rise to an improved edge prolongator because low-energy modes are better approximated. If the nodal problem is given by

$$K_1^{(n)} = T_1^T K_1^{(e)} T_1 = T_1^T M_1 T_1 \tag{3.4}$$

instead of discretizing (2.4), then (3.2) and (3.3) are now identical with $\gamma = \beta$ and $A = K_1^{(n)}$. That is, the new nodal prolongator corresponds to a *smoothed* version of the original piecewise-constant prolongator. Using (3.4) has the distinct advantage

that the user no longer needs to provide a separate nodal discretization matrix. Within the multigrid method, matrix $K_1^{(n)}$ can be constructed automatically as described in (3.4) by operators that are available. In fact, $K_1^{(n)}$ also appears in the distributed relaxation method in Figure 2.2 and so is already computed and available within the method. Additionally, the operator $T_k^T M_k T_k$ still incorporates material properties, σ, which are advantageous to utilize in the nodal aggregation phase.

It is now clear that the $\beta T_k D_{T,k}^{-1} T_k^T M_k$ term in (3.1) corresponds to smoothing the nodal prolongator. To complete our understanding of this term, however, it is necessary to look at the important role the nodal prolongator plays in the AMG iterations (even though it does not appear explicitly). To this end, we consider the Galerkin product and the coarse grid nodal matrix obtained by projecting the coarse edge operator into the null space. It is important to keep in mind that this matrix (which is used in relaxation) governs convergence in the null space. Specifically, we have

$$\begin{aligned} K_{k+1}^{(n)} &= (\mathcal{P}_k^{(n)})^T K_k^{(n)} \mathcal{P}_k^{(n)} \\ &= (\mathcal{P}_k^{(n)})^T T_k^T K_k^{(e)} T_k \mathcal{P}_k^{(n)} && \text{by (3.4)} \\ &= T_{k+1}^T (\mathcal{P}_k^{(e)})^T K_k^{(e)} \mathcal{P}_k^{(e)} T_{k+1} && \text{by (2.6)} \\ &= T_{k+1}^T K_{k+1}^{(e)} T_{k+1}. \end{aligned}$$

This implies that it is, in fact, the nodal interpolation operator that completely determines the null-space properties of the discretization matrix on the coarse meshes. Thus, an improved nodal prolongator improves the coarse discretization within the null space.

Before concluding this discussion of nodal prolongators, it is important to make one modification to (3.1). In particular, the M_k term can be simplified to significantly reduce the nonzeros in both $\mathcal{P}^{(e)}$ and the resulting coarse grid discretization matrices. To do this, we replace M_k by $\tilde{M}_k$, where $\tilde{M}_k$ is obtained by lumping the off-diagonal elements in M_k to the diagonal. This is a well-known technique in approximating mass matrices. In our context, it can be helpful in reducing the number of nonzeros and does not affect the commuting property. As a result, we now have

$$\mathcal{P}_k^{(e)} = (I - \alpha D_{S,k}^{-1} S_k + \beta T_k D_{T,k}^{-1} T_k^T \tilde{M}_k) P_k^{(e)}. \tag{3.5}$$

The $\alpha D_{S,k}^{-1} S_k$ term in (3.5) does not appear in the new nodal prolongator. In fact, for a given nodal prolongator there are several possible edge prolongators that satisfy the commuting property. To better understand the $\alpha D_{S,k}^{-1} S_k$ term, we rewrite (3.5) as

$$\begin{aligned} \mathcal{P}_k^{(e)} &= (I - \alpha D_{S,k}^{-1} S_k)(I + \beta T_k D_{T,k}^{-1} T_k^T \tilde{M}_k) P_k^{(e)} \\ &= (I - \alpha D_{S,k}^{-1} S_k) \hat{\mathcal{P}}_k^{(e)}. \end{aligned} \tag{3.6}$$

It can now be seen that $\hat{\mathcal{P}}_k^{(e)}$ is essentially a tentative edge prolongator obtained using the smoothed nodal prolongator. To improve $\hat{\mathcal{P}}_k^{(e)}$, a further smoothing step in the edge space is performed to arrive at $\mathcal{P}_k^{(e)}$. This additional smoothing step is needed because the edge prolongator may not be as accurate (or as smooth) as the corresponding nodal prolongator.

To better understand the relationship between nodal and smoothed prolongators, consider an operator, $Q^{(n)}$, that corresponds to linear nodal interpolation on a uniform mesh. Further, let us assume that we have obtained the operator $Q^{(e)}$ satisfying the commuting equation

$$Q^{(e)}T_{k+1} = T_k Q^{(n)}. \tag{3.7}$$

If the right-hand side of (3.7) is applied to a coarse grid linear function v, then the resulting function is essentially constant. This follows from the fact that $Q^{(n)}v$ produces a linear function; a discrete gradient T_k applied to $Q^{(n)}v$ yields a constant function. Combining this with (3.7) implies that

$$Q^{(e)}z = w, \tag{3.8}$$

where w is a constant and $z = T_{k+1}v$ (implying that z is a constant function). Clearly, there are several $Q^{(e)}$ that satisfy (3.8), including inaccurate piecewise-constant edge interpolation! The important conclusion to draw from this fact is that the commuting relationship does not imply that the edge prolongator is as accurate as the corresponding nodal prolongator. In our context, this has been observed experimentally and it has motivated the application of an additional edge smoothing step (3.6) to improve the properties of the edge prolongator.

To complete the prolongator description (3.5), we must choose the damping parameters α and β. These parameters are chosen according to standard smoothed aggregation multigrid criteria, based on energy minimization [13]. Specifically,

$$\alpha = \frac{4}{3}\rho(D_{S,k}^{-1}S_k)^{-1} \tag{3.9}$$

and

$$\beta = \frac{4}{3}\rho(D_{T,k}^{-1}T_k^T M_k T_k)^{-1}, \tag{3.10}$$

where $\rho(\cdot)$ is the spectral radius. This spectral radius is estimated using a few (e.g., 5–10) iterations of a symmetric eigenvalue solver (as in standard smoothed aggregation).

4. AMG operator complexity. The main AMG difficulty in solving (1.1) is that the grid transfers must satisfy the commuting relationship and, at the same time, be sufficiently accurate in both the null space and its complement. The remarkable aspect of (3.5) is that it improves the accuracy of the Reitzinger and Schöberl prolongator in both the null space and its complement *without* adversely affecting the overall cost per iteration of the AMG process. To see this, we first define multigrid operator complexity as follows:

$$\text{AMG operator complexity} = \frac{\sum_{k=1}^{N_{levels}} nnz(K_k^{(e)})}{nnz(K_1^{(e)})}, \tag{4.1}$$

where $nnz(A)$ is the number of nonzeros in the matrix A. Ideally, $nnz(K_k^{(e)}) \ll nnz(K_1^{(e)})$ for $k > 1$. This occurs when coarse grid matrices have significantly fewer rows and only a modest increase in the number of nonzeros per row relative to $K_1^{(e)}$.

To analyze nonzero behavior, we look more closely at the coarse grid discretization matrix given by the Galerkin formula

$$K_{k+1}^{(e)} = (\mathcal{P}_k^{(e)})^T K_k^{(e)} \mathcal{P}_k^{(e)}.$$

Substituting a simplified version of (3.5), we define

$$\hat{K}_{k+1}^{(e)} = (P_k^{(e)})^T (I - S_k + Z_k) K_k^{(e)} (I - S_k + Z_k) P_k^{(e)},$$

where $Z_k = T_k T_k^T$. $\hat{K}_{k+1}^{(e)}$ is identical to $K_{k+1}^{(e)}$ when the damping parameters are one, and the diagonal matrices are the identity in (3.5). These simplifications obviously do not affect multigrid operator complexity. If we multiply the three inner terms and keep only the higher order terms, we have

$$\tilde{K}_{k+1}^{(e)} = (P_k^{(e)})^T (S_k K_k^{(e)} S_k - S_k K_k^{(e)} Z_k - Z_k K_k^{(e)} S_k + Z_k K_k^{(e)} Z_k) P_k^{(e)}. \tag{4.2}$$

Once again, the nonzero pattern of $\tilde{K}_{k+1}^{(e)}$ is identical to that of $K_{k+1}^{(e)}$ as the higher order terms govern this pattern. The multigrid operator complexity of the AMG iteration is connected to understanding how the number of nonzeros per row grows in the above expression. For general unstructured matrices this is quite cumbersome. However, for simple restricted cases it is possible to show how the number of nonzeros behave. Specifically, consider a regular uniform mesh on a square. Let us further assume that each aggregate is a perfect 3×3 brick (as depicted in Figure 2.3). Typically, aggregates are defined by some greedy algorithm. A center node is picked, preferably one not adjacent to existing aggregates, and then this node along with its immediate neighbors defines a new aggregate. In the ideal case, perfect 3×3 bricks will be formed when the discretization of (2.4) on a uniform grid yields a 9-point stencil or when $K^{(n)}$ has the form (3.4) on a uniform grid. Though this case is idealized, it gives us insight into the multigrid operator complexity growth we might expect in more realistic settings. Clearly, if the number of nonzeros grows drastically in the ideal case, one should expect high multigrid operator complexity in the nonideal situation.

For the ideal case, it is possible to illustrate the support of a single basis function (or column) in $P_k^{(e)}$ and show how this support grows with the four terms in (4.2). Specifically, consider a vector, v, with a set of nonzero edge entries denoted E_v. These edges are incident to a set of nodes, denoted N_v, and a set of grid cells, denoted C_v.

The application of S_k or $K_k^{(e)}$ to v results in a new vector with nonzero elements in any edge contained in the cells C_v. The application of Z_k to v results in nonzero elements in any edge incident to N_v. Figures 4.1–4.4 show the multigrid operator complexity details. The three vertical lines in the center represent the jth column of $P_k^{(e)}$ and the additional lines illustrate the support growth. The key point to notice in the figures is that the support never touches bordering aggregates (aggregates that are only partially illustrated). This implies that the jth column of $\tilde{K}_{k+1}^{(e)}$ is zero for all coarse grid edges incident to these bordering aggregates. Thus, there are only seven nonzeros in the jth column corresponding to the seven coarse edges that connect the six central aggregates depicted in the figures. All of this means that the nonzeros per row do not grow in this simple case as the original fine grid stencil contains seven nonzeros. In three dimensions, the situation is identical when each aggregate corresponds to a $3 \times 3 \times 3$ brick. Here, there is once again no growth in the number of nonzeros per row. Of course, ideal aggregates will not generally occur. However, we have some confidence that the multigrid operator complexity will not grow drastically. Computed complexities will be given with the numerical results to support this claim.

TABLE 2
Interpolation used in experiments. Parameters α and β are chosen by (3.9) and (3.10), respectively.

$\mathcal{P}^{(e)}(\cdot,\cdot)$	Description of interpolants used in experiments
$\mathcal{P}^{(e)}(0,0)$	Reitzinger and Schöberl interpolation
$\mathcal{P}^{(e)}(\alpha,0)$	edge smoothed interpolation
$\mathcal{P}^{(e)}(\alpha,\beta)$	edge and nodal smoothed interpolation

5. Numerical experiments. To assess the interpolation strategy proposed in this paper, we compare three AMG methods. Each method uses $\mathcal{P}^{(e)}$ with different choices of α and β. See Table 2 for the choices of α and β. In each case a multigrid W-cycle is used as a preconditioner for a conjugate gradient iteration. The one exception is the first experiment, where we use both V- and W-cycles to demonstrate the efficacy of $\mathcal{P}^{(e)}(\alpha,\beta)$. The presmoother consists of two steps.

1. A damped Jacobi iteration. For an initial guess, $u^{(0)}$, and right-hand side, f, this gives $u^{(\frac{1}{2})} = u^{(0)} + \mu_1 D^{-1}(f - K_k^{(e)} u^{(0)})$, where D is the diagonal of $K_k^{(e)}$.
2. A damped Jacobi iteration for the projected equations. Defining $\tilde{D}$ as the diagonal of $T_k^T K_k^{(e)} T_k$ gives $u^{(1)} = u^{(\frac{1}{2})} + \mu_2 T_k \tilde{D}^{-1} T_k^T (f - K_k^{(e)} u^{(\frac{1}{2})})$.

These parameters are given by

$$\mu_1 = \frac{60}{31\rho(K_k^{(e)})} \qquad \text{and} \qquad \mu_2 = \frac{60}{31\rho(T_k^T K_k^{(e)} T_k)}.$$

The damping parameters correspond to a first-degree Chebyshev polynomial defined over the intervals $[\rho(K_k^{(e)})/30, \rho(K_k^{(e)})]$ and $[\rho(T_k^T K_k^{(e)} T_k)/30, \rho(T_k^T K_k^{(e)} T_k)]$, respectively. The intervals effectively define the range of "high frequencies" that must be damped by the smoother. The lower end point is given by dividing the upper end point by the approximate coarsening rate (ratio of unknowns between the fine and coarse meshes) of the multigrid algorithm. Details of this smoother can be found in [1]. It is oriented toward damping high frequency errors and uses only an estimate of the largest eigenvalue of the matrix. The postsmoother performs *step* 2 first and then *step* 1, thus guaranteeing the symmetry of the preconditioner. For the uniform-grid examples, a right-hand side is generated by taking a random vector and multiplying by the discretization matrix. A zero initial guess is used for the uniform-grid examples.

We use the following T-*norm* to evaluate convergence:

$$||r||_T = ||r||_2 + \gamma ||T_1^T r||_2. \tag{5.1}$$

The idea of this norm is to assure that the residual is reduced in both the range space and the null space of the (*curl*, *curl*) operator. This is needed to compensate for the poor representation of the error when M_1 is small and the two norm of the residual is used. This can be seen from (2.3). The factor γ in (5.1) is chosen so that the two terms are initially on the same scale. For example, $\gamma = h^2/\sigma$ for (1.1) discretized on a uniform quadrilateral mesh with constant conductivity. In general, one can choose

$$\gamma = \frac{||K_1^{(e)} v||_2}{||T_1^T K_1^{(e)} v||_2},$$

where $K_1^{(e)} = S_1 + M_1$ and v is a normalized random vector. In this way, we can equilibrate the two terms by the relative sizes of S_1 and M_1. In our experiments the

iterations terminate when $||r_{\text{final}}||_T/||r_0||_T < 10^{-8}$, where r_{final} is the final residual and r_0 is the initial residual.

Before proceeding with the experimental results, there are three practical implementation considerations that should be discussed. First, while in our analysis we assumed that the mass term M_1 is lumped, in practice we do not always lump. As is shown in the experiments, not lumping can result in slightly higher, but still acceptable, multigrid operator complexities. The second is that the mass and stiffness matrices must be projected separately (via the Galerkin product) due to the presence of S_k and $\tilde{M}_k$ in (3.5). This requires additional computation when compared to directly projecting $K_k^{(e)}$ (though this can be significantly reduced if M_k is lumped before projection). There is, however, an important advantage in maintaining the M_k's with respect to numerical cancellation (i.e., rounding errors). Cancellation can be significant when S_k is much larger than M_k and the nodal discretization (needed in the distributed relaxation) is computed via $T_k^T K_k^{(e)} T_k$. This cancellation can be avoided by using $T_k^T M_k T_k$ to compute the nodal discretization. If it is absolutely imperative that S_k and M_k not be stored explicitly (e.g., they are not available on the finest mesh) and it is known that the conductivity is relatively constant, (3.5) can be approximated. In particular, M_k can be ignored (equivalent to approximating it by a multiple of the identity) and $K_k^{(e)}$ can be used instead of S_k without significant convergence degradation.

The third implementation issue concerns the choice of β. We have found in our experimentation that convergence can be enhanced by using a larger β than that given by standard smooth aggregation arguments, (3.10). The reason for this can be seen in (3.6). Specifically, β determines not only the nodal prolongator, (3.2), but also the tentative edge prolongator. While (3.10) is given to optimize the nodal prolongator, it does not necessarily provide for the best tentative edge prolongator. That is, higher values of β can yield a better starting tentative edge prolongators while sacrificing a bit the nodal prolongator. We emphasize that having a good tentative edge prolongator is crucial; for example, just smoothing the original Reitzinger and Schöberl edge prolongator does not yield h-independent multigrid convergence rates. When combined with an appropriate edge smoothing parameter, α, an appropriate choice of β can yield an improved smoothed edge prolongator, $\mathcal{P}^{(e)}$. This difficulty of finding a single β that yields both suitable tentative edge prolongators and smoothed nodal prolongators leads us to suspect that the convergence of the resulting method is not always mesh independent. We are still exploring alternatives to (3.10) that may produce the best compromise.

5.1. AMG with constant conductivity. We first consider (1.1) discretized with rectangular elements on the unit square with periodic boundary conditions and a constant value of σ. Table 3 gives iteration counts and run times for CG preconditioned with a V-cycle. Table 4 gives iteration counts and run times for CG preconditioned with a W-cycle. Table 5 gives AMG multigrid operator complexity results for the 810×810 mesh.

There are several things to notice about the data in Tables 3 and 4. The main observation is that AMG using the full $\mathcal{P}^{(e)}(\alpha, \beta)$ operator exhibits near h-independence, as can be seen in Table 4. Neither $\mathcal{P}^{(e)}(0,0)$ (the original Reitzinger and Schöberl operator) nor $\mathcal{P}^{(e)}(\alpha, 0)$ has an h-independent convergence rate, even with W-cycles. Smoothing alone (i.e., $\alpha \neq 0$, $\beta = 0$) is beneficial but not enough for grid independence. These improved convergence rates translate directly into significantly improved run times (one example is more than five times faster). In addition, for a fixed problem

size, the iteration counts of the new prolongator is fairly insensitive to the size of the conductivity for this model problem. This is highly desirable for difficult problems with low conductivity. The operator complexity of the multigrid hierarchy is given in Table 5, where the first line corresponds to the multigrid operator complexity for the original Reitzinger and Schöberl algorithm. The complexity for AMG based on $\mathcal{P}^{(e)}(\alpha,\beta)$ requires some explanation. For larger σ, the mass in the third term of (3.1) results in nonzero growth of the coarser level operators. The contribution of the mass

term drops with σ. For small σ, these entries can be dropped, and we recover the nonzero pattern of $\mathcal{P}^{(e)}(0,0)$ and $\mathcal{P}^{(e)}(\alpha,0)$. As mentioned in section 4, an alternative to using the true mass term is approximating it with a lumped version. Although we did not use a mass approximation in this experiment, doing so has the advantage that there is no growth in the multigrid operator complexities due to the mass term. (See the final slotted-square problem for results using an approximation to the mass matrix.)

Similar results are given in Table 6 for a 3D cube. In this case, convergence is independent of the mesh size for the W-cycles, the overall multgrid operator complexity is quite low, and the new prolongator $\mathcal{P}^{(e)}(\alpha,\beta)$ results in significant run time improvements compared to the original prolongator $\mathcal{P}^{(e)}(0,0)$. See Table 7 for multigrid operator complexities. We note that in the case of $\mathcal{P}^{(e)}(\alpha,\beta)$ we omitted the

mass term, M, from the third term of (3.1); i.e., we used only $\beta T D^{-1} T^T$ (due to difficulty in extracting just the mass term within our software). Therefore, we cannot comment on the effect on multigrid operator complexity if the original M were used. If M is lumped, however, clearly there should be no effect on the multigrid operator complexities. We observe h-independent convergence rates for the model problem even without M.

5.2. AMG with conductivity jumps in a 2D domain. For the second experiment, we consider (1.1) discretized with rectangular elements on the unit square, Ω, with periodic boundary conditions. The domain is split into two regions, Ω_1 and Ω_2. Region Ω_1 is given by $[0, 1/3]^2$, and $\Omega_2 = \Omega \setminus \Omega_1$. In Ω_1, the conductivity is either $\sigma_1 = 10^{-3}$ or $\sigma_1 = 10^{-1}$, depending on the experiment. In Ω_2, the conductivity is $\sigma_2 = 1.0$. The domain is depicted in Figure 5.1.

Results are given for a W-cycle in Table 8. As with the previous experiments, only the $\mathcal{P}^{(e)}(\alpha,\beta)$ prolongator displays h-independence. There is iteration growth in both $\mathcal{P}^{(e)}(0,0)$ and $\mathcal{P}^{(e)}(\alpha,0)$ as the mesh size increases.

5.3. AMG on a nonorthogonal mesh. As our final computational example, we consider a slotted unit square with a mixture of Neumann and Dirichlet boundary conditions. The exact boundary conditions are given in Figure 5.2. Figure 5.3 illustrates the computational domain for a mesh with 1,994 edges. Each sphere represents

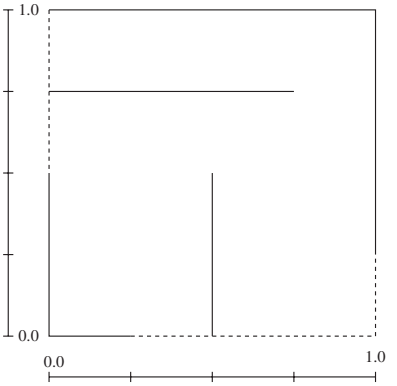

FIG. 5.2. *Boundary conditions for slotted unit square problem. The dashed lines are imposed Neumann conditions, and the solid lines are Dirichlet conditions.*

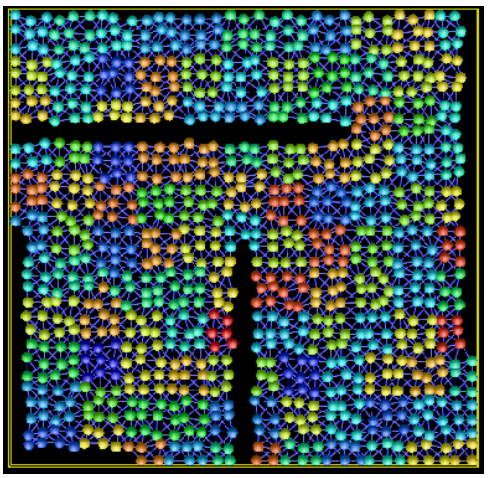

FIG. 5.3. *Visualization of aggregates for a* 33×33 *mesh.*

a nodal grid point. The colors of the spheres give an indication of the nodal aggregates used on the finest level. Due to color limitations in the visualization package, it is difficult to entirely distinguish all the aggregates (especially when two aggregates of similar color are adjacent to each other). However, it is clear that the aggregates are certainly not uniform or regular. For these experiments, the following function is used for the conductivity:

$$\sigma = \frac{\eta}{4000}(5 - \sin(2\pi xy + 3y)e^{(xy-2x)}), \tag{5.2}$$

where η is a scalar and the domain corresponds to $0 \le x \le 1$ and $0 \le y \le 1$. Figure 5.4 shows a plot of (5.2) for $\eta = 10$ on a 33×33 mesh on the unit square. The results given in Table 9 illustrate the convergence for different values of η. These results essentially mirror the other experiments given in this paper. In particular, the only convergence rates that are nearly mesh independent correspond to $\mathcal{P}^{(e)}(\alpha, \beta)$.

In these experiments, the mass matrix has many nonzeros (almost as many as the stiffness matrix). This is due to the nonorthogonality of the mesh. To avoid

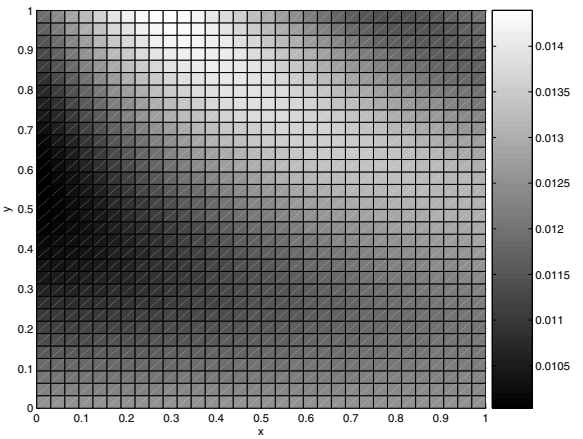

FIG. 5.4. *Variation in σ, as given by* (5.2)*, for $\eta = 10$ on a 33×33 mesh on the unit square.*

complexity growth, a simple diagonal approximation to the mass matrix is used in (3.5). This diagonal is obtained by simply summing the absolute values of the entries within each row. While this is relatively crude, it seems to be sufficient for these problems. In particular, the diagonal approximation ensures that the multigrid complexity is independent of the mass term, and therefore σ, as discussed in section 4. Multigrid complexities are given in Table 10. These complexities are very similar to those observed in the previous experiments.

6. Conclusions. We have proposed a new AMG grid transfer for Maxwell's equations. This operator depends on two parameters that are easy to calculate. Both the Reitzinger and Schöberl intergrid transfers and the smoothed intergrid transfers in [3] are special instances of this new operator. Numerical experiments on model

714,162	1.13	1.13	1.13

problems show that an AMG method based on this new operator has superior iteration counts and run times to previous operators. In certain cases, the AMG method has h-independent convergence rates. In general, the new AMG/CG method demonstrates improved convergence behavior and has only a slight growth in the number of iterations as the mesh size increases. Future research includes analyzing the behavior of this new method on systems with mass matrices that have coefficient jumps or that have large variation in conductivity.

A MULTIGRID METHOD FOR VARIABLE COEFFICIENT MAXWELL'S EQUATIONS*

J. JONES† AND B. LEE‡

Abstract. This paper presents a multigrid method for solving variable coefficient Maxwell's equations. The novelty in this method is the use of interpolation operators that do not produce multilevel commutativity complexes that lead to multilevel exactness. Rather, the effects of multilevel exactness are built into the level equations themselves—on the finest level using a discrete $T-V$ formulation and on the coarser grids through the Galerkin coarsening procedure of a $T-V$ formulation. These built-in structures permit the levelwise use of an effective hybrid smoother on the curl-free near-nullspace components and permit the development of interpolation operators for handling the curl-free and divergence-free error components separately. The resulting block-diagonal interpolation operator does not satisfy multilevel commutativity but has good approximation properties for both of these error components. Applying operator-dependent interpolation for each of these error components leads to an effective multigrid scheme for variable coefficient Maxwell's equations, where multilevel commutativity-based methods can degrade. Numerical results are presented to verify the effectiveness of this new scheme.

Key words. Maxwell's equations, multigrid method, edge finite elements

1. Introduction.

In recent years, there has been substantial interest in solving the curl-curl formulation of Maxwell's equations for the electric or magnetic field. This formulation commonly arises in the time-domain and frequency-domain approaches for solving time-dependent electromagnetic problems. For both approaches, the challenges in developing an efficient multigrid algorithm are formidable: the time-domain approach leads to variable coefficient equations with large near-nullspaces, as with the frequency-domain approach but with the added challenge of being indefinite. In this paper, we consider only the definite curl-curl formulation.

There exist several successful geometric [16], [2] and algebraic [20], [5] multigrid methods for solving the definite curl-curl equations. But the performance of these methods degrades as the variation of the material coefficients increases. The reason for this degradation can be traced back to the interpolation operator. For geometric schemes, even with nested finite element spaces, the natural finite element interpolation fails when the coefficients strongly vary much the same way the natural finite element interpolation fails for scalar diffusion equations with rapidly varying coefficients; i.e., finite element interpolation leads to simple arithmetic averaging of the coefficients on the coarser grids. For algebraic schemes, since the interpolation operator is constructed with the constraint that a multilevel commutativity complex is

formed (see (3.4)), divergence-free error components can be untouched or even amplified by this type of interpolation. In particular, interpolation operators constructed in this manner can handle at most only the curl-free error components, and thus, only half of the Helmholtz decomposition of the error. Thus, current geometric and algebraic multigrid methods do not satisfy the approximation property when the material coefficients vary substantially.

Satisfying the approximation property is not the only difficulty. For Maxwell's equations, the smoothing property is hard to obtain. For this system PDE, near-nullspace components occur on all grid scales, and thus, relaxation must be designed to handle error components of these form on all grid scales. This is in fact the purpose of having a multilevel commutativity complex. Such complex permits easy movement between two-term exact sequences on different grid levels. With a discretization that preserves this two-term exact sequence, nullspace components of the curl operator are explicitly known, and hence, hybrid smoothers [16], [2] can be constructed to effectively handle curl-free error components. Having this two-term sequence on each level then guarantees level smoothers that eliminate curl-free error of any grid scale, and having a multilevel commutativity complex guarantees that curl-free coarse grid corrections are indeed curl-free on the finer grid. But ideally, as previously explained, one would like a multilevel commutativity complex that spans over an exact sequence that also includes the divergence operator. This would involve developing separate interpolation operators for the curl-free and divergence-free components, which implies the existence of an exact discrete Helmholtz decomposition. Or, if an exact discrete Helmholtz decomposition does not exist, one needs an interpolation operator that acts appropriately (i.e., has good approximation) on both the curl-free and divergence-free components. Such an interpolation operator is unfortunately extremely difficult to construct.

The challenge in developing a multigrid scheme for variable coefficient curl-curl equations is then constructing interpolation operators that have good approximation property for both curl-free and divergence-free errors and such that the coarse grid problems constructed using these operators have the relevant effects of two-term exact sequences in order for a hybrid smoother or overlapping Schwarz smoother to be effective on coarser levels. Rather than constructing interpolation operators that satisfy these constraints, in this paper we develop a multigrid scheme that relaxes on the multilevel commutativity constraint and hence has more freedom in the construction of interpolation operators to handle the curl-free and divergence-free error components. This method involves a discrete $T - V$ formulation [19] on the finest level. The construction of this $T - V$ formulation can be obtained from the given curl-curl formulation matrix and a discrete gradient on the finest level.

The goal of this formulation is to introduce the nullspace of the curl operator, i.e., gradients, explicitly into the set of equations. This leads to a discrete system for the curl-free and approximate divergence-free components of the solution, which corresponds to a system PDE for these solution components. Separate operator-based interpolation operators are then constructed, using the original curl-curl equations and the Laplace operator derived from the introduction of the gradients. These block-diagonal interpolation operators are used in the Galerkin coarsening procedure to generate coarse grid problems for the curl-free and divergence-free components of the error. Thus, at all levels, the systems are blocked 2×2, with the diagonal blocks describing the coupling within the curl-free or divergence-free components and with the off-diagonal blocks describing their coupling. Now equations for the curl-free or near-nullspace gradients are explicitly available at all levels, so a hybrid smoother can be applied at each level.

It must be noted that the $T-V$ formulation is introduced discretely only to obtain an efficient multigrid solver. The target continuous curl-curl formulation of Maxwell's equations is not explicitly replaced by a continuous semidefinite $T-V$ formulation. Also, it must be noted that the above scheme resembles Griebel's subspace correction method [14]. However, unlike Griebel's scheme, which creates linearly dependent generating functions by collecting the finite element basis functions on all levels, the above scheme considers the "generating functions" from a Helmholtz decomposition perspective at each level. Indeed, the Helmholtz decomposition perspective gives guidance on developing effective interpolation operators and relaxation schemes, and is much more insightful for $H(\mathrm{div})$ and $H(\mathrm{curl})$ system PDEs than a general subspace correction perspective. In fact, the $T-V$ formulation exposes the extent to which the components of the Helmholtz decomposition can be coarsened separately.

This paper is organized as follows. In section 2 we introduce the curl-curl formulation of the definite Maxwell's equations, the functional setting for the variational problem, and the finite element spaces for the discretization. In section 3, because of their importance in understanding solution methods for the curl-curl formulation, we review the de Rham complex for the curl-curl formulation and the multilevel commutativity diagrams connecting the complexes on different levels. In particular, because the multigrid scheme developed in this paper can be viewed as a generalization of Hiptmair's approach [16] that does not satisfy multilevel commutativity, we need to examine what multilevel commutativity achieves and how much of it is needed in a multigrid solver. In fact, one purpose of this paper is to "isolate" de Rham sequences and commutativity from multigrid. To achieve this, in section 3 we will distinguish between multilevel commutativity and multilevel de Rham complexes and show that multigrid schemes with commutativity-based interpolation operators generally enforce only exactness, whereas multilevel de Rham complexes are really needed for multigrid effectiveness. In section 4 we describe our $T-V$ formulation and the operator-based interpolation operators to handle variable coefficients. An intuitive justification for our choice of operator-based interpolation operators is presented. In particular, since the $T-V$ system is used in the multigrid procedure, we examine the near-nullspace components of this system to show that operator collapsing [10], [11], [12] can be used to handle the curl-free error components and that AMGe element agglomeration [9] can be used to handle the remaining error components. Finally, in section 5 we present some preliminary numerical results illustrating the effectiveness of this multigrid scheme and, equally important, illustrating no need for multilevel commutativity complexes.

2. Curl-curl formulation in the electric field. Let $\Omega \times T$ be the Cartesian product of a bounded simply connected domain $\Omega \in \Re^n$, $n = 2, 3$, and a nonnegative time interval T. To guarantee appropriate regularity of the problem, let Ω have a smooth or polygonal boundary Γ. Electromagnetic phenomena in $\Omega \times T$ can be described by the differential equations

$$\begin{aligned} \nabla \times \mathbf{E} &= -\tfrac{\partial \mathbf{B}}{\partial t} \quad \text{in } \Omega \times T, \\ \nabla \times \mathbf{H} &= \tfrac{\partial \mathbf{D}}{\partial t} + \mathbf{j} \quad \text{in } \Omega \times T \end{aligned} \tag{2.1}$$

with the linear material constitutive relations [19]

$$\begin{aligned} \mathbf{D} &= \epsilon \mathbf{E} \quad \text{in } \Omega \times T, \\ \mathbf{B} &= \mu \mathbf{H} \quad \text{in } \Omega \times T, \\ \mathbf{j} &= \sigma \mathbf{E} \quad \text{in } \Omega \times T. \end{aligned} \tag{2.2}$$

The equations in (2.1) are Faraday and Ampere's laws of Maxwell's equations, and the third equation in (2.2) is a simple Ohm's law. Here, $\mathbf{E}$, $\mathbf{D}$, $\mathbf{H}$, $\mathbf{B}$, and $\mathbf{j}$ are, respectively, the electric field, electric flux, magnetic field, magnetic flux, and electric current; and ϵ, μ, and σ are, respectively, the electric permittivity, magnetic permeability, and electric conductivity, which we assume all to be spatially dependent but independent of t. Using (2.1) and (2.2), we have

$$\nabla \times \frac{1}{\mu} \nabla \times \mathbf{E} + \epsilon \frac{\partial^2 \mathbf{E}}{\partial^2 t} + \sigma \frac{\partial \mathbf{E}}{\partial t} = \mathbf{0}.$$

Differencing the time derivatives and, for simplicity, assuming that the boundary surface is perfectly conducting, we obtain a boundary-value problem of the form

$$\begin{aligned} \nabla \times \alpha \nabla \times \mathbf{E} + \beta \mathbf{E} &= \mathbf{f} \quad \text{in } \Omega, \\ \mathbf{n} \times \mathbf{E} &= \mathbf{0} \quad \text{on } \Gamma, \end{aligned} \tag{2.3}$$

where α and β are positive functions (in $L_\infty(\Omega)$). The parameter β is related to the time step size ($\beta = \frac{\alpha}{\Delta t}$) and may be quite small if large time steps are taken. We will call (2.3) the *curl-curl formulation* for the electric field. At each time step of the solution process for the time-dependent problem, an equation of the form (2.3) must be solved.

To describe the variational formulation of (2.3), several functional spaces are needed. Thus, we will denote the usual kth-order Sobolev spaces by $H^k(\Omega)$ and their homogeneous trace subspaces by $H_0^k(\Omega)$. We also need spaces

$$\begin{aligned} H(\mathrm{div}; \Omega) &= \left\{ \mathbf{v} \in [L^2(\Omega)]^n : \nabla \cdot \mathbf{v} \in L^2(\Omega) \right\}, \\ H(\mathrm{curl}; \Omega) &= \left\{ \mathbf{v} \in [L^2(\Omega)]^n : \nabla \times \mathbf{v} \in [L^2(\Omega)]^{2n-3} \right\}. \end{aligned}$$

We denote their homogeneous trace subspaces by $H_0(\mathrm{div}; \Omega)$ and $H_0(\mathrm{curl}; \Omega)$, respectively. Now, the variational formulation of (2.3) is to find $\mathbf{E} \in H_0(\mathrm{curl}; \Omega)$ such that

$$(\alpha \nabla \times \mathbf{E}, \nabla \times \mathbf{v}) + (\beta \mathbf{E}, \mathbf{v}) = (\mathbf{f}, \mathbf{v}) \qquad \forall \mathbf{v} \in H_0(\mathrm{curl}; \Omega). \tag{2.4}$$

To discretize the variational problem (2.4), the lowest-order Nedelec finite elements are used. Let $\mathcal{T}_h := \{T_i\}$ be a quasi-uniform and shape-regular triangulation of Ω with mesh size h [8]. The lowest-order local Nedelec finite element space is

$$\mathcal{ND}(T_i) := \{ \mathbf{v} = \mathbf{a} + \mathbf{b} \times \mathbf{x};\ \mathbf{x} \in T_i,\ \mathbf{a}, \mathbf{b} \in \Re^n \}.$$

The degrees of freedom are the tangential components along the edges of T_i; along the lth edge e_l,

$$\int_{e_l} \mathbf{t} \cdot \mathbf{v}\, ds.$$

The global finite element space is

$$\mathcal{ND}(\mathcal{T}_h) := \left\{ \mathbf{v}_h \in H_0(\mathrm{curl}; \Omega) : \mathbf{v}_{h|T_i} \in \mathcal{ND}(T_i)\ \ \forall T_i \in \mathcal{T}_h \right\}.$$

This choice of finite element space guarantees continuity of the tangential component of $\mathbf{v}_h$. With $\mathbf{E}_h$ denoting the discrete approximation to the solution of (2.4), the discrete variational problem is to find $\mathbf{E}_h \in \mathcal{ND}(\mathcal{T}_h)$ such that

$$(\alpha \nabla \times \mathbf{E}_h, \nabla \times \mathbf{v}_h) + (\beta \mathbf{E}_h, \mathbf{v}_h) = (\mathbf{f}, \mathbf{v}_h) \qquad \forall \mathbf{v}_h \in \mathcal{ND}(\mathcal{T}_h). \tag{2.5}$$

We also will need the standard first-order scalar Lagrange finite element space

$$\mathcal{H}_h(\mathcal{T}_h) := \left\{ v \in H_0^1(\Omega) : \, v_{|T_i} \in \mathcal{P}_1(T_i) \;\; \forall T_i \in \mathcal{T}_h \right\}$$

with the usual nodal degrees of freedom. Note that the gradient of an element of $\mathcal{H}_h(\mathcal{T}_h)$ is not only in $\mathcal{ND}(\mathcal{T}_h)$ but also in the nullspace of the curl operator. In fact, the assumption of simple-connectedness of Ω guarantees that the nullspace of the curl operator consists only of gradients. By cohomology theory, this is also true in the triangulated domain [7]. (The algorithm of this paper, as with other multigrid algorithms for solving (2.5), requires simple-connectedness of Ω. For domains such as tori, an additional procedure is needed to handle special troublesome subspaces of low dimension. These subspaces can be treated on a coarse grid [17].)

3. De Rham and commutativity complexes and multigrid. The multigrid scheme we will develop is a generalization of the algorithm described in [16]. But a major difference between these two schemes is that the method described in this paper does not produce multilevel commutativity complexes even when the levels are nested, whereas the method described in [16] does. Because of this, we explore de Rham and commutativity complexes and multigrid in this section. We examine whether multigrid efficiency is really a result of these multilevel complexes. In particular, our goal in this section is to isolate commutativity from the multigrid process and to show that effective multilevel complexes are too difficult to produce for variable coefficient Maxwell's equations. This will then lead to a simpler scheme, described in section 4.

Before reviewing de Rham and commutativity complexes, we outline the algorithm of [16] in order to have a base method to illustrate multilevel complexes. This algorithm has the standard multigrid structure:

Given an initial guess $\mathbf{E}^L$ and a right-hand side $\mathbf{f}^L$ on the finest level L

MG(l, $\mathbf{E}^l$, $\mathbf{f}^l$) Cycle:

1. if $l = 0$, the coarsest level, solve exactly, $\mathbf{E}^0 \leftarrow [A_{ee}^0]^{-1}\mathbf{f}^0$
2. else,
   a. presmooth $\mathbf{E}^l \leftarrow S_l(\mathbf{E}^l, \mathbf{f}^l)$
   b. $\mathbf{E}^{l-1} \leftarrow \mathbf{0}$
   c. MG($l-1$, $\mathbf{E}^{l-1}$, $[P_{l-1}^l]^t(\mathbf{f}^l - A_{ee}^l\mathbf{E}^l)$)
   d. coarse grid correction $\mathbf{E}^l \leftarrow \mathbf{E}^l + P_{l-1}^l\mathbf{E}^{l-1}$
   e. postsmooth $\mathbf{E}^l \leftarrow S_l(\mathbf{E}^l, \mathbf{f}^l)$,

where A_{ee}^l is the lth level discretized edge operator and S_l and P_{l-1}^l are, respectively, the lth level smoothing and interpolation operators. However, the smoother is nonstandard:

$S_l(\mathbf{E}^l, \mathbf{f}^l)$ Sweep:

1. Gauss–Seidel sweep on edge equations $A_{ee}^l\mathbf{E}^l = \mathbf{f}^l$
2. edge residual computation, $\mathbf{r}^l \leftarrow \mathbf{f}^l - A_{ee}^l\mathbf{E}^l$
3. transfer to scalar "potential" space (or set up of distributive relaxation), $\mathbf{w}^l \leftarrow [G_{en}^l]^t\mathbf{r}^l$
4. Gauss–Seidel sweep on scalar potential equation $A_{nn}^l\phi^l = \mathbf{w}^l$
5. potential solution correction $\mathbf{E}^l$, $\mathbf{E}^l \leftarrow \mathbf{E}^l + G_{en}^l\phi^l$,

where G_{en}^l is the level l discrete gradient operator mapping a node-based scalar potential into the Nedelec element space and A_{nn}^l is a discrete node-based diffusion operator. When the level edges are nested and the P_{l-1}^l's are the natural Nedelec finite element interpolation operators, then the multilevel de Rham and commutativity complexes are hidden in the interpolation and discrete gradient operators. When the level edges are nonnested, as generally is the case for unstructured grids, the P_{l-1}^l's

can be constructed so that a multilevel commutativity complex is formed (see [20] and [5]).

So, what are de Rham complexes? De Rham complexes describe a relationship between the gradient, curl, and divergence operators over appropriate spaces. They are an amazing tool for systematically describing stable discretizations of PDE systems [1]. Given a scalar or system of PDEs, subtle geometric properties of the PDEs can be exposed by de Rham sequences. These properties should be retained in the discretization for the sake of numerical stability. For the Maxwell's equations, which have intrinsic topological properties reflective of de Rham complexes [3], these complexes have been used to explain the stability of Nedelec finite elements for the curl-curl formulation [6], [1].

In the continuum, the de Rham complex of interest for Maxwell's equations is

$$H^1(\Omega) \xrightarrow{\nabla} H(\mathrm{curl};\Omega) \xrightarrow{\nabla\times} H(\mathrm{div};\Omega). \tag{3.1}$$

Here, we have a sequence of vector spaces defined on our domain Ω and a sequence of operators interrelating them. These vector spaces are *exact* in the sense that the range of an operator defined on the space to its left is in the kernel of the operator and domain space to its right—e.g., the kernel of $\nabla\times$ defined on $H(\mathrm{curl};\Omega)$ is $\nabla H^1(\Omega)$. Let $\{H_h^1,\, H_h(\mathrm{curl}),\, H_h(\mathrm{div})\}$ and $\{S_{2h},\, W_{2h},\, V_{2h}\}$ be two sets of finite elements that need not be nested and of which the first set forms a discrete analogue to (3.1):

$$H_h^1(\Omega) \xrightarrow{\nabla^h} H_h(\mathrm{curl};\Omega) \xrightarrow{\nabla\times^h} H_h(\mathrm{div};\Omega). \tag{3.2}$$

Of course, exactness means that the finite element spaces in the first set cannot be chosen separately. In our case, choosing the lowest-order Nedelec elements ($\mathcal{ND}_h$) for $H_h(\mathrm{curl};\Omega)$, the other finite element spaces are the first-order Lagrangian elements ($\mathcal{H}_h$) and lowest-order Raviart–Thomas elements ($\mathcal{RT}_h$) for $H_h^1(\Omega)$ and $H_h(\mathrm{div};\Omega)$. This consistent choice of finite element spaces is in fact a geometric property (e.g., for the above multigrid algorithm, $\mathbf{E}^l$ is defined on edges ($\mathcal{ND}_h$) and ϕ^l is defined on nodes ($\mathcal{H}_h$)). This shows that a discrete de Rham sequence is not simply a discretization of the functional spaces involved but a "discretization" of a calculus defined over a smooth manifold and its submanifolds [4], [13], [15]. In particular, a discrete de Rham sequence satisfies three properties. It is (i) a discretization of a smooth n-dimensional manifold $\mathcal{M}$ with so-called p-cubes or Euclidean simplices; (ii) a discretization of the *p-forms* defined on the manifold and its submanifolds; and (iii) a discretization of a so-called exterior differential operator so that a generalized Stokes theorem holds over the manifold and its submanifolds (this gives the exactness property). These discretizations are constructed so that the p-forms are simple, unisolvent, conforming, etc. [15]. In our case, $\mathcal{M}$ is a domain in $\Re^3$, the p-cubes are points, edges, and faces, and the p-forms are the above finite element spaces. The location of the degrees of freedom for these finite element spaces indeed reflects a *consistent* choice of simplices to guarantee exactness.

Now, denoting the induced finite element interpolation operators of $\mathcal{H}_h$, $\mathcal{ND}_h$, and $\mathcal{RT}_h$ by $\Pi^h_{\mathcal{H}}$, $\Pi^h_{\mathcal{ND}}$, and $\Pi^h_{\mathcal{RT}}$, the following commutativity complex holds:

$$\begin{array}{ccccc} H^1(\Omega) & \xrightarrow{\nabla} & H(\mathrm{curl};\Omega) & \xrightarrow{\nabla\times} & H(\mathrm{div};\Omega) \\ \downarrow \Pi^h_{\mathcal{H}} & & \downarrow \Pi^h_{\mathcal{ND}} & & \downarrow \Pi^h_{\mathcal{RT}} \\ \mathcal{H}_h & \xrightarrow{\nabla^h} & \mathcal{ND}_h & \xrightarrow{\nabla\times^h} & \mathcal{RT}_h. \end{array} \tag{3.3}$$

This complex relates a set of continuous spaces to a set of discretizations under a collection of commuting differential and interpolation operators. For the above multigrid algorithm and several others [20], [5], additional hierarchies of commutativity relating the level spaces are needed. These methods require a two-level commutativity complex of the form

$$
\begin{array}{lll}
H^1(\Omega) & \xrightarrow{\nabla} H(\mathrm{curl};\Omega) & \xrightarrow{\nabla\times} H(\mathrm{div};\Omega) \\
\downarrow \Pi^h_{\mathcal{H}} & \downarrow \Pi^h_{\mathcal{ND}} & \downarrow \Pi^h_{\mathcal{RT}} \\
\mathcal{H}_h & \xrightarrow{\nabla^h} \mathcal{ND}_h & \xrightarrow{\nabla\times^h} \mathcal{RT}_h \\
\uparrow P^h_{H^1} & \uparrow P^h_{H(\mathrm{curl})} & \uparrow P^h_{H(\mathrm{div})} \\
S_{2h} & \xrightarrow{\nabla^{2h}} W_{2h} & \xrightarrow{\nabla\times^{2h}} V_{2h}(\mathrm{div}),
\end{array}
\tag{3.4}
$$

where $P^h_{(\cdot)}$ are multilevel interpolation operators that are constructed to satisfy commutativity. Note that the second layer of (3.4) is a discrete de Rham sequence since it satisfies the above three properties. However, depending on the choice of $\{S_{2h}, W_{2h}, V_{2h}\}$, the third layer *only* forms an exact sequence between these sets since it may not satisfy condition (ii). Although multilevel exactness requires a consistent choice of coarse simplices, a multilevel de Rham structure also requires that $\{S_{2h}, W_{2h}, V_{2h}\}$ consist of proper p-forms. To stress this, consider the case when the coarse edges do not nest the fine edges, as is the case for the algorithms of [20] and [5]. Because of this nonnesting, $\{S_{2h}, W_{2h}\}$ consists of *weighted* averages generated by the $P^h_{(\cdot)}$, which are not the proper p-forms for the coarse simplices.

Let us return to the above multigrid algorithm and reflect on these complexes. For the curl-curl formulation of Maxwell's equation, some of the near-nullspace components are gradients, and these occur on all grid scales. Thus, not only must coarse scale gradients be in the range of the interpolation operator, but also relaxation on a level must effectively eliminate gradients of scale equal to the level's mesh size. This latter condition leads to the nonstandard smoother, using the level gradient operator G^l_{en}, in the algorithm at the beginning of this section. Of course, effective elimination of these level gradients by level relaxation assumes that each level operator has a curl-curl form. But all of this is reflective of a multigrid solver built on a multilevel commutativity complex: level exactness guarantees the above smoother to be effective on the level gradients.

A multilevel commutativity complex also guarantees good approximation to coarse scale near-nullspace gradient components. Consider the case where $\{S_{2h}, W_{2h}\}$ is a nested subspace of $\{\mathcal{H}_h, \mathcal{ND}_h\}$ and the $P_{(\cdot)}$'s are the natural finite element interpolation operators. Because of our assumption of quasi-uniformity, finite element approximation theory implies multilevel approximation property for the algebraically smooth eigenfunctions that are gradients. For algebraic multigrid on nonnested finite elements, a multilevel approximation property for the algebraically smooth gradient eigenfunctions also holds. Physically, this seems strange since the coarse degrees of freedom in algebraic multigrid are located on coarse edges that are generally not a subset of fine edges; i.e., physically, electric fields that have zero circulation over a given closed cycle (e.g., coarse cycle) generally do not have zero circulation over closed cycles not contained in that given cycle (e.g., fine cycles). But this "strangeness" can be explained away through the commutativity relation

$$
\nabla^h P^h_{H^1} = P^h_{H(\mathrm{curl})} \nabla^{2h}; \tag{3.5}
$$

i.e., a field with zero circulation on a coarse cycle corresponds to a coarse gradient, whose generating potential can be interpolated to a fine scalar function and then operated on with the fine gradient operator to produce a zero circulation field over the fine cycles. Hence, nonnesting of the coarse edges *does not pose a problem* for approximating gradient near-nullspace components.

Now, given an arbitrary coarse edge function that has a curl-free and a divergence-free component, commutativity interpolation interpolates the curl-free component correctly and achieves this without explicitly using $P^h_{H^1}$. But the fact that the divergence-free component may not be interpolated correctly begs the question of overall multigrid efficiency. We contend that multilevel de Rham sequences are needed to give multigrid efficiency. Suppose that the $\{S_{2h}, W_{2h}\}$ generated by $P^h_{H^1}$ and $P^h_{H(\mathrm{curl})}$ contains the proper discrete p-forms that approximate the continuous p-forms of $\{H^1(\Omega), H(\mathrm{curl};\Omega)\}$; i.e., $P^h_{H^1}$ and P^h_{curl} are the natural finite element interpolation operators. Then the set of coarse finite elements is stable, and by the finite element approximation property for each of these spaces, we have good multigrid approximation property everywhere. For example, let $\mathbf{v}_h$ be any type of near-nullspace component and let $\mathbf{v}$ be the continuous function it approximates. On the fine and coarse grids, by the finite element approximation property we have

$$\|\mathbf{v}-\mathbf{v}_h\|_{\mathrm{curl}} \le Ch \quad \text{and} \quad \|\mathbf{v}-P^h_{\mathrm{curl}}\mathbf{v}_{2h}\|_{\mathrm{curl}} = \|\mathbf{v}-\mathbf{v}_{2h}\|_{\mathrm{curl}} \le Ch,$$

where we used the induced finite element interpolation property of P^h_{curl} in the second inequality. Thus, we have good coarse grid approximation to $\mathbf{v}_h$:

$$\|\mathbf{v}_h - P^h_{\mathrm{curl}}\mathbf{v}_{2h}\|_{\mathrm{curl}} \le Ch.$$

When a multilevel de Rham structure does not exist, $P^h_{H(\mathrm{curl})}$ is generally not Nedelec interpolation, and so

$$\|\mathbf{v} - P^h_{H(\mathrm{curl})}\mathbf{v}_{2h}\|_{\mathrm{curl}}$$

can be large for divergence-free $\mathbf{v}$. Hence,

$$\|\mathbf{v}_h - P^h_{H(\mathrm{curl})}\mathbf{v}_{2h}\|_{\mathrm{curl}}$$

can be large, and multigrid performance degrades.

Except for geometric multigrid, constructing multilevel de Rham complexes is very difficult. Moreover, even if we have multilevel de Rham complexes, when the material coefficients vary substantially, $P^h_{H(\mathrm{curl})}$ should depend on these coefficients, which then may break multilevel commutativity. When multilevel de Rham complexes do not exist, to obtain multilevel efficiency, an interpolation operator that acts like $P^h_{H(\mathrm{curl})}$ on the curl-free components and $P^h_{H(\mathrm{div})}$ on the divergence-free components is needed. Construction of such an operator is also difficult. The fundamental misunderstanding is that multilevel communativity considers only a subspace of the whole space, whereas good multigrid performance requires good handling of the whole space (i.e., good handling of the whole multilevel nodal decomposition [16]). For an efficient multigrid scheme, one needs some explicit type of Helmholtz decomposition on each level, and one needs interpolation operators that give good coarse grid approximation to each part of this decomposition. To achieve both of these, explicitly having nodal (to represent the curl-free vector) and edge (to represent the divergence-free vector) degrees of freedom and separate interpolation operators for each part of the Helmholtz decomposition is desirable. This will require more computer memory and additional computational cost per multigrid cycle, but will give robustness and simplicity. We consider such an algorithm in the next section.

4. $T-V$ formulation. As one can derive from the last section, commutativity interpolation is difficult to construct and gives poor approximation to divergence-free error components. There is some computational reduction in using these operators since nodal interpolation is never performed in the solve phase. In some algebraic multigrid algorithms [20], [5], though, this reduction is only minor since the formation of auxiliary nodal interpolation and coarse grid operators is explicitly done in the setup phase but then discarded afterwards. In this section, we will develop an algorithm that recycles this discarded nodal information in the solve phase. Of course, this will lead to actual nodal structures in the solve phase. But, by keeping these structures, interpolation operators can be easily constructed without the commutativity constraints and can be constructed such that the coarse grid approximation property holds for all required bad components. The motivation behind such an approach is to develop an algorithm that can be easily fitted into the framework of existing multigrid codes.

We note that we could present this algorithm as a subspace iteration, like the one presented in [14]. However, we opt to present it in terms of a so-called $T-V$ formulation [19] since this formulation gives guidance on developing effective interpolation operators. We also note that the $T-V$ formulation is used only in the multigrid solution phase—we do not replace continuous problem (2.3) with a continuous semidefinite $T-V$ formulation. Nevertheless, this multigrid solver iterates over the PDE system of the $T-V$ formulation. Hence, interpolation operators must be based on the nontrivial near-nullspace components of this PDE system. Thus, in this section, we characterize these components. We consider the quantitative form of these near-nullspace components in order to justify our choice of interpolation operators.

Therefore, consider curl-curl equation (2.4) with the solution decomposition

$$\mathbf{E} = \mathbf{E}_1 + \nabla\phi, \qquad \mathbf{E}_1 \in H_0(\mathrm{curl};\Omega),\ \phi \in H_0^1(\Omega),$$

and the following variational problem: find $(\mathbf{E}_1, \phi) \in H_0(\mathrm{curl};\Omega) \times H_0^1(\Omega)$ such that

$$(\alpha\nabla\times(\mathbf{E}_1+\nabla\phi), \nabla\times(\mathbf{v}+\nabla\psi)) + (\beta(\mathbf{E}_1+\nabla\phi),(\mathbf{v}+\nabla\psi)) = (\mathbf{f},(\mathbf{v}+\nabla\psi)) \tag{4.1}$$

for all $\mathbf{v} \in H_0(\mathrm{curl};\Omega)$, $\psi \in H_0^1(\Omega)$. Respectively denoting the basis functions of $H_0(\mathrm{curl};\Omega)$ and $H_0^1(\Omega)$ as $\{\mathbf{v}_l\}$ and $\{\psi_i\}$, (4.1) can be written as a system variational problem

$$\begin{bmatrix} A_{ee} & A_{en} \\ A_{ne} & A_{nn} \end{bmatrix} \begin{bmatrix} \mathbf{E}_1 \\ \phi \end{bmatrix} = \begin{bmatrix} \mathbf{f}_e \\ \mathbf{f}_n \end{bmatrix}, \tag{4.2}$$

where

$$A_{ee} = [(\alpha\nabla\times\mathbf{v}_l, \nabla\times\mathbf{v}_m) + (\beta\mathbf{v}_l,\mathbf{v}_m)], \quad A_{en} = [(\beta\mathbf{v}_l, \nabla\psi_j)],$$
$$A_{ne} = [(\beta\nabla\psi_i,\mathbf{v}_m)], \quad A_{nn} = [(\beta\nabla\psi_i,\nabla\psi_j)],$$

and

$$\begin{bmatrix} \mathbf{f}_e \\ \mathbf{f}_n \end{bmatrix} = \begin{bmatrix} (\mathbf{f},\mathbf{v}_l) \\ (\mathbf{f},\nabla\psi_i) \end{bmatrix}$$

and for all $(\mathbf{v}_l,0)^t, (\mathbf{0},\psi_i)^t \in H_0(\mathrm{curl};\Omega)\times H_0^1(\Omega)$. To examine the near-nullspace component $(\tilde{\mathbf{E}},\tilde{\phi})^t$ of (4.2), let $\tilde{\mathbf{E}}$ have the Helmholtz decomposition

$$\tilde{\mathbf{E}} = \tilde{\mathbf{E}}_d + \tilde{\mathbf{E}}_c,$$

where $\tilde{\mathbf{E}}_d$ is divergence-free and $\tilde{\mathbf{E}}_c$ is curl-free. We consider first the quantitative form of two special near-nullspace components and then the quantitative form of a general near-nullspace component. The two special forms are $(\tilde{\mathbf{E}}, \tilde{\phi})^t$ where $\tilde{\mathbf{E}}$ is curl-free and $\tilde{\mathbf{E}}$ is divergence-free.

For near-nullspace component with curl-free $\tilde{\mathbf{E}}$, $\tilde{\mathbf{E}} = \tilde{\mathbf{E}}_c = \nabla\eta$, let us determine the corresponding nodal component $\tilde{\phi}$. From the second equation of (4.2), the nodal component must satisfy

$$(\beta\nabla\tilde{\phi}, \nabla\psi_i) \approx -(\beta\nabla\psi_i, \tilde{\mathbf{E}}_c) = -(\beta\nabla\psi_i, \nabla\eta) \qquad \forall i.$$

Thus $\tilde{\phi}$ is approximately $-\eta$. Substituting this into the first equation of (4.2), we have

$$(\alpha\nabla\times\tilde{\mathbf{E}}_c, \nabla\times\mathbf{v}_l) + (\beta\tilde{\mathbf{E}}_c, \mathbf{v}_l) - (\beta\mathbf{v}_l, \nabla\eta) = (\beta\nabla\eta, \mathbf{v}_l) - (\beta\mathbf{v}_l, \nabla\eta) = 0$$

so that $(\tilde{\mathbf{E}}, \tilde{\phi})^t = (\nabla\eta, -\eta)^t$ is indeed a near-nullspace component.

Next, consider the near-nullspace component with divergence-free $\tilde{\mathbf{E}}$, $\tilde{\mathbf{E}} = \tilde{\mathbf{E}}_d$. We will assume that α, β are sufficiently smooth and consider only interior estimates so that boundary terms produced by integration by parts can be omitted (near-nullspace components are locally interior). From the second equation of (4.2) and integration by parts,

$$\begin{aligned} -(\nabla\cdot\beta\tilde{\mathbf{E}}_d, \psi_i) + (\beta\nabla\tilde{\phi}, \nabla\psi_i) &= -(\nabla\beta\cdot\tilde{\mathbf{E}}_d + \beta\nabla\cdot\tilde{\mathbf{E}}_d, \psi_i) + (\beta\nabla\tilde{\phi}, \nabla\psi_i) \\ &= -(\nabla\beta\cdot\tilde{\mathbf{E}}_d, \psi_i) + (\beta\nabla\tilde{\phi}, \nabla\psi_i) \approx 0 \qquad \forall i \end{aligned} \tag{4.3}$$

or

$$(\beta\nabla\tilde{\phi}, \nabla\psi_i) \approx (\nabla\beta\cdot\tilde{\mathbf{E}}_d, \psi_i) \qquad \forall i.$$

If we further assume that β is smooth in the sense that $\|\nabla\beta\| \le \epsilon$, then using elliptic regularity and the Cauchy–Schwarz inequality,

$$\|\tilde{\phi}\|_1 \le C\|\nabla\beta\cdot\tilde{\mathbf{E}}_d\| \le C\|\nabla\beta\|\|\tilde{\mathbf{E}}_d\| \le C\epsilon\|\tilde{\mathbf{E}}_d\|.$$

That is, $\tilde{\phi}$ has small $H1$ energy or, equivalently, is a smooth eigenfunction of the diffusion operator $[\nabla\cdot\beta\nabla]$. Now for the first equation of (4.2), we have

$$(\alpha\nabla\times\tilde{\mathbf{E}}_d, \nabla\times\mathbf{v}_l) + (\beta\tilde{\mathbf{E}}_d, \mathbf{v}_l) \approx -(\beta\nabla\tilde{\phi}, \mathbf{v}_l) \qquad \forall l, \tag{4.4}$$

and because $\tilde{\phi}$ has small $H1$ energy, $\tilde{\mathbf{E}}_d$ has small scaled $H(\mathrm{curl})$ energy in the order of the size of the eigenvalue corresponding to $\tilde{\phi}$; i.e., coercivity of the curl-curl bilinear form implies

$$\|\tilde{\mathbf{E}}_d\|_{H(\mathrm{curl})} \le C\|\beta\nabla\tilde{\phi}\|,$$

and $\tilde{\phi}$ being a smooth eigenfunction implies

$$\|\tilde{\phi}\|_1 \le \|\tilde{\phi}\|_2 \le C\lambda.$$

Therefore, $\tilde{\mathbf{E}}_d$ is a smooth eigenfunction of the operator $[\nabla\times\alpha\nabla\times + \beta I]$. Moreover, using the identity

$$\begin{aligned} \nabla\times\alpha\nabla\times\mathbf{v} &= \nabla\alpha\times(\nabla\times\mathbf{v}) + \alpha\nabla\times\nabla\times\mathbf{v} \\ &= \nabla\alpha\times(\nabla\times\mathbf{v}) - \alpha\boldsymbol{\Delta}\mathbf{v} + \nabla\nabla\cdot\mathbf{v}, \end{aligned}$$

$\tilde{\mathbf{E}}_d$ is a smooth eigenfunction of

$$[-\alpha\boldsymbol{\Delta} + \nabla\alpha \times \nabla \times + \beta I]. \tag{4.5}$$

Thus, quantitative forms of two types of near-nullspace components of (4.2) are

$$\begin{pmatrix} \tilde{\mathbf{E}} \\ \tilde{\phi} \end{pmatrix} = \begin{pmatrix} \nabla\eta \\ -\eta \end{pmatrix} \quad \text{and} \quad \begin{pmatrix} \tilde{\mathbf{E}} \\ \tilde{\phi} \end{pmatrix} = \begin{pmatrix} \text{small scaled } H(\text{curl}) \text{ norm} \\ \text{small scaled } H1 \text{ norm} \end{pmatrix}. \tag{4.6}$$

Multigrid interpolation operators must be designed to approximate at least these components well. In fact, interpolation operators designed to handle these components will also handle other near-nullspace components. Consider the general case,

$$\tilde{\mathbf{E}} = \tilde{\mathbf{E}}_d + \tilde{\mathbf{E}}_c = \tilde{\mathbf{E}}_d + \nabla\eta.$$

Again using the second equation of (4.2) first, integration by parts leads to

$$\begin{aligned} (\tilde{\mathbf{E}}_d + \tilde{\mathbf{E}}_c, \beta\nabla\psi_i) + (\beta\nabla\tilde{\phi}, \nabla\psi_i) &= (\tilde{\mathbf{E}}_d, \beta\nabla\psi_i) + (\nabla\eta, \beta\nabla\psi_i) + (\beta\nabla\tilde{\phi}, \nabla\psi_i) \\ &= -(\nabla\beta \cdot \tilde{\mathbf{E}}_d, \psi_i) + (\beta\nabla(\eta + \tilde{\phi}), \nabla\psi_i) \\ &\approx 0 \end{aligned}$$

or

$$(\beta\nabla(\eta + \tilde{\phi}), \nabla\psi_i) \approx (\nabla\beta \cdot \tilde{\mathbf{E}}_d, \psi_i).$$

Elliptic regularity and the above smoothness assumption on β lead to

$$\|\eta + \tilde{\phi}\|_1 \leq C\epsilon\|\tilde{\mathbf{E}}_d\|.$$

Thus, $(\eta + \tilde{\phi})$ has small scaled $H1$ norm, from which we conclude $\tilde{\phi} \approx -\eta$. Using this result in the first equation of (4.2) then gives

$$(\alpha\nabla \times \tilde{\mathbf{E}}_d, \nabla \times \mathbf{v}_l) + (\beta\tilde{\mathbf{E}}_d, \mathbf{v}_l) \approx 0.$$

Hence, the general near-nullspace components of (4.2) have the form

$$\begin{pmatrix} \tilde{\mathbf{E}} \\ \tilde{\phi} \end{pmatrix} = \begin{pmatrix} \text{small scaled } H(\text{curl}) \text{ norm} + \nabla\eta \\ -\eta \end{pmatrix}.$$

But the components that must be handled well by coarse grid correction are the components that are left after relaxation. Applying a block relaxation on (4.2) for the nodes and edges, η will be smooth after relaxation on the nodes. After relaxation, η will have small scaled $H1$ norm and $\tilde{\mathbf{E}}$ will have small scaled $H(\text{curl})$ norm. Therefore, interpolation will be constructed based on (4.6).

Note that the $\tilde{\mathbf{E}}$ component of the system near-nullspace is the near-nullspace of (2.4). These must be well approximated by $P^h_{H(\text{curl})}$. Note also that when α, β are constants, the divergence-free near-nullspace components are smooth eigenfunctions of $[-\alpha\boldsymbol{\Delta} + \beta I]$. Hence, to obtain good approximation to these near-nullspace components, $P^h_{H(\text{curl})}$ should act like linear interpolation on the edge degrees of freedom. Constructing $P^h_{H(\text{curl})}$ under the commutativity constraints using $P^h_{H^1}$ generally will not attain this property. A special case when this is attained occurs when the

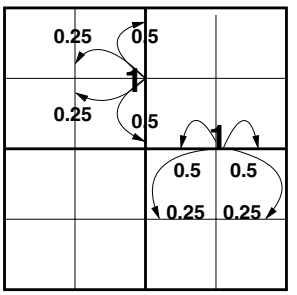

FIG. 1. *Nedelec linear interpolation of horizontal and vertical edges.*

edges are nested and $P^h_{H(\mathrm{curl})}$ is the Nedelec finite element interpolation operator (see Figure 1).

Having determined the quantitative form of the near-nullspace of (4.2), we now develop a multigrid algorithm. First, system (4.2) is discretized over $\mathcal{ND}(\mathcal{T}_h) \times \mathcal{H}_h(\mathcal{T}_h)$, which approximates the continuous near-nullspace well [6]:

$$\begin{bmatrix} A^h_{ee} & A^h_{en} \\ A^h_{ne} & A^h_{nn} \end{bmatrix} \begin{bmatrix} \mathbf{E}^h_1 \\ \psi^h \end{bmatrix} = \begin{bmatrix} \mathbf{f}^h_e \\ \mathbf{f}^h_n \end{bmatrix}. \tag{4.7}$$

From the above discussion, for the curl-free near-nullspace, since $\eta = -\tilde{\phi}$, we need only to approximate the diffusion operator $[-\nabla \cdot \beta \nabla]$ on the coarser grids. Good approximation to this same operator is also required in handling the nodal $\tilde{\phi}$ component of the divergence-free near-nullspace. For the edge component of this divergence-free vector, good approximation to vector "convection"-diffusion operator (4.5) or the curl-curl operator itself is needed on the coarser levels. To accomplish both of these approximation requirements, separate interpolation operators are used for the nodal and edge degrees of freedom. The nodal interpolation P_n will be based on the diffusion operator and the edge interpolation P_e will be based on the curl-curl operator. P_n can be constructed using AMG or BoxMG techniques [10], and P_e can be constructed using AMGe [9] or AMG techniques, since the convection-diffusion operator is being implicitly coarsened. The overall interpolation operator for (4.7) is

$$\begin{bmatrix} P_e & 0 \\ 0 & P_n \end{bmatrix}.$$

The validity of this block-diagonal interpolation operator was based under the assumption that $\|\nabla\beta\|$ is small. When $\|\nabla\beta\|$ is large, a full 2×2 interpolation operator may be needed (see [11], [12] for a numerical comparison of block-diagonal and full block interpolation operators on system PDEs).

With block-diagonal interpolation, the coarse grid operator is formed using Galerkin coarsening:

$$\begin{aligned} \begin{bmatrix} A^{2h}_{ee} & A^{2h}_{en} \\ A^{2h}_{ne} & A^{2h}_{nn} \end{bmatrix} &= \begin{bmatrix} P_e & 0 \\ 0 & P_n \end{bmatrix}^t \begin{bmatrix} A^h_{ee} & A^h_{en} \\ A^h_{ne} & A^h_{nn} \end{bmatrix} \begin{bmatrix} P_e & 0 \\ 0 & P_n \end{bmatrix} \\ &= \begin{bmatrix} P^t_e A^h_{ee} P_e & P^t_e A^h_{en} P_n \\ P^t_n A^h_{ne} P_e & P^t_n A^h_{nn} P_n \end{bmatrix}. \end{aligned} \tag{4.8}$$

Applying this recursively, the coarse grid operator on level i can be constructed.

This algorithm requires the additional computation and storage of the off-diagonal blocks $A_{en}^{2^ih} = (A_{ne}^{2^ih})^t$. However, as the above discussion suggests, the coarse grid problems capture the divergence-free and curl-free components separately, i.e., respectively using $A_{ee}^{2^ih}$ and $A_{nn}^{2^ih}$ only. Hence, omitting the off-diagonal blocks can also lead to an effective scheme. With the off-diagonal blocks, curl-free error components reintroduced when solving the edge correction can be suppressed.

This algorithm also appears to require more user data than just the fine grid stiffness matrix A_{ee}^h and a fine grid discrete gradient operator G_{en}^h : nodes $\rightarrow$ edges as required by commutativity-based multigrid methods. But, as in the commutativity-based methods, A_{nn}^h can be obtained using sparse matrix products and $A_{en}^h = (A_{ne}^h)^t$ can be obtained freely from this same matrix product:

$$A_{nn}^h = (G_{en}^h)^t \left[A_{ee}^h G_{en}^h\right],$$
$$A_{en}^h = A_{ee}^h G_{en}^h.$$

Note that once these operators are formed, discrete gradient operators are not needed on the coarser levels. This apparent minor detail actually implicates some structural differences between this multigrid algorithm and commutativity-based ones. Because these operators are not needed on the coarser grids, there need not be a connection between the coarse nodal and edge grids, although the nodal and edge degrees of freedom are connected through the off-diagonal blocks of (4.8). This implies that the coarse simplices do not have to satisfy a consistency condition; i.e., nodes and edges can be coarsened separately. In turn, this means that a two-term exactness property does not hold on the coarser levels. Even if coarse simplices were consistently chosen, an exactness property may still not hold because the weights generated by the separate interpolation operators lead to discrete differential operators that may not be consistent. All of this should not be surprising because we independently constructed the edge interpolation to capture mainly the divergence-free error and the nodal interpolation to capture the curl-free error, rather than having one edge interpolation constructed to produce exactness to capture the curl-free error. There also should be no concern that the exactness property does not hold on coarser levels because the nodal coarse grid problem defines the equation for the curl-free error; i.e., we have a relaxation procedure for these errors on the coarser levels. With no exactness property on the coarser levels, the multilevel complex for this algorithm is

$$\begin{array}{ccc}
H^1(\Omega) & \xrightarrow{\nabla} & H(\mathrm{curl};\Omega) \\
\downarrow \Pi_{\mathcal{H}}^h & & \downarrow \Pi_{\mathcal{ND}}^h \\
\mathcal{H}_h & \xrightarrow{\nabla^h} & \mathcal{ND}_h \\
\uparrow P_n^h & & \uparrow P_e^h \\
H_{2h}^1 & \overset{A_{en}^{2h}}{\cdots} & H_{2h}(\mathrm{curl}) \\
\vdots & & \vdots \\
H_{2^ih}^1 & \overset{A_{en}^{2^ih}}{\cdots} & H_{2^ih}(\mathrm{curl}),
\end{array}$$

where $H_{2^ih}^1$ and $H_{2^ih}(\mathrm{curl})$ are subspaces of $\mathcal{H}_h$ and $\mathcal{ND}_h$, and $\overset{A_{en}^{2^ih}}{\cdots}$ denotes only a connection between the node and edge degrees of freedom, not an exactness relation.

4.1. Interpolation schemes. There are many well-developed interpolation schemes for variable coefficient problems. In this paper, we will consider only struc-

tured grids and hence employ a BoxMG scheme [10] for P_n and an element agglomeration scheme [9] for P_e.

The BoxMG technique is well known. Let the 9-point stencil of A^h_{nn} be

$$\begin{bmatrix} a^{nw}_{nn} & a^{n}_{nn} & a^{ne}_{nn} \\ a^{w}_{nn} & a^{c}_{nn} & a^{e}_{nn} \\ a^{sw}_{nn} & a^{s}_{nn} & a^{se}_{nn} \end{bmatrix}_{IJ}$$

at coarse node IJ. This technique constructs P_n to satisfy

$$A^h_{nn} P_n \phi^{2h} = 0. \tag{4.9}$$

For fine nodes that underlie a coarse node, the interpolation weight is one; for fine nodes that are horizontally or vertically adjacent to a coarse node, stencil collapsing is used to determine the weights—e.g., for fine nodes that are directly east or west of node IJ, the interpolation weights are, respectively,

$$P^e_n = -\frac{(a^{ne}_{nn} + a^{e}_{nn} + a^{se}_{nn})_{IJ}}{(a^{n}_{nn} + a^{c}_{nn} + a^{s}_{nn})_{IJ}}, \qquad P^w_n = -\frac{(a^{nw}_{nn} + a^{w}_{nn} + a^{sw}_{nn})_{IJ}}{(a^{n}_{nn} + a^{c}_{nn} + a^{s}_{nn})_{IJ}}.$$

The weights for all other fine nodes are obtained using these computed weights and relation (4.9).

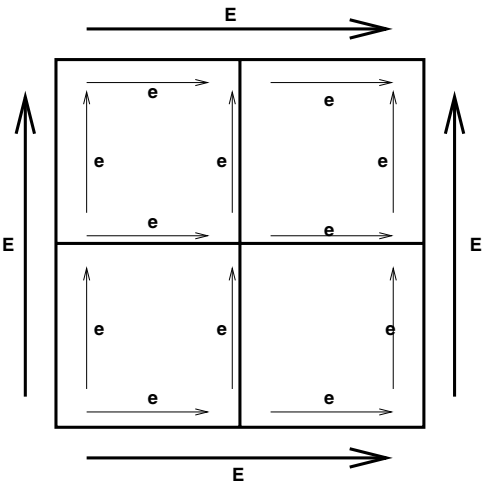

FIG. 2. *Coarse cell agglomerate. Coarse edges are labeled with E and fine edges are labeled with e.*

To describe the AMGe technique to construct P_e, we will refer to the two-dimensional uniform agglomerate shown in Figure 2. We divide the fine edges of this agglomerate into boundary (b) and interior (i) edges, and order them so that locally A^h_{ee} and P_e can be written as

$$A^h_{ee} = \begin{bmatrix} A^{bb}_{ee} & A^{bi}_{ee} \\ A^{ib}_{ee} & A^{ii}_{ee} \end{bmatrix}, \qquad P_e = \begin{bmatrix} P^b_e \\ P^i_e \end{bmatrix}.$$

The boundary edges are the fine edges e that nest a coarse edge E, and the interior edges are the remaining fine edges of the agglomerate. For the boundary edges, the interpolation weights can be defined physically. Since the edge degrees of freedom are voltage drops along the edges, the boundary weights are simply the ratio of the length of the boundary edge to the length of coarse edge that it nests. With these boundary weights, the interior weights are given by the local inversion

$$P_e^i = -[A_{ee}^{ii}]^{-1} A_{ee}^{ib} P_e^b.$$

4.2. Relaxation schemes. Since the equations for both the nodes and edges are Poisson-like, pointwise Gauss–Seidel can be used for each degree of freedom. But as in system PDEs, the sweeping order of relaxation produces different smoothers. One can relax all the nodes of the nodal grid and then all the edges of the edge grid to give the hybrid block Gauss–Seidel scheme of [16]. One can also apply a multiplicative Schwarz smoother similar to that of [2], but where now a node and all the edges branching out of it are solved simultanuously. This is more costly than the pointwise smoother, but it gives robustness. Yet an intermediate ordering is to update a node and then pointwise update all the edges branching out of this node in turn. Since an edge connects two nodes, a given edge is updated more than once in a sweep. Hence, this smoother is more costly than the pointwise hybrid smoother.

5. Numerical experiments. This multigrid algorithm has currently been tested on two-dimensional uniform grids. Three-dimensional problems and algebraic multigrid variants of this algorithm will be presented in a forthcoming paper. The problems solved in this paper are (2.3) on a unit square. Problems with constant and variable α and β are examined, both standard Nedelec interpolation and the operator-based interpolations described in the previous section are used, and the smoothers described in the previous section are employed. (Note that operator-based interpolation produces multilevel structures that do not satisfy exactness.) $V(1,1)$ cycles are used, and all experiments are performed with a zero right-hand side, a random initial guess, and a stopping criterion of twelve-order magnitude reduction of the $l2$ norm of the initial residual. The schemes used are as follows.

- Method 1: Hybrid Gauss–Seidel smoother—all nodes updated, then all edges.
- Method 2: Intermediate Gauss–Seidel smoother—pointwise update one node and then all edges branching out of it in turn.
- Method 3: Node-edge decoupling on coarse grids—i.e., only the block-diagonal terms of (4.8) are used on the coarse grids (see the discussion after (4.8)).
- Method 4: Multiplicative Schwarz smoother—simultaneously solve all edges connected to a node. The nodal degrees of freedom are not involved; this method is used for comparison.

Problem 1: $\alpha = 1$, $\beta =$ constant. This experiment was conducted to illustrate the robustness of the scheme as $\beta \to 0$, so that the operator becomes singular. Table 1 contains the $V(1,1)$ iteration counts. For each iteration column, the left count is for Nedelec interpolation, and the right count is for operator-based interpolation. From these results, all methods are robust with respect to the size of β. In particular, not preserving exactness on coarse grids does not affect convergence. Also, the number of iterations decreases as the smoother becomes "stronger" (Method 2), and Method 3 performs just as well as Method 1 because $\nabla\beta = 0$ so that the edge and nodal components of the divergence-free near-nullspace of (4.2) decouple.

Problem 2: Variable α, β. We consider the performance of this multigrid method on variable coefficient problems. Problem 2a will involve coefficients

TABLE 1
$V(1,1)$-cycle results for Problem 1, $\alpha = 1$, $\beta =$ constant. The iteration counts on the left and right are for Nedelec interpolation and operator-based interpolation, respectively.

	1/64	71/19	59/12	71/20	53/19
	1/128	57/23	53/14	57/23	50/16
	1/256	53/25	49/15	53/25	47/13
	1/512	49/26	45/15	49/26	44/13
2b	1/16	69/13	62/11	94/15	59/44
	1/32	127/15	96/12	126/18	85/26
	1/64	108/18	85/12	110/23	77/45
	1/128	141/23	102/13	140/23	87/43
	1/256	154/25	106/15	153/25	89/31
	1/512	127/26	92/15	127/26	78/21

$$\alpha = (2 + \sin 40\pi x)^2(2 + \cos 40\pi y)^2,$$
$$\beta = (2 + \cos 40\pi x)^2(2 + \sin 40\pi y)^2,$$

and Problem 2b will involve grid-aligned jump coefficients

$$\alpha = C(2 + \sin 40\pi x)^2(2 + \cos 40\pi y)^2,$$
$$\beta = C(2 + \cos 40\pi x)^2(2 + \sin 40\pi y)^2,$$

where jump C is described in Figure 3. The results are tabulated in Table 2. For both problems, we see poor performance when Nedelec interpolation is used, and a dramatic improvement when operator-based interpolation is used. Note that Method 3 performs just as Method 1, which is a bit surprising. Also note that Method 2 performs better than Method 4. Both of these methods do not satisfy exactness on the coarse grids, but only Method 2 has systems for the curl-free component on the coarse grids. Last, note that the performance of Methods 1–3 with operator-based interpolation are unaffected by jumps in the coefficients, whereas coefficient jumps noticeably affect the convergence when Nedelec interpolation is used in these methods.

We also consider an example that demonstrates the importance of using operator-based interpolation in the Galerkin coarsening procedure. In Table 3, we consider Problem 2a again but this time with operator-based interpolation used in the solve phase and Nedelec interpolation used in the Galerkin coarsening procedure. As this table shows, there is almost no improvement in using operator-based interpolation in the solve phase only (compare with the left columns of Table 2, Problem 2a). The coarse grid operators must be formed with these operators also.

Problem 3: Constant coefficient jumps. Our final experiment further examines jump coefficients, but now with jumps that are not grid-aligned on the coarse grids.

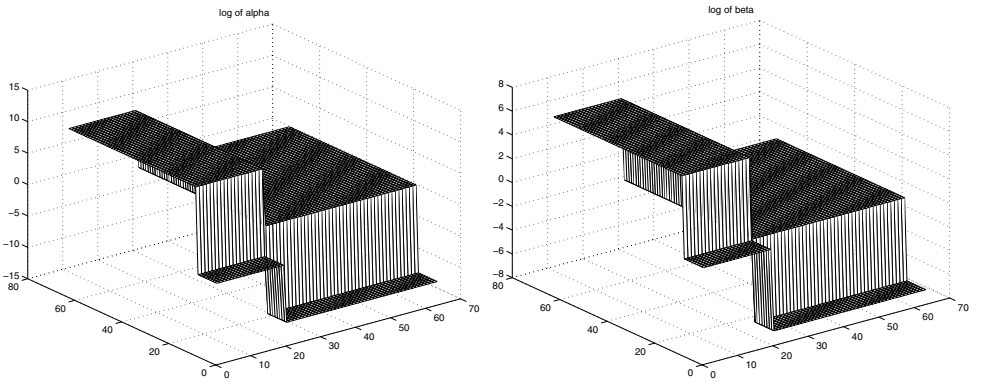

FIG. 4. *Log scale of jumps in α and β for Problem* 3a.

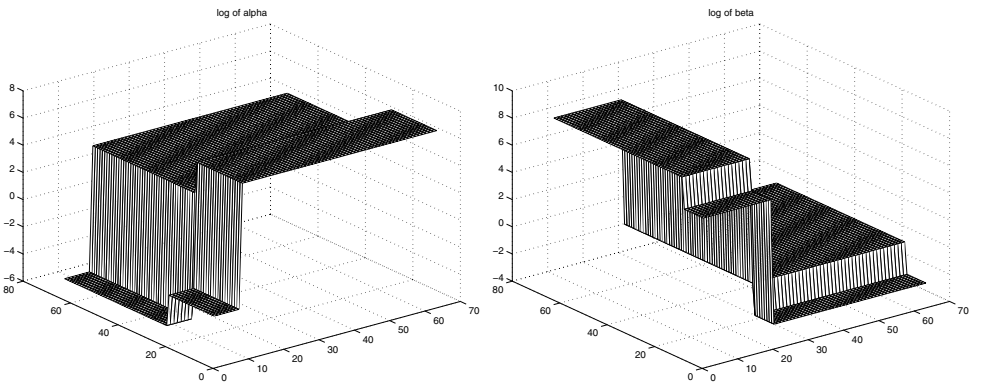

FIG. 5. *Log scale of jumps in α and β for Problem* 3b.

The log scale of the coefficients is shown in Figure 4 (Problem 3a) and Figure 5 (Problem 3b), which has a more dramatic jump pattern for α and β. The order of magnitude of the jumps are around 10. Results are given in Table 4. Again operator-based interpolation performs better than Nedelec interpolation but not as dramatically this time, especially for Problem 3a. This can be accredited to the localization of the coefficient variations. Also, Problem 3b shows Method 1 performing better than Method 3.

6. Conclusions. We presented a multigrid method for solving variable coefficient Maxwell's equations. This method does not construct interpolation operators

based on multilevel commutativity constraints, and hence, does not satisfy exactness on the coarse levels. Rather, interpolation operators are separately developed for the nodes and edges, and operator-based techniques are used to capture the coefficient variations. Moreover, the relevant effects of exactness are obtained by having equations for the curl-free gradients on the coarse levels. Numerical results demonstrate the effectiveness of this algorithm.

SOLUTION OF EQUILIBRIUM RADIATION DIFFUSION PROBLEMS USING IMPLICIT ADAPTIVE MESH REFINEMENT*

MICHAEL PERNICE† AND BOBBY PHILIP†

Abstract. Diffusion approximations to radiation transport feature a nonlinear conduction coefficient that leads to formation of a sharp front, or Marshak wave, under suitable initial and boundary conditions. The front can vary several orders of magnitude over a very short distance. Resolving the shape of the Marshak wave is essential, but using a global fine mesh can be prohibitively expensive. In such circumstances it is natural to consider using adaptive mesh refinement (AMR) to place a fine mesh only in the vicinity of the propagating front. In addition, to avoid any loss of accuracy due to linearization, implicit time integration should be used to solve the equilibrium radiation diffusion equation. Implicit time integration on AMR grids introduces a new challenge, as algorithmic complexity must be controlled to fully realize the performance benefits of AMR. A Newton–Krylov method together with a multigrid preconditioner addresses this latter issue on a uniform grid. A straightforward generalization is to use a multilevel preconditioner that is tuned to the structure of the AMR grid, such as the fast adaptive composite grid (FAC) method. We describe the resulting Newton–Krylov-FAC method and demonstrate its performance on simple equilibrium radiation diffusion problems.

1. Introduction.

Radiation transport plays an important role in numerous fields of study, including astrophysics, laser fusion, combustion applications, atmospheric dynamics, and medical imaging. When photon mean free paths are much shorter than characteristic length scales, a diffusion approximation provides a reasonably accurate description of radiation penetrating from a hot source to a cold medium. This approximation features a nonlinear conduction coefficient that leads to formation of a sharp front, in which the solution can vary several orders of magnitude over a very short distance. The shape of the front can be very complex as it interacts with different materials having different conduction properties. Resolving these localized features with a global fine mesh can be prohibitively expensive. It is natural to consider reducing the cost of accurately resolving these fronts by using adaptive mesh refinement (AMR), which concentrates computational effort by increasing spatial resolution only locally.

Classical solution techniques for equilibrium radiation diffusion use a linearized conduction coefficient to avoid the expense of solving a system of nonlinear equations at each time step. This introduces a first-order error in time that precludes effective use of higher-order time integration methods, and requires small time steps to maintain time accuracy. Analytic and computational results that demonstrate degradation in time accuracy associated with linearization in the presence of strong nonlinear coefficients can be found in [24, 15]. Such effects can be avoided by using im-

plicit time integration, which generally requires efficient nonlinear solution techniques to be competitive. Newton–Krylov methods, usually preconditioned by a multigrid method, have been instrumental in demonstrating that this approach is practical for equilibrium radiation diffusion problems [26].

We seek to combine the benefits of improved temporal accuracy of implicit time integration with the improved spatial accuracy that is made possible by AMR. Two important factors must be addressed in order to fully realize the potential efficiency gains. The first is the use of finer grids only in those regions where high resolution is required. This can be accomplished by determining regions where the spatial error is large or where localized solution features warrant enhanced resolution, and immediately translates into lower overall storage costs. The second is the use of algorithms whose arithmetic complexity scales linearly with problem size. This presents a significant challenge when using implicit time integration methods on AMR grids.

Prior efforts in implicit AMR have not adequately addressed the algorithmic scalability issue. Early work by Winkler, Norman, and Mihalas [31] uses r-refinement to solve coupled radiation-hydrodynamics problems. They use a fully coupled formulation, solved by a classical Newton's method, that includes a functional to determine new gridpoint locations for following features of the flow. Their approach is impractical for two- or three-dimensional problems, and even in one dimension difficulties with gridpoint movement are encountered. We use h-refinement, in particular structured AMR (SAMR), to avoid these problems. Both Trompert and Verwer [29, 30] and Li, Petzold, and Hyman [17] use incomplete factorization to precondition their linear solvers. Incomplete factorization can be expensive to set up, can have high storage overhead, scales poorly with increasing resolution, and is difficult to implement in parallel. In addition, this approach requires formation of the full Jacobian, through either analytic or automatic means. By using a Jacobian-free Newton–Krylov method, we eliminate the burden of supplying and storing the Jacobian.

We address the issue of algorithmic scalability by using the fast adaptive composite grid (FAC) method of McCormick [19] and McCormick and Thomas [20] to precondition the systems of linear equations that must be solved in every nonlinear iteration at every time step. FAC has low setup costs, low storage overhead, and converges at a rate independent of the number of refinement levels [20]. Similar approaches for elasto-plasticity [5] and equilibrium radiation diffusion [28] use multilevel methods on unstructured grids to solve the linearized equations but still require formation of the Jacobian. More recently, Howell and Greenough [14] solve a *linearized* radiation diffusion problem on a SAMR grid as part of a semi-implicit radiation-hydrodynamics algorithm. However, performance of the multilevel linear solver is not their primary focus, and no details about its performance are provided. With minor modifications, our approach could be used to implement a fully nonlinear version of their reflux step.

We report on efforts to solve equilibrium radiation diffusion problems using structured AMR and the Newton–Krylov-FAC method. While structured AMR facilitates reuse of existing software written for logically rectangular grids, discretization at locations near changes in resolution must be treated carefully in order to avoid the creation of artificial sources and to produce solutions with accuracy commensurate with the finest resolution on the AMR grid.

This paper is organized as follows. The next section discusses the equilibrium radiation diffusion model. A discussion of SAMR follows in section 3. Special considerations for spatial discretization on SAMR grids appear in section 4. We describe

our algorithmic components in section 5. Results of computations appear in section 6 and conclusions are summarized in section 7.

2. Equilibrium radiation diffusion. We provide a brief description of the equations that govern equilibrium radiation diffusion. See [21] for a more detailed discussion.

Propagation of a radiation field and its interaction with matter can be modeled by an integro-differential equation that accounts for transport, emission, absorption, and scattering of photons. When the radiation field is isotropic, detailed treatment of transport in angle is not needed. The dependence on angle can be averaged out to obtain a description based on spectral energy density and flux. In a static medium at local thermal equilibrium, absorption is independent of frequency, and thus dependence on frequency can also be averaged out. In this case, the radiative flux can be shown to be proportional to the gradient of the energy density, with the radiative conductivity proportional to the inverse of the opacity of the medium. Also, when the medium is in thermal equilibrium, emission equals absorption, and the total radiation energy density E is proportional to T^4, where T is the temperature of the medium. These considerations lead to a parabolic partial differential equation

$$\frac{\partial E}{\partial t} = \nabla \cdot D(E)\nabla E \ \text{ in } \Omega \subset \mathbb{R}^d,\ d \in \{1,2,3\},\ t > 0, \tag{2.1}$$

with initial conditions $E(t = 0) = E_0$. We use a flux-limited model of radiative conductivity

$$D(E) = \left(\frac{1}{Z^\alpha E^\beta} + \frac{\|\nabla E\|}{|E|} \right)^{-1}, \tag{2.2}$$

where $\alpha < 0$, $\beta \in [0,1]$, and Z is the atomic number of the medium. The term $\|\nabla E\|/|E|$ is Wilson's form for flux limiting [21, 32], which is an ad hoc adjustment introduced to prevent nonphysical behavior in the solution, and which reproduces the correct asymptotic behavior. The parameters α and β can be determined experimentally or through simulation [22]. In this work $\alpha = -3$ and $\beta = 0.75$.

Finally, boundary conditions for (2.1) must be prescribed. Penetration of heat into a cold medium at rest from a hot source can be modeled by assuming a constant imposed radiation field on a portion of the physical boundary $\partial\Omega_{\mathcal{R}} \subset \partial\Omega$. We also assume that the remainder of the physical boundary $\partial\Omega_{\mathcal{N}} = \partial\Omega - \partial\Omega_{\mathcal{R}}$ is perfectly insulating. Under the same assumptions that led to (2.1), the boundary conditions may be expressed as

$$\begin{aligned} \tfrac{1}{2}\mathsf{n} \cdot D(E)\nabla E + \tfrac{1}{4}E = R \text{ on } \partial\Omega_{\mathcal{R}},\ t > 0, \\ \mathsf{n} \cdot D(E)\nabla E = 0 \text{ on } \partial\Omega_{\mathcal{N}},\ t > 0, \end{aligned} \tag{2.3}$$

where n is the unit outward normal to $\partial\Omega$. These conditions lead to solutions of (2.1) known as Marshak waves, which were first described in [18].

3. Structured adaptive mesh refinement. Localized sharp propagation fronts and material discontinuities make the radiation diffusion problem an excellent candidate for AMR. h-refinement AMR techniques provide local mesh resolution by refining the computational mesh locally. SAMR is h-refinement with local fine grid patches placed over coarser grid patches providing increased local resolution. SAMR techniques enjoy several advantages. Regular array access patterns improve

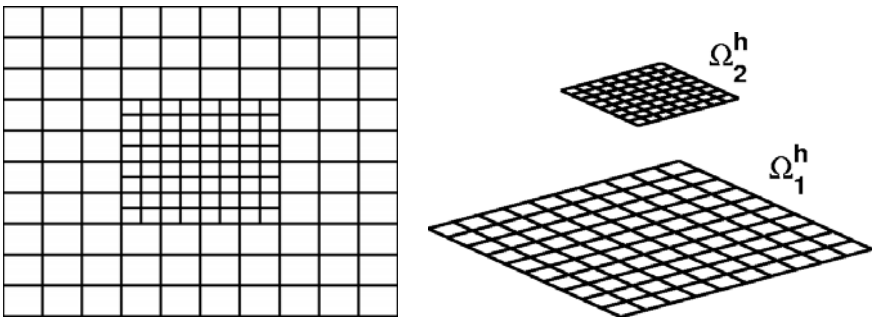

FIG. 3.1. *A composite grid Ω^c of two levels and its component grids Ω_1^h and Ω_2^h.*

cache performance, simple data structures for bookkeeping minimize the overhead for computations, uniform stencil discretizations provide increased accuracy, and reuse of software developed for structured grids is possible.

A SAMR grid consists of a collection of grid patches at different grid resolutions, which together cover the computational domain. Patches with the same mesh resolution are grouped together and form a refinement level. Patches at a refinement level are disjoint or touch along cell boundaries, but do not overlap. A fine grid patch overlying a coarse grid patch is called a child patch, with the underlying coarse patches being the parents. A child patch can have several parent patches and vice versa. The boundaries of child and parent patches are not assumed to align except possibly at physical domain boundaries. This leads to a natural hierarchical structure for SAMR grids that is exploited while designing multilevel algorithms. Operations on the composite grid are decomposed into operations on individual refinement levels which in turn further decompose into operations on individual patches. Valid degrees of freedom at level ℓ are defined in cells not covered by cells belonging to level $\ell+1$. Cells covered by grids at finer levels are "slave" cells with their values being derived from fine cells at the next finer level.

Notation is now introduced for a SAMR grid. Ω_J^c represents a composite SAMR grid with J refinement levels. The subscript is dropped when there is no ambiguity. Refinement level ℓ, $\ell = 1, 2, \ldots, J$, denoted by $\Omega_\ell^{h_\ell}$ or more simply as Ω_ℓ^h, consists of a collection $\{\mathcal{P}\}$ of grid patches at the same grid resolution h_ℓ. The refinement levels are ordered by increasing grid resolution with $h_\ell = r h_{\ell+1}$ $\ell = 1, 2, \ldots, J-1$, where $r \in \mathbb{N}^d$ is the refinement ratio. Each component of r is fixed at 2 in this application, typical values being 2, 3, and 4. The subdomain(s) covered by $\Omega_{\ell+1}^h$ fully nest within the subdomain(s) covered by Ω_ℓ^h. Figure 3.1 illustrates this multilevel structure; Figures 6.4 and 6.6 in section 6 provide more examples of multilevel grid configurations.

4. Discretization. We begin by first discretizing (2.1) in time. Let $t_{n+1} = t_n + \Delta t_n$, $n = 0, 1, \ldots$, where $t_0 = 0$ and Δt_n is a variable time step determined adaptively during the course of the simulation. At $t = t_{n+1}$ an equation of the form

$$E^{n+1} - \gamma \Delta t_n \nabla \cdot D(E^{n+1}) \nabla E^{n+1} - g_n = 0 \tag{4.1}$$

is solved, where E^{n+1} denotes an approximation to $E(t_{n+1})$, $\gamma \in \mathbb{R}$, and g_n is a real-valued function of past information that is determined by the specific choice of the discretization scheme. For backward Euler (BE), $\gamma = 1$ and $g_n(E^n) = E^n$, and for the second-order backward differentiation formula (BDF2), $\gamma = 2/3$ and $g_n(E^n, E^{n-1}) = \frac{4}{3}E^n - \frac{1}{3}E^{n-1}$ for constant Δt_n.

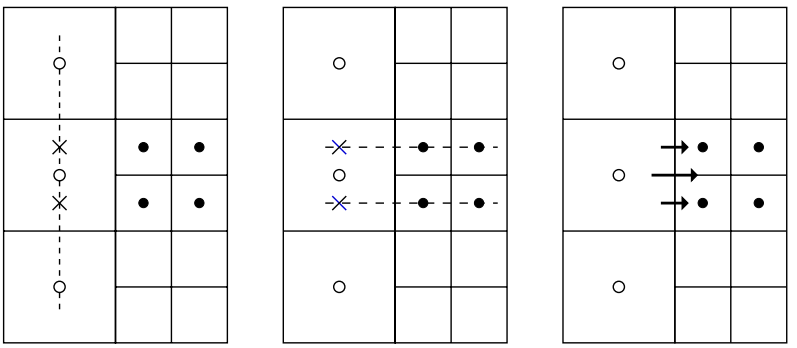

FIG. 4.1. *Schematic of finite volume discretization at interfaces between coarse and fine regions. Open circles represent coarse data; closed circles represent fine data; crosses represent interpolated coarse data; and arrows represent fluxes. The leftmost figure shows the first step, which is to interpolate coarse data to align it with fine data. The second step, shown in the middle figure, can use fine data to either center the aligned data in a ghost cell at the fine resolution, or proceed directly to calculate a flux on the fine face. Finally, fluxes computed at fine resolution must be synchronized with the flux on the underlying coarse face; this is depicted in the rightmost figure.*

Spatial discretization of (4.1) on uniform meshes is done by subdividing Ω into rectangular control volumes and employing standard finite volume discretization techniques. Cell centers are indexed with integer pairs (i, j), and fluxes are computed at faces $(i - \frac{1}{2}, j)$ and $(i, j - \frac{1}{2})$ via

$$\begin{aligned} (D(E)E_x)_{i-\frac{1}{2},j} &\approx F_{i-\frac{1}{2},j} \equiv D(E)_{i-\frac{1}{2},j} \frac{E_{i,j} - E_{i-1,j}}{\Delta x} \Delta y \,, \\ (D(E)E_y)_{i,j-\frac{1}{2}} &\approx F_{i,j-\frac{1}{2}} \equiv D(E)_{i,j-\frac{1}{2}} \frac{E_{i,j} - E_{i,j-1}}{\Delta y} \Delta x \,. \end{aligned} \tag{4.2}$$

A simple scheme is employed for specifying different materials with Z in (2.2) specified at cell centers. With this convention, it is natural to also define $D(E)$ at cell centers, so face-centered values need to be defined to compute these fluxes. For this, harmonic averages

$$\begin{aligned} D(E)_{i-\frac{1}{2},j} &= 2\left(\frac{1}{D(E)_{i-1,j}} + \frac{1}{D(E)_{i,j}}\right)^{-1}, \\ D(E)_{i,j-\frac{1}{2}} &= 2\left(\frac{1}{D(E)_{i,j-1}} + \frac{1}{D(E)_{i,j}}\right)^{-1} \end{aligned} \tag{4.3}$$

are used to define face-centered conductivities. Finally, the discrete spatial operator is obtained by differencing the fluxes on opposite faces and summing the result:

$$\nabla \cdot D(E)\nabla E \approx \left(F_{i+\frac{1}{2},j} - F_{i-\frac{1}{2},j}\right) + \left(F_{i,j+\frac{1}{2}} - F_{i,j-\frac{1}{2}}\right) \,. \tag{4.4}$$

On a SAMR grid, the same spatial discretization is used in patch interiors. There are numerous approaches to handling discretization near changes in resolution. A typical situation for finite volume discretization is depicted in Figure 4.1. In general, data at cell centers is not properly aligned across the change in resolution. The necessary alignment can be achieved by interpolating data on the coarse side of the coarse/fine interface. Fluxes at fine resolution can then be calculated directly from

the aligned data. Alternatively, the aligned data on the coarse side of the interface can be centered in a ghost cell at fine resolution by interpolating in a direction normal to the coarse/fine interface. Finally, the fluxes that reside on fine faces that coincide with a coarse face are summed to obtain a flux on the coarse face. Piecewise linear interpolation with adjustments leads to the symmetric scheme in [11]; piecewise quadratic interpolation is also commonly used [1]. The results presented in this paper use piecewise quadratic interpolation, though similar performance results have been obtained with piecewise linear interpolation.

For ghost points at coarse/fine interfaces, $D(E)$ is interpolated piecewise constant from the coarser level. Because $D(E)$ can exhibit large jumps across material interfaces, refinement regions must be placed carefully to ensure the accuracy of the spatial interpolation schemes.

5. Algorithmic components. The discretization described in section 4 leads to a large-scale system of nonlinear equations defined on a SAMR grid. In particular, note that *all* levels in the grid hierarchy are advanced simultaneously with the same time step, similar to [17] but in contrast to [29, 30]. This means that, on convergence, our solution conserves energy at coarse/fine interfaces, eliminating the need for reflux operations when using local time stepping as in [14]. The system of nonlinear equations at each time step is solved with an inexact Newton method. The linearized problems that must be solved at each iteration of the inexact Newton method are preconditioned by the FAC method. These algorithmic components are described in more detail in the following sections.

5.1. Jacobian-free Newton–Krylov methods. Let $F : \mathbb{R}^n \to \mathbb{R}^n$ be a nonlinear function and consider calculating the solution $x^\star \in \mathbb{R}^n$ of the system of nonlinear equations

$$F(x) = 0. \tag{5.1}$$

Starting with an initial approximation x_0 to $x^\star$, the classical Newton's method for solving (5.1) generates a sequence $\{x_k\}$ of approximations to $x^\star$ according to

$$\begin{aligned} F'(x_k)s_k &= -F(x_k) \\ x_{k+1} &= x_k + \theta s_k, \end{aligned} \tag{5.2}$$

where F' is the Jacobian of F evaluated at x_k and $\theta \in (0, 1]$ is a damping parameter. Newton's method is attractive because of its fast local convergence properties. However, for large-scale problems, it is impractical to determine the Newton step s_k in (5.2) with a direct method. Furthermore, when x_k is far from $x^\star$, the linearization that leads to (5.2) may be a poor approximation to $F(x)$. It may be more efficient to require only that s_k satisfy

$$\|F(x_k) + F'(x_k)s_k\| \le \eta \|F(x_k)\| \tag{5.3}$$

for some $\eta \in (0, 1)$ [8]. Appropriate selection of the forcing term η can lead to superlinear and even quadratic convergence [10]. While any iterative method can be used to find an s_k that satisfies (5.3), methods such as transpose-free Krylov subspace methods require only matrix-vector products, which can be approximated by finite differences

$$F'(x_k)v \approx \frac{F(x_k + \varepsilon v) - F(x_k)}{\varepsilon}.$$

In particular, we use GMRES because of its robustness in the presence of inexact matrix-vector products [7]. Such a *Jacobian-free Newton–Krylov* (JFNK) method is especially advantageous when F' is difficult to compute or expensive to store, and has proven to be effective on a wide variety of problems [16].

The damping parameter θ is determined by a combination of traditional linesearch backtracking [9] and problem-specific constraints. Physically, the radiation energy density E must be nonnegative. However, there is nothing to prevent the calculation of an inexact Newton step s_k that leads to $E < 0$ in some locations. We preclude this possibility by first scaling s_k to ensure that the updated solution satisfies the physical constraints. Linesearch backtracking is then invoked on the scaled step in the usual way.

JFNK methods facilitate use of an inexact Newton method, since an application only needs to provide methods to evaluate F, set up a preconditioner, and apply the preconditioner. On a SAMR grid, these operations should ideally exploit the structure of the grid. Considerations for evaluating F are described next; corresponding considerations for operations involving the preconditioner are described in section 5.2.

On a regular grid, evaluation of the discrete form of (4.1) is straightforward, and there are many ways to organize this calculation. One approach is the following.

ALGORITHM 1: NONLINEAR FUNCTION EVALUATION
Evaluate the radiation conductivity (2.2).
Compute the harmonic averages (4.3).
Compute radiative fluxes (4.2).
Difference fluxes to obtain (4.4).
Assemble the nonlinear residual (4.1).

On a SAMR grid, computation is performed in each patch in the grid hierarchy. Since each patch is logically rectangular, software that implements the steps in Algorithm 1 can be used on each of the patches. However, data on each patch must be supplemented to satisfy interpatch data dependencies. The considerations are similar to those needed for a parallel implementation of Algorithm 1, except that in the SAMR case the required data can come from three sources: other patches at the same resolution; data from a coarser level; or physical boundaries. As with parallel computation, these data dependencies are satisfied by supplementing the storage in each patch with a layer of ghost cells. Data is placed in these locations via copies from neighboring patches at the same refinement level, interpolating data from coarser levels as discussed in section 4, and extrapolating data at physical boundaries. In addition, fluxes on coarse faces must be properly synchronized with fluxes on fine faces (cf. the discussion in section 4), and the final result of Algorithm 1 must be synchronized in slave cells via interpolation. These considerations are summarized in Algorithm 2.

Thus, function evaluation on a SAMR grid is a straightforward generalization of function evaluation on a regular grid. Moreover, JFNK has an added advantage for problems on SAMR grids, since the burden of determining the structure and entries of the Jacobian at changes in resolution is eliminated. The additional bookkeeping needed for a SAMR grid can be provided by a SAMR grid management package [25]. However, the potential performance gains made possible by the use of AMR will be lost without effective preconditioning.

Algorithm 2: Nonlinear function evaluation
for $\ell = J$ **to** 1
  Fill ghost cells on Ω_ℓ^h.
  foreach $\mathcal{P} \in \Omega_\ell^h$
    Evaluate the radiation conductivity (2.2).
    Compute the harmonic averages (4.3).
    Compute radiative fluxes (4.2).
  if $\ell < J$
    Coarsen fluxes from $\Omega_{\ell+1}^h$ to Ω_ℓ^h.
for $\ell = 1$ **to** J
  foreach $\mathcal{P} \in \Omega_\ell^h$
    Difference fluxes to obtain (4.4).
    Assemble the nonlinear residual (4.1).
    if $\ell > 1$
      Interpolate the nonlinear residual from Ω_ℓ^h to $\Omega_{\ell-1}^h$.

5.2. Preconditioning. Preconditioning is essential to make the JFNK method competitive. Yet, in the absence of an explicit Jacobian, selection of a preconditioning matrix can be problematic. A simple linearization of (4.1) leads to the choice

$$M = \mathbb{I} - \gamma \nabla \cdot D(E_k^{n+1}) \nabla \tag{5.4}$$

as a preconditioner, where $D(E_k^{n+1})$ is the kth inexact Newton approximation to the time-advanced solution E^{n+1}. This choice was shown to be effective in [26] for problems on uniform grids. The task here is to solve systems of the form $Mz = r$ robustly, accurately, and efficiently when M is discretized on a SAMR grid. For this the FAC method [19] is employed.

FAC extends techniques from multigrid on uniform grids to AMR grids. FAC is a multiplicative Schwarz method. A V-cycle implementation of the method is optimal requiring $\mathcal{O}(n)$ operations where n is the number of degrees of freedom. As a preconditioner for NK methods, FAC employs smoothing on refinement levels with a coarse grid solve using an approximate solver like multigrid. Below we describe the FAC algorithm for completeness after introducing necessary notation.

- I_c^ℓ and I_ℓ^c denote interlevel data transfer operators (restriction and interpolation, respectively) between the composite fine grid Ω^c and refinement level Ω_ℓ^h. For example, in this paper I_ℓ^c is based on bilinear interpolation and I_c^ℓ is based on a simple averaging of fine cell data to coarse cells.
- $I_{\ell+1}^\ell$ and $I_\ell^{\ell+1}$ denote interlevel data transfer operators (restriction and interpolation, respectively) between adjacent refinement levels Ω_ℓ^h and $\Omega_{\ell+1}^h$. Operators I_ℓ^c and I_c^ℓ may be considered as compositions of these operators.
- M^c is the composite fine grid discrete operator obtained by discretizing (5.4) on Ω^c, and M^ℓ approximates M^c on level ℓ.

Expressed in the notation above, one iteration of a V-cycle FAC algorithm for linear problems with smoothing on refinement levels and an approximate solve on the coarsest grid is as follows.

ALGORITHM 3: FAST ADAPTIVE COMPOSITE GRID (FAC) METHOD

Initialize: $r^c = f^c - M^c x^c$; $f^\ell = I_c^\ell r^c$
foreach Ω_ℓ^h, $l = J, \ldots, 2$
  Smooth: $M^\ell e^\ell = f^\ell$
  Correct: $x^c = x^c + I_\ell^c e^\ell$
  Update: $r^c = f^c - M^c x^c$
  Set : $f^{\ell-1} = I_c^{\ell-1} r^c$
Solve : $M^1 e^1 = f^1$
Correct: $x^c = x^c + I_1^c e^1$
foreach Ω_ℓ^h, $l = 2, \ldots, J$
  Update: $r^c = f^c - M^c x^c$
  Set : $f^\ell = I_c^\ell r^c$
  Smooth: $M^\ell e^\ell = f^\ell$
  Correct: $x^c = x^c + I_\ell^c e^\ell$.

6. Numerical results. This section illustrates the performance of Newton–Krylov-FAC for equilibrium radiation diffusion problems on locally refined grids with a comparison to uniform grid calculations. Before describing the test cases, we first specify a few remaining details of the implementation.

Solvers and software. As described earlier, a JFNK solver preconditioned by FAC is used to solve (4.1). This is accomplished using the infrastructure detailed in [25]. This infrastructure provides access to the capabilities of SAMRAI [13] to implement SAMR-specific aspects of Algorithms 2 and 3, and access to an implementation of JFNK from PETSc's Scalable Nonlinear Equation Solver (SNES) package [2]. SNES iterations are terminated when an absolute tolerance $\|F(x_k)\| \leq \epsilon_{abs}$, a relative tolerance $\|F(x_k)\| \leq \epsilon_{rel}\|F(x_0)\|$, or a step tolerance $\|s_k\| \leq \epsilon_{step}$ is satisfied; we use $\epsilon_{abs} = \epsilon_{rel} = 10^{-8}$ and $\epsilon_{step} = 10^{-10}$. For the linear systems that must be solved at each inexact Newton step, GMRES is used with a maximum Krylov subspace dimension of 20, and $\eta = 0.05$ is used in (5.3) to terminate the linear iterations. Note that it was never necessary to restart the GMRES iterations with these choices of maximum Krylov subspace dimension and stopping criteria. The preconditioner is one V-cycle of FAC with two pre- and postsmoothing sweeps of red-black Gauss–Seidel on refinement levels. One V-cycle of semicoarsening multigrid (SMG) [27] implemented in *hypre* [12] is used on the coarsest level. All calculations were performed on Linux workstations with Intel Xeon 2.4 GHz processors in double precision arithmetic.

Time step control. Equilibrium radiation diffusion problems (2.1) are rarely solved in isolation, and are more often encountered as part of a more sophisticated approximation to radiation transport or as one component in a larger multiphysics application. Thus, time step selection for solving (2.1) must account for other time scale restrictions that may be present. In such circumstances, a commonly encountered strategy for choosing Δt is based on restricting the maximum fractional change of E to some prescribed percentage $\sigma \in (0, 1)$ [3, 26]:

$$\max_{(i,j)} \left(\frac{|E_{i,j}^{n+1} - E_{i,j}^n|}{|E_{i,j}^{n+1}|} \right) \leq \sigma \ .$$

For the time discretization schemes used (BE and BDF2), this leads to an effective time step control algorithm. For example, for BE this leads to

$$\Delta t \leq \sigma \min_{(i,j)} \left(\frac{|E_{i,j}^{n+1}|}{|(\nabla \cdot D(E^{n+1}) \nabla E^{n+1})_{i,j}|} \right) . \tag{6.1}$$

In practice, for a stand-alone solution of (2.1), this has several shortcomings. Initially, Δt based on (6.1) is too large, so instead the calculations begin with a smaller time step $\Delta t = 10^{-6}$, which is increased by 10% until (6.1) yields the smaller value for Δt. As the solution approaches steady state, (6.1) produces time steps that quickly become too large; consequently, the rate of growth of Δt is limited by 5% for $\Delta t \in (0.5, 10.0)$ and 3% for $\Delta t \geq 10.0$.

Selection of refinement regions. At regular intervals (specifically, every tenth time step[1]), regions are identified where enhanced resolution is desired. In this work, simple criteria are employed to identify features[2] of the solution that would benefit from enhanced resolution. A gradient detector is used to identify regions where the solution changes rapidly. We also use a curvature-based criterion [6]. It is found that, at least for this problem, the curvature-based criterion leads to slightly larger refinement regions, making it easier to ensure that the base of the thermal front is entirely contained within the finest refinement level without resorting to ad hoc procedures. However, the curvature-based criterion alone can miss relatively flat regions where the solution nevertheless changes rapidly. Finally, if a cell is marked for refinement, its eight nearest neighbors are also marked.

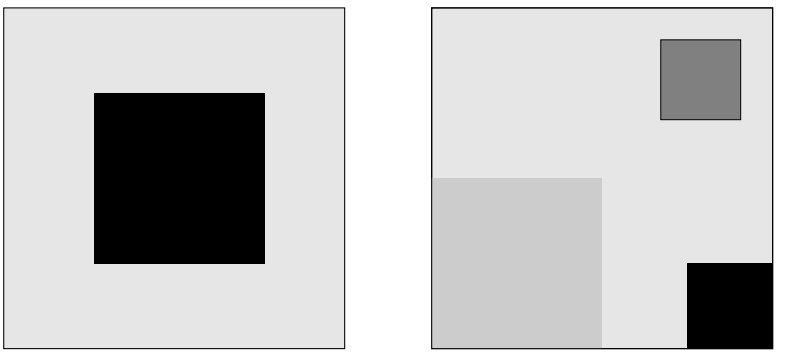

FIG. 6.1. *Material configuration for test cases. Case* 1 *is on the left and Case* 2 *is on the right.*

Test cases. Two test cases are used to illustrate the performance of Newton–Krylov-FAC for solving (2.1), which are depicted in Figure 6.1. In both test cases, $\Omega = [0, 1]^2$ and (2.3) is imposed at both the left $x = 0$ boundary and the right $x = 1$ boundary. Both cases are integrated to a final time of $t = 1500$. Case 1 is taken from [23], where it is used to illustrate the performance of a preconditioner for a

[1]This choice is based on trial and error, and represents a trade-off between the size of the refinement regions and ensuring that the base of the Marshak wave is always contained within the finest refinement level until the next regridding event occurs.

[2]Efforts to develop an *error*-based refinement criterion for this problem are deferred to later work.

nonequilibrium diffusion model. The material properties are defined by

$$Z(x,y) = \begin{cases} 100, & (x,y) \in [\frac{1}{4}, \frac{3}{4}]^2, \\ 10 & \text{otherwise.} \end{cases}$$

With $\alpha = -3$, this leads to a jump of three orders of magnitude in D at the material interface.

Case 2 is adapted from the problem solved in [23]. In this, the material properties are given by

$$Z(x,y) = \begin{cases} 100, & (x,y) \in [\frac{3}{4}, 1] \times [0, \frac{1}{4}], \\ 50, & (x,y) \in [\frac{5}{8}, \frac{5}{8}] \times [\frac{7}{8}, \frac{7}{8}], \\ 20, & (x,y) \in [0, \frac{1}{2}]^2, \\ 10 & \text{otherwise.} \end{cases}$$

6.1. Accuracy. Before presenting performance results for Newton–Krylov-FAC methods on unsteady equilibrium radiation diffusion problems, accuracy measurements are presented. For these measurements, the pattern of local refinement in the dynamic grid calculations is not controlled but allowed to evolve according to the strategies outlined above. Thus, this serves as a verification exercise for both the discretization scheme outlined in section 4 as well as the regridding operations, which collectively identify a new computational grid and transfer the solution from the old grid to the new grid.

The accuracy studies are conducted for Case 2 with BDF2 as the time integrator and $\sigma = 0.05$ in the time step control algorithm. For boundary conditions (2.3), $R = 25.0$ at the $x = 0$ boundary and $R = 0.25$ at the $x = 1$ boundary. Since an analytic solution is not available for comparison, a reference solution on a 512×512 uniform grid is first computed, and results obtained on locally refined grids are compared against this reference solution. In regions where the locally refined grid is not at the same resolution as the uniform grid for the reference solution, the comparison is based on piecewise linear interpolation of the four nearest uniform grid neighbors.

The first set of accuracy results uses a fixed base grid and fixed number of refinement levels, and examines errors over the course of the entire time integration. This appears in Figure 6.2. This shows the relative error over time in the solution computed on locally refined grids against the reference solution. The top curve is for a 32×32 grid with no refinement; each successive curve uses the same base grid but adds a level of refinement. As refinement levels are added, accuracy improvements that appear to be second order are observed. Once four refinement levels are added to the base grid, the finest level of the locally refined calculation is at the same resolution as the reference solution. There, at least three digits of agreement between the reference solution and solution obtained on the locally refined grid are observed.

The next set of accuracy results varies the base grid resolution as well as the number of refinement levels at fixed times. These results are given in Figure 6.3. Here we see excellent agreement among the solutions computed on different locally refined grids, at least until the finest grid level matches the resolution of the reference solution. Note that the finer base grids lead to better agreement with the reference solution.

6.2. Performance. Performance results are now presented for the two test cases described previously. In order to stress the performance of the solvers, we set $R = 2500$

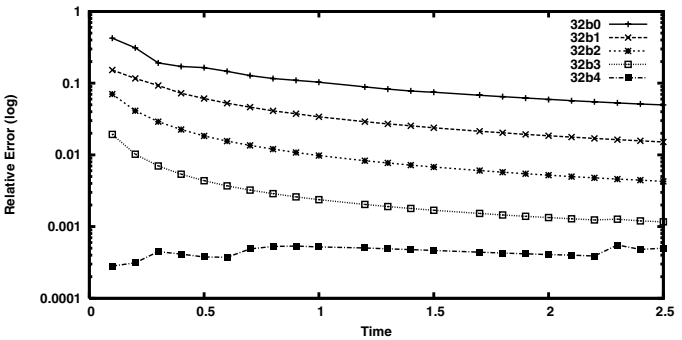

FIG. 6.2. *L2-norm of relative difference in locally refined solution against reference solution for a fixed base grid.*

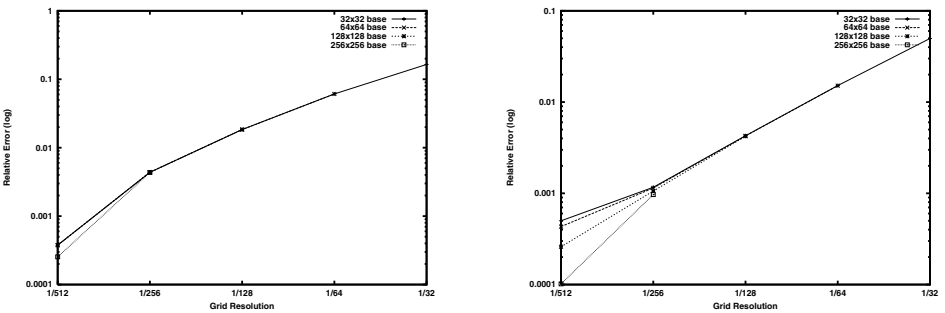

FIG. 6.3. *L2-norm of relative difference in locally refined solution against reference solution for varying base grids. Horizontal axis shows the mesh size of the finest grid level in any of the configurations. Time $t = 0.5$ is on the left, and time $t = 2.5$ is on the right.*

at the $x = 0$ boundary and $R = 0.25$ at the $x = 1$ boundary in (2.3), and set $\sigma = 0.1$ within the time step control algorithm. Performance results are presented for both BE and BDF2 computations.

6.2.1. Case 1. Time evolution of the solution and the grid hierarchy is shown in Figure 6.4. By $t = 0.25$, the incident energy has heated up the left side of the domain and a Marshak wave has propagated into the domain and begun to interact with the second material. Note that the finest level tracks the steepest part of the front, where the solution rapidly changes by three orders of magnitude. The finest level continues to track the front as it propagates further into the domain, and follows it as it wraps around the second material at time $t = 1$.

A comparison of the problem size needed for adaptive and uniform mesh calculations appears in Figure 6.5. In this example, the locally refined grid starts with a 32×32 coarse grid plus four refinement levels. Initially, refinement is automatically introduced only along the $x = 0$ boundary to resolve the increase in energy density due to the imposed radiation field. During this initial period the adaptive calculation requires less than 6% of the storage of the uniform grid calculation. As the front propagates into the domain, the refinement levels grow to capture the evolving front, and the storage required for the adaptive method increases until a maximum of 22% of the uniform grid calculation is needed. As the radiation energy in the interior

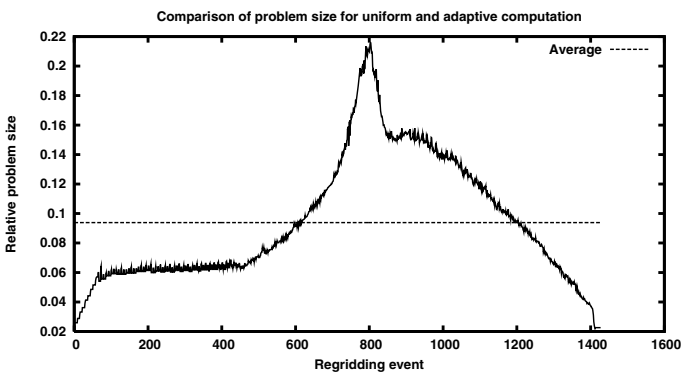

FIG. 6.5. *Comparison of problem size for adaptive vs. uniformly fine calculation.*

of the material increases, de-refinement takes place, until the simulation reaches close to steady state at the end of the calculation, and the adaptive calculation requires only 2% of the uniform grid calculation. The size of the adaptive calculation averages less than 10% of the size of the uniform calculation over the course of the simulation.

Similar behavior is observed when BDF2 is used for the time integration.

Next, we compare the number of iterations required by the adaptive and uniform mesh calculations for BE and BDF2 time integration. This is summarized as averages in Table 6.1. There is very little variation in the number of nonlinear iterations for a fixed base grid, and a slight decrease as the base grid is refined for a given number of refinement levels. Fixing resolution, we see a slight increase in the number of nonlinear iterations as the resolution of the base grid is increased. The number of linear iterations, which is a better reflection of the amount of work performed, shows similar trends, though with greater variation. This is not very surprising, as SMG's very robust semicoarsening/line relaxation algorithm on the global fine grid is being replaced with simple point relaxation, geometric interlevel transfers, and rediscretized operators at each refinement level. It must also be kept in mind that the larger iteration counts occur on much smaller problems. For example, we are comparing a combination of expensive SMG iterations on a 32×32 grid plus point Gauss–Seidel iterations on intermediate levels against SMG iterations on a 512×512 uniform grid.

TABLE 6.1

6.2.2. Case 2. Time evolution of the adaptive computation appears in Figure 6.6. By $t = 0.5$, the lower conductivity in Region 1 ($Z = 20$) has slowed the Marshak wave in comparison to the background material ($Z = 10$), which has been recognized by our refinement criteria. By $t = 0.75$, the front has begun to interact with Region 2 ($Z = 50$) and has begun to propagate towards Region 3 ($Z = 100$). Again, the finest region tracks this behavior. At $t = 1.0$, the front continues towards Region 3 and the thermal front has begun to wrap around Region 2 due to its lower conductivity. By $t = 1.25$, the Marshak wave has begun to interact with Region 3,

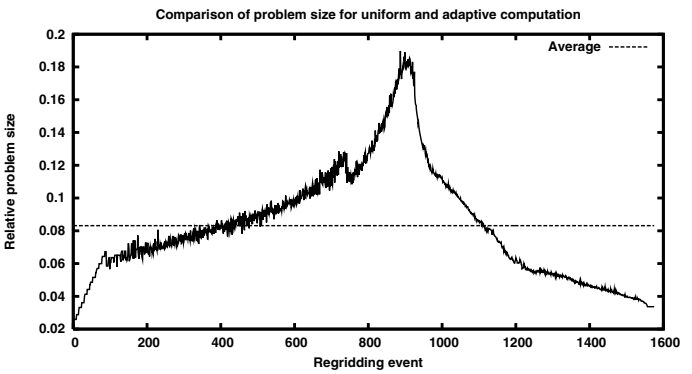

FIG. 6.7. *Comparison of problem size for adaptive vs. uniformly fine calculation.*

while the radiation energy in the interior of Region 2 begins increasing.

Comparison of problem sizes is presented in Figure 6.7. The situation is similar to what was seen for Case 1. This time, the number of cells in the adapted grid increases more quickly due to the presence of Region 1, adjacent to the $x = 0$ boundary.

Eventually there is a decrease in the size of the dynamic calculation as Region 1 is de-refined and before resolution is increased in Region 2. Two inflection points are seen in the size of the locally refined calculation, initially as Region 2 is fully resolved and resolution is increased around Region 3, and subsequently as Regions 2 and 3 are de-refined. The number of cells in the dynamic calculation peaks at less than 20% of the uniform grid calculation, then decreases steadily. On average the dynamic calculation is around 8% of the size of the uniform grid calculation.

Table 6.2 compares nonlinear and linear iteration counts per time step. Once again little variation is seen in the number of nonlinear iterations per time step for a fixed base grid size or for fixed finest resolution, and a small decrease is seen in this iteration count for a fixed number of refinement levels. In contrast, the number of linear iterations per time step increases slowly as more refinement levels are added, and increases by nearly half as we fix resolution and move from a global fine grid to a locally refined calculation. Again, this is likely due to the fact that operators on refinement levels are simply obtained by rediscretization, and interlevel transfer operators are purely geometric.

7. Conclusions and future work. The results presented demonstrate the feasibility of combining implicit time integration with AMR for equilibrium radiation diffusion problems. The numerical examples show that, for both first- and second-order time integration schemes, the multilevel FAC preconditioner effectively controls the number of linear iterations per time step. While good scalability with the number of refinement levels is also demonstrated, these results should be considered preliminary, since the refinement regions change as the number of levels is increased and the resolution of the coarsest level is decreased.

There are several issues in implicit AMR that merit improvement and further

exploration. In particular, the interlevel transfers use geometric interpolation, an approach that is known to lead to robustness problems in the presence of discontinuous coefficients. Coarse grid operators are defined via rediscretization rather than Galerkin coarsening. Evaluation of the parallel performance of the code is necessary, as is exploring the use of asynchronous multilevel preconditioners. The criteria for selecting refinement regions are based on feature detection and not estimation of spatial errors. A systematic evaluation of temporal and spatial convergence orders is needed to determine the efficacy of this approach. Before this can occur, the fact that previous information is no longer a solution after regridding must be addressed. We handle this by re-solving (2.1) on the new grid to update the most recent solution information. In [4] it was argued that this can be addressed with higher-order spatial interpolation, but this approach fails for this problem due to the presence of large spatial gradients. In [17] it is handled by reducing the size of the time step and the order of the integrator, but the effect on the order of temporal accuracy was not explored. We plan to investigate these issues in more detail in future work.

AN AGGREGATION MULTILEVEL METHOD USING SMOOTH ERROR VECTORS*

EDMOND CHOW†

Abstract. Many algebraic multilevel methods for solving linear systems assume that the slowly converging, algebraically smooth error is locally constant. This assumption is often not true and can lead to poor performance of the method. Other multilevel methods require a description of the algebraically smooth error via knowledge of the near-nullspace of the operator, but this information may not always be available. This paper presents an aggregation multilevel method for problems where the near-nullspace of the operator is not known. The method uses samples of low-energy error vectors to construct its interpolation operator. The basis vectors for an aggregate are computed via a singular value decomposition of the sample vectors locally over that aggregate. Compared to many other methods that automatically adjust to the near-nullspace, this method does not require that the element stiffness matrices are available.

Key words. preconditioning, multilevel and multigrid methods, smoothed aggregation

1. Introduction.

Algebraic multilevel methods use complementary smoothing and coarse-grid correction processes for solving linear systems from discretized partial differential equations (PDEs). In these methods, *slow-to-converge error*, or *algebraically smooth error*, is the error that remains after the smoother has been applied and that must be reduced at the next level. The *interpolation* or *prolongation* operator, P, must be able to represent this algebraically smooth error on the coarser level; i.e., P must be constructed such that the algebraically smooth error is in the range of P. To accomplish this, multilevel methods traditionally must make assumptions about the nature of the algebraically smooth error. In standard algebraic multigrid (AMG), algebraically smooth error is assumed to be locally constant or slowly varying along strong couplings [21].

In aggregation multilevel methods for elliptic PDEs, the near-nullspace of the discrete operator is assumed to locally form an approximate basis for the algebraically smooth error. For second- and fourth-order PDEs, these near-nullspace vectors are constants and linear functions [23]; for linear elasticity, these vectors are rigid body modes [9]. If it is known that the solution is physically smooth, then along with the constant vector, the geometric coordinate vectors of the grid points, x, y, and z, and monomial functions of these may locally represent the algebraically smooth error. Similarly, for p-version finite elements, appropriate basis vectors are also known [18].

Algebraic multilevel methods often fail because the above assumptions do not

hold. For example, a scaling of the matrix on the right by a nonconstant diagonal matrix (different values along the diagonal) will change the near-nullspace. (See [6] for other examples.) In other cases, the near-nullspace and the nature of the algebraically smooth error are simply not known. Further, for aggregation methods, it may be desirable for some problems to use other low-energy vectors in addition to the near-nullspace vectors. A procedure is then needed to compute and incorporate these additional vectors.

Multilevel methods that are designed to be more robust and more general by not making assumptions about the algebraically smooth error for a given problem have been developed. The earliest methods constructed interpolation to fit global low-energy eigenvectors, which were computed approximately, or approximate solutions to the homogeneous error equation, $Ae = 0$. These methods date back to some of the original AMG papers [20, 21, 19] (see also [6] for additional early references).

Recently developed methods generally fall into two categories: (1) those that attempt to reduce some measure of the interpolation error and usually involve eigenvector calculations for aggregate matrices (also called element agglomerate matrices) and (2) adaptive methods based on approximately solving the homogeneous error equation.

The interpolation operator, P, may be constructed by minimizing a measure of the interpolation error [2, 1, 4],

$$\min_P \left(\max_u \min_v \frac{\|u - Pv\|_2}{\|u\|_A} \right) \quad \forall u \neq 0, \tag{1.1}$$

where it is assumed that A is scaled to have a unit diagonal. A better minimum leads to a better convergence rate for a two-level method. However, to be practical, the minimization (1.1) must be localized over an aggregate of elements or grid points. In an element-based AMG method [4], the interpolation weights are determined essentially by fitting the eigenvectors of the aggregate matrices (which sum to the global matrix, without boundary conditions). For aggregation multilevel methods, a local basis for the algebraically smooth error for an aggregate is formed by the low-energy eigenvectors of the aggregate matrix [13, 7, 4, 10]. Additional basis vectors can be used to improve the convergence rate [7, 10]. The above approaches, however, are designed for finite element discretizations and require access to the element stiffness matrices. (See, however, approaches that avoid the explicit use of element stiffness matrices [14].)

Related to minimizing a measure of the interpolation error is the energy minimization technique [24]. Here, P is constructed by directly optimizing a constant in the subspace correction framework [25], thus improving the convergence rate. The stability and approximation inequalities are satisfied, guaranteeing mesh-independent convergence.

In the category of adaptive methods are techniques that avoid element stiffness matrices and eigenvectors altogether. In these strategies, a few iterations of the "current" method are applied to the homogeneous problem, $Ae = 0$, to reveal the components of the error that are slow to converge. These components can then be used to update the current method. Versions based on both smoothed aggregation (SA) [6] and AMG [3, 16, 5] have been developed. In bootstrap AMG [3], the interpolation weights are constructed via a least-squares fit of a block of algebraically smooth error vectors. The method is currently being extended to high-order PDEs [15]. In αAMG [16, 5], an interpolation formula involving an algebraically smooth error vector is

used. Adaptive AMG methods can also be defined when AMG is accelerated by a Krylov subspace method. For example, in a conjugate gradient iteration, the Ritz vectors corresponding to the smallest eigenvalues can be used to update the multigrid method's interpolation operator [17].

In this paper, we present a new method of utilizing samples of algebraically smooth error to build an interpolation operator for the SA method. Like bootstrap AMG, the interpolation operator is built by fitting a block of algebraically smooth error vectors simultaneously. However, the SA framework which we use requires only one minimization per aggregate rather than one minimization per fine grid point. The basis vectors for the aggregates are computed via a truncated singular value decomposition (SVD) of the sample vectors locally over each aggregate. The method can be made adaptive by approximately solving $Ae = 0$ and updating the set of algebraically smooth error vectors, like the adaptive methods described above.

In section 2, the new interpolation operator is described. The interpolation is matrix dependent; anisotropies and physical jumps in the PDE problem are reflected in the interpolation operator. The number of sample vectors and the number of basis vectors per aggregate are also discussed. Section 3 presents numerical results on isotropic and anisotropic diffusion problems and a plane strain problem, showing detailed results with different parameters. The section also illustrates the use of a Lanczos process to generate the algebraically smooth sample vectors. Section 4 concludes this paper.

2. Interpolation using algebraically smooth error vectors.

2.1. New interpolation operator. In this section, we describe an interpolation operator based on aggregating variables or grid points that is constructed from samples of low-energy vectors rather than eigenvectors of aggregate matrices. Here, we assume that disjoint aggregates are given. We also suppose that the coefficient matrix, A, at each grid level has been reordered such that the rows and columns of A for an aggregate are ordered together and consecutively by aggregates. This will simplify the notation in this paper. Finally, we will discuss the two-level case and defer the extension to multiple levels to section 2.5.

For aggregate i, let n_i denote the number of variables that are aggregated. Each aggregate will be represented by k_i variables on the coarser level, with $k_i \leq n_i$ and each variable corresponding to a basis vector used to interpolate the error over that aggregate.

As in SA [22, 23], we will smooth the tentative interpolation operator in order to reduce the energy of the basis functions. Thus, we begin by seeking a rectangular tentative interpolation operator of the form

$$\tilde{P} = \begin{bmatrix} \tilde{P}_1 & & & & \\ & \ddots & & & \\ & & \tilde{P}_i & & \\ & & & \ddots & \\ & & & & \tilde{P}_J \end{bmatrix}$$

for J aggregates, where $\tilde{P}_i$ is composed of the k_i tentative basis vectors for aggregate i. The matrix $\tilde{P}$ is block diagonal because the grid point aggregates are disjoint.

Let $S = [s_1, \ldots, s_m]$ be a block of m algebraically smooth error vectors. These vectors may be generated by applying the smoother (to be used in the multigrid

solution process) to the homogeneous equations,

$$As_i = 0, \quad i = 1, \ldots, m$$

(or $AS = 0$ in block form), with a random initial guess for each s_i. The components of the random initial guesses are chosen uniformly from $(-1, 1)$. Choosing positive components is very advantageous for some problems but is less general. (Another method for generating S will be discussed in section 3.3.) When the near-nullspace of A is known, then S should be composed of these near-nullspace vectors. In this case, the method will be the same as the SA method [23] if all k_i equal the number of near-nullspace vectors. The samples, S, may be partitioned as

$$S = \begin{bmatrix} S_1 \\ \vdots \\ S_i \\ \vdots \\ S_J \end{bmatrix},$$

corresponding to the partitioning of $\tilde{P}$.

Given S_i, the portion of the sample vectors corresponding to aggregate i, we seek $\tilde{P}_i$, a rank k_i approximate basis for S_i. Formally, we seek

$$\min_{\tilde{P}_i, W} \|S_i - \tilde{P}_i W\|_2$$

for a given k_i, with $k_i \leq m$. The minimum is achieved when

$$\tilde{P}_i W = U_{k_i} \Sigma_{k_i} V_{k_i}^T,$$

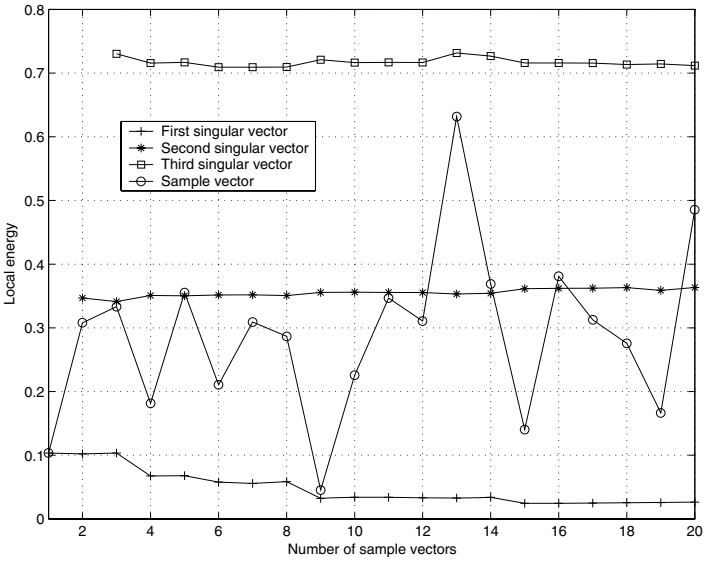
where $U_{k_i} \Sigma_{k_i} V_{k_i}^T$ is the rank k_i truncated SVD of S_i. By matching variables, $\tilde{P}_i$ is defined to be U_{k_i}, the first k_i left singular vectors. We note that the computations are small, dense SVD computations.

This technique exploits the fact that a local portion (over an aggregate) of an algebraically smooth sample vector may have larger or smaller local energy than the same portion of other algebraically smooth sample vectors. The truncated SVD reduces the effect of the higher-energy portions while capturing the desirable low-energy components which are more typical. By using more sample vectors than k_i (the minimum required), the constructed bases are generally improved, as will be shown in section 3.

Recalling (1.1), samples with lower energy must be better approximated by the basis vectors than samples with higher energy; i.e., we wish to have a smaller approximation residual corresponding to samples with smaller energy. This can be accomplished, although imprecisely, by scaling each sample vector, s_j, by $(s_j^T A s_j)^{-1}$ before computing the singular value decomposition. (Empirically this scaling was more effective than $(s_j^T A s_j)^{-1/2}$.) This is particularly important if the sample vectors have very different energy norms. Ideally, we would like to scale the local portion of the sample vectors by their *local* energy norms. However, this would require the construction of aggregate matrices.

Finally, to reduce the energy of the basis functions, $\tilde{P}$ is smoothed one step by a Jacobi smoother to construct the final P. The Jacobi smoother is

$$I - \frac{4}{3\rho} D^{-1} A, \tag{2.1}$$



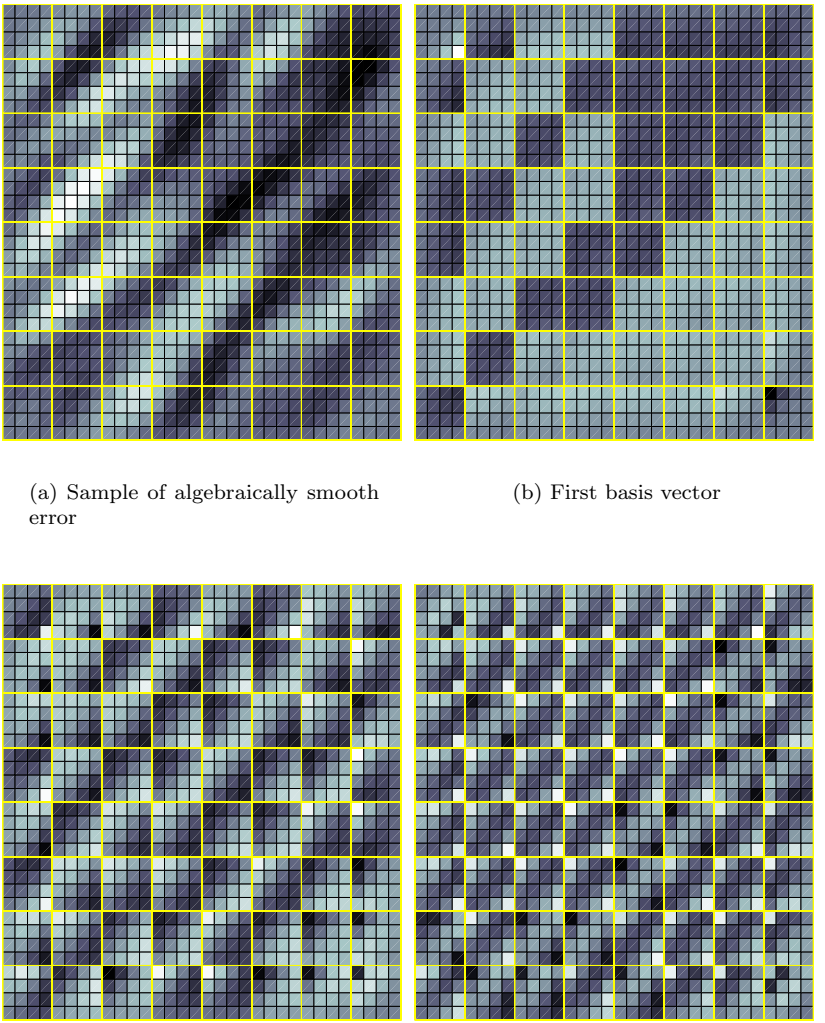


FIG. 2.1. *Local energy of samples and singular vectors versus number of sample vectors. The energy of the first singular vector generally decreases when more samples are used but decreases very slowly after a moderate number of samples. Note the decrease in the energy of the first singular vector when low-energy samples are generated at steps* 4, 9, *and* 15.

where D is the diagonal of A, and ρ is the spectral radius of $D^{-1}A$ estimated by a few steps of a Lanczos or Arnoldi method. This smoothing preserves the null vectors of A.

2.2. Number of sample vectors. The number of sample vectors is a parameter of this method. A larger number of sample vectors will improve the convergence rate, but this must be balanced with the cost of generating these sample vectors and the cost of larger SVD computations.

Figure 2.1 plots the local energy of each of 20 sample vectors for a 9-node aggregate of a one-dimensional isotropic diffusion operator. The sample vectors were generated by 3 steps of symmetric Gauss–Seidel (SGS) applied to the homogeneous error equation with random initial guesses. The figure also plots the local energies of the first, second, and third singular vectors as the number of sample vectors increases. It is evident that the first singular vector has the least energy compared to the second and third and that the energy of the first vector generally decreases when more sample vectors are used. Interestingly, the energy of this singular vector appears to decrease when a new sample vector with very low energy is generated. High-energy sample vectors do not dramatically affect the energy of the first few singular vectors. However, after a moderate number of sample vectors, the energy of the first singular vector then decreases very slowly. Thus, using a very large number of sample vectors is not efficient and should be balanced with the number of smoothing steps applied to each sample vector. This will also be reflected in the numerical tests of the convergence rate. We note that in these examples, the *local* energy of each sample is plotted. In practice, these local energies cannot be computed if the local aggregate matrices are not known.

(a) Sample of algebraically smooth error

(b) First basis vector

(c) Second basis vector

(d) Third basis vector

FIG. 2.2. *An anisotropic diffusion problem with Dirichlet boundary conditions. The first basis vectors* (b) *are nearly constant over each aggregate. The second* (c) *and third* (d) *basis vectors vary slowly in the direction of anisotropy and sharply in the cross direction, like the sample of algebraically smooth error* (a).

2.3. Example. Figure 2.2 shows a sample of algebraically smooth error and three basis vectors produced for an anisotropic diffusion problem with Dirichlet boundary conditions on a 32×32 grid. The direction of anisotropy is 45° (bottom left to top right). The aggregates, shown by the lighter boundary lines, are 4×4 grid points. The value at each grid point is indicated by the gray level of the grid point. For the illustration to be clear, 20 sample vectors were used, with 20 SGS smoothing steps for each vector.

As expected, in Figure 2.2(b), the first basis vector contains nearly locally con-

stant values over each aggregate. Some aggregates have positive values and others have negative values, which explains the two different gray levels predominant for this basis vector. It is also noticeable in the figure that at the Dirichlet boundaries there is a decay of the basis vectors toward zero. This problem-dependent behavior is a feature of this method.

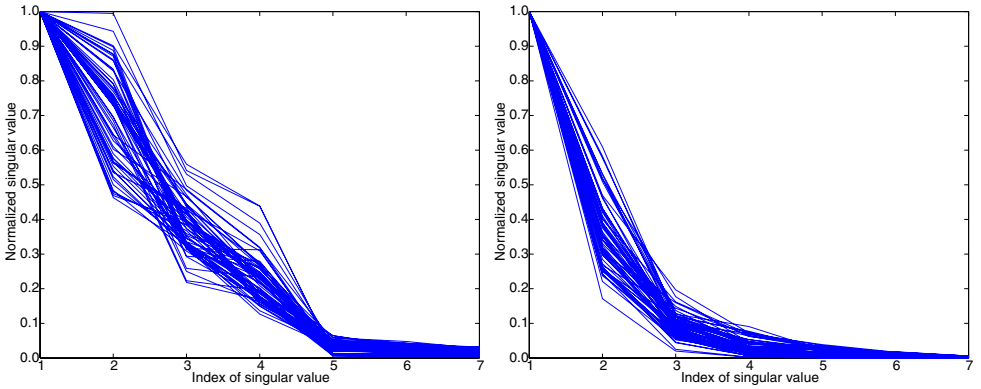
Figure 2.2(c) shows that the second basis vector over each aggregate varies slowly in the direction of anisotropy, like the algebraically smooth error, and varies sharply in the cross direction, again like the smooth error. Figure 2.2(d) shows that the third basis vector is oscillatory in the cross direction, which is very helpful in representing the algebraically smooth error in this example. This quadratic-like function would not normally be chosen by other methods; the standard choice of three basis vectors for this example is composed of the constant and the x- and y-coordinate vectors.

2.4. Number of basis vectors per aggregate. In the SA method [23], the number of basis vectors is chosen beforehand, with each vector being a near-nullspace vector that is known for the problem. In spectral AMGe [10] and the method in [7], the number of basis vectors may be different for each aggregate, and may be chosen such that (1.1) is bounded. In the method presented here, the number of basis vectors may also be different for each aggregate, but no bound on (1.1) is possible.

For aggregate i, the number of basis vectors, k_i, may be chosen based on the singular values from the singular value decomposition of S_i. More basis vectors will improve interpolation for the given aggregate, but increase the cost of the method. One strategy for selecting k_i is to choose the singular vectors that correspond to singular values that are larger than δ times the largest singular value, with $0 \leq \delta < 1$. A sharp decay of the singular values indicates that only a few singular vectors suffice to accurately represent the sample vectors.

To illustrate this, consider two anisotropic diffusion problems on a 32×32 grid using 4×4 aggregates. The two problems have different angles of anisotropy, 0° and 45°. Figures 2.3(a) and 2.3(b) plot the first seven singular values for every aggregate for these two problems. Each curve represents an aggregate, with the singular values scaled such that the largest one for each aggregate is unity. For an angle of anisotropy of 0°, it is natural to use four basis vectors since there are four lines of grid points in each aggregate, and this is reflected in the singular values. For an angle of anisotropy of 45°, a smaller number of basis vectors for many aggregates appears adequate.

2.5. Extension to multiple levels. Once P has been defined for an operator A, the operator at the next coarser level may be defined by the Galerkin coarse-grid operator, $A_c = P^T AP$. The method can be extended to multiple levels by applying the method recursively to solve the coarse-grid correction equations involving A_c.



To apply the method to A_c, a set of algebraically smooth error vectors for A_c is needed. These vectors may be generated from scratch, but the following procedure is more effective.

Recall that S denotes m low-energy vectors for A. We seek T, which denotes m low-energy vectors for A_c. If T is constructed such that

$$S = PT,$$

then $A_c T = P^T AS \approx 0$ and the vectors in T have small energy. Assuming that $P \approx \tilde{P}$, then aggregatewise we have

$$S_i \approx \tilde{P}_i T_i, \tag{2.2}$$

(a) anisotropy angle = 0° (b) anisotropy angle = 45°

FIG. 2.3. *First seven singular values for each aggregate (each curve represents an aggregate), scaled such that the first singular value equals unity. The plot suggests using four and three basis vectors for* (a) *and* (b)*, respectively.*

where T_i is the portion of T corresponding to aggregate i. From the SVD of S_i already computed,

$$S_i = U_i \Sigma_i V_i^T \tag{2.3}$$

$$\approx \tilde{P}_i \Sigma_{k_i} V_{k_i}^T, \tag{2.4}$$

and, by matching variables in (2.2) and (2.4), we define

$$T_i = \Sigma_{k_i} V_{k_i}^T. \tag{2.5}$$

Once T is formed, it is generally not smooth enough due to the approximations made and the fact that this is a representation of a smooth vector on a coarser grid. The energy of the vectors in T can be further reduced by applying a few steps of a relaxation procedure to $A_c T = 0$ using T as an initial guess. We have found that for small problems, only a small number of steps is needed, and additional steps do not significantly improve the convergence rate. For large problems, additional steps can be advantageous. After some experimentation, we used two steps of SGS relaxation, which is a compromise between small and large problems.

For efficiency, it is possible to perform these smoothing steps along with the spectral radius estimation required by the prolongation smoother (2.1) by performing matrix-vector products with a block of vectors simultaneously.

3. Numerical tests. In this section, we test smooth-vector interpolation in a multigrid-preconditioned Krylov method. For the multigrid method, restriction is defined to be the transpose of interpolation, the coarse-grid operator is the Galerkin coarse-grid operator, and V(1,1) cycles are used, with SGS smoothing. Unstructured aggregation of the grid points was performed using the algorithm of the SA method [23], with a strength threshold of 0.08. For coarser levels and nonscalar problems, the degrees of freedom corresponding to a grid point are always aggregated together. We denote this multigrid method by SVMG.

The test problems are discretizations of two-dimensional unstructured isotropic and anisotropic diffusion equations,

$$\begin{aligned} au_{xx} + bu_{yy} = f \quad & \text{in } \Omega = (0,1)^2, \\ u = 0 \quad & \text{on } \partial\Omega, \end{aligned}$$

where $a = b = 1$ for the isotropic problems and $a = 1$ and $b = 1000$ for the anisotropic problems. Random right-hand sides were used. The discretization was linear triangular finite elements. Most of the tests were performed with the largest test problems, UNI7 and ANI7 (isotropic and anisotropic, respectively), which have 205,761 equations and 1,436,481 nonzeros. Smaller test problems were also used. In addition, one test with a plane strain problem was performed and will be described later.

Conjugate gradient acceleration was used, with a zero initial guess. The iterations were stopped when the preconditioned residual norm was decreased by 8 orders of magnitude. The experiments were run on a Linux 1.5 GHz Intel Xeon computer with 256 kbytes of cache memory and 512 Mbytes of main memory. Due to the use of randomness in the interpolation, the iteration counts vary by a few steps from test to test.

3.1. Comparison with SA. The SA method is a powerful method when the near-nullspace of the problem is known. For scalar problems, the practice is to use a single basis vector, the vector of all ones. For UNI7, the PCG-SA method converges in 18 iterations. ANI7 is a much more difficult problem, due to the strong anisotropy on an unstructured grid. Here PCG-SA method converges in 118 iterations.

The new method, SVMG, is designed for the case where the near-nullspace of the operator is not known. When the near-nullspace is known, the SA method using this near-nullspace will perform better. To illustrate this point, we use the UNI7 problem along with a scaled version. Given the original problem matrix, A, the scaled problem is DAD, with $D = \text{diag}(10^{d_1}, 10^{d_2}, \ldots)$ and with the real numbers, d_i, selected randomly from $(0, 6)$. This scaling changes the near-nullspace and is discarded and not known to the SVMG method.

Table 3.1 shows results for UNI7 and its scaled version using SA and SVMG. The table shows PCG iteration counts as well as the time to construct the multigrid preconditioner ("Setup") and the time for the PCG iterations ("Solve"). Five levels were used by the methods. SA used 3 basis vectors: the constant and the x- and y-coordinate vectors. SVMG also used 3 basis vectors, constructed from 6 sample vectors, which were themselves generated by 6 SGS relaxation steps. Three basis vectors were used because a single vector might not be adequate when the exact near-nullspace is not known. This, of course, depends on the accuracy of the basis vectors (see also [6], where a single vector is used).

As expected, the results show that for the scaled problem, SVMG performs better than SA. However, for the given parameters, the performance of SVMG on the scaled problem does not match the performance of SVMG or SA on the original, unscaled problem.

The standard basis vectors used in SA for the scaled problem leads to a coarse-grid matrix with sharply varying coefficients. This leads the aggregation procedure to generate many small aggregates at the coarse levels. This in turn leads to very full coarse matrices on subsequent levels and explains the very high setup time for SA on the scaled problem.

3.2. Test results for isotropic and anisotropic problems. Tables 3.2 and 3.3 show SVMG test results with UNI7 and ANI7, respectively, with various numbers of smooth sample vectors and various numbers of SGS smoothing steps per vector. The top portion of each table shows results when a budget of 36 smoothing steps is used to generate the smooth vectors, either using fewer vectors and more smoothing steps per vector, or vice versa. Three basis vectors were used for each aggregate. Five levels were used in the method.

We express the storage used by the multilevel method in terms of the grid and operator complexities. These terms are common in the AMG literature, e.g., [8]. *Grid complexity* is the total number of degrees of freedom, on all grids, divided by

ANI7	205761	1436481	5	89	25.97	23.77	49.74

the number of degrees of freedom on the finest grid. *Operator complexity* is the total number of nonzero entries, in all coarse- and fine-grid matrices, divided by the number of nonzero entries in the fine-grid matrix. For the results in Tables 3.2 and 3.3, the grid and operator complexities were approximately 1.4 and 3.6, respectively. For scalar problems, these complexities are considered to be high, since a single basis vector is normally used, rather than three basis vectors as in our case. We use more than one basis vector because multiple basis vectors are readily available (from the SVD computation) and using multiple vectors generally improves the performance of the method when the near-nullspace is only approximated. A study using a smaller number of basis vectors will be given in Table 3.6.

Tables 3.2 and 3.3 show the main point of this paper: given a fixed budget of smoothing steps, it can be worthwhile to use more vectors that are less smooth rather than to apply all the smoothing steps to a small number of vectors. When conjugate gradient acceleration is not used, the effect is much more pronounced. In any code, the improvement depends on the portion of the preconditioner setup cost that is due to generating the smooth vectors. The disadvantage of using too many smooth vectors is the increased cost of the SVD calculations, and this is reflected in the setup timings.

Table 3.4 shows iteration counts for PCG-SVMG, varying the number of smoothing steps applied to T, the block of smooth vectors constructed from (2.5) at each coarse level. For UNI7 and ANI7, the results show no significant improvement if more than 2 smoothing steps are taken. As mentioned, we used 2 steps for the tests in this paper. For these results, 6 smooth sample vectors and 6 smoothing steps per sample vector were used.

Table 3.5 shows test results for increasing problem sizes, for both the isotropic and anisotropic problems. Again, 3 basis vectors were used for each aggregate, this time constructed from 12 smooth vectors, with each smooth vector generated using 36 SGS relaxation steps. The results show that grid-independent convergence is not present, particularly for the anisotropic problems. It is expected that for larger problems, a larger number of smoothing steps for the sample vectors is required to achieve a

TABLE 3.6

Test results using a variable number of basis vectors, selected via δ (defined in section 2.4) or k, the number of basis vectors. As the grid and operator complexities improve by using fewer basis vectors, the iteration counts increase.

	$\delta = 0.3$	1.37	2.93	47
	$\delta = 0.4$	1.32	2.40	59
	$\delta = 0.5$	1.27	1.97	76
	$k = 3$	1.40	3.03	46
	$k = 2$	1.26	1.90	89
	$k = 1$	1.13	1.22	124

convergence rate comparable to that for smaller problems.

Table 3.6 shows test results when a variable number of basis vectors is used for each aggregate. These tests were performed using a MATLAB code which had this functionality, but no timings are available. The test problems were UNI5 and ANI5 (see Table 3.5 for matrix information), and four levels were used in SVMG. We used a block of 12 sample vectors, each constructed from 3 SGS steps. The number of basis vectors was fixed at 1, 2, or 3, or was chosen based on δ (defined in section 2.4). Table 3.6 shows that a savings in storage can be achieved with a small impact on convergence rate, and in some cases a savings in time may be possible due to a lower operator complexity.

3.3. Using low-energy vectors from the Lanczos method. Instead of using SGS or another smoother to approximately solve the homogeneous error equation, the algebraically smooth error samples can be generated in other ways. For example, starting with a random vector, the Lanczos method can generate approximations to the extremal eigenvalues and eigenvectors of the fine-grid matrix. For SPD problems, it is natural to use the Ritz vectors corresponding to the smallest Ritz values to construct the smooth-vector interpolation operator. If a large number of Lanczos steps are desired, however, the method can be costly in terms of both storage (of the Lanczos vectors) and computation (forming the Ritz vectors).

We note also that SGS relaxation can be applied to a *block* of vectors, which is computationally very efficient. Block versions of the Lanczos method, on the other hand, generate poorer low-energy Ritz vectors, depending on the block size.

Tables 3.7 and 3.8 show test results using low-energy Ritz vectors for UNI7 and ANI7, respectively. Three basis vectors were used for each aggregate, and 5 levels were used in SVMG.

The tables show budgets of either 36 or 72 matrix-vector multiplies. (A budget of 72 corresponds to 36 SGS smoothing steps, but the computational cost is greater.) A different number of low-energy Ritz vectors were constructed. The results show that using more Ritz vectors will improve the convergence rate, and may also improve

TABLE 3.7

	12	170	21.22	45.45	66.67

the total time, depending on the increase in setup cost. In particular, for the ANI7 problem, the best timings are achieved when more than the minimum number of Ritz vectors are constructed.

3.4. Plane strain problem. We briefly consider a problem that strictly requires multiple basis vectors per aggregate, a plane strain problem on a square with homogeneous Dirichlet boundary conditions. The 3 rigid body modes are known from the geometry and grid for this problem and span the near-nullspace of the PDE operator.

The problem was discretized with 217×217 linear quadrilateral elements (93,312 equations). The nodes were aggregated regularly, using 3×3 node aggregates. Ten smooth vectors were used, with 10 SGS relaxation steps to generate each vector. Three basis vectors were used per aggregate. The multigrid method used 4 levels.

The original problem matrix, A, was generated, as well as a scaled matrix, DAD, with $D = \mathrm{diag}(10^{d_1}, 10^{d_2}, \ldots)$ and with the real numbers, d_i, selected randomly from $(0, 6)$.

Table 3.9 shows the results for the original problem matrix and the scaled matrix, using both the rigid body modes to construct the interpolation operator and the algebraically smooth vectors. Interpolation using the rigid body modes is ideal for the original matrix, but is entirely inappropriate for the scaled matrix. On the other hand, by using the algebraically smooth vectors, both problems can be solved. As expected, however, for the original matrix, the smooth-vector interpolation does not perform as well as interpolating using the rigid body modes.

TABLE 3.9

PCG iteration counts for the plane strain problem, using original and scaled matrices. SA or SVMG were compared as the preconditioner. 200+ *denotes that no convergence was achieved in* 200 *iterations.*

0.40	18	200+	49	97
0.45	24	200+	87	161

4. Concluding remarks. The smooth-vector interpolation operator presented in this paper is constructed to interpolate samples of algebraically smooth error. The interpolation operator is matrix dependent, but particular entries in the matrix are not needed once the aggregates have been chosen. When the budget for generating the sample vectors is fixed, it can be beneficial to use more samples than the number of basis vectors, even if each sample vector has more energy. This technique is particularly advantageous when many basis vectors are required, since additional vectors are available (from the SVD) at no additional cost. Compared to other methods such as spectral AMGe [10], this method does not require that the stiffness matrices for each aggregate be available. Generating the sample vectors may also be very efficient if blocks of vectors are relaxed simultaneously, but this was not tested in this paper.

We note that the performance of the method cannot be better than using the exact near-nullspace vectors if they are known and available. An apparent disadvantage of the method is that for larger problems, smoother sample vectors are required to maintain the same rate of convergence. Thus it may be necessary to use a multigrid method to help generate the sample vectors themselves, as in the adaptive multilevel methods described in the introduction. SVMG can be made adaptive by approximately solving $Ae = 0$ and updating the set of algebraically smooth error vectors used to construct the interpolation operator. Preliminary results were reported in [11].

We also note that it is also possible to perform the node aggregation using samples of algebraically smooth error, instead of using matrix entries. As in [12], nodes may be aggregated if the samples of algebraically smooth error show a strong coupling between the nodes. Incorporating such a strategy may help develop multigrid methods that are matrix-free.

A COMPARISON OF DEFLATION AND THE BALANCING PRECONDITIONER*

R. NABBEN† AND C. VUIK‡

Abstract. In this paper we compare various preconditioners for the numerical solution of partial differential equations. We compare the well-known balancing preconditioner used in domain decomposition methods with a so-called deflation preconditioner. We prove that the effective condition number of the deflated preconditioned system is always, i.e., for all deflation vectors and all restrictions and prolongations, below the condition number of the system preconditioned by the balancing preconditioner. Even more, we establish that both preconditioners lead to almost the same spectra. The zero eigenvalues of the deflation preconditioned system are replaced by eigenvalues which are one if the balancing preconditioner is used. Moreover, we prove that the A-norm of the errors of the iterates built by the deflation preconditioner is always below the A-norm of the errors of the iterates built by the balancing preconditioner. Depending on the implementation of the balancing preconditioner the amount of work of one iteration of the deflation preconditioned system is less than or equal to the amount of work of one iteration of the balancing preconditioned system. If the amount of work is equal, both preconditioners are sensitive with respect to inexact computations. Finally, we establish that the deflation preconditioner and the balancing preconditioner produce the same iterates if one uses certain starting vectors. Numerical results for porous media flows emphasize the theoretical results.

Key words. deflation, coarse grid correction, balancing, preconditioners, conjugate gradients, porous media flow, scalable parallel preconditioner

AMS subject classifications. 65F10, 65F50, 65N22

DOI. 10.1137/040608246

1. Introduction.

The conjugate gradient method is the most-used method to solve large linear systems of equations

$$Ax = b$$

whose coefficient matrices A are sparse and symmetric positive definite. Such systems are encountered, for example, when a finite volume/difference/element method is used to discretize an elliptic partial differential equation.

The convergence rate of the conjugate gradient method (CG-method) is bounded as a function of the condition number of the system matrix to which it is applied. If the condition number of A is large, it is advisable to solve, instead, a preconditioned system $M^{-1}Ax = M^{-1}b$, where the symmetric positive definite preconditioner M is chosen such that $M^{-1}A$ has a more clustered spectrum or a smaller condition number than that of A. Furthermore, system $Mz = r$ must be cheap to solve relative to the improvement it provides in convergence rate. A final desirable property in a preconditioner is that it should parallelize well, especially on distributed memory computers.

In [16] two different preconditioners are compared, namely a deflation preconditioner and an additive coarse grid correction preconditioner. It is shown that the deflation preconditioner leads to a smaller condition number than a coarse grid correction preconditioner like the BPS preconditioner by Bramble, Pasciak, and Schatz [1]. Here we compare the deflation preconditioner with the balancing preconditioner proposed by Mandel [11]. In the following we give a brief introduction into both preconditioning techniques.

To describe the deflation method we define the projection P_D by

$$P_D = I - AZ(Z^T AZ)^{-1} Z^T, \quad Z \in \mathbb{R}^{n \times r}, \tag{1.1}$$

where the column space of Z is the deflation subspace, i.e., the space to be projected out of the residual, and I is the identity matrix of appropriate size. We assume that $r \ll n$ and that Z has rank r. Under this assumption $E \equiv Z^T AZ$ may be easily computed and factored and is symmetric positive definite. Since $x = (I - P_D^T)x + P_D^T x$ and because

$$(I - P_D^T)x = Z(Z^T AZ)^{-1} Z^T Ax = ZE^{-1} Z^T b \tag{1.2}$$

can be immediately computed, we need only to compute $P_D^T x$. In light of the identity $AP_D^T = P_D A$, we can solve the deflated system

$$P_D A\tilde{x} = P_D b \tag{1.3}$$

for $\tilde{x}$ using the CG-method, premultiply this by P_D^T, and add it to (1.2).

Obviously (1.3) is singular. But a positive semidefinite system can be solved by the CG-method as long as the right-hand side is consistent (i.e., as long as $b = Ax$ for some x) [9]. This is certainly true for (1.3), where the same projection is applied to both sides of the nonsingular system. Since the null space never enters the iteration, the corresponding zero eigenvalues do not influence the convergence [9, 22]. Motivated by this fact, we define the *effective condition number* of a positive semidefinite matrix $C \in \mathbb{R}^{n \times n}$ with r zero eigenvalues to be the ratio of its largest to smallest *positive* eigenvalues:

$$\kappa_{eff}(C) = \frac{\lambda_n}{\lambda_{r+1}}.$$

It is possible to combine both a standard preconditioning and preconditioning by deflation (for details see [7]). The convergence is then described by the effective condition number of $M^{-1} P_D A$. For more details about the deflation preconditioner see [17, 15, 4, 13, 10, 25, 2, 24, 26, 7, 23, 16].

We compare the preconditioned deflation operator with the balancing preconditioner proposed by Mandel [11] and Mandel and Brezina [12] and analyzed by Dryja and Widlund [3], Pavarino and Widlund [18], and Toselli and Widlund [21]. As the FETI algorithm [5, 6] the balancing Neumann-Neumann preconditioner is one of the domain decomposition methods that have been most carefully implemented and severely tested on the very largest existing parallel computer systems.

Applied to some specific symmetric positive definite problems the balancing Neumann-Neumann preconditioner leads to moderately growing condition numbers if the size of the systems increases [20]. Moreover, if an appropriate scaling is used, the condition numbers are independent of jumps in the coefficients in the matrices [20].

In our notation the balancing preconditioner is given by

$$P_B = (I - ZE^{-1}Z^TA)M^{-1}(I - AZE^{-1}Z^T) + ZE^{-1}Z^T, \tag{1.4}$$

where $Z \in \mathbb{R}^{n\times r}$, $E = Z^TAZ$, and M is a symmetric positive definite matrix. Note that P_B is symmetric and positive definite. For more details we refer the reader to [11] and the books [20, 19, 21].

As a first comparison of both preconditioners we observe that the balancing preconditioner needs per iteration 3 matrix vector products and the coarse grid operator is used 2 times. This makes the balancing preconditioner per iteration more expensive than the deflation approach. However, if an optimal implementation of the balancing preconditioner is used (see, e.g., [21]), the amount of work per iteration is the same.

In this article we give a detailed comparison of these two preconditioners. We prove that the effective condition number of the deflated preconditioned system $M^{-1}P_DA$ is always below the condition number of the system preconditioned by the balancing preconditioner P_BA. Even more, we establish that the spectrum of P_BA is the same as $M^{-1}P_DA$, except the r zero eigenvalues are replaced by eigenvalues which are one.

This implies that for all matrices $Z \in \mathbb{R}^{n\times r}$ and all positive definite preconditioners M^{-1} the effective condition number of the deflated preconditioned system is below or equal to the condition number of the system preconditioned by the balancing preconditioner! However, the condition number is not the only parameter which influences the convergence behavior of the CG-method. The convergence may be significantly faster if the eigenvalues of A are clustered [22]. But we obtain from the above-mentioned result that the clustering of the eigenvalues of the two different preconditioned systems is the same. However, we have a cluster at zero in one case and at one in the other case. These results are stated in section 2.

There are other properties which influence the convergence behavior of the CG-method, e.g., the starting vector, the right-hand side, and the location of the clusters of eigenvalues. Therefore, a more detailed comparison is given in section 3. There we prove that the A-norm of the errors of the iterates built by the deflation preconditioner is always below the A-norm of the errors of the iterates built by the balancing preconditioner. Moreover, we establish that the deflation preconditioner and the balancing preconditioner produce the same iterates if one uses certain starting vectors. More precisely we show which terms in the preconditioned CG-method are the same for both methods and which terms are different. At the end of section 3 we prove that the condition of the balancing preconditioned system decreases if one takes a finer grid as a coarse grid.

In section 4 numerical results emphasize our theoretical results.

2. Spectral properties. In this section we compare the effective condition number for the deflation and balancing preconditioned matrices. In section 2.1 we give some definitions and preliminary results. Thereafter a comparison is made if the projection vectors are equal to eigenvectors (in section 2.2) and for general projection vectors (in section 2.3).

2.1. Notations and preliminary results. In the following we denote by $\lambda_i(M)$ the eigenvalues of a matrix M. If the eigenvalues are real, the $\lambda_i(M)$'s are ordered increasingly.

For two Hermitian $n \times n$ matrices A and B we write $A \succeq B$, if $A - B$ is positive semidefinite.

Next we mention well-known properties of the eigenvalues of Hermitian matrices.

LEMMA 2.1. *Let $A, B \in \mathbb{C}^{n\times n}$ be Hermitian. For each $k = 1, 2, \ldots, n$ we have*

$$\lambda_k(A) + \lambda_1(B) \leq \lambda_k(A + B) \leq \lambda_k(A) + \lambda_n(B).$$

From the above lemma we easily obtain the next lemma.

LEMMA 2.2. *If $A, B \in \mathbb{C}^{n\times n}$ are positive semidefinite with $A \succeq B$, then $\lambda_i(A) \geq \lambda_i(B)$.*

Moreover, we will use the following lemma.

LEMMA 2.3. *Let $A, B \in \mathbb{C}^{n\times n}$ be Hermitian and suppose that B has rank at most r. Then*

- $\lambda_k(A + B) \leq \lambda_{k+r}(A), \quad k = 1, 2, \ldots, n - r,$
- $\lambda_k(A) \leq \lambda_{k+r}(A + B), \quad k = 1, 2, \ldots, n - r.$

Lemma 2.1, Lemma 2.2, and Lemma 2.3 can be found, e.g., as Theorem 4.3.1, Corollary 7.7.4, and Theorem 4.3.6, respectively, in [8].

2.2. Projection vectors chosen as eigenvectors. In this section we compare the effective condition number of $P_D A$ and $P_B A$ if the projection vectors are equal to the eigenvectors of A.

DEFINITION 2.4. *Let λ_i be the eigenvalues of A. Choose the eigenvectors v_k of A such that $v_k^T v_j = \delta_{kj}$, and define $Z = [v_1 \ldots v_r]$.*

THEOREM 2.5. *Using Z as given in Definition 2.4 and preconditioner M equal to the identity, the spectrum of $P_B A$ is*

$$\mathit{spectrum}(P_B A) = \{1, \ldots, 1, \lambda_{r+1}, \ldots, \lambda_n\}.$$

Proof. For this choice of Z it appears that

$$E = Z^T A Z = \mathit{diag}(\lambda_1, \ldots, \lambda_r). \tag{2.1}$$

We consider $P_B A v_k$. For $k = 1, \ldots, n$ we obtain

$$P_B A v_k = \left(I - Z\,\mathit{diag}\left(\frac{1}{\lambda_1}, \ldots, \frac{1}{\lambda_r}\right) Z^T A\right)\left(I - AZ\,\mathit{diag}\left(\frac{1}{\lambda_1}, \ldots, \frac{1}{\lambda_r}\right) Z^T\right)\lambda_k v_k + Z\,\mathit{diag}\left(\frac{1}{\lambda_1}, \ldots, \frac{1}{\lambda_r}\right) Z^T \lambda_k v_k.$$

Using the orthogonality properties of the eigenvectors one obtains

$$P_B A v_k = v_k, \text{ for } k = 1, \ldots, r.$$

For $k = r + 1, \ldots, n$ the same orthogonality properties lead to

$$P_B A v_k = \lambda_k v_k, \text{ for } k = r + 1, \ldots, n. \qquad \square$$

In order to compare both approaches we note that

$$\kappa_{eff}(P_D A) = \frac{\lambda_n}{\lambda_{r+1}} \tag{2.2}$$

and

$$\kappa(P_B A) = \frac{\max\{1, \lambda_n\}}{\min\{1, \lambda_{r+1}\}}. \tag{2.3}$$

From (2.2) and (2.3) it follows that $\kappa(P_B A) \geq \kappa_{eff}(P_D A)$, so the convergence bound based on the effective condition number implies that deflated CG never converges slower than CG combined with the balancing preconditioner if both methods use the eigenvectors corresponding to the r smallest eigenvalues as projection vectors.

2.3. Projection vectors chosen as general vectors. In the previous section we showed that the deflation technique leads to a smaller effective condition number than the balancing preconditioner, if eigenvectors are used. However, computing the r smallest eigenvalues is mostly very expensive. Moreover, in multigrid methods and domain decomposition methods special interpolation and prolongation matrices are used to obtain grid independent convergence rates. So a comparison only for eigenvectors is not enough. But in this section we generalize the results of the last section. We prove that the effective condition number of the deflated preconditioned system is always, i.e., for all matrices $Z \in \mathbb{R}^{n\times r}$ and all preconditioners M^{-1}, below the condition number of the system preconditioned by the balancing preconditioner. To do this we repeat some properties of the projection operator P_D used in the deflation method (see [7]). The operator P_D is defined as

$$P_D = I - AZE^{-1}Z^T, \text{ where } E = Z^TAZ. \tag{2.4}$$

Furthermore, the following identities hold:

$$P_D^2 = P_D, \;\; P_DAZ = 0, \;\; Z^TP_D = P_D^TZ = 0, \;\; \text{and} \;\; AP_D^T = P_DA.$$

We start with a result for the deflation preconditioner which helps to compare the deflation and the balancing preconditioner.

PROPOSITION 2.6. *Let $A \in \mathbb{R}^{n\times n}$ be symmetric positive definite. Let $Z \in \mathbb{R}^{n\times r}$ with rank$Z = r$. Then*

$$\sigma(P_D^TM^{-1}P_DA) = \sigma(M^{-1}P_DA).$$

Proof. Since $AP_D^T = P_DA$ the following identities hold:

$$\sigma(P_D^TM^{-1}P_DA) = \sigma(M^{-1}P_DAP_D^T) = \sigma(M^{-1}P_D^2A) = \sigma(M^{-1}P_DA). \qquad \square$$

Using Proposition 2.6 we obtain the following theorem.

THEOREM 2.7. *Let $A \in \mathbb{R}^{n\times n}$ be symmetric positive definite. Let $Z \in \mathbb{R}^{n\times r}$ with rank$Z = r$. Then the preconditioner defined in* (1.1) *and* (1.4) *satisfies*

$$\lambda_n(M^{-1}P_DA) \le \lambda_n(P_BA), \tag{2.5}$$

$$\lambda_{r+1}(M^{-1}P_DA) \ge \lambda_1(P_BA). \tag{2.6}$$

Proof. We can write P_B as

$$P_B = P_D^TM^{-1}P_D + ZE^{-1}Z^T.$$

Thus

$$A^{\frac{1}{2}}P_BA^{\frac{1}{2}} = A^{\frac{1}{2}}P_D^TM^{-1}P_DA^{\frac{1}{2}} + A^{\frac{1}{2}}ZE^{-1}Z^TA^{\frac{1}{2}}.$$

Since $A^{\frac{1}{2}}ZE^{-1}Z^TA^{\frac{1}{2}}$ is a symmetric positive semidefinite matrix of rank r, we obtain with Lemma 2.2

$$\lambda_i(P_BA) = \lambda_i(A^{\frac{1}{2}}P_BA^{\frac{1}{2}}) \ge \lambda_i(A^{\frac{1}{2}}P_D^TM^{-1}P_DA^{\frac{1}{2}}) = \lambda_i(P_D^TM^{-1}P_DA).$$

Using Lemma 2.3 we get

$$\lambda_{r+1}(P_D^TM^{-1}P_DA) \ge \lambda_1(P_BA).$$

Using Proposition 2.6 we get the desired result. $\square$

It follows from Theorem 2.7 that

$$\kappa(P_B A) \geq \kappa_{eff}(M^{-1}P_D A),$$

so the convergence bound based on the effective condition number implies that preconditioned deflated CG never converges slower than CG preconditioned by the balancing preconditioner.

It appears that the results given in Theorem 2.5 can be generalized to general projection vectors.

THEOREM 2.8. *Suppose that the spectrum of $M^{-1}P_D A$ is given by*

$$spectrum(M^{-1}P_D A) = \{0, \ldots, 0, \mu_{r+1}, \ldots, \mu_n\}.$$

Then

$$spectrum(P_B A) = \{1, \ldots, 1, \mu_{r+1}, \ldots, \mu_n\}.$$

Proof. We know that $M^{-1}P_D AZ = 0$, so the eigenvectors corresponding to the zero eigenvalues of $M^{-1}P_D A$ are equal to $\{z_1, \ldots, z_r\}$. On the other hand, it is easy to check that

$$P_B AZ = (P_D^T M^{-1} P_D + ZE^{-1}Z^T)AZ = P_D^T M^{-1} P_D AZ + ZE^{-1}Z^T AZ = Z.$$

This implies that $\{z_1, \ldots, z_r\}$ are the eigenvectors corresponding to the eigenvalues of $P_B A$, which are equal to 1.

Now we consider the eigenvalue μ_i, with $r+1 \leq i \leq n$. Suppose v_i is the corresponding eigenvector of $M^{-1}P_D A$, and thus $M^{-1}P_D Av_i = \mu_i v_i$. Since

$$M^{-1}P_D Av_i = M^{-1}P_D^2 Av_i = M^{-1}P_D AP_D^T v_i = \mu_i v_i \neq 0,$$

the vector $P_D^T v_i$ is nonzero. Using this vector, it follows that

$$P_B A(P_D^T v_i) = (P_D^T M^{-1} P_D + ZE^{-1}Z^T)AP_D^T v_i \tag{2.7}$$

$$= P_D^T M^{-1} P_D AP_D^T v_i + ZE^{-1}Z^T AP_D^T v_i \tag{2.8}$$

$$= P_D^T M^{-1} P_D^2 Av_i = P_D^T M^{-1} P_D Av_i = \mu_i P_D^T v_i. \tag{2.9}$$

So the vectors $P_D^T v_i$ are eigenvectors of $P_B A$ corresponding to the eigenvalues μ_i. ∎

Thus both preconditioners lead to almost the same spectra with the same clustering. The zero eigenvalues of the deflation preconditioned system are replaced by eigenvalues which are one if the balancing preconditioner is used.

3. Comparing the norm of the residuals. In order to make a more detailed comparison of the deflation operator and the balancing preconditioner for general projection vectors we start to compare the vector spaces which contain the approximations of both methods. Using CG with P_B as preconditioner and start vector $x_{0,B} = 0$, it is well known that

$$x_{k,B} \in K^k\{P_B A, P_B b\},$$

where the Krylov subspace $K^k\{P_B A, P_B b\} = span\{P_B b, P_B AP_B b, \ldots, (P_B A)^{k-1}P_B b\}$.

THEOREM 3.1. *The Krylov space used in the CG method with P_B as preconditioner and start vector $x_{0,B} = 0$ has the following property:*

$$K^k\{P_B A, P_B b\} \subset span\{ZE^{-1}Z^T b, P_D^T M^{-1} P_D b, \ldots, P_D^T (M^{-1}P_D A)^{k-1} M^{-1} P_D b\}. \tag{3.1}$$

Proof. To start the proof we first note that

$$P_B b = P_D^T M^{-1} P_D b + Z E^{-1} Z^T b.$$

Therefore, the property holds for $k = 1$. For $k = 2$ we note that

$$P_B A P_B b = (P_D^T M^{-1} P_D + Z E^{-1} Z^T) A (P_D^T M^{-1} P_D + Z E^{-1} Z^T) b.$$

Writing out the various terms on the right-hand side one obtains

$$Z E^{-1} Z^T A Z E^{-1} Z^T b = Z E^{-1} Z^T b,$$

$$P_D^T M^{-1} P_D A P_D^T M^{-1} P_D b = P_D^T M^{-1} P_D P_D A M^{-1} P_D b = P_D^T M^{-1} P_D A M^{-1} P_D b,$$

where we have used that $A P_D^T = P_D A$ and $P_D^2 = P_D$. Finally, the terms

$$P_D^T M^{-1} P_D A Z E^{-1} Z^T \text{ and } Z E^{-1} Z^T A P_D^T M^{-1} P_D$$

are both zero because they contain the combination $P_D A Z = 0$ or $Z^T A P_D^T = (P_D A Z)^T = 0$. Repeating this argument for $(P_B A)^i P_B b$ for $i = 3, \ldots, k-1$ proves the theorem. ∎

With respect to the approximation using preconditioned CG combined with deflation, we note that $x = (I - P_D^T)x + P_D^T x = Z E^{-1} Z^T b + P_D^T x$. So after k iterations of preconditioned CG applied to $A P_D^T x = P_D A x = P_D b$ we get the approximation $\tilde{x}_{k,D}$. The approximation $x_{k,D}$ of the solution vector x is then given by $x_{k,D} = Z E^{-1} Z^T b + P_D^T \tilde{x}_{k,D}$. The vector $x_{k,D}$ is contained in the following space:

$$x_{k,D} \in Z E^{-1} Z^T b + span\{P_D^T M^{-1} P_D b, \ldots, P_D^T (M^{-1} P_D A)^{k-1} M^{-1} P_D b\}.$$

This implies that both approximations are elements of the same space. So the difference in quality of the approximation only depends on which norm is minimized.

LEMMA 3.2. *For the deflation iterates $x_{k,D}$ and $\tilde{x}_{k,D}$ with start vector $\tilde{x}_{0,D} = 0$ the following optimality property holds:*

$$\|x - x_{k,D}\|_A = \|P_D^T (x - \tilde{x}_{k,D})\|_A = \min_{\xi \in K^k\{M^{-1} P_D A, M^{-1} P_D b\}} \|P_D^T (x - \xi)\|_A. \tag{3.2}$$

Proof. The first equality follows from the fact that $x = (I - P_D^T)x + P_D^T x$. If CG is applied to the preconditioned system

$$L^{-1} P_D A L^{-T} y = L^{-1} P_D b, \tag{3.3}$$

the following expression holds:

$$\|\tilde{y} - y_k\|_{L^{-1} P_D A L^{-T}} = \min_{\eta \in K^k\{L^{-1} P_D A L^{-T}, L^{-1} P_D b\}} \|\tilde{y} - \eta\|_{L^{-1} P_D A L^{-T}}, \tag{3.4}$$

where $\tilde{y}$ is a solution of (3.3). Note that $\tilde{x} = L^{-T} \tilde{y}$ is a solution of $P_D A x = P_D b$. Rewriting (3.4) with $\xi = L^{-T} \eta$ leads to

$$\|L^T (\tilde{x} - \tilde{x}_{k,D})\|_{L^{-1} P_D A L^{-T}} = \min_{\xi \in K^k\{M^{-1} P_D A, M^{-1} P_D b\}} \|L^T (\tilde{x} - \xi)\|_{L^{-1} P_D A L^{-T}}.$$

Using the equalities

$$\|L^T (\tilde{x} - \tilde{x}_{k,D})\|^2_{L^{-1} P_D A L^{-T}} = (\tilde{x} - \tilde{x}_{k,D})^T P_D A (\tilde{x} - \tilde{x}_{k,D})$$
$$= (\tilde{x} - \tilde{x}_{k,D})^T P_D^2 A (\tilde{x} - \tilde{x}_{k,D}) = \|P_D^T (\tilde{x} - \tilde{x}_{k,D})\|^2_A = \|P_D^T (x - \tilde{x}_{k,D})\|^2_A$$

leads to the proof of the lemma. ∎

THEOREM 3.3. *Let $x_{k,D}$ and $\tilde{x}_{k,D}$ be the deflation iterates with start vector $\tilde{x}_{0,D} = 0$. For every $x_k \in span\{ZE^{-1}Z^Tb, P_D^TM^{-1}P_Db, \ldots, P_D^T(M^{-1}P_DA)^{k-1}M^{-1}P_Db\}$ the following inequality holds:*

$$\|x - x_{k,D}\|_A \leq \|x - x_k\|_A.$$

Proof. We decompose x_k as follows:

$$x_k = \alpha ZE^{-1}Z^Tb + P_D^T\xi, \text{ where } \xi \in K^k\{M^{-1}P_DA, M^{-1}P_Db\}.$$

Substituting this into $\|x - x_k\|_A^2$ shows that

$$\|x - x_k\|_A^2 = \|x - \alpha ZE^{-1}Z^Tb - P_D^T\xi\|_A^2.$$

Using the equation $x = (I - P_D^T)x + P_D^Tx = ZE^{-1}Z^Tb + P_D^Tx$ we obtain

$$\begin{aligned}\|x - x_k\|_A^2 &= \|(1-\alpha)ZE^{-1}Z^Tb - P_D^T(x-\xi)\|_A^2 \\ &= (1-\alpha)^2\|ZE^{-1}Z^Tb\|_A^2 + \|P_D^T(x-\xi)\|_A^2 \\ &\quad + (1-\alpha)b^TZE^{-1}Z^TAP_D^T(x-\xi) \\ &\quad + (1-\alpha)(x-\xi)^TP_DAZE^{-1}Z^Tb.\end{aligned}$$

The last two terms are equal to zero, because $Z^TAP_D^T = (P_DAZ)^T = 0$. For $x_{k,D}$ we know that $\alpha = 1$. This together with Lemma 3.2 implies

$$\|x - x_{k,D}\|_A^2 \leq (1-\alpha)^2\|ZE^{-1}Z^Tb\|_A^2 + \|P_D^T(x-\xi)\|_A^2 = \|x - x_k\|_A^2,$$

where $\xi \in K^k\{M^{-1}P_DA, M^{-1}P_Db\}$. ∎

Theorems 3.1 and 3.3 imply the following theorem.

THEOREM 3.4. *The iterates $x_{k,D}$ and $x_{k,B}$ of the CG-method with start vector zero and preconditioned by the deflation preconditioner and the balancing preconditioner, respectively, satisfy*

$$\|x - x_{k,D}\|_A \leq \|x - x_{k,B}\|_A.$$

Next we are able to prove that using a certain start vector the iterates $x_{k,D}$ are equal to the $x_{k,B}$.

THEOREM 3.5. *Using $x_{0,B} = ZE^{-1}Z^Tb$ and $\tilde{x}_{0,D} = 0$ it follows that $x_{k,D} = x_{k,B}$.*

Proof. Using the start vector $x_{0,B} = ZE^{-1}Z^Tb$ it appears that

$$r_{0,B} = b - Ax_{0,B} = (I - AZE^{-1}Z^T)b = P_Db.$$

This implies that the Krylov subspace is given by $K^k\{P_BA, P_BP_Db\}$. For $k = 1$ it follows from $P_D^2 = P_D$ and $Z^TP_D = Z^T(I - AZE^{-1}Z^T) = 0$ that

$$(P_D^TM^{-1}P_D + ZE^{-1}Z^T)P_Db = P_D^TM^{-1}P_Db.$$

For $k = 2$ we know from the proof of Theorem 3.1 that

$$P_BAP_BP_Db = ZE^{-1}Z^TP_Db + P_D^TM^{-1}P_DAM^{-1}P_D^2b.$$

Note that $Z^TP_D = Z^T(I - AZE^{-1}Z^T) = 0$, and thus

$$P_BAP_BP_Db = P_D^TM^{-1}P_DAM^{-1}P_Db.$$

Repeating this argument shows that

$$\begin{aligned} K^k\{P_BA, P_BP_Db\} &= span\{P_D^TM^{-1}P_Db, \ldots, P_D^T(M^{-1}P_DA)^{k-1}M^{-1}P_Db\} \\ &= P_D^TK^k\{M^{-1}P_DA, M^{-1}P_Db\}. \end{aligned}$$

We again use the fact that CG combined with the balancing preconditioner minimizes

$$(x - x_{k,B})^TA(x - x_{k,B}),$$

where

$$x_{k,B} = ZE^{-1}Z^Tb + P_D^T\xi, \text{ and } \xi \in K^k\{M^{-1}P_DA, M^{-1}P_Db\}$$

due to the choice of the start vector $x_{0,B} = ZE^{-1}Z^Tb$. We have that

$$x - x_{k,B} = x - ZE^{-1}Z^Tb - P_D^T\xi = P_D^T(x - \xi).$$

But by Lemma 3.2 the optimal ξ is nothing other than $\tilde{x}_{k,D}$. Thus we obtain

$$x - x_{k,B} = P_D^T(x - \tilde{x}_{k,D}).$$

Since $x = ZE^{-1}Z^Tb + P_D^Tx$ we get

$$x_{k,D} = ZE^{-1}Z^Tb + P_D^T\tilde{x}_{k,D} = x_{k,B}. \qquad \square$$

Using the identity $x_{k,D} = x_{k,B}$ it is easy to see that Theorem 2.11 of [16] implies that the balancing preconditioner with $x_{0,B} = ZE^{-1}Z^Tb$ never converges slower than the additive coarse grid preconditioner.

In the following we give a more detailed analysis of the preconditioned CG-method for both preconditioners if the above start vectors are used. We prove which quantities in the preconditioned CG-algorithm (PCG) are the same for both preconditioners and which are different. To make this paper self-contained we repeat the PCG-algorithm.

PCG-ALGORITHM for $Ax = b$ with preconditioner M^{-1}.
$r_0 := b - Ax_0, \quad z_0 = M^{-1}r_0, \quad p_0 := z_0$
For $j = 0, 1, \ldots$ until convergence, do
$\alpha_j := (r_j, z_j)/(Ap_j, p_j)$
$x_{j+1} := x_j + \alpha_jp_j$
$r_{j+1} := r_j - \alpha_jAp_j$
$z_{j+1} := M^{-1}r_{j+1}$
$\beta_j := (r_{j+1}, z_{j+1})/(r_j, z_j)$
$p_{j+1} := z_{j+1} + \beta_jp_j$
end

Moreover, we need the next proposition.

PROPOSITION 3.6. *Let P_D, P_B, and M^{-1} be defined as above. Then*

$$P_D^TP_BP_D = P_D^TM^{-1}P_D = P_D^TP_B = P_BP_D. \tag{3.5}$$

Proof. Since $P_D = I - AZE^{-1}Z^T$ we have $P_D^TZ = Z - ZE^{-1}Z^TAZ = 0$. Hence,

$$P_D^TP_BP_D = P_D^{T^2}M^{-1}P_D^2 + P_D^TZE^{-1}ZP_D = P_D^TM^{-1}P_D.$$

Similarly,

$$P_D^TP_B = P_D^{T^2}M^{-1}P_D + P_DZE^{-1}ZP_D = P_D^TM^{-1}P_D.$$

Since $P_D^TM^{-1}P_D$ is symmetric we also have $P_D^TM^{-1}P_D = P_BP_D$. $\square$

Now we can prove the following theorem.

THEOREM 3.7. *Using the PCG-algorithm with the balancing preconditioner P_B and $x_{0,B} = ZE^{-1}Z^Tb$ on one side and with the deflation preconditioner $M^{-1}P_D$ and $\tilde{x}_{0,D} = 0$ on the other side we have, for all j,*

$$\begin{aligned}(r_{j,D}, z_{j,D}) &= (r_{j,B}, z_{j,B}),\\ (P_DAp_{j,D}, p_{j,D}) &= (Ap_{j,B}, p_{j,B}),\\ r_{j+1,D} &= r_{j+1,B},\\ z_{j+1,B} &= P_D^T z_{j+1,D},\\ p_{j+1,B} &= P_D^T p_{j+1,D},\\ \beta_{j,B} &= \beta_{j,D},\\ x_{j+1,B} &= x_{j+1,D} = ZE^{-1}Z^T + P_D^T\tilde{x}_{j+1,D}.\end{aligned}$$

Proof. If we use PCG for

$$P_DAx = P_Db$$

with preconditioner M^{-1} and start vector $x_0 = 0$, we obtain

$$\begin{aligned}&x_{0,D} = 0, \quad r_{0,D} = P_Db, \quad z_{0,D} = M^{-1}P_Db,\\ &p_{0,D} = z_{0,D} = M^{-1}P_Db, \quad \alpha_{0,D} = \frac{(r_{0,D}, z_{0,D})}{(P_DAp_{0,D}, p_{0,D})},\\ &\tilde{x}_{1,D} = 0 + \alpha_{0,D}M^{-1}P_Db,\\ &x_{1,D} = ZE^{-1}Z^Tb + \alpha_{0,D}P_D^TM^{-1}P_Db.\end{aligned}$$

If we use PCG for

$$Ax = b$$

with preconditioner P_B and start vector $x_0 = ZE^{-1}Z^Tb$, we obtain

$$\begin{aligned}x_{0,B} = ZE^{-1}Z^Tb, \quad r_{0,B} = P_Db, \quad z_{0,B} = P_BP_Db,\\ p_{0,B} = z_{0,B} = P_BP_Db, \quad \alpha_{0,B} = \frac{(r_{0,B}, z_{0,B})}{(Ap_{0,B}, p_{0,B})},\\ x_{1,B} = ZE^{-1}Z^Tb + \alpha_{0,B}P_BP_Db.\end{aligned}$$

Obviously, we have for all iterates

$$P_Dr_{j+1,D} = P_D(P_Db - P_DAx_{j+1,D}) = r_{j+1,D}. \tag{3.6}$$

The identity

$$P_BP_D = P_D^TM^{-1}P_D^2 + ZE^{-1}Z^TP_D = P_D^TM^{-1}P_D$$

is frequently used in the following analysis.

