$$\frac{d^2 u_\nu}{dt^2} = D_+^x D_-^x u_\nu, \qquad \nu = 0, -1, -2, \ldots, -N+1, \tag{22}$$

$$\frac{d^2 w_\nu}{dt^2} = c^2 D_+^x D_-^x w_\nu, \qquad \nu = 1, 2, 3, \ldots, N-1, \tag{23}$$

subject to Dirichlet boundary conditions

$$u_{-N} = 0, \quad w_N = 0, \quad t \ge 0. \tag{24}$$

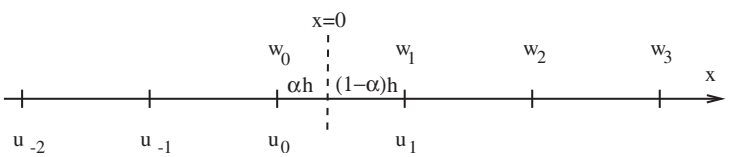

FIG. 4. *Notation for the one-dimensional problem.*

We discretize the jump conditions to second order accuracy by

$$(1-\alpha)u_0 + \alpha u_1 = (1-\alpha)w_0 + \alpha w_1, \tag{25}$$

$$D_+^x u_0 + h\left(\alpha - \frac{1}{2}\right) D_+^x D_-^x u_0 = c^2 \left(D_+^x w_0 + h\left(\alpha - \frac{1}{2}\right) D_+^x D_-^x w_1 \right). \tag{26}$$

By using (22) and (23), we can write (25), (26) as

$$\alpha u_1 + (\alpha - 1) w_0 = (\alpha - 1) u_0 + \alpha w_1,$$

$$u_1 + c^2 w_0 = u_0 + c^2 w_1 + h^2 \left(\alpha - \frac{1}{2}\right) \left(\frac{d^2 w_1}{dt^2} - \frac{d^2 u_0}{dt^2} \right).$$

Solving for w_0 and u_1 yields

$$w_0 = \frac{1}{1-\alpha(1-c^2)} \left(u_0 - \alpha(1-c^2) w_1 + h^2 \alpha \left(\alpha - \frac{1}{2}\right) \left(\frac{d^2 w_1}{dt^2} - \frac{d^2 u_0}{dt^2} \right) \right), \tag{27}$$

$$u_1 = \frac{1}{1-\alpha(1-c^2)} \Bigg(c^2 w_1 + (1-\alpha)(1-c^2) u_0 + h^2 (1-\alpha) \left(\alpha - \frac{1}{2}\right) \left(\frac{d^2 w_1}{dt^2} - \frac{d^2 u_0}{dt^2} \right) \Bigg). \tag{28}$$

By using (27)–(28) we can eliminate w_0, u_1 from (22)–(23) and obtain

$$b_{11} \frac{d^2 u_0}{dt^2} + b_{12} \frac{d^2 w_1}{dt^2} = \frac{1}{h^2} \left(a_{10} u_{-1} + a_{11} u_0 + a_{12} w_1 \right),$$

$$b_{21} \frac{d^2 u_0}{dt^2} + b_{22} \frac{d^2 w_1}{dt^2} = \frac{1}{h^2} \left(a_{21} u_0 + a_{22} w_1 + a_{23} w_2 \right).$$

Here,

$$b_{11} = 1 - \alpha(1-c^2) + \left(\alpha - \frac{1}{2}\right)(1-\alpha), \quad b_{12} = -\left(\alpha - \frac{1}{2}\right)(1-\alpha), \tag{29}$$

$$b_{21} = \alpha \left(\alpha - \frac{1}{2}\right), \quad b_{22} = \frac{1}{c^2} \left(1 - \alpha(1-c^2) - c^2 \alpha \left(\alpha - \frac{1}{2}\right) \right) \tag{30}$$

and

$$a_{10} = 1 - \alpha(1-c^2), \quad a_{11} = -2 + (1+\alpha)(1-c^2), \quad a_{12} = c^2, \tag{31}$$

$$a_{21} = 1, \quad a_{22} = -2 + \alpha(1-c^2), \quad a_{23} = 1 - \alpha(1-c^2). \tag{32}$$

We can write the semidiscrete problem in matrix form,

$$\begin{pmatrix} 1 & 0 & & & & & & & \\ & \ddots & & & & & & & \\ & 0 & 1 & 0 & & & & & \\ & & 0 & b_{11} & b_{12} & & & & \\ & & & b_{21} & b_{22} & 0 & & & \\ & & & & 0 & 1/c^2 & 0 & & \\ & & & & & & \ddots & & \\ & & & & & & 0 & 1/c^2 \end{pmatrix} \frac{d^2}{dt^2} \begin{pmatrix} u_{-N+1} \\ \vdots \\ u_{-1} \\ u_0 \\ w_1 \\ w_2 \\ \vdots \\ w_{N-1} \end{pmatrix}$$

$$= \frac{1}{h^2} \begin{pmatrix} -2 & 1 & & & & & & \\ & \ddots & & & & & & \\ & 1 & -2 & 1 & & & & \\ & & a_{10} & a_{11} & a_{12} & & & \\ & & & a_{21} & a_{22} & a_{23} & & \\ & & & & 1 & -2 & 1 & \\ & & & & & \ddots & & \\ & & & & & 1 & -2 \end{pmatrix} \begin{pmatrix} u_{-N+1} \\ \vdots \\ u_{-1} \\ u_0 \\ w_1 \\ w_2 \\ \vdots \\ w_{N-1} \end{pmatrix},$$

which we write as

$$\mathcal{B}\mathbf{w}_{tt} = \frac{1}{h^2}\mathcal{A}\mathbf{w}. \tag{33}$$

By (31), (32), the matrix $\mathcal{A}$ is negative diagonally dominant and the off-diagonal elements are positive. Therefore it can be symmetrized by a diagonal scaling $\mathcal{D} > 0$,

$$\tilde{\mathbf{w}} = \begin{pmatrix} \ddots & & & & & & & \\ & d_{-2} & & & & & & \\ & & d_{-1} & & & & 0 & \\ & & & d_0 & & & & \\ & 0 & & & d_1 & & & \\ & & & & & d_2 & & \\ & & & & & & \ddots & \end{pmatrix} \begin{pmatrix} \vdots \\ u_{-2} \\ u_{-1} \\ u_0 \\ w_1 \\ w_2 \\ \vdots \end{pmatrix} =: \mathcal{D}\mathbf{w}, \tag{34}$$

and (33) becomes

$$\tilde{\mathcal{B}}\tilde{\mathbf{w}}_{tt} = \frac{1}{h^2}\tilde{\mathcal{A}}\tilde{\mathbf{w}}, \quad \tilde{\mathcal{B}} = \mathcal{D}\mathcal{B}\mathcal{D}^{-1}, \quad \tilde{\mathcal{A}} = \mathcal{D}\mathcal{A}\mathcal{D}^{-1} = \tilde{\mathcal{A}}^* < 0. \tag{35}$$

Without restriction we can assume that $d_0 = 1$. Then d_1 is determined by the condition that

$$\begin{pmatrix} 1 & 0 \\ 0 & d_1 \end{pmatrix} \begin{pmatrix} a_{11} & a_{12} \\ a_{21} & a_{22} \end{pmatrix} \begin{pmatrix} 1 & 0 \\ 0 & d_1^{-1} \end{pmatrix} = \begin{pmatrix} a_{11} & d_1^{-1}a_{12} \\ d_1 a_{21} & a_{22} \end{pmatrix}$$

is symmetric. By (31), (32), $d_1 = \sqrt{a_{12}/a_{21}} = c$. The corresponding 2×2 submatrix of $\mathcal{B}$ becomes

$$\tilde{\mathcal{B}}_1 = \begin{pmatrix} 1 & 0 \\ 0 & d_1 \end{pmatrix} \begin{pmatrix} b_{11} & b_{12} \\ b_{21} & b_{22} \end{pmatrix} \begin{pmatrix} 1 & 0 \\ 0 & d_1^{-1} \end{pmatrix} = \begin{pmatrix} b_{11} & b_{12}/c \\ cb_{21} & b_{22} \end{pmatrix}.$$

We want to show that

$$\frac{1}{2}(\tilde{\mathcal{B}} + \tilde{\mathcal{B}}^*) > 0, \quad \tilde{\mathcal{B}} = \mathcal{D}\mathcal{B}\mathcal{D}^{-1}. \tag{36}$$

We need to prove this only for $\tilde{\mathcal{B}}_1$, since the remaining part of $\tilde{\mathcal{B}}$ is identical to $\mathcal{B}$, i.e., diagonal with positive elements. By (29), (30),

$$b_{11} = (1-\alpha)\left(\frac{1}{2} + \alpha\right) + \alpha c^2 > 0, \tag{37}$$

$$b_{22} = \frac{1}{c^2}\left(1 - \alpha + \alpha c^2 \left(\frac{3}{2} - \alpha\right)\right) > 0. \tag{38}$$

The characteristic equation, $\det(\frac{1}{2}(\tilde{\mathcal{B}}_1 + \tilde{\mathcal{B}}_1^*) - \mu I) = 0$, is

$$\mu^2 - \mu(b_{11} + b_{22}) + b_{11}b_{22} - \frac{1}{4}\left(\frac{b_{12}}{c} + cb_{21}\right)^2 = 0,$$

with discriminant

$$\Delta = (b_{11} + b_{22})^2 - 4\left(b_{11}b_{22} - \frac{1}{4}\left(\frac{b_{12}}{c} + cb_{21}\right)^2\right) = (b_{11} - b_{22})^2 + \left(\frac{b_{12}}{c} + cb_{21}\right)^2 > 0.$$

The roots are

$$\mu_{1,2} = \frac{1}{2}\left(b_{11} + b_{22} \pm \sqrt{\Delta}\right).$$

Since $b_{11} + b_{22} > 0$ and $\Delta > 0$, both roots are real and positive if $(b_{11} + b_{22})^2 > \Delta$. We have

$$\frac{1}{4}\left((b_{11} + b_{22})^2 - \Delta\right) = b_{11}b_{22} - \frac{1}{4}\left(\frac{b_{12}}{c} + cb_{21}\right)^2$$

$$= \frac{1}{c^2}\left((1-\alpha)\left(\frac{1}{2} + \alpha\right) + \alpha c^2\right)\left(1 - \alpha + \alpha c^2\left(\frac{3}{2} - \alpha\right)\right) - \frac{\left(\alpha - \frac{1}{2}\right)^2}{4}(1 - \alpha - \alpha c^2)^2$$

$$= \frac{1}{c^2}\left((1-\alpha)^2\left(\frac{1}{2} + \alpha\right) - \frac{(\alpha - \frac{1}{2})^2}{4}(1-\alpha)^2\right) > 0.$$

Thus $\frac{1}{2}(\tilde{\mathcal{B}} + \tilde{\mathcal{B}}^*)$ is positive definite.

If $\alpha = \frac{1}{2}$, then, by (29)–(30), $b_{12} = b_{21} = 0$ and $\tilde{\mathcal{B}} = \tilde{\mathcal{B}}^* > 0$. Since $\tilde{\mathcal{A}} = \tilde{\mathcal{A}}^* < 0$, there is an energy estimate and the method is stable.

If $\alpha \neq \frac{1}{2}$, then we make an eigenvector expansion. $\tilde{\mathbf{w}} = e^{\lambda t}\tilde{\mathbf{w}}_0$ is a solution of (35) if $\lambda, \tilde{\mathbf{w}}_0$ are solutions of the eigenvalue problem

$$\left(\lambda^2 \tilde{\mathcal{B}} - \frac{1}{h^2}\tilde{\mathcal{A}}\right)\tilde{\mathbf{w}}_0 = 0. \tag{39}$$

If we can prove that the eigenvalues λ^2 are real, distinct, and negative, then there are no growing modes and the approximation is stable.

If λ^2 is real, then $\tilde{\mathbf{w}}_0$ is also real and the symmetry of $\tilde{\mathcal{A}}$ gives us

$$\lambda^2\langle \tilde{\mathbf{w}}_0, \tilde{\mathcal{B}}\tilde{\mathbf{w}}_0\rangle = \frac{\lambda^2}{2}\langle \tilde{\mathbf{w}}_0, (\tilde{\mathcal{B}} + \tilde{\mathcal{B}}^*)\tilde{\mathbf{w}}_0\rangle = \frac{1}{h^2}\langle \tilde{\mathbf{w}}_0, \tilde{\mathcal{A}}\tilde{\mathbf{w}}_0\rangle,$$

where $\langle \mathbf{u}, \mathbf{v}\rangle$ denotes the usual L_2 inner product. Since $\tilde{\mathcal{A}} < 0$ and $\tilde{\mathcal{B}} + \tilde{\mathcal{B}}^* > 0$, it follows that $\lambda^2 < 0$.

We need the following lemma.

LEMMA 1. [illegible]

$$\begin{pmatrix} d_1 & e_1 & 0 & \cdots & \cdots & \cdots & 0 \\ l_2 & d_2 & e_2 & 0 & \cdots & \cdots & 0 \\ 0 & l_3 & d_3 & e_3 & 0 & \cdots & 0 \\ 0 & & & & 0 & l_n & d_n \end{pmatrix} \begin{pmatrix} z_1 \\ \\ \\ z_n \end{pmatrix} = 0, \tag{40}$$

[illegible] $\theta = 0$ [illegible] $e_j \neq 0$ [illegible] $l_j \neq 0$, [illegible] θ [illegible] (proof [illegible])

Assume that all $e_j \neq 0$ and θ is not a simple eigenvalue. Since the invariant subspace corresponding to θ has dimension larger than one, we can construct an eigenvector with $z_1 = 0$. But then $z_2 = z_3 = \cdots = z_n = 0$, which is a contradiction. Correspondingly, if all $l_j \neq 0$, then there is a solution with $z_n = 0$ which again implies that $z_{n-1} = z_{n-2} = \cdots = z_1 = 0$. This proves the lemma. □

We shall now prove that the eigenvalues λ^2 of (39) are simple for all $0 < \alpha < 1$. λ^2 is an eigenvalue of (39) if zero is an eigenvalue of the tridiagonal matrix $Q = h^2\lambda^2\tilde{\mathcal{B}} - \tilde{\mathcal{A}}$. The conditions of Lemma 1 are violated if there is some value of α where at least one element on the subdiagonal of Q is zero [illegible] one element on the superdiagonal of Q is zero. The only off-diagonal elements of $\tilde{\mathcal{B}}$ are $\tilde{b}_{12}$ and $\tilde{b}_{21}$, $\mathcal{D} > 0$, and $a_{10} = a_{23} = (1-\alpha) + \alpha c^2 > 0$ for all $0 \leq \alpha \leq 1$. Hence, Lemma 1 can only be violated if

$$h^2\lambda^2\tilde{b}_{12} - \tilde{a}_{12} = 0 \quad \text{and} \quad h^2\lambda^2\tilde{b}_{21} - \tilde{a}_{21} = 0. \tag{41}$$

By (29), (30), (31), and (32) we can write (41) as

$$-h^2\lambda^2\left(\alpha - \frac{1}{2}\right)(1-\alpha) - c^2 = 0, \quad h^2\lambda^2\alpha\left(\alpha - \frac{1}{2}\right) - 1 = 0,$$

i.e.,

$$\frac{\alpha - 1}{\alpha} = c^2,$$

which is a contradiction because $c^2 > 0$, but the left-hand side is negative for $0 < \alpha < 1$. Thus the eigenvalues λ^2 of (39) are simple. They are also real because they are solutions of the characteristic equation and smooth functions of α. For $\alpha = \frac{1}{2}$ they are real. Therefore they are real for all values of α because they can only become complex at some value $\alpha = \alpha_0$ if there is an eigenvalue which is not simple. This completes the proof of the following theorem.

THEOREM 1. [illegible] λ^2 [illegible] (39) [illegible] (22), (23) [illegible] (24) [illegible] (25), (26) [illegible]

3. The modified equation. Instead of the complete proof of the last section (which is quite complicated), we shall now use modified equations and show stability for the low and intermediate frequencies. Note that this analysis does not provide any information about the highest frequencies and therefore does not prove stability of the scheme. As we shall see in section 6, numerical calculations show that our A^TA-dissipation takes care of any instabilities caused by the highest frequencies in our scheme. We discuss the modified equation technique here because in the multi-dimensional case, the use of modified equations is the only way to obtain stability information. Such an analysis can be found in [2]. Since in [2] we neglected the truncation error in the normal direction, it is important that the restriction of the approximation to one dimension is completely stable.

Even though extensive numerical experiments with our two-dimensional scheme indicate that it is stable with A^TA-dissipation, we note that there might be other schemes with stable modified equations which are unstable.

We introduce the dependent variable

$$v(x,t) = u(-x,t),$$

assume $x_{min} \to \infty$, $x_{max} \to \infty$, and write (17), (18) as a half-plane problem for the system

$$\begin{pmatrix} v \\ w \end{pmatrix}_{tt} = \begin{pmatrix} 1 & 0 \\ 0 & c^2 \end{pmatrix} \begin{pmatrix} v \\ w \end{pmatrix}_{xx}, \quad 0 \le x < \infty, \quad t \ge 0, \tag{42}$$

with the modified jump conditions

$$v(0,t) + h^2\beta v_{xx}(0,t) = w(0,t) + h^2\beta w_{xx}(0,t), \tag{43}$$

$$v_x(0,t) + h^2\gamma v_{xxx}(0,t) = -c^2\left(w_x(0,t) + h^2\gamma w_{xxx}(0,t)\right). \tag{44}$$

We obtain (43) and (44) from (25) and (26) by adding the leading truncation error term. A simple but tedious calculation shows that

$$\beta = \frac{(1-\alpha)\alpha}{2}, \quad \gamma = \frac{-2+6\alpha-3\alpha^2}{6}.$$

We use mode analysis to discuss stability. The general solutions of type

$$\begin{pmatrix} v(x,t) \\ w(x,t) \end{pmatrix} = e^{st} \begin{pmatrix} \tilde{v}(x,s) \\ \tilde{w}(x,s) \end{pmatrix}, \quad \mathrm{Re}(s) \ge 0,$$

where $(\tilde{v}(x,s), \tilde{w}(x,s))$ are bounded, are given by

$$v(x,t) = e^{st}e^{-sx}v_0, \quad w(x,t) = e^{st}e^{-(s/c)x}w_0. \tag{45}$$

Introducing (45) into the boundary conditions (43), (44) gives us

$$\begin{aligned}(1+h^2\beta s^2)v_0 - (1+h^2\beta s^2)w_0 &= 0,\\ (1+h^2\gamma s^2)v_0 + c^2(1+h^2\gamma s^2)w_0 &= 0.\end{aligned}$$

Thus, nontrivial solutions exist if and only if

$$-(1+h^2\beta s^2)(1+h^2\gamma s^2) = 0.$$

Hence, instabilities can only be present for $s = \mathcal{O}(1/h)$, i.e., for high frequencies. (However, the proof in the previous section shows that this cannot happen.)

4. Solvability of the two-dimensional discrete jump conditions. Let the 2×2 matrix on the left-hand side of (16) be P. The linear system has a unique solution if $\det P \neq 0$. We have

$$\det P = g_0^D(\xi_\Gamma)g_0^N(\xi_I - \xi_\Gamma)/\rho_{II} + g_0^D(\xi_I - \xi_\Gamma)g_0^N(\xi_\Gamma)/\rho_I.$$

The coefficients in the Dirichlet formula (8) are

$$g_0^D(\xi) = \frac{(\xi_I - \xi)(2\xi_I - \xi)}{2\xi_I^2} + \delta, \quad g_I^D(\xi) = \frac{\xi(2\xi_I - \xi)}{\xi_I^2} - 2\delta, \quad g_{II}^D(\xi) = \frac{\xi(\xi - \xi_I)}{2\xi_I^2} + \delta,$$

where $\delta \approx 0.25$ is a constant that removes the small-cell time step restriction while preserving the second order accuracy; see [3]. The coefficients in the Neumann formula (9) are (see [2])

$$g_0^N(\xi) = \frac{3\xi_I - 2\xi}{2\xi_I^2}, \quad g_I^N(\xi) = \frac{2\xi - 2\xi_I}{\xi_I^2}, \quad g_{II}^N(\xi) = \frac{\xi_I - 2\xi}{2\xi_I^2}.$$

Since $0 \le \xi_\Gamma \le \xi_I$ and $\delta > 0$,

$$0 < \delta \le g_0^D \le 1 + \delta, \quad 0 < \frac{1}{2\xi_I} \le g_0^N \le \frac{3}{2\xi_I}.$$

Hence

$$\frac{\delta}{2\xi_I}\left(\frac{1}{\rho_I} + \frac{1}{\rho_{II}}\right) \le \det P \le \frac{3(1+\delta)}{2\xi_I}\left(\frac{1}{\rho_I} + \frac{1}{\rho_{II}}\right).$$

For all possible directions of the normal, $h \le \xi_I \le \sqrt{2}h$, and we conclude that

$$\det P \ge C > 0, \quad C = \frac{\delta}{2\sqrt{2}h}\left(\frac{1}{\rho_I} + \frac{1}{\rho_{II}}\right).$$

The fact that the lower bound of $\det P$ is proportional to δ shows that the δ-term is essential for the solvability of the discrete jump conditions for general locations of the interface relative to the grid. The δ-term was originally designed for Dirichlet boundary conditions to remove the small-cell time step restriction (cf. [3]), and it also serves that purpose here.

5. Time-integration and A^TA-dissipation. The discretized jump conditions (16) can in principle be used to eliminate all ghost points from the discrete approximation of the Laplacians of u and w (7). Since the jump conditions couple the solutions on both sides of the interface, the matrix form of the discrete Laplacian becomes

$$\begin{aligned} \Delta_h u(\boldsymbol{X}_I, t_n) &= A_{11}\boldsymbol{u}^n + A_{12}\boldsymbol{w}^n, \\ \Delta_h w(\boldsymbol{X}_{II}, t_n) &= A_{21}\boldsymbol{u}^n + A_{22}\boldsymbol{w}^n, \end{aligned} \qquad A = \begin{pmatrix} A_{11} & A_{12} \\ A_{21} & A_{22} \end{pmatrix}.$$

Here, $\boldsymbol{X}_I$ and $\boldsymbol{X}_{II}$ are vectors of all grid point coordinates inside Ω_I and Ω_{II}, respectively, and $\boldsymbol{u}$ and $\boldsymbol{w}$ are the discrete solutions at those grid points. If all eigenvalues of A are distinct, real, and negative, one can show that the scheme

$$\begin{pmatrix} \rho_I(\boldsymbol{u}^{n+1} - 2\boldsymbol{u}^n + \boldsymbol{u}^{n-1})/\delta_t^2 \\ \rho_{II}(\boldsymbol{w}^{n+1} - 2\boldsymbol{w}^n + \boldsymbol{w}^{n-1})/\delta_t^2 \end{pmatrix} = A \begin{pmatrix} \boldsymbol{u}^n \\ \boldsymbol{w}^n \end{pmatrix} + \boldsymbol{F}(t_n) \tag{46}$$

is stable for sufficiently small time steps δ_t [1]. However, the embedded boundary approximation of the jump conditions breaks the symmetry of the matrix A so it is not possible to guarantee this property. In fact, numerical examples (see section 6) indicate that the above scheme suffers from a mild instability.

In the previous embedded boundary methods for the wave equation subject to Neumann [2] and Dirichlet [3] boundary conditions, we damped the instability by adding a small fourth order term of the type $h^3 A^T A(\boldsymbol{u}_t, \boldsymbol{w}_t)^T$ to the right-hand side of (46). While this technique turned out to work very well in practice for the Neumann and Dirichlet problems, it is not directly amendable to the current problem because the matrix A couples the solutions across the interface. Consequently, it becomes complicated to evaluate A^T on a solution vector without explicitly forming the matrix A.

It is not difficult to modify the previous dissipation technique to work with the jump conditions. We first describe the idea for the continuous problem. For the wave equation (1)–(2) with jump conditions (5)–(6), we can evaluate the normal derivative of the solutions on either side of the interface as functions of time,

$$\frac{\partial u}{\partial n}(\boldsymbol{x}, t) =: f_I(\boldsymbol{x}, t), \quad \boldsymbol{x} \in \Gamma,\ t \geq 0, \tag{47}$$

$$\frac{\partial w}{\partial n}(\boldsymbol{x}, t) =: f_{II}(\boldsymbol{x}, t), \quad \boldsymbol{x} \in \Gamma,\ t \geq 0. \tag{48}$$

Hence, once the continuous problem with jump conditions has been solved, we can in principle recompute the same solution by solving two uncoupled Neumann problems:

$$\begin{aligned} \rho_I u_{tt} &= \Delta u + F(\boldsymbol{x}, t), && \boldsymbol{x} \in \Omega_I, && t \geq 0, \\ \frac{\partial u}{\partial n}(\boldsymbol{x}, t) &= f_I(\boldsymbol{x}, t), && \boldsymbol{x} \in \Gamma, && t \geq 0, \\ u(\boldsymbol{x}, 0) = U_0(\boldsymbol{x}), \quad u_t(\boldsymbol{x}, 0) &= U_1(\boldsymbol{x}), && && \boldsymbol{x} \in \Omega_I, \end{aligned} \tag{49}$$

and

$$\begin{aligned} \rho_{II} w_{tt} &= \Delta w + F(\boldsymbol{x}, t), && \boldsymbol{x} \in \Omega_{II}, && t \geq 0, \\ \frac{\partial w}{\partial n}(\boldsymbol{x}, t) &= f_{II}(\boldsymbol{x}, t), && \boldsymbol{x} \in \Gamma, && t \geq 0, \\ w(\boldsymbol{x}, 0) = W_0(\boldsymbol{x}), \quad w_t(\boldsymbol{x}, 0) &= W_1(\boldsymbol{x}), && && \boldsymbol{x} \in \Omega_{II}. \end{aligned} \tag{50}$$

Our basic idea is to use the stabilized embedded boundary scheme for the Neumann problem described in [2], where the forcing functions f_I and f_{II} are computed on the fly during the time evolution.

For conciseness, we describe only the details for the Neumann problem (49), which is discretized on the same Cartesian grid as above, leading to the same set of ghost points G_I where the discrete boundary conditions are applied,

$$B_{i,j}^N u^n = f_I(\boldsymbol{x}_{i,j}^\Gamma, t_n), \quad (i,j) \in G_I. \tag{51}$$

The formula (7) for discretizing the Laplacian of u is the same as before, but since the Neumann problem for u is decoupled from w, we now get the matrix representation

$$\Delta_h u(\boldsymbol{X}_I, t_n) = A_I \boldsymbol{u}^n + \boldsymbol{b}_I^n, \tag{52}$$

after all ghost points have been eliminated from (7). The vector $\boldsymbol{b}_I$ contains the discrete boundary forcing function corresponding to the forcing function $f_I(\boldsymbol{x}^\Gamma, t)$ and is only nonzero at grid points just inside the boundary; see [2] for details.

The stabilized scheme for the Neumann problem is

$$\begin{aligned}\rho_I(\boldsymbol{u}^{n+1} - 2\boldsymbol{u}^n + \boldsymbol{u}^{n-1})/\delta_t^2 &= A_I \boldsymbol{u}^n + \boldsymbol{b}^n + \boldsymbol{F}(t_n) \\ &\quad - \epsilon \frac{h^3}{\delta_t} A_I^T \left(A_I \boldsymbol{u}^n + \boldsymbol{b}^n - A_I \boldsymbol{u}^{n-1} - \boldsymbol{b}^{n-1} \right),\end{aligned} \tag{53}$$

where $\epsilon > 0$ is a small constant. Numerical experiments indicate that $\epsilon = \mathcal{O}(10^{-3})$ is sufficient to allow for very long time-integrations (10^6 time steps or more). The scheme (54) can be recast into an equivalent form that makes it easier to generalize to handle the jump conditions. Let us define an extended solution vector $\bar{\boldsymbol{u}}$ that includes the solution at all interior points as well as the ghost points. Given $\bar{\boldsymbol{u}}$, all values are defined to evaluate the discrete Laplacian $\Delta_h u_{i,j}$ (7) at all points $\boldsymbol{x}_{i,j} \in \Omega_I$. We write the discrete Laplacian at all these points as $\Delta_h \bar{\boldsymbol{u}}$ and arrive at the equivalent method:

1. Given $\boldsymbol{u}^n$, define $\bar{\boldsymbol{u}}^n$ by assigning all ghost points to satisfy the discretized Neumann boundary condition (51).
2. Update all interior points $\boldsymbol{x}_{i,j} \in \Omega_I$ by

$$\begin{aligned}\rho_I(\boldsymbol{u}^{n+1} - 2\boldsymbol{u}^n + \boldsymbol{u}^{n-1})/\delta_t^2 &= \Delta_h \bar{\boldsymbol{u}}^n + \boldsymbol{F}(t_n) \\ &\quad - \epsilon \frac{h^3}{\delta_t} A_I^T \left(\Delta_h \bar{\boldsymbol{u}}^n - \Delta_h \bar{\boldsymbol{u}}^{n-1} \right).\end{aligned} \tag{54}$$

Using this formulation shows that the matrix A_I is only needed to evaluate the dissipation term, and only for the matrix-vector product $A_I^T \boldsymbol{y}$, where $\boldsymbol{y} = \Delta_h \bar{\boldsymbol{u}}^n - \Delta_h \bar{\boldsymbol{u}}^{n-1}$. Note that the boundary forcing $f_I(\boldsymbol{x}^\Gamma, t)$ influences only the ghost point values and has no bearing on A_I^T.

To satisfy the discrete jump conditions (14)–(15), it appears that we must first calculate a corresponding value of f_I to use in (51). Given $\boldsymbol{u}^n$, this can be achieved by first calculating the values at all ghost points G_I by solving the 2×2 linear system (16). We can then use the embedded boundary formula (51) to evaluate f_I. However, it is a trivial exercise to see that enforcing (51) with this f_I results in the same ghost point values as those we started with. Hence, it is not necessary to calculate f_I, and we can simply replace the inhomogeneous Neumann condition by the discrete jump conditions (16). The same principle applies to the Neumann problem in Ω_{II} and we arrive at the damped scheme for the problem with jump conditions:

1. Given $\boldsymbol{u}^n$ and $\boldsymbol{w}^n$, define $\bar{\boldsymbol{u}}^n$ by assigning all ghost points $u_{i,j}$ to satisfy the discrete jump conditions along normals going through $(i,j) \in G_I$,

$$B^D_{i,j} u^n = V^D_{i,j} w^n,$$
$$\frac{1}{\rho_I} B^N_{i,j} u^n = -\frac{1}{\rho_{II}} V^N_{i,j} w^n.$$

2. Given $\boldsymbol{u}^n$ and $\boldsymbol{w}^n$, define $\bar{\boldsymbol{w}}^n$ by assigning all ghost points $w_{i,j}$ to satisfy the discrete jump conditions along normals going through $(i,j) \in G_{II}$,

$$B^D_{i,j} w^n = V^D_{i,j} u^n,$$
$$\frac{1}{\rho_{II}} B^N_{i,j} w^n = -\frac{1}{\rho_I} V^N_{i,j} u^n.$$

3. Update all interior points $\boldsymbol{x}_{i,j} \in \Omega_I$ by

$$\rho_I(\boldsymbol{u}^{n+1} - 2\boldsymbol{u}^n + \boldsymbol{u}^{n-1})/\delta_t^2 = \Delta_h \bar{\boldsymbol{u}}^n + \boldsymbol{F}(t_n) - \epsilon \frac{h^3}{\delta_t} A_I^T \left(\Delta_h \bar{\boldsymbol{u}}^n - \Delta_h \bar{\boldsymbol{u}}^{n-1}\right).$$

4. Update all interior points $\boldsymbol{x}_{i,j} \in \Omega_{II}$ by

$$\rho_{II}(\boldsymbol{w}^{n+1} - 2\boldsymbol{w}^n + \boldsymbol{w}^{n-1})/\delta_t^2 = \Delta_h \bar{\boldsymbol{w}}^n + \boldsymbol{F}(t_n) - \epsilon \frac{h^3}{\delta_t} A_{II}^T \left(\Delta_h \bar{\boldsymbol{w}}^n - \Delta_h \bar{\boldsymbol{w}}^{n-1}\right).$$

Here, A_{II} denotes the matrix representation of the discrete Laplacian subject to discrete Neumann conditions in Ω_{II}, and $\bar{\boldsymbol{w}}^n$ is the extended solution vector holding the solution at all interior grid points of Ω_{II} as well as at the ghost points G_{II}. Note that the matrices A_I and A_{II} do not need to be formed explicitly; cf. [2].

The wave equation subject to jump condition is equivalent to the two uncoupled wave equations subject to Neumann boundary conditions (49)–(50), and the theory in [2] shows that the $h^3 A^T A u_t$-dissipation term inflicts an error which is $\mathcal{O}(h^2)$ for these problems. Hence, we conclude that the dissipation term also inflicts an $\mathcal{O}(h^2)$ error for the wave equation with jump conditions.

6. Numerical examples. To test the accuracy of the numerical scheme, we begin by considering electromagnetic scattering of a plane incident wave by a dielectric circular cylinder of radius R. In this section, we follow the notation of electromagnetics and let $\kappa_e \geq 1$ denote the relative permittivity of the dielectric material but assume the same permeability inside and outside the dielectric. By assuming TE_z polarization and scaling time to obtain unit speed of light in vacuum, we arrive at the following problem for the z-component of the magnetic field:

$$\frac{\partial^2 H^{(z)}}{\partial t^2} = \Delta H^{(z)}, \qquad R^2 < x^2 + y^2 < \infty, \tag{55}$$

$$\frac{\partial^2 H^{(z)}}{\partial t^2} = \frac{1}{\kappa_e} \Delta H^{(z)}, \qquad x^2 + y^2 < R^2, \tag{56}$$

subject to the jump conditions

$$\left[H^{(z)}\right] = 0, \quad \left[\frac{1}{\kappa_e} \frac{\partial H^{(z)}}{\partial n}\right] = 0, \quad x^2 + y^2 = R^2.$$

Here, $\partial/\partial n$ denotes the normal derivative on the boundary of the dielectric cylinder and $\kappa_e = 1$ outside the cylinder. There is an analytical solution of this problem due

TABLE 1

Max error at time $T = 200.0$ for the case $\kappa_e = 2$ inside the dielectric cylinder (u_{err}) and outside of it (w_{err}). The coefficient in the A^TA-dissipation was $\epsilon = 10^{-3}$.

N	h	Time steps	u_{err}, A^TA	w_{err}, A^TA
201	1.5×10^{-2}	26,666	3.38×10^{-2}	3.57×10^{-2}
401	7.5×10^{-3}	53,333	8.42×10^{-3}	7.82×10^{-3}
801	3.75×10^{-3}	106,666	2.31×10^{-3}	1.97×10^{-3}

to Mie (see, for example, [28, p. 667]). Let the incident wave have angular frequency ω and wave number k:

$$H_I^{(z)}(x, y, t) = e^{i(kx-\omega t)}.$$

In polar coordinates (ρ, θ), the incident, scattered, and transmitted fields are

$$H_I^{(z)} = e^{i\omega t} \sum_{n=-\infty}^{\infty} i^{-n} J_n(k\rho) e^{in\theta}, \qquad \rho > R, \tag{57}$$

$$H_S^{(z)} = e^{i\omega t} \sum_{n=-\infty}^{\infty} i^{-n} a_n H_n^{(2)}(k\rho) e^{in\theta}, \quad \rho > R, \tag{58}$$

$$H_D^{(z)} = e^{i\omega t} \sum_{n=-\infty}^{\infty} i^{-n} b_n J_n(mk\rho) e^{in\theta}, \quad \rho < R, \tag{59}$$

where $m = \sqrt{\kappa_e}$, J_n is the Bessel function of the first kind of order n, and $H^{(2)}$ is the Hankel function of the second kind of order n (corresponding to waves propagating outward). The coefficients a_n and b_n are given in [28, p. 667].

The scattering problem was solved numerically for the case $R = 1$, $\kappa_e = 2$, $\omega = k = 2\pi$. The computational domain was the square $-1.5 \le x \le 1.5$, $-1.5 \le y \le 1.5$, and the exact solution was imposed as a Dirichlet boundary condition on the outer boundary. The exact solution was also imposed as initial condition. The error in the numerical solution measured in max norm over all internal grid points was evaluated at times $T = 10.0$ and $T = 200.0$; see Tables 1 and 2, respectively. Note that the error is second order accurate at both times and of the same order of magnitude for the same grid sizes. Studying the error as function of time (see Figure 5) reveals that the A^TA-dissipation is only necessary for long-time computations. Furthermore, there is no noticable growth of the error after long times when the dissipation is used, indicating that the damping is very weak.

As a second test, we consider the same geometry as above but reduce the wave speed inside the cylinder by setting $\kappa_e = 10$. Hence the wave length inside the cylinder

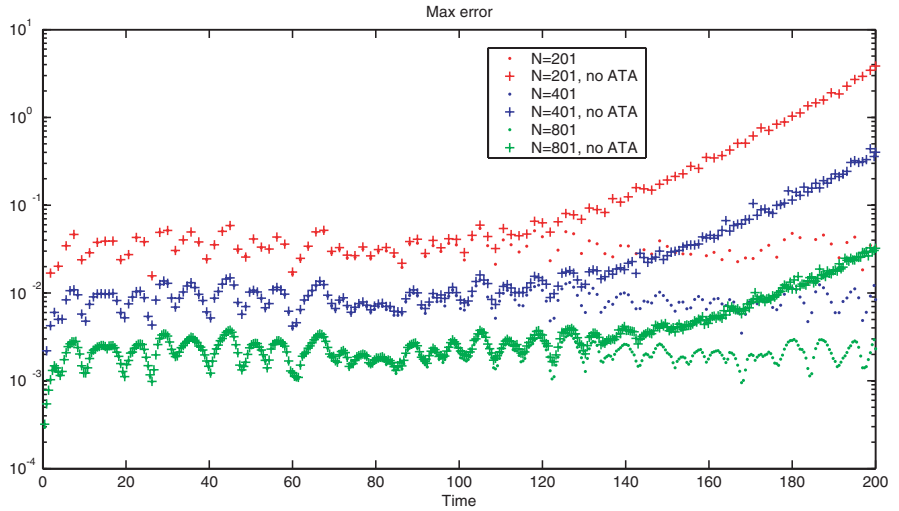

FIG. 5. *The max error inside the dielectric cylinder (u_{err}) as function of time for the case $\kappa_e = 2$, for different grid sizes, with and without A^TA-dissipation.*

TABLE 3

Max error at time $T = 10.0$ for the case $\kappa_e = 10$ inside the dielectric cylinder (u_{err}) and outside of it (w_{err}), with A^TA-dissipation ($\epsilon = 10^{-3}$) and without dissipation.

N	h	u_{err}	u_{err}, A^TA	w_{err}	w_{err}, A^TA
401	7.5×10^{-3}	2.17×10^{-1}	2.16×10^{-1}	6.52×10^{-2}	6.48×10^{-2}
801	3.75×10^{-3}	5.48×10^{-2}	5.47×10^{-2}	1.62×10^{-2}	1.61×10^{-2}

will be a factor $\sqrt{10}$ smaller than outside of it. For this reason, a smaller grid size is needed to resolve the solution and the grid with $N = 201$ is no longer adequate. The errors in the solution at times $T = 10$ and $T = 200$ are given in Tables 3 and 4, respectively. Even though the errors are larger in this case, they are still second order accurate at both times and of the same order of magnitude for the same grid sizes. The solution at time $T = 10$ is shown in Figure 6.

To illustrate that the method generalizes to many subdomains, we consider the scattering of a plane incoming wave on a media with different wave speeds inside each bubble; see Figure 7. This calculation was started from homogeneous initial data and driven on the left boundary by the data $u(-2, y, t) = \sin(8\pi t)$. The remaining outer boundaries had homogeneous Neumann conditions. The solution is shown at time $T = 5$. The ambient media has unit wave speed, so this time corresponds closely to the first arrival of the solution at the right boundary. Note that the speed inside the top bubble (which breaks the otherwise symmetrical configuration) equals the unit speed in the ambient media, but the jump conditions are enforced across its interface. Nevertheless, the contour lines of the numerical solution display a high degree of symmetry about the $y = 0$ axis, indicating that the truncation errors in the jump conditions are very small.

To further illustrate the flexibility of the method, we calculate the scattering around an irregular shape described by a periodic cubic spline curve; see Figure 8. Note that the interface has both concave and convex parts. The wave speed inside

Max error at time $T = 200.0$ for the case $\kappa_e = 10$ inside the dielectric cylinder (u_{err}) and outside of it (w_{err}). The coefficient in the A^TA-dissipation was $\epsilon = 10^{-3}$.

N	h	Time steps	u_{err}, A^TA	w_{err}, A^TA
401	7.5×10^{-3}	53,333	2.03×10^{-1}	7.16×10^{-2}
801	3.75×10^{-3}	106,666	5.81×10^{-2}	1.75×10^{-2}

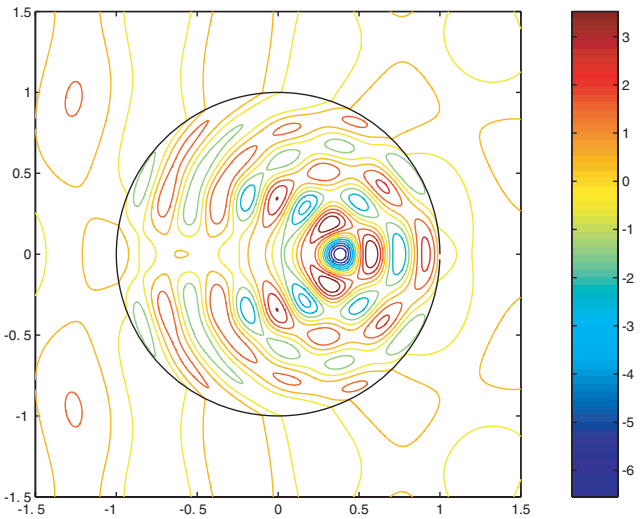

FIG. 6. *The Mie scattering solution at time $T = 10$ with $\kappa_e = 10$. Note the focusing of the wave inside the cylinder.*

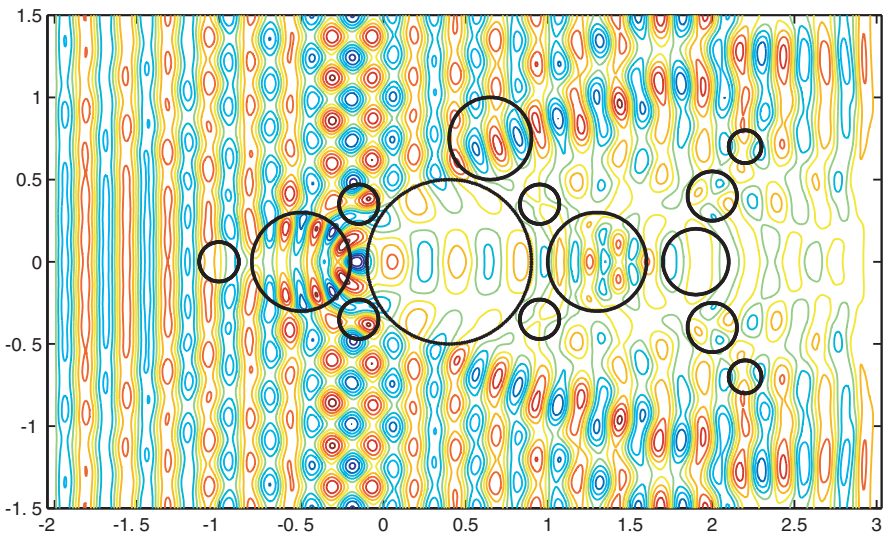

FIG. 7. *An incoming planar wave scattered by several bubbles with both larger and smaller wave speed compared to the ambient media.*

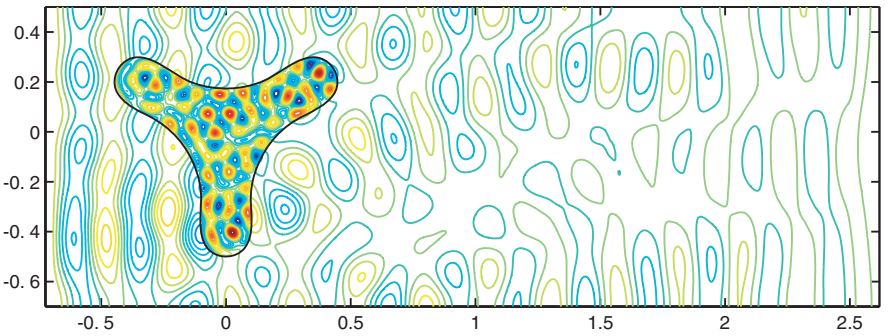

FIG. 8. *An incoming planar wave scattered by an irregular shape described by a periodic spline curve. The wave speed inside the curve was a factor* $\sqrt{10}$ *smaller than on the outside.*

the shape was $1/\sqrt{10}$ and the ambient wave speed was one. As in the previous example, the calculation was started from homogeneous initial conditions and driven on the left boundary by the data $u(-0.7, y, t) = \sin(8\pi t)$. Homogeneous Neumann conditions were imposed on the remaining boundaries. The solution is shown at time $T = 3.3$, which approximately corresponds to when the initial wave front reaches the right boundary.

7. Conclusions. We have developed a second order accurate embedded boundary method for the two-dimensional wave equation with discontinuous coefficients. The current method uses the same grid size throughout the computational domain, but as the jump in wave speed across the interface gets larger, it becomes obvious that this approach either overresolves the solution on one side of the interface or underresolves it on the other side. It would therefore be desirable to extend the method to handle different mesh sizes on different sides of the interface; some initial steps have been taken in this direction. We also expect to generalize the method to handle the more complicated jump conditions associated with the elastic wave equation with discontinuous coefficients.

ANALYSIS OF A FOURTH-ORDER SCHEME FOR A THREE-DIMENSIONAL CONVECTION-DIFFUSION MODEL PROBLEM*

ASHVIN GOPAUL† AND MUDDUN BHURUTH†

Abstract. We derive closed form expressions for the eigenvalues and discrete solution arising from a 19-point compact discretization of a three-dimensional convection-diffusion problem. It is shown that the coefficient matrix is positive definite when the cell-Reynolds number is greater than some critical value. By analyzing the terms composing the discrete solution, we prove that an oscillation-free discrete solution is guaranteed whenever the cell-Reynolds number exceeds a value which is grid-size dependent. An interesting result is that as the mesh size is refined, this value approaches the Golden Mean.

Key words. convection-diffusion equation, compact fourth-order scheme, eigenvalues, oscillations

1. Introduction.

Consider the three-dimensional problem

$$-\Delta u + (p,\, q,\, r)^{\mathrm{T}} \cdot \nabla u = f \tag{1.1}$$

on the unit cube $\Omega = (0,\, 1)^3$ subject to Dirichlet boundary conditions $u = g$ on $\partial\Omega$. We assume that the constants p, q, and r are positive on Ω. A central difference approximation to (1.1) leads to a seven-point stencil. Greif [4] has shown that applying one step of the cyclic reduction method followed by a reordering of the unknowns yields a reduced linear system with more favorable properties for solution by iterative methods. The reduced computational molecule uses 19 grid points and is noncompact.

In this paper we consider a 19-point compact fourth-order discretization [7] of the three-dimensional convection-diffusion equation (1.1). Comparison of the advantages and implementation costs of the fourth-order scheme with the central difference scheme have been carried out by Zhang [12]. The central difference scheme, although very accurate for small cell-Reynolds numbers, produces oscillatory solutions in the convection-dominated case. Although the upwind scheme is stable, discretizations over a fine mesh would result in very large linear systems and therefore slow convergence of the iterative schemes for computing the numerical solutions. One attractive advantage in using the fourth-order scheme analyzed for a model problem in this paper is that a much coarser discretization will give numerical solutions of comparable accuracy.

Numerical results reported by Gupta and Zhang [5] and our own experience with the fourth-order scheme for various convection-diffusion problems indicate that oscillation-free discrete solutions are obtained even in the convection-dominated case. The nonoscillatory property of the numerical solutions arising from fourth-order approximations and the unconditional stability with basic iterative methods has been

fully exploited in the efficient design of stable multigrid methods for convection-diffusion problems. The nonoscillatory property of the numerical solutions ensures that the residual is smooth and therefore there is no need to use defect-correction techniques. Stable multigrid methods using high-order compact discretizations for two-dimensional convection-diffusion problems are reported in [6, 8] and for three-dimensional problems in [5].

There has been no theoretical analysis of the matrix arising from the 19-point discretization of the three-dimensional problem (1.1). We carry out such an analysis here in the special case of convection in the x-direction, as the simplified matrix structure allows such an analysis, which is otherwise difficult. We also apply a Fourier technique to obtain an analytical expression for the discrete solution and we analyze the quality of the discrete solution produced by the fourth-order scheme. We do not address the question of convergence of iterative methods for the solution of the resulting nonsymmetric linear system.

2. A model three-dimensional problem. We consider the case when $q = r = 0$ in (1.1). On a uniform grid with grid spacing $h = 1/(n+1)$ on Ω, the unit cube, we denote $u_{i,j,k} = u(ih,\, jh,\, kh)$ and $f_{i,j,k} = f(ih,\, jh,\, kh)$, and we let $\gamma = ph/2$ denote the cell-Reynolds number. The 19-point computational molecule is shown in Figure 2.1. The coefficients are defined as follows: $s_1 = 24 + 4\gamma^2$, $s_2 = s_3 = s_4 = s_5 = -2$, $s_{12} = s_{13} = s_{14} = s_{15} = -(1-\gamma)$, $s_8 = s_9 = s_{10} = s_{11} = -1$, $s_6 = -2(1-\gamma+\gamma^2)$, $s_7 = -2(1+\gamma+\gamma^2)$, and $s_{16} = s_{17} = s_{18} = s_{19} = -(1+\gamma)$.

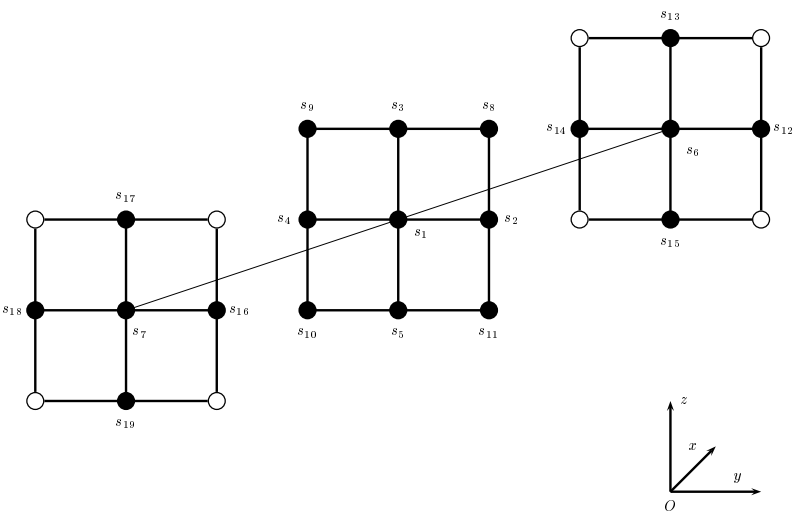

FIG. 2.1. *Computational molecule of a* 19*-point scheme.*

Considering the natural lexicographic ordering done by z-planes, the resulting linear system $A\mathbf{u} = \mathbf{f}$ has coefficient matrix

$$A = \text{blocktridiag}\,[A_-,\, A_0,\, A_+]\,, \tag{2.1}$$

TABLE 2.1
Elements of L_0, K_-, K_0, and K_+.

	a	b	c
L_0	-1	-2	-1
K_-	$-(1+\gamma)$	$-2(1+\gamma+\gamma^2)$	$-(1+\gamma)$
K_0	-2	$24+4\gamma^2$	-2
K_+	$-(1-\gamma)$	$-2(1-\gamma+\gamma^2)$	$-(1-\gamma)$

where the matrices A_-, A_0, and A_+ are given by

$$A_- = \text{tridiag}\,[L_-,\, K_-,\, L_-]\,, \quad A_0 = \text{tridiag}\,[L_0,\, K_0,\, L_0]\,, \quad A_+ = \text{tridiag}\,[L_+,\, K_+,\, L_+]\,.$$

The matrices L_0, K_-, K_0, and K_+ are of the form tridiag $[a, b, c]$, where the nonzero entries a, b, and c are shown in Table 2.1. The matrices L_- and L_+ are diagonal and we write them as $L_- = \text{diag}\,[-(1+\gamma)]$ and $L_+ = \text{diag}\,[-(1-\gamma)]$. The symmetric tridiagonal matrices L_0, K_-, K_0, and K_+ have the same eigenvector matrix $V = [\mathbf{v}_1, \mathbf{v}_2, \ldots, \mathbf{v}_n]$, where the eigenvectors $\mathbf{v}_j$ for $j = 1, 2, 3, \ldots, n$ are given by

$$\mathbf{v}_j = \sqrt{2h}\,[\sin\, j\pi h, \sin\, 2j\pi h, \ldots, \sin\, nj\pi h]^{\mathrm{T}}\,. \tag{2.2}$$

Denoting the eigenvalues of L_0, K_-, K_0, and K_+ by $\lambda_j^{(L_0)}$, $\lambda_j^{(K_-)}$, $\lambda_j^{(K_0)}$, and $\lambda_j^{(K_+)}$, respectively, we have

$$\begin{aligned}
\lambda_j^{(L_0)} &= -2 - 2\cos\, j\pi h,\\
\lambda_j^{(K_-)} &= -2(1+\gamma+\gamma^2) - 2(1+\gamma)\cos\, j\pi h,\\
\lambda_j^{(K_0)} &= 24 + 4\gamma^2 - 4\cos\, j\pi h,\\
\lambda_j^{(K_+)} &= -2(1-\gamma+\gamma^2) - 2\text{sign}(1-\gamma)|1-\gamma|\cos\, j\pi h.
\end{aligned}$$

For the eigenvalue problem $A_0\mathbf{w} = \theta^{(A_0)}\mathbf{w}$, we consider an eigenvector $\mathbf{w}$ of the form $\mathbf{w} = [\xi_1\mathbf{v}_j, \xi_2\mathbf{v}_j, \ldots, \xi_n\mathbf{v}_j]$, where the scalars ξ_i are to be determined from

$$\begin{aligned}
\xi_1 K_0\mathbf{v}_j + \xi_2 L_0\mathbf{v}_j &= \theta\xi_1\mathbf{v}_j,\\
\xi_{i-1}L_0\mathbf{v}_j + \xi_i K_0\mathbf{v}_j + \xi_{i+1}L_0\mathbf{v}_j &= \theta\xi_i\mathbf{v}_j \quad \text{for } i = 2, \ldots, n-1,\\
\xi_{n-1}L_0\mathbf{v}_j + \xi_n K_0\mathbf{v}_j &= \theta\xi_n\mathbf{v}_j.
\end{aligned} \tag{2.3}$$

Since $\mathbf{v}_j$ is an eigenvector of L_0 and K_0, (2.3) can be written in the form

$$\begin{bmatrix}
\lambda_j^{(K_0)} & \lambda_j^{(L_0)} & & & \\
\lambda_j^{(L_0)} & \lambda_j^{(K_0)} & \lambda_j^{(L_0)} & & \\
 & \ddots & \ddots & \ddots & \\
 & & \lambda_j^{(L_0)} & \lambda_j^{(K_0)} & \lambda_j^{(L_0)} \\
 & & & \lambda_j^{(L_0)} & \lambda_j^{(K_0)}
\end{bmatrix}
\begin{bmatrix} \xi_1 \\ \xi_2 \\ \vdots \\ \xi_n \end{bmatrix}
= \theta
\begin{bmatrix} \xi_1 \\ \xi_2 \\ \vdots \\ \xi_n \end{bmatrix}. \tag{2.4}$$

For a given j, the n eigenvalues $\theta_{j,k}^{(A_0)}$, $1 \le k \le n$, of the tridiagonal system (2.4) are given by

$$\begin{aligned}
\theta_{j,k}^{(A_0)} &= \lambda_j^{(K_0)} + 2\left(\text{sign}(\lambda_j^{(L_0)})\right)\lambda_j^{(L_0)}\cos k\pi h\\
&= 24 + 4\gamma^2 - 4\cos k\pi h - 4(1+\cos k\pi h)\cos j\pi h.
\end{aligned} \tag{2.5}$$

The eigenvector $\mathbf{w}_{j,k}$ corresponding to each $\theta_{j,k}$, $1 \leq k \leq n$, is given by

$$\mathbf{w}_{j,k} = [\sin k\pi h\, \mathbf{v}_j,\, \sin 2k\pi h\, \mathbf{v}_j,\, \ldots, \sin ik\pi h\, \mathbf{v}_j, \ldots \sin nk\pi h\, \mathbf{v}_j]^{\mathrm{T}}. \tag{2.6}$$

Now consider the eigenvalue problem $A_+\mathbf{w} = \theta^{(A_+)}\mathbf{w}$. Noting that L_+ is diagonal and K_+ is a symmetric tridiagonal matrix, we obtain the eigenvalues, $\{\theta_{j,k}^{(A_+)}\}_{1\leq j,k\leq n}$, of A_+ as

$$\begin{aligned}\theta_{j,\,k}^{(A_+)} &= \lambda_j^{(K_+)} + 2\left(\operatorname{sign}(\lambda_j^{(L_+)})\right)\lambda_j^{(L_+)}\cos k\pi h \\ &= -2(1-\gamma+\gamma^2) - 2\operatorname{sign}(1-\gamma)|1-\gamma|(\cos j\pi h + \cos k\pi h).\end{aligned} \tag{2.7}$$

Furthermore, A_+ has the same eigenvectors $\{\mathbf{w}_{j,k}\}_{1\leq j,k\leq n}$, as A_0.

Similarly, for the eigenvalue problem $A_-\mathbf{w} = \theta^{(A_-)}\mathbf{w}$, we find that the eigenvalues of A_- are given by

$$\begin{aligned}\theta_{j,\,k}^{(A_-)} &= \lambda_j^{(K_-)} + 2\left(\operatorname{sign}(\lambda_j^{(L_-)})\right)\lambda_j^{(L_-)}\cos k\pi h \\ &= -2(1+\gamma+\gamma^2) - 2(1+\gamma)(\cos j\pi h + \cos k\pi h),\end{aligned} \tag{2.8}$$

and the n^2 eigenvectors are the same vectors $\{\mathbf{w}_{j,k}\}_{1\leq j,k\leq n}$ as in (2.6).

For the eigenvalue problem $A\mathbf{z} = \phi\mathbf{z}$, we consider an eigenvector $\mathbf{z}$ [9] of the form $\mathbf{z} = [\psi_1\mathbf{w}_{j,k},\, \psi_2\mathbf{w}_{j,k},\, \ldots,\, \psi_{n^2}\mathbf{w}_{j,k}]$. The resulting set of equations is given by

$$\begin{aligned}\psi_1 A_0\mathbf{w}_{j,k} + \psi_2 A_+\mathbf{w}_{j,k} &= \phi\psi_1\mathbf{w}_{j,k}, \\ \psi_{i-1}A_-\mathbf{w}_{j,k} + \psi_i A_0\mathbf{w}_{j,k} + \psi_{i+1}A_+\mathbf{w}_{j,k} &= \phi\psi_i\mathbf{w}_{j,k}, \quad i = 2,\, \ldots, n^2-1, \\ \psi_{n^2-1}A_-\mathbf{w}_{j,k} + \psi_{n^2}A_0\mathbf{w}_{j,k} &= \phi\psi_{n^2}\mathbf{w}_{j,k}.\end{aligned} \tag{2.9}$$

Since $\mathbf{w}_{j,k}$ is a common eigenvector of A_0, A_+, and A_-, (2.9) can be written in the form

$$\begin{bmatrix} \theta_{j,k}^{(A_0)} & \theta_{j,k}^{(A_+)} & & & \\ \theta_{j,k}^{(A_-)} & \theta_{j,k}^{(A_0)} & \theta_{j,k}^{(A_+)} & & \\ & \ddots & \ddots & \ddots & \\ & & \theta_{j,k}^{(A_-)} & \theta_{j,k}^{(A_0)} & \theta_{j,k}^{(A_+)} \\ & & & \theta_{j,k}^{(A_-)} & \theta_{j,k}^{(A_0)} \end{bmatrix} \begin{bmatrix} \psi_1 \\ \psi_2 \\ \vdots \\ \psi_{n^2} \end{bmatrix} = \phi \begin{bmatrix} \psi_1 \\ \psi_2 \\ \vdots \\ \psi_{n^2} \end{bmatrix}. \tag{2.10}$$

For fixed j and k, the n eigenvalues $\phi_{i,\,j,\,k}$ of the tridiagonal system (2.10) are given by

$$\phi_{i,\,j,\,k} = \theta_{j,k}^{(A_0)} + 2\left(\operatorname{sign}(\theta_{j,k}^{(A_+)})\right)\sqrt{\theta_{j,k}^{(A_-)}\theta_{j,k}^{(A^+)}}\cos i\pi h,\ 1 \leq i \leq n. \tag{2.11}$$

It then follows from (2.5), (2.7), (2.8), and (2.11) that the n^3 eigenvalues $\{\phi_{i,\,j,\,k}\}_{1\leq i,\,j,\,k\leq n}$ of the three-dimensional coefficient matrix A in (2.1) are given by

$$\begin{aligned}\phi_{i,\,j,\,k} &= 24 + 4\gamma^2 - 4C_k - 4(1+C_k)C_j \\ &\quad + 4\left(1+\gamma^2+\gamma^4 + 2(C_j+C_k) + (1-\gamma^2)(C_j+C_k)^2\right)^{\frac{1}{2}} C_i,\end{aligned}$$

where $C_m = \cos m\pi h$ for $m = i, j, k$, and $1 \le i, j, k \le n$. By letting

$$\zeta = 1 + \gamma^2 + \gamma^4 + 2\left(\cos j\pi h + \cos k\pi h\right) + \left(1 - \gamma^2\right)\left(\cos j\pi h + \cos k\pi h\right)^2, \tag{2.12}$$

we have the following result.

THEOREM 2.1. [illegible] $\phi_{i,j,k}$ $1 \le i, j, k \le n$ [illegible] $n^3 \times n^3$ [illegible] A [illegible] (2.1) [illegible]

$$\phi_{i,j,k} = 24 + 4\gamma^2 - 4\cos k\pi h - 4\left(1 + \cos k\pi h\right)\cos j\pi h + 4\zeta^{\frac{1}{2}}\cos i\pi h. \tag{2.13}$$

In the following, we prove that for a given grid spacing h, the eigenvalues of A are all positive if the cell-Reynolds number γ lies outside a certain interval.

LEMMA 2.1. [illegible] n [illegible] j [illegible] k $1 \le j, k \le n$ [illegible]

$$\vartheta_{j,k} = \cos j\pi h + \cos k\pi h < -1.$$

[illegible] ζ [illegible] (2.12) [illegible] γ [illegible]

$$\left[\frac{1}{2}\left(1 + \vartheta_{j,k} + \sqrt{\vartheta_{j,k}^2 - 2\vartheta_{j,k} - 3}\,\right), \frac{1}{2}\left(-1 - \vartheta_{j,k} + \sqrt{\vartheta_{j,k}^2 - 2\vartheta_{j,k} - 3}\,\right)\right].$$

[illegible] We find that

$$1 + \gamma^2 + \gamma^4 + 2\vartheta_{j,k} + (1 - \gamma^2)\vartheta_{j,k}^2 = \left(\gamma^2 + \frac{1}{2}\left(1 - \vartheta_{j,k}\right)^2\right)^2 + \frac{1}{4}\left(3 - \vartheta_{j,k}\right)\left(1 + \vartheta_{j,k}\right)^3. \tag{2.14}$$

From (2.14), we deduce that $1 + \gamma^2 + \gamma^4 + 2\vartheta_{j,k} + (1 - \gamma^2)\vartheta_{j,k}^2$ is positive for all $\gamma > 0$ if $\vartheta_{j,k} \ge -1$. For $\vartheta_{j,k} < -1$,

$$1 + \gamma^2 + \gamma^4 + 2\vartheta_{j,k} + (1 - \gamma^2)\vartheta_{j,k}^2 = \left(\gamma - \varsigma_1\right)\left(\gamma - \varsigma_2\right)\left(\gamma - \varsigma_3\right)\left(\gamma - \varsigma_4\right),$$

where $\varsigma_1 = \frac{1}{2}(1 + \vartheta_{j,k} + \sqrt{\vartheta_{j,k}^2 - 2\vartheta_{j,k} - 3}\,)$, $\varsigma_2 = \frac{1}{2}(1 + \vartheta_{j,k} - \sqrt{\vartheta_{j,k}^2 - 2\vartheta_{j,k} - 3}\,)$, $\varsigma_3 = \frac{1}{2}(-1 - \vartheta_{j,k} + \sqrt{\vartheta_{j,k}^2 - 2\vartheta_{j,k} - 3}\,)$, and $\varsigma_4 = \frac{1}{2}(-1 - \vartheta_{j,k} - \sqrt{\vartheta_{j,k}^2 - 2\vartheta_{j,k} - 3}\,)$. Noting that the roots ς_2 and ς_4 are negative for all $\vartheta_{j,k} < -1$, we find that $1 + \gamma^2 + \gamma^4 + 2\vartheta_{j,k} + (1 - \gamma^2)\vartheta_{j,k}^2$ is positive if γ lies outside the interval

$$\left[\frac{1}{2}\left(1 + \vartheta_{j,k} + \sqrt{\vartheta_{j,k}^2 - 2\vartheta_{j,k} - 3}\,\right), \frac{1}{2}\left(-1 - \vartheta_{j,k} + \sqrt{\vartheta_{j,k}^2 - 2\vartheta_{j,k} - 3}\,\right)\right]. \qquad \square$$

Note that the above result applies for a given pair (j, k). Considering all those pairs (j, k) for which $\vartheta_{j,k} < -1$ gives the next result.

LEMMA 2.2. [illegible] $J = \{(j, k), 1 \le j, k \le n | \vartheta_{j,k} < -1\}$ [illegible] $(j, k) \in J$ [illegible] $I_{\vartheta_{j,k}}$ [illegible]

$$\left[\frac{1}{2}\left(1 + \vartheta_{j,k} + \sqrt{\vartheta_{j,k}^2 - 2\vartheta_{j,k} - 3}\,\right), \frac{1}{2}\left(-1 - \vartheta_{j,k} + \sqrt{\vartheta_{j,k}^2 - 2\vartheta_{j,k} - 3}\,\right)\right].$$

[illegible] $S = \bigcup_J I_{\vartheta_{j,k}}$ [illegible] $\gamma \notin S$ ζ [illegible] (2.12) [illegible]

Finally, we show that, for n large enough, the matrix A is positive definite if γ lies outside some subset of $(0, \infty)$.

THEOREM 2.2. [illegible] n $\gamma \notin \bigcup_J I_{\vartheta_{j,k}}$ [illegible] $\{\phi_{i,j,k}\}_{1\leq i,j,k\leq n}$ [illegible] (2.13) [illegible]

[illegible]. For $\gamma \notin \bigcup_J I_{\vartheta_{j,k}}$, the eigenvalues $\phi_{i,j,k}$ are all real and the minimum eigenvalue is given by

$$\phi_{n,1,1} \;=\; 24 \,+\, 4\gamma^2 \,-\, 8C_1 \,-\, 4C_1^2 \,+\, 4\bigg(1+\gamma^2+\gamma^4+4C_1+4(1-\gamma^2)C_1^2\bigg)^{\frac{1}{2}} C_n.$$

For n large enough, we have

$$\phi_{n,1,1} \approx 12 + 4\gamma^2 - 4\sqrt{\gamma^4 - 3\gamma^2 + 9}.$$

Writing

$$12 + 4\gamma^2 - 4\sqrt{\gamma^4 - 3\gamma^2 + 9} = \frac{144\gamma^2}{12 + 4\gamma^2 + 4\sqrt{\gamma^4 - 3\gamma^2 + 9}},$$

we find that the minimum eigenvalue $\phi_{n,1,1}$ is positive. It thus follows that all the eigenvalues are positive if $\gamma \notin \cup_J I_{\vartheta_{j,k}}$. ∎

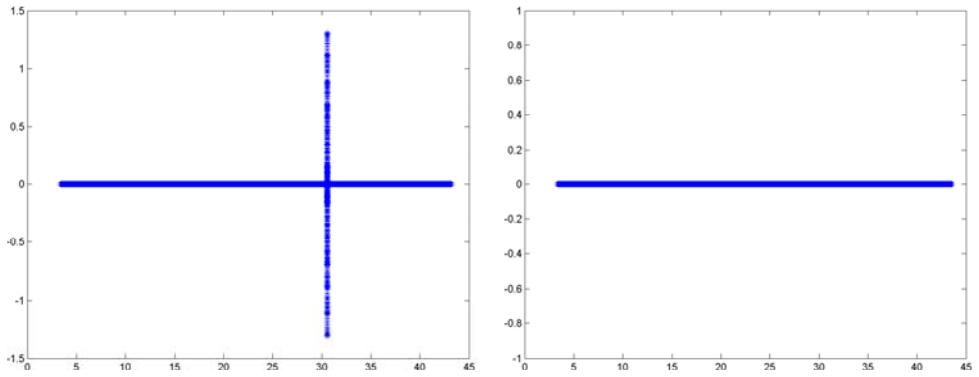
We show in Table 2.2, for different mesh sizes h, endpoints $\gamma_{\min}$ and $\gamma_{\max}$ of intervals outside which the eigenvalues of A are all positive. These endpoints are the analytical bounds computed by considering the set $\cup_J I_{\vartheta_{j,k}}$.

TABLE 2.2
Endpoints $\gamma_{\min}$ and $\gamma_{\max}$ of intervals for different mesh sizes h.

	$\gamma_{\min}$	$\gamma_{\max}$
$h = 1/8$	0.2581	1.4375
$h = 1/16$	0.1502	1.5729
$h = 1/24$	0.2038	1.5980
$h = 1/48$	0.1051	1.6130
$h = 1/96$	0.0355	1.6168

We show in Figure 2.2 the eigenspectrum of A for the cases $\gamma = 1.60$ and $\gamma = 1.62$. We have chosen a mesh size of $h = 1/65$. Observe that there are complex eigenvalues when $\gamma = 1.60$ as $\gamma \in \bigcup_J I_{\vartheta_{j,k}}$ for this case.

The above analysis reveals that the eigenvalues of A are positive if γ lies outside a small subset of $(0, \infty)$. It would therefore be interesting to detect values of γ for which the matrix A is symmetrizable so that the symmetrized linear system can be efficiently solved by the conjugate gradient method. Unfortunately the matrix A cannot be symmetrized by a real diagonal matrix $Q \in \mathbb{R}^{n^3\times n^3}$ when $\gamma > 0$. To see this, consider the block diagonal matrix $Q = \text{diag}\,[Q_1, Q_2, \ldots, Q_n]$, where each Q_i is an $n^2 \times n^2$ diagonal matrix and let Q_{ij}, $j = 1, 2, 3, \ldots n$, denote the $n\times n$ jth diagonal block of Q_i. For the matrix $\widehat{A} = Q^{-1}AQ$, we require that $\widehat{A}^{\mathrm{T}} = \widehat{A}$. Since A_0, the block diagonal entry of A, is symmetric, we need only to satisfy the condition $Q_i^{-1}A_-Q_{i-1} = Q_{i-1}^{-1}A_+Q_i$. This then results in the condition $Q_{ij}K_+Q_{i-1,j}^{-1} = Q_{ij}^{-1}K_-Q_{i-1,j}$. We can then show that we require that $(1+\gamma+\gamma^2)(1-\gamma) = (1-\gamma+\gamma^2)(1+\gamma)$. This condition is satisfied only in the case $\gamma = 0$.



(a) $\gamma = 1.60$. (b) $\gamma = 1.62$.

FIG. 2.2. *Eigenspectrum of A for two different values of* γ.

3. Discrete solutions of three-dimensional problem. Recently Elman and Ramage [2] have described a method to analyze the nature of the discrete solutions produced by the discretization of a model two-dimensional convection-diffusion equation using the Galerkin finite element method. In [3] we have derived analytical expressions for the discrete solution arising from a fourth-order compact discretization of a model two-dimensional convection-diffusion problem and by analyzing the terms composing the discrete solution, we showed that the discrete solution did not contain any oscillations. In this section, we extend the analysis to the three-dimensional equation

$$-\Delta u + pu_x = 0 \quad \text{on} \quad \Omega = (0,1) \times (0,1) \times (0,1), \tag{3.1}$$

with Dirichlet boundary conditions on $\partial\Omega$. For a uniform mesh $h = 1/(n+1)$, we consider the corresponding linear system $A\mathbf{u} = \mathbf{f}$ with coefficient matrix A given in (2.1).

Denoting by V the eigenvector matrix whose columns are the vectors $\mathbf{v}_j$, $j = 1, \ldots, n$, in (2.2), we obtain the decomposition $A_0 = (\mathcal{V}P)\,\mathcal{D}^{(A_0)}\,(\mathcal{V}P)^{\mathrm{T}}$, where $\mathcal{V}$ is a block diagonal matrix given by $\mathcal{V} = \operatorname{diag}(V, V, \ldots, V)$, P is an $n^2 \times n^2$ permutation matrix, and $\mathcal{D}^{(A_0)}$ is a block diagonal matrix with diagonal blocks $D_j^{(A_0)}$ given by

$$D_j^{(A_0)} = \operatorname{tridiag}\left[\lambda_j^{(L_0)}, \lambda_j^{(K_0)}, \lambda_j^{(L_0)}\right].$$

Similarly the matrices A_- and A_+ can be decomposed in the forms $A_+ = (\mathcal{V}P)\,\mathcal{D}^{(A_+)} \cdot (\mathcal{V}P)^{\mathrm{T}}$ and $A_- = (\mathcal{V}P)\,\mathcal{D}^{(A_-)}\,(\mathcal{V}P)^{\mathrm{T}}$, respectively, where the matrices $\mathcal{D}^{(A_-)}$ and $\mathcal{D}^{(A_+)}$ are block diagonal with diagonals blocks $D_j^{(A_-)}$ and $D_j^{(A_+)}$, respectively, given by

$$D_j^{(A_-)} = \operatorname{tridiag}\left[\lambda_j^{(L_-)}, \lambda_j^{(K_-)}, \lambda_j^{(L_-)}\right], \quad D_j^{(A_+)} = \operatorname{tridiag}\left[\lambda_j^{(L_+)}, \lambda_j^{(K_+)}, \lambda_j^{(L_+)}\right].$$

Also, the matrices $D_j^{(A_0)}$, $D_j^{(A_-)}$, and $D_j^{(A_+)}$ can be diagonalized as follows: $V^{\mathrm{T}} D_j^{(A_0)} V = \operatorname{diag}[\theta_{j,1}^{(A_0)}, \theta_{j,2}^{(A_0)}, \ldots, \theta_{j,n}^{(A_0)}]$, $V^{\mathrm{T}} D_j^{(A_-)} V = \operatorname{diag}[\theta_{j,1}^{(A_-)}, \theta_{j,2}^{(A_-)}, \ldots, \theta_{j,n}^{(A_-)}]$, and $V^{\mathrm{T}} D_j^{(A_+)} V = \operatorname{diag}[\theta_{j,1}^{(A_+)}, \theta_{j,2}^{(A_+)}, \ldots, \theta_{j,n}^{(A_+)}]$.

Now let $\mathcal{W}$ denote an $n^3 \times n^3$ block diagonal matrix with diagonal matrices equal to $\mathcal{V}P\mathcal{V}$ on the diagonals and let $\overline{P}$ be an $n^3 \times n^3$ permutation matrix. Then the matrix A can be decomposed as

$$A = \left(\mathcal{W}\overline{P}\right) \mathcal{T}^{(A)} \left(\mathcal{W}\overline{P}\right)^{\mathrm{T}}, \tag{3.2}$$

where $\mathcal{T}^{(A)}$ is a block diagonal matrix with diagonal blocks $T_{j,k}^{(A)}$ given by $T_{j,k}^{(A)} = \text{tridiag}[\theta_{j,k}^{(A_-)}, \theta_{j,k}^{(A_0)}, \theta_{j,k}^{(A_+)}]$. Using (3.2), we can now express the linear system $A\mathbf{u} = \mathbf{f}$ as

$$(\mathcal{W}\overline{P})\mathcal{T}^{(A)}(\mathcal{W}\overline{P})^{\mathrm{T}}\mathbf{u} = \mathbf{f}. \tag{3.3}$$

Letting $\mathbf{y} = (\mathcal{W}\overline{P})^{\mathrm{T}}\mathbf{u}$, (3.3) becomes

$$\mathcal{T}^{(A)}\mathbf{y} = \overline{P}^{\mathrm{T}}\mathcal{W}^{\mathrm{T}}\mathbf{f} = \widehat{\mathbf{f}}. \tag{3.4}$$

Since the matrix $\mathcal{T}^{(A)}$ is block diagonal, we find that (3.4) can be split into n^2 tridiagonal systems of size $n \times n$ given by

$$T_{j,k}^{(A)}\mathbf{y}_{j,k} = \widehat{\mathbf{f}}_{j,k}, \tag{3.5}$$

where $\mathbf{y}_{j,k} = [y_{1,j,k}, y_{2,j,k}, \ldots, y_{n,j,k}]^{\mathrm{T}}$ and $\widehat{\mathbf{f}}_{j,k} = [\widehat{f}_{1,j,k}, \widehat{f}_{2,j,k}, \ldots, \widehat{f}_{n,j,k}]^{\mathrm{T}}$. The discrete solution $\mathbf{u}$ arising from the fourth-order discretization of (3.1) is then obtained from $\mathbf{u} = \mathcal{W}\overline{P}\mathbf{y}$.

3.1. Solution of recurrence relation. The solution of each tridiagonal system (3.5) reduces to the solution of a three-term recurrence relation with constant coefficients given by

$$\theta_{j,k}^{(A_-)}y_{i-1,j,k} + \theta_{j,k}^{(A_0)}y_{i,j,k} + \theta_{j,k}^{(A_+)}y_{i+1,j,k} = \widehat{\mathbf{f}}_{j,k}, \tag{3.6}$$

with boundary conditions $y_{0,j,k}$ and $y_{n+1,j,k}$ which can be computed from the entries of $\widehat{\mathbf{f}}_{j,k}$. To obtain an explicit expression for $y_{i,j,k}$, we consider for given j and k the roots $\mu_1(j,k)$ and $\mu_2(j,k)$ of the auxiliary equation

$$\theta_{j,k}^{(A_+)}\mu(j,k)^2 + \theta_{j,k}^{(A_0)}\mu(j,k) + \theta_{j,k}^{(A_-)} = 0.$$

These roots are given by

$$\begin{aligned}
\mu_1(j,k) &= \frac{-\theta_{j,k}^{(A_0)} + \sqrt{\left(\theta_{j,k}^{(A_0)}\right)^2 - 4\theta_{j,k}^{(A_-)}\theta_{j,k}^{(A_+)}}}{2\theta_{j,k}^{(A_+)}}, \\
\mu_2(j,k) &= \frac{-\theta_{j,k}^{(A_0)} - \sqrt{\left(\theta_{j,k}^{(A_0)}\right)^2 - 4\theta_{j,k}^{(A_-)}\theta_{j,k}^{(A_+)}}}{2\theta_{j,k}^{(A_+)}}.
\end{aligned} \tag{3.7}$$

In the following we omit the indices j and k from the roots of the auxiliary equation and denote $\mu_1 = \mu_1(j,k)$ and $\mu_2 = \mu_2(j,k)$. The solution of (3.6) is given by [2]

$$y_{i,\,j,\,k} = \sum_{m=1}^{3} W_m(j,k)R_m(i,j,k), \tag{3.8}$$

where

$$
\begin{aligned}
R_1(i,j,k) &= \frac{\mu_1^i - \mu_2^i}{\mu_1^{n+1} - \mu_2^{n+1}},\\
R_2(i,j,k) &= \left(1-\mu_1^i\right) - \left(1-\mu_1^{n+1}\right)\left(\frac{\mu_1^i - \mu_2^i}{\mu_1^{n+1} - \mu_2^{n+1}}\right),\\
R_3(i,j,k) &= \mu_1^i - \mu_1^{n+1}\left(\frac{\mu_1^i - \mu_2^i}{\mu_1^{n+1} - \mu_2^{n+1}}\right).
\end{aligned}
\tag{3.9}
$$

The weight function $W_1(j,k)$ is related to the Dirichlet boundary conditions on the plane $x=1$, $W_3(j,k)$ is related to the boundary conditions on the plane $x=0$, and $W_2(j,k)$ combines the boundary conditions on the planes $y=0$, $y=1$, $z=0$, and $z=1$. Using the relation $R_3(i,j,k) = 1 - R_1(i,j,k) - R_2(i,j,k)$, (3.8) can be written in the form [2, Theorem 3.1]

$$
y_{i,\,j,\,k} = W_3(j,k) + \left[W_1(j,k) - W_3(j,k)\right] R_1(i,j,k) + \left[W_2(j,k) - W_3(j,k)\right] R_2(i,j,k).
\tag{3.10}
$$

The discrete solution $\mathbf{u} = \{u_{i,j,k}\}_{1\le i,j,k\le n}$ given by $\mathbf{u} = \mathcal{W}\overline{P}\mathbf{y}$ can then be expressed in the form

$$
u_{i,\,j,\,k} = \sqrt{\frac{2}{n+1}} \sum_{l=1}^{n} \sin(lj\pi h)\overline{y}_{i,\,l,\,k}, \quad \text{where} \quad \overline{y}_{i,\,j,\,k} = \sqrt{\frac{2}{n+1}} \sum_{l=1}^{n} \sin(lk\pi h) y_{i,\,j,\,l}.
\tag{3.11}
$$

3.2. Study of auxiliary roots. In this section, we study the roots, μ_1 and μ_2, of the auxiliary equation in order to determine the behavior of the discrete solution $\mathbf{u}$. We denote $C_j = \cos j\pi h$ and $C_k = \cos k\pi h$. From (2.5), (2.7), (2.8), and (3.7), we find that the auxiliary roots can be expressed as

$$
\mu_1 = \frac{6+\gamma^2 - C_j - C_k - C_jC_k - \sqrt{\chi}}{1-\gamma+\gamma^2+(1-\gamma)(C_j+C_k)}, \quad \mu_2 = \frac{6+\gamma^2 - C_j - C_k - C_jC_k + \sqrt{\chi}}{1-\gamma+\gamma^2+(1-\gamma)(C_j+C_k)},
$$

where

$$
\chi = 35 + 11\gamma^2 - 2(7+\gamma^2 - C_jC_k)(C_j+C_k) + \gamma^2(C_j^2+C_k^2) + C_jC_k(C_jC_k - 12).
$$

Denoting $\vartheta_{j,k} = C_j + C_k$, we first consider the denominator term in both μ_1 and μ_2 given by

$$
1-\gamma+\gamma^2+(1-\gamma)\vartheta_{j,k} = \left[\gamma - \frac{1}{2}(1+\vartheta_{j,k})\right]^2 + \frac{1}{4}\left[(3-\vartheta_{j,k})\,(\vartheta_{j,k}+1)\right].
$$

For $\vartheta_{j,k} \ge -1$, the denominator term is positive for all $\gamma > 0$. For $\vartheta_{j,k} < -1$, we determine the range of γ for which $1-\gamma+\gamma^2+(1-\gamma)\vartheta_{j,k}$ becomes negative. We see that $1-\gamma+\gamma^2+(1-\gamma)\vartheta_{j,k} = (\gamma-\varsigma_1)\,(\gamma-\varsigma_2)$, where $\varsigma_1 = \frac{1}{2}(1+\vartheta_{j,k} + \sqrt{\vartheta_{j,k}^2 - 2\vartheta_{j,k} - 3}\,)$ and $\varsigma_2 = \frac{1}{2}(1+\vartheta_{j,k} - \sqrt{\vartheta_{j,k}^2 - 2\vartheta_{j,k} - 3}\,)$. Because ς_2 is negative for $\vartheta_{j,k} < -1$, we find that $1-\gamma+\gamma^2+(1-\gamma)\vartheta_{j,k}$ will be negative only for $\gamma \in \widetilde{I}_{\vartheta_{j,k}}$ where the interval $\widetilde{I}_{\vartheta_{j,k}}$ for $\vartheta_{j,k} < -1$ is given by

$$
\widetilde{I}_{\vartheta_{j,k}} = \left(0,\, \frac{1}{2}\big(1+\vartheta_{j,k} + \sqrt{\vartheta_{j,k}^2 - 2\vartheta_{j,k} - 3}\,\big)\right).
$$

The term $6+\gamma^2-C_j-C_k-C_jC_k$ in the numerator is always positive for all j, k and for $\gamma > 0$. To find the range of γ for which the numerator is positive, we first note that

$$\chi = [11 + (C_j + C_k)(C_j + C_k - 2) - 2C_jC_k]\,\gamma^2 + [35 + 2(C_j + C_k)(C_jC_k - 7) + C_jC_k(C_jC_k - 12)]\,. \tag{3.12}$$

Since $-1 < C_j,\, C_k < 1$, the terms $11+(C_j+C_k)(C_j+C_k-2)-2C_jC_k$ and $35+2(C_j+C_k)(C_jC_k-7)+C_jC_k(C_jC_k-12)$ are always positive for any values of the indices j and k. It then follows that μ_2 is positive if its denominator $1-\gamma+\gamma^2+(1-\gamma)(C_j+C_k)$ is positive. This is true when $\gamma > \varsigma_1$. To show that the numerator of μ_1 is positive, we need to show that $6+\gamma^2-C_j-C_k-C_jC_k > \sqrt{\chi}$. Now,

$$\begin{aligned}(6+\gamma^2-C_j-C_k-C_jC_k)^2 - \big[&(11+(C_j+C_k)(C_j+C_k-2)-2C_jC_k)\,\gamma^2 \\ &+ (35+2(C_j+C_k)(C_jC_k-7)+C_jC_k(C_jC_k-12))\big] \\ &= \left[\gamma^2 + \frac{1}{2}\left(1-\vartheta_{j,k}^2\right)\right]^2 + \frac{1}{4}\left(3-\vartheta_{j,k}\right)\left(1+\vartheta_{j,k}\right)^3.\end{aligned}$$

Using a similar argument, we find that the numerator of μ_1 will be positive if

$$\gamma < \frac{1}{2}\left(1+\vartheta_{j,k}+\sqrt{\vartheta_{j,k}^2-2\vartheta_{j,k}-3}\right), \quad \text{or} \quad \gamma > \frac{1}{2}\left(-1-\vartheta_{j,k}+\sqrt{\vartheta_{j,k}^2-2\vartheta_{j,k}-3}\right),$$

as it was shown for (2.14).

The above analysis leads to the following result.

LEMMA 3.1. [illegible] $J = \{(j,k), 1 \le j,k \le n | \vartheta_{j,k} < -1\}$ [illegible] $(j,k) \in J$ [illegible] $\widetilde{I}_{\vartheta_{j,k}}^{(\mu_1)}$ [illegible] $\widetilde{I}_{\vartheta_{j,k}}^{(\mu_2)}$ [illegible]

$$\widetilde{I}_{\vartheta_{j,k}}^{(\mu_1)} = \left(0,\, \frac{1}{2}\left(-1-\vartheta_{j,k}+\sqrt{\vartheta_{j,k}^2-2\vartheta_{j,k}-3}\right)\right)$$

[illegible]

$$\widetilde{I}_{\vartheta_{j,k}}^{(\mu_2)} = \left(0,\, \frac{1}{2}\left(1+\vartheta_{j,k}+\sqrt{\vartheta_{j,k}^2-2\vartheta_{j,k}-3}\right)\right),$$

[illegible] $j,\, k$ [illegible] $1 \le j,\, k \le n$

- $\mu_1(j,k) > 0$ [illegible] $\gamma \notin \bigcup_J \widetilde{I}_{\vartheta_{j,k}}^{(\mu_1)}$
- $\mu_2(j,k) > 0$ [illegible] $\gamma \notin \bigcup_J \widetilde{I}_{\vartheta_{j,k}}^{(\mu_2)}$

For $\vartheta_{j,k} < -1$, we remark that the set $\bigcup_J \widetilde{I}_{\vartheta_{j,k}}^{(\mu_2)} \subset \bigcup_J \widetilde{I}_{\vartheta_{j,k}}^{(\mu_1)}$ and therefore we deduce that the auxiliary roots μ_1 and μ_2 are both positive if $\vartheta_{n,n} < -1$ and

$$\gamma > \frac{1}{2}\left(-1-\vartheta_{n,n}+\sqrt{\left(\vartheta_{n,n}-3\right)\left(\vartheta_{n,n}+1\right)}\right).$$

It is interesting to note that when the mesh size is refined, the lower bound on the range of values of γ approaches the Golden Mean $= \frac{1+\sqrt{5}}{2}$.

The next result states the condition under which the smaller root μ_1 is less than unity.

LEMMA 3.2. [illegible] (j,k) [illegible] $\mu_1(j,k)$ [illegible]

$$\gamma \notin \left(0,\, \frac{1}{2}\left(1+\vartheta_{j,k}+\sqrt{\vartheta_{j,k}^2-2\vartheta_{j,k}-3}\right)\right).$$

[illegible]. We need to show that

$$6+\gamma^2-(C_j+C_k)-C_jC_k-\sqrt{\chi} \;<\; 1-\gamma+\gamma^2+(1-\gamma)(C_j+C_k). \tag{3.13}$$

First, observe that

$$6+\gamma^2-(C_j+C_k)-C_jC_k-(1-\gamma+\gamma^2+(1-\gamma)(C_j+C_k)) = 5+(\gamma-2)(C_j+C_k)-C_jC_k.$$

Also,

$$\begin{aligned}(5+\vartheta_{j,k}(\gamma-2)-C_jC_k)^2-\chi \\ = 2\left(-5+2\vartheta_{j,k}+C_jC_k\right)\left(\gamma^2-(1+\vartheta_{j,k})\gamma+(1+\vartheta_{j,k})\right).\end{aligned} \tag{3.14}$$

To prove the inequality (3.13), it is sufficient to show that the right-hand side term in (3.14) is always negative.

As $2\left(-5+2\vartheta_{j,k}+C_jC_k\right)$ is always negative, we look for the range of γ for which

$$\gamma^2-(1+\vartheta_{j,k})\gamma+(1+\vartheta_{j,k})$$

is positive for all j and k. A similar analysis as in the other cases shows that the right-hand side of (3.14) is always negative when

$$\begin{aligned}\gamma < \varsigma_2 &= \frac{1}{2}\left(1+\vartheta_{j,k}-\sqrt{\vartheta_{j,k}^2-2\vartheta_{j,k}-3}\right), \quad \text{or}\\ \gamma > \varsigma_1 &= \frac{1}{2}\left(1+\vartheta_{j,k}+\sqrt{\vartheta_{j,k}^2-2\vartheta_{j,k}-3}\right).\end{aligned}$$

The same arguments as used above show that the smaller root μ_1 is always less than unity when $\gamma > (1+\vartheta_{j,k}+\sqrt{\vartheta_{j,k}^2-2\vartheta_{j,k}-3}\,)/2$. □

3.3. Analysis of recurrence relation solution. To investigate whether the recurrence relation solution $\mathbf{y} = \{y_{i,j,k}\}_{1\le i,j,k\le n}$ given by (3.10) is oscillatory, we consider the two functions $R_1(i,\,j,\,k)$ and $R_2(i,\,j,\,k)$. Note that $R_1(i,\,j,\,k) = [\frac{1-\left(\frac{\mu_1}{\mu_2}\right)^i}{1-\left(\frac{\mu_1}{\mu_2}\right)^{n+1}}]\mu_2^{i-n-1}$. When $\gamma > (-1-\vartheta_{j,k}+\sqrt{\vartheta_{j,k}^2-2\vartheta_{j,k}-3}\,)/2$, the roots μ_1 and μ_2 are positive, and thus in this range of γ, $0<\mu_1/\mu_2<1$ and $\mu_2>0$. We thus conclude that for given j and k, $R_1(i,\,j,\,k)$ is not an oscillatory function of i in this range. From (3.9), we find that $R_2(i,j,k) = (1-\mu_1^i)-(1-\mu_1^{n+1})R_1(i,j,k)$. Since $0<\mu_1<1$ when $\gamma > (1+\vartheta_{j,k}+\sqrt{\vartheta_{j,k}^2-2\vartheta_{j,k}-3}\,)/2$ and $R_1(i,j,k)$ is nonoscillatory when $\gamma > \frac{1}{2}(-1-\vartheta_{j,k}+\sqrt{\vartheta_{j,k}^2-2\vartheta_{j,k}-3})$, we find that, for given j and k, $R_2(i,j,k)$ is also a nonoscillatory function of i.

We summarize the above in the next theorem.

THEOREM 3.1. [illegible] (3.1) [illegible] $h = 1/(n+1)$ [illegible] $\mathbf{y}$ [illegible] (3.6) [illegible] γ [illegible] γ_c [illegible]

$$\gamma_c = \frac{1}{2}\left(2\cos\pi h - 1 + \sqrt{(2\cos\pi h+3)(2\cos\pi h-1)}\right). \tag{3.15}$$

From (3.15), we see that $\gamma_c \to (1+\sqrt{5})/2$ if $h \to 0$.

3.4. Numerical examples. We illustrate the behavior of the discrete solution $\mathbf{u}$ for some three-dimensional problems. We discretize (3.1) on a uniform mesh with grid size $h = 1/33$.

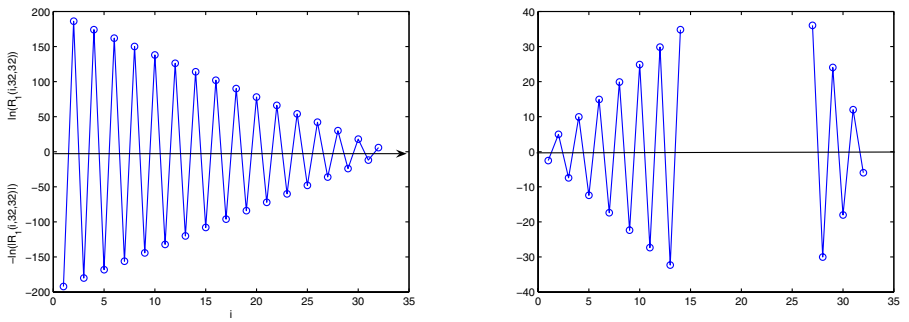
PROBLEM 3.1.

$$u(x, y, z) = \frac{e^{px/2}}{\sinh \sigma} \sin \pi y \sin \pi z \left(2e^{-p/2} \sinh \sigma x + \sinh \sigma(1 - x)\right)$$

$\sigma^2 = 2\pi^2 + p^2/4$ $p > 0$

Since there is no forcing function, the nonzero entries of the right-hand side vector arise from the boundary conditions. Let the Dirichlet boundary conditions on the sides of the unit cube $(0, 1)^3$ be described by the two-dimensional functions f_{z_0}, f_{z_1}, f_{y_0}, f_{y_1}, f_{x_0}, and f_{x_1}. For this problem, the boundary functions $f_{y_0} = f_{y_1} = f_{z_0} = f_{z_1} = 0$. Thus, there is no contribution of the weight W_2 in the recurrence relation solution (3.10). The functions f_{x_0} and f_{x_1} are then given by $f_{x_0}(j, k) = \sin j\pi h \sin k\pi h$ and $f_{x_1}(j, k) = 2 \sin j\pi h \sin k\pi h$.

We consider examples of each of the functions $R_1(i, j, k)$ and $R_2(i, j, k)$ for the case $h = 1/33$. For this mesh size the roots $\mu_2(j, k)$, $1 \le j, k \le n$, are all positive if $\gamma > 0.61648$ and the roots $\mu_1(j, k)$ are all positive if $\gamma > 1.60742$. For $\gamma = 0.6$, we have $\mu_1(32, 32) = -0.08327$ and $\mu_2(32, 32) = -404.561$. Both functions $R_1(i, 32, 32)$ and $R_2(i, 32, 32)$ are thus oscillatory functions of i.

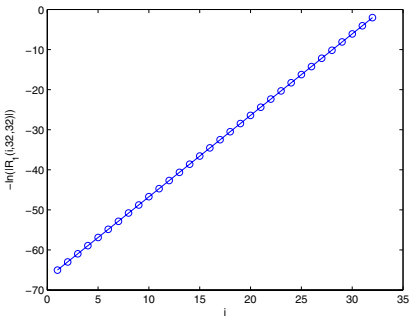


(a) $R_1(i, 32, 32)$, $\gamma = 0.6$. (b) $R_2(i, 32, 32)$, $\gamma = 0.6$.

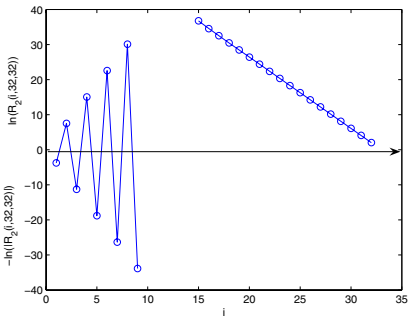
FIG. 3.1. *Functions* $R_1(i, 32, 32)$ *and* $R_2(i, 32, 32)$ *on a logarithmic scale for* $h = 1/33$ *and* $\gamma = 0.6$. *In this example* $\nu_{32,32} = -1.99$.

Figure 3.1 shows the graphs of $R_1(i, 32, 32)$ and $R_2(i, 32, 32)$ on a logarithmic scale when $\gamma = 0.6$. Successive values of $R_1(i, 32, 32)$ alternate in sign. However the large magnitude of the root μ_2 implies that the magnitudes of these oscillations are very small. To show the oscillatory nature of $R_1(i, 32, 32)$, we have plotted $\ln R_1(i, 32, 32)$ when $R_1(i, 32, 32) > 0$ and $-\ln |R_1(i, 32, 32)|$ when $R_1(i, 32, 32) < 0$. The values of $R_2(i, 32, 32)$ oscillate about the value 1. To observe the oscillatory nature of this function, we have plotted $\ln (R_2(i, 32, 32) - 1)$ when $R_2(i, 32, 32) > 1$ and $-\ln (1 - R_2(i, 32, 32))$ when $R_2(i, 32, 32) < 1$. The gap in the plot of $R_2(i, 32, 32)$ corresponds to cases when values of R_2 are practically 1.

In Figure 3.2 we show the plots of the functions $R_1(i, 32, 32)$ and $R_2(i, 32, 32)$

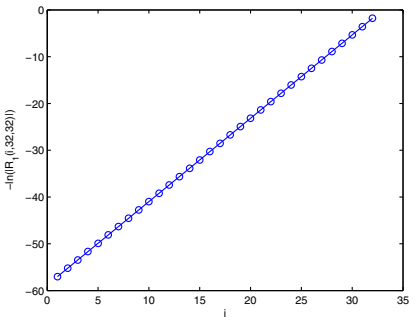


(a) $R_1(i, 32, 32)$, $\gamma = 1.4$.

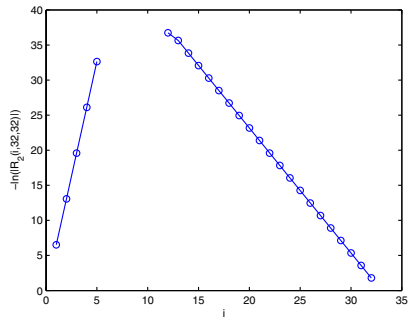


(b) $R_2(i, 32, 32)$, $\gamma = 1.4$.

FIG. 3.2. *Functions* $R_1(i, 32, 32)$ *and* $R_2(i, 32, 32)$ *on a logarithmic scale for* $h = 1/33$ *and* $\gamma = 1.4$. *In this example* $\nu_{32,32} = -1.99$.



(a) $R_1(i, 32, 32)$, $\gamma = 1.62$.



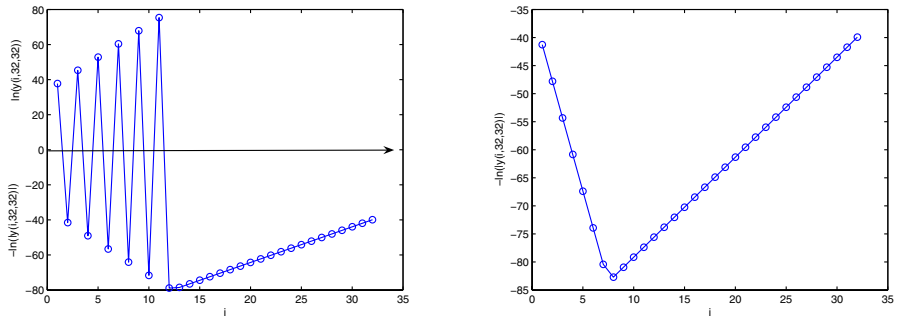
(b) $R_2(i, 32, 32)$, $\gamma = 1.62$.

FIG. 3.3. *Functions* $R_1(i, 32, 32)$ *and* $R_2(i, 32, 32)$ *on a logarithmic scale for* $h = 1/33$ *and* $\gamma = 1.62$. *In this example* $\nu_{32,32} = -1.99$.

for $\gamma = 1.4$. For this value of γ, the function $R_1(i, 32, 32)$ is nonoscillatory, but the theoretical results predict oscillations in $R_2(i, 32, 32)$.

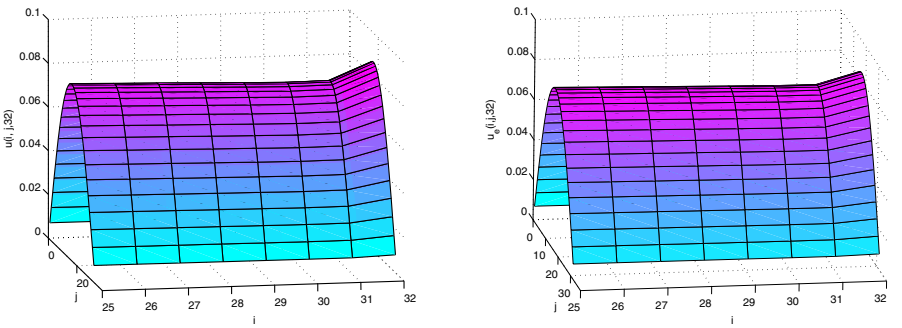
For the case $\gamma = 1.62 > \gamma_c$, our theoretical results predict no oscillations in both R_1 and R_2 and this nonoscillatory property is clearly observed in Figure 3.3. We show in Figure 3.4 the plots of the recurrence relation solution $y(i, 32, 32)$ on a logarithmic scale. We observe oscillations for the case when $\gamma = 1.4 < \gamma_c$. When $\gamma = 1.62 > \gamma_c$, we observe an oscillation-free recurrence relation solution as predicted by Theorem 3.1.

We show in Figures 3.5 and 3.6 plots of the discrete solution $\mathbf{u} = \{u(i, j, k)\}_{1 \le i,j,k \le n}$ and the exact solution $\mathbf{u}_e = \{u_e(i, j, k)\}_{1 \le i,j,k \le n}$ for two different values of γ. For the case $\gamma = 1.4 < \gamma_c$, we do not see any oscillation in the discrete solution $u(i, j, 32)$. This is probably due to the very small magnitude of the oscillations in the functions R_1 and R_2 and the smoothing effect that the transformation (3.11) has on the discrete



(a) $\gamma = 1.4$, $y\,(i, 32, 32)$. (b) $\gamma = 1.62$, $y\,(i, 32, 32)$.

FIG. 3.4. *Plots of the solutions* $y\,(i, 32, 32)$ *on a logarithmic scale when* $n = 32$ *for Problem* 3.1. *The critical value* $\gamma_c = 1.60742$.



(a) $\gamma = 1.4$, $u\,(i, j, 32)$. (b) $\gamma = 1.4$, $u_e\,(i, j, 32)$.

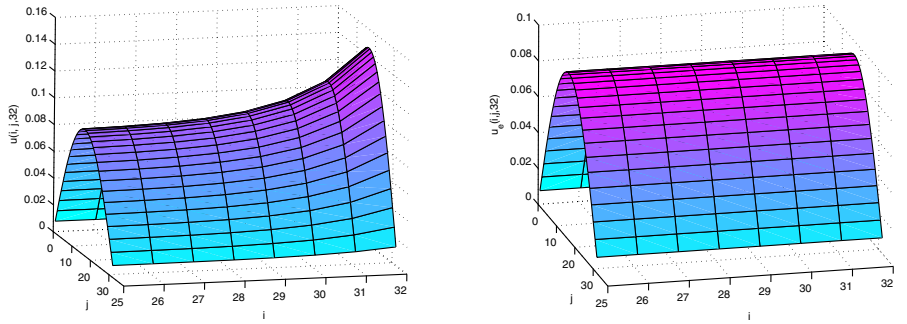
FIG. 3.5. *Plots of the discrete solution* $u\,(i, j, k)$ *and the exact solution* $u_e\,(i, j, k)$ *when* $n = 32$ *for Problem* 3.1.

solution u [2]. Figure 3.6 shows plots of the discrete and exact solutions when $\gamma = 10$. We remark that the discrete solution appears to be slightly diffusive. Similar to one- and two-dimensional problems, this phenomenon can be explained by the addition of some numerical viscosity by the fourth-order approximation scheme [3].

PROBLEM 3.2.

$$f_{x_0} = f_{x_1} = f_{y_0} = f_{y_1} = f_{z_0} = f_{z_1} = 1.$$

$u = 1$



(a) $\gamma = 10$, $u\,(i, j, 32)$. (b) $\gamma = 10$, $u_e\,(i, j, 32)$.

FIG. 3.6. *Plots of the discrete solution* $u\,(i, j, k)$ *and the exact solution* $u_e\,(i, j, k)$ *when* $n = 32$ *for Problem* 3.1.

For this problem, the terms in (3.10) are given as

$$W_1(j,k) = -\frac{4h(\gamma^2 - 3\gamma + 3)}{\theta_{j,k}^{(A_+)}} \left(\sum_{l=1}^{n} \sin j\, l\pi h\right) \left(\sum_{l=1}^{n} \sin k\, l\pi h\right),$$

$$W_3(j,k) = -\frac{4h(\gamma^2 + 3\gamma + 3)}{\theta_{j,k}^{(A_-)}} \left(\sum_{l=1}^{n} \sin j\, l\pi h\right) \left(\sum_{l=1}^{n} \sin k\, l\pi h\right),$$

and

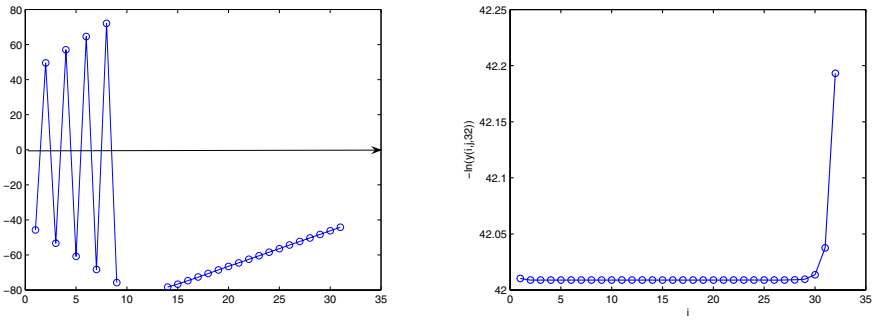
$$W_2(j,k) = \frac{12h}{\theta_{j,k}^{(A_-)} + \theta_{j,k}^{(A_0)} + \theta_{j,k}^{(A_+)}} S(j,\, k)$$

with

$$S(j,\, k) = \left((\sin j\pi h + \sin j\, n\pi h) \sum_{l=1}^{n} \sin k\, l\pi h + (\sin k\pi h + \sin k\, n\pi h) \sum_{l=1}^{n} \sin j\, l\pi h\right).$$

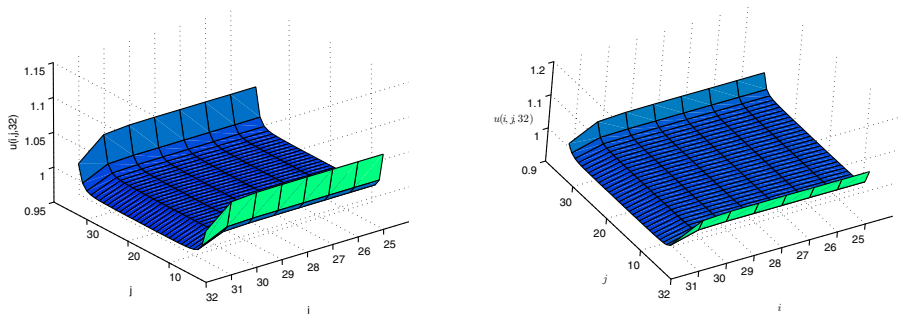
We show in Figure 3.7 plots of the recurrence relation solution for the case $h = 1/33$. For the case $\gamma = 1.4 < \gamma_c$, the recurrence relation solution oscillates. However, the magnitudes of these oscillations are of the order of 10^{-19}. By comparing the first seven significant figures of the first four values of $y(i,\, 32,\, 32)$ which are -5.831129, -5.695544, -5.698597, and -5.698527, we note that the differences between these successive values of $y(i,\, 32,\, 32)$ alternate in sign and therefore there are very tiny oscillations in $y(i,\, 32,\, 32)$. To show this oscillatory nature, we have plotted the successive differences on a logarithmic scale. For the case $\gamma = 1.62 > \gamma_c$ we do not observe any oscillations in the recurrence relation solution.

We show in Figure 3.8 the discrete solution produced by the fourth-order scheme. Recall that the theoretical analysis predicts oscillations in the recurrence relation solution $y(i, j, 32)$ for values of γ in the range $(0,\, \gamma_c)$. Again because of very tiny oscillations in the functions R_1 and R_2, these oscillations are not visible in the plot of the discrete solution $u(i, j, 32)$.



(a) $\gamma = 1.4$, $y\,(i, 32, 32)$. (b) $\gamma = 1.62$, $y\,(i, 32, 32)$.

FIG. 3.7. *Plots of the function* $y(i, j, k)$ *when* $n = 32$ *for Problem* 3.2.



(a) $\gamma = 1.4$, $u\,(i, j, 32)$. (b) $\gamma = 1.62$, $u\,(i, j, 32)$.

FIG. 3.8. *Plots of the discrete solutions* $u\,(i, j, 32)$ *when* $n = 32$ *for Problem* 3.2 *for* $\gamma = 1.4$ *and* $\gamma = 1.62$.

To end this section, we briefly mention a constant coefficient nongrid aligned flow problem. Numerical results described by Gupta and Zhang [5] for the problem (1.1) with $p = 10^3 \cos 35^\circ \cos 45^\circ$, $q = 10^3 \cos 35^\circ \sin 45^\circ$, $r = 10^3 \sin 35^\circ$, and the forcing function f chosen such that the exact solution is $u(x, y, z) = \sin \pi x \sin \pi y \sin \pi z$ indicate that the numerical solution is sufficiently accurate. Although the analysis carried out earlier does not apply here, our computations for this nongrid aligned flow problem indicate that the numerical solution retains the nonoscillatory property.

3.5. Solution accuracy. We consider the case when the convection-diffusion problem (1.1) has variable coefficients, $p(x, y, z)$, $q(x, y, z)$, and $r(x, y, z)$. An important requirement, in order to achieve the fourth-order accuracy, is that the convection coefficients p, q, and r and the forcing function f must be twice continuously differentiable and that the fourth-order derivatives of the solution u must be continuously differentiable.

In [5], Gupta and Zhang carry out accuracy comparisons between the numerical solutions of upwind and fourth-order approximations of four test problems. Here, for illustration on the quality of computed solutions, we did similar computations using Problem 2 from their paper. This convection-diffusion problem (1.1) has variable coefficients with

$$p = -R \sin y \sin z \cos x, \quad q = -R \sin x \sin z \cos y, \quad r = -R \sin x \sin y \cos z.$$

The forcing function f is chosen such that the solution is given by

$$u(x, y, z) = xyz(1-x)(1-y)(1-z)e^{x+y+z}.$$

The discrete solution on a mesh with grid size h is denoted by u^h. For $R = 10, 10^2, 10^3$ we compute the discrete L_∞ norm of the error defined by

$$\|u^h - u\|_\infty = \max_{i,j,k} |u^h(x_i, y_j, z_k) - u(x_i, y_j, z_k)|,$$

and we estimate the order of convergence, ϱ, by computing

$$\varrho = \log_2 \left(\frac{\|u^{2h} - u\|_\infty}{\|u^h - u\|_\infty} \right).$$

The numerical results in Table 3.1 show that the fourth-order compact scheme yields a fourth-order convergence rate when R is small but loses some accuracy when R becomes large. However, the convergence order is at least 3 compared to first-order accurate solutions for the upwind scheme.

TABLE 3.1
Maximum errors and order of convergence for fourth-order and upwind schemes.

	FOS			Upwind

Yavneh [11] analyzed a fourth-order compact scheme for a two-dimensional constant-coefficient convection-diffusion problem and he showed that, while the compact scheme does not suffer from a cross-stream artificial viscosity, it does include a streamwise artificial viscosity that is inversely proportional to the natural viscosity. Here we use similar arguments to discuss the accuracy of the fourth-order scheme for the three-dimensional problem.

Rescaling the convection-diffusion problem (1.1) by letting $t = \max(p, q, r)$, $\epsilon = 1/t$, $\bar{p} = \epsilon p$, $\bar{q} = \epsilon q$, $\bar{r} = \epsilon r$, and $\bar{f} = \epsilon f$, we obtain

$$-\epsilon \Delta u + (\bar{p}, \bar{q}, \bar{r})^{\mathrm{T}} \cdot \nabla u = \bar{f} \tag{3.16}$$

in the unit cube with the same boundary conditions. We denote the convection operator in the characteristic direction ξ by $D_\xi = (\bar{p}, \bar{q}, \bar{r})^{\mathrm{T}} \cdot \nabla$. On a uniform grid with mesh size h, the fourth-order compact scheme for (3.16) can be written in the form

TABLE 3.2
Maximum error and convergence order for $p = 10$, 50, and 100.

	$n = 15$	$n = 31$	Convergence order
$p = 10$	3.57(−04)	2.26(−05)	3.98
$p = 50$	4.31(−02)	4.42(−03)	3.26
$p = 100$	1.82(−01)	3.66(−02)	2.31

$$\left(-\epsilon\Delta^h + D_\xi^h - \frac{h^2}{12\epsilon}D_{\xi\xi}^h\right)u^h = \left(I^h + \frac{h^2}{12}\bar{\Delta}^h - \frac{h^2}{12\epsilon}\bar{D}_\xi^h\right)\bar{f}^h, \tag{3.17}$$

where I^h is the grid-h identity. Denoting the square of the convection operator D_ξ by $D_{\xi\xi}$, the stencils of the discrete operators in (3.17) are given by

$$\Delta^h = \frac{1}{6h^2}\left(\begin{array}{ccc|ccc|ccc} 0 & 1 & 0 & 1 & 2 & 1 & 0 & 1 & 0 \\ 1 & 2 & 1 & 2 & -24 & 2 & 1 & 2 & 1 \\ 0 & 1 & 0 & 1 & 2 & 1 & 0 & 1 & 0 \end{array}\right) = \Delta + \frac{h^2}{12}\Delta^2 + O(h^4),$$

$$\begin{aligned} D_\xi^h &= \frac{1}{12h}\left(\begin{array}{ccc|ccc|ccc} 0 & \bar{q}-\bar{r} & 0 & -\bar{p}+\bar{q} & 2\bar{q} & \bar{p}+\bar{q} & 0 & \bar{q}+\bar{r} & 0 \\ -\bar{p}-\bar{r} & -2\bar{r} & \bar{p}-\bar{r} & -2\bar{p} & 0 & 2\bar{p} & -\bar{p}+\bar{r} & \bar{r} & \bar{p}+\bar{r} \\ 0 & -\bar{q}-\bar{r} & 0 & -\bar{p}-\bar{q} & -2\bar{q} & \bar{p}-\bar{q} & 0 & -\bar{q}+\bar{r} & 0 \end{array}\right) \\ &= D_\xi + \frac{h^2}{6}\Delta D_\xi + O(h^4), \end{aligned}$$

$$\begin{aligned} D_{\xi\xi}^h &= \frac{1}{h^2}\left(\begin{array}{ccc|ccc|ccc} 0 & -\bar{q}\bar{r} & 0 & -\bar{p}\bar{q} & 2\bar{q}^2 & \bar{p}\bar{q} & 0 & \bar{q}\bar{r} & 0 \\ \bar{p}\bar{r} & 2\bar{r}^2 & -\bar{p}\bar{r} & 2\bar{p}^2 & -4(\bar{p}^2+\bar{q}^2+\bar{r}^2) & 2\bar{p}^2 & -\bar{p}\bar{r} & 2\bar{r}^2 & \bar{p}\bar{r} \\ 0 & \bar{q}\bar{r} & 0 & \bar{p}\bar{q} & 2\bar{q}^2 & -\bar{p}\bar{q} & 0 & -\bar{q}\bar{r} & 0 \end{array}\right) \\ &= D_{\xi\xi} + O(h^2), \end{aligned}$$

$$\bar{\Delta}^h = \frac{1}{h^2}\left(\begin{array}{ccc|ccc|ccc} 0 & 0 & 0 & 0 & 1 & 0 & 0 & 0 & 0 \\ 0 & 1 & 0 & 1 & -6 & 1 & 0 & 1 & 0 \\ 0 & 0 & 0 & 0 & 1 & 0 & 0 & 0 & 0 \end{array}\right) = \Delta + O(h^2),$$

$$\bar{D}_\xi^h = \frac{1}{h^2}\left(\begin{array}{ccc|ccc|ccc} 0 & 0 & 0 & 0 & q & 0 & 0 & 0 & 0 \\ 0 & -r & 0 & -p & 0 & p & 0 & r & 0 \\ 0 & 0 & 0 & 0 & -q & 0 & 0 & 0 & 0 \end{array}\right) = D_\xi + O(h^2).$$

Using the commutativity of Δ and D_ξ and substituting the differential operators and truncation terms in (3.17) lead to

$$\left(1 + \frac{h^2}{12}\Delta - \frac{h^2}{12\epsilon}D_\xi\right)\left(-\epsilon\Delta u^h + D_\xi u^h - \bar{f}^h\right) = O\left(\left(1 + \epsilon + \epsilon^{-1}\right)h^4\right). \tag{3.18}$$

Equation (3.18) shows that the fourth-order scheme becomes less accurate in the convection-dominated case. This is shown by the results in Table 3.2 for problem (3.1). However, when γ becomes large, the overall error is dominated by the error in the boundary layer and this is a common problem with discretization schemes on uniform grids if there are not enough grid points inside the boundary layer [1, 5].

4. Summary. Analytical expressions for the eigenvalues of the matrix arising from a fourth-order discretization of a model three-dimensional constant-coefficient convection-diffusion problem have been derived. It is shown that the matrix is positive definite if the cell-Reynolds number exceeds a certain value which depends on the size of the matrix. A recent method based on Fourier analysis for obtaining an analytical expression for the discrete solution of two-dimensional convection-diffusion problems has been extended to the three-dimensional case. One interesting result shown is that as the mesh size is refined, the recurrence relation solution is nonoscillatory for cell-Reynolds numbers exceeding the Golden Mean. For the convection-dominated case with cell-Reynolds number γ less than the critical value γ_c, in the numerical examples described, the discrete solutions do not present any visible oscillations even though these might be anticipated because of experience with the second-order central scheme.

We showed that although some accuracy is lost for convection-dominated problems, an advantage of the high-order compact scheme over the upwind scheme is that it allows coarser grids and thus smaller linear systems. For variable coefficient problems, we mentioned the regularity requirements on the convection coefficients and the forcing function in order to achieve fourth-order accuracy. Finally, we note that, for two-dimensional problems with thin boundary layers, the deterioration of computed accuracy due to an insufficient number of nodes inside the boundary layer has been successfully treated by employing the graded mesh techniques [10]. Similar techniques can be employed for three-dimensional problems.

Acknowledgments. We thank the referees for the careful reading of the manuscript and their helpful suggestions which considerably improved the work. We also thank the associate editor for his helpful remarks on the manuscript.

AN AUGMENTED LAGRANGIAN-BASED APPROACH TO THE OSEEN PROBLEM*

MICHELE BENZI† AND MAXIM A. OLSHANSKII‡

Abstract. We describe an effective solver for the discrete Oseen problem based on an augmented Lagrangian formulation of the corresponding saddle point system. The proposed method is a block triangular preconditioner used with a Krylov subspace iteration like BiCGStab. The crucial ingredient is a novel multigrid approach for the (1,1) block, which extends a technique introduced by Schöberl for elasticity problems to nonsymmetric problems. Our analysis indicates that this approach results in fast convergence, independent of the mesh size and largely insensitive to the viscosity. We present experimental evidence for both isoP2-P0 and isoP2-P1 finite elements in support of our conclusions. We also show results of a comparison with two state-of-the-art preconditioners, showing the competitiveness of our approach.

1. Introduction.

We consider the numerical solution of the steady Navier–Stokes equations governing the flow of a Newtonian, incompressible viscous fluid. Let $\Omega \subset \mathbb{R}^d$ $(d = 2, 3)$ be a bounded, connected domain with a piecewise smooth boundary $\partial\Omega$. Given a force field $\mathbf{f} : \Omega \to \mathbb{R}^d$ and boundary data $\mathbf{g} : \partial\Omega \to \mathbb{R}^d$, the problem is to find a velocity field $\mathbf{u} : \Omega \to \mathbb{R}^d$ and a pressure field $p : \Omega \to \mathbb{R}$ such that

$$-\nu\Delta\mathbf{u} + (\mathbf{u}\cdot\nabla)\,\mathbf{u} + \nabla p = \mathbf{f} \quad \text{in } \Omega, \tag{1.1}$$

$$\operatorname{div}\mathbf{u} = 0 \quad \text{in } \Omega, \tag{1.2}$$

$$\mathbf{u} = \mathbf{g} \quad \text{on } \partial\Omega, \tag{1.3}$$

where $\nu > 0$ is the kinematic viscosity coefficient (inversely proportional to the Reynolds number Re), Δ is the Laplace operator in $\mathbb{R}^d$, ∇ denotes the gradient, and div is the divergence. To determine p uniquely we may impose some additional condition, such as

$$(p,\, 1) = \int_\Omega p\, dx = 0.$$

Equation (1.1) represents conservation of momentum, while (1.2) represents the incompressibility condition, or mass conservation. Due to the presence of the convective term $(\mathbf{u}\cdot\nabla)\,\mathbf{u}$ in the momentum equations, the Navier–Stokes system is nonlinear. It can be linearized in various ways. A widely used linearization scheme is the one

based on Picard's iteration; see, e.g., [10, section 7.2.2]. Starting with an initial guess $\mathbf{u}^{(0)}$ (with $\operatorname{div}\mathbf{u}^{(0)} = 0$) for the velocity field, Picard's iteration constructs a sequence of approximate solutions $(\mathbf{u}^{(k)}, p^{(k)})$ by solving the linear [illegible]:

$$-\nu\Delta\mathbf{u}^{(k)} + (\mathbf{u}^{(k-1)} \cdot \nabla)\,\mathbf{u}^{(k)} + \nabla p^{(k)} = \hat{\mathbf{f}} \quad \text{in } \Omega, \tag{1.4}$$

$$\operatorname{div}\mathbf{u}^{(k)} = 0 \quad \text{in } \Omega, \tag{1.5}$$

$$\mathbf{u}^{(k)} = \mathbf{g} \quad \text{on } \partial\Omega \tag{1.6}$$

($k = 1, 2, \dots$). Note that no initial pressure needs to be specified. Under certain conditions on ν (which should not be too small) and $\hat{\mathbf{f}}$ (which should not be too large in an appropriate norm), the steady Navier–Stokes equations (1.1)–(1.3) have a unique solution $(\mathbf{u}_*, p_*)$, and the iterates $(\mathbf{u}^{(k)}, p^{(k)})$ converge to it as $k \to \infty$ for any choice of the initial velocity $\mathbf{u}^{(0)}$; see [10, Chapter 7] and the references therein.

Hence, at each Picard iteration one needs to solve an Oseen problem of the form

$$-\nu\Delta\mathbf{u} + (\mathbf{w} \cdot \nabla)\,\mathbf{u} + \nabla p = \hat{\mathbf{f}} \quad \text{in } \Omega, \tag{1.7}$$

$$\operatorname{div}\mathbf{u} = 0 \quad \text{in } \Omega, \tag{1.8}$$

$$\mathbf{u} = \mathbf{g} \quad \text{on } \partial\Omega \tag{1.9}$$

with a known, divergence-free coefficient $\mathbf{w}$. Discretization of (1.7)–(1.9) using LBB-stable finite elements [10, 26] results in a linear system of the form

$$\begin{pmatrix} A & B^T \\ B & O \end{pmatrix} \begin{pmatrix} u \\ p \end{pmatrix} = \begin{pmatrix} f \\ 0 \end{pmatrix}, \qquad \text{or} \qquad \mathcal{A}\,\mathbf{x} = \mathbf{b}, \tag{1.10}$$

in which u represents the discrete velocities and p the discrete pressure. Here $A = \operatorname{diag}(A_1, \dots, A_d)$ is a block diagonal matrix, where each block corresponds to a discrete convection-diffusion operator with the appropriate boundary conditions. Note that A is nonsymmetric. The rectangular matrix B^T represents the discrete gradient operator, while B represents its adjoint, the (negative) divergence operator. The solvability of this system is discussed, e.g., in [2, section 3.2]; here we assume that the coefficient matrix in (1.10) is nonsingular.

Linear systems of the form (1.10) are often referred to as [illegible]. In recent years, a great deal of effort has been invested in solving systems of this form. Most of the work has been aimed at developing effective preconditioning techniques; see [10], and [2] for an extensive survey. In spite of these efforts, there is still considerable interest in preconditioning techniques that are truly robust, i.e., techniques which result in convergence rates that are largely independent of problem parameters such as mesh size and viscosity. In this paper we describe a promising approach based on an augmented Lagrangian (AL) formulation. The success of this method crucially depends on the availability of a robust multigrid solver for the (1,1) block (submatrix) in the AL formulation of the saddle point system; we develop such a method by building on previous work by Schöberl [29], together with appropriate smoothers for convection-dominated flows. Rather than as a solver, this multigrid iteration will be used to define a block preconditioner for the outer iteration on the coupled saddle point system. We will show that this approach is especially appropriate for discretizations based on discontinuous pressure approximations, but can be used to construct preconditioners for other discretizations using continuous pressures. As an example of the finite element (FE) method with discontinuous pressures we will use the isoP2-P0 pair. In this case, our numerical experiments demonstrate a robust

behavior of the solver with respect to h and ν for some typical wind vector functions $\mathbf{w}$ in (1.7). Further, the isoP2-P1 FE pair is used for the continuous pressure-based approximation. For this case numerical experiments show h-independent convergence rates, with mild dependence on ν when the viscosity becomes very small.

The remainder of the paper is organized as follows. In section 2 we present the (standard) abstract formulation of the Oseen problem and discuss the FE approximations. In section 3 we describe the AL approach and the resulting block preconditioner and briefly discuss related approaches that can be found in the literature. Section 4 is devoted to a study of the spectrum of the preconditioned system, assuming exact solves for the (1,1) block. The multigrid solver for the (1,1) block is described in section 5. Numerical experiments on some two-dimensional (2D) model problems are presented in section 6. Here we also present a comparison with two of the best available preconditioning techniques, showing that our method is quite competitive in terms of convergence rates, robustness, and efficiency. Some concluding remarks are given in section 7.

2. Finite element method. For simplicity, we assume the boundary conditions in (1.9) to be Dirichlet homogeneous (i.e., $\mathbf{g} = \mathbf{0}$). The weak formulation of the Oseen problem reads as follows: Given $\mathbf{f} \in \mathbf{H}^{-1}(\Omega)$, find $\mathbf{u} \in \mathbf{H}_0^1(\Omega)$ and $p \in L_0^2(\Omega)$ such that

$$\begin{aligned}
&\mathcal{L}(\mathbf{u}, p; \mathbf{v}, q) \;=\; \langle \mathbf{f}, \mathbf{v} \rangle \qquad \forall\ \mathbf{v} \in \mathbf{H}_0^1(\Omega),\ q \in L_0^2(\Omega),\\
&\mathcal{L}(\mathbf{u}, p; \mathbf{v}, q) := \nu(\nabla \mathbf{u}, \nabla \mathbf{v}) + ((\mathbf{w} \cdot \nabla)\, \mathbf{u}, \mathbf{v}) - (p, \operatorname{div} \mathbf{v}) + (q, \operatorname{div} \mathbf{u}).
\end{aligned}$$

Given conforming FE spaces $\mathbb{V}_h \subset \mathbf{H}_0^1(\Omega)$ and $\mathbb{Q}_h \subset L_0^2(\Omega)$, the Galerkin FE discretization of (1.7)–(1.9) is based on the following weak formulation: Find $\{\mathbf{u}_h, p_h\} \in \mathbb{V}_h \times \mathbb{Q}_h$ such that

$$\mathcal{L}(\mathbf{u}_h, p_h; \mathbf{v}_h, q_h) = \langle \mathbf{f}, \mathbf{v}_h \rangle \qquad \forall\ \mathbf{v}_h \in \mathbb{V}_h,\ q_h \in \mathbb{Q}_h. \tag{2.1}$$

There are several critical issues associated with the Galerkin FE method for the Oseen problem. One is the compatibility of $\mathbb{V}_h$ and $\mathbb{Q}_h$, i.e., the validation of the LBB (inf-sup) stability condition, which guarantees that the FE velocity space is "rich enough" relative to the FE pressure space. This ensures well-posedness and full approximation order for the FE linear problem. For the numerical experiments in the paper we used the isoP2-P0 FE pair (piecewise constant pressure and piecewise linear continuous velocity on two-times finer triangulation) and the isoP2-P1 FE pair (piecewise linear pressure and piecewise linear continuous velocity on two-times finer triangulation). Both pairs are LBB stable: There exists a mesh-independent constant $\mu(\Omega)$ such that

$$\inf_{q_h \in \mathbb{Q}_h} \sup_{\mathbf{v}_h \in \mathbb{V}_h} \frac{(q_h, \operatorname{div} \mathbf{v}_h)}{\|\nabla \mathbf{v}_h\| \|q_h\|} = \mu_h \geq \mu(\Omega) > 0. \tag{2.2}$$

We note that the chosen FE pairs have stable higher order variants P2-P0 and P2-P1 (the latter is also known as Taylor–Hood element). All considerations and conclusions in the paper remain valid for these higher order finite elements. Piecewise linear velocity-based elements were used solely for the ease of implementation.

