The main practical limitation in using the FFTW is the limit in the amount of parallelism that is achievable: The FFTW requires partitioning the fluid data along the first dimension and at most N_1 processors can be deployed in a transform of size $N_1 \times N_2 \times N_3$. In order to be able to simulate larger immersed boundary systems it is necessary to develop an efficient fluid solver which uses more than N_1 processors. Such a fluid solver will require a more complex partition of the fluid into subdomains. We expect the extension of our fluid cache construction, and the distributed algorithm we have presented, to the case of the more general fluid partition to be straightforward.

Our algorithm assumes that the number of immersed boundary points is constant throughout the computation and the partition of these points to processors is carried out at the beginning of the computation and is held fixed throughout the computation. The case where immersed material is either created or destroyed during the simulation introduces an additional difficulty. In such a system the immersed boundary data structures may become concentrated in only a few of the available processors, leading to an unbalanced computation. This problem can be addressed by allowing the immersed boundary data structures to migrate between processors, but periodic reassignment of immersed boundary data structures to processors may be computationally expensive.

3-D MESH ADAPTATION ON MULTIPLE WEAK DISCONTINUITIES AND BOUNDARY LAYERS*

LAKHDAR REMAKI† AND WAGDI G. HABASHI†

Abstract. This paper presents new developments within an anisotropic mesh adaptation methodology, made essentially by the introduction of a metric modification and a shock-filter model that allow crisp capturing of weak shocks, as well as boundary layers and wakes. Inviscid and laminar external flow tests are used to demonstrate the efficiency of the method.

Key words. mesh adaptation, metric, shock filter

1. Introduction.

Unstructured meshes have made significant inroads in industrial applications of computational fluid dynamics (CFD) due to their inherent ability to more easily discretize complex geometrical domains and incorporate adaptive strategies. It is well established that such meshes will play a growing role in the numerical simulation of inviscid and viscous flows. The mesh adaptation strategy [1], [2], [3], [4], [5], [6], [7], [8], [9], [10], [11], [12], [13], [14], [15], [16], [17] is demonstrated to be a powerful tool to improve the solver accuracy and to handle large-scale simulations. To increase the accuracy and reduce the computational costs, the strategy consists of refining the grid in regions where physical details require more nodes to be well captured while coarsening in regions where the density of nodes is more than needed. The whole procedure is driven by an error indicator which is the core of the method. Different ways are proposed in the literature to compute this error, among them indicators based on large gradients of certain physical features; see, for instance, [3], [4], [6], [11], [14]. This approach achieves good results but unfortunately shows some shortcomings due to the fact that high errors are associated with large gradients, which is not necessary true for some situations; a linear solution could show very large gradients. In [7], [8], [9], a robust and efficient three-dimensional automatic mesh adaptation methodology, with CAD integrity, has been developed. The adaptation procedure uses an a posteriori interpolation error estimate, whose magnitude and direction are controlled by the matrix of local second derivatives of a selected flow variable. This error is projected over the mesh edges and drives the nodal movement algorithm, as well as the edge refinement and coarsening, and faces swapping strategies. This method exploits the notion of curvature of the solution; a Riemannian metric is derived from the Hessian of the solution, and then the Euclidean distance is replaced by a Riemannian distance. Consequently, by considering the surface defined by the solution as a manifold, edge lengths are close to geodesics between the nodes defining the edge, which is more natural.

Another interesting method that allows handling errors based on integral quantities rather than derivatives is the adjoint method. Solving the linear adjoint problem

allows connecting the indicator error directly to the local residual error of the primer solution. This method is well known and extensively used for a large range of optimization problems. Details of the formulation of the method to mesh adaptation could be found in [3], [18], [19], and important improvements and extensions are proposed in [11].

In the presence of multiple shocks, whatever the adaptation method used, one needs several solution-adaptation cycles to capture all shocks. Meshes tend to migrate towards the stronger shocks, at the detriment of the weaker ones, and it is almost impossible to capture the weaker shocks to the same level of accuracy. In this work we propose a preprocessing method that allows capturing all shocks, no matter their strength, in a limited number of adaptation cycles. This method consists of a combination of two complementary strategies. First, a correction to the metric is made to force the nodes to move towards discontinuities, even weak ones (such as diffuse shocks). Second, a shock filter is applied to the solution in order to enhance all shocks. Since boundary layers and wakes could also be considered smeared discontinuities, the method also yields an improvement in boundary layers and wake capturing. A considerable improvement is obtained, greatly enhancing the accuracy of CFD calculations, still considered to be the stumbling block for the adoption of the simulation over testing in cases where accuracy is of importance. Note that in this paper we will not do a comparison between methods since what we propose is a preprocessing that could be suitable for a great number of mesh adaptation methods. A comparison will be done with and without the proposed preprocessing for a given method to show its impact on mesh adaptation efficiency. The method developed in [7], [8], [9] is selected for such a purpose.

In section 2 an overview of the selected mesh adaptation methodology is given. The proposed metric correction and shock-filter model are detailed in section 3. The effectiveness of the proposed approach is demonstrated through numerical tests in section 4. Finally, conclusions are drawn in section 5.

2. Overview of the selected mesh adaptation methodology. As mentioned in the introduction, to demonstrate the efficiency of the proposed preprocessing, the mesh adaptation method developed in [7], [8], [9] is selected. This methodology, first developed by Peraire, Perión, and Morgan [14], Habashi et al. [7], and D'azevedo and Simpson [20], is coded in a home software, OptiGrid, in which the new developments are implemented. In this section a short survey of the methodology is given; for more details see the quoted references. The method is an h-adaptation method that includes node movement, edge refinement, coarsening, and swapping for hybrid grids consisting of any combinations of tetrahedra, prisms, hexahedra, and pyramids.

It is well known that for finite element and finite volume methods the computational error is bounded by the interpolation error, which is proportional to the second derivatives for the linear interpolation (see, for instance, [6], [7], [20]). This bound holds for the norm of the Sobolev space to which the solution of the continuous problem belongs. In the case of Navier–Stokes equations, which are our concern, the error estimation holds for the $\|.\|_{H^1}$ norm. The goal of mesh adaptation is to build a mesh in such a way that the interpolation error given by $\|u - r_h u\|_{H^1}$, with r_h the interpolation operator, is minimal. It is claimed in [6], [7] that a way to minimize this error is to equidistribute the interpolation pointwise error function $E(x) = |u(x) - r_h u(x)|$ over the whole computational domain.

Recall that the second derivative of a function g in a direction $\vec{v}$ ($\vec{v}$ is a unit

vector) is given by

$$\langle H\vec{v}, \vec{v}\rangle,$$

where H is the Hessian of g. When H is positive definite it defines a metric; therefore the error along a given vector could be interpreted as the length of the vector measured by the Hessian metric. Consequently, a metric is derived from the Hessian by considering its absolute value $|H| = R^t\,|\Lambda|\,R$, with R being the eigenvectors matrix of H and $|\Lambda| = \text{diag}\,\{|\lambda_1|, |\lambda_2|, |\lambda_3|\}$ the matrix composed by the absolute values of the eigenvalues of H. The adaptation procedure is then driven by the a posteriori error estimate based on the metric $|H|$ of a selected scalar flow variable. The eigenvectors give the direction of the stretching, while the eigenvalues give its magnitude, thus gradually creating anisotropy. As mentioned above, equidistributing the error on the original grid generates the adapted grid. The a posteriori error indicator ε along an edge $\vec{x}$ is computed as

$$\varepsilon = \int_0^1 \sqrt{\langle |H(s)|\,\vec{x}, \vec{x}\rangle} ds.$$

Note that, if e is the estimation of the interpolation error E using the second derivative's bound, the error indicator ε is related to e by $\varepsilon = h^2 e$, where h is the length of the edge $\vec{x}$.

In practice, we deal with a discrete scalar variable. Several methods are proposed in the literature to compute the Hessian of such functions. In this section we present the one used in our calculations. Let us describe first a method that computes a discrete gradient.

Let g be a given discrete scalar variable and n_j be a given node. We would like to estimate the gradient ∇g of g at node n_j. Let S_j be the set of nodes connected to node n_j and $card(S_j)$ the cardinality of S_j. Denote by g_k the value of g at node n_k and by $\vec{e}_{jk}$ the edge connecting nodes n_j and n_k. Using the first-order Taylor expansion we obtain

$$g_k - g_j = \nabla g.\vec{e}_{jk}. \tag{1}$$

Writing the equality (1) for all connected nodes to the concerned node n_j, we obtain the matricial relationship:

$$A\nabla g = B. \tag{2}$$

A is a $(card(S_j), 3)$ matrix (3 columns and $card(S_j)$ rows). In general, A is not a square matrix. The right-hand vector B is a $card(S_j)$-vector, and its components are given by $B_k = g_k - g_j$. Since A is not a square matrix, to approximate the gradient ∇g we seek a vector V that minimize the norm $\|AV - B\|_2 = \sqrt{\langle AV - V, AV - B\rangle}$, that is,

$$\nabla g \approx \underset{V \in IR^3}{\text{Inf}} \|AV - B\|_2\,. \tag{3}$$

The problem (3) is classical in optimization theory, and the solution is given by the pseudoinverse of the matrix A, namely

$$\nabla g \approx A^T \left[AA^T\right]^{-1} B. \tag{4}$$

Finally, the Hessian matrix is computed by applying the same process to the obtained gradient components.

The next sections discuss strategies for cost-efficient mesh adaptation. The intent is to minimize the number of solver-adaptation cycles, while at the same time making the approach more efficient and robust. The proposed preprocessing to achieve this goal is presented in detail.

3. Capturing multiple and weak discontinuities. It makes sense that the quality of the (initial) flow solution directly affects the ability of the error indicator to detect the dominant and secondary flow features, which will determine the outcome of the adaptation and provide even better solutions. On one hand, one aims at using as few points as possible for cost-effective CFD solutions and to minimize grid setup time; yet, on the other hand, the solution must be reasonably accurate for the salient features to at least be detected for adaptation. Obviously, the aim is to start with a mesh as coarse as possible, taking less time and effort to generate. However, when the initial grid is too coarse, discontinuities are badly defined, especially in the case of multiple shocks, whatever the solver used. As a remedy to enhance the adaptation of discontinuities, a shock-filter model is proposed. Furthermore, and in order to accelerate the adaptation process, a metric correction is added to force the nodes to move towards the discontinuities.

An adaptation process like the one described above requires a target error threshold selected by the user, in order to equidistribute the error around this threshold. However, the selection of this value is not evident, as error in itself is relative and has no scale, similar to a residual: it is just a relative measure of the magnitude and distribution of error. Choosing it in a heuristic fashion or on a trial-and-error basis can require a certain number of adaptation attempts to guess a suitable value and is thus not the most cost-effective approach. To overcome this shortcoming, we also propose a method, having its origin in signal processing, to automatically compute the starting value of the error density target on the initial mesh.

3.1. Automatic determination of error-density target. To illustrate the method, an error density distribution, obtained from a Mach solution of a laminar supersonic flow around a NACA0012 wing, is plotted in Figure 1(left). Note that there are distinct areas of low and high error. The sought-after error density is defined as the optimal threshold that separates these two areas and is obtained by maximizing the variance between them. This is a classical problem in statistics, also known in signal processing as Otsu's method [22]. Let $e(s),\ s = 1, \ldots, N_{nods}$, be the sorted error distribution over the N_{nods} nodes. The optimal threshold is given by $\beta = e(t^*)$, where $t^* = \text{ArgMax}(\delta_b^2)$ for the between-class variance:

$$\delta_b^2(t) = \frac{(\mu_T \omega(t) - \mu(t))^2}{\omega(t)(1-\omega(t))}, \tag{5}$$

where

$$\omega(t) = \sum_{k=1}^{t} p(k), \quad p(k) = \frac{n_k}{N_{nods}}, \quad n_k \text{ number of nodes with error } e(k),$$

$$\mu(t) = \sum_{k=1}^{t} e(k)p(k), \quad \text{and } \mu_T = \sum_{k=1}^{N_{nods}} e(k)p(k).$$

Figure 1(right) shows a binary image obtained by assigning a value of "one" to nodes with an error larger than the threshold β and of "zero" for nodes with an

error lower than β. This demonstrates the efficiency of Otsu's threshold to optimally separate the two areas of high and low error. This method is used in all test cases presented in this paper.

Note that there are many ways to compute this error threshold in the literature; however, most of them are weighted-average based methods. This makes their results depending on the whole domain size to the body size ratio, which is not desirable since this value is user dependent. Using the proposed Otsu threshold overcomes this shortcoming, which turns the method more robust.

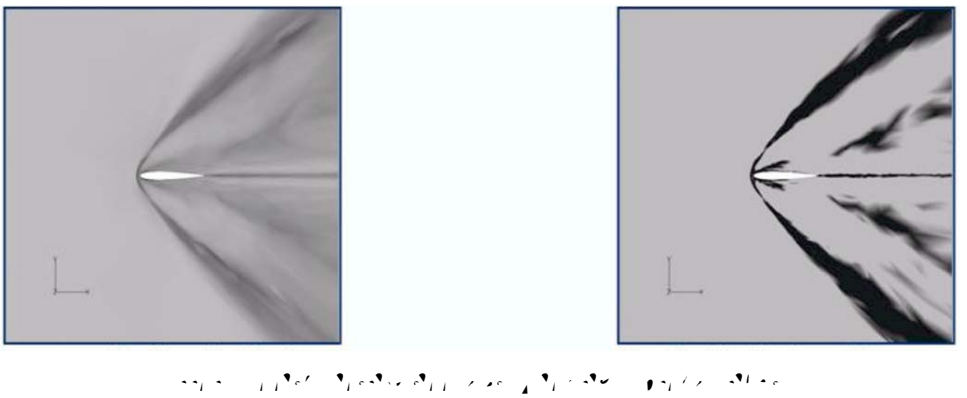

FIG. 1. *Error density distribution and Otsu's threshold binarization.*

3.2. Metric modification to accelerate adaptation of weak discontinuities. Let M be the metric obtained by taking the absolute value of the Hessian as described above, that is,

$$M = |H| = R^t\,|\Lambda|\,R. \tag{6}$$

Let e_i be a given edge; the error along the edge is given by

$$|e_i|_M^2 = \langle Me_i, e_i\rangle.$$

The idea of metric modification is to add to the edge error, the error of the edge projection on the solution gradient as shown on the Figure 2, namely

$$\|e_i\|_M^2 = \langle Me_i, e_i\rangle + \langle M(P_{\nabla U}e_i), (P_{\nabla U}e_i)\rangle,$$

where $P_{\nabla U}$ is the projection operator on the gradient of the solution∇U.

This will increase the error for edges that are oriented in the direction of the gradient, and they will be moved to be perpendicular to the gradient. This means that the corresponding connected nodes will move toward the shocks, since shocks are perpendicular to the scalar gradient.

The new error could be written as

$$\|e_i\|_{\bar{M}}^2 = \langle \bar{M}e_i, e_i\rangle, \tag{7}$$

where

$$\bar{M} = M + P_{\nabla U}MP_{\nabla U}. \tag{8}$$

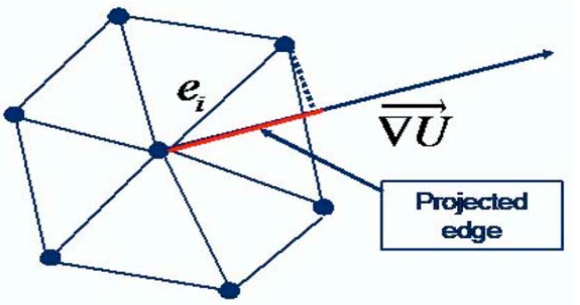

FIG. 2. *Illustration of the metric correction idea.*

In conclusion, the error correction is handled by a correction of the metric by adding the quantity $P_{\nabla U} M P_{\nabla U}$.

This metric correction could be seen as an upwinding of the original metric in the direction of the gradient. It makes sense since the maximum error around discontinuities and boundary layers is produced in the gradient direction. Therefore, and as in the case of several numerical methods, this shifting increases the stability and the robustness of the method. However, the main advantage of this correction is the convergence acceleration. Indeed, the node movement velocity, for instance, is described by the error intensities and orientations of the connected edges. Thus, by increasing the error intensities in the direction of discontinuities, what the metric correction allows us to do, nodes migrate faster towards these discontinuities.

Figure 3 shows the impact of metric correction on the adaptation for an oblique shock, using a hexahedral mesh. The test case is a supersonic flow on a ramp (more details of this test case are given below). As expected, the node movement is accelerated towards the shock in comparison to the case of adaptation without metric modification. This is demonstrated by the increase of the nodes' concentration around the shock. This obviously will reduce the necessary number of cycles of adaptation to converge to the right solution.

3.3. Shock-filter preprocessing (deconvolution) to enhance weak discontinuities. To enhance (sharpen) weak discontinuities, a shock-filter model, based on a quasi-linear hyperbolic equation, is proposed. It creates shocks at the zero-crossing of the Laplacian in the gradient direction:

$$(\mathrm{S}) \quad \begin{cases} \partial_t u^\varepsilon + F\left(\partial_\eta u^\varepsilon f'(u^\varepsilon), \partial_{\eta\eta} u_0^\varepsilon\right) \partial_\eta f(u^\varepsilon) = 0 \text{ on } IR^+ \times \Omega, \\ u^\varepsilon(0,x,y,z) = u_0^\varepsilon(x,y,z) \text{ on } \Omega, \\ \partial_n u^\varepsilon = 0 \text{ on } IR^+ \times \partial\Omega, \end{cases}$$

where Ω is an open set of IR^3 and $\partial_n$is the derivative in the outer normal direction $\vec{n}$ to $\partial\Omega$. The initial condition is smoothed in the model by a convolution product with a smooth function called a mollifier, that is, $u_0^\varepsilon = u_0 * \rho_\varepsilon$, where $*$ is a convolution product, $\rho_\varepsilon = \frac{1}{\varepsilon^3}\rho(x/\varepsilon, y/\varepsilon, z/\varepsilon)$, ρ is the mollifier, and ε is a scale parameter. This is a classical way to regularize the initial condition u_0, and the main result by doing so is that u_0^ε converges to u_0 when ε tends to zero in the L^p $1 \le p < \infty$ spaces. ∂_η and $\partial_{\eta\eta}$ are the first and second derivatives' operators in the gradient direction $\vec{\eta}$, and the functions F and f are regular (smooth) functions.

The function F, called the shock detection function, controls the position where the model must develop shocks that strengthen weak discontinuities. It satisfies the

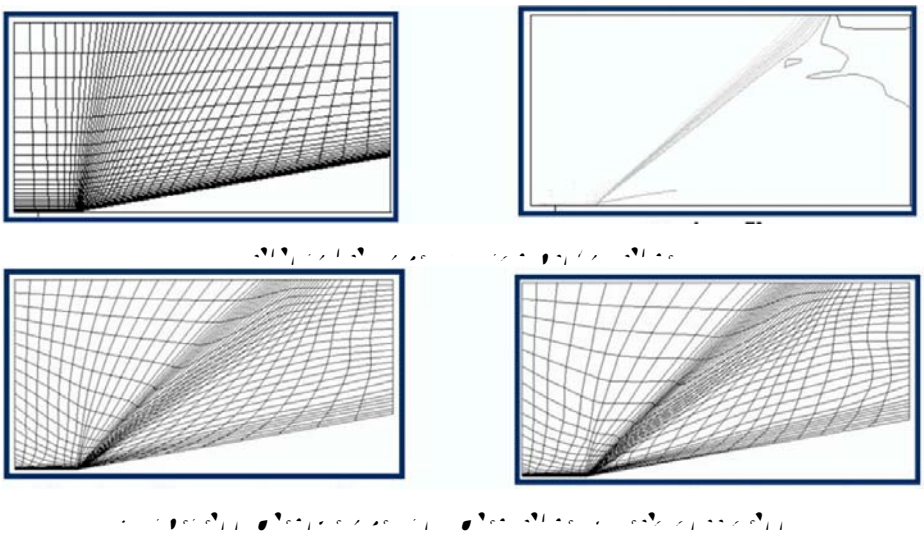

FIG. 3. *Inviscid supersonic flow on a ramp. The effect of metric correction: the concentration of nodes around the shock is more important when the metric correction is used.*

relationship $srF(s,r) > 0\ \forall (s,r) \in IR^* \times IR^*$, where $IR^* = IR \setminus \{0\}$. With the second derivatives the model distinguishes the concave and convex parts of the initial condition. The relationship satisfied by F allows the model to increase the concave parts and decrease the convex ones while leaving invariant the zero-crossing parts of the second derivatives leading to a creation of strong discontinuities (shocks). Note that the gradient direction is selected to compute derivatives because the gradient is perpendicular to shocks.

For the applications presented in this paper, we took $F(u,v) \equiv Sign(u)Sign(v)$. In theory, the function $Sign(.)$ must be regularized to obtain a C^∞ function. In practice, however, and since all functions are discrete functions, we do not need the regularization. Finally, note that any other type of functions that satisfy a shock detection condition such as sigmoid can be used. The function f controls the shock velocity according to the characteristics of the original solution (initial condition). The theoretical study (existence and uniqueness of a solution) and numerical study of such a model are developed in detail in [23], [24], [25].

To illustrate the effect of the shock filter, a one-dimensional gate signal is smoothed and a high-frequency sinusoidal noise is added. Figure 4 shows the result of applying the model to restore the signal, with the parameters $f(u) = \frac{1}{2}u^2$ and $F(u,v) \equiv Sign(u)Sign(v)$. The signal is restored quite well after only 5 time iterations.

Now, for adaptation purposes we consider the steady state of the shock filter, but before we do, we must make sure that this steady state exists. The following proposition proves such a claim.

PROPOSITION 3.1. (S) $\bar{U} \in L^\infty(\Omega)$.

. In [24], the following maximum principle for such equation is proven.

THEOREM 3.2 (maximum principle). u^ε (S) $IR^+ \times IR^3$ u_0^ε (x,y,z) $\text{Inf}\ u_0^\varepsilon(x,y,z) \leq u^\varepsilon(t,x,y,z) \leq \text{Sup}\ u_0^\varepsilon(x,y,z)$ $IR^+ \times IR^3$

Now let us give the proof of the existence of the steady state of (S). First, consider

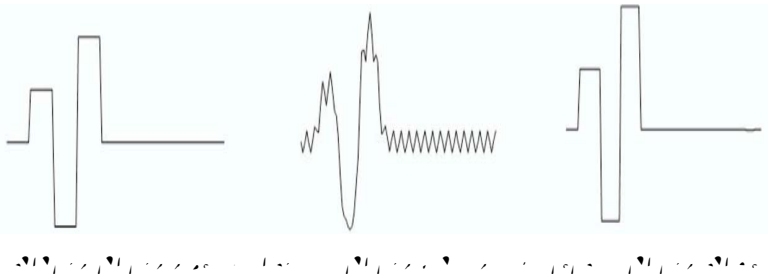

FIG. 4. *Restoration of a noisy and destroyed signal by the shock-filter process.*

the equivalent integral form of the equation:

$$u^\varepsilon(t,x,y,z) = u_0^\varepsilon(x,y,z) - \int_0^t F\left(\partial_\eta u^\varepsilon f'(u^\varepsilon), \partial_{\eta\eta} u_0^\varepsilon\right) \partial_\eta f(u^\varepsilon) dt. \tag{9}$$

Let t_n be a numerical nonnegative sequence that tends to infinity when n tend to infinity, and let (x_0, y_0, z_0) be a point such that $\partial_{\bar\eta\bar\eta} u_0^\varepsilon(x_0, y_0, z_0) > 0$.

The relationship $rsF(r,s) > 0$ implies that $\int_0^{t_n} F\left(\partial_\eta u^\varepsilon f'(u^\varepsilon), \partial_{\eta\eta} u_0^\varepsilon\right) \partial_\eta f(u^\varepsilon) dt > 0$. This, along with the maximum principle cited above, implies that $u^\varepsilon(t_n, x_0, y_0, z_0)$ is a monotone bounded sequence, which implies that it converges to a value denoted by $\bar u^\varepsilon(x_0, y_0, z_0)$.

Now let us show that this latter quantity does not depend on the sequence t_n. Let t_n and s_n be two sequences that tend to infinity, and consider the difference $|u^\varepsilon(s_n, x_0, y_0, z_0) - u^\varepsilon(t_n, x_0, y_0, z_0)|$. Let p be an integer such that $s_n < t_{n+p}$. Since $u^\varepsilon(t_n, x_0, y_0, z_0)$ is monotone, we have

$$|u^\varepsilon(s_n, x_0, y_0, z_0) - u^\varepsilon(t_n, x_0, y_0, z_0)| < |u^\varepsilon(t_{n+p}, x_0, y_0, z_0) - u^\varepsilon(t_n, x_0, y_0, z_0)|.$$

If $u^\varepsilon(t_n, x_0, y_0, z_0)$ is a [illegible] sequence, then $|u^\varepsilon(s_n, x_0, y_0, z_0) - u^\varepsilon(t_n, x_0, y_0, z_0)|$ tends to zero. This proves that there exists a steady state $\bar U$ such that $\bar U(x_0, y_0, z_0) = \bar u^\varepsilon(x_0, y_0, z_0) \forall (x_0, y_0, z_0) \in \Omega$. Moreover, and according to the maximum principle, $\bar U \in L^\infty(\Omega)$. For the case $\partial_{\bar\eta\bar\eta} u^\varepsilon(x_0, y_0, z_0) < 0$, we proceed analogously and achieve the same conclusions. □

As a corollary of this proposition, the steady state is a piecewise constant function. Consequently, the shocks are enhanced as shown in Figure 4, but certain useful curvatures may be lost and the adaptation in such areas may degrade. Thus, we propose adapting on an average scalar solution between the original solution and the steady state of the shock filter. This allows enhancing the discontinuities and preserving the curvatures since the steady state is a piecewise constant function. Figure 5 illustrates this claim.

For the rest of the paper, when we refer to the shock-filter output, we mean the steady state averaged by the initial condition. In the following subsection, a short discussion on the numerical aspect of the shock-filter model is given.

3.3.1. Numerical approximation. To apply the shock filter we need to perform two calculations: first compute the initial condition smoothing $u_0^\varepsilon = u_0 * \rho_\varepsilon$ and then compute the shock-filter solution iteratively to reach the steady state. For the smoothing calculation, the Gaussian kernel is selected as a mollifier. This choice is motivated by the fact that the convolution product with a Gaussian is equivalent to

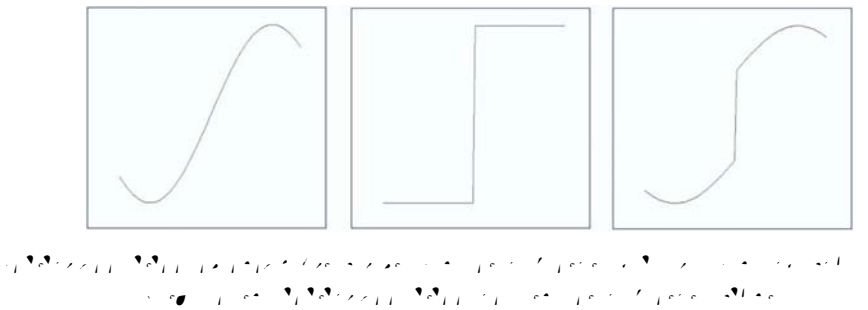

FIG. 5. *The average value of the original and steady state of the shock-filter model as scalar function of adaptation. The shock is enhanced and the curvature is preserved.*

solving the heat conduction equation, namely

$$\begin{cases} \partial_\tau u - \Delta u = 0, \\ u(0,.) = u_0, \end{cases} \quad \text{with } \varepsilon = \tau. \tag{10}$$

Then, instead of computing the convolution product, which is time-consuming, we solve (10).

For the discretization of the shock-filter equation itself, note first that for a given regular function g, the first and second derivatives in the gradient direction $\vec{\eta}$ are given by

$\partial_{\vec{\eta}} g = \sqrt{(\partial_x g)^2 + (\partial_y g)^2 + (\partial_z g)^2}$ and $\partial_{\vec{\eta}\vec{\eta}} g$

$$= \frac{(\partial_x g)^2 \partial_{xx} g + (\partial_y g)^2 \partial_{yy} g + (\partial_z g)^2 \partial_{zz} g + 2\partial_x g \partial_y g \partial_{xy} g + 2\partial_x g \partial_z g \partial_{xz} g + 2\partial_y g \partial_z g \partial_{yz} g}{(\partial_x g)^2 + (\partial_y g)^2 + (\partial_z g)^2}.$$

Any classical method such as FVM or first-order FEM could be used to discretize the equation, as one does not need high precision. Note that for both (S) and (10), the Neumann boundary condition $\partial_n u^\varepsilon = 0$ is considered.

We exploited the fact that the Laplacian operator does not change under axis rotation, which implies that if $(\vec{\zeta_1}(x,y,z), \vec{\zeta_2}(x,y.z))$ are two vectors such that $(\vec{\eta}, \vec{\zeta_1}, \vec{\zeta_2})$ forms an orthonormal reference at each point (x,y,z) of Ω, we have

$$\Delta u = \partial_{\vec{\eta}\vec{\eta}} u + \partial_{\vec{\zeta_1}\vec{\zeta_2}} u + \partial_{\vec{\zeta_2}\vec{\zeta_2}} u;$$

then we propose solving both heat conduction and shock-filter equations by the following explicit finite difference scheme.

We consider first a finite element discretization of the domain and classical first-order shape function for interpolation purposes. Now let $N_j = (x_j, y_j, z_j)$ be a given node on the mesh and h_j the minimum length of the connected edges to the node N_j. Let $K^+_{\vec{\eta}}$, $K^-_{\vec{\eta}}$, $K^+_{\vec{\zeta_1}}$, $K^-_{\vec{\zeta_1}}$ $K^+_{\vec{\zeta_2}}$, $K^-_{\vec{\zeta_2}}$ be the elements connected to node N_j, such that $K^+_{\vec{\eta}}$ contains the point $N_j + h_j\eta$ and $K^-_{\vec{\eta}}$ contains the point $N_j - h_j\eta$, and so on. Let $u^n_{j,1}$, $u^n_{j,-1}$, $u^n_{j,2}$, $u^n_{j,-2}$,$u^n_{j,3}$,$u^n_{j,-3}$ be the interpolated values (using first-order shape functions) at the positions $N_j + h_j\eta$, $N_j - h_j\eta$, $N_j + h_j\zeta_1$, $N_j - h_j\zeta_1$, $N_j + h_j\zeta_2$, $N_j - h_j\zeta_2$, respectively, and for the time step n. Then we make the following space approximations:

$$\partial_{\bar{\eta}\bar{\eta}} u^n_j \approx u^n_{j,1} - u^n_j + u^n_{j,-1}, \quad \partial_{\bar{\zeta_1}\bar{\zeta_1}} u^n_j \approx u^n_{j,2} - u^n_j + u^n_{j,-2}, \quad \partial_{\bar{\zeta_2}\bar{\zeta_2}} u^n_j \approx u^n_{j,3} - u^n_j + u^n_{j,-3},$$

$$\partial_{\bar{\eta}} u_j^n \approx \begin{cases} u_j^n - u_{j,-1}^n, & F(f'(u_j^n)(u_{j,1}^n - u_{j,1}^n), \partial_{\bar{\eta}\bar{\eta}} u_j^0) > 0, \\ u_{j,1}^n - u_j^n & \text{else.} \end{cases}$$

By replacing these quantities in the continuous equations and by using the Euler time discretization, we obtain an explicit centered finite difference scheme for the heat conduction equation and an explicit upwind finite difference scheme for the shock-filter equation. The CFL condition is obviously respected for the stability of the schemes.

Before showing the impact of the metric and shock-filter model on the adaptation on weak and multiple shocks, let us see the effect of the shock filter on a physical solution. Figure 6 shows the effect of shock enhancement filter on a Mach number solution of an inviscid flow around a NACA0012 airfoil: on the left is the original Mach profile and on the right is the shock-filter steady state. The figure shows a significant enhancement of the shocks that are much more diffusive in the original solution. Finally, note that the obtained solution of problem (S) has no physical meaning; it is used for adaptation purposes only. For readers that are not familiar with the NACA0012 test case and the Mach number notion, definitions are given in the appendix as well as very short introductory of the mechanics of the fluid.