Next, we prove the following identities by induction:

$$\begin{aligned}(r_{j,D}, z_{j,D}) = (r_{j,B}, z_{j,B}), \quad (r_{j+1,D}, z_{j+1,D}) = (r_{j+1,B}, z_{j+1,B}),\\ (P_DAp_{j,D}, p_{j,D}) = (Ap_{j,B}, p_{j,B}),\end{aligned}$$

$$
\begin{aligned}
r_{j+1,D} &= r_{j+1,B},\\
z_{j+1,B} &= P_D^T z_{j+1,D},\\
p_{j+1,B} &= P_D^T p_{j+1,D},\\
\beta_{j,B} &= \beta_{j,D},\\
x_{j+1,B} &= x_{j+1,D} = ZE^{-1}Z^T + P_D^T \tilde{x}_{j+1,D}.
\end{aligned}
$$

In the following we use Proposition 3.6 and (3.6). For $j = 0$ we have

$$
(r_{0,D}, z_{0,D}) = b^T P_D^T M^{-1} P_D b = b^T P_D^T P_B P_D b = (r_{0,B}, z_{0,B}).
$$

$$
\begin{aligned}
(P_D A p_{0,D}, p_{0,D}) &= b^T P_D^T M^{-1} P_D A M^{-1} P_D b\\
&= b^T P_D^T M^{-1} P_D A P_D^T M^{-1} P_D b\\
&= b^T P_D^T P_B A P_B P_D b\\
&= (A p_{0,B}, p_{0,B}).
\end{aligned}
$$

Hence, $\alpha_{0,D} = \alpha_{0,B}$.

$$
\begin{aligned}
r_{1,D} &= P_D b - \alpha_{0,D} P_D A M^{-1} P_D b = P_D b - \alpha_{0,D} A P_D^T M^{-1} P_D b\\
&= P_D b - \alpha_{0,B} A P_B P_D b\\
&= r_{1,B}.
\end{aligned}
$$

$$
\begin{aligned}
x_{1,D} &= ZE^{-1}Z^T b + \alpha_{0,D} P_D^T M^{-1} P_D b\\
&= ZE^{-1}Z^T b + \alpha_{0,B} P_B P_D b = x_{1,B}.
\end{aligned}
$$

$$
\begin{aligned}
P_D^T z_{1,D} &= P_D^T M^{-1} r_{1,D} = P_D^T M^{-1} P_D r_{1,D}\\
&= P_B P_D r_{1,D} = P_B r_{1,B} = z_{1,B}.
\end{aligned}
$$

Thus

$$
\begin{aligned}
(r_{1,B}, z_{1,B}) &= (r_{1,D}, P_D^T z_{1,D})\\
&= (P_D r_{1,D}, z_{1,D}) = (r_{1,D}, z_{1,D}).
\end{aligned}
$$

Hence $\beta_{0,D} = \beta_{0,B}$. Next,

$$
\begin{aligned}
p_{1,B} &= z_{1,B} + \beta_{0,B} p_{0,B}\\
&= P_D^T z_{1,D} + \beta_{0,B} P_B P_D b\\
&= P_D^T z_{1,D} + \beta_{0,B} P_D^T M^{-1} P_D b\\
&= P_D^T (z_{1,D} + \beta_{0,D} p_{0,D})\\
&= P_D^T p_{1,D}.
\end{aligned}
$$

Now assume that the above identities hold for $j-1$ and that $(r_{j,B}, z_{j,B}) = (r_{j,D}, z_{j,D})$ holds. We then have

$$
\begin{aligned}
(A p_{j,B}, p_{j,B}) &= (A P_D^T p_{j,D}, P_D^T p_{j,D})\\
&= p_{j,D}^T P_D A P_D^T p_{j,D}\\
&= (P_D A p_{j,D}, p_{j,D}).
\end{aligned}
$$

Hence, $\alpha_{j,D} = \alpha_{j,B}$. Since

$$\begin{aligned} x_{j+1,B} &= x_{j,B} + \alpha_{j,B} p_{j,B}, \\ \tilde{x}_{j+1,D} &= \tilde{x}_{j,D} + \alpha_{j,D} p_{j,D}, \end{aligned}$$

we obtain

$$\begin{aligned} x_{j+1,D} &= ZE^{-1}Z^T + P_D \tilde{x}_{j,D} + \alpha_{j,D} P_D^T p_{j,D} \\ &= x_{j,B} + \alpha_{j,B} p_{j,B} \\ &= x_{j+1,B}. \end{aligned}$$

$$\begin{aligned} r_{j+1,B} &= r_{j,B} - \alpha_{j,B} A p_{j,B} \\ &= P_D r_{j,D} - \alpha_{j,D} A P_D^T p_{j,D} \\ &= P_D r_{j,D} - \alpha_{j,D} P_D A p_{j,D} \\ &= P_D r_{j+1,D} \\ &= r_{j+1,D}. \end{aligned}$$

Moreover,

$$\begin{aligned} z_{j+1,B} &= P_B r_{j+1,B} = P_B P_D r_{j+1,D} \\ &= P_D^T M^{-1} P_D r_{j+1,D} = P_D^T M^{-1} r_{j+1,D} \\ &= P_D^T z_{j+1,D}. \end{aligned}$$

$$\begin{aligned} (r_{j+1,B}, z_{j+1,B}) &= (P_D r_{j+1,D}, P_D^T z_{j+1,D}) \\ &= r_{j+1,D}^T P_D^T z_{j+1,D} \\ &= (r_{j+1,D}, z_{j+1,D}). \end{aligned}$$

Hence, $\beta_{j,B} = \beta_{j,D}$. Next we have

$$\begin{aligned} p_{j+1,B} &= z_{j+1,B} + \beta_{j,B} p_{j,B} \\ &= P_D^T z_{j+1,D} + \beta_{j,D} P_D^T p_{j,D} \\ &= P_D^T p_{j+1,D}, \end{aligned}$$

which completes the proof. ∎

In the following we show how the eigenvalues and the condition number of the system preconditioned by balancing behave if we choose a finer coarse grid. Therefore, let $Z_1 \in \mathbb{R}^{n\times r}$ and $Z_2 \in \mathbb{R}^{n\times s}$ with $rank Z_1 = r$ and $rank Z_2 = s$. Define

$$\begin{aligned} E_1 := Z_1^T A Z_1 \quad \text{and} \quad E_2 := Z_2^T A Z_2, \\ P_{D_1} = I - A Z_1 E_1^{-1} Z_1^T \quad \text{and} \quad P_{D_2} = I - A Z_2 E_2^{-1} Z_2^T. \end{aligned}$$

Moreover, let

$$P_{B_1} = P_{D_1}^T M^{-1} P_{D_1} + Z_1 E_1^{-1} Z_1^T \text{ and } P_{B_2} = P_{D_2}^T M^{-1} P_{D_2} + Z_2 E_2^{-1} Z_2^T. \tag{3.7}$$

We then have the following theorem.

THEOREM 3.8. *Let A and $M \in \mathbb{R}^{n\times n}$ be symmetric positive definite. Let P_{B_1} and P_{B_2} be defined as in* (3.7). *If* $\mathrm{Im} Z_1 \subseteq \mathrm{Im} Z_2$, *then*

$$\lambda_n(P_{B_1} A) \geq \lambda_n(P_{B_2} A), \tag{3.8}$$

$$\lambda_{r+1}(P_{B_1} A) \leq \lambda_{s+1}(P_{B_2} A). \tag{3.9}$$

Moreover,

$$cond(P_{B_1}A) \geq cond(P_{B_2}A).$$

Proof. Theorem 2.12 in [16] states that

$$\lambda_n(M^{-1}P_{D_1}A) \geq \lambda_n(M^{-1}P_{D_2}A),$$
$$\lambda_{r+1}(M^{-1}P_{D_1}A) \leq \lambda_{s+1}(M^{-1}P_{D_2}A).$$

Thus, with Theorem 2.8 we get

$$\begin{aligned} cond(P_{B_1}A) &= \frac{\max(1, \lambda_n(M^{-1}P_{D_1}A))}{\min(1, \lambda_{r+1}(M^{-1}P_{D_1}A))} \\ &\geq \frac{\max(1, \lambda_n(M^{-1}P_{D_2}A))}{\min(1, \lambda_{s+1}(M^{-1}P_{D_2}A))} \\ &= cond(P_{B_2}A). \qquad \square \end{aligned}$$

If a finer grid is used as a coarse grid in the balancing preconditioner, the amount of work to solve the coarse grid system is increased. But then Theorem 3.8 states that the condition number of the system preconditioned by the balancing preconditioner decreases. In general this leads to fewer iterations, although more work is needed on the coarse grid problem.

4. Numerical experiments. In all our numerical experiments, the multiplication $y = E^{-1}b$ is done by solving y from $Ey = b$, where E is decomposed in its Cholesky factor. The choice of the boundary conditions is such that all problems have as exact solution the vector with components equal to 1. In order to make the convergence behavior representative for general problems, we chose a random vector as the starting solution instead of the zero start vector.

4.1. Artificial test problems. We apply both methods (deflation and balancing) to the Poisson equation. It appears that in the numerical experiments $\|x - x_{k,D}\|_A \leq \|x - x_{k,B}\|_A$, but for well-scaled problems the differences are very small. From Theorem 2.8 it follows that the spectrum of the balancing preconditioner consists of two parts: in one part the eigenvalues are equal to 1, and in the other part the eigenvalues are equal to the nonzero eigenvalues of the deflated matrix. This suggests that if the eigenvalues equal to 1 are interior eigenvalues, the convergence is close to the convergence of the preconditioned deflation method; otherwise these eigenvalues may influence the convergence.

Scaling properties. Note that P_DA is scaling invariant, whereas P_BA is not scaling invariant. This means that if deflation is applied to a system $\gamma Ax = \gamma b$ the effective condition number of $P_{D\gamma A}\gamma A = (I - \gamma AZ(Z^T\gamma AZ)^{-1}Z^T)\gamma A$ is independent of the scalar γ; i.e.,

$$\kappa_{eff}(P_{D\gamma A}\gamma A) = \frac{\gamma\lambda_n(P_{DA}A)}{\gamma\lambda_{r+1}(P_{DA}A)} = \kappa_{eff}(P_{DA}A),$$

whereas the condition number of $P_B\gamma A$ depends on the choice of γ,

$$\kappa(P_{B\gamma A}\gamma A) \neq \kappa(P_{BA}A).$$

To check this in practice, we do experiments with balancing using various values of γ. From Figure 4.1 it appears that the convergence of the balancing preconditioner

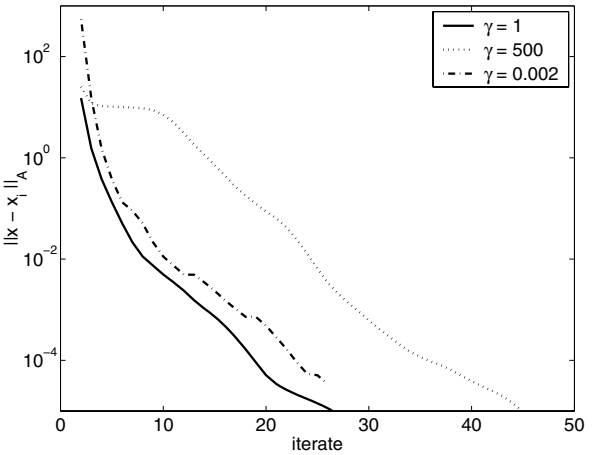

FIG. 4.1. *Comparison of the balancing preconditioner for various values of γ. The convergence of deflation is identical to the convergence of the balancing preconditioner with $\gamma = 1$.*

is worse if $\gamma \neq 1$. We note that the deflation method (for all values of γ) has the same convergence as the balancing method with $\gamma = 1$. In most preconditioning techniques an automatic scaling is used, which makes the combination scaling invariant. However, the resulting spectrum is not always clustered around 1. We used this example to illustrate what happens if the spectrum is far away from 1.

Inaccurate solution. If the dimensions of matrix E become large (i.e., many projection vectors are used), it seems to be a good idea to compute E^{-1} approximately (by an iterative method or a recursive procedure). It appears that the balancing preconditioner is insensitive to the accuracy of the approximation of E^{-1}, while deflation is sensitive to it.

To illustrate this we consider the same Poisson problem. In both examples seven projection vectors are used. We replace E^{-1} by $\tilde{E}^{-1} = (I + \epsilon R)E^{-1}(I + \epsilon R)$, where R is a symmetric $r \times r$ matrix with random elements chosen from the interval $[-\frac{1}{2}, \frac{1}{2}]$. From Figure 4.2 it follows that the convergence of the deflation preconditioner is good as long as $|\epsilon| < 10^{-6}$.

Starting solution for the balancing preconditioner. In Theorem 3.5 we have proven that $x_{k,B} = x_{k,D}$ if $x_{0,B} = ZE^{-1}Z^T b$ and $\tilde{x}_{0,D} = 0$. In this paragraph we illustrate this by numerical examples. In Figure 4.3 we plot the convergence of the balancing preconditioner with start vector $x_{0,B} = ZE^{-1}Z^T b$. It appears that the choice $\gamma = 500$ leads to the same results as $\gamma = 1$ (and deflation). Furthermore, the convergence for the choice $\gamma = 0.002$ is initially also the same, but later on the convergence becomes worse. This can be explained by rounding errors. Using the choice $\gamma = 0.002$ the eigenvalues equal to 1 are large with respect to the other eigenvalues. Initially, due to the start vector the components of the corresponding eigenvectors are zero or small. During the iterations, the perturbations in large eigencomponents increase, which leads to the same convergence as if the method is started with $x_{0,B} = 0$. To enlarge the rounding error effect we have also done experiments where the matrix E^{-1} is replaced by $\tilde{E}^{-1}$ with $\epsilon = 10^{-2}$. The results are given in Figure 4.4. Note that the same effect now appears for both values of $\gamma \neq 1$.

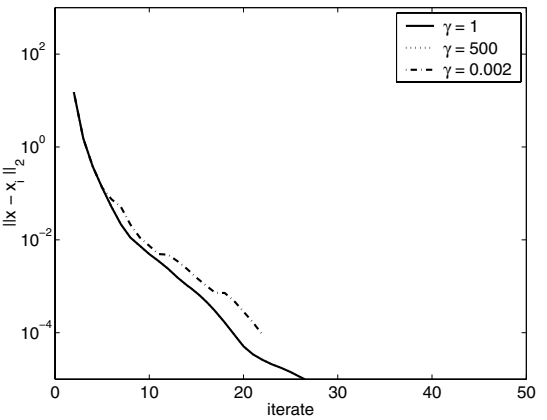

FIG. 4.3. *Convergence of the balancing preconditioner with* $x_{0,B} = ZE^{-1}Z^Tb$ *and* $\epsilon = 0$. *The convergence of deflation is identical to the convergence of the balancing preconditioner with* $\gamma = 1$.

4.2. Porous media flows. In this section we simulate a porous media oil flow in a 3-dimensional layered geometry, where the layers vary in thickness and orientation (see Figures 4.5 and 4.6 for a 4-layer problem). The fluid pressure and permeability are denoted by p and σ, respectively. The pressure p satisfies the equation

$$-\text{div}(\sigma \nabla p) = 0 \text{ on } \Omega, \tag{4.1}$$

with boundary conditions

$$p = 1 \text{ on } \partial\Omega^D \text{ (Dirichlet) and } \frac{\partial p}{\partial n} = 0 \text{ on } \partial\Omega^N \text{ (Neumann)},$$

where $\partial\Omega = \partial\Omega^D \cup \partial\Omega^N$. In this problem $\partial\Omega^D$ is the top boundary of the domain. Figure 4.5 shows a part of the earth's crust. The depth of this part varies between 3 and 6 kilometers, whereas horizontally its dimensions are 40×60 kilometers. The upper layer is a mixture of sandstone and shale and has a permeability of 10^{-4}. Below this layer, shale and sandstone layers are present with permeabilities of 10^{-7} and 10,

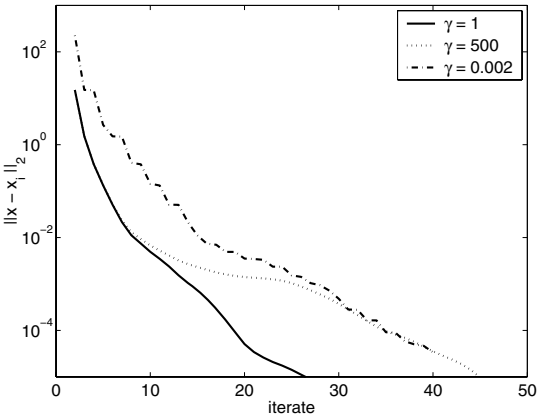

FIG. 4.4. *Convergence of the balancing preconditioner with* $x_{0,B} = ZE^{-1}Z^Tb$ *and* $\epsilon = 10^{-2}$.

respectively. An incomplete Cholesky factorization with no fill in is used as preconditioner [14]. We consider a problem with nine layers. Five sandstone layers are separated by four shale layers. Due to the Dirichlet boundary condition at the top, the preconditioned matrix has four small eigenvalues. We use four *physical* projection vectors [26] and stop if $\|r_k\|_2 \leq 10^{-5}$. Trilinear hexahedral elements are used and the total number of gridpoints is equal to 148185. The results are given in Table 4.1. It appears that the norms of the residuals for both preconditioners are the same. Due to extra work per iteration the balancing preconditioner costs more CPU time. We note that it is possible to implement the balancing preconditioner such that the costs are the same as those of deflation [11]. However, this implementation also leads to the same difficulties as deflation if the matrix E^{-1} is perturbed. The computations

are performed on an AMD Athlon, 1.4 GHz processor with 256 Mb of RAM. The code is compiled with FORTRAN g77 on LINUX.

5. Conclusions. In this paper we compared various preconditioners for the numerical solution of partial differential equations.

We have given a detailed comparison of the well-known balancing preconditioner used in domain decomposition methods and the deflation preconditioner.

We proved that both preconditioners lead to almost the same spectra. The zero eigenvalues of the deflation preconditioned system are replaced by eigenvalues which are one if the balancing preconditioner is used. Thus the effective condition number of the deflated preconditioned system is always, i.e., for all deflation vectors and all restrictions and prolongations, below or equal to the condition number of the system preconditioned by the balancing preconditioner. Moreover, we proved that the A-norm of the errors of the iterates built by the deflation preconditioner is always below the A-norm of the errors of the iterates built by the balancing preconditioner. Hence, the CG-method applied to the deflated preconditioned system never converges slower than the CG-method applied to the system preconditioned by the balancing preconditioner. Additionally, the amount of work of one iteration of the deflation preconditioned system is less than the amount of work of one iteration of the balancing preconditioned system. Hence the deflation preconditioner leads to fewer iterations and each iteration having less work.

Moreover, we established that the deflation preconditioner and the balancing preconditioner produce the same iterates if one uses certain starting vectors. More precisely, we showed which terms in the PCG-method are the same for both methods and which terms are different. Numerical results for porous media flows emphasized the theoretical results.

A COMPARATIVE STUDY OF ITERATIVE SOLVERS EXPLOITING SPECTRAL INFORMATION FOR SPD SYSTEMS*

LUC GIRAUD†, DANIEL RUIZ‡, AND AHMED TOUHAMI§

Abstract. When solving the symmetric positive definite (SPD) linear system $\mathbf{Ax}^\star = \mathbf{b}$ with the conjugate gradient method, the smallest eigenvalues in the matrix $\mathbf{A}$ often slow down the convergence. Consequently if the smallest eigenvalues in $\mathbf{A}$ could somehow be "removed," the convergence may be improved. This observation is of importance even when a preconditioner is used, and some extra techniques might be investigated to further improve the convergence rate of the conjugate gradient on the given preconditioned system. Several techniques have been proposed in the literature that consist of either updating the preconditioner or enforcing conjugate gradient to work in the orthogonal complement of an invariant subspace associated with the smallest eigenvalues. The goal of this work is to compare several of these techniques in terms of numerical efficiency. Among various possibilities, we exploit the PARTIAL SPECTRAL FACTORIZATION algorithm presented in [M. Arioli and D. Ruiz, Technical Report RAL-TR-2002-021, Rutherford Appleton Laboratory, Atlas Center, Didcot, Oxfordshire, England, 2002] to compute an orthonormal basis of a near-invariant subspace of $\mathbf{A}$ associated with the smallest eigenvalues. This eigeninformation is used in combination with different solution techniques. In particular we consider the deflated version of conjugate gradient. As representative of techniques exploiting the spectral information to update the preconditioner we consider also the approaches that attempt to shift the smallest eigenvalues close to one where most of the eigenvalues of the preconditioned matrix should be located. Finally, we consider an algebraic two-grid scheme inspired by ideas from the multigrid philosophy. In this paper, we describe these various variants and we compare their numerical behavior on a set of model problems from Matrix Market or arising from the discretization via the finite element technique of some two-dimensional (2D) heterogeneous diffusion PDE problems. We discuss their numerical efficiency, computational complexity, and sensitivity to the accuracy of the eigencalculation.

1. Introduction.

Many problems in engineering and physics require solving successively linear systems of the form

$$\mathbf{Ax}^\star = \mathbf{b} \tag{1.1}$$

with the same coefficient matrix $\mathbf{A}$ but different right-hand sides $\mathbf{b}$ not available simultaneously. We can reduce the cost of solving subsequent systems in the sequence by recycling some spectral information about the matrix $\mathbf{A}$ extracted from previous solves. This can be of particular interest, for instance, in the asymptotic development of solutions of thick plates problems. Indeed, this application requires solving successive symmetric positive definite (SPD) linear systems with the same matrix, but where each solution at a given order in the development depends upon the previous

order [22]. This type of situation can also occur in the solution of nonlinear systems by means of an approximate Newton method, where the approximate Jacobian matrix is frozen during several iterations and just the right-hand side is updated sequentially.

When the matrix $\mathbf{A}$ is large, sparse, and SPD, the Krylov solver of choice is the conjugate gradient [20], which constructs the kth iterate $\mathbf{x}^{(k)}$ as an element of

$$\mathbf{x}^{(0)} + \mathrm{Span}\{\mathbf{r}^{(0)}, \ldots, \mathbf{A}^{(\mathrm{k}-1)}\mathbf{r}^{(0)}\}$$

so that the $\mathbf{A}$-norm of the error, $||\mathbf{e}^{(k)}|| = ||\mathbf{x}^{(k)} - \mathbf{x}^{\star}||_{\mathbf{A}}$, is minimized, where $\mathbf{x}^{\star}$ is the exact solution of (1.1). The convergence of the conjugate gradient method is governed by the eigenvalues distribution in $\mathbf{A}$ [37]. A coarse characterization is given by the bound on the rate of convergence of the conjugate gradient method given by Concus, Golub, and O'Leary [8] viz.

$$||\mathbf{e}^{(k)}||_{\mathbf{A}} \leq \mathbf{2}\, ||\mathbf{e}^{(0)}||_{\mathbf{A}} \left(\frac{\sqrt{\kappa} - 1}{\sqrt{\kappa} + 1} \right)^{k}, \tag{1.2}$$

where $\kappa = \lambda_{\max}/\lambda_{\min}$ denotes the condition number of $\mathbf{A}$. From this bound, it can be seen that increasing the size of the smallest eigenvalues will substantially decrease the upper bound (1.2) on the convergence rate of the conjugate gradient.

Additionally, in the presence of clusters of eigenvalues at the extreme of the spectrum of $\mathbf{A}$, combined with some ill-conditioning, the classical conjugate gradient may show a convergence history with sequences of plateaux and sharp drops. These plateaux (see [37]) are well understood and correspond to the discovery of separate eigenvalues within a cluster. The problem is that these plateaux can be rather large, in terms of the number of iterations, even when these extreme clusters incorporate only a few eigenvalues. Block conjugate gradient can help to reduce the size of these plateaux but in general cannot remove them completely (see, e.g., [1, 6, 30]). Thus removing the bad effect of small eigenvalues in the matrix $\mathbf{A}$ might have a beneficial effect on the convergence.

In the following, we assume that $\mathbf{A}$ is a large SPD preconditioned matrix with a spectrum largely clustered, and the goal is to solve several linear systems in sequence, with the same matrix $\mathbf{A}$ but with changing right-hand sides that are computed sequentially. In this context, several techniques have been proposed in the literature to improve the convergence of conjugate gradient type methods on the solution of each system; these techniques consist of either updating the preconditioner or enforcing conjugate gradient to work in the orthogonal complement of an invariant subspace associated with the smallest eigenvalues. The aim of this work is to compare several of these techniques in terms of numerical efficiency.

In this paper, as one possible choice amongst several, we exploit the "partial spectral factorization" algorithm introduced in [2] to compute an orthonormal basis $\mathbf{W}$ of a near invariant subspace of $\mathbf{A}$ associated with the smallest eigenvalues. This basis is then exploited in combination with different solution techniques. In particular we consider the deflated version of conjugate gradient described in [34]. This algorithm exploits the link between the Lanczos algorithm and the standard conjugate gradient algorithm, and is mathematically equivalent to the Nicolaide's algorithm which is derived from a "deflated" Lanczos procedure [29]. In [23] Kolotilina uses a twofold deflation technique for simultaneously deflating the k largest and the k smallest eigenvalues using an appropriate deflating subspace of dimension k. An alternative technique consists in applying the deflation to eliminate the bad effects on

the convergence caused by the remaining small eigenvalues [10, 39]. This technique is used in [9] to solve electromagnetic problems with large jumps in the coefficients. Similar ideas have also been applied to nonsymmetric problems using the GMRES algorithm (see, e.g., [3, 7, 12, 25, 26, 27]). As representative of techniques exploiting spectral information to update the preconditioner, we consider the approach proposed in [4] that attempts to shift the smallest eigenvalues close to one, where most of the eigenvalues of the preconditioned matrix should be located. Finally, we consider an algebraic two-grid scheme inspired by ideas from the multigrid philosophy.

The outline of the paper is as follows. We devote section 2 to various solution techniques that exploit some spectral information extracted from the matrix $\mathbf{A}$, and we indicate how they can be combined with "partial spectral factorization" to construct efficient iterative solvers. In section 3, we compare these techniques in terms of numerical behavior on a set of model problems from Matrix Market, or arising from the discretization via the finite element technique of some heterogeneous diffusion PDEs in two dimensions. In section 4, we analyze in more detail the computational complexity of these different solution techniques, and we investigate how they can be used efficiently to solve a sequence of linear systems with the same matrix but changing right-hand sides. Finally, we conclude with some remarks and perspectives in section 5.

2. Alternative techniques for the solution of linear systems exploiting partial spectral decomposition. In this section, we consider solution techniques that exploit some spectral information of the matrix $\mathbf{A}$. The common general idea beneath all such techniques, as we will see in detail in the following paragraphs, is to use some precomputed *near*-invariant subspace $\mathbf{W}$, associated with the smallest eigenvalues in $\mathbf{A}$, to build a projection onto the orthogonal complement of $\mathbf{W}$ in some appropriate norm. This projector is then exploited to maintain, implicitly or explicitly, throughout the iterations, the computed residuals in this orthogonal complement. In this section, we discuss six different solution techniques that exploit this general idea, but each in a different manner.

A first idea can be to decompose the solution of (1.1) into two parts. The first can be obtained directly with an oblique projection of the right-hand side $\mathbf{b}$ onto the orthogonal complement of $\mathbf{W}$. The second part of this solution can then be obtained with the use of conjugate gradient with the first part of this solution as a starting guess, as detailed in section 2.1.

The following three techniques make use of such a projector explicitly throughout the iterations. The first one, as discussed in section 2.2, is to augment the Krylov space generated in the conjugate gradient iterations with the basis $\mathbf{W}$, and resumes in a deflation at each iteration of the generated Krylov vectors. The second one, introduced in section 2.3, is to run the conjugate gradient algorithm onto the projected system $\mathcal{P}\mathbf{A}\mathbf{x} = \mathcal{P}\mathbf{b}$, where $\mathcal{P}$ is a projector onto the orthogonal complement of $\mathbf{W}$ that commutes in some way with $\mathbf{A}$. The last technique, detailed in section 2.4, aims at building a preconditioner in $\mathbf{A}$ that shifts, by adding the value 1, those eigenvalues linked to the *near*-invariant subspace $\mathbf{W}$, and to run a preconditioned conjugate gradient in the usual way to compute the solution of (1.1).

In section 2.5, we describe the Chebyshev-based filtering technique combined with some Lanczos process used for computation of the partial spectral factorization with some chosen level of accuracy.

In section 2.6 Chebyshev iteration can also be used to compute the part of the solution associated with the largest eigenvalues in $\mathbf{A}$. The second part of the solution

is obtained with an oblique projection of the initial residual onto the *near*-invariant subspace, in order to get those eigencomponents in the solution corresponding to the smallest eigenvalues of $\mathbf{A}$, and exploits the precomputed partial spectral factorization of $\mathbf{A}$.

Finally, in section 2.7, we introduce algebraic two-grid methods which provide an alternative interpretation of some of the techniques discussed above and offer the possibility of deriving a family of iterative techniques based on the precomputation of the approximate invariant subspace $\mathbf{W}$.

2.1. Conjugate gradient with an oblique projection for the initial guess. As proposed in [32, 33, 34, 38], once an approximation of the invariant subspace $\mathbf{W}$ associated with the smallest eigenvalues is obtained, we can use it for the computation of further solutions. The idea is to perform an oblique projection of the initial residual onto this invariant subspace in order to get the eigencomponents in the solution corresponding to the smallest eigenvalues. The update of the initial guess is defined by (2.1). A classical conjugate gradient is performed to compute the remaining part of the solution vector. We call this algorithm INIT-CG (see, e.g., [13]).

$$\mathbf{x}^{(0)} = \mathbf{W}\Big(\mathbf{W}^T\mathbf{A}\mathbf{W}\Big)^{-1}\mathbf{W}^T\mathbf{b}. \tag{2.1}$$

Note that we do not project the given matrix in any way but that we just run the classical conjugate gradient with the original matrix and an initial guess which we expect to remove all the troubles that the classical conjugate gradient algorithm would encounter otherwise.

2.2. The deflated conjugate gradient. In this subsection, we consider the deflated version of conjugate gradient described in [34] and called DEF-CG. This algorithm exploits the link between the Lanczos algorithm and the standard conjugate gradient algorithm, and is mathematically equivalent to Nicolaide's algorithm which is derived from a "deflated" Lanczos procedure [29].

Let p real vectors $\mathbf{w}^{(1)}, \mathbf{w}^{(2)}, \ldots, \mathbf{w}^{(p)}$ be given, along with a unit vector $\mathbf{v}^{(1)}$ that is orthogonal to $\mathbf{w}^{(i)}$ for $i = 1, 2, \ldots, p$. Define $\mathbf{W} = [\mathbf{w}^{(1)}, \mathbf{w}^{(2)}, \ldots, \mathbf{w}^{(p)}]$. We assume that $[\mathbf{w}^{(1)}, \mathbf{w}^{(2)}, \ldots, \mathbf{w}^{(p)}]$ is a set of linearly independent vectors. The deflated conjugate gradient algorithm builds a sequence $\{\mathbf{v}^{(k)}\}_{k=1,2,\ldots}$ of vectors such that

$$\mathbf{v}^{(k+1)} \perp \mathrm{Span}\{\mathbf{W}, \mathbf{v}^{(1)}, \mathbf{v}^{(2)}, \ldots, \mathbf{v}^{(\mathrm{k})}\} \text{ and } ||\mathbf{v}^{(\mathrm{k}+1)}||_2 = 1.$$

Assume an initial guess $\mathbf{x}^{(0)}$ is given such that $\mathbf{r}^{(0)} = \mathbf{b} - \mathbf{A}\mathbf{x}^{(0)} \perp \mathbf{W}$. We set $\mathbf{v}^{(1)} = \mathbf{r}^{(0)}/||\mathbf{r}^{(0)}||_2$. Define

$$\mathcal{K}_{p,k}(\mathbf{A}, \mathbf{W}, \mathbf{r}^{(0)}) = \mathrm{Span}\{\mathbf{W}, \mathbf{v}^{(1)}, \mathbf{v}^{(2)}, \ldots, \mathbf{v}^{(\mathrm{k})}\},$$

where the $\mathbf{v}^{(k)}$ are the generated Krylov vectors at step k.

At the kth step of our projection method, we seek an approximate solution $\mathbf{x}^{(k)}$ with

$$\mathbf{x}^{(k)} \in \mathbf{x}^{(0)} + \mathcal{K}_{p,k}(\mathbf{A}, \mathbf{W}, \mathbf{r}^{(0)}) \quad \text{such that} \quad \mathbf{r}^{(k)} = \mathbf{b} - \mathbf{A}\mathbf{x}^{(k)} \perp \mathcal{K}_{p,k}(\mathbf{A}, \mathbf{W}, \mathbf{r}^{(0)}).$$

This technique resumes in performing, at the beginning of the conjugate gradient algorithm, an oblique projection of the initial residual onto the basis $\mathbf{W}$ and an update of the initial residual viz.

$$\mathbf{x}^{(0)} = \mathbf{W}(\mathbf{W}^T\mathbf{A}\mathbf{W})^{-1}\mathbf{W}^T\mathbf{b} \quad \text{and} \quad \mathbf{r}^{(0)} = \mathbf{b} - \mathbf{A}\mathbf{x}^{(0)}, \tag{2.2}$$

$$\mathbf{p}^{(0)} = \mathbf{r}^{(0)} - \mathbf{W}(\mathbf{W}^T\mathbf{A}\mathbf{W})^{-1}\mathbf{W}^T\mathbf{A}\mathbf{r}^{(0)}. \tag{2.3}$$

We then project, at each iteration, the newly constructed residual vector $\mathbf{r}^{(k)}$ onto the $\mathbf{A}$-orthogonal complement of the basis $\mathbf{W}$,

$$\mathbf{z}^{(k)} = \mathbf{r}^{(k)} - \mathbf{W}(\mathbf{W}^T\mathbf{A}\mathbf{W})^{-1}\mathbf{W}^T\mathbf{A}\mathbf{r}^{(k)}, \tag{2.4}$$

before building the next entry $\mathbf{p}^{(k)}$ in the $\mathbf{A}$-orthogonal basis of the current Krylov sequence. We refer to [34] for a complete description.

2.3. Deflation as a preconditioner. To describe this approach, which we call Proj-CG, we define the projection $\mathcal{P}$ by

$$\mathcal{P} = \mathbf{I} - \mathbf{A}\mathbf{W}(\mathbf{W}^T\mathbf{A}\mathbf{W})^{-1}\mathbf{W}^T,\ \mathbf{W} \in \mathbb{R}^{n\times p}, \tag{2.5}$$

where Span($\mathbf{W}$) is the deflation subspace, i.e., the space to be projected out of the residual, and $\mathbf{I}$ is the identity matrix. We assume $p \ll n$. We split the solution vector $\mathbf{x}$ into two parts:

$$\mathbf{x} = (\mathbf{I} - \mathcal{P}^T)\mathbf{x} + \mathcal{P}^T\mathbf{x}.$$

The first part $(\mathbf{I} - \mathcal{P}^T)\mathbf{x}$ is the component of $\mathbf{x}$ contained in $\mathbf{W}$, whereas the second part $\mathcal{P}^T\mathbf{x}$ is orthogonal to $\mathbf{W}$. The first part is computed from

$$\Big(\mathbf{I} - \mathcal{P}^T\Big)\mathbf{x} = \Big(\mathbf{A}\mathbf{W}(\mathbf{W}^T\mathbf{A}\mathbf{W})^{-1}\mathbf{W}^T\Big)^T\mathbf{x} = \mathbf{W}\Big(\mathbf{W}^T\mathbf{A}\mathbf{W}\Big)^{-1}\mathbf{W}^T\mathbf{b}.$$

To compute the second part $\mathcal{P}^T\mathbf{x}$, we use the property $\mathbf{A}\mathcal{P}^T\mathbf{x} = \mathcal{P}\mathbf{A}\mathbf{x} = \mathcal{P}\mathbf{b}$, and we then solve the system

$$\mathcal{P}\mathbf{A}\mathbf{x} = \mathcal{P}\mathbf{b}. \tag{2.6}$$

Kaasschieter [21] notes that a positive semidefinite system can be solved by conjugate gradient as long as the right-hand side is consistent (i.e., as long as $\mathbf{b} = \mathbf{A}\mathbf{x}$ for some $\mathbf{x}$). This is certainly true for (2.6), where the same projection is applied to both sides of the nonsingular system. Furthermore, he notes that, because the null space never enters the iteration, the corresponding zero-eigenvalues do not influence the convergence. We refer the reader to [28] for a complete description.

2.4. A spectral low-rank update preconditioner. In this subsection, we consider the approach proposed in [4] that attempts to remove the effect of the smallest eigenvalues in magnitude in the preconditioned matrix, which potentially can slow down the convergence of Krylov solvers. Roughly speaking, the proposed technique consists in building the preconditioner

$$\mathbf{M} = \mathbf{I} + \mathbf{W}\Big(\mathbf{W}^T\mathbf{A}\mathbf{W}\Big)^{-1}\mathbf{W}^T \tag{2.7}$$

that aims to shift, by adding the value 1, those eigenvalues in the matrix $\mathbf{A}$ linked to the *near*-invariant subspace $\mathbf{W}$.

We can then use this spectral preconditioner $\mathbf{M}$ to run the preconditioned conjugate gradient, that will benefit from the reduced condition number of the preconditioned matrix $\mathbf{MA}$, thus yielding the algorithm which we call SLRU (spectral low-rank update; see [4]).

2.5. A Chebyshev-based partial spectral factorization. The purpose of this subsection is to briefly describe the combination of Chebyshev filtering polynomials with a Lanczos-type technique (see, e.g., [17, 31, 36]) to derive a *near*-invariant subspace of $\mathbf{A}$ associated with the smallest eigenvalues in $\mathbf{A}$ with some chosen level of accuracy. This technique corresponds to the CHEBYSHEV-PSF algorithm detailed in [2], [14, sect. 2], and [35, sect. 2.3] and can be summarized as follows.

The CHEBYSHEV-PSF algorithm exploits Chebyshev polynomials in $\mathbf{A}$ to damp, in a set of vectors, the eigencomponents associated with all the eigenvalues in some predetermined range $[\mu, \lambda_{\max}(\mathbf{A})]$, where μ is some fixed (user-given) positive number. Let us denote by

$$\mathbf{A} = \mathbf{U}\Lambda\mathbf{U}^T = \mathbf{U}_1\Lambda_1\mathbf{U}_1^T + \mathbf{U}_2\Lambda_2\mathbf{U}_2^T$$

the eigendecomposition of the SPD matrix $\mathbf{A}$, Λ_1 being the diagonal matrix made with all eigenvalues of $\mathbf{A}$ less than μ, $\mathbf{U}_1$ the unitary matrix whose columns are the corresponding orthonormalized eigenvectors in matrix form, and Λ_2 and $\mathbf{U}_2$ the complementary corresponding matrices. We can then introduce the Chebyshev polynomials (see, e.g., [19]), $\mathcal{F}_m(\lambda)$, that have a minimum l_∞-norm on the interval $[\mu, \lambda_{\max}(\mathbf{A})]$ over all polynomials Q_m of degree less than or equal to m and satisfying $Q_m(0) = 1$. Let now $\mathbf{P}$ be a set of vectors, and consider

$$\mathbf{Z} = \mathcal{F}_m(\mathbf{A})\,\mathbf{P} = \mathbf{U}_1\mathcal{F}_m(\Lambda_1)\mathbf{U}_1^T\,\mathbf{P} + \mathbf{U}_2\mathcal{F}_m(\Lambda_2)\mathbf{U}_2^T\,\mathbf{P}. \tag{2.8}$$

For given values of μ, $\lambda_{\max}(\mathbf{A})$, and ε, we can fix the degree m of $\mathcal{F}_m$ such that $||\mathcal{F}_m(\Lambda_2)||_\infty < \varepsilon$, and using (2.8) we get

$$||\mathbf{U}_2^T\,\mathbf{Z}||_2 \leq ||\mathcal{F}_m(\Lambda_2)||_2\,||\mathbf{U}_2^T\,\mathbf{P}||_2 \leq \varepsilon\,||\mathbf{U}_2^T\,\mathbf{P}||_2. \tag{2.9}$$

Equation (2.9) explains explicitly how the action of the Chebyshev polynomials in $\mathbf{A}$ applied on a set of vectors can reduce, by some given factor ε, the eigencomponents with respect to the invariant subspace $\mathbf{U}_2$ relatively to the others. The idea in the CHEBYSHEV-PSF algorithm is then to combine such Chebyshev polynomials in $\mathbf{A}$ with Lanczos techniques (see, e.g., [17, 31, 36]) to directly build a *near*-invariant basis for the invariant subspace associated with all eigenvalues in the range $[\lambda_{\min}(\mathbf{A}), \mu]$.

As opposed to classical polynomial preconditioning techniques, and as explained by (2.9), the use of Chebyshev filtering polynomials in the context of the Lanczos iteration can be viewed as a way to perform implicitly some sort of deflation with respect to the invariant subspace linked with the largest eigenvalues in $\mathbf{A}$. Chebyshev filtering polynomials, in that respect, do not present the same nice properties as projectors used commonly in such deflation, which have explicit eigenvalues equal to 0 and 1. Still, they can partly mimic these properties, and offer an alternative to achieve the same behavior in the Lanczos iteration as with deflation techniques, but without having to effectively compute the basis vectors associated with this deflation.

Of course, to be efficient, the method relies on the fact that the spectrum of $\mathbf{A}$ is mostly concentrated in the range $[\mu, \lambda_{\max}(\mathbf{A})]$, with reasonable value of μ (like $\lambda_{\max}/100$ or $\lambda_{\max}/10$, for instance) so that the number of Chebyshev iterations required to reach a given filtering level ε are not too large. In that respect, a preliminary preconditioner applied to $\mathbf{A}$, with classical preconditioning techniques, can also be useful to transform and clusterize better the spectrum in the iteration matrix.

Additionally, the CHEBYSHEV-PSF algorithm is designed to control explicitly the level of filtering ε of the eigencomponents between $\mathbf{U}_1$ and $\mathbf{U}_2$ in the computed

approximate invariant subspace basis $\mathbf{W}$ (function of ε), as indicated in (2.9). In the following, we compare the different proposed approaches for the solution of linear systems with $\mathbf{A}$, combined with the computation of a *near*-invariant orthonormal basis $\mathbf{W}$ obtained with this Chebyshev-Partial Spectral Factorization. We shall also vary the level of filtering ε in this Chebyshev-PSF algorithm, and evaluate the performance of all these solution techniques with respect to this control of the numerical quality of the basis $\mathbf{W}(\varepsilon)$.

2.6. Combination of oblique projection and Chebyshev iteration. In this subsection, we describe how we use the *near*-invariant subspace $\mathbf{W}$ linked to the smallest eigenvalues to compute the solution of the linear system with $\mathbf{A}$.

The idea is to perform an oblique projection of the initial residual ($\mathbf{r}^{(0)} = \mathbf{b} - \mathbf{A}\mathbf{x}^{(0)}$) onto this *near*-invariant subspace in order to get the eigencomponents in the solution corresponding to the smallest eigenvalues, viz.

$$\begin{aligned} &\mathbf{r}^{(\mathrm{proj})} = \mathbf{r}^{(0)} - \mathbf{A}\mathbf{W}\Big(\mathbf{W}^T\mathbf{A}\mathbf{W}\Big)^{-1}\mathbf{W}^T\mathbf{r}^{(0)}, \\ \text{with} \quad &\mathbf{x}^{(\mathrm{proj})} = \mathbf{x}^{(0)} + \mathbf{W}\Big(\mathbf{W}^T\mathbf{A}\mathbf{W}\Big)^{-1}\mathbf{W}^T\mathbf{r}^{(0)}. \end{aligned} \tag{2.10}$$

To compute the remaining part of the solution vector $\mathbf{A}\widetilde{\mathbf{x}} = \mathbf{r}^{(\mathrm{proj})}$, one can then use the classical Chebyshev algorithm with eigenvalue bounds given by μ and $\lambda_{\max}(\mathbf{A})$. This technique is called Init-Chebyshev (for technical details, see [14, sect. 3.1]).

Note that, if $\mathbf{W}$ exactly spans the invariant subspace generated by $\mathbf{U}_1$, the Chebyshev iteration and the oblique projection steps in this solution phase can be performed, though sequentially, in any order a priori. However, since Span($\mathbf{W}$) is only an approximation of this invariant subspace, we prefer to perform the Chebyshev step first, followed then by the oblique projection, because this helps to increase the accuracy of the oblique projection by *minimizing* the influence of the eigencomponents in $\mathbf{U}_2$ relative to those in $\mathbf{U}_1$ in the scalar products $\mathbf{W}^T\mathbf{r}$ in (2.10). This is of particular interest when the filtering level ε used to compute the basis $\mathbf{W}$, as in section 2.5, is not close to machine precision.

The number of Chebyshev iterations to achieve a given level of filtering ε is directly related to the rate of convergence of Chebyshev polynomials on the interval $[\mu, \lambda_{\max}]$ (see, e.g., [15, 19]) which depends only on the ratio $\lambda_{\max}/\mu$. This technique also enables us to control a priori, with some forward error analysis (see, e.g., [2]), the $\mathbf{A}$-norm of the error in subsequent solutions of linear systems with the same matrix.

2.7. Algebraic two-grid cycle. The multigrid methods are among the fastest techniques to solve a linear system (1.1) arising from the discretization of elliptic PDEs [18]. The core of the multigrid algorithms is a two-grid procedure that is applied recursively. A classical two-grid cycle can be briefly described as follows.

On the fine grid a few iterations of a presmoother are applied that attempt to reduce the high frequencies of the error (i.e., the components of the error in the space spanned by the vectors associated with the largest eigenvalues of $\mathbf{A}$). The residual is then projected on the coarse grid where the low frequencies, that are the components associated with the smallest eigenvalues, can be captured and the coarse error equation is solved. The coarse error is prolongated back to the fine grid to update the approximation computed by the presmoother and a few more steps of the smoother are applied. Finally, if the new iterate is not accurate enough, this two-grid

cycle is applied iteratively, viz.

$$\begin{aligned} \mathbf{x}_1 &= \mathbf{S}(\mathbf{x}, \mathbf{b}, \xi), \\ \mathbf{x}_2 &= \mathbf{x}_1 + \mathbf{W}\mathbf{A}_c^{-1}\mathbf{W}^T(\mathbf{b} - \mathbf{A}\mathbf{x}_1), \\ \mathbf{x} &= \mathbf{S}(\mathbf{x}_2, \mathbf{b}, \xi), \end{aligned} \tag{2.11}$$

where $\mathbf{S}(\mathbf{x}, \mathbf{b}, \xi)$ defines the smoother that performs ξ iterations on the $\mathbf{x}$ to solve $\mathbf{A}\mathbf{x}^\star = \mathbf{b}$.

In classical multigrid, the coarse space is not defined explicitly through the knowledge of the eigenspaces but by the selection of a space that is expected to capture them. In this work, we explicitly define the coarse space by computing the eigenvectors $\mathbf{W}$ associated with the smallest eigenvalues of $\mathbf{A}$. For symmetric problems, the restriction operator is denoted $\mathbf{R} = \mathbf{W}^T$ and the prolongation operator is its transpose. The matrix associated with the coarse grid error problem is defined by a Galerkin formula $\mathbf{A}_c = \mathbf{R}\,\mathbf{A}\,\mathbf{R}^T$. In this scheme, different smoothers (CG, Chebyshev, damped Richardson) can be used. We refer to [5], where this approach is used to design preconditioners and where the spectral transformation associated with this scheme is analyzed.

3. Numerical experiments. In this section, we show some numerical results that compare the different approaches in terms of numerical efficiency for the solution of linear systems with the matrix $\mathbf{A}$. We discuss also their computational complexity and sensitivity to the accuracy of the spectral information. The precomputation of a *near*-invariant orthonormal basis $\mathbf{W}$ is obtained by means of the Chebyshev-Partial Spectral Factorization algorithm introduced in section 2.5. We shall also evaluate the impact of varying the level of filtering ε in the precomputation of the *near*-invariant basis $\mathbf{W}$(function of ε) on the performance of all these solution techniques.

In Table 3.1 we summarize for each matrix the size, the number of nonzero elements in $\mathbf{A}$, and the application in which this matrix arises. Matrices BCSSTK are obtained from the Harwell–Boeing collection [11]. PDE1 and PDE2 are extracted from the finite element discretization using **pdetool** under MATLAB of the partial differential equation problem

$$\left\{ \begin{array}{rcl} -\mathrm{div}\Big(\Lambda(x) \cdot \nabla u\Big) & = & f \quad \text{in} \quad \Omega, \\ u_{|\partial\Omega} & = & 0, \end{array} \right.$$

where $\Omega \subset \mathbb{R}^2$ is an L-shaped region as described in Figure 3.1. The major differences between PDE1 and PDE2 are in the settings for $\Lambda(x)$ and in the size of discretization.

In PDE1, $f = 10$, and the function $\Lambda(x) \in L^\infty(\Omega)$ takes different scalar values in each subdomain:

$$\Lambda(x) = \left\{ \begin{array}{ll} 1, & x \in \Omega_1 \cup \Omega_4, \\ 10^6, & x \in \Omega_2, \\ 10^4, & x \in \Omega_3. \end{array} \right.$$

In PDE2, $f = 200$, and the PDE problem incorporates some heterogeneity and

anisotropy, with the matrix $\Lambda(x)$ that takes the following values:

$$\Lambda(x) = \begin{cases} \begin{bmatrix} 1 & 4\,\lambda_1 \\ 4\,\lambda_1 & \lambda_1 \end{bmatrix} & \text{if } x \in \Omega_1 \quad \text{and} \quad \lambda_2\,\mathbf{I}_2 \quad \text{if } x \in \Omega_2, \\ \begin{bmatrix} \lambda_1 & -2\,\lambda_1 \\ -2\,\lambda_1 & 1 \end{bmatrix} & \text{if } x \in \Omega_4 \quad \text{and} \quad \lambda_3\,\mathbf{I}_2 \quad \text{if } x \in \Omega_3, \end{cases}$$

where $\lambda_1 = 6 \cdot 10^{-2}$, $\lambda_2 = 1 \cdot 10^{6}$, $\lambda_3 = 1 \cdot 10^{2}$, and $\mathbf{I}_2$ denotes the (2×2) identity matrix.

For all the numerical experiments reported in this section, a first level of preconditioner $\mathbf{M}_1 = \mathbf{L}\mathbf{L}^T$ is constructed using incomplete Cholesky factorization IC(t) of $\mathbf{A}$ with t as the threshold. The purpose of this first preliminary preconditioning of the given linear system is to better cluster the eigenvalues so that the invariant subspace associated with the smallest eigenvalues is of small dimension. We denote by $\widehat{\mathbf{b}} = \mathbf{L}^{-1}\mathbf{b}$ and $\widehat{\mathbf{A}} = \mathbf{L}^{-1}\mathbf{A}\mathbf{L}^{-T}$ the matrix symmetrically preconditioned with IC(t) which is SPD and similar to the matrix $\mathbf{M}_1^{-1}\mathbf{A}$. Additionally, in the different figures illustrating the experimental results, we shall denote by *classical CG* the preconditioned conjugate gradient with the incomplete Cholesky factorization as the first level of preconditioner only.

In Table 3.2, we give some insight about the effect of the incomplete Cholesky factorization on the eigenvalue distribution of the preconditioned matrix $\widehat{\mathbf{A}}$. For instance, we first notice the high classical condition number of order 10^{10} for the original BCSSTK14's matrix. We can also observe that the condition number of this preconditioned matrix is reduced to about 10^2. As mentioned before, a clustered

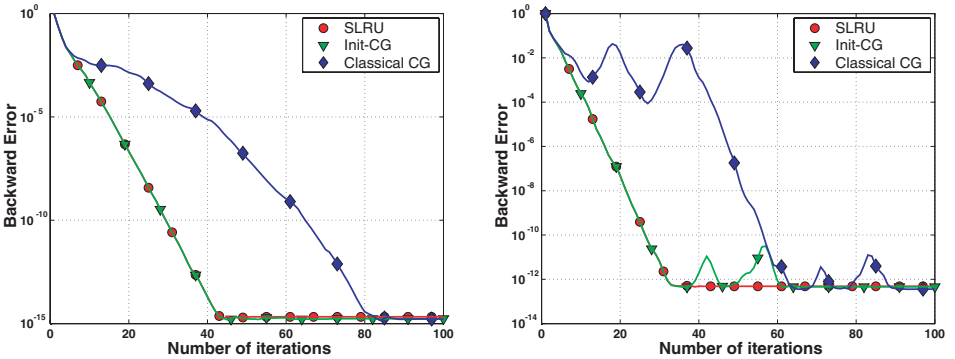
*In this case we take $\mu = \lambda_{\max}/2000$.



spectrum of the preconditioned matrix is usually considered a desirable property for fast convergence of Krylov solvers and makes the numerical techniques considered in this paper affordable because only a few eigencomponents have to be handled by a complementary approach.

The stopping criterion used in our tests is the backward error $||\widehat{\mathbf{b}} - \widehat{\mathbf{A}}\mathbf{x}^{(i)}||_2/||\widehat{\mathbf{b}}||_2$. In all our runs, we have monitored this backward error down to close to machine precision, when possible, to illustrate and study the complete convergence history of the schemes. All experiments were performed in 64 bits floating-point arithmetic using MATLAB. The initial guess is always $\mathbf{x}^{(0)} = 0$ and the right-hand side is chosen so that the solution of the initial linear system is the vector of all ones. The cut-off eigenvalue μ in the Chebyshev polynomial filters has been fixed to $\lambda_{\max}(\widehat{\mathbf{A}})/10$ whenever this was suitable, e.g., when the number of eigenvalues of the range $[0, \mu]$ was reasonably small. In particular, in the case of the larger size problem PDE2, we have preferred to keep under control the cost of the first level of preconditioning $\mathbf{M}_1$ (IC(0) in this case), and to move the cut-off value μ closer to zero ($\mu = \lambda_{\max}(\widehat{\mathbf{A}})/2000$) to incorporate only a small set of eigenvalues in the second level of preconditioning.

3.1. Comparison of the different techniques for the solution phase. In this subsection, we compare the numerical convergence behavior of the various algorithms described in section 2. As we will see in the following, the experiments show that the different algorithms exhibit very similar numerical behavior. This is particularly true when the precomputed *near*-invariant basis $\mathbf{W}(\varepsilon)$ is obtained with filtering level ε close to machine precision. In this case, this numerical behavior corresponds to the one that we would obtain in general with a linear system where the smallest eigenvalue is given by the cut-off value μ in the CHEBYSHEV-PSF algorithm, with a resulting reduced condition number of $\lambda_{\max}(\mathbf{A})/\mu$.

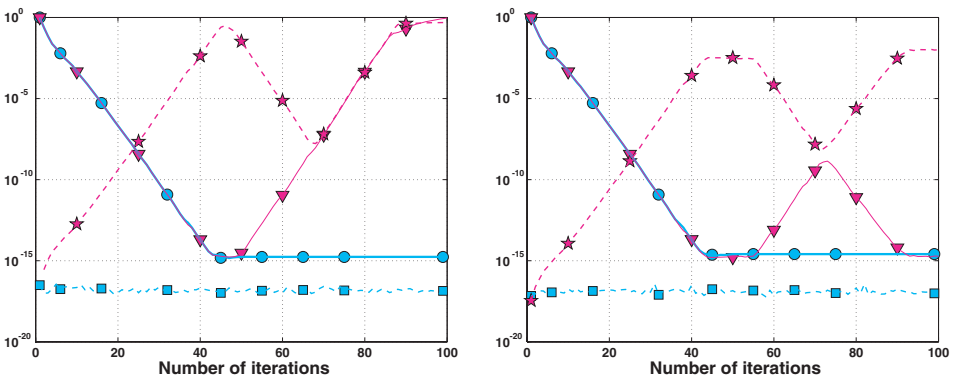


Figure 3.2 illustrates the convergence history of the conjugate gradient versus INIT-CG and SLRU obtained with a basis $\mathbf{W}(\varepsilon)$ computed with a level of filtering ε equal to 10^{-16}. The backward error of the standard conjugate gradient method tends to decrease very rapidly in the first few iterations, then decreases more slowly in an intermediate phase, during which oscillations may also appear, and finally stagnates. As opposed to this, INIT-CG and SLRU present convergence histories that coincide almost completely, except perhaps after stagnation.

DEF-CG and PROJ-CG also present the same type of convergence, at least in the first part of their convergence histograms as illustrated by the results in Figure 3.3. However, we can observe that these are also subject to some numerical instability, in particular after reaching the stagnation phase. Theoretically, the residuals $\mathbf{r}^{(k)}$ are supposed to stay orthogonal to all the columns of $\mathbf{W}(\varepsilon)$, but in practice, this

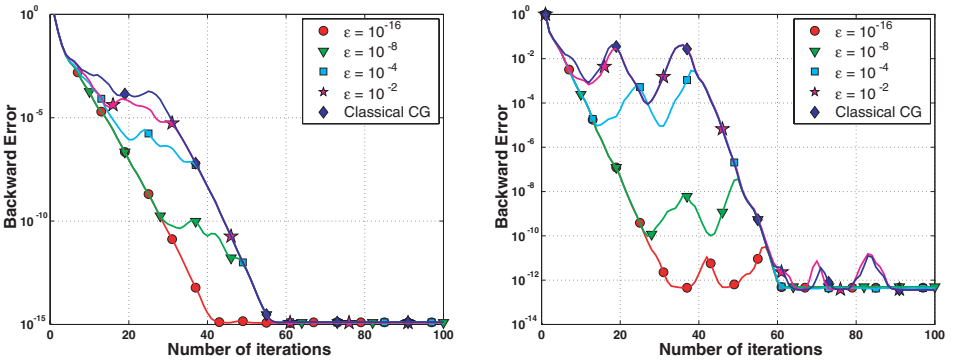
orthogonality is gradually lost as the iterations progress. Figure 3.3 shows, for matrix BCSSTK14, for instance, the histogram of

$$\text{ortho(k)} = \max_{\text{j}=1,2,\ldots,\text{p}} \left(\frac{\mathbf{w}^{(\text{j})^{\text{T}}} \mathbf{r}^{(\text{k})}}{||\mathbf{w}^{(\text{j})}||_2 ||\mathbf{r}^{(\text{k})}||_2} \right),$$

computed at each iteration k in DEF-CG and PROJ-CG. Both curves of the function ortho(k) show that loss of orthogonality is inversely proportional to the convergence of the backward error. One remedy to recover orthogonality as mentioned in [34] is to add the reorthogonalization step



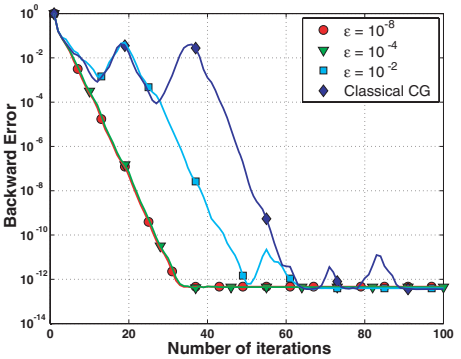
$$\mathbf{r}^{(k)} = \mathbf{r}^{(k)} - \mathbf{W}\left(\mathbf{W}^T\mathbf{W}\right)^{-1}\mathbf{W}^T\mathbf{r}^{(k)} \tag{3.1}$$

right after $\mathbf{r}^{(k)}$ is computed in DEF-CG and PROJ-CG. The computational cost of this extra step is of order $\mathcal{O}(p * n)$ per iteration.

The convergence curves with the additional correction of $\mathbf{r}^{(k)}$ are plotted with a (○, solid line) in Figure 3.3. In this case, the convergence history of DEF-CG and PROJ-CG are very much close to that of INIT-CG and SLRU as in Figure 3.2, with no more instability after convergence is reached.

In summary, when the *near*-invariant subspace basis $\mathbf{W}(\varepsilon)$ is computed with very high accuracy (i.e., with a filtering level ε close to machine precision), the INIT-CG is the algorithm of choice because it is less expensive, since it avoids the use of oblique projectors within the conjugate gradient iterations explicitly.

3.2. When the near-invariant subspace basis W is less accurate. The different solution techniques can however present very different convergence behavior when the computation of the *near*-invariant basis vectors $\mathbf{W}(\varepsilon)$ is obtained with larger values of level of filtering ε.



(a) *BCSSTK*15. (b) *PDE*1.

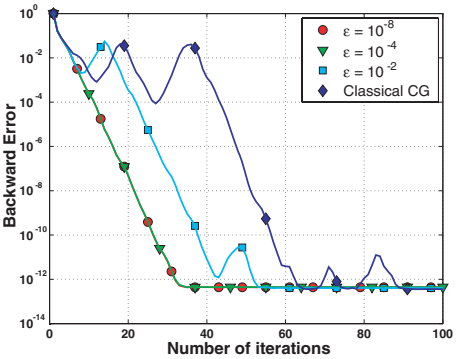


FIG. 3.4. *Convergence history of* INIT-CG *for different values of level of filtering* ε.

Figure 3.4 shows the impact of varying the filtering level ε (when computing the *near*-invariant $\mathbf{W}(\varepsilon)$ basis) on the convergence of INIT-CG. For example, when the level of filtering ε is equal to 10^{-8}, the phenomenon of plateaux occurs again, but at intermediate levels. Indeed, INIT-CG (conjugate gradient with initial oblique projection) shows two different phases in its numerical behavior. The first stage follows very closely the convergence history observed in Figure 3.2 when the computation of the $\mathbf{W}(\varepsilon)$ basis is very accurate. Then, the speed of convergence is disrupted at an intermediate level of the backward error closely related to the value of the filtering level ε, and the convergence history resembles again that of the conjugate gradient on the original system. The reason for this is that INIT-CG provides an initial residual to the conjugate gradient that has larger eigencomponents in the orthogonal complement of the basis $\mathbf{W}(\varepsilon)$ and eigencomponents of order ε in the $\mathbf{W}(\varepsilon)$ subspace. After the residual norm has been reduced to about the value of ε, the conjugate gradient is left again with a Krylov direction with eigencomponents all of about the same magnitude, and then exhibits the same type of convergence behavior linked to the complete spectrum of the given matrix. For efficiency, it is clear that one should then stop the iterations in INIT-CG at a backward error about the filtering level ε, before reaching this intermediate plateau.

As we can observe in Figure 3.6 (a), when the size of the linear system becomes very large, the phenomenon of plateaux can also occur in the numerical behavior of the INIT-CG algorithm, even with a very accurate *near*-invariant subspace basis

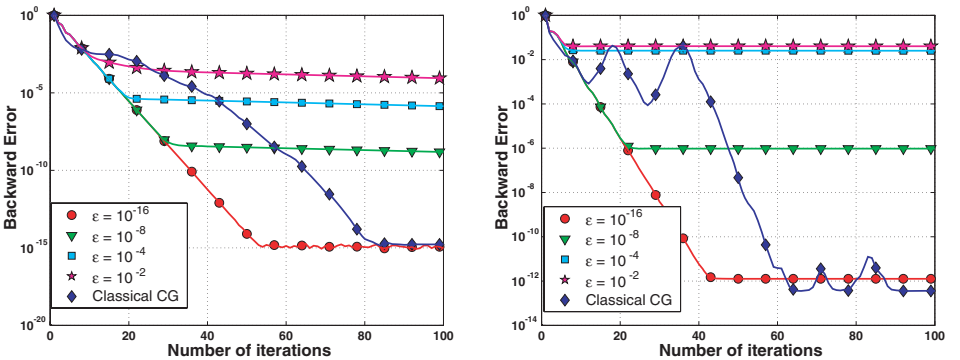
$\mathbf{W}(10^{-16})$. This is due to the sensitivity of the projector to the total size of the linear system [2].



The convergence history of DEF-CG and SLRU, depicted in Figure 3.5 for different values of the level of filtering ε, shows that these two algorithms exhibit very close numerical behaviors in any case. We can observe anyway that if the accuracy in the computation of the invariant subspace $\mathbf{W}(\varepsilon)$ is strongly deteriorated, as with a value $\varepsilon = 10^{-2}$, for instance, then the speed of convergence may vary slightly. Still, as opposed to INIT-CG, these algorithms show a constant numerical behavior close to the one observed in Figures 3.2 and 3.3, even when the filtering level is in the range 10^{-8} to 10^{-4}, as illustrated in Figure 3.5. This is the benefit of performing at each iteration of the conjugate gradient an oblique projection with the $\mathbf{W}(\varepsilon)$ basis that maintains throughout the iterations a fixed gap between the eigencomponents corresponding to the smallest eigenvalues and the others.

In Figure 3.6 (b), we compare the numerical behavior of DEF-CG and SLRU when the level of filtering ε is large. We can see that DEF-CG converges a little faster than SLRU. Knowing that the convergence of DEF-CG and PROJ-CG are very similar, a possible explanation of this (as mentioned in [28]) can be that the effective

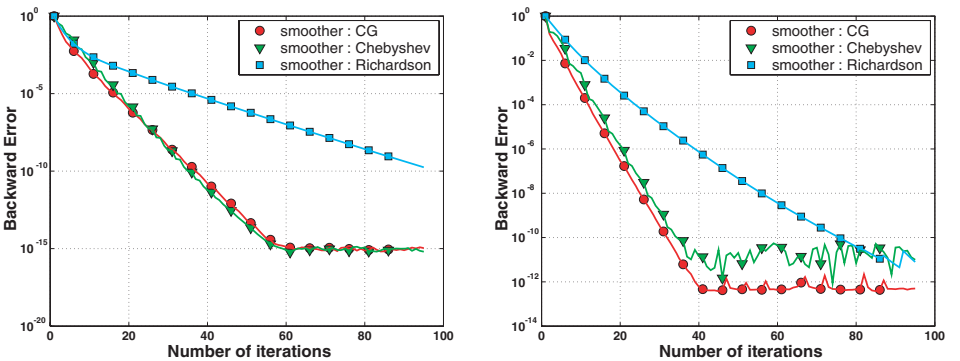
condition number of the projected system is always below the condition number of the system preconditioned by the corresponding coarse grid correction.

3.3. Combination of oblique projection and Chebyshev iteration. We have postponed in this section the discussion concerning the results for INIT-CHEBYSHEV, since it does not belong to Krylov techniques as the others. INIT-CHEBYSHEV basically corresponds to the juxtaposition of a Chebyshev iterative solver and an oblique projection that act independently on two separate subparts in the spectrum of $\mathbf{A}$. In that respect, it can be viewed either as a direct method, if the eigenspace is computed very accurately, or as a form of two-space cycle, where the smoother is defined by a few steps of Chebyshev iteration (see section 2.6).

For the sake of comparison with the results shown for the other Krylov-based iterative solution techniques, we present in Figure 3.7 the computed backward error obtained after each Chebyshev iteration combined directly with the application of the final oblique projection. Of course, this is not the way INIT-CHEBYSHEV should work, since the oblique projection should be applied only once at the end, after the termination of the Chebyshev iterations.

(a) *BCSSTK*14. (b) *PDE*1.

FIG. 3.7. *Convergence history of* INIT-CHEBYSHEV *for different values of level of filtering* ε.



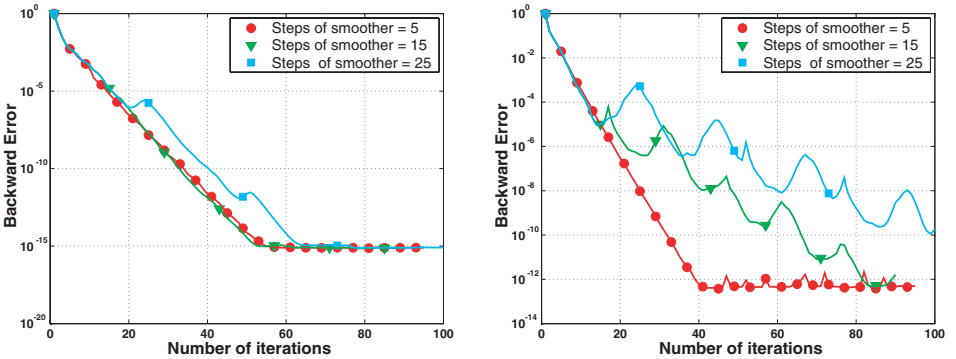
In Figure 3.7, we illustrate the effect of varying the filtering level ε (when computing the invariant basis $\mathbf{W}(\varepsilon)$) on the convergence behavior of INIT-CHEBYSHEV. When the level of filtering ε is equal to 10^{-16}, INIT-CHEBYSHEV behaves like the other algorithms, as illustrated in the previous sections, but with a little difference in the number of iterations. This is simply due to the different rates of convergence between the Chebyshev semi-iterative method and the conjugate gradient method in general.

However, for larger values of the filtering level ε, we can observe that the convergence history of INIT-CHEBYSHEV is disrupted, with a stagnation of the backward error at a level close to the actual value of ε. The reason for this is simply that the *near*-invariant basis $\mathbf{W}(\varepsilon)$ has eigencomponents of order ε with respect to those eigenvectors corresponding to eigenvalues in the range $[\mu, \lambda_{\max}]$. Obviously, this level of information is incorporated explicitly in the oblique projection onto this subspace that is applied as a final stage, and perturbs the eigencomponents in the final residual at about that level. For a more detailed analysis of this phenomenon, we refer the reader to [2].

It is also worth mentioning that this combination of oblique projection and Chebyshev iteration requires only matrix-vector products plus some vector updates, but no

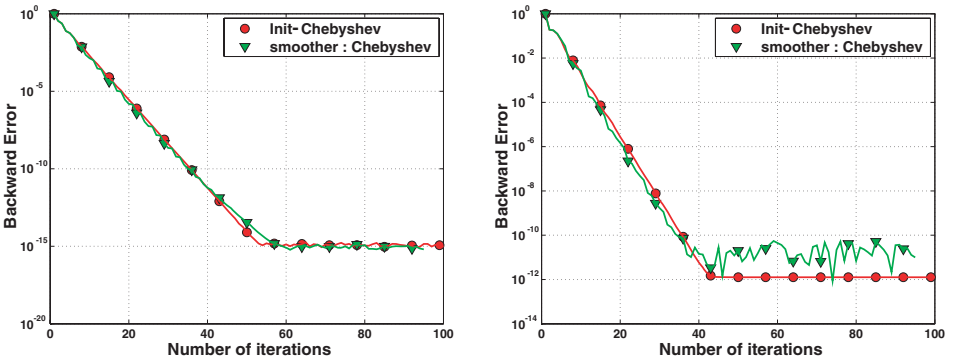
dot-products, as opposed to the other Krylov-based solution techniques. This remark is also of some importance in the context of parallel computing, and in particular in distributed memory environments where the computation of the dot-product requires particular attention.

3.4. Algebraic two-grid. As mentioned in section 2.7, one way to exploit the precomputed spectral information is to define a two-grid cycle that is run as a stationary iterative solver. This approach makes sense only when the spectral information is not computed with very high accuracy. In that latter case, the schemes based on a deflation to define the initial guess should be preferred because they require only one oblique projection. To illustrate the numerical behavior of these schemes, we depict in Figure 3.8 the convergence history of this algebraic two-grid solver using different smoothers. More precisely, for these experiments, we have implemented in our experiments a few steps of conjugate gradient, Chebyshev, or damped Richardson. For the Richardson iteration we select $\alpha_{opt} = 2/(\lambda_{\max}+\mu)$ and minimize the spectral radius of the iteration matrix (equal to $\max\{|1-\alpha\,\lambda_{\max}|, |1-\alpha\,\mu|\}$), assuming that the coarse grid correction has removed the effect of the eigenvalues in the range $[\lambda_{\min}, \mu]$. For the experiments illustrated in Figure 3.8, we have performed $\xi = 5$ smoothing steps. It can be seen that the three implementations exhibit a linear rate of convergence, and that conjugate gradient and Chebyshev have the same smoothing properties.



(a) *BCSSTK*14. (b) *PDE*1.

FIG. 3.8. *Convergence history of the two-grid cycle solver with different smoothers using a level of filtering* $\varepsilon = 10^{-4}$.



For the sake of efficiency one might want to use a value of ξ (number of smoothing steps) as large as possible in order to reduce the number of cycles, and consequently the number of oblique projections, while preserving the same rate of convergence. In Figure 3.9 we display the convergence history of the two-grid solver when the number of smoothing steps is varied; conjugate gradient is the smoother considered for those experiments. We can observe that using too large a value of ξ might delay the convergence. These situations occur when the smoother has succeeded in reducing most of the high frequencies of the error and makes only slight progress in reducing the low frequencies. Applying a coarse grid correction in that case is an efficient way to speed up the convergence. Based on this observation, a heuristic could be implemented to adapt the number of smoothing steps automatically, but we do not pursue this aspect further in this work.

The INIT-CHEBYSHEV algorithm can also be viewed as one step of a two-grid

(a) *BCSSTK*14. (b) *PDE*1.

FIG. 3.9. *Convergence history of the two-grid cycle solver when the number of smoothing steps using conjugate gradient is varied. The level of filtering is* $\varepsilon = 10^{-4}$.

FIG. 3.10. *Convergence history of the* INIT-CHEBYSHEV *algorithm obtained with a basis* $\mathbf{W}(\varepsilon)$ *computed with a level of filtering* ε *equal to* 10^{-16} *versus the Chebyshev-based two-grid solver with a number of smoothing steps* $\xi = 5$ *and a* near*-invariant* $\mathbf{W}(\varepsilon)$ *basis precomputed with a level* ε *of* 10^{-4}.

cycle, where the smoother corresponds to the Chebyshev iteration. In Figure 3.10, we compare the convergence history of the INIT-CHEBYSHEV algorithm, obtained with a basis $\mathbf{W}(\varepsilon)$ computed with a level of filtering ε equal to 10^{-16}, versus the Chebyshev-based two-grid solver with a number of smoothing steps $\xi = 5$, and a *near*-invariant $\mathbf{W}(\varepsilon)$ basis precomputed with a level ε of 10^{-4}. As mentioned in section 3.3, the convergence history of INIT-CHEBYSHEV is disrupted, with a stagnation of the backward error at a level close to the actual value of ε. As opposed to this, the two-grid cycle solver, with Chebyshev as the smoother, shows the same curve of convergence as that of the INIT-CHEBYSHEV algorithm obtained with a very accurately precomputed $\mathbf{W}(\varepsilon)$ basis ($\varepsilon = 10^{-16}$). This illustrates the benefit of using a two-grid cycle scheme when the spectral information is not very accurate.

In the case of our test examples, we have seen that the convergence rate of the two-grid cycle scheme, using conjugate gradient as the smoother and a suitable value of ξ (i.e., not too large), has a convergence history very similar to the one obtained with SLRU when ε is small enough (i.e., less than or equal to 10^{-4}). Consequently, the two-grid cycle scheme outperforms the SLRU algorithm in terms of floating-

point operations, since it requires far fewer oblique projections. This observation is no longer true when the *near*-invariant eigenspace poorly approximates the eigenspace (i.e., with $\varepsilon = 10^{-2}$, in our experiments). In that situation, the two-grid cycle scheme does not converge anymore with any of the smoothers, because the coarse grid correction systematically corrupts the iterates computed by the smoother. We recall (see Figure 3.5) that SLRU and DEF-CG still succeed in taking advantage of the approximate eigenspace in that case, as was also observed in [4].

Finally, we mention that the two-grid cycle using a stationary method as a smoother can also be used to define a preconditioner for the conjugate gradient; we refer the reader to [5] for more details on that approach.

4. Practical considerations. We first consider operations count. We assume that $p \ll n$ so that we neglect terms not containing n (p is the dimension of the *near*-invariant basis $\mathbf{W}$). All costs are evaluated in terms of the number of floating-point operations. The cost for a matrix-vector product is given by

$$\mathcal{C}_{\mathbf{A}} \approx 2\, nnz(\mathbf{A}) - n, \tag{4.1}$$

where $nnz(\mathbf{A})$ is the number of nonzero elements in $\mathbf{A}$.

The different algorithms compared in this paper perform an oblique projection of the initial residual onto the *near*-invariant basis $\mathbf{W}$ of size p, involving the same type of operator $\mathbf{W}\mathbf{A}_c^{-1}\mathbf{W}^T\mathbf{r}^{(0)}$, where $\mathbf{A}_c = \mathbf{W}^T\mathbf{A}\mathbf{W}$ is a dense matrix of order p. The computation of $\mathbf{A}_c$ has a cost of

$$\mathcal{C}_{\mathbf{A}_c} \approx n\,p^2 + 2\, nnz(\mathbf{A})\, p - n\,p. \tag{4.2}$$

We note that $\mathbf{A}_c$ is factorized once at the beginning of each algorithm, and the factors are used for any subsequent solution with $\mathbf{A}_c$.

In addition to the sparse matrix-vector product with $\mathbf{A}$ at each iteration, the CG iteration adds merely two dot-products (`_DOT`) and three vector updates (`_AXPY`). The cost of these extra operations is given by

$$\mathcal{C}_{\texttt{_AXPY}} \approx 2\,n \text{ and } \mathcal{C}_{\texttt{_DOT}} \approx 2\,n. \tag{4.3}$$

In the schemes DEF-CG and PROJ-CG (see sections 2.2 and 2.3), a computation of an oblique projection $\mathcal{P}\,\mathbf{r}^{(k)}$ (see formulas (2.4) and (2.5)) is also involved at each iteration. This can be done using common BLAS2 operations viz. $\mathbf{z}^{(k)} = (\mathbf{A}\mathbf{W})^T\mathbf{r}^{(k)}$ and $\mathbf{r}^{(k)} - \mathbf{W}\mathbf{A}_c^{-1}\mathbf{z}^{(k)}$. Considering that $\mathbf{A}\mathbf{W}$ and $\mathbf{A}_c$ are already computed and stored at the beginning of the algorithm, the cost of these operations is the same as that of the application of the SLRU preconditioner, $\mathbf{M}_{\text{SLRU}}$, which implements a rank-p update of the identity matrix of the form $\mathbf{I} + \mathbf{W}\mathbf{A}_c^{-1}\mathbf{W}^T$. The total cost of these BLAS2 operations is represented by

$$\mathcal{C}_{\text{Proj}} \approx 4\,(p+1)\,n. \tag{4.4}$$

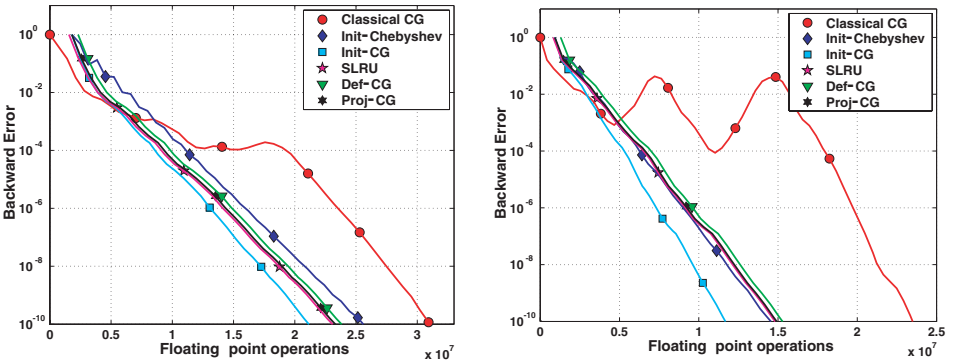
The INIT-CHEBYSHEV algorithm does not belong to the Krylov technique like the others do. It basically corresponds to the juxtaposition of a Chebyshev iterative solver which involves three vector updates, one sparse matrix-vector product with $\mathbf{A}$, and an oblique projection at the end. For ease of comparison, we shall consider the cost of this last oblique projection in the count of the operations performed "at the beginning." In Table 4.1, we summarize the total cost of floating-point operations for each algorithm, with an initial cost, and a cost per iteration.

TABLE 4.1
Cost in floating-point operations for different methods.

	The cost in floating-point operations	
	At the beginning	At each iteration
INIT-CG	$\mathcal{C}_{\mathbf{A}_c} + \mathcal{C}_{\text{Proj}} + \mathcal{C}_{\mathbf{A}} + 0$	$\mathcal{C}_{\mathbf{A}} + 0 + 3\mathcal{C}_{_\text{AXPY}} + 2\mathcal{C}_{_\text{DOT}}$
DEF-CG	$\mathcal{C}_{\mathbf{A}_c} + \mathcal{C}_{\text{Proj}} + \mathcal{C}_{\mathbf{A}} + \mathcal{C}_{\text{Proj}}$	$\mathcal{C}_{\mathbf{A}} + \mathcal{C}_{\text{Proj}} + 3\mathcal{C}_{_\text{AXPY}} + 2\mathcal{C}_{_\text{DOT}}$
PROJ-CG	$\mathcal{C}_{\mathbf{A}_c} + \mathcal{C}_{\text{Proj}} + \mathcal{C}_{\mathbf{A}} + 0$	$\mathcal{C}_{\mathbf{A}} + \mathcal{C}_{\text{Proj}} + 3\mathcal{C}_{_\text{AXPY}} + 2\mathcal{C}_{_\text{DOT}}$
SLRU	$\mathcal{C}_{\mathbf{A}_c} + \mathcal{C}_{\text{Proj}} + 0 + 0$	$\mathcal{C}_{\mathbf{A}} + \mathcal{C}_{\text{Proj}} + 3\mathcal{C}_{_\text{AXPY}} + 2\mathcal{C}_{_\text{DOT}}$
INIT-CHEBYSHEV	$\mathcal{C}_{\mathbf{A}_c} + \mathcal{C}_{\text{Proj}} + \mathcal{C}_{\mathbf{A}} + 0$	$\mathcal{C}_{\mathbf{A}} + 0 + 3\mathcal{C}_{_\text{AXPY}} + 0$

One of the major differences is that DEF-CG, PROJ-CG, and SLRU use this operator at each iteration whereas INIT-CG exploits this only at the beginning (for computing a starting vector $\mathbf{x}^{(0)}$). The two-grid algorithm is in between, in the sense that it performs an oblique projection for the coarse grid correction every other ξ steps of the smoother (which can be the conjugate gradient, Chebyshev, or Richardson iteration). In that respect, INIT-CG and INIT-CHEBYSHEV are less expensive, since they avoid the use of oblique projectors at each iteration, but, as we have seen previously in the experiments, they can suffer from some misconvergence when the basis $\mathbf{W}$ is not close to being *near*-invariant.

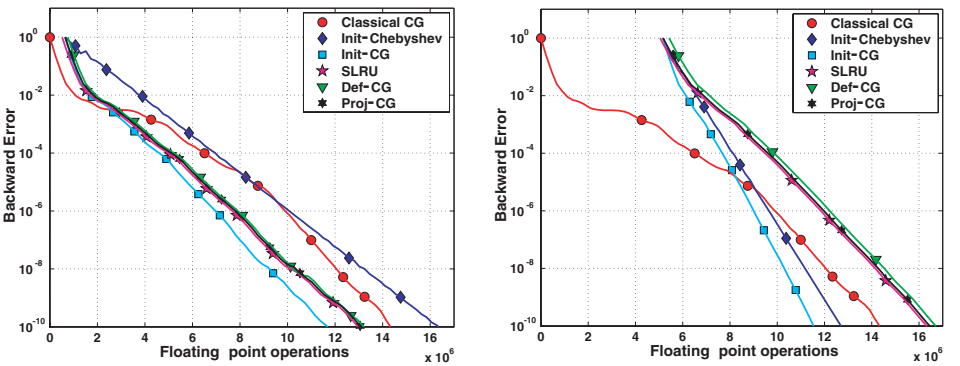
A final comment about the memory requirements of these five solution techniques (INIT-CG, INIT-CHEBYSHEV, DEF-CG, PROJ-CG, and SLRU): All these algorithms require about the same amount of extra storage, of order $2np$, to store $\mathbf{AW}$ and $\mathbf{W}$, the basis of the *near*-invariant subspace.



4.1. Comparison of the different techniques in terms of floating-point operations. In this subsection, we analyze the cost of the different algorithms introduced previously. As mentioned at the beginning of section 3, a first level of preconditioner $\mathbf{M}_1$ is also used, the purpose of which is to better clusterize the spectrum of our iteration matrix. The cost of the multiplication of $\mathbf{M}_1$ by a vector is represented by $\mathcal{C}_{\mathbf{M}_1}$. Since, in our experiments, $\mathbf{M}_1$ is constructed by means of the incomplete Cholesky factorization, $\mathcal{C}_{\mathbf{M}_1}$ can be estimated as

$$\mathcal{C}_{\mathbf{M}_1} \approx 4\, nnz(\mathbf{L}) - 2\, n, \tag{4.5}$$

where $nnz(\mathbf{L})$ is the number of nonzero elements in the factor $\mathbf{L}$ from the incomplete Cholesky factorization. The cost of this first level of preconditioning $\mathbf{M}_1$ must be incorporated in the floating-point counts detailed in Table 4.1. This simply resumes in adding $\mathcal{C}_{\mathbf{M}_1}$ to $\mathcal{C}_{\text{Proj}}$ (4.4) wherever it appears, or explicitly at each iteration for INIT-CG or INIT-CHEBYSHEV.



For simplicity, we exploit only the basis $\mathbf{W}(\varepsilon)$ obtained with maximum quality (level of filtering $\varepsilon = 10^{-16}$) so that we can directly observe and compare the behavior of the algorithms for a large range of the backward error, without any break in the slope of convergence due to potential lack of accuracy in the *near*-invariant subspace $\mathbf{W}(\varepsilon)$, as described and discussed already in the previous sections.

In Figures 4.1 and 4.2, we plot the histogram of the backward error versus the number of floating-point operations. The gap between the conjugate gradient and the other algorithms, at the beginning of these histograms, denotes the additional initial cost necssary to incorporate the $\mathbf{W}(\varepsilon)$ basis and to build the associated oblique projector. This gap is more or less large depending on the dimension of the basis $\mathbf{W}(\varepsilon)$. For instance, this dimension is of order 3–4 in Figures 4.1 (a), (b) and Figure

(a) *BCSSTK*15. (b) *PDE*1.

FIG. 4.1. *Floating-point operations with a level of filtering* ε *equal to* 10^{-16}.

FIG. 4.2. *Floating-point operations of various algorithms with a level of filtering* ε *equal to* 10^{-16} *on the BCSSTK*14 *matrix.*

4.2 (a), and of order 23 in Figure 4.2 (b). We can also observe the different slopes in these histograms, with major differences between INIT-CG or INIT-CHEBYSHEV and the other three (DEF-CG, PROJ-CG, and SLRU). Indeed, INIT-CG and INIT-CHEBYSHEV exploit the oblique projection only at the beginning, and the other three at each iteration.

When the basis $\mathbf{W}(\varepsilon)$ is of small dimension, and this is one of the desired features for our approach (with respect to the use of the CHEBYSHEV-PARTIAL SPECTRAL FACTORIZATION), it is clear that the extra cost at the beginning is not extremely important and can be quickly compensated after very few iterations, and this for reasonable backward error. When the basis is large, and this is the case in Figure 4.2 (b) where $\mathbf{W}(\varepsilon)$ is of dimension 23, the cost of using the oblique projector is very important, not only at the beginning but also within the iterations, and the gains in terms of speed of convergence may not be good enough to compensate for this extra cost, as we can observe for DEF-CG, PROJ-CG, and SLRU. Only those techniques like INIT-CG or INIT-CHEBYSHEV can eventually do better than the classical preconditioned conjugate gradient, since they perform the oblique projection only at the beginning. As a last comment, we mention that in the case of the experiments in Figure 4.2, the preconditioned conjugate gradient performs 65 iterations to reach a backward error

of 10^{-10}; the other Krylov techniques perform 51 iterations when $\mu = \lambda_{\max}/40$ and $\mathbf{W}(\varepsilon)$ is of size 3, and 30 iterations when $\mu = \lambda_{\max}/10$ and $\mathbf{W}(\varepsilon)$ is of size 23; and INIT-CHEBYSHEV performs 74 iterations in the first case and 36 iterations in the latter case (for the same final backward error).

There is of course a trade-off to manage, and this is problem dependent, between the overhead that is directly linked to the size of the *near*-invariant basis $\mathbf{W}(\varepsilon)$, and the resulting reduced condition number of the iteration matrix. As mentioned in section 2.5, the parameter μ splits the spectrum of the matrix into two subsets and determines the dimension p of the invariant subspace that will be computed in the partial spectral factorization phase, depending of course on the actual eigenvalue distribution in the iteration matrix $\widehat{\mathbf{A}}$. A direct consequence of this choice of μ can be observed in the behavior of the INIT-CHEBYSHEV algorithm, which is explicitly linked to the reduced condition number $\lambda_{\max}/\mu$, as opposed to other Krylov techniques which rely more on the global distribution of eigenvalues. Indeed, in Figure 4.2, we can see that INIT-CHEBYSHEV may not be a good competitor despite the small size of the $\mathbf{W}(\varepsilon)$ basis when μ is set to $\lambda_{\max}/40$ (and the $\mathbf{W}(\varepsilon)$ basis is of size 3) as opposed to $\lambda_{\max}/10$ (with a $\mathbf{W}(\varepsilon)$ basis is of size 23).

Finally, the different histograms show that the three techniques DEF-CG, PROJ-CG, and SLRU exhibit very similar behavior. A fine grain analysis based on the values given in Table 4.1 can help to conclude that SLRU is a little cheaper than the other two. However, if the *near*-invariant basis $\mathbf{W}(\varepsilon)$ is very accurate (independently of its size), INIT-CG is the algorithm of choice with respect to these three techniques, and even with respect to INIT-CHEBYSHEV, which will at any rate suffer from a slower speed of convergence.

4.2. Cost benefit and remarks. The purpose of this subsection is to compare, in terms of cost benefits, the various iterative solution techniques introduced in section 2. We now consider the situation where one is interested in consecutively solving several linear systems with the same coefficient matrix but with changing right-hand sides that are computed sequentially. We illustrate how the gains obtained at each solve can reduce quite substantially the total computational cost in the long run.

Concerning the precomputation of the *near*-invariant basis $\mathbf{W}(\varepsilon)$, we have used the CHEBYSHEV-PSF algorithm proposed by [2]. The main reason for the choice of the CHEBYSHEV-PSF algorithm was to enable the computation of an approximation of the invariant subspace linked to all eigenvalues in a given range $[\lambda_{\min}, \mu[$, without any a priori knowledge of their count, and to target directly a reduced condition number $\lambda_{\max}/\mu$. The only risk regarding the choice of the parameter μ is that, if it is not well located with respect to the actual clustering of the eigenvalues in the iteration matrix $\mathbf{A}$, the size of the constructed Krylov space can be large. However, and this is one requirement for the efficiency of the approach studied in this paper, the iteration matrix should have a spectrum well clusterized, and a first level of preconditioning should in general be incorporated to achieve this. Additionally, the CHEBYSHEV-PSF algorithm also offers the possibility to control the accuracy of the precomputed $\mathbf{W}(\varepsilon)$ basis and to reduce substantially the cost in this precomputation.

Other iterative techniques, like those available in ARPACK [24], for instance, can also be used to approximate a given number of eigenvalues or eigenvectors in the SPD iteration matrix $\mathbf{A}$. The difference here is that the ARPACK equivalent routines target in fact some fixed number of approximate eigenvalues. However, if this predetermined number of eigenvalues (denoted by p) is not large enough with respect to the eigenvalue distribution in $\mathbf{A}$, one may be left with a reduced condition number

$\lambda_{\max}(\mathbf{A})/\lambda_{p+1}(\mathbf{A})$ that is still rather large. The claim here is not that one method is better than the other, but just that the target is different since with CHEBYSHEV-PSF we control directly the range of eigenvalues, and with the latter technique, one can control better in general the total number of computations.

The precomputation of the *near*-invariant basis $\mathbf{W}(\varepsilon)$ has a cost which we denote by $\mathcal{C}_{\text{PSF}}$ and that depends on the dimension and on the accuracy of the computed *near*-invariant subspace. To be effective, the gains obtained in the acceleration of the convergence of the given iterative solvers must compensate, in some way, for the extra cost of the computation of this spectral information.

In the CHEBYSHEV-PSF algorithm, we perform the Chebyshev filtering polynomials in $\mathbf{A}$ at the beginning, to generate an initial filtered vector $\mathbf{w}^{(0)}$, and at each step, to maintain, under the level of filtering ε, the relative gap in the eigencomponents associated with all eigenvalues in the range $[\mu, \lambda_{\max}(\mathbf{A})]$ in the newly computed Lanczos vectors $\mathbf{w}^{(k+1)}$. The cost of one Chebyshev inner iteration is $\mathcal{C}_{\mathbf{A}} + 3\,\mathcal{C}_{\texttt{_AXPY}}$ (see the formulas (4.1), (4.3)). The CHEBYSHEV-PSF algorithm also involves the computation of $\left(\mathbf{I} - \mathbf{W}\mathbf{W}^T\right)\mathbf{A}\mathbf{w}^{(k)}$ at each Lanczos step, to get the next entry $\mathbf{w}^{(k+1)}$ in the Krylov basis $\mathbf{W}$, before filtering it again. This computation is a BLAS2 operation whose total cost for $(p-1)$ Lanczos steps is given by

$$\mathcal{C}_{\text{Lanczos}} \approx (p-1)\,\mathcal{C}_{\mathbf{A}} + 2\,p\,(p-1)\,n. \tag{4.6}$$

In addition, each iteration also requires two dot-products, for a total cost of $2\,(p-1)\,\mathcal{C}_{\texttt{_DOT}}$ (see (4.3)). Finally, at each iteration, the filtered Krylov entry $\mathbf{z}^{(k+1)}$ must again be orthogonalized against the current orthonormal basis $\mathbf{W}$ to build the new vector $\mathbf{w}^{(k+1)}$ in the *near*-invariant basis $\mathbf{W}$ (i.e., $\mathbf{z}^{(k+1)} - \mathbf{W}\mathbf{W}^T\mathbf{z}^{(k+1)}$). The total cost of these last operations after $(p-1)$ global iterations can be estimated as

$$\mathcal{C}_{\text{Ortho}} \approx 2\,n\,p^2 - n\,p - n. \tag{4.7}$$

Thus, the cost of precomputing the orthonormal basis $\mathbf{W}$ with the CHEBYSHEV-PSF algorithm is of order

$$\mathcal{C}_{\text{PSF}} \approx \left(\mathcal{C}_{\mathbf{A}} + 3\,\mathcal{C}_{\texttt{_AXPY}}\right) \times \texttt{ChebIt} + 2\,(p-1)\,\mathcal{C}_{\texttt{_DOT}} + \mathcal{C}_{\text{Ortho}} + \mathcal{C}_{\text{Lanczos}}, \tag{4.8}$$

where `ChebIt` is the total number of Chebyshev filtering iterations performed in the CHEBYSHEV-PSF algorithm.

In Table 4.2, we report the number of floating-point operations (in `Mflop`, and in `Gflop` for Problem PDE2 with largest size) and the total number of Chebyshev filtering steps in the CHEBYSHEV-PSF algorithm, and this for each matrix, and with different values for the filtering level ε.

In 4.3, 4.4, and 4.5, we illustrate, in the case of PDE1, BCSSTK15, and PDE2 test problems, the cost benefit of the various algorithms described in section 2. Let us consider, for instance, that we stop the iterations when the relative residual norm $||\widehat{\mathbf{b}} - \widehat{\mathbf{A}}\mathbf{x}^{(i)}||_2/||\widehat{\mathbf{b}}||_2$ is below 10^{-10}. For each level of filtering ε, we indicate in these tables the number of conjugate gradient iterations (`Nit`), and the number of floating-point operations (`Mflop`) to reach the above backward error.

We also compute the number of right-hand sides that have to be considered in subsequent consecutive solves before the extra cost $\mathcal{C}_{\text{PSF}}$ for the computation of the *near*-invariant basis $\mathbf{W}(\varepsilon)$ is compensated. This is indicated as the number of amortization vectors (`Amor.Vec`). To compute this number, we must compare the number of floating-point operations needed to reach the given level of backward error

$$\texttt{Amor. Vec} = \left\lfloor \frac{\mathcal{C}_{\text{PSF}} + \mathcal{C}_{\mathbf{A}_c}}{\mathcal{C}_{\text{CG}} - (\mathcal{C}_{Algo} - \mathcal{C}_{\mathbf{A}_c})} \right\rfloor + 1, \tag{4.9}$$

where $\mathcal{C}_{Algo}$ is the total cost in floating-point operations for the algorithm *Algo* (summarized in Table 4.1).

For instance, to reach a backward error of 10^{-10}, the conjugate gradient algorithm performs 57 iterations in the case of the PDE1 test problem with a cost of 23.76 `Mflop`, 45 iterations in the case of BCSSTK15 with a cost of 31.62 `Mflop`, and, in the case of the PDE2 anisotropic problem, 1060 iterations with a cost of 6.31 `Gflop`. If we consider the case of Problem PDE1, in particular, 42.87 `Mflop` are needed to compute a basis with a filtering level of $\varepsilon = 10^{-16}$ (see Table 4.2), out of which INIT-CG convergence is achieved in 27 iterations, with a cost of 11.88 `Mflop` (see Table 4.3). This yields a reduction of 47% compared to the run which does not use this spectral information, and the extra 42.87 `Mflop` in the spectral precomputation are paid back after only four consecutive runs of INIT-CG.

Tables 4.3 and 4.4 also show the impact of varying the filtering level ε on the actual number of amortization vectors. We can observe that the number of amortization vectors (`Amor. Vec`) is about the same for the three Krylov techniques (DEF-CG, PROJ-CG, and SLRU) for a given level of filtering ε. For example, when the *near*-invariant subspace $\mathbf{W}(\varepsilon)$ is computed with very high accuracy (i.e., with a filtering level ε close to machine precision), the extra cost is compensated in few consecutive runs, and this occurs with any of the iterative solvers considered here. As mentioned already in such a case, INIT-CG appears explicitly to be the algorithm of choice.

The INIT-CHEBYSHEV algorithm is particular since it does not belong to Krylov techniques as the others do. When the level of filtering ε is equal to 10^{-16}, INIT-

CHEBYSHEV overcomes the extra cost of the eigencomputation like the other Krylov algorithms (DEF-CG, PROJ-CG, and SLRU), as illustrated in Table 4.3, but with a little difference in the number of amortization vectors. This can be explained by the different rates of convergence between the Chebyshev method and the conjugate gradient method in general. However, when the spectral information is not extremely accurate, i.e., the level of filtering is in the range 10^{-8} to 10^{-4}, the simple use of a projector only at the beginning is not sufficient to reach a great accuracy in the Chebyshev solve.

The two-grid cycle scheme proposed in section 2.7 can be an alternative to still benefit from the available spectral information (despite its poor numerical quality), but without the expense of performing an oblique projection at each iteration as with DEF-CG, PROJ-CG, or SLRU. In Table 4.5, we indicate the cost benefit of such a scheme only with the Chebyshev iteration as the smoother, knowing that the convergence with conjugate gradient is very comparable. We also vary the number of smoothing steps in each cycle, depending on the actual accuracy of the precomputed basis $\mathbf{W}(\varepsilon)$, in order to minimize the number of coarse grid corrections (i.e., oblique projections) versus the total number of iterations.

The various numerical results illustrate that, when a great accuracy is required to solve several linear systems in sequence, the precomputed *near*-invariant subspace with a level of filtering ε higher than 10^{-2} should not be used. Furthermore, the best strategy to address this situation is to compute, if possible, an accurate *near*-invariant subspace basis $\mathbf{W}(\varepsilon)$, i.e., $(10^{-16} \leq \varepsilon \leq 10^{-8})$, and to carry out the INIT-CG algorithm or the conjugate gradient based TWO-GRID solver. We also note that, if we have a *near*-invariant subspace basis $\mathbf{W}(\varepsilon)$ not extremely but sufficiently accurate (for instance, $\varepsilon = 10^{-4}$), the use of the three other Krylov techniques (DEF-CG, PROJ-CG, and SLRU) is in general more efficient, and the TWO-GRID cycle scheme can even be a good alternative.

5. Conclusions and perspectives. In this paper, we have compared various iterative solution techniques that exploit partial spectral information about the matrix $\mathbf{A}$. The common general idea in all these techniques is to use some precomputed *near*-invariant subspace $\mathbf{W}(\varepsilon)$ to build a projection onto the orthogonal complement of $\mathbf{W}(\varepsilon)$ in some appropriate norm, and to exploit such a projector to maintain, implicitly or explicitly, throughout the iterations, the computed residuals in this orthogonal complement.

We have considered, for instance, the deflated version of the conjugate gradient algorithm [34], which consists in augmenting the generated Krylov space with the basis $\mathbf{W}(\varepsilon)$, and resumes in projecting at each conjugate gradient iteration the generated Krylov vectors. An alternative technique consists in applying the conjugate gradient algorithm to a projected system [28]. A third approach is based on a spectral low-rank update preconditioning technique [4], which aims to shift close to one the smallest eigenvalues in the original system. These three Krylov-based techniques enabled faster convergence in the conjugate gradient, with very similar linear rates of convergence that could be achieved even when the precomputed *near*-invariant basis $\mathbf{W}(\varepsilon)$ was obtained with very low accuracy.

For the sake of comparison, we have also experimented with three other *simpler* approaches, namely, the classical conjugate gradient algorithm and the Chebyshev and Richardson polynomial iterative methods, all three combined with a starting guess obtained with an oblique projection of the initial residual onto the orthogonal complement of $\mathbf{W}(\varepsilon)$. We have seen that, when the basis $\mathbf{W}(\varepsilon)$ is computed with an

accuracy close to machine precision, these three other techniques also present similar numerical behavior, with linear rates of convergence that differ slightly at any rate since their intrinsic numerical properties are different.

The resulting linear rates of convergence observed in all cases are directly connected to the cut-off value μ, which corresponds to the smallest eigenvalue in $\mathbf{A}$ that is not included in the set of eigenvalues approximated by the basis $\mathbf{W}(\varepsilon)$. More precisely, these rates correspond to those one would obtain with matrices having a reduced condition number equal to $\lambda_{\max}(\mathbf{A})/\mu$. In that respect, these last three techniques are very appealing since they exploit the oblique projection with the basis $\mathbf{W}(\varepsilon)$ only at the beginning. Finally, despite their relatively higher linear rates of convergence, the Chebyshev and Richardson polynomial iterative techniques present the additional advantage of not using any dot-products in their iterations, which can be quite beneficial when considering parallel implementations on distributed memory multiprocessor environments.

In summary, when the *near*-invariant subspace basis $\mathbf{W}(\varepsilon)$ is computed with very high accuracy (i.e., with a filtering level ε close to machine precision), the coarse-grid correction needs to be applied only once and algorithms of the type INIT-CG and INIT-CHEBYSHEV are the algorithms of choice, because they avoid the use of oblique projectors at each iteration and are much less expensive. When the computed *near*-invariant subspace basis $\mathbf{W}(\varepsilon)$ is not very accurate, the simple use of a projector only at the beginning is not sufficient to ensure a linear rate of convergence throughout the iterations. In particular, when the *near*-invariance of the precomputed basis is very poor, no improvements might be observed. As opposed to that, the first three Krylov techniques, which perform at each iteration an oblique projection with the $\mathbf{W}(\varepsilon)$ basis, do not suffer from these misconvergence problems and show a constant numerical behavior in almost every case. In the intermediate situations, e.g., when the precomputed *near*-invariant basis is not extremely but sufficiently accurate, we can use a two-grid cycle scheme to still benefit from the spectral information without the expense of performing a coarse grid correction (oblique projection) at each iteration.

The computational costs analyzed in section 4.2 have also shown that, when the spectrum of the iteration matrix is well clusterized and the $\mathbf{W}(\varepsilon)$ basis is small, the gains can be rather effective and the cost for precomputing this basis can rapidly be compensated when solving several linear systems with the same matrix but changing right-hand sides computed sequentially.

Our perspectives are to investigate the combination of conjugate gradient with Chebyshev filtering polynomials applied to a part of the spectrum of the coefficient matrix as preconditioners that help to put the conjugate gradient in a better situation for convergence. The expectation is to be capable of directly constructing a small dimensional Krylov basis naturally rich with respect to the smallest eigenvalues/eigenvectors [16].

Acknowledgments. We would like to thank the anonymous referees for their valuable remarks, questions, and comments that enabled us to substantially improve this paper.

SCHURRAS: A RESTRICTED VERSION OF THE OVERLAPPING SCHUR COMPLEMENT PRECONDITIONER*

ZHONGZE LI† AND YOUSEF SAAD‡

Abstract. This paper presents a preconditioner based on solving approximate Schur complement systems with the overlapping restricted additive Schwarz (RAS) methods. The construction of the preconditioner, called SchurRAS, is as simple as in the standard RAS. The communication requirements for each application of the preconditioning operation are also similar to those of the standard RAS approach. In the particular case when the degree of overlap is one, then SchurRAS and RAS involve exactly the same communication volume per step. In addition, SchurRAS has the same degree of parallelism as RAS. In some numerical experiments with a model problem, the convergence rate of the method was found to be similar to that of the multiplicative Schwarz (MS) method. The Schur-based RAS usually outperforms the standard RAS both in terms of iteration count and CPU time. For a few two-dimensional scaled problems, SchurRAS was about twice as fast as the stardard RAS on 64 processors.

Key words. parallel preconditioning, distributed sparse linear systems, Schur complement techniques, domain decomposition, additive Schwarz preconditioner, restricted additive Schwarz preconditioner

1. Introduction.

In the past few decades, *incomplete LU* (ILU) preconditioners, combined with Krylov subspace acceleration, have yielded techniques which offer a good compromise between robustness and efficiency when solving general large sparse linear systems of equations; see, e.g., [14, 21]. The extension of these techniques to parallel computing environments has followed two distinct paths. The first is to extract parallelism via a reordering of the unknowns. The second is to resort to domain decomposition ideas. Multicoloring is a standard way of uncovering parallel tasks in an algorithm such as Gaussian elimination. For example, parallel ILU-type preconditioners based on graph partitioning and multicoloring were recently presented [8, 6, 12]. Constructing a parallel ILU preconditioner with multicoloring starts with a coloring of the interface variables. The elimination proceeds with the interior nodes first, and this phase is perfectly parallel. Then the interface variables are eliminated in a certain order which is based on the colors of the interfaces. This basic idea was already exploited for a parallel implementation of ILU(0) in 1994 [11] (see also the 1996 edition of [14]).

Concerning the second class of methods mentioned above, domain decomposition methods (DDM) have given rise to a general-purpose strategy for constructing global

preconditioners for sparse linear systems [14, 21]. These methods were initially developed for solving partial differential equations (PDEs), but there is an increasing interest in DDM-like preconditioners for general sparse linear systems obtained from a purely algebraic viewpoint; see, e.g., [2, 13, 7, 10]. In DDM, the initial problem domain is partitioned into a number of subdomains, possibly with overlapping interfaces. Such extensions lead to *distributed sparse systems* [14], whereby the equations and associated unknowns are assigned to processors with the help of a graph partitioning approach. Using this viewpoint, many of the DDM can be retrofitted to the solution of distributed sparse linear systems. The idea is to compute an approximate solution from solutions in the subdomains, exploiting knowledge about the operator, discretization, and other properties of the problem when possible. In the simplest case of the additive Schwarz methods (ASM), the iterative process consists of simply solving independent problems and updating residuals in each domain after each iteration. Variants of ASM are obtained by varying the amount of overlap and the subdomain solvers. If the subdomains do not overlap, the procedure results in a method that essentially amounts to a *block Jacobi* preconditioner. It is important to note that Schwarz-type procedures are straightforward to extend to general sparse linear systems, at least from an algorithmic point of view. Though the body of theory that is available in DDM for PDEs does not easily extend without additional information, domain decomposition gives rise to fairly efficient methods for sparse linear systems, which have the advantage of being easy to implement [2].

In [3] Cai and Sarkis introduced an effective variant of the Schwarz procedure called the restricted additive Schwarz (RAS) method for the case where subdomains are overlapped and each subdomain problem is approximately solved using an incomplete factorization. The initial motivation that led to the discovery of RAS was to reduce communication costs—by omitting half of the communication in the standard overlapping ASM. However, it turns out that this omission often has the unexpected effect of also reducing the number of iterations.

In practice, ASM-type preconditioners are preferable to multicoloring ILU preconditioners in that they yield a better performance in most cases [4, 1]. ASM usually outperforms nonoverlapping block Jacobi preconditioners both in terms of iteration counts and execution times because the block Jacobi preconditioner ignores all interdomain couplings. To improve the performance for nonoverlapping domain decomposition, Schur complement-based preconditioners were advocated as alternatives to the simple block Jacobi techniques [15, 10]. Though Schur complement preconditioners take fewer iterations to converge, they lead to higher execution times to converge in some cases because of the additional costs incurred by the inner iterations when solving the Schur complement systems.

This paper presents a technique (SchurRAS) which, in effect, brings together the best of ASM on the one hand and Schur complement methods on the other. As in RAS, the new algorithm combines overlapping and nonoverlapping iterations. However, these iterations now involve Schur complements; i.e., they work on interface variables.

The rest of the paper is organized as follows. Section 2 introduces distributed sparse systems and Schwarz procedures, as well as Schur complements. Section 3 presents the restricted version of the Schur complement preconditioner, and section 4 gives some details on the parallel implementation of SchurRAS. Numerical experiments are shown in section 5, and some conclusions are drawn in section 6.

2. Distributed systems and distributed preconditioners. When solving a linear system $Ax = b$ on a distributed memory computer, it is common to start by partitioning the adjacency graph of the coefficient matrix A by a graph partitioner [9]. Recall that the *adjacency graph* of A is a graph $G = (V, E)$, where V is the set of all vertices representing the unknowns of the system, and E is the set of all edges representing the binary relation "a_{ij} is a nonzero entry" between vertices i and j [14]. Assuming that the matrix A has a symmetric nonzero pattern, the adjacency graph G is undirected. The partitioning of G will result in p nonoverlapping subgraphs $V_1, \ldots, V_p$. Typically, the group of equations associated with the set V_i will be assigned to processor i, along with the corresponding unknowns. Thus, each processor holds a set of equations (rows of the linear system) and vector components associated with these rows. Note that we assume a "vertex-based" partitioning. This means that vertices are assigned to processors (instead of edges or elements in a finite element problem). In this situation, unknowns can be categorized into three classes: (1) interior variables which are coupled only with local variables by the equations; (2) local interface variables which are coupled with nonlocal (external) variables as well as local variables; and (3) external interface variables (which are unknowns in other processors) that are coupled with local variables. Figure 1 illustrates this.

When putting together the equations assigned to a given processor, one observes that the coefficient matrix consists of two pieces: The first, called A_i, acts on local variables, and the other, called X_i, acts on external variables. Thus, the global linear system $Ax = b$ can be rewritten in each processor as

$$A_i x_i + X_i x_{i,ext} = b_i, \tag{2.1}$$

where x_i are the vector of local unknowns, $x_{i,ext}$ are the external interface variables, and b_i is the corresponding local part of the right-hand side vector. The above system is referred to as the "local system."

For convenience, a local reordering of the data is often exploited by splitting the local vector x_i into two parts: the subvector u_i of interior nodes followed by the subvector v_i of local interface nodes. The local right-hand side vector b_i is conformally split into the subvectors f_i and g_i, so that

$$x_i = \begin{pmatrix} u_i \\ v_i \end{pmatrix}, \quad b_i = \begin{pmatrix} f_i \\ g_i \end{pmatrix}. \tag{2.2}$$

With this reordering, (2.1) takes the form

$$\underbrace{\begin{pmatrix} B_i & E_i \\ F_i & C_i \end{pmatrix}}_{A_i} \begin{pmatrix} u_i \\ v_i \end{pmatrix} + \underbrace{\begin{pmatrix} 0 \\ \sum_{j \in N_i} E_{ij} v_j \end{pmatrix}}_{X_i x_{i,ext}} = \begin{pmatrix} f_i \\ g_i \end{pmatrix}. \tag{2.3}$$

Here, N_i is the set of indices for subdomains that are adjacent to the subdomain i. The term $E_{ij}v_j$ is the contribution to the local equation from neighboring subdomain j. The zero block in the second term of the left-hand side of (2.3) is due to the fact that local internal nodes are not coupled with external nodes.

2.1. Schwarz procedures for distributed systems. Let the global domain Ω be decomposed into p nonoverlapping subdomains Ω_i, obtained from a partitioning of V into p nonoverlapping subgraphs V_i^0. Here the superscript 0 is added to indicate that the domains do not overlap. Each subdomain Ω_i can then be extended to a larger

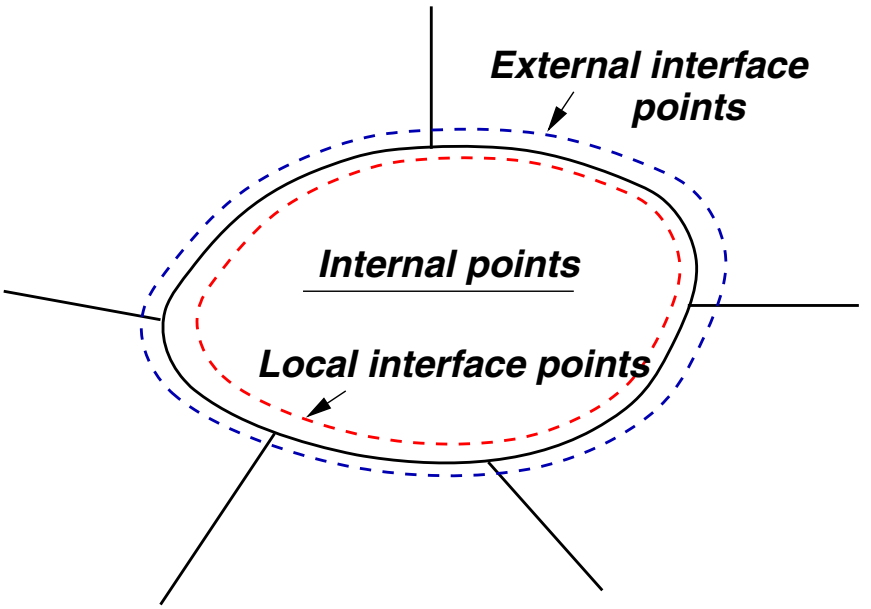

FIG. 1. *A local view of a distributed sparse matrix.*

subdomain Ω_i^1 to form a one-level overlapped subdomain by including all immediate neighboring nodes of V_i^0. We may similarly define a δ-level overlapped subdomain Ω_i^δ with the set of nodes V_i^δ. Associated with each subdomain Ω_i^δ, we can define the restriction operator

$$\begin{aligned} R_{i,\delta} : \Omega &\longrightarrow \Omega_i^\delta, \\ z &\longrightarrow z_{i,\delta}, \end{aligned}$$

where $z_{i,\delta} = R_{i,\delta} z$ is the vector of Ω_i^δ which consists of only components of z belonging to Ω_i^δ. It is common to use the transpose $R_{i,\delta}^T$ as the corresponding *extension* operator

$$\begin{aligned} R_{i,\delta}^T : \Omega_i^\delta &\longrightarrow \Omega, \\ z_{i,\delta} &\longrightarrow z, \end{aligned}$$

where $z = R_{i,\delta}^T z_{i,\delta}$ is the zero-extension of a vector $z_{i,\delta}$ on Ω_i^δ to Ω. The local matrix $A_{i,\delta}$ associated with the subdomain Ω_i^δ can be expressed as $A_{i,\delta} = R_{i,\delta}^T A R_{i,\delta}$. The additive Schwarz preconditioner can be written as [19]

$$\mathcal{B}_{[\delta,\delta]} = \sum_{i=1}^{p} R_{i,\delta}^T A_{i,\delta}^{-1} R_{i,\delta}. \tag{2.4}$$

In the case when there is no overlap, i.e., when $\delta = 0$, we obtain the special case of the *block Jacobi* preconditioner

$$\mathcal{B}_{[0,0]} = \sum_{i=1}^{p} R_{i,0}^T A_{i,0}^{-1} R_{i,0}. \tag{2.5}$$

Finally, using the same notation, the RAS proposed by Cai and Sarkis [3] can be written as

$$\mathcal{B}_{[0,\delta]} = \sum_{i=1}^{p} R_{i,0}^T A_{i,\delta}^{-1} R_{i,\delta}. \tag{2.6}$$

The solve with the matrix $A_{i,\delta}$ is rarely performed exactly. Instead, one can obtain an incomplete LU factorization and solve the systems with a preconditioned Krylov method. Examining the incomplete factorization carefully will also yield an approach based on Schur complements.

2.2. Schur complement-based preconditioners. Eliminating u_i from the top part of (2.3) leads to the relation

$$u_i = B_i^{-1}[f_i - E_i v_i], \tag{2.7}$$

which upon substitution into the bottom part, results in the following equation for v_i:

$$S_i v_i + \sum_{j \in N_i} E_{ij} v_j = g_i - F_i B_i^{-1} f_i \equiv g_i', \quad i = 1, \ldots, p, \tag{2.8}$$

where S_i is the "local" Schur complement matrix

$$S_i = C_i - F_i B_i^{-1} E_i. \tag{2.9}$$

Note that this elimination of the u_i's is local in that it can be carried out on each processor in parallel since interior unknowns of each subdomain are not coupled with variables of other subdomains.

Equations (2.8) for all subdomains constitute the global Schur complement system which involves only all interface variables v_i, $i = 1, \ldots, p$. The global Schur complement matrix has a natural block structure,

$$\begin{pmatrix} S_1 & E_{12} & E_{13} & \cdots & E_{1p} \\ E_{21} & S_2 & E_{23} & \cdots & E_{2p} \\ \vdots & & \ddots & & \vdots \\ \vdots & & & \ddots & \vdots \\ E_{p1} & E_{p2} & E_{p3} & \cdots & S_p \end{pmatrix} \begin{pmatrix} v_1 \\ v_2 \\ \vdots \\ \vdots \\ v_p \end{pmatrix} = \begin{pmatrix} g_1' \\ g_2' \\ \vdots \\ \vdots \\ g_p' \end{pmatrix}. \tag{2.10}$$

The above system can be written as

$$Sv = g',$$

where v consists of all interface variables $v_1, v_2, \ldots, v_p$ stacked into a long vector. The matrix S is the global Schur complement matrix.

If the global Schur complement system (2.10) is solved exactly, the u variables can be obtained from (2.7), and the exact solution of the whole system will then be obtained. Preconditioning techniques can be obtained by solving the Schur complement system approximately.

3. RAS versions of Schur complement preconditioners. Once interface variables v_i are available, all interior variables u_i can be computed via (2.7). This process can be carried out in parallel. If we simply drop the terms E_{ij} in (2.10), v_i can be computed via $S_i^{-1}g_i'$ without any communication among processors. This amounts to a block Jacobi preconditioner. In passing, we note that the block Jacobi preconditioner for the original linear system can be induced by the block Jacobi preconditioner for the global Schur complement system [14, 15]. Due to the local nature of the block Jacobi preconditioner, the resulting iteration will usually converge slowly, since one may expect that changes in a given domain will take quite a few steps before propagating to all domains.

One way to cure this is to attack the global Schur complement system directly, using Krylov subspace methods with block Jacobi or distributed ILU(0) as preconditioners [15, 10]. Solving the global Schur complement system more accurately will result in a preconditioner that is usually superior to the standard block Jacobi preconditioner for the original system. This superiority comes from the fact that Schur complement-based preconditioners tend to require fewer iterations than ASM to converge. However, note that because the inner steps for solving the global Schur complement systems are more expensive, the overall performance may be poorer in some cases [10].

Part of the problem with the Schur complement-based methods developed in [10, 15] lies in the ineffectiveness of the block Jacobi preconditioner which is used to solve the global Schur complement system. Since the RAS shows better performance than the block Jacobi for the original linear system, one can think of solving the global Schur complement system by using an RAS-like procedure. We will refer to this approach as SchurRAS. Because from some classes of problems the condition number of the Schur complement matrix is better than that of the original matrix [5, 19] and because RAS is a better preconditioner than the block Jacobi preconditioner, we may expect to obtain a more "exact" solution for the global Schur complement system. Therefore, SchurRAS should outperform the block Jacobi preconditioner. This will be borne out by the experiments.

3.1. The SchurRAS preconditioner. The local matrix $A_{i,\delta}$ can be written in the following block form:

$$A_{i,\delta} = \begin{pmatrix} B_{i,\delta} & E_{i,\delta} \\ F_{i,\delta} & C_{i,\delta} \end{pmatrix}, \tag{3.1}$$

where $B_{i,\delta}$ is the matrix associated with interior nodes of subdomain Ω_i^δ. Recall that interior nodes are those nodes which are coupled with unknowns from other domains. Assume that the ILU factorization of $B_{i,\delta}$ is available as

$$B_{i,\delta} \approx L_{i,\delta} U_{i,\delta}$$

and consider the following block ILU factorization of $A_{i,\delta}$:

$$\begin{aligned} A_{i,\delta} &\approx \begin{pmatrix} L_{i,\delta} & 0 \\ F_{i,\delta}U_{i,\delta}^{-1} & I \end{pmatrix} \begin{pmatrix} U_{i,\delta} & L_{i,\delta}^{-1}E_{i,\delta} \\ 0 & S_{i,\delta} \end{pmatrix} \\ &= \begin{pmatrix} L_{i,\delta} & 0 \\ F_{i,\delta}U_{i,\delta}^{-1} & I \end{pmatrix} \begin{pmatrix} I & 0 \\ 0 & S_{i,\delta} \end{pmatrix} \begin{pmatrix} U_{i,\delta} & L_{i,\delta}^{-1}E_{i,\delta} \\ 0 & I \end{pmatrix} \\ &\equiv \mathcal{L}_{i,\delta}\mathcal{D}_{i,\delta}\mathcal{U}^{i,\delta} \ . \end{aligned} \tag{3.2}$$

Then, using this approximation for $A_{i,\delta}$, the preconditioner (2.4) can be expressed as

$$\mathcal{B}_{[\delta,\delta]} = \sum_{i=1}^{p} R_{i,\delta}^T \mathcal{U}_{i,\delta}^{-1}\ \mathcal{D}_{i,\delta}^{-1}\ \mathcal{L}_{i,\delta}^{-1} R_{i,\delta}\ . \tag{3.3}$$

We can treat $\mathcal{U}_{i,\delta}$, $\mathcal{D}_{i,\delta}$ and $\mathcal{L}_{i,\delta}$ as three separate operators, in which case it helps to expand each of them as an operator on the whole space. Then (3.3) can be recast as

$$\mathcal{B}_{[\delta,\delta]}\ = \sum_{i=1}^{p} (R_{i,\delta}^T \mathcal{U}_{i,\delta}^{-1} R_{i,\delta})\ (R_{i,\delta}^T \mathcal{D}_{i,\delta}^{-1} R_{i,\delta})\ (R_{i,\delta}^T \mathcal{L}_{i,\delta}^{-1} R_{i,\delta}). \tag{3.4}$$

Similarly, in the nonoverlapping case the block Jacobi preconditioner (2.5) becomes

$$\mathcal{B}_{[0,0]} = \sum_{i=1}^{p} (R_{i,0}^T \mathcal{U}_{i,0}^{-1} R_{i,0})\ (R_{i,0}^T \mathcal{D}_{i,0}^{-1} R_{i,0})\ (R_{i,0}^T \mathcal{L}_{i,0}^{-1} R_{i,0}), \tag{3.5}$$

while the RAS preconditioner takes the form

$$\mathcal{B}_{[0,\delta]}\ = \sum_{i=1}^{p} (R_{i,0}^T \mathcal{U}_{i,\delta}^{-1} R_{i,\delta})\ (R_{i,\delta}^T \mathcal{D}_{i,\delta}^{-1} R_{i,\delta})\ (R_{i,\delta}^T \mathcal{L}_{i,\delta}^{-1} R_{i,\delta}). \tag{3.6}$$

Note that in the above equations, the solves with $\mathcal{D}_{i,\delta}$ correspond to solving Schur complement systems. The operations $(R_{i,\delta}^T \mathcal{L}_{i,\delta}^{-1} R_{i,\delta})$ and $(R_{i,\delta}^T \mathcal{U}_{i,\delta}^{-1} R_{i,\delta})$ are akin to a restriction and a prolongation operator, respectively. If we assume for a moment that the factorization $B_{i,\delta} = L_{i,\delta} U_{i,\delta}$ is exact, then one can expect that all that is required is an exact solution to the Schur complement system, to obtain an exact solution of the global problem. Keeping in mind the interpretation of $(R_{i,0}^T \mathcal{L}_{i,0}^{-1} R_{i,0})$ and $(R_{i,0}^T \mathcal{U}_{i,0}^{-1} R_{i,0})$ as "prolongation" and "restriction" operators, a careful look at (3.5) reveals that only the term $R_{i,0}^T \mathcal{D}_{i,0}^{-1} R_{i,0}$ needs to be improved to lead to an improvement to the global preconditioner. Recall that the assumption here is that the factorization of $B_{i,0}$ is exact. We can therefore focus on this operator and obtain a more exact solution by possibly using a preconditioned GMRES iteration [15, 10]. What is known about RAS can now be exploited, and we arrive naturally at the following definition of the SchurRAS preconditioner:

$$\mathcal{B} = \sum_{i=1}^{p} (R_{i,0}^T \mathcal{U}_{i,0}^{-1} R_{i,0})\ (R_{i,0}^T \mathcal{D}_{i,\delta}^{-1} R_{i,\delta})\ (R_{i,0}^T \mathcal{L}_{i,0}^{-1} R_{i,0}). \tag{3.7}$$

One may ask why we do not use the overlapping versions of the prolongation and restriction operators $(R_{i,\delta}^T \mathcal{L}_{i,\delta}^{-1} R_{i,\delta})$ and $(R_{i,\delta}^T \mathcal{U}_{i,\delta}^{-1} R_{i,\delta})$ in the above expressions. The purpose of SchurRAS is to construct a preconditioner for the original linear system by solving the Schur complement system with RAS. It is the nonoverlapping versions of the prolongation and restriction operators that lead to the Schur complement system, not the overlapping ones.

Comparing (3.6) and (3.7), we can see that SchurRAS and RAS have almost the same computational costs. Only the operator $R_{i,\delta}$ involves communications between neighboring processors. In particular, this means that SchurRAS and RAS involve the same communication when applying the preconditioner to a vector. According to

(2.3), the term E_{ij} remains unchanged after the (block) Gaussian elimination process. Accordingly, the couplings of the unknowns among neighboring subdomains for the global Schur complement system are the same as those of the original linear system. In particular, when $\delta = 1$, SchurRAS and RAS involve exactly the same volume of communication.

4. Parallel implementation. This section discusses some implementation details of the preprocessing phase in which the preconditioner is computed and the iteration phase in which the preconditioner is applied at each step.

4.1. Constructing the preconditioning matrix. Consider the local matrix A_i defined by (2.3). To compute the preconditioner, we make use of a relationship that was exploited in [15], between the Schur complement of A_i with respect to C_i, i.e., $S_i = C_i - F_i B_i^{-1} E_i$, and the block LU factorization of A_i. Specifically, we have

$$A_i = L_i U_i \equiv \begin{pmatrix} L_{i,B} & 0 \\ F_i U_{i,B}^{-1} & I \end{pmatrix} \begin{pmatrix} U_{i,B} & L_{i,B}^{-1} E_i \\ 0 & S_i \end{pmatrix}. \tag{4.1}$$

What is interesting is that the above factorization can be obtained via a simple variation of Gaussian elimination referred to as the "restricted" or "partial" Gaussian elimination [17, 16]. The algorithm proceeds as any form of Gaussian elimination but does not pursue the elimination in the (2,2) block of the matrix A_i. It is described next.

ALGORITHM 4.1. *Restricted IKJ version of Gaussian elimination*

1. *For* $i = 2, n$, *Do*
2. *For* $k = 1, \min(i\text{-}1, m)$, *Do*
3. $a_{i,k} := a_{i,k}/a_{k,k}$
4. *For* $j = k{+}1, n$, *Do*
5. $a_{i,j} := a_{i,j} - a_{i,k} * a_{k,j}$
6. *End Do*
7. *End Do*
8. *End Do*

Clearly, dropping will be used in this approximate factorization, resulting in an approximation $\tilde{S}_i$ to S_i. For clarity, we use the same symbol S_i for this approximation.

Once S_i is computed we then extend it by including rows associated with all external variables v_j that are adjacent to subdomain i. The extended matrix S_i' for the Schur complement matrix S_i has the following form:

$$S_i' = \begin{pmatrix} S_i & E_{i,ext} \\ G_i & H_i \end{pmatrix}. \tag{4.2}$$

In the above definition, $E_{i,ext}$ simply denotes the interdomain coupling matrix. The matrices G_i and H_i are matrices from neighboring subdomains which act on overlapping nodes. The matrix H_i is a Schur complement corresponding to overlapping variables with respect to external interface variables from other processors. Algorithm 4.1 describes the procedure for constructing the preconditioning matrix of SchurRAS.

ALGORITHM 4.2. *Construction of SchurRAS preconditioner*

1. *Construct approximate local Schur complement matrix* S_i.
2. *Extend* S_i *to* S_i' *by including rows corresponding to external variables received from neighboring processors.*
3. *Compute the ILU factorization of* S_i'.

It is also interesting to note that the SchurRAS procedure for two subdomains can be thought of as a variant of the global ILU factorization performed in parallel on each subdomain with different global orderings. First, S_1 and S_2 can be constructed in parallel on each processor as described in section 2.2. This corresponds to eliminating u_1 and u_2 from a global point of view. Then, we can obtain the extended Schur complement matrices S_1' and S_2', which have the following forms:

$$S_1' = \begin{pmatrix} S_1 & E_{12} \\ E_{21} & S_2 \end{pmatrix}, \qquad S_2' = \begin{pmatrix} S_2 & E_{21} \\ E_{12} & S_1 \end{pmatrix}. \tag{4.3}$$

Last, the ILU factorizations for S_1' and S_2' are performed in parallel on each processor. It is easy to understand that the whole process corresponds to a global ILU factorization performed on processor 1 with the order u_1, u_2, v_1, v_2 and on processor 2 with the order of u_2, u_1, v_2, v_1.

In contrast, the additive Schwarz preconditioner (with overlap) processes the ILU factorization for the rows associated with the overlapping variables differently: It does not take into account contributions from interior nodes to the external overlapping variables. In other words, the S_2 block in the left-hand side of (4.3) would be replaced by a matrix similar to the C_2 matrix on processor 2 (albeit with a different ordering). Similarly for the right-hand side matrix S_2'.

This argument should make it clear that we expect the Schur-based preconditioner SchurRAS to outperform the additive Schwarz, at least on two processors.

4.2. Applying the preconditioner. Once the Schur complement system (2.8) has been computed, we could also extend the right-hand side into the vector $(g_i', g_{i,ext}')$. Here, $g_{i,ext}'$ is obtained from neighboring subdomains. The extended local equation on subdomain i for the global Schur complement system $SV = g'$ can be written as follows:

$$\begin{pmatrix} S_i & E_{i,ext} \\ G_i & H_i \end{pmatrix} \begin{pmatrix} v_i \\ v_{i,ext} \end{pmatrix} = \begin{pmatrix} g_i' \\ g_{i,ext}' \end{pmatrix}, \tag{4.4}$$

where $v_{i,ext}$ corresponds to the components of external variables on neighboring subdomains of subdomain i, and $g_{i,ext}'$ denotes components of the associated right-hand side vectors.

After (4.4) is approximately solved (e.g., using an ILU factorization), we obtain v_i by simply dropping the overlapping term $v_{i,ext}$; see [3]. Finally, u_i can be computed by back substitution from (2.7). The whole process is described in the next algorithm.

ALGORITHM 4.3. *Applying SchurRAS to a vector* z

1. *Compute* $g_i' = L_i^{-1} z$.
2. *Exchange interface variables in* g_i'.
3. *Compute* v_i *by solving* (4.4).
4. *Compute* u_i *using* (2.7).

5. Numerical experiments. This section presents a few experiments with the SchurRAS preconditioning technique. The first test is with a model test problem on a regular rectangular grid. The second considers a more realistic linear system related to a magnetohydrodynamics (MHD) problem. The experiments were performed on an SGI Origin 3800 with 64 CPUs at the Institute of Computational Mathematics and Scientific/Engineering Computing, Chinese Academy of Sciences, China.

5.1. Scaled problem: Two-dimensional case. Consider the elliptic PDE

$$-\Delta u + 100\frac{\partial}{\partial x}\left(e^{xy}u\right) + 100\frac{\partial}{\partial y}\left(e^{-xy}u\right) - 10u = f \tag{5.1}$$

on a square region with Dirichlet boundary conditions, discretized with a five-point centered finite-difference scheme on an $n_x \times n_y$ grid, excluding boundary points. The mesh is mapped to a virtual $p_x \times p_y$ grid of processors, such that a subrectangle of $r_x = n_x/p_x$ points in the x direction and $r_y = n_y/p_y$ points in the y direction is mapped to a processor. In the following experiments, the mesh size in each processor is kept constant at $r_x = 100$, $r_y = 100$. As the number of processors increases, the problem size increases proportionally. For example, on 4 processors the mesh is $(2r_x, 2r_y)$ leading to a problem size of $40,000$, and on 16 processors the mesh is $(4r_x, 4r_y)$ leading to a problem size of $160,000$. The resulting problems become harder as the number of processors grows. In a perfectly scalable situation, the final execution time for solving the problem with size $n = 160,000$ on 64 processors should be identical with the time for solving the problem of size $n = 40,000$ on 4 processors. Note that in order to maintain the aspect ratio of the physical domain, we need to consider *square* processor grids of increasing size.

In the following tests, ILU with threshold (ILUT) [14] is used as the local preconditioner. The fill-in parameter is 20, and the dropping tolerance is set to 0.001. Table 1 shows a comparison of preconditioners. Here, *its* indicates the number of iterations, t_{set} denotes the time for building the preconditioner, and t_{it} is the iteration time. BJ, RAS, and SchurRAS stand for the block Jacobi, the restricted additive Schwarz, and the Schur additive Schwarz method, respectively. The amount of overlap is 1 for RAS and SchurRAS. Flexible GMRES (FGMRES) [14] with the subspace size of 60 was used as an accelerator in all tests. The iteration is stopped when the residual norm is reduced by a factor of 10^6.

As shown in Table 1, the construction phase for all three preconditioners exhibits good scalability: The time for constructing preconditioners is almost a constant for three preconditioners as the number of processors increases. It is relatively more expensive to construct the preconditioning for SchurRAS due to the extra cost of constructing the approximate Schur complement matrix with Algorithm 4.1. If one of the methods in ARMS (Algebraic Recursive Multilevel Solvers) [16] is used as the local preconditioner instead of ILUT, then this additional cost can be reduced because the Schur complement matrix can be naturally obtained as a by-product of the ARMS preconditioning matrix. Table 1 also shows that when iteration counts and iteration times are considered, SchurRAS is the fastest of the three preconditioners. As the number of processors increases, the increase in the iteration counts for SchurRAS is more moderate than for the other two methods. The number of iterations taken by the SchurRAS on 64 processors is almost exactly half that required by RAS, which is itself almost exactly half that required by block Jacobi. The observations regarding iteration times are similar: The resulting iteration time for SchurRAS on 64 processors is about half that of RAS, which is about 55% that of BJ. This means in particular that the computational costs to apply the preconditioner to a vector is almost the same for SchurRAS and RAS. According to [19], for the Poisson equation, the multiplicative Schwarz (MS) preconditioner requires about half the iterations of the additive Schwarz preconditioner. Since the operator in this example is not quite a Laplacian, one cannot strictly make a comparison of the convergence rates of SchurRAS and MS though we expect them to be similar.

TABLE 1
Comparison of preconditioners without inner iteration for a two-dimensional PDE problem with fixed problem size. The times are in seconds.

5.2. Using inner iterations. It is natural to ask whether the performance can be improved by employing an inner iteration for the Schur complement system. Specifically we can use the GMRES accelerator to solve the Schur complement using SchurRAS as a preconditioner. The test problem is the same as the one in the previous section. The subspace size of GMRES is 5 and the tolerance for inner iteration is 10^6 (stop iteration when initial residual norm is reduced by a factor of 10^6). Table 2 compares two different preconditioners. One is the block Jacobi combined with GMRES(5) for solving the Schur complement system. The corresponding induced preconditioner, denoted by Schur–BJ, was presented in [15]. The other preconditioner, denoted by Schur–SchurRAS, is the preconditioner induced by solving the Schur complement system with GMRES(5) with SchurRAS as a preconditioner. A comparison between Tables 1 and 2 reveals that the numbers of iterations for SchurRAS and Schur–BJ are essentially identical. At the same time, and to our surprise, Table 2 shows that Schur–SchurRAS also takes about the same number of iterations to converge as SchurRAS. The interpretation of what has happened is as follows. In all cases, the resulting Schur complement system is the same since it involves the same (interface) variables and the same approximations coming from the same ILUT. By iterating on the Schur complement system, this system is solved to an accuracy that has become better than the accuracy used to compute the Schur complement system itself (ILUT). While these iterations are helpful in the BJ case (they solve the Schur complement more accurately), they seem to be useless in the SchurRAS case. The only explanation for this is that SchurRAS solves the complement systems *very accurately, i.e., within the range of accuracy with which the Schur complement matrices are computed*. The end result is that the SchurRAS is still the fastest since it involves no inner iterations.

5.3. Test with a matrix from an MHD simulation. The test matrix used in the following experiment originates from the simulation of MHD flows. The flow equations are represented as coupled Maxwell equations and the Navier–Stokes equations. The conservative MHD system is modeled by the Maxwell equations, written as

$$\frac{\partial \mathbf{B}}{\partial t} - \nabla \times (\mathbf{u} \times \mathbf{B}) + \eta \nabla \times (\nabla \times \mathbf{B}) + \nabla \mathbf{q} = 0, \tag{5.2}$$

$$\nabla \cdot \mathbf{B} = 0, \tag{5.3}$$

where η, $\mathbf{B}$, $\mathbf{u}$, and q are, respectively, the magnetic diffusivity coefficient, magnetic induction field, velocity field, and the scalar Lagrange multiplier for the magnetic-free divergence constraint. In fully coupled MHD, this system is solved along with the incompressible Navier–Stokes equations. In the tests that follow, we solve problems which arise from the Maxwell equations only. A preset periodic induction field $\mathbf{u}$ is used in the Maxwell equation (5.2). The physical region is the three-dimensional unit cube $[-1, 1]^3$. The discretization uses tetrahedral elements, with a Galerkin–least-squares stabilized formulation. The magnetic diffusivity coefficient is $\eta = 1$. Details on the discretization, the time-stepping procedure, and the choice of various numerical parameters can be found in [20] as well as in [18]. The matrix is of size $n = 470,596$ and has $nnz = 23,784,208$ nonzero entries. Note that in contrast with the scaled performance experiment of section 5.1 the problem size remains the same in this experiment, regardless of the number of processors used.

The following input parameters have been selected to solve this problem: The residual is to be reduced by 10^6, the FGMRES restart value is 60, the fill-in parameter used for ILUT is 40, and the dropping tolerance is 0.001. SchurRAS always takes fewer iterations than RAS and BJ. Note, for example, that SchurRAS takes 76 iterations to converge on two processors, which is even less than the number of iterations—78—required by BJ on one processor. The execution times are 84.46s and 161.27s, respectively. The efficiency is 0.95. It is verified that SchurRAS on two processors is a variant of global ILU factorization. It takes the same number of iterations (or even fewer) as BJ on one processor. RAS and BJ converge in 86 and 117 iterations on two processors, respectively. On the SGI Origin 3800, this amounts to 128.18s and 94.43s, respectively. The corresponding efficiencies are 0.629 and 0.854, respectively. SchurRAS always takes fewer iterations than BJ and RAS. As the number of processors increases, the number of iterations required by SchurRAS exhibits moderate growth, as shown in Figure 2. Because the computational costs of SchurRAS are similar to those of RAS, the reduction in the iteration number also leads to a reduction in the execution time as shown in Figure 3.

6. Conclusions. We presented a new preconditioner, called SchurRAS, which consists of solving the approximate Schur complement system with the restricted form of the additive Schwarz method. This preconditioner can be thought of as the combination of the overlapping additive Schwarz preconditioner and the nonoverlapping Schur complement preconditioner. The new technique has two main advantages. First, the construction of the preconditioning matrix for SchurRAS is not only easy to code from existing routines but also nicely scalable. This is in contrast with parallel ILU-based preconditioners or more standard Schur complement techniques. Second, SchurRAS has the same degree of parallelism as the additive Schwarz.

The experimental tests show that SchurRAS is superior to the widely used additive Schwarz preconditioner and the Schur complement-based preconditioner. For a

model two-dimensional scaled problem, the convergence rate of SchurRAS is similar to that of the MS preconditioner. For the same model problem and using 64 processors, we found that SchurRAS is about twice as fast as the RAS.

Work is under way to implement a fully recursive multilevel version of SchurRAS. Once the approximate Schur complement is obtained by performing partial Gaussian elimination, two neighboring subdomains can be merged into a larger subdomain, as in substructuring methods [19]. Some of the interface unknowns for the above two subdomains become interior unknowns for the newly merged larger subdomain. One may construct the approximate Schur complement system for the merged subdomains, and the process can be performed recursively. The recursion is stopped when the last approximate Schur complement system is small enough. Finally, a multilevel SchurRAS can be constructed by applying RAS to the last approximate Schur complement system.

Acknowledgments. The computing resources for this work were provided by the State Key Laboratory of Scientific/Engineering Computing (LSEC), Chinese Academy of Sciences, China. The authors would like to thank Prof. Azzeddine Soulaimani (Ecole de Technologie Superieure, Montreal, Canada) for providing them with the MHD test example used in the experiments.

COMPUTATIONAL STUDY OF FAST METHODS FOR THE EIKONAL EQUATION*

PIERRE A. GREMAUD† AND CHRISTOPHER M. KUSTER†

Abstract. A computational study of the fast marching and the fast sweeping methods for the eikonal equation is given. It is stressed that both algorithms should be considered as "direct" (as opposed to iterative) methods. On realistic grids, fast sweeping is faster than fast marching for problems with simple geometry. For strongly nonuniform problems and/or complex geometry, the situation may be reversed. Finally, fully second order generalizations of methods of this type for problems with obstacles are proposed and implemented.

Key words. Hamilton–Jacobi, eikonal, viscosity solution, fast marching, fast sweeping

AMS subject classifications. 65N06, 65Y20, 49L25, 35F30

DOI. 10.1137/040605655

1. Introduction. Steady state Hamilton–Jacobi equations play a major role in countless applications. While the *discretization* of those equations is approaching maturity (at least for single equations and convex Hamiltonians), the *resolution* of the nonlinear discretized systems is an active topic of research.

In this paper, two methods are compared: the fast marching (FM) method [13, 14, 17] and the fast sweeping (FS) method [4, 8, 16, 19]. The two-dimensional eikonal equation is taken as a test problem: given a slowness field F (a positive function), we look for a time of propagation u satisfying

$$|\nabla u| = F \qquad \text{in } \Omega \subset \mathrm{R}^2, \tag{1.1}$$

$$u = 0 \qquad \text{on } \Gamma \subset \mathrm{R}^2. \tag{1.2}$$

The two-dimensional domain Ω is the computational domain; Γ is a source, i.e., a closed subset of $\bar{\Omega}$ in which u is zero. The slowness field F can be unbounded, corresponding to the presence of obstacles.

We refer the reader to [8, 15] for issues related to the application of the above methods to the more general problem

$$H(x, \nabla u) = F. \tag{1.3}$$

While clearly of importance, those considerations are related more to discretization than they are to resolution and are not the focus of this paper. Discretization algorithms are only briefly reviewed in section 2. In section 3, three nonlinear solvers are described (Gauss–Jacobi, FM, and FS/nonlinear Gauss–Seidel). Section 4 presents an adaption of the FM and FS methods to problems with obstacles. The relative efficiency of FM and FS is discussed in section 5. Concluding remarks are offered in section 6.

2. Discretization. The basic construction principles for numerical Hamiltonians are well known [10] and are easily described on a Cartesian grid. There, the basic scheme takes the form

$$\mathcal{H}(D_+^x U_{ij}, D_-^x U_{ij}; D_+^y U_{ij}, D_-^y U_{ij}) = \mathcal{F}_{ij}, \tag{2.1}$$

with the obvious notation. In that case, we recall that $\mathcal{H}$ is consistent if

$$\mathcal{H}(p,p;q,q) = H(p,q) \qquad \forall p,q, \tag{2.2}$$

where H is the Hamiltonian of the problem under consideration (here $H(p,q) = \sqrt{p^2+q^2}$). The numerical Hamiltonian is monotone if nonincreasing in its first and third arguments and nondecreasing in the other two: $\mathcal{H}(\downarrow,\uparrow,\downarrow,\uparrow)$ [6]. Consistency ensures that the correct problem is approximated while monotonicity guarantees convergence to the correct viscosity solution [5, 12].

Many numerical Hamiltonians can be found in the literature; most of them are derived from corresponding numerical fluxes for conservation laws. The main examples are the Godunov flux $\mathcal{H}^G$ and the Lax–Friedrichs flux $\mathcal{H}^{LF}$, which here take the form

$$\begin{aligned}
\mathcal{H}^G(p_+,p_-;q_+,q_-) &= \sqrt{\max\{p_-^+, p_+^-\}^2 + \max\{q_-^+, q_+^-\}^2}, \\
\mathcal{H}^{LF}(p_+,p_-;q_+,q_-) &= \sqrt{\left(\frac{p_+ + p_-}{2}\right)^2 + \left(\frac{q_+ + q_-}{2}\right)^2} \\
&\quad - \sigma_x \frac{p_+ - p_-}{2} - \sigma_y \frac{q_+ - q_-}{2},
\end{aligned}$$

where $\sigma_x \geq \max|\frac{\partial H}{\partial p}|$ and $\sigma_y \geq \max|\frac{\partial H}{\partial q}|$, where $(\cdot)^+ = \max\{\cdot, 0\}$ and $(\cdot)^- = -\min\{\cdot, 0\}$. Upwind discretizations such as the Godunov method are especially simple to implement for (1.1) and for convex Hamiltonians in general. However, $\mathcal{H}^G$, for instance, becomes very involved for general Hamiltonians. While centered methods such as Lax–Friedrichs do not suffer from that problem, they require special treatment at the boundary of the computational domain [8]. The discretization used below is essentially $\mathcal{H}^G$.

Many applications call for the use of non-Cartesian or unstructured meshes; see [1, 7, 9, 14, 15] for a few examples of such methods. Following [14, 15], consider a node X_0 at which the solution U is to be computed and two neighboring nodes X_1 and X_2 at which the values of U (U_ℓ, $\ell = 1,2$) and its derivatives ($\partial_x U_\ell, \partial_y U_\ell$, $\ell = 1,2$) are known or have already been computed. We set

$$N_\ell = \frac{X_0 - X_\ell}{|X_0 - X_\ell|}, \quad \ell = 1,2, \quad \text{and} \quad \mathcal{N} = \left[\frac{N_1}{N_2}\right],$$

where $\mathcal{N}$ is a 2×2 nonsingular matrix, assuming X_0, X_1, and X_2 are not lined up. The directional derivatives in the directions N_1 and N_2 are approximated by

$$D_\ell U = \frac{U_0 - U_\ell}{|X_0 - X_\ell|}, \qquad \ell = 1,2 \quad \text{(first order formula)}, \tag{2.3}$$

$$D_\ell U = 2\frac{U_0 - U_\ell}{|X_0 - X_\ell|} - N_\ell \cdot [\partial_x U_\ell, \partial_y U_\ell], \qquad \ell = 1,2 \quad \text{(second order formula)}. \tag{2.4}$$

Those approximate directional derivatives are linked to the gradient by

$$D_\ell U = N_\ell \cdot \nabla U + \mathcal{O}(|X_0 - X_i|^\alpha) \qquad \text{or} \qquad DU = \mathcal{N}\nabla U + \mathcal{O}(h^\alpha), \tag{2.5}$$

where $DU = [D_1U, D_2U]$, $h = \max\{|X_0 - X_1|, |X_0 - X_2|\}$, and $\alpha = 1$ or 2 depending on whether (2.3) or (2.4), respectively, is used. Solving for ∇U and plugging into (1.1), one finds the (quadratic) equation defining the unknown U_0,

$$DU^t(\mathcal{N}\mathcal{N}^t)^{-1}DU = (F(X_0))^2. \tag{2.6}$$

The above methods are well understood theoretically: convergence to the viscosity solution when the Godunov flux $\mathcal{H}^G$ is used was established in [12]; see also [15] for additional results and references.

3. Resolution. The system of coupled quadratic equations corresponding to imposing (2.6) at all nodes has to be solved. If θ denotes the angles between N_1 and N_2, the matrix $\mathcal{N}\mathcal{N}^t$ is symmetric positive definite provided $0 < \theta < \pi$; its condition number is $\frac{1+\cos\theta}{1-\cos\theta}$. Therefore, regardless of the choice of stencil (first or second order), (2.6) has two real solutions. This situation is generic for Hamilton–Jacobi equations.

Let $(U_1, U_2, \ldots, U_N)$ be the unknowns for an arbitrary ordering of the nodes. The resulting system can be written symbolically as

$$f(U) = f(U_1, U_2, \ldots, U_N) = 0. \tag{3.1}$$

An iterative scheme, essentially a fixed point method or Gauss–Jacobi method, was proposed in [12]. One step of the algorithm is as follows.

Gauss–Jacobi algorithm.

- Choose a node and regard the neighboring values as fixed.
- Solve (2.6) for the value at the considered node; the largest of the two possible solutions is selected, in agreement with the viscosity criterion.
- Repeat until convergence (fixed point).

The corresponding pseudocode is

```
k = 0
U^0 = (0, ..., 0)
while  U^k ≠ U^{k+1}  or  k ≠ 0
       k = k + 1
       for  ℓ = 1  to  N
            solve f(U_1^{k-1}, ..., U_{ℓ-1}^{k-1}, U_ℓ^k, U_{ℓ+1}^{k-1}, ..., U_N^{k-1}) = 0  for  U_ℓ^k
       end
end
```

This approach is obviously slow, as each node has to be revisited several times before the numerical solution settles down. Further, no advantage is taken of the propagation character of the problem.

With marching methods, the nodes are considered in an order consistent with the way the wave fronts propagate, i.e., with the Huygens principle [13, 14, 17]. This leads to (quasi) single pass algorithms. The fast marching algorithm, FM, is based on the monotonicity of the solution along the characteristics. The nodes are divided into three sets: the already-computed nodes, the not-yet-considered nodes, and the nodes "on the propagation front."

Fast Marching algorithm.

- The node with lowest value in the "front" set is removed from it and added to the "computed" set; its not-yet-computed neighbors are added to the "front."
- The values of all the nodes in the "front" are recomputed using (2.6).
- Repeat until all the nodes are "computed."

The list operations are handled by the heap sort algorithm [3, 18], which is the key to the speed of FM. This type of sort has the advantage that every tree operation (insertion, removal, update) is of order $\log_2 n$, where n is the number of elements in the tree, i.e., the number of "front" nodes at that step. Note that n is of order $\sqrt{N}$ at every step, where N is the total number of nodes in the mesh. By placing the "front" nodes into this structure, the computational complexity is kept at the order of $N \log_2 N$. The pseudocode for FM is

$\mathtt{U} = (\infty, \ldots, \infty)$
"front" = "source"
while "front" $\neq \emptyset$
    $\mathtt{U}_{\min} = \min \mathtt{U} \in$ "front"
    "front" = "front" + neighbors of $\mathtt{U}_{\min}$
    remove $\mathtt{U}_{\min}$ from "front"
    for $\mathtt{U}_\ell \in$ "front"
        solve $\mathtt{f}(\mathtt{U}_1, \ldots, \mathtt{U}_{\ell-1}, \mathtt{U}_\ell, \mathtt{U}_{\ell+1}, \ldots, \mathtt{U}_\mathtt{N}) = 0$ for $\mathtt{U}_\ell$
    end
end

A third type of method has recently been proposed, the fast sweeping (FS) method; see among others [4, 8, 16, 19]. FS aims at improving on the first Gauss–Jacobi method by using a Gauss–Seidel-type update process. This change alone would not improve on the performance of Gauss–Jacobi very significantly because of the upwind condition (see (4.1) below): an ordering process is needed. Instead of proceeding in a way consistent with the underlying wave propagation, FS considers sweeps in predetermined directions. The directions of sweep can correspond, for instance, to the direction of the coordinate axes. For two-dimensional problems, four sweeping directions can be considered. More precisely, in an $M \times M$ matrix, we would have $i = 1 : M, j = 1 : M$ (upper left to lower right, ULLR); $j = 1 : M, i = M : 1$ (lower left to upper right, LLUR); $i = M : 1, j = M : 1$ (lower right to upper left, LRUL); $j = M : 1, i = 1 : M$ (upper right to lower left, URLL).

Fast Sweeping algorithm.

- Choose a direction of sweep and a corresponding ordering.
- Loop through of all the nodes in the chosen order and successively solve (2.6) for each of them.
- Repeat for the other directions of sweep.
- Repeat until convergence.

The corresponding pseudocode is

$\mathtt{k} = 0$
$\mathtt{U}^0 = (\infty, \ldots, \infty)$
$\mathtt{order} = [\mathtt{ULLR}, \mathtt{LLUR}, \mathtt{LRUL}.\mathtt{URLL}]$
while $\mathtt{U}^\mathtt{k} \neq \mathtt{U}^{\mathtt{k}+1}$ or $\mathtt{k} = 0$
    $\mathtt{k} = \mathtt{k} + 1$
    $\mathtt{i} = \mathtt{mod}(\mathtt{k} - 1, 4) + 1$
    $\mathtt{ordering} = \mathtt{order}[\mathtt{i}]$

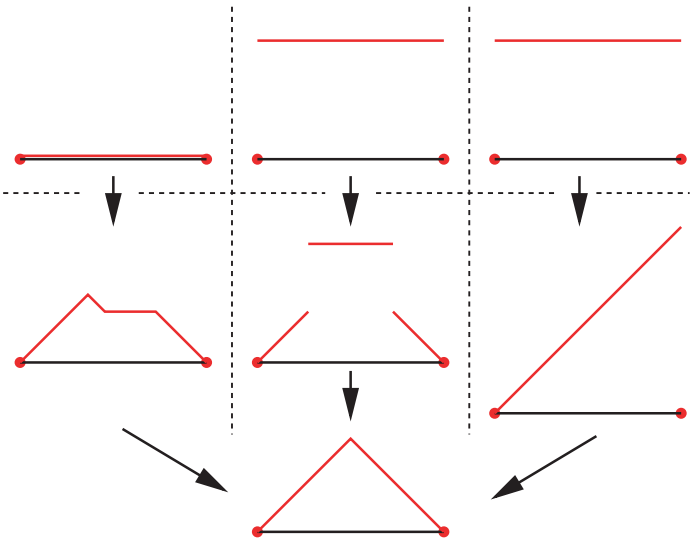

FIG. 1. *Schematic representation of the update process for Gauss–Jacobi (left), FM (center), and FS (right) for a one-dimensional eikonal equation with homogenous boundary conditions.*

```
        for  ℓ = 1  to  N
             solve f(U_1^k, ..., U_{ℓ-1}^k, U_ℓ^k, U_{ℓ+1}^{k-1}, ..., U_N^{k-1}) = 0  for  U_ℓ^k
        end
    end
```

The update process for the above three methods is schematically represented in Figure 1. Also, as a result of the absence of a true ordering process (only the way arrays are accessed changes), the complexity of the above algorithm can be shown to be of order N [19], as opposed to $N \log_2 N$ for FM. However, whether this translates into a computational advantage depends on the geometry of the problem; see section 5.

Unlike what is proposed in [16, 19], we consider FS as a direct method for two reasons. First, as shown in section 4, the algorithm has to be run to its completion. Second, the following result gives a natural stopping criterion.

LEMMA 3.1. *Let U^k, $k = 0, \ldots, \infty$, be the iterates generated by the FS method applied to* (1.1), (1.2). *Then there exists $\bar{k}$ such that $U^k = U^{\bar{k}}$ for all $k \geq \bar{k}$.*

Proof. Consider an arbitrary node i at which the solution has been computed. There exists a path made of successive upwind neighbors from i to Γ. By construction, each successive sweep determines the final value of at least one node on that path, starting on Γ and moving successively to i. This clearly leads to a finite algorithm. The numerical solution at node i depends only on the values at its neighbors. If those values do not change at step $\bar{k}+1$, then $U_i^k = U_i^{\bar{k}}$ for $k \geq \bar{k}$. □

Essentially, the three methods differ in the order in which the nodes are computed. Gauss–Jacobi takes no particular order, FM uses an ordering based on partial numerical solutions, while FS uses a mesh-based ordering. As described above, FS makes full use of the Cartesian structure of the mesh.

4. Problems with obstacles and implementation. An obstacle is a domain in which waves propagate at infinitely slow speed: $F(x, y) = \infty$ if and only if (x, y) belongs to the obstacle. Problems with obstacles require additional care if both accuracy and efficiency, i.e., marching character, of the methods are to be preserved.

For future reference, we now introduce three specific test problems used in this paper. In all three cases, we consider (1.1), (1.2) with $\Omega = (0,6)^2$, $\Gamma = (0,0)$.

Example 1. $F(x,y) = C$ for all $(x,y) \in \Omega$, no obstacle.[1]

Example 2.

$$F(x,y) = \begin{cases} \infty & \text{if } (x-3)^2 + (y-3)^2 <= 1, \\ C & \text{otherwise,} \end{cases}$$

circular obstacle.

Example 3.

$$F(x,y) = \begin{cases} \infty & \text{if } (x,y) \in \Xi, \\ C & \text{otherwise,} \end{cases}$$

where Ξ is the "rings" of Figure 7.

If no local adaption is made when treating problems with obstacles such as Examples 2 and 3, accuracy is lost. Taking, for instance, Example 2, a straightforward discretization would consist of applying any of the above three methods *outside* the circular obstacle using a simple Cartesian mesh. The left half of Table 1 illustrates the loss accuracy incurred by the first and second order FM methods, respectively, i.e., using (2.3) and (2.4).

TABLE 1

Convergence study for formally first and second order methods in the presence of a circular obstacle (Example 2); M measures the number of nodes on one edge of Ω, i.e., total number of nodes $N = \mathcal{O}(M^2)$.

As can be seen from those results, the standard first order method converges with an average order of only about .75 (in the L^1 norm) while the standard formally second order method loses a full order (the average rate in the L^1 norm is about 1.0).

[1] In all the calculations that follow, C was chosen as $\tan 40^o$; see [2] for a related application to granular piles. This choice does not affect the numerical results.

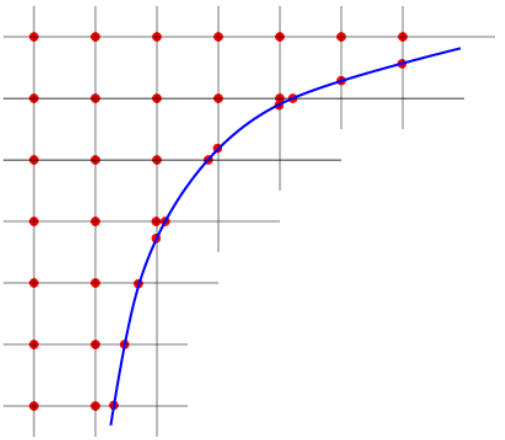

FIG. 2. *Mesh structure around the obstacle.*

The results in the L^2 norm are comparable, while the L^∞ rates are significantly lower. This is not surprising since the underlying solution presents a "shock" at the back of the obstacle (discontinuity of the first derivatives).

In [2], we started the study of a generalization of the FM method from [14, 15] to problems with obstacles. The nodes are defined on a uniform Cartesian mesh away from the obstacle. Near the obstacle, additional nodes corresponding to the intersection of the obstacle's boundary with the mesh lines are added; see Figure 2. The detailed solving process is as follows for the modified FM algorithm.

Let X_0 be a node to be updated. Let X_1 and X_2 be a pair of primary neighbors of X_0. Following [15], an upwinding criterion is considered: the characteristic direction should point into the simplex defined by X_0, X_1, and X_2. This is equivalent to requiring the approximate gradient defined by (2.5) to have positive components when expressed in terms of the unit vectors $N_1 = \frac{X_0 - X_1}{|X_0 - X_1|}$ and $N_2 = \frac{X_0 - X_2}{|X_0 - X_2|}$. In other words,

$$(\mathcal{N}\mathcal{N}^t)^{-1} DU > 0. \tag{4.1}$$

The value U_0 at X_0 is then determined as follows:

$$U_0 = \min \begin{cases} \text{solution of (2.6) with second order stencil (2.4) if (4.1) is true,} \\ \text{solution of (2.6) with first order stencil (2.3) if (4.1) is true,} \\ \min_{i=1,2}\{U_i + |X_0 - X_i| F(X_0)\}. \end{cases} \tag{4.2}$$

Regardless of the choice of stencil (first or second order), (2.6) has two real solutions, from which we always consider the larger one only, to be consistent with causality. In the first two cases, the values of the partial derivatives of U at X_0 are updated using $\nabla U = \mathcal{N}^{-1} DU$. In the third case, we set $\nabla U = N_i F(X_0)$, where i is the index corresponding to the case of lowest value for U_0. This process is repeated for all pairs of primary neighbors X_1 and X_2, and the lowest resulting value of U_0 is kept.

As checking (4.1) accounts for a sizable part of the runtime, the following result is useful in practice.

LEMMA 4.1. *Let θ, $0 < \theta < \pi$, be the angle between N_1 and N_2. The upwind condition* (4.1) *is equivalent to*

$$| D_1 U - D_2 U | < (1 - \cos\theta)\, F(X_0). \tag{4.3}$$

Proof. The result is easy to verify geometrically. Setting $d_i = D_i U$, $i = 1, 2$, the scheme (2.6) takes the form

$$d_1^2 - 2\cos\theta\, d_1 d_2 + d_2^2 = \sin^2\theta\, F(X_0)^2.$$

This defines an ellipse in the $d_1 d_2$-plane with major (respectively, minor) semiaxis of length $\frac{\sin\theta}{\sqrt{1-\cos\theta}} F(X_0)$ (respectively, $\frac{\sin\theta}{\sqrt{1+\cos\theta}} F(X_0)$) in the direction $[1, 1]$ (respectively, $[1, -1]$). The upwind condition (4.1) reads as

$$d_1 - \cos\theta\, d_2 > 0 \text{ and } d_2 - \cos\theta\, d_1 > 0.$$

As Figure 3 and a little algebra show, the portion of the ellipse that satisfies the above conditions can also be characterized by $|\, d_1 - d_2\,| < (1 - \cos\theta) F(X_0)$. Note that this last condition also admits a set of solutions opposite the desired ones on the ellipse depicted in Figure 3. Those solutions are, however, never encountered in practice since only the largest of the two roots of the quadratic equation is retained. ∎

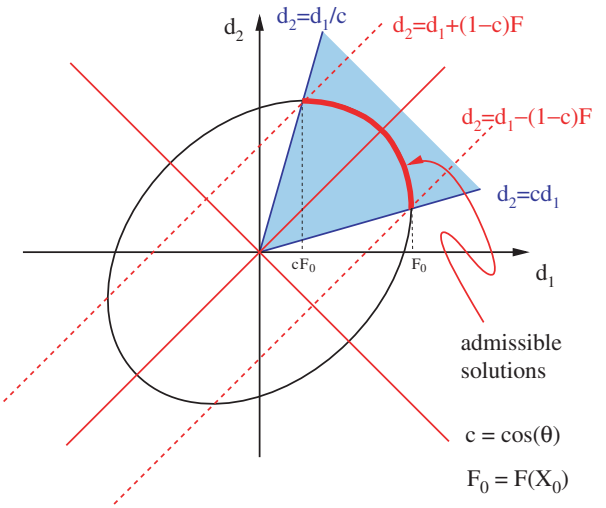

FIG. 3. *Upwind condition; see Lemma* 4.1 *and its proof.*

For general meshes, the above condition requires the calculation of U_0 and has to be checked a posteriori. For a uniform Cartesian mesh of size Δx, (4.3) reads as

$$|\, U_1 - U_2\,| < \Delta x\, F(X_0)$$

and can be checked a priori, i.e., *without* having to solve the quadratic equation (2.6). This explains the large discrepancies in runtimes in favor of the low accuracy method on uniform Cartesian grids reported in Table 2 (see Figure 5 for a comparison of runtime versus accuracy).

As observed in [11], in the presence of a point source, a singularity of the travel time field is clearly located at the source itself. Unless special care is taken near that source, a loss of accuracy ensues. The problem can be fixed by defining a mesh-

TABLE 2

Runtimes illustrating the overhead due to higher accuracy for the FM method applied to Example 2; see text for full details.

M	Time 1	Time 2	Time 3
100	0.02	0.57	0.60
200	0.10	2.20	2.38
400	0.43	8.93	9.45
800	2.02	34.5	38.1
1600	10.1	143	154
3200	53.0	610	654

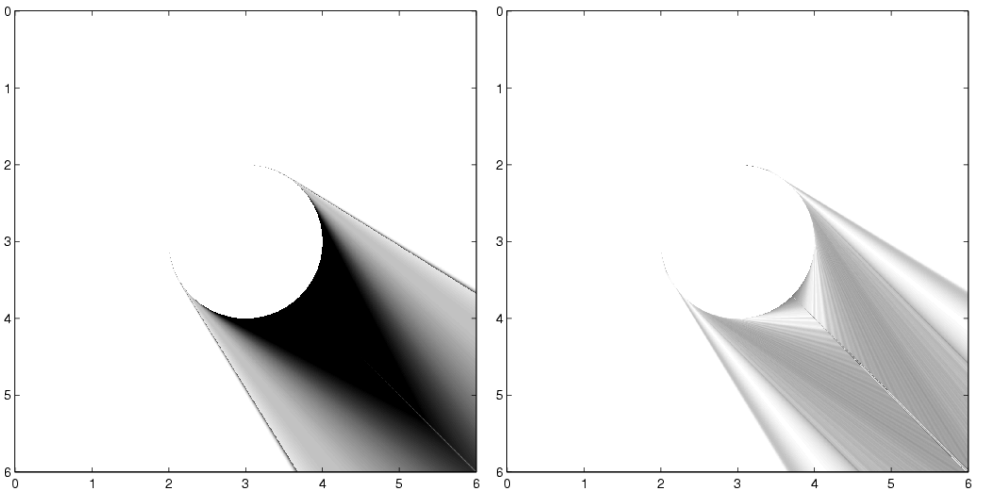

FIG. 4. *Error propagation downstream of the obstacle for the standard (left) and modified (right) second order FM method (Example 2, $M = 1600$, $N = \mathcal{O}(M^2)$). The source is located at $(0, 0)$.*

independent domain around the source and initializing the values at the nodes there to the corresponding values of the exact solution. This fix was applied to all methods under study here. As illustrated in Table 1, the modified scheme is found to preserve first and second order accuracy in the L^1 norm even in the presence of obstacles. For the second order version, the L^2 rates of convergence are slightly below 2, while the method appears to converge with order 1 in the maximum norm. In all cases and all norms, the modified method exhibits much better accuracy than the standard method. Error propagation downstream from the obstacle is illustrated in Figure 4 for both standard and modified methods.

It should be noted that second order convergence for the finer meshes was obtained only after rewriting the quadratic formula for solving (2.6) in a form that limits cancellation effects. (Standard IEC559 double precision was used throughout.)

Higher accuracy does not come for free. In Table 2, the overhead corresponding to maintaining optimal accuracy is described in terms of computational time and number of operations.

Table 2 compares three different algorithms. Time 1 corresponds to the computational time and number of operations for the standard method where full advantage has been taken of the uniform Cartesian mesh in the implementation: simplification

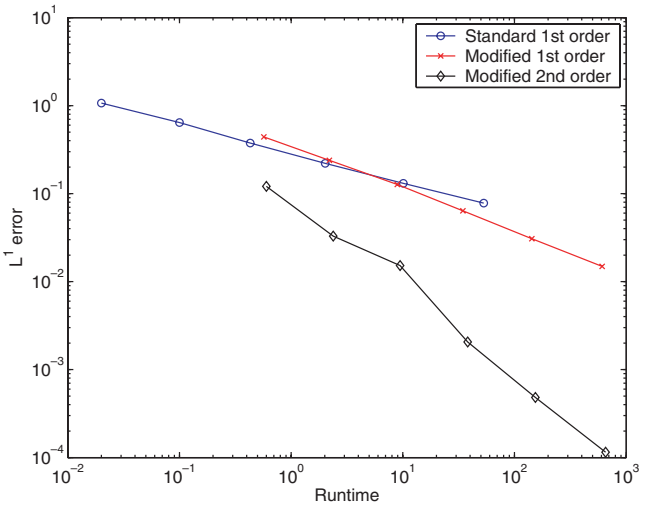

FIG. 5. *L^1 error versus runtime for the standard "first" order method, the modifed first order method, and the modified second order method applied to Example* 2.

of the quadratic equation (2.6) and of the upwinding condition (see remarks above). The results for the fully first and second order methods correspond, respectively, to Time 2 and Time 3. The fully second order method is found to be only marginally slower than the fully first order one. It is clear from Table 2 that a significant price has to be paid for the increase in accuracy. However, Figure 5 shows that the advantage in speed for the standard first order is offset by its relative lack of accuracy and slow convergence as the mesh is refined.

FS as described in [16, 19], for instance, is proposed as an iterative method, i.e., the algorithm is stopped before completion according to a stopping criterion of the type $\|u^{k+1} - u^k\|_{L^1} < \delta = 10^{-10}$. Figure 6 illustrates the convergence history of the numerical solution toward the exact solution of the *discretized* problem for Example 3. The discrepancy falls down to zero if one additional step is taken. It is observed that stopping on small decreases, as suggested by the previous criterion, is not advisable. Therefore, running FS until completion appears to be the best strategy, and the algorithm has to be considered as a "direct" method.

For both FM and FS, obstacles can be implemented as domains with truly infinite speed (in which case, no calculations are made at nodes inside the obstacle), or a sufficiently large but finite slowness can be assigned to nodes inside the obstacle and the solution can be computed there. Our implementation uses the former approach. As can be expected and is illustrated in Figure 6, those choices do not affect the solutions of the discretized problems.

5. Algorithms comparison. The three examples from section 4 were implemented. As the implementation on FS on a non-Cartesian grid was not attempted, first order FM and FS were compared on Cartesian grids. Therefore in Table 3, both methods share the same (in)accuracy. Note that each algorithm was run until "convergence." For FM, this means until exhaustion of the nodes in the "front," while for FS it means until a fixed point has been reached (no change after a sweep; see Lemma 3.1). As can be seen from that table, FS is faster for the first (trivial) example;

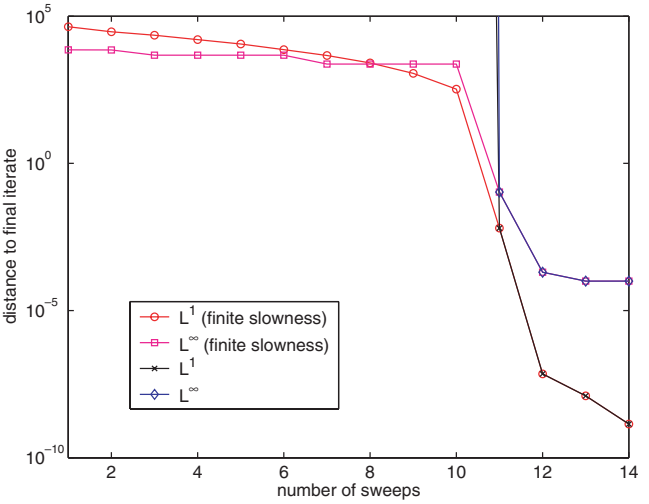

FIG. 6. *L^1 and L^∞ norms of the difference between the exact solution of the* discretized *problem with the FS method and iterates after each sweep; rings (Example* 3*); $M = 1600$. The curves with "finite slowness" are obtained by treating the obstacle as a domain with large slowness; the other curves correspond to a genuine obstacle (slowness $= \infty$).*

both methods perform in a way very similar to Example 2, with a slight advantage for FS, while on Example 3 FM is faster for all but the finest mesh.[2]

The results from Table 3 also show that, for moderate mesh sizes, the more complicated the domain is, the better FM performs with respect to FS. Indeed, while FM continually advances the wavefront, FS has to do another set of sweeps every time the direction of propagation changes. In the case of Example 3, for instance, that direction changes several times; see Figure 7. In Table 4, the runtimes for a modified Example 3 are reported: the number of partial rings was increased from zero to a total of five as displayed in Figure 7. It is observed that the runtime is roughly constant for FM as the complexity of the domain (number of rings) increases. For FS, however, the runtime increases, although in a nonuniform way. This nonuniformity results from both the geometry of the domain (odd/even number of rings) and our specific implementation.

As argued in [19], FS has an asymptotic computational complexity of $\mathcal{O}(N)$ while FM's is $\mathcal{O}(N \log_2 N)$. Eventually, FS overcomes FM, even for nontrivial examples such as Example 3, as the mesh gets fine enough. The constants of proportionality involved in those asymptotic relations are not easy to analyze. For specific examples, those constants can be estimated numerically. Assuming runtimes for FS and FM to be, respectively, equal to $C_{FS} mN$ and $C_{FM} N \log_2 N$, where m is the number of sweeps required by FS, one can use results similar to those from Table 3 to roughly determine the two constants C_{FS} and C_{FM}. An empirical condition under which FS is faster than FM can then be derived. Using best fits to the above examples and cases, one finds here

$$m \lessapprox .6 \log_2 N.$$

[2]In an initial version of this paper (technical report), the reported runtimes had been obtained by codes that were not fully optimized for use on uniform Cartesian meshes. One of those optimization steps removed unnecessary checks from FS; those redundant operations were, by construction, not present in the FM algorithm. Therefore, the two codes were not equally affected. To the authors' knowledge, the current codes are fully optimized for uniform Cartesian grids.

TABLE 3
Runtime for first order FM and FS on a uniform Cartesian mesh for Examples 1, 2, *and* 3 *($N = \mathcal{O}(M^2)$).*

M	FM (time)	FS (time)	# sweeps
Example 1: no obstacle			
100	0.01	0.01	2
200	0.09	0.03	2
400	0.43	0.13	2
800	2.03	0.54	2
1600	10.1	2.16	2
3200	53.6	8.59	2
Example 2: circular obstacle			
100	0.02	0.01	5
200	0.10	0.09	6
400	0.43	0.37	6
800	2.02	1.45	6
1600	10.1	5.91	6
3200	53.0	23.5	6
Example 3: "rings"			
100	0.02	0.05	16
200	0.10	0.22	16
400	0.48	0.91	16
800	2.28	3.44	16
1600	11.4	14.3	16
3200	57.5	56.8	16

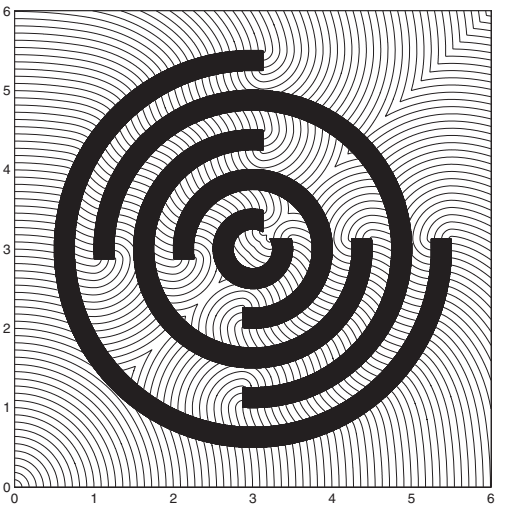

FIG. 7. *Propagation around an obstacle: Example* 3*, FM with $M = 800$. The source is located at $(0, 0)$.*

In other words, for a "reasonable" 800×800 mesh ($N = 800^2$), FS will be faster than FM as long as the number of sweeps necessary for convergence does not exceed about 11. This is in good agreement with Table 4.

6. Conclusion. We have brought to the fore three main points. First, ordered methods for the eikonal equation can be modified to retain optimal convergence rates (first or second order), even on low regularity problems, while retaining their efficiency. This can be done in a natural way for FM, but it is more cumbersome for FS, which is

TABLE 4
Runtime and operation count with differing numbers of concentric partial rings ($M = 800$).

Rings	FM (time)	FS (time)	# sweeps
0	2.03	0.54	2
1	2.05	2.15	8
2	2.12	2.09	8
3	2.12	3.02	12
4	2.24	2.89	12
5	2.28	3.44	16

much less flexible. Second, the examples considered show that both methods should be thought of as direct and not iterative algorithms. This is obvious for FM. For FS, a natural stopping criterion is proposed and justified. Finally, FS and FM have asymptotic orders of complexity of, respectively, $\mathcal{O}(mN)$ and $\mathcal{O}(N \log_2 N)$, where m is the number of sweeps and N is the total number of nodes. On a realistic grid, FS will be faster than FM for problems with simple geometry. For strongly nonuniform problems and/or complex geometry, the situation may be reversed.

Both methods can be relatively easily extended to more general convex Hamiltonians [15, 16]. Behaviors similar to those reported here are expected. The case of nonconvex Hamiltonians is more complex, even with respect to the construction of appropriate numerical fluxes. Very few schemes have been proposed (see, for instance, [8], where a Lax–Friedrichs sweeping method is introduced); more needs to be done to develop fast and accurate methods for those problems.

Acknowledgments. The authors are grateful to Hongkai Zhao for his helpful comments and to the referees for remarks that led to a better presentation of the results.

COMPOSITION METHODS FOR DIFFERENTIAL EQUATIONS WITH PROCESSING*

S. BLANES†, F. CASAS‡, AND A. MURUA§

Abstract. We construct numerical integrators for differential equations up to order 12 obtained by composition of basic integrators. The following cases are considered: (i) composition for a system separable in two solvable parts, (ii) composition using as basic methods a first-order integrator and its adjoint, (iii) composition using second-order symmetric methods, and (iv) composition using fourth-order symmetric methods. Each scheme is implemented with a processor or corrector to improve their efficiency, and this can be done virtually cost-free.

Key words. composition methods, geometric integrators, processing technique, cheap postprocessor, initial value problems

1. Introduction.

A widely used technique in the geometric integration of ordinary differential equations (ODEs) is to compose one or more low-order basic one-step methods (usually first or second order) with appropriately chosen weights to achieve a higher-order scheme. The resulting composition method then inherits the relevant geometric properties that the basic scheme shares with the exact solution (if these properties are preserved by composition). In close connection with composition is the splitting idea: if the differential equation can be split into two or more parts that are either solvable or simpler to integrate than the original system, it is also possible to build integrators by composition of the corresponding flows. These splitting methods are frequently used in celestial mechanics, quantum mechanics, molecular dynamics, and accelerator physics and, in general, for solving numerically Hamiltonian systems, as well as Poisson systems and reversible differential equations [8, 16, 21].

It has been widely recognized that the class of numerical integrators which preserve the geometric properties of the exact flow (the so-called *geometric integrators*) provide a better description of the system than standard methods, even with respect to the accumulation of numerical errors along the evolution, making them the best option for carrying out a long time integration. However, for short time integrations they are typically less efficient. For this reason it is important to build more efficient high-order geometric integrators which are also competitive in this setting.

Given the ODE

$$x' = f(x), \qquad x_0 = x(0) \in \mathbb{R}^D, \tag{1.1}$$

with $f : \mathbb{R}^D \longrightarrow \mathbb{R}^D$ and associated vector field (or Lie operator associated with f)

$$F = \sum_{i=1}^{D} f_i(x) \frac{\partial}{\partial x_i}, \tag{1.2}$$

a one-step numerical integrator for a time step h, $\psi_h : \mathbb{R}^D \longrightarrow \mathbb{R}^D$, can be regarded as a smooth family of maps with parameter h such that ψ_0 is the identity map. The integrator ψ_h is said to be of order q if $\psi_h = \varphi_h + \mathcal{O}(h^{q+1})$ as $h \to 0$, where φ_h is the h-flow of the ODE (1.1). In other words, an approximation to the exact solution $x(h)$ is given by $x_h = \psi_h(x_0) = \varphi_h(x_0) + \mathcal{O}(h^{q+1})$.

In this work we consider methods obtained by enhancing an integrator ψ_h with processing, i.e., algorithms of the form

$$\hat{\psi}_h = \pi_h \circ \psi_h \circ \pi_h^{-1}. \tag{1.3}$$

Here ψ_h is referred to as the *kernel* and the map $\pi_h : \mathbb{R}^D \longrightarrow \mathbb{R}^D$ as the *postprocessor* or *corrector*. The method ψ_h is of *effective order* q if a postprocessor π_h exists for which $\hat{\psi}_h$ is of (conventional) order q [6]. Application of $\hat{\psi}_h$ over n steps with constant step size h leads to

$$\hat{\psi}_h^n = \pi_h \circ \psi_h^n \circ \pi_h^{-1}.$$

The computation of the preprocessor π_h^{-1} has to be done only at the beginning of the integration; then the kernel ψ_h acts once per step, and finally π_h is evaluated when output is required.

The analysis of the order conditions of the method $\hat{\psi}_h$ has shown that many of them can be satisfied by π_h, so that ψ_h must fulfill a much reduced set of restrictions [1, 3, 7, 14]. This allows us to take kernels of effective order q involving far fewer function evaluations than a conventional integrator of order q.

In the course of constructing composition methods of a given order, the processing technique also presents additional advantages. In general, it is necessary to solve numerically a system of nonlinear polynomial equations in the coefficients (the order conditions), whose number and complexity grow very rapidly with the order. Numerically finding every solution and eventually determining the optimal solution turns into a very complicated task for nonprocessed methods, even for relatively small orders. However, this problem simplifies for processed composition schemes because the analysis has to be carried out only for the kernel. Since the number of order conditions for the kernel is smaller, one can analyze in more detail the set of solutions, even for moderate orders, and eventually find very efficient methods [25, 3, 1, 15].

Once a kernel is chosen, it remains for us to build a postprocessor such that the whole method has the required order. We can also impose additional conditions to reduce the leading order error terms. Then the coefficients of the postprocessor π_h usually have to satisfy a large number of conditions. Many different solutions can be found, and since usually their different contributions affect only higher-order terms, we can choose one with moderately small coefficients (to avoid large higher-order error terms), which considerably simplifies the numerical search.

In any case, very often the postprocessors thus constructed are more expensive than the kernel ψ_h, so that the use of processed schemes in this form has to be confined to problems in which intermediate results are not frequently required; otherwise the overall efficiency of the methods is decreased. To overcome this difficulty, a technique is developed in [2] which allows us to obtain approximations to the postprocessor virtually cost-free and without loss of accuracy. The key point is to replace π_h by a new integrator $\hat{\pi}_h \simeq \pi_h$ obtained from the intermediate stages in the computation of ψ_h. It is recommended that one have a very accurate preprocessor π_h^{-1} but, on the other hand, the postprocessor can safely be replaced by a cheap approximation satisfying only the order conditions.

In the analysis of composition methods it is useful to apply the notion of adjoint of a given integrator ψ_h [21]. By definition, this is the method ψ_h^* such that $\psi_h^* = \psi_{-h}^{-1}$. A method that is its own adjoint is called self-adjoint or (time-)*symmetric*. In this case, $\psi_{-h} \circ \psi_h = \mathrm{id}$. The order of a symmetric method is necessarily even. In addition, only even powers of h appear in the asymptotic expansion of the global error [21] so that the order equations are considerably simplified and its number is reduced. Time-symmetry is often a desirable property when one aims to discretize the differential equation in such a way that qualitative features of the system are preserved [8, 16]. In the context of processed methods, if the kernel ψ_h is symmetric and the postprocessor π_h is an even function of h ($\pi_{-h} = \pi_h$), then the processed integrator $\hat{\psi}_h$ has also the time-symmetry property.

In this paper we construct and analyze new high-order processed geometric integrators. We consider several families of kernels which are symmetric compositions of different basic methods of first, second, and fourth order and whose postprocessors can be implemented essentially at no additional computational cost. The procedure is largely based on the theoretical analysis of the processing technique done in [2], to which we will refer often in what follows.

2. Families of composition methods.

2.1. Classes of methods. Next we present the different classes of schemes analyzed, whose common feature is that they are defined as the composition of simpler maps.

1. Let us assume that the ODE (1.1) can be written as $x' = f_a(x) + f_b(x)$ and that the vector field F is split accordingly as $F = F_a + F_b$. Suppose that the corresponding h-flows $\varphi_h^{[a]}$ and $\varphi_h^{[b]}$ can be computed exactly. Then one can form the following group $\mathcal{G}_1$ of schemes:

   (2.1)
   $$\mathcal{G}_1 = \left\{ \varphi^{[b]}_{\beta_{2s}h} \circ \varphi^{[a]}_{\beta_{2s-1}h} \circ \cdots \circ \varphi^{[b]}_{\beta_2 h} \circ \varphi^{[a]}_{\beta_1 h} : \ s \geq 1, \ (\beta_1, \ldots, \beta_{2s}) \in \mathbb{R}^{2s} \right\}.$$

2. Let $\chi_h : \mathbb{R}^D \longrightarrow \mathbb{R}^D$ be any first-order integration scheme. An important class $\mathcal{G}_2$ of integrators is obtained by considering compositions of χ_h and its adjoint χ_h^*, namely,

   (2.2)
   $$\mathcal{G}_2 = \left\{ \chi_{\alpha_{2s}h} \circ \chi^*_{\alpha_{2s-1}h} \circ \cdots \circ \chi_{\alpha_2 h} \circ \chi^*_{\alpha_1 h} : \ s \geq 1, \ (\alpha_1, \ldots, \alpha_{2s}) \in \mathbb{R}^{2s} \right\}.$$

   This family $\mathcal{G}_2$ of integrators clearly has (with the composition) a group structure. As shown in [13], if $\sum_{i=1}^{s} \beta_{2i-1} = \sum_{i=1}^{s} \beta_{2i}$, $\mathcal{G}_2$ is closely related to $\mathcal{G}_1$

when $\chi_h = \varphi_h^{[a]} \circ \varphi_h^{[b]}$, $\beta_i = \alpha_i + \alpha_{i-1}$ $(i = 1, \dots, 2s)$, and $\alpha_0 = \alpha_{2s} = 0$. Consistency of the schemes requires that $\sum_{i=1}^{s} \beta_{2i-1} = \sum_{i=1}^{s} \beta_{2i} = \sum_{i=1}^{2s} \alpha_i = 1$, and the order conditions at higher orders are equivalent in both cases [13]. Methods in $\mathcal{G}_2$ are more general and can also be used if the system is split into more than two parts, i.e., $x' = f_a + f_b + f_c + \cdots$, just taking $\chi_h = \varphi_h^{[a]} \circ \varphi_h^{[b]} \circ \varphi_h^{[c]} \circ \cdots$ $(\chi_h^* = \cdots \circ \varphi_h^{[c]} \circ \varphi_h^{[b]} \circ \varphi_h^{[a]})$.

3. Another well-known class $\mathcal{G}_3$ of integrators [13] is introduced as follows. If $\mathcal{S}_h^{[2]} : \mathbb{R}^D \longrightarrow \mathbb{R}^D$ is any second-order self-adjoint integrator, then

$$\mathcal{G}_3 = \left\{ \mathcal{S}^{[2]}_{\alpha_s h} \circ \cdots \circ \mathcal{S}^{[2]}_{\alpha_1 h} : \ s \geq 1, \ (\alpha_1, \dots, \alpha_s) \in \mathbb{R}^s \right\}. \tag{2.3}$$

This family of integrators also has group structure. In fact, if $\mathcal{S}_h^{[2]}$ is chosen as $\mathcal{S}_h^{[2]} = \chi_{h/2} \circ \chi_{h/2}^*$, then $\mathcal{G}_3$ is a subgroup of $\mathcal{G}_2$ (in [18], it is shown that any self-adjoint integrator can be written in this form; the choice of χ_h is not unique, however).

4. Finally, if $\mathcal{S}_h^{[4]} : \mathbb{R}^D \longrightarrow \mathbb{R}^D$ is any fourth-order self-adjoint integrator, then another class $\mathcal{G}_4$ of integrators is

$$\mathcal{G}_4 = \left\{ \mathcal{S}^{[4]}_{\alpha_s h} \circ \cdots \circ \mathcal{S}^{[4]}_{\alpha_1 h} : \ s \geq 1, \ (\alpha_1, \dots, \alpha_s) \in \mathbb{R}^s \right\}. \tag{2.4}$$

Methods in $\mathcal{G}_4$ could be compositions of schemes in $\mathcal{G}_l$, $l = 1, 2, 3$. They can be useful in some problems where, due to their particular structure, it is possible to build a very efficient integrator $\mathcal{S}_h^{[4]}$, as is the case for the second-order differential equation $x'' = g(x)$ [11].

Composition integrators $\psi_h \in \mathcal{G}_l$ $(l = 1, 2, 3, 4)$ are time-symmetric whenever they have left-right palindromic sequences of coefficients α_i—more specifically, if the following apply:

1. In $\mathcal{G}_1$, if either $\beta_{2s} = 0$, $\beta_{2s-i} = \beta_i$ or $\beta_1 = 0$, $\beta_{2s+1-i} = \beta_{i+1}$. Then one of the maps $\varphi^{[a]}_{\beta_i h}$ and $\varphi^{[b]}_{\beta_i h}$ is computed s times and the other $s-1$ times. Now the computations done for the last map can be reused for the first map in the following step. (This feature is known as the FSAL (first same as last) property.) Then both maps $\varphi^{[a]}_{\beta_i h}$ and $\varphi^{[b]}_{\beta_i h}$ are computed $s-1$ times.
2. In $\mathcal{G}_l$, $l = 2, 3, 4$, if $\alpha_{\bar{s}+1-i} = \alpha_i$ with $\bar{s} = 2s$ or $\bar{s} = s$.

2.2. Associated graded Lie algebra. It is well known that for each infinitely differentiable map $g : \mathbb{R}^D \longrightarrow \mathbb{R}$, $g(\varphi_h(x))$ admits an expansion of the form [19]

$$g(\varphi_h(x)) = e^{hF}[g](x) = g(x) + \sum_{k \geq 1} \frac{h^k}{k!} F^k[g](x), \qquad x \in \mathbb{R}^D,$$

where F is the vector field (1.2). Similarly, for the maps $\hat{\psi}_h$, ψ_h, and π_h one has

$$g(\hat{\psi}_h(x)) = e^{\hat{F}_h}[g](x), \qquad g(\psi_h(x)) = e^{F_h}[g](x), \qquad g(\pi_h(x)) = e^{P_h}[g](x),$$

with

$$\hat{F}_h = \sum_{k \geq 1} h^k \hat{F}_k, \qquad F_h = \sum_{k \geq 1} h^k F_k, \qquad P_h = \sum_{k \geq 1} h^k P_k;$$

i.e., $\hat{\psi}_h$, ψ_h, and π_h are formally the exact 1-flows of the vector fields $\hat{F}_h$, F_h, and P_h, respectively.

If the kernel ψ_h belongs to $\mathcal{G}_l$ ($l = 1, 2, 3, 4$), then the corresponding (h-dependent) vector fields $h^k F_k$ belong to a certain graded Lie algebra $\mathcal{L} = \bigoplus_{k\geq 1} \mathcal{L}_k$ such that $hF \in \mathcal{L}_1$, $h^k F_k \in \mathcal{L}_k$ for each $k \geq 1$ and $[\mathcal{L}_k, \mathcal{L}_m] \subset \mathcal{L}_{k+m}$. Each $\mathcal{L}_k$ ($k \geq 1$) is the subspace $\mathcal{L}$ of vector fields affected by a kth power of h, and we denote $n_k = \dim \mathcal{L}_k$. We give $\mathcal{L}$ explicitly in each case.

1. If $\psi_h \in \mathcal{G}_1$, then $\mathcal{L} = \bigoplus_{k\geq 1} \mathcal{L}_k$ is the graded Lie algebra generated by the vector fields $\{hF_a, hF_b\}$. Here, $hF_1 + h^2 F_2 + \cdots$ can be obtained, for instance, by repeated application of the Baker–Campbell–Hausdorff (BCH) formula [24] to the expression

$$\Psi_h = \exp(h\beta_1 F_a) \exp(h\beta_2 F_b) \cdots \exp(h\beta_{2s-1} F_a) \exp(h\beta_{2s} F_b)$$

since, formally, $g \circ \psi_h = \Psi_h[g]$ and $F_h = \log(\Psi_h)$ [2, 8].

2. For $\mathcal{G}_2$, we have for the basic method $g(\chi_h(x)) = e^{Y_h}[g](x)$ with $Y_h = \sum_{k\geq 1} h^k Y_k$ and for its adjoint $g(\chi_h^*(x)) = e^{-Y_{-h}}[g](x)$. Then

$$\Psi_h = \exp(-Y_{-h\alpha_1}) \exp(Y_{h\alpha_2}) \cdots \exp(-Y_{-h\alpha_{2s-1}}) \exp(Y_{h\alpha_{2s}}),$$

and F_h can be obtained by repeated application of the BCH formula, which shows that $h^k F_k \in \mathcal{L}_k$ for each $k \geq 1$ and $\mathcal{L} = \bigoplus_{k\geq 1} \mathcal{L}_k$ is the graded Lie algebra generated by the vector fields $\{hY_1, h^2 Y_2, h^3 Y_3, \dots\}$ where, by consistency, $Y_1 = F$.

3. For $\mathcal{G}_3$, the series of differential operators S_h associated with the integrator $\mathcal{S}_h^{[2]}$, i.e., such that $g \circ \mathcal{S}_h^{[2]} = S_h[g]$, can be written as $S_h = \exp(Y_h)$, where $Y_h = hY_1 + h^3 Y_3 + h^5 Y_5 + \cdots$, $Y_1 = F$, and

$$\Psi_h = \exp(Y_{h\alpha_1}) \cdots \exp(Y_{h\alpha_s}).$$

One similarly [13] arrives at an expansion $hF_1 + h^3 F_3 + h^4 F_4 + \cdots$, where $h^k F_k \in \mathcal{L}_k$ for the graded Lie algebra $\mathcal{L} = \bigoplus_{k\geq 1} \mathcal{L}_k$ generated by the vector fields $\{hY_1, h^3 Y_3, h^5 Y_5, \dots\}$.

4. The case of $\mathcal{G}_4$ can be considered as a particular case of $\mathcal{G}_3$ with $Y_3 = 0$.

2.3. Effective order conditions. According to the theory developed in [2] the following theorem applies to the processed methods considered here.

THEOREM 1 (see [2]). *An integrator ψ_h has effective order $p \geq q$ if and only if there exist vector fields $P_1, \dots, P_{q-1}$ such that*

$$F_1 = F, \quad [P_{n-1}, F] = F_n + R_n(P_1, \dots, P_{n-2}, F_1, \dots, F_{n-1}), \quad 1 < n \leq q, \tag{2.5}$$

hold, where

$$R_n = -\sum_{j=1}^{n-2} [P_j, F_{n-j}] + \sum_{k\geq 2} \frac{(-1)^k}{k!} \sum_{j_1+\cdots+j_{k+1}=n} [P_{j_1}, [P_{j_2}, \dots [P_{j_k}, F_{j_{k+1}}] \dots]].$$

Under the premises of Theorem 1, $[P_k, F] \in \mathcal{L}_{k+1}$. As shown in [2], if such vector fields P_k ($1 \leq k \leq q-1$) exist, then they are not unique. We will hereafter consider vector fields P_k belonging to $\mathcal{L}_k$. Uniqueness is then achieved by requiring that $P_k \in \mathcal{L}_k^*$, where $\mathcal{L}_k^*$ is a subspace of $\mathcal{L}_k$ of minimal dimension, n_k^*, among all

subspaces V_k of $\mathcal{L}_k$ such that $[F, V_k] = [F, \mathcal{L}_k]$. It must be stressed that such a requirement does not restrict the choice of the processed integrator [2]. Since the graded Lie algebras associated with $\mathcal{G}_l$ ($l = 1, 2, 3, 4$) are free, then $\mathcal{L}_1 = \mathcal{L}_1^* \oplus F$, $\mathcal{L}_k^* = \mathcal{L}_k$ for $k > 1$, and $P_1 \in \mathcal{L}_1^*$. Therefore, $n_1^* = n_1 - 1$ and $n_k^* = n_k$ for $k > 1$.