Another potential source of instabilities in (2.1) is the presence of dominating convection terms. This necessitates stabilization of the discrete system if the mesh is not sufficiently fine to resolve the stiff behavior of the system. We outline below the SUPG-type method we used. Many more details on the family of SUPG stabilization

methods can be found in, e.g., [6, 28, 31]. Using (2.1) as the starting point, a weighted residual for the FE solution multiplied by a solution-dependent test function is added:

$$\mathcal{L}(\mathbf{u}_h, p_h; \mathbf{v}_h, q_h) + \sum_{\tau \in T_h} \sigma_\tau (-\nu \Delta \mathbf{u}_h + \mathbf{w}\cdot\nabla \mathbf{u}_h + \nabla p_h - \mathbf{f}, \mathbf{w}\cdot\nabla \mathbf{v}_h)_\tau = (\mathbf{f}, \mathbf{v}_h) \qquad \forall\ \mathbf{v}_h \in \mathbb{V}_h,\ q_h \in \mathbb{Q}_h. \tag{2.3}$$

The "new" term in (2.3) is evaluated elementwise for each element τ of a triangulation T_h. The parameters σ_τ are element- and problem-dependent. The general idea behind the choice of σ_τ is to add almost no additional stabilization terms in regions of small mesh Reynolds numbers, so as to recover optimality of the Galerkin method, but to add them in regions of large mesh Reynolds numbers. Several recipes for the particular choice of the stabilization parameters can be found in the literature. We use the one from [22]:

$$\sigma_\tau = \bar{\sigma} \frac{h_\tau}{\|\mathbf{w}\|_{L_2(\tau)}} \frac{2Re_\tau}{1 + Re_\tau}, \qquad Re_\tau := \frac{\|\mathbf{w}\|_{L_2(\tau)} h_\tau}{\nu}. \tag{2.4}$$

This formula for the parameter with $\bar{\sigma} \in [0.2, 1]$ was successfully used in many numerical experiments in [31]. In our experiments we take $\bar{\sigma} = 0.3$.

Remark 2.1. The particular choice of stabilization parameters σ_τ can be quite important for the discrete solution accuracy. On the other hand, using high order finite elements [20] or sufficiently fine meshes may dispense with the need to stabilize the problem. We found, however, that in order to have an efficient solver it is still important to add stabilization to the [illegible] in the multigrid method (see details in section 5). Additionally, the efficiency of the iterative solver described below was found to be essentially independent of the particular choice of $\bar{\sigma} = O(1)$ or of different formulae for σ_τ known from the literature for convection-diffusion problems (see, e.g., [11]). We can also assume that any pressure-dependent part in the stabilization term enters the nonlinear residual in the Picard iterations, thus preserving the saddle point structure (1.10) of the problem.

3. Augmented Lagrangian formulation. Some of the most effective solvers for the Oseen problem found in the literature are based on block triangular preconditioners of the form

$$\mathcal{P} = \begin{pmatrix} \hat{A} & B^T \\ O & \hat{S} \end{pmatrix}, \tag{3.1}$$

where $\hat{A}$ and $\hat{S}$ are approximations to A and to the Schur complement $S = -BA^{-1}B^T$, respectively; see, e.g., [2, 10]. The approximation $\hat{A}$ often consists of an inexact solver for linear systems with coefficient matrix A, such as one or more iterations of an appropriate multigrid solver for convection-diffusion equations. The search for good approximations $\hat{S}$ to the Schur complement (or its inverse) has generated much research in recent years [10]. Note that $S = -BA^{-1}B^T$ is a dense matrix. When ν is relatively large (moderate Reynolds numbers), then S is well conditioned and can be well approximated by the pressure mass matrix M_p, provided that the discretization is LBB-stable. When ν is small, however, finding good and inexpensive approximations to S is not easy. While the best available methods exhibit h-independent convergence of the preconditioned iterations [10], some degradation in the rate of convergence is

observed as $\nu \to 0$. For large Reynolds numbers, the number of iterations can be high.

Here we follow an approach that bypasses the need for a good approximation to the dense matrix S. Suppose we replace the original problem (1.10) with the "regularized" one,

$$\begin{pmatrix} A & B^T \\ B & -\frac{1}{\gamma}W \end{pmatrix} \begin{pmatrix} u \\ p \end{pmatrix} = \begin{pmatrix} f \\ 0 \end{pmatrix}, \tag{3.2}$$

where $\gamma > 0$ is a parameter and W is a positive definite matrix. The solution $[u(\gamma), p(\gamma)]$ of (3.2) tends to the solution of (1.10) for $\gamma \to \infty$. Observing that the Schur complement of the (1,1) block in the coefficient matrix of (3.2) (sometimes referred to as the "primal" or "velocity" Schur complement) is $A + \gamma B^T W^{-1} B$, we expect

$$\mathcal{P}(\gamma) = \begin{pmatrix} A + \gamma B^T W^{-1} B & B^T \\ O & -\frac{1}{\gamma}W \end{pmatrix} \tag{3.3}$$

(or, in practice, some inexact version of it) to be an effective preconditioner for the regularized problem (3.2). Note that if W is diagonal, or block diagonal with small blocks, the matrix $A + \gamma B^T W^{-1} B$ is also going to be sparse. Our choice of W is discussed in the next section.

There is, however, a well-known difficulty with this approach. The matrix in the regularized problem is close to the original one only for γ large, and for large γ the (1,1) block $A + \gamma B^T W^{-1} B$ becomes increasingly ill conditioned (note that $B^T B$ has a null space of dimension $n - m$ for $n = \dim \mathbb{V}_h$, $m = \dim \mathbb{Q}_h$). Hence, finding an effective inexact solver for the (1,1) block becomes difficult. It is therefore preferable to keep the value of γ moderate, say, $\gamma = O(1)$ or, for reasons of scaling, $\gamma \approx \|\mathbf{w}\|$. This is the idea behind the classical AL approach. In its simplest form, this method consists of replacing the original system (1.10) with the equivalent

$$\begin{pmatrix} A + \gamma B^T W^{-1} B & B^T \\ B & O \end{pmatrix} \begin{pmatrix} u \\ p \end{pmatrix} = \begin{pmatrix} f \\ 0 \end{pmatrix}, \qquad \text{or} \qquad \widehat{\mathcal{A}}\,\mathbf{x} = \mathbf{b}. \tag{3.4}$$

Clearly, this system has precisely the same solution as the original one (1.10). We refer to [13] for an extensive discussion of AL techniques and their applications. We propose to precondition the AL system (3.4) with the block triangular preconditioner

$$\mathcal{P} = \begin{pmatrix} \hat{A}_\gamma & B^T \\ O & \hat{S} \end{pmatrix}, \tag{3.5}$$

where the action of $\hat{A}_\gamma^{-1}$ is computed via an appropriate (inexact) solver for linear systems involving the matrix $A + \gamma B^T W^{-1} B$,

$$\hat{A}_\gamma \approx A + \gamma B^T W^{-1} B, \tag{3.6}$$

and $\hat{S}$ is implicitly defined through its inverse,

$$\hat{S}^{-1} := -\nu \hat{M}_p^{-1} - \gamma W^{-1}. \tag{3.7}$$

Here $\hat{M}_p^{-1}$ denotes an approximate solve with the pressure mass matrix. This choice of $\hat{S}$ is motivated by Lemma 4.1 below and will be analyzed in the next section. The

pressure mass matrix M_p is diagonal for FE pairs based on piecewise constant pressure approximations. For higher order pressure approximations M_p is no longer diagonal but it is spectrally equivalent to a diagonal matrix $\bar{M}_p$; see [34]. Thus, linear systems with M_p can be solved easily, either exactly or approximately.

It follows from the identity

$$\mathcal{P}^{-1} = \begin{pmatrix} \hat{A}_\gamma^{-1} & O \\ O & I_m \end{pmatrix} \begin{pmatrix} I_n & B^T \\ O & -I_m \end{pmatrix} \begin{pmatrix} I_n & O \\ O & -\hat{S}^{-1} \end{pmatrix} \tag{3.8}$$

that the action of the preconditioner on a given vector requires one application of $\hat{A}_\gamma^{-1}$, one of $\hat{S}^{-1}$, and one sparse matrix-vector product with B^T. The question of the adequacy of the augmented Schur complement preconditioner (3.7) will be addressed in sections 4 and 6. Besides this, the major issue is the definition of $\hat{A}_\gamma^{-1}$, the approximate (1,1) block solver. Developing such a solver is a nontrivial task. Note that the introduction of the additional term $\gamma B^T W^{-1} B$ in the (1,1) block of the saddle point matrix introduces a coupling between the components of the velocity vector, which is originally avoided in the Oseen linearization compared to the Newton one. For vanishing convection the (1,1) block essentially reduces to the one for the classical elasticity problem. For moderate and high Reynolds numbers, however, it becomes increasingly nonsymmetric. It is nevertheless possible to develop efficient iterative solvers for the (1,1) block, at least for some choices of the FE discretization. In section 5 we describe an effective multigrid method for the (1,1) block.

We conclude this section with a brief discussion of related work. An AL approach to the Oseen problem can already be found in [13, Chapter 2], in the context of the classical Uzawa's method. However, the crucial aspect of how to efficiently solve linear systems involving $A + \gamma B^T W^{-1} B$ was not discussed there. Among more recent papers, we mention [7], where a preconditioner based on (3.2) is applied to (symmetric) linear incompressible elasticity problems. The inexact solution of systems involving (3.2) is accomplished by a "primal" Schur complement approach, leading to an overall preconditioning strategy which resembles the approach taken here. There are, however, important differences. Our preconditioner is applied to the AL formulation (3.4), whereas the authors of [7] work with the original saddle point formulation. A more important difference is the fact that the problem tackled in [7] is symmetric; thus, the authors are able to leverage existing techniques for linear elasticity problems when developing an efficient solver for the (1,1) block. We mention that a related approach has been used in [17] to construct block preconditioners for saddle point systems arising from the curl-curl formulation of the time-harmonic Maxwell's equations, also a symmetric problem.

The paper [14] applies a preconditioning technique similar to the one in [7] to Stokes and linearized Navier–Stokes problems. The numerical evidence reported in [14] indicates that as the Reynolds number increases, the rate of convergence of the inner iterative solver used for the (1,1) block (a two-level overlapping additive Schwarz preconditioner with a multiplicative coarse grid correction) tends to deteriorate as the mesh is refined. The deterioration of this solver is already noticeable for a 2D driven cavity problem with Reynolds number $Re = 400$, a fairly easy problem (close to Stokes flow). Furthermore, no analysis of the preconditioner is given. On the positive side, the solver in [14] appears to be well suited for massively parallel architectures, an aspect which we do not address in this paper.

Finally, adding the product $\gamma(\operatorname{div} \mathbf{u}_h, \operatorname{div} \mathbf{v}_h)$ on the left-hand side of the FE method formulation (2.1) is well known in the literature on stabilized FE methods

for fluid problems and sometimes called "the ∇ div-stabilization." Using this stabilization may change the FE solution. However, the effect on the iterative solution of (1.10) is similar to the one resulting from adding $\gamma B^T W^{-1} B$ (with $W = M_p$) to the (1,1) block of the linear algebraic system. This linear algebra aspect of the ∇ div-stabilization was studied for the Stokes problem in [24] and for the linearized rotation form of the Navier–Stokes problem in [25]. In particular, numerical experiments in [25] demonstrate ν-independent convergence of the preconditioned BiCGstab method if $\gamma = O(1)$ and if exact solves are used for systems involving the (1,1) block. However, in [24] and [25] the question of finding a robust solver or preconditioner for the (1,1) block with respect to the ratio ν/γ was left open.

4. Analysis of the preconditioner. It is well known that characterizing the rate of convergence of nonsymmetric preconditioned iterations can be a difficult task. In particular, eigenvalue information alone may not be sufficient to give meaningful estimates of the convergence rate of a method like preconditioned GMRES [16]. The situation is even more complicated for a method like BiCGStab, for which virtually no convergence theory exists. Nevertheless, experience shows that for many linear systems arising in practice, a well-clustered spectrum (away from zero) usually results in rapid convergence of the preconditioned iteration.

In this section we show that for the preconditioner (3.5), the eigenvalues of the preconditioned matrix $\mathcal{M} = \mathcal{P}^{-1}\widehat{\mathcal{A}}$ are enclosed in a rectangular region contained in the right half-plane $\Re(z) > 0$, the sides of which do not depend on the mesh size h and for sufficiently large γ do not depend on ν. Here we assume exact solves for the (1,1) block, i.e., $\hat{A}_\gamma = A + \gamma B^T W^{-1} B$. Hence, at least for this "ideal" version of the preconditioner, the eigenvalues of the preconditioned matrix are bounded away from zero, independently of h and ν. Our analysis makes use of the following simple lemma, which is a straightforward consequence of [12, Exercise 12.12] or [15, Proposition 2.1].

LEMMA 4.1. Let $A \in \mathbb{R}^{n\times n}$, $B \in \mathbb{R}^{m\times n}$ $(m \le n)$, and let $\gamma \in \mathbb{R}$ be such that A, $A + \gamma B^T W^{-1} B$, $BA^{-1}B^T$, and $B(A + \gamma B^T W^{-1} B)^{-1} B^T$ are nonsingular. Then

$$\left[B(A + \gamma B^T W^{-1} B)^{-1} B^T\right]^{-1} = \left(BA^{-1}B^T\right)^{-1} + \gamma W^{-1}. \tag{4.1}$$

We note that the conditions of Lemma 4.1 are satisfied if we assume that B has full row rank and that A is positive real (i.e., the symmetric part of A is positive definite); see [2, section 3]. These conditions are satisfied, in particular, for the matrices considered in this paper.

Recall that $\mathcal{P}^{-1}\widehat{\mathcal{A}}$ and $\widehat{\mathcal{A}}\mathcal{P}^{-1}$ have the same eigenvalues. A simple calculation shows that

$$\widehat{\mathcal{A}}\mathcal{P}^{-1} = \begin{pmatrix} I_n & O \\ B(A + \gamma B^T W^{-1} B)^{-1} & -B(A + \gamma B^T W^{-1} B)^{-1} B^T \hat{S}^{-1} \end{pmatrix}. \tag{4.2}$$

Hence, the preconditioned matrix has the eigenvalue 1 of multiplicity n, with the remaining eigenvalues λ_i $(1 \le i \le m)$ being solutions of the generalized eigenproblem

$$B(A + \gamma B^T W^{-1} B)^{-1} B^T p = -\lambda \hat{S} p.$$

Setting $W = M_p$ and $\hat{M}_p = M_p$, Lemma 4.1 implies

$$(\nu + \gamma)\lambda_i^{-1} = \gamma + \mu_i^{-1},$$

where μ_i satisfies the generalized eigenproblem

$$BA^{-1}B^T q = \mu M_p\, q. \tag{4.3}$$

Hence, the nonunit eigenvalues of $\mathcal{P}^{-1}\widehat{\mathcal{A}}$ are given by

$$\lambda_i = \frac{\gamma+\nu}{\gamma+\mu_i^{-1}}, \quad 1 \le i \le m. \tag{4.4}$$

It has been shown in [8] that the eigenvalues of (4.3) are enclosed in a rectangle contained in the half-plane $\Re(z) > 0$; using this result and the relation (4.4), we can conclude that the same is true of the eigenvalues of $\mathcal{P}^{-1}\widehat{\mathcal{A}}$. If we denote by a_i and b_i the real and imaginary parts of μ_i, respectively, easy manipulations result in the following expressions for the real and the imaginary parts of λ_i:

$$\Re(\lambda_i) = \frac{(\nu+\gamma)(a_i+\gamma(a_i^2+b_i^2))}{(\gamma a_i+1)^2+(\gamma b_i)^2} \qquad \text{and} \qquad \Im(\lambda_i) = \frac{(\nu+\gamma)b_i}{(\gamma a_i+1)^2+(\gamma b_i)^2}. \tag{4.5}$$

The following result is an immediate consequence of (4.5).

THEOREM 4.2. [illegible] $W = M_p$ [illegible] $\mathcal{P}^{-1}\widehat{\mathcal{A}}$ [illegible] 1 [illegible] n [illegible] m [illegible] λ_i [illegible] (4.4) [illegible] $\mu_i = a_i + \mathrm{i}\, b_i$ [illegible] (4.3) [illegible]

$$1 - \frac{1}{\gamma a_i + 1} \le \Re(\lambda_i) < 1 + \nu\gamma^{-1} \quad \text{and} \quad |\Im(\lambda_i)| < (1+\nu\gamma^{-1}) \min\left\{\gamma b_i, \frac{1}{\gamma b_i}\right\}.$$

[illegible] 1 [illegible] $\gamma \to \infty$

The bounds in Theorem 4.2, while independent of h, will generally depend on ν in an implicit way through a_i and b_i. For the case of the Galerkin FE method (2.1) (with no stabilization), the results in [8] provide us with the following estimates for the eigenvalues of (4.3):

$$c\,\nu \le a_i \le C\,\nu^{-1}, \qquad |b_i| \le C_1 \nu^{-1} \tag{4.6}$$

for some h- and ν-independent positive constants c, C, C_1 (here we assume $0 < \nu \le 1$). Together with the estimates from Theorem 4.2, this result implies that it is sufficient to set $\gamma = O(\nu^{-1})$ to ensure that all nonunit eigenvalues of $\mathcal{P}^{-1}\widehat{\mathcal{A}}$ are contained in a box $[\mathtt{a}, \mathtt{A}] \times [-\mathtt{b}, \mathtt{b}]$, $\mathtt{a} > 0$, in the complex plane, with $\mathtt{a}, \mathtt{A}, \mathtt{b}$ independent of ν and h. We note that this theoretical result is of somewhat limited use, since in practice we found that it is unnecessary to use large values of γ (!), or to solve linear systems involving the (1,1) block "exactly" (the latter being perhaps less surprising).

[illegible] 4.3. In numerical experiments we found that using $\gamma \approx \|\mathbf{w}\|$ already provides ν- and h-independent convergence of the Krylov subspace method for a wide range of values of ν and h (it should be noted that we also use streamline diffusion-type velocity stabilization). Furthermore, assume that $\hat{A}_\gamma^{-1}$ is not a solver but a preconditioner for the (1,1) block and that its efficiency deteriorates with $\nu/\gamma \to 0$. Then the optimal value of γ in the Krylov subspace method will be quite modest for $\nu \ll 1$ (see Table 6.2 in section 6).

[illegible] 4.4. The result of the theorem remains valid if one considers $W = \bar{M}_p$ and with $\bar{M}_p$ replacing M_p in (4.3). Following the arguments in [8], it can be easily verified that (4.6) still holds. In general, W is not necessarily an approximation to a mass matrix or identity; see the discussion in [15] in conjunction with other saddle point problems. In this paper, however, we do not pursue other choices of W.

5. A multigrid method for the (1,1) block. In this section we develop a multigrid method to (approximately) solve the system of equations for the discrete velocity at each outer iteration. For the purpose of analysis in this section we consider $W = M_p$; however, in the implementation it is more practical to set $W = \bar{M}_p$. By a simple scaling argument one can assume $\|\mathbf{w}\|_\infty = 1$; thus we can let $\gamma = 1$. The system one needs to solve is

$$A\,u + B^T M_p^{-1} B\,u = f. \tag{5.1}$$

To define an FE counterpart of (5.1) we introduce the orthogonal projector $P_h : L_0^2 \to \mathbb{Q}_h$. The corresponding FE problem takes the form

$$\begin{aligned}\nu(\nabla \mathbf{u}_h, \nabla \mathbf{v}_h) + \sum_{\tau \in T_h} \sigma_\tau (\mathbf{w}\cdot\nabla \mathbf{u}_h, \mathbf{w}\cdot\nabla \mathbf{v}_h)_\tau + ((\mathbf{w}\cdot\nabla)\,\mathbf{u}_h, \mathbf{v}_h) \\ + (P_h \operatorname{div} \mathbf{u}_h, \operatorname{div} \mathbf{v}_h) = (f, \mathbf{v}_h) \qquad \forall\ \mathbf{v}_h \in \mathbb{V}_h.\end{aligned} \tag{5.2}$$

An ideal multigrid method for solving (5.1) should be robust with respect to ν and different types of wind $\mathbf{w}$ and have optimal computational complexity. There are several difficulties in developing such a method. First, note that matrix B has a kernel of dimension $n - m$. In the case of $\nu \ll 1$ and if $\mathbf{w}$ is small in part of Ω, some vectors from $\ker(B)$ may nearly vanish after multiplication by $A + B^T M_p^{-1} B$; see Figure 5.1 for an example of locally supported functions from $\ker(B)$ for a particular FE pair. Thus, common relaxation iterations like Gauss–Seidel could fail to smooth out oscillatory components from $\ker(B)$ that may be present in the error. At the same time, if a local Reynolds number is large, the problem has convection-dominated character at least [illegible] B. Building robust multigrid methods for convection-dominated problems is a well-known challenge; see the overview in [23].

To define the necessary components of the multigrid method, let us consider two pairs of finite element spaces $\mathbb{V}_h \times \mathbb{Q}_h$ and $\mathbb{V}_H \times \mathbb{Q}_H$, corresponding to fine and coarse grids, respectively.

It was shown in [27, 10, 23] that a stable direct discretization on the coarse grid is the preferred choice in geometric multigrid methods for convection-diffusion problems. Additionally, in the case of elasticity-type problems ($\mathbf{w} = \mathbf{0}$ in (2.1)), stability of the coarse grid problem means that velocity and auxiliary pressure approximations on the coarser grid remain compatible, so as to avoid the so-called locking phenomenon [1]. Thus, to build a matrix for a coarse grid problem in our multigrid method we consider the FE formulation

$$\begin{aligned}\nu(\nabla \mathbf{u}_H, \nabla \mathbf{v}_H) + \sum_{\tau \in T_H} \sigma_\tau (\mathbf{w}\cdot\nabla \mathbf{u}_H, \mathbf{w}\cdot\nabla \mathbf{v}_H)_\tau + ((\mathbf{w}\cdot\nabla)\,\mathbf{u}_H, \mathbf{v}_H) \\ + (P_H \operatorname{div} \mathbf{u}_H, \operatorname{div} \mathbf{v}_H) = (f, \mathbf{v}_H) \qquad \forall\ \mathbf{v}_H \in \mathbb{V}_H,\end{aligned}$$

where the new set of parameters σ_τ corresponds to the coarse grid and P_H projects on $\mathbb{Q}_H$. We further define the problem-dependent "energy" norms on $\mathbf{H}_0^1$,

$$\|\mathbf{v}\|_h^2 = \nu(\nabla \mathbf{v}, \nabla \mathbf{v}) + (P_h \operatorname{div} \mathbf{v}, \operatorname{div} \mathbf{v}) \quad \text{and} \quad \|\mathbf{v}\|_H^2 = \nu(\nabla \mathbf{v}, \nabla \mathbf{v}) + (P_H \operatorname{div} \mathbf{v}, \operatorname{div} \mathbf{v}),$$

and set $a_h(\mathbf{u}, \mathbf{v}) = \nu(\nabla \mathbf{u}, \nabla \mathbf{v}) + (P_h \operatorname{div} \mathbf{u}, \operatorname{div} \mathbf{v})$. Consider the standard prolongation operator $p : \mathbb{V}_H \to \mathbb{V}_h$ induced by the embedding $\mathbb{V}_H \subset \mathbb{V}_h$. This is a common choice in a multigrid method for solving elliptic problems. However, it appears not

to work well for (5.1) in the case of small ν. The reason is that $\mathbf{v}_H \in \ker(P_H \operatorname{div})$ does not yield in general $\mathbf{v}_H \in \ker(P_h \operatorname{div})$. Therefore, the standard prolongation is not uniformly stable in the energy norm; i.e., the constant C in the estimate

$$\|p\,\mathbf{v}_H\|_h \le C\,\|\mathbf{v}_H\|_H \qquad \forall\ \mathbf{v}_H \in \mathbb{V}_H \tag{5.3}$$

could grow unboundedly for $\nu \to 0$. In [29] it is suggested that to enforce the stability of the prolongation one can make a correction of $\mathbf{v}_H$ on a fine grid in a way involving solution of local problems. To present this idea in a general setting we consider the L^2-orthogonal decomposition

$$\mathbb{Q}_h = \mathbb{Q}_H \oplus \tilde{\mathbb{Q}}_h. \tag{5.4}$$

We prove the following lemma.

LEMMA 5.1. [illegible] $\tilde{\mathbb{V}}_h \subset \mathbb{V}_h$ [illegible] c [illegible] h [illegible]

$$\inf_{\tilde{q}_h \in \tilde{\mathbb{Q}}_h} \sup_{\tilde{\mathbf{v}}_h \in \tilde{\mathbb{V}}_h} \frac{(\tilde{q}_h, \operatorname{div} \tilde{\mathbf{v}}_h)}{\|\nabla \tilde{\mathbf{v}}_h\| \|\tilde{q}_h\|} \ge c > 0 \tag{5.5}$$

[illegible] $\tilde{\mathbb{V}}_h \subset \ker(P_H \operatorname{div})$ [illegible] $\mathbf{u}_H$ [illegible] $\tilde{\mathbf{u}}_h$ [illegible]

$$a_h(\tilde{\mathbf{u}}_h, \tilde{\mathbf{v}}_h) = a_h(\mathbf{u}_H, \tilde{\mathbf{v}}_h) \qquad \forall\ \tilde{\mathbf{v}}_h \in \tilde{\mathbb{V}}_h. \tag{5.6}$$

[illegible] $p : \mathbb{V}_H \to \mathbb{V}_h$ [illegible]

$$p\,\mathbf{u}_H = \mathbf{u}_H - \tilde{\mathbf{u}}_h. \tag{5.7}$$

[illegible] p [illegible] (5.3) [illegible] C [illegible] h [illegible] ν [illegible]. Define the following bilinear form on $\mathbf{H}_0^1 \times L_0^2$:

$$\mathcal{B}(\mathbf{u}, p; \mathbf{v}, q) := \nu(\mathbf{u}, \mathbf{v}) + (p, \operatorname{div} \mathbf{v}) + (q, \operatorname{div} \mathbf{u}) - (p, q).$$

For given $\mathbf{u}_H$ denote

$$p_H = P_H \operatorname{div} \mathbf{u}_H. \tag{5.8}$$

Define $\tilde{\mathbf{u}}_h \in \tilde{\mathbb{V}}_h$ and $\tilde{p}_h \in \tilde{\mathbb{Q}}_h$ by solving

$$\mathcal{B}(\tilde{\mathbf{u}}_h, \tilde{p}_h; \tilde{\mathbf{v}}_h, \tilde{q}_h) = \mathcal{B}(\mathbf{u}_H, p_H; \tilde{\mathbf{v}}_h, \tilde{q}_h) \quad \forall\ \tilde{\mathbf{v}}_h \in \tilde{\mathbb{V}}_h,\ \tilde{q}_h \in \tilde{\mathbb{Q}}_h. \tag{5.9}$$

This problem is well-posed thanks to (5.5). Taking $\tilde{\mathbf{v}}_h = 0$ in (5.9) we get

$$(\operatorname{div}(\mathbf{u}_H - \tilde{\mathbf{u}}_h), \tilde{q}_h) = (p_H - \tilde{p}_h, \tilde{q}_h) \quad \forall\ \tilde{q}_h \in \tilde{\mathbb{Q}}_h. \tag{5.10}$$

Also, since (5.8) implies $(p_H - \operatorname{div} \mathbf{u}_H, q_H) = 0$ and the assumptions $\tilde{\mathbb{V}}_h \subset \ker(P_H \operatorname{div})$ and $\tilde{\mathbb{Q}}_h \perp \mathbb{Q}_H$ imply $(\tilde{p}_h, q_H) = (\operatorname{div} \tilde{\mathbf{u}}_h, q_H) = 0$ for any $q_H \in \mathbb{Q}_H$, we get

$$(\operatorname{div}(\mathbf{u}_H - \tilde{\mathbf{u}}_h), q_H) = (p_H - \tilde{p}_h, q_H) \quad \forall\ q_H \in \mathbb{Q}_H. \tag{5.11}$$

Since $\mathbb{Q}_h = \mathbb{Q}_H \oplus \tilde{\mathbb{Q}}_h$, relations (5.10) and (5.11) yield

$$P_h \operatorname{div}(\mathbf{u}_H - \tilde{\mathbf{u}}_h) = p_H - \tilde{p}_h. \tag{5.12}$$

Using (5.12) and (5.9) with $\tilde{q}_h = 0$ we can see that $\mathbf{u}_H$ and $\tilde{\mathbf{u}}_h$ found from (5.9) satisfy

$$\nu(\nabla\tilde{\mathbf{u}}_h, \nabla\tilde{\mathbf{v}}_h) + (P_h \operatorname{div}\tilde{\mathbf{u}}_h, \operatorname{div}\tilde{\mathbf{v}}_h) = \nu(\nabla\mathbf{u}_H, \nabla\tilde{\mathbf{v}}_h) + (P_h \operatorname{div}\mathbf{u}_H, \operatorname{div}\tilde{\mathbf{v}}_h) \quad \forall\ \tilde{\mathbf{v}}_h \in \tilde{\mathbb{V}}_h.$$

This is the same as (5.6).

Thanks to the stability assumption (5.5) the bilinear form $\mathcal{B}$ is stable with respect to the norm $(\nu\|\mathbf{u}\|^2 + \nu^{-1}\|p\|^2)^{-\frac{1}{2}}$ (this can be easily verified by rescaling the problem to a Stokes problem with the penalty term $\nu(p,q)$). Thus, for the solution of the problem (5.9) we obtain the estimate

$$\begin{aligned}(5.13)\quad (\nu\|\tilde{\mathbf{u}}_h\|^2 + \nu^{-1}\|\tilde{p}_h\|^2)^{-\frac{1}{2}} &\le C \sup_{\tilde{\mathbf{v}}_h, \tilde{q}_h \in \mathbb{V}_h \times \mathbb{Q}_h} \frac{\mathcal{B}(\tilde{\mathbf{u}}_h, \tilde{p}_h; \tilde{\mathbf{v}}_h, \tilde{q}_h)}{(\nu\|\tilde{\mathbf{v}}_h\|^2 + \nu^{-1}\|\tilde{q}_h\|^2)^{-\frac{1}{2}}} \\ &= C \sup_{\tilde{\mathbf{v}}_h, \tilde{q}_h \in \mathbb{V}_h \times \mathbb{Q}_h} \frac{\mathcal{B}(\mathbf{u}_H, p_H; \tilde{\mathbf{v}}_h, \tilde{q}_h)}{(\nu\|\tilde{\mathbf{v}}_h\|^2 + \nu^{-1}\|\tilde{q}_h\|^2)^{-\frac{1}{2}}} \le 2C\,\nu\|\mathbf{u}_H\|.\end{aligned}$$

Using the triangle inequality and (5.13) we get

$$\nu\|\mathbf{u}_H - \tilde{\mathbf{u}}_h\|^2 + \|p_H - \tilde{p}_h\|^2 \le C\,((\nu + \nu^2)\|\mathbf{u}_H\|^2 + \|p_H\|^2).$$

Thanks to (5.8) and (5.12) the last inequality is equivalent to

$$\nu\|\mathbf{u}_H - \tilde{\mathbf{u}}_h\|^2 + \|P_h \operatorname{div}(\mathbf{u}_H - \tilde{\mathbf{u}}_h)\|^2 \le C\,(\nu\|\mathbf{u}_H\|^2 + \|P_H \operatorname{div}\mathbf{u}_H\|^2),$$

which is (5.3) for the prolongation defined in (5.7). □

Note that for isoP2-P0 or P2-P0 finite elements, the spaces $\tilde{\mathbb{Q}}_h$ and the appropriate $\tilde{\mathbb{V}}_h$ are easy to describe. Indeed, let T_H be the coarse grid (pressure) triangulation. Then

$$\begin{aligned}\tilde{\mathbb{Q}}_h &= \left\{\tilde{q}_h \in \mathbb{Q}_h : \int_\tau \tilde{q}_h\,dx = 0 \quad \forall\ \tau \in T_H\right\}, \\ \tilde{\mathbb{V}}_h &= \left\{\tilde{\mathbf{v}}_h \in \mathbb{V}_h : \tilde{\mathbf{v}}_h|_{\partial\tau} = 0 \quad \forall\ \tau \in T_H\right\}.\end{aligned}$$

The assumptions of Lemma 5.1 can be readily checked. For this choice of the subspace $\tilde{\mathbb{V}}_h$, solving (5.6) requires the solution of N_p independent problems of small dimension (for regular subdivisions the dimension is 6 in two dimensions, and 9 in three dimensions), where N_p is the number of elements in T_H. On the other hand, for isoP2-P1 or P2-P1 finite elements we are unable to find a simple choice for $\tilde{\mathbb{V}}_h$ leading to easily solved local problems (5.6). Therefore, in this case we compute the correction $\tilde{\mathbf{v}}_h$ in (5.7) by solving locally (5.6) on each element $\tau \in T_H$, taking for $\tilde{\mathbb{V}}_h$ all $\mathbf{v}_h \in \mathbb{V}_h$ vanishing on $\partial\tau$. From experiments we saw that such a prolongation still improves the robustness of the multigrid method in the case of continuous pressure discretization compared to the canonical prolongation ($\tilde{\mathbf{u}}_h = 0$). Moreover, some further improvement in this case was observed if the $\mathbf{w}$-dependent terms were included in the definition of the bilinear form a_h in (5.6). However, the observed improvement in this case was not as dramatic as for isoP2-P0 elements; see also Remark 5.2.

Typically the restriction operator $r : \mathbb{V}_h \to \mathbb{V}_H$ is taken to be the adjoint of the prolongation. This choice is also convenient for theoretical analysis [29]. However, an operator adjoint to (5.7) is not easily computable. Therefore, as a restriction we use the L^2-orthogonal projection from $\mathbb{V}_h$ to $\mathbb{V}_H$. It is well known that the L^2-orthogonal projection on $\mathbb{V}_H$ is stable in the H^1-norm (see, e.g., [4]) under some assumptions on T_H. Although we did not find in the literature any results which would allow us

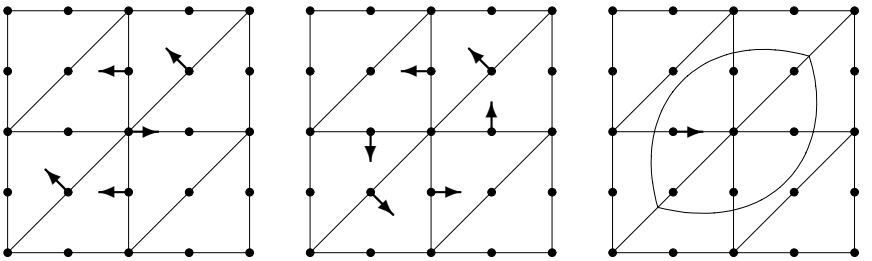

FIG. 5.1. *Basis of weakly divergence-free functions for isoP2-P0 and P2-P0. Pressures from $\mathbb{Q}_h$ are constants on each triangle; dots denote velocity nodes.*

to conclude the stability of the L^2-orthogonal projection with respect to the norms $\|\cdot\|_h$, $\|\cdot\|_H$ if $\nu \to 0$, this choice works very well as the restriction operator in our multigrid method.

Finally, we describe the smoother. As already mentioned, an effective smoother should effectively eliminate the oscillatory components in the kernel of $P_h \operatorname{div}$. For piecewise constant pressure-based FE pairs one finds that $\mathbf{u}_h \in \ker(P_h \operatorname{div})$ if and only if for any $\tau \in T_h$ the total flux for $\mathbf{u}_h$ through $\partial\tau$ equals zero. Thus, the kernel of $P_h \operatorname{div}$ can be described explicitly. For example, basis functions for $\ker(P_h \operatorname{div})$ in the case of P2-P0 finite elements are shown in Figure 5.1 [5, 29] (these are actually three of nine basis functions "captured" inside the oval on the right). Note that all basis functions have local support. Therefore an efficient smoother can be built as a block relaxation procedure, where degrees of freedom (DOFs) supporting each basis function from $\ker(P_h \operatorname{div})$ are organized in one block. The blocks can be overlapping. This is described more formally below.

We used a block Gauss–Seidel method, which can be written as a sequential subspace correction method (in the terminology of Xu [36]) based on the decomposition $\mathbb{V}_h = \sum_{i=0}^{l} \mathbb{V}_i$, $\mathbb{V}_i \subset \mathbb{V}_h$, where the sum is not necessarily a direct sum. Let A_i be the stiffness matrix for (5.2) on $\mathbb{V}_i$. Then one relaxation iteration consists of the following steps: Let $u^0 = u^{old}$, then compute

$$u^{i+1} = u^i - p_i A_i^{-1} r_i((A + B^T M_p^{-1} B)\, u^i - f) \quad \text{for } i = 0, \dots, l, \tag{5.14}$$

and put $u^{new} = u^{l+1}$. Restriction r_i in (5.14) is the simple nodal one and $p_i = r_i^T$.

For isoP2-P0 or P2-P0 finite elements the natural choice is to gather nodal DOFs for velocity inside ovals similar to the one in Figure 5.1. To be more precise, let s_i, $i = 1, \dots, l$, be the set of all interior vertices of T_h. For each i define $\boldsymbol{\tau}^i$ as a union of all triangles $\tau \in T_h$ sharing s_i. Then

$$\mathbb{V}_i := \{\mathbf{v}_h \in \mathbb{V}_h : \mathbf{v}_h = 0 \quad \text{in } \Omega \setminus \boldsymbol{\tau}^i\}.$$

We note that in the case of piecewise linear pressure FE pairs (e.g., isoP2-P1) it is harder to describe the kernel of $P_h \operatorname{div}$. Thus, in this case we simply use the same choice of $\mathbb{V}^i$ to define the relaxation step (5.14). As we will see, the resulting smoother remains quite effective.

As usual for Gauss–Seidel type methods, the performance of the iterations (5.14) depends on the ordering of blocks of unknowns. Since the definition of $\mathbb{V}^i$ is solely based on the choice of a node s_i, the relaxation method (5.14) is uniquely defined by the ordering of nodes in T_h. It is well known that smoothing iterations for convection-dominated problems are sensitive to the numbering of unknowns and that the fastest

convergence is achieved for the streamwise ordering of nodes; see, e.g., [3, 18, 23]. Finding appropriate orderings may be a difficult task, especially for complex three-dimensional (3D) flow fields $\mathbf{w}$. However, our numerical experiments suggest that the multigrid method with the above-described block Gauss–Seidel smoothing applied to (5.1) is not very sensitive to the numbering of nodes. Because of this, in our implementation we used a lexicographical ordering of the blocks of unknowns. One smoothing iteration consists of two relaxation steps (5.14): one with left-right/top-bottom ordering, the other with top-bottom/left-right ordering.

We conclude the section with some remarks about the implementation and performance of the multigrid scheme.

REMARK 5.2. While the multigrid method described above turns out to be very robust for (iso)P2-P0 finite elements, in the case of (iso)P2-P1 discretization some degradation of convergence is still observed as $\frac{\nu}{\gamma} \to 0$. This results in a large number of outer iterations. One way to improve convergence is to increase the number of smoothing steps on each level as $\frac{\nu}{\gamma} \to 0$. Another, more efficient way (followed in the numerical experiments; see section 6) is to take somewhat smaller γ for $\nu \ll 1$, keeping the number of smoothing steps constant and low. Doing this, one ensures that the cost of one outer iteration does not increase. At the same time one sacrifices slightly the quality of the Schur complement preconditioner in (3.7): Indeed, for $\gamma = 0$ the preconditioner from (3.7) is poor for small ν (see [8]). Nevertheless, the total number of outer iterations stays quite low for all reasonable values of ν (see section 6).

REMARK 5.3. In general we found the W-cycle to be more robust than the V-cycle. For the problems we tested, the V-cycle needs approximately twice or three times as many smoothing steps as the W-cycle to demonstrate similar convergence rates. Thus, the results in the next section are those obtained with the W-cycle implementation. However, for problems with locally refined grids using the V-cycle instead may be preferable in order to preserve the optimal complexity of the multigrid method.

REMARK 5.4. The dimension of the subspace $\mathbb{V}_i$ equals 14 in the 2D case (two velocity components for each node inside the oval in Figure 5.1). In the 3D case and for a regular subdivision we get $\dim \mathbb{V}_i = 39$. It is a common practice in using block smoothers for flow problems (such as Vanka smoothing [33]) that instead of applying A_i^{-1} in (5.14) one considers a simple, e.g., diagonal or triangular, approximation of A_i [31, section 2.4.1]. This helps reduce significantly the computational cost of one smoothing iteration. In this paper we solve subproblems with A_i exactly. A multigrid scheme based on inexact block inverses will be studied elsewhere.

6. Numerical experiments. In this section we present results for both isoP2-P0 and isoP2-P1 elements. We focus on two commonly used model problems on the unit square. In the first problem the wind function is constant and is given by

$$\mathbf{w} = \begin{pmatrix} 1 \\ 0 \end{pmatrix}. \tag{6.1}$$

The second problem is a classical recirculating flow problem. Here the wind is a "rotating vortex," i.e., the vector field

$$\mathbf{w} = \begin{pmatrix} 4(2y-1)(1-x)x \\ -4(2x-1)(1-y)y \end{pmatrix}. \tag{6.2}$$

In the experiments we use our preconditioner with the Krylov subspace method BiCGStab [32]. Inexact solves involving the (1,1) block consist of a single W(1,1)-cycle with the multigrid method described in the previous section, that is, one W-cycle

TABLE 6.1
Results for AL approach, isoP2-P0 finite elements.

Number of preconditioned BiCGStab iterations
($\hat{A}_\gamma^{-1}$ is one W(1,1)-cycle, $\gamma = 1$).

with one presmoothing and one postsmoothing step on each level. Each smoothing step consists of two iterations of block Gauss–Seidel relaxation with the alternating ordering described at the end of the previous section. The number of levels is such that the coarsest grid problem corresponds to $h = \frac{1}{2}$. The coarsest grid problem is solved exactly.

We set $W = \bar{M}_p$ in all experiments. Solves involving the (2,2) block are inexpensive. The action of $\hat{S}^{-1}$ on a vector is computed via (3.7). For isoP2-P0 elements this amounts to a diagonal scaling operation. For the case of isoP2-P1 elements, the pressure mass matrix is not diagonal. Linear systems involving M_p are approximately solved by performing a fixed number (fifteen) of stationary Richardson-type relaxations with parameter $\alpha = 1.75$. Note that the condition number of M_p is bounded by a constant independent of h (and of ν). Since we use a fixed number of stationary iterations for both the (1,1) and the (2,2) blocks, the overall preconditioner remains constant from one outer iteration to the next. Hence, we can use a standard Krylov subspace method such as BiCGStab for the outer iteration. In all runs we stop the outer iteration once the 2-norm of the initial residual has been reduced by at least six orders of magnitude, and we always use the zero vector as the initial guess.

The results for isoP2-P0 elements are reported in Table 6.1. For both choices of the wind function, the convergence rate is h-independent. For the constant wind problem, the convergence rate is also independent of ν, even for values of ν as small as 10^{-4}. For the recirculating flow problem, the results are virtually the same except for an increase in the number of iterations for the smallest value of the viscosity, $\nu = 10^{-4}$. Even in this extreme case, however, the convergence is quite fast.

Results for the isoP2-P1 discretization are reported in Table 6.2. The results are still quite good. For the smallest values of the viscosity we found that γ must be reduced in order to retain fast convergence (see Remarks 4.3 and 5.2 for a discussion). The results are, in all cases, h-independent; some increase in the iteration count occurs for the smallest values of ν, but overall the convergence properties remain excellent.

6.1. Other methods. In this subsection we report the results obtained when solving the same model problems with the [illegible] (PCD) preconditioner developed in [21] and with a full [illegible] method as a preconditioner (see, e.g., [19, 33]). Both techniques are based on the original, nonaugmented

($\hat{A}_\gamma^{-1}$ is one W(1,1)-cycle).

formulation ($\gamma = 0$). The PCG preconditioner is built upon separately solving velocity and pressure subproblems, while Vanka's approach is a geometric multigrid method for a coupled problem (1.10); see the review paper [35] discussing this class of methods.

The PCD method is widely regarded as one of the best available preconditioners in the class of block solvers for the steady Oseen problem, at least in the case of continuous pressure approximations. The preconditioner is of the form (3.1), where $\hat{S}$, the approximate pressure Schur complement, is defined through the action of its inverse:

$$\hat{S}^{-1} = M_p^{-1} F_p A_p^{-1}. \tag{6.3}$$

In (6.3) M_p denotes the pressure mass matrix, F_p denotes a convection-diffusion operator acting on the pressure space, and A_p represents the pressure Laplacian; for the latter two operators, care should be taken to enforce the appropriate boundary conditions. For the given model problems we used Neumann conditions on the entire boundary. In the case of piecewise linear pressure approximations F_p was constructed following [10, page 348]. For piecewise constant pressure elements we set $A_p := BM_u^{-1}B^T$ (so-called mixed approximation of the pressure Poisson problem) and $F_p := r_{u\to p}\, A_x\, r_{p\to u}$, where A_x is the x-subblock of A, $r_{u\to p}$ and $r_{p\to u}$ are suitable mappings from $\mathbb{Q}_h$ to $\mathbb{V}_h$, and vice versa.

Note that in two dimensions each application of the PCD preconditioner requires solving two convection-diffusion problems for the velocities and one Poisson-type problem for the pressure. These solves are usually performed inexactly in order to reduce costs. In our implementation we used [illegible] solves for both the (1,1) block and for the inverses appearing in (6.3).

As recommended in [10], we use the PCD preconditioner with BiCGStab(2) [30]. This Krylov subspace method requires four matrix-vector multiplies and four applications of the preconditioner per iteration. In order to facilitate the comparison with the results obtained with BiCGStab and our own preconditioner, we report in Table 6.3 the number of "BiCGStab-equivalent iterations" (i.e., the number of BiCGStab(2)

iterations multiplied by 2). We also experimented with BiCGStab, but the results were not better.

It appears from these results that the PCD preconditioner is generally less robust and effective than the AL-based preconditioner, especially for small ν. We note, however, that PCD preconditioners can be built on a basis of various solvers for the (1,1) block and for the pressure Poisson problem; in particular, algebraic multigrid methods can be used, while the efficient implementation of the AL-based preconditioner described in this paper requires a hierarchy of grids to be available, as usual for a geometric multigrid method. Also, it should be mentioned that the PCD preconditioner results in preconditioned operators for which some of the eigenvalues have an imaginary part growing like $O(\nu^{-1})$; see [9]. It is well known that BiCG-type methods tend to perform poorly for such problems. Thus, it is possible that better results could be obtained for small ν if PCD preconditioning is used with GMRES or with BiCGStab(ℓ) with larger values of ℓ.

The Vanka preconditioner is built on a geometric multigrid method with block Gauss–Seidel smoothing for system (1.10). One relaxation step consists of l sequential updates:

$$\begin{pmatrix} u^{i+1} \\ p^{i+1} \end{pmatrix} = \begin{pmatrix} u^{i} \\ p^{i} \end{pmatrix} - r_i^T \mathcal{C}_i^{-1} r_i \left(\mathcal{A} \begin{pmatrix} u^{i} \\ p^{i} \end{pmatrix} - \begin{pmatrix} f \\ 0 \end{pmatrix} \right) \quad \text{for } i = 0, \dots, l. \tag{6.4}$$

Restriction r_i is the simple nodal one. Entries of matrices $\mathcal{C}_i$ are those from $\mathcal{A}$ corresponding to unknowns in the ith block. For approximations based on discontinuous pressure, unknowns in one block consist of all pressure and velocity DOFs tied to one cell (triangle). For isoP2-P0 elements this results in a matrix of the form

$$\mathcal{C}_i = \begin{pmatrix} A_i & B_i^T \\ B_i & 0 \end{pmatrix}, \tag{6.5}$$

where the block A_i is 12×12 and B_i is 1×12. Since for a regular subdivision in two dimensions the number of cells is approximately twice the number of vertices and the dimension of A_i in (5.14) is 14×14, we conclude that for isoP2-P0 elements one smoothing step in Vanka's method is more computationally expensive than in the multigrid method from section 5.

1/128	4 / 4	4 / 4	4 / 5	9 / 13	> 400 / 67

Number of preconditioned BiCGStab iterations.

For approximations based on the continuous pressure it is recommended in [19] that unknowns in a block should consist of all the pressure and velocity DOFs tied to one vertex. For isoP2-P1 elements this results in a matrix of the same structure as (6.5). However, now each matrix $\mathcal{C}_i$ has dimension 39×39 for a regular 2D triangulation (196×196 in three dimensions). This makes one relaxation step considerably more expensive than in (5.14). To facilitate comparison we include in a block only velocity DOFs in the corresponding vertex and next to it (i.e., exactly the same as in the multigrid method described in section 5). Taking into account one pressure unknown in the vertex, this results in a 15×15 matrix $\mathcal{C}_i$. Thus the computational cost of one smoothing step is nearly the same as in the multigrid method used in the AL-based preconditioner. One problem with this reduction is that now the $\mathcal{C}_i$ matrix for isoP2-P1 is LBB-unstable and the relaxation fails to smooth the error in the pressure. As typical for stabilized methods, the solution is to replace the zero (2,2) "block" in (6.5) (its dimension is actually 1×1) by the matrix $-\sigma(\mathbf{x})I$, where $\sigma(\mathbf{x})$ is an element-dependent stabilization parameter. Numerical experiments reveal that multigrid convergence is very sensitive to the value of $\sigma(\mathbf{x})$. An ad hoc choice which we found to be close to optimal for various values of h and ν is $\sigma(\mathbf{x}) = (\nu/2 + 2\|\mathbf{w}(\mathbf{x})\|h^2)^{-1}$, where $\|\mathbf{w}(\mathbf{x})\|$ is the Euclidean norm of vector $\mathbf{w}(\mathbf{x})$ in the corresponding vertex.

Results for the Vanka multigrid preconditioner and both FE pairs are shown in Table 6.4. Similar to the multigrid used in the AL-based method, one smoothing iteration in Vanka consists of two relaxation steps with alternating ordering directions.

From the results reported in the table, it appears that the Vanka-type multigrid preconditioner gives good results for a wide range of values of h and ν. For very small values of the viscosity, however, the performance of the method may in some cases deteriorate, and the preconditioned iteration may even fail to converge.

7. Conclusions. The paper presents a new preconditioning technique for finite element discretizations of the Oseen problem arising from Picard linearizations of the steady Navier–Stokes equations. The approach is based on an AL formulation of the resulting saddle point system. The preconditioner is block triangular and requires an efficient approximate solver for the (1,1) block; the second block is essentially a scaled mass matrix and is easy to invert. The (1,1) block can be seen as the discretization of a nonconventional, nonsymmetric operator consisting of a linear elasticity operator plus a convection term. We have developed an effective inexact solver for this opera-

tor by combining a multigrid method of Schöberl (originally designed for symmetric problems) with a suitable smoother. We have shown that assuming exact solves for the (1,1) block, the preconditioner clusters the eigenvalues in a small rectangular region of the complex plane around the point $(1, 0)$, and that the sides of this rectangle are independent of both h and ν. Our numerical experiments on some 2D model problems indicate that in practice, a single W(1,1)-cycle is sufficient to achieve fast, h-independent convergence of the outer BiCGStab iteration. Furthermore, the rate of convergence appears to be essentially ν-independent, except for a slight degradation for extremely low values of ν. The preconditioner is especially effective for isoP2-P0 and P2-P0 elements, but excellent performance is also observed for discretizations using piecewise linear pressure approximations. In the latter case, a good choice of the parameter γ is important for $\nu \ll 1$.

Finally, we mention that while in this paper we have focused on the steady 2D case, our approach can be extended to the solution of unsteady and 3D problems.

Acknowledgments. We would like to thank Clark Dohrmann for his helpful comments on an earlier version of the paper. Thanks also to David Silvester, Andy Wathen, and an anonymous referee for their careful reading of the manuscript. This work was done while the second author was visiting the Department of Mathematics and Computer Science at Emory University during fall 2005. The hospitality and support of Emory University are gratefully acknowledged.

AN ADAPTIVE WEM ALGORITHM FOR SOLVING ELLIPTIC BOUNDARY VALUE PROBLEMS IN FAIRLY GENERAL DOMAINS*

S. BERRONE† AND T. KOZUBEK‡

Abstract. In this paper, we introduce a simple adaptive wavelet element algorithm similar to the Cohen–Dahmen–DeVore algorithm [A. Cohen, W. Dahmen, and R. DeVore, *Math. Comp.*, 70 (2001), pp. 27–75]. The main difference is that we do not assume knowledge of the many constants appearing therein. The algorithm is easy to implement and applicable to a large class of problems in fairly general domains. The efficiency is illustrated by several two-dimensional numerical examples and compared with an adaptive finite element method.

Key words. adaptive wavelet and finite element methods, elliptic operator equations, rates of convergence

1. Introduction.

Wavelets have become an efficient tool for solving many problems arising in theory and in practice. Let us mention, for example, signal analysis, compression of information, geometry representation, and numerical analysis. In this paper we deal with wavelets used for the solution of elliptic boundary value problems in $\mathbb{R}^d$, $d = 1, 2, 3$. Adaptivity is a key ingredient in modern numerical computation which helps to improve significantly the performance of the method. When dealing with the finite element method (FEM), adaptivity occurs in the context of grid refinement, in contrast to the function selection used in wavelet discretization methods such as the wavelet element method (WEM). A detailed discussion of the adaptive (nonlinear) refinement advantages with respect to the uniform (linear) refinement can be found in [12, 23].

We introduce an adaptive WEM algorithm applicable to a large class of problems defined in fairly general domains. The key ideas of our algorithm follow the fundamental Cohen–Dahmen–DeVore approach to wavelet adaptivity for PDEs [2, 12, 13], but we do not assume knowledge of the many constants appearing therein. Industrial applications of the Cohen–Dahmen–DeVore algorithm in all its aspects still seem to be quite hard. Here we propose an adaptive algorithm based on the same ideas, but whose practical application is easier. For the proposed algorithm we do not provide any proof of either convergence or optimality, as in [12]. Our goal is rather (i) CG, BiCG, GMRES (ii) (iii) Ω $\mathbb{R}^d$; (iv)

To construct multiresolution systems on fairly general domains in $\mathbb{R}^d$, we use a WEM construction described in [10, 11, 4], but the proposed algorithm itself does not depend on the type of the used wavelet basis [20, 26] nor on the WEM construction [22, 14, 10]. The key point of the WEM is the splitting of the domain into subdomains in such a way that each of them can be mapped to a reference hypercube. Bases on the reference domain in $\mathbb{R}^d$ are constructed by the tensor product of scaling and wavelet functions defined on the unit interval. In our implementation wavelet bases on the interval are formed by biorthogonal B-spline wavelets with optimal localization introduced in [26]. To obtain a globally continuous biorthogonal wavelet basis, one has to enforce matching conditions across interelement boundaries. The construction enables one to fulfill additional important features such as symmetry, vanishing moments, and a minimal support.

Problem setting and general requirements on the wavelet bases are briefly mentioned in section 2. For space reasons we assume some knowledge of these aspects, referring for more details to [16, 17, 18] and the references therein. In section 3, we introduce the adaptive WEM algorithm and describe all ingredients in details. In section 4, we illustrate the applicability of this adaptive WEM method to quite general situations; some numerical examples involving singularities and two-dimensional complex geometries requiring mapping and matching are considered. Conclusions are summarized in section 5. Finally, in the appendix, we compare some results obtained by the proposed algorithm with results obtained using a well-assessed adaptive finite element code [30, 1]. This comparison does not attempt to claim that one method outperforms the other, but aims at comparing some aspects of the solution process of the two adaptive methods.

2. General settings. In this section, we introduce a class of elliptic boundary value problems which are the focus of our interest. Finally, using such basis, we show how to transform the problem into an equivalent l_2-problem.

2.1. Problem setting. Let Ω be a bounded domain in $\mathbb{R}^d$, $d = 1, 2, 3$, with the Lipschitz boundary $\partial\Omega$. Further, let $H := H(\Omega)$ be a Hilbert space and $\mathcal{A} : H \to H'$ an elliptic operator of the second order, where H' is a dual to H and $H \hookrightarrow L^2(\Omega) \hookrightarrow H'$. Due to simplicity of our presentation we will be concerned with the following abstract pure Dirichlet boundary value problem: for given $f \in H' := H^{-1}(\Omega)$ find $u \in H := H_0^1(\Omega)$ such that

$$\begin{cases} \mathcal{A}u = f & \text{in } \Omega, \\ u = 0 & \text{on } \partial\Omega. \end{cases} \tag{2.1}$$

The corresponding weak form to (2.1) is

$$\begin{cases} \text{Find } u \in H \text{ such that} \\ a(u, v) = \langle f, v \rangle \quad \forall v \in H, \end{cases} \tag{2.2}$$

where $a(.\,,.) : H \times H \to \mathbb{R}$ is the continuous bilinear form defined by $a(u, v) := \langle \mathcal{A}u, v \rangle$ and $\langle .\,,. \rangle$ denotes the standard duality pairing between H and H'.

We assume that problem (2.2) is well-posed, i.e., there are positive finite constants $c_{\mathcal{A}}$, $C_{\mathcal{A}}$ such that $c_{\mathcal{A}}\|v\|_H \le \|\mathcal{A}v\|_{H'} \le C_{\mathcal{A}}\|v\|_H$, $v \in H$. This immediately implies the existence of a unique solution to (2.2).

2.2. General requirements on the wavelet bases. We are interested in solving problem (2.2) using the [illegible], i.e., a Galerkin method with a suitably chosen wavelet basis for H in $\boldsymbol{\psi} = \{\psi_\lambda : \lambda \in \mathcal{J}\}$, where $\mathcal{J}$ is an infinite index set, and an adaptive procedure for the basis functions selection. In the following, we list the relevant properties of the wavelet basis $\boldsymbol{\psi}$.

For any $v \in L^2(\Omega)$ we have a [illegible] expansion $v = \sum_{\lambda\in\mathcal{J}} v_\lambda\psi_\lambda = \mathbf{v}^T\boldsymbol{\psi}$ which induces an isomorphism between H and l_2. More precisely, there is a scaling diagonal matrix $\mathbb{D} = \operatorname{diag}(d_\lambda : \lambda \in \mathcal{J})$ and positive constants c_ψ, C_ψ such that $c_\psi\|\mathbf{v}\|_{l_2} \le \|\mathbf{v}^T\mathbb{D}^{-1}\boldsymbol{\psi}\|_H \le C_\psi\|\mathbf{v}\|_{l_2}$. For example, when H is the Sobolev space $H^t(I)$ with $I = [0,1]$, a canonical choice of d_λ is $d_\lambda = 2^{t|\lambda|}$; in general for $H = H^1(\Omega)$ we choose $d_\lambda = \sqrt{a(\psi_\lambda,\psi_\lambda)}$ [19, 21, 27, 28]. We assume that basis functions have [illegible] and are [illegible] with $\operatorname{diam}(\operatorname{supp}\psi_\lambda) \sim 2^{-|\lambda|}$, where $\lambda \in \mathcal{J}$ and $|\lambda|$ is the level of the basis function ψ_λ (see [20, 26, 10]).

2.3. An equivalent l_2-problem. Given a basis with the mentioned properties, we can transform problem (2.2) over a function space H into an algebraic system of equations over the corresponding sequence space. More precisely, we obtain the following equivalent l_2-problem: $\mathbb{A}\mathbf{x} = \mathbf{f}$, where $\mathbb{A} = \mathbb{D}^{-1}\langle\mathcal{A}\boldsymbol{\psi},\boldsymbol{\psi}\rangle\mathbb{D}^{-1} = \left(d_\lambda^{-1}d_\mu^{-1}\langle\mathcal{A}\psi_\mu,\psi_\lambda\rangle\right)_{\lambda,\mu\in\mathcal{J}}$ is an infinite matrix and $\mathbf{f} = \mathbb{D}^{-1}\langle f,\boldsymbol{\psi}\rangle = \left(d_\lambda^{-1}\langle f,\psi_\lambda\rangle\right)_{\lambda\in\mathcal{J}}$ is an infinite vector. It is well known [12, 13, 16, 18] that if $u = \mathbf{x}^T\mathbb{D}^{-1}\boldsymbol{\psi}$ is the scaled wavelet representation of the solution to (2.2), the problem $\mathbb{A}\mathbf{x} = \mathbf{f}$ is an equivalent problem in l_2 to $\mathcal{A}u = f$. In addition, there are positive constants $c_{\mathbb{A}}$, $C_{\mathbb{A}}$ such that $c_{\mathbb{A}}\|\mathbf{v}\|_{l_2} \le \|\mathbb{A}\mathbf{v}\|_{l_2} \le C_{\mathbb{A}}\|\mathbf{v}\|_{l_2}$, $\mathbf{v} \in l_2$, with lower and upper estimates $c_{\mathbb{A}} \ge c_\psi^2 c_{\mathcal{A}}$ and $C_{\mathbb{A}} \le C_\psi^2 C_{\mathcal{A}}$, respectively.

Our infinitely dimensional problem $\mathbb{A}\mathbf{x} = \mathbf{f}$ can be now approximated by a finite-dimensional approximation

$$\mathbb{A}_{\Lambda\times\Lambda}\mathbf{x}_\Lambda = \mathbf{f}_\Lambda, \tag{2.3}$$

where $\mathbf{f}_\Lambda = \left(d_\lambda^{-1}\langle f,\psi_\lambda\rangle\right)_{\lambda\in\Lambda}$, $\mathbb{A}_{\Lambda\times\Lambda} = \left(d_\lambda^{-1}d_\mu^{-1}\langle\mathcal{A}\psi_\mu,\psi_\lambda\rangle\right)_{\lambda,\mu\in\Lambda}$, $\Lambda \subset \mathcal{J}$, and the approximation of the solution u is given by

$$u_\Lambda = \sum_{\mu\in\Lambda} d_\mu^{-1}x_\mu\psi_\mu = \mathbf{x}_\Lambda^T\mathbb{D}_\Lambda^{-1}\boldsymbol{\psi}_\Lambda. \tag{2.4}$$

With $\mathbb{A}$ positive definite, all finite sections $\mathbb{A}_{\Lambda\times\Lambda}$ have $\|\mathbb{A}_{\Lambda\times\Lambda}\|_2 \sim 1$, $\|\mathbb{A}_{\Lambda\times\Lambda}^{-1}\|_2 \sim 1$, and $1 \sim \operatorname{cond}_2(\mathbb{A}_{\Lambda\times\Lambda}) \le \operatorname{cond}_2(\mathbb{A}) < \infty$ [19, 21, 27].

3. An adaptive WEM algorithm. In this section, we present our adaptive algorithm; particular settings of the parameters are presented in section 4.

We start initializing all parameters of the algorithm and choosing an appropriate solver of the resulting algebraic systems. The algorithm consists of an outer adaptive iterative process, where all iterations consist of several steps. At iteration n, we have three sets of basis functions, whose sets of indices will be denoted by Λ_n, $\tilde{\Lambda}_n$, and $\overline{\Lambda}_n$. More precisely, Λ_n is the set of indices of the active basis functions, whereas $\tilde{\Lambda}_n$ consists of indices corresponding to the functions that can be activated in this iteration. In the definition of this set one can include essential information on the data of the problem to deal with particular situations. Finally, $\overline{\Lambda}_n$ is the set of indices

of basis functions after a thresholding step in which we remove from Λ_n the indices of those basis functions whose coefficients are less significant. We name the sets Λ_n, $\tilde{\Lambda}_n$ and the corresponding functions [illegible] and [illegible], respectively.

The first step of each iteration consists in enlarging the set $\overline{\Lambda}_{n-1}$ to get Λ_n. In the first iteration $n = 0$ of the adaptive procedure, we add the indices of all scaling functions at the starting scaling level to $\overline{\Lambda}_{-1} = \emptyset$. We obtain the active set Λ_0. In the next iterations, we use the set $\tilde{\Lambda}_{n-1}$ which is constructed by the indices of suitably chosen basis functions whose supports interact with the supports of the functions in $\overline{\Lambda}_{n-1}$. We compute the coefficients of the residual function corresponding to the solution of the previous outer iteration with respect to the dual basis functions whose primal functions are in $\tilde{\Lambda}_{n-1}$. Then, to get Λ_n, we add to $\overline{\Lambda}_{n-1}$ a set of suitably chosen indices $\delta\Lambda_{n-1} \subset \tilde{\Lambda}_{n-1}$ chosen in order to catch as much as possible the bulk of the residuum with the minimum number of new basis functions. We use all active functions corresponding to $\Lambda_n = \overline{\Lambda}_{n-1} \cup \delta\Lambda_{n-1}$ to assemble the stiffness matrix $\mathbb{A}_{\Lambda_n \times \Lambda_n}$ and the right-hand side vector $\mathbf{f}_{\Lambda_n}$. Using a chosen iterative method for the inner iterations, we improve the current approximation of the solution coefficients $\mathbf{x}_{\Lambda_n}$ by approximately solving the corresponding linear algebraic system $\mathbb{A}_{\Lambda_n \times \Lambda_n} \mathbf{x}_{\Lambda_n} = \mathbf{f}_{\Lambda_n}$. Further, we remove the indices of all negligible functions corresponding to the smallest (less significant) absolute entries of the coefficient vector $\mathbf{x}_{\Lambda_n}$ from Λ_n to keep $\overline{\Lambda}_n$ as small as possible. We check an appropriate stopping criterion for the outer iteration in terms of the reduction of the residuum, and if it is not satisfied, we repeat all of the above-mentioned steps. Otherwise, we accept the actual approximation of the coefficient vector as the final solution and stop iterations.

3.1. Computation of $\mathbb{A}_{\Lambda\times\Lambda}$ and $\mathbf{f}_\Lambda$. When we have chosen our finite set of indices Λ the solution of the linear system (2.3) gives the approximation u_Λ of the solution u by (2.4). An efficient approximation of the integrals involved in the definitions of the elements $a_{\lambda,\mu}$ of the stiffness matrix and f_λ of the right-hand side vector plays a fundamental role [8, 7]. In this subsection, we recall some results of [8] which are independent of the algorithm presented there for the approximation of the integrals. We introduce a relative precision $\mathrm{tol}_{int} < 1$ in computing the elements of the stiffness matrix and the right-hand side vector. Let us denote by $\mathbb{A}^*_{\Lambda\times\Lambda}$ and $\mathbf{f}^*_\Lambda$ the numerical approximations of the stiffness matrix and the right-hand side vector, respectively. Set $\mathbb{E}_\Lambda = \mathbb{A}_{\Lambda\times\Lambda} - \mathbb{A}^*_{\Lambda\times\Lambda}$, $\mathbf{h}_\Lambda = \mathbf{f}_\Lambda - \mathbf{f}^*_\Lambda$ and define

$$i(\lambda,\mu) = \begin{cases} 1 & \text{if } |\operatorname{supp}\psi_\lambda \cap \operatorname{supp}\psi_\mu| > 0, \\ 0 & \text{otherwise.} \end{cases}$$

PROPOSITION 3.1. [illegible] λ [illegible] μ [illegible] $l^1(\mathbb{N})$ [illegible] $\delta = (\delta_l)_{l\in\mathbb{N}}$ [illegible] $l^1(\mathbb{N})$ [illegible] $\mathbb{E}_\Lambda = (e_{\lambda,\mu})_{\lambda,\mu\in\Lambda}$ [illegible]

$$|e_{\lambda,\mu}| \precsim \mathrm{tol}_{int}\, i(\lambda,\mu)\delta_{||\lambda|-|\mu||} 2^{-d/2||\lambda|-|\mu||} \|\mathbb{A}_{\Lambda\times\Lambda}\|_2. \tag{3.1}$$

[illegible] $\|\mathbb{E}_\Lambda\|_2 \precsim \mathrm{tol}_{int}\|\mathbb{A}_{\Lambda\times\Lambda}\|_2$

$\mathbb{A}$ being positive definite, we simply have $\|\mathbb{E}_\Lambda\|_2 \precsim \mathrm{tol}_{int}$.

PROPOSITION 3.2. [illegible] λ [illegible] $l^2(\mathbb{N})$ [illegible] $\delta = (\delta_l)_{l\in\mathbb{N}}$ [illegible] $l^2(\mathbb{N})$ [illegible] $\mathbf{h}_\Lambda = (h_\lambda)_{\lambda\in\Lambda}$ [illegible]

$$|h_\lambda| \precsim \mathrm{tol}_{int}\delta_{|\lambda|} 2^{-d/2|\lambda|} \|\mathbf{f}_\Lambda\|_2. \tag{3.2}$$

$\|\mathbf{h}_\Lambda\|_2 \precsim \mathrm{tol}_{int}\|\mathbf{f}_\Lambda\|_2$.

In each iteration n we verify (3.2) with the approximation of $\|\mathbf{f}_\Lambda\|_2$ given by $\|\mathbf{f}_{\Lambda_n}\|_2$. In our adaptive algorithm we usually form a sequence of enlarging sets Λ_n, $n = 0, 1, \ldots$, so $\|\mathbf{f}_{\Lambda_n}\|_2$ is increasing and we do not need to recompute any previously computed elements of $\mathbf{f}_{\Lambda_k}$, $k = 0, \ldots, n-1$.

Under the assumptions of the previous propositions and for our finite-dimensional l_2-problem we can conclude that there is $\mathrm{tol}_{int_0} > 0$ such that for all $0 < \mathrm{tol}_{int} \leq \mathrm{tol}_{int_0}$ the following estimate holds:

$$\|\mathbf{x}_\Lambda - \mathbf{x}^*_\Lambda\|_2 \precsim \mathrm{tol}_{int}\|\mathbf{x}_\Lambda\|_2,$$

where $\mathbf{x}^*_\Lambda$ is the coefficient vector computed from the approximated linear system $\mathbb{A}^*_{\Lambda\times\Lambda}\mathbf{x}^*_\Lambda = \mathbf{f}^*_\Lambda$ and $u^*_\Lambda = (\mathbf{x}^*_\Lambda)^T\mathbb{D}^{-1}_\Lambda\boldsymbol{\psi}_\Lambda$ is the corresponding approximate solution.

In the following it will be useful to evaluate the effect of the approximation in computing the integrals on the norm of the residuum. Let us define $\mathcal{J}_n = \Lambda_n \cup \tilde{\Lambda}_n$, $\mathbf{r}_{\mathcal{J}_n} = \mathbf{f}_{\mathcal{J}_n} - \mathbb{A}_{\mathcal{J}_n\times\Lambda_n}\mathbf{x}_{\Lambda_n}$, and $\mathbf{r}^*_{\mathcal{J}_n} = \mathbf{f}^*_{\mathcal{J}_n} - \mathbb{A}^*_{\mathcal{J}_n\times\Lambda_n}\mathbf{x}^*_{\Lambda_n}$. According to the results of the previous propositions and properties such as the well conditioning and stability of the l_2-problem, we have

$$\|\mathbf{r}_{\mathcal{J}_n} - \mathbf{r}^*_{\mathcal{J}_n}\|_2 \precsim \mathrm{tol}_{int}\|\mathbf{f}_{\mathcal{J}_n}\|_2.$$

In our algorithm we want to find a solution $\mathbf{x}_\Lambda$ which satisfies $\|\mathbf{f}_\mathcal{J} - \mathbb{A}_{\mathcal{J}\times\Lambda}\mathbf{x}_\Lambda\|_{l_2} \leq \varepsilon\|\mathbf{f}_\mathcal{J}\|_{l_2}$. Therefore we propose to choose the parameter tol_{int} such that $\mathrm{tol}_{int}\|\mathbf{f}_{\mathcal{J}_n}\|_2$ is negligible with respect to $\varepsilon\|\mathbf{f}_{\mathcal{J}_n}\|_2$, i.e., $\mathrm{tol}_{int} \ll \varepsilon$.

Different approaches for computing entries of stiffness matrix and right-hand side can be found in [2, 3].

3.2. Initialization part. We choose an appropriate solver of the resulting linear algebraic systems, such as , and set its stopping tolerance tol_{grad}, which is an upper bound for the ratio between the final algebraic residuum and the algebraic residuum corresponding to the initial guess of the current outer iteration (see (3.3)). The choice of tol_{int} has to be done in such a way that the approximation of the integrals gives a negligible contribution in the approximation of the bulk of the residuum. Further, we set all remaining parameters: relative activating and thresholding tolerances tol_{on} and tol_{off} involved in adding and removing indices of basis functions to and from the active set Λ, respectively. Finally, we set the relative target accuracy ε of the adaptive process, i.e., the final reduction factor of the total residuum.

3.3. Activating new basis functions. In each iteration $n > 0$ we want to catch and reduce the bulk of the residuum $\mathbf{r} = \mathbf{f}_\mathcal{J} - \mathbb{A}_{\mathcal{J}\times\overline{\Lambda}_{n-1}}\overline{\mathbf{x}}_{\overline{\Lambda}_{n-1}}$ and improve the solution with its components corresponding to the most significant entries of the residuum. In practice, we choose those significant components of the residuum whose indices belong to the activable set $\tilde{\Lambda}_{n-1}$. This procedure is realized by sorting the absolute values of the entries of the vector $\tilde{\mathbf{r}}_{\tilde{\Lambda}_{n-1}} = \tilde{\mathbf{f}}_{\tilde{\Lambda}_{n-1}} - \mathbb{A}_{\tilde{\Lambda}_{n-1}\times\overline{\Lambda}_{n-1}}\overline{\mathbf{x}}_{\overline{\Lambda}_{n-1}}$ in decreasing order, summing successively the squares of the largest ones and adding the corresponding indices to $\delta\Lambda_{n-1}$, until the target percentage of $\|\tilde{\mathbf{r}}_{\tilde{\Lambda}_{n-1}}\|_2^2$ is reached, i.e., while $\sum_{\lambda\in\delta\Lambda_{n-1}}|\tilde{r}_\lambda|^2 \leq \mathrm{tol}^2_{on}\|\tilde{\mathbf{r}}_{\tilde{\Lambda}_{n-1}}\|_2^2$. Then we set $\Lambda_n = \overline{\Lambda}_{n-1} \cup \delta\Lambda_{n-1}$ and extend the old approximation of the coefficient vector $\overline{\mathbf{x}}_{\overline{\Lambda}_{n-1}}$ by zeros at the positions corresponding to indices $\lambda \in \delta\Lambda_{n-1}$ to get the initial coefficient vector $\mathbf{x}^{\mathrm{init}}_{\Lambda_n}$. In the first outer iteration $n = 0$ we have $\overline{\Lambda}_{-1} = \emptyset$, $\overline{\mathbf{x}}_{\overline{\Lambda}_{-1}} = 0$ and $\delta\Lambda_{-1}$ is the set of indices

of all scaling functions at the starting level j_0 greater than or equal to the minimum construction level of basis functions.

FUNCTION $[\Lambda_n, \delta\Lambda_{n-1}] =$ Activate$(\overline{\Lambda}_{n-1}, \tilde{\Lambda}_{n-1}, \tilde{\mathbf{r}}_{\tilde{\Lambda}_{n-1}}, \mathrm{tol}_{on})$.

(i) $N := \operatorname{card} \tilde{\Lambda}_{n-1}$ $\tilde{\mathbf{r}}_{\tilde{\Lambda}_{n-1}}$ $\lambda^* := \lambda^*(\tilde{\mathbf{r}}_{\tilde{\Lambda}_{n-1}}) = (\lambda_1^*, \lambda_2^*, \dots, \lambda_N^*)$ $\tilde{\mathbf{r}}^*_{\tilde{\Lambda}_{n-1}} = (|\tilde{r}_{\lambda_1^*}|, |\tilde{r}_{\lambda_2^*}|, \dots, |\tilde{r}_{\lambda_N^*}|)$ $\tilde{\mathbf{r}}_{\tilde{\Lambda}_{n-1}}$ $\|\tilde{\mathbf{r}}_{\tilde{\Lambda}_{n-1}}\|_2^2$

(ii) $k = 1, 2, \dots$ $\sum_{l=1}^{k} |\tilde{r}_{\lambda_l^*}|^2$ k $\mathrm{tol}_{on}^2 \|\tilde{\mathbf{r}}_{\tilde{\Lambda}_{n-1}}\|_2^2$ k $\delta\Lambda_{n-1} := \{\lambda_l^*;\ l = 1, \dots, k\}$ $\Lambda_n := \overline{\Lambda}_{n-1} \cup \delta\Lambda_{n-1}$

FUNCTION $\mathbf{x}^{\mathrm{init}}_{\Lambda_n} =$ Extend$(\overline{\mathbf{x}}_{\overline{\Lambda}_{n-1}}, \overline{\Lambda}_{n-1}, \delta\Lambda_{n-1})$.

(i) $\mathbf{x}^{\mathrm{init}}_{\Lambda_n}$ $\overline{\mathbf{x}}_{\overline{\Lambda}_{n-1}}$ $\overline{\Lambda}_{n-1}$ ψ_μ $\mu \in \delta\Lambda_{n-1}$

3.4. Assembling $\mathbf{f}_{\Lambda_n}$ and $\mathbb{A}_{\Lambda_n \times \Lambda_n}$. For a given Λ_n we need to assemble the right-hand side vector $\mathbf{f}_{\Lambda_n}$ and the stiffness matrix $\mathbb{A}_{\Lambda_n \times \Lambda_n}$. In the computation of $a_{\lambda,\mu}$ and f_λ we use numerical quadrature formulas that allow us to control the approximation of the elements as in Propositions 3.1 and 3.2.

Computing the entries of $\mathbf{f}_{\Lambda_n}$. We form a sequence $\{\mathbf{f}^{(J)}_{\Lambda_n}\}_{J \in \mathbb{N}}$ of approximations to $\mathbf{f}_{\Lambda_n}$ with increasing accuracy to satisfy the test criterion (3.2):

1. $J > \max|\lambda| + 2$ $\mathbf{f}^{(J)}_{\Lambda_n}$
2. $\mathbf{f}^{(J-1)}_{\Lambda_n}$ $J - 1$
3. $\mathbf{h}^{(J)}_{\Lambda_n} := \mathbf{f}^{(J)}_{\Lambda_n} - \mathbf{f}^{(J-1)}_{\Lambda_n}$ $\mathbf{f}^{(J+1)}_{\Lambda_n} := \mathbf{f}^{(J)}_{\Lambda_n}$
4. $h^{(J)}_\lambda$ $\mathbf{h}^{(J)}_{\Lambda_n}$
   - $|h^{(J)}_\lambda| > \mathrm{tol}_{int} \delta_{|\lambda|} 2^{-d/2|\lambda|} \|\mathbf{f}^{(J)}_{\Lambda_n}\|_2$, $f^{(J+1)}_\lambda$ $\mathbf{f}^{(J+1)}_{\Lambda_n}$ $J + 1$
5. $h^{(J)}_\lambda$ $\lambda \in \Lambda_n$ $J = J + 1$ 3 $\mathbf{f}_{\Lambda_n} := \mathbf{f}^{(J+1)}_{\Lambda_n}$

We set $\delta_{|\lambda|} = 1/|\lambda|$ in (3.2), and the level J is chosen in such a way that we are able to detect all singularities in f.

3.3. The choice $J > \max|\lambda| + 2$ in the previous algorithm is not optimal. Nevertheless, in many applications in which the maximal level needed by the approximation process is not too large, the evaluation of the right-hand side on a fine fixed grid leads to a faster approximation of the integrals than an adaptive method like the one presented for the entries of the stiffness matrix. An algorithm similar to the one proposed for the stiffness matrix can be applied for the right-hand side too.

Computing the entries of $\mathbb{A}_{\Lambda_n \times \Lambda_n}$. In this case, we apply a composite Gauss quadrature formula to compute $a_{\lambda,\mu}$. To satisfy (3.1) for all entries we can use a modification of the above-mentioned adaptive scheme applying a sequence of Gauss quadrature formulas on each dyadic cube in the intersection of the supports of test and trial functions [5] to satisfy the test criterion (3.1), where $\delta_{||\lambda|-|\mu||} = 1/(||\lambda|-|\mu||^2)$. In this approach only dyadic cubes of level $\max\{|\lambda|, |\mu|\}$ are involved in the computation of the integrals.

For $n > 0$, the entries $a_{\lambda,\mu}$ and f_λ with $\lambda \in \delta\Lambda_{n-1} \subset \tilde{\Lambda}_{n-1}$ and $\mu \in \overline{\Lambda}_{n-1}$ have been computed and stored in the previous iteration during the computation of the residuum $\tilde{\mathbf{r}}_{\tilde{\Lambda}_{n-1}}$. Thus we compute only the remaining entries.

FUNCTION $[\mathbb{A}_{\Lambda_n\times\Lambda_n}, \mathbf{f}_{\Lambda_n}] = \text{Assemble}(\overline{\Lambda}_{n-1}, \delta\Lambda_{n-1})$.

(i) [illegible] $a_{\lambda,\mu}$ [illegible] $(\lambda,\mu) \in \{\{\overline{\Lambda}_{n-1}\times\delta\Lambda_{n-1}\}\cup\{\delta\Lambda_{n-1}\times\delta\Lambda_{n-1}\}\}$

(ii) [illegible] $\mathbb{A}_{\Lambda_n\times\Lambda_n}$ [illegible] $\mathbf{f}_{\Lambda_n}$ [illegible]

3.5. Iterative improvement of $\mathbf{x}_{\Lambda_n}$. For each outer iteration we successively improve the current approximation of the coefficient vector $\mathbf{x}^{\text{init}}_{\Lambda_n}$ by approximately solving the linear algebraic system $\mathbb{A}_{\Lambda_n\times\Lambda_n}\mathbf{x}_{\Lambda_n} = \mathbf{f}_{\Lambda_n}$ using the chosen iterative method. We stop iterations when the following relative stopping criterion is matched:

$$\|\mathbf{r}_{\Lambda_n}\|_2^2 \le \text{tol}^2_{grad}\|\mathbf{f}_{\Lambda_n} - \mathbb{A}_{\Lambda_n\times\Lambda_n}\mathbf{x}^{\text{init}}_{\Lambda_n}\|_2^2, \tag{3.3}$$

where $\mathbf{r}_{\Lambda_n} = \mathbf{f}_{\Lambda_n} - \mathbb{A}_{\Lambda_n\times\Lambda_n}\mathbf{x}_{\Lambda_n}$ is the residual vector corresponding to the active set Λ_n. The parameter tol_{grad} is a given relative stopping tolerance. The idea of the iterative improvement is to solve in each outer iteration the corresponding algebraic system to a moderate accuracy, in order to avoid oversolving the linear system when the discretization error is still large.

FUNCTION $[\mathbf{x}_{\Lambda_n}, \mathbf{r}_{\Lambda_n}] = \text{GradMethod}(\mathbb{A}_{\Lambda_n\times\Lambda_n}, \mathbf{f}_{\Lambda_n}, \mathbf{x}^{\text{init}}_{\Lambda_n}, tol_{grad})$. [illegible] symmetric positive definite matrices [illegible] GradMethod [illegible] steepest descent CG [illegible] non-symmetric matrices [illegible] GradMethod [illegible] BiCG GMRES [illegible]

3.6. Removing negligible basis functions. Some basis functions ψ_λ, $\lambda \in \Lambda_n$, can have negligible energy contributions $|x_\lambda|^2$ to the solution, i.e., their coefficients are less significant so we remove them from Λ_n to get $\overline{\Lambda}_n$, in order to keep Λ_{n+1} as small as possible. The number of basis functions, which we may remove, is related to the total energy $\|\mathbf{x}_{\Lambda_n}|_{\delta\Lambda_{n-1}}\|_2^2$ of newly added functions ψ_μ, $\mu \in \delta\Lambda_{n-1}$. We call this process [illegible], and it can be realized by sorting absolute values of the entries of $\mathbf{x}_{\Lambda_n}$ in decreasing order, successively summing (starting from the bottom of the sorted vector) squares of the smallest ones, while this sum is less than $\text{tol}^2_{off}\|\mathbf{x}_{\Lambda_n}|_{\delta\Lambda_{n-1}}\|_2^2$. We remove these entries from $\mathbf{x}_{\Lambda_n}$ and their indices from Λ_n [illegible]. The particular realization is similar to the routine Activate and appears as follows.

FUNCTION $[\overline{\mathbf{x}}_{\overline{\Lambda}_n}, \overline{\Lambda}_n] = \text{Threshold}(\mathbf{x}_{\Lambda_n}, \Lambda_n, \delta\Lambda_{n-1}, \text{tol}_{off})$.

(i) [illegible] $N := \text{card}\,\Lambda_n$ [illegible] $\mathbf{x}_{\Lambda_n}$ [illegible] $\lambda^* := \lambda^*(\mathbf{x}_{\Lambda_n}) = (\lambda_1^*, \lambda_2^*, \dots, \lambda_N^*)$ [illegible] $\mathbf{x}^*_{\Lambda_n} = (|x_{\lambda_1^*}|, |x_{\lambda_2^*}|, \dots, |x_{\lambda_N^*}|)$ [illegible] $\|\mathbf{x}_{\Lambda_n}|_{\delta\Lambda_{n-1}}\|_2^2$

(ii) [illegible] $k = 1, 2, \dots,$ [illegible] $\sum_{l=1}^{k}|x^*_{\lambda_{N-l+1}}|^2$ [illegible] k [illegible] $\text{tol}^2_{off}\|\mathbf{x}_{\Lambda_n}|_{\delta\Lambda_{n-1}}\|_2^2$ [illegible] k [illegible] $\overline{\Lambda}_n := \{\lambda_l^*;\ l = 1, \dots, N-k\} \cup \{$ [illegible] $\lambda_m^*,\ m > N-k,$ [illegible] $\}$ [illegible] $\overline{\mathbf{x}}_{\overline{\Lambda}_n} := \mathbf{x}_{\Lambda_n}|_{\overline{\Lambda}_n}$

3.7. Construction of the activable set $\tilde{\Lambda}_n$. We start with the empty set $\tilde{\Lambda}_n$. For all $\lambda \in \overline{\Lambda}_n$, the indices μ of all functions ψ_μ constructed at the level $|\mu| = |\lambda| + 1$ whose supports have nonempty intersections with the support of ψ_λ and $\mu \notin \overline{\Lambda}_n$

are added to $\tilde{\Lambda}_n$. The number of activable functions ψ_μ, $\mu \in \tilde{\Lambda}_n$, can be many times greater than the number of active functions corresponding to $\overline{\Lambda}_n$. Therefore it is convenient to introduce a spatial truncation rule to keep $\tilde{\Lambda}_n$ small. We use contracted support instead of considering intersections with the whole support of ψ_λ, using a contraction factor c. Typical choices are $c = 1/4$ or $c = 1/8$. Another possibility is to select only adjacent wavelets with respect to the positions of their central dyadic nodes, i.e., 2 functions in one dimension, 8 in two dimensions and 26 in three dimensions.

FUNCTION $\tilde{\Lambda}_n$ = ConstructActivableSet($\overline{\Lambda}_n$).

(i) [illegible] $\tilde{\Lambda}_n := \emptyset$

(ii) [illegible] $\lambda \in \overline{\Lambda}_n$ [illegible] $\tilde{\Lambda}_n$ [illegible] μ [illegible] ψ_μ [illegible]
$|\mu| = |\lambda| + 1$ [illegible] $\mu \notin \overline{\Lambda}_n$ [illegible]

Var. 1. $\operatorname{supp}\psi_\mu$ [illegible] $\operatorname{supp}\psi_\lambda$ [illegible] $c \in (0, 1]$ [illegible]

Var. 2. ψ_μ [illegible]

[illegible]

3.8. Assembling the residual vector $\tilde{\mathbf{r}}_{\tilde{\Lambda}_n}$. For given $\tilde{\Lambda}_n$ we assemble the residual vector $\tilde{\mathbf{r}}_{\tilde{\Lambda}_n}$ using the activable functions ψ_λ, $\lambda \in \tilde{\Lambda}_n$. The entries $\tilde{r}_\lambda$ are computed by

$$\tilde{r}_\lambda = \tilde{f}_\lambda - d_\lambda^{-1}\langle \mathcal{A}\overline{u}_{\overline{\Lambda}_n}, \psi_\lambda\rangle \quad \forall \lambda \in \tilde{\Lambda}_n, \tag{3.4}$$

where $\tilde{f}_\lambda = d_\lambda^{-1}\langle f, \psi_\lambda\rangle$ and $\overline{u}_{\overline{\Lambda}_n}$ is given by

$$\overline{u}_{\overline{\Lambda}_n} = \sum_{\mu \in \overline{\Lambda}_n} d_\mu^{-1}\overline{x}_\mu \psi_\mu = \overline{\mathbf{x}}_{\overline{\Lambda}_n}^T \mathbb{D}_{\overline{\Lambda}_n}^{-1} \boldsymbol{\psi}_{\overline{\Lambda}_n}. \tag{3.5}$$

We substitute the expansion (3.5) of $\overline{u}_{\overline{\Lambda}_n}$ into (3.4) and we obtain

$$\tilde{r}_\lambda = \tilde{f}_\lambda - \sum_{\forall \mu \in \overline{\Lambda}_n} d_\lambda^{-1} d_\mu^{-1} \overline{x}_\mu \langle \mathcal{A}\psi_\mu, \psi_\lambda\rangle \quad \forall \lambda \in \tilde{\Lambda}_n,$$

or in matrix form, $\tilde{\mathbf{r}}_{\tilde{\Lambda}_n} = \tilde{\mathbf{f}}_{\tilde{\Lambda}_n} - \mathbb{A}_{\tilde{\Lambda}_n \times \overline{\Lambda}_n} \overline{\mathbf{x}}_{\overline{\Lambda}_n}$.

To compute the entries of $\tilde{\mathbf{f}}_{\tilde{\Lambda}_n}$ and $\mathbb{A}_{\tilde{\Lambda}_n \times \overline{\Lambda}_n}$ we use the same quadrature formulas as for computing the entries of $\mathbf{f}_{\Lambda_n}$ and $\mathbb{A}_{\Lambda_n \times \Lambda_n}$. The resulting routine appears as follows.

FUNCTION $[\tilde{\mathbf{r}}_{\tilde{\Lambda}_n}, \tilde{\mathbf{f}}_{\tilde{\Lambda}_n}]$ = Residual($\tilde{\Lambda}_n, \overline{\Lambda}_n, \overline{\mathbf{x}}_{\overline{\Lambda}_n}$).

(i) [illegible] $\tilde{f}_\lambda$ $a_{\lambda,\mu}$ [illegible] $\tilde{r}_\lambda$ [illegible] $\lambda \in \tilde{\Lambda}_n$ [illegible] $\mu \in \overline{\Lambda}_n$ [illegible]
[illegible]

3.9. Stopping criterion. A natural stopping criterion of the outer loop is based on the achievement of the sufficient (relative) reduction of the total residuum $\|\mathbf{f}_\mathcal{J} - \mathbb{A}_{\mathcal{J}\times\Lambda_n}\mathbf{x}_{\Lambda_n}\|_{l_2}$. If we admit that the sets $\tilde{\Lambda}_n$ catch the bulk of the residuum in each iteration, $\|\mathbf{f}_\mathcal{J} - \mathbb{A}_{\mathcal{J}\times\Lambda_n}\mathbf{x}_{\Lambda_n}\|_{l_2}$ is well approximated by $\sqrt{\|\mathbf{r}_{\Lambda_n}\|_2^2 + \|\tilde{\mathbf{r}}_{\tilde{\Lambda}_n}\|_2^2}$ and $\|\mathbf{f}_\mathcal{J}\|_{l_2}$ by $\sqrt{\|\mathbf{f}_{\Lambda_n}\|_2^2 + \|\tilde{\mathbf{f}}_{\tilde{\Lambda}_n}\|_2^2}$ for n sufficiently large. Our final stopping criterion is as follows:

if $(\|\mathbf{r}_{\Lambda_n}\|_2^2 + \|\tilde{\mathbf{r}}_{\tilde{\Lambda}_n}\|_2^2 \le \varepsilon^2 (\|\mathbf{f}_{\Lambda_n}\|_2^2 + \|\tilde{\mathbf{f}}_{\tilde{\Lambda}_n}\|_2^2))$,
then $\mathbf{x}(\varepsilon) := \overline{\mathbf{x}}_{\overline{\Lambda}_n}$, $\Lambda(\varepsilon) := \overline{\Lambda}_n$ and stop the outer iterations.

3.10. ADWEM solver. In this subsection, we summarize the above-mentioned ingredients of the algorithm by the calling sequence of the functions corresponding to the previous different steps.

ADWEM SOLVER.
$\Lambda_{-1} = \overline{\Lambda}_{-1} = \emptyset$ $\overline{\mathbf{x}}_{\overline{\Lambda}_{-1}} = 0$ $\delta\Lambda_{-1} = \{indices\ of\ all\ scaling\ functions\}$
For $n = 0, 1, \dots$ **do**
If $(n = 0)$ then $\Lambda_0 = \delta\Lambda_{-1}$ else $[\Lambda_n, \delta\Lambda_{n-1}] = \text{Activate}(\overline{\Lambda}_{n-1}, \tilde{\Lambda}_{n-1}, \tilde{\mathbf{r}}_{\tilde{\Lambda}_{n-1}}, \text{tol}_{on})$.
$\mathbf{x}^{\text{init}}_{\Lambda_n} = \text{Extend}(\overline{\mathbf{x}}_{\overline{\Lambda}_{n-1}}, \overline{\Lambda}_{n-1}, \delta\Lambda_{n-1})$.
$[\mathbb{A}_{\Lambda_n \times \Lambda_n}, \mathbf{f}_{\Lambda_n}] = \text{Assemble}(\overline{\Lambda}_{n-1}, \delta\Lambda_{n-1})$.
$[\mathbf{x}_{\Lambda_n}, \mathbf{r}_{\Lambda_n}] = \text{GradMethod}(\mathbb{A}_{\Lambda_n \times \Lambda_n}, \mathbf{f}_{\Lambda_n}, \mathbf{x}^{\text{init}}_{\Lambda_n}, \text{tol}_{grad})$ until $(\|\mathbf{r}_{\Lambda_n}\|_2^2 \le \text{tol}^2_{grad} \|\mathbf{f}_{\Lambda_n} - \mathbb{A}_{\Lambda_n \times \Lambda_n} \mathbf{x}^{\text{init}}_{\Lambda_n}\|_2^2)$.
$[\overline{\mathbf{x}}_{\overline{\Lambda}_n}, \overline{\Lambda}_n] = \text{Threshold}(\mathbf{x}_{\Lambda_n}, \Lambda_n, \delta\Lambda_{n-1}, \text{tol}_{off})$.
$\tilde{\Lambda}_n = \text{ConstructActivableSet}(\overline{\Lambda}_n)$.
$[\tilde{\mathbf{r}}_{\tilde{\Lambda}_n}, \tilde{\mathbf{f}}_{\tilde{\Lambda}_n}] = \text{Residual}(\tilde{\Lambda}_n, \overline{\Lambda}_n, \overline{\mathbf{x}}_{\overline{\Lambda}_n})$.
If $\|\mathbf{r}_{\Lambda_n}\|_2^2 + \|\tilde{\mathbf{r}}_{\tilde{\Lambda}_n}\|_2^2 \le \varepsilon^2 (\|\mathbf{f}_{\Lambda_n}\|_2^2 + \|\tilde{\mathbf{f}}_{\tilde{\Lambda}_n}\|_2^2)$ then $\mathbf{x}(\varepsilon) := \overline{\mathbf{x}}_{\overline{\Lambda}_n}$ $\Lambda(\varepsilon) := \overline{\Lambda}_n$
end.

3.4. In the previous description we use a fixed tolerance tol_{grad}. Nevertheless it is possible to use a changing tolerance. We propose the following rule for choosing tol_{grad} at each iteration: given tol_{grad_0}, define

$$\text{tol}_{grad_n} := \min \left\{ \text{tol}_{grad_0}, \mathcal{C} \frac{\|\mathbf{f}_{\Lambda_{n-1}} - \mathbb{A}_{\Lambda_{n-1} \times \Lambda_{n-1}} \mathbf{x}_{\Lambda_{n-1}}\|_2}{\|\mathbf{f}_{\Lambda_n} - \mathbb{A}_{\Lambda_n \times \Lambda_n} \mathbf{x}^{\text{init}}_{\Lambda_n}\|_2} \right\}, \qquad \mathcal{C} \in (0, 1).$$

For this choice, the residuum norm $\|\mathbf{r}_{\Lambda_n}\|_2$ decreases minimally with the rate $\mathcal{C}$ with increasing outer iteration n.

4. Numerical examples. In this section, we illustrate the behavior of the introduced adaptive algorithm. In Example 1, the computational domain Ω is a curved quadrilateral and the forcing function f induces in the solution two Gaussian peaks of different heights, slopes, and positions (see Figures 4.1 and 4.2). We expect the adaptive algorithm to feel at first the higher peak and, after reaching a good approximation of this peak, the algorithm should reveal the smaller one. For this case, we illustrate sensitivity to the ADWEM parameters tol_{off}, tol_{on}, and the support contraction c. In Example 2, we take the same geometry and split it into two subdomains with different mappings. The particular geometries are depicted in Figures 4.4 and 4.10, respectively. With these examples we want to investigate the effects of mapping and matching on the adaptive method.

The remaining two examples correspond to an L-shaped domain. These cases are interesting because f is everywhere infinitely differentiable and a singularity of u is generated by the shape of the domain (see Figures 4.14 and 4.15). The last example is aimed at showing the difference in terms of rates of convergence between the linear and the nonlinear approximations, respectively, depending on the Sobolev and the Besov regularities. Further numerical results and comparisons can be found in [6].

In our numerical experiments we use piecewise linear and piecewise quadratic biorthogonal B-splines, with $L = 2$, $\tilde{L} = 2$ and $L = 3$, $\tilde{L} = 5$, respectively. We denote by L and $\tilde{L}$ the exactness order of the primal and dual basis, respectively, i.e., polynomials up to the degree $L - 1$ and $\tilde{L} - 1$ are reproduced exactly [26]. If

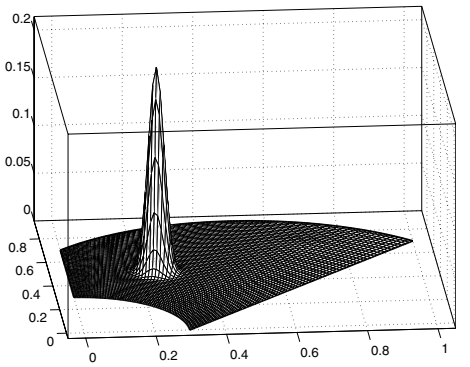

FIG. 4.1. *Example* 1. *Exact solution* u_{ex} *(linear scale).*

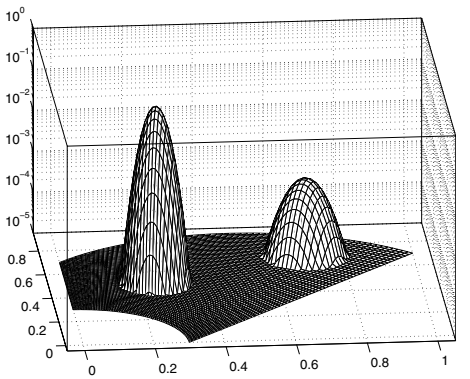

FIG. 4.2. *Example* 1. *Exact solution* u_{ex} *(log scale).*

not specified, the starting scaling level j_0 is equal to 4. The operator we consider is elliptic and self-adjoint; therefore we replace GradMethod by CG. We set the stopping tolerance $\text{tol}_{grad_0} = 1e-4$ and $\mathcal{C} = 0.9$. Other parameters of the adaptive algorithm are the relative activating and thresholding tolerances $\text{tol}_{on} = 0.99$ and $\text{tol}_{off} = 1e-3$ and the relative target accuracy ε of the adaptive process ($\varepsilon = 1e-3$ for Examples 1 and 2 and $\varepsilon = 5e-2$ for Examples 3 and 4). In computing the entries $a_{\lambda,\mu}$, f_λ we use the relative tolerance $\text{tol}_{int} = 1e-6$. We set $c = 0.125$ in the relation that selects the activable functions (see the routine ConstructActivableSet).

1. Let $\Omega \subset \mathbb{R}^2$ be the curved quadrilateral depicted in Figure 4.4. The corresponding mapping $F : \hat{\Omega} \to \Omega$ is chosen in such a way that it maps the reference unit square $\hat{\Omega}$ to the set

$$\Omega = \left\{(x,y) \in \mathbb{R}^2 \, : x > 0, y > x - 0.3, x^2 + y^2 > 0.09, (x-0.5)^2 + (y-0.2)^2 < 0.5\right\}.$$

Let us consider the problem

$$\begin{cases} -\triangle u = f & \text{in } \Omega, \\ u = 0 & \text{on } \partial\Omega \end{cases} \tag{4.1}$$

with $f = -\triangle u_{ex}$ and

$$u_{ex}(x,y) = x(y - x + 0.3)(0.5 - (x-0.5)^2 - (y-0.2)^2)(x^2 + y^2 - 0.09)\ g,$$

where $g = 20e^{-1000r_1^2} + 0.02e^{-300r_2^2}$ with $r_1^2 = (x - 0.25)^2 + (y - 0.5)^2$ and $r_2^2 = (x - 0.7)^2 + (y - 0.7)^2$. The plots of f in the linear scale and u_{ex} in the linear and logarithmic scales are plotted in Figures 4.3, 4.1, and 4.2, respectively.

Sensitivity of ADWEM algorithm with respect to the parameters tol_{off}, tol_{on}, and support contraction c considered are shown in Tables 4.1–4.4. As expected, larger values of tol_{on} imply a faster activation of new basis functions and a parallel reduction of the error. On the other hand, for steady problems the thresholding step is in practice less important, and this can be observed from the smooth dependence of the number of basis functions and of the error on the parameter tol_{off}. The number of active functions $N = \#\Lambda_n$ grows slowly as c increases, since the parameter c mainly affects the number of activable basis functions at each iteration than the number of active basis functions.

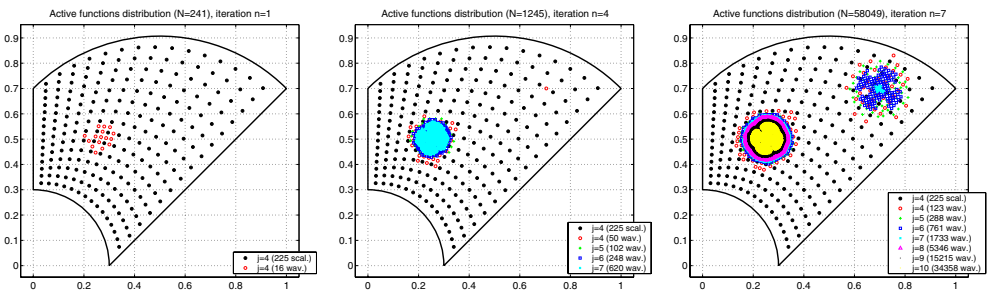

FIG. 4.4. *Example* 1. *Distribution of active functions,* $n = 1, 4, 7$, $N = \#\Lambda_n$.

In Figure 4.4, we successively plot the distributions of active basis functions in outer iterations $n = 1, 4, 7$ for the choice $L = 2$, $\tilde{L} = 2$. We observe that the adaptive algorithm recognizes at first the deficiency corresponding to the higher peak and activates new basis functions near its center. When the adaptive process reaches a good approximation of the higher peak (iteration 4) it reveals another deficiency corresponding to the smaller peak and starts to add new basis functions there as well. The approximate solution u_{Λ_n} and the difference $|u_{\Lambda_n} - u_{ex}|$ are depicted in the logarithmic scale in Figures 4.5 and 4.6, respectively, for $n = 1, 4, 7$. The terms involved in the stopping criterion of the adaptive algorithm are depicted in Figure 4.7.

Finally, we plot the relative errors

$$\delta_{L^2} = \frac{\|u_{\Lambda_n} - u_{ex}\|_{L^2(\Omega)}}{\|u_{ex}\|_{L^2(\Omega)}}, \quad \delta_{H^1} = \frac{\|u_{\Lambda_n} - u_{ex}\|_{H^1(\Omega)}}{\|u_{ex}\|_{H^1(\Omega)}}$$

of the approximate solution u_{Λ_n} in Figure 4.8 with respect to the number of active functions $N = \#\Lambda_n$. The above-mentioned L^2- and H^1-norms are evaluated using

the Simpson composite formula at the fixed very fine grid of level 13. For comparison purposes we depict the relative errors of the best N-term approximations in $L^2(\Omega)$ and $H^1(\Omega)$ computed using the wavelet coefficients in the final iteration n as the wavelet coefficients of the exact solution. The numerical values of the relative errors δ_{L^2} and δ_{H^1} are listed in Table 4.5. In this table we report also the number of iterations of the CG iterative solver (CG iters.) and the number of active basis functions ($\#\Lambda_n$). We remark that the number of CG iterations is not growing with the number of basis functions and its levels. This is due to the good conditioning of the matrix $\mathbb{A}$ in all the outer iterations. In Figures 4.8 and 4.9 and in Tables 4.5 and 4.6, we report the behavior of the relative errors using linear and quadratic basis functions.

The rates of convergence α of the least squares approximations cN^{α} of the relative errors with respect to $N = \#\Lambda_n$ are given in Table 4.7 for both linear and quadratic basis functions using all iterations reported in Tables 4.5 and 4.6. The

theoretical rates of convergence are determined by the polynomial degree of the used basis functions [23].

2. In this case, we split the domain Ω of the previous example into two parts, Ω_1 (lower) and Ω_2 (upper), as shown in Figure 4.10. The mapping consists of two components which map the reference unit square $\hat{\Omega}$ to Ω_1 and Ω_2, respectively. We remark that the splitting intersects one of the Gaussian peaks.

In Figure 4.10, we successively plot the distributions of active basis functions in outer iterations $n = 1, 4, 7$ ($L = 2$, $\tilde{L} = 2$). The behavior of the adaptive algorithm

$L = 3$, $\tilde{L} = 5$	$-3/2$	-2.059	-1	-1.702

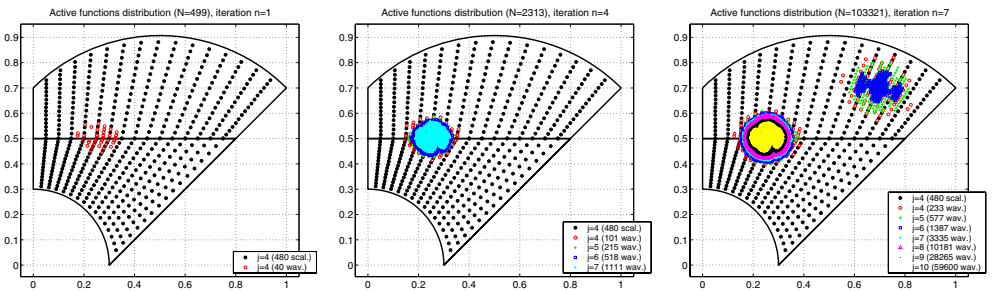

FIG. 4.10. *Example* 2. *Distribution of active functions,* $n = 1, 4, 7$, $N = \#\Lambda_n$.

is similar to the previous case, but we have approximately twice as many candidates for activation. This results from the splitting of Ω into two subdomains Ω_1 and Ω_2 and the use of the same starting scaling level $j_0 = 4$ as in the previous examples in both subdomains. Therefore the algorithm activates more basis functions in the equivalent outer iterations for the same fixed activating and thresholding tolerances than in Example 1 (compare Tables 4.5 and 4.8). The terms involved in the stopping criterion of the adaptive algorithm are depicted in Figure 4.11. Finally, we plot the relative errors $\delta_{L^2(\Omega)}$ and $\delta_{H^1(\Omega)}$ of the approximate solution u_{Λ_n} in Figures 4.12 and 4.13 for $L = 2$, $\tilde{L} = 2$ and $L = 3$, $\tilde{L} = 5$, respectively, together with the relative errors of the best N-term approximations in $L^2(\Omega)$ and $H^1(\Omega)$. The numerical values are listed for $L = 2$, $\tilde{L} = 2$ in Table 4.8. The rates of convergence of the least squares approximations of the errors with respect to N are given in Table 4.9 for both linear and quadratic basis functions.

We remark that the matching induces a faster increase of the number of basis functions caused by the constraint of a minimum construction level and to the larger supports of matched basis functions. These facts do not affect too much the rates of convergence of the ADWEM algorithm because it causes just a shift of the curves (Figures 4.8, 4.9 and 4.12, 4.13).

3 (see [2]). Let $\Omega \subset \mathbb{R}^2$ be the L-shaped domain depicted in Figure 4.16 and let us consider again the problem (4.1) in Ω. Introducing polar coordinates (r, φ),

the right-hand side f is defined in such a way that the corresponding exact solution is [2] $u_{ex}(r,\varphi) = h(r)r^{2/3}\sin\left(\frac{2}{3}(\varphi + \frac{\pi}{2})\right)$, where $h \in C^\infty(\Omega)$ is the following truncation function:

$$h(r) = \frac{w(3/4 - r)}{w(r - 1/2) + w(3/4 - r)}, \quad w(r) = \begin{cases} e^{-1/r^2} & \text{if } r > 0, \\ 0 & \text{else.} \end{cases}$$

The plots of the right-hand side f and the exact solution u_{ex} are depicted in Figures 4.14 and 4.15, respectively.

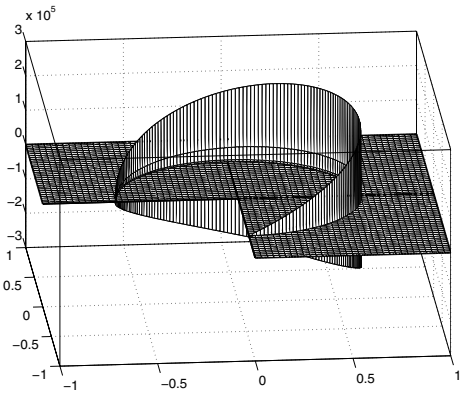

FIG. 4.14. *Example* 3. f *(linear scale).*

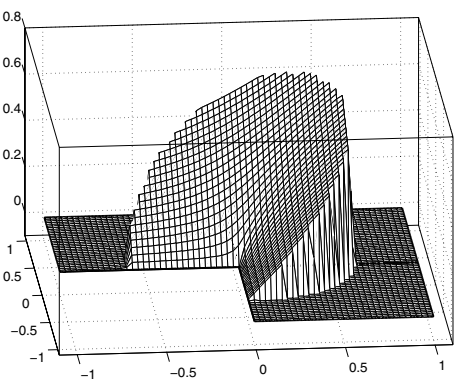

FIG. 4.15. *Example* 3. u_{ex} *(linear scale).*

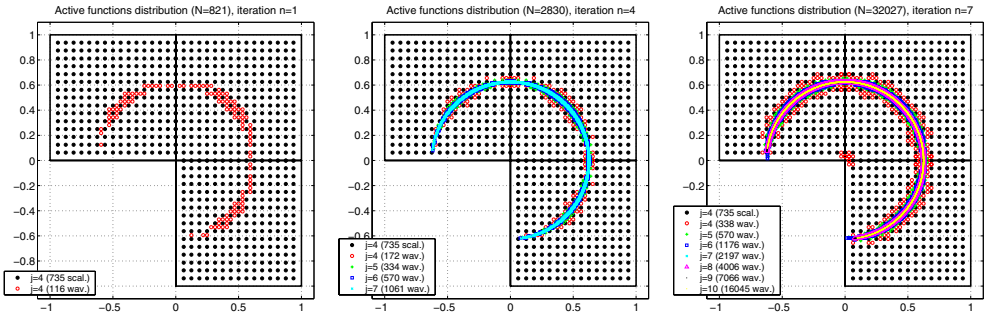

FIG. 4.16. *Example* 3. *Distribution of active functions,* $n = 1, 4, 7$, $N = \#\Lambda_n$.

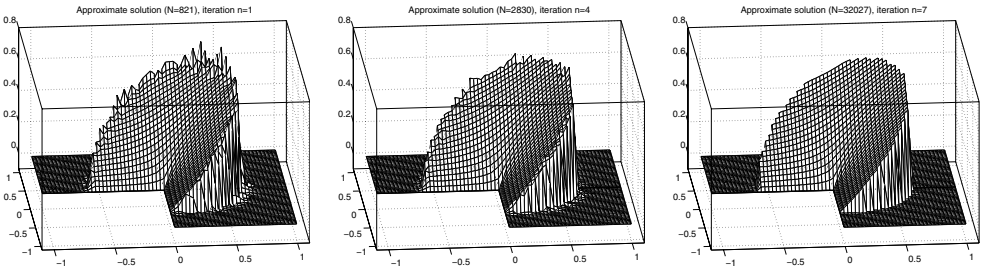

FIG. 4.17. *Example* 3. *Computed solution* u_{Λ_n}, $n = 1, 4, 7$, $N = \#\Lambda_n$.

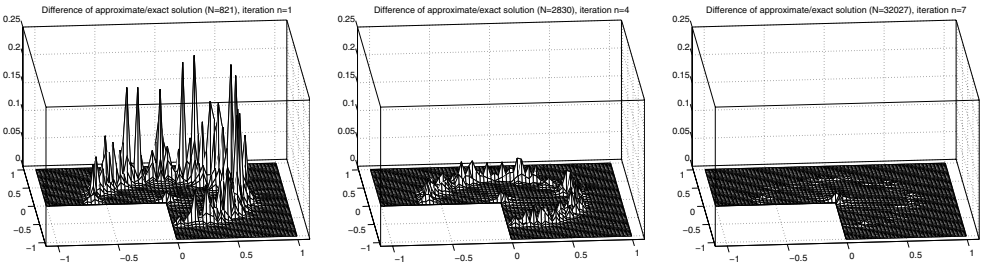

FIG. 4.18. *Example* 3. *Error of the computed solution* $|u_{\Lambda_n} - u_{ex}|$, $n = 1, 4, 7$, $N = \#\Lambda_n$.

In Figure 4.16, we plot successively the distributions of active basis functions in outer iterations $n = 1, 4, 7$ ($L = 2$, $\tilde{L} = 2$). At first the algorithm recognizes the deficiency corresponding to the right-hand side f and activates new basis functions in the region where f displays strong gradients (see Figure 4.14). In iteration 6, the adaptive process reaches a good approximation of the behavior of f, and it reveals another deficiency around the reentrant corner of the L-shaped domain and starts to add new basis functions also there. The approximate solution u_{Λ_n} and the difference $|u_{\Lambda_n} - u_{ex}|$ are depicted in the linear scale in Figures 4.17 and 4.18, respectively, for $n = 1, 4, 7$. In Figures 4.19, 4.20, and 4.21 we plot the behavior of the relative errors corresponding to linear wavelets with $j_0 = 3$, $j_0 = 4$ and quadratic wavelets with $j_0 = 4$, together with the relative errors of the best N-term approximations in $L^2(\Omega)$ and $H^1(\Omega)$. The numerical values of these relative errors for linear basis functions are listed in Table 4.10 ($j_0 = 4$).

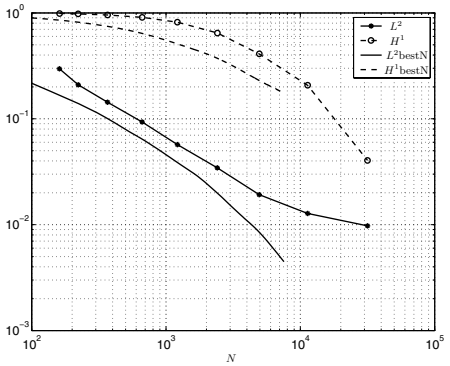

FIG. 4.19. *Example* 3. *Relative errors* $L = 2$, $\tilde{L} = 2$, $j_0 = 3$.

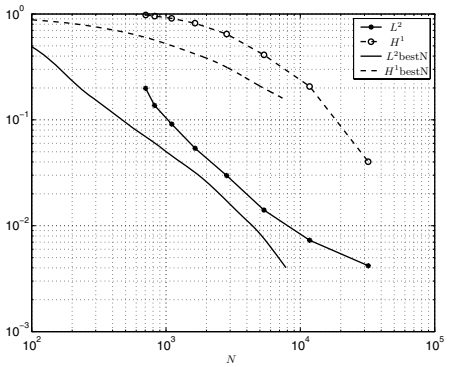

FIG. 4.20. *Example* 3. *Relative errors* $L = 2$, $\tilde{L} = 2$, $j_0 = 4$.

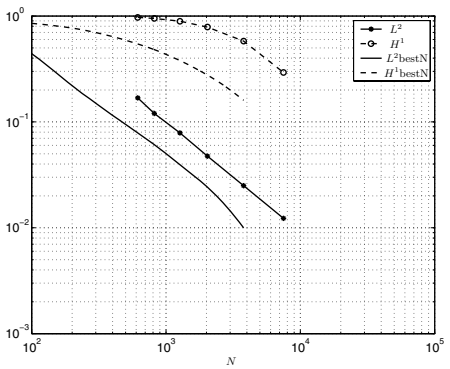

FIG. 4.21. *Example* 3. *Relative errors* $L = 3$, $\tilde{L} = 5$.

The least squares approximations cN^{α} of the errors in the L^2- and H^1-norms with respect to N are given in Table 4.11. In this case, $f \in C^{\infty}(\Omega)$ and $u_{ex} \in H^s(\Omega)$ only for $s < 5/3$ due to its singularity around the reentrant corner [25]. Moreover, u_{ex} belongs to the Besov spaces $B^s_{\tau,\tau}(\Omega)$ for all $s > 0$ and $1/\tau = s/2 + 1/2$ [15]. The upper bound in the Sobolev regularity implies an upper bound in the theoretical rate of convergence for uniform refinement, whereas for the unbounded Besov regularity

TABLE 4.12
Example 4. $L = 2$, $\tilde{L} = 2$. *Comparison of asymptotic constants in the error decay.*

	Theoretical uniform	Computed uniform	Theoretical adaptive	Computed adaptive (1)	Computed adaptive (2)
L^2	$c_0^u N^{-5/6+\epsilon}$	$2.227N^{-0.783}$	$c_0^a N^{-1}$	$17.564N^{-1.131}$	$6.339N^{-0.981}$
H^1	$c_1^u N^{-1/3+\epsilon}$	$2.580N^{-0.456}$	$c_1^a N^{-1/2}$	$6.763N^{-0.636}$	$5.023N^{-0.588}$

we expect a higher theoretical asymptotic rate of convergence for the adaptive case bounded by the order of the polynomial approximation of the basis functions. The theoretically derived rates of convergence for a uniform refinement are $-5/6+\epsilon$ in L^2 and $-1/3+\epsilon$ in H^1 with $\epsilon > 0$.

A similar problem with a L-shape domain with curved boundaries was considered in [6], and results similar to the ones presented above were obtained, meaning that for this kind of problem a nonaffine mapping in the subdomains does not affect the behavior of the method.

EXAMPLE 4. Let us consider now the same problem as in Example 3, but with the truncation function h defined by

$$h(r) = \frac{w(3/4 - r)}{w(r - 1/4) + w(3/4 - r)}, \quad w(r) = \begin{cases} r^2 & \text{if } r > 0, \\ 0 & \text{else.} \end{cases}$$

In contrast to the solution of Example 3, this solution does not present any sharp structure. Thus both adaptive and uniform refinement methods can reach the asymptotic rates of convergence with relatively few degrees of freedom. For this problem we consider two adaptive solutions with the following refinement parameters: $\text{tol}_{on} = 0.9$, $\text{tol}_{off} = 0.01$ (case 1) and $\text{tol}_{on} = 0.99$, $\text{tol}_{off} = 0.001$ (case 2), respectively, and a uniform refinement with linear basis functions.

In Table 4.12, we report the least squares approximations cN^{α} of the errors in L^2- and H^1-norms. The numerical computations give results very close to the expected

theoretical rates of convergence, and in this case the constants of the adaptive case, proportional to the Besov norm of the exact solution, are larger than the constant of the uniform case, proportional to the Sobolev norm of the exact solution.

5. Conclusion. The origin of wavelets (signal processing, harmonic analysis) is far from the numerical solution of boundary value problems in general bounded domains. Yet, the adaptive wavelets algorithm that we have investigated shows that wavelet expansions can be employed in this task as well, with encouraging results. The proposed algorithm shows good behavior with respect to efficiency and reliability in all considered examples, and also when the discretization of the problem requires mapping and splitting into subdomains. To our knowledge this is the first time that these aspects of an adaptive wavelet Galerkin method have been thoroughly investigated. In our tests, we find that the asymptotic behavior of the error is parallel to that of the best N-term approximation in H^1, although the number of basis functions involved in the solution process depends also on the mapping and the splitting. The comparison of results obtained in Examples 1 and 2 clearly suggests keeping the number of subdomains as small as possible.

The efficiency of a wavelet discretization method with respect to other methods (finite elements, spectral methods) is strongly dependent on the specific data structures and algorithms used to represent the discrete operator equations (matrix against matrix-free, approximation of integrals, etc.). By comparing the number of unknowns needed by some well-assessed adaptive FEMs (mentioned in the appendix) and by our ADWEM method to reach the same H^1-relative error on the proposed examples, we find that our method requires significantly fewer basis functions, denoting a good capability of adaptive wavelets methods to catch and resolve very sharp structures in the solution and singularities. However, by comparing the CPU-time, the FEMs are faster, the assembling of the linear system in our method being still quite slow. The gap in CPU-time between the two methods can be strongly reduced with some suitable choices of the data structures, and many improvements are still possible. We remark that wavelet discretization methods offer other advantages; for example, for systems of equations they allow easy choices of different basis functions for different unknowns without mesh constraint. These advantages can be relevant in some applications.

Appendix. Comparison with adaptive FEMs. In this appendix, we compare some results achieved by our algorithm ($L = \tilde{L} = 2$, corresponding to linear wavelets) with the results produced using linear finite elements by the well-assessed adaptive finite element code ALBERTA (Adaptive multiLevel finite element toolbox using Bisectioning refinement and Error control by Residual Techniques for scientific Applications) [30, 1]. For adaptive FEMs, as for the adaptive wavelets methods, important results on the convergence and optimality are known [24, 29, 9, 31].

We point out that the comparisons reported here are aimed at drawing indications about viability of the proposed ADWEM approach and not to establish a competition between the software or the implementations of the methods.

A.1. Residual based adaptive FEM algorithms. In order to discretize problem (2.2), we introduce a regular family of conforming partitions $\{\mathcal{T}_h\}_h$ of the domain $\overline{\Omega}$ into triangles; let us denote by h_T the diameter of the element $T \in \mathcal{T}_h$. The space H in (2.2) is approximated by $V_h = \left\{v_h \in H \cap \mathcal{C}^0(\overline{\Omega}) : \ v_{h|_T} \in \mathbb{P}_1(T) \text{ for all } T \in \mathcal{T}_h\right\}$, where $\mathbb{P}_1(T)$ is the space of polynomials of degree at most 1, on the element $T \in \mathcal{T}_h$. For simplicity we do not consider any approximation of the data. For problem (4.1)

an equivalence relation between the true error $\|u-u_h\|_{H^1(\Omega)}$ and a residual-based a posteriori error estimator can be proved [32].

For all triangles $T\in\mathcal{T}_h$ we denote by $\mathcal{E}(T)$ the set of its edges and by $\mathcal{E}_{h,\Omega}$ the set of all edges of the triangulation $\mathcal{T}_h$ inside the domain Ω. For each edge $E\in\mathcal{E}_{h,\Omega}$, $\hat{n}_E$ represents a unit vector which is orthogonal to E and $\omega_E=\bigcup_{\{T':\ E\in\mathcal{E}(T')\}}T'$. Given $E\in\mathcal{E}_{h,\Omega}$ and $\varphi\in \mathrm{L}^2(\,\omega_E\,)$ with $\varphi_{|_{T'}}\in\mathcal{C}^0(\,T'\,)$ for all $T'\in\omega_E$, we denote by $[\![\varphi]\!]_E$ the jump of φ across E in the direction $\hat{n}_E$. Finally, let us define the [illegible] $R_{T,h}$ and the [illegible] $J_{E,h}$ for this problem,

$$R_{T,h}=-\triangle u_h-f|_T\,,\qquad J_{E,h}=\left[\!\!\left[\frac{\partial u_h}{\partial\,\hat{n}_E}\right]\!\!\right]_E,$$

and the local and global error estimators,

$$\eta_{R,T}^2=C_0^2\,\|\,R_{T,h}\,\|_{L^2(T)}^2+C_1^2\sum_{E\in\mathcal{E}(T)\,\cap\,\mathcal{E}_{h,\Omega}}\|\,J_{E,h}\,\|_{L^2(E)}^2,\qquad \eta_\Omega^2=\sum_{T\in\mathcal{T}_h}\eta_{R,T}^2\,.$$

The following equivalence relation between the global error estimator and the true error holds: $c\,\eta_\Omega^2\le\|\,u_h-u\,\|_{H^1(\Omega)}^2\le C\,\eta_\Omega^2$.

We refer to the online manual of the code [1] or to [30] for a detailed description of the adaptive methods implemented in ALBERTA. We are presenting results obtained applying the following strategies: uniform refinement, maximum strategy (MS), equidistribution strategy (ES), and guaranteed error reduction strategy (GERS). We briefly recall these adaptive marking strategies for refinement:

MS: mark T with $\eta_{R,T}>\gamma\max_{T'\in\mathcal{T}_h}\eta_{R,T'}$.

ES: mark T with $\eta_{R,T}>\theta\mathrm{tol}/\sqrt{N_T}$, where N_T is the number of elements in $\mathcal{T}_h$.

GERS: mark $T\in\mathcal{A}$ such that $\sum_{T\in\mathcal{A}}R_{T,h}^2>(1-\theta_*)^2\,\eta_\Omega^2$; see [24, 29] for more details on the choice of the set $\mathcal{A}$.

In all the numerical experiments, coarsening is allowed and we use the following parameters, which correspond, except for polynomial_degree and max_iteration, to the default values [1].

Member	Value	Member	Value
polynomial_degree	1	MS_gamma	0.5
estimator C0	1.0	MS_gamma_c	0.1
estimator C1	1.0	ES_theta	0.9

refine_bisection	2	GERS_theta_star	0.6
coarsen_allowed	1	GERS_nu	0.1
coarse_bisections	2	GERS_theta_c	0.1

A.2. Numerical examples. Let us consider Examples 3 and 4 in section 4. We will solve them by the adaptive FEMs implemented in ALBERTA and by uniform refinement. These results should be compared with the corresponding ones from the previous section.

Example 3. The solution is obtained using ALBERTA with tolerance tol = 4.0 (chosen to have a final H^1-relative error close to the one in Table 4.10) starting from a coarse grid with $N=2113$ nodes. In Table A.1 we report the quantities δ_{L^2} and δ_{H^1}; in Table A.2 we report the constant c and the slope α of the least squares approximations cN^α of the relative errors with respect to the number of nodes. From these data we can conclude that the behavior of the relative error on these meshes

TABLE A.1

is still far from the asymptotic one. Comparing results reported in Table A.1 with the results of Table 4.10 we can clearly see the very effective capability of a wavelets method to catch and resolve sharp structures and singularities. The comparison of the number of basis functions (DOF) between the two methods is not necessarily related to the computational cost. In fact, the task of assembling the linear system is usually more expensive for wavelet codes than for FEMs. Moreover, the state of the art for the finite element codes is widely more assessed than for the few and recent wavelets codes, and many improvements may be possible.