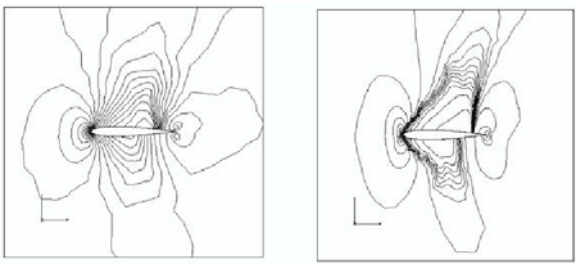

FIG. 6. *The enhancement effect of the shock filter.*

4. Numerical results.

4.1. Convergence improvement. Let us first see the impact of the proposed preprocessing (shock filter and metric correction) on the solution convergence. For this purpose an inviscid supersonic flow on a ramp is chosen. The angle of attack (AoA) is taken to be equal to 0 and the Mach number (M) equal to 2. We compare the results obtained on the original grid and those obtained after two cycles of adaptation in both situations (with and without the preprocessing). Figure 7 shows the grids and the Mach profile as well as the corresponding residual curves. The figure shows clearly the improvement of the convergence rate after mesh adaptation with a substantial improvement when the preprocessing is used. Note also the effect of the preprocessing filter on the shock-capturing quality. More convincing effects of the preprocessing on the whole process of adaptation solution are demonstrated through the following test cases.

4.2. Shock capturing. The following figures show the effect of shock-filter preprocessing and metric correction on capturing shocks. Figure 8 shows a transonic inviscid flow around a NACA0012 at an angle of attack AoA = 1 degree and Mach M= 0.85. The solution is obtained on a coarse grid. Note that one of the two shocks is quite smeared. Figure 9 shows different adapted grids and corresponding solutions obtained without shock-filter preprocessing and metric correction. As shown in the

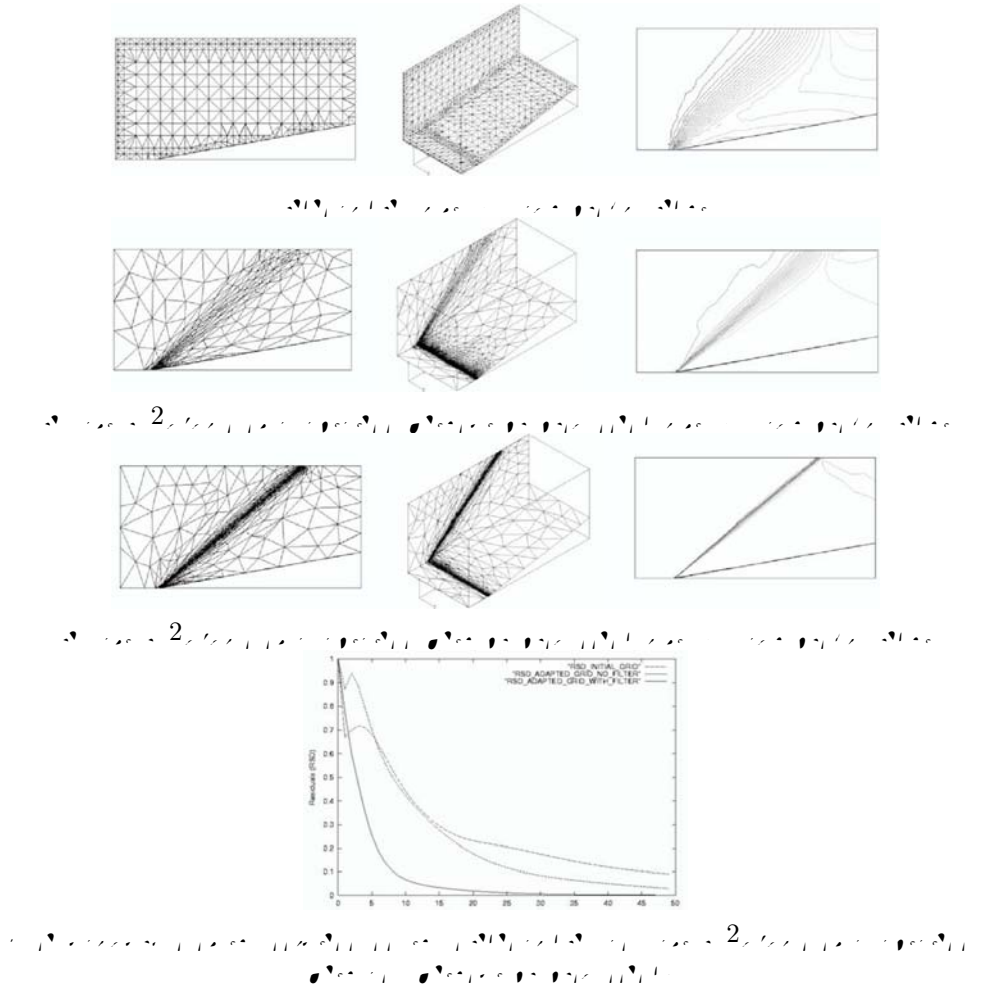

FIG. 7. *Inviscid supersonic flow around a ramp;* $A0A = 0, M = 2.0$.

figure, 7 solution-adaptation cycles are necessary to converge to the solution. Figure 10 shows the same test case using the proposed shock filter and metric correction. One can see that the shocks are well captured after only 3 solution-adaptation cycles and that, moreover, the results are improved for both mesh and solution.

The next test is that of an inviscid flow around a NACA0012 at AoA =1.25, M=0.8. Figure 11 shows the initial grid and the corresponding Cp profile: one can see that one of the shocks is very weak compared to the other and is smeared. The test demonstrates the capability of the proposed method to capture shocks in such extreme situations where the amplitudes of shocks are sensibly different. Figure 12 shows the adaptation without shock filter and metric correction. After 6 cycles, the weak shock is still not captured, and, moreover, the mesh is coarsened around the position of that shock. This means that even if the adaptation process continued, the shock would not be captured unless the number of nodes were sufficiently increased, which is contrary to the philosophy of mesh optimization. Figure 13 shows the effect of the shock-filter and metric modification preprocessing: both shocks are well captured

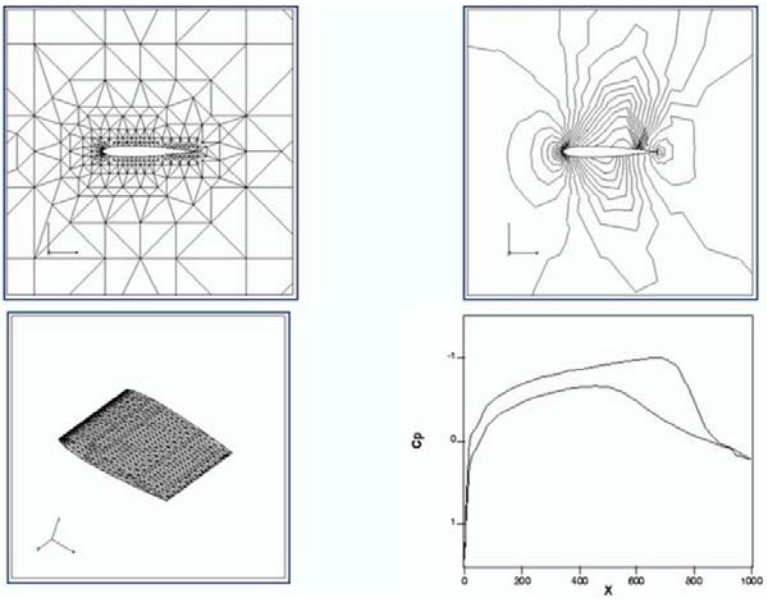

FIG. 8. *NACA*0012 *inviscid flow;* $AoA = 1, M = 0.8$. *The original grid and the Cp solution.*

with a smaller number of adaptation cycles (4) and without increasing the number of nodes, namely 50,000 nodes.

1. A question that naturally arises is what would happen if an artificial shock is created by the shock-filter, which is possible especially for internal flows. First, as mentioned in section 3.3 the adaptation is done on the steady state of the shock-filter equation averaged by the original solution; as a result any prejudicial coarsening of regions of interest in terms of physical features is avoided. Consequently, in such a situation a high concentration of nodes (more then necessary) is produced in a region where the artificial shock is detected; therefore this will not affect the result of the solver. Moreover, when all physical shocks are captured by the solver we stop applying the preprocessing since it becomes unnecessary, and then by doing only one more adaptation cycle the unneeded concentration of nodes disappears. Note that based on the explanation given above, the last operation is not necessary; it is more for aesthetic than for convergence purposes. The test case of Figure 13 illustrates very clearly this situation. The shock filter seems to consider the extension around the leading edge as a weak shock. The first three adapted grids show an artificial shock starting from the leading edge and growing to the back, while the corresponding solutions are not at all affected. Moreover, this artificial shock disappears in the last grid where the adaptation is done without the shock filter.

4.3. Effect on boundary layers and wakes. Even if the proposed shock-filter model was originally developed to enhance shocks and allow capturing weak and multiple shocks, this filter is also able to improve boundary layers and wake capturing. As with shocks, it improves the quality of the results and reduces the solution-adaptation cycles. Let us first see the effect of the shock filter on a laminar solution; considering the boundary layers and wakes to be smeared discontinuities, Figure 14 shows how the shock filter is able to sharpen the boundary layer thickness

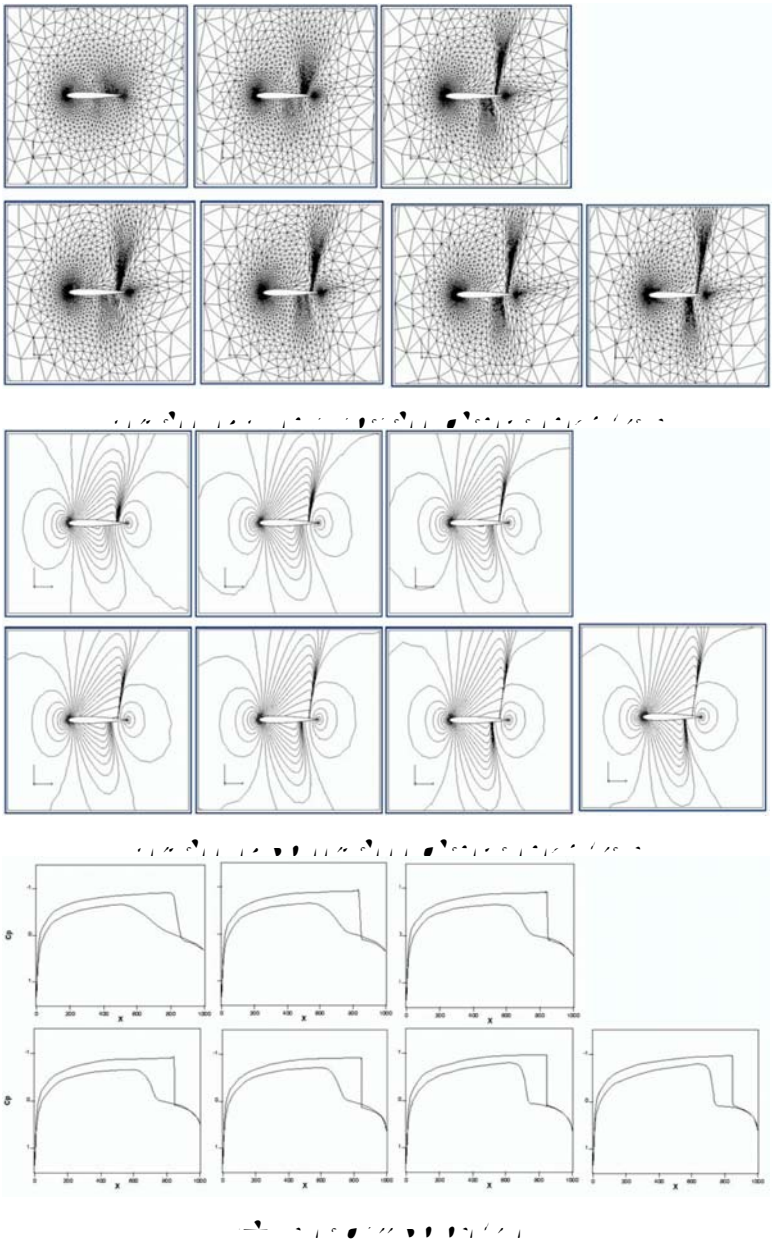

FIG. 9. *NACA*0012 *inviscid flow;* $AoA = 1, M = 0.8$. *Different cycles of adaptation without shock filter and metric correction.*

and to reinforce the wake.

Figures 15 and 16 show a laminar supersonic test case around a NACA0012 wing at AoA=0, M=2, and Re=2000. The results demonstrate that, in addition to sharpening weak discontinuities, the shock-filter and metric correction preprocessing improve the boundary layers and wake capturing. The solution and grid achieve a high quality, as well as a sensitive reduction of the solution-adaptation cycle numbers (from 7 to 3 for this test case), as in the case of inviscid shock solutions.

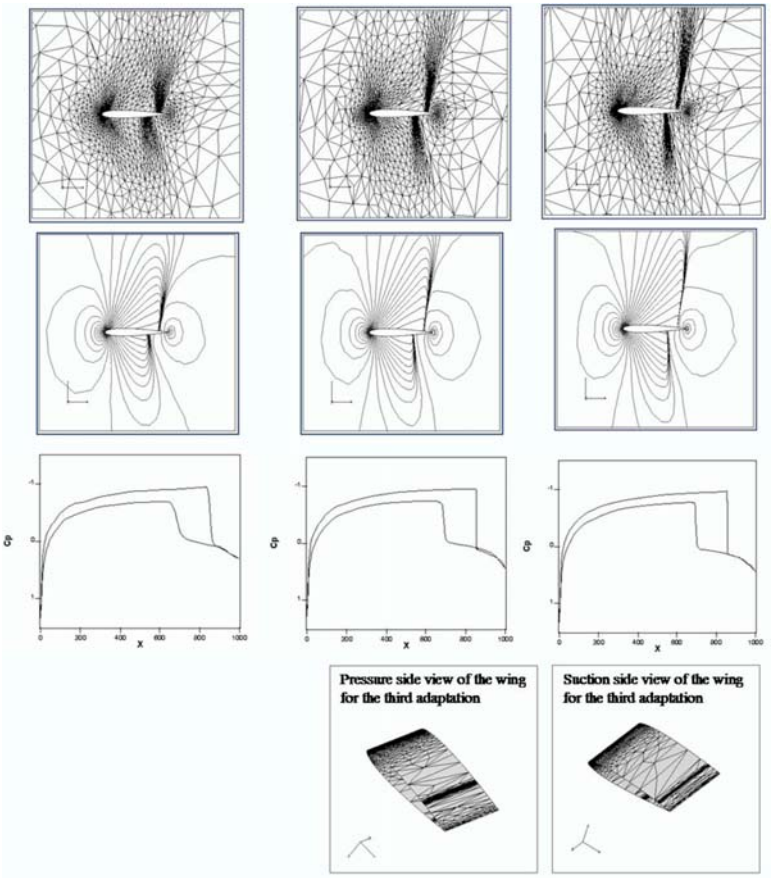

FIG. 10. *NACA*0012 *inviscid flow; AoA* $= 1, M = 0.8$. *Different cycles of adaptation with shock filter and metric correction.*

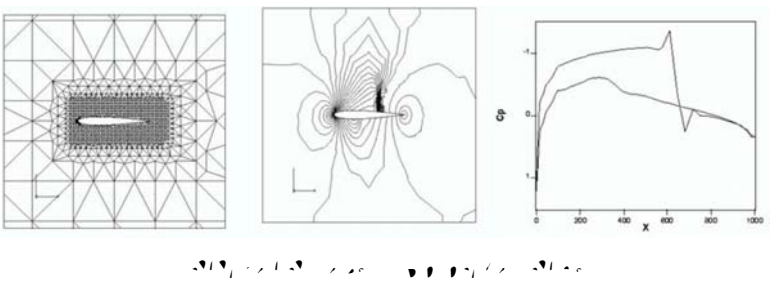

FIG. 11. *NACA*0012 *inviscid flow; AoA* $= 1.25, M = 0.85$. *The original grid and the Cp solution.*

Finally, note that the cost of the proposed preprocessing is negligible and does not increase the complexity of the global adaptation process.

5. Conclusions. This paper has proposed an original and efficient method to crisply capture weak discontinuities in multiple shocks cases, as well as boundary layers and wakes. At the same time, the method significantly reduces the number of solution-adaptation cycles. The method consists of complementary techniques. First,

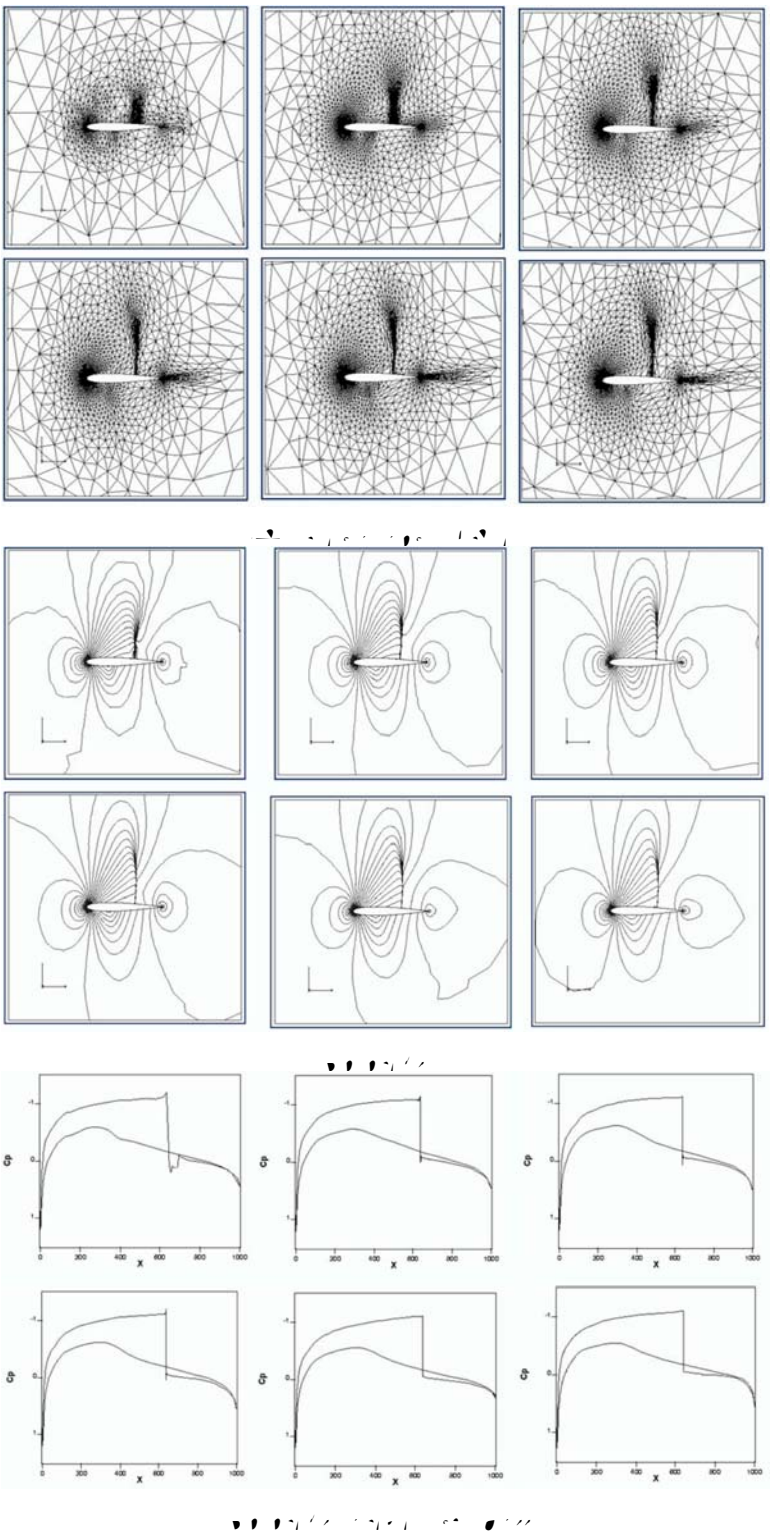

FIG. 12. *NACA*0012 *inviscid flow;* $AoA = 1.25, M = 0.8$. *Different cycles of adaptation without shock filter and metric correction.*

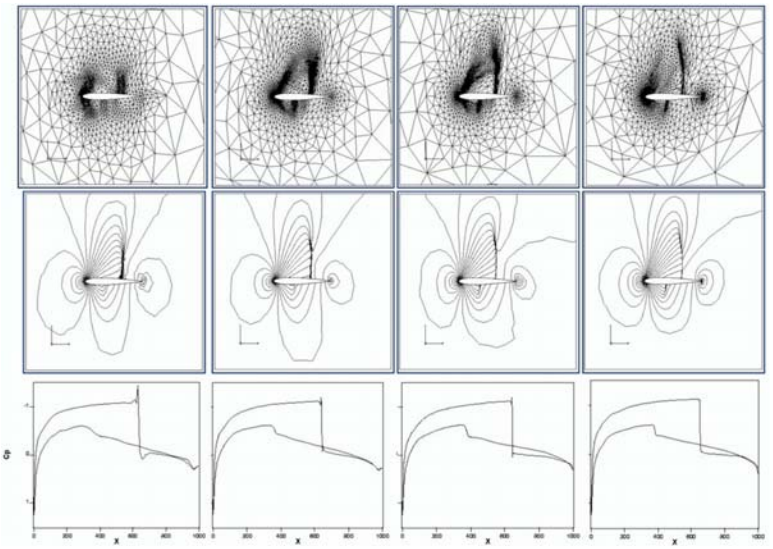

FIG. 13. *NACA*0012 *inviscid flow; AoA* $= 1.25, M = 0.8$. *Different cycles of adaptation with shock filter and metric correction.*

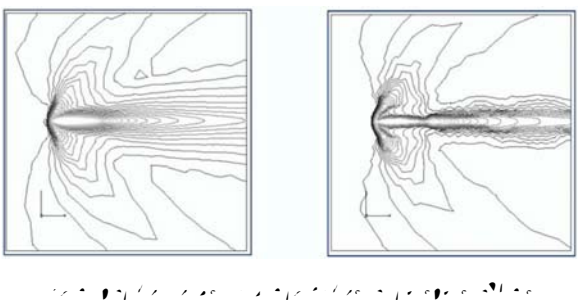

FIG. 14. *NACA*0012 *laminar supersonic flow. The effect of shock filter on boundary layer and wake.*

a shock filter is applied to the solution to enhance shocks, boundary layers, and wakes. Then a modification of the metric is proposed to speed up adaptation, by forcing the nodes to move toward the desired areas. The output of the shock filter is averaged by the selected original solution in order to conserve curvatures. The shock filter is modeled by a hyperbolic quasi-linear equation whose well-posedness was studied in previous works. However, a proof of the existence of a steady state is given within this paper. An automatic target error value is also proposed in this paper. Finally, the efficiency of the method is demonstrated by means of inviscid and laminar test cases, the general adaptation scheme having been shown to be equally and successfully applicable to turbulent flow cases, as well.

Appendix. Some definitions. The motion of a fluid (such as water and gas) is governed by the following Navier–Stokes equations:

$\partial_t \rho + \nabla \bullet (\rho \vec{v}) = 0$ (continuity equation),

$\partial_t(\rho \vec{v}) + \nabla \bullet (\rho \vec{v} \otimes \vec{v}) + \nabla p = \rho \vec{f} + \nabla(\lambda \nabla \bullet \vec{v}) + \nabla \bullet (2\mu D)$ (momentum equation),

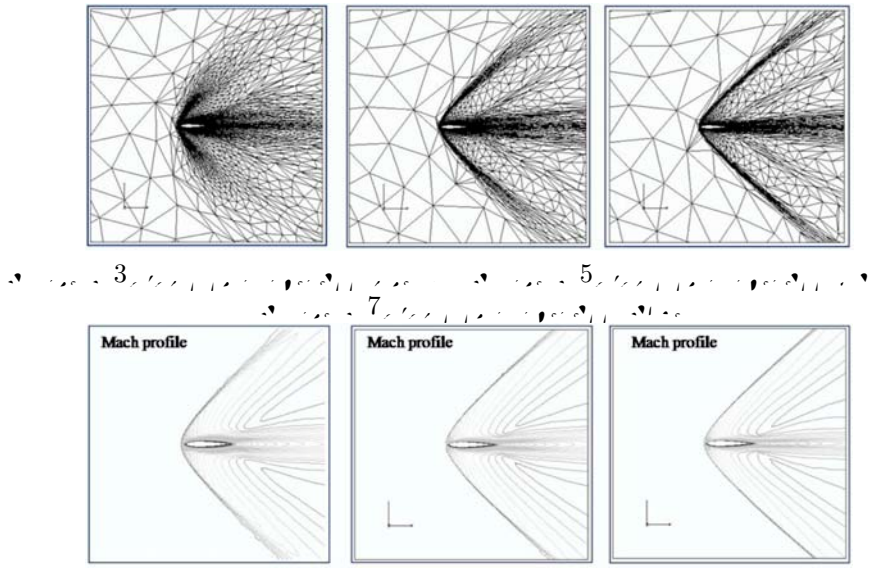

FIG. 15. *NACA*0012 *laminar supersonic flow;* $AoA = 0.0, M = 2.0$. *Different cycles of adaptation without shock filter and metric correction.*

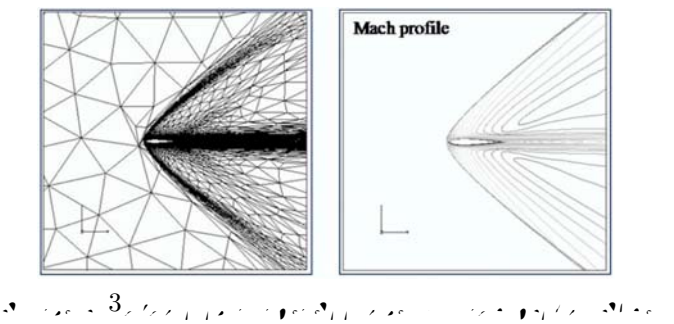

FIG. 16. *NACA*0012 *laminar supersonic flow;* $AoA = 0.0, M = 2.0$. *The third cycle of adaptation with shock filter and metric correction.*

$\partial_t(\rho E) + \nabla \bullet [(\rho E + p)\vec{v}] + \nabla p = \rho \vec{f} \bullet \vec{v} + \nabla \bullet (\kappa \nabla \theta) + \nabla \bullet (\lambda(\nabla \bullet \vec{v})\vec{v}) + \nabla \bullet (2\mu D\vec{v})$ (energy equation),

where ρ is the density, $\vec{v} = (v_1, v_2, v_3)^T$ the velocity of the fluid, $D = \frac{1}{2}(\frac{\partial v_i}{\partial x_j} + \frac{\partial v_j}{\partial x_i})_{ij}$ the deformation tensor, $\vec{f}$ the external force, $E = e + |\vec{v}|^2/2$ the specific total energy, e the specific internal energy, p the pressure, θ the temperature, λ, μ the Lamé viscosity coefficients, and κ the heat conductivity

The Navier–Stokes equations describe how the velocity, pressure, temperature, and density of the fluid are related. When the viscous effects are neglected the equations are called Euler equations and the flow is called inviscid. As we can see, these equations are composed of one equation of conservation of mass, three equations of momentum, and one equation of conservation of energy. Some important physical features are derived from the primitive physical variable mentioned above, among them the Mach number. Let us give describe this feature.

A.1. Mach number definition. As an aircraft moves through the air, the air molecules near the aircraft are disturbed and move around the aircraft. If the aircraft passes at a low speed, the density of the air remains constant. But for higher speeds, some of the energy of the aircraft goes into compressing the air and locally changing the density of the air. This compressibility effect alters the amount of resulting force on the aircraft. The ratio of the speed of the aircraft to the speed of sound in the gas determines the magnitude of many of the compressibility effects. Because of the importance of this speed ratio, aerodynamicists have designated it with a special parameter called the Mach number in honor of Ernst Mach, a late 19th century physicist who studied gas dynamics. The Mach number M allows us to define flight regimes in which compressibility effects vary. Subsonic conditions occur for Mach numbers less than one. When the speed of the object approaches the speed of sound (the flight Mach number is nearly equal to one), the flow is said to be transonic. At flight speed exactly equal to the speed of sound (Mach number equal to one) the flow is said to be sonic. Supersonic conditions occur for Mach numbers greater than one. For speeds greater than five times the speed of sound, the flow is said to be hypersonic. Shocks appear in the flow for the transonic, supersonic, and hypersonic regimes. The Mach number could be computed using the following formula: $M = \frac{|V|}{\sqrt{1.4P/\rho}}$.

Another important feature is the angle of attack, which represents the direction of the flow in the referential in which the Navier–Stokes (or Euler) equations are solved. This is specified by the boundary conditions on the inlet through the velocity components.

Let us now give a short definition of the NACA0012 test case used in this paper.

A.2. NACA0012 definition. An airfoil is the cross section of a wing. The NACA0012 is an airfoil belonging to the family NACA airfoils designs invented by the NACA organization that became NASA (National Aeronautics and Space Administration). NACA0012 foil is a 12% foil shape, meaning the maximum cord depth (rudder thickness) is 12% of chord length (distance from the most forward point of the rudder to the most aft point). Figure 17 shows the NACA0012 geometry meshed with triangles.

FIG. 17. *A meshed NACA*0012 *geometry.*

A STABLE HIGH-ORDER METHOD FOR TWO-DIMENSIONAL BOUNDED-OBSTACLE SCATTERING*

DAVID P. NICHOLLS† AND JIE SHEN‡

Abstract. A stable and high-order method for solving the Helmholtz equation on a two-dimensional domain exterior to a bounded obstacle is developed in this paper. The method is based on a boundary perturbation technique ("transformed field expansions") coupled with a well-conditioned high-order spectral-Galerkin solver. The method is further enhanced with numerical analytic continuation, implemented via Padé approximation. Ample numerical results are presented to show the accuracy, stability, and versatility of the proposed method.

Key words. electromagnetic scattering, acoustic scattering, high-order methods, boundary perturbations, spectral-Galerkin methods

AMS subject classifications. 78A45, 65N35, 35J05, 41A58

DOI. 10.1137/050632920

1. Introduction.

A wide variety of numerical techniques have been proposed for the approximation of electromagnetic and acoustic scattering returns from irregular obstacles (see, e.g., the book of Colton and Kress [9] and the survey papers of Warnick and Chew [35] and Reitich and Tamma [28]). Among the most compelling of these methods are those based on boundary perturbations, which can be originally traced to the work of Rayleigh [27] and Rice [29]. These methods are simple to implement, extremely fast, and quite robust within their domain of applicability. These properties have lead to not only low- and high-order implementations of these boundary perturbation algorithms, but also questions regarding their convergence, conditioning, and accuracy.

In a series of recent papers, Bruno and Reitich [3], Nicholls and Nigam [20], and Nicholls and Reitich [24, 25] have rigorously shown that not only are the scattered (acoustic/electromagnetic) fields , , , functions of the grating height (slope) parameter, ε, but also they can be analytically continued for any real value of ε. These analytical results demonstrate the convergence of boundary perturbation expansions, and would appear to justify the classical algorithms of Rayleigh [27] and Rice [29] (pursued to higher orders by Bruno and Reitich [4, 5, 6, 7, 8]; see also Milder [14, 15, 17, 16] and others [18, 19, 12]). However, it was shown in [24, 25] that, in fact, these approaches rely on significant , , , , for their convergence. Consequently these numerical implementations are highly ill-conditioned when pursued to high order, as demonstrated in [24] and, to a more limited extent, section 3.4 of the current work.

A new boundary perturbation algorithm, advocated in [25] and specified in section 2.3, which overcomes this issue of poor conditioning, follows the perturbation philosophy of Rayleigh [27] and Rice [29] , , by a change of variables, which

"flattens" the shape of the scatterer to a flat configuration. This "transformed field expansions" (TFE) method proves to be not only accurate and stable, but also robust at high order, and provides reliable estimates of both near- and far-field information.

The purpose of the current research is to extend the work of Nicholls and Reitich [24, 25] in several important directions. First, we present the TFE algorithm in the setting of bounded-obstacle scattering problems, which, while related to grating scattering problems, present their own difficulties. Such difficulties include, e.g., the different nature of solutions reflected in the appearance of Hankel functions rather than complex exponential functions in the fundamental solution, and the algorithmic challenges presented by the singular nature of the Laplacian in polar coordinates.