Let us denote by $\{E_{k,i}\}_{i=1}^{n_k}$ a basis of $\mathcal{L}_k$ with $E_{1,1} = F$. Then one can write

$$F_k = \sum_{i=1}^{n_k} f_{k,i} E_{k,i}, \qquad R_k = \sum_{i=1}^{n_k} r_{k,i} E_{k,i}, \qquad P_{k-1} = \sum_{i=1}^{n_{k-1}^*} p_{k-1,i} E_{k-1,i}, \tag{2.6}$$

where $P_0 = 0$, $P_1 = \sum_{i=1}^{n_1} p_{1,i} E_{1,i}$ with $p_{1,1} = 0$, and the coefficients $r_{k,i}$ can be written as polynomials in the indeterminates $f_{l,j}, p_{l-1,j}$, $l < k$.

The order conditions (2.5) can be expressed as a system of (polynomial) equations in $f_{k,i}, p_{k-1,i}$. Such equations have a particularly simple form if the basis of each $\mathcal{L}_{k+1}$ is constructed (from a given basis of $\mathcal{L}_k$) in such a way that

$$E_{k+1,n_{k+1}-n_k^*+i} = [F, E_{k,i}], \qquad 1 \le i \le n_k^*, \quad k \ge 1. \tag{2.7}$$

THEOREM 2 (see [2]). *Assume that the chosen basis of each $\mathcal{L}_k$ is such that* (2.7) *holds. The kernel ψ_h has effective order $p \ge q$ if and only if it is consistent ($F_1 = F$) and the vector fields* (2.6) *in Theorem* 1 *satisfy the equations*

$$f_{k,i} = -r_{k,i}, \qquad 1 \le i \le l_k := n_k - n_{k-1}^*, \quad 2 \le k \le q, \tag{2.8}$$

$$p_{k-1,i} = -f_{k,l_k+i} - r_{k,l_k+i}, \qquad 1 \le i \le n_{k-1}^*, \quad 2 \le k \le q. \tag{2.9}$$

If ψ_h is self-adjoint, then for even values of k, conditions (2.8) *are automatically satisfied and equations* (2.9) *reduce to $p_{k-1,i} = 0$.*

When the coefficients $f_{k,i}$ are written in terms of the parameters $\boldsymbol{\alpha} \equiv (\alpha_1, \dots, \alpha_{\bar{s}})$ ($\bar{s} = 2s$ or $\bar{s} = s$) of the kernel ψ_h, repeated substitution of (2.9) into the recursive expressions (2.8)–(2.9) leads to an equivalent system of equations where (2.8) is replaced by a polynomial equation in the parameters α_j, $N_{k,i}(\boldsymbol{\alpha}) = 0$, and (2.9) is transformed into an expression of the form $p_{k-1,i} = Q_{k,i}(\boldsymbol{\alpha})$, with $Q_{k,i}$ a polynomial in $\boldsymbol{\alpha}$.

The total number of equations $N_{k,i}(\boldsymbol{\alpha}) = 0$ required to achieve effective order q depends on the dimensions n_k in the following way.

COROLLARY 2.1. *There exists a system of $s(q) = n_q + 1$ polynomial equations on the parameters $\boldsymbol{\alpha}$ that guarantees that the corresponding kernel $\psi_h \in \mathcal{G}_1$ (resp., $\psi_h \in \mathcal{G}_l$, $l = 2, 3, 4$) has effective order $q > 1$ for arbitrary basic vector fields $\{F_a, F_b\}$ (resp., $\{Y_k\}_l$). If ψ_h is self-adjoint, this number reduces to $\hat{s}(2) = n_1$, $\hat{s}(2n) = n_1 + \sum_{k=2}^{n} (n_{2k-1} - n_{2k-2})$, $n > 1$.*

The numbers of effective order conditions given by Corollary 2.1 for each class of integrators are displayed in Table 1 for nonsymmetric, $s(q)$, and symmetric, $\hat{s}(q)$, kernels.

For a kernel of effective order q (i.e., satisfying (2.8) for $k \le q$ but not for $k = q+1$) one can in principle determine a postprocessor such that equations (2.9) hold also for all $k > q$. We refer to that postprocessor as optimal, as it causes many terms of each $\hat{F}_k = \sum_{i=1}^{n_k} \hat{f}_{k,i} E_{k,i}$ to cancel ($\hat{f}_{k,n_k-n_{k-1}^*+i} = 0$, $i = 1, \dots, n_{k-1}^*$), and denote by $\mathbb{P}_k$ the set of maps $\pi_h : \mathbb{R}^D \longrightarrow \mathbb{R}^D$ whose Taylor expansion coincides with the optimal postprocessor up to order k (i.e., their difference is $\mathcal{O}(h^{k+1})$). With this notation, the processed integrator $\hat{\psi}_h$ in (1.3) is of order q if the kernel ψ_h is of effective order q and the postprocessor $\pi_h \in \mathbb{P}_{q-1}$. Note that optimality of a postprocessor depends on the chosen basis in each $\mathcal{L}_k$ (see [2] for more details).

TABLE 1
Total number of effective order conditions for nonsymmetric ($s(q)$) and symmetric ($\hat{s}(q)$) kernels of effective order q.

Effective order	$\mathcal{G}_1$		$\mathcal{G}_2$		$\mathcal{G}_3$		$\mathcal{G}_4$	
q	$s(q)$	$\hat{s}(q)$	$s(q)$	$\hat{s}(q)$	$s(q)$	$\hat{s}(q)$	$s(q)$	$\hat{s}(q)$
1	2	–	1	–	1	–	1	–
2	2	2	2	1	1	1	1	1
3	3	–	3	–	2	–	1	–

5	7	–	7	–	3	–	2	–
6	10	6	10	5	3	3	2	2
7	19	–	19	–	5	–	3	–
8	31	15	31	14	6	5	3	3
9	57	–	57	–	9	–	4	–
10	100	40	100	39	12	8	4	4
11	187	–	187	–	19	–	6	–
12	335	127	335	126	26	15	7	6

Remark. For schemes in $\mathcal{G}_1$ it is clear that $\mathcal{L}_1 = \mathrm{span}(E_{1,1} = F = F_a + F_b,\ E_{1,2} = F_a - F_b)$, $\mathcal{L}_1^* = \mathrm{span}(E_{1,1}^* = E_{1,2})$, and thus $n_1 = 2$, $n_1^* = 1$, whereas in $\mathcal{G}_2$ one has $\mathcal{L}_1 = \mathrm{span}(E_{1,1} = F = Y_1)$, $\mathcal{L}_1^* = \emptyset$, so that $n_1 = 1$, $n_1^* = 0$. Moreover, n_k for $k \geq 2$ and $s(k)$ for $k \geq 3$ are identical in $\mathcal{G}_1$ and $\mathcal{G}_2$, but $s(1) = s(2) = 2$ in $\mathcal{G}_1$ and $s(1) = 1$, $s(2) = 2$ in $\mathcal{G}_2$. In consequence, *any first-order method in $\mathcal{G}_1$ has always effective order 2, but this is not the case in $\mathcal{G}_2$.*

For example, let us consider the first-order scheme $\chi_h = \varphi_h^{[a]} \circ \varphi_h^{[b]}$ belonging to $\mathcal{G}_1$ and $\mathcal{G}_2$. If we take $\pi_h = \varphi_{h/2}^{[b]} \in \mathcal{G}_1$, then the processed method $\pi_h \circ \chi_h \circ \pi_h^{-1}$ is the well-known second-order leapfrog scheme. On the other hand, because a general postprocessor in $\mathcal{G}_1$, $\exp(P_h) = \exp\big(h(p_{1,1}F_a + p_{1,2}F_b) + \mathcal{O}(h^2)\big)$, cannot be written as a composition in $\mathcal{G}_2$ unless $p_{1,1} = p_{1,2}$, the effective order of χ_h in $\mathcal{G}_2$ is only one. However, if the kernel is a second-order method (as is the case of symmetric kernels), then $p_{1,1} = p_{1,2} = 0$ and any composition postprocessor in $\mathcal{G}_1$ can be expressed as a composition in $\mathcal{G}_2$; the effective order conditions are equivalent in both cases. □

2.4. Cost saving using the processing technique. For the families of composition methods considered in this work, the number of stages is frequently used as a measure of the computational cost. Here and in the following, the number of basic maps involved in a composition method or kernel will be referred to as the number of stages (i.e., $2s$ in (2.1) and (2.2) and s in (2.3) and (2.4)). In general, the minimum number of stages to obtain a method of order, or effective order, q is given by the total number of order conditions, $N_q = \sum_{k=1}^{q} n_k$, or effective order conditions, $s(q) = n_q + 1$. Then, the use of processed schemes is more advantageous as the value of

$$r_q = \frac{N_q}{s(q)} = \frac{\sum_{k=1}^{q} n_k}{n_q + 1}$$

increases. Observe that r_q depends on how fast $n_k = \dim \mathcal{L}_k$ grows, and thus it is important to analyze its asymptotic behavior.

Let us suppose that $\{X_1, X_2, \dots\}$ are a countable set of generators of a graded free Lie algebra with grades $w_i = w(X_i)$ and suppose that the formal sum $1 - \sum_{i=1}^{\infty} T^{w_i}$ converges to a rational function $P(T) = q(T)/r(T)$, as is the case for the Lie algebras previously considered. If the roots of $q(T)$ and $r(T)$ are denoted by $\lambda_1, \dots, \lambda_m$ and

$\gamma_1, \dots, \gamma_{\bar{m}}$, respectively, then n_k is given as [9, 16, 17]

$$n_k = \frac{1}{k} \sum_{d|k} \mu(d) \left(\sum_{j=1}^{m} \lambda_j^{-k/d} - \sum_{i=1}^{\bar{m}} \gamma_i^{-k/d} \right), \tag{2.10}$$

where the first sum ranges over all integers which divide k, and $\mu(d)$ is the Möbius function: $\mu(1) = 1$, $\mu(d) = (-1)^q$ if d is the product of q distinct prime factors, and $\mu(d) = 0$ otherwise. Let $\rho = 1/\min\{\lambda_1, \dots, \lambda_m\} > 1$ denote the *entropy* of the system, so that $n_k \sim \rho^k/k$ [16]. By instead assuming $n_k \sim \rho^k$, a rough estimation of the value of r_q is obtained as

$$N_q = \sum_{k=1}^{q} n_k \sim \sum_{k=1}^{q} \rho^k \sim \frac{\rho^{q+1}}{\rho - 1} \quad \Longrightarrow \quad r_q \sim \frac{\rho}{\rho - 1}, \tag{2.11}$$

and thus *the cost saving of the processing technique increases when ρ decreases.*

For $\mathcal{G}_1$ and $\mathcal{G}_2$ one has $P(T) = 1 - 2T$ and $P(T) = (1-2T)/(1-T)$, respectively, and $\rho = 2$. In $\mathcal{G}_3$, $P(T) = (1 - T - T^2)/(1 - T^2)$, so $\rho = 1.618$, and in $\mathcal{G}_4$, $P(T) = (1 - T - T^2 + T^3 - T^5)/(1 - T^2)$, so $\rho = 1.443$. It is worth noticing that the values of n_k (and thus the number of order conditions) collected in Table 1 can be obtained through the respective functions $P(T)$ and (2.10).

2.5. Order conditions for methods in $\mathcal{G}_3$. For the sake of illustration we next consider kernels $\psi_h \in \mathcal{G}_3$. Recall that in that case $\mathcal{L} = \bigoplus_{k \geq 1} \mathcal{L}_k$ is the graded free Lie algebra generated by the symbols $\{Y_1, Y_3, Y_5, \dots\}$ ($Y_1 = F$). Now $\mathcal{L}_1^* = \emptyset$, $\mathcal{L}_2 = \emptyset$, so that $n_k^* = n_k$ for all k. We derive the effective order conditions up to order 11 and the corresponding postprocessor coefficients when the basis of $\mathcal{L}_k$, $k \leq 11$, is chosen according to (2.7) (see Table 2 for the particular basis taken).

TABLE 2
Basis of $\mathcal{L}_k$ ($k \leq 11$) chosen for kernels in $\mathcal{G}_3$.

$\mathcal{L}_i$	Basis of $\mathcal{L}_i$		
$\mathcal{L}_1$	$E_{1,1} = Y_1 = F$		
$\mathcal{L}_3$	$E_{3,1} = Y_3$		
$\mathcal{L}_4$	$E_{4,1} = [F, E_{3,1}]$		
$\mathcal{L}_5$	$E_{5,1} = Y_5$	$E_{5,2} = [F, E_{4,1}]$	
$\mathcal{L}_6$	$E_{6,i} = [F, E_{5,i}]$	$i = 1, 2$	
$\mathcal{L}_7$	$E_{7,1} = Y_7$	$E_{7,2} = [E_{3,1}, E_{4,1}]$	
	$E_{7,2+i} = [F, E_{6,i}]$	$i = 1, 2$	
$\mathcal{L}_8$	$E_{8,1} = [E_{3,1}, E_{5,1}]$	$E_{8,i+1} = [F, E_{7,i}]$	$i = 1, \dots, 4$
$\mathcal{L}_9$	$E_{9,1} = Y_9$	$E_{9,i+1} = [E_{3,1}, E_{6,i}]$	$i = 1, 2$
	$E_{9,3+j} = [F, E_{8,j}]$	$j = 1, \dots, 5$	
$\mathcal{L}_{10}$	$E_{10,i} = [E_{3,1}, E_{7,i}]$	$i = 1, \dots, 3$	
	$E_{10,3+j} = [F, E_{9,j}]$	$j = 1, \dots, 8$	
$\mathcal{L}_{11}$	$E_{11,1} = Y_{11}$	$E_{11,i+1} = [E_{3,1}, E_{8,i}]$	$i = 1, \dots, 5$
	$E_{11,7} = [E_{5,1}, E_{6,1}]$	$E_{11,7+j} = [F, E_{10,j}]$	$j = 1, \dots, 11$

As previously stated, if $\psi_h \in \mathcal{G}_3$ the corresponding series of differential operators can be written as $\Psi_h = \exp(Y_{h\alpha_1}) \cdots \exp(Y_{h\alpha_s}) \equiv \exp(F_h)$, with $F_h = hF_1 + h^3 F_3 + h^4 F_4 + \cdots$, and each $f_{k,i}$ in (2.6) is a polynomial in the coefficients $\alpha_1, \dots, \alpha_s$. Consistency ($F_1 = F$) is achieved by requiring that $\sum \alpha_i = 1$. Since $n_1 = 1$, $n_1^* = n_2 = 0$, then $F_2 = 0$, $P_1 = P_2 = 0$ [2]. If we consider a self-adjoint

kernel, a straightforward computation shows that

$$R_2 = R_3 = R_4 = R_5 = R_6 = 0, \qquad R_7 = f_{3,1}p_{4,1}E_{7,2}, \qquad R_8 = 0,$$
$$R_9 = f_{5,1}p_{4,1}(E_{9,2} - E_{9,4}) + \left(f_{5,2}p_{4,1} + \frac{1}{2}p_{4,1}^2 + f_{3,1}p_{6,2}\right) E_{9,3} - p_{4,1}\left(f_{5,2} + \frac{1}{2}p_{4,1}\right) E_{9,6},$$

with similar (but larger) expressions for R_{10}, R_{11}. Equations (2.8) and (2.9) finally lead, after rearranging and simplifying terms, to the order conditions collected in Table 3.

TABLE 3

Order conditions for the kernel and postprocessor up to order q in $\mathcal{G}_3$ when the kernel is self-adjoint ($f_{2k,i} = 0,\ p_{2k-1,j} = 0$).

q	Eff. order conditions	Postprocessor conditions
1	$f_{1,1} = 1$	
3	$f_{3,1} = 0$	
5	$f_{5,1} = 0$	$p_{4,1} = -f_{5,2}$
7	$f_{7,1} = f_{7,2} = 0$	$p_{6,i} = -f_{7,i+2}, \quad i = 1, 2$
9	$f_{9,1} = f_{9,2} = 0$	$p_{8,i} = -f_{9,i+3}, \quad i = 1, 2, 4, 5$
	$f_{9,3} = \frac{1}{2}f_{5,2}^2$	$p_{8,3} = -f_{9,6} - \frac{1}{2}f_{5,2}^2$
11	$f_{11,i} = 0,\ i = 1, 2, 3, 4, 7$	$p_{10,i} = -f_{11,i+7}, \quad i = 1, 2, 4, 7, 8, 10, 11$
	$f_{11,5} = f_{5,2}f_{7,3}$	$p_{10,3} = -f_{11,10} - \frac{3}{2}f_{5,2}f_{7,3}; \quad p_{10,5} = \frac{1}{2}f_{5,2}f_{7,3} - f_{11,12}$
	$f_{11,6} = f_{5,2}f_{7,4}$	$p_{10,6} = -f_{11,13} - \frac{5}{2}f_{5,2}f_{7,4}; \quad p_{10,9} = \frac{3}{2}f_{5,2}f_{7,4} - f_{11,16}$

3. Construction of the processor. Once a kernel satisfying the effective order conditions is proposed, there is still much freedom in the choice of the preprocessor and postprocessor π_h to ensure that $\hat{\psi}_h$ has the required order. The kernel fixes the accuracy that is possible to reach. This can be attained with the optimal postprocessor, defined as the exact 1-flow of an infinite series of vector fields P_h. In practice, one must look for a preprocessor and a postprocessor close to this optimal one (an approximate map in $\mathbb{P}_{q-1}$ or preferably in $\mathbb{P}_q$), and at the same time it has to be easy and/or cheap to compute. In the following we propose two different techniques which satisfy the above requirements.

3.1. Composition postprocessors, $\pi_h^{(c)}$. Since the kernel is a composition of basic methods in $\mathcal{G}_l$, it seems appropriate to approximate the optimal map π_h by a similar composition, $\pi_h^{(c)}$, so that the algorithm employed to compute the kernel can also be used. The resulting processed methods are also in $\mathcal{G}_l$. The coefficients of the composition $\pi_h^{(c)}$ are chosen such that (2.9) are verified. It turns out, however, that finding real solutions for the resulting system of polynomial equations can be difficult, and the composition requires typically at least as many basic integrators as the kernel.

As we mentioned in the introduction, if the kernel is time-symmetric and $\pi_{-h} = \pi_h$, then the processed method is also time-symmetric, but this equality cannot be satisfied by $\pi_h^{(c)}$. Instead we impose that $\pi_{-h}^{(c)} - \pi_h^{(c)} = \mathcal{O}(h^l)$, $l \geq q$, for a postprocessor $\pi_h^{(c)} \in \mathbb{P}_{q-1}$. In this sense, it is sometimes helpful to construct $\pi_h^{(c)}$ as a composition of the form $\pi_h^{(c)} = \omega_h \circ \omega_{-h}$, or even of the form $\pi_h^{(c)} = \omega_{-h} \circ \omega_h^2 \circ \omega_{-h}$. With these special structures many order conditions of the form $p_{2i-1,j} = 0$ in Theorem 2 are automatically satisfied, but the order conditions (2.9) of even k must still be enforced, which still account for more equations than the kernel itself. Since the preprocessor

is computed only once, it makes sense to use $(\pi_h^{(c)})^{-1}$ as an accurate approximation to π_h^{-1}, whereas $\pi_h^{(c)}$ should be used if intermediate output is not frequently required.

3.2. Cheap postprocessors, $\hat{\pi}_h$. For a number of problems, the output has to be computed for most steps. It is therefore reasonable to look for an approximation $\hat{\pi}_h$ to the optimal postprocessor as cheap to compute as possible. Usually $\hat{\pi}_h$ will be a less accurate approximation to π_h than the composition $\pi_h^{(c)}$, but the error $\hat{\pi}_h(z_n) - \pi_h^{(c)}(z_n)$ is of local character and will eventually be overtaken by the global error of the underlying optimally processed integrator (if the global error grows at least linearly in time) [2].

Here we approximate π_h by reusing intermediate calculations obtained when evaluating the kernel ψ_h [2], so that the procedure can be considered virtually cost-free. More specifically, if $z_n \equiv \psi_h^n(\pi_h^{-1}(x_0))$, then the numerical solution $x_n = \pi_h(z_n)$ is approximated by the linear combination

$$x_n \approx \sum_{i=-\bar{s}}^{\bar{s}} w_i Z_i \tag{3.1}$$

of intermediate values Z_i computed when evaluating $z_n = \psi_h(z_{n-1})$ and $z_{n+1} = \psi_h(z_n)$. In particular, we always take $Z_{-\bar{s}} = z_{n-1}$, $Z_0 = z_n$, and $Z_{\bar{s}} = z_{n+1}$. For the set $\mathcal{G}_l$ $(l = 1, 2, 3, 4)$, the intermediate values Z_i that we propose for approximating x_n are the following.

1. In the case of $\mathcal{G}_1$, we have $\bar{s} = 2s$, and

$$Z_{-2s} = z_{n-1}, \quad Z_{2i-1} = \varphi^{[a]}_{\beta_{2i-1}h}(Z_{2i-2}), \quad Z_{2i} = \varphi^{[b]}_{\beta_{2i}}(Z_{2i-1}), \tag{3.2}$$

   where $-(s-1) \le i \le s$ and $\beta_{j-2s} = \beta_j$ for each j.
2. For $\mathcal{G}_2$,

$$Z_{-2s} = z_{n-1}, \quad Z_{2i-1} = \chi^*_{\alpha_{2i-1}h}(Z_{2i-2}), \quad Z_{2i} = \chi_{\alpha_{2i}}(Z_{2i-1}), \tag{3.3}$$

   with $-(s-1) \le i \le s$ and $\alpha_{j-2s} = \alpha_j$ for each j.
3. For $\mathcal{G}_3$ and $\mathcal{G}_4$, we take $\bar{s} = s$, and

$$Z_{-s} = z_{n-1}, \quad Z_i = \mathcal{S}^{[2]}_{\alpha_i h}(Z_{i-1}) \qquad (\text{resp., } Z_i = \mathcal{S}^{[4]}_{\alpha_i h}(Z_{i-1})), \tag{3.4}$$

   with $-(s-1) \le i \le s$ and $\alpha_{j-s} = \alpha_j$ for each j.

Remark. As we will see, the number of conditions to be imposed on the coefficients w_i so that the cheap postprocessor (3.1) achieves a given accuracy is smaller in $\mathcal{G}_2$ than in $\mathcal{G}_1$. Nevertheless, implementing $\psi_h \in \mathcal{G}_1$ as an integrator in $\mathcal{G}_2$ considering the relation between (2.1) and (2.2) is in general more costly because explicitly obtaining the intermediate values Z_i in (3.3) requires the computation of additional basic flows, which does not in general pay off for the extra accuracy of the postprocessor. An important exception is the case in which f_a and f_b come from a partitioned ODE of the form $q' = f_1(p)$, $p' = f_2(q)$. Then an integrator in $\mathcal{G}_1$ can be seen as an explicit partitioned Runge–Kutta method. In that case, there is no practical overhead in implementing the kernel $\psi_h \in \mathcal{G}_1$ as an integrator in $\mathcal{G}_2$ because it does not require additional evaluations of $f_1(p)$ and $f_2(q)$, and then it is recommended to do it that way. □

Each Z_i can be written as $Z_i = \phi_h^{(i)}(z_n)$, where $\phi_h^{(i)} \in \mathcal{G}_l$ $(l = 1, 2, 3, 4,\ -\bar{s} \le i \le \bar{s})$ implies that there exists a series $F_h^{(i)} = \sum_{k\ge1} h^k F_k^{(i)} \in \mathcal{L}$ such that formally

$g \circ \phi_h^{(i)} = \exp(F_h^{(i)})[g]$ for each infinitely differentiable map $g : \mathbb{R}^D \longrightarrow \mathbb{R}$ (see [2] for more details). Clearly, (3.1) can be expressed as

$$x_n \approx \hat{\pi}_h(z_n), \qquad \text{where} \qquad \hat{\pi}_h(z) = \sum_{i=-\bar{s}}^{\bar{s}} w_i \phi_h^{(i)}(z). \tag{3.5}$$

Notice that, in general, $\hat{\pi}_h \notin \mathcal{G}_l$. Our goal is to find coefficients w_i in such a way that $\hat{\pi}_h \in \mathbb{P}_l$ with l as large as possible. This is guaranteed for a given $l \geq 1$ if

$$\sum_{i=-\bar{s}}^{\bar{s}} w_i \exp(F_h^{(i)}) = \exp(P_h) + \mathcal{O}(h^{l+1}), \tag{3.6}$$

where $P_h = \sum_{k\geq 1} h^k P_k \in \mathcal{L}$ is the vector field corresponding to the optimal postprocessor.

The exponential of a formal series in the graded Lie algebra $\mathcal{L}$ can be represented as an element of the universal enveloping algebra $\mathcal{A}$ of $\mathcal{L}$. The algebra $\mathcal{A}$ is also graded, with $\mathcal{A} = \bigoplus_{k\geq 0} \mathcal{A}_k$, and $\mathcal{A}_0 = \text{span}(I)$. Let us now consider a fixed basis $\{D_{k,j}\}_{j=1}^{m_k}$ of the homogeneous subspace $\mathcal{A}_k$ for each $k \geq 1$, with $m_k = \dim \mathcal{A}_k$. The values of m_k for $\mathcal{G}_l$ ($l = 1, 2, 3, 4$) are displayed in Table 4 [2]. Then $\exp(P_h)$ and $\exp(F_h^{(i)})$ can be expressed as

$$\exp(P_h) = I + \sum_{k\geq 1} h^k \sum_{j=1}^{m_k} \pi_{k,j} D_{k,j}, \qquad \exp(F_h^{(i)}) = I + \sum_{k\geq 1} h^k \sum_{j=1}^{m_k} \phi_{k,j}^{(i)} D_{k,j}$$

for $-\bar{s} \leq i \leq \bar{s}$, where $\pi_{k,j}$ and $\phi_{k,j}^{(i)}$ are polynomials in the coefficients α_j, $1 \leq j \leq \bar{s}$. Hence, (3.6) is equivalent to a system of linear equations on the unknowns w_i, i.e.,

$$\sum_{i=-\bar{s}}^{\bar{s}} w_i \phi_{k,j}^{(i)} = \pi_{k,j}, \qquad 1 \leq j \leq m_k, \qquad 0 \leq k \leq l. \tag{3.7}$$

In particular, $\hat{\pi}_h \in \mathbb{P}_0$ requires that $\sum_{i=-\bar{s}}^{\bar{s}} w_i = 1$. The total number of equations (3.7) required for $\hat{\pi}_h \in \mathbb{P}_l$ is $1 + m_1 + \cdots + m_l$ ($m_0 = 1$).

TABLE 4

Dimensions m_k of $\mathcal{A}_k$ for each class of integrators. If the kernel is self-adjoint, only the dimensions m_{2j} are relevant (bold numbers).

	m_1	m_2	m_3	m_4	m_5	m_6	m_7	m_8
$\mathcal{G}_1$	2	**4**	8	**16**	32	**64**	128	**256**
$\mathcal{G}_2$	1	**2**	4	**8**	16	**32**	64	**128**
$\mathcal{G}_3$	1	**1**	2	**3**	5	**8**	13	**21**
$\mathcal{G}_4$	1	**1**	1	**1**	2	**3**	5	**7**

For self-adjoint composition kernels, $P_{-h} = P_h$ and $F_h^{(-i)} = F_{-h}^{(i)}$, which implies that $\phi_{k,j}^{(-i)} = (-1)^k \phi_{k,j}^{(i)}$. The choice $w_{-i} = w_i$ for all i in (3.1) then makes sense, as this guarantees that (3.7) is automatically satisfied for odd values of k. If in addition $w_0 = 1 - 2\sum_{i=1}^{\bar{s}} w_i$ (so that $\hat{\pi}_h \in \mathbb{P}_l$ at least with $l = 0$), (3.7) holds if

$$2\sum_{i=1}^{\bar{s}} w_i \phi_{2k,j}^{(i)} = \pi_{2k,j}, \qquad 1 \leq j \leq m_{2k}, \quad 1 \leq k \leq \frac{l}{2}. \tag{3.8}$$

Hence, the number of equations that remain to be satisfied by the unknowns $w_1, \ldots, w_{\bar{s}}$ in order that $\hat{\pi}_h \in \mathbb{P}_{2r+1}$ is $m_2 + \cdots + m_{2r}$.

When the number of unknowns w_i is larger than the number of equations (3.7) required so that $\hat{\pi}_h \in \mathbb{P}_l$ for a given l, then one can use this freedom to minimize the difference with the optimal postprocessor at higher orders.

4. New processed methods. In this section we construct self-adjoint composition kernels in $\mathcal{G}_l$ satisfying certain optimization criteria and a simplifying choice of the coefficients. For the kernels collected here we also provide in Appendix A the corresponding postprocessor, built according to the procedure of section 3.

4.1. Construction of the kernel. For building a specific kernel ψ_h of effective order q by composition in $\mathcal{G}_l$, one typically has to take as many basic integrators as the total number, $s(q) = n_q + 1$, of effective order conditions. As a matter of fact, more stages are frequently required (a) due to the nonexistence of real solutions or (b) to diminish the size of higher ($> q+1$)–order error terms (usually of large magnitude) [5, 13, 15]. In any case, introducing extra parameters makes more difficult the task of finding the numerical values of $\boldsymbol{\alpha}$ which solve the equations $N_{k,i}(\boldsymbol{\alpha}) = 0$. For this reason one usually considers self-adjoint kernels: although this symmetry fixes half of the coefficients, it also solves (in most cases) approximately the same number of equations.

Here the following symmetric compositions in $\mathcal{G}_l$, $l = 2, 3, 4$ (schemes in $\mathcal{G}_1$ and $\mathcal{G}_2$ are studied together), at different orders are considered:

$$\psi_h^{[2]} = \chi_{\alpha_1 h} \circ \chi^*_{\alpha_2 h} \circ \cdots \circ \chi_{\alpha_2 h} \circ \chi^*_{\alpha_1 h}, \tag{4.1}$$

$$\psi_h^{[3]} = \mathcal{S}^{[2]}_{\alpha_1 h} \circ \cdots \circ \mathcal{S}^{[2]}_{\alpha_{m-1} h} \circ \mathcal{S}^{[2]}_{\alpha_m h} \circ \mathcal{S}^{[2]}_{\alpha_{m-1} h} \circ \cdots \circ \mathcal{S}^{[2]}_{\alpha_1 h}, \tag{4.2}$$

$$\psi_h^{[4]} = \mathcal{S}^{[4]}_{\alpha_1 h} \circ \cdots \circ \mathcal{S}^{[4]}_{\alpha_{m-1} h} \circ \mathcal{S}^{[4]}_{\alpha_m h} \circ \mathcal{S}^{[4]}_{\alpha_{m-1} h} \circ \cdots \circ \mathcal{S}^{[4]}_{\alpha_1 h}, \tag{4.3}$$

where $\psi_h^{[2]}$ involves $2m$ stages (or m different evaluations of $\varphi_h^{[a]}$ and $\varphi_h^{[b]}$ if $\chi_h = \varphi_h^{[a]} \circ \varphi_h^{[b]}$), whereas $\psi_h^{[3]}$ and $\psi_h^{[4]}$ have $(2m-1)$ stages, and all of them have $\alpha_1, \ldots, \alpha_m$ to solve the effective order conditions.

Among the different solutions, one is interested in those that minimize the $l_{q+1} = n_{q+1} - n_q^*$ noncorrectable terms at order $q+1$, according to some criterion previously adopted. For instance, one could consider a norm in $\mathcal{L}_{q+1}$ and use it to devise some objective function of the parameters α_i to be minimized, aimed at measuring the size of the error. Unfortunately, it is by no means obvious how to characterize the performance of the integrators applied to all initial value problems, since for different problems the dominant error terms are not necessarily the same.

At least two objective functions have been used in the literature:

$$E_1(\boldsymbol{\alpha}) = \sum_{i=1}^{\bar{m}} |\alpha_i| \qquad \text{and} \qquad E_2(\mathbf{d}, \boldsymbol{\alpha}) = \bar{m} \, \|\mathbf{d} \cdot \mathbf{f}_{q+1}\|^{1/q}, \tag{4.4}$$

where $\bar{m} = 2m$ or $2m-1$ (depending on the set $\mathcal{G}_l$ considered), $\alpha_{\bar{m}+1-i} = \alpha_i$, and $\mathbf{f}_{q+1} = (f_{q+1,1}, \ldots, f_{q+1,l_{q+1}})$ and $\mathbf{d} = (d_1, \ldots, d_{l_{q+1}})$ are weight parameters fixed in advance. Methods with small values of E_1 usually have large stability domains and small error terms. It has been successfully used to find efficient nonprocessed methods in $\mathcal{G}_3$ up to order 10 [10, 8], although it is not possible to compare the efficiency of schemes with different number of stages. On the other hand, the optimal

weight vector $\mathbf{d}$ present in E_2 is problem dependent. For methods in $\mathcal{G}_1$ it is usual to consider $\mathbf{d}^{(1)} = (1, \dots, 1)$ (we denote $E_{21} \equiv E_2(\mathbf{d}^{(1)}, \boldsymbol{\alpha})$), whereas in $\mathcal{G}_3$ it is suggested [15] that one take $\mathbf{d}^{(2)} = (1, 0 \dots, 0)$ (and denote $E_{22} \equiv E_2(\mathbf{d}^{(2)}, \boldsymbol{\alpha})$), since $f_{q+1,1} = \sum_{i=1}^{\bar{m}} \alpha_i^{q+1}$ is the dominant error term for a number of problems.

Here we adopt the following criterion: we look for methods with small values of E_1 which, in addition, have small values of E_{21} for schemes in $\mathcal{G}_1$ and/or E_{22} for schemes in $\mathcal{G}_l$, $l = 2, 3, 4$. Of course, one could propose other vectors $\mathbf{d}^{(j)}$ and thus different objective functions to minimize.

As we mentioned before, the number of coefficients in the composition is usually larger than the number of order conditions, so that there are l ($< m$) free parameters $\alpha_1, \dots, \alpha_l$. Recently, McLachlan [15] has proposed an idea to find (in a relatively simple way) efficient methods in $\mathcal{G}_3$: he takes the free parameters $(\alpha_1, \dots, \alpha_l)$ equal to the first (and last) coefficient α_{l+1} of the symmetric composition with the minimum number of stages necessary to satisfy the order conditions. Then, instead of many multidimensional families of solutions, only isolated solutions are obtained which are very easy to analyze. For methods up to effective order 6 in $\mathcal{G}_3$, the solutions obtained by applying this *rule of thumb* correspond to simultaneous local minima of E_1 and E_{22}. For higher orders, this is not necessarily the case, although the corresponding solutions seem to stay very close to the minima.

Here we propose to extend this rule in the following way: we take $\alpha_1 = \alpha_2 = \cdots = \alpha_l \equiv \alpha$ as free parameter and solve the effective order conditions for different values of α. Notice that $\alpha = \alpha_{l+1}$ corresponds to McLachlan's rule of thumb. A numerical search with values $\alpha_1, \dots, \alpha_l$ chosen at random also has been carried out, but the solutions thus found do not lead to smaller values of E_1 and E_2 (see Appendix B for more details). In fact, there exists a strong correlation between E_1 and E_2, but their absolute minima do not necessarily coincide (E_2 can be zero for some choice of $\mathbf{d}$, whereas E_1 is always nonvanishing).

In view of the number of effective order conditions to be satisfied by symmetric kernels in $\mathcal{G}_l$ and collected in Table 1, it seems reasonable to consider methods up to order 6 in $\mathcal{G}_1$ and $\mathcal{G}_2$, up to order 10 in $\mathcal{G}_3$, and up to order 12 in $\mathcal{G}_4$. The new methods are denoted by $\mathrm{P}_{\bar{m}}q$: a processed method of order q with an $\bar{m}$-stage self-adjoint kernel.

4.2. Kernels in $\mathcal{G}_1$ and $\mathcal{G}_2$ up to effective order 6. Several fourth- and sixth-order schemes in $\mathcal{G}_1$ (also valid in $\mathcal{G}_2$) are available in the literature, both as standard composition methods [5] and as processed algorithms [3]. These integrators, however, have been designed to be efficient only in $\mathcal{G}_1$. In contrast, the methods we present here have been optimized to be used both in $\mathcal{G}_1$ and $\mathcal{G}_2$.

Fourth-order. In [3] symmetric kernels with $m = 3$ and $m = 4$ are designed (with $m = 2$ the order conditions do not admit real solutions). We have built kernels with $m = 5, 6, 7$, obtaining solutions with very small values of E_1 and E_{21} and/or E_{22}. In Table 5 (first column) we present the coefficients of the selected kernel with $\bar{m} = 2m = 12$ stages.

Sixth-order. With $m = 5$ it is possible to solve all the order conditions [3], but the resulting schemes are not very efficient. We have considered kernels with m up to 10. The most efficient methods found have $m = 9$ and $m = 10$ and their coefficients are collected in Table 5 (second and third columns). These methods are discussed in more detail in Appendix B. We should remark that, if $\chi_h = \varphi_h^{[a]} \circ \varphi_h^{[b]}$, these kernels require m evaluations of $\varphi_h^{[a]}$ and $\varphi_h^{[b]}$ (due to the FSAL property).

	$\alpha_9 = 1/2 - (\alpha_1 + \cdots + \alpha_8)$	$\alpha_{10} = 1/2 - (\alpha_1 + \cdots + \alpha_9)$
	$\alpha_{19-i} = \alpha_i, \quad i = i, \ldots, 9$	$\alpha_{21-i} = \alpha_i, \quad i = i, \ldots, 10$

4.3. Kernels in $\mathcal{G}_3$ up to effective order 10. Nonprocessed methods up to order 10 are available in [26, 23, 13, 10, 8] and up to order 6 using processing in [1, 15]. Based on the symmetric $(2m-1)$-stage composition (4.2) we present the following kernels.

Sixth-order. With $m = 3$ (5 stages) the effective order conditions $f_{1,1} = 1$, $f_{3,1} = f_{5,1} = 0$ possess two real solutions, but both of them lead to high values of the noncorrectable error terms $f_{7,1}$ and $f_{7,2}$ [1]. With $l = 1, \ldots, 5$ free parameters we have obtained a number of methods with small values of E_1 and E_{22}. We propose taking the 11-stage kernel given in [15] ($P_{11}6$) and the 13-stage kernel ($P_{13}6$) which, in addition, satisfies $f_{7,2} = 0$ (see Table 6).

Eighth-order. With $m \geq 5$ (at least 9 stages) one has enough variables to achieve effective order 8, although the solutions obtained give poorly efficient schemes. Additional stages are considered by taking up to $l = 5$ free parameters. We choose two solutions, one with $l = 2$ ($P_{13}8$) and the other with $l = 5$ ($P_{19}8$). The coefficients are collected in Table 6. The solution with $l = 2$ does not follow exactly the rule of thumb, but it is quite close to it ($\alpha_1 = \alpha_2 \simeq \alpha_5$).

Tenth-order. If $m \geq 8$ (at least 15 stages) one has enough parameters to achieve effective order 10. Kernels with $l = 0, \ldots, 5$ free parameters have been analyzed, and the schemes $P_{19}10$ and $P_{23}10$ whose coefficients are collected in Table 6 have been selected.

4.4. Kernels in $\mathcal{G}_4$ up to effective order 12. Next we consider the symmetric $(2m-1)$-stage composition (4.3). The numerical search for methods of order q in $\mathcal{G}_3$ and of order $q+2$ in $\mathcal{G}_4$ is closely related because the corresponding equations are very similar. In fact, the number of order conditions is smaller in $\mathcal{G}_4$, and the numerical search is easier. Now the methods chosen exactly follow the rule of thumb.

Eighth-order. If $m \geq 3$ (at least 5 stages) one has enough variables to get effective order 8. With $m = 3$, solutions with large values of the noncorrectable leading error term $f_{9,1}$ are obtained [1]. The coefficients of a 9-stage kernel (P_98) are collected in Table 7. Kernels with more stages have also been analyzed, but their performance is not clearly superior.

Tenth-order. At least 7 stages ($m \geq 4$) are necessary to achieve effective order 10. Kernels with up to $l = 5$ free parameters have been considered, and the kernel $P_{13}10$ with coefficients given in Table 7 is finally selected.

Twelfth-order. If $m \geq 6$ (at least 11 stages) a twelfth-order integrator can be obtained. Kernels with up to $l = 6$ free parameters have been analyzed. The coefficients for the composition with 19 stages, $P_{19}12$, are collected in Table 7.

4.5. On the accuracy of the coefficients. The coefficients of the previous kernels have been obtained with only 15 digits, even when the order of the scheme is 10 or 12. The error introduced due to the accuracy of the coefficients is propagated along the integration, and thus one could think that a 15-digit precision is not sufficient for carrying out very accurate computations. It turns out, however, that this is not observed in practice. To explain this phenomenon notice that, since the kernel is self-adjoint, the asymptotic expansion of the error contains only odd powers of h: hf_{1,i_1}, $h^3 f_{3,i_3}$, $h^5 f_{5,i_5}, \ldots$, and the step size h has to be small enough to guarantee convergence and sufficiently high accuracy. Now the consistency conditions for f_{1,i_1} are exactly satisfied (up to roundoff), and the error in the lowest-order conditions $N_{3,i}(\boldsymbol{\alpha}) = 0$ and $N_{5,i}(\boldsymbol{\alpha}) = 0$ is approximately $h^3 10^{-15}$ and $h^5 10^{-15}$, respectively, which is sufficiently accurate for most problems. If, for a given method, one is interested in obtaining more precise coefficients, the process illustrated by the following example can be applied.

Example. Suppose that the coefficients of the kernel for the processed method $P_{23}10$ in $\mathcal{G}_3$ are desired with higher accuracy. We show how to increase the actual precision from $h^3 10^{-15}$ to $h^5 10^{-15}$ just by adding some extra digits to one of the coefficients α_j.

First we consider the lowest effective order conditions $f_{1,1} = \sum_i \alpha_i = 1$, $N_{3,1}(\boldsymbol{\alpha}) = f_{3,1} = \sum_i \alpha_i^3 = 0$. Let us fix all values of α_i from Table 6 except one, say α_{11} (as well as α_{12} to ensure that condition $f_{1,1} = 1$ is exactly satisfied). Next, solve $N_{3,1}(\boldsymbol{\alpha}) = 0$ with as many digits as desired. For example, with 25 digits one gets $\alpha_{11} = 0.0709527009577666581583926$, and the error of the method due to the accuracy of the coefficients is $h^3 10^{-25} + h^5 10^{-15} \sim h^5 10^{-15}$. This process can also be used to increase the accuracy to $h^7 10^{-15}$ just by taking two parameters to solve $N_{3,1}(\boldsymbol{\alpha}) = 0$ and $N_{5,1}(\boldsymbol{\alpha}) = f_{5,1} = 0$.

5. Numerical examples. In this section we test the performance of the new processed methods on some numerical examples. A rigorous test is very difficult because the relative performance between the methods usually depend on the particular problem analyzed. If the vector field considered involves some parameters, this relative performance may depend also on them as well as on the particular splitting or basic method used for the integration. It may also depend on the initial conditions and even on the final time at which the comparison is done (although this dependence can be minimized taking an average of the error along the integration). For this reason our experiments involve several problems depending on parameters and a comparison of the processed integrators with other schemes available in the literature for different values of parameters, initial conditions, and splitting or basic methods used. In particular, we compare with the following methods (the order, number of stages, and the class $\mathcal{G}_l$ to which they belong is indicated):

- *Order* 4.
  $\mathcal{G}_1$, $\mathcal{G}_2$ ($\mathrm{BM}_6 4$): the 6-stage method (optimized in $\mathcal{G}_1$) given in [5];
  $\mathcal{G}_3$ ($\mathrm{Y}_3 4$): the well-known 3-stage method of [26] (only used as a reference);
  $\mathcal{G}_3$ ($\mathrm{S}_5 4$): the 5-stage method of [22].
- *Order* 6.
  $\mathcal{G}_1$, $\mathcal{G}_2$ ($\mathrm{BM}_{10} 6$): the 10-stage method (optimized in $\mathcal{G}_1$) given in [5];
  $\mathcal{G}_3$ ($\mathrm{M}_9 6$): the optimized 9-stage method $(S, m = 9)$ of [13].
- *Order* 8.
  $\mathcal{G}_3$ ($\mathrm{M}_{17} 8$): the 17-stage method $(S, m = 17)$ of [13];
  $\mathcal{G}_4$ ($\mathrm{B}_7 8$): the 7-stage method of [1].
- *Order* 10.
  $\mathcal{G}_3$ ($\mathrm{R}_{33} 10$): the 33-stage method (s33odr10c) of [10];
  $\mathcal{G}_3$ ($\mathrm{G}_{33} 10$): the 33-stage method of [8].
  $\mathcal{G}_4$ ($\mathrm{O}_{13} 10$): the 13-stage method of [20].
- *Order* 12.
  $\mathcal{G}_4$ ($\mathrm{O}_{23} 12$): the 23-stage method of [20].

In the comparison, the computational cost (or the number of evaluations) of the kernel is taken as the cost of the processed method. All computations are always started with the most accurate composition preprocessor $(\pi_h^{(c)})^{-1}$ available. For postprocessing we take $\pi_h^{(c)}$, although very similar results are obtained when the alternative cheap postprocessor $\hat{\pi}_h$ is used instead, in agreement with the results exposed in [2].

Example 1. We consider the Lotka–Volterra system

$$u' = u(v-2), \qquad v' = v(1-u), \tag{5.1}$$

which has as first integral $I(u,v) = \ln(uv^2) - (u+v)$. For simplicity, we split the vector field as $f = f_a + f_b$, with $f_a = (u(v-2), 0)$ and $f_b = (0, v(1-u))$, which allows us to consider explicit methods which preserve the Poisson structure. This implies, in particular, that the first integral $I(u,v)$ is approximately preserved (for in that case, splitting

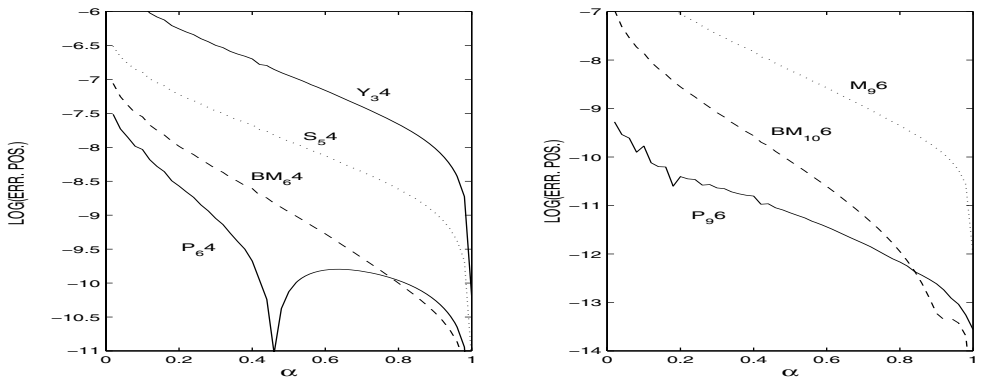

FIG. 1. *Average relative error in position for the methods in $\mathcal{G}_1$ ($\mathcal{G}_2$) and for different initial conditions: $(u_0, v_0) = (\alpha, 2\alpha)$, $0 < \alpha < 1$. The methods* $Y_3 4$, $S_5 4$, *and* $M_9 6$, *belonging to $\mathcal{G}_3$, are included as reference since they are frequently used. Time steps used are $h = m/270$ for the fourth-order methods denoted by $X_m 4$ with X=Y, S, BM, P, so that the four methods require the same number of function evaluations. Similarly, for the sixth-order methods $X_m 6$ with X=M, BM, P, we have taken $h = m/180$.*

methods are, with an appropriate change of variables, symplectic methods applied to a Hamiltonian system with Hamiltonian function $H(p, q) := I(u(p, q), v(p, q)))$. The problem can be integrated by schemes in $\mathcal{G}_1/\mathcal{G}_2$. In the region $0 < u, v$ the system has periodic trajectories around $(u, v) = (1, 2)$. We take as initial conditions $(u_0, v_0) = (\alpha, 2\alpha)$ for different values of $\alpha \in (0, 1)$, and integrate for $t \in [0, 50]$. In this way all periodic trajectories are considered. For each initial condition we compute the error at $t = 1, 2, \ldots, 50$ and measure the average relative error in phase space. The time step is chosen in such a way that (i) all the methods of the same order in the same figure require approximately the same number of function evaluations and (ii) the relative performance between them does not change qualitatively when h is reduced. Figure 1 shows the results obtained for the fourth- and sixth-order methods in $\mathcal{G}_1$ and $\mathcal{G}_2$. We observe that the relative performance between the methods highly depend on the initial conditions but, in general, the new processed methods are more efficient.

To compare the performance of the methods in $\mathcal{G}_3$ we take $\mathcal{S}_h^{[2]} = \varphi_{h/2}^{[a]} \circ \varphi_h^{[b]} \circ \varphi_{h/2}^{[a]}$ as the basic self-adjoint second-order integrator. The corresponding results are shown in Figure 2. Again, the processed methods are clearly superior. When the symmetric second-order implicit midpoint rule is taken as $\mathcal{S}_h^{[2]}$, we have observed that the results of the schemes are more sensitive to initial conditions giving, in general, more accurate results when α is close to 1. Then, depending on the value of α and the qualitative properties which we desire to preserve, one has to choose the most appropriate basic integrator. However, what it is important for our analysis is that the relative performance of the compared methods does not change considerably.

Finally, to compare the behavior of methods of different orders we plot efficiency diagrams. For this test we fix α to a representative value of the performance of the methods: in view of Figures 1 and 2, we take $\alpha = 1/3$. Figure 3 shows the average relative error in phase space as a function of the number of function evaluations for different time steps. The high efficiency achieved by the processed methods $P_9 6$ and $P_{13} 8$ is apparent.

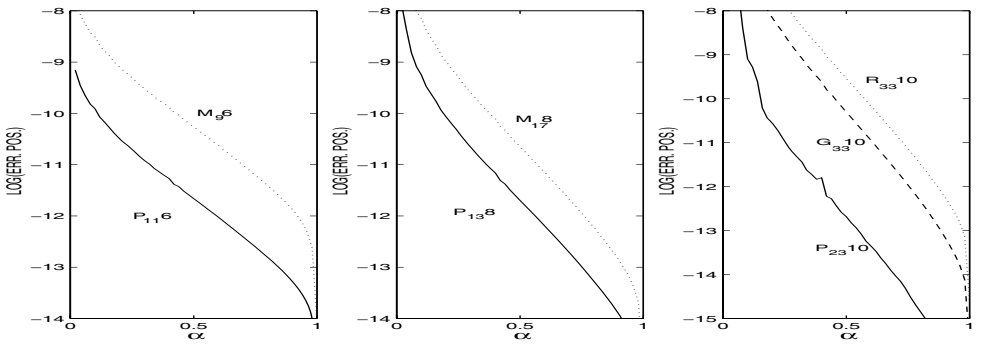

FIG. 2. *Same as Figure* 1 *but for methods in* $\mathcal{G}_3$ *taking* $h = m/396$ *for* X_m6, $h = m/(13\times17)$ *for* X_m8 *(X=M, P),* $h = 1/8$ *for* $G_{33}10$, $R_{33}10$, *and* $h = 1/12$ *for* $P_{23}10$, *so that all methods separately in each plot require, approximately, the same number of function evaluations.*

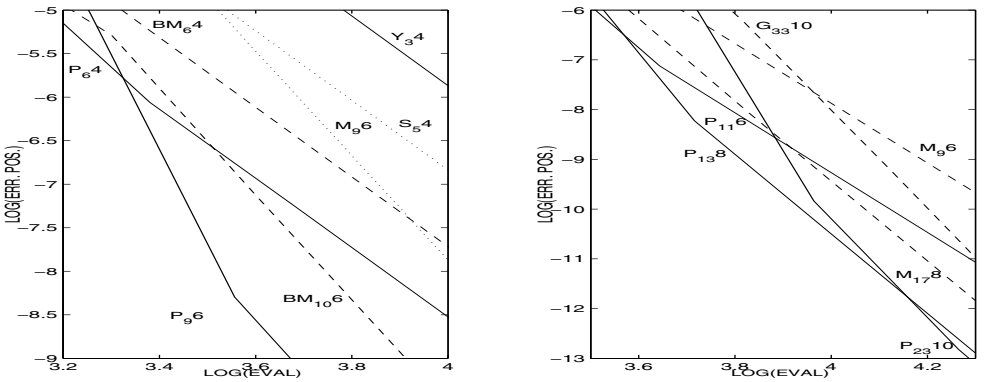

FIG. 3. *Average error in phase space versus the number of evaluations for the methods of Figures* 1 *and* 2 *taking different time steps and* $\alpha = 1/3$.

Example 2. Let us consider now the ABC-flow [8, 16], with equations

$$x' = \mathcal{B}\cos y + \mathcal{C}\sin z, \qquad y' = \mathcal{C}\cos z + \mathcal{A}\sin x, \qquad z' = \mathcal{A}\cos x + \mathcal{B}\sin y, \tag{5.2}$$

which has been studied as a model volume-preserving three-dimensional flow. The vector field f is separable into three solvable parts, namely

$$f = f_a + f_b + f_c = \mathcal{A}(0, \sin x, \cos x) + \mathcal{B}(\cos y, 0, \sin y) + \mathcal{C}(\sin z, \cos z, 0).$$

For $\mathcal{B} = \mathcal{C} = 1$, $\mathcal{A} = \alpha$ we take as initial condition $(x_0, y_0, z_0) = (3.14, 2.77, 0)$ and integrate until $t = 20$ for different values of $\alpha \in [0, 1]$. The α-dependent vector field can be used to test integrators in $\mathcal{G}_l$, $l = 2, 3, 4$. We choose the following explicit basic methods: (i) in $\mathcal{G}_2$, the first-order scheme $\chi_h = \varphi_h^{[a]} \circ \varphi_h^{[b]} \circ \varphi_h^{[c]}$ and its adjoint $\chi_h^* = \varphi_h^{[c]} \circ \varphi_h^{[b]} \circ \varphi_h^{[a]}$; (ii) in $\mathcal{G}_3$, the symmetric composition $\mathcal{S}_h^{[2]} = \chi_{h/2} \circ \chi_{h/2}^*$; and (iii) in $\mathcal{G}_4$, the well-known 3-stage fourth-order scheme $\mathcal{S}_h^{[4]} = \mathcal{S}_{\alpha_1 h}^{[2]} \circ \mathcal{S}_{\alpha_2 h}^{[2]} \circ \mathcal{S}_{\alpha_1 h}^{[2]}$, with $\alpha_1 = 1/(2-2^{1/3})$ and $\alpha_2 = 1-2\alpha_1$. Obviously, more efficient self-adjoint fourth-order basic methods $\mathcal{S}_h^{[4]}$ could improve the accuracy of the results, but at this stage, we are mainly interested in the relative performance of the different integrators, and this does not change considerably with the basic method.

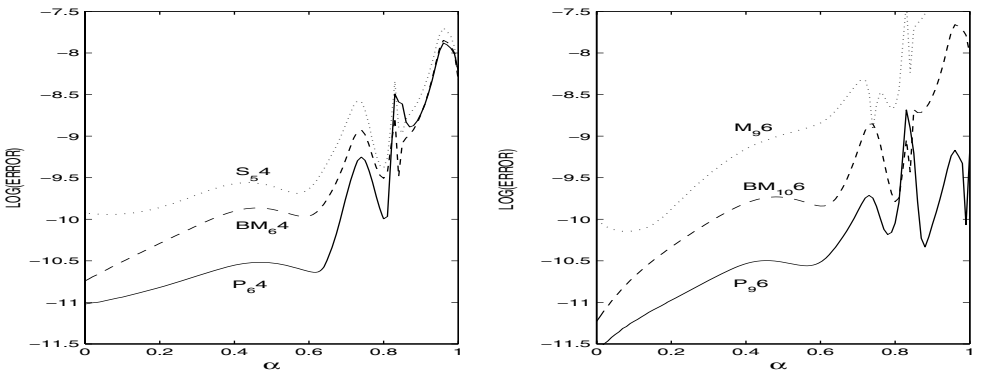

FIG. 4. *Error in position for the ABC-flow with $\mathcal{B} = \mathcal{C} = 1$ at the same computational cost for the fourth- (left) and sixth-order methods (right) in $\mathcal{G}_2$ taking different values of the parameter $\mathcal{A} = \alpha$, $0 \le \alpha \le 1$, and initial condition $(x_0, y_0, z_0) = (3.14, 2.77, 0)$.*

The time step size used for each method is such that all the integrators of the same order appearing in the same figure require approximately the same number of evaluations, and the results have the expected asymptotic behavior corresponding to the respective order. Figure 4 shows the results obtained with the fourth- and sixth-order methods in $\mathcal{G}_2$, whereas Figure 5 corresponds to the sixth-, eighth-, and tenth-order methods in $\mathcal{G}_3$. We have repeated the experiment with different initial conditions, and the relative performance of the methods also changes. However, we have observed a superiority of the processed integrators which, on average, is well represented by Figures 4 and 5.

On the other hand, since we have taken $\mathcal{B} = \mathcal{C}$, the system has a reversing symmetry group with 16 elements [16], not preserved by the preceding splitting. However, if we consider

$$f = f_a + f_b = \mathcal{B}(\cos y + \sin z, 0, 0) + (0, \mathcal{B}\cos z + \mathcal{A}\sin x, \mathcal{A}\cos x + \mathcal{B}\sin y), \tag{5.3}$$

this splitting does preserve the reversing symmetry group. Notice that f_a is explicitly integrable, but f_b is not. We can integrate f_b, $\varphi_h^{[b]}$, with the midpoint rule, $\widetilde{\varphi}_h^{[b]}$, which preserves all the properties [16]. We repeated the experiments shown in Figure 5 using as the basic method $\mathcal{S}_h^{[2]} = \varphi_{h/2}^{[a]} \circ \widetilde{\varphi}_h^{[b]} \circ \varphi_{h/2}^{[a]}$ and the same time steps. The midpoint rule was implemented with the Newton method (three iterations usually gave enough accuracy). The results are shown in Figure 6, where we observe that the relative performance between the methods change, but the processed methods are more accurate.

Finally, Figure 7 shows the results obtained by the methods in $\mathcal{G}_4$ using the explicit methods. Now the processed integrators are always between three and four orders of magnitude more accurate at the same cost, in agreement with the size of the leading order error coefficients.

Example 3. Finally, to illustrate the interest of using methods in $\mathcal{G}_4$, we consider the two-body gravitational problem. The corresponding evolution equation may be written as

$$x_i'' = -\frac{x_i}{(x_1^2 + x_2^2)^{3/2}}, \qquad i = 1, 2, \tag{5.4}$$

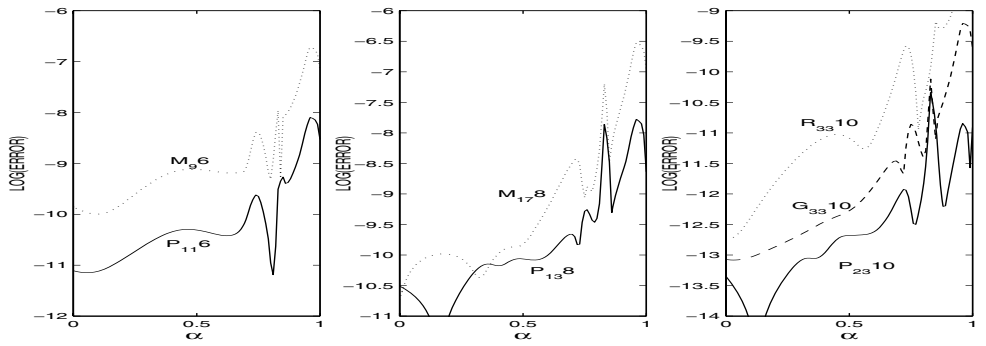

FIG. 5. *Same as Figure* 4 *for the sixth-, eighth-, and tenth-order methods in* $\mathcal{G}_3$ *taking* $h = m/99$ *for* X_m6, $h = 4m/(13 \times 17)$ *for* X_m8 *(X=M, P),* $h = 5/23$ *for* $G_{33}10$, $R_{33}10$, *and* $h = 5/33$ *for* $P_{23}10$.

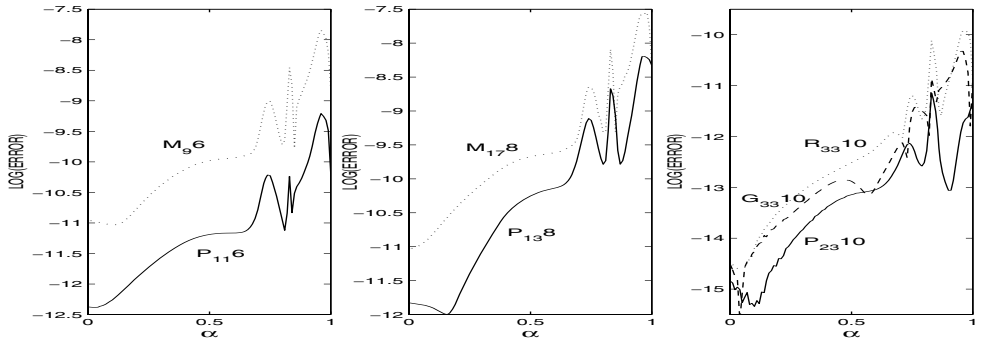

FIG. 6. *Same as Figure* 4 *for the sixth-, eighth-, and tenth-order methods in* $\mathcal{G}_3$ *for the splitting given in* (5.3) *and using the implicit midpoint rule to solve the equation for* f_b.

and we take as initial condition $x_1(0) = 1-e$, $x_2(0) = x_1'(0) = 0$, $x_2'(0) = [(1+e)/(1-e)]^{1/2}$, which produces an orbit with eccentricity e. With the value $e = 1/4$, the orbit is determined numerically for 100 periods and the mean error in positions is computed. This problem is suited to integration by symplectic Runge–Kutta–Nyström methods [21], and moreover, modified potentials can also be used [4, 12]. In particular, Koseleff [11] designed an efficient self-adjoint fourth-order scheme, which can be used as the basic method:

$$\mathcal{S}_h^{[4]} = \varphi_{h/6}^{[b]} \circ \varphi_{h/2}^{[a]} \circ \varphi_{2h/3,h^3/72}^{[b,c]} \circ \varphi_{h/2}^{[a]} \circ \varphi_{h/6}^{[b]}. \tag{5.5}$$

Here

$$\varphi_{\alpha h}^{[a]}(x_i) = x_i + \alpha h x_i', \qquad \varphi_{\beta h,\gamma h^3}^{[b,c]}(x_i') = x_i' - x_i G\,(\beta + \hat{\gamma}\, G)\,, \qquad i = 1, 2, \tag{5.6}$$

with $\hat{\gamma} = 4\gamma h$, $G = h/(x_1^2 + x_2^2)^{3/2}$, and $\varphi_{\beta h}^{[b]}$ corresponds to taking $\gamma = 0$ in the modified flow $\varphi_{\beta h,\gamma h^3}^{[b,c]}$. Notice that the cost of evaluating $\varphi_{\beta h,\gamma h^3}^{[b,c]}$ instead of $\varphi_{\beta h}^{[b]}$ increases only by one addition and one multiplication, so that it can be neglected.

We compare the new processed methods in $\mathcal{G}_4$, taking (5.5) as the basic integrator with the nonprocessed schemes $M_{17}8$ and $G_{33}10$ in $\mathcal{G}_3$ and using as basic second-order symmetric integrator the well-known Störmer–Verlet/leapfrog method. Figure

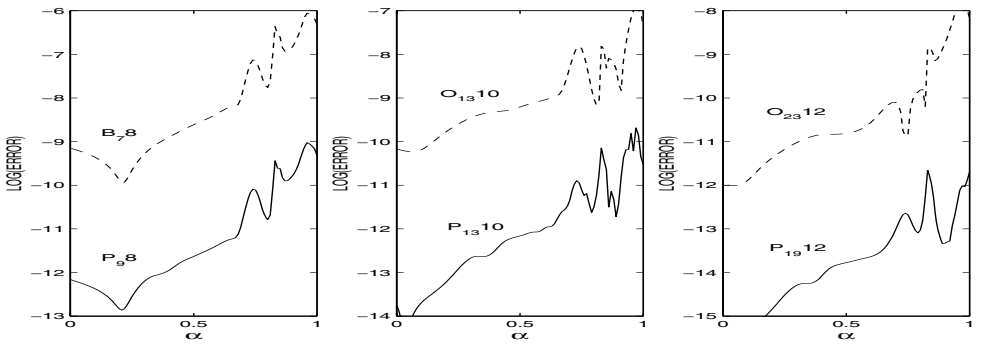

FIG. 7. *Same as Figure* 4 *for the eighth-, tenth-, and twelfth-order methods in* $\mathcal{G}_4$.

8 shows the average relative error in position versus the number of $\varphi_{\beta h}^{[b]}$ evaluations (one evaluation of (5.5) is considered to involve two $\varphi_{\beta h}^{[b]}$ evaluations due to the FSAL property). It is worth noticing the excellent performance of the processed methods $P_9 8$ and $P_{13}10$. In particular, for the step sizes considered in the figure $P_{13}10$ behaves as a twelfth-order integrator: in fact, one has to take a much smaller h to recover the asymptotic behavior expected for a tenth-order method. A similar pattern can be observed in the diagram corresponding to $P_9 8$.

This example clearly shows that in certain circumstances and depending on the particular structure of the system at hand, it can be advantageous to design an efficient fourth-order scheme $\mathcal{S}_h^{[4]}$ and then build by composition higher-order integrators based on it. Obviously, the performance of the methods highly depend on the particular fourth-order basic scheme and a more detailed analysis of this could even improve the performance observed in Figure 8.

We must also remark that after 100 revolutions it is still possible to obtain an accuracy of 18 digits. However, the coefficients for the numerical methods in Table 7 are given with only 15 digits. This is so because the lowest-order condition is multiplied by h^5, which is also a small number. In other words, the comments of section 4.5 are valid here.

6. Conclusions. In this paper we have constructed numerical integrators for differential equations up to order twelve by composition of basic integrators and using the processing technique. Four families of integrators are considered: (i) fourth- and sixth-order composition methods for a system separable into two solvable parts or (ii) using as basic methods a first-order integrator and its adjoint; (iii) sixth-, eighth-, and tenth-order composition methods using second-order self-adjoint methods; and (iv) eighth-, tenth-, and twelfth-order composition methods using fourth-order self-adjoint methods.

Our starting point is a theoretical analysis of the processing technique for the cases considered here, which allows us to obtain in a relatively simple way the number and explicit form of the order conditions for the kernel. The analysis clearly shows that the processing technique is a very promising procedure to obtain efficient methods when implemented with constant time step. In that case, the cost of the postprocessor can be neglected even if the output has to be frequently computed since, if desired, it can be approximated using intermediate stages of the kernel.

Next, we have carried out a numerical search of the coefficients of different com-

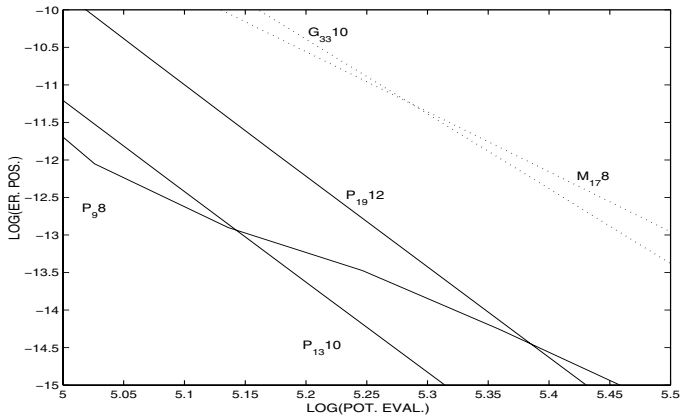

FIG. 8. *Average error in position versus number of evaluations.* $P_9 8$, $P_{13} 10$, *and* $P_{19} 12$ *are processed methods in* $\mathcal{G}_4$ *using* (5.5) *as the basic method (considered as two evaluations of the potential).* $M_{17} 8$ *and* $G_{33} 10$ *are methods in* $\mathcal{G}_3$ *using the Störmer–Verlet leapfrog method (one evaluation of the potential).*

positions to get efficient kernels for the cases considered. Compositions with more stages than strictly required to solve the order conditions are considered for optimization purposes by following, mainly, the rule of thumb proposed in [15]. In this way, the higher accuracy obtained compensates the increase in the computational cost of the methods.

A large number of numerical experiments have been carried out to compare the performance of the new processed methods with other well-established nonprocessed methods, and some representative results are shown. We have considered different initial conditions, values of the parameters, basic methods, and splittings to better appreciate the performance of the methods.

We think that some comments about the choice and applicability of the different methods proposed here could be of interest for the potential user. If a given problem can be integrated using methods in $\mathcal{G}_1$, then it is clear that it can also be integrated with methods in $\mathcal{G}_2, \mathcal{G}_3$, and $\mathcal{G}_4$, but for the same order, methods in $\mathcal{G}_1$ and $\mathcal{G}_2$ are more efficient than schemes in $\mathcal{G}_3$ and $\mathcal{G}_4$. Thus, if one is interested in fourth- or sixth-order methods, it is, in general, preferable to consider methods in $\mathcal{G}_1$ or $\mathcal{G}_2$; for orders 8 or 10 we recommend methods in $\mathcal{G}_3$, and only for higher-order methods or when a very efficient fourth-order scheme is available do we recommend methods in $\mathcal{G}_4$. The same comments are valid for a problem which can be integrated in $\mathcal{G}_2$ but not in $\mathcal{G}_1$.

Although the processing technique has become, during the past few years, a standard technique for constructing efficient high-order composition integrators, there are still some issues which need to be clarified.

- Which is the most appropriate objective function to minimize leading to the most efficient methods for a given class of problems?
- We have considered self-adjoint kernels with more stages than necessary to solve the effective order conditions. On the other hand, for nonsymmetric kernels such a number of stages would contain a larger number of free parameters. The question is, With such assumptions, could other interesting solutions not contemplated in this work exist?

- Could there exist other possible symmetries for the coefficients and different *rules of thumb* which would allow one to obtain more efficient methods?
- How can one build specific fourth-order methods for a given problem that when used as a basic scheme in $\mathcal{G}_4$ would lead to very efficient higher-order composition methods?
- Would it be possible to construct more efficient composition methods for particular problems of physical relevance for which the Lie algebra involved presents a simpler structure than those analyzed in this work?

Appendix A. Construction of specific postprocessors. Next we present several composition and cheap postprocessors for some of the kernels collected in section 4. The resulting integrators provide the most efficient results on different test examples (analyzed in section 5).

With respect to composition postprocessors, in accordance with the comments in section 4.1, we take $\pi_h^{(c)} = w_h^{[i]} \circ w_{-h}^{[i]}$, $i = 2, 3, 4$, for the composition postprocessor, with

$$w_h^{[2]} = \chi_{\gamma_{2r}h} \circ \chi^*_{\gamma_{2r-1}h} \circ \cdots \circ \chi_{\gamma_2 h} \circ \chi^*_{\gamma_1 h}, \tag{A.1}$$

$$w_h^{[3]} = \mathcal{S}^{[2]}_{\gamma_r h} \circ \cdots \circ \mathcal{S}^{[2]}_{\gamma_1 h}, \tag{A.2}$$

$$w_h^{[4]} = \mathcal{S}^{[4]}_{\gamma_r h} \circ \cdots \circ \mathcal{S}^{[4]}_{\gamma_1 h} \tag{A.3}$$

and require that $\pi_h^{(c)} \in \mathbb{P}_{q-1}$, although in some cases a more accurate composition $\pi_h^{(c)} \in \mathbb{P}_q$ is also built, particularly when the number of stages required is not too large. On the other hand, the cheap postprocessors are constructed by following the procedure outlined in section 3.2.

Postprocessors in $\mathcal{G}_1$ and $\mathcal{G}_2$. Condition $p_{1,1} = \sum_i \gamma_i = 0$ produces a composition $\pi_h^{(c)} = w_h^{[2]} \circ w_{-h}^{[2]} \in \mathbb{P}_2$, whereas 4 and 15 order conditions have to be satisfied if $\pi_h^{(c)} \in \mathbb{P}_j$, $j = 4, 6$, respectively. In Table 8 we give coefficients for $\pi_h^{(c)}$ in $\mathbb{P}_4$ ($\mathrm{P}_6 4$). Since the kernel $\mathrm{P}_9 6$ of effective order 6 is the most efficient in practice, we present two possible postprocessors: one in $\mathbb{P}_5$ ($r = 4$) and a more accurate one in $\mathbb{P}_6$ ($r = 9$), which is recommended for use in both $\mathcal{G}_1$ and $\mathcal{G}_2$. Finally, we provide a cheap postprocessor $\hat{\pi}_h \in \mathbb{P}_3$ for $\mathrm{P}_6 4$.

Postprocessors in $\mathcal{G}_3$. For a sixth-order processed integrator it is required that $\pi_h \in \mathbb{P}_5$ and, according to Table 3, this is accomplished if $p_{4,1} = -f_{5,2}$ and $p_{1,1} = p_{3,1} = p_{5,1} = p_{5,2} = 0$. In fact, with $\pi_h^{(c)} = w_h^{[3]} \circ w_{-h}^{[3]}$, $w_h^{[3]}$ given by (A.2) and satisfying $\sum_{i=1}^r \gamma_i = 0$, we need only to enforce $p_{4,1} = -f_{5,2}$. If, in addition, $p_{6,1} = -f_{7,3}$ and $p_{6,2} = -f_{7,4}$ hold, then $\pi_h^{(c)} \in \mathbb{P}_6$, whereas if condition $\sum_{i=1}^r \gamma_i^3 = 0$ is satisfied, then $\pi_h^{(c)} \in \mathbb{P}_7$: this is, in fact, the composition postprocessor collected in Table 9 for $\mathrm{P}_{11} 6$ and $\mathrm{P}_{13} 6$, preserving time-symmetry up to $\mathcal{O}(h^9)$. Taking into account the conditions on $p_{8,i}$, $i = 1, \ldots, 5$, one gets $\pi_h^{(c)} \in \mathbb{P}_8$, and so on. For $\mathrm{P}_{13} 8$ (which works in practice more efficiently than $\mathrm{P}_{19} 8$) we provide a composition postprocessor in $\mathbb{P}_8$ and a 24-stage $\pi_h^{(c)} \in \mathbb{P}_9$ for $\mathrm{P}_{23} 10$. One could get a postprocessor in $\mathbb{P}_{10}$ for the tenth-order case, but this would require 11 new conditions to be satisfied by $w_h^{[3]}$, giving a 46-stage postprocessor. We also present the coefficients of cheap processors $\hat{\pi}_h \in \mathbb{P}_{q-1}$, $q = 6, 8$, valid for $\mathrm{P}_{11} 6$ and $\mathrm{P}_{13} 8$, respectively. A similar $\hat{\pi}_h$ could be obtained for $\mathrm{P}_{23} 10$, but from Table 4, it would need at least 33 coefficients w_i.

Postprocessors in $\mathcal{G}_4$. In Table 10 we present accurate composition postprocessors $\pi_h^{(c)} = w_h^{[4]} \circ w_{-h}^{[4]}$ belonging to $\mathbb{P}_8$ and $\mathbb{P}_{10}$ for $P_9 8$ and $P_{13} 10$, respectively, whereas the postprocessor for the twelfth-order method belongs to $\mathbb{P}_{11}$.

Appendix B. Here we illustrate the validity of the criteria adopted in section 4 for the choice of the particular kernels collected there. We fix our attention, in particular, on the compositions of effective order 6 in $\mathcal{G}_2$ and effective order 8 in $\mathcal{G}_3$. In the first case we take the symmetric composition (4.1) with the minimum number of maps required to satisfy the effective order conditions ($m = 5$) $\psi(m)$, and then we introduce $l \leq 5$ additional maps with free parameters $\alpha_1, \ldots, \alpha_l$ in the composition.

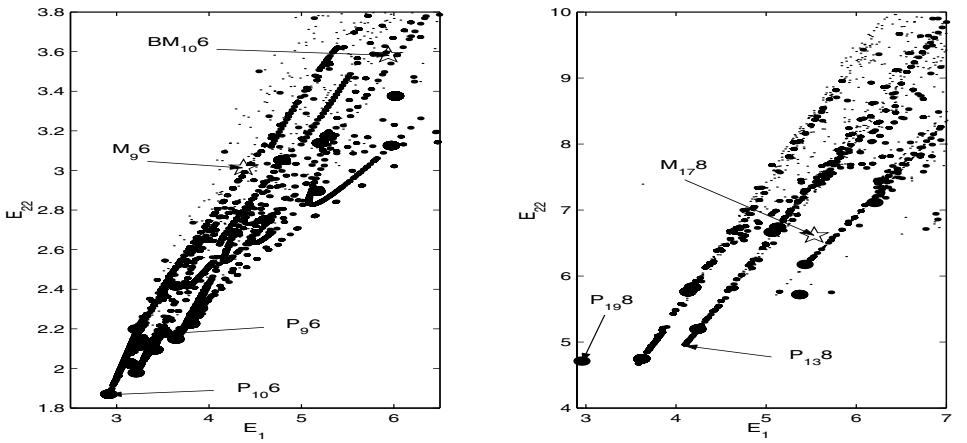

FIG. 9. *Values of E_1 and E_{22} for self-adjoint kernels using l free parameters when they are chosen randomly (small dots), applying the generalized rule of thumb (medium dots) and using McLachlan's rule of thumb (big dots). Only the results for the kernels of effective order 6 in $\mathcal{G}_1/\mathcal{G}_2$ with $l = 3, 4, 5$ (left) and the results for the kernels of effective order 8 in $\mathcal{G}_3$ with $l = 1, 2, 3$ (right) are shown.*

For instance, when $l = 4$ the kernel has the form

$$\psi_h^{[2]} = \chi_{\alpha_1 h} \circ \chi_{\alpha_2 h}^* \circ \chi_{\alpha_3 h} \circ \chi_{\alpha_4 h}^* \circ \psi(m) \circ \chi_{\alpha_4 h} \circ \chi_{\alpha_3 h}^* \circ \chi_{\alpha_2 h} \circ \chi_{\alpha_1 h}^*.$$

Next, for each l and given values of $\alpha_1, \ldots, \alpha_l$, we solve the effective order conditions and compute the objective functions E_1 and E_{22}. In Figure 9 (left) we collect the results obtained when (i) the free parameters $\alpha_1, \ldots, \alpha_l$ are chosen at random (small dots); (ii) $\alpha_1 = \cdots = \alpha_l = \alpha$ for different values of α (medium dots); and (iii) applying McLachlan's rule of thumb, i.e., $\alpha_1 = \cdots = \alpha_l = \alpha_{l+1}$ (big dots). For clarity, only the results with $l = 3, 4, 5$ and a small fraction of points in (i) are shown. It is worth noticing that a random selection of $\alpha_1, \ldots, \alpha_l$ does not lead to smaller values of E_1 and E_{22} than those obtained by applying the rule of thumb or its generalization. In fact, the medium dots lie on curves, whereas the big dots are located in the neighborhood of their minima. For comparison, we also include the values obtained with the nonprocessed 10-stage method $\mathrm{BM}_{10}6$ (optimized as a method in $\mathcal{G}_1$) given in [5] when $\chi_h = \varphi_h^{[a]} \circ \varphi_h^{[b]}$ and the optimized method $\mathrm{M}_9 6$ with $\mathcal{S}_h^{[2]} = \chi_{h/2} \circ \chi_{h/2}^*$ (stars).

This figure should be interpreted with caution: from the obtained values of E_1 and E_{22}, $\mathrm{M}_9 6$ should be more efficient than $\mathrm{BM}_{10}6$, but in practice it is just the opposite.

In fact, the value of E_{21} (using a basis of $\mathcal{L}$ in $\mathcal{G}_1$) is smaller with $\mathrm{BM}_{10}6$. This example indicates some of the difficulties involved in the choice of the best objective functions for methods in $\mathcal{G}_1$ and $\mathcal{G}_2$. Among the different solutions in the lower left corner of the figure we have selected two of them: $\mathrm{P}_{10}6$ (providing the minimum of E_1 and E_{22}) and $\mathrm{P}_9 6$ (with the smallest value of E_{21}). In practice, the kernel $\mathrm{P}_9 6$ shows the best performance.

In Figure 9 (right) we show the results obtained with the kernel of effective order 8 in $\mathcal{G}_3$. Now $l = 1, 2, 3$ free parameters are considered. We also include the values given by the 17-stage method $\mathrm{M}_{17}8$ and the 19-stage kernel $\mathrm{P}_{19}8$ of Table 6.

Acknowledgment. The authors would like to thank the referees for their careful reading of the manuscript and their comments, which helped to improve this paper a great deal.

ISOPERIMETRIC PARTITIONING: A NEW ALGORITHM FOR GRAPH PARTITIONING*

LEO GRADY† AND ERIC L. SCHWARTZ‡

Abstract. We present a new algorithm for graph partitioning based on optimization of the combinatorial isoperimetric constant. It is shown empirically that this algorithm is competitive with other global partitioning algorithms in terms of partition quality. The isoperimetric algorithm is easy to parallelize, does not require coordinate information, and handles nonplanar graphs, weighted graphs, and families of graphs which are known to cause problems for other methods. Compared to spectral partitioning, the isoperimetric algorithm is faster and more stable. An exact circuit analogy to the algorithm is also developed with a natural random walks interpretation. The isoperimetric algorithm for graph partitioning is implemented in our publicly available Graph Analysis Toolbox [L. Grady, Ph.D. thesis, Boston University, Boston, MA, 2004], [L. Grady and E. L. Schwartz, Technical report TR-03-021, Boston University, Boston, MA, 2003] for MATLAB obtainable at http://eslab.bu.edu/software/graphanalysis/. This toolbox was used to generate all of the results compiled in the tables of this paper.

1. Introduction.

In the graph partitioning problem, one chooses subsets of the vertex set of a graph such that the sets share a minimal number of spanning edges while satisfying a specified cardinality constraint. Applications of graph partitioning include parallel processing [63], solving sparse linear systems [58], VLSI circuit design [4], and image segmentation [61, 68, 32].

Methods of graph partitioning take different forms, depending on the number of partitions required—whether or not the nodes have coordinates—and the cardinality constraints of the sets. In this paper, we use the term *partition* to refer to the assignment of each node in the vertex set into two (not necessarily equal) parts. We propose an algorithm termed *isoperimetric partitioning*, since it is derived and motivated by the isoperimetric constant defined for continuous manifolds [15]. The isoperimetric algorithm most closely resembles spectral partitioning in its use and ability to create hybrids with other algorithms (e.g., multilevel spectral partitioning [40] and geometric-spectral partitioning [14]). However, it requires the solution to a large, sparse system of equations rather than solving the eigenvector problem for a large, sparse matrix. This difference leads to improved speed and numerical stability.

The paper is organized as follows: we begin by deriving the isoperimetric algorithm from the isoperimetric constant of a graph in section 2, followed in section 3 by two physical analogies for the isoperimetric algorithm, and in section 4 by proving a few formal properties of the algorithm. In section 5, we review the most popular and

effective graph partitioning algorithms and the relation of the present work. Section 6 provides examples intended to build intuition about the algorithm behavior. Section 7 validates the present method on various general types of graphs and several specific graphs, followed by the conclusion.

2. Isoperimetric algorithm. A *graph* is a pair $G = (V, E)$ with vertices $v \in V$ and edges $e \in E \subseteq V \times V$. An edge, e, spanning two vertices, v_i and v_j, is denoted by e_{ij}. Let $n = |V|$ and $m = |E|$, where $|\cdot|$ denotes cardinality. A *weighted graph* has a value (here assumed to be nonnegative and real) assigned to each edge called a *weight*. The weight of edge e_{ij} is denoted by $w(e_{ij})$ or w_{ij}. Since weighted graphs are more general than unweighted graphs (i.e., $w(e_{ij}) = 1$ for all $e_{ij} \in E$ in the unweighted case), we develop all our results for weighted graphs.

Graph partitioning has been strongly influenced by properties of a combinatorial formulation of the classic isoperimetric problem: *For a fixed area, find the shape with minimum perimeter* [16]. The approach to graph partitioning presented here is a polynomial time heuristic for the NP-hard [55] problem of finding a graph with minimum perimeter for a fixed area.

Cheeger defined [15] the *isoperimetric constant* h of a manifold as

$$h = \inf_S \frac{|\partial S|}{\mathrm{Vol}_S}, \tag{2.1}$$

where S is a region in the manifold, Vol_S denotes the volume of region S, $|\partial S|$ is the area of the boundary of region S, and h is the infimum of the ratio over all possible S. For a compact manifold, $\mathrm{Vol}_S \leq \frac{1}{2}\mathrm{Vol}_{\mathrm{Total}}$, and for a noncompact manifold, $\mathrm{Vol}_S < \infty$ (see [55, 54]).

For a graph, G, the *isoperimetric number* [55], h_G, is

$$h_G = \inf_S \frac{|\partial S|}{\mathrm{Vol}_S}, \tag{2.2}$$

where $S \subset V$ and

$$\mathrm{Vol}_S \leq \frac{1}{2}\mathrm{Vol}_V. \tag{2.3}$$

In finite graphs, the infimum in (2.2) becomes a minimum. The boundary of a set, S, is defined as $\partial S = \{e_{ij} | i \in S, j \in \overline{S}\}$ and on a weighted graph

$$|\partial S| = \sum_{e_{ij} \in \partial S} w(e_{ij}). \tag{2.4}$$

In the context of graph partitioning, combinatorial volume is typically taken as

$$\mathrm{Vol}_S = |S|. \tag{2.5}$$

For a given set of nodes, S, we term the ratio of its boundary to its volume as the *isoperimetric ratio* and denote it by $h(S)$. The *isoperimetric sets* for a graph, G, are any S and $\overline{S}$ for which $h(S) = h_G$. The specification of a set satisfying (2.3), together with its complement, may be considered as a *partition*, and therefore we use the term interchangeably with the specification of a set satisfying (2.3). A good partition is defined to be one with a low isoperimetric ratio (i.e., the optimal partition consists of the isoperimetric sets themselves). Therefore, our goal is to maximize Vol_S

while minimizing $|\partial S|$. Finding isoperimetric sets is an NP-hard problem [55], so our algorithm is a heuristic for finding a set with a low isoperimetric ratio that runs in polynomial time.

Define an indicator vector that takes a binary value at each node

$$x_i = \begin{cases} 0 & \text{if } v_i \in S, \\ 1 & \text{if } v_i \in \overline{S}. \end{cases} \tag{2.6}$$

A specification of x also defines a partition. Define the $n \times n$ matrix L of a graph as

$$L_{v_i v_j} = \begin{cases} d_i & \text{if } i = j, \\ -w(e_{ij}) & \text{if } e_{ij} \in E, \\ 0 & \text{otherwise,} \end{cases} \tag{2.7}$$

where d_i denotes the weighted *degree* of vertex v_i

$$d_i = \sum_{e_{ij}} w(e_{ij}) \ \ \forall\, e_{ij} \in E. \tag{2.8}$$

The notation $L_{v_i v_j}$ is used to indicate that the matrix L is being indexed by vertices v_i and v_j. This matrix is also known as the *admittance matrix* in the context of circuit theory or the *Laplacian matrix* (see [51] for a review).

By definition of L

$$|\partial S| = x^T L x, \tag{2.9}$$

and $\mathrm{Vol}_S = x^T r$, where r denotes the vector of all ones. Maximizing the volume of S subject to $\mathrm{Vol}_S = k$ for some constant $k \leq \frac{1}{2}\mathrm{Vol}_V$ may be done by asserting the constraint

$$x^T r = k. \tag{2.10}$$

In terms of the indicator vector, the isoperimetric number of a graph (2.2) is given by

$$h_G = \min_x \frac{x^T L x}{x^T r}. \tag{2.11}$$

Given an indicator vector, x, then $h(x)$ is used to represent the isoperimetric ratio associated with that partition.

The constrained optimization of the isoperimetric ratio is made into a free variation via the introduction of a Lagrange multiplier [6], Λ, and relaxation of the binary definition of x to take nonnegative real values. Therefore, solving for an optimal partition may be accomplished by minimizing the function

$$Q(x) = x^T L x - \Lambda(x^T r - k). \tag{2.12}$$

Since L is positive semidefinite (see [8, 26]) and $x^T r$ is nonnegative, $Q(x)$ will be at a minimum at its critical points. Differentiating $Q(x)$ with respect to x yields

$$\frac{dQ(x)}{dx} = 2Lx - \Lambda r. \tag{2.13}$$

Thus, the problem of finding the x that minimizes (2.12) (i.e., the minimal partition) reduces to solving the linear system

$$2Lx = \Lambda r. \tag{2.14}$$

Henceforth, the scalar multiplier 2 and the scalar Λ are ignored since, as will be seen later, we are only concerned with the relative values of the solution.

The matrix L is singular: all rows and columns sum to zero (i.e., the vector r spans its nullspace), so finding a unique solution to (2.14) requires an additional constraint.

The graph is assumed to be connected, since the optimal partitions are clearly each connected component (i.e., $h(x) = h_G = 0$) if the graph is disconnected. A linear time breadth-first search may be performed to check for connectivity of the graph. Note that, in general, a graph with c connected components will correspond to a matrix L with rank $(n - c)$ [8]. If a node, v_g, is arbitrarily designated to include in S (i.e., fix $x_g = 0$), this is reflected in (2.14) by removing the gth row and column of L, and the gth row of x and r such that

$$L_0 x_0 = r_0, \tag{2.15}$$

where L_0 indicates the Laplacian with a row/column removed, x_0 is the vector x with the corresponding removed entry, and r_0 is r with the removed row. Note that (2.15) is a nonsingular system of equations.

Solving (2.15) for x_0 yields a nonnegative, real-valued solution that may be converted into a partition by setting a threshold. Nodes with an x_i below the threshold are placed in S and nodes with an x_j above the threshold are placed in $\overline{S}$. Setting a threshold is referred to as a *cut* since it divides the nodes into S and $\overline{S}$. We use x to collectively refer to the x_0 and the designated $x_g = 0$ value. As in spectral partitioning, common methods [64] of defining a threshold are the *median cut*, which chooses the median value of x as the threshold (thereby guaranteeing $|S| = |\overline{S}|$), the *jump cut*, which chooses a threshold that separates nodes on either side of the largest "jump" in a sorted x, and the *criterion cut*, which chooses the threshold that gives the lowest value of $h(x)$ (called the "ratio cut" in [64]).

2.1. Algorithmic details. The isoperimetric algorithm for partitioning a graph may be summarized as follows:

1. Choose a ground node, v_g.
2. Solve (2.15).
3. Cut x based on the method of choice to obtain S and $\overline{S}$.

There are several possible strategies for choosing the ground node. Anderson and Morley [5] proved that the spectral radius of L, $\rho(L)$, satisfies $\rho(L) \leq 2d_{\max}$, suggesting that grounding the node of maximum degree may have the most beneficial effect on the conditioning of (2.15). In the comparison section of this paper, we employ two grounding strategies (grounding the maximum degree node and grounding a random node).

The main computational hurdle of the isoperimetric algorithm is the solution of (2.15). An advantage of using the method of conjugate gradients is that an efficient parallelization of this technique is known [20, 33], suggesting that the majority of computation in the isoperimetric algorithm may be parallelized. In fact, cheap parallel machines in the form of commodity graphics hardware have already proven to be effective in executing the conjugate gradients method [9].

3. Physical analogies. The solution to (2.15) may be interpreted as the solution to a set of electrical potentials of a particular circuit and, with a slight change, in the context of a random walk. These analogies are primarily introduced in order to guide intuition about the behavior of the algorithm and will be relied upon in section 6 to provide understanding of the examples contained there. However, an added benefit of the circuit analogy is the adoption of terminology used to describe the node fixed to zero and the solution to (2.15).

3.1. Circuit analogy. Equation (2.14) occurs in circuit theory when solving for the electrical potentials of an ungrounded circuit in the presence of current sources [11, 65]. After grounding a node in the circuit (i.e., fixing its potential to zero), determination of the remaining potentials requires a solution of (2.15). Therefore, we refer to the node, v_g, for which we set $x_g = 0$ as the *ground node*. Likewise, the solution, x_i, obtained from (2.15) at node v_i, will be referred to as the *potential* for node v_i. The need for fixing an $x_g = 0$ to constrain (2.14) may be seen not only from the necessity of grounding a circuit powered only by current sources in order to find unique potentials, but also from the need to provide a boundary condition in order to find a solution to Poisson's equation, of which (2.14) is a combinatorial analogue. In our case, the "boundary condition" is that the grounded node is fixed to zero.

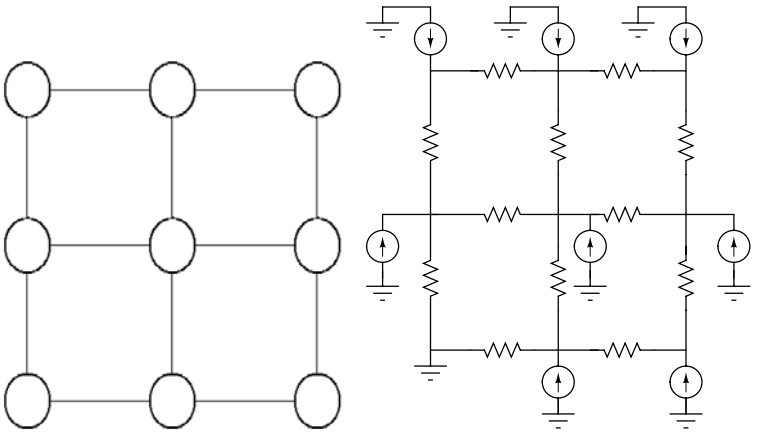
Define the $m \times n$ edge-node *incidence matrix* as

$$A_{e_{ij}v_k} = \begin{cases} +1 & \text{if } i = k, \\ -1 & \text{if } j = k, \\ 0 & \text{otherwise} \end{cases} \tag{3.1}$$

for every vertex v_k and edge e_{ij}, where e_{ij} has been arbitrarily assigned an orientation. As with the Laplacian matrix, $A_{e_{ij}v_k}$ is used to indicate that the incidence matrix is indexed by edge e_{ij} and node v_k. As an operator, A may be interpreted as a combinatorial gradient operator and A^T as a combinatorial divergence [10, 65]. The $m \times m$ *constitutive matrix*, C, is the diagonal matrix with the weights of each edge along the diagonal.

As in the familiar continuous setting, the combinatorial Laplacian is equal to the composition of the combinatorial divergence operator with the combinatorial gradient operator, $L = A^T A$. The constitutive matrix defines a weighted inner product of edge values, i.e., $\langle y, Cy \rangle$ for a vector of edge values, y [65, 11]. Therefore, the combinatorial Laplacian operator generalizes to the combinatorial Laplace–Beltrami operator via $L = A^T C A$. The case of a uniform (unit) metric (i.e., equally weighted edges) reduces to $C = I$ and $L = A^T A$. Removing a column of the incidence matrix produces what is known as the *reduced incidence matrix*, A_0 [27].

With this interpretation of the notation used above, the three fundamental equations of circuit theory (Kirchhoff's current and voltage laws and Ohm's law) may be written for a grounded circuit as



$$A_0^T y = f \quad \text{(Kirchhoff's current law)}, \tag{3.2}$$

$$Cp = y \quad \text{(Ohm's law)}, \tag{3.3}$$

$$p = A_0 x \quad \text{(Kirchhoff's voltage law)} \tag{3.4}$$

for a vector of branch currents, y, current sources, f, and potential drops (voltages), p [11]. Note that there are no voltage sources present in this formulation. These three equations may be combined into the linear system

$$A_0^T C A_0 x = L_0 x = f, \tag{3.5}$$

(a) (b)

FIG. 3.1. *An example of a simple graph* (a)*, and its equivalent circuit* (b)*. Solving* (2.15) (*using the node in the lower left as ground*) *for the graph depicted in* (a) *is equivalent to connecting* (b) *and measuring the potential values at each node.*

since $A^T CA = L$ [8].

In summary, the solution to (2.15) in the isoperimetric algorithm is provided by the steady state of a circuit where each edge has a conductance equal to the edge weight and each node is attached to a current source of magnitude equal to the degree (i.e., the sum of the conductances of incident edges) of the node. The potentials that are established on the nodes of this circuit are exactly those which are being solved for in (2.15). An example of this equivalent circuit is displayed in Figure 3.1.

One final remark on the circuit analogy to (2.15) follows from Maxwell's principle of least dissipation of power: a circuit with minimal power dissipation provides a solution to Kirchhoff's current and voltage laws [50]. Explicitly, solving (2.15) for x is equivalent to solving the dual equation for $y = CAx$. The power of the equivalent circuit is $P = I^2 R = y^T C^{-1} y$ subject to the constraint from Kirchhoff's law that $A^T y = f$. Therefore, the y found via $y = CAx$ also minimizes the above expression [65, 7]. Thus, our approach to minimizing the combinatorial isoperimetric ratio is identical to minimizing the power of the equivalent electrical circuit with the specified current sources and ground [65].

3.2. Random walk interpretation. In section 2, the combinatorial "volume" of a node set was defined by (2.5) as the cardinality of the set. However, this definition of combinatorial volume can lead to strange conclusions when trying to develop the general theory of Riemannian manifolds on a combinatorial space [17, 18, 54]. The alternate definition proposed by [18] defines volume as

$$\text{Vol}_S = \sum_{v_i \in S} d_i. \tag{3.6}$$

Using this notion of volume in the formulation of the isoperimetric constant in (2.2) yields the problem studied under the name of the *minimum quotient cut* [48].

Substituting this notion of volume (which is equivalent up to a scale factor on a

regular graph) into the above development leads to the solution of

$$L_0 x_0 = d_0, \tag{3.7}$$

where d_0 is the reduced vector of node degrees.

The solution, x_i, of (3.7) may be interpreted [67, 21] as the expected number of steps taken by a random walker leaving node v_i before it reaches the ground node, where the transition probability between nodes v_i and v_j is derived from the weights as $p_{ij} = \frac{w_{ij}}{d_i}$.

We note that, in the formulation of their Laplacian matrix, this same notion of "volume" was effectively used in the domain of image segmentation by Shi and Malik's "normalized cuts" algorithm [61].

4. Some formal properties of the algorithm. In this section, we prove one property of the algorithm and examine the behavior of the solution on two classes of graphs: trees and fully connected graphs.

4.1. Connectivity. It is known that at least one of the isoperimetric sets (if not unique) is such that both partitions are connected [55]. Therefore, it is of interest to examine the connectivity properties of a partitioning algorithm. Fiedler proved that partitioning a graph by thresholding the values in the Fiedler vector is guaranteed to produce connected partitions [25]. In this section, we examine the connectivity properties of the partitions obtained by thresholding the potentials solved for in (2.15) (or (3.7)). We prove that the partition containing the grounded node (i.e., the set S) must be connected, regardless of how a threshold (i.e., cut) is chosen. The strategy for establishing this will be to show that every node has a path to ground with a monotonically decreasing potential. We note that the partition not containing the ground may or may not be connected (cf. Figures 6.1 and 6.2).

PROPOSITION 4.1. *If the set of vertices, V, is connected then, for any α, the subgraph with vertex set $N \subseteq V$ defined by $N = \{v_i \in V | x_i < \alpha\}$ is connected when x_0 satisfies $L_0 x_0 = f_0$ for any $f_0 \geq 0$.*

This proposition follows directly from the proof of the following lemma.

LEMMA 4.2. *For every node, v_i, there exists a path to the ground node, v_g, defined by $P_i = \{v_i, v^1, v^2, \ldots, v_g\}$ such that $x_i \geq x^1 \geq x^2 \geq \cdots \geq 0$, when $L_0 x_0 = f_0$ for any $f_0 \geq 0$.*

Proof. By (2.15) each nongrounded node assumes a potential

$$x_i = \frac{1}{d_i} \sum_{e_{ij} \in E} w_{ij} x_j + \frac{f_i}{d_i}, \tag{4.1}$$

i.e., the potential of each nongrounded node is equal to a nonnegative constant added to the (weighted) average potential of its neighbors. Note that (4.1) is a combinatorial formulation of the mean value theorem [1] in the presence of sources. For any connected subset, $S \subseteq V$, $v_g \notin S$, denote the set of nodes on the boundary of S as $S_b \subset V$, such that $S_b = \{v_i |\, e_{ij} \in E,\ \exists\, v_j \in S,\ v_i \notin S\}$.

Now, either

1. $v_g \in S_b$, or
2. $\exists\, v_i \in S_b$, such that $x_i \leq \min x_j$ for all $v_j \in S$ by (4.1), since the graph is connected.

By induction, every node has a path to ground with a monotonically decreasing potential (i.e., start with $S = \{v_i\}$; add nodes with a nonincreasing potential until ground is reached). ∎

4.2. Spanning trees. Since a tree will have a unique path from any node to ground, Lemma 4.2 guarantees that the nodes in this path will have a nonincreasing potential. However, since a tree is a special case of a graph, and its reduced incidence matrix is square, there is an alternate derivation of this result. A theorem by Branin [10] shows that for node v_k, edge e_{ij}, and ground v_g, the inverse of the reduced incidence matrix for a spanning tree, $B = A_0^{-1}$, is

$$B_{v_k e_{ij}} = \begin{cases} +1 & \text{if } e_{ij} \text{ is positively traversed in the path from } v_k \text{ to } v_g, \\ -1 & \text{if } e_{ij} \text{ is negatively traversed in the path from } v_k \text{ to } v_g, \\ 0 & \text{otherwise.} \end{cases} \tag{4.2}$$

Therefore,

$$L_0^{-1} = (A_0^T C A_0)^{-1} = B^T C^{-1} B. \tag{4.3}$$

Each value of L_0^{-1} may therefore be interpreted as the sum of the reciprocal weights (i.e., the *resistances*) of shared edges along the unique path to v_g between nodes v_i and v_j, i.e., the shared *distance* of the unique paths from v_i and v_j to v_g in the metric interpretation.

It follows that the potential values taken by x_0 in $x_0 = L_0^{-1} f_0$ are monotonically increasing along the path from v_g to any other node for nonnegative f_0 and C.

4.3. Fully connected graphs. The isoperimetric algorithm will produce a solution to (2.15) that prefers each node equally when applied to fully connected graphs with uniform weights. Any set with cardinality equal to half the cardinality of the vertex set is a solution to the isoperimetric problem for a fully connected graph with uniform weights. For a uniform edge weight, $w(e_{ij}) = \kappa$ for all $e_{ij} \in E$, the solution, x_0, to (2.15) will be $x_i = 1/\kappa$ for all $v_i \in V$. The use of the median or criterion cut method will choose half of the nodes arbitrarily. Although it should be pointed out that using a median or criterion cut to partition a vector of randomly assigned potentials will also produce equal-sized (in the case optimal) partitions, the solution to (2.15) is unique for a specified ground (in contrast to spectral partitioning, which has $n-1$ solutions) and explicitly gives no preference to a node by returning all potentials as equal.

5. Review of previous work. Many approaches have been proposed for the graph partitioning problem and its related guises (e.g., circuit placement) in the past 50 years. Consistently, however, the most popular algorithms for graph partitioning are spectral partitioning [35] and the (multilevel) Kernighan–Lin partitioning method [41, 22].

5.1. Algebraic methods. Converting the partitioning problem into a system of linear equations is not new. In fact, Kodres' work [45, 44] specifies two subsets of nodes as being in different partitions. This specification converts the "minimal cut" minimization of (2.9) into a tractable problem with nontrivial (i.e., not the all-zeros) solution. The solution to the system of equations obtained by Kodres is also a real-valued solution that must be converted into a "hard" partitioning with a threshold. Similarly, the GORDIAN algorithm [42] imposes constraints on multiple nodes to obtain a linear system and is later modified [62] to include a modified cost function (weighted by a linear factor). These approaches were combined in the PARABOLI method [59], with the addition that the fixed nodes are those that obtain extremal

values from the solution to the eigenvector problem. However, as indicated by Hall [35], it is often unclear how to designate the nodes that will belong to different partitions. In contrast, our approach assigns only a single node to a partition, which would eventually be assigned to a partition anyway. In general, the multiple-node constraint (MNC) approach differs from the present approach in the following ways:

1. An MNC approach designates some set of nodes to be in opposite partitions, a priori, instead of allowing that decision to be dictated by the graph structure.
2. The isoperimetric algorithm permits one of the partitions (that which does not contain the ground) to be disconnected, while an MNC approach forces both partitions to be connected (for two constrained nodes).
3. On a regular lattice, the isoperimetric algorithm naturally imitates the known solution to the isoperimetric problem on the plane (see Figure 6.1). However, an MNC approach requires a contrived constraint placement to achieve the same.

The *skewed graph partitioning* approach pursued in [38] permits specification of affinities for each node to belong to a particular partition. Viewed in the context of skewed graph partitioning, one might interpret the isoperimetric algorithm as asking the question: given definite knowledge of the partition membership of a single node (i.e., the ground is in set S), compute a good partitioning in which the remaining nodes are biased to be in the opposite partition (i.e., in $\overline{S}$). Under this interpretation, each remaining node is given either a unity bias to belong to $\overline{S}$ or a bias equal to the node degree, depending on the notion of volume employed. Viewed in this context, the approach taken by the isoperimetric algorithm appears reasonable—since the grounded node must fall into one of the two partitions, the problem is to determine which of the remaining nodes fall into the opposite partition.

Finally, we note that grounding node v_i and performing the matrix inversion of (2.15) may also be interpreted algebraically as computing the ith term of the generalized inverse of the Laplacian, termed the *Eichinger matrix* by Kunz [46].

5.2. Spectral partitioning. Building on the early work of Fiedler [24, 25, 23], Alon [3, 2], and Cheeger [15] who demonstrated the relationship between the second smallest eigenvalue of the Laplacian matrix (the *Fiedler value*) for a graph and its isoperimetric number, spectral partitioning was one of the first graph partitioning algorithms to be successful [35, 19, 57]. The algorithm partitions a graph by finding the eigenvector corresponding to the Fiedler value, termed the *Fiedler vector*, and cutting the graph based on the value in the Fiedler vector associated with each node. A physical analogy for the Fiedler vector is the second harmonic of a vibrating surface. Like isoperimetric partitioning, the output of spectral partitioning is a set of values assigned to each node, which allows a cut to be a perfect bisection by choosing a zero threshold (the median cut) or by choosing the threshold that generates a partition with the best isoperimetric ratio (the criterion cut). The flexibility of spectral partitioning allows it to be used as a part of hybridized graph partitioning algorithms, such as geometric-spectral partitioning [14] and multilevel approaches [37, 12].

Spectral partitioning attempts to minimize the isoperimetric ratio of a partition by solving

$$Lz = \lambda z, \tag{5.1}$$

with L defined as above and λ representing the Fiedler value. Since the vector of all ones, r, is an eigenvector corresponding to the smallest eigenvalue (zero) of L, the goal is to find the eigenvector associated with the second smallest eigenvalue of L.

Requiring $z^T r = 0$ and $z^T z = n$ may be viewed as additional constraints employed in the derivation of spectral partitioning to circumvent the singularity of L (for an explicit formulation of spectral partitioning from this viewpoint, see [39]). Therefore, one way of viewing the difference between the isoperimetric and the spectral methods is in the choice of the additional constraint that regularizes the singular nature of the Laplacian L.

In the context of spectral partitioning, the indicator vector z is usually defined as

$$z_i = \begin{cases} -1 & \text{if } v_i \in \overline{S}, \\ +1 & \text{if } v_i \in S, \end{cases} \tag{5.2}$$

such that z is orthogonal to r for an equal-sized partition. The two definitions of the indicator vector ((2.6) and (5.2)) are related through $x = \frac{1}{2}(z + r)$. Since r is in the nullspace of L, these definitions are equivalent up to a scaling.

Simple, unhybridized, unilevel spectral partitioning lags behind modern multilevel algorithms (e.g., [37]) in terms of partition quality. However, compared with other global graph partitioning algorithms, spectral partitioning still performs well. Furthermore, spectral partitioning is one of the only approaches that does not require prior specification of node coordinates or the partition cardinalities, instead offering the flexibility to automatically choose the partition cardinalities that offer the best cut.

The major drawbacks of spectral partitioning are its speed and numerical stability. Even using the Lanczos algorithm [30] to find the Fiedler vector for a sparse matrix, spectral partitioning is still much slower than many other partitioning algorithms. Furthermore, the Lanczos algorithm becomes unstable as the Fiedler value approaches its neighboring eigenvalues (see [36, 30] for discussion of this problem). In fact, the eigenvector problem becomes fully degenerate if the Fiedler value assumes algebraic multiplicity greater than 1. For example, consider finding the Fiedler vector of a fully connected graph, for which the Fiedler value has algebraic multiplicity equal to $n-1$. This situation could allow the Lanczos algorithm to converge to any vector in the subspace spanned by the eigenvectors corresponding to the Fiedler value.

In Figure 5.1, we compare the speed of the isoperimetric and spectral algorithms. Both partitions were computed using MATLAB, where the sparse, Lanczos-based, method for finding eigenvectors employs ARPACK [47] and solution to the system of linear equations is computed using the sparse linear solvers detailed in [28]. These experiments were done on a machine with a 2.39 GHz Intel Xeon chip and 3 GB of RAM. In order to illustrate the convergence problems for graphs having a Fiedler value with algebraic multiplicity greater than 1, we compared the two algorithms on a simple, square, unweighted, 4-connected lattice, for which the algebraic multiplicity of the Fiedler value is known to be 2. Graphs were tested with a number of nodes between $9 \leq N \leq 50,000$. Each algorithm is exhibited to have nearly linear behavior, although the constant is about an order of magnitude less for the isoperimetric algorithm when the algebraic multiplicity of the Fiedler value is greater than 1. Figure 5.1 also shows the experiments run with a graph composed of points placed randomly in the two-dimensional (2D) unit square with a uniform distribution and connected via a Delaunay triangulation. Here we still see an improvement for the speed of the isoperimetric algorithm (with a speed increase of about three times), but the behavior of the spectral runtimes illustrates the degeneracy problem—for those random graphs in which the second and third smallest eigenvalues are equal, or nearly equal, the running time of the spectral algorithm jumps to the plot obtained for the lattice. In other words, our experiments indicate that the isoperimetric algorithm operates

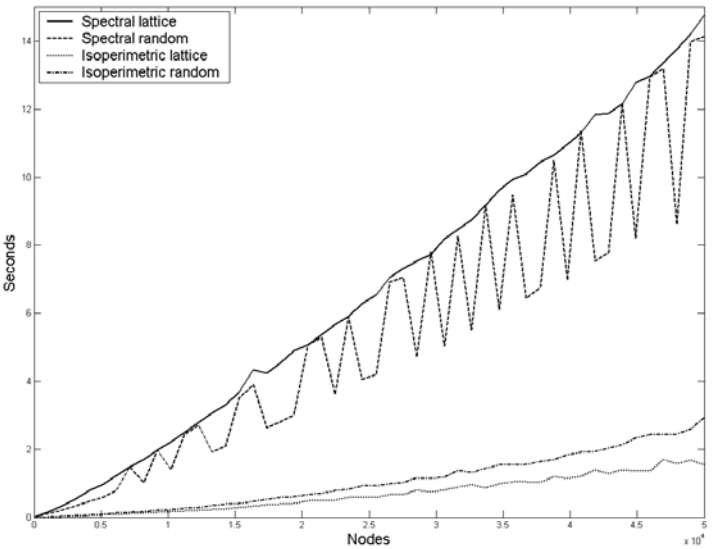


FIG. 5.1. *Speed comparison of the spectral method to the isoperimetric algorithm for two classes of graphs: a square, 4-connected lattice, and a randomly distributed, planar, point set connected via Delaunay. See the text for details.*

between three and ten times faster than the spectral algorithm, depending on the separation of the second and third eigenvalues. Additionally, the second experiment was run with just 30 randomly placed graphs with Delaunay connectivity. Therefore, the situations for which the degeneracy of the spectral approach is a concern do not appear to be rare. We note that the degeneracy problem of the spectral approach also precludes prediction of which runtime plot the spectral algorithm will employ (unless the spectrum is known a priori), while the isoperimetric algorithm has no such concerns. Finally, we note that the runtimes for the isoperimetric algorithm for each type of graph appear in Figure 5.1 to have a slightly different constant. We presume that this discrepancy is because the banded structure of the lattice Laplacian permits a simpler decomposition.

Finally, it has been pointed out [34] that a class of graphs exists for which spectral partitioning will produce consistently poor partitions.

5.3. Geometric partitioning. Geometric partitioning [29] is only defined for graphs with nodal coordinates specified (e.g., finite-element meshes). Furthermore, the geometric partitioning algorithm assumes that the nodes are locally connected and computes a good *spatial* separator (i.e., ignoring topology altogether). Building on theoretical results of [53, 52], geometric partitioning works by stereographically projecting nodes from the plane to the Riemann sphere, conformally mapping the nodes on the sphere such that a special point (called the *centerpoint*) is at the origin, and then randomly choosing any great circle on the Riemann sphere to divide the points into two equal halves. In practice, several great circles are randomly chosen and the best one is used as the output.

Although geometric partitioning is computationally inexpensive (albeit using multiple trials) and produces good partitions, the major drawback of the geometric partitioning algorithm is its inapplicability to graphs without coordinates or to graphs that are not locally connected (e.g., nonplanar graphs).

5.4. Geometric-spectral partitioning. Geometric-spectral partitioning [14] combines elements of both spectral partitioning and geometric partitioning. By finding the eigenvectors corresponding to both the second and third smallest eigenvalues, one may treat the nodes as having *spectral coordinates* by viewing the values associated with each node in the two eigenvectors as 2D coordinates in the plane. Applying geometric partitioning to the spectral coordinates of the nodes instead of actual coordinates (if available) heuristically gives better partitions than either spectral or geometric partitioning alone.

Geometric-spectral partitioning represents a more general algorithm than straightforward geometric partitioning since it applies to more general graphs (i.e., graphs without coordinates) and because it takes advantage of topological information in computing the spectral coordinates. However, geometric-spectral partitioning is more computationally expensive than spectral partitioning since it requires the computation of two eigenvectors instead of one. Numerically, the algorithm is also prone to more numerical problems than spectral partitioning, since the Lanczos algorithm has increased error as more "interior" eigenvectors are computed [30], and because the spectral coordinates are not unique if either the second or the third eigenvalue of L has an algebraic multiplicity greater than one.

5.5. Multilevel Kernighan–Lin. The Kernighan–Lin algorithm [41] employs a greedy approach for graph partitioning. Although fast, the final solution is highly dependent on the initial (random) partition used to speed the algorithm. Due to the speed, this algorithm may be run multiple times in order to achieve an acceptable partition.

By far the most successful use of the Kernighan–Lin algorithm is as a *refinement* technique. A multilevel representation of a graph may be obtained through the use of a maximal independent set [66]. If the coarsest level of the graph is partitioned through some means (e.g., spectral, geometric), then the quality of the partition may be refined to the next level by employing Kernighan–Lin. This multilevel Kernighan–Lin approach is the backbone for state-of-the-art graph partitioning software packages such as Chaco [36] and Metis [40]. We include the Metis [40] package in the comparison section.

One expects these algorithms to perform the best since they take into account multiple levels of graph representation. However, multilevel Kernighan–Lin may be easily combined with other graph partitioning techniques by employing the secondary technique to perform the partitioning at the coarsest level. Independent of the multilevel scheme, Kernighan–Lin may be used to refine a partition given by another algorithm.

One problem with the Kernighan–Lin approach is that the size of the partitions must be specified. This is not an issue for the graph bisection problem, where the partition size is required to be half of the node set. However, if one is interested in finding partitions close to the isoperimetric sets, then the algorithm must be flexible enough to find the best partitions of arbitrary size.

6. Algorithm behavior. As with spectral methods, the solution of (2.15) (or (3.7)) yields a continuous-valued result that must then be converted into a bipartition by thresholding. In this section we introduce two examples that illustrate the distribution of the potentials and their relationship to the ground node.

Figure 6.1 shows the solution to the spectral problem and (3.7) on a simple, square, 4-connected grid. Note that the square grid causes the degeneracy of the Fiedler vector required by the spectral approach, since the algebraic multiplicity of the Fiedler value is 2. Consequently, even for this simple graph, the Lanczos method

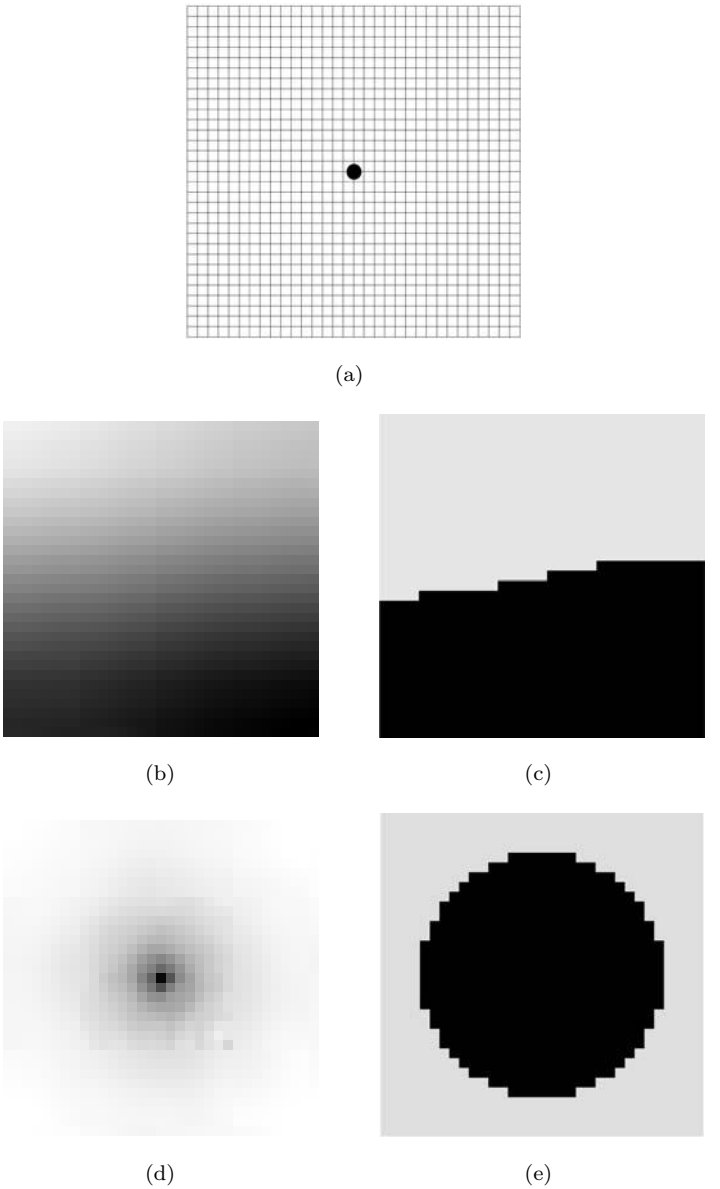

FIG. 6.1. *Comparison of spectral and isoperimetric solutions on a square, unweighted, 4-connected lattice.* (a) *Original lattice. The black dot represents the location of the ground point for the isoperimetric algorithm.* (b) *Spectral solution. Note that the algebraic multiplicity of the Fiedler vector results in a degenerate solution—any vector in the subspace spanned by the Fiedler vectors is a valid output of the Lanczos algorithm.* (c) *Cut obtained from the spectral solution.* (d) *Solution of the isoperimetric algorithm, given a ground point in the lattice center.* (e) *Cut obtained from the isoperimetric solution. Despite the Manhattan distance imposed by 4-connectivity, note the similarity with the well-known solution to the isoperimetric problem in the Euclidean plane—a circle.*

takes longer to converge and returns a vector in the subspace spanned by the multiple Fielder vectors (as seen in Figure 5.1). In contrast, given a ground node in the center of the lattice, the isoperimetric algorithm returns a unique solution. The fact that our algorithm returns a "circle" on this graph lends justification to the name

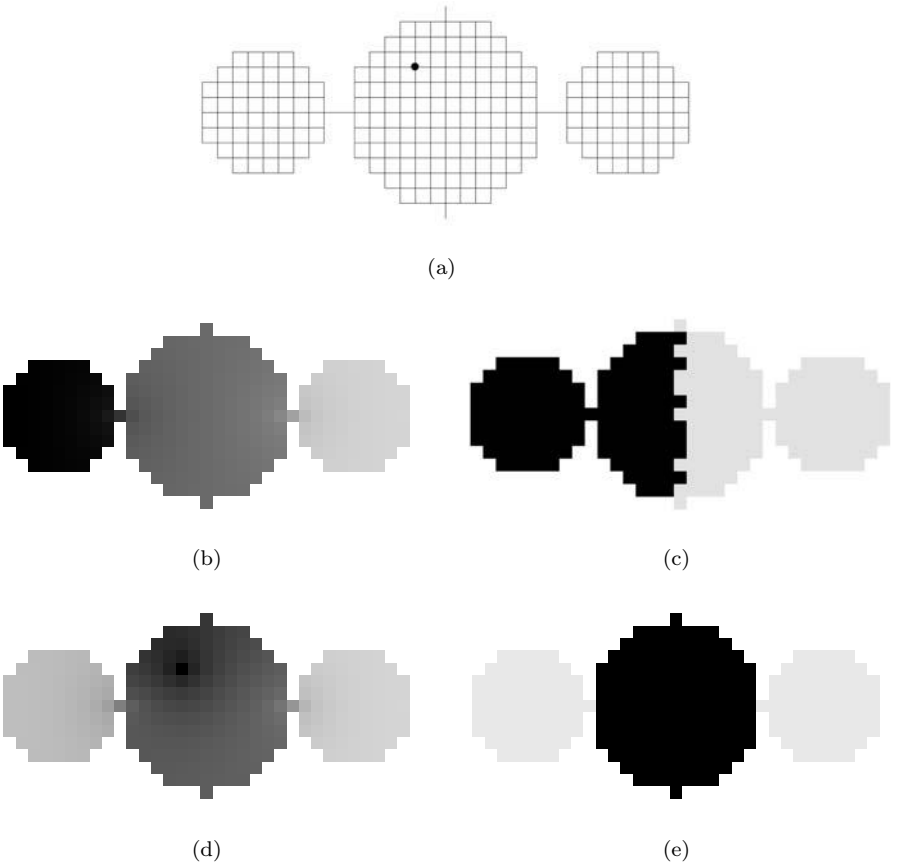

FIG. 6.2. *Comparison of spectral and isoperimetric solutions on a graph comprises a large, central, "circle" with smaller, side "circles." This graph is intended to build the reader's intuition about the solution.* (a) *Original graph.* (b) *Spectral. The symmetry of the graph results in a symmetric solution over the central axis of symmetry.* (c) *Cut obtained from the spectral solution. Since the spectral solution is symmetric over the central axis of symmetry, the equal partition cut must also lie along this axis. For graphs of this type, such a solution may be arbitrarily poor.* (d) *Solution of the isoperimetric algorithm, given a ground point in the central circle, designated by the black dot. Note that the ground is offset from the circle center.* (e) *Cut obtained from the isoperimetric solution. Note that the cut is not simply a circle (relative to the graph distance), as otherwise the partition would tilt toward the side circle closer to the ground, which it does not.*

"isoperimetric" algorithm, since the circle has been known since antiquity to be the solution to the isoperimetric problem in the Euclidean plane [56] and a lattice is widely used as a discrete approximation to the plane when solving PDEs, etc. This appearance of the circle should be no surprise, given the motivation of the algorithm or the random walks interpretation, since it is well known in the Euclidean plane that one is expected to stand on a circle with radius $\sqrt{n}$ after taking n random steps from a central point [49] (given here by the grounded node). However, we stress that the "circle" partition in Figure 6.1 is *not* simply the locus of points within a certain distance from the ground, since the 4-connectivity of the lattice would induce a diamond-shaped locus.

Figure 6.2 shows another simple graph, constructed by windowing a 4-connected lattice in the shape of a large, central "circle," weakly connected to two side "circles,"

such that the cardinality of the central circle equals the sum of the side circles. The symmetry of this graph across an unfavorable cut axis (i.e., the center of the large circle) leads to problems for the spectral algorithm, as well illustrated in Guattery and Miller's "roach" graph [34]. In contrast, the isoperimetric algorithm cuts the side circles off the central circle, even though the ground is offset from the center of the circle. Again, this should be no surprise given the electrical circuit analogy—all of the "current" entering nodes in the side circles must flow through the connecting branch, yielding a huge voltage drop across this edge. Consequently, the center circle is widely separated from the side circles. These experiments demonstrate that the "background" partition (i.e., $\overline{S}$) may or may not be connected. As with the above experiment, the partition is not simply the locus of all points equidistant from the ground. The ground point was offset from the center of the large circle in Figure 6.2, but the partition boundary does not "leak" into the closer side circle.

7. Comparison of algorithms. The graph partition quality produced by the algorithms reviewed above was examined on weighted and unweighted planar, nonplanar and three-dimensional (3D) graphs, as well as some specialized graphs. All algorithms were compared by considering the number of edges spanning the two equally sized partitions produced by each algorithm (i.e., the median cut, for the isoperimetric and spectral algorithms). The spectral and isoperimetric algorithms were additionally compared in terms of the isoperimetric ratio by employing the criterion cut to find the best partition (i.e., not necessarily partitions of equal size). Note that the "uniform" volume definition, i.e., (2.5), was used to evaluate the isoperimetric ratio for these algorithms, since this is the definition most commonly desired in graph partitioning problems. As was noted in [60] we found that the distribution of spanning edges and $h(x)$ resembled Gaussian distributions. For this reason, we report the mean and variance of the number of edges spanning the partitions (or $h(x)$) for the 1,000 graphs generated of each type.

Four versions of the isoperimetric algorithm are compared with the algorithms reviewed above on the graph partitioning problem. The four versions are obtained from the two notions of volume corresponding to (2.15) and (3.7) and two grounding strategies: grounding the maximum degree node and grounding a random node. In the following tables, grounding strategies are denoted by "MG" for maximum degree ground and "RG" for random ground. Volume definitions are designed by "Uni" for the cardinality definition of volume of (2.15) or "Deg" for the degree-based definition of volume given by solution to (3.7). For each random ground partition, three randomly chosen grounds were tried and the best one chosen. The geometric, and geometric-spectral, partitions were all obtained through the MESHPART software package for MATLAB [29] and Metis was executed using the Metis package of [40].

Relative runtimes of the algorithms were considered for a 10,000-node, randomly connected, planar graph of the type described in section 7.1. From fastest to slowest were Metis (0.031 s), Isoperimetric (0.329 s), Geometric (0.500 s), Spectral (2.125 s), and Geo-Spectral (6.531 s). However, as was mentioned above, the code to execute each of these algorithms was written by different groups, with varying dependence on MATLAB.

7.1. Planar graphs. Planar graphs were generated by uniformly sampling 1,000 points from a 2D unit square and connecting them with a Delaunay triangulation. One thousand such graphs were generated for both the weighted and unweighted trials. In the weighted trial, weights were randomly assigned to each edge from a uniform distribution on the interval $[0, 1 \times 10^4]$. Results for the median cut comparison are

found in Table 7.1 and for the criterion cut comparison are found in Table 7.2.

7.2. Nonplanar graphs. Purely random graphs (typically nonplanar) were generated by connecting each pair of 1,000 nodes with a 1% probability. One thousand such graphs were generated for both the weighted and unweighted trials. In the weighted trial, weights were randomly assigned to each edge from a uniform distribution on the interval $[0, 1 \times 10^4]$. Since coordinate information was meaningless, only those algorithms which made use of topological information were compared (i.e., the isoperimetric, spectral, geometric-spectral, and Metis approaches). Results for the median cut comparison are found in Table 7.3 and for the criterion cut comparison in Table 7.4.

7.3. 3D graphs. Modeling and computer graphics applications frequently require the use of locally connected points in three dimensions. One thousand graphs were generated by uniformly sampling 1,000 points in the unit cube and connecting them via the 3D Delaunay. Both weighted and unweighted graphs were generated. In the weighted trial, weights were randomly assigned to each edge from a uniform distribution on the interval $[0, 1 \times 10^4]$. Results for the median cut comparison are found in Table 7.5 and for the criterion cut comparison in Table 7.6.

The meshes were obtained through the ftp site of John Gilbert and the Xerox Corporation at ftp.parc.xerox.com from the file /pub/gilbert/meshpart.uu. The list of graphs used is given in Table 7.7. The results using the median cut comparison are found in Table 7.8 and for the criterion cut comparison are found in Table 7.9.

The set of algorithms were also applied to three graph families of theoretical interest. The first of these is the "roach" graph of [34] with the total length of the roach ranging from 10 to 50 nodes long (i.e., 20–100 nodes total). The family of roach graphs is known to result in poor partitions when spectral partitioning is employed with the median cut. For a roach with an equal number of "body" and "antennae" segments, the spectral algorithm will always produce a partition with $|\partial S| = \Theta(n)$ (where $\Theta(\cdot)$ is the function of [43]) instead of the constant cut set of two edges obtained

TABLE 7.9

The isoperimetric ratio obtained by applying the criterion cut method to the output of the isoperimetric and spectral partitioning algorithms (see section 7.4).

Algorithm	Epp	Tapir	Tri	Air1	Air2	Air3	Crack	Spiral

TABLE 7.10

The mean number of edges cut by the equal-sized partitions output by the various algorithms over a parameter range for each family of graphs (see section 7.4). The three graph families here (roach, TreeXPath, and "badmesh") are of theoretical interest in that they are known to produce poor results for different classes of partitioning algorithms.

Algorithm	Mean cut roach	Mean cut TreeXPath	Mean cut "badmesh"
Iso MG Uni	2	27.1	2.98
Iso MG Deg	2	26.7	2.98
Iso RG Uni	2.37	29.3	3.34
Iso RG Deg	2.32	27.8	3.1
Spectral	15.2	38	12.5
Geometric	2	26.4	453
Spectral geometric	2	27	2.98
Metis	2	27.5	2.98

TABLE 7.11

The mean isoperimetric ratio obtained using a criterion cut on the output of the partitioning algorithms when applied to three graph families of theoretical interest (see section 7.4). Means are calculated over a range of parameters defining the graph family (see the text for details).

Algorithm	Mean $h(x)$ roach	Mean $h(x)$ TreeXPath	Mean $h(x)$ "badmesh"
Iso MG Uni	0.0815	0.128	0.0297
Iso MG Deg	0.0815	0.128	0.0297
Iso RG Uni	0.0798	0.129	0.0294
Iso RG Deg	0.0798	0.127	0.0294
Spectral	0.0796	0.128	0.0294

by cutting the antennae from the body. It has been demonstrated [64] that the spectral approach may be made to correctly partition the roach graph if additional processing is performed. For this reason, the partitions obtained through use of the criterion cut are reasonable for the spectral algorithm. The second graph family of theoretical interest, referred to as "TreeXPath" [34], is known to result in poor partitions when spectral partitioning is used with the median cut. For purposes of benchmarking here, the cardinality of the 3D point set was varied between 50 and 1,000 nodes. The final graph family of theoretical interest is the so-called "badmesh" [13] for which no quality straight-line separator exists. Badmeshes were generated with node sets varying between 200 and 4,000, with a constant ratio of $\frac{4}{5}$ between shell sizes. Mean values across the nodal range are reported in Table 7.10 for partitions obtained with the median cut and Table 7.11 using the criterion cut.

8. Conclusion. We have presented a new algorithm for partitioning graphs that requires the solution to a sparse, symmetric, positive-definite system of equations.

Analogous to Fiedler's examination of the connectivity behavior of the spectral algorithm [25], we examined the connectivity of the partitions returned by the isoperimetric algorithm and proved that the partition containing the ground node must be connected. Formal behavior of the algorithm was also examined on fully connected graphs and trees. Empirically, the solution to the system of equations was examined on two graphs and interpreted in the context of two physical interpretations of the equations. The partition returned by application of the isoperimetric algorithm to a 4-connected, 2D lattice was shown to resemble the known solution to the isoperimetric problem on the 2D Euclidean plane—a circle.

Based on the above trials, it appears that a random ground approach generally works better than grounding the node with maximum degree. Therefore, we suggest the strategy of grounding the node with maximum degree and, if possible, additionally trying random grounds in order to choose the best partition. Although the difference in partition quality between the two definitions of combinatorial volume is slight, it seems the definition of (3.6) fared better over that of (2.5) for the equally sized partition, yet favored the cardinality-based volume measure in computing the partition with minimum isoperimetric ratio. However, the latter should not be surprising, since the isoperimetric ratio was computed using the cardinality-based volume measure. In practice, neither notion of volume suggests recommendation over the other for an equally sized cut. However, if trying to compute the partition with minimum isoperimetric ratio (i.e., the quotient cut), one should employ the appropriate notion of volume.

While competitive with the algorithms compared in this work, we acknowledge that the isoperimetric algorithm appears to give slightly higher averages than the other algorithms, most notably the multilevel KL approach. However, the isoperimetric algorithm has the following qualities not shared by all of the comparison algorithms:

1. Coordinate information is not needed, allowing application on abstract graphs.
2. Edge weights are taken into account when computing the partitions.
3. The algorithm returns a family of partitions (corresponding to different threshold choices) that allows a partition with the "best" cardinality to be chosen, instead of prespecifying the partition cardinality.

In fact, the only algorithm included here that shares these three properties is spectral partitioning, which is shown above to produce partitions of similar quality, but more slowly and at the risk of a degenerate solution. Furthermore, the isoperimetric algorithm appears to perform better (relative to the other algorithms) on the specific benchmark graphs than on the experimental random graphs. Therefore, it is possible that the family of random graphs used in the experiments may be unfavorable to the algorithm. In contrast, the experiments shown on the "roach," "TreeXPath," and "badmesh" graph families, which were designed to be problematic for other algorithms, showed little problem for the isoperimetric algorithm. We also note that some of the better-performing algorithms (e.g., spectral geometric) use the spectral approach as a component. Therefore, hybridization with the isoperimetric algorithm instead of the spectral approach might improve speed/stability issues associated with the spectral component of such an approach.

The isoperimetric algorithm for graph partitioning is implemented in the publicly available graph analysis toolbox [31, 32] for MATLAB obtainable at http://eslab.bu.edu/software/graphanalysis/. This toolbox was used to generate all of the results compiled in the tables of this paper. Further work with this algorithm might include

the development of a more principled grounding strategy and hybridization with other partitioning methods.

Acknowledgment. The authors would like to thank Jonathan Polimeni for many fruitful discussions and suggestions.

A BLOCK PRECONDITIONER FOR HIGH-ORDER MIXED FINITE ELEMENT APPROXIMATIONS TO THE NAVIER–STOKES EQUATIONS*

DAVID KAY† AND EMIL LUNGU‡

Abstract. An iterative solver for the linear system arising from a discretization by high-order mixed finite elements for the linearized steady state Navier–Stokes problem is presented. Two mixed finite elements are considered: $\mathbf{P}_{k+1}P_k$ and $\mathbf{P}_{k+2}P_k$. The iterative solver is based on the GMRES method with right preconditioning where the preconditioner has a block upper triangular form. Computational results show that the convergence rate seems to be independent of the grid size parameter h and the polynomial degree k but is slightly affected by the increasing of the Reynolds number.

Key words. Navier–Stokes, high-order mixed finite elements, preconditioning

DOI. 10.1137/040609045

1. Introduction.

In this paper we present a numerical study of the mixed finite element method applied to the steady state Navier–Stokes problem:

$$-\nu\Delta u + (u\cdot\nabla)u + \nabla p = 0 \quad \text{in } \Omega, \tag{1.1}$$

$$-\nabla\cdot u = 0 \quad \text{in } \Omega, \tag{1.2}$$

$$\mathcal{B}(u,p) = g \quad \text{on } \Gamma, \tag{1.3}$$

where Ω is a bounded open polygonal domain in $\mathbb{R}^2$ with boundary Γ, $u = (u_1, u_2)$ is the velocity of the fluid, p is the pressure, and ν is the viscosity parameter. The boundary conditions are represented by the operator $\mathcal{B}$, which may be a differential operator to allow for the derivative boundary conditions.

The nonlinear equation (1.1) is linearized and the solution is obtained via a fixed point iteration. For a given iteration (u_n, p_n) we construct the next iteration by solving the following problem, known as the Oseen equation:

$$-\nu\Delta u_{n+1} + (u_n\cdot\nabla)u_{n+1} + \nabla p_{n+1} = 0 \quad \text{in } \Omega, \tag{1.4}$$

$$-\nabla\cdot u_{n+1} = 0 \quad \text{in } \Omega, \tag{1.5}$$

$$\mathcal{B}(u_{n+1}, p_{n+1}) = g \quad \text{on } \Gamma. \tag{1.6}$$

The starting iteration is taken to be the solution of the associated Stokes problem with the same boundary condition.

A discretization by a mixed finite element method produces the linear system of equations

$$\mathcal{L}\begin{pmatrix} u \\ p \end{pmatrix} = \begin{pmatrix} f \\ g \end{pmatrix}, \tag{1.7}$$

where

$$\mathcal{L} = \begin{pmatrix} F & B^T \\ B & 0 \end{pmatrix}$$

and $F = \nu A + N$ with A and N block diagonal corresponding to the discrete Laplace operator for each component of the velocity and the discrete velocity convection operator, respectively. B corresponds to the discrete divergence operator for the mixed velocity-pressure formulation. In the case of using stabilized formulation the zero block is replaced by a stabilization term, C. The stabilized matrix C is symmetric and positive semidefinite.

In Murphy, Golub, and Wathen [16], a block diagonal preconditioner is presented. The preconditioner has the form

$$\mathcal{P} = \begin{pmatrix} F & 0 \\ 0 & S \end{pmatrix},$$

where $S = BF^{-1}B^T$ is the Schur complement. The matrix $\mathcal{P}^{-1}\mathcal{L}$ of the preconditioned system has three distinct eigenvalues. This assures the convergence of Krylov subspace methods in at most three iterations; see, e.g., [17]. Calculating the action of the preconditioning matrix, $\mathcal{P}$, requires the solution of two separate linear systems corresponding to the blocks F and S.

Elman and Silvester [11] suggested a triangular preconditioner

$$\mathcal{P} = \begin{pmatrix} F & B^T \\ 0 & S \end{pmatrix}.$$

In the case where S is the exact Schur complement, this leads to a preconditioned system, $\mathcal{L}\mathcal{P}^{-1}$. This system has minimal polynomial of degree two, thus guaranteeing convergence in two iterations.

The practical implementation of these preconditioners relies upon the ability to approximate the inverse of both the F and the S blocks. In Kay, Loghin, and Wathen [14] a practical approximation to the Schur complement is given. It generalizes the idea of Elman and Silvester and is based on the Green's tensor for the Oseen operator. This choice is

$$\tilde{S} = A_p F_p^{-1} M_p,$$

where A_p, M_p, and F_p are the discrete Laplacian, identity, and convection diffusion operator on the pressure space. When using this preconditioner, it was seen that the convergence was independent of h, the mesh size parameter, and it had mild dependence on the viscosity. This paper aims to show that increasing the polynomial degree, k, of the finite element space does not affect the optimality of the preconditioner.

The practical implementation of the preconditioned iterative scheme requires the solution of a system with the matrix $\tilde{S}$, which is equivalent to solving a discrete

Poisson problem followed by a multiplication by F_p and finally a solution of a system with the mass matrix M_p.

In this paper we examine the effect of the above preconditioner on high-order mixed finite element approximations; see [5]. Examples of preconditioning for high-order quadrilateral elements can be seen in [15], [7], [8].

The advantage of high-order piecewise polynomial approximations is that they can exploit the smoothness of a solution and gain exponential rates of convergence away from singularities in the solution; see, e.g., Babuska and Suri [3].

The remainder of the paper is organized in three sections. In section 2 we present the two mixed p-version finite element discretization of the Navier–Stokes equations. In section 3 we introduce the preconditioner. The final section contains numerical experiments which show the efficiency of the preconditioner. We also show a numerical result for an hp-finite element discretization; see [4].

2. The discretization. In this section we consider the Oseen equation

$$-\nu\Delta u + (w \cdot \nabla)u + \nabla p = 0 \quad \text{in } \Omega, \tag{2.1}$$

$$-\nabla \cdot u = 0 \quad \text{in } \Omega, \tag{2.2}$$

where w is a divergence-free vector. We assume that the boundary $\overline{\Gamma} = \overline{\Gamma}_D \bigcup \overline{\Gamma}_N$ with $\Gamma_D \neq \emptyset$ and $\Gamma_D \bigcap \Gamma_N = \emptyset$. The boundary conditions are given by

$$u = g \quad \text{on } \Gamma_D, \tag{2.3}$$

$$\nu\nabla u \cdot n - p \cdot n = 0 \quad \text{on } \Gamma_N. \tag{2.4}$$

The weak formulation of (2.1) and (2.2) is defined in terms of subsets of the standard Sobolev spaces $H^1(\Omega)$ and $L^2(\Omega)$. We define the velocity space

$$X := (H^1_D(\Omega))^2 = \{v \in (H^1(\Omega))^2 : v = g \text{ on } \Gamma_D\}$$

and the pressure space

$$M := L^2_0(\Omega) = \left\{ q \in L^2(\Omega) : \int_\Omega q dx = 0 \right\}$$

if $\Gamma_N = \emptyset$; else $M = L^2(\Omega)$.

We also define

$$X_0 := (H^1_0(\Omega))^2 = \{v \in (H^1(\Omega))^2 : v = 0 \text{ on } \Gamma_D\}.$$

The weak formulation is given by the following: find $(u, p) \in X \times M$ such that

$$a(w; u, v) + b(p, v) = 0 \quad \forall\, v \in X_0, \tag{2.5}$$

$$b(q, u) = 0 \quad \forall\, q \in M, \tag{2.6}$$

where

$$a(w; v_1, v_2) := \nu(\nabla v_1, \nabla v_2) + ((w \cdot \nabla)v_1, v_2) \quad \forall\, v_1 \in X,\ v_2 \in X_0$$

and

$$b(q, v) = -(q, \nabla \cdot v) \quad \forall\, q \in M,\ v \in X_0.$$

Here $(\cdot, \cdot)$ denotes the $L^2(\Omega)$ inner product.

It can be shown that $a(\cdot,\cdot)$ is continuous and coercive and that there exists a $\kappa \in \mathbb{R}$ such that the continuous inf-sup condition

$$\sup_{v \in X} \frac{b(q,v)}{||v||_{H^1(\Omega)}} \geq \kappa ||q||_{L^2(\Omega)} \quad \forall\, q \in M$$

holds. Using these properties it can be shown that this problem has a unique solution; see [13].

For the discrete formulation of the problem (2.5), (2.6) we will use the mixed finite element method.

Let τ_h be a triangulation of the domain Ω and denote $h = \max_{T \in \tau_h} h_T$ ($h_T = diam(T)$). We denote by V_h^k the space of continuous piecewise polynomials of degree no more than k on τ_h, i.e.,

$$V_h^k = \{v \in C^0(\Omega) : v|_T \in \mathbf{P}_k[T] \ \forall\, T \in \tau_h\}. \tag{2.7}$$

Here $\mathbf{P}_k[T]$ is the space of the polynomial functions defined on triangle T which have degree at most k.

A local basis in $\mathbf{P}_k[T]$ is given starting from a basis on the reference triangle (see [1], [2]) via a linear mapping. In our experiments we used the integrated Legendre polynomial.

We now define the finite element spaces $X_D^{h,k+1} \subset X$ for velocity and $M_h^k \subset M$ for pressure as follows:

$$X_D^{h,k+1} = \{v \in V_h^{k+1} \times V_h^{k+1} : v = \bar{g} \text{ on } \Gamma_D\}, \tag{2.8}$$

and if $\Gamma_N = \emptyset$,

$$M_h^k = \left\{ q \in V_h^k : \int_\Omega q dx = 0 \right\} \quad (\text{else} \quad M_h^k = V_h^k). \tag{2.9}$$

Here $\bar{g}$ is a continuous piecewise polynomial function of degree at most $k+1$ which interpolates the function g on Γ_D. We will denote this space by $P_{k+1}P_k := X_D^{h,k+1} \times M_h^k$.

The discrete problem is to find $(u_h, p_h) \in P_{k+1}P_k$ such that

$$\nu(\nabla u_h, \nabla v_h) + ((w \cdot \nabla)u_h, v_h) - (p_h, \nabla v_h) = 0 \quad \forall\, v_h \in X_0^{h,k+1}, \tag{2.10}$$

$$-(\nabla \cdot u_h, q_h) = 0 \quad \forall\, q_h \in M_h^k. \tag{2.11}$$

Let us write the velocity solution as $u_h = u_D + u_0$, where $u_0 \in X_0^{h,k+1}$ and $u_D \in X_D^{h,k+1}$ is zero on the triangles which do not have any points on the boundary Γ_D. The function u_0 satisfies equations similar to (2.10) and (2.11) in which the right-hand sides are not zero.

In order to reduce the weak formulation on the finite element spaces to a linear algebra problem we now consider the finite element basis sets

$$X_0^{h,k+1} = span\{\phi_i\}_{i=1}^n, \qquad M_h^k = span\{\psi_j\}_{j=1}^m$$

and associate with the basis functions u_0 and p_h the vectors $u \in \mathbb{R}^n$ and $p \in \mathbb{R}^m$, that is, $u_0 = \sum_{i=1}^n u_i \phi_i$ and $p_h = \sum_{j=1}^m p_j \psi_j$.

Defining, respectively, the $n \times n$ convection and diffusion matrices

$$N_{ij} = (w_h \cdot \nabla \phi_i, \phi_j)$$

and

$$A_{ij} = (\nabla \phi_i, \nabla \phi_j)$$

and also the $m \times n$ divergence matrix

$$B_{ij} = -(\nabla \cdot \phi_i, \psi_j),$$

(2.10) and (2.11) lead to a linear system of the form

$$\begin{pmatrix} \nu A + N & B^T \\ B & 0 \end{pmatrix} \begin{pmatrix} u \\ p \end{pmatrix} = \begin{pmatrix} f \\ g \end{pmatrix}. \tag{2.12}$$

Classical h finite element refinement leads to the approximation result: Given $w \in H_D^m(\Omega)$ there exists a $\pi_h w \in X_D^{h,k}$ such that, for $0 \le l \le k+1$,

$$||w - \pi_h w||_{H^l(\Omega)} \le C(k) h^\mu ||u||_{H^m(\Omega)},$$

where

$$\mu = \min(m - l, k + 1 - l).$$

The advantage of increasing polynomial degree over standard h finite element refinements is that approximation is restricted only by the smoothness of the solution and not by the degree of approximation. From [3] we have the standard approximation result: Given $u \in H_D^m(\Omega)$ there exists a $\pi_k u \in X_D^{h,k}$ such that, for $0 \le l \le m$,

$$||w - \pi_k w||_{H^l(\Omega)} \le C(h) k^{-(m-l)} ||w||_{H^m(\Omega)}.$$

Combining these approximation properties with standard a priori error estimates for the Navier–Stokes equations (see [13]), we obtain convergence rates of $O(h^\mu)$ and $O(k^{-(m-l)})$ for the h and k refinement strategies, respectively. Hence, if we have a smooth solution, then we expect uniform k refinements to give better approximations than uniform h refinements for a given number of degrees of freedom.

Remark 2.1. The discrete inf-sup condition is given by

$$\sup_{v \in X_D^{h,k+1}} \frac{b(q,v)}{||v||_{H^1(\Omega)}} \ge \gamma ||q||_{L^2(\Omega)} \quad \forall\, q \in M^{h,k}. \tag{2.13}$$

For guaranteed optimal convergence of the finite element approximation with respect to both h and k, it is required that γ not tend to zero as $h \to 0$ and/or $k \to \infty$; see [13].

The element $P_{k+1}P_k$ does not satisfy this condition in general as $k \to \infty$; see pressure solutions in section 4.

Due to lack of inf-sup stability for the $P_{k+1}P_k$ we will also consider the mixed finite element spaces

$$P_{k+2}P_k := X_D^{h,k+2} \times M_h^k.$$

Although stability with respect to k is still an issue, this element is seen to be stable for the numerical results presented. It is known (see [9], [6]) that when using spectral elements a k independent inf-sup constant can be obtained. When using this element we will lose the balance of approximation between the velocity error and the pressure error if the convergence is algebraic. On the other hand, if the solution is smooth, this will not change the overall convergence, and exponential rates are to be expected.

3. Preconditioner. The matrix $\mathcal{L}$ of the linear system (1.7) is nonsymmetric, and the condition number grows rapidly with increasing k and decreasing h. We will consider preconditioned GMRES to solve this system; see Saad and Schultz [17]. For good convergence a preconditioning strategy which produces eigenvalues of the preconditioned system clustered in a region independent of both k and h is desirable.

In what follows we introduce our preconditioner under the assumption that a fast solver is available for the convection diffusion system $Fu = f$. Let us consider the preconditioner to be of block upper triangular form:

$$\mathcal{P}^{-1} = \begin{pmatrix} F^{-1} & R \\ 0 & S^{-1} \end{pmatrix}$$

with the matrices $R \in \mathbb{R}^{n\times m}$ and $S \in \mathbb{R}^{m\times m}$ given by

$$R = F^{-1}B^T S^{-1}$$

and

$$S = BF^{-1}B^T.$$

This choice reduces the preconditioned matrix $\mathcal{L}\mathcal{P}^{-1}$ to a lower triangular form having all diagonal entries equal to 1. Consequently the spectrum $\sigma(\mathcal{L}\mathcal{P}^{-1}) = \{1\}$, and this guarantees the convergence of the preconditioned GMRES in at most two iterations; see [16].

Implementation of a right preconditioner for GMRES requires the solution of a system with matrix $\mathcal{P}$ at every iteration. In an explicit form this means that we have to compute a vector $(v;\ q)^T$ satisfying

$$\begin{pmatrix} v \\ q \end{pmatrix} = \begin{pmatrix} F^{-1} & F^{-1}B^T S^{-1} \\ 0 & S^{-1} \end{pmatrix} \begin{pmatrix} r \\ s \end{pmatrix}$$

for given vectors $r \in \mathbb{R}^n$ and $s \in \mathbb{R}^m$. This is equivalent to the following sequence of operations:

$$\begin{aligned} &\text{Solve for } q: && Sq = s, \\ &\text{Solve for } v: && Fv = -r - B^T q. \end{aligned}$$

In order to obtain a practical method, the exact preconditioner described above is replaced by an approximation which consists in the replacing of the operators S and F by S_* and F_*, respectively. These new operators have to be easy to implement and they should produce a preconditioned Oseen operator which has a tightly clustered spectrum. Thus, the operators S_* and F_* are chosen such that $\sigma(SS_*^{-1}) \subset \omega_S$ and $\sigma(FF_*^{-1}) \subset \omega_F$, where ω_S and ω_F represent small convex sets in the right half of the complex plane; ideally, these sets would be independent of the problem parameters ν, h, and k.

Following Kay, Loghin, and Wathen [14], we approximate the Schur complement, S, by the matrix

$$S_p := A_p F_p^{-1} M_p,$$

where A_p, F_p, and M_p are the pressure space diffusion, convection-diffusion, and identity matrices, respectively.

The approximate inversion of the matrices A_p and M_p is produced by using preconditioned conjugate gradients. The preconditioner was chosen to be of block diagonal form according to the decomposition of the basis functions into three categories, vertex, edge, and interior functions; see Babuska et al. [5]. Given a positive definite matrix A, we denote N iterations of preconditioned conjugate gradients by $PCG(A, N)$. This leads to the practical approximation of the Schur complement

$$(S_p^*)^{-1} := PCG(M_p, N)F_pPCG(A_p, N),$$

where N is a mesh- and degree-independent positive integer.

Remark 3.1. In most calculations we found that $N = 40$ was a robust amount of iterations. This is slightly larger than would be desired.

4. Results. The following examples show how the iterative solver is affected by h and k refinements and also the viscosity parameter ν.

Example 4.1. The first application of the mixed finite element method using high-degree polynomials is the Stokes equation applied to the driven cavity flow problem:

$$-\Delta u + \nabla p = 0 \quad \text{on } \Omega, \tag{4.1}$$

$$-\nabla \cdot u = 0 \quad \text{on } \Omega, \tag{4.2}$$

where Ω is the unit square $[0, 1] \times [0, 1]$.

The boundary conditions are given by

$$u(x, y) = \begin{cases} (1, 0) & \text{for } y = 1,\ x \in [0, 1], \\ (0, 0) & \text{otherwise,} \end{cases} \quad (x, y) \in \partial\Omega.$$

Our experiments were done on three different meshes. The first one is depicted in Figure 1, while the second and the third are obtained by two successive uniform h refinements.

Since the system is symmetric, instead of the block triangular preconditioner we used a block diagonal preconditioner of the following form:

$$\mathcal{P}^{-1} = \begin{pmatrix} F^{-1} & 0 \\ 0 & S^{-1} \end{pmatrix}.$$

For the theoretical results concerning this preconditioner the reader may consult the paper of Silvester and Wathen [19]. Applying the preconditioner $\mathcal{P}^{-1}$ is equivalent to solving the system corresponding to the two blocks.

For the approximate preconditioner we use a preconditioned conjugate gradient method for each block. The preconditioner for each velocity component was PCG $(F_{ii}, 40)$, $i = 1, 2$. Since this is the Stokes equation, the approximate Schur complement is given by the pressure mass matrix. Hence, we use $PCG(M_p, 40)$.

The results are summarized in Table 1. The entries of this table represent the iteration counts necessary for solving the linear system with a tolerance established at 10^{-6}. We clearly see that the solver is optimal with respect to the polynomial degree and element mesh size. Furthermore, the fact that this element is not inf-sup stable with respect to k does not affect the solver.

Example 4.2. In the second example we present the results obtained for the Navier–Stokes equation on the same domain and with the same boundary conditions as in the previous example. The convection diffusion blocks for the velocity space are calculated exactly.

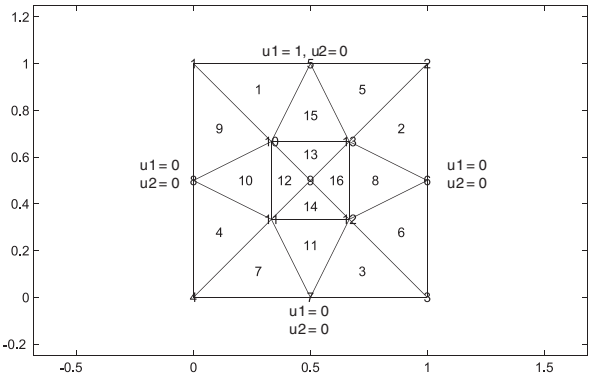

FIG. 1. *Triangulation.*

TABLE 1
GMRES iteration counts for Stokes driven cavity flow discretized by $P_{k+1}P_k$ elements.

k	1	2	3	4	5	6
V_h	10	20	20	20	20	21
$V_{h/2}$	16	20	20	22	20	22
$V_{h/4}$	18	20	20	20	20	22

For $P_{k+1}P_k$ and $P_{k+2}P_k$, respectively, Tables 2 and 3 show the maximum number of iterations required to solve an iteration of the fixed point iteration over all fixed point iterations performed. The number of fixed point iterations required was given by a tolerance set on the convergence of 10^{-6}.

From Tables 2 and 3 we can clearly see the independence of the solver with respect to both h and k refinements. We also can see the dependence of the solver on the viscosity. This dependence seems to be proportional to $\sqrt{\nu}$; see [18], [14].

Example 4.3. The third example treats the Navier–Stokes problem of flow past a backward facing step. The boundary conditions are detailed in Figure 2, and they correspond to an inflow on the edge AB and an outflow on the edge EF. As in the earlier examples the experiments were done on two successive levels of refinement of an initial mesh, which is also depicted in Figure 2.

Tables 4 and 5 show that the solver has no dependence on both the h and k refinements for both $P_{k+1}P_k$ and $P_{k+2}P_k$, respectively.

Figures 3 and 4 show the approximate pressures obtained by discretization with P_7P_6 and P_8P_6, respectively. In Figure 3 one notices some oscillations of the pressure solution near the inflow boundary. These oscillations do not appear in the case of discretization by $P_{k+2}P_k$ elements. The reason for these oscillations is that the mesh given in Figure 2 does not satisfy the stability condition according to the definition given in [10], having triangles with two edges on the boundary of the domain. Experiments made on the mesh given in Figure 5 produced solutions that did not exhibit these oscillations; see Figure 6.

Example 4.4. We now introduce an inexact solver for F using preconditioned GMRES. The preconditioner will take the same block diagonal form as that given earlier for the symmetric matrices A_p and M_p. For the F block the maximum number of GMRES iterations is 30, with a maximum of 3 restarts and a tolerance of 10^{-3} on

the solver. We denote the fully practical GMRES solver by $GMRES^*$. We apply this fully practical solver to the lid driven cavity problem.

Comparing Table 3 with Table 6 we see that the iteration counts increase slightly when using an inexact solver on the F block. This increase is not significant and the key characteristics of the solver are maintained. The inexact solver on the F block is not ideal, since it is not robust with respect to ν, k. In particular, as ν decreases

the inexact solver fails for large k. This failure can be seen in Table 6, where the GMRES* iteration counts grew too large as ν decreased and k increased.

Example 4.5. In what follows we want to show that our preconditioner is efficient for the *hp* version as well. As a model we consider the backward facing step problem. It is known that the analytical pressure solution has a singularity in the corner C(1,1). This behavior can also be noticed by looking at the graphic representation of the approximate pressure solution. From theory we know that in such cases the convergence rate, with respect to k, is not an exponential one, but it is comparable with the convergence rate of the h-version. Therefore, we are tempted to use high-order elements away from the corner C(1,1) combined with low-order elements near the corner. In our experiments we considered a $\mathbf{P}_2P_1$ discretization for the triangles of the mesh, which lie inside the square centered at C and having the side length equal to 0.5. For the triangles outside of this square we considered a $\mathbf{P}_{k+1}P_k$ discretization. Figure 7 represents the mesh refined near the corner.

The results given in Table 7 clearly show the desired robustness of this solver with respect to nonuniform refinement.

5. Conclusions. The preconditioned iterative solver presented is shown to converge rapidly. This convergence rate is independent of both the mesh size and the

polynomial degree. Furthermore, it seems to be robust to nonuniform mesh and polynomial refinement. This makes the scheme very attractive when trying to efficiently produce accurate approximations to the Navier–Stokes equations, using *hp* finite elements.

We also see that in the case where the inf-sup condition is not satisfied, convergence rates are maintained. This is surprising, since if we consider the symmetric Stokes problem with block diagonal preconditioning, the standard convergence results for MINRES are of the form

$$\frac{||\mathbf{r}_n||^2_{\mathcal{P}^{-1}}}{||\mathbf{r}_0||^2_{\mathcal{P}^{-1}}} \leq \min_{p\in\Pi_n, p(0)=1} \max_{\lambda\in\Lambda(\mathcal{M})} |p(\lambda)|,$$

where $\mathbf{r}_n$ is the residual at the nth iteration, $\mathcal{M} = \mathcal{P}^{-1}\mathcal{L}$ is the preconditioned system, and Π_n is the space of polynomials of degree at most n. Hence, if an eigenvalue, $\lambda(k)$,

of the preconditioned system is such that

$$\lambda(k) \to 0 \quad \text{as} \quad k \to \infty,$$

then the convergence rate will be degree dependent.

It can be shown (see Elman, Silvester, and Wathen [12] or Silvester et al. [18]) that the convergence rate of a possible group of eigenvalues to zero is bounded below by the discrete inf-sup value $\gamma(k)$. Hence, if $\gamma(k)$ is converging slowly to zero, or the min max polynomial can capture this set of eigenvalues quickly and all other eigenvalues are tightly clustered together in a region independent of k, then we would not expect to see a dramatic loss in convergence as k increases.

In the case of stable mixed elements, $\gamma(k)$ is bounded below independently of k, and in this case we would expect convergence rates independent of k. For the backward facing step problem this may account for the slightly improved iteration counts when using $P_{k+2}P_k$ over $P_{k+1}P_k$; see Tables 5 and 4, respectively.

EFFICIENT MINIMIZATION METHODS OF MIXED $\ell 2$-$\ell 1$ AND $\ell 1$-$\ell 1$ NORMS FOR IMAGE RESTORATION*

HAOYING FU†, MICHAEL K. NG‡, MILA NIKOLOVA§, AND JESSE L. BARLOW†

Abstract. Image restoration problems are often solved by finding the minimizer of a suitable objective function. Usually this function consists of a data-fitting term and a regularization term. For the least squares solution, both the data-fitting and the regularization terms are in the $\ell 2$ norm. In this paper, we consider the least absolute deviation (LAD) solution and the least mixed norm (LMN) solution. For the LAD solution, both the data-fitting and the regularization terms are in the $\ell 1$ norm. For the LMN solution, the regularization term is in the $\ell 1$ norm but the data-fitting term is in the $\ell 2$ norm. Since images often have nonnegative intensity values, the proposed algorithms provide the option of taking into account the nonnegativity constraint. The LMN and LAD solutions are formulated as the solution to a linear or quadratic programming problem which is solved by interior point methods. At each iteration of the interior point method, a structured linear system must be solved. The preconditioned conjugate gradient method with factorized sparse inverse preconditioners is employed to solve such structured inner systems. Experimental results are used to demonstrate the effectiveness of our approach. We also show the quality of the restored images, using the minimization of mixed $\ell 2$-$\ell 1$ and $\ell 1$-$\ell 1$ norms, is better than that using only the $\ell 2$ norm.

1. Introduction.

The problem of image restoration is considered. The observed image is the convolution of a shift invariant blurring function with the true image plus some additive noise. Let $f(x, y)$ be the original scene, $g(x, y)$ the observed scene, and $h(x, y)$ the blurring function. The image formation process can be modeled as follows:

$$g(x, y) = h(x, y) \star f(x, y) + w(x, y). \tag{1.1}$$

Here $w(x, y)$ is the additive noise and $\star$ denotes two-dimensional convolution. Let $\mathbf{f}$, $\mathbf{g}$, and $\mathbf{w}$ be the discretized original scene, observed scene, and additive noise, respectively. Let H be the corresponding blurring matrix of appropriate size built according to the discretized point spread function $\mathbf{h}$. Then the discretized image formation process can be put into matrix-vector form:

$$\mathbf{g} = H\mathbf{f} + \mathbf{w}. \tag{1.2}$$

Assuming that the discretized scenes have $m \times n$ pixels, then $\mathbf{f}$, $\mathbf{g}$, and $\mathbf{w}$ are vectors of length mn, and H is a matrix of $mn \times mn$. We remark that H is a matrix of block

Toeplitz with Toeplitz blocks (BTTB) when zero boundary conditions are applied, and block Toeplitz-plus-Hankel with Toeplitz-plus-Hankel blocks (BTHTHB) when Neumann boundary conditions are used [36].

Image restoration problems tend to be very ill-conditioned. Directly solving (1.2) will yield a solution that is extremely sensitive to noise; therefore, regularization methods are needed to stabilize the solution. For example, the linear least squares problem with Tikhonov's regularization [48] takes the following form:

$$\min_{\mathbf{f}} \|\mathbf{g} - H\mathbf{f}\|_2^2 + \alpha \|R\mathbf{f}\|_2^2. \tag{1.3}$$

In this optimization problem, the second term is a regularization term that measures the "irregularity" of the solution. We call R the regularization operator and α the regularization parameter. Very often R is chosen to be the difference operator, for example, the first order or second order finite difference operator.

Assuming the additive noise is white Gaussian and the prior distribution of $\mathbf{f}$ is also Gaussian, and that exact information of the blurring matrix is available, the solution of (1.3) can be interpreted as the "maximum a posteriori (MAP) estimator" of the original scene; see [6], for instance. However, due to the presence of edges, the prior distribution of an image rarely satisfies the Gaussian assumption well. In many cases, the additive noise does not satisfy the Gaussian assumption either; for instance, the noise may follow a Laplace distribution [6]. In the literature, there has been a growing interest in using the $\ell 1$ norm for parameter estimation [4, 6, 5, 26, 9, 10, 44] and for image restoration [3, 12, 21, 28, 35, 38, 39, 25]. The advantage of using the $\ell 1$ norm is that the solution is more robust than when using the $\ell 2$ norm in statistical estimation problems. In particular, a small number of outliers have less influence on the solution; see, for instance, [9, 38].

Since edges in an image lead to outliers in the regularization term, it is natural to consider using the $\ell 1$ norm for this term:

$$\min_{\mathbf{f}} \|\mathbf{g} - H\mathbf{f}\|_2^2 + \alpha \|R\mathbf{f}\|_1. \tag{1.4}$$

We call the solution to (1.4) the least mixed norm (LMN) solution. It is worth pointing out that model (1.4) is closely related to the total variation regularization in image restoration. In the one-dimensional case, if R is chosen to be the first order difference operator, then $\|R\mathbf{f}\|_1$ is the discrete version of the total variation norm. Li and Santosa used a piecewise linear $\ell 1$ function as a measure of total variation in [29]. For details about total variation regularization, we refer the reader to [43, 29, 13, 24, 11, 23].

If the additive noise does not satisfy the Gaussian assumption either, we consider using the $\ell 1$ norm for both the data-fitting and the regularization terms:

$$\min_{\mathbf{f}} \|\mathbf{g} - H\mathbf{f}\|_1 + \alpha \|R\mathbf{f}\|_1. \tag{1.5}$$

We call the solution to (1.5) the least absolute deviation (LAD) solution. Recently, minimizers of cost-functions involving $\ell 1$ data-fidelity have been studied by Nikolova [38, 39], Chan and Esedoglu [12], and Kärkkäinen, Kunisch, and Majava [25]. Applications to the processing of outliers and the removal of impulse noise are considered in denoising problems [38, 39, 25].

Another assumption that must be satisfied in order for (1.3) to yield the MAP estimator and which is often violated is that the exact information of the blurring matrix H is available. Many papers (for instance, [34, 37, 42, 20, 33]) address the issue

of inexact H but still assume white Gaussian noise and Gaussian prior distribution of $\mathbf{f}$. In this work, we assume that the exact information for H is available and focus on the issues of non-Gaussian noise and non-Gaussian prior distribution.

Since the objective functions are nonsmooth, problems (1.4) and (1.5) are difficult to solve [6, 9]. For instance, Mammone and Eichmann [32] solved an $\ell 1$ approximation problem with a nonnegative solution using linear programming techniques, and Abdelmalek and Kasvand [2, 1] solved the problem as a quadratic programming problem whose solution is nonnegative and bounded. However, they studied the algebraic image restoration problem in one dimension only, for example, separable blurring functions. Pruessner and O'Leary [42] considered minimization of total least $\ell 1$ norm by using linear programming for image restoration. However, since they simply use the MATLAB [19] function `linprog.m` to solve the linear programming problem, their algorithm is restricted to very small images. In [15, 16, 17, 18], Dax investigated regularized least norm problems where the identity matrix is used as the regularization operator (i.e., $R = I$) and developed row-relaxation methods for solving such least norm problems. The row-relaxation method is suitable for solving problems in which H is sparse. On the total variation regularization, Li and Santosa [29] employed both the steepest descent and an affine scaling Newton method, Ito and Kunisch [24] presented an active set strategy based on the augmented Lagrangian formulation, and Hintermüller and Kunisch [23] solved it as a bilaterally constrained optimization problem. Also Combettes [14] used an adaptive level set method for nondifferentiable constrained image recovery.

Usually, images satisfy

$$\mathbf{f} \geq 0,$$

that is, pixels have nonnegative values. However, this constraint is often omitted in restoration methods, mainly because of the numerical intricacies it entails. Hanke, Nagy, and Vogel [22] considered and studied three nonnegatively constrained restorations schemes: constrained least squares, maximum likelihood, and maximum entropy. Saunders [46] used primal-dual interior point methods for nonnegative least squares image restoration problems.

The main contribution of this work is to develop efficient algorithms for the minimization of mixed $\ell 2$-$\ell 1$ and $\ell 1$-$\ell 1$ norms for image restoration problems. The novelty comes by taking into account the nonnegativity constraint. We first formulate (1.4) as a linear programming problem and (1.5) as a quadratic programming problem. Then we solve these problems by combining an interior point method and a preconditioned conjugate gradient method. In each interior point iteration, a structured linear system is obtained and solved. The form of the coefficient matrix of this structured linear system is given by $D + H^T D' H + R^T D'' R$, where H is a BTTB matrix, and D, D', and D'' are diagonal matrices. To solve such inner systems quickly, we employ the preconditioned conjugate gradient method with factorized sparse inverse preconditioners. In [30], it is shown that factorized sparse inverse preconditioners are better than circulant preconditioners for certain image restoration problems. In this paper, we further demonstrate that factorized sparse inverse preconditioners are quite effective for minimization of mixed $\ell 2$-$\ell 1$ and $\ell 1$-$\ell 1$ norms in image restoration problems.

The rest of this paper is outlined as follows. In section 2, we formulate (1.5) as a linear programming problem and solve it by an interior point method. The major work of each iteration of the interior point method is to solve a large structured

linear system. We propose to solve this system by iterative methods. In this section, we also discuss finding an initial feasible point and keeping the iterates feasible. In section 3, we formulate (1.4) as a quadratic programming problem and also solve it by an interior point method. In section 4, we discuss how to precondition the structured linear systems encountered in sections 2 and 3. Experimental results are presented in section 5. Conclusions are made in section 6.

2. The LAD solution.

2.1. Formulating the problem as a linear programming problem. Problem (1.5), with the nonnegativity constraint imposed, can be formulated as a linear programming problem as follows. If the nonnegativity constraint is not desired, only slight modifications of this procedure are needed.

Let $\mathbf{u} = H\mathbf{f} - \mathbf{g}$; let $\mathbf{v} = \alpha R\mathbf{f}$. We split $\mathbf{u}$ and $\mathbf{v}$ into their nonnegative and nonpositive parts. That is, $\mathbf{u} = \mathbf{u}^+ - \mathbf{u}^-$ and $\mathbf{v} = \mathbf{v}^+ - \mathbf{v}^-$, where $\mathbf{u}^+ = \max(\mathbf{u}, 0)$, $\mathbf{u}^- = \max(-\mathbf{u}, 0)$, $\mathbf{v}^+ = \max(\mathbf{v}, 0)$, and $\mathbf{v}^- = \max(-\mathbf{v}, 0)$. The problem can now be written as

$$\begin{aligned} \min_{\mathbf{f},\mathbf{u}^+,\mathbf{u}^-,\mathbf{v}^+,\mathbf{v}^-} \quad & \mathbf{1}^T\mathbf{u}^+ + \mathbf{1}^T\mathbf{u}^- + \mathbf{1}^T\mathbf{v}^+ + \mathbf{1}^T\mathbf{v}^- \\ \text{subject to} \quad & H\mathbf{f} - \mathbf{g} = \mathbf{u}^+ - \mathbf{u}^-, \\ & \alpha R\mathbf{f} = \mathbf{v}^+ - \mathbf{v}^-, \\ & \mathbf{u}^+,\ \mathbf{u}^-,\ \mathbf{v}^+,\ \mathbf{v}^-,\ \mathbf{f} \geq 0. \end{aligned} \tag{2.1}$$

We use $\mathbf{1}$ to denote the vector of all ones of appropriate size. This notation is used throughout this paper.

Clearly (2.1) can be written as a linear programming problem in the standard form:

$$\min_{\mathbf{x}} \mathbf{c}^T\mathbf{x} \quad \text{subject to} \quad A\mathbf{x} = \mathbf{b}, \quad \mathbf{x} \geq 0, \tag{2.2}$$

where A, $\mathbf{b}$, $\mathbf{c}$, and $\mathbf{x}$ are defined by

$$A = \begin{bmatrix} H & -I & I & 0 & 0 \\ \alpha R & 0 & 0 & -I & I \end{bmatrix}, \quad \mathbf{b} = \begin{bmatrix} \mathbf{g} \\ 0 \end{bmatrix},$$

$$\mathbf{x} = \begin{bmatrix} \mathbf{f} \\ \mathbf{u}^+ \\ \mathbf{u}^- \\ \mathbf{v}^+ \\ \mathbf{v}^- \end{bmatrix}, \quad \text{and} \quad \mathbf{c} = \begin{bmatrix} 0 \\ \mathbf{1} \\ \mathbf{1} \\ \mathbf{1} \\ \mathbf{1} \end{bmatrix}.$$

The Lagrangian function for (2.2) is

$$\mathcal{L}(\mathbf{x}, \boldsymbol{\lambda}, \mathbf{s}) = \mathbf{c}^T\mathbf{x} - \boldsymbol{\lambda}^T(A\mathbf{x} - \mathbf{b}) - \mathbf{s}^T\mathbf{x}. \tag{2.3}$$

Here $\boldsymbol{\lambda}$ and $\mathbf{s}$ are the Lagrange multiplier vectors for the constraints $A\mathbf{x} = \mathbf{b}$ and $\mathbf{x} \geq 0$, respectively. For clarity, we partition $\boldsymbol{\lambda}$ as

$$\boldsymbol{\lambda} = \begin{bmatrix} \boldsymbol{\lambda}_u \\ \boldsymbol{\lambda}_v \end{bmatrix}, \tag{2.4}$$

where $\boldsymbol{\lambda}_u$ is the Lagrange multiplier vector for the constraint $H\mathbf{f} - \mathbf{u}^+ + \mathbf{u}^- = \mathbf{g}$, and $\boldsymbol{\lambda}_v$ is for $\alpha R - \mathbf{v}^+ + \mathbf{v}^- = 0$.

2.2. Interior point methods. Primal-dual interior point methods have become a popular choice for solving large linear programming problems. We briefly outline our adapted interior point method below. A detailed description of interior point methods for linear programming can be found in [49, Chapter 14] or [40, Chapter 1].

The optimality condition for (2.2) is as follows:

$$F(\mathbf{x}, \boldsymbol{\lambda}, \mathbf{s}) = \begin{bmatrix} A^T\boldsymbol{\lambda} + \mathbf{s} - \mathbf{c} \\ A\mathbf{x} - \mathbf{b} \\ XS\mathbf{1} \end{bmatrix} = 0, \quad \mathbf{x} \geq 0, \quad \mathbf{s} \geq 0, \tag{2.5}$$

where

$$X = \operatorname{diag}(\mathbf{x}) \quad \text{and} \quad S = \operatorname{diag}(\mathbf{s}). \tag{2.6}$$

Primal-dual interior point methods have their origin in Newton's method for the system of nonlinear equations (2.5). Newton's method starts with some initial guess for the solution and calculates a search direction at each iteration by solving a linearized model of the original system. A detailed description of Newton's method for nonlinear systems can be found in [40, Chapter 11]. In the primal-dual interior point algorithm, the basic Newton step is modified such that the search directions are aimed at points on the *central path* $(\mathbf{x}_\tau, \boldsymbol{\lambda}_\tau, \mathbf{s}_\tau)$, which is defined as

$$F(\mathbf{x}_\tau, \boldsymbol{\lambda}_\tau, \mathbf{s}_\tau) = \begin{bmatrix} 0 \\ 0 \\ \tau\mathbf{1} \end{bmatrix}, \quad \mathbf{x}_\tau > 0, \quad \mathbf{s}_\tau > 0. \tag{2.7}$$

Very often τ is written as $\sigma\mu$, where $\sigma \in [0, 1]$ is a *centering parameter*, and μ is the *duality measure* defined by

$$\mu = \frac{1}{n}\sum_{i=1}^{n} x_i s_i = \frac{\mathbf{x}^T\mathbf{s}}{n}. \tag{2.8}$$

The step length at each iteration is chosen such that the new iterate is strictly positive, that is, $\mathbf{x} > 0$ and $\mathbf{s} > 0$.

The Newton search direction, $(\triangle\mathbf{x}, \triangle\boldsymbol{\lambda}, \triangle\mathbf{s})$, is computed by solving the following linear system:

$$\begin{bmatrix} 0 & A^T & I \\ A & 0 & 0 \\ S & 0 & X \end{bmatrix} \begin{bmatrix} \triangle\mathbf{x} \\ \triangle\boldsymbol{\lambda} \\ \triangle\mathbf{s} \end{bmatrix} = \begin{bmatrix} -\mathbf{r}_c \\ -\mathbf{r}_b \\ -\mathbf{r}_a \end{bmatrix}, \tag{2.9}$$

where

$$\mathbf{r}_c = A^T\boldsymbol{\lambda} + \mathbf{s} - \mathbf{c}, \quad \mathbf{r}_b = A\mathbf{x} - \mathbf{b}, \quad \mathbf{r}_a = XS\mathbf{1} - \sigma\mu\mathbf{1}.$$

By eliminating $\triangle\mathbf{s}$ in (2.9), we obtain

$$\begin{bmatrix} -X^{-1}S & A^T \\ A & 0 \end{bmatrix} \begin{bmatrix} \triangle\mathbf{x} \\ \triangle\boldsymbol{\lambda} \end{bmatrix} = \begin{bmatrix} -\hat{\mathbf{r}}_c \\ -\mathbf{r}_b \end{bmatrix}, \tag{2.10}$$

where $\hat{\mathbf{r}}_c = \mathbf{r}_c - X^{-1}\mathbf{r}_a$. Let $D = S^{-1/2}X^{1/2}$; then (2.10) can be written as

$$\begin{bmatrix} -D^{-2} & A^T \\ A & 0 \end{bmatrix} \begin{bmatrix} \triangle\mathbf{x} \\ \triangle\boldsymbol{\lambda} \end{bmatrix} = \begin{bmatrix} -\hat{\mathbf{r}}_c \\ -\mathbf{r}_b \end{bmatrix}. \tag{2.11}$$

Note that since the components of $\mathbf{x}$ and $\mathbf{s}$ are strictly positive, all the diagonal elements of D are well defined.

From here the standard approach is to reduce (2.11) to the following form and solve it for step $\triangle\boldsymbol{\lambda}$:

$$AD^2A^T\triangle\boldsymbol{\lambda} = -AD^2\hat{\mathbf{r}}_c - \mathbf{r}_b. \tag{2.12}$$

The application of the preconditioned MINRES [41] or the preconditioned GMRES [45] to (2.10) may be considered. For example, the preconditioner of Benzi and Golub [7], which is briefly described in section 4, could be used to solve (2.10).

However, after comparing the performance of the different implementations, we found that it is advantageous to proceed as follows. System (2.11) can be written as

$$\begin{bmatrix} -D_1^{-2} & 0 & 0 & 0 & 0 & H^T & \alpha R^T \\ 0 & -D_2^{-2} & 0 & 0 & 0 & -I & 0 \\ 0 & 0 & -D_3^{-2} & 0 & 0 & I & 0 \\ 0 & 0 & 0 & -D_4^{-2} & 0 & 0 & -I \\ 0 & 0 & 0 & 0 & -D_5^{-2} & 0 & I \\ H & -I & I & 0 & 0 & 0 & 0 \\ \alpha R & 0 & 0 & -I & I & 0 & 0 \end{bmatrix} \begin{bmatrix} \triangle\mathbf{f} \\ \triangle\mathbf{u}^+ \\ \triangle\mathbf{u}^- \\ \triangle\mathbf{v}^+ \\ \triangle\mathbf{v}^- \\ \triangle\boldsymbol{\lambda}_u \\ \triangle\boldsymbol{\lambda}_v \end{bmatrix} = \begin{bmatrix} -\hat{\mathbf{r}}_{c1} \\ -\hat{\mathbf{r}}_{c2} \\ -\hat{\mathbf{r}}_{c3} \\ -\hat{\mathbf{r}}_{c4} \\ -\hat{\mathbf{r}}_{c5} \\ -\mathbf{r}_{b1} \\ -\mathbf{r}_{b2} \end{bmatrix}.$$

Here D_i (for $i = 1, 2, 3, 4, 5$) are submatrices of D of the appropriate size, and $\hat{\mathbf{r}}_{ci}$ (for $i = 1, 2, 3, 4, 5$) and $\mathbf{r}_{bi}$ (for $i = 1, 2$) are subvectors of the appropriate size of $\hat{\mathbf{r}}_c$ and $\mathbf{r}_b$, respectively.

By eliminating $\triangle\mathbf{u}^+$, $\triangle\mathbf{u}^-$, $\triangle\mathbf{v}^+$, and $\triangle\mathbf{v}^-$, we obtain

$$\begin{bmatrix} -D_1^{-2} & H^T & \alpha R^T \\ H & D_2^2 + D_3^2 & 0 \\ \alpha R & 0 & D_4^2 + D_5^2 \end{bmatrix} \begin{bmatrix} \triangle\mathbf{f} \\ \triangle\boldsymbol{\lambda}_u \\ \triangle\boldsymbol{\lambda}_v \end{bmatrix} = \begin{bmatrix} -\hat{\mathbf{r}}_{c1} \\ -\hat{\mathbf{r}}_{b1} \\ -\hat{\mathbf{r}}_{b2} \end{bmatrix}, \tag{2.13}$$

where

$$\hat{\mathbf{r}}_{b1} = \mathbf{r}_{b1} - D_2^2\hat{\mathbf{r}}_{c2} + D_3^2\hat{\mathbf{r}}_{c3} \quad \text{and} \quad \hat{\mathbf{r}}_{b2} = \mathbf{r}_{b2} - D_4^2\hat{\mathbf{r}}_{c4} + D_5^2\hat{\mathbf{r}}_{c5}.$$

By eliminating $\triangle\boldsymbol{\lambda}_u$ and $\triangle\boldsymbol{\lambda}_v$ from (2.13), we obtain

$$\left[D_1^{-2} + H^T(D_2^2 + D_3^2)^{-1}H + \alpha^2 R^T(D_4^2 + D_5^2)^{-1}R\right]\triangle\mathbf{f} = \tilde{\mathbf{r}}_{c1}, \tag{2.14}$$

where

$$\tilde{\mathbf{r}}_{c1} = \hat{\mathbf{r}}_{c1} - H^T(D_2^2 + D_3^2)^{-1}\hat{\mathbf{r}}_{b1} - \alpha R^T(D_4^2 + D_5^2)^{-1}\hat{\mathbf{r}}_{b2}.$$

System (2.14) can be viewed as the normal equations for a linear least squares problem with the following coefficient matrix:

$$\begin{bmatrix} D_1^{-1} \\ (D_2^2 + D_3^2)^{-1/2}H \\ \alpha(D_4^2 + D_5^2)^{-1/2}R \end{bmatrix} = \begin{bmatrix} D_1^{-1} & & \\ & (D_2^2 + D_3^2)^{-1/2} & \\ & & (D_4^2 + D_5^2)^{-1/2} \end{bmatrix} \begin{bmatrix} I \\ H \\ \alpha R \end{bmatrix}. \tag{2.15}$$

Clearly the second factor in the right-hand side of (2.15) has full column rank and is well-conditioned. Since the matrices D_i are all diagonal matrices with positive diagonal elements, the first factor in the right-hand side of (2.15) has full column

rank. It follows that the coefficient matrix in (2.14) is symmetric positive definite and can be solved by the conjugate gradient method.

In general, when the iterates are close to the solution, if the primal variable is close to zero, then the corresponding dual variable will be far away from zero. This means the corresponding element in D will be very small. On the other hand, if the primal variable is far away from zero, then the corresponding dual variable will be very close to zero, leading to a large entry in D. Therefore, when the iterates are close to the solution, the matrix D will have both huge and tiny elements, causing ill-conditioning. In section 4, we discuss how to precondition system (2.14) efficiently.

Once we have solved (2.14) for $\triangle\mathbf{f}$, the other unknowns in (2.9) can be recovered by the following equations:

$$\begin{cases} \triangle\boldsymbol{\lambda}_u = (D_2^2 + D_3^2)^{-1}(-\hat{\mathbf{r}}_{b1} - H\triangle\mathbf{f}), \\ \triangle\boldsymbol{\lambda}_v = (D_4^2 + D_5^2)^{-1}(-\hat{\mathbf{r}}_{b2} - \alpha R\triangle\mathbf{f}), \\ \triangle\mathbf{u}^+ = D_2^2(\hat{\mathbf{r}}_{c2} - \triangle\boldsymbol{\lambda}_u), \\ \triangle\mathbf{u}^- = D_3^2(\hat{\mathbf{r}}_{c3} + \triangle\boldsymbol{\lambda}_u), \\ \triangle\mathbf{v}^+ = D_4^2(\hat{\mathbf{r}}_{c4} - \triangle\boldsymbol{\lambda}_v), \\ \triangle\mathbf{v}^- = D_5^2(\hat{\mathbf{r}}_{c5} + \triangle\boldsymbol{\lambda}_v), \\ \triangle\mathbf{s} = -\mathbf{r}_c - A^T\triangle\boldsymbol{\lambda}. \end{cases} \tag{2.16}$$

2.3. Finding an initial feasible point and staying feasible. Define the *strictly feasible set* $\mathcal{F}^0$ as

$$\mathcal{F}^0 = \{(\mathbf{x}, \boldsymbol{\lambda}, \mathbf{s}) | A\mathbf{x} = \mathbf{b}, A^T\boldsymbol{\lambda} + \mathbf{s} = \mathbf{c}, \mathbf{x} > 0, \mathbf{s} > 0\}. \tag{2.17}$$

Finding an initial strictly feasible point is not straightforward in many linear programming problems. For our problem, an initial strictly feasible point can be found as follows. Let ϵ be some positive value. Let $\mathbf{f}_{ls}$ be any estimate of the sought-after solution, for example, the least squares solution. We choose $\mathbf{f}^{(0)}$ to be

$$\mathbf{f}^{(0)}[i] = \max\{\mathbf{f}_{ls}[i], \epsilon\}.$$

We let $\mathbf{u}^{+(0)}$ be the sum of ϵ and the nonnegative part of $H\mathbf{f}^{(0)}$ and we let $\mathbf{u}^{-(0)}$ be the sum of ϵ and the nonpositive part of $H\mathbf{f}^{(0)}$. Then the vector

$$\mathbf{x}^{(0)} = \begin{bmatrix} \mathbf{f}^{(0)} \\ \mathbf{u}^{+(0)} \\ \mathbf{u}^{-(0)} \\ \mathbf{v}^{+(0)} \\ \mathbf{v}^{-(0)} \end{bmatrix}$$

satisfies $A\mathbf{x}^{(0)} = \mathbf{b}$. Furthermore, $\mathbf{x}^{(0)} \geq \epsilon$. There are many ways that we can find $\boldsymbol{\lambda}^{(0)}$ and $\mathbf{s}^{(0)}$ such that $\mathbf{s}^{(0)} > 0$ and $A^T\boldsymbol{\lambda}^{(0)} + \mathbf{s}^{(0)} - \mathbf{c} = 0$. Since our focus is on the problem where H corresponds to a shift invariant blurring operator, we can let $\boldsymbol{\lambda}_u^{(0)}$ be a constant vector of -0.5 and let $\boldsymbol{\lambda}_v^{(0)}$ be the zero vector. If Neumann boundary conditions are used, and the blurring function is normalized such that it integrates to 1, then $H^T\boldsymbol{\lambda}_u^{(0)} = 0.5 \cdot \mathbf{1}$. Therefore, if we let $\mathbf{s}^{(0)} = \mathbf{c} - A^T\boldsymbol{\lambda}^{(0)}$, then $\mathbf{s}^{(0)} \geq 0.5 \cdot \mathbf{1}$, and $(\mathbf{x}^{(0)}, \boldsymbol{\lambda}^{(0)}, \mathbf{s}^{(0)})$ is strictly feasible. If zero boundary conditions are used, this procedure would still give an initial strictly feasible point under weak assumptions on the blurring function.

If the current iterate is in the strictly feasible set, and (2.9) is solved exactly, and if a step length is chosen such that the new iterate satisfies $\mathbf{x} > 0$ and $\mathbf{s} > 0$, then the new iterate is strictly feasible.

However, when we use the conjugate gradient method to solve (2.14), only an approximate solution is given. Therefore, even if the current iterate is strictly feasible, the new iterate may not satisfy the conditions

$$A\mathbf{x} = \mathbf{b} \quad \text{and} \quad A^T\boldsymbol{\lambda} + \mathbf{s} - \mathbf{c} = 0$$

to very high accuracy. Thus, if no precaution is taken, the subsequent iterates could move further from the feasible set due to error propagation.

Fortunately, it is easy to show that if (2.16) is used to recover the other unknowns after (2.14) is solved, the conditions $A\mathbf{x} = \mathbf{b}$ and $A^T\boldsymbol{\lambda} + \mathbf{s} - \mathbf{c} = 0$ will be satisfied to machine precision even if (2.14) is solved inexactly. Therefore, if a proper step length is chosen, the next iterate will be strictly feasible.

2.4. Summary of the adapted interior point algorithm. There are many variants of the interior point method. Our algorithm, summarized below, is based on the simplest framework, that is, framework PD in [49, p. 8].

ALGORITHM. INTERIOR POINT FOR THE LAD SOLUTION.

1. Initialize $(\mathbf{x}^{(0)}, \boldsymbol{\lambda}^{(0)}, \mathbf{s}^{(0)}) \in \mathcal{F}^o$.
2. for $k = 0, 1, 2 \ldots$
   - choose $\sigma \in [0, 1]$.
   - solve (2.14) for $\triangle\mathbf{f}$.
   - Use (2.16) to recover $\triangle\mathbf{u}^+$, $\triangle\mathbf{u}^-$, $\triangle\mathbf{v}^+$, $\triangle\mathbf{v}^-$, $\triangle\boldsymbol{\lambda}$, $\triangle\mathbf{s}$.
   - choose β^{pri} and β^{dual}.
   - $\mathbf{x}^{(k+1)} = \mathbf{x}^{(k)} + \beta^{pri}\triangle\mathbf{x}$
   - $\boldsymbol{\lambda}^{(k+1)} = \boldsymbol{\lambda}^{(k)} + \beta^{dual}\triangle\boldsymbol{\lambda}$
   - $\mathbf{s}^{(k+1)} = \mathbf{s}^{(k)} + \beta^{dual}\triangle\mathbf{s}$

   end

Since we use iterative methods to solve the linear systems, no predictor-corrector strategy is involved.

A word needs to be said about the choices of centering parameter σ and step lengths β^{pri} and β^{dual}. It is a common practice to choose the primal and dual step lengths β^{pri} and β^{dual} as follows:

$$\beta^{pri} = \min\left(1, \eta\beta^{pri}_{max}\right), \quad \beta^{dual} = \min\left(1, \eta\beta^{dual}_{max}\right).$$

Here β^{pri}_{max} and β^{dual}_{max} are the maximum steps that can be taken before violating the nonnegativity condition, and $\eta \in [0.9,\ 1.0)$. We simply choose $\eta = 0.95$. Our experiments led us to choose the centering parameter σ to be 0.1 at the first iteration, and

$$\sigma = \max(0.01, (1 - \min(\beta^{pri}, \beta^{dual}))^3)$$

in other iterations. This prevents the iterates from moving too far from the central path and allows significant reduction in duality at each iteration.

3. The LMN solution. Problem (1.4), with the nonnegativity constraint imposed, can be restated as a quadratic programming problem as follows. We let

$\mathbf{v} = \alpha R\mathbf{f}$, and split $\mathbf{v}$ into its nonnegative and nonpositive parts $\mathbf{v}^+$ and $\mathbf{v}^-$. Then (1.4) can be written as

$$\begin{aligned} \min_{\mathbf{f},\mathbf{v}^+,\mathbf{v}^-} \ & \mathbf{1}^T\mathbf{v}^+ + \mathbf{1}^T\mathbf{v}^- + \|H\mathbf{f} - \mathbf{g}\|_2^2 \\ \text{subject to} \ & \alpha R\mathbf{f} = \mathbf{v}^+ - \mathbf{v}^-, \\ & \mathbf{v}^+, \mathbf{v}^-, \mathbf{f} \geq 0. \end{aligned} \tag{3.1}$$

Problem (3.1) can be written as

$$\min_{\mathbf{x}} \frac{1}{2}\mathbf{x}^T G\mathbf{x} + \mathbf{c}^T\mathbf{x} \quad \text{subject to} \quad A\mathbf{x} = \mathbf{b}, \quad \mathbf{x} \geq 0, \tag{3.2}$$

where G, A, $\mathbf{b}$, $\mathbf{c}$, and $\mathbf{x}$ are defined by

$$G = \begin{bmatrix} 2H^TH & 0 & 0 \\ 0 & 0 & 0 \\ 0 & 0 & 0 \end{bmatrix}, \quad A = \begin{bmatrix} \alpha R & -I & I \end{bmatrix},$$

$$\mathbf{b} = \mathbf{0}, \quad \mathbf{x} = \begin{bmatrix} \mathbf{f} \\ \mathbf{v}^+ \\ \mathbf{v}^- \end{bmatrix}, \quad \text{and} \quad \mathbf{c} = \begin{bmatrix} -2H^T\mathbf{g} \\ \mathbf{1} \\ \mathbf{1} \end{bmatrix}.$$

We remark that the objective function is convex since G is symmetric positive semidefinite. Problem (3.2) can also be solved by an interior point method. The Lagrangian function for (3.2) is

$$\mathcal{L}(\mathbf{x}, \boldsymbol{\lambda}, \mathbf{s}) = \frac{1}{2}\mathbf{x}^T G\mathbf{x} + \mathbf{c}^T\mathbf{x} - \boldsymbol{\lambda}^T(A\mathbf{x} - \mathbf{b}) - \mathbf{s}^T\mathbf{x}, \tag{3.3}$$

where $\boldsymbol{\lambda}$ and $\mathbf{s}$ are the generalized Lagrange multiplier vectors for the constraints $A\mathbf{x} = \mathbf{b}$ and $\mathbf{x} \geq 0$, respectively.