Example 4. The solution is obtained using tolerance tol = 0.03, starting from a coarse grid with $N = 2113$ nodes. The final relative errors are $\delta_{L^2(\Omega)} \approx 3\text{e}{-4}$ and $\delta_{H^1(\Omega)} \approx 5\text{e}{-3}$ for the three adaptive methods considered. In Table A.3 (compare with Table 4.12), we report the data of the least squares approximations cN^{α} of

the relative errors in L^2- and H^1-norms obtained by the adaptive algorithms and a uniform refinement. In this case, as for the ADWEM algorithm, we note a very good agreement between the theoretical values and the obtained ones for the H^1-norm [9], while for the L^2-norm we have a small mismatch and the slope is closer to the expected one for a linear approximation technique (uniform refinement) than to the expected one for a nonlinear approximation technique (adaptivity).

Acknowledgments. The authors would like to thank the editor and two anonymous referees for several helpful comments and suggestions which significantly improved the paper. This work was written when the second author was at the Dipartimento di Matematica of Politecnico di Torino.

A PREDICTOR-CORRECTOR ALGORITHM FOR REACTION-DIFFUSION EQUATIONS ASSOCIATED WITH NEURAL ACTIVITY ON BRANCHED STRUCTURES*

M. J. REMPE† AND D. L. CHOPP†

Abstract. In this paper, we present a numerical method for solving reaction-diffusion equations on one-dimensional branched structures. The method effectively decouples the many branches at the nodal junctions so that the equations can be solved as a system of smaller problems that are purely tridiagonal. This strategy enables a number of improvements. In particular, difficulties associated with implicit methods for closed loops in the network are eliminated, and spatial adaptivity can be easily implemented. We apply this method to the electrical activity of a neuron. A neuron can be effectively represented as a one-dimensional branched structure, and the model equations, based on the Hodgkin–Huxley cable equations, are a set of reaction equations coupled to a single diffusion process. Spatially adaptive methods are particularly effective for neuronal simulations as the region of activity is often very localized in space. Since the algorithm scales with activity instead of network size, it will make a substantial reduction in computational cost over existing methods.

Key words. reaction-diffusion equation, neural biology, finite difference methods

1. Background. In this paper, we propose a numerical method for solving reaction-diffusion equations on a branched system of one-dimensional structures. More precisely, let $B_i = [0, L_i]$ for each $i = 1, \ldots, N_b$ be individual branches. The branches are joined by nodal points p_j, $j = 1, \ldots, N_n$, which couple two or more branches, $B_{i_j^\pm}$, through their end points. The "$\pm$" indicates whether the $x = 0$ or $x = L_{i_j}$ end of B_{i_j} is joined at p_j. For example, Figure 1.1 illustrates a typical relationship between three branches and a node. The reaction-diffusion system can then be expressed as follows, coupled with appropriate boundary conditions on branch ends that are not joined at a node:

$$V_t^i = AV_{xx}^i + R(V^i), \quad x \in B_i,\ i = 1, \ldots, N_b, \tag{1.1}$$

$$W_t^j = \sum_{i_j} \pm AW_x^{i_j} + R(W^j) \quad \text{at } p_j,\ j = 1, \ldots, N_n. \tag{1.2}$$

Here $V^i(x)$ is the value of the solution along branch B_i, W^j is the solution at the single node p_j, and $R(V)$ is a possibly nonlinear reaction term. Thus, we have a collection of separate reaction-diffusion equations, (1.1), coupled at nodes where conservation-of-flux equation (1.2) is applied.

One example of where this type of system arises is in modeling excitation of neurons. In this case V represents the voltage across the cell membrane, and $R(V)$ represents the currents due to the movement of ions through channels in the membrane. Written out with all the reaction terms, and their corresponding ordinary differential equations, the system is referred to as the Hodgkin–Huxley equations [10].

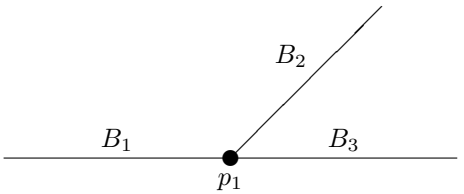

FIG. 1.1. *Sample branched structure with three branches and one node. The node p_1 joins B_{1+}, B_{2-}, and B_{3-}.*

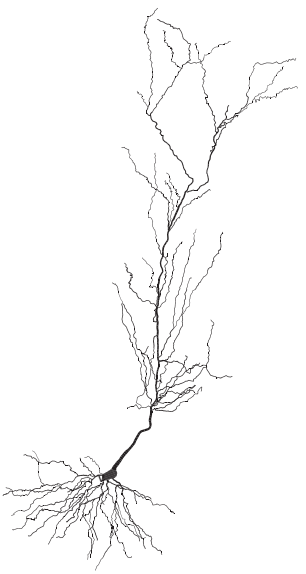

FIG. 1.2. *Example cell shape. This is the shape of a subicular pyramidal cell from rat hippocampus. Branches extend outward from the cell body, or soma.*

In terms of structure, one neuron may have hundreds of branches, called dendrites. A representative example of a neuron's shape is shown in Figure 1.2, which is a pyramidal cell neuron from the subiculum region of rat hippocampus. This shape was traced out using a real cell that was stained and reconstructed on a computer. Note the large number of long, slender branches extending out in a tree-like manner. It is important to note that for each branch, since the length is so much greater than the diameter, a one-dimensional mathematical model for the branches is reasonable. A number of software packages, including NEURON [8] and GENESIS [1], take this approach to solve the Hodgkin–Huxley reaction-diffusion system on realistic models of branched neurons. These neuron simulation packages trace their roots to the key work of Cooley and Dodge, who presented a numerical algorithm to solve the Hodgkin–Huxley equations using Crank–Nicolson for the diffusion term and an iterative procedure for the nonlinear reaction term [3]. This was the first time a second-order numerical method was demonstrated for the Hodgkin–Huxley equations.

Hines [6] followed up the work of Cooley and Dodge by presenting a number of numerical techniques that increase the efficiency of the numerical method, especially on branched structures. One of the improvements was a method for numbering the branches of the structure and the compartments within each branch such that the

resulting linear system for the voltage on the entire structure can be made upper triangular and solved as efficiently as the system for an unbranched cable. Cai, Walsh, and McGee [2] also presented a similar branch-numbering procedure to update the voltage of the tree in $O(N)$ operations. Note that both Hines's and Cai's approaches use one linear system for the entire tree structure and hence are not easily made spatially adaptive.

Mascagni [12] took a different approach to the same problem by using an exact domain decomposition algorithm on the branched structure. For each branch the principle of superposition is employed to construct the solution as the sum of two or three solutions to linear systems for that branch. This approach separates the problem into small linear systems, one for each branch. These linear systems are tridiagonal, so the computational cost for updating one branch is $O(N)$ operations, where N is the number of compartments in that branch. The benefits of this approach are that it is easily made parallelizable and that it can handle closed loops, which the earlier methods could not. However, the superposition approach requires an additional solution of a dense linear system corresponding to the voltage at the branch points, which couples all the branches together, and consequently the evolution on the whole cell is again required.

One observation about neuronal activity is that often large regions of the network are essentially at equilibrium. For this reason, spatial adaptivity is expected to yield improved performance for computing large neuron simulations. None of the aforementioned methods can be made spatially adaptive. In this paper, we present a numerical method that combines an implicit method on the branches with a predictor-corrector scheme for the branch points of the tree structure, allowing the structure to be split up into individual branches. In this way our numerical method provides a framework for parallelization: each branch of the tree structure can be computed independently by a separate processor. In contrast to the method developed by Mascagni, our method avoids the dense linear system for the nodes and hence is more easily parallelized. In addition, our method is able to do local spatial adaptivity because each branch is completely uncoupled from the other branches. Furthermore, because the branches are uncoupled, incorporating spatial adaptivity is natural and straightforward: branches are updated only if they are active and turned off as they return to the equilibrium resting voltage. Spatial adaptivity within the tree structure is a novel development in neural simulations.

To explain our algorithm for splitting up a branched structure we will focus on the Hodgkin–Huxley equations on a branched neuron; the details are presented in section 2. In section 3, we describe the application of Crank–Nicolson and backward Euler methods to the Hodgkin–Huxley cable equations. In section 4, we present both first- and second-order accurate versions of the new predictor-corrector scheme. We will discuss the convergence and stability properties of the new methods in sections 5 and 6, respectively. In section 7 we present an example for both methods and compare the accuracy of the results to those of standard methods. In section 8 we present a number of examples of simulations involving the spatial adaptivity algorithm including simulations on complex branched structures. Finally, in section 9 we give an example on a closed loop.

2. Hodgkin–Huxley mathematical model. The Hodgkin–Huxley equations are written out as follows:

$$C_m \frac{\partial V}{\partial t} = \frac{a}{2R_a} \frac{\partial^2 V}{\partial x^2} - R(V), \tag{2.1a}$$

where

(2.1b)
$$R(V) = \overline{g_{Na}} m^3 h (V - E_{Na}) + \overline{g_K} n^4 (V - E_K) + g_{leak}(V - E_{leak}) - \frac{I_e}{2\pi a}\delta(x - x_0),$$

(2.1c)
$$\begin{aligned} \frac{dm}{dt} &= \alpha_m(V)(1-m) - \beta_m(V)m, \\ \frac{dn}{dt} &= \alpha_n(V)(1-n) - \beta_n(V)n, \\ \frac{dh}{dt} &= \alpha_h(V)(1-h) - \beta_h(V)h, \end{aligned}$$

(2.1d)
$$\begin{aligned} \alpha_m(V) &= \frac{0.1(25-V)}{e^{(25-V)/10}-1}, \qquad \beta_m(V) = 4e^{-V/18}, \\ \alpha_n(V) &= \frac{0.01(10-V)}{e^{(10-V)/10}-1}, \qquad \beta_n(V) = 0.125e^{-V/80}, \\ \alpha_h(V) &= 0.07e^{-V/20}, \qquad \beta_h(V) = \frac{1}{e^{30-V/10}+1}, \end{aligned}$$

where I_e is the stimulating current from an electrode, C_m is the membrane capacitance, R_a is the resistance, a is the radius, and $\overline{g_{Na}}$, $\overline{g_K}$, g_{leak}, E_{Na}, E_K, and E_{leak} are constants. The final term in (2.1c) represents the current due to a stimulating electrode at a location x_0. The variables m, n, and h are dimensionless. Equations (2.1c) describe the kinetics of the variables m, n, and h used in (2.1c). Equation (2.1d) gives the form of $\alpha(V)$ and $\beta(V)$ used in (2.1c). In this case, $R(V)$ is a current, and the terms in (2.1c) model the flow of current, through the membrane due to the movement of ions through channels. The Hodgkin–Huxley model in particular includes the currents due to the movement of sodium ions and potassium ions, as well as a general nonspecific ion current referred to as "leak" current. These currents are each reasonably modeled using Ohm's law: $I = gV$. However, before being used in this model, Ohm's law has been modified from its simple form in two ways. First, instead of the absolute membrane voltage, V, the voltage relative to each ion's reversal potential (E_{Na}, E_K, or E_{leak}) is used. Second, since the conductance depends on channels in the membrane that open and close, the conductance, g, is not constant but instead is the product of a constant and one or more dimensionless rate variables (m^3h in the case of sodium, n^4 in the case of potassium). Also referred to as "gating variables," these rate variables range from 0 to 1, where a value of 0 means all of the channels for that ion are closed and 1 means all of the channels for that ion are open. For instance, a value of 1 for n would mean that the potassium conductance is at its maximum, $\overline{g_K}$. The equations (2.1d) were determined empirically by Hodgkin–Huxley to fit experimental data.

The Hodgkin–Huxley model serves as the framework for a multitude of other mathematical models that include the influence of many different kinds of ion channels, not just sodium and potassium. Each of these can be modeled analogously to the sodium and potassium channels used in the Hodgkin–Huxley model. The constant conductances, the form of the gating variables, and the form of the rate functions are often not known beforehand but instead are determined by fitting the model to

experimental data. A common practice with mathematical models of this sort is to vary the form of the rate functions α and β along with the constant conductances to make the model output match up with experimental results. Once the model is fit to data, it can be used to make predictions that can be verified by experiments.

3. Numerical methods. The most common way to solve this reaction-diffusion system for the voltage involves using an implicit method for the diffusion term, either Crank–Nicolson [7], [3] or backward Euler [11]. The nonlinear reaction terms are then updated separately using an iterative procedure [3], [11] or with the trapezoidal rule using a staggered time step [6]. In this section we describe both the backward Euler and the Crank–Nicolson methods for solving the system (2.1) on a single branch.

3.1. Backward Euler. Assuming constant grid spacing, Δx, and using backward Euler to discretize the system (2.1) yields the equation

$$\lambda V_{i-1}^{t+\Delta t} - 2\lambda V_i^{t+\Delta t} + \lambda V_{i+1}^{t+\Delta t} = \mu\left(V_i^{t+\Delta t} - V_i^t\right) + \Gamma^{t+\Delta t} V_i^{t+\Delta t} - \gamma^{t+\Delta t}, \tag{3.1}$$

where we have made the following substitutions to simplify the notation:

$$\begin{aligned}
\lambda &= \frac{a}{2R_a \Delta x^2},\\
\Gamma^t &= \overline{g_{Na}} m^3(t) h(t) + \overline{g_K} n^4(t) + g_{leak},\\
\gamma^t &= \overline{g_{Na}} m^3(t) h(t) E_{Na} + \overline{g_K} n^4(t) E_K + g_{leak} E_{leak},\\
\mu &= \frac{C_m}{\Delta t}.
\end{aligned}$$

In this case since the reaction term, R, is linear in $V_i^{t+\Delta t}$ we can group the $V_i^{t+\Delta t}$ terms to the left-hand side, giving a matrix equation for the voltage:

$$\lambda V_{i-1}^{t+\Delta t} - \left(2\lambda + \mu + \Gamma^{t+\Delta t}\right) V_i^{t+\Delta t} + \lambda V_{i+1}^{t+\Delta t} = -\mu V_i^t - \gamma^{t+\Delta t}. \tag{3.2}$$

To update the gating variables, m, n, and h, we discretize (2.1c) using backward Euler as well:

$$\frac{m^{t+\Delta t} - m^t}{\Delta t} = \alpha_m(V^{t+\Delta t})(1 - m^{t+\Delta t}) - \beta_m(V^{t+\Delta t}) m^{t+\Delta t}. \tag{3.3}$$

When solved for $m^{t+\Delta t}$ this yields

$$m^{t+\Delta t} = \frac{m^t + \Delta t \alpha_m(V^{t+\Delta t})}{1 + \Delta t \beta_m(V^{t+\Delta t}) + \Delta t \alpha_m(V^{t+\Delta t})}. \tag{3.4}$$

Since (3.2) and (3.4) are coupled through $V^{t+\Delta t}$, they must be solved simultaneously. One approach to solving this nonlinear system is Picard iteration as outlined in [11] and [13]. The solution procedure is as follows:

1. Solve (3.2) for the voltage at time $t + \Delta t$ using values for m, n, and h at time t.
2. Update m, n, and h using (3.4) and the voltage computed in step 1.
3. Correct the voltage using (3.2) and m, n, and h computed in step 2.
4. Correct the gating variables using the new voltage computed in step 3.
5. Return to step 2 until the voltage and gating variables have converged.

Since backward Euler is first order in time anyway, a simpler approach is to update the voltage and the gating variables only once instead of using Picard iteration [9].

3.2. Crank–Nicolson. A similar numerical method used to solve (2.1) is the Crank–Nicolson method. Hines's algorithm [6] performs Crank–Nicolson in two separate steps. The first step is a backward Euler step of size $\Delta t/2$ for (2.1a), which is exactly the same as in (3.2) except that a step size of $\Delta t/2$ is used instead of Δt:

$$\lambda V_{i-1}^{t+\Delta t/2} - \left(2\lambda + 2\mu + \Gamma^{t+\Delta t/2}\right) V_i^{t+\Delta t/2} + \lambda V_{i+1}^{t+\Delta t/2} = -2\mu V_i^t - \gamma^{t+\Delta t/2}. \tag{3.5}$$

Having solved (3.5) for $V_i^{t+\Delta t/2}$, an explicit step is used to update V from time t to time $t + \Delta t$:

$$V_i^{t+\Delta t} = 2V_i^{t+\Delta t/2} - V_i^t. \tag{3.6}$$

The combination of (3.5) and (3.6) to advance V over a full time interval is equivalent to the Crank–Nicolson method [4]. Note that (3.5) is linear in V if the dimensionless gating variables (m, n, and h) are known at time $t + \Delta t/2$, a property referred to as "conditional linearity" by Mascagni and Sherman [13]. Because the system is conditionally linear, full second-order accuracy in time can be maintained if the values of m, n, and h are known at offset time steps. That is, if the voltage is computed at times t, $t + \Delta t$, $t + 2\Delta t$, etc. and the gating variables are computed at times $t + \Delta t/2$, $t + 3\Delta t/2$, $t + 5\Delta t/2$, then they can be used directly in (3.5) to update the voltage at time $\Delta t/2$. The final ingredient needed to make sure the method is second order in time is a second-order accurate method updating the gating variables. This is achieved by applying the trapezoidal rule to (2.1c):

$$\frac{m^{t+\Delta t/2} - m^{t-\Delta t/2}}{\Delta t} = \alpha_m(V^t) - (\alpha_m(V^t) + \beta_m(V^t))\frac{m^{t+\Delta t/2} + m^{t-\Delta t/2}}{2}. \tag{3.7}$$

Solving this for $m^{t+\Delta t/2}$ yields

$$m^{t+\Delta t/2} = \left(\frac{\alpha_m}{\frac{1}{\Delta t} + \frac{1}{2}(\alpha_m + \beta_m)}\right) + \left(\frac{\frac{1}{\Delta t} - \frac{1}{2}(\alpha_m + \beta_m)}{\frac{1}{\Delta t} + \frac{1}{2}(\alpha_m + \beta_m)}\right) m^{t-\Delta t/2}. \tag{3.8}$$

Once m, n, and h are updated in this manner, they can be placed in the coefficient matrix which multiplies the voltage vector in (3.5). Since this linear system is tridiagonal, its solution can be found in $O(N)$ operations, and consequently, the overall computational cost to update one branch is $O(N)$.

3.3. Branching. At the points where branches connect, an additional conservation equation needs to be solved:

$$\frac{1}{A} \sum_{\substack{branches \\ into \\ node}} \pm \left(\frac{\pi a^2}{R_a}\frac{\partial V}{\partial x}\right) = C_m \left.\frac{\partial V}{\partial t}\right|_{node} + \Gamma V_{node} - \gamma, \tag{3.9}$$

where Γ, γ are defined as before and A is the surface area of the node.

This equation represents a conservation of charge at the node: the sum of the axial currents coming into the node due to the branches (left-hand side) is equal to the current flowing out of the node through the membrane (the right-hand side). When evaluating the axial currents, care must be taken with regard to the direction of flow, hence the need for the $\pm$ sign.

Since Hines's method updates the entire branching structure using one large linear system, his method handles branch points by simply changing the corresponding lines

in the linear system to solve (3.9) instead of (3.5). The result is a linear system for the tree that can be solved in $O(N)$ operations, where N is the number of compartments in the tree structure. One of the main purposes of the algorithm presented here is to avoid the use of this large linear system and instead use small linear systems, one for each branch.

4. Predictor-corrector numerical schemes. To split up the structure into branches and nodes, we propose two predictor-corrector schemes for the nodes, one to be used with backward Euler for the branches and one to be used with the two-step version of Crank–Nicolson for the branches. For the case of backward Euler, the numerical scheme for the nodes gives a numerical method that is second order in space and first order in time, while for the Crank–Nicolson case the scheme is second order in time and space. Each method costs $O(N)$ operations. To illustrate the algorithm, consider the simple branching structure of two branches connected by a node as shown in Figure 4.1. The point labeled V_0 represents the node. Both the predictor-corrector algorithms for updating the node will be described using this structure.

4.1. Backward Euler predictor-corrector. To update both branches and the node from time t to time $t + \Delta t$, the backward Euler predictor-corrector algorithm proceeds as follows. First, (3.9) is discretized using an explicit method:

$$C_m \frac{V_0^* - V_0^t}{\Delta t} = \frac{1}{A}\left[\frac{\pi a^2}{R_a}\left\{\frac{V_1^t - V_0^t}{\Delta x} - \frac{V_0^t - V_{-1}^t}{\Delta x}\right\}\right] - \Gamma^{t+\Delta t} V_0^* + \gamma^{t+\Delta t}, \tag{4.1}$$

where V_0^* is a tentative approximation for $V_0^{t+\Delta t}$. Solving for V_0^* gives the update

$$V_0^* = \left(\frac{1}{1 + \frac{1}{\mu}\Gamma^{t+\Delta t}}\right)\left[V_0^t + \frac{\Delta t \pi}{C_m A}\frac{a^2}{R_a}\left\{\frac{V_1^t - V_0^t}{\Delta x} - \frac{V_0^t - V_{-1}^t}{\Delta x}\right\} + \frac{1}{\mu}\gamma^{t+\Delta t}\right]. \tag{4.2}$$

Second, update the voltage, $V_i^{t+\Delta t}$ for $i \neq 0$, on the branches using backward Euler for a full time step using (3.2):

$$\lambda V_{i-1}^{t+\Delta t} - \left(2\lambda + \mu + \Gamma^{t+\Delta t}\right) V_i^{t+\Delta t} + \lambda V_{i+1}^{t+\Delta t} = -\mu V_i^t - \gamma^{t+\Delta t} \quad \text{for } |i| > 1, \tag{4.3}$$

$$\lambda V_{-2}^{t+\Delta t} - \left(2\lambda + \mu + \Gamma^{t+\Delta t}\right) V_{-1}^{t+\Delta t} = -\lambda V_0^* - \mu V_{-1}^t - \gamma^{t+\Delta t}, \tag{4.4}$$

$$-\left(2\lambda + \mu + \Gamma^{t+\Delta t}\right) V_1^{t+\Delta t} + \lambda V_2^{t+\Delta t} = -\lambda V_0^* - \mu V_1^t - \gamma^{t+\Delta t}. \tag{4.5}$$

Note that in (4.3)–(4.5), the unknowns are on the left side of the equations, and the known values are on the right. Note also that (4.4) and (4.5) are the same as equation (4.3) with $V_0^{t+\Delta t}$ replaced with V_0^*.

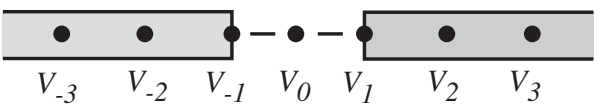

FIG. 4.1. *Sample branching structure. This simple two-branch, one-node structure is used to illustrate the predictor-corrector updating scheme.*

Third, the values for the nodes at time $t+\Delta t$ are corrected using an implicit-like corrector step. This step comes from discretizing (3.9) using backward Euler and is meant to mimic what would have happened at the node if it was updated using backward Euler like the branches:

$$C_m \frac{V_0^{t+\Delta t} - V_0^t}{\Delta t} = \frac{1}{A}\left[\frac{\pi a^2}{R_a}\left\{\frac{V_1^{t+\Delta t} - V_0^{t+\Delta t}}{\Delta x} - \frac{V_0^{t+\Delta t} - V_{-1}^{t+\Delta t}}{\Delta x}\right\}\right] - \Gamma^{t+\Delta t} V_0^{t+\Delta t} + \gamma^{t+\Delta t}. \tag{4.6}$$

Since $V_{-1}^{t+\Delta t}$ and $V_1^{t+\Delta t}$ were computed in the second step, this can be solved explicitly for $V_0^{t+\Delta t}$, the corrected node voltage at time $t+\Delta t$. The update looks like

$$V_0^{t+\Delta t} = \frac{1}{\mu + \frac{2\pi a^2}{A R_a \Delta x} + \Gamma^{t+\Delta t}}\left[\mu V_0^t + \frac{1}{A}\left\{\frac{\pi a^2}{R_a \Delta x}\left(V_1^{t+\Delta t} + V_{-1}^{t+\Delta t}\right)\right\} + \gamma^{t+\Delta t}\right]. \tag{4.7}$$

This completes the update for the nodes and branches using backward Euler. The steps of this algorithm are illustrated on a two-branch structure in Figure 4.2a.

4.2. Crank–Nicolson predictor-corrector. The Crank–Nicolson version of the predictor-corrector scheme is similar to the backward Euler version, but requires offsetting the update of the voltage and the gating variables, as described in section 3.2. The first two steps are exactly like the backward Euler predictor-corrector except that a step of size $\Delta t/2$ is taken instead of Δt:

$$V_0^* = \left(\frac{1}{1 + \frac{1}{2\mu}\Gamma^{t+\Delta t/2}}\right)\left[V_0^t + \frac{\Delta t \pi}{C_m A}\frac{a^2}{R_a}\left\{\frac{V_1^t - V_0^t}{\Delta x} - \frac{V_0^t - V_{-1}^t}{\Delta x}\right\} + \frac{1}{2\mu}\gamma^{t+\Delta t/2}\right]. \tag{4.8}$$

As before, V_0^* is a tentative approximation for $V_0^{t+\Delta t/2}$.

Second, the voltage of the branches is updated for half of a time step using the backward Euler method, (3.2):

$$\lambda V_{i-1}^{t+\Delta t/2} - \left(2\lambda + 2\mu + \Gamma^{t+\Delta t/2}\right) V_i^{t+\Delta t/2} + \lambda V_{i+1}^{t+\Delta t/2} = -2\mu V_i^t - \gamma^{t+\Delta t/2} \quad \text{for } |i| > 1, \tag{4.9}$$

$$\lambda V_{-2}^{t+\Delta t/2} - \left[2\lambda + 2\mu + \Gamma^{t+\Delta t/2}\right] V_{-1}^{t+\Delta t/2} = -\lambda V_0^* - 2\mu V_{-1}^t - \gamma^{t+\Delta t/2}, \tag{4.10}$$

$$-\left[2\lambda + 2\mu + \Gamma^{t+\Delta t/2}\right] V_1^{t+\Delta t/2} + \lambda V_2^{t+\Delta t/2} = -\lambda V_0^* - 2\mu V_1^t - \gamma^{t+\Delta t/2}. \tag{4.11}$$

Third, the same implicit-like corrector step as for backward Euler is used for the nodes, except for a time step of $\Delta t/2$:

$$C_m \frac{V_0^{t+\Delta t/2} - V_0^t}{\Delta t/2} = \frac{1}{A}\left[\frac{\pi a^2}{R_a}\left\{\frac{V_1^{t+\Delta t/2} - V_0^{t+\Delta t/2}}{\Delta x} - \frac{V_0^{t+\Delta t/2} - V_{-1}^{t+\Delta t/2}}{\Delta x}\right\}\right] - \Gamma^{t+\Delta t/2} V_0^{t+\Delta t/2} + \gamma^{t+\Delta t/2}. \tag{4.12}$$

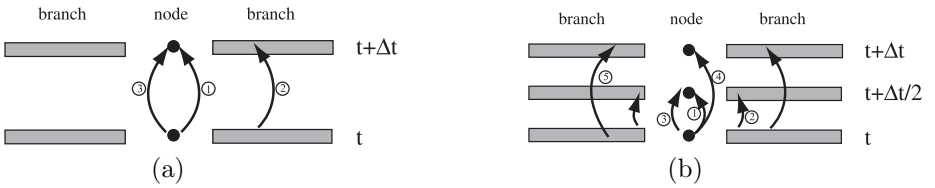

FIG. 4.2. *Each node update scheme is illustrated on a simple configuration of two branches connected by a node. Shown in* (a) *is the backward Euler predictor-corrector method. The steps are as follows:* (1) *An explicit step of size* Δt *is taken for the nodes.* (2) *The branches use this temporary value as a boundary condition as they are updated a full time step using backward Euler.* (3) *Finally the node value is corrected using an implicit-like corrector step as described in the text. Shown in* (b) *are the steps of the Crank–Nicolson predictor-corrector algorithm:* (1) *an explicit step of size* $\Delta t/2$ *for the nodes,* (2) *a backward Euler step of size* $\Delta t/2$ *for the branches,* (3) *an implicit-like corrector step of size* $\Delta t/2$ *for the nodes,* (4) *an explicit step for the branches to update them a full time step, and finally,* (5) *an explicit step for the nodes to update them the full time step.*

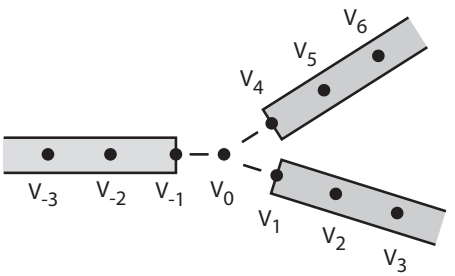

FIG. 4.3. *Three-branch structure. The predictor-corrector updating scheme is described on this three-branch structure.*

As for backward Euler, $V_{-1}^{t+\Delta t/2}$ and $V_1^{t+\Delta t/2}$ come from the second step of the algorithm, so this equation can be solved explicitly for $V_0^{t+\Delta t/2}$. The update looks like

$$V_0^{t+\Delta t/2} = \frac{1}{2\mu + \frac{2\pi a^2}{R_a \Delta x} + \Gamma^{t+\Delta t/2}} \times \left[2\mu V_0^t + \frac{1}{A} \left\{ \frac{\pi a^2}{R_a \Delta x} (V_1^{t+\Delta t/2} + V_{-1}^{t+\Delta t/2}) \right\} + \gamma^{t+\Delta t/2} \right]. \tag{4.13}$$

Finally, the explicit step, (3.6), is carried out for both the branches and the nodes to update the entire tree a full time step. See the schematic in Figure 4.2(b) for a step-by-step description of the Crank–Nicolson update of this simple two-branch, one-node structure.

4.3. Backward Euler predictor-corrector on a three-branch structure. Both schemes presented here for two branches and one node are easily extended to nodes connecting many branches. Consider the three-branch structure shown in Figure 4.3.

To update this node, the first step is an explicit step analogous to (4.1):

$$C_m \frac{V_0^* - V_0^t}{\Delta t} = \frac{1}{A} \left[\frac{\pi a^2}{R_a} \left\{ \frac{V_1^t - V_0^t}{\Delta x} + \frac{V_4^t - V_0^t}{\Delta x} - \frac{V_0^t - V_{-1}^t}{\Delta x} \right\} \right] - \Gamma^{t+\Delta t} V_0^* + \gamma^{t+\Delta t}. \tag{4.14}$$

Solving for V_0^* gives the update for this case:

(4.15)
$$V_0^* = \left(\frac{1}{1+\frac{1}{\mu}\Gamma^{t+\Delta t}}\right)\left[V_0^t + \frac{\Delta t\pi}{C_m A}\frac{a^2}{R_a}\left\{\frac{V_1^t - V_0^t}{\Delta x} + \frac{V_4^t - V_0^t}{\Delta x} - \frac{V_0^t - V_{-1}^t}{\Delta x}\right\} + \frac{1}{\mu}\gamma^{t+\Delta t}\right].$$

The update for the branches is identical to (4.3)–(4.5). The third step is also the same as in (4.6) and (4.7) with the addition of a term corresponding to the third branch:

(4.16)
$$C_m\frac{V_0^{t+\Delta t} - V_0^t}{\Delta t} = \frac{1}{A}\left[\frac{\pi a^2}{R_a}\left\{\frac{V_1^{t+\Delta t} - V_0^{t+\Delta t}}{\Delta x} + \frac{V_4^{t+\Delta t} - V_0^{t+\Delta t}}{\Delta x} - \frac{V_0^{t+\Delta t} - V_{-1}^{t+\Delta t}}{\Delta x}\right\}\right] - \Gamma^{t+\Delta t}V_0^{t+\Delta t} + \gamma^{t+\Delta t}.$$

With this additional term the update is

(4.17)
$$V_0^{t+\Delta t} = \frac{1}{\mu + \frac{3\pi a^2}{AR_a\Delta x} + \Gamma^{t+\Delta t}}\left[\mu V_0^t + \frac{1}{A}\left\{\frac{\pi a^2}{R_a\Delta x}\left(V_1^{t+\Delta t} + V_{-1}^{t+\Delta t}\right)\right\} + \gamma^{t+\Delta t}\right].$$

This step completes the update for the node and the three branches connected to it. The Crank–Nicolson method on this three-branch structure is analogous. It should be clear how a node with n branches connected to it can be updated with this technique. Each additional branch connecting to the node adds another term to the summation in (3.9), which means that (4.14), (4.15), and (4.16) each have an additional term. The added term is of the form $\frac{V_j - V_0}{\Delta x}$. The corrector step, (4.17), then includes the voltage from all n branches, and the coefficient in the denominator of (4.17) reflects the number of branches connected to this node.

Notice how both predictor-corrector methods reduce the problem of updating the entire tree to solving a relatively small linear system for each branch instead of one large system for the entire cell. While the Crank–Nicolson predictor-corrector scheme has more intermediate steps to update the voltage one time step as compared to Hines's method, the overall order of the method is still $O(N)$ and does not introduce any additional linear systems to be solved. Considering that the number of nodes in a neuron is relatively much smaller than the number of compartments in the model, the extra computing done in the predictor-corrector scheme for the nodes makes a negligible contribution to overall computing time.

5. Convergence. We expect the overall accuracy of the new predictor-corrector method to be the same as the underlying numerical methods (backward Euler and Crank–Nicolson). The first test we performed to investigate the numerical convergence of our schemes was to use them on the simple configuration mentioned in section 3: two branches connected by a node.

Figure 5.1 shows convergence plots for the backward Euler predictor-corrector scheme for both grid size and time step indicating second-order convergence in space and first-order in time. To test the space convergence, we fixed the time step while successively reducing the grid spacing. The analogous test was carried out to test the time convergence. Since there is not an exact solution to compare to, a solution was found with a very small time step and grid spacing that did not change when the grid

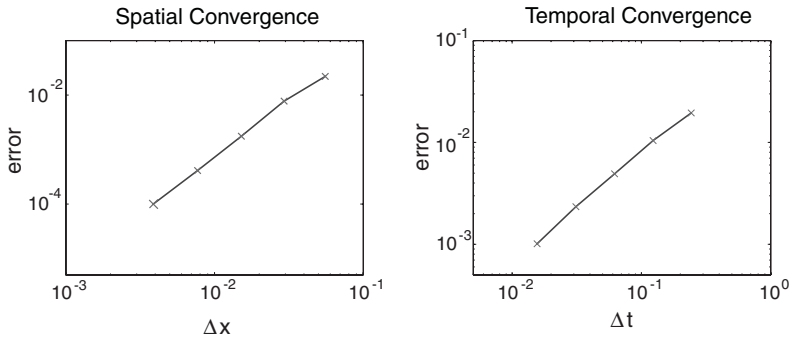

FIG. 5.1. *Convergence of the backward Euler method. Spatial convergence of the backward Euler method holding Δt fixed (left). Temporal convergence of backward Euler method holding Δx fixed (right). As can be seen, an $O(10^{-1})$ change in grid size reduces the error by $O(10^{-2})$, whereas an $O(10^{-1})$ change in time step size reduces the error by $O(10^{-1})$, indicative of an $O(\Delta x^2, \Delta t)$ method. In both cases the error was computed using a 2-norm as compared to the solution found using a very small grid spacing and a small time step*

size or time step were further reduced, indicating that it had converged. The error was computed by comparing to this "smallest grid" solution using an L^2-norm. As can be seen in the plot, the introduction of our predictor-corrector scheme for the nodes has not affected the overall accuracy of the backward Euler method.

We performed the same convergence study for the Crank–Nicolson version of the predictor-corrector scheme, with the results shown in Figure 5.2. In this case we did

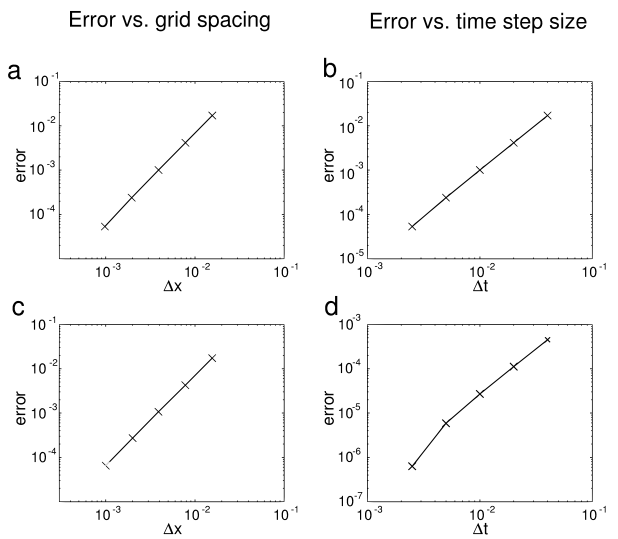

FIG. 5.2. *Second order convergence. Spatial convergence of the numerical scheme presented with* (a) *the ratio $\Delta x/\Delta t$ fixed and* (c) *holding Δt fixed. Temporal convergence of the numerical scheme presented with* (b) *the ratio $\Delta x/\Delta t$ fixed and* (d) *holding Δx fixed. In all cases, an $O(10^{-1})$ change in grid size or time step produces an $O(10^{-2})$ change in error, indicative of an $O(\Delta x^2, \Delta t^2)$ method. In all cases the error was computed using a 2-norm as compared to the solution found using a very small grid spacing and a small time step.*

two separate tests: first we held the ratio of $\Delta x/\Delta t$ fixed and successively reduced the grid spacing. Next, we fixed the time step while reducing the grid spacing. In both cases, when the grid size was cut in half, the error was reduced by a factor of 4, indicating second-order convergence. The two analogous tests were done for the convergence in time, and similar results were found.

To further verify the convergence, the model was run with only passive properties so an exact solution could be computed and used in calculating error. If g_{Na}, g_K, and E_{leak} are 0, then the resulting equation is the passive cable equation

$$C_m \frac{\partial V}{\partial t} = \frac{a}{2R_a} \frac{\partial^2 V}{\partial x^2} - g_{leak} V. \tag{5.1}$$

Rewriting this equation to make the time constant and diffusion coefficient more explicit yields the following:

$$\frac{\partial V}{\partial t} = k \frac{\partial^2 V}{\partial x^2} - \frac{V}{\tau}, \quad \text{where} \quad k = \frac{a}{2C_m R_a} \quad \text{and} \quad \tau = \frac{C_m}{g_{leak}}. \tag{5.2}$$

Given appropriate boundary conditions on a cable of length L and an initial distribution of the voltage, $f(x)$, this equation can be solved explicitly using separation of variables. Assuming that both ends are electrically insulated, the general form of the solution is

$$V(x,t) = A_0 e^{-t/\tau} + \sum_{n=1}^{\infty} A_n cos\left(\frac{n\pi x}{L}\right) e^{-\left(\left(\frac{n\pi}{L}\right)^2 + \frac{1}{k\tau}\right)kt}, \tag{5.3}$$

where

$$A_0 = \frac{1}{L} \int_0^L f(x) dx$$

and

$$A_n = \frac{2}{L} \int_0^L f(x) cos\left(\frac{n\pi x}{L}\right) dx.$$

To simulate the response to a brief current injection, a delta function was used as an initial condition. To construct a delta function located at $x = x_0$, we used the following cosine series:

$$\delta(x) \approx \frac{1}{L} + \frac{2}{L} \sum_{n=1}^{\infty} \cos\left(\frac{n\pi x_0}{L}\right) \cos\left(\frac{n\pi x}{L}\right). \tag{5.4}$$

When this expression is used as the initial condition in (5.3), the result is

$$V(x,t) = \frac{1}{L} e^{-t/\tau} + \frac{2}{L} \sum_{n=1}^{\infty} \cos\left(\frac{n\pi x_0}{L}\right) \cos\left(\frac{n\pi x}{L}\right) e^{-\left(\left(\frac{n\pi}{L}\right)^2 + \frac{1}{k\tau}\right)kt}. \tag{5.5}$$

Computing this sum gives an "exact" solution that can be used to compute the error introduced by our numerical method.

To determine how many terms to use in the Fourier series expansion of the exact solution, the error between finite sums was computed using a 2-norm. The number

of terms used in the series was doubled until it was found that the difference between using 100 terms in the series and 200 was $O(10^{-15})$. At this point it was determined that 100 terms was sufficient. To be consistent with the previous examples in this section, the 100-term summation was used as an "exact" solution for two cables connected by a node. It should be noted, however, that these results are equivalent to simulating a branching structure which follows some geometric constraints. Rall [15], [14] showed that a branching tree structure whose branch points follow the "three-halves" rule for their diameters, i.e., $d_0^{3/2} = d_1^{3/2} + d_2^{3/2}$, can be collapsed into a single equivalent cylinder whose exact solution can be found from (5.5). So the results presented here can be extended to complex branching structures that follow the three-halves rule.

Figure 5.3 shows the convergence results for both numerical methods. In both cases errors are computed using an L^2-norm to measure the relative difference between the computed solution and the exact solution found using the cosine series. The same protocol was used as in Figure 5.1, where the grid size was fixed and the time step was successively reduced and vice versa. In each case, the spatial and temporal convergence rates are the same as for standard backward Euler and Crank–Nicolson.

It should be noted here that we chose parameter values that gave a smaller amount of diffusion so that convergence could be calculated before the δ-function completely diffused away. These values are not realistic for most neural simulations, but the convergence properties demonstrated here are not limited to this choice of parameters.

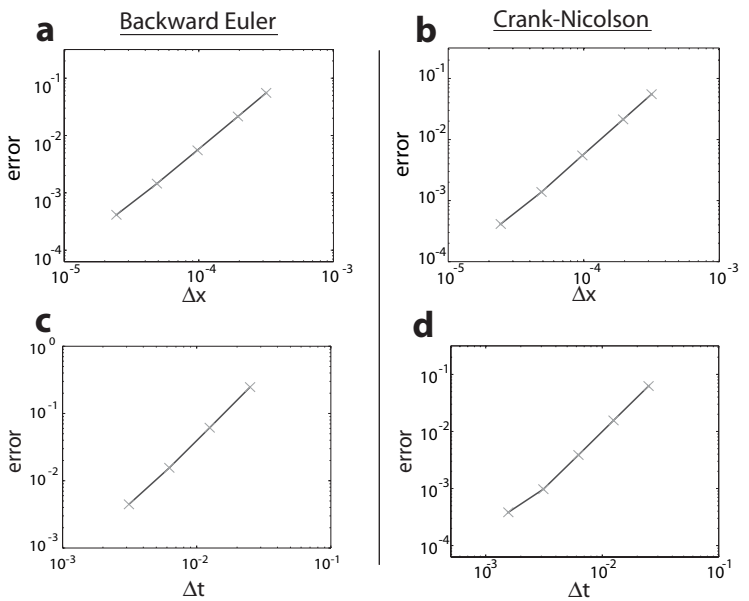

FIG. 5.3. *Convergence of methods as found by comparing to an exact solution. Spatial (*(a) *and* (b)*), and temporal convergence (*(c) *and* (d)*) of both predictor-corrector methods used to simulate a passive cable on a similar two-branch structure as used in Figures* 5.1 *and* 5.2*. In this case, the relative errors were computed using a* 2*-norm as compared to the exact solution,* (5.5)*. Both methods show their usual convergence properties: backward Euler shows* $O(\Delta x^2, \Delta t)$*, while Crank–Nicolson exhibits* $O(\Delta x^2, \Delta t^2)$ *convergence. The parameter values used were* $a = 2\ \mu m$*,* $C_m = 0.1\ mF/cm^2$*,* $R_a = 400\ \Omega cm$*, and* $g_{leak} = 3 \cdot 10^{-4}\ S/cm^2$*.*

6. Stability. Since the new predictor-corrector methods are not truly implicit, we must check that they are stable for the same range of time step size and grid spacing as would be used by the regular backward Euler and Crank–Nicolson implementations. To test the numerical stability of the schemes, we implemented both methods on the same structure used in section 5. Each branch was 80 μm long with a radius of 0.2 μm. A grid spacing of 8 μm was used as this is a conservative choice. Larger choices of grid spacing would only be more stable. An initial time step of 0.025 ms was chosen since that is the default time step size used in NEURON. Figure 6.1 shows the computed error versus the time step size for both predictor-corrector methods. As the time step size was increased, while holding the grid spacing constant, both numerical methods were numerically stable for reasonable choices of time step size, but produced significant errors when the time step became too large. In the case of backward Euler, a time step size of 0.5 ms, double the default used in NEURON, produced stable results, while further increases produced large errors.

As expected, the Crank–Nicolson scheme is stable using a larger time step than the backward Euler method. The case corresponding to the largest time step (0.167 ms) is deemed unacceptable even though the error is still relatively small, since it introduces nonphysical oscillations into the solution. The time step restriction introduced by the method is a very modest one since the time step size that was considered unacceptable is more than six times larger than the default time step used in NEURON (indicated with an arrow in both plots). With a reasonable choice of grid spacing and time step size, the time step restriction introduced by the explicit step is not actually very restrictive for typical neural simulations.

One reason why the time step restriction is not actually very constraining is because the predictor-corrector method is not used in every point of the tree but only at the branch points. In general the number of branch points in a tree is far fewer than the number of points being resolved within the branches using Crank–Nicolson. For instance, for the model cell used in section 7, there were 242 total points being resolved within the branches, while only 11 nodes. In a representative example of an entire neuron, not just the upper apical tuft, the ratio is much more striking: 574 compartments in the entire cell and just 38 nodes. This results in a time step

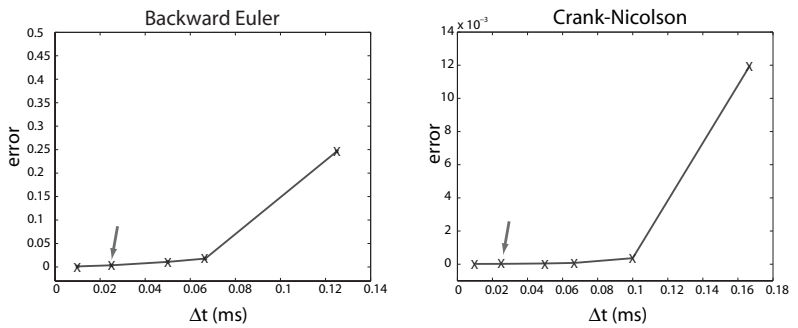

FIG. 6.1. *Both methods are numerically stable for reasonable values of* Δt*. Error versus time step size for the backward Euler version (left) and the Crank–Nicolson version (right) of the predictor-corrector scheme. The values of* Δt *used in both cases were* 0.01 *ms,* 0.025 *ms,* 0.05 *ms,* 0.067 *ms, and* 0.125 *ms. With the largest time step, the backward Euler version of the method produces unacceptable error. The Crank–Nicolson is stable for larger values of* Δt*, but produces unphysical oscillations when* $\Delta t = 0.167$*. The default time step used in NEURON is indicated with an arrow.*

restriction in practice that is not nearly as severe as would result if each of the points in the tree were updated with the predictor-corrector scheme.

7. Accuracy. To test the accuracy of both the backward Euler predictor-corrector and the Crank–Nicolson predictor-corrector methods, we programmed both methods and compared them to their corresponding counterparts which use one large matrix system for the entire tree. The branched structure used was the dendritic tree shown in Figure 7.1(a).

This is the distal portion of the dendritic arbor of a CA1 pyramidal cell from rat hippocampus. In a previous study this reconstruction was used to construct a mathematical model which was compared to experimental results [5]. For the current study Hodgkin–Huxley type channels were added to all of the branches in the tree, making the entire tree excitable. The tree structure was stimulated at its base with a 0.5 nA current for 0.5 ms. This caused an action potential to spread upward throughout the tree. Figure 7.1(b) shows the time course of the membrane voltage as measured part way up the tree (indicated with an arrow in Figure 7.1(a)) using both predictor-corrector numerical methods presented here. Also plotted are the corresponding simulations computed using one large matrix for the entire tree. As can be seen, in both cases the traces made using the predictor-corrector scheme closely match the simulations carried out using one large matrix, indicating that accuracy has not been lost by employing the predictor-corrector schemes.

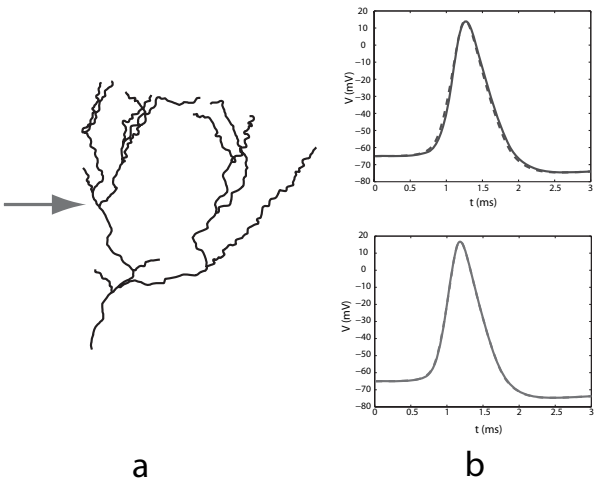

FIG. 7.1. *Accuracy comparison of both predictor-corrector methods. The dendritic tree shown in* (a) *was stimulated at the base of its trunk with a* 0.5 *nA stimulus lasting for* 0.5 *ms. Shown in* (b) *are the time courses of the voltage at the location marked with the arrow in* (a). *The top graph shows the solution computed using the backward Euler version of our predictor-corrector method (solid trace) and using Hines's implementation of backward Euler (dashed trace). The bottom graph is a comparison of the Crank–Nicolson version of our predictor-corrector method (solid trace) and Hines's implementation of Crank–Nicolson (dashed trace). Each trace made using the predictor-corrector method matches the corresponding method using Hines's formulation. The parameters used were* $T = 20°\,C$, $R_i = 150\ \Omega cm$, $C_m = .001\ \mu F/cm$, $\Delta x = 8\ \mu m$, *and* $\Delta t = .015$ *ms.*

8. Spatial adaptivity. One of the main benefits of the numerical methods presented here is that they can be used as the foundation for spatially adaptive numerical methods for neural simulations. Since the computation on each branch and node is done separately, computational effort can be focused where it is needed. We present

here a description of the adaptivity algorithm. To implement the idea of spatial adaptivity, the simulation is started with only a minimum number of branches "active" or computing. All of the other branches have their voltage set to the resting voltage. Those nodes connected to active branches are "listening" for activity to reach them, while the other nodes are set to the resting voltage like the inactive branches. The listening nodes calculate the charge flux coming into them from the active branches using the following expression:

$$\left(\frac{\pi a^2}{R_a}\frac{\partial V}{\partial x}\right). \tag{8.1}$$

This is simply the term in the summation on the left-hand side of (3.9) and is approximated the same way as in (4.1):

$$\frac{\pi a^2}{R_a}\sum_{i=0}^{N}\pm\frac{V_i^t - V_0^t}{\Delta x} \quad \text{for } N-1 \text{ branches connected to this node.} \tag{8.2}$$

If a listening node computes a charge flux that is above a predetermined tolerance, this indicates that there is activity in the corresponding branch. The node then "turns on" all of the other branches connected to it, meaning that the algorithm begins computing the differential equations on those branches. When branches are turned on, the nodes connected to them are sent into the "listening" state and the process repeats itself.

Meanwhile, activity within the branches is monitored to determine when a branch becomes inactive. The branch is considered inactive if the following two criteria are met. The first criterion is that the charge fluxes coming in either end of the branch must be below a predetermined tolerance. These charge fluxes are computed exactly as they were for the node, using (8.2), except now they are thought of as flux into or out of the branch end, instead of the node. The second criteria for turning off a branch is that the voltage everywhere in the branch is within tolerance of the resting voltage. If it is determined that the voltage everywhere in the branch is within tolerance of rest and the charge fluxes coming into or out of the branch ends are small, the branch can then be turned off. When a branch is turned off its voltage is set to the resting potential and is not updated on subsequent time steps. Even though the voltage is within tolerance of the resting voltage when it is turned off and the flux out the ends is small, sometimes prescribing the voltage in this manner can be problematic. In some cases this causes an unphysical charge flux to be introduced into the node connected to the branch that has just been turned off.

To counteract this effect, we have instituted the following rule: if any of the branches connected to a node are turned off, the total flux through that node is set to 0, its value when all of the branches are at the same voltage. In this way, the unnatural flux introduced by setting the branch to the resting voltage is ignored and the charge flux is balanced between the remaining branches. A common situation is when one branch is within tolerance and should be turned off, and the other branches connected to that node are near tolerance, but are not turned off yet because of some remaining activity at the other end. In this case, simply turning off the inactive branch and computing as usual can result in the other branches settling to a voltage that is not the resting voltage. This unnatural effect is negated by setting the total flux through the node to zero. Finally, to complete the spatial adaptivity algorithm, a node is turned off if all the branches connected to it are turned off.

8.1. Example of spatial adaptivity on one cell. To demonstrate the algorithm with spatial adaptivity, we used the cell shown in Figure 1.2. For the purpose of this simulation Hodgkin–Huxley channels were placed throughout the tree making the entire tree excitable. The tree was stimulated at its base with a current injection of 1 nA for 0.5 ms causing an action potential to move upward throughout the tree. Figure 8.1 shows snapshots of the solution at different times. Only those branches that are active are plotted.

Figure 8.2 is an accuracy comparison between the spatially adaptive simulation to the nonadaptive simulation. Shown in the insets are the voltage traces at the corresponding locations pointed to in the tree. As can be seen, in both cases the adaptive trace and the nonadaptive trace overlay, indicating that the spatial adaptivity has not affected the accuracy of the simulation.

To quantify the savings brought about by the spatial adaptivity, we performed many simulations on this cell with and without adaptivity. Due to the variability in timing from one simulation to the next, average computing times were calculated for the algorithm with adaptivity and without it. The results, shown in Figure 8.3, indicate a 30% decrease in computing time for this example. We expect the relative savings to increase as we continue to develop the technique and as the scale of the simulations becomes larger. It is important to note that for this algorithm the computational effort scales with activity, not with the number of cells.

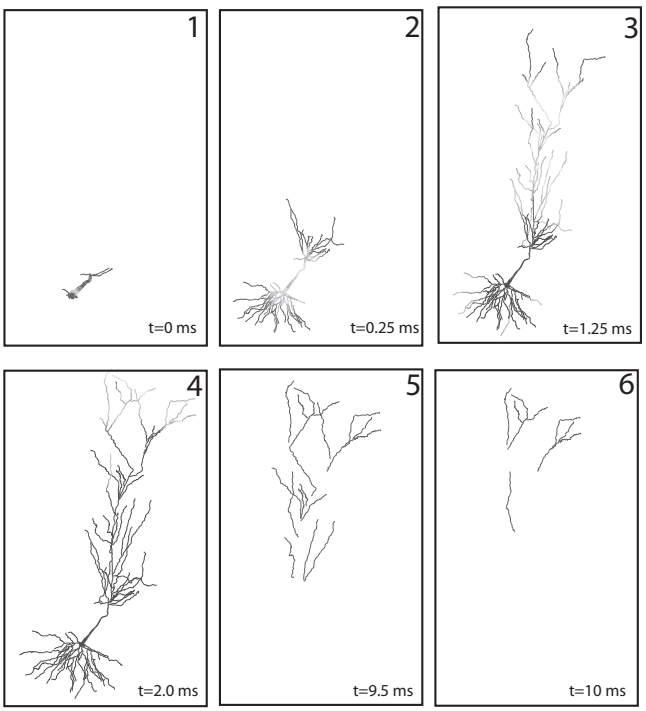

FIG. 8.1. *Snapshots of response to a somatic current injection of* 1 *nA for* 0.5 *ms. Only the branches that are computing are plotted. Shading indicates voltage, with the depolarized regions shaded in light colors and hyperpolarized regions in dark colors. For this simulation an action potential travels outward from the cell body until it leaves the cell entirely. As the cell returns to its resting voltage, branches are turned off.*

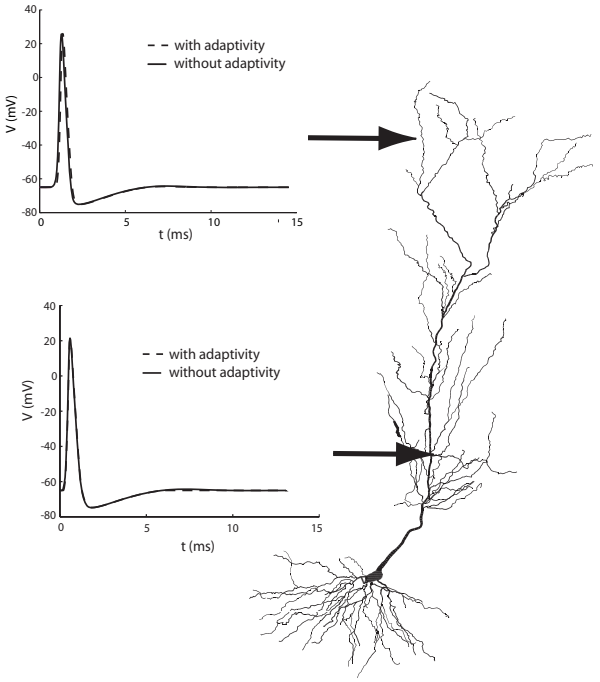

FIG. 8.2. *Comparison of voltage at a specific location on tree. On the right is the shape of the neuron used to compare the methods with and without adaptivity. Shown on the left is the computed voltage versus time at the location marked with the arrow. Since the two traces overlay, the adaptive method is able to accurately resolve the voltage without introducing any additional errors.*

8.2. Example of spatial adaptivity on two cells connected together. As another example, we applied the spatially adaptive algorithm to a simulation of two cells connected by a synapse. The first cell is a pyramidal cell from the CA1 region, while the second cell is the same subicular cell used previously in this section. The CA1 cell was stimulated with a current injection into its cell body, causing an action potential to spread throughout its branches and down its axon, the long branch connecting it to the other cell. Once the action potential reaches the end of the axon, a timer is started. This timer is designed to mimic the delay associated with the

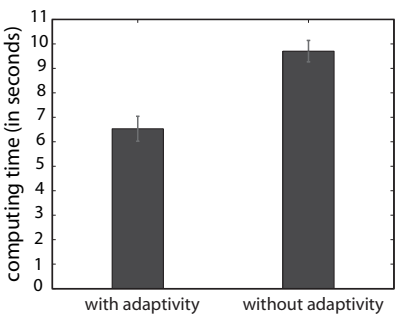

FIG. 8.3. *Comparison of computing times between the methods with and without spatial adaptivity. For this example the spatially adaptive method results in a* 30% *decrease in computing time.*

physiological processes that happen at a synapse before the postsynaptic cell fires. Once the requisite time has passed, a current is injected into the soma of the second cell. This injected current is designed to mimic the time course and size of a typical synaptic current. For the purpose of this example the synapse was made strong enough that it is able to make the second cell fire an action potential that starts in the soma and spreads throughout the cell. Typically, many synapses would be required to make the second cell fire, but the effect is analogous. Snapshots of this simulation are shown in Figure 8.4. Again, only the active branches are plotted. As can be seen, the branches are turned on as needed and turned off again once they inactivate.

To measure the effectiveness of spatial adaptivity for this example, the same test of timing was done as for the previous example, with the results shown in Figure 8.5. In this case, spatial adaptivity brings about a savings of about 50%. Looking closely at the snapshots, this is reasonable since at each snapshot, roughly half of the total branches are active at any one time.

It should be noted that certain simulations are particularly well suited to the spatially adaptive algorithm, in particular, those simulations involving networks of complex cell models where activity is localized within the network. In this case, many of the cells are inactive, allowing our algorithm to only compute on the branches of the few cells that are active, instead of updating each branch of every cell in the network, regardless of activity. Also, sometimes researchers perform many simulations on the same cell model while varying the values of some physical parameters. This

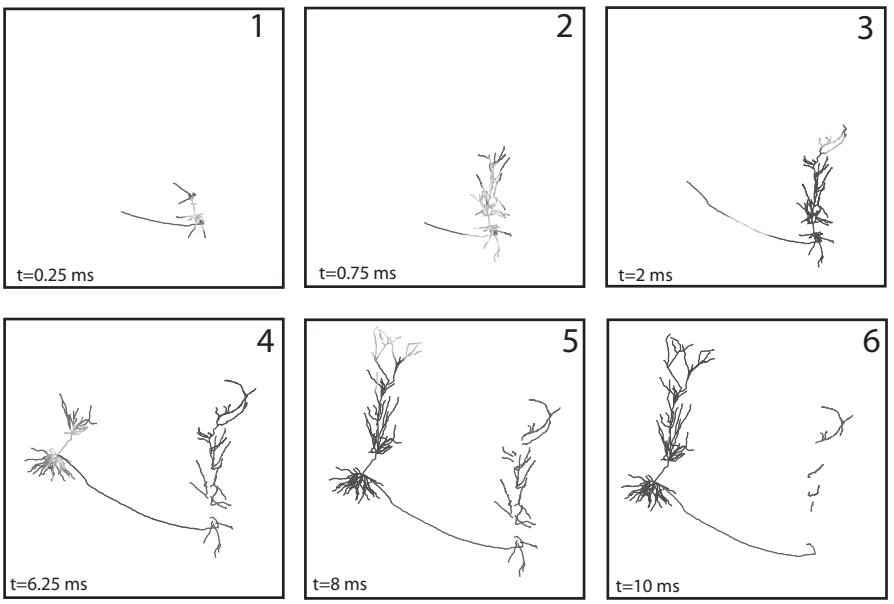

FIG. 8.4. *Snapshots of the response to a current injection of* 1 *nA for* 0.5 *ms into the cell body of a CA*1 *pyramidal cell connected synaptically to a subicular pyramidal cell. The stimulation causes an action potential to form and spread throughout the cell and down its axon. When the activity reaches the end of the axon, a simulated excitatory postsynaptic current was injected into the soma of the subiculum cell after a* 2 *ms delay. This causes the second cell to fire its own action potential. Only the branches that are computing are plotted. Shading indicates voltage, with the depolarized regions shaded in light colors and hyperpolarized regions in dark colors.*

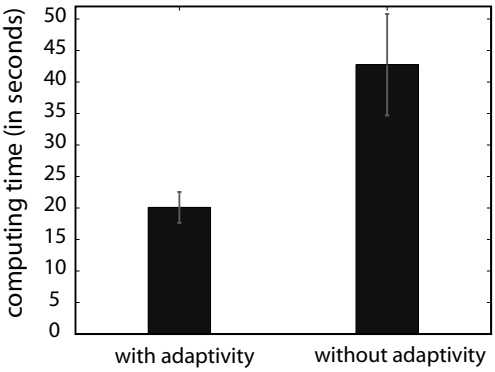

FIG. 8.5. *Comparison of computing times between the methods with and without spatial adaptivity. Using the spatially adaptive method results in a* 50% *decrease in computing time.*

allows them to determine the combination of parameters that yields results matching experimental data. Some combinations of these parameters may not result in an action potential forming and spreading throughout the cell. Conventional methods would require the same amount of effort and time for those simulations with an action potential and those without. Our method, however, would compute on a minimal number of branches and therefore save time and effort on those combinations of parameters that do not result in an action potential.

Furthermore, simulations run out to large times often exhibit large regions of inactivity as the active regions return to rest. Our algorithm would stop computing on those inactive branches, meaning that a simulation like this run out to long times would require only minimal extra effort as compared to a simulation run out to a short time. Conventional methods, on the other hand, scale linearly with simulation time, regardless of activity.

8.3. Example of spatial adaptivity on branches connected together in a straight line. The numerical methods we have presented here allow for spatial adaptivity, but at the cost of introducing extra steps into the update algorithm. In order to quantify the additional computational cost of the predictor-corrector numerical method for the nodes and the relative savings brought about by adaptivity, we compared all 3 methods: the method used by Hines [6], our predictor-corrector method for the nodes without adaptivity, and our predictor-corrector method with adaptivity. For each method we simulated 4 different "super branches" of length 500 μm, 1000 μm, 2000 μm, and 4000 μm, respectively. Each "super branch" was made up of individual branches of length 32 μm connected by nodes. Although these structures are longer than what is commonly seen in real neurons, the total number of branches and nodes is well within reason for typical cells. Figure 8.6 shows the timings of each of the three methods plotted against cable length. In each case the predictor-corrector method without adaptivity is slightly more costly than the corresponding computation done with one large matrix. This is expected due to the additional calculations performed in the predictor-corrector method. Both of these methods scale linearly with the cable length. In contrast, since the adaptive method only computes on the few branches that contain the action potential, its computational cost does not significantly increase as the cable length increases.

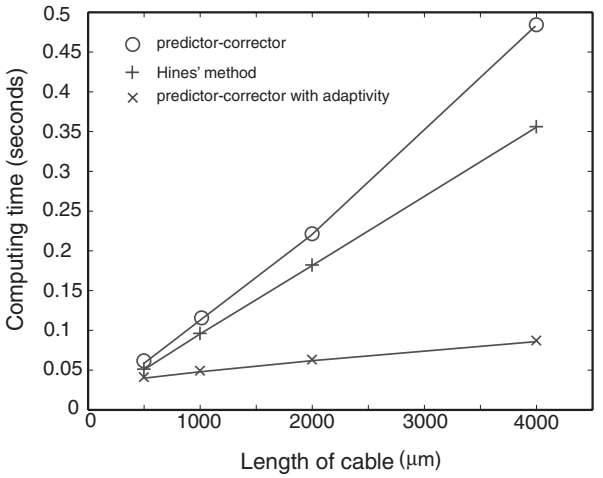

FIG. 8.6. *Timing comparison of* 3 *methods on various length cables. Shown is the computing time in seconds to simulate an action potential on a single cable of various lengths. Each cable is made up of several branches that are each* 32 μm *long and are connected by nodes. The three methods being compared are Hines's method, our predictor-corrector method using Crank–Nicolson for the nodes, and our predictor-corrector method using Crank–Nicolson and adaptivity. Both Hines' method and our method without adaptivity show a linear increase in computing time as the length of cable increases. The predictor-corrector is slightly slower than the method of Hines due to the additional overhead of computing the predictor-corrector steps at each node. Note, however, that since the adaptive method only computes on a few branches that are affected by the action potential, the computational cost is nearly independent of the length of the cable.*

9. Closed loop. Another advantage of the numerical methods presented here is the fact that they make no limitations on the branching nature of the structures being simulated. In particular, there is no restriction on trees connecting back onto themselves. This is in contrast to the method used in [6]. Consider the structure shown in Figure 9.1. This hypothetical structure is one large branch connected back onto itself via a one-way connection representing a synapse (indicated with a circle

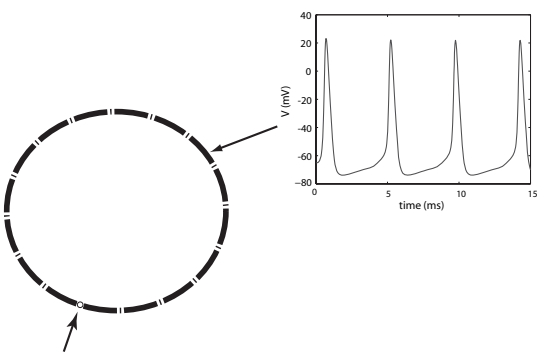

FIG. 9.1. *Loop of branches connected together by nodes. The arrow on the bottom indicates the location of the synapse. The synapse completes the loop and provides only one-way communication in the counterclockwise direction. The branch to the right of the synapse is stimulated, causing an action potential to form and propagate counterclockwise. This action potential continues to move around the circle indefinitely. Shown in the inset is the voltage versus time of one of the branches, indicating the persistent activity.*

in the figure). The large branch is made up of several smaller branches connected by ordinary nodes.

This object produces an output whose time course is similar to that of a real synapse, but whose amplitude has been increased such that it is able to make the connecting branch fire on its own. This synaptic connection is indicated with an arrow in the lower portion of the loop. The output of the synapse causes the branch just to the right to fire an action potential that travels in the counterclockwise direction. The action potential spreads around the circle of branches and triggers the synapse which activates the first branch and starts the action potential once again. The result is sustained propagation of an action potential that travels around the loop of branches indefinitely. Shown in the inset is the voltage versus time in one of the branches, indicating recurrent activity.

Having shown that closed loops of branches can be simulated without difficulty, it is easy to see that the method could naturally be extended to simulate large networks of cells connected by chemical or electrical synapses by simply dividing the network into its respective pieces: branches, nodes, and synapses. Synapses could be modeled in a manner similar to nodes, but instead of firing an action potential like a node, a synapse would have an output that matches that of a real synapse and acts in only one direction. Combining synapses with the spatial adaptivity algorithm would require that synapses perform the same listening task as the nodes but are never allowed to turn off. In this manner, when the synapse begins to have activity, it is always ready to turn on the branches connected to it.

10. Discussion. Two of the most common numerical methods used to solve the equations that describe electrical activity in neurons are Crank–Nicolson and backward Euler. We present a predictor-corrector numerical method to be used with each of these methods that splits a tree into its individual branches. The approaches presented here are advantageous on a number of fronts: (1) They require $O(N)$ operations. (2) They exhibit the same accuracy, respectively, as the methods used within the branches. (3) The voltage update for the tree involves solving a linear system for the voltage on each branch instead of one large linear system for the entire tree. The linear system for each branch is relatively much smaller and is truly tridiagonal, allowing for very efficient solution. (4) These methods do not introduce any dense linear systems to be solved for the nodes. (5) This approach provides a framework for spatially adaptive methods and parallel numerical methods. (6) These methods can handle closed loops.

CONSTRUCTING EMBEDDED LATTICE RULES FOR MULTIVARIATE INTEGRATION*

RONALD COOLS†, FRANCES Y. KUO‡, AND DIRK NUYENS†

Abstract. Lattice rules are a family of equal-weight cubature formulae for approximating high-dimensional integrals. By now it is well established that good generating vectors for lattice rules having n points can be constructed component-by-component for integrands belonging to certain weighted function spaces, and that they can achieve the optimal rate of convergence. Although the lattice rules constructed this way are extensible in dimension, they are not extensible in n; thus when n is changed the generating vector needs to be constructed anew. In this paper we introduce a new algorithm for constructing good generating vectors for embedded lattice rules which can be used for a range of n while still being extensible in dimension. By using an adaptation of the fast component-by-component construction algorithm (which makes use of fast Fourier transforms), we are able to obtain good generating vectors for thousands of dimensions and millions of points, under both product weight and order-dependent weight settings, at the cost of $\mathcal{O}(dn(\log(n))^2)$ operations. With a sufficiently large number of points and good overall quality, these embedded lattice rules can be used for practical purposes in the same way as a low-discrepancy sequence. We show for a range of weight settings in an unanchored Sobolev space that our embedded lattice rules achieve the same (optimal) rate of convergence $\mathcal{O}(n^{-1+\delta})$, $\delta > 0$, as those constructed for a fixed number of points, and that the implied constant gains only a factor of 1.30 to 1.55.

Key words. numerical integration, quasi-Monte Carlo methods, rank-1 lattice rules, fast component-by-component construction, embedded lattice rules, extensible lattice sequences

1. Introduction.

Integrals with hundreds or even thousands of dimensions occur in many practical applications in areas such as statistics and mathematical finance. After some appropriate transformations, these integrals can be formulated over the d-dimensional unit cube $[0,1]^d$:

$$I_d(f) = \int_0^1 \cdots \int_0^1 f(x_1, \ldots, x_d)\, \mathrm{d}x_1 \cdots \mathrm{d}x_d = \int_{[0,1]^d} f(\boldsymbol{x})\, \mathrm{d}\boldsymbol{x}\,,$$

where f is a function of d variables and $\boldsymbol{x} = (x_1, \ldots, x_d)$. In this paper we develop an algorithm for constructing "embedded lattice rules" for evaluating such integrals, in the mathematical setting of "weighted reproducing kernel Hilbert spaces." The details about our methods and our function space settings will be discussed in the next section. Here in the introduction we shall give a general overview of the historical background relevant to the new construction.

When d is large, it is too costly to approximate these integrals using product rules based on low-dimensional integration formulae. The [illegible] is an

equal-weight cubature rule of the form

$$Q_{n,d}(f) \;=\; \frac{1}{n}\sum_{k=0}^{n-1} f(\boldsymbol{t}_k)\,,$$

where the n cubature points $\boldsymbol{t}_0,\ldots,\boldsymbol{t}_{n-1}$ are independent and identically distributed uniform random samples from $[0,1]^d$. The expected error for the Monte Carlo method is $\sigma(f)/\sqrt{n}$, where $\sigma^2(f)$ is the variance of f. This leads to a rate of convergence of $\mathcal{O}(n^{-1/2})$ and the convergence is independent of the dimension d provided that $f \in L_2([0,1]^d)$. [illegible] have the same form as the Monte Carlo method, but the cubature points $\boldsymbol{t}_0,\ldots,\boldsymbol{t}_{n-1}$, instead of being generated randomly, are chosen deterministically, in the hope of obtaining a better rate of convergence than the Monte Carlo order $\mathcal{O}(n^{-1/2})$. QMC error bounds are typically in the form of a Koksma–Hlawka-type inequality

$$|I_d(f) - Q_{n,d}(f)| \;\le\; D(\boldsymbol{t}_0,\ldots,\boldsymbol{t}_{n-1})\,V(f)\,, \tag{1.1}$$

where $D(\boldsymbol{t}_0,\ldots,\boldsymbol{t}_{n-1})$ is the [illegible] which measures the nonuniformity of the point set, and $V(f)$ measures the variability of f. Error bounds of this form separate the dependence on the cubature points from the dependence on the integrand. In general we do not have control over the integrand and so we focus on choosing cubature points so that the discrepancy is as small as possible. QMC point sets with discrepancy of order $\mathcal{O}(n^{-1}(\log n)^d)$ or better are collectively known as [illegible] (see, e.g., [12]). This includes, for example, the well-known Sobol′ sequences and Niederreiter sequences. Note that the word "sequences" used in this context implies a special feature: the construction of the point set is independent of the number of points n and the dimension d. Thus these low-discrepancy sequences are "extensible" in the sense that if we need more cubature points or if we need to increase the dimension, we need only to compute the additional points or the additional components of the points.

Lattice rules are a family of QMC rules which were traditionally used to approximate integrals of periodic functions. The oldest and simplest form of lattice rules, now known as [illegible], have the point set

$$\left\{\left\{\frac{k\boldsymbol{z}}{n}\right\} : k = 0,1,\ldots,n-1\right\}.$$

Here $\boldsymbol{z} = (z_1,\ldots,z_d)$, known as the [illegible], is a d-dimensional integer vector having no factor in common with n, and the braces around a vector indicate that each component of the vector is to be replaced by its fractional part. Lattice point sets are low-discrepancy point sets although their constructions are typically not extensible. For a long time the most popular way to construct lattice rules in higher dimensions was to take the generating vector of the [illegible]:

$$\boldsymbol{z} \;=\; (1,a,a^2,\ldots,a^{d-1}) \bmod n\,, \qquad 1 \le a \le n-1,\ \gcd(a,n) = 1\,. \tag{1.2}$$

For a given value of n and a given value of d, an optimal value of a can be chosen by minimizing some discrepancy measure. However, this value of a is only good for the specific pair of n and d, and so if either n or d is changed, we need to obtain a new value of a. (One could use a chosen value of a for higher dimensions simply by taking higher powers of a modulo n, in which case the projections of the points over

consecutive dimensions will remain stationary. Unfortunately, this does not guarantee that the discrepancy measure which we are interested in will remain small.)

In 2002 Sloan and his collaborators (see, e.g., [16]) developed the "component-by-component (CBC)" construction: the components of $\boldsymbol{z}$ are constructed one at a time to minimize the [illegible] in some weighted function space. The details about worst-case analysis and weighted function spaces will be given in the next section. For now we can think of the worst-case error as some form of discrepancy which measures the quality of our lattice rule. Let $e_{n,d}(\boldsymbol{z}) = e_{n,d}(z_1, \ldots, z_d)$ denote the worst-case error for a rank-1 lattice rule with generating vector $\boldsymbol{z}$. The CBC algorithm is as follows.

ALGORITHM 1 (CBC algorithm). [illegible] n

1. [illegible] $z_1 = 1$
2. [illegible] $d = 2, 3, \ldots$
   [illegible] $z_1, \ldots, z_{d-1}$ [illegible]
   [illegible] z_d [illegible] $\{1 \le z \le n-1 : \gcd(z,n) = 1\}$
   [illegible] $e_{n,d}(z_1, \ldots, z_{d-1}, z_d)$

This construction is extensible in d in the sense that if further dimensions are needed, the algorithm can be restarted in an obvious way. It is, however, not extensible in n and so a different value of n means that a completely new $\boldsymbol{z}$ must be constructed.

It has been proved by Hickernell and Niederreiter in 2003 (see [8]) that good generating vectors for extensible lattice sequences do exist; that is, there exists some vector $\boldsymbol{z}$ which is good for all n and all d. However their proof is nonconstructive and it leaves no clues as to how to find such a vector $\boldsymbol{z}$. Since n can be arbitrarily large, the components of the generating vector $\boldsymbol{z}$ can also be arbitrarily large, making it rather difficult to find one generating vector that is good simultaneously for all values of n. Back in 2000, Hickernell and his collaborators (see [7]) had already experimented with the construction of extensible lattice sequences in an empirical setting. By assuming that

$$n = b^m, \quad b \ge 2, \quad m_1 \le m \le m_2, \quad \text{and} \quad 1 \le d \le d_{\max},$$

they designed an algorithm which finds a generating vector of the Korobov form (1.2), with the parameter a chosen by minimizing a loss function

$$G_{m_1,m_2,d_{\max}}(a) := \max_{\substack{m_1 \le m \le m_2 \\ 1 \le d \le d_{\max}}} \frac{D_{b^m,d}(a)}{D^{(\mathrm{asy})}_{b^m,d}}.$$

Here $D_{b^m,d}(a)$ is some discrepancy measure for a d-dimensional b^m-point lattice rule with Korobov parameter a, and $D^{(\mathrm{asy})}_{b^m,d}$ is some asymptotically derived normalization chosen to ensure that for various values of m and d the discrepancy $D_{b^m,d}(a)$ is scaled appropriately for comparison.

Lattice rules constructed in [7] are not so much "extensible" as "embedded" in their nature, the distinction being that extensible rules would leave n unbounded while embedded rules have n bounded. Therefore, with each d-dimensional generating vector $\boldsymbol{z}$, we have a sequence of point sets

$$\{L_m\}_{m_1 \le m \le m_2},$$

where each L_m is the point set for a lattice rule with b^m points, and all the points in L_m are also points of L_{m+1}. For example, when $b = 2$, the number of points doubles

as we move along the sequence, and each rule in the sequence contains all the points from the previous rule together with an equal number of new points. This embedding property is very attractive in practice because not only can we easily increase the number of points without wasting any function evaluations, but also we can estimate the error based on the results from successive rules in the sequence.

Finally we come to the point where we can discuss our new construction. Our algorithm is similar to that of [7], but rather than making use of the Korobov form, our algorithm is based on CBC constructions and so there is no need to assume that d is bounded. For each m from m_1 to m_2, we use Algorithm 1 to find a generating vector $\boldsymbol{z}^{(m)}$ for a b^m-point rule and we store the resulting worst-case error $e_{b^m,d}(\boldsymbol{z}^{(m)})$ for each $d = 1, 2, \ldots$. We define a new error measure for our embedded lattice rule by

$$X_{m_1,m_2,d}(\boldsymbol{z}) := \max_{m_1 \le m \le m_2} \frac{e_{b^m,d}(\boldsymbol{z})}{e_{b^m,d}(\boldsymbol{z}^{(m)})}, \tag{1.3}$$

where we use $e_{b^m,d}(\boldsymbol{z}^{(m)})$ as our reference error to provide a good normalization. Our new algorithm is as follows.

ALGORITHM 2 (CBC algorithm for embedded lattice rules). [illegible] b m_1 m_2 [illegible] $e_{b^m,d}(\boldsymbol{z}^{(m)})$ [illegible] $m_1 \le m \le m_2$ [illegible] $d = 1, 2, \ldots$

1. [illegible] $z_1 = 1$
2. [illegible] $d = 2, 3, \ldots$
   [illegible] $z_1, \ldots, z_{d-1}$ [illegible]
   [illegible] z_d [illegible] $\{1 \le z \le b^{m_2} - 1 : \gcd(z, b) = 1\}$
   [illegible] $X_{m_1,m_2,d}(z_1, \ldots, z_{d-1}, z_d)$

Just as is the case for the algorithm in [7], our new algorithm does not come with an a priori error bound, nor does it give us a fully extensible lattice sequence that can be used for arbitrarily large n. Having said that, in addition to the bonus that d need not be bounded, our algorithm does have two advantages over the algorithm of [7]. First, it is proved in [10] and in [4] that the CBC algorithm can achieve a rate of convergence of $\mathcal{O}(n^{-1+\delta})$, $\delta > 0$, if we "randomly shift" the lattice points (see below). Thus the worst-case error $e_{b^m,d}(\boldsymbol{z}^{(m)})$ can be said to be almost optimal, which means that we are using a fairly reliable normalization. The quantity $X_{m_1,m_2,d}(\boldsymbol{z})$ represents how much worse our chosen vector $\boldsymbol{z}$ is compared with the vectors $\boldsymbol{z}^{(m)}$ which are the near-optimal choices for different $n = b^m$. With all the benefits of having embedded rules, we would be happy with a value of $X_{m_1,m_2,d}(\boldsymbol{z})$ that is no more than 2, and this indeed turns out to be the case in all our computations. Thus in practice our construction comes with an a posteriori worst-case error bound that is of optimal order, and within a factor of 2 of that achieved by the original CBC algorithm.

The second advantage of our algorithm is that, surprisingly, it has a relatively low computational cost. Nuyens and Cools [13, 14] developed a fast implementation of the CBC algorithm by making use of fast Fourier transforms which allows the construction with n in the millions and d in the thousands within a feasible time frame. Thus the precomputation of $\boldsymbol{z}^{(m)}$ for each m can be done in a fast way. In fact if we take b to be prime, our new algorithm based on minimizing $X_{m_1,m_2,d}(\boldsymbol{z})$ can also be done in a fast way, and the cost depends only on m_2 rather than the sum of all m. The total computational cost of Algorithm 2, including the precomputations of Algorithm 1, is $\mathcal{O}(dn(\log(n))^2)$ operations.

The description above was a bit simplified: it is actually "randomly shifted" rank-1 lattice rules that we construct generating vectors for. [illegible] 1 [illegible]

are QMC rules with the point set

$$\left\{ \left\{ \frac{k\boldsymbol{z}}{n} + \boldsymbol{\Delta} \right\} : k = 0, 1, \ldots, n-1 \right\},$$

where $\boldsymbol{z}$ is the generating vector as in a rank-1 lattice rule, and $\boldsymbol{\Delta} \in [0,1]^d$ is the [illegible]. In particular, we are interested in using [illegible] shifts. There are several advantages in doing this: we need only to determine the generating vector; the error expression is simpler (see section 2); and most importantly, we can obtain a probabilistic error estimate (see section 5).

The paper is organized as follows. In section 2 we discuss weighted reproducing kernel Hilbert spaces. We consider weighted Korobov spaces and weighted Sobolev spaces, as it is already known that the CBC algorithm leads to lattice rules which achieve the optimal rate of convergence in these spaces, under suitable conditions on the weights. In section 3 we outline some important properties of embedded lattice rules. In section 4 we discuss the implementation of our new algorithm under two different weight settings: the product weights and the order-dependent weights. We consider lattice rules with $n = b^m$ points, and for simplicity we consider only prime base b. In section 5 we provide some notes on how to use these embedded lattice rules as a sequence and how to obtain practical error estimation by using random shifts. In section 6 we carry out some numerical experiments to see how well our new lattice rules perform for some finance problems. Finally a brief summary is given in section 7. In the appendix we list one generating vector up to 360 dimensions (obtained with $b = 2$, $m_1 = 10$, and $m_2 = 20$) which is good for n ranging from 1024 to 1048576.

2. Function space setting. In this section we briefly review the mechanics behind worst-case analysis in a reproducing kernel Hilbert space and the concept of weighted function spaces. For more details, see, e.g., [6, 17, 5].

2.1. Worst-case analysis in reproducing kernel Hilbert spaces. Suppose that our integrands belong to some reproducing kernel Hilbert space H. A reproducing kernel $K(\boldsymbol{x}, \boldsymbol{y})$ is a symmetric and positive definite function satisfying $K(\boldsymbol{x}, \cdot) \in H$ for all $\boldsymbol{x} \in [0,1]^d$, and $\langle K(\boldsymbol{x}, \cdot), f \rangle_H = f(\boldsymbol{x})$ for all $f \in H$ and all $\boldsymbol{x} \in [0,1]^d$. The existence of a reproducing kernel follows from the Riesz representation theorem, under the assumption that point evaluations are bounded linear functionals in H. We assume that the function $h(\boldsymbol{x}) := \int_{[0,1]^d} K(\boldsymbol{x}, \boldsymbol{y}) \, \mathrm{d}\boldsymbol{y}$ belongs to the space H. Then multivariate integration I_d is a well-defined continuous linear functional, with h as its representer in H, and the [illegible] for multivariate integration is

$$\|I_d\| = \|h\|_H = \left(\int_{[0,1]^{2d}} K(\boldsymbol{x}, \boldsymbol{y}) \, \mathrm{d}\boldsymbol{x} \, \mathrm{d}\boldsymbol{y} \right)^{1/2}.$$

To ensure that H is embedded in $L_2([0,1]^d)$, we assume that $\int_{[0,1]^d} K(\boldsymbol{x}, \boldsymbol{x}) \, \mathrm{d}\boldsymbol{x} < \infty$ which also guarantees that the initial error is finite.

The [illegible] for a QMC rule $Q_{n,d}$ with point set $P_n = \{\boldsymbol{t}_0, \ldots, \boldsymbol{t}_{n-1}\}$ in H is defined by

$$e_{n,d}(P_n, K) := \sup_{f \in H, \, \|f\|_H \le 1} |I_d(f) - Q_{n,d}(f)|.$$

Clearly $|I_d(f) - Q_{n,d}(f)| \le e_{n,d}(P_n, K) \|f\|_H$. Thus the worst-case error can be

thought of as a type of discrepancy measure (see (1.1)). Using the reproducing property of K one can derive an expression for the squared worst-case error

(2.1)
$$e^2_{n,d}(P_n, K) = \int_{[0,1]^{2d}} K(\boldsymbol{x},\boldsymbol{y})\,\mathrm{d}\boldsymbol{x}\,\mathrm{d}\boldsymbol{y} - \frac{2}{n}\sum_{k=0}^{n-1}\int_{[0,1]^d} K(\boldsymbol{t}_k,\boldsymbol{x})\,\mathrm{d}\boldsymbol{x} + \frac{1}{n^2}\sum_{k=0}^{n-1}\sum_{\ell=0}^{n-1} K(\boldsymbol{t}_k,\boldsymbol{t}_\ell).$$

This explicit expression is especially useful when the reproducing kernel has a simple closed form.

The error expression is simpler for [illegible] kernels. A shift-invariant kernel is one which satisfies

$$K(\{\boldsymbol{x}+\boldsymbol{\Delta}\},\{\boldsymbol{y}+\boldsymbol{\Delta}\}) = K(\boldsymbol{x},\boldsymbol{y}) = K(\{\boldsymbol{x}-\boldsymbol{y}\},\boldsymbol{0}) \qquad \forall \boldsymbol{x},\boldsymbol{y},\boldsymbol{\Delta}\in[0,1]^d\,.$$

For any arbitrary kernel K, there is an associated shift-invariant kernel K^{sh} defined by

$$K^{\mathrm{sh}}(\boldsymbol{x},\boldsymbol{y}) := \int_{[0,1]^d} K(\{\boldsymbol{x}+\boldsymbol{\Delta}\},\{\boldsymbol{y}+\boldsymbol{\Delta}\})\,\mathrm{d}\boldsymbol{\Delta}\,.$$

Let $P_n+\boldsymbol{\Delta} := \{\{\boldsymbol{t}+\boldsymbol{\Delta}\} : \boldsymbol{t}\in P_n\}$ denote the point set obtained by adding a shift $\boldsymbol{\Delta}$ to every point in P_n and then taking the fractional part of every component. One can easily derive the important property that

$$\begin{aligned} e^2_{n,d}(P_n, K^{\mathrm{sh}}) &= \int_{[0,1]^d} e^2_{n,d}(P_n+\boldsymbol{\Delta}, K)\,\mathrm{d}\boldsymbol{\Delta} \\ &= -\int_{[0,1]^d} K^{\mathrm{sh}}(\boldsymbol{x},\boldsymbol{0})\,\mathrm{d}\boldsymbol{x} + \frac{1}{n^2}\sum_{k=0}^{n-1}\sum_{\ell=0}^{n-1} K^{\mathrm{sh}}\left(\{\boldsymbol{t}_k-\boldsymbol{t}_\ell\},\boldsymbol{0}\right). \end{aligned} \tag{2.2}$$

We want to use randomly shifted rank-1 lattice rules in the function space with kernel K. It makes sense to study this "shift-averaged" error given by (2.2). In addition, the double sum reduces to a single sum for lattice rules; explicitly we have

$$e^2_{n,d}(\boldsymbol{z}) = -\int_{[0,1]^d} K^{\mathrm{sh}}(\boldsymbol{x},\boldsymbol{0})\,\mathrm{d}\boldsymbol{x} + \frac{1}{n}\sum_{k=0}^{n-1} K^{\mathrm{sh}}\left(\left\{\tfrac{k\boldsymbol{z}}{n}\right\},\boldsymbol{0}\right). \tag{2.3}$$

We shall refer to this quantity as [illegible] 1 [illegible], and it is this worst-case error which we shall consider throughout the rest of the paper. Note that $K^{\mathrm{sh}} = K$ if K is already shift-invariant.

2.2. Weighted function spaces. In this paper we consider reproducing kernel Hilbert spaces H with kernels of the form

$$K(\boldsymbol{x},\boldsymbol{y}) = \sum_{\mathfrak{u}\subseteq\{1,\ldots,d\}} \gamma_{\mathfrak{u}} \prod_{j\in\mathfrak{u}} \eta(x_j,y_j)\,,$$

with $\eta(x,y)=\eta(y,x)$. This general form of kernels has been considered in [17, 5]. The space H is a direct sum of 2^d reproducing kernel Hilbert spaces $H_{\mathfrak{u}}$, where each $H_{\mathfrak{u}}$ is a $|\mathfrak{u}|$-dimensional tensor-product space with kernel $K_{\mathfrak{u}}(\boldsymbol{x}_{\mathfrak{u}},\boldsymbol{y}_{\mathfrak{u}}) = \gamma_{\mathfrak{u}}\prod_{j\in\mathfrak{u}}\eta(x_j,y_j)$.

Functions in $H_{\mathfrak{u}}$ depend only on the set of variables $\boldsymbol{x}_{\mathfrak{u}} := \{x_j : j \in \mathfrak{u}\}$. Functions $f \in H$ have the natural decomposition

$$f(\boldsymbol{x}) = \sum_{\mathfrak{u} \subseteq \{1,\ldots,d\}} f_{\mathfrak{u}}(\boldsymbol{x}_{\mathfrak{u}}), \quad \text{with} \quad f_{\mathfrak{u}}(\boldsymbol{x}_{\mathfrak{u}}) = \langle K_{\mathfrak{u}}(\boldsymbol{x}_u, \cdot), f \rangle_H \quad \text{and} \quad f_{\mathfrak{u}} \in H_{\mathfrak{u}}.$$

We associate a [illegible] parameter $\gamma_{\mathfrak{u}}$ with each set of variables $\boldsymbol{x}_{\mathfrak{u}}$, which describes the level of [illegible] between the variables in $\boldsymbol{x}_{\mathfrak{u}}$. The 2^d weights $\gamma_{\mathfrak{u}}$ together model the relative importance between various sets of variables. Roughly speaking, a small $\gamma_{\mathfrak{u}}$ means that the contribution of the term $f_{\mathfrak{u}}$ is small compared with the other terms. To fix the scaling we set $\gamma_\emptyset = 1$. The limiting case of $\gamma_{\mathfrak{u}} = 0$ implies that there is no $f_{\mathfrak{u}}$ term in the decomposition, or in other words, there is no interaction between the variables in $\boldsymbol{x}_{\mathfrak{u}}$.

The worst-case error for randomly shifted rank-1 lattice rules (see (2.3)) is expressed in terms of the associated shift-invariant kernel

$$K^{\mathrm{sh}}(\boldsymbol{x}, \boldsymbol{y}) = \sum_{\mathfrak{u} \subseteq \{1,\ldots,d\}} \gamma_{\mathfrak{u}} \prod_{j \in \mathfrak{u}} \omega(\{x_j - y_j\}), \quad \text{with} \quad \omega(x) = \int_0^1 \eta(\{x + \Delta\}, \Delta) \, \mathrm{d}\Delta.$$

Note that ω is symmetric, i.e., $\omega(x) = \omega(1-x)$. For simplicity we impose the additional condition $\int_0^1 \omega(x) \, \mathrm{d}x = 0$. The initial error is then 1 and the worst-case error (2.3) then satisfies

$$e^2_{n,d}(\boldsymbol{z}) = -1 + \frac{1}{n} \sum_{k=0}^{n-1} \sum_{\mathfrak{u} \subseteq \{1,\ldots,d\}} \gamma_{\mathfrak{u}} \prod_{j \in \mathfrak{u}} \omega\left(\left\{\tfrac{k z_j}{n}\right\}\right). \tag{2.4}$$

(If the initial error were not 1, we could consider instead the relative error; that is, we divide $e^2_{n,d}(\boldsymbol{z})$ by the squared initial error. The expression for the relative error would be of the same form as (2.4), but with rescaled weights $\gamma_{\mathfrak{u}}$.)

To have a function space that best describes our integrand f, we must choose the weights $\gamma_{\mathfrak{u}}$ according to the dimension structure of f. (See [3] for two notions of [illegible], and see [19] for numerical schemes to estimate them.) When the nominal dimension is d, there are 2^d weights $\gamma_{\mathfrak{u}}$ to decide upon. Here are a few options to help limit the choices.

(i) [illegible]. Here $\gamma_{\mathfrak{u}} := \prod_{j \in \mathfrak{u}} \gamma_{\{j\}}$; that is, the weight associated with the set of variables $\boldsymbol{x}_{\mathfrak{u}}$ is automatically assigned the product of the weights for each individual variable x_j in this set. The product-weight setting leads to a tensor-product space H, and the worst-case error for randomly shifted rank-1 lattice rules satisfies

$$e^2_{n,d}(\boldsymbol{z}) = -1 + \frac{1}{n} \sum_{k=0}^{n-1} \prod_{j=1}^{d} \left(1 + \gamma_j \, \omega\left(\left\{\tfrac{k z_j}{n}\right\}\right)\right).$$

(ii) [illegible]. Here $\gamma_{\mathfrak{u}} := \Gamma_{|\mathfrak{u}|}$; that is, the weight associated with the set of variables $\boldsymbol{x}_{\mathfrak{u}}$ depends only on the cardinality of $\mathfrak{u}$. In this case the worst-case error for randomly shifted rank-1 lattice rules can be written as

$$e^2_{n,d}(\boldsymbol{z}) = \frac{1}{n} \sum_{k=0}^{n-1} \sum_{\ell=1}^{d} \Gamma_\ell \sum_{\substack{\mathfrak{u} \subseteq \{1,\ldots,d\} \\ |\mathfrak{u}| = \ell}} \prod_{j \in \mathfrak{u}} \omega\left(\left\{\tfrac{k z_j}{n}\right\}\right).$$

(iii) [illegible]. Here $\gamma_{\mathfrak{u}} = 0$ for all $|\mathfrak{u}| > q$, with some fixed number q. The finite-order-weight setting can be very useful because many high-dimensional integrals in practice do appear to have a finite order of just 2 or 3. We often combine the finite-order-weight setting with the order-dependent-weight setting.

We end this section with two important examples of such spaces.

[illegible] 1 (weighted Korobov spaces). The weighted Korobov space consists of one-periodic functions with absolutely convergent Fourier series; see, e.g., [5]. The reproducing kernel is already shift-invariant, with

$$\eta(x,y) \,=\, \omega(\{x-y\}) \quad \text{and} \quad \omega(x) \,=\, \sum_{h\in\mathbb{Z}\setminus\{0\}} \frac{e^{2\pi \mathrm{i} h x}}{|h|^{\alpha}}\,,$$

where $\alpha > 1$ is a smoothness parameter which corresponds to the rate of decay of the Fourier coefficients. It is known that good (unshifted or randomly shifted) rank-1 lattice rules can be constructed using the CBC algorithm to achieve the optimal rate of convergence $\mathcal{O}(n^{-\alpha/2+\delta})$, $\delta > 0$ (see [10, 4]). Note that when α is an even integer, ω can be written in terms of the Bernoulli polynomial of degree α:

$$\omega(x) \,=\, \frac{(2\pi)^{\alpha}}{(-1)^{\frac{\alpha}{2}-1}\alpha!} B_{\alpha}(x)\,.$$

[illegible] 2 (weighted Sobolev spaces). The weighted Sobolev space (with smoothness one) consists of functions with square-integrable mixed first derivatives; see, e.g., [17]. These functions are in general nonperiodic. There are a few variants of these spaces depending on how the inner product is defined. One popular variant, now commonly referred to as the [illegible] Sobolev space, corresponds to

$$\eta(x,y) \,=\, \tfrac{1}{2} B_2(\{x-y\}) + \left(x-\tfrac{1}{2}\right)\left(y-\tfrac{1}{2}\right) \quad \text{and} \quad \omega(x) \,=\, B_2(x) \,=\, x^2 - x + \tfrac{1}{6}\,,$$

which satisfies the condition $\int_0^1 \omega(x)\,\mathrm{d}x = 0$. This space has a direct association with the ANOVA decomposition of functions (see, e.g., [3, 19]). It is known that good randomly shifted rank-1 lattice rules can be constructed using the CBC algorithm to achieve the optimal rate of convergence $\mathcal{O}(n^{-1+\delta})$, $\delta > 0$, in a probabilistic sense (see [10, 4]).

3. Properties of embedded lattice rules. Before we get into the ideas behind the fast implementations of CBC algorithms, we need to review some fundamental properties of embedded lattice rules.

Given an integer base $b \geq 2$, a fixed dimension d, and any integer vector $\boldsymbol{z} \in \mathbb{Z}^d$ whose components are all coprime with b, define

$$L_m \,=\, L_m(\boldsymbol{z}) \,:=\, \left\{ \left\{ \frac{k\boldsymbol{z}}{b^m} \right\} : k = 0, 1, \ldots, b^m - 1 \right\}, \quad m = 0, 1, \ldots\,. \tag{3.1}$$

The following properties hold for all $m \geq 0$.

[illegible] 1. Clearly L_m is a point set for a rank-1 lattice rule with b^m distinct points.

[illegible] 2. The generating vector for the lattice point set L_m can be reduced modulo b^m to give the same point set; i.e., $L_m(\boldsymbol{z}) = L_m(\boldsymbol{z} \bmod b^m)$.

[illegible] 3. The lattice point set L_m is embedded in L_{m+1}; i.e., $L_m \subset L_{m+1}$.

[illegible] 4. The points in L_m are exactly those points in L_{m+1} whose indices k in (3.1) are multiples of b.

For a given m, we can construct a generating vector $\boldsymbol{z}$ using Algorithm 1 with $n = b^m$ so that L_m is a "good" lattice point set with b^m points. Due to Property 2, we can restrict our search for the components of $\boldsymbol{z}$ to a finite set as indicated in Algorithm 1, with the largest possible choice being $b^m - 1$. Note that the goodness of the point set L_m in no way implies that all smaller lattice point sets embedded in L_m are good. On the contrary, it is quite possible that the same generating vector $\boldsymbol{z}$ leads to a very poor point set L_ℓ for $\ell < m$ (as will be demonstrated in section 6.1).

This brings us to Algorithm 2, where a generating vector $\boldsymbol{z}$ is constructed with the hope that the lattice point sets L_m, for all values of m in a finite range $m_1 \le m \le m_2$, would be good simultaneously. The assumption that m is bounded from above by m_2 means that the maximum number of points is b^{m_2}; hence we can restrict the components of $\boldsymbol{z}$ to be at most $b^{m_2} - 1$, ensuring a finite search space. The quality of this generating vector $\boldsymbol{z}$ is assessed by the error measure $X_{m_1,m_2,d}(\boldsymbol{z})$ defined in (1.3), which compares the worst-case error of $\boldsymbol{z}$ with the worst-case error of the near-optimal generating vectors constructed by Algorithm 1 for each m in our range. Put differently, $X_{m_1,m_2,d}(\boldsymbol{z})$ measures how much worse than optimal our "one for all" vector $\boldsymbol{z}$ is, and Algorithm 2 selects a vector $\boldsymbol{z}$ so that $X_{m_1,m_2,d}(\boldsymbol{z})$ is as small as possible for m in the prescribed range. This can be described as the "mini-max" optimization of the worst-case error ratios. The quality of $\boldsymbol{z}$ as a "one for all" vector is ensured as long as $X_{m_1,m_2,d}(\boldsymbol{z})$ is uniformly bounded by a small constant, say, 2.

4. Fast construction of embedded lattice rules. Before we can use Algorithm 2, we need to use Algorithm 1 to find the near-optimal generating vectors for each m from m_1 to m_2 and store the worst-case errors in each dimension. The apparent cost of Algorithm 1 for n points up to dimension d is $\mathcal{O}(d^2n^2)$, and so the cost of the precomputations for Algorithm 2 up to $n = b^{m_2}$ points can be $\mathcal{O}(d^2n^2\log(n))$. Once this is done, the cost of Algorithm 2 appears to be another $\mathcal{O}(d^2n^2\log(n))$. Thus unless we can speed up the computations in some way, Algorithm 2 would be a mere theoretical exercise.

Three ideas are used to obtain a fast alternative for Algorithm 2 (the first two were already known for Algorithm 1).

(i) The nature of the CBC algorithm is iterative with respect to the dimension. Therefore we will store previous calculations, sacrificing memory for speed. This reduces the construction cost of Algorithm 1 to $\mathcal{O}(dn^2)$.

(ii) The calculation of the worst-case errors resembles a structured matrix-vector product which can be computed in a fast way. Thus the construction cost of Algorithm 1 can be dramatically reduced, to $\mathcal{O}(dn\log(n))$, implying that the cost of the precomputations for Algorithm 2 is $\mathcal{O}(dn(\log(n))^2)$.

(iii) The calculation of the worst-case error $e_{n,d}(\boldsymbol{z})$ for the maximum number of points $n = b^{m_2}$ contains within it all worst-case errors $e_{b^m,d}(\boldsymbol{z})$ for $m \le m_2$. This means that, with a slight adaptation of the algorithm, the actual cost of Algorithm 2 is only $\mathcal{O}(dn\log(n))$ while the cost for those precomputations based on Algorithm 1 is $\mathcal{O}(dn(\log(n))^2)$. In other words, we get the embedded rule almost for free.

In the next three subsections we will explain these ideas as independently of each other as possible.

4.1. Matrix-vector formulation. Suppose we are at the point in the CBC algorithm where we want to choose the dth component z_d. It makes sense to consider the squared worst-case error $e^2_{n,d}(\boldsymbol{z}) = e^2_{n,d}(z_1,\dots,z_d)$ as a function of z_d, and we denote it by $E^2_d(z_d)$. First we will rewrite the expression for $E^2_d(z_d)$ in a form that is

more suitable for recursion with respect to d. For computational efficiency we consider only two types of weights.

(i) [illegible]:

$$E_d^2(z_d) \;=\; -1 + \frac{1}{n}\sum_{k=0}^{n-1}\left(1+\gamma_d\,\omega\left(\left\{\frac{kz_d}{n}\right\}\right)\right)\underbrace{\prod_{j=1}^{d-1}\left(1+\gamma_j\,\omega\left(\left\{\frac{kz_j}{n}\right\}\right)\right)}_{p_{d-1}(k)}$$

$$= e_{n,d-1}^2(z_1,\ldots,z_{d-1}) + \frac{\gamma_d}{n}\sum_{k=0}^{n-1}\omega\left(\left\{\frac{kz_d}{n}\right\}\right)p_{d-1}(k)\,, \tag{4.1}$$

where $e_{n,0}^2 := 0$ and the products $p_d(k)$ are defined recursively by

$$\begin{aligned} p_0(k) &:= 1\,,\\ p_d(k) &:= \left(1+\gamma_d\,\omega\left(\left\{\tfrac{kz_d}{n}\right\}\right)\right)p_{d-1}(k)\,. \end{aligned} \tag{4.2}$$

(ii) [illegible] (q):

$$E_d^2(z_d) \;=\; \frac{1}{n}\sum_{k=0}^{n-1}\sum_{\ell=1}^{\min(q,d)}\Gamma_\ell\left(\underbrace{\sum_{\substack{\mathfrak{u}\subseteq\{1,\ldots,d-1\}\\|\mathfrak{u}|=\ell}}\prod_{j\in\mathfrak{u}}\omega\left(\left\{\frac{kz_j}{n}\right\}\right)}_{p_{d-1,\ell}(k)} + \omega\left(\left\{\frac{kz_d}{n}\right\}\right)\underbrace{\sum_{\substack{\mathfrak{u}\subseteq\{1,\ldots,d-1\}\\|\mathfrak{u}|=\ell-1}}\prod_{j\in\mathfrak{u}}\omega\left(\left\{\frac{kz_j}{n}\right\}\right)}_{p_{d-1,\ell-1}(k)}\right)$$

$$= e_{n,d-1}^2(z_1,\ldots,z_{d-1}) + \frac{1}{n}\sum_{k=0}^{n-1}\omega\left(\left\{\frac{kz_d}{n}\right\}\right)\left(\sum_{\ell=1}^{\min(q,d)}\Gamma_\ell\,p_{d-1,\ell-1}(k)\right), \tag{4.3}$$

where $e_{n,0}^2 := 0$ and the products $p_{d,\ell}(k)$ are defined recursively by

$$\begin{aligned} p_{d,0}(k) &:= 1\,,\\ p_{d,\ell}(k) &:= p_{d-1,\ell}(k) + \omega\left(\left\{\tfrac{kz_d}{n}\right\}\right)p_{d-1,\ell-1}(k)\,. \end{aligned} \tag{4.4}$$

Let $\mathbb{Z}_n := \{0,1,\ldots,n-1\}$ denote the set of the integers modulo n, and U_n the multiplicative group of integers modulo n, i.e.,

$$U_n \;:=\; \{u\in\mathbb{Z}_n : \gcd(u,n)=1\}\,,$$

with the cardinality of U_n given by the Euler totient function $\phi(n)=|U_n|$. We need to evaluate $E_d^2(z_d)$ for every choice of $z_d\in U_n$, which suggests the definition of the vectors

$$\boldsymbol{E}_d^2 := \left[E_d^2(z)\right]_{z\in U_n}\,,\quad \boldsymbol{p}_d := \left[p_d(k)\right]_{k\in\mathbb{Z}_n}\,,\quad \boldsymbol{p}_{d,\ell} := \left[p_{d,\ell}(k)\right]_{k\in\mathbb{Z}_n} \tag{4.5}$$

and the matrix

$$\boldsymbol{\Omega}_n \;:=\; \left[\omega\left(\left\{\frac{kz}{n}\right\}\right)\right]_{\substack{z\in U_n\\ k\in\mathbb{Z}_n}} \;=\; \left[\omega\left(\frac{kz \bmod n}{n}\right)\right]_{\substack{z\in U_n\\ k\in\mathbb{Z}_n}}. \tag{4.6}$$

We now observe from (4.1) and (4.3) that the squared worst-case error vector $\boldsymbol{E}_d^2$ can be expressed in terms of a matrix-vector product with the matrix $\boldsymbol{\Omega}_n$ as

$$\boldsymbol{E}_d^2 \;:=\; \mathbf{1}_{\phi(n)}\, e_{n,d-1}^2(z_1,\ldots,z_{d-1}) \;+\; \frac{\gamma_d}{n}\,\boldsymbol{\Omega}_n\,\boldsymbol{p}_{d-1} \qquad \text{(product)},$$

$$\boldsymbol{E}_d^2 \;:=\; \mathbf{1}_{\phi(n)}\, e_{n,d-1}^2(z_1,\ldots,z_{d-1}) \;+\; \frac{1}{n}\,\boldsymbol{\Omega}_n \left(\sum_{\ell=1}^{\min(q,d)} \Gamma_\ell\,\boldsymbol{p}_{d-1,\ell-1}\right) \qquad \text{(order-dependent)},$$

where $\mathbf{1}_t$ denotes a vector of ones of length t. Algorithm 1 picks the value of $z_d \in U_n$ which corresponds to the smallest entry in $\boldsymbol{E}_d^2$. Then it is clear from (4.2) and (4.4) that the vectors $\boldsymbol{p}_d$ or $\boldsymbol{p}_{d,\ell}$ for the next iteration can be obtained recursively via

$$\boldsymbol{p}_d \;:=\; (\mathbf{1}_n + \gamma_d\,\boldsymbol{\Omega}_n(z_d)) \mathbin{.*} \boldsymbol{p}_{d-1} \qquad \text{(product)}, \tag{4.7}$$

$$\boldsymbol{p}_{d,\ell} \;:=\; \boldsymbol{p}_{d-1,\ell} + \boldsymbol{\Omega}_n(z_d) \mathbin{.*} \boldsymbol{p}_{d-1,\ell-1} \qquad \text{(order-dependent)}, \tag{4.8}$$

where $\boldsymbol{\Omega}_n(z_d)$ denotes the row of $\boldsymbol{\Omega}_n$ corresponding to the chosen z_d, and the operator $.*$ denotes the element-wise vector multiplication. Since the vectors $\boldsymbol{p}_{d-1}$ or $\boldsymbol{p}_{d-1,\ell}$ are no longer needed in the next iteration, we can simply overwrite $\boldsymbol{p}_{d-1}$ with $\boldsymbol{p}_d$ or overwrite $\boldsymbol{p}_{d-1,\ell}$ with $\boldsymbol{p}_{d,\ell}$. Hence, starting with the vectors $\boldsymbol{p}_0 := \mathbf{1}_n$ or $\boldsymbol{p}_{0,\ell} := \mathbf{1}_n$, we require only $\mathcal{O}(n)$ storage for product weights and $\mathcal{O}(qn)$ storage for order-dependent weights of finite order q.

The trick now is to order the indices $z \in U_n$ and $k \in \mathbb{Z}_n$ in (4.5) and (4.6) in a clever way to allow fast matrix-vector multiplications.

4.2. Fast matrix-vector product. To get an idea of the general concept, we first consider the matrix $\boldsymbol{\Omega}_n$ for n prime. Using the Rader factorization [15, 18], this matrix can be reordered such that it has a circulant submatrix of size $(n-1)\times(n-1)$. This is achieved by taking the indices as $z = g^i$ and $k = g^{-i'}$ for $0 \le i, i' \le n-2$, where g is a primitive root of n (i.e., g is a generator for the cyclic group U_n). We denote this particular ordering of $\boldsymbol{\Omega}_n$ by $\boldsymbol{\Omega}_n^{\langle g\rangle}$.

The effect of such reordering is explained most easily by an example. Take $n = 11$; then the possible components for the generating vector which we want to consider are

$$U_{11} \;=\; \{1,2,3,4,5,6,7,8,9,10\}.$$

Since n is prime, we can always find a generator for this group. For our example we choose $g = 2$. The ordering for the z indices we want to use is then

$$[g^i : 0 \le i \le 9] \;=\; [1,2,4,8,5,10,9,7,3,6].$$

For the indices $k \neq 0$ we take the negative powers of g,

$$[g^{-i'} : 0 \le i' \le 9] \;=\; [1,6,3,7,9,10,5,8,4,2],$$

which can easily be seen as reversing the order of the z indices, but keeping the first index fixed (the zeroth power of g). This reordering, together with a column of zeros

for $k = 0$, gives a matrix with the following structure:

$$\boldsymbol{\Omega}_{11}^{\langle 2\rangle} = \omega \left(\frac{1}{11} \left[\begin{array}{cccccccccc|c} 1 & 6 & 3 & 7 & 9 & 10 & 5 & 8 & 4 & 2 & 0 \\ 2 & 1 & 6 & 3 & 7 & 9 & 10 & 5 & 8 & 4 & 0 \\ 4 & 2 & 1 & 6 & 3 & 7 & 9 & 10 & 5 & 8 & 0 \\ 8 & 4 & 2 & 1 & 6 & 3 & 7 & 9 & 10 & 5 & 0 \\ 5 & 8 & 4 & 2 & 1 & 6 & 3 & 7 & 9 & 10 & 0 \\ 10 & 5 & 8 & 4 & 2 & 1 & 6 & 3 & 7 & 9 & 0 \\ 9 & 10 & 5 & 8 & 4 & 2 & 1 & 6 & 3 & 7 & 0 \\ 7 & 9 & 10 & 5 & 8 & 4 & 2 & 1 & 6 & 3 & 0 \\ 3 & 7 & 9 & 10 & 5 & 8 & 4 & 2 & 1 & 6 & 0 \\ \underbrace{6 \quad 3 \quad 7 \quad 9 \quad 10 \quad 5 \quad 8 \quad 4 \quad 2 \quad 1}_{\boldsymbol{C}_{11}} & 0 \end{array} \right] \right).$$

As was proved in [13], we can halve the number of rows and the number of columns of the submatrix $\boldsymbol{C}_{11}$ due to the symmetry $\omega(x) = \omega(1 - x)$. More specifically, we can write $\boldsymbol{C}_{11}$ in a reduced form (denoted by a $\sim$ instead of $=$)

$$\boldsymbol{\Omega}_{11}^{\langle 2\rangle} \sim \omega \left(\frac{1}{11} \left[\begin{array}{ccccc\|c} 1 & 6 & 3 & 7 & 9 & 0 \\ 2 & 1 & 6 & 3 & 7 & 0 \\ 4 & 2 & 1 & 6 & 3 & 0 \\ 8 & 4 & 2 & 1 & 6 & 0 \\ \underbrace{5 \quad 8 \quad 4 \quad 2 \quad 1}_{\widetilde{\boldsymbol{C}}_{11}} & 0 \end{array} \right] \right),$$

where we remember that the full matrix $\boldsymbol{\Omega}_{11}^{\langle 2\rangle}$ can be obtained by doubling each partition vertically and also horizontally up to the double bar.

A matrix with a structure like the submatrix $\boldsymbol{C}_{11}$ (as well as $\widetilde{\boldsymbol{C}}_{11}$) is called a [illegible] and is completely defined by its first column $\boldsymbol{c}$. Moreover, matrix-vector multiplication with a circulant matrix of order n can be done in $\mathcal{O}(n \log(n))$ using fast Fourier transforms.

LEMMA 4.1 (fast matrix-vector product with a circulant matrix). [illegible] $\boldsymbol{C}_n$ [illegible] n [illegible] $\boldsymbol{c}$ [illegible] $\mathcal{O}(n \log(n))$ [illegible] $\mathcal{O}(n^2)$ [illegible] $\mathcal{O}(n)$ [illegible] $\boldsymbol{F}_n$ [illegible] $\boldsymbol{F}_n^{-1}$

$$\begin{aligned} \boldsymbol{C}_n \, \boldsymbol{x} &= \boldsymbol{F}_n^{-1} \, \operatorname{diag}(\boldsymbol{F}_n \, \boldsymbol{c}) \, \boldsymbol{F}_n \, \boldsymbol{x} \\ &= \operatorname{IFFT}(\operatorname{FFT}(\boldsymbol{c}) \mathbin{.*} \operatorname{FFT}(\boldsymbol{x})) \,. \end{aligned}$$

A fast CBC algorithm based on this fast matrix-vector product was first introduced for n prime in [13] and later extended for composite n in [14]. The general idea for composite n is that the complete matrix $\boldsymbol{\Omega}_n$ can be partitioned in blocks which have a circulant or block-circulant structure. Basically, we consider a vertical partition $\boldsymbol{A}_{d_i}^{\langle g\rangle}$ for each divisor d_i of n

$$\boldsymbol{\Omega}_n^{\langle g\rangle} := \left[\begin{array}{c|c|c|c} \boldsymbol{A}_{d_1}^{\langle g\rangle} & \boldsymbol{A}_{d_2}^{\langle g\rangle} & \cdots & \boldsymbol{A}_{d_\nu}^{\langle g\rangle} \end{array} \right],$$

where g is a generator (or technically, a set of generators) for the group U_n, and each $\boldsymbol{A}_{d_i}^{\langle g\rangle}$ is constructed out of circulant (or technically, nested block-circulant) matrices $\boldsymbol{B}_{n/d_i}^{\langle g\rangle}$. The full details can be found in [14], which describes how the ordering is done and why a matrix-vector multiplication with $\boldsymbol{\Omega}_n^{\langle g\rangle}$ takes $\mathcal{O}(n\log(n))$ time using $\mathcal{O}(n)$ memory.

For embedded lattice rules, we shall restrict ourselves to n being a power of a prime p, because in this case the matrix $\boldsymbol{\Omega}_{p^m}^{\langle g\rangle}$ is of a particularly simple form. For this case we have $|U_{p^m}| = p^{m-1}(p-1)$. We will state the results for $p \neq 2$ and $p = 2$ in two separate theorems below; both results follow from [14, Theorem 4 and Corollary 4]. These two theorems differ in subtle yet crucial ways: the form of the matrices $\boldsymbol{B}_{p^m}^{\langle g\rangle}$ differs, and there are two degenerate cases $\boldsymbol{B}_{2^1}^{\langle 5\rangle}$ and $\boldsymbol{B}_{2^0}^{\langle 5\rangle}$ for $p = 2$, while there is only one degenerate case $\boldsymbol{B}_{p^0}^{\langle g\rangle}$ for $p \neq 2$. In the theorems $\mathbf{1}_t \otimes \boldsymbol{B}$ denotes the stacking of t replications of a matrix $\boldsymbol{B}$.

THEOREM 4.2 (block partitioning $\boldsymbol{\Omega}_{p^m}$, p prime, $p \neq 2$). [illegible]

$$\boldsymbol{\Omega}_{p^m} := \left[\omega\left(\frac{kz \bmod p^m}{p^m}\right)\right]_{\substack{z\in U_{p^m}\\ k\in\mathbb{Z}_{p^m}}},$$

[illegible] $\omega(x) = \omega(1-x)$ [illegible] p^m [illegible]

$$\boldsymbol{\Omega}_{p^m}^{\langle g\rangle} := \left[\begin{array}{c|c|c|c} \mathbf{1}_{p^0}\otimes \boldsymbol{B}_{p^m}^{\langle g\rangle} & \mathbf{1}_{p^1}\otimes \boldsymbol{B}_{p^{m-1}}^{\langle g\rangle} & \cdots & \mathbf{1}_{p^{m-1}}\otimes \boldsymbol{B}_{p^1}^{\langle g\rangle} \;\big|\; \mathbf{1}_{p^{m-1}(p-1)}\otimes \boldsymbol{B}_{p^0}^{\langle g\rangle} \end{array}\right],$$

[illegible] g [illegible] U_{p^m} [illegible] $\boldsymbol{B}_{p^0}^{\langle g\rangle} := [\omega(0)]$ [illegible] $\ell \geq 1$ [illegible] $\boldsymbol{B}_{p^\ell}^{\langle g\rangle}$ [illegible] $p^{m-\ell}$ [illegible]

$$\boldsymbol{B}_{p^\ell}^{\langle g\rangle} := \left[\begin{array}{c|c} \boldsymbol{M}_{p^\ell}^{\langle g\rangle} & \boldsymbol{M}_{p^\ell}^{\langle g\rangle} \\ \hline \boldsymbol{M}_{p^\ell}^{\langle g\rangle} & \boldsymbol{M}_{p^\ell}^{\langle g\rangle} \end{array}\right],$$

[illegible]

$$\boldsymbol{M}_{p^\ell}^{\langle g\rangle} := \left[\omega\left(\frac{kz \bmod p^\ell}{p^\ell}\right)\right]_{\substack{z\in \langle\!\langle g\rangle\!\rangle_{p^\ell}\\ k\in\langle\!\langle g^{-1}\rangle\!\rangle_{p^\ell}}}.$$

[illegible] $\langle\!\langle g\rangle\!\rangle_{p^\ell}$ [illegible] $[g^i \bmod p^\ell : 0 \leq i \leq \phi(p^\ell)/2 - 1]$ [illegible] U_{p^ℓ} [illegible]

THEOREM 4.3 (block partitioning $\boldsymbol{\Omega}_{2^m}$). [illegible]

$$\boldsymbol{\Omega}_{2^m} := \left[\omega\left(\frac{kz \bmod 2^m}{2^m}\right)\right]_{\substack{z\in U_{2^m}\\ k\in\mathbb{Z}_{2^m}}},$$

[illegible] $\omega(x) = \omega(1-x)$ [illegible] 2^m [illegible]

$$\boldsymbol{\Omega}_{2^m}^{\langle 5\rangle} := \left[\begin{array}{c|c|c|c} \mathbf{1}_{2^0}\otimes \boldsymbol{B}_{2^m}^{\langle 5\rangle} & \mathbf{1}_{2^1}\otimes \boldsymbol{B}_{2^{m-1}}^{\langle 5\rangle} & \cdots & \mathbf{1}_{2^{m-1}}\otimes \boldsymbol{B}_{2^1}^{\langle 5\rangle} \;\big|\; \mathbf{1}_{2^{m-1}(2-1)}\otimes \boldsymbol{B}_{2^0}^{\langle 5\rangle} \end{array}\right],$$

[illegible] $\boldsymbol{B}_{2^0}^{\langle 5\rangle} := [\omega(0)]$ [illegible] $\boldsymbol{B}_{2^1}^{\langle 5\rangle} := [\omega(1/2)]$ [illegible] $\ell \geq 2$ [illegible] $\boldsymbol{B}_{2^\ell}^{\langle 5\rangle}$ [illegible] $2^{m-\ell}$ [illegible]

$$\boldsymbol{B}_{2^\ell}^{\langle 5\rangle} := \left[\begin{array}{c|c} \boldsymbol{M}_{2^\ell}^{\langle 5\rangle} & \boldsymbol{M}_{2^\ell}^{\langle 5\rangle} \\ \hline \boldsymbol{M}_{2^\ell}^{\langle 5\rangle} & \boldsymbol{M}_{2^\ell}^{\langle 5\rangle} \end{array}\right], \tag{4.9}$$

$$\boldsymbol{M}_{2^\ell}^{\langle 5\rangle} \;:=\; \left[\omega\left(\frac{kz \bmod 2^\ell}{2^\ell}\right)\right]_{\substack{z\in\langle 5\rangle_{2^\ell}\\ k\in\langle 5^{-1}\rangle_{2^\ell}}} .$$

$\langle 5\rangle_{2^\ell}$ $[5^i \bmod 2^\ell : 0 \le i \le 2^{\ell-2}-1]$ U_{2^ℓ}

We will illustrate this theorem with an example shortly. First we discuss the effect of the symmetry of ω. Note that Theorem 4.3 rests upon the partition

$$U_{2^\ell} \;=\; \langle 5\rangle_{2^\ell} \cup (-1)\langle 5\rangle_{2^\ell} \qquad \text{for } \ell \ge 2\,. \tag{4.10}$$

If we do not make use of the symmetry of ω, formula (4.9) would actually look like

$$\widehat{\boldsymbol{B}}_{2^\ell}^{\langle 5\rangle} \;:=\; \left[\begin{array}{c|c} \boldsymbol{M}_{2^\ell}^{\langle 5\rangle} & \boldsymbol{M}_{2^\ell}^{\langle 5\rangle\star} \\ \hline \boldsymbol{M}_{2^\ell}^{\langle 5\rangle\star} & \boldsymbol{M}_{2^\ell}^{\langle 5\rangle} \end{array}\right], \text{ with } \left\{\begin{array}{rcl} \boldsymbol{M}_{2^\ell}^{\langle 5\rangle} &=& \left[\omega\left(\frac{kz \bmod 2^\ell}{2^\ell}\right)\right]_{\substack{z\in\langle 5\rangle_{2^\ell}\\ k\in\langle 5^{-1}\rangle_{2^\ell}}}, \\ \boldsymbol{M}_{2^\ell}^{\langle 5\rangle\star} &=& \left[\omega\left(\frac{-kz \bmod 2^\ell}{2^\ell}\right)\right]_{\substack{z\in\langle 5\rangle_{2^\ell}\\ k\in\langle 5^{-1}\rangle_{2^\ell}}}, \end{array}\right.$$

and the stacking of the matrices $\widehat{\boldsymbol{B}}_{2^\ell}^{\langle 5\rangle}$ would be

$$\widehat{\boldsymbol{\Omega}}_{2^m}^{\langle 5\rangle} \;:=\; \left[\; \boldsymbol{R}_{2^0}\,\widehat{\boldsymbol{B}}_{2^m}^{\langle 5\rangle} \;\middle|\; \cdots \;\middle|\; \boldsymbol{R}_{2^{m-2}}\,\widehat{\boldsymbol{B}}_{2^2}^{\langle 5\rangle} \;\middle|\; \mathbf{1}_{2^{m-1}} \otimes \boldsymbol{B}_{2^1}^{\langle 5\rangle} \;\middle|\; \mathbf{1}_{2^{m-1}} \otimes \boldsymbol{B}_{2^0}^{\langle 5\rangle} \;\right], \tag{4.11}$$

where $\boldsymbol{R}_{2^\ell} := \boldsymbol{I}_2 \otimes \mathbf{1}_{2^\ell} \otimes \boldsymbol{I}_{2^{m-\ell-2}}$, which stacks the top and bottom half of $\widehat{\boldsymbol{B}}_{2^{m-\ell}}^{\langle 5\rangle}$ separately. The symmetry of ω implies $\boldsymbol{M}_{2^\ell}^{\langle 5\rangle} = \boldsymbol{M}_{2^\ell}^{\langle 5\rangle\star}$ from which the theorem follows.