Second, and perhaps most importantly, we construct a new, highly efficient and accurate, well-conditioned spectral-Galerkin solver for the Helmholtz equation in an annulus (with a boundary condition involving the Dirichlet–Neumann operator (DNO)), which needs to be solved repeatedly in the TFE algorithm. This solver is highly efficient and accurate since it takes advantage of the fact that the DNO, although global in physical space, is local in frequency space. Hence, we can reduce the two-dimensional problem into a sequence of one-dimensional problems with a spectrally accurate approximation to the DNO. This solver is also well-conditioned since, as is done in a series of papers [30, 31, 32, 33], we construct basis functions which lead to sparse and well-conditioned linear systems. The good conditioning properties of this new method allow us to investigate the behavior of the TFE algorithm as the frequency of scattered radiation is varied from low to moderate, which is the final extension we present. Furthermore, based upon the preliminary investigations of [34] for radially symmetric scatterers, we can speculate that this new method will be quite effective in simulating problems with high frequencies (though it is not "specially designed" for this setting; see, e.g., [2] for a high-frequency boundary integral method). However, such calculations quickly become quite large and time-consuming, and we focus, in this first phase of this project, on modest calculations that illustrate the fundamental properties of the TFE algorithm in the bounded-obstacle configuration.

In section 2.1 we review the equations which govern the scattering of electromagnetic and acoustic radiation from bounded obstacles in two dimensions. In section 2.2 we review the classical "field expansions" (FE) method for numerically computing scattering returns, and in section 2.3 we generalize the stabilized TFE algorithm to bounded-obstacle configurations. In section 2.4 we discuss new algorithmic enhancements that improve the conditioning properties of the TFE method, and in section 3 we present numerical results that display the properties of both the classical FE and stabilized TFE approaches. In particular, in section 3.4 we exhibit the instabilities present in the FE method due to cancellations which are no longer present in the new, TFE recursions. In section 4 we examine the behavior of the TFE algorithm for computing plane-wave scattering problems in a variety of scenarios. After recalling how Padé approximation can be brought to bear on such problems in section 4.1, we conclude in section 4.2 with a series of numerical experiments that illuminate the capabilities of this new TFE algorithm. We present concluding remarks and future directions in section 5.

2. Boundary perturbation methods. In this study we will focus on the problem of approximating electromagnetic and acoustic plane-wave scattering returns from bounded obstacles. For simplicity we restrict our attention to the scalar case in two dimensions, and leave the more general three-dimensional setting for future work. In this section we state the governing equations and notations of bounded-obstacle

scattering and recall a classical boundary perturbation algorithm. To conclude we derive a new, stabilized method, and then discuss numerical implementation issues.

2.1. Governing equations. We consider a two-dimensional time-harmonic acoustic or electromagnetic plane wave,

$$\tilde{v}_i(r,\theta,t) = e^{i\omega t} v_i(r,\theta) = e^{i\omega t} e^{ir(\alpha\cos(\theta)-\beta\sin(\theta))},$$

which is incident upon a bounded obstacle

$$\Sigma = \{(r,\theta) : 0 \leq r < a + g(\theta), 0 \leq \theta < 2\pi\}$$

and generates a scattered field

$$\tilde{v}_s(r,\theta,t) = e^{i\omega t} v_s(r,\theta).$$

Here $\tilde{v} = \tilde{v}_i + \tilde{v}_s$ denotes the pressure in acoustics or the component of the electric or magnetic field parallel to the invariant (z) direction in electromagnetics. The reduced scattered field, v_s, obeys the Helmholtz equation

$$\Delta v_s + k^2 v_s = 0, \quad (r,\theta) \in \Omega, \tag{2.1}$$

where

$$\Omega = \{(r,\theta) : r > a + g(\theta), 0 \leq \theta < 2\pi\},$$

and the wavenumber k satisfies

$$k^2 = \alpha^2 + \beta^2 = (2\pi/\lambda)^2,$$

where λ is the wavelength of the radiation. Of course the scattered field must be periodic in θ, but there are several physically relevant boundary conditions that can be specified at the surface of the object. For definiteness we work with a pressure release (acoustics) or perfectly conducting (TE in electromagnetics) surface where

$$v_s(a+g(\theta),\theta) = -v_i(a+g(\theta),\theta) = -e^{i(a+g(\theta))(\alpha\cos(\theta)-\beta\sin(\theta))}. \tag{2.2}$$

Finally, the scattered solution must satisfy the Sommerfeld radiation condition (SRC) to guarantee a physical solution,

$$\lim_{r\to\infty} r^{1/2}(\partial_r v_s - ikv_s) = 0. \tag{2.3}$$

Gathering equations (2.1), (2.2), and (2.3); denoting v_s by v; and giving the Dirichlet data, (2.2), the generic name ξ, we state the fundamental equations of two-dimensional time-harmonic bounded-obstacle scattering:

$$\Delta v + k^2 v = 0, \qquad (r,\theta) \in \Omega, \tag{2.4a}$$

$$v(a+g(\theta),\theta) = \xi(\theta), \tag{2.4b}$$

$$\lim_{r\to\infty} r^{1/2}(\partial_r v - ikv) = 0. \tag{2.4c}$$

An equivalent statement of this problem, which not only conveniently expresses the SRC but also poses the problem on a [illegible] domain, can be made in terms of the DNO, also called the Dirichlet-to-Neumann (DtN) map. Let $b > a + |g|_{L^\infty}$; then,

using a classical argument of separation of variables, the general solution of (2.4a) and (2.4c) for $r \geq b$ can be expressed as

$$v(r,\theta) = \sum_{p=-\infty}^{\infty} a_p H_p^{(1)}(kr) e^{ip\theta},$$

where $H_p^{(1)}$ is the pth Hankel function of the first kind. Therefore, if $v(b,\theta)$ is given,

$$v(b,\theta) = \psi(\theta) = \sum_{p=-\infty}^{\infty} \hat{\psi}_p e^{ip\theta},$$

the coefficients $\{a_p\}$ can be uniquely determined; namely, we have

$$v(r,\theta) = \sum_{p=-\infty}^{\infty} \hat{\psi}_p \frac{H_p^{(1)}(kr)}{H_p^{(1)}(kb)} e^{ip\theta}.$$

We define a DNO, T, by

$$T\ \psi \equiv \partial_r v(b,\theta) = \sum_{p=-\infty}^{\infty} k \frac{d_z H_p^{(1)}(kb)}{H_p^{(1)}(kb)} \hat{\psi}_p e^{ip\theta}, \tag{2.5}$$

where

$$d_z H_p^{(1)}(kb) = \left. \frac{dH_p^{(1)}(z)}{dz} \right|_{z=kb},$$

which takes Dirichlet data, ψ, to Neumann data, $\partial_r v|_{r=b}$. Thus, (2.4) can be equivalently restated as

$$\Delta v + k^2 v = 0, \qquad (r,\theta) \in \Omega_{a+g,b}, \tag{2.6a}$$

$$v(a + g(\theta), \theta) = \xi(\theta), \tag{2.6b}$$

$$\partial_r v(b,\theta) - T\ v(b,\theta) = 0, \tag{2.6c}$$

where

$$\Omega_{a+g,b} = \{(r,\theta) : a + g(\theta) < r < b,\ 0 \leq \theta < 2\pi\}.$$

2.2. Field expansions. Considering a sufficiently smooth boundary deformation of the form $g(\theta) = \varepsilon f(\theta)$, it is known [3, 20, 24, 25] that the field, v, depends analytically on the parameter ε; i.e., we have the strongly convergent expansion

$$v(r,\theta;\varepsilon) = \sum_{n=0}^{\infty} v_n(r,\theta)\ \varepsilon^n.$$

This observation serves as the basis for the method of "field expansions" (FE); see [7, 8] and the references therein. This algorithm consists of finding $\{v_n\}$ recursively by solving a sequence of Helmholtz problems in the unperturbed domain

$$\Omega_{a,b} = \{(r,\theta) : a < r < b,\ 0 \leq \theta < 2\pi\}.$$

More precisely, it is not hard to derive from (2.6) that the v_n must satisfy

$$\Delta v_n + k^2 v_n = 0, \qquad (r,\theta) \in \Omega_{a,b}, \tag{2.7a}$$

$$v_n(a,\theta) = R_n(\theta), \tag{2.7b}$$

$$\partial_r v_n(b,\theta) - T\ v_n(b,\theta) = 0, \tag{2.7c}$$

where

$$R_n(\theta) = \delta_{n,0}\ \xi(\theta) - \sum_{l=0}^{n-1} \frac{f^{n-l}}{(n-l)!} \partial_r^{n-l} v_l(a,\theta) \tag{2.7d}$$

and $\delta_{n,m}$ is the Kronecker delta. Equations (2.7a) and (2.7c) imply that

$$v_n(r,\theta) = \sum_{p=-\infty}^{\infty} d_{n,p} \frac{H_p^{(1)}(kr)}{H_p^{(1)}(ka)} e^{ip\theta}, \tag{2.8}$$

while (2.7b) provides a recursion for the $d_{n,p}$. At order zero, $d_{0,p} = \hat{\xi}_p$, the pth Fourier coefficient of $\xi(\theta)$, and for $n > 0$

$$d_{n,p} = -\sum_{l=0}^{n-1} \sum_{q=-\infty}^{\infty} C_{n-l,p-q} \frac{d_z^{n-l} H_q^{(1)}(ka)}{H_q^{(1)}(ka)} d_{l,q}, \tag{2.9}$$

where the $C_{l,q}$ are defined by

$$\frac{(kf)^l}{l!} = \sum_{q=-\infty}^{\infty} C_{l,q} e^{iq\theta}.$$

Provided that we truncate the number of Fourier coefficients in f and retain only a finite number of terms $d_{l,p}$ (say, $0 \le l \le N$ and $-N_\theta/2 \le p \le N_\theta/2 - 1$), we have completely specified the [illegible] FE algorithm with (2.9). The only detail remaining is that the convolution product appearing in (2.9) is performed via FFT acceleration.

2.3. Transformed field expansions. As we shall see in section 3.4, the FE method outlined above suffers from severe ill-conditioning due to significant cancellations which occur in the recursion (2.9). However, a simple change of variables coupled to the FE design philosophy leads to a [illegible], high-order boundary perturbation scheme we call "transformed field expansions" (TFE) [21, 22, 23, 20, 24, 25]. The change of variables

$$r' = \frac{(b-a)r - bg(\theta)}{(b-a) - g(\theta)} = \frac{dr - bg}{d - g}, \qquad \theta' = \theta,$$

where $d = (b-a)$, maps the perturbed geometry $\Omega_{a+g,b}$ to the annulus $\Omega_{a,b}$. We now seek to restate (2.6) in these transformed coordinates. We note that

$$(d - g(\theta))\partial_\theta = (d - g(\theta'))\partial_{\theta'} - B(r',\theta')\partial_{r'}, \tag{2.10a}$$

$$(d - g(\theta))\partial_r = d\ \partial_{r'}, \tag{2.10b}$$

$$(d - g(\theta))D_r = d\ D_{r'} + A(r',\theta')\partial_{r'}, \tag{2.10c}$$

where $D_r = r\partial_r$,

$$A(r', \theta') = g(\theta')(b - r'),$$

and

$$B(r', \theta') = \partial_{\theta'} A = (\partial_{\theta'} g(\theta'))(b - r');$$

we note for future reference that

$$d\ r = d\ r' + A(r', \theta').$$

To begin the transformation we start with the Helmholtz equation, (2.6a):

$$\begin{aligned} 0 &= \Delta v + k^2 v = r^2 \Delta v + r^2 k^2 v \\ &= D_r^2 v + \partial_\theta^2 v + r^2 k^2 v \\ &= (d-g)^2 D_r^2 v + (d-g)^2 \partial_\theta^2 v + (d-g)^2 r^2 k^2 v \\ &= [(d-g)D_r][(d-g)D_r]v + [(d-g)\partial_\theta][(d-g)\partial_\theta]v \\ &\quad + (\partial_\theta g)[(d-g)\partial_\theta]v + (d-g)^2 r^2 k^2 v. \end{aligned} \tag{2.11}$$

Writing

$$u(r', \theta') = v(r' + A/d, \theta')$$

and replacing v in (2.11) by u, we obtain

$$\begin{aligned} 0 &= [dD_{r'} + A\partial_{r'}][dD_{r'} + A\partial_{r'}]u + [(d-g)\partial_{\theta'} - B\partial_{r'}][(d-g)\partial_{\theta'} - B\partial_{r'}]u \\ &\quad + (\partial_\theta g)[(d-g)\partial_{\theta'} - B\partial_{r'}]u + (d-g)^2 (r' + A/d)^2 k^2 u \\ &= d^2 D_{r'}^2 u + dA\partial_{r'} D_{r'} u + dD_{r'}[A\partial_{r'} u] + A\partial_{r'}[A\partial_{r'} u] \\ &\quad + d^2 \partial_{\theta'}^2 u - dg\partial_{\theta'}^2 u - d\partial_{\theta'}[g\partial_{\theta'} u] + g\partial_{\theta'}[g\partial_{\theta'} u] - dB\partial_{r'}\partial_{\theta'} u + B\partial_{r'}[g\partial_{\theta'} u] \\ &\quad - d\partial_{\theta'}[B\partial_{r'} u] + g\partial_{\theta'}[B\partial_{r'} u] + B\partial_{r'}[B\partial_{r'} u] \\ &\quad + d(\partial_{\theta'} g)\partial_{\theta'} u - g(\partial_{\theta'} g)\partial_{\theta'} u - (\partial_{\theta'} g)B\partial_{r'} u \\ &\quad + d^2 (r')^2 k^2 u + \sum_{j=1}^{4} C_j(g) k^2 u, \end{aligned}$$

where

$$\begin{aligned} C_1(g) &= -2d\ g(r')^2 + 2d\ Ar', \\ C_2(g) &= g^2 (r')^2 - 4gAr' + A^2, \\ C_3(g) &= (2/d)Ag^2 r' - (2/d)gA^2, \\ C_4(g) &= (1/d^2)g^2 A^2. \end{aligned}$$

We rewrite this as

$$D_{r'}^2 u + \partial_{\theta'}^2 u + (r')^2 k^2 u = F(r', \theta'; u),$$

where

$$\begin{aligned} -d^2 F &= dA\partial_{r'} D_{r'} u + dD_{r'}[A\partial_{r'} u] + A\partial_{r'}[A\partial_{r'} u] \\ &\quad - dg\partial_{\theta'}^2 u - d\partial_{\theta'}[g\partial_{\theta'} u] + g\partial_{\theta'}[g\partial_{\theta'} u] - dB\partial_{r'}\partial_{\theta'} u + B\partial_{r'}[g\partial_{\theta'} u] \\ &\quad - d\partial_{\theta'}[B\partial_{r'} u] + g\partial_{\theta'}[B\partial_{r'} u] + B\partial_{r'}[B\partial_{r'} u] \\ &\quad + d(\partial_{\theta'} g)\partial_{\theta'} u - g(\partial_{\theta'} g)\partial_{\theta'} u - (\partial_{\theta'} g)B\partial_{r'} u + \sum_{j=1}^{4} C_j(g) k^2 u. \end{aligned}$$

The Dirichlet condition, (2.6b), simply transforms to

$$u(a,\theta') = \xi(\theta'),$$

while (2.6c) can be written as

$$\begin{aligned} 0 &= \partial_r v(b,\theta) - Tv(b,\theta) \\ &= (d-g)\partial_r v(b,\theta) - (d-g)Tv(b,\theta) \\ &= d\ \partial_{r'} u(b,\theta') - d\ T'u(b,\theta') + g(\theta')T'u(b,\theta'). \end{aligned}$$

Since $T' = T$, (2.6c) transforms to

$$\partial_{r'} u(b,\theta') - Tu(b,\theta') = J(\theta'),$$

where

$$d\ J(\theta') = -g(\theta')Tu(b,\theta').$$

Collecting these transformations, we find that the transformed field u, upon dropping primes, satisfies

$$D_r^2 u + \partial_\theta^2 u + r^2 k^2 u = F(r,\theta;u), \qquad (r,\theta) \in \Omega_{a,b}, \tag{2.12a}$$

$$u(a,\theta) = \xi(\theta), \tag{2.12b}$$

$$\partial_r u(b,\theta) - T\ u(b,\theta) = J(\theta). \tag{2.12c}$$

Again, letting $g = \varepsilon f$, if f is sufficiently smooth, the analyticity of the [illegible] field u (see [20]) implies that

$$u(r,\theta;\varepsilon) = \sum_{n=0}^{\infty} u_n(r,\theta)\ \varepsilon^n. \tag{2.13}$$

Inserting the above into (2.12), it is straightforward, albeit tedious, to derive the following recursions for $\{u_n\}$:

$$D_r^2 u_n + \partial_\theta^2 u_n + r^2 k^2 u_n = F_n(r,\theta), \qquad (r,\theta)\ \in \Omega_{a,b}, \tag{2.14a}$$

$$u_n(a,\theta) = \delta_{n,0}\ \xi(\theta), \tag{2.14b}$$

$$\partial_r u_n(b,\theta) - T\ u_n(b,\theta) = J_n(\theta), \tag{2.14c}$$

where

$$\begin{aligned} -d^2 F_n = {} & d\ A\ \partial_{r'} D_{r'} u_{n-1} + d\ D_{r'}[A\partial_{r'} u_{n-1}] + A\partial_{r'}[A\partial_{r'} u_{n-2}] \\ & - d\ f\ \partial_{\theta'}^2 u_{n-1} - d\ \partial_{\theta'}[f\partial_{\theta'} u_{n-1}] + f\partial_{\theta'}[f\partial_{\theta'} u_{n-2}] \\ & - d\ B\partial_{r'}\partial_{\theta'} u_{n-1} + B\partial_{r'}[f\partial_{\theta'} u_{n-2}] \\ & - d\ \partial_{\theta'}[B\partial_{r'} u_{n-1}] + f\partial_{\theta'}[B\partial_{r'} u_{n-2}] + B\partial_{r'}[B\partial_{r'} u_{n-2}] \\ & + d(\partial_{\theta'} f)\partial_{\theta'} u_{n-1} - f(\partial_{\theta'} f)\partial_{\theta'} u_{n-2} - (\partial_{\theta'} f)B\partial_{r'} u_{n-2} \\ & + \sum_{j=1}^{4} C_j(f) k^2 u_{n-j} \end{aligned} \tag{2.14d}$$

and

$$d\ J_n = -f\ Tu_{n-1}(b,\theta). \tag{2.14e}$$

In the derivation of (2.14d) it is important to remember that A and B depend on g and therefore εf.

Remark 2.1. We note at this point the fundamentally inhomogeneous nature of (2.14). If we now wish to include effects from distributed sources, resulting in an inhomogeneous term—say, $M(r,\theta)$—appearing on the right-hand side of (2.1), the only modification to our TFE algorithm is that M will appear as F_0. By contrast, the FE recursions must be completely rederived, and even a boundary integral/element method will require a new implementation (though at the same computational cost).

2.4. TFE: Numerical implementation. It is clear from the above that the efficiency and accuracy of the TFE method depends greatly on how rapidly and accurately we can solve the Helmholtz equation (2.14a)–(2.14c) on an annular domain with the nonstandard outer boundary condition (expressed using a DNO). We now describe an efficient and accurate spectral-Galerkin method for the following problem (which is slightly more general than (2.14a)–(2.14c)):

$$D_r^2 U + \partial_\theta^2 U + r^2 k^2 U = F, \qquad (r,\theta) \in \Omega_0, \tag{2.15a}$$

$$U(a,\theta) = \xi(\theta), \tag{2.15b}$$

$$\partial_r U(b,\theta) - T\,U(b,\theta) = \eta(\theta), \tag{2.15c}$$

where $F(r,\theta)$, $\xi(\theta)$, and $\eta(\theta)$ are given functions. Expanding $U(r,\theta)$, $F(r,\theta)$, $\xi(\theta)$, and $\eta(\theta)$ in Fourier series, e.g.,

$$(U(r,\theta), F(r,\theta)) = \sum_{p=-\infty}^{\infty} (\hat{u}_p(r), \hat{f}_p(r)) e^{ip\theta}, \qquad (\xi(\theta), \eta(\theta)) = \sum_{p=-\infty}^{\infty} (\hat{\xi}_p, \hat{\eta}_p) e^{ip\theta},$$

and recalling the definition of the DNO in (2.5), we can decompose (2.15) into the following sequence of one-dimensional problems ($p = 0, \pm 1, \pm 2, \ldots$):

$$D_r^2 \hat{u}_p + (r^2 k^2 - p^2)\hat{u}_p = \hat{f}_p, \qquad r \in (a,b), \tag{2.16a}$$

$$\hat{u}_p(a) = \hat{\xi}_p, \tag{2.16b}$$

$$\partial_r \hat{u}_p(b) - k \frac{d_z H_p^{(1)}(kb)}{H_p^{(1)}(kb)} \hat{u}_p(b) = \hat{\eta}_p. \tag{2.16c}$$

It is known (see Lemma 3.2 in [10], and [11]) that

$$\operatorname{Im}\left\{ \frac{d_z H_p^{(1)}(kb)}{H_p^{(1)}(kb)} \right\} > 0, \qquad \operatorname{Re}\left\{ \frac{d_z H_p^{(1)}(kb)}{H_p^{(1)}(kb)} \right\} < 0,$$

$$-\frac{d_z H_p^{(1)}(kb)}{H_p^{(1)}(kb)} \sim \frac{p+1}{b} \quad \text{as } p \to \pm\infty, \tag{2.17}$$

which enables the well-posedness of the problem (2.16) to be directly established.

We now describe a spectral-Galerkin method for (2.16). To this end, let us first make a change of variable $x = \frac{2(r-a)}{b-a} - 1$, which maps $r \in (a,b)$ to $x \in I \equiv (-1,1)$. If we define

$$\tilde{u}_p(x) = \hat{u}_p(r), \quad \tilde{f}_p(x) = \hat{f}_p(r), \quad \tilde{\eta}_p = \frac{b-a}{2}\hat{\eta}_p, \quad \tilde{\xi}_p = \hat{\xi}_p,$$

$$c = \frac{b+a}{b-a}, \quad \omega = \frac{k(b-a)}{2}, \quad T_p = k\frac{d_z H_p^{(1)}(kb)}{H_p^{(1)}(kb)},$$

then (2.16) becomes

$$(x+c)\partial_x((x+c)\partial_x\tilde{u}_p),+((x+c)^2\omega^2-p^2)\tilde{u}_p=\tilde{f}_p,\qquad x\in I, \tag{2.18a}$$

$$\tilde{u}_p(-1)=\tilde{\xi}_p, \tag{2.18b}$$

$$\partial_x\tilde{u}_p(1)-T_p\tilde{u}_p(1)=\tilde{\eta}_p. \tag{2.18c}$$

One verifies easily that

$$h_p(x)=\frac{\tilde{\eta}_p+T_p\tilde{\xi}_p}{1-2T_p}x+\frac{\tilde{\eta}_p+\tilde{\xi}_p-T_p\tilde{\xi}_p}{1-2T_p}$$

satisfies the two boundary conditions in (2.18). Hence, setting

$$d=\frac{\tilde{\eta}_p+T_p\tilde{\xi}_p}{1-2T_p},\quad f_p=\tilde{f}_p-((x+c)^2\omega^2-p^2)h_p-d(x+c),$$
$$\tilde{u}_p(x)=u_p(x)+h_p(x),$$

we can rewrite (2.18) into the following problem with homogeneous boundary conditions:

$$(x+c)\partial_x((x+c)\partial_x u_p)+((x+c)^2\omega^2-p^2)u_p=f_p,\qquad x\in I, \tag{2.19a}$$

$$u_p(-1)=0, \tag{2.19b}$$

$$\partial_x u_p(1)-T_p u_p(1)=0. \tag{2.19c}$$

Let us denote by P_N the space of complex polynomials of degree less than or equal to N. We set

$$X_N^{(p)}=\{u\in P_N : u(-1)=0,\ \partial_x u(1)-T_p u(1)=0\}. \tag{2.20}$$

The spectral-Galerkin method for (2.19) is to find $u_N^{(p)}\in X_N^{(p)}$ such that

$$\int_I (x+c)\partial_x((x+c)\partial_x u_N^{(p)})\bar{v}_N\,dx\ +\int_I((x+c)^2\omega^2-p^2)u_N^{(p)}\bar{v}_N\,dx$$
$$=\int_I f_p\bar{v}_N\,dx\quad\forall v_N\in X_N^{(p)}, \tag{2.21}$$

where $\bar{v}_N$ is the complex conjugate of v_N.

The well-posedness of (2.21) follows from (2.16). However, a complete error analysis is still elusive. In [34], an error analysis was carried out for the case where T_p is replaced by its zeroth-order approximation, ip. The analysis was based on a new, uniform a priori estimate for the approximate solution. However, the extension of that procedure to the current situation appears to be subtle and is the subject of ongoing research.

We now describe an efficient numerical algorithm for solving (2.21). We recall that if T_p is a real number and P_N consists of real polynomials, it is shown in [30, 31] that there exist unique real pairs $(\alpha_k^{(p)},\beta_k^{(p)})$ such that

$$X_N^{(p)}=\text{span}\{\phi_0^{(p)},\phi_1^{(p)},\dots,\phi_{N-2}^{(p)}\}$$

with $\phi_k^{(p)}(x)=L_k(x)+\alpha_k^{(p)}L_{k+1}(x)+\beta_k^{(p)}L_{k+2}(x)$; we recall that L_k is the kth Legendre polynomial. It is easy to see that this is still true if we allow $(\alpha_k^{(p)},\beta_k^{(p)})$ to be complex

for complex T_p and P_N, $X_N^{(p)}$ as defined above. In fact, one verifies easily that

$$\alpha_k^{(p)} = \frac{(2k+3)}{(k+2)^2 - 2T_p}, \qquad \beta_k^{(p)} = \alpha_k^{(p)} - 1.$$

We recall from (2.17) that $\mathrm{Re}(T_p) < 0$; hence, $(\alpha_k^{(p)}, \beta_k^{(p)})$ are always well defined. Therefore, setting

$$\begin{aligned}
u_N^{(p)} &= \sum_{j=0}^{N-2} u_j^{(p)} \phi_j, \qquad \mathbf{u} = (u_0^{(p)}, u_1^{(p)}, \ldots, u_{N-2}^{(p)})^T, \\
a_{jl}^{(p)} &= \int_I (x+c)\partial_x((x+c)\partial_x \phi_l^{(p)})\bar{\phi}_j^{(p)}\, dx, \qquad A^{(p)} = (a_{jl}^{(p)}), \\
b_{jl}^{(p)} &= \int_I ((x+c)^2\omega^2 - p^2)\phi_l^{(p)}\bar{\phi}_j^{(p)}\, dx, \qquad B^{(p)} = (b_{jl}^{(p)}), \\
f_j^{(p)} &= \int_I f_p \bar{\phi}_j^{(p)}\, dx, \qquad \mathbf{f}^{(p)} = (f_0^{(p)}, f_1^{(p)}, \ldots, f_{N-2}^{(p)})^T,
\end{aligned}$$

the system (2.21) becomes the following complex matrix equation:

$$(A^{(p)} + B^{(p)})\mathbf{u}^{(p)} = \mathbf{f}^{(p)}. \tag{2.22}$$

Thanks to the special form of $\phi_j^{(p)}$, we have that

$$b_{jl}^{(p)} = 0, \quad |j-l| > 4; \qquad a_{jl}^{(p)} = 0, \quad l < j-2.$$

Hence, for each p, the linear system (2.22) can be solved in $\mathcal{O}(N^2)$ operations by using a direct Gaussian elimination process. Renaming N as N_r, the Fourier–Legendre approximation for (2.15) is given (with $x = \frac{2(r-a)}{b-a} - 1$) by

$$U_{N_r,N_\theta}(r,\theta) = \sum_{p=-N_\theta/2-1}^{N_\theta/2} \sum_{j=0}^{N_r-2} (u_j^{(p)}\phi_j^{(p)}(x) + h_p(x))e^{ip\theta}, \tag{2.23}$$

which is the solution of the following approximate variational problem:

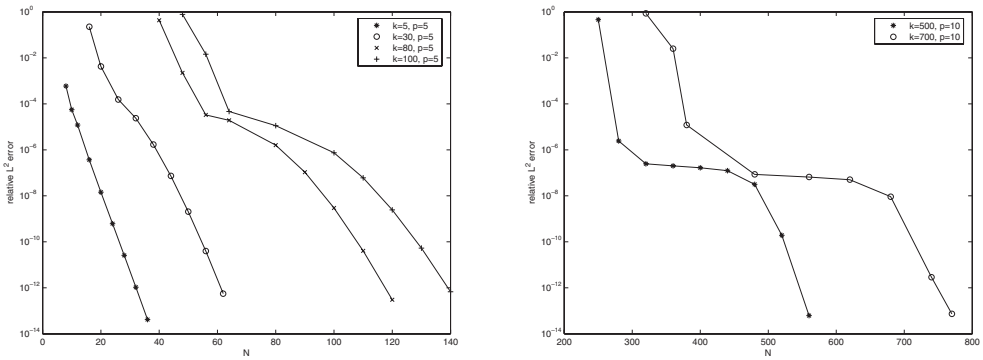
$$\begin{aligned}
&-(r\partial_r U_{N_r,N_\theta}, \partial_r(rv)) - (\partial_\theta U_{N_r,N_\theta}, \partial_\theta v) \\
&\quad + k^2(r^2 U_{N_r,N_\theta}, v) = (F, v) \quad \forall v \in V_{N_r,N_\theta}, \qquad \text{(2.24a)} \\
&U_{N_r,N_\theta}(a,\theta) = \xi_{N_\theta}(\theta), \qquad \text{(2.24b)} \\
&(\partial_r - T_{N_\theta})U_{N_r,N_\theta}(b,\theta) = \eta_{N_\theta}(\theta), \qquad \text{(2.24c)}
\end{aligned}$$

where

$$V_{N_r,N_\theta} = \mathrm{span}\{\phi_j^{(p)}(x(r))e^{ip\theta} : -N_\theta/2 \le p \le N_\theta/2 - 1;\ 0 \le j \le N_r - 2\}, \tag{2.25a}$$

$$(\xi_{N_\theta}(\theta), \eta_{N_\theta}(\theta)) = \sum_{p=-N_\theta/2}^{N_\theta/2-1} (\hat{\xi}_p, \hat{\eta}_p)e^{ip\theta}, \tag{2.25b}$$

$$T_{N_\theta}\psi(\theta) = \sum_{p=-N_\theta/2}^{N_\theta/2-1} k\frac{d_z H_p^{(1)}(kb)}{H_p^{(1)}(kb)}\hat{\psi}_p e^{ip\theta} \quad \text{for } \psi(\theta) = \sum_{p=-\infty}^{\infty} \hat{\psi}_p e^{ip\theta}. \tag{2.25c}$$



(a) Moderate Frequencies

(b) High Frequencies

FIG. 2.1. *Relative L^2 error versus N_r with $N_\theta = 20$, as compared to an exact solution.*

The total cost for obtaining U_{N_r,N_θ} is $\mathcal{O}(N_r^2 N_\theta \log(N_\theta))$.

We now present some numerical results demonstrating the accuracy of the above scheme. As a test example, we consider the canonical problem (2.15) with $a = 1$, $b = 2$ and take

$$F(r,\theta) = 0, \quad \xi(\theta) = H_p^{(1)}(ka)e^{ip\theta}, \quad \eta(\theta) = 0.$$

In this case the exact solution is $U(r,\theta) = H_p^{(1)}(kr)e^{ip\theta}$. It is clear that for given p, $e^{ip\theta}$ can be exactly determined with $N_\theta \geq 2p$. Thus we will concentrate on the approximation behavior of our scheme with respect to the frequency k. In Figure 2.1, we present the relative L^2 error versus N_r for a wide range of frequencies. We note that for k relatively small, the errors quickly enter the asymptotic range and converge at an exponential rate. For moderate to large k, the errors exhibit an initial sharp drop at $N_r \sim k/2$, then decay slowly until $N_r \sim k$, and finally enter the asymptotic range, converging at an exponential rate. These results indicate that (i) the approximate solution U_{N_r,N_θ} will converge to the exact solution $U(r,\theta)$ exponentially fast as $N_r, N_\theta \to +\infty$, provided that all $F(r,\theta)$, $\xi(\theta)$, and $\eta(\theta)$ are analytic in Ω; and (ii) our numerical scheme is stable for large N_r and capable of providing accurate results for large frequencies.

3. Numerical results: Comparison with an exact solution. In this section we present the results of a numerical experiment conducted with the two algorithms outlined above: the FE method of section 2.2 and the TFE method of section 2.3. We begin by outlining the diagnostic test (based upon an exact solution), which we have found useful in measuring the performance of these methods. We then describe how the FE algorithm suffers from severe numerical ill-conditioning, while the TFE approach is largely immune from such issues.