The optimality condition for (3.2) is

$$F(\mathbf{x}, \boldsymbol{\lambda}, \mathbf{s}) = \begin{bmatrix} G\mathbf{x} + \mathbf{c} - A^T\boldsymbol{\lambda} - \mathbf{s} \\ A\mathbf{x} - \mathbf{b} \\ XS\mathbf{1} \end{bmatrix} = 0, \quad \mathbf{x} \geq 0, \quad \mathbf{s} \geq 0. \tag{3.4}$$

The central path, $(\mathbf{x}_{\sigma\mu}, \boldsymbol{\lambda}_{\sigma\mu}, \mathbf{s}_{\sigma\mu})$, is defined similarly as in the previous section:

$$F(\mathbf{x}_{\sigma\mu}, \boldsymbol{\lambda}_{\sigma\mu}, \mathbf{s}_{\sigma\mu}) = \begin{bmatrix} 0 \\ 0 \\ \sigma\mu\mathbf{1} \end{bmatrix}. \tag{3.5}$$

Recall that $\sigma \in (0, 1)$ and μ is defined as in (2.8). The Newton step, $(\triangle\mathbf{x}, \triangle\boldsymbol{\lambda}, \triangle\mathbf{s})$, is computed by solving the following linear system:

$$\begin{bmatrix} G & -A^T & -I \\ A & 0 & 0 \\ S & 0 & X \end{bmatrix} \begin{bmatrix} \triangle\mathbf{x} \\ \triangle\boldsymbol{\lambda} \\ \triangle\mathbf{s} \end{bmatrix} = \begin{bmatrix} -\mathbf{r}_c \\ -\mathbf{r}_b \\ -\mathbf{r}_a \end{bmatrix}, \tag{3.6}$$

where

$$\mathbf{r}_c = G\mathbf{x} + \mathbf{c} - A^T\boldsymbol{\lambda} - \mathbf{s}, \quad \mathbf{r}_b = A\mathbf{x} - \mathbf{b}, \quad \mathbf{r}_a = XS\mathbf{1} - \sigma\mu\mathbf{1}.$$

By eliminating $\triangle \mathbf{s}$, we obtain

$$\begin{bmatrix} G + X^{-1}S & -A^T \\ A & 0 \end{bmatrix} \begin{bmatrix} \triangle \mathbf{x} \\ \triangle \boldsymbol{\lambda} \end{bmatrix} = \begin{bmatrix} -\hat{\mathbf{r}}_c \\ -\mathbf{r}_b \end{bmatrix}, \tag{3.7}$$

where $\hat{\mathbf{r}}_c = \mathbf{r}_c + X^{-1}\mathbf{r}_a$. This system can be made symmetric by a change of variable:

$$\begin{bmatrix} G + X^{-1}S & A^T \\ A & 0 \end{bmatrix} \begin{bmatrix} \triangle \mathbf{x} \\ -\triangle \boldsymbol{\lambda} \end{bmatrix} = \begin{bmatrix} -\hat{\mathbf{r}}_c \\ -\mathbf{r}_b \end{bmatrix}. \tag{3.8}$$

Let $D = S^{-1/2}X^{1/2}$. Note that the elements of D are well defined. Partition D as

$$D = \ \mathrm{diag}(D_1, D_2, D_3),$$

where D_1, D_2, and D_3 are matrices of appropriate size such that system (3.8) can be put into the following form:

$$\begin{bmatrix} 2H^TH + D_1^{-2} & 0 & 0 & \alpha R^T \\ 0 & D_2^{-2} & 0 & -I \\ 0 & 0 & D_3^{-2} & I \\ \alpha R & -I & I & 0 \end{bmatrix} \begin{bmatrix} \triangle \mathbf{f} \\ \triangle \mathbf{v}^+ \\ \triangle \mathbf{v}^- \\ -\triangle \boldsymbol{\lambda} \end{bmatrix} = \begin{bmatrix} -\hat{\mathbf{r}}_{c1} \\ -\hat{\mathbf{r}}_{c2} \\ -\hat{\mathbf{r}}_{c3} \\ -\mathbf{r}_b \end{bmatrix}. \tag{3.9}$$

Here $\hat{\mathbf{r}}_{ci}$ (for $i = 1,\ 2,\ 3$) are subvectors of the appropriate size of $\hat{\mathbf{r}}_c$. By eliminating $\triangle \mathbf{v}^+$ and $\triangle \mathbf{v}^-$, we get

$$\begin{bmatrix} 2H^TH + D_1^{-2} & \alpha R^T \\ \alpha R & -D_2^2 - D_3^2 \end{bmatrix} \begin{bmatrix} \triangle \mathbf{f} \\ -\triangle \boldsymbol{\lambda} \end{bmatrix} = \begin{bmatrix} -\hat{\mathbf{r}}_{c1} \\ -\hat{\mathbf{r}}_b \end{bmatrix}, \tag{3.10}$$

where

$$\hat{\mathbf{r}}_b = \mathbf{r}_b + D_2^2\hat{\mathbf{r}}_{c2} - D_3^2\hat{\mathbf{r}}_{c3}.$$

Eliminating $\triangle \boldsymbol{\lambda}$, we get

$$\left[2H^TH + D_1^{-2} + \alpha^2 R^T(D_2^2 + D_3^2)^{-1}R\right] \triangle \mathbf{f} = -\tilde{\mathbf{r}}_{c1}, \tag{3.11}$$

where

$$\tilde{\mathbf{r}}_{c1} = \hat{\mathbf{r}}_{c1} + \alpha R^T(D_2^2 + D_3^2)^{-1}\hat{\mathbf{r}}_b.$$

Similar to system (2.14), system (3.11) can be viewed as the normal equations of a linear least squares problem, whose coefficient matrix has full column rank. Therefore, the coefficient matrix in (3.11) is symmetric positive definite, and system (3.11) can be solved by the preconditioned conjugate gradient method.

Once (3.11) has been solved, the other unknowns can be calculated by the following equations:

$$\begin{cases} \triangle \boldsymbol{\lambda} = (D_2^2 + D_3^2)^{-1}(-\hat{\mathbf{r}}_b - \alpha R \triangle \mathbf{f}), \\ \triangle \mathbf{v}^+ = D_2^2(-\hat{\mathbf{r}}_{c2} - \triangle \boldsymbol{\lambda}), \\ \triangle \mathbf{v}^- = D_3^2(-\hat{\mathbf{r}}_{c3} + \triangle \boldsymbol{\lambda}), \\ \triangle \mathbf{s} = G \triangle \mathbf{x} - A^T \triangle \boldsymbol{\lambda} + \mathbf{r}_c. \end{cases} \tag{3.12}$$

An initial feasible point can be found in a similar manner as was done for the LAD solution. Moreover, if (3.12) is used to recover the rest of the unknowns after (3.11) is solved approximately, and a proper step length is chosen, then the iterates will stay feasible.

The interior point algorithm for the LMN solution is quite similar to that for the LAD solution. One difference that is worth pointing out is that β^{pri} and β^{dual} are allowed to take different values in the algorithm for the LAD solution but have to be the same in that for the LMN solution.

4. Preconditioning the structured linear systems. As mentioned earlier, linear systems (2.14) and (3.11) become ill-conditioned as the iterates get close to the solution. Thus preconditioners are needed to accelerate the convergence of the conjugate gradient iterations.

For the nonnegative least squares image restoration problem, Saunders [46] used preconditioned LSQR to solve the linear system at each interior point iteration. He used a diagonal preconditioner. However, the effectiveness of diagonal preconditioners is limited in that preconditioned LSQR needed more than 1000 iterations to converge to a desired level of accuracy at the final stages of the interior point algorithm. Our experimental results indicate that the conditions of systems (2.14) and (3.11) tend to be worse than that of the systems in the nonnegative least squares problem. This should be no surprise since our problems are transformed from nonsmooth problems.

4.1. Saddle point preconditioners. For linear systems (2.10), Benzi and Golub [7] proposed using the preconditioned GMRES to solve the equivalent system

$$\begin{bmatrix} D^{-2} & -A^T \\ A & 0 \end{bmatrix} \begin{bmatrix} \triangle \mathbf{x} \\ \triangle \boldsymbol{\lambda} \end{bmatrix} = \begin{bmatrix} \hat{\mathbf{r}}_c \\ -\mathbf{r}_b \end{bmatrix}. \tag{4.1}$$

Their preconditioning strategy is based on the symmetric/skew-symmetric splitting of the coefficient matrix, that is, they propose using the following matrix as the preconditioner:

$$\mathcal{M}_\gamma = \begin{bmatrix} D^{-2} + \gamma I & 0 \\ 0 & \gamma I \end{bmatrix} \begin{bmatrix} \gamma I & -A^T \\ A & \gamma I \end{bmatrix}, \tag{4.2}$$

where γ is some positive constant. Linear systems in the form of $\mathcal{M}_\gamma \mathbf{z} = \mathbf{r}$ can be solved by first solving

$$\begin{bmatrix} D^{-2} + \gamma I & 0 \\ 0 & \gamma I \end{bmatrix} \tilde{\mathbf{z}} = \mathbf{r}, \tag{4.3}$$

followed by

$$\begin{bmatrix} \gamma I & -A^T \\ A & \gamma I \end{bmatrix} \mathbf{z} = \tilde{\mathbf{z}}. \tag{4.4}$$

Solving (4.3) is a simple dotwise division. Since our focus is on the shift invariant blur, system (4.4) can be solved by the discrete cosine transform if the blur is symmetric and Neumann boundary conditions are applied; see [36], for instance. This preconditioning technique can also be applied to (2.13), which yields better results in practice.

4.2. Factorized sparse inverse preconditioner. Our experimental results indicate that the most efficient way to compute the Newton step is to apply the factorized sparse inverse preconditioner (FSIP) [27, 8, 47] to systems (2.14) and (3.11). Let B be a symmetric positive definite matrix, and let its Cholesky factorization be $B = CC^T$. The idea of FSIP is to find the lower triangular matrix L with the sparsity pattern $\mathcal{S}$ such that

$$\|I - CL\|_F$$

is minimized, where $\|\cdot\|_F$ denotes the Frobenius norm. Kolotilina and Yeremin [27] showed that L can be obtained by the following algorithm.

Algorithm. Construction of FSIP.
1. Compute $\hat{L}$ with sparsity pattern $\mathcal{S}$ such that $\left[\hat{L}B\right]_{ij} = \delta_{ij}, \quad (i,j) \in \mathcal{S}$.
2. Let $\hat{D} = (\mathrm{diag}(\hat{L}))^{-1}$ and $L = \hat{D}^{1/2}\hat{L}$.

According to this algorithm, n small linear systems need to be solved, where n is the number of rows in the matrix B. These systems can be solved in parallel. Thus the above algorithm is well suited for modern parallel computing.

A special type of FSIP, the factorized banded inverse preconditioner (FBIP), was proposed by Lin, Ng, and Ching [30] for Toeplitz related matrices. We say that $B \in \mathbb{R}^{m\times n}$ has *lower bandwidth* p if $b_{ij} = 0$ whenever $i > j + p$. The *upper bandwidth* of a matrix is defined similarly. Note that by this definition, a tridiagonal matrix has upper and lower bandwidth of 1.

Lin, Ng, and Ching [30] proved the following theorem.

Theorem 4.1. *Let T be a Hermitian Toeplitz matrix. Denote the kth diagonal of T by t_k. Assume the diagonals of T satisfy*

$$|t_k| \le ce^{-\gamma|k|} \tag{4.5}$$

for some $c > 0$ and $\gamma > 0$, or

$$|t_k| \le c(|k| + 1)^{-s} \tag{4.6}$$

for some $c > 0$ and $s > 3/2$. Then for any given $\epsilon > 0$, there exists $p' > 0$ such that for all $p > p'$,

$$\|L_p - C^{-1}\| \le \epsilon,$$

where L_p is the FBIP of T with the lower bandwidth p, and C is the Cholesky factor of T.

This theorem indicates that if a Toeplitz matrix T has certain off-diagonal decay property, then the FBIP will be a good approximation to T^{-1}. Note that if a Toeplitz matrix is banded, then both (4.5) and (4.6) are satisfied trivially.

Lin, Ng, and Ching [30] also considered Toeplitz-related systems of the form $I + T^T DT$, where D is a positive diagonal matrix, and proved the following corollary.

Corollary 4.2. *Let T be a Toeplitz matrix with its diagonals satisfying* (4.5) *or* (4.6). *Let $D = \mathrm{diag}(d_i)$ with $0 < d_i \le d$, and*

$$B = I + T^T DT.$$

Then for any given $\epsilon > 0$, there exists $p' > 0$ such that for all $p > p'$,

$$\|L_p - C^{-1}\| \leq \epsilon,$$

where L_p is the FBIP of B with the lower bandwidth p, and C is the Cholesky factor of B.

The matrices we are trying to precondition are the coefficient matrices in (2.14) and (3.11), that is, $B = D_1^{-2} + H^T(D_2^2 + D_3^2)^{-1}H + \alpha^2 R^T(D_4^2 + D_5^2)^{-1}R$ and $B = 2H^TH + D_1^{-2} + \alpha^2 R^T(D_2^2 + D_3^2)^{-1}R$. Although the focus of this research is on two-dimensional images, we have the following lemma for the one-dimensional problem.

LEMMA 4.3. *Let T be a Toeplitz matrix with its diagonals satisfying* (4.5) *or* (4.6). *Let D_1, D_2, and D_3 be diagonal matrices with positive diagonal entries. Let*

$$B = T^T D_1 T + D_2 + R^T D_3 R \tag{4.7}$$

be a well-conditioned matrix, where R is the first order or the second order difference operator. Then for any given $\epsilon > 0$, there exists $p' > 0$ such that for all $p > p'$,

$$\|L_p - C^{-1}\| \leq \epsilon,$$

where L_p is the FBIP of B with lower bandwidth p, and C is the Cholesky factor of B.

Proof. The proof is similar to the proof of Corollary 4 in [30]. ∎

Lemma 4.3 indicates that the linear system in the one-dimensional LMN and LAD problems can be efficiently preconditioned by the FBIP.

It is important to note that in order to construct the FBIP for B, it is not necessary to explicitly calculate all the elements of B when p is small. The following lemma indicates that only certain diagonals of B need to be calculated.

LEMMA 4.4. *Let L_p be the FBIP with lower bandwidth p for a symmetric matrix B. Then L_p can be determined by the first p bands of the lower triangular part of B.*

Proof. For $i = 1, 2, \ldots, p-1$, the nonzero elements of the ith row of L_p is $L(i, 1 : i)$. They are determined by $B(1 : i, 1 : i)$.

On the other hand, for $i = p, p+1, \ldots, n$, the nonzero elements of the ith row of L_p is $L(i, i+1-p : i)$. They are determined by $B(i+1-p : i, i+1-p : i)$.

Therefore, L_p can be determined by the first upper and lower p bands of B. Since B is symmetric, the result follows. ∎

For two-dimensional problems, we assume that the blurring matrix H has a block-level off-diagonal decay property, and each block also has off-diagonal decay property. This is true if the blurring function decays in spatial domain, or if the support of the blur is small. In this case, we can set the FSIP to be a triangular block banded matrix with each block being a banded matrix. Let p be the block-level lower bandwidth of the FSIP and let q be the lower and the upper bandwidths of each block. Figure 4.1(a) shows the sparsity pattern of an FSIP with $p = 2$ and $q = 1$. Note that if $p = q = 0$, then the FSIP becomes a diagonal preconditioner.

Similar to the one-dimensional case, when constructing the FSIP, it is not necessary to calculate all the elements of the coefficient matrix in (2.14) or (3.11). However, the situation for the two-dimensional case is a bit more complicated.

LEMMA 4.5. *Let L be the FSIP of the coefficient matrix in* (2.14) *or* (3.11), *and let p be the block-level lower bandwidth and q the upper and the lower bandwidths of the blocks of L. Then L can be determined by those elements that are in the lower*

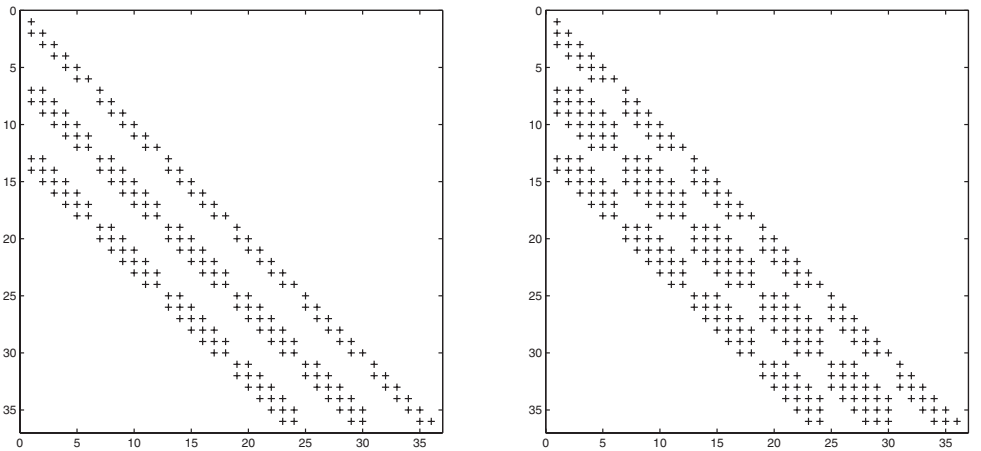

FIG. 4.1. (a) *FSIP with* $p = 2$ *and* $q = 1$. (b) *Sparsity pattern of the elements of the coefficient matrix that needs to be calculated.*

triangular part of the coefficient matrix and have a block-level lower bandwidth of p *with each block having upper and lower bandwidth of* $2q$.

Lemma 4.5 is actually a bit conservative. Figure 4.1(b) shows the sparsity pattern of the elements of the coefficient matrix that needs to be calculated if the FSIP has a sparsity pattern shown in Figure 4.1(a). Note that the blocks in the last block diagonal have lower bandwidth of q. If the original blurring matrix H is sparse enough such that there is no need to use the FFT [31] for matrix multiplications, the cost of calculating these elements is no more than $(p + 1)(2q + 1)$ plain conjugate gradient iterations.

Other than explicitly calculating certain diagonals of the coefficient matrix in (2.14) or (3.11), the cost of constructing the FSIP consists of calculating the lower triangular factor L. Since this step solves mn linear systems of size $(p+1)(2q+1)\times(p+1)(2q+1)$, the complexity of this step is $O(p^3q^3mn)$. Because this cost grows cubically with the increase of p and q, the benefit of the decrease in the number of iterations will be offset by the cost of constructing the preconditioner with the increase of p and q. Therefore, it is important to choose suitable values of p and q in practical applications.

Usually the linear system to be solved is well-conditioned at the first few interior point iterations. Due to the initial cost of constructing the FSIP, it is too expensive to choose a big p or q for early iterates. However, as the iterates get close to the solution, the ill-conditioning of the linear system makes choosing bigger p and q necessary. Therefore, the best strategy is to choose small p and q (say $p = q = 0$) at the beginning, and increase p and q gradually. For details, see experimental results in the next section.

5. Experimental results. Most of our experiments are based on the cameraman image shown in Figure 5.1. The blurring function is chosen to be a two-dimensional Gaussian,

$$h(i, j) = e^{-2(i/3)^2-2(j/3)^2},$$

truncated such that the function has a support of 7×7.

We generate two observed images. For the first one, a Gaussian white noise with standard deviation 0.05 is added. For the second one, we randomly pick 50% of the pixels to be contaminated by noise; the type and standard deviation of the noise is the same as in the first one. The observed images are shown in Figure 5.2. For the

FIG. 5.1. *The original image.*

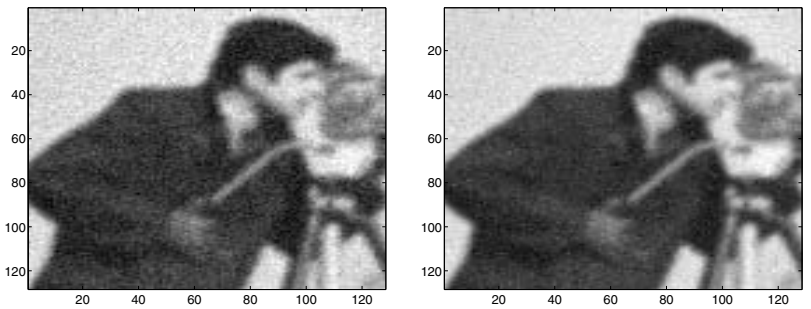

FIG. 5.2. *Observed images:* (a) *all pixels are contaminated by noise;* (b) *only* 50% *of the pixels are contaminated by noise.*

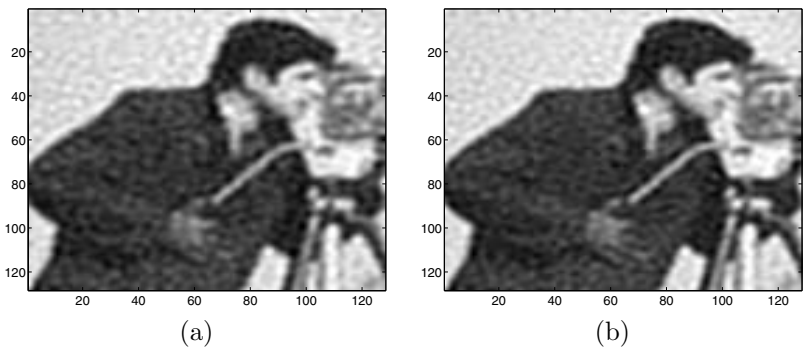

FIG. 5.3. (a) *The least squares solutions for the first observed image, PSNR* = 20.46 *db.* (b) *The least squares solution for the second observed image, PSNR* = 20.87 *db.*

first observed image, since the noise is normal, we consider only the LMN solution. For the second one, we consider both the LMN solution and the LAD solution.

Neumann boundary conditions are used to build the blurring matrix H. Figure 5.3 shows the least squares restoration of the two observed images, respectively. The optimal regularization parameter (the one that yields the highest peak signal-to-noise ratio (PSNR)) is used.

The interior point algorithms are implemented in MATLAB, except the construction of the FSIP, which is written as a MATLAB callable C function. Recall that in order to construct the FSIP, mn small linear systems need to be solved. Doing this

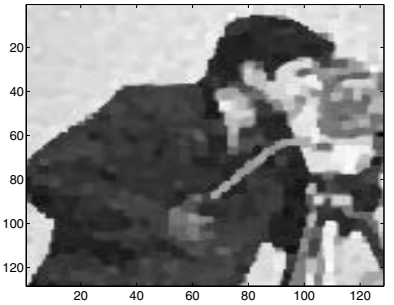

FIG. 5.4. *The LMN solution for the first observed image, PSNR* = 20.78 *db.*

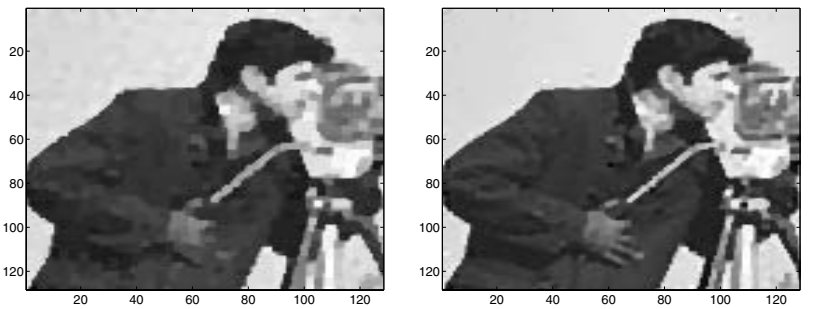

FIG. 5.5. (a) *The LMN solution for the second observed image, PSNR* = 21.30 *db.* (b) *The LAD solution for the second observed image, PSNR* = 22.82 *db.*

in MATLAB would be slow because MATLAB loops are inefficient.

The LMN solution for the first observed image is shown in Figure 5.4. The PSNR of this image indicates it is superior to the least squares solution. It is interesting to note that the LMN solution is quite different from the least squares solution. The least squares solution tends to smooth out the edges but undersmooths flat areas. The LMN solution tends to sharpen the edges and makes flat areas even flatter.

The LAD and LMN solutions for the second observed image is shown in Figure 5.5. As can be seen, both solutions have a higher PSNR than the least squares solution. Furthermore, the LAD solution is superior to the LMN solution.

Similar to the total variation deblurring [43], using the ℓ_1 norm for the regularization term is very effective in recovering "blocky" images. Using the ℓ_1 norm for the residual term yields very good results if only a small portion of the pixels are contaminated by noise. Figure 5.6(a)–(e) show an original "blocky" image, blurred image with 50% of the pixels contaminated by additive noise, least squares restoration, the LMN solution, and the LAD restoration.

Figures 5.7 and 5.8 show the convergence of the primal-dual interior point algorithm for the LMN and LAD solutions, respectively. Theoretically, the interior point iterations should exhibit superlinear convergence. The experimental results do not seem to confirm the theoretical predictions. This can be explained as follows. The linear systems are approximately solved such that the residual is below a certain level. Because the conditions of the linear systems get worse as the iterates get closer to the solution, the error in the calculated search directions becomes bigger, causing poorer convergence. In fact, for small images, if direct methods are used to solve the linear

systems, a slightly superlinear convergence is observed.

Table 5.1 shows the number of conjugate gradient iterations and CPU time at each interior point iteration for the LAD solution when different preconditioning strategies are used. The CPU time listed here includes the time for constructing the preconditioners. Table 5.2 shows the same kind of results for the linear systems in the LMN solution. As can be seen, in both cases, the FSIP with proper choices of p and q can significantly speed up the convergence.

We remark that the performance of the FSIP depends on the support of the blurring function and on how fast the function decays in space. The effect of the support of the blurring matrix on the effectiveness of the FSIP is twofold. On one hand, a big support means a relatively dense blurring matrix, therefore, allowing the preconditioner to be relatively dense. On the other hand, a big support usually means a relatively dense preconditioner is needed in order to improve the condition significantly. Table 5.3 shows the performance of the FSIP with a different choice of p and q when the support of the blur is 5×5 (the same Gaussian blur is used). Table 5.4 shows the same kind of information when the support of the blur is 9×9.

In general, the faster the blurring function decays in space, the more effective the FSIP is. In that sense, the worst blurring function is a uniform blur. Table 5.5 shows the performance of the FSIP if a 7×7 uniform blur is used.

6. Conclusions. In conclusion, we have proposed efficient algorithms for finding the LAD or LMN solution for the image restoration problem. We formulated these problems as solutions to smooth linear or quadratic programming problems, which are solved by a primal-dual interior point method. The linear system at each interior point iteration is first reduced to a more compact system and then solved by the PCG method. The FSIP is used to speed up the convergence of the conjugate gradient method.

Experimental results indicate that the LAD and LMN solutions have advantages over the least squares solution. We also demonstrated that the FSIP can speed up the convergence considerably if a proper sparsity pattern is chosen.

FAST ALGORITHMS FOR SPHERICAL HARMONIC EXPANSIONS*

VLADIMIR ROKHLIN† AND MARK TYGERT‡

Abstract. An algorithm is introduced for the rapid evaluation at appropriately chosen nodes on the two-dimensional sphere S^2 in $\mathbb{R}^3$ of functions specified by their spherical harmonic expansions (known as the inverse spherical harmonic transform), and for the evaluation of the coefficients in spherical harmonic expansions of functions specified by their values at appropriately chosen points on S^2 (known as the forward spherical harmonic transform). The procedure is numerically stable and requires an amount of CPU time proportional to $N^2(\log N)\log(1/\varepsilon)$, where N^2 is the number of nodes in the discretization of S^2, and ε is the precision of computations. The performance of the algorithm is illustrated via several numerical examples.

Key words. spherical harmonics, fast algorithms, expansions

AMS subject classification. 65T50

DOI. 10.1137/050623073

1. Introduction. Spherical harmonic expansions are a widely used and well-understood tool of applied mathematics; they are encountered, inter alia, in weather and climate modeling, in the representation of gravitational, topographic, and magnetic data in geophysics, in the numerical solution of certain partial differential equations, etc. The role of spherical harmonic expansions in diagonalizing the Laplacian in three dimensions is similar to the role played by Fourier series expansions in two dimensions.

The spherical harmonic expansion of a function f in $\mathcal{L}^2(S^2)$ is the series of the form

$$f(\theta,\varphi)=\sum_{l=0}^{\infty}\sum_{m=-l}^{l}\alpha_l^m\,P_l^{|m|}(\cos\theta)\,e^{im\varphi}, \tag{1.1}$$

where (θ,φ) are the standard spherical coordinates on the two-dimensional sphere S^2 in $\mathbb{R}^3$, $0\le\theta<\pi$ and $0\le\varphi<2\pi$, and P_l^m is the associated Legendre function of degree l and order m. While the functions $\{P_l^{|m|}(\cos\theta)\,e^{im\theta}\}$ constitute a basis of $\mathcal{L}^2(S^2)$ that is orthogonal, that is,

$$\int_{-1}^{1}P_k^{|m|}(x)\,P_l^{|m|}(x)\,dx=0 \tag{1.2}$$

when $l\ne k$, their norms are not equal to 1; in fact, they are so badly normalized as to be virtually unusable in numerical calculations (see section 2.1 for a detailed discussion of the associated Legendre functions). Therefore, it is customary to replace

expansions of the form (1.1) with expansions of the form

$$f(\theta, \varphi) = \sum_{l=0}^{\infty} \sum_{m=-l}^{l} \alpha_l^m \, \overline{P}_l^{|m|}(\cos\theta) \, e^{im\varphi}, \tag{1.3}$$

where $\overline{P}_l^{|m|}$ denotes the normalized version of the associated Legendre function $P_l^{|m|}$, defined on $[-1, 1]$ via the formula

$$\overline{P}_l^{|m|}(x) = (-1)^{|m|} \sqrt{\frac{2l+1}{2} \, \frac{(l-|m|)!}{(l+|m|)!}} \, P_l^{|m|}(x), \tag{1.4}$$

so that

$$\int_{-1}^{1} \left(\overline{P}_l^{|m|}(x) \right)^2 \, dx = 1. \tag{1.5}$$

In numerical practice, the series (1.3) is truncated after a finite number of terms, leading to expressions of the form

$$f(\theta, \varphi) \sim \sum_{l=0}^{N} \sum_{m=-l}^{l} \alpha_l^m \, \overline{P}_l^{|m|}(\cos\theta) \, e^{im\varphi}. \tag{1.6}$$

Formula (1.6) is viewed as an approximation to the function f, and N is called the order of the expansion (1.6). Obviously, the expansion (1.6) contains $(N+1)^2$ terms; the order N required to obtain a prescribed accuracy of the approximation is determined by the complexity of the function f.

Frequently, the need arises to evaluate the coefficients in an expansion of the form (1.6) for a function f given by a table of its values at a collection of appropriately chosen nodes on S^2; conversely, given the coefficients in (1.6), one often needs to evaluate f at a collection of points on S^2. The former is usually called the forward spherical harmonic transform, and the latter is known as the inverse spherical harmonic transform. A standard discretization of S^2 is the "tensor product," consisting of all pairs of the form (θ_k, φ_j), with equispaced nodes $\theta_0, \theta_1, \ldots, \theta_{N-1}, \theta_N$ discretizing the interval $[0, \pi]$, defined by the formula

$$\theta_k = \frac{\pi(k+1/2)}{N+1}, \tag{1.7}$$

and equispaced nodes $\varphi_0, \varphi_1, \ldots, \varphi_{2N-1}, \varphi_{2N}$ discretizing the interval $[0, 2\pi]$, defined by the formula

$$\varphi_j = \frac{2\pi(j+1/2)}{2N+1}. \tag{1.8}$$

This leads immediately to numerical schemes for both the forward and inverse spherical harmonic transforms costing $\mathcal{O}(N^3)$ operations. Indeed, given a function f defined on S^2 by the formula (1.6), one can rewrite (1.6) in the form

$$f(\theta, \varphi) = \sum_{m=-N}^{N} e^{im\varphi} \sum_{l=|m|}^{N} \alpha_l^m \, \overline{P}_l^{|m|}(\cos\theta). \tag{1.9}$$

For a fixed value of θ, each of the inner sums in (1.9) contains no more than $N+1$ terms, and there are $2N+1$ such sums (one for each value of m); since the inverse spherical harmonic transform involves $N+1$ values $\theta_0, \theta_1, \ldots, \theta_{N-1}, \theta_N$, the cost of evaluating all inner sums in (1.9) is $\mathcal{O}(N^3)$. Once all inner sums have been evaluated, evaluation of each outer sum costs $\mathcal{O}(N)$ operations (since each of them contains $2N+1$ terms), and there are $\mathcal{O}(N^2)$ such sums to be evaluated, leading to $\mathcal{O}(N^3)$ CPU time requirements for the evaluation of all outer sums in (1.9). The cost of the evaluation of the whole inverse spherical harmonic transform (in the form (1.9)) is the sum of the costs for the inner and outer sums, and is also $\mathcal{O}(N^3)$; a virtually identical calculation shows that the cost of evaluating the forward spherical harmonic transform is also $\mathcal{O}(N^3)$.

A trivial modification of the scheme described in the preceding paragraph uses the fast Fourier transform to evaluate the outer sums in (1.9), roughly halving the CPU time requirements of the whole procedure. Several other considerations (see, for example, [2], [18]) can be used to reduce the CPU time requirements by a further factor of 4 or so, but there is no simple trick for reducing the asymptotic CPU time requirements of the whole spherical harmonic transform (either forward or inverse) below N^3. In this paper, we introduce algorithms for both forward and inverse spherical harmonic transforms with CPU time requirements proportional to $N^2(\log N)\log(1/\varepsilon)$, where ε is the precision of computations.

The algorithm of this paper is a procedure for the rapid evaluation of the inner sums in expressions of the form (1.9). It is based principally on two observations, as follows.

1. The differential equations defining the functions $\overline{P}_l^m$ with arbitrary positive integer m are very close to the differential equations defining the functions $\overline{P}_l^1$ and $\overline{P}_l^2$.

2. There exist fast algorithms for decomposing functions into and reconstructing functions from sums of the forms

$$f(x) = \sum_{l=0}^{N} p_l^1 \, \overline{P}_l^1(x), \tag{1.10}$$

$$f(x) = \sum_{l=0}^{N} p_l^2 \, \overline{P}_l^2(x). \tag{1.11}$$

We use the connections between the functions $\overline{P}_l^m$ with arbitrary positive integer m and the functions $\overline{P}_l^1$ and $\overline{P}_l^2$ to apply rapidly to arbitrary vectors the matrices converting between expansions of the forms (1.10) and (1.11) and expansions of the form

$$f(x) = \sum_{l=0}^{N} p_l^m \, \overline{P}_l^m(x). \tag{1.12}$$

This step utilizes the observation made in [4] that the $N \times N$ matrix of eigenvectors of the sum of a diagonal matrix and a semiseparable matrix (see section 2.4 for the definition of a semiseparable matrix) can be applied to an arbitrary vector of length N for a cost proportional to $N(\log N)\log(1/\varepsilon)$ operations, where ε is the precision of computations.

During the last several years, the interest in fast transforms has been growing, stimulated by the combination of recent progress in fast algorithms of various kinds

with the importance of the fast Fourier transform in computational mathematics, electrical engineering, etc., and by the success of various types of multilevel computational techniques. In particular, several prior attempts have been made to construct numerically stable fast spherical harmonic transforms.

Schemes have been constructed that are fast, but unstable in floating point arithmetic; [10], [9], [12] elucidate this approach, and the ongoing efforts to stabilize algorithms of this type. Other schemes have been proposed that are instead approximate, performing calculations up to an arbitrary but fixed precision ε. In [13], a procedure is described with the asymptotic CPU time estimate $\mathcal{O}(N^{5/2}(\log N)\log(1/\varepsilon))$ for either the forward or the inverse spherical harmonic transform. Also in [13], an algorithm is proposed whose asymptotic CPU time requirements are conjectured to be $\mathcal{O}(N^2(\log N)^2\log(1/\varepsilon))$; this estimate is not fully proved in [13], and the numerical results presented there do not unequivocally support it. A different approach is proposed in [16], [17]; like the approaches of both [13] and the present paper, the scheme of [17] is based on analytical (rather than algebraic) techniques. The asymptotic CPU time requirements of the procedure described in [17] are $\mathcal{O}(N^2(\log N)\log(1/\varepsilon))$; while [16], [17] report work in progress, we expect this attack to be successful. Finally, it should be observed that some of the papers describing fast spherical transforms compare the actual timings obtained in them to those produced by the straightforward matrix-vector multiplication scheme, while others compare to the "semi-naive" algorithm described in [10], [2]. It should be kept in mind that the "semi-naive" scheme is about twice as fast as the straightforward one.

It should also be observed that the algorithm of this paper is not intended to be used as a component in what are known as "spherical filters" (see, for example, [11]); special purpose schemes of the type originated in [11] tend to be considerably faster than the scheme presented here.

The structure of this paper is as follows. In section 2, we summarize a number of facts (from both mathematical and numerical analysis) to be used in the rest of the paper; all of the content of section 2 is either well known or follows easily from well-known facts. In section 3, we build the analytical apparatus to be used in the construction of the algorithms of this paper. Section 4 contains an informal description of the algorithm, and in section 5 the procedure is described in detail. The performance of the scheme is illustrated with numerical examples in section 6, and section 7 contains a discussion of possible applications of the approach of this paper in other environments.

2. Mathematical and numerical preliminaries. In this section, we summarize several facts from mathematical and numerical analysis. Please note that in this section and throughout this paper, the variable x always takes arbitrary values in $[-1,\,1]$, θ takes values in $[0,\,\pi]$, and φ takes values in $[0,\,2\pi]$. We will always use the term "eigenvector" to mean "normalized eigenvector."

2.1. Spherical harmonics and associated Legendre functions. In this section, we summarize a number of properties of spherical harmonics and associated Legendre functions; all of these can be found, for example, in [1].

The coefficients in the spherical harmonic expansion (1.6) of a function f in $\mathcal{L}^2(S^2)$ are given by the formula

$$\alpha_l^m = \int_0^\pi \int_0^{2\pi} \overline{P}_l^{|m|}(\cos\theta)\, e^{-im\varphi}\, f(\theta,\,\varphi)\, \sin\theta\, d\varphi\, d\theta. \tag{2.1}$$

For the forward spherical harmonic transform of order N, we have to compute the coefficients (2.1) from the values $f(\theta_k, \varphi_j)$, where θ_0, $\theta_1, \ldots, \theta_{N-1}$, θ_N are defined in (1.7), and $\varphi_0, \varphi_1, \ldots, \varphi_{2N-1}, \varphi_{2N}$ are defined in (1.8). For a cost of $\mathcal{O}(N^2 \log N)$, we use the fast Fourier transform to obtain the $2(2N+1)(N+1)$ values $g^m(\theta_k)$ and $h^m(\theta_k)$ ($m = -N, -N+1, \ldots, N-1, N$; $k = 0, 1, \ldots, N-1, N$) of the functions g^m and h^m defined on $[0, \pi]$ by the formulae

$$g^m(\theta) = \sum_{j=0}^{2N} \cos(m\,\varphi_j)\, f(\theta, \varphi_j), \tag{2.2}$$

$$h^m(\theta) = \sum_{j=0}^{2N} \sin(m\,\varphi_j)\, f(\theta, \varphi_j). \tag{2.3}$$

We then evaluate the coefficients (2.1) via the formula

$$\alpha_l^m = \int_0^\pi \overline{P}_l^{|m|}(\cos\theta)\, g^m(\theta)\, \sin\theta\, d\theta - i \int_0^\pi \overline{P}_l^{|m|}(\cos\theta)\, h^m(\theta)\, \sin\theta\, d\theta. \tag{2.4}$$

To evaluate the integrals in (2.4), we have to convert the values $f^m(\cos\theta_k)$ into the coefficients p_m^m, $p_{m+1}^m, \ldots, p_{N-1}^m$, p_N^m in expansions of functions f^m on $[-1, 1]$ of the form

$$f^m(x) = \sum_{l=m}^{N} p_l^m\, \overline{P}_l^m(x), \tag{2.5}$$

$$p_l^m = \int_{-1}^{1} \overline{P}_l^m(x)\, f^m(x)\, dx, \tag{2.6}$$

where m is any integer with $0 \le m \le N$.

The principal purpose of this paper is the construction of a "fast" scheme for computing the coefficients (2.6) from the values $f^m(\cos\theta_k)$, and for computing the inverse of this transformation, that is, for computing the values $f^m(\cos\theta_k)$ of the function f^m defined in (2.5) from the coefficients (2.6).

For any nonnegative integers l and m with $m \le l$, the associated Legendre function P_l^m on $[-1, 1]$ is defined by the formula

$$P_l^m(x) = (-1)^m \sqrt{1-x^2}^m\, \frac{d^m}{dx^m} P_l(x), \tag{2.7}$$

where P_l is the Legendre polynomial of degree l. Obviously, P_l^m is a polynomial when m is even and a polynomial multiplied by $\sqrt{1-x^2}$ when m is odd.

For any nonnegative integer m, we define the differential operator L_m by the formula

$$L_m(f)(x) = -\frac{d}{dx}\left((1-x^2)\,\frac{d}{dx} f(x)\right) + \frac{m^2}{1-x^2}\, f(x) \tag{2.8}$$

for any function f on $[-1, 1]$ with a continuous second derivative. For any nonnegative integers l and m with $m \le l$, the function $\overline{P}_l^m$ satisfies the differential equation

$$L_m\left(\overline{P}_l^m\right)(x) = l(l+1)\, \overline{P}_l^m(x), \tag{2.9}$$

where the differential operator L_m is defined in (2.8).

For any integers l and m with $0 \le m \le l$ and $l > 0$,

$$(2l+1)\, x\, P_l^m(x) = (l+m)\, P_{l-1}^m(x) + (l-m+1)\, P_{l+1}^m(x). \tag{2.10}$$

For any nonnegative integers l and m with $1 \le m \le l$,

$$\int_{-1}^{1} \overline{P}_l^m(x)\, \frac{1}{1-x^2}\, \overline{P}_l^m(x)\, dx = \frac{2l+1}{2m}. \tag{2.11}$$

LEMMA 2.1. *Suppose that l and m are even integers such that $2 \le m \le l$. Then, there exist $l/2$ real numbers ξ_0, $\xi_1, \ldots, \xi_{l/2-2}$, $\xi_{l/2-1}$ such that*

$$\overline{P}_l^m(x) = \sum_{k=0}^{l/2-1} \xi_k\, \overline{P}_{2k+2}^2(x). \tag{2.12}$$

LEMMA 2.2. *Suppose that l and m are integers such that m is even, l is odd, and $2 \le m < l$. Then, there exist $(l-1)/2$ real numbers ξ_0, $\xi_1, \ldots, \xi_{(l-1)/2-2}$, $\xi_{(l-1)/2-1}$ such that*

$$\overline{P}_l^m(x) = \sum_{k=0}^{(l-1)/2-1} \xi_k\, \overline{P}_{2k+3}^2(x). \tag{2.13}$$

LEMMA 2.3. *Suppose that l and m are integers such that m is odd, l is even, and $1 \le m < l$. Then, there exist $l/2$ real numbers ξ_0, $\xi_1, \ldots, \xi_{l/2-2}$, $\xi_{l/2-1}$ such that*

$$\overline{P}_l^m(x) = \sum_{k=0}^{l/2-1} \xi_k\, \overline{P}_{2k+2}^1(x). \tag{2.14}$$

LEMMA 2.4. *Suppose that l and m are odd integers such that $1 \le m \le l$. Then, there exist $(l+1)/2$ real numbers ξ_0, $\xi_1, \ldots, \xi_{(l+1)/2-2}$, $\xi_{(l+1)/2-1}$ such that*

$$\overline{P}_l^m(x) = \sum_{k=0}^{(l+1)/2-1} \xi_k\, \overline{P}_{2k+1}^1(x). \tag{2.15}$$

2.2. Chebyshev polynomials. In this section, we cite the existence of a fast algorithm for computing with Chebyshev polynomials.

For any nonnegative integer k, we define T_k to be the Chebyshev polynomial of degree k of the first kind, defined by the formula

$$T_k(\cos\theta) = \cos(k\theta) \tag{2.16}$$

for any real θ, and U_k to be the Chebyshev polynomial of degree k of the second kind, defined by the formula

$$U_k(\cos\theta) = \frac{\sin((k+1)\theta)}{\sin\theta} \tag{2.17}$$

for any real θ.

The following observation cites the relationship between the fast Fourier transform and expansions in series of Chebyshev polynomials.

Observation 2.5. Suppose that $N \geq 0$ is an integer, $c_0,\ c_1, \ldots, c_{N-1},\ c_N$ and $u_0,\ u_1, \ldots, u_{N-1},\ u_N$ are real numbers, and f and g are the functions on $[-1,\ 1]$ defined by the formulae

$$f(x) = \sum_{k=0}^{N} c_k\, T_k(x), \tag{2.18}$$

$$g(x) = \sum_{k=0}^{N} u_k \sqrt{1-x^2}\, U_k(x). \tag{2.19}$$

Then, there exists an algorithm which uses $\mathcal{O}(N \log N)$ operations to convert the coefficients $c_0,\ c_1, \ldots, c_{N-1},\ c_N$ into the values $f(x_0),\ f(x_1), \ldots, f(x_{N-1}),\ f(x_N)$, and to convert the coefficients $u_0, u_1, \ldots, u_{N-1}, u_N$ into the values $g(x_0), g(x_1), \ldots, g(x_{N-1}),$ $g(x_N)$, where the sampling locations $x_0, x_1, \ldots, x_{N-1}, x_N$ are defined by the formula

$$x_k = \cos\left(\frac{\pi(k+1/2)}{N+1}\right). \tag{2.20}$$

Moreover, there exists an algorithm which uses $\mathcal{O}(N \log N)$ operations to convert the values $f(x_0),\ f(x_1), \ldots, f(x_{N-1}),\ f(x_N)$ into the coefficients $c_0,\ c_1, \ldots, c_{N-1},\ c_N$, and to convert the values $g(x_0),\ g(x_1), \ldots, g(x_{N-1}),\ g(x_N)$ into the coefficients $u_0,\ u_1, \ldots,$ u_{N-1}, u_N (see, for example, [14]).

2.3. Associated Legendre functions of low orders. In this section, we summarize certain simple relationships between Chebyshev polynomials and associated Legendre functions of orders 1 and 2. These relationships are a straightforward consequence of formulae 7.112.1, 8.339.1, 8.339.2, 8.700.1, 8.752.1, 8.826.1, 8.828.1, 8.832.2, and 8.911.4 of [7].

We define the function Λ on $[0,\ \infty)$ by the formula

$$\Lambda(z) = \frac{\Gamma(z+1/2)}{\Gamma(z+1)}, \tag{2.21}$$

where Γ is the Euler gamma function.

For any integer $n \geq 1$ and $l, k = 0,\ 1, \ldots, n-2,\ n-1$, we define the entry $A^{n,1,+}_{l,k}$ of the $n \times n$ matrix $A^{n,1,+}$ by the formulae

$$A^{n,1,+}_{l,k} = -\frac{4l+3}{2(2k+2l+3)(2k-2l-1)}\, \Lambda\,(k-l)\ \Lambda\left(\frac{2k+2l+1}{2}\right) \times \sqrt{\frac{4(l+1)(2l+1)}{4l+3}} \tag{2.22}$$

when $k \geq l$, and

$$A^{n,1,+}_{l,k} = 0 \tag{2.23}$$

otherwise (when $k < l$).

For any integer $n \geq 1$ and $l, k = 0,\ 1, \ldots, n-2,\ n-1$, we define the entry $A^{n,1,-}_{l,k}$ of the $n \times n$ matrix $A^{n,1,-}$ by the formulae

$$A^{n,1,-}_{l,k} = -\frac{4l+5}{2(2k+2l+5)(2k-2l-1)}\, \Lambda\,(k-l)\ \Lambda\left(\frac{2k+2l+3}{2}\right) \times \sqrt{\frac{4(l+1)(2l+3)}{4l+5}} \tag{2.24}$$

when $k \geq l$, and

$$A^{n,1,-}_{l,k} = 0 \tag{2.25}$$

otherwise (when $k < l$).

For any integer $n \geq 1$ and $k, l = 0, 1, \ldots, n-2, n-1$, we define the entry $B^{n,1,+}_{k,l}$ of the $n \times n$ matrix $B^{n,1,+}$ by the formulae

$$B^{n,1,+}_{k,l} = 2 \, \frac{2k+1}{\pi} \, \Lambda\,(l-k) \, \Lambda\,(l+k+1) \, \sqrt{\frac{4l+3}{4(l+1)(2l+1)}} \tag{2.26}$$

when $k \leq l$, and

$$B^{n,1,+}_{k,l} = 0 \tag{2.27}$$

otherwise (when $k > l$).

For any integer $n \geq 1$ and $k, l = 0, 1, \ldots, n-2, n-1$, we define the entry $B^{n,1,-}_{k,l}$ of the $n \times n$ matrix $B^{n,1,-}$ by the formulae

$$B^{n,1,-}_{k,l} = 4 \, \frac{k+1}{\pi} \, \Lambda\,(l-k) \, \Lambda\,(l+k+2) \, \sqrt{\frac{4l+5}{4(l+1)(2l+3)}} \tag{2.28}$$

when $k \leq l$, and

$$B^{n,1,-}_{k,l} = 0 \tag{2.29}$$

otherwise (when $k > l$).

For any integer $n \geq 1$, $l = 0, 1, \ldots, n-2, n-1$, and $k = 0, 1, \ldots, n-1, n$, we define the entry $A^{n,2,+}_{l,k}$ of the $n \times (n+1)$ matrix $A^{n,2,+}$ by the formulae

$$\begin{aligned} A^{n,2,+}_{l,k} = \Bigg(& 4 + \frac{2k \, (6(l+1)(2l+3) - 2(2k-1)(2k+1))}{(2k+2l+3)(2k-2l-3)} \, \Lambda\,(k-l-1) \\ & \times \Lambda\left(\frac{2k+2l+1}{2}\right) \Bigg) \sqrt{\frac{4l+5}{8(l+1)(l+2)(2l+1)(2l+3)}} \end{aligned} \tag{2.30}$$

when $k \geq l+1$, and

$$A^{n,2,+}_{l,k} = 4 \sqrt{\frac{4l+5}{8(l+1)(l+2)(2l+1)(2l+3)}} \tag{2.31}$$

otherwise (when $k < l+1$).

For any integer $n \geq 1$, $l = 0, 1, \ldots, n-2, n-1$, and $k = 0, 1, \ldots, n-1, n$, we define the entry $A^{n,2,-}_{l,k}$ of the $n \times (n+1)$ matrix $A^{n,2,-}$ by the formulae

$$\begin{aligned} A^{n,2,-}_{l,k} = \Bigg(& 4 + \frac{(2k+1) \, (6(l+2)(2l+3) - 8k(k+1))}{(2k+2l+5)(2k-2l-3)} \, \Lambda\,(k-l-1) \\ & \times \Lambda\left(\frac{2k+2l+3}{2}\right) \Bigg) \sqrt{\frac{4l+7}{8(l+1)(l+2)(2l+3)(2l+5)}} \end{aligned} \tag{2.32}$$

when $k \geq l+1$, and

$$A_{l,k}^{n,2,-} = 4\sqrt{\frac{4l+7}{8(l+1)(l+2)(2l+3)(2l+5)}} \tag{2.33}$$

otherwise (when $k < l+1$).

For any integer $n \geq 1$, $k = 0, 1, \ldots, n-1, n$, and $l = 0, 1, \ldots, n-2, n-1$, we define the entry $B_{k,l}^{n,2,+}$ of the $(n+1) \times n$ matrix $B^{n,2,+}$ by the formulae

$$B_{k,l}^{n,2,+} = \frac{2(l+1)(2l+3) - 8k^2}{\pi} \Lambda(l-k+1)\, \Lambda(l+k+1) \times \sqrt{\frac{4l+5}{8(l+1)(l+2)(2l+1)(2l+3)}} \tag{2.34}$$

when $k = 0$,

$$B_{k,l}^{n,2,+} = 2\,\frac{2(l+1)(2l+3) - 8k^2}{\pi} \Lambda(l-k+1)\, \Lambda(l+k+1) \times \sqrt{\frac{4l+5}{8(l+1)(l+2)(2l+1)(2l+3)}} \tag{2.35}$$

when $0 < k \leq l+1$, and

$$B_{k,l}^{n,2,+} = 0 \tag{2.36}$$

otherwise (when $k > l+1$).

For any integer $n \geq 1$, $k = 0, 1, \ldots, n-1, n$, and $l = 0, 1, \ldots, n-2, n-1$, we define the entry $B_{k,l}^{n,2,-}$ of the $(n+1) \times n$ matrix $B^{n,2,-}$ by the formulae

$$B_{k,l}^{n,2,-} = \frac{4(l+2)(2l+3) - 4(2k+1)^2}{\pi} \Lambda(l-k+1)\, \Lambda(l+k+2) \times \sqrt{\frac{4l+7}{8(l+1)(l+2)(2l+3)(2l+5)}} \tag{2.37}$$

when $k \leq l+1$, and

$$B_{k,l}^{n,2,-} = 0 \tag{2.38}$$

otherwise (when $k > l+1$).

The following four lemmas are proven via mechanical but rather tedious manipulations of formulae 7.112.1, 8.339.1, 8.339.2, 8.700.1, 8.752.1, 8.826.1, 8.828.1, 8.832.2, and 8.911.4 of [7].

The following lemma provides explicit expressions for the matrix $B^{n,1,+}$ converting coefficients in linear combinations of associated Legendre functions of order 1 of odd degrees into coefficients in linear combinations of even Chebyshev polynomials of the second kind, scaled by $\sqrt{1-x^2}$, and for the matrix $A^{n,1,+}$ converting the latter into the former.

LEMMA 2.6. *Suppose that $n \geq 1$ is an integer, $q = (q_0, q_1, \ldots, q_{n-2}, q_{n-1})^{\mathrm{T}}$ is a real vector, and f is the function on $[-1, 1]$ defined by the formula*

$$f(x) = \sum_{l=0}^{n-1} q_l\, \overline{P}_{2l+1}^{1}(x). \tag{2.39}$$

Then,

$$f(x) = \sum_{k=0}^{n-1} u_k \sqrt{1-x^2}\, U_{2k}(x), \tag{2.40}$$

where $u = (u_0, u_1, \ldots, u_{n-2}, u_{n-1})^{\mathrm{T}}$ *is the real vector defined by the formula*

$$u = B^{n,1,+}\, q, \tag{2.41}$$

and $B^{n,1,+}$ *is defined in* (2.21), (2.26), *and* (2.27). *Furthermore,*

$$q = A^{n,1,+}\, u, \tag{2.42}$$

where $A^{n,1,+}$ *is defined in* (2.21), (2.22), *and* (2.23).

The following lemma provides explicit expressions for the matrix $B^{n,1,-}$ converting coefficients in linear combinations of associated Legendre functions of order 1 of even degrees into coefficients in linear combinations of odd Chebyshev polynomials of the second kind, scaled by $\sqrt{1-x^2}$, and for the matrix $A^{n,1,-}$ converting the latter into the former.

LEMMA 2.7. *Suppose that* $n \geq 1$ *is an integer,* $q = (q_0, q_1, \ldots, q_{n-2}, q_{n-1})^{\mathrm{T}}$ *is a real vector, and* f *is the function on* $[-1, 1]$ *defined by the formula*

$$f(x) = \sum_{l=0}^{n-1} q_l\, \overline{P}^{\,1}_{2l+2}(x). \tag{2.43}$$

Then,

$$f(x) = \sum_{k=0}^{n-1} u_k \sqrt{1-x^2}\, U_{2k+1}(x), \tag{2.44}$$

where $u = (u_0, u_1, \ldots, u_{n-2}, u_{n-1})^{\mathrm{T}}$ *is the real vector defined by the formula*

$$u = B^{n,1,-}\, q, \tag{2.45}$$

and $B^{n,1,-}$ *is defined in* (2.21), (2.28), *and* (2.29). *Furthermore,*

$$q = A^{n,1,-}\, u, \tag{2.46}$$

where $A^{n,1,-}$ *is defined in* (2.21), (2.24), *and* (2.25).

The following lemma provides explicit expressions for the matrix $B^{n,2,+}$ converting coefficients in linear combinations of associated Legendre functions of order 2 of even degrees into coefficients in linear combinations of even Chebyshev polynomials of the first kind, and for the matrix $A^{n,2,+}$ converting the latter into the former.

LEMMA 2.8. *Suppose that* $n \geq 1$ *is an integer,* $p = (p_0, p_1, \ldots, p_{n-2}, p_{n-1})^{\mathrm{T}}$ *is a real vector, and* f *is the function on* $[-1, 1]$ *defined by the formula*

$$f(x) = \sum_{l=0}^{n-1} p_l\, \overline{P}^{\,2}_{2l+2}(x). \tag{2.47}$$

Then,

$$f(x) = \sum_{k=0}^{n} c_k\, T_{2k}(x), \tag{2.48}$$

where $c = (c_0, c_1, \ldots, c_{n-1}, c_n)^{\mathrm{T}}$ *is the real vector defined by the formula*

$$c = B^{n,2,+}\, p, \tag{2.49}$$

and $B^{n,2,+}$ *is defined in* (2.21), (2.34), (2.35), *and* (2.36). *Furthermore,*

$$p = A^{n,2,+}\, c, \tag{2.50}$$

where $A^{n,2,+}$ *is defined in* (2.21), (2.30), *and* (2.31).

The following lemma provides explicit expressions for the matrix $B^{n,2,-}$ converting coefficients in linear combinations of associated Legendre functions of order 2 of odd degrees into coefficients in linear combinations of odd Chebyshev polynomials of the first kind, and for the matrix $A^{n,2,-}$ converting the latter into the former.

LEMMA 2.9. *Suppose that* $n \geq 1$ *is an integer,* $p = (p_0, p_1, \ldots, p_{n-2}, p_{n-1})^{\mathrm{T}}$ *is a real vector, and* f *is the function on* $[-1, 1]$ *defined by the formula*

$$f(x) = \sum_{l=0}^{n-1} p_l\, \overline{P}^2_{2l+3}(x). \tag{2.51}$$

Then,

$$f(x) = \sum_{k=0}^{n} c_k\, T_{2k+1}(x), \tag{2.52}$$

where $c = (c_0, c_1, \ldots, c_{n-1}, c_n)^{\mathrm{T}}$ *is the real vector defined by the formula*

$$c = B^{n,2,-}\, p, \tag{2.53}$$

and $B^{n,2,-}$ *is defined in* (2.21), (2.37), *and* (2.38). *Furthermore,*

$$p = A^{n,2,-}\, c, \tag{2.54}$$

where $A^{n,2,-}$ *is defined in* (2.21), (2.32), *and* (2.33).

Observation 2.10. Suppose that $n \geq 1$ is an integer. Then, there exists an algorithm which uses $\mathcal{O}(n \log(n/\varepsilon))$ operations to apply to an arbitrary vector any of the matrices $A^{n,1,+}$, $B^{n,1,+}$, $A^{n,1,-}$, $B^{n,1,-}$, $A^{n,2,+}$, $B^{n,2,+}$, $A^{n,2,-}$, and $B^{n,2,-}$ defined in (2.21)–(2.38), where ε is the precision of computations (see [3]).

2.4. Semiseparable matrices. For any integer $n > 0$, a semiseparable real $n \times n$ matrix S is a matrix whose entry $S_{j,k}$ is given by the formulae

$$S_{j,k} = a_j\, b_k \tag{2.55}$$

when $j \leq k$, and

$$S_{j,k} = a_k\, b_j \tag{2.56}$$

when $j > k$, where $a = (a_0, a_1, \ldots, a_{n-2}, a_{n-1})^{\mathrm{T}}$ and $b = (b_0, b_1, \ldots, b_{n-2}, b_{n-1})^{\mathrm{T}}$ are real vectors.

Matrices of the form

$$G = D + S, \tag{2.57}$$

where D is a diagonal real matrix and S is a semiseparable real matrix, will be encountered repeatedly throughout this paper. The matrix U of eigenvectors of the matrix G in (2.57) will be particularly important; U is orthogonal and diagonalizes G, so that

$$U^{\mathrm{T}} G U = \Lambda, \tag{2.58}$$

where Λ is a diagonal real matrix.

The principal numerical tool of this paper is the following observation, made in [8] and [4].

Observation 2.11. The matrices U and U^{T} in (2.58) can be applied to an arbitrary vector of length N for a cost of $\mathcal{O}(N(\log N)\log(1/\varepsilon))$ operations, where ε is the precision of computations. More precisely, there exists a constant C independent of N, of ε, and of the particular matrix G in (2.58) such that the matrices U and U^{T} can be applied for a cost of at most $C\,N(\log N)\log(1/\varepsilon)$ operations.

Remark 2.12. Strictly speaking, only the numerical apparatus behind Observation 2.11 is constructed in [4]. However, the observation itself is stated explicitly in a very similar environment in [8]. In our implementation, we used a minor modification of the apparatus in [4], to be reported at a later date.

3. Analytical apparatus. In this section, we construct the principal analytical tools used in this paper.

In section 3.1, we observe that when the function $\overline{P}_l^m$ is represented as a linear combination of functions $\overline{P}_j^1$ or $\overline{P}_j^2$ (depending on whether m is even or odd), the Sturm–Liouville problem (2.9) becomes an eigenvector problem for the matrix G in (2.57). Thus, according to Observation 2.11, there exists an algorithm that uses $\mathcal{O}\left(N(\log N)\log(1/\varepsilon)\right)$ operations to apply the matrices U and U^{T} in (2.58) to arbitrary vectors of length N, where ε is the precision of computations.

In section 3.2, we observe that the problem of evaluating expansions of the form (1.12) can be reduced to the problem of evaluating expansions of the forms (1.10) and (1.11), via the matrices U and U^{T} in (2.58). These matrices can be applied to arbitrary vectors efficiently, due to Observation 2.11.

3.1. Associated Legendre differential equations in terms of associated Legendre functions of low orders. For any even integers n and m with $2 \le m \le n$, and for $j, k = 0,\, 1, \ldots, n/2-2,\, n/2-1$, we define the entry $G^{n,m}_{j,k}$ of the $n/2 \times n/2$ matrix $G^{n,m}$ by the formula

$$G^{n,m}_{j,k} = \int_{-1}^{1} \overline{P}^2_{2j+2}(x)\;\; L_m\left(\overline{P}^2_{2k+2}\right)(x)\,dx, \tag{3.1}$$

where the differential operator L_m is defined in (2.8).

For any odd integer n and even integer m with $2 \le m < n$, and for $j, k = 0,\, 1, \ldots, (n-1)/2-2,\, (n-1)/2-1$, we define the entry $G^{n,m}_{j,k}$ of the $(n-1)/2 \times (n-1)/2$ matrix $G^{n,m}$ by the formula

$$G^{n,m}_{j,k} = \int_{-1}^{1} \overline{P}^2_{2j+3}(x)\;\; L_m\left(\overline{P}^2_{2k+3}\right)(x)\,dx, \tag{3.2}$$

where the differential operator L_m is defined in (2.8).

For any even integer n and odd integer m with $1 \le m < n$, and for $j,k = 0, 1, \ldots, n/2-2, n/2-1$, we define the entry $G^{n,m}_{j,k}$ of the $n/2 \times n/2$ matrix $G^{n,m}$ by the formula

$$G^{n,m}_{j,k} = \int_{-1}^{1} \overline{P}^1_{2j+2}(x)\ L_m\left(\overline{P}^1_{2k+2}\right)(x)\,dx, \tag{3.3}$$

where the differential operator L_m is defined in (2.8).

For any odd integers n and m with $1 \le m \le n$, and for $j,k = 0, 1, \ldots, (n+1)/2-2, (n+1)/2-1$, we define the entry $G^{n,m}_{j,k}$ of the $(n+1)/2 \times (n+1)/2$ matrix $G^{n,m}$ by the formula

$$G^{n,m}_{j,k} = \int_{-1}^{1} \overline{P}^1_{2j+1}(x)\ L_m\left(\overline{P}^1_{2k+1}\right)(x)\,dx, \tag{3.4}$$

where the differential operator L_m is defined in (2.8).

The following lemma states that the coefficients in the expansion of the function $\overline{P}^m_l$ in terms of either the functions $\overline{P}^1_j$ or the functions $\overline{P}^2_j$ (depending on whether m is even or odd) are the entries in an eigenvector of the matrix $G^{n,m}$.

LEMMA 3.1. *Suppose that m and n are integers such that $1 \le m \le n$.*

Then, when m and n are both even, $l(l+1)$ is an eigenvalue of the matrix $G^{n,m}$ defined in (3.1)*, for any even integer l with $m \le l \le n$, and the coordinates $\xi_0, \xi_1, \ldots, \xi_{n/2-2}$, $\xi_{n/2-1}$ of the corresponding eigenvector are the coefficients in the expansion*

$$\overline{P}^m_l(x) = \sum_{k=0}^{n/2-1} \xi_k\, \overline{P}^2_{2k+2}(x). \tag{3.5}$$

When m is even and n is odd, $l(l+1)$ is an eigenvalue of the matrix $G^{n,m}$ defined in (3.2)*, for any odd integer l with $m < l \le n$, and the coordinates ξ_0, $\xi_1, \ldots, \xi_{(n-1)/2-2}$, $\xi_{(n-1)/2-1}$ of the corresponding eigenvector are the coefficients in the expansion*

$$\overline{P}^m_l(x) = \sum_{k=0}^{(n-1)/2-1} \xi_k\, \overline{P}^2_{2k+3}(x). \tag{3.6}$$

When m is odd and n is even, $l(l+1)$ is an eigenvalue of the matrix $G^{n,m}$ defined in (3.3)*, for any even integer l with $m < l \le n$, and the coordinates ξ_0, $\xi_1, \ldots, \xi_{n/2-2}$, $\xi_{n/2-1}$ of the corresponding eigenvector are the coefficients in the expansion*

$$\overline{P}^m_l(x) = \sum_{k=0}^{n/2-1} \xi_k\, \overline{P}^1_{2k+2}(x). \tag{3.7}$$

When m and n are both odd, $l(l+1)$ is an eigenvalue of the matrix $G^{n,m}$ defined in (3.4)*, for any odd integer l with $m \le l \le n$, and the coordinates ξ_0, $\xi_1, \ldots, \xi_{(n+1)/2-2}$, $\xi_{(n+1)/2-1}$ of the corresponding eigenvector are the coefficients in the expansion*

$$\overline{P}^m_l(x) = \sum_{k=0}^{(n+1)/2-1} \xi_k\, \overline{P}^1_{2k+1}(x). \tag{3.8}$$

Proof. We outline the proof in the case that m and n are both even; the proofs in the other three cases are similar.

Substituting (2.12) into (2.9) and using (1.2) and (1.5), we obtain from (3.1) that the numbers $\xi_0, \xi_1, \ldots, \xi_{l/2-2}, \xi_{l/2-1}$ from (2.12), along with the numbers $\xi_{l/2} = 0$, $\xi_{l/2+1} = 0, \ldots, \xi_{n/2-2} = 0$, $\xi_{n/2-1} = 0$ when $l < n$, are the coordinates of the eigenvector of $G^{n,m}$ with corresponding eigenvalue $l(l+1)$, giving (3.5). ∎

The following lemma states that $G^{n,m}$ is the sum of a diagonal matrix and a semiseparable matrix and provides expressions for the entries of $G^{n,m}$.

LEMMA 3.2. *Suppose that m and n are integers such that $1 \leq m \leq n$.*

Then, the matrix $G^{n,m}$ defined in (3.1)–(3.4) *has the form*

$$G^{n,m} = D + S, \tag{3.9}$$

where D is a diagonal matrix and S is a semiseparable matrix.

When m and n are both even, D is the diagonal $n/2 \times n/2$ matrix with the diagonal entries $D_{0,0}$, $D_{1,1}, \ldots, D_{n/2-2,n/2-2}$, $D_{n/2-1,n/2-1}$ defined by the formula

$$D_{k,k} = (2k+2)(2k+3), \tag{3.10}$$

and S is the semiseparable $n/2 \times n/2$ matrix with the entry $S_{j,k}$ defined by the formulae

$$S_{j,k} = a_j \, b_k \tag{3.11}$$

when $j \leq k$, and

$$S_{j,k} = a_k \, b_j \tag{3.12}$$

otherwise (when $j > k$), where the numbers a_0, $a_1, \ldots, a_{n/2-2}$, $a_{n/2-1}$ and b_0, $b_1, \ldots, b_{n/2-2}, b_{n/2-1}$ are defined by the formulae

$$a_k = \sqrt{\frac{(2k+1)(2k+2)(2k+3)(2k+4)(4k+5)}{8 \cdot 15}}, \tag{3.13}$$

$$b_k = (m^2 - 4) \sqrt{\frac{15(4k+5)}{2(2k+1)(2k+2)(2k+3)(2k+4)}}. \tag{3.14}$$

When m is even and n is odd, D is the diagonal $(n-1)/2 \times (n-1)/2$ matrix with the diagonal entries $D_{0,0}, D_{1,1}, \ldots, D_{(n-1)/2-2,(n-1)/2-2}$, $D_{(n-1)/2-1,(n-1)/2-1}$ defined by the formula

$$D_{k,k} = (2k+3)(2k+4), \tag{3.15}$$

and S is the semiseparable $(n-1)/2 \times (n-1)/2$ matrix with the entry $S_{j,k}$ defined by the formulae

$$S_{j,k} = a_j \, b_k \tag{3.16}$$

when $j \leq k$, and

$$S_{j,k} = a_k \, b_j \tag{3.17}$$

otherwise (when $j > k$), where the numbers a_0, $a_1, \ldots, a_{(n-1)/2-2}$, $a_{(n-1)/2-1}$ and b_0, $b_1, \ldots, b_{(n-1)/2-2}, b_{(n-1)/2-1}$ are defined by the formulae

$$a_k = \sqrt{\frac{(2k+2)(2k+3)(2k+4)(2k+5)(4k+7)}{14 \cdot 15}}, \tag{3.18}$$

$$b_k = (m^2-4)\sqrt{\frac{7 \cdot 15(4k+7)}{8(2k+2)(2k+3)(2k+4)(2k+5)}}. \tag{3.19}$$

When m is odd and n is even, D is the diagonal $n/2 \times n/2$ matrix with the diagonal entries $D_{0,0}, D_{1,1}, \ldots, D_{n/2-2,n/2-2}, D_{n/2-1,n/2-1}$ defined by the formula

$$D_{k,k} = (2k+2)(2k+3), \tag{3.20}$$

and S is the semiseparable $n/2 \times n/2$ matrix with the entry $S_{j,k}$ defined by the formulae

$$S_{j,k} = a_j\, b_k \tag{3.21}$$

when $j \leq k$, and

$$S_{j,k} = a_k\, b_j \tag{3.22}$$

otherwise (when $j > k$), where the numbers a_0, $a_1, \ldots, a_{n/2-2}, a_{n/2-1}$ and b_0, $b_1, \ldots, b_{n/2-2}, b_{n/2-1}$ are defined by the formulae

$$a_k = \sqrt{\frac{(2k+2)(2k+3)(4k+5)}{30}}, \tag{3.23}$$

$$b_k = (m^2-1)\sqrt{\frac{15(4k+5)}{2(2k+2)(2k+3)}}. \tag{3.24}$$

When m and n are both odd, D is the diagonal $(n+1)/2 \times (n+1)/2$ matrix with the diagonal entries $D_{0,0}$, $D_{1,1}, \ldots, D_{(n+1)/2-2,(n+1)/2-2}$, $D_{(n+1)/2-1,(n+1)/2-1}$ defined by the formula

$$D_{k,k} = (2k+1)(2k+2), \tag{3.25}$$

and S is the semiseparable $(n+1)/2 \times (n+1)/2$ matrix with the entry $S_{j,k}$ defined by the formulae

$$S_{j,k} = a_j\, b_k \tag{3.26}$$

when $j \leq k$, and

$$S_{j,k} = a_k\, b_j \tag{3.27}$$

otherwise (when $j > k$), where the numbers a_0, $a_1, \ldots, a_{(n+1)/2-2}$, $a_{(n+1)/2-1}$ and b_0, $b_1, \ldots, b_{(n+1)/2-2}$, $b_{(n+1)/2-1}$ are defined by the formulae

$$a_k = \sqrt{\frac{(2k+1)(2k+2)(4k+3)}{6}}, \tag{3.28}$$

$$b_k = (m^2 - 1) \sqrt{\frac{3(4k+3)}{2(2k+1)(2k+2)}}. \tag{3.29}$$

Proof. We outline the proof in the case that m and n are both even; the proofs in the other three cases are similar.

We define the entry $D_{j,k}$ of the $n/2 \times n/2$ matrix D by the formula

$$D_{j,k} = \int_{-1}^{1} \overline{P}^2_{2j+2}(x) \;\; L_2 \left(\overline{P}^2_{2k+2} \right)(x) \, dx, \tag{3.30}$$

where the differential operator L_2 is defined in (2.8), and we define the entry $S_{j,k}$ of the $n/2 \times n/2$ matrix S by the formula

$$S_{j,k} = \int_{-1}^{1} \overline{P}^2_{2j+2}(x) \, \frac{m^2 - 4}{1 - x^2} \, \overline{P}^2_{2k+2}(x) \, dx. \tag{3.31}$$

We now show that $G^{n,m} = D + S$, D is diagonal, and S is semiseparable.

Combining (3.1), (3.30), (3.31), and (2.8), we obtain the decomposition (3.9).

Substituting (2.9) into (3.30), and using (1.2) and (1.5), we observe that the matrix D is diagonal with the diagonal entries given by (3.10).

In order to obtain the formulae (3.11)–(3.14), we define the entry $M_{j,k}$ of the infinite-dimensional matrix M, for $j, k = 0, 1, 2, \ldots$, by the formula

$$M_{j,k} = \int_{-1}^{1} \overline{P}^2_{2j+2}(x) \, \frac{m^2 - 4}{1 - x^2} \, \overline{P}^2_{2k+2}(x) \, dx \tag{3.32}$$

and observe that the entry $(M^{-1})_{j,k}$ of the inverse M^{-1} of the matrix M is given by the formula

$$(M^{-1})_{j,k} = \int_{-1}^{1} \overline{P}^2_{2j+2}(x) \, \frac{1 - x^2}{m^2 - 4} \, \overline{P}^2_{2k+2}(x) \, dx, \tag{3.33}$$

since M represents the operator acting on functions on $[-1, 1]$ by multiplication by the factor

$$\frac{m^2 - 4}{1 - x^2}, \tag{3.34}$$

whereas M^{-1} represents the operator acting on functions on $[-1, 1]$ by multiplication by the inverse factor

$$\frac{1 - x^2}{m^2 - 4}. \tag{3.35}$$

Using (1.2), (1.5), (2.10), and (3.33), we observe that M^{-1} is tridiagonal. So, M is the inverse of a tridiagonal matrix, and, as such, M is semiseparable (see, for example, [6]). But, for $j, k = 0, 1, \ldots, n/2 - 2, n/2 - 1$, (3.31) and (3.32) show that $S_{j,k} = M_{j,k}$, so that S is also semiseparable.

Integrating by parts a few times, while using (1.2), (1.5), and (2.7), together with the definition (3.31), yields explicit expressions for the uppermost entries $S_{0,0}, S_{0,1}, \ldots, S_{0,n/2-2}, S_{0,n/2-1}$ of S. Combining (1.2), (1.5), (2.11), and (3.31) yields explicit expressions for the diagonal entries $S_{0,0}, S_{1,1}, \ldots, S_{n/2-2,n/2-2}, S_{n/2-1,n/2-1}$ of S. Combining all of these explicit expressions with the fact that S is semiseparable, we obtain the formulae (3.11)–(3.14). ∎

3.2. Associated Legendre expansions of arbitrary orders and associated Legendre expansions of low orders. Lemmas 3.3, 3.4, 3.5, and 3.6 of this section follow immediately from Lemma 3.1.

Lemma 3.3 states that the matrix of eigenvectors of the matrix $G^{n,m}$ in (3.9) converts the coefficients in the expansion of a function f in terms of the functions $\overline{P}_m^m, \overline{P}_{m+2}^m, \ldots, \overline{P}_{n-2}^m, \overline{P}_n^m$ into the coefficients in the expansion of the function f in terms of the functions $\overline{P}_2^2, \overline{P}_4^2, \ldots, \overline{P}_{n-2}^2, \overline{P}_n^2$. Lemma 3.3 states, moreover, that the adjoint of the matrix of eigenvectors converts the latter coefficients into the former coefficients.

LEMMA 3.3. *Suppose that n and m are even integers such that $2 \le m \le n$, $p^m = (p_0^m, p_1^m, \ldots, p_{n/2-2}^m, p_{n/2-1}^m)^{\mathrm{T}}$ is a real column vector such that $p_{(n-m)/2+1}^m = 0, p_{(n-m)/2+2}^m = 0, \ldots, p_{n/2-2}^m = 0$, $p_{n/2-1}^m = 0$, and f is the function defined on $[-1, 1]$ by the formula*

$$f(x) = \sum_{j=0}^{(n-m)/2} p_j^m \, \overline{P}_{2j+m}^m(x). \tag{3.36}$$

Then,

$$f(x) = \sum_{l=0}^{n/2-1} p_l^2 \, \overline{P}_{2l+2}^2(x), \tag{3.37}$$

where $p^2 = (p_0^2, p_1^2, \ldots, p_{n/2-2}^2, p_{n/2-1}^2)^{\mathrm{T}}$ is the real vector defined by the formula

$$p^2 = U \, p^m, \tag{3.38}$$

and U is an $n/2 \times n/2$ matrix of eigenvectors of the symmetric matrix $G^{n,m}$ in (3.9) with

$$\overline{P}_{2j+m}^m(x) = \sum_{l=0}^{n/2-1} U_{l,j} \, \overline{P}_{2l+2}^2(x) \tag{3.39}$$

for $j = 0, 1, \ldots, (n-m)/2 - 1, (n-m)/2$. Moreover,

$$p^m = U^{\mathrm{T}} \, p^2. \tag{3.40}$$

Lemmas 3.4, 3.5, and 3.6 are analogues of Lemma 3.3 for different conditions on m and n.

LEMMA 3.4. *Suppose that n and m are integers such that m is even, n is odd, $2 \le m < n$, $p^m = (p_0^m, p_1^m, \ldots, p_{(n-5)/2}^m, p_{(n-3)/2}^m)^{\mathrm{T}}$ is a real column vector such that $p_{(n-m+1)/2}^m = 0$, $p_{(n-m+3)/2}^m = 0, \ldots, p_{(n-5)/2}^m = 0$, $p_{(n-3)/2}^m = 0$, and f is the function defined on $[-1, 1]$ by the formula*

$$f(x) = \sum_{j=0}^{(n-m-1)/2} p_j^m \, \overline{P}_{2j+m+1}^m(x). \tag{3.41}$$

Then,

$$f(x) = \sum_{l=0}^{(n-3)/2} p_l^2 \, \overline{P}_{2l+3}^2(x), \tag{3.42}$$

where $p^2 = (p^2_0, p^2_1, \ldots, p^2_{(n-5)/2}, p^2_{(n-3)/2})^{\mathrm{T}}$ *is the real vector defined by the formula*

$$p^2 = U\, p^m, \tag{3.43}$$

and U *is an* $(n-1)/2 \times (n-1)/2$ *matrix of eigenvectors of the symmetric matrix* $G^{n,m}$ *in* (3.9) *with*

$$\overline{P}^m_{2j+m+1}(x) = \sum_{l=0}^{(n-3)/2} U_{l,j}\, \overline{P}^2_{2l+3}(x) \tag{3.44}$$

for $j = 0, 1, \ldots, (n-m-3)/2, (n-m-1)/2$. *Moreover,*

$$p^m = U^{\mathrm{T}}\, p^2. \tag{3.45}$$

LEMMA 3.5. *Suppose that* n *and* m *are integers such that* m *is odd,* n *is even,* $1 \le m < n$, $p^m = (p^m_0, p^m_1, \ldots, p^m_{n/2-2}, p^m_{n/2-1})^{\mathrm{T}}$ *is a real column vector such that* $p^m_{(n-m+1)/2} = 0$, $p^m_{(n-m+3)/2} = 0, \ldots, p^m_{n/2-2} = 0$, $p^m_{n/2-1} = 0$, *and* f *is the function defined on* $[-1, 1]$ *by the formula*

$$f(x) = \sum_{j=0}^{(n-m-1)/2} p^m_j\, \overline{P}^m_{2j+m+1}(x). \tag{3.46}$$

Then,

$$f(x) = \sum_{l=0}^{n/2-1} p^1_l\, \overline{P}^1_{2l+2}(x), \tag{3.47}$$

where $p^1 = (p^1_0, p^1_1, \ldots, p^1_{n/2-2}, p^1_{n/2-1})^{\mathrm{T}}$ *is the real vector defined by the formula*

$$p^1 = U\, p^m, \tag{3.48}$$

and U *is an* $n/2 \times n/2$ *matrix of eigenvectors of the symmetric matrix* $G^{n,m}$ *in* (3.9) *with*

$$\overline{P}^m_{2j+m+1}(x) = \sum_{l=0}^{n/2-1} U_{l,j}\, \overline{P}^1_{2l+2}(x) \tag{3.49}$$

for $j = 0, 1, \ldots, (n-m-3)/2, (n-m-1)/2$. *Moreover,*

$$p^m = U^{\mathrm{T}}\, p^1. \tag{3.50}$$

LEMMA 3.6. *Suppose that* n *and* m *are odd integers such that* $1 \le m \le n$, $p^m = (p^m_0, p^m_1, \ldots, p^m_{(n-3)/2}, p^m_{(n-1)/2})^{\mathrm{T}}$ *is a real column vector such that* $p^m_{(n-m)/2+1} = 0$, $p^m_{(n-m)/2+2} = 0, \ldots, p^m_{(n-3)/2} = 0$, $p^m_{(n-1)/2} = 0$, *and* f *is the function defined on* $[-1, 1]$ *by the formula*

$$f(x) = \sum_{j=0}^{(n-m)/2} p^m_j\, \overline{P}^m_{2j+m}(x). \tag{3.51}$$

Then,

$$f(x) = \sum_{l=0}^{(n-1)/2} p_l^1 \, \overline{P}_{2l+1}^1(x), \tag{3.52}$$

where $p^1 = (p_0^1, p_1^1, \ldots, p_{(n-3)/2}^1, p_{(n-1)/2}^1)^{\mathrm{T}}$ *is the real vector defined by the formula*

$$p^1 = U \, p^m, \tag{3.53}$$

and U *is an* $(n+1)/2 \times (n+1)/2$ *matrix of eigenvectors of the symmetric matrix* $G^{n,m}$ *in* (3.9) *with*

$$\overline{P}_{2j+m}^m(x) = \sum_{l=0}^{(n-1)/2} U_{l,j} \, \overline{P}_{2l+1}^1(x) \tag{3.54}$$

for $j = 0, 1, \ldots, (n-m)/2 - 1, (n-m)/2$. *Moreover,*

$$p^m = U^{\mathrm{T}} \, p^1. \tag{3.55}$$

4. Informal description of the algorithm. In this section, we outline a "fast" algorithm for the conversion of the values $f_0, f_1, \ldots, f_{N-1}, f_N$ of the function f tabulated at the nodes $x_0, x_1, \ldots, x_{N-1}, x_N$, defined by the formula

$$x_k = \cos\left(\frac{\pi(k+1/2)}{N+1}\right), \tag{4.1}$$

into the coefficients $p_0, p_1, \ldots, p_{N-m-1}, p_{N-m}$ in the expansion

$$f(x) = \sum_{l=0}^{N-m} p_l \, \overline{P}_{l+m}^m(x). \tag{4.2}$$

(The inverse procedure of converting the coefficients $p_0, p_1, \ldots, p_{N-m-1}, p_{N-m}$ into the values $f_0, f_1, \ldots, f_{N-1}, f_N$ is quite similar, so we omit its description.)

The procedure consists of four steps, described briefly below. Since the procedure when m is odd is virtually the same as when m is even, we describe the procedure only for the case that m is even. For definitiveness, we assume also that N is even.

Step 1. We separate f into its even and odd parts f^+ and f^-, defined by the formulae

$$f^+(x) = \frac{f(x) + f(-x)}{\sqrt{2}}, \tag{4.3}$$

$$f^-(x) = \frac{f(x) - f(-x)}{\sqrt{2}}. \tag{4.4}$$

All subsequent processing is performed separately for f^+ and f^-. Since the procedures for f^+ and f^- are virtually identical, we describe only the procedure for the even part f^+.

Step 2. Using the fast Fourier transform as in Observation 2.5, we convert the values $f_0^+, f_1^+, \ldots, f_{N-1}^+, f_N^+$ of the function f^+, defined in (4.3), at the points $x_0, x_1,$

$\ldots$, x_{N-1}, x_N, defined in (4.1), into the coefficients c_0, $c_1, \ldots, c_{N/2-1}$, $c_{N/2}$ in the expansion

$$f^+(x) = \sum_{k=0}^{N/2} c_k \, T_{2k}(x). \tag{4.5}$$

Step 3. Using Lemma 2.8 and Observation 2.10, we convert the coefficients c_0, $c_1, \ldots, c_{N/2-1}$, $c_{N/2}$ in the expansion (4.5) into the coefficients p_0^2, $p_1^2, \ldots, p_{N/2-2}^2$, $p_{N/2-1}^2$ in the expansion

$$f^+(x) = \sum_{l=0}^{N/2-1} p_l^2 \, \overline{P}_{2l+2}^2(x). \tag{4.6}$$

Step 4. Using Lemmas 3.2 and 3.3 and Observation 2.11, we convert the coefficients p_0^2, p_1^2, $\ldots$, $p_{N/2-2}^2$, $p_{N/2-1}^2$ in the expansion (4.6) into the coefficients p_0^m, p_1^m, $\ldots$, $p_{(N-m)/2-1}^m$, $p_{(N-m)/2}^m$ in the expansion

$$f^+(x) = \sum_{l=0}^{(N-m)/2} p_l^m \, \overline{P}_{2l+m}^m(x). \tag{4.7}$$

Remark 4.1. Clearly, Step 1 takes $\mathcal{O}(N)$ operations. As per Observation 2.5, Step 2 takes $\mathcal{O}(N \log N)$ operations. As per Observation 2.10, Step 3 takes $\mathcal{O}(N \log(N/\varepsilon))$ operations, where ε is the precision of computations. As per Observation 2.11, Step 4 takes $\mathcal{O}(N(\log N)\log(1/\varepsilon))$ operations, where ε is the precision of computations used in this step. All together, Steps 1–4 take $\mathcal{O}(N(\log N)\log(1/\varepsilon))$ operations.

Remark 4.2. To handle f^- when m is even, we substitute Lemma 2.9 for Lemma 2.8 in Step 3 and Lemma 3.4 for Lemma 3.3 in Step 4. For f^- when m is even, we find that $p_{N/2-1}^2 = 0$ and $c_{N/2} = 0$, since, when m is even, f^- is a linear combination of only $N/2-1$ functions $\overline{P}_3^2$, $\overline{P}_5^2, \ldots, \overline{P}_{N-3}^2$, $\overline{P}_{N-1}^2$ (or, equivalently, of the $N/2$ Chebyshev polynomials of the first kind T_1, $T_3, \ldots, T_{N-3}$, T_{N-1}).

To handle f^+ when m is odd, we substitute Lemma 2.6 for Lemma 2.8 in Step 3 and Lemma 3.6 for Lemma 3.3 in Step 4.

To handle f^- when m is odd, we substitute Lemma 2.7 for Lemma 2.8 in Step 3 and Lemma 3.5 for Lemma 3.3 in Step 4.

When computing the coefficients (2.1) in the spherical harmonic expansion (1.6), we tabulate the function f on $[-1, 1]$ at the same $N+1$ sampling locations x_0, $x_1, \ldots,$ x_{N-1}, x_N when m is odd as when m is even, even though when m is odd, f is a linear combination of only N functions $\overline{P}_1^1$, $\overline{P}_2^1, \ldots,$ $\overline{P}_{N-1}^1$, $\overline{P}_N^1$ (or, equivalently, of the N Chebyshev polynomials of the second kind $\sqrt{1-x^2}\,U_0$, $\sqrt{1-x^2}\,U_1, \ldots,$ $\sqrt{1-x^2}\,U_{N-2}$, $\sqrt{1-x^2}\,U_{N-1}$, which are scaled by $\sqrt{1-x^2}$).

5. Detailed description of the algorithm. In this section, we describe in detail the algorithm described informally in section 4.

PRECOMPUTATIONS.

COMMENT [Compute all the data that Steps 3 and 4 require that do not depend on f.]

Compute all the data that Step 3 requires to apply fast the matrix $A^{N/2,2,+}$ from Lemma 2.8 (i.e., "compress" the matrix $A^{N/2,2,+}$).

Compute all the data that Step 4 requires to apply fast the adjoint of the matrix U from Lemmas 3.2 and 3.3 (i.e., "compress" the matrix U^{T}).

STEP 1.

COMMENT [Convert the values f_0, $f_1, \ldots, f_{N-1}$, f_N into the values f_0^+, $f_1^+, \ldots,$ f_{N-1}^+, f_N^+.]
do $n = 0, \ldots, N$
Set $f_n^+ = (f_n + f_{N-n})/\sqrt{2}$.
enddo

STEP 2.

COMMENT [Convert the values $f_0^+, f_1^+, \ldots, f_{N-1}^+, f_N^+$ into the coefficients $c_0, c_1, \ldots,$ $c_{N/2-1}, c_{N/2}$ of the Chebyshev polynomials $T_0, T_2, \ldots, T_{N-2}, T_N$.]
Use the discrete cosine transform (see, for example, [14]) to convert the values $f_0^+, f_1^+, \ldots, f_{N-1}^+, f_N^+$ into the coefficients $c_0, c_1, \ldots, c_{N/2-1}, c_{N/2}$.

STEP 3.

COMMENT [Convert the coefficients $c_0, c_1, \ldots, c_{N/2-1}, c_{N/2}$ of the Chebyshev polynomials $T_0, T_2, \ldots, T_{N-2}, T_N$ into the coefficients $p_0^2, p_1^2, \ldots, p_{N/2-2}^2, p_{N/2-1}^2$ of the associated Legendre functions $\overline{P}_2^2, \overline{P}_4^2, \ldots, \overline{P}_{N-2}^2, \overline{P}_N^2$.]
Use Observation 2.10 to apply the matrix $A^{N/2,2,+}$ from Lemma 2.8 to the vector $c = (c_0, c_1, \ldots, c_{N/2-1}, c_{N/2})^{\mathrm{T}}$, in order to obtain the vector $p^2 = (p_0^2, p_1^2, \ldots, p_{N/2-2}^2, p_{N/2-1}^2)^{\mathrm{T}}$.

STEP 4.

COMMENT [Convert the coefficients $p_0^2, p_1^2, \ldots, p_{N/2-2}^2, p_{N/2-1}^2$ of the associated Legendre functions $\overline{P}_2^2, \overline{P}_4^2, \ldots, \overline{P}_{N-2}^2, \overline{P}_N^2$ of order 2 into the coefficients $p_0^m, p_1^m, \ldots, p_{(N-m)/2-1}^m, p_{(N-m)/2}^m$ of the associated Legendre functions $\overline{P}_m^m, \overline{P}_{m+2}^m, \ldots, \overline{P}_{N-2}^m, \overline{P}_N^m$.]
Use Observation 2.11 to apply the adjoint of the matrix U from Lemmas 3.2 and 3.3 to the vector $p^2 = (p_0^2, p_1^2, \ldots, p_{N/2-2}^2, p_{N/2-1}^2)^{\mathrm{T}}$, in order to obtain the vector $p^m = (p_0^m, p_1^m, \ldots, p_{N/2-2}^m, p_{N/2-1}^m)^{\mathrm{T}}$.

COMMENT [Only the first $(N-m)/2+1$ entries of p^m interest us; the other entries vanish: $p_{(N-m)/2+1}^m = 0$, $p_{(N-m)/2+2}^m = 0, \ldots, p_{N/2-2}^m = 0$, $p_{N/2-1}^m = 0$.]

6. Numerical results. The algorithms described in this paper have been implemented in Fortran. Tables 1–8 report the results of applying the algorithm to functions f defined on $[-1, 1]$ by the formulae

$$f(x) = \sum_{l=0}^{(N-m)/2} \varepsilon_l \, \overline{P}_{2l+m}^m(x) \tag{6.1}$$

when m is even and degrees are even,

$$f(x) = \sum_{l=0}^{(N-m-2)/2} \varepsilon_l \, \overline{P}_{2l+m+1}^m(x) \tag{6.2}$$

when m is even and degrees are odd,

$$f(x) = \sum_{l=0}^{(N-m-1)/2} \varepsilon_l \, \overline{P}_{2l+m+1}^m(x) \tag{6.3}$$

when m is odd and degrees are even, and

$$f(x) = \sum_{l=0}^{(N-m-1)/2} \varepsilon_l \, \overline{P}_{2l+m}^{m}(x) \tag{6.4}$$

when m is odd and degrees are odd; ε_0, ε_1, ε_2, ... are randomly generated numbers in the interval $[-1, 1]$. The decomposition algorithm computes from the sample values of f the coefficients in the representation of f as a linear combination of the functions $\overline{P}_m^m$, $\overline{P}_{m+1}^m$, ..., $\overline{P}_{N-1}^m$, $\overline{P}_N^m$; the reconstruction algorithm computes the sample values of f from the coefficients in the representation of f as a linear combination of the functions $\overline{P}_m^m$, $\overline{P}_{m+1}^m$, ..., $\overline{P}_{N-1}^m$, $\overline{P}_N^m$. The CPU times are in seconds. The errors are relative root-mean-square errors.

The columns labeled "'fast' transformation" list the times taken by the algorithm to evaluate one sum of the form (6.1), (6.2), (6.3), or (6.4).

The columns labeled "third of applying an $\frac{N}{2} \times \frac{N}{2}$ matrix" list the times, divided by 3, taken to apply an $\frac{N}{2} \times \frac{N}{2}$ matrix once to a vector of length $\frac{N}{2}$. These times scale quadratically with N; the figures in parentheses are estimates used when the memory required by direct calculations would be excessive.

Remark 6.1. The columns labeled "third of applying an $\frac{N}{2} \times \frac{N}{2}$ matrix" give some indication of how much time current implementations of the decompositions and reconstructions take to run; these times are believed to be reasonable estimates of how a standard package like Spherepack (see [2], [18]) would perform, using the "semi-naive" algorithm described in [10], for example. Clearly, for sufficiently small N, the "slow" implementation would actually run faster than the "fast" implementation.

The code was compiled with the Lahey–Fujitsu compiler, with optimization flag `--o2`, and run on a 2.8 GHz Intel Pentium Xeon microprocessor with 512 KB of L2 cache.

No effort was made to optimize the precomputations. To simplify the implementation, precomputations that take $\mathcal{O}(N^2)$ operations were used, even though the techniques described in [4] lead naturally to precomputations that would take only $\mathcal{O}(N \log N)$ operations. The precomputations were run to yield approximately 6 digits of accuracy, running all computations (including the precomputations) in double precision arithmetic.

Observation 6.2. Asymptotically, the algorithm should require a number of operations proportional to $N(\log N) \log(1/\varepsilon)$ to evaluate one sum of the form (6.1), (6.2), (6.3), or (6.4), where $\varepsilon \approx 10^{-6}$. The times in the columns labeled "'fast' transformation" appear to be consistent with this estimate. The algorithm appears to break even with standard matrix multiplication methods for computing spherical harmonic expansions between $N = 4096$ and $N = 8192$; however, no serious effort has been made to optimize our implementation.

7. Generalizations. The algorithm of this paper admits a number of generalizations and extensions. The following list is not intended to be exhaustive; subjects in it are under investigation, and these investigations will be reported at a later date.

1. *Different discretizations of* S^2. Throughout this paper, we have assumed that the meridians on S^2 are discretized in an equispaced manner, i.e., that the points θ_0, $\theta_1, \ldots, \theta_{N-1}$, θ_N subdivide the interval $[0, \pi]$ into equal subintervals. This limitation is easily removed via techniques described in [11], [19], and [5]; however, to maintain numerical stability, the nodes have to satisfy certain quite restrictive criteria. One important collection of nodes that does in fact lead to stable algorithms is given

by the formula

$$\theta_k = \cos^{-1}(x_k), \tag{7.1}$$

where x_0, $x_1, \ldots, x_{N-1}$, x_N are Gaussian nodes on the interval $[-1, 1]$ (see, for example, [2]).

Furthermore, the nodes φ_0, $\varphi_1, \ldots, \varphi_{2N-1}$, φ_{2N} in the discretizations of the parallels on S^2 do not have to be equispaced, provided some form of nonequispaced fast Fourier transform is used; again, numerical stability requires that φ_0, $\varphi_1, \ldots, \varphi_{2N-1}, \varphi_{2N}$ be fairly close to being equispaced.

2. *Associated Laguerre functions.* Associated Laguerre functions are defined on the entire half-line $[0, \infty)$, but are very small outside of a finite interval. The Sturm–Liouville problem that generates the associated Laguerre functions becomes an eigenvector problem for the sum of a diagonal matrix and a semiseparable matrix when discretized using associated Laguerre functions of low orders (very much like the associated Legendre functions).

3. *Prolate spheroidal wave functions.* The Sturm–Liouville problem that generates the prolate spheroidal wave functions becomes an eigenvector problem for a tridiagonal matrix when discretized using Legendre polynomials.

4. *Associated prolate spheroidal wave functions.* The Sturm–Liouville problem that generates the associated prolate spheroidal wave functions becomes an eigenvector problem for the sum of a tridiagonal matrix and a semiseparable matrix when discretized using associated Legendre functions of low orders.

Acknowledgments. The authors would like to thank R. R. Coifman for many useful and inspiring discussions, and P. N. Swarztrauber, M. J. Mohlenkamp, and the referees for several suggestions that have improved the exposition.

SENSITIVITY ANALYSIS OF ODEs/DAEs USING THE TAYLOR SERIES METHOD*

ROBERTO BARRIO†

Abstract. This paper studies the applicability of the Taylor method for the sensibility analysis of ODEs and DAEs. Extended automatic differentiation rules are introduced for the calculus of partial derivatives of Taylor series. The numerical method is implemented using an efficient variable-step variable-order scheme. Finally, some numerical tests are presented showing the benefits of the formulation.

Key words. Taylor method, sensitivity analysis, automatic differentiation, partial derivatives

AMS subject classifications. 65L05, 65L80, 41A58

DOI. 10.1137/030601892

1. Introduction.

In recent years the sensitivity analysis of ordinary differential equations (ODEs) [16, 27, 42] and differential-algebraic equations (DAEs) [8, 9, 11, 17, 31] has attracted much research. The principal motivation comes from mathematical models used to investigate physical phenomena where some parameters may not be accurately known, and, therefore, sensitivity analysis becomes a useful tool. One important need for sensitivities is in parameter identification where we would like to use a Newton-type method to adjust parameters so that a function fits some data set.

Another important field where sensitivity analysis plays a very important role is in dynamical systems [12, 21, 29]. For example, periodic orbits, the Lyapunov exponents, chaos indicators, and bifurcation analysis are fundamental objects for the complete study of a dynamical system, and they require computation of the sensitivities with respect to the initial conditions of the problem. In [12, 21, 29] the numerical integration of the dynamical systems is done by using the Taylor method, but the sensitivities are obtained by means of the numerical integration of the variational equations or by a link with an external software for automatic differentiation (AD). In this paper we extend the Taylor method in such a way that the explicit construction of the variational equations is not needed. On the other hand, Taylor methods are also used in the validated solutions of ODEs/DAEs by means of interval analysis [26, 35], and a validated solution of first-order sensitivity equations (variational equations) has been recently studied in [43]. The approach presented in this paper, which directly uses Taylor methods, may simplify the validated solution of the sensitivity equations of any order.

The plan of the paper is as follows. Section 2 reviews the Taylor method for ODEs and DAEs. Section 3 introduces the sensitivity analysis problem. Section 4 describes the generation of the Taylor coefficients of the partial derivatives of a function. Finally, section 5 presents several numerical tests and an application to a chaos indicator that confirm the promise of the present approach.

2. Taylor methods for ODEs/DAEs. The Taylor method is one of the oldest numerical methods for solving ODEs. Let us consider the initial value problem

$$\frac{d\boldsymbol{y}(t)}{dt} = \boldsymbol{f}(t, \boldsymbol{y}(t)), \quad \boldsymbol{y}(t_0) = \boldsymbol{y}_0, \quad \boldsymbol{y} \in \mathbb{R}^s,\ t \in \mathbb{R}.$$

The value of the solution at t_i (that is, $\boldsymbol{y}(t_i)$) is approximated by $\boldsymbol{y}_i$ from the nth degree Taylor polynomial of $\boldsymbol{y}(t)$ at $t = t_i$. In this paper we consider that $\boldsymbol{f}$ is analytic. Denoting $h_i = t_i - t_{i-1}$,

$$\begin{aligned}
&\boldsymbol{y}(t_0) =: \boldsymbol{y}_0,\\
&\boldsymbol{y}(t_i) \simeq \boldsymbol{y}(t_{i-1}) + \frac{d\boldsymbol{y}(t_{i-1})}{dt}\, h_i + \frac{1}{2!}\, \frac{d^2\boldsymbol{y}(t_{i-1})}{dt^2}\, h_i^2 + \cdots + \frac{1}{n!}\, \frac{d^n\boldsymbol{y}(t_{i-1})}{dt^n}\, h_i^n\\
&\qquad \simeq \boldsymbol{y}_{i-1} + \boldsymbol{f}(t_{i-1}, \boldsymbol{y}_{i-1})\, h_i + \frac{1}{2!}\, \frac{d\boldsymbol{f}(t_{i-1}, \boldsymbol{y}_{i-1})}{dt}\, h_i^2 + \cdots\\
&\qquad\quad + \frac{1}{n!}\, \frac{d^{n-1}\boldsymbol{f}(t_{i-1}, \boldsymbol{y}_{i-1})}{dt^{n-1}}\, h_i^n =: \boldsymbol{y}_i.
\end{aligned} \tag{1}$$

We must determine the Taylor coefficients $\{1/j!\, d^j\boldsymbol{y}(t_{i-1})/dt^j\}$, which may be obtained directly by differentiating the right-hand side of the differential equation $\boldsymbol{f}(t, \boldsymbol{y}(t))$. This approach is useful only in theoretical studies because when n increases, the complexity of the explicit computation of the derivatives becomes too cumbersome. Another approach is the use of AD techniques [19, 41] as in [11, 13, 28, 30]. In the literature different preprocessing codes have been designed to get the recurrence formulae of the Taylor coefficients via AD [11, 13, 28]. In this paper we have used a preprocessor called MARSTIN [3, 30], a *Mathematica* package, to obtain the Taylor series solution of an ODE problem. The output is the `FORTRAN77` program that computes the recurrence formulae to integrate the differential system by recurrent power series, that is, the coefficients of the Taylor method.

The Taylor method presents several advantages. It gives directly a dense output in the form of a power series, and it can be formulated as an interval method [34, 35] giving guaranteed integration methods. In addition, Taylor methods may directly manage high-order differential equations taking into account only the fact that the Taylor coefficients for the solution and its derivatives $\boldsymbol{y}, \boldsymbol{y}', \ldots$ are evidently related ($d^n\boldsymbol{y}^{(k)}/dt^n = (n+1)_k\, d^{n+k}\boldsymbol{y}/dt^{n+k}$, $(a)_k = a\,(a+1)\cdots(a+k-1)$ being the Pochhammer symbol). Also, as Taylor methods of degree n are also of order n, the use of Taylor methods of a high degree gives us numerical methods of a high order. Therefore, they are very useful for a high-precision solution of ODEs [3].

It is well known that Taylor methods are not A-stable (they are only in the infinite case, taking the infinite series development). In fact, the stability function for the Taylor method of degree n is $R_n(z) = \sum_{i=0}^{n} z^i/i!$, the same as for explicit Runge–Kutta (RK) methods with the same order as the number of internal stages for order lower than 5 (no explicit RK method exists of order n with n stages for $n \geq 5$ [22, 23]). When the order increases, the stability domain approaches a semicircle in the negative complex plane with its center at the origin. In [3] the radius of the semicircle is approximated (using numerical data up to degree 60) by a linear L_2 fit, obtaining $r(n) \simeq 1.3614 + 0.3725\, n$. Hence, high-order Taylor methods can be used with moderately stiff equations because for large n the stability domain is large enough. Obviously, Taylor methods cannot be used for highly stiff systems, where it is necessary to use implicit A-stable methods. Implicit versions of Taylor methods that are A-stable have been developed in [6, 15].

In the practical implementation of a numerical method for the solution of ODEs, the use of variable stepsizes is a crucial point because it permits an automatic control of the error. Several formulations of variable-stepsize Taylor methods can be found in [13, 28, 30]. Here we use the approach given in [1, 3, 30]. In Taylor methods there is no rejected step as occurs in any variable-stepsize formulation for RK or multistep methods because we choose the stepsize once the series are generated to obtain a required precision level. Furthermore, we use a variable-order formulation of the Taylor method developed in [3] to obtain a more adaptive method. To reach this goal it is necessary to know a priori an estimation of both the computational time (we use the fact that the computational complexity of each step of the Taylor method is $\mathcal{O}(n^2)$ [19, 28], although a better estimation may be obtained by recording series generation time vs. order to give a second-order curve fit $a_0 + a_1\, n + a_2\, n^2$ of the computational time) and the stepsize for a fixed error tolerance for different orders (for more details see [3]).

In the case of smooth DAEs the Taylor method was first applied by Chang and Corliss [11, 13] and a systematic study was done by Pryce in [36, 39, 40]. Consider a DAE system

$$\boldsymbol{F}\boldsymbol{y} := \boldsymbol{f}(t,\, \boldsymbol{y},\, \boldsymbol{y}', \dots) = 0, \tag{2}$$

$$\boldsymbol{\Phi}\, \boldsymbol{y}_0 := \boldsymbol{\phi}(t_0,\, \boldsymbol{y}_0,\, \boldsymbol{y}_0', \dots) = 0 \tag{3}$$

with $\boldsymbol{y}, \boldsymbol{y}', \dots \in \mathbb{R}^s$. Consistent initial conditions are given by (3). The Taylor series method for DAEs involves a preanalysis stage where one solves an assignment problem (the Σ-*method* [40]). The solvability of a DAE system by means of the Taylor series method is given by the following theorem.

THEOREM 1 (Pryce [39]). *Let the DAE* $\boldsymbol{F}\boldsymbol{y} = 0$ *be analytic in a neighborhood of a consistent point. Then the Taylor series method applied at this point succeeds iff the* $s \times s$ *matrix* J *is nonsingular at this point, where*

$$J_{ij} = \begin{cases} \dfrac{\partial f_i}{\partial y_j^{(d_j - c_i)}} & \text{if this derivative is present,} \\ 0 & \text{otherwise.} \end{cases}$$

The indices d_j and c_i give, respectively, the appropriate derivatives of the system variables y_j and the number of differentiations of the ith equation needed to convert to an explicit ODE system (see [39, 40]).

For a practical implementation of Taylor methods for DAEs first we enter into the preanalysis stage [36, 39, 40], which gives us the new equations used in the Taylor scheme $\widetilde{\boldsymbol{F}}\boldsymbol{y} := \widetilde{\boldsymbol{f}}(t,\, \boldsymbol{y}, \boldsymbol{y}', \dots, \boldsymbol{y}^{(\mathbf{d})}) = 0$, where we denote $\boldsymbol{y}^{(\mathbf{d})} = (y_1^{(d_1)}, \dots, y_s^{(d_s)})^{\mathrm{T}}$. Then, we use AD in the generation of the Taylor coefficients of $\widetilde{\boldsymbol{f}}$ in a way similar to that in the case of ODEs, and afterwards we solve for each Taylor coefficient a linear system with the same coefficient matrix J (defined in Theorem 1),

$$-J \cdot (\boldsymbol{y}^{(\mathbf{d})})_i = (\widetilde{\boldsymbol{F}}\boldsymbol{y})_{i0} := (\widetilde{\boldsymbol{f}}(t,\, \boldsymbol{y}, \boldsymbol{y}', \dots, \boldsymbol{y}^{(\mathbf{d})}))_{i0},$$

with $(\boldsymbol{y}^{(\mathbf{d})})_i = ((y_1^{(d_1)})_i, \dots, (y_s^{(d_s)})_i)^{\mathrm{T}}$, where $(g)_i$ stands for the ith Taylor coefficient of g and $(\widetilde{\boldsymbol{f}}(t,\, \boldsymbol{y}, \boldsymbol{y}', \dots, \boldsymbol{y}^{(\mathbf{d})}))_{i0}$ is the ith Taylor coefficient of $\widetilde{\boldsymbol{f}}$ considering $(\boldsymbol{y}^{(\mathbf{d})})_i = 0$. We may use the relation among the Taylor coefficients of a function and its derivatives to obtain the series of the solution $\boldsymbol{y}$. On each step we must also obtain the first Taylor coefficients in such a way that the solution is consistent with

the DAE at the point of the development of the Taylor polynomial. This involves solving nonlinear equations (3) with the constraints of the DAEs. Apart from the initial conditions, the convergence of, for example, the Newton methods on this problem with the numerical values of the Taylor polynomial as an initial guess is quite fast (in general, one iteration is enough) because these values are very good approximations of a solution. This step is essentially a projection onto all the constraint manifolds (the given constraints (3) and the hidden constraints obtained after the preanalysis stage [36, 39, 40]), but this is done at the beginning of the step (to obtain the first Taylor coefficients) and not at the end, as a standard projection method does (so we may call it a "preprojection" [1]). If we do not project onto all the constraints and we use only (3), we retain consistency with the DAEs but we solve the DAEs less well because we are forgetting the hidden constraints.

For more details about the use of the Taylor method in the numerical solution of DAEs, see [1, 36, 39, 40].

3. Sensitivity analysis. Consider the ODE system

$$\boldsymbol{y}' = \boldsymbol{f}(t, \boldsymbol{y}; \boldsymbol{p}), \quad \boldsymbol{y}(0) = \boldsymbol{y}_0$$

with $\boldsymbol{y} \in \mathbb{R}^s$ and a set of parameters $\boldsymbol{p} \in \mathbb{R}^p$. Sensitivity analysis entails finding the derivative of the above system with respect to each parameter. This produces an additional $p \cdot s$ sensitivity equations

$$\boldsymbol{s}_k' = \frac{\partial \boldsymbol{f}}{\partial \boldsymbol{y}}\, \boldsymbol{s}_k + \frac{\partial \boldsymbol{f}}{\partial p_k}, \quad k = 1, \ldots, p,$$

where $\boldsymbol{s}_k = \partial \boldsymbol{y}/\partial p_k$. A common situation is $\boldsymbol{p} = \boldsymbol{y}_0$.

In some applications we are also interested in higher-order partial derivatives. For example, they are necessary for nonlinear equations and when we need parameter–parameter interactions. Therefore, we also need the second- (or higher-) order sensitivity equations

$$(\boldsymbol{s}_{kj})_m' = \frac{\partial f_m}{\partial \boldsymbol{y}}\, \boldsymbol{s}_{kj} + (\boldsymbol{s}_j)^{\mathrm{T}}\, \frac{\partial^2 f_m}{\partial \boldsymbol{y}^2}\, \boldsymbol{s}_k + \frac{\partial^2 f_m}{\partial p_j\, \partial \boldsymbol{y}}\, \boldsymbol{s}_k + \frac{\partial^2 f_m}{\partial p_k\, \partial \boldsymbol{y}}\, \boldsymbol{s}_j + \frac{\partial^2 f_m}{\partial p_k\, \partial p_j}$$

for $m = 1, \ldots, s$ and where $(\boldsymbol{s}_{kj})_m = \partial^2 y_m / \partial p_k\, \partial p_j$.

In the sensitivity analysis several methods have been used in the literature: "brute force," in which the differential equation is solved, and the sensitivity values are computed by means of finite differences [42]; numerical integration of the differential and the variational equations [16, 42]; the use of AD techniques on the numerical integration of the differential equations [16, 27], that is, to use an AD library (e.g., ADIFOR [7]) to create a code that generates the sensitivity values given the code for generating the solution of the ODE. Each of these methods usually computes only first-order sensitivities.

Instead, we propose to use extended AD rules to obtain both the solution of the ODE and the sensitivity values: "the Taylor series method." This method permits computing any order of sensitivities. Also, once the differential system is introduced we do not need to perform any additional precompilation process to generate any sensitivity. Taylor polynomials with partial derivatives have already been used by Berz [4, 5, 33], computing the partial derivatives using rules for the composition of polynomials considering the whole Taylor polynomials (in fact the Taylor polynomial

and the remainder in [33], the "Taylor model") at the same time or computing multivariate Taylor polynomials. On the contrary, in this paper, we give rules for the direct computation of Taylor coefficients of the partial derivatives that gives the univariate Taylor polynomials of the sensitivities. Our approach gives easier methods to program because we only have to do the precompilation of the original system and the sensitivities are obtained just by the extended differentiation rules.

The Taylor series method computes the Taylor polynomials of the solution of the differential equation (1) and the Taylor polynomials of the partial derivatives of the solution

$$\boldsymbol{s}_k(t_i) \simeq \boldsymbol{s}_k(t_{i-1}) + \frac{d\boldsymbol{s}_k(t_{i-1})}{dt}\, h_i + \frac{1}{2!}\, \frac{d^2\boldsymbol{s}_k(t_{i-1})}{dt^2}\, h_i^2 + \cdots + \frac{1}{n!}\, \frac{d^n\boldsymbol{s}_k(t_{i-1})}{dt^n}\, h_i^n,$$

$$\boldsymbol{s}_{kj}(t_i) \simeq \boldsymbol{s}_{kj}(t_{i-1}) + \frac{d\boldsymbol{s}_{kj}(t_{i-1})}{dt}\, h_i + \frac{1}{2!}\, \frac{d^2\boldsymbol{s}_{kj}(t_{i-1})}{dt^2}\, h_i^2 + \cdots + \frac{1}{n!}\, \frac{d^n\boldsymbol{s}_{kj}(t_{i-1})}{dt^n}\, h_i^n.$$

We compute the coefficients $d^l\boldsymbol{s}_k(t_{i-1})/dt^l$, $d^l\boldsymbol{s}_{kj}(t_{i-1})/dt^l$ by partial derivation of the coefficients of the Taylor polynomials

$$\frac{d^l\boldsymbol{s}_k(t_{i-1})}{dt^l} = \frac{\partial}{\partial p_k}\, \frac{d^l\boldsymbol{y}(t_{i-1})}{dt^l}, \quad \frac{d^l\boldsymbol{s}_{kj}(t_{i-1})}{dt^l} = \frac{\partial^2}{\partial p_k\, \partial p_j}\, \frac{d^l\boldsymbol{y}(t_{i-1})}{dt^l}.$$

Hence, we need extended AD rules for the computation of the coefficients of the Taylor expansions of partial derivatives of any order of any elementary function.

In the case of DAE systems, the first-order sensitivity analysis produces additional sensitivity equations (to simplify the notation, we have considered the case $\boldsymbol{F}\boldsymbol{y} := \boldsymbol{f}(t, \boldsymbol{y}, \boldsymbol{y}'; \boldsymbol{p}) = 0$)

$$\frac{\partial \boldsymbol{f}}{\partial \boldsymbol{y}}\, \boldsymbol{s}_k + \frac{\partial \boldsymbol{f}}{\partial \boldsymbol{y}'}\, \boldsymbol{s}'_k + \frac{\partial \boldsymbol{f}}{\partial p_k} = 0, \tag{4}$$

$$\frac{\partial \boldsymbol{\phi}}{\partial \boldsymbol{y}}\, \boldsymbol{s}_k(t_0) + \frac{\partial \boldsymbol{\phi}}{\partial \boldsymbol{y}'}\, \boldsymbol{s}'_k(t_0) + \frac{\partial \boldsymbol{\phi}}{\partial p_k} = 0, \tag{5}$$

where $\boldsymbol{s}_k = \partial\boldsymbol{y}/\partial p_k$. Consistent initial conditions are given by (5). For a second-order sensitivity analysis, the additional equations are ($m = 1, \ldots, s$)

$$\begin{aligned}
&\frac{\partial f_m}{\partial \boldsymbol{y}}\, \boldsymbol{s}_{kj} + \frac{\partial f_m}{\partial \boldsymbol{y}'}\, (\boldsymbol{s}_{kj})' + (\boldsymbol{s}_j)^{\mathrm{T}}\, \frac{\partial^2 f_m}{\partial \boldsymbol{y}^2}\, \boldsymbol{s}_k + (\boldsymbol{s}'_k)^{\mathrm{T}}\, \frac{\partial^2 f_m}{\partial \boldsymbol{y}'^2}\, \boldsymbol{s}'_j \\
&\quad + (\boldsymbol{s}'_k)^{\mathrm{T}}\, \frac{\partial^2 f_m}{\partial \boldsymbol{y}'\, \partial \boldsymbol{y}}\, \boldsymbol{s}_j + (\boldsymbol{s}_k)^{\mathrm{T}}\, \frac{\partial^2 f_m}{\partial \boldsymbol{y}\, \partial \boldsymbol{y}'}\, \boldsymbol{s}'_j + \frac{\partial^2 f_m}{\partial p_j\, \partial \boldsymbol{y}}\, \boldsymbol{s}_k \\
&\quad + \frac{\partial^2 f_m}{\partial p_k\, \partial \boldsymbol{y}}\, \boldsymbol{s}_j + \frac{\partial^2 f_m}{\partial p_j\, \partial \boldsymbol{y}'}\, \boldsymbol{s}'_k + \frac{\partial^2 f_m}{\partial p_k\, \partial \boldsymbol{y}'}\, \boldsymbol{s}'_j + \frac{\partial^2 f_m}{\partial p_k\, \partial p_j} = 0.
\end{aligned}$$

This problem (in the case of first-order sensitivities) has been extensively treated by Petzold et al. [8, 9, 17, 31] using the simultaneous corrector method (to solve simultaneously the DAE system and the sensitivity equations), the staggered direct method, and the adjoint sensitivity analysis. Again, we propose using the Taylor series method. For each Taylor coefficient and partial derivative, we solve a linear system with the same coefficient matrix J. For instance, up to second-order sensitivity analysis we have

$$-J \cdot (\boldsymbol{y}')_i = (\boldsymbol{F}\boldsymbol{y})_{i0}, \quad -J \cdot (\boldsymbol{s}'_k)_i = \left(\frac{\partial}{\partial p_k}\boldsymbol{F}\boldsymbol{y}\right)_{i0}, \quad -J \cdot (\boldsymbol{s}'_{kj})_i = \left(\frac{\partial^2}{\partial p_k\, \partial p_j}\boldsymbol{F}\boldsymbol{y}\right)_{i0},$$

where the second members of the linear system are obtained by using the extended AD rules of the next section and where in $(\partial \boldsymbol{F}\boldsymbol{y}/\partial p_k)_{i0}$ and $(\partial^2 \boldsymbol{F}\boldsymbol{y}/\partial p_k \partial p_j)_{i0}$ we consider $(\boldsymbol{s}'_k)_i = 0$ and $(\boldsymbol{s}''_{kj})_i = 0$, respectively.

The first Taylor coefficients of the sensitivities have to satisfy the constraint equations (5) for the sensitivities, but now the constraint equations are linear with respect to the sensitivities. Therefore, for the sensitivities we do not have to solve any nonlinear equation (in the case of obtaining the solution of the DAEs system we have to solve the nonlinear constraint equations for the first coefficients).

Another important question for the development of a good scientific software package is the storage requirement, since the efficiency of the Taylor method depends deeply on the precompilation process where we minimize the polynomial operations and additional polynomial storage. For the DAE problem a very detailed analysis of the Taylor method was recently done in [36].

4. Automatic differentiation: Partial derivatives. In the practical determination of the Taylor coefficients of a function we use the classical rules for AD of the elementary operations and standard functions ($\pm$, $\times$, /, ln, sin, ...) developed by, among others, Moore [34, 41]. AD gives a recursive procedure to obtain the numerical value of the reiterated derivatives of the elementary functions at a given point [19, 41]. For example, for the real power function (for a complete list, see [19, 34, 41]), if $f : t \in \mathbb{R} \mapsto \mathbb{R}$ is a function of class $\mathcal{C}^n$ and denoting

$$f^{[j]}(t) = \frac{1}{j!} f^{(j)}(t),$$

we have, if $h(t) = f(t)^\alpha$ ($\alpha \in \mathbb{R}$),

$$h^{[0]}(t) = (f^{[0]}(t))^\alpha, \quad h^{[n]}(t) = \frac{1}{n\, f^{[0]}(t)} \sum_{i=0}^{n-1} (n\,\alpha - i(\alpha+1))\; f^{[n-i]}(t)\, h^{[i]}(t). \tag{6}$$

In this paper, as we focus our attention on partial derivatives, we have extended the classical formulae of the Taylor coefficients of a function to a set of formulae that gives us the Taylor coefficients of a function and/or its partial derivatives of any order. In the following we denote by $\mathbb{N}_0$ the set of the natural numbers with zero ($\mathbb{N}_0 := \mathbb{N} \cup \{0\}$).

PROPOSITION 2. *If $f(t, \boldsymbol{y}(t)), g(t, \boldsymbol{y}(t)) : (t, \boldsymbol{y}) \in \mathbb{R}^{s+1} \mapsto \mathbb{R}$ are functions of class $\mathcal{C}^n$, $\mathbf{i} = (i_1, i_2, \ldots, i_s) \in \mathbb{N}_0^s$ a vector with the partial derivative orders, $\mathbf{i}^* = \mathbf{i} - (0, \ldots, 0, 1, 0, \ldots, 0) = (i_1, i_2, \ldots, i_k - 1, 0, \ldots, 0)$ (that is, we subtract 1 from the last nonzero element i_k of $\mathbf{i}$ if $\mathbf{i} \neq \mathbf{0}$), and $\|\mathbf{i}\| = \sum_{j=1}^s i_j$ the total order of derivation, we denote*

$$f^{[j,\,\mathbf{i}]} := \frac{1}{j!} \frac{\partial^{\|\mathbf{i}\|} f^{(j)}(t)}{\partial y_1^{i_1}\, \partial y_2^{i_2} \cdots \partial y_s^{i_s}}, \quad f^{[j,\,\mathbf{0}]} := f^{[j]} = \frac{1}{j!} \frac{d^j f(t)}{dt^j},$$

that is, the jth Taylor coefficient of the partial derivative of $f(t, \boldsymbol{y}(t))$ with respect to $\mathbf{i}$ and

$$\widetilde{h}^{[j,\,\mathbf{v}]}_{n,\,\mathbf{i}} = h^{[j,\,\mathbf{v}]} \quad (j \neq n \text{ or } \mathbf{v} \neq \mathbf{i}), \quad \widetilde{h}^{[n,\,\mathbf{i}]}_{n,\,\mathbf{i}} = 0.$$

In addition, given $\mathbf{v} = (v_1, \ldots, v_s) \in \mathbb{N}_0^s$ we define the multicombinatorial number $\binom{\mathbf{i}}{\mathbf{v}} = \binom{i_1}{v_1} \cdot \binom{i_2}{v_2} \cdots \binom{i_s}{v_s}$, and we consider the classical partial order in $\mathbb{N}_0^s$. Then we have the following:

(i) *If* $h(t) = f(t) \pm g(t)$, *then* $h^{[n,\,\mathbf{i}]} = f^{[n,\,\mathbf{i}]} \pm g^{[n,\,\mathbf{i}]}$.
(ii) *If* $h(t) = \alpha\, f(t)$ *with* $\alpha \in \mathbb{R}$, *then* $h^{[n,\,\mathbf{i}]} = \alpha\, f^{[n,\,\mathbf{i}]}$.
(iii) *If* $h(t) = f(t) \cdot g(t)$, *then*

$$h^{[n,\,\mathbf{i}]} = \sum_{\mathbf{v} \le \mathbf{i}} \binom{\mathbf{i}}{\mathbf{v}} \left\{ \sum_{j=0}^{n} f^{[n-j,\,\mathbf{v}]} \cdot g^{[j,\,\mathbf{i}-\mathbf{v}]} \right\}.$$

(iv) *If* $h(t) = f(t)/g(t)$, *then*

$$h^{[n,\,\mathbf{i}]} = \frac{1}{g^{[0]}} \left(f^{[n,\,\mathbf{i}]} - \sum_{\mathbf{v} \le \mathbf{i}} \binom{\mathbf{i}}{\mathbf{v}} \left\{ \sum_{j=0}^{n} \widetilde{h}_{n,\,\mathbf{i}}^{[n-j,\,\mathbf{v}]} \cdot g^{[j,\,\mathbf{i}-\mathbf{v}]} \right\} \right).$$

(v) *If* $h(t) = f(t)^{\alpha}$ *with* $\alpha \in \mathbb{R}$, *then*

$$h^{[0,\,\mathbf{0}]} = (f^{[0]}(t))^{\alpha},$$

$$h^{[0,\,\mathbf{i}]} = \frac{1}{f^{[0]}} \sum_{\mathbf{v} \le \mathbf{i}^*} \binom{\mathbf{i}^*}{\mathbf{v}} \left\{ \alpha\, h^{[0,\,\mathbf{v}]} \cdot f^{[0,\,\mathbf{i}-\mathbf{v}]} - \widetilde{h}_{0,\,\mathbf{i}}^{[0,\,\mathbf{i}-\mathbf{v}]} \cdot f^{[0,\,\mathbf{v}]} \right\}, \qquad \mathbf{i} > \mathbf{0},$$

$$h^{[n,\,\mathbf{i}]} = \frac{1}{n\, f^{[0]}} \sum_{j=0}^{n} \big(n\,\alpha - j(\alpha+1) \big) \left\{ \sum_{\mathbf{v} \le \mathbf{i}} \binom{\mathbf{i}}{\mathbf{v}} \widetilde{h}_{n,\,\mathbf{i}}^{[j,\,\mathbf{v}]} \cdot f^{[n-j,\,\mathbf{i}-\mathbf{v}]} \right\}, \quad n > 0,\ \mathbf{i} > \mathbf{0}.$$

(vi) *If* $h(t) = \exp(f(t))$, *then*

$$h^{[0,\,\mathbf{0}]} = \exp(f^{[0]}(t)),$$

$$h^{[0,\,\mathbf{i}]} = \sum_{\mathbf{v} \le \mathbf{i}^*} \binom{\mathbf{i}^*}{\mathbf{v}} h^{[0,\,\mathbf{v}]} \cdot f^{[0,\,\mathbf{i}-\mathbf{v}]}, \qquad \mathbf{i} > \mathbf{0},$$

$$h^{[n,\,\mathbf{i}]} = \frac{1}{n} \sum_{j=0}^{n-1} (n-j) \left\{ \sum_{\mathbf{v} \le \mathbf{i}} \binom{\mathbf{i}}{\mathbf{v}} h^{[j,\,\mathbf{v}]} \cdot f^{[n-j,\,\mathbf{i}-\mathbf{v}]} \right\}, \qquad n > 0,\ \mathbf{i} > \mathbf{0}.$$

(vii) *If* $h(t) = \ln(f(t))$, *then*

$$h^{[0,\,\mathbf{0}]} = \ln(f^{[0]}(t)),$$

$$h^{[0,\,\mathbf{i}]} = \frac{1}{f^{[0]}} \left(f^{[0,\,\mathbf{i}]} - \sum_{\mathbf{0} < \mathbf{v} \le \mathbf{i}^*} \binom{\mathbf{i}^*}{\mathbf{v}} h^{[0,\,\mathbf{i}-\mathbf{v}]} \cdot f^{[0,\,\mathbf{v}]} \right), \qquad \mathbf{i} > \mathbf{0},$$

$$h^{[n,\,\mathbf{i}]} = \frac{1}{f^{[0]}} \left(f^{[n,\,\mathbf{i}]} - \frac{1}{n} \sum_{j=0}^{n-1} (n-j) \left\{ \sum_{\mathbf{v} \le \mathbf{i}} \binom{\mathbf{i}}{\mathbf{v}} \widetilde{h}_{n,\,\mathbf{i}}^{[n-j,\,\mathbf{i}-\mathbf{v}]} \cdot f^{[j,\,\mathbf{v}]} \right\} \right), \quad n > 0,\ \mathbf{i} > \mathbf{0}.$$

(viii) *If* $g(t) = \cos(f(t))$ *and* $h(t) = \sin(f(t))$, *then*

$$\begin{cases} g^{[0,\,\mathbf{0}]} = \cos(f^{[0]}(t)), \\ g^{[0,\,\mathbf{i}]} = -\displaystyle\sum_{\mathbf{v} \le \mathbf{i}^*} \binom{\mathbf{i}^*}{\mathbf{v}} h^{[0,\,\mathbf{v}]} \cdot f^{[0,\,\mathbf{i}-\mathbf{v}]}, \qquad \mathbf{i} > \mathbf{0}, \\ g^{[n,\,\mathbf{i}]} = -\dfrac{1}{n} \displaystyle\sum_{j=1}^{n} j \left\{ \sum_{\mathbf{v} \le \mathbf{i}} \binom{\mathbf{i}}{\mathbf{v}} h^{[n-j,\,\mathbf{v}]} \cdot f^{[j,\,\mathbf{i}-\mathbf{v}]} \right\}, \qquad n > 0,\ \mathbf{i} > \mathbf{0}, \end{cases}$$

$$\begin{cases} h^{[0,\,\mathbf{0}]} = \sin(f^{[0]}(t)), \\ \\ h^{[0,\,\mathbf{i}]} = \displaystyle\sum_{\mathbf{v}\leq \mathbf{i}^*} \binom{\mathbf{i}^*}{\mathbf{v}}\, g^{[0,\,\mathbf{v}]}\cdot f^{[0,\,\mathbf{i}-\mathbf{v}]}, \qquad \mathbf{i}>\mathbf{0}, \\ \\ h^{[n,\,\mathbf{i}]} = \dfrac{1}{n}\displaystyle\sum_{j=1}^{n} j\left\{\sum_{\mathbf{v}\leq \mathbf{i}} \binom{\mathbf{i}}{\mathbf{v}}\, g^{[n-j,\,\mathbf{v}]}\cdot f^{[j,\,\mathbf{i}-\mathbf{v}]}\right\}, \qquad n>0,\ \mathbf{i}>\mathbf{0}. \end{cases}$$

(ix) *If* $h(t)=\arctan(f(t))$, *then*

$$f_2^{[n,\,\mathbf{i}]} = \sum_{\mathbf{v}\leq \mathbf{i}} \binom{\mathbf{i}}{\mathbf{v}} \left\{\sum_{j=0}^{n} f^{[n-j,\,\mathbf{v}]}\cdot f^{[j,\,\mathbf{i}-\mathbf{v}]}\right\}, \qquad n\geq 0,\ \mathbf{i}\geq\mathbf{0},$$

$$h^{[0,\,\mathbf{0}]} = \arctan(f^{[0]}(t)),$$

$$h^{[0,\,\mathbf{i}]} = \frac{1}{1+(f^{[0]})^2}\left\{f^{[0,\,\mathbf{i}]} - \sum_{\mathbf{0}<\mathbf{v}\leq \mathbf{i}^*} \binom{\mathbf{i}^*}{\mathbf{v}}\, h^{[0,\,\mathbf{i}-\mathbf{v}]}\cdot f_2^{[0,\,\mathbf{v}]}\right\}, \qquad \mathbf{i}>\mathbf{0},$$

$$h^{[n,\,\mathbf{i}]} = \frac{1}{1+(f^{[0]})^2}\left(f^{[n,\,\mathbf{i}]} - \frac{1}{n}\sum_{j=0}^{n-1}(n-j)\left\{\sum_{\mathbf{v}\leq \mathbf{i}} \binom{\mathbf{i}}{\mathbf{v}}\, \widetilde{h}_{n,\,\mathbf{i}}^{[n-j,\,\mathbf{i}-\mathbf{v}]}\cdot f_2^{[j,\,\mathbf{v}]}\right\}\right), \qquad n>0,\ \mathbf{i}>\mathbf{0}.$$

Proof. As the proof of all the statements is technical, we present only the proof of two cases.

If $h(t)=f(t)^\alpha$ (case (v)), then formula (6) gives

$$h^{[n]}\, f^{[0]} = \frac{1}{n}\sum_{j=0}^{n-1}\left(n\,\alpha - j(\alpha+1)\right) h^{[j]}\, f^{[n-j]}.$$

By applying Leibniz's formula for partial derivatives, we obtain

$$\begin{aligned} \frac{\partial^{\|\mathbf{i}\|}\, h^{[n]}\, f^{[0]}}{\partial y_1^{i_1}\,\partial y_2^{i_2}\cdots\partial y_s^{i_s}} &= \sum_{\mathbf{v}\leq \mathbf{i}} \binom{\mathbf{i}}{\mathbf{v}}\, h^{[n,\,\mathbf{v}]}\cdot f^{[0,\,\mathbf{i}-\mathbf{v}]} \\ &= \frac{\partial^{\|\mathbf{i}\|}}{\partial y_1^{i_1}\,\partial y_2^{i_2}\cdots\partial y_s^{i_s}}\left\{\frac{1}{n}\sum_{j=0}^{n-1}\left(n\,\alpha - j(\alpha+1)\right) h^{[j]}\cdot f^{[n-j]}\right\} \\ &= \frac{1}{n}\sum_{j=0}^{n-1}\left(n\,\alpha - j(\alpha+1)\right)\left\{\sum_{\mathbf{v}\leq \mathbf{i}} \binom{\mathbf{i}}{\mathbf{v}}\, h^{[j,\,\mathbf{v}]}\cdot f^{[n-j,\,\mathbf{i}-\mathbf{v}]}\right\}. \end{aligned}$$

Therefore,

$$\begin{aligned} h^{[n,\,\mathbf{v}]} = \frac{1}{f^{[0]}}\Bigg\{&\frac{1}{n}\sum_{j=0}^{n-1}\left(n\,\alpha - j(\alpha+1)\right)\sum_{\mathbf{v}\leq \mathbf{i}} \binom{\mathbf{i}}{\mathbf{v}}\, h^{[j,\,\mathbf{v}]}\cdot f^{[n-j,\,\mathbf{i}-\mathbf{v}]} \\ &- \sum_{\mathbf{v}<\mathbf{i}} \binom{\mathbf{i}}{\mathbf{v}}\, h^{[n,\,\mathbf{v}]}\cdot f^{[0,\,\mathbf{i}-\mathbf{v}]}\Bigg\}. \end{aligned}$$

That expression, taking into account the definition of $\widetilde{h}_{n,\,\mathbf{i}}^{[j,\,\mathbf{v}]}$, gives us the formula for $n>0$ in (v). The case $h^{[0,\,\mathbf{i}]}$ is obtained by taking first a partial derivative of the

equation $h^{[0,\,\mathbf{0}]} := h^{[0]}(t) = (f^{[0]}(t))^{\alpha}$ with respect to $\mathbf{e}_k = (0, \ldots, 0, 1, 0, \ldots, 0)$, giving

$$h^{[0,\,\mathbf{e}_k]} = \alpha (f^{[0]})^{\alpha-1}\, f^{[0,\,\mathbf{e}_k]} = \alpha\, h^{[0]}\, f^{[0,\,\mathbf{e}_k]} / f^{[0]}.$$

Therefore, $h^{[0,\,\mathbf{e}_k]}\, f^{[0]} = \alpha\, h^{[0]}\, f^{[0,\,\mathbf{e}_k]}$, and from partial derivation with respect to $\mathbf{i}^* = \mathbf{i} - \mathbf{e}_k$, we obtain by applying Leibniz's rule

$$\sum_{\mathbf{v} \le \mathbf{i}^*} \binom{\mathbf{i}^*}{\mathbf{v}} h^{[0,\,\mathbf{i}-\mathbf{v}]} \cdot f^{[0,\,\mathbf{v}]} = \alpha \sum_{\mathbf{v} \le \mathbf{i}^*} \binom{\mathbf{i}^*}{\mathbf{v}} h^{[0,\,\mathbf{v}]} \cdot f^{[0,\,\mathbf{i}-\mathbf{v}]}.$$

And, after manipulation, we obtain the result.

If $h(t) = \arctan(f(t))$ (case (ix)), then, taking derivatives, we obtain $h'(t)\,(1 + f^2(t)) = f'(t)$. Therefore, the coefficients of the partial derivatives are obtained as in the previous case by partial derivation of the Taylor coefficients of the arctan function [19, 34] and of the function $(1 + f^2(t))$. □

In the above formulae one can easily add more elementary functions such as tan, arccos, arcsin, cosh, sinh, etc., just by using similar arguments.

Proposition 2 is also valid for the computation of the partial derivatives of a function (in fact $f^{[0,\,\mathbf{i}]}(t) := \partial^{\|\mathbf{i}\|} f(t) / \partial y_1^{i_1}\, \partial y_2^{i_2} \cdots \partial y_s^{i_s}$) and for just the determination of the Taylor coefficients of an elementary function. In this case the vector of partial derivatives is the null vector $\mathbf{i} = \mathbf{0}$, and we denote $f^{[0,\,\mathbf{0}]} := f^{[0]}(t)$. Therefore, in the generation of the Taylor polynomials of a function and its partial derivatives we need only the formulae of the above proposition. This fact is useful in practical implementation of the algorithm because we need only one set of subroutines.

The problem of evaluating partial derivatives was recently studied in [20, 37] but not in the context of obtaining the Taylor polynomials that give us the sensitivity values of an ODE or DAE differential system.

Once we have the formulae for the Taylor coefficients, we are interested in the computational cost of such formulae. In the case of the Taylor coefficients the complexity is well known [28, 34].

PROPOSITION 3. *If the evaluation of $f(t, \boldsymbol{y}(t))$ involves k elementary functions $(\times, /, \ln, \exp, \sin, \cos, \ldots)$, then the computational complexity of the evaluation of $f^{[0]}, f^{[1]}, \ldots, f^{[n-1]}$ is $\mathcal{O}(k\, n^2)$.*

We notice that the above result is based on counting floating point operations (FLOPS), and currently, on modern architectures, this measure is not related linearly to the CPU time (the real measure of interest). Therefore, such a complexity result is just a theoretical analysis.

In the case of obtaining the coefficients of the partial derivatives we only have to determine, given a vector with the indices of the partial derivatives $\mathbf{i} = (i_1, i_2, \ldots, i_s)$, the number of vectors $\mathbf{v} \in \mathbb{N}_0^s$ such that $\mathbf{v} \le \mathbf{i}$ because in all the elementary functions $(\times, /, \ln, \exp, \sin, \cos, \ldots)$ there appears a sum of the type $\sum_{\mathbf{v} \le \mathbf{i}}$. This number is $\prod_{j=1}^{s} (i_j + 1)$, a result that proves the following proposition.

PROPOSITION 4. *If the evaluation of $f(t, \boldsymbol{y}(t))$ involves k elementary functions $(\times, /, \ln, \exp, \sin, \cos, \ldots)$, and given $\mathbf{i} = (i_1, i_2, \ldots, i_s) \in \mathbb{N}_0^s$, then the computational complexity of the evaluation of $f^{[0,\,\mathbf{i}]}, f^{[1,\,\mathbf{i}]}, \ldots, f^{[n-1,\,\mathbf{i}]}$, supposing all the derivatives of index $\mathbf{v} < \mathbf{i}$ are already known, is*

$$\mathcal{O}\left(\prod_{j=1}^{s} (i_j + 1) \cdot k\, n^2 \right).$$

As before, the above result is a theoretical result. On modern computers the CPU time may evolve in a slightly different way.

If the function $f(t,\, \boldsymbol{y}(t))$ is a linear function (involves only additions/subtractions and multiplication by scalars), then the computational complexity is evidently $\mathcal{O}(n)$.

COROLLARY 5. *The computational complexity of evaluating the Taylor coefficients of a partial derivative of f is twice the complexity of evaluating the Taylor coefficients of f, and the computational complexity of evaluating the Taylor coefficients of a second-order partial derivative of f is, once the coefficients of the first-order partial derivatives are known, four times the complexity of evaluating the Taylor coefficients of f in the case of $\partial^2 f/\partial y_i\, \partial y_j\ (i \neq j)$ and three times in the case $\partial^2 f/\partial y_i^2$.*

In the case of sensitivities with respect to a parameter different from the initial conditions we use the above formulae, but we also have to consider the partial derivatives with respect to the parameters. This can be done in an automatic way by using another set of extended AD rules, in which we use an extended vector of variables with the variables and the parameters, but where the length of the Taylor polynomials of the parameters depends on the function with the parameter (in some cases just one coefficient). Therefore, we will have to consider the Taylor coefficients of elementary functions with polynomials of different length (in some cases with one constant argument). We do not detail the formulae because the essence is Proposition 2. On the other hand, in most of the applications related with dynamical systems, as periodic orbits, Lyapunov exponents, chaos indicators, bifurcation analysis, and so on, the partial derivatives are calculated with respect to the variables (we are interested in the Jacobian) or with respect to the initial conditions (we are interested in the solution of the variational equations), and we use Proposition 2 with the initial conditions of the identity matrix on each integration step or just at the first step, respectively.

$s_1^{[m]} = \boxed{x \times x}^{[m]} + \boxed{y \times y}^{[m]}$	$s_1^{[m,\mathbf{v}]} = \boxed{x \times x}^{[m,\mathbf{v}]} + \boxed{y \times y}^{[m,\mathbf{v}]}$
$s_2^{[m]} = \boxed{(s_1)^{-3/2}}^{[m]}$	$s_2^{[m,\mathbf{v}]} = \boxed{(s_1)^{-3/2}}^{[m,\mathbf{v}]}$
$x^{[m+2]} = -\boxed{x \times s_2}^{[m]}/c$	$x^{[m+2,\mathbf{v}]} = -\boxed{x \times s_2}^{[m,\mathbf{v}]}/c$
$y^{[m+2]} = -\boxed{y \times s_2}^{[m]}/c$	$y^{[m+2,\mathbf{v}]} = -\boxed{y \times s_2}^{[m,\mathbf{v}]}/c$
	`end`
`end`	`end`

At this point it is interesting to note that the programs to integrate an ODE/DAE or to integrate an ODE/DAE and any order sensitivity value are the "same." That is, once we have obtained the scheme for the series development we do not have to modify this scheme to introduce the calculus of different sensitivity orders. On the contrary, other methods to obtain sensitivity values need to obtain the additional sensitivity equations, and this process may be highly cumbersome. In Table 4.1 we present the kernel of the series development program for the classical Kepler problem (see the next section for a description) in the case of obtaining just the solution and

in the case of obtaining both the solution and sensitivity values up to any order with respect to the initial conditions. Any operation inside a box stands for an operation among Taylor polynomials. In the example we need only the formulae for the Taylor coefficients of the partial derivatives of the product and the real power function of Taylor polynomials (formulae (iii) and (v) of Proposition 2).

5. Numerical tests. We have performed several numerical tests on a Windows PC Pentium III-866 MHz using `g77` (GNU `FORTRAN77`). We perform comparisons with the well-established software `dop853` developed by Hairer, Nørsett, and Wanner [22] (based on an explicit RK of order $8(5,3)$ given by Prince and Dormand [38] with stepsize control and dense output) for nonstiff problems, and `radau5` and `radau` developed by Hairer and Wanner [23, 24] (based on implicit RK schemes, Radau IIA, of order 5 or variable order, 5, 9, or 13, respectively, and equipped with stepsize control and dense output) for the stiff case. In these comparisons we use for the determination of the sensitivity values the simultaneous corrector method [17] in the `dop853`, `radau5`, and `radau` codes for the DAE problems. The reference values have been obtained using quadruple precision and the Taylor series method with an error tolerance of 10^{-30}.

5.1. ODE problems. We have taken three classical ODE problems as test problems.

• A *Galactic dynamics model* [22]. This problem is a Hamiltonian ODE problem with coordinates q_1, q_2, q_3 and moments p_1, p_2, p_3. The Hamiltonian function and parameter values (the initial conditions have been fixed to obtain $\mathcal{H} = 2$) are

$$\mathcal{H} = \frac{1}{2}\,(p_1^2 + p_2^2 + p_3^2) + \Omega\,(p_1\,q_2 - p_2\,q_1) + \ln\left(1 + \frac{q_1^2}{(1.25)^2} + q_2^2 + \frac{q_3^2}{(0.75)^2}\right),$$

$$q_1(0) = 2.5, \quad q_2(0) = q_3(0) = p_1(0) = 0, \quad p_2(0) = \frac{25 + \sqrt{6961 - 3200\,\ln 5}}{40}, \quad p_3(0) = 0.2.$$

In the tests we have considered $\Omega = 0.25$ and the integration interval is $[0,\, 1000]$.

• The *Lorenz model* [22] with Saltzman's values ($b = 8/3$, $\sigma = 10$, $r = 28$). This problem is a classic example of chaotic behavior:

$$x' = -\sigma\,(x - y), \quad y' = -x\,z + r\,x - y, \quad z' = x\,y - b\,z, \quad (x_0,\, y_0,\, z_0) = (-8,\, 8,\, r - 1).$$

The integration interval is $[0,\, 16]$.

• The *Kepler problem* describes planar two-body motion:

$$x'' = -x/(x^2 + y^2)^{3/2}, \quad y'' = -y/(x^2 + y^2)^{3/2},$$

$$x_0 = 1 - e, \quad x_0' = 0, \quad y_0 = 0, \quad y_0' = \sqrt{(1 + e)/(1 - e)}.$$

The integration interval is 20 orbital periods, that is, $[0,\, 40\pi]$.

In Figure 5.1 we show precision-computer time (in seconds) diagrams in logarithmic scale for the `dop853` code and the Taylor method for the computation of first- and second-order sensitivities for all the above three problems. These graphs show the relative error and computer time, and each point corresponds to a different requested accuracy. Because the algorithms are adaptive, neither relative error nor computer time depends continuously on the requested accuracy, although we present the graphs connected with continuous lines to help the visualization. In particular, we show first-order sensitivities with respect to the parameter Ω (graphs (g1) and (g2)) and

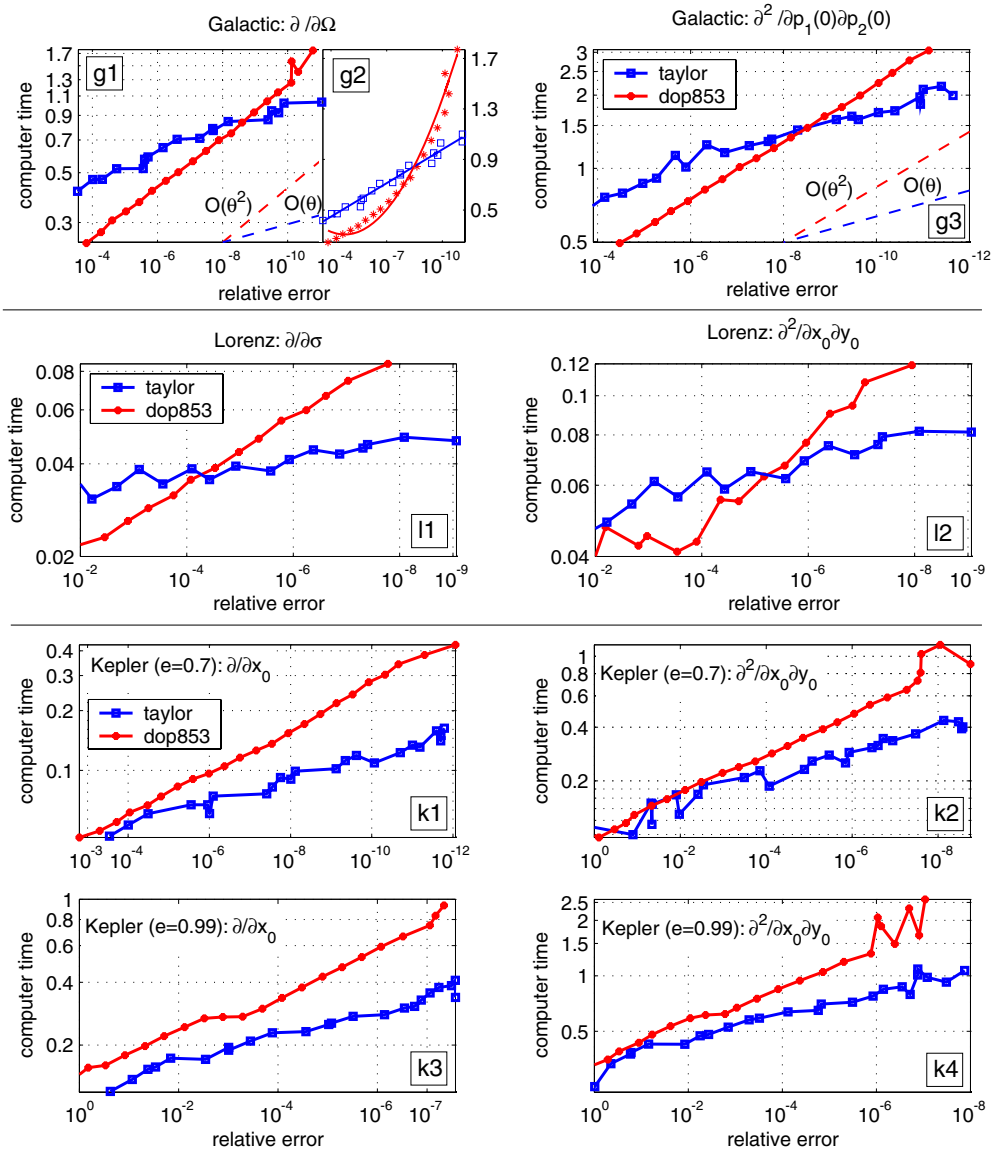

FIG. 5.1. *Precision-computer time diagrams for the Galactic, Lorenz, and Kepler problems in the first- and second-order sensitivities.*

second-order sensitivities with respect to the initial conditions $p_1(0)$ and $p_2(0)$ (graph (g3)) for the Galactic problem, first-order sensitivities with respect to the parameter σ (graph (l1)) and second-order sensitivities with respect to the initial conditions x_0 and y_0 (graph (l2)) for the Lorenz model, and first-order sensitivities with respect to the initial condition x_0 (graphs (k1) and (k3)) and second-order sensitivities with respect to the initial conditions x_0 and y_0 (graphs (k2) and (k4)) for the Kepler problem for two values of the eccentricity ($e = 0.7$ and $e = 0.99$). In all the simulations the relative error is computed at the end of the integration time using the infinity norm.

From the graphs we observe that for low-precision demands the RK code is faster,

but for high-precision demands the Taylor method becomes faster. This means that, increasing the accuracy request, the computer time increases much more rapidly for the RK method than for the Taylor method (due mainly to the variable order formulation of the Taylor method that gives a more adaptive method) and, therefore, the slopes of both curves are different. Thus, the Taylor method is especially useful for very high precision demands [3] (as they occur if we use quadruple precision or multiple precision libraries). In graphs (g1) and (g2) of Figure 5.1 we show the diagrams for the computation of first-order sensitivities with respect to the parameter Ω for the Galactic problem, (g1) in the logarithmic scale for both axis (`loglog`) and (g2) in the logarithmic scale only the relative error axis. From the (g2) graph we may observe that the evolution of the computer time for the RK code is $\mathcal{O}(\theta^2)$, while for the Taylor method it is $\mathcal{O}(\theta)$ with $\theta = -\log_{10} \|\texttt{error}\|$ (we also present a quadratic L_2-fit for the RK and a linear L_2-fit for the Taylor method in the continuous lines; the data are represented by symbols). Therefore, on a `loglog` scale (g1) the RK graph will be a straight line with a slope double the slope of the graph of the Taylor method. At the bottom right of graphs (g1) and (g3) we show with dashed lines the evolution of two straight lines in the `loglog` figures, one with a slope double that of the other.

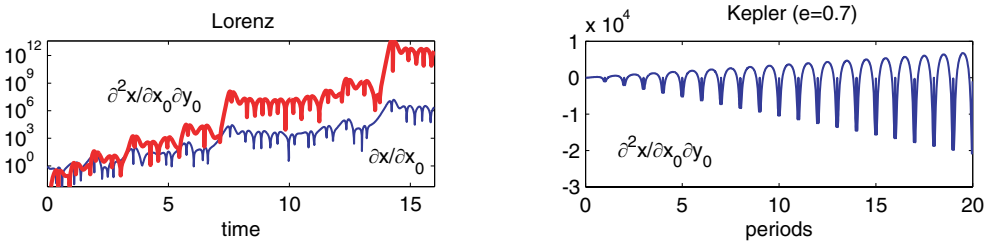

FIG. 5.2. *Evolution of the sensitivity values $\partial x/\partial x_0$ and $\partial^2 x/\partial x_0\,\partial y_0$ for the Lorenz model and $\partial^2 x/\partial x_0\,\partial y_0$ for the Kepler problem.*

Finally, in Figure 5.2, where we give the evolution of some sensitivity values, we observe the exponential dependence in the initial conditions of the Lorenz model but not in the Kepler problem, giving an indicator of chaos (see section 5.3 for a brief comment about chaos indicators).

5.2. DAE problems. We have taken three classical DAE problems (two of them are slightly stiff) as test problems.

• *Nonlinear simple pendulum.* A DAE system of index 3 (we consider the values $L = g = 1$):

$$\left\{\begin{array}{r} x'' + x\,\lambda = 0, \\ y'' + y\,\lambda - g = 0, \\ x^2 + y^2 - L^2 = 0, \end{array}\right. \quad \left|\begin{array}{l} x_0 = 1/2, \quad x_0' = 1, \\ y_0 = -\sqrt{1 - x(0)^2}, \quad y_0' = -x_0\,x_0'/y_0, \\ \lambda_0 = y_0 + (x_0')^2 + (y_0')^2 = \frac{1}{6}\,(8 - 3\,\sqrt{3}). \end{array}\right.$$

The integration interval is [0, 100].

• *Transistor–amplifier problem* (a simplified version given in [23] of Problem 6 of [32]). This problem is an example of a stiff DAE system of index 1:

$$M\,\frac{d\boldsymbol{U}}{dt} = \boldsymbol{f}(\boldsymbol{U}), \qquad \boldsymbol{U}(0) = \left(0,\, \frac{U_b\,R_1}{R_1 + R_2},\, \frac{U_b\,R_1}{R_1 + R_2},\, U_b,\, 0\right)^{\mathrm{T}}$$

with

$$M = \begin{pmatrix} -C_1 & C_1 & 0 & 0 & 0 \\ C_1 & -C_1 & 0 & 0 & 0 \\ 0 & 0 & -C_2 & 0 & 0 \\ 0 & 0 & 0 & -C_3 & C_3 \\ 0 & 0 & 0 & C_3 & -C_3 \end{pmatrix},$$

$$\boldsymbol{f}(\boldsymbol{U}) = \begin{pmatrix} -\dfrac{U_e(t)}{R_0} + \dfrac{U_1}{R_0} \\ -\dfrac{U_b}{R_2} + U_2\left(\dfrac{1}{R_1} + \dfrac{1}{R_2}\right) + (1-\alpha)\, g(U_2 - U_3) \\ \dfrac{U_3}{R_3} - g(U_2 - U_3) \\ -\dfrac{U_b}{R_4} + \dfrac{U_4}{R_4} + \alpha\, g(U_2 - U_3) \\ \dfrac{U_5}{R_5} \end{pmatrix},$$

$$g(x) = 10^{-6}\left(\exp\left(\frac{x}{0.026}\right) - 1\right), \quad U_e(t) = 0.4\sin(200\,\pi\, t), \quad \alpha = 0.99,$$

$$R_0 = 1000, \quad R_1 = \cdots = R_5 = 9000, \quad U_b = 6, \quad C_1 = 10^{-6}, \quad C_k = k\, C_1\ (k = 2, 3).$$

The integration interval is [0, 0.5].

• *The chemical Akzo problem* (Problem 1 of [32]). This problem is an example of a stiff DAEs system of index 1:

$$M\,\frac{d\boldsymbol{y}}{dt} = \boldsymbol{f}(\boldsymbol{y}), \quad \boldsymbol{y}(0) = (0.444,\, 0.00123,\, 0,\, 0.0017,\, 0,\, K_s \cdot y_1(0) \cdot y_4(0))^{\mathrm{T}}$$

with

$$M = \begin{pmatrix} 1 & 0 & 0 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 & 0 & 0 \\ 0 & 0 & 1 & 0 & 0 & 0 \\ 0 & 0 & 0 & 1 & 0 & 0 \\ 0 & 0 & 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 \end{pmatrix}, \quad \boldsymbol{f}(\boldsymbol{y}) = \begin{pmatrix} -2r_1 + r_2 - r_3 - r_4 \\ -\frac{1}{2}\, r_1 - r_4 - \frac{1}{2}\, r_5 + F_{in} \\ r_1 - r_2 + r_3 \\ -2_2 + r_3 - 2r_4 \\ r_2 - r_3 + r_5 \\ K_s \cdot y_1 \cdot y_4 - y_6, \end{pmatrix},$$

$$r_1 = k_1 \cdot y_1^4 \cdot y_2^{\frac{1}{2}}, \qquad r_2 = k_2 \cdot y_3 \cdot y_4, \qquad r_3 = \frac{k_2}{K} \cdot y_1 \cdot y_5,$$

$$r_4 = k_3 \cdot y_1 \cdot y_4^2, \qquad r_5 = k_4 \cdot y_6^2 \cdot y_2^{\frac{1}{2}}, \qquad F_{in} = klA \cdot \left(\frac{p(\mathrm{CO}_2)}{H} - y_2\right).$$

The value of the parameters k_1, k_2, k_3, k_4, K, klA, $p(\mathrm{CO}_2)$, and H are $k_1 = 18.7$, $k_2 = 0.58$, $k_3 = 0.09$, $k_4 = 0.42$, $K_s = 115.83$, $K = 34.4$, $p(\mathrm{CO}_2) = 0.9$, $klA = 3.3$, and $H = 737$. The integration interval is [0, 180].

In Figure 5.3 we show precision-computer time diagrams in logarithmic scale for the `dop853` (only for the pendulum problem), `radau5` and `radau` codes, and the Taylor

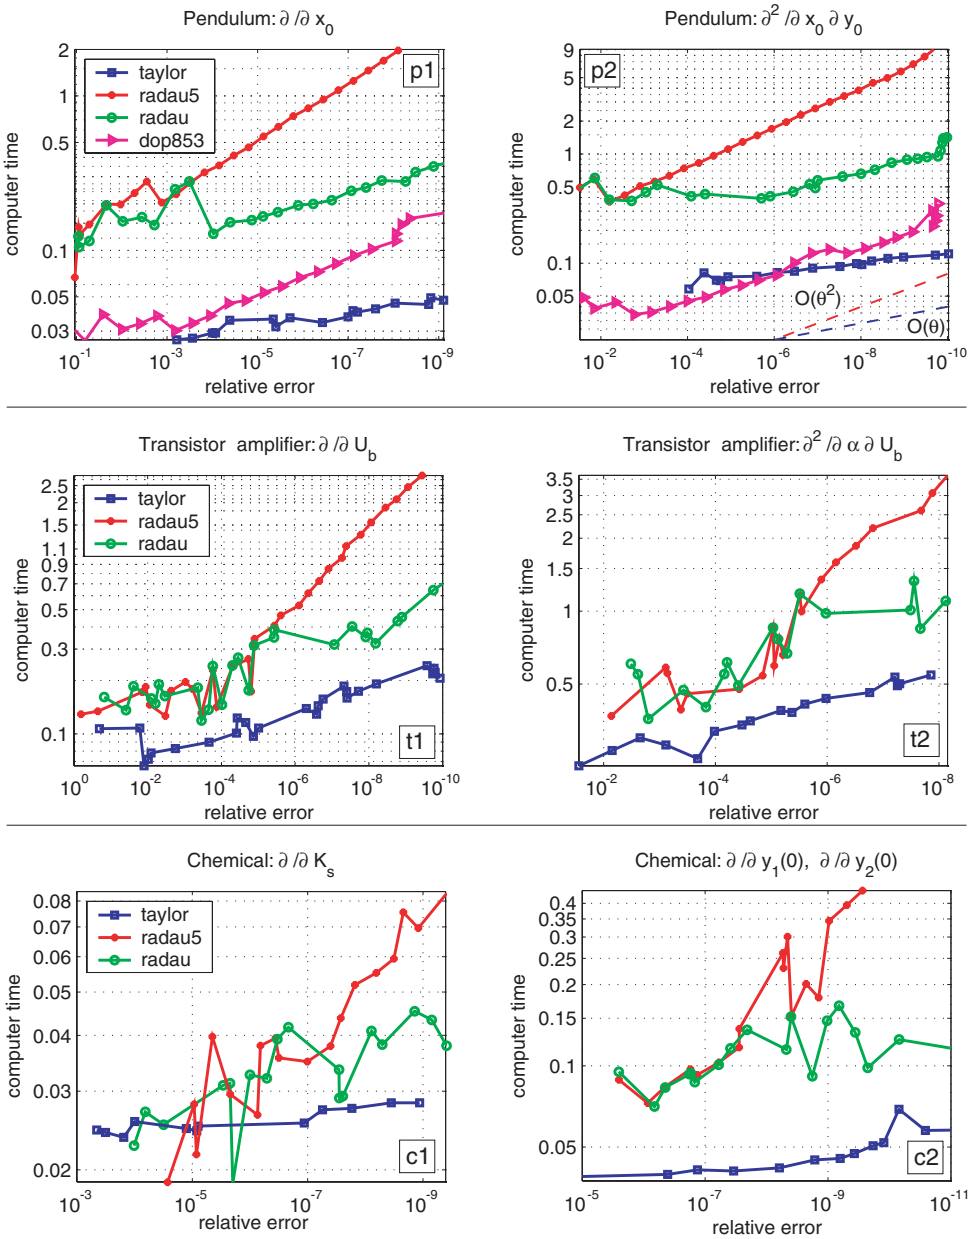

FIG. 5.3. *Precision-computer time diagrams for the pendulum, transistor–amplifier, and chemical problems in first- and second-order sensitivities.*

method for the computation of first- and second-order sensitivities for all the above three problems. Again, these graphs show the relative error and the computer time, and each point corresponds to a different requested accuracy. Because the algorithms are adaptive, neither the relative error nor the computer time depends continuously on the requested accuracy, which is more clear for DAEs than for ODEs, although we present the graphs connected with continuous lines to help the visualization. In

particular, we show first-order sensitivities with respect to the initial condition x_0 (graph (p1)) and second-order sensitivities with respect to the initial conditions x_0 and y_0 (graph (p2)) for the pendulum problem, first-order sensitivities with respect to the parameter U_b (graph (t1)) and second-order sensitivities with respect to the parameters α and U_b (graph (t2)) for the transistor–amplifier problem, and first-order sensitivities with respect to the parameter K_s (graph (c1)) and first-order sensitivities with respect to the initial conditions $y_1(0)$ and $y_2(0)$ (graph (c2)) for the chemical Akzo problem. In all the simulations the relative error is computed at the end of the integration time using the infinity norm.

From the graphs we observe that for low-precision demands the explicit methods (`dop853` for the pendulum problem and the Taylor method) are the most efficient, with the Taylor method the fastest for high-precision demands. Therefore, as occurs on the ODE tests, the slopes of the curves, for fixed-order RK (`dop853` and `radau5`) on one hand, and variable-order RK (`radau`) and the Taylor method on the other hand, are different due to the variable-order formulation that gives a more adaptive method. For very high precision demands the Taylor method is the method of choice (see [3] for numerical tests). At the bottom-right of graph (p2) we show with dashed lines the evolution of two straight lines in the `loglog` figures, one with a slope double that of the other.

In the DAE problems the initial conditions for the sensitivity values have to be consistent with the problem. For example, on the nonlinear pendulum we have taken as consistent initial conditions for first-order sensitivities:

$$\left(\frac{\partial x}{\partial x_0}(0),\, \frac{\partial x'}{\partial x_0}(0),\, \frac{\partial y}{\partial x_0}(0),\, \frac{\partial y'}{\partial x_0}(0),\, \frac{\partial \lambda}{\partial x_0}(0)\right) = \left(1,\, 0,\, \frac{1}{\sqrt{3}},\, \frac{8}{3\sqrt{3}},\, \frac{8+3\sqrt{3}}{9}\right).$$

In graphs (t1), (t2), (c1), and (c2) the code `dop853` does not work as the problems are stiff, but the Taylor method of high order works, and it is the fastest method. Although the Taylor method may be used for these moderately stiff problems, this is not true for highly stiff systems, where we need implicit methods.

5.3. Dynamical systems: Application to a chaos indicator. The above tests show that the Taylor method may be competitive in the numerical computation of sensitivities for some problems. Now, we present an application to dynamical systems (a discipline where Taylor methods may be quite useful [21, 29]), in particular to the determination of the $\mathrm{OFLI}^2_{\mathrm{TT}}$ chaos indicator [2]. These chaos indicator techniques try to analyze if a given initial condition generates a chaotic orbit or the orbit lies on an invariant torus. In the literature there exist several numerical tools as the Poincaré surfaces of section, the maximum Lyapunov exponent, the heliticity and twist angles, frequency map analysis, the mean exponential growth factor of nearby orbits (MEGNO), the fast Lyapunov indicator (FLI) [18], and the smaller alignment index (SALI). Most of them need the computation of first-order variational equations. A new chaos indicator called $\mathrm{OFLI}^2_{\mathrm{TT}}$, based on the FLI indicator, was recently introduced in [2]. The $\mathrm{OFLI}^2_{\mathrm{TT}}$ indicator at the final time t_f is defined as

$$\mathrm{OFLI}^2_{\mathrm{TT}} := \sup_{0<t<t_f} \log \left\| \left\{ \delta \boldsymbol{y}(t) + \frac{1}{2}\, \delta^2 \boldsymbol{y}(t) \right\}^{\perp} \right\|,$$

where $\delta \boldsymbol{y}$ and $\delta^2 \boldsymbol{y}$ are first- and second-order sensitivities with respect to carefully chosen initial vectors. In this case the variational equations are up to second-order

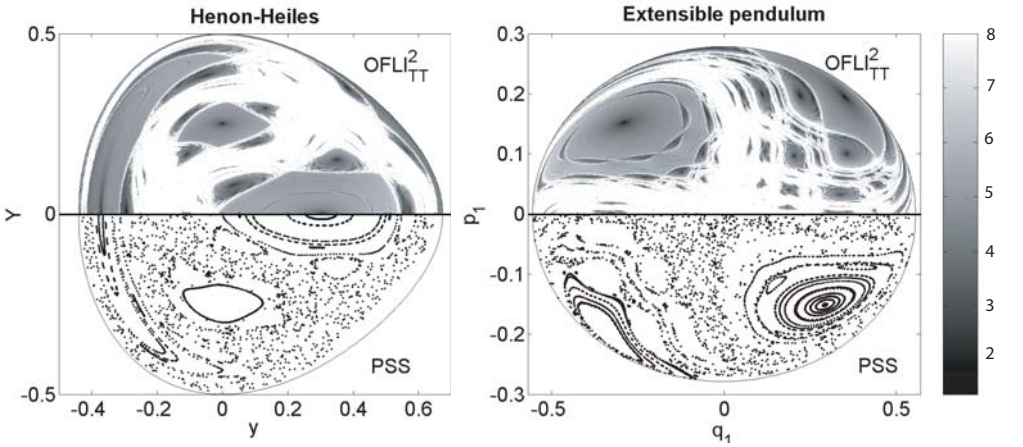

FIG. 5.4. $\mathrm{OFLI}^2_{\mathrm{TT}}$ *and Poincaré surfaces of section (PSS) of the Hénon–Heiles and the extensible-pendulum problems.*

and the initial conditions are

$$\frac{d\boldsymbol{y}}{dt} = \boldsymbol{f}(t,\boldsymbol{y}), \qquad \boldsymbol{y}(0) = \boldsymbol{y}_0,$$

$$\frac{d\,\delta\boldsymbol{y}}{dt} = \frac{\partial \boldsymbol{f}(t,\boldsymbol{y})}{\partial \boldsymbol{y}}\,\delta\boldsymbol{y}, \qquad \delta\boldsymbol{y}(0) = \boldsymbol{T}_0 := \frac{\boldsymbol{f}(0,\boldsymbol{y}_0)}{\|\boldsymbol{f}(0,\boldsymbol{y}_0)\|},$$

$$\frac{d\,\delta^2\boldsymbol{y}}{dt} = \frac{\partial \mathbf{f}}{\partial \boldsymbol{y}}\,\delta^2\boldsymbol{y} + \frac{\partial^2 \mathbf{f}}{\partial \boldsymbol{y}^2}\,(\delta\boldsymbol{y})^2, \quad \delta^2\boldsymbol{y}(0) = \mathbf{0}.$$

In the definition $\boldsymbol{v}^{\perp}$ stands for the component of $\boldsymbol{v}$ orthogonal to the flow. The $\mathrm{OFLI}^2_{\mathrm{TT}}$ requires the computation of second-order sensitivities with respect to a vector, and therefore the Taylor method may be used, requiring only the first- and second-order directional derivatives and not all the partial derivatives. We notice that the problems usually studied in dynamical systems are of low dimension and without a very complicated right-hand side. In this kind of problem the Taylor method gives a very good performance [3].

In Figure 5.4 we show the $\mathrm{OFLI}^2_{\mathrm{TT}}$ and the classical Poincaré sections of two classical problems in dynamical systems: the Hénon–Heiles and the extensible-pendulum problems. The Hénon–Heiles system [25] is given by the Hamiltonian

$$\mathcal{H}(x,\,y,\,X,\,Y) = \frac{1}{2}\,(X^2 + Y^2 + x^2 + y^2) + x^2\,y - \frac{1}{3}y^3,$$

and the extensible-pendulum problem [10] is given by the Hamiltonian

$$\mathcal{H}(q_1,\,q_2,\,p_1,\,p_2) = \frac{1}{2}\,(p_1^2 + p_2^2) + \frac{1}{2}\big((1-c)\,q_1^2 + q_2^2 - c\,q_1^2\,q_2\big).$$

On the tests we have considered $c = 0.75$. Due to the symmetry of the problems we show in the upper part of Figure 5.4 the $\mathrm{OFLI}^2_{\mathrm{TT}}$ and in the bottom part the Poincaré sections for the value of the energy $E = 1/8$ and $E = 31/800$ for the Hénon–Heiles and the extensible pendulum, respectively. The new technique permits us to obtain much more information than the Poincaré sections. The Taylor method has been

employed with a local error tolerance level of 10^{-12} for both techniques. For the Poincaré sections we use a *G-stop* criteria [14] (when $x = 0$ for the Hénon–Heiles and $q_2 = 0$ for the extensible pendulum) taking advantage of the continuous output as a power series. For the $\mathrm{OFLI}^2_{\mathrm{TT}}$ we use the Taylor method for computing sensitivities that permits a fast and easy computation of the values of the indicator (easy because the code is the "same" for just the integration and the integration and computation of the sensitivities). In the figure a high value of the chaos indicator (white) implies a chaotic behavior, whereas the lowest value (black) is associated with periodic orbits and the intermediate values (gray) are in the KAM tori. For more details about chaos indicators, the $\mathrm{OFLI}^2_{\mathrm{TT}}$, and its dynamical implications, see [2].

6. Conclusions. We have introduced the Taylor series method for the sensitivity analysis of ODE/DAE systems. In order to use this method we need a set of AD rules for the determination of the Taylor coefficients of the partial derivatives. From the numerical tests we observe that this method may be quite useful for low-dimensional problems such as in many interesting problems in dynamical systems [12, 21], where we are also interested in high precision. For this kind of problem the use of the Taylor series method gives an attractive alternative to other schemes. Although the numerical tests presented in this paper are not an exhaustive comparison among the different methods for computing sensitivity values, our numerical tests show that the Taylor series method is useful and provides good performance, at least for some kinds of problems.

Acknowledgments. The author thanks an anonymous referee for the numerous suggestions, remarks, and corrections that have contributed to improving the paper. The author thanks Professor J. D. Pryce for sending him a preprint of reference [36].

SYSTEMATIC DERIVATION OF JUMP CONDITIONS FOR THE IMMERSED INTERFACE METHOD IN THREE-DIMENSIONAL FLOW SIMULATION*

SHENG XU† AND Z. JANE WANG†

Abstract. In this paper, we systematically derive jump conditions for the immersed interface method [*SIAM J. Numer. Anal.*, 31 (1994), pp. 1019–1044; *SIAM J. Sci. Comput.*, 18 (1997), pp. 709–735] to simulate three-dimensional incompressible viscous flows subject to moving surfaces. The surfaces are represented as singular forces in the Navier–Stokes equations, which give rise to discontinuities of flow quantities. The principal jump conditions across a closed surface of the velocity, the pressure, and their normal derivatives have been derived by Lai and Li [*Appl. Math. Lett.*, 14 (2001), pp. 149–154]. In this paper, we first extend their derivation to generalized surface parametrization. Starting from the principal jump conditions, we then derive the jump conditions of all first-, second-, and third-order spatial derivatives of the velocity and the pressure. We also derive the jump conditions of first- and second-order temporal derivatives of the velocity. Using these jump conditions, the immersed interface method is applicable to the simulation of three-dimensional incompressible viscous flows subject to moving surfaces, where near the surfaces the first- and second-order spatial derivatives of the velocity and the pressure can be discretized with, respectively, third- and second-order accuracy, and the first-order temporal derivatives of the velocity can be discretized with second-order accuracy.

Key words. immersed interface method, immersed boundary method, Cartesian grid methods, jump conditions, three-dimensional Navier–Stokes equations, singular force

1. Introduction.

Blood flow in the heart [23, 24, 25], aquatic animal locomotion [10, 15], bird and insect flight [31, 32, 3, 8, 9, 13], and flow passing a compliant wall [35, 6, 14, 4] are examples of fluid dynamics problems where it is essential to understand the coupling between moving surfaces and fluids. A main difficulty in direct numerical simulation of these problems is to accurately and efficiently resolve the moving surfaces and their effects on the fluids.

Cartesian grid methods, for example [28, 5, 30, 22, 21], avoid mesh regeneration and allow for fast flow solvers, and thus have the advantage of simplicity and efficiency for this type of problem. The immersed boundary method is a robust Cartesian grid method. It was originally proposed by Peskin [23, 24] and later further developed in [29, 26, 27, 16]. In this method, the moving surface of an immersed object is parametrized by a set of Lagrangian points comoving with a fluid. The relative positions of the Lagrangian points determine a singular force distribution on the surface based on the solid model of the object. The communication between the surface and the fluid is achieved through the spreading of the singular force and the interpolation of the surface velocity using discrete Dirac δ functions. The method has been applied to a wide variety of problems [10, 11, 25, 1, 37].

The initial implementations of the immersed boundary method were only first-order accurate in space due to the use of grid-dependent discrete Dirac δ functions.

Beyer and LeVeque [2] examined the accuracy of the method for the one-dimensional diffusion equation and found that additional terms for the discrete approximation of the Dirac δ function are sometimes necessary in order to achieve second-order accuracy, but it is unclear how to maintain the second-order accuracy by incorporating additional terms in fluid dynamics problems of higher dimensions. Although a formally second-order immersed boundary method was proposed [16], it is second-order accurate only if the Dirac δ function is replaced by a grid-independent smooth function; in practice, it is still first-order accurate. Realizing that only the divergence-free portion of the singular force contributes to the temporal evolution of the velocity, and that the projection of discrete Dirac δ functions onto a divergence-free space may be computed analytically, Cortez and Minion [7] devised the blob projection immersed boundary method, which displays the formally fourth-order convergence rate of their background flow solver. However, the analytical form of the projection depends on the velocity boundary conditions imposed on a computational domain. Thus the method may be limited to particular boundary conditions in simple geometries. It is also unclear how accurately the pressure can be recovered.

Motivated by the goal of eventually obtaining second-order accuracy in Peskin's immersed boundary method, LeVeque and Li [18, 19] have developed the immersed interface method (IIM). The IIM was originally proposed for elliptic equations [18] and Stokes equations [19]. Later, it was extended to one-dimensional nonlinear parabolic equations [33], Poisson equations with Neumann boundary conditions [34, 12], and two-dimensional incompressible Navier–Stokes equations [20]. The key idea of the IIM, which is also its main difference from the immersed boundary method, is to incorporate the known jump conditions of a solution and its derivatives into finite difference schemes in the neighborhood of the discontinuities arising from the Dirac δ function. For fluid dynamics problems with moving surfaces, the coupling between the moving surfaces and the fluids is now translated into the incorporation of the jump conditions.

If necessary jump conditions are known, the IIM can achieve second-order or even higher-order accuracy. The two-dimensional Navier–Stokes simulations by Li and Lai [20] using the IIM have indicated fully second-order accuracy for the velocity and nearly second-order accuracy for the pressure in the infinity norm. Solutions computed by the IIM are sharper across surfaces than those computed by the immersed boundary method. Furthermore, the IIM shows better conservation of the mass enclosed by a no-penetration surface.

Like any other method, the IIM has its limitations. For instance, the current IIM applies only to flows with closed smooth surfaces, as seen in its presentation later in this paper. Both the IIM and the immersed boundary method also inherit the shortcomings of fixed Cartesian grid methods. For example, thin boundary layers developed along a moving boundary and fine geometric details can be adequately resolved only if the uniform computational mesh is fine enough. It should also be noted that, for many bio-fluid dynamics problems, the computation of the singular force distribution is a modeling process, and improvement in the accuracy of the IIM or the immersed boundary method cannot eliminate modeling errors.

The applicability of the IIM depends on whether the necessary jump conditions are all known. The principal jump conditions across a closed surface of the velocity, the pressure, and their normal derivatives have been derived by Lai and Li [17] for three-dimensional incompressible viscous flows. The main contribution of our paper is to derive for the IIM the necessary jump conditions of flow variables and their

derivatives to achieve a given-order discretization accuracy in three-dimensional flow simulation. Other contributions include generalized Taylor expansion, which is the basis for devising finite difference schemes for the IIM; a generalized Gauss theorem, which serves as the basic tool in the derivation of the principal jump conditions; the principal jump conditions in generalized surface parametrization, which bring the flexibility to parametrize a singular surface in practical applications; and the jump conditions of temporal derivatives, which are required to achieve first-order or higher-order temporal discretization accuracy.

The content of the paper is organized as follows. In section 2, the governing equations are described; they are the starting point for the derivation of the principal jump conditions. In section 3, the principal jump conditions are derived. In section 4, finite difference schemes with jump conditions incorporated are presented. In sections 5 and 6, the required spatial and temporal jump conditions are derived. A simple example is also provided in section 6 to address the proper discretization of temporal derivatives. In section 7, the possibility of improving the IIM to arbitrarily high-order discretization accuracy is discussed.

Since the original submission of this paper, we have implemented and tested the IIM in two-dimensional flow simulations with jump conditions obtained from our theoretical derivation below. Please refer to Xu and Wang [36] for the full numerical implementation and the test results. The test results serve in part to verify our derivation in the current paper. We have also progressed on the development of a three-dimensional code. We hope to provide the three-dimensional results soon.

2. Governing equations. Incompressible Navier–Stokes equations subject to singular force are

$$\rho\left(\frac{\partial u^i}{\partial t}+u^j\frac{\partial u^i}{\partial x^j}\right)=-\frac{\partial p}{\partial x^i}+\mu\frac{\partial^2 u^i}{\partial x^j\partial x^j}+F^i, \tag{2.1}$$

$$\frac{\partial u^i}{\partial x^i}=0, \tag{2.2}$$

where $x^i(i=1,2,3)$ is in Cartesian coordinates, t is time, ρ is fluid density, u^i is velocity, p is pressure, μ is dynamic fluid viscosity, and F^i is the singular force. Taking the divergence of momentum equation (2.1) and applying continuity condition (2.2) gives the Poisson equation for pressure p as

$$\frac{\partial^2 p}{\partial x^i\partial x^i}=\frac{\partial F^i}{\partial x^i}-\frac{\partial}{\partial x^i}\left(\rho\frac{\partial u^i}{\partial t}+\rho u^j\frac{\partial u^i}{\partial x^j}\right). \tag{2.3}$$

We consider the situation that the singular force is applied on the closed surface of an immersed object, and we call the surface singular surface $\mathcal{S}$. Referring to Figure 2.1, singular force F^i is given by

$$F^i=\int_{\mathcal{S}} f^i(\alpha^1,\alpha^2,t)\delta(\mathbf{x}-\mathbf{X}(\alpha^1,\alpha^2,t))\mathrm{d}\alpha^1\mathrm{d}\alpha^2, \tag{2.4}$$

in which $\mathbf{x}:=(x^1,x^2,x^3)$ is the Cartesian coordinates, $\mathbf{X}(\alpha^1,\alpha^2,t):=(X^1,X^2,X^3)$ is the coordinates of the singular surface, $\delta(\mathbf{x}-\mathbf{X}(\alpha^1,\alpha^2,t))$ is the three-dimensional Dirac δ function, $f^i(\alpha^1,\alpha^2,t)$ is force density, and α^1 and α^2 are two Lagrangian parameters which parametrize the singular surface at a reference time. We assume

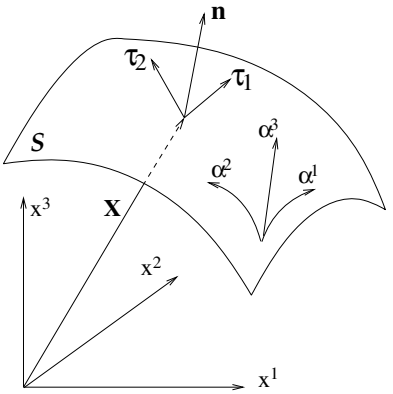

FIG. 2.1. *Cartesian coordinates* $x^i (i = 1, 2, 3)$ *and curvilinear coordinates* $\alpha^i (i = 1, 2, 3)$. α^1 *and* α^2 *are two Lagrangian parameters which parametrize the singular surface* $\mathcal{S}$ *at a reference time.* $\mathbf{X}$ *is the coordinates of the singular surface.* $\boldsymbol{\tau_1}$, $\boldsymbol{\tau_2}$, *and* $\mathbf{n}$ *are respectively the two tangential vectors and the normal vector at* $\mathbf{X}$.

that $f^i(\alpha^1, \alpha^2, t)$ is a smooth function of α^1, α^2, and t. Mathematically, F^i can be regarded as a distribution function with the property

$$\int_\Omega F^i \mathrm{d}\Omega = \int_{\Omega \cap \mathcal{S}} f^i(\alpha^1, \alpha^2, t) \mathrm{d}(\Omega \cap \mathcal{S}),$$

where Ω can be a volume or a surface.

3. Principal jump conditions. We now derive the principal jump conditions of the velocity, u^i, the pressure, p, and their normal derivatives, $\frac{\partial u^i}{\partial \mathbf{n}}$ and $\frac{\partial p}{\partial \mathbf{n}}$, across the singular surface, $\mathcal{S}$.

We assume that the velocity, the pressure, and their derivatives are piecewise smooth with discontinuities only at the singular surface. The singular surface, $\mathcal{S}$: $\mathbf{X} = (X^1, X^2, X^3)$, is assumed geometrically regular and orientable. For every point on the surface, the parametrization by α^1 and α^2 generates a rank-two matrix

$$\begin{pmatrix} \dfrac{\partial X^1}{\partial \alpha^1} & \dfrac{\partial X^2}{\partial \alpha^1} & \dfrac{\partial X^3}{\partial \alpha^1} \\ \dfrac{\partial X^1}{\partial \alpha^2} & \dfrac{\partial X^2}{\partial \alpha^2} & \dfrac{\partial X^3}{\partial \alpha^2} \end{pmatrix}.$$

The row vectors in the above matrix are two independent tangential vectors at the point (see Figure 2.1)

$$\boldsymbol{\tau_1} := (\tau_1^1, \tau_1^2, \tau_1^3) = \left(\frac{\partial X^1}{\partial \alpha^1}, \frac{\partial X^2}{\partial \alpha^1}, \frac{\partial X^3}{\partial \alpha^1} \right),$$
$$\boldsymbol{\tau_2} := (\tau_2^1, \tau_2^2, \tau_2^3) = \left(\frac{\partial X^1}{\partial \alpha^2}, \frac{\partial X^2}{\partial \alpha^2}, \frac{\partial X^3}{\partial \alpha^2} \right).$$

A unit normal vector can be expressed by

$$\mathbf{n} := (n^1, n^2, n^3) = \frac{\boldsymbol{\tau_1} \times \boldsymbol{\tau_2}}{\|\boldsymbol{\tau_1} \times \boldsymbol{\tau_2}\|} = \frac{\boldsymbol{\tau_1} \times \boldsymbol{\tau_2}}{\mathcal{J}},$$

where $\|\cdot\|$ denotes the length of a vector and $\mathcal{J} := \|\tau_{\mathbf{1}} \times \tau_{\mathbf{2}}\|$; see Figure 2.1. In Cartesian coordinates, $\mathbf{n} = (n^1, n^2, n^3) = (n_1, n_2, n_3)$, where $n^i (i = 1, 2, 3)$ is a contravariant component and $n_i (i = 1, 2, 3)$ a covariant component.

PROPOSITION 3.1. *For a flow defined by* (2.1) *and* (2.2)*, the velocity,* u^i*, is finite and continuous at the immersed singular surface,* $\mathcal{S}$*; i.e.,*

$$[u^i] = 0, \tag{3.1}$$

where $[\cdot]$ *denotes a jump as* $[\cdot] := (\cdot)_{\mathbf{X}^+} - (\cdot)_{\mathbf{X}^-}$*, with* $\mathbf{X}^+$ *representing the point at the side of* $\mathcal{S}$ *in the direction of normal* $\mathbf{n}$ *and* $\mathbf{X}^-$ *the point at the other side.*

Continuity equation (2.2) assures only the continuity of the normal velocity component across the singular surface. In our applications, the singular surface is a physical boundary immersed in an incompressible viscous fluid. No-slip and no-penetration conditions on this physical boundary require the velocity to be continuous across the singular surface and the singular surface to move with the local flow velocity, as expressed mathematically by Proposition 3.1.

COROLLARY 3.2.

$$\left[\frac{\partial u^i}{\partial t} + u^j \frac{\partial u^i}{\partial x^j}\right] = \left[\frac{\partial u^i}{\partial t}\right] + u^j \left[\frac{\partial u^i}{\partial x^j}\right] = 0. \tag{3.2}$$

Proof. A jump condition is a function of the time t and the surface coordinates $\mathbf{X}(\alpha^1, \alpha^2, t)$, i.e., $[\cdot] = [\cdot](\mathbf{X}, t)$. Differentiating (3.1) with respect to time t gives

$$\begin{aligned}
\frac{\mathrm{d}[u^i](\mathbf{X}, t)}{\mathrm{d}t} &= \frac{\mathrm{d}u^i(\mathbf{X}^+, t)}{\mathrm{d}t} - \frac{\mathrm{d}u^i(\mathbf{X}^-, t)}{\mathrm{d}t} \\
&= \frac{\partial u^i(\mathbf{X}^+, t)}{\partial t} + \frac{\partial u^i(\mathbf{X}^+, t)}{\partial x^j}\frac{\mathrm{d}X^{j+}}{\mathrm{d}t} \\
&\quad - \left(\frac{\partial u^i(\mathbf{X}^-, t)}{\partial t} + \frac{\partial u^i(\mathbf{X}^-, t)}{\partial x^j}\frac{\mathrm{d}X^{j-}}{\mathrm{d}t}\right) \\
&= \left[\frac{\partial u^i}{\partial t} + \frac{\partial u^i}{\partial x^j}\frac{\mathrm{d}X^j}{\mathrm{d}t}\right] = 0.
\end{aligned}$$

From Proposition 3.1, we have $\frac{\mathrm{d}X^{j+}}{\mathrm{d}t} = \frac{\mathrm{d}X^{j-}}{\mathrm{d}t} = u^j$. Thus, the result follows. ∎

The notion of a jump condition, $[\cdot]$, commutes with a differentiation, and we can therefore write the function form of a jump condition as $[\cdot(\mathbf{X}, t)]$ to carry out the differentiation hereafter.

To derive the other principal jump conditions, we need to generalize Gauss's theorem. Gauss's theorem in the usual form reads

$$\int_{\mathcal{V}} \frac{\partial G^i}{\partial x^i} \mathrm{d}\mathcal{V} = \oint_{\mathcal{A}} G^i N_i \mathrm{d}\mathcal{A},$$

where $\mathcal{A}$ is a regular and positively oriented closed surface, $\mathcal{V}$ is the region enclosed by $\mathcal{A}$, and N_i is a normal to $\mathcal{A}$. It is required that the function G^i and its divergence $\frac{\partial G^i}{\partial x^i}$ be continuous over $\mathcal{A}$ and $\mathcal{V}$. We generalize Gauss's theorem to relax these continuity restrictions.

THEOREM 3.3 (generalized Gauss theorem). *If* G^i *and* $\frac{\partial G^i}{\partial x^i}$ *are continuous over* $\mathcal{A}$ *and* $\mathcal{V}$ *except that* G^i *has finite jumps or a singularity of the Dirac* δ *function type at the singular surface* $\mathcal{S}$ *enclosed in* $\mathcal{V}$*, then*

$$\int_{\mathcal{V}} \frac{\partial G^i}{\partial x^i} \mathrm{d}\mathcal{V} = \oint_{\mathcal{A}} G^i N_i \mathrm{d}\mathcal{A}. \tag{3.3}$$

The proof of Theorem 3.3 is given in Appendix A.

LEMMA 3.4. *For a flow defined by* (2.1) *and* (2.2)*, the jump conditions across singular surface* $\mathcal{S}$ *of pressure* p *and normal velocity derivative* $\frac{\partial u^i}{\partial \mathbf{n}}$ *satisfy*

$$[p] = \frac{f^k n_k}{\mathcal{J}}, \tag{3.4}$$

$$\left[\frac{\partial u^i}{\partial \mathbf{n}}\right] = \frac{(f^k n_k)n^i - f^i}{\mu \mathcal{J}}. \tag{3.5}$$

Equation (3.4) states that the normal force on the singular surface is balanced by the difference of the pressure force across the singular surface, and (3.5) states that the tangential force on the singular surface is balanced by the difference of the shear force across the singular surface. Below, we prove Lemma 3.4 through the force balance on a control volume. The same results were obtained by Lai and Li [17] by using the test function method.

Proof. Take an infinitesimal area, $\delta\mathcal{S} = \mathcal{J}\delta\alpha^1\delta\alpha^2$, on singular surface $\mathcal{S}$, which corresponds to an infinitesimal area, $\delta\alpha^1\delta\alpha^2$, in the parameter space. Translate $\delta\mathcal{S}$ in the directions of $\mathbf{n}$ and $-\mathbf{n}$ by $\epsilon/2$, and denote the swept region $\delta\mathcal{V}$. Integrating (2.1) over $\delta\mathcal{V}$ and letting $\epsilon \to 0$ yields

$$\lim_{\epsilon\to 0}\int_{\delta\mathcal{V}} \rho\left(\frac{\partial u^i}{\partial t} + u^j\frac{\partial u^i}{\partial x^j}\right)\mathrm{d}\mathcal{V} = \lim_{\epsilon\to 0}\int_{\delta\mathcal{V}} \frac{\partial}{\partial x^j}\left(-p\delta^{ij} + \mu\frac{\partial u^i}{\partial x^j}\right)\mathrm{d}\mathcal{V} + \lim_{\epsilon\to 0}\int_{\delta\mathcal{V}} F^i \mathrm{d}\mathcal{V}, \tag{3.6}$$

where δ^{ij} is the Kronecker symbol. Applying (2.2) and the Reynolds transport theorem, the left-hand side of (3.6) becomes

$$\lim_{\epsilon\to 0}\int_{\delta\mathcal{V}} \rho\left(\frac{\partial u^i}{\partial t} + u^j\frac{\partial u^i}{\partial x^j}\right)\mathrm{d}\mathcal{V} = \lim_{\epsilon\to 0}\int_{\delta\mathcal{V}} \left(\frac{\partial \rho u^i}{\partial t} + \frac{\partial \rho u^i u^j}{\partial x^j}\right)\mathrm{d}\mathcal{V} = \lim_{\epsilon\to 0}\frac{\mathrm{d}}{\mathrm{d}t}(\rho u^i \delta\mathcal{V}) = 0.$$

Applying our generalized Gauss theorem to the first term on the right-hand side of (3.6) yields

$$\begin{aligned}\lim_{\epsilon\to 0}\int_{\delta\mathcal{V}} \frac{\partial}{\partial x^j}\left(-p\delta^{ij} + \mu\frac{\partial u^i}{\partial x^j}\right)\mathrm{d}\mathcal{V} &= \lim_{\epsilon\to 0}\int_{\delta\mathcal{S}} n_j\left[-p\delta^{ij} + \mu\frac{\partial u^i}{\partial x^j}\right]\mathrm{d}\mathcal{S} \\ &= \left(-[p]n^i + \mu\left[\frac{\partial u^i}{\partial x^k}\right]n^k\right)\delta\mathcal{S}.\end{aligned}$$

The last term in (3.6) is

$$\begin{aligned}\lim_{\epsilon\to 0}\int_{\delta\mathcal{V}} F^i \mathrm{d}\mathcal{V} &= \lim_{\epsilon\to 0}\int_{\mathcal{S}}\int_{\delta\mathcal{V}} f^i(\alpha^1,\alpha^2,t)\delta(\mathbf{x} - \mathbf{X}(\alpha^1,\alpha^2,t))\mathrm{d}\mathcal{V}\mathrm{d}\alpha^1\mathrm{d}\alpha^2 \\ &= f^i(\alpha^1,\alpha^2,t)\delta\alpha^1\delta\alpha^2.\end{aligned}$$

Thus,

$$\begin{aligned}\left(-[p]n^i + \mu\left[\frac{\partial u^i}{\partial x^k}\right]n^k\right)\delta\mathcal{S} + f^i(\alpha^1,\alpha^2,t)\delta\alpha^1\delta\alpha^2 &= 0 \\ \Rightarrow -[p]n^i + \mu\left[\frac{\partial u^i}{\partial x^k}\right]n^k &= -\frac{f^i(\alpha^1,\alpha^2,t)}{\mathcal{J}}.\end{aligned}$$

Multiplying n_i above and applying the facts that $n^k n_i + \tau^k \tau_i + b^k b_i = \delta_i^k$ (where δ_i^k is the Kronecker symbol, and $\mathbf{n}$, τ, and $\mathbf{b}$ are mutually orthogonal unit vectors), $\frac{\partial u^i}{\partial x^i} = 0$, and $[\frac{\partial u^i}{\partial \tau}] = [\frac{\partial u^i}{\partial \mathbf{b}}] = 0$ (from $[u^i] = 0$), we obtain

$$[p] = \frac{f^i n_i}{\mathcal{J}},$$
$$\mu \left[\frac{\partial u^i}{\partial x^k}\right] n^k = \frac{-f^i}{\mathcal{J}} + [p] n^i \Rightarrow \left[\frac{\partial u^i}{\partial \mathbf{n}}\right] = \frac{(f^k n_k) n^i - f^i}{\mu \mathcal{J}}. \qquad \square$$

Now we use the test function method to derive the jump condition of the normal pressure derivative, $\frac{\partial p}{\partial \mathbf{n}}$, across the singular surface with generalized surface parametrization. To prepare for the derivation, we first introduce a coordinate transformation (see Figure 2.1) between Cartesian coordinates $x^i (i = 1, 2, 3)$ and curvilinear coordinates $\alpha^i (i = 1, 2, 3)$ as

$$x^i = x^i(\alpha^1, \alpha^2, \alpha^3),$$
$$\alpha^i = \alpha^i(x^1, x^2, x^3),$$

where α^3 is a new coordinate with $\mathbf{x}(\alpha^1, \alpha^2, \alpha^3 = 0, t) = \mathbf{X}(\alpha^1, \alpha^2, t)$ corresponding to the singular surface, $\mathcal{S}$, and α^3 is chosen to satisfy

$$\frac{\partial \mathbf{x}(\alpha^1, \alpha^2, \alpha^3 = 0, t)}{\partial \alpha^3} = \mathbf{n}.$$

It can be shown that

$$\nabla \alpha^3 = \mathbf{n},$$

where ∇ is the gradient operator in the Cartesian coordinate system. Let $\tilde{f}^i$ be a contravariant component of the forcing density vector in the curvilinear coordinate system. It is related to f^i through

$$\tilde{f}^i = \frac{\partial \alpha^i}{\partial x^j} f^j,$$

where $\frac{\partial \alpha^i}{\partial x^j}$ satisfies

$$\frac{\partial x^k}{\partial \alpha^i} \frac{\partial \alpha^i}{\partial x^j} = \delta_j^k,$$

in which δ_j^k is the Kronecker symbol and $\frac{\partial x^k}{\partial \alpha^i}$ can be written in a matrix form on the singular surface $\mathcal{S}$ as

$$C_1^T := \begin{pmatrix} \tau_1^1 & \tau_1^2 & \tau_1^3 \\ \tau_2^1 & \tau_2^2 & \tau_2^3 \\ n^1 & n^2 & n^3 \end{pmatrix}^T, \tag{3.7}$$

where superscript T denotes the transposition of a matrix. As the determinant of C_1 is $|C_1| = \mathbf{n} \cdot (\tau_\mathbf{1} \times \tau_\mathbf{2}) \neq 0$, C_1 is nonsingular.