We consider now the example $n = 2^4 = 16$, initially without using the symmetry of ω. Following (4.10), the first half of U_{16} is generated by 5,

$$[5^i \bmod 16 : 0 \le i \le 3] \;=\; [1, 5, 9, 13]\,,$$

where i stays less than $\phi(n)/2$ since this is only half of the group U_{16}. The second half is a "copy" of this subgroup, but multiplied with $(-1) \equiv 15 \,(\mathrm{mod}\, 16)$,

$$[(-1)\,5^i \bmod 16 : 0 \le i \le 3] \;=\; [15, 11, 7, 3]\,.$$

With this row ordering we can associate a column ordering to get the circulant structure. This can be achieved by reversing the row ordering except for the first element. We obtain the first submatrix for the divisor $2^0 = 1$:

$$\widehat{\boldsymbol{B}}_{16}^{\langle 5\rangle} \;=\; \omega\left(\frac{1}{16}\left[\begin{array}{cccc|cccc} 1 & 13 & 9 & 5 & 15 & 3 & 7 & 11 \\ 5 & 1 & 13 & 9 & 11 & 15 & 3 & 7 \\ 9 & 5 & 1 & 13 & 7 & 11 & 15 & 3 \\ 13 & 9 & 5 & 1 & 3 & 7 & 11 & 15 \\ \hline 15 & 3 & 7 & 11 & 1 & 13 & 9 & 5 \\ 11 & 15 & 3 & 7 & 5 & 1 & 13 & 9 \\ 7 & 11 & 15 & 3 & 9 & 5 & 1 & 13 \\ 3 & 7 & 11 & 15 & 13 & 9 & 5 & 1 \end{array}\right]\right).$$

The submatrices for the other divisors can be constructed similarly, and we get

$$\widehat{\boldsymbol{B}}_8^{\langle 5\rangle} = \omega\left(\frac{1}{8}\left[\begin{array}{cc|cc} 1 & 5 & 7 & 3 \\ 5 & 1 & 3 & 7 \\ \hline 7 & 3 & 1 & 5 \\ 3 & 7 & 5 & 1 \end{array}\right]\right), \widehat{\boldsymbol{B}}_4^{\langle 5\rangle} = \omega\left(\frac{1}{4}\left[\begin{array}{c|c} 1 & 3 \\ \hline 3 & 1 \end{array}\right]\right),$$
$$\boldsymbol{B}_2^{\langle 5\rangle} = \omega\left(\frac{1}{2}\left[\begin{array}{c} 1 \end{array}\right]\right), \boldsymbol{B}_1^{\langle 5\rangle} = \omega(\left[\begin{array}{c} 0 \end{array}\right]).$$

Note that all these matrices (except for the last two trivial ones) have a block-circulant-with-circulant-blocks structure, which is consistent with the two partitions in their multiplicative groups (see (4.10)). Using (4.11), the full matrix looks like this (where italic font means redundancy)

$$\widehat{\boldsymbol{\Omega}}_{16}^{\langle 5\rangle} = \omega\left(\frac{1}{16}\left[\begin{array}{cccc|cccc|cccc|cc|cc} 1 & 13 & 9 & 5 & 15 & 3 & 7 & 11 & 2 & 10 & 14 & 6 & 4 & 12 & 8 & 0 \\ 5 & 1 & 13 & 9 & 11 & 15 & 3 & 7 & 10 & 2 & 6 & 14 & \prime & & & \\ 9 & 5 & 1 & 13 & 7 & 11 & 15 & 3 & & & \prime & \cdot & \prime & & & \\ 13 & 9 & 5 & 1 & 3 & 7 & 11 & 15 & & & \cdot & \prime & \prime & & & \\ \hline 15 & 3 & 7 & 11 & 1 & 13 & 9 & 5 & 14 & 6 & 2 & 10 & 12 & 4 & & \\ 11 & 15 & 3 & 7 & 5 & 1 & 13 & 9 & 6 & 14 & 10 & 2 & & \prime & & \\ 7 & 11 & 15 & 3 & 9 & 5 & 1 & 13 & \prime & \cdot & & & & \prime & & \\ 3 & 7 & 11 & 15 & 13 & 9 & 5 & 1 & \cdot & \prime & & & & \prime & & \end{array}\right)\right).$$

We now apply the symmetry of ω by mapping each $k \in \mathbb{Z}_n$ to $\min(n-k, k)$ and we get the matrix

$$\boldsymbol{\Omega}_{16}^{\langle 5\rangle} = \omega\left(\frac{1}{16}\left[\begin{array}{cccc|cccc|cc|cc|cc} 1 & 3 & 7 & 5 & & & & & 2 & 6 & \cdot & 4 & \prime & 8 & 0 \\ 5 & 1 & 3 & 7 & & & & & 6 & 2 & \cdot & \prime & \prime & & \\ 7 & 5 & 1 & 3 & & & & & \cdot & \cdot & \cdot & \prime & \prime & & \\ 3 & 7 & 5 & 1 & & & & & \cdot & \cdot & \cdot & \prime & \prime & & \\ \hline & & & & & & & & \cdot & \cdot & \cdot & \prime & \prime & & \\ & & & & & & & & \cdot & \cdot & \cdot & \prime & \prime & & \\ & & & & & & & & \cdot & \cdot & \cdot & \prime & \prime & & \\ & & & & & & & & \cdot & \cdot & \cdot & \prime & \prime & & \end{array}\right)\right),$$

as promised in Theorem 4.3. We can then represent this matrix in a reduced form:

$$\boldsymbol{\Omega}_{16}^{\langle 5\rangle} \sim \omega\left(\frac{1}{16}\left[\begin{array}{cccc|cc|c||c|c} 1 & 3 & 7 & 5 & 2 & 6 & 4 & 8 & 0 \\ 5 & 1 & 3 & 7 & 6 & 2 & \prime & & \\ 7 & 5 & 1 & 3 & & \cdot & \prime & & \\ 3 & 7 & 5 & 1 & \cdot & & \prime & & \end{array}\right)\right). \tag{4.12}$$

If we write out the reordering from Theorems 4.2 and 4.3 explicitly by means of permutations $\Pi_g^\top$ and $\Pi_{g^{-1}}$ on the rows and columns induced by g, we obtain

$$\boldsymbol{y} = \boldsymbol{\Omega}_{p^m}\,\boldsymbol{x} \quad \Leftrightarrow \quad \Pi_g^\top\,\boldsymbol{y} = \underbrace{\Pi_g^\top\,\boldsymbol{\Omega}_{p^m}\,\Pi_{g^{-1}}}_{\boldsymbol{\Omega}_{p^m}^{\langle g\rangle}}\,\Pi_{g^{-1}}^\top\,\boldsymbol{x} = \boldsymbol{\Omega}_{p^m}^{\langle g\rangle}\,\Pi_{g^{-1}}^\top\,\boldsymbol{x}.$$

Note that the permutations do not complicate matters, since the starting vectors are all ones and we know that the vectors

$$\begin{aligned}
\boldsymbol{p}_d^{\langle g^{-1}\rangle} &:= \Pi_{g^{-1}}^{\top}\,\boldsymbol{p}_d \;=\; (\mathbf{1}_n + \gamma_d\,\boldsymbol{\Omega}_{p^m}^{\langle g\rangle}(z_d)) \mathbin{.*} \boldsymbol{p}_{d-1}^{\langle g^{-1}\rangle} && \text{(product)},\\
\boldsymbol{p}_{d,\ell}^{\langle g^{-1}\rangle} &:= \Pi_{g^{-1}}^{\top}\,\boldsymbol{p}_{d,\ell} \;=\; \boldsymbol{p}_{d-1,\ell}^{\langle g^{-1}\rangle} + \boldsymbol{\Omega}_{p^m}^{\langle g\rangle}(z_d) \mathbin{.*} \boldsymbol{p}_{d-1,\ell-1}^{\langle g^{-1}\rangle} && \text{(order-dependent)}
\end{aligned}$$

have the same symmetry structure as the rows of the matrix $\boldsymbol{\Omega}_{p^m}^{\langle g\rangle}$, which means that we can keep a reduced version in memory and never have to refer to the unpermuted version. Also, from the resulting vector $\boldsymbol{E}_d^2$ we need only the index of the minimal entry, from which we obtain z_d via the sequence $\langle g\rangle_{p^m}$.

Combining this with Lemma 4.1, we observe that we need only the fast Fourier transforms of the first column of the smaller circulant matrices in the reduced matrix. This requires $\mathcal{O}(n)$ memory. A matrix-vector product with a vector of length $n \times 1$ involves $m+1$ (the number of divisors) smaller matrix-vector products with circulant matrices, with a total cost of

$$\sum_{\ell=0}^{m} \phi(p^{m-\ell}) \log(\phi(p^{m-\ell})) \;=\; \mathcal{O}(n \log(n))\,.$$

We can calculate all these circulant matrix-vector products in turn, starting from the smallest matrix up to the largest matrix, while accumulating the results. In each step the previous result vector is replicated $p-1$ times before the next result vector is added. The summing alone has a memory complexity of $\mathcal{O}(n)$ and a time complexity of $\mathcal{O}(n)$, which is negligible against the $\mathcal{O}(n \log(n))$ cost of the matrix-vector products. Again we specify this as a specialized version of the general case in [14, Theorem 5]. (There is no need for a special summing order as is the case for general n in [14].)

THEOREM 4.4 (fast matrix-vector product $\boldsymbol{\Omega}_{p^m}\,\boldsymbol{p}$). [illegible] $\boldsymbol{\Omega}_{p^m}\,\boldsymbol{p}$ [illegible] $\boldsymbol{p}$ [illegible] (4.7) [illegible] (4.8) [illegible] $\mathcal{O}(n \log(n))$ [illegible] $\mathcal{O}(n)$ [illegible] $\boldsymbol{B}_{p^\ell}^{\langle g\rangle}$ [illegible]

4.3. Exploiting the embedding structure. In Theorems 4.2 and 4.3 we used implicitly the property that a generator g for the group U_{p^m} also generates U_{p^ℓ} for all $\ell \le m$, with the obvious adjustment for $p=2$ where 5 generates U_{2^ℓ} in two partitions for all $\ell \le m$. This actually follows from the fact (see, e.g., [1, section 24.3.4]) that if we have a generator r for U_p, then a generator g for U_{p^ℓ}, $\ell \ge 2$, can be found by taking

$$g \;=\; \begin{cases} r+p & \text{if } r^{p-1} \equiv 1 \,(\mathrm{mod}\, p^2)\,,\\ r & \text{otherwise}\,. \end{cases} \tag{4.13}$$

It can be checked that if one searches for generators in increasing numerical order starting from 2, then the first p for which the smallest generator of U_p does not generate U_{p^2} is as high as 40487 (and the first p for which one of its generators does not generate U_{p^2} is $p=29$). In other words, as long as p is smaller than 40487, the smallest generator of U_p also generates U_{p^ℓ} for all $\ell \ge 1$. Furthermore, the most logical choice in practice is $p=2$ for which we can always pick 5 as a pseudogenerator. This gives us a way to extend a matrix for p^m points to a matrix for p^{m+1} points by simply adding one block in front.

We now show the extension to $\mathbf{\Omega}_{32}^{\langle 5\rangle}$ starting from $\mathbf{\Omega}_{16}^{\langle 5\rangle}$:

$$\mathbf{\Omega}_{32}^{\langle 5\rangle} \;=\; \left[\begin{array}{c|c} \boldsymbol{B}_{32}^{\langle 5\rangle} & \begin{array}{c}\mathbf{\Omega}_{16}^{\langle 5\rangle}\\ \hline \mathbf{\Omega}_{16}^{\langle 5\rangle}\end{array}\end{array}\right],$$

where we have recursively

$$\mathbf{\Omega}_{16}^{\langle 5\rangle} \;=\; \left[\begin{array}{c|c} \boldsymbol{B}_{16}^{\langle 5\rangle} & \begin{array}{c}\mathbf{\Omega}_{8}^{\langle 5\rangle}\\ \hline \mathbf{\Omega}_{8}^{\langle 5\rangle}\end{array}\end{array}\right],\; \mathbf{\Omega}_{8}^{\langle 5\rangle} \;=\; \left[\begin{array}{c|c} \boldsymbol{B}_{8}^{\langle 5\rangle} & \begin{array}{c}\mathbf{\Omega}_{4}^{\langle 5\rangle}\\ \hline \mathbf{\Omega}_{4}^{\langle 5\rangle}\end{array}\end{array}\right],\; \mathbf{\Omega}_{4}^{\langle 5\rangle} \;=\; \left[\begin{array}{c|c} \boldsymbol{B}_{4}^{\langle 5\rangle} & \begin{array}{c}\mathbf{\Omega}_{2}^{\langle 5\rangle}\\ \hline \mathbf{\Omega}_{2}^{\langle 5\rangle}\end{array}\end{array}\right],$$

with $\mathbf{\Omega}_{2}^{\langle 5\rangle} = [\boldsymbol{B}_{2}^{\langle 5\rangle} | \boldsymbol{B}_{1}^{\langle 5\rangle}]$. In reduced form (and a common scaling of $1/32$) we have

$$\mathbf{\Omega}_{32}^{\langle 5\rangle} \sim$$

$$\omega\left(\frac{1}{32}\left[\begin{array}{cccccccc|cccc|cc|c||c|c}
1 & 13 & 9 & 11 & 15 & 3 & 7 & 5 & 2 & 6 & 14 & 10 & 4 & 12 & 8 & 16 & 0\\
5 & 1 & 13 & 9 & 11 & 15 & 3 & 7 & 10 & 2 & 6 & 14 & 12 & 4 & & & \\
7 & 5 & 1 & 13 & 9 & 11 & 15 & 3 & 14 & 10 & 2 & 6 & & & & & \\
3 & 7 & 5 & 1 & 13 & 9 & 11 & 15 & 6 & 14 & 10 & 2 & & & & & \\
15 & 3 & 7 & 5 & 1 & 13 & 9 & 11 & & & & & & & & & \\
11 & 15 & 3 & 7 & 5 & 1 & 13 & 9 & & & & & & & & & \\
9 & 11 & 15 & 3 & 7 & 5 & 1 & 13 & & & & & & & & & \\
13 & 9 & 11 & 15 & 3 & 7 & 5 & 1 & & & & & & & & &
\end{array}\right]\right).$$

In section 4.2 we explained how to sum up the result vectors of a matrix-vector multiplication with the matrix $\mathbf{\Omega}_{p^m}$ in $\mathcal{O}(n\log(n))$ time. In fact, since n is of the form p^m, any method used to sum up the intermediate result vectors would have been sufficient to get at the $\mathcal{O}(n\log(n))$ time complexity (see [14]). By accumulating the result vectors from the smallest matrix upward, we obtain intermediate result vectors which are precisely the matrix-vector products with the matrices $\mathbf{\Omega}_{p^\ell}$ for ℓ going from 0 up to $m-1$. Thus in an attempt to compute $e_{p^m,d}$, we get along the way the values of $e_{p^\ell,d}$ for ℓ from 0 to $m-1$ at no extra cost.

The availability of all these intermediate results is a nice side effect since then the cost for calculating $X_{m_1,m_2,d}$, which involves $e_{p^\ell,d}$ for all ℓ from m_1 to m_2, is no worse than the cost for calculating just $e_{p^{m_2},d}$. This brings us to the main result of this paper.

THEOREM 4.5 (fast construction of embedded lattice rules). $n = p^{m_2}$ p 2 $\mathcal{O}(dn\log(n))$ $\mathcal{O}(n)$ $\mathcal{O}(qn)$ q 1 $\mathcal{O}(dn(\log(n))^2)$

5. Using embedded lattice rules.

5.1. Ordering of lattice points. The main advantage of having a sequence of embedded lattice rules $L_0 \subset L_1 \subset L_2 \subset \cdots$ is that we can increase the number of points without having to throw away already computed function values. When the base is b (not necessarily prime anymore), we increase the number of points by a factor of b at each step along the sequence. For $\ell \geq 1$, let $\Delta L_\ell := L_\ell \setminus L_{\ell-1}$ denote the set of additional points from the point set $L_{\ell-1}$ to L_ℓ. We recall from Property 4 that the points in $L_{\ell-1}$ are generated by the indices k which are multiples of b in $\mathbb{Z}_{b^\ell}$.

Thus we can write

$$L_m \;=\; L_0 \,\cup\, \left(\bigcup_{\ell=1}^{m} \Delta L_\ell \right), \tag{5.1}$$

with $L_0 = \{\mathbf{0}\}$ and

$$\Delta L_\ell \;=\; \left\{ \left\{ \frac{k\boldsymbol{z}}{b^\ell} \right\} : k \in (\mathbb{Z}_{b^\ell} \setminus b\mathbb{Z}_{b^{\ell-1}}) \right\}. \tag{5.2}$$

Letting $m \to \infty$ in (5.1) leads formally to an extensible lattice sequence L_∞ with an infinite number of points. In this paper we consider lattice point sets where the number of points is finite, that is, the union in (5.1) goes only to a predefined upper limit m_2. But, due to the fast construction, this limit can be taken rather large.

Note that the set of additional points ΔL_ℓ from the point set $L_{\ell-1}$ to L_ℓ actually comprises of $b-1$ shifted versions of $L_{\ell-1}$. We put this forward as another property of embedded lattice rules (see also [7, Theorem 2.3]).

[illegible] 5. The lattice point set L_m can be considered as the union of b shifted versions (dependent on $\boldsymbol{z}$) of the lattice point set L_{m-1}, as well as the union of b^2 shifted versions of L_{m-2}, and so on. Trivially, L_m is the union of b^m shifted versions of the initial point $\mathbf{0}$.

Explicitly, we have

$$L_m \;=\; \bigcup_{k_0=0}^{b-1} \cdots \bigcup_{k_\ell=0}^{b-1} \left(L_{m-\ell-1} + \frac{k_\ell \boldsymbol{z}}{b^{m-\ell}} + \cdots + \frac{k_0 \boldsymbol{z}}{b^m} \right) \quad \forall\, \ell = 0, \ldots, m-1\,,$$

where the addition is interpreted as in the definition $P_n + \boldsymbol{\Delta} := \{\{\boldsymbol{t} + \boldsymbol{\Delta}\} : \boldsymbol{t} \in P_n\}$ (the inner braces indicate taking the fractional part).

With the generating vector constructed by Algorithm 2 for n ranging from b^{m_1} to b^{m_2}, we can start with an approximation of the integral using the point set L_{m_1}, and then gradually add blocks of additional points $\Delta L_{m_1+1}, \Delta L_{m_1+2}, \ldots, \Delta L_{m_2}$ until we are satisfied with the error (provided that m_2 is large enough). This usage of the sequence of embedded lattice rules is justified by the knowledge that every lattice point set L_m is good for $m_1 \le m \le m_2$.

A more interesting usage would be to apply the lattice rule one point at a time, i.e., as a low-discrepancy sequence. Since we may end up with an incomplete lattice point set, there is no guarantee that these additional points will be well distributed over the unit cube, and we could even end up with these points all falling in one half of the cube. In fact, we are sure to get a bad ordering of the points if we generate the points from each block ΔL_ℓ according to the natural order of the k indices in (5.2). The solution to this inappropriate ordering of the points is given by replacing k/b^ℓ in (5.2) with the radical inverse function, possibly in combination with Gray code ordering. These schemes provide a better ordering of the numbers k/b^ℓ in the unit interval, and this property is preserved under multiplication by $\boldsymbol{z}$ (and then taking the fractional part) so that the ordering of every one-dimensional projection of the lattice points is good. Both schemes are well-known tools borrowed from the vast literature on digital sequences; see, for example, [12].

The [illegible] function takes an integer in base b and mirrors it around the radix point. For an integer $k = \sum_{\ell=0}^{m-1} k_\ell b^\ell = (k_{m-1} \ldots k_0)_b$ the radical inverse is given as $\phi_b(k) = \sum_{\ell=0}^{m-1} k_\ell b^{-(\ell+1)} = (0.k_0 k_1 \ldots k_{m-1})_b$. The [illegible] variant uses

this same transformation but starts with a Gray code ordering in base b of the k indices (i.e., successive indices differ only in one b-ary digit). The latter is computationally more efficient since then the next index can be obtained from the previous one by a simple digit change and the actual radical inversion can be avoided.

We summarize the usage of these schemes as a property of embedded lattice rules. Note that they preserve the embedding property $L_0 \subset L_1 \subset \cdots$ of the lattice point sets, while providing a better ordering of the points within each block of additional points ΔL_ℓ. More discussions can be found in [7].

PROPERTY 6. The lattice point set L_m can be used as a low-discrepancy sequence if the points are generated in the order

$$\boldsymbol{t}_k \;=\; \{\varphi_b(k)\,\boldsymbol{z}\} \qquad \text{for} \quad k = 0, 1, \ldots, b^m - 1\,,$$

where $\varphi_b(k)$ denotes either the radical inverse $\phi_b(k)$ of k in base b, or the corresponding Gray code variant.

We end this subsection with a simple illustration for the most practical case of $b = 2$:

$$\underbrace{\underbrace{\underbrace{\underbrace{\boldsymbol{t}_0 = \boldsymbol{0}}_{L_0},\ \underbrace{\boldsymbol{t}_1 = \tfrac{\boldsymbol{1}}{\boldsymbol{2}}}_{\Delta L_1}}_{L_1},\ \underbrace{\boldsymbol{t}_2, \boldsymbol{t}_3}_{\Delta L_2}}_{L_2},\ \underbrace{\boldsymbol{t}_4, \boldsymbol{t}_5, \boldsymbol{t}_6, \boldsymbol{t}_7}_{\Delta L_3}}_{L_3},\ \underbrace{\boldsymbol{t}_8, \boldsymbol{t}_9, \boldsymbol{t}_{10}, \boldsymbol{t}_{11}, \boldsymbol{t}_{12}, \boldsymbol{t}_{13}, \boldsymbol{t}_{14}, \boldsymbol{t}_{15}}_{\Delta L_4},\ \ldots\,.}_{L_4}$$

The number of points doubles as we move along the sequence, and the set of additional points ΔL_ℓ is generated by $\{k\boldsymbol{z}/2^\ell\}$ with k running through all the odd numbers up to $2^\ell - 1$. In Table 5.1 we show how the points are ordered under radical inverse and the Gray code variant.

TABLE 5.1
Ordering of lattice points.

	k	Natural order	Radical inverse	Gray code variant
L_0	0	0	0	0
ΔL_1	1	$1/2 = 0.5$	$(0.1)_2 = 0.5$	$(0.1)_2 = 0.5$
ΔL_2	2	$1/4 = 0.25$	$(0.01)_2 = 0.25$	$(0.11)_2 = 0.75$
	3	$3/4 = 0.75$	$(0.11)_2 = 0.75$	$(0.01)_2 = 0.25$
ΔL_3	4	$1/8 = 0.125$	$(0.001)_2 = 0.125$	$(0.011)_2 = 0.375$
	5	$3/8 = 0.375$	$(0.101)_2 = 0.625$	$(0.111)_2 = 0.875$
	6	$5/8 = 0.625$	$(0.011)_2 = 0.375$	$(0.101)_2 = 0.625$
	7	$7/8 = 0.875$	$(0.111)_2 = 0.875$	$(0.001)_2 = 0.125$
ΔL_4	8	$1/16 = 0.0625$	$(0.0001)_2 = 0.0625$	$(0.0011)_2 = 0.1875$
	9	$3/16 = 0.1875$	$(0.1001)_2 = 0.5625$	$(0.1011)_2 = 0.6875$
	10	$5/16 = 0.3125$	$(0.0101)_2 = 0.3125$	$(0.1111)_2 = 0.9375$
	11	$7/16 = 0.4375$	$(0.1101)_2 = 0.8125$	$(0.0111)_2 = 0.4375$
	12	$9/16 = 0.5625$	$(0.0011)_2 = 0.1875$	$(0.0101)_2 = 0.3125$
	13	$11/16 = 0.6875$	$(0.1011)_2 = 0.6875$	$(0.1101)_2 = 0.8125$
	14	$13/16 = 0.8125$	$(0.0111)_2 = 0.4375$	$(0.1001)_2 = 0.5625$
	15	$15/16 = 0.9375$	$(0.1111)_2 = 0.9375$	$(0.0001)_2 = 0.0625$
$\vdots$				

5.2. Error estimation. There is a comprehensive discussion on error estimation in [7] including error estimation based on the embedding structure of the lattice rules. Here we focus only on the simplest form of error estimation using random shifts.

In practice, once we have found a good generating vector $\boldsymbol{z}$, we generate a number of independent random shifts $\boldsymbol{\Delta}_1, \boldsymbol{\Delta}_2, \ldots, \boldsymbol{\Delta}_w$ and compute the approximations $Q_1, Q_2, \ldots, Q_w$, where Q_i is the shifted lattice rule approximation to the integral $I_d(f)$ based on the generating vector $\boldsymbol{z}$ and the shift $\boldsymbol{\Delta}_i$. Then we take the average

$$\overline{Q} := \frac{1}{w}(Q_1 + Q_2 + \cdots + Q_w)$$

as our final approximation to $I_d(f)$. An unbiased estimate for the standard error of our approximation is given by

$$\hat{\sigma} := \sqrt{\frac{1}{w(w-1)} \sum_{i=1}^{w} (Q_i - \overline{Q})^2}\,.$$

Using the Chebyshev inequality we can obtain a $(100 - 100/v^2)\%$ confidence interval $\overline{Q} \pm v\hat{\sigma}$ (with $v > 1$).

6. Numerical experiments.

6.1. Results from CBC construction. We construct good generating vectors of embedded lattice rule up to 360 dimensions using Algorithm 2 for n ranging from 2^{10} to $2^{20} \approx 1$ million (i.e., $b = 2$, $m_1 = 10$, and $m_2 = 20$). Our search criterion is the quantity $X_{m_1,m_2,d}(\boldsymbol{z})$ defined in (1.3), i.e.,

$$X_{10,20,d}(\boldsymbol{z}) \;=\; \max_{10 \le m \le 20} \frac{e_{2^m,d}(\boldsymbol{z})}{e_{2^m,d}(\boldsymbol{z}^{(m)})}\,,$$

where $\boldsymbol{z}^{(m)}$ is the generating vector constructed using Algorithm 1 for a 2^m-point rule (which we refer to as a good "fixed" rule). Let $\boldsymbol{z}^\star$ denote the vector resulting from Algorithm 2. Then the quantity $X_{10,20,d}(\boldsymbol{z}^\star)$ tells us how far off the vector $\boldsymbol{z}^\star$ is compared with the vectors $\boldsymbol{z}^{(m)}$ in terms of the maximum (over m) ratio of the worst-case errors.

We consider weighted Sobolev spaces (see Example 2) with both product weights and order-dependent weights. In particular, we consider equal product weights, decaying product weights, order-2 weights and order-3 weights. Our choices of weights together with the maxima of $X_{10,20,d}$ over all $1 \le d \le 360$ are given in Table 6.1.

TABLE 6.1
Maximum of $X_{10,20,d}(\boldsymbol{z}^\star)$ for various weights.

Weights	$\max_d X_{10,20,d}(\boldsymbol{z}^\star)$
product 1	1.53
product 0.5	1.48
product 0.3	1.47
product 0.1	1.41
product 0.05	1.37
product 0.01	1.30
product 0.9^j	1.50
product 0.75^j	1.42
product 0.5^j	1.30

Weights	$\max_d X_{10,20,d}(\boldsymbol{z}^\star)$
product $1/j$	1.41
product $1/j^2$	1.31
order-2	1.43
order-3 1	1.42
order-3 0.5	1.55
order-3 0.3	1.45
order-3 0.1	1.47
order-3 0.05	1.45
order-3 0.01	1.43

The product-type weights in the table are self-explanatory: "product 0.5" means $\gamma_j = 0.5$ and "product $1/j$" means $\gamma_j = 1/j$. We shall explain briefly our choices of order-2 and order-3 weights. First, since all one-dimensional projections of our lattice rules are left-rectangle rules with all points distinct, the weight Γ_1 in an order-dependent weight setting has no essential effect on the choice of the rule. We thus set $\Gamma_1 = 1$. Second, if we decide to construct a rule based on order-2 weights (i.e., if $\Gamma_\ell = 0$ for $\ell > 2$), then the rule is unique regardless of how we choose Γ_2, since in this case Γ_2 rescales only the worst-case error. Therefore without lost of generality we set $\Gamma_2 = 1$. In other words, such a rule is universally applicable for all order-2 problems. For order-3 weights, the rule depends only on the ratio Γ_3/Γ_2. Hence we use Γ_3 to specify the importance of order-3 interactions compared with order-2 interactions. In our table "order-3 0.1" corresponds to the choice $\Gamma_1 = \Gamma_2 = 1$ and $\Gamma_3 = 0.1$. Note that having equal product weights $\gamma_j = r$ is equivalent to having order-dependent weights with $\Gamma_\ell = r^\ell$. The generating vector for the order-2 rule is given in the appendix. From Table 6.1, the worst-case errors for the order-2 rule in the appendix are within a factor of 1.43 of the worst-case errors obtained with the results from the original CBC construction.

Starting from $X_{10,20,1}(\boldsymbol{z}^\star) = 1$, the empirical observation is that in most cases the numbers $X_{10,20,d}(\boldsymbol{z}^\star)$ increase initially as d increases, and then they decrease from some dimension onward. We see from Table 6.1 that $X_{10,20,d}(\boldsymbol{z}^\star)$ is substantially less than 1.6 for all our choices of weights. Thus we conclude that, in all our experiments, the embedded lattice rules are at most 1.6 times worse than the near-optimal rules constructed from Algorithm 1 for specific values of n. Put differently, we have rules with the optimal rate of convergence, but with a constant which is a factor of at most 1.6 times larger.

Enlarging the range of m reduces the overall quality. Figure 6.1 shows the profile of $X_{10,m_2,d}(\boldsymbol{z}^\star)$ with increasing d for order-2 rules with $m_2 = 15$, 20, and 25.

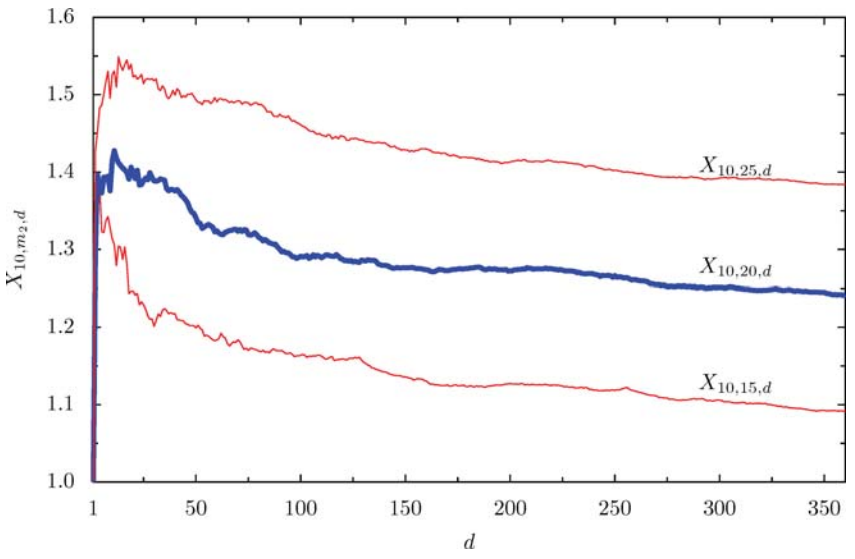

FIG. 6.1. *Profile of $X_{10,m_2,d}(\boldsymbol{z}^\star)$ for order-2 rules with $m_2 = 15$, 20, and 25 as d increases.*

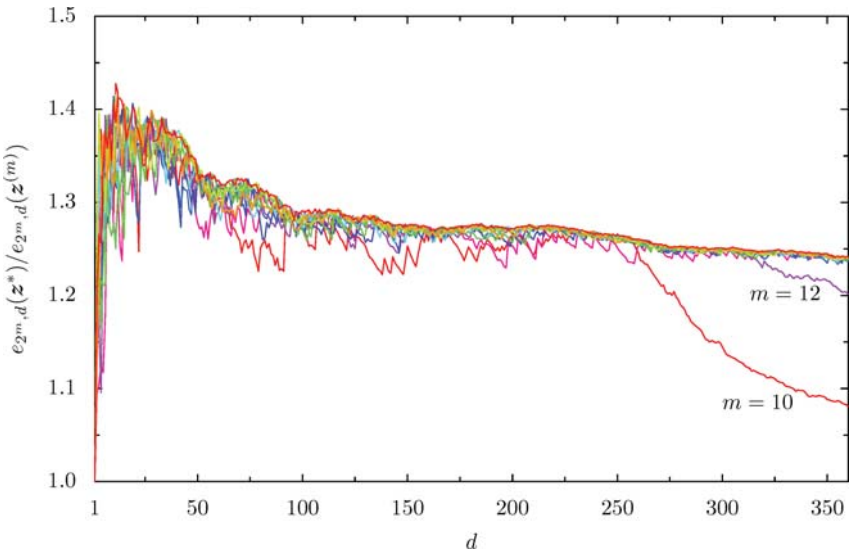

FIG. 6.2. *Initial segments of a good embedded lattice rule.*

It is understandable that by allowing the range of n to grow, the quality of the point set is sacrificed. But we observe that the quality remains very good for all feasible values of m_2.

Using initial segments of a good embedded lattice rule works as expected. The criterion $X_{10,20,d}(\boldsymbol{z}^\star)$ ensures that the resulting vector $\boldsymbol{z}^*$ is good for a 2^m-point rule for all values of m between 10 and 20. In other words, every point set in the embedded sequence $L_{10} \subset L_{11} \subset \cdots \subset L_{20}$ is good. (We refer to the smaller lattice point sets L_ℓ with $\ell < 20$ as the "initial segments" of the point set L_{20}.) In Figure 6.2 we plot the worst-case error ratios

$$\frac{e_{2^m,d}(\boldsymbol{z}^\star)}{e_{2^m,d}(\boldsymbol{z}^{(m)})}$$

for the case of the order-2 rule in the appendix and every $m = 10, \ldots, 20$.

As expected, the maximum of all these graphs corresponds to the graph for $X_{10,20,d}(\boldsymbol{z}^\star)$ in Figure 6.1. For most values of m we do better than $X_{10,20,d}(\boldsymbol{z}^\star)$ promises, but we note that all the individual curves actually stay close to $X_{10,20,d}(\boldsymbol{z}^\star)$. We also see that these curves cross each other in an erratic manner, which is important; otherwise we could redefine the error measure to make use of some assumed ordering. That said, in general it can be observed that the curves for higher m tend to be closer to the top.

For high dimensions we see that the curves for $m = 10$ and $m = 12$ depart from the general trend. This might be explained by observing that the differences between the worst-case errors of different choices for a new component decrease as the dimension increases. In other words, the different choices of generating vectors are equally bad when there are very few points in very high dimensions.

Using initial segments of a good fixed lattice rule does not work. We could wonder if it would be satisfactory to just use the initial segments from a good 2^{20}-point lattice rule with generating vector $\boldsymbol{z}^{(20)}$ constructed by Algorithm 1. (As

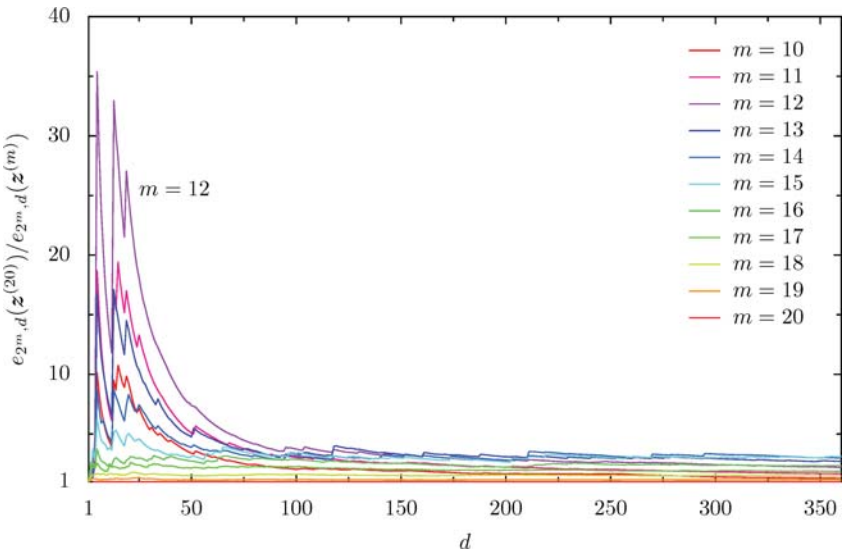

FIG. 6.3. *Initial segments of a good fixed lattice rule.*

before, by initial segments we mean the smaller lattice point sets L_ℓ embedded in L_{20} with $\ell < 20$.) If these initial segments would be any good, then there would be little point to using Algorithm 2. In Figure 6.3 we plot the worst-case error ratios

$$\frac{e_{2^m,d}(\boldsymbol{z}^{(20)})}{e_{2^m,d}(\boldsymbol{z}^{(m)})}$$

for every $m = 10, \ldots, 20$.

It is obvious from the figure that using a large good fixed lattice rule for a maximum number of points $n = 2^{m_2}$ tells one nothing about the goodness of the initial segments of this lattice rule. While $X_{10,20,d}(\boldsymbol{z}^\star)$ is bounded by 1.45 for the good embedded lattice rule, for the fixed lattice rule, the corresponding ratio is 35 times worse than the optimal fixed lattice rule for $m = 12$. Once again there is no direct ordering in these curves, but it is obvious that the curves corresponding to higher m are lower on the graph. For $m = 20$ we have a horizontal line at 1, and the line just above this constant line is the one for $m = 19$. It is not surprising that using half of the points of a good fixed lattice rule would also give a reasonable rule. The maximum of all these curves is clearly very bad. We can draw a very clear conclusion from this graph: the embedded lattice rule constructed by Algorithm 2 works very well in comparison with a more simple-minded strategy.

6.2. Pricing an Asian option. We test the performance of the embedded lattice rules constructed in this paper for calculating the pricing of an Asian call option. This problem is extensively documented, both in the financial literature and in the QMC literature [9, 11, 2]. For an Asian option (also called average option) the payoff is determined by the average value of the underlier (i.e., a stock price) during its lifetime. We will consider a (European style) Asian option with an arithmetic average of d equally spaced stock prices S_j at times $t_j = jT/d$, with expiry time T.

The payoff for such a call option can be written as

$$C(T) \;=\; \max\left(\frac{1}{d}\sum_{j=1}^{d} S_j - K, 0\right) \;=\; \left(\frac{1}{d}\sum_{j=1}^{d} S_j - K\right)^{+},$$

where K is the strike price at the expiry time $T = t_d$. We assume the risk-neutral measure of the Black–Scholes model for the path of the stock prices

$$S_j \;=\; S_0 \exp\left((r - \sigma^2/2)\, t_j + \sigma w_j\right),$$

where S_0 is the initial stock price, r is the risk-free interest rate, σ the volatility of the stock price, and w_j are samples of a Brownian motion at times t_j, i.e., w_j is normally distributed with variance t_j, or $w_j \sim \mathcal{N}(0, t_j)$. This sampled Brownian motion has mean 0 and covariance matrix $\boldsymbol{\Sigma} = [\min(t_i, t_j)]_{i,j=1,\ldots,d}$.

The value of the Asian option at time 0 can then be written as the actualized expected payoff at time T,

$$\begin{aligned} C(0) \;&=\; \mathbb{E}\left(\exp(-rT)\, C(T)\right) \\ &=\; \exp(-rT) \int_{\mathbb{R}^d} \left(\frac{1}{d}\sum_{j=1}^{d} S_0 \exp\left((r - \sigma^2/2)\, t_j + \sigma w_j\right) - K\right)^{+} \mathcal{N}(\boldsymbol{w}; \mathbf{0}, \boldsymbol{\Sigma})\, \mathrm{d}\boldsymbol{w}\,. \end{aligned}$$

We transform this integral to $[0,1]^d$ by using the inverse of the cumulative normal distribution function, Φ^{-1}, and deal with the correlation in our sample points by using a factorization of the covariance matrix, $\boldsymbol{\Sigma} = \boldsymbol{A}^{\top}\boldsymbol{A}$. Then our lattice rule approximation to $C(0)$ is given by

$$\widehat{C}(0) \;=\; \frac{\exp(-rT)}{n} \sum_{k=0}^{n-1} \left(\frac{1}{d}\sum_{j=1}^{d} S_0 \exp\left((r - \sigma^2/2)\, t_j + \sigma w_{k,j}\right) - K\right)^{+},$$

where $\boldsymbol{w}_k = \boldsymbol{A}\, \Phi^{-1}(\boldsymbol{t}_k)$ with lattice point $\boldsymbol{t}_k$ for $k = 0, 1, \ldots, n-1$.

For our particular example we choose the following parameters:

$$S_0 = 100\,, \qquad r = 0.1\,, \qquad \sigma = 0.2\,, \qquad T = 1\,, \qquad K = 100\,, \qquad d = 100\,.$$

We choose the principal component analysis method to factorize the matrix $\boldsymbol{\Sigma}$; that is, $\boldsymbol{A} = [\sqrt{\lambda_1}\boldsymbol{v}_1, \ldots, \sqrt{\lambda_d}\boldsymbol{v}_d]$ where $\lambda_1 \geq \cdots \geq \lambda_d$ are the eigenvalues of $\boldsymbol{\Sigma}$ and $\boldsymbol{v}_1, \ldots, \boldsymbol{v}_d$ are the corresponding unit-length eigenvectors.

In Table 6.2 we present the results obtained with order-2 weights using 10 random shifts. As a comparison we also include results obtained by the Monte Carlo method (where we also used 10 random shifts). In Figure 6.4 we plot the graphs of the standard errors obtained by adding one point at a time. (The values of n in both Table 6.2 and Figure 6.4 correspond to the number of points used from the sequence. Due to the use of 10 random shifts, the actual number of function evaluations in each case is $10n$.) The results for the order-2 rule clearly show a rate of convergence close to $\mathcal{O}(n^{-1})$ while the Monte Carlo error decays like $\mathcal{O}(n^{-1/2})$. Furthermore, the graph assures us that it is quite all right to use the embedded lattice rules as a sequence, since the standard error goes down nicely (with some minor zigzag behavior, as expected) as the number of points is increased one at a time.

7. Conclusion. We presented an algorithm for constructing good embedded lattice rules that are extensible in the dimension d and can be used for any number of points n in a predefined range. The algorithm utilized both the CBC construction principle and the fast implementation idea. For product weights and order-dependent weights, the total construction cost is $\mathcal{O}(dn(\log(n))^2)$ operations, with a linear memory dependence on n. Numerical experiments with the unanchored Sobolev space demonstrated that these rules achieve the same optimal rate of convergence $\mathcal{O}(n^{-1+\delta})$, $\delta > 0$, as those constructed for a fixed number of points, and that the implied constant gains only a factor of 1.30 to 1.55.

Appendix. Order-2 embedded lattice rule for $2^{10} \le n \le 2^{20}$.

MODELING WATER TRANSPORT ACROSS ELASTIC BOUNDARIES USING AN EXPLICIT JUMP METHOD*

ANITA T. LAYTON†

Abstract. A mathematical model is presented to simulate water and solute transport in a highly viscous fluid with a water-permeable, elastic immersed membrane. In this model, fluid motion is described by Stokes flow, whereas water fluxes across the membrane are driven by transmural pressure and solute concentration differences. The elastic forces, arising from the membrane being distorted from its relaxed configuration, and the transmembrane water fluxes introduce into model solutions discontinuities across the membrane. Such discontinuities are faithfully captured using a second-order explicit jump method [A. Mayo, *SIAM J. Numer. Anal.*, 21 (1984), pp. 285–299], in which jumps in the solution and its derivatives are incorporated into a finite-difference scheme. Numerical results suggest that the method exhibits desirable volume accuracy and mass conservation.

Key words. explicit jump, finite difference, immersed boundary, mass conservation, Stokes flow

1. Introduction.

Substantial effort has been directed to developing computational techniques for simulating moving boundaries or interfaces within a viscous fluid domain. Perhaps the most notable example is the immersed boundary method, developed by Peskin [27] for solving the full incompressible Navier–Stokes equations with moving boundaries. The immersed boundary method was originally developed for studying blood flow through a beating heart [26], but has since been applied to a wide variety of problems, including inner ear fluid dynamics [3], bacterial swimming [9], sperm motility in the presence of boundaries [12], ciliary beating [4, 10], and flow through an arteriole [1].

In this paper, we consider a water-permeable but solute-impermeable membrane immersed in a highly viscous fluid. Our goal is to describe a model and a computational technique that accurately simulates the fluid motion, membrane motion, and solute concentration. In the limit of zero Reynolds number, the inertial acceleration and advection terms in the Navier–Stokes equations can be neglected, and the resulting fluid motion can be described using the simpler Stokes equations. Despite their simplicity relative to the full Navier–Stokes equations, the Stokes equations have many applications. Indeed, the Stokes equations with an immersed membrane have been used to simulate the deformation and cleavage of fluid droplets [22] and to simulate biofilms [6].

The method we use to track fluid motion and solute transport is based on a method developed by Mayo for elliptic problems on an irregular domain [24, 25]. Mayo's method is similar to the immersed interface method later developed by LeVeque and Li [18, 19]; see [20] for a review of the immersed interface method. Both methods are second-order Cartesian grid methods (though higher-order immersed interface methods have recently been developed [14, 23]), with the key idea being the incorporation of known jumps in the solution or its derivatives into the finite-difference

schemes. Following Wiegmann and Bube [31], we will refer to the method used in this study as an "explicit jump method."

The immersed boundary or immersed interfacial problems previously investigated have assumed a water-impermeable boundary or membrane, i.e., one that does not allow water movement across. In such models, fluid velocity is continuous across the membrane, and the membrane moves at the same velocity as the local fluid. In contrast, the membrane considered in this work is assumed to be permeable to water but not to solute; water fluxes are assumed to be driven by transmural pressure and solute concentration differences. Water permeability of the membrane is assumed to be finite. As a result of water movement across the membrane, the fluid volume enclosed by the membrane may evolve over time. In addition, transmural water fluxes induce corresponding changes in local solute concentration. A principal goal of this work is to accurately compute these model variables.

2. Model formulation. The model represents an evolving, closed membrane Γ that is assumed to be water permeable. Γ, which we will refer to interchangeably as a membrane or boundary, is assumed to have zero thickness. Γ separates the fluid domain Ω into two subdomains Ω^+ and Ω^-, where Ω^- is the region enclosed by membrane, whereas Ω^+ lies outside. Thus, $\Omega = \Omega^+ + \Omega^- + \Gamma$. The membrane Γ is assumed to be elastic, so that when it is distorted from its relaxed state by stretching or compressing, it exerts a force on the local fluid.

One solute is represented throughout Ω, and the membrane Γ is assumed to be impermeable to the solute. We assume a dilute solution in which the volume occupied by the solute is negligible.

We assume that the viscosity of the fluid is sufficiently high that its dynamics can be modeled as a creeping flow using the Stokes equations. In two dimensions, the Stokes equations take the form

$$p_x(x,y,t) = \mu(u_{xx}(x,y,t) + u_{yy}(x,y,t)) + F_1(x,y,t), \tag{2.1}$$

$$p_y(x,y,t) = \mu(v_{xx}(x,y,t) + v_{yy}(x,y,t)) + F_2(x,y,t), \tag{2.2}$$

$$u_x(x,y,t) + v_y(x,y,t) = 0, \tag{2.3}$$

where u and v are the fluid velocities in the x and y directions, respectively; p is the pressure; $\mu > 0$ is the fluid viscosity, assumed constant throughout Ω; and F_1 and F_2 are the singular force components in the x and y directions, respectively, and are supported only along Γ (see below). Biperiodic boundary condition is assumed for Ω.

The forces F_1 and F_2 are elastic or tension forces that arise from Γ being stretched or compressed. These singular forces can be written as

$$F_i(\vec{x},t) = \int_0^{L_0} f_i(s,t)\delta(\vec{x} - \vec{X}(s,t))ds \tag{2.4}$$

for $i = 1, 2$. L_0 is the length of Γ at its relaxed state; $\vec{x} \in \Omega$ and $\vec{X}(s,t)$ gives the location of Γ at time t, parameterized by the arclength s at the unstretched state for $0 \le s \le L_0$; f_i is the force strength at this point; and δ is the two-dimensional delta function. The force strength f is given by

$$\vec{f}(s,t) = \frac{\partial}{\partial s}\left(T(s,t)\vec{\tau}(s,t)\right), \tag{2.5}$$

where the tension $T(s,t)$ is given by

$$T(s,t) = T_0 \left(\left| \frac{\partial \vec{X}}{\partial s} \right| - 1 \right). \tag{2.6}$$

The tension coefficient T_0 describes the elastic properties of the membrane and is assumed to be a constant in this model. The vector tangential to Γ is given by $\vec{\tau}(s,t)$, where

$$\vec{\tau}(s,t) = \frac{\partial \vec{X}/\partial s}{\left| \partial \vec{X}/\partial s \right|}. \tag{2.7}$$

Thus, the force density can be computed directly from the location $\vec{X}$ of the membrane Γ. Note that at the relaxed state $\partial \vec{X}/\partial s = 1$ and tension vanishes.

A water-impermeable membrane moves at the velocity of the local fluid. That is, if $\vec{X}(s,t)$ denotes the position of Γ at time t at s, then

$$\frac{\partial}{\partial t} \vec{X}(s,t) = \vec{u}(\vec{X}(s,t),t). \tag{2.8}$$

With a water-permeable membrane, some water is allowed to pass through. To handle this case, let $g(s,t)$ denote transmural water transport in the direction normal to Γ at s, assumed positive for outward-directed fluxes. The water flux g can be driven by hydraulic pressure difference or concentration difference across Γ. The velocity of the membrane is then denoted by $\vec{U} \equiv (U,V)$, which is the difference of the local fluid velocity and the water flux:

$$U(\vec{X}(s,t),t) = u(\vec{X}(s,t),t) + g(s,t)\cos\theta, \tag{2.9}$$

$$V(\vec{X}(s,t),t) = v(\vec{X}(s,t),t) - g(s,t)\sin\theta, \tag{2.10}$$

where θ denotes the angle between the tangent line and the x-axis.

Advection and diffusion of the solute is coupled to the fluid velocity (u,v). The advection-diffusion equation is given for a solute of concentration $c(x,y,t)$ by

$$c_t + Gc + c_x u^* + c_y v^* = \nu(c_{xx} + c_{yy}), \tag{2.11}$$

where $\nu > 0$ is the solute diffusivity, assumed constant throughout Ω. We have suppressed in (2.11) the x, y, and t dependence for brevity. The advective velocity (u^*, v^*) is equal to the fluid velocity except at Γ, where it is set to the membrane velocity, i.e.,

$$u^*(\vec{x},t) = u(\vec{x},t), \quad v^*(\vec{x},t) = v(\vec{x},t), \quad \vec{x} \notin \Gamma, \tag{2.12}$$

$$u^*(\vec{x},t) = U(\vec{x},t), \quad v^*(\vec{x},t) = V(\vec{x},t), \quad \vec{x} \in \Gamma. \tag{2.13}$$

The second term on the left of (2.11) represents the changes in c induced by transmural water fluxes, with G given by

$$G(\vec{x},t) = \int_0^{L_0} g(s,t)\delta\left(\vec{x} - \vec{X}^+(s,t)\right) ds - \int_0^{L_0} g(s,t)\delta\left(\vec{x} - \vec{X}^-(s,t)\right) ds. \tag{2.14}$$

Note that G is zero everywhere except along the two sides of Γ, where it is singular. G can be considered as a pair of fluid source and sink, which have equal magnitude

(but opposite directions or signs), and which are singularly supported along each side of the membrane.

Because the membrane is assumed impermeable to the solute, the total amount of solute, given by $\int_{\Omega^\pm} c(\vec{x},t)d\vec{x}$, remains constant inside and outside the membrane for all time t. As water is driven across the membrane, the influx or efflux of water induces a local change in c near the membrane. For example, on the side of Γ where $g < 0$ (i.e., water loss), the solute is locally concentrated. This increase in c would have been singularly supported along Γ if ν were set to 0. In the case where $\nu > 0$, the change in c is finite and affects the entire subdomain (Ω^+ or Ω^-); see below.

3. Numerical method. The model equations (2.1), (2.2), (2.3), and (2.11) together describe the dynamics of the fluid, the position of the membrane, and the solute concentration as functions of time. In this section we present numerical procedures that, given a set of initial conditions, advance the system in time until a steady state is reached.

In the numerical discretization, let $\Delta t > 0$ denote the time step and let $t_n \equiv n\Delta t$ be the nth time-level for $n = 0, 1, \ldots$. Let h denote the spatial grid interval, and let $x_i \equiv ih$ and $y_j \equiv jh$ be the ith and jth spatial grid points along the x- and y-axes, respectively, where $i, j = 0, 1, 2, \ldots, N$. Let $\psi(x_i, y_j, t_n)$ be denoted by $\psi^n_{i,j}$ for an arbitrary function $\psi(x, y, t)$. Owing to the assumption of biperiodic boundary conditions, $\psi(x_0, y_j, t_n) = \psi(x_N, y_j, t_n)$ and $\psi(x_i, y_0, t_n) = \psi(x_i, y_N, t_n)$, and analogous equality applied to the derivatives of ψ.

The position of the membrane at t_n is represented by a set of boundary markers (X^n_k, Y^n_k) for $k = 0, 1, 2, \ldots, N_k$, where $(X^n_0, Y^n_0) = (X^n_{N_k}, Y^n_{N_k})$ because the membrane is assumed to be a simple closed curve. The kth boundary marker approximates $(X(s_k, t_n), Y(s_k, t_n))$, where $s_k = kL_0/N_k$; that is, the boundary markers are chosen such that in an unstretched or relaxed state, they are equally spaced. Let the value of an arbitrary function ψ on each side of Γ be denoted by $\psi_{b^\pm}$, i.e., $\psi_{b^\pm} = \lim_{\epsilon \to 0^+} \psi(\vec{X} \pm \epsilon\vec{n}, t)$, where $\vec{n}$ is the unit vector normal to the membrane. Let the value of ψ at the kth boundary marker (X^n_k, Y^n_k) be denoted by ψ^n_k.

3.1. Jump conditions. As in many immersed boundary problems, the solution of our model is unsmooth. Unless special care is taken, these discontinuities tend to introduce substantial inaccuracy into the computed solution obtained by means of a finite-difference method. One remedy for achieving better accuracy is the approach used in the immersed boundary method and its variants, in which the Dirac delta function in (2.4) and (2.14) is replaced by an approximate or discrete delta function that is smooth and compact, thereby eliminating the singularity in the forces [27]. However, by distributing the force terms to nearby grid points, the discrete delta function approach approximates the discontinuous solutions as continuous functions with large gradients, and thus does not faithfully represent the jump discontinuity in solutions. In our model, this artificial smoothing is particularly problematic for pressure, inasmuch as its jump discontinuity is required in the computation of transmural water fluxes (see the numerical examples in section 4). Thus, we adopt an alternative approach—the explicit jump method based on Mayo [24]. That method is similar to the immersed interface method [20], both of which generate second-order accuracy in space.

An explicit jump method requires that the jump discontinuities in the solution and its derivatives be specified along the membrane. Those jump conditions are specified below. To compute the fluid motion given by (2.1), (2.2), and (2.3), we follow the approach by LeVeque and Li [19], in which (2.1), (2.2), and (2.3) are reduced to a

sequence of three Poisson problems, one for each variable. For the pressure, one solves

$$\nabla^2 p = \nabla \cdot \vec{F}. \tag{3.1}$$

The derivative of the singular force term $\vec{F}$, a dipole source, in the Poisson equation (3.1) renders p discontinuous, along with its derivatives. To define these jump conditions, we let the net jump discontinuity of a function ψ be

$$[\psi(\vec{X},t)] = \lim_{\epsilon \to 0^+} \psi(\vec{X}^+ + \epsilon\vec{n},t) - \lim_{\epsilon \to 0^+} \psi(\vec{X}^- - \epsilon\vec{n},t). \tag{3.2}$$

With this notation, the jump conditions for pressure are given by

$$[p(s,t)] = f_n(s,t), \quad [p_n(s,t)] = \frac{\partial}{\partial s} f_\tau(s,t), \tag{3.3}$$

where f_n and f_τ denote the normal and tangential components of $\vec{f}$, respectively. The derivation of (3.3) can be found in [19].

Fluid velocity (u,v) is continuous across the membrane; the normal velocity component is continuous as the membrane moves at the same speed as the fluid, and the tangential component is also continuous owing to the presence of viscosity and the no-slip boundary conditions between the membrane and the fluid on each side. However, the normal derivatives of the velocity components may have jump discontinuities:

$$[u] = [v] = 0, \tag{3.4}$$

$$[\mu u_n(s,t)] = f_\tau(s,t)\sin\theta, \quad [\mu v_n(s,t)] = -f_\tau(s,t)\cos\theta, \tag{3.5}$$

where θ denotes the angle between the tangent line and the x-axis. The derivation of (3.5) for a water-impermeable membrane can again be found in [19].

Furthermore, the water fluxes introduce a jump discontinuity in the concentration and its derivatives across the membrane. Unlike the jump conditions for p, u, and v, the jumps in c cannot be represented in terms of the membrane configuration or the elastic forces. Thus, they are estimated by applying extrapolation or one-sided finite-difference to grid-point c values. To approximate $[c]$, we first estimate c at boundary markers $\vec{X}_k$ on the two sides of Γ using a one-sided interpolation,

$$c^{\mathrm{I}}_{k^\pm} = \sum_{i,j} \xi_{i,j} c_{i,j}, \tag{3.6}$$

and using neighboring grid-point values $c_{i,j}$ such that the $x_{i,j}$ all reside on the same subdomain $\Omega^\pm$ and such that the interpolation yields second-order accuracy. The jump $[c_k]$ is then given by

$$[c_k] = c^{\mathrm{I}}_{k^+} - c^{\mathrm{I}}_{k^-}. \tag{3.7}$$

The correction terms needed to obtain a second-order approximation of the derivatives of c, using a finite-difference stencil that crosses the membrane, involve $[c']$ and $[c'']$ (see (A.8) and (A.10)). In most cases, these jumps can be estimated using one-sided finite difference. However, along portions of the membrane one may not find a sufficient number of grid points on one side of Γ to form the one-sided finite-difference stencil. One such example is shown in Figure 3.1. At (x^*, y_j) where Γ crosses the $y = y_j$ line, c and its derivatives are discontinuous. These jumps are needed for a

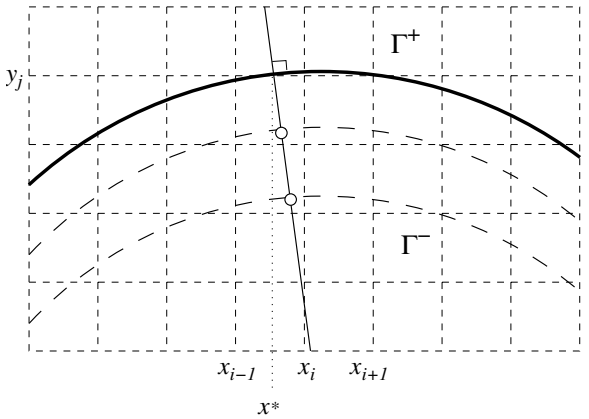

FIG. 3.1. *An example scenario where only one grid point (x_i, y_j) can be found along $y = y_j$ in Γ^-. c_n is approximated at (x^*, y_j) using one-sided finite difference, and using interpolated values (indicated by open circles) and boundary value along the normal line.*

finite-difference approximation of c_x or c_{xx} at (x_i, y_j) to yield high-order accuracy. However, in this example the lone grid point along $y = y_j$ that also lies in Γ^- is (x_i, y_j), and that is not enough to form a second-order, one-sided finite-difference approximation of c_x at (x^*, y_j). One solution is to increase grid resolution around Γ, an approach that was used by Linnick and Fasel [23]. We adopt an alternative approach where, instead of estimating $[c_x]$ and $[c_{xx}]$, we estimate $[c_n]$. To that end, we first approximate c values along normal lines to the membrane at $\vec{X}^{\pm}{}_k^{m+1} \pm lh$, where $l = 0, 1, 2$, by interpolating nearby grid-point c values on the same subdomain $\Omega^{\pm}$. Then we compute $[c_n]$ by estimating c_n at $\vec{X}_k^{\pm}$ using one-sided finite difference (denoted by ${c_n^{\mathrm{FD}}}_{k^{\pm}}$), and then taking the difference; i.e.,

$$[c_{n\,k}] = {c_n^{\mathrm{FD}}}_{k^+} - {c_n^{\mathrm{FD}}}_{k^-}. \tag{3.8}$$

The normal jump at any point $\vec{X}(s)$ along Γ can be obtained by interpolating $[c_{n\,k}]$ values.

The correction terms for the second-order finite-difference operator involve also arclength derivatives of the jumps in functions and in the normal derivative (e.g., $\partial[p]/\partial s$ and $\partial[p_n]/\partial s$, where s denotes the arclength; see the appendix). Those derivatives are obtained by applying second-order finite differencing along s to the values of the jumps at boundary markers.

We advance the solution of the system in time in sequential steps. First, we compute the fluid pressure and velocity by solving (2.1), (2.2), and (2.3). Then we update the solute concentration in a second step using known fluid velocity and water fluxes. The method generates a solution that is first order in time and second order in space.

3.2. Computing fluid and boundary motion. As in [19], we compute p by eliminating the singular source terms from (3.1) to yield $\nabla^2 p = 0$, which we then solve together with the jump conditions specified across the interface (3.3) using the technique of Mayo [24]. Specifically, we solve a difference equation of the form

$$\frac{1}{h^2}\left(p_{i+1,j} + p_{i-1,j} + p_{i,j+1} + p_{i,j-1} - 4p_{i,j}\right) = C_{i,j}. \tag{3.9}$$

The derivation for the correction terms $C_{i,j}$ is shown in the appendix. The Poisson equations are solved by means of fast Fourier transforms.

Once p is computed, (2.1) and (2.2) are independent Poisson problems for u and v, respectively. Neglecting the singular terms as we did for the Poisson problem for p, we obtain

$$\nabla^2 u = \frac{1}{\mu} p_x, \quad \nabla^2 v = \frac{1}{\mu} p_y. \tag{3.10}$$

Equations (3.10) are solved again using the explicit jump method with the jump conditions (3.4) and (3.5), together with the jumps in p_x and p_y, incorporated. The derivatives p_x and p_y are computed using a second-order finite-difference scheme, with the jump conditions (3.3) taken into account, an approach that has been shown to yield second-order accuracy for solution gradient [2].

The position $\vec{X}$ of Γ is determined by the location of a set of boundary markers along Γ; and at a given time t, Γ is represented by a cubic spline through those markers [19]. To advance the membrane by one time step, we move the boundary markers according to

$$\frac{\partial}{\partial t} \vec{X}(x,t) = \vec{U}(\vec{X}(s,t),t), \tag{3.11}$$

where $\vec{U}$ is given in (2.9) and (2.10). To compute $\vec{U}$, the local fluid velocity is determined by interpolating the velocity fields $\vec{u}_{ij}$ at grid points to the kth marker to yield $\vec{u}_k^I$, with care taken to incorporate jumps in their normal derivatives into the interpolation formulae. Then $\vec{U}$ is computed by incorporating g using (2.9) and (2.10), and forward Euler is used to advance the kth marker $\vec{X}_k$ by one time step.

3.3. Computing solute concentration. Once we have obtained the fluid pressure p^{m+1}, velocity $\vec{u}^{m+1}$, and membrane position $\vec{X}^{m+1}$, we proceed to update the solute concentration c, using the explicit jump method and a time-split method as described below. Our strategy is to (1) compute provisional grid-point values $c_{i,j}$ while neglecting transmural water fluxes; (2) compute boundary concentration $c_{b^\pm}$; and (3) incorporate the effects of water fluxes into $c_{i,j}$.

Computing provisional grid-point concentration values $c_{i,j}$. We first consider concentration values at grid points $\vec{x}_{i,j} \notin \Gamma^\pm$. Away from the membrane, $G = 0$. Thus, (2.11) simplifies to

$$c_t = -(c_x u + c_y v) + \nu(c_{xx} + c_{yy}). \tag{3.12}$$

Equation (3.12) is integrated by an explicit update of the advection terms, and, to avoid a prohibitive restriction on Δt, an implicit update of diffusion. That is, we solve for $c_{i,j}^{m+1,*}$ at regular grid points the following elliptic equation:

$$(1 - \nu\nabla^2) c^{m+1,*} = c^m - \Delta t(u^m c_x^m + v^m c_y^m). \tag{3.13}$$

As is done for p and (u, v), (3.13) is solved by incorporating the jumps in c and its derivatives into a finite-difference scheme. However, the implicit treatment of the diffusion means that the jumps $[c^{m+1,*}]$ and $[c_n^{m+1,*}]$ are needed for the explicit jump method. Unlike the jump conditions for p (3.3) and for $\vec{u}$ (3.4)–(3.5), $[c]$ and $[c_n]$ cannot be expressed in terms of the membrane configuration, elastic forces, or the fluid dynamics variables that are already computed. Instead, jump conditions

for concentration can only be computed once c and its derivatives are known at the boundary. Thus, to advance c according to (3.12), we first approximate these jumps by computing a provisional solution $c^{m+1,**}$. To that end, we integrate (3.12) explicitly; i.e., we compute

$$c^{m+1,**} = c^m - \Delta t\big(u^m c_x^m + v^m c_y^m - \nu\nabla^2 c^m\big). \tag{3.14}$$

The corrected finite-difference approximations for c_x^m, c_y^m, and $\nabla^2 c^m$ require jumps at t_m, i.e., $[c^m]$ and $[c_n^m]$, which are known. Once $c^{m+1,**}$ has been computed, estimates for $[c^{m+1,**}]$ and $[c_n^{m+1,**}]$ can be made (see section 3.1). Setting $[c^{m+1,*}] = [c^{m+1,**}]$ and $[c_n^{m+1,*}] = [c_n^{m+1,**}]$, we then solve the implicit diffusion equation (3.13) by incorporating these jumps into the second-order finite difference scheme, a procedure that is analogous to the solution of the three Poisson problems for the fluid pressure and velocity.

Computing boundary concentration values $c_{b^\pm}$. On the immediate sides of the membrane (i.e., $\Gamma^\pm$), concentration is affected by water transport represented by the flux terms Gc in (2.11). To compute boundary concentration, we first rewrite the mass transport equation (2.11) in the Lagrangian form

$$\frac{dc_{b^\pm}}{dt} = \xi g\delta(\vec{0})c_{b^\pm} + \nu(c_{b^\pm xx} + c_{b^\pm yy}), \tag{3.15}$$

where $\xi = \pm 1$ for $\vec{x} \in \Gamma^\pm$, and where $d/dt \equiv \partial/\partial t + u\partial/\partial x + v\partial/\partial y$. As noted previously, there are two "layers" of c_b values, one on each side of Γ (i.e., $\Gamma^\pm$).

Equation (3.15) is integrated in time using a splitting approach as follows. We let

$$c_{b^\pm}^{m+1} = \bar{c}_{b^\pm}^{m+1} + \hat{c}_{b^\pm}^{m+1}, \tag{3.16}$$

where

$$\bar{c}_{b^\pm}^{m+1} = c_{b^\pm}^m + \Delta t\nu(\bar{c}_{b^\pm xx}^{m+1} + \bar{c}_{b^\pm yy}^{m+1}), \tag{3.17}$$

$$\hat{c}_{b^\pm}^{m+1} = \int_{t_m}^{t_{m+1}} \left(\xi g(t)\delta(\vec{0})c_{b^\pm}(t) + \nu(c_{b^\pm xx}(t) + c_{b^\pm yy}(t))\right)\, dt. \tag{3.18}$$

The $\bar{c}_{b^\pm}$ term describes the evolution of the concentration of a bolus that travels along $\Gamma^\pm$, starting with a concentration of $c_{b^\pm}^m$ at t_m and having undergone diffusion for one time step. The $\hat{c}_{b^\pm}$ term represents the effects of transmural water fluxes coupled with solute diffusion. The time-stepping used to obtain $\hat{c}_{b^\pm}^{m+1}$ is discussed below.

Note that $\bar{c}_{b^\pm}^{m+1} = c^{m+1,*}(\vec{X}^\pm)$, the provisional concentration obtained via the solution of (3.12). The advection terms in (3.13) are incorporated into the Lagrangian derivative in (3.15). Thus we approximate $\bar{c}_{b^\pm}^{m+1}$ from the grid-point values $c_{i,j}^{m+1,*}$ using one-sided extrapolation.

To compute $\hat{c}_{b^\pm}^{m+1}$, we employ a time-split approach and treat the Dirac delta and the diffusion operator in (3.18) sequentially. Recall that the solution to

$$\phi_t = \nu(\phi_{xx} + \phi_{yy}), \tag{3.19}$$

with initial condition $\phi(x, y, 0) = \delta(x, y)$, $x, y \in [0, \infty)$, reflective boundaries at $x = 0$ and at $y = 0$, is given by

$$\phi(x, y, t) = \frac{1}{2\pi\nu t} \exp\left(-\frac{x^2 + y^2}{4\nu t}\right). \tag{3.20}$$

We compute $\hat{c}_{b^\pm}^{m+1}$ as the Gaussian solution (3.20) generated by the application of the diffusion operator $\nu(c_{b^\pm xx} + c_{b^\pm yy})$ to a Dirac delta function $\Delta t \xi g \delta(\vec{0}) c_{b^\pm}^m$ for one time step Δt; i.e.,

$$\hat{c}_{b^\pm}^{m+1} = \frac{\Delta t \xi g c_{b^\pm}^m}{2\pi\nu\Delta t}. \tag{3.21}$$

Combining (3.21) with $\bar{c}_{b^\pm}^{m+1}$, we obtain

$$c_{b^\pm}^{m+1} = \bar{c}_{b^\pm}^{m+1} + \frac{\xi g c_{b^\pm}^m}{2\pi\nu}. \tag{3.22}$$

Incorporating water fluxes into grid-point values $c_{i,j}$. The provisional grid-point values $c_{i,j}^{m+1,*}$ do not include the effects of water fluxes, effects that must be incorporated to preserve mass. Indeed, the Gaussian (3.20) is global and nonzero for each subdomain $\Omega^\pm$, although it decays exponentially fast away from the membrane (especial for sufficiently small ν). The final step in updating c is to incorporate the effect of water fluxes, using (3.20), to the provisional solution $c_{i,j}^{m+1,*}$ at regular grid points. To that end,

$$c_{i,j}^{m+1} = c_{i,j}^{m+1,*} + \int_0^{L_o} \frac{\xi g c_{b^\pm}^m}{2\pi\nu} \exp\left(-\frac{(x_j - X^\pm(s))^2 + (y_j - Y^\pm(s))^2}{4\nu\Delta t} \right) ds, \tag{3.23}$$

where $\xi = \pm 1$ for $(x_i, y_j) \in \Omega^\pm$. The integral in (3.23) is approximated using the trapezoidal rule and the boundary marker values $\hat{c}_{b^\pm}^{m+1}$, i.e.,

$$c_{i,j}^{m+1} = c_{i,j}^{m+1,*} + \Delta s \sum_{l=1}^{N_k} \frac{\xi g c_{l^\pm}^m}{2\pi\nu} \exp\left(-\frac{(x_i - X_l^\pm)^2 + (y_j - Y_l^\pm)^2}{4\nu\Delta t} \right). \tag{3.24}$$

Evaluating (3.24) for every pair of grid point and boundary marker requires $\mathcal{O}(N^2 N_k)$ computational time, which likely dominates the overall calculations for a sufficiently refined spatial grid. Thus in practice the summation in (3.24) only includes terms involving grid-point–boundary-marker pairs that are sufficiently close, i.e., for (i, j, k) such that $(x_i - X_k^\pm)^2 + (y_j - Y_k^\pm)^2 < d$. The error introduced by ignoring the contributions from grid points outside of that neighborhood can be shown to be

$$E_d = \int_0^L \frac{\sqrt{\Delta t}|g(s)|(c_{b^+}^m(s) + c_{b^-}^m(s))}{\nu} \left(1 - \operatorname{erf}\left(\frac{d}{2\sqrt{2\pi\Delta t}} \right) \right) ds. \tag{3.25}$$

A smaller Δt or a larger ν increases E_d. Additional errors are present in (3.24) from discretizing the integral in (3.23) using the trapezoidal rule.

4. Numerical examples. In this section we present numerical results obtained for two examples. Our main focus is on the accuracy with which our method captures jumps in the solutions and on the mass-conserving properties of the method. All calculations reported below were performed using Fortran programs, which were executed in double precision on a computer with an Intel Pentium IV 3.2 GHz processor and 1 GB of RAM.

4.1. Hydraulic pressure-driven water fluxes. This example was used by Tu and Peskin to test their immersed boundary method [30], and by LeVeque and Li to test their immersed interface method [19]. The initial membrane is an ellipse

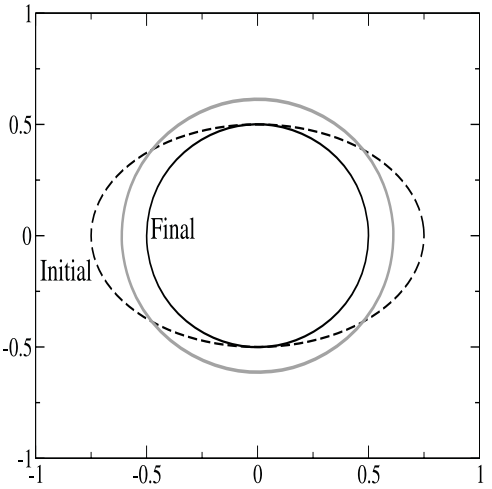

FIG. 4.1. *Membrane configuration at initial time* (*dotted line*) *and steady state* (*solid dark line*) *Gray line shows steady state if there were no water fluxes.*

with major and minor axes set to $a = 0.75$ and $b = 0.5$, respectively (dashed line in Figure 4.1). The unstretched membrane was set to a circle with radius $r_0 = 0.5$ (solid dark line in Figure 4.1). The computational domain was set to $[-1, 1] \times [-1, 1]$. Transmural water fluxes were assumed to be driven by hydraulic pressure [13, 29]

$$g(s,t) = -\sigma[p(s,t)], \tag{4.1}$$

where $\sigma > 0$ represents the water permeability of the membrane; in this example we set $\sigma = 0.01$. Thus, a higher pressure in the enclosed fluid, i.e., $[p] < 0$, will generate outward-directed water fluxes, i.e., $g > 0$, and vice versa. Solute concentration was initialized to $c(\vec{x}, 0) = 1$ in the enclosed fluid (i.e., for $\vec{x} \in \Omega^-$) and to $c(\vec{x}, 0) = 2$ in the outside fluid (i.e., for $\vec{x} \in \Omega^+$).

In the *absence* of transmembrane water fluxes (i.e., if $g(s,t)$ were set to 0), the initial ellipse will converge to a steady state with radius $r_e = \sqrt{ab} \approx 0.6124$, which is larger than for the unstretched membrane but which has the same area as the initial ellipse (gray line in Figure 4.1) owing to the incompressibility of the enclosed fluid. At steady state, p will attain constant values inside and outside the membrane, with a jump $[p] < 0$ (because the membrane was initialized to a stretched state); fluid velocity will vanish everywhere.

In the presence of transmural pressure-driven water fluxes, the higher pressure of the enclosed fluid continues to drive water outward, until the membrane reaches the unstretched position, at which time transmural pressure difference vanishes.

Thus in this case the steady-state membrane configuration is the unstretched one (solid dark line in Figure 4.1). Note that although the fluid is incompressible, the volume of the enclosed fluid is not conserved.

Because the membrane is assumed impermeable to the solute, the total amount of solute (given by $\int_{\Omega^\pm} c(\vec{x}, t) d\vec{x}$) remains unchanged in each of the subdomains Ω^+ and Ω^- for all time. Because the amount of fluid (or area) in each subdomain changes in time (though the total amount of fluid in Ω is constant owing to periodic boundary conditions), c changes. In this case, because the membrane is initialized to a stretched state, at steady state there is a net outward migration of water; thus, c increases in

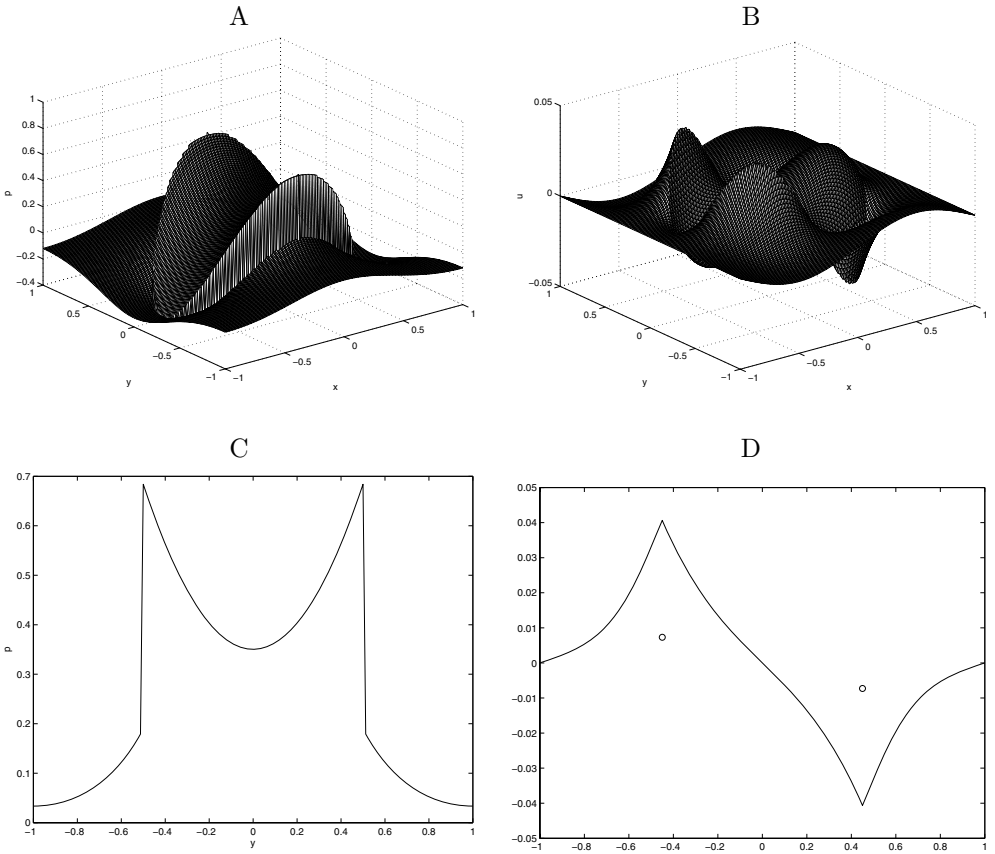

FIG. 4.2. A: *initial pressure field.* B: *initial x-component of velocity field* (u). C: *initial pressure at* $x = 0$. D: *initial* u *at* $y = -0.4$. *Open circles in panel* D *indicate membrane velocity.*

Ω^-. Let $t = \infty$ denote steady state. At steady state, c is constant in each of $\Omega^{\pm}$, with $c(\vec{x}, \infty) = (A^-(0)/A^-(\infty))c(\vec{x}, 0) = 1.5$, where $\vec{x} \in \Omega^-$, $c(\vec{x}, \infty)$ denotes steady-state concentration, and $A^-(0)$ and $A^-(\infty)$ denote initial and steady-state areas, respectively, enclosed by the membrane. An analogous calculation yields a steady-state outside concentration $c(\vec{x}, \infty) = 1.667$, $\vec{x} \in \Omega^+$.

We set the diffusion coefficients to $\mu = 1$ and $\nu = 0.001$. Note that the steady-state solution is independent of μ and ν, although the transient solution depends on their values. The tension coefficient T_0 was set to 0.5. To solve the Stokes equations (2.1), (2.2), and (2.3), we used a time step $\Delta t = 0.1$. Because at each time step the concentration jumps $[c^{m+1,*}]$ and $[c_n^{m+1,*}]$ were estimated using an explicit time-integration, a smaller time step was required to integrate the solute conservation equation (2.11) to maintain numerical stability. Nonetheless that time-step restriction is less than the restriction that would have been imposed by a purely explicit integration of diffusion. Thus, for each fluid step Δt, we took 20 concentration steps using a time step of $\Delta t/20$. During those 20 concentration time steps, p, u, and v were held constant. To obtain an approximate steady-state solution, model equations were integrated to $t = 1000$, at which time $p < 10^{-6}$ in Ω^- (at true steady state $p = 0$).

Given a membrane configuration, pressure and fluid velocity can be computed. Figure 4.2 shows p and u at $t = 0$, in two dimensions (panels A and B), along $x = 0$

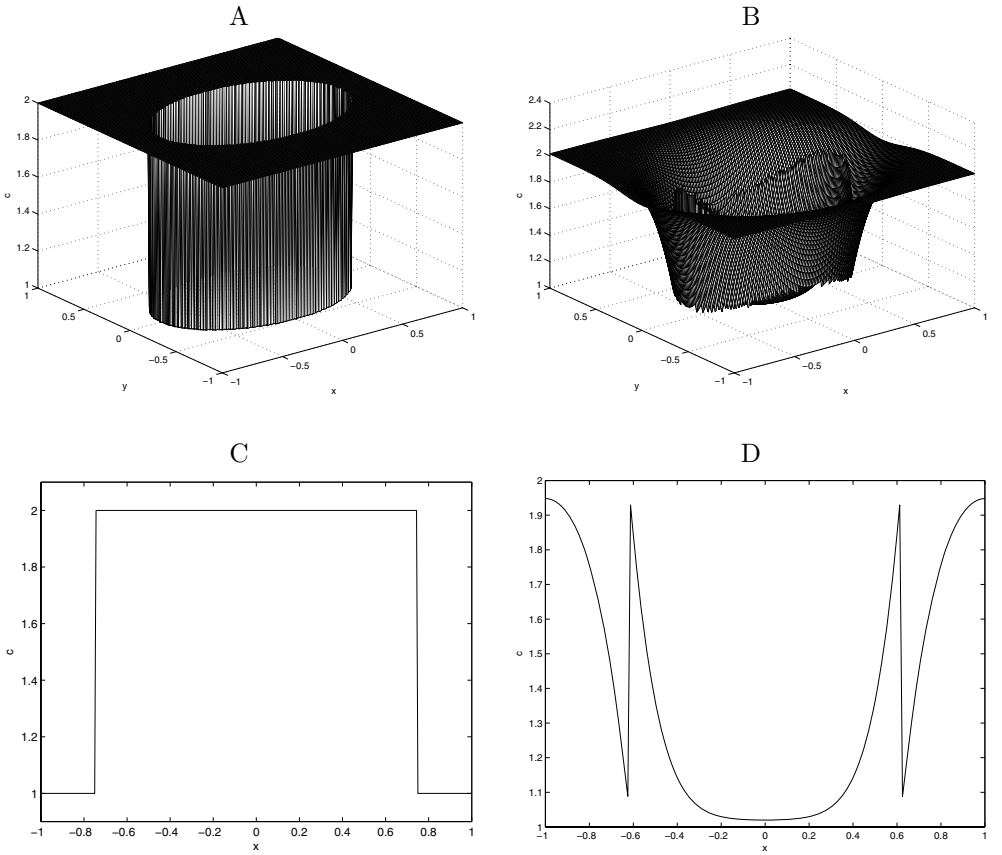

FIG. 4.3. A, C: *concentration at* $t = 0$. B, D: *concentration at* $t = 200$. C, D: *concentration along* $y = 0$.

(panel C), and along $y = -0.4$ (panel D). These results were obtained using $N = 160$. The singular normal elastic force renders p discontinuous across the membrane. In particular, p has jump discontinuities at $(0, \pm 0.5)$ at initial time, as shown in Figure 4.2C. The singularities of p at $\Gamma^{\pm}$, induced by G, are not shown. The net jump discontinuities in pressure and in the normal derivatives of the fluid velocity were captured sharply by the explicit jump method. The velocity at which the membrane moves is shown in Figure 4.2D as open circles.

Figure 4.3 shows solute concentration at $t = 0$ and 200. As previously noted, solute concentration was initialized to be a step function (see panels A and C). Along the portions of the membrane that is stretched (e.g., at $(x, y) = (\pm 0.75, 0)$), water is driven outward, introducing an increase in local concentration within the membrane, and a corresponding decrease on the opposite side of the membrane. Thus, after a sufficiently long integration, interior solute concentration exceeds that of the exterior. As can be noted in Figure 4.3D, the concentration discontinuities at $x = \pm 0.75$ (and elsewhere, not shown) are captured sharply by the explicit jump method. As the simulation proceeds further, interior and exterior concentrations converge to their respective constant values of 1.5 and 1.6667.

Table 4.1 shows volume accuracy and solute conservation results for $N = 80$, 160, 320, and 640. The same N was used to discretize the membrane, i.e., $N_k = N$. The

TABLE 4.1

Convergence results for an example with hydraulic pressure-driven water fluxes. $A^-(\infty)$, steady-state area enclosed by membrane; $M^-(\infty)$, steady-state total solute enclosed by membrane. The errors in $A^-(\infty)$ and $M^-(\infty)$, denoted by error$_{A-}$ and error$_{M-}$, were computed using exact solution $A^-(\infty) = M^-(\infty) = 0.7853981635$. Results show second-order spatial convergence.

N	$A^-(\infty)$	error$_{A-}$	$M^-(\infty)$	error$_{M-}$
80	0.7819365415	3.462E-3	0.5955737106	1.898E-1
160	0.7845370713	8.611E-4	0.7784843941	6.914E-3
320	0.7851768010	2.214E-4	0.7831280790	2.227E-3
640	0.7853426842	5.548E-5	0.7847976120	6.006E-4

steady-state enclosed volume $A^-(\infty)$ was obtained by approximating the integral $\int_{\Omega^-} d\vec{x}$ using a second-order integration method. That method approximates the area of the h^2 squares that the boundary cuts through as a triangle, a trapezoid, or a sum of the areas of a rectangle and a trapezoid, depending on whether one, two, or three of the four corners of the square lie in Ω^-. The amount of enclosed solute $M^-(\infty)$ was estimated analogously using the integral $\int_{\Omega^-} c(\vec{x}, \infty) d\vec{x}$. Until steady state was reached, there was a net efflux of water, driven by the higher interior pressure; thus, the volume enclosed by the membrane is not conserved. Results in Table 4.1 exhibit second-order convergence in space. Analogous volume accuracy and mass conservation results were also obtained for the exterior region Ω^+ and thus for the entire domain Ω. The errors are larger in solute conservation than in volume accuracy, especially for small $N \leq 80$. That difference may be attributable to the substantial solute concentration gradient near the boundary during transient states, which gave rise to significant extrapolation errors when boundary concentration was estimated from grid-point values, e.g., in the computation of $\bar{c}_b^{m+1}$. When the spatial grid failed to sufficiently resolve the concentration gradient near the boundary, the grid-point values $c_{i,j}$ used to extrapolate $\hat{c}_b^{m+1}$ were essentially flat and would thus yield an under- or overestimate, depending on whether the spatial gradient was positive or negative along $\vec{n}$.

4.2. Osmotic and hydraulic pressure-driven water fluxes. In the next example, we represent also water fluxes arising from transmural osmotic or concentration difference:

$$g(s,t) = -\sigma([p(s,t)] - [c(s,t)]). \tag{4.2}$$

At steady state, $g(s, \infty) = 0$, with the transmural pressure and concentration gradients in balance. The previous example in section 4.1, which represents hydraulic pressure-driven fluxes only, yielded a steady-state pressure that is constant everywhere (i.e., $[p] = 0$]) and a piecewise constant steady-state concentration with $[c] = 0.1667$. Had osmotic pressure-driven water fluxes (4.2) been included in the model, that transmural concentration difference would have given rise to an efflux of water, from the interior region of lower concentration to the exterior region of higher concentration. The loss of water would have reduced the interior area, compressed the elastic membrane, and generated an outward-directed tension force. The resulting negative pressure gradient $[p] < 0$ would then favor water fluxes into the interior region, an effect that opposes the concentration difference. Thus, a new steady state would be reached in which the transmural pressure and concentration gradients balance. At steady state, fluid velocity vanishes as before.

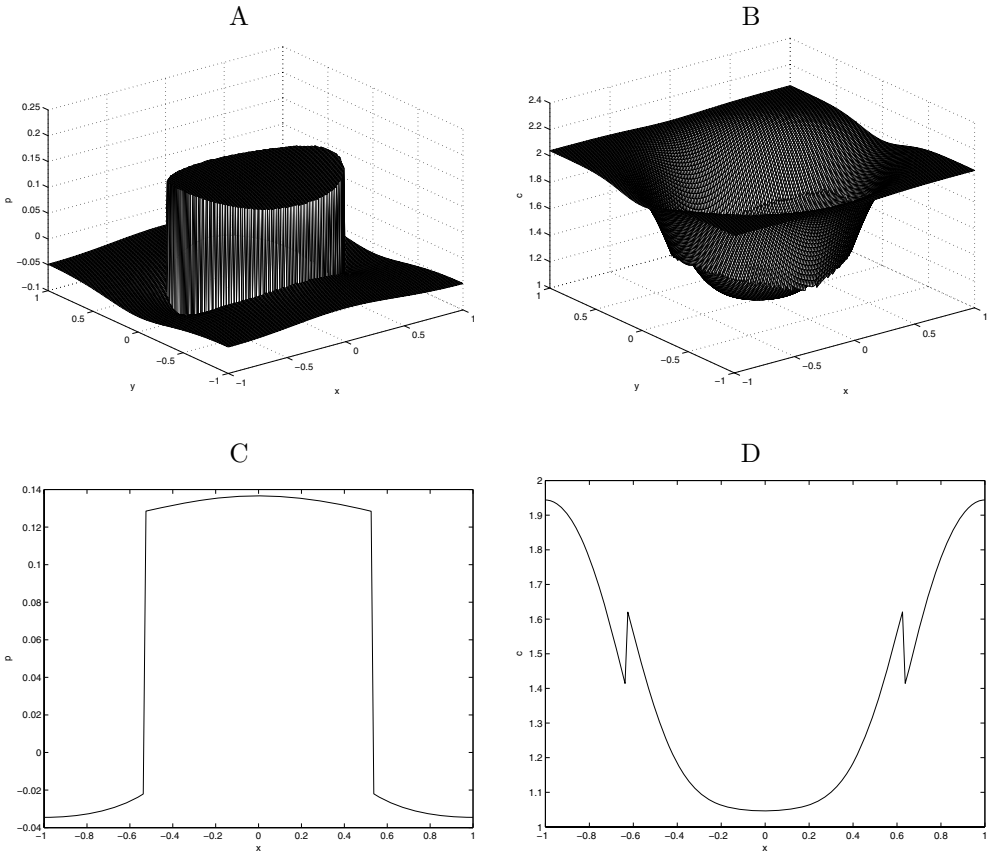

FIG. 4.4. *Pressure and concentration at* $t = 200$. C, D: *along* $y = 0$.

The steady-state balance of transmural pressure and concentration gradients allows us to obtain analytic solutions for steady-state concentrations and pressure:

$$c^+(\infty) - c^-(\infty) = p^+(\infty) - p^-(\infty). \tag{4.3}$$

Applying mass conservation, one obtains that

$$c^+(0)\frac{1-ab}{1-r(\infty)^2} - c^-(0)\frac{ab}{r(\infty)^2} = T_0(r(\infty) - r_0). \tag{4.4}$$

The initial membrane configuration, initial concentration, tension coefficient, membrane permeability, and diffusion coefficients were set to the same values used in the previous example. Using (4.4), we computed steady-state membrane configuration, pressure jump, and concentration to be $r(\infty) = 0.479205$, $[p(\infty)] = -0.0103975$, $c^+(\infty) = 1.622613$, and $c^-(\infty) = 1.633009$. Note that $[c(\infty)] = [p(\infty)]$.

Figure 4.4 shows pressure and solute concentration at $t = 200$, in two dimensions (panels A and B) and along $y = 0$ (panels C and D). Results were obtained for $N = 160$. The jump discontinuities in both pressure and concentration were reproduced sharply by the explicit jump method. Throughout the simulation concentration jump $[c]$ was generally less than the previous example. This difference can be attributed

TABLE 4.2

320	0.7202750053	1.152E-3	1.175660264	2.437E-3
640	0.7211253473	3.015E-4	1.177467860	6.294E-4

to the osmotic water fluxes induced by the concentration gradient, which, taken in isolation, tend to reduce that gradient.

Volume accuracy and solute conservation results for $N = 80$, 160, 320, and 640 are shown in Table 4.2. These results exhibit second-order convergence at sufficiently large N's. Analogous volume accuracy and mass conservation results were also obtained for the exterior region Ω^+. At $N = 80$, there was substantial water and solute loss in Ω^-, and similar gain in Ω^+ (results not shown), owing to the underresolved concentration gradient near Γ as previously noted. Volume accuracy is less robust in this example than in the results shown for the previous example in Table 4.1. This discrepancy can again be attributed to the larger errors in calculating the boundary concentrations, which are required in the computation of water fluxes (but not in the previous example), thus adversely affecting volume accuracy. Nonetheless, with a grid that is sufficiently refined to resolve the near-boundary transient concentration gradient, volume and mass are approximately conserved. For example, for $N \geq 160$, the relative errors in $A^-(\infty)$ and $M^-(\infty)$ are $\leq 1\%$.

5. Discussion. We have presented a model and a computational technique for simulating fluid motion and solute transport in a highly viscous fluid, described by the Stokes equations, with an immersed elastic membrane. This work extends previous immersed boundary models in two significant ways: Previous models have generally assumed water-impermeable membranes. In contrast, our model represents transmural osmotic and hydraulic pressure-driven water fluxes by modifying the boundary velocity. Also, our model simulates the advection and diffusion of a solute, the concentration of which is discontinuous across the membrane. Numerical results suggest that our method adequately preserves mass conservation of the solute.

The original immersed boundary method and many of its variants, e.g., the blob projection method [8], transfer the singular boundary forces onto the underlying fluid using approximate (smooth) Dirac delta functions typically with $\mathcal{O}(h)$ support. This approach does not capture the jump discontinuity in solution (e.g., p) but rather approximates the solution as a continuous function with a large gradient. In a model where hydraulic pressure-driven water fluxes are represented, the transmural jump in pressure is required. For this reason, an explicit jump method is used in this work. Nonetheless, our model equations can be solved by means of the immersed boundary method, the blob projection method, the method of regularized Stokelets by Cortez [7], or the ghost fluid method [15]. The transmural pressure difference may be approximated using pressure values some grid spacings away from the membrane.

Our method computes a solution to the Stokes equations by solving three separate Poisson problems for p, u, and v, with the singular terms neglected and with the jumps incorporated into the finite-difference scheme. This approach is similar to how

LeVeque and Li [19] used the immersed interface method to solve the Stokes equations. However, the way we calculated the correction terms (see the appendix) follows the method by Mayo [24]. The difference between the immersed interface method and Mayo's method lies in the directions along which correction terms are computed: the immersed interface method follows the directions normal and tangential to the interface, whereas in Mayo's method (and in the present work, as well as in [31]) correction terms are computed along the coordinate lines. A previous study has suggested that, at least for the test cases considered there, the solution errors are similar in the two methods [2]. Indeed, our model equation can just as easily be solved by means of the immersed interface method.

The current model assumes biperiodic boundary conditions, which allow us to decouple the Stokes equations into three Poisson problems for p, u, and v. When other boundary conditions are specified (e.g., no-slip conditions at solid walls), boundary conditions for p may be obtained via the introduction of additional variables and equations (see discussion in [19]), or an integral equation can be solved as in [2] for free boundary. Also in [2] Beale and Layton showed how one may solve the Stokes equations with two distinct fluid viscosities on each side of the membrane in free space by combining the integral equation approach with explicit jump methods. The two-fluid case can also be handled by the immersed interface method using an augmented approach [21].

Transmural water fluxes drive solute concentration up or down on the two sides of the membrane. Consequently, large concentration gradients may develop near the membrane at transient states, especially for sufficiently small solute diffusivity ν's, even though the steady-state concentration converges to a stepwise constant function. Thus, a sufficiently refined spatial grid is needed to resolve that concentration gradient, leading to large computation times when a uniform spatial grid is used. Substantial savings in computation time will likely be gained via the use of adaptive mesh refinement. Indeed, adaptive mesh refinement was successfully applied to the immersed boundary method by Roman, Peskin, and Berger [28], and recently to a high-order immersed interface method by Linnick and Fasel [23].

In the current implementation, the membrane position is updated using an explicit time-stepping method. Also, the jumps in c and its normal derivation are first estimated in a provisional step using an explicit integration of the advection-diffusion equation for solute. Thus, with a sufficiently stiff membrane, or with a sufficiently large solute diffusivity, the restriction on time-step size may become stringent. Development of implicit versions of the method, perhaps similar to the implicit or pseudo-implicit versions of the immersed interface methods [17, 19] and of the immersed boundary method [30], is a worthwhile effort.

The present method is second order in space, but only first order in time. We opted for a first-order time-stepping scheme because of the simplicity of a first-order operator splitting, and because of the likelihood (not verified) that order reduction, which is attributable to the stiffness of the membrane and to diffusion, would restrict solution accuracy to first order regardless. Indeed, solution errors appear to be dominated by spatial errors because of the large concentration gradient (see above) and because of the small time step used. Nonetheless, a version of the method that is second or higher order in time, combined with adaptive mesh refinement to resolve the concentration gradient, should be useful. Strang splitting can be used to develop a second-order time-stepping method with operator-splitting. For third- or higher-order methods with operator-splitting, the multi-implicit Picard deferred correction

approach (formerly known as multi-implicit spectral deferred correction [5]) may be used to generate a high-order solution using a low-order time integration method and a low-order splitting, using an iterative procedure.

We regard this model as a step toward a more sophisticated model that simulates the interactions of fluid, solutes, and an elastic, permeable membrane. A solute-permeable membrane can also be represented through the inclusion of a solute flux term in the solute conservation equation (2.11). Additional solutes, which may have different diffusivities and membrane permeabilities, and which may react with each other, can be represented. Also, although in this work we considered only two-dimensional Stokes flows in the zero Reynolds number limit, our methodology can be extended to three dimensions and to the more comprehensive Navier–Stokes equations. These extensions are the focus of an ongoing project.

The methodology developed in this work is useful in many applications, especially in biofluids. One application can be found in the kidney, which exhibits complex dynamics. In particular, the peristaltic contractions of the renal pelvis "milk" the papilla and interrupts flows along the renal tubules by forcing them to collapse [11]. Thus, peristaltic waves likely have a significant impact on the water and solute transport properties of the renal tubules [16]. Our model can be used to simulate flows along renal tubules undergoing peristalsis and to assess the significance of peristalsis in water and solute transport in the kidney.

Appendix. Derivation of correction terms. In this appendix, we derive correction terms for a finite-difference approximation of u_{xx} that gives second-order accuracy when u and its derivatives have jump discontinuities at $x^* = x_i + \theta h$. We consider here the one-dimensional case where $u = u(x)$; generalization to higher dimensions is straightforward.

Suppose we wish to approximate $u_{xx}(x_i)$ using u_{i-1}, u_i, and u_{i+1}. We first consider the case where $0 < \theta \le 1$. We start by deriving the correction terms for a finite-difference approximation for $u_x(x_i + h/2)$ using u_i and u_{i+1}. Let $u_*^R \equiv u(x^{*+})$ and $u_*^L \equiv u(x^{*-})$. With this notation, Taylor's expansion yields

$$u_{i+1} = u_*^R + u_*'^R(1-\theta)h + \frac{1}{2}u_*''^R(1-\theta)^2h^2 + \mathcal{O}(h^3), \tag{A.1}$$

$$u_i = u_*^L - u_*'^L(1-\theta)h + \frac{1}{2}u_*''^L(1-\theta)^2h^2 + \mathcal{O}(h^3). \tag{A.2}$$

Taking the difference, one obtains

$$u_{i+1} - u_i = [u] + (1-\theta)h[u'] + hu_*'^L + \frac{1}{2}(1-\theta)^2h^2[u''] + \frac{1}{2}(1-2\theta)h^2u_*''^L + \mathcal{O}(h^3). \tag{A.3}$$

Using $u_i' = u_*'^L - \theta h u_*''^L + \mathcal{O}(h^2)$ or $hu_*'^L - \theta h^2 u_*''^L = hu_i' + \mathcal{O}(h^3)$, one obtains

$$u_{i+1} - u_i = [u] + (1-\theta)h[u'] + \frac{1}{2}(1-\theta)^2h^2[u''] + hu_i' + \frac{1}{2}h^2u_*''^L + \mathcal{O}(h^3). \tag{A.4}$$

Since $u_*''^L = u_i'' + \mathcal{O}(h)$, (A.4) can be expressed in terms of u' and the jumps:

$$u_{i+1} - u_i = hu_i' + \frac{1}{2}h^2u_i'' + [u] + (1-\theta)h[u'] + \frac{1}{2}(1-\theta)^2h^2[u''] + \mathcal{O}(h^3). \tag{A.5}$$

If there is no jump in $[x_{i-1}, x_i]$, then

$$u_i - u_{i-1} = hu_i' - h^2 u_i'' + \mathcal{O}(h^3). \tag{A.6}$$

Taking the difference equations (A.5) and (A.6), one obtains the correction terms C_i, where

$$u_i'' = \frac{1}{h^2}\left(u_{i+1} - 2u_i + u_{i-1} + C_i\right), \tag{A.7}$$

$$C_i = -[u] - (1-\theta)h[u'] - \frac{1}{2}(1-\theta)^2 h^2 [u'']. \tag{A.8}$$

Similarly if $x^* = -\theta h$, $0 < \theta \leq 1$, then we have

$$u_{i-1} - u_i = -hu_i' + \frac{1}{2}h^2 u_i'' - [u] + (1-\theta)h[u'] - \frac{1}{2}(1-\theta)^2 h^2 [u''] + \mathcal{O}(h^3). \tag{A.9}$$

Combining (A.9) with $u_{i+1} - u_i = hu_i' + h^2 u_i'' + \mathcal{O}(h^3)$, one obtains the correction terms

$$C_i = [u] - (1-\theta)h[u'] + \frac{1}{2}(1-\theta)^2 h^2 [u'']. \tag{A.10}$$

As discussed in section 3.1, the jump conditions are given for the model variables and for their normal derivatives, not their x- and y-derivatives directly. Thus, we express $[u']$ and $[u'']$ in terms of $[u]$, $[u_n]$, and their arclength derivatives. Suppose $\nabla^2 u = f$, $[u] = \alpha$, and $[u_n] = \beta$. Further suppose that the closed boundary is parameterized by the arclength s, such that $\vec{n} = (\dot{y}, -\dot{x})$, $(\ddot{x}, \ddot{y}) = \kappa(\dot{y}, -\dot{x})$, where κ denotes the curvature and the dots indicate derivatives with respect to s. Then one can obtain the relations

$$[u_x] = \dot{x}\dot{\alpha} + \dot{y}\beta, \tag{A.11}$$

$$[u_y] = \dot{y}\dot{\alpha} - \dot{x}\beta, \tag{A.12}$$

$$[u_{xx}] = 2\kappa\dot{x}\dot{y}\dot{\alpha} + \kappa(\dot{y}^2 - \dot{x}^2)\beta + (\dot{x}^2 - \dot{y}^2)\ddot{\alpha} + 2\dot{x}\dot{y}\dot{\beta} + \dot{y}^2[f], \tag{A.13}$$

$$[u_{yy}] = -2\kappa\dot{x}\dot{y}\dot{\alpha} + \kappa(\dot{x}^2 - \dot{y}^2)\beta + (\dot{y}^2 - \dot{x}^2)\ddot{\alpha} - 2\dot{x}\dot{y}\dot{\beta} + \dot{x}^2[f]. \tag{A.14}$$

ANALYSIS AND COMPARISON OF GEOMETRIC AND ALGEBRAIC MULTIGRID FOR CONVECTION-DIFFUSION EQUATIONS*

CHIN-TIEN WU† AND HOWARD C. ELMAN‡

Abstract. The discrete convection-diffusion equations obtained from streamline diffusion finite element discretization are solved on both uniform meshes and adaptive meshes. Estimates of error reduction rates for both geometric multigrid (GMG) and algebraic multigrid (AMG) are established on uniform rectangular meshes for a model problem. Our analysis shows that GMG with line Gauss–Seidel smoothing and bilinear interpolation converges if $h \gg \epsilon^{2/3}$, and AMG with the same smoother converges more rapidly than GMG if the interpolation constant β in the approximation assumption of AMG satisfies $\beta \ll (\frac{h}{\sqrt{\epsilon}})^{\alpha}$, where $\alpha = \begin{cases} 1, & h<\sqrt{\varepsilon}, \\ 2, & h\geq\sqrt{\varepsilon}. \end{cases}$ On unstructured triangular meshes, the performance of GMG and AMG, both as solvers and as preconditioners for GMRES, are evaluated. Numerical results show that GMRES with AMG preconditioning is a robust and reliable solver on both type of meshes.

Key words. convection-diffusion equations, multigrid, adaptive mesh refinement

1. Introduction.

The purpose of this paper is to evaluate different solution strategies for the linear systems obtained from discretization of the convection-diffusion equation

$$\begin{cases} -\epsilon \triangle u + b \cdot \nabla u = f & \text{on } \Omega, \\ u = g & \text{on } \partial\Omega, \end{cases} \tag{1.1}$$

where b and f are sufficiently smooth and the domain Ω is convex with Lipschitz boundary $\partial\Omega$. We are interested in the convection-dominated case, i.e., $|b| \gg \epsilon$. In this setting, the solution typically has steep gradients in some parts of the domain. These may take the form of boundary layers caused by Dirichlet conditions on the outflow boundaries or internal layers caused by discontinuities in the inflow boundaries.

Let $\Im_h$ be a given quasi-uniform mesh of triangles on Ω and let V_h be the linear finite element space on $\Im_h$. It is well known that the standard Galerkin finite element discretization on uniform grids produces inaccurate oscillatory solutions to convection-diffusion problems. Here, we will discretize (1.1) on V_h using the streamline diffusion finite element method (SDFEM) [7], a variant of the standard Galerkin method, where extra diffusion in the streamline direction is introduced. The SDFEM formulation entails finding $u_h \in V_h$ such that

$$B_{sd}(u_h, v_h) = f_{sd}(v_h) \quad \text{for all } v_h \in V_h, \tag{1.2}$$

where

$$B_{sd}(u_h, v_h) = \epsilon(\nabla u_h, \nabla v_h) + (b \cdot \nabla u_h, v_h) + \sum_{T \in \Im_h} \delta_T (b \cdot \nabla u_h, b \cdot \nabla v_h)_T,$$

$$f_{sd}(v_h) = (f_h, v_h) + \sum_{T \in \Im_h} (f, \delta_T b \cdot \nabla v_h),$$

and δ_T is a stabilization parameter. With a carefully chosen value of δ_T, the streamline diffusion finite element discretization is able to eliminate most oscillations and produce accurate solutions in the regions where no layers are present [7]. As shown in [6], a good choice of δ_T is

$$\delta_T = \begin{cases} \frac{1}{2\|b\|_T} \left(1 - \frac{1}{P_{e_T}}\right) & \text{if } P_{e_T} > 1, \\ 0 & \text{if } P_{e_T} < 1, \end{cases} \tag{1.3}$$

where

$$P_{e_T} = \frac{\|b\|_T \, h_T}{2\epsilon} \quad \text{for } T \in \Im_h \text{ with diameter } h_T$$

is the mesh Peclét number.

This strategy does not produce accurate solutions in regions containing layers that are not resolved by the grid. Accuracy can be achieved at reasonable cost in such regions by adaptive mesh refinement, in which an a posteriori error estimation strategy is used to identify regions where errors are large, and a marking strategy is used to select elements to be refined. An adaptive solution strategy is to start with a coarse mesh, compute the discrete system, solve the linear system, and then locally refine the mesh using the information provided by an a posteriori error estimation. This adaptive solution process can be applied repeatedly until the a posteriori error estimator is less than a prescribed tolerance or the maximal number of mesh refinement steps is reached.

In this paper, we use the local error estimator proposed by Kay and Silvester [8], with the maximum marking strategy [11], and regular mesh refinement strategy for the adaptive refinement process. We are concerned with the costs of performing this computation with emphasis on the costs of solving the discrete systems that arise at each step of the mesh refinement. Let $A_h u_h = f_h$ denote the discrete system of equations derived from (1.2). Since adaptive mesh refinement produces a sequence of nested meshes, multigrid methods are natural candidates for solving this linear system. Here, we would like to explore the effectiveness of the geometric multigrid (GMG) [5] and algebraic multigrid (AMG) [17] methods. Since the linear system is nonsymmetric, Krylov subspace linear solvers such as the generalized minimal residual method (GMRES) [18] are also good choices. In order to accelerate the convergence of the Krylov subspace linear solvers, good preconditioners are needed. We would also like to investigate the performance of GMRES preconditioned by GMG and AMG.

This paper is organized as follows: Details of the error estimator and refinement strategy are given in section 2 where numerical studies that demonstrate the efficiency of the error indicator are presented. In section 3, multigrid algorithms and some estimates of two-level multigrid convergence are analyzed and numerical results that support our theoretical analysis are given. A comparison of the solvers is shown in section 4. This comparison examines both standalone versions of multilevel multigrid as well as versions in which multigrid is used as a preconditioner for GMRES. We also

compare these with unpreconditioned GMRES, and with a preconditioned GMRES algorithm in which the smoother used for multigrid is used as a preconditioner. These experiments are performed using the following two benchmark problems.

Problem 1: *Constant flow with characteristic and downstream layers.* Equation (1.1) is given with the coefficient $b = (\sin(\phi), \cos(\phi))$, where ϕ measures the angle of the flow direction from the y-axis, and the right-hand side $f = 0$ on the domain $\Omega = [-1, 1] \times [-1, 1]$. The Dirichlet boundary condition is set as $g = 1$ on the segments $y = -1 \cap x > 0$ and $x = 1$, and $g = 0$ elsewhere.

Problem 2: *Flow with closed characteristics:* Here, the coefficient vector (b_1, b_2) is $(2y(1-x^2), 2x(1-y^2))$ and the right-hand side $f = 0$ on the domain $\Omega = [-1, 1] \times [-1, 1]$. The Dirichlet boundary condition is $g = 1$ on the segments $y = 1$ and $g = 0$ elsewhere.

These examples are chosen because they exhibit many of the important features of flow problems so that their effect on discretization and multigrid solvers can be identified. In particular, Problem 1 has an exponential boundary layer at the outflow boundary and a characteristic internal layer induced by a discontinuity on the inflow boundary. Both of these can be treated using adaptive mesh refinement. Moreover, by varying the angle ϕ, we can assess the effect of flow direction on performance of solvers. Problem 2 also has a (characteristic) boundary layer caused by discontinuous boundary conditions, and its recirculating flow requires that care be taken in choosing smoothers for multigrid computations.

Finally, in section 5, we draw our conclusions.

2. Adaptive mesh refinement by a posteriori error estimation. One common technique to increase the accuracy of the finite element solution is mesh refinement. Unlike uniform mesh refinement, the adaptive mesh refinement process refines meshes only in the regions where errors between the weak solution of the partial differential equation and the corresponding finite element solution are large. In general, the adaptive mesh refinement process consists of loops of the following form:

$$\underbrace{\textit{Solve}}_{1} \rightarrow \underbrace{\textit{Compute error indicator}}_{2} \rightarrow \underbrace{\textit{Refine mesh}}_{3}$$

In step 3, elements in which the value of the a posteriori error estimator is large are marked for refinement according to some element selection algorithm. On a given triangulation $\Im_h$, for any element $T \in \Im_h$, let η_T be the a posteriori error indicator of element T. A heuristic marking strategy is the *maximum marking strategy* where an element T^* is marked for refinement if

$$\eta_{T^*} > \theta \max_{T \in \Im_h} \eta_T, \tag{2.1}$$

with a prescribed threshold $0 < \theta < 1$. For other marking strategies, we refer to [11]. Once decisions on where to refine are made, commonly used mesh refinement schemes are regular refinement, where a triangle is divided into four triangles equally, and longest side bisection [15], [16], where a triangle is divided into two triangles by adding a new node to the midpoint of the longest edge. The maximum marking strategy and regular refinement scheme are used in our experiments.

A reliable computable a posteriori error estimator in step 2 is the key for the adaptive mesh refinement process to succeed. For the convection-diffusion equation discretized by SDFEM, the first a posteriori error estimation where the error is estimated by computing the residual was proposed by Verfürth [21], and the first a posteriori error estimation where the error is estimated by solving a local problem was

developed by Kay and Silvester [8]. In this study, we use the Kay and Silvester a posteriori error estimator, which we have found to be a more effective choice in [23]. Hereafter, we call this indicator the KS-indicator. First, let us introduce the following abbreviations. Let $\|\cdot\|_{0,\Omega}$ and $\|\cdot\|_{0,T}$ denote the L^2 norm on domain Ω and element T, respectively. Let $\mathcal{E}(T)$ be the set of edges of T and $\omega_T = \cup_{T' \cap T \in \mathcal{E}(T)} T'$, i.e., ω_T is the set of triangles T' that share a common edge with T. Let P_T^0 be the L^2 projection onto the space of polynomials of degree 0 on element T. The interior residual R_T of element T and the interelement flux jump R_E of edge E are defined as follows:

$$
\begin{aligned}
R_T &= (f - b \cdot \nabla u_h)|_T, \\
R_T^0 &= \mathcal{P}_T^0(R_T), \\
R_E &= \begin{cases} [\frac{\partial u_h}{\partial n_E}]_E & \text{if } E \in \Omega, \\ 0 & \text{if } E \in \partial\Omega, \end{cases}
\end{aligned}
$$

where $[\cdot]_E$ is the jump across edge E.[1] Let Φ be the element affine mapping from the physical domain to the computational domain and let χ_i be the nodal basis function of node i. The approximation space is denoted as $Q_T = Q_T \bigoplus B_T$, where

$$
\begin{aligned}
Q_T = span\{\psi_E \circ \Phi^{-1} |\ \psi_E = 4\chi_i\chi_j,\ i,j \text{ are the endpoints of } E \text{ and} \\
E \in \partial T \bigcap (\Omega \bigcup \Gamma_N)\}
\end{aligned}
$$

is the space spanned by quadratic edge bubble functions and

$$
B_T = span\left\{\psi_T \circ \Phi^{-1} |\ \psi_T = 27 \prod_{i=1}^{3} \chi_i\right\}
$$

is the space spanned by cubic interior bubble functions. For details, see [8]. On each element T, the error estimator is then given by $\eta_{h,T} = \|\nabla e_T\|_{0,T}$, where $e_T \in Q_T$ satisfies

$$
\epsilon(\nabla e_T, \nabla v)_T = (R_T^0, v)_T - \frac{1}{2}\epsilon \sum_{E \in \partial T} (R_E, v)_E. \tag{2.2}
$$

Let $e_h = u - u_h$. The a posteriori error estimation is specified as follows:

(global upper bound)

$$
\|\nabla(e_h)\|_{0,\Omega} \le C \left(\sum_{T \in \Im_h} \eta_{h,T}^2 + \sum_{T \in \Im_h} \left(\frac{h}{\epsilon}\right)^2 \left\|R_T - R_T^0\right\|_{0,T}^2 \right)^{1/2} \tag{2.3}
$$

(local lower bound)

$$
\eta_{h,T} \le c \left(\|e_h\|_{0,\omega_T} + \sum_{T \subset \omega_T} \frac{h_T}{\epsilon} \|b \cdot \nabla e_h\|_{0,T} + \sum_{T \subset \omega_T} \frac{h_T}{\epsilon} \left\|R_T - R_T^0\right\|_{0,T} \right), \tag{2.4}
$$

where constants C and c are independent of the diffusion parameter ϵ and mesh size h.

[1] This definition of R_E for $E \in \partial\Omega$ is for Dirichlet boundary conditions. We don't consider Neumann conditions in this study; in case $E \in \partial\Omega$ and a Neumann condition holds, the flux jump R_E would be set to $-2(\frac{\partial u_h}{\partial n_E})$ [8].

The sharpness of the error indicator can be revealed by computing the local effectivity index,

$$E_T = \max_{t \in \Im_h} \frac{\eta_{h,T}}{|u - u_h|_{1,T}},$$

and the global effectivity index,

$$E_\Omega = \frac{(\sum_{T \in \Im_h} \eta_{h,T}^2)^{1/2}}{|u - u_h|_{1,\Omega}},$$

where $|\cdot|_{1,\Omega}$ and $|\cdot|_{1,T}$ represent the H^1 seminorms on domain Ω and element T, respectively. If both indices are close to 1, the error indicator is reliable and efficient. The global upper bound provides an estimate of the error over the whole domain, and the local lower bound locates where the error is large. It has been shown that E_Ω grows in proportion to $\sqrt{Pe}$ and E_T grows in proportion to Pe for the KS-indicator [8]. The following numerical results support this conclusion.

Consider here equation (1.1) on the domain $\Omega = [0,1] \times [0,1]$ with $b = (\beta_1, \beta_2) = (\sin 75^\circ, \cos 75^\circ)$ and the Dirichlet boundary condition is obtained from the analytic solution

$$u(x,y) = \frac{e^{\beta_1 x/\varepsilon} - 1}{e^{\beta_1/\varepsilon} - 1} + \frac{e^{\beta_2 y/\varepsilon} - 1}{e^{\beta_2/\varepsilon} - 1}. \tag{2.5}$$

Both global effectivity index E_Ω and local effectivity index E_T are computed. In order to see how the effectivity indices change in terms of the diffusion parameter ϵ and mesh size h, the problem is solved over uniform meshes with mesh size $h = \frac{1}{8}, \frac{1}{16}, \frac{1}{32}$, and $\frac{1}{64}$ for $\epsilon = \frac{1}{64}, \frac{1}{256}, \frac{1}{1024}$, and $\frac{1}{4096}$. For accurately approximating the true error $u - u_h$, a very fine mesh $\Im_f$, as shown in Figure 2.1, consisting of 11272 nodes and 21379 elements is generated by first solving the above test problem with $\epsilon = 10^{-3}$ on a 64×64 mesh followed by three mesh refinement steps where a large threshold $\theta = 0.75$ in the maximum marking strategy (2.1) is used to prevent unnecessary over refinement. An approximation of the exact error is then computed on $\Im_f$ by

$$|u - u_h|_{1,\Omega^*} = \left(\sum_{\tau \in \Im_f \cup \Omega^*} |u - u_h|_{1,\tau}^2 \right)^{1/2} \quad \text{for } \Omega^* = \Omega \text{ or } T \in \Im_h,$$

where the discrete true solution u is evaluated directly from (2.5) on $\Im_f$ and the SDFEM solution u_h is prolonged from $\Im_h$ onto $\Im_f$ by standard bilinear interpolation. In Table 2.1, for $h \gg \epsilon$, E_Ω and E_T decrease by factors approximately of size $\sqrt{2}$ and 2, respectively, as the mesh size is halved. Also, E_Ω and E_T double and quadruple, respectively, when ϵ is reduced by a factor of four. Thus, $E_T = O(P_e)$ and $E_\Omega = O(\sqrt{P_e})$, as shown in [8].

Although there is deterioration in reliability and efficiency for these error indicators, the regions with large errors can still be located when a good threshold value θ is chosen. Next, we give a representative picture of how the adaptive solution process improves the solution quality. We use the KS-indicator for mesh refinement in solving Problem 1 with the diffusion parameter $\epsilon = 10^{-3}$ and $\phi = 0$. From the local lower bound (2.4), we suspect that the value of the indicator $\eta_{h,T}$ in the outflow boundary layer regions is $O(\frac{h}{\epsilon})$ larger than its value in the internal layer regions. Therefore, for the case considered here, a threshold value $\theta = 0.01 \approx \frac{\epsilon}{h}$ is chosen so that both the boundary and internal layer regions can be refined by the maximum marking strategy (2.1). A sequence of adaptively refined meshes is shown in Figure 2.2 in which ele-

ments in both boundary layer and internal layer regions are refined. It can be seen in Figure 2.3 that both the characteristic and downstream layers are resolved accurately by the mesh refinement process.

3. The multigrid algorithms. Given a sequence of meshes $\Im_1, \Im_2, \ldots, \Im_n$, let V_k be the piecewise linear finite element subspace associated with $\Im_k$, let A_k be the matrix defined on $\Im_k$, and let w_k be the initial guess. Let MG_1 represent the direct solver on the coarsest grid $\Im_1$. The general form of the k-level multigrid algorithm is shown in Algorithm 1, where f_k is the right-hand side obtained from discretization of data function f on $\Im_k$, M_k^{-1} represents the smoothing operator, and the operators I_k^{k-1} and I_{k-1}^k represent the grid transfers, restriction and prolongation, between $\Im_{k-1}$ and $\Im_k$. The multigrid V-cycle and W-cycle are defined by choosing $m = 1$ and $m = 2$, respectively.

Unlike in solving self-adjoint elliptic problems, GMG methods usually do not possess mesh-independent convergence for the convection-diffusion equation with dominant convection unless the mesh size $h \ll \epsilon$ or special treatments are employed for the meshes, interpolations, and relaxation [4] when $h \gg \epsilon$. For $h \ll \epsilon$ (and coarse grid size also $< \epsilon$), Bramble et al. [1], [2] and Wang [22] have shown GMG converges with a rate independent of mesh size by using a *compact perturbation technique*. To achieve mesh-independent convergence for $h \gg \epsilon$, Reusken and Olshanskii have recently shown L^2-convergence by using semicoarsening, matrix-dependent prolongation, and line relaxation for Problem 1 discretized by an upwind finite difference method [9], [14], and Szepessy proved L^1-convergence on R^2 by residual damping through large smoothing steps [12]. On the other hand, the convergence of AMG is essentially based on an M-matrix property of the discrete system [17]. No convergence result of algebraic multigrid for the convection-diffusion equation exists to our knowledge. In this section, we describe the versions of GMG and AMG considered here. We restrict our attention to the 2-level V-cycle multigrid and show some convergence results for Problem 1 on uniform rectangular meshes. For this problem, the matrix from SDFEM discretization with stabilization parameter $\delta_T = \frac{h}{2}$ has the form

$$A_k = \begin{bmatrix} D & -U & & & & \\ -L & D & -U & & 0 & \\ & -L & \ddots & \ddots & & \\ & & \ddots & \ddots & -U & \\ & 0 & & -L & D & -U \\ & & & & -L & D \end{bmatrix}, \tag{3.1}$$

Algorithm 1 Multigrid algorithm.

1. set $x_k = w_k$,
2. (presmoothing) $x_k = w_k + M_k^{-1}(g_k - A_k w_k)$,
3. (restriction) $\bar{g}_k = I_k^{k-1}(g_k - A_k x_k)$,
4. (correction) $q_i = MG_{k-1}(q_{i-1}, \bar{g}_k)$ for $1 \le i \le m$, $m = 1$ or 2 and $q_0 = 0$,
5. (prolongation) $\bar{q}_m = I_{k-1}^k q_m$,
6. set $x_k = x_k + \bar{q}_m$,
7. (postsmoothing) $x_k = x_k + M_k^{-1}(g_k - A_k x_k)$,
8. set $y_k = MG_k(w_k, g_k) = x_k$.

where the block tridiagonal matrices

$$
\begin{aligned}
D &= h \times \text{tridiag}\left[\frac{1}{6} - \frac{1}{3}\frac{\epsilon}{h}, \frac{2}{3} + \frac{8}{3}\frac{\epsilon}{h}, \frac{1}{6} - \frac{1}{3}\frac{\epsilon}{h}\right], \\
L &= h \times \text{tridiag}\left[\frac{1}{6} + \frac{1}{3}\frac{\epsilon}{h}, \frac{2}{3} + \frac{1}{3}\frac{\epsilon}{h}, \frac{1}{6} + \frac{1}{3}\frac{\epsilon}{h}\right], \\
U &= \epsilon \times \text{tridiag}\left[\frac{1}{3}, \frac{1}{3}, \frac{1}{3}\right].
\end{aligned} \tag{3.2}
$$

In the following, we describe each component of the multigrid methods used here. First, we use the same smoother in both GMG and AMG. On uniform rectangular meshes, one step of a horizontal line Gauss–Seidel (HLGS) smoother is used. The HLGS method uses the block lower triangle of A_k as a splitting operator. (Thus, the HLGS sweep can be viewed as proceeding along horizontal lines, one line at a time, in the vertical direction.) Second, in GMG, (1) the coarse grids are obtained directly from the mesh refinement process; (2) the grid transfer is via linear interpolation for prolongation, and the restriction operator I_k^{k-1} is then taken to be the transpose of the prolongation operator I_{k-1}^k; and (3) the matrix A_k is obtained directly from SDFEM discretization in the refinement process. For AMG, we use the method developed by Ruge and Stüben [17] (AMG): (1) a coarse grid at level $k-1$ is generated by coarsening the fine grid along the so-called strong connection direction of matrix graph $\mathcal{G}$ of $A_k = (a_{i,j})$ where a directive edge $\overrightarrow{e}_{i,j} \in \mathcal{G}$ is defined to be strongly connected from node i to node j if $\mu \le \frac{-a_{i,j}}{\max_{m \neq i}(-a_{i,m})}$ for a given parameter $0 < \mu < 1$; (2) the interpolation operator I_{k-1}^k is defined dynamically by a sophisticated algebraic formula during the AMG coarsening process [17]; and (3) the matrix A_{k-1} for a coarse grid is computed by $I_k^{k-1} A_k I_{k-1}^k$. The above process is repeated until all coarse grids are generated.

Next, we show the convergence behavior of 2-level V-cycle multigrid for Problem 1. Let E_k^s be the error reduction operator of the HLGS smoother and let $E_k^c = I - I_{k-1}^k A_{k-1}^{-1} I_k^{k-1} A_k$ be the coarse grid correction operator. The error reduction operators of multigrid methods can then be written as $E_k^s E^c E_k^s$. The notation E_k^{mg} and E_k^{amg} denotes the error reduction operators of geometric multigrid and the algebraic multigrid, respectively. The notation $\|\cdot\|$ denotes the usual discrete L^2 norm for any vector and matrix. The notation $\|\cdot\|_0$ and $\|\cdot\|_1$ represents the continuous L^2 and H^1 norms. Variants of these norms are specified using matrix notation in (3.17) below.

In order to show convergence, the following auxiliary lemmas are needed.

LEMMA 3.1. *Given two symmetric matrices B_1 and B_2, assume that $B_1, B_2 \ge 0$, B_1 is irreducible, and B_2 is positive definite. The following properties hold.*

1. *There exists a positive eigenvector x^+ of $B_2^{-1}B_1$ such that*

$$B_2^{-1}B_1 x^+ = \rho(B_2^{-1}B_1)x^+. \tag{3.3}$$

2. *If $\alpha I - B_2^{-1}B_1$ is nonsingular and $(\alpha I - B_2^{-1}B_1)^{-1} \ge 0$, then $\rho(B_2^{-1}B_1) < \alpha$.*

Proof. The existence of a positive eigenvector satisfying (3.3) is essentially a generalization of the well-known Perron–Frobenius theorem [20, Theorem 2.7]. Using (3.3), one can prove the second result using a standard argument of the Perron–Frobenius theory; see Theorem 3.16 in [20]. ∎

LEMMA 3.2. *Let L and D be the matrices defined in* (3.2). *For any $\delta \ge (1 + \frac{2\epsilon}{h})\frac{h}{\epsilon}$, the matrix $\delta(D-L) - D$ is an M-matrix.*

Proof. Let us choose $\delta = \frac{h\gamma}{\epsilon}$ for some $\gamma > 0$. From (3.2), $D - L = \frac{\epsilon}{3} \times$ tridiag$[-2, 7, -2]$. Therefore, we have

$$\begin{aligned}\delta(D-L) - D &= h \times \text{tridiag}\left[\frac{-2\gamma}{3}, \frac{7\gamma}{3}, \frac{-2\gamma}{3}\right] - h \times \text{tridiag}\left[\frac{1}{6} - \frac{\epsilon}{3h}, \frac{2}{3} + \frac{8\epsilon}{h}, \frac{1}{6} - \frac{\epsilon}{3h}\right] \\ &= h \times \text{tridiag}\left[-\left(\frac{2\gamma}{3} + \frac{1}{6} - \frac{\epsilon}{3h}\right), \frac{7\gamma}{3} - \frac{2}{3} - \frac{8\epsilon}{3h}, -\left(\frac{2\gamma}{3} + \frac{1}{6} - \frac{\epsilon}{3h}\right)\right].\end{aligned}$$

Since

$$\frac{7\gamma}{3} - \frac{2}{3} - \frac{8\epsilon}{3h} - 2\left(\frac{2\gamma}{3} + \frac{1}{6} - \frac{\epsilon}{3h}\right) = \gamma - 1 - \frac{2\epsilon}{h},$$

clearly, for $\gamma \geq 1 + \frac{2\epsilon}{h}$, the matrix $\delta(D-L) - D$ is irreducible and weakly diagonal dominant. This implies that the matrix $\delta(D-L) - D$ and $(\delta(D-L) - D)^{-1}$ are positive definite. Moreover, since the off-diagonal entries of $(\delta(D-L) - D)$ are all negative, the matrix $\delta(D-L) - D$ is an M-matrix for $\delta \geq (1 + \frac{2\epsilon}{h})\frac{h}{\epsilon}$. ∎

LEMMA 3.3. *For $h \gg \epsilon$, the error reduction matrix E_k^s of the HLGS iterative method for the matrix obtained from SDFEM discretization of Problem* 1 *satisfies the following inequality:*

$$\|E_k^s\| \leq 3\frac{\epsilon}{h^2} \min\left\{\frac{3h}{\sqrt{\epsilon}}, 1\right\}. \tag{3.4}$$

Proof. With A_k from (3.1), E_k^s is the product of the inverse of the block lower triangular part of A_k and the strict block upper triangular part of A_k. By direct computation, one has $E_k^s = G_1 G_2$, where

$$G_1 = \begin{bmatrix} 0 & I & & & \\ 0 & D^{-1}L & \ddots & & \\ \vdots & \vdots & \ddots & I & \\ 0 & (D^{-1}L)^{n-2} & \cdots & D^{-1}L & I \\ 0 & (D^{-1}L)^{n-1} & \cdots & (D^{-1}L)^2 & D^{-1}L \end{bmatrix}, \; G_2 = \begin{bmatrix} 0 & & & \\ & D^{-1}U & & \\ & & \ddots & \\ & & & D^{-1}U \end{bmatrix}.$$

From the Gerschgorin circle theorem, the following inequalities hold for $h \gg \epsilon$:

$$\begin{aligned}\|U\| &= \rho(U) \leq \epsilon, \\ \left\|D^{-1}\right\| &= \rho(D^{-1}) = \frac{1}{\lambda_{min}(D)} < \frac{1}{\frac{h}{3} + \frac{10\epsilon}{3}} \leq \frac{3}{h}.\end{aligned}$$

Therefore, we have

$$\|G_2\| \leq 3\frac{\epsilon}{h}. \tag{3.5}$$

Next, we estimate $\|G_1\|$. First, let us estimate $\left\|D^{-1}L\right\|$. Considering $D^{-1}L = I - D^{-1}(D-L)$, we have

$$\alpha I - D^{-1}L = D^{-1}(D-L) - (1-\alpha)I = (1-\alpha)\left\{D^{-1}\left[\frac{1}{1-\alpha}(D-L) - D\right]\right\}. \tag{3.6}$$

Let us choose α satisfying $\frac{1}{1-\alpha} = \delta = (1 + \frac{2\epsilon}{h})\frac{h}{\epsilon}$. Lemma 3.2 implies that the matrix $\frac{1}{1-\alpha}(D-L)-D$ is an M-matrix. Consequently, $(\frac{1}{1-\alpha}(D-L)-D)^{-1} \geq 0$. Then using (3.6) and the fact that $D \geq 0$, it follows that the matrix $\alpha I - D^{-1}L > 0$. Since D is also positive definite, by Lemma 3.1 we can conclude that

$$\rho(D^{-1}L) < \alpha = 1 - \frac{1}{\delta} = 1 - \frac{\epsilon}{h}\left(\frac{1}{1+2\frac{\epsilon}{h}}\right) < 1 - \frac{\epsilon}{3h}. \tag{3.7}$$

Let $x = (x_1, x_2, \ldots, x_N) \in V_h$, where $x_i \in R^N$ and $\sum_{i=1}^{N} \|x_i\|^2 = 1$. We have that $\|G_1 x\| < \|G_1 y\|$ for $y = (\|x_1\| x^+, \|x_2\| x^+, \ldots, \|x_N\| x^+)$, where x^+ is the Perron–Frobenius eigenvector of $D^{-1}L$. Therefore, the eigenvector corresponding to the maximum eigenvalue has the following form:

$$y = (0, \beta_1 x^+, \beta_2 x^+, \ldots, \beta_{N-1} x^+), \text{ where } \sum_{i=1}^{N-1} \beta_i^2 = 1.$$

By direct computation,

$$\begin{aligned}\|G_1 y\| &\leq \left\{ \sum_{i=1}^{N} \left\| \sum_{k=1}^{i} \beta_k (D^{-1}L)^{i-k} x^+ \right\|^2 \right\}^{1/2} \\ &= \left\{ \sum_{i=1}^{N} \left(\sum_{k=1}^{i} \beta_k l^{i-k} \right)^2 \right\}^{1/2},\end{aligned}$$

where $l = \rho(D^{-1}L)$. Since $l < 1$ and $\sum_{i=1}^{N-1} \beta_i^2 = 1$, the inequalities

$$\|G_1\| \leq \left\{ \sum_{i=1}^{N-1} \left(\sum_{k=1}^{i} \beta_k \right)^2 \right\}^{1/2} \leq \left(\sum_{i=1}^{N-1} i \right)^{1/2} \leq N \tag{3.8}$$

and

$$\begin{aligned}\|G_1\| &\leq \left\{ \sum_{i=1}^{N-1} \left[\sum_{k=1}^{i} \beta_k^2 \right] \left[\sum_{k=1}^{i} (l^{i-k})^2 \right] \right\}^{1/2} \leq \left\{ \sum_{i=1}^{N-1} \sum_{k=1}^{i} (l^{i-k})^2 \right\}^{1/2} \\ &\leq \left\{ \frac{1}{1-l^2} \left(\sum_{i=1}^{N-1} 1 - l^{2i} \right) \right\}^{1/2} \leq \left(\frac{N}{1-l} \right)^{1/2}\end{aligned} \tag{3.9}$$

hold. Recall that $l < 1 - \frac{\epsilon}{3h}$ from (3.7). By combining (3.8) and (3.9), we have

$$\|G_1\| \leq \frac{1}{h} \min\left\{ \frac{3h}{\sqrt{\epsilon}}, 1 \right\}. \tag{3.10}$$

Therefore, from (3.5) and (3.10), inequality (3.4) holds. ∎

LEMMA 3.4 (smoothing property). *Let E_k^s be the error reduction operator of the HLGS iterative method on V_k. The following inequality holds:*

$$\|A_k(E_k^s)\| \leq \epsilon \left(1 + 3\frac{\epsilon}{h_k^2} \min\left\{ \frac{3h_k}{\sqrt{\epsilon}}, 1 \right\} \right). \tag{3.11}$$

Proof. By directly multiplying A_k and E_k^s, we have

$$A_k E_k^s = \begin{bmatrix} 0 & U - U(D^{-1}L)D^{-1}U & -UD^{-1}U & & \\ 0 & -U(D^{-1}L)^2D^{-1}U & \ddots & \ddots & \\ \vdots & \vdots & \ddots & -U(D^{-1}L)D^{-1}U & -UD^{-1}U \\ 0 & -U(D^{-1}L)^{n-1}D^{-1}U & \cdots & -U(D^{-1}L)^2D^{-1}U & -U(D^{-1}L)D^{-1}U \\ 0 & 0 & \cdots & 0 & 0 \end{bmatrix}$$

$$= \operatorname{diag}[U](T_1 - T_2G_2),$$

where

$$T_1 = \begin{bmatrix} 0 & I & & & \\ 0 & 0 & \ddots & & \\ \vdots & \vdots & \ddots & I & \\ 0 & 0 & \cdots & 0 & I \\ 0 & 0 & \cdots & 0 & 0 \end{bmatrix} \text{ and } T_2 = \begin{bmatrix} 0 & D^{-1}L & I & & \\ 0 & (D^{-1}L)^2 & \ddots & \ddots & \\ \vdots & \vdots & \ddots & D^{-1}L & I \\ 0 & (D^{-1}L)^{n-1} & \cdots & (D^{-1}L)^2 & D^{-1}L \\ 0 & 0 & \cdots & 0 & 0 \end{bmatrix}.$$

Using the same argument as in the proof of Lemma 3.3, one can show

$$\|T_2G_2\| \le 3\frac{\epsilon}{h_k^2} \min\left\{\frac{3h_k}{\sqrt{\epsilon}}, 1\right\}.$$

Therefore,

$$\begin{aligned} \|A_k E_k^s\| &\le \epsilon\left(1 + 3\frac{\epsilon}{h_k^2} \min\left\{\frac{3h_k}{\sqrt{\epsilon}}, 1\right\}\right) \\ &= \epsilon\left(1 + 3\frac{\epsilon}{h_k^2} \min\left\{\frac{3h_k}{\sqrt{\epsilon}}, 1\right\}\right). \qquad \square \end{aligned}$$

Using the inequalities in Lemmas 3.3 and 3.4, our multigrid convergence results can be shown. In the following, estimates of the error reduction operators of GMG and AMG are given in Theorems 3.5 and 3.7, respectively.