3.1. A diagnostic test. For the testing of numerical algorithms it is extremely useful to compare approximations with exact solutions whenever possible. In the case of scattering from a bounded obstacle, we consider again solutions of the form

$$v_p(r,\theta) = a_p H_p^{(1)}(kr)e^{ip\theta}, \tag{3.1}$$

which satisfy (2.6a) and (2.6c). Given a profile $g(\theta) = \varepsilon f(\theta)$, we have a solution to (2.6), provided that we set

$$\xi(\theta) = \xi_p(\theta) = v_p(a + \varepsilon f(\theta), \theta).$$

So, provided with (ε, f, ξ_p), both the FE and TFE algorithms deliver approximations to the field which can be compared with the exact field, v_p. Of course one need not compare the entire field and may choose, instead, to simply compare the field in the "near field" (at $r = a + \varepsilon f$) or the "far field" (at $r = b$). Additionally, derivatives of the field have physical interpretations and may be measured as well. In particular, the normal derivative of the field on a surface has the interpretation in electromagnetics as the current, and it is useful to measure this in both the near and far fields.

In this paper we focus on the most challenging computation mentioned above, the current at the surface of the obstacle; here the effects of the geometric perturbation are felt most strongly. We define this surface current as

$$\nu(\theta) = \nabla v|_{r=a+g} \cdot N_g,$$

where $N_g = ((a + g), -\partial_\theta g)^T$ is chosen unnormalized to match the definition of the DNO studied in Nicholls and Nigam [20] and Nicholls and Reitich [24, 25]. With this choice of normal it is easy to see that

$$\nu(\theta) = (a + g)\, \partial_r v|_{r=a+g} - \frac{(\partial_\theta g)}{(a + g)}\, \partial_\theta v|_{r=a+g} \tag{3.2}$$

so that, given (ε, f, ξ_p), an [illegible] current ν_p can be specified using (3.2) and compared with FE and TFE approximations.

3.2. Computation of the surface current: Field expansions. The FE approximation to the surface current can be generated by noting that (3.2), upon multiplication by $(a + g)$, can be rewritten as

$$\begin{aligned}\nu = a\, \partial_r v|_{r=a+g} + 2g\, \partial_r v|_{r=a+g} + \frac{1}{a} g^2\, \partial_r v|_{r=a+g} \\ - \frac{1}{a}(\partial_\theta g)\, \partial_\theta v|_{r=a+g} - \frac{1}{a} g\, \nu.\end{aligned}$$

Setting $g = \varepsilon f$, recalling our FE expansion, (2.8),

$$v(r, \theta, \varepsilon) = \sum_{n=0}^{\infty} \varepsilon^n \sum_{p=-\infty}^{\infty} d_{n,p} \frac{H_p^{(1)}(kr)}{H_p^{(1)}(ka)} e^{ip\theta},$$

and using the fact that $\nu(\theta, \varepsilon)$ is analytic in ε (see [20, 24, 25]),

$$\nu(\theta, \varepsilon) = \sum_{n=0}^{\infty} \nu_n(\theta)\, \varepsilon^n,$$

it is not difficult to see that

$$\begin{aligned}\nu_n = (ak)\sum_{l=0}^{n}\frac{(kf)^l}{l!}\sum_{p=-\infty}^{\infty}\frac{d_z^{l+1}H_p^{(1)}(ka)}{H_p^{(1)}(ka)}d_{n-l,p}e^{ip\theta}\\ +2f\sum_{l=0}^{n-1}\frac{(kf)^l}{l!}\sum_{p=-\infty}^{\infty}\frac{d_z^{l+1}H_p^{(1)}(ka)}{H_p^{(1)}(ka)}d_{n-1-l,p}e^{ip\theta}\\ +\frac{1}{a}f^2\sum_{l=0}^{n-2}\frac{(kf)^l}{l!}\sum_{p=-\infty}^{\infty}\frac{d_z^{l+1}H_p^{(1)}(ka)}{H_p^{(1)}(ka)}d_{n-2-l,p}e^{ip\theta}\\ -\frac{1}{a}(\partial_\theta f)\sum_{l=0}^{n-1}\frac{(kf)^l}{l!}\sum_{p=-\infty}^{\infty}\frac{d_z^{l}H_p^{(1)}(ka)}{H_p^{(1)}(ka)}(ip)d_{n-1-l,p}e^{ip\theta}\\ -\frac{1}{a}f\ \nu_{n-1}.\end{aligned}\tag{3.3}$$

3.3. Computation of the surface current: Transformed field expansions. To use the TFE algorithm in a simulation of the current ν, (3.2), we perform the following manipulations:

$$\begin{aligned}(a+g)(d-g)\nu &= (a+g)^2(d-g)\ \partial_r v|_{r=a+g} - (\partial_\theta g)(d-g)\ \partial_\theta v|_{r=a+g}\\ &= (a+g)^2 d\ \partial_{r'}u|_{r'=a} - (\partial_{\theta'}g)(d-g)\ \partial_{\theta'}v|_{r'=a}\\ &\quad +(\partial_{\theta'}g)^2 d\ \partial_{r'}v|_{r'=a}\,,\end{aligned}$$

where we have used (2.10) to change coordinates. Solving for $\nu(\theta')$, we find

$$\begin{aligned}\nu = a\ \partial_{r'}u + 2g\ \partial_{r'}u + \frac{1}{a}g^2\partial_{r'}u - \frac{1}{a}(\partial_{\theta'}g)\partial_{\theta'}u + \frac{1}{ad}g(\partial_{\theta'}g)\partial_{\theta'}u\\ +\frac{1}{a}(\partial_{\theta'}g)^2\partial_{r'}u + \frac{a-d}{ad}g\nu + \frac{1}{ad}g^2\nu,\end{aligned}\tag{3.4}$$

where all u quantities are evaluated at $r'=a$. Setting $g=\varepsilon f$, this normal current in the new coordinates can also be shown to be analytic in ε [20, 24, 25] so that

$$\nu(\theta',\varepsilon) = \sum_{n=0}^{\infty}\nu_n(\theta')\ \varepsilon^n,$$

and (3.4) can be used to show that

$$\begin{aligned}\nu_n = a\ \partial_{r'}u_n + 2f\partial_{r'}u_{n-1} + \frac{1}{a}f^2\partial_{r'}u_{n-2} - \frac{1}{a}(\partial_{\theta'}f)\partial_{\theta'}u_{n-1}\\ +\frac{1}{ad}f(\partial_{\theta'}f)\partial_{\theta'}u_{n-2} + \frac{1}{a}(\partial_{\theta'}f)^2\partial_{r'}u_{n-2} + \frac{a-d}{ad}f\nu_{n-1} + \frac{1}{ad}f^2\nu_{n-2},\end{aligned}\tag{3.5}$$

where terms with negative index are set to zero.

3.4. Cancellations. It is a well-established phenomenon [21, 22, 23, 24, 25] that boundary perturbation algorithms such as the FE approach of section 2.2 are numerically ill-conditioned, due to subtle but significant cancellations present in the recursions whereby finite quantities are computed as differences of nearly equal, but arbitrarily large, numbers. For a brief demonstration of this property in the present context we consider the diagnostic calculation outlined in section 3.1 for a specified profile to high perturbation order.

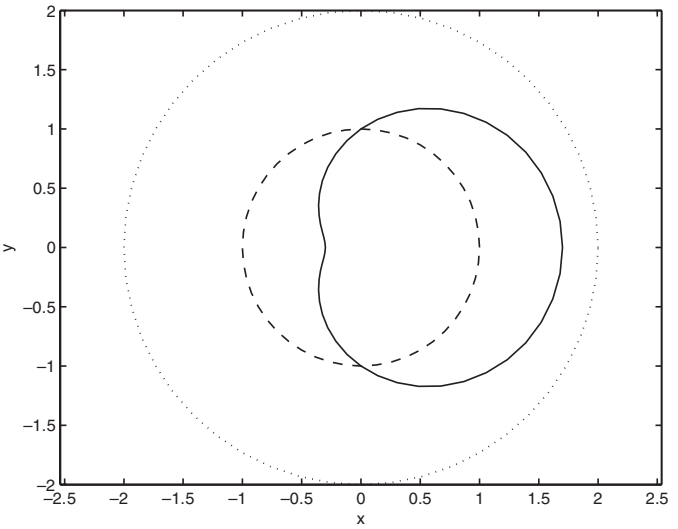


FIG. 3.1. *Geometry of a scattering configuration with smooth perturbation, $f(\theta) = \cos(\theta)$, $\varepsilon = 0.7$. The scattering profile is given by the solid line, and the artificial boundary at $r = 2$ is depicted with the dotted line. The dashed line portrays the unperturbed scatterer at $r = 1$.*

For an FE approximation we compute the $d_{n,p}$ of (2.8) using the recursion (2.9) for $-N_\theta/2 \le p \le N_\theta/2 - 1$ and $0 \le n \le N$. With these coefficients we approximate ν by

$$\nu^N(\theta, \varepsilon) = \sum_{n=0}^{N} \nu_n(\theta)\varepsilon^n, \tag{3.6}$$

where we use (3.3) to compute ν_n. For a TFE simulation we generate the $u_j^{(p)}$ (cf. (2.23)) from the algorithm outlined in section 2.4 for $-N_\theta/2 \le p \le N_\theta/2 - 1$, $0 \le j \le N_r - 2$, and $0 \le n \le N$. Again, with these coefficients we approximate ν by (3.6); however, we now use (3.5) to compute the ν_n.

In Figure 3.1 we display the geometry of a numerical experiment where we consider a large ($\varepsilon = 0.7$, $a = 1$) but smooth deformation, $f(\theta) = \cos(\theta)$, of a circle with artificial boundary at $r = b = 2$. The results of this experiment are summarized in Figure 3.2 with measurements of L^∞ error versus perturbation order N. The numerical parameters are $N_\theta = 48$, $N_r = 48$, and $N = 23$, and the frequency is $k = 1$, while the parameter p in (3.1) is set to one. We point out the abrupt and explosive divergence of the FE approximation from the exact solution beyond $N = 7$. In contrast, the TFE simulation gives progressively more accurate answers throughout all orders N. In particular, we note that the best answer that the FE method can ever deliver has L^∞ accuracy of 10^{-1} (when $N = 7$), while the TFE method gives answers reliable to 10^{-4} (at $N = 23$). As demonstrated in [22, 24], while the [illegible] features of Figure 3.2 are quite generic as a function of profile size (ε) and shape (f), the [illegible] details of the plot (e.g., divergence order of FE, slope of convergence for TFE, etc.) can be manipulated by an astute choice of ε and f.

Of course there are many questions one can ask regarding the cancellations present in the FE recursions. For instance, one can ask whether an "extended precision" implementation of the FE recursions could prevent the divergence witnessed in Figure 3.2, resulting in a reliable high-order method. In fact, this precise implementation was

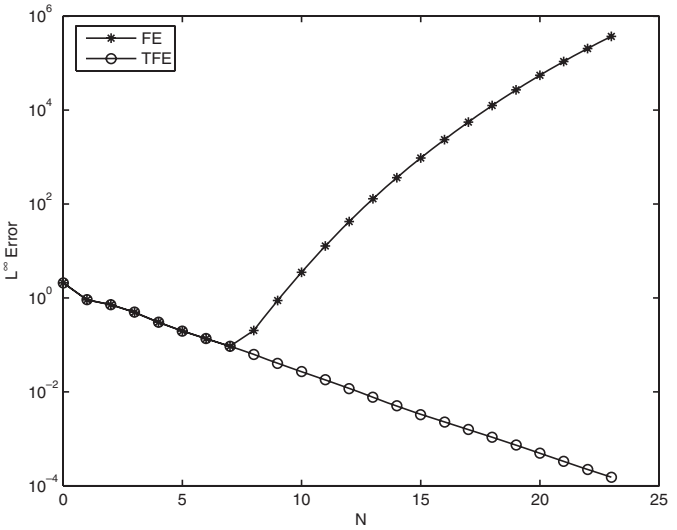

FIG. 3.2. *L^∞-norm of difference between exact current at the surface of a scatterer and the numerical approximation, versus perturbation order N. Both the FE (stars) and TFE (circles) approximations are plotted for the smooth perturbation $f(\theta) = \cos(\theta)$, $\varepsilon = 0.7$, with parameters $N_\theta = 48$, $N_r = 48$, $N = 23$, $a = 1$, $b = 2$, $k = 1$, $p = 1$. Notice the abrupt divergence of the FE approximation beyond $N = 7$ and the predictable, progressive convergence of the TFE approach throughout all orders.*

made for the FE recursions in the related context of traveling water waves in [26]. For this problem [illegible] precision calculations were necessary to display the strong cancellations present in this problem. From these experiments we learned that extended precision can [illegible] the onset of divergent behavior but will never eliminate it. Furthermore, with the computational cost of current software implementations of extended precision it was [illegible] computationally advantageous to use the FE recursions. We direct the interested reader to [21, 22, 23, 24, 25, 26] (particularly [24]) for a complete discussion of these issues and their resolution.

4. Numerical results: Plane-wave scattering. In this section we present the results of numerical experiments conducted with the TFE method of section 2.3 in a variety of physical configurations. At this point we abandon the convenient "diagnostic test" calculations described in section 3.1 and return to our original problem of plane-wave scattering. Of course in this scenario there are no exact solutions for nontrivial geometries, so we appeal to a high-order integral equation (IE) method (Maue's method; see [13, 9]) to provide an "exact solution." We first investigate the performance of the TFE method as the frequency of radiation is increased from low to moderate values, and then study its behavior as the size and smoothness of the obstacle perturbation are changed from small to large and from smooth to rough.

4.1. Padé approximation. Before we describe our plane-wave numerical experiments we comment on one final enhancement to our algorithm: analytic continuation via Padé approximation. Recall that the TFE method computes a spectral approximation to the current, ν, of the form (cf. (3.6))

$$\nu_{N_\theta}^N(\theta,\varepsilon) = \sum_{n=0}^{N} \sum_{p=-N_\theta/2}^{N_\theta/2-1} a_{n,p} e^{ip\theta} \varepsilon^n = \sum_{p=-N_\theta/2}^{N_\theta/2-1} S_p^N(\varepsilon) e^{ip\theta}$$

TABLE 4.1
Summary of numerical experiments.

for ε small, where $S_p^N(\varepsilon)$ is the truncated Taylor series of the pth Fourier coefficient $S_p(\varepsilon)$. The analytic continuation results of [23, 20] indicate that the functions $S_p(\varepsilon)$ can be extended beyond the disk of convergence of their power series about $\varepsilon = 0$; a numerical technique for this analytic continuation is the Padé approximation method [1]. We recall that the [P,Q] Padé approximant to a series

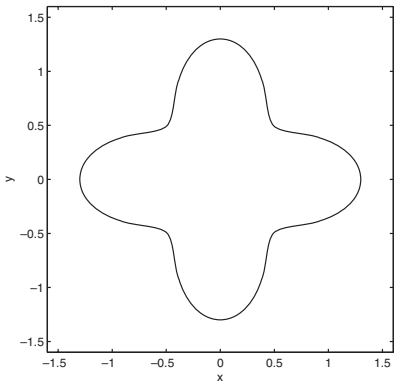
$$S(\varepsilon) = \sum_{n=0}^{\infty} a_n \varepsilon^n \tag{4.1}$$

is the unique rational function of order P over Q, which coincides with $S(\varepsilon)$ to order $P+Q+1$. In the experiments below we use diagonal or paradiagonal Padé sequences. It is well known that Padé approximants have some remarkable properties of approximation of (a large subclass of) analytic functions from their Taylor series (4.1) for points far outside their radii of convergence; see, e.g., [1]. They can be calculated by first solving a set of linear equations for the denominator coefficients, and then using simple formulas to compute the numerator coefficients.

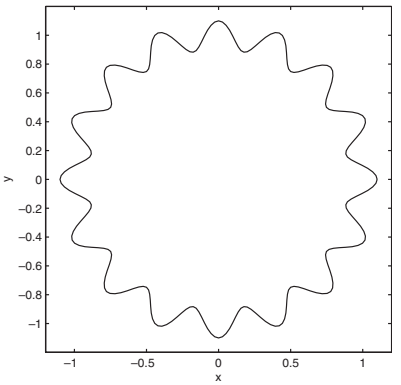
4.2. Numerical experiments. We now report upon six numerical experiments of plane-wave scattering, which are summarized in Table 4.1. In the first five the obstacle shape is quite smooth, in fact a sinusoidal perturbation of a circle, described by the equation

$$r = a + \varepsilon f_q(\theta), \qquad f_q(\theta) = \cos(q\theta); \tag{4.2}$$

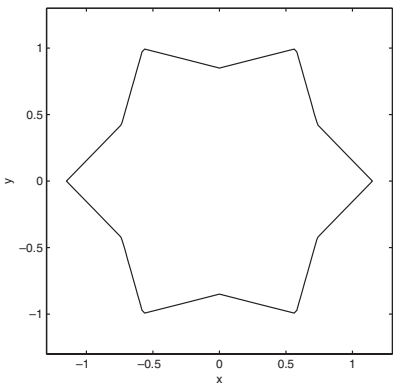
see Figure 4.1(a) ($q = 4$, $\varepsilon = 0.1$, and $a = 1$). The final experiment features a very rough, Lipschitz, scatterer of "star-like" shape; see Figure 4.1(b).



(a) Large



(b) Oscillatory



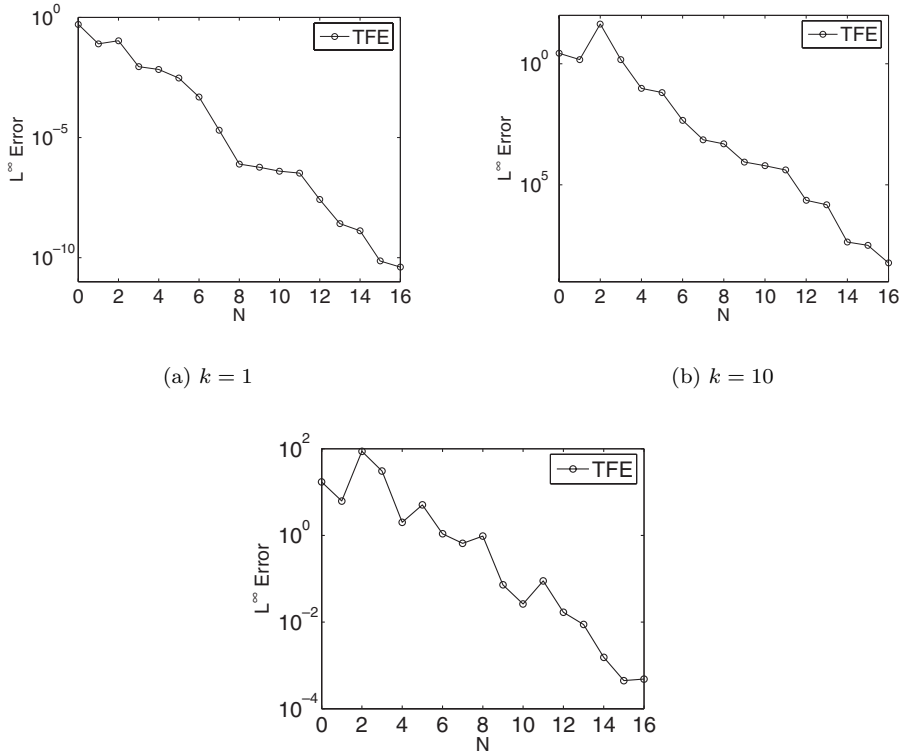
(c) Star-like

FIG. 4.2. *Shape of large* (*cf.* (4.2) *with* $\varepsilon = 0.3$ *and* $q = 4$)*, oscillatory* ((4.2) *with* $\varepsilon = 0.1$ *and* $q = 16$)*, and star-like scatterers.*

In the first three experiments we study the performance of the TFE method as the plane-wave frequency is increased from low to moderate. For this we use a small/smooth obstacle ($\varepsilon = 0.1$ and $q = 4$ in (4.2); see Figure 4.1(a) with $k = 1$, 10, and 50. In the final three experiments we gauge the capabilities of the TFE algorithm as the regularity of the obstacle is changed. We consider large/smooth ($\varepsilon = 0.3$ and $q = 4$), small/oscillatory ($\varepsilon = 0.1$ and $q = 16$), and Lipschitz (star-like) profiles for these experiments; see Figure 4.2.

In the final column of Table 4.1 we report the minimum number of discretization points necessary to guarantee a "well-resolved" IE approximation for each experiment. To measure the accuracy of the IE solution we compute the relative error in a "factor of two" refinement of an IE computation:

$$E_{\text{rel}}^N = \frac{\left|\nu_N^{IE} - \nu_{N/2}^{IE}\right|}{\left|\nu_N^{IE}\right|},$$



(a) $k = 1$

(b) $k = 10$

(c) $k = 50$

FIG. 4.3. *L^∞-norm of difference between highly resolved IE approximation of current at the surface of a scatterer and TFE approximation, versus perturbation order N. The shape of the scatterer is specified by* (4.2) *($\varepsilon = 0.1$ and $q = 4$), and the wavenumbers of the incident radiation are $(\alpha, \beta) = (1, 0), (10, 0)$, and $(50, 0)$, in subfigures* (a), (b), *and* (c), *respectively.*

where ν_N^{IE} represents an IE approximation to the surface current with N discretization points. The N_{IE} listed in the final column of Table 4.1 is the smallest N such that

$$E_{\text{rel}}^N < 10^{-10}.$$

4.2.1. Variation of frequency. The results of our first set of experiments (as the frequency is varied from low to moderate) are summarized in Figure 4.3. The physical and numerical parameters for each experiment are collected in Table 4.2; note that, for uniformity, in the first experiment we actually use more discretization points than necessary in the IE solver. In each of these experiments we note that the TFE algorithm makes steady improvement (as compared to the IE exact solution) as the perturbation order is refined. In the cases $k = 1$, 10, and 50, accuracies of 10^{-10}, 10^{-9}, and 10^{-4}, respectively, are realized by $N = 16$; furthermore it is [illegible] to utilize these higher perturbation orders in order to realize this accuracy. In addition, a quite modest number of degrees of freedom are all that is required to properly resolve each configuration. Based upon the findings of [34] and the numerical results of section 2.4, we anticipate no problems simulating situations with k very large, as our new algorithm is numerically well-conditioned as [illegible] discretization parameters

TABLE 4.2
Summary of physical and numerical parameters: variation of frequency experiments ($q = 4$ *and* $\varepsilon = 0.1$).

(c) *Cauchy convergence of TFE approximation measured in the* L^∞*-norm as a function of perturbation order* N. *The wavenumber of the incident radiation is* $(\alpha, \beta) = (1, 0)$. *The shape of the scatterer is depicted in Figure* 4.1(b).

(N_θ, N_r, and N) are refined. We note, however, that our method is not "specially designed" for the high-frequency regime in the manner of, e.g., [2].

4.2.2. Variation of shape. In the second set of experiments we recall that the frequency is fixed to be quite small ($k = 1$) while the profile shape is varied. For depictions of the scatterers for Experiments 4 (large/smooth profile), 5 (small/oscillatory profile), and 6 (Lipschitz profile) please see Figures 4.2(a), 4.2(b), and 4.2(c), respectively.

The results of these experiments are summarized in Figure 4.4. We note that for

TABLE 4.3
Summary of physical and numerical parameters: variation of shape experiments ($k = 1$).

Experiment number	ε	q	a	b	N_θ	N_r	N	$N(IE)$
4	0.3	4	1	2	256	48	16	256
5	0.1	16	1	2	256	48	16	1024
6	N.A.	N.A.	1	2	256	48	16	N.A.

the final simulation a different, "Cauchy," measure of convergence was utilized due to the Lipschitz character of the star-like profile. In this case the IE solver cannot be used without nontrivial modification, so in order to avoid this issue (essentially that of quickly and accurately resolving quadratures involving singular kernels), we focus upon the TFE algorithm and measure, again in L^∞, the difference between the TFE approximation at orders $0 \leq n < N$ and the "best resolution" TFE approximation at order N. The physical and numerical parameters for these experiments are collected in Table 4.3.

Once again we point out the consistent improvement which the TFE algorithm makes for all profiles at every perturbation order. For each profile we realize errors on the order of 10^{-2} by $N = 16$. This convergence is quite independent of the obstacle shape, although, of course, the rate of convergence does deteriorate with increasing roughness of the profile. Notice that this remains true even in the case of the Lipschitz profile, which we simply approximate by a truncated Fourier series. Again, each of these simulations could be further refined in a numerically stable fashion by increasing any of the algorithm parameters, N_θ, N_r, or N.

5. Conclusion and future directions. We have developed and implemented a stable, high-order method for numerical simulation of two-dimensional bounded-obstacle scattering. The method consists of five steps: (a) The problem (naturally posed on an unbounded domain) is reduced to one stated on a bounded domain via the Dirichlet–Neumann operator; (b) as suggested by previous theoretical work, this bounded domain is then mapped to an annulus; (c) a boundary perturbation expansion is then performed on the transformed equations, leading to a sequence of nonhomogeneous, constant-coefficient Helmholtz equations on the annulus; (d) an efficient and stable spectral-Galerkin method is developed for solving this sequence of Helmholtz problems; (e) Padé approximation is used to enhance and extend the summation of the power series representations we have formed. The resulting algorithm is shown to be very efficient and capable of handling small to moderate frequencies and scatterers with quite complex shapes.

The preliminary success of this TFE algorithm, of course, raises several natural questions which we consider as future directions for our research. It is clear that the basic ingredients of our numerical method can be extended to not only three-dimensional, bounded-obstacle configurations but also high-frequency problems in two and three dimensions. However, what is unclear is how this algorithm will compare with the popular finite element and integral equation methodologies already present in the literature. The highly accurate and efficient TFE algorithm together with its essentially exact treatment of far-field boundary conditions should make it a competitive choice compared with finite element approaches, particularly at moderate to high frequencies. On the other hand, its ability to seamlessly address problems with distributed sources will make this algorithm a compelling alternative to integral equation schemes. It is our intention to conduct an exhaustive study along these lines in future work.

Acknowledgments. The authors thank Fernando Reitich for providing a MATLAB script implementing the integral equations solver (Maue's method) for plane-wave scattering. They would also like to thank three anonymous referees for their thoughtful comments.

HIGH ORDER TERMS FOR CONDITION ESTIMATION OF UNIVARIATE POLYNOMIALS*

JOAB R. WINKLER†

Abstract. The established expressions for the condition numbers of a root of a polynomial assume that the perturbations in its coefficients are small, such that only the lowest order terms in a Taylor series need be considered. This restriction to the lowest order terms is considered in this paper, and it is shown that there exists a well-defined class of polynomial for which it is not valid. In particular, if a root x_0 of a polynomial $p(x)$ is close to but distinct from its neighboring roots $x_i, i = 1, \ldots, r$, it is shown that it is necessary to consider higher order terms in the Taylor series. These additional terms imply that a closed form expression for the condition number of x_0 cannot be obtained, and numerical methods must therefore be employed. In this paper, a high order Taylor series is used to compute the region in the complex plane in which the perturbed root $x_0 + \delta x_0$ lies, and this enables the variation of the condition number of x_0 with the distances to its neighboring roots to be established. It is shown that this extra information, which cannot be obtained if only the lowest order terms are used, is significant.

1. Introduction.

There has been considerable research into the numerical condition of the roots of a polynomial, and significant progress has been made [1, 2, 3, 6, 7, 8]. Closed form expressions for worst case and average case measures of the condition numbers of a root of a polynomial in an arbitrary basis have been developed [3, 10, 12, 13], and excellent agreement between the computed and theoretical results has been obtained. The derivation of these expressions requires that the perturbations in the coefficients of the polynomial are small, such that only the lowest order terms in the Taylor series of the perturbed polynomial need be considered. In this paper, the restrictions that are imposed by this assumption are considered, and it is shown that there exists a well-defined class of polynomial for which it is invalid. In particular, higher order terms in the Taylor series of the perturbed polynomial must be considered if the root x_0, whose condition number is sought, is near its neighboring roots. Numerical methods must, however, be used because closed form expressions for the numerical condition of x_0 cannot be obtained in this circumstance.

The derivation of an expression for the componentwise condition number of a root of a polynomial is reviewed in section 2, and examples of low degree polynomials are included in order to show the restrictions that must be imposed on this expression when the roots of a polynomial are close. These restrictions are removed by the inclusion of higher order terms in the Taylor series of the perturbed polynomial, and this is considered in section 3. It is shown that it is instructive to consider the region in the complex plane in which a perturbed root lies because this geometric information explains the numerical answers.

Section 4 contains the results of computational experiments that show that the

†Department of Computer Science, The University of Sheffield, Regent Court, 211 Portobello Street, Sheffield S1 4DP, UK (j.winkler@dcs.shef.ac.uk).

roots of a perturbed polynomial lie along well-defined trajectories, or principal axes, and that calculations that are based on these results may differ significantly from results that are based on the condition number. Section 5 contains a summary of the work that is described in this paper and future work that follows from it.

The work that is described in this paper is related to the pseudozeros of polynomials [4, 5]. In particular, the pseudozero set of a polynomial $p(x)$ is the set of zeros of the polynomials that are obtained when the coefficients of $p(x)$ are perturbed, and it quantifies the numerical condition of the roots of $p(x)$. It enables the numerical condition of $p(x)$ to be considered geometrically because the pseudozero set is plotted as a set of contours in the complex plane, where each contour represents a perturbation of different magnitude in the coefficients. The condition numbers in [1, 2, 3] are used in these papers on pseudozeros, and thus the work that is described in this paper extends the use of pseudozeros to a polynomial for which high order terms must be included in the Taylor series of its perturbed form.

2. The condition number of a root of a polynomial. This section contains a proof of the expression for the componentwise condition number of a root of a polynomial. Although this proof has been established [3], its inclusion in this paper is required because reference will be made to particular lines in the proof when the assumptions required for its establishment are considered. Examples are given in order to show the situations in which this formula is or is not valid.