LEMMA 3.5. *The jump condition of normal pressure derivative* $\frac{\partial p}{\partial \mathbf{n}}$ *across the singular surface is*

$$\left[\frac{\partial p}{\partial \mathbf{n}}\right] = \frac{1}{\mathcal{J}} \left(\frac{\partial \tilde{f}^1}{\partial \alpha^1} + \frac{\partial \tilde{f}^2}{\partial \alpha^2}\right). \tag{3.8}$$

Proof. Take control volume $\mathcal{V}_s$ so that $\mathcal{V}_s$ is a layer with thickness ϵ containing singular surface $\mathcal{S}$. Denote the surface of $\mathcal{V}_s$ by $\mathcal{A}$. Multiplying a smooth test function, $\phi(\mathbf{x})$, by (2.3) and then integrating over $\mathcal{V}_s$ with $\epsilon \to 0$ yields

$$\lim_{\epsilon\to 0}\int_{\mathcal{V}_s}\phi\frac{\partial^2 p}{\partial x^i\partial x^i}\mathrm{d}\mathcal{V}=\lim_{\epsilon\to 0}\int_{\mathcal{V}_s}\phi\frac{\partial F^i}{\partial x^i}\mathrm{d}\mathcal{V}-\lim_{\epsilon\to 0}\int_{\mathcal{V}_s}\phi\frac{\partial}{\partial x^i}\left(\rho\frac{\partial u^i}{\partial t}+\rho u^j\frac{\partial u^i}{\partial x^j}\right)\mathrm{d}\mathcal{V}. \tag{3.9}$$

With Theorem 3.3, the term on the left-hand side of (3.9) can be written as

$$\begin{aligned}\lim_{\epsilon\to 0}\int_{\mathcal{V}_s}\phi\frac{\partial^2 p}{\partial x^i\partial x^i}\mathrm{d}\mathcal{V}&=\lim_{\epsilon\to 0}\int_{\mathcal{V}_s}\left(\frac{\partial}{\partial x^i}\left(\phi\frac{\partial p}{\partial x^i}\right)+p\frac{\partial^2\phi}{\partial x^i\partial x^i}-\frac{\partial}{\partial x^i}\left(p\frac{\partial\phi}{\partial x^i}\right)\right)\mathrm{d}\mathcal{V}\\&=\int_{\mathcal{S}}\left(\phi\left[\frac{\partial p}{\partial x^i}\right]n^i-[p]\frac{\partial\phi}{\partial x^i}n^i\right)\mathrm{d}\mathcal{S}\\&=\int_{\mathcal{S}}\left(\phi\left[\frac{\partial p}{\partial \mathbf{n}}\right]-[p]\frac{\partial\phi}{\partial\mathbf{n}}\right)\mathcal{J}\mathrm{d}\alpha^1\mathrm{d}\alpha^2.\end{aligned}$$

Due to Theorem 3.3, the first term on the right-hand side of (3.9) becomes

$$\begin{aligned}\lim_{\epsilon\to 0}\int_{\mathcal{V}_s}\phi\frac{\partial F^i}{\partial x^i}\mathrm{d}\mathcal{V}&=\lim_{\epsilon\to 0}\int_{\mathcal{V}_s}\frac{\partial(\phi F^i)}{\partial x^i}\mathrm{d}\mathcal{V}-\lim_{\epsilon\to 0}\int_{\mathcal{V}_s}F^i\frac{\partial\phi}{\partial x^i}\mathrm{d}\mathcal{V}\\&=-\lim_{\epsilon\to 0}\int_{\mathcal{V}_s}F^i\frac{\partial\phi}{\partial x^i}\mathrm{d}\mathcal{V}=-\int_{\mathcal{S}}f^i(\alpha^1,\alpha^2,t)\frac{\partial\phi}{\partial x^i}\mathrm{d}\alpha^1\mathrm{d}\alpha^2\\&=-\int_{\mathcal{S}}\left(\tilde{f}^1\frac{\partial\phi}{\partial\alpha^1}+\tilde{f}^2\frac{\partial\phi}{\partial\alpha^2}+\mathbf{f}\cdot\mathbf{n}\frac{\partial\phi}{\partial\mathbf{n}}\right)\mathrm{d}\alpha^1\mathrm{d}\alpha^2\\&=\int_{\mathcal{S}}\phi\left(\frac{\partial\tilde{f}^1}{\partial\alpha^1}+\frac{\partial\tilde{f}^2}{\partial\alpha^2}\right)\mathrm{d}\alpha^1\mathrm{d}\alpha^2-\int_{\mathcal{S}}\mathbf{f}\cdot\mathbf{n}\frac{\partial\phi}{\partial\mathbf{n}}\mathrm{d}\alpha^1\mathrm{d}\alpha^2.\end{aligned}$$

In the last step above, we used the fact that the singular surface is closed. With (3.2), the last term on the right-hand side of (3.9) becomes

$$\begin{aligned}&\lim_{\epsilon\to 0}\int_{\mathcal{V}_s}\phi\frac{\partial}{\partial x^i}\left(\rho\frac{\partial u^i}{\partial t}+\rho u^j\frac{\partial u^i}{\partial x^j}\right)\mathrm{d}\mathcal{V}\\&=\lim_{\epsilon\to 0}\int_{\mathcal{V}_s}\frac{\partial}{\partial x^i}\left(\phi\rho\frac{\partial u^i}{\partial t}+\phi\rho u^j\frac{\partial u^i}{\partial x^j}\right)\mathrm{d}\mathcal{V}-\lim_{\epsilon\to 0}\int_{\mathcal{V}_s}\frac{\partial\phi}{\partial x^i}\left(\rho\frac{\partial u^i}{\partial t}+\rho u^j\frac{\partial u^i}{\partial x^j}\right)\mathrm{d}\mathcal{V}\\&=\int_{\mathcal{S}}\phi\rho\left(\left[\frac{\partial u^i}{\partial t}\right]+u^j\left[\frac{\partial u^i}{\partial x^j}\right]\right)n^i\mathrm{d}\mathcal{S}-\lim_{\epsilon\to 0}\frac{\mathrm{d}}{\mathrm{d}t}\int_{\mathcal{V}_s}\left(\frac{\partial\phi}{\partial x^i}\rho u^i\right)\mathrm{d}\mathcal{V}=0.\end{aligned}$$

Plugging the equalities for the three terms back into (3.9) and applying (3.4) gives

$$\int_{\mathcal{S}}\phi\left(\left[\frac{\partial p}{\partial\mathbf{n}}\right]\mathcal{J}-\frac{\partial\tilde{f}^1}{\partial\alpha^1}-\frac{\partial\tilde{f}^2}{\partial\alpha^2}\right)\mathrm{d}\alpha^1\mathrm{d}\alpha^2=0.$$

Because ϕ is arbitrary, we have

$$\left[\frac{\partial p}{\partial\mathbf{n}}\right]\mathcal{J}-\frac{\partial\tilde{f}^1}{\partial\alpha^1}-\frac{\partial\tilde{f}^2}{\partial\alpha^2}=0,$$

which ends the proof. ∎

We have by now derived all the principal jump conditions. They are

$$[u^i] = 0, \tag{3.10}$$

$$[p] = \frac{f^k n_k}{\mathcal{J}}, \tag{3.11}$$

$$\left[\frac{\partial u^i}{\partial \mathbf{n}}\right] = \frac{(f^k n_k)n^i - f^i}{\mu \mathcal{J}}, \tag{3.12}$$

$$\left[\frac{\partial p}{\partial \mathbf{n}}\right] = \frac{1}{\mathcal{J}}\left(\frac{\partial \tilde{f}^1}{\partial \alpha^1} + \frac{\partial \tilde{f}^2}{\partial \alpha^2}\right). \tag{3.13}$$

4. Finite differencing in the IIM. The fundamental idea of the IIM in a flow simulation is to incorporate jump conditions in finite differencing at discontinuities caused by the singular force. A finite difference scheme has its usual form if its stencil does not cross the singular surface. If its stencil crosses the singular surface, it contains additional terms. The additional terms are composed of the jump conditions and are referred to the jump contribution to the finite difference scheme hereafter. To determine the form of the jump contribution in a finite difference scheme, we follow generalized Taylor expansion for a piecewise smooth function, which is given below as a lemma.

LEMMA 4.1 (generalized Taylor expansion). *Assume function $g(z)$ has discontinuity points of the first kind at $z_1, z_2, \ldots, z_m$ in $(z_0, z_{m+1}), z_0 < z_1 < z_2 < \cdots < z_m < z_{m+1}$, and $g(z) \in \mathcal{C}^\infty(z_0, z_1) \cup (z_1, z_2) \cup \cdots \cup (z_m, z_{m+1})$. $g(z)$ can be either continuous or discontinuous at z_0 and z_{m+1}. Let $[g^{(n)}(z_l)] = g^{(n)}(z_l^+) - g^{(n)}(z_l^-)(n = 1, 2, \ldots; l = 1, 2, \ldots, m)$. Then*

$$g(z_{m+1}^-) = \sum_{n=0}^{\infty} \frac{g^{(n)}(z_0^+)}{n!}(z_{m+1} - z_0)^n + \sum_{l=1}^{m}\sum_{n=0}^{\infty} \frac{[g^{(n)}(z_l)]}{n!}(z_{m+1} - z_l)^n. \tag{4.1}$$

Proof. Taylor expansion for $g^{(n)}(z_l^-)$ about z_{l-1}^+ yields

$$g^{(n)}(z_l^-) = \sum_{\beta=0}^{\infty} \frac{g^{(n+\beta)}(z_{l-1}^+)}{\beta!}(z_l - z_{l-1})^\beta.$$

With the use of the binomial theorem, we thus find that

$$\begin{aligned}
\sum_{n=0}^{\infty} \frac{g^{(n)}(z_l^-)}{n!}(z_{m+1} - z_l)^n &= \sum_{n=0}^{\infty}\sum_{\beta=0}^{\infty} \frac{g^{(n+\beta)}(z_{l-1}^+)(z_l - z_{l-1})^\beta}{n!\beta!}(z_{m+1} - z_l)^n \\
&= \sum_{\gamma=0}^{\infty}\sum_{\beta=0}^{\gamma} g^{(\gamma)}(z_{l-1}^+)\frac{(z_l - z_{l-1})^\beta (z_{m+1} - z_l)^{(\gamma-\beta)}}{\beta!(\gamma-\beta)!} \\
&= \sum_{\gamma=0}^{\infty} \frac{g^{(\gamma)}(z_{l-1}^+)}{\gamma!}(z_{m+1} - z_{l-1})^\gamma.
\end{aligned}$$

With $g^{(n)}(z_{l-1}^+) = g^{(n)}(z_{l-1}^-) + [g^{(n)}(z_{l-1})]$, thus

$$\begin{aligned}
\sum_{n=0}^{\infty} \frac{g^{(n)}(z_l^-)}{n!}(z_{m+1} - z_l)^n &= \sum_{n=0}^{\infty} \frac{g^{(n)}(z_{l-1}^-)}{n!}(z_{m+1} - z_{l-1})^n \\
&\quad + \sum_{n=0}^{\infty} \frac{[g^{(n)}(z_{l-1})]}{n!}(z_{m+1} - z_{l-1})^n.
\end{aligned} \tag{4.2}$$

With $g^{(n)}(z_m^+) = g^{(n)}(z_m^-) + [g^{(n)}(z_m)]$, Taylor expansion for $g(z_{m+1}^-)$ at z_m^+ yields

$$\begin{aligned} g(z_{m+1}^-) &= \sum_{n=0}^{\infty} \frac{g^{(n)}(z_m^+)}{n!}(z_{m+1} - z_m)^n \\ &= \sum_{n=0}^{\infty} \frac{g^{(n)}(z_m^-)}{n!}(z_{m+1} - z_m)^n + \sum_{n=0}^{\infty} \frac{[g^{(n)}(z_m)]}{n!}(z_{m+1} - z_m)^n. \end{aligned}$$

Using recursion (4.2) repeatedly above gives the desired result. □

COROLLARY 4.2. *The Taylor expansion for $g(z_0^+)$ about z_{m+1}^- is*

$$g(z_0^+) = \sum_{n=0}^{\infty} \frac{g^{(n)}(z_{m+1}^-)}{n!}(z_0 - z_{m+1})^n + \sum_{l=1}^{m}\sum_{n=0}^{\infty} \frac{-[g^{(n)}(z_l)]}{n!}(z_0 - z_l)^n. \tag{4.3}$$

Jump conditions at the singular surface enter a finite difference scheme in the neighborhood of the singular surface. The form of the finite difference scheme can be found by applying Lemma 4.1 and Corollary 4.2. Here, we construct central finite difference schemes for first-order and second-order derivatives in the situation where there is a discontinuity point ξ between stencil points x_{i-1} and x_i and a discontinuity point η between stencil points x_i and x_{i+1}. If there are more discontinuity points in the stencil, they can easily be included in a similar manner.

LEMMA 4.3 (generalized central finite differences). *Let $x_{i+1} - x_i = x_i - x_{i-1} = h > 0$ and $x_{i-1} < \xi < x_i \le \eta < x_{i+1}$. Suppose that $u(x)$ is infinitely smooth except at discontinuity points of the first kind ξ and η. Further, $u(x)$ can be either continuous or discontinuous at x_{i+1} and x_{i-1}. Then*

$$\begin{aligned} \frac{\mathrm{d}u(x_i^-)}{\mathrm{d}x} &= \frac{u(x_{i+1}^-) - u(x_{i-1}^+)}{2h} \\ &\quad + \frac{1}{2h}\left(\sum_{n=0}^{2} \frac{-[u^{(n)}(\xi)]}{n!}(x_{i-1}-\xi)^n - \sum_{n=0}^{2} \frac{[u^{(n)}(\eta)]}{n!}(x_{i+1} - \eta)^n\right) + O(h^2), \end{aligned} \tag{4.4}$$

$$\begin{aligned} \frac{\mathrm{d}^2u(x_i^-)}{\mathrm{d}x^2} &= \frac{u(x_{i+1}^-) - 2u(x_i) + u(x_{i-1}^+)}{h^2} \\ &\quad - \frac{1}{h^2}\left(\sum_{n=0}^{3} \frac{-[u^{(n)}(\xi)]}{n!}(x_{i-1}-\xi)^n + \sum_{n=0}^{3} \frac{[u^{(n)}(\eta)]}{n!}(x_{i+1} - \eta)^n\right) + O(h^2). \end{aligned} \tag{4.5}$$

Other finite difference schemes with different orders can also be constructed based on Lemma 4.1 and Corollary 4.2, but the number of jump conditions sets an upper limit on the order of accuracy, as stated in the following proposition.

PROPOSITION 4.4. *The highest order of a finite difference scheme for $u^{(n)}(x)$ with a stencil containing a discontinuity point ζ is $m - n + 1$, where m is the maximum number for known jump conditions $[u^{(l)}(\zeta)]$ $(l = 0, 1, 2, \ldots, m)$.*

Navier–Stokes equations (2.1), (2.2) and pressure Poisson equation (2.3) have first- and second-order spatial derivatives. According to Proposition 4.4, to discretize the first-order spatial derivatives with second-order accuracy or the second-order spatial derivatives with first-order accuracy near the singular surface, the jump conditions of the velocity, the pressure, and their first- and second-order spatial derivatives are needed. To discretize the first-order spatial derivatives with third-order accuracy or the second-order spatial derivatives with second-order accuracy near the singular

surface, the jump conditions of their third-order derivatives are needed as well. All these spatial jump conditions are derived in section 5.

If the singular surface is moving, there will be jumps in the temporal derivatives of the velocity at a grid point whenever the surface crosses that grid point. Suppose that the singular surface passes the grid point at time $t_1, t_2, \ldots, t_m$ between time t_0 and t_{m+1}; then

$$u^i(t_{m+1}) = \sum_{n=0}^{\infty} \frac{\partial^n u^i(t_0)}{\partial t^n} \frac{(t_{m+1}-t_0)^n}{n!} + \sum_{l=1}^{m} \sum_{n=0}^{\infty} \left[\!\!\left[\frac{\partial^n u^i(t_l)}{\partial t} \right]\!\!\right] \frac{(t_{m+1}-t_l)^n}{n!}, \tag{4.6}$$

where $[\![\cdot]\!]$ denotes a jump at time t as $[\![\cdot]\!] := (\cdot)_{t^+} - (\cdot)_{t^-}$. Equation (4.6) follows directly from Lemma (4.1). Thus, to achieve first-order accuracy when discretizing $\frac{\partial u^i}{\partial t}$ in (2.1), we need $[\![u^i]\!]$ and $[\![\frac{\partial u^i}{\partial t}]\!]$; to achieve second-order accuracy, we also need $[\![\frac{\partial^2 u^i}{\partial t^2}]\!]$. All these temporal jump conditions are derived in section 6.1.

It should be noted that the spatial convergence rate of a simulation even in terms of the infinity norm can be of the same order as the numerical scheme away from a singular surface, even though the discretization of some derivatives in the Navier–Stokes equations and the pressure Poisson equation is of lower order accuracy near the singular surface. Examples can be found in Li and Lai [20] and Xu and Wang [36], where, with second-order central finite difference discretization of all spatial derivatives away from a singular surface, a simulation had second-order spatial convergence rates in terms of the infinity norm for both the velocity and the pressure, even though the discretization of the Laplace operator was only first-order accurate near the singular surface.

5. Jump conditions of spatial derivatives. The spatial jump conditions of velocity u^i and pressure p are given in (3.10) and (3.11). In this section we present how to derive the spatial jump conditions of all the first-, second-, and third-order velocity and pressure derivatives:

$$\left[\frac{\partial u^i}{\partial x^j}\right], \quad \left[\frac{\partial p}{\partial x^j}\right]; \quad \left[\frac{\partial^2 u^i}{\partial x^j \partial x^k}\right], \quad \left[\frac{\partial^2 p}{\partial x^j \partial x^k}\right]; \quad \left[\frac{\partial^3 \mathbf{u}}{\partial x^i \partial x^j \partial x^k}\right], \quad \left[\frac{\partial^3 p}{\partial x^i \partial x^j \partial x^k}\right];$$

where $\mathbf{u}$ is used to represent the velocity vector and a superscript (i, j, or k) takes a value $1, 2$, or 3 in three-dimensional simulation.

5.1. Jump conditions $\left[\frac{\partial u^i}{\partial x^j}\right]$ and $\left[\frac{\partial p}{\partial x^j}\right]$. Differentiate (3.10) with respect to α^m $(m = 1, 2)$ to obtain

$$\frac{\partial [u^i]}{\partial \alpha^m} = \left[\frac{\partial u^i}{\partial x^k}\frac{\partial X^k}{\partial \alpha^m}\right] = \frac{\partial X^k}{\partial \alpha^m}\left[\frac{\partial u^i}{\partial x^k}\right] = 0. \tag{5.1}$$

Write (3.12) as

$$\left[\frac{\partial u^i}{\partial \mathbf{n}}\right] = n^j \left[\frac{\partial u^i}{\partial x^j}\right] = \frac{(f^k n_k) n^i - f^i}{\mu \mathcal{J}}. \tag{5.2}$$

Combining (5.1) and (5.2) gives

$$C_1 \begin{bmatrix} \dfrac{\partial u^i}{\partial x^1} \\ \dfrac{\partial u^i}{\partial x^2} \\ \dfrac{\partial u^i}{\partial x^3} \end{bmatrix} = \begin{pmatrix} 0 \\ 0 \\ \dfrac{(f^k n_k)n^i - f^i}{\mu \mathcal{J}} \end{pmatrix}, \tag{5.3}$$

where $\left[\vdots\right]$ denotes a jump for a column vector, and where the nonsingular coefficient matrix C_1 is defined in (3.7). From (5.3), jump conditions of first-order velocity derivatives can be solved.

Similarly, jump conditions of first-order pressure derivatives are found to satisfy

$$C_1 \begin{bmatrix} \dfrac{\partial p}{\partial x^1} \\ \dfrac{\partial p}{\partial x^2} \\ \dfrac{\partial p}{\partial x^3} \end{bmatrix} = \begin{pmatrix} \dfrac{\partial}{\partial \alpha^1}\left(\dfrac{f^i n_i}{\mathcal{J}}\right) \\ \dfrac{\partial}{\partial \alpha^2}\left(\dfrac{f^i n_i}{\mathcal{J}}\right) \\ \dfrac{1}{\mathcal{J}}\left(\dfrac{\partial \tilde{f}^1}{\partial \alpha^1} + \dfrac{\partial \tilde{f}^2}{\partial \alpha^2}\right) \end{pmatrix}, \tag{5.4}$$

from which, jump conditions of first-order pressure derivatives can be solved.

5.2. Jump conditions $\left[\frac{\partial^2 u^i}{\partial x^j \partial x^k}\right]$ and $\left[\frac{\partial^2 p}{\partial x^j \partial x^k}\right]$. Differentiating equation (5.1) with respect to α^n $(n = 1, 2)$, we have

$$\frac{\partial^2 [u^i]}{\partial \alpha^m \partial \alpha^n} = \left[\frac{\partial^2 u^i}{\partial x^j \partial x^k}\frac{\partial X^j}{\partial \alpha^n}\frac{\partial X^k}{\partial \alpha^m} + \frac{\partial u^i}{\partial x^k}\frac{\partial^2 X^k}{\partial \alpha^m \partial \alpha^n}\right] = 0$$

$$\Rightarrow \frac{\partial X^j}{\partial \alpha^n}\frac{\partial X^k}{\partial \alpha^m}\left[\frac{\partial^2 u^i}{\partial x^j \partial x^k}\right] = -\frac{\partial^2 X^k}{\partial \alpha^m \partial \alpha^n}\left[\frac{\partial u^i}{\partial x^k}\right]. \tag{5.5}$$

Differentiating (3.12) with respect to α^m $(m = 1, 2)$, we have

$$\frac{\partial}{\partial \alpha^m}\left[\frac{\partial u^i}{\partial \mathbf{n}}\right] = \left[\frac{\partial^2 u^i}{\partial x^j \partial x^k}\frac{\partial X^k}{\partial \alpha^m}n^j + \frac{\partial u^i}{\partial x^j}\frac{\partial n^j}{\partial \alpha^m}\right] = \frac{\partial}{\partial \alpha^m}\frac{(f^k n_k)n^i - f^i}{\mu \mathcal{J}}$$

$$\Rightarrow n^j \frac{\partial X^k}{\partial \alpha^m}\left[\frac{\partial^2 u^i}{\partial x^j \partial x^k}\right] = \frac{\partial}{\partial \alpha^m}\frac{(f^k n_k)n^i - f^i}{\mu \mathcal{J}} - \frac{\partial n^j}{\partial \alpha^m}\left[\frac{\partial u^i}{\partial x^j}\right]. \tag{5.6}$$

With (3.2), equation (2.1) yields

$$\left[\rho\left(\frac{\partial u^i}{\partial t} + u^j \frac{\partial u^i}{\partial x^j}\right)\right] = -\left[\frac{\partial p}{\partial x^i}\right] + \mu\left[\frac{\partial^2 u^i}{\partial x^j \partial x^j}\right] = 0. \tag{5.7}$$

Combining (5.5), (5.6), and (5.7) gives

$$
\begin{aligned}
(5.8)\qquad C_2 \begin{bmatrix} \dfrac{\partial^2 u^i}{\partial x^1 \partial x^1} \\ \dfrac{\partial^2 u^i}{\partial x^1 \partial x^2} \\ \dfrac{\partial^2 u^i}{\partial x^1 \partial x^3} \\ \dfrac{\partial^2 u^i}{\partial x^2 \partial x^2} \\ \dfrac{\partial^2 u^i}{\partial x^2 \partial x^3} \\ \dfrac{\partial^2 u^i}{\partial x^3 \partial x^3} \end{bmatrix} &= \begin{pmatrix} 0 \\ 0 \\ 0 \\ \dfrac{\partial}{\partial \alpha^1} \dfrac{(f^k n_k) n^i - f^i}{\mu \mathcal{J}} \\ \dfrac{\partial}{\partial \alpha^2} \dfrac{(f^k n_k) n^i - f^i}{\mu \mathcal{J}} \\ \dfrac{1}{\mu} \left[\dfrac{\partial p}{\partial x^i} \right] \end{pmatrix} \\
&\quad - \begin{pmatrix} \dfrac{\partial^2 X^1}{\partial \alpha^1 \partial \alpha^1} & \dfrac{\partial^2 X^2}{\partial \alpha^1 \partial \alpha^1} & \dfrac{\partial^2 X^3}{\partial \alpha^1 \partial \alpha^1} \\ \dfrac{\partial^2 X^1}{\partial \alpha^2 \partial \alpha^2} & \dfrac{\partial^2 X^2}{\partial \alpha^2 \partial \alpha^2} & \dfrac{\partial^2 X^3}{\partial \alpha^2 \partial \alpha^2} \\ \dfrac{\partial^2 X^1}{\partial \alpha^1 \partial \alpha^2} & \dfrac{\partial^2 X^2}{\partial \alpha^1 \partial \alpha^2} & \dfrac{\partial^2 X^3}{\partial \alpha^1 \partial \alpha^2} \\ \dfrac{\partial n^1}{\partial \alpha^1} & \dfrac{\partial n^2}{\partial \alpha^1} & \dfrac{\partial n^3}{\partial \alpha^1} \\ \dfrac{\partial n^1}{\partial \alpha^2} & \dfrac{\partial n^2}{\partial \alpha^2} & \dfrac{\partial n^3}{\partial \alpha^2} \\ 0 & 0 & 0 \end{pmatrix} \begin{bmatrix} \dfrac{\partial u^i}{\partial x^1} \\ \dfrac{\partial u^i}{\partial x^2} \\ \dfrac{\partial u^i}{\partial x^3} \end{bmatrix},
\end{aligned}
$$

where C_2 is

$$
\begin{aligned}
C_2 &= \begin{pmatrix} \tau_1^1\tau_1^1 & \tau_1^1\tau_1^2+\tau_1^2\tau_1^1 & \tau_1^1\tau_1^3+\tau_1^3\tau_1^1 & \tau_1^2\tau_1^2 & \tau_1^2\tau_1^3+\tau_1^3\tau_1^2 & \tau_1^3\tau_1^3 \\ \tau_2^1\tau_2^1 & \tau_2^1\tau_2^2+\tau_2^2\tau_2^1 & \tau_2^1\tau_2^3+\tau_2^3\tau_2^1 & \tau_2^2\tau_2^2 & \tau_2^2\tau_2^3+\tau_2^3\tau_2^2 & \tau_2^3\tau_2^3 \\ \tau_1^1\tau_2^1 & \tau_1^1\tau_2^2+\tau_1^2\tau_2^1 & \tau_1^1\tau_2^3+\tau_1^3\tau_2^1 & \tau_1^2\tau_2^2 & \tau_1^2\tau_2^3+\tau_1^3\tau_2^2 & \tau_1^3\tau_2^3 \\ \tau_1^1 n^1 & \tau_1^1 n^2+\tau_1^2 n^1 & \tau_1^1 n^3+\tau_1^3 n^1 & \tau_1^2 n^2 & \tau_1^2 n^3+\tau_1^3 n^2 & \tau_1^3 n^3 \\ \tau_2^1 n^1 & \tau_2^1 n^2+\tau_2^2 n^1 & \tau_2^1 n^3+\tau_2^3 n^1 & \tau_2^2 n^2 & \tau_2^2 n^3+\tau_2^3 n^2 & \tau_2^3 n^3 \\ 1 & 0 & 0 & 1 & 0 & 1 \end{pmatrix} \\
(5.9)\qquad &:= \begin{pmatrix} C_2^{11} & C_2^{12} & C_2^{13} & C_2^{14} & C_2^{15} & C_2^{16} \\ C_2^{21} & C_2^{22} & C_2^{23} & C_2^{24} & C_2^{25} & C_2^{26} \\ C_2^{31} & C_2^{32} & C_2^{33} & C_2^{34} & C_2^{35} & C_2^{36} \\ C_2^{41} & C_2^{42} & C_2^{43} & C_2^{44} & C_2^{45} & C_2^{46} \\ C_2^{51} & C_2^{52} & C_2^{53} & C_2^{54} & C_2^{55} & C_2^{56} \\ C_2^{61} & C_2^{62} & C_2^{63} & C_2^{64} & C_2^{65} & C_2^{66} \end{pmatrix}.
\end{aligned}
$$

Nonsingularity of coefficient matrix C_2 is proved in Appendix B, and the right-hand side of (5.8) is known from (5.3). Thus, from (5.8), jump conditions of all second-order velocity derivatives can be found.

With the use of Poisson equation (2.3) for the pressure, jump conditions of all second-order pressure derivatives can be found in the similar way to satisfy

$$
\begin{aligned}
(5.10)\quad C_2 \begin{bmatrix} \dfrac{\partial^2 p}{\partial x^1 \partial x^1} \\ \dfrac{\partial^2 p}{\partial x^1 \partial x^2} \\ \dfrac{\partial^2 p}{\partial x^1 \partial x^3} \\ \dfrac{\partial^2 p}{\partial x^2 \partial x^2} \\ \dfrac{\partial^2 p}{\partial x^2 \partial x^3} \\ \dfrac{\partial^2 p}{\partial x^3 \partial x^3} \end{bmatrix} &= \begin{pmatrix} \dfrac{\partial^2}{\partial \alpha^1 \partial \alpha^1}\left(\dfrac{f^i n_i}{\mathcal{J}}\right) \\ \dfrac{\partial^2}{\partial \alpha^2 \partial \alpha^2}\left(\dfrac{f^i n_i}{\mathcal{J}}\right) \\ \dfrac{\partial^2}{\partial \alpha^1 \partial \alpha^2}\left(\dfrac{f^i n_i}{\mathcal{J}}\right) \\ \dfrac{\partial}{\partial \alpha^1}\left(\dfrac{1}{\mathcal{J}}\dfrac{\partial \tilde{f}^1}{\partial \alpha^1} + \dfrac{1}{\mathcal{J}}\dfrac{\partial \tilde{f}^2}{\partial \alpha^2}\right) \\ \dfrac{\partial}{\partial \alpha^2}\left(\dfrac{1}{\mathcal{J}}\dfrac{\partial \tilde{f}^1}{\partial \alpha^1} + \dfrac{1}{\mathcal{J}}\dfrac{\partial \tilde{f}^2}{\partial \alpha^2}\right) \\ -\rho\left[\dfrac{\partial u^i}{\partial x^j}\dfrac{\partial u^j}{\partial x^i}\right] \end{pmatrix} \\
&\quad - \begin{pmatrix} \dfrac{\partial^2 X^1}{\partial \alpha^1 \partial \alpha^1} & \dfrac{\partial^2 X^2}{\partial \alpha^1 \partial \alpha^1} & \dfrac{\partial^2 X^3}{\partial \alpha^1 \partial \alpha^1} \\ \dfrac{\partial^2 X^1}{\partial \alpha^2 \partial \alpha^2} & \dfrac{\partial^2 X^2}{\partial \alpha^2 \partial \alpha^2} & \dfrac{\partial^2 X^3}{\partial \alpha^2 \partial \alpha^2} \\ \dfrac{\partial^2 X^1}{\partial \alpha^1 \partial \alpha^2} & \dfrac{\partial^2 X^2}{\partial \alpha^1 \partial \alpha^2} & \dfrac{\partial^2 X^3}{\partial \alpha^1 \partial \alpha^2} \\ \dfrac{\partial n^1}{\partial \alpha^1} & \dfrac{\partial n^2}{\partial \alpha^1} & \dfrac{\partial n^3}{\partial \alpha^1} \\ \dfrac{\partial n^1}{\partial \alpha^2} & \dfrac{\partial n^2}{\partial \alpha^2} & \dfrac{\partial n^3}{\partial \alpha^2} \\ 0 & 0 & 0 \end{pmatrix} \begin{bmatrix} \dfrac{\partial p}{\partial x^1} \\ \dfrac{\partial p}{\partial x^2} \\ \dfrac{\partial p}{\partial x^3} \end{bmatrix}.
\end{aligned}
$$

Note that

$$
\begin{aligned}
\left[\frac{\partial u^i}{\partial x^j}\frac{\partial u^j}{\partial x^i}\right] &= 2\left(\frac{\partial u^i}{\partial x^j}\right)_{\mathcal{S}^+}\left[\frac{\partial u^j}{\partial x^i}\right] - \left[\frac{\partial u^i}{\partial x^j}\right]\left[\frac{\partial u^j}{\partial x^i}\right] \\
&= 2\left(\frac{\partial u^i}{\partial x^j}\right)_{\mathcal{S}^-}\left[\frac{\partial u^j}{\partial x^i}\right] + \left[\frac{\partial u^i}{\partial x^j}\right]\left[\frac{\partial u^j}{\partial x^i}\right],
\end{aligned}
$$

and $\left(\frac{\partial u^i}{\partial x^j}\right)_{\mathcal{S}^+}$ or $\left(\frac{\partial u^i}{\partial x^j}\right)_{\mathcal{S}^-}$ can be interpolated from the known velocity field which is used to solve pressure Poisson equation (2.3). The interpolation scheme is given in Xu and Wang [36]. From (5.10), jump conditions of all second-order pressure derivatives can be solved.

5.3. Jump conditions $\left[\frac{\partial^3 \mathbf{u}}{\partial x^i \partial x^j \partial x^k}\right]$ and $\left[\frac{\partial^3 p}{\partial x^i \partial x^j \partial x^k}\right]$. Differentiate (5.5) with respect to α^l $(l = 1, 2)$ and obtain

$$\frac{\partial^3[\mathbf{u}]}{\partial\alpha^l\partial\alpha^m\partial\alpha^n}=0\Rightarrow\frac{\partial X^j}{\partial\alpha^n}\frac{\partial X^i}{\partial\alpha^l}\frac{\partial X^k}{\partial\alpha^m}\left[\frac{\partial^3\mathbf{u}}{\partial x^i\partial x^j\partial x^k}\right]$$

$$=-\frac{\partial^3X^i}{\partial\alpha^l\partial\alpha^m\partial\alpha^n}\left[\frac{\partial\mathbf{u}}{\partial x^i}\right] \tag{5.11}$$

$$-\left(\frac{\partial^2X^k}{\partial\alpha^l\partial\alpha^m}\frac{\partial X^j}{\partial\alpha^n}+\frac{\partial^2X^k}{\partial\alpha^l\partial\alpha^n}\frac{\partial X^j}{\partial\alpha^m}+\frac{\partial^2X^j}{\partial\alpha^m\partial\alpha^n}\frac{\partial X^k}{\partial\alpha^l}\right)\left[\frac{\partial^2\mathbf{u}}{\partial x^j\partial x^k}\right].$$

As $(l,m,n)=(1,1,1),(2,2,2),(1,1,2)$, or $(2,2,1)$, we have four equations for $\left[\frac{\partial^3\mathbf{u}}{\partial x^i\partial x^j\partial x^k}\right]$. Differentiate (5.6) with respect to α^l $(l=1,2)$ and obtain

$$\frac{\partial^2}{\partial\alpha^l\partial\alpha^m}\left[\frac{\partial\mathbf{u}}{\partial\mathbf{n}}\right]=\frac{\partial^2}{\partial\alpha^l\partial\alpha^m}\frac{(f^kn_k)\mathbf{n}-\mathbf{f}}{\mu\mathcal{J}}\Rightarrow n^j\frac{\partial X^i}{\partial\alpha^l}\frac{\partial X^k}{\partial\alpha^m}\left[\frac{\partial^3\mathbf{u}}{\partial x^i\partial x^j\partial x^k}\right]$$

$$=\frac{\partial^2}{\partial\alpha^l\partial\alpha^m}\frac{(f^kn_k)\mathbf{n}-\mathbf{f}}{\mu\mathcal{J}}-\frac{\partial^2n^j}{\partial\alpha^l\partial\alpha^m}\left[\frac{\partial\mathbf{u}}{\partial x^j}\right] \tag{5.12}$$

$$-\left(\frac{\partial n^j}{\partial\alpha^m}\frac{\partial X^k}{\partial\alpha^l}+n^j\frac{\partial^2X^k}{\partial\alpha^l\partial\alpha^m}+\frac{\partial n^j}{\partial\alpha^l}\frac{\partial X^k}{\partial\alpha^m}\right)\left[\frac{\partial^2\mathbf{u}}{\partial x^j\partial x^k}\right].$$

As $(l,m)=(1,1),(2,2)$, or $(1,2)$, we have three other equations. Since a superscript (i, j, or k) can take values 1, 2, or 3, the number of unknowns $\left[\frac{\partial^3\mathbf{u}}{\partial x^i\partial x^j\partial x^k}\right]$ is ten. Three additional equations need to be found. Differentiating (2.1) with respect to x^k $(k=1,2,3)$ and applying (3.2), we find

$$\left[\frac{\partial^3\mathbf{u}}{\partial x^j\partial x^j\partial x^k}\right]=\frac{1}{\mu}\left[\frac{\partial}{\partial x^k}\nabla p\right]+\frac{\rho}{\mu}\left(\left[\frac{\partial^2\mathbf{u}}{\partial t\partial x^k}\right]+\left[\frac{\partial u^j}{\partial x^k}\frac{\partial\mathbf{u}}{\partial x^j}\right]+u^j\left[\frac{\partial^2\mathbf{u}}{\partial x^j\partial x^k}\right]\right), \tag{5.13}$$

which provides three additional equations if $\left[\frac{\partial^2\mathbf{u}}{\partial t\partial x^k}\right]$ is known. Jump conditions $\left[\frac{\partial^2\mathbf{u}}{\partial t\partial x^k}\right]$ are derived in section 6.1. Thus, combining (5.11), (5.12), and (5.13) gives a 10×10 system for ten unknowns $\left[\frac{\partial^3\mathbf{u}}{\partial x^i\partial x^j\partial x^k}\right]$.

To simplify the system, let

$$\mathbf{d}^j_{lm}=\frac{\partial X^i}{\partial\alpha^l}\frac{\partial X^k}{\partial\alpha^m}\left[\frac{\partial^3\mathbf{u}}{\partial x^i\partial x^j\partial x^k}\right], \tag{5.14}$$

and denote the right-hand sides of (5.11) and (5.12) as $\mathbf{r}^n_{lm}$ $(n=1,2)$ and $\mathbf{r}^3_{lm}$, respectively. Then, we can rewrite (5.11) and (5.12) as

$$C_1\begin{pmatrix}\mathbf{d}^1_{lm}\\ \mathbf{d}^2_{lm}\\ \mathbf{d}^3_{lm}\end{pmatrix}=\begin{pmatrix}\mathbf{r}^1_{lm}\\ \mathbf{r}^2_{lm}\\ \mathbf{r}^3_{lm}\end{pmatrix},$$

from which we can solve $\mathbf{d}^j_{lm}$ $(j=1,2,3)$ since C_1 is nonsingular. After $\mathbf{d}^j_{lm}$ is solved,

we can combine (5.14) and (5.13) to obtain a simplified system as

$$C_3 \begin{bmatrix} \dfrac{\partial^3 \mathbf{u}}{\partial x^1 \partial x^1 \partial x^1} \\ \dfrac{\partial^3 \mathbf{u}}{\partial x^1 \partial x^1 \partial x^2} \\ \dfrac{\partial^3 \mathbf{u}}{\partial x^1 \partial x^1 \partial x^3} \\ \dfrac{\partial^3 \mathbf{u}}{\partial x^1 \partial x^2 \partial x^2} \\ \dfrac{\partial^3 \mathbf{u}}{\partial x^1 \partial x^2 \partial x^3} \\ \dfrac{\partial^3 \mathbf{u}}{\partial x^1 \partial x^3 \partial x^3} \\ \dfrac{\partial^3 \mathbf{u}}{\partial x^2 \partial x^2 \partial x^2} \\ \dfrac{\partial^3 \mathbf{u}}{\partial x^2 \partial x^2 \partial x^3} \\ \dfrac{\partial^3 \mathbf{u}}{\partial x^2 \partial x^3 \partial x^3} \\ \dfrac{\partial^3 \mathbf{u}}{\partial x^3 \partial x^3 \partial x^3} \end{bmatrix} = \begin{pmatrix} \mathbf{d}_{11}^1 \\ \mathbf{d}_{22}^1 \\ \mathbf{d}_{12}^1 \\ \mathbf{d}_{11}^2 \\ \mathbf{d}_{22}^2 \\ \mathbf{d}_{12}^2 \\ \mathbf{d}_{11}^3 \\ \mathbf{d}_{22}^3 \\ \mathbf{d}_{12}^3 \\ \mathbf{d}_{11}^4 \\ \mathbf{d}_{22}^4 \\ \mathbf{d}_{12}^4 \end{pmatrix}, \tag{5.15}$$

where

$$C_3 = \begin{pmatrix} C_2^{11} & C_2^{12} & C_2^{13} & C_2^{14} & C_2^{15} & C_2^{16} & 0 & 0 & 0 & 0 \\ C_2^{21} & C_2^{22} & C_2^{23} & C_2^{24} & C_2^{25} & C_2^{26} & 0 & 0 & 0 & 0 \\ C_2^{31} & C_2^{32} & C_2^{33} & C_2^{34} & C_2^{35} & C_2^{36} & 0 & 0 & 0 & 0 \\ 0 & C_2^{11} & 0 & C_2^{12} & C_2^{13} & 0 & C_2^{14} & C_2^{15} & C_2^{16} & 0 \\ 0 & C_2^{21} & 0 & C_2^{22} & C_2^{23} & 0 & C_2^{24} & C_2^{25} & C_2^{26} & 0 \\ 0 & C_2^{31} & 0 & C_2^{32} & C_2^{33} & 0 & C_2^{34} & C_2^{35} & C_2^{36} & 0 \\ 0 & 0 & C_2^{11} & 0 & C_2^{12} & C_2^{13} & 0 & C_2^{14} & C_2^{15} & C_2^{16} \\ 0 & 0 & C_2^{21} & 0 & C_2^{22} & C_2^{23} & 0 & C_2^{24} & C_2^{25} & C_2^{26} \\ 0 & 0 & C_2^{31} & 0 & C_2^{32} & C_2^{33} & 0 & C_2^{34} & C_2^{35} & C_2^{36} \\ 1 & 0 & 0 & 1 & 0 & 1 & 0 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 & 0 & 0 & 1 & 0 & 1 & 0 \\ 0 & 0 & 1 & 0 & 0 & 0 & 0 & 1 & 0 & 1 \end{pmatrix}, \tag{5.16}$$

with matrix elements defined in (5.9) and

$$\mathbf{d}_{11}^4 = \frac{1}{\mu}\left[\frac{\partial}{\partial x^1}\nabla p\right] + \frac{\rho}{\mu}\left(\left[\frac{\partial^2 \mathbf{u}}{\partial t \partial x^1}\right] + \left[\frac{\partial u^j}{\partial x^1}\frac{\partial \mathbf{u}}{\partial x^j}\right] + u^j\left[\frac{\partial^2 \mathbf{u}}{\partial x^j \partial x^1}\right]\right),$$

$$\mathbf{d}_{22}^4 = \frac{1}{\mu}\left[\frac{\partial}{\partial x^2}\nabla p\right] + \frac{\rho}{\mu}\left(\left[\frac{\partial^2 \mathbf{u}}{\partial t \partial x^2}\right] + \left[\frac{\partial u^j}{\partial x^2}\frac{\partial \mathbf{u}}{\partial x^j}\right] + u^j\left[\frac{\partial^2 \mathbf{u}}{\partial x^j \partial x^2}\right]\right),$$

$$\mathbf{d}_{12}^4 = \frac{1}{\mu}\left[\frac{\partial}{\partial x^3}\nabla p\right] + \frac{\rho}{\mu}\left(\left[\frac{\partial^2 \mathbf{u}}{\partial t \partial x^3}\right] + \left[\frac{\partial u^j}{\partial x^3}\frac{\partial \mathbf{u}}{\partial x^j}\right] + u^j\left[\frac{\partial^2 \mathbf{u}}{\partial x^j \partial x^3}\right]\right).$$

To obtain a unique solution to (5.15) we need to show $\operatorname{rank}(C_3) = 10$, which is done in Appendix C.

Similarly, with the use of Poisson equation (2.3), we can obtain an equation system for $\left[\frac{\partial^3 p}{\partial x^i \partial x^j \partial x^k}\right]$ as

$$C_3 \begin{bmatrix} \frac{\partial^3 p}{\partial x^1 \partial x^1 \partial x^1} \\ \frac{\partial^3 p}{\partial x^1 \partial x^1 \partial x^2} \\ \frac{\partial^3 p}{\partial x^1 \partial x^1 \partial x^3} \\ \frac{\partial^3 p}{\partial x^1 \partial x^2 \partial x^2} \\ \frac{\partial^3 p}{\partial x^1 \partial x^2 \partial x^3} \\ \frac{\partial^3 p}{\partial x^1 \partial x^3 \partial x^3} \\ \frac{\partial^3 p}{\partial x^2 \partial x^2 \partial x^2} \\ \frac{\partial^3 p}{\partial x^2 \partial x^2 \partial x^3} \\ \frac{\partial^3 p}{\partial x^2 \partial x^3 \partial x^3} \\ \frac{\partial^3 p}{\partial x^3 \partial x^3 \partial x^3} \end{bmatrix} = \begin{pmatrix} D^1_{11} \\ D^1_{22} \\ D^1_{12} \\ D^2_{11} \\ D^2_{22} \\ D^2_{12} \\ D^3_{11} \\ D^3_{22} \\ D^3_{12} \\ D^4_{11} \\ D^4_{22} \\ D^4_{12} \end{pmatrix}, \tag{5.17}$$

in which

$$D^j_{lm} = \frac{\partial X^i}{\partial \alpha^l} \frac{\partial X^k}{\partial \alpha^m} \left[\frac{\partial^3 p}{\partial x^i \partial x^j \partial x^k}\right], \tag{5.18}$$

with $j = 1, 2, 3$ and $(l, m) = (1, 1), (2, 2)$, or $(1, 2)$, and

$$\begin{aligned} D^4_{11} =& -\frac{\partial \rho}{\partial x^i}\left(\left[\frac{\partial^2 u^i}{\partial t \partial x^1}\right] + u^j \left[\frac{\partial^2 u^i}{\partial x^j \partial x^1}\right] + \left[\frac{\partial u^j}{\partial x^1}\frac{\partial u^i}{\partial x^j}\right]\right) \\ & - \frac{\partial \rho}{\partial x^1}\left[\frac{\partial u^j}{\partial x^i}\frac{\partial u^i}{\partial x^j}\right] - 2\rho\left[\frac{\partial u^j}{\partial x^i}\frac{\partial^2 u^i}{\partial x^j \partial x^1}\right], \\ D^4_{22} =& -\frac{\partial \rho}{\partial x^i}\left(\left[\frac{\partial^2 u^i}{\partial t \partial x^2}\right] + u^j \left[\frac{\partial^2 u^i}{\partial x^j \partial x^2}\right] + \left[\frac{\partial u^j}{\partial x^2}\frac{\partial u^i}{\partial x^j}\right]\right) \\ & - \frac{\partial \rho}{\partial x^2}\left[\frac{\partial u^j}{\partial x^i}\frac{\partial u^i}{\partial x^j}\right] - 2\rho\left[\frac{\partial u^j}{\partial x^i}\frac{\partial^2 u^i}{\partial x^j \partial x^2}\right], \\ D^4_{12} =& -\frac{\partial \rho}{\partial x^i}\left(\left[\frac{\partial^2 u^i}{\partial t \partial x^3}\right] + u^j \left[\frac{\partial^2 u^i}{\partial x^j \partial x^3}\right] + \left[\frac{\partial u^j}{\partial x^3}\frac{\partial u^i}{\partial x^j}\right]\right) \\ & - \frac{\partial \rho}{\partial x^3}\left[\frac{\partial u^j}{\partial x^i}\frac{\partial u^i}{\partial x^j}\right] - 2\rho\left[\frac{\partial u^j}{\partial x^i}\frac{\partial^2 u^i}{\partial x^j \partial x^3}\right]. \end{aligned}$$

If fluid density ρ is a constant, we have

$$D_{11}^4 = -2\rho\left[\frac{\partial u^j}{\partial x^i}\frac{\partial^2 u^i}{\partial x^j \partial x^1}\right],$$

$$D_{22}^4 = -2\rho\left[\frac{\partial u^j}{\partial x^i}\frac{\partial^2 u^i}{\partial x^j \partial x^2}\right],$$

$$D_{12}^4 = -2\rho\left[\frac{\partial u^j}{\partial x^i}\frac{\partial^2 u^i}{\partial x^j \partial x^3}\right].$$

We solve D_{lm}^j from

$$C_1\begin{pmatrix} D_{lm}^1 \\ D_{lm}^2 \\ D_{lm}^3 \end{pmatrix} = \begin{pmatrix} R_{lm}^1 \\ R_{lm}^2 \\ R_{lm}^3 \end{pmatrix},$$

where R_{lm}^n $(n = 1, 2)$ and R_{lm}^3 are

$$\begin{aligned} R_{lm}^n = {} & \frac{\partial^3}{\partial\alpha^l \partial\alpha^m \partial\alpha^n}\left(\frac{f^i n_i}{\mathcal{J}}\right) - \frac{\partial^3 X^i}{\partial\alpha^l \partial\alpha^m \partial\alpha^n}\left[\frac{\partial p}{\partial x^i}\right] \\ & - \left(\frac{\partial^2 X^k}{\partial\alpha^l \partial\alpha^m}\frac{\partial X^j}{\partial\alpha^n} + \frac{\partial^2 X^k}{\partial\alpha^l \partial\alpha^n}\frac{\partial X^j}{\partial\alpha^m} + \frac{\partial^2 X^j}{\partial\alpha^m \partial\alpha^n}\frac{\partial X^k}{\partial\alpha^l}\right)\left[\frac{\partial^2 p}{\partial x^j \partial x^k}\right], \\ R_{lm}^3 = {} & \frac{\partial^2}{\partial\alpha^l \partial\alpha^m}\left(\frac{1}{\mathcal{J}}\frac{\partial \tilde{f}^1}{\partial\alpha^1} + \frac{1}{\mathcal{J}}\frac{\partial \tilde{f}^2}{\partial\alpha^2}\right) - \frac{\partial^2 n^j}{\partial\alpha^l \partial\alpha^m}\left[\frac{\partial p}{\partial x^j}\right] \\ & - \left(\frac{\partial n^j}{\partial\alpha^m}\frac{\partial X^k}{\partial\alpha^l} + n^j\frac{\partial^2 X^k}{\partial\alpha^l \partial\alpha^m} + \frac{\partial n^j}{\partial\alpha^l}\frac{\partial X^k}{\partial\alpha^m}\right)\left[\frac{\partial^2 p}{\partial x^j \partial x^k}\right]. \end{aligned}$$

6. Jump conditions of temporal derivatives. When singular surface $\mathcal{S}$ is passing a fixed point $\mathbf{x}^*$ in space at time t^*, using $\mathbf{X}^*$ to denote the point on $\mathcal{S}$ which coincides with the point $\mathbf{x}^*$, for flow quantity ψ, we have the following relation between $[\![\psi(\mathbf{X}^*, t^*)]\!] = (\psi)_{t^{*+}} - (\psi)_{t^{*-}}$ and $[\psi(\mathbf{X}^*, t^*)] = (\psi)_{\mathcal{S}^+} - (\psi)_{\mathcal{S}^-}$:

$$[\![\psi]\!] = \begin{cases} [\psi], & \mathbf{u}(\mathbf{x}^*)\cdot\mathbf{n}(\mathbf{X}^*) < 0, \\ -[\psi], & \mathbf{u}(\mathbf{x}^*)\cdot\mathbf{n}(\mathbf{X}^*) > 0. \end{cases} \tag{6.1}$$

If $\mathbf{u}(\mathbf{x}^*)\cdot\mathbf{n}(\mathbf{X}^*) = 0$, we can approximate temporal derivatives at $\mathbf{x}^*$ by those at $\mathbf{X}^*|_{\mathcal{S}^+}$ or $\mathbf{X}^*|_{\mathcal{S}^-}$ with $[\![\cdot]\!] = 0$. Thus, instead of deriving $[\![u^i]\!]$, $\left[\!\left[\frac{\partial u^i}{\partial t}\right]\!\right]$, and $\left[\!\left[\frac{\partial^2 u^i}{\partial t^2}\right]\!\right]$, we turn to deriving $[u^i]$, $\left[\frac{\partial u^i}{\partial t}\right]$, and $\left[\frac{\partial^2 u^i}{\partial t^2}\right]$. We also need to derive $\left[\frac{\partial^2 u^i}{\partial t \partial x^k}\right]$, which appears in the right-hand side of (5.13). The spatial jump condition of velocity, $[u^i]$, is already given in (3.10).

Note that we need interpolation to obtain t^* and jump conditions evaluated at t^* in simulation practice. The interpolation procedures are given in Xu and Wang [36].

6.1. Jump conditions $\left[\frac{\partial \boldsymbol{u}^i}{\partial \boldsymbol{t}}\right]$, $\left[\frac{\partial^2 \boldsymbol{u}^i}{\partial \boldsymbol{t}^2}\right]$, and $\left[\frac{\partial^2 \boldsymbol{u}^i}{\partial \boldsymbol{t}\partial \boldsymbol{x}^k}\right]$. From (3.2), we directly have

$$\left[\frac{\partial u^i}{\partial t}\right] = -u^j\left[\frac{\partial u^i}{\partial x^j}\right]. \tag{6.2}$$

Differentiating (6.2) with respect to t, we have

$$\left[\frac{\partial^2 u^i}{\partial t^2}\right] = -2u^j\left[\frac{\partial^2 u^i}{\partial t \partial x^j}\right] - \left[\frac{\partial u^j}{\partial t}\frac{\partial u^i}{\partial x^j}\right] - u^j u^k\left[\frac{\partial^2 u^i}{\partial x^j \partial x^k}\right] - u^k\left[\frac{\partial u^j}{\partial x^k}\frac{\partial u^i}{\partial x^j}\right], \tag{6.3}$$

where $\left[\frac{\partial^2 u^i}{\partial t \partial x^k}\right]$ also appears on the right-hand side of (5.13).

Differentiating (6.2) with respect to α^l $(l = 1, 2)$, we obtain

$$\frac{\partial X^k}{\partial \alpha^l}\left[\frac{\partial^2 u^i}{\partial t \partial x^k}\right] = \frac{\partial X^k}{\partial \alpha^l}\left(\left[\frac{\partial u^i}{\partial x^j}\frac{\partial u^j}{\partial x^k}\right] + u^j\left[\frac{\partial^2 u^i}{\partial x^j \partial x^k}\right]\right). \tag{6.4}$$

Differentiating (3.5) with respect to time t, we obtain

$$n^k\left[\frac{\partial^2 u^i}{\partial t \partial x^k}\right] = \frac{\mathrm{d}}{\mathrm{d}t}\frac{(f^k n_k)n^i - f^i}{\mu \mathcal{J}} - \frac{\mathrm{d}n^k}{\mathrm{d}t}\left[\frac{\partial u^i}{\partial x^k}\right] - n^k u^j\left[\frac{\partial^2 u^i}{\partial x^k \partial x^j}\right]. \tag{6.5}$$

Denote the right-hand side of (6.4) by r_t^{il} $(l = 1, 2)$ and the right-hand side of (6.5) by r_t^{i3}. Combining (6.4) and (6.5) then gives

$$C_1\begin{bmatrix} \dfrac{\partial^2 u^i}{\partial t \partial x^1} \\ \dfrac{\partial^2 u^i}{\partial t \partial x^2} \\ \dfrac{\partial^2 u^i}{\partial t \partial x^3} \end{bmatrix} = \begin{pmatrix} r_t^{i1} \\ r_t^{i2} \\ r_t^{i3} \end{pmatrix}, \tag{6.6}$$

from which we can solve $\left[\frac{\partial^2 u^i}{\partial t \partial x^k}\right]$.

6.2. A numerical example. Here, we implement the IIM in a one-dimensional linear wave equation with a moving singular source. This simple example is designed to illustrate the necessity of including temporal jump conditions in the discretization of temporal derivatives. We also examine the convergence property of the IIM in this example.

The system has the following form:

$$\begin{cases} \dfrac{\partial u}{\partial t} + a\dfrac{\partial u}{\partial x} = c(t)\delta(x - X(t)), \quad X(t) = bt, \quad L \le x \le R, \\ u(x, 0) = g(x), \\ \dfrac{\partial u(L, t)}{\partial x} = 0, \end{cases}$$

where a and b are constants satisfying $a > 0$ and $a \neq b$. The analytical solution to the problem is

$$u(x, t) = g(x - at) + \frac{h(x - bt) + h(at - x)}{2(a - b)} c\left(\frac{x - at}{b - a}\right),$$

where $h(x)$ is the step function.

Integrating the wave equation with respect to x from $X^-(t)$ to $X^+(t)$, the jump condition of u at $x = X(t)$ can be obtained as

$$[u] = \frac{c(t)}{a - b},$$

where $[\cdot] = (\cdot)_{X^+} - (\cdot)_{X^-}$. Following the procedure described in sections 5 and 6.1, we have derived the jump conditions at the singular source $x = X(t)$:

$$[u] = \frac{c(t)}{a-b}, \quad \left[\frac{\partial u}{\partial x}\right] = -\frac{1}{(a-b)^2}\frac{\mathrm{d}c(t)}{\mathrm{d}t}, \quad \left[\frac{\partial^2 u}{\partial t \partial x}\right] = 0, \quad \left[\frac{\partial^2 u}{\partial x^2}\right] = 0,$$
$$[\![u]\!] = -\frac{c(t)}{a-b}, \quad \left[\!\left[\frac{\partial u}{\partial t}\right]\!\right] = -\frac{a}{(a-b)^2}\frac{\mathrm{d}c(t)}{\mathrm{d}t}, \quad \left[\!\left[\frac{\partial^2 u}{\partial x \partial t}\right]\!\right] = 0, \quad \left[\!\left[\frac{\partial^2 u}{\partial t^2}\right]\!\right] = 0,$$

where $[\![\cdot]\!] = (\cdot)_{t^+} - (\cdot)_{t^-}$. At the wave front generated by the singular source, i.e., at $x = X(0) + at$, the solution is continuous but unsmooth, and the corresponding jump conditions are

$$[u] = 0, \quad \left[\frac{\partial u}{\partial x}\right] = \frac{1}{(a-b)^2}\frac{\mathrm{d}c(t)}{\mathrm{d}t}, \quad \left[\frac{\partial^2 u}{\partial t \partial x}\right] = 0, \quad \left[\frac{\partial^2 u}{\partial x^2}\right] = 0,$$
$$[\![u]\!] = 0, \quad \left[\!\left[\frac{\partial u}{\partial t}\right]\!\right] = \frac{a}{(a-b)^2}\frac{\mathrm{d}c(t)}{\mathrm{d}t}, \quad \left[\!\left[\frac{\partial^2 u}{\partial x \partial t}\right]\!\right] = 0, \quad \left[\!\left[\frac{\partial^2 u}{\partial t^2}\right]\!\right] = 0.$$

The Crank–Nicolson method is used to discretize the problem on a uniform mesh:

$$\left(\frac{u_i^{n+1} - u_i^n}{\Delta t} + CT_i^n\right) + \frac{a}{2}\left(\left(\frac{u_{i+1}^n - u_{i-1}^n}{2\Delta x} + CX_i^n\right) + \left(\frac{u_{i+1}^{n+1} - u_{i-1}^{n+1}}{2\Delta x} + CX_i^{n+1} + CXT_i^n\right)\right) = 0,$$

where n denotes a time layer, i an interior grid point, Δt a time step, Δx a space step, CT the jump contribution in the finite difference of the temporal derivative, CX the jump contribution in the finite difference of the spatial derivative, and CXT the jump contribution to keep the second-order temporal accuracy of the Crank–Nicolson scheme. The jump contributions CT, CX, and CXT are caused by the unsmoothness of the solution. We calculate CT and CX according to generalized Taylor expansion to achieve $\mathcal{O}((\Delta t)^2)$ and $\mathcal{O}((\Delta x)^2)$ accuracy of the finite differences. The calculation of CXT originates from the following generalized Taylor expansion:

$$\left(\frac{\partial u}{\partial x}\right)^{n+1} = \left(\frac{\partial u}{\partial x}\right)^n + \left(\frac{\partial^2 u}{\partial x \partial t}\right)^n \Delta t + \left(\left[\!\left[\frac{\partial u}{\partial x}\right]\!\right] + \left[\!\left[\frac{\partial^2 u}{\partial x \partial t}\right]\!\right]\Delta t\right) + \mathcal{O}(\Delta t)^2.$$

If there is a grid point I satisfying $X^n < x_I \le X^{n+1}$ from time layer n to time layer $(n+1)$, then we let $x_I = X((n+\beta)\Delta t), 0 < \beta \le 1$, and compute CT_i^n and CXT_i^n as

$$\begin{cases} CT_I^n = -\dfrac{1}{\Delta t}\left([\![u]\!] + \left[\!\left[\dfrac{\partial u}{\partial t}\right]\!\right](1-\beta)\Delta t + \dfrac{1}{2}\left[\!\left[\dfrac{\partial^2 u}{\partial t^2}\right]\!\right](1-\beta)^2(\Delta t)^2\right), \\ CT_i^n = 0, \quad i \ne I. \end{cases}$$

and

$$\begin{cases} CXT_I^n = -\left(\left[\!\left[\dfrac{\partial u}{\partial x}\right]\!\right] + \left[\!\left[\dfrac{\partial^2 u}{\partial x \partial t}\right]\!\right]\Delta t\right), \\ CXT_i^n = 0, \quad i \ne I. \end{cases}$$

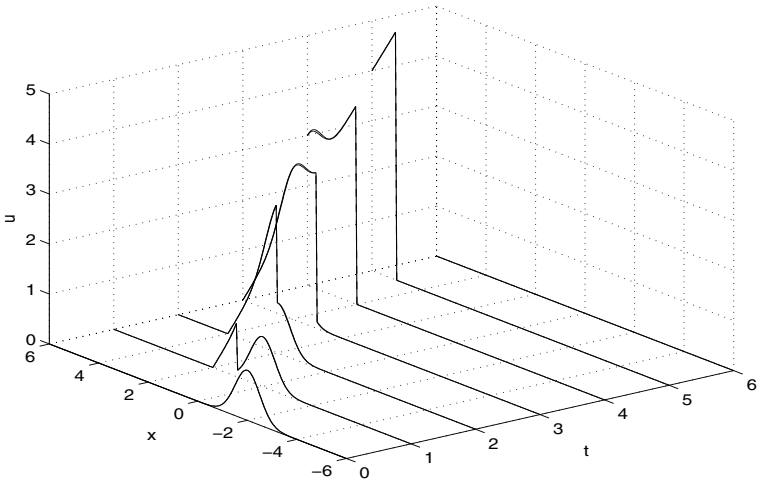

FIG. 6.1. *Comparison between the numerical solution (solid lines) and the analytical solution (dashed lines, hidden by solid lines). For the numerical solution,* $\Delta x = 0.02$ *and* $CFL = \frac{2\Delta t}{\Delta x} = 0.4$.

Otherwise, we have $CT_i^n = 0$ and $CXT_i^n = 0$ for any grid point i. If $x_{I-1} \le X^n < x_I$ at time n, then we can compute CX_i^n as

$$\begin{cases} CX_I^n = -\dfrac{1}{2\Delta x}\left([u] + \left[\dfrac{\partial u}{\partial x}\right](x_{I-1} - X^n) + \dfrac{1}{2}\left[\dfrac{\partial^2 u}{\partial x^2}\right](x_{I-1} - X^n)^2\right), \\ CX_{I-1}^n = -\dfrac{1}{2\Delta x}\left([u] + \left[\dfrac{\partial u}{\partial x}\right](x_I - X^n) + \dfrac{1}{2}\left[\dfrac{\partial^2 u}{\partial x^2}\right](x_I - X^n)^2\right), \\ CT_i^n = 0, \quad i \ne I, I-1. \end{cases}$$

Similarly, we can compute CX_i^{n+1}. At the outlet $x = R$ of the domain, an upwind finite difference scheme is used to approximate the spatial derivative, and the correction CX takes a different form. We also treat the effect of the discontinuity at $x = X(0) + at$ in the same way.

The results presented below are for $a = 2$, $b = 1$, $c(t) = t$, $L = -6$, $R = 6$, and $g(x) = \mathrm{e}^{-2(x+2)^2}$. Figure 6.1 shows the numerical solution and the analytical solution at times $t = 0, 1, 2, \ldots, 6$. After time $t = 6$, the initial wave, the singular source, and the wave generated by the singular source have all exited from the domain. The IIM produces the sharp jumps in the numerical solution and the correct wave-source interaction.

To check the accuracy of the numerical scheme near the singular source, we look at the solutions at time $t = 2$, when the position of the singular source is at $x = 2$. As spatial resolution changes, Figure 6.2(a) shows the change of the infinity norm of the error based on the analytical solution. For each spatial resolution, a very small time step corresponding to $CFL = \frac{2\Delta t}{\Delta x} = 0.002$ is used to ensure that the temporal discretization error is negligible compared with the spatial one. Second-order accuracy in space is indicated in Figure 6.2(a), as expected.

In order to check temporal accuracy, we obtain an accurate reference solution by using a very small time step corresponding to $CFL = 0.002$. We compute the numerical solution using different time steps with the same spatial resolution $\Delta x = 0.05$ as a reference. By subtracting the reference solution from a numerical solution

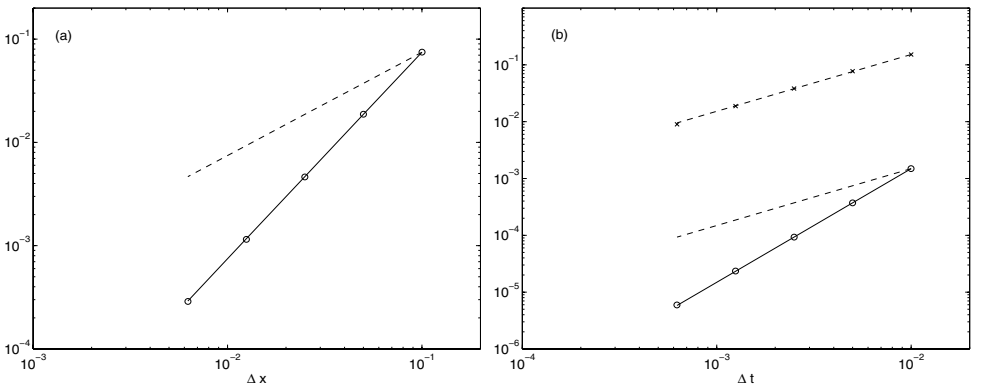

FIG. 6.2. *The infinity norm of the error as a function of* (a) *spatial resolution with* $CFL = 0.002$ *and* (b) *temporal resolution with* $\Delta x = 0.05$. *Open circles: numerical error with the jump contribution* CXT, *x-marks: numerical error without the jump contribution* CXT, *solid lines: second-order accuracy, dashed lines: first-order accuracy.*

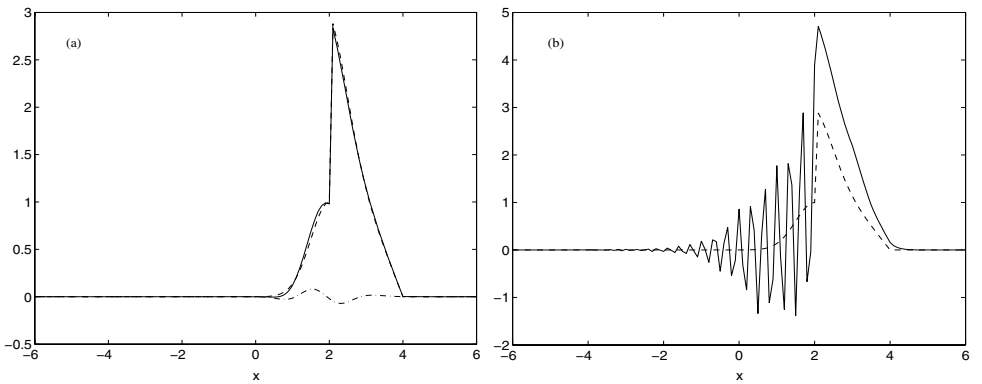

FIG. 6.3. *The effect of the jump contributions in the temporal discretization. Results* (a) *with temporal jump contributions,* (b) *without temporal jump contributions. calculated using the same space step but a different time step, we cancel out the spatial discretization error and obtain the temporal error. The results are plotted in Figure 6.2(b). Second-order accuracy in time is seen. If the jump contribution CXT is not included, only first-order accuracy in time can be achieved, as seen in Figure 6.2(b).

Figure 6.3(a) compares the numerical and analytical results at time $t = 2$ with $\Delta x = 0.1$ and $CFL = 0.4$. The amplitude of the jump contribution CT has the same order as the jump contribution CX when Δt is of the same order as Δx. If the jump contribution CT is not included, a numerical result can be totally wrong, as also shown in Figure 6.3(b).

As the velocity can be piecewise smooth across a singular surface in a viscous flow, jump contributions in the discretizations of the temporal terms in Navier–Stokes equations can be nonzero. If they are of the same order as the leading ones in spatial discretizations, the inclusion of the jump contributions in the temporal discretizations may be necessary. The moving interface problem simulated by Li and Lai [20] is

an exception. They considered the relaxation of a perturbed two-dimensional balloon immersed in an incompressible viscous fluid. The tangential force along the balloon surface is always zero in their case, so the velocity is smooth in both space and time, though the pressure is not. The jump contributions in temporal discretizations are always zero in this case. Recently, we designed an oscillating Taylor–Couette flow to look at the effect of jump contributions for temporal discretization on temporal convergence rate and temporal accuracy [36]. We found that the effect is very small. Whether this is true in general remains to be investigated.

7. Discussion. Naturally, we ask whether we can improve discretization accuracy in the IIM to arbitrarily high order for three-dimensional incompressible Navier–Stokes flows. We can derive equations for jump conditions by differentiating the principal jump conditions with respect to the Lagrangian parameters and differentiating the governing equations with respect to the Cartesian coordinates, as presented in sections 5 and 6.1. To examine this possibility, we need to know whether the number of derived equations is enough for unknown jump conditions and whether the equation system has a unique solution.

Regarding the number of equations and unknowns, we introduce a lemma.

LEMMA 7.1. *Paint m indistinctive balls with n different colors. Each ball has to be painted with one and only one color. The number of different nonordered color combinations for the m balls is*

$$\mathcal{H}_m^n = \sum_{k_1=0}^{m} \sum_{k_2=0}^{k_1} \sum_{k_3=0}^{k_2} \cdots \sum_{k_{n-2}=0}^{k_{n-3}} \sum_{k_{n-1}=0}^{k_{n-2}} \mathcal{H}_{k_{n-1}}^1, \tag{7.1}$$

with $\mathcal{H}_0^i = 1$ and $\mathcal{H}_i^1 = 1$, where i is a positive integer.

Proof. Paint $k_1\,(k_1 = 0, 1, 2, \ldots, m)$ balls using the same color. There are $n-1$ colors and $m - k_1$ balls left. Therefore, for a particular value of k_1, the number of different outcomes is $\mathcal{H}_{m-k_1}^{n-1}$. Summing $\mathcal{H}_{m-k_1}^{n-1}$ over all possible values of k_1 yields

$$\mathcal{H}_m^n = \sum_{k_1=0}^{m} \mathcal{H}_{m-k_1}^{n-1} = \sum_{k_1=0}^{m} \mathcal{H}_{k_1}^{n-1}. \tag{7.2}$$

Using recursion (7.2) repeatedly, the lemma follows. ∎

If we want the discretization accuracy of the second-order velocity and pressure derivatives to be order of $m-1\,(m \geq 2)$ in Navier–Stokes flow simulation, we need jump conditions of all velocity and pressure derivatives of order m. In a simulation of space dimension n, the number of unknown jump conditions of the velocity derivatives of order m is $\mathcal{H}_m^n$. Differentiating (3.10) with respect to the Lagrangian parameters can provide $\mathcal{H}_m^{n-1}$ equations for the unknowns, differentiating (3.12) can provide $\mathcal{H}_{m-1}^{n-1}$, and differentiating (2.1) with respect to the Cartesian coordinates and then subtracting the resulting equation at $\mathcal{S}^-$ from that at $\mathcal{S}^+$ can give $\mathcal{H}_{m-2}^n$ equations. For closure, we require

$$\mathcal{H}_m^{n-1} + \mathcal{H}_{m-1}^{n-1} + \mathcal{H}_{m-2}^n \geq \mathcal{H}_m^n.$$

The same requirement applies to the unknown jump conditions of the pressure derivatives of order m.

In three-dimensional simulations, $n = 3$, $\mathcal{H}_m^2 = m + 1$, and $\mathcal{H}_m^3 = \frac{(m+1)(m+2)}{2}$ according to (7.1). Hence, we have

$$\mathcal{H}_m^2 + \mathcal{H}_{m-1}^2 + \mathcal{H}_{m-2}^3 = \mathcal{H}_m^3;$$

that is, the number of equations is equal to the number of unknowns, supposing $\mathcal{H}^n_{m-2}$ jump conditions for temporal derivatives in the equations (for example, $\left[\frac{\partial^2 u^i}{\partial t \partial x^k}\right]$ in (5.13) in the case when $m = 3$ and $n = 3$) are known. The equation system may have a unique solution, which may be verified by induction with the use of the method given in Appendix C. However, the $\mathcal{H}^n_{m-2}$ jump conditions for the temporal derivatives are not directly available. We need to find equations for them too. As shown in section 6.1, a unique solution to the required temporal-derivative jump conditions can be obtained when $m = 3$. When $m > 3$, it is not clear whether a unique solution can be found. Thus with the method that we present in this paper for deriving jump conditions, ascending the discretization accuracy to arbitrarily high order is not achievable in the IIM for three-dimensional Navier–Stokes flows.

Appendix A. Proof of Theorem 3.3. First consider the situation in which G^i has finite jumps at $\mathcal{S}$. If necessary, smoothly extend $\mathcal{S}$ so that it cuts $\mathcal{V}$ into two separated regions. Form a banded region $\mathcal{V}_s$ which encloses $\mathcal{S}$ with surface $\mathcal{S}^+_{\epsilon/2}$ at one side of $\mathcal{S}$ and $\mathcal{S}^-_{\epsilon/2}$ at the other, where $\mathcal{S}^+_{\epsilon/2}$ and $\mathcal{S}^-_{\epsilon/2}$ are away from $\mathcal{S}$ by a small distance $\frac{\epsilon}{2}$. Thus,

$$\int_{\mathcal{V}_s} \frac{\partial G^i}{\partial x^i} \mathrm{d}\mathcal{V} = \int_{\mathcal{S}} \int_{-\frac{\epsilon}{2}}^{+\frac{\epsilon}{2}} \frac{\partial G^i}{\partial x^i} \mathrm{d}r\mathrm{d}\mathcal{S},$$

where $r = (\mathbf{x} - \mathbf{X}_{\mathrm{d}\mathcal{S}}) \cdot \mathbf{n}$ with $\mathbf{X}_{\mathrm{d}\mathcal{S}}$ representing a fixed point at the infinitesimal surface $\mathrm{d}\mathcal{S}$ and $\mathbf{n}$ normal at $\mathbf{X}_{\mathrm{d}\mathcal{S}}$ pointing to side $\mathcal{S}^+_{\epsilon/2}$. Denote the region between $\mathcal{S}^+_{\epsilon/2}$ and $\mathcal{S}$ as $\mathcal{V}_1$ and the region between $\mathcal{S}^-_{\epsilon/2}$ and $\mathcal{S}$ as $\mathcal{V}_2$. Analytically extend G^i in region $\mathcal{V}_1$ to region $\mathcal{V}_2$, and name the extended function G^i_1. Analytically extend G^i in region $\mathcal{V}_2$ to region $\mathcal{V}_1$, and name the extended function G^i_2. Introduce step function $h(r)$ as

$$h(r) = \begin{cases} 0, & r < 0, \\ 1, & r > 0. \end{cases}$$

Then,

$$\begin{aligned}
\int_{\mathcal{S}} \int_{-\frac{\epsilon}{2}}^{+\frac{\epsilon}{2}} \frac{\partial G^i}{\partial x^i} \mathrm{d}r\mathrm{d}\mathcal{S} &= \int_{\mathcal{S}} \int_{-\frac{\epsilon}{2}}^{+\frac{\epsilon}{2}} \frac{\partial (h(r)G^i_1 + h(-r)G^i_2)}{\partial x^i} \mathrm{d}r\mathrm{d}\mathcal{S} \\
&= \int_{\mathcal{S}} \int_{-\frac{\epsilon}{2}}^{+\frac{\epsilon}{2}} \frac{\partial (G^i_2 + h(r)(G^i_1 - G^i_2))}{\partial x^i} \mathrm{d}r\mathrm{d}\mathcal{S} \\
&= \int_{\mathcal{S}} \int_{-\frac{\epsilon}{2}}^{+\frac{\epsilon}{2}} \left(h(r) \frac{\partial G^i_1}{\partial x^i} + h(-r) \frac{\partial G^i_2}{\partial x^i} + \frac{\partial h(r)}{\partial x^i} (G^i_1 - G^i_2) \right) \mathrm{d}r\mathrm{d}\mathcal{S} \\
&= \int_{\mathcal{V}_1} \frac{\partial G^i_1}{\partial x^i} \mathrm{d}\mathcal{V} + \int_{\mathcal{V}_2} \frac{\partial G^i_2}{\partial x^i} \mathrm{d}\mathcal{V} + \int_{\mathcal{S}} \int_{-\frac{\epsilon}{2}}^{+\frac{\epsilon}{2}} \frac{\partial h(r)}{\partial x^i} (G^i_1 - G^i_2) \mathrm{d}r\mathrm{d}\mathcal{S}.
\end{aligned}$$

With $\frac{\partial h(r)}{\partial x^i} = \delta(r) n^i$, where $\delta(r)$ is the Dirac δ function, we thus have

$$\lim_{\epsilon \to 0} \int_{\mathcal{V}_s} \frac{\partial G^i}{\partial x^i} \mathrm{d}\mathcal{V} = \int_{\mathcal{S}} \int_{-\frac{\epsilon}{2}}^{+\frac{\epsilon}{2}} \delta(r) n^i [G^i] \mathrm{d}r\mathrm{d}\mathcal{S} = \int_{\mathcal{S}} n^i [G^i] \mathrm{d}\mathcal{S},$$

where $[\cdot]$ denotes a jump calculated by $(\cdot)_{\mathcal{S}^+} - (\cdot)_{\mathcal{S}^-}$. Here $\mathcal{S}^+$ represents $\mathcal{S}^+_{\epsilon/2}(\epsilon \to 0)$, and $\mathcal{S}^-$ represents $\mathcal{S}^-_{\epsilon/2}(\epsilon \to 0)$.

$\mathcal{V}_s$ divides $\mathcal{V}$ into three regions: $\mathcal{V}_s$ itself, $\mathcal{V}^+$, and $\mathcal{V}^-$, where $\mathcal{V}^+$ and $\mathcal{S}^+$ are at the same side of $\mathcal{S}$ and $\mathcal{V}^-$ and $\mathcal{S}^-$ are at the same side. Hence, as $\epsilon \to 0$,

$$\begin{aligned}\int_{\mathcal{V}} \frac{\partial G^i}{\partial x^i} \mathrm{d}\mathcal{V} &= \int_{\mathcal{V}^+} \frac{\partial G^i}{\partial x^i} \mathrm{d}\mathcal{V} + \int_{\mathcal{V}^-} \frac{\partial G^i}{\partial x^i} \mathrm{d}\mathcal{V} + \int_{\mathcal{V}_s} \frac{\partial G^i}{\partial x^i} \mathrm{d}\mathcal{V} \\ &= \oint_{\mathcal{A}} G^i N_i \mathrm{d}\mathcal{A} + \int_{\mathcal{S}^+} (-n_i G^i) \mathrm{d}\mathcal{S} + \int_{\mathcal{S}^-} n_i G^i \mathrm{d}\mathcal{S} + \int_{\mathcal{S}} n_i [G^i] \mathrm{d}\mathcal{S} = \oint_{\mathcal{A}} G^i N_i \mathrm{d}\mathcal{A},\end{aligned}$$

which completes the proof for the first situation that G^i has finite jumps at $\mathcal{S}$.

The second situation, in which G^i has a singularity of Dirac δ function type, can be proved by treating the Dirac δ function as a weak limit of a hat function and then using the result from the first situation.

Appendix B. Nonsingularity of C_2. By writing the third row of C_2 twice and then rearranging rows, we expand C_2 to C_2^e as follows:

$$C_2^e = \begin{pmatrix} \tau_1^1\tau_1^1 & \tau_1^1\tau_1^2 + \tau_1^2\tau_1^1 & \tau_1^1\tau_1^3 + \tau_1^3\tau_1^1 & \tau_1^2\tau_1^2 & \tau_1^2\tau_1^3 + \tau_1^3\tau_1^2 & \tau_1^3\tau_1^3 \\ \tau_1^1\tau_2^1 & \tau_1^1\tau_2^2 + \tau_1^2\tau_2^1 & \tau_1^1\tau_2^3 + \tau_1^3\tau_2^1 & \tau_1^2\tau_2^2 & \tau_1^2\tau_2^3 + \tau_1^3\tau_2^2 & \tau_1^3\tau_2^3 \\ \tau_1^1 n^1 & \tau_1^1 n^2 + \tau_1^2 n^1 & \tau_1^1 n^3 + \tau_1^3 n^1 & \tau_1^2 n^2 & \tau_1^2 n^3 + \tau_1^3 n^2 & \tau_1^3 n^3 \\ \tau_1^1\tau_2^1 & \tau_1^1\tau_2^2 + \tau_1^2\tau_2^1 & \tau_1^1\tau_2^3 + \tau_1^3\tau_2^1 & \tau_1^2\tau_2^2 & \tau_1^2\tau_2^3 + \tau_1^3\tau_2^2 & \tau_1^3\tau_2^3 \\ \tau_2^1\tau_2^1 & \tau_2^1\tau_2^2 + \tau_2^2\tau_2^1 & \tau_2^1\tau_2^3 + \tau_2^3\tau_2^1 & \tau_2^2\tau_2^2 & \tau_2^2\tau_2^3 + \tau_2^3\tau_2^2 & \tau_2^3\tau_2^3 \\ \tau_2^1 n^1 & \tau_2^1 n^2 + \tau_2^2 n^1 & \tau_2^1 n^3 + \tau_2^3 n^1 & \tau_2^2 n^2 & \tau_2^2 n^3 + \tau_2^3 n^2 & \tau_2^3 n^3 \\ 1 & 0 & 0 & 1 & 0 & 1 \end{pmatrix}.$$

We can rewrite C_2^e as

$$C_2^e = C_1^e C_2^* = \begin{pmatrix} C_1 & \mathbf{0} & \mathbf{0} \\ \mathbf{0} & C_1 & \mathbf{0} \\ \mathbf{0} & \mathbf{0} & 1 \end{pmatrix} \begin{pmatrix} \tau_1^1 & \tau_1^2 & \tau_1^3 & 0 & 0 & 0 \\ 0 & \tau_1^1 & 0 & \tau_1^2 & \tau_1^3 & 0 \\ 0 & 0 & \tau_1^1 & 0 & \tau_1^2 & \tau_1^3 \\ \tau_2^1 & \tau_2^2 & \tau_2^3 & 0 & 0 & 0 \\ 0 & \tau_2^1 & 0 & \tau_2^2 & \tau_2^3 & 0 \\ 0 & 0 & \tau_2^1 & 0 & \tau_2^2 & \tau_2^3 \\ 1 & 0 & 0 & 1 & 0 & 1 \end{pmatrix}.$$

As C_1 is nonsingular, C_1^e is also nonsingular with inverse

$$(C_1^e)^{-1} = \begin{pmatrix} C_1^{-1} & \mathbf{0} & \mathbf{0} \\ \mathbf{0} & C_1^{-1} & \mathbf{0} \\ \mathbf{0} & \mathbf{0} & 1 \end{pmatrix}.$$

Thus, if $\operatorname{rank}(C_2^*) = 6$, then C_2 is nonsingular. We present two methods to show $\operatorname{rank}(C_2^*) = 6$.

B.1. Method I. As $\tau_\mathbf{1} \neq 0$, one of τ_1^1, τ_1^2, or τ_1^3 must be nonzero. Through row and column permutations, C_2^* can be transformed to one of the following two matrices:

$$\begin{pmatrix} \tau_1^2 & \tau_1^3 & \tau_1^1 & 0 & 0 & 0 \\ 0 & \tau_1^2 & 0 & \tau_1^3 & \tau_1^1 & 0 \\ 0 & 0 & \tau_1^2 & 0 & \tau_1^3 & \tau_1^1 \\ \tau_2^2 & \tau_2^3 & \tau_2^1 & 0 & 0 & 0 \\ 0 & \tau_2^2 & 0 & \tau_2^3 & \tau_2^1 & 0 \\ 0 & 0 & \tau_2^2 & 0 & \tau_2^3 & \tau_2^1 \\ 1 & 0 & 0 & 1 & 0 & 1 \end{pmatrix}, \qquad \begin{pmatrix} \tau_1^3 & \tau_1^2 & \tau_1^1 & 0 & 0 & 0 \\ 0 & \tau_1^3 & 0 & \tau_1^2 & \tau_1^1 & 0 \\ 0 & 0 & \tau_1^3 & 0 & \tau_1^2 & \tau_1^1 \\ \tau_2^3 & \tau_2^2 & \tau_2^1 & 0 & 0 & 0 \\ 0 & \tau_2^3 & 0 & \tau_2^2 & \tau_2^1 & 0 \\ 0 & 0 & \tau_2^3 & 0 & \tau_2^2 & \tau_2^1 \\ 1 & 0 & 0 & 1 & 0 & 1 \end{pmatrix}.$$

Both have the same structure and similar element ordering as C_2^*. Therefore, we suppose $\tau_1^1 \neq 0$ and need to work on only this case.

Using elementary operations, we can transform C_2^* to C_2^{**} as

$$C_2^* \to C_2^{**} = \begin{pmatrix} 1 & 0 & 0 & 1 & 0 & 1 \\ 0 & \tau_1^1 & 0 & \tau_1^2 & \tau_1^3 & 0 \\ 0 & 0 & \tau_1^1 & 0 & \tau_1^2 & \tau_1^3 \\ 0 & 0 & 0 & -s_3 & -2\tau_1^2\tau_1^3 & -s_2 \\ 0 & 0 & 0 & 0 & e & f \\ 0 & 0 & 0 & 0 & g & h \\ 0 & 0 & 0 & 0 & N^3 & -N^2 \end{pmatrix},$$

with the following definitions:

$$\begin{aligned} s_2 &= \tau_1^1\tau_1^1 + \tau_1^3\tau_1^3, \\ s_3 &= \tau_1^1\tau_1^1 + \tau_1^2\tau_1^2, \\ N^2 &= \tau_1^3\tau_2^1 - \tau_2^3\tau_1^1, \\ N^3 &= \tau_1^1\tau_2^2 - \tau_2^1\tau_1^2, \\ e &= (\tau_2^2\tau_1^3 + \tau_1^2\tau_2^3)s_3 - 2\tau_1^2\tau_1^3 d_3, \\ f &= d_2 s_3 - d_3 s_2, \\ g &= N^2 s_3 + 2\tau_1^2\tau_1^3 N^3, \\ h &= s_2 N^3, \end{aligned}$$

where

$$\begin{aligned} d_2 &= \tau_1^1\tau_2^1 + \tau_1^3\tau_2^3, \\ d_3 &= \tau_1^1\tau_2^1 + \tau_1^2\tau_2^2. \end{aligned}$$

If $N^2 = N^3 = 0$, then as $\tau_1^1 \neq 0$,

$$\boldsymbol{\tau_1} \cdot (\boldsymbol{\tau_1} \times \boldsymbol{\tau_2}) = \tau_1^1 N^1 + \tau_1^2 N^2 + \tau_1^3 N^3 = 0 \Rightarrow N^1 = 0 \Rightarrow \boldsymbol{\tau_1} \times \boldsymbol{\tau_2} = 0,$$

where $N^1 = \tau_1^2\tau_2^3 - \tau_2^2\tau_1^3$. This is impossible. Thus, one of N^2 and N^3 must be nonzero. Suppose $N^3 \neq 0$. By elementary operations, we can transform C_2^{**} to

$$\begin{pmatrix} 1 & 0 & 0 & 0 & 0 & 0 \\ 0 & \tau_1^1 & 0 & \tau_1^2 & \tau_1^3 & 0 \\ 0 & 0 & \tau_1^1 & 0 & \tau_1^2 & \tau_1^3 \\ 0 & 0 & 0 & -s_3 & -2\tau_1^2\tau_1^3 & -s_2 \\ 0 & 0 & 0 & 0 & N^3 & -N^2 \\ 0 & 0 & 0 & 0 & 0 & N^3 f + N^2 e \\ 0 & 0 & 0 & 0 & 0 & N^3 h + N^2 g \end{pmatrix}.$$

Since

$$N^3 h + N^2 g = \tau_1^1\tau_1^1 \|\boldsymbol{\tau_1} \times \boldsymbol{\tau_2}\|^2 \neq 0,$$

we can conclude that $\operatorname{rank}(C_2^{**}) \geq 6$. Supposing $N^2 \neq 0$, we can similarly show $\operatorname{rank}(C_2^{**}) \geq 6$. C_2^e is expanded from C_2, and thus $\operatorname{rank}(C_2^e) \leq 6$. Therefore, $\operatorname{rank}(C_2^e) = \operatorname{rank}(C_2^*) = \operatorname{rank}(C_2^{**}) = 6$. The proof is completed. This proof gives a way to solve (5.8).

B.2. Method II. As $\tau_{\mathbf{1}} \times \tau_{\mathbf{2}} \neq 0$, there exist matrices P_r and P_c such that

$$P_r \begin{pmatrix} \tau_1^1 & \tau_1^2 & \tau_1^3 \\ \tau_2^1 & \tau_2^2 & \tau_2^3 \end{pmatrix} P_c = T,$$

where P_r is a 2×2 elementary matrix, P_c is a 3×3 elementary matrix without permutation operations, and $T = \begin{pmatrix} e_t^1 & e_t^2 & e_t^3 \\ e_b^1 & e_b^2 & e_b^3 \end{pmatrix}$ is one of

$$\begin{pmatrix} 1 & 0 & 0 \\ 0 & 1 & 0 \end{pmatrix}, \quad \begin{pmatrix} 1 & 0 & 0 \\ 0 & 0 & 1 \end{pmatrix}, \quad \begin{pmatrix} 0 & 1 & 0 \\ 0 & 0 & 1 \end{pmatrix}.$$

Construct elementary matrices E_r and E_c as

$$E_r = \begin{pmatrix} P_r & \mathbf{0} \\ \mathbf{0} & I_{5\times 5} \end{pmatrix}, \quad E_c = \begin{pmatrix} P_c & \mathbf{0} \\ \mathbf{0} & I_{3\times 3} \end{pmatrix},$$

where $I_{n\times n}$ denotes an $n \times n$ unit matrix. With a series of actions by permutations and E_r and E_c, C_2^* can be transformed as follows:

$$\begin{aligned} C_2^* &\to E_r \begin{pmatrix} \tau_1^1 & \tau_1^2 & \tau_1^3 & 0 & 0 & 0 \\ \tau_2^1 & \tau_2^2 & \tau_2^3 & 0 & 0 & 0 \\ 0 & \tau_1^1 & 0 & \tau_1^2 & \tau_1^3 & 0 \\ 0 & \tau_2^1 & 0 & \tau_2^2 & \tau_2^3 & 0 \\ 0 & 0 & \tau_1^1 & 0 & \tau_1^2 & \tau_1^3 \\ 0 & 0 & \tau_2^1 & 0 & \tau_2^2 & \tau_2^3 \\ 1 & 0 & 0 & 1 & 0 & 1 \end{pmatrix} E_c = \begin{pmatrix} e_t^1 & e_t^2 & e_t^3 & 0 & 0 & 0 \\ e_b^1 & e_b^2 & e_b^3 & 0 & 0 & 0 \\ 0 & \tau_1^1 & 0 & \tau_1^2 & \tau_1^3 & 0 \\ 0 & \tau_2^1 & 0 & \tau_2^2 & \tau_2^3 & 0 \\ 0 & 0 & \tau_1^1 & 0 & \tau_1^2 & \tau_1^3 \\ 0 & 0 & \tau_2^1 & 0 & \tau_2^2 & \tau_2^3 \\ 1 & 0 & 0 & 1 & 0 & 1 \end{pmatrix} \\ &\to E_r \begin{pmatrix} \tau_1^1 & \tau_1^2 & \tau_1^3 & 0 & 0 & 0 \\ \tau_2^1 & \tau_2^2 & \tau_2^3 & 0 & 0 & 0 \\ e_t^2 & 0 & 0 & e_t^1 & e_t^3 & 0 \\ e_b^2 & 0 & 0 & e_b^1 & e_b^3 & 0 \\ 0 & 0 & \tau_1^2 & 0 & \tau_1^1 & \tau_1^3 \\ 0 & 0 & \tau_2^2 & 0 & \tau_2^1 & \tau_2^3 \\ 0 & 1 & 0 & 1 & 0 & 1 \end{pmatrix} E_b = \begin{pmatrix} e_t^1 & e_t^2 & e_t^3 & 0 & 0 & 0 \\ e_b^1 & e_b^2 & e_b^3 & 0 & 0 & 0 \\ e_t^2 & 0 & 0 & e_t^1 & e_t^3 & 0 \\ e_b^2 & 0 & 0 & e_b^1 & e_b^3 & 0 \\ 0 & 0 & \tau_1^2 & 0 & \tau_1^1 & \tau_1^3 \\ 0 & 0 & \tau_2^2 & 0 & \tau_2^1 & \tau_2^3 \\ 0 & 1 & 0 & 1 & 0 & 1 \end{pmatrix} \\ &\to E_r \begin{pmatrix} \tau_1^1 & \tau_1^2 & \tau_1^3 & 0 & 0 & 0 \\ \tau_2^1 & \tau_2^2 & \tau_2^3 & 0 & 0 & 0 \\ 0 & e_t^3 & 0 & e_t^1 & e_t^2 & 0 \\ 0 & e_b^3 & 0 & e_b^1 & e_b^2 & 0 \\ e_t^3 & 0 & 0 & e_t^2 & 0 & e_t^1 \\ e_b^3 & 0 & 0 & e_b^2 & 0 & e_b^1 \\ 0 & 0 & 1 & 0 & 1 & 1 \end{pmatrix} E_c = \begin{pmatrix} e_t^1 & e_t^2 & e_t^3 & 0 & 0 & 0 \\ e_b^1 & e_b^2 & e_b^3 & 0 & 0 & 0 \\ 0 & e_t^3 & 0 & e_t^1 & e_t^2 & 0 \\ 0 & e_b^3 & 0 & e_b^1 & e_b^2 & 0 \\ e_t^3 & 0 & 0 & e_t^2 & 0 & e_t^1 \\ e_b^3 & 0 & 0 & e_b^2 & 0 & e_b^1 \\ 0 & 0 & 1 & 0 & 1 & 1 \end{pmatrix}. \end{aligned}$$

As matrix T takes different choices, the last matrix above correspondingly takes

$$\begin{pmatrix} 1 & 0 & 0 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 1 & 0 & 0 \\ 0 & 0 & 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 0 & 0 & 1 \\ 0 & 0 & 0 & 1 & 0 & 0 \\ 0 & 0 & 1 & 0 & 1 & 1 \end{pmatrix}, \quad \begin{pmatrix} 1 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 1 & 0 & 0 & 0 \\ 0 & 0 & 0 & 1 & 0 & 0 \\ 0 & 1 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 1 \\ 1 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 1 & 0 & 1 & 1 \end{pmatrix}, \quad \begin{pmatrix} 0 & 1 & 0 & 0 & 0 & 0 \\ 0 & 0 & 1 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 1 & 0 \\ 0 & 1 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 1 & 0 & 0 \\ 1 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 1 & 0 & 1 & 1 \end{pmatrix}.$$

Thus, $\operatorname{rank}(C_2^*) = 6$.

Appendix C. rank(C_3) = 10. Expand C_3 to C_3^e as

$$C_3^e = \begin{pmatrix}
C_2^{11} & C_2^{12} & C_2^{13} & C_2^{14} & C_2^{15} & C_2^{16} & 0 & 0 & 0 & 0 \\
C_2^{31} & C_2^{32} & C_2^{33} & C_2^{34} & C_2^{35} & C_2^{36} & 0 & 0 & 0 & 0 \\
C_2^{31} & C_2^{32} & C_2^{33} & C_2^{34} & C_2^{35} & C_2^{36} & 0 & 0 & 0 & 0 \\
C_2^{21} & C_2^{22} & C_2^{23} & C_2^{24} & C_2^{25} & C_2^{26} & 0 & 0 & 0 & 0 \\
0 & C_2^{11} & 0 & C_2^{12} & C_2^{13} & 0 & C_2^{14} & C_2^{15} & C_2^{16} & 0 \\
0 & C_2^{31} & 0 & C_2^{32} & C_2^{33} & 0 & C_2^{34} & C_2^{35} & C_2^{36} & 0 \\
0 & C_2^{31} & 0 & C_2^{32} & C_2^{33} & 0 & C_2^{34} & C_2^{35} & C_2^{36} & 0 \\
0 & C_2^{21} & 0 & C_2^{22} & C_2^{23} & 0 & C_2^{24} & C_2^{25} & C_2^{26} & 0 \\
0 & 0 & C_2^{11} & 0 & C_2^{12} & C_2^{13} & 0 & C_2^{14} & C_2^{15} & C_2^{16} \\
0 & 0 & C_2^{31} & 0 & C_2^{32} & C_2^{33} & 0 & C_2^{34} & C_2^{35} & C_2^{36} \\
0 & 0 & C_2^{31} & 0 & C_2^{32} & C_2^{33} & 0 & C_2^{34} & C_2^{35} & C_2^{36} \\
0 & 0 & C_2^{21} & 0 & C_2^{22} & C_2^{23} & 0 & C_2^{24} & C_2^{25} & C_2^{26} \\
1 & 0 & 0 & 1 & 0 & 1 & 0 & 0 & 0 & 0 \\
0 & 1 & 0 & 0 & 0 & 0 & 1 & 0 & 1 & 0 \\
0 & 0 & 1 & 0 & 0 & 0 & 0 & 1 & 0 & 1
\end{pmatrix}.$$

If $\operatorname{rank}(C_3^e) = 10$, then $\operatorname{rank}(C_3) = 10$.

Define a corner block

$$C_3^c := \begin{pmatrix}
C_2^{11} & C_2^{12} & C_2^{13} & C_2^{14} & C_2^{15} & C_2^{16} \\
C_2^{31} & C_2^{32} & C_2^{33} & C_2^{34} & C_2^{35} & C_2^{36} \\
C_2^{31} & C_2^{32} & C_2^{33} & C_2^{34} & C_2^{35} & C_2^{36} \\
C_2^{21} & C_2^{22} & C_2^{23} & C_2^{24} & C_2^{25} & C_2^{26}
\end{pmatrix},$$

and decompose C_3^c as

$$\begin{aligned}
C_3^c &= \begin{pmatrix}
\tau_1^1\tau_1^1 & \tau_1^1\tau_1^2+\tau_1^2\tau_1^1 & \tau_1^1\tau_1^3+\tau_1^3\tau_1^1 & \tau_1^2\tau_1^2 & \tau_1^2\tau_1^3+\tau_1^3\tau_1^2 & \tau_1^3\tau_1^3 \\
\tau_1^1\tau_2^1 & \tau_1^1\tau_2^2+\tau_1^2\tau_2^1 & \tau_1^1\tau_2^3+\tau_1^3\tau_2^1 & \tau_1^2\tau_2^2 & \tau_1^2\tau_2^3+\tau_1^3\tau_2^2 & \tau_1^3\tau_2^3 \\
\tau_1^1\tau_2^1 & \tau_1^1\tau_2^2+\tau_1^2\tau_2^1 & \tau_1^1\tau_2^3+\tau_1^3\tau_2^1 & \tau_1^2\tau_2^2 & \tau_1^2\tau_2^3+\tau_1^3\tau_2^2 & \tau_1^3\tau_2^3 \\
\tau_2^1\tau_2^1 & \tau_2^1\tau_2^2+\tau_2^2\tau_2^1 & \tau_2^1\tau_2^3+\tau_2^3\tau_2^1 & \tau_2^2\tau_2^2 & \tau_2^2\tau_2^3+\tau_2^3\tau_2^2 & \tau_2^3\tau_2^3
\end{pmatrix} \\
&:= L_1R_1 = \begin{pmatrix}
\tau_1^1 & 0 & \tau_1^2 & 0 & \tau_1^3 & 0 \\
\tau_2^1 & 0 & \tau_2^2 & 0 & \tau_2^3 & 0 \\
0 & \tau_1^1 & 0 & \tau_1^2 & 0 & \tau_1^3 \\
0 & \tau_2^1 & 0 & \tau_2^2 & 0 & \tau_2^3
\end{pmatrix}
\begin{pmatrix}
\tau_1^1 & \tau_1^2 & \tau_1^3 & 0 & 0 & 0 \\
\tau_2^1 & \tau_2^2 & \tau_2^3 & 0 & 0 & 0 \\
0 & \tau_1^1 & 0 & \tau_1^2 & \tau_1^3 & 0 \\
0 & \tau_2^1 & 0 & \tau_2^2 & \tau_2^3 & 0 \\
0 & 0 & \tau_1^1 & 0 & \tau_1^2 & \tau_1^3 \\
0 & 0 & \tau_2^1 & 0 & \tau_2^2 & \tau_2^3
\end{pmatrix}.
\end{aligned}$$

Through permutations, we can transform C_3^c as

$$C_3^c \to L_1^*R_1^* := \begin{pmatrix}
\tau_1^2 & 0 & \tau_1^3 & 0 & \tau_1^1 & 0 \\
\tau_2^2 & 0 & \tau_2^3 & 0 & \tau_2^1 & 0 \\
0 & \tau_1^2 & 0 & \tau_1^3 & 0 & \tau_1^1 \\
0 & \tau_2^2 & 0 & \tau_2^3 & 0 & \tau_2^1
\end{pmatrix}
\begin{pmatrix}
\tau_1^2 & \tau_1^3 & \tau_1^1 & 0 & 0 & 0 \\
\tau_2^2 & \tau_2^3 & \tau_2^1 & 0 & 0 & 0 \\
0 & \tau_1^2 & 0 & \tau_1^3 & \tau_1^1 & 0 \\
0 & \tau_2^2 & 0 & \tau_2^3 & \tau_2^1 & 0 \\
0 & 0 & \tau_1^2 & 0 & \tau_1^3 & \tau_1^1 \\
0 & 0 & \tau_2^2 & 0 & \tau_2^3 & \tau_2^1
\end{pmatrix}$$

or

$$C_3^c \to L_1^{**} R_1^{**} := \begin{pmatrix} \tau_1^3 & 0 & \tau_1^2 & 0 & \tau_1^1 & 0 \\ \tau_2^3 & 0 & \tau_2^2 & 0 & \tau_2^1 & 0 \\ 0 & \tau_1^3 & 0 & \tau_1^2 & 0 & \tau_1^1 \\ 0 & \tau_2^3 & 0 & \tau_2^2 & 0 & \tau_2^1 \end{pmatrix} \begin{pmatrix} \tau_1^3 & \tau_1^2 & \tau_1^1 & 0 & 0 & 0 \\ \tau_2^3 & \tau_2^2 & \tau_2^1 & 0 & 0 & 0 \\ 0 & \tau_1^3 & 0 & \tau_1^2 & \tau_1^1 & 0 \\ 0 & \tau_2^3 & 0 & \tau_2^2 & \tau_2^1 & 0 \\ 0 & 0 & \tau_1^3 & 0 & \tau_1^2 & \tau_1^1 \\ 0 & 0 & \tau_2^3 & 0 & \tau_2^2 & \tau_2^1 \end{pmatrix}.$$

Since L_1, L_1^*, and L_1^{**} have the same structure and similar element ordering, and so do R_1, R_1^*, and R_1^{**}, we suppose $\tau_1^1 \neq 0$ and need to work on only this case.

As $\tau_1^1 \neq 0$ and $\boldsymbol{\tau_1 \times \tau_2} \neq 0$, there exists matrix P such that

$$\begin{pmatrix} \tau_1^1 & \tau_1^2 & \tau_1^3 \\ \tau_2^1 & \tau_2^2 & \tau_2^3 \end{pmatrix} P = T,$$

where P is a 3×3 elementary matrix without permutation operations and $T = \begin{pmatrix} e_t^1 & e_t^2 & e_t^3 \\ e_b^1 & e_b^2 & e_b^3 \end{pmatrix}$ is one of

$$\begin{pmatrix} 1 & 0 & 0 \\ 0 & 1 & 0 \end{pmatrix}, \quad \begin{pmatrix} 1 & 0 & 0 \\ 0 & 0 & 1 \end{pmatrix}.$$

Construct elementary matrix E as

$$E = \begin{pmatrix} P & \mathbf{0} \\ \mathbf{0} & I_{3\times 3} \end{pmatrix}.$$

With a series of actions by permutations and E, C_3^c can be transformed as follows:

$$\begin{aligned} C_3^c = L_1 R_1 &\to L_1 R_1 E = L_1 \begin{pmatrix} e_t^1 & e_t^2 & e_t^3 & 0 & 0 & 0 \\ e_b^1 & e_b^2 & e_b^3 & 0 & 0 & 0 \\ 0 & \tau_1^1 & 0 & \tau_1^2 & \tau_1^3 & 0 \\ 0 & \tau_2^1 & 0 & \tau_2^2 & \tau_2^3 & 0 \\ 0 & 0 & \tau_1^1 & 0 & \tau_1^2 & \tau_1^3 \\ 0 & 0 & \tau_2^1 & 0 & \tau_2^2 & \tau_2^3 \end{pmatrix} \\ &\to \begin{pmatrix} \tau_1^2 & 0 & \tau_1^1 & 0 & \tau_1^3 & 0 \\ \tau_2^2 & 0 & \tau_2^1 & 0 & \tau_2^3 & 0 \\ 0 & \tau_1^2 & 0 & \tau_1^1 & 0 & \tau_1^3 \\ 0 & \tau_2^2 & 0 & \tau_2^1 & 0 & \tau_2^3 \end{pmatrix} \begin{pmatrix} \tau_1^1 & \tau_1^2 & \tau_1^3 & 0 & 0 & 0 \\ \tau_2^1 & \tau_2^2 & \tau_2^3 & 0 & 0 & 0 \\ e_t^2 & 0 & 0 & e_t^1 & e_t^3 & 0 \\ e_b^2 & 0 & 0 & e_b^1 & e_b^3 & 0 \\ 0 & 0 & \tau_1^2 & 0 & \tau_1^1 & \tau_1^3 \\ 0 & 0 & \tau_2^2 & 0 & \tau_2^1 & \tau_2^3 \end{pmatrix} \\ &:= L_2 R_2 \to L_2 R_2 E = L_2 \begin{pmatrix} e_t^1 & e_t^2 & e_t^3 & 0 & 0 & 0 \\ e_b^1 & e_b^2 & e_b^3 & 0 & 0 & 0 \\ e_t^2 & 0 & 0 & e_t^1 & e_t^3 & 0 \\ e_b^2 & 0 & 0 & e_b^1 & e_b^3 & 0 \\ 0 & 0 & \tau_1^2 & 0 & \tau_1^1 & \tau_1^3 \\ 0 & 0 & \tau_2^2 & 0 & \tau_2^1 & \tau_2^3 \end{pmatrix} \\ &\to \begin{pmatrix} \tau_1^3 & 0 & \tau_1^1 & 0 & \tau_1^2 & 0 \\ \tau_2^3 & 0 & \tau_2^1 & 0 & \tau_2^2 & 0 \\ 0 & \tau_1^3 & 0 & \tau_1^1 & 0 & \tau_1^2 \\ 0 & \tau_2^3 & 0 & \tau_2^1 & 0 & \tau_2^2 \end{pmatrix} \begin{pmatrix} \tau_1^1 & \tau_1^2 & \tau_1^3 & 0 & 0 & 0 \\ \tau_2^1 & \tau_2^2 & \tau_2^3 & 0 & 0 & 0 \\ e_t^3 & 0 & 0 & e_t^2 & 0 & e_t^1 \\ e_b^3 & 0 & 0 & e_b^2 & 0 & e_b^1 \\ 0 & e_t^3 & 0 & e_t^1 & e_t^2 & 0 \\ 0 & e_b^3 & 0 & e_b^1 & e_b^2 & 0 \end{pmatrix} \end{aligned}$$

$$:= L_3R_3 \to L_3R_3E = L_3 \begin{pmatrix} e_t^1 & e_t^2 & e_t^3 & 0 & 0 & 0 \\ e_b^1 & e_b^2 & e_b^3 & 0 & 0 & 0 \\ e_t^3 & 0 & 0 & e_t^2 & 0 & e_t^1 \\ e_b^3 & 0 & 0 & e_b^2 & 0 & e_b^1 \\ 0 & e_t^3 & 0 & e_t^1 & e_t^2 & 0 \\ 0 & e_b^3 & 0 & e_b^1 & e_b^2 & 0 \end{pmatrix} := L_4R_4.$$

When

$$T = \begin{pmatrix} e_t^1 & e_t^2 & e_t^3 \\ e_b^1 & e_b^2 & e_b^3 \end{pmatrix} = \begin{pmatrix} 1 & 0 & 0 \\ 0 & 1 & 0 \end{pmatrix},$$

we continue to transform C_3^c as

$$\begin{aligned} L_4R_4 &= \begin{pmatrix} \tau_1^3 & 0 & 0 & \tau_1^2 & 0 & \tau_1^1 \\ \tau_2^3 & 0 & 0 & \tau_2^2 & 0 & \tau_2^1 \\ 0 & \tau_1^3 & 0 & \tau_1^1 & \tau_1^2 & 0 \\ 0 & \tau_2^3 & 0 & \tau_2^1 & \tau_2^2 & 0 \end{pmatrix} \to \begin{pmatrix} \tau_1^1 & \tau_1^2 & \tau_1^3 & 0 & 0 & 0 \\ \tau_2^1 & \tau_2^2 & \tau_2^3 & 0 & 0 & 0 \\ 0 & \tau_1^1 & 0 & \tau_1^2 & \tau_1^3 & 0 \\ 0 & \tau_2^1 & 0 & \tau_2^2 & \tau_2^3 & 0 \end{pmatrix} E \\ &= \begin{pmatrix} 1 & 0 & 0 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 & 0 & 0 \\ 0 & \tau_1^1 & 0 & \tau_1^2 & \tau_1^3 & 0 \\ 0 & \tau_2^1 & 0 & \tau_2^2 & \tau_2^3 & 0 \end{pmatrix} \to \begin{pmatrix} \tau_1^1 & \tau_1^2 & \tau_1^3 & 0 & 0 & 0 \\ \tau_2^1 & \tau_2^2 & \tau_2^3 & 0 & 0 & 0 \\ 0 & 0 & 0 & 1 & 0 & 0 \\ 1 & 0 & 0 & 0 & 0 & 0 \end{pmatrix} E \\ &= \begin{pmatrix} 1 & 0 & 0 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 1 & 0 & 0 \\ 1 & 0 & 0 & 0 & 0 & 0 \end{pmatrix} \to \begin{pmatrix} 1 & 0 & 0 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 1 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 \end{pmatrix}. \end{aligned}$$

When

$$T = \begin{pmatrix} e_t^1 & e_t^2 & e_t^3 \\ e_b^1 & e_b^2 & e_b^3 \end{pmatrix} = \begin{pmatrix} 1 & 0 & 0 \\ 0 & 0 & 1 \end{pmatrix},$$

we continue to transform C_3^c as

$$\begin{aligned} L_4R_4 &= \begin{pmatrix} \tau_1^3 & 0 & 0 & \tau_1^2 & 0 & \tau_1^1 \\ \tau_2^3 & 0 & 0 & \tau_2^2 & 0 & \tau_2^1 \\ \tau_1^1 & \tau_1^2 & \tau_1^3 & 0 & 0 & 0 \\ \tau_2^1 & \tau_2^2 & \tau_2^3 & 0 & 0 & 0 \end{pmatrix} \to \begin{pmatrix} \tau_1^1 & \tau_1^2 & \tau_1^3 & 0 & 0 & 0 \\ \tau_2^1 & \tau_2^2 & \tau_2^3 & 0 & 0 & 0 \\ 0 & 0 & \tau_1^1 & \tau_1^2 & \tau_1^3 & 0 \\ 0 & 0 & \tau_2^1 & \tau_2^2 & \tau_2^3 & 0 \end{pmatrix} E \\ &= \begin{pmatrix} 1 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 1 & 0 & 0 & 0 \\ 0 & 0 & \tau_1^1 & \tau_1^2 & \tau_1^3 & 0 \\ 0 & 0 & \tau_2^1 & \tau_2^2 & \tau_2^3 & 0 \end{pmatrix} \to \begin{pmatrix} \tau_1^1 & \tau_1^2 & \tau_1^3 & 0 & 0 & 0 \\ \tau_2^1 & \tau_2^2 & \tau_2^3 & 0 & 0 & 0 \\ 0 & 0 & 0 & 1 & 0 & 0 \\ 1 & 0 & 0 & 0 & 0 & 0 \end{pmatrix} E \\ &= \begin{pmatrix} 1 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 1 & 0 & 0 & 0 \\ 0 & 0 & 0 & 1 & 0 & 0 \\ 1 & 0 & 0 & 0 & 0 & 0 \end{pmatrix} \to \begin{pmatrix} 1 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 1 & 0 & 0 & 0 \\ 0 & 0 & 0 & 1 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 \end{pmatrix}. \end{aligned}$$

Combining all the row-operating elementary matrices as a 4×4 elementary matrix E_r^c and all the column-operating elementary matrices as a 6×6 elementary matrix E_c^c, we can write transformations to C_3^c as

$$C_3^c \to E_r^c C_3^c E_c^c = \begin{pmatrix} 1 & 0 & 0 & 0 & 0 & 0 \\ 0 & \gamma^1 & \gamma^2 & 0 & 0 & 0 \\ 0 & 0 & 0 & 1 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 \end{pmatrix},$$

where (γ^1, γ^2) equals $(1, 0)$ or $(0, 1)$.

Construct elementary matrices Q_r and Q_c as

$$Q_r = \begin{pmatrix} E_r^c & \mathbf{0} \\ \mathbf{0} & I_{11\times 11} \end{pmatrix}, \quad Q_c = \begin{pmatrix} E_c^c & \mathbf{0} \\ \mathbf{0} & I_{4\times 4} \end{pmatrix}.$$

With a series of actions by permutations, Q_r and Q_c, C_3^e can be transformed as follows:

$$C_3^e \to Q_r C_3^e Q_c = \begin{pmatrix}
1 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\
0 & \gamma^1 & \gamma^2 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\
0 & 0 & 0 & 1 & 0 & 0 & 0 & 0 & 0 & 0 \\
0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\

DETERMINISTIC SIMULATION OF THE BOLTZMANN–POISSON SYSTEM IN GAAS-BASED SEMICONDUCTORS*

MARÍA J. CÁCERES†, JOSÉ A. CARRILLO‡, AND ARMANDO MAJORANA§

Abstract. In this work we present a deterministic numerical scheme solving the one-dimensional Boltzmann–Poisson system for semiconductor materials with a complicated band structure such as GaAs. The model is based on a system of two kinetic equations for the electron population in each of the relevant valleys coupled through the Poisson equation to consider the self-consistent potential. Interaction of electrons with the crystal is taken into account by treating the most important inter- and intravalley scattering mechanisms in GaAs. The numerical scheme follows the main ideas in [J. A. Carrillo, I. M. Gamba, A. Majorana, and C.-W. Shu, *J. Comput. Phys.*, 184 (2003), pp. 498–525] already developed for Si-based devices. The newest numerical features are the intervalley scattering, the singularity of the kernels of impurities, and optical polar phonon scattering. The charge conservation of the scheme is achieved by a suitable discretization of the collision operator within the accuracy of the middle-point integration rule. A detailed study of this numerical scheme is made by showing results on the bulk material, numerically validating the results by comparison to direct simulation Monte Carlo (DSMC) results, and testing our results for diodes and Gunn oscillations.

1. Introduction.

The most simplified, but relevant, band structure for GaAs semiconductor devices needs to take into account transport on the lowest energy conduction band. In its description, the most important information comes from the absolute and local minima since they typically concentrate most of the electrons in the conduction band. These minima are called valleys, and we will consider them as different populations in our model.

In GaAs the most interesting part of the valley structure is given by an absolute minimum at the center of the Brillouin zone, called the Γ-valley, and four local minima through the crystal orientation, called the L-valleys, which are considered equivalent [18]. The dispersion relation in each valley is given by the Kane model:

$$\mathcal{E}_A(\mathsf{k}_A) = \frac{\hbar^2|\mathsf{k}_A|^2}{m_A^* + \sqrt{(m_A^*)^2 + 2\,\alpha_A\, m_A^*\,\hbar^2|\mathsf{k}_A|^2}}, \qquad A = \Gamma, L, \tag{1.1}$$

where α_A is called the nonparabolicity factor.

We study the transport of electrons in each valley by a linear transport Boltzmann equation:

$$\frac{\partial f_\Gamma}{\partial t} + \frac{1}{\hbar}\nabla_{\mathsf{k}_\Gamma}\mathcal{E}_\Gamma \cdot \nabla_{\mathsf{x}} f_\Gamma - \frac{e}{\hbar}E \cdot \nabla_{\mathsf{k}_\Gamma} f_\Gamma = Q_\Gamma(f_\Gamma, f_L), \tag{1.2}$$

$$\frac{\partial f_L}{\partial t} + \frac{1}{\hbar}\nabla_{\mathsf{k}_L}\mathcal{E}_L \cdot \nabla_{\mathsf{x}} f_L - \frac{e}{\hbar}E \cdot \nabla_{\mathsf{k}_L} f_L = Q_L(f_L, f_\Gamma), \tag{1.3}$$

and the only relation between electrons is given by electrostatic interaction through the electric potential V and its field E given by

$$\Delta V = \frac{e}{\epsilon_0}\left[\rho(t,\mathsf{x}) - C(\mathsf{x})\right], \qquad E = -\nabla_{\mathsf{x}} V, \tag{1.4}$$

where $f_A(t,\mathsf{x},\mathsf{k}_A)$ is the density function in phase space of electrons in the valley A at time $t \geq 0$ and position x with k_A its corresponding wave-number. Physical parameters and functions are the electron charge e, reduced Planck constant $\hbar$, dielectric constant ϵ_0, effective mass m_A^*, and donor-acceptor concentration C.

The macroscopic density of electrons is computed by the weighted average of the densities in each of the valleys,

$$\rho(t,\mathsf{x}) = Z_{L\Gamma}\rho_\Gamma(t,\mathsf{x}) + Z_{\Gamma L}\rho_L(t,\mathsf{x}), \tag{1.5}$$

where $\rho_\Gamma,\ \rho_L$ denote

$$\rho_\Gamma(t,\mathsf{x}) = \int_{\mathbb{R}^3} f_\Gamma(\mathsf{k}_\Gamma)\ d\mathsf{k}_\Gamma \quad \text{and} \quad \rho_L(t,\mathsf{x}) = \int_{\mathbb{R}^3} f_L(\mathsf{k}_L)\ d\mathsf{k}_L,$$

and $Z_{\Gamma L}$ and $Z_{L\Gamma}$ are the degeneration numbers from Γ-valley to L-valley and vice versa, namely, the number of possibilities for transferring electrons after scattering from Γ-valley to L-valley and vice versa. $Z_{\Gamma L}$ is 4, since there are four equivalent L-valleys, and $Z_{L\Gamma}$ is 1 (see Table 1.1 and Figure 1). FIG. 1. *Scheme of the conduction band for GaAs.*

right-hand side, of (1.2) and (1.3) take into account the interaction of the electrons with the crystal vibrations, and therefore $Q_D(f_A, f_B)$, with $A, B, D = \Gamma, L$, are *linear* operators of the distribution functions. The main scattering mechanisms in GaAs [12, 18] are intravalley scatterings—impurities, acoustic phonon and polar optical phonon—while we take into account nonpolar optical intervalley scattering. These *linear* operators can be written in the form

$$Q_A^{(\gamma)}(f_A, f_A) = \int_{\mathbb{R}^3} \left[S^{(\gamma)}(\mathsf{k}'_A, \mathsf{k}_A) f_A(\mathsf{k}'_A) - S^{(\gamma)}(\mathsf{k}_A, \mathsf{k}'_A) f_A(\mathsf{k}_A) \right] d\mathsf{k}'_A, \tag{1.6}$$

$$Q_A^{(\gamma)}(f_A, f_B) = Z_{AB} \int_{\mathbb{R}^3} \left[S^{(\gamma)}(\mathsf{k}_B, \mathsf{k}_A) f_B(\mathsf{k}_B) - S^{(\gamma)}(\mathsf{k}_A, \mathsf{k}_B) f_A(\mathsf{k}_A) \right] d\mathsf{k}_B, \tag{1.7}$$

where $S^{(\gamma)}(\mathsf{k}, \mathsf{k}')$ is the transition probability from state k to k' per unit of time and the superscript (γ) identifies each scattering mechanism.

These scattering operators satisfy the detailed balance

$$S^{(\gamma)}(\mathsf{k}_B, \mathsf{k}_A) = S^{(\gamma)}(\mathsf{k}_A, \mathsf{k}_B) \exp\left(-\frac{\mathcal{E}_A - \mathcal{E}_B + \Delta_{AB}}{k_B T} \right),$$

where k_B is the Boltzmann constant, T is the lattice temperature, and $\Delta_{AB} = \mathcal{E}_{0A} - \mathcal{E}_{0B}$ is the energy gap between the minima of the two valleys. Therefore, the collision operators which appear in (1.2)–(1.3) (denoted in general as $Q_D(f_A, f_B)$, with $A, B, D = \Gamma, L$ above) are summations of the corresponding scattering processes $Q^{(\gamma)}$. The detailed expression of this transition probability depends on each scattering mechanism. In the case of scattering with randomly placed impurities, it reads

$$S^{(imp)}(\mathsf{k}_A, \mathsf{k}'_A) = \frac{K_{imp}}{(|\mathsf{k}_A - \mathsf{k}'_A|^2 + \beta^2)^2} \, \delta(\mathcal{E}'_A - \mathcal{E}_A),$$

with

$$K_{imp} = \frac{N_I Z^2 e^4}{4\pi^2 \hbar \epsilon_0^2}, \qquad \beta = \sqrt{\frac{e^2 N_I}{\epsilon_0 k_B T}},$$

where β is the inverse of the Debye length and N_I and $Z\,e$ are the impurities concentration and its charge, respectively. All physical parameters involved in the following are explained and detailed in Table 1.1.

The scattering with crystal vibrations in the acoustic mode is taken into account in the elastic approximation and is given by

$$S^{(ac)}(\mathsf{k}_A, \mathsf{k}'_A) = K_{ac}\, \delta(\mathcal{E}'_A - \mathcal{E}_A),$$

with

$$K_{ac} = \frac{k_B T \Xi_d^2}{4\pi^2 \hbar \rho_0 v_s^2}.$$

Nonpolar optical phonon interaction is considered in the inelastic approximation, and thus we consider emission and absorption of phonons of energy $\hbar\omega_{np}$:

$$S^{(np)}(\mathsf{k}_A, \mathsf{k}_B) = K_{np}\, \left[n_{np} \delta(\mathcal{E}_B - \mathcal{E}_A - \hbar\omega^+_{np}) + (1 + n_{np}) \delta(\mathcal{E}_B - \mathcal{E}_A + \hbar\omega^-_{np}) \right],$$

with

$$K_{np} = \frac{(D_t K)^2}{8\pi^2 \rho_0 \omega_{np}}, \qquad n_{np} = \frac{1}{\exp(\hbar\omega_{np}/(k_B T)) - 1},$$
$$\hbar\omega^+_{np} = \hbar\omega_{np} + \Delta_{AB}, \qquad \hbar\omega^-_{np} = \hbar\omega_{np} - \Delta_{AB}.$$

The occupation number n_{np} is given by the equilibrium Bose–Einstein distribution, and Z_{AB} is the degeneration number from A- to B-valley. GaAs solid-state properties imply that nonpolar optical phonon scattering contributes to the intervalley scattering for both valleys (Γ and L) and to the intravalley scattering only for the L-valley, since there exists only one Γ-valley, i.e., $Z_{\Gamma\Gamma} = 0$ (see [18] and (6.31) in the appendix).

Finally, polar optical phonon scattering has a transition probability

$$S^{(p)}(\mathsf{k}_A, \mathsf{k}'_A) = K_p \frac{G(\mathsf{k}_A, \mathsf{k}'_A)}{|\mathsf{k}_A - \mathsf{k}'_A|^2} \left[n_p \delta(\mathcal{E}'_A - \mathcal{E}_A - \hbar\omega_p) + (1 + n_p) \delta(\mathcal{E}'_A - \mathcal{E}_A + \hbar\omega_p) \right],$$

with

$$K_p = \frac{\hbar\omega_p e^2}{8\pi^2 \hbar} \left(\frac{1}{\epsilon_\infty} - \frac{1}{\epsilon_0} \right), \qquad n_p = \frac{1}{\exp(\hbar\omega_p/(k_B T)) - 1};$$

here $\hbar\omega_p$ is the polar optical phonon energy, n_p its occupation number, and the overlapping factor

$$G(\mathsf{k}_A, \mathsf{k}'_A) = \left[a_A a'_A + c_A c'_A \cos(\mathsf{k}_A, \mathsf{k}'_A) \right]^2,$$

with

$$a_A = \sqrt{\frac{1 + \alpha_A \mathcal{E}_A}{1 + 2\,\alpha_A \mathcal{E}_A}}, \qquad a'_A = \sqrt{\frac{1 + \alpha_A \mathcal{E}'_A}{1 + 2\,\alpha_A \mathcal{E}'_A}},$$
$$c_A = \sqrt{\frac{\alpha_A \mathcal{E}_A}{1 + 2\,\alpha_A \mathcal{E}_A}}, \qquad c'_A = \sqrt{\frac{\alpha_A \mathcal{E}'_A}{1 + 2\,\alpha_A \mathcal{E}'_A}}.$$

The equations are simplified by changing variables to suitable energy-type variables in which the scattering operators become either simple evaluations or linear integral operators with singular kernels. This change of variables was introduced first

in [9] in the parabolic band approximation and in [13] for general dispersion relations for the energy formula (1.1). This change of variables and a suitable nondimensionalization is performed for GaAs devices and summarized in section 2. Each of the scattering mechanisms gives a contribution to the nondimensional collision operator, as is fully detailed in the appendix.

The numerical scheme is based on ideas analogous to the one introduced in [3] for Si-based devices and quickly revisited and adapted to our case in section 2. Here, the new numerical difficulties are the preservation of total charge due to the intervalley scattering mechanisms and the singular character of the kernels of the impurities and polar optical phonon scattering. The rest of section 2 focuses on these new difficulties: we propose a charge conservative numerical approximation of the collision operator in which all integrals involving the singular kernels can be computed explicitly.

In this paper, we show the flexibility of the numerical scheme proposed in [3] in dealing with several scattering mechanisms. In order to make this work more readable the somewhat tedious previous work of deriving the expressions of these scattering mechanisms in the energy-based variables is relegated to the appendix. Nevertheless, once this preprocessing work is done, the deterministic numerical results deal with high gradient regions of the macroscopic quantities of interest in a remarkable way without the appearance of numerical noise typical of direct simulation Monte Carlo (DSMC) or particle-based methods [6, 7, 8, 11, 18], due to the high order accuracy of the method. Other advantages of our scheme are the accurate computation of the distribution function, and thus of all its moments, and the possibility of the transient study of the solution. The main drawback is the high dimensionality of the problem resulting in a much higher computational cost than the DSMC or particle methods but achievable with today's computer technology in a timely fashion in the one-dimensional case and by parallelized-coding techniques in the realistic two-dimensional case. Standard coding techniques have been used in a two-dimensional metal semiconductor field effect transistor Si-(MESFET) recently in [4] but require a huge computational time. In the case of GaAs-based devices, this drawback is more pronounced due to the higher number of unknowns.

Finally, we validate our scheme in the one-dimensional case by computing the electron valley occupancy, velocity, and energy of the homogeneous case (bulk material) and by comparing the results with the DSMC results for matching experimental data in [18]. Later we use this scheme to analyze the transport of electrons in $N^+ - N_i - N^+$ diodes, where N_i stands for the intrinsic concentration of the material, and we take advantage of this to apply our scheme to the Gunn-oscillator [1, 5, 16]. All these numerical tests are reported in section 3.

2. Equivalent system and numerical scheme. In this section, we will focus on explaining the numerical scheme applied to a system equivalent to (1.2), (1.3), and (1.4) and on highlighting the main differences with respect to the Si case [3].

The system equivalent to (1.2), (1.3), and (1.4) is obtained upon changing variables in (6.1) from the wave-momentum vector k_A, $A = \Gamma, L$, to energy variables and by choosing suitable units for the system. The new variables are the A-valley dimensionless electron energy w_A, the polar ϕ_A, and the azimuthal angles of the wave-momentum vector k_A. However, it is easier to work with the cosine of the azimuthal angle μ_A for computational reasons. Moreover, since we are considering the one-dimensional spatial case, we assume that the doping profile and the potential depend only on the third spatial component z of $\mathsf{x} \in \mathbb{R}^3$ and that the distribution function is cylindrically symmetric with respect to the axis of the electric field, and thus, that f_A does not depend on the polar angle ϕ_A.

Following the details of this change of variables (6.1) and the nondimensionalization, which we postponed to the appendix (see subsection 6.1.1) for reader's sake, our system can be written equivalently as a system of two transport equations in conservative form coupled to the Poisson equation, i.e.,

$$\frac{\partial \Phi_A}{\partial t} + \frac{\partial}{\partial z}\left(a_1^A\,\Phi_A\right) + \frac{\partial}{\partial w_A}\left(a_2^A \Phi_A\right) + \frac{\partial}{\partial \mu_A}\left(a_3^A \Phi_A\right) = \bar{Q}(\Phi_A), \qquad A = \Gamma, L, \tag{2.1}$$

where Φ_A is the new unknown function depending on dimensionless time $t \geq 0$, dimensionless spatial variable z, dimensionless energy w_A, and cosine of the angle with respect to field direction μ_A for each valley $A = \Gamma, L$. Here, the flux coefficients are

$$\begin{aligned} a_1^A &= a_1^A(w_A, \mu_A) = c_{1,A}\,\frac{\mu_A\,\sqrt{2\,w_A(1+\bar{\alpha}_A w_A)}}{1+2\,\bar{\alpha}_A w_A}, \\ a_2^A &= a_2^A(w_A, \mu_A) = -c_{2,A}\,\bar{E}\,\mu_A\,\frac{\sqrt{2\,w_A(1+\bar{\alpha}_A w_A)}}{1+2\bar{\alpha}_A w_A}, \\ a_3^A &= a_3^A(w_A, \mu_A) = -c_{2,A}\,\bar{E}\,\frac{1-\mu_A^2}{\sqrt{2\,w_A(1+\bar{\alpha}_A w_A)}}, \end{aligned} \tag{2.2}$$

with $c_{1,A}$, $c_{2,A}$ constants (6.4) depending on the effective masses of each valley and the lattice temperature (assumed constant along the evolution). These equations are coupled to the dimensionless Poisson equation

$$\begin{aligned} \Delta_z \bar{V}(t,z) = c_p \Bigg(& c_\Gamma \int_0^\infty \int_{-1}^1 \Phi_\Gamma(t,z,w_\Gamma,\mu_\Gamma)\,d\mu_\Gamma\,dw_\Gamma \\ & + c_L \int_0^\infty \int_{-1}^1 \Phi_L(t,z,w_L,\mu_L)\,d\mu_L\,dw_L - \bar{C}(z)\Bigg), \end{aligned} \tag{2.3}$$

with c_p, c_Γ, and c_L defined in (6.33). We refer to the appendix for the exact values of all the constants involved. Here, $\bar{Q}(\Phi_A)$ is the nondimensional collision operator after the change of variables (6.31).

Let us point out that coefficients a_1^A and a_2^A are regular as functions of the variables w_A and μ_A. However, the coefficient a_3^A presents a singularity when the energy vanishes ($w_A = 0$), but we can expect that the factor $s_A(w_A)$, the Jacobian of the coordinate transformation up to constants (6.2), in the definition of Φ_A (6.3) compensates this singularity. This fact also makes it appealing to approximate numerically the derivative in μ_A by a conservative flux-finite difference method in which we approximate the whole flux.

For every valley, $A = \Gamma$, L, we will consider as initial value a local Maxwellian distribution with temperature T,

$$\Phi_A(0,z,w_A,\mu_A) = \mathcal{M}\,\bar{C}(z)\,M_A(w_A), \qquad A = \Gamma,\, L,$$

where

$$M_A(w_A) = s_A(w_A)\,e^{w_A - \bar{\mathcal{E}}_{0A}}, \qquad A = \Gamma,\, L,$$

and $\mathcal{M}$ is a constant chosen in such way that the initial density is equal to the doping density $\bar{C}(z)$.

2.1. Numerical scheme. We consider the same mesh for both valleys (Γ and L):

$$
\begin{aligned}
z_i &= \left(i - \frac{1}{2}\right)\Delta z, && i = 1, 2, \dots, N_z,\\
w_j &= \left(j - \frac{1}{2}\right)\Delta w, && j = 1, 2, \dots, N_w,\\
\mu_k &= -1 + \left(k - \frac{1}{2}\right)\Delta \mu, && k = 1, 2, \dots, N_\mu,
\end{aligned}
\tag{2.4}
$$

where $\Delta z = L/N_z$, $\Delta w = w_{max}/N_w$, and $\Delta\mu = 2/N_\mu$ are grid steps in each direction; w_{max} is taken as a multiple of $\alpha_n = \alpha_{np}$ (we will denote this quantity as α); and $\Delta w = \alpha/n_{multiple}$. Here, $n_{multiple}$ is an integer chosen in order that the evaluations of the distribution functions Φ_A needed in the collision term are on the grid, and thus we avoid interpolations that might introduce additional errors. We remark that $n_{multiple}$ has to be chosen in a suitable way to take into account all the scattering processes. The meshes are cell-centered in order to impose the boundary conditions and to avoid the singularity of a_3^A at $w_A = 0$. Let us point out that the energy gap between valleys is taken also as a multiple of the phonon energy to avoid again an additional source of errors due to interpolation. When these ratios are not integers, an interpolation procedure has to be done [14].

For every valley, system (2.1) is numerically solved using a conservative finite difference weighted essentially nonoscillatory (WENO) scheme of fifth order in the transport variables. The evolution on time is done by a third order Runge–Kutta TVD scheme. Details are referred to [3] since the numerical scheme has been widely explained therein. Boundary conditions are treated in the same way as in [3], and basically they amount to imposing zero flux conditions on the boundaries in energy and angle, and inflow Maxwellian boundary conditions in space. Poisson's equation is discretized and numerically solved by a standard central finite differences scheme. Stability in time for the resulting scheme is ensured by computing time steps verifying the following CFL condition: given

$$
t_A = \left(\frac{\max(|a_1^A|)}{\Delta z} + \frac{\max(|a_2^A|)}{\Delta w} + \frac{\max(|a_3^A|)}{\Delta \mu}\right), \qquad A = \Gamma, L,
$$

then $\Delta t = CFL/\max(t_\Gamma, t_L)$. Let us remark that the maximum is taken over all the points in the mesh, and since a_3^A is singular for $w_A = 0$, we may consider this CFL condition quite restrictive. Except for the circuit equation, in which we are interested in the transients for a long period of time compared to the typical relaxation time of the collision operator, the CFL condition is not restrictive in practice. In our simulations we considered CFL = 0.6 for the stationary case and 0.9 for the Gunn diode. Improvements of the method can come by using implicit-explicit Runge–Kutta methods [17] or solving the equation by splitting methods and/or implicit time-solvers. A semi-Lagrangian approach for the convective part of the equation may avoid the CFL condition [10].

2.2. Charge conservation. The Boltzmann equation for this system gives as a result a conservation law for the total charge. Therefore also, the proposed numerical scheme should preserve it. For a silicon device, this property holds numerically, since the collision operator is approximated by simple evaluations in mesh points. In our

case the complexity of the collision operator produces a new numerical difficulty, since it involves the functions I_4 and I_5, which are not smooth enough (see the appendix).

To be more precise, we deal with the following general problem: *Consider* Φ *the unknown in the Boltzmann equation and assume* $Q(\Phi) = Q_G(\Phi) - Q_L(\Phi)$*, where the gain term is*

$$Q_G(\Phi)(w,\mu) = s(w)\int_{-1}^{+1} I(w,\mu,\mu')\Phi(w,\mu')d\mu',$$

$I(w,\mu,.) \in C^\infty((-1,1)) \cap L^1((-1,1))$ *for all* $\mu \in (-1,1)$ *and* $I(w,\mu,\mu') = I(w,\mu',\mu)$*, and the loss term is*

$$Q_L(\Phi) = N(w)s(w)\Phi(w,\mu).$$

The functions I *and* N *are related by*

$$\int_{-1}^{+1} I(w,\mu,\mu')\,d\mu = N(w)$$

(independently of μ'*), and thus*

$$\int_{-1}^{1}\int_{0}^{+\infty} Q(\Phi)\,dw\,d\mu = 0. \tag{2.5}$$

We will apply this general framework to the singular functions in the angle variable μ, $I_{4,A}$ and $I_{5,A}$, which appear in the impurity and polar scattering process (see the appendix for a detailed expression of these functions, (6.22)–(6.23), (6.25)–(6.28)).

Expression (2.5), which means that we are dealing with a conservation law, is a consequence of the relation between I and N, since it can be rewritten as

$$\int_{-1}^{1}\int_{0}^{+\infty}\left[s(w)\int_{-1}^{+1} I(w,\mu,\mu')\Phi(w,\mu')d\mu'\right]dw\,d\mu = \int_{-1}^{1}\int_{0}^{+\infty} N(w)s(w)\Phi(w,\mu)\,dw\,d\mu.$$

In order to obtain a numerical method which preserves the charge, we consider the following approximation for the gain term:

$$Q_G(\Phi)(w,\mu_k) \approx s(w)\sum_{j=1}^{N_\mu}\Phi(w,\mu_j')\int_{I_j}\left[\frac{1}{\Delta\mu}\int_{I_k} I(w,\mu,\mu')d\mu\right]d\mu', \tag{2.6}$$

where

$$\mu_j' := -1 + (j-0.5)\Delta\mu\,, \quad I_j = [-1+(j-1)\Delta\mu, -1+j\Delta\mu]\,, \quad j = 1,2,\dots,N_\mu.$$

The numerical conservation of charge is obtained, taking into account (2.6), within the accuracy of the composite middle-point integration rule. In fact, we deduce that

$$\int_{-1}^{1} Q_G(\Phi)(w,\mu)\,d\mu \approx s(w)\Delta\mu\sum_{k=1}^{N_\mu}\sum_{j=1}^{N_\mu}\Phi(w,\mu_j')\int_{I_j}\left[\frac{1}{\Delta\mu}\int_{I_k} I(w,\mu,\mu')d\mu\right]d\mu'$$

$$= s(w)N(w)\Delta\mu\sum_{j=1}^{N_\mu}\Phi(w,\mu_j') \approx \int_{-1}^{1} Q_L(\Phi)(w,\mu)\,d\mu.$$

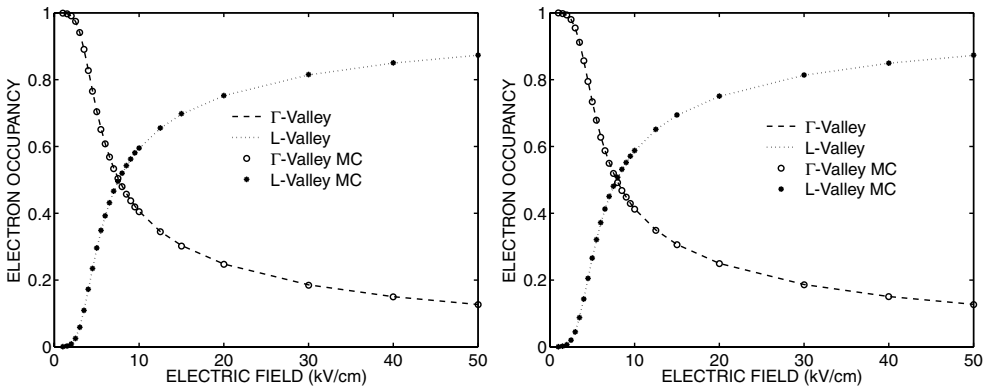

FIG. 2. *Electron occupation at room temperature for two different impurity concentrations: left* $N_I = 1 \times 10^{14}\, cm^{-3}$*, right* $N_I = 1 \times 10^{17}\, cm^{-3}$.

The double integrals

$$\int_{I_j} \left[\frac{1}{\Delta\mu} \int_{I_k} I(w, \mu, \mu') d\mu \right] d\mu'$$

may be evaluated numerically, using high order accurate integration formulas as adaptive Gaussian formulas. In our case, both for I_4 and I_5, it is possible to compute the double integration analytically. Here, we do not give the cumbersome formulas.

3. Numerical validation of the scheme: Bulk case. In this section, we check the main properties of the solution in a homogeneous-in-space setting for which there is an extensive literature from experiments [12] and from simulation with the Monte Carlo (MC) method [12, 18]. We will show that our results in the bulk material agree remarkably well with the results of MC codes in [18] that were already cross-checked with experiments.

In the results of this section we use two different values for the impurity concentration, $N_I = 10^{14}\,\mathrm{cm}^{-3}$ and $N_I = 10^{17}\,\mathrm{cm}^{-3}$, to which we will refer as low and high impurities cases. We will compute for each case the occupancy of each valley (rate of density of each valley with respect to total density), mean electron velocity and energy in terms of the constant force field, and the time evolution of mean electron velocity. We have run our program till stabilization of the mean velocity and energy up to six digits.

In this way, we recover in our model the following physical phenomena well-known in the literature:

- Figure 2: Γ-occupancy (resp., L-occupancy) decreases (resp., increases) monotonically for higher fields due to the jump of high energy electrons from the Γ- to the L-valley. Let us point out that the occupancies with different impurity concentrations are quite similar, since the values of the electric field at which the maximum of the velocity and the energy are reached are almost equal (see Figures 3 and 4).
- Figure 3: The mean electron energy behaves almost linearly for low fields and high fields, with a quick transition in the region in which the transfer of electrons from Γ-valley to the L-valley takes place.
- Figure 4: We observe that the mean electron velocity is not monotonically increasing as in the case of silicon, and it preserves a global maximum, after

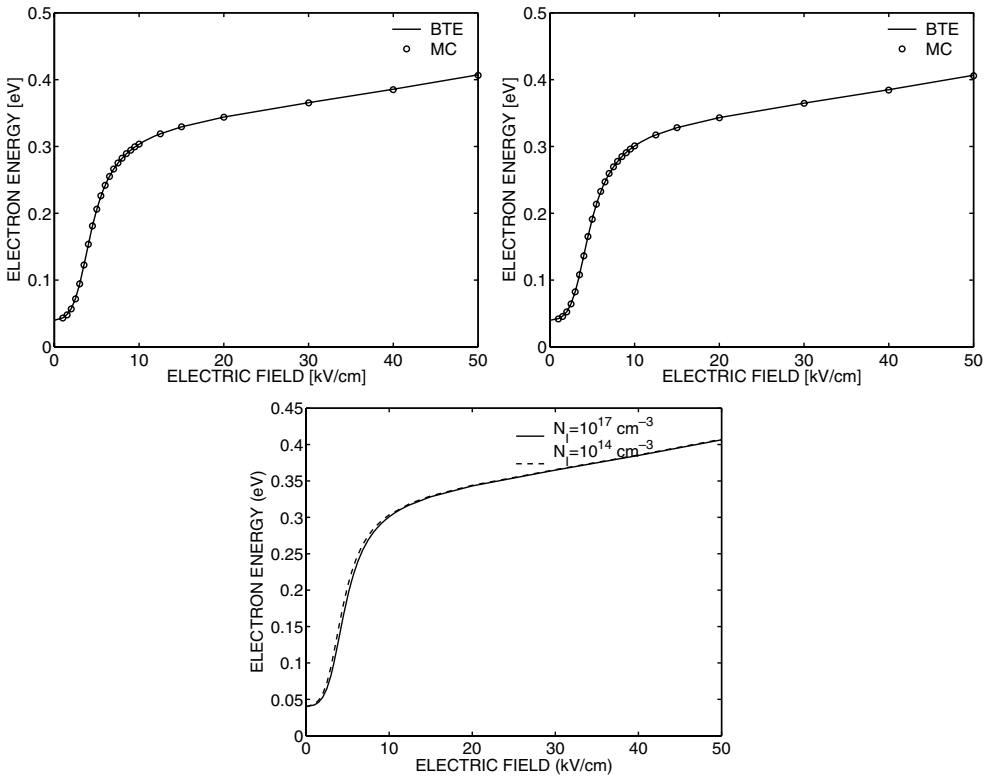

FIG. 3. *Electron energy at room temperature for two different impurity concentrations: top left* $N_I = 1 \times 10^{14}\, cm^{-3}$*, top right* $N_I = 1 \times 10^{17}\, cm^{-3}$*. We compare both results in the bottom figure.*

which it decreases to finally increase towards a *saturation speed value*. This phenomenon is known as the *negative differential conductivity*. It can be checked that the global maximum (maximum speed) and the initial slope (low-field mobility) decrease by increasing the impurity concentration. This is due to the lower value of the effective mass for the Γ-valley than for the L-valley.

- Figure 5: We can observe the *velocity overshooting* phenomenon in which the evolution of the mean velocity in time is not increasing and achieves a maximum before decaying monotonically to the stationary speed value. This is due to the lower momentum relaxation time compared to the energy relaxation time for high energies, i.e., high fields.

As a conclusion from previous figures and simulations, we have validated our numerical scheme, since we recover both qualitative and quantitative improvements by comparison to MC simulations (cf. the results in [12, 18]). We finally show in Figure 6 the steady state distribution function for a particular case.

4. Inhomogenous case. Once our numerical scheme has been validated, we show its flexibility by simulating a one-dimensional diode computing its transients, evolution of moments, and stationary states. On the other hand, we analyze a periodic-in-time circuit in which the main issue is to resolve in an effective way the oscillation of the potential. For all the inhomogeneous cases we choose the lower value for impurity concentration (see Table 1.1).

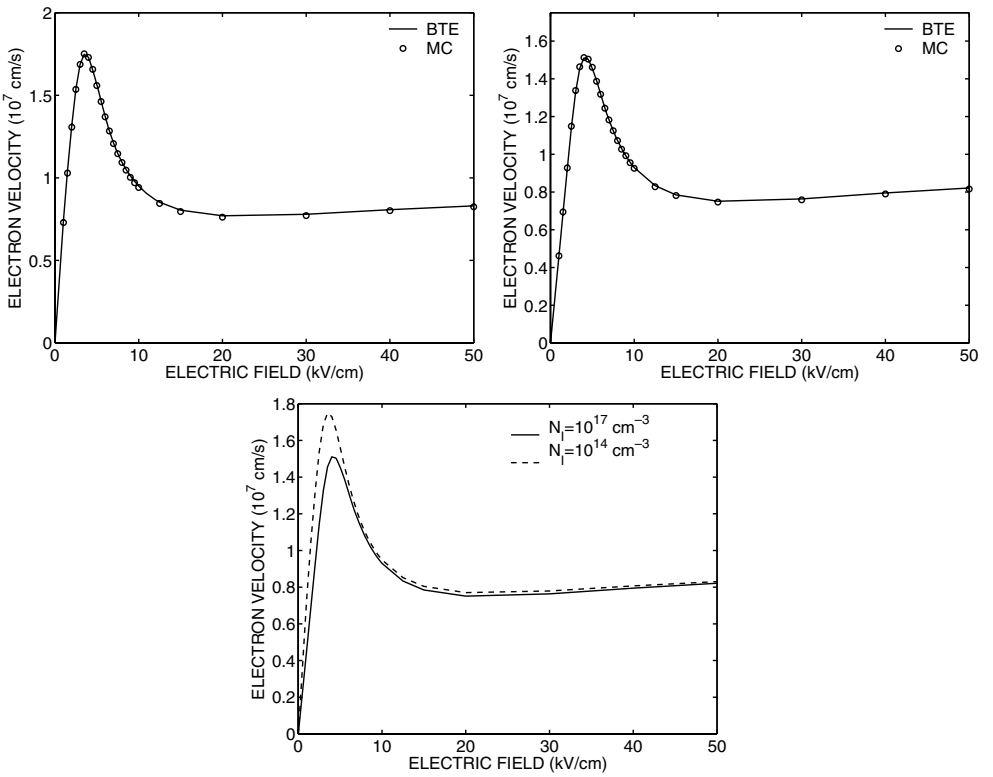

FIG. 4. *Electron velocity at room temperature for two different impurity concentrations: top left* $N_I = 1 \times 10^{14}\, cm^{-3}$, *top right* $N_I = 1 \times 10^{17}\, cm^{-3}$. *We compare both results in the bottom figure.*

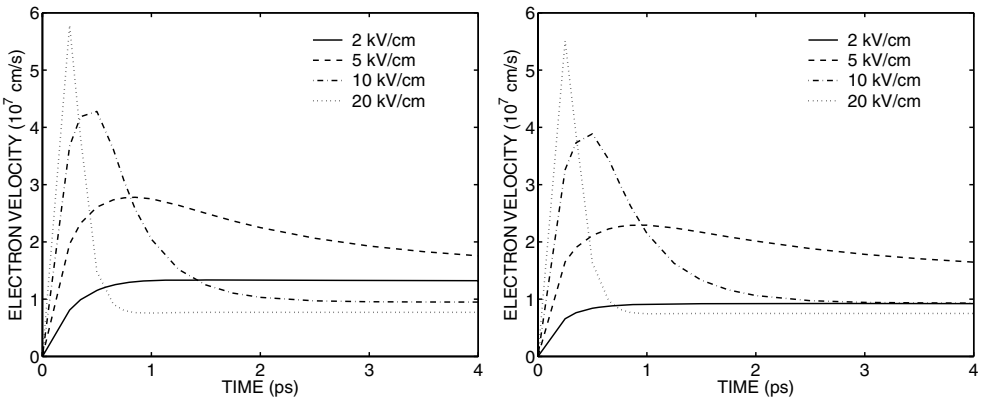

FIG. 5. *Time evolution of the electron velocity at room temperature for two different impurity concentrations: left* $N_I = 1 \times 10^{14}\, cm^{-3}$, *right* $N_I = 1 \times 10^{17}\, cm^{-3}$.

4.1. Stationary case. In this subsection we simulate the stationary state of a $N^+ - N_i - N^+$ diode based in GaAs, which means an active zone N_i-layer of 0.25 μm (see Table 1.1) sandwiched between two highly doped N^+-layers of 0.15 μm (cathode and anode), with $N^+ = 2{\times}10^{17}\mathrm{cm}^{-3}$. The intrinsic concentration is the concentration of the material itself, when the impurities are low and the concentration in the valence

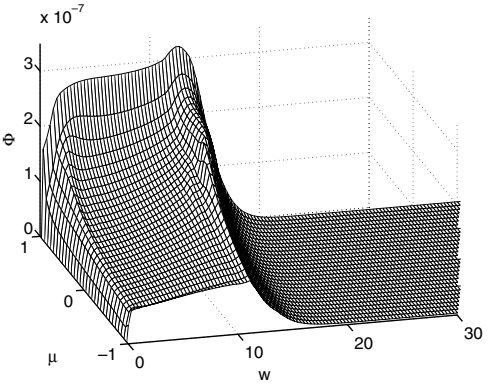

FIG. 6. *Snapshot of the distribution function for bulk material in valley* Γ *with* $E = 10\,kV/cm$ *applied field at equilibrium.*

band is the same as the concentration in the conduction band. This common value is the intrinsic concentration:

$$N_i = \left(\frac{2\pi k_B T\sqrt{m_n m_p}}{\hbar^2}\right)^{3/2} \exp\left(\frac{-E_g}{2k_B T}\right),$$

where m_n and m_p are the electron and hole effective masses, respectively, and E_g is the band gap energy. Therefore, the device has a length of 0.55 μm with two contacts: at 0.15 μm and 0.4 μm from the cathode.

We will focus our simulations on this device considered at room temperature with 0.25 V and 0.75 V applied bias. Our results are validated by MC simulations in Figure 7 by comparing density, mean velocity, energy, potential, and force field after reaching the stationary state. We consider the steady state to have been achieved once the energy, mean velocity, and energy are stabilized up to six digits. The results show a good agreement, the difference at the end of the channel being due in part to the need of having different meshes for both valleys in energy to improve the resolution in energy of the distribution function in the L-valley.

In Figures 8 and 9, we observe the evolution in time of macroscopic quantities, with an applied potential of 0.25 V and 0.75 V, respectively. Computation time was 9.26 ps when the system reached the stationary state in the first case, while we ran for only 3 ps in the second one. In both cases, we clearly see that the evolution towards stabilization is quite fast and that results for time 2.5 ps are already relevant (2 digits stabilized) for comparison with the MC steady state values in the 0.25 V case.

In the evolution of the velocity for the 0.75 V case, we appreciate the presence of a wave in the channel, which travels from left to right, still slightly noticeable after 3 ps. Similar phenomena happen for the density. This phenomenon is due to the electron accumulation in the active zone, close to the anode. The transit of electrons around the valleys Γ and L determines the shape of the macroscopic quantities. We observe that the mean velocity attains its maximum value around $z = 0.3\,\mu$m, and after that it quickly decreases to the anode. On the other hand, if we analyze the density picture, we find that it is again around $z = 0.3\,\mu$m, where the charge is accumulated. When the applied potential is 0.25 V, the charge accumulation disappears.

Finally, we conclude our stationary study by analyzing the transients for the distribution functions. As happens for an Si device with a 50 nm channel and a large applied potential [3], the distribution functions in some points of the device are far

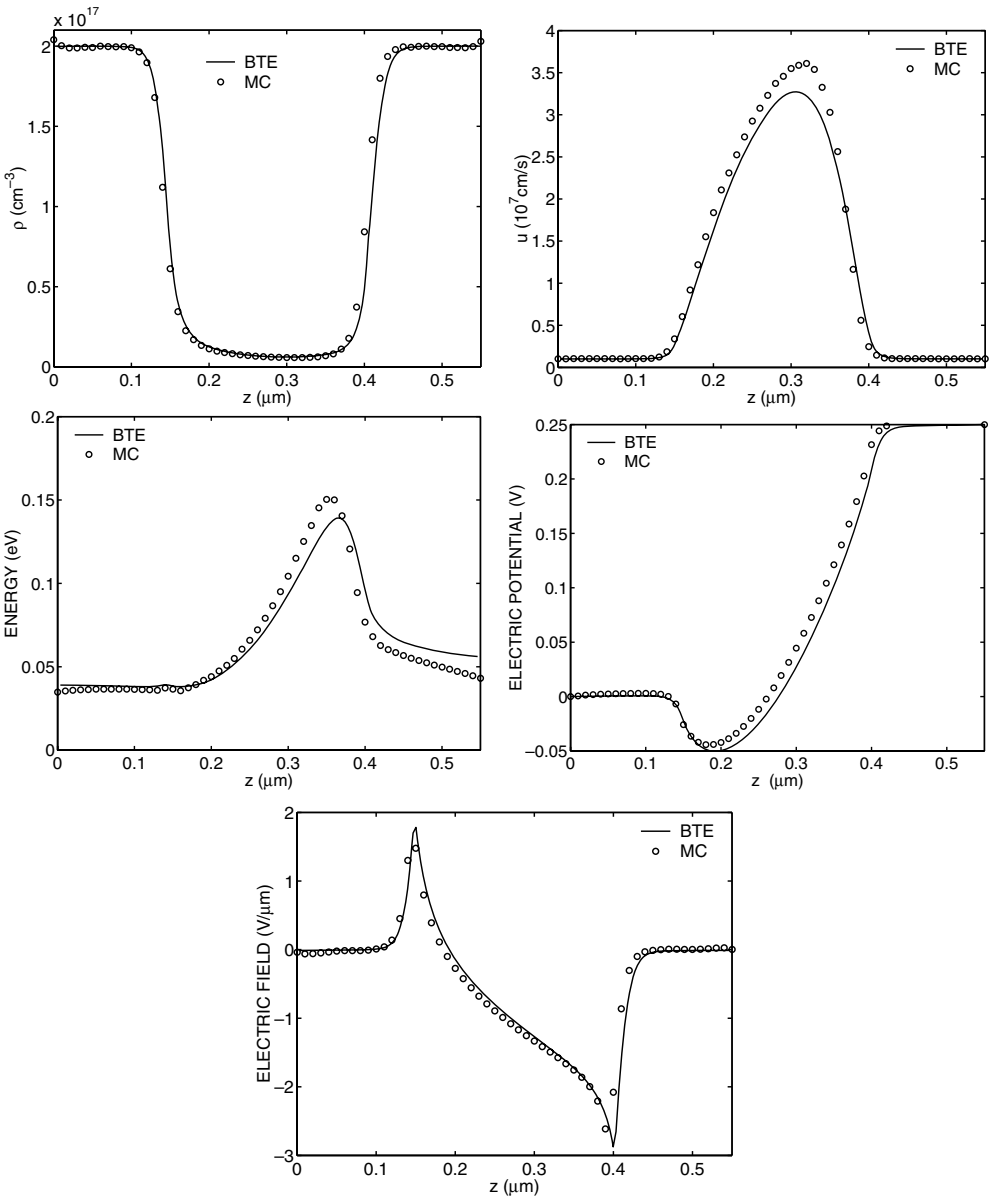

FIG. 7. *Macroscopic quantities after* 9 *ps for the* $N^+ - N_i - N^+$ *diode with* 0.25 *V applied bias at room temperature: density (top left), velocity (top right), energy (middle left), potential (middle right), and force field (bottom left).*

from being shifted Maxwellians typical of dynamics well described by hydrodynamical systems (remember $\mu = 1$ is the direction of the field and $\mu = -1$ is the opposite). The distribution function close to the second junction is not spherically symmetric.

The behavior of the distribution functions in both valleys is similar. Before the first contact and after the second one, they are practically Maxwellians. However, in the middle of the channel and just before the second contact, the distribution functions present purely kinetic features. We observe this fact in Figure 10, in which we show the time evolution of the distribution function in the Γ-valley just at the

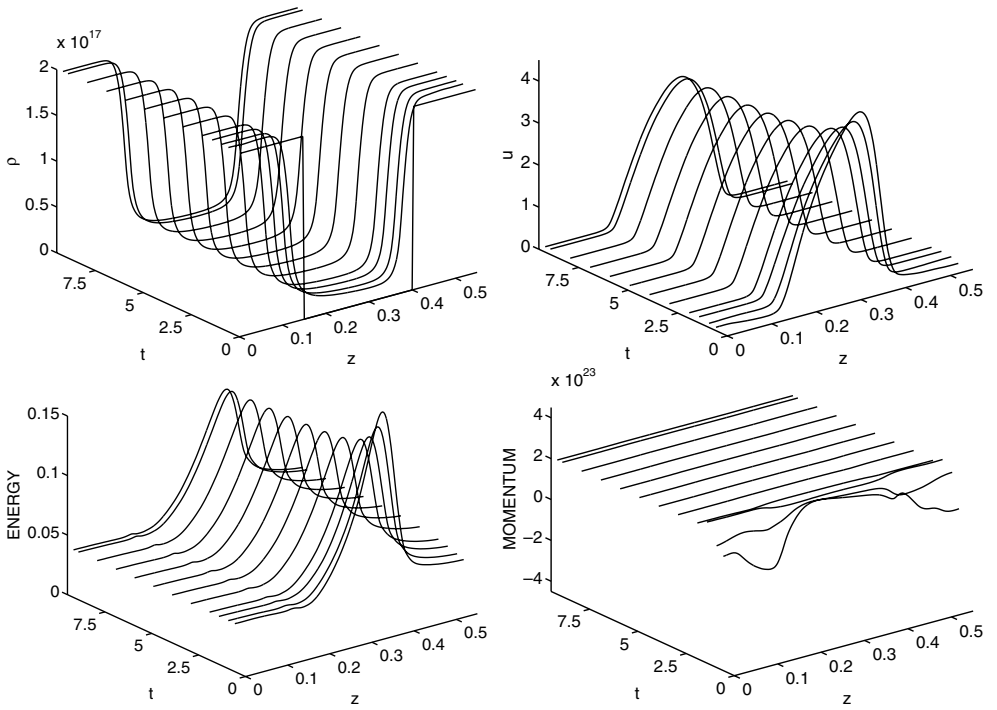

FIG. 8. *Macroscopic quantities evolution for the diode* $N^+ - N_i - N^+$ *under* 0.25 *V applied bias at room temperature* 300 *K: density* (cm^{-3}, *top left), velocity* ($10^7\, cm/s$, *top right), energy* (*eV*, *bottom left), and momentum* ($cm^{-2}\, s^{-1}$, *bottom right).*

edge of the channel. We show the distribution Γ-function at times 1, 1.5, 2, 2.5, 3 ps and the distribution L-function at time 3 ps.

4.2. Gunn diode. We conclude our numerical study by considering a GaAs notched diode. Simulations for this kind of device were shown in [1, 5, 16] through hydrodynamical models and the MC method. Here we use the same physical parameters considered in [1, 5]. We consider the same diode as it was dealt in previous references; a diode with $\mathcal{L} = 2\mu$m of length and the doping profile

$$C(\mathsf{x}) = \begin{cases} 10^{23}\,\mathrm{m}^{-3} & \text{if} \quad \mathsf{x} < 0.125\mu\mathrm{m}, \\ 10^{22}\,\mathrm{m}^{-3} & \text{if} \quad 0.125\mu\mathrm{m} < \mathsf{x} < 0.15\mu\mathrm{m}, \\ 0.5 \times 10^{22}\,\mathrm{m}^{-3} & \text{if} \quad 0.15\mu\mathrm{m} < \mathsf{x} < 0.1875\mu\mathrm{m}, \\ 10^{22}\,\mathrm{m}^{-3} & \text{if} \quad 0.1875\mu\mathrm{m} < \mathsf{x} < 1.875\mu\mathrm{m}, \\ 10^{23}\,\mathrm{m}^{-3} & \text{if} \quad 1.875\mu\mathrm{m} < \mathsf{x}. \end{cases} \tag{4.1}$$

In this case we substitute the V_{bias} by a circuit in order to simulate Gunn oscillations, as was done by Chen et al. [5]; the voltage V across the device and the current I through the battery satisfy differential equations

$$\frac{dV}{dt} = \frac{1}{C_{ap}}\left(I - I_d - \frac{V}{R}\right), \qquad \frac{dI}{dt} = \frac{1}{\Lambda}\left(V_B - V\right), \tag{4.2}$$

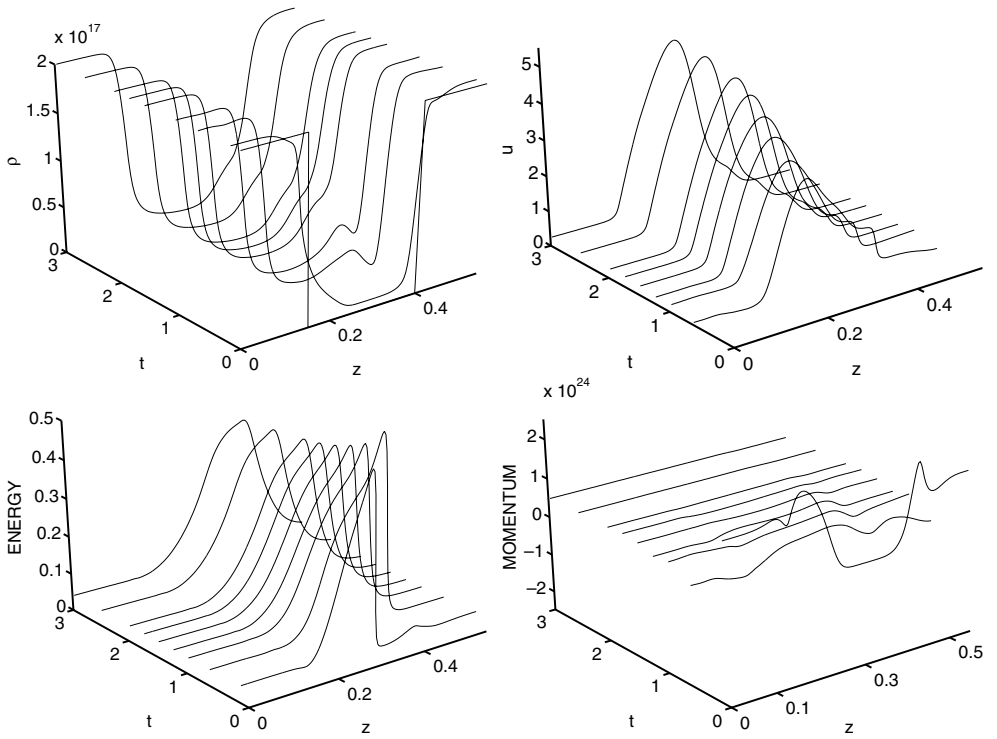

FIG. 9. *Macroscopic quantities evolution for the diode* $N^+ - N_i - N^+$ *under* 0.75 *V applied bias at room temperature* 300 K*: density (*cm^{-3}*, top left), velocity (*$10^7\, cm/s$*, top right), energy (eV, bottom left), and momentum (*$cm^{-2}\, s^{-1}$*, bottom right).*

where

$$I_d = -\frac{eA}{\mathcal{L}} \int_0^{\mathcal{L}} \left(Z_{L\Gamma} \rho_\Gamma u_\Gamma + Z_{\Gamma L} \rho_L u_L \right)\, dx \tag{4.3}$$

is the particle current in the device and where u_Γ and u_L are the mean velocities for every valley (see subsection 6.2 for details). Physical parameters for the capacitance, C_{ap}, resistance, R, inductance, Λ, and cross-section area, A, of the circuit are

$$C_{ap} = \frac{\epsilon A}{\mathcal{L}} + 0.82 \times 10^{-12}, \quad R = 25, \quad \Lambda = 3.5 \times 10^{-12}, \quad A = 10^{-9}, \quad V_B = 2.$$

Units are detailed in Table 4.1. As in the previous references about this device, we engage the circuit after 75 ps, when the diode is assumed to have reached the steady state. Therefore, to solve the oscillator (4.2) we consider the initial value at $t_0 = 75$ ps when the circuit is connected:

$$V(t_0) = V_B, \quad I(t_0) = 0.$$

The evolution on time of the voltage is shown in Figure 11. Our results reflect that at the beginning, when the circuit is engaged, the voltage evolves with one large oscillation during 10 ps, and afterwards the voltage oscillations are damped until 150 ps. Finally, the voltage becomes almost constant at 2 V. These results are in qualitative agreement with the results obtained by hydrodynamic models in [15, 16] and by MC methods in [1], but in our case voltage oscillations are damped faster. Finally,

let us point out that parabolic-band results for the evolution on time of the voltage are similar to the nonparabolic ones. We refer to [2] and the references therein for connected problems and information about the Gunn effect in superlattices.

5. Conclusions. A deterministic numerical scheme for solving the one-dimensional Boltzmann–Poisson system for semiconductor devices based on GaAs has been presented in this work. We have followed the same philosophy as in silicon case [3]: spherical change of coordinates, Boltzmann equation rewritten in conservative form, and finally numerical resolution using a high-order WENO-scheme in finite differences.

The band structure of a semiconductor based on GaAs is more complicated than for that based on silicon. The main numerical issue posed by this fact has been the charge conservation. We have proposed a numerical treatment of the gain and loss term giving us charge conservation within the accuracy of the middle-point integration rule.

The numerical results have been split in bulk and inhomogenous cases. The results obtained for the bulk case are excellent and validate our scheme (compared to Monte Carlo results). As a conclusion, we have checked the known phenomena typical of this material: distribution of electrons around the different valleys (occupation), negative differential conductivity, and velocity overshoot.

For the inhomogenous case we have considered two different problems: simulations of the steady state of $N^+ - N_i - N^+$ diodes and of the oscillation potential when a circuit is engaged to the device. The stationary state of $N^+ - N_i - N^+$ diode is analyzed by means of its macroscopic quantities and transients of the distribution function for each valley. Simulations for the evolution in time of the distribution functions in each valley show that the steady states in some points of the device are far from being shifted Maxwellian distributions.

In the inhomogeneous case, the agreement between MC simulations and deterministic solutions is still good, but not excellent. We have carefully checked that the differences arise from the boundary conditions. In fact, we use a condition on the fluxes (as in [3]) when the Boltzmann–Poisson system is solved and the well-known charge neutrality condition for the DSMC. We remark that in the stochastic model, at each time step, some particles (not few in our simulations) are injected, and they increase their energy when they arrive near junctions. We believe that, due to the high velocity in the channel, the particles do not reach a stationary state here. In

fact, we observe velocity and energy DSMC values greater then the corresponding values obtained by solving the Boltzmann–Poisson system. Further understanding of boundary conditions at the level of DSMC methods compared to deterministic kinetic boundary conditions needs to be done. As a summary, let us remark that the DSMC method and the deterministic method are based on the same equations and the same physical parameters, and thus the discrepancies between them are due to their different treatment of the boundary conditions.

For the Gunn-oscillator case the results are in qualitative concordance with the results obtained by hydrodynamic models and MC schemes; however, the voltage oscillations in our case are damped faster.

We have shown in this paper the flexibility of the approach in [3] for solving Boltzmann transport equation (BTE) for semiconductors in including many relevant scattering effects and different valley populations and thus the possibility of solving them for different semiconductor materials with complicated band structure.

6. Appendix: Change of variables and nondimensionalization. This appendix is devoted to summarizing the computations which transform system (1.2)–(1.4) into system (2.1), (2.3). The appendix is split in two subsections: the first one is devoted to the change of variables and nondimensionalization, while the last subsection reports the precise expression of the hydrodynamic quantities shown in the previous section. Tedious but simple computations are skipped.

6.1. Change of variables and nondimensionalization. We consider the change of variables

(6.1)
$$\mathsf{k}_A = \frac{\sqrt{m_A^* k_B T}}{\hbar}\sqrt{2\,w_A\,(1+\bar\alpha_A\,w_A)}\left(\sqrt{1-\mu_A^2}\cos\phi_A, \sqrt{1-\mu_A^2}\,\mathrm{sen}\,\phi_A, \mu_A\right),$$

where $\bar\alpha_A = k_B T\,\alpha_A$ is the nonparabolicity factor without dimension, w_A is the dimensionless energy variable, μ_A is the cosine of the angle between the wave vector k_A and the z-axis, and ϕ_A is the polar angle ($A = \Gamma, L$). Since we assume that the doping profile and the potential (and consequently the electric field) are only z dependent, our device will be considered in the z direction with $\mathsf{x} = (x, y, z)$.

In order to introduce the dimensionless parameters and variables, let us consider t_* and l_* the characteristic time and length, respectively. We denote by $\bar{}$ the dimensionless variables and parameters:

$$t = t_*\,\bar t, \qquad \mathsf{x} = l_*\bar{\mathsf{x}},$$
$$\mathsf{k}_A = \frac{1}{\hbar}\sqrt{m_A^* k_B T}\,\bar{\mathsf{k}}_A, \qquad \frac{\mathcal{E}(\mathsf{k}_A)}{k_B T} = \bar{\mathcal{E}}_A(\bar{\mathsf{k}}_A) = \frac{\|\bar{\mathsf{k}}_A\|^2}{1+\sqrt{1+2\,\bar\alpha_A\|\bar{\mathsf{k}}_A\|^2}},$$
$$E(t,\mathsf{x}) = \frac{\sqrt{m_X^* k_B T}}{e\,t_*}\,\bar E(\bar t,\bar{\mathsf{x}}), \qquad V(t,\mathsf{x}) = \frac{l_*\sqrt{m_X^* k_B T}}{e\,t_*}\,\bar V(\bar t,\bar{\mathsf{x}}),$$
$$C(\mathsf{x}) = \left(\frac{\sqrt{m_X^* k_B T}}{\hbar}\right)^3 \bar C(\bar{\mathsf{x}}), \qquad f_A(t,\mathsf{x},\mathsf{k}_A) = \bar f_A(\bar t,\bar{\mathsf{x}},\bar{\mathsf{k}}_A),$$
$$\alpha_p = \frac{\hbar\omega_p}{k_B T}, \qquad a_p = \frac{n_p+1}{n_p} = \exp(\alpha_p),$$
$$\alpha_{np} = \frac{\hbar\omega_{np}}{k_B T}, \qquad a_{np} = \frac{n_{np}+1}{n_{np}} = \exp(\alpha_{np}),$$
$$\Delta_{AB} = k_B T\,\bar\Delta_{AB}, \qquad \bar\alpha_A = k_B T\,\alpha_A.$$

In the following, according to the same rule, we denote by $\bar{g}$ the function g after introducing dimensionless variables.

As we can observe later (in the Poisson equation), we need to introduce a characteristic mass m_X^*. This mass might be chosen as m_Γ^* or m_L^*. In our simulations we have considered m_X^* as the electron mass (see Table 1.1).

The unknown f_A in terms of the new variables is denoted by F_A. We denote by s_A the Jacobian of the dimensionless change of variables $\bar{\mathsf{k}}_A(w_A, \mu_A, \phi_A)$. It can be easily verified to be

$$s_A(w_A) = \sqrt{2\, w_A\, (1 + \bar{\alpha}_A w_A)}\, (1 + 2\, \bar{\alpha}_A w_A), \tag{6.2}$$

and we consider the new unknown

$$\Phi_A(t, z, w_A, \mu_A) = F_A(t, z, w_A, \mu_A)\, s_A(w_A), \tag{6.3}$$

with $z \in [0, L]$, $w_A \in [0, w_{max}]$, and $\mu_A \in [-1, 1]$, where w_{max} is the maximum value of the energy, chosen in such a way that for our simulations

$$F_A(t, z, w_A, \mu_A) \approx 0 \qquad \text{for } w_A \geq w_{max}, \quad \forall\, t, z, \mu_A,$$

for both valleys.

Remark 6.1. Our nondimensionalization fixes $\bar{\mathcal{E}}_A(\bar{\mathsf{k}}_A) = w_A$, and thus w_A is the dimensionless energy. Moreover, since the function $s_A(w_A)$ is proportional to the Jacobian of the change of variables, we can evaluate moments of the distribution function directly using Φ_A.

The rest of the section is devoted to writing the Boltzmann–Poisson system in terms of the new unknown Φ_A. We split the computations into three parts: transport term, collision operator, and Poisson equation.

6.1.1. Transport term. *Nondimensionalization.* Defining

$$c_{1,A} = \frac{t_*}{l_*} \sqrt{\frac{k_B T}{m_A^*}} \quad \text{and} \quad c_{2,A} = \sqrt{\frac{m_X^*}{m_A^*}}, \tag{6.4}$$

we obtain

$$\frac{1}{\hbar} \nabla_{\mathsf{k}_A} \mathcal{E}_A \cdot \nabla_{\mathsf{x}} f_A = \frac{c_{1,A}}{t_*} \frac{\bar{\mathsf{k}}_A}{1 + 2\, \bar{\alpha}_A \bar{\mathcal{E}}_A} \cdot \nabla_{\bar{\mathsf{x}}} \bar{f}_A$$

and

$$-\frac{e}{\hbar} E \cdot \nabla_{\mathsf{k}_A} f_A = -\frac{c_{2,A}}{t_*} \bar{E} \cdot \nabla_{\bar{\mathsf{k}}_A} \bar{f}_A$$

Therefore, the transport operator in terms of $\bar{f}_A$ is written as

$$\frac{1}{t_*} \left(\frac{\partial \bar{f}_A}{\partial \bar{t}} + c_{1,A} \frac{\bar{\mathsf{k}}_A}{1 + 2\, \bar{\alpha}_A \bar{\mathcal{E}}_A} \cdot \nabla_{\bar{\mathsf{x}}} \bar{f}_A - c_{2,A} \bar{E} \cdot \nabla_{\bar{\mathsf{k}}_A} \bar{f}_A \right). \tag{6.5}$$

Change of coordinates. The next step is to find the expression of the transport operator in terms of F_A:

$$c_{1,A} \frac{\bar{\mathsf{k}}_A}{1 + 2\, \bar{\alpha}_A \bar{\mathcal{E}}_A} \cdot \nabla_{\bar{\mathsf{x}}} \bar{f}_A = c_{1,A} \frac{\mu_A \sqrt{2\, w_A (1 + \bar{\alpha}_A w_A)}}{1 + 2\, \bar{\alpha}_A w_A} \cdot \nabla_z F_A.$$

Since we are considering the one-dimensional case taking the direction of the electric field, in order to avoid a tedious notation we use $\bar{E}$ indistinctly to denote $\bar{E} = (0, 0, \bar{E}_z)$ and $\bar{E}_z$. Thus,

$$\bar{E} \cdot \nabla_{\bar{\mathsf{k}}_A} \bar{f}_A = \bar{E} \left(\frac{\partial F_A}{\partial w_A} \frac{\partial w_A}{\partial \bar{\mathsf{k}}_{A3}} + \frac{\partial F_A}{\partial \mu_A} \frac{\partial \mu_A}{\partial \bar{\mathsf{k}}_{A3}} \right), \tag{6.6}$$

where $\bar{\mathsf{k}}_A = (\bar{\mathsf{k}}_{A1}, \bar{\mathsf{k}}_{A2}, \bar{\mathsf{k}}_{A3})$. Since $|\bar{\mathsf{k}}_A|^2 = 2w_A(1 + \bar{\alpha}_A w_A)$,

$$\nabla_{\bar{\mathsf{k}}_A} |\bar{\mathsf{k}}_A|^2 = \nabla_{\bar{\mathsf{k}}_A} \left[2w_A(1 + \bar{\alpha}_A w_A) \right],$$

and we deduce

$$2\,\bar{\mathsf{k}}_A = 2\,(1 + 2\bar{\alpha}_A w_A) \nabla_{\bar{\mathsf{k}}_A} w_A.$$

In this way,

$$\nabla_{\bar{\mathsf{k}}_A} w_A = \frac{\sqrt{2\,w_A(1 + \bar{\alpha}_A w_A)}}{1 + 2\bar{\alpha}_A w_A} \left(\sqrt{1 - \mu_A^2} \cos\phi_A, \sqrt{1 - \mu_A^2}\, \mathrm{sen}\, \phi_A, \mu_A \right),$$

and consequently

$$\frac{\partial w_A}{\partial \bar{\mathsf{k}}_{A3}} = \frac{\sqrt{2\,w_A(1 + \bar{\alpha}_A w_A)}}{1 + 2\bar{\alpha}_A w_A}\, \mu_A. \tag{6.7}$$

On the other hand, recalling $\bar{\mathsf{k}}_{A3} = \mu_A \sqrt{2\,w_A(1 + \bar{\alpha}_A w_A)}$ and

$$\frac{\partial}{\partial \bar{\mathsf{k}}_{A3}} \left(\mu_A \sqrt{2\,w_A(1 + \bar{\alpha}_A w_A)} \right) = \frac{\partial \bar{\mathsf{k}}_{A3}}{\partial \bar{\mathsf{k}}_{A3}} = 1,$$

we get

$$\sqrt{2\,w_A(1 + \bar{\alpha}_A w_A)}\, \frac{\partial \mu_A}{\partial \bar{\mathsf{k}}_{A3}} + \mu_A \frac{1 + 2\,\bar{\alpha}_A w_A}{\sqrt{2\,w_A(1 + \bar{\alpha}_A w_A)}}\, \frac{\partial w_A}{\partial \bar{\mathsf{k}}_{A3}} = 1,$$

and then using (6.7),

$$\frac{\partial \mu_A}{\partial \bar{\mathsf{k}}_{A3}} = \frac{1 - \mu_A^2}{\sqrt{2\,w_A(1 + \bar{\alpha}_A w_A)}}. \tag{6.8}$$

By substituting (6.7) and (6.8) into (6.6), the final expression for the field transport term is deduced.

Final expression. Therefore, after the change of coordinates and nondimensionalization, the transport operator is rewritten as

$$\begin{aligned} &\frac{1}{t_*} \left(\frac{\partial F_A}{\partial \bar{t}} + c_{1,A} \frac{\mu_A \sqrt{2\,w_A(1 + \bar{\alpha}_A w_A)}}{1 + 2\,\bar{\alpha}_A w_A} \frac{\partial}{\partial z} F_A \right) \\ &\qquad - \frac{c_{2,A} \bar{E}}{t_*} \left(\frac{\partial F_A}{\partial w_A} \frac{\sqrt{2\,w_A(1 + \bar{\alpha}_A w_A)}}{1 + 2\bar{\alpha}_A w_A} \mu_A + \frac{\partial F_A}{\partial \mu_A} \frac{1 - \mu_A^2}{\sqrt{2 w_A(1 + \bar{\alpha}_A w_A)}} \right). \end{aligned} \tag{6.9}$$

Finally, multiplying the previous expression by $s_A(w_A)$, we obtain

$$\frac{1}{t_*}\left[\frac{\partial \Phi_A}{\partial \bar{t}} + \frac{\partial}{\partial z}\left(a_1^A\,\Phi_A\right) + \frac{\partial}{\partial w_A}\left(a_2^A \Phi_A\right) + \frac{\partial}{\partial \mu_A}\left(a_3^A \Phi_A\right)\right], \tag{6.10}$$

where

$$a_1^A = a_1^A(w_A,\mu_A) = c_{1,A}\,\frac{\mu_A\,\sqrt{2\,w_A(1+\bar{\alpha}_A w_A)}}{1+2\,\bar{\alpha}_A w_A},$$

$$a_2^A = a_2^A(w_A,\mu_A) = -c_{2,A}\,\bar{E}\,\mu_A\frac{\sqrt{2\,w_A(1+\bar{\alpha}_A w_A)}}{1+2\bar{\alpha}_A w_A},$$

and

$$a_3^A = a_3^A(w_A,\mu_A) = -c_{2,A}\,\bar{E}\,\frac{1-\mu_A^2}{\sqrt{2\,w_A(1+\bar{\alpha}_A w_A)}}.$$

Therefore, considering (6.10) multiplied by t_*, we obtain the dimensionless left-hand side

$$\frac{\partial \Phi_A}{\partial \bar{t}} + \frac{\partial}{\partial z}\left(a_1^A\,\Phi_A\right) + \frac{\partial}{\partial w_A}\left(a_2^A \Phi_A\right) + \frac{\partial}{\partial \mu_A}\left(a_3^A \Phi_A\right). \tag{6.11}$$

6.1.2. Collision operator. *Intravalley scattering.* The expression of the kernel is given by

(6.12)

$$\begin{aligned} S_A(\mathsf{k}_A,\mathsf{k}'_A) = &\left[K_{ac} + \frac{K_{imp}}{(|\mathsf{k}_A-\mathsf{k}'_A|^2+\beta^2)^2}\right]\delta(\mathcal{E}'_A-\mathcal{E}_A)\\ &+ K_P\,\frac{G(\mathsf{k}_A,\mathsf{k}'_A)}{|\mathsf{k}_A-\mathsf{k}'_A|^2}\left[n_p\delta(\mathcal{E}'_A-\mathcal{E}_A-\hbar\omega_p)+(1+n_p)\delta(\mathcal{E}'_A-\mathcal{E}_A+\hbar\omega_p)\right]\\ &+ Z_{AA}K_{np}\left[n_{np}\delta(\mathcal{E}'_A-\mathcal{E}_A-\hbar\omega_{np})+(1+n_{np})\delta(\mathcal{E}'_A-\mathcal{E}_A+\hbar\omega_{np})\right]. \end{aligned}$$

Using the new dimensionless variables, (6.12) is rewritten as

$$\begin{aligned} S_A(\mathsf{k}_A,\mathsf{k}'_A) = &\left[K_{ac} + \frac{K_{imp}\,\hbar^4\,(m_A^* k_B T)^{-2}}{\left[\varphi(w_A,w'_A,\mu_A,\mu'_A,\phi_A,\phi'_A)+{\beta_A}^2\right]^2}\right]\delta(k_BT(w'_A-w_A))\\ &+ K_p\,\frac{\bar{G}(w_A,w'_A,\mu_A,\mu'_A)}{\varphi(w_A,w'_A,\mu_A,\mu'_A,\phi_A,\phi'_A)}\,n_p\\ &\quad\cdot\left[\delta(k_BT(w'_A-w_A-\alpha_p))+a_p\delta(k_BT(w'_A-w_A+\alpha_p))\right]\\ &+ Z_{AA}K_{np}n_{np}\\ &\quad\cdot\left[\delta(k_BT(w'_A-w_A-\alpha_{np}))+a_{np}\delta(k_BT(w'_A-w_A+\alpha_{np}))\right], \end{aligned} \tag{6.13}$$

$\bar{G}(w_A,w'_A,\mu_A,\mu'_A)$ is the corresponding dimensionless function $G(\mathsf{k}_A,\mathsf{k}'_A)$ written in the new variables, and

$$\begin{aligned} \varphi(w_A,w'_A,\mu_A,\mu'_A,\phi_A,\phi'_A) = {} & q_A(w_A)+q_A(w'_A)-2\sqrt{q_A(w_A)\,q_A(w'_A)}\\ &\cdot\left(\sqrt{1-{\mu_A}^2}\,\sqrt{1-{\mu'_A}^2}\cos(\phi_A-\phi'_A)+\mu_A\mu'_A\right), \end{aligned}$$

with

$$q_A(w_A) = 2w_A(1+\bar{\alpha}_A w_A), \qquad \beta_A = \frac{\hbar\,\beta}{\sqrt{m_A^* k_B T}},$$

(6.14)

$$\begin{aligned} S_A(\mathsf{k}_A,\mathsf{k}'_A)\,d\mathsf{k}'_A = &\left[\left[K_{ac} + \frac{K_{imp}\,\hbar^4\,(m_A^* k_B T)^{-2}}{\left[\varphi(w_A,w'_A,\mu_A,\mu'_A,\phi_A,\phi'_A)+{\beta_A}^2\right]^2}\right]\delta(k_B T(w'_A - w_A))\right. \\ &+ K_p\,\frac{\bar{G}(w_A,w'_A,\mu_A,\mu'_A)}{\varphi(w_A,w'_A,\mu_A,\mu'_A,\phi_A,\phi'_A)}\,n_p \\ &\cdot[\delta(k_B T(w'_A - w_A - \alpha_p)) + a_p\delta(k_B T(w'_A - w_A + \alpha_p))] \\ &+ Z_{AA}K_{np}n_{np} \\ &\left.\cdot\,[\delta(k_B T(w'_A - w_A - \alpha_{np})) + a_{np}\delta(k_B T(w'_A - w_A + \alpha_{np}))]\right] \\ &\cdot\,\frac{(m_A^* k_B T)^{3/2}}{\hbar^3}\,dw'_A\,d\mu'_A\,d\phi'_A. \end{aligned}$$

Using the properties of the Dirac delta function,

(6.15)

$$\begin{aligned} S_A(\mathsf{k}_A,\mathsf{k}'_A)\,d\mathsf{k}'_A = &\left[\left[K_{ac} + \frac{K_{imp}\,\hbar^4\,(m_A^* k_B T)^{-2}}{\left[\varphi(w_A,w'_A,\mu_A,\mu'_A,\phi_A,\phi'_A)+{\beta_A}^2\right]^2}\right]\delta(w'_A - w_A)\right. \\ &+ K_p\,\frac{\bar{G}(w_A,w'_A,\mu_A,\mu'_A)}{\varphi(w_A,w'_A,\mu_A,\mu'_A,\phi_A,\phi'_A)}\,n_p \\ &\cdot[\delta(w'_A - w_A - \alpha_p) + a_p\delta(w'_A - w_A + \alpha_p)] \\ &\left.+\,Z_{AA}K_{np}n_{np}\,[\delta(w'_A - w_A - \alpha_{np}) + a_{np}\delta(w'_A - w_A + \alpha_{np})]\right] \\ &\cdot\,\frac{(m_A^* k_B T)^{3/2}}{k_B T\hbar^3}\,dw'_A\,d\mu'_A\,d\phi'_A. \end{aligned}$$

In order to obtain an easier notation, we introduce the constants

$$c_{3,A} = K_{ac}\,\frac{t_*(m_A^*)^{3/2}(k_B T)^{1/2}}{\hbar^3}, \qquad c_{4,A} = K_{imp}\,\frac{t_*\hbar}{k_B T\sqrt{m_A^* k_B T}},$$

$$c_{5,A} = K_p\,\frac{t_* n_p\sqrt{m_A^*}}{\hbar\sqrt{k_B T}}, \qquad c_{6,A} = Z_{AA}K_{np}\,\frac{t_*(m_A^*)^{3/2}(k_B T)^{1/2}}{\hbar^3};$$

thus

$$
\begin{aligned}
S_A(\mathsf{k}_A, \mathsf{k}'_A)\, d\mathsf{k}'_A = \Bigg[\Bigg[c_{3,A} + \frac{c_{4,A}}{\left[\varphi(w_A, w'_A, \mu_A, \mu'_A, \phi_A, \phi'_A) + {\beta_A}^2\right]^2}\Bigg]\delta(w'_A - w_A) \\
+ \frac{c_{5,A}\,\bar{G}(w_A, w'_A, \mu_A, \mu'_A)}{\varphi(w_A, w'_A, \mu_A, \mu'_A, \phi_A, \phi'_A)} \\
\cdot \left[\delta(w'_A - w_A - \alpha_p) + a_p \delta(w'_A - w_A + \alpha_p)\right] \\
+ c_{6,A}\left[\delta(w'_A - w_A - \alpha_{np}) + a_{np}\delta(w'_A - w_A + \alpha_{np})\right]\Bigg] \\
\cdot \frac{1}{t_*}\, dw'_A\, d\mu'_A\, d\phi'_A.
\end{aligned} \tag{6.16}
$$

Intervalley scatterings.

$$
\begin{aligned}
S(\mathsf{k}_A, \mathsf{k}_B) = K_{np}\left[n_{np}\delta(\mathcal{E}_B - \mathcal{E}_A - \hbar\omega_{np} - \Delta_{AB})\right. \\
\left. + (1 + n_{np})\delta(\mathcal{E}_B - \mathcal{E}_A + \hbar\omega_{np} - \Delta_{AB})\right].
\end{aligned} \tag{6.17}
$$

After the nondimensionalization and change of coordinates,

$$
\begin{aligned}
S(\mathsf{k}_A, \mathsf{k}_B) = K_{np} n_{np}\left[\delta(k_B T(w_B - w_A - \alpha_{np} - \bar{\Delta}_{AB}))\right. \\
\left. + a_{np}\delta(k_B T(w_B - w_A + \alpha_{np} - \bar{\Delta}_{AB}))\right]
\end{aligned} \tag{6.18}
$$

and

$$
\begin{aligned}
S(\mathsf{k}_A, \mathsf{k}_B)\, d\mathsf{k}_D = K_{np} n_{np}\left[\delta(k_B T(w_B - w_A - \alpha_{np} - \bar{\Delta}_{AB}))\right. \\
\left. + a_{np}\delta(k_B T(w_B - w_A + \alpha_{np} - \bar{\Delta}_{AB}))\right] \\
\cdot \frac{(m^*_D k_B T)^{3/2}}{\hbar^3}\, dw_D\, d\mu_D\, d\phi_D.
\end{aligned} \tag{6.19}
$$

And finally, denoting

$$
c_{7,D} = K_{np} n_{np} \frac{t_* {m^*_D}^{3/2}\sqrt{k_B T}}{\hbar^3},
$$

we obtain

$$
\begin{aligned}
S(\mathsf{k}_A, \mathsf{k}_B)\, d\mathsf{k}_D = c_{7,D}\left[\delta(w_B - w_A - \alpha_{np} - \bar{\Delta}_{AB})\right. \\
\left. + a_{np}\delta(w_B - w_A + \alpha_{np} - \bar{\Delta}_{AB})\right]\frac{1}{t_*}\, dw_D\, d\mu_D\, d\phi_D.
\end{aligned} \tag{6.20}
$$

To conclude this subsection it just remains to compute

$$\int_{\mathbb{R}^3} S(\mathsf{k}_A,\mathsf{k}'_A)d\mathsf{k}'_A, \qquad \int_{\mathbb{R}^3} S(\mathsf{k}'_A,\mathsf{k}_A)f_A(\mathsf{k}'_A)d\mathsf{k}'_A,$$

$$\int_{\mathbb{R}^3} S(\mathsf{k}_B,\mathsf{k}_A)d\mathsf{k}'_A, \qquad \int_{\mathbb{R}^3} S(\mathsf{k}_A,\mathsf{k}_B)f_A(\mathsf{k}_A)d\mathsf{k}'_A.$$

These quantities are easily obtained using (6.16) and (6.20). Let us denote the positive part of $g(s)$ by $g^+(s)$,

(6.21)

$$\begin{aligned}
&\int_{\mathbb{R}^3} S_A(\mathsf{k}_A,\mathsf{k}'_A)\,d\mathsf{k}'_A \\
&\quad= \int_0^\infty\!\!\int_{-1}^1\!\!\int_0^{2\pi} \left[\left[c_{3,A}+\frac{c_{4,A}}{\left[\varphi(w_A,w'_A,\mu_A,\mu'_A,\phi_A,\phi'_A)+{\beta_A}^2\right]^2}\right]\delta(w'_A-w_A)\right. \\
&\qquad + \frac{c_{5,A}\bar{G}(w_A,w'_A,\mu_A,\mu'_A)}{\varphi(w_A,w'_A,\mu_A,\mu'_A,\phi_A,\phi'_A)}\left[\delta(w'_A-w_A-\alpha_p)+a_p\delta(w'_A-w_A+\alpha_p)\right] \\
&\qquad \left. + c_{6,A}\left[\delta(w'_A-w_A-\alpha_{np})+a_{np}\delta(w'_A-w_A+\alpha_{np})\right]\right]\frac{s_A(w'_A)}{t_*}\;d\phi'_A\;d\mu'_A\;dw'_A \\
&\quad= \left[4\pi\,c_{3,A}s_A(w_A)+4\pi\,c_{4,A}\frac{s_A(w_A)}{{\beta_A}^2\left(4q_A(w_A)+{\beta_A}^2\right)}\right. \\
&\qquad + c_{5,A}\left[N_{5,A}(w_A,w_A+\alpha_p)\,s_A(w_A+\alpha_p)\right. \\
&\qquad\qquad \left. + a_pN^+_{5,A}(w_A,w_A-\alpha_p)\,s^+_A(w_A-\alpha_p)\right] \\
&\qquad \left. + c_{6,A}\,4\pi\left[s_A(w_A+\alpha_{np})+a_{np}s^+_A(w_A-\alpha_{np})\right]\right]\frac{1}{t_*}.
\end{aligned}$$

Here,

$$N_{5,A}(w_A,w'_A)=\int_{-1}^1\!\!\int_0^{2\pi}\frac{\bar{G}(\bar{\mathsf{k}}_A,\bar{\mathsf{k}}'_A)}{|\bar{\mathsf{k}}_A-\bar{\mathsf{k}}'_A|^2}\;d\phi'_A\;d\mu'_A, \tag{6.22}$$

which is written as

$$N_{5,A}(w_A,w'_A)=2\pi\left[2\hat{B}\left(2\hat{A}\hat{D}-\hat{B}\hat{C}\right)\hat{D}^{-2}+\hat{D}^{-3}\left(\hat{A}\hat{D}-\hat{B}\hat{C}\right)^2\log\left|\frac{\hat{C}+\hat{D}}{\hat{C}-\hat{D}}\right|\right], \tag{6.23}$$

with

$$\hat{A} = \bar{a}_A\,\bar{a}'_A, \quad \hat{B} = \bar{c}_A\,\bar{c}'_A, \quad \hat{C} = q_A(w_A) + q_A(w'_A), \quad \hat{D} = -2\sqrt{q_A(w_A)\,q_A(w'_A)}$$

after some computations

(6.24)

$$\begin{aligned}
&\int_{\mathbb{R}^3} S_A(\mathsf{k}'_A, \mathsf{k}_A) f_A(\mathsf{k}'_A)\, d\mathsf{k}'_A \\
&\quad = \int_0^{\infty}\int_{-1}^{1}\int_0^{2\pi} \left[\left[c_{3,A} + \frac{c_{4,A}}{\left[\varphi(w_A, w'_A, \mu_A, \mu'_A, \phi_A, \phi'_A) + {\beta_A}^2\right]^2}\right]\delta(w'_A - w_A)\right. \\
&\qquad\qquad + c_{5,A}\frac{\bar{G}(w_A, w'_A, \mu_A, \mu'_A)}{\varphi(w_A, w'_A, \mu_A, \mu'_A, \phi_A, \phi'_A)} \\
&\qquad\qquad\qquad \cdot \left[\delta(w'_A - w_A - \alpha_p) + a_p\delta(w'_A - w_A + \alpha_p)\right] \\
&\qquad\qquad \left. + c_{6,A}\left[\delta(w'_A - w_A - \alpha_{np}) + a_{np}\delta(w'_A - w_A + \alpha_{np})\right]\right] \\
&\qquad \cdot \frac{s_A(w'_A)\, F_A(w'_A, \mu'_A)}{t_*}\; d\phi'_A\; d\mu'_A\; dw'_A \\
&\quad = \int_{-1}^{1}\Big[2\pi c_{3,A} s_A(w_A) F_A(w_A, \mu'_A) \\
&\qquad + c_{4,A} I_{4,A}(w_A, \mu_A, \mu'_A) F_A(w_A, \mu'_A) s_A(w_A) \\
&\qquad + c_{5,A}\Big[I^+_{5,A}(w_A, w_A - \alpha_p, \mu_A, \mu'_A) F^+_A(w_A - \alpha_p, \mu'_A)\, s^+_A(w_A - \alpha_p) \\
&\qquad + a_p I_{5,A}(w_A, w_A + \alpha_p, \mu_A, \mu'_A) F_A(w_A + \alpha_p, \mu'_A)\, s_A(w_A + \alpha_p)\Big] \\
&\qquad + c_{6,A}\, 2\pi\left[F^+_A(w_A - \alpha_{np}, \mu'_A) s^+_A(w_A - \alpha_{np})\right. \\
&\qquad \left. + \; a_{np} F_A(w_A + \alpha_{np}, \mu'_A) s_A(w_A + \alpha_{np})\right]\Big]\, \frac{1}{t_*}\; d\mu'_A.
\end{aligned}$$

Where

$$I_{4,A}(w_A, \mu_A, \mu'_A) = \int_0^{+\infty}\int_0^{2\pi} \frac{1}{\left(|\bar{\mathsf{k}}_A - \bar{\mathsf{k}}'_A|^2 + \beta_A^2\right)^2}\delta(w'_A - w_A)\; d\phi'_A\; dw'_A \tag{6.25}$$

and we show that

(6.26)

$$I_{4,A}(w_A, \mu_A, \mu'_A) = \frac{2\,\pi\left[2\,q_A(w_A)\,(1 - \mu_A\,\mu'_A) + \beta_A^2\right]}{\left[4\,q_A^2(w_A)\,(\mu_A - \mu'_A)^2 + \beta_A^4 + 4\,\beta_A^2\,q_A(w_A)\,(1 - \mu_A\mu'_A)\right]^{3/2}}.$$

While

$$I_{5,A}(w_A, w'_A, \mu_A, \mu'_A) = \int_0^{2\pi} \frac{\bar{G}(\bar{\mathsf{k}}_A, \bar{\mathsf{k}}'_A)}{|\bar{\mathsf{k}}_A - \bar{\mathsf{k}}'_A|^2}\, d\phi'_A, \tag{6.27}$$

again after some computations we obtain

$$\begin{aligned} I_{5,A}(w_A, w'_A, \mu_A, \mu'_A) =& \frac{\pi}{2} A_* \frac{4 + \bar{\alpha}_A \left(4 + \bar{\alpha}_A C_*\right) C_*}{\sqrt{C_*^2 + 4B_*^2 \left(\mu_A^2 + {\mu'_A}^2 - 1\right) - 4B_* C_* \mu_A \mu'_A}} \\ & - \frac{\pi}{2} A_* \bar{\alpha}_A \left(2\bar{\alpha}_A B_* \mu_A \mu'_A + \bar{\alpha}_A C_* + 4\right) \end{aligned} \tag{6.28}$$

with

$$\begin{aligned} A_* &= \frac{1}{2(1 + 2\bar{\alpha}_A w_A)(1 + 2\bar{\alpha}_A w'_A)}, \\ B_* &= \frac{\sqrt{w_A w'_A}}{\sqrt{(1 + \bar{\alpha}_A w_A)(1 + \bar{\alpha}_A w'_A)}}, \\ C_* &= \frac{w_A}{1 + \bar{\alpha}_A w_A} + \frac{w'_A}{1 + \bar{\alpha}_A w'_A}. \end{aligned}$$

The last two terms are easily computed, and we obtain

$$\int_{\mathbb{R}^3} S(\mathsf{k}_B, \mathsf{k}_A)\, d\mathsf{k}_A = 4\pi\, c_{7,A} \left[s_A^+(w_B + \alpha_{np} + \bar{\Delta}_{BA}) + a_{np} s_A^+(w_B - \alpha_{np} + \bar{\Delta}_{BA}) \right] \frac{1}{t_*}, \tag{6.29}$$

$$\begin{aligned} &\int_{\mathbb{R}^3} S(\mathsf{k}_A, \mathsf{k}_B) f_A(\mathsf{k}_A)\, d\mathsf{k}_A \\ &\quad = 2\pi\, c_{7,A} \int_{-1}^{1} \left[F_A^+(w_B - \alpha_{np} - \bar{\Delta}_{AB}, \mu_A) s_A^+(w_B - \alpha_{np} - \bar{\Delta}_{AB}) \right. \\ &\qquad \left. + a_{np} F_A^+(w_B + \alpha_{np} - \bar{\Delta}_{AB}, \mu_A) s_A^+(w_B + \alpha_{np} - \bar{\Delta}_{AB}) \right] \frac{1}{t_*}\, d\mu_A. \end{aligned} \tag{6.30}$$

Finally, collecting (6.21), (6.24), (6.29), and (6.30) and multiplying them by $t_* s_A(w_A)$,

the collision operator can be rewritten as

(6.31)

$$\begin{aligned}\bar{Q}(\Phi_A) = s_A(w_A)\int_{-1}^{1}\Big\{&2\,\pi\,c_{3,A}\Phi_A(w_A,\mu_A')+c_{4,A}I_{4,A}(w_A,\mu_A,\mu_A')\Phi_A(w_A,\mu_A')\\ &+c_{5,A}\Big[I_{5,A}^{+}(w_A,w_A-\alpha_p,\mu_A,\mu_A')\Phi_A^{+}(w_A-\alpha_p,\mu_A')\\ &\quad+a_pI_{5,A}(w_A,w_A+\alpha_p,\mu_A,\mu_A')\Phi_A(w_A+\alpha_p,\mu_A')\Big]\\ &+c_{6,A}\,2\,\pi\left[\Phi_A^{+}(w_A-\alpha_{np},\mu_A')+a_{np}\,\Phi_A(w_A+\alpha_{np},\mu_A')\right]\Big\}\;d\mu_A'\\ -\Big\{&4\,\pi\,c_{3,A}s_A(w_A)+4\,\pi\,c_{4,A}\frac{s_A(w_A)}{{\beta_A}^2(4\,q_A(w_A)+{\beta_A}^2)}\\ &+c_{5,A}\Big[N_{5,A}(w_A,w_A+\alpha_p)s_A(w_A+\alpha_p)\\ &\quad+a_p\,N_{5,A}^{+}(w_A,w_A-\alpha_p)s_A^{+}(w_A-\alpha_p)\Big]\\ &+c_{6,A}\,4\pi\,\left[s_A(w_A+\alpha_{np})+a_{np}\,s_A^{+}(w_A-\alpha_{np})\right]\Big\}\,\Phi_A(w_A,\mu_A)\\ +Z_{AB}s_A(w_A)\,c_{7,B}\,2\pi\int_{-1}^{1}&\left[\Phi_B^{+}(w_A-\alpha_{np}-\bar{\Delta}_{BA},\mu_B)\right.\\ &\left.+a_{np}\Phi_B^{+}(w_A+\alpha_{np}-\bar{\Delta}_{BA},\mu_B)\right]\,d\mu_B\\ -Z_{AB}\,c_{7,B}\,4\pi&\left[s_B^{+}(w_A+\alpha_{np}+\bar{\Delta}_{AB})\right.\\ &\left.+a_{np}\,s_B^{+}(w_A-\alpha_{np}+\bar{\Delta}_{AB})\right]\Phi_A(w_A,\mu_A).\end{aligned}$$

6.1.3. Poisson equation. The right-hand side of the Poisson equation (1.4) satisfies

$$\Delta_{\bar{\mathsf{x}}}\bar{V}(\bar{t},\bar{\mathsf{x}}) = \frac{e\,t_*\,l_*}{\sqrt{m_X^*\,k_BT}}\,\Delta_{\mathsf{x}}V(t,\mathsf{x}).$$

The dimensionless ρ_Γ and ρ_L are given by

$$\rho_\Gamma(t,\mathsf{x}) = 2\,\pi\,\left(\frac{\sqrt{m_\Gamma^* k_BT}}{\hbar}\right)^3\int_0^\infty\int_{-1}^{1}\,\Phi_\Gamma(t,z,w_\Gamma,\mu_\Gamma)d\mu_\Gamma\;dw_\Gamma$$

and

$$\rho_L(t,\mathsf{x}) = 2\,\pi\,\left(\frac{\sqrt{m_L^* k_BT}}{\hbar}\right)^3\int_0^\infty\int_{-1}^{1}\Phi_L(t,z,w_L,\mu_L)\;d\mu_L\;dw_L.$$

Finally, using the dimensionless doping density, we obtain the dimensionless Poisson equation

$$\Delta_z \bar{V}(\bar{t},z) = c_p \left(c_\Gamma \int_0^\infty \int_{-1}^1 \Phi_\Gamma(\bar{t},z,w_\Gamma,\mu_\Gamma)\; d\mu_\Gamma\; dw_\Gamma + c_L \int_0^\infty \int_{-1}^1 \Phi_L(\bar{t},z,w_L,\mu_L)\; d\mu_L\; dw_L - \bar{C}(z) \right), \tag{6.32}$$

where

$$c_p = \frac{e^2\, t_*\, l_*\, m_X^*\, k_B T}{\epsilon_0\, \hbar^3}, \quad c_\Gamma = 2\,\pi\, Z_{L\Gamma} \left(\frac{m_\Gamma^*}{m_X^*}\right)^{3/2}, \quad c_L = 2\,\pi\, Z_{\Gamma L} \left(\frac{m_L^*}{m_X^*}\right)^{3/2}. \tag{6.33}$$

6.2. Macroscopic quantities. To conclude, we give the expression of the macroscopic quantities: mean density,

$$\rho(t,\mathsf{x}) = Z_{L\Gamma}\rho_\Gamma(t,\mathsf{x}) + Z_{\Gamma L}\rho_L(t,\mathsf{x}),$$

mean velocity,

$$u(t,\mathsf{x}) = \frac{1}{\hbar\,\rho(t,\mathsf{x})} \left(Z_{L\Gamma} \int_{\mathbb{R}^3} \nabla_{\mathsf{k}_\Gamma} \mathcal{E}_\Gamma(\mathsf{k}_\Gamma)\, f_\Gamma(t,\mathsf{x})\; d\mathsf{k}_\Gamma + Z_{\Gamma L} \int_{\mathbb{R}^3} \nabla_{\mathsf{k}_L} \mathcal{E}_L(\mathsf{k}_L)\, f_L(t,\mathsf{x})\; d\mathsf{k}_L \right),$$

energy,

$$\frac{1}{\rho(t,\mathsf{x})} \left(Z_{L\Gamma} \int_{\mathbb{R}^3} \mathcal{E}_\Gamma(\mathsf{k}_\Gamma)\, f_\Gamma(t,\mathsf{x})\; d\mathsf{k}_\Gamma + Z_{\Gamma L} \int_{\mathbb{R}^3} \mathcal{E}_L(\mathsf{k}_L)\, f_L(t,\mathsf{x})\; d\mathsf{k}_L \right),$$

and momentum,

$$\frac{1}{\hbar} \left(Z_{L\Gamma} \int_{\mathbb{R}^3} \nabla_{\mathsf{k}_\Gamma} \mathcal{E}_\Gamma(\mathsf{k}_\Gamma)\, f_\Gamma(t,\mathsf{x})\; d\mathsf{k}_\Gamma + Z_{\Gamma L} \int_{\mathbb{R}^3} \nabla_{\mathsf{k}_L} \mathcal{E}_L(\mathsf{k}_L)\, f_L(t,\mathsf{x})\; d\mathsf{k}_L \right).$$

Acknowledgments. We thank the anonymous referees, who certainly helped in improving the results and the presentation of this work.