THEOREM 3.5. *Let E_k^{mg} be the error reduction operator of the 2-level V-cycle geometric multigrid in Algorithm 1 with the HLGS smoother and bilinear interpolation prolongation on a uniform rectangular mesh $\Im_k$ for Problem 1. The following estimate for E_k^{mg} holds:*

$$\|E_k^{mg}\| \le c\frac{\epsilon}{h^{3/2}} \quad \textit{for some constant } c. \tag{3.12}$$

Proof. First, in general, the error reduction operator of GMG can be written as

$$E_k^{mg} = E_k^s E^c E_k^s = E_k^s(I - I_{k-1}^k(I - E_{k-1}^{mg})A_{k-1}^{-1}I_k^{k-1}A_k)E_k^s. \tag{3.13}$$

For 2-level GMG, since $E_{k-1}^{mg} = 0$, we have

$$\begin{aligned} \|E_k^{mg}\| &= \left\|E_k^s(I - I_{k-1}^k A_{k-1}^{-1} I_k^{k-1} A_k)E_k^s\right\| \\ &\le \|E_k^s\| \left\|(I - I_{k-1}^k A_{k-1}^{-1} I_k^{k-1} A_k)E_k^s\right\|. \end{aligned} \tag{3.14}$$

Let $P_k : H^1 \mapsto V_k$ be the projection operator defined by $B_{sd}(P_k u, v) = B_{sd}(u, v)$ for all $v \in V_k$ for all k. We have $I_k^{k-1} A_k = A_{k-1} P_{k-1}$ on V_k. Therefore, let $e^s = E_k^s(e)$ for any $e \in V_k \subset H^1$,

$$\begin{aligned}
\left\|(I - I_{k-1}^k A_{k-1}^{-1} I_k^{k-1} A_k) E_k^s(e)\right\| &= \left\|(I - I_{k-1}^k P_{k-1}) e^s\right\| \\
&\le c h_k^{-2} \left\|(I - P_{k-1}) e^s\right\|_0 \le c h_k^{-2} \frac{1}{\sqrt{\epsilon}} \left\|(I - P_{k-1}) e^s\right\|_1 \\
&\le c h_k^{-2} \sqrt{\frac{h_k}{\epsilon}} |e^s|_1 \quad \text{by the a priori error estimation,} \\
&\le c h_k^{-2} \sqrt{\frac{h_k}{\epsilon^2}} \left\|A_k E_k^s(e)\right\|_0 \quad \text{by the regularity estimate,} \\
&\le c\sqrt{h_k} \left(1 + 3\frac{\epsilon}{h_k^2} \min\left\{\frac{3h_k}{\sqrt{\epsilon}}, 1\right\}\right) \|e\| \quad \text{by (3.11),}
\end{aligned}$$

where c is a constant independent of h and ϵ. By combining the above estimate and (3.4), inequality (3.14) implies

$$\|E_k^{mg}\| \le c \frac{\epsilon}{h^{3/2}} \min\left\{\frac{h}{\sqrt{\epsilon}}, 1\right\} \left(1 + \frac{\epsilon}{h^2} \min\left\{\frac{h}{\sqrt{\epsilon}}, 1\right\}\right) \le c \frac{\epsilon}{h^{3/2}}. \qquad \square$$

Remark 3.6. From inequality (3.12), it is clear that the geometric multigrid converges when $h_k \gg \epsilon^{2/3}$. The above 2-level analysis can be generalized by mathematical induction and estimation of (3.13). In [23], we have found that the multigrid V-cycle converges when $h \gg \sqrt{\epsilon}$.

Next, we analyze AMG convergence. The framework to prove the convergence of algebraic multigrid is based on the *smoothing assumption*,

$$\exists\ \alpha > 0 \text{ such that } \|E_k^s e_h\|_1^2 \le \|e_h\|_1^2 - \alpha \|e_h\|_2^2 \text{ for any } e_h \in V_k, \tag{3.15}$$

and the *approximation assumption*,

$$\min_{e_H \in V_{k-1}} \left\|e_h - I_H^h e_H\right\|_0^2 \le \beta \|e_h\|_1^2 \text{ with } \beta > 0 \text{ independent with } e_h \in V_k, \tag{3.16}$$

where

$$\|v\|_0^2 = \langle Dv, v\rangle, \quad \|v\|_1^2 = \langle A_k v, v\rangle, \quad \text{and} \quad \|v\|_2^2 = \langle D^{-1} A_k v, A_k v\rangle \tag{3.17}$$

for any $v \in V_k$. For problems where the coefficient matrix is an M-matrix, Ruge and Stüben have proved that 2-level AMG converges when both the smoothing assumption and the approximation assumption hold for M-matrices. It has also been shown that the smoothing assumption holds for the usual point Gauss–Seidel relaxation, and the approximation assumption holds for some simple coarse grid selection algorithms

with algebraic interpolation formula [17]. The classical algebraic multigrid coarsening algorithm is designed to satisfy the approximation assumption based on the property of algebraically smooth error, whereby the smooth errors vary slowly along the strong connection directions.

For the discrete convection-diffusion Problem 1, the matrix obtained from SDFEM discretization is nonsymmetric and not an M-matrix. As a result, the usual framework of AMG analysis cannot be applied directly. In Lemma 3.2 of [14], Reusken has shown that there is a constant c independent of ϵ and h such that $\|E^c\| \leq c$ for a two-grid method with a coarse grid from semicoarsening and a matrix-dependent prolongation. In the following, we take this as an assumption and estimate the error reduction rate of AMG in terms of the parameter β in the approximation assumption (3.16) by using (3.4) and (3.11).

THEOREM 3.7. *Assume the approximation assumption* (3.16) *holds. Then the following inequality holds:*

$$\|E_k^{amg}\| \leq \sqrt{3}c\frac{\epsilon^2}{h^3}\min\left\{\frac{h}{\sqrt{\epsilon}},1\right\}\frac{\beta}{\sqrt{h}}, \tag{3.18}$$

where c is some constant independent of ϵ and h.

Proof. For any $e \in V_k$, we have

$$\|E_k^{amg}(e)\| = \|E_k^s E^c E_k^s(e)\| \leq \frac{\epsilon}{h^2}\min\left\{\frac{h}{\sqrt{\epsilon}},1\right\}\|E^c E_k^s(e)\|. \tag{3.19}$$

Let $\bar{e} = E_k^s(e)$. Since $\mathrm{Ker}(E^c) = Rang(I_{k-1}^k)$, we have

$$\begin{aligned}
\|E^c(\bar{e})\| &\leq c\min_{e_H\in V_{k-1}}\left\|\bar{e} - I_{k-1}^k e_H\right\| \leq c\sqrt{\frac{3}{h}}\min_{e_H\in V_{k-1}}\left\|\bar{e} - I_{k-1}^k e_H\right\|_0 \\
&\leq c\sqrt{\frac{3}{h}}\beta\|\bar{e}\|_1 \text{ by approximation assumption (3.16)}, \\
&\leq \sqrt{\frac{3}{h}}\beta(\|A_k E_k^s(e)\|\,\|E_k^s(e)\|)^{1/2} \\
&\leq c\sqrt{\frac{3}{h}}\beta\left(\epsilon\left[1+\frac{\epsilon}{h^2}\min\left\{\frac{h}{\sqrt{\epsilon}},1\right\}\right]\left[\frac{\epsilon}{h^2}\min\left\{\frac{h}{\sqrt{\epsilon}},1\right\}\right]\right)^{1/2}\|e\| \\
&\qquad \text{by (3.4) and (3.11)} \\
&\leq c\sqrt{\frac{3}{h}}\frac{\epsilon}{h}\beta\|e\|.
\end{aligned} \tag{3.20}$$

By combining (3.19) and (3.20), inequality (3.18) holds. ∎

Remark 3.8. Inequality (3.18) can be rewritten as

$$\|E_k^{amg}\| \leq c\frac{\epsilon}{h^{3/2}}\min\left\{\frac{h}{\sqrt{\epsilon}},1\right\}\frac{\beta\epsilon}{h^2} = c\frac{\epsilon}{h^{3/2}}\left(\frac{\sqrt{\epsilon}}{h}\right)^{\alpha}\beta,$$

where $\alpha = \begin{cases} 1, & h<\sqrt{\epsilon}, \\ 2, & h\geq\sqrt{\epsilon}. \end{cases}$ Comparison with the estimate of E_k^{mg} in (3.12) suggests that algebraic multigrid will converge more rapidly than geometric multigrid if the parameter β in the approximation assumption is less than $(\frac{h}{\sqrt{\epsilon}})^{\alpha}$. Although we have not

TABLE 3.1
Comparison of GMG and AMG for Problem 1 *on uniform rectangular meshes.*

ϵ	10^{-1}	10^{-2}	10^{-3}	10^{-4}
$h=\frac{1}{8}$	5	4	2	2
$h=\frac{1}{16}$	5	4	3	2
$h=\frac{1}{32}$	5	5	4	2

(a) GMG iterative steps.

ϵ	10^{-1}	10^{-2}	10^{-3}	10^{-4}
$h=\frac{1}{8}$	4	3	2	2
$h=\frac{1}{16}$	4	3	3	2
$h=\frac{1}{32}$	5	4	3	2

(b) AMG iterative steps.

yet estimated β for the interpolation operator from AMG coarsening, AMG converges more rapidly than GMG, as shown in Table 3.1. Moreover, in Table 3.1, the facts that both GMG and AMG converge more rapidly as ϵ becomes smaller and converge more slowly as the mesh size h decreases are also consistent with our theoretical analysis. In these numerical studies, the stopping tolerance is set to be

$$\|r_m\| \leq 10^{-6}\,\|r_0\|\,, \tag{3.21}$$

where r_0 is the initial residual and r_m is the residual at the mth iteration.

Remark 3.9. Since the row-sum $\sum_j(a_{i,j})$ and column-sum $\sum_i(a_{i,j})$ are equal for the matrix A_k arising from Problem 1, the following equality holds:

$$\|e\|_1^2 = (A_k e, e) = \sum_{i,j} a_{i,j}e_i e_j = \frac{1}{2}\left(\sum_{i,j}(-a_{i,j})(e_i-e_j)^2\right) + \sum_i s_i e_i^2, \tag{3.22}$$

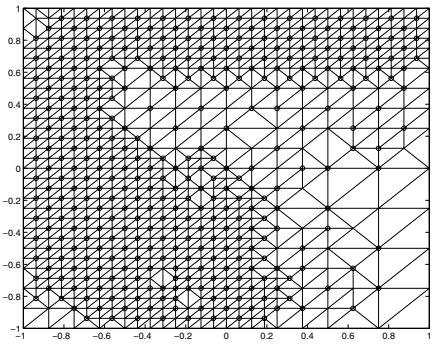
where $s_i = \sum_j(a_{i,j})$. Recall that the algebraically smooth error e_s is characterized by $E_k^s(e_s) \approx e_s$. Clearly, inequalities (3.4) and (3.11) imply

$$\begin{aligned}
&\langle A_k e_s, e_s\rangle \approx \langle A_k E_k^s e_s, E_k^s e_s\rangle \leq \frac{c}{h}\|A_k E_k^s\|\|E_k^s\|\|e_s\|_0^2\\
&\leq c\frac{\varepsilon^2}{h^3}\min\left\{\frac{3h}{\sqrt{\varepsilon}},1\right\}\left(1+\frac{3\varepsilon}{h^2}\min\left\{\frac{3h}{\sqrt{\varepsilon}},1\right\}\right)\|e_s\|_0^2\\
&\leq c\frac{\varepsilon^2}{h^3}\|e_s\|_0^2.
\end{aligned}$$

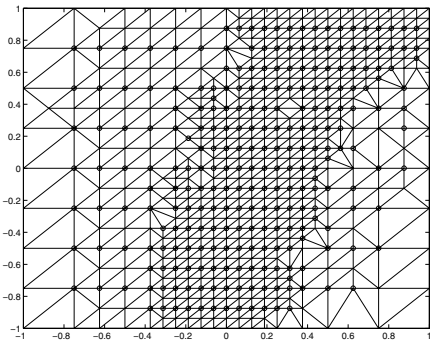
For $h \gg \epsilon^{2/3}$, $\|e_s\|_1^2 \ll \|e_s\|_0^2$ follows from the above estimate. Moreover, by (3.22), this is equivalent to

$$\begin{aligned}
&\frac{1}{2}\sum_i\sum_{j\neq i-1,i+1}(-a_{i,j})(e_i-e_j)^2 + \sum_i s_i e_i^2\\
&\ll \sum_i a_{i,i}e_i^2 + a_{i,i-1}(e_i-e_{i-1})^2 + a_{i,i+1}(e_i-e_{i+1})^2\\
\Rightarrow &\frac{1}{2}\sum_i\sum_{j\neq i-1,i+1}\left(\frac{-a_{i,j}}{a_{i,i}}\right)(e_i-e_j)^2 \ll \sum_i e_i^2 + \frac{1}{4}(e_i-e_{i-1})^2 + \frac{1}{4}(e_i-e_{i+1})^2.
\end{aligned}$$

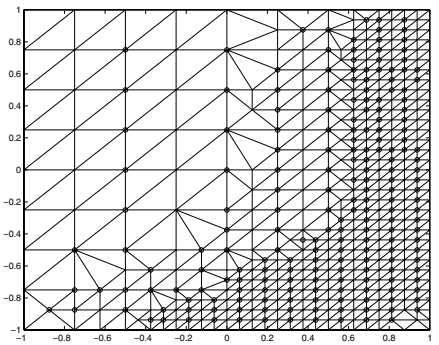
It can be seen from (3.1) that the weights $\frac{a_{i,j}}{a_{i,i}} = O(1)$ for downstream indices j and $O(\frac{\epsilon}{h})$ for upstream. Therefore, we can conclude that the smooth error tends to vary more slowly in downstream directions than in upstream directions. Since the strong



(a) $\phi = -45^\circ$ on an adaptive mesh.



(b) $\phi = 15^\circ$ on an adaptive mesh.



(c) $\phi = 75^\circ$ on an adaptive mesh.

FIG. 3.1. *Coarse grid points selected by AMG coarsening.*

connectivity of the matrix A_k is also along the downstream direction, we expect the AMG coarsening to select a large number of downstream nodes, and the resulting strategy tends to resemble one of semicoarsening.

In the following, we show the AMG coarse grids for the Problem 1 with $\epsilon = 10^{-3}$ and $\phi = -45^\circ$, 15°, and 75°, where the connection parameter is $\mu = 0.25$. Each fine grid is generated by two adaptive mesh refinement steps from an initial 8×8 mesh and the threshold value θ in (2.1) is set to 0.01. In Figure 3.1, the fine grid is plotted and the coarse grid points, selected by AMG coarsening, are marked by $\circ$. Evidently, the AMG coarsening process is sensitive to the flow direction mentioned in Remark 3.9 and generates meshes by means of semicoarsening. The numerical results in Table 3.1, and Table 4.3 and 4.4 of the next section, shows that AMG converges more quickly than GMG for Problem 1. This leads us to conjecture that the algebraically smooth errors are well in the range of the AMG interpolation operator, i.e., the parameter β in the approximation assumption is small. Analysis of the AMG interpolation and approximation assumption will be considered in a future study.

For Problem 2, multigrid convergence is much harder to prove. In fact, the presence of a stagnation point leads to poor performance of multigrid methods when the equation is discretized by a first order upwind scheme [10], [4]. However, many

numerical studies have shown that GMG- and AMG-accelerated Krylov space methods, such as GMRES and BiCGSTAB, achieve nearly mesh-independent convergence [10], [19]. Recently, Ramage has demonstrated that GMRES with GMG preconditioning achieves mesh-independent convergence when SDFEM with an optimal stabilization parameter is employed for discretization on uniform rectangular mesh [13]. In the next section, GMG and AMG are used as a preconditioner for GMRES in some numerical tests.

4. Numerical results. In this section, the performances of different linear solvers, including GMG, AMG, and preconditioned GMRES, for the discrete convection-diffusion equation are compared on both adaptively refined meshes and uniform meshes. We use both Problem 1 with $\phi = 0$ and Problem 2. In both problems, (1.1) is discretized by SDFEM with the stabilization parameter δ_T defined in (1.3) on both a uniform 32×32 mesh and an adaptively refined mesh for $\epsilon = 10^{-2}, 10^{-3}$, and 10^{-4}. Here, a 32×32 mesh is generated from 3 uniform refinements starting with a 4×4 initial mesh, and the adaptively refined mesh is generated by refining an initial 8×8 mesh 4 times, where full multigrid is used with those coarse meshes. The threshold value θ in the maximum marking strategy is chosen such that elements in the regions containing large errors can be refined for both problems.

For Problem 1, $\theta = 0.1$, 0.01, and 0.001 for $\epsilon = 10^{-2}, 10^{-3}$, and 10^{-4}, respectively. The adaptive meshes are shown in Figure 4.1. For Problem 2, $\theta = 0.1$ for all ϵ and the adaptive meshes are shown in Figure 4.2.

Since there are no natural "lines" in unstructured meshes or in the coarse meshes of AMG, only point-versions of the Gauss–Seidel method are used for smoothing. Grid points are numbered in lexicographical order where the y-coordinate is the primary

key and the x-coordinate is the secondary key. The point Gauss–Seidel method associated with this node ordering is called the forward horizontal Gauss–Seidel (forward-HGS) method. Naturally, one can obtain another lexicographical order where the x-coordinate is the primary key and the y-coordinate is the secondary key. The point Gauss–Seidel method associated with this node ordering is then called the forward vertical Gauss–Seidel (forward-VGS) method. The backward-HGS and backward-VGS methods are obtained from the forward-HGS and forward-VGS methods, respectively, by simply reversing the node ordering. In Problem 1, one step of forward-HGS is used in both presmoothing and postsmoothing. In Problem 2, the smoother consists of four point Gauss–Seidel sweeps (forward-HGS, forward-VGS, backward-HGS, and backward-VGS). Hereafter, this smoother is abbreviated as ADGS (namely, alternating direction Gauss–Seidel).

Both problems are solved by GMG, AMG, GMRES, and right-preconditioned GMRES with zero initial guess, and the stopping tolerance (3.21) is used here for these iterative solvers. The preconditioned GMRES methods with HGS, ADGS, GMG, and AMG preconditioners are denoted as GMRES-HGS, GMRES-ADGS, GMRES-GMG, and GMRES-AMG, respectively. In the following tables, increases in level numbers correspond to finer meshes, where level 1 represents the coarsest mesh in multigrid solver. The notation "-" represents that the number of iterations is greater than 400.

First, Tables 4.1 and 4.2 show some details about the meshes used by GMG and AMG. Table 4.1 shows the number of coarse grid points obtained starting from a uniform 32×32 fine grid of elements. Listed under "GMG" is simply the number of points in the hierarchical set of uniform coarse grids. Listed under "AMG" is the number of grid points derived using the AMG coarsening strategy. Table 4.2 shows what happens when adaptive grid refinement is used. That is, GMG uses the hierarchical set of grids obtained from adaptive refinement. In contrast, AMG starts with the fine grid produced by grid refinement, but then it generates *its own* set of coarse grids using its coarsening strategy. Table 4.1 shows that when AMG starts with a uniform fine mesh, it generates more coarse grid points than are found in the hierarchical coarse grids. On the other hand, Table 4.2 shows that if AMG starts with a fine mesh obtained from adaptive refinement, the coarse grids it generates often contain fewer points than are found in the adaptively refined coarse grids.

Tables 4.3–4.6 examine the iteration counts for both multigrid strategies as a function of the levels at which the solver is used. Tables 4.3 and 4.4 show that both solvers display "textbook" performance on Problem 1 for $\epsilon = 10^{-2}$. As ϵ is reduced, however, performance of GMG decreases and becomes mesh-dependent, especially on uniform grids. In contrast, the performance of AMG is robust and shows weaker

dependence on ϵ and mesh size. Problem 2, with a recirculating flow, is more difficult for both solvers. On a uniform grid, GMG diverges for $\epsilon = 10^{-4}$, but AMG manages to converge, as shown in Table 4.5. On adaptive meshes, as shown in Table 4.6, textbook-like performance is achieved for both methods. However, AMG is considerably slower than GMG, especially for small $\epsilon = 10^{-4}$ on the finest mesh. Our speculation

is that this is caused by inadequacy of the grid transfer operator used in AMG and the fact that the number of coarse grid points generated by AMG coarsening is only about half the number of coarse grid points used in GMG, as shown in Table 4.2(b). AMG interpolation can be improved by the recently developed AMGe methods [3]. As we will show below, performance can also be remedied using a Krylov space acceleration.

Next, we compare the performance of preconditioned GMRES methods on both the finest uniform mesh and the finest adaptive mesh. Tables 4.7 and 4.8 examine the iteration counts for various versions of preconditioned GMRES. The Krylov space acceleration of the convergence of GMG and AMG is observed in most cases. The numerical results indicate that the AMG-preconditioned GMRES requires the fewest iterations to converge, compared to GMG, AMG, and other versions of GMRES. Particularly in Problem 2, despite the fact that AMG converges more slowly than GMG, GMRES-AMG outperforms GMRES-GMG. This observation suggests that AMG can be a good preconditioner for Krylov space solvers in solving complex flow problems. Moreover, in Table 4.9, iterations of GMRES-AMG on each level of the adaptive meshes are shown for $\epsilon = 10^{-2} \cdots 10^{-4}$. It is clear that the convergence of GMRES-AMG depends only weakly on the mesh size and ϵ on adaptive meshes.

Remark 4.1. Notice a difference between performance of GMG for Problem 1

here and the bounds shown in section 3 which suggest convergence is essentially independent of ϵ. The latter result holds only in special settings and depends on having a very accurate smoother. Similar ϵ-independent results for this problem can be found in [9], [12], [14]. In contrast, the better performance of AMG is due to matrix-dependent grid transfer operators and the superior choice of coarse mesh identified by AMG coarsening, for which the smoother is better able to mimic the flow characteristics.

5. Conclusion. In this work, we have explored solution strategies for the convection-diffusion equation using adaptive gridding techniques and a multigrid algorithm. In section 3, the convergence analysis for both GMG with bilinear interpolation and line Gauss–Seidel smoother and AMG with the same smoother not only shows that GMG converges for Problem 1 when $h \gg \epsilon^{2/3}$, but also suggests that AMG converges faster than GMG on uniform rectangular meshes. Although the AMG interpolation and approximation assumption remain to be analyzed, our numerical results support this observation on both triangular and rectangular uniform meshes. In addition, numerical studies in section 4 show that the convergence rates of both GMG and AMG deteriorates as the diffusion parameter ϵ decreases. To overcome this drawback, we have found that Krylov space acceleration significantly improves the convergence of both GMG and AMG, especially when ϵ is small. Moreover, GMRES-AMG converges more rapidly than GMRES-GMG in all of our test cases on both uniform and adaptive meshes.

With adaptive mesh refinement, GMG seems to be a natural choice because the coarse grids, correction operators, and interpolations are ready to be used in GMG. However, GMG convergence is slower than AMG for some examples of both tested problems even though more coarse grid points are employed in GMG. On the other hand, the most important strength of AMG is that it can be treated as a black-box solver. There is no need to compute coarse grids and interpolations explicitly in AMG. The facts that AMG is applicable to a wider range of applications, AMG

converges for all of our test cases, and GMRES-AMG outperforms all other solvers in our numerical studies make AMG very attractive for solving the SDFEM-discretized convection-diffusion problems.

CENTRAL WENO SCHEMES FOR HAMILTON–JACOBI EQUATIONS ON TRIANGULAR MESHES*

DORON LEVY†, SUHAS NAYAK†, CHI-WANG SHU‡, AND YONG-TAO ZHANG§

Abstract. We derive Godunov-type semidiscrete central schemes for Hamilton–Jacobi equations on triangular meshes. High-order schemes are then obtained by combining our new numerical fluxes with high-order WENO reconstructions on triangular meshes. The numerical fluxes are shown to be monotone in certain cases. The accuracy and high-resolution properties of our scheme are demonstrated in a variety of numerical examples.

Key words. Hamilton–Jacobi equations, central schemes, unstructured grids

AMS subject classifications. Primary, 65M06; Secondary, 35L99

DOI. 10.1137/040612002

1. Introduction.

We consider Cauchy problems for Hamilton–Jacobi (HJ) equations of the form

$$\begin{cases} \phi_t(x,t) + H(x,\phi(x,t),\nabla\phi(x,t)) = 0, \quad x \in \Omega \subset \mathbb{R}^2, \\ \phi(x,t=0) = \phi_0(x). \end{cases} \tag{1.1}$$

HJ equations are being used in a variety of applications, such as optimal control problems, differential games, geometric optics, and the calculus of variations.

It is well known that solutions of (1.1) may develop discontinuous derivatives in finite time, and hence it is necessary to interpret solutions of (1.1) in an appropriate weak sense. Such a formulation in terms of the so-called viscosity solutions is due to Crandall, Evans, Ishii, Lions, among others (see [10, 11, 25] and the references therein).

We are interested in approximating solutions of (1.1) on a given conforming triangulation of the domain Ω. While general theory for approximating solutions of (1.1) can be found in the works of Barles, Lions, and Souganidis [4, 33, 26], in this work we focus on Godunov-type schemes for approximating such problems. Godunov-type schemes are based on a global reconstruction which is evolved exactly in time and sampled at the grid nodes at the next time step. A subclass of these schemes are central schemes in which the evolution stage is carried out at points that are located away from the discontinuities. Such a procedure eliminates the necessity of dealing with (generalized) Riemann problems on the cell-interfaces. In addition, systems can be solved componentwise without a characteristic decomposition. These features make central schemes particularly suitable for multidimensional problems and complicated geometries.

§Department of Mathematics, University of California, Irvine, CA 92697 (zyt@math.uci.edu).

First- and second-order fully discrete central schemes were introduced by Lin and Tadmor [23, 24] (see also [7]). Their schemes were based on the first-order Lax–Friedrichs scheme [12] and its second-order extension, the Nessyahu–Tadmor scheme [28], for approximating solutions of hyperbolic conservation laws.

Semidiscrete central schemes (on Cartesian meshes) were derived by Kurganov and Tadmor [21]. The main goal there was to reduce the numerical dissipation by estimating the local speeds of propagation of information from the interfaces between neighboring computational cells. The numerical dissipation in these schemes was further reduced by keeping an even more accurate account of the different local speeds [20]. Semidiscrete schemes have a lower numerical dissipation when compared with fully discrete schemes, which make them particularly suitable for long-time simulations, steady-state calculations, and approximating solutions of viscous problems.

The fully discrete schemes of [7, 23, 24] were extended to high-order in [8]. Such extensions were obtained by using suitable weighted essentially nonoscillatory (WENO) reconstructions that were designed following the WENO schemes of Liu, Osher, and Chan [27] and Jiang and Shu [17]. It is important to note that these ideas extend the essentially nonoscillatory (ENO) schemes of Harten et al. [14]. High-order versions of the semidiscrete scheme [21] were obtained by combining the semidiscrete numerical fluxes with WENO reconstructions [9]. This work also provided the theoretical foundation for the monotonicity of the fluxes of [20, 21]. A version of these schemes with reduced numerical dissipation was recently derived in [6].

It is important to note that the progress with central schemes for HJ equations parallels the advances made with upwind schemes for HJ equations. These include the ENO schemes of Osher, Sethian, and Shu [30, 31] and the WENO schemes of Jiang and Peng [16]. Similar methods on triangular meshes include the pioneering works of Abgrall [1, 2], Augoula and Abgrall [3], Barth and Sethian [5], Kossioris, Makridakis, and Souganidis [19], and the recent work of Zhang and Shu [35] on WENO schemes for HJ equations on triangular meshes. The high-order WENO reconstructions on triangular meshes that were used in [35] were based on the results of Hu and Shu [15].

In this paper we present the first semidiscrete *central* scheme for approximating solutions of (1.1) on triangular meshes. Our scheme combines a new numerical flux (that was announced in [22]) with the high-order WENO reconstructions of [35].

We would like to emphasize that the main benefit of the new scheme is in its development as a Godunov-type scheme, in which a global reconstruction is evolved exactly according to the equation. This probably also means that one can expect to obtain for this scheme convergence results in the spirit of the works of Lin and Tadmor [23, 24].

The structure of this paper is as follows: We start in section 2 with the derivation of the numerical flux for HJ equations on triangular meshes. A couple of examples of high-order reconstructions on triangular meshes are then discussed in section 3. Numerical examples that verify the expected order of accuracy of the schemes as well as the high-resolution properties of the resulting solutions are given in section 4. Concluding remarks summarize this work in section 5.

2. Central schemes for Hamilton–Jacobi equations.

2.1. The scheme. To simplify the discussion and the notation, we consider equations of type (1.1) with a Hamiltonian that depends only on $\nabla\phi$, i.e.,

$$\begin{cases} \phi_t(x,t) + H(\nabla\phi(x,t)) = 0, \quad x \in \Omega \subset \mathbb{R}^2, \\ \phi(x, t=0) = \phi_0(x). \end{cases} \tag{2.1}$$

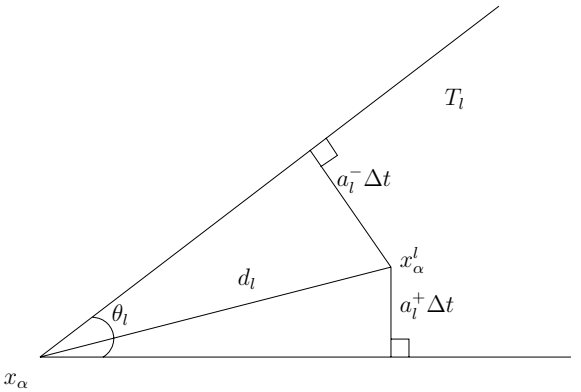

FIG. 2.1. *The evolution point x_α^l that is derived from the maximal local speeds of propagation into T_l, a_l^+, and a_l^-.*

We assume a given triangulation, $\mathfrak{T}$, of Ω, denote the grid points by x_α, and assume that every such point is surrounded by m_α angular sectors T_l^α that are ordered counterclockwise. For simplicity we use the simpler notation $T_l = T_l^\alpha$ (see Figure 2.1).

Given a time-step Δt, we denote the approximate value at time $t^n = n\Delta t$ of $\phi(x_\alpha, t^n)$ by φ_α^n. Assuming that the values of φ_α^n at the grid points x_α are known, we reconstruct a piecewise-polynomial interpolant $\tilde{\varphi}_\alpha$. This interpolant has discontinuous gradients along the cell-interfaces. We denote the approximation of the gradient at x_α that is obtained from the reconstruction in the cell T_l by $\nabla\tilde{\varphi}_{\alpha,l}$. For the purpose of developing the numerical flux there is no need to assume any particular reconstruction. A WENO reconstruction will be described in section 3.

The reconstruction $\tilde{\varphi}_\alpha$ can now be used to estimate the maximal speeds of propagation of information from the cell-interfaces in a direction that is perpendicular to the interfaces. In every sector, T_l, we denote the counterclockwise speed of propagation by a_l^+ and the speed of propagation on the other interface by a_l^- (see Figure 2.1). These speeds can be estimated by

(2.2)
$$a_l^+ = \max\left\{\max_{T_l}\left\{|\nabla H(\nabla\tilde{\varphi}_\alpha(x))\cdot\vec{n}_{l-1,l}|\right\},\ \max_{T_{l-1}}\left\{|\nabla H(\nabla\tilde{\varphi}_\alpha(x))\cdot\vec{n}_{l-1,l}|\right\}\right\},$$

$$a_l^- = \max\left\{\max_{T_l}\left\{|\nabla H(\nabla\tilde{\varphi}_\alpha(x))\cdot\vec{n}_{l+1,l}|\right\},\ \max_{T_{l+1}}\left\{|\nabla H(\nabla\tilde{\varphi}_\alpha(x))\cdot\vec{n}_{l+1,l}|\right\}\right\}.$$

Here, $\vec{n}_{j,l}$ is the normal vector on the interface between T_j and T_l pointing into T_l.

The evolution stage of Godunov-type schemes will be carried out at points x_α^l that are located away from the interfaces, assuming that the time-step is sufficiently small (see Figure 2.1). The distance of the evolution point x_α^l from x_α is denoted by d_l. Clearly, d_l depends on the local speeds of propagation $a_l^\pm$ and on the angle θ_l. A straightforward computation allows us to define d_l as

$$d_l = \Delta t \hat{d}_l, \tag{2.3}$$

where

$$\hat{d}_l^2 = \frac{(a_l^-)^2 + 2a_l^- a_l^+ \cos\theta_l + (a_l^+)^2}{\sin^2\theta_l}. \tag{2.4}$$

We now evolve the interpolant $\tilde{\varphi}(\vec{x}, t^n)$ to the next time-step t^{n+1} at the points x_α^l according to (2.1). Since the evolution points are located away from the propagating discontinuities, the value at the next time-step can be approximated with a first-order Taylor expansion in time, i.e.,

$$\varphi(x_\alpha^l, t^{n+1}) = \tilde{\varphi}(x_\alpha^l, t^n) - \Delta t H(\nabla\tilde{\varphi}(x_\alpha^l, t^n)) + O(\Delta t^2). \tag{2.5}$$

Here, the value of the gradient, $\nabla\tilde{\varphi}(x_\alpha^l, t^n)$, is obtained from the reconstruction, $\tilde{\varphi}$. Expressions of the form (2.5) hold for every evolution point, x_α^l, around x_α.

In order to combine all these values of φ into one value φ_α^{n+1}, we write a convex combination of the values from the different sectors with weights $s_l \geq 0$ that are yet to be determined:

$$\varphi_\alpha^{n+1} = \frac{\sum_{l=1}^{m_\alpha} s_l \varphi(x_\alpha^l, t^{n+1})}{\sum_{l=1}^{m_\alpha} s_l} = \frac{\sum_{l=1}^{m_\alpha} s_l \left[\tilde{\varphi}(x_\alpha^l, t^n) - \Delta t H(\nabla\tilde{\varphi}(x_\alpha^l, t^n)\right]}{\sum_{l=1}^{m_\alpha} s_l}. \tag{2.6}$$

We now define ρ_l to be the unit vector in the direction of x_α^l from x_α and write a Taylor expansion in space:

$$\tilde{\varphi}(x_\alpha^l, t^n) = \tilde{\varphi}(x_\alpha, t^n) + d_l \rho_l \cdot \nabla\tilde{\varphi}(x_\alpha^l, t^n) + O(\Delta t^2).$$

Here by $\nabla\tilde{\varphi}(x_\alpha^l, t^n)$ we refer to the value of the gradient at x_α that is associated with the reconstruction in sector T_l at x_α^l. We may therefore rewrite (2.6) as the fully discrete scheme

$$\varphi_\alpha^{n+1} = \tilde{\varphi}_\alpha^n + \frac{\Delta t}{\sum_{l=1}^{m_\alpha} s_l} \sum_{l=1}^{m_\alpha} s_l \left[\hat{d}_l \rho_l \cdot \nabla\tilde{\varphi}(x_\alpha^l, t^n) - H(\nabla\tilde{\varphi}(x_\alpha^l, t^n))\right]. \tag{2.7}$$

A semidiscrete scheme can now be obtained in the limit $\Delta t \to 0$,

$$\frac{d}{dt}\varphi_\alpha(t) = \lim_{\Delta t \to 0} \frac{\varphi_\alpha^{n+1} - \varphi_\alpha^n}{\Delta t} = \frac{1}{\sum_{l=1}^{m_\alpha} s_l} \sum_{l=1}^{m_\alpha} s_l \left[\hat{d}_l \rho_l \cdot \nabla\tilde{\varphi}_\alpha^l(t) - H(\nabla\tilde{\varphi}_\alpha^l(t))\right], \tag{2.8}$$

where for each l, $\nabla\tilde{\varphi}_\alpha^l(t)$ denotes $\lim_{\Delta t \to 0} \nabla\tilde{\varphi}(x_\alpha^l, t^n)$. All that remains is to determine the coefficients s_l in (2.8). The consistency of the scheme implies that if the value of the gradient is identical in every sector that surrounds x_α, then the numerical Hamiltonian should become the differential Hamiltonian. Hence, we are seeking coefficients s_l, such that

$$\sum_{l=1}^{m_\alpha} s_l \hat{d}_l \rho_l = 0. \tag{2.9}$$

These coefficients can be determined using the results of Abgrall [2]. We denote by $\mu_{l+1/2}$ a unit vector in a direction that is aligned with the interface between the sectors T_l and T_{l+1}, and we assume that $\theta_l < \pi$ (which is indeed the case with a triangulation). It was shown in [2] that

$$\sum_{l=1}^{m_\alpha} \xi_{l+\frac{1}{2}} \mu_{l+\frac{1}{2}} = 0, \tag{2.10}$$

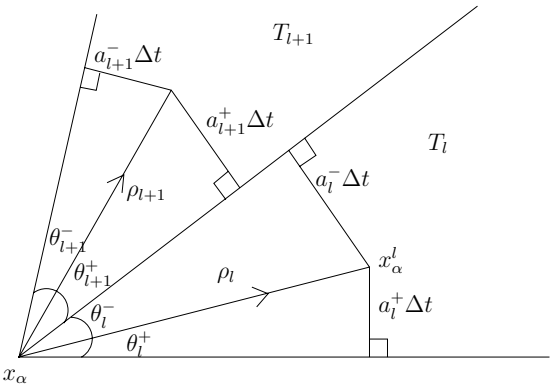

FIG. 2.2. *The angles around* x_α.

provided that

$$\xi_{l+\frac{1}{2}} = \left[\tan\left(\frac{\theta_l}{2}\right) + \tan\left(\frac{\theta_{l+1}}{2}\right)\right]. \tag{2.11}$$

In order to incorporate (2.10)–(2.11) into our framework, we split each angle θ_l into two parts, $\theta_l^{\pm}$, that are defined as

$$\theta_l^{\pm} = \arcsin\frac{a_l^{\pm}}{\hat{d}_l} \tag{2.12}$$

(see Figure 2.2). The consistency condition (2.9) is then satisfied if the weights s_l are taken as $s_l = \beta_l/\hat{d}_l$, where

$$\beta_l = \tan\left(\frac{\theta_l^{+} + \theta_{l-1}^{-}}{2}\right) + \tan\left(\frac{\theta_l^{-} + \theta_{l+1}^{+}}{2}\right).$$

We note that if $\forall l$, $\theta_l^{+} + \theta_{l-1}^{-} \le \pi$, then β_l are guaranteed to be positive. With this notation, a consistent, semidiscrete scheme is given by

$$\frac{d}{dt}\varphi_\alpha(t) = \frac{1}{\sum_{l=1}^{m_\alpha}\frac{\beta_l}{\hat{d}_l}}\sum_{l=1}^{m_\alpha}\beta_l\left[\rho_l\cdot\nabla\tilde{\varphi}_\alpha^l(t) - \frac{H(\nabla\tilde{\varphi}_\alpha^l(t))}{\hat{d}_l}\right]. \tag{2.13}$$

Remarks.

1. It is straightforward to extend scheme (2.13) to more general problems, such as general Hamiltonians of the form present in (1.1) or viscous HJ problems. Examples of these obvious generalizations in the Cartesian case can be found, e.g., in [7, 8, 9, 20, 21].
2. The order of accuracy of the scheme (2.13) is determined by the order of accuracy of the reconstruction $\tilde{\varphi}_\alpha$, and the order of the ODE solver. Due to the known properties of viscosity solutions of HJ equations and the structure of Godunov-type schemes, we assume a global underlying piecewise-smooth reconstruction. We note that, in practice, the final semidiscrete scheme (2.13) uses only values of the gradient computed in the different cells around each grid point x_α. This means that all that we need from the reconstruction are the values of these gradients. High-order reconstructions on triangular meshes are discussed in section 3.

3. There are several ways to simplify the scheme (2.13). One possibility is to replace the different speeds of propagation at every grid point by their maximum, i.e., $a_\alpha = \max_l\{a_l^+, a_l^-\}$. This implies that $\hat{d}_l = a_\alpha/\sin(\theta_l/2)$. In this case (2.13) becomes

$$\frac{d}{dt}\varphi_\alpha(t) = \frac{a_\alpha}{\sum_{l=1}^{m_\alpha}\beta_l \sin\frac{\theta_l}{2}} \sum_{l=1}^{m_\alpha} \beta_l \left[\rho_l \cdot \nabla\tilde{\varphi}_\alpha^l(t) - \frac{\sin\frac{\theta_l}{2}}{a} H(\nabla\tilde{\varphi}_\alpha^l(t))\right]. \tag{2.14}$$

If, in addition, the triangulation of the domain is such that the angles are identical around each point, i.e., $\theta = \theta_l \ \forall\, l$, then (2.14) takes the simpler form

$$\frac{d}{dt}\varphi_\alpha(t) = \frac{1}{m_\alpha} \sum_{l=1}^{m_\alpha} \left[\frac{a_\alpha}{\sin\frac{\theta}{2}} \rho_l \cdot \nabla\tilde{\varphi}_\alpha^l(t) - H(\nabla\tilde{\varphi}_\alpha^l(t))\right]. \tag{2.15}$$

In the special case of a Cartesian grid with equal spacing in the x- and y-directions, the number of angular sectors at each point is $m_\alpha = 4$, and $\sin(\theta/2) = \sin(\pi/4) = \sqrt{2}/2$. If we assume that the velocities are identical in both directions, then (2.15) becomes

$$\begin{aligned}\frac{d}{dt}\varphi_\alpha(t) = {} & \frac{a_\alpha}{2}\left(\varphi_x^+ - \varphi_x^- + \varphi_y^+ - \varphi_y^-\right) \\ & -\frac{1}{4}\left[H\left(\varphi_x^+, \varphi_y^+\right) + H\left(\varphi_x^-, \varphi_y^+\right) + H\left(\varphi_x^+, \varphi_y^-\right) + H\left(\varphi_x^-, \varphi_y^-\right)\right],\end{aligned} \tag{2.16}$$

with the obvious notation; e.g., $H(\varphi_x^+, \varphi_y^+)$ is the Hamiltonian evaluated at the gradient at x_α that is taken from the first quadrant. The scheme (2.16) is identical to the semidiscrete central scheme for Cartesian grids [9, 21].

4. The following Lax–Friedrichs-type scheme on triangular meshes was derived by Abgrall [2]:

$$\frac{d}{dt}\varphi_\alpha(t) = \frac{a}{\pi} \sum_{l=1}^{m_\alpha} \beta_{l+\frac{1}{2}} \mu_{l+\frac{1}{2}} \cdot \left(\frac{\nabla\tilde{\varphi}_\alpha^l(t) + \nabla\tilde{\varphi}_\alpha^{l+1}(t)}{2}\right) - H\left(\frac{\sum_{l=1}^{m_\alpha}\theta_l \nabla\tilde{\varphi}_\alpha^l}{2\pi}\right). \tag{2.17}$$

Here $\mu_{l+1/2}$ is the unit vector in the direction of the interface between the sectors T_l and T_{l+1}, and $\beta_{l+1/2} = \tan(\theta_l/2) + \tan(\theta_{l+1}/2)$. The derivation of (2.17) involved evolution points that were located on the interfaces between the sectors. This resulted in the form of the dissipative term in (2.17) that contains averages of gradients in adjacent sectors. Also, the scheme (2.17) involves a Hamiltonian that is evaluated at the average of the derivatives that are computed in different sectors (with weights that are proportional to the angles). This Hamiltonian term was postulated to be in this form, but could have had other forms. In our case (2.13), this term takes the form of an average over the Hamiltonian that is evaluated in different sectors and is dictated by the derivation of the scheme.

5. We would like to emphasize that the main benefit of the new scheme is in its development as a Godunov-type scheme, in which a global reconstruction is evolved exactly according to the equation. It is a different approach to the "standard" line of schemes for HJ equations in which a monotone flux is

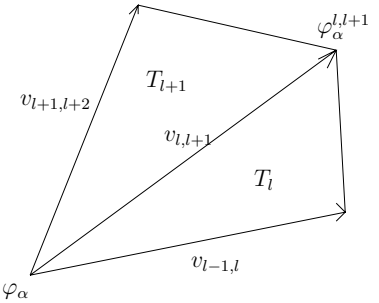

FIG. 2.3. *Grid value at x_α and two triangles containing x_α and grid vectors v.*

combined with a high-order reconstruction. This probably also means that one can expect to obtain for this scheme convergence results in the spirit of the works of Lin and Tadmor [23, 24]. For this purpose, such a construction of a scheme is probably more favorable than traditional constructions.

2.2. Monotonicity. In this section we provide a partial result regarding the monotonicity of our scheme (2.13). Monotonicity is one of the main ingredients in the convergence theory of Barles and Souganidis [4]. Roughly speaking, a stable, consistent, and monotone approximation for an equation that satisfies an underlying comparison principle converges to the viscosity solution.

For simplicity we consider the monotonicity of the scheme in the case where the speeds of propagation do not depend on the gradients of the reconstruction, i.e., they are all equal to a constant that is determined based on a priori bounds. Hence, we assume $a = \max_{l,\pm} a_l^{\pm}$, which also implies that $\theta_l^+ = \theta_l^- = \theta_l/2$.

Monotonicity means that if we rewrite our scheme (2.13) in terms of grid differences,

$$\frac{d}{dt}\varphi_\alpha(t) = F(\varphi_\alpha, \varphi_\alpha - \varphi'), \tag{2.18}$$

where $\varphi_\alpha - \varphi'$ is a vector of grid differences that involve the central node, then F is nonincreasing in all arguments (see, e.g., [4, 11, 29, 31]).

We assume that the gradient of φ in the triangle T_l is constant in that triangle. The normal to the plane connecting the three corners of T_l is given by

$$(v_{l,l+1}^x, v_{l,l+1}^y, \varphi_\alpha^{l,l+1} - \varphi_\alpha) \times (v_{l-1,l}^x, v_{l-1,l}^y, \varphi_\alpha^{l-1,l} - \varphi_\alpha),$$

where $\times$ denotes the cross-product between the vectors. Hence, the gradient of φ in the sector T_l, $\nabla\varphi_\alpha^l$ is given by (see Figure 2.3)

$$\frac{1}{C}\left((\varphi_\alpha - \varphi_\alpha^{l-1,l})v_{l,l+1}^y - (\varphi_\alpha - \varphi_\alpha^{l,l+1})v_{l-1,l}^y, (\varphi_\alpha - \varphi_\alpha^{l,l+1})v_{l-1,l}^x - (\varphi_\alpha - \varphi_\alpha^{l-1,l})v_{l,l+1}^x\right).$$

Here, $C = (v_{l,l+1} \times v_{l-1,l}) \cdot k$ and k is the unit vector pointing out of the plane. The superscripts x and y denote the x- and y-components of the various vectors. We note that C is a negative quantity. Letting $u_1 = \varphi_\alpha - \varphi_\alpha^{l,l+1}$, the derivative of the gradient of φ_α^l with respect to u_1 is given by

$$\frac{\partial}{\partial u_1}\nabla\varphi_\alpha^l = \frac{1}{C}(-v_{l-1,l}^y, v_{l-1,l}^x).$$

This means that

$$\rho_l \cdot \frac{\partial}{\partial u_1} \nabla \varphi_\alpha^l = \frac{1}{C} \rho_l \cdot n_{l-1,l} ||v_{l-1,l}|| = \frac{1}{C} \sin\left(\frac{\theta_l}{2}\right) ||v_{l-1,l}||,$$

where $n_{l-1,l}$ is the unit normal vector pointing into T_l (and is in the plane defined by T_l). Similarly

$$\frac{\partial}{\partial u_1} \nabla \varphi_\alpha^{l+1} = \frac{1}{C'} (v_{l+1,l+2}^y, -v_{l+1,l+2}^x) = \frac{1}{C'} ||v_{l+1,l+2}|| n_{l+2,l+1},$$

where $C' = (v_{l+1,l+2} \times v_{l,l+1}) \cdot k$ and $n_{l+2,l+1}$ is the normal vector from T_{l+2} pointing into T_{l+1}.

Since these are the only two quantities in F that involve u_1, we may evaluate the partial derivative of F with respect to u_1. Letting $K = 1/\sum_{l=1}^{m_\alpha} \frac{\beta_l}{\hat{d}_l}$ (which we note is a positive quantity) we have

$$\begin{aligned}
\frac{\partial F}{\partial u_1} &= \frac{1}{K} \frac{\beta_l ||v_{l-1,l}||}{C \hat{d}_l} \left(\hat{d}_l \rho_l \cdot n_{l-1,l} - \nabla H(\nabla \varphi_\alpha^l) \cdot n_{l-1,l} \right) \\
&\quad + \frac{1}{K} \frac{\beta_{l+1} ||v_{l+1,l+2}||}{C' \hat{d}_{l+1}} \left(\hat{d}_{l+1} \rho_{l+1} \cdot n_{l+2,l+1} - \nabla H(\nabla \varphi_\alpha^{l+1}) \cdot n_{l+2,l+1} \right) \\
&= \frac{1}{K} \frac{\beta_l ||v_{l-1,l}||}{C \hat{d}_l} \left(\hat{d}_l \sin\left(\frac{\theta_l}{2}\right) - \nabla H(\nabla \varphi_\alpha^l) \cdot n_{l-1,l} \right) \\
&\quad + \frac{1}{K} \frac{\beta_{l+1} ||v_{l+1,l+2}||}{C' \hat{d}_{l+1}} \left(\hat{d}_{l+1} \sin\left(\frac{\theta_{l+1}}{2}\right) - \nabla H(\nabla \varphi_\alpha^{l+1}) \cdot n_{l+2,l+1} \right).
\end{aligned} \tag{2.19}$$

We consider only the first term, as an analogous argument holds for the second term. Equation (2.12) implies that $\sin(\theta_l/2) = a/\hat{d}_l$. Also, from (2.2) we know that $\nabla H(\nabla \varphi_\alpha^l) \cdot n_{l-1,l} \le a$, which means that

$$\hat{d}_l \sin\left(\frac{\theta_l}{2}\right) - \nabla H(\nabla \varphi_\alpha^l) \cdot n_{l-1,l} \ge 0.$$

Since $C < 0$ and since we assume that the triangulation is such that the β_l's are positive, we can conclude that the first term in (2.19) is nonpositive. By similar arguments the second term in (2.19) is nonpositive, which means that F is nonincreasing in u_1. The same is true for all the variables of F and hence the scheme is monotone.

3. High-order reconstructions on triangular meshes. In this section we review two third-order reconstructions from [35] (see also [15]). We start with a linear-weights reconstruction. First, we solve an interpolation problem on a large stencil. We then split the large stencil into smaller pieces, obtaining a (low-order) interpolant on each. We conclude with a convex combination of the low-order interpolants that provides the desired (formal) accuracy. The second reconstruction is of WENO type. Here, we replace the linear weights in the convex combination by nonlinear weights. This procedure reduces the spurious oscillations that otherwise develop at singularities. We would like to emphasize that the scheme developed in section 2, i.e., (2.13), does not depend on any particular reconstruction, and the reconstructions described here are provided for the sake of completeness. Extensions to fourth-order are described in [35].

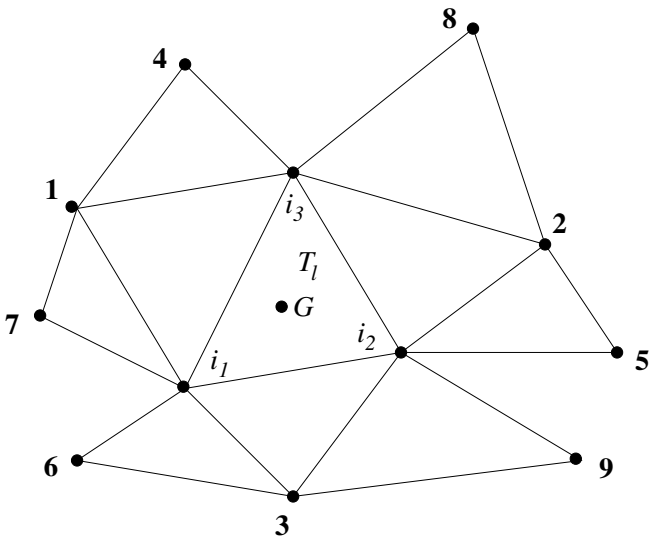

FIG. 3.1. *The nodes used for the large stencil of the third-order reconstruction around T_l. The point G is the barycenter of the cell T_l.*

3.1. A linear-weights reconstruction. We provide an overview of the linear-weights third-order reconstruction from [35]. The problem can be formulated as an interpolation problem, in which the main question is how to choose the interpolation points. The solution is not so obvious, in particular since the geometry of the mesh might not be uniform, which means that stability considerations might imply that it might be better to use different stencils around different triangular sectors.

Assuming a given triangular sector, T_l, the procedure for approximating the components of the derivatives at its three nodes is composed of two steps. First, we look for a large stencil that will provide a stable, third-order approximation of the derivative. There are many ways for choosing such a stencil around any given sector, and we are interested in a compact stencil and a stable reconstruction. In the second step we break the large stencil into several small stencils (all of which are based on grid points that are in the large stencil). Each small stencil provides a second-order approximation of the derivative. These stencils are chosen following compactness and stability considerations. We take sufficiently many such stencils (which will amount to five) such that they can be linearly combined to achieve the desired accuracy of the derivative.

We start by considering an angular sector, T_l, with its three nodes denoted by i_1, i_2, i_3. To obtain a third-order approximation of the derivative at these points, $(\nabla\varphi)_{i_1}, (\nabla\varphi)_{i_2}, (\nabla\varphi)_{i_3}$, we first construct a cubic polynomial. Since we are solving a two-dimensional problem, there are ten free parameters that we have to determine. These will be given by interpolation requirements on a stencil that is yet to be determined. In our numerical interpolation we use normalized coordinates, $(x-x_G)/\sqrt{|T_l|}$, where x_G is the coordinate of the barycenter G and $|T_l|$ is the area of the triangle T_l (see Figure 3.1).

With this in mind, we number the nodes in the neighboring mesh points as $\{1,\dots,9\}$ (in the way that is portrayed in Figure 3.1) and consider the ordered set $W = \{1,\dots,9\}$. The nodes are numbered as in Figure 3.1 in order to avoid biasing the stencil in any particular direction. We note that the geometry of the mesh might

imply that some of these points can be identical. If this is the case, more remote points are added to the list. We omit the details and refer to [35]. We now set a threshold δ and use the following algorithm:

1. Set the interpolation points as $S_0 = \{i_1, i_2, i_3, 1, \ldots, 7\}$.
2. Form the 10×10 interpolation coefficients matrix A and compute its reciprocal condition number, $c(A)$.
3. While $c(A) < \delta$, add the next node in W to S_0 and compute the least squares interpolation coefficients matrix A from the nodes in S_0. Compute $c(A)$.
4. The final S_0 is the large stencil.

Remark. The numerical simulations of [35] showed that at most 12 nodes are needed in order to satisfy the condition $c(A) \geq \delta$ when the threshold is set as $\delta = 10^{-3}$. This is the value that was used in our simulations in section 4.

We denote the interpolation polynomial that is obtained from the stencil S_0 by $p^3(x, y)$. This polynomial, $p^3(x, y)$, can be used to estimate a third-order approximation of the derivatives at the three nodes of T_l. Our goal now is to split the stencil S_0 into several small stencils in such a way that we will be able to recover the third-order accuracy with a convex combination of these smaller stencils. In this case, we will generate five quadratic polynomials, p_s, $s = 1, \ldots, 5$, such that a third-order approximation to the derivatives in the x- and y-directions at $\{i_1, i_2, i_3\}$ will be given by

$$
\begin{aligned}
\frac{\partial}{\partial x}\varphi(x_{i_j}, y_{i_j}) &\approx \frac{\partial}{\partial x}p^3(x_{i_j}, y_{i_j}) = \sum_{s=1}^{5} \gamma_{s,x,i_j} \frac{\partial}{\partial x} p_s(x_{i_j}, y_{i_j}), \qquad j = 1, 2, 3, \\
\frac{\partial}{\partial y}\varphi(x_{i_j}, y_{i_j}) &\approx \frac{\partial}{\partial y}p^3(x_{i_j}, y_{i_j}) = \sum_{s=1}^{5} \gamma_{s,y,i_j} \frac{\partial}{\partial y} p_s(x_{i_j}, y_{i_j}), \qquad j = 1, 2, 3.
\end{aligned} \tag{3.1}
$$

Here, γ_{s,x,i_j} and γ_{s,y,i_j} are the linear weights for the derivatives in the x- and y-directions, respectively. They depend only on the local geometry of the mesh and should satisfy the normalization constraints, $\sum_{s=1}^{5} \gamma_{s,x,i_j} = 1$ and $\sum_{s=1}^{5} \gamma_{s,y,i_j} = 1$. Under these additional conditions, a simple calculation shows that the number of quadratic interpolants has to be greater than or equal to five, which is the reason we set it as five [15, 35].

We are now seeking five small stencils Γ_s, $s = 1, \ldots, 5$, for the target triangle T_l such that $S_0 = \cup_{s=1}^{5} \Gamma_s$. We associate with each such stencil a quadratic polynomial p_s. We note that while the stencils are going to be identical for all the nodes in a given angular sector and in both directions, the linear weights γ_{s,x,i_j} and γ_{s,y,i_j} can be different for each node and for each direction. We summarize the stages given in [35, Procedure 2.2] as follows (for further details see [35]):

1. Obtain a large stencil S_0.
2. For each $s = 1, \ldots, 5$ find a set of candidate small stencils $W_s = \{\Gamma_s^{(r)}, r = 1, \ldots, n_s\}$ in the following way. The nodes i_1, i_2, i_3 are included in every $\Gamma_s^{(r)}$. Let $A_s^{(r)}$ denote the center of $\Gamma_s^{(r)}$, where $A_s^{(r)}$ is given in Table 3.1. Find at least three additional nodes other than i_1, i_2, i_3 such that they have the shortest distance from $A_s^{(r)}$ and the points in $\Gamma_s^{(r)}$ induce an interpolation coefficient matrix A with a good reciprocal condition number ($c(A) \geq \delta$). Based on the experiments in [35] a maximum number of 8 nodes is required to reach the threshold $\delta = 10^{-3}$.
3. Obtain $n_1 \times \cdots \times n_5$ groups of small stencils by taking one small stencil $\Gamma_s^{(r_s)}$ from each W_s, $s = 1, \ldots, 5$. Eliminate the groups that contain the same small stencils and those that do not satisfy the condition $\cup_{s=1}^{5} \Gamma_s^{(r_s)} = S_0$.

TABLE 3.1
The values of $A_s^{(r)}$. The entries refer to the node numbers in Figure 3.1.

s	n_s	$A_s^{(1)}$	$A_s^{(2)}$	$A_s^{(3)}$
1	1	G	–	–
2	3	1	4	7
3	3	2	5	8
4	3	3	6	9
5	≤ 9	$A_5^{(r)}$ are 4–9 and the middle points of 4–8, 5–9, 6–7		

4. For each group $\{\Gamma_s^{(r_s)}, s = 1, \ldots, 5\}$ compute the associated linear weights $\gamma_{s,x,i_j}^{(r_s)}$ and $\gamma_{s,y,i_j}^{(r_s)}$, such that (3.1) is satisfied for $\{i_1, i_2, i_3\}$. Candidate stencils that involve solving ill-posed linear systems are eliminated from further consideration.
5. For the remaining groups, find the minimum value γ_l of all the linear weights $\gamma_{s,x,i_j}^{(r_s)}, \gamma_{s,y,i_j}^{(r_s)}$ on the three vertices $\{i_1, i_2, i_3\}$. The group for which γ_l is the biggest is taken as the final five small stencils for the sector T_l. These five small stencils are denoted by Γ_s, $s = 1, \ldots, 5$.

Remark. Since the linear weights depend on the geometry of the triangulation, some of them might be negative. It is therefore required to take special measures to avoid the stability problems that result from negative weights in the presence of large gradients. In the numerical simulations we apply the technique for handling negative weights in WENO schemes that was recently proposed in [32].

3.2. A WENO reconstruction. In the previous section we showed how to obtain a third-order reconstruction of the derivatives in the x- and y-directions in each grid point. This was done by finding an accurate linear combination of small stencils (each of which results with a second-order reconstruction) such that the overall combination is a third-order reconstruction of the derivative. We now use these results to derive a WENO reconstruction of the derivative. This is done, as usual, by replacing the linear weights by nonlinear weights aiming at reducing the spurious oscillations that might develop in regions that contain discontinuities.

We consider the x-directional derivative at the vertex i of the cell T_l, whose coordinates are (x_i, y_i). Following section 3.1, we denote by $p_s(x, y)$, $s = 1, \ldots, 5$, the sth interpolation polynomial associated with the sth stencil on the cell T_l. A third-order WENO reconstruction for the x-derivative is given in terms of the convex combination

$$(\varphi_x)_i = \sum_{s=1}^{5} w_s \frac{\partial}{\partial x} p_s(x_i, y_i). \tag{3.2}$$

The weights, w_s, associated with $p_s(x, y)$ are given by

$$w_s = \frac{\tilde{w}_s}{\sum_{m=1}^{5} \tilde{w}_m}, \tag{3.3}$$

with

$$\tilde{w}_s = \frac{\gamma_{s,x}}{(\epsilon + \beta_s)^2}, \qquad s = 1, \ldots, 5. \tag{3.4}$$

Here, $\gamma_{s,x}$ is the linear weight associated with stencil s for computing the x-derivative at (x_i, y_i), ϵ is set as a small number to prevent the denominator from vanishing, and β_s is the oscillation indicator associated with the sth stencil.

The oscillatory indicator, β_s, is given by

$$\beta_s = \sum_{|\eta|=2} \int_{T_l} (D^\eta p_s(x,y))^2 dxdy. \tag{3.5}$$

An expression analogous to (3.2) holds for the derivative in the y-direction.

4. Numerical examples. In the numerical examples we use two kinds of triangular meshes. Both are shown in Figure 4.1. The first kind is a "uniform triangular mesh" shown in Figure 4.1 (left). The particular mesh in Figure 4.1 (left) is a coarse mesh with $h = 2/5$, where h is the length of the right-angled side. The second mesh is a "nonuniform triangular mesh" such as the one shown in Figure 4.1 (right). The mesh in the figure is a coarse mesh with $N = 105$ nodes. Refinements of nonuniform meshes are done by splitting each triangle into four similar triangles. The reconstructions we use in all the simulations are the third-order linear and WENO reconstructions from section 3. We refer to the flux (2.13) together with the linear-weights reconstruction of section 3.1 as the "linear scheme." We refer to (2.13) together with the WENO reconstruction of section 3.2 as the "WENO scheme." The ODE solver we used is the third-order strong stability preserving Runge–Kutta (SSP-RK) method [13].

Example 1. A two-dimensional linear equation. Consider the two-dimensional (2D) linear equation

$$\begin{cases} \phi_t + \phi_x + \phi_y = 0, & -2 \le x < 2, -2 \le y < 2, \\ \phi(x,y,0) = \sin(\frac{\pi}{2}(x+y)), \end{cases} \tag{4.1}$$

with periodic boundary conditions.

We solve (4.1) with the linear-weights and the WENO schemes on nonuniform meshes up to time $t = 2$. Since this is a linear problem with constant coefficients, the flux with the local speeds and the flux with the global speeds are identical. The L^1- and L^∞-errors and orders of accuracy, shown in Table 4.1, confirm the expected third-order accuracy.

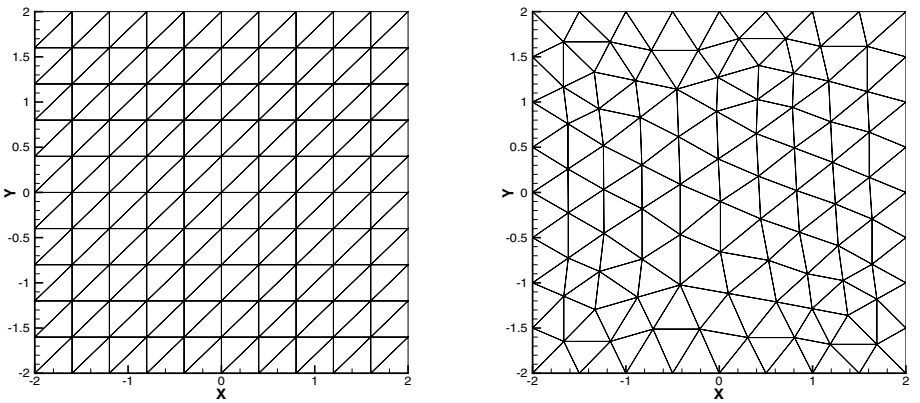

FIG. 4.1. *Left: coarsest uniform mesh with $h = 2/5$. Right: coarsest nonuniform mesh with $N = 105$ nodes.*

Example 2. A 2D Burgers equation. Consider the 2D Burgers equation

$$\begin{cases} \phi_t + \frac{1}{2}(\phi_x + \phi_y + 1)^2 = 0, & -2 \le x < 2, -2 \le y < 2, \\ \phi(x, y, 0) = -\cos\left(\frac{\pi}{2}(x + y)\right), \end{cases} \tag{4.2}$$

augmented with periodic boundary conditions.

We use this example to investigate the difference between fluxes that use a global constant speed and those that use local speeds. A scheme with a global constant speed is obtained from (2.14) when we replace a_α by $a = \max_\alpha a_\alpha$. We solve (4.2) on nonuniform meshes up to time $t = 0.5/\pi^2$. This is before the solution develops any singularities. Table 4.2 shows the L^1- and L^∞-accuracy results that are obtained with the scheme that used a global constant speed. Table 4.3 shows the L^1- and L^∞-errors and orders of accuracy that are obtained when local speeds are taken into account in the numerical flux. In both cases we use linear and WENO schemes. In all cases we verify the expected third-order of accuracy. Indeed, the errors obtained when using a global speed are larger than the error obtained when accounting for local speeds. These results are comparable to those obtained using Abgrall's scheme [2].

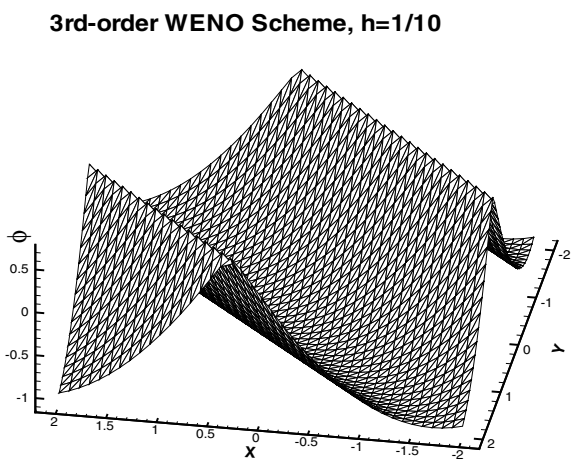

FIG. 4.2. *The 2D Burgers equation* (4.2) *at* $t = 1.5/\pi^2$ *on a uniform mesh with* $h = 1/10$. *The solution is obtained with a third-order WENO scheme and a local speeds flux.*

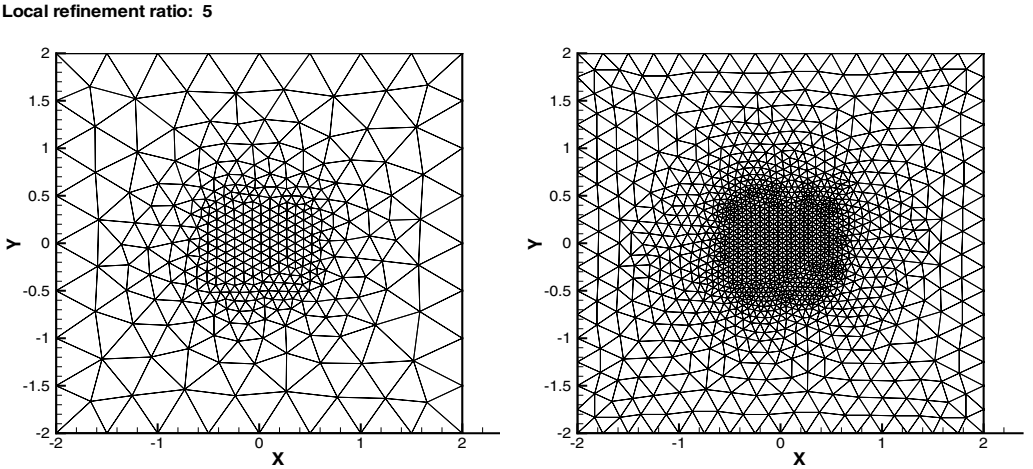

FIG. 4.3. *Left: coarsest very nonuniform mesh with* $N = 353$ *nodes. Right: the refinement of left mesh, with* $N = 1377$ *nodes.*

In Figure 4.2 we plot the solution of (4.2) at time $t = 1.5/\pi^2$, after the solution developed discontinuous derivatives. The solution is obtained with a third-order WENO scheme and a uniform mesh with mesh spacing $h = 1/10$.

We repeat the convergence study, this time using very nonuniform meshes that are shown in Figure 4.3. These meshes are obtained by adding more points in the middle region $[-0.5, 0.5] \times [-0.5, 0.5]$ of the domain $[-2, 2] \times [-2, 2]$.

Table 4.4 includes the accuracy and the minimum and maximum values of local speeds a_l^- for those meshes as shown in Figure 4.3. The same ranges hold for a_l^+. The range of local speeds is from $\approx 10^{-3}$ to ≈ 6.0, which is a relatively large range of such local speeds.

TABLE 4.4

Accuracy and the range of local speeds for the 2D Burgers equation (4.2) on very nonuniform meshes of Figure 4.3 with third-order Linear and WENO schemes at $t = 0.5/\pi^2$. Using the flux with local speeds of propagation.

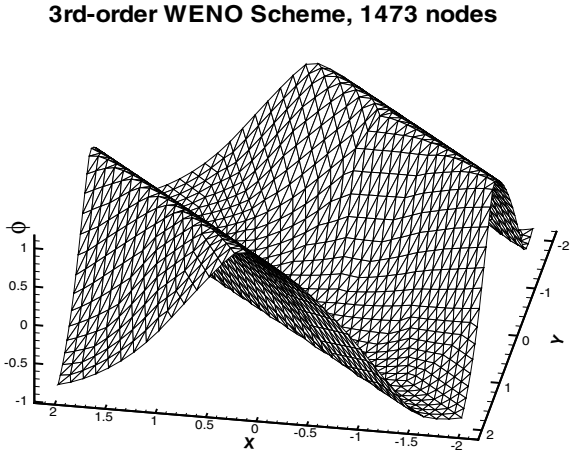

FIG. 4.4. *A 2D HJ equation with a nonconvex flux (4.3) at $t = 1.5/\pi^2$. The solution is obtained with a third-order WENO scheme on a nonuniform mesh with $N = 1473$ nodes and a local speeds flux.*

Example 3. A nonconvex flux. Consider the following HJ equation with a nonconvex flux:

$$\begin{cases} \phi_t - \cos(\phi_x + \phi_y + 1) = 0, & -2 \le x < 2, -2 \le y < 2, \\ \phi(x, y, 0) = -\cos(\frac{\pi(x+y)}{2}), \end{cases} \tag{4.3}$$

augmented with periodic boundary conditions.

In this example we use a nonuniform mesh with $N = 1473$ nodes. At $t = 1.5/\pi^2$ the solution develops a discontinuous derivative. In Figure 4.4 we show the results obtained using the third-order WENO scheme with the local speeds flux.

Example 4. A 2D Riemann problem. Consider the following 2D Riemann problem:

$$\begin{cases} \phi_t + \sin(\phi_x + \phi_y) = 0, & -1 < x < 1, -1 < y < 1, \\ \phi(x, y, 0) = \pi(|y| - |x|). \end{cases} \tag{4.4}$$

We solve (4.4) on a uniform triangular mesh with $40 \times 40 \times 2$ elements. The scheme we use is a third-order WENO scheme with a local speeds flux. Figure 4.5 shows the results obtained at time $t = 1$.

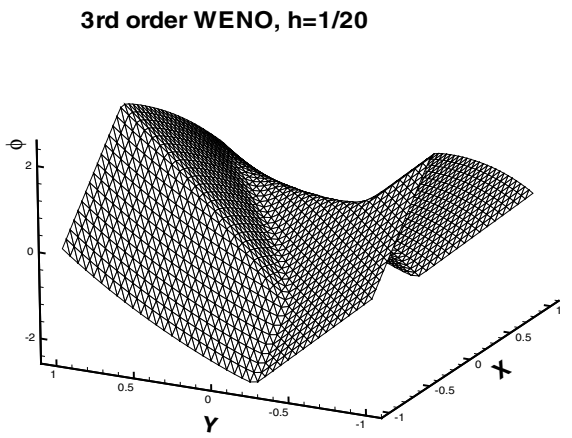

FIG. 4.5. *The 2D Riemann problem* (4.4) *at* $t = 1$. *The solution is obtained with a third-order WENO scheme and a local speeds flux on a uniform triangular mesh with* $h = 1/20$.

Example 5. An optimal control problem. Consider the optimal control problem

$$\begin{cases} \phi_t + (\sin y)\phi_x + (\sin x + \operatorname{sgn}(\phi_y))\phi_y - \frac{1}{2}\sin^2 y - (1-\cos x) = 0, & -\pi < x < \pi, -\pi < y < \pi, \\ \phi(x,y,0) = 0, \end{cases} \tag{4.5}$$

with periodic boundary conditions; see [31]. This problem captures some of the main features and difficulties of control problems, such as the nonsmoothness of the Hamiltonian.

We approximate solutions of (4.5) on a uniform triangular mesh with $40 \times 40 \times 2$ elements using a third-order WENO scheme with a local speeds flux. The solution at $t = 1$ is shown in Figure 4.6 (left). The corresponding optimal control $\omega = \operatorname{sgn}(\phi_y)$ is shown in Figure 4.6 (right).

Example 6. A 2D eikonal equation. Consider the following 2D eikonal equation which arises in geometric optics [18]:

$$\begin{cases} \phi_t + \sqrt{\phi_x^2 + \phi_y^2 + 1} = 0, & 0 \le x < 1, 0 \le y < 1, \\ \phi(x,y,0) = 0.25(\cos(2\pi x) - 1)(\cos(2\pi y) - 1) - 1. \end{cases} \tag{4.6}$$

We approximate solutions of (4.6) using the third-order WENO scheme with a local speeds flux. We use the nonuniform mesh that is shown in Figure 4.7 (left). The solution at $t = 0.6$ is shown in Figure 4.7 (right).

Example 7. A level set equation in a ring. Consider the evolution of the level set function in a ring, as modeled by

$$\begin{cases} \phi_t + sign(\phi_0)(\sqrt{\phi_x^2 + \phi_y^2} - 1) = 0, & \frac{1}{2} < \sqrt{x^2 + y^2} < 1, \\ \phi(x,y,0) = \phi_0(x,y). \end{cases} \tag{4.7}$$

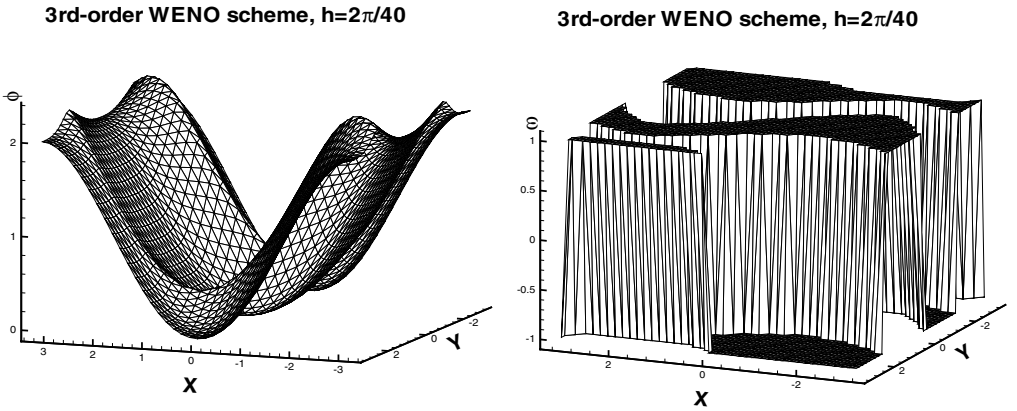

FIG. 4.6. *An optimal control problem* (4.5) *at* $t = 1$ *solved on a uniform triangular mesh with* $h = 2\pi/40$. *The solution is obtained with a third-order WENO scheme and a local speeds flux. Left: the solution. Right: the optimal control* $\omega = sgn(\phi_y)$.

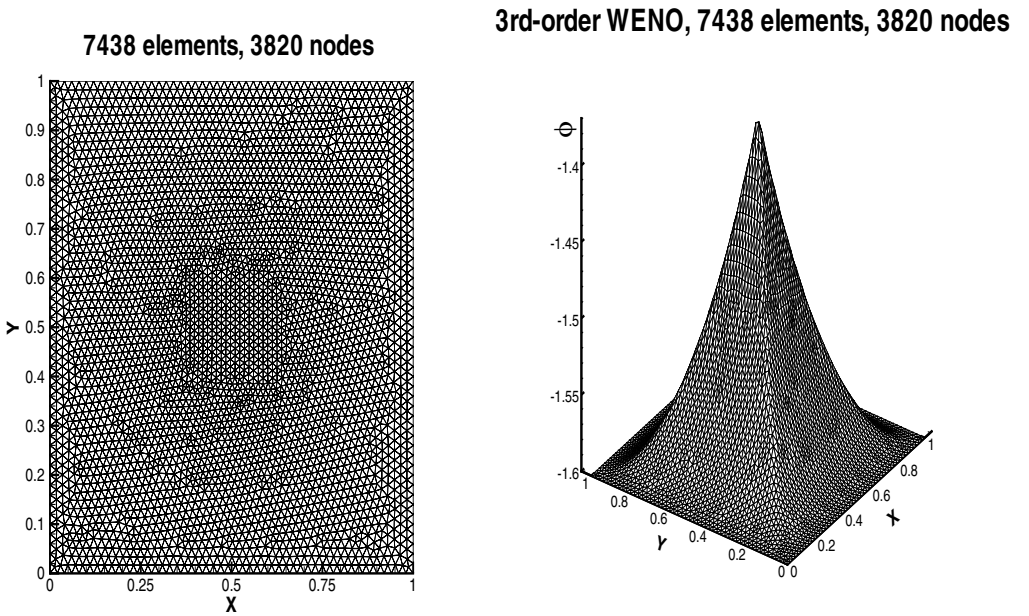

FIG. 4.7. *The* 2*D eikonal equation* (4.6). *Left: the nonuniform mesh used in this example. Right: the solution at* $t = 0.6$ *obtained with the third-order WENO scheme with a local speeds flux.*

This problem is from [34]. The solution ϕ to (4.7) has the same zero level set as ϕ_0, and the steady-state solution is the distance function to that zero level curve. In this example, the exact steady-state solution is the distance function to the inner boundary of the domain. We compute the time-dependent problem to reach the steady-state solution. The exact solution of the steady state is the boundary condition. The mesh with 1420 triangles is shown in Figure 4.8 (left), and the numerical result on that mesh using our third-order scheme is shown in Figure 4.8 (right).

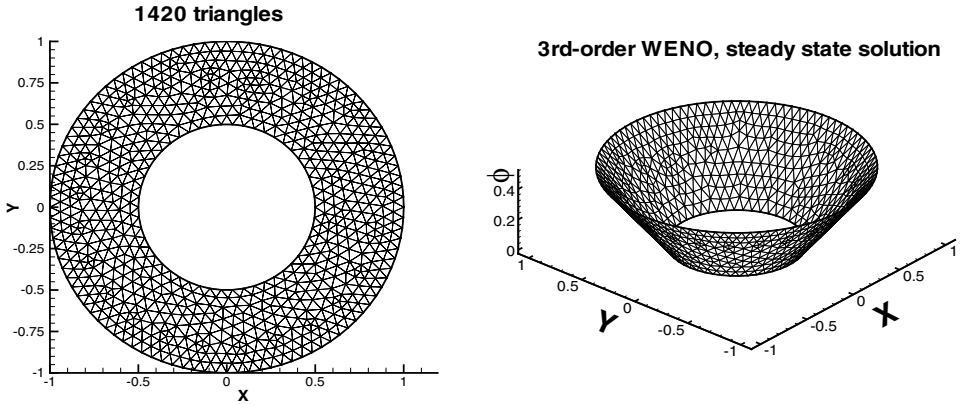

FIG. 4.8. *Solving the level set equation* (4.7) *in a ring. Left: the mesh with* 1420 *triangles. Right: the steady-state solution obtained with our third-order scheme.*

5. Conclusion. In this paper we derived the first central scheme for Hamilton–Jacobi equations on unstructured grids. Similarly to any other Godunov-type method, this scheme is obtained by an exact evolution of a reconstruction which is then projected back onto the mesh points. The order of accuracy of the scheme is determined by the accuracy of the reconstruction and the accuracy of the ODE solver. The reconstructions we used were the third-order linear and WENO reconstructions on triangular meshes [35].

While we have proved the monotonicity of the scheme (with a piecewise-linear reconstruction) in the special case of a global constant local speeds of propagation, we believe that the scheme is monotone in the general case (for a proper choice of the speeds where some global bounds are taken into consideration, see [31]). This point remains as an open problem which we hope to address in the future.

Acknowledgment. We would like to thank Adam Oberman for helpful discussions.

SEMI-IMPLICIT COVOLUME METHOD IN 3D IMAGE SEGMENTATION*

S. CORSARO†, K. MIKULA‡, A. SARTI§, AND F. SGALLARI¶

Abstract. We introduce a three-dimensional (3D) semi-implicit complementary volume numerical scheme for solving the level set formulation of (Riemannian) mean curvature flow problem. We apply the scheme to segmentation of objects (with interrupted edges) in 3D images. The method is unconditionally stable and efficient regarding computational times. The study of its experimental order of convergence on 3D examples shows its second order accuracy for smooth solutions and first order accuracy for highly singular solutions with vanishing gradients as arising in image segmentation.

Key words. partial differential equations, numerical methods, image segmentation, semi-implicit scheme, complementary volume method

1. Introduction.

In this paper we introduce a fast and stable computational method for a three-dimensional (3D) image segmentation based on a solution of the following Riemannian mean curvature flow equation:

$$u_t = \sqrt{\varepsilon^2 + |\nabla u|^2}\nabla . \left(g(|\nabla G_\sigma * I^0|) \frac{\nabla u}{\sqrt{\varepsilon^2 + |\nabla u|^2}} \right). \tag{1.1}$$

Here, $u(t,x)$ is an unknown; we call it *segmentation function* or *subjective surface* [31, 32, 33], defined in $Q_T \equiv [0,T] \times \Omega$. The computational domain $\Omega \subset \mathbb{R}^d$, $d = 3$, is bounded by a Lipschitz continuous boundary $\partial\Omega$. The endpoint of the interval $[0,T]$ represents a time when the final segmentation result is obtained. In practice it is chosen a posteriori; the segmentation is stopped when a change of solution in time (e.g., in L_2-norm) is less than a prescribed threshold. The Riemannian mean curvature flow (1.1) is weighted by a function g giving edge detection information from the segmented image I^0. The function $g : \mathbb{R}_0^+ \to \mathbb{R}^+$ is nonincreasing, $g(0) = 1$, admitting $g(s) \to 0$ for $s \to \infty$, e.g., $g(s) = 1/(1 + Ks^2)$, $K \geq 0$ [29]. $G_\sigma \in C^\infty(\mathbb{R}^d)$ is a smoothing kernel, e.g., the Gauss function, which is used in presmoothing of image gradients by the convolution. We will use the notation $g^0 = g(|\nabla G_\sigma * I^0|)$, and, due to properties of convolution, $1 \geq g^0 \geq \delta_\sigma > 0$ [8, 17]. The model parameter $1 \geq \varepsilon > 0$ shifts the model from the mean curvature flow of graphs ($\varepsilon = 1$) to the mean curvature flow of level sets ($\varepsilon = 0$) [15]. For segmentation of objects without corrupted boundaries (e.g., due to a noise or occlusion) the choice $\varepsilon = 1$ is optimal.

When segmenting an object with gaps in encompassing edges, then smaller ε, close to zero, should be used.

Together with the variational approaches following the seminal idea of Mumford and Shah [25], the curve and surface evolution models are powerful techniques used in image segmentation [1, 19, 5, 22, 6, 7, 20, 24]. Equation (1.1) can be formally understood as an Evans–Spruck ε-regularization [15]

$$|\nabla u| \approx |\nabla u|_\varepsilon = \sqrt{\varepsilon^2 + |\nabla u|^2} \tag{1.2}$$

of the segmentation equation

$$u_t = |\nabla u| \nabla . \left(g^0 \, \frac{\nabla u}{|\nabla u|} \right), \tag{1.3}$$

which is called geodesic or conformal mean curvature flow equation in the level set formulation [6, 7, 20].

In [15], the ε-regularization (1.2) was used as a tool to prove existence of the viscosity solution [12, 10] of the mean curvature motion in the level set formulation given by (1.3) with $g^0 \equiv 1$ [28]. The basic idea is that if the motion of a graph by mean curvature is rescaled by a factor $\frac{1}{\varepsilon}$, and letting $\varepsilon \to 0$, it gives the evolution of level sets. Equations (1.3) and (1.1), respectively, were studied analytically in [20, 7] and [32, 11], respectively.

In (1.3), where $0 < g^0 \leq 1$, the motion of level sets is influenced by the image features expressed in g^0. In the case $\varepsilon = 1$, (1.1) gives the motion of a graph by mean curvature with respect to a specific Riemann metric depending on g^0. Rescaling this motion by $\frac{1}{\varepsilon}$ (or, correspondingly, rescaling the Riemann metric) helps to complete the interrupted edges. The idea to use such special Riemannian mean curvature flow of graphs to extract the so-called subjective contours [18] and to segment images with interrupted edges originates in [31, 32, 33]; such an approach is called the *subjective surface method*. Unlike in (1.3), the subjective surface method does not move one particular (e.g., zero) level set to the boundary of the segmented object, but it moves all the level sets there. The forming discontinuity (shock) in the evolving graph of solution of (1.1) is used to detect object boundaries. Thus the standard level set methods preventing discontinuity formation by reinitialization of the front and applying, e.g., higher order (ENO or WENO) schemes cannot be used here.

Concerning numerical solution, in all previous approaches, the level set type equation (1.3), respectively (1.1), was rewritten into the advection-diffusion form

$$u_t = g^0 |\nabla u| \nabla . \left(\frac{\nabla u}{|\nabla u|} \right) + \nabla g^0 . \nabla u, \tag{1.4}$$

where $|\nabla u|_\varepsilon$ is used instead of $|\nabla u|$ in the case of (1.1). Then this form of equation was solved by a finite difference scheme using upwind in the advection term and explicit time stepping in the curvature term [6, 7, 20, 31, 32, 33]. As it will be discussed in section 3.3, such an approach is computationally inefficient mainly due to severe stability restrictions both in advection and curvature parts.

In spite of the previous methods based on (1.4), our 3D covolume technique suggested in this paper relies on discretization of (1.3) or, more precisely, of its ε-regularization (1.1). Using formulation (1.1) and employing its variational structure we develop an unconditionally stable semi-implicit time discretization scheme which gives the image segmentation in a computationally fast way. The main goal of this paper is to suggest such a method for high-scale 3D image segmentation problems and

show its stability, computational efficiency, and experimental convergence properties. Since the method can be used for any $\varepsilon > 0$ with $\varepsilon \to 0$, it can be applied to efficient solution of level set flows also in any other mean curvature driven applications.

The covolume technique (also called complementary volume or finite volume element method) is a combination of finite element (see, e.g., [4]) and finite volume methods; see, e.g., [21, 23]. The discrete equations are derived using the finite volume methodology, i.e., integrating equation in the so-called control (complementary, finite) volume. The control volumes are constructed as elements of a dual (complementary) grid to a primal finite element triangulation (tetrahedral grid in the 3D case). Employing the methodology of the finite element method, the piecewise linear representation of solution on a tetrahedral grid is used to evaluate in a clear and simple way the nonlinear quantities, the absolute value of gradients, in the numerical solution of (1.1).

A two-dimensional (2D) covolume technique for solving the level set formulation of mean curvature flow was first introduced in [35]. There also a particular nonlinear fully implicit time discretization scheme was given. The nonlinear scheme was designed in such a way that the basic properties of a continuous solution, namely L_∞- and $W^{1,1}$-stability, are fulfilled also for discrete solutions.

In [16] a linear semi-implicit 2D covolume level set method was given and studied. The same basic stability properties were proven for the semi-implicit scheme. Since it solves in every discrete time step linear (instead of nonlinear) algebraic systems, it gives solution in a more efficient way. In [16], the semi-implicit scheme was applied to 2D image filtering problem represented by the nonlinear diffusion level set type equation [2]

$$u_t = g(|\nabla G_\sigma * u|)|\nabla u| \nabla . \left(\frac{\nabla u}{|\nabla u|} \right). \tag{1.5}$$

In this paper we present for the first time a semi-implicit covolume scheme in three dimensions for solving level set type problems and apply the scheme to a different high-scale application—3D image segmentation. The previous 2D covolume strategy is not straightforwardly extended to the 3D case, but a new primal-dual grid construction is developed respecting discrete voxel structure of 3D images. Our new covolume scheme is related to 3D image data representation known in computer graphics as a centered-cubic-lattice method [9]. From the numerical point of view, it avoids any grid orientation effect, which is important for simulation of curve and surface evolution on a fixed grid; we illustrate this phenomenon in section 3.3. Although (1.5), studied in [16], and (1.1) and (1.3), respectively, look similar, their structure is different. In (1.1) and (1.3) the weighting term $g^0 = g(|\nabla G_\sigma * I^0|)$ is inside the divergence which brings a new advective phenomenon into the model; cf. (1.4). The advective term given by the vector field $-\nabla g^0$ is very important in the segmentation context; it drives all level sets to the image edges. Without the convective term (let us think about (1.5) with g^0 instead of $g(|\nabla G_\sigma * u|)$ in the right-hand side), the model is unable to segment nonconvex objects, as discussed in section 3.3, and so the method from [16] cannot be applied to image segmentation. Fortunately, the semi-implicit covolume strategy handles the weighting term inside divergence naturally, without going to advection-diffusion form (1.4), and allows us to develop a fast and stable numerical scheme for 3D image segmentation.

The paper is organized as follows. In section 2 we introduce in detail our 3D semi-implicit covolume method. In section 3 we study its experimental order of convergence in nontrivial examples of the level set evolution and thus its reliability in

simulations. We also discuss segmentation experiments with artificial and real (medical) 3D images and compare the method with other approaches. In this paper we concentrate mainly on algorithmic and computational aspects of the method. A full theoretical convergence analysis is not a simple task, and it is out of scope of this paper; however, it is a subject of our current research.

2. Computational method. We present our method formally in the discretization of (1.3), although we always use its ε-regularization (1.1) with a specific $\varepsilon > 0$. The notation is simpler in the case of (1.3), and it will be clear where regularization appears in the numerical scheme.

Equation (1.1) is accompanied either with Dirichlet boundary conditions

$$u(t,x) = u^D \quad \text{in } [0,T] \times \partial\Omega, \tag{2.1}$$

or Neumann boundary conditions

$$\frac{\partial u}{\partial s}(t,x) = 0 \quad \text{in } [0,T] \times \partial\Omega, \tag{2.2}$$

where s is unit normal to $\partial\Omega$, and with the initial condition

$$u(0,x) = u^0(x) \quad \text{in } \Omega. \tag{2.3}$$

In the image segmentation we use Dirichlet boundary conditions, and without loss of generality we may assume $u^D = 0$. The zero Neumann boundary conditions are often used in computations of interface motions in free boundary problems (see, e.g., [34, 27]) or in morphological image smoothing (see, e.g., [2, 16]). In this paper, we use Dirichlet boundary conditions in computing 3D image segmentations and in comparisons with known exact solutions u. The zero Neumann boundary conditions are used here in testing the accuracy of the method when dealing with the known motion of a particular level set of function u without knowing the exact evolution of the entire function u. In 3D image segmentation, the computational domain Ω is usually a subdomain of the image domain; it should include the segmented object. Along with the boundary conditions an initial condition (2.3) is also prescribed, and we assume that the initial function is bounded, i.e., $u^0 \in L_\infty(\Omega)$.

2.1. Semi-implicit time discretization. First, we choose a uniform discrete time step τ and a variance σ of the smoothing kernel G_σ. Then we replace the time derivative in (1.3) by backward difference. The nonlinear terms of the equation are treated from the previous time step, while the linear ones are considered on the current time level; this means semi-implicitness of the time discretization. By such an approach we get our semi-discrete in time scheme:

Let τ and σ be fixed numbers, g^0 be given by an image I^0, and u^0 be a given initial segmentation function. Then, for every discrete time moment $t_n = n\tau$, $n = 1, \dots N$, we look for a function u^n, solution of the equation

$$\frac{1}{|\nabla u^{n-1}|}\frac{u^n - u^{n-1}}{\tau} = \nabla.\left(g^0\ \frac{\nabla u^n}{|\nabla u^{n-1}|}\right). \tag{2.4}$$

2.2. Covolume spatial discretization in three dimensions. A 3D digital image is given on a structure of voxels with cubic shape, in general. Since discrete values of image intensity I^0 are given in voxels and they influence the model, we will

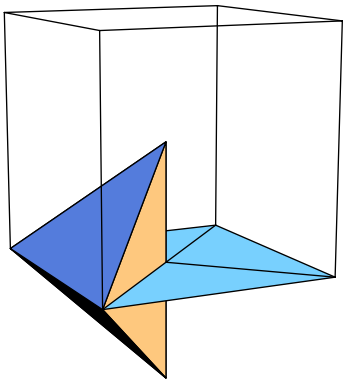

FIG. 2.1. *A tetrahedron of our primal grid together with its intersection with the bottom face of voxel covolume is shown.*

relate spatially discrete approximations of the segmentation function u also to the voxel structure, more precisely, to voxel centers. In every discrete time step t_n of the method (2.4) we have to evaluate gradient of the segmentation function at the previous step $|\nabla u^{n-1}|$. Toward that goal we put a 3D tetrahedral grid into the voxel structure and take a piecewise linear approximation of the segmentation function on such a grid. Such an approach will give a constant value of gradient in tetrahedra (which is the main feature of the covolume [35, 16] and linear finite element [13, 14] methods in solving mean curvature flow in the level set formulation), allowing simple, clear, and fast construction of a fully discrete system of equations.

The formal construction of our covolumes will be given in the next paragraph, and we will see that the covolume mesh corresponds back to the image voxel structure, which is reasonable in image processing applications. On the other hand, the construction of covolume mesh has to use a 3D tetrahedral finite element grid to which it is complementary. This will be possible using the following approach. First, every cubic voxel is split into six pyramids with vertex given by the voxel center and base surfaces given by the voxel boundary faces. The neighboring pyramids of neighboring voxels are joined together to form an octahedron which is then split into four tetrahedra using diagonals of the voxel boundary face—see Figure 2.1. In such a way we get our 3*D tetrahedral grid*. Two nodes of every tetrahedron correspond to centers of neighboring voxels, and further two nodes correspond to voxel boundary vertices; every tetrahedron intersects the common face of neighboring voxels. Let us note that due to our image processing application in mind, we restrict all further considerations only to this type of grid. In our method, only the centers of voxels will represent degree of freedom nodes (DF nodes); i.e., solving the equation at a new time step we update the segmentation function only in these DF nodes. Additional nodes of tetrahedra will not represent degrees of freedom; we will call them nondegree of freedom nodes (NDF nodes), and they will be used in piecewise linear representation of segmentation function. Let a function u be given by discrete values in the voxel centers, i.e., in DF nodes. Then in NDF nodes we take the average value of the neighboring DF nodal values. By such defined values in NDF nodes a piecewise linear approximation u_h of u on the tetrahedral grid is built.

For the tetrahedral grid $\mathcal{T}_h$, given by the previous construction, we construct a covolume (dual) mesh. We modify the approach given in [35, 16] in such a way that

our covolume mesh will consist of cells p associated only with DF nodes p of $\mathcal{T}_h$, let us say $p = 1, \ldots, M$. Since there will be one-to-one correspondence between covolumes and DF nodes, to avoid any confusion, we use the same notation for them. For each DF node p of $\mathcal{T}_h$ let C_p denote the set of all DF nodes q connected to the node p by an edge. This edge will be denoted by σ_{pq} and its length by h_{pq}. Then every *covolume* p is bounded by the planes e_{pq} that bisect and are perpendicular to the edges $\sigma_{pq}, q \in C_p$. By this construction, if e_{pq} intersects σ_{pq} in its center, the covolume mesh corresponds exactly to the voxel structure of the image inside the computational domain Ω where the segmentation is provided. Then the covolume boundary faces do cross in NDF nodes. So we can also say that NDF nodes correspond to zero-measure covolumes, and thus they do not add additional equations to discrete model, and they do not represent degrees of freedom in the covolume method. We denote by $\mathcal{E}_{pq}$ the set of tetrahedra having σ_{pq} as an edge. In our situation (see Figure 2.1) every $\mathcal{E}_{pq}$ consists of four tetrahedra. For each $T \in \mathcal{E}_{pq}$ let c_{pq}^T be the area of the portion of e_{pq} that is in T, i.e., $c_{pq}^T = m(e_{pq} \cap T)$, where m is the measure in $\mathbb{R}^{d-1}$. Let $\mathcal{N}_p$ be the set of all tetrahedra that have DF node p as a vertex. Let u_h be a piecewise linear function on $\mathcal{T}_h$. We will denote a constant value of $|\nabla u_h|$ on $T \in \mathcal{T}_h$ by $|\nabla u_T|$ and define regularized gradients by

$$|\nabla u_T|_\varepsilon = \sqrt{\varepsilon^2 + |\nabla u_T|^2}. \tag{2.5}$$

We will use notation $u_p = u_h(x_p)$, where x_p is the coordinate of DF node p of $\mathcal{T}_h$.

With these notations, we are ready to derive covolume spatial discretization. As it is usual in finite volume methods [21, 23], we integrate (2.4) over every covolume p, $i = 1, \ldots, M$, and using divergence theorem we get an integral formulation

$$\int_p \frac{1}{|\nabla u^{n-1}|} \frac{u^n - u^{n-1}}{\tau} dx = \sum_{q \in C_p} \int_{e_{pq}} \frac{g^0}{|\nabla u^{n-1}|} \frac{\partial u^n}{\partial \nu} ds. \tag{2.6}$$

The exact "fluxes" $\int_{e_{pq}} \frac{g^0}{|\nabla u^{n-1}|} \frac{\partial u^n}{\partial \nu} ds$ in the right-hand side and "capacity function" $\frac{1}{|\nabla u^{n-1}|}$ in the left-hand side (see, e.g., [21]) will be approximated numerically using piecewise linear reconstruction of u^{n-1} on triangulation $\mathcal{T}_h$. If we denote g_T^0 approximation of g^0 on a tetrahedron $T \in \mathcal{T}_h$, then for the approximation of the right-hand side of (2.6) we get

$$\sum_{q \in C_p} \left(\sum_{T \in \mathcal{E}_{pq}} c_{pq}^T \frac{g_T^0}{|\nabla u_T^{n-1}|} \right) \frac{u_q^n - u_p^n}{h_{pq}}, \tag{2.7}$$

and the left-hand side of (2.6) is approximated by

$$M_p m(p) \frac{u_p^n - u_p^{n-1}}{\tau}, \tag{2.8}$$

where $m(p)$ is the measure in $\mathbb{R}^d$ of covolume p and M_p is an approximation of the capacity function inside the finite volume p. For that goal we use either the averaging of the gradients proposed by Walkington [35], i.e.,

$$M_p = \frac{1}{|\nabla u_p^{n-1}|}, \quad |\nabla u_p^{n-1}| = \sum_{T \in \mathcal{N}_p} \frac{m(T \cap p)}{m(p)} |\nabla u_T^{n-1}|, \tag{2.9}$$

or

$$M_p = \sum_{T \in \mathcal{N}_p} \frac{m(T \cap p)}{m(p)} \frac{1}{|\nabla u_T^{n-1}|}, \tag{2.10}$$

which is close to finite element approximation with the mass lumping. Then the regularization of both approximations of the capacity function is given either by

$$M_p^\varepsilon = \frac{1}{|\nabla u_p^{n-1}|_\varepsilon} \tag{2.11}$$

or by

$$M_p^\varepsilon = \sum_{T \in \mathcal{N}_p} \frac{m(T \cap p)}{m(p)} \frac{1}{|\nabla u_T^{n-1}|_\varepsilon}, \tag{2.12}$$

and if we define coefficients (where the ε-regularization is taken into account)

$$b_p^{n-1} = M_p^\varepsilon m(p), \tag{2.13}$$

$$a_{pq}^{n-1} = \frac{1}{h_{pq}} \sum_{T \in \mathcal{E}_{pq}} c_{pq}^T \frac{g_T^0}{|\nabla u_T^{n-1}|_\varepsilon}, \tag{2.14}$$

we get from (2.7)-(2.8) our fully discrete semi-implicit covolume scheme:
Let u_p^0, $p = 1, \dots, M$, be given discrete initial values of the segmentation function. Then, for $n = 1, \dots, N$ we look for u_p^n, $p = 1, \dots, M$, satisfying

$$b_p^{n-1}\ u_p^n + \tau \sum_{q \in C_p} a_{pq}^{n-1}(u_p^n - u_q^n) = b_p^{n-1}\ u_p^{n-1}. \tag{2.15}$$

Applying either Neumann or Dirichlet boundary conditions, our fully discrete scheme gives the system of linear equations with the matrix which is a symmetric and diagonally dominant M-matrix. Using a similar technique as in [16] we get the following.

THEOREM. *There exists unique solution $(u_1^n, \dots, u_M^n)$ of the scheme (2.15) for any $\tau > 0$, $\varepsilon > 0$ and for every $n = 1, \dots, N$. The system matrix is a symmetric and diagonally dominant M-matrix. For any $\tau > 0$, $\varepsilon > 0$ the following L_∞ stability estimate holds:*

$$\min_p\ u_p^0 \le \min_p\ u_p^n \le \max_p\ u_p^n \le \max_p\ u_p^0, \quad 1 \le n \le N. \tag{2.16}$$

One can solve the system (2.15) by any efficient preconditioned linear iterative solver suitable for sparse, symmetric, diagonally dominant M-matrices, e.g., by SOR (successive overrelaxation) or PCG (preconditioned conjugate gradient) methods [30]. In the experiments presented in section 3 we use the SOR method. The iterative process is stopped if $R^{(l)} < \text{TOL}\ R^{(0)}$, where $R^{(l)}$ represents the squared residual in the lth iteration. Reporting experimental order of convergence we use TOL=10^{-6}. In the segmentation one can increase TOL, e.g., to 10^{-2}, in order to use fewer SOR iterations and consequently to decrease overall segmentation time. No significant influence to a precision of the segmentation result is usually observed.

The evaluation of g_T^0 included in coefficients (2.14) can be done in several ways. First, we may replace the convolution by the weighted average to get $I_\sigma^0 := G_\sigma * I^0$

(see, e.g., [23]) and then relate discrete values of I^0_σ to voxel centers. Then, as above, we may construct its piecewise linear representation on a grid and get a constant value of $g^0_T \equiv g(|\nabla I^0_\sigma|)$ on every tetrahedron $T \in \mathcal{T}_h$. Another possibility is to solve a numerically linear heat equation for time t corresponding to variance σ with initial datum given by I^0 (see, e.g., [4]) by the same method as above. The convolution represents a preliminary smoothing of the data. It is also a theoretical tool to have bounded gradients and thus a strictly positive weighting coefficient g^0. In practice, the evaluation of gradients on a fixed discrete grid (e.g., described above) always gives bounded values. So, working on a fixed grid, one can also avoid the convolution, especially if preliminary denoising is not needed or not desirable. Then it is possible to work directly with gradients of piecewise linear representation of I^0 in evaluation of g^0_T.

3. Discussion of numerical results. In this section we study experimental order of convergence of the method in case of mean curvature driven level set flow (i.e., for (1.1) with $g \equiv 1$ and $\varepsilon \to 0$), and then we present some 3D segmentation examples. The comparison with nontrivial exact solutions shows the second order accuracy for smooth (or mildly singular) solutions and the first order accuracy for highly singular solutions (i.e., when gradient is vanishing on a large subset of a domain and discontinuity set of the gradient field is nontrivial). It means that the method is accurate in computing interface motions, and it is reliable also for computing evolutions including flat regions as arising in the subjective surface based segmentation method.

3.1. Experimental order of convergence. In the first example we test the method using the exact solution [26]

$$u(x, y, z, t) = (x^2 + y^2 + z^2 - 1)/4 + t \tag{3.1}$$

of the level set equation

$$u_t = |\nabla u| \nabla . \left(\frac{\nabla u}{|\nabla u|} \right) \tag{3.2}$$

and consider Dirichlet boundary conditions given by this exact solution.

This problem, and all further computed examples in this subsection, are solved in the spatial domain $\Omega = [-1.25, 1.25]^3$ and in the time interval $T = 0.16$. We have taken subsequent grid refinement with $M = n^3$ covolumes (DF nodes), $n = 10, 20, 40, 80, 160$. So the grid size is $h = 2.5/n$. The time step τ is chosen proportionally to h^2 and we measure errors in $L_\infty((0, T), L_2(\Omega))$-norm (cf. [13]), which is natural for testing the schemes for solving parabolic problems.

Let us assume that the error of the scheme in some norm is proportional to some power of the grid size, i.e., $Error(h) = Ch^\alpha$, with a constant C. Then halving the grid size we have $Error(h/2) = C(h/2)^\alpha$ from where we can simply extract

$$\alpha = \log_2(Error(h)/Error(h/2)). \tag{3.3}$$

The α is called the *experimental order of convergence* (EOC) and can be determined by comparing numerical solutions and exact solutions on subsequently refined grids.

In Table 3.1 we report errors in $L_\infty((0, T), L_2(\Omega))$-norm for refined grids and for several choices of ε. In all cases we observe $\alpha = 2$, where the coupling $\varepsilon \approx h^2$ seems optimal (see also other examples), but as one can see, choosing ε even smaller can get even smaller errors on coarse grids.

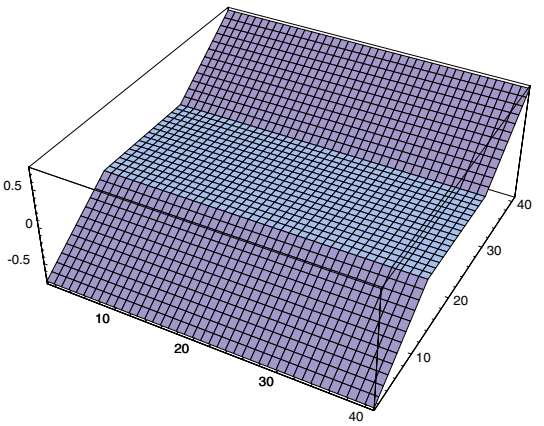

FIG. 3.1. *Exact solution* (3.4) *remaining unchanged under mean curvature flow (plot at $z = 0$).*

Next an interesting example comes from [14] and is given by (see Figure 3.1)

$$
\begin{aligned}
u(x,y,z,t) &= x + 0.5, \ x \le -0.5 \\
&= 0, \ -0.5 \le x \le 0.5 \\
&= x - 0.5, \ x \ge 0.5.
\end{aligned} \tag{3.4}
$$

The level sets of u are planes, with zero mean curvature, and so the solution remains unaltered by the flow. There is also a large part of the solution where gradient is vanishing; however, the set of discontinuity in gradient is relatively simple (two planes) regarding a possible orientation of our grid (we can make it parallel). Mathematically, it is a trivial example, but it is a good test for a numerical scheme. One can observe (see Table 3.2) that the error of the scheme in this example is proportional just to regularization parameter ε, and thus it can be made as small as desirable. This is a simple consequence of the *consistency* of our scheme in the sense that it gives exact solution for any linear initial function and for any choice of regularization parameter ε, any grid size h, and any size of time step τ. Such a property can be checked by inspection of the scheme (2.15). For the linear function, the gradients in all tetrahedra are the same, and so we get the system with the same structure as given by the backward Euler scheme for solving a linear diffusion equation with constant coefficients, and such a scheme does not alter a steady state.

In the next example we compare our numerical solution with the highly singular solution given by

$$u(x,y,z,t) = \min((x^2 + y^2 + z^2 - 1)/4 + t, 0). \tag{3.5}$$

The initial function and numerical result at $T = 0.16$ are plotted in Figure 3.2. We

see only slight smoothing in numerical solution along singularity; numerical solution converges to viscosity solution with $\alpha = 1$, as reported in Table 3.3.

In the last example we test experimental order of convergence comparing the numerical and exact evolution of one particular level set. Namely, we use the exact solution given by shrinking sphere with exact radius $r(t) = \sqrt{r(0) - 4t}$, starting with $r(0) = 1$. Our initial level set function is a 3D cone (signed distance function) having zero value on the unit sphere. We consider zero Neumann boundary conditions, and so we do not know the exact solution for evolution of the whole level set function. At every time step we evaluate $L_2(S^2)$-norm of error, where S^2 is the unit sphere, comparing the exact shrinking sphere and the numerical zero level set, and then we take $L_\infty((0,T),L_2(S^2))$-norm for the overall error in time interval $T = 0.16$. Figure 3.3 represents the initial sphere and the numerical zero level set at $T = 0.16$. Table 3.4 documents the higher order rate of convergence, where again the coupling $\varepsilon = h^2$ is used. Similarly to the first example, different couplings or choice of a fixed small ε give similar errors and convergence rates.

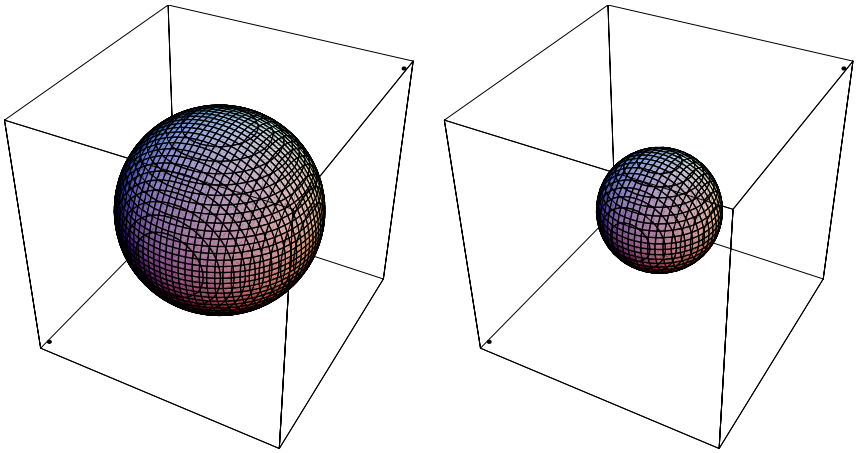

FIG. 3.3. *Numerical solution corresponding to exact shrinking sphere with radius* $r(t) = \sqrt{r(0) - 4t}$, $r(0) = 1$, *plotted at times* $t = 0$ *(left) and* $t = 0.16$.

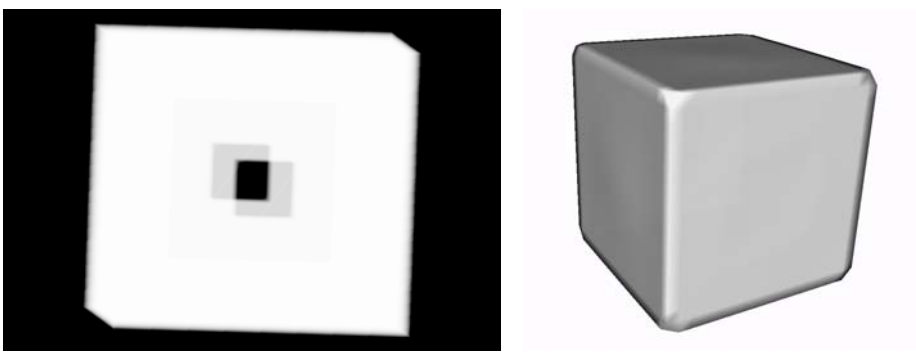

FIG. 3.4. *Segmentation (right) of a* 3*D cube with two holes (left).*

3.2. Segmentation examples. Here we present two 3D segmentation examples. The first one is simple; in the image with resolution 40^3 voxels is an object, a cube with two holes (see Figure 3.4(left)); the holes are in front and back faces. Figure 3.4 gives a reconstructed surface with the perfect hole filling (see Figure 3.4(right)). Due to the advection term all level sets are attracted to the faces of the cube. Due to the mean curvature flow type diffusion the level sets continue inside the gaps in the form of planar surfaces. Since in the holes area $g^0 \equiv 1$ and $\nabla g^0 \equiv 0$ just the mean curvature motion of level sets plays the role inside the gaps, and the planar

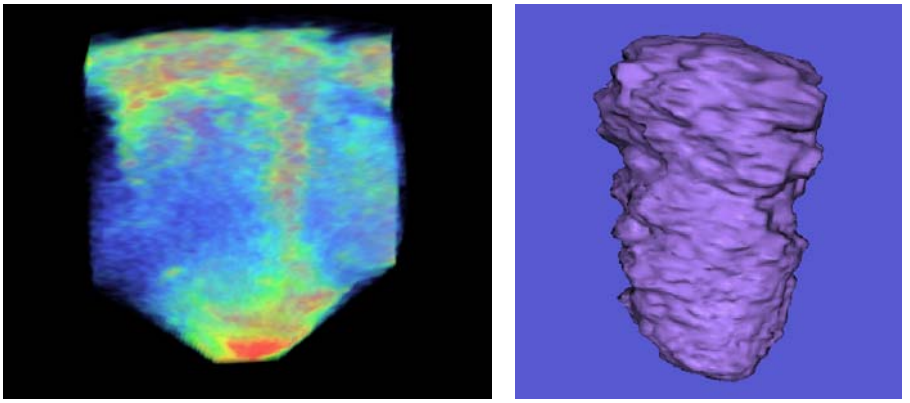

FIG. 3.5. *Volume rendering of original 3D data set (left) and segmentation of the ventricle (right).*

filling is then a consequence of the basic property of mean curvature flow, namely the minimization of surface area. Segmentation of an object of this size takes few seconds (on a 2.4GHz PC); one time step takes 0.15 sec, and we need few tens of time steps to find the result. A change in L_2-norm of numerical solutions in subsequent time steps is used to stop the segmentation process. We check whether

$$\sqrt{\sum_p m(p)\ (u_p^n - u_p^{n-1})^2} < \delta \tag{3.6}$$

with a prescribed threshold δ. In Figure 3.4(right) we visualize isosurface of the segmentation function close to its maximum. In all segmentation examples computed by our semi-implicit scheme we take $K = 1$, $h = \frac{1}{n_1}$, n_1 number of voxels in the horizontal direction, $\tau \approx 10 \times h^2$, and $\delta = 10^{-5}$. We start all computations with the initial function given as a peak centered in a "focus point" inside the segmented object. At a sphere with center s and radius R the initial function can be described by $u^0(x) = \frac{1}{|x-s|+v}$, where s corresponds to the focus point and $\frac{1}{v}$ gives a maximum of u^0. Outside that sphere we take values of u^0 equal to $\frac{1}{R+v}$. R usually corresponds to the halved inner diameter of the image domain. For small objects a smaller R can be used to speed up computations. In this example the maximum of the initial segmentation function (the focus point s) is taken in the image center.

The second example is given by 3D echocardiography of size $81 \times 87 \times 166$. As one can see from volume rendering visualization (Figure 3.5(left)), the 3D image is very noisy; however, the surface of the ventricle is observable. How noisy the image intensity is can be seen also from Figure 3.6, where one can see 2D image intensity and its graph in one 2D slice. Now we start the segmentation process with few "points of view" inside the object of interest, i.e., the initial segmentation function having several maxima, and let it evolve until the difference in L_2-norm of two subsequent time steps is less than the prescribed threshold. Then we look to a 2D slice with relatively good boundary edges (Figure 3.6), where we see accumulation of level sets along the inner boundary of the ventricle (Figure 3.6(left)). The largest gap in the histogram (Figure 3.7(left)) indicates the shock in the segmentation function, and so we choose one level inside the gap and plot it inside the slice (Figure 3.7(right)). We can check how this level set looks like in other noisy slices (Figure 3.8) and then make

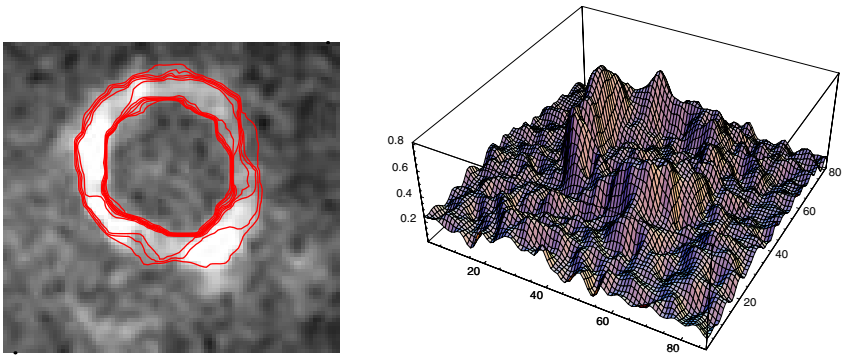

FIG. 3.6. *Plot of accumulated level sets in the slice* $k = 130$ *(left) and* $3D$ *graphical view of this slice (right).*

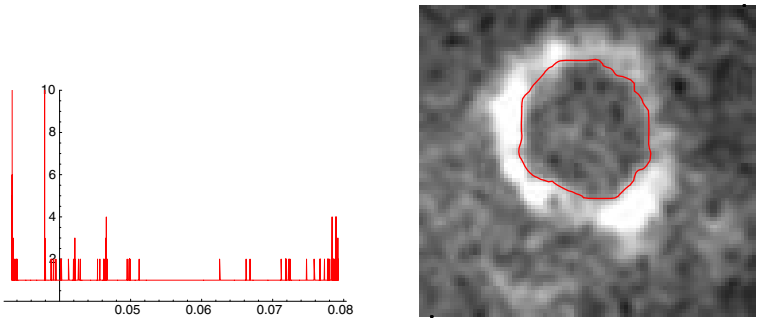

FIG. 3.7. *The histogram of the segmentation function in the slice* $k = 130$ *(middle); image intensity with level set* $u = 0.052$ *(right). Visualization of the* $3D$ *surface in Figure* 3.5 *is done with the same level set.*

a 3D isosurface visualization (Figure 3.5(right)) which gives realistic representation of the left ventricle.

The computation of one time step takes 3 seconds on a 2.4GHz one processor PC and takes 200 steps to finish segmentation, and so the overall computing time for this image size is in a range of few minutes. The MPI parallel implementation [3] of our 3D segmentation scheme has been built under the support of the Project HPC-EUROPA at CINECA SuperComputing Center, Bologna, and so the segmentation

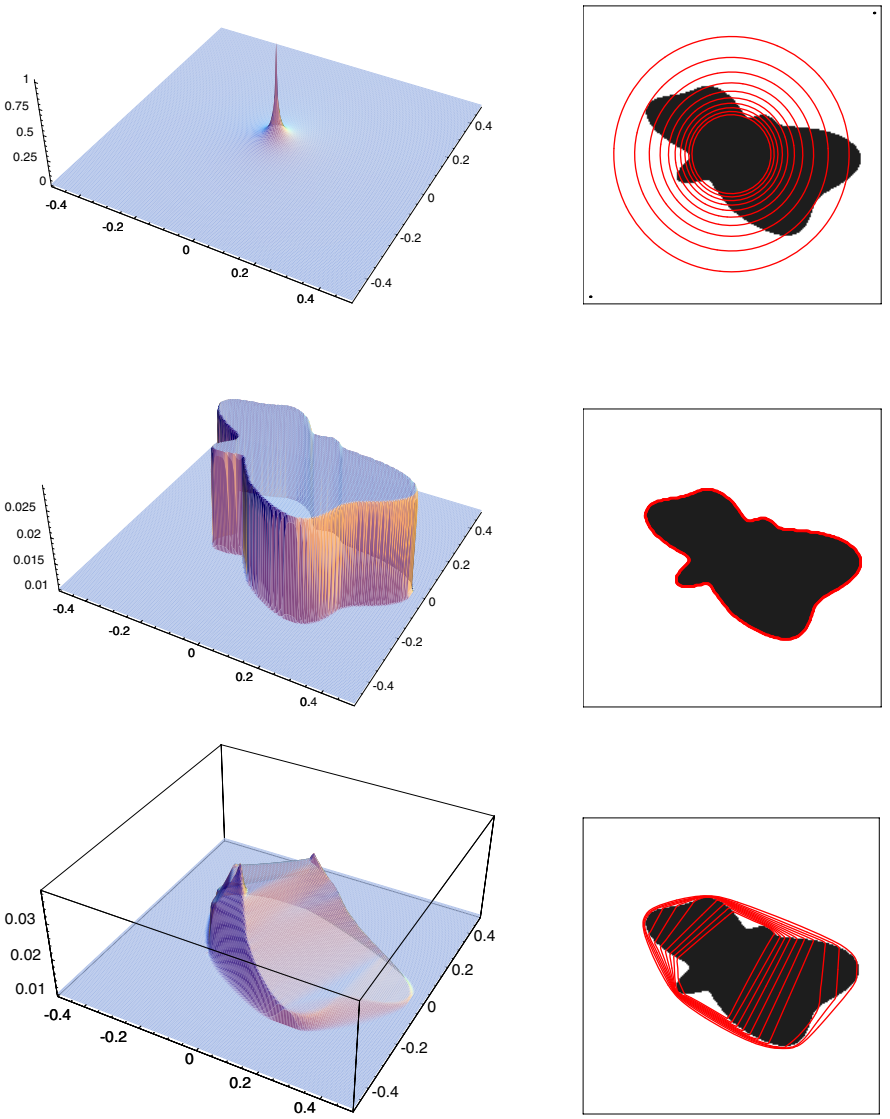

FIG. 3.9. *Successful subjective surface based segmentation* (1.4) *of a "batman" image, in the middle. Nonsuccessful segmentation only by slowed mean curvature motion* (1.5), *in the bottom.*

time is even speeding up depending on the number of available processors (e.g., in Linux cluster). The MPI parallelization of our algorithm is straightforward, because it uses classical structures of scientific computing methodology for solving partial differential equations and linear algebra problems (see, e.g., [3]).

3.3. Comparison with different models and methods. First, we show the difference between segmentation model (1.4) and (1.5) with g^0 instead of $g(|\nabla G_\sigma * u|)$; i.e., we document the role of convective term which appears in the model if g^0 is inside the divergence term. This comparison also shows that the method from [16] cannot be straightforwardly transferred from image smoothing to image segmentation problems.

Let us consider a simple nonconvex black object on a white background as plotted in Figure 3.9. If we start with the initial function plotted in the top left subfigure, isolines of which are plotted in the top right subfigure, and apply model (1.4), we end up with results as in the middle subfigures, while applying (1.5) we end up in the long run with the bottom subfigures. In the middle we see accumulation of all level lines on the object boundary due to the convective term, and any of these level lines can be used to represent segmentation of the object. In the case of (1.5), the motion of level lines is slowed down along the edges; however, level lines shrinking from outside, due to minimizing length (property of mean curvature motion), cannot go inside the nonconvex regions, and they accumulate on a convex envelope of the object.