2.1. An expression for the condition number. Consider a root x_0 of a polynomial $p(x)$, which is of degree n and expressed in an arbitrary basis $\{\phi_i\}_{i=0}^{n}$ with coefficients $a_i,\ i = 0, \ldots, n$,

$$p(x) = \sum_{i=0}^{n} a_i \phi_i(x). \tag{2.1}$$

Each coefficient a_i is perturbed to $a_i + \delta a_i = a_i(1 + r_i \varepsilon_c)$, where r_i is a random variable that is uniformly distributed in the interval $[-1, +1]$ and ε_c is a constant, and thus

$$|\delta a_i| \leq \varepsilon_c |a_i|, \qquad i = 0, \ldots, n. \tag{2.2}$$

THEOREM 2.1. [illegible] a_i, $p(x)$ [illegible] $a_i + \delta a_i$ [illegible] [illegible] x_0, $p(x)$ [illegible] m [illegible] m [illegible] $x_0 + \delta x_0$ [illegible] [illegible] x_0

$$\kappa_c(x_0) = \max_{|\delta a_i| \leq \varepsilon_c |a_i|} \frac{|\delta x_0|}{|x_0|} \frac{1}{\varepsilon_c} = \frac{1}{\varepsilon_c^{1-\frac{1}{m}}} \frac{1}{|x_0|} \left(\frac{m!}{\left|p^{(m)}(x_0)\right|} \sum_{i=0}^{n} |a_i \phi_i(x_0)| \right)^{\frac{1}{m}}. \tag{2.3}$$

[illegible]. Consider the perturbed polynomial $p(x + \delta x)$,

$$\begin{aligned} p(x + \delta x) &= \sum_{i=0}^{n} a_i \phi_i(x + \delta x) \\ &= \sum_{i=0}^{n} (a_i + \delta a_i) \phi_i(x + \delta x) - \sum_{i=0}^{n} \delta a_i \phi_i(x + \delta x). \end{aligned}$$

By definition, $p(x_0) = 0$, and it is assumed that the change δa in the coefficients a causes a change δx_0 in the root x_0; that is,

$$\sum_{i=0}^{n} (a_i + \delta a_i)\, \phi_i (x_0 + \delta x_0) = 0,$$

from which it follows that

$$p(x_0 + \delta x_0) = -\sum_{i=0}^{n} \delta a_i \phi_i (x_0 + \delta x_0).$$

By Taylor's theorem,

$$p(x_0 + \delta x_0) = \sum_{k=0}^{n} \frac{\delta x_0^k}{k!} p^{(k)}(x_0)$$

and

$$\phi_i(x_0 + \delta x_0) = \sum_{k=0}^{n} \frac{\delta x_0^k}{k!} \phi_i^{(k)}(x_0),$$

and hence

$$\sum_{k=0}^{n} \frac{\delta x_0^k}{k!} p^{(k)}(x_0) = -\sum_{i=0}^{n} \delta a_i \sum_{k=0}^{n} \frac{\delta x_0^k}{k!} \phi_i^{(k)}(x_0). \tag{2.4}$$

Since x_0 is an m-tuple root, $p^{(k)}(x_0) = 0$ for $0 \le k \le m-1$, and the perturbation δx_0 is assumed to be small, it follows that

$$\delta x_0^m = -\frac{m!}{p^{(m)}(x_0)} \sum_{i=0}^{n} \delta a_i \sum_{k=0}^{n} \frac{\delta x_0^k}{k!} \phi_i^{(k)}(x_0), \tag{2.5}$$

and hence

$$\begin{aligned} |\delta x_0| &= \left| \frac{m!}{p^{(m)}(x_0)} \right|^{\frac{1}{m}} \left| \sum_{i=0}^{n} \delta a_i \sum_{k=0}^{n} \frac{\delta x_0^k}{k!} \phi_i^{(k)}(x_0) \right|^{\frac{1}{m}} \\ &\le \left(\frac{m!}{\left|p^{(m)}(x_0)\right|} \sum_{i=0}^{n} |\delta a_i| \sum_{k=0}^{n} \left| \frac{\delta x_0^k}{k!} \phi_i^{(k)}(x_0) \right| \right)^{\frac{1}{m}} \\ &\le \varepsilon_c^{\frac{1}{m}} \left(\frac{m!}{\left|p^{(m)}(x_0)\right|} \sum_{i=0}^{n} |a_i \phi_i(x_0)| \right)^{\frac{1}{m}}, \end{aligned} \tag{2.6}$$

because only the term corresponding to $k = 0$ is retained. Thus

$$\frac{|\delta x_0|}{|x_0|} \frac{1}{\varepsilon_c} \le \frac{1}{\varepsilon_c^{1-\frac{1}{m}}} \frac{1}{|x_0|} \left(\frac{m!}{\left|p^{(m)}(x_0)\right|} \sum_{i=0}^{n} |a_i \phi_i(x_0)| \right)^{\frac{1}{m}},$$

and the result (2.3) is established. □

Examination of this proof shows that only the term of order m is considered on the left-hand side, and only the term corresponding to $k = 0$ is considered on the right-hand side, of (2.4). The restrictions that are implied by these lowest order approximations must be considered in order to determine the class of polynomial for which (2.3) is valid. In particular, it follows from (2.4) that the change δx_0 in x_0 must satisfy

$$\sum_{j=m+1}^{n} \frac{\left|\delta x_0^j p^{(j)}(x_0)\right|}{j!} \ll \frac{\left|\delta x_0^m p^{(m)}(x_0)\right|}{m!} \tag{2.7}$$

and

$$\sum_{k=1}^{n} \left|\frac{\delta x_0^k}{k!}\phi_i^{(k)}(x_0)\right| \ll |\phi_i(x_0)|, \qquad i = 0, \ldots, n, \tag{2.8}$$

in order that (2.3) be valid. The next section contains an example that shows the restrictions that the conditions (2.7) and (2.8) impose on the condition number (2.3).

2.2. The restrictions of lowest order terms on condition estimation. Consider the polynomial

$$p(x) = (x-1)^2(x-1-\alpha) = x^3 - (3+\alpha)x^2 + (3+2\alpha)x - (1+\alpha), \tag{2.9}$$

for which, from (2.1),

$$\begin{array}{llll} a_0 = 1, & a_1 = -(3+\alpha), & a_2 = 3+2\alpha, & a_3 = -(1+\alpha), \\ \phi_0(x) = x^3, & \phi_1(x) = x^2, & \phi_2(x) = x, & \phi_3(x) = 1, \end{array} \tag{2.10}$$

and $\alpha \geq 0$. It is readily verified that the componentwise condition numbers of the double root $x_0 = 1$, the simple root $x_1 = (1+\alpha)$ (assuming the specific condition $\alpha > 0$), and the treble root $x_2 = 1$, corresponding to the condition $\alpha = 0$, are

$$\kappa_c(x_0) = \frac{2}{\sqrt{\varepsilon_c}}\left(\frac{2+\alpha}{\alpha}\right)^{\frac{1}{2}}, \qquad \kappa_c(x_1) = 2\left(\frac{2+\alpha}{\alpha}\right)^2, \tag{2.11}$$

and

$$\kappa_c(x_2) = \frac{2}{\varepsilon_c^{\frac{2}{3}}}, \tag{2.12}$$

respectively.

It follows from (2.7) that the perturbation δx_0 in the double root x_0 must satisfy $|\delta x_0| \ll \alpha$, and if it is assumed, for simplicity, that only the term defined by $k = 1$ on the left-hand side of (2.8) need be considered because $|\delta x_0| \ll 1$, from which it follows that the terms corresponding to the indices $k = 2$ and $k = 3$ are small, then this equation reduces to

$$\left|\delta x_0 \phi_i^{(1)}(x_0)\right| \ll |\phi_i(x_0)|, \qquad i = 0, \ldots, 3,$$

which yields

$$|\delta x_0| \ll \frac{1}{3}.$$

TABLE 2.1
The maximum value of ε_c for four values of the root separation α for the double root $x_0 = 1$ and the simple root $x_1 = (1 + \alpha)$.

α	$x_0 = 1$ max ε_c	$x_1 = (1+\alpha)$ max ε_c
1	9.3×10^{-5}	1.4×10^{-3}
0.1	1.2×10^{-6}	5.2×10^{-6}
0.01	1.2×10^{-9}	6.1×10^{-9}
0.001	1.2×10^{-12}	6.2×10^{-12}

If it is assumed that a factor of 10 is sufficient to replace the $\ll$ by $\leq$, then these strict inequalities can be written as

$$|\delta x_0| \leq \frac{\alpha}{10} \qquad \text{and} \qquad |\delta x_0| \leq \frac{1}{30},$$

and their satisfaction is required in order that the condition number (2.3) be valid. Also, it follows from (2.6) that the maximum value of the perturbation δx_0 is equal to

$$|\delta x_0|_{\max} = 2\varepsilon_c^{\frac{1}{2}} \left(\frac{2+\alpha}{\alpha} \right)^{\frac{1}{2}},$$

and thus the root separation α must satisfy

$$|\delta x_0|_{\max} = 2\varepsilon_c^{\frac{1}{2}} \left(\frac{2+\alpha}{\alpha} \right)^{\frac{1}{2}} \leq \min \left\{ \frac{\alpha}{10}, \ \frac{1}{30} \right\}, \tag{2.13}$$

in order that the condition number $\kappa_c(x_0)$ in (2.11) be valid.

This analysis can be repeated for the simple root $x_1 = (1 + \alpha)$, in which case (2.13) becomes

$$|\delta x_1|_{\max} = 2\varepsilon_c(1+\alpha) \left(\frac{2+\alpha}{\alpha} \right)^{2} \leq \min \left\{ \frac{1+\alpha}{30}, \ \frac{\alpha}{20} \right\}. \tag{2.14}$$

The maximum allowable value of the componentwise relative error ε_c for four values of the root separation α, computed from (2.13) and (2.14), is shown in Table 2.1, and it is seen that as α decreases, the maximum value of ε_c decreases. It is noted that if α is sufficiently small, the restriction on the value of ε_c may be too severe for practical applications, such that the condition number (2.3) is not a realistic measure of the numerical stability of the double root $x_0 = 1$ and the simple root $x_1 = (1 + \alpha)$.

It follows from (2.13) and (2.14), respectively, that

$$|\delta x_0|_{\max} = \begin{cases} \frac{\alpha}{10} & \text{if } 0 < \alpha \leq \frac{1}{3}, \\ \\ \frac{1}{30} & \text{if } \frac{1}{3} < \alpha, \end{cases}$$

and

$$|\delta x_1|_{\max} = \begin{cases} \frac{\alpha}{20} & \text{if } 0 < \alpha \leq 2, \\ \\ \frac{1+\alpha}{30} & \text{if } 2 < \alpha, \end{cases}$$

and hence

$$|\delta x_0|_{\max} + |\delta x_1|_{\max} = \begin{cases} \frac{3\alpha}{20} & \text{if } 0 < \alpha \leq \frac{1}{3}, \\ \frac{\alpha}{20} + \frac{1}{30} & \text{if } \frac{1}{3} < \alpha \leq 2, \\ \frac{1+\alpha}{30} + \frac{1}{30} & \text{if } 2 < \alpha. \end{cases}$$

It follows from this equation that

$$|\delta x_0|_{\max} + |\delta x_1|_{\max} < \alpha,$$

which implies that if only the lowest order terms are used in the Taylor series of the perturbed polynomial, the circular regions in which the perturbed roots $x_0 + \delta x_0$ and $x_1 + \delta x_1$ lie cannot intersect because α is the root separation. This is problematic because one would expect that these regions would merge for sufficiently small values of α and, moreover, form one region when $\alpha = 0$, corresponding to the perturbation region of the treble root $x_2 = 1$. The failure of the perturbed roots to satisfy this requirement is a direct consequence of the limitations that are imposed when only lowest order terms are used. It will be shown, however, in section 3.1, and particularly in Figures 3.1 and 3.2, that this problem is not present when higher order terms are included in the Taylor series of the perturbed polynomial.

More examples that show the restrictions on the condition number (2.3), and its relation to the backward error of a root of a polynomial, are in section 4 in [9]. These examples, and the example above, show that higher order terms must be included in a Taylor series when it is required to compute the condition number of a root that is near another root.

3. High order terms for condition estimation. The inclusion of high order terms in the Taylor series of a perturbed polynomial implies that a closed form expression for the condition number of a root cannot be obtained, and numerical methods must be employed. The theoretical derivation for this situation proceeds up to (2.4), but all the terms are retained on both the left- and right-hand sides of this equation. In order to establish the method that will be used, consider the polynomial $f(x)$ of degree n,

$$f(x) = \prod_{i=0}^{r} (x - x_i)^{m_i}, \qquad \sum_{i=0}^{r} m_i = n,$$

whose distinct roots are $x_i,\ i = 0, \ldots, r$, and the multiplicity of the root x_k is m_k. The computation of the condition number of the root x_0 proceeds as follows:

1. Expand both sides of (2.4) such that all terms are retained, and consider the modulus of both sides of this equation.
2. Apply the componentwise error model (2.2) to the right-hand side of (2.4), thereby obtaining an inequality for the perturbation δx_0, which may be complex, in terms of the coefficients a_i and the componentwise relative error ε_c. The values of δx_0 that satisfy this inequality define the region R in the complex plane in which the perturbed root $x_0 + \delta x_0$ lies.
3. The point on the boundary of R that is furthest away from the point in the complex plane that represents the root x_0 defines the condition number of x_0.

It is important to note that the restrictions that are imposed when only the lowest order terms are used, as shown in section 2.2 and section 4 in [9], do not arise when this method is used for condition estimation because all terms in the series on both sides of (2.4) are now used.

The next section shows the implementation of this method for the third order polynomial (2.9).

3.1. An example of condition estimation using high order Taylor series. Consider the polynomial (2.9) whose roots are $x_0 = 1$ (twice) and $x_1 = (1 + \alpha) = (x_0 + \alpha)$ (once), and it is recalled that $\alpha \geq 0$. Since

$$p^{(2)}(x_0) = -2\alpha \qquad \text{and} \qquad p^{(3)}(x_0) = 6,$$

it follows that

$$p(x_0 + \delta x_0) = -\alpha \delta x_0^2 + \delta x_0^3.$$

This term is used on the left-hand side of (2.4), and the completeness of the Taylor expansion is noted. Equation (2.4) therefore becomes

$$\begin{aligned} \left|\delta x_0^3 - \alpha \delta x_0^2\right| &= \left| \sum_{i=0}^{3} \delta a_i \sum_{k=0}^{3} \frac{\delta x_0^k}{k!} \phi_i^{(k)}(x_0) \right| \\ &\leq \sum_{i=0}^{3} |\delta a_i| \left| \sum_{k=0}^{3} \frac{\delta x_0^k}{k!} \phi_i^{(k)}(x_0) \right| \\ &\leq \varepsilon_c \sum_{i=0}^{3} |a_i| \left| \sum_{k=0}^{3} \frac{\delta x_0^k}{k!} \phi_i^{(k)}(x_0) \right|, \end{aligned}$$

and (2.10) enables the right-hand side of this equation to be simplified,

$$\begin{aligned} \left|\delta x_0^3 - \alpha \delta x_0^2\right| \leq \varepsilon_c \Big\{ &\left|(1 + \delta x_0)^3\right| + (3 + \alpha) \left|(1 + \delta x_0)^2\right| \\ &+ (3 + 2\alpha) |1 + \delta x_0| + (1 + \alpha) \Big\}. \end{aligned}$$

The values of δx_0 that satisfy this inequality define the region R in the complex plane in which the perturbed root $x_0 + \delta x_0$ lies.

The condition number of x_0 is defined by the point on the boundary of R that is furthest from the point in the complex plane with coordinates $(1, 0)$, which corresponds to the root x_0, and thus the condition estimation problem can be posed as one of constrained maximization:

$$\underset{\delta x_0 \in \mathbb{C}}{\text{maximize}} \quad \frac{1}{\varepsilon_c} \frac{|\delta x_0|}{|x_0|}$$

subject to

$$\begin{aligned} \left|\delta x_0^3 - \alpha \delta x_0^2\right| = \varepsilon_c \Big\{ &\left|(1 + \delta x_0)^3\right| + (3 + \alpha) \left|(1 + \delta x_0)^2\right| \\ &+ (3 + 2\alpha) |1 + \delta x_0| + (1 + \alpha) \Big\}. \end{aligned} \tag{3.1}$$

It is instructive to examine how the region R changes as the root separation α changes, and it is therefore desirable to plot this region for different values of α. It will be

shown that this geometric information will explain an important, but unexpected, phenomenon that is observed as α increases. The computation of the condition number then follows easily from these diagrams.

The plot of the boundary B of R requires all the complex solutions of (3.1), but their computation is not trivial. A simple approximation, however, enables points on B to be computed easily, and a check on the error that is introduced by this approximation is obtained by substituting these approximate solutions into (3.1) and verifying that the normalized residual is small.

The substitution of the approximation

$$|1 + \delta x_0| \approx 1 + |\delta x_0| \tag{3.2}$$

into (3.1) enables this equation to be approximated by

$$\begin{aligned} \left|\delta x_0^3 - \alpha \delta x_0^2\right| = \varepsilon_c \Big\{ &\left(1 + |\delta x_0|\right)^3 + (3+\alpha)\left(1 + |\delta x_0|\right)^2 \\ &+ (3+2\alpha)\left(1 + |\delta x_0|\right) + (1+\alpha) \Big\}. \end{aligned} \tag{3.3}$$

It is noted that the error introduced by the approximation (3.2) is small because $|\delta x_0| \ll 1$, and it is therefore expected that the solutions of (3.3) will be very good approximations to the solutions of (3.1).

The transformation to polar coordinates

$$\delta x_0 = r \exp i\theta, \qquad r \geq 0, \qquad 0 \leq \theta < 2\pi, \tag{3.4}$$

allows the left-hand side of (3.3) to be written as

$$r^2 \left(\left(r\cos\theta - \alpha\right)^2 + r^2 \sin^2\theta \right)^{\frac{1}{2}},$$

and it enables the right-hand side to be defined by the polynomial $g(r)$,

$$g(r) := \varepsilon_c \left\{ \left(1 + r\right)^3 + (3+\alpha)\left(1 + r\right)^2 + (3+2\alpha)(1+r) + (1+\alpha) \right\}.$$

Equation (3.3) can therefore be written as

$$r^2 \left(\left(r\cos\theta - \alpha\right)^2 + r^2 \sin^2\theta \right)^{\frac{1}{2}} = g(r),$$

from which it follows that

$$\cos\theta = \frac{1}{2\alpha r}\left(r^2 + \alpha^2 - \frac{g^2(r)}{r^4} \right). \tag{3.5}$$

Since $-1 \leq \cos\theta \leq 1$, the radius r satisfies the polynomial inequalities

$$\begin{aligned} r^6 - 2\alpha r^5 + \alpha^2 r^4 - g^2(r) \leq 0, \\ r^6 + 2\alpha r^5 + \alpha^2 r^4 - g^2(r) \geq 0. \end{aligned} \tag{3.6}$$

These inequalities are, in general, satisfied by several ranges $(r_1, r_2), (r_3, r_4), \ldots$ of r, but it is necessary to select, from these mathematical solutions, the unique solution that represents the perturbation region of x_0. The following procedure is therefore used.

The ranges of values of r that satisfy these inequalities are easily determined, and the corresponding ranges of θ can then be calculated from (3.5). The values of δx_0 are then computed from (3.4), and thus the regions in the complex plane that are mathematical solutions of (3.6) are easily determined. The following two points must be noted:

1. Since $r \geq 0$, interest is restricted to positive values of r that satisfy (3.6).
2. If there exists more than one range of values of r that satisfies (3.6), then the region in the complex plane is computed from (3.4) and (3.5) for each range $I_{jk} = (r_j, r_k)$, as specified above. It is clear that (Real δx_0, Imag δx_0) defines a local coordinate system that is centered about the point $(1, 0)$ in the complex plane. The region in which the perturbed root lies must necessarily include the point (Real δx_0, Imag δx_0) = (0,0) in this local coordinate system, and this allows the range I_{pq} that contains this point to be selected.

The substitution of these computed values of δx_0 into the exact equation (3.1) is then used to verify that the error in these approximate solutions is small.

It is easily shown from (2.4) that (3.1) is replaced by

$$\left|(\alpha + \delta x_1)^2 \delta x_1\right| = \varepsilon_c \Big\{ \left|(1 + \alpha + \delta x_1)^3\right| + (3 + \alpha)\left|(1 + \alpha + \delta x_1)^2\right| + (3 + 2\alpha)\,|1 + \alpha + \delta x_1| + (1 + \alpha) \Big\} \tag{3.7}$$

for the simple root, and it is seen that this equation follows from (3.1) by the substitution

$$\delta x_0 = \delta x_1 + \alpha. \tag{3.8}$$

This result can be obtained directly because $x_1 = x_0 + \alpha$, and thus

$$p(x_1 + \delta x_1) = p(x_0 + \alpha + \delta x_1) = p(x_0 + \delta x_0),$$

which yields (3.8). It therefore follows that if δx_0^* satisfies (3.1), then $\delta x_1^* = \delta x_0^* - \alpha$ satisfies (3.7), and thus the perturbations and condition numbers of the simple and double roots can be computed from (3.1) only, and (3.7) is not required.

Equations (2.13) and (2.14) show that if $\varepsilon_c = 10^{-7}$, the condition numbers $\kappa_c(x_0)$ and $\kappa_c(x_1)$, which are defined in (2.11), are valid if

$$\alpha \geq 4.34 \times 10^{-2} \qquad \text{and} \qquad \alpha \geq 2.56 \times 10^{-2},$$

respectively. In particular, if $\alpha < 4.34 \times 10^{-2}$, the condition number $\kappa_c(x_0)$ cannot be used because the conditions for its validity are not satisfied, and similarly, if $\alpha < 2.56 \times 10^{-2}$, the condition number $\kappa_c(x_1)$ is not valid. Condition estimation for values of α in these ranges requires, therefore, that high order terms be retained in the Taylor series of the perturbed polynomial, and this is shown in the following numerical computations.

The results of the application of this algorithm to the polynomial (2.9) are shown in Figure 3.1 for $\varepsilon_c = 10^{-7}$. This figure shows the perturbation regions, in the complex plane, of the double root $x_0 = 1$ and simple root $x_1 = (1 + \alpha)$, as the separation α of the roots increases. These regions are equal to one another for each of the stated values of α, and the constriction of the perturbation region narrows as α increases, such that it is very thin when $\alpha = 0.017698$ (Figure 3.1(d)).

Figure 3.2 is the same as Figure 3.1, but for $\alpha \geq 0.0177$. In particular, Figures 3.1(d) and 3.2(a) show that a minor change in the value of α from 0.017698 to 0.0177

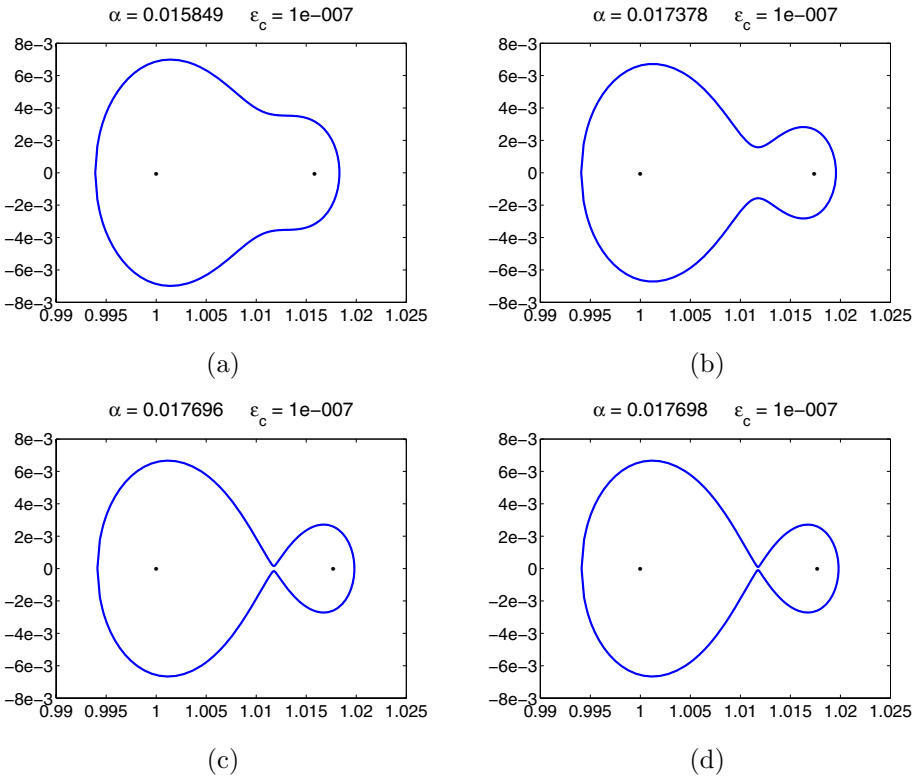

FIG. 3.1. *The perturbation regions, in the complex plane, for the double root* $x_0 = 1$ *and the simple root* $x_1 = (1 + \alpha)$*, for several values of* α*. The roots* x_0 *and* x_1 *are marked by dots.*

causes a significant change because the closed region that defines the perturbation region of both roots for $\alpha \leq 0.017698$ breaks down into two nonintersecting regions. It therefore follows that if $\varepsilon_c = 10^{-7}$ and $\alpha \geq 0.0177$, there does not exist a perturbation in the coefficients of the polynomial such that the simple root can merge into the double root, and thereby create a treble root. The figures show that as α increases, the perturbation region of each root becomes circular, which is expected. (It is noted that the scales on the axes are different, and thus although the perturbation regions appear elliptical with a distortion, they are circular with a distortion.)

Figures 3.1 and 3.2 show that the greatest displacement of the roots of $p(x)$ occurs in the region between them. Specifically, it is seen from these figures that the perturbation region of the double root $x_0 = 1$ is significantly greater on its right side than it is on its left side, and similarly, the perturbation region of the simple root $x_1 = (1 + \alpha)$ is significantly greater on its left side than it is on its right side. Finally, it was noted in section 2.2 that the restriction to the lowest order terms in the Taylor series of the perturbed polynomial necessarily implies that the regions in which the perturbed roots $x_0 + \delta x_0$ and $x_1 + \delta x_1$ lie cannot intersect, even though a merger of these regions would be expected for sufficiently small values of α, and it is necessary for $\alpha = 0$. It is clear from Figures 3.1 and 3.2 that the inclusion of high order terms in this Taylor series solves this problem because the intersection of these regions is not empty for small values of α.

The polynomial (2.9) is relatively simple, and thus the diagrams in Figures 3.1

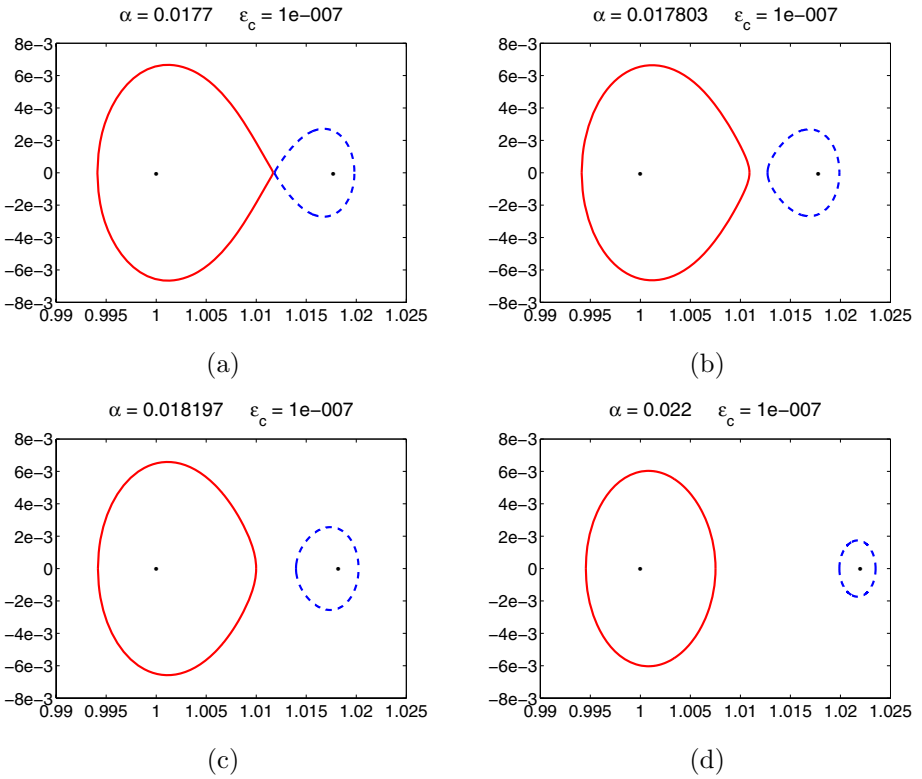

FIG. 3.2. *The perturbation regions, in the complex plane, for the double root* $x_0 = 1$ *(solid line) and the simple root* $x_1 = (1 + \alpha)$ *(dashed line), for several values of* α. *The roots* x_0 *and* x_1 *are marked by dots.*

and 3.2 could also have been generated using standard tools in a graphics package. These tools are not, however, suitable for higher degree polynomials with a more complex root structure, for which the method of high order Taylor series of a perturbed polynomial used in this paper is superior.

It was noted above that an approximation is required to obtain the plots in Figures 3.1 and 3.2, and a simple measure of the error that is introduced by this approximation is obtained by calculating the normalized residual. In particular, if $\delta\hat{x}_0$ is a solution of (3.3), then the normalized residual $r_{\delta\hat{x}_0}$ is defined by

$$r_{\delta\hat{x}_0} := \frac{h_1}{h_2},$$

where h_1 follows from (3.1),

$$h_1 = \left|\delta\hat{x}_0^3 - \alpha\delta\hat{x}_0^2\right| - \varepsilon_c\Big\{\left|(1+\delta\hat{x}_0)^3\right| + (3+\alpha)\left|(1+\delta\hat{x}_0)^2\right| + (3+2\alpha)\left|1+\delta\hat{x}_0\right| + (1+\alpha)\Big\},$$

and the denominator h_2 is equal to the sum of the absolute values of the coefficients of $\delta\hat{x}_0^3$, $\delta\hat{x}_0^2$, $\delta\hat{x}_0$, and 1,

$$h_2 = (1+\alpha) + \varepsilon_c\left\{8 + 4(3+\alpha) + 2(3+2\alpha) + (1+\alpha)\right\}.$$

For example, the coefficients of $(1+\delta\hat{x_0})^3$ are $1,3,3,1$, and their sum is equal to 8. The normalized residual was computed, and its maximum value was less than $10^{-7.5}$ for all values of α, thereby confirming that the plots in Figures 3.1 and 3.2 are excellent approximations to the perturbation regions of the double and simple roots.

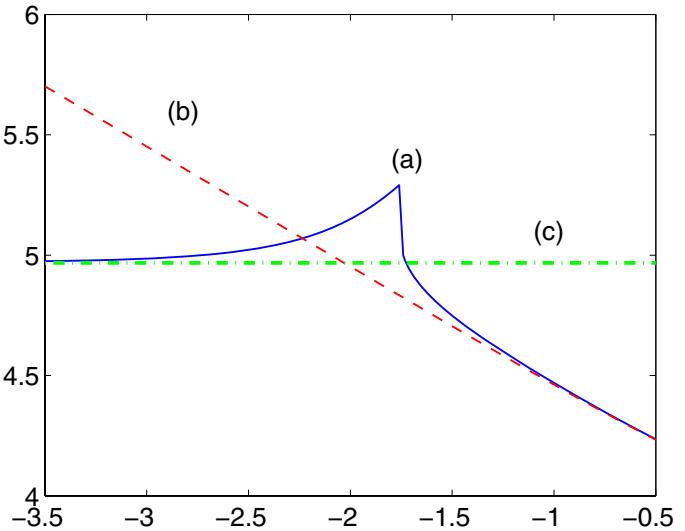

FIG. 3.3. *The variation of the logarithm, to base* 10, *of* (a) *the condition number of the double root* $x_0 = 1$*;* (b) *the condition number* $\kappa_c(x_0)$*, which is defined in* (2.11)*; and* (c) *the condition number* (2.12) *of the treble root* $x_2 = 1$ *of the polynomial* $(x-1)^3 = 0$*, against* $\log_{10}\alpha$.

Figures 3.1 and 3.2 enable the variation of the condition numbers of the double and simple roots with α to be easily computed because they are given by, respectively,

$$\max_{\delta x_0 \in \mathbb{C}} \frac{1}{\varepsilon_c}\frac{|\delta x_0|}{|x_0|} \qquad \text{and} \qquad \max_{\delta x_1 \in \mathbb{C}} \frac{1}{\varepsilon_c}\frac{|\delta x_1|}{|x_1|}.$$

This variation for the double root is shown in Figure 3.3, and the limiting values of this condition number for $\alpha \to 0$ and $\alpha \gg 0$ are also shown. In particular, the double root x_0 approaches the treble root $x_2 = 1$ of the polynomial $(x-1)^3 = 0$ as $\alpha \to 0$, the condition number of which is given in (2.12). If, however, $\alpha \gg 0$, then the condition number of x_0 is given by $\kappa_c(x_0)$, which is defined in (2.11). It is clear that, as expected, these limiting values of the condition number are obtained.

The more important feature from Figure 3.3 is the variation of the condition number with α between these limiting values. In particular, it is seen that as α increases, the condition number increases to a value that is larger than the condition number of the treble root $x_2 = 1$, and then decreases, initially very rapidly and then more slowly. This decrease is easily explained from Figures 3.1(d) and 3.2(a) because a minor change in α from 0.017698 to 0.0177 causes a significant reduction in the maximum distance between the point $(1,0)$ in the complex plane and the boundary of the region in which the perturbed root may lie. This reduction necessarily implies that the condition number of the root x_0 is also reduced significantly.

Figure 3.4 is the same as Figure 3.3 but for the simple root x_1, and it is seen that the condition number of this root also increases initially, and then decreases,

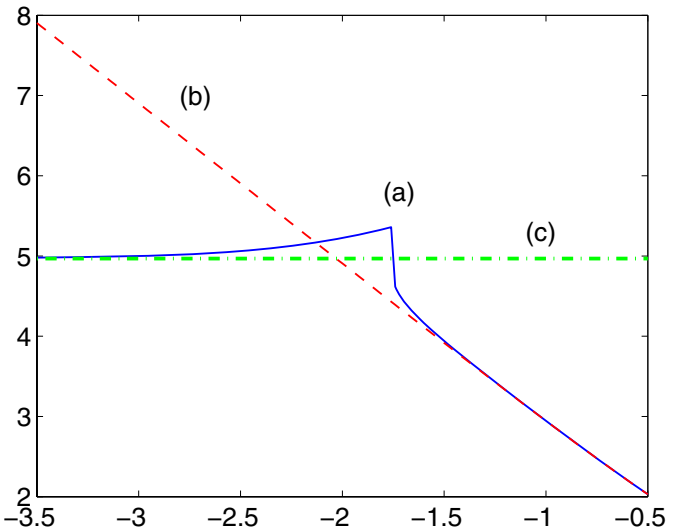

FIG. 3.4. *The variation of the logarithm, to base* 10, *of* (a) *the condition number of the simple root* $x_1 = (1+\alpha)$; (b) *the condition number* $\kappa_c(x_1)$, *which is defined in* (2.11); *and* (c) *the condition number* (2.12) *of the treble root* $x_2 = 1$ *of the polynomial* $(x-1)^3 = 0$, *against* $\log_{10}\alpha$.

as α increases. It is clear that the sharp decrease in the condition number after this initial increase can also be explained with the help of Figures 3.1(d) and 3.2(a). These numerical and geometrical results show that the inclusion of high order terms in the Taylor series of the perturbed form of $p(x)$ adds significant extra information, and not merely more accurate estimates of the condition numbers of the roots of $p(x)$.