GENERAL LINEAR METHODS FOR VOLTERRA INTEGRO-DIFFERENTIAL EQUATIONS WITH MEMORY*

CHENGJIAN ZHANG† AND STEFAN VANDEWALLE‡

Abstract. A new class of numerical methods for Volterra integro-differential equations with memory is developed. The methods are based on the combination of general linear methods with compound quadrature rules. Sufficient conditions that guarantee global and asymptotic stability of the solution of the differential equation and its numerical approximation are established. Numerical examples illustrate the convergence and effectiveness of the numerical methods.

Key words. stability, general linear methods, Volterra delay-integro-differential equation

1. Introduction. Volterra integro-differential equations (VIDEs) arise widely in the mathematical modeling of physical and biological phenomena. Significant advances in the theoretical analysis of such equations and in the numerical analysis and implementation of time-integration techniques for these problems have been made in the last few decades. For a survey of early results we refer the reader to the books [9, 26]. More recently, one has found that VIDEs with memory (MVIDEs), also called Volterra delay-integro-differential equations (VDIDEs), can be even more effective than standard VIDEs for the modeling of real-life problems; see, e.g., [8, 22]. This fact has led researchers to develop a theory and numerical analysis for MVIDEs. For example, numerical time-integration techniques of one-step collocation and Runge–Kutta (RK) type were investigated in [10, 17, 11, 23, 34, 21]. Linear multistep based methods were studied in [1, 2, 3, 27, 33].

So far, very few papers have discussed the *nonlinear stability* of MVIDEs. This is quite different from the case of delay differential equations (DDEs) without distributed delay, for which many results have been reported. For example, linear stability results for DDEs from [28] were extended in [29] to the nonlinear DDE case. In that paper it was proved that certain RK methods satisfy a so-called B_ρ-stability property. For the implicit Euler rule, [30] shows a contractivity result, which is a quite strong nonlinear stability property. Based on the concept of BN_f-stability, the authors of [6, 7, 31, 32] obtained a series of stability and contractivity results for continuous RK methods. In [32] it was shown that the requirement of BN_f-stability for a numerical method is a very strong requirement that leads to an order barrier. In order to avoid that order barrier, in [19, 20] numerical stability results have been derived for nonlinear DDEs based on the concept of algebraic stability of the underlying methods.

Stability results for MVIDEs were obtained in [5, 33, 34], where the authors investigated the nonlinear stability of continuous RK methods, discrete RK methods,

and backward differentiation (BDF) methods, respectively. For a study of MVIDEs of neutral type we refer the reader to [12], where the concept of BN_f-stability is used as the basic assumption. For adaptations of RK methods towards general Volterra functional differential equations, we would like to point out the recent paper [25]. There, stability results have been derived based on B-stability of the underlying schemes. These results are applicable for time-integration on a finite time interval. Here, we will study the nonlinear stability of numerical schemes for MVIDEs based on the use of general linear (GL) methods. Our stability results will be applicable on infinite time intervals.

This paper is organized as follows. In section 2, a fairly general class of MVIDEs is defined. This class contains the problems considered in [33, 34]. We present a stability criterion for such problems, which generalizes the criteria in the above references. In section 3, a class of extended GL methods is derived for solving MVIDEs. They are obtained by combining classical GL methods with compound quadrature rules. In section 4, some technical lemmas are derived. These lemmas will play a key role in the derivation of the numerical stability results. In sections 5 and 6, we study the global and asymptotic stability of the extended GL methods. In section 7 we present some numerical examples in order to illustrate the convergence of the methods. These results show that the new methods are quite effective. Finally, in section 8, we end with some concluding remarks.

2. A class of MVIDEs and its stability.

2.1. A general stability result. We consider a complex N-dimensional system of MVIDEs with constant delay $\tau > 0$ of the form

$$\begin{cases} y'(t) = f(t, y(t), y(t-\tau), \int_{t-\tau}^{t} g(t, v, y(v))dv), & t \in [t_0, +\infty), \\ y(t) = \varphi(t), & t \in [t_0 - \tau, t_0], \end{cases} \tag{2.1}$$

where the functions f, g, and φ are smooth enough such that system (2.1) has a unique solution $y(t)$. We assume in particular that the following conditions are satisfied:

$$\Re\langle f(t, x, y, z) - f(t, \tilde{x}, \tilde{y}, \tilde{z}), x - \tilde{x}\rangle \le \alpha\|x - \tilde{x}\|^2 + \beta\|y - \tilde{y}\|^2 + \sigma\|z - \tilde{z}\|^2, \tag{2.2}$$

$$\|g(t, v, x) - g(t, v, \tilde{x})\| \le \gamma\|x - \tilde{x}\|, \quad (t, v) \in \mathbb{D}, \tag{2.3}$$

for $t \in [t_0, +\infty)$, $\mathbb{D} = \{(t, v) : t \in [t_0, +\infty),\ v \in [t-\tau, t]\}$, and $x, y, z, \tilde{x}, \tilde{y}, \tilde{z} \in \mathbb{C}^N$. The notations $\langle\cdot,\cdot\rangle$ and $\|\cdot\|$ denote a given inner product in $\mathbb{C}^N$ and its induced norm. The constants $(-\alpha)$, β, σ, and γ are nonnegative. Problems of type (2.1) with (2.2) and (2.3) will be called *problems of class* $\mathbb{GRI}(\alpha, \beta, \sigma, \gamma)$. Some examples will be given in section 7. For problems of class $\mathbb{GRI}(\alpha, \beta, \sigma, \gamma)$, we can derive the following stability result.

THEOREM 2.1. *Assume that system* (2.1) *belongs to the class* $\mathbb{GRI}(\alpha, \beta, \sigma, \gamma)$ *with* $\beta + \sigma\gamma^2\tau^2 < -\alpha$. *Then the following global and asymptotic stability properties hold:*

$$\|y(t) - \tilde{y}(t)\| \le \max_{\theta \in [t_0 - \tau,\, t_0]} \|\varphi(\theta) - \psi(\theta)\| \quad \forall t \ge t_0, \tag{2.4}$$

$$\lim_{t \to +\infty} \|y(t) - \tilde{y}(t)\| = 0, \tag{2.5}$$

where $\tilde{y}(t)$ *is the solution of* (2.1) *with* $\varphi(t)$ *replaced by* $\psi(t)$.

Proof. Denote by $\Delta y(t)$ the difference $y(t) - \tilde{y}(t)$. Using (2.2) and (2.3), we find

$$\begin{aligned}\frac{d}{dt}(\|\Delta y(t)\|^2) &= 2\Re\langle \Delta y(t), (\Delta y(t))'\rangle \\ &\le \alpha\|\Delta y(t)\|^2 + \beta\|\Delta y(t-\tau)\|^2 + \sigma\left\|\int_{t-\tau}^{t}[g(t,v,y(v)) - g(t,v,\tilde{y}(v))]dt\right\|^2 \\ &\le \alpha\|\Delta y(t)\|^2 + \beta\|\Delta y(t-\tau)\|^2 + \sigma\gamma^2\tau^2 \max_{t-\tau\le v\le t}\|\Delta y(v)\|^2 \\ &\le \alpha\|\Delta y(t)\|^2 + (\beta + \sigma\gamma^2\tau^2)\max_{t-\tau\le v\le t}\|\Delta y(v)\|^2.\end{aligned}$$

Application of the generalized Halanay inequality from [4] leads to

$$\|\Delta y(t)\|^2 \le \max_{\theta\in[t_0-\tau,\,t_0]}\|\varphi(\theta)-\psi(\theta)\|^2 \ \ \forall t \ge t_0 \quad \text{and} \quad \lim_{t\to+\infty}\|\Delta y(t)\|^2 = 0.$$

Thus, (2.4) and (2.5) are satisfied. ∎

REMARK 2.2. *The* $\mathbb{GRI}$ *class includes the* $\mathbb{DI}$ *and* $\mathbb{RI}$ *problem classes that were investigated in* [33, 34]. *The relation among these classes is as follows:*

$$\mathbb{DI}(\alpha,\beta,(\sigma_1,\sigma_2),\gamma) \subset \mathbb{RI}(\alpha,\beta\sigma_1,\beta\sigma_2,\gamma) \subset \mathbb{GRI}(\alpha+\beta(\sigma_1+\sigma_2)/2,\beta\sigma_1/2,\beta\sigma_2/2,\gamma).$$

The research in the framework of class $\mathbb{GRI}$ *extends the results from* [33, 34].

REMARK 2.3. *When the distributed delay argument is absent from* (2.1), *the problem becomes a DDE. In that case, Theorem* 2.1 *can be applied with* $\gamma = \sigma = 0$, *which leads to the stability condition* $\beta < -\alpha$.

2.2. Relation to earlier work. The result from Remark 2.3 can be related to earlier results on analytical stability of DDEs. In [28, 29], Reverdy dealt respectively with linear and nonlinear DDEs of class $\mathbb{GRI}(-\rho,\rho,0,0)$, with $\rho > 0$. This class contains, for example, the linear DDE

$$\begin{cases} y'(t) = py(t) + qy(t-\tau), & t \in [t_0,+\infty), \\ y(t) = \varphi(t), & t \in [t_0-\tau, t_0], \end{cases} \tag{2.6}$$

with $\Re(p) \le -|q|$, by setting $\rho = -\Re(p)/2$. It was proved for $\mathbb{GRI}(-\rho,\rho,0,0)$ that

$$\mathcal{N}[y(t)-\tilde{y}(t)] \le \mathcal{N}[y(t_0)-\tilde{y}(t_0)] \quad \forall t \ge t_0, \tag{2.7}$$

where $\mathcal{N}[y(t)] = \frac{1}{2}\|y(t)\|^2 + \rho\int_{t-\tau}^{t}\|y(\theta)\|^2 d\theta$. Note that stability property (2.7) follows from our somewhat stronger result (2.4).

In [30] Torelli considered DDEs with a variable delay $\tau(t)$:

$$\begin{cases} y'(t) = f(t,y(t),y(t-\tau(t))), & t \in [t_0,+\infty), \\ y(t) = \varphi(t), & t \in \left[\inf\limits_{t\ge t_0}\{t-\tau(t)\}, t_0\right], \end{cases} \tag{2.8}$$

with $\beta(t) \le -\alpha(t)$ and $\alpha(t) < 0$ for $t \ge t_0$, where $\alpha(t)$ and $\beta(t)$ are defined as

$$\alpha(t) = \sup_{x,\tilde{x},y,\in\mathbb{C}^n,\, x\ne\tilde{x}} \Re\langle f(t,x,y) - f(t,\tilde{x},y), x-\tilde{x}\rangle/\|x-\tilde{x}\|^2, \tag{2.9}$$

$$\beta(t) = \sup_{x,y,\tilde{y}\in\mathbb{C}^n,\, y\ne\tilde{y}} \|f(t,x,y) - f(t,x,\tilde{y})\|/\|y-\tilde{y}\|. \tag{2.10}$$

In that paper it was proven that (2.8) satisfies the global stability property (2.4).

System (2.8) was analyzed by Zennaro in [32] under a different set of conditions:

(I) there exists a constant τ_0 such that $\tau(t) \geq \tau_0$ for all $t \geq t_0$;
(II) the delayed argument $t - \tau(t)$ is a strictly increasing function for all $t \geq t_0$;
(III) $\lim_{t\to+\infty} t - \tau(t) = +\infty$;
(IV) there are two continuous functions, $\hat{\alpha}(t)$ and $\hat{\beta}(t)$, and two real numbers, $0 \leq r < 1$ and $\alpha_0 < 0$, such that $\alpha(t) \leq \hat{\alpha}(t) \leq \alpha_0$ and $\beta(t) \leq \hat{\beta}(t) \leq -r\hat{\alpha}(t)$ for $t \geq t_0$.

It was proven in [32] that, under those conditions, system (2.8) satisfies the asymptotic stability (2.5).

The above results by Torelli and by Zennaro can be applied to the constant delay case, i.e., with $\tau(t) \equiv \tau$. Assume there exists an α and β such that $\alpha := \sup_{t\geq t_0} \alpha(t) < 0$ and $\beta := \sup_{t\geq t_0} \beta(t) < -\alpha$. Then, system (2.8) satisfies the stability properties (2.4) and (2.5) by the results from [30] and [32], respectively. This conclusion, however, is just the special case from our results, as expressed in Remark 2.3.

3. The extended GL methods. The numerical methods we suggest for (2.1) will be based on GL methods for ODEs of the form $y'(t) = f(t, y(t))$ with $y(t_0) = y_0$; see [13, 15, 16]. A GL method can be formulated as follows:

$$\text{(3.1)} \qquad \begin{cases} Y_i^{(n)} = h\displaystyle\sum_{j=1}^{s} c_{ij}^{(11)} f(t_n + c_j h, Y_j^{(n)}) + \sum_{j=1}^{r} c_{ij}^{(12)} y_j^{(n-1)}, \quad i = 1, 2, \ldots, s, \\ y_i^{(n)} = h\displaystyle\sum_{j=1}^{s} c_{ij}^{(21)} f(t_n + c_j h, Y_j^{(n)}) + \sum_{j=1}^{r} c_{ij}^{(22)} y_j^{(n-1)}, \quad i = 1, 2, \ldots, r, \end{cases}$$

with real coefficients $c_{ij}^{(IJ)}$ for $I, J = 1, 2$, with a step size $h > 0$, and with $t_n = t_0 + nh$ for $n \geq 0$. The vector $Y_i^{(n)}$ approximates $y(t_n + c_i h)$. The precise nature of vector $y_i^{(n)}$ differs from method to method; generally, it contains the necessary information for doing the next time-integration step. For use in the subsequent analysis, we introduce the coefficient matrices $C_{IJ} = (c_{ij}^{(IJ)})$ and the abscissa vector $c = (c_1, c_2, \ldots, c_s)^T$.

An important subclass of the GL methods, which will be considered further on, is the multistep Runge–Kutta (MRK) methods (see, e.g., [14, 24]):

$$\text{(3.2)} \qquad \begin{cases} Y_i^{(n)} = h\displaystyle\sum_{j=1}^{s} a_{ij} f(t_n + c_j h, Y_j^{(n)}) + \sum_{j=1}^{r} \hat{a}_{ij} y_{n+j-1}, \quad i = 1, 2, \ldots, s, \\ y_{n+r} = h\displaystyle\sum_{j=1}^{s} b_j f(t_n + c_j h, Y_j^{(n)}) + \sum_{j=1}^{r} \hat{b}_j y_{n+j-1}. \end{cases}$$

These methods can be written in the form (3.1) when setting $y_{n+i} = y_i^{(n)}$. With $b = (b_1, b_2, \ldots, b_s)^T$ and $\hat{b} = (\hat{b}_1, \hat{b}_2, \ldots, \hat{b}_r)^T$, we can identify the coefficient matrices:

$$C_{11} = (a_{ij}), \quad C_{12} = (\hat{a}_{ij}), \quad C_{21} = \begin{bmatrix} 0 \\ b^T \end{bmatrix}, \quad C_{22} = \begin{bmatrix} 0 & I_{r-1} \\ & \hat{b}^T \end{bmatrix}.$$

For the formulation of other numerical methods as a GL method, we refer the reader to [16].

First, we recall a number of elementary concepts of GL methods that will be important for our stability analysis.

DEFINITION 3.1. *Let* $R(z) = C_{22} + zC_{21}(I_s - zC_{11})^{-1}C_{12}$, *where* $z \in \mathbb{C}$ *and where* I_s *denotes the* $s \times s$ *identity matrix. A GL method is called strictly stable at infinity if* $R(\infty) := \lim_{z\to\infty} R(z)$ *exists and if its spectral radius satisfies* $\rho(R(\infty)) < 1$.

DEFINITION 3.2 (cf. [13]). *A GL method is called* (k, l)*-algebraically stable if there exist real constants* k *and* l, *a symmetric positive-definite matrix* $G = (g_{ij}) \in \mathbb{R}^{r\times r}$, *and a nonnegative diagonal matrix* $D = \mathrm{diag}(d_1, d_2, \ldots, d_s) \in \mathbb{R}^{s\times s}$ *such that matrix* $M = (m_{ij}) \in \mathbb{R}^{(r+s)\times(r+s)}$ *is nonnegative definite, with*

$$M = \begin{bmatrix} kG - C_{22}^T GC_{22} - 2lC_{12}^T GC_{12} & C_{12}^T D - C_{22}^T GC_{21} - 2lC_{12}^T DC_{11} \\ DC_{12} - C_{21}^T GC_{22} - 2lC_{11}^T DC_{12} & DC_{11} + C_{11}^T D - C_{21}^T GC_{21} - 2lC_{11}^T DC_{11} \end{bmatrix}.$$

In particular, a $(1, 0)$*-algebraically stable method is called algebraically stable.*

Adapting method (3.1) to MVIDE (2.1) and considering the case where the step size $h = \tau/m$ for m a given positive integer yield the following numerical scheme:

(3.3)
$$\begin{cases} Y_i^{(n)} = h\displaystyle\sum_{j=1}^{s} c_{ij}^{(11)} f(t_n + c_j h, Y_j^{(n)}, Y_j^{(n-m)}, Z_j^{(n)}) + \sum_{j=1}^{r} c_{ij}^{(12)} y_j^{(n-1)}, \quad i = 1, 2, \ldots, s, \\ y_i^{(n)} = h\displaystyle\sum_{j=1}^{s} c_{ij}^{(21)} f(t_n + c_j h, Y_j^{(n)}, Y_j^{(n-m)}, Z_j^{(n)}) + \sum_{j=1}^{r} c_{ij}^{(22)} y_j^{(n-1)}, \quad i = 1, 2, \ldots, r. \end{cases}$$

$Z_j^{(n)}$ is an approximation to

$$Z(t_n + c_j h) := \int_{t_{n-m}+c_j h}^{t_n+c_j h} g(t_n + c_j h, v, y(v))dv$$

and is computed by a convergent, compound quadrature formula

$$Z_j^{(n)} = h\sum_{q=0}^{m} \nu_q g(t_n + c_j h, t_{n-q} + c_j h, Y_j^{(n-q)}), \quad j = 1, 2, \ldots, s. \tag{3.4}$$

Such a quadrature formula can be derived from a uniform repeated rule (cf. [3, 9, 33]). For our stability analysis we need the rule to satisfy the following condition:

$$h\sqrt{(m+1)\sum_{q=0}^{m} |\nu_q|^2} < \nu \quad \text{with } mh = \tau \text{ and a positive constant } \nu. \tag{3.5}$$

This condition holds for many of the common quadrature rules. For example, the compound trapezoidal (CT) rule of second order,

$$\int_0^\tau \Phi(s)ds \cong h\left[\frac{1}{2}\Phi(0) + \sum_{q=1}^{m-1} \Phi((m-q)h) + \frac{1}{2}\Phi(mh)\right], \quad \text{where } mh = \tau,$$

satisfies

$$h\sqrt{(m+1)\sum_{q=0}^{m} |\nu_q|^2} = h\sqrt{(m+1)[(1/2)^2 + m - 1 + (1/2)^2]} \le h(m+1) \le 2mh = 2\tau.$$

The compound Gregory (CG) rule of order 3 (cf. [9]),

$$\int_0^\tau \Phi(s)ds \cong \frac{h}{12}\left[5\Phi(0) + 13\Phi(h) + 12\sum_{q=2}^{m-2} \Phi((m-q)h) + 13\Phi((m-1)h) + 5\Phi(mh)\right],$$

TABLE 1
Value for the bound ν in (3.5) for different compound quadrature rules.

	CT rule	CG rule	CS rule	CN rule
ν	$2\,\tau$	$2\,\tau$	$\sqrt{20}\,\tau/3$	$2\sqrt{1194}\,\tau/45$

with $mh = \tau$, satisfies

$$h\sqrt{(m+1)\sum_{q=0}^{m}|\nu_q|^2} = h\sqrt{(m+1)\left[\frac{5^2+13^2+(m-3)12^2+13^2+5^2}{12^2}\right]}$$
$$= h\sqrt{(m+1)\left(m-\frac{11}{36}\right)} \le h(m+1) \le 2mh = 2\tau.$$

The values for ν for the fourth order compound Simpson (CS) rule and for the sixth order compound Newton–Cotes (CN) rule have been derived in [33]; see Table 1.

We end this section with some more notational conventions. When the extended GL method is applied to system (2.1) with the initial function $\varphi(t)$ replaced by $\psi(t)$, the resulting numerical approximations will be denoted by $\tilde{Y}_j^{(n)}$, $\tilde{Z}_j^{(n)}$, and $\tilde{y}_i^{(n)}$. Also, when a time point t_n or $t_n + c_j h$ falls in the initial interval $[t_0 - \tau, t_0]$, we set the approximation at that point equal to the corresponding (known) true solution.

4. Some elementary lemmas. In this section, we will derive some technical lemmas, which are important for the derivation of the main results in the subsequent sections. First, we introduce some more notation:

$$\Delta y_j^{(n)} = y_j^{(n)} - \tilde{y}_j^{(n)}, \quad \Delta Y_j^{(n)} = Y_j^{(n)} - \tilde{Y}_j^{(n)}, \quad \Delta Z_j^{(n)} = Z_j^{(n)} - \tilde{Z}_j^{(n)},$$

$$\Delta f_j^{(n)} = f(t_j^{(n)}, Y_j^{(n)}, Y_j^{(n-m)}, Z_j^{(n)}) - f(t_j^{(n)}, \tilde{Y}_j^{(n)}, \tilde{Y}_j^{(n-m)}, \tilde{Z}_j^{(n)}),$$

$$\Delta y^{(n)} = \begin{pmatrix} \Delta y_1^{(n)} \\ \Delta y_2^{(n)} \\ \vdots \\ \Delta y_r^{(n)} \end{pmatrix}, \quad \Delta Y^{(n)} = \begin{pmatrix} \Delta Y_1^{(n)} \\ \Delta Y_2^{(n)} \\ \vdots \\ \Delta Y_s^{(n)} \end{pmatrix}, \quad \Delta f^{(n)} = \begin{pmatrix} \Delta f_1^{(n)} \\ \Delta f_2^{(n)} \\ \vdots \\ \Delta f_s^{(n)} \end{pmatrix}.$$

With (3.3) we can write the relation between the above quantities compactly as

$$\begin{cases} \Delta Y^{(n)} = h(C_{11} \otimes I_N)\Delta f^{(n)} + (C_{12} \otimes I_N)\Delta y^{(n-1)}, \\ \Delta y^{(n)} = h(C_{21} \otimes I_N)\Delta f^{(n)} + (C_{22} \otimes I_N)\Delta y^{(n-1)}, \end{cases} \tag{4.1}$$

where the symbol $\otimes$ denotes the Kronecker product. We will use the following inner product and norms on $\mathbb{C}^{Ns}$:

$$\langle U, V\rangle = \sum_{i=1}^{s}\langle u_i, v_i\rangle, \quad \|U\| = \sqrt{\langle U, U\rangle}, \quad \|U\|_G = \sqrt{\langle U, GU\rangle},$$

where vectors $U = (u_1^T, u_2^T, \ldots, u_s^T)^T$, $V = (v_1^T, v_2^T, \ldots, v_s^T)^T \in \mathbb{C}^{Ns}$, and $u_i, v_i \in \mathbb{C}^N$.

LEMMA 4.1. *Suppose that the GL method* (3.1) *is* (k,l)*-algebraically stable with* $0 < k \le \theta \le 1$. *Suppose that the quadrature formula* (3.4) *satisfies* (3.5) *and that the conditions* (2.2) *and* (2.3) *hold. Set* $d = \sum_{j=1}^{s} d_j$. *Then, method* (3.3) *satisfies*

$$\begin{aligned}\|\Delta y^{(n)}\|_G^2 \le \theta^n \|\Delta y^{(0)}\|_G^2 &+ 2\beta\tau\theta^{n-m} d \max_{-m\le i\le -1} \max_{1\le j\le s} \{\|\Delta Y_j^{(i)}\|^2\} \\ &+ 2[(h\alpha - l)\theta^m + h\beta] \sum_{i=0}^{n-1} \theta^{n-m-i-1} \sum_{j=1}^{s} d_j \|\Delta Y_j^{(i)}\|^2 \\ &+ \frac{2h\sigma(\nu\gamma)^2}{m+1} \sum_{i=0}^{n-1} \theta^{n-i-1} \sum_{j=1}^{s} \sum_{q=0}^{m} d_j \|\Delta Y_j^{(i-q)}\|^2, \quad n \ge 1. \end{aligned} \tag{4.2}$$

Proof. It follows from a fairly straightforward (but tedious) computation and (k,l)-algebraic stability that (compare also [13, 20])

$$\begin{aligned}\|\Delta y^{(n)}\|_G^2 - k\|\Delta y^{(n-1)}\|_G^2 - 2\sum_{j=1}^{s} d_j \Re\langle \Delta Y_j^{(n)}, h\Delta f_j^{(n)} - l\Delta Y_j^{(n)}\rangle &= -\sum_{i=1}^{r+s}\sum_{i=1}^{r+s} m_{ij}\langle \omega_i, \omega_j\rangle \\ &\le 0,\end{aligned}$$

where $M = (m_{ij})$, as defined in Definition 3.2, and

$$\omega_i = \begin{cases} y_i^{(n-1)}, & 1 \le i \le r, \\ h\Delta f_i^{(n)}, & r+1 \le i \le r+s. \end{cases}$$

This, together with the condition $0 < k \le \theta$, implies

$$\|\Delta y^{(n)}\|_G^2 \le \theta\|\Delta y^{(n-1)}\|_G^2 + 2\sum_{j=1}^{s} d_j \Re\langle \Delta Y_j^{(n)}, h\Delta f_j^{(n)} - l\Delta Y_j^{(n)}\rangle. \tag{4.3}$$

By condition (2.2) one has

$$\sum_{j=1}^{s} d_j \Re\langle \Delta Y_j^{(n)}, h\Delta f_j^{(n)}\rangle \le h\sum_{j=1}^{s} d_j[\alpha\|\Delta Y_j^{(n)}\|^2 + \beta\|\Delta Y_j^{(n-m)}\|^2 + \sigma\|\Delta Z_j^{(n)}\|^2].$$

When this bound is inserted into (4.3), one finds

$$\begin{aligned}\|\Delta y^{(n)}\|_G^2 \le \theta\|\Delta y^{(n-1)}\|_G^2 &+ 2(h\alpha - l)\sum_{j=1}^{s} d_j \|\Delta Y_j^{(n)}\|^2 \\ &+ 2h\beta\sum_{j=1}^{s} d_j \|\Delta Y_j^{(n-m)}\|^2 + 2h\sigma\sum_{j=1}^{s} d_j \|\Delta Z_j^{(n)}\|^2. \end{aligned} \tag{4.4}$$

An induction argument applied to (4.4) yields

$$\begin{aligned}\|\Delta y^{(n)}\|_G^2 \le \theta^n\|\Delta y^{(0)}\|_G^2 &+ 2(h\alpha - l)\sum_{i=0}^{n-1} \theta^{n-i-1} \sum_{j=1}^{s} d_j \|\Delta Y_j^{(i)}\|^2 \\ &+ 2h\beta\sum_{i=0}^{n-1} \theta^{n-i-1} \sum_{j=1}^{s} d_j \|\Delta Y_j^{(i-m)}\|^2 + 2h\sigma\sum_{i=0}^{n-1} \theta^{n-i-1} \sum_{j=1}^{s} d_j \|\Delta Z_j^{(i)}\|^2. \end{aligned} \tag{4.5}$$

With (2.3), (3.5), and the Cauchy inequality, we have

$$\|\Delta Z_j^{(i)}\|^2 \le (h\gamma)^2 \left(\sum_{q=0}^{m} |\nu_q| \|\Delta Y_j^{(i-q)}\|\right)^2 \le (h\gamma)^2 \left(\sum_{q=0}^{m} |\nu_q|^2\right) \left(\sum_{q=0}^{m} \|\Delta Y_j^{(i-q)}\|^2\right)$$

$$\le \frac{(\gamma\nu)^2}{m+1} \sum_{q=0}^{m} \|\Delta Y_j^{(i-q)}\|^2. \tag{4.6}$$

Moreover, we have

$$h \sum_{i=0}^{n-1} \theta^{n-i-1} \sum_{j=1}^{s} d_j \|\Delta Y_j^{(i-m)}\|^2$$

$$= h \sum_{i=0}^{n-m-1} \theta^{n-m-i-1} \sum_{j=1}^{s} d_j \|\Delta Y_j^{(i)}\|^2 + h \sum_{i=-m}^{-1} \theta^{n-m-i-1} \sum_{j=1}^{s} d_j \|\Delta Y_j^{(i)}\|^2$$

$$\le h \sum_{i=0}^{n-1} \theta^{n-m-i-1} \sum_{j=1}^{s} d_j \|\Delta Y_j^{(i)}\|^2 + \tau \theta^{n-m} d \max_{-m\le i\le -1} \max_{1\le j\le s} \{\|\Delta Y_j^{(i)}\|^2\}. \tag{4.7}$$

Substituting (4.6) and (4.7) into (4.5) results in (4.2). ∎

The second lemma gives an existence condition for the stability function $R(z)$ that is referred to in Definition 3.1.

LEMMA 4.2. *Suppose that a GL method is (k,l)-algebraically stable for a symmetric positive-definite matrix $G \in \mathbb{R}^{r\times r}$ and a positive diagonal matrix $D \in \mathbb{R}^{s\times s}$. Then the limit $R(\infty) := \lim_{z\to\infty} R(z)$ exists.*

Proof. It suffices to prove the existence of $C_0 := \lim_{\varepsilon\to 0} C_{21}(C_{11} + \varepsilon I_s)^{-1}$. This can be shown in a similar way as Lemma 3.8 of [20] is proven (compare also [18]), i.e., by considering the nonnegative definiteness of the bottom right-hand principal minor $DC_{11} + C_{11}^T D - C_{21}^T G C_{21} - 2l C_{11}^T D C_{11}$ of matrix M. ∎

REMARK 4.3. *In* [18, 20] *the positivity of the diagonal matrix D is guaranteed by requiring the underlying methods to be irreducible and algebraically stable. Here, we loosen these conditions by requesting positivity for D explicitly. This allows us to consider more general (k,l)-algebraically stable GL methods.*

REMARK 4.4. *When the conditions in Lemma* 4.2 *are satisfied, it holds that*

$$R(\infty) = \begin{cases} C_{22} - C_{21}C_{11}^{-1}C_{12} & \text{if } C_{11} \text{ is invertible,} \\ C_{22} - C_0 C_{12} & \text{if } C_{11} \text{ is singular.} \end{cases}$$

Two inequalities from [34] will also play important roles in the subsequent sections.

LEMMA 4.5. *Suppose that $\{A_i\}_{i=0}^n$ and $\{B_i\}_{i=-m}^n$ are two arbitrary nonnegative real sequences. Then the following two inequalities hold for all $n, m \ge 0$:*

$$\sum_{i=0}^{n} \left(A_i \sum_{j=0}^{m} B_{i-j}\right) \le \sum_{j=0}^{m}\sum_{i=0}^{n} A_{i+j}B_i + \left(\sum_{j=1}^{m}\sum_{i=1}^{j} A_{j-i}\right) \max_{-m\le q\le -1}\{B_q\}, \tag{4.8}$$

$$\sum_{i=0}^{n}\sum_{j=0}^{m} B_{i-j} \le (m+1)\sum_{i=0}^{n} B_i + \frac{m(m+1)}{2} \max_{-m\le q\le -1}\{B_q\}. \tag{4.9}$$

Finally, we mention an asymptotic property of vector difference equations that can be derived easily from a combination of Theorems 105B and 123D of [16].

LEMMA 4.6. *Given a matrix $\mathcal{A} \in \mathbb{C}^{Q\times Q}$ and a sequence $V_n \in \mathbb{C}^Q$, the solution sequence $\{X_n\} \subseteq \mathbb{C}^Q$ of the linear difference equation $X_n = \mathcal{A}X_{n-1} + V_n$ satisfies $\lim_{n\to\infty} \|X_n\| = 0$ if and only if $\rho(\mathcal{A}) < 1$ and $\lim_{n\to\infty} \|V_n\| = 0$.*

5. Global stability of the extended GL methods. Numerical stability is an important feature of an effective numerical method. An unstable numerical method may be consistent of high order, yet arbitrarily small perturbations will eventually cause large deviations from the true solution. In this section, we will focus on the global stability of the extended GL methods.

DEFINITION 5.1. *The extended GL method* (3.3) *and* (3.4) *is called globally stable for problems of class $\mathbb{GRI}(\alpha,\beta,\sigma,\gamma)$ if there exists a constant $\mathcal{H} > 0$, which depends only on $\alpha,\beta,\sigma,\gamma,\tau,\nu$, and the method, such that*

$$\|\Delta y^{(n)}\| \le \mathcal{H} \max\left\{\|\Delta y^{(0)}\|, \max_{-m\le i\le -1}\max_{1\le j\le s}\{\|\Delta Y_j^{(i)}\|\}\right\} \quad \forall n \ge 1. \tag{5.1}$$

REMARK 5.2. *For the extended one-step RK methods, we have $\Delta y^{(n)} = \Delta y_n := y_{n+1} - \tilde{y}_{n+1}$. Also, under the usual assumption that $0 \le c_i \le 1$, it holds that*

$$\max\left\{\|\Delta y_0\|, \max_{-m\le i\le -1}\max_{1\le j\le s}\{\|\Delta Y_j^{(i)}\|\}\right\} \le \max_{t_0-\tau\le t\le t_0}\|\varphi(t) - \psi(t)\|.$$

Hence, we have for (5.1) *the following equivalent formulation:*

$$\|\Delta y_n\| \le \mathcal{H} \max_{t_0-\tau\le t\le t_0}\|\varphi(t) - \psi(t)\|.$$

Thus, the concept of global stability in Definition 5.1 *is slightly stronger than that in* [34].

THEOREM 5.3. *Suppose that the GL method* (3.1) *is (k,l)-algebraically stable for a nonnegative diagonal matrix $D = \mathrm{diag}(d_1,d_2,\ldots,d_s) \in \mathbb{R}^{s\times s}$ and a symmetric positive-definite matrix $G = (g_{ij}) \in \mathbb{R}^{r\times r}$, where $0 < k \le 1$, and suppose the quadrature formula* (3.4) *satisfies condition* (3.5). *Then the extended GL method* (3.3) *and* (3.4) *is globally stable for the class $\mathbb{GRI}(\alpha,\beta,\sigma,\gamma)$ with stability constant*

$$\mathcal{H} = \sqrt{\frac{\lambda_{max}^G + d\tau(2\beta + \sigma\gamma^2\nu^2)}{\lambda_{min}^G}}, \tag{5.2}$$

where λ_{min}^G and λ_{max}^G denote the minimum and maximum eigenvalues of matrix G and $d = \sum_{j=1}^s d_j$, when the following condition holds:

$$h(\alpha + \beta + \sigma\gamma^2\nu^2) \le l. \tag{5.3}$$

Proof. Setting $\theta = 1$ in (4.2) gives

(5.4)

$$\begin{aligned}\|\Delta y^{(n)}\|_G^2 \le{}& \|\Delta y^{(0)}\|_G^2 + 2\beta\tau d \max_{-m\le i\le -1}\max_{1\le j\le s}\{\|\Delta Y_j^{(i)}\|^2\}\\ &+ 2[h(\alpha+\beta) - l]\sum_{i=0}^{n-1}\sum_{j=1}^{s} d_j\|\Delta Y_j^{(i)}\|^2 + \frac{2h\sigma(\nu\gamma)^2}{m+1}\sum_{i=0}^{n-1}\sum_{j=1}^{s}\sum_{q=0}^{m} d_j\|\Delta Y_j^{(i-q)}\|^2.\end{aligned}$$

Also, by virtue of inequality (4.9), we have for $n \geq 1$

(5.5)
$$\sum_{i=0}^{n-1}\sum_{q=0}^{m}\|\Delta Y_j^{(i-q)}\|^2 \leq (m+1)\sum_{i=0}^{n-1}\|\Delta Y_j^{(i)}\|^2 + \frac{m(m+1)}{2}\max_{-m\leq i\leq -1}\{\|\Delta Y_j^{(i)}\|^2\}.$$

Inserting (5.5) into (5.4) and using the condition that $mh = \tau$ yield

$$\begin{aligned}\|\Delta y^{(n)}\|_G^2 \leq \|\Delta y^{(0)}\|_G^2 &+ d\tau(2\beta + \sigma\gamma^2\nu^2)\max_{-m\leq i\leq -1}\max_{1\leq j\leq s}\{\|\Delta Y_j^{(i)}\|^2\}\\ &+ 2[h(\alpha+\beta+\sigma\gamma^2\nu^2) - l]\sum_{i=0}^{n-1}\sum_{j=1}^{s} d_j\|\Delta Y_j^{(i)}\|^2. \end{aligned} \tag{5.6}$$

With condition (5.3) this leads to

$$\|\Delta y^{(n)}\|_G^2 \leq \|\Delta y^{(0)}\|_G^2 + d\tau(2\beta + \sigma\gamma^2\nu^2)\max_{-m\leq i\leq -1}\max_{1\leq j\leq s}\{\|\Delta Y_j^{(i)}\|^2\}.$$

Considering that $\lambda_{min}^G\|\Delta y^{(n)}\|^2 \leq \|\Delta y^{(n)}\|_G^2$ and that $\|\Delta y^{(0)}\|_G^2 \leq \lambda_{max}^G\|\Delta y^{(0)}\|^2$, we arrive at stability inequality (5.1) with stability constant (5.2). □

Example 5.1. As an application of Theorem 5.3, we consider an extended GL method with $s = 1$ and $r = 2$, induced by the combination of the two-step BDF method and the CT rule:

$$\begin{cases} Y^{(n)} = \frac{2}{3}hF^{(n)} + \left[\left(\frac{4}{3}, -\frac{1}{3}\right)\otimes I_N\right] y^{(n-1)},\\ y^{(n)} = h\left[\begin{pmatrix}\frac{2}{3}\\ 0\end{pmatrix}\otimes I_N\right]F^{(n)} + \left[\begin{pmatrix}\frac{4}{3} & -\frac{1}{3}\\ 1 & 0\end{pmatrix}\otimes I_N\right] y^{(n-1)}, \end{cases} \tag{5.7}$$

where $Y^{(n)} = y_{n+2}$, $y_n \cong y(t_n)$, $y^{(n)} = (y_{n+2}^T, y_{n+1}^T)^T$, and

$$\begin{aligned} F^{(n)} &= f_{n+2} := f\left(t_{n+2}, Y^{(n)}, Y^{(n-m)}, Z^{(n)}\right),\\ Z^{(n)} &= h{\sum_{q=0}^{m}}'' g\left(t_{n+2}, t_{n+2-q}, Y^{(n-q)}\right), \end{aligned} \tag{5.8}$$

where the special summation symbol stands for a sum with the first and last term halved. By Table 1 we know that (5.8) satisfies (3.5) with $\nu = 2\tau$. In [15], it was shown that the two-step BDF method is $(1/(1-2l), l)$-algebraically stable with $l \leq 0$ for $D = 1$ and the 2×2 real symmetric positive-definite matrix

$$G := \begin{pmatrix}(5-2l)/2 & -1\\ -1 & 1/2\end{pmatrix}.$$

Note that $0 < k \leq 1$ whenever $l \leq 0$ and that there always exists an l such that (5.3) holds whenever $\beta + \sigma\gamma^2\nu^2 \leq -\alpha$. Hence, we may conclude that the method is globally stable for the class $\mathbb{GRI}(\alpha, \beta, \sigma, \gamma)$ whenever $\beta + \sigma\gamma^2\nu^2 \leq -\alpha$. For the parameters in the formula of the stability constant, the following values are used:

$$d = 1, \quad \nu = 2\tau, \quad \lambda_{min}^G = \frac{3 - l - \sqrt{(l-2)^2+4}}{2}, \quad \lambda_{max}^G = \frac{3 - l + \sqrt{(l-2)^2+4}}{2}.$$

TABLE 2
l-value minimizing (5.9) *and corresponding stability constant* $\mathcal{H}$ *of the extended two-step BDF method for the MVIDEs in* (7.1) *and* (7.2).

	MVIDE (7.1)		MVIDE (7.2)	
m	l	$\mathcal{H}$	l	$\mathcal{H}$
8	−0.2224	6.4650	−0.0554	7.1616
16	−0.1112	6.8497	−0.0277	7.2997
32	−0.0556	7.0912	−0.0138	7.3733
64	−0.0278	7.2279	−0.0069	7.4116

The range of l is given by $h(\alpha+\beta+\sigma\gamma^2\nu^2) \le l \le 0$. In particular, when the extended two-step BDF method with a fixed step size h is applied to a concrete problem of class $\mathbb{GRI}(\alpha,\beta,\sigma,\gamma)$, one should look for the value of l that minimizes the stability constant $\mathcal{H}$. This leads one to consider the following constrained minimization problem:

$$\begin{cases} \text{minimize} \quad \mathcal{H} := \sqrt{\frac{3-l+\sqrt{(l-2)^2+4}+4\tau(\beta+2\sigma\gamma^2\tau^2)}{3-l-\sqrt{(l-2)^2+4}}} \\ \text{subject to} \quad h(\alpha+\beta+\sigma\gamma^2\nu^2) \le l \le 0. \end{cases} \tag{5.9}$$

In section 7 results of numerical experiments will be reported for two concrete MVIDEs. The first of those, specified in (7.1), belongs to class $\mathbb{GRI}(-4, \frac{1}{2}, \frac{1}{2}, 1)$; the second one, specified in (7.2), belongs to class $\mathbb{GRI}(-4+\frac{\sqrt{2}}{2}, \frac{\sqrt{2}}{4}, \frac{\sqrt{2}}{4}, 2)$. We have numerically solved problem (5.9) for these two examples. The l-value at which the minimum is obtained and the corresponding $\mathcal{H}$-value are given in Table 2 as a function of the parameter m, with $h = \tau/m$.

The method in the above example is also algebraically stable. For such methods, a general result can be derived immediately from Theorem 5.3.

COROLLARY 5.4. *Suppose that GL method* (3.1) *is algebraically stable for a nonnegative diagonal matrix* $D = \mathrm{diag}(d_1, d_2, \ldots, d_s) \in \mathbb{R}^{s\times s}$ *and a symmetric positive-definite matrix* $G = (g_{ij}) \in \mathbb{R}^{r\times r}$*, and suppose the quadrature formula* (3.4) *satisfies condition* (3.5)*. Then the extended GL method* (3.3) *and* (3.4) *is globally stable for the class* $\mathbb{GRI}(\alpha,\beta,\sigma,\gamma)$ *with stability constant* (5.2) *when the following condition holds:*

$$\beta + \sigma\gamma^2\nu^2 \le -\alpha. \tag{5.10}$$

In [14], Burrage has derived a class of s-stage MRK methods of order $2s$ of the form (3.2) that satisfy

$$\begin{cases} B(2s),\ C(s),\ E(s);\ c_i \ne c_j \ \text{ whenever } \ i \ne j; \\ \displaystyle\sum_{j=1}^{r} \hat{b}_j = 1,\ i = 1,2,\ldots,s;\ \hat{b}_1 > 0,\ \hat{b}_j \ge 0,\ j = 2,3,\ldots,r, \end{cases} \tag{5.11}$$

where $B(2s)$, $C(s)$, and $E(s)$ denote the usual order conditions. It was shown that these methods are algebraically stable for the matrices

$$G := \mathrm{diag}\left(\hat{b}_1, \hat{b}_1+\hat{b}_2, \ldots, \sum_{j=1}^{r}\hat{b}_j\right), \quad D := \mathrm{diag}(b_1, b_2, \ldots, b_s). \tag{5.12}$$

TABLE 3
Coefficients of the fourth order MRK method from Example 5.2.

a_{11}	a_{12}	a_{21}	a_{22}
0.47790690818421	0.87165188291653	−0.08663699023763	0.50361252124048

b_1	b_2	$\hat{b}_1$	$\hat{b}_2$
0.95532987568936	0.79063681672548	$2\sqrt{15}-7$	$8-2\sqrt{15}$
	c_1	c_2	
	1.59379439197950	0.44316674917114	

Obviously, those are positive-definite. Hence, (5.10) is sufficient as a condition for global stability of the corresponding extended GL method.

Example 5.2. By combining the fourth order MRK method from [14] with the CS quadrature rule of order 4, we can obtain an extended GL method with $r = 2$ and $s = 2$. It is written schematically below; for the values of the coefficients we refer the reader to Table 3.

$$\begin{cases} Y^{(n)} = h\left[\begin{pmatrix} a_{11} & a_{12} \\ a_{21} & a_{22} \end{pmatrix} \otimes I_N\right] F^{(n)} + \left[\begin{pmatrix} \hat{a}_{11} & \hat{a}_{12} \\ \hat{a}_{21} & \hat{a}_{22} \end{pmatrix} \otimes I_N\right] y^{(n-1)}, \\ y^{(n)} = h\left[\begin{pmatrix} 0 & 0 \\ b_1 & b_2 \end{pmatrix} \otimes I_N\right] F^{(n)} + \left[\begin{pmatrix} 0 & 1 \\ \hat{b}_1 & \hat{b}_2 \end{pmatrix} \otimes I_N\right] y^{(n-1)}, \end{cases} \tag{5.13}$$

where $Y^{(n)} = ({Y_1^{(n)}}^T, {Y_2^{(n)}}^T)^T$ and $y^{(n)} = ({y_{n+1}}^T, {y_{n+2}}^T)^T$, with $Y_i^{(n)} \cong y(t_n + c_i h)$ and $y_n \cong y(t_n)$, and

$$F^{(n)} = \left(f\left(t_n + c_1 h, Y_1^{(n)}, Y_1^{(n-m)}, Z_1^{(n)}\right)^T, f\left(t_n + c_2 h, Y_2^{(n)}, Y_2^{(n-m)}, Z_2^{(n)}\right)^T \right)^T.$$

$Z_j^{(n)}$ is computed by the CS rule with an even integer $m \geq 4$:

$$\begin{aligned} Z_j^{(n)} = \frac{h}{3}\Bigg[& g\left(t_{n,j}, t_{n,j}, Y_j^{(n)}\right) + 4\sum_{q=1}^{m/2} g\left(t_{nj}, t_{n-2q+1,j}, Y_j^{(n-2q+1)}\right) \\ & + 2\sum_{q=1}^{(m-2)/2} g\left(t_{n,j}, t_{n-2q,j}, Y_j^{(n-2q)}\right) + g\left(t_{n,j}, t_{n-m,j}, Y_j^{(n-m)}\right)\Bigg]. \end{aligned} \tag{5.14}$$

Here the notation $t_{n,j}$ is used as shorthand for $t_n + c_j h$. This rule satisfies (3.5) for $\nu = \frac{\sqrt{20}}{3}\tau$. Under condition (5.10) this extended MRK method is globally stable. The stability constant (5.2) can be computed using $d = 1.7460$, $\nu = \frac{\sqrt{20}}{3}\tau$, $\lambda_{min}^G = 2\sqrt{15} - 7$, and $\lambda_{max}^G = 1$.

In [24], the MRK methods that satisfy (5.11) are called *MRK methods of the first class*. Five more classes of MRK methods are identified by Li in the above reference. All of those are proven to be algebraically stable for the matrices (5.12). Hence, Corollary 5.4 is immediately applicable to the corresponding extended GL methods.

TABLE 4
Coefficients of the third order MRK method from Example 5.3.

	c_1	c_2	
	1.80000000000000	0.91245791245791	

Example 5.3. We present an example of the second MRK class. Using formulas (3.11)–(3.16) of [24], we compute the coefficients for a two-stage third order MRK method. Its combination with the CG rule of order 3 (cf. [9]) yields another extended GL method of the form (5.13). The coefficients are given in Table 4. The $Z_j^{(n)}$-values are computed as follows:

$$\begin{aligned} Z_j^{(n)} = \frac{h}{12}\Bigg[& 5\, g(t_{n,j}, t_{n,j}, Y_j^{(n)}) + 13\, g(t_{n,j}, t_{n-1,j}, Y_j^{(n-1)}) \\ & + 12 \sum_{q=2}^{m-2} g(t_{n,j}, t_{n-q,j}, Y_j^{(n-q)}) + 13\, g(t_{n,j}, t_{n-m+1,j}, Y_j^{(n-m+1)}) \\ & + 5\, g(t_{n,j}, t_{n-m,j}, Y_j^{(n-m)}) \Bigg]. \end{aligned} \tag{5.15}$$

Since the corresponding underlying method is algebraically stable, and since the CG rule satisfies (3.5) with $\nu = 2\tau$, we immediately have global stability of the extended GL method under condition (5.11). The stability constant (5.2) can be computed using $d = 1.1500$, $\nu = 2\tau$, $\lambda_{min}^G = 0.15$, and $\lambda_{max}^G = 1$.

6. Asymptotic stability of the extended GL methods. In this section, we focus on the concept of asymptotic stability.

DEFINITION 6.1. *The extended GL method* (3.3) *and* (3.4) *is called asymptotically stable for problems of class* $\mathbb{GRI}(\alpha, \beta, \sigma, \gamma)$ *if* $\lim_{n\to\infty} \|\Delta y^{(n)}\| = 0$.

THEOREM 6.2. *Suppose that GL method* (3.1) *is* (k, l)*-algebraically stable for a nonnegative diagonal matrix* $D = \mathrm{diag}(d_1, d_2, \ldots, d_s) \in \mathbb{R}^{s\times s}$ *and a real symmetric positive-definite matrix* $G = (g_{ij}) \in \mathbb{R}^{r\times r}$*, where* $0 < k < 1$*, and suppose the quadrature formula* (3.4) *satisfies* (3.5)*. Then the extended GL method* (3.3) *and* (3.4) *is asymptotically stable for the class* $\mathbb{GRI}(\alpha, \beta, \sigma, \gamma)$ *when the following condition holds:*

$$h(\alpha + \beta + \sigma\gamma^2\nu^2) < l. \tag{6.1}$$

Proof. Define the quantity $\theta = \max\{k, [\frac{h(\beta+\sigma\gamma^2\nu^2)}{l-h\alpha}]^{\frac{1}{m}}\}$. From $0 < k < 1$ and (6.1) it follows that $0 < k \le \theta < 1$. Hence, bound (4.2) from Lemma 4.1 holds. We will simplify its right-hand side. By using (4.8), we can derive the following bound:

$$h\sum_{i=0}^{n-1}\theta^{-i}\sum_{q=0}^{m}\|\Delta Y_j^{(i-q)}\|^2$$
$$\le h\left[\sum_{q=0}^{m}\sum_{i=0}^{n-1}\theta^{-(i+q)}\|\Delta Y_j^{(i)}\|^2+\left(\sum_{q=1}^{m}\sum_{i=1}^{q}\theta^{-(q-i)}\right)\max_{-m\le\hat{q}\le-1}\{\|\Delta Y_j^{(\hat{q})}\|^2\}\right]$$
$$\le (m+1)h\sum_{i=0}^{n-1}\theta^{-(i+m)}\|\Delta Y_j^{(i)}\|^2+m\tau\theta^{1-m}\max_{-m\le i\le-1}\{\|\Delta Y_j^{(i)}\|^2\}. \tag{6.2}$$

Substituting (6.2) into the last term of the right-hand side of (4.2) yields

$$\|\Delta y^{(n)}\|_G^2\le\theta^n\|\Delta y^{(0)}\|_G^2+2\tau\theta^{n-m}d\left[\beta+\frac{m\sigma\gamma^2\nu^2}{m+1}\right]\max_{-m\le i\le-1}\max_{1\le j\le s}\{\|\Delta Y_j^{(i)}\|^2\}$$
$$+2[(h\alpha-l)\theta^m+h(\beta+\sigma\gamma^2\nu^2)]\sum_{i=0}^{n-1}\theta^{n-m-i-1}\sum_{j=1}^{s}d_j\|\Delta Y_j^{(i)}\|^2. \tag{6.3}$$

By the definition of θ and with the inequalities $h\alpha\le h(\alpha+\beta+\sigma\gamma^2\nu^2)<l$, one finds

$$(h\alpha-l)\theta^m+h(\beta+\sigma\gamma^2\nu^2)\le 0.$$

This inequality, together with the knowledge that $0<\theta<1$ and (6.3), leads to $\lim_{n\to\infty}\|\Delta y^{(n)}\|_G=0$ or $\lim_{n\to\infty}\|\Delta y^{(n)}\|=0$. ∎

REMARK 6.3. *The major difference between Theorems* 6.2 *and* 5.3 *lies in the strict inequalities present in both* $k<1$ *and* (6.1).

Example 6.1. As an illustration we consider the method (5.7) and (5.8) again. Recall that (5.8) satisfies (3.5) with $\nu=2\tau$ and that the underlying GL method (5.7) is $(1/(1-2l),l)$-algebraically stable for any $l\le 0$. Thus, we have $0<k<1$ whenever $l<0$. Moreover, there always exists an $l\,(<0)$ such that $h(\alpha+\beta+\sigma\gamma^2\nu^2)<l$ whenever $\beta+\sigma\gamma^2\nu^2<-\alpha$. Hence, the latter is sufficient as a condition for asymptotic stability.

From Theorem 6.2, it is not immediately possible to derive a corollary that applies specifically for algebraically stable methods because of the condition $k<1$. To remedy this situation, we present an alternative approach for proving asymptotic stability, where the parameter k will be allowed to take the value 1.

THEOREM 6.4. *Suppose that the GL method* (3.1) *is strictly stable at infinity and* (k,l)*-algebraically stable for a positive diagonal matrix* $D=\operatorname{diag}(d_1,d_2,\dots,d_s)\in\mathbb{R}^{s\times s}$ *and a real symmetric positive-definite matrix* $G=(g_{ij})\in\mathbb{R}^{r\times r}$*, where* $0<k\le 1$*. Suppose the quadrature formula* (3.4) *satisfies* (3.5)*. Then the extended GL method* (3.3) *and* (3.4) *is asymptotically stable for the class* $\mathbb{GRI}(\alpha,\beta,\sigma,\gamma)$ *when* (6.1) *holds.*

Proof. Inequality (5.6) can be written as

$$\|\Delta y^{(n)}\|_G^2+2[l-h(\alpha+\beta+\sigma\gamma^2\nu^2)]\sum_{i=0}^{n-1}\sum_{j=1}^{s}d_j\|\Delta Y_j^{(i)}\|^2$$
$$\le\|\Delta y^{(0)}\|_G^2+d\tau(2\beta+\sigma\gamma^2\nu^2)\max_{-m\le i\le-1}\max_{1\le j\le s}\{\|\Delta Y_j^{(i)}\|^2\}. \tag{6.4}$$

Since D is a positive diagonal matrix and since (6.1) holds, we may conclude from (6.4) that $\lim_{n\to\infty}\|\Delta Y_j^{(n)}\|^2=0$ for $j=1,2,\dots,s$, and thus

$$\lim_{n\to\infty}\|\Delta Y^{(n)}\|=\lim_{n\to\infty}\sqrt{\sum_{j=1}^{s}\|\Delta Y_j^{(n)}\|^2}=0. \tag{6.5}$$

The remainder of the proof is divided into two parts. First, we consider the case where matrix C_{11} is invertible. Then, by (4.1), we have

$$\Delta y^{(n)} = [R(\infty) \otimes I_N]\Delta y^{(n-1)} + [C_{21}C_{11}^{-1} \otimes I_N]\Delta Y^{(n)}, \tag{6.6}$$

where $R(\infty) = C_{22} - C_{21}C_{11}^{-1}C_{12}$. Because of the strict stability at infinity, one has

$$\rho[R(\infty) \otimes I_N] = \rho[R(\infty)] < 1. \tag{6.7}$$

Therefore, applying Lemma 4.6 to (6.6) yields $\lim_{n\to\infty} \|\Delta y^{(n)}\| = 0$.

Next, we consider the case that matrix C_{11} is singular. We replace it in (6.6) by the invertible matrix $(C_{11} + \varepsilon I_s)$ and let $\varepsilon \to 0$. This gives

$$\Delta y^{(n)} = [R(\infty) \otimes I_N]\Delta y^{(n-1)} + (C_0 \otimes I_N)\Delta Y^{(n)}, \tag{6.8}$$

where $R(\infty) = C_{22} - C_0C_{12}$ and $C_0 = \lim_{\varepsilon\to 0} C_{21}(C_{11} + \varepsilon I_s)^{-1}$, whose existence is ensured by Lemma 4.2. Another application of Lemma 4.6 completes the proof. ∎

When the GL method satisfies algebraic stability, Theorem 6.4 can be simplified.

COROLLARY 6.5. *Suppose that the GL method* (3.1) *is strictly stable at infinity and algebraically stable for a positive diagonal matrix* $D = \mathrm{diag}(d_1, d_2, \ldots, d_s) \in \mathbb{R}^{s\times s}$ *and a real symmetric positive-definite matrix* $G = (g_{ij}) \in \mathbb{R}^{r\times r}$*, and suppose the quadrature formula* (3.4) *satisfies* (3.5)*. Then the extended GL method* (3.3) *and* (3.4) *is asymptotically stable for the class* $\mathbb{GRI}(\alpha, \beta, \sigma, \gamma)$ *when the following condition holds:*

$$\beta + \sigma\gamma^2\nu^2 < -\alpha. \tag{6.9}$$

Example 6.2. Consider the extended GL method from Example 5.2. A computation shows that $\rho[R(\infty)] \cong 0.9816 < 1$, which implies strict stability. So, the method is asymptotically stable for problem class $\mathbb{GRI}(\alpha, \beta, \sigma, \gamma)$ under condition (6.9).

Example 6.3. Consider the extended GL method from Example 5.3. Now, we find that $\rho[R(\infty)] \cong 0.6158 < 1$. Hence, also for this method (6.9) is a sufficient condition to guarantee asymptotic stability.

7. Numerical experiments and convergence. In the previous sections we have proven that the extended GL methods possess an excellent stability behavior under a set of suitable conditions. Naturally, one also wishes to find out the actual computational performance and their accuracy in particular. Therefore, we will apply the methods from Examples 5.1, 5.2, and 5.3 to two MVIDE systems. In order to measure the quality of the numerical methods, we introduce the following:

$$err := \|y(t_n) - y_n\|_\infty, \quad \varepsilon := \max_{0\le n\le N_f} \|y(t_n) - y_n\|_\infty, \quad p := \ln(\varepsilon)\,/\,\ln(h),$$

where N_f is a positive integer such that $N_f h = T$ with T being the length of the solution interval. The symbols *err*, ε, and p denote the error at time point t_n, the maximum error over the interval, and the convergence order of the method, respectively.

We will pay particular attention to the estimate of the convergence order. Our numerical results will seem to indicate that the convergence order of the extended GL method equals the minimum of the orders of the underlying GL method and the quadrature rule. These results are not entirely unexpected (see, e.g., the discussion of the combined order problem in [9, section 3.4]), and will be verified through a number

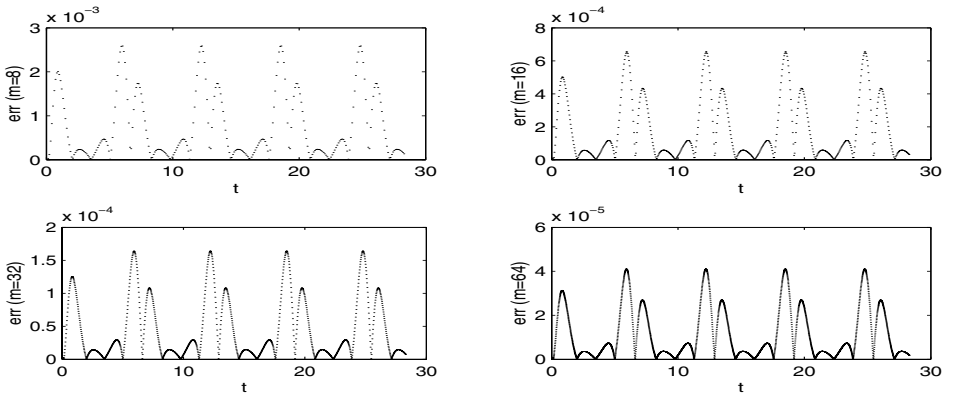

FIG. 7.1. *Error of the method from Example* 5.1 *with* $m = 8, 16, 32, 64$ *for* (7.1) *on* $[0, 9\pi]$.

of examples. In the first two examples, the methods of Examples 5.1, 5.2, and 5.3 will be used. Those are characterized by a correct match between the orders of the GL method and the quadrature rule (order 2 for Example 5.1, order 3 for Example 5.3, and order 4 for Example 5.2). Further on, we will also consider methods where the order of the GL method is different from that of the quadrature rule.

Example 7.1. Consider the linear system with partially variable coefficients:

$$y'(t) = -(6 + \sin t)y(t) + y\left(t - \frac{\pi}{4}\right) - \int_{t-\frac{\pi}{4}}^{t} \sin(v)y(v)dv + 5\exp(\cos t), \ t \geq 0, \tag{7.1}$$

with an initial condition on $[-\pi/4, 0]$ such that the exact solution is given by $y(t) = \exp(\cos t)$. One may check that the problem belongs to class $\mathbb{GRI}(-4, \frac{1}{2}, \frac{1}{2}, 1)$. With Theorem 2.1 we conclude that system (7.1) satisfies stability properties (2.4) and (2.5). Moreover, based on our earlier discussions, we deduce that the numerical methods from Examples 5.1, 5.2, and 5.3 retain the stability properties of the analytical solution; for this problem they are also globally and asymptotically stable.

In order to check the convergence behavior and accuracy of the extended GL methods, they will be applied using a sequence of step lengths characterized by the parameter m on the time interval $[0, 9\pi]$. The accuracy of the obtained numerical solutions is displayed in Figures 7.1–7.3. The numerically estimated convergence orders are given in Table 5. The numerical results show that the methods are quite effective and preserve the inherent order of accuracy of the underlying components.

Example 7.2. Consider the following two-dimensional nonlinear system:

$$\begin{aligned} \frac{d}{dt}\begin{pmatrix} y_1(t) \\ y_2(t) \end{pmatrix} &= -4\begin{pmatrix} y_1(t) \\ y_2(t) \end{pmatrix} + \begin{pmatrix} 0 & \sin t \\ \cos t & 0 \end{pmatrix}\begin{pmatrix} y_1(t-\frac{\pi}{5}) \\ y_2(t-\frac{\pi}{5}) \end{pmatrix} \\ &\quad + \frac{1}{\sqrt{2}}\int_{t-\frac{\pi}{5}}^{t} \begin{pmatrix} \frac{(1+\sin^2 v)y_1^2(v)}{1+y_1^2(v)} \\ \frac{(1+\cos^2 v)y_2^2(v)}{1+y_2^2(v)} \end{pmatrix} dv + \begin{pmatrix} f(t) \\ g(t) \end{pmatrix}, \quad 0 \leq t. \end{aligned} \tag{7.2}$$

Functions $f(t)$ and $g(t)$ and the initial condition on $[-\pi/5, 0]$ are chosen in such a way that the solution equals $y(t) = (\sin t, \cos t)^T$. This problem belongs to class $\mathbb{GRI}(-4 + \frac{\sqrt{2}}{2}, \frac{\sqrt{2}}{4}, \frac{\sqrt{2}}{4}, 2)$. It follows that (7.2) satisfies stability properties (2.4) and

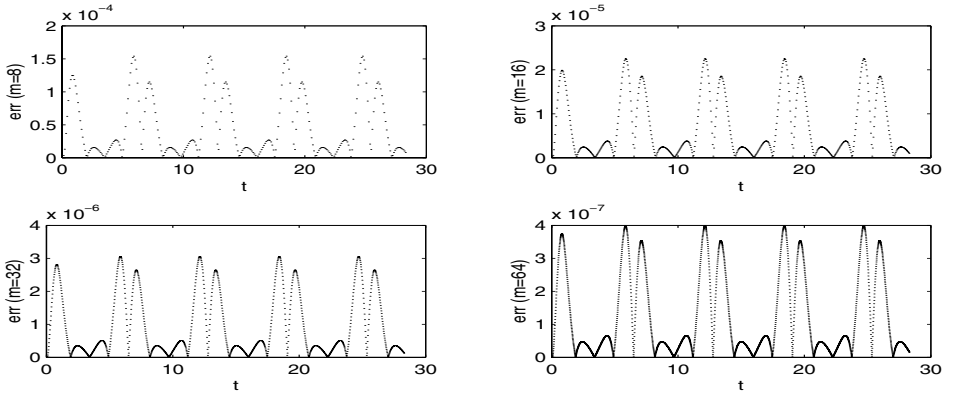

FIG. 7.2. *Error of the method from Example* 5.3 *with* $m = 8, 16, 32, 64$ *for* (7.1) *on* $[0, 9\pi]$.

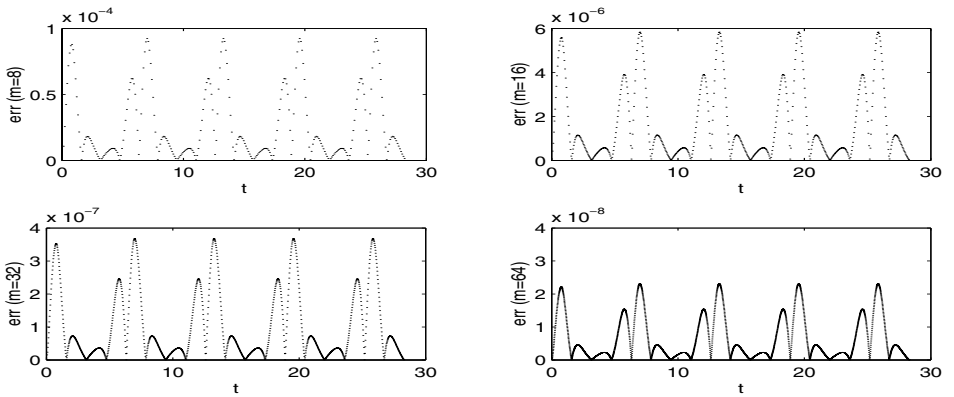

FIG. 7.3. *Error of the method from Example* 5.2 *with* $m = 8, 16, 32, 64$ *for* (7.1) *on* $[0, 9\pi]$.

TABLE 5

Convergence order of extended GL methods for system (7.1). *Example* 5.1*: 2nd order BDF + 2nd order quadrature; Example* 5.3*: 3rd order MRK + 3rd order quadrature; Example* 5.2*: 4th order MRK + 4th order quadrature.*

m	Example 5.1	Example 5.3	Example 5.2
8	2.5666	3.7821	4.0022
16	2.4327	3.5499	3.9982
32	2.3510	3.4254	3.9964
64	2.2956	3.3491	3.9960

(2.5) and that our three GL methods are globally and asymptotically stable. We consider the numerical results obtained when these methods are applied to (7.2). Note that a nonlinear equation is to be solved in every time-step. To that end, we adopted a Newton iteration, with initial values obtained by a backward interpolation formula

$$\hat{Y}_i^{(n)} = y_{n+1} + \sum_{j=1}^{Q} \frac{1}{j!} (c_i - 1)c_i(c_i + 1)(c_i + 2) \cdots (c_i + j - 2)\nabla^j y_{n+1}, \quad i = 1, 2, \ldots,$$

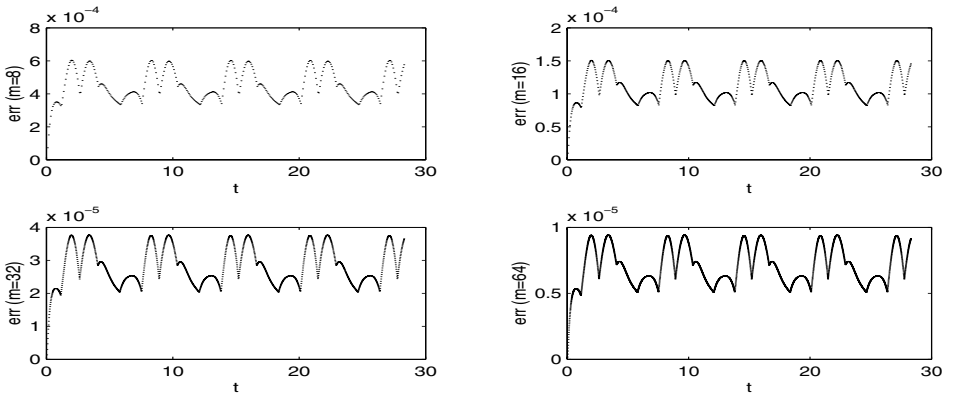

FIG. 7.4. *Error of the method from Example* 5.1 *with* $m = 8, 16, 32, 64$ *for* (7.2) *on* $[0, 9\pi]$.

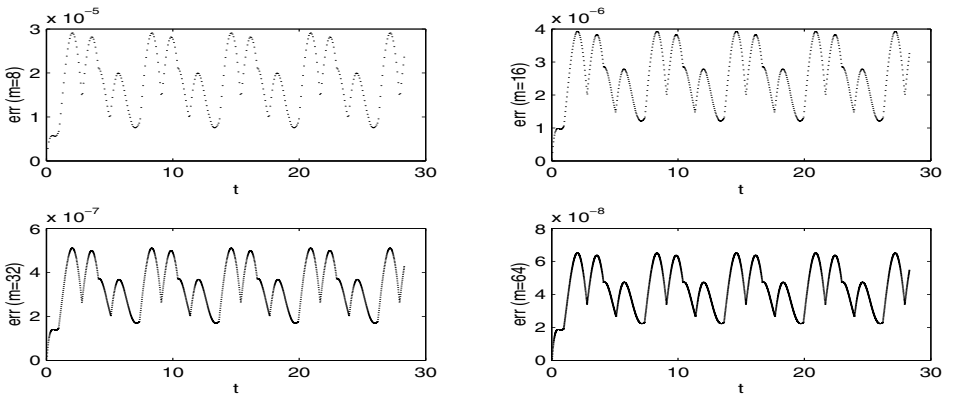

FIG. 7.5. *Error of the method from Example* 5.3 *with* $m = 8, 16, 32, 64$ *for* (7.2) *on* $[0, 9\pi]$.

where $\hat{Y}_i^{(n)} \cong y(t_n + c_i h)$ $(= y(t_{n+1} + (c_i - 1)h))$, $0 < c_i \leq 2$. More precisely, in order to get a starting value with accuracy order matching the estimated order of the extended GL methods, we take $Q = 2$, 3, 4 for the methods of Example 5.1, 5.3, and 5.2, respectively. This proved to provide a great savings in computational cost. The accuracy of the numerical solutions are shown in Figures 7.4–7.6, and the estimated convergence orders are given in Table 6. As in the previous example, the methods again seem to preserve the inherent accuracy of the underlying components.

Example 7.3. Naturally, one also wishes to know what happens to an extended GL method when the order of the underlying method differs from that of the quadrature formula. In order to gain some insight, we considered the third order MRK method from Example 5.3 combined with the first order quadrature formula

$$Z_j^{(n)} = h \sum_{q=0}^{m} g(t_{n,j}, t_{n-q,j}, Y_j^{(n-q)}), \quad j = 1, 2, \tag{7.3}$$

combined with the second order quadrature formula

$$Z_j^{(n)} = h \sum_{q=0}^{m}{}'' \, g\left(t_{n,j}, t_{n-q,j}, Y_j^{(n-q)}\right), \quad j = 1, 2, \tag{7.4}$$

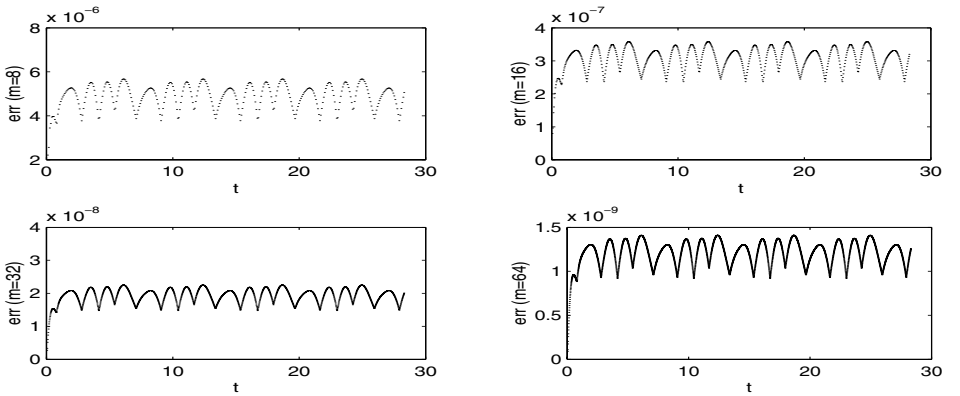

FIG. 7.6. *Error of the method from Example* 5.2 *with* $m = 8, 16, 32, 64$ *for* (7.2) *on* $[0, 9\pi]$.

64	1.3489	2.8821	3.5787	3.6492

and combined with the fourth order quadrature formula (5.14). The estimated convergence orders are given in Table 7. For completeness, we also added the second column from Table 6, where the method was combined with a third order quadrature method. Finally, in Table 8, we present similar results for the fourth order MRK method from Example 5.2 combined with four quadrature rules of different orders.

All of these results seem to indicate that the order of the extended GL method is equal to the minimum of the orders of its two components: the underlying GL method and the quadrature rule. A proof for this observation and a derivation of the conditions under which it would hold for class $\mathbb{GRI}(\alpha, \beta, \sigma, \gamma)$ remain to be found.

8. Concluding remarks. We have investigated the stability of extended GL methods for a class of nonlinear MVIDEs. Numerical examples illustrate the convergence and the effectiveness of the methods. Our findings extend and improve

our earlier results reported in [33]. Specializing our results to the DDE $y'(t) = f(t, y(t), y(t-\tau))$, we find our results to be consistent with those in [20], slightly weaker than those in [30], and substantially different from those in [28, 29, 6, 7, 31, 32, 25]. As a conclusion, we would like to point out the precise differences.

In [30], the author studied the implicit Euler method for DDEs and proved that this method satisfies the following stability property:

$$\|y_n - \tilde{y}_n\| \leq \max_{t_0-\tau\leq t\leq t_0} \|\varphi(t) - \psi(t)\| \quad \forall n \geq 0. \tag{8.1}$$

This strong property could be derived thanks to the relatively simple structure of the Euler scheme. The approach cannot be generalized to more complex methods.

In [28, 29], linear and nonlinear DDEs of class $\mathbb{GRI}(-\rho, \rho, 0, 0)$ with $\rho > 0$ are considered. When an A-stable RK method is used in the linear case or an algebraically stable RK method is used in the nonlinear case, a specialized stability result can be derived, called B_ρ-stability. In particular, it is shown that

$$\lceil y_{n+1} - \tilde{y}_{n+1} \rceil \leq \lceil y_n - \tilde{y}_n \rceil, \tag{8.2}$$

where the notation $\lceil \cdot \rceil$ is defined as follows:

$$\lceil y_n \rceil^2 = \frac{1}{2}\|y_n\|^2 + h\rho \sum_{n-m\leq j\leq n-1} \sum_{i=1}^{s} b_i \|y_i^{(j)}\|.$$

This clearly shows the perturbation behavior of a combination of the numerical solution and the stage value approximations. In practice, however, one usually wishes to check the perturbation behavior of the numerical solution only.

In [6, 31], based on the concept of (semi-) BN_f-stability of the underlying continuous RK methods, the authors derived (RN-) GRN-stability results for RK methods for DDEs, with a stability inequality characterized by (8.1). The special cases of continuous RK methods applied to linear autonomous and nonautonomous DDE problems are also considered. The concept of BN_f-stability is then specialized into that of A_f-stability and that of AN_f-stability, respectively. Under those conditions, (8.1) is obtained again. For more details and some extensions we refer the reader to [7]. The assumption of (semi-) BN_f-stability is rather strong, however, as it leads to an order barrier for the underlying RK methods. Indeed, in [32] it is shown that four is a sure order barrier for any BN_f-stable RK method. Moreover, at this moment, only two BN_f-stable RK methods have been found: the implicit Euler method and the Lobatto IIIC method with linear interpolation. Our research on the contrary is based on algebraic stability, which does not usually suffer from such a strong order barrier.

In [25], Li studies RK methods applied to general Volterra functional differential equations. Under the condition of B-stability, it is shown that the numerical solutions y_n and $\tilde{y}_n$ obtained from two different sets of initial data $\{\varphi(t), y_1, y_2, \ldots, y_k\}$ and $\{\psi(t), \tilde{y}_1, \tilde{y}_2, \ldots, \tilde{y}_k\}$ satisfy the following stability inequality:

$$\|y_n - \tilde{y}_n\| \leq \exp(c(t_n - t_k)) \max \left\{ \max_{1\leq i\leq k} \|y_i - \tilde{y}_i\|, \max_{t_0-\tau\leq t\leq t_0} \|\varphi(t) - \psi(t)\| \right\}, \tag{8.3}$$

where c is a positive constant and h_n a variable step size. Note that the stability function $\mathcal{H}(t) := \exp(c(t-t_k))$ in (8.3) is increasing for $t \geq t_0$ and will tend to infinity when $t \to +\infty$. Hence, (8.3) is applicable only on a finite time interval. Our stability results on the contrary can be applied on the infinite time interval since the stability function is a constant $\mathcal{H}$ and is independent of the time variable t.

CONTACT ANALYSIS OF CABLE NETWORKS BY USING SECOND-ORDER CONE PROGRAMMING*

YOSHIHIRO KANNO† AND MAKOTO OHSAKI‡

Abstract. A method based on mathematical programming is proposed for large deformation and contact analysis of cable networks. By explicitly considering these nonsmooth behaviors, we formulate the linear complementarity problems over symmetric cones under some practically acceptable assumptions. We also present the equivalent second-order cone programming (SOCP) problems, which can be regarded as the minimization problem of total potential energy and complementary energy with the subsidiary constraints on the displacements and contact forces, respectively. By solving the presented SOCP problems by using the primal-dual interior-point method, the equilibrium configurations and internal forces of several cable networks are obtained without any assumptions on stress states and contact conditions.

Key words. second-order cone programming, cable network, contact problem, complementarity problem, primal-dual interior-point method

1. Introduction.

Nonsmooth behavior of mechanical systems, such as contact mechanics, slackening of cables, and wrinkling of membranes, has received increasing attention [14, 31]. In particular, contact problems have been extensively studied in the literature. The variational inequality formulations of the elastostatic frictional unilateral contact problem were reviewed in [28, 29]. The frictionless unilateral contact problem, which is well known as the Signorini problem, is classical but still important [1, 11, 20, 23]. For multi–rigid-body systems, both formulations and algorithms for the static, quasi-static, and dynamic contact problems were investigated [3, 34, 38, 41]. The general frameworks for the frictional contact problem were presented based on the complementarity problems [33]. For two-body contact problems, various numerical approaches, such as the finite element method, have been developed [15, 16, 27].

Stress-unilateral behaviors have also received much attention due to their wide field of application, which includes equilibrium analysis of masonry structures [8, 10] and membrane structures [6, 12, 25, 35]. For cable networks, however, few studies have dealt explicitly with the slackening of cables [5, 9, 32].

This paper deals with two types of nonsmooth behaviors; i.e., we consider the cable networks where each member can transmit only tension force, and suppose that some members may possibly make contact with each other or with rigid obstacles at the equilibrium state. Geometrical nonlinearity due to large deformation is also considered.

In the conventional approaches to contact problems, we typically choose a set of contact candidates. Each candidate is defined as the pair of node and contact surface for unilateral contact problems [28], or that of two nodes for two-body contact

problems [20]. We should choose an appropriate set of candidates satisfying some assumptions, e.g., the assumption that the contact occurs only at these candidates. It is difficult, however, to choose such sets generally, especially if we allow finite deformation. We shall show that, for contact problems of cable networks, we do not have to identify the locations of candidate nodes but only have to choose some members as candidates. Therefore, it is rather easy to select an appropriate set of candidates, which is illustrated by using an example in section 4. The contact conditions between the two cables, and between the cable and obstacle, respectively, are formulated as the complementarity conditions in sections 3 and 4.

Concerning stress-unilateral behavior, in the existing incremental methods based on the tangent stiffness [4], the tangent stiffness matrix should be constructed by using the information on the stress states. Since such information and the obtained displacement increments may conflict, these methods sometimes cannot find a convergent solution [19]. Another difficulty exists in the singularity of the tangent stiffness matrix in the case where many cable members are slackening. In contrast, we formulate the constitutive law in terms of the internal force vector and the member deformation vector as the complementarity condition over *second-order cones* [7].

By explicitly considering these nonsmooth behaviors, we formulate the linear complementarity problems over symmetric cones to obtain the equilibrium configurations of cable networks under the contact conditions. We also present the equivalent *second-order cone programming* (SOCP) [7] problems. SOCP is a class of nonlinear convex programming including linear programming and convex quadratic programming. The primal-dual interior-point algorithms have been developed for SOCP, which can obtain the global optimal solution in time polynomial in the problem size [7, 30, 39, 40]. It should be emphasized that the equilibrium configuration can be obtained by solving an SOCP problem which is convex and independent of both the stress states of cable members and contact states.

This paper is organized as follows. In section 2, we introduce SOCP and, in order to make this paper self-contained, we revisit the SOCP formulation presented in [19], which has the same optimizer as the minimization of total potential energy for cable networks without contact conditions. In section 2.2, we formulate the constitutive law considering the slackening of cable and geometrical nonlinearity into the complementarity conditions over the second-order cones which will play a key role in sections 3 and 4. Sections 3 and 4, respectively, are devoted to formulating SOCP problems for the two-body contact problem and unilateral contact problem of cable networks. By introducing the concept of auxiliary frictionless node, we define the contact candidates as the pairs of two members of the cable network, or those of members and edges of the obstacle. Under some practically acceptable assumptions, we formulate the complementarity problems over second-order cones and present the equivalent SOCP problems. In section 5, equilibrium configurations of cable networks with various contact conditions are obtained by solving the proposed SOCP problem by using the primal-dual interior-point method [39]. Some technical results are proved in section 6. We conclude the paper in section 7.

2. Preliminaries.

2.1. Second-order cone program. For any $\boldsymbol{p} \in \mathbf{R}^n$, let $\|\boldsymbol{p}\|$ denote the standard Euclidean norm defined by $\|\boldsymbol{p}\| = (\boldsymbol{p}^\top \boldsymbol{p})^{1/2}$. All the vectors are assumed to be column vectors. However, for vectors $\boldsymbol{p} \in \mathbf{R}^n$ and $\boldsymbol{q} \in \mathbf{R}^m$, we often write $(\boldsymbol{p}, \boldsymbol{q}) = (\boldsymbol{p}^\top, \boldsymbol{q}^\top)^\top \in \mathbf{R}^{n+m}$ in order to simplify the notation.

Let $\mathbf{R}^n_+ \subset \mathbf{R}^n$ and $\mathbf{L}^n_+ \subset \mathbf{R}^n$ denote the nonnegative orthant and the *second-order cone* (or the *Lorentz cone*) [7], respectively, which are defined as

$$\mathbf{R}^n_+ = \{\boldsymbol{x} = (x_1, \ldots, x_n) \in \mathbf{R}^n \,|\, x_i \geq 0 \ (i = 1, \ldots, n)\},$$
$$\mathbf{L}^n_+ = \{\boldsymbol{x} = (x_0, \boldsymbol{x}_1) \in \mathbf{R}^n \,|\, x_0 \geq \|\boldsymbol{x}_1\|\}.$$

Let $\mathcal{K} \subset \mathbf{R}^n$ denote a convex cone. $\mathcal{K}^* \subset \mathbf{R}^n$ denotes the dual cone of $\mathcal{K}$ defined by $\mathcal{K}^* = \{\boldsymbol{s} \in \mathbf{R}^n \,|\, \boldsymbol{x}^\top \boldsymbol{s} \geq 0 \ (\forall \boldsymbol{x} \in \mathcal{K})\}$. The following pair of problems is known to be a primal-dual pair of *conic linear programming* (cone LP) problems [7]:

$$(\mathrm{P}_{\mathrm{cone}}): \quad \min \quad \boldsymbol{c}^\top \boldsymbol{x} \qquad \text{s.t.} \quad \boldsymbol{A}\boldsymbol{x} = \boldsymbol{b}, \quad \boldsymbol{x} \in \mathcal{K}, \tag{2.1}$$

$$(\mathrm{D}_{\mathrm{cone}}): \quad \max \quad \boldsymbol{b}^\top \boldsymbol{y} \qquad \text{s.t.} \quad \boldsymbol{c} - \boldsymbol{A}^\top \boldsymbol{y} \in \mathcal{K}^*, \tag{2.2}$$

where $\boldsymbol{A} \in \mathbf{R}^{m \times n}$, $\boldsymbol{b} \in \mathbf{R}^m$, and $\boldsymbol{c} \in \mathbf{R}^n$ are constants, and $\boldsymbol{x} \in \mathbf{R}^n$ and $\boldsymbol{y} \in \mathbf{R}^m$ are variables. In this paper, we deal with the special class of cone LP problems; i.e., suppose that $\mathcal{K} \subset \mathbf{R}^n$ is written as $\mathcal{K} = \mathcal{K}_1 \times \cdots \times \mathcal{K}_k$, where $\mathcal{K}_i = \mathbf{R}^{n_i}_+$ or $\mathbf{L}^{n_i}_+$, and $n = \sum_{i=1}^k n_i$. Since $\mathbf{R}^n_+$ and $\mathbf{L}^n_+$ have self-dual properties [7], i.e., $(\mathbf{R}^n_+)^* = \mathbf{R}^n_+$ and $(\mathbf{L}^n_+)^* = \mathbf{L}^n_+$, we have $\mathcal{K}^* = \mathcal{K}$. By introducing $\boldsymbol{x}_i \in \mathbf{R}^{n_i}$, $\boldsymbol{A}_i \in \mathbf{R}^{m \times n_i}$, and $\boldsymbol{c}_i \in \mathbf{R}^{n_i}$ $(i = 1, \ldots, k)$, (2.1) and (2.2) are explicitly rewritten as

$$\begin{cases} (\mathrm{P}): \quad \min \quad \displaystyle\sum_{i=1}^k \boldsymbol{c}_i^\top \boldsymbol{x}_i \\ \qquad\quad \text{s.t.} \quad \displaystyle\sum_{i=1}^k \boldsymbol{A}_i \boldsymbol{x}_i = \boldsymbol{b}, \quad \boldsymbol{x}_i \in \mathcal{K}_i \quad (i = 1, \ldots, k), \end{cases} \tag{2.3}$$

$$\begin{cases} (\mathrm{D}): \quad \max \quad \boldsymbol{b}^\top \boldsymbol{y} \\ \qquad\quad \text{s.t.} \quad \boldsymbol{c}_i - \boldsymbol{A}_i^\top \boldsymbol{y} \in \mathcal{K}_i \quad (i = 1, \ldots, k), \end{cases} \tag{2.4}$$

which are classified as the SOCP problems [2]. Since $\mathbf{R}^n_+ = (\mathbf{L}_+)^n$, SOCP includes the *linear programming* (LP) problem as a special case. SOCP has received increasing attention for its wide fields of application [7, 17, 24, 37]. The primal-dual interior-point methods, which were developed for LP [21] at first, have been naturally extended to SOCP [2, 30, 40]. It is theoretically guaranteed that the primal-dual interior-point method converges to the global optimal solution of (P) and (D) within the number of arithmetic operations bounded by a polynomial of m and n.

We make the following assumptions:

1. (2.3) and (2.4) have interior feasible solutions;
2. rows of the matrix $(\boldsymbol{A}_1, \ldots, \boldsymbol{A}_n) \in \mathbf{R}^{m \times n}$ are linearly independent.

Under the first assumption, it is known that (2.3) and (2.4) have optimal solutions which have the same optimal value, and that solving (2.3) and (2.4) is equivalent to finding the following $\boldsymbol{x} = (\boldsymbol{x}_1, \ldots, \boldsymbol{x}_k)$, $\boldsymbol{y}$ and $\boldsymbol{s} = (\boldsymbol{s}_1, \ldots, \boldsymbol{s}_k)$ [7, 40]:

$$\begin{cases} (\mathrm{PD}): \quad \boldsymbol{s}_i^\top \boldsymbol{x}_i = 0 \quad (i = 1, \ldots, k), \\ \qquad\quad \displaystyle\sum_{i=1}^k \boldsymbol{A}_i \boldsymbol{x}_i = \boldsymbol{b}, \quad \boldsymbol{x}_i \in \mathcal{K}_i \quad (i = 1, \ldots, k), \\ \qquad\quad \boldsymbol{s}_i = \boldsymbol{c}_i - \boldsymbol{A}_i^\top \boldsymbol{y} \in \mathcal{K}_i \quad (i = 1, \ldots, k). \end{cases} \tag{2.5}$$

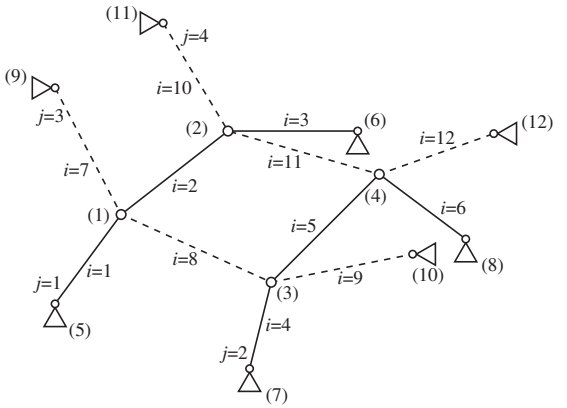

FIG. 1. *Cable network with frictionless joints.*

2.2. Complementarity conditions for frictionless cable networks. Consider a cable network in three-dimensional space. A physically continuous cable connecting a support and a pin-joint or two pin-joints is simply referred to as a *cable*. A cable is divided into several *members* by *frictionless joints*, which can move freely along the cable.

Let n^{m} and n^{c} denote the numbers of members and cables, respectively. $\boldsymbol{x} \in \mathbf{R}^{n^{\mathrm{d}}}$ denotes the vector of coordinates of internal nodes at the deformed state, where n^{d} is the number of degrees of freedom of displacements. Let $\boldsymbol{h}_i \in \mathbf{R}^3$ denote the vector that has the same length and direction as those of the ith member at the deformed state. Then $\boldsymbol{h}_i$ is written as

$$\boldsymbol{h}_i = \boldsymbol{B}_i \boldsymbol{x} - \boldsymbol{d}_i \quad (i = 1, \ldots, n^{\mathrm{m}}), \tag{2.6}$$

where $\|\boldsymbol{h}_i\|$ coincides with the member length at the deformed state. For each $i = 1, \ldots, n^{\mathrm{m}}$, $\boldsymbol{B}_i \in \mathbf{R}^{3 \times n^{\mathrm{d}}}$ is a constant matrix determined only by the connectivity of nodes and the ith member, each element of which is either $\{-1, 0, 1\}$. $\boldsymbol{d}_i \in \mathbf{R}^3$ is a constant vector that consists of the specified coordinates of support if the ith member is connected to the support; otherwise $\boldsymbol{d}_i = \boldsymbol{0}$. Consider a simple example of a cable network illustrated in Figure 1, which consists of four cables indicated as $j = 1, \ldots, 4$. These cables are connected by frictionless joints (1)–(4), whereas nodes (5)–(12) are fixed supports. Hence, we see $n^{\mathrm{c}} = 4$, $n^{\mathrm{m}} = 12$, and $n^{\mathrm{d}} = 12$.

The subset $\mathcal{I}_j$ of $\{1, 2, \ldots, n^{\mathrm{m}}\}$ is defined for each $j = 1, \ldots, n^{\mathrm{c}}$ such that the ith member satisfying $i \in \mathcal{I}_j$ belongs to the jth cable, where $\mathcal{I}_{j_1} \cap \mathcal{I}_{j_2} = \emptyset$ $(j_1 \neq j_2)$ and $\mathcal{I}_1 \cup \cdots \cup \mathcal{I}_{n^{\mathrm{c}}} = \{1, 2, \ldots, n^{\mathrm{m}}\}$. For example, in the case of the cable network illustrated in Figure 1, the cable $j = 1$ is divided into members $i = 1, 2, 3$; i.e., we have $\mathcal{I}_1 = \{1, 2, 3\}$, $\mathcal{I}_2 = \{4, 5, 6\}$, $\mathcal{I}_3 = \{7, 8, 9\}$, and $\mathcal{I}_4 = \{10, 11, 12\}$. Letting ℓ_j^0 and c_j denote the specified initial unstressed length and the elongation at the deformed state of the jth cable, respectively, we see that

$$c_j = \sum_{i \in \mathcal{I}_j} \|\boldsymbol{h}_i\| - \ell_j^0 \quad (j = 1, \ldots, n^{\mathrm{c}}), \tag{2.7}$$

which is regarded as the geometrically exact compatibility condition. Assume that

the strain energy w_j and the axial force q_j of the jth cable are written as

$$w_j(c_j) = \begin{cases} k_j c_j^2/2 & (c_j \geq 0), \\ 0 & (-\ell_j^0 \leq c_j < 0), \end{cases} \qquad q_j = \frac{\partial w_j(c_j)}{\partial c_j}, \tag{2.8}$$

where $k_j > 0$ denotes the specified extensional stiffness. Notice here that the constitutive law (2.8) represents the nonsmooth behavior due to slackening of cables. The relation between the member deformation $\boldsymbol{h}_i \in \mathbf{R}^3$ and the internal force $\boldsymbol{v}_i \in \mathbf{R}^3$ of the ith member is written as

$$\boldsymbol{v}_i \|\boldsymbol{h}_i\| = q_j \boldsymbol{h}_i. \tag{2.9}$$

If $\boldsymbol{h}_i \neq \boldsymbol{0}$, then (2.9) is reduced to

$$\boldsymbol{v}_i = \begin{cases} q_j \boldsymbol{h}_i / \|\boldsymbol{h}_i\| & (q_j \geq 0), \\ \boldsymbol{0} & (q_j = 0), \end{cases} \tag{2.10}$$

which implies that $\boldsymbol{h}_i$ and $\boldsymbol{v}_i$ must share a common direction.

For each $j = 1, \ldots, n^{\mathrm{c}}$, consider the conditions

$$\begin{aligned} &q_j = k_j y_j, \quad q_j(y_j + \ell_j^0) - \sum_{i \in \mathcal{I}_j} \boldsymbol{v}_i^\top \boldsymbol{h}_i = 0, \\ &y_j + \ell_j^0 \geq \sum_{i \in \mathcal{I}_j} \|\boldsymbol{h}_i\|, \quad q_j \geq \|\boldsymbol{v}_i\| \quad (i \in \mathcal{I}_j), \end{aligned} \tag{2.11}$$

which can be regarded as the linear complementarity conditions over second-order cones $\mathbf{L}_+^4$ (see, e.g., [13]). The following lemma implies that (2.8) and (2.9) can be reformulated into (2.11).

LEMMA 2.1. *For each $j = 1, \ldots, n^{\mathrm{c}}$, a set of $\boldsymbol{h}_i$, c_j, y_j, q_j, and $\boldsymbol{v}_i$ $(i \in \mathcal{I}_j)$ satisfies* (2.7)–(2.9) *and*

$$y_j = \begin{cases} c_j & (c_j \geq 0), \\ 0 & (c_j < 0) \end{cases} \tag{2.12}$$

if and only if (2.7) *and* (2.11) *are satisfied.*

Proof. See section 6. ∎

Notice here that the nonsmooth property due to slackening of cable as well as the compatibility conditions can be expressed via the complementarity conditions (2.11). In (2.11), we see that the compatibility conditions $y_j + \ell_j^0 = \sum_{i \in \mathcal{I}_j} \|\boldsymbol{h}_i\|$ and the relations $q_j = \|\boldsymbol{v}_i\|$ $(i \in \mathcal{I}_j)$ are relaxed into inequalities. Moreover, (2.11) lacks the relation (2.9) between $\boldsymbol{h}_i$ and $\boldsymbol{v}_i$. Lemma 2.1 implies that all these conditions are satisfied at a solution of (2.7) and (2.11). See [18] for detailed discussions of this issue for pin-jointed cable networks without frictionless joints.

Let $\mathcal{L}_{\mathrm{f}}$ denote the set of all indices for both frictionless joints and pin-joints. In accordance with the notation used in the following sections, we put here $\mathcal{L}_{\mathrm{f}} = \{1, 2, \ldots, n^{\mathrm{n}}\}$, where n^{n} denotes the number of unconstrained nodes. For example, in Figure 1, we have $n^{\mathrm{n}} = 4$ and $\mathcal{L}_{\mathrm{f}} = \{1, 2, 3, 4\}$. The coordinates of the lth node $\boldsymbol{x}_l \in \mathbf{R}^3$ can be rewritten as

$$\boldsymbol{x}_l = \boldsymbol{C}_l \boldsymbol{x} \quad (l \in \mathcal{L}_{\mathrm{f}}), \tag{2.13}$$

where $\boldsymbol{C}_l \in \mathbf{R}^{3\times n^{\mathrm{d}}}$ is a constant matrix determined only by the indices of freedom of displacements of the lth node, and each element of $\boldsymbol{C}_l$ is either $\{0, 1\}$. We specify the vector of external loads $\boldsymbol{f}_l \in \mathbf{R}^3$ applied at the lth node. The equilibrium equations allowing the finite deformations are written as

$$\sum_{i=1}^{n^{\mathrm{m}}} \boldsymbol{B}_i^{\top} \boldsymbol{v}_i = \sum_{l\in\mathcal{L}_{\mathrm{f}}} \boldsymbol{C}_l^{\top} \boldsymbol{f}_l. \tag{2.14}$$

The equilibrium configuration and internal forces can be obtained by solving the system of (2.6)–(2.9) and (2.14). Suppose that a set of $\boldsymbol{x}$, $\boldsymbol{h}_i$, y_j, q_j, and $\boldsymbol{v}_i$ satisfies the system of (2.6), (2.11), and (2.14). Then c_j is obtained from (2.7). Lemma 2.1 implies that the obtained set of $\boldsymbol{x}$, $\boldsymbol{h}_i$, c_j, q_j, and $\boldsymbol{v}_i$ solves the system (2.6)–(2.9) and (2.14). The relation between y_j and c_j is given by (2.12). Thus, in order to obtain the equilibrium configurations and internal forces of cable networks, we can solve the second-order cone complementarity problem (2.6), (2.11), and (2.14) instead of the system of (2.6)–(2.9) and (2.14).

3. Two-body contact problem of cable networks. In this section, suppose that some members of the cable network may possibly make contact with each other. Let $\mathcal{N}^{\mathrm{m}} = \{1, 2, \ldots, n^{\mathrm{m}}\}$. We define contact candidates as

$$\boldsymbol{\zeta}_l = (i_l^{\mathrm{U}}, i_l^{\mathrm{D}}), \quad i_l^{\mathrm{U}} \in \mathcal{N}^{\mathrm{m}}, \quad i_l^{\mathrm{D}} \in \{\mathcal{N}^{\mathrm{m}} \setminus i_l^{\mathrm{U}}\} \quad (l \in \mathcal{L}_{\mathrm{c}}),$$

each of which is a pair of the indices i_l^{U} and i_l^{D} of members. $\mathcal{L}_{\mathrm{c}}$ denotes the set of all indices of the candidates. At the equilibrium state, the i_l^{U}th member should exist *above* the i_l^{D}th member (rigorously defined below).

For each candidate $\boldsymbol{\zeta}_l$ ($l \in \mathcal{L}_{\mathrm{c}}$), we assign a pair of auxiliary nodes $\boldsymbol{x}_l^{\mathrm{U}} \in \mathbf{R}^3$ and $\boldsymbol{x}_l^{\mathrm{D}} \in \mathbf{R}^3$ on the i_l^{U}th and the i_l^{D}th members, respectively, which are regarded as frictionless joints. These nodes are added to the list of the unconstrained nodes. Recalling that n^{n} denotes the number of unconstrained nodes, we see $\mathcal{L}_{\mathrm{c}} \subset \mathcal{N}^{\mathrm{n}} := \{1, 2, \ldots, n^{\mathrm{n}}\}$. The set $\mathcal{L}_{\mathrm{f}}$ of all indices of original nodes satisfies $\mathcal{L}_{\mathrm{f}} = \{\mathcal{N}^{\mathrm{n}} \setminus \mathcal{L}_{\mathrm{c}}\}$. Notice here that $\mathcal{L}_{\mathrm{f}}$, $\mathcal{L}_{\mathrm{c}}$, and $\mathcal{N}^{\mathrm{n}}$ are not necessarily taken as sets of successive sequence of natural numbers; e.g., we may take $\mathcal{L}_{\mathrm{f}} = \{1, 3\}$, $\mathcal{L}_{\mathrm{c}} = \{2, 5\}$, and $\mathcal{N}^{\mathrm{n}} = \{1, 2, 3, 5\}$ without any mismatching.

In a manner similar to (2.13), the coordinates of auxiliary nodes can be written as

$$\boldsymbol{x}_l^{\mathrm{D}} = \boldsymbol{C}_l^{\mathrm{D}} \boldsymbol{x} \quad (l \in \mathcal{L}_{\mathrm{c}}),$$

where $\boldsymbol{C}_l^{\mathrm{U}}$ and $\boldsymbol{C}_l^{\mathrm{D}} \in \mathbf{R}^{3\times n^{\mathrm{d}}}$ are constant matrices and $\boldsymbol{x}_l^{\mathrm{U}}$ and $\boldsymbol{x}_l^{\mathrm{D}}$ are the nodal coordinates at the deformed state. For each $l \in \mathcal{L}_{\mathrm{c}}$, we also assign a constant orthogonal matrix $\boldsymbol{T}_l \in \mathbf{R}^{3\times 3}$. The local orthogonal coordinate system $\boldsymbol{\xi}_l = (\xi_{l1}, \xi_{l2}, \xi_{l3})$ is defined by using $\boldsymbol{T}_l$ such that the locations of auxiliary nodes $\boldsymbol{x}_l^{\mathrm{U}}$ and $\boldsymbol{x}_l^{\mathrm{D}}$ are expressed as

$$\boldsymbol{\xi}_l^{\mathrm{U}} = \boldsymbol{T}_l \boldsymbol{x}_l^{\mathrm{U}}, \quad \boldsymbol{\xi}_l^{\mathrm{D}} = \boldsymbol{T}_l \boldsymbol{x}_l^{\mathrm{D}}. \tag{3.1}$$

Define the vector $\boldsymbol{g}_l \in \mathbf{R}^3$ ($l \in \mathcal{L}_{\mathrm{c}}$) by

$$\boldsymbol{g}_l = \boldsymbol{\xi}_l^{\mathrm{U}} - \boldsymbol{\xi}_l^{\mathrm{D}}, \tag{3.2}$$

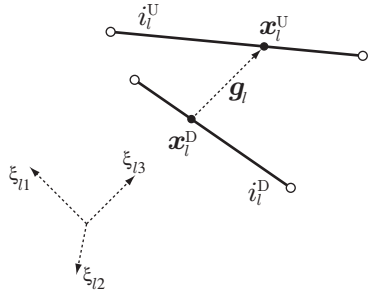

FIG. 2. *Local coordinate* $\boldsymbol{\xi}_l$.

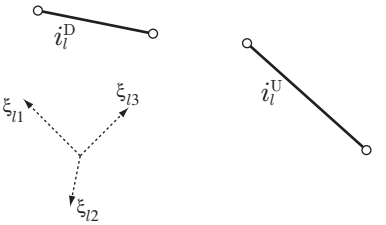

FIG. 3. *Inadmissible case of Assumption* 3.1.

which can be rewritten as $\boldsymbol{g}_l = \boldsymbol{A}_l \boldsymbol{x}$, where a constant matrix $\boldsymbol{A}_l \in \mathbf{R}^{3\times n^{\mathrm{d}}}$ is defined by

$$\boldsymbol{A}_l := \boldsymbol{T}_l(\boldsymbol{C}_l^{\mathrm{U}} - \boldsymbol{C}_l^{\mathrm{D}}).$$

The relations among $\boldsymbol{x}_l^{\mathrm{U}}$, $\boldsymbol{x}_l^{\mathrm{D}}$, $\boldsymbol{\xi}_l$, and $\boldsymbol{g}_l$ are illustrated in Figure 2.

In the conventional approach to two-body contact problems [22], we define the gap vector by using the closest points of two bodies. Notice here that $\boldsymbol{g}_l$ coincides with the usual gap vector only if we take $\boldsymbol{T}_l$ such that $\boldsymbol{g}_l$ is normal to both the i_l^{U}th and i_l^{D}th members. Since $\boldsymbol{T}_l$ satisfying these conditions depends on the deformation of the cable network, it is difficult to estimate such $\boldsymbol{T}_l$ a priori for the case of large deformation. Therefore, we assume the following quite weak condition on $\boldsymbol{T}_l$.

Assumption 3.1. Suppose that the cable network attains the equilibrium state, which is referred to as the actual equilibrium state. For each $l \in \mathcal{L}_{\mathrm{c}}$, a system of coordinates $\boldsymbol{\xi}_l$ is defined. We assume that there exist the points $\boldsymbol{\xi}_l^{\mathrm{U}}$ and $\boldsymbol{\xi}_l^{\mathrm{D}}$ on the i_l^{U}th and i_l^{D}th members, respectively, satisfying

$$\xi_{l1}^{\mathrm{U}} = \xi_{l1}^{\mathrm{D}}, \quad \xi_{l2}^{\mathrm{U}} = \xi_{l2}^{\mathrm{D}}, \quad \xi_{l3}^{\mathrm{U}} \geq \xi_{l3}^{\mathrm{D}} \tag{3.3}$$

at the actual equilibrium state.

In other words, we assume that the orthogonal projections of the two members onto the $\xi_{l1}\xi_{l2}$-plane at the actual equilibrium state have a nonempty intersection. We assign the inverse images of the intersection which exist on the i_l^{U}th and the i_l^{D}th members as $\boldsymbol{x}_l^{\mathrm{U}}$ and $\boldsymbol{x}_l^{\mathrm{D}}$, respectively. Then the i_l^{U}th member exists *above* the i_l^{D}th member in the sense that the ξ_{l3} coordinate of $\boldsymbol{x}_l^{\mathrm{U}}$ is greater than or equal to that of $\boldsymbol{x}_l^{\mathrm{D}}$. An example of an inadmissible case of Assumption 3.1 is as illustrated in Figure 3, where there exists no intersection of the orthogonal projections of the i_l^{U}th and i_l^{D}th members onto the $\xi_{l1}\xi_{l2}$-plane. Since $\boldsymbol{\xi}_l$ is required to satisfy only Assumption 3.1, $\boldsymbol{g}_l$ defined by (3.2) does not necessarily correspond to the gap vector defined by using the closest points of the i_l^{U}th and the i_l^{D}th members. Hence, we may assign an appropriate $\boldsymbol{T}_l$ satisfying Assumption 3.1 more easily than in the conventional methods. On the other hand, it is not still clear what kind of constraints on kinematic and/or static variables should be considered in order to formulate the analysis problems.

Defining the cone $\mathcal{G} \subset \mathbf{R}^3$ by

$$\mathcal{G} = \{\boldsymbol{z} = (z_i) \in \mathbf{R}^3 |\, z_1 = z_2 = 0,\ z_3 \geq 0\}, \tag{3.4}$$

the conditions (3.3) are reduced to $\boldsymbol{g}_l \in \mathcal{G}$ $(l \in \mathcal{L}_{\rm c})$. The dual cone $\mathcal{G}^* \subset \mathbf{R}^3$ of $\mathcal{G}$ is obtained as

$$\mathcal{G}^* = \{\boldsymbol{\tau} = (\tau_i) \in \mathbf{R}^3 | \, \boldsymbol{\tau}^\top \boldsymbol{z} \geq 0 \ (\forall \boldsymbol{z} \in \mathcal{G})\} = \{\boldsymbol{\tau} \in \mathbf{R}^3 | \, \tau_3 \geq 0\}.$$

Let $\boldsymbol{\tau}_l \in \mathbf{R}^3$ $(l \in \mathcal{L}_{\rm c})$ denote the vector of contact forces, which may act between the nodes $\boldsymbol{x}_l^{\rm U}$ and $\boldsymbol{x}_l^{\rm D}$. Notice again that $\boldsymbol{g}_l$ does not correspond to the conventional gap vector, from which it follows that τ_{l3} is not necessarily equal to the normal reaction in general. Recall that, for the contact candidate $\boldsymbol{\zeta}_l$ $(l \in \mathcal{L}_{\rm c})$, the nodes $\boldsymbol{x}_l^{\rm U}$ and $\boldsymbol{x}_l^{\rm D}$ are modeled as frictionless joints, which move along with the $i_l^{\rm D}$th and the $i_l^{\rm U}$th members freely without friction. Hence, if $g_{l3} > 0$ and $\boldsymbol{\tau}_l \neq \boldsymbol{0}$, then these frictionless nodes move on the members, which implies that this situation does not correspond to an equilibrium state. Therefore, the equilibrium equations guarantee that $\boldsymbol{\tau}_l = \boldsymbol{0}$ is satisfied at an equilibrium state automatically if $g_{l3} > 0$. Consequently, the contact conditions can be written as the following complementarity conditions:

$$\boldsymbol{\tau}_l^\top \boldsymbol{g}_l = 0, \quad \boldsymbol{g}_l \in \mathcal{G}, \quad \boldsymbol{\tau}_l \in \mathcal{G}^* \quad (l \in \mathcal{L}_{\rm c}). \tag{3.5}$$

Let $\boldsymbol{v}_i \in \mathbf{R}^3$ $(i = 1, \ldots, n^{\rm m})$ denote the internal force vector of the ith member. The equilibrium equations allowing the finite deformations are written as

$$\sum_{i=1}^{n^{\rm m}} \boldsymbol{B}_i^\top \boldsymbol{v}_i = \sum_{l \in \mathcal{L}_{\rm c}} \boldsymbol{A}_l^\top \boldsymbol{\tau}_l + \sum_{l \in \mathcal{L}_{\rm f}} \boldsymbol{C}_l^\top \boldsymbol{f}_l. \tag{3.6}$$

It follows from Lemma 2.1, (3.5), and (3.6) that the equilibrium configuration of a cable network can be obtained as a solution to the following second-order cone complementarity problem (3.7)–(3.10):

$$\text{(CP)}: \quad q_j = k_j y_j \quad (j = 1, \ldots, n^{\rm c}), \tag{3.7}$$

$$q_j(y_j + \ell_j^0) - \sum_{i \in \mathcal{I}_j} \boldsymbol{v}_i^\top \boldsymbol{h}_i = 0, \tag{3.8}$$

$$y_j + \ell_j^0 \geq \sum_{i \in \mathcal{I}_j} \|\boldsymbol{h}_i\|, \quad q_j \geq \|\boldsymbol{v}_i\| \quad (i \in \mathcal{I}_j; \ j = 1, \ldots, n^{\rm c}),$$

$$\boldsymbol{\tau}_l^\top \boldsymbol{A}_l \boldsymbol{x} = 0, \quad \boldsymbol{A}_l \boldsymbol{x} \in \mathcal{G}, \quad \boldsymbol{\tau}_l \in \mathcal{G}^* \quad (l \in \mathcal{L}_{\rm c}), \tag{3.9}$$

$$\sum_{i=1}^{n^{\rm m}} \boldsymbol{B}_i^\top \boldsymbol{v}_i = \sum_{l \in \mathcal{L}_{\rm c}} \boldsymbol{A}_l^\top \boldsymbol{\tau}_l + \sum_{l \in \mathcal{L}_{\rm f}} \boldsymbol{C}_l^\top \boldsymbol{f}_l, \tag{3.10}$$

where the relation between y_j and the actual elongation c_j of the jth cable is given by (2.12). The relation between $\boldsymbol{h}_i$ and $\boldsymbol{x}$ is given by (2.6). Notice here that both $\mathcal{G}$ and $\mathcal{G}^*$ can be represented as second-order cones, i.e., $\mathbf{L}_+^1$, which verifies that (3.7)–(3.10) can be embedded into (2.5). We can show that the system (3.7)–(3.10) can be embedded into (2.5) and coincides with the Karush–Kuhn–Tucker (KKT) conditions

[36, Theorem 4.2] of the following primal-dual pair of SOCP problems:

$$
\left\{
\begin{array}{ll}
\min & \phi = \displaystyle\sum_{j=1}^{n^{\mathrm{c}}} \frac{1}{2} k_j y_j^2 - \sum_{l \in \mathcal{L}_{\mathrm{f}}} \boldsymbol{f}_l^{\top} \boldsymbol{C}_l \boldsymbol{x} \\
\text{s.t.} & y_j + \ell_j^0 \geq \displaystyle\sum_{i \in \mathcal{I}_j} \| \boldsymbol{B}_i \boldsymbol{x} - \boldsymbol{d}_i \| \quad (j = 1, \ldots, n^{\mathrm{c}}), \\
& \boldsymbol{A}_l \boldsymbol{x} \in \mathcal{G} \quad (l \in \mathcal{L}_{\mathrm{c}}),
\end{array}
\right. \tag{3.11}
$$

$$
\left\{
\begin{array}{ll}
\min & \phi^* = \displaystyle\sum_{j=1}^{n^{\mathrm{c}}} \frac{q_j^2}{2k_j} + \sum_{j=1}^{n^{\mathrm{c}}} \ell_j^0 q_j + \sum_{i=1}^{n^{\mathrm{m}}} \boldsymbol{d}_i^{\top} \boldsymbol{v}_i \\
\text{s.t.} & \displaystyle\sum_{i=1}^{n^{\mathrm{m}}} \boldsymbol{B}_i^{\top} \boldsymbol{v}_i = \sum_{l \in \mathcal{L}_{\mathrm{c}}} \boldsymbol{A}_l^{\top} \boldsymbol{\tau}_l + \sum_{l \in \mathcal{L}_{\mathrm{f}}} \boldsymbol{C}_l^{\top} \boldsymbol{f}_l, \\
& q_j \geq \| \boldsymbol{v}_i \| \quad (i \in \mathcal{I}_j;\ j = 1, \ldots, n^{\mathrm{c}}), \\
& \boldsymbol{\tau}_l \in \mathcal{G}^* \quad (l \in \mathcal{L}_{\mathrm{c}}).
\end{array}
\right. \tag{3.12}
$$

Hence, we can obtain the equilibrium configuration and the internal forces, respectively, of the cable network by solving the SOCP problems (3.11) and (3.12). It follows from Lemma 2.1 that $\boldsymbol{h}_i$ and $\boldsymbol{v}_i$ share a common direction as investigated in (2.10).

The authors have shown that ϕ^* in (3.12) is the complementary energy function for cable network in geometrical nonlinear theory [18]. In (3.12), we minimize ϕ^* over the equilibrium equations, and an optimal solution coincides with a set of internal forces and contact forces at the equilibrium state; i.e., (3.12) is the minimization problem of complementary energy with contact conditions only in terms of stress components, although it allows finite deformation.

Notice again that we can choose any matrix $\boldsymbol{T}_l$ satisfying Assumption 3.1, because the solution to (3.7)–(3.10) does not depend on $\boldsymbol{T}_l$. Let y_j^*, q_j^* $(j = 1, \ldots, n^{\mathrm{c}})$, $\boldsymbol{h}_i^*$, $\boldsymbol{v}_i^*$ $(i = 1, \ldots, n^{\mathrm{m}})$, $\boldsymbol{\tau}_l^*$ $(l \in \mathcal{L}_{\mathrm{c}})$, and $\boldsymbol{x}^*$ solve the complementarity problem (3.7)–(3.10) for an appropriately defined $\boldsymbol{T}_l$. Suppose that we replace $\boldsymbol{T}_l$ with $\boldsymbol{T}_l'$ satisfying Assumption 3.1. Then $\boldsymbol{A}_l$ in (3.9) and (3.10) is replaced with $\boldsymbol{A}_l' := \boldsymbol{T}_l'(\boldsymbol{C}_l^{\mathrm{U}} - \boldsymbol{C}_l^{\mathrm{D}})$. Let $\boldsymbol{\tau}_l'$ denote the vector satisfying $\boldsymbol{A}_l^{\top} \boldsymbol{\tau}_l^* = (\boldsymbol{A}_l')^{\top} \boldsymbol{\tau}_l'$. Then we see that $\boldsymbol{v}_i^*$ $(i = 1, \ldots, n^{\mathrm{m}})$, $\boldsymbol{\tau}_l'$ $(l \in \mathcal{L}_{\mathrm{c}})$, and $\boldsymbol{x}^*$ satisfy (3.9) and (3.10). Thus, $\boldsymbol{x}^*$ remains to be a solution of (3.7)–(3.10). The contact forces $\boldsymbol{T}_l^{\top} \boldsymbol{\tau}_l$ $(l \in \mathcal{L}_{\mathrm{c}})$ in the global coordinate system are also independent of the choice $\boldsymbol{T}_l$, because we have $\boldsymbol{T}_l^{\top} \boldsymbol{\tau}_l^* = (\boldsymbol{T}_l')^{\top} \boldsymbol{\tau}_l'$.

4. Unilateral contact problem with rigid convex obstacles. In this section, we consider a class of frictionless unilateral contact problem, or Signorini's problem [20], where the rigid obstacle is modeled as the union of some convex polyhedra. Suppose that there exist some rigid obstacles $\mathcal{H}_p$ $(p \in \mathcal{P})$, each of which is a convex polyhedron fixed in three-dimensional space, and that $\mathcal{P}$ denotes the set of indices of $\mathcal{H}_p$. π_q denotes a plane which contains a surface of a polyhedron and is defined as

$$
\pi_q = \{ \boldsymbol{z} \in \mathbf{R}^3 \,|\, \boldsymbol{a}_q^{\top} (\boldsymbol{z} - \boldsymbol{b}_q) = 0 \} \quad (q \in \mathcal{Q}). \tag{4.1}
$$

Here, $\boldsymbol{a}_q \in \mathbf{R}^3$ is a constant unit outer normal vector along a surface of $\mathcal{H}_p$, $\boldsymbol{b}_q \in \mathbf{R}^3$ is a constant location vector on π_q, and $\mathcal{Q}$ is a set of indices of π_q. By using the appropriate subset $\mathcal{Q}_p$ of $\mathcal{Q}$, we can give the expression of $\mathcal{H}_p$ as

$$
\mathcal{H}_p = \bigcap_{q \in \mathcal{Q}_p} \{ \boldsymbol{z} \in \mathbf{R}^3 \,|\, \boldsymbol{a}_q^{\top} (\boldsymbol{z} - \boldsymbol{b}_q) \leq 0 \} \tag{4.2}
$$

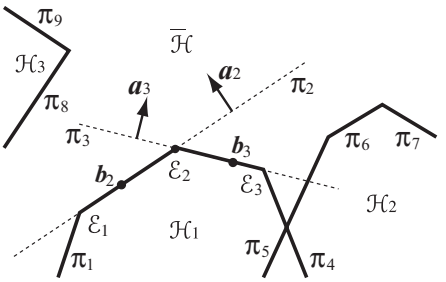

FIG. 4. *Definitions of $\mathcal{H}_p$ and π_q.*

without redundancy. An example is illustrated in Figure 4, where $\mathcal{P} = \{1, 2, 3\}$, $\mathcal{Q}_1 = \{1, 2, 3, 4\}$, $\mathcal{Q}_2 = \{5, 6, 7\}$, $\mathcal{Q}_3 = \{8, 9\}$, and $\mathcal{Q} = \{1, \ldots, 9\}$. Although we consider the polyhedra $\mathcal{H}_p$ ($p \in \mathcal{P}$) in three-dimensional space, Figure 4 illustrates only the cross sections of $\mathcal{H}_p$ so that a plane π_q is reduced to a line. Let $\mathcal{H} = \bigcup_{p\in\mathcal{P}} \mathcal{H}_p$. The admissible region $\mathcal{X}^{\mathrm{ad}} \subset \mathbf{R}^3$ of the location vector of any point on the cable network is given by

$$\mathcal{X}^{\mathrm{ad}} = \bigcap_{p\in\mathcal{P}} \left\{ \bigcup_{q\in\mathcal{Q}_p} \{\boldsymbol{z} \in \mathbf{R}^3 |\, \boldsymbol{a}_q^\top (\boldsymbol{z} - \boldsymbol{b}_q) \geq 0\} \right\}.$$

Although $\mathcal{H}_p$ is convex, $\mathcal{X}^{\mathrm{ad}}$ is not convex in general. The equilibrium configuration can be obtained by directly incorporating the constraints into the minimization problem of total potential energy such that all the points on the cable network should exist in $\mathcal{X}^{\mathrm{ad}}$. However, this problem is not tractable, since it is a nonconvex problem, not to mention the fact that it requires infinite number of constraints. As a conventional approach to contact problems [20], we may assign some contact candidates, each of which is a pair of the node of the cable network and the particle of the surface of $\mathcal{H}$. To verify that the cable network contacts $\mathcal{H}$ only at these candidates, we must solve complementarity problems successively with respect to infinitesimal displacements with a large number of candidates. This is the major difficulty of contact problems, and it motivates us to formulate an SOCP problem such that the optimal solution coincides with the equilibrium configuration under some weak assumptions.

Let $\mathcal{F}_q$ and $\mathcal{E}_j$ denote the faces and edges, respectively, of the polyhedra $\mathcal{H}_p$ ($p \in \mathcal{P}$). $\mathcal{J}$ denotes the set of indices of $\mathcal{E}_j$. By using the appropriate $\mathcal{Q}_j^{\mathcal{E}} \subseteq \mathcal{Q}_p$ satisfying $|\mathcal{Q}_j^{\mathcal{E}}| \geq 2$, we can write

$$\mathcal{F}_q = \mathcal{H}_p \cap \pi_q \qquad (p \in \mathcal{P},\ q \in \mathcal{Q}), \tag{4.3}$$

$$\mathcal{E}_j = \mathcal{H}_p \cap \left\{ \bigcap_{q\in\mathcal{Q}_j^{\mathcal{E}}} \pi_q \right\} \quad (p \in \mathcal{P},\ j \in \mathcal{J}). \tag{4.4}$$

Recall the example in Figure 4, where the cross sections of edges $\mathcal{E}_j$ are illustrated as the points. For the edges $\mathcal{E}_1$, $\mathcal{E}_2$, and $\mathcal{E}_3$ of $\mathcal{H}_1$, we have $\mathcal{Q}_1^{\varepsilon} = \{1, 2\}$, $\mathcal{Q}_2^{\varepsilon} = \{2, 3\}$, and $\mathcal{Q}_3^{\varepsilon} = \{3, 4\}$. For the convex reformulation, we define contact candidates as

$$\boldsymbol{\zeta}_l^{\mathrm{aux}} = (i_l, j_l) \in \mathcal{N}^{\mathrm{m}} \times \mathcal{J} \quad (l \in \mathcal{L}^{\mathrm{aux}}),$$
$$\boldsymbol{\zeta}_l^{\mathrm{org}} = (l, q_l) \in \{l\} \times \mathcal{Q} \quad (l \in \mathcal{L}^{\mathrm{org}} \subseteq \mathcal{L}_{\mathrm{f}}).$$

For each $l \in \mathcal{L}^{\rm aux}$, the first and second elements of $\boldsymbol{\zeta}_l^{\rm aux}$ denote the indices of a member and an edge, respectively, where the i_lth member may contact $\mathcal{H}$ at the edge $\mathcal{E}_{j_l}$ at the equilibrium state. Then we set an auxiliary node $\boldsymbol{x}_l \in \mathbf{R}^3$ on the i_lth member, which is regarded as a frictionless joint. Note that these nodes are added to the list of unconstrained nodes. For each $l \in \mathcal{L}^{\rm org}$, q_l is defined as an index of a face, where the original node $\boldsymbol{x}_l$ may contact $\mathcal{H}$ on the face $\mathcal{F}_{q_l}$. $\mathcal{L}^{\rm aux}$ and $\mathcal{L}^{\rm org}$, respectively, denote the sets of indices of $\boldsymbol{\zeta}_l^{\rm aux}$ and $\boldsymbol{\zeta}_l^{\rm org}$, where $\mathcal{L}^{\rm aux} \cap \mathcal{L}^{\rm org} = \emptyset$.

Recall that $\mathcal{L}_{\rm f}$ denotes the set of all indices of original frictionless joints and pin-joints, which implies $\mathcal{L}^{\rm org} \subseteq \mathcal{L}_{\rm f}$. The auxiliary nodes are added to the list of the unconstrained nodes, i.e., $\mathcal{L}^{\rm aux} \cup \mathcal{L}_{\rm f} = \mathcal{N}^{\rm n}$ and $\mathcal{L}^{\rm aux} \cap \mathcal{L}_{\rm f} = \emptyset$. Define $\mathcal{G}_l \subset \mathbf{R}^3$ and $\mathcal{X}_l \subset \mathbf{R}^3$ as

$$\mathcal{G}_l = \begin{cases} \{\boldsymbol{z} \in \mathbf{R}^3 | \, \boldsymbol{a}_q^\top \boldsymbol{z} \geq 0 \ (q \in \mathcal{Q}_{j_l}^{\mathcal{E}})\} & (l \in \mathcal{L}^{\rm aux}), \\ \{\boldsymbol{z} \in \mathbf{R}^3 | \, \boldsymbol{a}_{q_l}^\top \boldsymbol{z} \geq 0\} & (l \in \mathcal{L}^{\rm org}), \end{cases}$$

$$\mathcal{X}_l = \begin{cases} \{\boldsymbol{z} \in \mathbf{R}^3 | \, \boldsymbol{a}_q^\top (\boldsymbol{z} - \boldsymbol{b}_q) \geq 0 \ (q \in \mathcal{Q}_{j_l}^{\mathcal{E}})\} & (l \in \mathcal{L}^{\rm aux}), \\ \{\boldsymbol{z} \in \mathbf{R}^3 | \, \boldsymbol{a}_{q_l}^\top (\boldsymbol{z} - \boldsymbol{b}_q) \geq 0\} & (l \in \mathcal{L}^{\rm org}), \end{cases}$$

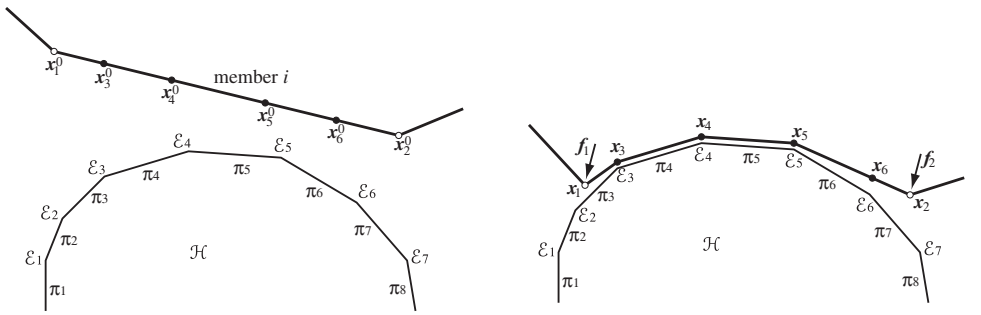
where $(i_l, j_l) = \boldsymbol{\zeta}_l^{\rm aux}$ for $l \in \mathcal{L}^{\rm aux}$ and $(l, q_l) = \boldsymbol{\zeta}_l^{\rm org}$ for $l \in \mathcal{L}^{\rm org}$. We assume that the cable network may contact $\mathcal{H}$ only at the contact candidates $l \in \mathcal{L}^{\rm aux} \cup \mathcal{L}^{\rm org}$. Moreover, these contact candidates should be chosen to satisfy the following assumption.

Assumption 4.1. Define the actual equilibrium configuration as the equilibrium configuration of the cable network, with the subsidiary conditions such that any point on the cables should exist in $\mathcal{X}^{\rm ad}$. We assume that the actual equilibrium configuration satisfies the following assumptions:

(i) for each $l \in \mathcal{L}^{\rm org}$, $\boldsymbol{x}_l \in \mathcal{X}_l$ is satisfied;

(ii) for each $l \in \mathcal{L}^{\rm aux}$, $\boldsymbol{\zeta}_l = (i_l, j_l)$ satisfies that the i_lth member and $\mathcal{X}_l$ have a nonempty intersection.

Let $\boldsymbol{e}_j \in \mathbf{R}^3$ denote a position vector on the edge $\mathcal{E}_j$ $(j \in \mathcal{J})$ or on the face $\mathcal{F}_q$ $(q \in \mathcal{Q})$. Define the vector $\boldsymbol{g}_l \in \mathbf{R}^3$ as



$$\boldsymbol{g}_l = \boldsymbol{x}_l - \boldsymbol{e}_l \quad (l \in \mathcal{L}^{\rm aux} \cup \mathcal{L}^{\rm org}), \tag{4.5}$$

where $\boldsymbol{x}_l$ is related to $\boldsymbol{x}$ by (2.13). Then conditions (i) and (ii) in Assumption 4.1 are equivalent to $\boldsymbol{g}_l \in \mathcal{G}_l$ $(l \in \mathcal{L}^{\rm org} \cup \mathcal{L}^{\rm aux})$.

Note that, for $l \in \mathcal{L}^{\rm aux}$, $\boldsymbol{g}_l$ defined by (4.5) is different from the conventional gap vector in contact mechanics. Let $\boldsymbol{p}_l^0 \in \mathbf{R}^3$ denote the coordinate of the lth node, which is not a frictionless joint but a pin-joint, on the lth member at the undeformed state. For $l \in \mathcal{L}^{\rm aux}$, the conventional gap vector is defined as the unique vector $\boldsymbol{g}_l' := \boldsymbol{p}_l^0 - \boldsymbol{e}_l'$, where $\boldsymbol{p}_l$ may contact the obstacle at the point $\boldsymbol{e}_l'$. Thus, we must specify the position vector $\boldsymbol{e}_l'$ on the obstacle. However, it is difficult to estimate such $\boldsymbol{e}_l'$ and $\boldsymbol{p}_l^0$ a priori if we allow the large deformation in the formulations. On the other hand, $\boldsymbol{g}_l$ $(l \in \mathcal{L}^{\rm aux})$ in (4.5) is defined with respect to the nodal coordinates at the deformed state and an arbitrary position vector $\boldsymbol{e}_l$ on the edge. Hence, we have to estimate neither $\boldsymbol{e}_l'$ nor $\boldsymbol{p}_l^0$. Moreover, by introducing $\boldsymbol{g}_l$ along with the concept of frictionless auxiliary joints, we can formulate the contact conditions allowing large deformations in the linear complementarity conditions over convex cones.

On the contrary, for $l \in \mathcal{L}^{\rm org}$, we have to estimate the face $\mathcal{F}_l$ corresponding to the lth node, which is the same task as that required in conventional formulation.

Since we use $\boldsymbol{g}_l$ defined by (4.5) instead of the conventional gap vector, it is not clear what kind of constraints should be included in the minimization problem of

(a) undeformed state (b) equilibrium state

FIG. 5. *Example of Remark* 1.

total potential energy in order to find the equilibrium configurations. Notice here that $\boldsymbol{g}_l = \boldsymbol{0}$ if and only if $\boldsymbol{x}_l$ is in contact with $\mathcal{H}$. Clearly, Assumption 4.1 requires no information as to whether $\boldsymbol{x}_l$ will contact $\mathcal{H}$ or not. It should be emphasized that we need not identify the coordinate of a contact node $\boldsymbol{p}_l^0$ on members, but need only identify a pair of a member and an edge.

Remark 1. The advantage of our approach relies on the fact that, in practical situations, the candidates $\boldsymbol{\zeta}_l^{\mathrm{aux}}$ satisfying Assumption 4.1 often can be easily found. Indeed, if we can find $\boldsymbol{\zeta}_l^{\mathrm{org}}$ satisfying $\boldsymbol{x}_l \in \mathcal{X}_l$ ($l \in \mathcal{L}^{\mathrm{org}}$), it is rather easy to look for appropriate $\boldsymbol{\zeta}_l^{\mathrm{aux}}$; i.e., if we know the face $\mathcal{F}_{q_l}$ satisfying $\boldsymbol{x}_l \in \mathcal{X}_l$ for each $\boldsymbol{x}_l$ ($l \in \mathcal{L}^{\mathrm{org}}$), we can easily conjecture whether the i'th member has a nonempty intersection with $\mathcal{X}_{j'}$ or not. If the conjecture has a positive answer, we should add a candidate $\boldsymbol{\zeta}_l^{\mathrm{aux}} = (i', j')$. Consequently, Assumption 4.1 is practically acceptable, even for very complicated obstacles and/or cable networks, if we can estimate the correct $\boldsymbol{\zeta}_l^{\mathrm{org}} = (l, q_l)$. For example, consider the ith member and the obstacle $\mathcal{H}$, as illustrated in Figure 5, where undeformed cable and only the cross section of the obstacle are illustrated in Figure 5(a). Figure 5(b) illustrates the equilibrium configuration under the existence of external forces. $\boldsymbol{x}_1$ and $\boldsymbol{x}_2$ are the original nodes, i.e., $\mathcal{L}_{\mathrm{f}} = \{1, 2\}$. The surface of $\mathcal{H}$ consists of the planes $\pi_1, \ldots, \pi_8$. The edges $\mathcal{E}_1, \ldots, \mathcal{E}_7$ are defined by $\mathcal{Q}_j^{\mathcal{E}} = \{j, j+1\}$ ($j = 1, \ldots, 7$); i.e., $\mathcal{E}_j$ is the intersection of π_j and π_{j+1}. We may regard all of the original nodes as the contact candidates, i.e., $\mathcal{L}^{\mathrm{org}} = \mathcal{L}_{\mathrm{f}}$. Suppose that we guess that

$$\boldsymbol{a}_3^\top (\boldsymbol{x}_1 - \boldsymbol{b}_3) \geq 0, \quad \boldsymbol{a}_7^\top (\boldsymbol{x}_2 - \boldsymbol{b}_7) \geq 0 \tag{4.6}$$

are satisfied at the actual equilibrium state; i.e., $q_1 = 3$ and $q_2 = 7$ in accordance with Assumption 4.1. From this, we can see that the ith member may possibly contact $\mathcal{H}$ only at $\mathcal{E}_3, \ldots, \mathcal{E}_6$. Hence, we should consider more candidates $\boldsymbol{x}_3, \ldots, \boldsymbol{x}_6$, i.e., $\mathcal{L}^{\mathrm{aux}} = \{3, 4, 5, 6\}$ and $\boldsymbol{\zeta}_l^{\mathrm{aux}} = (i, j)$ ($j = 3, \ldots, 6$). Here, the definitions of $\mathcal{X}_1$ and $\mathcal{X}_6$ are illustrated in Figure 6. If (4.6) holds at the actual equilibrium state, it is easy to see that the actual equilibrium configuration satisfies condition (ii) in Assumption 4.1; i.e., the ith member has a nonempty intersection with each of $\mathcal{X}_3, \ldots, \mathcal{X}_6$. Hence, in this example, we only have to find appropriate q_1 and q_2. □

Let $\boldsymbol{\tau}_l \in \mathbf{R}^3$ ($l \in \mathcal{L}_{\mathrm{c}}$) denote the vector of contact forces at $\boldsymbol{x}_l$. The equilibrium equations are written as

$$\sum_{i=1}^{n^{\mathrm{m}}} \boldsymbol{B}_i^\top \boldsymbol{v}_i = \sum_{l \in \mathcal{L}^{\mathrm{aux}} \cup \mathcal{L}^{\mathrm{org}}} \boldsymbol{C}_l^\top \boldsymbol{\tau}_l + \sum_{l \in \mathcal{L}_{\mathrm{f}}} \boldsymbol{C}_l^\top \boldsymbol{f}_l. \tag{4.7}$$

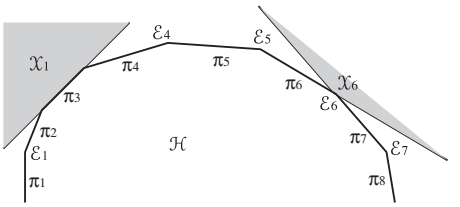


FIG. 6. *Definitions of* $\mathcal{X}_1$ *and* $\mathcal{X}_6$.

Notice here that we do not consider the original nonpenetration constraints such that any point on the cable network should exist in $\mathcal{X}^{\rm ad}$ in what follows. Moreover, for $l \in \mathcal{L}^{\rm aux}$, the definition of $\mathcal{X}_l$ does not coincide with the conventional admissible region of the position vector of contact candidate node. Therefore, it is not clear at present whether the original nonpenetration conditions can be expressed by using some conditions in terms of the kinematic and static variables of auxiliary nodes.

Since the i_lth member may contact the edge $\mathcal{E}_{j_l}$ without friction, $\boldsymbol{\tau}_l \in \mathcal{G}_l^*$ is satisfied, where the dual cone $\mathcal{G}_l^*$ of $\mathcal{G}_l$ is obtained as

$$\mathcal{G}_l^* = \begin{cases} \left\{ \sum_{q \in \mathcal{Q}_{j_l}^{\mathcal{E}}} \lambda_q \boldsymbol{a}_q \middle| \lambda_q \geq 0 \ (q \in \mathcal{Q}_{j_l}^{\mathcal{E}}) \right\} & (l \in \mathcal{L}^{\rm aux}), \\ \{ \lambda_{q_l} \boldsymbol{a}_{q_l} | \lambda_{q_l} \geq 0 \} & (l \in \mathcal{L}^{\rm org}). \end{cases}$$

For $l \in \mathcal{L}^{\rm aux}$, the i_lth member may contact $\mathcal{H}$ at the edge $\mathcal{E}_{j_l}$, and the contact force $\boldsymbol{\tau}_l$ should be expressed as the nonnegative linear combination of $\boldsymbol{a}_q$'s, each of which is normal to the plane π_q that includes $\mathcal{E}_{j_l}$. On the contrary, for $l \in \mathcal{L}^{\rm org}$, the original node $\boldsymbol{x}_l$ may contact the face $\mathcal{F}_{q_l}$, and the contact force $\boldsymbol{\tau}_l$ should be in the direction of the outer normal vector of $\mathcal{F}_{q_l}$.

Recall that $\boldsymbol{x}_l$ ($l \in \mathcal{L}^{\rm aux}$) is regarded as the frictionless joint. If the i_lth member does not contact the edge $\mathcal{E}_{j_l}$ at the actual equilibrium state, then $\boldsymbol{x}_l$ satisfies the equilibrium conditions at any point on the i_lth member. Assumption 4.1 guarantees the existence of a point in the intersection of $\mathcal{X}_l$ and the i_lth member at the actual equilibrium state. On the other hand, if the i_lth member contacts $\mathcal{E}_{j_l}$ at the actual equilibrium state, then the intersection of the i_lth member and $\mathcal{X}_l$ is reduced to a point in $\mathcal{E}_{j_l} \cap \mathcal{X}_l$. Hence, at each contact candidate $l \in \mathcal{L}^{\rm aux} \cup \mathcal{L}^{\rm org}$, the contact condition can be written as

$$\boldsymbol{\tau}_l^\top \boldsymbol{g}_l = 0, \quad \boldsymbol{g}_l \in \mathcal{G}_l, \quad \boldsymbol{\tau}_l \in \mathcal{G}_l^*, \tag{4.8}$$

which is a linear complementarity condition.

It follows from Lemma 2.1, (4.7), and (4.8) that the equilibrium configuration of the cable network can be obtained as a solution to the following system:

$$\text{(CP)}: \quad q_j = k_j y_j \quad (j = 1, \ldots, n^{\rm c}), \tag{4.9}$$

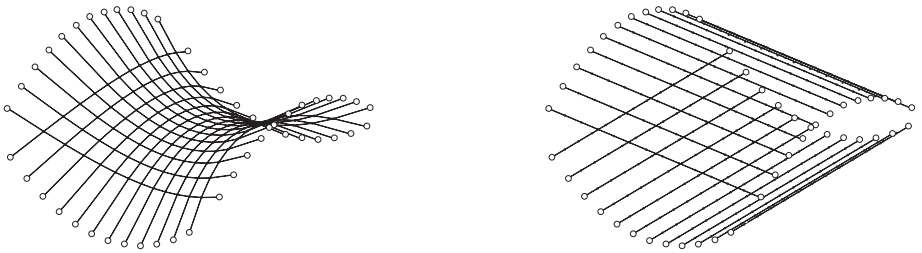
$$q_j (y_j + \ell_j^0) - \sum_{i \in \mathcal{I}_j} \boldsymbol{v}_i^\top \boldsymbol{h}_i = 0,$$

$$y_j + \ell_j^0 \geq \sum_{i \in \mathcal{I}_j} \|\boldsymbol{h}_i\|, \quad q_j \geq \|\boldsymbol{v}_i\| \quad (i \in \mathcal{I}_j;\ j = 1, \ldots, n^{\rm c}), \tag{4.10}$$

$$\boldsymbol{\tau}_l^\top \boldsymbol{g}_l = 0, \quad \boldsymbol{g}_l \in \mathcal{G}_l, \quad \boldsymbol{\tau}_l \in \mathcal{G}_l^* \quad (l \in \mathcal{L}^{\rm aux} \cup \mathcal{L}^{\rm org}), \tag{4.11}$$

$$\sum_{i=1}^{n^{\rm m}} \boldsymbol{B}_i^\top \boldsymbol{v}_i = \sum_{l \in \mathcal{L}^{\rm aux} \cup \mathcal{L}^{\rm org}} \boldsymbol{C}_l^\top \boldsymbol{\tau}_l + \sum_{l \in \mathcal{L}_{\rm f}} \boldsymbol{C}_l^\top \boldsymbol{f}_l. \tag{4.12}$$

Since both $\mathcal{G}$ and $\mathcal{G}^*$ can be represented as the second-order cones, the system (4.9)–(4.12) can also be embedded into (2.5). In a manner similar to that in section 3, we can show that (4.9)–(4.12) coincide with the KKT conditions of the following primal-dual pair of SOCP problems:



$$
(4.13)\qquad \begin{cases} \min & \displaystyle\sum_{j=1}^{n^{\mathrm{c}}} \frac{1}{2} k_j y_j^2 - \sum_{l \in \mathcal{L}_{\mathrm{f}}} \boldsymbol{f}_l^{\top} \boldsymbol{C}_l \boldsymbol{x} \\ \text{s.t.} & y_j + \ell_j^0 \geq \displaystyle\sum_{i \in \mathcal{I}_j} \| \boldsymbol{B}_i \boldsymbol{x} - \boldsymbol{d}_i \| \quad (j = 1, \ldots, n^{\mathrm{c}}), \\ & \boldsymbol{C}_l \boldsymbol{x} \in \mathcal{X}_l \quad (l \in \mathcal{L}^{\mathrm{aux}} \cup \mathcal{L}^{\mathrm{org}}), \end{cases}
$$

$$
(4.14)\qquad \begin{cases} \min & \displaystyle\sum_{j=1}^{n^{\mathrm{c}}} \frac{q_j^2}{2k_j} + \sum_{j=1}^{n^{\mathrm{c}}} \ell_j^0 q_j + \sum_{i=1}^{n^{\mathrm{m}}} \boldsymbol{d}_i^{\top} \boldsymbol{v}_i + \sum_{l \in \mathcal{L}^{\mathrm{aux}} \cup \mathcal{L}^{\mathrm{org}}} \sum_{q \in \mathcal{Q}_{j_l}^{\mathcal{E}}} \boldsymbol{b}_q^{\top} \lambda_q^l \boldsymbol{a}_q \\ \text{s.t.} & \displaystyle\sum_{i=1}^{n^{\mathrm{m}}} \boldsymbol{B}_i^{\top} \boldsymbol{v}_i = \sum_{l \in \mathcal{L}^{\mathrm{aux}} \cup \mathcal{L}^{\mathrm{org}}} \boldsymbol{C}_l^{\top} \boldsymbol{\tau}_l + \sum_{l \in \mathcal{L}_{\mathrm{f}}} \boldsymbol{C}_l^{\top} \boldsymbol{f}_l, \\ & q_j \geq \| \boldsymbol{v}_i \| \quad (i \in \mathcal{I}_j;\ j = 1, \ldots, n^{\mathrm{c}}), \\ & \boldsymbol{\tau}_l = \displaystyle\sum_{q \in \mathcal{Q}_{j_l}^{\mathcal{E}}} \lambda_q^l \boldsymbol{a}_q \in \mathcal{G}_l^* \quad (l \in \mathcal{L}^{\mathrm{aux}}), \\ & \boldsymbol{\tau}_l = \lambda_{q_l} \boldsymbol{a}_{q_l} \in \mathcal{G}_l^* \quad (l \in \mathcal{L}^{\mathrm{org}}). \end{cases}
$$

Note that (4.13) is independent of both the stress states and contact states of cable members. Moreover, (4.13) and (4.14) are embedded into the dual and primal standard forms of SOCP problems (2.4) and (2.3), respectively, which can be solved easily by using the primal-dual interior-point method [7].

5. Numerical examples. In order to obtain the equilibrium configurations of cable networks, the presented SOCP problems are transformed into the pair of standard forms (2.3) and (2.4) and are solved by using SeDuMi [39], which implements the self-dual embedding technique for optimization over self-dual homogeneous cones and operates under the MATLAB environment. Computation has been carried out on a Pentium III (844MHz with 256MB memory) with MATLAB Version 6.5 [26] and SeDuMi Version 1.05. In the following examples, the elastic modulus and the cross-sectional area, respectively, are specified as $E = 205.8$ GPa and $A_j = 10^{-2}$ cm^2 for each cable, and the elongation stiffness is computed as $k_j = EA_j/\ell_j^0$.

5.1. Two-body contact problems of cable networks. Equilibrium configurations are found for two cable networks with 10×10 and 12×12 grids, which are referred to as Models (I) and (II), respectively. Each cable network projected to the horizontal plane makes a grid with 1 m $\times$ 1 m squares. The (x, y)-axes are defined along the grid, and the origin is set at the center of each cable network. Then the z-coordinates of the nodes are given as $z = (x^2 - y^2)/(4\alpha)$, where $\alpha = 11$ and 13 (m), respectively, for Models (I) and (II). The nodes indicated by circles in Figure 7(a) are supported. n^{d}, n^{m}, and n^{c} of each model are listed in Table 1. For each contact candidate $\boldsymbol{\zeta}_l$ $(l \in \mathcal{L}_{\mathrm{c}})$, there exist two auxiliary nodes. However, from the definition (3.4) of $\mathcal{G}$, the constraint $\boldsymbol{A}_l \boldsymbol{x} \in \mathcal{G}$ in Problem (3.11) implies that, for each pair of auxiliary nodes related to $\boldsymbol{\zeta}_l$, the number of degrees of freedom becomes four.

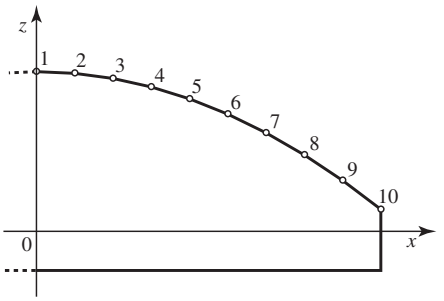
	Frictionless	540	940	2.85	300	220	20	24	$(\mathbf{L}^3_+)^{20} \times (\mathbf{L}^4_+)^{220}$
	Contact-(a)	640	1040	2.65	400	220	20	20	$\mathbf{R}^{100}_+ \times (\mathbf{L}^3_+)^{20} \times (\mathbf{L}^4_+)^{220}$
	Contact-(b)	640	1040	2.46	400	220	20	20	$\mathbf{R}^{100}_+ \times (\mathbf{L}^3_+)^{20} \times (\mathbf{L}^4_+)^{220}$
(II)	Contact-(a)	912	1464	4.23	576	312	24	22	$\mathbf{R}^{144}_+ \times (\mathbf{L}^3_+)^{24} \times (\mathbf{L}^4_+)^{312}$
	Contact-(b)	912	1464	3.98	576	312	24	21	$\mathbf{R}^{144}_+ \times (\mathbf{L}^3_+)^{24} \times (\mathbf{L}^4_+)^{312}$

Set $\ell^0_1 = \cdots = \ell^0_{n^{\mathrm{c}}} = 8$ (m) and $k_1 = \cdots = k_{n^{\mathrm{c}}}$. The self-equilibrium configurations with $\boldsymbol{f} = \boldsymbol{0}$ are computed. Note that the self-equilibrium configurations are independent of k_j. We assume $\boldsymbol{T}_l = \boldsymbol{I}$ (for all $l \in \mathcal{L}_{\mathrm{c}}$) in (3.1), where $\boldsymbol{I} \in \mathbf{R}^{3\times 3}$ denotes a unit matrix. We consider two problems for each model, which are referred to as *contact*-(a) and *contact*-(b), respectively. In the problem contact-(a), we suppose that all the cables parallel to the y-axis are above the cables parallel to the x-axis. In contrast, in the problem contact-(b), all the cables parallel to the x-axis are supposed to be above the cables parallel to the y-axis.

The primal-dual pair of problems (3.11) and (3.12) is solved in order to obtain the configurations, internal forces, and contact forces at the equilibrium state. For each model, m, n, $\mathcal{K}$, CPU time in seconds, and number of iterations are listed in Table 1. The equilibrium configurations of Model (II) are shown in Figure 7. Note that all the pairs of contact candidate members are in contact state at a solution of contact-(a), whereas they are free at a solution of contact-(b). We see that the obtained configuration of contact-(a) is the same as the case where all the internal joints are frictionless in the direction of the cables, while all the cables of contact-(b) make straight lines. It can be observed from Table 1 that the CPU time does not increase drastically even if we incorporate the contact conditions as additional constraints.

5.2. Signorini's problem of a cable. Consider a cable with one (original) frictionless joint and a fixed parabolic rigid obstacle $\mathcal{H}$. We specify the initial unstressed length $\ell^0_j = 50.0$ cm of the cable, and the two end points are fixed. $\mathcal{H}$ is approximated as a convex polyhedron, the surface of which consists of 18 planes as



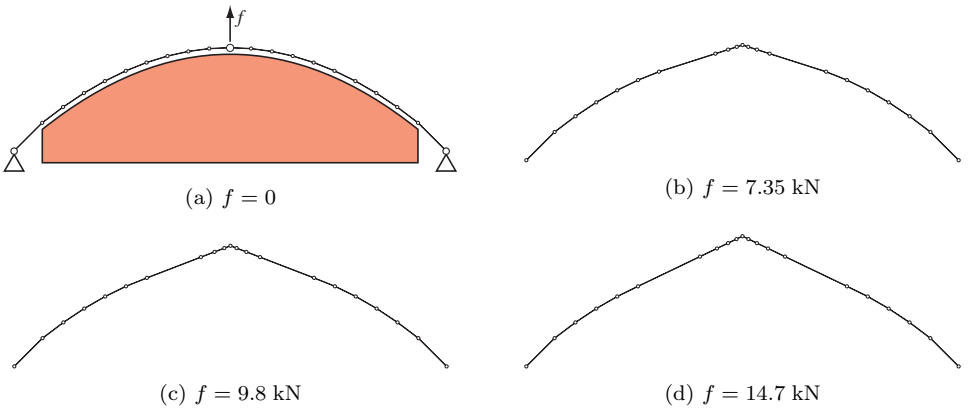


FIG. 8. *Symmetric half-part of* $\mathcal{H}$.

FIG. 9. *Equilibrium configurations of cable.*

shown in Figure 8, where the coordinates of the edges are listed in Table 2 for one of two symmetric parts. Thus, we have 18 auxiliary frictionless joints and one original frictionless joint, i.e., $n^{\mathrm{d}} = 57$, $n^{\mathrm{m}} = 20$, and $n^{\mathrm{c}} = 1$.

The external force f is applied in the positive direction of the z-axis at the original frictionless joint. The equilibrium configuration without external force is as shown in Figure 9(a), where the cable is in tension and contacts $\mathcal{H}$ at all the auxiliary joints. The pair of standard forms (2.3) and (2.4) with $\mathcal{K} = \mathbf{R}_+^{38} \times \mathbf{L}_+^3 \times (\mathbf{L}_+^4)^{20}$ is solved for various values of f, and the corresponding equilibrium configurations are as shown in Figure 9(b)–(d).

5.3. 2 × 9 cable network with rigid obstacle. Consider a cable network, the image of which projected to the horizontal plane makes a grid with 10 cm × 10.2 cm squares, illustrated in Figure 10. The nodes indicated by ○ are fixed, where the z-coordinates (cm) of the nodes are given as $z = -\gamma(y/1.02 - 5)(y/1.02 + 5) - 7$ with a positive parameter γ. The nodes indicated by ⊕ are also fixed in the xy-plane. We consider the obstacle $\mathcal{H}$ defined by (4.2) with $\mathcal{P} = \{1\}$, $\mathcal{Q}_1 = \{1, 2\}$, $\boldsymbol{a}_1 = (-3/\sqrt{109}, 0, 10/\sqrt{109})$, $\boldsymbol{a}_2 = (3/\sqrt{109}, 0, 10/\sqrt{109})$, and $\boldsymbol{b}_1 = \boldsymbol{b}_2 = (0, 0, -3)$. The nodes indicated by ⊗ and ● are pin-joints and auxiliary frictionless joints, respectively, where $n^{\mathrm{m}} = 56$, $n^{\mathrm{c}} = 47$, and $n^{\mathrm{d}} = 81$. The initial unstressed length of each cable is specified as $\ell_j^0 = 10.3$ cm. The external force 49 kN is applied at each node indicated by ⊗ in the negative direction of the z-axis. The equilibrium configuration at $\gamma = 0.4$ without external forces is illustrated in Figure 11.

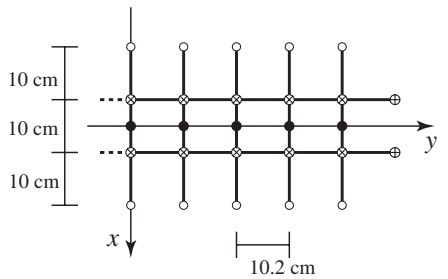

FIG. 10. *Symmetric half-part of Model* (III).

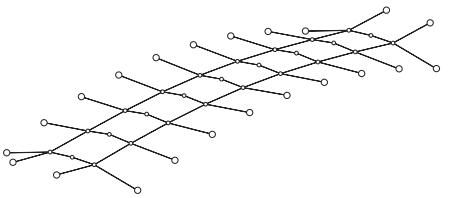

FIG. 11. *Equilibrium configuration of Model* (III) ($f = 0$, $\gamma = 0.4$).

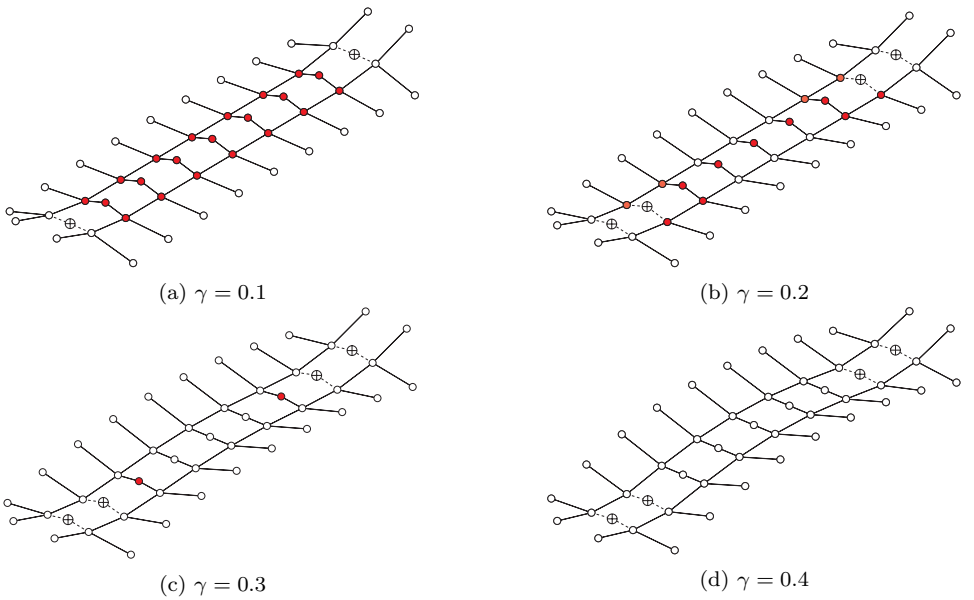

FIG. 12. *Equilibrium configurations of Model* (III).

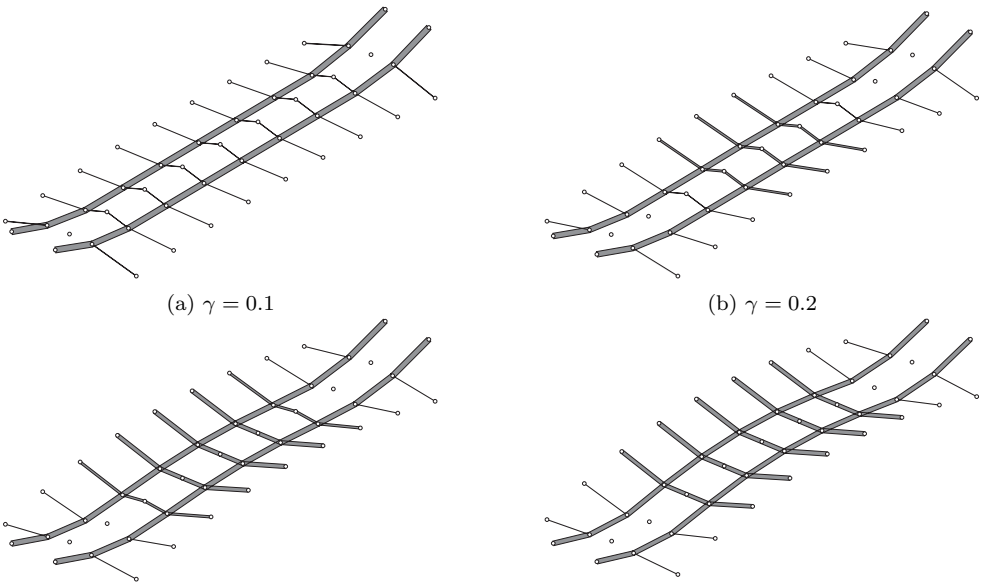

For various magnitudes of γ, the primal-dual pair of problems (4.13) and (4.14) is solved, where $\mathcal{K} = \mathbf{R}_+^{36} \times (\mathbf{L}_+^3)^{47} \times (\mathbf{L}_+^4)^{56}$, $m = 184$, and $n = 401$ in (2.4). The obtained configurations are shown in Figure 12. The cable network contacts $\mathcal{H}$ at the nodes indicated by $\bullet$ and $\oplus$, respectively, with and without contact forces. The dotted lines indicate slackening members. The stress state of each case is shown in Figure 13, where the width of each member is proportional to its axial force.

6. Proof of Lemma 2.1. Observe that the "only if" part of the lemma is immediately shown by substituting (2.7)–(2.9) and (2.12) into (2.11).

Next, we show the "if" part; i.e., suppose that (2.7) and (2.11) hold. The last inequality in (2.11) implies $q_j \geq 0$. On the other hand, from the first equality in (2.11), we have $y_j = q_j/k_j$. Consequently, we obtain

$$y_j \geq 0. \tag{6.1}$$

The two situations such that $y_j + \ell_j^0 = \sum_{i \in \mathcal{I}_j} \|\boldsymbol{h}_i\|$ and $y_j + \ell_j^0 > \sum_{i \in \mathcal{I}_j} \|\boldsymbol{h}_i\|$ are

(a) $\gamma = 0.1$ (b) $\gamma = 0.2$

(c) $\gamma = 0.3$ (d) $\gamma = 0.4$

FIG. 13. *Stress states of Model* (III).

investigated. Assume

$$y_j + \ell_j^0 = \sum_{i \in \mathcal{I}_j} \|\boldsymbol{h}_i\|. \tag{6.2}$$

From (2.7) and (6.2), we see that

$$y_j = c_j. \tag{6.3}$$

It is easy to see that (6.2) implies that

$$q_j(y_j + \ell_j^0) - \sum_{i \in \mathcal{I}_j} \boldsymbol{v}_i^\top \boldsymbol{h}_i = \sum_{i \in \mathcal{I}_j} (q_j \|\boldsymbol{h}_i\| - \boldsymbol{v}_i^\top \boldsymbol{h}_i). \tag{6.4}$$

By substituting Schwarz's inequality $-\boldsymbol{v}_i^\top \boldsymbol{h}_i \geq -\|\boldsymbol{v}_i\|\|\boldsymbol{h}_i\|$ into (6.4), we obtain

$$q_j \|\boldsymbol{h}_i\| - \boldsymbol{v}_i^\top \boldsymbol{h}_i \geq (q_j - \|\boldsymbol{v}_i\|)\|\boldsymbol{h}_i\| \geq 0, \tag{6.5}$$

where the second inequality follows the fourth condition in (2.11). Observe that, as a consequence of (6.4), the second condition in (2.11) is satisfied if and only if

$$q_j \|\boldsymbol{h}_i\| - \boldsymbol{v}_i^\top \boldsymbol{h}_i = 0 \quad (i \in \mathcal{I}_j). \tag{6.6}$$

If $\boldsymbol{h}_i = \boldsymbol{0}$, then it is easy to see that (2.9) is satisfied. On the other hand, if $\boldsymbol{h}_i \neq \boldsymbol{0}$ $(i \in \mathcal{I}_j)$, then it follows from the second inequality in (6.5) that (6.6) holds if and only if

$$q_j = \|\boldsymbol{v}_i\| \tag{6.7}$$

is satisfied. By substituting (6.7) into (6.6), we have $\|\boldsymbol{v}_i\|\|\boldsymbol{h}_i\| - \boldsymbol{v}_i^\top \boldsymbol{h}_i = 0$, which is reduced to (2.9). Moreover, (6.1) and (6.3) verify (2.12); from this and the first equality in (2.11) we obtain (2.8).

Alternatively, assume $y_j + \ell_j^0 > \sum_{i\in\mathcal{I}_j} \|\boldsymbol{h}_i\|$; from this and (2.7), we see

$$y_j > c_j. \tag{6.8}$$

Assume $q_j > 0$ for contradiction. It follows from the last condition in (2.11) and Schwarz's inequality that

$$q_j(y_j + \ell_j^0) - \sum_{i\in\mathcal{I}_j} \boldsymbol{v}_i^\top \boldsymbol{h}_i > \sum_{i\in\mathcal{I}_j} (q_j\|\boldsymbol{h}_i\| - \boldsymbol{v}_i^\top \boldsymbol{h}_i) \geq \sum_{i\in\mathcal{I}_j} (\|\boldsymbol{v}_i\|\|\boldsymbol{h}_i\| - \boldsymbol{v}_i^\top \boldsymbol{h}_i) \geq 0,$$

which contradicts the second condition in (2.11). Hence, $q_j = 0$ holds; from this and (6.8) and the first equality in (2.11) we obtain the second expression of (2.12). It is also seen that (2.8) is satisfied. The last inequality in (2.11) and $q_j = 0$ imply $\boldsymbol{v}_i = \boldsymbol{0}$ $(i \in \mathcal{I}_j)$, which verifies (2.9). ∎

7. Concluding remarks. In this paper, we have studied the contact problems of cable networks. These problems are characterized by the nonsmooth behaviors such that (i) some members of the cable network may possibly contact each other or the rigid obstacles at the equilibrium state and (ii) each member can transmit only tension force.

By introducing the concept of the auxiliary frictionless node, we define a contact candidate as a pair of two members of the cable network, or that of a member and an edge of the obstacle. Under some practically acceptable assumptions, we formulate the complementarity problems over second-order cones, which provides the configuration and contact forces at the equilibrium state. We show that the complementarity problem presented can be equivalently rewritten as a primal-dual pair of SOCP problems, which corresponds to the pair of minimization problems of total potential energy and complementary energy.

In the examples with various contact conditions, equilibrium configurations have been obtained by using the primal-dual interior-point method for SOCP. It has been shown in the examples that the computational cost of the proposed method does not increase drastically even if we incorporate the contact conditions as additional constraints. Although the proposed method requires the assumption that the candidate nodes should exist in some regions at the equilibrium state, it does not require any assumption on either contact conditions or stress states of cable members.

In addition to these advantages, the proposed SOCP problem can be solved efficiently by using well-developed software based on primal-dual interior-point methods. Therefore, our task is only to input the geometrical and material properties of cable networks, and no effort is required to develop any analysis software. Since the primal-dual interior-point methods solve both the primal and dual SOCP problems simultaneously, we can obtain the equilibrium configurations, cable elongation, internal forces, and contact forces simultaneously.

Acknowledgment. The authors thank two anonymous referees for their careful reading of the manuscript and their suggestions for improvements.

ON THE REGULARIZING POWER OF MULTIGRID-TYPE ALGORITHMS*

MARCO DONATELLI† AND STEFANO SERRA-CAPIZZANO†

Abstract. We consider the deblurring problem of noisy and blurred images in the case of known space invariant point spread functions with four choices of boundary conditions. We combine an algebraic multigrid previously defined ad hoc for structured matrices related to space invariant operators (Toeplitz, circulants, trigonometric matrix algebras, etc.) and the classical geometric multigrid studied in the partial differential equations context. The resulting technique is parameterized in order to have more degrees of freedom: a simple choice of the parameters allows us to devise a quite powerful regularizing method. It defines an iterative regularizing method where the smoother itself has to be an iterative regularizing method (e.g., conjugate gradient, Landweber, conjugate gradient for normal equations, etc.). More precisely, with respect to the smoother, the regularization properties are improved and the total complexity is lower. Furthermore, in several cases, when it is directly applied to the system $A\mathbf{f} = \mathbf{g}$, the quality of the restored image is comparable with that of all the best known techniques for the normal equations $A^TA\mathbf{f} = A^T\mathbf{g}$, but the related convergence is substantially faster. Finally, the associated curves of the relative errors versus the iteration numbers are "flatter" with respect to the smoother (the estimation of the stop iteration is less crucial). Therefore, we can choose multigrid procedures which are much more efficient than classical techniques without losing accuracy in the restored image (as often occurs when using preconditioning). Several numerical experiments show the effectiveness of our proposals.

Key words. image restoration, multigrid, iterative regularization methods

1. Introduction.

We consider the classical deblurring problem of noisy and blurred images in the case of space invariant point spread functions (PSFs). More precisely the problem is described by the following discrete problem (possible infinite) with shift invariant kernel, which leads to a system whose ith equation is given by

$$g(i) = \sum_{j \in \mathbf{Z}^2} h_{i-j} f(j) + \nu(i), \qquad i \in \mathbf{Z}^2. \tag{1.1}$$

Here the mask $H = (h_s)_{s \in \mathbf{Z}^2}$ represents the blurring operator; $\nu(s)$, $s \in \mathbf{Z}^2$, is the noise contribution; and $g(s)$, $s \in \mathbf{Z}^2$, is the blurred and noisy observed image; the problem is to recover the unknown true image $f(s)$ in the window of observation described by $s \in \{1, \ldots, n\}^2$. We assume that H is known, e.g., through experimental measurements.

It is clear that the system described by (1.1) is underdetermined since we have n^2 equations and $(n+m)^2$ unknowns involved when the support of the PSF is a square of size $m \times m$. In general, if the support of the PSF contains more than one point, then the number of unknowns exceeds the number of equations by at least n. In order to take care of this problem we can compute a least square solution or use appropriate boundary conditions (linear or affine relations between the unknowns outside the

window of observation and the unknowns inside the windows of observation) leading to a square linear system. The least square solution in principle is computationally very expensive even though recently a clever trick for reducing the related cost has been devised (see [4, 31]). The use of the boundary conditions (BCs) approach is usually preferred by practitioners. Among the BCs we count zero Dirichlet, periodic, reflective or Neumann, and antireflective. As proved in [19, 25], the last two BCs provide much more precise results with respect to the classical zero Dirichlet and periodic BCs. Moreover, in the noise-free case [25], the antireflective BCs improve by one order of approximation the restoration of the true object when compared with the reflective BCs. Indeed, the reflective and antireflective BCs have been introduced in order to reduce or eliminate some artifacts located close to the borders of the image and called ringing effects. These results are confirmed in the presence of noise also when the use of regularization methods is highly recommended: in [10] we applied Tikhonov-like methods and conjugate gradient (CG) with optimal parameters for a slight modification of the linear system called reblurred linear system. When using antireflective BCs, these techniques work better than the classical Tikhonov method (see [28]) and CG for normal equations with optimal parameters, while for the remaining BCs the reblurred modification and the classical methods coincide when the PSF is symmetric.

In this paper we propose the use of multigrid methods as regularizing procedures (for the notion of regularization, see [3, 11, 28]): in order to gain in efficiency, the multigrid methods that we consider are designed ad hoc for the structured linear systems arising from the various BCs. We observe two-level Toeplitz structures when applying zero Dirichlet BCs, we have two-level circulant matrices when applying periodic BCs, and we find two-level matrices from the DCT-III algebra and from the DST-I algebra when enforcing reflective and anti-reflective BCs, respectively. The good news is that for all these structured matrices very efficient multigrid methods have been devised [13, 26, 8]. When the two-level matrices are also banded at each level, then the related overall cost is of the order of $O(n^2)$ arithmetic operations; if the matrices considered are dense, then the cost is of the order of $O(n^2 \log(n))$ arithmetic operations (for the algorithmic proposals see [13, 26, 8], and for the theoretical cost and convergence analysis see [1, 24]). In conclusion, we can assume that from the viewpoint of the complexity the multigrid proposal is a very good one. Here, taking into account the presence of noise, we discuss how to modify the method in order to introduce proper regularization features; in fact, this is the main aim of the paper.

In part of the numerical experiments we will assume that the image is located in a uniform background (but this requirement is not absolutely essential as shown by the example in section 5.1, and our proposal works essentially unchanged with general images where we are forced to use a more precise BC such as the reflective or antireflective). Under these special assumptions (often fulfilled in astronomical imaging), the four mentioned BCs are equivalent from the model viewpoint, and indeed we do not observe ringing effects. Therefore, in this ideal setting we can concentrate on checking the quality of the reconstruction with respect to the deblurring/denoising procedure.

To this end many techniques have been proposed: Tikhonov's method, Riley's method (a variant of the Tikhonov technique when the blurring matrix is symmetric and close to positive definite), Landweber, CG and its version applied to normal equations (CGNE) with early stopping, and so on. Here we propose a new iterative technique with early stopping of the iterations, which is of multigrid type. We

combine an algebraic multigrid previously defined ad hoc for structured matrices related to space invariant operators (Toeplitz, circulants, trigonometric matrix algebras, etc.) and the classical geometric multigrid designed for discretized partial differential equations (PDEs). In particular the reduction to lower dimension is made by using the Galerkin approach (without rediscretization); the structure of the prolongation operator and of the restriction operator or projector (essentially the transpose of the prolongation operator) is that of the algebraic multigrid indicated in [1] in order to maintain the structure of the problem at each level; and finally, from the viewpoint of the compact Fourier analysis [29], the prolongation operator is that of the classical geometric multigrid, i.e., the one representing the linear interpolation (a low-pass filter). The resulting technique is parameterized in order to have more degrees of freedom. A simple choice of the parameters allows one to devise a powerful regularizing method whose features are the following:

(a) It is used with early stopping (as in CG, CGNE, and the Landweber method), and its cost per iteration is about 1/3 of the cost of the method used as a smoother (CG, Landweber, CGNE);
(b) it can be adapted to work with all the BCs used in the literature (Dirichlet, periodic, Neumann/reflective or antireflective) since the basic algebraic multigrid considered in [1] is an optimally convergent method for any of the involved structures (Toeplitz, circulant, cosine-algebra, or sine-algebra) which naturally arise from the chosen BCs;
(c) the minimal relative error with respect to the true image is significantly lower with regard to all the best known techniques directly applied to the system $A\mathbf{f} = \mathbf{g}$ (Riley, CG, preconditioned CG, etc.), with optimal parameters, and the associated curve of the relative errors with respect to the iterations is "flatter" (at least in our set of experiments);
(d) when the smoothing step is applied to the normal equations $A^TA\mathbf{f} = A^T\mathbf{g}$ we observe that the minimal relative error and the total complexity are slightly lower in comparison with all the best known techniques (Tikhonov, CGNE, Landweber, etc.) with optimal parameters, and the associated curve of the relative errors versus the iterations number is, at least in our set of experiments, "flatter" (therefore, the quality of the reconstruction is not critically dependent on the choice of iteration at which to stop);
(e) when the smoothing step is applied to the system $A\mathbf{f} = \mathbf{g}$ the minimal relative error is comparable with regard to all the best known techniques for the normal equations $A^TA\mathbf{f} = A^T\mathbf{g}$, but in this case the convergence is much faster;
(f) it can be combined with nonnegativity constraints (by using a simple projection at every step); in that case we observed a substantial improvement in the total cost and in the precision when compared with the very precise but extremely slowly convergent projected CGNE and Landweber. Furthermore, in principle, it can be used in connection with edge preserving procedures such as total variation, Bayesian methods, and deterministic strategies (see, e.g., [21, 18, 14, 5]). Indeed, the nonconvex optimization (which characterizes all these quite expensive techniques) should be solved by some kind of iterative method which uses linearization, and our multigrid procedure can be applied at this level (instead of using preconditioning as suggested in [7, 2]). Finally, a priori information on the statistical nature of the noise could also be exploited for defining more appropriate interpolation and smoothing operators. All these issues will be investigated in future work.

Due to the applications in astronomy, we preferred the use of periodic BCs and therefore the version of an algebraic multigrid for two-level circulant matrices (see [26, 1]). However, as clearly discussed in sections 3 and 4, the regularizing power of our multigrid technique does not depend on the BCs (only the algebraic part of the procedure has to be conveniently adapted). Indeed, with reflective BCs the structure is related to the DCT-III algebra, with antireflective BCs the structure is related to the DST-I algebra, and optimal algebraic multigrid methods have been devised for both (see [8, 13, 1]). Extensive numerical experiments in this direction, in order to check the regularizing features of our multigrid with all the BCs considered, will be part of a future work. We tried several images and, concerning items (c) and (d), the results of our reconstruction are uniformly better with respect to the classical methods (Riley, CG, Richardson); moreover, the associated complexity is of the same order as the usual techniques. Concerning items (e) and (f), the conclusions are in some sense dual since the quality of our reconstruction is comparable to or slightly better than the best methods (Tikhonov, CGNE, Landweber with optimal parameters), but our procedure is much faster when compared with the classical iterative regularizers such as CGNE and Landweber.

We stress that multigrid procedures have already been considered in the image restoration literature by Chan, Chan, and Wan [6], Huckle and Staudacher [17], and the first author [9]. However, these works represent only numerical linear algebra contributions and do not concern regularization. The authors consider the regularized system (by using total variation and standard Tikhonov approaches, respectively), and then they use multigrid in order to obtain a fast convergence on the algebraic system (and not for regularization purposes). Our approach tries to combine numerical linear algebra requests (low complexity, exploitation of the structured matrices, etc.) and regularization issues (a good precision at the optimal iteration). No explicit comparison is made with the preconditioned conjugate gradient (PCG) and the PCG for normal equation (PCGNE) methods since the quality of their reconstructions is generally worse (see, e.g., [16, 12]) when compared with standard CG and CGNE methods; consequently, in terms of quality reconstruction and numerical complexity, a comparison with the latter two techniques is sufficient.

In summary, the main aim of this paper is to show that the proposed multigrid method (MGM) is a general framework: it can be used to improve the quality of the restored image and/or to reduce the computational cost of an iterative regularizing method which is used as a smoother in the multigrid approach. Furthermore, it inherits all the properties of the iterative regularizing methods; for instance, it can be combined with nonnegativity constraints. Finally, we emphasize that usually it is not strictly necessary to resort to a smoother applied to the normal equations since the multilevel strategy performs a further filtering.

The paper is organized as follows: in section 2, we describe the classical (geometric) multigrid, while the algebraic multigrid for shift-invariant structured matrices (belonging to trigonometric matrix algebras or to the Toeplitz class) is described in section 3. In section 4 we adapt the algebraic multigrid algorithm to the image restoration case: we essentially use projectors classically employed in the context of PDEs but now interpreted in the language of signals and images; furthermore, we give a theoretical explanation of why the technique is effective and furnish an analysis of the arithmetic cost (per iteration). In section 5 we present a wide experimentation with various choices of PSFs and signal to noise ratios (SNRs). Moreover, we compare our proposal with other iterative regularizing methods like CG, CGNE, Richardson,

Landweber, and the Tikhonov technique in terms of both resulting accuracy and complexity. In section 6 we show that the multigrid regularization is a general framework which can lead to several generalizations. Section 7 is then devoted to discussing the perspectives that such a class of multigrid-type algorithms offers in terms of regularizing features.

2. The multigrid algorithm. For solving the linear system $A_n\mathbf{x}_n = \mathbf{b}_n$, the two-grid method (TGM) refers to a smaller linear system $A_k\mathbf{x}_k = \mathbf{b}_k$ with $k < n$. In its simpler version, the TGM is the combination of two fixed-point methods: the smoother and the coarse grid correction (CGC). More precisely we have

$$\mathbf{y}_n := \mathsf{TGM}(\mathbf{x}_n, \mathbf{b}_n, S_n, \nu)$$

$$\begin{aligned}
&\texttt{If (size}(\mathbf{b}_n) \le c\texttt{) Then } \mathbf{y}_n = A_n^{-1}\mathbf{b}_n \\
&\texttt{Else } \tilde{\mathbf{x}} := \mathsf{Smooth}\big(\mathbf{x}_n, \mathbf{b}_n, S_n, \nu\big) \\
&\qquad \mathbf{b}_k := P_n^k(\mathbf{b}_n - A_n\tilde{\mathbf{x}}_n) \\
&\qquad\qquad (P_n^k\mathbf{b}_n \text{ in precomputing phase}) \\
&\qquad A_k := P_n^k A_n (P_n^k)^T \ \text{(in precomputing phase)} \\
&\qquad \mathbf{y}_k := A_k^{-1}\mathbf{b}_k \\
&\qquad \mathbf{y}_n := \tilde{\mathbf{x}}_n + (P_n^k)^T\mathbf{y}_k,
\end{aligned} \tag{2.1}$$

where c is a small constant dimension under which it is not useful to apply a two-grid strategy. By $\mathsf{Smooth}\big(\mathbf{x}_n, \mathbf{b}_n, S_n, \nu\big)$ we denote the application of ν steps of the smoother method defined by the iteration matrix S_n. In this work we do not use postsmoothing, so the presmoother is simply called the smoother. The smoother is a fixed-point iteration of the kind

$$\mathbf{x}_n^{(j+1)} = S_n\mathbf{x}_n^{(j)} + \mathbf{c}_n, \tag{2.2}$$

where $\mathbf{c}_n$ is easily computable (low cost) and is implicitly defined as $A_n(I_n - S_n)^{-1}\mathbf{c}_n = \mathbf{b}_n$ with I_n being the identity matrix of dimension n. Usually the smoother is a method like damped Jacobi, Richardson, or Gauss–Seidel, which generally are slowly convergent iterative solvers when applied to ill-conditioned linear systems. The CGC operator projects the error equation into a subspace of dimension k (usually $k \approx n/2^d$ in d dimensional problems), solves the smaller system, and then interpolates the solution to come back to the space of higher dimension n. Formally, the corresponding iteration matrix is defined as

$$CGC_n = I_n - P_k^n A_k^{-1} P_n^k A_n, \tag{2.3}$$

where the full-rank $P_\alpha^\beta \in \mathbb{R}^{\beta\times\alpha}$ projects $\mathbb{R}^\alpha$ into $\mathbb{R}^\beta$ and $A_k \in \mathbb{R}^{k\times k}$ is the projected version of A_n in the lower dimensional space. Following the Galerkin formulation, we have $A_k = P_n^k A_n P_k^n$ and $P_k^n = c(P_n^k)^T$ with c constant and where, without loss of generality, we take $c = 1$. We stress that CGC_n defined in (2.3) is a projection matrix having eigenvalues equal to zero or to one (it is a filter in the space spanned by the columns of $A_n^{-1}P_n^k$), and therefore it is not a convergent iterative method. However, its combination with the smoother is the TGM whose iteration matrix is $TGM_n = CGC_n \cdot S_n^\nu$: if we choose the projector P_k^n and/or the smoother S_k^n in such a way that CGC_n and S_n^ν have spectral complementary behavior [23], then the resulting TGM can be very effective for the solution of linear systems arising from elliptic PDEs [15] or with structured coefficient matrices related to space invariant operators [1, 13, 8]. More precisely, from an algebraic point of view [22, 23], in order to obtain

an effective method the smoother and the CGC must bring down the error in two orthogonal subspaces. Therefore, we can freeze CGC_n and then choose the smoother appropriately as in the geometric multigrid, or we can consider a fixed smoother and then choose the projector appropriately for the CGC as in [22, 1]. Now we are ready to introduce and describe a true multigrid method. In fact, the main difference with respect to the TGM is as follows. Instead of solving the linear system directly with coefficient matrix A_k, we can apply recursively the projection strategy obtaining an MGM: in this case the CGC operator CGC_n is replaced by an approximation, since the matrix A_k^{-1} is approximated by $(I_k - MGM_k^{\gamma})\, A_k^{-1}$ as implicitly described in (2.5) with $k = n_{l-1}$. Concerning notation, we will emphasize the recursion levels. If l is the maximal number of recursive calls, then MGM_i, $i = 1, \ldots, l$, denotes MGM_{n_i} with $0 < n_0 < n_1 < \cdots < n_l = n$ and n_j being the real matrix sizes. In this way $MGM_l = MGM_{n_l} = MGM_n$, $S_l = S_{n_l} = S_n$, $\mathbf{b}_l = \mathbf{b}_{n_l} = \mathbf{b}_n$, $\mathbf{x}_l^{(j)} = \mathbf{x}_{n_l}^{(j)} = \mathbf{x}_n^{(j)}$, and the smaller dimension k of the TGM method will become the dimension after the first recursive call, i.e., $k = n_{l-1}$. Let γ be the number of recursive calls at each level, let $\boldsymbol{\nu} = (*, \nu_1, \nu_2, \ldots, \nu_l)$ with ν_i being the number of smoothing steps at level i (at level zero, of course, $\nu_0 = *$ means that no smoothing is applied), and let us use the Galerkin formulation. Then the corresponding multigrid algorithm generates the approximate solution $\mathbf{x}_n^{(j+1)} = \mathsf{MGM}(l, \mathbf{x}_n^{(j)}, \mathbf{b}_n, S_n, \boldsymbol{\nu}, \gamma)$ according to the following rule:

$\mathbf{y}_i := \mathsf{MGM}(i, \mathbf{x}_i, \mathbf{b}_i, S_i, \boldsymbol{\nu}, \gamma)$

(2.4)

```
If (i = 0) Then Solve(A_0 y_0 = b_0)
           Else x̃_i    := Smooth(x_i, b_i, S_i, ν_i)
                b_{i-1} := P_i^{i-1}(b_i − A_i x̃_i)
                                  (P_i^{i-1} b_i in precomputing phase)
                A_{i-1} := P_i^{i-1} A_i (P_i^{i-1})^T  (in precomputing phase)
                y_{i-1} := 0_{i-1}
                for k = 1, γ
                    y_{i-1} := MGM(i − 1, y_{i-1}, b_{i-1}, S_{i-1}, ν, γ)
                y_i     := x̃_i + (P_i^{i-1})^T y_{i-1}.
```

Since the multigrid is again a fixed-point method, we can express $\mathbf{x}_n^{(j+1)}$ as $MGM_l \mathbf{x}_n^{(j)} + (I_n - MGM_l) A_n^{-1} \mathbf{b}_n$, where the iteration matrix MGM_l is recursively defined as follows [29]:

(2.5)
$$\begin{cases} MGM_0 = O, \\ MGM_i = \left[I_{n_i} - (P_i^{i-1})^T \left(I_{n_{i-1}} - MGM_{i-1}^{\gamma} \right) A_{i-1}^{-1} P_i^{i-1} A_i \right] \cdot S_i^{\nu_i}, \quad i = 1, \ldots, l. \end{cases}$$

For $\gamma = 1$ and $\gamma = 2$ we have the V-cycle and the W-cycle, respectively, and for $\gamma = 1$ and $l = 1$ we obtain the TGM algorithm if $\mathsf{Solve}(A_1 \mathbf{y}_1 = \mathbf{b}_1)$ is $\mathbf{y}_1 = A_1^{-1} \mathbf{b}_1$.