Next we compare computational efficiency of our semi-implicit scheme with standard methods based on classical level set strategy and explicit time stepping. Such explicit schemes are usually based on formulation (1.4), where, moreover, all derivatives are expanded to get mean curvature and advection terms. Then, in three dimensions, (1.1) is written in the form

$$\begin{aligned} u_t = g^0((\varepsilon + u_{x_2}^2 + u_{x_3}^2)u_{x_1x_1} + (\varepsilon + u_{x_1}^2 + u_{x_3}^2)u_{x_2x_2} + (\varepsilon + u_{x_1}^2 + u_{x_2}^2)u_{x_3x_3} \\ -2u_{x_1}u_{x_2}u_{x_1x_2} - 2u_{x_1}u_{x_3}u_{x_1x_3} - 2u_{x_2}u_{x_3}u_{x_2x_3})/ \\ (\varepsilon + u_{x_1}^2 + u_{x_2}^2 + u_{x_3}^2) + g_{x_1}^0 u_{x_1} + g_{x_2}^0 u_{x_2} + g_{x_3}^0 u_{x_3}, \end{aligned} \tag{3.7}$$

where u_s means partial derivative of a function u with respect to a variable s. The explicit time stepping and central finite difference approximation is used in the mean curvature term, and upwind finite difference approximation is used in convective term [33]. For the computational comparison we use a representative 3D example where we segment a sphere with four holes (white object on black background in 80^3 voxels image); the 2D cut by equatorial plane is given in the upper left of Figure 3.10. In the upper right of Figure 3.10 we see the reconstructed sphere, and in the bottom part of Figure 3.10 we see the 2D cut of the shock profile of the segmentation function which is used to extract the upper sphere. This state of the segmentation function is achieved after 1450 time steps using discretization [33] of (3.7). Although CPU time for one explicit time update is small, due to stability reasons, both in curvature and convective parts, we have to choose a small time step, $\tau = 0.00002$, and need many of them to achieve a piecewise constant profile of the segmentation function. So the overall CPU time is 380 secs. In spite of that our semi-implicit discretization (2.15) fulfills unconditionally the discrete minimum-maximum principle (L_∞-stability); i.e., no spurious oscillations appear for any length of discrete time step. We get the same 3D segmentation result in 28 steps with $\tau = 0.002$. Although one step of the semi-implicit scheme is more complex, we have to solve the linear system, the overall CPU time is 45 secs, and there is a benefit of almost 10 times speed-up. This speed-up ratio is quite a common observation in many 3D segmentation comparisons of semi-implicit and explicit schemes.

At the end we illustrate removing a grid orientation effect which can be observed in numerical results of previously studied algorithms [35, 16]. There either "left oriented" or "right oriented" triangulations (see Figure 3.11) have been used for solving the level-set-like problems, and, especially on coarse grids, the influence of grid orientation can be observable. To show this phenomenon in a transparent way we present a 2D experiment where the initial unit circle is moving by mean curvature and expanding with unit speed in the outer normal direction at the same time. In such a case, $Fm(p)$, $F = -1$ is added to the right-hand side of the fully discrete scheme (2.15). Since there is a balance between curvature and driving force the unit circle is the

exact solution, and so it should remain stable also computationally. Using the "right oriented" triangulation with 20×20 covolumes and the method from [16], at time $T = 1$, we get the result plotted in Figure 3.12(left). We see exact solution plotted by the dashed line and its slight distortion visualizing the numerical solution. On the other hand, using the 2D analogy of the method presented in this paper, i.e., "symmetric" triangulation plotted in the middle part of Figure 3.11, we get the numerical result presented in Figure 3.12(right), where the circular shape is not distorted. Our 3D tetrahedral mesh and covolume grid construction transfer such "symmetry" of the

method into the 3D case, and in this sense the previous covolume techniques are improved.

A PARALLEL MULTISTAGE ILU FACTORIZATION BASED ON A HIERARCHICAL GRAPH DECOMPOSITION*

PASCAL HÉNON† AND YOUSEF SAAD‡

Abstract. PHIDAL (parallel hierarchical interface decomposition algorithm) is a parallel incomplete factorization method which exploits a hierarchical interface decomposition of the adjacency graph of the coefficient matrix. The idea of the decomposition is similar to that of the well-known wirebasket techniques used in domain decomposition. However, the method is devised for general, irregularly structured, sparse linear systems. This paper describes a few algorithms for obtaining good quality hierarchical graph decompositions and discusses the parallel implementation of the factorization procedure. Numerical experiments are reported to illustrate the scalability of the algorithm and its effectiveness as a general purpose parallel linear system solver.

Key words. parallel incomplete LU factorization, ILU, sparse Gaussian elimination, wirebasket decomposition, interface decomposition, preconditioning, ILU with threshold, iterative methods, sparse linear systems

DOI. 10.1137/040608258

1. Introduction.

A number of incomplete LU (ILU) factorization techniques have been developed in recent years which attempt to combine some of the general-purpose features of standard ILU preconditioners with the good scalability attributes of multi-level methods. Examples include the ILU with multielimination (ILUM) [13], the multilevel ILU (MLILU) [3] and matrix renumbering ILU (MRILU) algorithms [4], and the algebraic recursive multilevel solver (ARMS) [16] and its parallel version pARMS [9]. An ingredient that is common to all these methods is to reorder the linear system to enable a parallel (incomplete) elimination of groups of unknowns. Solution algorithms which implement similar strategies within domain decomposition have also been developed and can be found, for example, in the pARMS [9] package. This paper presents a new technique in this category. The main attraction of the new method is that it exploits a static "hierarchical" decomposition of the graph which yields natural parallelism in the factorization process. This is in contrast with the methodology used in pARMS in which the independent sets and levels are defined dynamically. The underlying ordering on which the method is based is reminiscent of the "wirebasket" techniques of domain decomposition methods [17, 18], in which cross points in a domain partitioning play an important role. Cross points have played a special role in many domain decomposition techniques; see [5], for example. One can also view the methods from the angle of an ILU factorization combined with a form of nested dissection ordering in which cross points in the separators play a special role. In this regard, the method bears some resemblance to the FETI method [6]. The ideas discussed in this paper also bear resemblance to those sketched by Magolu monga Made and van der Vorst [12, 10, 11] for matrices arising from finite difference

discretizations of 2-dimensional partial differential equations.

The algorithm described in this paper is based on defining a "hierarchical interface structure." The hierarchical decomposition starts with a partitioning of the graph, with one layer of overlap. Then, "stages" or "levels" are defined from this partitioning, with each level consisting of a set of groups or connectors (small connected subgraphs). The levels obey an important property which is that each connector of a given level is a separator for connectors of a lower level. Thus, for a simple 5-point graph the connectors at level 1 are the sets of interior nodes for each subdomain obtained from the partitioning. Level 2 includes the interfaces between domains at the exclusion of cross points, and level 3 consists of all the cross points. The vertices are globally ordered by level, in increasing order of level number. The incomplete factorization process proceeds by level from lowest to highest. Because of the separation property of the connectors at different levels, it turns out that this process can be made highly parallel by tuning the dropping strategy to the levels. More precisely, the dropping strategies will attempt to maintain the independent set structure extracted from the interface decomposition.

As was already mentioned, a major difference between this method and existing methods of this type, such as pARMS, is that the preordering used for parallelism is performed at the outset instead of dynamically. This has both advantages and disadvantages. Because the ordering is static, the factorization is rather fast. On the other hand, the ordering may face difficulties in the case when, for example, zero or small pivots are encountered. In pARMS, some form of diagonal pivoting is performed to bypass this difficulty.

The main ingredient of the ILU factorization is the hierarchical interface decomposition of the graph. It is fairly easy to find definitions which will achieve the desired goals of yielding a hierarchy of subgraphs which separate each other. For example, just assigning to each node a label which is defined as the number of subdomains to which the node belongs yields, under certain conditions, a decomposition into levels of independent sets, given by the labels. This is the case for simple graphs such as the one of a 5-point finite difference matrix. Thus, in the illustration of Figure 2.1, this strategy would yield 3 different labels. Nodes labeled "1" are interior nodes, nodes labeled "2" are interface nodes (excluding cross points), and nodes labeled "4" are the cross points. Cross points are separators for interfaces which are separators for the sets of interior nodes for each domain. This is just the desired decomposition.

This simple strategy does not always work. It will fail, for example, if a 9-point discretization is used. In such situations, there are usually ways to modify the labels to yield the desired hierarchical decomposition. However, decompositions obtained in this way are often suboptimal for "rich" graphs, in that they may yield a large number of levels. This is an important issue to which a substantial part of the paper is devoted.

The next section discusses the hierarchical decomposition of a graph. Section 3 presents the details of the parallel elimination process. Section 6 reports on some experiments. The paper ends with some concluding remarks and tentative ideas for future work.

2. Hierarchical interface decomposition. Let $\mathcal{G} = (\mathcal{V}, \mathcal{E})$ be the adjacency graph of a sparse matrix A which has a symmetric pattern so that $\mathcal{G}$ is undirected. Assume that $\mathcal{G}$ is partitioned into p subgraphs. An edge-based partitioning is used, in the sense that edges are primarily assigned to subdomains, and therefore vertices at the interfaces overlap two or more domains. This is the common situation which arises,

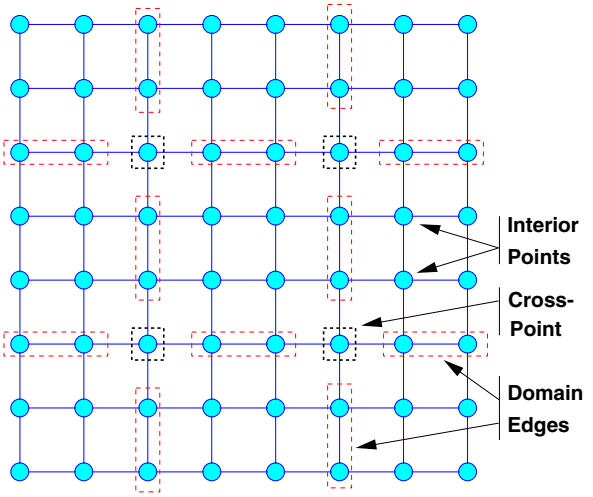

FIG. 2.1. *Partition of an* 8×8 5*-point mesh into* 9 *subdomains and the corresponding hierarchical interface structure.*

for example, when elements in finite element methods are assigned to processors.

We begin by illustrating the hierarchical decomposition process on a matrix A which arises from a simple 5-point finite difference discretization of a Laplacean in 2-dimensional space. The vertex set $\mathcal{V}$ consists of three types of vertices representing the common "interior vertices," "domain-edges," and "cross points" of the partition; see Figure 2.1 for an illustration. These three types of points are grouped in sets which will be referred to as "connectors." Thus, the interior points of a given domain form one connector, and the domain-edges, i.e., the set of interface points linking two given subdomains (excluding cross points), also form a connector. In this case, levels of connectors are also naturally defined. Level-1 connectors are the sets of interior points, level-2 connectors are the domain-edges, and level-3 connectors are the cross points.

This decomposition of the vertices has the interesting property that different connectors at the same level are not coupled. Another interesting property is that the higher-level connectors separate the lower-level connectors: Interior domains (level-1 connectors) are separated by domain-edges and cross points (level-2 and level-3 connectors) and domain-edges are themselves separated by cross points. These properties can be exploited in a parallel context by taking advantage of the block structure of the matrix A obtained by reordering the unknowns according to this decomposition. If the unknowns are reordered according to their level numbers, from the lowest to highest, the block structure of the reordered matrix would be as shown in Figure 2.2. In this figure we can see that for a 5-point mesh, this kind of ordering will naturally yield a diagonal block structure for each level of connectors. Notice that the block structure leads to natural parallelism if an ILU decomposition is performed, provided that fill-in is avoided where it would hamper parallel processing of the factorization. Our goal is to generalize this ordering to irregularly structured graphs in order to obtain a similar matrix structure which can be exploited in a parallel solver. It is worth mentioning that the regularity of the block structure in Figure 2.2 (all connectors of a level have the same size) is related to the regularity of the mesh and the particular partitioning used. Similarly, the tridiagonal structure of the diagonal blocks is also

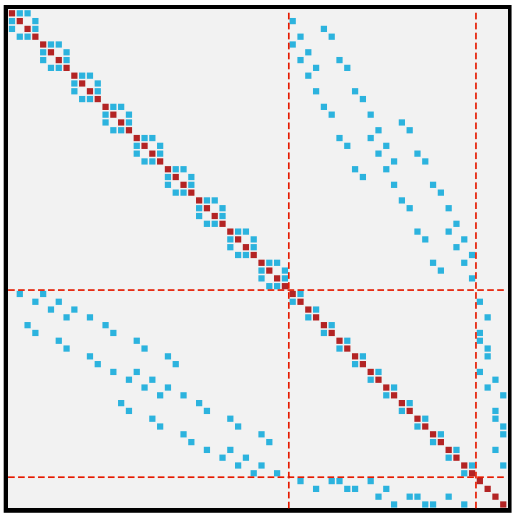

FIG. 2.2. *Matrix associated with an* 8×8 *5-point mesh reordered according to the hierarchical interface decomposition.*

due to the nature of the problem. It is not the goal of the ordering to achieve such a regular structure. Based on the hierarchical graph decomposition, the block structure of the matrix A is obtained by using an ordering that

- labels unknowns in the same connector by consecutive numbers,
- labels unknowns in a connector of level l with smaller numbers than those in connectors of level $m > l$.

The remainder of this section will discuss extensions of the "wirebasket" structure (which was just seen for the 5-point mesh example) to irregularly structured graphs. We will refer to this structure as a "hierarchical interface decomposition" of the graph. Given the general definition, we will then propose in the next section some heuristics to compute the interface decomposition.

We begin with a formal definition of a hierarchical decomposition of a graph. We will call a *connector* a connected subgraph of $\mathcal{G}$. A *connector decomposition*, or *interface decomposition*, is a grouping of connectors into *levels*. So, a *level* is simply a set of connectors. Levels are labeled from 1 to p. Two connectors are *adjacent* (or "coupled") if there is at least one edge linking a vertex from one connector to a vertex of the other. A *hierarchical interface decomposition* is defined as follows.

DEFINITION 2.1. *A set of levels labeled* $1, \ldots, p$ *is a hierarchical decomposition of* $\mathcal{G}$ *if it satisfies the following conditions:*

(1) *The connectors are disjoint and together form a partition of the graph.*
(2) *Connectors of the same level are not adjacent.*
(3) *Connectors of a given level* $l > 1$ *are separators for connectors at level* $l - 1$. *This means that the removal of a connector of level* l *will disconnect (in the original graph) at least two connectors of level* $l - 1$.

Condition (2) by itself implies that two connectors C_1, C_2 which are not adjacent in the original graph and which belong to the same level l must be separated by some connector C_3 from a different level. Condition (3) simply states that the level number

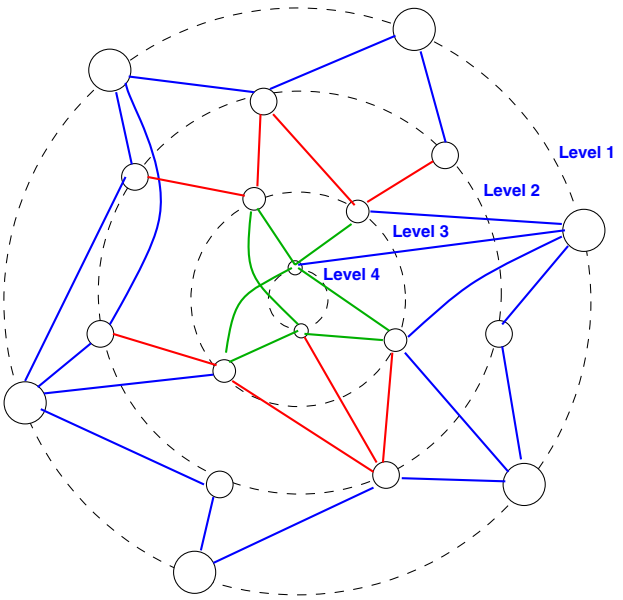

FIG. 2.3. *An example of a hierarchical decomposition of a graph. The circles are connectors, and the links show the adjacencies between them. The connectors are grouped into* 4 *levels indicated by the dashed concentric circles.*

of C_3 must be $l+1$. An illustration of the definition is given in Figure 2.3.

The issue now is to obtain such hierarchical decompositions. We may attempt to develop algorithms specifically for this task. In other words, we could seek algorithms that would take a graph and produce a partition into connectors satisfying the above conditions. In addition, the algorithm would also attempt to yield a good load balancing. This is not attempted in this paper. Instead, we will use as a starting point a partitioned graph, where the partitioning results from a standard graph partitioner such as METIS [8].

A few additional clarifications regarding the above definition may be helpful. The term "interface" is used only because of the nature of the algorithms that will produce the decomposition. The term "hierarchical" refers to the levelization of the connector sets with the property that the connectors of a given level l separate those connectors of lower levels $m < l$. For the 5-point example a good levelization was achieved by defining the level number of a connector from the number of adjacent domains. For general irregular domains and partitions, the situation is more complex, and this process, when it works, will yield a poor levelization in the sense that the resulting levelization may produce levels which contain few connectors, resulting in a high number of levels. Figure 2.4 shows an irregular domain partition (the figure shows only the connectors, not the graph vertices and edges). In this case, there are 5 levels. Clearly, a better level-structure of the connectors is achieved by grouping all the connectors represented as dots together, resulting in only 3 sets of independent connectors. In subsection 2.3, we discuss an algorithm that is able to extract a good level partitioning.

Before continuing, it may be insightful to consider alternatives for obtaining hierarchical interface decompositions. A first viewpoint can be realized by looking at the matrix in Figure 2.2, which is very similar to one that would be obtained from

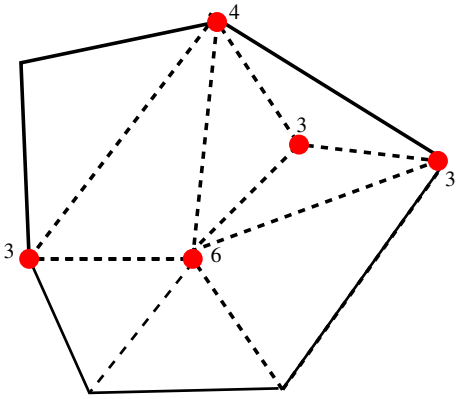

FIG. 2.4. *Connector levels resulting from an irregular domain partition. The solid lines represent the domain boundaries. The dashed lines represent level-2 connectors. The big dots are the level-i connectors with $i > 2$. The level labels for these connectors are shown next to them.*

multicoloring. In fact it can be viewed as a "block" multicoloring of the graph, in the same way that the orderings considered in ARMS [16] can be viewed as block versions of independent set orderings. While this is correct, the main issue is to define connectors first from the partitioned graph. Once these are obtained a multicoloring process can be called to define the levels. The point is that the difficulty resides in getting good connectors, not in getting the levels.

2.1. Algorithms for building hierarchical decompositions of a graph. We begin with some definitions and notation that will be used in the remainder of the paper. We are given an initial partitioning of the graph with overlap. The algorithm to define the hierarchical decomposition for general graphs will exploit the freedom to reassign the interface nodes to the neighboring subdomains so that certain properties of the modified partitioning are satisfied. In order to do this in a systematic manner, we associate with each vertex u a unique key $Key(u)$,

$$Key(u) = \{i_1, \ldots, i_m\},$$

which contains a list of all subdomains i_k to which u belongs in the graph partitioning. It is to be understood here that the assignment of u to subdomains will be altered dynamically by the procedure which defines the decomposition and thus the key will be changing in the course of the procedure. We also denote by $C_{i_1,\ldots,i_m}$ the set of vertices which are overlapped by subdomains $i_1, i_2, \ldots, i_m$. In particular note that

$$Key(u) = \{i_1, \ldots, i_m\} \Leftrightarrow u \in C_{i_1,\ldots,i_m}.$$

The subsets $C_{i_1,\ldots,i_m}$ are termed connectors. The notation $Key(C) = \{i_1, \ldots, i_m\}$ will also be used for the connector $C = C_{i_1,\ldots,i_m}$. We will also denote by $deg(C)$ the cardinality of the key of C, i.e.,

$$deg(C) = |Key(C)|,$$

which is the number of subdomains that include C. Note that C is an intersection of subdomains, so there is no ambiguity in this definition. Similarly, we can also define the *domain degree* of a node by $deg(u) = |Key(u)|$, which is again the number of

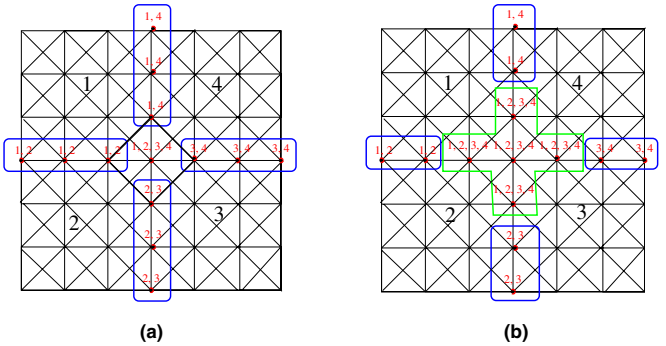

FIG. 2.5. (a) *Partition of a* 9*-point grid into* 4 *subdomains. Connectors induced by the domain partitioning are not independent.* (b) *One solution for recovering independent sets of connectors.*

domains with which u is associated. By abuse of language we will sometimes call this the degree of u, which is to be distinguished from the actual degree of u in the graph.

The purpose of the keys is to help build good connectors. Given an arbitrary set of domain labels $\{i_1, i_2, \ldots, i_k\}$, one can formally define any connector $C_{i_1,i_2,\ldots,i_k}$ as the set of all nodes belonging to subdomains $i_1, \ldots, i_k$ (most connectors defined this way will be empty). For any particular partitioning, $Key(u) = \{i_1, \ldots, i_k\}$ if and only if u belongs to $C_{i_1,i_2,\ldots,i_k}$. The connectors depend on the particular partitioning. The algorithms to be described in this section will slightly alter the partitioning, i.e., the keys, or equivalently, the connectors, to achieve certain properties. In the proposed algorithms, these slight modifications will affect only the overlapping regions of the subdomains.

In the example of the grid, the partition of the interface into domain-edges and cross points defines a partition of connectors: Interior domains are connectors of degree 1, domain-edges are connectors of degree 2, and cross points are connectors of degree 4. If C is a domain-edge between domains 1 and 2, then $Key(C) = \{1, 2\}$. As was mentioned above, in more complex cases, it will be necessary to redefine keys in order for the connectors to be independent. Though section 2.2 is devoted to this issue we provide an example in Figure 2.5 to illustrate the idea.

Figure 2.5(a) is an original partitioning of a 9-point grid into 4 subdomains. The middle lines overlap, and the center point is assigned to all 4 subdomains. The initial keys associated with this mapping are shown above each node. This example shows that level-2 connectors defined directly from the domain degree $|Key(u)|$ may be adjacent. There are several possible remedies to change the keys so that the new connectors become independent. Figure 2.5(b) shows one possible and natural solution which consists of expanding $Key(u)$ so that it contains the list of all the domains of each member of $adj(u)$, i.e., the set of all subdomains of the nearest neighbors of u. As will be seen in section 2.2, this is not necessarily the best solution.

The original decomposition of a graph sometimes yields a hierarchical decomposition such that the connectors of the same level are uncoupled: This was the case for the 5-point mesh example seen earlier. By this we mean that in such situations, sets of connectors of the same degree will constitute a level for the hierarchical decomposition. Unfortunately, this situation is special. For an arbitrary irregular graph, the connectors obtained in this manner will not in general form a hierarchical interface decomposition. Indeed, connectors of the same degree can be adjacent. In

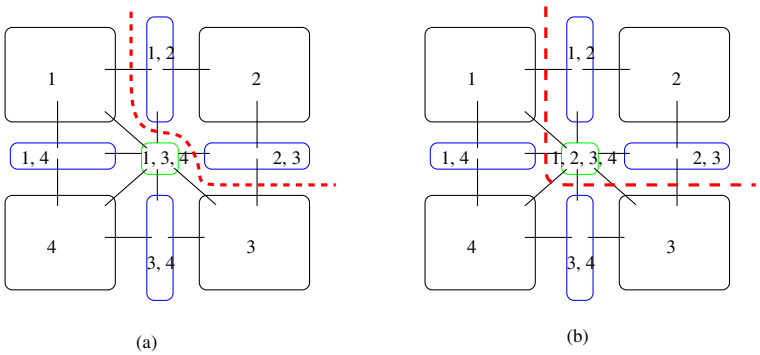

FIG. 2.6. (a) *Nonconsistent interface decomposition.* (b) *Consistent interface decomposition.*

the remainder of this section, we define first what properties we want to obtain from the interface decomposition and then we discuss algorithms to modify any interface decomposition in order to achieve these properties.

We need a property of a connector decomposition which will be called *consistency.* It is given next.

DEFINITION 2.2. *An interface decomposition is said to be consistent if any pair of connectors* C_1, C_2 *verifies*

- C_1 *is adjacent to* $C_2 => Key(C_1) \subsetneq Key(C_2)$ *or* $Key(C_2) \subsetneq Key(C_1)$.

Another way to state the definition is that when two connectors are adjacent in a consistent interface decomposition, then one connector key must be a strict superset of the other. In particular, two adjacent connectors must have different degrees, and the key of the one with higher degree contains (strictly) the key of the other. Figure 2.6 shows an example of a consistent and a nonconsistent interface decomposition. In case (a) the connector $C_{1,2}$ is adjacent to $C_{1,2,3}$ and yet neither of the keys $\{1, 2\}$ and $\{1, 3, 4\}$ is included in the other. Similarly, $C_{2,3}$ is adjacent to $C_{1,3,4}$, yet $\{2, 3\} \not\subseteq \{1, 3, 4\}$ and $\{1, 3, 4\} \not\subseteq \{2, 3\}$. Modifying the key of a connector is equivalent to modifying the overlap between subdomains. Thus, the dashed line in Figure 2.6 shows the boundary of subdomain 2 (overlap included). Note that subdomain k is the union of all connectors whose key contains the index k. In case (a) the connector $C_{1,3,4}$ is not a part of subdomain 2, whereas in case (b) the modified connector $C_{1,2,3,4}$ becomes a part of subdomain (2) as shown. The modification consisted of adding label (2) to the key of the connector $C_{1,3,4}$.

An interface decomposition which satisfies the consistency requirement obeys two important properties which can be helpful in a parallel block ILU factorization.

LEMMA 2.1. *In a consistent interface decomposition, two connectors of the same degree cannot be adjacent.*

The proof of Lemma 2.1 was essentially stated above, namely, two adjacent connectors have different degrees.

This property allows an independent elimination of all connectors of the same degree in a block ILU(0) factorization. Assume that a Gaussian elimination process is undertaken whereby the unknowns are ordered by blocks corresponding to the connector partition of the graph. The connectors, i.e., the blocks of unknowns, are ordered by increasing degree. Recall that in an ILU factorization based on the level-of-fill [14] there exists a fill-in entry of level k if and only if there exists a fill-path of length $k + 1$ in the adjacency graph of the matrix. A fill-path is a path between

The cases a) and b) show all possible fill-paths of length ≤ 3 in the connector quotient graph. In these cases, the connectors in the fill path belong to at least a domain listed in the "minimum" connector key (the intersection of all keys of the connectors) of the path.
Thus, in case a) we have $Key(C_2) \subsetneq Key(C_1)$ and $Key(C_2) \subsetneq Key(C_3)$. In this situation $Key(C_1) \bigcap Key(C_2) \bigcap Key(C_3) = Key(C_2)$. In the case b), we also have $Key(C_1) \bigcap Key(C_2) \bigcap Key(C_3) \bigcap Key(C_4) = Key(C_3)$. This is true for the scenarios at the left and right of the case figure.
Case c) illustrates the fact that for a longer path we cannot say anything since $\bigcap_{i=1}^{5} Key(C_i) = Key(C_2) \bigcap Key(C_4)$, which may be empty. This is a situation where there is no common intersection (minimum) to all connectors: there are two local minima.

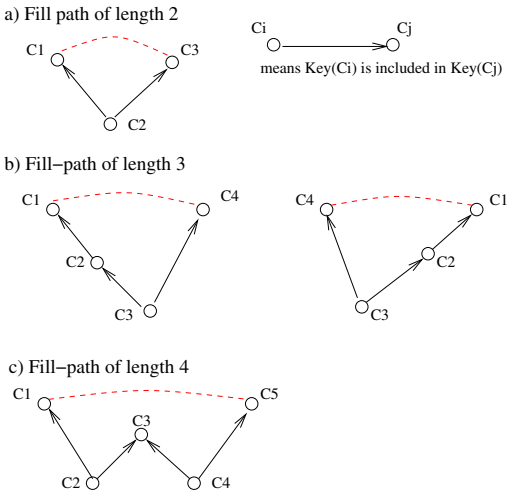

FIG. 2.7. *Proof of Lemma* 2.2.

two vertices v_i and v_j such that all intermediate vertices in the path have a lower label than those of v_i and v_j. Consider now a *block* ILU(k) factorization in which the blocks correspond to a partitioning of the unknown according to the interface decomposition. In the block factorization, fill-in is allowed in a given block by just using the level-of-fill pattern obtained from the quotient graph corresponding to the connectors. In this situation, blocks that are initially zero in the matrix A, and where fill-in will occur in the block ILU(k) factorization, correspond to fill-paths of length $\leq k+1$ in this quotient graph, which we call the connector graph. Note that in this graph, an edge between two connectors represents the adjacency between these connectors. A fill-path of length k is then a path of connectors $C_1, \ldots, C_k$ in the connector graph $\mathcal{C}$ such that

$$\forall i,\ 1 < i < k,\ deg(C_i) < deg(C_1)\ \ and\ \ deg(C_i) < deg(C_k)$$

since all connectors are numbered by ascending degree.

LEMMA 2.2. *Consider the connector graph $\mathcal{C}$ associated with a consistent interface decomposition. Then for a fill-path of length ≤ 3 there is always at least one domain number that is listed in all the keys of the connectors of the path.*

The proof is given in Figure 2.7 with some illustrative examples. A corollary of Lemma 2.2 is that the fill-in induced by a block ILU(k) factorization with $k \leq 2$ of a matrix reordered and partitioned using a consistent interface decomposition is always contained in the local matrix of a subdomain. Section 3 will reconsider this in detail.

2.2. Algorithms for obtaining consistent decompositions. In the remainder of this section, we will discuss first an algorithm for obtaining a consistent decomposition of the interface into connectors. Then an algorithm to obtain levels of independent connectors will be discussed.

Figure 2.5(a) shows that level-2 connectors defined directly from the domain degree $|Key(u)|$ may be adjacent. One possible remedy in this case is to define $Key(u)$

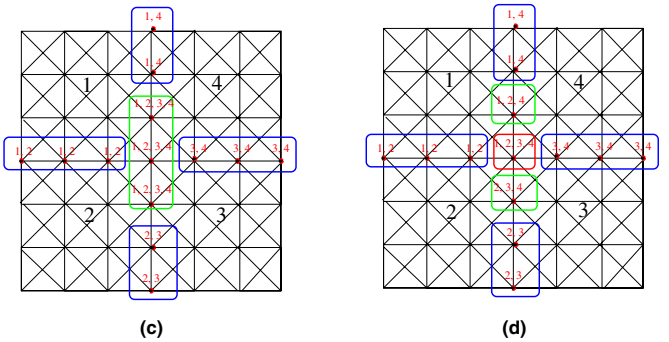

FIG. 2.8. *Two additional possible solutions to get independent connectors in each level by modifying some vertex keys.*

differently. For example, we could define $Key(u)$ as containing the list of all the domains of each member of $adj(u)$, i.e., the set of all subdomains of the nearest neighbors of u. This fixes the problem but leads to interfaces that are unnecessarily "thick" in some cases. Thus, in the example of the 9-point matrix of Figure 2.5(a), the domain interfaces will be 3 lines wide instead of just 1 line wide. In this case, there is a remedy, which is to define $Key(u)$ in this manner only for noninterior nodes. This will give the solution shown in Figure 2.5(b). A more general solution to get a consistent connector set is to start with a connector decomposition based on the initial overlap given by the partition and then refine it by *modifying, in a certain way, the keys* $Key(u)$ *of some overlapped nodes at the interface of the subdomains.* Thus, the solution in Figure 2.5(b) consists of modifying 4 keys in the manner just described. Figure 2.8 shows two additional solutions to get independent connectors in a level, based on modifying keys.

Several possibilities arise in redefining keys to comply with the requirements of a hierarchical interface decomposition, and some solutions appear to be better than others. In Figure 2.8 the solution (c) produces 3 levels (including the first level of interior node) in the overlap of the interface, whereas solution (d) produces 4 levels. In Figure 2.5(b) 4 keys are modified, resulting in 3 levels (degrees 1, 2, and 4), while in Figure 2.8(c) 2 keys are modified, resulting again in 3 levels, and in Figure 2.8(d) 2 keys are modified, resulting in 4 levels. Note that case (d) is not a consistent connector decomposition (Key $\{3,4\}$ is not included in key $\{1,2,4\}$, but the corresponding connectors are adjacent). This example illustrates the fact that some postprocessings of the keys are more desirable than others.

In the previous examples, we discussed two important criteria to use in an irregular graph to find a good interface partitioning. The first is to limit the number of vertices whose key must be expanded to obtain a consistent connector set. The second is to obtain as small a number of levels as possible. Thus, *the ideal interface decomposition should yield a small number of levels by modifying as few keys as possible.* In the general case, the problem of finding the best hierarchical decomposition of an interface is NP-complete because the problem of finding the minimum vertex set to be modified in order to get independent level connectors is similar to a minimun set cover problem [1]. Therefore, to define the connectors and levels as described before, we use two heuristics. The first algorithm aims at modifying the minimum number of vertex keys to enforce the consistency requirement. The second algorithm aims at building larger level sets in order to minimize the number of levels.

The principle of the first algorithm, Algorithm 2.1, is to "expand" iteratively some vertex keys of the same length, in order to uncouple connectors with the same degree. Note that expanding a vertex key means that this vertex will be overlapping more subdomains than those given by the initial partitioning. In this algorithm we use the following notation:

- p is the number of subdomains;
- L^l is the set of vertices whose keys have a cardinality equal to l (i.e., vertices of domain-degree l);
- $V^l(i)$ is the set of vertices belonging to L^l and adjacent to vertex i;
- $Kdeg_u$ is the number of neighbors in $V^l(u)$ that have a key different from $Key(u)$.

ALGORITHM 2.1. Computation of Independent Connectors.

1. **Initialization:**
2. For each vertex $u \in \mathcal{V}$
3. $Key(u) :=$ list of subdomains containing vertex u.
4. end
5. For each vertex $u \in \mathcal{V}$
6. $Kdeg_u := |\{\ v \in V^l(u)\ /\ Key(v) \neq Key(u)\}|$.
7. end
8. For $l = 1$ to p Do:
9. $L^l = \{u \in \mathcal{V}\ /\ |Key(u)| == l\}$
10. end
11. **Main loop:**
12. For $l = 2$ to p Do:
13. For each vertex $u \in L^l$ do
14. $Key(u) := Key(u) \cup \bigcup_{k=1,\ldots,l-1}(\bigcup_{v \in V^k(u)} Key(v))$
15. end
16. While all vertices in L^l have not been processed
17. Get u the vertex in L^l such that $Kdeg_u$ is maximum.
18. $Key(u) := Key(u) \cup \bigcup_{v \in V^l(u)} Key(v)$
19. $m = |Key(u)|$
20. if $m > l$, then
21. $L^l := L^l \setminus \{u\}$
22. $L^m := L^m \cup \{u\}$
23. For each $v \in V^l(u)$
24. $Kdeg_v := Kdeg_v - 1$
25. end
26. end
27. end
28. end

At the initialization of Algorithm 2.1, the key of each vertex u is set to the list of subdomains that contain vertex u. In the main loop, the keys of each vertex u of degree 2 that is connected to another vertex of degree 2 with a different key are expanded by the union of all the keys from vertices in $V^l(u)$. Then the vertex u is set in a higher degree connector. This is continued iteratively over all the sets of connectors that have the same degree. Lines 13–15 of Algorithm 2.1 ensure the property of consistency (Definition 2.2). In this algorithm, the traversal order of the vertices of same degree is important since two different traversals can give very

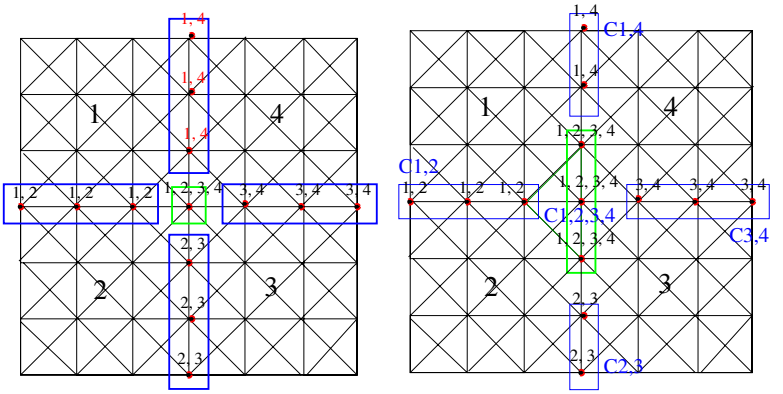

FIG. 2.9. *Partition of a* 9*-point grid into* 4 *subdomains. The connectors and values of the keys are shown at the beginning and at completion of the algorithm.*

different results with a different number of vertices moved to an upper level. This heuristic finds a good traversal of the vertices of the same degree in order to modify as few vertex keys as possible to enforce the consistency condition. The principle is to define $Kdeg(u)$ as the number of neighbors in $V^l(u)$ which have a key different from $Key(u)$ and then choose the next vertex u in the traversal as the one that has the maximum $Kdeg(u)$ (line 17). For this we need to update on the fly the $Kdeg$ of the neighbors when a vertex expands its key (lines 23, 24, 25). An implementation strategy is to sort the vertices by increasing order of $Kdeg$ in a max heap; the cost to obtain the maximum vertex is then constant, and the cost to update the rank of a vertex neighbor is bounded by $O(log(n_i))$, where n_i is the number of vertices in the interfaces. If we denote by d_{max} the maximum degree of a vertex in the interface subgraph, then a pessimistic bound on the complexity of the main loop of Algorithm 2.1 is in $O(n+d_{max}.n_i.log(n_i))$. The initialization requires a loop over all the vertices to decide which ones are on an interface; thus it has a linear complexity with respect to the total number of vertices.

At the end of the algorithm, the key of a vertex u indicates the connector with which it has been associated, i.e., $C_{i_1,\ldots,i_m} = \{u \in \mathcal{V} \mid Key(u) = \{i_1,\ldots,i_m\}\}$. Figure 2.9 illustrates the results of this algorithm on the 9-point grid example.

2.3. The levelization algorithm. We have seen earlier that defining the level label of a connector as equal to its degree may yield a poor interface decomposition because an irregular domain partition may produce a large number of levels. A better definition of the levels from the keys is required to alleviate this problem. This definition requires an order relation $\overset{c}{>}$ for pairs of adjacent connectors.

DEFINITION 2.3. *For two adjacent connectors* C_1 *and* C_2*,*

$$C_1 \overset{c}{>} C_2 \quad \longleftrightarrow \quad Key(C_2) \subsetneq Key(C_1).$$

Note that for consistent decompositions, two adjacent connectors are always comparable with the relation $\overset{c}{>}$. The idea of the level computation algorithm is to compute iteratively the level as the set of local minimum for $\overset{c}{>}$ in the set of all unleveled connectors.

On irregular graphs, the connector decomposition can produce connectors that are of no benefit to the main goal of separating the graph into levels of independent

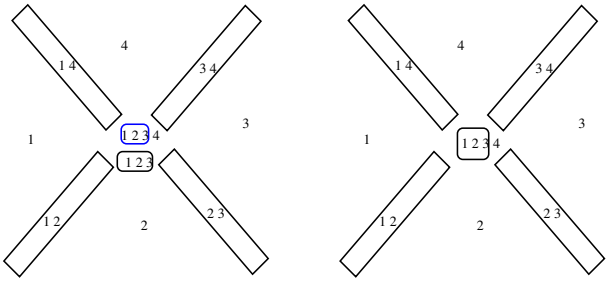

FIG. 2.10. *On the left, connector $C_{1,2,3,4}$ is singular. On the right, the singular connector has been merged.*

sets. For example, Figure 2.10 shows a decomposition which produces two connectors $C_{1,2,3}$ and $C_{1,2,3,4}$ which should clearly be merged into one. Indeed, it is meaningless to differentiate between these two connectors because connector $C_{1,2,3,4}$ does not separate two connectors of the level immediately above it. A connector such as $C_{1,2,3,4}$ in Figure 2.10 will be termed a *singular connector*. A singular connector is always merged with a connector of a level immediately below it. The merge operation takes place just after a new level has been computed. The principle, described in Algorithm 2.3, is to merge any neighbor of the current level connectors such that the new merged connector is still a local minimum for $\overset{c}{>}$ in the set of all unleveled connectors.

In Algorithms 2.2 and 2.3, $\mathcal{C}_{unleveled.}$ is the set of all unleveled connectors, and $\mathcal{C}^i$ is the set of level-i connectors.

ALGORITHM 2.2. Level Computation Algorithm.

1. $i := 0$;
2. While $\mathcal{C}_{unleveled.} \neq \emptyset$
3. $\quad i := i + 1$
4. $\quad \mathcal{C}^i :=$ the set of all minimum connectors in $\mathcal{C}_{unleveled.}$ for $\overset{c}{>}$.
5. $\quad \mathcal{C}_{unleveled.} := \mathcal{C}_{unleveled.} \setminus \mathcal{C}^i$
6. $\quad$ Merge all the singular connectors for level i.
7. end

ALGORITHM 2.3. Merge singular connectors for level i.

1. For each connector $C \in \mathcal{C}^i$ Do:
2. $\quad$ For each connector $V \in \mathcal{V}(C) \bigcap \mathcal{C}_{unleveled.}$
3. $\quad\quad$ if $C \cup V$ is a minimum for $\overset{c}{>}$ in $\mathcal{C}_{unleveled.} \cup \mathcal{C}^i$, then
4. $\quad\quad\quad C = C \cup V$
5. $\quad\quad\quad Key(C) = Key(C) \cup Key(V)$
6. $\quad\quad\quad \mathcal{C}_{unleveled.} = \mathcal{C}_{unleveled.} \setminus V$
7. $\quad\quad$ End
8. $\quad$ End
9. End

One can notice that Algorithm 2.2 will always produce a number of levels that is less than or equal to the number of different degrees in the connector set. If we denote by D_{max} the maximum degree of a connector in the connector graph, by l the number of levels, and by c the number of connectors, then a pessimistic bound of the complexity is in $O(l.c.D_{max})$.

3. Parallel incomplete factorizations based on hierarchical interface decompositions. The previous section defined what we termed a "hierarchical interface decomposition" related to a partitioning of the graph $\mathcal{G}$. This hierarchical interface decomposition consists of several levels of connectors which have the property of forming an independent set at each level. If the global matrix is (implicitly) reordered by level, starting with the nodes of level 1, followed by those of level 2, and so on, the independent sets will lead naturally to parallel ILU-type factorizations if careful dropping is used. This technique bears some similarity to the ARMS discussed in [16, 9] with a major difference being that in ARMS the independent sets are determined dynamically, whereas in the new algorithm, the ordering is set in advance. In addition, dropping is especially adapted to the partitioning, as is explained in the next section.

3.1. Consistent dropping strategies. The interface decomposition and the keys associated with each node will be intimately related to the ILU factorization process. In particular, this decomposition and the keys will help define a suitable fill-pattern. The goal is to retain as much parallelism as possible in the ILU factorization.

The first principle of the elimination is to proceed by levels: Nodes in the connectors of level 0 are eliminated first, followed by those in connectors of level 1, etc. All nodes of the zeroth level can be eliminated independently since there is no fill-in between nodes i and j of two different connectors of level 0 (interior of the subdomain). In contrast, fill-ins may appear between connectors from level 1 down to the last level of the interface connectors. These fill-ins will cause some uncoupled connectors to become coupled, and so they will no longer form an independent set. This will result in reduced parallelism.

Recall that in the standard static ILU factorization a nonzero pattern is selected in advance based on the sparsity pattern of A. For example, the nonzero pattern for the ILU(0) factorization is simply the set of all pairs (i, j) such that $a_{ij} \neq 0$; i.e., it is equal to the nonzero pattern of the original matrix. For details and extensions, see a standard text on iterative methods, e.g., [14, 2]. As was mentioned above, certain nonzero patterns will allow more parallelism than others during the factorization. Certain choices of nonzero patterns may also lead to simpler implementations.

We consider two possible options. The first is not to allow any fill-ins between two uncoupled connectors of the same level. In this fashion, the elimination of all connectors at a certain level can always proceed in parallel. The second option, which is less restrictive, is to allow fill-ins but to restrict them to occur only when i, j are associated to a common subdomain. In this case, elimination should be done in a certain order, and parallel execution can be maintained by exploiting independent sets. Figure 3.2 draws the block structure of the global matrix reordered according to the hierarchical interface decomposition (HID) of the domain illustrated in Figure 3.1. Figure 3.2 illustrates the two dropping strategies.

3.2. Strictly consistent nonzero patterns. A nonzero pattern P is said to be strictly consistent with the HID if it does not allow any fill-in between any two connectors of the same level. This implies that an entry (i, j) will be in the nonzero pattern P only if vertices i and j belong to two adjacent connectors. In regard to the consistency requirement, this means that

$$P \subset \{(i,j) \mid Key(i) \subset Key(j) \text{ or } Key(i) \subset Key(j)\} .$$

In a block representation of the matrix, where blocking is done according to the levels, this means that this approach would discard all fill-ins between blocks, thus preserving

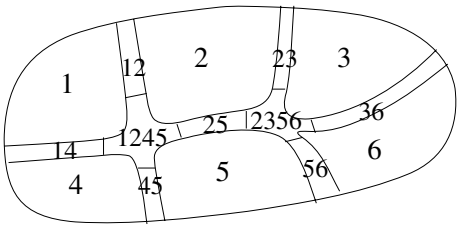

FIG. 3.1. *Domain partition into* 6 *subdomains. Connectors and their keys are represented.*

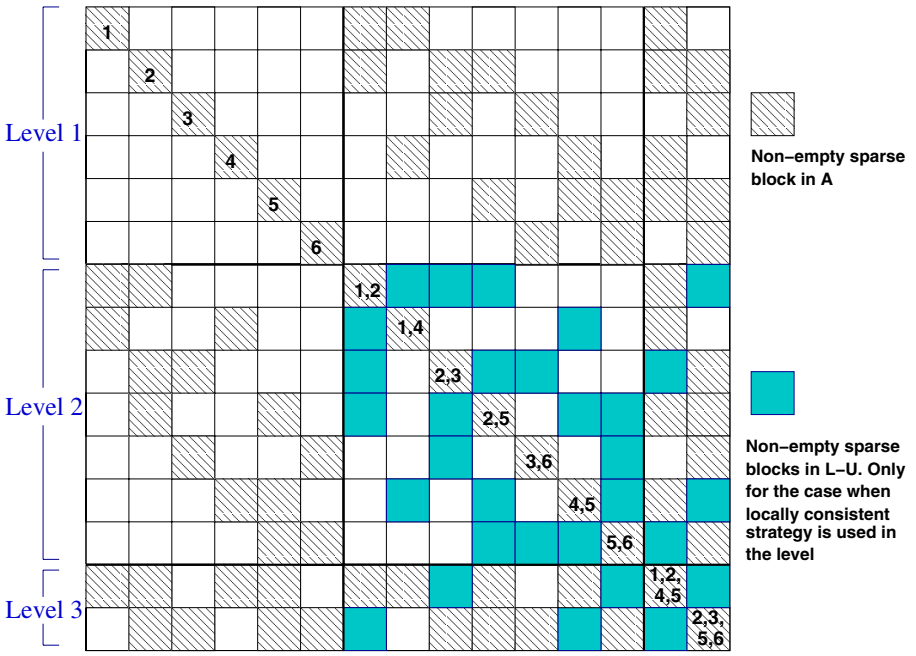

FIG. 3.2. *Block decomposition of the matrix according to the HID reordering. For convenience, all blocks have been drawn at the same size; using a real scale, the blocks become significantly smaller in the high levels.*

the initial global block structure. A typical way to define strictly consistent nonzero patterns is to take a common dropping strategy and restrict the dropping further by imposing the above rule.

An important consequence of the restriction embodied in the above definition is that all connectors of the same level will form an independent set throughout the elimination process. Indeed, any fill-in in the diagonal block submatrices (corresponding to connectors that have the same level label) is discarded, and thus the diagonal block structure is kept. In particular all eliminations will proceed in parallel at all stages. There remains only to consider how to handle the rows resulting from the elimination in different processors when these rows share two or more subdomains. Since these nodes are represented in more than one subdomain, they will undergo different modifications in each subdomain because the elimination performed in each subdomain is incomplete. In order to complete the process, we have two options. If i is the vertex index, we can have each processor in $Key(i)$ perform the same operations.

Communication is required locally so that all processors will get the modifying rows. The second option is to select one processor in $Key(i)$ to perform all modifications. Once the modifications are completed, this processor will then send the final row to its neighbors. In the algorithms to be described later, this option is retained.

3.3. Locally consistent nonzero pattern. This type of nonzero pattern is less restrictive and allows *fill-ins* only between connectors belonging to the same subdomain. In other words, a fill-in is allowed in location (i, j) if $Key(i) \cap Key(j) \neq \emptyset$, as stated in the following definition.

DEFINITION 3.1. *The nonzero pattern P is said to be locally consistent with the hierarchical interface decomposition if*

$$P \subset \{(i, j) \mid Key(i) \cap Key(j) \neq \emptyset\} .$$

Thus, an entry in location (i, j) of L or U is permitted only if $Key(i)$ and $Key(j)$ have at least one common index, i.e., only when i and j share one common subdomain. This permits an easy characterization of fill-ins based on the interface decomposition. Again, one can select a fill-in pattern such as ILU(k) or a dynamic one such as ILU with threshold (ILUT)—with an additional constraint that no fill-in is allowed in locations not satisfying the compatibility property defined above. For the special case of ILU(k) with $k \leq 2$, it is interesting to note that no additional dropping would be exercised for the locally consistent dropping pattern for any number of domains. This property is a direct consequence of Lemma 2.2, since a scalar ILU(k) nonzero pattern is always contained in the block ILU(k) nonzero pattern.

In this situation, elimination can proceed simultaneously for nodes of two connectors of the same level whose keys are disjoint. As mentioned above, Gaussian elimination will eliminate the unknowns of the connectors level by level. A good way to exploit parallelism is to partition the set of connectors in the level into maximum weighted independents sets. Here, the independent sets are for a graph whose vertices are connectors (identified by a key K) and whose edges represent the binary relation $Key_1 \cap Key_2 \neq \emptyset$.

DEFINITION 3.2. *A set of connectors is "independent" if any two connectors of the set have disjoint keys. Such a set is "maximal" if it cannot be augmented by other connectors.*

Note that a maximal independent set is not one which has a maximum cardinality among all possible independent sets. The term "block independent sets" or "group independent sets" was used in [16, 9] for sets of subsets of vertices which are uncoupled. The idea of using independent sets of nodes (or subsets of nodes) in parallel Gaussian elimination is not new. Multicoloring was employed, for example, to define parallel ILU factorizations [7, 14]. Essentially, a global order—called "schedule" in [7]—in which to process the connectors is required. This global order can be defined by processing all those connectors which will not be coupled by any fill-in.

Figure 3.3 illustrates the elimination order that can be obtained in our incomplete factorization when a locally consistent strategy is used in all levels, on a simple example. With a strictly consistent strategy there is no need to find any special elimination connector ordering in a level since connectors can be eliminated independently.

3.4. Ordering of the unknowns inside the connector subsets. In addition to the global ordering of the connectors, a local ordering can be applied within each connector. In our codes, we apply a reordering of the interior domain unknowns (i.e., nodes within each level-1 connector are reordered) to minimize fill-in for direct

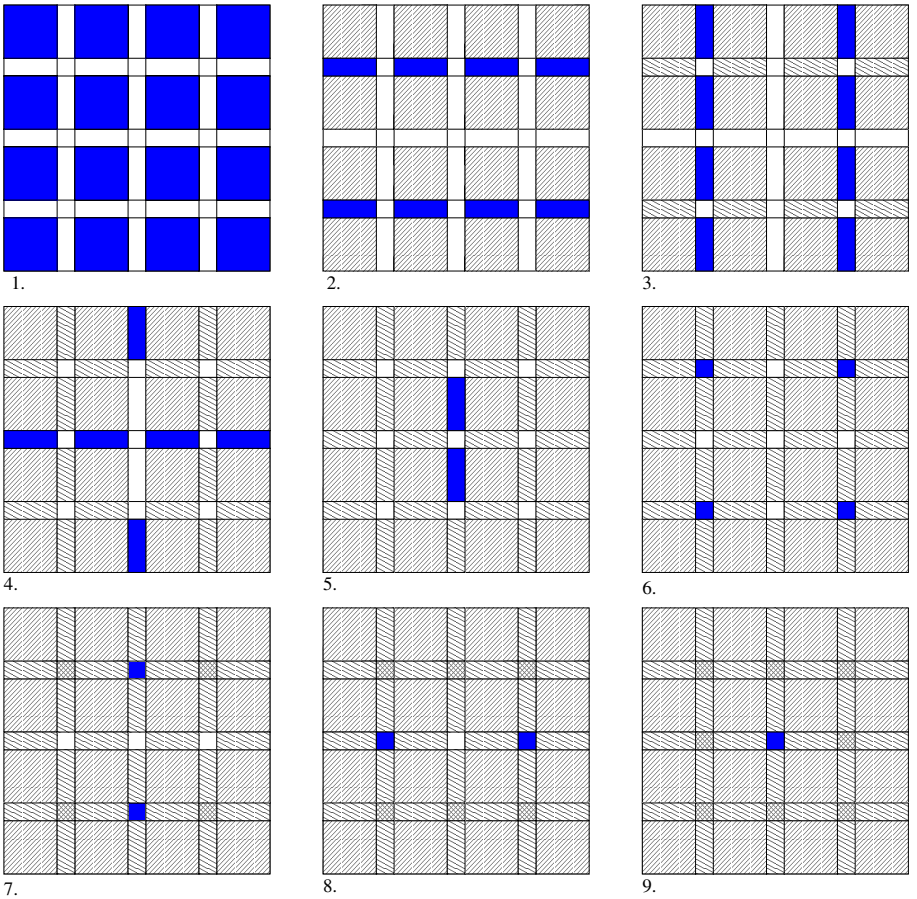

FIG. 3.3. *Elimination of the connectors. The dense connectors are the maximum independent set selected for elimination. The dashed connectors are those already eliminated.*

factorization. Such reorderings are provided by METIS. No special reordering is applied to the higher-level connectors.

3.5. Interpretation and generalizations. An interesting observation regarding the consistent dropping strategies just defined is that they can be viewed from the angle of quotient graphs. Define the quotient graph of connectors as a graph whose vertices represent the connectors and the edges the adjacency relationship between them. The dropping strategy can be viewed as a 2-level strategy which considers dropping within each connector independently from the dropping strategy between connectors. The former uses the original graph, whereas the latter uses both the original graph and the connector graph.

In particular, notice that because the partitioning considered is edge-based (i.e., an edge never straddles two different subdomains), an edge in the connector graph between two connectors C_1 and C_2 implies that the two connectors are in the same subdomain. Consider now a zero fill strategy *on the connector graph*. In this strategy no edge will be created during the elimination process. Of course the ordering of the connector graph is consistent with that of the reordered matrix. An illustration is shown in Figure 3.4. In the case of strictly consistent dropping strategy, the block fill-

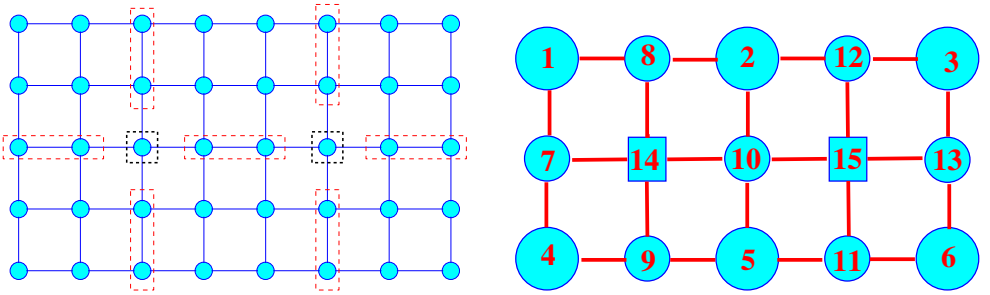

FIG. 3.4. *Hierarchical decomposition and corresponding quotient graph. Large circles show level-*1 *sets, small circles level-*2 *sets, and squares level-*3 *sets.*

in pattern is the same as that implied by an ILU(0) pattern on the connector quotient graph. Fill-in is obviously allowed within each connector. Because connectors that are adjacent in the quotient graph belong to the same domain, the second strategy defined earlier corresponds to allowing fill-ins of level ≤ 2 in the quotient graph (see Lemma 2.2). Generalizations can now be made. On can imagine applying a block ILU(k) with $k > 2$ on the connector quotient graph in the same way that this is defined in ILU(k) factorizations. Of course such dropping rules will entail more communication and a more complicated processing; for instance, fill-ins may appear between connectors which do not share a common subdomain.

4. Parallel factorization. The partition of the unknowns into connectors induces a block structure of the matrix which enables an easy expression of the parallel algorithm. Figure 4.1 shows one such structure. The figure zooms in on the block matrix associated with subdomain 2. The diagonal blocks correspond to all the connectors which are part of domain 2, and the off-diagonal blocks correspond to the coupling between these connectors. If each subdomain k is assigned to processor k, then the label on each block is a list of all the processors which own a copy of the block. For example, the subblock in position (4,6) of the block matrix is labeled with 2 and 5, and therefore it is located in both processors 2 and 5. The label of a diagonal block is the key of the corresponding connector as defined previously. The label of an off-diagonal block (i, j) in the local block matrix is the intersection of the labels of the blocks (i, i) and (j, j). For convenience, in the rest of this paper we will denote by $Key(i, j)$ the label of the block (i, j). Therefore, using previous notation,

$$Key(i, j) = Key(i) \cap Key(j).$$

The parallel factorization algorithm is given below (Algorithm 4.1). The following symbols are used in the algorithm.

- E represents the local matrix associated with processor p.
- C represents a local matrix where a block $C_{i,j}$ is a temporary location to add up all the updates to the block $E_{i,j}$. This matrix is empty at the start of the algorithm.
- `leader`$(p_1, \ldots, p_m)$ is a function which selects a processor from a processor subset (see below for details).
- P is the nonzero block pattern of the matrix.

The function "leader" is used to choose a unique processor to process a block matrix operation when several choices of processor are possible. In other words, this function

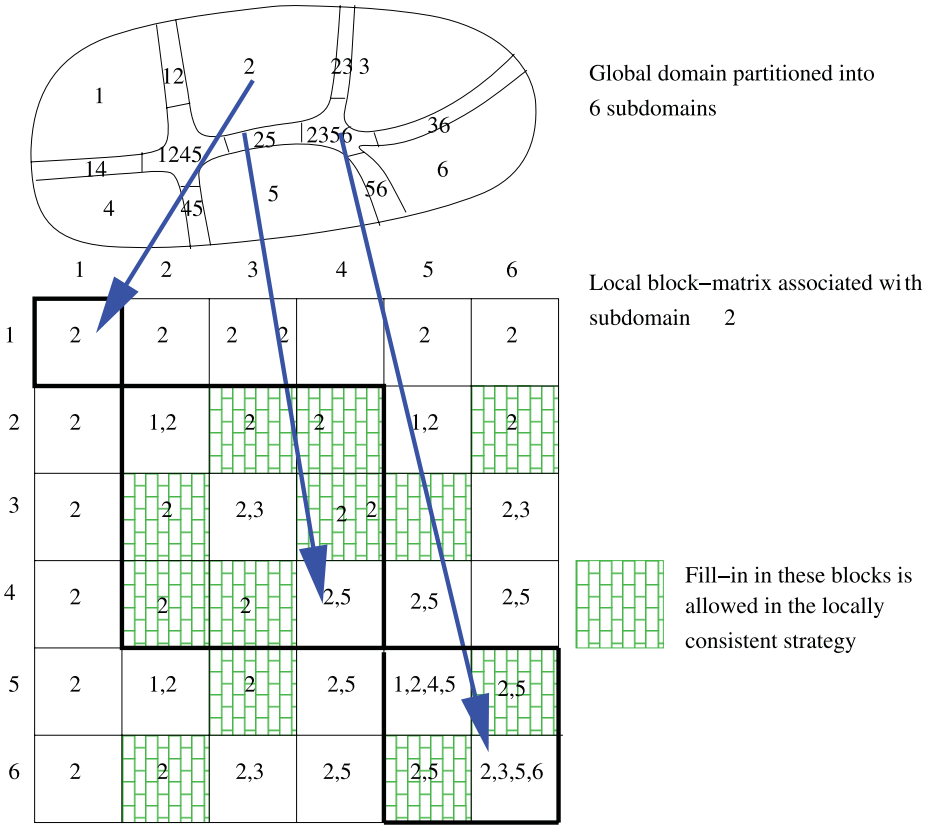

FIG. 4.1. *Block partition of a local matrix.*

is used to balance the workload and storage related to blocks overlapped by several local matrices on different processors.

Note that because of the ordering into levels, there is no explicit distinction between the levels in the algorithm. This distinction is inherent to the algorithm and is implicitly defined by the keys.

ALGORITHM 4.1. Parallel Elimination Algorithm.

0. Let N = block dimension of local matrix, and p = label of this processor.
1. For $i := 1$ to N
2. If $p = \text{leader}(Key(i,i)$
3. Receive and add in $E_{i,i}$ all $C_{i,i}$ from processors $\in Key(i,i)$
4. Factorize $E_{i,i}$ into $L_i.U_i$
5. Send $\{L_i, U_i\}$ to processors $\in Key(i,i) \setminus p$
6. Else
7. Receive L_i, U_i from leader$(Key(i,j))$
8. EndIf
9. For $j := i+1$ to N, such that $(i,j) \in P$ and $p = \text{leader}(Key(i,j))$
10. Receive and add in $E_{i,j}, E_{j,i}$ all $C_{i,j}, C_{j,i}$ from processors $\in Key(i,j)$
11. $E_{i,j} := L_i^{-1}.E_{i,j}$
12. $E_{j,i} := E_{j,i}.U_i^{-1}$
13. Send $\{E_{i,j}, E_{j,i}\}$ to processors $\in Key(i,j) \setminus p$

```
14.       EndFor
15.       For j := i + 1 to N, such that (i, j) ∈ P and p ≠ leader(Key(i, j))
16.            Receive {E_{i,j}, E_{j,i}} from leader(Key(i, j))
17.       EndFor
18.       For j := i + 1 to N, such that (j, i) ∈ P
19.            For k := j to N, such that (i, k) ∈ P
20.                 If p = leader(Key(j, i) ∩ Key(i, k))
21.                      C_{j,k} = C_{j,k} − E_{j,i}.E_{i,k}
22.                      If j ≠ k
23.                           C_{k,j} = C_{k,j} − E_{k,i}.E_{i,j}
24.                      EndIf
25.                      If all local contributions have been added up in C_{j,k}
26.                           Send {C_{j,k}, C_{k,j}} to processors ∈ Key(j, k)\p
27.                      EndIf
28.                 EndIf
29.            EndFor
30.       EndFor
31.  EndFor
```

A few additional details on the implementation will now be given. First, it is important to note that the forward and backward solves are also parallel at each level. The outer (level) loop is sequential. This is due to the structure of the diagonal blocks associated with the levels. Second, no pivoting is performed, but the standard forms of pivoting in the context of LU can be applied. For example, "static pivoting" can be performed whereby diagonal entries are increased in an attempt to prevent the need for pivoting. Alternatively, we can also perform local block pivoting whereby the pivot row is confined to stay within the dense block.

5. The preconditioning operation. The solution process consists in using the incomplete factorization as a right preconditioner combined with an iterative accelerator such as GMRES. The current version of PHIDAL includes two ways of using the incomplete factorization. If we partition the matrix A according to an ordering associated with listing interior points first, followed by interface points, then we can define a block incomplete LU factorization as follows:

$$A = \begin{pmatrix} B & F \\ E & C \end{pmatrix} \approx \begin{pmatrix} L & \\ EU^{-1} & L_S \end{pmatrix} \times \begin{pmatrix} U & L^{-1}F \\ & U_S \end{pmatrix} \equiv M.$$

Here we assume that $B \approx LU$ is an incomplete factorization of B and that $L_S U_S$ is some incomplete factorization of an approximation to the Schur complement matrix $S = C - (EU^{-1})(L^{-1}F)$. In practice, with the above factorization we need only store the factors L, U, L_S, U_S and the original blocks E, F. Given a right-hand side $y = \left(\begin{smallmatrix} y_B \\ y_C \end{smallmatrix}\right)$, the solution $x = \left(\begin{smallmatrix} x_B \\ x_C \end{smallmatrix}\right)$ to the system $Mx = y$ can be computed as follows:

$$\begin{cases} x_C = U_S^{-1} L_S^{-1} (y_C - EU^{-1} L^{-1} y_B), \\ x_B = U^{-1}(L^{-1} y_B - L^{-1} F x_C). \end{cases} \tag{5.1}$$

An alternative is to explicitly compute and store some approximations G and W to the matrices $L^{-1}F$ and EU^{-1}, respectively. In this case the solution can be obtained from

$$\begin{cases} x_C = U_S^{-1} L_S^{-1} (y_C - WL^{-1} y_B), \\ x_B = U^{-1}(L^{-1} y_B - G x_C). \end{cases} \tag{5.2}$$

We refer to this as the M_{GW} preconditioner. One advantage of using the first variant (without the approximations G, W) is that it does not require us to store the submatrices G and W. These matrices are actually available during the factorization process as they are needed to obtain S; thus no additional computation is incurred in this approach. In this version the G, W matrices are discarded after they are used and no longer needed. Another advantage is that this approach will tend to be more accurate than one which uses the approximations G, W. Therefore, the preconditioner M is usually more efficient than M_{GW}. On the other hand, the use of the G, W approximation will be slightly more expensive in general. Indeed, the number of floating point operations required to apply the preconditioner M is

$$ope_M \approx 2\,(\mathrm{nnz}(L) + \mathrm{nnz}(U)) + \mathrm{nnz}(L_S) + \mathrm{nnz}(U_S) + \mathrm{nnz}(E) + \mathrm{nnz}(F).$$

In contrast, applying the preconditioner M_{GW}, which uses the G, W approximations, costs roughly

$$ope_{M_{GW}} \approx \mathrm{nnz}(L) + \mathrm{nnz}(U) + \mathrm{nnz}(L_S) + \mathrm{nnz}(U_S) + \mathrm{nnz}(G) + \mathrm{nnz}(W).$$

In the situation when the B block is large, the M preconditioner will cost more to apply in general, depending on the sparseness of the matrices W, G. Note that similar choices and issues were also discussed in the context of the ARMS preconditioner [16]. In the numerical tests presented in the next section, the option $KeepGW = 0$ refers to the preconditioner M, and $KeepGW = 1$ refers to the preconditioner M_{GW}.

6. Numerical tests. Algorithm 4.1 allows many possible variations depending on, for example, the version of ILU that is used, whether consistent or strictly consistent dropping is applied, and the selection of the various threshold parameters for dropping small terms. The current version of PHIDAL is based on an ILUT factorization (a numerical threshold is used to drop small entries). One can use two threshold parameters in the ILUT factorization: $thresh_L$ and $thresh_U$ corresponding to the damping criterion for the lower triangular part and the upper triangular part of the matrix. In all our tests we set the same numerical threshold $thresh$ for L and U. The accelerator was GMRES with a restart parameter of 60. In section 5, we mentioned two variants for using the incomplete factorization as a preconditioner ($KeepGW = 1$ and $KeepGW = 0$). In all the tables the fill ratio is defined as the number of nonzeros stored in the preconditioner divided by the number of nonzeros in the original coefficient matrix A. Thus, the fill ratio is smaller with the option $KeepGW = 0$ than with $KeepGW = 1$.

The preconditioning strategies used in the following tests utilize a combination of strictly and locally consistent dropping. Indeed, it appears appealing to use locally consistent strategies in the first few levels only and the less accurate and costly strictly consistent strategy at other levels. In the experiments, the number "locally consistent levels" refers to the number of the first few levels (in the interface) in which dropping is performed in a locally consistent way. Strictly consistent dropping is performed thereafter.

We used the graph partitioner METIS to get the initial domain partition and to reorder the interior domain unknowns in order to reduce fill-in. Similar results can be obtained by other graph partitioners and reordering algorithms to minimize fill-in.

6.1. Discretized 3-dimensional Poisson equation. The problem solved is the elliptic partial equation $-\Delta.u = f$ on a square region with Dirichlet boundary conditions discretized with a seven-point centered finite difference scheme on an $n_x \times$

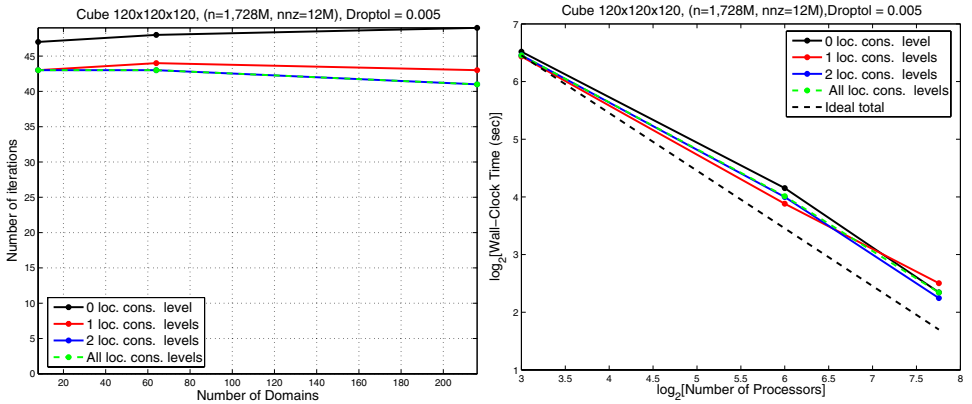

FIG. 6.1. *Performance of GMRES accelerated with PHIDAL for a* $120 \times 120 \times 120$ *Poisson equation as the number of processors varies.*

$n_y \times n_z$ (3-dimensional) grid, excluding boundary points. The mesh is mapped to a virtual 3-dimensional grid of $p_x \times p_y \times p_z$ processors. Therefore, subcubes of $r_x = n_x/p_x$, $r_y = n_y/p_y$, and $r_z = n_z/p_z$ points are mapped into each processor in the x, y, and z directions, respectively.

The numerical dropping thresholds in the factorization were set to 0.005. With this drop tolerance the fill factor, i.e., the ratio of the memory required by the factorization over that for the original matrix, was about 5. The relative residual precision of the solution is 10^{-7}. The machine used to run the tests was the IBM SP3 (named seaborg) of the NERSC, a computer equipped with NightHawks nodes clocked at 375Mhz. Each node has 16 processors which share a common pool of between 16 and 64 GB of shared memory.

In this case, the decomposition in the interface is naturally defined by the partition (see Figure 2.1 in section 2). The left part of Figure 6.1 suggests that the number of iterations required for convergence is almost independent of the number of subdomains. The various cases shown correspond to the number of levels in the interface on which locally consistent dropping is performed. In the case of a cube there are 4 levels of connectors (interior domain points, faces, edges, and cross points), and we can choose a locally consistent strategy for only three connector levels in the interface (faces, edges, and cross points). Thus the curves for *all locally consistent levels* correspond to the case of 3 *locally consistent levels*. The right curves show that the time to precondition and solve the problem scales very well with the number of processors; this shows that for this model problem and for a good initial partition of the graph the parallel factorization and the triangular solves are almost perfectly scalable in time.

We also ran an isoscalability test on the same problem, where each processor was assigned a subdomain of size $40 \times 40 \times 40$. This means, for example, that on a virtual $3 \times 3 \times 3$ processor grid, the whole discretized problem is a $120 \times 120 \times 120$ mesh ($n \approx 1.7 * 10^6, nnz \approx 12 * 10^6$). Similarly, on a virtual $6 \times 6 \times 6$ processor grid the discretized problem corresponds to a $240 \times 240 \times 240$ mesh ($n = 13.8 * 10^6, nnz = 96.4 * 10^6$). Table 6.1 shows the iteration counts and the execution times for different numbers of processors. The numerical dropping thresholds in the factorization were set to 0.01 for these tests; with this threshold the fill rate in the factors was about 4.

TABLE 6.1
Scaled performance experiment: 3-dimensional grids $40\times40\times40$ *per processor, locally consistent strategy in all levels, numerical threshold set to* 0.01*, and* $KeepGW = 1$.

$p_x \times p_y \times p_z$	Facto time in sec	Solve time in sec	Iter nbr	Fill ratio
3x3x3	6.10	28.85	52	3.98
4x4x4	6.58	42.05	63	3.98
5x5x5	6.80	57.60	78	3.99
6x6x6	6.81	66.53	84	3.99

These results were obtained with preconditioner M_{GW} (option $KeepGW = 1$).

6.2. Tests on a magnetohydrodynamic problem. The matrices used in the following tests arise from a magnetohydrodynamic flow problem that couples Maxwell's equation

$$\frac{\partial \mathbf{B}}{\partial t} - \nabla \times (\mathbf{u} \times \mathbf{B}) + \eta \, \nabla \times (\nabla \times \mathbf{B}) + \nabla \mathbf{q} = 0,$$
$$\nabla \cdot \mathbf{B} = 0,$$

with the Navier–Stokes equation. Coupling is through the body force $\mathbf{f} = \frac{1}{\mu}(\nabla \times \mathbf{B}) \times \mathbf{B}$. In the following test, u is imposed, and Maxwell's equation is solved for B. The finite element mesh is composed of mixed tetrahedra and hexahedra elements. Two matrices, MHD1 and MHD2, are used. The matrix MHD1 is of size $n = 485,597$ and has $nnz = 24,233,141$ nonzeros. MHD2, which uses a different Reynolds number, is of size $n = 470,596$ and has $nnz = 23,784,208$ nonzero entries. For additional details on this problem, see [15, 19]. The machine used to run these tests was a cluster of IBM power5 SMP nodes, where each node is composed of 16 processors sharing a common pool of 32 GB of memory.

Levelization algorithm. Figure 6.2 shows the algorithm of levelization in action for both MHD1 and MHD2 when the number of processors used is 256. The plots show the various levels obtained with the straightforward use of Algorithm 2.1 and then with the improved strategy based on Algorithm 2.2. For each of these levels the $\log_2$ of the number of nodes at that level is plotted. In the ideal situation we would have a small number of levels or, equivalently, we should obtain very few levels that have a small number of nodes as this hampers parallel execution. As can be seen, this is the case for both matrices. We should point out that for MHD2, the basic algorithm created 4 empty levels, i.e., levels with zero nodes, out of the 23 levels. These are the levels 18, 19, 20, and 22. Also, as expected, the effect of the levelization is not nearly as significant for fewer processors.

Table 6.2 gives the times (in seconds) to perform the hierarchical interface decomposition ordering for different numbers of domains on the MHD1 matrix. The first line indicates the percentage of nodes in the interface from the total number of nodes for the domain decomposition given in input. The second line gives the number of levels obtained before and after the levelization algorithm. The last line gives the time needed to perform the hierarchical interface decomposition ordering: It includes the times of Algorithm 2.1 (independent connector computation) and the times of Algorithms 2.2 and 2.3 (levelization algorithms).

We omit the details on the various times spent in each of these algorithms (we report only the total) because Algorithms 2.2 and 2.3 cost very little relative to Algorithm 2.1. The fact that the time of the ordering for 32 domains is slightly

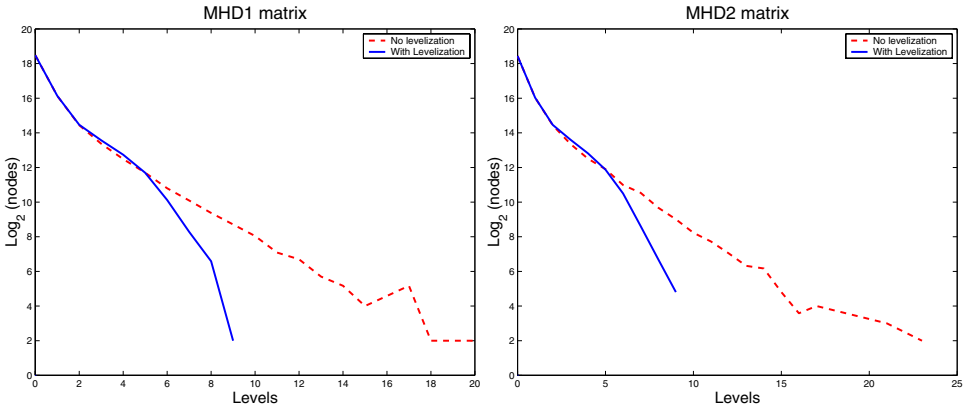

FIG. 6.2. *Effect of the levelization algorithm. The plot shows the* $\log_2$ *of the number of nodes at each level obtained for a* 256 *domain partition. As desired, the levelization results in fewer levels (*9 *instead of* 20*) and, indirectly, in far fewer small-size levels.*

TABLE 6.2

*Hierarchical decomposition for MHD*1 $n = 485597$. *The first line gives the number of domains. The second line gives the percentage of nodes in the interface between domains. The third line gives the number of connector levels obtained before/after the levelization algorithm. The fourth line gives the total time to compute the hierarchical interface decomposition.*

Number of domains	16	32	64	128	256
Nodes in interface	9.1 %	12.3 %	15.4 %	20.1 %	24.4 %
Number of levels	6/5	10/6	11/8	15/9	20/9
Time (sec)	4.97	4.79	5.11	7.01	11.28

smaller than for 16 processors is not significant and is certainly due to the accuracy of the timing.

The ordering time does not vary very much until the number of domains reaches 64. This is explained by the fact that in these cases a major part of the time is spent initializing Algorithm 2.1, consuming a time that is linear in the total number of nodes (interior domain and interface). When the number of domains increases, the number of nodes in the interface grows and the time spent in the main loop of Algorithm 2.1 grows, but the whole ordering time is still acceptable considering that the domain decomposition is usually done only once in a realistic physical simulation.

Effect of the type of dropping. The next experiments will show the effect of the dropping strategy on the quality of the preconditioner. Recall that we can define a strictly consistent scheme whereby no fill-in is allowed between connectors and locally consistent schemes whereby fill-ins are allowed between connectors at a given level when these connectors are located in the same processor. We can also define an arbitrary number of levels that remain strictly consistent. Strictly consistent dropping allows us to save memory but, as can be expected, sacrifices a little on the quality of the preconditioner. Clearly, the first level is always treated as a strictly consistent level. Beyond level 1, our code can decide to process as many levels in "locally" consistent mode as desired. It is important to process the last levels in strictly consistent mode since these will tend to generate a large amount of fill-in. Thus, a parameter is used to define how many levels from the second level down are processed in locally consistent mode. The experiments reported in Tables 6.3–6.6 show the executions obtained for

TABLE 6.3
Left-hand table is for MHD1, and right-hand table is for MHD2. Number of locally consistent levels = 1, thresh = 0.002, KeepGW = 1.

"zero" locally consistent levels (meaning that all levels are treated in strictly consistent mode), one locally consistent level (meaning that the second level is treated in locally consistent mode), and all locally consistent levels. Table 6.3 reports results obtained with the option $KeepGW = 1$ while Tables 6.4–6.6 were obtained with the option $KeepGW = 0$. Table 6.3 is given as a comparison to Table 6.5 to show the effect of the option $KeepGW$. In the following experiments the threshold was always set to 0.002. The restart parameter in GMRES was again 60, and the stopping criterion was a reduction of the residual norm by a factor of 10^{-7}.

The main observation from the experiments is the remarkable behavior of the iteration number for the "all" consistent levels and, to a lesser extent, for the one consistent level case. This iteration number remains about the same. On the other hand, this comes at a higher factorization cost, especially for the "all" locally consistent case.

The compromise of using one locally consistent level seems a good one for this case. Note that this experiment suggests that using one or a few locally consistent levels would improve robustness without sacrificing performance too much.

On these problems, with higher numbers of locally consistent levels, the iteration counts remain small while the overall solution times as well as memory costs are higher. This trend is all the more important when the number of processors increases. It is difficult to set a general rule on the number of locally consistent levels to use, which may vary as a function of the desired precision, the matrix condition number, and the connectivity of the adjacency graph of the matrix. Nevertheless, one locally consistent level should be a good choice in general since the bulk of the unknowns are usually interior points and points of the first level of connectors in the interface, whereas the higher connector levels contain few unknowns but require much more communication and synchronizations between processors when they are treated with a locally consistent strategy.

Comparison with pARMS. We compared the performance of PHIDAL with that of pARMS on the MHD matrices discussed in earlier sections. These comparisons are not easy to set up because pARMS uses different orderings which depend on numerical properties (see [9] for details) in the interior subdomain as well as different rules for dropping small terms in the ILUT factorization. We used a set of parameters which seem to offer an acceptable comparison in terms of fill-in ratio with PHIDAL. Because an iterative solver will usually require fewer iterations and less time if more fill-in is allowed in the preconditioner, an ideal comparison of quality would consist of testing both algorithms under the same (or close) memory requirements. Therefore, the parameters were set to achieve a fill-factor which is close for both methods. While

pARMS allows the option of using an inner iteration for solving the Schur complement system of the interface, this feature is not yet available in PHIDAL. We use 5 inner iterations for pARMS; that is, each time the preconditioner is applied, 5 inner GMRES iterations are invoked to solve the last Schur complement system, which is a much smaller system. Another test which did not use inner iterations showed little difference in performance and is not reported here. It required roughly the same execution times but sightly more outer iterations to converge.

The *thresh* parameter in ILUT was set to 0.002 for PHIDAL and pARMS. pARMS also uses a fill parameter that was set to 50. We used a relative residual tolerance of 10^{-6} for these tests. With this tolerance pARMS gives good results on both MHD1 and MHD2 with these parameters. For a tolerance of 10^{-7} pARMS does not converge in fewer than 200 outer iterations for the MHD1 test case, though some other parameters would have allowed us to solve this problem. The results of PHIDAL are reported for the option $KeepGW = 0$, and all levels are treated in strictly consistent mode.

The slight differences of factorization time in Tables 6.7, 6.8, and 6.4 are due only to the fact that these tests were run a second time for this comparison (the relative residual precision of the solution was different).

The comparison was limited to 64 processors because the pARMS test program which uses METIS as a graph partitioner requires that the whole matrix graph be loaded on one processor. The cluster on which the tests were performed does not offer sufficient memory per processor (when we ask for 128 processors) to run METIS on the whole matrix graph on one processor. Note that this is not a limitation of the pARMS library but a limitation due to the test program (provided in pARMS) which uses METIS as a graph partitioner. It is possible to use PARMETIS to circumvent the problem, but this was not attempted.

Comparing the PHIDAL and pARMS total execution times shows a slight superiority of PHIDAL over pARMS for a small number of processors, but the times become quite close when the number of processors increases. In both cases, the number of iterations is generally lower for PHIDAL than for pARMS.

Since this comparison is for only two sample problems which are of the same type, it is not necessarily representative of a general situation. What can be said is that, overall, the performance is rather comparable for this problem and that more testing is required, specifically with a larger number of processors and larger problems, to reach a conclusion. Such an exhaustive comparison is beyond the scope of this paper.

7. Concluding remarks. We have presented a Schur complement-type preconditioner which is designed to work for general sparse linear systems. The preconditioner is a multistage or multilevel technique which exploits a graph-based interface structure. Experiments show that the method scales quite well for model Laplacean problems, both in terms of time and iterations. Scalability was also shown to be quite good for general sparse systems arising from harder problems.

A number of improvements are still possible and are currently being investigated. The first concerns the inclusion of pivoting. Adding some form of local pivoting to PHIDAL is straightforward. A second issue is related to the graph partitioning.

One may ask if it is possible to develop partitioning strategies that are especially tailored to enhance the overall performance of PHIDAL. In fact, partitionings that yield balanced graphs (with overlap) are still difficult to obtain in spite of the existence of excellent graph partitioners such as METIS. Finally, we plan to explore the impact of including an inner accelerator for solving the systems which arise at each level. This is a natural extension given the local matrix structure provided by the hierarchical interface decomposition.

Acknowledgments. The authors benefited from insightful discussions with John Wallis on the topic of hierarchical interface decomposition. In particular, the levelization algorithm was inspired from suggestions he made on reducing the number of levels and connectors. The authors also acknowledge Zhongze Li's extensive help in setting up the comparison with pARMS. Finally, we wish to thank two anonymous referees for their very careful reviews of the paper.

2-D PARACHUTE SIMULATION BY THE IMMERSED BOUNDARY METHOD*

YONGSAM KIM† AND CHARLES S. PESKIN‡

Abstract. Parachute aerodynamics involves an interaction between the flexible, elastic, porous parachute canopy and the high speed airflow (relative to the parachute) through which the parachute falls. Computer simulation of parachute dynamics typically simplifies the problem in various ways, e.g., by considering the parachute as a rigid bluff body. Here, we avoid such simplification by using the immersed boundary (IB) method to study the full fluid-structure interaction. The IB method is generalized to handle porous immersed boundaries, and the generalized method is used to study the influence of porosity on parachute stability.

Key words. parachute, canopy, payload, porosity, oncoming velocity, control mechanism, stability, immersed boundary method

1. Introduction.

The purpose of this paper is to show that the immersed boundary (IB) method can be properly applied to the parachute problem and to demonstrate how the porosity of the parachute canopy affects the stability of parachute motion. The problem of parachute aerodynamics encompasses several of the most complex phenomena in classical fluid dynamics, such as porous bluff body aerodynamics and highly deformable structures. The cloth part of the parachute, which is called the canopy, acts as a bluff body resisting a moving flow and changes its shape rapidly in response to the surrounding flow field, but the airflow that generates the aerodynamic forces depends on the shape of the parachute canopy. Thus, parachute aerodynamics is inherently a fluid-structure interaction phenomenon, and to express this requires the time-dependent position of the parachute as well as the usual variables that appear in the Navier–Stokes equation [4, 13, 19, 21].

The IB method [22] was developed to study flow patterns around heart valves and is a generally useful method for problems in which elastic materials interact with a viscous incompressible fluid. In the IB formulation, the action of the elastic canopy immersed in the air flow appears as a localized body force acting on the fluid. This body force arises from the elastic stresses in the parachute canopy. Moreover, the parachute canopy is required to move at the local fluid velocity as a consequence of the no-slip condition. This condition is modified, however, in the case of canopy porosity, as described below. The central idea of the IB method is that the Navier–Stokes solver does not need to know anything about the complicated time-dependent geometry of the elastic boundary, and that therefore we can escape from the difficulties caused by the interaction between the elastic boundary and the fluid flow. This whole approach has been applied successfully to problems of blood flow in the heart [14, 16, 17, 18, 28],

wave propagation in the cochlea [3, 6], platelet aggregation during blood clotting [8], and several other problems [1, 9, 10, 12, 29].

An interesting and important fact about the parachute problem is that it is a porous bluff-body motion. Because the purpose of a parachute is to provide drag, parachute fluid dynamics is irrevocably associated with the airflow around and through a bluff body. This bluff body naturally causes air flowing around the parachute to separate and induces vortex shedding [2]. But since the vorticity behind the bluff canopy shape usually is not symmetric and is too complicated to predict and control, it may affect canopy motion in an asymmetric way and induce an instability of the parachute motion [19]. The parachute canopy is generally equipped with a vent at its apex, which helps to control the inflation process and to stabilize the near-wake region. Even with an extremely small opening through the apex, the reduction of drag as well as the suppression of asymmetric wake oscillations are observed [11]. Besides its central vent, a typical parachute also has a lot of gaps between ribbons or ringslots on its canopy that effectively make it a porous body. Air flow allowed to go through this porous body collides with and then suppresses large-scale vortex motion behind the canopy and helps to stabilize parachute motion. For more details concerning parachute design and the porosity effect, see [4, 13, 21].

Besides demonstrating the application of the IB method to the parachute problem, the main purpose of this paper is to give porosity to the parachute and investigate its effect on parachute movement. The real parachute has many discrete holes in the canopy that make it porous such as a vent at the apex of the canopy and gaps between ribbons and ringslots. In the computation, however, it is impractical to resolve these holes individually. To do so would require that each hole be at least a few fluid meshwidths in diameter. Otherwise the hole would be effectively closed. Thus a very fine mesh would be required. Instead of modeling each hole individually, we give the canopy as a whole a porosity which depends neither on the meshwidth of the boundary nor on that of the fluid.

The idea of how to do this comes from the fact that porosity reduces the drag force of fluid. The drag force is the most significant aerodynamic characteristic of the parachute, but a drag force produced by a porous body is smaller than when a body has no porosity. In the usual application of the IB method, the immersed boundary moves at the local fluid velocity. This is the familiar no-slip condition of a viscous fluid. In the case of a porous immersed boundary, however, we have to allow relative slip between the boundary and the surrounding fluid. This slip is only in the normal direction; the tangential no-slip condition still holds. We assume that the normal relative velocity is determined by Darcy's law [20], i.e., that the normal relative velocity is proportional to the pressure difference across the boundary. Fortunately, there is no need to evaluate this pressure difference directly, since the IB method provides the force that the immersed boundary applies to the fluid, and the normal component of this force is proportional to the pressure difference across the boundary [25]. Thus we allow a relative slip between boundary and fluid, in the normal direction only, by an amount proportional to the normal component of the boundary force. The constant of proportionality is called the porosity.

2. Equations of motion. We begin by stating the mathematical formulation of the equations of motion for a system comprised of a two-dimensional (2-D) viscous incompressible fluid containing an immersed, elastic, massless, porous boundary:

$$\rho\left(\frac{\partial \mathbf{u}}{\partial t} + \mathbf{u}\cdot\nabla\mathbf{u}\right) = -\nabla p + \mu\nabla^2\mathbf{u} + \mathbf{f}, \tag{1}$$

$$\nabla \cdot \mathbf{u} = 0, \tag{2}$$

$$\mathbf{f}(\mathbf{x},t) = \int \mathbf{F}(s,t)\delta(\mathbf{x} - \mathbf{X}(s,t))ds, \tag{3}$$

$$\begin{aligned}\frac{\partial \mathbf{X}}{\partial t}(s,t) &= \mathbf{u}(\mathbf{X}(s,t),t) + \lambda(\mathbf{F}(s,t)\cdot\mathbf{n}(s,t))\mathbf{n}(s,t)\\ &= \int \mathbf{u}(\mathbf{x},t)\delta(\mathbf{x} - \mathbf{X}(s,t))d\mathbf{x} + \lambda(\mathbf{F}(s,t)\cdot\mathbf{n}(s,t))\mathbf{n}(s,t),\end{aligned} \tag{4}$$

$$\mathbf{F}(s,t) = \frac{\partial}{\partial s}(T(s,t)\boldsymbol{\tau}(s,t)), \tag{5}$$

$$T(s,t) = c\Big(\Big|\frac{\partial \mathbf{X}(s,t)}{\partial s}\Big| - 1\Big), \tag{6}$$

$$\boldsymbol{\tau}(s,t) = \frac{\partial \mathbf{X}(s,t)/\partial s}{|\partial \mathbf{X}(s,t)/\partial s|}, \tag{7}$$

$$\mathbf{n}(s,t) = \boldsymbol{\tau}(s,t) \times \mathbf{e}_3. \tag{8}$$

Equations (1) and (2) are the familiar Navier–Stokes equations for a viscous incompressible fluid. The constant parameters ρ and μ are the fluid density and viscosity, respectively. The unknown functions in the fluid equations are the fluid velocity, $\mathbf{u}(\mathbf{x},t)$; the fluid pressure, $p(\mathbf{x},t)$; and the force per unit area applied by the immersed boundary to the (2-D) fluid, $\mathbf{f}(\mathbf{x},t)$, where $\mathbf{x} = (x,y)$ are fixed Cartesian coordinates and t is the time.

Equations (5)–(8) are the IB equations which are written in Lagrangian form. The unknown $\mathbf{X}(s,t)$ completely describes the motion of the immersed boundary and also its spatial configuration at any given time. Other unknown functions of (s,t) that appear in the boundary equations are the unit tangent vector to the boundary, $\boldsymbol{\tau}(s,t)$; the tension, $T(s,t)$; force density at the boundary, $\mathbf{F}(s,t)$; and the unit normal to the boundary $\mathbf{n}(s,t) = \boldsymbol{\tau}(s,t) \times \mathbf{e}_3$, where $\mathbf{e}_3$ is a constant unit vector normal to the plane of the (2-D) flow. The equation for the elastic tension T follows Hooke's law for a simple spring which resists both stretching and contracting with a linear constitutive relation but does not resist bending. But it could be easily generalized to include bending resistance or a more complicated nonlinear constitutive law.

Finally, we come to the interaction equations (3) and (4). These both involve the 2-D Dirac delta function $\delta(\mathbf{x}) = \delta(x)\delta(y)$, which expresses the local character of the interaction. Equation (3) simply expresses the relation between the two corresponding force densities $\mathbf{f}(\mathbf{x},t)d\mathbf{x}$ and $\mathbf{F}(s,t)ds$. We can see this fact by integrating each side of (3) over an arbitrary region Ω. It should be noted, however, that, in (3), since $\delta(\mathbf{x})$ is the 2-D Dirac delta function, but integration is only over a one-dimensional (1-D) boundary contour, $\mathbf{f}(\mathbf{x},t)$ is a singular function like a 1-D delta function.

Equation (4) is the equation of motion of the immersed elastic boundary. It is explained as follows. First consider the special case $\lambda = 0$. Then (4) is the familiar no-slip condition. In the first form of (4), the expression $\mathbf{u}(\mathbf{X}(s,t),t)$ is the fluid

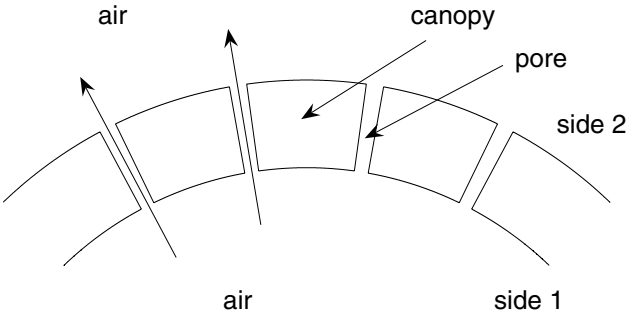

FIG. 1. *Porous boundary. The pores have small diameter in comparison to their length (the thickness of the boundary).*

velocity evaluated at the boundary. This is rewritten in terms of the Dirac delta function in the second form of (4). We do so in order to expose a certain symmetry with (3), in which the force generated by the immersed boundary is reexpressed as a body force acting on the fluid. This symmetry is important in the construction of our numerical scheme. In the following discussion of porosity, however, we shall simply use the notation $\mathbf{U}(s,t)$ for the fluid velocity evaluated at the boundary point $\mathbf{X}(s,t)$, i.e,

$$\mathbf{U}(s,t) = \mathbf{u}(\mathbf{X}(s,t),t) = \int \mathbf{u}(\mathbf{x},t)\delta(\mathbf{x}-\mathbf{X}(s,t))d\mathbf{x}. \tag{9}$$

Now consider the porosity of the immersed elastic boundary. (This discussion will be phrased in terms of the 2-D case, but of course a similar discussion could be made in three dimensions, with a few changes of units.) Consider the interval $(s, s+ds)$ of the immersed elastic boundary. Let β be the number density of pores, in the sense that βds is the number of pores in the interval $(s, s+ds)$. Let each pore have an aerodynamic conductance (reciprocal of resistance) equal to γ. This means that the flux through the pore is equal to $\gamma(p_1 - p_2)$, where p_1 and p_2 are the pressures on the two sides of the boundary; see Figure 1. Then the flux through the interval $(s, s+ds)$ of the boundary is given by $\beta\gamma(p_1 - p_2)ds$. This flux can be evaluated in another way by considering the difference between the fluid velocity at the boundary and the velocity of the boundary itself. The resulting expression for the flux is

$$\left(\mathbf{U}(s,t) - \frac{\partial \mathbf{X}}{\partial t}(s,t)\right) \cdot \mathbf{n} \left|\frac{\partial \mathbf{X}(s,t)}{\partial s}\right| ds, \tag{10}$$

where $\mathbf{n}$ is the unit normal to the boundary pointing from side 1 towards side 2. The factor $\left|\frac{\partial \mathbf{X}(s,t)}{\partial s}\right|$ appears because $\left|\frac{\partial \mathbf{X}(s,t)}{\partial s}\right| ds$ is the arc length of the segment $(s, s+ds)$. Setting these two expressions for the flux equal to each other, we get

$$\beta\gamma(p_1 - p_2)ds = \left(\mathbf{U}(s,t) - \frac{\partial \mathbf{X}}{\partial t}(s,t)\right) \cdot \mathbf{n} \left|\frac{\partial \mathbf{X}(s,t)}{\partial s}\right| ds. \tag{11}$$

But $(p_1 - p_2)$ can be related to the normal component of the boundary force $\mathbf{F}(s,t)$. The normal equilibrium of our massless boundary requires that

$$(p_1 - p_2)\left|\frac{\partial \mathbf{X}}{\partial s}(s,t)\right| ds + \mathbf{F}(s,t) \cdot \mathbf{n} ds = 0. \tag{12}$$

Combining these equations, we find

$$\left(\frac{\partial \mathbf{X}}{\partial t}(s,t) - \mathbf{U}(s,t)\right) \cdot \mathbf{n} = \frac{\beta\gamma}{|\partial \mathbf{X}(s,t)/\partial s|^2} \mathbf{F}(s,t) \cdot \mathbf{n}. \tag{13}$$

We also need a tangential component for the porous boundary condition. This is a complicated issue; see, for example, [3], where a slip boundary condition is derived at the interface of a fluid and a porous solid. In that paper, the solid has isotropic porosity. Here we assume that the parachute canopy is a thin shell of porous material *with pores oriented normal to the surface of the shell*. Moreover, we assume that the pores have small diameter in comparison to their length (the thickness of the shell). Under these conditions, the flow in each pore is normal to the surface of the canopy, so the tangential velocity of the flow in each pore is zero. Between the pores, we also have zero tangential velocity by the no-slip condition at a solid-fluid interface (see Figure 1). Combining these observations, it seems clear that the appropriate tangential boundary condition is the familiar no-slip condition, despite the porosity:

$$\left(\frac{\partial \mathbf{X}(s,t)}{\partial t} - \mathbf{U}(s,t)\right) \cdot \boldsymbol{\tau} = 0. \tag{14}$$

Then

$$\frac{\partial \mathbf{X}}{\partial t}(s,t) = \mathbf{U}(s,t) + \frac{\beta\gamma}{|\partial \mathbf{X}(s,t)/\partial s|^2} (\mathbf{F}(s,t) \cdot \mathbf{n})\mathbf{n}, \tag{15}$$

which is equivalent to (4), provided that we set

$$\lambda = \frac{\beta\gamma}{|\partial \mathbf{X}(s,t)/\partial s|^2}. \tag{16}$$

A question that still remains is whether β and γ depend on $|\partial \mathbf{X}(s,t)/\partial s|$. Recall that $|\partial \mathbf{X}(s,t)/\partial s|$ is the ratio of arc length to unstressed arc length, so it measures how stretched the material is. Intuitively, one would think that stretch would tend to increase either the number of pores or their conductance or both. Thus, one would expect $\beta\gamma$ to increase with $|\partial \mathbf{X}(s,t)/\partial s|$ but in a manner that would be hard to determine a priori. Here we make the simple assumption that λ is independent of $|\partial \mathbf{X}(s,t)/\partial s|$, i.e, that $\beta\gamma$ is proportional to $|\partial \mathbf{X}(s,t)/\partial s|^2$. More information about the material would be needed to refine this assumption.

3. Numerical method. We now describe a formally second-order IB method to solve the equations of motion [15, 18]. The word "formally" is used as a reminder that this scheme is only second-order accurate for problems with smooth solutions. Even though our solutions are not smooth (the velocity has jumps in derivative across the immersed boundary), the use of the formally second-order method results in improved accuracy; see [15].

The specific formally second-order method that we use is the one described in [18]. In this method, each time step proceeds in two substeps, which are called the preliminary and final substeps. In the preliminary substep, we get data at time level $n + \frac{1}{2}$ from data at n by a first-order accurate method. Then the final step starts

again at time level n and proceeds to time level $n+1$ by a second-order accurate method. This Runge–Kutta framework allows the second-order accuracy of the final substep to be the overall accuracy of the scheme.

We use a superscript to denote the time level. Thus $\mathbf{X}^n(s)$ is shorthand for $\mathbf{X}(s, n\Delta t)$, where Δt is the duration of the time step, and similarly for all other variables. Our goal is to compute updated $\mathbf{u}^{n+1}$ and $\mathbf{X}^{n+1}$ from given data $\mathbf{u}^n$ and $\mathbf{X}^n$.

Before describing how this is done, we have to say a few words about the spatial discretization. There are two such discretizations: one for the fluid and one for the elastic boundary. The grid on which the fluid variables are defined is a fixed uniform lattice of meshwidth $h = \Delta x_1 = \Delta x_2$. Now we define the central difference operator D_i, defined for $i = 1, 2$ as follows:

$$(D_i\phi)(\mathbf{x}) = \frac{\phi(\mathbf{x} + h\mathbf{e}^i) - \phi(\mathbf{x} - h\mathbf{e}^i)}{2h}, \tag{17}$$

where $\mathbf{e}^i$ is the unit vector in the ith coordinate direction. As the notation suggests, the difference operator in ith direction D_i corresponds to the ith component of the differential operator ∇. Thus $\mathbf{D}p$ will be the discrete gradient of p, and $\mathbf{D} \cdot \mathbf{u}$ will be the discrete divergence of $\mathbf{u}$.

We shall also make use the central difference Laplacian L.

$$(L\phi)(\mathbf{x}) = \sum_{i=1}^{2} \frac{\phi(\mathbf{x} + h\mathbf{e}^i) + \phi(\mathbf{x} - h\mathbf{e}^i) - 2\phi(\mathbf{x})}{h^2}. \tag{18}$$

The IB variables are defined as functions of s with meshwidth Δs. For any function $\phi(s)$, define D_s:

$$(D_s\phi)(s) = \frac{\phi(s + \Delta s/2) - \phi(s - \Delta s/2)}{\Delta s}. \tag{19}$$

The fluid mesh and the elastic boundary mesh defined above are connected by a smoothed approximation to the Dirac delta function. It is denoted δ_h and is of the following form:

$$\delta_h(\mathbf{x}) = h^{-2}\phi(\frac{x_1}{h})\phi(\frac{x_2}{h}), \tag{20}$$

where $\mathbf{x} = (x_1, x_2)$, and the function ϕ is given by

$$\phi(r) = \begin{cases} \frac{3-2|r|+\sqrt{1+4|r|-4r^2}}{8} & , \text{ if } |r| \le 1 \\ \frac{5-2|r|-\sqrt{-7+12|r|-4r^2}}{8} & , \text{ if } 1 \le |r| \le 2 \\ 0 & , \text{ if } 2 \le |r|. \end{cases} \tag{21}$$

The motivation and derivation for this particular choice is discussed in [23, 24].

We are now ready to describe a typical time step of the numerical scheme. The preliminary substep, which goes from time level n to $n + \frac{1}{2}$, proceeds as follows.

First, update the position of the massless boundary $\mathbf{X}^{n+\frac{1}{2}}(s)$:

$$\frac{\mathbf{X}^{n+\frac{1}{2}} - \mathbf{X}^n}{\Delta t/2} = \sum_{\mathbf{x}} \mathbf{u}^n(\mathbf{x})\delta_h(\mathbf{x} - \mathbf{X}^n(s))h^2 + \lambda(\mathbf{F}^n \cdot \mathbf{n}^n)\mathbf{n}^n, \tag{22}$$

where $\mathbf{n}^n$ is the unit normal to the boundary $\mathbf{X}^n$ and $\mathbf{F}^n$ can be calculated from $\mathbf{X}^n$ (see below). In general $\mathbf{n} = \boldsymbol{\tau} \times \mathbf{e}_3$ in (22), but $\boldsymbol{\tau}$ is not defined at each boundary point. To overcome this, we use

$$\boldsymbol{\tau}^n(s) = \frac{\mathbf{X}^n(s+\Delta s) - \mathbf{X}^n(s-\Delta s)}{|\mathbf{X}^n(s+\Delta s) - \mathbf{X}^n(s-\Delta s)|} \tag{23}$$

and then get $\mathbf{n}^n(s) = \mathbf{e}_3 \times \boldsymbol{\tau}^n(s)$.

Next, we calculate the force density $\mathbf{F}^{n+\frac{1}{2}}$ from the deformation of elastic boundary $\mathbf{X}^{n+\frac{1}{2}}$. The force density $\mathbf{F}^{n+\frac{1}{2}}$ can be obtained by the discretization of (5)–(7):

$$\boldsymbol{\tau}^{n+\frac{1}{2}} = \frac{D_s \mathbf{X}^{n+\frac{1}{2}}}{|(D_s \mathbf{X}^{n+\frac{1}{2}})|}, \quad T^{n+\frac{1}{2}} = c(|D_s \mathbf{X}^{n+\frac{1}{2}}| - 1), \quad \mathbf{F}^{n+\frac{1}{2}} = D_s(T^{n+\frac{1}{2}} \boldsymbol{\tau}^{n+\frac{1}{2}}). \tag{24}$$

Note that, since $\boldsymbol{\tau}^{n+\frac{1}{2}}$ and $T^{n+\frac{1}{2}}$ are defined at values of s halfway between those at which $\mathbf{X}^{n+\frac{1}{2}}$ is defined, $\mathbf{F}^{n+\frac{1}{2}}$ are defined at the same values of s as $\mathbf{X}^{n+\frac{1}{2}}$.

Now we have to change this elastic force defined on Lagrangian grid points into the force at Eulerian spatial grid points to be applied in the Navier–Stokes equations:

$$\mathbf{f}^{n+\frac{1}{2}}(\mathbf{x}) = \sum_s \mathbf{F}^{n+\frac{1}{2}}(s) \delta_h(\mathbf{x} - \mathbf{X}^{n+\frac{1}{2}}(s)) \Delta s, \tag{25}$$

where $\mathbf{x}$ is any point of the fluid mesh. With $\mathbf{f}^{n+\frac{1}{2}}$ in hand, we can turn to solving the Navier–Stokes equations

$$\rho \left(\frac{u_i^{n+\frac{1}{2}} - u_i^n}{\Delta t/2} + \frac{1}{2}(\mathbf{u} \cdot \mathbf{D} u_i + \mathbf{D} \cdot (\mathbf{u} u_i))^n \right) + D_i p^{n+\frac{1}{2}} = \mu L u_i^{n+\frac{1}{2}} + f_i^{n+\frac{1}{2}} \tag{26}$$

for $i = 1, 2$, together with

$$\mathbf{D} \cdot \mathbf{u}^{n+\frac{1}{2}} = 0. \tag{27}$$

Note that the unknowns in (26) and (27) are $u_i^{n+\frac{1}{2}}$ and $p^{n+\frac{1}{2}}$ and that they enter into these equations linearly. Since all the coefficients of these equations are constants, the system of equations (26)–(27) can be solved by the fast Fourier transform with the periodic boundary condition [23, 24].

The final step is the correction of $\mathbf{u}^{n+\frac{1}{2}}$ and $\mathbf{X}^{n+\frac{1}{2}}$ obtained in the preliminary step.

First, using the fluid velocity $\mathbf{u}^{n+\frac{1}{2}}$, we can find the boundary configuration $\mathbf{X}^{n+1}$:

$$\frac{\mathbf{X}^{n+1} - \mathbf{X}^n}{\Delta t} = \sum_{\mathbf{x}} \mathbf{u}^{n+\frac{1}{2}}(\mathbf{x}) \delta_h(\mathbf{x} - \mathbf{X}^{n+\frac{1}{2}}(s)) h^2 + \lambda(\mathbf{F}^{n+\frac{1}{2}} \cdot \mathbf{n}^{n+\frac{1}{2}}) \mathbf{n}^{n+\frac{1}{2}}, \tag{28}$$

where $\mathbf{n}^{n+\frac{1}{2}}$ is the unit normal to the boundary $\mathbf{X}^{n+\frac{1}{2}}$ and can be obtained in the same manner as $\mathbf{n}^n$ in the preliminary step.

The last thing that we have to do is to update the fluid velocity data by solving the following system of equations for the unknowns $\mathbf{u}^{n+1}$ and $p^{n+1/2}$:

$$\rho \left(\frac{u_i^{n+1} - u_i^n}{\Delta t} + \frac{1}{2}(\mathbf{u} \cdot \mathbf{D} u_i + \mathbf{D} \cdot (\mathbf{u} u_i))^{n+\frac{1}{2}} \right) + D_i p^{n+\frac{1}{2}} = \frac{1}{2} \mu L (u_i^{n+1} + u_i^n) + f_i^{n+\frac{1}{2}} \tag{29}$$

for $i = 1, 2$, together with

$$\mathbf{D} \cdot \mathbf{u}^{n+1} = 0. \tag{30}$$

Note that $p^{n+1/2}$ here is not the same as $p^{n+1/2}$ in (26). They are different approximations to the pressure at time level $n + 1/2$. The method of solving (29)–(30) is the same as that of solving (26)–(27), and indeed the same subroutines can be reused for this purpose. Since we have now computed $\mathbf{u}^{n+1}$ and $\mathbf{X}^{n+1}$, the time step is complete.

4. Two-dimensional parachute model. In this section we introduce a 2-D computational model of a parachute. We present the initial configuration of our model and display the physical and computational parameters which are used in the numerical experiments.

Consider the incompressible viscous fluid in a square box $(0, 4\text{m}) \times (0, 4\text{m})$ with periodic boundary conditions (but see below) which contains an immersed elastic parachute. Figure 2 shows the initial constructed configuration of a 2-D parachute and a part of the computational domain. The canopy has as its initial shape an upper half-ellipse centered at $(0, 0)$ which is expressed $\{(a\cos(s), b\sin(s)) : 0 \leq s \leq \pi\}$ as a parameterized curve. Linking the two end points of the canopy to the payload position completes the basic symmetric parachute which is then rotated about the

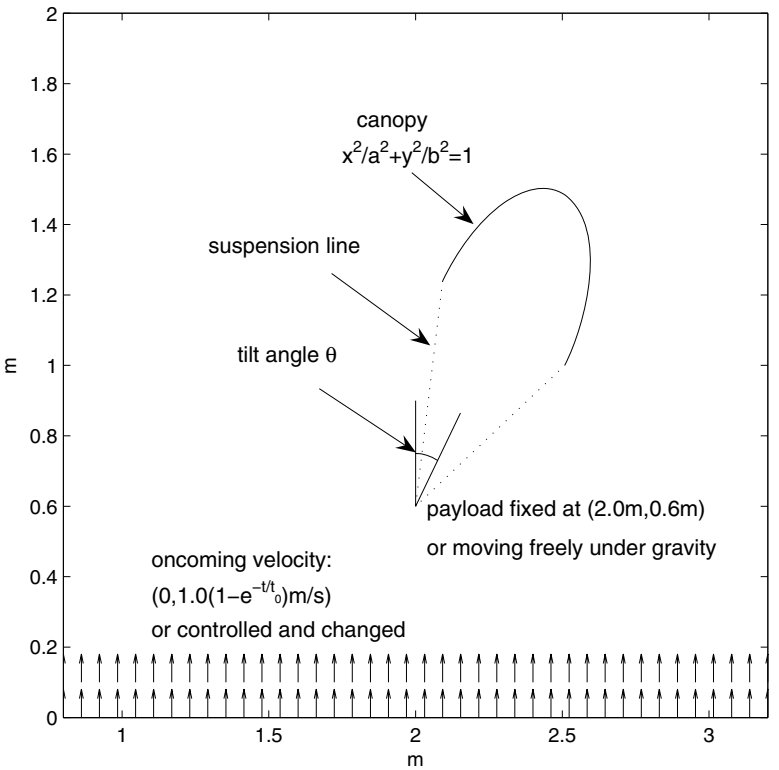

FIG. 2. *The initial configuration of the parachute. The tilt angle from the y-axis is the initial attack angle θ with respect to the oncoming velocity $\mathbf{u}_0 = (0, V_0(t))$. The payload is either fixed or moving freely. While the oncoming velocity is prescribed in the fixed-payload case, it changes determined by a control mechanism in the free-payload case.*

payload point by an arbitrary angle θ. The first simulation has its payload position fixed at the point (2.0m, 0.6m) which does not move and, in each time step, is just attached to two end points of the updated canopy position with two straight lines. These two lines, which are called suspension lines, are pure force generators. They do not interact with the fluid along their length, but simply act as linear springs which apply force to the two end points of the canopy.

The most natural way to model a parachute would be to let it fall, under the influence of gravity acting on its payload, through air which would be at rest at a large distance from the parachute. Here, however, we drive the air upwards and keep the parachute within the computational domain either by attaching the payload to a fixed point or by letting the payload fall freely through the rising air under the influence of gravity and adjusting the velocity of the rising air so that the parachute stays near a fixed level. In either case, we need a way to specify the "oncoming velocity" of the air that is coming up from below the parachute. This is done by applying an external force per unit volume equal to

$$\mathbf{f}_0(\mathbf{x},t) = \begin{cases} \alpha_0(\mathbf{u}_0(t) - \mathbf{u}(\mathbf{x},t)), & \mathbf{x} \in \Omega \\ 0 & \text{otherwise,} \end{cases} \tag{31}$$

where Ω is a rectangular strip along the bottom of the domain in which we want to specify the oncoming velocity. In practice, we choose Ω two meshwidths wide on the coarsest grid that we employ for these computations. Then, since Ω represents a fixed physical region, the number of horizontal meshlines within Ω must increase inversely with the meshwidth as the meshwidth is refined.

For the fixed payload case, for example, the oncoming velocity $\mathbf{u}_0(t)$ is given by $(0, 1.0(1 - \exp(-\frac{t}{t_0}))\text{m/s})$. Here, in order to avoid the abrupt change of velocity field and then parachute configuration, we set the oncoming velocity as a function of time which is initially $(0, 0)$ but increases gradually up to a constant value (0,1.0m/s).

Although this method of specifying the oncoming velocity is crude, it is not quite as crude as one might think. We address here two concerns that may occur to the reader. First, does the velocity field on Ω really match the oncoming velocity $\mathbf{u}_0(t)$? When we look closely at the velocity field in this region, we can see that the real velocity in this region quickly catch up with the oncoming velocity and becomes very close to it. Second, since the pressure is computed by solving a periodic problem, doesn't this result in unwanted interaction between the top and bottom of the domain? To investigate this, we have compared the pressures above and below the lines on which the oncoming velocity is specified. After an initial transient, these pressures are actually *anti*correlated, thus showing that the specified oncoming velocity has effectively broken the periodicity, as one would expect by considering, say, the effect of a thin porous plug in a circular pipe.

The second simulation is done with the same parachute as before but we remove the tethered point and allow the payload to move. The point payload of our model has no direct effect on the fluid such as vortex shedding, and its movement is independent of the local fluid velocity around the payload. But it has a point mass M and therefore feels a gravitational force $M\mathbf{g}$, where $\mathbf{g}$ is the downward acceleration $(0, -g)$. Since the payload is also loaded by the stresses of two suspension lines, let $T_i(t)(i = 1, 2)$ be the tension of each suspension line and $\boldsymbol{\tau}_i(t), (i = 1, 2)$ be the unit vectors pointing from the payload to the two end points of the canopy, respectively. We then have the

total force $\mathbf{F}_p(t)$ acting on the payload,

$$\mathbf{F}_p(t) = M\mathbf{g} + \sum_{i=1}^{2} T_i(t)\boldsymbol{\tau}_i(t). \tag{32}$$

Let the velocity of the payload be $\mathbf{U}_p(t)$ and the position be $\mathbf{X}_p(t)$; then we have the equations of motion:

$$\frac{d\mathbf{U}_p(t)}{dt} = \frac{\mathbf{F}_p(t)}{M}, \tag{33}$$

$$\frac{d\mathbf{X}_p(t)}{dt} = \mathbf{U}_p(t). \tag{34}$$

In the fixed-payload case, the oncoming velocity was arbitrary, but with a free payload if we specify the oncoming velocity arbitrarily we shall find that it is either too small, in which case the parachute will fall out the bottom of the domain, or too large, in which case the parachute will rise out the top of the computational domain. To keep the parachute within the domain, and away from the meshlines on which the oncoming velocity is specified, we use a control mechanism to adjust the oncoming velocity in such a manner that the y-coordinate of the payload settles to a predetermined value. The equation governing this control mechanism is as follows:

$$\frac{dV_0(t)}{dt} = k(y_{target} - Y_p(t)) - \sigma V_p(t). \tag{35}$$

In (35), $Y_p(t)$ and $V_p(t)$ are obtained by taking the y-components of $\mathbf{X}_p(t)$ and $\mathbf{U}_p(t)$ from (33) and (34), respectively. The velocity $(0, V_0(t)) = \mathbf{u}_0$ is the oncoming velocity at time t, y_{target} is the fixed value at which the y-coordinate of the payload is supposed to have its equilibrium, and k and σ are constant coefficients. The equation says that if, at some time, the height of the payload $Y_p(t)$ is lower than the target position of the payload y_{target}, the oncoming velocity increases, and if $Y_p(t)$ is greater than y_{target}, the oncoming velocity decreases. But the change of the oncoming velocity is damped according to $V_p(t)$ in order to avoid large oscillations of the oncoming velocity. The coefficients k and σ are chosen so that the y-coordinate of the payload is stable around the target position y_{target}. Note, however, that we allow the parachute to move out the side of the domain, in which case we should handle the data outside the domain by duplicating them into the domain in a periodic way.

The readers may wonder in the free-payload case, why we need an oncoming velocity at all. Why not use the periodicity to let the parachute fall out the bottom of the domain and reappear as it does so at the top? Aside from the interaction of the parachute with its own wake that would then occur, there is a more fundamental problem. Since the periodic domain contains only a finite mass of fluid to which a constant force (the weight of the payload) is applied, the total downward momentum of the system will increase linearly with time, and no terminal velocity will exist. We avoid this difficulty through the use of the oncoming velocity.

The overall performance of a parachute can be summarized by the relationship between the drag force it generates and the speed at which it is falling (relative to the air at a large distance from the parachute). The two types of computer experiments introduced above assess this relationship in different ways. When the payload is fixed in place and the oncoming velocity is arbitrary, then the speed of the parachute

TABLE 1
Physical parameters.

Physical parameters	Symbol	Magnitude	Unit
Density	ρ	1.2	kg/m^3
Viscosity	μ	0.002	$kg/(m \cdot s)$
Gravitational acceleration	g	9.8	m/s^2
Mass of payload	M	0.08	kg
Computational domain		4×4	$m \times m$
Canopy length		1.0561	m
Suspension line length		0.6462	m
Opening length	$2a$	$0.1 - 0.48$	m
Porosity	λ	$0.0 - 0.2$	$m^2/(N \cdot s)$
Initial tilt angle	θ	$0.0 - \pi/6$	

(relative to the distant air) is the independent variable, and the drag force is computed. Indeed, the drag force can be determined simply by examining the tensions and angles of the suspension lines. When the payload is free and the oncoming velocity is adjusted to keep the parachute from falling or rising, then the drag force is the independent variable, since it has to be equal to the specified weight of the payload. In this case, the speed corresponding to the given drag force is just the equilibrium value of the oncoming velocity, as set by the control mechanism. Although we would expect to get the same steady-state relationship between speed and drag force from either type of computational experiment, the dynamics of the two cases could certainly be different. This is because the free-payload case has two additional degrees of freedom and one additional parameter (the payload mass), which might well be expected to influence the dynamics.

Two important parameters of our computational experiments are the initial tilt angle θ (defined in Figure 2) and the porosity λ (defined in (16) and discussed above). An initial tilt angle is needed to break the left-right symmetry of the problem in order to explore the possibility that the symmetric configuration of the parachute may be unstable, and that the parachute may oscillate from side to side. If the symmetric configuration is linearly unstable, then any nonzero initial tilt angle will lead to such oscillations. But if it is only nonlinearly unstable, then there may be a threshold value of the initial tilt angle below which the parachute settles into a steady symmetrical configuration and above which it settles into a sustained side-to-side oscillation. The porosity λ is introduced in order to study its influence on the stability of the steady, symmetrical parachute configuration. To avoid numerical difficulties at the ends of the parachute canopy, we make λ a function of s that is constant at its maximum value near the center of the parachute canopy and then tapers smoothly to zero at the ends of the canopy. When we report a numerical value of λ, that refers to the maximum value.

Table 1 shows other physical parameters in addition to θ and λ. Our model of parachute is chosen to have a small dimension compared to that of real parachutes. The density is the same as that of air, but the dynamic viscosity is 0.002, which is 100 times bigger than that of air. The reason for the small size of parachute and the large viscosity is to reduce the Reynolds number. We believe that, with computational resolution affordable so far, we can properly compute up to a Reynolds number of several hundreds. With those values, we have the Reynolds number as large as 400 based on the oncoming velocity and the diameter of the canopy. The initial canopy

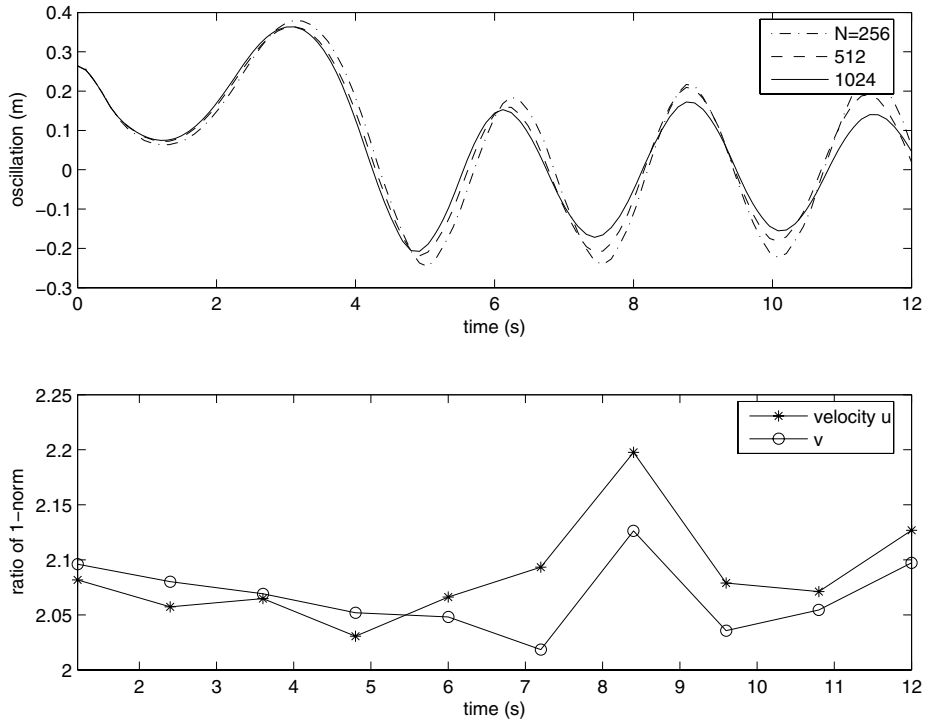

FIG. 3. *The top graph plots the difference between the x-coordinate of the midpoint of the canopy and the payload of the parachute (in meters) as a function of time (in seconds), which represents the side-to-side oscillations. The three curves show results obtained with three different resolutions: $N = 256$, 512, and 1024. The lower panel plots the convergence ratios of the velocity field (u, v) in the 1-norm. The convergence ratio 2 implies that the scheme is first-order accurate.*

configuration is a half-ellipse with semiaxes a and b. In our numerical experiments, the data that we vary are the porosity λ, the initial tilt angle θ, and the initial opening length $2a$. The ranges of these parameters are given in Table 1.

5. Results and discussion. We first verify that the IB method as applied to a porous boundary is robust and consistent. To do that, we choose a parachute with porosity coefficient $\lambda = 0.09$ m^2/(N·s), tilt angle $\theta = \pi/12$, and the initial opening length $2a = 0.48$m. The parachute is connected to a payload fixed at (2.0m, 0.6m) by two suspension lines. For $N = 256$, 512, and 1024, we change the time step $\Delta t = 0.0256/N$, the space meshwidth $h = 4/N$, and the boundary meshwidth $\Delta s = (128L_0)/(70N)$, where L_0 is the canopy length. That is, when we refine the meshwidths h and Δs by a factor of 2, the time step Δt is also reduced by the same factor.

The top of Figure 3 shows the x-coordinate of the midpoint of the parachute canopy relative to that of the fixed point as a function of time. This indicates the deviation of the parachute from its symmetrical falling configuration and shows whether the parachute is falling straight down or oscillating from side to side. The oscillations computed on the three different meshwidths track each other quite well through the four cycles of oscillation shown. To get a more quantitative measure of convergence, we compare the velocity fields computed on the three different meshwidths. The con-

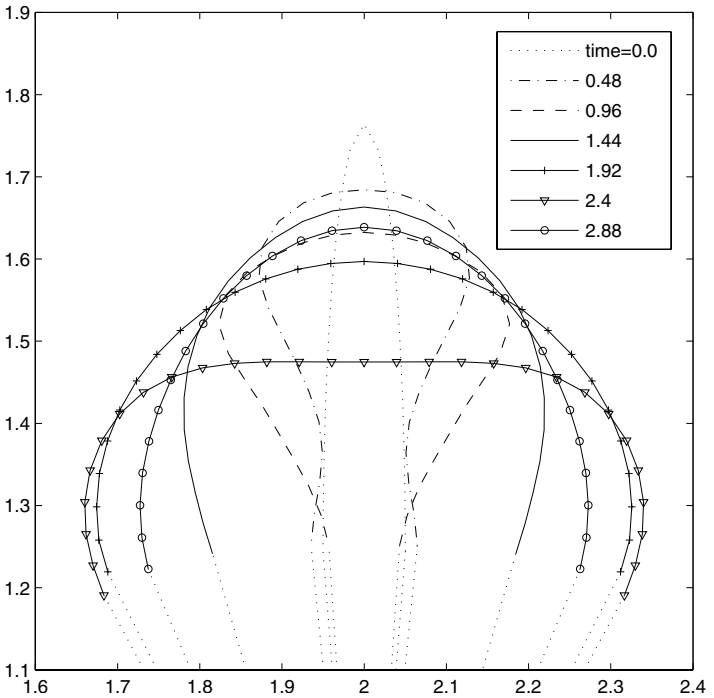

FIG. 4. *Inflation of parachute at early times. Note that inflation occurs first in the upper part of the canopy. In fact the suspension lines actually move slightly closer together at first but then move apart as inflation spreads to the entire canopy.*

vergence ratio is roughly equal to 2 in the L_1 norm. Let (u_N, v_N) be the velocity field, and let $||\cdot||_1$ be L_1 norm. Then the bottom of Figure 3 shows the convergence ratios $||u_{256} - u_{512}||_1/||u_{512} - u_{1024}||_1$ and $||v_{256} - v_{512}||_1/||v_{512} - v_{1024}||_1$ as functions of time. The convergence ratio 2 implies that the scheme has first-order accuracy which is typical of the IB method as applied to problems with thin elastic boundaries (for second-order convergence of the IB method in the case of an immersed elastic structure of finite thickness, see [7]). Throught the rest of this paper, we use $N = 512$, which is the intermediate resolution of the convergence study depicted in Figure 3.

The first simulation that we consider involves the process of parachute inflation, starting from a nearly closed configuration and studying the changes in shape of the parachute at early times; see Figure 4. Of all the results that we consider, it is this one that shows most clearly the need for a method that can handle the unknown changes in shape of the parachute canopy. In the IB method, this is done without any regridding, since the canopy is represented in the fluid dynamics computation by a force field defined on a uniform grid. For alternative approaches, see [5, 26, 27].

Figure 4 shows the inflation of a parachute which has the payload tethered at $(2.0\text{m}, 0.6\text{m})$ and has no initial tilt angle, and for which the porosity coefficient $\lambda = 0\ \text{m}^2/(N{\cdot}\text{s})$ and the initial opening length $2a = 0.1$ m. At the beginning of parachute inflation, the upper part of canopy is expanding more than the lower part. But air captured by the canopy finally applies enough pressure to inflate the parachute completely. After time proceeds beyond the last time shown in Figure 4, the parachute moves stably without further change in its configuration.