4. Principal axes of perturbed roots. The contours that are shown in Figures 3.1 and 3.2 define the regions within which the roots lie when each coefficient is perturbed by a uniformly distributed random variable. It may be thought that the roots of the perturbed polynomial are randomly distributed in these regions, but this does not occur. Specifically, the roots of the perturbed polynomial show preferred directions, or principal axes, along which they lie.

The value $\varepsilon_c = 10^{-7}$ was retained, and the roots of the polynomial (2.9) were computed 1000 times, for a given value α. This experiment was repeated for several values of α, and the results, which are plotted in Figure 4.1, show that the roots of the perturbed polynomials lie along well-defined axes. Figure 4.1(a) shows that if $\alpha = 0$, the roots lie, to a very good approximation, along six radial arms. This computational result follows easily from (2.5), which reduces to

$$\delta x_0^3 = -\sum_{j=0}^{3} \delta a_j$$

to lowest order, and thus

$$\delta x_0 = \exp\frac{(2k+1)\pi i}{3}\left(\sum_{j=0}^{3}\delta a_j\right)^{\frac{1}{3}}, \qquad k = 0, 1, 2.$$

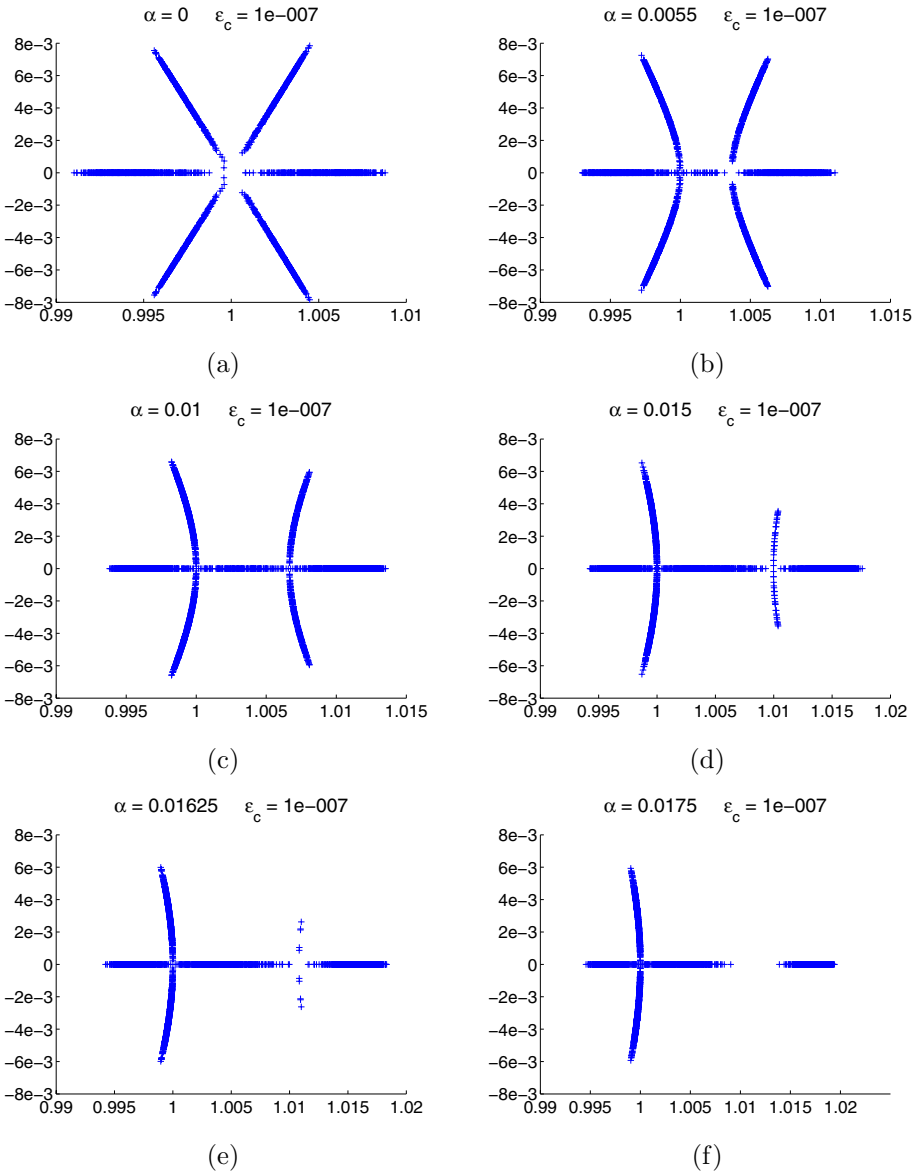

FIG. 4.1. *The principal axes of the roots of the perturbed form of $p(x)$, for six values of α.*

The sum in this expression can take both positive and negative values because each random variable δa_j has zero mean. It follows, therefore, that the set of the maximum values (in magnitude) of the computed solutions that are obtained when the perturbed polynomial is solved a large number of times is equal to

$$\delta x_0^+ \bigcup \delta x_0^-, \tag{4.1}$$

where δx_0^+ and δx_0^- are the sets of the maximum positive and minimum negative

computed values of δx_0, respectively,

$$\delta x_0^+ = \left\{ \left(\sum_{j=0}^{3} |\delta a_j| \right)^{\frac{1}{3}} \exp \frac{(2k+1)\pi i}{3} \exp \frac{2l\pi i}{3}, \qquad k,l = 0,1,2 \right\},$$

$$\delta x_0^- = \left\{ \left(\sum_{j=0}^{3} |\delta a_j| \right)^{\frac{1}{3}} \exp \frac{(2k+1)\pi i}{3} \exp \frac{(2l+1)\pi i}{3}, \qquad k,l = 0,1,2 \right\}.$$

It is readily verified that the union (4.1) of the sets δx_0^+ and δx_0^- yields a set of radial vectors of length $(\sum_{j=0}^{3} |\delta a_j|)^{\frac{1}{3}}$, which are aligned at angles of $\frac{k\pi i}{3}$, $k = 0, \ldots, 5$, to the real axis. Furthermore, it follows from (2.2) and (2.10) that

$$\max \left(\sum_{j=0}^{3} |\delta a_j| \right)^{\frac{1}{3}} = \left(8 \times 10^{-7}\right)^{\frac{1}{3}} = 9.3 \times 10^{-3},$$

and Figure 4.1(a) shows that this theoretical value is in excellent agreement with its computed value.

As α increases, the principal axes that are aligned at $\pm\frac{\pi}{3}$ move to the right and decrease in length. Furthermore, the decreasing number of roots that lie along these principal axes shows that the probability of a root lying along them decreases, and the principal axes of the double and simple roots split at a value $\alpha = \alpha^*$, where $0.01625 < \alpha^* < 0.0175$. It is interesting to note that Figure 3.2(a) shows that, if worst case perturbations are used, then the perturbation regions of the roots become disjoint when $\alpha = 0.0177$. Figure 4.1(f) shows that the principal axes at $\pm\frac{\pi}{2}$ for the double root are slightly curved when $\alpha = 0.0175$, which implies that this root interacts, albeit slightly, with the simple root for this value of α.

Figure 4.2 shows the difference, for six values of α, between the region R that defines the area within which the roots of the perturbed polynomials lie, as shown in Figures 3.1 and 3.2, and the principal axes of the roots. The principal axes in Figure 4.2 were obtained by computing the roots of the perturbed polynomial 1000 times for each value of α. The figure clearly shows that the probability of a root of a perturbed polynomial lying in most of the region R is vanishingly small, and thus a computation based on R may yield results that differ significantly from those that are based on the principal axes of the roots.

Finally, it is noted that computational experiments showed that the principal axes of the roots of a family of perturbed polynomials lose their well-defined property as the multiplicities of the roots of the exact polynomial increase.

5. Discussion and summary. This paper has considered the use of high order Taylor series for the computation of the componentwise condition number of a root of a polynomial that is near one or more other roots. The results in this paper cannot be obtained by its established formula (2.3) because it uses only the lowest order terms in the Taylor series of the perturbed polynomial. It was shown that if a multiple root x_0 splits up into a series of distinct roots x_i, $i = 1, \ldots, r$, of lower multiplicities, then the componentwise condition number of each of these distinct roots increases initially as the distance between them and x_0 increases.

It was stated in section 1 that the numerical and geometric issues that arise when high order Taylor series are used for the computation of the condition number of a

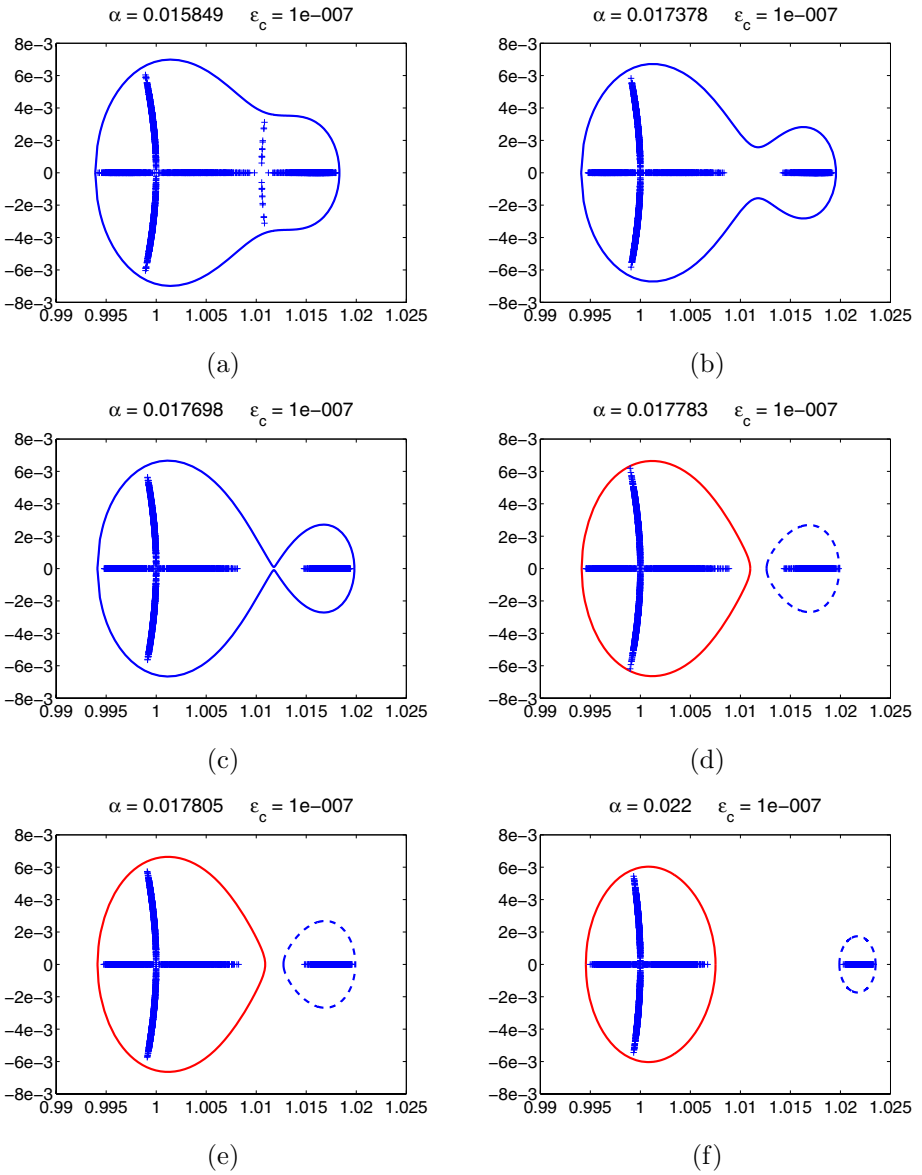

FIG. 4.2. *The regions within which the roots of the perturbed polynomial $p(x)$ lie, and their principal axes, for six values of α. The perturbation regions of the double and simple roots are equal to one another in* (a), (b), *and* (c), *but they are disjoint in* (d), (e), *and* (f), *where the solid line (–) and dashed line (- -) are the boundaries of the perturbation regions for the double and simple roots, respectively.*

root of a polynomial are considerable, and they therefore pose issues that require further work:

- The simple example in the paper showed that it is advantageous to plot the boundary of the region in the complex plane in which the perturbed root lies because it adds geometric insight and enables the condition number to be computed easily and quickly. The computation of this boundary for an

arbitrary polynomial is, however, difficult because it requires the computation of the complex solutions of a nonlinear equation in a complex variable. Also, there exist several methods for tracing a curve $f(z) = 0$, but plotting the boundary of the region in which the perturbed root lies is difficult because $f(z)$ is not differentiable for all values of z.

- It was shown that the roots of a set of perturbed polynomials lie along principal axes, and that a result that is based on them may differ from the equivalent result that is based on the condition number. This difference makes it desirable to be able to compute these principal axes.

It has recently been shown [11] that when it is required to compute the condition number of a point on an algebraic curve, and this point is near a singularity, the restriction to lowest order terms imposes constraints that are very similar to those that are described in section 2.2, and high order terms must be included in order to remove these restrictions.

Acknowledgments. The work that is described in this paper was performed when the author visited Professor Gene Golub at The Department of Computer Science at Stanford University, and he wishes to thank Professor Golub for his hospitality and for the enjoyable environment that he provided during the visit. The author also wishes to thank an anonymous referee whose comments improved the paper significantly.

EFFICIENT AND RELIABLE MULTIPRECISION IMPLEMENTATION OF ELEMENTARY AND SPECIAL FUNCTIONS*

ANNIE CUYT†, BRIGITTE VERDONK†, AND HAAKON WAADELAND‡

Abstract. Special functions are pervasive in all fields of science. The most well-known application areas are in physics, engineering, chemistry, computer science, and statistics. Because of their importance, several books and a large collection of papers have been devoted to the numerical computation of these functions. The technique for providing a floating-point implementation of a function differs substantially when going from a fixed finite precision context to a finite multiprecision context. In the former, the aim is to provide an optimal mathematical model, valid on a reduced argument range and requiring as few operations as possible. Here optimal means that, in relation to the model's complexity, the truncation error is as small as it can get. The total relative error, including round-off error and possible argument reduction effect, should not exceed a prescribed threshold. In a finite multiprecision context, the goal is to provide a more generic technique, from which an approximant yielding the user-defined accuracy can be deduced at runtime. Hence best approximants are not an option since these models have to be recomputed every time the precision is altered and a function evaluation is requested. At the same time the generic technique should generate an approximant of as low complexity as possible. In the current approach we point out how continued fraction representations of functions can be helpful in the multiprecision context. The newly developed generic technique is based mainly on the use of sharpened a priori truncation error estimates for real continued fraction representations of a real variable, developed in section 3. As illustrated in section 4, the technique is very efficient and even quite competitive when compared to the traditional fixed precision implementations. The implementation is reliable in the sense that it allows one to return a sharp interval enclosure for the requested function evaluation, at the same cost. The paper follows a recipe style. In section 2 we gather the ingredients for the new results. In section 3 we construct or prepare, for a general function $f(x)$, a continued fraction approximant satisfying all requirements of a proper implementation. In section 4 the procedure is illustrated with results obtained for several specific functions $f(x)$.

1. Introduction.

Virtually all present-day computer systems, from personal computers to the largest supercomputers, implement the IEEE 64-bit floating-point arithmetic standard, which provides 53 binary or approximately 16 decimal digits accuracy. For most scientific applications, this is more than sufficient. However, for a rapidly expanding body of applications, 64-bit IEEE arithmetic is no longer sufficient. These applications range from some interesting new mathematical investigations to large-scale physical simulations performed on highly parallel supercomputers. Moreover, in these applications, portions of the code typically involve numerically sensitive calculations, which produce results of questionable accuracy using conventional arithmetic. These inaccurate results may in turn induce other errors, such as taking the wrong path in a conditional branch. Such blocks of code benefit enormously from a

combination of reliable numeric techniques and the use of high-precision arithmetic. Indeed, the aim of reliable numeric techniques is to deliver, together with the computed result, a guaranteed upper bound on the total error or, equivalently, to compute an enclosure for the exact result.

To date, even environments such as Maple, Mathematica, and MATLAB and libraries such as IMSL, CERN, and NAG offer no routines for the reliable evaluation of special functions. The following quotes concisely express the need for new developments in the evaluation of special functions:

- [illegible] D. Lozier, general director of the Digital Library for Mathematical Functions project, and F. Olver [3].
- [illegible] 20 [illegible] 30 [illegible] Cleve Moler, founder of MATLAB [13].

2. Ingredients. A lot of well-known constants in mathematics, physics, and engineering, as well as elementary and special functions, enjoy very nice and rapidly converging continued fraction representations. Among these, we almost always find one or more limit-periodic continued fractions. In this paper we focus on the use of these limit-periodic continued fractions in the reliable multiprecision implementation of the functions they represent. We restrict ourselves to the real-valued case. This implementation is built on top of multiprecision IEEE 754-854 compliant computer arithmetic.

2.1. IEEE-based arithmetic. Let us assume to have at our disposal a multiprecision IEEE 754-854 compliant floating-point implementation of the basic operations, comparisons, and base and type conversions. Such an implementation is characterized by four parameters: the internal base β, the precision t, and the exponent range $[L, U]$. In the current generic context, we are at least aiming at implementations for $\beta = 2$ at nonstandard precisions $t > 64$, and at implementations for use with $\beta = 2^i$ where $i > 1$ or $\beta = 10^j$ where $j \geq 1$. An IEEE compliant implementation offers four rounding modes: upward $\triangle$, downward $\triangledown$, truncation $\bowtie$, and round-to-nearest $\bigcirc$. We are especially interested in the first two rounding modes because a correct implementation in these rounding modes provides a reliable enclosure of the exact function value.

To provide an implementation of a function $f(x)$ in a particular precision t, one first needs to develop a mathematical model or approximation $F(x)$ for $f(x)$ that enjoys a very small relative error compared to the precision in use. This is usually a very time-consuming effort because the model changes whenever the precision does. The sum of the truncation error $|f(x) - F(x)|/|f(x)|$ and the rounding error $|F(x) - \mathtt{F}(x)|/|f(x)|$, where $\mathtt{F}(x)$ denotes the machine implementation of the model $F(x)$, should preferably not exceed a few `ulp`, where

$$1\ \mathtt{ulp} = \beta^{-t+1}. \tag{1}$$

A typical double precision implementation ($\beta = 2,\ t = 53$) of the elementary functions achieves this in about 25 basic operations. When analyzing the efficiency of our

multiprecision implementation, we compare the number of basic operations, required in the new approach when the precision is set to $t = 53$, to this reference.

Since the accumulated rounding error is included in the total error which we bound by only a few `ulp` (typically 1 or 2), the actual evaluation of $f(x)$ needs to take place in a slightly larger working precision $s > t$. The optimal working precision is determined dynamically, depending on the rounding error analysis and the required accuracy. If applicable (not for special functions), our rounding error analysis also takes the effect of argument reduction into account. In any case a fully reliable evaluation of $f(x)$ over the domain is guaranteed.

2.2. Continued fraction representations and tails. Let us consider a continued fraction representation of the form

$$f = \frac{a_1}{1+\frac{a_2}{1+\cdots}} = \frac{a_1\rfloor}{\lceil 1}+\frac{a_2\rfloor}{\lceil 1}+\cdots=\sum_{n=1}^{\infty}\frac{a_n\rfloor}{\lceil 1}, \qquad a_n := a_n(x), \qquad f := f(x). \tag{2}$$

Here a_n is called the nth partial numerator. We use the notation f and $f(x)$ interchangeably. The latter is preferred when the dependence on x needs to be emphasized. We denote by the Nth approximant $f_N(w)$ or $f_N(x;w)$ and Nth tail t_N or $t_N(x)$ of (2), respectively, the values

$$f_N(w) = f_N(x;w) = \sum_{n=1}^{N-1}\frac{a_n\rfloor}{\lceil 1}+\frac{a_N\rfloor}{\lceil 1+w}, \tag{3}$$

$$t_N = t_N(x) = \sum_{n=N+1}^{\infty}\frac{a_n\rfloor}{\lceil 1}. \tag{4}$$

We also need approximants of tails and therefore introduce the notation $f_N^{(k)}(w)$ or $f_N^{(k)}(x;w)$ for

$$f_N^{(k)}(w) = f_N^{(k)}(x;w) = \sum_{n=k+1}^{k+N-1}\frac{a_n\rfloor}{\lceil 1}+\frac{a_{N+k}\rfloor}{\lceil 1+w}, \qquad f_N^{(0)}(w) = f_N(w).$$

Sometimes the notation $f^{(k)}$ is used for the tail t_k. A continued fraction is said to converge if $\lim_{N\to\infty} f_N(0)$ exists. Note that convergence to ∞ is allowed. In the present paper we assume the continued fractions to converge. Moreover, we restrict ourselves to the case where some $w \neq 0$ can be chosen such that $\lim_{N\to\infty} f_N(w) = \lim_{N\to\infty} f_N(0)$.

The Nth approximant of a continued fraction can also be written as

$$f_N(w) = (s_1 \circ \cdots \circ s_N)(w), \qquad s_n(w) = \frac{a_n}{1+w}, \qquad n = N,\dots,1.$$

Using the linear fractional transformations s_n, one can define a sequence $\{V_n\}_{n\in\mathbb{N}}$ of value sets for f by

$$s_n(V_n) = \frac{a_n}{1+V_n} \subseteq V_{n-1}, \qquad n \geq 1. \tag{5}$$

The importance of such a sequence of sets lies in the fact that these sets keep track of where certain values lie. For instance, if $w \in V_N$, then $f_N(w) \in V_0$ and $f_{N-k}^{(k)}(w) \in V_k$.

Also $t_N \in \overline{V}_N$ and $f \in \overline{V}_0$, where $\overline{V}$ denotes the closure of V. An equally important role is played by a sequence of convergence sets $\{E_n\}_{n\in\mathbb{N}}$, of which the elements guarantee convergence of the continued fraction (2) as long as each partial numerator a_n belongs to the respective set E_n:

$$\forall n \geq 1 : a_n \in E_n \Rightarrow \sum_{n=1}^{\infty} \frac{a_n\rfloor}{\lceil 1} \text{ converges.} \tag{6}$$

A sequence $\{V_n\}_{n\in\mathbb{N}}$ is called a sequence of value sets for a sequence $\{E_n\}_{n\in\mathbb{N}}$ of convergence sets if (5) holds for all $a_n \in E_n$. Value sets can also be defined for nonconvergent continued fractions (then the E_n are called element sets), but in the current context this form of generality does not interest us.

It is well known that the tail or rest term of a convergent Taylor series expansion converges to zero. It is less well known that the tail of a convergent continued fraction representation does not need to converge to zero; it does not even need to converge at all. We give an example for each of the cases. Take, for instance, the continued fraction expansion

$$\frac{\sqrt{1+4x}-1}{2} = \sum_{n=1}^{\infty} \frac{x\rfloor}{\lceil 1}, \qquad x \geq -\frac{1}{4}.$$

Each tail t_N converges to $\frac{1}{2}(\sqrt{1+4x}-1)$ as well. More remarkable is that the even-numbered tails of the convergent continued fraction

$$\sqrt{2}-1 = \sum_{n=1}^{\infty} \left(\frac{(3+(-1)^n)/2\rfloor}{\lceil 1} \right) = \frac{1\rfloor}{\lceil 1} + \frac{2\rfloor}{\lceil 1} + \frac{1\rfloor}{\lceil 1} + \frac{2\rfloor}{\lceil 1} + \cdots$$

converge to $\sqrt{2}-1$ while the odd-numbered tails converge to $\sqrt{2}$ (hence the sequence of tails does not converge), and that the sequence of tails $\{t_N\}_{N\geq 1} = \{N+1\}_{N\geq 1}$ of

$$1 = \sum_{n=1}^{\infty} \frac{n(n+2)\rfloor}{\lceil 1}$$

converges to $+\infty$.

When carefully monitoring the behavior of these continued fraction tails, very accurate approximants $f_N(w)$ for f can be computed by making an appropriate choice for w. We call a continued fraction of the form (2) limit-periodic with period k if

$$\lim_{p\to\infty} a_{pk+q} = \tilde{a}_q, \qquad q = 1, \ldots, k.$$

More can be said about tails of limit-periodic continued fractions with period one, also called limit-periodic continued fractions. Let (2) converge and be limit-periodic with $a_n \geq -\frac{1}{4}$ and $\lim_{n\to\infty} a_n = \tilde{a} < \infty$. If $\tilde{w}$ is the in modulus smaller fixpoint of the linear fractional transformation $s(w) = \tilde{a}/(1+w)$, then

$$\tilde{w} = -\frac{1}{2} + \sqrt{\tilde{a} + \frac{1}{4}} = \lim_{N\to\infty} t_N$$

and, according to [15],

$$\lim_{N\to\infty} \left| \frac{f(x) - f_N(x;\tilde{w})}{f(x) - f_N(x;0)} \right| = 0. \tag{7}$$

Hence a suitable choice of w in (3) may result in more rapid convergence of the approximants ($w = 0$ is usually used as a reference).

In this paper we replace the condition that (2) converges, in the case of limit-periodic continued fractions, with the conditions $a_n \geq -\frac{1}{4}$ and the sequence $\{a_n\}_{n\in\mathbb{N}}$ is bounded [11, pp. 150–159]. These easier conditions automatically imply that $\tilde{a} \geq -\frac{1}{4}$ and $\tilde{w}$ is real. They also simplify the description of the results, which can, however, be generalized to the particular situations where $a_n \leq -\frac{1}{4}$, $\tilde{a} = -\frac{1}{4}$, and (2) converges because the convergence speed of the partial numerators can be termed safe (see [11, p. 159]).

2.3. The oval sequence theorem. Most truncation error upper bounds for $|f(x) - f_N(x;w)|$ are given for the classical choice $w = 0$. For continued fractions with partial numerators of the form $a_n(x) = \alpha_n x$ with $\alpha_n > 0$ we refer among others to the a priori Gragg–Warner bound

(8)
$$|f(x) - f_N(x;0)| \leq 2\frac{|a_1|}{\cos\phi}\prod_{k=2}^{N}\frac{\sqrt{1+4|a_k|/\cos^2(\phi)}-1}{\sqrt{1+4|a_k|/\cos^2(\phi)}+1}, \qquad -\pi < 2\phi = \arg(x) < \pi,$$

which holds for $N \geq 2$, and the a posteriori Henrici–Pfluger bound

$$|f(x) - f_N(x;0)| \leq \begin{cases} |f_N(x;0) - f_{N-1}(x;0)|, & |\arg(x)| \leq \pi/2, \\ \dfrac{|f_N(x;0) - f_{N-1}(x;0)|}{|\sin(\arg(x))|}, & \pi/2 < |\arg(x)| < \pi. \end{cases}$$

A posteriori bounds are usually slightly sharper because they exploit the information contained in already computed approximants. But they are of no use in a variable precision context: One does not want to scan all approximants until the truncation error threshold is satisfied. The Gragg–Warner a priori bound does not suffer from this disadvantage, but it is only valid when $a_n(x) = \alpha_n x$ with $\alpha_n > 0$. In this paper we develop a practical and sharp truncation error bound for the case $w \neq 0$, which is valid for all continued fractions with real partial numerators $a_n(x)$. Our point of departure for this is the oval sequence theorem from which a priori truncation error estimates can be obtained in case $w \neq 0$.

In the general formulation of the oval sequence theorem (see Theorem 1) [11, pp. 145–147], which holds in the complex plane, the value sets V_n are disks and the convergence sets E_n are Cartesian ovals (the situation where the continued fraction does not necessarily converge can also be considered but is of no interest to us). We denote the complex conjugate of the center C_n by $\overline{C}_n$.

In the real case both V_n and E_n reduce to intervals. We reformulate the more specific real version in Theorem 2 (which allows for point intervals) and provide an elegant short proof.

THEOREM 1. [illegible] $0 < r_n < |1 + C_n|$ [illegible] $n \geq 0$ [illegible] $|C_{n-1}|r_n < |1 + C_n|r_{n-1}$ [illegible] $n \geq 1$ [illegible] $\{V_n\}_{n\in\mathbb{N}}$ [illegible]

$$V_n = \{w \in \mathbb{R} : |C_n - w| < r_n\}$$

[illegible] $\{E_n\}_{n\in\mathbb{N}_0}$ [illegible]

$$E_n = \{a \in \mathbb{R} : |a(1+\overline{C}_n) - C_{n-1}(|1+C_n|^2 - r_n^2)| + r_n|a| \leq r_{n-1}(|1+C_n|^2 - r_n^2)\}.$$

[illegible] $w \in V_N$ [illegible] $|f(x) - f_N(x;w)|$ [illegible]

$$|f(x) - f_N(x;w)| \le 2r_N \frac{|C_0| + r_0}{|1 + C_N| - r_N} \times \prod_{k=1}^{N-1} M_k, \tag{9}$$

[illegible] $M_k = \max\{|u/(1+u)| : u \in \overline{V}_k\}$

In the real case the set E_n given above is actually an interval. The set $\overline{V}_k = [C_k - r_k, C_k + r_k]$ and the maximum M_k is given by

$$M_k = \max\left(\left|\frac{C_k - r_k}{1 + C_k - r_k}\right|, \left|\frac{C_k + r_k}{1 + C_k + r_k}\right|\right)$$

since the function $w/(1+w)$ is a strictly increasing function. Let us simplify the statement and proof of the oval sequence theorem for the case of real interval sequences. At the same time, the new proof delivers a bound for the relative error instead of the absolute error, and we have $M_k \le 1$. In what follows we refer to this theorem as the interval sequence theorem.

THEOREM 2. [illegible] n [illegible] L_n [illegible] R_n [illegible] $-\frac{1}{2} \le L_n \le R_n < \infty$ [illegible]

$$\begin{aligned} b_n &:= (1 + \operatorname{sign}(L_n) \max(|L_n|, |R_n|))\, L_{n-1}, \\ c_n &:= (1 + \operatorname{sign}(L_n) \min(|L_n|, |R_n|))\, R_{n-1} \end{aligned}$$

[illegible] $b_n \le c_n$ [illegible] $0 \le b_n c_n$ [illegible] $\{V_n\}_{n\in\mathbb{N}}$ [illegible] $V_n = [L_n, R_n]$ [illegible] [illegible] $\{E_n\}_{n\in\mathbb{N}}$ [illegible]

$$E_n = [b_n, c_n] = \begin{cases} [(1 + R_n)L_{n-1}, (1 + L_n)R_{n-1}], & b_n \ge 0, \\ [(1 + L_n)L_{n-1}, (1 + R_n)R_{n-1}], & b_n \le 0. \end{cases}$$

[illegible] $w \in V_N$ [illegible] $|f(x) - f_N(x;w)|/|f(x)|$ [illegible]

$$\left|\frac{f(x) - f_N(x;w)}{f(x)}\right| \le \frac{R_N - L_N}{1 + L_N} \prod_{k=1}^{N-1} M_k, \tag{10}$$

[illegible] $M_k = \max\{|u/(1+u)| : u \in V_k\} = \max\{|L_k/(1+L_k)|, |R_k/(1+R_k)|\}$ [illegible]. The relation between E_n and V_n is expressed in (5). For $E_n = [b_n, c_n] \subset \mathbb{R}^+$ this translates to

$$\begin{aligned} L_{n-1} &\le \frac{b_n}{1 + R_n}, \\ R_{n-1} &\ge \frac{c_n}{1 + L_n}, \end{aligned}$$

while for $E_n \subset \mathbb{R}^-$ it translates to

$$\begin{aligned} L_{n-1} &\le \frac{b_n}{1 + L_n}, \\ R_{n-1} &\ge \frac{c_n}{1 + R_n}. \end{aligned}$$

Using the notation $f^{(j)}(x)$ for the jth tail of the continued fraction $f(x)$, we obtain

$$\begin{aligned} f(x) - f_N(x;w) &= \frac{a_1}{1+f^{(1)}(x)} - \frac{a_1}{1+f_{N-1}^{(1)}(x;w)} \\ &= \frac{-f^{(0)}(x)(f^{(1)}(x) - f_{N-1}^{(1)}(x;w))}{1+f_{N-1}^{(1)}(x;w)} \\ &= -f(x)\frac{f^{(N)}(x)-w}{1+w}\prod_{j=1}^{N-1}\left(\frac{-f^{(j)}(x)}{1+f_{N-j}^{(j)}(x;w)}\right). \end{aligned}$$

Hence

$$\left|\frac{f(x)-f_N(x;w)}{f(x)}\right| \le \frac{R_N - L_N}{1+w}\left|\prod_{j=1}^{N-1}\frac{f^{(j)}(x)}{1+f_{N-j}^{(j)}(x;w)}\right|.$$

Now for $1 \le k \le \lfloor (N-1)/2 \rfloor$, we have

$$\begin{aligned} &\frac{f^{(2k)}(x)}{1+f_{N-2k}^{(2k)}(x;w)}\,\frac{f^{(2k-1)}(x)}{1+f_{N-2k+1}^{(2k-1)}(x;w)} \\ &\quad= \frac{f^{(2k)}(x)}{1+f_{N-2k}^{(2k)}(x;w)}\,\frac{a_{2k}}{1+f^{(2k)}(x)}\,\frac{1}{1+f_{N-2k+1}^{(2k-1)}(x;w)} \\ &\quad= \frac{f^{(2k)}(x)}{1+f^{(2k)}(x)}\,\frac{f_{N-2k+1}^{(2k-1)}(x;w)}{1+f_{N-2k+1}^{(2k-1)}(x;w)}. \end{aligned}$$

If $N-1$ is odd, then the last factor can be combined with $1/(1+w)$ into

$$\frac{f^{(N-1)}(x)}{1+f_1^{(N-1)}(x;w)}\,\frac{1}{1+w} = \frac{f_1^{(N-1)}(x;w)}{1+f_1^{(N-1)}(x;w)}\,\frac{1}{1+f^{(N)}(x)}.$$

Since $\max_{u\in V_k}|u/(1+u)| = M_k$, the theorem is proved. □

An upper bound for the truncation error $|f(x) - f_N(x;w)|$ is obtained by multiplying the right-hand side of (10) by R_0 which is an upper bound for $|f(x)|$.