When considering the classical geometric multigrid, $(P_i^{i-1})^T$ is fixed and usually represents the linear interpolator, while the smoother is a simple iterative method (usually damped). For the algebraic multigrid described in [1], the smoother is a priori decided to be the damped Richardson, while P_i^{i-1} is a function of the entries of the coefficient matrix.

3. A multigrid scheme for shift invariant operators. As already mentioned in the introduction, the use of BCs leads to linear systems with coefficient matrices belonging to the two-level Toeplitz class or to two-level matrix algebras:

BCs	A_n essentially is a
Dirichlet	two-level Toeplitz
periodic	two-level circulant
reflective (Neumann)	two-level DCT-III
antireflective	two-level DST-I.

More specifically, when considering the first three choices of the BCs, the related structure is exact while, in the case of antireflective BCs, we do not find exactly a DST-I matrix. However, the solution of the associated linear system can be reduced to the solution of a linear system with a coefficient matrix belonging to the two-level DST-I algebra (see [25]).

As briefly observed in the introduction, the choice of the BCs is relevant for the precision of the restored image. In particular, when inappropriate BCs are employed, some artifacts appear close to the borders of the image and often, due to the ill-conditioning of the discrete blur operator, they spread throughout the image. More precisely, these artifacts, called ringing effects, come from artificial discontinuities introduced in the image by the imposed BCs. In this respect and with regard to computational requirements, a simple classification can be made. Zero Dirichlet BCs impose an artificial discontinuity at the borders, and the resulting structure is two-level Toeplitz (i.e., block Toeplitz with Toeplitz blocks); periodic BCs can again impose an artificial discontinuity at the borders and the resulting structure is two-level circulant (i.e., block circulant with circulant blocks). Symmetric or reflective or Neumann BCs preserve the continuity of the image but not the continuity of its normal derivative; as a consequence the ringing effects are significantly reduced (by one order of magnitude), and the resulting structure is two-level Toeplitz + Hankel. Finally, antireflective BCs preserve the continuity of the image and of its normal derivative, and the resulting structure is two-level Toeplitz + Hankel + low rank correction. From a linear algebra viewpoint, for two-level circulant matrices both solution of a linear system and matrix-vector product can be achieved in $O(n^2 \log n)$ complex operations by fast Fourier transforms (FFTs); for two-level Toeplitz or Hankel matrices the multiplication by a vector can be done in $O(n^2 \log n)$ complex operations by using FFTs, while the solution of an associated linear system is extremely costly in general. However, if the PSF is doubly symmetric for reflective and antireflective BCs, the matrix-vector multiplication and the solution of a linear system can be obtained in $O(n^2 \log n)$ real operations by fast cosine transforms (DCT-III) [19] or by fast sine transforms (DST-I) [25], respectively.

The rest of the section is devoted to the definition of the relevant matrix classes (circulants, DCT-III and DST-I algebras, Toeplitz structures) and to a brief description of the essentials of the related multigrid procedures.

3.1. Matrix algebras and Toeplitz matrices. We introduce the matrix algebras by following a unifying approach first in the one-dimensional (1D) case (signals) and then in the 2D case (images). Therefore, we denote with the multi-index n the size of the problem, which is $n = (n^{(1)}, n^{(2)})$ in the 2D case for an $n^{(1)} \times n^{(2)}$ problem with algebraic size $N = n^{(1)} \cdot n^{(2)}$, while in the 1D case it is simply $n = n^{(1)} = N$.

In the 1D case let $f : \mathbb{R} \to \mathbb{R}$ and let Q_n be the unitary matrix (i.e., $Q_n^{-1} = Q_n^H$) related to our matrix algebras. We can define the Hermitian matrix $A_n = Q_n^H \cdot \mathrm{Diag} f(\mathbf{w}^{[n]}) \cdot Q_n$, where $\mathbf{w}^{[n]}$ is a fixed vector of $\mathbb{R}^n$ and $f(\mathbf{w}^{[n]})$ denotes the

vector whose components are $f(w_i^{[n]})$, $i = 1, \ldots, n$. As a consequence $\mathbf{q}_i^{[n]} = Q_n^H \mathbf{e}_i$ is a unitary eigenvector of A_n related to the eigenvalue $f(w_i^{[n]})$. Furthermore, the generating function f defines A_n univocally, and hence we can denote A_n by $\mathcal{A}_n(f)$, where $\mathcal{A} \in \{\mathcal{C}, \mathcal{N}, \mathcal{S}\}$, which means that $\mathcal{C}_n(f)$ is circulant, $\mathcal{N}_n(f)$ is DCT-III, and $\mathcal{S}_n(f)$ is DST-I. For any of the considered algebras, the mathematical objects Q_n and $\mathbf{w}^{[n]}$ are defined in Table 3.1.

TABLE 3.1
Matrix algebras in the 1D case.

Algebra	$\mathcal{A}$	$\mathcal{I}_n$	$[\mathbf{w}^{[n]}]_{i \in \mathcal{I}_n}$	$[Q_n]_{i,j \in \mathcal{I}_n}$
Circulant	$\mathcal{C}$	$0, \ldots, n-1$	$w_i^{[n]} = \frac{2\pi i}{n}$	$\frac{1}{\sqrt{n}}\left[\mathrm{e}^{\mathbf{i}jw_i^{[n]}}\right]$
DCT-III	$\mathcal{N}$	$0, \ldots, n-1$	$w_i^{[n]} = \frac{\pi i}{n}$	$\sqrt{\frac{2-\delta_{j,1}}{n}}\left[\cos\left((j+\frac{1}{2})w_i^{[n]}\right)\right]$ $\delta_{1,1} = 1,\ \delta_{j,1} = 0$ for $j \neq 1$
DST-I	$\mathcal{S}$	$1, \ldots, n$	$w_i^{[n]} = \frac{\pi i}{n+1}$	$\sqrt{\frac{2}{n+1}}\left[\sin\left(jw_i^{[n]}\right)\right]$

In the 2D case, a two-level matrix of partial dimensions $n = (n^{(1)}, n^{(2)})$ and true dimension $N = n^{(1)} \cdot n^{(2)}$ can be described as an $n^{(1)} \times n^{(1)}$ block matrix whose elements are $n^{(2)} \times n^{(2)}$ block matrices. The two-level Toeplitz matrix $T_n(f)$ is defined as

$$T_n(f) = T_{n^{(1)},n^{(2)}}(f) = \sum_{|j_1|<n^{(1)}} \sum_{|j_2|<n^{(2)}} a_{(j_1,j_2)} J_{n^{(1)}}^{[j_1]} \otimes J_{n^{(2)}}^{[j_2]}$$

by means of the Fourier coefficients of f

$$a_{(j_1,j_2)} = \frac{1}{4\pi^2} \int_{[-\pi,\pi]^2} f(x,y) \mathrm{e}^{-\mathbf{i}(j_1 x + j_2 y)} \mathrm{d}x \mathrm{d}y, \qquad \mathbf{i}^2 = -1.$$

Here $J_m^{[j]} \in \mathbb{R}^{m \times m}$ is the matrix whose entry (s,t) equals 1 if $s - t = j$ and is 0 elsewhere. The circulant, DCT-III, and DST-I two-level matrix algebras can be defined as the matrix algebras generated from $Q_{n^{(1)}} \otimes Q_{n^{(2)}}$, with $Q_{n^{(1)}}$ and $Q_{n^{(2)}}$ selected in the same row of Table 3.1. Of course we can associate multilevel matrices $\mathcal{C}_n(f)$, $\mathcal{N}_n(f)$, and $\mathcal{S}_n(f)$ to every bivariate function $f : \mathbb{R}^2 \to \mathbb{R}$. Therefore, $\mathcal{A}_n(f) = \mathcal{A}_{n^{(1)},n^{(2)}}(f) = (Q_{n^{(1)}} \otimes Q_{n^{(2)}})^T \mathrm{Diag} f(\mathbf{w}^{[n]})(Q_{n^{(1)}} \otimes Q_{n^{(2)}})$, where $\mathbf{w}^{[n]} = \mathbf{w}^{[n^{(1)}]} \times \mathbf{w}^{[n^{(2)}]}$ and $\mathbf{w}^{[n_j]}$, $j = 1, 2$, are the same as $\mathbf{w}^{[n]}$ in Table 3.1.

It is known (see, e.g., [25, 19]) that if f is a nonnegative trigonometric polynomial, all the matrices $\mathcal{A}_n(f)$, $\mathcal{A} \in \{\mathcal{C}, \mathcal{N}, \mathcal{S}, T\}$, are (essentially) banded and, whenever f takes the zero value, they are ill conditioned. Furthermore, we require f even (with respect to each variable) in the DCT-III and DST-I cases.

3.2. A multigrid algorithm preserving the structure. We define a multigrid algorithm for two-level Toeplitz, circulant, DCT-III, and DST-I matrices using the Galerkin formulation. The algebraic requirement to define an MGM is that, for each recursion level $i = 1, \ldots, l$, the coefficient matrix A_i has to belong to the same matrix class (Toeplitz, circulant, DCT-III, or DST-I) allowing the recursive application of the algorithm. Let N_i be the dimension of the problem at the level i ($N_l = N$);

TABLE 3.2
Dimensions and cutting operators in the 1D case for $i = 1, \dots, l$.

	Circulant	Toeplitz & DST-I	DCT-III
n_l	2^k	$2^k - 1$	2^k
n_{i-1}	$\frac{n_i}{2}$	$\frac{n_i - 1}{2}$	$\frac{n_i}{2}$
$K_{n_i} \in \mathbb{R}^{n_{i-1} \times n_i}$	$\begin{bmatrix} 1 & 0 & & & \\ & 1 & 0 & & \\ & & \ddots & \ddots & \\ & & & 1 & 0 \end{bmatrix}$	$\begin{bmatrix} 0 & 1 & 0 & & \\ & 0 & 1 & 0 & \\ & & \ddots & \ddots & \ddots \\ & & & 0 & 1 & 0 \end{bmatrix}$	$\begin{bmatrix} 1 & 1 & 0 & & \\ & 1 & 1 & 0 & \\ & & \ddots & \ddots & \ddots \\ & & & 0 & 1 & 1 \end{bmatrix}$

the algebraic requirement is fulfilled with an appropriate choice of the projector $P_i^{i-1} : \mathbb{R}^{N_i} \to \mathbb{R}^{N_{i-1}}$. More precisely, in the 1D case we have $P_i^{i-1} = K_{n_i} \mathcal{A}_{n_i}(p_i)$ for $i = 1, \dots, l$, where $\mathcal{A}_{n_i}(p_i)$ belongs to the same class as $\mathcal{A}_{n_i}(f_i)$ and K_{n_i} is the cutting matrix defined in Table 3.2 that preserves the same structure at each level (p_i is a trigonometric polynomial whose choice will be discussed a bit later).

We stress that in the algebraic case we have $\mathcal{A}_{n_i}(p_i)\mathcal{A}_{n_i}(f_i) = \mathcal{A}_{n_i}(p_i f_i)$, while for the Toeplitz class the structure is preserved at each level only if p_i has degree at most one (for p_i of greater degree we can change K_{n_i}, adding some zero columns at the beginning and at the end; see [1]). The choice of p_i is a technical task and, in order to obtain a fast solver which converges within a constant number of iterations independent of the size of the problem, it has to satisfy two analytic conditions for which we refer to [24, 1, 8]. In the present work we need only a simple projector, which is the classic linear interpolation used in the geometric multigrid and such that it preserves the structure of the matrix at each level. Therefore we take P_i^{i-1} associated with the related BCs generated by $p_i(x) = (1 + \cos(x))$, which maintains also the Toeplitz structure in the case of Dirichlet BCs.

In the 2D case we have $N_i = n_i^{(1)} n_i^{(2)}$, where the dimensions $n_i^{(1)}$ and $n_i^{(2)}$ evolve as in the Table 3.2. Moreover, $P_i^{i-1} = (K_{n_i^{(1)}} \otimes K_{n_i^{(2)}})\, \mathcal{A}_{n_i^{(1)}, n_i^{(2)}}(p_i)$, with p_i being a bivariate trigonometric polynomial. In this work, extending the 1D choice, we take

$$p_i(x, y) = (1 + \cos(x))(1 + \cos(y)), \tag{3.1}$$

that is, bilinear interpolation.

When damped Richardson (iteration matrix given by $S_i = I_i - \omega_i \mathcal{A}_i(f_i)$) is used as the smoother for $A_i = \mathcal{A}_i(f_i)$, the relaxation parameter ω_i has to be in $[0, 2/\|f_i\|_\infty]$. In our experimentation we take $\omega_i = 1/\|f_i\|_\infty$ (classical Richardson without damping) according to the choice performed in [1], but, of course, different values of ω_i can be explored.

From a computational cost point of view, the assembling of $A_i = \mathcal{A}_i(f_i)$, for $i = 0, \dots, l-1$, does not increase the cost of the whole iterative method since the number of nonzero entries of P_i^{i-1} in the 1D case is less than $3N_i$ and in the 2D case is less than $5N_i$ for $i = 1, \dots, l$. Therefore, A_{i-1} can be computed within a number of operations substantially lower than the matrix-vector product which involves the matrix A_i. Furthermore, all the matrices A_i can be formed in a setup phase before starting the MGM and with a total computational cost lower than the matrix-vector product with the matrix A_l. Indeed, the considered precomputing phase cost is of $O(\log(N))$ if f is a trigonometric polynomial with few nonzero entries with respect to N (A_l sparse), and it is of $O(N \log(N))$ if A_l is a dense matrix.

Concerning the arithmetic cost of one multigrid iteration, for a PSF with small support (sparse linear systems), up to constant order terms, and without considering the recursive calls, the computational cost at each level i is lower than cN_i with c constant. Therefore, the total computational cost $C(\mathsf{MGM}_n)$ of one complete multigrid cycle in 2D is

$$C(\mathsf{MGM}_n) \leq \begin{cases} \frac{4}{3}cN + O(\log(N)), & \gamma = 1, \\ 2cN + O(\log(N)), & \gamma = 2, \\ 4cN + O(\log(N)), & \gamma = 3, \\ O(N\log(N)), & \gamma = 4 \end{cases} \tag{3.2}$$

(see [29] for further details).

4. A multigrid algorithm with regularizing properties. In this section we describe a multigrid algorithm which is able to improve the regularizing properties of the iterative method used as a smoother. The considered feature derives from a particular choice of the projector which is obtained by linking the geometric multigrid with its interpretation in terms of algebraic multigrid. First we give the idea behind the regularization through projection and we explain why it works, and then we use it to define a multigrid regularizing strategy.

4.1. Regularization through projection. We give some arguments to explain why MGM can improve the regularization property of iterative methods like CG, Richardson, CGNE, or Landweber. For the sake of simplicity, the description is provided in the 1D case, but the same analysis works in the multidimensional case as well.

When the PSF is space invariant and we impose BCs the coefficient matrix is generated by a function that is zero or close to zero in a (possibly large) neighborhood of π and reaches the maximum value (which is 1, thanks to the normalization condition) at zero. For instance, in Figure 4.1 a Gaussian PSF with mask $\mathbf{a} = [\mathrm{e}^{-\mathbf{x}^2}]/\mathrm{c}$ and its generating function $z(y) = \sum_{i=-50}^{50} a_i \mathrm{e}^{-\mathrm{i}y}$ are shown. Here $\mathbf{x}$ is an equispaced sampling of 101 points in $[-10, 10]$, and c is a normalization constant such that $\sum_i a_i = 1$. Let $\mathcal{A}_n(z)$ be Toeplitz, circulant, DCT-III, or DST-I; then its eigenvalues are about an evaluation of $z(y)$ over a uniform sampling of y in $[0, \pi]$, and the eigenvectors are discrete frequency vectors whose frequency is about $\frac{yn}{2\pi}$ (see [25, 30]). Therefore, since the ill-conditioned subspace is associated with small eigenvalues, from Figure 4.1 we can see that this degenerating subspace has very large dimension (this characterizes the discretized ill-posed problems) and it essentially contains the high frequencies subspace where the noise usually lives. Classical iterative methods like CG and Richardson first reduce the error in the well-conditioned subspace, low frequencies in our case [1, 6, 26]. For instance, using the previous PSF and the original signal $\mathbf{f}$ defined as a uniform sampling of $f(x) = \sin(x)$ in $[0, \pi]$, we create the observed signal $\mathbf{g}$ as $\mathbf{g} = \mathcal{A}_n(z)\mathbf{f}$. Solving the linear system $\mathcal{A}_n(z)\mathbf{x} = \mathbf{g}$ with Richardson, taking an initial error which has components in low and high frequencies, the low frequencies are reduced after a few iterations, while the high frequencies are still almost unchanged after 10 iterations (see Figure 4.2). Therefore, the error has the usual semiconvergence property: it decreases while we are working in the low frequencies subspace, reaches a minimum, and then increases again when we arrive to work in the (unfortunately large) ill-conditioned subspace (high frequencies in our case).

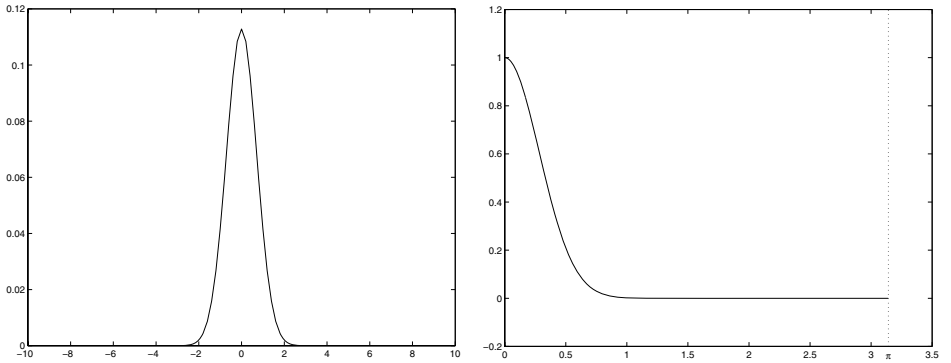

FIG. 4.1. *Gaussian PSF normalized with a constant c and its generating function.*

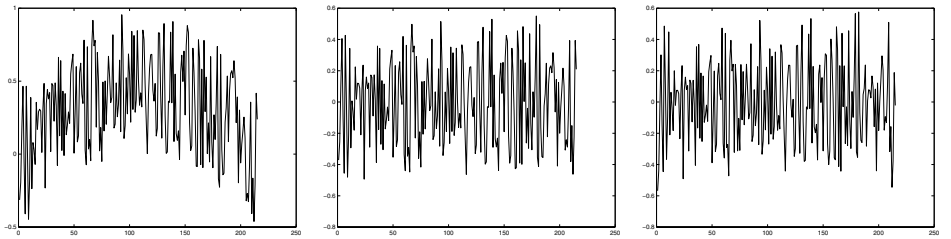

FIG. 4.2. *Components of the restoration error.*

In order to obtain an effective and fast method according to the algebraic multigrid theory [1], the algebraic multigrid used in [9] projects the system in the high frequencies subspace because this is the space where the smoother is ineffective and where we would like to obtain a better approximation. Unfortunately, the high frequencies not only contain fundamental parts of the image (e.g., the nonnegligible high frequency portion of the edges) but also a substantial part of the noise. Therefore, as already shown in [9], we obtain the noise explosion already after a few iterations, and consequently we must resort to the Tikhonov regularization and apply the algebraic multigrid to the regularized system. The good news is that we obtain a robust method which, in some cases, shows a convergence speed independent of both the matrix size and the regularization parameter (see [1, 26, 9]).

Here we would like to propose a different approach, that is, use the MGM directly as a regularizer. Instead of projecting into the high frequencies subspace, the idea is to project into a subspace where we would like to discriminate between the noise contribution and the edges which are of great importance for identifying an image. The latter important feature can be obtained via projection techniques employed in the geometric multigrid. It is well known that the MGM is an optimal solver for PDEs, where the ill-conditioned subspace is spanned by low frequencies. For instance, in the Poisson problem we have as coefficient matrix $T_n(z)$, where $z(x) = 2 - 2\cos(x)$, $x \in [0, \pi]$, that vanishes at zero and grows monotonically in $[0, \pi]$, reaching its maximum

at π. The simplest projector used for PDEs is the weighted average

$$P_i^{i-1} = \frac{1}{4}\begin{bmatrix} 1 & 2 & 1 & & & & & \\ & & 1 & 2 & 1 & & & \\ & & & & \ddots & \ddots & & \\ & & & & & 1 & 2 & 1 \end{bmatrix}_{n_{i-1}\times n_i},$$

while the interpolation operator is the simple linear interpolation $2(P_i^{i-1})^T$. We observe that the jth column of the interpolation operator is given by

$$0.5\left[\mathbf{e}_{j-1} + 2\mathbf{e}_j + \mathbf{e}_{j+1}\right], \quad \mathbf{e}_k = k\text{th canonical vector}.$$

These vectors, looked at as samplings of functions, have nontrivial components in lower frequencies, but their high-frequency contribution is not generic since it is associated with the necessity of preserving the jumps which characterize the edges of an image. Indeed the jth column of the interpolation operator can be seen as the sum of box functions or can be interpreted as a local linear spline: note that it is reminiscent of the basis functions in the wavelets theory. Of course in a real image restoration, 2D case, the projector will be a tensor product of a given pair of functions having the aforementioned shape.

We remark that P_i^{i-1} is the same projector used in the algebraic multigrid when considering Dirichlet BCs and with a related generating function having only one zero at the origin with order almost two. More generally, the projection into the low frequencies subspace can be obtained as $P_i^{i-1} = K_i\mathcal{A}_i(p)$ with $p(x) = 1 + \cos(x)$, where $\mathcal{A} \in \{\mathcal{C}, \mathcal{N}, \mathcal{S}, T\}$ according to the BCs used. Therefore, the latter is a good choice since it allows one to project into the low frequencies subspace where there is less noise explosion. In this way we force the smoother to better solve the problem in the subspace where there is less noise. We remark that by projecting into the low frequencies subspace we lose the optimality property of the algebraic multigrid, but now the MGM is used as a regularizer and not as a fast solver for algebraic systems. Finally, if we have a regularizing iterative method like CG, Richardson, CGNE, or Landweber, we can include it as a smoother, thereby improving the quality of the restored image.

From another point of view the effect of P_i^{i-1} on the observed image $\mathbf{g}$ is like a reblurring (see [3, 10]) obtained from a weighted average and after a down-sampling by a factor of two as a compression operation. Moreover, the effect of the linear interpolation $(P_i^{i-1})^T$ on the solution computed in the coarser grid is a smoothing effect, since the linear interpolation can reproduce well only the smooth components; it is unable to reproduce those highly oscillating components which contain the highest percentage of noise.

4.2. Two-level regularization. Using the idea described in the previous section we can define a two-level (TL) regularizing method with the following algorithm:

$$\mathbf{y}_n := \mathsf{TL}(\mathbf{x_n}, \mathbf{b}_n, S_n, \beta)$$

$$\begin{array}{l} \mathbf{b}_k := P_n^k(\mathbf{b}_n - A_n\mathbf{x_n}) \ (P_n^k\mathbf{b}_n \text{ in precomputing phase}) \\ A_k := P_n^k A_n (P_n^k)^T \qquad (\text{in precomputing phase}) \\ \mathbf{y}_k := \mathsf{Smooth}\big(\mathbf{0}_k, \mathbf{b}_k, S_k, \beta\big) \\ \mathbf{y}_n := \mathbf{x_n} + (P_n^k)^T\mathbf{y}_k. \end{array} \tag{4.1}$$

Here S_k is the same smoother as S_n but of different size (which has to be a regularizing method) applied to A_k, and β is defined in order to reach the best restoration error (instead of defining β, it is possible to apply an early stopping criterion to the coarser system $A_k\mathbf{y}_k = \mathbf{b}_k$). The TL looks like a TGM where at the finer level no smoother is applied. But perhaps the main difference between TL and TGM is that, at the coarser level, instead of solving the system directly, TL applies β iterations of the smoother.

Moreover, employing a uniform multigrid language, the above algorithm belongs to the classical multigrid scheme where, following the notation of section 2, it can be formulated as

$$\begin{aligned} &\mathsf{TL}(\mathbf{x}_n, \mathbf{b}_n, S_n, \beta) = \mathsf{MGM}(1, \mathbf{x}_n, \mathbf{b}_n, S_n, (*, 0), 1), \quad \text{where} \\ &\mathsf{Solve}(A_0\mathbf{y}_0 = \mathbf{b}_0) \to \mathbf{y}_0 := \mathsf{Smooth}\big(\mathbf{0}_0, \mathbf{b}_0, S_0, \beta\big). \end{aligned} \tag{4.2}$$

Since at the finer level we do not apply any smoother, we can also interpolate the solution obtained at each iteration and apply the early stopping criterion at the finer level. This means that performing one iteration of TL and β iterations of smoother is exactly the same as performing β iterations of TL and one of smoother.

PROPOSITION 4.1. *Let* $\mathbf{x}_n^{(j+1)} = \mathsf{TL}(\mathbf{x}_n^{(j)}, \mathbf{b}_n, S_n, 1)$, *for* $j = 0, \ldots, \beta - 1$, *and let* $\mathbf{y}_n^{(\beta)} = \mathsf{TL}(\mathbf{x}_n^{(0)}, \mathbf{b}_n, S_n, \beta)$. *Then* $\mathbf{x}_n^{(\beta)} = \mathbf{y}_n^{(\beta)}$.

Proof. It is sufficient to prove the assertion for $\beta = 2$; indeed, for a generic β the claim follows by induction. Furthermore, since TL is a fixed-point method and since the starting point $\mathbf{x}_n^{(0)}$ is the same for the two iterations, it is sufficient to show that the two methods which generate $\mathbf{x}_n^{(\beta)}$ and $\mathbf{y}_n^{(\beta)}$ have the same iteration matrix. Recalling that the smoother is defined as in (2.2), it holds that

$$\begin{aligned} \mathbf{x}_n^{(1)} &= \mathsf{TL}(\mathbf{x}_n^{(0)}, \mathbf{b}_n, S_n, 1) = (I_n - R_nA_n)\mathbf{x}_n^{(0)} + R_n\mathbf{b}_n, \\ R_n &= (P_n^k)^T(I_k - S_k)A_k^{-1}P_n^k, \end{aligned}$$

and therefore $\mathbf{x}_n^{(2)} = (I_n - R_nA_n)^2\mathbf{x}_n^{(0)} + (2I_n - R_nA_n)R_n\mathbf{b}_n$. Furthermore,

$$\begin{aligned} \mathbf{y}_n^{(2)} &= \mathsf{TL}(\mathbf{x}_n^{(0)}, \mathbf{b}_n, S_n, 2) = (I_n - Q_nA_n)\mathbf{x}_n^{(0)} + Q_n\mathbf{b}_n, \\ Q_n &= (P_n^k)^T(S_k + I_k)(I_k - S_k)A_k^{-1}P_n^k, \end{aligned}$$

and we have only to prove that $(I_n - R_nA_n)^2 = (I_n - Q_nA_n)$. Since $A_k = P_n^kA_n(P_n^k)^T$, we finally infer

$$\begin{aligned} (I_n - R_nA_n)^2 &= I_n - 2R_nA_n + R_nA_nR_nA_n \\ &= I_n - 2(P_n^k)^T(I_k - S_k)A_k^{-1}P_n^kA_n + (P_n^k)^T(I_k - S_k)^2A_k^{-1}P_n^kA_n \\ &= I_n - (P_n^k)^T(I_k - S_k)(I_k + S_k)A_k^{-1}P_n^kA_n \\ &= I_n - Q_nA_n, \end{aligned}$$

and the proof is concluded. ∎

We remark that the latter proposition could be used for analyzing the convergence features and the regularization effects of the TL. Indeed, informally speaking, if we use an iterative regularizing method as smoother (let us say Richardson, CGNE, etc.), then in our two-level algorithm we are anticipating or postponing a low-pass filter, and therefore it is not possible that the global two-level iteration amplifies the noise contributions.

4.3. Multigrid regularization. According to the description in section 2, the TGM leads to an MGM in a natural way. Similarly, the TL regularization previously proposed can be applied recursively, obtaining a multigrid regularization. To this end, the definition contained in (4.2) with $\beta = 1$ is especially useful. In terms of regularization, this means that at the coarser level we apply a smoothing iteration and then we project again into the well-conditioned subspace. This can be repeated until we reach a small grid (e.g., 8×8), where the associated linear system can be solved directly since the problem is computationally negligible, and the noise explosion is easily controllable and avoidable. If the observed image is of size $n^{(1)} \times n^{(2)}$, then we obtain a regularizing multigrid algorithm taking

1. $l = \min\{\log_2(n^{(1)} - 8), \log_2(n^{(2)} - 8)\}$,
2. $\boldsymbol{\nu} = (*, 1, \ldots, 1, 0)$,
3. $\mathsf{Solve}(A_0\mathbf{y}_0 = \mathbf{b}_0) \to \mathbf{y}_0 = A_0^{-1}\mathbf{b}_0$,
4. $S_n =$ an iterative regularizing method.

The choice of γ will be discussed in section 6: we notice that its value can be increased in order to perform more work in the well-conditioned subspace. However, the V-cycle (i.e., $\gamma = 1$) can be a good choice for every kind of problem (high or low percentage noise, good or bad BCs, etc.). Therefore, in the following experimentation we will use the notation $\mathsf{MGM}(S_n, \gamma)$ instead of $\mathsf{MGM}(\min\{\log_2(n^{(1)} - 8), \log_2(n^{(2)} - 8)\}, \mathbf{x}_n^{(j)}, \mathbf{b}_n, S_n, (*, 1, \ldots, 1, 0), \gamma)$, because with the latter choices S_n and γ are the only free parameters. For damped Richardson the relaxation parameter is chosen according to section 3.2, and so $S_n = I_n - A_n(f)/\|f\|_\infty$ is briefly denoted by $S_n =$ Rich. The Landweber method is exactly the application of Richardson to the normal equations, and hence it will be denoted by $S_n =$ RichNE. The classical MGM theory requires that the smoother be a stationary method even if better performances can be observed when nonstationary methods are used, possibly with flexible preconditioning (for the theory of flexible preconditioning, see, e.g., the very interesting paper [27]). Here the point of view is different since we are interested in the regularization features of the method, i.e., in its semiconvergence. We will denote the use of the CG method as a smoother by $S_n =$ CG, and when it is applied to the normal equations we write $S_n =$ CGNE. Since all the parameters of the problem are fixed, as for the MGM, concerning the TL method we indicate only the smoother (i.e., $\mathsf{TL}(S_n)$) since we assume $\beta = 1$ to compute the restoration error at each iteration.

When the observed image has a high percentage of noise or the PSF is not positive definite, it is necessary to resort to the normal equations, and usually the preferred iterative methods are CGNE or Landweber. These methods require only matrix-vector products and thus they can be plainly applied to the normal equations without requiring the effective computation of the matrix $A_n^T A_n$. When we use the Galerkin formulation in the MGM, the coefficient matrix at each level is obtained through projections, and hence it is necessary to assemble the coefficient matrices $A_i^T A_i$ at every level i. For Dirichlet BCs, this leads to a loss of the TL Toeplitz structure. When considering the remaining BCs, for which the related computations can be performed by convolutions, we observe again computational problems. More precisely, the resulting coefficient matrices at each level have a double block bandwidth, and each block has a double bandwidth: therefore, every matrix-vector product is increased by a factor of 4 instead of 2, as happens when applying CG to the normal equations (CGNE) or Landweber. To avoid this kind of problem and to emphasize the robustness of the proposed technique, we propose using the classic Galerkin formulation, projecting at each level i only the matrix A_i, and applying as smoother an iterative method for

normal equations like CGNE or Landweber. This choice follows the philosophy according to which the proposed MGM is a framework for improving the regularization properties of a classic regularizing method, and therefore it should be applied directly to the original system with coefficient matrix A_n.

4.4. Computational cost analysis. In this section we analyze the computational cost of one iteration of the multigrid regularizing method $\mathsf{MGM}(S_n, \gamma)$. More specifically, we will consider (3.2) by giving details on the constants involved and by comparing the resulting cost with that of a single smoothing iteration.

For the sake of simplicity, we consider square images of size $n \times n$, with $n = 2^l$, and therefore the algebraic size of the linear system at each recursion level is $N_i = n_i^2$, with $N_{i-1} = N_i/4$, $i = 0, \ldots, l$, according to Table 3.2 (in the Toeplitz and DST-I cases this is not exactly true since we work with odd dimensions, but the same considerations hold). The computational cost of $\mathsf{MGM}(S_{n_i}, \gamma)$ at a fixed level i is

$$C(\mathsf{MGM}(S_{n_i}, \gamma)) = \gamma C(\mathsf{MGM}(S_{n_{i-1}}, \gamma)) + P(n_i) + W(n_i), \qquad i = 1, \ldots, l, \tag{4.3}$$

where $P(n_i)$ is the projection cost and $W(n_i)$ is the cost of one smoother iteration S_{n_i}. Without loss of generality we assume $C(\mathsf{MGM}(S_{n_0}, \gamma)) = 1$; indeed, in a practical implementation we stop the recursion a little before, but for n large enough the direct solution at the coarsest level is negligible.

The computational cost of the projection at the level i is the sum of two matrix-vector products, one with P_i^{i-1} and the other with $(P_i^{i-1})^T$, since we take p_i as in (3.1)—the first one is $7/4N_i$ and the second one is $7/8N_i$. However, more generally (it will be useful later), we have

$$P(n_i) = bN_i, \tag{4.4}$$

and in our case $b = 21/8$.

We consider a PSF with small support with respect to the size of the image, obtaining $W(n) = aN$ with $a > b > 1$. Usually $a \gg b$, especially if the smoother is applied to the normal equations. From the analysis in [1], the bandwidth of A_{i-1} is about half of the bandwidth of A_i along both directions (at blocks and inside each block); hence

$$W(n_i) < aN_i.$$

Since $N_{i-1} = N_i/4$, $i = 1, \ldots, l$, from (4.3) we have the following general behavior:

$$C(\mathsf{MGM}(S_n, \gamma)) = \begin{cases} O(N), & \gamma < 4, \\ O(N \log(n)), & \gamma = 4, \\ O(N^{\log_4(\gamma)}), & \gamma > 4. \end{cases} \tag{4.5}$$

However, in the cases $\gamma = 1, 2, 3$ we can provide an explicit evaluation of the constants involved as functions of a and b. Indeed, by applying relation (4.3) recursively and

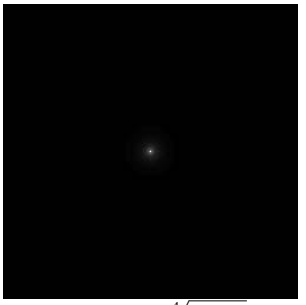
assuming $W(n_l) = 0$, we infer

$$\begin{aligned} C(\mathsf{MGM}(S_n,\gamma)) &= \gamma C(\mathsf{MGM}(S_{n_2},\gamma)) + P(n_1) = \cdots \\ &= \sum_{i=0}^{l-1} P(n_{l-i})\gamma^i + \sum_{i=1}^{l-1} W(n_{l-i})\gamma^i + \gamma^l \\ &< \sum_{i=0}^{l-1} P(n_{l-i})\gamma^i + \sum_{i=1}^{l} W(n_{l-i})\gamma^i \\ &< bN \sum_{i=0}^{l-1} \left(\frac{\gamma}{4}\right)^i + aN \sum_{i=1}^{l} \left(\frac{\gamma}{4}\right)^i \\ &< \frac{(4b+\gamma a)N}{4-\gamma}, \end{aligned}$$

which can be summarized as

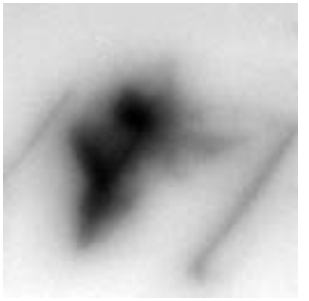
$$C(\mathsf{MGM}(S_n,\gamma)) < \begin{cases} \left(\frac{4b}{3} + \frac{a}{3}\right)N, & \gamma = 1, \\ (2b+a)N, & \gamma = 2, \\ (4b+3a)N, & \gamma = 3. \end{cases}$$

Therefore, under the assumption $a \gg b$, which is usually satisfied in every practical application, we deduce the following relationship between the computational cost of $\mathsf{MGM}(S_n,\gamma)$ and that of the smoothing step:



$$C(\mathsf{MGM}(S_n,\gamma)) \approx \begin{cases} \frac{1}{3}W(N), & \gamma = 1, \\ W(N), & \gamma = 2, \\ 3W(N), & \gamma = 3. \end{cases} \tag{4.6}$$

We emphasize that the case of the V-cycle ($\gamma = 1$) is very interesting since its cost is about one third of a standard smoother applied to the finest grid. Moreover, when the assumption about the small support of the PSF is not satisfied, then the advantage of the multigrid algorithms with respect to the smoothers becomes even stronger. More specifically, for a generic PSF, the matrix-vector product is computed through fast discrete transforms and then $W(n_i) = O(N_i \log(N_i))$, while the projection is identical. Therefore, the computational cost of the smoother dominates the computational cost of the projection, and the latter can be neglected. Consequently, taking into account that the smoothers considered are extremely slow (see next section), the conclusion is that in general the $\mathsf{MGM}(S_n,\gamma)$ algorithm is more efficient than the smoother at the finest level alone.



5. Numerical experiments. We present a wide experimentation in order to show the regularization properties of the proposed technique. We consider periodic BCs since they are widely used in astronomical imaging. However, similar results can also be obtained by employing other BCs like Dirichlet, reflective, or antireflective since, as discussed in section 3, similar multigrid methods have been defined also for linear systems arising from these types of BCs [1, 8]. Since we know the true image $\mathbf{x}$ at each iteration j, we can evaluate and plot the relative error norm $e_j = \|\mathbf{x} - \mathbf{x}^{(j)}\|_2 / \|\mathbf{x}\|_2$ for each iterative regularization method. The algorithms are implemented in Fortran 90 using double precision, while the images and the graphs are made by using MATLAB.

Minimum error and related number of iterations

FIG. 5.2. *Airplane with* $SNR = 100$: *relative error norm versus number of iterations.*

5.1. An airplane with periodic BCs. The PSF is created as a uniform sampling of 51 points of $e^{-\sqrt[4]{x^2+y^2}}$ in $[-20, 20] \times [-20, 20]$, while for the noise we add a random vector with uniform distribution and SNR equal to 100. The original airplane image and its blurred and noisy version are shown in Figure 5.1 (the original picture is a portion of a larger image from which the blurred one is obtained). The smallest eigenvalue of the coefficient matrix is of the order of 10^{-3}, and the matrix is positive definite. As a matter of fact, it is not strictly necessary to apply CG or Richardson to the normal equations, but it is recommended in order to obtain a good quality of the deblurred image. It is interesting to observe that the proposed multigrid, with the simple Richardson method as smoother, leads to a restoration error lower than the one obtained by CGNE or Landweber (see Figure 5.2). In this example the TL and MGM with a smoother for normal equations do not improve the quality of the restored image, because the value 0.112 is about the minimum error norm from a modelistic point of view. Indeed, by Tikhonov regularization, solving the linear system $(A_n^T A_n + \mu I_n)\mathbf{x}_n = A_n^T \mathbf{b}_n$, and choosing μ as the experimental optimal value ($\mu = 0.001$), the minimum restoration error is 0.1127, which is essentially the same value that we obtain by MGM(Rich, 1).

For higher levels of noise, e.g., SNR $= 10$, using CG or Richardson we observe noise explosion already after very few iterations, and therefore it is necessary to resort to the normal equations. In Figure 5.3, for SNR $= 10$ we can see that both the TL strategy and the MGM regularization techniques, with CGNE or Landweber as smoother,

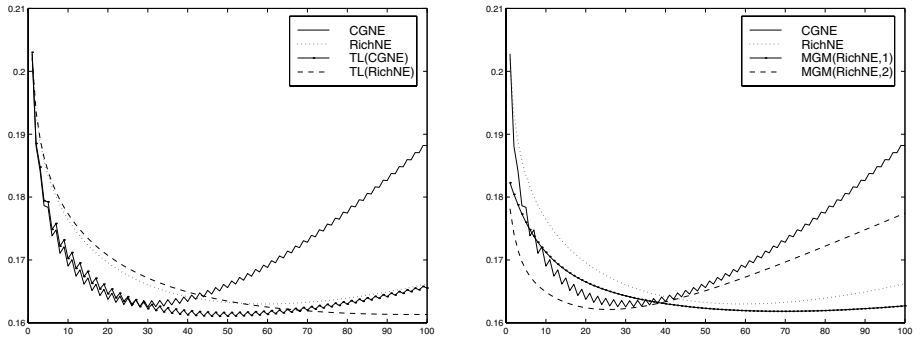

FIG. 5.3. *Airplane with $SNR = 10$: relative error norm versus number of iterations.*

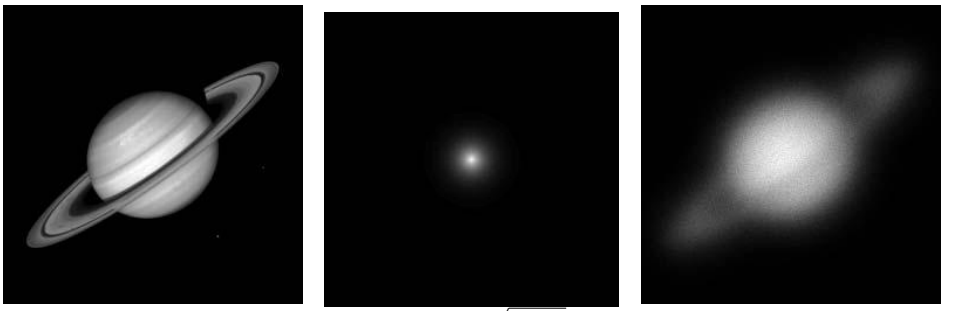

TABLE 5.1
Airplane with $SNR = 10$: minimum error and related number of iterations.

Method	$\min_{j=1,\dots}(e_j)$	$\arg\min_{j=1,\dots}(e_j)$
CGNE	0.1625	30
RichNE	0.1630	59

MGM(RichNE,1)	0.1618	69
MGM(RichNE,2)	0.1621	26
MGM(Rich,1)	0.1648	3
MGM(Rich,2)	0.1630	1

show an error curve with a lower minimum and a flatter behavior with regard to CGNE and Landweber alone. Of course, this is good news since the evaluation of the early stopping criterion becomes much easier. Moreover, for MGM with Richardson as smoother, we observe about the same restoration error norm as the one obtained by CGNE or by Landweber, again without resorting to normal equations and with a significantly smaller number of iterations (see Table 5.1).

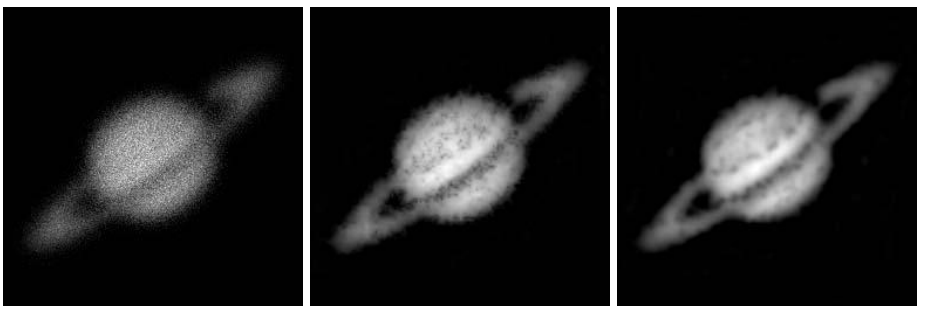
This example clearly shows that the multigrid strategy not only improves the regularization properties of the iterative method used as smoother, but usually it does not require resorting to normal equations at all. In this way we obtain about the same (or a slightly lower) restoration error as the best iterative regularization methods applied to the normal equations, but with a measurable reduction in the arithmetic cost.

5.2. An astronomical image with nonnegativity constraints. In this example we use the PSF, the original 256×256 image of Saturn, and its blurred and noisy (with Poisson noise) version in Figure 5.4. Since this is an astronomical image, we consider a black extension outside of the image, and thus all the BCs are equivalent and do not introduce any approximation error in the model. The PSF is created as a uniform sampling of $e^{-\sqrt{x^2+y^2}}$ of 101 points in $[-5, 5] \times [-5, 5]$. Therefore, not only is the coefficient matrix ill-conditioned in a subspace of very large dimension (it happens in the case of Gaussian-like blurs, as clearly shown in the second part of Figure 4.1), but it also has some small negative eigenvalues with magnitude of order of 10^{-4}. Regarding the noise, we add Poisson noise to the blurred image with SNR = 30.

Original image of Saturn PSF = $e^{-\sqrt{x^2+y^2}}$ Blurred image + SNR = 30

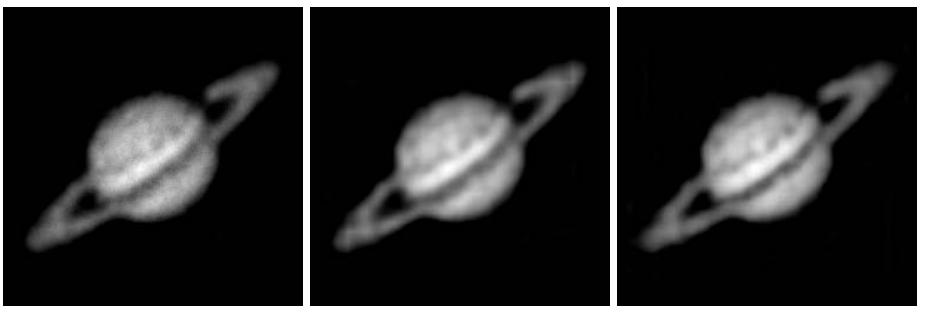
FIG. 5.4. *PSF and images of Saturn (Poisson noise).*

From a practical point of view one should impose nonnegativity constraints. This task can be accomplished by projecting into the convex set of nonnegative entries, leading to a nonlinear operator. Despite its nonlinearity it can easily be implemented by setting to zero the negative entries of the current approximation for each step of an iterative regularizing method. A procedure of this kind widely used in astronomical imaging is the projected Landweber method. Usually it converges very slowly, and therefore it is often used in connection with accelerating techniques employing preconditioning strategies (see [20]). However, while our multigrid accelerates the smoother convergence by keeping the reconstruction error low, often the effect of the preconditioning is to (partially) spoil the quality of the restored image (see, e.g., [12, 16]). In this context our multigrid can be extended in two directions:



(1) projecting each approximation into the nonnegative cone (e.g., using Landweber as smoother and $\mathbf{x}^{(j+1)} = P_+\mathsf{MGM}(\mathbf{x}^{(j)})$ instead of $\mathbf{x}^{(j+1)} = \mathsf{MGM}(\mathbf{x}^{(j)})$, where P_+ projects into the nonnegative cone),
(2) using a projected method as smoother (e.g., projected Landweber).

The first choice is the classic strategy for the projection into the nonnegative cone for a generic iterative method. The second choice does not assure the nonnegativity: the projection is a weighted average or a linear interpolation, so it preserves the nonnegativity constraint of the smoother, but at the coarsest level the direct solution destroys the nonnegativity. Therefore, the latter strategy has to be combined with the previous one, or we have to project the coarsest level solution into the nonnegative cone. Experimentally, we obtain better results by using the first proposal, that is, by projecting both the smoother and every global iteration.



In the following the projected version of an iterative method will be denoted by the plus symbol (e.g., the projected Landweber is denoted by RichNE$^+$, and choice (1) is denoted by $\mathsf{MGM}(\cdot,\cdot)^+$). In Table 5.2 we report the minimal values reached by every method and the corresponding iteration. We can see that the first choice is uniformly better than the second (we recall that the latter does not preserve the nonnegativity), and their combination gives the best results; furthermore, all these strategies are much more effective than classic projected iterative methods (such as CG and Richardson) when applied alone to the linear system $A_n\mathbf{x} = \mathbf{b}$. Moreover, a useful property of our method (e.g., $\mathsf{MGM}(\text{Rich}^+, 2)^+$) is that the reconstruction quality is similar to the one obtained by the projected Landweber or projected CGNE but with the use of a much smaller number of iterations and without resorting to the normal equations (see Figure 5.5). However, if the main wish is to further improve the quality of the deblurred image, we can use projected Landweber or projected

TABLE 5.2
Saturn: Minimum relative error norm and its number of iterations (projected methods).

CG^+ (2 iter.) | $\mathsf{MGM}(\mathrm{Rich}^+, 2)^+$ (5 iter.) | $\mathsf{MGM}(\mathrm{Rich}^+, 2)^+$ ($\alpha = 5$ in 14 iter.)

CGNE^+ (442 iter.) | $\mathsf{MGM}(\mathrm{CGNE}^+, 1)^+$ (337 iter.) | $\mathsf{MGM}(\mathrm{CGNE}^+, 2)^+$ (26 iter.)

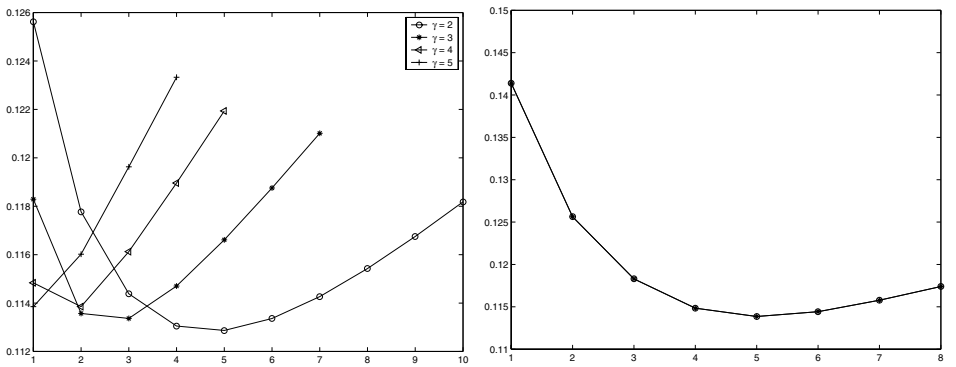
FIG. 5.5. *Restored images at the minimum relative error norm value.*

CGNE as the smoother in the MGM with a total computational cost which is again significantly lower than for the standard projected methods. To reduce the error to 0.238 the projected CGNE requires 442 iterations and the projected Landweber requires 676 iterations, while $\mathsf{MGM}(\mathrm{CGNE}^+, 2)^+$ requires 26 iterations to reduce the error to 0.235 (see Table 5.2). We emphasize that one W-cycle iteration requires approximately the same arithmetic cost as one smoother iteration (see (4.6)): this fact results in a huge saving in time (in addition to a slightly better reconstruction).

TABLE 5.3
Minimum relative error norm for MGM(Rich$^+$, 2)$^+$ varying the degree α of the transfer grid operator ($\alpha = 1$ is the linear interpolation).

α	$\min_{j=1,\dots}(e_j)$	$\arg\min_{j=1,\dots}(e_j)$
1	0.2473	5
2	0.2421	7
3	0.2408	9
4	0.2398	12
5	0.2392	14

Finally, we study the behavior of our MGM proposal by changing a different degree of freedom. In particular we consider the choice of the multigrid transfer grid operator in order to obtain approximately the best restored image without resorting to the normal equations for the smoothing step. Here the PSF has a large support, and the periodic BCs are exact. As shown in Table 5.2, iterative methods for the normal equations require an unacceptably large number of iterations, while the MGM(Rich$^+$, 2)$^+$ loses some details (when compared to the projected CGNE) in the reconstructed image (even if its quality is still reasonably good (see Figure 5.5)). In order to overcome the problem without using a smoother for the normal equations, we can improve the filtering properties of the multigrid transfer grid operator. In fact, instead of employing linear interpolation, we choose cubic interpolation or, more generally, an operator whose generating function is equal to $(1+\cos(x))^\alpha(1+\cos(y))^\alpha$ with $\alpha \in \mathbb{N}^+$ (the linear interpolation is recovered by setting $\alpha = 1$). In Table 5.3 it is shown that, using MGM(Rich$^+$, 2)$^+$ already for $\alpha = 4, 5$, the minimum restoration error norm is slightly greater than the one obtained by CGNE$^+$. Indeed, in Figure 5.5 we can see that MGM(Rich$^+$, 2)$^+$ with $\alpha = 5$ and CGNE$^+$ produces images with about the same level of detail. Furthermore MGM(Rich$^+$, 2)$^+$ with $\alpha = 5$ is much cheaper than CGNE$^+$, since not only does it require 14 iterations instead of 442, but one of its iterations has about the same computational cost as one Richardson iteration. As a matter of fact, the value of b in (4.4) grows linearly with α. More precisely, the size of the stencil related to $\mathcal{A}_{N_i}(p_i)$ is $(2\alpha+1) \times (2\alpha+1)$, and therefore, for small values of α (let us say at most 5), a projection operation is again cheaper than the matrix-vector product with A_i and hence favorable with respect to the normal equation approach.



We remark that the improvement of the projector is an idea which has some analogies with the reblurring proposed in [10]. Indeed, since $A_{i-1} = P_i^{i-1} A_i (P_i^{i-1})^T$ and since $P_i^{i-1} = K_{N_i}\mathcal{A}_{N_i}(p_i)$, before the application of the cutting matrices K_{N_i} and $K_{N_i}^T$ we perform a double reblurring to the left and to the right with matrices $\mathcal{A}_{N_i}(p_i)$ and $(\mathcal{A}_{N_i}(p_i))^T$.

6. The γ regularization. As already observed, the proposed regularizing MGM leads to several generalizations which show the great flexibility of a multigrid approach. For instance, by increasing the work in the projected subspace we obtain a better deblurred image with fewer iterations. More precisely, we consider a bigger value of γ and, as a result, the associated MGM is no longer of iterative type, but it is a regularization direct method where the only parameter to be estimated is γ. We are not able to define an optimal choice of γ, but this can be the subject of future research.

As an example we consider the airplane deblurring described in section 5.1 with

TABLE 6.1
Relative error norms varying γ in the case of the airplane image with $SNR = 100$.

γ	e_1	$\min_{j=1,\dots}(e_j)$	$\arg\min_{j=1,\dots}(e_j)$
1	0.1414	0.1127	12
2	0.1256	0.1129	5
3	0.1183	0.1134	4
4	0.1148	0.1139	2
5	0.1139	0.1139	1
6	0.1144	0.1144	1
7	0.1158	0.1158	1

Error norm vs. number of iterations

Error at the first iteration e_1 vs. γ

FIG. 6.1. *Airplane with $SNR = 100$: relative error norm varying γ.*

SNR = 100 (see Figures 5.1 and 5.2). Here we study the behavior of the relative error norm after only one iteration of MGM(Rich, γ) when γ grows (as shown in Figure 6.1). By varying γ, the relative error norm at the first iteration e_1 decreases, reaches its minimum value for $\gamma = 5$, and then increases again; see also Table 6.1. We remark that the optimal restoration error obtained in one iteration with $\gamma = 5$ ($e_1 = 0.1139$) is about the same optimal value obtained by CGNE or Landweber (that is, 0.1135). However, the latter two methods require many more iterations (178 iterations for CGNE and 352 iterations for Landweber) and are applied to normal equations.

In the case of SNR = 10, in Table 5.1 it was already shown that the minimum e_1 is reached for $\gamma = 2$ and that it is the same value obtained by the Landweber method in 59 iterations.

As already observed, for a PSF with a numerically small support, i.e., a TL banded coefficient matrix with $O(N)$ nonzero entries, the computational cost of MGM(S_n, γ) grows with γ according to (4.5).

In conclusion, the considered extension of the regularization MGM is evidence that the multigrid techniques can represent a general framework which is the basis for further investigations. As an example, we should think about the optimal choice of the projector, of the smoother, of $\boldsymbol{\nu}$ (number of smoothing steps at the various levels), and of course of the number γ of recursive calls.

7. Conclusions. In this work we have presented a class of regularizing multigrid algorithms whose features are the following: if it is compared with other regularizing procedures (CG, Richardson, Riley) applied directly to the system $A\mathbf{f} = \mathbf{g}$, then the curve of relative errors is much flatter, the quality of the reconstruction is higher,

and the total arithmetic costs are similar; if it is compared with the best regularizing methods for the normal equations $A^TA\mathbf{f} = A^T\mathbf{g}$ (CGNE, Landweber, Tikhonov), then the accuracy of the restored image is similar (at most slightly better), the structure of the error curve is essentially the same, but the cost is greatly reduced. In every case, our multigrid can use normal equation methods only for the smoother, while the projection to a coarser grid is done always on the original coefficient matrix; this usually allows us to obtain a slightly better reconstruction and a lesser computational time compared with the best regularizing methods for the normal equations.

Furthermore, we stress that the presented approach can be looked at as a general framework which has the potential of leading to several extensions and improvements, and, in this respect, a lot of analysis must still be done. For instance, open questions concern the analysis of convergence and, more interestingly, the theoretical proof of the regularizing effects of the proposed method or the choice of γ in order to obtain a direct (one-step!) multigrid regularization.

Further observations could be considered. In the case where we apply a regularizing scheme directly to the original system, when the minimum reached is close to that of other regularizing procedures, this is often due to border effects. Therefore, we should also investigate a combination of our technique with recently defined BCs (e.g., reflective or antireflective BCs) or with the idea in [4, 31] in order to eliminate the artifacts due to the so-called ringing effects. With the combination of these two ingredients we have to expect that the ringing effects will also be noticeably reduced when considering generic (not necessarily with uniform background) images. Consequently, as in the cases previously considered in this paper, we believe that the proposed multigrid-type procedures will perform better than classical regularizing methods in terms of precision and/or computational cost.

Finally, we would like to investigate how our multigrid proposal can be used in connection with edge preserving procedures such as total variation, Bayesian methods, and deterministic strategies (see, e.g., [21, 18, 14, 5]). Indeed, the nonconvex optimization (which characterizes all these quite expensive techniques) should be solved by some kind of iterative method which uses linearization, and our multigrid procedure can be applied at this level (instead of using preconditioning as suggested in [7, 2]) not only for accelerating the procedures but also for regularizing purposes. Also, a priori information on the statistical nature of the noise could be exploited, specifically for defining more appropriate interpolation and smoothing operators: all these issues will be considered in future work.

Acknowledgments. Warm thanks to the referees for very pertinent and useful remarks.

AMGe—COARSENING STRATEGIES AND APPLICATION TO THE OSEEN EQUATIONS*

MARKUS WABRO†

Abstract. We provide some extensions to the algebraic multigrid method based on element interpolation (AMGe), concerning the agglomeration process, the application to nonconforming elements, and the application to the mixed finite element discretization of the Oseen linearized Navier–Stokes equations.

This last point, using AMGe for mixed finite elements, becomes straightforward because of the availability of coarse-level topologies. We show this exemplarily for the Crouzeix–Raviart element (including a stability result).

The numerical results show that it really pays off to take a closer look at the agglomeration strategy. A "wrong" choice can lead to insufficient convergence or even divergence of the overall multigrid method.

1. Introduction.

The algebraic multigrid (AMG) method was introduced by Ruge and Stüben [14] and Brandt, McCormick, and Ruge [3] mainly for two reasons. First, one obtains a multilevel method without the need to perform any mesh refinements, which is helpful in situations with large problems and limited amount of computer memory. Second, it is intended to be used as "black-box" solver, e.g., as a coarse-grid solver in some geometric multigrid (GMG) methods. An overview of the technique itself and its applications can be found, e.g., in Stüben [16].

Unfortunately there are situations (especially when the operators are not represented by symmetric, positive definite M-matrices) where classical AMG might fail. For finite element (FE) discretized problems one way out was the development of the *algebraic multigrid method based on element interpolation* (AMGe).

Until now this method has undergone three important stages of development. It was introduced by Brezina et al. [4], where the classical techniques for the coarse node/fine node (C/F) splitting are used, but a new method of constructing the interpolation operator, based on the local element stiffness matrices, is introduced. In [8] the coarse grid construction is changed in a way that allows one to extract topological information on coarse levels (coarse faces, edges, and elements and their connectivity). The interpolation still depends on the element stiffness matrices, which are assembled to Neumann-type stiffness matrices on local patches (e.g., the coarse-level elements) and which have to be stored during the whole setup process. This problem is overcome by the approach in [7]. Here, an extension (extrapolation) operator (depending only on the assembled stiffness matrix) is used to construct an approximation to the local Neumann-type matrices.

The full availability of the topological information on all levels opens up the possibility of constructing AMGe methods for various types of FE discretizations, especially for mixed FE discretizations of saddle point problems.

We will exploit this property when we construct a coupled AMGe (cAMGe) method for the Oseen linearized Navier–Stokes equations. "Coupled" here is meant in contrast to methods where pressure and velocity equations are iteratively decoupled (e.g., using SIMPLE or Uzawa methods) and AMG is used for the resulting scalar problems. We want to have an "all-at-once" approach, although we then have to deal with an indefinite system and with possible (inf-sup) stability problems. Some possibilities of coupled AMG (not AMGe) methods for the Oseen problem can be found in [20]; in [19] there are also first steps towards cAMGe.

In this article we will exemplarily construct a cAMGe method for the Crouzeix–Raviart (P_1^{nc}-P_0) discretization of the coupled problem and show its coarse-level stability.

Besides the development of this coupled AMGe method, the second emphasis of this work is put on the construction of the coarse levels, i.e., how to agglomerate fine-level elements to coarse-level elements. As we will see, this has a crucial influence on the performance of the method.

The article is organized as follows. After describing the main ingredients of an (element agglomerating) AMGe method, we present three new techniques for the agglomeration process, and we show how to build the interpolations for three different FE types. In the third section we apply the ideas to the Crouzeix–Raviart discretized Oseen equations and derive a stability result. The article is concluded with numerical experiments for the presented methods.

1.1. Notation. We want to construct an AMG method for a set of linear equations

$$K_1 x = b_1, \tag{1.1}$$

where K_1 is a regular $n_1 \times n_1$ matrix and b_1 is a given right-hand side. The index indicates the level; 1 is the finest level, and L will be the coarsest.

At the moment we do not specify more properties of the matrix, as we try to be as general as possible. The methods in sections 2.1 and 2.2 are in fact independent of the matrix (at least in their versions presented here), in section 2.3 we will need regularity of some submatrices (sufficient conditions will be given there), and the results in section 3 apply only for the special mixed FE discretization of the Oseen equations given there.

We create full rank prolongation matrices $P_{l+1}^l : \mathbb{R}^{n_{l+1}} \to \mathbb{R}^{n_l}$, $l = 1, \dots, L-1$ and $n_1 > n_2 > \cdots > n_L$, and a set of coarse-level matrices K_l with

$$K_{l+1} = (P_{l+1}^l)^T K_l P_{l+1}^l. \tag{1.2}$$

The system in (1.1) originates in an FE discretization of some partial differential equation (PDE) on a polygonal (resp., polyhedral) domain $\Omega \subset \mathbb{R}^d$, $d \in \{2, 3\}$. We consider FEs based on triangles (resp., tetrahedra) with straight (flat) edges (faces); thus we assume that some partitioning of Ω into triangles (resp., tetrahedra) $\Omega = \bigcup_i \tau_i$ is given, and we denote the set of elements $\mathcal{T}_h := \{\tau_1, \tau_2, \dots\}$.

2. AMGe building blocks. In this section we will present the ingredients of the coarse-level construction of an element agglomerating AMGe method:

1. the C/F splitting, which in most cases consists of

(i) the element agglomeration process and
(ii) the identification of coarse-level faces, edges, and nodes,

2. the construction of the interpolation matrix from the coarse degrees of freedom (dofs) to the fine dofs.

We want to remark that (different from some other AMG approaches) for the methods presented in this paper we will assume that total information on the fine grid is available (topology, mesh width, etc.).

2.1. Identification of the coarse-level topology. Assume that on one level (e.g., on the discretization level) we know the element-to-node connectivity, i.e., which nodes are part of a given element. Assume further that a method for the agglomeration of elements is known, satisfying the requirements that each element is part of one unique agglomerate and that each agglomerate is a connected set, meaning that for any two elements that are part of the same agglomerate there exists a path of elements of this agglomerate connecting the two elements, where each two consecutive "path-elements" are connected via edges (in 2 dimensions) or faces (in 3 dimensions). Then we can apply the following algorithm for the creation of the coarse-level topology (as presented in [8]).

ALGORITHM 1. AMGE COARSE-LEVEL TOPOLOGY.

1. Agglomerate the fine elements to coarse elements E_j (with the above properties).

2. Consider all intersections $E_j \cap E_k$ for all pairs of different agglomerated elements E_j and E_k. If such an intersection is maximal, i.e., is not contained in any other intersection, then it is called a face.

3. Consider the faces as sets of nodes. For each node n compute the intersection $\bigcap\{\text{all faces which contain } n\}$. Now the set of minimal, nonempty intersections defines the vertices.

We have formulated the algorithm for the 3D case, but it can be directly applied to 2D problems (then the "faces" correspond to edges). If (in the 3D case) one additionally wants to identify edges, then this can be done in step 3 using the set of minimal, nonempty intersections which are not already vertices.

2.2. Element agglomeration process. For the agglomeration of fine elements to coarse elements we present four different techniques, a classical one and three new possibilities. All four techniques are presented in their "standard" form; i.e., for example no anisotropies or parameter jumps which could (or should) be handled by the agglomeration process are considered.

2.2.1. Jones–Vassilevski element agglomeration. We will start with the "classical" Jones–Vassilevski algorithm [8].

ALGORITHM 2. JONES–VASSILEVSKI ELEMENT AGGLOMERATION.

Assume we have a set of finer level elements $\{e_j\}$ and faces $\{f_j\}$, and introduce an integer weight $w(f_j)$ for each face f_j.

initiate. Set $w(f) \leftarrow 0$ for all faces f;

global search. Find a face f with maximal $w(f)$, if $w(f) = -1$ we are done; set $E \leftarrow \emptyset$;

1. Set $E \leftarrow E \cup e_1 \cup e_2$, where $e_1 \cap e_2 = f$ and set $w_{\max} \leftarrow w(f)$, $w(f) \leftarrow -1$;

2. Increment $w(f_1) \leftarrow w(f_1) + 1$ for all faces f_1 such that $w(f_1) \neq -1$ and f_1 is a neighbor of f;

3. Increment $w(f_2) \leftarrow w(f_2) + 1$ for all faces f_2 such that $w(f_2) \neq -1$, f_2 is a neighbor of f, and f_2 and f are faces of a common element;

4. From the neighbors of f, choose a face g with maximal $w(g)$; if $w(g) \geq w_{\max}$ set $f \leftarrow g$ and go to step 1;

5. If all neighbors of f have smaller weight than $w_{\max}$, the agglomerated element E is complete; set $w(g) \leftarrow -1$ for all faces of the elements e contained in E;
go to **global search**.

Remark 1. In [8] also modifications to this algorithm are presented which allow some kind of semicoarsening, i.e., coarsening with the focus in one specific direction (for example determined by convection).

For the 2D case this algorithm mostly produces nice agglomerated elements, but in the 3D case some strange shapes may occur; therefore some adjustments of the algorithm seem to be necessary.

2.2.2. Red-grey-black element agglomeration. A second method which is fast and produces good-looking agglomerates but often leads to a too strong coarsening (what has a disadvantageous influence on the h-independence) is the following.

Algorithm 3. Red-grey-black element agglomeration.
At the beginning no element is colored.
repeat until all elements are colored
begin
choose an uncolored element, this is colored black;
color all uncolored or grey neighboring elements red
(where "neighboring" could be induced by faces, edges, or nodes);
color all uncolored elements neighboring red elements grey;
end
the black elements plus surrounding red elements build the agglomerated elements; each grey element is appended to the agglomerate where it "fits best" (e.g., to the agglomerate it shares the largest face with).

This algorithm has some similarities to the aggregation technique by Vanek, Mandel, and Brezina [17], with one main difference: there nodes are aggregated, but here elements are aggregated.

2.2.3. Optimization approach. Another class of methods (which originally was aimed at the coarse-level construction of multigrid methods for finite volume discretizations) was developed by Moulitas and Karypis [12] and implemented in the software package MGridGen [11]. They formulate an optimization problem where a coarse grid is generated that minimizes some objective function F (i.e., maximizes the quality of the grid in some sense), and the size of the coarse grid elements is subject to some upper and lower bounds. Examples for such objective functions are the sum or the maximum of the aspect ratios of the coarse elements.

The method for solving these optimization problems is based on a multilevel technique described in [12] and the references therein; we sketch it roughly.

Algorithm 4. MGridGen.

1. *Coarsening phase:* A sequence of approximate representations of the optimization problem is generated by constructing coarser and coarser graphs (this sequence of graphs has nothing to do with the levels in our multigrid method!).

2. *Initial solution phase:* The optimization problem is solved on the coarsest level.

3. *Uncoarsening phase:* The optimization problem is solved (approximately) on the finer levels, using the solution on the coarser levels.

As the MGridGen library is freely available, the application of the method is particularly easy.

2.2.4. Bottom-up graph partitioning. The three methods above have in common a top-down strategy; i.e., we start on the finest level and agglomerate elements to obtain the next coarser level. The following method will work the other way round, i.e., bottom-up.

ALGORITHM 5. BOTTOM-UP GRAPH PARTITIONING.

1. Build the element-element connectivity graph for the fine level mesh.
2. Utilize any mesh/graph partitioning algorithm to obtain a (small) number of subgraphs. This set of subgraphs is used as the coarsest level (each subgraph is an element).
3. Now apply this strategy recursively on the subgraphs, until only one-node-graphs remain: the finest level.

Remark 2. It may happen that the penultimate level is very close to the finest level. In this case this level should be ignored to avoid a waste of memory resources.

For the graph partitioning algorithm mentioned in step 2 of Algorithm 5 we use the METIS library by Karypis and Kumar [10]. (The underlying techniques are explained in [9].)

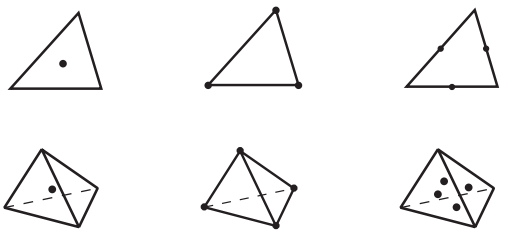
LEMMA 2.1. *If one of Algorithms* 2, 3, *or* 4 *is applied in the construction of an AMGe method, the number of arithmetical operations during the setup phase* $\mathcal{Q}_i^S(n_1)$, $i = 2, 3, 4$, *is* $\mathcal{O}(n_1)$. *For Algorithm* 5 *we obtain* $\mathcal{Q}_5^S(n_1) = \mathcal{O}(n_1 \log(n_1))$.

Proof. Assume for all algorithms a constant coarsening (or refinement) rate r and a minimal number of coarsest grid nodes n_c. Then the number of levels is given by

$$L = \log_r \left(\frac{n_c}{n_1} \right) + 1,$$

and the total complexity for Algorithms 2, 3, and 4 (assuming that the complexity on each level is proportional to the number of nodes) is calculated as

$$\begin{aligned} \mathcal{Q}_i^S(n_1) &= \mathcal{O}\left(n_1 + r n_1 + \cdots + r^{L-2} n_1\right) \\ &= \mathcal{O}\left(n_1 \cdot \frac{1 - r^{L-1}}{1 - r}\right) = \mathcal{O}\left(\frac{n_1 - n_c}{1 - r}\right) \\ &= \mathcal{O}(n_1) \quad \text{for } i = 2, 3, 4. \end{aligned}$$



For Algorithm 5 the complexity on each level stays constant; thus the overall complexity is calculated as

$$\mathcal{Q}_5^S(n_1) = \mathcal{O}((L-1) \cdot n_1) = \mathcal{O}(n_1 \log n_1). \qquad \square$$

2.3. Interpolation. For the construction of the interpolation we can utilize the topological information we have obtained in section 2.1. We will show this exemplarily for three types of finite elements.

2.3.1. P_0-element. For the FE with piecewise constant shape functions (as in Figure 1(a)) the construction of the interpolation is particularly easy. Each fine-level element is part of exactly one coarse-level agglomerate; thus we can use identity prolongation.

2.3.2. P_1-element. For piecewise linear, continuous elements (Figure 1(b)) we apply a strategy described by Henson and Vassilevski [7], which generalizes the method used by Jones and Vassilevski [8].

(a) P_0 (b) P_1 (c) P_1^{nc}

FIG. 1. *Some mixed finite elements for triangles and tetrahedra. Dots indicate dofs.*

We first define the neighborhood of a (fine-level) node n by

$$\Omega(n) := \bigcup \{\text{all agglomerated elements that contain } n\}$$

and the minimal set by

$$\Lambda(n) := \bigcap \{\text{all agglomerated elements that contain } n\}.$$

($\Lambda(n)$ can be a node, edge, face, or element.) The set of coarse dofs in $\Omega(n)$ is denoted by $\Omega_c(n)$. Then we define the extended neighborhood

$$\overline{\Omega}(n) := \{j \notin \Omega(n) : k_{ij} \neq 0 \text{ for some } i \in \Omega(n) \setminus \Omega_c(n)\} \cup \Omega(n)$$

(where k_{ij} is the (i,j)th entry of the fine-level matrix K_l).

As the coarse nodes form a subset of the fine nodes the values there can be identically prolongated. For the edges, faces, and cells we proceed recursively as follows. Assume for a set $\Lambda(n)$ that the interpolation on the unknowns in $\partial\Lambda(n)$ has been fixed,[1] and we want to calculate the interpolation on the nodes in $\Lambda(n) \setminus \partial\Lambda(n)$. For that we build the local matrix of $\Omega(n)$ (extracted from the global matrix K_l) with the underlying partitioning $(\Omega(n) \setminus \partial\Lambda(n)) \cup \partial\Lambda(n) \cup \big(\overline{\Omega}(n) \setminus \Omega(n)\big)$

$$K_{\overline{\Omega}(n)} = \begin{pmatrix} K_{ii} & K_{ib} & K_{ie} \\ K_{bi} & K_{bb} & K_{be} \\ K_{ei} & K_{eb} & K_{ee} \end{pmatrix} \begin{matrix} \} \\ \} \\ \} \end{matrix} \begin{matrix} \Omega(n) \setminus \partial\Lambda(n) \\ \partial\Lambda(n) \\ \overline{\Omega}(n) \setminus \Omega(n) \end{matrix}$$

(i stands for interior, b for boundary, e for extended neighborhood). In [8] the small matrix

$$K_{\Omega(n)} = \begin{pmatrix} \tilde{K}_{ii} & \tilde{K}_{ib} \\ \tilde{K}_{bi} & \tilde{K}_{bb} \end{pmatrix} \tag{2.1}$$

is built using the local stiffness matrices; therefore it is a Neumann-type operator. Extracting it directly from the global stiffness matrix would lead to a Dirichlet-type

[1] The definition of the "boundary" $\partial\Lambda(n)$ is straightforward: if $\Lambda(n)$ is a face/edge, then $\partial\Lambda(n)$ are those nodes of $\Lambda(n)$ which belong to more than one face/edge; if $\Lambda(n)$ is an agglomerated element, then $\partial\Lambda(n)$ is the union of faces of this element.

operator. Thus, in [7] an extension mapping $E(n) : \Omega(n) \to \overline{\Omega}(n)$ is built, which with the above partitioning can be written as

$$E(n) = \begin{pmatrix} I & 0 \\ 0 & I \\ E_{ei} & E_{eb} \end{pmatrix}$$

and is used to get something similar to (2.1):

$$\hat{K}_{\Omega(n)} = \begin{pmatrix} \hat{K}_{ii} & \hat{K}_{ib} \\ \hat{K}_{bi} & \hat{K}_{bb} \end{pmatrix} := \begin{pmatrix} K_{ii} + K_{ie}E_{ei} & K_{ib} + K_{ie}E_{eb} \\ K_{bi} + K_{be}E_{ei} & K_{bb} + K_{be}E_{eb} \end{pmatrix}.$$

With this technique the storing of the element stiffness matrices is no longer needed (if $E(n)$ can be constructed independently of them). Now the prolongation on $\Lambda(n) \setminus \partial\Lambda(n)$ is built by extracting the corresponding entries of

$$-\hat{K}_{ii}^{-1}\hat{K}_{ib}.$$

Remark 3. In this section we have assumed that the matrices K_{ii} and $\hat{K}_{ii}$ are invertible. For symmetric positive semidefinite matrices $K_{\overline{\Omega}(n)}$ and a sufficiently rich set of boundary dofs $\partial\Lambda(n)$ this can be shown for K_{ii} (see Lemma 2.1 in [8]). Furthermore if E_{ei} is sufficiently small in norm, then $\hat{K}_{ii}$ also will be invertible (as stated in [7]).

Remark 4. For the situation in (2.1) and for symmetric positive definite K_l the setting

$$u_i = -\tilde{K}_{ii}^{-1}\tilde{K}_{ib}u_b$$

solves the minimal-energy problem: For given u_b, find u_i such that

$$(u_i^T u_b^T)K_{\Omega(n)} \begin{pmatrix} u_i \\ u_b \end{pmatrix}$$

is minimized.

What still has to be specified is the extension $E(n)$. In [7] various possibilities can be found, and we use what is called there the "A-extension" (which in our case is in fact a "K-extension"). If we want to extend a vector v to a dof $i \in \overline{\Omega}(n) \setminus \Omega(n)$, this extension is given by

$$v(i) = \frac{1}{\sum_{j\in S} |k_{ij}|} \sum_{j\in S} \left(|k_{ij}| \cdot v(j)\right),$$

where $S = \{j \in \Omega(i) : k_{ij} \neq 0\}$.

2.3.3. Nonconforming P_1-element (P_1^{nc}). For the nonconforming P_1^{nc} element with piecewise linear shape functions, continuous at the midpoints of the edges (resp., faces), illustrated in Figure 1(c), we propose the following strategy.

All dofs on fine edges/faces which are part of the same coarse edge/face are set equal to the dof value of this coarse edge/face.

For the dofs which lie in the interior of a coarse agglomerate we follow the same strategy as in section 2.3.2 (but without the necessity of either storing the element stiffness matrices or constructing some extension operators). The prolongation matrices for the interior of coarse elements are given by

$$-K_{ii}^{-1}K_{ib},$$

where K_{ii} and K_{ib} can be directly extracted from the global stiffness matrix.

3. Application to the Oseen equations. The methods above can now be directly applied to the mixed FE discretization of the Oseen equations (i.e., the fixed-point linearized stationary, incompressible Navier–Stokes equations) in $\Omega \subset \mathbb{R}^d$, $d \in \{2, 3\}$:

$$-\nu\Delta\mathbf{u} + (\mathbf{w}\cdot\nabla)\mathbf{u} + \nabla p = \mathbf{f}, \tag{3.1a}$$

$$\operatorname{div}\mathbf{u} = 0, \tag{3.1b}$$

where $\mathbf{u}(\mathbf{x})$ denotes the velocity of the fluid at point $\mathbf{x}$, $p(\mathbf{x})$ is the pressure, $\mathbf{f}(\mathbf{x})$ is some given right-hand side, ν is the given viscosity (which we assume constant in $\mathbf{x}$), and $\mathbf{w}(\mathbf{x})$ is the old approximation of the velocity.

For simplicity we assume Dirichlet boundary conditions on the whole boundary $\Gamma := \partial\Omega$:

$$\mathbf{u}|_\Gamma = \bar{\mathbf{u}}.$$

We discretize the system using a mixed FE method (for details we refer the reader, e.g., to Brezzi and Fortin [5] or Braess [1]) and obtain the following problem: Find a couple $(\mathbf{u}_h, p_h)$ in some mixed FE space $\mathbf{U}_h \times Q_h$ such that

$$\bar{a}(\mathbf{w}_h; \mathbf{u}_h, \mathbf{v}_h) + b(\mathbf{v}_h, p_h) = \langle F, \mathbf{v}_h\rangle \quad \text{for all } \mathbf{v}_h \in \mathbf{U}_h, \tag{3.2a}$$

$$b(\mathbf{u}_h, q_h) = 0 \quad \text{for all } q_h \in Q_h, \tag{3.2b}$$

where

$$\bar{a}(\mathbf{w}_h; \mathbf{u}_h, \mathbf{v}_h) = a_D(\mathbf{u}_h, \mathbf{v}_h) + a_C(\mathbf{w}_h; \mathbf{u}_h, \mathbf{v}_h) + a_S(\mathbf{w}_h; \mathbf{u}_h, \mathbf{v}_h)$$

and

$$a_D(\mathbf{u}_h, \mathbf{v}_h) = \nu(\nabla\mathbf{u}_h, \nabla\mathbf{v}_h), \qquad b(\mathbf{u}_h, q_h) = -(\operatorname{div}\mathbf{u}_h, q_h),$$
$$a_C(\mathbf{w}_h; \mathbf{u}_h, \mathbf{v}_h) = \left((\mathbf{w}_h\cdot\nabla)\mathbf{u}_h, \mathbf{v}_h\right), \qquad \langle F, .\rangle = (\mathbf{f}, .),$$

and $a_S(.; ., .)$ originates in some convection stabilization ("D" stands for diffusion, "C" for convection, and "S" for stabilization; $(., .)$ is the standard L_2 inner product). We use the *streamline upwinding Petrov Galerkin method* (SUPG) and therefore

$$a_S(\mathbf{w}_h; \mathbf{u}_h, \mathbf{v}_h) = \beta_h\left((\mathbf{w}_h\cdot\nabla)\mathbf{u}_h, (\mathbf{w}_h\cdot\nabla)\mathbf{v}_h\right),$$

with some stabilization parameter β_h (details can be found, e.g., in [13]).

We denote the *FE isomorphisms* between the discrete spaces and the spaces of coefficient vectors by $\phi_U : (\mathbb{R}^n)^d \to \mathbf{U}_h$ and $\phi_Q : \mathbb{R}^m \to Q_h$. The underlined notation is used to indicate their inverses, i.e.,

$$\phi_U\underline{\mathbf{v}}_h = \mathbf{v}_h, \qquad \underline{\phi_U\underline{\mathbf{v}}_h} = \underline{\mathbf{v}}_h, \tag{3.3a}$$

$$\phi_Q\underline{q}_h = q_h, \qquad \underline{\phi_Q\underline{q}_h} = \underline{q}_h. \tag{3.3b}$$

If it is clear from the context we omit the underlines and ϕ's and identify $\mathbf{v}_h \in \mathbf{U}_h$ and the associated $\underline{\mathbf{v}}_h \in (\mathbb{R}^n)^d$ and analogously q_h and $\underline{q}_h$.

If the mixed FE is now built of elements for which the construction of an AMGe interpolation is known, we can easily generate a cAMGe method. The coarsening is independent of the concrete element, the interpolations have to be built separately for the pressure and velocity hierarchies.

After having constructed the coarse-level hierarchies we need an appropriate smoother. Possibilities are well known smoothers for GMG methods, such as transforming smoothers (Wittum [21, 22]), the Braess–Sarazin smoother (see [2] and Zulehner [23]), or Vanka smoothers (see [18] and Schöberl and Zulehner [15]). Although developed for the GMG case, they can be directly applied to AMG.

In principal we now have everything we need for an AMG method. But it is not obvious a priori that the method works, as the (inf-sup) stability of the coarse-level systems is not automatically given (and a lack thereof would destroy the convergence properties of the method; cf. Wabro [20, 19]).

For the *Crouzeix–Raviart* element P_1^{nc}-P_0 we exemplarily show how a stability result can be obtained. The technique of the proof heavily depends on the fact that on each level a topology is available.

We first introduce the following notations. The intergrid transfer operators for pressure will be denoted by J_{l+1}^l, for velocity by $\tilde{I}_{l+1}^l$, for velocity components by I_{l+1}^l, i.e.,

$$P_{l+1}^l = \begin{pmatrix} \tilde{I}_{l+1}^l & \\ & J_{l+1}^l \end{pmatrix}, \quad \tilde{I}_{l+1}^l = \begin{pmatrix} I_{l+1}^l & & \\ & I_{l+1}^l & \\ & & I_{l+1}^l \end{pmatrix} \quad \text{(in 3 dimensions)}.$$

We denote the spaces for velocity and pressure unknown vectors at level l by $\underline{\mathbf{U}}_l := (\mathbb{R}^{n_l})^d$ and $\underline{Q}_l := \mathbb{R}^{m_l}$ and the coarse function spaces by

$$\begin{aligned} \mathbf{U}_l &:= \left\{ \mathbf{v} \in \mathbf{U}_h : \ \exists \underline{\mathbf{w}} \in \underline{\mathbf{U}}_l \text{ such that } \underline{\mathbf{v}} = \tilde{I}_2^1 \tilde{I}_3^2 \dots \tilde{I}_l^{l-1} \underline{\mathbf{w}} \right\}, \\ Q_l &:= \left\{ p \in Q_h : \ \exists \underline{q} \in \underline{Q}_l \text{ such that } \underline{p} = J_2^1 J_3^2 \dots J_l^{l-1} \underline{q} \right\}. \end{aligned}$$

We want to emphasize that because of this construction, all coarse-level function spaces are included in the finest-level function spaces.

Analogous to (3.3) we introduce the *FE-AMG isomorphisms*

$$\phi_U^l : \underline{\mathbf{U}}_l \to \mathbf{U}_l \ \text{ and } \ \phi_Q^l : \underline{Q}_l \to Q_l, \tag{3.4}$$

and we will often identify elements of $\underline{\mathbf{U}}_l$ and $\mathbf{U}_l$ and $\underline{Q}_l$ and Q_l.

The following lemma is just a translation of the well-known result of Fortin [6].

LEMMA 3.1. *Assume that for given l there exists a linear operator $\Pi_{l-1}^l : \mathbf{U}_{l-1} \to \mathbf{U}_l$ with*

$$b(\Pi_{l-1}^l \mathbf{v}_{l-1}, q_l) = b(\mathbf{v}_{l-1}, J_l^{l-1} q_l) \quad \textit{for all } q_l \in Q_l \textit{ and } \mathbf{v}_{l-1} \in \mathbf{U}_{l-1} \tag{3.5}$$

and that

$$\|\Pi_{l-1}^l \mathbf{v}_{l-1}\|_1 \le \delta \|\mathbf{v}_{l-1}\|_1 \quad \textit{for all } \mathbf{v}_{l-1} \in \mathbf{U}_{l-1}, \tag{3.6}$$

with δ independent of h and l.

Assume that on level $l-1$ an inf-sup condition holds, i.e.,

$$\inf_{0 \neq q_{l-1} \in Q_{l-1}} \sup_{\mathbf{0} \neq \mathbf{v}_{l-1} \in \mathbf{U}_{l-1}} \frac{b(\mathbf{v}_{l-1}, q_{l-1})}{\|\mathbf{v}_{l-1}\|_1 \|q_{l-1}\|_0} \ge \beta_{l-1}.$$

Then an inf-sup condition holds on level l.

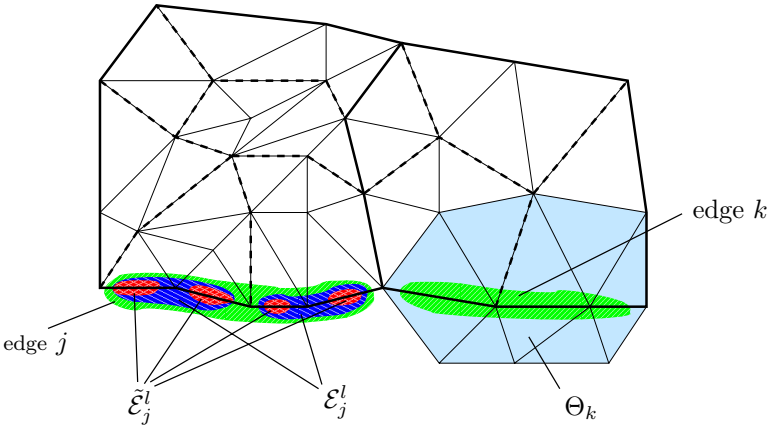


FIG. 2. *The solid thick black lines describe two level-l elements, the dashed lines level* $(l-1)$*-elements, and the solid thin lines the finest-level elements. For edge* j *this figure shows the sets* $\mathcal{E}_j^l$ *and* $\tilde{\mathcal{E}}_j^l$*, and for edge* k *it shows the tube* Θ_k*.*

Proof.

$$\begin{aligned}\inf_{0\neq q_l\in Q_l}\sup_{\mathbf{0}\neq\mathbf{v}_l\in\mathbf{U}_l}\frac{b(\mathbf{v}_l,q_l)}{\|\mathbf{v}_l\|_1\|q_l\|_0} &\geq \inf_{0\neq q_l\in Q_l}\sup_{\mathbf{0}\neq\mathbf{v}_{l-1}\in\mathbf{U}_{l-1}}\frac{b(\Pi_{l-1}^l\mathbf{v}_{l-1},q_l)}{\|\Pi_{l-1}^l\mathbf{v}_{l-1}\|_1\|q_l\|_0}\\ &= \inf_{0\neq q_l\in Q_l}\sup_{\mathbf{0}\neq\mathbf{v}_{l-1}\in\mathbf{U}_{l-1}}\frac{b(\mathbf{v}_{l-1},J_l^{l-1}q_l)}{\|\mathbf{v}_{l-1}\|_1\|q_l\|_0}\cdot\frac{\|\mathbf{v}_{l-1}\|_1}{\|\Pi_{l-1}^l\mathbf{v}_{l-1}\|_1}\\ &\geq \frac{\beta_{l-1}}{\delta}. \qquad \square\end{aligned}$$

THEOREM 3.2. *Assume that*

- *on the finest level we have*

$$\frac{h_{max}}{h_{min}}\leq c_0, \tag{3.7}$$

  where h_{max} *is the maximal element diameter,* h_{min} *is the minimal diameter, and* c_0 *is a positive constant,*
- *assume that the (finest-level) mesh is shape regular, i.e.,*

$$\frac{(\textit{length of longest edge of }\tau_j)^2}{V(\tau_j)}<c_1 \tag{3.8}$$

  for all triangles (resp., tetrahedra) τ_j*, where* $V(\tau_j)$ *is the area (resp., volume) of* τ_j *and* c_1 *is a positive constant, and*
- *assume that the coarse levels are built as described in section* 2*, and the prolongations are as in sections* 2.3.1 *and* 2.3.3 *but based on the Stokes operator (i.e.,* $\bar{a}(\mathbf{u}_h,\mathbf{v}_h)=\bar{a}(\mathbf{0},\mathbf{u}_h,\mathbf{v}_h)$*).*

Then the inf-sup condition holds on all levels.

As we want to apply Lemma 3.1 to show this result, we construct an operator Π_{l-1}^l in the following way. Consider the 2D case first (illustrated in Figure 2). Define on level l the index sets $\mathcal{E}_j^l$ of all $(l-1)$-level edges which are part of l-level edge j.

We define the length of an l-level edge recursively by

$$e_j^l := \sum_{k \in \mathcal{E}_j^l} e_k^{l-1} \quad (\text{for } l > 1).$$

For $l = 1$ it is determined by the mesh.

We now construct Π_{l-1}^l as follows. For some $(l-1)$-level function v_{l-1} the l-level function $\Pi_{l-1}^l v_{l-1}$ is determined by its values on the (l-level) edges. We set the value on a certain l-level edge to the weighted mean of the values of v_{l-1} on the $(l-1)$-level edges which are part of the edge, i.e.,

$$\left(\underline{\Pi_{l-1}^l v_{l-1}}\right)_j = \frac{1}{e_j^l} \sum_{k \in \mathcal{E}_j^l} e_k^{l-1} \left(\underline{v}_{l-1}\right)_k .$$

For a vector-valued function $\mathbf{v}_{l-1}$ the term $\Pi_{l-1}^l \mathbf{v}_{l-1}$ will denote the application of Π_{l-1}^l to the components.

LEMMA 3.3. *The operator $\Pi_{l-1}^l : \mathbf{U}_{l-1} \to \mathbf{U}_l$, constructed as above, fulfills* (3.5)*:*

$$b(\Pi_{l-1}^l \mathbf{v}_{l-1}, q_l) = b(\mathbf{v}_{l-1}, J_l^{l-1} q_l) \quad \textit{for all } q_l \in Q_l \textit{ and } \mathbf{v}_{l-1} \in \mathbf{U}_{l-1}.$$

Proof. We want to show that

$$\sum_j \int_{\tau_j} \operatorname{div}(\Pi_{l-1}^l \mathbf{v}_{l-1}) \cdot q_l \, \mathrm{d}\mathbf{x} = \sum_j \int_{\tau_j} \operatorname{div} \mathbf{v}_{l-1} \cdot (J_l^{l-1} q_l) \, \mathrm{d}\mathbf{x}.$$

Because $q_l = J_l^{l-1} q_l$ (in functional notation), because q_l is piecewise constant on the l-level agglomerates E_j, and because both $\mathbf{v}_{l-1}$ and $\Pi_{l-1}^l \mathbf{v}_{l-1}$ are piecewise linear on the (finest-level) elements τ_j and continuous at the midpoints of their edges, we can use partial integration to derive

$$\sum_j \int_{\tau_j} \operatorname{div}(\Pi_{l-1}^l \mathbf{v}_{l-1}) \cdot q_l \, \mathrm{d}\mathbf{x} = \sum_j q_l(E_j) \int_{\partial E_j} (\Pi_{l-1}^l \mathbf{v}_{l-1}) \cdot \mathbf{n}$$

(where $q_l(E_j)$ is the constant value of q_l on E_j) and

$$\sum_j \int_{\tau_j} \operatorname{div} \mathbf{v}_{l-1} \cdot (J_l^{l-1} q_l) \, \mathrm{d}\mathbf{x} = \sum_j q_l(E_j) \int_{\partial E_j} \mathbf{v}_{l-1} \cdot \mathbf{n}.$$

By the definition of Π_{l-1}^l we see that

$$\int_{\partial E_j} (\Pi_{l-1}^l \mathbf{v}_{l-1}) \cdot \mathbf{n} = \int_{\partial E_j} \mathbf{v}_{l-1} \cdot \mathbf{n} \quad \text{for all agglomerates } E_j;$$

therefore (3.5) is shown to be true. ∎

LEMMA 3.4. *The operator Π_{l-1}^l, constructed as above, also fulfills* (3.6)*:*

$$\|\Pi_{l-1}^l \mathbf{v}_{l-1}\|_1 \le \delta \|\mathbf{v}_{l-1}\|_1 \quad \textit{for all } \mathbf{v}_{l-1} \in \mathbf{U}_{l-1}.$$

Proof. The idea of this proof is the introduction of an auxiliary operator $\tilde{\Pi}_{l-1}^l$ on the finer level $\mathbf{U}_{l-1}$, which fulfills (3.6) and which is identical to Π_{l-1}^l on the coarse edges. Because we use energy minimization for the interpolation in the interior of

agglomerates, we will then be able to estimate Π_{l-1}^l by $\tilde{\Pi}_{l-1}^l$ which will complete the proof.

We define $\tilde{\Pi}_{l-1}^l : \mathbf{U}_{l-1} \to \mathbf{U}_{l-1}$ by

$$\underline{\tilde{\Pi}}_{l-1}^l(\underline{v}_{l-1})_j := \begin{cases} (\underline{v}_{l-1})_j & \text{if } j \notin \mathcal{E}_k^l \text{ for all } k, \\ \left(\underline{\Pi_{l-1}^l v_{l-1}}\right)_k & \text{if } j \in \mathcal{E}_k^l \text{ for a certain } k. \end{cases}$$

Note that $\tilde{\Pi}_{l-1}^l v_{l-1}$ still "lives" on level $l-1$, only the values at the l-level faces are averaged.

We try to find an upper bound for $|v_{l-1} - \tilde{\Pi}_{l-1}^l v_{l-1}|_1$. Define $\tilde{\mathcal{E}}_j^l$ as the index set of all *finest*-level edges which lie on coarse edge j. Set $\tilde{v}_1$ (component of finest-level function $\tilde{\mathbf{v}}_1 \in \mathbf{U}_1$) equal to $v_{l-1} - \tilde{\Pi}_{l-1}^l v_{l-1}$ on all (finest-level) dofs in $\bigcup_j \tilde{\mathcal{E}}_j^l$ and zero on all other (finest-level) dofs. Then because of the energy minimization in the prolongation,

$$\begin{aligned} \int_\Omega \nabla\left(v_{l-1} - \tilde{\Pi}_{l-1}^l v_{l-1}\right) \nabla\left(v_{l-1} - \tilde{\Pi}_{l-1}^l v_{l-1}\right) \mathrm{d}\mathbf{x} &\le \int_\Omega \nabla\tilde{v}_1 \nabla\tilde{v}_1 \,\mathrm{d}\mathbf{x} \\ &\le \sum_{\substack{l\text{-level} \\ \text{edges } j}} \int_{\Theta_j} \nabla\tilde{v}_1 \nabla\tilde{v}_1 \,\mathrm{d}\mathbf{x}, \end{aligned} \tag{3.9}$$

where Θ_j is the tube of (finest-level) elements which share a point or edge with l-level edge number j (cf. Figure 2).

For a (finest-level) triangle PQR and the basis function φ_{PQ}, which is equal to 1 at the midpoint of PQ and zero at the midpoints of QR and RP, one can easily calculate

$$\int_{PQR} \nabla\varphi_{PQ} \nabla\varphi_{PQ} \,\mathrm{d}\mathbf{x} = \frac{|PQ|^2}{A(PQR)},$$

where $A(PQR)$ denotes the area of the triangle PQR. Now with (3.8) we get

$$\begin{aligned} \int_{\Theta_j} \nabla\tilde{v}_1 \nabla\tilde{v}_1 \,\mathrm{d}\mathbf{x} &\le c_1 \sum_{s\in\tilde{\mathcal{E}}_j^l} \left((\underline{\tilde{v}}_1)_s\right)^2 \\ &= c_1 \sum_{s\in\tilde{\mathcal{E}}_j^l} \left[\frac{1}{\sum_{k\in\tilde{\mathcal{E}}_j^l} e_k} \sum_{k\in\tilde{\mathcal{E}}_j^l} e_k \left(\left(\phi_U^{1\,-1} v_{l-1}\right)_s - \left(\phi_U^{1\,-1} v_{l-1}\right)_k \right) \right]^2 \\ &\le c_1 \frac{\sum_{k\in\tilde{\mathcal{E}}_j^l} e_k^2}{\left(\sum_{k\in\tilde{\mathcal{E}}_j^l} e_k\right)^2} \sum_{\substack{s\in\tilde{\mathcal{E}}_j^l, \\ k\in\tilde{\mathcal{E}}_j^l}} \left(\left(\phi_U^{1\,-1} v_{l-1}\right)_s - \left(\phi_U^{1\,-1} v_{l-1}\right)_k \right)^2 \\ &\le c_1 \sum_{\substack{s\in\tilde{\mathcal{E}}_j^l, \\ k\in\tilde{\mathcal{E}}_j^l}} \left(\left(\phi_U^{1\,-1} v_{l-1}\right)_s - \left(\phi_U^{1\,-1} v_{l-1}\right)_k \right)^2 \\ &\le \bar{c}_1 \sum_{\substack{s\in\mathcal{E}_j^l, \\ k\in\mathcal{E}_j^l}} \left(\left(\underline{v}_{l-1}\right)_s - \left(\underline{v}_{l-1}\right)_k \right)^2, \end{aligned} \tag{3.10}$$

where $\phi_U^{1\,-1} v$ is the representation of a coarse function v on $\underline{\mathbf{U}}_1$ as in (3.4).

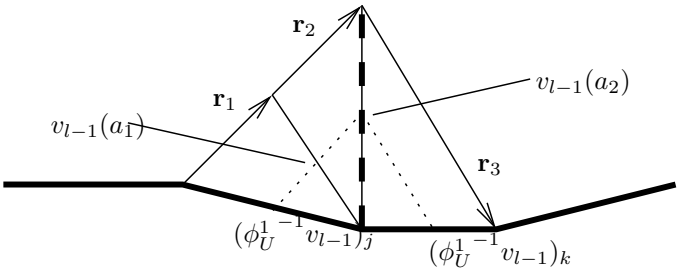

FIG. 3. *Detail of Figure* 2, *the set* $\mathcal{S}_m^{l-1}$.

We note that ∇v_{l-1} is constant on each finest-level element. Therefore we can derive the following estimate (illustrated in Figure 3). Assume that the $(l-1)$-level edges j and k share the node m. We denote the set of all finest-level elements which share the node m with $\mathcal{S}_m^{l-1}$, its index set with $\underline{\mathcal{S}}_m^{l-1}$ (where we assume without loss of generality that $\underline{\mathcal{S}}_m^{l-1} = \{1, 2, \ldots, i+1\}$). For each element τ_e in $\mathcal{S}_m^{l-1}$ we denote the edge-vector of the edge not connected to m ("in direction" $j \to k$) with $\mathbf{r}_e$. Then

$$\begin{aligned}
&(\underline{v}_{l-1})_k - (\underline{v}_{l-1})_j \\
&= ((\underline{v}_{l-1})_k - v_{l-1}(a_1)) + (v_{l-1}(a_1) - v_{l-1}(a_2)) + \cdots + (v_{l-1}(a_i) - (\underline{v}_{l-1})_j) \\
&= \frac{1}{2}\left(\nabla v_{l-1}|_{\tau_1} \cdot \mathbf{r}_1 + \cdots + \nabla v_{l-1}|_{\tau_{i+1}} \cdot \mathbf{r}_{i+1}\right) \\
&\le \frac{1}{2}\left(\sqrt{\nabla v_{l-1}|_{\tau_1} \cdot \nabla v_{l-1}|_{\tau_1}}|\mathbf{r}_1| + \cdots + \sqrt{\nabla v_{l-1}|_{\tau_{i+1}} \cdot \nabla v_{l-1}|_{\tau_{i+1}}}|\mathbf{r}_{i+1}|\right),
\end{aligned}$$

where $a_1, \ldots, a_i$ are finest-level edge midpoints as in Figure 3; thus (using the algebraic-geometric mean inequality)

$$\begin{aligned}
\left((\underline{v}_{l-1})_k - (\underline{v}_{l-1})_j\right)^2 &\le \frac{i+1}{4}\left[|\mathbf{r}_1|^2 \left(\nabla v_{l-1}|_{\tau_1}\right)^2 + \cdots + |\mathbf{r}_{i+1}|^2 \left(\nabla v_{l-1}|_{\tau_{i+1}}\right)^2\right] \\
&\le c_2 \int_{\mathcal{S}_m^{l-1}} \nabla v_{l-1} \nabla v_{l-1}\, \mathrm{d}\mathbf{x}.
\end{aligned} \tag{3.11}$$

We apply this estimate to the last term in (3.10), which is done directly for those $(l-1)$-level edges s and k which share a node. For all others we have to build a chain of connecting edges.

This leads to

$$\int_{\Theta_l} \nabla \tilde{v}_1 \nabla \tilde{v}_1\, \mathrm{d}\mathbf{x} \le c_3 \int_{\Theta_l} \nabla v_{l-1} \nabla v_{l-1}\, \mathrm{d}\mathbf{x}.$$

Now because of (3.9) we get

$$\left\| v_{l-1} - \tilde{\Pi}_{l-1}^l v_{l-1} \right\|_1 \le c_4 \|v_{l-1}\|_1;$$

thus

$$\left\| \tilde{\Pi}_{l-1}^l v_{l-1} \right\|_1 \le (1 + c_4) \|v_{l-1}\|_1.$$

Because we use energy minimization for the interpolation in the interior of coarse agglomerates, $\tilde{I}_l^{l-1} \underline{\Pi_{l-1}^l v_{l-1}}$ has minimal energy among all $(l-1)$-level functions which

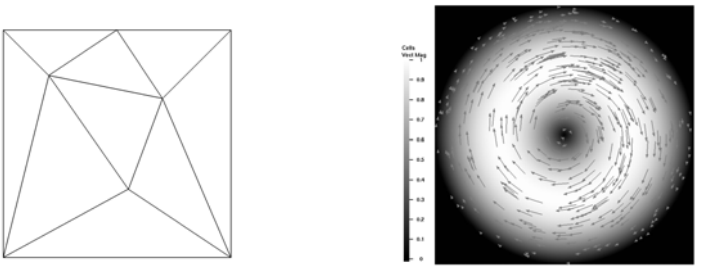

FIG. 4. *Coarsest unit-square mesh and given convection speed* $\mathbf{w}$ *for first problem.*

are identical to it on the l-level edges. Therefore

$$\left\|\Pi_{l-1}^{l} v_{l-1}\right\|_1 \le c_5 \left\|\tilde{\Pi}_{l-1}^{l} v_{l-1}\right\|_1 \le c_5(1+c_4)\|v_{l-1}\|_1. \qquad \square \tag{3.12}$$

The 3*D case.* For 3D tetrahedral elements we replace c_1 in (3.10) with $c_1 h_{j,\max}$, where $h_{j,\max}$ is the maximal element height in tube Θ_j, and c_2 in (3.11) with $c_2/h_{j,\min}$, where $h_{j,\min}$ is the minimal element height in this tube. Then because of (3.7) the argumentation remains unchanged, but the scaling argument is based on the (finest-level) tetrahedron $PQRS$:

$$\int_{PQRS} \nabla\varphi_{PQR} \nabla\varphi_{PQR} \,\mathrm{d}\mathbf{x} = \frac{A(PQR)^2}{V(PQRS)}.$$

The proof of Theorem 3.2 is completed by combining Lemmas 3.3 and 3.4 with Lemmas 3.1.

Remark 5. The constants $c_0, \ldots, c_5$ that appear in the proofs depend on the finest-level triangulation and on the agglomeration strategy (e.g., on how many fine-level edges are part of one coarse-level edge). In general they may result in $\delta > 1$ (in Lemma 3.1); thus the inf-sup constant will get worse for each additional level.

4. Numerical results. The numerical experiments were carried out using three different geometries (resp., meshes), the inevitable unit square (with meshes built by the refinement of the coarse mesh in Figure 4), the domain around a 2D symmetric valve (provided by AVL List GmbH, Graz, Austria), and the domain around two 3D valves (also provided by AVL List).

In Figures 5 and 6 we find the coarsest-level agglomerates of the valve geometries for the different techniques. One can notice that the agglomerates produced with the classical Jones–Vassilevski algorithm have frayed edges in 3D even holes. A comparison to the bottom-up approach would not be fair (as the coarsest agglomerates are the first ones, so the algorithm has full freedom to produce nice ones), but the topologies originating in the other two approaches look much better than the classical ones.

In two dimensions this is caused by the fact that the classical algorithm is the only one considered here which uses only information originating in the topology (not the geometry or the matrix). In [8] matrix-dependent variants are discussed, but they do not influence the fact that the algorithm is purely 2D and has its problems in three dimensions.

For the following tests we introduce a measure for (time) efficiency:

$$T_{0.1} := \frac{\begin{pmatrix}\text{average CPU time in minutes for the reduction}\\ \text{of the norm of the residual by a factor of 0.1}\end{pmatrix}}{\text{number of unknowns}}.$$

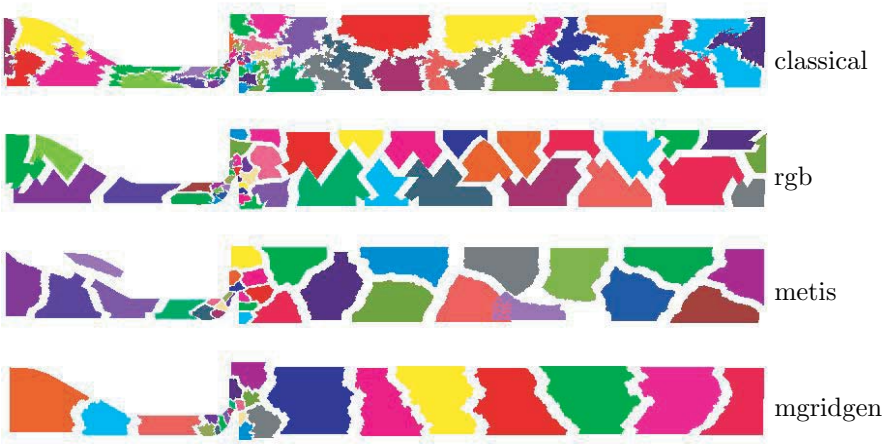

FIG. 5. *Coarsest-level agglomerates for the 2D valve. ("Classical" = Jones–Vassilevski agglomeration, "rgb" = red-gray-black, "metis" = bottom-up partitioning using metis, and "mgridgen" = optimization approach.)*

FIG. 6. *Coarsest level agglomerates for the 3D valves. ("Classical" = Jones–Vassilevski agglomeration, "rgb" = red-gray-black, "metis" = bottom-up partitioning using metis, and "mgridgen" = optimization approach; the black circles in the leftmost figure indicate holes in the agglomerates.)*

This number would be constant for different levels of refinement if we had an optimal method, i.e., if the work for a given reduction of the residual is $\mathcal{O}(n)$, where n is the number of unknowns.

All coarsening procedures are stopped at the last level with more than 20 dofs (respectively, are started there in the case of the bottom-up method). The coarse grid solver is a standard LU decomposition.

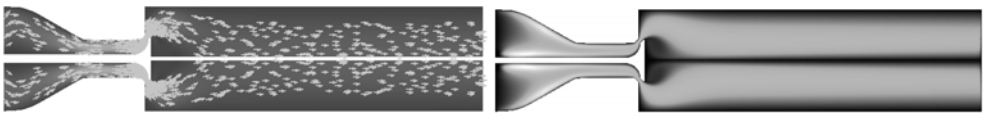

FIG. 7. *A solution of the 2D valve problem (right part of the figure) with* $\mathbf{w}$ *given as in the left part of the figure. On the symmetry plane homogeneous Dirichlet conditions are imposed.*

Remark 6. As we do not want to compare different smoothing strategies and multigrid cycles but only different coarsening strategies, we have fixed the cycle, the smoother, and the number of smoothing steps for each of the following tests.

In order to get "multigrid-like" behavior, i.e., convergence rates (mostly) independent of the refinement level, the number of smoothing steps has to be sufficiently large. For some situations this can be significantly larger as in GMG methods.

4.1. Convection-diffusion equations. For all examples in this section we use a P_1-discretization of the convection-diffusion equation in some domain $\Omega \subset \mathbb{R}^d$:

$$-\nu\Delta u + (\mathbf{w}\cdot\nabla)u = f, \tag{4.1}$$

with given (divergence-free) convective speed $\mathbf{w}$, right-hand side f, viscosity ν, and Dirichlet boundary conditions $u|_\Gamma = \bar{u}$.

The first problem we are considering lives on the unit square, with

$$\mathbf{w}(\mathbf{x}) = \begin{pmatrix} m_2 - x_2 \\ x_1 - m_1 \end{pmatrix} \cdot \begin{cases} -16\|\mathbf{m}-\mathbf{x}\| + 8 & \text{if } \|\mathbf{m}-\mathbf{x}\| < 0.5, \\ 0 & \text{otherwise,} \end{cases} \quad \mathbf{m} = \begin{pmatrix} 0.5 \\ 0.5 \end{pmatrix}$$

$$f(\mathbf{x}) = \begin{cases} 1 & \text{if } \|\mathbf{0}-\mathbf{x}\| < 1, \\ 0 & \text{otherwise} \end{cases}$$

(cf. Figure 4), and $\bar{u} = 0$.

The second problem was the 2D valve, with $\mathbf{w}$ originating in the solution of the full Navier–Stokes equations, with a source ($f \neq 0$) near the inlet (see Figure 7 for a visualization of $\mathbf{w}$ and a solution of the problem).

For both problems we performed h-dependence tests (cf. Table 1 and Figure 8; for both we used a W-8-8 cycle with Gauss–Seidel smoothers). The values there concern only the iteration phase, not the setup. A comparison of the CPU time needed for setup (construction of the topology and of the prolongation) and the actual solution phase can be found in Figure 9(a).

The next test deals with the ν dependence (on a fixed grid). The results can be found in Table 2 and Figure 10 (cycles used are the same as before, i.e., W-8-8, Gauss–Seidel smoother).

Some h- and ν-dependence test for the 3D valves (again with $\mathbf{w}$ coming from the solution of a Navier–Stokes problem) can be found in Table 3 (W-8-8 cycles, Gauss–Seidel smoothers). The timings for the preprocessing phases and the multigrid iterations are illustrated in Figure 9(b). Here, the red-gray-black algorithm leads to a rather unbalanced method. The edges of the coarser levels are somehow joined by many neighboring elements, and thus the systems which have to be solved for the edge prolongation grow large, leading to the huge setup time.

TABLE 1

Dependence of the reduction per multigrid step (red/step) and $T_{0.1}$ on grid refinements for the unit-square problem ($\nu = 0.01$) and the 2D valve ($\nu = 0.001$).

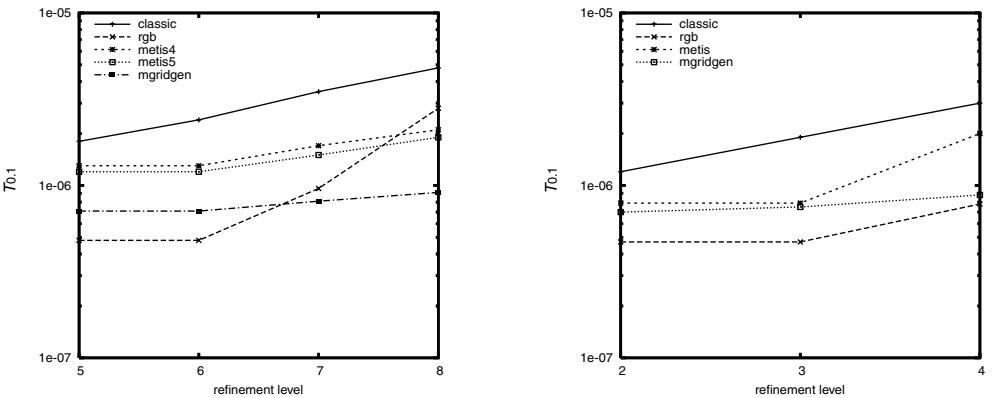

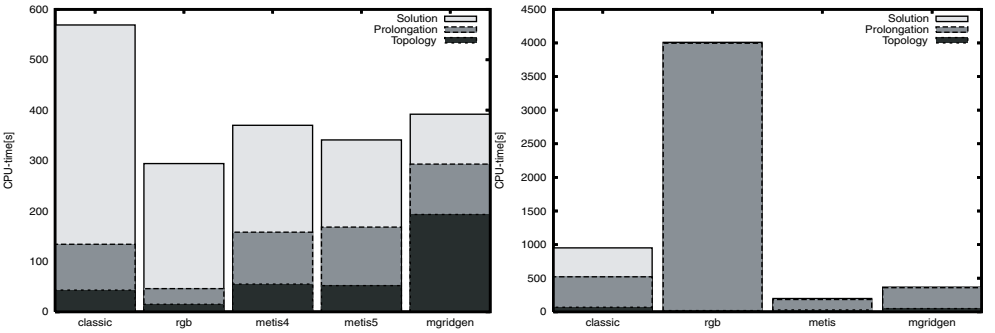

FIG. 8. *Dependence of the efficiency on the refinement level for the unit-square (left) and the 2D valve problem (right).*

In Table 4 we have collected the values for grid complexities σ^{Ω} and operator complexities σ^{A} for representative test cases.[2] In all tests the operator complexities for the classical method are higher than for the other methods, caused by more neighbors on the coarse level, and leading to the high solve times despite the reasonable reduction rates (cf. Figure 9, Table 1). In three dimensions this gets even worse, although this must not be overrated, because as already stated, the direct application of this method in three dimensions may not be sensible.

The tests show that the choice of the agglomeration strategy has a strong influence on the efficiency of the method, sometimes even on the question, if the method is converging. The general tendency which can be observed is that the optimization

[2] σ^{Ω} is the ratio of the total number of unknowns on all levels to that on the finest level, whereas σ^{A} is the ratio of the total number of nonzero entries in all matrices to that in the finest-level matrix.

approach of MGridGen leads to the best results, although the costs for the topology construction are pretty high (but for 3D problems are low in comparison to the prolongation construction). The red-gray-black method seems rather unpredictable; sometimes it is quite good, sometimes (especially for stronger convection) it is insufficient, and sometimes it is the systems to be solved for the prolongation grow uncontrollably, leading to large setup times. The bottom-up and the classical methods lie in between; the agglomerates which are produced by the classical methods sometimes look disadvantageous (bad aspect ratio) and result in a slow convergence.

4.2. Oseen equations. To check the h-dependence of the cAMGe method for the P_1^{nc}-P_0 element we solve the Oseen equations for the driven cavity problem (unit square, $\bar{\mathbf{u}} = (1\ 0)^T$ at the top edge, $\bar{\mathbf{u}} = \mathbf{0}$ at the other edges), with $\mathbf{w}$ near the solution of the full Navier–Stokes problem and mild convection ($\nu = 0.1$). The results of the tests (with Vanka smoother and W-2-2 cycle) can be found in Table 5 and Figure 11.

	$T_{0.1}$	1.6e-6	2.3e-6	2.7e-6	2.9e-6

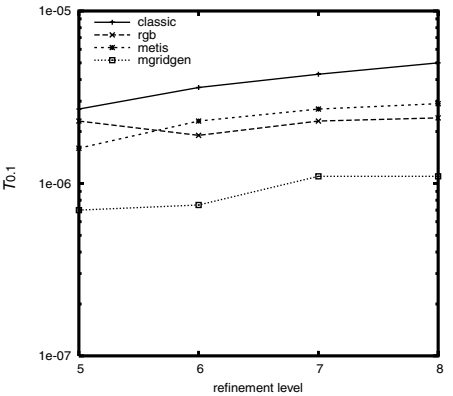

FIG. 11. *Results for the solution of the Oseen equations for the driven cavity problem ($\nu = 0.1$).*

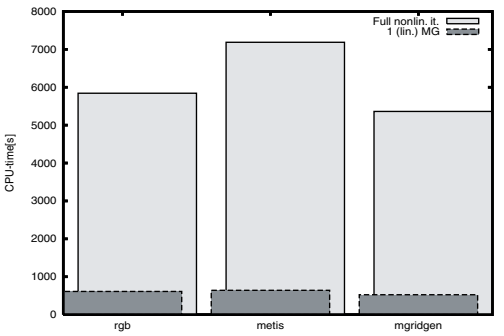

FIG. 12. *The timings for the full nonlinear problem on the 3D valves (light gray). The dark gray boxes in the foreground illustrate the time needed for the solution of one (the last) linear problem.*

What we finally want to compare is the usability of the methods for a full nonlinear Navier–Stokes problem. Here the construction of the topology has to be performed only once (except some kind of semicoarsening depending on intermediate solutions is wanted), the interpolations can also be kept for more than one nonlinear iteration. The solver itself should be fast (but it has to be kept in mind that there is no need to solve the linear problems with very high precision). We have applied the methods for the Navier–Stokes problem on the 3D valves with $\nu = 0.001$ and illustrated the timings in Figure 12. The method with the classical topology construction did not reach a solution with a reasonable number of smoothing steps and within reasonable time.

5. Conclusions. We have shown numerically that the strategy for the construction of the agglomerates has a crucial influence on the efficiency of the method. The optimization approach, which is the most sophisticated upon the methods tested (and also needs the most CPU time), in general leads to the best results.

As already mentioned in [8, 7] the AMGe method should only be used if classical AMG methods fail. The AMGe setup phase is costly, and the memory consumption can get very high, as many connectivity matrices containing the topological information are stored.

One situation where it is sensible to use AMGe is the coupled approach for a mixed FE discretization of the Oseen equations. First, it appears to be a flexible possibility for generalizations (we have demonstrated this for the P_1^{nc}-P_0 element), and second—because of the underlying topological information—it gives rise to analytic techniques which are not available for other methods (which we have exploited for a stability result). In this situation we reach the same conclusion as in [20], that it is advantageous to use knowledge from GMG methods and to give up the "black-box" character of AMG.

A STABILITY NOTION FOR LATTICE BOLTZMANN EQUATIONS*

M. K. BANDA†, W.-A. YONG‡, AND A. KLAR§

Abstract. Lattice Boltzmann equations are usually constructed to satisfy some physical requirements such as Galilean invariance and isotropy, to possess a velocity-independent pressure and no compressible effects, and so on. In this paper, a stability requirement is introduced as a new criterion for the constructions. With this requirement, we derive some relations of parameters for several lattice Boltzmann models. Interestingly, these relations are satisfied by many choices of parameters used in the literature.

Key words. lattice Boltzmann equations, incompressible Navier–Stokes equations, stability

AMS subject classifications. 76M28, 35L40, 82C35

DOI. 10.1137/040606211

1. Introduction.

Lattice Boltzmann equations provide a simple and alternative numerical method to simulate various hydrodynamic systems involving incompressible Navier–Stokes equations. A review on the method can be found in [6]. Although the lattice Boltzmann method evolved from lattice-gas automata [10, 11, 28], it can be viewed as a particular discretization of some discrete-velocity Boltzmann equations [27]. These are hyperbolic systems of partial differential equations with stiff source terms. Such equations, also called relaxation systems, have been intensively studied in the last years. To ensure a well-behaved relaxation limit, different stability criteria such as the structural stability conditions [29], the subcharacteristic condition [17], or some dissipative entropy principles [2] have been proposed for these systems.

In contrast, the lattice or discrete-velocity Boltzmann equations are constructed to satisfy some physical requirements such as Galilean invariance and isotropy, to possess a velocity-independent pressure and no compressible effects; see [21, 5, 23, 4, 32, 14, 13]. Recall that discrete-velocity lattice Boltzmann equations can also be interpreted as a discretized version of the continuum Boltzmann equation. Because the latter satisfies a dissipative entropy condition (Boltzmann's H-theorem) [3], one might expect that a stability criterion for the discrete-velocity Boltzmann equations is an analogue of the entropy condition. Unfortunately, it was proven in [30, 31] that such entropies do not exist for many widely used lattice Boltzmann models. However, the structural stability conditions in [29] can still be used here.

In this work, we adapt the structural stability conditions in [29] to the lattice Boltzmann equations. In doing so, we introduce a definition of stable lattice Boltzmann equations. For stable models thus defined, one can prove that the diffusive

limit of the discrete-velocity Boltzmann equations is the incompressible Navier–Stokes equation at least in the regime of smooth flows. A complete proof can be done in exactly the same fashion as in [18] for d'Humières's generalized models [16]. Thus, it seems reasonable to consider the stability notion as a new requirement in constructing lattice Boltzmann equations for the Navier–Stokes equations. Note that the present theory is valid only for isothermal models.

To explain how the new stability requirement guides the construction of lattice Boltzmann equations, we derive some relations of parameters for the parametrized models from [27, 13] so that the models are stable when the relations are fulfilled. Interestingly, all the choices of parameters used in [23, 26, 1, 13, 15, 21] satisfy these relations. Moreover, computational experiments have been undertaken on some examples commonly used in literature. These tests confirm the usefulness of the stability notion.

Note that a general procedure with details is presented in sections 2 and 3 to derive the aforementioned relations for two specific parametrized models. It is hoped that the procedure can be adopted or revised by practitioners using the lattice Boltzmann method to choose various adjustable parameters.

We point out that our stability theory is different from the previous works [27, 22] on the stability of the lattice Boltzmann method (an explicit difference scheme). Those previous works are all based on the von Neumann stability analysis for the difference scheme and the resulting growth matrix was not treated analytically. In both [27] and [22], approximation methods for linear algebra were used to compute the eigenvalues of the growth matrix, while a perturbation technique was also employed in [22]. In contrast, our theory is based on a rigorous asymptotic analysis [18] for the lattice Boltzmann equations (partial differential equations). Thus it is useful not only for the lattice Boltzmann method but also for other discretizations of the hyperbolic systems. Moreover, our derivation of the parameter relations is purely analytic (see section 3).

The paper is organized as follows. In section 2 we present the definition and state a convergence theorem for the simplest lattice Boltzmann model. In section 3 we use the stability requirement to derive some relations of parameters for the parametrized models from [13, 27]. Finally, numerical results are presented in section 4 to verify our theory.

2. A stability notion. Lattice Boltzmann equations are of the form

$$\frac{\partial f_i}{\partial t} + c_i \cdot \nabla f_i = J_i(f), \qquad i = 1, 2, \ldots, N. \tag{2.1}$$

Here $f_i = f_i(x,t)$ are unknown (scalar) distribution functions, $(x,t) \in \mathbb{R}^d \times \mathbb{R}_+$, $c_i \cdot \nabla$ is the directional x-derivative along the mesoscopic velocity $c_i \in \mathbb{R}^d$, $J_i(f)$ stands for a collision term, and $f = (f_1, f_2, \ldots, f_N)^T$ with superscript T for the transpose.

By integrating (2.1) along the characteristics, we obtain

$$f_i(x + c_i\Delta t, t + \Delta t) = f_i(x,t) + \int_0^{\Delta t} J_i(f)(x + c_i\sigma, t + \sigma)d\sigma$$

with Δt a time step. Approximating the integral by the simple rectangle rule ($\sigma = 0$) yields

$$f_i(x + c_i\Delta t, t + \Delta t) = f_i(x,t) + \Delta t J_i(f)(x,t). \tag{2.2}$$

This is the usual lattice Boltzmann method and is widely used in a *long-time large-scale* limit to simulate incompressible flows. The latter are traditionally described with the Navier–Stokes equations

$$\begin{aligned} \text{div}\mathbf{u} &= 0, \\ \frac{\partial \mathbf{u}}{\partial t} + \mathbf{u}\cdot\nabla\mathbf{u} + \nabla p &= \nu\Delta\mathbf{u} \end{aligned} \tag{2.3}$$

with initial and boundary conditions. Here $\mathbf{u}$, p, and ν stand for the fluid velocity, pressure, and viscosity coefficient (a given positive constant), respectively.

Quantitatively, the long-time large-scale limit is characterized by the diffusive scaling

$$t \longrightarrow t/\epsilon^2, \qquad x \longrightarrow x/\epsilon$$

with ϵ a small positive parameter. In this scaling, (2.1) becomes

$$\frac{\partial f_i}{\partial t} + \frac{c_i}{\epsilon}\cdot\nabla f_i = \frac{J_i(f)}{\epsilon^2}, \qquad i = 1, 2, \ldots, N. \tag{2.4}$$

For the lattice Boltzmann models used in the simulation of incompressible flows, the c_i's and $J_i(f)$'s are always chosen such that the Chapman–Enskog expansion of the scaled system (2.4) yields the Navier–Stokes equations. Such lattice Boltzmann models will be called *consistent* (with the Navier–Stokes equations).

Now we introduce our *stability* notion for the lattice Boltzmann equations (2.1).

DEFINITION 2.1. *Let f_* be a constant state satisfying $J(f_*) = 0$. The lattice Boltzmann model* (2.1) *is called* stable *at $f = f_*$ if there is an invertible matrix $P \in \mathbb{R}^{N\times N}$ such that P^TP is diagonal and $PJ_f(f_*) = -diag(\lambda_1, \lambda_2, \ldots, \lambda_N)P$ with $\lambda_i = 0$ for $i \le d+1$ and $\lambda_i > 0$ for $i > d+1$. Here $J_f(f) \in \mathbb{R}^{N\times N}$ is the Jacobian of $J(f) = (J_1(f), J_2(f), \ldots, J_N(f))^T$.*

REMARK 2.1. *This definition is based on the stability conditions* [29] *for hyperbolic systems with source terms. Note that the usual entropy structure is not valid for many widely used lattice Boltzmann equations* [30, 31].

REMARK 2.2. *In* [18]*, the generalized lattice Boltzmann models from* [16] *were shown to be stable provided that some parameters satisfy a constraint. With such a stability property, it was further proven there that the generalized models converge in the diffusive limit $\epsilon \to 0$ towards the Navier–Stokes equations. In general, for consistent and stable lattice Boltzmann models, similar convergence results can be proven with the approach in* [18].

Next we check the above stability definition for a simple example and state a convergence theorem for the following lattice Boltzmann model:

$$\begin{aligned} &d = 2, \qquad N = 6, \\ &c_i = \big(\cos\big(\pi(i-1)/3\big), \sin\big(\pi(i-1)/3\big)\big)^T, \\ &J_i(f) = \frac{f_i^{eq}(n,\mathbf{u}) - f_i}{\tau}. \end{aligned} \tag{2.5}$$

In (2.5), τ is a positive parameter (relaxation time) and

$$\begin{aligned} &f_i^{eq}(n,\mathbf{u}) = n/6 + \mathbf{u}c_i/3 + 2(\mathbf{u}c_i)^2/3 - |\mathbf{u}|^2/3, \\ &n = \sum_{i=1}^{6} f_i(x,t), \qquad \mathbf{u} = \sum_{i=1}^{6} c_i f_i(x,t). \end{aligned} \tag{2.6}$$

The consistency of this model is well known (see, e.g., [20]). To show its stability, we note that

$$\begin{aligned}\sum_{i=1}^{6} f_i^{eq}(n,\mathbf{u}) &= n = \sum_{i=1}^{6} f_i(x,t),\\ \sum_{i=1}^{6} f_i^{eq}(n,\mathbf{u})c_i &= \mathbf{u} = \sum_{i=1}^{6} f_i(x,t)c_i.\end{aligned} \tag{2.7}$$

By computing

$$\frac{\partial f_i^{eq}(n,\mathbf{u})}{\partial f_j} = \frac{1}{6} + \frac{c_i c_j}{3} + \frac{4(\mathbf{u}c_i)c_j c_i}{3} - \frac{2\mathbf{u}c_j}{3} \tag{2.8}$$

and using (2.7), we deduce from (2.8) that

$$\left[f_{if_j}^{eq}(n,\mathbf{u})\right]^2 = \left[f_{if_j}^{eq}(n,\mathbf{u})\right],$$

that is, the Jacobian $[f_{if_j}^{eq}(n,\mathbf{u})]$ is a projection matrix. Thus, the eigenvalues of $J_f(f) := ([f_{if_j}^{eq}(n,\mathbf{u})] - I_6)/\tau$ are 0 and $-1/\tau$.

Take $f_* = f^{eq}(1,0)$. Set $e = (1,1,\ldots,1) \in \mathbb{R}^6$ and $\mathbf{c} = (c_1,\ldots,c_6)$. From (2.8) we see that

$$\left[f_{if_j}^{eq}(n,\mathbf{u})\right]\big|_{\mathbf{u}=0} = \mathbf{c}^T\mathbf{c}/3 + e^T e/6 \tag{2.9}$$

is symmetric. Note that

$$e\mathbf{c}^T = 0 \quad \text{and} \quad \mathbf{c}\mathbf{c}^T = 3I_2.$$

The relation (2.9) indicates that the rank of $[f_{if_j}^{eq}(n,\mathbf{u})]|_{\mathbf{u}=0}$ is 3. Since $[f_{if_j}^{eq}(n,\mathbf{u})]$ is a projection matrix and

$$\tau J_f(f_*) = [f_{if_j}^{eq}(n,\mathbf{u})]|_{\mathbf{u}=0} - I_6,$$

the rank of $J_f(f_*)$ is 3.

On the other hand, since $\left[f_{if_j}^{eq}(n,\mathbf{u})\right]\big|_{\mathbf{u}=0}$ is symmetric, there is a unitary matrix P such that

$$J_f(f_*) = P^T \Lambda P/\tau$$

with Λ a diagonal matrix. Since Λ is similar to $\tau J_f(f_*)$, we may as well assume that

$$\Lambda = -\mathrm{diag}(0,0,0,1,1,1).$$

Thus, we have shown the following.

PROPOSITION 2.1. *The 2-dimensional 6-velocity model* (2.5)–(2.6) *is stable at* $f_* = f^{eq}(1,0)$.

Based on the stability and consistency results, one can prove a convergence theorem for the model (2.5)–(2.6). For this purpose, we need the following existence result [19] for the Navier–Stokes equations on the d-dimensional torus $\mathbb{T}^d$.

LEMMA 2.2 (see [19]). *Let* $s \geq [d/2]+1$ *be an integer and* $\bar{\mathbf{u}} \in H^s$ *with* $\mathrm{div}\bar{\mathbf{u}} = 0$. *Then there exists* $T_* \in (0,\infty)$, *depending only on* $\|\bar{\mathbf{u}}\|_s$, *such that the Navier–Stokes*

equations (2.3) *with* $\mathbf{u}(x,0)=\bar{\mathbf{u}}(x)$ *and* $\int p(x,t)dx=0$ *have a unique solution* $(\mathbf{u},p)$ *satisfying*

$$\mathbf{u}\in C(0,T_*;H^s)\cap L^1(0,T_*;H^{s+1}),\qquad p\in L^1(0,T_*;H^{s+1}).$$

Here and below, H^s is the Sobolev space of functions which, together with their distributional x-derivatives of order $\le s$, are square integrable on $\mathbb{T}^d$. Its norm is denoted by $\|\cdot\|_s$. The integral $\int$ is taken over a period, say, $(0,1]^d$. In addition, $C(0,T;H^s)$ and $L^1(0,T;H^s)$ denote the Banach space of H^s-valued continuous and integrable functions on $[0,T]$, respectively.

Now we are in a position to state the following convergence result, which is an analogue of Theorem 4.1 in [18] and can be proven similarly.

THEOREM 2.3. *Let* $s\ge 2$ *be an integer,* $\bar{\mathbf{u}}\in H^{s+5}$ *with* $\operatorname{div}\bar{\mathbf{u}}=0$*, and* $\bar{p}$ *the solution of* $\Delta p=-\operatorname{div}(\bar{\mathbf{u}}\cdot\nabla\bar{\mathbf{u}})$ *with* $2\int\bar{p}=-\int|\bar{\mathbf{u}}|^2$*. Then the lattice Boltzmann equations* (2.4) *with* (2.5), (2.6)*,* $\tau=4\nu$*, and initial data*

$$f_i^\epsilon(x,t)=f_i^{eq}(1,\epsilon\bar{\mathbf{u}})+\epsilon^2(2\bar{p}+|\bar{\mathbf{u}}|^2-8\nu c_i\cdot\nabla\bar{\mathbf{u}}c_i)/6$$

have a unique solution $f^\epsilon\in C(0,T_*;H^s)$ *for* $\epsilon>0$ *sufficiently small. Moreover, there is a constant* K*, independent of* ϵ*, such that*

$$\Big\|\mathbf{u}(\cdot,t)-\frac{\mathbf{u}^\epsilon(\cdot,t)}{\epsilon}\Big\|_s\le K\epsilon^2,$$

$$\Big\|p(\cdot,t)-\frac{1}{2\epsilon^2}\Big[n^\epsilon(\cdot,t)-|\mathbf{u}^\epsilon|^2+\int|\mathbf{u}^\epsilon|^2-1\Big]\Big\|_s\le K\epsilon$$

for all $t\le T_*$*. Here* $\mathbf{u}^\epsilon=\sum_i c_i f_i^\epsilon$*,* $n^\epsilon=\sum_i f_i^\epsilon$*, and* $(\mathbf{u},p)$ *denotes the above solution of the Navier–Stokes equations.*

Similar theorems can be proven for other consistent and stable lattice Boltzmann models. On the other hand, the requirement that lattice Boltzmann models are stable may be used as a guideline to construct such models. Consistent models chosen in such a way will automatically converge to the Navier–Stokes equations in the diffusive limit.

3. Determination of parameters. In this section, we fix some parameters for several parametrized lattice Boltzmann models by requiring that they are stable. These models are taken from [13, 27] and their consistency is already shown there.

3.1. 2-dimensional 8-velocity models (D2Q8). We begin with an incompressible model from [13], which is (2.1) with $d=2$, $N=8$,

$$\{c_i: i=1,2,3,4\}=\{(\pm1,0)^T,(0,\pm1)^T\},$$
$$\{c_i: i=5,6,7,8\}=\{(\pm1,\pm1)^T\},$$

and

$$J_i(f)=\frac{f_i^{eq}(\mathbf{u},p)-f_i}{\tau}.$$

Here τ is a positive constant (relaxation time) and

$$f_i^{eq}(\mathbf{u},p)=\begin{cases}\big(3\mathbf{u}c_i+(3\mathbf{u}c_i)^2/2-3|\mathbf{u}|^2/2\big)/9+\lambda p, & i=1,2,3,4,\\ \big(3\mathbf{u}c_i+(3\mathbf{u}c_i)^2/2-3|\mathbf{u}|^2/2\big)/36+\gamma p, & i=5,6,7,8,\end{cases}$$

with two parameters λ and γ, where

$$\mathbf{u} = \sum_{i=1}^{8} c_i f_i(x,t), \qquad p = \frac{1}{4(\lambda+\gamma)}\left[\sum_{i=1}^{8} f_i(x,t) - \frac{2|\mathbf{u}|^2}{3}\right].$$

It can be directly verified that

$$\begin{aligned} \sum_{i=1}^{8} f_i^{eq}(\mathbf{u},p) &= \sum_{i=1}^{8} f_i(x,t), \\ \sum_{i=1}^{8} f_i^{eq}(\mathbf{u},p)c_i &= \mathbf{u} = \sum_{i=1}^{8} f_i(x,t)c_i. \end{aligned} \tag{3.1}$$

As for the 2-dimensional 6-velocity model, by computing

$$\frac{\partial f_i^{eq}(\mathbf{u},p)}{\partial f_j} = \begin{cases} \dfrac{\left(3c_jc_i + 9(\mathbf{u}c_i)c_jc_i - 3\mathbf{u}c_j\right)}{9} + \dfrac{1-4\mathbf{u}c_j/3}{4(\lambda+\gamma)}\lambda, & i = 1,2,3,4, \\ \dfrac{\left(3c_jc_i + 9(\mathbf{u}c_i)c_jc_i - 3\mathbf{u}c_j\right)}{36} + \dfrac{1-4\mathbf{u}c_j/3}{4(\lambda+\gamma)}\gamma, & i = 5,6,7,8, \end{cases} \tag{3.2}$$

and using (3.1), we deduce from (3.2) that

$$\left[f_{if_j}^{eq}(\mathbf{u},p)\right]^2 = \left[f_{if_j}^{eq}(\mathbf{u},p)\right];$$

that is, the Jacobian $[f_{if_j}^{eq}(\mathbf{u},p)]$ is a projection matrix. Thus, the eigenvalues of $J_f(f) := ([f_{if_j}^{eq}(\mathbf{u},p)] - I_8)/\tau$ are 0 and $-1/\tau$.

In addition, take $f_* = f^{eq}(0,1)$ and set $e = (1,1,\ldots,1) \in \mathbb{R}^8$, $\mathbf{c} = (c_1,\ldots,c_8)$, and

$$A_0 = 9\ \mathrm{diag}\big(I_4, 4I_4\big). \tag{3.3}$$

From (3.2) and (3.3) we see that

$$A_0\left[f_{if_j}^{eq}(\mathbf{u},p)\right]\big|_{\mathbf{u}=0} = 3\mathbf{c}^T\mathbf{c} + A_0(\lambda,\lambda,\lambda,\lambda,\gamma,\gamma,\gamma,\gamma)^T e/(4(\lambda+\gamma)) \tag{3.4}$$

is symmetric if

$$\lambda = 4\gamma. \tag{3.5}$$

Note that

$$e\mathbf{c}^T = 0 \qquad \text{and} \qquad \mathbf{c}\mathbf{c}^T = 6I_2.$$

The relation (3.4) indicates that the rank of $[f_{if_j}^{eq}(\mathbf{u},p)]|_{\mathbf{u}=0}$ is 3. Since $[f_{if_j}^{eq}(\mathbf{u},p)]$ is a projection matrix and $\tau J_f(f_*) = [f_{if_j}^{eq}(\mathbf{u},p)]|_{\mathbf{u}=0} - I_8$, the rank of $J_f(f_*)$ is 5.

On the other hand, since $A_0\left[f_{if_j}^{eq}(\mathbf{u},p)\right]\big|_{\mathbf{u}=0}$ is symmetric and A_0 is symmetric positive definite, it is well known that there is an invertible matrix P such that

$$A_0 = P^TP \qquad \text{and} \qquad A_0J_f(f_*) = P^T\Lambda P/\tau$$

with Λ a diagonal matrix. Note that Λ is similar to $\tau J_f(f_*)$. We may as well assume that

$$\Lambda = -\mathrm{diag}(0,0,0,1,1,1,1,1).$$

Thus we have proven the following.

PROPOSITION 3.1. *If $\lambda = 4\gamma$, then the model in* [13] *is stable at $f_* = f^{eq}(0,1)$.*

REMARK 3.1. *In* [13]*, the authors derived a consistency condition $\lambda + 2\gamma = 1/2$. This condition alone allows infinite many choices of the parameters. However, in the numerical tests reported in* [13]*, only $\lambda = 1/3$ was used. The authors neither explained how to get this λ nor mentioned numerical results with other choices of λ. Note that the tested choice is exactly that given by our stability condition* (3.5) *and the above consistency condition.*

REMARK 3.2. *A similar convergence theorem as in section* 2 *can be established for the D2Q8 model with the above consistency and stability constraints.*

REMARK 3.3. *Proposition* 3.1 *is proven with almost the same procedure as that for Proposition* 2.1*. Similar procedures can be applied to other models. We state several results in the following subsections but omit the detailed proofs, leaving them as exercises for the interested reader.*

3.2. 2-dimensional 9-velocity models (D2Q9). Next we consider a D2Q9 parametrized model [27], i.e., (2.1) with $c_9 = 0$, other c_i equal to that of the above incompressible D2Q8 model, and

$$J_i(f) = \frac{f_i^{eq}(n,\mathbf{u}) - f_i}{\tau}.$$

Here τ is a relaxation time, $f_9^{eq}(n,\mathbf{u}) = \alpha n - \dfrac{2}{3}n|\mathbf{u}|^2$,

$$\begin{aligned} f_i^{eq}(n,\mathbf{u}) =& \beta n + \frac{n}{3}\mathbf{u}c_i + \frac{n}{2}(\mathbf{u}c_i)^2 - \frac{n}{6}|\mathbf{u}|^2, \qquad 1 \le i \le 4, \\ f_i^{eq}(n,\mathbf{u}) =& \frac{(1-\alpha-4\beta)}{4}n + \frac{n}{12}\mathbf{u}c_i + \frac{n}{8}(\mathbf{u}c_i)^2 - \frac{n}{24}|\mathbf{u}|^2, \qquad 5 \le i \le 8, \end{aligned}$$

with

$$n = \sum_{i=1}^{9} f_i(x,t), \qquad n\mathbf{u} = \sum_{i=1}^{9} c_i f_i(x,t).$$

For this parametrized model, we have the following.

PROPOSITION 3.2. *If $\alpha \in (0,1)$ and $\alpha + 5\beta = 1$, then the D2Q9 model is stable at $f_* = f^{eq}(1,0)$.*

It is remarkable that the condition of Proposition 3.2 is satisfied by both $(\alpha,\beta) = (4/9, 1/9)$ used in the well-known D2Q9 model and $(\alpha,\beta) = (2/7, 1/7)$ used in [26].

3.3. 3-dimensional 15-velocity models (D3Q15). A D3Q15 parametrized model from [27] is (2.1) with $c_{15} = 0$,

$$\begin{aligned} \{c_i : i = 1,\dots,6\} &= \{(\pm1,0,0)^T, (0,\pm1,0)^T, (0,0,\pm1)^T\}, \\ \{c_i : i = 7,\dots,14\} &= \{(\pm1,\pm1,\pm1)^T\}, \end{aligned}$$

and

$$J_i(f) = \frac{f_i^{eq}(n,\mathbf{u}) - f_i}{\tau}.$$

Here τ is a relaxation time, $f_{15}^{eq}(n,\mathbf{u}) = \alpha n - \frac{n}{3}|\mathbf{u}|^2$,

$$f_i^{eq}(n,\mathbf{u}) = \beta n + \frac{n}{3}\mathbf{u}c_i + \frac{n}{2}(\mathbf{u}c_i)^2 - \frac{n}{6}|\mathbf{u}|^2, \qquad 1 \le i \le 6,$$
$$f_i^{eq}(n,\mathbf{u}) = \frac{(1-\alpha-6\beta)}{8}n + \frac{n}{24}\mathbf{u}c_i + \frac{n}{16}(\mathbf{u}c_i)^2 - \frac{n}{48}|\mathbf{u}|^2, \qquad 7 \le i \le 14,$$

with

$$n = \sum_{i=1}^{15} f_i(x,t), \qquad n\mathbf{u} = \sum_{i=1}^{15} c_i f_i(x,t).$$

For this parametrized model, we have the following.

PROPOSITION 3.3. *If $\alpha \in (0,1)$ and $\alpha + 7\beta = 1$, then the $D3Q15$ model is stable at $f_* = f^{eq}(1,0)$.*

It is remarkable that the condition of Proposition 3.3 is satisfied by both $(\alpha,\beta) = (1/8,1/8)$ used in [1] and $(\alpha,\beta) = (2/9,1/9)$ used in [23].

Following the arguments above, we expect that the stability requirement leads to a good choice of the parameters. Moreover, choosing parameters outside the range required by the stability condition should in general yield unstable methods. These statements will be further verified with numerical tests presented in the next section.

4. Numerical results. In this section we report a number of numerical experiments to verify that the stability criteria presented in Propositions 3.1, 3.2, and 3.3 for the different models give reasonable ranges for the corresponding parameters. The goal is to show that the choices given in the propositions always work well. On the other hand, choices outside the ranges suggested in the propositions lead in general to unreliable or unstable results. The numerical experiments in this section use the standard lattice Boltzmann discretization (2.2) on a few examples commonly used in the literature.

4.1. Test examples.

4.1.1. Taylor vortex flow. The first example models the decay of a Taylor vortex in a 2π periodic domain. We refer to [24] and [8] for details. In two dimensions the initial conditions are

$$u(x,y,0) = \cos x \sin y,$$
$$v(x,y,0) = \sin x \cos y,$$

where u (resp., v) is the flow velocity in the x- (resp., y-) direction. The tests are performed at $\mathrm{Re} = 100$. In the initial step, the pressure field is generated from the velocity field by taking the divergence of the momentum equation in the Navier–Stokes system and then solving for pressure. Since the velocity field $\mathbf{u} = (u,v)$ is divergence free, the pressure p solves

$$\nabla^2 p = -\nabla \cdot (\mathbf{u} \cdot \nabla \mathbf{u}).$$

In three dimensions we choose the initial velocity distribution as follows:

$$u(x,0) = U_0 \cos x \sin y \cos z,$$
$$v(x,0) = -U_0 \sin x \cos y \cos z,$$
$$w(x,0) = 0,$$

where $U_0 = 0.2$. We consider $\mathrm{Re} = 200$.

4.1.2. Poiseuille flow. This example is taken from [13] or [7]. The flow is restricted in the region $\{(x,y)|0 \le x \le 2,\ 0 \le y \le 1\}$ with initial and boundary conditions

$$\begin{aligned} u(x,y,0) = v(x,y,0) = 0, \quad & p(x,y,0) = p_0, \\ u(x,0,t) = u(x,1,t) = v(x,0,t) = v(x,1,t) = 0, & \\ p(0,y,t) = p_{\text{in}}, p(2,y,t) = p_{\text{out}}, & \end{aligned}$$

where $p_0 = 0.5(p_{\text{in}} + p_{\text{out}})$ with $p_{\text{in}} = 1.1$ and $p_{\text{out}} = 1.0$. To determine the steady state we apply the following criterion, as in [13]:

$$\frac{\sum_{ij} |u_{ij}^{(n+1)} - u_{ij}^{(n)}|}{\sum_{ij} |u_{ij}^{(n+1)}|} \le 5.0 \times 10^{-9},$$

where u_{ij}^n is the discrete flow velocity in the x-direction.

4.1.3. Driven cavity flow. The last example is a driven cavity flow. In two dimensions we consider a square cavity whose top plate moves from left to right with a constant velocity, while the other three boundaries are fixed. Numerical simulations of the driven cavity have been studied by many authors using traditional schemes such as finite difference [9, 25] and multigrid methods [12]. The lattice Boltzmann simulation for the D2Q9 model was performed in [15] with a detailed analysis and for the D2Q8 model in [13]. The Reynolds number is determined by $\text{Re} = LU/\nu$, where L is the height or width of the cavity, U is the uniform velocity of the top plate, and ν is the kinematic viscosity. We set $U = 0.1$ and ν depends on the Reynolds number. Numerical simulations are performed with $\text{Re} = 400, 1000, 2000$ on a 257×257 lattice. The initial condition is $u = v = 0$ and $p = 1$. A steady state is reached when the difference between the velocities at the center of the cavity for successive 1000 steps is less than 5×10^{-6}, as in [13].

In three dimensions the fluid is bounded by a cubic enclosure and the flow is driven by a uniform translation of the top in the x-direction. The top boundary moves in the x-direction with velocity U. The cavity has a $65 \times 65 \times 65$ lattice. Initially the velocities at all nodes, except the top ones, are set to zero. The x-velocity of the top is $U = 0.01$ for $\text{Re} = 100$ and $U = 0.1$ for higher Re. The y- and z-velocities are zero. Uniform fluid density $\rho = 2.7$ is imposed initially. The Reynolds number used in the cavity is $\text{Re} = UL_N/\nu$, where U is the uniform velocity at the top plate, L_N is the number of lattice units along one side of the cavity, and ν is the kinematic viscosity. The scheme and the boundary condition implemented in this example are the same as in [15].

4.2. Results for the different models.

4.2.1. The D2Q8 model. For details of the computation of the Taylor vortex flow we refer to [24]. We perform tests on different ratios of λ and γ: $\lambda = 4\gamma$, 2γ, and 6γ, which also satisfy the consistency condition $\lambda + 2\gamma = 1/2$. All of them give stable results for this test case. In Figure 1, the results obtained with the different parameters are compared to the exact solution. In addition, an extra test is made with $\lambda = 4\gamma$ and $\gamma = 1/3$. In this case the consistency condition does not hold. Figure 1 (right-hand side) shows that the model leads to a stable but unacceptable result.

For the Poiseuille flow example we consider the same parameters. The results obtained here lead to the same conclusions as those for the Taylor vortex flow. We

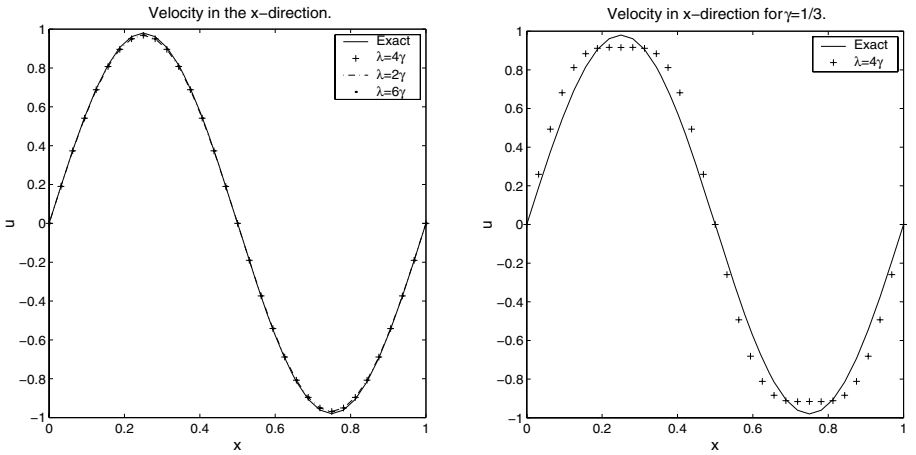

FIG. 1. *Taylor vortex flow with different parameter ratios of* λ *and* γ. $t = 1$, $y = \pi$.

also test the inconsistent choice of parameters $\lambda = 4\gamma$ and $\gamma = 1/3$ for the present flow model.

The last example for the D2Q8 model is the driven cavity flow. To verify the stability criterion we choose λ as in the two examples above. In all cases $\lambda = 4\gamma$ and $\lambda = 6\gamma$ yield stable results, while $\lambda = 2\gamma$ is unstable. Figure 2 presents the stable results for $\mathrm{Re} = 1000$.

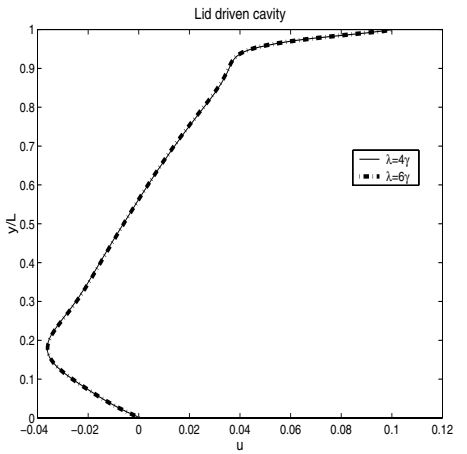

FIG. 2. *Lid driven cavity flow (velocity in the* x*-direction) with different parameter ratios of* λ *and* γ*, and* $Re = 1000$. *A cross-section taken in the middle of the cavity:* $x/L = 0.5$.

In conclusion we obtain the following results for the D2Q8 model.

1. The ratio $\lambda = 4\gamma$ gives stable results for all examples, even when the consistency condition is violated. This is backed by the theory.
2. The ratio $\lambda = 2\gamma$ gives stable results for the first two flow models, but unstable ones for the driven cavity problem, in accordance with the theory.
3. The ratio $\lambda = 6\gamma$ gives stable results for all examples. This does not necessarily contradict the stability theory. The ratio $\lambda = 6\gamma$ seems to be a good

choice for the examples considered here—although not backed by the stability theory—and thus remains to be tested on more complicated flows.

4.2.2. The D2Q9 model. We test the same configurations as in the last section. Tests are made with $\alpha = 0, 2/7, 4/9, 0.5, 1.0, 1.5, 2.0, 10.0$ and β satisfying the stability requirement given in Proposition 3.2.

For Taylor vortex flow we perform tests with the above values of α and see that $\alpha = 1.0$ still works but $\alpha > 1$ gives unacceptable results, as illustrated in Figure 3.

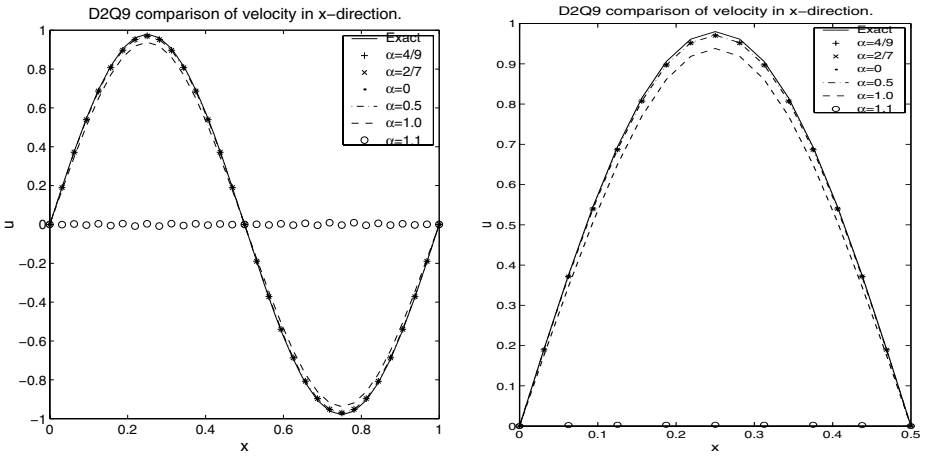

FIG. 3. *Taylor vortex flow with different values of α and β with $\alpha + 5\beta = 1$. $t = 1$, $y = \pi$.*

Further tests are made to investigate the behavior of the D2Q9 model for the Taylor vortex flow problem when $\alpha \in (0, 1)$ and $\alpha + 5\beta \neq 1$. We observe, for example, that the model leads to unacceptable results when $\alpha = 0.5$, $\beta = 0.5$, i.e., $\alpha + 5\beta = 3$.

For the Poiseuille flow problem, one obtains stable results for $\alpha = 0, 1/2, 4/9, 2/7$. For all other cases where $\alpha \in (0, 1)$ and $\alpha + 5\beta \neq 1$, the model gives unacceptable results. We observe, for example, that the model leads to unacceptable results when $\alpha = 0.5$, $\beta = 0.5$, i.e., $\alpha + 5\beta = 3$.

Finally, we consider the driven cavity flow. The results for $\mathrm{Re} = 1000$ are displayed in Figure 4. We obtain stable results for parameters $\alpha = 2/7, 4/9, 0.5$ and $\alpha + 5\beta = 1$. Parameters $\alpha = 0, 1.0, 1.5, 2.0, 10.0$ which are outside the range given by the theory give unstable results.

For this flow problem we also test $\alpha \in (0, 1)$ with $\alpha + 5\beta \neq 1$ for $\mathrm{Re} = 100$ and $U = 0.01$. The results are unacceptable.

In conclusion, we have investigated cases with the parameters $\alpha \in (0, 1)$ with $\alpha + 5\beta = 1$ which satisfies the stability requirement. Moreover, cases with $\alpha \notin (0, 1)$ with $\alpha + 5\beta = 1$ and $\alpha \in (0, 1)$ with $\alpha + 5\beta \neq 1$ are considered.

1. For $\alpha \in (0, 1)$ with $\alpha + 5\beta = 1$ all results are reasonable, which supports the theory.
2. For $\alpha \notin (0, 1)$ and $\alpha + 5\beta = 1$ all cases tested for the driven cavity problem give unstable or unacceptable results. The same is the case for $\alpha \in (0, 1)$ with $\alpha + 5\beta \neq 1$.

4.2.3. The D3Q15 model. For the Taylor–Green vortex flow we use parameter values of $\alpha = 0.0$, 1/8, 2/9, 0.5, 0.8, and 1.0. All of them give stable results, although

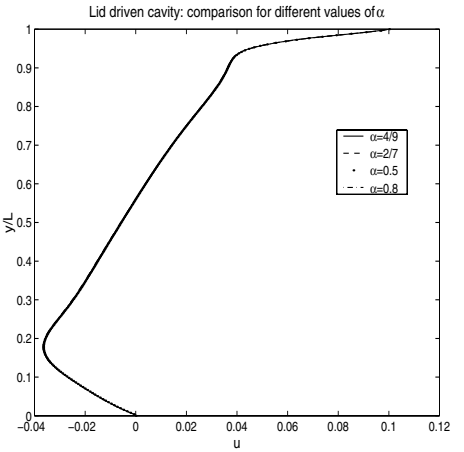

FIG. 4. *Comparison of the velocity in the x-direction for different parameters* α, $\alpha + 5\beta = 1$ *for the lid driven cavity flow problem,* $Re = 1000$. *A cross-section taken in the middle of the cavity:* $x/L = 0.5$.

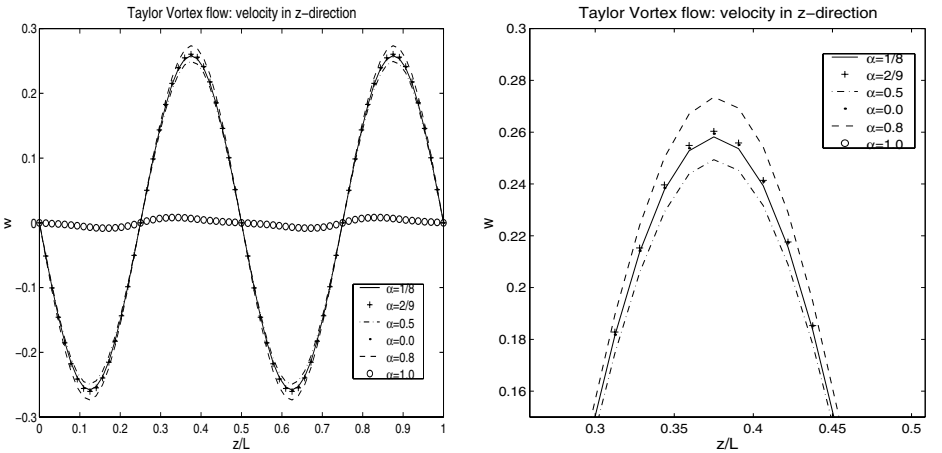

FIG. 5. *Comparison for different parameters* α, $\alpha + 7\beta = 1$ *for the Taylor–Green vortex flow problem. Profiles are taken at middle cross-sectional planes of the cube for velocity in the z-direction.*

$\alpha = 1.0$ gives unacceptable ones. The results are displayed in Figure 5, where the velocity in the z-direction is shown.

For the three-dimensional driven cavity flow we test the cases Re = 100, 400. Stable results for both cases are found only for $\alpha = 1/8$, $2/9$, 0.5, 0.8 as predicted by the theory. The results are displayed in Figure 6 for Re = 100, 400, respectively. In particular, for the case Re = 400 the cases $\alpha = 0$ and $\alpha = 1$ are unstable.

For Re = 400 and $U = 0.1$ we also test cases with $\alpha \in (0, 1)$ and $\alpha + 7\beta \neq 1$. We used $\alpha = 2/9$, $1/8$ with $\alpha + 7\beta = 0$ and $\alpha + 7\beta = 2$. In all these cases no reasonable results are obtained.

In conclusion, the D3Q15 model has been tested on two examples to verify the stability theory. We considered $\alpha \in (0, 1)$ with $\alpha + 7\beta = 1$, $\alpha \notin (0, 1)$ with $\alpha + 7\beta = 1$, and $\alpha \in (0, 1)$ with $\alpha + 7\beta \neq 1$.

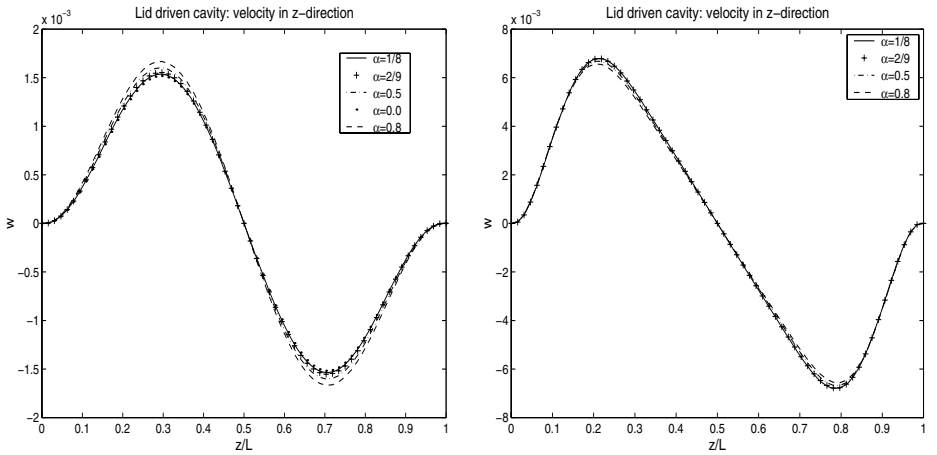

FIG. 6. *Comparison for different parameters* α, $\alpha+7\beta=1$ *for the lid driven cavity flow problem using the* $D3Q15$ *model,* $Re=100$ *and* $Re=400$. *Profiles are taken at middle cross-sectional planes of the cube for velocity in the z-direction.*

1. For all tests, $\alpha \in (0,1)$ with $\alpha+7\beta=1$ produces reasonable results.
2. $\alpha \notin (0,1)$ with $\alpha+7\beta=1$ is unstable or unacceptable for all tested parameter values for the driven cavity problem with $\mathrm{Re}=400$, and so is $\alpha \in (0,1)$ with $\alpha+7\beta \neq 1$.

These results are in perfect agreement with the theory developed in section 2.

5. Conclusions.

- In this paper we introduce a new stability notion for constructing lattice Boltzmann equations. With the stability requirement, new relations of parameters have been derived for several well-known parametrized models.
- Computational results are presented to verify the stability theory for a few examples commonly used in the literature. They show that the stability requirement gives some reliable choices of parameters.

A REORDERING FOR THE PAGERANK PROBLEM*

AMY N. LANGVILLE† AND CARL D. MEYER‡

Abstract. We describe a reordering particularly suited to the PageRank problem, which reduces the computation of the PageRank vector to that of solving a much smaller system and then using forward substitution to get the full solution vector. We compare the theoretical rates of convergence of the original PageRank algorithm to that of the new reordered PageRank algorithm, showing that the new algorithm can do no worse than the original algorithm. We present results of an experimental comparison on five datasets, which demonstrate that the reordered PageRank algorithm can provide a speedup of as much as a factor of 6. We also note potential additional benefits that result from the proposed reordering.

Key words. Markov chains, PageRank, reorderings, power method, convergence, stationary vector, dangling nodes

1. Introduction. It is well known that many subsets of the web contain a large proportion of dangling nodes, i.e., webpages with no outlinks. Dangling nodes can result from many sources: a page containing an image or a PostScript or pdf file; a page of data tables; or a page whose links have yet to be crawled by the search engine's spider. These dangling nodes can present philosophical, storage, and computational issues for a search engine such as Google that employs a ranking system for ordering retrieved webpages.

Let us introduce some notation. The hyperlink structure of the web defines a directed graph, which can be expressed as a sparse matrix. The founders of Google, Brin and Page, defined the elements of a hyperlink matrix $\mathbf{H}$ as $h_{ij} = 1/|O_i|$ if there exists a hyperlink from page i to page j, and 0 otherwise. The scalar $|O_i|$ is the number of outlinks from page i. Thus, the nonzero rows of $\mathbf{H}$ sum to 1. The matrix $\mathbf{H}$ contains a $\mathbf{0}^T$ row for each dangling node. Brin and Page define the PageRank vector, a vector holding the global measure of importance for each page, to be the stationary vector for a Markov chain related to $\mathbf{H}$ [3, 4]. This definition is intuitive, as the stationary vector gives the long-run proportion of time the chain will spend in each state. For Brin and Page's application, the stationary elements represent the long-run proportion of time a random web surfer will spend on a page in the web, and thus provide a measure of a page's importance or popularity. One problem with the hyperlink matrix $\mathbf{H}$ created strictly from the web's structure is that it is not stochastic, and a Markov chain is defined only for stochastic matrices. To remedy this and create the stochastic matrix called $\mathbf{S}$, Brin and Page suggest replacing each $\mathbf{0}^T$ row (corresponding to a dangling node) of the sparse hyperlink matrix with a dense vector. The original fix for the dangling node problem used a uniform vector $\mathbf{e}^T/n$ ($\mathbf{e}$ is the vector of all ones), which was later replaced by the more general probability vector

$\mathbf{v}^T$, known as the personalization or teleportation vector. Of course, if this suggestion were to be implemented explicitly, storage requirements would increase dramatically. Instead, the stochasticity fix can be modeled implicitly with the construction of one vector denoted $\mathbf{a}$. Element $a_i = 1$ if row i of $\mathbf{H}$ corresponds to a dangling node, and 0 otherwise. Then $\mathbf{S}$ can be written as a rank-one update of $\mathbf{H}$; $\mathbf{S} = \mathbf{H} + \mathbf{a}\mathbf{v}^T$.

Before the existence of the stationary PageRank vector could be guaranteed, Brin and Page had to make one final adjustment to the hyperlink matrix. Because the web is reducible, their original PageRank algorithm would often get caught in a rank sink, causing convergence problems. To remedy this, and thereby guarantee the existence and uniqueness of the PageRank vector, Brin and Page added another rank-one update, this time an irreducibility adjustment in the form of a dense perturbation matrix $\mathbf{e}\mathbf{v}^T$ that creates direct connections between each page. The stochastic, irreducible matrix called the Google matrix $\mathbf{G}$ is given by

$$\begin{aligned}\mathbf{G} &= \alpha\,\mathbf{S} + (1-\alpha)\,\mathbf{e}\mathbf{v}^T \\ &= \alpha\,\mathbf{H} + \alpha\,\mathbf{a}\mathbf{v}^T + (1-\alpha)\,\mathbf{e}\mathbf{v}^T \\ &= \alpha\,\mathbf{H} + (\alpha\,\mathbf{a} + (1-\alpha)\,\mathbf{e})\mathbf{v}^T,\end{aligned}$$

where $0 < \alpha < 1$. Brin and Page, and consequently Google, then use the power method to compute the unique stationary vector of this enormous Markov chain, thereby producing their famous PageRank vector.

We now turn to the philosophical issue of the presence of dangling nodes. In one of their early papers [2], Brin et al. report that they "often remove dangling nodes during the computation of PageRank, then add them back in after the PageRanks have converged." From this vague statement it is hard to say exactly how Brin and Page compute PageRank for the dangling nodes. However, the removal of dangling nodes at any time during the power method does not make intuitive sense. Some dangling nodes should receive high PageRank. For example, a very authoritative pdf file could have many inlinks from respected sources and thus should receive a high PageRank. Simply removing the dangling nodes biases the PageRank vector unjustly. (See [5] and [13] for additional arguments against removal of dangling nodes.) Further, incorporating dangling nodes into the PageRank power method is very simple and inexpensive. The power method treats PageRank as an eigenvector problem and follows the iterative formula

$$\begin{aligned}\mathbf{x}^{(k)T} &= \mathbf{x}^{(k-1)T}\mathbf{G} \\ &= \alpha\mathbf{x}^{(k-1)T}\mathbf{S} + (1-\alpha)\mathbf{x}^{(k-1)T}\mathbf{e}\mathbf{v}^T \\ &= \alpha\mathbf{x}^{(k-1)T}\mathbf{S} + (1-\alpha)\mathbf{v}^T \\ &= \alpha\mathbf{x}^{(k-1)T}\mathbf{H} + \alpha\mathbf{x}^{(k-1)T}\mathbf{a}\mathbf{v}^T + (1-\alpha)\mathbf{v}^T, \qquad (1)\end{aligned}$$

since $x^{(k-1)T}$ is a probability vector, and thus, $\mathbf{x}^{(k-1)T}\mathbf{e} = 1$. This shows that the power method applied to $\mathbf{G}$ can be implemented with vector-matrix multiplications on the extremely sparse $\mathbf{H}$, and $\mathbf{G}$ and $\mathbf{S}$ are never formed or stored. Since the vector-matrix multiplications involve enormous entities, an important question to ask is how many iterations can we expect until the power method converges to the PageRank vector. It has been proven that the asymptotic rate of convergence of the power method applied to the Google matrix (after the stochasticity and irreducibility adjustments) is the rate at which $\alpha^k \to 0$. Since Google uses $\alpha = .85$, one can expect roughly 114 power iterations to give a convergence tolerance (as measured by the norm

of the difference of successive iterates) of less than 10^{-8}. Further, this means that on the order of $O(114 \cdot nnz(\mathbf{H}))$ operations must be performed to compute the PageRank vector with that prescribed tolerance, where $nnz(\mathbf{H})$ is the number of nonzeros in $\mathbf{H}$. Since $\mathbf{H}$ is so sparse, this is not a prohibitive cost, but it does nevertheless take days of computation when n, the number of pages in the index, is billions.

At this point, we have arrived at the computational issue associated with the dangling nodes. Since the dangling nodes form identical rows in the $\mathbf{H}$ matrix, they can be conveniently lumped into one class and the theory of lumpable and aggregated Markov chains can be used to compute the PageRank vector quickly. Lee, Golub, and Zenios were the first to notice and exploit the structure provided by the dangling nodes [13]. Their iterative power method implementation on aggregated Markov chains led to drastic improvements in the computation of PageRank. On some sample datasets dangling nodes make up over 80% of the webpages, meaning the Lee–Golub–Zenios algorithm can compute PageRank with a factor of 5 speedup, since the aggregated chain is roughly 1/5 the size of the full chain.

In this paper, we present an analogous formulation of the Lee–Golub–Zenios algorithm (section 2). Our formulation uses a linear system formulation rather than a Markov chain formulation. Then we extend the idea of exploiting the dangling nodes to reduce computation, thereby producing a convenient reordering of the Google matrix, which has several advantageous properties (section 3). In section 4, we present the results of our reordering algorithm on several sample datasets.

2. A linear system formulation for exploiting dangling nodes. Although the size of the Google problem makes the power method with its eigenvector formulation ($\boldsymbol{\pi}^T = \boldsymbol{\pi}^T\mathbf{G}$ and $\boldsymbol{\pi}^T\mathbf{e} = 1$) one of the few practical solution methods for obtaining the PageRank vector $\boldsymbol{\pi}^T$, there are other formulations of the problem that are theoretically possible. The following theorem shows that a related linear system exists.

THEOREM 2.1 (linear system for Google problem). *Solving the linear system*

$$\mathbf{x}^T(\mathbf{I} - \alpha\mathbf{H}) = \mathbf{v}^T \tag{2}$$

and letting $\boldsymbol{\pi}^T = \mathbf{x}^T/\mathbf{x}^T\mathbf{e}$ *produces the PageRank vector.*

Proof. $\boldsymbol{\pi}^T$ is the PageRank vector if it satisfies $\boldsymbol{\pi}^T\mathbf{G} = \boldsymbol{\pi}^T$ and $\boldsymbol{\pi}^T\mathbf{e} = 1$. Clearly, $\boldsymbol{\pi}^T\mathbf{e} = 1$. Showing $\boldsymbol{\pi}^T\mathbf{G} = \boldsymbol{\pi}^T$ is equivalent to showing $\boldsymbol{\pi}^T(\mathbf{I} - \mathbf{G}) = \mathbf{0}^T$, which is equivalent to showing $\mathbf{x}^T(\mathbf{I} - \mathbf{G}) = \mathbf{0}^T$:

$$\begin{aligned}\mathbf{x}^T(\mathbf{I} - \mathbf{G}) &= \mathbf{x}^T(\mathbf{I} - \alpha\mathbf{H} - \alpha\mathbf{a}\mathbf{v}^T - (1-\alpha)\mathbf{e}\mathbf{v}^T)\\ &= \mathbf{x}^T(\mathbf{I} - \alpha\mathbf{H}) - \mathbf{x}^T(\alpha\mathbf{a} + (1-\alpha)\mathbf{e})\mathbf{v}^T\\ &= \mathbf{v}^T - \mathbf{v}^T = \mathbf{0}^T.\end{aligned}$$

The above line results from the fact that $\mathbf{x}^T(\alpha\mathbf{a} + (1-\alpha)\mathbf{e})\mathbf{v}^T = 1$ because

$$\begin{aligned}1 &= \mathbf{v}^T\mathbf{e}\\ &= \mathbf{x}^T(\mathbf{I} - \alpha\mathbf{H})\mathbf{e}\\ &= \mathbf{x}^T\mathbf{e} - \alpha\mathbf{x}^T\mathbf{H}\mathbf{e}\\ &= \mathbf{x}^T\mathbf{e} - \alpha\mathbf{x}^T(\mathbf{e} - \mathbf{a})\\ &= (1-\alpha)\mathbf{x}^T\mathbf{e} + \alpha\mathbf{x}^T\mathbf{a}. \qquad \square\end{aligned}$$

Thus, PageRank is both the stationary distribution of a Markov chain and the solution of a linear system. While these two views are inherently linked, they suggest

different methods for finding the PageRank vector. Future advances in computation will likely require a thorough understanding and use of both views.

As a result, we examine the linear system view, which has received much less attention. The coefficient matrix $(\mathbf{I}-\alpha\mathbf{H})$ of the linear system has many nice properties, which were proven in [12]. Some that are relevant for this paper are as follows:

- $(\mathbf{I}-\alpha\mathbf{H})$ is nonsingular.
- The row sums of $(\mathbf{I}-\alpha\mathbf{H})^{-1}$ are equal to 1 for the dangling nodes and less than or equal to $1/(1-\alpha)$ for the nondangling nodes.
- The row of $(\mathbf{I}-\alpha\mathbf{H})^{-1}$ corresponding to dangling node i is $\mathbf{e}_i^T$, where $\mathbf{e}_i$ is the ith column of the identity matrix.

The last property makes the computation of the PageRank vector especially efficient. Suppose the rows and columns of $\mathbf{H}$ are permuted (i.e., the indices are reordered) so that the rows corresponding to dangling nodes are at the bottom of the matrix:

$$\mathbf{H} = \begin{matrix} \\ ND \\ D \end{matrix} \begin{matrix} \begin{matrix} ND & \quad D \end{matrix} \\ \begin{pmatrix} \mathbf{H}_{11} & \mathbf{H}_{12} \\ \mathbf{0} & \mathbf{0} \end{pmatrix} \end{matrix}, \tag{3}$$

where ND is the set of nondangling nodes and D is the set of dangling nodes. Then the coefficient matrix in the sparse linear system formulation becomes

$$(\mathbf{I}-\alpha\mathbf{H}) = \begin{pmatrix} \mathbf{I}-\alpha\mathbf{H}_{11} & -\alpha\mathbf{H}_{12} \\ \mathbf{0} & \mathbf{I} \end{pmatrix},$$

and the inverse of this matrix is

$$(\mathbf{I}-\alpha\mathbf{H})^{-1} = \begin{pmatrix} (\mathbf{I}-\alpha\mathbf{H}_{11})^{-1} & \alpha(\mathbf{I}-\alpha\mathbf{H}_{11})^{-1}\mathbf{H}_{12} \\ \mathbf{0} & \mathbf{I} \end{pmatrix}.$$

Therefore, the unnormalized PageRank vector $\mathbf{x}^T = \mathbf{v}^T(\mathbf{I}-\alpha\mathbf{H})^{-1}$ can be written as

$$\mathbf{x}^T = \begin{pmatrix} \mathbf{v}_1^T(\mathbf{I}-\alpha\mathbf{H}_{11})^{-1} & | & \alpha\mathbf{v}_1^T(\mathbf{I}-\alpha\mathbf{H}_{11})^{-1}\mathbf{H}_{12} + \mathbf{v}_2^T \end{pmatrix},$$

where the personalization vector $\mathbf{v}^T$ has been partitioned into nondangling ($\mathbf{v}_1^T$) and dangling ($\mathbf{v}_2^T$) sections. In summary, we now have an algorithm that computes the PageRank vector using only the nondangling portion of the web, exploiting the rank-one structure of the dangling node fix.

ALGORITHM 1.

1. Reorder the states of the Markov chain so that the reordered matrix has the structure of (3).
2. Solve for $\mathbf{x}_1^T$ in $\boldsymbol{\pi}_1^T(\mathbf{I}-\alpha\mathbf{H}_{11}) = \mathbf{v}_1^T$.
3. Compute $\mathbf{x}_2^T = \alpha\boldsymbol{\pi}_1^T\mathbf{H}_{12} + \mathbf{v}_2^T$.
4. Normalize $\boldsymbol{\pi}^T = [\mathbf{x}_1^T \;\; \mathbf{x}_2^T]/\|[\mathbf{x}_1^T \;\; \mathbf{x}_2^T]\|_1$.

This algorithm is much simpler and cleaner than, but equivalent to, the specialized iterative method proposed by Lee, Golub, and Zenios [13], which exploits the dangling nodes to reduce computation of the PageRank vector, sometimes by a factor of 5.

3. A PageRank algorithm based on a reordering of the Google matrix.

3.1. The reordered PageRank algorithm. The linear system formulation of section 2 leads to a deeper examination of the structure of the Google matrix $\mathbf{H}$. Since the presence of zero rows in the matrix is so advantageous, we hope to find more zero rows in the submatrix $\mathbf{H}_{11}$, which is needed to solve the system in step 1 of Algorithm 1. This process of locating zero rows can be repeated recursively on smaller and smaller submatrices of $\mathbf{H}$, continuing until a submatrix is created that has no zero rows. The result of this process is a decomposition of the $\mathbf{H}$ matrix that looks like Figure 1. This process amounts to a simple reordering of the indices of the Markov chain. The top part shows the original $\mathbf{H}$ matrix, and the bottom part is the reordered matrix according to the recursive dangling node idea. The dataset `CA.dat` (available from http://www.cs.cornell.edu/Courses/cs685/2002fa/) is a typical subset of the web. It contains 9,664 nodes and 16,773 links pertaining to the query topic of "california."

In general, after this symmetric reordering, the hyperlink matrix $\mathbf{H}$ has the following structure:

$$\mathbf{H} = \begin{pmatrix} \mathbf{H}_{11} & \mathbf{H}_{12} & \mathbf{H}_{13} & \cdots & \mathbf{H}_{1b} \\ & \mathbf{0} & \mathbf{H}_{23} & \cdots & \mathbf{H}_{2b} \\ & & \mathbf{0} & \cdots & \mathbf{H}_{3b} \\ & & & \ddots & \\ & & & & \mathbf{0} \end{pmatrix}, \tag{4}$$

where $b \geq 2$ is the number of square diagonal blocks in the reordered matrix. Therefore, the coefficient matrix of the linear system formulation of the PageRank problem (2) has the following structure:

$$(\mathbf{I} - \alpha\mathbf{H}) = \begin{pmatrix} \mathbf{I} - \alpha\mathbf{H}_{11} & -\alpha\mathbf{H}_{12} & -\alpha\mathbf{H}_{13} & \cdots & -\alpha\mathbf{H}_{1b} \\ & \mathbf{I} & -\alpha\mathbf{H}_{23} & \cdots & -\alpha\mathbf{H}_{2b} \\ & & \mathbf{I} & \cdots & -\alpha\mathbf{H}_{3b} \\ & & & \ddots & \\ & & & & \mathbf{I} \end{pmatrix}. \tag{5}$$

As a result, the PageRank system in (2) after reordering can be solved by forward substitution. The only system that must be solved directly is the first subsystem, $\mathbf{x}_1^T(\mathbf{I} - \alpha\mathbf{H}_{11}) = \mathbf{v}_1^T$, where $\mathbf{x}^T$ and $\mathbf{v}^T$ have also been partitioned according to the number and size of the blocks. The remaining subvectors of $\mathbf{x}^T$ are computed quickly and efficiently by forward substitution. In the `CA.dat` example, a $2{,}622 \times 2{,}622$ system can be solved instead of the full $9{,}664 \times 9{,}664$ system, or even the once-reduced $5{,}132 \times 5{,}132$ system of Algorithm 1. The reordered PageRank algorithm is an extension of the dangling node method of section 2. This reordered PageRank idea can also be written in a Markov chain formulation, thereby extending the ideas in [13]. The steps of the reordered PageRank (in its linear system formulation) are enumerated in Algorithm 2.

ALGORITHM 2.

1. Reorder the states of the Markov chain so that the reordered matrix has the structure of (4).
2. Solve for $\mathbf{x}_1^T$ in $\mathbf{x}_1^T(\mathbf{I} - \alpha\mathbf{H}_{11}) = \mathbf{v}_1^T$.
3. For $i = 2$ to b, compute $\mathbf{x}_i^T = \alpha \sum_{j=1}^{i-1} \mathbf{x}_j^T \mathbf{H}_{ji} + \mathbf{v}_i^T$.
4. Normalize $\boldsymbol{\pi}^T = [\mathbf{x}_1^T \ \mathbf{x}_2^T \ \cdots \ \mathbf{x}_b^T]/\|[\mathbf{x}_1^T \ \mathbf{x}_2^T \ \cdots \ \mathbf{x}_b^T]\|_1$.

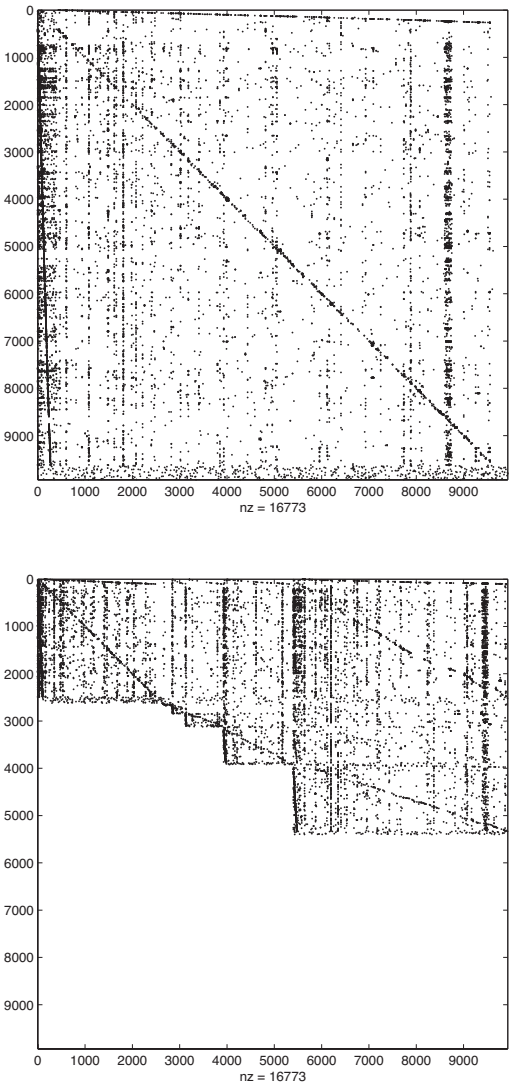

FIG. 1. *Original* **H** *(top) and reordered* **H** *matrix (bottom) for* `CA.dat`.

3.2. Analysis of the reordered PageRank algorithm. We discuss each step of Algorithm 2. The reordering, step 1 of Algorithm 2, can be accomplished with a simple recursive scheme that successively locates zero rows of submatrices within **H**, and thus amounts to the work of a few power iterations on the full matrix. However, the memory manipulation required to successively reorder the submatrices can make this step time consuming and potentially of less value than Algorithm 1 (see the experiments of section 4). The forward substitution step of Algorithm 2, step 3, amounts to slightly less than the work of one power iteration. Of course, step 4 is trivial. Thus, the small system solve of step 2 is the most time-consuming step. Table 1 in section 4 gives an enlightening numerical comparison of the amount of work spent on each step.

Some hyperlink matrices $\mathbf{H}$ can be particularly suited to the reordered PageRank algorithm. In this case, large sets of zero rows are consecutively extracted, and the remaining $\mathbf{H}_{11}$ block is very small. In the worst case, $b = 2$ and $nnz(\mathbf{H}_{11})/nnz(\mathbf{H})$ is close to 1. Regardless, the smaller system $\mathbf{x}_1^T(\mathbf{I} - \alpha\mathbf{H}_{11}) = \mathbf{v}_1^T$ can be solved by any appropriate direct or iterative method. However, we have found that the sparsity of the $\mathbf{H}_{11}$ matrix makes a simple iterative method very attractive. The Jacobi method [14] is especially simple due to the properties of the $\mathbf{H}_{11}$ matrix. The diagonal elements of $\mathbf{H}_{11}$ are 0, since by convention no webpage links to itself. This means that the diagonal matrix $\mathbf{D}$ involved in the splitting of the coefficient matrix $(\mathbf{I} - \alpha\mathbf{H}_{11})$ is the identity matrix $\mathbf{I}$. Therefore, the Jacobi iterates are

$$\mathbf{x}^{(k)T} = \alpha\mathbf{x}^{(k-1)T}\mathbf{H}_{11} + \mathbf{v}_1^T. \tag{6}$$

This stationary iterative process converges to a unique solution for all starting iterates because $\rho(\alpha\mathbf{H}_{11}) \leq 1$. ($\mathbf{H}_{11}$ is substochastic.) The asymptotic rate of convergence of the iterative reordered PageRank process is the same as or better than the asymptotic rate of convergence of the standard PageRank power method. In fact, the reordered PageRank method will require about $O(\frac{\log(\tau)}{\log(\alpha)} \cdot nnz(\mathbf{H}_{11}))$ operations to reach a convergence tolerance of τ. In summary, Algorithm 2, the reordered PageRank method, requires roughly $\frac{nnz(\mathbf{H}_{11})}{nnz(\mathbf{H})}\%$ of the time that the original PageRank method requires. The Jacobi iterates of (6), like the power iterates of the original PageRank algorithm, also allow for easy parallelization, which is essential due to the scale of the matrices involved in practical applications. Further, acceleration methods [1, 6, 8, 9, 10], such as extrapolation and preconditioners, can be applied to the small $\mathbf{H}_{11}$ system to achieve even greater speedups.

4. Experiments with the reordering method. We compare the reordered PageRank algorithm to the original PageRank algorithm, experimenting with four datasets. The first two datasets are small, containing fewer than 10,000 pages. The remaining two datasets are much larger, with one containing over 325,000 pages and the other over 450,000 pages. Each dataset is a different type of subset of the web. The `CA.dat` dataset contains 9,664 pages pertaining to the query topic of "california." `NCSU.dat` is a crawl that started at the North Carolina State homepage and stopped once 10,000 pages were reached. Most of the pages are internal to the NCSU domain, but some are external. The dataset `ND.dat` contains 325,729 pages within the Notre Dame domain. Finally, `SU450k.dat` contains 451,237 pages from a 2001 crawl of the Stanford domain by the Stanford WebBase project.

The experiments in this section were conducted on a 867 MHz Mac G4 with 1.5 GB of RAM. We used $\alpha = .9$ as the scaling factor and $\tau = 10^{-10}$ as the convergence tolerance. The original PageRank algorithm and both reordered PageRank algorithms (Algorithms 1 and 2) were run on each dataset. The results are summarized in Table 1.

The reordered PageRank algorithm beats the original PageRank algorithm by a factor of almost 6 on some datasets. The speedup depends on the ratio $\frac{nnz(\mathbf{H})}{nnz(\mathbf{H}_{11})}$, which depends on the properties of a particular dataset and the number of zero rows that can be successively squeezed out of the submatrices. The reordered PageRank algorithm is guaranteed to outperform the original PageRank method as long as some dangling nodes are present, i.e., $b \geq 2$.

Unfortunately, Table 1 clearly shows that Algorithm 2 is not necessarily an improvement over Algorithm 1 because the cost of memory management required by the reordering step often offsets the decrease in the size of the system solve. Nevertheless,

TABLE 1
Comparison of original PageRank and reordered PageRank algorithms.

compared to the original PageRank algorithm, both algorithms do drastically improve the time required to compute the PageRank vector.

5. Future work. The relationship between the spectrum of $\mathbf{G}$ and that of $\mathbf{S}$ is known [7, 12]. However, their relationship to the spectrum of $\mathbf{H}$ is not known. Recall that $\mathbf{S}$ and $\mathbf{G}$ are web matrices that have been artificially enhanced to generate advantageous mathematical properties in the matrices. The true web matrix is $\mathbf{H}$, yet little is known about how far $\mathbf{S}$ and $\mathbf{G}$ and their corresponding ranking vectors stray from the web's true nature. The reordering presented here may illuminate this unknown relationship. The symmetric reordering shows that the eigenvalues of $\mathbf{H}$ are the eigenvalues of $\mathbf{H}_{11}$ plus many 0 eigenvalues for the $\mathbf{0}$ diagonal blocks. The size of $\mathbf{H}_{11}$ may be small enough that its subdominant eigenvalues and eigenvectors can be computed. These subdominant eigenvectors can provide beneficial information about the community structure of a subset of the web [11]. Further, since $\mathbf{S}$ is created from a rank-one update to $\mathbf{H}$, perturbation theory for eigenvalues and eigenvectors can provide additional information about the PageRank vector with respect to its original hyperlink structure ($\mathbf{H}$, not $\mathbf{S}$ or $\mathbf{G}$).

6. Conclusions. Reorderings for linear systems have been well studied. Some popular reorderings, such as the minimum degree reordering, the reverse Cuthill–McKee reordering, and the Dulmage–Mendelson reordering, do not give the nice structure of (5), which requires only one small system solve plus a quick forward substitution that amounts to the work of one power iteration. This reordering naturally produces an efficient alternative to the original PageRank algorithm, which we have called the reordered PageRank algorithm. The reordered algorithm has an asymptotic rate of convergence that is as good as or better than the asymptotic rate of convergence of the original method. The reordered algorithm produces a dataset-dependent speedup over the original algorithm. We presented experimental results

comparing the reordered PageRank algorithm to the original PageRank algorithm on five datasets, showing a factor of nearly 6 speedup on one dataset. This reordering and its linear system formulation also open the door for new PageRank acceleration techniques beyond the usual power method acceleration techniques.

Acknowledgments. The paper [13] by Chris Lee of Stanford University and discussions with Michele Benzi of Emory University sparked the reordering idea presented in this paper. We thank Cleve Moler (Mathworks), Ronny Lempel (IBM Research Labs), and Jon Kleinberg (Cornell) for providing us with several small datasets that we used for testing. Our large dataset from the Stanford web crawl was provided by Chris Lee.

NUMERICAL STOCHASTIC INTEGRATION FOR QUASI-SYMPLECTIC FLOWS*

R. MANNELLA†

Abstract. Algorithms for the numerical integration of Langevin equations obeying detailed balance are introduced. The algorithms are derived fulfilling the requirements that they should become symplectic in the deterministic frictionless limit, and should reproduce the equilibrium distributions to some higher order in the integration time step when the equilibrium distribution exists. Extensions to the case when the system volume or pressure are kept constant are discussed. Comparisons with other integration schemes are carried out both for static and dynamical quantities.

Key words. numerical integration, stochastic differential equations, symplectic integration

AMS subject classifications. 65C30, 65Z05

1. Introduction.

Stochastic processes are well known to be at the heart of many physical systems.[1] Several approaches have therefore been developed to understand the dynamics realized by specific models: among others, one of techniques which is widely used is Monte Carlo integration of the equations of motion.

The literature on the numerical integration of stochastic differential equations (SDEs) is huge; we will limit ourselves to mentioning a couple of classical citations widely used in the physics community [2, 3, 4]. Additional comments and references can be found in [5]. The numerical algorithms presented in these works are very general ones and can be applied to basically any stochastic flow; however, they might not be the optimal ones for cases when additional information about the system under study is available.

An important class for which specialized algorithms can be derived is given by the equations of motion

$$\begin{aligned} \dot{x} &= v, \\ \dot{v} &= -\gamma v + F(x) + \xi(t), \end{aligned} \tag{1.1}$$

where $\xi(t)$ is a random Gaussian noise, with zero average and standard deviation

$$\langle \xi(t)\xi(s) \rangle = 2\gamma T \delta(t-s). \tag{1.2}$$

In the following, we will also use $V(x)$, defined as $F(x) \equiv -V'(x)$. Note that although for simplicity we will first deal with only one Brownian walker, we will then extend the algorithms to the case of many walkers, where x and v are vectors, and $F_i(x)$, the force acting on the ith walker, is a function of all other walkers and/or an external field.

The above equation is commonly found in the liquid state literature (for numerical schemes appropriate in the integration of the Brownian dynamics of a liquid, see among others [6, 7, 8, 9, 10, 11, 12, 13]), and some algorithms have been proposed,

[1] For a classical introduction, see [1].

over the years, for its numerical integration. Note also that the dynamics implicit in (1.1) is of a system in thermal equilibrium with a thermostat at a temperature T. In the case of many walkers in contact with a thermostat, other approaches have been developed which attempt to reproduce the correct equilibrium properties without using stochastic terms (the reason being the possibility of using algorithms for ordinary differential equations; see below). We will show that the algorithms derived here are a viable alternative to these methods.