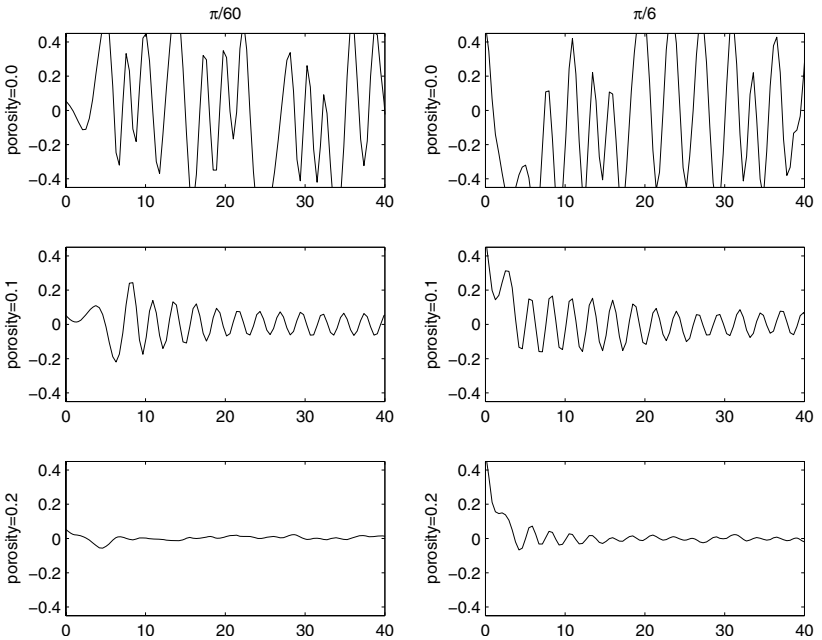

FIG. 5. *These graphs compare the stability of parachutes which have* $\pi/60$ *(left column) and* $\pi/6$ *(right column) as the initial tilt angle, and different coefficients* λ *of porosity equal to* 0 *(top row),* 0.1 $m^2/(N{\cdot}s)$ *(middle row), and* 0.2 $m^2/(N{\cdot}s)$ *(bottom row). Each graph plots the difference between the* x*-coordinates of the midpoint of the parachute canopy and the fixed payload (in meters) as a function of time (in seconds). Three qualitatively distinct behaviors are seen: unstable oscillations with large variable amplitude (top), oscillating steady state with damped amplitude (middle), or a rapid approach to the symmetrical steady state (upon which only small movements, possibly related to asymmetric vortex shedding, are superimposed).*

An important theme of this paper is the relationship between porosity and stability. The effect of porosity on stability is investigated in Figures 5 and 6. Each panel of Figure 5 is a graph showing the oscillation of the parachute in terms of the difference between the x-coordinates of the midpoint of the parachute canopy and the fixed position of the payload as a function of time. In the left-hand column, the initial tilt angle is $\theta = \pi/60$, which we regard as a small perturbation from symmetry about a line x=2. In the right-hand column, a larger initial tilt angle ($\theta = \pi/6$) is used. In each row of Figure 5, the parachute canopy has a different porosity, beginning with $\lambda = 0.0$ (no porosity) at the top and increasing to 0.1 in the middle and 0.2 $\mathrm{m}^2/(\mathrm{N{\cdot}s})$ at the bottom.

The top row shows that the oscillating steady state (limit cycle) is unstable for a parachute with no porosity, at least under the conditions of our simulation. For both initial conditions tried, the parachute does not settle into an oscillating steady state in which it rocks back and forth in a regular way. Instead its oscillatory motion looks somewhat chaotic. The parachute of the middle row has the intermediate porosity $\lambda = 0.1$ $\mathrm{m}^2/(\mathrm{N{\cdot}s})$. With this porosity, we can see the oscillation damped, and the parachute seems to be settling into the oscillating steady state (limit cycle). Finally, the bottom row suggests that the symmetrical steady state is globally stable for sufficiently high porosity, as almost no oscillations are seen in this case for either of the two initial conditions tried.

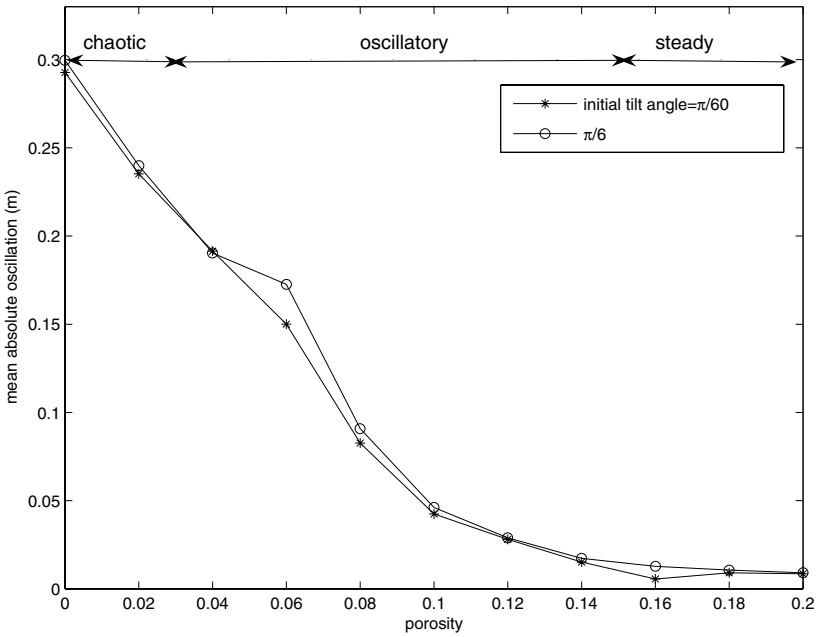

FIG. 6. *The mean absolute oscillation which is obtained by averaging the absolute oscillation over the time interval from* 25*s to* 42*s is plotted in terms of porosity. The mean oscillation of the parachute deceases almost linearly with the increasing porosity independent of the initial perturbation.*

We have found that the transition point from the chaotic motion to the oscillating steady state is when the porosity is around 0.025 $\mathrm{m}^2/(\mathrm{N}\cdot\mathrm{s})$. As the porosity increases beyond that point, the amplitude of the oscillation decreases almost linearly. The transition from the oscillating steady state to the symmetrical steady state happens at about a porosity of 0.15 $\mathrm{m}^2/(\mathrm{N}\cdot\mathrm{s})$. The amplitude of parachute motion with the same porosity is independent of the initial perturbation. The only difference is that the parachute with a larger initial tilt angle takes more time to settle down to its eventual chaotic, oscillatory, or steady state. Figure 6 shows the mean absolute oscillation for both cases. For each porosity, we plot the mean oscillation averaged over the time interval from 25s to 42s, thus avoiding the initial transient. Note that the results in Figure 6 are essentially the same for the two different initial conditions. The mean oscillation decreases linearly with porosity until a porosity of about 0.15 $\mathrm{m}^2/(\mathrm{N}\cdot\mathrm{s})$, above which there is essentially no oscillation and the parachute falls symmetrically in a steady manner.

The next result concerns the parachute with a moving payload. As discussed above, to prevent the parachute from leaving the computational domain, we use the oncoming velocity controlled by (35) with $k = 0.25\ \mathrm{s}^{-2}$ and $\sigma = 0.5\ \mathrm{s}^{-1}$. These values are chosen through numerical experiments to make the parachute with payload stay in the domain.

Figure 7 shows that, with these values of the parameters, the control mechanism of (35) behaves in a stable manner. In the upper graph, as time goes on, while the y-coordinate of the payload $Y_p(t)$ is converging to the target position $y_{target} = 1.2$ m for the parachute with porosity coefficient λ=0.1 $\mathrm{m}^2/(\mathrm{N}\cdot\mathrm{s})$, $Y_p(t)$ oscillates around the target position for the parachute without porosity. Similarly, the oncoming velocity

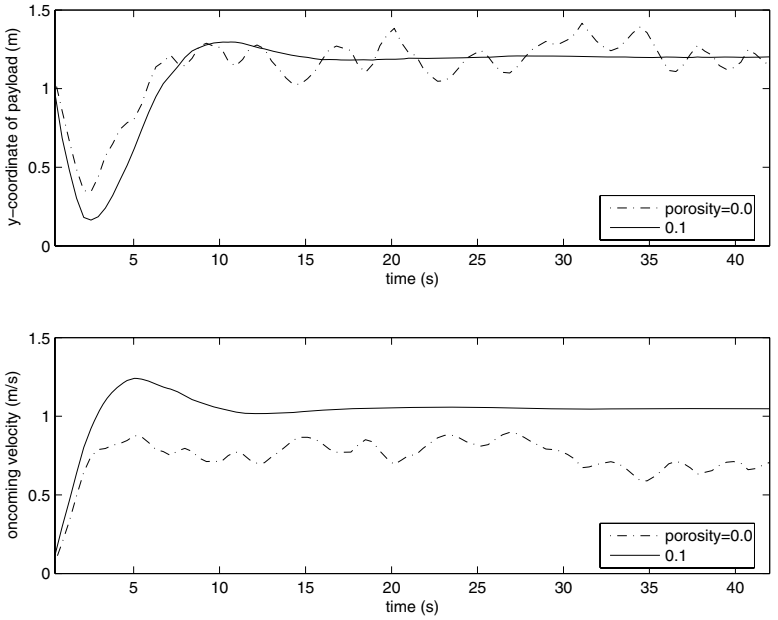

FIG. 7. *Behavior of the control mechanism that regulates the oncoming velocity in the free-payload case. Upper graph shows the y-coordinate of the payload $Y_p(t)$ as a function of time. $Y_p(t) \to 1.2m = y_{target}$ as $t \to \infty$ (with porosity) or $Y_p(t)$ fluctuates around y_{target} (without porosity). Lower graph shows the oncoming velocity $V_0(t)$ as a function of time. $V_0(0) = 0$ m/s, and $V_0(t) \to 1.05$ m/s as $t \to \infty$ for the parachute with porosity $\lambda = 0.1$ $m^2/(N{\cdot}s)$, but $V_0(t)$ changes around 0.76 m/s for the parachute with no porosity.*

$V_0(t)$ stays near one value after a short time with porosity 0.1 (lower graph), but the result in the case of no porosity goes through an unstable oscillation around another value. These fluctuations around the expected equilibrium values for the parachute with no porosity are related to its chaotic oscillatory motion; see below. Note from the lower graph that the parachute with porosity needs a larger oncoming velocity than the parachute without porosity to support the payload. Because porosity reduces the drag force of the fluid and causes the parachute with porosity to fall faster, a larger oncoming velocity is needed to generate a drag equal to the weight of the payload.

In this relatively stable situation, which we can regard as y-directional stability, we now investigate the relation between the porosity and the x-directional stability of the parachute. Figure 8 compares the x-directional stabilities of two parachutes which have the same initial tilt angle $\pi/12$, the initial opening length 0.48 m and two different porosities $\lambda = 0$ and 0.1 $\mathrm{m}^2/(\mathrm{N}{\cdot}\mathrm{s})$. From the top panel, which compares the x-coordinates of the payloads of the two parachutes, we can see that the parachute with porosity settles quickly to a fixed lateral position, but the parachute without porosity wanders considerably from side to side. The bottom panel shows the oscillation (difference between the x-coordinates of the midpoint of canopy and the payload) of the two parachutes. The parachute with porosity $\lambda = 0.1$ $\mathrm{m}^2/(\mathrm{N}{\cdot}\mathrm{s})$ moves more steadily than the parachute without porosity.

From Figures 5–8, we can see that porosity helps to stabilize the parachute against both side-to-side motion about the payload and x-directional motion as a whole (free payload only). As stated in the introduction, asymmetry of vortex shedding is the

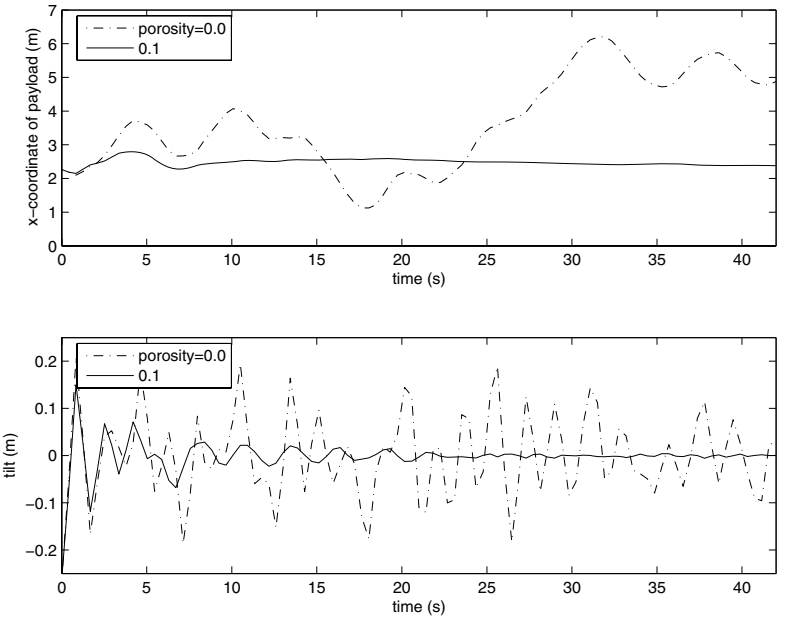

FIG. 8. *The graph compares the lateral stability of parachutes which have the same initial tilt angle $\pi/10$ but different coefficient λ of porosity. For each parachute, the x-coordinate of the payload is plotted in the upper panel, and the "tilt," i.e., the difference between the x-coordinate of the midpoint of the canopy and that of the payload, is plotted in the lower panel.*

probable cause of the parachute instability, but porosity can reduce the asymmetry of the vortex wake in the neighborhood of the canopy. To see that this idea is plausible, Figure 9 compares the vorticity contours of three cases of parachutes which have the same initial tilt angle $\theta = \pi/60$ but different porosity. The parachutes have fixed payloads. The parachute in the first column has no porosity, the one in the second column has porosity $\lambda = 0.1$ m^2/(N·s), and the one in the third column has $\lambda = 0.2$ m^2/(N·s). Each row represents a certain fixed time. At time 0, all parachutes have the same configuration as the initial configuration shown in Figure 2, and there is neither wind velocity nor vorticity. Figure 9 shows that the porous parachute settles into the oscillating steady state (second column) or symmetrical steady state (third column), but the parachute without porosity continues to oscillate in an unstable, chaotic way. We can also observe that the no-porosity case has very large and asymmetric vorticity. The parachute with porosity 0.1 shows a more regular version of alternate vortex shedding, and the parachute with porosity 0.2 has a nearly symmetrical distribution of vorticity in its wake.

6. Summary and conclusions. We have presented numerical experiments concerning the parachute problem in the 2-D case. Two basic configurations have been studied: one with a fixed payload in a prescribed updraft and the other with a free payload in a controlled updraft, the controller being designed to adjust the updraft so that the parachute stays within the computational domain. The coupled equations of motion of the air and the flexible parachute canopy have been solved by the IB method. We have used this methodology to simulate the details of parachute inflation and to study the influence of canopy porosity on the lateral stability of the parachute.

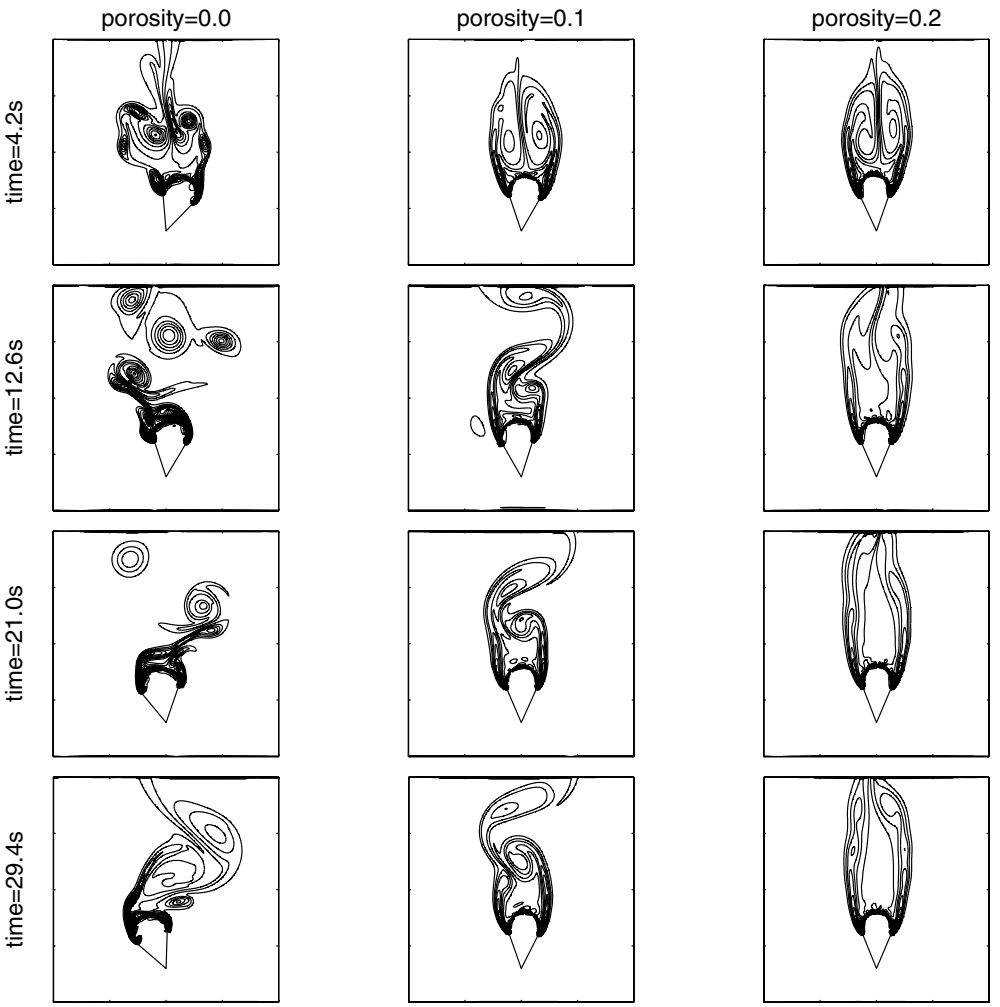

FIG. 9. *Vorticity contours in the wake of parachutes with fixed payloads. The parachute in the first column has zero porosity, the parachute in the second column porosity* $\lambda = 0.1$*, and the parachute in the third column* $\lambda = 0.2$ $m^2/(N{\cdot}s)$*. Each row shows a different time. A side-to-side oscillation and a very asymmetric vortex wake are observed in the case of the parachute with zero porosity. The parachute with porosity* 0.1 *still shows alternate vortex shedding but in a more regular manner, and the parachute with porosity* 0.2 *has an essentially symmetrical voticity distribution in its wake.*

Future work will include the generalization to the three-dimensional case, and studies concerning the influence of wind shear on parachute dynamics.

DISCRETE MAXIMUM PRINCIPLE AND ADEQUATE DISCRETIZATIONS OF LINEAR PARABOLIC PROBLEMS*

ISTVÁN FARAGÓ† AND RÓBERT HORVÁTH‡

Abstract. In this paper, we analyze the connections between the different qualitative properties of numerical solutions of linear parabolic problems with Dirichlet-type boundary condition. First we formulate the qualitative properties for the differential equations and shed light on their relations. Then we show how the well-known discretization schemes can be written in the form of a one-step iterative process. We give necessary and sufficient conditions of the main qualitative properties of these iterations. We apply the results to the finite difference and Galerkin finite element solutions of linear parabolic problems. In our main result we show that the nonnegativity preservation property is equivalent to the maximum-minimum principle and they imply the maximum norm contractivity. In one, two, and three dimensions, we list sufficient a priori conditions that ensure the required qualitative properties. Finally, we demonstrate the above results on numerical examples.

Key words. parabolic problems, heat conduction, numerical solution, qualitative properties, discrete maximum principle, nonnegativity, contractivity in maximum norm

1. Introduction.

Let us consider the partial differential equation $\mathcal{L}v = f$, where $\mathcal{L}$ denotes some linear partial differential operator, f is a given function, and v is the unknown function to be determined. A function g is also given, which prescribes the values of v on certain parts of the boundary of the solution domain.

Several problems for partial differential equations possess some characteristic qualitative properties, which are typical of the phenomenon the partial differential equation describes. The three most important of them are the *maximum-minimum principle* (MP), the *nonnegativity preservation* (NP), and the *maximum norm contractivity* (MNC). The MP states that the solution of a differential equation can be estimated from above and below by means of the given functions f and g. For example, when $f = 0$, the solution takes its extremal values on the boundary of the solution domain as well. The NP property means that the nonnegativity of f and g implies the nonnegativity of the solution v. The MNC property, which makes sense for time-dependent problems only, says that for two arbitrary initial functions the maximum norm of the difference of the solutions at every time level is not greater than the maximum norm of the difference of the initial functions.

In most cases, a partial differential equation cannot be solved in a useful form. In some particular cases, the solution can be written in the form of an infinite Fourier series, but this is also useless from the practical point of view. Thus, the use of numerical methods is a necessary step to obtain an approximate solution. It is a

natural requirement of an adequate numerical method that it has to possess the discrete equivalents of the qualitative properties the continuous problem satisfies.

The discrete version of the MP is the so-called *discrete maximum-minimum principle* (DMP). The topic of validity of various DMPs arose 30 years ago and was first investigated for elliptic problems (see, e.g., [4, 5, 18, 23]). The DMP was generally guaranteed by some geometrical conditions for the meshes. The DMP for parabolic problems was discussed in [8, 10, 11, 20]. In [11], based on the acuteness of the tetrahedral meshes, a sufficient condition of the DMP was obtained for the Galerkin finite element solution of certain parabolic problems. In the paper [8], a necessary and sufficient condition of the DMP was derived for Galerkin finite element methods and sufficient conditions were given for hybrid meshes. About the DMP, a comprehensive survey can be found in papers [2] and [3]; [17] investigates nonlinear problems.

The conditions of the *discrete nonnegativity preservation property* (DNP) were discussed in [7, 12] for linear finite elements in one, two, and three dimensions, and in [6] in one dimension with the combination of the finite difference and finite element methods. The DNP is investigated for nonlinear problems in [24].

The *discrete maximum norm contractivity property* (DMNC) was analyzed for one-dimensional (1D) parabolic problems in [13, 19]. In both references the necessary and sufficient conditions were given. In the first one, the dependence on the spatial discretization was also discussed.

For 1D problems, we can deduce some other remarkable qualitative properties such as the preservation of the shape and the monotonicity of the initial function, and the sign-stability (see, e.g., [9, 14, 15, 16, 22]).

Although some sufficient conditions (and in certain cases the necessary ones as well) are known for the above-listed three main qualitative properties, the relations and the implications between them have not been revealed yet. The main goal of this paper is to establish the connections between the MP, the NP, and the MNC both for linear parabolic problems and their numerical solutions. In this paper, we will show the implications

$$(D)NP \Longleftrightarrow (D)MP \Longrightarrow (D)MNC;$$

that is, the MP is equivalent to the NP property and both imply the MNC. We give necessary and sufficient conditions for the adequate (qualitatively correct) discrete models. Furthermore, we also give some useful sufficient conditions.

The paper is organized as follows. In section 2, we discuss the qualitative properties of continuous problems. In section 3, we give the linear algebraic form of the finite difference and finite element discretization of the investigated problem. We prove the existence and the uniqueness of the numerical solution. In section 4, we construct a one-step iterative process, we define its qualitative properties, and we formulate necessary and sufficient conditions of their preservation. In section 5, we apply the results of section 4 to the discretizations given in section 3. In section 6, some sufficient conditions are listed in order to guarantee the numerical qualitative properties a priori. In the last section, we demonstrate our results on numerical examples.

For simplicity, we denote zero matrices and zero vectors by the symbol $\mathbf{0}$, whose size is always chosen according to the context. The ordering relation for vectors and matrices is always meant elementwise.

2. Qualitative properties of linear parabolic problems. Let Ω and $\partial\Omega$ denote, respectively, a bounded domain in $\mathbb{R}^d$ ($d \in \mathbb{N}^+$) and its boundary and we

introduce the sets

$$Q_\tau = \Omega \times (0,\tau), \qquad Q_{\bar\tau} = \Omega \times (0,\tau], \qquad \Gamma_\tau = (\partial\Omega \times [0,\tau]) \cup (\Omega \times \{0\})$$

for any arbitrary positive number τ. For some fixed number $T > 0$, we consider the linear partial differential operator

$$\mathcal{L} \equiv \frac{\partial}{\partial t} - \sum_{0<|\varsigma|\le\delta} a_\varsigma \frac{\partial^{|\varsigma|}}{\partial^{\varsigma_1} x_1 \dots \partial^{\varsigma_d} x_d} \equiv \frac{\partial}{\partial t} - \sum_{0<|\varsigma|\le\delta} a_\varsigma D^\varsigma, \tag{2.1}$$

where $\delta \ge 1, \varsigma_1, \dots, \varsigma_d$ denote nonnegative integers, $|\varsigma|$ is defined as $|\varsigma| = \varsigma_1 + \dots + \varsigma_d$ for the multi-index $\varsigma = (\varsigma_1, \dots, \varsigma_d)$, and the coefficient functions $a_\varsigma : Q_T \to \mathbb{R}$ are bounded on the set Q_T. We define the domain of the operator $\mathcal{L}$, denoted by $\operatorname{dom}\mathcal{L}$, as the space of functions $v \in C(Q_T \cup \Gamma_T)$, for which the derivatives $D^\varsigma v$ $(0 < |\varsigma| \le \delta)$ and $\partial v/\partial t$ exist in Q_T and they are bounded. It can be seen easily that $\mathcal{L}v$ is bounded on $Q_{\bar t_1}$ for each $v \in \operatorname{dom}\mathcal{L}$ and $0 < t_1 < T$. Thus $\inf_{Q_{\bar t_1}} \mathcal{L}v$ and $\sup_{Q_{\bar t_1}} \mathcal{L}v$ are finite.

Definition 2.1. *We say that the operator $\mathcal{L}$ satisfies the MP if for any function $v \in \operatorname{dom}\mathcal{L}$ the inequality*

$$\min_{\Gamma_{t_1}} v + t_1 \cdot \min\{0, \inf_{Q_{\bar t_1}} \mathcal{L}v\} \le v(\mathbf{x}, t_1) \le \max_{\Gamma_{t_1}} v + t_1 \cdot \max\{0, \sup_{Q_{\bar t_1}} \mathcal{L}v\}$$

is satisfied for all $\mathbf{x} \in \Omega$, $0 < t_1 < T$.

The following statement shows that, in case of the MP, the functions from $\operatorname{dom}\mathcal{L}$ are uniquely determined by their values on the boundary Γ_T.

Theorem 2.2. *Let $t_1 \in (0,T)$ be any arbitrary fixed number. If $\mathcal{L}$ satisfies the MP, then for any two functions $v^\star, v^{\star\star} \in \operatorname{dom}\mathcal{L}$ the relations $\mathcal{L}v^\star|_{Q_{t_1}} = \mathcal{L}v^{\star\star}|_{Q_{t_1}}$ and $v^\star|_{\Gamma_{t_1}} = v^{\star\star}|_{\Gamma_{t_1}}$ imply $v^\star|_{Q_{t_1}} = v^{\star\star}|_{Q_{t_1}}$.*

Proof. Let us choose an arbitrary number satisfying the condition $0 < t_0 < t_1$, and we consider the function $\bar v = v^\star - v^{\star\star}$. For this function the relations $\mathcal{L}\bar v|_{Q_{\bar t_0}} = 0$ and $\bar v|_{\Gamma_{t_0}} = 0$ are valid. Thus, based on the MP we have $\bar v(\mathbf{x}, t_0) = 0$ for all $\mathbf{x} \in \Omega$ and $0 < t_0 < t_1$. This completes the proof. ∎

Definition 2.3. *The operator $\mathcal{L}$ is called nonnegativity preserving when the relations $\min_{\Gamma_{t_1}} v \ge 0$ and $\mathcal{L}v|_{Q_{\bar t_1}} \ge 0$ imply $v|_{Q_{\bar t_1}} \ge 0$ for all $0 < t_1 < T$.*

Definition 2.4. *The operator $\mathcal{L}$ is called contractive in maximum norm when for all arbitrary two functions $v^\star$, $v^{\star\star} \in \operatorname{dom}\mathcal{L}$ with $\mathcal{L}v^\star|_{Q_{\bar t_1}} = \mathcal{L}v^{\star\star}|_{Q_{\bar t_1}}$ and $v^\star|_{\partial\Omega\times[0,t_1]} = v^{\star\star}|_{\partial\Omega\times[0,t_1]}$ the relation*

$$\max_{\mathbf{x}\in\bar\Omega} |v^\star(\mathbf{x}, t_1) - v^{\star\star}(\mathbf{x}, t_1)| \le \max_{\mathbf{x}\in\bar\Omega} |v^\star(\mathbf{x}, 0) - v^{\star\star}(\mathbf{x}, 0)|$$

is valid for all $0 < t_1 < T$.

The main connections between the above properties of the operator $\mathcal{L}$ are listed in the next two theorems.

Theorem 2.5. *The operator $\mathcal{L}$ defined in* (2.1) *satisfies the MP if and only if it preserves the nonnegativity.*

Proof. The necessity of the condition is trivial. In order to show the sufficiency, we choose an arbitrary function $v \in \operatorname{dom}\mathcal{L}$ and apply the operator $\mathcal{L}$ to the function $\bar v = v - \min_{\Gamma_{t_1}} v - t \cdot \min\{0, \inf_{Q_{\bar t_1}} \mathcal{L}v\}$. Clearly, $\bar v|_{\Gamma_{t_1}} \ge 0$. Moreover, we obtain that

$$\mathcal{L}\bar v|_{Q_{\bar t_1}} = (\mathcal{L}v - \min\{0, \inf_{Q_{\bar t_1}} \mathcal{L}v\})|_{Q_{\bar t_1}} \ge 0,$$

which implies that $\bar{v}$ is nonnegative on $Q_{\bar{t}_1}$ by virtue of the NP assumption. Thus the lower estimation $\min_{\Gamma_{t_1}} v + t_1 \cdot \min\{0, \inf_{Q_{\bar{t}_1}} \mathcal{L}v\} \le v(\mathbf{x}, t_1)$ is satisfied.

By choosing

$$\bar{v} = \max_{\Gamma_{t_1}} v - v + t \cdot \max\{0, \sup_{Q_{\bar{t}_1}} \mathcal{L}v\},$$

the upper bound is proved similarly. This completes the proof. □

THEOREM 2.6. *If the operator $\mathcal{L}$ defined in* (2.1) *is nonnegativity preserving, then it is contractive in maximum norm.*

Proof. Let $v^\star$ and $v^{\star\star} \in \operatorname{dom}\mathcal{L}$ be two arbitrary functions with $\mathcal{L}v^\star|_{Q_{\bar{t}_1}} = \mathcal{L}v^{\star\star}|_{Q_{\bar{t}_1}}$ and $v^\star|_{\partial\Omega\times[0,t_1]} = v^{\star\star}|_{\partial\Omega\times[0,t_1]}$. We consider the functions $\bar{v}_\pm = \zeta \pm (v^\star - v^{\star\star})$ with $\zeta = \max_{\mathbf{x}\in\bar{\Omega}} |v^\star(\mathbf{x}, 0) - v^{\star\star}(\mathbf{x}, 0)|$. For these functions, the estimations $\mathcal{L}\bar{v}_\pm|_{Q_{\bar{t}_1}} = 0 \ge 0$ and $\min_{\Gamma_{t_1}} \bar{v}_\pm \ge 0$ are true, which implies the nonnegativity of $\bar{v}_\pm$ on $Q_{\bar{t}_1}$. Thus, we have

$$\max_{\mathbf{x}\in\bar{\Omega}} |v^\star(\mathbf{x}, t_1) - v^{\star\star}(\mathbf{x}, t_1)| \le \max_{\mathbf{x}\in\bar{\Omega}} |v^\star(\mathbf{x}, 0) - v^{\star\star}(\mathbf{x}, 0)|.$$

This completes the proof. □

In what follows, we consider the initial-boundary value problem in the form

$$\mathcal{L}v = f \quad \text{in } Q_T, \tag{2.2}$$

$$v|_{\Gamma_T} = g, \tag{2.3}$$

where $g : \Gamma_T \to \mathbb{R}$, $f : Q_T \to \mathbb{R}$ are arbitrary given functions. The operator $\mathcal{L}$ is defined in (2.1). (In the usual context, $g|_{\Omega\times\{0\}}$ is the initial and $g|_{\partial\Omega\times[0,T]}$ is the boundary condition, respectively.) We are interested in finding a function $v \in \operatorname{dom}\mathcal{L}$ that satisfies equalities (2.2)–(2.3). We say that the problem (2.2)–(2.3) is nonnegativity preserving and contractive in maximum norm and satisfies the MP if the operator $\mathcal{L}$ in (2.2) possesses the same properties. According to Theorems 2.5 and 2.6, the MP is valid for the problem (2.2)–(2.3) if and only if it is nonnegativity preserving; in this case the problem is contractive in maximum norm as well. If the MP is valid for the problem, then its solution (when it exists) is unique (cf. Theorem 2.2).

In this paper we investigate the parabolic problem

$$C\frac{\partial v}{\partial t} - \nabla(\kappa \cdot \nabla v) = f, \quad (\mathbf{x}, t) \in Q_T, \tag{2.4}$$

$$v|_{\Gamma_T} = g, \tag{2.5}$$

where $C : \Omega \to \mathbb{R}$ is a known bounded function with the property $0 < C_{\min} \le C \equiv C(\mathbf{x}) \le C_{\max}$, the known bounded function $\kappa : \Omega \to \mathbb{R}$ has continuous first derivatives and fulfills the property $0 < \kappa_{\min} \le \kappa \equiv \kappa(\mathbf{x}) \le \kappa_{\max}$, the function $g : \Gamma_T \to \mathbb{R}$ is continuous on Γ_T, the function $f : Q_T \to \mathbb{R}$ is bounded in Q_T, ∇ denotes the usual nabla operator, and the solution v is sought in $C^{2,1}(Q_T \cup \Gamma_T)$.

Remark 2.7. The problem (2.4)–(2.5) is generally applied for the description of heat conduction processes, where v denotes the temperature, C is the product of the specific heat and the density, κ is the thermal conductivity, and f gives the density of heat sources. The variables $\mathbf{x}$ and t play the role of the space and time variables, respectively. Problem (2.4)–(2.5) is suitable to describe diffusion and transport phenomena as well.

We show that the problem (2.4)–(2.5) is nonnegativity preserving and contractive in maximum norm and satisfies the MP. Because (2.4)–(2.5) can be written in the form of the problem (2.2)–(2.3) dividing both sides of the equation by the positive function C (that is, $\mathcal{L} \equiv \partial/\partial t - (1/C)\nabla(\kappa\nabla)$), we have to show only the validity of the NP (see Theorems 2.5 and 2.6). The proof will be based on the next theorem.

THEOREM 2.8. *For any $t_1 \in (0,T)$ and $\mathbf{x} \in \Omega$, the solution v of the problem* (2.4)–(2.5) *satisfies the inequality*

$$\sup_{\lambda>0}\left(e^{\lambda t_1}\min\left\{\min_{\Gamma_{t_1}} ve^{-\lambda t}, \frac{1}{\lambda}\inf_{Q_{\bar{t}_1}}\frac{fe^{-\lambda t}}{C}\right\}\right) \le v(\mathbf{x},t_1) \le \inf_{\lambda>0}\left(e^{\lambda t_1}\max\left\{\max_{\Gamma_{t_1}} ve^{-\lambda t}, \frac{1}{\lambda}\sup_{Q_{\bar{t}_1}}\frac{fe^{-\lambda t}}{C}\right\}\right), \tag{2.6}$$

where $Q_{\bar{t}_1} = Q_{t_1} \cup (\Omega \times \{t_1\})$.

Proof. For any arbitrary number $\lambda > 0$ we define the function $\hat{v}(\mathbf{x},t) = v(\mathbf{x},t)e^{-\lambda t}$, where v stands for the solution of (2.4). It can be seen easily that $\hat{v} \in C(Q_T \cup \Gamma_T)$, $\hat{v}|_{\Gamma_T} = (ve^{-\lambda t})|_{\Gamma_T}$, and $\hat{v}$ satisfies the equation

$$C\frac{\partial \hat{v}}{\partial t} - \nabla(\kappa\nabla\hat{v}) + C\lambda\hat{v} = fe^{-\lambda t} \tag{2.7}$$

in Q_T. As $\hat{v}$ is continuous on $\bar{Q}_{t_1}$, it takes its maximum either on the boundary Γ_{t_1} or in $\Omega \times (0,t_1]$ at some point $(\mathbf{x}^0,t^0)$. In the first case we trivially have

$$\sup_{Q_{t_1}} \hat{v} \le \max_{\Gamma_{t_1}} \hat{v}. \tag{2.8}$$

In the second case, the relations

$$\sup_{Q_{t_1}} \hat{v} \le \hat{v}(\mathbf{x}^0,t^0),\ \frac{\partial \hat{v}}{\partial t}(\mathbf{x}^0,t^0) \ge 0,\ \frac{\partial \hat{v}}{\partial x_i}(\mathbf{x}^0,t^0) = 0,\ \frac{\partial^2 \hat{v}}{\partial x_i^2}(\mathbf{x}^0,t^0) \le 0 \tag{2.9}$$

hold for $i = 1,\dots,d$, where the last two relations imply that $\nabla(\kappa\nabla\hat{v})(\mathbf{x}^0,t^0) \le 0$. This relation, combined with the second one in (2.9) and with (2.7), results in

$$0 \le f(\mathbf{x}^0,t^0)e^{-\lambda t^0} - C(\mathbf{x}^0)\hat{v}(\mathbf{x}^0,t^0)\lambda,$$

which can be rewritten in the form

$$\hat{v}(\mathbf{x}^0,t^0) \le \frac{1}{\lambda C(\mathbf{x}^0)} f(\mathbf{x}^0,t^0)e^{-\lambda t^0} \le \sup_{Q_{\bar{t}_1}} \frac{fe^{-\lambda t}}{C\lambda}. \tag{2.10}$$

Thus, in the general case, using the upper bounds (2.8) and (2.10) we obtain the estimation

$$\hat{v}(\mathbf{x},t_1) \le \sup_{Q_{t_1}} \hat{v} \le \max\left\{\max_{\Gamma_{t_1}} \hat{v}, \sup_{Q_{\bar{t}_1}} \frac{fe^{-\lambda t}}{C\lambda}\right\}.$$

Multiplying both sides by $e^{\lambda t_1}$ and taking into account that the relation is true for all positive numbers $\lambda > 0$, we obtain the inequality on the right-hand side of (2.6). The lower bound can be proved similarly. ∎

Remark 2.9. The proof of the above theorem is based on the proof of Theorem 2.1 in [20]. Let us notice, however, that we did not confine ourselves to second order operators, and leaving the zeroth order derivative out of the expression of $\mathcal{L}$, we arrived at a stronger estimation.

THEOREM 2.10. *The problem* (2.4)–(2.5) *preserves the nonnegativity, and consequently it is contractive in maximum norm and satisfies the MP.*

Proof. The proof is based on the previous theorem. Let $t_1 \in (0,T)$ be an arbitrary number, and let us suppose that $\mathcal{L}v|_{Q_{t_1}} \equiv (f/C)|_{Q_{t_1}} \geq 0$ and $v|_{\Gamma_{t_1}} \equiv g|_{\Gamma_{t_1}} \geq 0$. Then, for any $t_0 \in (0,t_1)$, we have $(f/C)|_{Q_{\bar{t}_0}} \geq 0$ and $v|_{\Gamma_{t_0}} \geq 0$, which result in $0 \leq v(\mathbf{x},t_0)$ in view of (2.6). That is v is nonnegative in Q_{t_1}. ∎

3. Numerical models of linear parabolic problems. The two most widely used numerical methods for solving the problem (2.4)–(2.5) are the finite difference and the Galerkin finite element methods. Finite difference methods are typically applied when the solution domain Ω is relatively simple (an interval, a rectangle, or a block), while finite element methods can be used also with more complicated geometrical structures (e.g., polyhedrons). Both methods start with the discretization of the computational space $\Omega \subset \mathbb{R}^d$ in order to get a system of ordinary differential equations. This is the so-called semidiscretization. Then the system of ordinary differential equations is solved by some time-integration method, such as the well-known θ-method. In this paper we consider only the three-dimensional (3D) case; the 1D and two-dimensional (2D) cases can be derived in the same manner by omitting the corresponding terms.

3.1. Spatial semidiscretization with the finite difference method. In the case of the finite difference method, the function v is approximated at the points of a rectangular mesh defined on the rectangular domain Ω. Let us denote the interior mesh points by $P_1,\dots,P_N \in \Omega$, and the points on the boundary by $P_{N+1},\dots,P_{N+N_\partial} \in \partial\Omega$, respectively. For the sake of simplicity, we also use the notation P_{i+x} (P_{i-x}) for the grid point adjoint to P_i in positive (negative) x-direction. We also define $\bar{N} = N + N_\partial$. After denoting the semidiscrete approximation of $v(\mathbf{x},t)$ at a grid point $\mathbf{x} = P_i$ by $v_i(t)$, we can approximate (2.4) at each inner point P_i of Ω as

$$C_i \frac{\mathrm{d}v_i(t)}{\mathrm{d}t} - (v_{ixx}(t) + v_{iyy}(t) + v_{izz}(t)) = f_i(t), \quad i = 1,\dots,N. \tag{3.1}$$

Here $f_i(t)$ denotes some approximation to $f(\mathbf{x},t)$ at the point P_i (the most typical choice is $f_i(t) = f(P_i,t)$); furthermore, $v_{ixx}(t)$ approximates the derivative

$$\frac{\partial}{\partial x}\left(\kappa \frac{\partial v}{\partial x}\right)$$

of the function v at the point P_i and at the time instant t, and has the form

$$v_{ixx}(t) = \frac{2}{h_{i+x} + h_{i-x}} \left(\kappa_{i+x/2} \frac{v_{i+x}(t) - v_i(t)}{h_{i+x}} - \kappa_{i-x/2} \frac{v_i(t) - v_{i-x}(t)}{h_{i-x}} \right). \tag{3.2}$$

The distances between the points P_{i+x}, P_i and P_{i-x}, P_i are denoted by h_{i+x} and h_{i-x}, respectively. The values $\kappa_{i-x/2}$ and $\kappa_{i+x/2}$ denote the approximate values of the material parameter κ on the segments $[P_{i-x}, P_i]$ and $[P_i, P_{i+x}]$ (typically the midpoint

values), and C_i denotes the approximate value of C at the point P_i (typically $C_i = C(P_i)$ for continuous functions). The terms $v_{iyy}(t)$ and $v_{izz}(t)$ are defined similarly.

Hence the semidiscretization (3.1) and the boundary condition (2.5) result in a Cauchy problem for the system of ordinary differential equations

$$\mathbf{M}\frac{\mathrm{d}\mathbf{v}(t)}{\mathrm{d}t} + \mathbf{K}\mathbf{v}(t) = \mathbf{f}(t), \tag{3.3}$$

$$\mathbf{v}(0) = [g(P_1,0),\dots,g(P_N,0),g(P_{N+1},0),\dots,g(P_{\bar N},0)]^\top,$$

where

$$\begin{aligned}\mathbf{v}(t) &\equiv [v_1(t),\dots,v_N(t),v_{N+1}(t),\dots,v_{\bar N}(t)]^\top\\ &= [v_1(t),\dots,v_N(t),g(P_{N+1},t),\dots,g(P_{\bar N},t)]^\top,\\ \mathbf{f}(t) &\equiv [f_1(t),\dots,f_N(t)]^\top\end{aligned} \tag{3.4}$$

and $\mathbf{M}$ and $\mathbf{K}$ are sparse $N \times \bar N$ matrices. For the entries of $\mathbf{M}$ we have

$$M_{ij} = \begin{cases} C_i & \text{if } i = j,\\ 0 & \text{if } i \neq j,\end{cases} \quad i = 1,\dots,N;\ j = 1,\dots,\bar N, \tag{3.5}$$

and the entries of $\mathbf{K}$ can be computed using (3.1) and (3.2). The nonzero elements of the ith row of $\mathbf{K}$ are $K_{i,i-x}, K_{i,i+x}, K_{i,i-y}, K_{i,i+y}, K_{i,i-z}, K_{i,i+z}, K_{i,i}$, where

$$K_{i,i-x} = \frac{-2\kappa_{i-x/2}}{h_{i-x}(h_{i-x}+h_{i+x})}, \quad K_{i,i+x} = \frac{-2\kappa_{i+x/2}}{h_{i+x}(h_{i-x}+h_{i+x})}, \tag{3.6}$$

$$K^x_{i,i} = \frac{2\kappa_{i+x/2}}{h_{i+x}(h_{i-x}+h_{i+x})} + \frac{2\kappa_{i-x/2}}{h_{i-x}(h_{i-x}+h_{i+x})},$$

$K_{i,i-y}, K_{i,i+y}, K_{i,i-z}, K_{i,i+z}, K^y_{i,i}, K^z_{i,i}$ are defined similarly, and

$$K_{i,i} = K^x_{i,i} + K^y_{i,i} + K^z_{i,i}. \tag{3.7}$$

3.2. Semidiscretization with the Galerkin finite element method. In the case of the Galerkin finite element method we cover the domain Ω with the following meshes $\mathcal{T}_h$ (h is a discretization parameter): the 1D mesh consists of intervals, the 2D mesh is a so-called hybrid mesh, which is a combination of triangles and rectangles, and the 3D mesh is a tetrahedron or a block mesh. Figure 3.1 shows a 2D hybrid mesh. As before, $P_1,\dots,P_N$ denote the interior nodes of $\mathcal{T}_h$, and $P_{N+1},\dots,P_{\bar N}$ the boundary ones. Let $\phi_1,\dots,\phi_{\bar N}$ be basis functions defined as follows: each ϕ_i is required to be continuous, piecewise linear (over intervals, triangular, or tetrahedral elements) or multilinear (over rectangular or block elements), such that $\phi_i(P_j) = \delta_{ij}$, $i,j = 1,\dots,\bar N$, where δ_{ij} is Kronecker's symbol. (Multilinearity means that it is bilinear in case of rectangles and trilinear in case of blocks.) It is obvious that such basis functions have the properties

$$\phi_i \geq 0,\ i = 1,\dots,\bar N,$$

$$\sum_{i=1}^{\bar N} \phi_i \equiv 1 \ \text{ in } \bar\Omega.$$

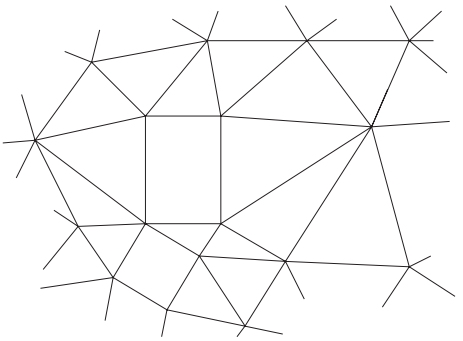

FIG. 3.1. *Hybrid mesh in two dimensions.*

We search for the semidiscrete solution of (2.4)–(2.5) in the form

$$\sum_{i=1}^{N} v_i(t)\phi_i(\mathbf{x}) + \sum_{i=1}^{N_\partial} g(P_{N+i}, t)\phi_{N+i}(\mathbf{x}).$$

Using the weak formulation of the problem, we arrive at a Cauchy problem again that has the form (3.1) with

$$\mathbf{M} = [M_{ij}]_{N\times\bar{N}}, \quad M_{ij} = \int_\Omega C(\mathbf{x})\phi_j(\mathbf{x})\phi_i(\mathbf{x})\,\mathrm{d}\mathbf{x},$$

$$\mathbf{K} = [K_{ij}]_{N\times\bar{N}}, \quad K_{ij} = \int_\Omega \kappa(\mathbf{x})\ \mathrm{grad}\phi_j(\mathbf{x})\ \mathrm{grad}\phi_i(\mathbf{x})\ \mathrm{d}\mathbf{x},$$

$$\mathbf{f}(t) = [f_i(t)]_{N\times 1}, \quad f_i(t) = \int_\Omega f(\mathbf{x}, t)\phi_i(\mathbf{x})\,\mathrm{d}\mathbf{x}$$

(see [8]). The above-defined matrices $\mathbf{M}$ and $\mathbf{K}$ are called *mass and stiffness matrices*, respectively.

3.3. Fully discretized model. To get a fully discrete numerical scheme, we choose a time-step $\Delta t > 0$. We denote the approximation to $\mathbf{v}(n\Delta t)$ by $\mathbf{v}^n$, and we set $\mathbf{f}^n = \mathbf{f}(n\Delta t)$ $(n = 0, 1, \ldots)$. The time-discretization of (3.1) with the θ-method ($\theta \in [0, 1]$ is a given parameter) can be written in the form of the systems of linear algebraic equations

$$\mathbf{M}\frac{\mathbf{v}^{n+1} - \mathbf{v}^n}{\Delta t} + \theta\mathbf{K}\mathbf{v}^{n+1} + (1-\theta)\mathbf{K}\mathbf{v}^n = \mathbf{f}^{(n,\theta)} := \theta\mathbf{f}^{n+1} + (1-\theta)\mathbf{f}^n, \tag{3.8}$$

where $n = 0, 1, \ldots$ and $\theta \in [0, 1]$ is a given parameter. Clearly, (3.8) can be rewritten as

$$(\mathbf{M} + \theta\Delta t\mathbf{K})\mathbf{v}^{n+1} = (\mathbf{M} - (1-\theta)\Delta t\mathbf{K})\mathbf{v}^n + \Delta t\ \mathbf{f}^{(n,\theta)}. \tag{3.9}$$

In what follows, the matrices $\mathbf{M} + \theta\Delta t\mathbf{K}$ and $\mathbf{M} - (1-\theta)\Delta t\mathbf{K}$ will be denoted by $\mathbf{A}$ and $\mathbf{B}$, respectively. We shall use the following partitions of the matrices and vectors:

$$\mathbf{A} = [\mathbf{A}_0|\mathbf{A}_\partial], \quad \mathbf{B} = [\mathbf{B}_0|\mathbf{B}_\partial], \quad \mathbf{v}^n = \begin{bmatrix} \mathbf{u}^n \\ \mathbf{g}^n \end{bmatrix},$$

where $\mathbf{A}_0$ and $\mathbf{B}_0$ are square matrices from $\mathbb{R}^{N\times N}$, $\mathbf{A}_\partial, \mathbf{B}_\partial \in \mathbb{R}^{N\times N_\partial}$, $\mathbf{u}^n \equiv [u_1^n, \dots, u_N^n]^\top \in \mathbb{R}^N$, and $\mathbf{g}^n \equiv [g_1^n, \dots, g_{N_\partial}^n]^\top \in \mathbb{R}^{N_\partial}$. Similar partition is used for the matrices $\mathbf{M}$ and $\mathbf{K}$. Then, iteration (3.9) can be written as

$$[\mathbf{A}_0|\mathbf{A}_\partial] \begin{bmatrix} \mathbf{u}^{n+1} \\ \mathbf{g}^{n+1} \end{bmatrix} = [\mathbf{B}_0|\mathbf{B}_\partial] \begin{bmatrix} \mathbf{u}^{n} \\ \mathbf{g}^{n} \end{bmatrix} + \Delta t\, \mathbf{f}^{(n,\theta)}. \tag{3.10}$$

The relation (3.10) defines a one-step iterative process with respect to the unknown vector $\mathbf{u}^{n+1}$.

Remark 3.1. For the finite difference method, the choice $\theta = 0$ results in an explicit scheme, due to the diagonality of $\mathbf{M}$. This is the so-called explicit Euler method. The choice $\theta = 1$ gives the so-called implicit Euler method and $\theta = 1/2$ is the Crank–Nicolson method. However, the schemes obtained by the Galerkin finite element method are always implicit for any choice of θ.

In order to guarantee the existence and the uniqueness of $\mathbf{u}^{n+1}$ in (3.10), we have to show that $\mathbf{A}_0$ is a nonsingular matrix.

THEOREM 3.2. *The matrix $\mathbf{A}_0 \in \mathbb{R}^{N\times N}$ is nonsingular for both the finite difference and the Galerkin finite element methods.*

Proof. The case of the finite difference method: Because of the relation $\mathbf{A}_0 = \mathbf{M}_0 + \theta\Delta t\mathbf{K}_0$ and the equalities in (3.6), the off-diagonal elements of $\mathbf{A}_0$ are nonpositive and the diagonal ones are positive. Moreover, considering (3.6) and (3.7) we have

$$K_{i1} + \cdots + K_{i\bar{N}} = 0 \quad (i = 1, \dots, N).$$

Thus, the estimate

$$\begin{aligned}(\mathbf{A}_0)_{i1} + \cdots + (\mathbf{A}_0)_{iN} &= C_i + \theta\Delta t(K_{i1} + \cdots + K_{iN}) \\ &\geq C_i + \theta\Delta t(K_{i1} + \cdots + K_{i\bar{N}}) = C_i \geq C_{\min} > 0\end{aligned}$$

is true $(i = 1, \dots, N)$, which shows that $\mathbf{A}_0$ is a strictly diagonally dominant matrix; hence it is nonsingular.

The case of the Galerkin finite element method: The elements of $\mathbf{A}_0$ are

$$(\mathbf{A}_0)_{ij} = \int_\Omega (C(\mathbf{x})\phi_j(\mathbf{x})\phi_i(\mathbf{x}) + \theta\Delta t\, \kappa(\mathbf{x})\, \mathrm{grad}\phi_j(\mathbf{x})\, \mathrm{grad}\phi_i(\mathbf{x}))\, \mathrm{d}\mathbf{x} \quad (i, j = 1, \dots, N).$$

The right-hand side defines a scalar product on the vector space $\mathrm{span}\{\phi_1, \dots, \phi_N\}$. Thus $\mathbf{A}_0$ is a Gram-matrix of the linearly independent functions $\phi_1, \dots, \phi_N$; hence it is nonsingular and also positive definite. ∎

Remark 3.3. It is important to notice that in the case of the finite difference method, $\mathbf{A}_0$ is a so-called M-matrix (see [1, p. 137]). This can be seen from the sign-structure and the strict diagonal dominance of $\mathbf{A}_0$. That is, in addition to the nonsingularity, $\mathbf{A}_0$ has a nonnegative inverse too. In the finite element method the nonnegativity of $\mathbf{A}_0^{-1}$ is not satisfied automatically.

4. Qualitative properties of one-step iterative models. As we mentioned in the introduction, it is a natural requirement for the numerical solution that it has to possess some basic qualitative properties. The numerical solution can be obtained by the iteration (3.10). Hence, the qualitative properties of the numerical solution will be defined as the qualitative properties of such iteration processes.

We use the denotations

$$\mathbf{e} = \mathbf{e}^{(\bar{N})},\ \mathbf{e}_0 = \mathbf{e}^{(N)},\ \mathbf{e}_\partial = \mathbf{e}^{(N_\partial)} \text{ with } \mathbf{e}^{(k)} = [1, \dots, 1]^\top \in \mathbb{R}^k.$$

4.1. Partitioned one-step (PO-) iterations. Based on the iteration (3.10), we will investigate the general one-step iteration

$$[\mathbf{A}_0|\mathbf{A}_\partial]\begin{bmatrix}\mathbf{u}^{n+1}\\ \mathbf{g}^{n+1}\end{bmatrix} = [\mathbf{B}_0|\mathbf{B}_\partial]\begin{bmatrix}\mathbf{u}^{n}\\ \mathbf{g}^{n}\end{bmatrix} + \mathbf{h}^n,\ n=0,1,\dots, \tag{4.1}$$

or equivalently

$$\mathbf{A}\mathbf{v}^{n+1} = \mathbf{B}\mathbf{v}^n + \mathbf{h}^n,\ n=0,1,\dots. \tag{4.2}$$

Here $\mathbf{h}^n \equiv [h_1^n,\dots,h_N^n]^\top \in \mathbb{R}^N$ and all matrices and vectors have the same dimension as in the previous section. We emphasize that now they are assumed to be *arbitrary* with the only restriction being that the matrix $\mathbf{A}_0$ is nonsingular. Iteration (4.2) is called a *partitioned one-step iteration* or shortly PO-iteration.

4.2. Qualitative properties of PO-iterations. Comparing the form

$$\mathbf{u}^{n+1}-\mathbf{u}^n = (\mathbf{A}_0^{-1}\mathbf{B}_0-\mathbf{I})\mathbf{u}^n - \mathbf{A}_0^{-1}\mathbf{A}_\partial\mathbf{g}^{n+1} + \mathbf{A}_0^{-1}\mathbf{B}_\partial\mathbf{g}^n + \mathbf{A}_0^{-1}\mathbf{h}^n$$

of (4.1) with (2.4), we define the equivalents of the qualitative properties for the PO-iterations.

DEFINITION 4.1. *A PO-iteration is said to satisfy the discrete nonnegativity preservation property (DNP) if the inequality* $\mathbf{u}^{n+1} \ge \mathbf{0}$ *is valid for all nonnegative vectors* $\mathbf{u}^n, \mathbf{g}^n, \mathbf{g}^{n+1}$, *and* $\mathbf{A}_0^{-1}\mathbf{h}^n$.

THEOREM 4.2. *A PO-iteration satisfies the DNP if and only if the inequalities* $-\mathbf{A}_0^{-1}\mathbf{A}_\partial \ge \mathbf{0}$ *and* $\mathbf{A}_0^{-1}\mathbf{B} \ge \mathbf{0}$ *hold.*

Proof. The statement follows directly from the following equivalent form of (4.1):

$$\mathbf{u}^{n+1} = -\mathbf{A}_0^{-1}\mathbf{A}_\partial\mathbf{g}^{n+1} + \mathbf{A}_0^{-1}\mathbf{B}\begin{bmatrix}\mathbf{u}^{n}\\ \mathbf{g}^{n}\end{bmatrix} + \mathbf{A}_0^{-1}\mathbf{h}^n,\quad n=0,1,\dots. \tag{4.3}$$

∎

DEFINITION 4.3. *A PO-iteration is said to satisfy the discrete maximum norm contractivity property (DMNC) if for all vectors* $\hat{\mathbf{u}}^n, \tilde{\mathbf{u}}^n, \mathbf{g}^n, \mathbf{g}^{n+1}, \mathbf{h}^n$ *the relation*

$$\|\hat{\mathbf{u}}^{n+1}-\tilde{\mathbf{u}}^{n+1}\|_\infty \le \|\hat{\mathbf{u}}^n-\tilde{\mathbf{u}}^n\|_\infty \tag{4.4}$$

is valid, where $\hat{\mathbf{u}}^{n+1}$ *and* $\tilde{\mathbf{u}}^{n+1}$ *are computed from* (4.1) *by setting* $\mathbf{u}^n = \hat{\mathbf{u}}^n$ *and* $\mathbf{u}^n = \tilde{\mathbf{u}}^n$.

THEOREM 4.4. *A PO-iteration satisfies the DMNC if and only if* $\|\mathbf{A}_0^{-1}\mathbf{B}_0\|_\infty \le 1$.

Proof. We apply (4.3) with the two different vectors $\mathbf{u}^n = \hat{\mathbf{u}}^n$ and $\mathbf{u}^n = \tilde{\mathbf{u}}^n$. Hence we obtain

$$\hat{\mathbf{u}}^{n+1}-\tilde{\mathbf{u}}^{n+1} = \mathbf{A}_0^{-1}\mathbf{B}_0(\hat{\mathbf{u}}^n-\tilde{\mathbf{u}}^n).$$

The relation (4.4) is valid for all $\hat{\mathbf{u}}^n$ and $\tilde{\mathbf{u}}^n$ vectors if and only if $\|\mathbf{A}_0^{-1}\mathbf{B}_0\|_\infty \le 1$. ∎

DEFINITION 4.5. *A PO-iteration is said to satisfy the discrete maximum-minimum principle (DMP) if the relation*

$$\begin{aligned}\min\{\mathbf{u}^n,\mathbf{g}^n,\mathbf{g}^{n+1}\} + \min\{0,\mathbf{A}_0^{-1}\mathbf{h}^n\}\\ \le u_i^{n+1} \le \max\{\mathbf{u}^n,\mathbf{g}^n,\mathbf{g}^{n+1}\} + \max\{0,\mathbf{A}_0^{-1}\mathbf{h}^n\}\end{aligned} \tag{4.5}$$

is valid for each choice $\mathbf{u}^n, \mathbf{g}^n, \mathbf{g}^{n+1}, \mathbf{h}^n$, $i=1,\dots,N$, *and* $n \ge 0$. *(The* max *and* min *are understood elementwise.)*

Now some necessary conditions are listed for the DMP.

LEMMA 4.6. *For PO-iterations the DMP implies the DNP.*

Proof. Let us suppose that the DMP is valid for the PO-iteration and $\mathbf{u}^n$, $\mathbf{g}^n$, $\mathbf{g}^{n+1}$, $\mathbf{A}_0^{-1}\mathbf{h}^n$ are nonnegative vectors. Then the left inequality in (4.5) shows the nonnegativity of $\mathbf{u}^{n+1}$. ∎

LEMMA 4.7. *If a PO-iteration satisfies the DMP, then* $\mathbf{Ae} = \mathbf{Be}$.

Proof. Choosing the vectors $\mathbf{h}^n = \mathbf{0}$, $\mathbf{u}^n = \mathbf{e}_0$, $\mathbf{g}^n = \mathbf{g}^{n+1} = \mathbf{e}_\partial$, (4.5) results in $\mathbf{u}^{n+1} = \mathbf{e}_0$. That is, $\mathbf{Ae} = \mathbf{Be}$ in view of (4.1), which completes the proof. ∎

LEMMA 4.8. *For PO-iterations the DNP and condition* $\mathbf{Ae} = \mathbf{Be}$ *imply the DMNC.*

Proof. The DNP ensures the relations $-\mathbf{A}_0^{-1}\mathbf{A}_\partial \geq \mathbf{0}$ and $\mathbf{A}_0^{-1}\mathbf{B} \geq \mathbf{0}$. Hence

$$\mathbf{A}_0^{-1}\mathbf{B}_0\mathbf{e}_0 \leq \mathbf{A}_0^{-1}\mathbf{Be} = \mathbf{A}_0^{-1}\mathbf{Ae} = \mathbf{A}_0^{-1}\mathbf{A}_0\mathbf{e}_0 + \mathbf{A}_0^{-1}\mathbf{A}_\partial\mathbf{e}_\partial \leq \mathbf{e}_0.$$

This shows that $\|\mathbf{A}_0^{-1}\mathbf{B}_0\|_\infty \leq 1$; that is, the DMNC is valid. ∎

Remark 4.9. Because the DMP implies both the DNP and condition $\mathbf{Ae} = \mathbf{Be}$, the DMP implies the DMNC.

LEMMA 4.10. *If a PO-iteration satisfies the DNP and condition* $\mathbf{Ae} = \mathbf{Be}$*, then* $\mathbf{0} \leq -\mathbf{A}_0^{-1}\mathbf{A}_\partial\mathbf{e}_\partial \leq \mathbf{e}_0$.

Proof. The DNP ensures the relations $-\mathbf{A}_0^{-1}\mathbf{A}_\partial \geq \mathbf{0}$ and $\mathbf{A}_0^{-1}\mathbf{B} \geq \mathbf{0}$. Thus, the relation $\mathbf{0} \leq -\mathbf{A}_0^{-1}\mathbf{A}_\partial\mathbf{e}_\partial$ is trivial. Let us multiply the equality $\mathbf{Ae} = \mathbf{A}_0\mathbf{e}_0 + \mathbf{A}_\partial\mathbf{e}_\partial = \mathbf{Be}$ by the matrix $\mathbf{A}_0^{-1}$, and let us express the term $-\mathbf{A}_0^{-1}\mathbf{A}_\partial\mathbf{e}_\partial$. We obtain the inequality

$$\mathbf{0} \leq -\mathbf{A}_0^{-1}\mathbf{A}_\partial\mathbf{e}_\partial = \mathbf{e}_0 - \mathbf{A}_0^{-1}\mathbf{Be} \leq \mathbf{e}_0$$

by virtue of the nonnegativity of the vector $\mathbf{A}_0^{-1}\mathbf{Be}$. This completes the proof. ∎

4.3. Qualitatively adequate one-step iterations. We have seen in the previous section that the properties

$$\begin{array}{ll} \text{(P1)} & \mathbf{A}_0^{-1}\mathbf{B} \geq \mathbf{0}, \\ \text{(P2)} & -\mathbf{A}_0^{-1}\mathbf{A}_\partial \geq \mathbf{0}, \\ \text{(P3)} & \mathbf{Ae} = \mathbf{Be} \end{array}$$

are necessary conditions of the DMP for PO-iterations. In the next theorem, we prove that they are sufficient conditions as well. In order to make the expressions much simpler, we introduce some notation. We define the values

$$v_{\min}^n = \min\{\mathbf{v}^n\}, \quad v_{\max}^n = \max\{\mathbf{v}^n\},$$

and vectors

$$\mathbf{v}_{\max}^n = v_{\max}^n\mathbf{e} \in \mathbb{R}^{\bar{N}}, \quad \mathbf{v}_0^n = v_{\max}^n\mathbf{e}_0 \in \mathbb{R}^N, \quad \mathbf{v}_\partial^n = v_{\max}^n\mathbf{e}_\partial \in \mathbb{R}^{N_\partial}.$$

THEOREM 4.11. *A PO-iteration satisfies the DMP if and only if it satisfies the conditions* (P1)–(P3).

Proof. The necessity of the condition follows directly from Theorem 4.2 and Lemmas 4.6 and 4.7. To show the sufficiency, we first prove the inequality on the right-hand side in (4.5). It follows from (P3) that $\mathbf{Bv}_{\max}^n = \mathbf{Av}_{\max}^n$. Using (P1), we

obtain

$$\begin{aligned}
\mathbf{u}^{n+1} &= -\mathbf{A}_0^{-1}\mathbf{A}_\partial\, \mathbf{g}^{n+1} + \mathbf{A}_0^{-1}\mathbf{B}\mathbf{v}^n + \mathbf{A}_0^{-1}\mathbf{h}^n \\
&\le -\mathbf{A}_0^{-1}\mathbf{A}_\partial\, \mathbf{g}^{n+1} + \mathbf{A}_0^{-1}\mathbf{B}\mathbf{v}^n_{\max} + \mathbf{A}_0^{-1}\mathbf{h}^n \\
&= -\mathbf{A}_0^{-1}\mathbf{A}_\partial\, \mathbf{g}^{n+1} + \mathbf{A}_0^{-1}\mathbf{A}\mathbf{v}^n_{\max} + \mathbf{A}_0^{-1}\mathbf{h}^n \\
&\le -\mathbf{A}_0^{-1}\mathbf{A}_\partial\, \mathbf{g}^{n+1} + \mathbf{A}_0^{-1}[\mathbf{A}_0|\ \mathbf{A}_\partial]\mathbf{v}^n_{\max} + \max\{0, \mathbf{A}_0^{-1}\mathbf{h}^n\}\mathbf{e}_0 \\
&= -\mathbf{A}_0^{-1}\mathbf{A}_\partial\, \mathbf{g}^{n+1} + \mathbf{v}_0^n + \mathbf{A}_0^{-1}\mathbf{A}_\partial\mathbf{v}_\partial^n + \max\{0, \mathbf{A}_0^{-1}\mathbf{h}^n\}\mathbf{e}_0.
\end{aligned}$$

Regrouping the above inequality, we get

$$\mathbf{u}^{n+1} - \mathbf{v}_0^n - \max\{0, \mathbf{A}_0^{-1}\mathbf{h}^n\}\mathbf{e}_0 \le -\mathbf{A}_0^{-1}\mathbf{A}_\partial \left(\mathbf{g}^{n+1} - \mathbf{v}_\partial^n\right).$$

Hence, for the ith coordinate of both sides we obtain

$$\begin{aligned}
u_i^{n+1} - v^n_{\max} - \max\{0, \mathbf{A}_0^{-1}\mathbf{h}^n\} &\le \sum_{j=1}^{N_\partial} \left(\left(-\mathbf{A}_0^{-1}\mathbf{A}_\partial\right)_{ij} \cdot \left(g_j^{n+1} - v^n_{\max}\right)\right) \\
&\le \left(\sum_{j=1}^{N_\partial} \left(-\mathbf{A}_0^{-1}\mathbf{A}_\partial\right)_{ij} \right) \cdot \max\{0, \max_j\{g_j^{n+1} - v^n_{\max}\}\} \\
&\le \max\{0, \max_j\{g_j^{n+1} - v^n_{\max}\}\},
\end{aligned}$$

where we applied property (P2) and Lemma 4.10. Finally, expressing u_i^{n+1} we obtain the required inequality. The inequality on the left-hand side of (4.5) can be proved similarly. This completes the proof. ∎

Theorem 4.11, Lemma 4.6, and Remark 4.9 yield that a PO-iteration possesses all three qualitative properties (DMP, DNP, and DMNC) if and only if it satisfies the properties (P1)–(P3). Hence the iterative process (4.1) with the properties (P1)–(P3) is called a *qualitatively adequate one-step iteration*.

5. Qualitative properties of the numerical solutions of parabolic problems. We apply the results, which were formulated for arbitrary PO-iterations, of the previous section for the fully discretized numerical model (3.9). Based on Theorem 3.2, the finite difference and Galerkin finite element methods can be written in the form of a PO-iteration with the choice $\mathbf{h}^n = \Delta t \mathbf{f}^{(n,\theta)}$. This is why the qualitative properties (DMP, DNP, and DMNC) of the numerical methods can be defined in the same manner as those of the PO-iterations.

THEOREM 5.1. *Relation* (P3) *holds both for the finite difference and finite element methods.*

Proof. Owing to the relation $\mathbf{A} - \mathbf{B} = (\mathbf{M} + \theta\Delta t\mathbf{K}) - (\mathbf{M} - (1-\theta)\Delta t\mathbf{K}) = \Delta t\mathbf{K}$, property (P3) is equivalent to the equality $\mathbf{K}\mathbf{e} = \mathbf{0}$. For the finite difference method the statement follows directly from the equalities in (3.6). For the finite element method, we have

$$\begin{aligned}
(\mathbf{K}\mathbf{e})_i &= \sum_{j=1}^{\bar N} K_{ij} = \sum_{j=1}^{\bar N} \int_\Omega \kappa(\mathbf{x}) \cdot \mathrm{grad}\phi_j(\mathbf{x}) \cdot \mathrm{grad}\phi_i(\mathbf{x})\, \mathrm{d}\mathbf{x} \\
&= \int_\Omega \kappa(\mathbf{x}) \cdot \mathrm{grad} \left(\sum_{j=1}^{\bar N} \phi_j(\mathbf{x}) \right) \cdot \mathrm{grad}\phi_i(\mathbf{x})\, \mathrm{d}\mathbf{x} \\
&= \int_\Omega \kappa(\mathbf{x}) \cdot \mathrm{grad}1 \cdot \mathrm{grad}\phi_i(\mathbf{x})\, \mathrm{d}\mathbf{x} = 0. \qquad \blacksquare
\end{aligned}$$

THEOREM 5.2. *For the finite difference and Galerkin finite element models of the problem* (2.4)–(2.5), *the implications*

$$DNP \Longleftrightarrow DMP \Longrightarrow DMNC$$

are valid. That is the DMP and DNP are equivalent and both imply the DMNC.

Proof. The first part of the statement follows from Theorem 4.2, Lemma 4.6, and Theorem 5.1. The second one is a consequence of Lemma 4.8. □

COROLLARY 5.3. *A finite difference or a Galerkin finite element method for the problem* (2.4)–(2.5) *is qualitatively adequate if and only if it satisfies properties* (P1)–(P2), *that is, if the method preserves the nonnegativity.*

Remark 5.4. In view of the results of [13], there exist parameter choices when the finite difference or the finite element method is contractive in maximum norm, but it does not preserve the nonnegativity.

Remark 5.5. Let us notice that our results can be applied not only to the finite difference and the Galerkin finite element method but also to any numerical method that can be written in the form of a PO-iteration.

6. Sufficient a priori conditions of the qualitative properties. The necessary and sufficient conditions in the previous sections cannot be checked easily without computing the elements of the matrices. More precisely, the theorems do not state anything explicitly about the choice of the mesh and the choice of the parameters θ and Δt (which define the elements of the matrices $\mathbf{M}$ and $\mathbf{K}$) in order to guarantee the qualitative properties. Our aim is to find conditions that can be checked a priori and imply the DNP / DMP. Then, these conditions, according to Theorem 5.2, imply the qualitative adequateness of the discrete models. In this section, we will give some a priori conditions. In order to present a complete work for researchers involved in scientific computing, we also added two corresponding results from the literature.

THEOREM 6.1. *The Galerkin finite element solution of problem* (2.4)–(2.5), *combined with the θ-method in the time discretization, satisfies the DMP if the conditions*

$$\begin{aligned}
&\text{(S1)} \quad K_{ij} \le 0, \quad i \ne j,\ i = 1, \dots, N,\ j = 1, \dots, \bar{N},\\
&\text{(S2)} \quad A_{ij} = M_{ij} + \theta \Delta t K_{ij} \le 0, \quad i \ne j,\ i = 1, \dots, N,\ j = 1, \dots, \bar{N},\\
&\text{(S3)} \quad B_{ii} = M_{ii} - (1-\theta)\Delta t K_{ii} \ge 0, \quad i = 1, \dots, N,
\end{aligned}$$

are fulfilled. The DMP is valid for the finite difference solution of the problem if (S3) *holds.*

Proof. We have to show that under the assumptions of the theorem the properties $(P1)$–$(P2)$ hold. For the finite difference method $\mathbf{A}_0^{-1} \ge \mathbf{0}$ and conditions (S1) and (S2) are fulfilled automatically. This implies property (P2). Condition (S3) implies that the main diagonal of $\mathbf{B}$ is nonnegative. The off-diagonal of $\mathbf{B}$ is also nonnegative because the off-diagonal of $\mathbf{K}$ is nonpositive. Hence, by virtue of $\mathbf{A}_0^{-1} \ge \mathbf{0}$, we obtain property (P1).

In the case of the finite element method, relations (S1) and (S3) yield $\mathbf{B} \ge \mathbf{0}$. Condition $\mathbf{A}_\partial \le \mathbf{0}$ follows from (S2). $\mathbf{A}_0$ is a Gram-matrix, and because of (S2), the off-diagonal elements of $\mathbf{A}_0$ are nonpositive. This implies that $\mathbf{A}_0$ is an M-matrix (see [1, p. 134]); thus $\mathbf{A}_0^{-1} \ge \mathbf{0}$. These facts yield (P1) and (P2), and thus the DMP. □

In the expressions of this section, for the sake of simplicity, fractions with zero denominators are understood as infinity.

6.1. Conditions for the finite difference method. Let us consider the finite difference method, where, because of the relations (3.5)–(3.7), condition (S3) is valid for 1D problems if

$$C_i - (1-\theta)\Delta t \left(\frac{2\kappa_{i+x/2}}{(h_{i+x}+h_{i-x})h_{i+x}} + \frac{2\kappa_{i-x/2}}{(h_{i+x}+h_{i-x})h_{i-x}} \right) \geq 0, \quad i = 1, \ldots, N.$$

The condition

$$\Delta t \leq \frac{C_{\min} h_{\min}^2}{2\kappa_{\max}(1-\theta)}$$

guarantees the validity of the above relations, where $h_{\min}$ is the minimal spatial step size in the mesh and $\kappa_{\max} = \sup_{\mathbf{x}\in\Omega}\{\kappa(\mathbf{x})\}$. In two dimensions, similarly, we obtain the sufficient condition

$$\Delta t \leq \frac{C_{\min} h_{\min}^2}{4\kappa_{\max}(1-\theta)},$$

and in three dimensions

$$\Delta t \leq \frac{C_{\min} h_{\min}^2}{6\kappa_{\max}(1-\theta)}.$$

The above results can be summarized as follows.

THEOREM 6.2. *The DMP is always satisfied for the implicit Euler ($\theta = 1$) finite difference method. For other finite difference methods, the DMP can be guaranteed by the condition*

$$\Delta t \leq \frac{C_{\min} h_{\min}^2}{2d\kappa_{\max}(1-\theta)} \quad (\theta \neq 1)$$

(d is the dimension of Ω).

Remark 6.3. For the explicit Euler method, Theorem 6.2 yields the condition

$$\Delta t \leq \frac{C_{\min} h_{\min}^2}{2d\kappa_{\max}},$$

and for the Crank–Nicolson method we obtain

$$\Delta t \leq \frac{C_{\min} h_{\min}^2}{d\kappa_{\max}}.$$

We remark that for 1D problems on uniform meshes of step-size h, with constant material parameters (C_0, κ_0), the necessary and sufficient condition of the DMP is [6]

$$\Delta t \leq \frac{C_0 h^2}{2\kappa_0(1-\theta)}.$$

6.2. Conditions for the finite element method. For finite element methods, condition (S1) is generally guaranteed by some geometrical requirements for the mesh. Moreover, conditions (S2) and (S3) can be achieved by some lower and upper bounds for the time-step.

6.2.1. Finite element method in one dimension. Computing the elements of the stiffness matrix, we can check that the off-diagonal elements are nonpositive, and thus condition (S1) is satisfied. Computing additionally the elements of the mass matrix we obtain that (S2) and (S3) are valid if

$$\frac{C_{\max}h_{\max}^2}{6\theta\kappa_{\min}} \le \Delta t \le \frac{C_{\min}h_{\min}^2}{3(1-\theta)\kappa_{\max}}.$$

Thus we obtain the next theorem.

THEOREM 6.4. *The Galerkin finite element solution of the* 1*D problem* (2.4)–(2.5) *with piecewise linear elements satisfies the DMP if*

$$\frac{C_{\max}h_{\max}^2}{6\theta\kappa_{\min}} \le \Delta t \le \frac{C_{\min}h_{\min}^2}{3(1-\theta)\kappa_{\max}}, \quad \theta \in [\theta_l, 1)\,,$$

$$\frac{C_{\max}h_{\max}^2}{6\kappa_{\min}} \le \Delta t, \quad \theta = 1,$$

where $\theta_l = C_{\max}\kappa_{\max}h_{\max}^2/(C_{\max}\kappa_{\max}h_{\max}^2 + 2C_{\min}\kappa_{\min}h_{\min}^2)$.

Let us notice that unlike in the case of finite difference methods, the above theorem yields a lower bound for the time-step. This is a general phenomenon for finite element methods. This lower bound exists not only in sufficient conditions but in necessary and sufficient conditions, too. This is shown by the next theorem obtained in [6] for the DNP.

THEOREM 6.5. *The Galerkin finite element solution of the* 1*D problem* (2.4)–(2.5) *with piecewise linear elements on uniform grid and with constant material parameters satisfies the DMP if and only if the relations*

$$\frac{C_0h^2}{6\theta\kappa_0} \le \Delta t \le \frac{C_0h^2}{3(1-\theta)\kappa_0}, \quad \theta \in [1/3, 1)\,,$$

$$\frac{C_0h^2}{6\kappa_0} \le \Delta t, \quad \theta = 1,$$

hold.

6.2.2. Finite element method in two dimensions. In two dimensions we apply the hybrid mesh in the spatial discretization. On triangular elements linear basis functions are used, and on rectangular elements bilinear basis functions are used.

Let us consider a hybrid mesh $\mathcal{T}_h$. Let us define the number

$$\sigma_T = \min\{\cot\alpha_1, \cot\alpha_2, \cot\alpha_3\}$$

for each triangle T of the mesh, where α_1, α_2, and α_3 denote the angles of the triangle. Let us define $\sigma = \min_{T\in\mathcal{T}_h}\sigma_T$. Furthermore, let us introduce the value

$$\mu_R = \frac{2\min^2\{a,b\} - \max^2\{a,b\}}{ab}$$

for each rectangle R, where a and b denote the edges of the rectangle. Let us define $\mu = \min_{R\in\mathcal{T}_h}\mu_R$. The hybrid mesh $\mathcal{T}_h$ is said to be of strictly compact type if $\sigma > 0$

and $\mu > 0$. The condition $\sigma > 0$ means that each angle of the triangles in the mesh is of acute type, and $\mu > 0$ means that the longer edges of the rectangles are not greater than $\sqrt{2}$ times the shorter ones. The main result of [8] is formulated as follows.

THEOREM 6.6. *The Galerkin finite element solution of the 2D problem* (2.4)–(2.5) *using linear/bilinear basis functions on a hybrid mesh of strictly compact type satisfies the DMP if*

$$\frac{C_{\max}}{6\,\theta\,\kappa_{\min}\,\min\{\frac{\mu}{3\lambda^{\#}_{\max}},\frac{\sigma}{\lambda^{\triangle}_{\max}}\}} \le \Delta t \le \frac{C_{\min}}{9\,(1-\theta)\,\kappa_{\max}\,\max\{\frac{\gamma^{\#}_{\max}}{3\lambda^{\#}_{\min}},\frac{\gamma^{\triangle}_{\max}}{4\,\lambda^{\triangle}_{\min}}\}} \tag{6.1}$$

is fulfilled, where

$$\gamma^{\triangle}_{\max} = \max_{T\in\mathcal{T}_h}\left\{\frac{l^2_{\max}}{\operatorname{area}(T)}\right\},\quad \gamma^{\#}_{\max} = \max_{R\in\mathcal{T}_h}\left\{\frac{a^2+b^2}{\operatorname{area}(R)}\right\},$$

$$\lambda^{\triangle}_{\min} = \min_{T\in\mathcal{T}_h}\operatorname{area}(T),\ \lambda^{\triangle}_{\max} = \max_{T\in\mathcal{T}_h}\operatorname{area}(T),$$

$$\lambda^{\#}_{\min} = \min_{R\in\mathcal{T}_h}\operatorname{area}(R),\ \lambda^{\#}_{\max} = \max_{R\in\mathcal{T}_h}\operatorname{area}(R).$$

The symbols $\operatorname{area}(T)$ *and* $\operatorname{area}(R)$ *denote the area of the triangle* T *and the rectangle* R*, respectively.* $l_{\max}$ *is the length of the longest edge in* T*.*

Thus, for strictly compact meshes, the off-diagonal elements of the stiffness matrix are nonpositive; hence condition (S1) is fulfilled. Relation (6.1) implies the conditions (S2) and (S3).

Remark 6.7. For purely rectangular meshes, we have the weaker lower bound for Δt in the form

$$\Delta t \ge \frac{C_{\max}\lambda^{\#}_{\max}}{3\,\theta\,\kappa_{\min}\,\mu}.$$

For a square mesh with step-size h and with constant material parameters a sufficient condition of the DMP is

$$\frac{C_0 h^2}{3\theta\kappa_0} \le \Delta t \le \frac{C_0 h^2}{6(1-\theta)\kappa_0},\quad \theta\in[2/3,1).$$

(In case of $\theta = 1$ the upper bound disappears.) This shows that in this case the DMP can be guaranteed only (with our sufficient condition) for methods with $\theta \ge 2/3$.

6.2.3. Finite element method in three dimensions. In three dimensions we investigate two different meshes. The first one is the rectangular mesh and the second one is the tetrahedral mesh. Let us start with the first one, where trilinear basis functions are applied. With simple but tedious calculations we can compute the elements of the mass and stiffness matrices, and we can notice that the condition (S1) can be valid only for uniform meshes. Moreover, we can observe that condition (S2) cannot be guaranteed, because there are also positive off-diagonal elements in the matrix $\mathbf{A}$. Thus $\mathbf{A}_0$ is not an M-matrix in this case. We have to guarantee the nonnegative matrix inverse by means of other tools. In [12], the so-called Lorenz-criterion [21] was applied.

THEOREM 6.8. *The Galerkin finite element solution of the* 3*D problem* (2.4)–(2.5) *using trilinear basis functions on a uniform rectangular mesh with constant material parameters satisfies the DMP if*

$$\frac{(259+13\sqrt{409})C_0h^2}{36\theta\kappa_0} \le \Delta t \le \frac{C_0h^2}{9(1-\theta)\kappa_0}, \quad \theta \in [0.9924, 1),$$

$$14.4975\frac{C_0h^2}{\kappa_0} \approx \frac{(259+13\sqrt{409})C_0h^2}{36\kappa_0} \le \Delta t, \quad \theta = 1.$$

For tetrahedral meshes the DMP was discussed in [11]. We will recall this result. Let us consider a tetrahedral mesh $\mathcal{T}_h$ of the solution domain Ω, and define the number σ_T for each tetrahedron T of $\mathcal{T}_h$ as $\sigma_T = \min\{\cos\beta_1, \dots, \cos\beta_6\}$, where $\beta_1, \dots, \beta_6$ denote the angles made by any two faces of the tetrahedron T. If each angle is less than $\pi/2$, then $\sigma_T > 0$. Let us set $\sigma = \min_{T\in\mathcal{T}_h} \sigma_T$. If $\sigma > 0$, then the mesh is called of strictly acute type.

THEOREM 6.9. *The Galerkin finite element solution of the* 3*D problem* (2.4)–(2.5) *with constant material parameters using linear basis functions on a strictly acute type tetrahedral mesh satisfies the DMP if the condition*

$$\frac{C_0p_{\max}^2}{20\sigma\theta\kappa_0} \le \Delta t \le \frac{C_0p_{\min}^2}{10(1-\theta)\kappa_0}$$

holds, where $p_{\min}$ *and* $p_{\max}$ *denote the minimal and maximal perpendicular length in the mesh.*

7. Numerical examples. In this section, we demonstrate the validity of our results on some numerical examples in one, two, and three dimensions. For the sake of simplicity, we suppose that the problem (2.4)–(2.5) describes a heat conduction process (see Remark 2.7). The material parameters are set to be constant one. Furthermore, we suppose that there are no heat sources or sinks present in the computational domain.

7.1. Examples in one dimension. In the first example, the 1D heat equation is solved with the Crank–Nicolson ($\theta = 1/2$) finite difference method on the interval [0,1]. We are interested in the approximation of the temperature at the time-level $t = 1$. We apply an equidistant mesh with the spatial step-size $h = 1/30$. The temperatures at the left and right boundaries are given by the functions $\mu_1(t) = 1$ and $\mu_2(t) = 0$, respectively. A nonnegative approximation of a continuous and nonnegative initial function can be seen in Figure 7.1. Using this initial grid-function, the approximations of the temperature at the time-level $t = 1$ can be seen in Figure 7.2. The figures on the left-hand and right-hand sides were obtained using the time-steps $\Delta t = 1/11$ and $\Delta t = 1/31$, respectively. These approximations show that neither the NP nor the MP is valid for the above chosen time-steps. In order to get a qualitatively correct approximation, Δt has to satisfy the condition

$$\Delta t \le \frac{h^2}{2(1-\theta)} = \frac{1}{900}$$

(cf. (6.3)). This bound shows that Δt was chosen to be too large in the previous numerical example. Naturally, the above upper bound is the necessary and sufficient

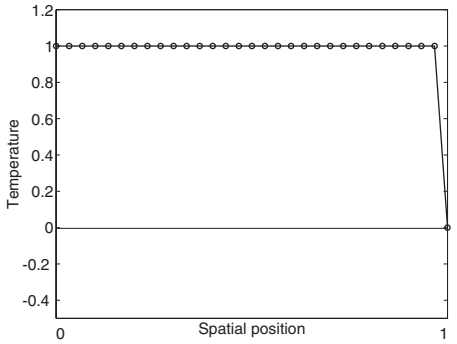

FIG. 7.1. *Approximation of the initial function.*

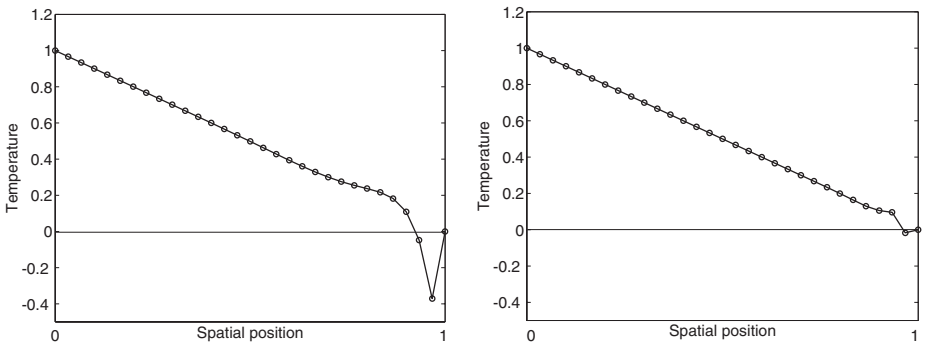

FIG. 7.2. *Approximations at the time-level* $t = 1$ *with the time-steps* $\Delta t = 1/11$ *and* $\Delta t = 1/31$.

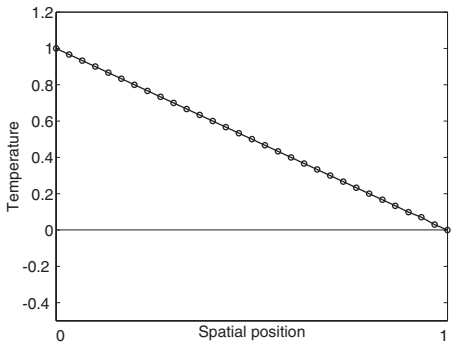

FIG. 7.3. *Approximation at the time-level* $t = 1$ *with the time-step* $\Delta t = 1/51$.

condition of the DMP (DNP) for all initial functions. This means that for certain initial functions, larger time-steps can also result in a qualitatively correct numerical solution. For example, Figure 7.3 shows a nonnegative approximation with the time-step $\Delta t = 1/51\,1/900$ at the time-level $t = 1$.

One can think that by choosing the time-step to be sufficiently small we can obtain a qualitatively adequate solution. The next example shows that this is generally not

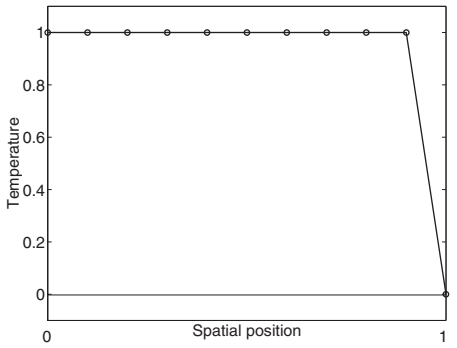

FIG. 7.4. *Approximation of the initial function.*

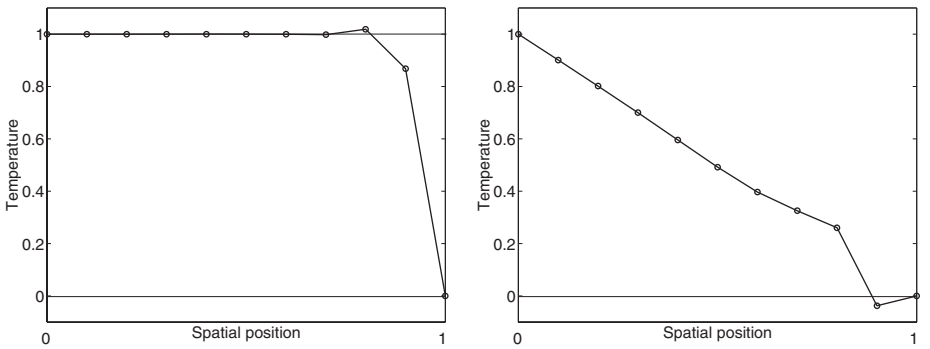

FIG. 7.5. *Approximations at the time-levels* $t = 1/1000$ *and* $t = 1$ *applying the time-steps* $\Delta t = 1/100000$ *and* $\Delta t = 1/9$*, respectively.*

the case. Namely, as we have shown, for finite element methods not only upper but also lower bounds do exist.

Let us solve the 1D heat equation with the Galerkin finite element method on the interval [0,1] using the Crank–Nicolson ($\theta = 1/2$) scheme in the time integration. Let us suppose that the initial function is a nonnegative continuous function and it takes on values only from the interval $[0, 1]$. The discretization of the initial function is carried out on an equidistant mesh with $h = 1/10$ (Figure 7.4). The temperatures at the left and right boundaries are given by the functions $\mu_1(t) = 1$ and $\mu_2(t) = 0$, respectively. The numerical solutions calculated at the time-levels $t = 1/1000$ and $t = 1$ with the time steps $\Delta t = 1/100000$ and $\Delta t = 1/9$ can be seen, respectively, on the left-hand and right-hand sides of Figure 7.5. Both numerical solutions are qualitatively incorrect. Namely, the MP is broken because the solutions have nonnegative values and values that are greater than one. In order to obtain qualitatively adequate solutions we can apply Theorem 6.4, which states that the MP is valid providing that Δt is chosen according to the relation $1/300 = 0.0033 \leq \Delta t \leq 0.0067 = 2/300$. In Figure 7.6, the numerical solution is calculated at the time-level $t = 1$ with the time-step $\Delta t = 0.005$, which falls into the above interval. As it was expected, the solution has values only from the interval $[0, 1]$.

In the third example we solve again the 1D heat equation on the interval [0,1]. The temperature at the right-hand side is equal to one ($\mu_2(t) = 1$), while the temperature

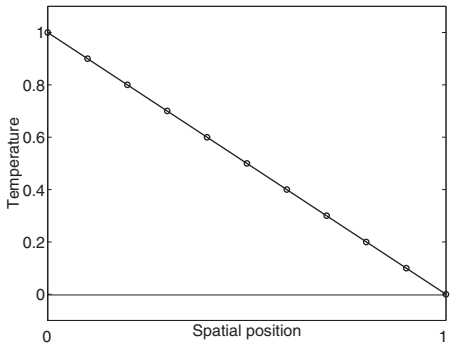

FIG. 7.6. *Approximation at the time-level* $t = 1$ *with the time-step* $\Delta t = 0.005$.

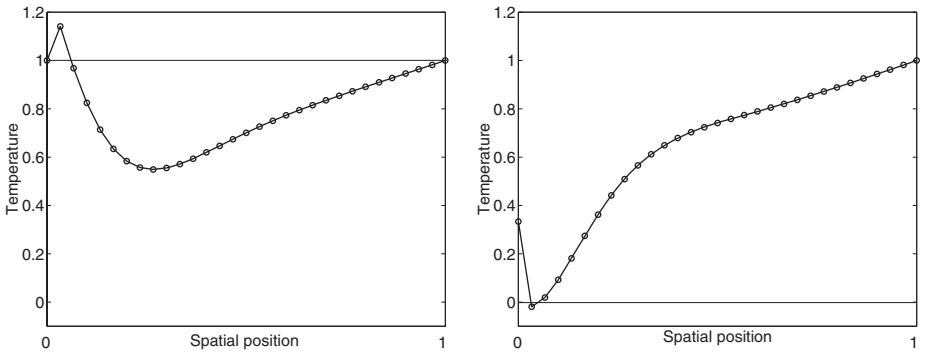

FIG. 7.7. *Approximations at the time-levels* $t = 300/30$ *and* $t = 302/30$ *applying the time-step* $\Delta t = 1/30$.

at the left-hand side changes periodically according to the function

$$\mu_1(t) = 2|-\mathrm{frac}(100t/2) + 0.5|$$

(frac$(100t/2)$ means the fractional part of $100t/2$). Naturally, $0 \le \mu_1(t) \le 1$. Let the initial function be the constant one function in $(0, 1)$.

Our aim is to approximate the solution at the time-level $t = 10$. We apply the finite difference method on the equidistant mesh with $h = 1/30$. We choose the Crank–Nicolson method for the time-integration with $\Delta t = 1/30$. The numerical solution is depicted on the left-hand side of Figure 7.7. Two time-levels further, that is, at $t = 302/30$, we obtain the solution shown on the right-hand side of the same figure. In the case of the numerical solutions shown in Figure 7.7, the MP is broken. The time-step was chosen to be too large (cf. (6.3)). We can observe that the numerical solution will be periodic after the transient period ($t > 3$) (the boundary condition is periodic and the effect of the initial function disappears). The approximations shown in Figure 7.7 appear regularly in every third time-step. Thus the numerical example demonstrates that it is possible that the qualitatively bad behavior of the numerical solution does not disappear while increasing the time-level at which the numerical solution is computed.

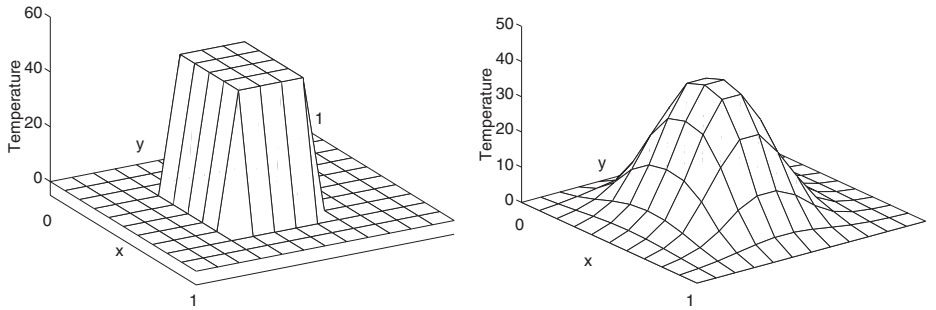

FIG. 7.8. *Approximation of the initial function. Approximation at the first time-level with* $\Delta t = 0.01$.

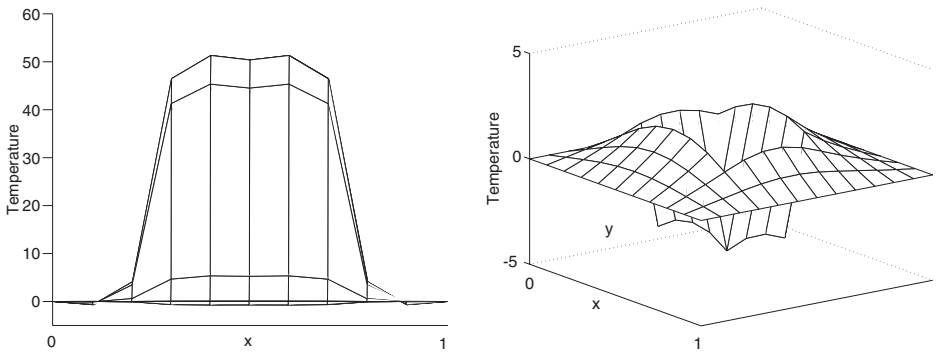

FIG. 7.9. *Approximations at the first time-level with* $\Delta t = 0.0005$ *and* $\Delta t = 0.5$.

7.2. Examples in two dimensions. We solve the 2D heat equation on the unit square $[0,1]\times[0,1]$ with homogeneous boundary condition. We apply the finite element method with bilinear elements on a rectangular mesh with $\Delta x = 1/10$ and $\Delta y = 1/12$. In the time-discretization the θ-method is used with $\theta = 0.9$ and with a fixed time-step Δt. A nonnegative discretization of a nonnegative and continuous initial function can be seen on the left-hand side of Figure 7.8. With this discretization, however, the approximation of the temperature at the first time-level has negative value both for $\Delta t = 0.0005$ and $\Delta t = 0.5$ (see the left-hand and right-hand sides in Figure 7.9). We remark that, with $\Delta t = 0.0005$, the numerical solution has negative components at the first 11 time-levels, while with $\Delta t = 0.5$, the solution has negative components at every time-level. Choosing the time-step to be $\Delta t = 0.01$, we obtain an adequate approximation (right-hand side of Figure 7.8).

We can calculate the necessary and sufficient condition of the DNP using Theorem 4.2, which results in the condition $0.0050 \le \Delta t \le 0.0155$. This shows that the chosen time-steps were too small or too large. A sufficient condition obtained applying the results of Theorem 6.6 is $0.0066 \le \Delta t \le 0.0136$.

In the second example, we apply the finite difference method with $\theta = 0.9$ for the initial approximation seen on the left-hand side of Figure 7.8. The results at the

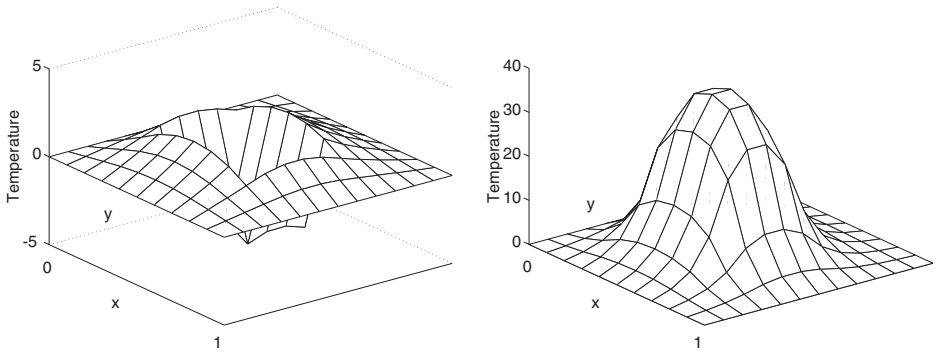

FIG. 7.10. *Approximations at the first time-level with* $\Delta t = 0.5$ *and* $\Delta t = 0.01$.

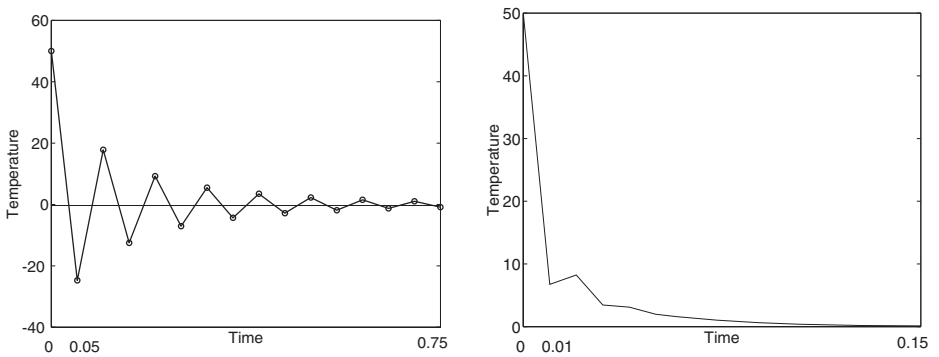

FIG. 7.11. *Approximations of the temperature at the point* $(5/10, 4/10, 4/10)$ *using the time-steps* $\Delta t = 0.05$ *and* $\Delta t = 0.01$.

first time-levels with $\Delta t = 0.5$ and $\Delta t = 0.01$ can be seen, respectively, on the left-hand and right-hand sides of Figure 7.10. In order to obtain a qualitatively adequate numerical approximation, it is enough to choose Δt to be not greater than 0.017 (Theorem 6.2).

7.3. Example in three dimensions. In order to give a 3D example, we solve the homogeneous heat equation on the unit cube. We apply the finite difference method with the Crank–Nicolson time-integration. The spatial discretization is performed with an equidistant mesh, where $\Delta x = \Delta y = \Delta z = 1/10$. The approximation of a continuous nonnegative initial function is zero in every grid point excepting 27 grid points in the middle of the region, where the temperature is approximated by 50. The approximations of the temperature at the point $(5/10, 4/10, 4/10)$ using the time-steps $\Delta t = 0.05$ and $\Delta t = 0.01$ can be seen in Figure 7.11. The time-step $\Delta t = 0.05$ results in negative temperatures, which contradicts the NP property. Theorem 6.2 gives a sufficient condition of the nonnegativity, namely, Δt must be not greater than $1/300$.

8. Conclusions. In this paper, we have shed light on the connections between the main qualitative properties of parabolic partial differential equations and their numerical solution methods. We have found that the MP, the NP, and the MNC are equivalent properties for the continuous problem, but this is not the case when we

consider the finite difference or Galerkin finite element solutions of the problem. In this case, the MP is equivalent to the NP, and the MNC yields a weaker condition as this property is implied by the properties mentioned earlier. Thus, to achieve a qualitatively adequate method, we have to apply an NP method, which can be guaranteed by the sufficient conditions of Theorem 6.1 and by its special cases listed in section 6.

Acknowledgments. The authors thank the referees for reading the manuscript thoroughly. All of their suggestions, especially the ones regarding the inclusion of demonstrative numerical tests, contributed to the improvement of the paper.

ITERATIVE VALIDATION OF EIGENSOLVERS: A SCHEME FOR IMPROVING THE RELIABILITY OF HERMITIAN EIGENVALUE SOLVERS*

JAMES R. McCOMBS† AND ANDREAS STATHOPOULOS†

Abstract. Iterative eigenvalue solvers for large, sparse matrices may miss some of the required eigenvalues that are of high algebraic multiplicity or tightly clustered. Block methods, locking, a posteriori validation, or simply increasing the required accuracy are often used to avoid missing or to detect a missed eigenvalue, but each has its own shortcomings in robustness or performance. To resolve these shortcomings, we have developed a postprocessing algorithm, *iterative validation of eigensolvers* (IVE), that combines the advantages of each technique. IVE detects numerically multiple eigenvalues among the approximate eigenvalues returned by a given solver, adjusts the block size accordingly, then calls the given solver using locking to compute a new approximation in the subspace orthogonal to the current approximate eigenvectors. This process is repeated until no additional missed eigenvalues can be identified. IVE is general and can be applied as a wrapper to any Rayleigh–Ritz-based, Hermitian eigensolver. Our experiments show that IVE is very effective in computing missed eigenvalues even with eigensolvers that lack locking or block capabilities, although such capabilities may further enhance robustness. By focusing on robustness in a postprocessing stage, IVE allows the user to decouple the notion of robustness from that of performance when choosing the block size or the convergence tolerance.

Key words. deflation, locking, block, Krylov methods, multiple eigenvalues

1. Introduction.

Sparse, iterative eigenvalue solvers are effective at computing the extremal eigenvalues of large, Hermitian matrices or matrices represented as functions [17, 7, 28, 27]. However, iterative methods may miss some of the desired eigenvalues if these are of high algebraic multiplicity or are tightly clustered. Moreover, certain initial guesses, eigenvalue distributions, and preconditioning can cause eigenvalues to converge out of the expected order and thus to be missed. Some techniques have been developed to improve robustness, i.e., to avoid missing eigenvalues or to detect any missed ones, but a robust and automated process that combines the advantages of each technique has yet to be investigated.

A few a posteriori techniques have been used to deal with missed eigenpairs. Sylvester's matrix inertia [11] is one technique that can be used to determine how many eigenvalues of a Hermitian matrix exist within a particular interval. Although this technique has enabled the development of robust eigenvalue software [13], it requires the LDL^T factorization of the matrix, which can be prohibitively expensive for large, sparse matrices, or even impossible if the matrix is represented as a function. In such cases, practitioners may call the solver again with a random initial guess to obtain an additional eigenvector in the orthogonal complement of the current set of converged approximations, hopefully identifying a missed eigenpair.

Locking and block iterations are two techniques that attempt to reduce the number of eigenvalues missed *during* the iterative process. Locking [4, 31, 18] is performed by freezing converged eigenvector approximations (locked vectors) and keeping current and future vectors in the search space orthogonal to them. The search space can then approximate other eigenpairs without duplicating the locked ones. Alternatively, solvers may be implemented in a nonlocking way [19, 33], where converged eigenvectors keep participating in the search space, thereby improving their accuracy. Regardless of implementation, locking a set of a priori known eigenvectors can be performed outside a solver. Locking can be effective in obtaining more than one eigenvector belonging to a multiple eigenvalue, especially with Krylov methods. It also allows for a smaller active search space, which reduces iteration costs, and this has made it popular with with many preconditioned or non-Krylov solvers with more expensive iterations [4, 29]. Whether locking delivers the purported robustness depends significantly on the implementation details, and typically the most robust implementation may not be the most efficient.

Block iterative methods [27, 3, 26, 37, 25, 36, 13] that extend the subspace by k vectors per iteration, where k is the block size, are a more robust alternative to locking. With appropriate initial guesses, the block Lanczos method with block size k will find all k eigenvectors of a multiple eigenvalue [24]. Although not guaranteed in general, this property is observed in other methods as well. Block methods can also result in better cache utilization and improved performance if a fine-tuned implementation is available. However, block methods are not without drawbacks. Excessively large block sizes can increase the number of matrix-vector multiplications and result in more frequent restarts, thereby slowing convergence.

Locking and blocking can be combined to improve the robustness of iterative eigensolvers [5, 10, 2, 20]. Still, the resulting robustness depends on the problem solved and the parameters chosen by the user. What makes this choice difficult is the conflicting requirements between robustness and performance. A lower than required convergence threshold is less likely to miss eigenvalues but it takes more time. Moreover, the choice of a block size that optimizes simultaneously cache performance, convergence, and robustness is not possible to know a priori. Our approach in this paper is to let the user choose the most efficient parameters as default, and to provide a postprocessing technique that corrects any robustness shortcomings, and only when these are needed. This way, we decouple the issue of robustness from that of performance (cache or convergence).

Our goal is not to provide another Hermitian eigensolver but to develop a robust detection algorithm that uses any given solver in a methodical way to identify whether the requirements posed by the user have been met by the solver. Borrowing a term from software engineering, we call our algorithm *iterative validation of eigensolvers* (IVE), as it does not verify whether the approximations are correct but rather adjusts the solver to find the correct approximations. IVE works in conjunction with any Rayleigh–Ritz-based Hermitian eigenvalue solver. The IVE algorithm accepts as input and locks the converged eigenvector approximations. If a block solver is available, IVE adjusts the block size based on the largest numerical multiplicity found and calls the solver again so that any missed eigenvalues in the orthogonal complement of the locked vectors can be computed. Any missed eigenvalues detected by IVE are locked out and the process is repeated until no additional missed eigenvalues are computed. Although the structure of the IVE algorithm is general, we apply it only to Hermitian eigenproblems where the monotonic convergence of eigenvalues facilitates a robust detection of missed eigenvalues.

We have used our IVE to wrap several well-known eigensolvers. The solvers may differ substantially in their ability to use locking or blocking efficiently and robustly, but they invariably miss eigenvalues. Our results show that IVE restores robustness in several pathologically hard cases. Moreover, running the solver through default parameters followed by a certain IVE configuration improves performance, thus demonstrating the desired decoupling of performance and robustness.

In section 2, we discuss why eigensolvers miss eigenvalues and the available techniques for increasing robustness. In section 3, we describe in detail the IVE algorithm. In section 4, we present results using IVE on a variety of solvers. Throughout the paper we assume that we seek the lowest nev eigenvalues $\tilde{\lambda}_i$ and eigenvectors $\tilde{x}_i$, $i = 1, \ldots, nev$, of a sparse, Hermitian matrix A.

2. Reasons behind missing eigenvalues and current approaches. A large arsenal of sparse Hermitian eigenvalue solvers is available, some based on Krylov methods, others on nonlinear optimization, preconditioning, and a host of other underlying principles [32]. Most of these methods employ the Rayleigh–Ritz (RR) minimization to extract their approximations from a search space. The eigenvalue and eigenvector approximations are called Ritz values and Ritz vectors, respectively. For Hermitian eigenproblems, the Ritz values minimize the Rayleigh quotient over the search space, thus leading to a monotonic convergence toward the required eigenvalues.

Despite their individual strengths, solvers can miss some of the required extreme eigenvalues. Three, often interrelated, reasons are (a) the presence of multiple or highly clustered eigenvalues, (b) the out-of-order convergence of some eigenvalues, and (c) a starting vector that is (almost) deficient in certain required eigenvector components.

It is well known that in exact arithmetic Krylov methods cannot compute more than one eigenvector belonging to a multiple eigenvalue. Krylov methods produce the next vector in the search space as $r = p(A)v_0$, where v_0 is the starting vector and $p(A)$ is the characteristic polynomial of the Lanczos tridiagonal matrix [27]. If a multiple eigenvalue λ_i and one of its corresponding eigenvectors have already been found, then $p(\lambda_i) = 0$ and r contains no components in the kernel: $\mathrm{Null}(A - \lambda_i I)$. In practice, floating-point arithmetic introduces noise toward these directions, allowing their eventual computation. To allow the solver enough time to amplify the missing eigencomponents, a low convergence tolerance must be required. Otherwise, a more interior eigenpair may converge first as one of the nev smallest ones. A similar situation may occur with non-Krylov methods, as these use the (possibly preconditioned) residual to expand the search space. When the Rayleigh quotient in the residual is an exact multiple eigenvalue, the residual is devoid of kernel components. Although preconditioning may reintroduce some kernel components, more interior eigenpairs may already be close to convergence, causing multiple eigenvalues to be missed.

Clustered eigenvalues present similar difficulties as multiple ones. This is not surprising because, until the solver has resolved an eigenvalue to an error that is smaller than its distance from a nearby eigenvalue, it views both eigenvalues as multiple and could miss one if larger tolerances are specified. The slow convergence of solvers toward clustered eigenvalues exacerbates the problem.

More generally, eigenvalues are missed when an interior eigenvalue converges before the solver has identified the existence of an outer one. In Krylov methods this is not the expected order of convergence, causing robustness problems to solvers that are based on the assumption that the nev smallest eigenvalues will be found first. The assumption, although usually true, does not hold in general. As shown recently [16],

eigenvalue distributions exist for which Krylov methods converge to the eigenvalues in the middle of the spectrum first and to the extreme ones last. In practice, smaller order reversals may be observed, which can cause eigenvalues to be missed.

The out-of-order convergence is more frequently observed with non-Krylov methods that use preconditioning or solve approximately a correction equation to speed up convergence [7, 29, 23]. For example, consider a matrix A, whose absolute smallest eigenvalues are required, and the generalized Davidson method using a preconditioner $M \approx A^{-1}$. Because M and A do not share the same eigenvectors, the convergence benefits from M are not necessarily greater for eigenvalues closest to zero, thus yielding an arbitrary convergence order. For methods that solve a correction equation at every step the choice of shift in the equation strongly biases the order in which eigenvalues converge. Moreover, fast convergence implies that even small biases of the starting vector toward interior eigendirections may lead to misconvergence. Davidson-type methods also use various targeting schemes [33], i.e., which Ritz vector is improved at every step, directly affecting the order in which eigenvalues converge. In floating point arithmetic, targeting effects are observed even without preconditioning [22, 35].

2.1. Current approaches. To increase confidence in the computed eigenpairs, practitioners typically ask for more accuracy than needed. Although beneficial in many cases, in general we may not know the accuracy that is sufficient for resolving multiple eigenvalues or avoiding out-of-order convergence. Also, this approach may be unnecessarily expensive, especially when a very low tolerance is used to find a large number of eigenvalues of which only a few would have been missed with a larger tolerance. Finally, the problem with higher multiplicities in Krylov methods persists.

Another common strategy is to compute more eigenpairs than required. This works if the reversals in the order of convergence are localized, e.g., the tenth smallest eigenvalue converges before the ninth, but not before the second. In general, we do not know how many more eigenpairs to compute, so the strategy can be unnecessarily expensive. Most important, it still may not find multiple or clustered eigenpairs.

Deflation of converged eigenpairs is commonly used in many eigensolvers so that more eigenpairs can be obtained without repeating the already computed ones. Locking is the preferred form of deflation because of its numerical stability [27, 4]. When an eigenvector converges, it is extracted from the search space and all current and future vectors of the search space are kept orthogonal to that (locked) vector. Locked vectors are inactive otherwise, they do not participate in the RR (as future Ritz vectors should not have any components in them), and therefore they are not modified further. Computationally, the smaller active search space reduces the costs of the RR and restarting phases of eigensolvers, more so when a large number of eigenpairs are sought. This is one of the reasons that locking is preferred to non-locking implementations for subspace iteration and Jacobi–Davidson-type methods [5, 29].

Locking provides also a more reliable means of computing the invariant spaces of multiple eigenvalues, especially with Krylov methods. Assume that a subset X of the invariant subspace associated with λ has been computed and locked. This is equivalent to calling the solver with the deflated operator $A|_{X^\perp}$, in which all the eigenvalues associated with X are absent. Unlike the polynomial deflation $p(A)v_0$ in Krylov methods which removes all the invariant subspace of λ from the vector iterates, locking removes only the computed part of $\mathrm{Null}(A - \lambda I)$. More eigenvectors of λ can then be obtained. This deflation behavior is not restricted only to Krylov methods. Finally, locking also speeds up the convergence to any missed, single eigenvalues which are

amidst other converged ones. In the deflated operator such eigenvalues are better isolated and therefore are easier to find. However, even with locking, misconvergence can still occur if some tightly clustered or multiple eigenpairs converge out of order. Moreover, not all solvers implement locking, and when they do, their implementation details and thus robustness may vary. For example, locking can be implemented transparently to the solver if we use the deflated operator in the matrix-vector multiplication, but the solver must return the converged eigenpairs before they are locked. Alternatively, some solvers implement locking as part of the orthogonalization phase. We discuss these issues further in the next section.

Block methods are usually more effective in computing multiple eigenvalues. As long as the k initial guesses in the block contain sufficient components in the direction of the eigenvectors associated with the multiple eigenvalue, then block Krylov methods are guaranteed to find at least k of the multiple values [24]. Moreover, more uniform convergence of the block vectors is observed, reducing the likelihood of out-of-order misconvergence. Blocking is known to improve robustness in all iterative methods, but the effects are more emphasized in Krylov methods [12]. Block methods also improve cache performance with larger k [8], seemingly offering a panacea to all problems.

Despite the better cache utilization, robustness comes at a cost in execution time. Although the number of iterations decreases, the overall number of matrix-vector operations (and thus flops) performed is usually higher than their single-vector counterparts [14]. Especially with spectra that are easily computed, block methods tend to require close to k times more matrix-vector operations than single-vector methods, completely canceling any caching benefits. Additionally, the number of iterations may also increase if k is too large relative to the maximum basis size. This would cause very frequent restarts impairing the convergence of most methods; this is apparent in some experiments later in this paper. When k equals the maximum basis size, the solver reverts to subspace iteration, losing the subspace acceleration [32]. In general, an optimal choice for k must ensure appropriate cache utilization, robustness, and the smallest possible increase in flops. Except for caching which depends on the architecture, none of the other variables are known ahead of time. In particular, the k needed to detect all the required eigenvectors is not known, and even if it were, it could conflict with the optimal choice for cache performance and convergence. Finally, unlike locking, blocking can be used only if implemented by the available solver.

We conclude our discussion with the importance of the initial guess. In all the aforementioned techniques, a critical assumption is that the initial vector has sufficient components in the desired directions. In lack of better information, a random vector is typically the best initial guess. Yet, as the iterative process progresses, certain required directions may be diminished or removed as in the case of Krylov methods and multiple eigenvalues. A possibility is to insert a random vector in the search space or in the block, replacing an eigenpair that converges. This can be performed trivially in (Jacobi–)Davidson or subspace iteration methods, but techniques have also been proposed for the implicitly restarted Lanczos method [31, 30]. Still, the newly introduced directions may not be amplified fast enough to prevent out-of-order convergence of an interior eigenpair which was almost converged before the insertion of the random vector. A drastic solution would be to dispense with the whole search space after an eigenpair converges and restart the solver anew with a random guess. A related approach that does not completely get rid of the search space is suggested in [21]. Based on our discussion on locking, a newly rebuilt search space would offer the best possible robustness. However, it would also be very slow, especially if no eigenvalues were going to be missed.

A recurring theme is the dichotomy between robustness and performance. To achieve robustness, solvers would have to make extreme choices on parameters such as block size and tolerance that may impair performance. In the following section we present our postprocessing approach to validating the parameters of a given solver that are required to achieve robustness.

3. Iterative validation of eigensolvers. Our proposed IVE algorithm is implemented as a wrapper around any existing sparse, iterative, Hermitian eigensolver that utilizes the RR minimization procedure. IVE automates the process of computing eigenvalues missed by the solver, by combining as many of the techniques mentioned in section 2.1 as the solver implements. In other words, IVE is not a solver, nor does it compute eigenvalues. IVE merely identifies difficulties in the computed spectrum and sets locked vectors, initial guesses, and block size appropriately so that the chosen eigensolver may compute any missed eigenvalues on its own. In this sense, it is similar to the validation process of a software engineering cycle, where a software is modified appropriately (different solver parameters) to meet the customer requirements (which eigenpairs to find), rather than verifying whether the software meets the specifications (produces converged eigenpairs). Therefore, the measures of performance and robustness achieved by IVE can only be in reference to the underlying solver. Also, by being a postprocessing algorithm, IVE may be switched off if no validation is needed.

The enabling property for IVE is that the Ritz values of RR-based Hermitian eigensolvers converge monotonically, if their Ritz vectors are retained in the search space during restarts or truncations. Once a Ritz value becomes smaller than a converged eigenvalue, we are sure that a previously undetected eigenvalue exists. Although Newton eigensolver schemes can be derived without RR, most current algorithms and software incorporate it, so our assumption is not restrictive in practice.

Assume the solver has returned an initial set of nev converged Ritz pairs (λ_i, x_i), where $\lambda_i \leq \lambda_{i+1}$, $i = 1, \ldots, nev - 1$. The IVE algorithm analyzes the converged λ_i and the norms of their residuals, $r_i = Ax_i - \lambda_i x_i$, to determine an appropriate block size. IVE then calls the solver with new initial guesses, using the converged $X = \{x_i\}$ as locked vectors, in an attempt to find any missed eigenvalues. An eigenvalue is a missed eigenvalue if it is smaller than the largest locked eigenvalue λ_{nev}. If it is, then its eigenvector replaces the locked eigenvector x_{nev} in the set of locked vectors. The IVE algorithm then repeats an analysis of the block size and proceeds as before. IVE works also with solvers that do not provide locking or blocking. First, we discuss some issues on locking and how to choose a block size. Then we present the IVE algorithm, describing how it chooses initial guesses and how many additional eigenpairs it finds.

3.1. Locking variants. One way to compute eigenvectors orthogonal to the set X is for the solver to provide a mechanism to lock (orthogonalize against) a set of externally provided vectors [20, 1]. This feature is a relatively simple extension to the orthogonalization procedure that most solvers employ. It is also numerically stable because the orthogonalization procedure should guarantee that no components of X appear in the search space. In this case, IVE simply passes X to the solver. Note that a solver that locks against an externally provided X does not have to implement locking internally for the eigenpairs it computes.

When a solver does not provide the above external locking feature, an alternative is to provide all the converged X together with a random vector as initial guesses to the solver and ask for a few more eigenpairs. This works with many solvers such as (Jacobi–)Davidson, subspace iteration, or methods where X can be provided as part

of the initial block, but it does not work with Lanczos algorithms. In addition, the solver must accommodate a large enough search space, and all X eigenvectors have to be rechecked and possibly modified.

A third alternative is to use explicit deflation, by calling the solver not with the matrix A, but with a function that implements the action of the operator:

$$(I - XX^T)(A - \sigma I). \tag{3.1}$$

The preconditioner may be deflated in a similar way as shown in [28]. The shift σ plays an important role. If $\sigma = 0$ and the smallest eigenvalues of A are positive, the eigenvalues of (3.1) associated with X are zero and thus they are still the smallest. In exact arithmetic this is equivalent to the external locking above, and no X components should appear in the search space. In floating point, however, when new vectors are orthogonalized against the search space inside any solver, they may lose their orthogonality against X. As X is not available within the solver, orthogonality cannot be recovered through reorthogonalization. Thus, components of X will start to emerge in the RR, and their zero eigenvalues will be recomputed.

The role of σ is to shift the spectrum so that zero is far from the smallest eigenvalues, ideally in the middle or at the other end of the spectrum. Then, the X components that emerge in the search space will be in the unwanted part of the spectrum and they will not be chosen by RR (purged internally [18]). When explicit locking is necessary, we have used $\sigma = \|A\|_F/\sqrt{n}$ as a lower bound to the largest eigenvalue of positive spectra, where $\|A\|_F$ is the Frobenius norm and n the dimension of A. Other shifts can also be used, if estimates of λ_n are known [27]. This technique yields significant autonomy to IVE, not depending on the locking features of the solver.

3.2. Determining block sizes. Assume that a block eigensolver is available. Our theoretical premise is that a block size equal to the largest multiplicity should be sufficient to resolve any problems. The IVE algorithm selects such a block size based on the largest "numerical multiplicity" observed in the converged Ritz pairs.

Let δ_i be an error bound and $[\lambda_i - \delta_i, \lambda_i]$ the error interval corresponding to the Ritz value λ_i. Because the matrix is Hermitian, $\tilde{\lambda}_i \leq \lambda_i$. Depending on the eigenvalue distribution and on the size of the user-specified tolerance, the error intervals associated with the Ritz values may overlap. Two Ritz values whose error intervals overlap are *numerically multiple*. This means that we cannot distinguish between the two with certainty at this accuracy level. It is possible for three or more Ritz values to be numerically multiple, but this requires a more general definition. The Ritz values $\{\lambda_i, i \in \{i_1, i_2, \ldots, i_k\}\}$ are *numerically multiple* if and only if $[\lambda_i - \delta_i, \lambda_i]$ overlaps with $[\lambda_j - \delta_j, \lambda_j]$ for all $i, j \in \{i_1, i_2, \ldots, i_k\}$.

Sharp bounds on the δ_i are well known when the approximations are computed through the RR procedure [24]. Let $\tilde{\lambda}$ be the single eigenvalue closest to a Ritz value λ, and let r be the residual corresponding to λ. The following inequality holds:

$$|\tilde{\lambda} - \lambda| \leq \delta = \min\left(\|r\|_2, \frac{\|r\|_2^2}{\min\left(|\tilde{\lambda}_i - \lambda|,\ \tilde{\lambda}_i \neq \tilde{\lambda}\right)}\right). \tag{3.2}$$

At convergence (after the solver returns), the upper bound δ in (3.2) can be estimated by substituting the Ritz value closest to λ for $\tilde{\lambda}_i$. At that time, this is the best available estimate. Note that the bound can be influenced by the inaccuracy in the Ritz values only if the estimated gap is larger than $\|r\| \leq Tol$. However, in that case

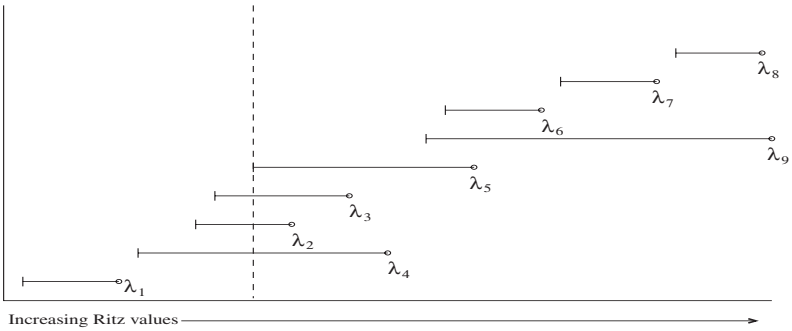

FIG. 3.1. *Sample distribution of converged Ritz values and their associated error intervals. The maximum algebraic numerical multiplicity in this example is four because a point of maximum overlap, indicated by the dashed vertical line, crosses four error intervals. The rest of the eigenvalues have multiplicities* $\lambda_1(1), \lambda_2(4), \lambda_3(4), \lambda_4(4), \lambda_5(4), \lambda_6(3), \lambda_7(2), \lambda_8(2), \lambda_9(3)$.

the computed Ritz values are separated by more than $\|r\|$ and therefore cannot be numerically multiple.

Let the *algebraic numerical multiplicity*, m_i, of a Ritz value λ_i be defined as the size of the largest set of Ritz values that include λ_i and are numerically multiple. Thus, an algebraic numerical multiplicity is an upper bound to the algebraic multiplicity of an eigenvalue, and it becomes equal to it when the $\delta_i \to 0$.

A robust choice for block size can be the maximum m_i taken over all Ritz values. The rationale is that other required eigenvalues may have been missed that have the same multiplicity. Although this works well for small m_i, for large m_i it is highly uncommon that the eigenvalue with the maximum m_i is still missing half its actual multiplicity, making this a pessimistic choice. In addition, the block size should not become too large relative to the maximum size of the search space, depending on the solver. For example, for LOBPCG [15] the block size must be a third of the basis size; Lanczos and Davidson solvers work better when the block size is much smaller than the basis size. Because of these external to IVE factors, or because some information about the problem may be known (multiplicity or cluster size), the user may put a maximum cap on the block size. We emphasize that a cap based on the underlying solver and its maximum basis size does not reduce robustness, because for larger block sizes that solver's own robustness and convergence would deteriorate. Also, blocking is just one of the robustness techniques that IVE employs.

Computing the maximum algebraic numerical multiplicity is equivalent to finding a "point of maximum overlap," i.e., a point that has the largest number of error intervals overlapping it. It can be shown that there will always be a point of maximum overlap at one of the endpoints of the intervals [6]. Figure 3.1 shows an example distribution of Ritz values and their associated error intervals. Figure 3.2 gives an algorithm, MaxAlgNumMult, for computing the maximum m_i in $O(nev^2)$. Interestingly, the p_i in the algorithm do not correspond to the m_i for all i, yet the maximum m_i is computed correctly. A more efficient, $O(nev \log_2 nev)$ time algorithm exists, but its implementation is involved. Moreover, as $nev \ll n$ and RR already requires $O(nev^3)$ time, the execution time of our algorithm is negligible, obviating the use of the lower complexity algorithm. To our knowledge, this is the first algorithm to find the maximum multiplicity in a set of approximate eigenpairs.