The smaller the sets V_n, in other words, the smaller $R_n - L_n$, and the more precisely one knows the M_k, the smaller the upper bound on the truncation error $|f(x) - f_N(x;w)|/|f(x)|$ becomes. We come back to this issue in section 3.

In section 3 we also combine the interval sequence theorem with the characteristic monotonicity behavior of the tails of some limit-periodic continued fraction representations, which we derive now.

2.4. Monotonicity properties of tails. To prepare these results, we prove some easy lemmas. Lemma 1 mainly serves to establish computable upper bounds for tails of continued fractions, while Lemma 2 provides additional information about the relation between continued fraction approximants and tail estimates. In Lemmas 3 and 4 we obtain some results on the boundedness and monotonicity behavior of the sequence of tails. In the formulation of these lemmas the notions increasing and decreasing for sequences of numbers are never meant in the strict sense: A constant sequence can be considered to be decreasing as well as increasing.

To obtain monotonicity results about the continued fraction tails, we further distinguish between

- the fractions where $a_n \to \tilde{a}$ from one side, say $\{a_n\}_{n\in\mathbb{N}}$ is a decreasing (or increasing) sequence with $\lim_{n\to\infty} a_n = \tilde{a}$, and
- the fractions where $a_n \to \tilde{a}$ in an alternating fashion, say the sequences $\{a_{2n+1}\}_{n\in\mathbb{N}}$ and $\{a_{2n}\}_{n\in\mathbb{N}}$, respectively, decrease and increase toward $\tilde{a}$.

For continued fractions with positive a_n it suffices to study the latter case in detail, while the former case is the basic building block when dealing with continued fractions with negative a_n. This becomes clear in section 4 where all different types of behavior for the partial numerators are illustrated and can be dealt with, starting from the two mentioned basic types. How to deal with a continued fraction containing both positive and negative partial numerators is explained in section 3.4. From section 3.4 it should be clear that the condition in most lemmas for the partial numerators to be either all positive or all negative is not a true restriction but merely reflects a choice made by the authors to simplify the description of the results.

LEMMA 1.

1. [illegible] $a_n > 0$ [illegible] (2) [illegible] $k > 0$ [illegible] $\{f_{2n}^{(k)}(0)\}_{n\in\mathbb{N}}$ [illegible] $\{f_{2n+1}^{(k)}(0)\}_{n\in\mathbb{N}}$ [illegible]

$$f_{2n}^{(k)}(0) \le t_k \le f_{2n+1}^{(k)}(0).$$

2. [illegible] $a_n < 0$ [illegible] $\{a_n\}_{n\in\mathbb{N}}$ [illegible] $\lim_{n\to\infty} a_n = \tilde{a} \ge -\frac{1}{4}$ [illegible] $k > 0$ [illegible] t_k [illegible] (2) [illegible]

$$\frac{-1+\sqrt{4\tilde{a}+1}}{2} \le t_k \le \frac{-1+\sqrt{4a_{k+1}+1}}{2}.$$

[illegible]. Part 1 is well known from continued fraction literature [1, p. 223]. It remains to prove part 2. We give the proof for the upper bound in part 2 because the lower bound is proved analogously. Consider the approximant $f_n^{(k)}$ of t_k. Since $0 \le 1 + a_{k+n-j} \le 1 + a_{k+1}$ for $j = 0, \ldots, n-1$, we find that

$$\begin{aligned}
\frac{a_{k+n-1}}{1+a_{k+n}} &\le \frac{a_{k+1}}{1+a_{k+1}},\\
\frac{a_{k+n-2}}{1+\frac{a_{k+n-1}}{1+a_{k+n}}} &\le \frac{a_{k+1}}{1+\frac{a_{k+1}}{1+a_{k+1}}}\\
&\vdots\\
f_n^{(k)} &\le \frac{a_{k+1}}{\left\lfloor 1\right\rfloor} + \cdots + \frac{a_{k+1}}{\left\lfloor 1\right\rfloor}.
\end{aligned}$$

In the limit the inequality is preserved because of the convergence of (2), leading to

$$t_k \le \frac{-1+\sqrt{4a_{k+1}+1}}{2},$$

which concludes this part of the proof. □

The condition that (2) converges is automatically satisfied in part 2 of Lemma 1 and in Lemmas 2, 3, and 4 because of the boundedness of the partial numerators a_n.

LEMMA 2. [illegible] $a_n \ge -\frac{1}{4}$ [illegible] $\{a_n\}_{n\in\mathbb{N}}$ [illegible]

1. $t_k \ge -\frac{1}{2}$ [illegible] $\operatorname{sign}(t_k) = \operatorname{sign}(a_{k+1})$ [illegible] k

2. [illegible] $a_n > 0$ [illegible] $0 \le w_{1,k} \le t_k \le w_{2,k}$ [illegible] k [illegible]

$$f_{2n}(w_{1,2n}) \le f \le f_{2n+1}(w_{1,2n+1}), \tag{11a}$$

$$f_{2n}(w_{2,2n}) \ge f \ge f_{2n+1}(w_{2,2n+1}). \tag{11b}$$

3. [illegible] $a_n < 0$ [illegible] $-\frac{1}{2} \le w_{1,k} \le t_k \le w_{2,k}$ [illegible] k [illegible]

$$f_n(w_{1,n}) \le f \le f_n(w_{2,n}). \tag{11c}$$

[illegible]. The proof is straightforward. We prove, for instance, the second inequality of part 3. From $0 \ge w_{2,n} \ge t_n \ge -\frac{1}{2}$ follows

$$\begin{aligned} \frac{a_n}{1+w_{2,n}} &\ge \frac{a_n}{1+t_n} \\ &\vdots \\ f_n(w_{2,n}) &\ge f_n(t_n) = f \end{aligned}$$

and similarly for the other equations. □

LEMMA 3.

1. [illegible] (2) [illegible] $a_n > 0$ [illegible] $\{a_{2n+1}\}_{n\in\mathbb{N}}$ [illegible] $\{a_{2n}\}_{n\in\mathbb{N}}$ [illegible] $\{t_{2n}\}_{n\in\mathbb{N}}$ [illegible] $\{t_{2n+1}\}_{n\in\mathbb{N}}$ [illegible]
2. [illegible] k [illegible] $\ell, a_{2k+1} > a_{2\ell}$ [illegible] k [illegible] ℓ [illegible] (2) [illegible] $t_{2k} \ge t_{2\ell+1}$

[illegible]. Since $a_{2n+3} \le a_{2n+1}$ and $a_{2n+4} \ge a_{2n+2}$, we find that

$$\begin{aligned} f_2^{(2n+2)}(0) = \frac{a_{2n+3}}{1+a_{2n+4}} &\le f_2^{(2n)}(0) = \frac{a_{2n+1}}{1+a_{2n+2}} \\ &\vdots \\ f_k^{(2n+2)}(0) &\le f_k^{(2n)}(0), \qquad k > 2. \end{aligned}$$

In the limit the last inequality remains true, yielding $t_{2n+2} \le t_{2n}$. The case $t_{2n+3} \ge t_{2n+1}$ follows in the same way, and we proceed to part 2. Let us first prove the statement for $k = \ell$. Since $a_{2k+1} > a_{2k+2}, a_{2k+2} < a_{2k+3}$ and so on, we have

$$\begin{aligned} f_2^{(2k)}(0) &> f_2^{(2k+1)}(0) \\ &\vdots \\ f_s^{(2k)}(0) &> f_s^{(2k+1)}(0), \qquad s > 2. \end{aligned}$$

Taking limits, the last inequality becomes $t_{2k} \ge t_{2k+1}$. For $k < \ell$, we use

$$t_{2\ell} \ge t_{2\ell+1} \ge t_{2k+1}$$

and for $k > \ell$, we use

$$t_{2\ell} \ge t_{2k} \ge t_{2k+1},$$

which concludes the proof. □

LEMMA 4. [illegible] a_n [illegible] $-\frac{1}{4} \leq a_n < 0$ [illegible] $\{a_n\}_{n\in\mathbb{N}}$ [illegible] $\{t_n\}_{n\in\mathbb{N}}$ [illegible]. Consider for $k \geq 1$ and $n \geq 1$ the approximant $f_n^{(k)}$ of the tail t_k. Since $0 \leq 1 + a_{k+n+1} \leq 1 + a_{k+n}$, we find with $a_{k+n} < 0$ and $a_{k+n-1} < 0$ that

$$\frac{a_{k+n}}{1 + a_{k+n+1}} \leq \frac{a_{k+n-1}}{1 + a_{k+n}}$$

and analogously

$$f_n^{(k+1)} \leq f_n^{(k)}.$$

In the limit this inequality is preserved and becomes

$$t_{k+1} \leq t_k,$$

which concludes the proof. □

2.5. Backward recurrence algorithm. Several algorithms exist for the computation of $f_N(w)$. The easiest to use, because N can be determined concurrently with $f_N(w)$, is the forward recurrence algorithm

$$\begin{aligned} A_{-1} &= 1, \qquad A_0 = 0, \\ B_{-1} &= 0, \qquad B_0 = 1, \\ A_n &= A_{n-1} + a_n A_{n-2}, \qquad n = 1, \ldots, N-1, \\ B_n &= B_{n-1} + a_n B_{n-2}, \qquad n = 1, \ldots, N-1, \\ f_N(w) &= \frac{(1+w)A_{N-1} + a_N A_{N-2}}{(1+w)B_{N-1} + a_N B_{N-2}}. \end{aligned} \tag{12}$$

The most stable, however [5], is the backward recurrence algorithm

$$\begin{aligned} F_{N+1}^{(N)} &= w, \\ F_n^{(N)} &= \frac{a_n}{1 + F_{n+1}^{(N)}}, \qquad n = N, N-1, \ldots, 1, \\ f_N(w) &= F_1^{(N)}. \end{aligned}$$

For the backward recurrence algorithm to be useful in a variable precision context, it must be possible to determine rather easily a priori which approximant to compute, in other words, to decide which N guarantees a prescribed total error upper bound. For the determination of N from the truncation error upper bound, we refer to sections 3.1 and 3.2. The results follow from combining the interval sequence theorem with Lemmas 1–4. Choosing a suitable estimate for the tail t_N is discussed in section 3.3. The rounding error is subsequently controlled by determining a suitable working precision in which to execute the backward recurrence algorithm. The latter is dealt with in detail in section 3.5.

3. Preparation. The realization of a machine implementation of $f(x)$ is a three-step process:

1. When given an argument x for a function f, the evaluation $f(x)$ is often reduced to the evaluation of f for another argument $\tilde{x}$ lying within specified

bounds and for which there exists an easy relationship between $f(x)$ and $f(\tilde{x})$. For instance, for the exponential function in a base β implementation,

$$\exp(x) = \beta^k \exp(\tilde{x}), \qquad \tilde{x} = \operatorname{mod}(x, \ln \beta), \qquad |\tilde{x}| \leq \frac{\ln \beta}{2}.$$

Although the given argument x is known exactly, because it is a given floating-point number, usually the reduced argument $\tilde{x}$ cannot be computed exactly but is subject to a rounding error.

2. After the reduced argument is determined, the mathematical model F for f is constructed and a truncation error comes into play.
3. When implemented, in other words, evaluated, this mathematical model F is also subject to a rounding error.

Finally, the effect of switching from the argument x to the reduced argument $\tilde{x}$ must be taken into account. This introduces a final additional error. Let us now have a look at how all these errors can be controlled.

The issue of argument reduction is a topic in itself and is not the subject of this paper. We mention it here because we want to emphasize that in our implementation this effect is taken into account, by which we mean that the error upper bound we guarantee holds for the entire argument range and not only for the reduced range. Detailed information on argument reduction can be found in [14, 4] and [12]. For each of the functions discussed in detail in section 4, we briefly outline the argument reduction technique used.

For the use of continued fraction approximants in steps 2 and 3 we still need to address the following issues:

- How do we determine N such that the upper bound for the relative error on $f_N(x; w)$ does not exceed a threshold ϵ_T?
- How do we obtain an easily computable tail estimate $w \in V_N$ (or $w_N \in V_N$) for the evaluation of $f_N(x; w)$?

A rounding error analysis of the backward recurrence algorithm is given in section 3.5.

3.1. Determination of N. The a priori Gragg–Warner bound is expressed entirely in terms of the partial numerators a_n and the function's argument x. Except for the result given in [11, p. 151], this cannot be said of the oval sequence or interval sequence bounds. Theorem 1 as well as Theorem 2 assumes that the value sets are given and that convergence sets can be associated with them.

The aim of this section is slightly different from what we have obtained in Theorem 2, where the sets E_n are deduced from the intervals $V_n = [L_n, R_n]$ and the bounds of E_n are formulated in terms of L_n and R_n. Here we want to formulate L_n and R_n in terms of the bounds on a_n in E_n and hence associate intervals V_n with given intervals E_n, instead of the other way around. In Lemma 5 we further specify the bounds L_n and R_n introduced in Theorem 2, for some appropriately chosen convergence sets E_n. We show that the bounds L_n and R_n are in fact tails.

Let $E_n = [b_n, c_n]$ with $-\frac{1}{4} \leq b_n \leq c_n$ and $b_n c_n \geq 0$. The smallest useful E_n equals $[\bigtriangledown(a_n), \bigtriangleup(a_n)]$, where $\bigtriangledown(a_n)$ and $\bigtriangleup(a_n)$ denote the machine representations of the partial numerator a_n obtained using the downward and upward rounding modes, respectively. The usual machine representation of a_n, namely $\bigcirc(a_n)$ which results from round-to-nearest, is contained in such E_n. In case a_n is itself the result of a computation, then the interval E_n can be taken slightly larger. The condition that

b_n and c_n have the same sign means nothing more than that at least sign(a_n) is kept fixed in E_n.

LEMMA 5. [illegible] $\{E_n\}_{n\in\mathbb{N}}$ [illegible] $E_n = [b_n, c_n]$ [illegible] $b_n \geq -\frac{1}{4}$ [illegible] $0 \leq b_n c_n$ [illegible] $\{V_n\}_{n\in\mathbb{N}}$ [illegible] $V_n = [L_n, R_n]$ [illegible] L_n [illegible] R_n [illegible]

$$\begin{aligned} \hat{D} &= \frac{b_1\rfloor}{\lceil 1} + \frac{c_2\rfloor}{\lceil 1} + \frac{b_3\rfloor}{\lceil 1} + \frac{c_4\rfloor}{\lceil 1} + \cdots, \\ \hat{U} &= \frac{c_1\rfloor}{\lceil 1} + \frac{b_2\rfloor}{\lceil 1} + \frac{c_3\rfloor}{\lceil 1} + \frac{b_4\rfloor}{\lceil 1} + \cdots, \end{aligned} \tag{13}$$

$$\begin{aligned} \check{D} &= \frac{b_1\rfloor}{\lceil 1} + \frac{b_2\rfloor}{\lceil 1} + \frac{b_3\rfloor}{\lceil 1} + \frac{b_4\rfloor}{\lceil 1} + \cdots, \\ \check{U} &= \frac{c_1\rfloor}{\lceil 1} + \frac{c_2\rfloor}{\lceil 1} + \frac{c_3\rfloor}{\lceil 1} + \frac{c_4\rfloor}{\lceil 1} + \cdots. \end{aligned} \tag{14}$$

[illegible] $\hat{D}, \check{D}$ [illegible] $\hat{U}, \check{U}$ [illegible] $\hat{D}^{(n)}, \check{D}^{(n)}$ [illegible] $\hat{U}^{(n)}, \check{U}^{(n)}$ [illegible] $b_n \geq 0$

$$\begin{aligned} L_{2j} &= \hat{D}^{(2j)}, \qquad L_{2j-1} = \hat{U}^{(2j-1)}, \\ R_{2j} &= \hat{U}^{(2j)}, \qquad R_{2j-1} = \hat{D}^{(2j-1)}, \end{aligned} \tag{15}$$

[illegible] $b_n \leq 0$

$$L_n = \check{D}^{(n)}, \qquad R_n = \check{U}^{(n)}. \tag{16}$$

[illegible] A sequence of value sets $\{V_n\}_{n\in\mathbb{N}}$ associated with the sequence of convergence sets $\{E_n\}_{n\in\mathbb{N}}$ satisfies

$$\frac{a_n}{1+V_n} \subseteq V_{n-1}, \qquad a_n \in E_n.$$

Hence, if $V_n \subset \mathbb{R}^+$, expressions for the left and right endpoints L_n and R_n of the intervals V_n need to satisfy the condition

$$(1+L_n)R_{n-1} \geq (1+R_n)L_{n-1} \tag{17}$$

and if $V_n \subset \mathbb{R}^-$, they need to satisfy

$$R_{n-1}(1+R_n) \geq L_{n-1}(1+L_n). \tag{18}$$

Let us first write down explicit formulas for suitable bounds L_n and R_n in case we are dealing with a sequence of convergence sets that allow only positive a_n.

Each V_n contains the tail t_n of (2) since $V_n = \overline{V}_n$. The smallest possible value for the tail t_n of (2) is obtained when the partial numerators $a_{n+j} \in E_{n+j}$ with $j \geq 1$ alternatively take the smallest and largest values $b_{n+1} \in E_{n+1}$, $c_{n+2} \in E_{n+2}, \ldots$. A similar result holds for the largest value of the tail which is attained when the a_{n+j} alternatively take the largest and smallest values c_{n+1}, $b_{n+2}, \ldots$. Hence, for the convergence sets $E_n = [b_n, c_n]$, the corresponding value sets V_n are given by $V_n = [L_n, R_n]$ with

$$\begin{aligned} L_n &= \frac{b_{n+1}\rfloor}{\lceil 1} + \frac{c_{n+2}\rfloor}{\lceil 1} + \frac{b_{n+3}\rfloor}{\lceil 1} + \frac{c_{n+4}\rfloor}{\lceil 1} + \cdots, \\ R_n &= \frac{c_{n+1}\rfloor}{\lceil 1} + \frac{b_{n+2}\rfloor}{\lceil 1} + \frac{c_{n+3}\rfloor}{\lceil 1} + \frac{b_{n+4}\rfloor}{\lceil 1} + \cdots. \end{aligned}$$

It is now easy to check that (17) holds.

When the convergence sets allow only negative a_n, then the proof goes as follows. Consider $f_n^{(k)}$. Since $0 \le 1 + b_{k+n} \le 1 + a_{k+n} \le 1 + c_{k+n}$, we find that

$$\frac{b_{k+n-1}}{1+b_{k+n}} \le \frac{a_{k+n-1}}{1+a_{k+n}} \le \frac{c_{k+n-1}}{1+c_{k+n}}$$

and analogously

$$\check{D}_n^{(k)} \le f_n^{(k)} \le U_n^{(k)}.$$

In the limit this inequality is preserved and becomes

$$\check{D}^{(k)} \le t_k \le \check{U}^{(k)}.$$

Again, (18) is easy to check. □

Given the accuracy with which the partial numerators can be obtained, in other words, the width of the convergence sets E_n, we can now determine the bounds L_n and R_n in terms of the bounds on E_n and use these in (10). This way, the right-hand side of (10) can be evaluated for consecutive values of N until the relative error is sufficiently small. Note, however, that L_n and R_n are infinite expressions and hence not computable. The practical computation of $M_k = \max\{|L_k/(1+L_k)|, R_k/(1+R_k)\}$ in the right-hand side of (10) is further detailed in section 3.3.

We also prefer a bound that requires the computation of as few expressions as possible, for instance, either the sequence $\{R_n\}_{n\in\mathbb{N}}$ or the sequence $\{L_n\}_{n\in\mathbb{N}}$ but not both. This can easily be guaranteed when the value sets V_n are small enough to ensure that $L_n R_n \ge 0$. Then in case $L_n \le 0$, the bound $M_n = |L_n/(1+L_n)|$, and in case $L_n \ge 0$, we have $M_n = R_n/(1+R_n)$ since $L_n \le R_n$ in all cases. According to Lemma 2, $L_n R_n \ge 0$ is guaranteed by $b_n c_n \ge 0$ because the sign of R_n and L_n is determined by the sign of either b_n or c_n.

In addition, when $0 \le b = \lim_{n\to\infty} b_n$ and $0 \le c = \lim_{n\to\infty} c_n$, the tails L_n and R_n, respectively, converge to

$$\begin{aligned} \lim_{n\to\infty} L_n = L &= \frac{b-c-1+\sqrt{(c-b)^2+2(c+b)+1}}{2}, \\ \lim_{n\to\infty} R_n = R &= \frac{c-b-1+\sqrt{(c-b)^2+2(c+b)+1}}{2} \end{aligned} \tag{19}$$

with $L \le R$. In case $b \le 0$ and $c \le 0$, we have

$$\begin{aligned} \lim_{n\to\infty} L_n = L &= \frac{-1+\sqrt{4b+1}}{2}, \\ \lim_{n\to\infty} R_n = R &= \frac{-1+\sqrt{4c+1}}{2}. \end{aligned} \tag{20}$$

In section 4 we illustrate that the bound given by (10) combined with the formulas (15) and (16) is as sharp with respect to the true truncation error for the modified approximant $f_N(x;w)$ as the Gragg–Warner bound is when compared to the unmodified approximant $f_N(x;0)$. Both are also of the same a priori form.

3.2. Explicit formula for N. In this section we want to use formula (10) to deduce an explicit formula for N from the truncation error bound, rather than the bound from the knowledge of N. To this end we need to be able to bound the R_n from above by a value $\overline{R}$, from a certain $n_R \leq N$ on, and bound the L_n from below by $\overline{L}$ from a possibly different $n_L \leq N$ on. The continued fractions and convergence sets that satisfy such conditions are discussed in detail in section 4. Sometimes we want to make use of Lemma 6.

LEMMA 6. [illegible] $\{x_n\}_{n\in\mathbb{N}}$ [illegible] $\{y_n\}_{n\in\mathbb{N}}$ [illegible] n $x_n \geq -d$ [illegible] $y_n \geq -d$ [illegible] $d \in \mathbb{R}$ [illegible]

$$\left\{\frac{y_n - x_n}{d + x_n}\right\}_{n\in\mathbb{N}}$$

[illegible]. For fixed ℓ we define the sequence $\{z_n^{(\ell)}\}_{n\in\mathbb{N}}$ with

$$z_n^{(\ell)} = \frac{y_\ell - x_n}{d + x_n}.$$

Because for every ℓ it holds that $y_\ell \geq -d$, the function $(y_\ell - x)/(d+x)$ is an increasing function on $]-d, +\infty[$. Hence the sequence $\{z_n^{(\ell)}\}_{n\in\mathbb{N}}$ is a decreasing sequence and consequently

$$\frac{y_n - x_n}{d + x_n} \geq \frac{y_{n+1} - x_n}{d + x_n} = z_n^{(n+1)} \geq z_{n+1}^{(n+1)} = \frac{y_{n+1} - x_{n+1}}{d + x_{n+1}}. \qquad \square$$

When the R_n and L_n satisfy the required monotonicity properties, we can bound the factor $(R_N - L_N)/(1 + L_N)$ for $N \geq \max(n_R, n_L)$ by $(\overline{R} - \overline{L})/(1 + \overline{L})$. In case the sequence $\{R_n\}_{n\in\mathbb{N}}$ is decreasing and the sequence $\{L_n\}_{n\in\mathbb{N}}$ is increasing, we can take $\overline{R} = R_K$ and $\overline{L} = L_K$ for $K \leq N$. In addition, the product of the factors M_k can then be bounded above by

$$\prod_{k=1}^{N-1} M_k \leq \left(\prod_{k=1}^{K-1} M_k\right) \times M_K^{N-K}, \qquad K \leq N. \tag{21}$$

Although cruder, (21) allows one to determine N explicitly in terms of a given threshold ϵ_T. Taking the logarithm of the new bound (21) for the product $M_1 \cdots M_{N-1}$ in (10) and an imposed threshold ϵ_T results in

$$(N - K)(-\log M_K) \geq \log\left(\frac{R_K - L_K}{1 + L_K}\right) + \sum_{k=1}^{K-1} \log M_k - \log \epsilon_T. \tag{22}$$

How $w \in [L_N, R_N]$ is obtained cheaply (in terms of numerical operations) is discussed together with some practical ways to obtain a computational upper bound for M_k.

3.3. Obtaining M_k and w. Lemmas 1 and 2 show the way to compute an upper bound for M_k. We discuss two cases in somewhat more detail.

When all partial numerators $a_n > 0$, then $L_k \geq 0$ and $M_k = R_k/(1 + R_k)$. Let us denote the jth approximants of R_k and L_k by $R_{k,j}$ and $L_{k,j}$, respectively, and use part 1 of Lemma 1 (the correct notation for these approximants is actually $R_{k,j}(0)$ and $L_{k,j}(0)$, but we drop the suffix (0) to further simplify the notation). Because

the tails R_k and L_k themselves cannot be computed, odd-numbered approximants $R_{k,2j+1} \geq R_k$ and an even-numbered approximant $L_{N,2j} \leq L_N$ are computed. In practice, for instance, formula (10) becomes

$$\frac{|f(x) - f_N(x;w)|}{|f(x)|} \leq \frac{R_{N,2j+1} - L_{N,2j}}{1 + L_{N,2j}} \prod_{k=1}^{N-1} \frac{R_{k,2j+1}}{1 + R_{k,2j+1}}, \qquad w \in [L_N, R_N]. \tag{23}$$

Here $R_{k,2j+1}$ equals in turn $\hat{U}_{2j+1}^{(2\ell)}$ or $\hat{D}_{2j+1}^{(2\ell+1)}$ depending on whether k is even ($k = 2\ell$) or odd ($k = 2\ell+1$). When replacing the odd-numbered approximants $R_{k,2j+1}$ in (23) by approximate values $\breve{R}_{k,2j+1}$ computed in rounded arithmetic, one should be careful not to violate the condition $\breve{R}_{k,2j+1} \geq R_k$.

When all $a_n < 0$, then $M_k = |L_k/(1 + L_k)|$. If, in addition, the sequences $\{a_n\}_{n\in\mathbb{N}}, \{b_n\}_{n\in\mathbb{N}}$ and $\{c_n\}_{n\in\mathbb{N}}$ from Lemma 5 decrease, then the lower bound for L_k given in part 2 of Lemma 1 can be used to obtain an upper bound for M_k, while the factor $(R_N - L_N)/(1 + L_N)$ can be bounded by (here we keep the suffix (w) because it varies between R_N and L_N)

$$\frac{R_N - L_N}{1 + L_N} \leq \frac{R_{N,j}\left(\frac{-1+\sqrt{4a_{N+1}+1}}{2}\right) - L_{N,j}(-\frac{1}{2})}{1 + L_{N,j}(-\frac{1}{2})}.$$

This results for (10) in

$$\frac{|f(x) - f_N(x;w)|}{|f(x)|} \leq \frac{R_{N,j}\left(\frac{-1+\sqrt{4a_{N+1}+1}}{2}\right) - L_{N,j}(-\frac{1}{2})}{1 + L_{N,j}(-\frac{1}{2})} \prod_{k=1}^{N-1} \left|\frac{L_{k,j}(-\frac{1}{2})}{1 + L_{k,j}(-\frac{1}{2})}\right|,$$

$$w \in [L_N, R_N]. \tag{24}$$

Similar bounds can be given when the sequences $\{a_n\}_{n\in\mathbb{N}}, \{b_n\}_{n\in\mathbb{N}}$, and $\{c_n\}_{n\in\mathbb{N}}$ are increasing.

The simplest choice for w, in case of a limit-periodic continued fraction with $\lim_{n\to\infty} a_n = \tilde{a} < \infty$, is given by

$$w = \frac{-1 + \sqrt{4\tilde{a} + 1}}{2}. \tag{25}$$

The question is, of course, whether this w belongs to $V_N = [L_N, R_N]$. For the continued fractions discussed in section 4, we indicate how this can be assured. It comes down to choosing the convergence sets E_n appropriately, by which we mean that the sequence of value sets $\{V_n\}_{n\in\mathbb{N}}$ has a nonempty intersection. When choosing the E_n too small, such that the sequence of value sets $\{V_n\}_{n\in\mathbb{N}}$ has an empty intersection, it may take some additional computations to obtain a suitable $w = w_N \in V_N$.

So in the ideal situation the sets V_n are small enough to bring the truncation error bound (10) down as much as possible, while at the same time the sets V_n are large enough to allow a nonempty intersection.

3.4. Fractions with positive and negative partial numerators. The condition that (2) has either only positive or only negative partial numerators a_n can be

relaxed for $n < N$, as long as it is satisfied from N on. In that case Lemma 2, which gives us a tail estimate, still remains valid, while Lemma 5 is adapted as follows.