To date, perhaps the most widely used algorithms for the integration of (1.1) are the ones derived in [6], where a couple of algorithms have been proposed (see also references therein). We will benchmark against one of them, and to this end we will briefly review it below. Note that the system of (1.1) becomes symplectic when $\gamma \to 0$ and, until some recent works [14, 15, 16], the symplectic nature was not really exploited in deriving numerical schemes. Algorithms which also use low order symplectic schemes as base schemes are the ones in [11, 12, 13]. Among them, the best known is the so-called Brunger, Brooks, and Karplus (BBK) scheme, which we will review in the next section and which will also be used as a benchmark.

In [17] we reported already on quasi-symplectic integrators, focusing on one Brownian walker and studying the behavior of the various schemes for large and small dampings γ. Here, we will limit ourselves to the small damping regime, extending, first, the comparison to include schemes not considered in [17]. We will then turn to the case of many interacting walkers, develop higher order symplectic schemes, and finally apply the algorithms to the integration of the equations of motion of many interacting Brownian walkers in contact with a thermostat and for fixed volume or fixed pressure. There is going to be, hence, some overlap between the first two sections and the material in [17], repeated here to make this paper clearer and as self-contained as possible.

The approach we will follow is to derive numerical algorithms having in mind two requirements: (i) the algorithm should become symplectic in the deterministic, frictionless limit ($T = \gamma = 0$); and (ii) the numerical algorithm should reproduce as closely as possible the equilibrium distribution, when this is defined (i.e., for $V(x)$ bounded from below; see next section), of the system given by (1.1). The requirement $T = 0$ seems redundant once $\gamma = 0$ is imposed. It is, however, possible to have symplectic stochastic dynamics, see for instance [14, 15, 18], i.e., with $\gamma = 0$. Looking at the structure of (1.1) and at the condition of detailed balance (1.2), this would imply an infinite T, and we need to explicitly exclude this situation. As we will see below, to the best of our knowledge either the former or the latter requirements have been enforced in the derivation of numerical schemes, but never both of them, before [17].

2. Some definitions and a brief review of the benchmark algorithms. To assess how well each algorithm is performing, we start from the knowledge that for $V(x)$ which are bounded from below, (1.1) leads to an equilibrium distribution $P(x, v)$ for the variables x and v of the form

$$P(x, v) = N \exp\left\{-\left(v^2/2 + V(x)\right)/T\right\}, \tag{2.1}$$

where N is a normalization constant. Other approaches can be used, but here we are going to compare the exact theoretical equilibrium distribution to the equilibrium distribution obtained from the simulations. It is possible, in principle, to check theoretically what is the equilibrium distribution which is expected when integrating using a given numerical scheme, following [19]. Suppose we have a numerical scheme

of the form

$$x_i(t+h) = x_i(t) + hW_i(x_i, \xi).$$

Then the probability distribution of x_i satisfies the Kramers–Moyal expansion

$$P(x_i, t+h) - P(x_i, t) = \sum_{n=1}^{\infty} \sum_{x_i} \frac{\partial}{\partial x_i}, \ldots, \frac{\partial}{\partial x_n} K_{1,\ldots,n} P(x_i, t) \tag{2.2}$$

with

$$K_{1,\ldots,n} \equiv (-1)^n \frac{1}{n!} \langle W_{x_1} \ldots W_{x_n} \rangle_\xi,$$

where $\langle \ldots \rangle_\xi$ means averaging over the noise realizations and the $K_{1,\ldots,n}$ depend explicitly on the integration time step h and its powers. Equation (2.2) is obtained [19] from the evolution equation for $P(x,t)$,

$$P(x_i, t+h) = \left\langle \int dx_i(t) P(x_i, t) \times \Pi_i \delta(x_i(t+h) - x_i(t) - hW_i(x_i, \xi)) \right\rangle_\xi,$$

by Taylor expanding the δ function in powers of W.

A system in detailed balance at temperature T, like the one given by (1.1), has some theoretical equilibrium distribution (for $V(x)$ bounded from below). A numerical scheme, however, will in general generate an equilibrium distribution which differs from the theoretical one. Following [19], we expect that

$$P(x_i, t=\infty)_{sim} = P(x_i, \infty)_{true} \times \exp\left(\sum_{n=1}^{\infty} h^n S_n / T \right),$$

where P_{sim} is the equilibrium distribution generated in the simulations, and P_{true} is the theoretical equilibrium distribution. Given the explicit form of the numerical scheme, the various $K_{1,\ldots,n}$ can be computed: applying (2.2) with P_{sim} on the right-hand side (R.H.S.) as $P(x_i, t)$ and expanding the R.H.S. of (2.2) in the small parameter h, assuming (equilibrium) that $P(x_i, t+h) - P(x_i, t) = 0$, we can derive the equations satisfied by the S_i annihilating the coefficients in a h power series. Note that the lowest order in h is the "standard" Fokker–Planck equation for the system under study. The first nonzero S_i yields the correction to the true equilibrium distribution generated by the numerical scheme.

The algebra to derive the correction to the equilibrium distribution induced by the numerical scheme in the general case and for a given high order integration scheme can be formidable. Therefore, we are going to show how to use (2.2) taking as an example a simple case, the Euler integration scheme. The Euler scheme integrates (1.1) using the prescription

$$\begin{aligned} x(t+h) &= x(t) + hv(t), \\ v(t+h) &= v(t) + hF(x(t)) - h\gamma v(t) + \eta, \end{aligned} \tag{2.3}$$

where η is a random Gaussian variable with zero average and moment

$$\langle \eta^2 \rangle = 2\gamma T h.$$

We compute first some of the lowest K's, up to $\langle W^4 \rangle$, i.e., up to terms like K_{ijkl}. To give a glimpse of the procedure followed, we have, for instance,

$$K_x = -hv(t),$$

$$K_{vv} = \frac{1}{2}\left[hF(x(t) - h\gamma v(t))^2 + \langle \eta^2 \rangle\right],$$

$$K_{xxv} = -\frac{1}{6}h^3 v^2(t)(F(x(t)) - \gamma v(t)),$$

and so on. Assuming that (see (2.1), with $S \equiv S_1$)

$$P(x,v) = N \exp\left\{-\left[v^2/2 + V(x) + hS(x,v)\right]/T\right\},$$

plugging the scheme of (2.3) into (2.2), and using the computed expressions of K's, we have that $S(x,v)$ satisfies the PDE

$$2\gamma T \frac{\partial^2 S(x,v)}{\partial v^2} - 2v\frac{\partial S(x,v)}{\partial x} - 2\left(F(x) + \gamma v\right)\frac{\partial S(x,v)}{\partial v}$$

$$+ T\gamma^2 - v^2\gamma^2 - F(x)^2 - F'(x)(2T - v^2) - 2v\gamma F(x) = 0.$$

It is clear that $S(x,v) = 0$ is not a solution of this PDE, and this implies that this algorithm fails to reproduce the correct equilibrium distribution at $O(h)$ in the exponent.

Before deriving the quasi-symplectic schemes, let us briefly mention some of the most-used algorithms for the integration of (1.1). In the limit of small γ, in [6] an algorithm is proposed, which reads

$$\begin{aligned} x(t+h) &= x(t) + c_1 h v(t) + c_2 h^2 F(x(t)) + \eta_1, \\ v(t+h) &= c_0 v(t) + (c_1 - c_2)hF(x(t)) + c_2 hF(x(t+h)) + \eta_2, \end{aligned} \tag{2.4}$$

where

$$c_0 = e^{-\gamma h}, \quad c_1 = \frac{1 - c_0}{\gamma h}, \quad c_2 = \frac{1 - c_1}{\gamma h},$$

and η_1 and η_2 are two random Gaussian variables with zero average and moments

$$\langle \eta_1^2 \rangle = \frac{Th}{\gamma}\left(2 - \frac{3 - 4e^{-\gamma h} + e^{-2\gamma h}}{\gamma h}\right),$$

$$\langle \eta_2^2 \rangle = T\left(1 - e^{-2\gamma h}\right),$$

$$\langle \eta_1 \eta_2 \rangle = \frac{T}{\gamma}\left(1 - e^{-\gamma h}\right)^2.$$

Using (2.2) to evaluate the correction to the true equilibrium distribution generated by this algorithm, we find that the contribution S_1 vanishes, and we are left with the term S_2. In other words, this algorithm reproduces the correct equilibrium distribution at $O(h)$, but there are still corrections $O(h^2)$ in the exponent. The algorithm given in (2.4) is one of reference algorithms which we propose to improve in the next section. We will refer to this algorithm as "Li" (from *li*quid) in the following.

A second widely used algorithm is the BBK scheme [11, 12, 13]. The BBK scheme integrates (1.1) as

$$\tilde{v} = v(t) + \frac{h}{2}F(x(t)),$$
$$x(t+h) = x(t) + \frac{[1-\exp(-\gamma h)]}{\gamma}\tilde{v} + \sqrt{2T/\gamma}\eta_2,$$
$$v(t+h) = \exp(-\gamma h)\tilde{v} + \frac{h}{2}F(x(t+h)) + \sqrt{2T\gamma}\eta_1.$$

For the stochastic variables η_1, η_2 one has [11, 12, 13]

$$\eta_1 = \sqrt{\tau_2}w_1,$$

$$\eta_2 = \frac{\tau_1 - \tau_2}{\sqrt{\tau_2}}w_1 + \sqrt{h - \frac{\tau_1^2}{\tau_2}}w_2,$$

where w_1 and w_2 are two uncorrelated Gaussian variables with average zero and standard deviation one, $\tau_1 = (1/\gamma)\left[1 - e^{-\gamma h}\right]$, and $\tau_2 = (1/2\gamma)\left[1 - e^{-2\gamma h}\right]$. The BBK algorithm reproduces the equilibrium distribution at order $o(h^2)$ in the exponent; the correction obeys the equation ($S \equiv S_2$):

$$0 = -\gamma F(x)^2 - (2\gamma T + 3\gamma v^2)F'(x) - v^3F''(x)12\gamma v\frac{\partial S(x,v)}{\partial v}$$
$$- F(x)\left[\gamma^2 v + 3vF'(x) + 12\frac{\partial S(x,v)}{\partial v}\right] + 12\gamma T\frac{\partial^2 S(x,v)}{\partial v^2} - 12v\frac{\partial S(x,v)}{\partial x}.$$

In the following, we will use also the Heun algorithm to carry out the various comparisons. To make this paper as self-contained as possible, we recall here that the Heun algorithm for a system like the one in (1.1) is given by the following prescription:

$$x_1 = x(t) + hv(t),$$
$$v_1 = v(t) - h\gamma v(t) + hF(x(t)) + \sqrt{2\gamma Th}\eta,$$
$$x_2 = x(t) + hv_1,$$
$$v_2 = v(t) - h\gamma v_1 + hF(x_1) + \sqrt{2\gamma Th}\eta,$$
$$x(t+h) = \frac{x_1 + x_2}{2}, \quad v(t+h) = \frac{v_1 + v_2}{2},$$

where η is a Gaussian random variable of zero average and standard deviation 1. The Heun algorithm, which is a fairly widely used algorithm for the integration of generic stochastic equations, does not make use of the (quasi-) symplectic nature of the flow; we expect that it will not fare too well in the limit of small γ. We recall that it is known [5] that the equilibrium distribution generated by the Heun algorithm is accurate up to $o(h^2)$ in the exponent. We will refer to the Heun scheme as "He."

3. Quasi-symplectic algorithms. A symplectic algorithm is a numerical scheme which aims to preserve the 2-forms $dq_i \times dp_i$ during the integration of a Hamiltonian flow. The quantity q_i is a generalized coordinate, and p_i is the corresponding conjugate momentum. A nice introduction to the symplectic integration

can be found in [20, 21]; in particular, we will use one of the results of [20] in what follows. Given the Hamiltonian $H(q_i, p_i)$ and the equations of motion

$$\dot{q}_i = \{q_i, H\}, \qquad \dot{p}_i = \{p_i, H\},$$

a symplectic integrator will conserve some quantity $\hat{H}$, which in general reads

$$\hat{H} = H + h^n G(p_i, q_i),$$

where h is the integration time step, and G is a function which depends on the numerical scheme (read the symplectic scheme) used for the integration. The problem of Hamiltonian flows in the presence of fluctuations has been addressed also in [14, 15], whereas quasi-symplectic schemes were derived in [16] (see also below, where various comparisons are carried out).

Given that we are interested here in the integration of (1.1), the starting point will be the symplectic integration of Hamiltonians which are separable and quadratic in the velocities. There are very many different possible symplectic schemes; however, having in mind that we are seeking a scheme which should be used in the integration of a SDE, we restrict ourselves to considering schemes in the form

$$\begin{aligned} p(i) &= p(i-1) + hb_i F(q(i-1)), \\ q(i) &= q(i-1) + ha_i p(i) \end{aligned} \tag{3.1}$$

for i between 1 and N, where $q(0) = q(t = 0)$, $q(N) = q(t = h)$, etc., and h is the integration time step in the simulations. The coefficients $a(i)$ and $b(i)$ are chosen as to minimize, in some sense, the quantity $G(p, q)$.

The lowest possible symplectic algorithm one can write to integrate (1.1) following this approach reads, when $\gamma = T = 0$ (this scheme is also known as "leap frog"),

$$\begin{aligned} \tilde{x} &= x(t) + \frac{h}{2} v(t), \\ v(t+h) &= v(t) + hF(\tilde{x}), \\ x(t+h) &= \tilde{x} + \frac{h}{2} v(t+h), \end{aligned} \tag{3.2}$$

where x is the position and v is the velocity. This scheme conserves the quantity $H - h^3(vFF' + v^3F''/6)/4$, where $H \equiv v^2/2 + V(x)$. Higher order schemes can be found in the quoted references [20, 21]. Paralleling the procedure of [17] (see also [22]), it is then possible to reintroduce both the dissipation $(-\gamma v)$ and the noise, writing the tentative scheme

$$\begin{aligned} \tilde{x} &= x(t) + \frac{h}{2} v(t), \\ v(t+h) &= c_2 \left[c_1 v(t) + hF(\tilde{x}) + d_1 \eta \right], \\ x(t+h) &= \tilde{x} + \frac{h}{2} v(t+h), \end{aligned} \tag{3.3}$$

where η is a Gaussian variable with standard deviation one and average zero. We use again (2.2), and, imposing that the term $O(h)$ in the exponent (i.e., the term hS_1) vanishes, we find that the unknown arbitrary quantities c_1, c_2, and d_1 read

$$\begin{aligned} c_1 &= 1 - \frac{\gamma h}{2}, \\ c_2 &= \frac{1}{1 + \gamma h/2}, \\ d_1 &= \sqrt{2T\gamma h}. \end{aligned} \tag{3.4}$$

Although we will carry out more extensive comparisons further down, let us briefly compare this scheme to the scheme of (2.4). The present scheme is by construction well behaved in the limit of $\gamma \to 0$; it has the same accuracy in computing the equilibrium distribution as (2.4), but it requires only one random deviate per integration time step (as opposed to two deviates for the scheme of (2.4)), so it will run faster. In the following, we will refer to the algorithm of (3.3) as symplectic low order (SLO).

Looking at the structure of the previous algorithm, we can try to derive an algorithm of higher order. In the derivation of (3.3), when we applied (2.2), given the number of unknown quantities we could only impose that the term $O(h)$ in the exponent disappeared. If we could somehow increase the number of unknown quantities when applying (2.2), while keeping the algorithm simple, we might be able to make the terms $O(h^2)$ in the exponent disappear. We start combining two steps, each one of the form of (3.3), done with an integration time step $h/2$,

$$\begin{aligned} x_1 &= x(t) + \frac{h}{4} v(t), \\ v_1 &= c_2 \left[c_1 v(t) + \frac{h}{2} F(x_1) + \sqrt{\gamma T h} (a_1 \eta_1 + a_2 \eta_2) \right], \\ x_2 &= x_1 + \frac{h}{2} v_1, \\ v(t+h) &= c_2 \left[c_1 v_1 + \frac{h}{2} F(x_2) + \sqrt{\gamma T h} (b_1 \eta_1 + b_2 \eta_2) \right], \\ x(t+h) &= x_2 + \frac{h}{4} v(t+h), \end{aligned} \tag{3.5}$$

where $c_1 = (1 - \gamma h/4)$ and $c_2 = 1/(1 + \gamma h/4)$. Here, η_1 and η_2 are two random Gaussian variables of standard deviation one and average zero. The idea is now to choose the coefficients a's and b's in such a way as to annihilate S_1, and possibly minimize S_2. This is done using (3.5) in (2.2), which results in a number of algebraic equations for a_i and b_i. The algebra, although straightforward, is cumbersome and we will simply report here the results. For a given a_1, the following choice for the other three parameters will ensure that S_1 vanishes identically:

$$b_1 = -\frac{a_1}{7} + \frac{2\sqrt{14 - 12a_1^2}}{7},$$

$$b_2 = -\frac{\sqrt{7 + 282a_1^2 + 24a_1\sqrt{14 - 16a_1^2}}}{\sqrt{42}},$$

$$a_2 = \frac{\sqrt{42} b_2 (-7\sqrt{2} + 6\sqrt{2}a_1^2 + 24a_1\sqrt{7 - 6a_1^2})}{\sqrt{3}(-14 + 588a_1^2)}.$$

As a function of a_1, we can now write the equations satisfied by S_2: we find that S_2 vanishes for a particular choice of the parameter a_1. Summarizing the numerics, the set of a's and b's which simultaneously makes S_1 and S_2 vanish are

$$\begin{aligned} a_1 &= -1.0691860043307065\ldots, \\ a_2 &= -0.1533230407019893\ldots, \\ b_1 &= 0.3044913128854065\ldots, \\ b_2 &= -1.0363164126095790\ldots. \end{aligned} \tag{3.6}$$

Note that there is a symmetry: quantities with indexes 1 and 2 can be exchanged. The conclusion is that the algorithm given by (3.5) and (3.6) is symplectic in the limit $\gamma, T \to 0$ (conserving the quantity $H - h^3(vFF' + v^3F''/6)/16$), whereas for finite γ and T it reproduces the correct equilibrium distribution with an error $O(h^3)$ in the exponent. We will refer to this algorithm as to symplectic high order (SHO).

We want to compare our algorithms to the quasi-symplectic algorithms of [16]. We should mention here that really the latter are weak integration schemes (for a definition of weak and strong integration schemes, see [2]); hence they are bound to give worse results than the other schemes when, as we do, average quantities are considered, and in particular for mean first passage times. The two algorithms used in the numerical simulations of [16] integrate with the prescriptions ([16] should be consulted for more details and for higher order algorithms; here we are using only the ones explicitly considered by the authors of [16]):

MT1:

$$\begin{aligned} x(t+h) &= x(t) + hv(t+h)\,, \\ v(t+h) &= v(t) - hV'(x(t+h)) - h\gamma v(t+h) \\ &\quad + \sqrt{2Th\gamma}\eta\,, \end{aligned} \tag{3.7}$$

where $v(t+h)$ and $x(t+h)$ should be found recursively.

MT2:

$$\begin{aligned} v(t+h) &= (1-\gamma h)(v(t) - hV'(x(t)) + \sqrt{2Th\gamma}\eta), \\ x(t+h) &= x(t) + h(v(t) - hV'(x(t))). \end{aligned} \tag{3.8}$$

The random variables η take the values ± 1. These variables are faster to generate than a Gaussian variable, hence these algorithms will run faster, allowing for a smaller integration time step to compensate for less accuracy when averaged quantities are considered. However, having said this, if we used (2.2) to assess these two algorithms, we would find that they both have a correction to the equilibrium distribution $O(h)$ in the exponent. These will reflect in the numerical experiments, as we will comment below.

Finally, it should be noted that given the structure of the Hamiltonian in the limit $T \to 0$, $\gamma \to 0$, which is $H = v^2/2 + V(x)$, the equilibrium distribution for (1.1) can also be written as

$$P(x, v) \propto \exp -H/T.$$

At first sight, it may appear that the request of a symplectic integration scheme is redundant, once we made sure that the "correct" equilibrium distribution is generated in the numerical integration. This is not right: the limit $T \to 0$ is singular, hence a symplectic form for the numerical scheme when $T = 0$ can (and should) be imposed as an additional condition.

We proceed now to compare the algorithms taking as benchmarks two very simple dynamical systems. We consider first how the different algorithms reproduce the equilibrium properties: we integrate the equations of motion and compute some momenta. For the systems we have in mind, it is possible to derive theoretically the momenta considered in the simulations, for a better comparison. The equilibrium distribution is computed from the integrated trajectories, sampled at time intervals larger than the typical timescales, which corresponds to $1/\gamma$ for the parameter ranges

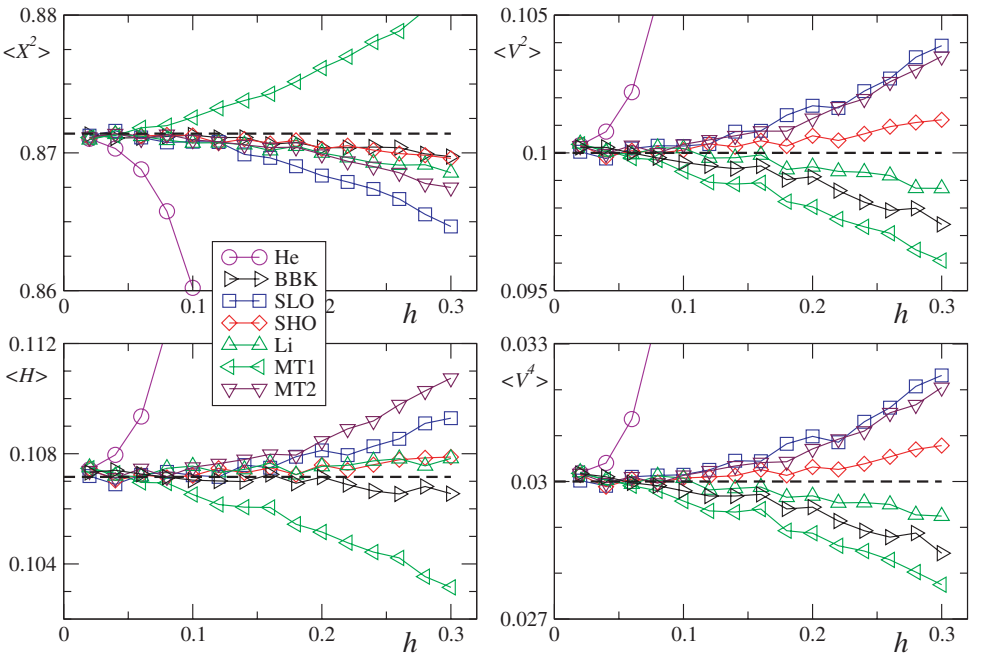

FIG. 3.1. *Result of simulations for different integration schemes, as a function of the integration time step h, for the system in* (3.9). *Various moments are considered (see text for details), taking* $T = 0.1$ *and* $\gamma = 10^{-2}$. *The number of averages is* 4×10^5.

considered. For the random number generation we used the algorithms of [23, 24, 25]. The systems considered will be

$$\dot{x} = v,$$
$$\dot{v} = -\gamma v - V'(x) + \sqrt{2\gamma T}\eta,$$

with the potentials

$$V(x) = x^4/4 - x^2/2 \tag{3.9}$$

and

$$V(x) = x^4/4 + x^2/2. \tag{3.10}$$

The first case is a double well anharmonic oscillator with minima located at $x \pm 1$, and the second one is a single well oscillator, with a minimum located at $x = 0$. In the simulations, $T = 0.1$. The results of the simulations are summarized in Figures 3.1 and 3.2, respectively. In both figures, the results of the digital simulations are shown by symbols with a grey line as a guide for the eye; the bold dashed line is the (expected) theoretical value for the quantity considered. For the number of averages considered, the statistical error is of the order of the symbol size. Also, $\langle H \rangle \equiv \langle v^2/2 + V(x) \rangle$.

Let us comment on the results. It is evident that the Heun method (He in figures) is not very appropriate, given the small dampings considered, and it is outperformed by the SLO scheme (3.3); note that the SLO is somewhat faster than He, given that it requires only one evaluation of the deterministic force for each integration time step.

The algorithms MT1 and MT2 are reasonably accurate; it should be noted that MT2 seems to be more accurate than MT1 for a given integration time step. Considering that MT2 is much faster than MT1, the conclusion seems to be that MT2

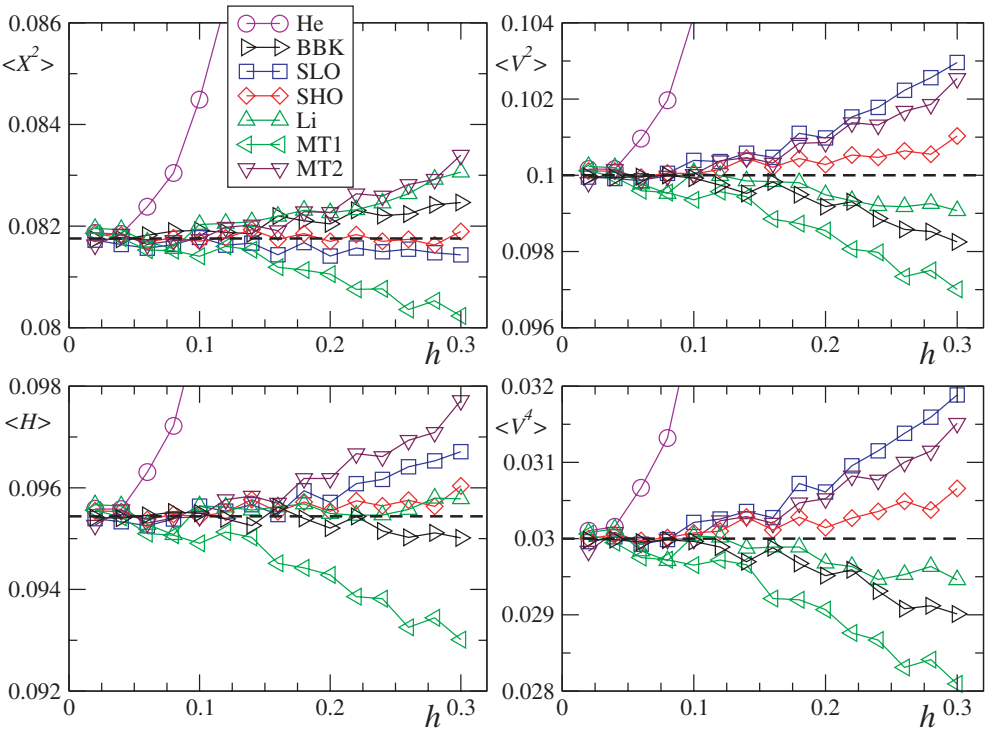

FIG. 3.2. *Result of simulations for different integration schemes, as a function of the integration time step h, for the system in* (3.10). *Various moments are considered (see text for details), taking* $T = 0.1$ *and* $\gamma = 10^{-2}$. *The number of averages is* 4×10^5.

ought to be preferred between these two schemes. Note also that the error on the moments for these two schemes seems to grow linearly with the integration time step h, which is related to the $O(h)$ error in the exponent which was mentioned in the previous section.

The Li and BBK algorithms are less accurate than SHO when the x^2 moments are considered. The SHO is the algorithm which gives the most accurate results for the x^2 moment, with results comparable to or better than those obtained with Li of BBK for the v^2 and v^4 moments. It is only when $\langle H \rangle$ is considered that Li and BBK seem to be more accurate than SHO. However, care is necessary in drawing conclusions from $\langle H \rangle$: looking, for instance, at Figure 3.1, we note that Li and BBK underestimate both v^2 and x^2 (in particular, of these three algorithms, BBK shows a fairly large departure from the correct $\langle v^2 \rangle$). Recalling the structure of the potential $V(x) = -x^2/2 + x^4/4$, it is clear that these two underestimates tend to cancel out, leading to a $\langle H \rangle$ closer to the theoretical one, but only by virtue of a coincidental cancellation.

It is also interesting and important to assess some dynamical quantities: similar calculations, for instance, would be carried out in multistable systems to compute escape rates. In most cases these quantities are not known theoretically, and stochastic simulations are one of the tools to determine them. Using the system of (3.9), we computed the mean first passage times (MFPTs) to go from one of the minima to the other one (the minima are located at $x = \pm 1$). The results of the simulations are summarized in Figure 3.3, after averaging a suitable number of passage times between

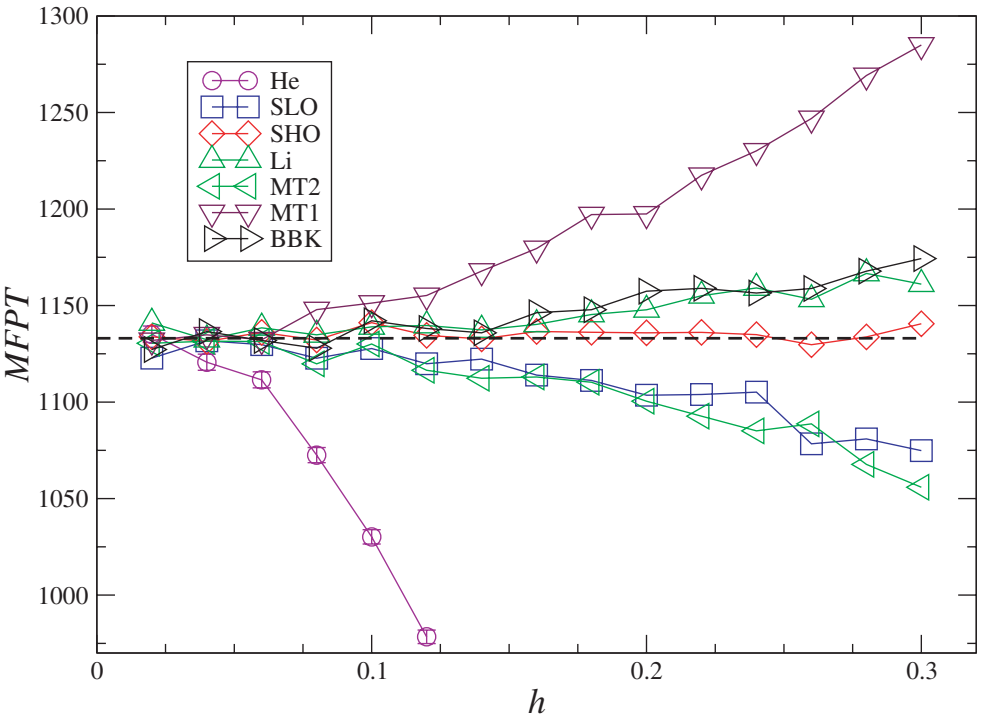

FIG. 3.3. *Result of simulations for different integration schemes, as a function of the integration time step h, for the system in* (3.9). *The MFPT between the minima is considered (see text for details), taking $T = 0.1$ and $\gamma = 10^{-2}$. The number of averages used to compute each point in the figure is in excess of 7×10^3.*

the minima. In the caption we quote a lower bound on the number of averages taken; each point was actually computed using a slightly different number of averages. Given the fairly large value of the noise intensity ($T = 0.1$), there is no theory available to compute an "exact" MFPT for comparison with the simulated MFPTs. To have some reference, we took as reference value the average of the MFPTs obtained via the algorithms Li and SHO for the three smallest h values used in the simulations and drew the dashed line at this value. While showing an error which grows only quadratically in h, clearly He is the algorithm which performs worst. MT1 and MT2 give more reasonable results, and they yield MFPTs comparable to the ones obtained using SLO. SHO outperforms Li and BBK, giving MFPTs closer to the "exact" ones over the whole h range considered. Li and BBK, while close to each other, on the other hand, seem to give results which are roughly equivalent to the ones obtained using MT2 or SLO. For all simulations the statistical error due to the sample finiteness is of the size of the symbols used.

4. Higher order quasi-symplectic schemes Nosé–Hoover dynamics. In real situations, the SDEs one has to integrate are typically multidimensional, with (very) different timescales; there are also typically many Brownian walkers interacting with each other. The quasi-symplectic schemes derived above, in the deterministic frictionless limit, are relatively low order algorithms. As such, they might have problems (read they might require a too small integration time step) when used for the integration of the dynamics of real systems. The solution could be to use symplectic

TABLE 4.1
Coefficients used in our quasi-symplectic fourth order integrator.

schemes which, in the deterministic frictionless limit, are of higher order than the leap frog algorithm considered above and which are the building block of SLO and SHO.

Indeed, it is possible to obtain quasi-symplectic algorithms of arbitrarily high order in the frictionless deterministic limit which reproduce the correct equilibrium distribution to $O(h)$ in the exponent (i.e., at the same order of SLO above). Given a generic deterministic symplectic scheme of order N (see (3.1)), there is a corresponding quasi-symplectic algorithm which reads

$$\begin{aligned} p(i) &= c_{2,i}\left[c_{1,i}p(i-1) + b_i\left(hF(q(i-1)) + \eta\right)\right], \\ q(i) &= q(i-1) + ha_i p(i), \end{aligned} \tag{4.1}$$

$i = 1, N$, where

$$c_{1,i} \equiv 1 - \frac{h}{2}\gamma b_i, \qquad c_{2,i} \equiv \frac{1}{1 + \gamma h b_i/2}$$

and where η is a random Gaussian variable with average zero and standard deviation $2T\gamma h$. It is important to stress that the variable η is the *same* for each of the steps' i's within the integration time step h. Of course, η will be changed once the time h is reached, and so on. The statement that the algorithm of (4.1) has the correct frictionless deterministic properties follows trivially taking the limit $\gamma, T \to 0$ in the scheme; the stochastic properties, i.e., the fact that it reproduces the correct equilibrium distribution at $o(h^2)$ in the exponent, follow by direct substitution in (2.2) and after carrying out the necessary algebra. It should be appreciated that this implies that better quasi-symplectic algorithms could be obtained from the research on symplectic schemes. In the following, besides SLO we will also use a fourth order quasi-symplectic scheme for which we took the coefficients summarized in Table 4.1 (from one of the fourth order symplectic schemes proposed in [20]).

We turn now to possible realistic applications of the algorithms discussed so far. An important class of simulations described by (1.1) where quasi-symplectic schemes could be used is molecular dynamics simulations of many interacting particles, done keeping fixed either temperature and volume or temperature and pressure throughout the simulation. The systems simulated in this way are relevant for studying chemical kinetics.

As we mentioned in the introduction, the evolution given by (1.1) corresponds to the evolution of a system in contact with a thermostat. The evolution of dynamical systems in contact with a thermostat has been extensively studied via the Nosé–Hoover dynamics, rather than via integration of (1.1). This means that if we were interested in the integration of (1.1), we could also proceed replacing the true dynamics with the Nosé–Hoover one, integrating the latter rather than directly (1.1). We refer the interested reader to [26, 27, 28, 29, 30] for a deeper discussion of the Nosé–Hoover approach (see also [6]); here, we will briefly recall how a simulation for constant temperature and volume is typically done using the Nosé–Hoover dynamics.

Starting with the N particles Hamiltonian ($m = 1$)

$$H(\vec{p}, \vec{x}) = \sum_{i=1}^{N} \vec{p}_i^2/2 + V(\vec{x}),$$

the Nosé–Hoover dynamics prescribes that the equations of motion one should integrate are

$$\begin{aligned} \ddot{x}_i &= -z\dot{x}_i - \frac{\partial V(\vec{x})}{\partial x_i}, \\ \dot{z} &= \sum_{i}^{N} \dot{x}_i^2 - NT, \end{aligned} \tag{4.2}$$

where T is the temperature which is meant to stay constant, and z is an auxiliary variable. From the structure of the above equations, it is clear that when the kinetic energy of the system is larger than $NT/2$, z increases: this means that the particles become more and more damped. On the other hand, when the kinetic energy is smaller than $NT/2$, z decreases, to the point that it could be negative; when negative, it acts as a pushing force on the particles, increasing their energy. The finite volume is implemented through the boundary conditions. The idea behind the Nosé–Hoover dynamics is a clever one: it should be appreciated that it does not require any stochastic force. Hence one has available, while integrating (4.2), all the theoretical results and the numerical tricks normally used in the integration of ordinary differential equations. The Nosé–Hoover dynamics is of course not "real": in fact, it should be used only to reach thermal equilibrium, at which point the simulations should proceed without any reference to z.

The quasi-symplectic algorithms introduced here are a possible, very interesting alternative to the Nosé–Hoover dynamics. The requirement of constant temperature is in fact automatically built into the quasi-symplectic structure of the equations. Even more important, one could ask the question as to what is responsible for the evolution towards thermal equilibrium. Typically, this equilibrium is reached thanks also to the coupling with the thermal bath, which does not simply give rise to temperature (fluctuations), but also to some dissipation (damping). And if some guesses are available as to the strength and speed of these processes, the quasi-symplectic algorithms would be capable of not simply generating the statics (equilibrium) but also of tracking the actual relaxation towards equilibrium.

We also note that the Nosé–Hoover dynamics controls *only* the overall energy of the system, relying on the internal dynamics to get equilibrium. When this internal dynamics is not strong enough (for instance, in the case of diluted particles) we might even experience problems. We now turn again to some numerical experiments.

The system looked at is an ensemble of particles interacting pairwise via a Lennard–Jones (LJ) potential

$$V(r) = 4\epsilon \left[\left(\frac{\sigma}{r}\right)^{12} - \left(\frac{\sigma}{r}\right)^{6} \right],$$

where r is the distance between two particles. The simulations were done in three dimensions. We recall that the minimum of the LJ potential is located at

$$r_{LJ} = \sigma 2^{1/6}.$$

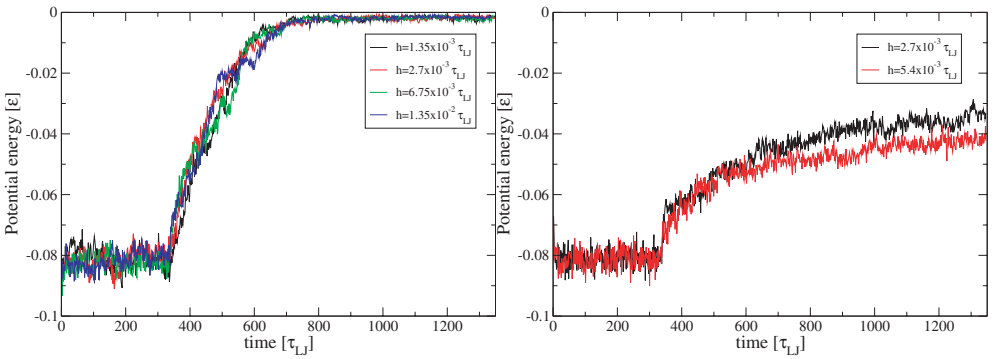

FIG. 4.1. *Result of simulations for different integration time step h's for* 125 *particles interacting via a LJ potential. The quantity plotted is the average potential energy vs. time (see text for details about the simulation); $T = 0.8\epsilon$. Left: SLO scheme, $1/\gamma = 100\tau_{LJ}$. Right: Nosé–Hoover dynamics.*

We took the mass of the particles to be 40. In the following, times will be scaled on τ_{LJ}, the period of small oscillations around the LJ potential minimum for the given mass, and energies and distances will be measured in units of ϵ and σ, respectively. Roughly speaking, the chosen mass is Argon's: if the other LJ parameters were taken to be the Argon's ones, τ_{LJ} would be in the range of ps.

We took 125 particles and, for the first case, fixed the volume: particles hitting the boundaries were reflected assuming elastic scattering from a rigid wall. Typically, the system was prepared in a small cubic box with sides equal to $6r_{LJ}$. After waiting until equilibrium was reached, the box was suddenly deformed, keeping constant the size along z but increasing the size along x and y to be $60r_{LJ}$. For the sake of comparison, we decided to look at the average potential energy in our system. For these simulations, we superimposed a static potential of the form

$$V(x, y) = \epsilon \left[\cos(x/\sigma) + \cos(y/\sigma)\right], \tag{4.3}$$

where $\{x, y, z\}$ is the coordinate of each particle, with the superimposed potential slowing down the x, y diffusion. The result of the simulations for $T = 0.8\epsilon$ and different time steps is shown in Figure 4.1. The system is initially allowed to relax within the small box. Then at times $337.5\tau_{LJ}$ the box is suddenly increased as described above, and the potential energy monitored. On the left plate of Figure 4.1 we show the result of using a quasi-symplectic SLO scheme: we observe no dependence on the integration time step h in the relaxation towards equilibrium. The equilibrium is reached around $800\tau_{LJ}$, and, in case we were interested in computing equilibrium quantities, from that time onward we would be in position to start the averaging.

It is striking to compare this with the results obtained integrating using the Nosé–Hoover dynamics (right plate of Figure 4.1). We observe that (a) the relaxation depends on the integration time step, and (b) even waiting for times as large as $1300\tau_{LJ}$, we are still very far from the equilibrium state. Hence, we are still not in position to start averaging over the equilibrium distribution. The Nosé–Hoover dynamics was integrated using a fourth order Adams–Bashforth predictor, followed by a fourth order Adams–Moulton corrector.

There is no doubt that the relaxation towards equilibrium in the SLO integration is dictated by the value of γ. But as mentioned, at worst the SLO can be used as the Nosé–Hoover dynamics is used—to reach the new equilibrium state—at which

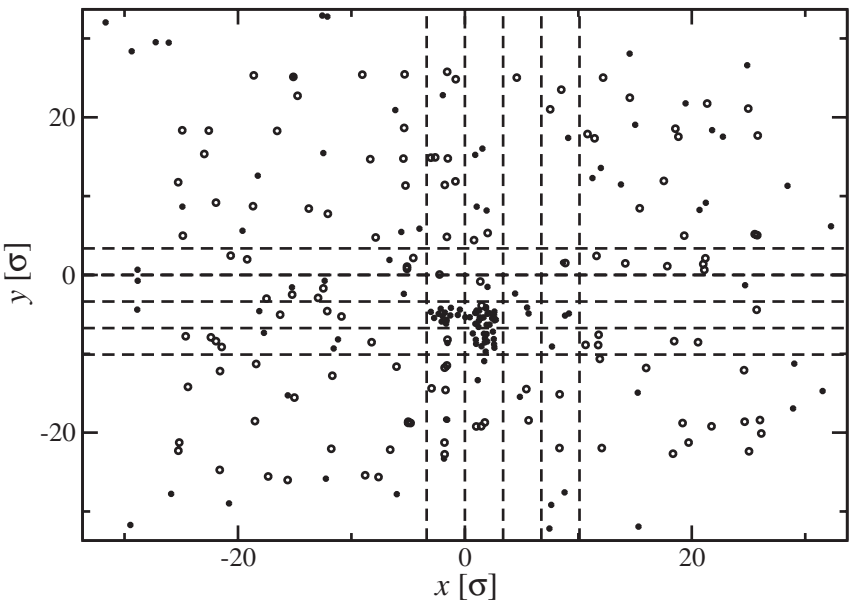

FIG. 4.2. *Position of* 125 *particles interacting through a LJ potential projected onto the* x, y *plane. The projection was done (see Figure* 4.1*) at times equal to* $1200\tau_{LJ}$*. The symbols are the particles (full circles, Nosé–Hoover dynamics; empty circles, quasi-symplectic algorithm); the dashed lines mark some of the maxima of the periodic potential of* (4.3) *lying closer to the origin.* $h = 2.7 \times 10^{-3}\tau_{LJ}$.

point nothing prevents us from simply switching off the damping, taking $\gamma = 0$: we will be left with a symplectic integrator and an evolving system where averages can be taken. But, on the other hand, if γ is chosen to resemble the actual interactions between particles and thermal bath, we would be simulating even the off equilibrium properties (i.e., the relaxation towards equilibrium), something which is not possible with the Nosé–Hoover dynamics.

The lack of equilibrium in the Nosé–Hoover dynamics is easily understood looking at the position of the particles at larger times (Figure 4.2). In the Nosé–Hoover dynamics even for the larger times considered many particles are stuck at the bottom of the potential minima. For the configuration in Figure 4.2 we have that $\sum_i p_i^2/2 \approx NT/2$, and $z \approx 0$ in (4.2). This implies that the only possibility to increase the energy of the low energy particles (the ones in the wells) is via scattering with the particles already outside, a process which is clearly inefficient given that the typical distances over which the LJ acts are around σ (i.e., of the order of the distance between the dashed lines in Figure 4.2).

We note, furthermore, that the SLO, requiring only one evaluation of the deterministic force per integration time step, is approximatively twice as fast as methods based on a predictor corrector, for the same time step. Also, in practice we observed that we could not increase the integration time step in the Nosé–Hoover integration much further than what is shown in the legend of Figure 4.1: when we tried to make the integration time step larger, the integration broke down. To summarize, SLO proved to be faster and allowed for larger integration time steps.

We mentioned that the Nosé–Hoover dynamics is used also for the integration at fixed temperature and pressure. It is possible to carry out similar integrations using the quasi-symplectic schemes proposed here. The approach to follow is to also actually

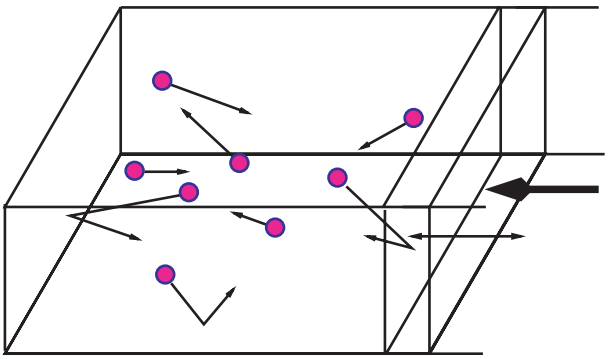

FIG. 4.3. *Scheme of how simulations at constant pressure and temperature could be carried out with the quasi-symplectic schemes. The dynamical system is enlarged to include a moving set (shown on the right) with an applied external constant force (the bold arrow on the right). The other walls are rigid, and particles scatter elastically from them.*

simulate what should keep the pressure constant, like a moving set with a constant applied force. It will be the scattering with the moving set which will yield the constant pressure. This is exemplified in Figure 4.3: the figure shows some interacting particles, the moving set (on the right), and the applied external constant force.

We tested the algorithms, simulating both single particles and dymers (couples of elastically bounded particles), interacting via a LJ potential, in three dimensions. The integration was carried out using a fourth order quasi-symplectic algorithm. Before turning to a quantitative comparison, we think that it could be interesting for the reader to look at some short movies showing the dynamics generated. The movies, available at http://www.df.unipi.it/~mannella/simulations.html, show clearly the formation of droplets for smaller temperatures and the evaporation of the droplets as the temperature is increased; they also show the moving set interacting with the particles. We found that in practice rather than using a hard moving set, it proved numerically simpler to have a "soft" moving set. In the simulations, assuming that the moving set closes the box from the right (like in the movies and in Figure 4.3), we took an interacting potential between the moving set and particles of the form

$$V(x_s, x_p) = \theta(x_p - x_s)(x_p - x_s)\frac{\epsilon}{\sigma},$$

where x_s and x_p are the x coordinates of, respectively, the moving set and of a particle, and $\theta(x)$ is 0 (1) for $x < 0$ (> 0). This leads to a smooth transition into the region where the moving set is, making the numerical integration simpler.

We turn now to some quantitative assessment of the quasi-symplectic algorithms for the integration at fixed temperature and pressure. The simulations are again done in the three-dimensional case, using a soft moving set and taking 125 particles interacting via a pairwise LJ potential. The equations of motion were integrated in a box with the y size equal to $60r_{LJ}$ and the z size equal to $6r_{LJ}$. The moving set was free to move along the x direction.

In the first numerical experiment, we fixed the value of the temperature and, changing the force applied to the moving set, we computed the average distance between the moving set and the opposite wall, once equilibrium was reached: this is proportional to the volume taken by the particles. It should be appreciated that in our simulations the moving set does move around some average position, as shown in

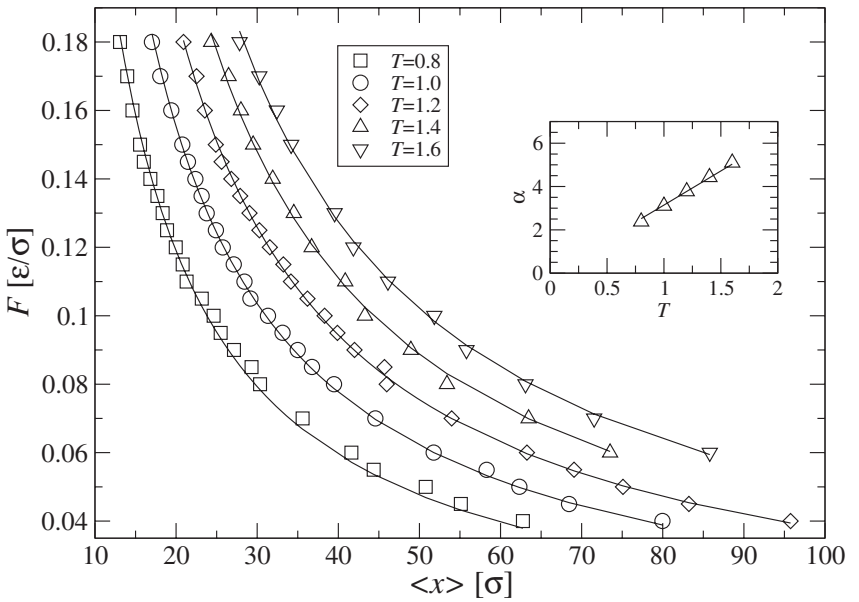

FIG. 4.4. *Relation between applied force F and average position of the moving set $\langle x\rangle$. The latter is proportional to the volume occupied by the* 125 *particles interacting via a LJ potential. Integration is done using a fourth order quasi-symplectic algorithm, with* $1/\gamma = 10^4\tau_{LJ}$ *and* $h = 1.35\times10^{-2}\tau_{LJ}$. *The symbols are simulations; the solid line is best fit with* $F = \alpha/\langle x\rangle$, *where* α *is the (only) fitting parameter. Inset, relation between* α *and temperature* T: *symbols are obtained from the fit; the solid line is the result of a linear fit using the function* $\alpha = \beta T$, *with* β *fitting parameter.*

the movies. We recall that there is proportionality between the force and the pressure felt by the particles, of the form, for our geometry,

$$P[\epsilon/\sigma^3] = F[\epsilon/\sigma]/(360 \times 2^{1/3}\sigma^2).$$

We should recover Boyle's law for ideal gases in the simulations. The result of the numerics is summarized in Figure 4.4. The symbols are the results for different temperatures, showing the relation between applied force, F, and average position of the set, $\langle x\rangle$. The solid lines are fits done with the function $F = \alpha/\langle x\rangle$, where α is the fitting parameter. The functional form of the fit is obviously suggested by Boyle's law. We note that the simulations follow closely the fitting formula. The inset of Figure 4.4 shows a plot of α as a function of the system temperature: if Boyle's law applied, we should recover a linear dependence of α on T, which is indeed the case.

Given the attractive nature of the LJ for a range of distances, we expect that for high enough pressures and/or small temperatures we should observe a phase transition to the liquid state. This is indeed the case, as seen in Figure 4.5, where we plotted the volume taken by the particles as a function of temperature. We applied a constant force $F = 0.1\epsilon/\sigma$, which would imply a pressure of $P = 1/(3600 \times 2^{1/3})\epsilon/\sigma^3$, and changed temperature. For larger temperatures, we again observe Boyle's law: the solid line in the figure is a fit done with a linear dependence of volume on temperature. However, as we decreased the temperature, we observed a sharp drop in the volume occupied by the particles. By direct inspection of the state reached by the particles in the simulations, we observed the formation of a droplet with all particles attached together—the transition to the liquid state.

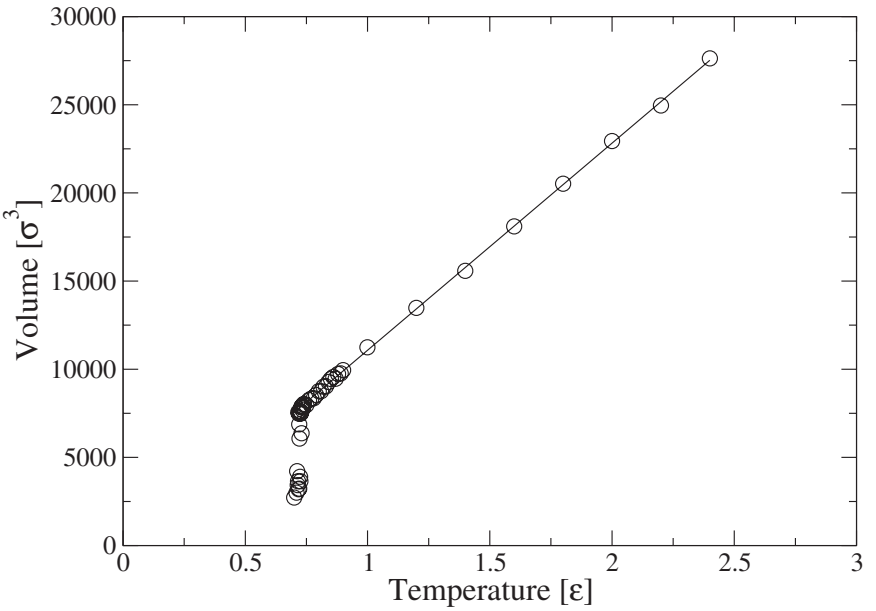

FIG. 4.5. *Average volume occupied by* 125 *particles interacting via a LJ potential for different temperatures and constant pressure. Integration is done using a fourth order quasi-symplectic algorithm, with* $1/\gamma = 10^4 \tau_{LJ}$ *and* $h = 1.35 \times 10^{-2} \tau_{LJ}$. *The symbols are simulations; the solid line is best linear fit.*

We conclude this section noting that indeed the quasi-symplectic algorithms are capable of correctly integrating the dynamics of systems for which we are required to keep either temperature and volume or temperature and pressure constant.

5. Conclusions. We introduced quasi-symplectic algorithms for the numerical integration of Langevin equations obeying detailed balance. The features of these algorithms are that they become symplectic when the damping and the temperature in the Langevin equation are taken to be zero, and give the correct equilibrium distribution to some higher order in the integration time steps for a finite damping and temperature. This, in turn, leads to more accuracy when dynamical quantities are considered (like the MFPT) than when leading existing integration schemes are used. We showed that possible applications of these algorithms are in the integration of the dynamics in the liquid state, where the speed up provided by algorithms which are stable for fairly large time steps may help in improving current simulations. The algorithms make it possible to perform simulations for both constant temperature and volume and constant temperature and pressure. They appear to be a viable alternative to approaches like the Nosé–Hoover dynamics, currently the leading method used to handle the simulation of systems in contact with a thermal bath. Finally, the approach followed here can be used to derive higher order quasi-symplectic schemes by simply exploring the possibilities of symplectic schemes.

RECYCLING SUBSPACE INFORMATION FOR DIFFUSE OPTICAL TOMOGRAPHY*

MISHA E. KILMER† AND ERIC DE STURLER‡

Abstract. We discuss the efficient solution of a long sequence of slowly varying linear systems arising in computations for diffuse optical tomographic imaging.

The reconstruction of three-dimensional absorption and scattering information by matching computed solutions from a parameterized model to measured data leads to a nonlinear least squares problem that we solve using the Gauss–Newton method with a line search. This algorithm requires the solution of a long sequence of linear systems. Each choice of parameters in the nonlinear least squares algorithm results in a different matrix describing the optical properties of the medium. These matrices change slowly from one step to the next, but may change significantly over many steps. For each matrix we must solve a set of linear systems with multiple shifts and multiple right-hand sides.

For this problem, we derive strategies for recycling Krylov subspace information that exploit properties of the application and the nonlinear optimization algorithm to significantly reduce the total number of iterations over all linear systems. Furthermore, we introduce variants of GCRO that exploit symmetry and that allow simultaneous solution of multiple shifted systems using a single Krylov subspace in combination with recycling. Although we focus on a particular application and optimization algorithm, our approach is applicable generally to problems where sequences of linear systems must be solved. This may guide other researchers to exploit the opportunities of tunable solvers.

We provide results for two sets of numerical experiments to demonstrate the effectiveness of the resulting method.

1. Introduction.

In diffuse optical tomography (DOT), data is obtained by transmitting near-infrared light into a highly absorbing and scattering medium and then recording the photon flux. The goal is to use the diffuse optical data measured on the surface to reconstruct three-dimensional (3D) images of the absorption and "reduced scattering" functions in the medium. In the case of breast tissue imaging, differences in the absorption and scattering may indicate the presence of a tumor or other anomaly.

The *forward problem* is the determination of synthetic data (photon flux) for given absorption and scattering functions from some mathematical model. A number of mathematical models have been proposed in the literature [2]. We focus on the frequency-domain diffusion model in which the data is a nonlinear function of the absorption and scattering functions. In order to solve the imaging problem—the determination of the absorption and reduced scattering functions—one must solve many instances of the forward problem. This fact implies a huge computational

bottleneck for the imaging problem. The goal of this paper is to discuss techniques for reducing the computational complexity of forward solves, thereby greatly improving the execution time of the nonlinear imaging problem.

In [26], we recycle the subspaces that are generated automatically by the methods used. In the present paper, we analyze the application, its solutions, and the nonlinear optimization algorithm to derive strategies for selecting subspaces for recycling that enhance convergence even further. In particular, we explore which information to keep and which to save as the damped Gauss–Newton (GN) method progresses. Furthermore, we present a variant of GCRO [10] that exploits the symmetry of the matrix and that can solve multiple shifted complex systems simultaneously with a single Krylov subspace in combination with recycling. The symmetry means that there is no need to restart for a single linear system to save on storage.

We consider the solution of a sequence of linear systems of the form

$$(A(p_j) + i\gamma I)x_{s,\omega}^{(j)} = b_s \tag{1.1}$$

that arise in a 3D imaging algorithm for DOT. Here, $i = \sqrt{-1}$, γ is a positive constant that depends on the frequency, ω, and the vector p_j denotes the vector of parameters that define the diffusion and absorption in tissue at the jth step of a GN iteration to solve the nonlinear least squares problem (defined below) for an optimal set of parameters. The sparse, symmetric positive definite matrix A depends on the parameters p_j and arises from the discretization of the diffusion-absorption equation with mixed boundary conditions and some further matrix manipulation (see section 3). Therefore, Krylov iterative solvers such as MINRES [25, 4] are good candidates for solving these linear systems.

We observe that in our application the matrices $A(p_j)$ vary slowly from one GN step or line search step to the next, but they change significantly over multiple GN steps. In addition, we need to solve for multiple (complex) shifts and multiple right-hand sides for each matrix. In order to solve this problem in the most efficient way we must exploit all these features. For each of these features separately, suggestions have been made to reduce the overall cost (for example, see [19, 18, 22] for solving for a group of matrices that differ by a constant times the identity and [17, 31, 9, 26, 21] for solving for multiple right-hand sides). However, the various methods have not been combined to address all these features at once, and this is not a trivial issue.

The problem of solving a sequence of systems where the matrix changes slowly is the most complicated feature to exploit. In [26] we propose to *recycle* from one linear system to the next the Krylov subspaces that solvers like GCRO [10], GCROT [11], and GMRESDR [24] retain to improve the convergence for a single linear system. GMRESDR cannot recycle a subspace for a subsequent linear system, as it requires a Krylov space to work with; therefore, we introduced the variant GCRODR [26].

Other approaches have been proposed as well. If all matrices in a set of symmetric positive definite linear systems are pairwise close to each other and all right-hand sides are available simultaneously, the methods proposed by Chan and Ng [7] can be used. However, this is not the case for our application. For the Hermitian positive definite case, Rey and Risler have proposed to reduce the effective condition number by augmenting the search space either with all converged Ritz vectors from previous CG iterations or with all previously generated Krylov spaces for a few iterations to implicitly approximate dominant eigenvectors [27, 28]. Clearly, both in memory and floating point operations these methods are very expensive. Moreover, in their approach, although they use CG, full recurrences are required. Finally, both approaches

lack the possibility to gradually improve the recycled space and to adapt it for a sequence of linear systems that change gradually but substantially over many steps. For this reason, Rey and Risler also make the assumption that all matrices remain close. Fischer has proposed to project right-hand sides from subsequent time steps onto the space of previous right-hand sides and to solve only for the remainder [16]. This leads to a better starting guess if the right-hand sides are correlated, but his algorithm does not maintain orthogonality to this subspace and, in general, does not improve the rate of convergence.

Multigrid methods might provide an alternative for the methods proposed here, as they have lower complexity than Krylov methods for diffusion type problems, and several papers have discussed how to deal effectively with large jumps in the diffusion and absorption coefficients [1, 5, 34]. However, it is not clear that the convergence rate of multigrid methods can be significantly improved for a sequence of matrices and/or right-hand sides when subsequent solutions differ significantly, as is accomplished by the methods proposed here (see also [26]). Adaptations of multigrid methods for sequences of problems mainly involve the judicious choice on which grids to update an old solution [5]. This approach is not suitable if the new solution differs significantly from the previous solution because it does not improve convergence in general. It just reduces the work in updating a slightly changed solution. In addition, our algorithms compute solutions for multiple shifts more or less for free; in a multigrid setting this is not possible. Finally, we can improve the convergence of the algorithm over multiple right-hand sides, which is not straightforward with multigrid methods.

As mentioned above, our problem includes the solution of a small set of right-hand sides for each matrix (with fixed p_j and γ). As was shown in [9, 26], subspace recycling is quite effective for this problem. However, other approaches or variations have been successful as well, in particular block methods [17, 31] and seed methods [8, 21]. Subspace recycling is the easiest to implement, as it can solve the right-hand sides one by one as individual linear systems, simply recycling the selected search space [26]. This avoids changes to the program to deal with varying block sizes and deflation if the vectors inside a block become dependent.

Finally, we also want to solve for multiple shifts using a single Krylov space. This is not complicated in itself, as the Krylov space for a shifted problem equals the Krylov space for the original problem. However, it is not easily combined with recycling Krylov subspaces, because the images of recycled spaces under matrices with different shifts are not the same. We derive an extension to the GCRO method in section 5 to deal with this problem.

The paper is organized as follows. Section 2 gives some background on GCRO and subspace recycling. In section 3, we give background information for the imaging problem in DOT, and we derive the sequence of linear systems of the form (1.1) that we wish to solve. In section 4, we discuss characteristics of the system that favor the use of recycling. We describe our algorithm in section 5, and give numerical results in section 6. Conclusions and future work are the subject of section 7.

2. Recycling Krylov subspaces. The ideas we exploit in this paper find their origin in attempts to improve the convergence of restarted and truncated Krylov subspace methods for a single, nonsymmetric, linear system. Restarting GMRES [30] may lead to poor convergence and even stagnation. Therefore, recent research has focused on truncated methods that improve convergence by retaining a selected subspace when they restart [3, 10, 11, 24, 26, 29]. We refer to this subspace as the *recycled* subspace. These methods aim to maintain convergence close to that of full

GMRES while significantly reducing memory and CPU costs. A taxonomy of popular choices is given in [15], and approaches to convergence theory for GMRES that are relevant here can be found in [32, 35].

An important choice for the present paper is to recycle an approximate invariant subspace [23, 24]. An alternative method that adapts the recycled space based on its effectiveness is given in [11]. In [10] the updates to the solution (residual) are recycled. This is also proposed in [3], but the recycled space is used slightly differently. In this paper, we exploit knowledge of the physics underlying DOT, the solutions in a general sense, and the nonlinear optimization algorithm to combine the strategies from [10, 24, 16, 26] for a sequence of linear systems.

The GCRO method provides a general mechanism for Krylov methods to include arbitrary additional subspaces in the search space. We explain briefly how GCRO combines the recycled space with a newly generated Krylov subspace to obtain an optimal approximation over the sum of these spaces. To prepare for the extension to the simultaneous solution of a set of linear systems with matrices that differ only by a constant times the identity using a single Krylov subspace, we present the basic steps from [10] in a slightly different way.

Consider the linear system $Ax = b$, where $A \in \mathbb{R}^{N\times N}$ and $b \in \mathbb{R}^N$. Assume we have the matrix $U \in \mathbb{R}^{N\times n_c}$, such that $AU = C$ and $C^TC = I$. There are no other restrictions on the matrix U. The approximate solution in range(U) that minimizes the 2-norm of the residual yields the residual $r = b - CC^Tb$ that is orthogonal to range(C). If this solution is not adequate, we expand the subspace as follows [10]. Let $v_1 = (I-CC^T)b/\|(I-CC^T)b\|_2$. We use an Arnoldi recurrence with $(I-CC^T)A$ and v_1 to generate the recurrence relation

$$\begin{aligned}(I - CC^T)AV_m &= V_{m+1}\underline{\mathrm{H}}_m \Leftrightarrow\\ AV_m &= CC^TAV_m + V_{m+1}\underline{\mathrm{H}}_m.\end{aligned} \tag{2.1}$$

Next, we compute the approximate solution in range$([V_m\ U])$ that minimizes the 2-norm of the residual, $\|b - A(V_my + Uz)\|_2$, as follows:

$$\begin{aligned}&\min_{y,z}\left\|b - A[U\ V_m]\begin{bmatrix} z\\ y\end{bmatrix}\right\|_2\\ &= \min_{y,z}\left\|b - [C\ V_{m+1}]\begin{bmatrix} I & C^TAV_m\\ 0 & \underline{\mathrm{H}}_m\end{bmatrix}\begin{bmatrix} z\\ y\end{bmatrix}\right\|_2\\ &= \min_{y,z}\left\|\begin{bmatrix} C^Tb\\ \xi e_1\end{bmatrix} - \begin{bmatrix} I & C^TAV_m\\ 0 & \underline{\mathrm{H}}_m\end{bmatrix}\begin{bmatrix} z\\ y\end{bmatrix}\right\|_2,\end{aligned} \tag{2.2}$$

where e_1 denotes the first Cartesian basis vector in $\mathbb{R}^{m+1}$ and $\xi = \|(I-CC^T)b\|_2$. The minimization in (2.2) corresponds to a small least squares problem, whose solution requires only the QR decomposition of the submatrix $\underline{\mathrm{H}}_m$ using Givens rotations as in [30]. We will show below that this approach is also extended easily to a set of matrices $A + i\gamma I$. In this case, we need to deal with the problem that range$((A + i\gamma I)U) \not\subset$ range(C), and of course range$((A + i\gamma I)U)$ depends on γ.

If we have found a matrix U that speeds up the convergence significantly, we can recycle this matrix for the next right-hand side (with the same A and γ) and possibly improve it. This does not require any changes to the algorithm, and it allows the algorithm to learn as it computes the solutions for subsequent right-hand sides which spaces are best to recycle. This improves the convergence for multiple right-hand

sides and a constant matrix without requiring extra storage. This algorithm can also be extended to a block method [37].

Now, consider a sequence of systems with coefficient matrices $A^{(j)}$. If we have found a matrix U that speeds up convergence significantly for $A^{(j)}$, and $A^{(j+1)} - A^{(j)}$ is small, it makes sense to reuse the matrix U, possibly extended with other search directions, for the linear systems with $A^{(j+1)}$. In this case, we need to update C to reflect the new operator. In many cases this can be done very cheaply. This process is not complicated, and we refer to [26] for details.

3. The DOT imaging application. In this section, we introduce the image reconstruction problem for DOT. Here, we derive the systems of the form (1.1) that must be solved at each step of the nonlinear reconstruction algorithm.

3.1. The forward and inverse problems. We assume that the region to be imaged is a box with a limited number of N_s sources on the top and a limited number of N_d detectors on either the top or bottom or both. We use the diffusion model [2] for photon flux/fluence $\phi_{s,\omega}(r)$ given input $f_s(r)$:

$$\begin{aligned} -\nabla D(r)\nabla\phi_{s,\omega}(r) + \mu_a(r)\phi_{s,\omega}(r) + i\frac{\omega}{\nu}\phi_{s,\omega}(r) &= f_s(r) \\ \text{for } r = (x,y,z) \text{ and } -a < x < a,\ -b < y < b,\ 0 < z < c, & \\ \phi_{s,\omega}(r) = 0 \quad \text{if } 0 \le z \le c \text{ and either } x = -a,\ x = a,\ y = -b, \text{ or } y = b, & \\ .25\phi_{s,\omega}(r) + \frac{D(r)}{2}\frac{\partial\phi_{s,\omega}(r)}{\partial\eta} &= 0 \text{ for } z = 0 \text{ or } z = c. \end{aligned}$$

Here, $D(r)$ denotes the diffusion, which is related to the "reduced scattering" function $\mu_s'(r)$ by $D = 1/(3\mu_s'(r))$, and $\mu_a(r)$ denotes absorption [2]. We have used $i = \sqrt{-1}$, while ω represents the frequency modulation of light, and ν is the speed of light in the medium. The integer subscript s indicates the model with a single source at a known position. The function $f_s(r)$ is the source and $\phi_{s,\omega}(r)$ is the photon flux/fluence due to the source at frequency ω, given the functions $\mu_a(r)$ and $D(r)$. The function $\phi_{s,\omega}(r)$ is complex-valued if ω is nonzero. Knowing the source and the functions $\mu_a(r), D(r)$, we can compute the corresponding $\phi_s(r)$ everywhere, in particular at the detectors (i.e., at a subset of gridpoints where $z = 0$ or $z = c$).

We discretize the PDE using finite differences [6] on a uniform grid in such a way as to achieve second-order accuracy away from the boundary. The meshwidth in each direction is h centimeters. We use first-order forward or backward differences, as appropriate, on the boundary. The unknowns become $\phi_{s,\omega}(x_l, y_j, z_k)$ for $l = 1 : N_x, j = 1 : N_y, k = 1 : N_z$. We will order the unknowns so that $\phi_{s,\omega}$ values at points on the top of the box come first (i.e., let $k = 1$ and loop over all l, j), then the $\phi_{s,\omega}$ corresponding to points on the bottom (i.e., let $k = N_z$ and loop over all l, j), followed by the rest of the values by ordering in increasing l, then j, then k. We denote the corresponding vector with entries $\phi_{s,\omega}(x_l, y_j, z_k)$ as $\boldsymbol{\phi_{s,\omega}}$. Likewise, we denote the vector with entries $\mu_a(x_l, y_j, z_k)$ as $\boldsymbol{\mu_a}$. The vector $\boldsymbol{D}$ is comprised from sampling D at both whole and half integer gridpoints, because of the particular discretization we are using.

The corresponding matrix equation, after multiplication by h^2, has the following block structure:

$$\begin{bmatrix} B & D_1 \\ D_2 & (F + i\frac{\omega h^2}{\nu} I) \end{bmatrix} \begin{bmatrix} w_{s,\omega} \\ x_{s,\omega} \end{bmatrix} = \begin{bmatrix} \boldsymbol{f_s}^{(1)} \\ \boldsymbol{f_s}^{(2)} \end{bmatrix}, \tag{3.1}$$

where $w_{s,\omega}$ and $x_{s,\omega}$ denote the discretization of $\phi_{s,\omega}(r)$ on the boundary and at internal points, respectively. The measured data *due to source s* **predicted** by this forward model is a subsampled version of the subvector $w_{s,\omega}$, which we call $\boldsymbol{\psi_{s,\omega}}$. It is important to note that in our application $\boldsymbol{f_s}^{(2)} = 0$ and $\boldsymbol{f_s}^{(1)} = h^2 e_i$, where e_i is the ith Cartesian unit vector and the position of the 1 corresponds to the location of the source.

Let $y_{s,\omega}$ denote the data subvector **measured** at all the detectors for a fixed source s and frequency ω, and let $W_{s,\omega}$ denote the diagonal weighting matrix whose diagonal entries are the inverses of the standard deviations of the noise in the data. Recall that p is a vector of parameters that describe the diffusion and absorption at all points in the region of interest. We will briefly discuss the choice of p below and refer the interested reader to [20] for more details. The 3D imaging problem then becomes one of finding the parameters that minimize the difference between the data predicted by the model and the measured data. That is, we wish to solve

$$\min_p \sum_{s,\omega} \|W_{s,\omega}(y_{s,\omega} - \boldsymbol{\psi_{s,\omega}}(p))\|_2^2 \equiv \min_p \|W(\mathbf{y} - \boldsymbol{\psi}(p))\|_2^2, \tag{3.2}$$

where $\mathbf{y}$ denotes the vector obtained by stacking the subvectors $y_{s,\omega}$, $\boldsymbol{\psi}(p)$ is the vector obtained by stacking the subvectors $\boldsymbol{\psi_{s,\omega}}(p)$, and W is the block matrix whose diagonal blocks are the matrices $W_{s,\omega}$. Let $\epsilon(p)$ denote the residual vector $W(\mathbf{y} - \boldsymbol{\psi}(p))$. We use the following damped GN iteration to solve this nonlinear least squares problem [14], where $J(p)$ denotes the Jacobian of the residual, evaluated at p:

1. compute $\epsilon(p_k)$, $J(p_k)$,
2. solve $J(p_k)^T J(p_k) s_k = -J(p_k)^T \epsilon(p_k)$,
3. $p_{k+1} = p_k + \lambda_k s_k$,

with λ_k chosen using a backtracking line search [14].

If the number of parameters used to define diffusion and absorption is small, the Jacobian will only have a small number of columns, and therefore step 2, solving for the search direction, is not computationally intensive. However, to compute $\epsilon(p_k)$ and to compute the entries in the Jacobian using an adjoint-type approach (called a "co-state" method in [36]) requires solutions of the matrix equation in (3.1) for every source and every frequency. Furthermore, each line search step requires evaluation of residual and Jacobian at a new point. Therefore, the rest of this paper is devoted to analyzing the systems (3.1) and methods for computing their solutions efficiently.

3.2. The matrix revisited. Here, we describe properties of the matrices and submatrices involved in solving for each $\boldsymbol{\phi_{s,\omega}}$. First, regarding the blocks in (3.1),

- B is an invertible diagonal matrix,
- D_1 has at most one nonzero per row, and these occur only in the first $N_x N_y$ and last $N_x N_y$ columns,
- D_2, although it has different entries, has the same sparsity pattern as D_1^T.

A MATLAB sparsity plot of the matrix in (3.1) is given in Figure 1 to give the reader a visual interpretation of the structure just mentioned.

To solve systems involving this matrix, we consider the decomposition $G = LU$, where L is block unit lower triangular, U is block upper triangular, and G represents the block matrix in (3.1). It can readily be shown that

$$G = \begin{bmatrix} I & 0 \\ D_2 B^{-1} & I \end{bmatrix} \begin{bmatrix} B & D_1 \\ 0 & F - D_2 B^{-1} D_1 + i\gamma I \end{bmatrix},$$

where $\gamma = h^2\omega/\nu$. Hence, the system $G \begin{bmatrix} w_{s,\omega} \\ x_{s,\omega} \end{bmatrix} = \begin{bmatrix} \boldsymbol{f_s}^{(1)} \\ 0 \end{bmatrix}$ can be solved as follows.

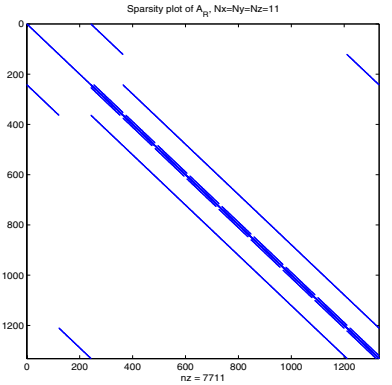

FIG. 1. *Sparsity plot of matrix G.*

Step 1. Solve the equation $L \begin{bmatrix} a_s \\ b_s \end{bmatrix} = R \begin{bmatrix} \boldsymbol{f_s}^{(1)} \\ 0 \end{bmatrix}$:

(a) $a_s = \boldsymbol{f_s}^{(1)}$,

(b) $b_s = -D_2(B^{-1}a_s)$.

Step 2. Solve the equation $U \begin{bmatrix} w_{s,\omega} \\ x_{s,\omega} \end{bmatrix} = \begin{bmatrix} a_s \\ b_s \end{bmatrix}$:

(a) solve $(F - D_2B^{-1}D_1 + i\gamma I)x_{s,\omega} = b_s$,

(b) $w_{s,\omega} = B^{-1}(a_s - D_1x_{s,\omega})$.

Multiplying with B^{-1} can be done very cheaply because B is diagonal, and D_1 and D_2 have only $(2N_xN_y)$ nonzero entries each. The computationally intensive part of this procedure is Step 2(a). Note that the system in Step 2(a) is exactly the system in (1.1).

We conclude this section with the proof that $F - D_2B^{-1}D_1$ is symmetric and positive definite. The matrix F is symmetric and positive definite because it corresponds to the finite difference discretization of the operator $-\nabla D(r)\nabla I + \mu_a(r)I$ at the internal points on the box assuming zero boundary conditions. B is a diagonal matrix of size $2N_xN_y \times 2N_xN_y$ with entries $.25h^2 + \frac{h}{2}\boldsymbol{D}_{l,j,m}$ with $m = 1$ or $m = N_z$. Due to the lexicographical ordering of the internal nodes, D_1 is $2N_xN_y \times (N_xN_y(N_z - 2))$ with only one nonzero per row and D_2 is $(N_xN_y(N_z-2))\times 2N_xN_y$ with only one nonzero per column. The nonzero entries in D_1 are of the form $-\frac{h}{2}\boldsymbol{D}_{l,j,m}$ with $m = 1$ or $m = N_z$. The nonzero entries in D_2 are $-\boldsymbol{D}_{l,j,\frac{3}{2}}$ or $-\boldsymbol{D}_{l,j,N_z-\frac{1}{2}}$. Therefore, $D_2B^{-1}D_1$ is a diagonal matrix with nonzero (positive) entries only in the first and last N_xN_y positions. We now use the previous two facts to prove the following theorem.

THEOREM 3.1. *The matrix $F - D_2B^{-1}D_1$ is symmetric and positive definite.*

Proof. Symmetry follows from the symmetry of F and $D_2B^{-1}D_1$. Matrices $F-D_2B^{-1}D_1$ and F differ only in the first and last N_xN_y components on the diagonal. Since the nonzeros in the second matrix are strictly positive, the first and last N_xN_y diagonal entries of $F - D_2B^{-1}D_1$ are smaller than the corresponding diagonal entries of F. Therefore, it is sufficient to consider the Gershgorin disks corresponding to these rows. Consider the first N_xN_y rows (the argument for the last N_xN_y is analogous). From Gershgorin's theorem we observe

$$\left(-\frac{\boldsymbol{D}_{i,j,1.5}\boldsymbol{D}_{i,j,1}}{0.5h + \boldsymbol{D}_{i,j,1}} + \boldsymbol{D}_{i,j,1.5}\right) + h^2\boldsymbol{\mu_a}_{i,j,1} \leq \lambda,$$

where λ is an eigenvalue. Since the first term on the left in parentheses is positive, together with lower bounds from all other Gershgorin disks, it follows that the eigenvalues are greater than zero. ∎

4. Summary of system properties. In the previous section, we observed that solving the forward problem efficiently boils down to solving the systems in Step 2(a) efficiently. The remainder of this paper is therefore devoted to this cause.

In this section, we discuss those system properties that can be exploited to develop efficient recycling Krylov methods for solving the systems in the previous section. We repeat the form of these systems here for convenience:

$$(\underbrace{F - D_2 B^{-1} D_1}_{A^{(j)}} + i\gamma I) x_{s,\omega}^{(j)} = b_s. \tag{4.1}$$

The superscript is used to denote dependence on the parameter vector, p_j. To simplify notation, we use $x_s^{(j)}$ for the case when $\omega = 0$.

The parametric model. As in [20], we use a piecewise continuous model for both the diffusion and absorption. In particular, we have

$$\boldsymbol{D} = \alpha_1 \Xi_1 + (\mathbf{1} - \Xi_1) B_1 \beta_1 \qquad \text{and} \qquad \boldsymbol{\mu_a} = \alpha_2 \Xi_2 + (\mathbf{1} - \Xi_2) B_2 \beta_2.$$

The vectors Ξ_i are discrete characteristic functions, having a "1" in a position corresponding to an anomaly and a 0 otherwise. The matrices B_1, B_2 are known and contain "basis" vectors while β_1 and β_2 are the unknown expansion coefficients. In a piecewise constant model, for instance, B_1 and B_2 would be vectors of all ones and the β_i would give the background value of diffusion and absorption, respectively. A more realistic model, however, accounts for the fact that tissue is not homogeneous, and in this case B_1, B_2 would correspond to vectorized "images" of a lumpy background. The vectors Ξ_i are unknown, but we assume that anomalies are modeled by ellipsoids. In this case, the entries in the vectors are determined by the parameters specifying center location, rotation, and axis lengths. Therefore, the list of unknown parameters includes $\alpha_i, \beta_i, i = 1, 2$, and up to 6 length-3 vectors specifying the locations of the 2 ellipsoids. For more details, see [20].

Diffusion, absorption, and matrix updates. Typical values for μ_a in our application range from .005 to .3 cm^{-1} whereas typical values for D range from 1/6 to 1/45 cm^{-1}. Usually, we have or can obtain good approximations to the average background values of diffusion and absorption and use these as starting guesses for the GN iteration [20]. As the GN iteration progresses, we begin to localize and characterize anomalous regions of absorption and diffusion whereas the background values become well resolved early on. This is due to the fact that the anomalies are so small relative to the size of the background that the data contains primarily information about the average background values. This means that during a single line search or when moving from one GN step to the next, $A^{(j+1)} = A^{(j)} + E_1 + E_2$, where $\|E_1\|$ is small (corresponding to a slight change in the background parameters) and E_2 has small relative rank (corresponding to a change in the shape of the object and values inside the object).

Eigenvalues and invariant subspaces. We are interested most in the smallest eigenvalues of the $A^{(j)}$. It appears that, for our examples, the matrices $A^{(j)}$ have a number of small eigenvalues occurring in clusters that remain disjoint from one system to the next, even if the eigenvalues themselves differ from one matrix to the next (see Figure 4, for example). This suggests that the corresponding invariant subspaces for subsequent matrices remain close. We discuss this further in the next subsection.

Similarity among right-hand sides. Recall that $\boldsymbol{f_s}$ has only one nonzero coefficient in, say, position m_s. It follows that $b_s^{(j)} = -\frac{(D_2)_{m_s,m_s}h^2}{B_{m_s,m_s}} e_{m_s}$, and so the $b_s^{(j)}$ are the same up to a scalar factor. The latter has no influence on the solver. Therefore, in the remaining discussion we study the convergence of iterative methods applied to the systems

$$(A^{(j)} + i\gamma I)x_{s,\omega}^{(j)} = e_{m_s}. \tag{4.2}$$

Similarity among solutions. From (4.2), it is easy to see that the solutions to any pair of (nonshifted) systems, say systems k and j, during the GN iteration are related by

$$x_s^{(k)} = (A^{(k)})^{-1}A^{(j)}x_s^{(j)}.$$

Thus, the solutions do not change much as long as the matrices $A^{(j)}$ and $A^{(k)}$ remain close, especially with respect to the smallest eigenvalues and corresponding eigenvectors; see also the following discussion on smooth solutions. The reason why we expect, in particular, the smooth components of the matrices to remain close is discussed in section 4.1. This expectation is borne out in the numerical experiments. It is important to note that the indices j and k need not be consecutive, nor must they refer to systems from within the same line search. See section 5 for details.

Smooth solutions. The vector e_{m_s} is comprised mostly of high frequency Fourier components. Furthermore, the eigenvectors corresponding to the smallest eigenvalues of $A^{(j)}$ represent low frequency (smooth) modes while the eigenvectors corresponding to the largest eigenvalues represent high frequency modes. The matrix $(A^{(j)})^{-1}$ corresponds to an integration operator that acts as a blurring operator. Therefore, we expect $x_s^{(j)}$ to be well represented in terms of the eigenvectors of $A^{(j)}$ that correspond to the smallest eigenvalues.

Multiple frequencies. The Krylov vectors generated to solve $A^{(j)}x_s^{(j)} = e_{m_s}$ also span the Krylov subspace generated by the shifted matrix $(A^{(j)} + i\gamma I)$ and e_{m_s} (see [22] and the references cited therein). When subspace recycling is used, however, it is not straightforward to produce solutions to the complex shifted systems. We discuss the extension of the algorithm to this case in section 5.4.

4.1. Invariant subspaces. In deciding whether or not it is worthwhile to recycle an approximate invariant subspace corresponding to small eigenvalues obtained from previous matrices, we must explore the relationships among these invariant subspaces of a sequence of matrices. In the previous discussion, we noted that from experiments it appears that the smallest eigenvalues of the $A^{(j)}$ do not change much and remain in more or less disjoint clusters. For a small enough perturbation $E = A^{(k)} - A^{(j)}$, this shows that the corresponding invariant subspaces from these matrices must remain close. Unfortunately, $\|E\|$ is too large to assume this without considering further details. However, recall the observation above that $E = E_1 + E_2$, where E_1 corresponds to very small changes in the background parameters and E_2 corresponds to a small rank update describing the shape of the object. From this we conjecture that most of the changes in the matrix correspond to the high frequency components and larger eigenvalues. Given this conjecture, we now show under which conditions the invariant subspaces corresponding to the smallest eigenvalues remain about the same even if the corresponding eigenvalues are not very well separated from the remaining eigenvalues.

To simplify notation, we remove all subscript and superscript notation and deal specifically with a symmetric and positive definite matrix A and a corresponding symmetric perturbation E.

Let A be a symmetric positive definite matrix, and let A have the eigendecomposition

$$A = [Q_1\ Q_2\ Q_3]\,\mathrm{diag}(\Lambda_1, \Lambda_2, \Lambda_3)\,[Q_1\ Q_2\ Q_3]^T, \tag{4.3}$$

where $Q = [Q_1\ Q_2\ Q_3]$ is an orthogonal matrix, $\Lambda_1 = \mathrm{diag}(\lambda_1^{(1)}, \ldots, \lambda_{k1}^{(1)})$, and Λ_2 and Λ_3 are defined analogously. Furthermore,

$$\lambda_1^{(1)} \le \cdots \le \lambda_{k1}^{(1)} < \lambda_1^{(2)} \le \cdots \le \lambda_{k2}^{(2)} < \lambda_1^{(3)} \le \cdots \le \lambda_{k3}^{(3)}.$$

In relation to our algorithm, Q_1 corresponds to the recycled invariant subspace (or a subspace of that), but Q_2 and Q_3 can be chosen to fit the theorem. Now we consider the changes in the invariant subspace $\mathrm{range}(Q_1)$ and the eigenvalues $\lambda_i^{(1)}$ under a symmetric perturbation E of A, where E is not small, but the projection of E onto the subspace $\mathrm{range}([Q_1\ Q_2])$ is small, say $\|E[Q_1\ Q_2]\|_F \le \varepsilon$, and $\|EQ_3\|_F = \eta \approx \|E\|_F$. We also assume that $\|E\|_F$ is small relative to $\mathrm{sep}(\Lambda_1, \Lambda_3) = \lambda_1^{(3)} - \lambda_{k1}^{(1)}$ and that ε is small relative to $\mathrm{sep}(\Lambda_1, \Lambda_2) = \lambda_1^{(2)} - \lambda_{k1}^{(1)}$. However, we do not need to assume that $\mathrm{sep}(\Lambda_1, \Lambda_2)$ is large. We now prove that the matrix $A + E$ has an invariant subspace $\mathrm{range}(\hat{Q}_1)$ such that the canonical angles between $\mathrm{range}(Q_1)$ and $\mathrm{range}(\hat{Q}_1)$ are small. This result shows that an invariant subspace whose associated eigenvalues are not well separated from the remaining eigenvalues is still insensitive to perturbations that are concentrated in an invariant subspace whose eigenvalues are sufficiently far removed.

We define the following notation. For two matrices $Y, Z \in \mathbb{R}^{N\times m}$, where $N \ge m$, $\Theta(\mathrm{range}(Y), \mathrm{range}(Z))$ denotes the diagonal matrix with the canonical angles between $\mathrm{range}(Z)$ and $\mathrm{range}(Y)$ as coefficients, and $\theta_1(\mathrm{range}(Y), \mathrm{range}(Z))$ denotes the largest canonical angle between $\mathrm{range}(Z)$ and $\mathrm{range}(Y)$. We use $\mathcal{L}(A)$ to denote the set of eigenvalues of A, and $\lambda_{\max}(A)$ and $\lambda_{\min}(A)$ to denote $\max \mathcal{L}(A)$ and $\min \mathcal{L}(A)$, respectively.

Furthermore, we assume that

$$\delta \equiv \min(\lambda_1^{(2)} - \varepsilon, \lambda_1^{(3)} - \eta) - 2\varepsilon - (\lambda_{k1}^{(1)} + \varepsilon) \gg \varepsilon, \tag{4.4}$$

$$\hat{\delta} = \delta\left(1 - \frac{2\varepsilon^2}{\delta^2}\right) + \lambda_{k1}^{(1)} + \varepsilon, \tag{4.5}$$

and as a consequence of (4.4) that $\delta > 2\varepsilon$.

THEOREM 4.1. *Let A be s.p.d. and have the eigendecomposition given in* (4.3)*, and let E, ε, η, δ, and $\hat{\delta}$ be defined as above. Then, there exists a matrix $\hat{Q}_1$ conforming to Q_1 such that* $\mathrm{range}(\hat{Q}_1)$ *is a simple invariant subspace of $A + E$, and*

$$\tan\theta_1\left(\mathrm{range}(Q_1), \mathrm{range}(\hat{Q}_1)\right) \le \frac{\varepsilon}{\hat{\delta}}.$$

Furthermore, for each eigenvalue $\hat{\lambda}_j^{(1)}$ of $A+E$ corresponding to the invariant subspace $\mathrm{range}(\hat{Q}_1)$*, there exists a value $\lambda_i^{(1)}$ such that*

$$|\hat{\lambda}_j^{(1)} - \lambda_i^{(1)}| \le \varepsilon + \frac{2\varepsilon^2}{\delta},$$

and in particular,

$$\lambda_{\max}(\,\hat{Q}_1^T(A+E)\hat{Q}_1\,) \le \lambda_{k1}^{(1)} + \varepsilon + \frac{2\varepsilon^2}{\delta}.$$

Proof. We consider the perturbation E, such that

$$Q^T(A+E)Q = \begin{pmatrix} \Lambda_1+\mathcal{E}_{11} & 0 & 0 \\ 0 & \Lambda_2+\mathcal{E}_{22} & \mathcal{E}_{32}^T \\ 0 & \mathcal{E}_{32} & \Lambda_3+\mathcal{E}_{33} \end{pmatrix} + \begin{pmatrix} 0 & \mathcal{E}_{21}^T & \mathcal{E}_{31}^T \\ \mathcal{E}_{21} & 0 & 0 \\ \mathcal{E}_{31} & 0 & 0 \end{pmatrix}. \tag{4.6}$$

By the assumptions above we also have

$$\left\| \begin{pmatrix} \mathcal{E}_{21} \\ \mathcal{E}_{31} \end{pmatrix} \right\|_F \le \varepsilon,$$

$\|\mathcal{E}_{11}\|_F \le \varepsilon$, $\|\mathcal{E}_{22}\|_F \le \varepsilon$, and $\|\mathcal{E}_{33}\|_F \le \eta$. From (4.6) we see that

$$\begin{aligned} L_1 \;&\equiv\; Q_1^T(A+E)Q_1 = \Lambda_1 + \mathcal{E}_{11}, \\ L_{23} \;&\equiv\; [Q_2\; Q_3]^T(A+E)[Q_2\; Q_3] = \begin{pmatrix} \Lambda_2+\mathcal{E}_{22} & \mathcal{E}_{32}^T \\ \mathcal{E}_{32} & \Lambda_3+\mathcal{E}_{33} \end{pmatrix}. \end{aligned}$$

From [33, Corollary IV.3.4] it follows that

$$\lambda_{\max}(\Lambda_1+\mathcal{E}_{11}) \le \lambda_{k1}^{(1)} + \|\mathcal{E}_{11}\| \le \lambda_{k1}^{(1)} + \varepsilon, \tag{4.7}$$

$$\lambda_{\min}(\Lambda_2+\mathcal{E}_{22}) \ge \lambda_1^{(2)} - \|\mathcal{E}_{22}\| \ge \lambda_1^{(2)} - \varepsilon, \tag{4.8}$$

$$\lambda_{\min}(\Lambda_3+\mathcal{E}_{33}) \ge \lambda_1^{(3)} - \|\mathcal{E}_{33}\| \ge \lambda_1^{(3)} - \eta. \tag{4.9}$$

Now we can apply [33, Corollary IV.3.4] once more to obtain

$$\lambda_{\min}(L_{23}) \ge \min(\lambda_1^{(2)} - \varepsilon, \lambda_1^{(3)} - \eta) - 2\varepsilon. \tag{4.10}$$

From (4.7)–(4.10) we have $\mathrm{sep}(L_1, L_{23}) > \delta$. Furthermore, let $R \equiv (A+E)Q_1 - Q_1L_1 = Q_2\mathcal{E}_{21} + Q_3\mathcal{E}_{31}$. Then, from symmetry it follows that $Q_1^T(A+E) - L_1Q_1^T = R^T$, and we have $\|R\|_F = \|R^T\|_F \le \varepsilon$. Finally, we have

$$\frac{\|R\|_F\|R^T\|_F}{\mathrm{sep}(L_1, L_{23})^2} \le \frac{\varepsilon^2}{\delta^2} < \frac{1}{4},$$

and by [33, Corollary V.2.2] we know there exists a matrix $\hat{Q}_1$ conforming to Q_1 such that $\mathrm{range}(\hat{Q}_1)$ is a simple invariant subspace of $A+E$, and

$$\tan\theta_1\left(\mathrm{range}(Q_1), \mathrm{range}(\hat{Q}_1)\right) \;\le\; \|\tan\Theta\left(\mathrm{range}(Q_1), \mathrm{range}(\hat{Q}_1)\right)\|_F \;\le\; 2\frac{\varepsilon}{\delta}. \tag{4.11}$$

Since A and $A+E$ are symmetric and we have established the existence of $\hat{Q}_1$, we can obtain a better bound using [33, Theorem V.3.10]. This theorem conforms nicely to our special case. However, we need to establish the minimal distance between eigenvalues of L_1 and the eigenvalues of $\hat{L}_{23} \equiv \hat{Q}_{23}^T(A+E)\hat{Q}_{23}$, where $\mathrm{range}(\hat{Q}_{23}) = \mathrm{range}(\hat{Q}_1)^\perp$ and $\hat{Q}_{23}$ has orthonormal columns. From [33, Theorem V.2.1] specialized to the symmetric case, we know there exists a matrix P, such that $\|P\|_F \le 2\varepsilon/\delta$ and

$\mathcal{L}(\hat{L}_{23}) = \mathcal{L}(L_{23} - P[\mathcal{E}_{21}^T\ \mathcal{E}_{31}^T])$. From $\|P[\mathcal{E}_{21}^T\ \mathcal{E}_{31}^T]\| \le 2\varepsilon^2/\delta$ and [33, Corollary IV.3.4], we have the following bound (with $\hat{\delta}$ defined in (4.5)):

$$\lambda_{\min}(\hat{L}_{23}) \ge \min(\lambda_1^{(2)} - \varepsilon, \lambda_1^{(3)} - \eta) - 2\varepsilon - \frac{2\varepsilon^2}{\delta} = \hat{\delta}. \tag{4.12}$$

Finally, we obtain from [33, Theorem V.3.10]

$$\tan\theta_1(\mathrm{range}(Q_1), \mathrm{range}(\hat{Q}_1)) \le \|\tan\Theta(\mathrm{range}(Q_1), \mathrm{range}(\hat{Q}_1))\|_F \le \frac{\varepsilon}{\hat{\delta}},$$

which is better than (4.11) by about a factor 2 or more. Analogously to (4.12) we observe from [33, Theorem V.3.10] that for each eigenvalue $\hat{\lambda}_j^{(1)}$ of $\hat{Q}_1^T(A+E)\hat{Q}_1$ there exists a number, $\lambda_i^{(1)}$, such that

$$|\hat{\lambda}_j^{(1)} - \lambda_i^{(1)}| \le \varepsilon + \frac{2\varepsilon^2}{\delta}.$$

In particular, this gives

$$\lambda_{\max}(\hat{Q}_1^T(A+E)\hat{Q}_1) \le \lambda_{k1}^{(1)} + \varepsilon + \frac{2\varepsilon^2}{\delta}. \qquad \square$$

Our numerical experiments confirm our conjecture except for a few GN steps, when the new matrix is quite far from previous ones. In those cases, the projection of E on the (smooth) invariant subspace corresponding to the smallest eigenvalues is still small, but $\|E\|$ is large enough that the invariant subspaces corresponding to large eigenvalues might perturb those corresponding to the smallest ones. Because of the problem size we cannot check the projection of E on invariant subspaces corresponding to medium or larger eigenvalues. However, Figures 4 and 9 include examples with relatively large canonical angles between invariant subspaces associated with the smallest eigenvalues for systems at the start of a line search.

5. Algorithm. Let us outline some aspects related to the optimization algorithm. We combine the GN algorithm with a line search. As we will see in the numerical results section, the final steps in each line search tend to be small. Therefore, the solutions obtained toward the end of each line search are not too different for a few GN iterations. However, over many GN steps they tend to differ more significantly; see Figure 2. An obvious way to exploit this is by using the solution of the previous step as a starting guess. However, this will work better or worse depending on whether the previous step was the first step of a line search, towards the start or the end of a line search, and so on. In practice, it is not easy to choose the best among several previous solutions as the best choice is governed by the progression of the algorithm (it is not necessarily the latest one). However, recycling a small subspace of previous solutions for the search space relieves this problem. In fact, we can vary this additional subspace depending on whether we are at the start of a line search or near the end and on how large the line search parameter is. We can also update this additional search space as we go. Strategies based on this approach turn out to be very effective; we will give more details later in this section when we discuss the application and the optimization algorithm. The idea to use previous solutions was also proposed in [16], although in [16] they were only used to provide a better initial guess.

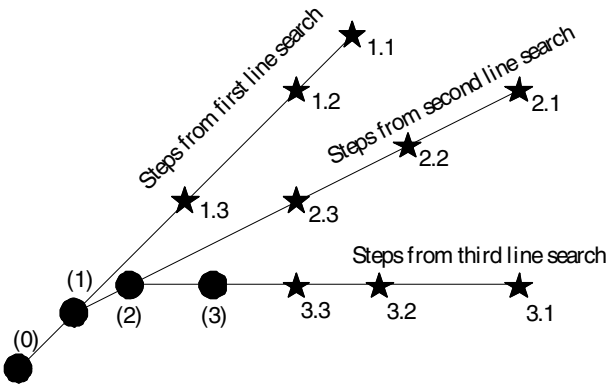

FIG. 2. *Conceptual overview of three complete steps of the GN with line search algorithm. The black circle marked* (0) *indicates the start of the overall procedure. The other black circles denote the end of a line search (the end of the first line search is marked* (1)*, etc.). The black stars denote the first and intermediate steps from each line search as indicated (the first step of line search* 1 *is indicated by* (1.1)*, etc.).*

The recycling strategy that we propose is based on the observations in the previous section. In particular, we use the proximity of certain invariant subspaces and tune which old solutions to recycle to the phase of the GN algorithm with line search.

5.1. Recycled GCRO for DOT. Consider the sequence of systems

$$A^{(j)}x_1^{(j)} = e_{m_1},$$

for the source $s = 1$. We will always recycle, in a matrix U, the most recent solution that occurred at the end of a line search. We may recycle previous solutions from within a particular line search. We do not know whether a line search is complete until after the corresponding system has been solved. However, before we solve a system, we can test whether we are "close" to the end of a line search. We assume this is the case if the relative residual norm of the current system for the solution at the end of the previous line search is below a certain threshold. This information helps to keep the smallest possible recycling space. It may not be necessary to keep a large approximate invariant subspace to reduce the initial residual over that part of the spectrum when we keep solutions in the recycle space that have the effect of reducing the residual over the same part of spectrum anyway (see the discussion in section 5.2).

To keep the notation as simple as possible, we begin by reviewing a basic GCRO algorithm that implements the recycling strategy mentioned above; then we discuss modifications that allow us to solve for multiple right-hand sides and multiple frequencies. Below, the MATLAB notation $[C, R] = qr(C, 0)$ is used to mean that C is overwritten with the orthogonal matrix from its compact QR factorization and R is the upper triangular factor.

ALGORITHM 1.

1. *Solve* $A^{(1)}x_1^{(1)} = e_{m_1}$ *with MINRES. Set* $x^{(curr)} = x_1^{(1)}, x^{(beg)} = []$.
2. *Form approximate eigenvectors for* $A^{(1)}$ *from information generated from the MINRES run. Save these eigenvectors in the matrix* W.

3. ***For*** $j = 2, \ldots$
   (a) ***If*** $(\|A^{(j)}x^{(curr)} - e_{m_1}\|/\|e_{m_1}\| \leq tol)$ ***and not at beginning of LS***
   $U = [W_{ind}, x^{(curr)}]$,
   Else
   $U = [W, x^{(curr)}, x^{(beg)}]$.
   (b) $A^{(j)}U = C$, $[C, R] = qr(C, 0)$, *set*[1] $U = UR^{-1}$.
   (c) *Compute* $x_0 = U(C^T e_{m_1})$. *(Ensures* x_0 *is optimal in the sense that the residual is minimized over all solutions in* range(U)*.)*
   (d) *Set* $P = (I - CC^T)$. *Compute* $r_0 = Pb$.
   (e) *Solve* $PA^{(j)}Pv = r_0$ *by MINRES.*[2]
   (f) *Update* x, r.
   (g) ***If*** *(at end of LS),* $x^{(curr)} = x_1^{(j)}$.
   (h) ***If*** *(at beginning of LS),* $x^{(beg)} = x_1^{(j)}$.

The index j is the index for the system within the GN algorithm, and therefore the loop on j terminates when GN converges for (3.2). Here, W_{ind} indicates that we may wish to keep fewer approximate eigenvectors according to the discussion preceding the algorithm (see also the discussion in section 5.2 and numerical example 1). The logic for tailoring the choice of the columns of U to the GN process comes from the discussion in the previous section. First, based on our observations for this application, we expect the approximate invariant subspace corresponding to the smallest eigenvalues of the first matrix to be close to an invariant subspace of other matrices in the GN sequence corresponding to the smallest eigenvalues. If the GN iteration is converging, we expect that at the end of two consecutive line searches the corresponding matrices will be related since the purpose of the line search is to produce a parameter update vector that allows the GN process to converge. Likewise, if we are at the beginning of a line search sequence, matrices from that sequence should be related, too. An analysis of the effect of these choices on the convergence of the MINRES steps is provided in the next subsection.

5.2. Algorithm analysis. Given that U always contains the matrix W, which we assume is a good approximation for the invariant subspace corresponding to the smallest eigenvalues for all the systems, we expect the systems in 3(e) to converge as if the smallest eigenvalues have been deflated from $A^{(j)}$. This is the case, in fact, as Theorem 4.1 from [26] (which closely follows Theorem 2.1 in [32]) implies.

Next, we consider the effect of keeping a previous solution, $x^{(curr)}$, in U. Let the current matrix U have n_c columns. For ease of discussion, we may assume that the first column of U is $x^{(curr)}$, since this does not change the orthogonal projector. Now, at the end of 3(b), we observe that $A^{(j)}x^{(curr)} = \rho_1 c_1$, where c_1 is the first column of C and ρ_1 an appropriate scaling. However, $x^{(curr)} = (A^{(k)})^{-1}e_{m_s}$ for some previous index k, and hence $A^{(j)}(A^{(k)})^{-1}e_{m_s} = \rho_1 c_1$. We have $A^{(j)}(A^{(k)})^{-1} = I + \tilde{E}$ for error matrix $\tilde{E} = -E_1(A^{(k)})^{-1} - E_2(A^{(k)})^{-1}$, with E_1, E_2 as the small norm and relatively small rank terms defined previously. Therefore,

$$\tilde{v} \equiv (I - c_1 c_1^T)e_{m_s} = e_{m_s} - c_1 c_1^T(\rho_1 c_1 - \tilde{E}e_{m_s}) = e_{m_s} - \rho_1 c_1 + c_1(c_1^T \tilde{E} e_{m_s}).$$

[1] From an implementation standpoint, we would not perform the matrix-matrix product UR^{-1}. Rather, we would keep R around, and when we needed to perform UR^{-1} times a vector, as in the next step, we would do backward substitution with R followed by multiplication with U. However, this explicit notation simplifies the introduction of the algorithm.

[2] Since all the Krylov vectors in the MINRES iteration are orthogonal to C, we do not need to apply P on the right. This choice of notation serves only to illustrate the symmetry of the matrix operator and therefore the applicability of MINRES.

Then the initial residual is $r_0 = (I - C_{n_c-1}C_{n_c-1}^T)\tilde{v}$, where C_{n_c-1} contains the remaining columns in C. Thus we have

$$\begin{aligned} r_0 &= (I - C_{n_c-1}C_{n_c-1}^T)(e_{m_s} - \rho_1 c_1) + (c_1^T \tilde{E} e_{m_s})c_1 \\ &= (I - C_{n_c-1}C_{n_c-1}^T)(A^{(k)} - A^{(j)})x^{(curr)} + (c_1^T \tilde{E} e_{m_s})c_1. \end{aligned}$$

The solution $x^{(curr)}$ is smooth and, as seen earlier, $A^{(k)} - A^{(j)}$ is small over the invariant subspace of $A^{(j)}$ corresponding to the smallest eigenvalues. Thus, the vector $e_{m_s} - \rho_1 c_1$ should already be small in norm. Since C_{n_c-1} contains approximate eigenvectors corresponding to the smallest (and smoothest) eigenvectors, then clearly r_0 will be even smaller in norm, particularly if $(e_{m_s} - \rho_1 c_1)$ lies predominately in the direction of these eigenvectors anyway. Furthermore, we have $c_1^T \tilde{E} e_{m_s} = -c_1^T E_1 x^{(curr)} - c_1^T E_2 x^{(curr)}$. The first term in this expression is small in norm. The second term must also be small, since E_2 lies predominantly in the direction corresponding to larger magnitude eigenvalues whereas $x^{(curr)}$ is smooth. In summary, not only do we observe that the norm of r_0 is small, but the smoothness properties ensure it is smallest in directions corresponding to the larger magnitude eigenvalues and that it has been reduced in directions corresponding to the smallest magnitude eigenvalues. This is demonstrated clearly by the reduction of the norm of the initial residual as the GN iteration progresses in Figures 7 and 12 and also by the eigenvector components of $r_0^{(j)}$ given in Figure 5. Hence, corrections to the residual occur primarily over the remaining subspace, which accounts for the convergence behavior observed in our numerical examples.

5.3. Multiple right-hand sides. The next consideration is the solution for multiple right-hand sides. First, we expand step 2 in Algorithm 1 to accommodate the right-hand sides. Once the first system for the first source has been solved, we have approximate eigenvector information. We can use this eigenvector information when we solve for the remaining right-hand sides, and we can also collect additional eigenvector information. Thus, the new step 2 becomes the following:

- Form approximate eigenvectors for $A^{(1)}$ from information generated from the MINRES run. Save these eigenvectors in the matrix W.
- **For** $s = 2, \ldots, N_s$
  - Set $U = W$.
  - Perform steps 3b–3e of Algorithm 1 (only updates of U and C).
  - Update $x_s^{(1)}$ with this information.
  - Add columns to W if desired.

Additional (approximate) invariant subspace information might be computed either from range(V_m) or from range($[U\, V_m]$). Then, to solve for $x_s^{(j)}$ for the remaining sources, we insert a loop over the remaining sources just after step 3 which would run over all s and contain steps 3(a)–3(h).

In this way, all the right-hand sides use a different last column (or two) in the U matrix, depending on the source. However, for every right-hand side, the first several columns of the U matrix are comprised of the (final) approximate eigenvector matrix W. Therefore, step 3(b) is cheaper for sources $s \geq 2$, since all but the last column (or two) of C were determined during the run on the first source.

5.4. Multiple shifts γ. To account for multiple frequencies, in step 3(e), we have $v_1 = (I - CC)^T e_{m_s}/\|(I - CC^T)e_{m_s}\|_2$ and the matrix recurrence (cf. (2.1))

$$AV_m = CB_m + V_{m+1}\underline{T}_m, \tag{5.1}$$

where $B_m = C^T A V_m$ and the leading $m \times m$ submatrix of $\underline{\mathrm{T}}_m$ is symmetric and positive definite. From this recurrence, we obtain

$$\begin{aligned}(A + i\gamma I)[V_m\ U] &= [V_{m+1}(\underline{\mathrm{T}}_m + i\gamma \underline{\mathrm{I}}_m) + CB_m\ \ C + i\gamma U] \\ &= [V_{m+1}\ \ C\ \ U] \begin{bmatrix} \underline{\mathrm{T}}_m + i\gamma \underline{\mathrm{I}}_m & 0 \\ B_m & I \\ 0 & i\gamma I \end{bmatrix} \\ &= [V_{m+1}\ \ C\ \ \hat{U}] \begin{bmatrix} I & 0 & V_{m+1}^T \hat{U} \\ 0 & I & C^T U \\ 0 & 0 & N \end{bmatrix} \begin{bmatrix} \underline{\mathrm{T}}_m + i\gamma \underline{\mathrm{I}}_m & 0 \\ B_m & I \\ 0 & i\gamma I \end{bmatrix},\end{aligned}$$

where the last step involves the reduced QR decomposition of $[V_{m+1}\ C\ U]$, so that $[V_{m+1}\ C\ \hat{U}]$ has orthonormal columns. Notice that $[V_{m+1}\ C]$ is already an orthogonal matrix. Restricting our approximate solutions to be in range$(U) \oplus$ range(V_m), we need to solve the small least squares problem

$$\begin{bmatrix} I & 0 & V_{m+1}^T U \\ 0 & I & C^T U \\ 0 & 0 & N \end{bmatrix} \begin{bmatrix} \underline{\mathrm{T}}_m + \gamma \underline{\mathrm{I}}_m & 0 \\ B_m & I \\ 0 & \gamma I \end{bmatrix} \begin{bmatrix} y \\ z \end{bmatrix} \approx \begin{bmatrix} \xi e_1 \\ C^T e_{m_s} \\ 0 \end{bmatrix}$$

for every choice of γ, and put $x_{s,\omega}^{(j)} = V_m y + U z$. This is equivalent to solving

$$\begin{bmatrix} \underline{\mathrm{T}}_m + i\gamma \underline{\mathrm{I}}_m & i\gamma V_{m+1}^T U \\ B_m & I + i\gamma C^T U \\ 0 & i\gamma N \end{bmatrix} \begin{bmatrix} y \\ z \end{bmatrix} \approx \begin{bmatrix} \xi e_1 \\ C^T e_{m_s} \\ 0 \end{bmatrix}. \tag{5.2}$$

This equation leads to an algorithm for updating the solutions to systems in which $\gamma \neq 0$. After step 3(e) in Algorithm 1, we insert the following piece of code:

ALGORITHM 2a: based on solving (5.2)

For each γ

- Solve (5.2) for $\begin{bmatrix} y \\ z \end{bmatrix}$.
- Set $x_{s,\omega}^{(j)} = V_m y + U z$.

Care must be taken in solving (5.2) if a subspace of range(U) is very close to an invariant subspace of $A^{(j)}$. In particular, if range(U) is an invariant subspace of $A^{(j)}$, then $U = C\Delta$, for some Δ. In this case, the least squares problems simplify considerably as both $V_{m+1}^T U = 0$ and $N = 0$. Hence, we need to solve only the following least squares problems (compare to (2.2)):

$$\begin{bmatrix} I + i\gamma\Delta & B_m \\ 0 & \underline{\mathrm{T}}_m + i\gamma \underline{\mathrm{I}}_m \end{bmatrix} \begin{bmatrix} z \\ y \end{bmatrix} \approx \begin{bmatrix} C^T e_{m_s} \\ \xi e_1 \end{bmatrix}. \tag{5.3}$$

Having to solve only (5.3) is the ideal situation because this problem can be solved as two separate minimization problems: the first to compute y, the second to compute z. However, we do not need y explicitly, only the products $V_m y$ and $B_m y = C^T A V_m y$, which can be obtained from short-term recurrences using a MINRES-type approach without keeping the vectors V_m around. The short-term recurrences are similar to the MINRES algorithm and therefore their derivation is left out for brevity.

ALGORITHM 2b: based on solving (5.3)

For each γ

- Determine $V_m y$ using short-term recurrences.

- Determine z.
- Set $x_{s,\omega}^{(j)} = V_m y + Uz$.

On the other hand, if the columns of U do not span an invariant subspace of $A^{(j)}$, we should solve (5.2). Unfortunately, there exists no short-term recurrence for $V_m y$ in this case, and thus we are forced to save the V_m in order to form $x_{s,\omega}^{(j)}$. However, for a fixed source, only one set of vectors V_m needs to be saved from which solutions at all other frequencies can be computed. Moreover, the generation of V_m itself requires only short-term recurrences, so no extra work is required.

We advocate Algorithm 2b when storage is at a premium and/or when we know that U is a good approximate invariant subspace, and Algorithm 2a otherwise.

We make one further modification to Algorithm 1 to solve these shifted systems simultaneously with the nonshifted systems. We change step 3(a) to append to U also the column $\text{imag}(x_{s,\omega}^{(curr)})$ and possibly $\text{imag}(x_{s,\omega}^{(beg)})$ depending on which part of the conditional statement is executed. The justification is as follows. Let $E = A^{(j)} - A^{(k)}$, and therefore $E = A_\omega^{(j)} - A_\omega^{(k)}$ as well. One can show that $A^{(j)}(x_s^{(j)} - x_s^{(k)}) = Ex_s^{(k)}$ and $A_\omega^{(j)}(x_{s,\omega}^{(j)} - x_{s,\omega}^{(k)}) = Ex_{s,\omega}^{(k)}$. Given the eigendecomposition $A^{(j)} = Q\Lambda Q^T$, we have

$$x_{s,\omega}^{(k)} = (A^{(k)} + i\gamma I)^{-1} e_{m_s} = \sum_\ell q_\ell \frac{q_\ell^T e_{m_s}}{\lambda_\ell + i\gamma},$$

where γ is reasonably small compared to the (real) eigenvalues λ_ℓ. Hence, the real part of $x_{s,\omega}^{(k)}$ is close to $x_s^{(k)}$, and the difference between $Ex_s^{(k)}$ and $Ex_{s,\omega}^{(k)}$ is primarily due to the (small) imaginary part of $x_{s,\omega}^{(k)}$. Since we look for solutions to the complex system in $\text{range}(U) \oplus \text{range}(V_m)$, it makes sense to include $\text{imag}(x_{s,\omega}^{(k)})$ in U.

We expect either algorithm to perform sufficiently well when $\gamma = h^2\omega/\nu$ is not too large in an absolute sense. In our application, γ will typically be less than or equal to $O(10^{-4})$, and we will not be solving the system for very many values of γ. This means that if MINRES had been applied directly to the shifted system, the number of iterations required for convergence would be about the same as the number of iterations required for the unshifted system. However, if γ is much larger, neither algorithm will necessarily produce solutions with a small relative residual norm. This stems from the fact that in solving the projected problem, we may leave out directions from the Krylov subspace in which the solutions to the complex systems have large components. On the other hand, if γ is very large relative to the smallest eigenvalue of the $A^{(j)}$ (which is not the case in our application), the eigenvalues of the shifted matrix will be well clustered. In the latter case, MINRES applied to this shifted problem would converge quickly, and recycling may not be necessary.

5.5. Computational issues. In this subsection, we briefly outline the computational complexity and storage issues associated with Algorithm 1 and its variants. We focus on overhead introduced by our algorithmic changes compared with MINRES. This overhead is offset by the reduction in iterations. Clearly, due to storage limitations we cannot have too many columns for U if the dimension of the problem is large. In addition, we must balance the cost of orthogonalizing the Krylov vectors against the columns of C with the reduction in the total number of iterations times the cost per iteration. If the cost of the matrix-vector product and preconditioning is large we can invest more time in orthogonalizations to reduce the number of iterations. In general, the idea is to find U with as few columns as possible such that the number of MINRES iterations is significantly reduced.

Computational cost. We consider only the complexity of computational steps that are linear in the size of the system matrix, i.e., $O(N)$. The costs of the various computations on small matrices, such as the solution of least squares problems and the computation of (selected) eigenvalues and eigenvectors, are negligible.

The main overhead introduced by our method compared with standard MINRES is the orthogonalization of each Krylov vector against the matrix C, indicated by the left multiplication by P in step 3(e) in Algorithm 1. Let the number of columns in C be n_c. Then the orthogonalizations introduce a cost of $4n_cN$ floating point operations (flops) per iteration. For each linear system, the initialization of x_0 and r_0 in 3(c) and 3(d) takes about $4n_cN$ flops, and the correction to the solution with the term $U(B_my)$, $x = (x_0 + V_my) - UB_my$ (see [10]), after the MINRES iteration, costs an additional $2n_cN$ flops. For each new matrix (but not for each right-hand side) we have the cost of n_c matrix-vector products and the cost of the QR decomposition of an N-by-n_c matrix (about $2n_c^2N$ flops) in 3(b). If k indicates the average number of nonzeros per row in the matrix, the cost for the matrix-vector products from which C is formed is $2n_ckN$ flops. However, these matrix-vector products have been accounted for in Figures 6 and 11, whereas they do not correspond to iterations. In that respect they actually represent a reduction in computational cost compared with MINRES. Note that, in general, the multiplication of the matrix times a block of vectors takes less time than multiplying each vector separately. Since we vary one or two columns in C for each right-hand side there are an additional one or two matrix-vector products per right-hand side.

Finally, we use the information generated by the solver for the first system matrix and a few right-hand sides to approximate invariant subspace information. If we approximate eigenvectors over range(V_m), the only $O(N)$ cost arises from constructing approximate eigenvectors for $A^{(1)}$ from the eigenvectors of the $m \times m$ leading principal submatrix of $\underline{T}_m$ (5.1) generated in the MINRES iteration. This costs approximately $2mN$ flops per approximate eigenvector, where m is the length of the MINRES run at the time the invariant subspace is computed. This may vary and need not be at the end of the MINRES run. Approximating eigenvectors over range($[V_m\ U]$) takes approximately $2(m + n_c)N$ flops per eigenvector plus $2(n_c^2 + mn_c)N$ flops to set up the generalized eigenvalue problem. Since the invariant subspace associated with the smallest eigenvalues changes only little in our application and high accuracy is not needed, this is done typically only for the first few eigenvectors for one of the matrices early in the GN iteration. Thus, these costs are incurred only once.

For Algorithm 2a, the only additional cost of $O(N)$ arises from the orthogonalization of the U matrix against the matrices V_{m+1} and C and an additional $2n_cN$ flops for updating the residual with the $\hat{U}$ component. For the solution there is no change in cost with respect to Algorithm 1. The additional cost of the orthogonalization is $2n_c(2m+3n_c)N$. Note that there is significant overlap with the computation of eigenvectors. Thus, in steps where eigenvectors are computed or updated the additional cost is negligible. Finally, note that the significant reduction in the number of iterations per right-hand side helps in reducing the actual overhead. For Algorithm 2b no additional costs arise. The matrix Δ is available from the computation of the invariant subspace.

Parallel implementation. Realistic problems from DOT are very large and therefore well suited to straightforward parallelization by distributing each matrix row-wise following a good domain partitioning. The special structure of the matrix (see section 4) allows this in spite of the factored form of the matrix. Therefore, the

parallel implementation of the algorithms outlined above can follow the discussion in, for example, [13, 12]. In addition, we could parallelize over the right-hand sides. This can be done with minor variations of the algorithms presented here. Since we can solve for multiple shifts with a single Krylov subspace, there is little benefit in parallelizing over the shifts.

6. Numerical results. In this section, we give the results of our proposed algorithm on two sequences of matrices generated from two different runs of the parametric nonlinear inversion scheme outlined previously. In the first experiment, a piecewise constant model for diffusion and absorption was used. In the second, we used a nonhomogenous model for the diffusion and absorption in the background whereas the diffusion and absorption inside the anomalies were constant. There were 16 sources and 32 detectors. In both experiments, the nonlinear inversion scheme was run using only data for the 0 frequency case; however, we apply our algorithm to both the 0 frequency case and shifted systems at 5 MHz in order to test our algorithm. The region was discretized[3] into $31 \times 31 \times 21$ voxels of volume h^3, with $h = .2$ cm. The sizes of the matrices in both experiments were $18{,}259 \times 18{,}259$. The sources and detectors were located in a 3 cm $\times$ 3 cm plane over the center of the grid. The starting guesses for the ellipsoids describing the anomaly were the largest possible ellipsoids fitting in the 3 cm $\times$ 3 cm $\times$ 4 cm region under the sources. Starting guesses for the other parameters were then obtained by fixing the shape parameters and using 1–5 GN steps to find the best values for those starting ellipsoids.

All experiments were conducted in MATLAB using IEEE double precision floating point arithmetic.

6.1. Experiment 1. We ran our algorithm on the first 40 systems that were generated by a damped GN run trying to reconstruct piecewise constant absorption and diffusion images. Systems numbered 2, 5, 7, 10, 13–19 (odd), 22–40 (even) correspond to the beginning of a line search; systems numbered 4, 6, 9, 12, 14–18 (even), 21–41 (odd) correspond to the end of a line search; and the remaining systems correspond to the middle of a line search.

First, we test our hypothesis that the invariant subspaces corresponding to the smallest eigenvalues of these matrices do not change much, whether we compare within a line search or across line searches. Recall that if the columns of $W^{(j)}$ form an orthonormal basis for the eigenspace associated with the smallest M eigenvalues for matrix $A^{(j)}$, and the same holds for $W^{(k)}$ and $A^{(k)}$, then the cosines of the canonical angles between range$(W^{(k)})$ and range$(W^{(j)})$ are given by [33, Corollary I.5.4]

$$\cos\Theta[\text{range}(W^{(j)}), \text{range}(W^{(k)})] = \Sigma[(W^{(j)})^T W^{(k)}],$$

where $\Sigma[V]$ denotes the singular values of the argument V. The sines of the canonical angles are therefore $\sqrt{1-\sigma_i^2}$, where the σ_i denote the cosines of the canonical angles. In Figure 3, we display the sines of the canonical angles between pairs of subspaces corresponding to the smallest eigenvalues of matrices. We observe that the invariant subspaces corresponding to the smallest eigenvalues are in fact relatively close, as predicted by Theorem 4.1. The plots for the sines with $M = 3$ and $M = 12$ illustrate the relative insensitivity of the invariant subspaces corresponding to the smallest 3 and smallest 12 eigenvalues, respectively. The indices have no correspondence with

[3]These experiments represent small test cases designed to test the regularization scheme itself. Ideal practical implementations of the inversion routine, which are not feasible without fast forward solvers such as those we present here, will require voxelations giving millions of unknowns.

the eigenvectors themselves, nor do the canonical angles reflect the angles between corresponding eigenvectors. The values of j and k in the pictures were selected to illustrate the fact that the relevant invariant subspaces of matrices corresponding to (final) updates in the GN process remain fairly close to each other (e.g., 1 and 4, 4 and 6), whereas those from matrices from distinct phases in the line search differ more (e.g., 1 and 5, 1 and 10). Nevertheless, even these do not differ that much, particularly if a larger dimensional invariant subspace is used. The smallest 12 eigenvalues of $A^{(j)}$ for $j = 1, 2, 3$ are given in Figure 4.

We tested Algorithm 1, adjusted according to section 5.3 for the multiple right-hand side problem for zero frequency, and also adjusted for an additional nonzero frequency of $\omega = 5$ MHz using Algorithms 2a and 2b. For the first 6 right-hand sides in the initial phase of Algorithm 1, we saved 2 harmonic Ritz vectors at the end of each MINRES run to approximate the invariant subspace of $A^{(1)}$ corresponding to the 12 smallest eigenvalues. We used a threshold value of 10^{-3}, derived by trial and error, to distinguish between the beginning of a line search step and steps near the end. The left plot in Figure 5 shows the magnitudes of the spectral coefficients of the initial residuals for systems 2 through 5 which correspond to the 50 smallest eigenvalues, while the right plot gives the magnitudes corresponding to the 50 largest eigenvalues. Systems 2, 3, and 4 are all from the same line search, and we observe that the spectral

components decrease by roughly one order of magnitude with each system. System 5 corresponds to the beginning of a new line search whose matrix and solution are not as close to those from the first line search. We observe a corresponding increase in the magnitudes of the spectral coefficients over the small eigenvalues, whereas a comparison of the figures shows that the initial residual is typically smaller over the subspace corresponding to the largest eigenvalues. This behavior is consistent both with the analysis of the initial residual in section 5.2 and with the observed convergence behavior for system 5 in the sense that the solver must work harder to reduce the residual significantly over these components.

Figure 6 gives the total number of matrix-vector products to solve each system using our recycling algorithm. This number includes the matrix-vector products required to compute the columns of C. Note that these represent a lower computational cost than actual iterations. The residuals for all the real systems were required to have a relative norm of 10^{-6}. Note the savings in matrix-vector products for the

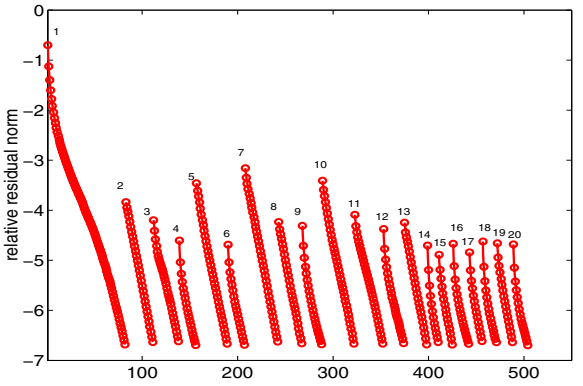

FIG. 7. *Experiment* 1. *Relative residual norms are displayed for the first* 20 *systems, source* 1.

right-hand sides other than the first of a single system, because most of the columns of C are computed only once for each s. Moreover, the projection has the desired effect of reducing the total number of iterations required for the projected system.

For comparison purposes, we note that if we used MINRES with a zero starting guess for every system and right-hand side, the number of matrix-vector products would be roughly constant at about 81 iterations for each system. Even MINRES with the solution at the end of the most recent line search as a starting guess could not achieve the reduction in the number of iterations we achieve with our algorithm, as demonstrated in Figure 6. Additionally, the matrix-matrix product $(A^{(j)}U)$ performed prior to running MINRES on the projected system runs faster than the equivalent number of matrix-vector products performed inside (unprojected) MINRES.

The relative residual norms for the first 20 systems, for source 1, are given in Figure 7. Note the convergence rate becomes higher and the initial relative residual norm becomes smaller as we move through one sequence of systems in a line search.

The plot in Figure 8 illustrates the relative residual norms that are achieved when solving the complex system with $\omega = 5$ MHz when Algorithms 2a and 2b are used to update the complex solution vectors. In neither case do we exactly attain a relative residual norm of 10^{-6}, the stopping criterion for the corresponding real

system. However, for our application we feel this is sufficient, and perhaps more than sufficient since the measured data that defines the least squares problem contains noise at a level several orders of magnitude larger than 10^{-6}. On the other hand, we need to take the (unknown) conditioning of the algebraic system into account. Since previous solutions occur in the U matrix, this accounts for the slight upward creep of the graphs toward the end of the sequence of systems.

6.2. Experiment 2. In this experiment, the background diffusion and absorption were generated to have a "lumpy" variation [20], and thus the matrices that were generated correspond to piecewise continuous, rather than piecewise constant, absorption and diffusion. The total number of GN steps was 24 and the total number of system matrices was 51. For the first 40 systems the indices corresponding to the beginning of a line search are 2, 5, 8, 10, 13–39 (odd), while indices corresponding to the end of a line search are 4 ,7, 9, 12, 14–40 (even).

The sines of the canonical angles between different pairs of invariant subspaces associated with the smallest eigenvalues and for different subspace dimensions are given in Figure 9. In Figure 10 the smallest 12 eigenvalues are displayed. Consistent with Theorem 4.1 and our conjecture that the changes in the matrices are concentrated

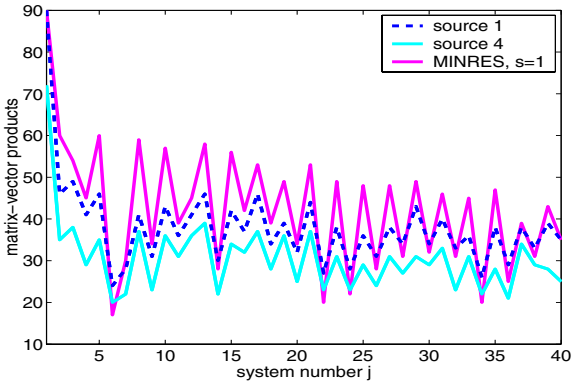

FIG. 11. *Experiment* 2. *Number of matrix-vector products per system solve for systems* 1:40 *and sources* 1 *and* 4. *The number of matrix-vector products for source* 4 *is representative of all sources after source* 1. *For comparison we give the number of matrix-vector products required for MINRES on the systems for source* 1 *where the starting guesses for each system were the solutions at the end of the most recent line search. Without subspace recycling, these numbers for source* 1 *are representative for all sources.*

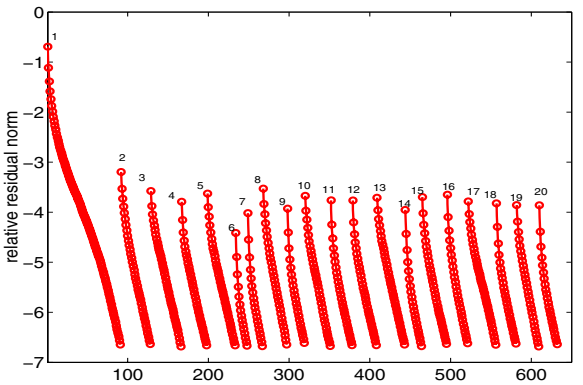

FIG. 12. *Experiment* 2. *Relative residual norms for systems* 1 *to* 20, *source* 1.

in the invariant subspaces corresponding to higher frequencies (larger eigenvalues), the smallest eigenvalues remain in disjoint clusters.

Figures 9 and 10 seem to indicate that the smallest 8 or so eigenvalues correspond to an invariant subspace that remains well separated from its orthogonal complement. Therefore, in the initialization phase of Algorithm 1, we added two vectors to W corresponding to the smallest harmonic Ritz values of $\tilde{T}_m$ (i.e., the matrix in (5.3) with $\gamma = 0$) for each of the first 4 sources. In Figure 11, we see the effect of keeping these 8 columns plus the other vectors proposed in section 5.3. In this experiment, $W_{ind} = W$, and a threshold value was used to distinguish the phase within the line search. Just as for the first experiment, note the savings in matrix-vector products for the right-hand sides after the first for a single system. Again, we compare our results to MINRES with $x^{(curr)}$ from Algorithm 1 as the starting guess.

Relative residual norms for Algorithm 1 for the first 20 systems for source 1 are given in Figure 12. We observe an increased rate of convergence and smaller initial residuals in the course of a line search.

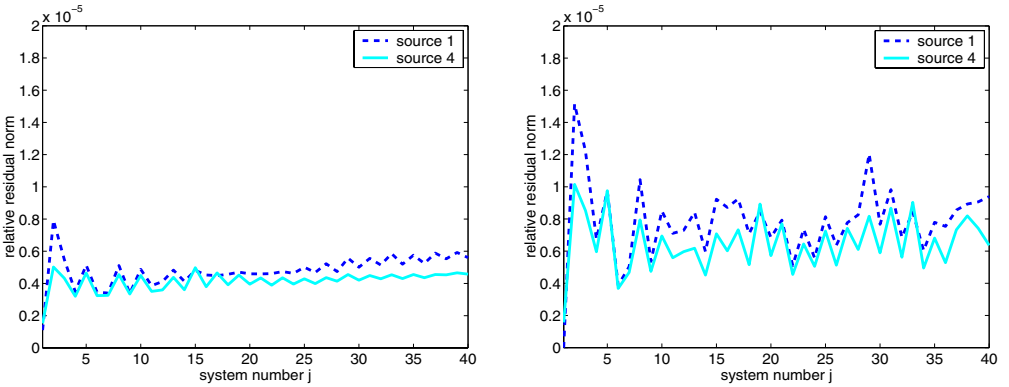

FIG. 13. *Experiment* 2. *Left: Relative residual norms for systems* 1 *to* 40*, sources* 1 *and* 4*,* $\omega = 5$ *MHz using Algorithm* 2a. *Right: Relative residual norms for systems* 1 *to* 40*, sources* 1 *and* 4*,* $\omega = 5$ *MHz using Algorithm* 2b.

Finally, the relative residual norms for the complex systems at $\omega = 5$ MHz are given in Figure 13 for Algorithm 2a and 2b. In general, the behavior is more uniform for these systems versus those in the first experiment since the invariant subspaces corresponding to the small eigenvalues among the matrices are more closely related.

7. Conclusions and future work. We have discussed various strategies for Krylov subspace recycling to improve the convergence of linear solvers for a sequence of slowly changing linear systems arising in computations for optical tomography. We have combined strategies of recycling approximate invariant subspaces and strategies of recycling subspaces from previous solutions. Furthermore, our algorithms are based on a careful analysis of which strategy is most useful at each stage of the optimization algorithm. This analysis also takes the underlying application, DOT, and matrix symmetry into account. Additionally, we have adapted the GCRO algorithm to combine subspace recycling with solving for multiple shifted systems using a single Krylov subspace. Our numerical results, based on two model problems for DOT, show that our strategies are quite effective. Although we have focused on a particular application and optimization algorithm, we feel that this approach to tuning the linear solver is applicable generally to problems where many linear systems must be solved.

Important future work includes the study of how characteristics of the matrices arising in DOT, such as invariant subspaces and eigenvalues, change for small changes in model parameters. This may lead to further improvements for linear solvers and also improved line search strategies for the nonlinear solver. This issue is, of course, equally important for other applications where we must solve a long sequence of slowly changing problems, such as crack propagation [26]. Future work will combine modeling aspects from applications with matrix theory. Other useful extensions that we plan to research are the use of GCROT-like techniques [11] to measure the effectiveness of the recycled subspace and update the space accordingly, to combine our current algorithms with a block approach [37], and to further tune the nonlinear algorithm, in particular the line search.

Acknowledgment. We would like to thank the referees for their comments, which helped us to improve the presentation of this paper.

BOUNDING THE SOLUTIONS OF PARAMETER DEPENDENT NONLINEAR ORDINARY DIFFERENTIAL EQUATIONS*

ADAM B. SINGER† AND PAUL I. BARTON†

Abstract. This paper presents two techniques for generating rigorous bounds on the solution of parameter dependent nonlinear ordinary differential equations. The first technique is an extension of differential inequalities that enables the construction of tight time varying state bounds by utilizing prior knowledge of the solution of the differential equations. The second technique provides a method for constructing pointwise in time convex and concave relaxations of the image of the solution of a system of parameter dependent differential equations on subsets of a Euclidean space. Two examples are presented to demonstrate the construction of the bounds. The examples include a brief discussion of a computer program written to automatically generate the bounds.

Key words. differential inequalities, dynamic optimization, convex relaxations

1. Introduction.

Many applications involve the study of nonlinear ordinary differential equations (ODEs) dependent on parameters:

$$\dot{\mathbf{x}} = \mathbf{f}(t, \mathbf{x}, \mathbf{p}), \quad \mathbf{x}(t_0) = \mathbf{x}_0(\mathbf{p}), \tag{1.1}$$

where $\mathbf{x}(t, \mathbf{p}) \in \mathbb{R}^{n_x}$ and $\mathbf{p} \in P \subset \mathbb{R}^{n_p}$. This paper studies two distinct problems concerning bounds on the solutions $\mathbf{x}(t, \mathbf{p})$ for $\mathbf{p} \in P$. The first problem concerns computing tight time varying state bounds $\mathbf{x}^L(t)$ and $\mathbf{x}^U(t)$ containing the image of $\mathbf{p}$ under the solution of (1.1). The second issue concerns deriving pointwise in time convex underestimators and concave overestimators on P of the solution of (1.1). The original motivation for studying both issues stems from the development of algorithms for global optimization with ODEs embedded [8]; for linear systems, we have already addressed both issues [8]. This paper focuses exclusively on the theory for generating bounds for nonlinear parameter dependent differential equations; application of this theory to global optimization problems is found in [7].

The majority of research concerning the bounding of differential equations originated with the study of differential inequalities. While the roots of differential inequalities may be traced to the early part of the 20th century, the book by Walter [11] provides an excellent overview of the salient concepts. One important application of differential inequalities is computing time varying lower and upper bounds on the solution of systems of ODEs. Essentially, the analysis demonstrates that solving differential equations whose right-hand sides underestimate the right-hand sides of the original system at all points including the initial condition provides rigorous lower bounds for the original state variables. An analogous result applies to constructing upper bounds. Harrison [2] extended these results from Walter to parameter embedded ODEs. Unfortunately, except under stringent conditions of quasimonotonicity,

the bounds generated via differential inequalities are typically weak and often suffer from bound explosion, a situation in which the solution of the bounding differential equations tends rapidly toward infinity, hence rendering the resulting bounds effectively useless on some time scales of interest.

The remainder of the paper is divided into five sections. In the first section, a method is presented for computing tight time varying state bounds for a system of ODEs, given prior information concerning the evolution of the solution to the ODEs. Utilizing the tight state bounds, the second section details a technique for generating pointwise in time parameter dependent convex and concave relaxations for the solution of parameter dependent ODEs. Next, an illustrative example is presented demonstrating the application of the state bounding theory. As will be evidenced, the application of the theory is complex even for small problems. The next section briefly discusses a program, GDOC, that was developed to automate the application of the theory; the program utilizes code generation. Finally, a short section applies GDOC to an analytically intractable nonlinear problem to generate a convex and concave relaxation.

2. Time varying state bounds. As previously mentioned, the theory of differential inequalities provides a method for computing time varying bounds on the solution of a system of differential equations. In particular, we are interested in computing a superset of the image of the solution of a system of ODEs on a parameter set. The traditional techniques such as Harrison's technique depend exclusively on information obtained from the mathematical statement of the differential equations and their corresponding initial conditions. However, differential equations of practical interest to scientists and engineers are derived from physical systems for which more information is known about the behavior of the system dynamics than the information embodied by the differential equations alone. For example, for a system undergoing decay, the state never exceeds its initial condition. In another example, differential equations modeling mass and heat transfer obey conservation principles. In this section, we demonstrate how these natural bounds and differential invariants may be applied in conjunction with differential inequalities to produce tight bounds on the solution of ODEs. We make one very important note before beginning this discussion, which is that this technique is not applicable to bounds imposed upon the system such as path constraints or bounds on a control variable. The technique is only applicable given additional information that naturally governs the evolution of the solution of the ODEs.

For the duration of this paper, two relatively mild assumptions are made concerning the solution of the ODEs. First, we assume that a solution exists and is unique for each $\mathbf{p} \in P$. This assumption permits the use of regular inequalities rather than strict inequalities in the results. Second, we assume that the ODEs possess a solution in the sense of Carathéodory. That is, an admissible solution is one that satisfies the ODEs almost everywhere (a.e.). Therefore, this assumption immediately implies that our derivative exists everywhere except possibly on a set of measure zero. This exception poses no difficulty, for at points where the derivative does not exist, we can either replace the derivative with the Dini derivative or simply remove the points of nonexistence by extending the function by continuation without altering the solution of the ODEs. We begin by presenting a slight variant of a fundamental lemma from Walter [11].

LEMMA 2.1. *Suppose the vector functions $\boldsymbol{\varphi}(t)$ and $\boldsymbol{\psi}(t)$ are differentiable a.e. in $(t_0, t_f]$. For some index i and fixed $\underline{t} \in (t_0, t_f]$, if $\dot{\varphi}_i(\underline{t}) < \dot{\psi}_i(\underline{t})$ when $\boldsymbol{\varphi}(\underline{t}) \leq \boldsymbol{\psi}(\underline{t})$,*

$\varphi_i(\underline{t}) = \psi_i(\underline{t})$, then we have precisely one of the following two cases:

(i) $\boldsymbol{\varphi} < \boldsymbol{\psi}$ *in* $(t_0, t_f]$,

(ii) $\boldsymbol{\varphi}(t_{0^+}) < \boldsymbol{\psi}(t_{0^+})$ *does not hold; i.e., there exists an arbitrary small* $\bar{t} \in (t_0, t_f]$ *such that* $\varphi_i(\bar{t}) \geq \psi_i(\bar{t})$ *for at least one index* i.

Proof. For the proof, see Lemma 12.I in [11]. □

Remark 2.2. Clearly, a symmetric result for $\boldsymbol{\varphi} > \boldsymbol{\psi}$ holds.

We wish to extend Lemma 2.1 to a method for bounding the solution of (1.1) given prior knowledge concerning some set $\overline{\mathcal{X}}(t, \mathbf{p})$ containing the solution of (1.1). For example, given an ODE that describes the consumption of a chemical species, the set $\overline{\mathcal{X}}(t, \mathbf{p})$ could be defined as $[0, x(t_0, \mathbf{p})]$, where x is the concentration of a chemical species. The derivation is performed in several steps. First, we present an extension of Walter's fundamental result concerning the construction of superfunctions and subfunctions, given the set $\overline{\mathcal{X}}(t, \mathbf{p})$. From this fundamental theorem, two corollaries are constructed. The first corollary extends the result to differential equations with embedded parameters and yields a parameter dependent solution for which the inequality holds pointwise in the parameter. A second corollary follows, which illustrates a method for constructing a solution valid for all parameter values in a given set. This second corollary yields the desired result which bounds the image of the solution to a parameter embedded ODE on a subset of a Euclidean space.

THEOREM 2.3. *Let* $\mathbf{x}(t)$ *be a solution of*

$$\dot{\mathbf{x}} = \mathbf{f}(t, \mathbf{x}), \quad \mathbf{x}(0) = \mathbf{x}_0 \tag{2.1}$$

in $(t_0, t_f]$, *and further suppose that* $\mathbf{x}(t) \in \overline{\mathcal{X}}(t)$, *where* $\overline{\mathcal{X}}(t)$ *is known independently from the solution of* (2.1). *For* $i = 1, \ldots, n_x$, *if*

(i) $\mathbf{v}(t_0) < \mathbf{x}(t_0) < \mathbf{w}(t_0)$

and if $\forall\ \mathbf{v}(t), \mathbf{w}(t) \in G(t)$,

(ii) $\dot{v}_i = g_i(t, \mathbf{v}, \mathbf{w}) < \inf_{\substack{\mathbf{z} \in \overline{\mathcal{X}}(t) \cap G(t) \\ z_i = v_i(t)}} f_i(t, \mathbf{z})$,

(iii) $\dot{w}_i = h_i(t, \mathbf{v}, \mathbf{w}) > \sup_{\substack{\mathbf{z} \in \overline{\mathcal{X}}(t) \cap G(t) \\ z_i = w_i(t)}} f_i(t, \mathbf{z})$,

where $G(t) = \{\mathbf{z} \mid \mathbf{v}(t) \leq \mathbf{z} \leq \mathbf{w}(t)\}$, *then*

$$\mathbf{v}(t) < \mathbf{x}(t) < \mathbf{w}(t) \quad \forall\ t \in (t_0, t_f].$$

Proof. Hypotheses (i), (ii), and (iii) guarantee that if there exists some $\underline{t} \in (t_0, t_f]$ such that $\mathbf{v}(\underline{t}) \leq \mathbf{x}(\underline{t}) \leq \mathbf{w}(\underline{t})$, $v_i(\underline{t}) = x_i(\underline{t}) = w_i(\underline{t})$ for some index i, we have

$$\dot{v}_i = g_i(\underline{t}, \mathbf{v}, \mathbf{w}) < \inf_{\substack{\mathbf{z} \in \overline{\mathcal{X}}(t) \cap G(t) \\ z_i = v_i(t)}} f_i(\underline{t}, \mathbf{z}) \leq f_i(\underline{t}, \mathbf{x}) = \dot{x}_i,$$

$$\dot{w}_i = h_i(\underline{t}, \mathbf{v}, \mathbf{w}) > \sup_{\substack{\mathbf{z} \in \overline{\mathcal{X}}(t) \cap G(t) \\ z_i = w_i(t)}} f_i(\underline{t}, \mathbf{z}) \geq f_i(\underline{t}, \mathbf{x}) = \dot{x}_i,$$

where the last inequality in each equation above holds because we have already established $\mathbf{x}(\underline{t}) \in G(\underline{t})$, and $\mathbf{x}(\underline{t}) \in \overline{\mathcal{X}}(\underline{t})$ by hypothesis. We have now established the hypothesis of Lemma 2.1 and therefore know that either Lemma 2.1(i) or 2.1(ii) holds. However, (i) is inconsistent with 2.1(ii). □

Remark 2.4. By asserting uniqueness of the solution of the differential equations, the hypotheses of the above theorem may be relaxed to

(i) $\mathbf{v}(t_0) \leq \mathbf{x}(t_0) \leq \mathbf{w}(t_0)$,

(ii) $\dot{v}_i = g_i(t,\mathbf{v},\mathbf{w}) \leq \inf\limits_{\substack{\mathbf{z}\in\overline{\mathcal{X}}(t)\cap G(t)\\ z_i=v_i(t)}} f_i(t,\mathbf{z})$,

(iii) $\dot{w}_i = h_i(t,\mathbf{v},\mathbf{w}) \geq \sup\limits_{\substack{\mathbf{z}\in\overline{\mathcal{X}}(t)\cap G(t)\\ z_i=w_i(t)}} f_i(t,\mathbf{z})$

(see Remarks 12.X in [11]). Furthermore, by asserting regular inequalities above, the result of the theorem also permits $\mathbf{v}(t) \leq \mathbf{x}(t) \leq \mathbf{w}(t)\ \forall\ t \in (t_0, t_f]$. For the remainder of this paper, since uniqueness of the solution of the differential equations has been assumed, it is understood that reference to Theorem 2.3 refers also to the regular inequalities in this remark.

The following corollary extends Theorem 2.3 to pointwise in $\mathbf{p}$ bounds for (1.1). While not needed for bounding the solution of a parameter dependent differential equation, Corollary 2.5 is needed directly for proving the results on convex bounding in the subsequent section.

COROLLARY 2.5. *Let* $\mathbf{x}(t,\mathbf{p})$ *be a solution of* (1.1)*, and let* $\mathbf{x}(t,\mathbf{p}) \in \overline{\mathcal{X}}(t,\mathbf{p})$ *for each* $\mathbf{p} \in P$*, where* $\overline{\mathcal{X}}(t,\mathbf{p})$ *is known independently from the solution of* (1.1)*. If for* $i = 1,\ldots,n_x$ *and for each* $\mathbf{p} \in P$

(i) $\mathbf{v}(t_0,\mathbf{p}) \leq \mathbf{x}(t_0,\mathbf{p}) \leq \mathbf{w}(t_0,\mathbf{p})$,

and if $\forall\ \mathbf{v}(t,\mathbf{p}), \mathbf{w}(t,\mathbf{p}) \in \overline{\mathcal{X}}(t,\mathbf{p}) \cap G(t,\mathbf{p})$,

(ii) $\dot{v}_i = g_i(t,\mathbf{v},\mathbf{w},\mathbf{p}) \leq \inf\limits_{\substack{\mathbf{z}\in\overline{\mathcal{X}}(t,\mathbf{p})\cap G(t,\mathbf{p})\\ z_i=v_i(t,\mathbf{p})}} f_i(t,\mathbf{z},\mathbf{p})$,

(iii) $\dot{w}_i = h_i(t,\mathbf{v},\mathbf{w},\mathbf{p}) \geq \sup\limits_{\substack{\mathbf{z}\in\overline{\mathcal{X}}(t,\mathbf{p})\cap G(t,\mathbf{p})\\ z_i=w_i(t,\mathbf{p})}} f_i(t,\mathbf{z},\mathbf{p})$,

where $G(t,\mathbf{p}) = \{\mathbf{z} \mid \mathbf{v}(t,\mathbf{p}) \leq \mathbf{z} \leq \mathbf{w}(t,\mathbf{p})\}$*, then for each fixed* $\mathbf{p} \in P$*,*

$$\mathbf{v}(t,\mathbf{p}) \leq \mathbf{x}(t,\mathbf{p}) \leq \mathbf{w}(t,\mathbf{p}) \qquad \forall\ t \in (t_0, t_f].$$

Proof. Theorem 2.3 holds for any fixed $\mathbf{p} \in P$. □

The following corollary is the fundamental result for bounding the image of a parameter embedded differential equation on the parameter set P. The resulting bounding equations are not necessarily exact. That is, the derived bounding set may actually be a superset of the true image of the solution on P.

COROLLARY 2.6. *Let* $\mathbf{x}(t,\mathbf{p})$ *be a solution of* (1.1)*, and let* $\mathbf{x}(t,\mathbf{p}) \in \overline{\mathcal{X}}(t,\mathbf{p})$ *for each* $\mathbf{p} \in P$*, where* $\overline{\mathcal{X}}(t,\mathbf{p})$ *is known independently from the solution of* (1.1)*. Furthermore, let* $\overline{\mathcal{X}}(\underline{t})$ *be defined pointwise in time by*

$$\overline{\mathcal{X}}(\underline{t}) = \left[\inf_{\mathbf{q}\in P} \overline{\mathcal{X}}(\underline{t},\mathbf{q}),\ \sup_{\mathbf{q}\in P} \overline{\mathcal{X}}(\underline{t},\mathbf{q})\right].$$

If for $i = 1,\ldots,n_x$*,*

(i) $\mathbf{v}(t_0) \leq \inf\limits_{\mathbf{q}\in P} \mathbf{x}(t_0,\mathbf{q})$,

(ii) $\mathbf{w}(t_0) \geq \sup\limits_{\mathbf{q}\in P} \mathbf{x}(t_0,\mathbf{q})$,

and if $\forall\ \mathbf{v}(t), \mathbf{w}(t) \in G(t)$

(iii) $\dot{v}_i = g_i(t,\mathbf{v},\mathbf{w}) \leq \inf\limits_{\substack{\mathbf{z}\in\overline{\mathcal{X}}(t)\cap G(t),\ \mathbf{q}\in P\\ z_i=v_i(t)}} f_i(t,\mathbf{z},\mathbf{q})$,

(iv) $\dot{w}_i = h_i(t,\mathbf{v},\mathbf{w}) \geq \sup\limits_{\substack{\mathbf{z}\in\overline{\mathcal{X}}(t)\cap G(t),\ \mathbf{q}\in P\\ z_i=w_i(t)}} f_i(t,\mathbf{z},\mathbf{q})$,

then

$$\mathbf{v}(t) \leq \mathbf{x}(t, \mathbf{p}) \leq \mathbf{w}(t) \qquad \forall\ (t, \mathbf{p}) \in (t_0, t_f] \times P.$$

Proof. The proof is a trivial extension of the proof of Theorem 2.3. □

Remark 2.7. Because the functions $\mathbf{v}$ and $\mathbf{w}$ from the above corollary bound $\mathbf{x}(\cdot, \mathbf{p})$ for all values of $\mathbf{p} \in P$, when used in the above context, these state bounds are labeled $\mathbf{x}^L$ and $\mathbf{x}^U$, respectively. Pointwise in time, we label the interval $[\mathbf{x}^L(\underline{t}), \mathbf{x}^U(\underline{t})]$ as $\mathcal{X}(\underline{t})$ for each fixed $\underline{t} \in (t_0, t_f]$.

From inspection of Corollary 2.6, the most difficult aspect of applying the corollary appears to be bounding the solutions of the parametric optimization problems defining the right-hand sides of the bounding differential equations. While computing the exact solution to the optimization problem would yield the tightest bounds possible from this method, actually solving the optimization problems at each integration step in a numerical integration would be a prohibitively expensive task. Instead, the solution of the optimization problem on the right-hand side of the differential equation is estimated by interval arithmetic [5] pointwise in time. To apply interval arithmetic, the set $\overline{\mathcal{X}}(\underline{t}) \cap G(\underline{t})$ must be representable as an interval pointwise in time. For some fixed $\underline{t} \in (t_0, t_f]$, let $\overline{\mathcal{X}}(\underline{t}) = [\overline{\mathbf{x}}^L(\underline{t}), \overline{\mathbf{x}}^U(\underline{t})]$; then pointwise in time, the set $\overline{\mathcal{X}}(\underline{t}) \cap G(\underline{t})$ is given by

$$[\max\{\overline{x}_1^L(\underline{t}), x_1^L(\underline{t})\}, \min\{\overline{x}_1^U(\underline{t}), x_1^U(\underline{t})\}] \times \cdots \times [\max\{\overline{x}_{n_x}^L(\underline{t}), x_{n_x}^L(\underline{t})\}, \min\{\overline{x}_{n_x}^U(\underline{t}), x_{n_x}^U(\underline{t})\}].$$

We note that, given an inclusion monotonic interval function [5] for the right-hand sides of the differential equation, the bounds approach the original function when the parameter space approaches degeneracy. Therefore, satisfying the right-hand side of the bounding differential equations is a relatively straightforward task.

Another interesting aspect of formulating the bounding differential equations as constrained optimization problems is that these optimization problems may have no feasible point. Assume that such an infeasibility occurs in the bounding problem for the ith variable. Such infeasibilities usually arise from the equality constraint on the ith variable. This situation immediately implies that the ith bound lies outside the set $\overline{\mathcal{X}}(t)$. In this case, any finite value for the right-hand side of the differential equation is valid, for any finite instantaneous rate of change in the ith bounding variable ensures that the bound remains outside $\overline{\mathcal{X}}(t)$. In practice, when employing interval techniques, the interval computation provides a finite value for the right-hand side of the differential equation, regardless of the feasibility of the optimization problem.

In some special cases, the optimization problems of Corollary 2.6 are trivially satisfied by the structure of the right-hand side of (1.1). In particular, vast simplifications can be applied under certain monotonicity assumptions. Due to space limitations, however, the interested reader is referred to [6] to see these results.

3. Pointwise in time convex and concave bounds. As described in the introduction, one motivation for the results presented in this paper is algorithms for global optimization with ODEs embedded. In regular optimization problems, the objective function is expressed in terms of compositions of explicitly represented functions. In dynamic optimization problems, however, the objective function is typically defined as a function of the states and parameters, where the state variables' dependence on the optimization parameters is not known explicitly but can be evaluated via numerical solution of the ODEs. Thus, the crux of the global optimization algorithm lies in computing a convex relaxation for a composition of functions where the

functional form of the composition is unknown a priori. In his seminal paper on computing global solutions of nonconvex optimization problems [4], McCormick outlined a technique for deriving convex relaxations of functions defined by composition. In order to apply the technique, one needs to derive convex underestimators and concave overestimators for the inner functions in the composition. For dynamic optimization problems, this problem reduces to deriving pointwise in time convex underestimators and concave overestimators for the image of the solution of a nonlinear parameter dependent ODE on a parameter space. Before presenting this novel result, we define a notation for the pointwise in time linearization of a function at a reference trajectory.

DEFINITION 3.1. *Let* $\mathcal{L}_{\mathbf{f}}(t,\mathbf{y},\mathbf{q})\big|_{\mathbf{y}^*(t),\mathbf{q}^*}$ *be a linearization of* $\mathbf{f}(t,\mathbf{x},\mathbf{p})$ *at* $(\mathbf{y}^*(t),\mathbf{q}^*)$. *The linearization is given for* $i=1,\ldots,n_x$ *by the following:*

$$\mathcal{L}_{f_i}(t,\mathbf{y},\mathbf{q})\big|_{\mathbf{y}^*(t),\mathbf{q}^*} = f_i(t,\mathbf{y}^*(t),\mathbf{q}^*) + \sum_{j=1}^{n_x} \left.\frac{\partial f_i}{\partial x_j}\right|_{\mathbf{y}^*(t),\mathbf{q}^*} \left(y_j - y_j^*(t)\right) + \sum_{j=1}^{n_p} \left.\frac{\partial f_i}{\partial p_j}\right|_{\mathbf{y}^*(t),\mathbf{q}^*} \left(q_j - q_j^*\right). \tag{3.1}$$

We now present the following theorem utilized for constructing convex underestimators and concave overestimators for the solution of a parameter dependent ODE.

THEOREM 3.2. *Consider differential equation* (1.1) *and the set* $\mathcal{X}(t)$ *as defined in Remark* 2.7. *Let* P *be convex. For* $i=1,\ldots,n_x$ *and each fixed* $\underline{t}\in(t_0,t_f]$, *let* $u_i(\underline{t},\mathbf{x},\mathbf{p})$ *be a convex underestimator for* f_i *on* $\mathcal{X}(\underline{t})\times P$, *and let* $o_i(\underline{t},\mathbf{x},\mathbf{p})$ *be a concave overestimator for* f_i *on* $\mathcal{X}(\underline{t})\times P$. *For* $i=1,\ldots,n_x$, *consider the differential equations*

$$\dot{c}_i = g_{c,i}(t,\mathbf{c},\mathbf{C},\mathbf{p}) = \inf_{\substack{\mathbf{z}\in\mathcal{C}(t,\mathbf{p})\\ z_i=c_i(t)}} \mathcal{L}_{u_i}(t,\mathbf{z},\mathbf{p})\big|_{\mathbf{x}^*(t),\mathbf{p}^*},$$

$$\dot{C}_i = g_{C,i}(t,\mathbf{c},\mathbf{C},\mathbf{p}) = \sup_{\substack{\mathbf{z}\in\mathcal{C}(t,\mathbf{p})\\ z_i=C_i(t)}} \mathcal{L}_{o_i}(t,\mathbf{z},\mathbf{p})\big|_{\mathbf{x}^*(t),\mathbf{p}^*}$$

for some reference trajectory $(\mathbf{x}^*(\underline{t}),\mathbf{p}^*)\in\mathcal{X}(\underline{t})\times P$ *(differentiability of* u_i *and* o_i *is assumed along the reference trajectory) with initial conditions*

$$\mathbf{c}(t_0)\le\mathbf{x}(t_0,\mathbf{p})\le\mathbf{C}(t_0)\qquad\forall\ \mathbf{p}\in P, \tag{3.2}$$

where $\mathcal{C}(t,\mathbf{p})=\{\mathbf{z}\mid\mathbf{c}(t,\mathbf{p})\le\mathbf{z}\le\mathbf{C}(t,\mathbf{p})\}$. *Then for each fixed* $\underline{t}\in(t_0,t_f]$, $\mathbf{c}(\underline{t},\mathbf{p})$ *is a convex underestimator for* $\mathbf{x}(\underline{t},\mathbf{p})$ *on* P, *and* $\mathbf{C}(\underline{t},\mathbf{p})$ *is a concave overestimator for* $\mathbf{x}(\underline{t},\mathbf{p})$ *on* P.

Proof. Because for each fixed $\underline{t}\in(t_0,t_f]$, $u_i(\underline{t},\mathbf{x},\mathbf{p})$ is a convex underestimator for f_i on $\mathcal{X}(\underline{t})\times P$, the linearization $\mathcal{L}_{u_i}(\underline{t},\mathbf{z},\mathbf{p})\big|_{\mathbf{x}^*(\underline{t}),\mathbf{p}^*}$ validly supports f_i on $\mathcal{X}(\underline{t})\times P$ from below. Analogously, $\mathcal{L}_{o_i}(\underline{t},\mathbf{z},\mathbf{p})\big|_{\mathbf{x}^*(\underline{t}),\mathbf{p}^*}$ supports f_i on $\mathcal{X}(\underline{t})\times P$ from above. For each fixed $\underline{t}\in(t_0,t_f]$ and all $(\mathbf{z},\mathbf{p})\in\mathcal{X}(\underline{t})\times P$, the pointwise inequalities

$$\mathcal{L}_{u_i}(\underline{t},\mathbf{z},\mathbf{p})\big|_{\mathbf{x}^*(\underline{t}),\mathbf{p}^*}\le u_i(\underline{t},\mathbf{z},\mathbf{p})\le f_i(\underline{t},\mathbf{z},\mathbf{p}),$$

$$\mathcal{L}_{o_i}(\underline{t},\mathbf{z},\mathbf{p})\big|_{\mathbf{x}^*(\underline{t}),\mathbf{p}^*}\ge o_i(\underline{t},\mathbf{z},\mathbf{p})\ge f_i(\underline{t},\mathbf{z},\mathbf{p})$$

are therefore established for $i=1,\ldots,n_x$, which immediately implies

$$\dot{c}_i = \inf_{\substack{\mathbf{z}\in\mathcal{C}(t,\mathbf{p})\\ z_i=c_i(t)}} \mathcal{L}_{u_i}(t,\mathbf{z},\mathbf{p})\big|_{\mathbf{x}^*(t),\mathbf{p}^*}\le\inf_{\substack{\mathbf{z}\in\mathcal{X}(t)\cap\mathcal{C}(t,\mathbf{p})\\ z_i=c_i(t)}} f_i(t,\mathbf{z},\mathbf{p}), \tag{3.3a}$$

$$\dot{C}_i = \sup_{\substack{\mathbf{z}\in\mathcal{C}(t,\mathbf{p})\\ z_i=C_i(t)}} \mathcal{L}_{o_i}(t,\mathbf{z},\mathbf{p})\big|_{\mathbf{x}^*(t),\mathbf{p}^*} \geq \sup_{\substack{\mathbf{z}\in\mathcal{X}(t)\cap\mathcal{C}(t,\mathbf{p})\\ z_i=C_i(t)}} f_i(t,\mathbf{z},\mathbf{p}) \tag{3.3b}$$

for $i = 1,\ldots,n_x$. We note that the infimum (supremum) over $\mathcal{C}(t,\mathbf{p})$ is less (greater) than the infimum (supremum) over $\mathcal{X}(t)\cap\mathcal{C}(t,\mathbf{p})$, for the infimum (supremum) over a larger set cannot increase the tightness of the bound. Given initial condition (3.2) and (3.3a) and (3.3b), the hypotheses of Corollary 2.5 are satisfied, and we have that for each $\mathbf{p}\in P$,

$$\mathbf{c}(\underline{t},\mathbf{p}) \leq \mathbf{x}(\underline{t},\mathbf{p}) \leq \mathbf{C}(\underline{t},\mathbf{p})$$

in $(t_0,t_f]$. Because $\mathcal{L}_{u_i}(\underline{t},\mathbf{z},\mathbf{p})\big|_{\mathbf{x}^*(t),\mathbf{p}^*}$ and $\mathcal{L}_{o_i}(\underline{t},\mathbf{z},\mathbf{p})\big|_{\mathbf{x}^*(t),\mathbf{p}^*}$ are both affine in $\mathbf{z}$ for fixed $\underline{t}\in(t_0,t_f]$, the infimum and supremum are attained at the vertices of the set $\mathcal{C}(t,\mathbf{p})$ ($z_i = c_i(t)$) and are respectively given by

$$\begin{aligned}\dot{c}_i = \inf_{\substack{\mathbf{z}\in\mathcal{C}(t,\mathbf{p})\\ z_i=c_i(t)}} \mathcal{L}_{u_i}(t,\mathbf{z},\mathbf{p})\big|_{\mathbf{x}^*(t),\mathbf{p}^*} &= u_i(t,\mathbf{x}^*(t),\mathbf{p}^*) + \left.\frac{\partial u_i}{\partial x_i}\right|_{\mathbf{x}^*(t),\mathbf{p}^*}(c_i - x_i^*(t))\\ &+ \sum_{j\neq i}\min\left\{\left.\frac{\partial u_i}{\partial x_j}\right|_{\mathbf{x}^*(t),\mathbf{p}^*} c_j,\ \left.\frac{\partial u_i}{\partial x_j}\right|_{\mathbf{x}^*(t),\mathbf{p}^*} C_j\right\} - \left.\frac{\partial u_i}{\partial x_j}\right|_{\mathbf{x}^*(t),\mathbf{p}^*} x_j^*(t)\\ &+ \sum_{j=1}^{n_p}\left.\frac{\partial u_i}{\partial p_j}\right|_{\mathbf{x}^*(t),\mathbf{p}^*}\left(p_j - p_j^*\right)\end{aligned} \tag{3.4}$$

and

$$\begin{aligned}\dot{C}_i = \sup_{\substack{\mathbf{z}\in\mathcal{C}(t,\mathbf{p})\\ z_i=C_i(t)}} \mathcal{L}_{o_i}(t,\mathbf{z},\mathbf{p})\big|_{\mathbf{x}^*(t),\mathbf{p}^*} &= o_i(t,\mathbf{x}^*(t),\mathbf{p}^*) + \left.\frac{\partial o_i}{\partial x_i}\right|_{\mathbf{x}^*(t),\mathbf{p}^*}(C_i - x_i^*(t))\\ &+ \sum_{j\neq i}\max\left\{\left.\frac{\partial o_i}{\partial x_j}\right|_{\mathbf{x}^*(t),\mathbf{p}^*} c_j,\ \left.\frac{\partial o_i}{\partial x_j}\right|_{\mathbf{x}^*(t),\mathbf{p}^*} C_j\right\} - \left.\frac{\partial o_i}{\partial x_j}\right|_{\mathbf{x}^*(t),\mathbf{p}^*} x_j^*(t)\\ &+ \sum_{j=1}^{n_p}\left.\frac{\partial o_i}{\partial p_j}\right|_{\mathbf{x}^*(t),\mathbf{p}^*}\left(p_j - p_j^*\right)\end{aligned} \tag{3.5}$$

for $i = 1,\ldots,n_x$. By construction, $\mathbf{c}\leq\mathbf{C}$. Therefore,

$$\min\left\{\left.\frac{\partial u_i}{\partial x_j}\right|_{\mathbf{x}^*(t),\mathbf{p}^*} c_j,\ \left.\frac{\partial u_i}{\partial x_j}\right|_{\mathbf{x}^*(t),\mathbf{p}^*} C_j\right\} = \begin{cases}\left.\dfrac{\partial u_i}{\partial x_j}\right|_{\mathbf{x}^*(t),\mathbf{p}^*} c_j & \text{if } \left.\dfrac{\partial u_i}{\partial x_j}\right|_{\mathbf{x}^*(t),\mathbf{p}^*}\geq 0,\\ \left.\dfrac{\partial u_i}{\partial x_j}\right|_{\mathbf{x}^*(t),\mathbf{p}^*} C_j & \text{otherwise}\end{cases} \tag{3.6}$$

and

(3.7)

$$\max\left\{\left.\frac{\partial o_i}{\partial x_j}\right|_{\mathbf{x}^*(t),\mathbf{p}^*} c_j,\ \left.\frac{\partial o_i}{\partial x_j}\right|_{\mathbf{x}^*(t),\mathbf{p}^*} C_j\right\} = \begin{cases} \left.\dfrac{\partial o_i}{\partial x_j}\right|_{\mathbf{x}^*(t),\mathbf{p}^*} c_j & \text{if } \left.\dfrac{\partial o_i}{\partial x_j}\right|_{\mathbf{x}^*(t),\mathbf{p}^*} \leq 0, \\ \left.\dfrac{\partial o_i}{\partial x_j}\right|_{\mathbf{x}^*(t),\mathbf{p}^*} C_j & \text{otherwise.} \end{cases}$$

Thus, (3.4) and (3.5) reduce to linear differential equations with a finite number of discontinuities fixed in time in the coefficient matrix multiplying the states. The assumption that the number of discontinuities is finite is valid, for it is not unreasonable to assume that $u_i(t, \mathbf{x}, \mathbf{p})$ and $o_i(t, \mathbf{x}, \mathbf{p})$ are chosen such that their derivatives do not switch sign infinitely in a finite interval. That the discontinuities are fixed in time is clear because the discontinuities are defined by functions of the reference trajectories and are hence independent of the parameter. The solution to such a system of differential equations has been shown in [3] to be affine in $\mathbf{p}$ for fixed time; therefore, $\mathbf{c}(t, \mathbf{p})$ and $\mathbf{C}(t, \mathbf{p})$ are both concave and convex on P for each fixed $\underline{t} \in (t_0, t_f]$. □

Remark 3.3. Differentiability of u_i and o_i along the reference trajectory is assumed in order to employ Definition 3.1 to establish a formulaic representation of the linearization. Theorem 3.2 still holds for nondifferentiable convex functions u_i and nondifferentiable concave functions o_i, provided that any suitable subgradient is chosen for construction. That is, the linearization employed may be any valid hyperplane supporting the relaxation along the reference trajectory. In practice, nondifferentiability typically arises from taking the maximum or minimum of two valid supporting hyperplanes (e.g., the relaxation of a bilinear function). In this case, arbitrarily choosing either of the two hyperplanes yields a valid relaxation; this selection process is discussed in detail in [6].

Remark 3.4. If the initial condition depends on $\mathbf{p}$, then $\mathbf{c}_0$ and $\mathbf{C}_0$ may also depend on $\mathbf{p}$, provided that they are both affine in $\mathbf{p}$ and underestimate and overestimate $\mathbf{x}(t_0, \mathbf{p})$ for each $\mathbf{p} \in P$, respectively. This condition can also be met via a linearization on a convex/concave relaxation of the initial condition.

Following Corollary 2.5, we noted that simplifications to the theory were possible under the stronger assumptions of monotonicity. Such simplifications are also possible for Theorem 3.2. Again, the interested reader is referred to [6] for these omitted details.

4. A simple bounds example. The following section presents a small example demonstrating the state bounding techniques developed earlier in the paper. The example bounds a bimolecular reversible chemical kinetics problem. The system is not quasi-monotone and exhibits bounds explosion when Corollary 2.6 is applied without utilizing natural bounds.

Example 4.1. Consider the following bimolecular reversible chemical reaction:

$$A + B \rightleftharpoons C$$

with forward rate constant k_f and reverse rate constant k_r. Given a bounding set $[k_f^L, k_f^U] \times [k_r^L, k_r^U]$ for the rate constants, we wish to compute bounds for the concentrations of the three chemical species over a specified time interval, given the following

differential equations describing the evolution of the species concentrations:

$$\begin{aligned}\dot{x}_A &= -k_f x_A x_B + k_r x_C,\\ \dot{x}_B &= -k_f x_A x_B + k_r x_C,\\ \dot{x}_C &= k_f x_A x_B - k_r x_C,\\ x_A(0) = x_{A0}, \quad x_B(0) &= x_{B0}, \quad x_C(0) = x_{C0}.\end{aligned}$$

Without loss of generality, we will assume that $x_{B0} \geq x_{A0}$.

In order to compute state bounds for Example 4.1, a trade-off exists between the ease of computing bounds and the quality of the computed bounds. For this example, we choose to satisfy Corollary 2.6 via interval arithmetic. The bounds are first derived without employing a priori information concerning the behavior of the states using Harrison's theorem [2]. This analysis yields the following differential equations for $\dot{x}_A^L$ and $\dot{x}_A^U$ (see [6] for the complete system of ODEs):

$$\begin{aligned}\dot{x}_A^L = &-\max\{\min\{k_f^L x_A^L,\, k_f^U x_A^L\}x_B^L,\, \min\{k_f^L x_A^L,\, k_f^U x_A^L\}x_B^U,\, \max\{k_f^L x_A^L,\\ &k_f^U x_A^L\}x_B^L,\, \max\{k_f^L x_A^L,\, k_f^U x_A^L\}x_B^U\} + \min\{k_r^L x_C^L,\, k_r^L x_C^U,\, k_r^U x_C^L,\, k_r^U x_C^U\},\end{aligned} \tag{4.1a}$$

$$\begin{aligned}\dot{x}_A^U = &-\min\{\min\{k_f^L x_A^U,\, k_f^U x_A^U\}x_B^L,\, \min\{k_f^L x_A^U,\, k_f^U x_A^U\}x_B^U,\, \max\{k_f^L x_A^U,\\ &k_f^U x_A^U\}x_B^L,\, \max\{k_f^L x_A^U,\, k_f^U x_A^U\}x_B^U\} + \max\{k_r^L x_C^L,\, k_r^L x_C^U,\, k_r^U x_C^L,\, k_r^U x_C^U\},\end{aligned} \tag{4.1b}$$

subject to the initial condition $x_A^L(0) = x_A^U(0) = x_{A0}$.

Despite their unwieldy appearance, because the right-hand sides of the above differential equations are Lipschitz continuous, numerically integrating the differential equations is not difficult. In order to compute a numerical solution, the following values are assigned to the constants:

$$k_f^L = 100,\ k_f^U = 500,\ k_r^L = 0.001,\ k_r^U = 0.01,\ x_{A0} = 1,\ x_{B0} = 1.5,\ x_{C0} = 0.5,$$

where the units for concentration are mol/L, the units for the forward rate constant are L/(mol·min), and the units for the reverse rate constant are min^{-1}. The time interval of interest is set to 1.5 minutes. A plot of the upper bound for species B is shown in Figure 4.1. Clearly, from the figure, the bounding method is not acceptable. From physical considerations, we know that the upper bound should not exceed the sum of initial concentrations of species B and C in the system. However, because the system is not quasi-monotone, the upper bound for species B explodes (in fact, the upper bound for the concentrations of all species explodes). For Figure 4.1, the integration was terminated when the bound exceeded 10^3.

In order to correct the bounds explosion, Corollary 2.6 is now applied to the system in Example 4.1, utilizing the a priori information we know from considering species mole balances on the system. Given the assumption that x_{B0} is greater than x_{A0}, from the kinetics of Example 4.1, we know that the following inequalities hold:

$$\begin{aligned}0 \leq x_A(t) &\leq x_{A0} + x_{C0},\\ x_{B0} - x_{A0} \leq x_B(t) &\leq x_{B0} + x_{C0},\\ 0 \leq x_C(t) &\leq x_{A0} + x_{C0}.\end{aligned}$$

Corollary 2.6 may now be implemented by several different methods; three methods are presented here. The first method is a trivial extension of applying interval arithmetic. Recalling that the optimization is now performed over the intersection of the physical and differential bounds, if we set $\overline{\mathcal{X}}(t) = [\overline{\mathbf{x}}^L(t), \overline{\mathbf{x}}^U(t)]$ and

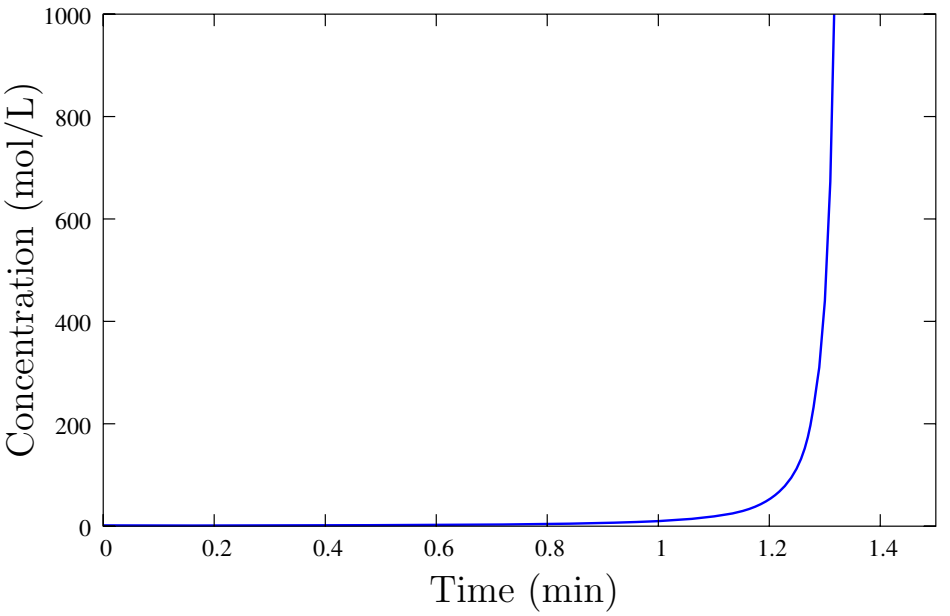

FIG. 4.1. *Upper bound for species B from Example* 4.1 *without utilizing a priori information.*

$G(t) = [\mathbf{x}^L(t), \mathbf{x}^U(t)]$, the right-hand side can be represented as an optimization over the set

$$\overline{\mathcal{X}}((t)) \cap G(t) = [\max\{x_A^L(t), \overline{x}_A^L(t)\}, \min\{x_A^U(t), \overline{x}_A^U(t)\}] \times \cdots \times [\max\{x_C^L(t), \overline{x}_C^L(t)\}, \min\{x_C^U(t), \overline{x}_C^U(t)\}]. \tag{4.2}$$

Therefore, much tighter bounds are achieved by simply assigning the values

$$\begin{aligned} x_A^L &:= \max\{0, x_A^L\}, & x_A^U &:= \min\{x_{A0} + x_{C0}, x_A^U\}, \\ x_B^L &:= \max\{x_{B0} - x_{A0}, x_B^L\}, & x_B^U &:= \min\{x_{B0} + x_{C0}, x_B^U\}, \\ x_C^L &:= \max\{0, x_C^L\}, & x_C^U &:= \min\{x_{A0} + x_{C0}, x_C^U\} \end{aligned}$$

into the right-hand sides of (4.1). The resulting bounds for species B together with the natural bounds are shown in Figure 4.2. There are several important features to note in these new bounds. First and foremost, the bounds no longer explode, because when the right-hand sides of the differential equations exceed a limit (dictated by the interval arithmetic), the right-hand side of the differential equation becomes a constant, thus bounding the slope of the state. Second, the bounds are smooth. This phenomenon occurs because the right-hand sides of the differential equations are continuous, assuring the everywhere existence of the derivatives of the states. Finally, while the upper bound is an improvement over the natural bound, we note that the lower bound is still not at least as good as the natural bounds on the system.

The second application of Corollary 2.6 alleviates the problem that the integrated state bounds exceed the a priori bounds at the expense of smoothness of the resulting bounds and ease of numerical integration. In the discussion following Corollary 2.6, the case where the optimization problem becomes infeasible was discussed. In addition

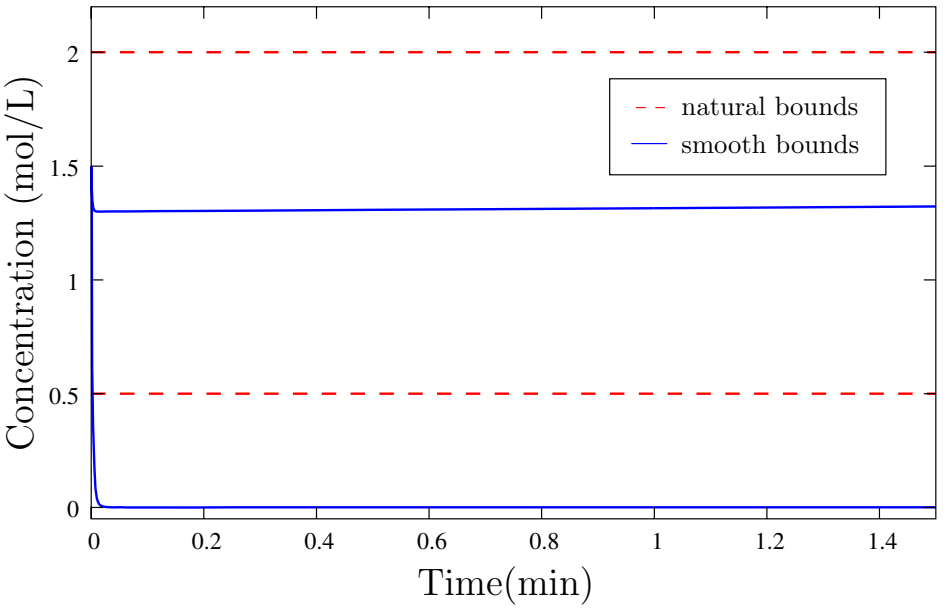

FIG. 4.2. *Bounds for species B from Example* 4.1 *utilizing a priori information.*

to optimizing over the constraint set $\overline{\mathcal{X}}(t) \cap G(t)$, we must also remember that we are subject to the equality constraint $z_i = v_i(t)$ for the lower bounding problems and $z_i = w_i(t)$ for the upper bounding problems. However, because of the constraint set $\overline{\mathcal{X}}(t)$, the equality $z_i = v_i(t)$ is impossible to satisfy when $x_i^L(t) < \overline{x}_i^L(t)$, and the equality $z_i = w_i(t)$ is impossible to satisfy when $x_i^U(t) > \overline{x}_i^U(t)$. In this situation, we can choose any finite number for the right-hand side of the differential equation. The obvious choice for this number is zero, for this forces the integrated bound to equal the natural bound. We note that for the upper bound, choosing a positive number yields a bound looser than the natural bound, and choosing a negative number causes chattering in the numerical integrator. Therefore, for $i = 1, \ldots, n_x$, very tight bounds can be obtained via Corollary 2.6 by defining the right-hand sides of the ODEs to equal the differential equations derived via interval analysis if $x_i^L, x_i^U \in \overline{\mathcal{X}}(t)$ and letting $\dot{x}_i^L = \dot{x}_i^U = 0$ otherwise. For Example 4.1, the lower bound for species B from this analysis and the lower bound as previously computed via the interval arithmetic approach to Corollary 2.6 are shown for comparison in Figure 4.3.

In the third method of bounding the differential equations, we incorporate an invariant in the differential equation defining the system. From an extent of reaction analysis, the following equality may be derived for this system:

$$x_A + x_B + 2x_C = x_{A0} + x_{B0} + 2x_{C0}. \tag{4.3}$$

Corollary 2.6 is now applied where the natural bounding set $\overline{\mathcal{X}}(t)$ is defined by the intersection of the plane in (4.3), and $\overline{\mathcal{X}}(t)$ is defined by (4.2). Effectively, for each bounding differential equation, (4.3) is utilized to eliminate one variable from the optimization problem defining the right-hand side of the bounding differential equation. The selection of which variables are eliminated in each optimization problem is not unique. Theoretically, the addition of this invariant creates more constrained optimization problems, and the infimum (supremum) of these new optimization problems

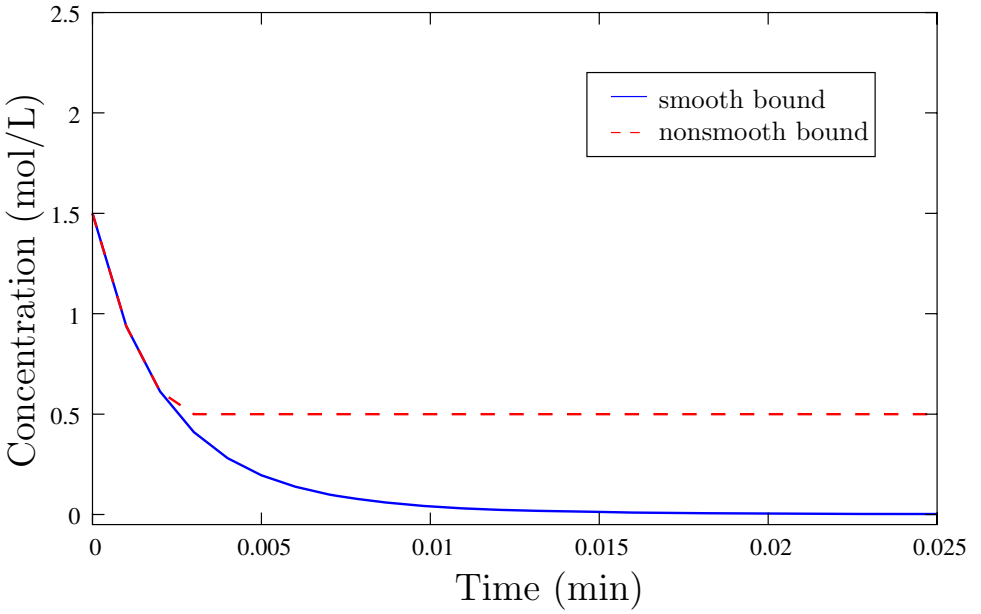

FIG. 4.3. *Bounds for species B from Example* 4.1 *utilizing a priori information and bounds truncation.*

is at least no worse than the infimum (supremum) of the optimization problems derived without the invariant. In practice, however, because the optimization problems are estimated using interval arithmetic, the quality of the state bound is very dependent on the quality of the interval arithmetic methods employed for bounding the right-hand sides of the differential equations. Both elimination of variables and distinct factorization strategies can lead to vastly different outcomes, and these different outcomes sometimes lead to worse state bounds than not including the invariant at all.

For this example, the invariant was used to eliminate x_C from the optimization problems defining $\dot{x}_A^L$, $\dot{x}_A^U$, $\dot{x}_B^L$, $\dot{x}_B^U$, and x_B from the equations defining $\dot{x}_C^L$, $\dot{x}_C^U$. The resulting differential equations for $\dot{x}_A^L$ and $\dot{x}_A^U$ are given by the following (see [6] for the complete system of ODEs):

$$\begin{aligned}
\dot{x}_A^L = &-\max\{\min\{k_f^L x_A^L,\, k_f^U x_A^L\}\max\{x_B^L,\, 0.5\},\, \min\{k_f^L x_A^L,\, k_f^U x_A^L\}\min\{x_B^U,\, 2\},\\
&\qquad \max\{k_f^L x_A^L,\, k_f^U x_A^L\}\max\{x_B^L,\, 0.5\},\, \max\{k_f^L x_A^L,\, k_f^U x_A^L\}\min\{x_B^U,\, 2\}\}\\
&+\min\{k_r^L(1.75 - 0.5x_A^L - \max\{0.5\max\{x_B^L,\, 0.5\},\, 0.5\min\{x_B^U,\, 2\}\}),\\
&\qquad k_r^L(1.75 - 0.5x_A^L - \min\{0.5\max\{x_B^L,\, 0.5\},\, 0.5\min\{x_B^U,\, 2\}\}),\\
&\qquad k_r^U(1.75 - 0.5x_A^L - \max\{0.5\max\{x_B^L,\, 0.5\},\, 0.5\min\{x_B^U,\, 2\}\}),\\
&\qquad k_r^U(1.75 - 0.5x_A^L - \min\{0.5\max\{x_B^L,\, 0.5\},\, 0.5\min\{x_B^U,\, 2\}\})\},\\
\dot{x}_A^U = &-\min\{\min\{k_f^L x_A^U,\, k_f^U x_A^U\}\max\{x_B^L,\, 0.5\},\, \min\{k_f^L x_A^U,\, k_f^U x_A^U\}\min\{x_B^U,\, 2\},\\
&\qquad \max\{k_f^L x_A^U,\, k_f^U x_A^U\}\max\{x_B^L,\, 0.5\},\, \max\{k_f^L x_A^U,\, k_f^U x_A^U\}\min\{x_B^U,\, 2\}\}\\
&+\max\{k_r^L(1.75 - 0.5x_A^U - \max\{0.5\max\{x_B^L,\, 0.5\},\, 0.5\min\{x_B^U,\, 2\}\}),\\
&\qquad k_r^L(1.75 - 0.5x_A^U - \min\{0.5\max\{x_B^L,\, 0.5\},\, 0.5\min\{x_B^U,\, 2\}\}),\\
&\qquad k_r^U(1.75 - 0.5x_A^U - \max\{0.5\max\{x_B^L,\, 0.5\},\, 0.5\min\{x_B^U,\, 2\}\}),\\
&\qquad k_r^U(1.75 - 0.5x_A^U - \min\{0.5\max\{x_B^L,\, 0.5\},\, 0.5\min\{x_B^U,\, 2\}\})\}.
\end{aligned}$$

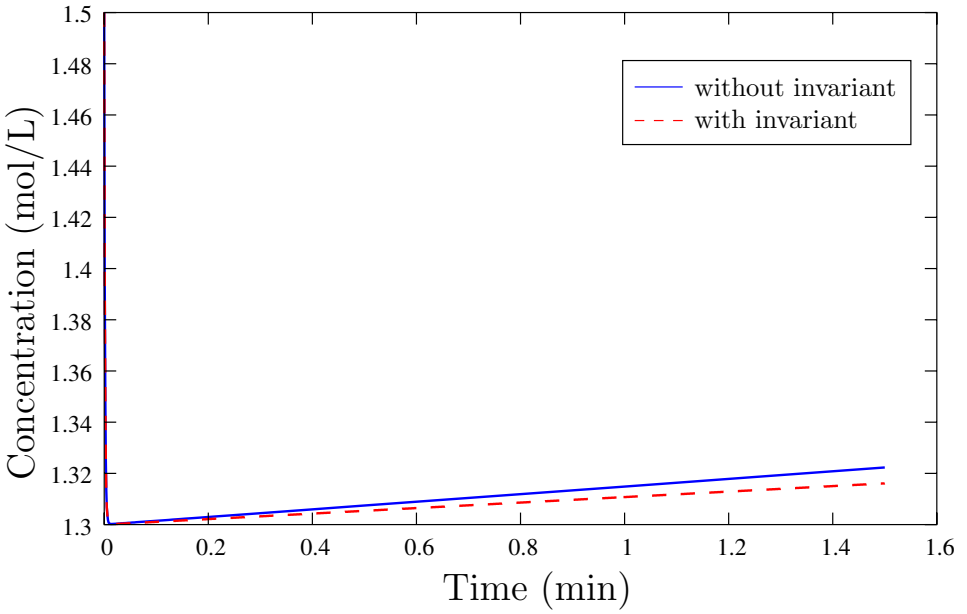

FIG. 4.4. *Bounds for species B from Example* 4.1 *utilizing the reaction invariant.*

The marginal improvement of utilizing the reaction invariant is illustrated for the upper bound of species B in Figure 4.4. We note that even for this simple example problem, different factorizations of the objective function prior to applying interval arithmetic can lead to bounds worse than those computed without the invariant.

5. Automatic generation of relaxations. From the previous simple example, one quickly notes that application of the theory presented in this paper is both tedious and error-prone, even for trivial problems. As previously mentioned, the techniques developed in this paper were originally motivated by a desire to solve globally optimization problems containing differential equations. In order for this objective to be accomplished feasibly, a suite of programs, named GDOC [9], was developed to solve dynamic optimization problems automatically, utilizing the relaxation strategy developed in this paper. GDOC has proven its utility for globally solving dynamic optimization problems in several case studies [6, 7, 10].

One component of GDOC, the gdoc-compiler, was designed specifically to accept a text input file written in the GDOC language, apply the theorems developed in this paper, and generate a Fortran 77 residual file for input to a numerical ODE solver. The compiler consists of three separate components: the compiler front end, the intermediate code representation and symbolic analysis tool, and the compiler back end. The compiler front end is responsible for scanning, parsing, and generating the intermediate code representation. The compiler back end is a custom written output routine that accepts output from the symbolic analyzer, automatically formats the results in Fortran 77, and writes an ODE residual file. The intermediate code and symbolic analysis tool is responsible for applying the theory developed in this paper; this step is described in more detail below.

The scanning and parsing steps in the gdoc-compiler accept equations written as text and generate object-oriented parse trees to be operated on by the symbolic

analyzer. The symbolic analyzer first transforms the parse tree representation of the input equations into a code tape representation. For the purposes of this discussion, a code tape is a representation of a system of equations as a decomposition into a sequence of elementary operations containing only unary or binary operations of the input variables or generated intermediate variables [1]; transformation to a code tape eliminates the computation of common subexpressions. Second, the symbolic analyzer creates a second code tape that applies Corollary 2.6 to each equation in the input code tape in order to generate state bounds; Corollary 2.6 is implemented via interval arithmetic. Third, the symbolic analyzer creates a third code tape that computes the convex and concave relaxations of the right-hand side of the input ODE. This code tape is generated by applying McCormick's relaxation technique [4] to the code tape of the original ODE using the bounds generated by the second code tape as necessary. Fourth, the symbolic analyzer creates a fourth code tape by linearizing the relaxation code tape along the user-specified reference trajectory. The linearizations are generated by applying the forward mode of algorithmic differentiation to the relaxation code tape. Steps three and four combined represent the application of Theorem 3.2. All four code tapes are then passed to the compiler back end, where the residual file is generated. The gdoc-compiler is described in much greater detail in [6].

6. Control problem. In this section, the theory developed in this paper is applied to a problem for which a closed form solution is impossible and manual application of the theory is impractical. The problem considered is an optimal control problem contrived to demonstrate the application of the theory to a nonlinear system of ODEs. The problem is stated as follows:

$$\min_{u(t)} x_4(t_f),$$

subject to

$$\begin{aligned} \dot{x}_1 &= \exp(-x_2) + x_1/x_4, \\ \dot{x}_2 &= x_3^2/(u+0.1), \\ \dot{x}_3 &= x_4 x_3 u, \\ \dot{x}_4 &= 3x_1/(t+1), \\ \mathbf{x}_0 &= (1,\ -1,\ 1,\ 0.5), \\ t \in (0,1], &\quad 0 \le u(t) \le 4. \end{aligned}$$

Because this problem does not derive from a physical system, no bounding set $\mathcal{X}$ exists. Consider a piecewise constant control profile on two equally spaced time intervals. The objective function is nonconvex, and hence, in order to solve this problem globally, convex and concave relaxations $c_{x_4}(t_f, \mathbf{u})$ and $C_{x_4}(t_f, \mathbf{u})$ are required at each node in the branch-and-bound tree. Utilizing the compiler component of GDOC, a plot of the objective function and its relaxations is depicted in Figure 6.1; the relaxations were generated for the reference trajectory $(\mathbf{x}^*, \mathbf{u}^*) = (\mathbf{x}^{mid}, \mathbf{u}^{mid})$. Because the GDOC compiler generates lengthy Fortran files, the generated source code for this problem is not included in this paper. However, both the input and output files for this example are available from the second author's website, http://yoric.mit.edu/gdoc/index.html. We note that in [7] we prove that $c_{x_4}(t_f, \mathbf{u})$ and $C_{x_4}(t_f, \mathbf{u})$ both converge to $x_4(t_f, \mathbf{u})$ as the interval $U = [0,4]^2$ shrinks to any degenerate point $\mathbf{u}^{\mathbf{d}} \in \mathbf{U}$. This convergence property implies the convergence of the branch-and-bound algorithm utilized to solve this problem globally.

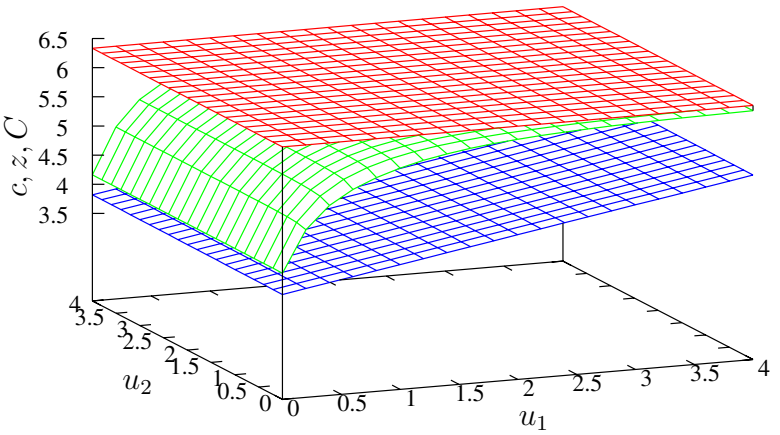

FIG. 6.1. *Objective function and relaxations for a control problem.*

7. Conclusions. In this paper, we have presented two novel results on bounding the solution of ODEs. In the first section, we demonstrated a method for extending differential inequalities to include natural bounds on the system. The method is useful for practical problems, for it provides a differential technique to generate reasonably tight bounds for systems that are not quasi-monotone. Utilizing these time varying state bounds, we presented a method for providing pointwise in time convex and concave relaxations for the image of the solution of a system of nonlinear parametric differential equations on a parameter space. The method is applied by constructing a convex and concave relaxation of the right-hand sides of the differential equations. These relaxations are then linearized at a reference trajectory. By construction, the linearizations are known to rigorously bound the original right-hand sides of the differential equations; therefore, integration provides rigorous bounds for the original states. Convexity and concavity results from the affine nature of the solution to a system of linear differential equations.

In the second half of the paper, two examples were presented demonstrating the application of the theory developed in the first half of the paper. The first example illustrated the utilization of Corollary 2.6 for an analytically tractable problem. The difficulty in manually applying the theory motivated the discussion of a program, GDOC, that utilizes algorithmic differentiation techniques to apply the theory automatically. A second example then demonstrated the application of Theorem 3.2 on a nonlinear problem utilizing GDOC.