3.3. The IVE algorithm. The IVE algorithm given in Figure 3.3 first computes the residual norms of the converged Ritz vectors (step 4). This step is not required

ALGORITHM. MaxAlgNumMult(λ, r, nev).
1. Compute δ_i the error estimate from (3.2) corresponding to λ_i.
2. MaxAlgNumMult = 0
3. lowerBound(i) = $\lambda_i - \delta_i$, $i = 1, \ldots, nev$
   Let p_i be the number of overlapping intervals at endpoint $\lambda_i - \delta_i$
4. **for** $i = 1, nev$
5. $p_i = 0$
6. **for** $j = 1, nev$
7. **if** (lowerBound(i) $\geq$ lowerBound(j) **and** lowerBound(i) $\leq \lambda_j$)
8. $p_i = p_i + 1$
9. **end**
10. MaxAlgNumMult = **max**(MaxAlgNumMult, p_i)
11. **end**

FIG. 3.2. *Algorithm for computing the maximum algebraic numerical multiplicity among a set of Ritz values corresponding to the smallest eigenvalues of a Hermitian matrix.*

ALGORITHM. [X, λ] = IVE(A, X, λ, resNorms, initialBlockSize, maxBasisSize).
Let X and λ be the converged Ritz vectors and Ritz values.
Let initialBlockSize be the block size used to compute X.
Let maxBlockSize be the maximum block size allowed
1. numNew = 1
2. X_{missed} = [ ], $X_{unconverged}$ = [ ]
3. **repeat**
4. resNorms = ComputeResNorms(A, X, λ)
5. newMult = MaxAlgNumMult(λ, resNorms)
6. **if** (solver implements block)
   blockSize = **min**(maxBlockSize, **max**(newMult, initialBlockSize, 2))
   else
   blockSize = 1
7. X_0 = [X_{missed}, **rand**(blockSize - **size**($X_{unconverged}$))]
8. **if** (solver implements external locking)
   [$X_{new}, \lambda_{new}, X_{unconverged}, \lambda_{unconverged}$] = Solver($A$, numNew, X_0, X)
   else
   [$X_{new}, \lambda_{new}, X_{unconverged}, \lambda_{unconverged}$] =
   Solver($(I - XX^T)(A - \sigma I)$, numNew, X_0), as described in section 3.1

if the eigensolver returns this information. Then, IVE determines the maximum algebraic numerical multiplicity using MaxAlgNumMult (step 5). In step 6, if the solver implements a block method, the block size is chosen so that it does not increase beyond the maximum value maxBlockSize. Below that value, it is set at the maximum

9. **end**

FIG. 3.4. *Insertion sort algorithm for identifying and inserting missed eigenvalues into λ. Handling of boundary cases is not shown. In actual implementations, the eigenvalues are inserted first, and the eigenvectors are inserted only at the end to avoid unnecessary memory copying.*

of the current maximum m_i, the block size chosen by the user to compute the initial set of converged Ritz values, and two. A block size of at least two is used to force a block method when no numerically multiple eigenvalues have been detected. If the initial run of the solver used a block size of k, there is no incentive to use anything else for validation. Still, the user can overwrite it by passing initialBlockSize = 1. In step 7, the initial guesses, X_0, are chosen. In the first IVE iteration, X_0 is a set of all random initial guesses. In subsequent IVE iterations, X_0 includes also any unconverged Ritz vectors that are known to be missed during the previous IVE iteration (see below). As we discussed in section 2.1, it is always important to include some random guesses.

In step 8, the eigensolver is called with the initial guesses X_0 and locked vectors X to find numNew more eigenpairs. Depending on the solver, external or explicit locking can be performed. Note that the IVE algorithm assumes that the chosen solver returns not only the numNew converged Ritz values in λ_{new} but also the remaining blockSize−numNew unconverged Ritz values in $\lambda_{unconverged}$. Solvers that do not return the unconverged Ritz pairs by default can be easily modified to do so, if the source code is available. Otherwise, we can set numMissedUnconv = 0.

In step 9, an insertion sort (see Figure 3.4 for details) is called to insert any converged, missed eigenpairs in λ_{new} and X_{new} into λ and X, respectively. For every missed Ritz value inserted into the λ array, the largest λ_{nev} in the array and the corresponding vector in X are removed. If enough storage is available, those removed converged eigenvectors can still remain in the locked array to avoid possible recomputation. We choose not to take advantage of this feature in our experiments. If none of the recently converged Ritz values were missed, then the IVE algorithm will terminate at step 13.

Step 10 calls the algorithm NumMissedValues in Figure 3.5 to determine how many of the unconverged Ritz values in $\lambda_{unconverged}$ are missed values. A Ritz value in $\lambda_{unconverged}$ is considered missed if it is smaller than λ_{nev}. Because of monotonic convergence, these Ritz values will only continue to decrease and approach missed eigenvalues. Therefore, it is wise to use the corresponding unconverged Ritz vectors in $X_{unconverged}$ as initial guesses (step 11). These can significantly reduce validation time when many eigenvalues are missed, because they enable the solver to avoid repeating convergence through random guesses.

Finally, step 12 sets the new number of Ritz values the solver must compute. Clearly, we should continue and find the numMissedUnconv missed ones that step 10 may have identified. If numMissedUnconv = 0, we have no indication that more

ALGORITHM. NumMissedValues(λ, nev, $\lambda_{unconverged}$, numUconv).

```
1.  NumMissedValues = 0
2.  for i = 1, numUconv
3.      j = nev
4.      while (j > 0 and  λ(j) < λ_unconverged(i)) , j = j − 1 ;  end
5.      if j == nev,  break ;
6.      λ = [λ(1 : j), λ_unconverged(i), λ(j + 1 : nev − 1)]
7.      NumMissedValues = NumMissedValues + 1
8.  end
```

FIG. 3.5. *Algorithm for computing the number of unconverged Ritz values that have been skipped. The corresponding Ritz vectors will be used as initial guesses at the next IVE iteration.*

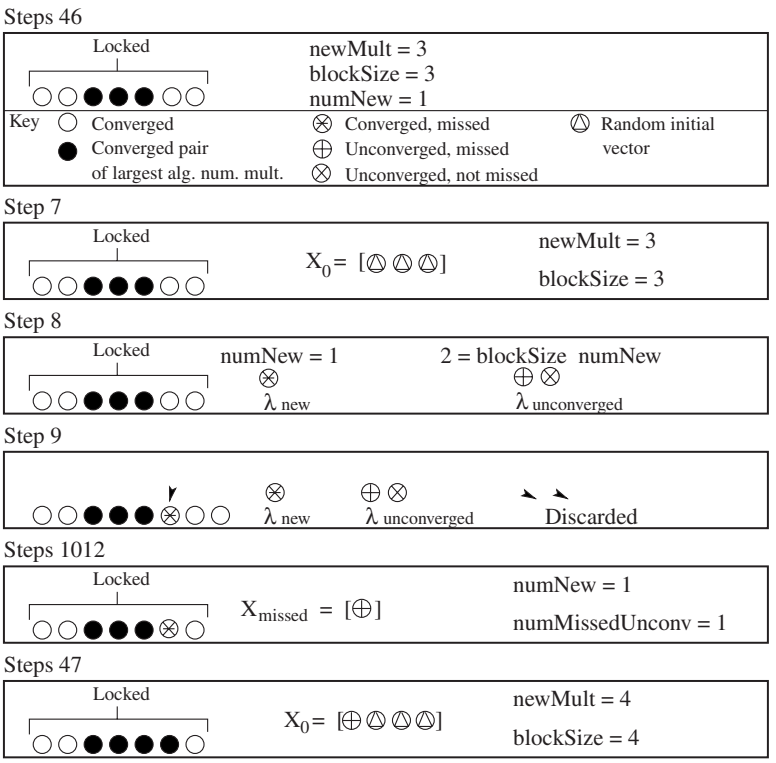

FIG. 3.6. *Example validation problem.*

eigenvalues may be missing, so it would be wasteful to find more than one additional eigenvalue. The IVE algorithm terminates in step 13 if no missed eigenvalues (converged or unconverged) were discovered, or it continues with the next IVE iteration.

We present an example in Figure 3.6 to illustrate the steps taken by the iterative validation algorithm. Suppose we seek the $nev = 8$ smallest eigenvalues of a symmetric matrix. In steps 4 through 6 the residual norms are computed and the maximum algebraic numerical multiplicity is determined to be 3. All random initial guesses are selected in step 7 because it is still the first iteration. In step 8 the solver is called and returns numNew = 1 converged Ritz value in λ_{new}, and two other Ritz values in

$\lambda_{unconverged}$, because the block size is three. Next, InsertionSort is called in step 9 to determine if λ_{new} is a missed eigenvalue. It is, so it is inserted into its proper position and the largest element in λ is discarded. In steps 10 through 12, NumMissedValues determines that one of the $\lambda_{unconverged}$ was converging toward a missed eigenvalue. The corresponding missed vector is placed in X_{missed} to be used as an initial guess in the next IVE iteration, and numNew is set to 1 to indicate that an additional eigenvalue has been skipped. At the next IVE iteration, steps 4 through 7 determine the algebraic numerical multiplicity to be 4, set the block size accordingly, and assign X_{missed} and three random vectors as initial guesses. The IVE iterations continue until no more missed eigenvalues are detected.

4. Experimental evaluation. Our primary goal is to show that IVE restores robustness in any Hermitian eigensolver, even for pathological cases with large multiplicities, or tightly clustered eigenvalues. The importance of increased confidence in the computed results, sometimes at any cost, cannot be overstated. Of particular interest are cases of eigensolvers that fail to find all the required eigenvalues, regardless of the initial choice of parameters, yet guided by IVE, they succeed. A secondary goal is to demonstrate how IVE can decouple robustness from performance, so that solvers are run with default settings for best performance and any missed eigenpairs are obtained later in a shorter IVE cycle.

4.1. Eigensolvers used in the evaluation. We have used five different eigensolvers from three eigensolver packages. The first is IRBL, the implicitly restarted Block Lanczos method [2, 1], which uses implicit restarting combined with Leja shifts to improve convergence of the standard Lanczos method. IRBL is a block method and implements both external and internal locking. For our tests, we have added three lines of code in IRBL to allow it to return all Ritz pairs in the block, not only the converged ones. IRBL is implemented in MATLAB, and therefore it is used mainly to demonstrate the IVE benefits on robustness and convergence; not on timings.

The second symmetric solver is the function dsaupd from the popular software package ARPACK [19]. Henceforth, we will refer to the particular eigensolver as ARPACK. ARPACK is based also on implicit restarting, but unlike IRBL, it uses the Ritz values as the restarting shifts. ARPACK is a single vector method and does not implement external or internal locking. Thus, in a sense, it represents a worst-case scenario, as IVE cannot employ all its techniques. In particular, IVE is restricted to using blockSize = 1, numMissedUnconv = 0, and thus numNew = 1, and locking must be implemented explicitly in IVE. No modifications were made to the ARPACK code which is implemented in Fortran 77.

The remaining three solvers come from PRIMME, a software package that we have developed in C and which is freely available [20]. PRIMME (PReconditioned Iterative MultiMethod Eigensolver) is based on a Davidson-type main iteration, but it implements various techniques such as blocking, external and internal locking, CG-type restarting, and adaptive inner-outer iterations that allow it to transform to any current eigenvalue method. We choose three methods for their popularity and efficiency.

The first is the generalized Davidson method with CG-restarting, or GD+k [34]. We use it with block and locking enabled. Its main characteristic is the near optimal convergence in terms of matrix-vector products for small nev. But this also means that there is little room for convergence improvement through larger block sizes. Therefore, for one of the easier matrices, we also use the original generalized Davidson without CG-restarting [23].

```
N = 30000; clusters = 30; multiplicity = 8; DeltaCluster = 1e-8;
D = zeros(N,1); Ones = ones(multiplicity,1);
D(1:multiplicity) = eps*Ones; value = 1.e-6;
for i = 1:clusters-1
   D(i*multiplicity+1:(i+1)*multiplicity) = value*Ones;
   value = value+DeltaCluster;
end
% The rest well separated and equidistant
row = clusters*multiplicity+1; separation = (1-1e-3)/(N-row);
D(row:N) = 1e-3+ (row-1:N-1)*separation;
A = spdiags(D,0,N,N);
```

FIG. 4.1. *The Matlab code that generates the diagonal matrix DIAG.*

The second method is the JDQMR variant of the Jacobi–Davidson method [32, 29]. It is used with block and locking options enabled, although the correction equation corresponding to each block vector is solved independently. JDQMR adaptively stops the inner iteration for each correction equation, yielding convergence near that of GD+k, but the per-iteration cost of JDQMR is much less expensive.

The third method is LOBPCG-W, which is a variant of the increasingly popular LOBPCG method [15], and it differs from it in the following two ways. First, LOBPCG-W maintains an orthogonal search space to guarantee numerical stability of the process. Second, LOBPCG-W uses a window approach, i.e., the blockSize is allowed to be smaller than *nev*, and as eigenvalues are found in the block they are locked out, and the window progresses until all *nev* pairs have been found.

4.2. Experimental setup and environment. We perform experiments on three matrices, each highlighting a different aspect of the IVE capabilities. The first matrix, BCSSTK16 from the Harwell–Boeing collection [9], has an eigenvalue with unusually high multiplicity. The second matrix, DIAG, is diagonal and is constructed as shown in Figure 4.1 to have a large number of clusters of multiple eigenvalues. The third matrix, LAPLACE, comes from the usual seven-point discretization of the anisotropic three-dimensional Laplacian operator $-\partial^2/(\partial x)^2 - \partial^2/(\partial y)^2 - 100\partial^2/(\partial z)^2$ on the uniform grid $30 \times 30 \times 30$ with Dirichlet boundary conditions, and most of its eigenvalues have multiplicity two.

Although we make an effort to use similar parameters for all methods (tolerance, basis and block sizes, etc.), the reader should not focus on comparisons across methods. Different implementations make such comparison difficult, but most important, IVE improvements can be understood only in reference to the same method.

We perform experiments with two or three different tolerances, which is the only variable from section 2.1 that IVE does not vary. For IRBL, we request that the 2-norm of the residual is less than $\tau\lambda_{max}$. For ARPACK, we provide the tolerance τ to the method. For all PRIMME solvers we request that the 2-norm of the residual is less than $\tau\|A\|_F$. If $\epsilon = 2.2204^{-16}$ is the machine precision, we consider three cases; $\tau = \epsilon$, $\tau = \sqrt{\epsilon}$, and a large τ that is just small enough to differentiate between wanted and unwanted eigenvalues. Thus, the actual value of τ may vary across methods to achieve similar convergence accuracy. For these tolerances and for a variety of block sizes, we first perform an initial run of a solver and record the number of desired eigenvalues it was able to find and its performance. Then, using the approximations produced by a certain initial run, we let IVE guide the solver under various values

TABLE 4.1

for maxBlockSize and record the total number of desired eigenvalues found and the corresponding performance. For each method and matrix, results appear in one table.

IRBL experiments are run under Matlab 6 on a Sun Microsystems Ultra 60 workstation. All other experiments are run on a PowerMac G5, with 1 GB of memory, 512 KB of L2 cache, 1 GHz memory bus, and two 2 GHz PowerPC processors, of which only one is used. ARPACK is compiled with g77 and -O optimization, while PRIMME solvers are compiled with gcc version 4.0.0, and -O optimization. All codes are linked with the Mac optimized VecLib library that includes LAPACK and BLAS.

4.3. Results with matrix BCSSTK16. The dimension of the matrix is 4884, and we seek the 74 smallest eigenvalues which are all 1.0. The next largest eigenvalue is O(1e6), and the largest one is 4.5e+9. This matrix is useful for showing the behavior of solvers and IVE in the presence of an exact, high multiplicity.

First, we test IRBL in Table 4.1. In Table 4.1A we perform several initial runs with block sizes k, each using a maximum basis size of $m = k\lfloor 100/k \rfloor$, a maximum degree of the dampening polynomial equal to the dimension of the matrix, and a size of the dampening interval of $m/2$. For the smallest tolerance, IRBL finds all needed eigenvalues with $k > 4$. The best performance is with $k = 74$, but we assume we do not know the multiplicity a priori. For the larger tolerances, IRBL cannot produce the invariant space of the multiple eigenvalue without $k = 74$.

Table 4.1B shows the performance of various IVE runs, each for a different maximum block size (mxk) and starting after the underlined initial run in Table 4.1A was performed. IVE helps IRBL find all 74 required eigenvalues for all tolerances τ and mxk. Because IRBL is a method that benefits in general from larger block sizes, it is advisable to allow larger values of mxk. Indeed, the number of matrix-vector operations taken by the initial run followed by the IVE($mxk = 10$) is comparable to or significantly smaller than the most robust initial run for $\tau = \epsilon, \tau =$2e-5. For certain

TABLE 4.2

GD+k on matrix BCSSTK16. Table A shows results for computing the 74 smallest eigenvalues. For each block size (k) and tolerance ($\tau\|A\|_F$) we report (nevFound, MV, time), where nevFound is how many of the 74 computed eigenvalues are the required ones, MV the number of matrix-vector multiplications, and time is in seconds. We underline the case that provided the initial set of vectors for the later IVE run. Table B shows the IVE results. For all maximum block sizes (mxk) and tolerances, IVE recovers all the 74 required eigenvalues, so we only report the number of MV and time taken during validation alone. The bottom of Table B shows the total MV and time required (initial run plus IVE), considering the fastest IVE run. The initial block k and the best mxk are also provided. IVE is required for robustness ($\sqrt{\epsilon}$ and 1e-6), and can improve time (ϵ).

moderate values of mxk, performance of IRBL-IVE improves further. Therefore, users are free to tune their code for performance without worrying about its robustness.

Table 4.2 shows similar results for the GD+k method. The maximum basis size used for both initial and IVE runs was 30 for $k < 10$ and $6k$ for $k \geq 10$. The GD+k method requires a larger block size to find the desired invariant space, however, at a great cost in performance. It is thus more effective to select a block size for its caching performance in the initial run (e.g., $k = 3$ in $\tau = \epsilon$ case) and then let IVE resolve the multiplicity with a similar block size. For the $\tau = \epsilon$ case, this strategy improves performance often by a factor of two or three over just using GD+k with a sufficiently large block. For the larger tolerance cases, IVE is the only way to compute the required eigenvalues.

Table 4.3 shows the results with the JDQMR method. The maximum basis sizes used were as in the GD+k method. Despite its efficiency, JDQMR has trouble identifying high multiplicities even with large block sizes. For inner-outer methods, such as JDQMR, this is not surprising as they focus mostly on improving particular eigenvectors, and thus are prone to misconvergence. Also, large block sizes are usually not beneficial. For all three tolerances, IVE restores robustness to JDQMR, and for a relatively low cost. Note that the best times observed would not increase substantially if a larger mxk were used.

Table 4.4 shows results with LOBPCG-W. This method requires that the maximum basis size is $3k$. LOBPCG is inherently a block method that should benefit from larger k. Although, the initial run of the method finds more required eigenvalues with small k than other methods do, a few are always missed, even with $k = 74$. A surprising exception is the $k = 1$ in the $\tau = \epsilon$ case, which finds all of them, but such

behavior is not expected in general. IVE guided LOBPCG-W finds all eigenvalues, and at very competitive times.

Table 4.5 shows results with ARPACK, for three different tolerances. ARPACK, as classical Krylov method without locking, can only identify a few of the eigenvectors in the multiplicity. As with the experiments in LOBPCG-W and JDQMR, decreasing the convergence tolerance does not solve the problem. Yet, with the guidance of the simplified IVE, ARPACK can solve the problem with no difficulties.

TABLE 4.5

ARPACK on matrix BCSSTK16. This is not a block method, so we vary only the tolerance τ. We report (nevFound, MV, time) for the initial run of ARPACK and the total (nevFound, MV, time) taken by both initial and the subsequent IVE runs. The robustness gains are significant.

	Initial runs			IVE run		
τ	evals	MV	Time	evals	Total MV	Total time

TABLE 4.6

GD+k on matrix DIAG. Table A shows results for computing the eight smallest eigenvalues, and Table B shows the subsequent IVE results. We follow the same format as in previous tables, reporting (nevFound, MV, time) for the initial as well as the IVE runs. A higher block size is needed in case $\tau = 5.49E-9$ to find all the desired eigenvalues. Although GD+k does not benefit from large block size in general, performance improves through an efficient initial run followed by a robust IVE run.

For BCSSTK16 and for all methods tested, a maximum block size (mxk) of one was sufficient for robustness in IVE, showing the synergetic effects of the rest of its features, such as locking, computing more eigenpairs, and systematically introducing random guesses. As we show next, larger mxk may be needed in other cases.

4.4. Results with matrix DIAG. We seek the lowest eight eigenvalues which are equal to machine precision. Despite the lower multiplicity, most eigensolvers misconverge to some of the eigenvalues in the second nearby cluster.

Results from GD+k tests appear in Table 4.6. For $\tau = \epsilon$, the method misses a few eigenvalues if the block size is less than three, which is a typical block size for GD+k. With the larger τ, GD+k finds a dimension of the required invariant subspace equal to the block size. This is a typical case, where the block size must be increased for robustness in a code whose performance deteriorates with larger block sizes. IVE avoids this trade-off, thus decoupling performance and robustness. By choosing an mxk such as 2 or 3, which is reasonable for low tolerances in GD+k (and not depending on the particular problem), IVE helps GD+k find all required eigenvalues and much faster than any initial run by GD+k. As expected, a slightly larger block may be needed for larger tolerances, but its exact value does not significantly affect performance. Note that for $\tau = 5.49E-9$, IVE must be allowed to set a block size larger than one to recover robustness.

In Table 4.7 we show results from JDQMR on the DIAG matrix. As with GD+k, IVE can recover robustness for JDQMR if it is allowed to use a larger block size.

TABLE 4.7

JDQMR on matrix DIAG. Initial and IVE runs are shown similarly to Table 4.6. *Typically, JDQMR is used with block size of one, although a larger one does not affect it significantly. Except for the larger block sizes in $\tau = \epsilon$, a combination of initial and IVE runs matches the performance of the most robust JDQMR, but without a priori knowledge of optimal block.*

k,mxk	2, 1	4, 4

Moreover, mxk does not have to match the multiplicity sought (as is necessary in the initial runs), because the synergy of the many IVE features compensates for smaller block sizes. For this solver, IVE execution times are relatively insensitive to mxk, matching the best performance of the initial runs and with the added robustness.

In Table 4.8, LOBPCG-W finds all the required eigenvalues for $\tau = \epsilon$ and for all k, except for $k = 2$ for which IVE recovers the missing eigenvalue for a relatively small additional cost. Surprisingly, for $\tau = 5.49E-9$ LOBPCG-W cannot identify the full invariant subspace in the initial run, regardless of block size. When IVE is allowed to increase the block size above three, all eigenvalues are found.

Finally, in Table 4.9, we show the results from ARPACK on the DIAG matrix and for three different tolerances. Through a combination of locking, restarting, and finding more eigenvalues, IVE is able to recover all needed eigenvalues, except when

TABLE 4.9

ARPACK on matrix DIAG. As in Table 4.5*, IVE is able to achieve the required robustness on the DIAG matrix for the two smallest tolerances, and with minimal additional overhead. The need of a larger block size is evident for such pathological cases and for large tolerances (τ =1e-7).*

	Initial runs			IVE run

	14756, 166.8
k,mxk	1, 1

$\tau = 1e{-}7$, which is close to the first intercluster gap (`DeltaCluster` in Figure 4.1). As with the other methods, a slightly larger block size would have resolved the problem.

Up to now, we have seen test cases where keeping $mxk = 1$ achieved both the required robustness and the minimum time, cases where a larger mxk was required for performance, and cases where a larger mxk was required for robustness. But the optimum choice of mxk does not depend on the problem but depends mainly on the solver and the accuracy needed. For example, given a Krylov solver with basis size m, it makes no sense in terms of convergence to set $mxk > m/3$, with values less than $m/5$ being more reasonable. In the above IVE tests and for all solvers, the maximum multiplicity was larger than $m/5$, hence the observed decrease in performance with larger mxk. Other solvers with larger basis sizes could behave differently. Nevertheless, IVE restores robustness even with very modest block sizes, and therefore users can decouple the choices of parameters that are needed for convergence and cache performance from the parameters needed for robustness on a particular problem.

4.5. Results with a Laplacian matrix. The LAPLACE matrix is closer to a real world problem. We seek the 19 algebraically smallest eigenvalues, 16 of which come in multiple pairs. In particular, the 18th and 19th eigenvalues are a multiple pair. We give results only for τ =1e-9, and for $mxk = 1, 2$ as IVE will not go beyond the maximum observed multiplicity. Table 4.10 shows the results of the GD method, which is identical to GD+k but without the CG-type restarting. An initial block size of 1 misses one eigenvalue, which is easily restored by IVE and in shorter time than to run an initial block size of 2. Table 4.11 for GD+k shows that even when the method does not miss an eigenvalue, the validation step is not expensive relatively. Table 4.12 shows similar results with JDQMR, where IVE restores robustness in better or similar time as the most robust initial run. Table 4.13 shows that LOBPCG-W with block size of one is neither robust nor efficient, unlike the BCSSTK16 case, but IVE

TABLE 4.11
GD+k on matrix LAPLACE. Similar to Table 4.10*, Table A shows results for initial runs and Table B for various IVE runs. Best performance is not included because the initial run does not miss eigenvalues. Yet, the additional IVE expense is not significant.*

TABLE 4.14
ARPACK on matrix DIAG. As in Table 4.5*, IVE is able to achieve the required robustness on the LAPLACE matrix. Note that ARPACK missed three eigenvalues despite a relatively low tolerance.*

	Initial runs			IVE run		
τ	evals	MV	Time	evals	Total MV	Total time
1e-9	16	2874	72	19	6042	137

recovers the missing eigenvalue quite inexpensively. Finally Table 4.14 demonstrates the robustness of IVE with ARPACK, even with only a few IVE features enabled.

5. Conclusions. Hermitian, iterative eigenvalue solvers cannot guarantee, without factorizing the matrix, that the eigenvalues they compute are the required ones. Eigenvalues that are tightly clustered or of high algebraic multiplicity can be missed by any type of eigensolver. There are many techniques to alleviate this: ask for more than the required eigenpairs, and to better than sufficient accuracy, or use a block size larger than the maximum multiplicity sought. Choosing these parameters, however, requires a priori knowledge about the problem, and increasing them beyond a certain value slows convergence and reduces cache performance. Alternatively, locking

converged eigenvectors, and restarting the solver with new random vectors improves robustness, also at the cost of convergence. Typically, robust choices lead to unnecessarily slow codes, especially for the easier parts of the required spectrum.

Our a posteriori IVE is essentially a wrapper around any given eigensolver that automates all the above choices of techniques, except for accuracy, to provide robustness when this is needed. Relying on the synergy of these techniques, IVE keeps calling the solver to find additional eigenpairs, until no missed eigenvalues can be identified. IVE works with both single-vector and block solvers, requiring no changes to the solver.

There are two key ideas in IVE. The first is the repeated Rayleigh–Ritz minimization in the space orthogonal to all converged eigenvectors, each time starting with at least one random initial guess. The second is an automatic way to increase the block size based on the largest multiplicity computed thus far, hence increasing the chances of finding missed eigenvalues of similar multiplicity.

Both key ideas can be very expensive during the initial run of any eigensolver, but as an a posteriori technique they focus only on the problematic part of the spectrum, and only if needed. Moreover, the ability to resolve multiple or clustered eigenvalues during a postprocessing phase frees the user to employ in the solver the block size that gives the best cache performance and the tolerance required by the problem. Even when the block size is limited to modest values in IVE, the synergetic effects of the rest of the techniques can deliver the desired robustness. Our experiments support both the robustness of IVE on some very hard problems and its ability to decouple robustness from performance choices.

In future work, we plan to investigate the applicability and effectiveness of IVE for interior eigenvalues and for non-Hermitian eigenproblems. The major obstacle is that the Rayleigh–Ritz procedure does not provide monotonic convergence toward interior eigenvalues. Thus, the existence of a Ritz value that is closer to a value σ than any previously computed eigenvalue is does not imply that an eigenvalue was missed. A harmonic-Ritz procedure, which may provide a solution to this problem, unfortunately does not extend to non-Hermitian problems.

Acknowledgment. We thank the referees for helping us shape a better paper.

MULTISCALE MODELING OF PHYSICAL PHENOMENA: ADAPTIVE CONTROL OF MODELS*

J. TINSLEY ODEN†, SERGE PRUDHOMME†, ALBERT ROMKES‡, AND PAUL T. BAUMAN†

Abstract. It is common knowledge that the accuracy with which computer simulations can depict physical events depends strongly on the choice of the mathematical model of the events. Perhaps less appreciated is the notion that the error due to modeling can be defined, estimated, and used adaptively to control modeling error, provided one accepts the existence of a base model that can serve as a datum with respect to which other models can be compared. In this work, it is shown that the idea of comparing models and controlling model error can be used to develop a general approach for multiscale modeling, a subject of growing importance in computational science. A posteriori estimates of modeling error in so-called quantities of interest are derived and a class of adaptive modeling algorithms is presented. Several applications of the theory and methodology are presented. These include preliminary work on random multiphase composite materials, molecular statics simulations with applications to problems in nanoindentation, and analysis of molecular dynamics models using various techniques for scale bridging.

Key words. multiscale modeling, goal-oriented adaptive modeling, a posteriori error estimation

1. Introduction.

1.1. Introductory remarks. The development of mathematical and computational modeling techniques for simulating physical events that occur across several spatial and temporal scales has become one of the most challenging and important areas of computational science. Advances in nanotechnolgy, semiconductors, cell and molecular biology, biomedicine, geological and earth sciences, and many other areas hinge upon understanding the interactions of events at scales that could range from subatomic dimensions and nanoseconds to macroscales and hours or even centuries. Available computational methods have largely been designed to model events that take place over one, or rarely two, spatial scales and are generally nonapplicable to multiscale phenomena. Molecular dynamics (MD), for example, may provide an acceptable basis for modeling atomistic or molecular motions over a time period on the order of nanoseconds, while nanodevice fabrications may involve events occurring over seconds or minutes.

In the present exposition, we develop a general approach to multiscale modeling based on the notion of a posteriori estimation of modeling error and on adaptive modeling using so-called Goals algorithms. By a mathematical model we mean a collection of mathematical constructions—partial differential, integral, ordinary, or algebraic equations, boundary and initial conditions, constraints, and data—that provide

an abstraction of a class of physical phenomena covered by scientific theory. Traditionally, a model is selected by a modeler, the analyst, who chooses a model, based on experience or empirical evidence, heuristics, and personal judgment, to depict events assumed to involve well-defined spatial and temporal scales. Events at different scales require, in general, the use of different models. Thus, multiscale models should generally involve a blending or adaptation of models of one scale of events with those of another. It would seem to follow, therefore, that successful multiscale modeling techniques should be able to compare models of different structure and to adapt features of different models so that they deliver results of an accuracy sufficient to capture essential features of the response or to make engineering decisions. This is the basis for the methodologies developed in the present work.

This presentation reviews and extends the theory and methodology developed in earlier works (e.g., [25]) and extends the scope of applications to a broad range of problems, including problems in multiphase random materials and molecular statics. The general tact is different from other techniques proposed in the rapidly growing literature on multiscale modeling.

Several surveys of the literature on multiscale modeling have been published, and we mention in particular the articles of Liu et al. [19], E, Li, and Vanden-Eijnden [12], and Curtin and Miller [8]. In [19], it is asserted that multiscale methods can be naturally grouped into two categories: concurrent and hierarchical. Concurrent methods simultaneously solve a fine-scale model in some local region of interest and a coarser-scale model in the remainder of the domain. Hierarchical, or serial coupling methods [11], use results of a fine-scale model simulation to acquire data for a coarser-scale model that is used globally, e.g., to determine parameters for constitutive equations. The methodologies we develop here are more akin to concurrent approaches since the notion of adaptive modeling fits naturally within that framework. Additionally, the various applications we present here are largely described in terms of problems in mechanics and materials science, although the framework is very general and is applicable to multiscale problems in virtually all areas of science.

We identify three main thrusts in the current literature for implementing multiscale methods. The first involves dimensional reduction approaches such as that used by Tadmor, Ortiz, and Phillips in the quasicontinuum method (QCM) [44, 46]. The QCM has been applied to quasistatic fracture [20, 23], grain-boundary interaction [39], and nanoindentation [45, 43]. In these applications, the QCM has led to a dramatic reduction in the number of degrees of freedom while still resolving physical features of interest.

A second line of research in concurrent multiscale methods is the decomposition-of-scales technique used by Liu et al. in the bridging-scale method (BSM) [51, 32, 47, 48]. The scale decomposition provides a natural separation of spatial and temporal scales for coupling MD and continuum models and has successfully reduced spurious wave reflection in preliminary tests. A static formulation has been applied to the deformation of carbon nanotubes in [35], and a three-dimensional generalization to problems in dynamic fracture is presented in [31].

Finally, widely used concurrent methods are those that directly interface atomistic and continuum models using "pad," "overlap," or "hand-shake" regions. The first method to use such schemes was the FEAt method [18], which was used to simulate the fracture of body-centered cubic (b.c.c.) crystals using a molecular and continuum model. The FEAt method later provided the foundations of the well-known molecular, atomistic, ab initio dynamics (MAAD) or coupling of length scales (CLS) method [7], which was the first to concurrently couple quantum, molecular,

and continuum scales. The atomistic-continuum interface in the MAAD method was extended by Belytschko and Xiao with the bridging-domain method [5, 52] by using an augmented Lagrange method to enforce displacement boundary conditions in the overlap region as well as separating temporal scales in the numerical implementation. The coupled atomistic and discrete dislocation plasticity (CADD) method [41] was developed by Shilkrot, Miller, and Curtin to interface an atomistic model, similar to the QCM, with a more complex continuum model that incorporates descriptions for dislocation movement [49]. In this way, dislocations can be passed to the continuum model, or vice-versa, thereby preserving degrees of freedom that would otherwise be needed to track the dislocation movement. Published implementations of the CADD method are two-dimensional and static, although work in developing three-dimensional and dynamic models is reportedly underway [42].

There also exist more general schemes that develop modeling frameworks rather than concentrating on the details of model interfaces. The heterogeneous multiscale method (HMM) [10], proposed by E and Engquist, provides such a framework for designing multiscale methods based upon the particular nature of the problem. The HMM has been applied to many mathematical problems that possess solutions with multiple scales (see, e.g., [11]), and some work has been done in a priori error estimation for elliptic problems [13].

The idea of estimating modeling error and controling error through model adaptivity was inspired by work on a posteriori estimation of numerical approximation error and control of error through adaptive meshing [1, 24, 4]. Oden, Zohdi, and coworkers [53, 30, 29] used global error estimates to drive adaptivity of models of multiphase heterogeneous elastic materials. Upper and lower bounds of modeling errors in local quantities of interest for this class of problems were presented in [28] and model adaptivity based on the Goals algorithm was first presented in [50]. Further extensions of these approaches are described in [36, 26], and a general theory for model error estimation is proposed in [25].

In the remainder of this introduction, we review the basic ideas behind our error estimation methodology and the Goals algorithm for adaptive modeling, and we lay down notation and assumptions prerequisite to subsequent developments. The basic theorems on model error estimation are taken up in section 2. Discussions of some technicalities connected with ensemble averaging and homogenization are given in section 3. The Goals algorithms are discussed in section 4. There we describe two general versions of these types of algorithms that have proved to be very effective in several application areas. A brief account of global error estimates is given in section 5. Applications are discussed in section 6, and conclusions are collected in a final section.

1.2. Basic ideas. The basic idea behind the multiscale modeling approach to be described here is one of computing and controling modeling error. We first assume that we can define a general mathematical model of a physical system which can serve as a datum with respect to which other models can be compared. This *fine* or *base* model may be highly complex, even intractable, it may involve incomplete data, and, in general, it is never "solved." In studying multiscale phenomena, this base model will depict events that take place on the finest (smallest) spatial and temporal scales. An abstract setting for many base models is embodied in the problem

$$\text{Find } u \in V \text{ such that } A(u) = F \text{ in } V',$$

where V is an appropriate topological vector space, $A(\cdot)$ is a nonlinear operator mapping V into its dual, V', and F is given data in V'. If $\langle \cdot, \cdot \rangle$ denotes duality pairing on $V' \times V$, then the above problem is equivalent to

(1)
$$\boxed{\begin{array}{l}\text{Find } u \in V \text{ such that} \\ \qquad B(u; v) = F(v) \quad \forall v \in V\end{array}}$$

where

$$B(u; v) = \langle A(u), v \rangle, \quad F(v) = \langle F, v \rangle, \tag{2}$$

the semicolon signaling that $B(\cdot; \cdot)$ may be a nonlinear function of the argument u to the left of the semicolon, but linear in the test vector v to the right of it.

Now, in all applications of interest, we do not merely want to characterize the vectors u satisfying (1), but rather we want to find a particular physical event or feature of the system that depends upon u. Such *quantities of interest* are characterized by functionals Q of the solutions to (1). Thus, our actual target problem is this:

(3)
$$\boxed{\begin{array}{l}\textit{If } u \textit{ is a solution of } (1), \textit{ find } Q(u), \textit{ where } Q : V \to \mathbb{R} \\ \textit{is a given functional defining a quantity of interest.}\end{array}}$$

If (1) is intractable, so is (3). We must therefore seek an approximation to $Q(u)$.

Let u_0 be an arbitrary member of V. In the case that the forms $B(\cdot; \cdot)$ and $Q(\cdot)$ are sufficiently smooth (twice differentiable in a certain functional sense), it is shown in [25] that the error

$$\varepsilon = Q(u) - Q(u_0) \tag{4}$$

coincides with the sum of a *residual functional*,

$$\mathcal{R}(u_0, p) = F(p) - B(u_0; p), \tag{5}$$

p being the solution of an appropriately defined dual or adjoint problem, and higher order terms involving the error $e_0 = u - u_0$. We examine this result in more detail in section 2.

An important observation is that the trial solution u_0 may itself be the solution of some other *surrogate* mathematical models, characterized by a different semilinear form $B_0(\cdot; \cdot)$ and linear form $F_0(\cdot)$; i.e., u_0 is then the solution of the problem

$$\text{Find } u_0 \in V : \quad B_0(u_0; v) = F_0(v) \quad \forall v \in V. \tag{6}$$

Thus, the fact that the error between the quantity of interest $Q(\cdot)$ computed using the base model (1) and that computed using any other surrogate model (6) can be estimated in some manner provides a means for comparing the appropriateness of different models and, presumably, controlling modeling error relative to the base model. The surrogate problem(s) (6) will therefore correspond to models of coarser (larger) scales than (1). Still, the base model may never be solved; it remains a datum with respect to which various surrogates are measured.

If modeling error can be effectively estimated, the next challenge is to adaptively control it by systematically changing the surrogate models. This is the goal of the Goals algorithms: to adapt the mathematical model so that preset tolerances in the

error in the specific quantity of interest can be met. Here we will describe a general family of algorithms that include earlier methods as special cases (see [28, 50]). The surrogate model that can approximate the base model well enough to lead to a small tolerable error may often be a hybrid consisting of components involving several different spatial or temporal scales. We take this subject up in section 4.

1.3. Notation: Functional derivatives and Taylor formulas. We define the functional or Gâteaux derivative of the semilinear form $B(u;v)$ in (1) as

$$B'(u;w,v) = \lim_{\theta\to 0} \theta^{-1}[B(u+\theta w;v) - B(u;v)]$$

assuming this limit exists. Higher derivatives of $B(u;v)$ are defined analogously:

$$\begin{aligned}
B''(u;w_1,w_2,v) &= \lim_{\theta\to 0} \theta^{-1}[B'(u+\theta w_2;w_1,v) - B'(u;w_1,v)],\\
B'''(u;w_1,w_2,w_3,v) &= \lim_{\theta\to 0} \theta^{-1}[B''(u+\theta w_3;w_1,w_2,v) - B''(u;w_1,w_2,v)]\\
&\vdots
\end{aligned}$$

Thus, for each $u \in V$, $B'(u;w,v)$ is a bilinear form in v and w, $B''(u;w_1,w_2,v)$ is a trilinear form in w_1, w_2, and v, etc. Similarly, if the target output functionals (the quantities of interest Q) are differentiable, we use the following notation for various Gâteaux derivatives:

$$\begin{aligned}
Q'(u;v_1) &= \lim_{\theta\to 0} \theta^{-1}[Q(u+\theta v_1) - Q(u)],\\
Q''(u;v_1,v_2) &= \lim_{\theta\to 0} \theta^{-1}[Q'(u+\theta v_2;v_1) - Q'(u;v_1)],\\
Q'''(u;v_1,v_2,v_3) &= \lim_{\theta\to 0} \theta^{-1}[Q''(u+\theta v_3;v_1,v_2) - Q''(u;v_1,v_2)]\\
&\vdots
\end{aligned}$$

Taylor formulas with integral remainders can easily be constructed for such differentiable functionals and semilinear forms. Among many such expansions, we list as examples the following:

$$\begin{aligned}
Q(u+v) - Q(u) &= \int_0^1 Q'(u+sv;v)ds,\\
Q(u+v) - Q(u) &= Q'(u;v) + \int_0^1 Q''(u+sv;v,v)(1-s)ds,\\
Q(u+v) - Q(u) &= \frac{1}{2}Q'(u;v) + \frac{1}{2}Q'(u+v;v)\\
&\qquad + \frac{1}{2}\int_0^1 Q'''(u+sv;v,v,v)(s-1)s\ ds
\end{aligned}$$

and

$$\begin{aligned}
B(u+w;v) - B(u;v) &= \int_0^1 B'(u+sw;w,v)ds,\\
B(u+w;v) - B(u;v) &= B'(u;w,v) + \int_0^1 B''(u+sw;w,w,v)(1-s)ds.
\end{aligned}$$

We shall say that $B(\cdot;\cdot)$ and $Q(\cdot)$ belong to $C^r(V)$ whenever the limits defining functional derivatives of order r exist. In all of the theory and applications we consider in subsequent sections, V is a reflexive Banach space with norm $\|\cdot\|$. The theory can be extended to more general settings.

2. A posteriori estimates of modeling error. We begin with the observation that the target problem (3) can be viewed as a problem of optimal control: find an extremum of Q subject to the constraint (1):

$$Q(u) = \inf_{v \in M} Q(v); \quad M = \{w \in V;\ B(w;q) = F(q) \quad \forall q \in V\}. \tag{7}$$

The Lagrangian associated with (7) is

$$L(v,q) = Q(v) + F(q) - B(v;q), \tag{8}$$

and, assuming Q and B are Gâteaux differentiable, solutions to the constrained optimization problem (7) are pairs (u,p) such that

$$L'((u,p);(v,q)) = 0 \quad \forall (v,q) \in V \times V;$$

i.e., (u,p) is a solution of the coupled problem

$$\boxed{\begin{array}{l}\text{Find } (u,p) \in V \times V \text{ such that} \\ \qquad B(u;q) = F(q) \qquad \forall q \in V, \\ \qquad B'(u;v,p) = Q'(u;v) \qquad \forall v \in V\end{array}} \tag{9}$$

We refer to $(9)_1$ as the *primal* base problem and to $(9)_2$ as the *dual* base problem. The dual problem is thus always linear in p. The dual solution p is called the *influence vector* (or *function*) or the *generalized Green's function*. In the cases in which $B(\cdot;\cdot)$ is a bilinear form and $Q(\cdot)$ is a linear functional, the dual problem $(9)_2$ reduces to

$$B(v,p) = Q(v) \quad \forall v \in V$$

so that

$$Q(u) = B(u,p) = F(p). \tag{10}$$

This is recognized as a generalization of the property of Green's functions for linear initial- and boundary-value problems.

Now let us suppose that the system (9) is intractable and that we seek an approximation (u_0,p_0) to (u,p). The following theorem [25] provides the error in the quantity of interest Q.

THEOREM 1. *Let the semilinear form $B(\cdot;\cdot)$ in (9) belong to $C^3(V)$ and let the quantity of interest $Q(\cdot) \in C^3(V)$. Let $(u,p) \in V \times V$ be a solution of the base problem (9) and let (u_0,p_0) be an arbitrary pair in $V \times V$. Then the error in $Q(u)$ produced by u_0 is given by*

$$\mathcal{E}(u_0) = Q(u) - Q(u_0) = \mathcal{R}(u_0;p_0) + \mathcal{R}(u_0;\varepsilon_0) + \Delta_1(u_0,p_0,e_0,\varepsilon_0), \tag{11}$$

where $\mathcal{R}(u_0;v)$ is the residual functional,

$$\mathcal{R}(u_0;v) = F(v) - B(u_0;v), \quad v \in V, \tag{12}$$

and $\Delta_1 = \Delta_1(u_0, p_0, e_0, \varepsilon_0)$ *is the remainder,*

$$\begin{aligned}\Delta_1 = \frac{1}{2}\int_0^1 \{&B''(u_0 + se_0; e_0, e_0, p_0 + s\varepsilon_0) \\ &- Q''(u_0 + se_0; e_0, e_0)\}ds \\ + \frac{1}{2}\int_0^1 \{&Q'''(u_0 + se_0; e_0, e_0) - 3B''(u_0 + se_0; e_0, e_0, \varepsilon_0) \\ &- B'''(u_0 + se_0; e_0, e_0, e_0, p_0 + s\varepsilon_0)\}(s-1)sds\end{aligned} \tag{13}$$

with

$$e_0 = u - u_0 \text{ and } \varepsilon_0 = p - p_0. \tag{14}$$

We observe that $\Delta_1 \equiv 0$ whenever $B(\cdot;\cdot)$ is bilinear and $Q(\cdot)$ is linear. In that case, $Q(u) - Q(u_0) = \mathcal{R}(u_0; p_0) + \mathcal{R}(u_0; \varepsilon_0) = \mathcal{R}(u_0; p_0) + B(e_0, \varepsilon_0)$. Equation (11) establishes that the error $\mathcal{E}(u_0)$ is dominated by the residual functional evaluated at the influence functional p_0 to within terms of higher order in the error components (14).

An alternative representation of the error $\mathcal{E}(u_0)$, involving the residuals associated with the primal and dual problems, is given in the following corollary [25].

COROLLARY 1. *Let the assumptions of Theorem* 1 *hold. Then the error in* $Q(u)$ *produced by* u_0 *is given by*

$$\mathcal{E}(u_0) = \mathcal{R}(u_0; p_0) + \frac{1}{2}(\mathcal{R}(u_0; \varepsilon_0) + \bar{\mathcal{R}}(u_0, p_0; e_0)) + \Delta_2(u_0, p_0, e_0, \varepsilon_0), \tag{15}$$

where $\bar{\mathcal{R}}(u_0, p_0; v)$ *is the residual functional for the dual problem*

$$\bar{\mathcal{R}}(u_0, p_0; v) = Q'(u_0; v) - B'(u_0; v, p_0), \quad v \in V, \tag{16}$$

and $\Delta_2 = \Delta_2(u_0, p_0, e_0, \varepsilon_0)$ *is given by*

$$\begin{aligned}\Delta_2 = \frac{1}{2}\int_0^1 \{&Q'''(u_0 + se_0; e_0, e_0) - 3B''(u_0 + se_0; e_0, e_0, \varepsilon_0) \\ &- B'''(u_0 + se_0; e_0, e_0, e_0, p_0 + s\varepsilon_0)\}(s-1)sds.\end{aligned} \tag{17}$$

We note that the remainder in (17) should be smaller in practical applications than the one in (11) at the expense of having to determine or estimate both e_0 and ε_0. Results similar to those in Theorem 1 and Corollary 1 for finite element approximation errors were presented in Oden and Prudhomme [24] and Becker and Rannacher [4]. A detailed account of the versions of the methods of [4] is given in [3].

It is emphasized that the surrogate functions (u_0, p_0) in (11)–(14) are completely arbitrary vectors in $V \times V$. However, the most natural choice of these vectors are those which are solutions of a *surrogate problem* of the form

$$\boxed{\begin{array}{l}\text{Find } (u_0, p_0) \in V \times V \text{ such that} \\ \qquad B_0(u_0; v) = F_0(v) \qquad \forall\, v \in V, \\ \qquad B_0'(u_0; v, p_0) = Q_0'(u_0; v) \qquad \forall\, v \in V\end{array}} \tag{18}$$

where $B_0(\cdot;\cdot)$ is a semilinear form for a coarser-scale problem and $F_0(\cdot)$ and $Q_0(\cdot)$ are coarse-scale approximations of $F(\cdot)$ and $Q(\cdot)$. In most cases, B_0, F_0, and Q_0 are obtained through an appropriate homogenization or averaging process. Thus, (18) could represent models of events that occur at scales larger than those of the base model. Theorem 1 then provides a means for comparing models of different scales.

3. Homogenization and construction of surrogates.

3.1. Some general remarks. Symbolically, one can envision a multiscale model in which the quantity of interest $Q(u)$ of the base model is the target output, $Q(u_1)$ is the approximation of that output produced by a coarser-scale model obtained through a homogenization process, $Q(u_2)$ is the approximation due to a still coarser scale, and so on. If u_N denotes the surrogate solution to the coarsest-scale model, the various modeling error components are

$$Q(u) - Q(u_N) = \underbrace{Q(u) - Q(u_1)}_{\text{error in scale 1 model}} + \underbrace{Q(u_1) - Q(u_2)}_{\substack{\text{error in scale 2 model} \\ \text{relative to scale 1}}} + \cdots + \underbrace{Q(u_{N-1}) - Q(u_N)}_{\substack{\text{error in scale } N \text{ model} \\ \text{relative to scale } N-1}}.$$

Each error component, of course, depends upon how the successive coarser models are obtained through a homogenization process. As will be seen in applications discussed later, if a target error level is specified, the models that can ultimately deliver that accuracy may involve a mosaic of component models of several different scales.

It can be argued that the limit processes carrying models of one scale to those of larger scales, such as the limiting process from molecular models to continuum models, is a central problem to the mathematical foundations of multiscale modeling. It is a subject in which some progress has been made in recent years (see, e.g., [6, 15]) but for which much additional work remains to be done. It is a remarkable fact, however, that even when these processes are not understood and when only crude averaging procedures are employed, the adaptive modeling algorithms described later may still produce acceptable results, albeit at slow rates of convergence.

Finally, we note that in all applications we are only able to compute a numerical approximation u_0^h of any particular surrogate problem solution u_0. However, we can write

$$\underbrace{Q(u) - Q(u_0^h)}_{\text{total error}} = \underbrace{Q(u) - Q(u_0)}_{\text{modeling error}} + \underbrace{Q(u_0) - Q(u_0^h)}_{\text{approximation error}}.$$

The total error $Q(u) - Q(u_0^h)$ can be estimated with the aid of Theorem 1 using u_0^h instead of u_0. The approximation error $Q(u_0) - Q(u_0^h)$ can be accurately estimated and controlled using the theory and methodology discussed in [24] (see also [1, 4, 3, 27]). Finally, an estimate of the modeling error is obtained by substracting the approximation error from the total error.

It should be understood that while models involving an ascending sequence of scales can, in theory, be obtained through some sort of ensemble averaging (homogenization) process, the actual surrogate pairs (u_0, p_0) appearing in the error estimate (11) are not necessarily solutions of a homogenized problem defined for coarser-scale models. In fact, the coarse-scale models obtained through homogenization processes may even belong to different function spaces than those appearing in the base problem. For example, if the base model is discrete, such as is the case in which the base model corresponds to a crystalline lattice model or an MD model, and a homogenization process produces a continuum model, then the continuum model cannot be used as the surrogate within the context of our theory. Another step is needed.

Let the following denote a model obtained from the base model through some homogenization

$$\begin{aligned} &(\tilde{u}, \tilde{p}) \in V_0 \times V_0 : \\ &\qquad \tilde{B}(\tilde{u}; \tilde{v}) = \tilde{F}(\tilde{v}) \qquad \forall \tilde{v} \in V_0, \\ &\qquad \tilde{B}'(\tilde{u}; \tilde{v}, \tilde{p}) = \tilde{Q}'(\tilde{u}; \tilde{v}) \qquad \forall \tilde{v} \in V_0, \end{aligned}$$

where $\tilde{B}(\cdot;\cdot)$, $\tilde{F}(\cdot)$, and $\tilde{Q}(\cdot)$ are functionals produced from $B(\cdot,\cdot)$, $F(\cdot)$, and $Q(\cdot)$ through homogenization. Let $\Pi(\cdot)$ denote a map,

$$\Pi:\ V_0 \longrightarrow V; \quad \Pi\tilde{u} = u_0,\ \Pi\tilde{p} = p_0.$$

Then, for any appropriate choice of Π, we use (u_0, p_0) as the solutions of the surrogate models, and the error in the quantity of interest is estimated with respect to $Q(u_0)$. We provide examples of such surrogates in section 6.

3.2. Fine-scale fluctuations about a mean. Various methods for treating the interactions of events at two or more scales begin with the separation of the fine-scale solution u into a "mean" component $\bar{u}$ and a fluctuation u' about the mean (see, e.g., [47, 48])

$$u = \bar{u} + u'. \tag{19}$$

Comparing this to our notation, if $V_0 \subset V$, the component $\bar{u}$ and u' can be identified with u_0 and $e_0 = u - u_0$ as

$$\bar{u} = u_0 \quad \text{and} \quad u' = e_0. \tag{20}$$

Using the developments laid down thus far, it is a straightforward exercise to determine approximate relationships for coarse-scale/fine-scale interactions and for computing the fluctuations.

Ignoring higher order terms in the component u' (assumed small compared to $\bar{u}$), we have, for any $v \in V$,

$$F(v) = B(\bar{u} + u'; v) \approx B(\bar{u}; v) + B'(\bar{u}; u', v).$$

Thus

$$\boxed{B'(\bar{u}; u', v) \approx \mathcal{R}(\bar{u}; v) \qquad \forall v \in V} \tag{21}$$

That is, the fluctuations u' satisfy the transpose of the dual problem with u replaced by $\bar{u}$ and with $Q'(u; v)$ replaced by the residual functional $\mathcal{R}(\bar{u}; v)$. Then, with p the solution of the corresponding primal dual problem,

$$\boxed{B'(\bar{u}; u', p) \approx \mathcal{R}(\bar{u}; p) \approx Q(u) - Q(\bar{u})} \tag{22}$$

The result establishes a relationship between the fine-scale fluctuations u' and the error $\mathcal{E}(\bar{u})$ in the quantity of interest. The fine-scale fluctuations thus affect the error in the quantity of interest at positions of the space-time domain within the support of the dual solution p.

At the heart of many multiscale methods is the particular homogenization strategy used to compute the mean component $\bar{u}$. If $\Pi : V_0 \to V$ is a given extension of the space containing the surrogate solution such that $\Pi u_0 = \bar{u}$, then one can construct the "filter," $Pu = \bar{u}$, so that the fluctuations $u - Pu = u'$ are minimized in some sense. We describe one such approach in section 6.

4. The Goals algorithms. The Goals algorithms, introduced in [28, 50] and implemented in various versions in [26, 36, 37], are designed to reduce estimated modeling error by systematically adapting the model using a sequence of surrogates. In [28], reference is made to the "Goal-Oriented Adaptive Local Solutions" algorithms; hence we have the term "Goals." We refer to these general algorithms as Goals or goal-oriented algorithms. As will be shown, not all employ "local" solutions.

The general ideas can be described in the following setting:

1. Let the domain of the solution $(u, p) \in V \times V$ of the base problem (9) be an open region $D \subset \mathbb{R}^d$, and let $\{\Theta_j\}_{j=0}^k$ be a partition of D:

$$\overline{D} = \bigcup_{j=0}^{k} \overline{\Theta}_j, \quad \Theta_i \bigcap \Theta_j = \varnothing, \quad i \neq j,\ 0 \leq i,\ j \leq k.$$

The semilinear and linear forms in (9) can be broken into $k+1$ components so that

$$B(u; v) = \sum_{j=0}^{k} B_{\Theta_j}(u; v), \quad F(v) = \sum_{j=0}^{k} F_{\Theta_j}(v) \tag{23}$$

for $u, v \in V$, with $B_{\Theta_j}(\cdot;\cdot)$, $F_{\Theta_j}(\cdot)$ being the values of the forms produced by restrictions of u and v to Θ_j.
2. Next, through an averaging or homogenization process, we construct a surrogate problem of the form (18) and compute the surrogate solutions $(u_0, p_0) \in V \times V$ defined over all of D.
3. To assess the accuracy of the surrogate solution, we seek to estimate the modeling error in the quantity of interest and call upon Theorem 1 to note that to within higher order terms,

$$\mathcal{E}(u_0) \approx \mathcal{R}(u_0, p) = \mathcal{R}(u_0; p_0) + \mathcal{R}(u_0; p - p_0). \tag{24}$$

The first term is computable, whereas the remaining term is generally intractable and has to be estimated. However, the derivation of an estimate depends heavily on the type of problem that is analyzed. Examples of error estimates for problems in molecular statics, elastostatics, and elastodynamics are given in [26, 28, 37, 36].
4. If the error estimate is to within a user defined error tolerance δ_{TOL}, the analysis stops and provides the analyst with the prediction of the quantity of interest $Q(u_0)$.
5. If the error exceeds the tolerance, the algorithm proceeds by enhancing or improving the surrogate model in a subdomain $D_L \subset D$, called the *domain of influence*. Suppose that the quantity of interest Q involves features of the solution confined to a subdomain $D_Q \subset D$ (e.g., $Q(u)$ could be the average of u or its derivatives over D_Q). Then the initial choice of D_L is generally the union of subdomains Θ_i that intersect with D_Q.
6. There are several possibilities to then compute a correction $(\tilde{u}, \tilde{p})$ of (u_0, p_0) using the enhanced surrogate model.
   I. *Global Goals algorithms.* Let

$$\tilde{B}(\tilde{u}; v) = B_{D_L}(\tilde{u}_{D_L}; v_{D_L}) + B_{0,D\backslash D_L}(\tilde{u}_{D\backslash D_L}; v_{D\backslash D_L}), \tag{25}$$

where $\tilde{u}_{D_L} = \tilde{u}|_{D_L}$, etc., and $B_{0,D\backslash D_L}(\cdot;\cdot)$ is the semilinear form for the surrogate problem defined on restrictions of functions in V to $D\backslash D_L$. Thus, $\tilde{B}(\cdot,\cdot)$ includes fine-scale features of the base model over domain D_L while it is characterized by coarse-scale features of the surrogate model over $D\backslash D_L$. We calculate $(\tilde{u}, \tilde{p}) \in V \times V$ such that

$$\begin{aligned} &\tilde{B}(\tilde{u}; v) = F(v) \quad \forall v \in V, \\ &\tilde{B}'(\tilde{u}; v, \tilde{p}) = Q'(\tilde{u}; v) \quad \forall v \in V. \end{aligned} \tag{26}$$

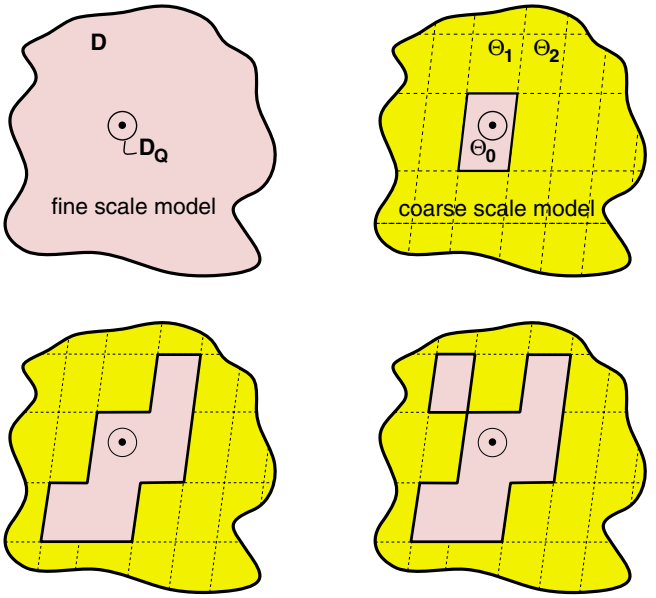

FIG. 1. *(Top left) A fine-scale base model and a subdomain D_Q surrounding features of a quantity of interest Q; (top right) a partition of Ω into subdomains with an initial domain of influence $D = \Theta_0$; (bottom) successive enlargements of D designed to reduce the modeling error.*

II. *Local Goals algorithms.* In this case, we compute a correction $(\tilde{u}, \tilde{p})$ that coincides with (u_0, p_0) outside the initial domain of influence but uses the base problem data (the "fine-scale data") within D_L:

$$\begin{aligned} &B_{D_L}(\tilde{u}; v) = F_{D_L}(v) \quad \forall v \in V(D_L) \quad \text{with} \quad \tilde{u} = u_0 \text{ in } \overline{D}\backslash D_L, \\ &B'_{D_L}(\tilde{u}; v, \tilde{p}) = Q'_{D_L}(\tilde{u}; v) \quad \forall v \in V(D_L) \quad \text{with} \quad \tilde{p} = p_0 \text{ in } \overline{D}\backslash D_L \end{aligned} \tag{27}$$

and $V(D_L)$ is the space of restrictions of functions in V to the domain of influence D_L. The situation is illustrated in Figure 1.

7. As done in step 3, we can derive an estimate of the modeling error of the enhanced solution $\tilde{u}$,

$$\mathcal{E}(\tilde{u}) \approx \mathcal{R}(\tilde{u}; p).$$

Again, the estimation of this term depends on the type of problem (e.g., see [28, 36]). In this work, we introduce an alternative estimator by noting that

$$\mathcal{E}(\tilde{u}) = Q(u) - Q(\tilde{u}) = [Q(u) - Q(u_0)] + [Q(u_0) - Q(\tilde{u})]. \tag{28}$$

The last term in this equation is computable and the first can be estimated by again using Theorem 1:

$$\begin{aligned} \mathcal{E}(\tilde{u}) &\approx \mathcal{R}(u_0; p) + Q(u_0) - Q(\tilde{u}) \\ &= \mathcal{R}(u_0; \tilde{p}) + \mathcal{R}(u_0; p - \tilde{p}) + Q(u_0) - Q(\tilde{u}) \\ &\approx \mathcal{R}(u_0; \tilde{p}) + Q(u_0) - Q(\tilde{u}). \end{aligned} \tag{29}$$

8. If the error estimate is within a user defined error tolerance δ_{TOL}, the analysis stops and provides the analyst with the prediction in the quantity of interest $Q(\tilde{u})$.

9. If the error exceeds the tolerance, we obtain an indication of the error contribution of each subdomain (outside the domain of influence) by computing its contribution to the upper bound of the residual $\mathcal{R}(u_0; p)$ (e.g., see [28, 36, 37]). We then expand the domain of influence D_L by adding the subdomains $\{\Theta_i\}$ whose error contributions, with respect to the maximal contribution, exceed a user defined tolerance γ and return to step 6.

Steps 1–9 characterize a family of Global and Local Goals algorithms for adaptive modeling. Several remarks are in order.

REMARK 1. *While the global versions of the Goals algorithms may involve the solution of surrogate problems of a larger size than the local solution algorithms, they have the advantage of accounting for possible interactions of fine-scale and large-scale behavior. Thus, we expect that they may lead to faster convergence rates than the simpler local methods.*

REMARK 2. *The initial domain of interest, of course, can be a multiconnected domain, depending upon the number and structure of the quantities of interest.*

5. Global estimates. The quality of goal-oriented error estimates, as can be seen in Theorem 1, strongly depends on the accuracy of the coarse solutions u_0 and p_0. We show here how the errors e_0 $(= u - u_0)$ and ε_0 $(= p - p_0)$ are related to the norms of the residuals. Global estimates of modeling error can be obtained for specific forms of $B(\cdot;\cdot)$ and $Q(\cdot)$. In cases in which $B(\cdot;\cdot)$ is a symmetric, positive-definite, bilinear form, global estimates of e_0 and ε_0 can be used to construct upper and lower bounds of errors in quantities of interest [28, 50, 36]. Here we provide a derivation of such bounds for cases in which $B(\cdot;\cdot)$ and $Q(\cdot)$ satisfy a priori conditions.

Let V be a Banach space with norm $\|\cdot\|$. We observe that

$$\begin{aligned}
&B(u+w;v) = B(u;v) + B'(u;w,v) + \Delta_4(u,w,v),\\
&Q'(u+w;v) = Q'(u;v) + \Delta_5(u,w,v),\\
&B'(u+w_2;w_1,v) = B'(u;w_1,v) + \Delta_6(u,w_1,w_2,v),
\end{aligned}$$

where

$$\begin{aligned}
\Delta_4(u,w,v) &= \int_0^1 B''(u+sw;w,w,v)(1-s)ds,\\
\Delta_5(u,w,v) &= \int_0^1 Q''(u+sw;w,v)ds,\\
\Delta_6(u,w_1,w_2,v) &= \int_0^1 B''(u+sw_2;w_1,w_2,v)ds
\end{aligned}$$

for all u, v, w, w_1, and w_2 in V. With this notation, and recalling that $u = u_0 + e_0$ and $p = p_0 + \varepsilon_0$, we have

$$\left.\begin{aligned}
&B(u;v) = B(u_0;v) + B'(u_0;e_0,v) + \Delta_4(u_0,e_0,v)\\
&Q'(u;v) = Q'(u_0;v) + \Delta_5(u_0,e_0,v)\\
&B'(u;v,p) = B'(u_0;v,p_0) + B'(u_0;v,\varepsilon_0) + \Delta_6(u_0,v,e_0,p_0+\varepsilon_0)
\end{aligned}\right\}. \tag{30}$$

Then the primal and dual base models can be written as

$$\boxed{\begin{aligned}
&\text{Find } (e_0,\varepsilon_0) \in V\times V \text{ such that}\\
&\quad B(u_0;v) + B'(u_0;e_0,v) + \Delta_4(u_0,e_0,v) = F(v) \qquad \forall v\in V,\\
&\quad B'(u_0;v,p_0) + B'(u_0;v,\varepsilon_0) + \Delta_6(u_0,v,e_0,p_0+\varepsilon_0)\\
&\qquad\qquad = Q'(u_0;v) + \Delta_5(u_0,e_0,v) \qquad \forall v\in V
\end{aligned}} \tag{31}$$

Thus, the errors e_0 and ε_0 satisfy the following equations:

$$
\begin{aligned}
&B'(u_0;e_0,v)+\Delta_4(u_0,e_0,v)=\mathcal{R}(u_0;v) \qquad \forall v\in V,\\
&B'(u_0;v,\varepsilon_0)+\Delta_6(u_0,v,e_0,p_0+\varepsilon_0)\\
&\qquad\qquad =\bar{\mathcal{R}}(u_0,p_0;v)+\Delta_5(u_0,e_0,v) \qquad \forall v\in V,
\end{aligned}
\tag{32}
$$

where $\mathcal{R}(u_0;v)$ and $\bar{\mathcal{R}}(u_0,p_0;v)$ are the residual functionals in (12) and (16).

If $B(\cdot;\cdot)$ and $Q(\cdot)$ are a bilinear form and a linear form, respectively, then Δ_4, Δ_5, and Δ_6 vanish, $B'=B$, $Q'=Q$, so that the errors are governed by

$$
\begin{aligned}
B(e_0,v)&=\mathcal{R}(u_0;v) \qquad \forall v\in V,\\
B(v,\varepsilon_0)&=\bar{\mathcal{R}}(u_0,p_0;v) \qquad \forall v\in V.
\end{aligned}
$$

Otherwise, we shall assume that constants $C_4=C_4(u_0)$, $C_5=C_5(u_0)$, and $C_6=C_6(u_0,p_0)$ exist such that

$$
\left.
\begin{aligned}
&|\Delta_4(u_0,e_0,v)|\le C_4\|e_0\|^2\|v\|\\
&|\Delta_5(u_0,e_0,v)|\le C_5\|e_0\|\,\|v\|\\
&|\Delta_6(u_0,v,e_0,p_0+\varepsilon_0)|\le C_6\|e_0\|\,\|v\|
\end{aligned}
\right\}
\tag{33}
$$

and that it is possible to find a $u_0\in V$ such that $\infty>\alpha(u_0),\beta(u_0)>0$, where $\alpha(u_0)$ and $\beta(u_0)$ are given by

$$
\begin{aligned}
\alpha(u_0)&=\inf_{w\in V\setminus\{0\}}\sup_{v\in V\setminus\{0\}}\frac{|B'(u_0;w,v)|}{\|w\|\,\|v\|},\\
\beta(u_0)&=\inf_{w\in V\setminus\{0\}}\sup_{v\in V\setminus\{0\}}\frac{|B'(u_0;v,w)|}{\|w\|\,\|v\|}.
\end{aligned}
$$

Then we easily obtain

$$
\begin{aligned}
\alpha(u_0)\|e_0\|&\le\|\mathcal{R}(u_0)\|_*+C_4\|e_0\|^2,\\
\beta(u_0)\|\varepsilon_0\|&\le\|\bar{\mathcal{R}}(u_0,p_0)\|_*+(C_5+C_6)\|e_0\|,
\end{aligned}
$$

where $\|\cdot\|_*$ denotes the norm on the dual space V':

$$
\begin{aligned}
\|\mathcal{R}(u_0)\|_*&=\sup_{v\in V\setminus\{0\}}\frac{|\mathcal{R}(u_0;v)|}{\|v\|},\\
\|\bar{\mathcal{R}}(u_0,p_0)\|_*&=\sup_{v\in V\setminus\{0\}}\frac{|\bar{\mathcal{R}}(u_0,p_0;v)|}{\|v\|}.
\end{aligned}
$$

These results show that for e_0 sufficiently small, when the assumed properties prevail, the modeling errors e_0 and ε_0 are globally bounded by the norms of the residuals.

6. Examples.

6.1. Random heterogeneous materials. We now show an application of the Local Goals algorithms to the analysis of the elastostatics of *random* multiphase composite materials (see also [37]). In section 6.1.1, we first define the model problem and notation. We then introduce a brief overview on the surrogate models and the estimation of modeling errors in section 6.1.2 and present a specific example application to a two-phase composite material in section 6.1.3.

6.1.1. Model problem and notation. We consider a material body, occupying an open and bounded domain $D \subset \mathbb{R}^d$, $d = 1, 2, 3$, with boundary $\partial D = \overline{\Gamma_u \cup \Gamma_t}$, $\Gamma_u \cap \Gamma_t = \varnothing$, $meas(\Gamma_t) > 0$, $meas(\Gamma_u) > 0$, Γ_u and Γ_t being portions of ∂D on which displacements and tractions are to be specified, respectively. The body is in static equilibrium under the action of deterministic applied forces $\boldsymbol{f} \in L^2(D)^d$, a surface traction $\boldsymbol{t} \in L^2(\Gamma_t)^{d-1}$, and a prescribed displacement $\boldsymbol{U} \in L^2(\Gamma_u)^d$ on Γ_u. We assume the body is composed of a multiphase, composite, elastic material with highly oscillatory material properties. The geometrical features and material properties of its constituents are functions of a *random vector* $\boldsymbol{\omega} \in \Omega$, where Ω denotes the collection of all possible realizations. The governing *probability distribution density function* $\rho : \Omega \longrightarrow [0, 1]$ is assumed to be known.

Let $\boldsymbol{u} = \boldsymbol{u}(\boldsymbol{x}, \boldsymbol{\omega})$ denote the random displacement vector field defined on $D \times \Omega$ and let $\boldsymbol{\nabla u}$ denote the spatial gradient. Then the Cauchy stress tensor $\boldsymbol{\sigma}(\boldsymbol{x}, \boldsymbol{\omega})$ satisfies $\boldsymbol{\sigma}(\boldsymbol{x}, \boldsymbol{\omega}) = \boldsymbol{E}(\boldsymbol{x}, \boldsymbol{\omega})\boldsymbol{\nabla u}(\boldsymbol{x}, \boldsymbol{\omega})$, where $\boldsymbol{E}(\boldsymbol{x}, \boldsymbol{\omega})$ is the fourth order tensor of elasticities with components $E_{ijkl}(\boldsymbol{x}, \boldsymbol{\omega}) \in L^\infty(D, L^2(\Omega))^{d \times d}$. The standard symmetry and ellipticity conditions hold for a.e. $\boldsymbol{x} \in D$ and a.s. $\boldsymbol{\omega} \in \Omega$:

$$E_{ijkl}(\boldsymbol{x}, \boldsymbol{\omega}) = E_{jikl}(\boldsymbol{x}, \boldsymbol{\omega}) = E_{ijlk}(\boldsymbol{x}, \boldsymbol{\omega}) = E_{klij}(\boldsymbol{x}, \boldsymbol{\omega}),$$
$$\alpha_0 \xi_{ij} \xi_{ij} \le E_{ijkl}(\boldsymbol{x}, \boldsymbol{\omega}) \xi_{ij} \xi_{kl} \le \alpha_1 \xi_{ij} \xi_{ij}, \qquad \alpha_1 \ge \alpha_0 > 0.$$

We introduce a space of test functions V,

$$V = \left\{ \boldsymbol{v} \in H^1(D, L^2(\Omega)) : \ \boldsymbol{v}(\boldsymbol{x}, \boldsymbol{\omega}) = 0 \ \ \forall \boldsymbol{x} \in \Gamma_u, \ \boldsymbol{\omega} \in \Omega \right\}, \tag{34}$$

where $H^1(D, L^2(\Omega))$ is the Hilbert space,

$$H^1(D, L^2(\Omega)) = \left\{ \boldsymbol{v}(\boldsymbol{x}, \boldsymbol{\omega}) : \ \int_\Omega \int_D \left[\boldsymbol{\nabla v} : \boldsymbol{\nabla v} + \boldsymbol{v} \cdot \boldsymbol{v} \right] \ \rho(\boldsymbol{\omega}) \, \mathrm{d}\boldsymbol{x} \, \mathrm{d}\boldsymbol{\omega} < \infty \right\}.$$

Having established the necessary notations and conventions, we now recall the variational formulation (9) of our linear, stochastic, elastostatics problem, where [37]

$$\begin{aligned} F(\boldsymbol{v}) &= \int_\Omega \int_D (\boldsymbol{f} : \boldsymbol{v}) \ \rho(\boldsymbol{\omega}) \ \mathrm{d}\boldsymbol{x} \, \mathrm{d}\boldsymbol{\omega} + \int_\Omega \int_{\Gamma_t} (\boldsymbol{t} : \boldsymbol{v}) \ \rho(\boldsymbol{\omega}) \ \mathrm{d}s \, \mathrm{d}\boldsymbol{\omega}, \\ B(\boldsymbol{u}, \boldsymbol{v}) &= \int_\Omega \int_D (\boldsymbol{E} \boldsymbol{\nabla u} : \boldsymbol{\nabla v}) \ \rho(\boldsymbol{\omega}) \, \mathrm{d}\boldsymbol{x} \, \mathrm{d}\boldsymbol{\omega}, \end{aligned} \tag{35}$$

where $\boldsymbol{n}$ and $\boldsymbol{s}$ denote the unit normal and position vector on ∂D, respectively. Following the approach in sections 1.2 and 2, we define the target of the analysis as a linear functional $Q(\cdot)$ of the solution $\boldsymbol{u}$.

6.1.2. Surrogate models and modeling errors. To implement versions of the Goals algorithms, we compute a surrogate solution pair $(\boldsymbol{u}_0, \boldsymbol{p}_0)$ of (18), where the bilinear form $B_0(\cdot, \cdot)$ is obtained by first computing the statistical mean $\bar{\boldsymbol{E}}(\boldsymbol{x})$ of $\boldsymbol{E}(\boldsymbol{x}, \boldsymbol{\omega})$ and by then using standard homogenization methods or classical Hashin–Shtrikman bounds [16] to obtain the *deterministic*, *homogeneous*, elasticity tensor $\boldsymbol{E}_0$. Thus,

$$B_0(\boldsymbol{u}_0, \boldsymbol{v}) = \int_\Omega \int_D (\boldsymbol{E}_0 \boldsymbol{\nabla u}_0 : \boldsymbol{\nabla v}) \ \rho(\boldsymbol{\omega}) \, \mathrm{d}\boldsymbol{x} \, \mathrm{d}\boldsymbol{\omega}. \tag{36}$$

By recalling the surrogate primal problem $(18)_1$ and the fact that the applied external forces $\mathbf{f}$ and $\mathbf{t}$ are deterministic, the above choice for the bilinear form $B_0(\cdot, \cdot)$ implies

that $\mathbf{u}_0$ is deterministic. This does not generally extend to the dual solution $\mathbf{p}_0$, which is deterministic only for certain choices of quantities of interest. The incurred modeling errors are denoted as $\boldsymbol{e}_0(\boldsymbol{x},\boldsymbol{\omega}) = \boldsymbol{u}(\boldsymbol{x},\boldsymbol{\omega}) - \boldsymbol{u}_0(\boldsymbol{x})$ and $\boldsymbol{\varepsilon}_0(\boldsymbol{x},\boldsymbol{\omega}) = \boldsymbol{p}(\boldsymbol{x},\boldsymbol{\omega}) - \boldsymbol{p}_0(\boldsymbol{x},\boldsymbol{\omega})$. The corresponding residual functionals (12) and (16) reduce to [37]

$$
\begin{aligned}
\mathcal{R}(\boldsymbol{u}_0,\boldsymbol{v}) &= -\int_\Omega\int_D (\boldsymbol{E}\mathcal{I}_0\boldsymbol{\nabla}\boldsymbol{u}_0 : \boldsymbol{\nabla}\boldsymbol{v})\ \rho(\boldsymbol{\omega})\,\mathrm{d}\boldsymbol{x}\,\mathrm{d}\boldsymbol{\omega},\\
\overline{\mathcal{R}}(\boldsymbol{p}_0,\boldsymbol{z}) &= -\int_\Omega\int_D (\boldsymbol{E}\mathcal{I}_0\boldsymbol{\nabla}\boldsymbol{z} : \boldsymbol{\nabla}\boldsymbol{p}_0)\ \rho(\boldsymbol{\omega})\,\mathrm{d}\boldsymbol{x}\,\mathrm{d}\boldsymbol{\omega},
\end{aligned}
\tag{37}
$$

where $\mathcal{I}_0(\boldsymbol{x},\boldsymbol{\omega}) = \boldsymbol{I} - \boldsymbol{E}^{-1}\boldsymbol{E}_0$ denotes the *deviation tensor*. We can now call upon Corollary 1 to establish the error in the quantity of interest,

$$
\mathcal{E}(\boldsymbol{u}_0) = \mathcal{R}(\boldsymbol{u}_0;\boldsymbol{p}_0) + \frac{1}{2}(\mathcal{R}(\boldsymbol{u}_0,\boldsymbol{\varepsilon}_0) + \overline{\mathcal{R}}(\boldsymbol{p}_0,\boldsymbol{e}_0)) + \Delta_2(\boldsymbol{u}_0,\boldsymbol{p}_0,\boldsymbol{e}_0,\boldsymbol{\varepsilon}_0).
$$

Ignoring the higher order term $\Delta_2(\boldsymbol{u}_0,\boldsymbol{p}_0,\boldsymbol{e}_0,\boldsymbol{\varepsilon}_0)$, we consider the estimate,

$$
\mathcal{E}(\boldsymbol{u}_0) \approx \mathcal{R}(\boldsymbol{u}_0;\boldsymbol{p}_0) + \frac{1}{2}(\mathcal{R}(\boldsymbol{u}_0,\boldsymbol{\varepsilon}_0) + \overline{\mathcal{R}}(\boldsymbol{p}_0,\boldsymbol{e}_0)).
\tag{38}
$$

The last two terms in the RHS of (38) are generally intractable and further steps need to be taken to derive a computable estimate of the error. We here introduce an example of an estimator derived in [37] which is used in the example problem in section 6.1.3:

$$
\boxed{\mathcal{E}(\boldsymbol{u}_0) \approx \eta_{\mathrm{est,upp}} = \mathcal{R}(\boldsymbol{u}_0,\boldsymbol{p}_0) + \frac{1}{4}(\eta^+_{\mathrm{upp}})^2 - \frac{1}{4}(\eta^-_{\mathrm{upp}})^2}
$$

where

$$
\eta^\pm_{\mathrm{upp}} = \sqrt{\int_\Omega\int_D \boldsymbol{E}\mathcal{I}_0\boldsymbol{\nabla}(\boldsymbol{u}_0 \pm \boldsymbol{p}_0) : \mathcal{I}_0\boldsymbol{\nabla}(\boldsymbol{u}_0 \pm \boldsymbol{p}_0)\ \rho(\boldsymbol{\omega})\,\mathrm{d}\boldsymbol{x}\,\mathrm{d}\boldsymbol{\omega}}.
$$

The Goals algorithm provides two approaches to reduce the error $\mathcal{E}(\boldsymbol{u}_0)$ and compute enhanced solutions $(\tilde{\boldsymbol{u}},\tilde{\boldsymbol{p}})$ of $(\boldsymbol{u}_0,\boldsymbol{p}_0)$: the Local or the Global Goals version (see section 4). In either case, we use the estimator $\tilde{\eta}_{\mathrm{est}}$, derived from (29), to assess the error in the quantity of interest of the enhanced solutions,

$$
\mathcal{E}(\tilde{\boldsymbol{u}}) \approx \tilde{\eta}_{\mathrm{est}} = \mathcal{R}(\boldsymbol{u}_0,\tilde{\boldsymbol{p}}) + Q(\boldsymbol{u}_0) - Q(\tilde{\boldsymbol{u}}).
$$

6.1.3. Numerical example. For the base problem, we consider a two-phase composite material consisting of isotropic, linearly elastic constituents. Cylindrical inclusions account for 30 percent of the volume and have been randomly dispersed in the matrix material, as depicted in Figure 2. The structure is subjected to a traction $\boldsymbol{t}$ at the top and has prescribed zero displacements at the base $y = 0$. The Young's modulus and Poisson ratio of the matrix material are deterministic and given by $E_{\mathrm{m}} = 5$ GPa and $\nu_{\mathrm{m}} = 0.345$. The material properties of the inclusions, however, are functions of the random vector $\boldsymbol{\omega} = \{\omega_1,\omega_2\} \in (0,1)\times(0,1)$, such that

$$
\begin{aligned}
E_{\mathrm{incl}}(\boldsymbol{\omega}) &= E_{\mathrm{incl}}(\omega_1) = 110 + 20\times\omega_1, \quad [\mathrm{GPa}]\\
\nu_{\mathrm{incl}}(\boldsymbol{\omega}) &= \nu_{\mathrm{incl}}(\omega_2) = 0.28 + 0.4\times\omega_2.
\end{aligned}
$$

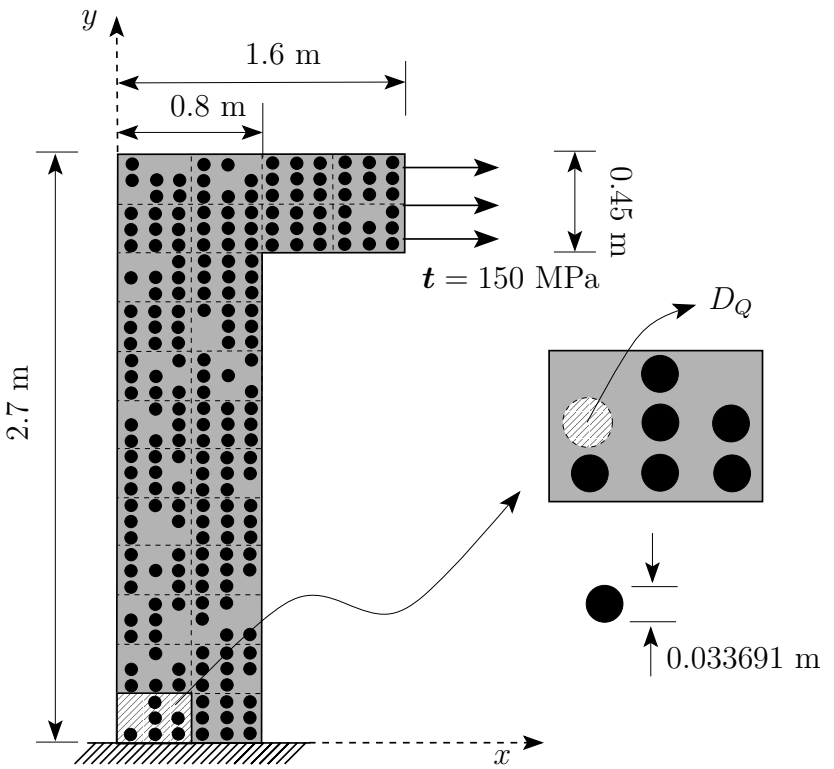

FIG. 2. *A structural component constructed from a two-phase composite material in equilibrium under the action of applied stress* $\boldsymbol{t}$ *and prescribed zero displacements at* $y = 0$.

We assume that ω_1 and ω_2 are statistically independent which implies that $\rho(\boldsymbol{\omega}) = \rho_1(\omega_1)\ \rho_2(\omega_2)$. We additionally assume that $\rho_i(\omega_i)$, $i = 1, 2$, are *truncated Gaussian distribution density functions*,

$$\rho_i(\omega_i) = 2\,\frac{A}{\sqrt{2\pi}}\ e^{-(2\omega_i - 1)^2/2\pi}, \quad i = 1, 2,$$
$$A = 2\left[\operatorname{erf}\left(\frac{1}{\sqrt{2\pi}}\right) - \operatorname{erf}\left(-\frac{1}{\sqrt{2\pi}}\right)\right]^{-1}.$$

In this example, our target $Q(\boldsymbol{u})$ is the statistical average of the average strain ε_{yy} over a small circular area D_Q near the support of the structure, with a radius $r = 0.017$m (see Figure 2).

We establish the surrogate problem (18) by computing the average of the Hashin-Shtrikman upper and lower bounds [16] of the material coefficients in the base model. Using these averaged coefficients, we construct a surrogate $\boldsymbol{E}_0$ whose coefficients are obviously *homogeneous and deterministic*. It is easy to show [38] that with the current choice of $Q(\mathbf{u})$ not only $\boldsymbol{u}_0$ but also $\boldsymbol{p}_0$ is deterministic. In Figure 3, the strain field ε^0_{yy} is shown which is obtained by using overkill finite element approximations of $(\boldsymbol{u}_0, \boldsymbol{p}_0)$ (the finite element models were implemented using the commercial package ProPHLEX [2]).

For comparison, the base solution $\boldsymbol{u}(\boldsymbol{x}, \omega)$ has also been computed by using overkill Monte Carlo and finite element approximations and the statistical average

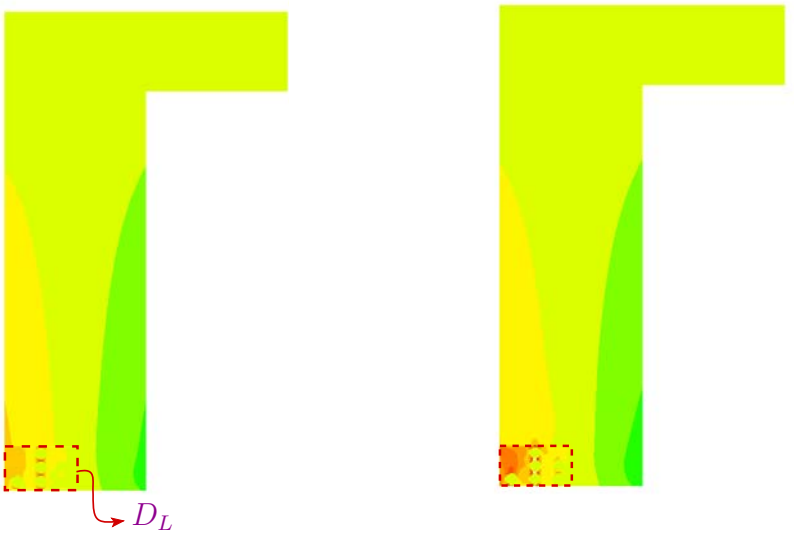
of the resulting strain field $\varepsilon_{yy}(\boldsymbol{x},\omega)$ is shown in Figure 4, where the area of interest around D_Q has been magnified. In Table 1, the relative error in the quantity of interest and the effectivity indices of the estimate $\eta_{\text{est,upp}}$ is given. Even though the relative error is large, the estimator $\eta_{\text{est,upp}}$ provides a fairly accurate assessment of the error with an effectivity index of 1.22.

To reduce the error, we perform two separate series of local enhancements. In one series, we employ the Local Goals algorithm, while the Global Goals is used in a second series. In Table 2, the relative errors and the effectivity indices of the error estimator $\tilde{\eta}_{\text{est}}$ are listed for three steps of both approaches. Also, in Figures 5 and 6, the statistical averages of the enhanced strain fields $\tilde{\varepsilon}_{yy}$ that are obtained after the first and third step, respectively, are shown. In these figures, the boundary of the domain of influence ∂D_L is highlighted red.

As expected (see Remark 1), the results in Table 2 reveal that, although the Global Goals algorithm requires solving a larger problem, the rate of decrease in the error in the target quantity is more pronounced with this approach. In both approaches, the



(a) Local Goals (b) Global Goals

FIG. 5. *Mean values of the strain field $\tilde{\varepsilon}_{yy}$ after the first step of local enhancement using the Local and Global Goals algorithms.*

estimator $\tilde{\eta}_{\text{est}}$ exhibits good accuracy with effectivity indices close to unity. For the Global Goals version, the effectivity is slightly worse, but this is due to the fact that the error has been reduced to much smaller values. In these applications, we have observed that the estimates become less accurate as the actual error decreases.

6.2. Nanoindentation application. In this section, we consider the problem of determining static equilibrium configurations of a regular lattice of N atoms. The base problem is derived by minimization of the potential energy of the system involving all atoms in the lattice. However, for many applications, the base problem is intractable due to the very large number of atoms N. We construct here surrogate problems using the popular QCM [44, 45, 46] which allows for the reduction of the number of active atoms as needed.

6.2.1. The base and surrogate problems. Let $\mathcal{L}$ be a regular lattice of N atoms in $\mathbb{R}^d$, $d = 2$ or 3. The positions of the atoms in the reference configuration are given by the vectors $\hat{\boldsymbol{x}}_i \in \mathbb{R}^d$, $i = 1, \ldots, N$, and in the equilibrium configuration by $\boldsymbol{x}_i = \hat{\boldsymbol{x}}_i + \boldsymbol{u}_i$, $i = 1, \ldots, N$, where $\boldsymbol{u}_i$ is the displacement of atom i. We assume that the lattice in the reference configuration covers the region $\bar{\Omega}$, where Ω is an open bounded set of $\mathbb{R}^d$ with boundary $\partial\Omega$. For a more detailed analysis, see [34]. We introduce the finite-dimensional vector space $V = (\mathbb{R}^d)^N$, and we use the notation $\boldsymbol{u} = (\boldsymbol{u}_1, \boldsymbol{u}_2, \ldots, \boldsymbol{u}_N) \in V$ to refer to the displacements of the collection of N atoms.

(a) Local Goals (b) Global Goals

FIG. 6. *Mean values of the strain field $\tilde{\varepsilon}_{yy}$ after the third step of local enhancement using the Local and Global Goals algorithms.*

The total potential energy of the system is assumed to be the sums

$$E(\boldsymbol{u}) = -\sum_{i=1}^{N} \boldsymbol{f}_i \cdot \boldsymbol{u}_i + \sum_{k=1}^{N} E_k(\boldsymbol{u}), \tag{39}$$

where $\boldsymbol{f}_i$ is the external load applied to an interior atom i and $E_k(\boldsymbol{u})$ is the energy of atom k determined from interatomic potentials.

The goal of molecular statics is to find the equilibrium state $\boldsymbol{u} \in V$ that minimizes the total potential energy of the system, i.e., $\boldsymbol{u} = \operatorname{argmin}_{\boldsymbol{v}\in V} E(\boldsymbol{v})$. This minimization problem can be recast into the variational problem:

$$\textit{Find } \boldsymbol{u} \in V \textit{ such that} \quad B(\boldsymbol{u};\boldsymbol{v}) = F(\boldsymbol{v}) \quad \forall \boldsymbol{v} \in V, \tag{40}$$

where, for any $\boldsymbol{u} \in V$ and $\boldsymbol{v} \in V$,

$$\begin{aligned} B(\boldsymbol{u};\boldsymbol{v}) &= \sum_{i=1}^{N} \left[\sum_{k=1}^{N} \frac{\partial E_k}{\partial \boldsymbol{u}_i}(\boldsymbol{u}) \right] \cdot \boldsymbol{v}_i, \\ F(\boldsymbol{v}) &= \sum_{i=1}^{N} \boldsymbol{f}_i \cdot \boldsymbol{v}_i. \end{aligned} \tag{41}$$

Here $\partial/\partial \boldsymbol{u}_i$ is the gradient vector with respect to each component $u_{\alpha,i}$ of the displacement vector $\boldsymbol{u}_i$; i.e., $\partial/\partial \boldsymbol{u}_i = (\partial/\partial u_{1,i}, \ldots, \partial/\partial u_{d,i})$.

We briefly recall the main features of the quasicontinuum method (QCM). For more details, see [44, 40, 21]. The first step consists of choosing a set of R representative atoms, the so-called *repatoms*, and of approximating $\boldsymbol{u} \in V$ by a reduced

vector $\boldsymbol{u}_0 \in W = (\mathbb{R}^d)^R$, $R \ll N$, with $\boldsymbol{u}_0 = (\boldsymbol{u}_{0,1}, \boldsymbol{u}_{0,2}, \ldots, \boldsymbol{u}_{0,R}) \in W$. The displacements $\boldsymbol{u}_0$ represent the active degrees of freedom of the system and the repatoms are conveniently identified with the nodes of a finite element partition $\mathcal{P}_h$ of Ω. The displacements of the $(N-R)$ slave atoms are then interpolated from $\boldsymbol{u}_0$ by piecewise linear polynomials using the finite element mesh.

The second step of the QCM is devoted to the approximation of the total energy $E(\Pi \boldsymbol{u}_0)$ (recall section 3.1) by summing only over the repatoms such that

$$E(\Pi \boldsymbol{u}_0) \approx E_0(\boldsymbol{u}_0) = -\sum_{r=1}^{R} n_r \, \boldsymbol{f}_{0,r} \cdot \boldsymbol{u}_{0,r} + \sum_{r=1}^{R} n_r E_r(\boldsymbol{u}_0), \tag{42}$$

where n_r is an appropriate weight function associated with repatom r so as to account for all atoms in the lattice, i.e., $\sum_r n_r = N$, and $\boldsymbol{f}_{0,r}$ is the averaged external force acting on repatom r. For further details, see [21].

The minimization of the energy $E_0(\boldsymbol{u}_0)$ yields the surrogate problem

$$\textit{Find } \boldsymbol{u}_0 \in W \textit{ such that} \quad B_0(\boldsymbol{u}_0; \boldsymbol{v}) = F_0(\boldsymbol{v}) \quad \forall \boldsymbol{v} \in W, \tag{43}$$

where the semilinear form $B_0(\cdot;\cdot)$ and linear form $F_0(\cdot)$ are defined as

$$\begin{aligned} B_0(\boldsymbol{u}; \boldsymbol{v}) &= \sum_{i=1}^{R} \left[\sum_{r=1}^{R} n_r \frac{\partial E_r}{\partial \boldsymbol{u}_i}(\boldsymbol{u}) \right] \cdot \boldsymbol{v}_i, \\ F_0(\boldsymbol{v}) &= \sum_{i=1}^{R} n_i \, \boldsymbol{f}_{0,i} \cdot \boldsymbol{v}_i. \end{aligned} \tag{44}$$

6.2.2. Error estimation and adaptivity. In the nanoindentation problem that will be presented in the next section, the quantity of interest is the force that the crystal exerts on the indenter. Let the atoms, in contact with the lower surface of the indenter, be numbered from 1 to M. The quantity of interest is

$$Q(\boldsymbol{u}) = -\sum_{i=1}^{M} f_{y,i} = -\sum_{i=1}^{M} \frac{\partial E_i}{\partial u_{y,i}}(\boldsymbol{u}), \tag{45}$$

where $f_{y,i}$ and $u_{y,i}$ are the force and the displacement in the y-direction with respect to atom i. We assume that the meshes are such that the M atoms under the indenter are representative atoms, and all the forces are computed by the nonlocal approach (see [21]). The objective is then to estimate the error quantity

$$\mathcal{E} = Q(\boldsymbol{u}) - Q(\Pi \boldsymbol{u}_0). \tag{46}$$

The dual problem associated with the base problem (40) reads

$$\textit{Find } \boldsymbol{p} \in V \textit{ such that} \quad B'(\boldsymbol{u}; \boldsymbol{v}, \boldsymbol{p}) = Q'(\boldsymbol{u}; \boldsymbol{v}) \quad \forall \boldsymbol{v} \in V, \tag{47}$$

where the derivatives are given in the molecular statics case by

$$\begin{aligned} B'(\boldsymbol{u}; \boldsymbol{v}, \boldsymbol{p}) &= \sum_{j=1}^{N} \sum_{i=1}^{N} \boldsymbol{v}_j \cdot \left[\sum_{k=1}^{N} \frac{\partial^2 E_k}{\partial \boldsymbol{u}_j \partial \boldsymbol{u}_i}(\boldsymbol{u}) \right] \cdot \boldsymbol{p}_i, \\ Q'(\boldsymbol{u}; \boldsymbol{v}) &= -\sum_{j=1}^{N} \boldsymbol{v}_j \cdot \left[\sum_{i=1}^{M} \frac{\partial^2 E_i}{\partial \boldsymbol{u}_j \partial u_{y,i}}(\boldsymbol{u}) \right]. \end{aligned} \tag{48}$$

The surrogate dual problem is then

$$\text{Find } \boldsymbol{p}_0 \in W \text{ such that } \quad B_0'(\boldsymbol{u}_0; \boldsymbol{v}, \boldsymbol{p}_0) = Q_0'(\boldsymbol{u}_0; \boldsymbol{v}) \quad \forall \boldsymbol{v} \in W, \tag{49}$$

where by Q_0 we mean $Q_0(\boldsymbol{v}) = Q(\Pi \boldsymbol{v})$. The errors $\boldsymbol{e}_0 \in V$ and $\boldsymbol{\varepsilon}_0 \in V$ in $\Pi \boldsymbol{u}_0$ and $\Pi \boldsymbol{p}_0$, respectively, are defined as $\boldsymbol{e}_0 = \boldsymbol{u} - \Pi \boldsymbol{u}_0$ and $\boldsymbol{\varepsilon}_0 = \boldsymbol{p} - \Pi \boldsymbol{p}_0$. Then, the error in $Q(\boldsymbol{u})$ produced by $\Pi \boldsymbol{u}_0$ is given by, using Theorem 1,

$$\mathcal{E} = Q(\boldsymbol{u}) - Q(\Pi \boldsymbol{u}_0) = \mathcal{R}(\Pi \boldsymbol{u}_0; \boldsymbol{p}) + \Delta_1(\Pi \boldsymbol{u}_0, \Pi \boldsymbol{p}_0, \boldsymbol{e}_0, \boldsymbol{\varepsilon}_0), \tag{50}$$

where $\mathcal{R}(\Pi \boldsymbol{u}_0; \boldsymbol{v})$ is the residual functional, with respect to the base model problem

$$\mathcal{R}(\Pi \boldsymbol{u}_0; \boldsymbol{v}) = F(\boldsymbol{v}) - B(\Pi \boldsymbol{u}_0; \boldsymbol{v}), \quad \boldsymbol{v} \in V. \tag{51}$$

For details on the error estimator, see [34].

The adaptivity algorithm then proceeds as follows:

1. Initialize the load step s = 0. Input user-tolerance δ_{tol}.
2. s = s + 1.
3. Solve the primal and dual problems.
4. Compute the error estimates.
5. Check: $|\eta| > \delta_{\text{tol}} |Q(\boldsymbol{u}_0)|$. If false: go to step 2. If true: mark those elements with $|\eta_K(\Pi \boldsymbol{u}_0, \tilde{\boldsymbol{p}})| > \alpha \max_K |\eta_K(\Pi \boldsymbol{u}_0, \tilde{\boldsymbol{p}})|$, where α is a user-supplied number between 0 and 1.
6. Refine flagged elements and go to step 3.

6.2.3. A numerical example. The performance of the error estimator and adaptive strategy is demonstrated for a nanoindentation problem proposed by Tadmor et al. [33, 40, 45]. The simulation is actually provided as a model example accompanying the open source software package [22]. In this example, a thin film of aluminum crystal is indented by a rigid rectangular indenter, 9.31 Å wide and infinite in the out-of-plane direction, as depicted in Figure 7. The dimensions for the block of crystal are 2000×1000 (in Angströms) in the [111] and [$\bar{1}$10] directions of the crystal. The crystal rests on a rigid support so that homogeneous boundary conditions $\boldsymbol{u}_i = \boldsymbol{0}$ are prescribed for those atoms i located at $y = 0$. The indenter is moved downward in a succession of 30 load-step increments $\delta l = 0.2$. The boundary conditions for the atoms i just below the indenter are given by $\boldsymbol{u}_i = (0, -m\,\delta l, 0)$, $m = 1, \ldots, 30$. Quasistatic steps are then considered to solve for the displacements.

The site energies $E_k(\boldsymbol{u})$ of the aluminum crystal are computed here using the embedded atom method (EAM) (see, e.g., [9, 14]). Briefly, the semiempirical potential energy for atom k is given by the sum of an electron-density dependent embedding energy and pairwise interatomic potentials. The QCM also employs a cutoff function to approximate the interatomic potentials as the potential function decays rapidly with respect to the interatomic distance.

The interatomic distances in the undeformed configuration of the crystal are 2 Å in the x- and y-directions. One $(\bar{1}, \bar{1}, 0)$ layer of the film contains about 500,000 atoms. Rather than solving for the solution $\boldsymbol{u}$ of the full base problem (40), we have opted to consider as our reference solution an "overkill" solution of the surrogate problem (43). This solution is hereafter referred to as the base model solution as it involves a sufficiently high number of degrees of freedom so that it is a very accurate approximation of $\boldsymbol{u}$.

The base model solution is compared to the solution $\boldsymbol{u}_0$ obtained by the QCM on a much coarser discretization. In the quasicontinuum (QC) solution, the refinement

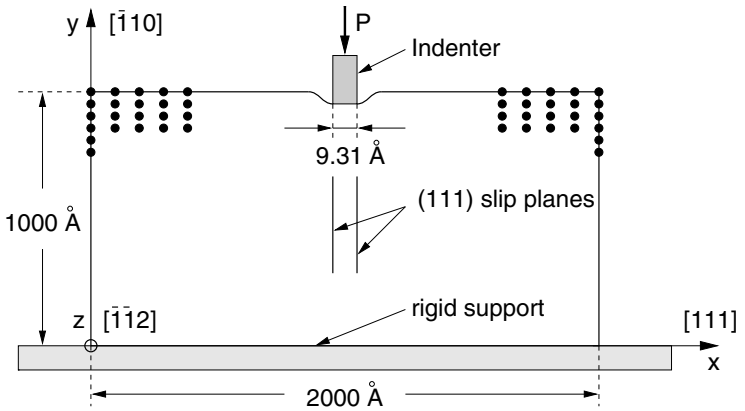


FIG. 7. *Nanoindentation of an aluminum crystal (the schematic representation is inspired by Figure* 1 *in* [45]*).*

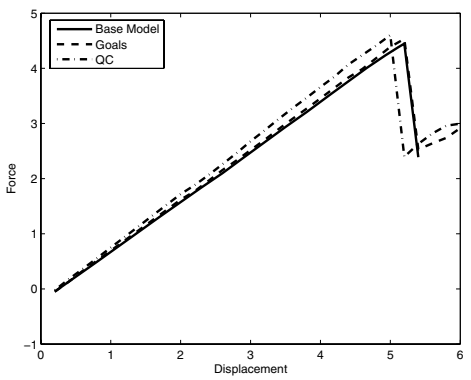

FIG. 8. *Force-displacement curve comparing the evolution of the base model, QC, and Goals solutions.*

parameter was set according to the authors' recommendations [22] to .075 while the Goals solution was set to a 5 percent error tolerance in the quantity of interest. Next, the force under the indenter is shown in Figure 8 for the base model solution, the QC solution, and the Goals algorithm. This force represents a quantity of physical interest as it can be experimentally measured and clearly indicates the nucleation of the dislocation. The QCM produces a stiffer material so that the critical force for dislocation nucleation occurs one load-step earlier than the base model solution. On the other hand, the Goals solution produces a remarkably accurate representation of the force-displacement curve when compared to the base model. Shown in Figure 9 are the relative errors and effectivity indices for each load-step, demonstrating the effectiveness of the error estimator used. Note that the effectivity index at loadstep 2 is far from unity due to the fact that the error is very near zero. As can be seen, the error in the solution is controlled to within the preset tolerance of 5 percent with the exception of the third and final load-steps. Although the error estimator overestimates the exact error for most of the load-steps in this example, this behavior may not be true for other cases. It is not proved that this is a guaranteed upper bound.

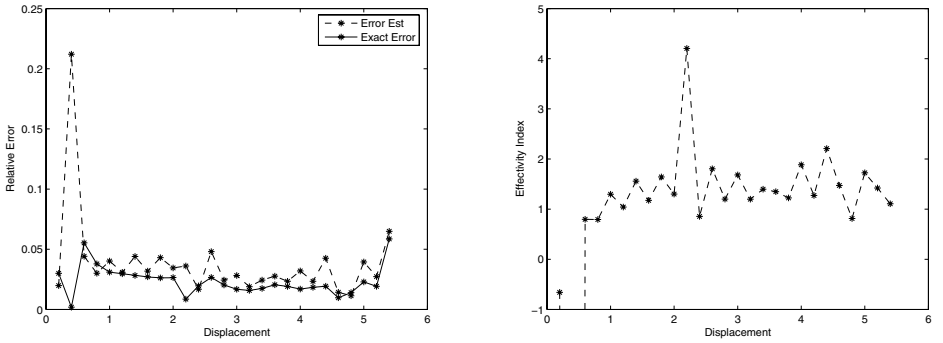

FIG. 9. *Exact and estimated relative errors for the Goals solution (left). Effectivity indices (right).*

6.3. Molecular dynamics application. We present in this section an application to modeling the dynamics of atoms whose motion is determined by molecular dynamics (MD) principles. We consider here surrogate models generated by the bridging-scale method (BSM) of Wagner and Liu [51] and the pseudospectral multiscale method (PMM) of Tang, Hou, and Liu [48]. We will show only preliminary results, but future work will include the development of automatic model adaptivity algorithms and the investigation of other surrogate models such as that put forth by Xiao and Belytschko [52].

6.3.1. The base model. Let $\Omega \subset \mathbb{Z}^d$ be an open bounded set, $d = 1$, 2, or 3. Let $\mathcal{L}$ denote the lattice of n atoms covering $\overline{\Omega}$. The initial positions of the atoms are given by the vectors $\boldsymbol{x}_i \in \mathbb{R}^d$ and the respective displacements by $\boldsymbol{u}_i \in \mathbb{R}^d$, $i = 1, \ldots, n$. The notation $\boldsymbol{u} = (\boldsymbol{u}_1, \boldsymbol{u}_2, \ldots, \boldsymbol{u}_n)$ collectively represents the displacement of the n atoms. We denote by $\boldsymbol{M}$ the mass matrix of the system $M_{ij} = m_{(i)}\delta_{ij}$, where m_i is the mass of atom i. Additionally, the interatomic potential energy (assumed to be given) is represented by $E(\boldsymbol{u})$ and the interatomic forces are computed as $\boldsymbol{f}(\boldsymbol{u}) = -\partial_{\boldsymbol{u}} E(\boldsymbol{u})$.

The MD problem is then characterized by the following system of ordinary differential equations for the displacements $\boldsymbol{u} = \boldsymbol{u}(t)$:

$$\boldsymbol{M}\ddot{\boldsymbol{u}} = \boldsymbol{f}(\boldsymbol{u}), \quad \boldsymbol{u}(0) = \boldsymbol{U}_0, \quad \dot{\boldsymbol{u}}(0) = \boldsymbol{V}_0 \tag{52}$$

subjected to appropriate boundary conditions. Note that external forces on the atoms have been neglected for simplicity. The superimposed dot implies differentiation with respect to time. Assuming $\boldsymbol{u}, \boldsymbol{v} \in \mathbb{V} = C^2\left((0,T); \left(\mathbb{R}^d\right)^n\right)$, we may recast the above problem into the weak form (1) with

$$\begin{aligned} B(\boldsymbol{u};\boldsymbol{v}) &= \int_0^T \boldsymbol{v}^T \left(\boldsymbol{M}\ddot{\boldsymbol{u}} - \boldsymbol{f}(\boldsymbol{u})\right) dt + \boldsymbol{v}^T(0)\boldsymbol{M}\dot{\boldsymbol{u}}(0) - \dot{\boldsymbol{v}}^T(0)\boldsymbol{M}\boldsymbol{u}(0), \\ F(\boldsymbol{v}) &= \boldsymbol{v}^T(0)\boldsymbol{M}\boldsymbol{V}_0 - \dot{\boldsymbol{v}}^T(0)\boldsymbol{M}\boldsymbol{U}_0. \end{aligned} \tag{53}$$

Note that the initial conditions in the above formulation are weakly imposed. Similarly, it is not difficult to derive the first derivative of the semilinear form $B(\cdot;\cdot)$. Indeed, we have for $\boldsymbol{p}, \boldsymbol{v} \in \mathbb{V}$,

$$\begin{aligned} B'(\boldsymbol{u};\boldsymbol{v},\boldsymbol{p}) = \int_0^T \left(\boldsymbol{M}\ddot{\boldsymbol{p}} - (\boldsymbol{f}'(\boldsymbol{u}))^T\boldsymbol{p}\right)^T \boldsymbol{v}\, dt \\ + (\boldsymbol{M}\boldsymbol{p}(T))^T\dot{\boldsymbol{v}}(T) - (\boldsymbol{M}\dot{\boldsymbol{p}}(T))^T\boldsymbol{v}(T), \end{aligned} \tag{54}$$

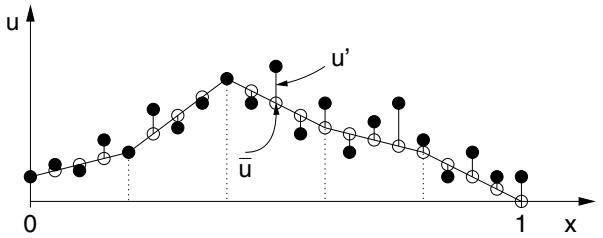

FIG. 10. *Illustration of the scale decomposition for BSM.*

where $\boldsymbol{f}'(\boldsymbol{u}) = \partial_{\boldsymbol{u}} \boldsymbol{f}(\boldsymbol{u})$ is the Hessian of $E(\boldsymbol{u})$ evaluated at $\boldsymbol{u}$.

6.3.2. The surrogate models: BSM and PMM. We consider as surrogate models those determined by the BSM [47, 51] and the PMM [48]. These methods are similar and their overall objectives are the following:

1. Construct a coarse-scale model from the MD model.
2. Solve the MD model only over a subdomain $\Omega_{MD} \subset \Omega$ and solve the coarse-scale model in the complementary subdomain $\Omega_C = \Omega \setminus \Omega_{MD}$. One difficulty is then to develop proper interface conditions to reduce/eliminate spurious wave reflection at the interface of Ω_{MD} and Ω_C.

The starting point of the BSM and the PMM is based on the classical decomposition of scales (see, e.g., [17]):

$$\boldsymbol{u} = \bar{\boldsymbol{u}} + \boldsymbol{u}', \quad \bar{\boldsymbol{u}} = \boldsymbol{P}\boldsymbol{u}, \quad \boldsymbol{u}' = \boldsymbol{Q}\boldsymbol{u} = (\boldsymbol{I} - \boldsymbol{P})\boldsymbol{u}, \tag{55}$$

where $\bar{\boldsymbol{u}}$ and $\boldsymbol{u}'$ define the coarse-scale displacements and the fine-scale fluctuations (see Figure 10), respectively, $\boldsymbol{P}$ is a general projection operator, and $\boldsymbol{I}$ is the identity matrix. One main difference between the BSM and the PMM is that $\bar{\boldsymbol{u}}$ is obtained in terms of piecewise linear functions in the case of the BSM and of a spectral representation in the case of the PMM.

Considering the subdomains Ω_{MD} and Ω_C, the solution $\boldsymbol{u}$ can be further decomposed into the following form:

$$\boldsymbol{u} = \begin{bmatrix} \boldsymbol{u}_{MD} \\ \boldsymbol{u}_C \end{bmatrix} = \begin{bmatrix} \bar{\boldsymbol{u}}_{MD} \\ \bar{\boldsymbol{u}}_C \end{bmatrix} + \begin{bmatrix} \boldsymbol{u}'_{MD} \\ \boldsymbol{u}'_C \end{bmatrix} \qquad \begin{matrix} \text{in } \Omega_{MD}, \\ \text{in } \Omega_C, \end{matrix} \tag{56}$$

where $\boldsymbol{u}_{MD}$ and $\boldsymbol{u}_C$ are the parts of the solution in Ω_{MD} and in Ω_C, respectively. In essence, the BSM and the PMM consist in approximating the large scales $\bar{\boldsymbol{u}}_{MD} + \bar{\boldsymbol{u}}_C$ by constructing a coarse-scale model over the whole domain Ω (see [51, 47, 48] for details) and by using $\bar{\boldsymbol{u}}_C$ to define the boundary conditions for the full MD model in Ω_{MD}. However, it is well known that such a coarse model may yield spurious wave reflection at the interface of the two domains. In order to alleviate this issue, the BSM and the PMM propose to calculate the fine-scale components in Ω_C corresponding to those atoms that are within the cutoff radius of atoms in Ω_{MD}. Therefore, the vector $\boldsymbol{u}'_C$ is approximated by a vector, say, $\boldsymbol{u}'_G$, that has zero entries, except at the position of these atoms "close" to the interface boundary. It follows that the surrogate models using the BSM or the PMM produce solutions in the form

$$\tilde{\boldsymbol{u}} = \begin{bmatrix} \boldsymbol{u}_{MD}, \\ \bar{\boldsymbol{u}}_C, \end{bmatrix} \qquad \begin{matrix} \text{in } \Omega_{MD}, \\ \text{in } \Omega_C. \end{matrix} \tag{57}$$

Once again, the readers are referred to [51, 47, 48] for the full description of the methods. Our main interest in the present work is to provide error estimates with respect to quantities of interest for the surrogate solutions $\tilde{\boldsymbol{u}}$.

6.3.3. Error estimates. The residual functional with respect to the MD problem can be written as

$$\mathcal{R}(\tilde{\boldsymbol{u}}, \boldsymbol{v}) = \int_0^T \boldsymbol{v}^T (\underbrace{\boldsymbol{M}\ddot{\tilde{\boldsymbol{u}}} - \boldsymbol{f}(\tilde{\boldsymbol{u}})}_{\boldsymbol{r}(\tilde{\boldsymbol{u}})}) dt = \int_0^T \sum_{i=1}^n \boldsymbol{v}_i \cdot \boldsymbol{r}_i(\tilde{\boldsymbol{u}}) dt. \tag{58}$$

The local residual $\boldsymbol{r}_i$ simply indicates how the second Newton law fails to be satisfied at atom i. Given a quantity of interest $Q(\boldsymbol{u})$, the modeling error in $Q(\tilde{u})$ can be approximated by

$$Q(\boldsymbol{u}) - Q(\tilde{\boldsymbol{u}}) \approx \mathcal{R}(\tilde{\boldsymbol{u}}, \boldsymbol{p}) = \int_0^T \sum_{i=1}^n \boldsymbol{p}_i \cdot \boldsymbol{r}_i(\tilde{u}) dt, \tag{59}$$

where $\boldsymbol{p}$ is the dual solution associated with $Q(\boldsymbol{u})$. The computational domain is divided here into a partition $\{\Theta\}_{j=0}^k$, as indicated in section 4. In the case of the BSM, the subdomains are conveniently constructed from the coarse lattice used in the solution of the coarse-scale model. We note that the error quantity can then be decomposed into local contributions either in time, η_t, or in space, η_j, as

$$\eta_t = \sum_{i=1}^n \boldsymbol{p}_i \cdot \boldsymbol{r}_i(\tilde{\boldsymbol{u}}), \qquad \eta_j = \int_0^T \sum_{i \in \Theta_j} \boldsymbol{p}_i \cdot \boldsymbol{r}_i(\tilde{\boldsymbol{u}}) dt, \tag{60}$$

and that the error can be rewritten in terms of these local contributions as

$$Q(\boldsymbol{u}) - Q(\tilde{\boldsymbol{u}}) \approx \mathcal{R}(\tilde{\boldsymbol{u}}, \boldsymbol{p}) = \int_0^T \eta_t dt = \sum_{j=0}^k \eta_j. \tag{61}$$

We will show in the following example the distribution of the contributions η_i and the evolution of the contributions η_t.

6.3.4. Numerical example. The performance of the error estimator and of the Local Goals algorithm is demonstrated here for the one-dimensional model problem studied in [47]. In this problem, $\Omega = [-2, 2]$, $\Omega_{MD} = [-0.35, 0.35]$, with atomic spacing $h_a = 0.005$. The atoms in domains Ω_{MD} and Ω_C are represented in black and red, respectively, in Figure 11 and subsequent figures. The initial conditions are given by

$$V_0(x_i) = 0, \qquad x_i \in \Omega, \tag{62}$$

and

$$U_0(x_i) = \begin{cases} 0.005\,(1 + 0.1\cos(80\pi x_i))\,\dfrac{e^{-100x_i^2} - e^{-6.25}}{1 - e^{-6.25}}, & |x_i| \le 0.25, \\ 0 & \text{otherwise.} \end{cases} \tag{63}$$

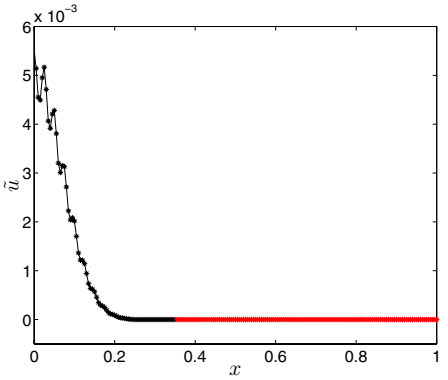

FIG. 11. *Initial displacement $U_0(x_i)$. The points in black represent atoms in Ω_{MD} while points in red denote atoms in Ω_C.*

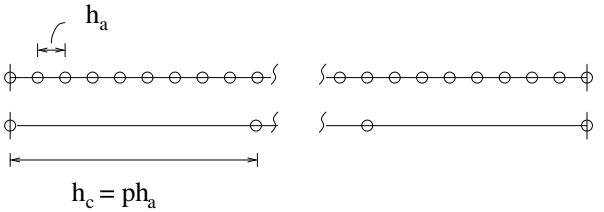

FIG. 12. *Schematic illustrating the construction of the coarse lattice on which the coarse-scale displacements $\bar{\boldsymbol{u}}$ are computed (BSM).*

Furthermore, $m_i = 1$, $i = 1, \ldots, n$, and the interatomic forces are given by linear springs:

$$\boldsymbol{f}(\boldsymbol{u}) = \boldsymbol{K}\boldsymbol{u}, \qquad \boldsymbol{K} = \begin{bmatrix} -2 & 1 & & \\ 1 & -2 & \ddots & \\ & \ddots & \ddots & 1 \\ & & 1 & -2 \end{bmatrix}. \tag{64}$$

In the case of the BSM, the coarse lattice is constructed by placing a coarse grid point at every p atom in Ω so that the coarse grid spacing $h_c = ph_a$; see Figure 12. The time integration scheme is identical to that used by Wagner and Liu [51]. In this example, we suppose that we are interested in the locally averaged displacement

$$Q(\boldsymbol{u}) = \frac{1}{M} \sum_{i \in \mathcal{M}} u_i, \qquad \mathcal{M} = \{i : |x_i| \leq 0.0025\}, \tag{65}$$

for which the strong form of the dual problem is

$$\boldsymbol{M}\ddot{\boldsymbol{p}} - \left(\boldsymbol{f}'(\boldsymbol{u})\right)^T \boldsymbol{p} = \boldsymbol{0}, \qquad -\boldsymbol{M}\dot{\boldsymbol{p}}(T) = \boldsymbol{q}, \qquad \boldsymbol{p}(T) = \boldsymbol{0}, \tag{66}$$

where M is the number of atoms considered in set $\mathcal{M}$ and $\boldsymbol{q}$ is the vector defined such that $Q(\boldsymbol{u}) = \boldsymbol{q}^T\boldsymbol{u}$. The dual problem is solved by integrating (66) backward in time using a numerical scheme similar to that used in the forward time integration of the primal problem.

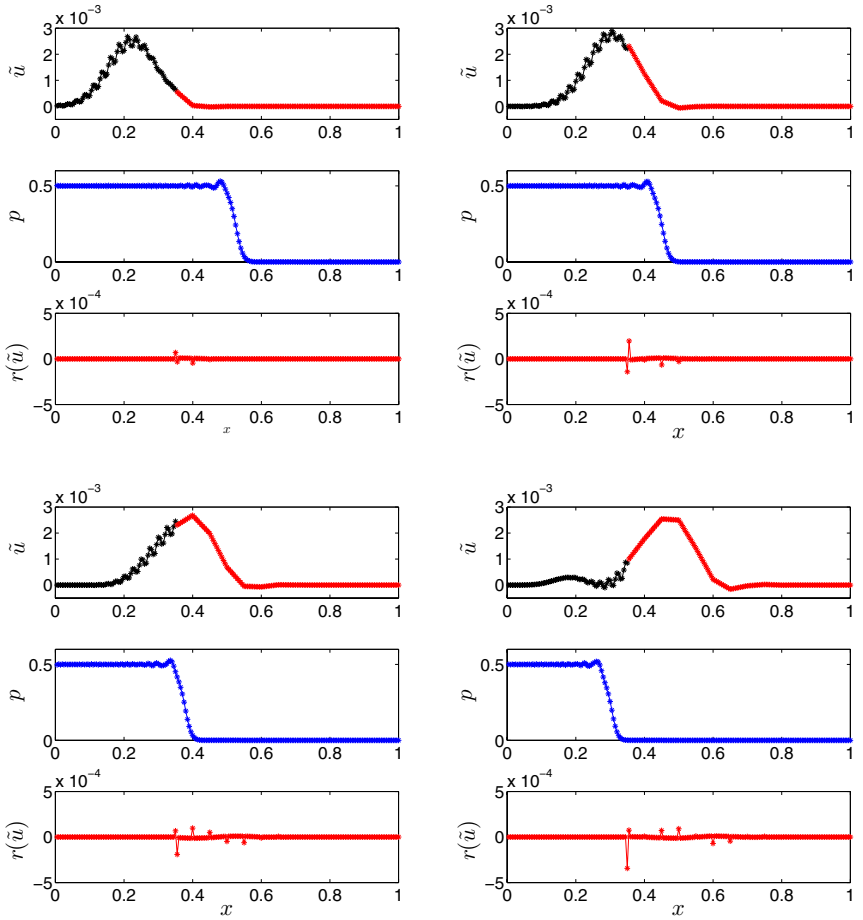

FIG. 13. *Time snapshots of the primal, dual, and force residual at* $t = 45, 60, 75, 90$ *(BSM).*

The first set of experiments deals with the BSM. The surrogate solution $\tilde{\boldsymbol{u}}$, the dual solution $\boldsymbol{p}$, and the local residuals $\boldsymbol{r}(\tilde{\boldsymbol{u}})$ are shown in Figure 13 for four specific times. Observe how the dual solution propagates in time in the opposite direction to the primal solution. The dual solution indicates how the local residuals $\boldsymbol{r}(\tilde{\boldsymbol{u}})$ influence the error in the quantity of interest. In particular, it can be seen that, as the front moves left to right, the dual solution reduces to zero. This simply means that the sources of error introduced in those spatial regions in which the dual solution is zero do not have enough time to propagate and pollute the quantity of interest. In the meantime, the local residuals become significant when the fine-scale noise starts to move across the interface boundary. The combination of both effects implies that the major contributions to the error in the quantity of interest are generated during the time interval $0.35 \leq t \leq 0.90$ and in the subregion $0.35 \leq x \leq 0.5$ as shown in Figure 14.

Since the sources of error, according to Figure 14, are essentially created in the space intervals $[0.35, 0.5]$ and $[-0.5, -0.35]$ (by symmetry), we choose to enlarge Ω_{MD} to $[-0.5, 0.5]$ in a one adaptive step of the Goals algorithm. Figure 15 displays the new

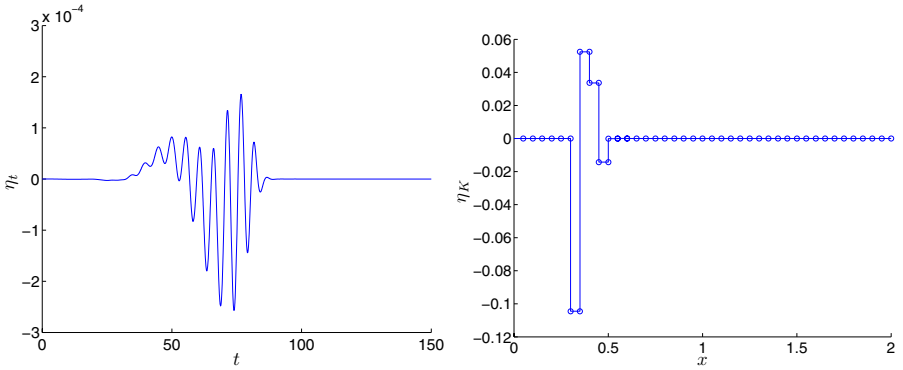

FIG. 14. *The temporal contribution to the error (left) and the spatial contribution (right) (BSM).*

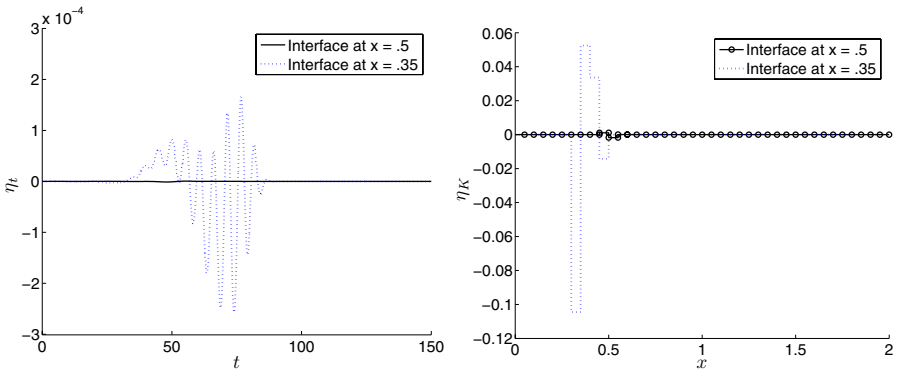

FIG. 15. *The temporal contribution to the error (left) and the spatial contribution (right) following model adaptivity (BSM).*

error contributions along the preadapted solution errors for comparison. As clearly shown, the modeling error has been effectively eliminated. Note that the dual solution $\boldsymbol{p}$ in the present numerical experiment was computed using the fine-scale model. A major task will be to construct adequate and reliable surrogate models for the dual problem.

We repeat the same experiments in the case of the PMM. Here we show only the results of the adaptive algorithm by considering $\Omega_{MD} = [-0.5, 0.5]$, $[-0.4, 0.4]$, and $[-0.45, 0.45]$. Figure 16 shows how contribution to the errors is reduced by successive refinement of the model problem.

7. Concluding comments. That mathematical models of physical events are almost always imperfect abstractions of nature is a truism universally understood by all students of science and engineering. The possibility of quantifying in some way the level of imperfection is therefore an intriguing proposition. Our approach is to measure this imperfection as estimates of error in specific quantities that we single out as important features of the behavior of the system under consideration. But even then we do not escape the necessity of using another imperfect model, the base model of the event. Nevertheless, we believe that the relatively straightforward machinery we describe for comparing models by estimating modeling error can be very valuable, particularly when two or more models of events that occur at different scales are

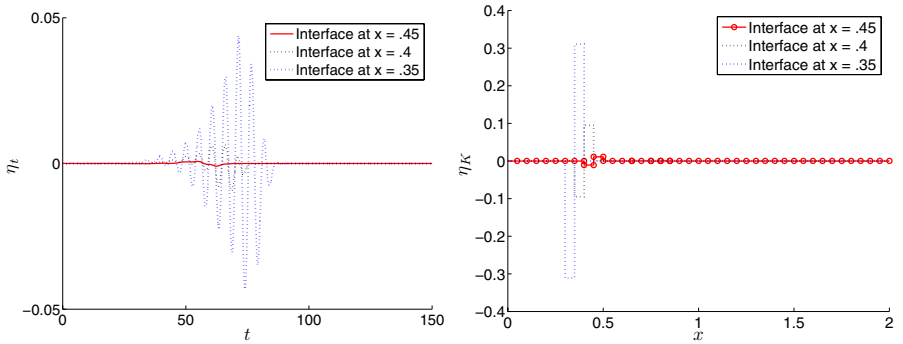

FIG. 16. *The temporal contribution to the error (left) and the spatial contribution (right) following model adaptivity (PMM).*

considered. If this process can be tied to physical measurements as well, it may be possible to develop powerful techniques for simulating events at multiple scales with a level of reliability beyond that thought possible in recent times.

There are many open issues that remain to be resolved. Given a list of quantities of interest for a base model at the finest scale, a systematic approach for developing the optimal ensemble-averaged or homogenized characterizations of these quantities at coarser scales is needed. We have offered some examples in this work, but further work on how these averaging techniques affect accuracy of estimates and convergence rates of the adaptive process is needed.

Adaptive modeling techniques are in early stages of development. The Global and Local Goals algorithms presented here represent only two of many possible approaches. Other techniques could be inspired by many of the multigrid methods in use in linear and nonlinear solvers. The role of various hand-shake methods for interfacing models of different scales as a basis for adaptive modeling is also a topic worthy of further study.

There is also the issue of modifying the definition of a quantity of interest as one progresses to coarser-scale models. In a two-scale situation, the coarse-scale model is a surrogate: an artifact of a computational process. In more general situations, it can be conceived that coarser-scale models may possess features of interest themselves, not always tied to fine-scale quantities of interest. The procedures we develop here should be applicable to such situations with straightforward modifications. Of overriding importance is the goal of estimating the relative error in quantities delivered by two or more models.