LEMMA 7. [illegible] $\{E_n\}_{n\in\mathbb{N}}$ [illegible] $E_n = [b_n, c_n]$ [illegible] $b_n \geq -\frac{1}{4}$ [illegible] $0 \leq b_n c_n$ [illegible] $\{V_n\}_{n\in\mathbb{N}}$ [illegible] $V_n = [L_n, R_n]$ [illegible]

$$L_n = \sum_{k=1}^{\infty} \frac{\beta_{n+k}}{\left\lfloor 1 \right\rfloor}, \qquad R_n = \sum_{k=1}^{\infty} \frac{\gamma_{n+k}}{\left\lfloor 1 \right\rfloor},$$

[illegible] β_{n+k} [illegible] γ_{n+k} [illegible] k [illegible] $a_{n+1}\cdots a_{n+k-1} > 0$ [illegible] k [illegible] $a_{n+1}\cdots a_{n+k-1} < 0$ [illegible] $\beta_{n+k} = b_{n+k}$ [illegible] $\gamma_{n+k} = c_{n+k}$ [illegible] $\beta_{n+k} = c_{n+k}$ [illegible] $\gamma_{n+k} = b_{n+k}$ [illegible] The rule dictating whether β_{n+k} and γ_{n+k} equal either b_{n+k} or c_{n+k}, where $a_{n+k} \in [b_{n+k}, c_{n+k}]$, comes from the following considerations:

- Irrespective of the sign of a_{n+k} we find that the inequalities $b_{n+k} \leq a_{n+k} \leq c_{n+k}$ are flipped around by the division and result in

$$\frac{1}{1+c_{n+k}} \leq \frac{1}{1+a_{n+k}} \leq \frac{1}{1+b_{n+k}}.$$

- For every negative a_{n+k-1} we know that $|c_{n+k-1}| \leq |a_{n+k-1}| \leq |b_{n+k-1}|$ and hence the inequalities are flipped around once more to

$$\frac{c_{n+k-1}}{1+c_{n+k}} \geq \frac{a_{n+k-1}}{1+a_{n+k}} \geq \frac{b_{n+k-1}}{1+b_{n+k}}.$$

Hence the number of divisions plus the number of negative partial numerators encountered before one reaches a_{n+k} determines whether the largest and smallest fraction values are attained with a_{n+k} replaced by either b_{n+k} or c_{n+k}. □

When the restriction that (2) has either only positive or only negative partial numerators a_n holds from a certain $n \geq M$ on, one can also proceed as follows. A truncation error bound for $|f - f_N(w)|$ can be obtained from a truncation error bound for $|f^{(M)} - f^{(M)}_{N-M}(w)|$ by means of the relation [10, p. 420]

$$f - f_N(w) = \frac{(-1)^M a_1 \cdots a_M}{B_{M-1}^2 \left(h_M + f^{(M)}\right)\left(h_M + f^{(M)}_{N-M}(w)\right)} (f^{(M)} - f^{(M)}_{N-M}(w)). \tag{26}$$

Here the sequence $\{h_k\}_{k\in\mathbb{N}}$ is the so-called critical tail sequence given by

$$\begin{aligned} h_1 &= 1, \\ h_k &= 1 + \frac{a_k}{\left\lfloor 1 \right\rfloor} + \ldots + \frac{a_2}{\left\lfloor 1 \right\rfloor}, \qquad k \geq 2, \end{aligned}$$

and B_k is the kth denominator of (2), which can be computed by means of (12). From (26) we obtain the estimate

$$|f - f_N(w)| \leq \frac{|a_1 \cdots a_M|}{|B_{M-1}|^2 \min^2\left(|L_M + h_M|, |R_M + h_M|\right)} \left| f^{(M)} - f^{(M)}_{N-M}(w) \right|.$$

3.5. Rounding error. When implementing $f_N(w)$, we need to take into account that each basic operation $* \in \{+, -, \times, \div\}$ is being replaced by a machine operation $\circledast \in \{\oplus, \ominus, \otimes, \oslash\}$ and hence is subject to a relative error of at most $\frac{1}{2}$ `ulp`. Also each partial numerator a_n needs to be converted to a machine number $\breve{a}_n$, hence entailing a relative rounding error ϵ_n given by

$$\breve{a}_n = a_n(1 + \epsilon_n).$$

Here $|\epsilon_n|$ is mostly bounded by $\frac{1}{2}$ `ulp` if $a_n = a_n(x)$ is not a compound expression. Otherwise $|\epsilon_n|$ may be somewhat larger.

Without loss of generality, we assume that $w \in V_N$ is a machine number estimating t_N. So we need only take into account the distance of w to t_N, which is present in the truncation error via the parameters C_N and r_N determining V_N. We do not have to take into account an additional rounding error on w representing t_N.

When executing the backward recurrence, each computed $\breve{F}_n^{(N)}, n = N, \ldots, 1$, differs from the true $F_n^{(N)}$ by a rounding error $\epsilon_n^{(N)}$:

$$\begin{aligned}
\breve{F}_{N+1}^{(N)} &= w, \qquad \epsilon_{N+1}^{(N)} = 0, \\
\breve{F}_n^{(N)} &= \breve{a}_n \oslash (1 \oplus \breve{F}_{n+1}^{(N)}), \qquad n = N, \ldots, 1, \\
&= \frac{\breve{a}_n}{1 + \breve{F}_{n+1}^{(N)}}(1 + \delta_n) \\
&= F_n^{(N)}(1 + \epsilon_n^{(N)}), \\
\breve{F}_1^{(N)} &= F_1^{(N)}(1 + \epsilon_1^{(N)}).
\end{aligned}$$

Here δ_n is the relative rounding error introduced in step n of the algorithm. The main question is, How large is $|\epsilon_1^{(N)}|$? This question is answered in Lemma 8 and Theorem 3, the latter being a slight generalization of a result proved in [9] for which we omit the simple proof. Let us introduce the notation

$$\gamma_n^{(N)} = F_{n+1}^{(N)}/(1 + F_{n+1}^{(N)}), \qquad n = 1, \ldots, N.$$

LEMMA 8. $\{V_n\}_{n=1}^{\infty}$ (2) $F_{N+1}^{(N)} = w \in V_N$ $1 \le n \le N$

$$|\gamma_n^{(N)}| = \left| \frac{F_{n+1}^{(N)}}{1 + F_{n+1}^{(N)}} \right| \le M = \max_{n=1,\ldots,N} M_n.$$

THEOREM 3. $F_{N+1}^{(N)} = w$ $n = 1, \ldots, N$

$$\begin{aligned}
|\epsilon_n| &\le \epsilon \ \texttt{ulp}, \\
|\delta_n| &\le \delta \ \texttt{ulp}, \\
|\gamma_n^{(N)}| &\le M.
\end{aligned}$$

β t

$$\beta^{-t+1}\left(1 + M(1 + 2\epsilon + 2\delta)\frac{M^{N-1} - 1}{M - 1}\right) < 1.$$

$|\epsilon_1^{(N)}|$

$$|\epsilon_1^{(N)}| \leq \epsilon_R := \frac{1}{2}(1+2\epsilon+2\delta)\frac{M^N-1}{M-1}\ \texttt{ulp}. \tag{27}$$

If the partial numerators a_n of the continued fraction (2) satisfy $a_n \geq -\frac{1}{4}$, then we know that

- in case all $a_n > 0$ and $w \leq t_n$, the even approximants satisfy $f_{2k}(x;w) \leq f(x)$,
- in case all $a_n < 0$ and $w \leq t_n$, all approximants satisfy $f_n(x;w) \leq f$.

From Theorem 3 we then obtain for even $N = 2n$ with $F_1^{(N)} = f_{2n}(x;w)$ and $w \leq t_N$, or for general N with $F_1^{(N)} = f_N(x;w)$ and $w \leq t_N$,

$$\frac{|f_N(x;w) - \breve{F}_1^{(N)}|}{|f(x)|} = \left|\epsilon_1^{(N)}\right| \frac{|F_1^{(N)}|}{|f(x)|} \leq \epsilon_R.$$

Clearly, ϵ_R is a function of the precision because of its dependence on the `ulp`. When targeting a threshold for ϵ_R, a suitable precision in which to evaluate the continued fraction by means of the backward recurrence algorithm can be computed from this condition. In what follows this precision is called the working precision s, to distinguish it from the user-defined precision t from which the targeted threshold ϵ is usually obtained.

4. Savoring. In the following we distinguish a number of special cases for the partial numerators a_n:

- $\{a_{2n}\}_{n\in\mathbb{N}}$ increasing and $\{a_{2n+1}\}_{n\in\mathbb{N}}$ decreasing with

$$0 < a_n, \qquad 0 < \lim_{n\to\infty} a_{2n} = \tilde{a} = \lim_{n\to\infty} a_{2n+1};$$

- $\{a_n\}_{n\in\mathbb{N}}$ decreasing with $\lim_{n\to\infty} a_n = \tilde{a} \geq 0$;
- $\{a_n\}_{n\in\mathbb{N}}$ decreasing with

$$a_n < 0, \qquad \lim_{n\to\infty} a_n = \tilde{a} \geq -1/4;$$

- $\{a_n\}_{n\in\mathbb{N}}$ increasing with $\lim_{n\to\infty} a_n = \tilde{a} \leq 0$.

These cases cover almost all known limit-periodic continued fractions of the elementary functions and a large number of special functions.

4.1. The case $a_{2n} \nearrow \tilde{a}, a_{2n+1} \searrow \tilde{a}, \tilde{a} > 0$. Let the sequences of positive real numbers $\{a_{2n+1}\}_{n\in\mathbb{N}}$ and $\{a_{2n}\}_{n\in\mathbb{N}}$ be decreasing and increasing, respectively. Let for any $p, q \in \mathbb{N}$,

$$a_{2p+1} > a_{2q}.$$

If the a_n can be obtained from a single rounding, then we can choose the convergence sets $E_n = [b_n, c_n] = [\triangledown(a_n), \triangle(a_n)]$. If the a_n are more complicated, then we choose $[b_n, c_n]$ somewhat larger. In both cases the intervals $V_n = [L_n, R_n]$ with L_n and R_n given by (15) are the corresponding value sets, and the bounds (10) and (23) hold.

In addition, we now investigate the monotonicity properties of the sequences $\{L_n\}_{n\in\mathbb{N}}$ and $\{R_n\}_{n\in\mathbb{N}}$. To this end we reconsider the continued fractions $\hat{D}$ and $\hat{U}$ defined in (13) with tails $\hat{D}^{(n)}$ and $\hat{U}^{(n)}$.

Since the sequences $\{\triangledown(a_{2n})\}_{n\in\mathbb{N}}$ and $\{\triangle(a_{2n+1})\}_{n\in\mathbb{N}}$ are, respectively, increasing and decreasing as a consequence of the monotonicity of the rounding functions $\triangledown$

and $\triangle$, Lemma 3 guarantees that the even-numbered tails $\hat{U}^{(2n)} = R_{2n}$ and the odd-numbered tails $\hat{U}^{(2n+1)} = L_{2n+1}$ form a decreasing and increasing sequence, respectively, and that for any $p, q \in \mathbb{N}$, $\hat{U}^{(2q+1)} \leq \hat{U}^{(2p)}$. The same conclusion holds for the tails $\hat{D}^{(2n)} = L_{2n}$ and $\hat{D}^{(2n+1)} = R_{2n+1}$. If the interval $[b_n, c_n]$ is somewhat larger, the same conclusion holds if we can ensure that the sequences $\{b_{2n}\}_{n\in\mathbb{N}}$ and $\{c_{2n+1}\}_{n\in\mathbb{N}}$ are, respectively, increasing and decreasing.

Following the line of proof of Lemma 3, we can show in addition that

$$\begin{aligned} R_{2n+1} &\leq R_{2k}, \qquad k, n \in \mathbb{N}, \\ L_{2n+1} &\leq L_{2k}, \qquad k, n \in \mathbb{N}. \end{aligned}$$

Hence

$$\bigcap_{k=1}^{\infty} V_{2k-1} = L, \qquad \bigcap_{k=1}^{\infty} V_{2k} = R$$

with L and R given by (19). When choosing $E_n = [b_n, c_n]$ equal to

$$[b_{2k}, c_{2k}] = [a_{2k}, \tilde{a}], \qquad [b_{2k-1}, c_{2k-1}] = [\tilde{a}, a_{2k-1}], \qquad k \geq 1, \tag{28}$$

inequalities (10) and (23) remain valid, while, moreover,

$$L = L_{2n} = R_{2n-1} = R = \frac{1}{2}(-1 + \sqrt{4\tilde{a} + 1}).$$

Then, mathematically, a suitable $w \in V_N$ is easy to determine since for all N now $w = -\frac{1}{2} + \sqrt{\tilde{a} + \frac{1}{4}} \in V_N$. In practice, the above is applied with $\tilde{a}$ and a_{2k-1} in E_{2k-1} replaced by $\bigtriangledown(\tilde{a})$ and $\triangle(a_{2k-1})$, respectively, and $\tilde{a}$ and a_{2k} in E_{2k} replaced by $\triangle(\tilde{a})$ and $\bigtriangledown(a_{2k})$ or similar lower and upper bounds. Then L and R differ slightly, because in an implementation they are given by (19) with $b = \bigtriangledown(\tilde{a})$ and $c = \triangle(\tilde{a})$ or similarly. Choosing w alternately equal to L or R depending on whether N is odd or even is a valid choice (care must be taken during the actual computation of w that it is rounded in the appropriate direction, with "appropriate" meaning inside V_N).

Examples of elementary functions illustrating this case include the hyperbolic arcsine

$$\frac{\operatorname{asinh}(x)}{x\sqrt{1+x^2}} = \cfrac{1}{1} + \sum_{n=1}^{\infty} \cfrac{2\lfloor\frac{n+1}{2}\rfloor(2\lfloor\frac{n+1}{2}\rfloor - 1)x^2/(4n^2-1)}{1}, \qquad \lim_{n\to\infty} a_n(x) = \frac{x^2}{4},$$

the hyperbolic arctangent

$$x \operatorname{atanh}(x) = \cfrac{x^2/(1-x^2)}{1} + \sum_{n=1}^{\infty} \cfrac{2\lfloor\frac{n+1}{2}\rfloor(2\lfloor\frac{n+1}{2}\rfloor - 1)x^2/\left((4n^2-1)(1-x^2)\right)}{1},$$

$$\lim_{n\to\infty} a_n(x) = \frac{x^2}{4(1-x^2)},$$

and the natural logarithm

$$\frac{x}{\ln(x+1)} - 1 = \sum_{n=1}^{\infty} \cfrac{nx/(4n-2)}{1} + \cfrac{nx/(4n+2)}{1}, \qquad \lim_{n\to\infty} a_n(x) = x/4.$$

We discuss the natural logarithm in more detail in section 4.2.

Examples of special functions to which the technique applies are the hypergeometric functions

$$ {}_2F_1(a,1;c;x), \qquad a \neq 3/2, \qquad x<0, \qquad \tilde{a} = -x/4. $$

For $a = 3/2$, the technique described in section 4.3 applies.

4.2. Natural logarithm. A useful continued fraction for which the results of section 4.1 hold is

$$ f(x) = \frac{x}{\ln(x+1)} - 1 = \sum_{n=1}^{\infty} \frac{nx/(4n-2)\big\rfloor}{\lceil 1} + \frac{nx/(4n+2)\big\rfloor}{\lceil 1}, \qquad x+1 \geq 0. $$

Since $\ln(0) = -\infty$, $\ln(1) = 0$, and for $0 < x < 1$ the relation $\ln(x) = -\ln(1/x)$ holds, we have to consider only the case $x > 1$. For a given floating-point number

$$ x = +d_0 \,.\, d_1 \cdots d_{t-1} \times \beta^{e_x} = +m_x \times \beta^{e_x}, \qquad d_0 \neq 0,\ 0 \leq d_i \leq \beta - 1,\ i = 0, \ldots, t-1, $$

as operand, and a choosen integer $\ell > 0$, we construct the reduced operand $\tilde{x}$,

$$ \begin{aligned} j_x &= \lfloor \log_{\beta^{1/\ell}} m_x, \rfloor, \\ \tilde{x} &= +d_0 \,.\, d_1 \cdots d_{t-1} \times \beta^{-j_x/\ell} - 1, \end{aligned} $$

which satisfies

$$ \ln(x) = \frac{\tilde{x}}{1+\ln(\tilde{x})} + \left(e_x + \frac{j_x}{\ell} \right) \ln(\beta). \tag{29} $$

For $\beta = 2$ and $\ell = 8$, the range of the reduced argument $\tilde{x}$ is then $[1, 2^{1/8}]$.

With $t = 53$ in (1) and $\epsilon_T = 2^{-52} = 1\mathtt{ulp} \approx 2.22 \times 10^{-16}$, we obtain from (23) that $f_N(w)$ with $N = 9$, $w = \frac{1}{2}(-1 + \sqrt{x+1})$, and $2j+1 = 3$ satisfies

$$ \frac{|f(\sqrt[8]{2}-1) - f_9(w)|}{|f(\sqrt[8]{2}-1)|} = 7.98 \times 10^{-17} \leq \frac{R_{9,3} - L_{9,2}}{1 + L_{9,2}} \prod_{k=1}^{8} \frac{R_{k,3}}{1+R_{k,3}} \leq 1.98 \times 10^{-16} < \epsilon_T. $$

This compares nicely to the targeted complexity of 25 operations for double precision. The backward algorithm uses $2N = 18$ operations for the computation of $f_9(w)$, and the functional relationship (29) employs another 6. In the next section the comparison with the state-of-the-art double precision algorithms is even more favorable. For the luxury of having a multiprecision version we have to pay the price of obtaining N from (10) or (22) though, while in a fixed precision implementation N is fixed a priori. Of course we do not have to add this additional work to the complexity count when comparing the algorithm's complexity to that of a fixed precision algorithm.

Because of the specific behavior of the sequences $\{R_n\}_{n\in\mathbb{N}}$ and $\{L_n\}_{n\in\mathbb{N}}$ when E_n is given by (28), we have with K even in (22) that $\overline{R} = R_K$ and $\overline{L} = L$. With $K = 4$ formula (22) also predicts $N = 9$. With $K = 2$ we obtain a slight overestimate of N, namely $N = 10$ instead of $N = 9$:

$$ \frac{|f(\sqrt[8]{2}-1) - f_{10}(w)|}{|f(\sqrt[8]{2}-1)|} \leq \left(\frac{R_{2,3} - L}{1+L} \right) M_1 \left(\frac{R_{2,3}}{1+R_{2,3}} \right)^4 M_2^4 \leq 1.06 \times 10^{-17} < \epsilon_T. $$

When comparing these results to the classical results obtained for $w = 0$ using (8) (where we approximate $f(\sqrt[8]{2}-1)$ in the denominator of the relative error by $f_K(x;0)$ with K even), we see that

$$\frac{|f(\sqrt[8]{2}-1) - f_{11}(0)|}{|f(\sqrt[8]{2}-1)|} = 1.89\times10^{-17} \le \frac{2a_1}{f_K(x;0)} \prod_{k=2}^{11} \frac{\sqrt{1+4a_k}-1}{\sqrt{1+4a_k}+1} = 3.77\times10^{-17} < \epsilon_T.$$

This implies a gain of about 20% in complexity: $N = 9$ is predicted by (22) and (23) while $N = 11$ is predicted by the Gragg–Warner bound (8). From the multitude of experiments we have conducted we can confirm that this gain is typical when comparing the new technique for hardware precisions. In addition, the precision with which w needs to be computed is determined by the width of V_N, which is at least as wide as $R_{N,2j} - L_{N,2j+1}$. When the precision t is increased while maintaining the rather wide sets E_n specified in (28), often w need not be computed to full precision.

Now let us consider $\epsilon_T = 2^{-511} \approx 1.50 \times 10^{-154}$ and slightly refine the sets E_n. Restricting the variation in the partial numerators to that of the double precision rounding of $a_n(x)$ amounts to choosing E_n like $E_n = [a_n(1-\delta), a_n(1+\delta)]$ with $|\delta| \le 2^{-52}$. We find that for the same argument x and with $N = 84$ and $2j+1 = 11$,

$$\frac{|f(\sqrt[8]{2}-1) - f_{84}(w)|}{|f(\sqrt[8]{2}-1)|} \le 5.82 \times 10^{-156} < \epsilon_T, \qquad w \in V_{84}.$$

Here all factors in the upper bound (23) are computed only in double precision. At the same time, the Gragg–Warner bound predicts $N = 94$. Hence the newly developed technique offers a gain of 20 high precision computations ($\Delta N = 94 - 84$). The practical problem here is to find $w_N \in V_N$. A possible choice is $w_{84} = L_{84,11}$ costing 22 double-precision basic operations ($2j+1 = 11$). This choice for w is valid only if $L_N \le L_{N,2j+1}$ belongs to V_N, meaning that $L_{N,2j+1} \le R_N$.

4.3. The case $a_n \searrow \tilde{a} \ge 0$. Let each partial numerator a_n satisfy $\tilde{a} \le a_n$ where the sequence $\{a_n\}_{n\in\mathbb{N}}$ is a decreasing sequence of positive numbers and $0 \le \tilde{a} = \lim_{n\to\infty} a_n$. So all a_n are strictly positive. For $E_n = [\triangledown(a_n), \triangle(a_n)]$ the corresponding value sets are $V_n = [L_n, R_n]$ with L_n and R_n given by (15). For these V_n the bounds (10) and (23) hold. To guarantee that (25) is in $[L_N, R_N]$, we consider slightly larger convergence sets E_n.

For the convergence sets $E_n = [\tilde{a}, a_n]$ the value sets $V_n = [L_n, R_n]$ are bounded by

$$L_n = \cfrac{\tilde{a}}{\left\lceil 1\right\rfloor} + \cfrac{a_{n+2}}{\left\lceil 1\right\rfloor} + \cfrac{\tilde{a}}{\left\lceil 1\right\rfloor} + \cfrac{a_{n+4}}{\left\lceil 1\right\rfloor} + \cdots,$$
$$R_n = \cfrac{a_{n+1}}{\left\lceil 1\right\rfloor} + \cfrac{\tilde{a}}{\left\lceil 1\right\rfloor} + \cfrac{a_{n+3}}{\left\lceil 1\right\rfloor} + \cfrac{\tilde{a}}{\left\lceil 1\right\rfloor} + \cdots.$$

Following the line of proof of Lemma 3 we find that the sequence $\{R_n\}_{n\in\mathbb{N}}$ is decreasing and that $\{L_n\}_{n\in\mathbb{N}}$ is increasing. Now

$$\bigcap_{k\in\mathbb{N}} V_k = [L, R]$$

with $L = R = (-1 + \sqrt{4\tilde{a}+1})/2$. Hence we can choose for all N the tail estimate $w = (-1 + \sqrt{4\tilde{a}+1})/2$. In practice this is applied to $E_n = [\triangledown(\tilde{a}), \triangle(a_n)]$, replacing

in L_n, R_n, and (22) every occurrence of $\tilde{a}$ by $\bigtriangledown(\tilde{a})$ and every occurrence of a_n by $\bigtriangleup(a_n)$. Use of these roundings makes $L < R$ and, consequently, all $w \in [L, R]$ a valid choice.

With $\tilde{a} = 0$, we have $E_k = [0, a_k], R_k = a_{k+1}$, and $L_k = 0$. The truncation error bound simplifies to

$$\frac{|f(x) - f_N(x; w)|}{|f(x)|} \leq a_{N+1} \prod_{k=1}^{N-1} \frac{a_{k+1}}{1 + a_{k+1}}. \tag{30}$$

Here $w = 0$ can be used, which is a more classical choice.

Examples taken from the class of functions satisfying the conditions imposed in this section involve the arccosine function

$$\frac{x\ \mathrm{acos}(x)}{\sqrt{1-x^2}} = \left\lfloor \frac{1}{1} \right\rfloor + \sum_{n=1}^{\infty} \left\lfloor \frac{n^2(1-x^2)/\left((2n-1)(2n+1)x^2\right)}{1} \right\rfloor, \qquad \lim_{n\to\infty} a_n(x) = \frac{(1-x^2)}{4x^2},$$

the arctangent function

$$x\ \arctan(x) = \left\lfloor \frac{x^2}{1} \right\rfloor + \sum_{n=1}^{\infty} \left\lfloor \frac{n^2x^2/(4n^2-1)}{1} \right\rfloor, \qquad \lim_{n\to\infty} a_n(x) = \frac{x^2}{4},$$

and the arccotangent function

$$\frac{\mathrm{acot}(x)}{x} = \left\lfloor \frac{x^{-2}}{1} \right\rfloor + \sum_{n=1}^{\infty} \left\lfloor \frac{n^2x^{-2}/(4n^2-1)}{1} \right\rfloor, \qquad \lim_{n\to\infty} a_n(x) = \frac{x^{-2}}{4}.$$

The arctangent is discussed in detail in section 4.4. Examples where (30) applies include the hyperbolic tangent function

$$x\ \tanh(x) = \left\lfloor \frac{x^2}{1} \right\rfloor + \sum_{n=1}^{\infty} \left\lfloor \frac{x^2/(4n^2-1)}{1} \right\rfloor$$

and the exponential function

$$\frac{2x}{\exp(x)-1} = 2 - x + \left\lfloor \frac{x^2/6}{1} \right\rfloor + \sum_{n=2}^{\infty} \left\lfloor \frac{x^2/\left(4(4n^2-1)\right)}{1} \right\rfloor.$$

Also, several special functions belong to this class, including the confluent hypergeometric functions ${}_1F_1(1; c; x)$.

4.4. Arctangent function. The conditions imposed in section 4.3 hold for the following continued fraction representation of the arctangent function:

$$\arctan(x) = \left\lfloor \frac{x}{1} \right\rfloor + \sum_{n=1}^{\infty} \left\lfloor \frac{n^2x^2/(4n^2-1)}{1} \right\rfloor, \qquad \lim_{n\to\infty} a_n(x) = \frac{x^2}{4}.$$

Since $\arctan(-x) = -\arctan(x)$, we need to focus on only positive arguments. Moreover, by using the fact that

$$2-\sqrt{3} < x \le 1 \Rightarrow \left|\frac{x\sqrt{3}-1}{x+\sqrt{3}}\right| \le 2-\sqrt{3}, \qquad \arctan(x) = \arctan\left(\frac{x\sqrt{3}-1}{x+\sqrt{3}}\right) + \frac{\pi}{6},$$

$$1 < x \le 2+\sqrt{3} \Rightarrow \left|\frac{\sqrt{3}-x}{x\sqrt{3}+1}\right| \le 2-\sqrt{3}, \qquad \arctan(x) = -\arctan\left(\frac{\sqrt{3}-x}{x\sqrt{3}+1}\right) + \frac{\pi}{3},$$

$$2+\sqrt{3} < x \Rightarrow 1/x < 2-\sqrt{3}, \qquad \arctan(x) = -\arctan(1/x) + \frac{\pi}{2},$$

one can reduce the argument of $\arctan(x)$ to the interval $[0, 2-\sqrt{3}]$. For $x \in [0, 2-\sqrt{3}]$ the value $\arctan(x) \in [0, \pi/12]$. The sequence of partial numerators is a decreasing positive sequence from the very first partial numerator on.

With $t = 53$ in (1) and $\epsilon_T = 2^{-52} = 1\mathtt{ulp}$, we obtain from (23) that $f_N(w)$ with $N = 8$, $w = \frac{1}{2}(-1+\sqrt{x^2+1})$, and $2j+1 = 3$ satisfies

(31)
$$\frac{|f(2-\sqrt{3}) - f_8(w)|}{|f(2-\sqrt{3})|} = 4.74 \times 10^{-17} \le \frac{R_{8,3}-L_{8,2}}{1+L_{8,2}} \prod_{k=1}^{7} \frac{R_{k,3}}{1+R_{k,3}} \le 5.26 \times 10^{-17} < \epsilon_T.$$

When using (22) with $K = 3$ we find $N = 9$. With $K = 4$ we obtain again $N = 8$. The upper bound for the truncation error is then estimated by

$$\frac{|f(2-\sqrt{3}) - f_8(w)|}{|f(2-\sqrt{3})|} \le \left(\frac{R_{8,3}-L_{8,2}}{1+L_{8,2}}\right) M_1\ M_2\ M_3\ M_4^4 < \epsilon_T.$$

Comparing this to the Gragg–Warner bound for the classical approximant $f_N(0)$, we find

(32)
$$\frac{|f(2-\sqrt{3}) - f_9(0)|}{|f(2-\sqrt{3})|} = 2.18 \times 10^{-16} \le \epsilon_T,$$

$$\frac{|f(2-\sqrt{3}) - f_{11}(0)|}{|f(2-\sqrt{3})|} \le \frac{2a_1}{f_K(0)} \prod_{k=2}^{11} \frac{\sqrt{1+4a_k}-1}{\sqrt{1+4a_k}+1} = 7.56 \times 10^{-18} < \epsilon_T.$$

Hence the new technique delivers $N = 8$ while the traditional Gragg–Warner bound estimates $N = 11$, which is an overestimate of N in (32) by 2. Again the use of a nonzero tail estimator in (31) together with the newly developed bounds offers a clear advantage.

Choosing $t = 113$ (as in the quadruple precision supported by Sun) and $\epsilon_T = 2^{-112} \approx 1.93 \times 10^{-34}$, we find with $N = 18, w = \frac{1}{2}(-1+\sqrt{x^2+1})$, and $2j+1 = 3$

$$\frac{|f(2-\sqrt{3}) - f_{18}(w)|}{|f(2-\sqrt{3})|} = 5.65 \times 10^{-39} \le \frac{R_{18,3}-L_{18,2}}{1+L_{18,2}} \prod_{k=1}^{17} \frac{R_{k,3}}{1+R_{k,3}} \le 3.35 \times 10^{-35} < \epsilon_T.$$

The traditional Gragg–Warner bound for use with $w = 0$ delivers $N = 21$ while

$$\frac{|f(2-\sqrt{3}) - f_{20}(0)|}{|f(2-\sqrt{3})|} = 9.35 \times 10^{-36}.$$

Again, this is a clear advantage of a nonzero choice for w over the standard $w = 0$.

4.5. The case $a_n \searrow \tilde{a} \geq -\frac{1}{4}$. For simplicity we take all $a_n < 0$. When this is only the case from an index $n = M$ on, then the technique described in section 3.4 can be used to estimate the truncation error from the beginning of the fraction, given the truncation error from a_M on. Since all $L_n \geq -\frac{1}{2}$, the error bound (10) remains valid.

We choose $E_n = [a_{n+1}, a_n]$ and compute $V_n = [L_n, R_n]$ with L_n and R_n given by (16). Apparently $L_n = t_{n+1}$ and $R_n = t_n$. The sequences $\{R_n\}_{n\in\mathbb{N}}$ and $\{L_n\}_{n\in\mathbb{N}}$ are decreasing with

$$\lim_{n\to\infty} R_n = \frac{-1+\sqrt{4\tilde{a}+1}}{2} = \lim_{n\to\infty} L_n.$$

Combining part 2 of Lemma 1 and part 3 of Lemma 2 provides the computable bounds

$$L_{n,j}\left(\frac{-1+\sqrt{4\tilde{a}+1}}{2}\right) \leq L_n \leq R_n \leq R_{n,j}\left(\frac{-1+\sqrt{4a_{n+1}+1}}{2}\right), \qquad j \geq 1.$$

Under the condition that $L_N \leq R_{N,j}(\frac{1}{2}(-1+\sqrt{4\tilde{a}+1}))$, a valid choice for $w_N \in V_N$ is given by $w_N = R_{N,j}(\frac{1}{2}(-1+\sqrt{4\tilde{a}+1}))$. Computational remarks similar to those in sections 3.3 and 4.1 apply, concerning the effect of rounding errors on the computed $L_{n,j}, R_{n,j}$, and w_N.

Special functions enjoying a limit-periodic continued fraction with $a_n \geq -\frac{1}{4}$ and $\tilde{a} = -\frac{1}{4}$ are

(33)

$$\mathrm{E}_m(x) = \cfrac{\exp(-x)/(x+m)}{1} + \sum_{n=2}^{\infty} \cfrac{\frac{-n(m+n-2)}{(x+m+2(n-1))(x+m+2(n-2))}}{1}, \quad m \neq 1, x \neq 0,$$

$$\operatorname{erfc}(x) = \cfrac{\frac{\exp(-x^2)}{2\sqrt{\pi}x(2x^2+1)}}{1} + \sum_{n=2}^{\infty} \cfrac{\frac{-2n(2n-1)}{(2x^2+1+4n)(2x^2+1+4(n-1))}}{1}, \quad x \neq 0.$$

As an illustration of the technique we compute the function $f(x)$, defined by the first tail of (33), up to 80 bits accuracy, in other words, with $\epsilon_T = 2^{-79} \approx 1.65 \times 10^{-24}$. This function has only negative partial numerators. With E_n and V_n as given above and $x = 2$, the bound (10) is less than ϵ_T for $N \geq 59$. For $j = 12$ we obtain in addition that

$$t_{N+1} = L_N < L_{N,j}\left(\frac{-1+\sqrt{4a_{N+2}+1}}{2}\right) < R_{N,j}\left(-\frac{1}{2}\right) < R_N = t_N$$

and hence that all w satisfying

$$L_{N,j}\left(\frac{-1+\sqrt{4a_{N+2}+1}}{2}\right) < -3.7626 \times 10^{-1} \leq w \leq -3.7527 \times 10^{-1} < R_{N,j}\left(-\frac{1}{2}\right)$$

are valid choices for the approximation of $f(x)$ by $f_N(x; w)$, since they are guaranteed to belong to V_N.

4.6. The case $a_n \nearrow \tilde{a} \leq 0$. When the partial numerators a_n are negative and increasing with $\lim_{n\to\mathbb{N}} a_n = \tilde{a}$, we can choose $E_n = [a_n, \tilde{a}]$. The value sets V_n are then given by $V_n = [L_n, R_n] = [t_n, \frac{-1+\sqrt{4\tilde{a}+1}}{2}]$, where it can be proved as in Lemma

4 that the sequence $\{t_n\}_{n\in\mathbb{N}}$ is increasing. Following the line of proof of part 2 of Lemma 1, we find that

$$\frac{-1+\sqrt{4a_{n+1}+1}}{2} \le L_n.$$

Hence the truncation error can be bounded by

$$|f(x) - f_N(x;w)| \le \frac{1-\sqrt{4a_{N+1}+1}}{1+\sqrt{4a_{N+1}+1}} \prod_{k=1}^{N-1} \frac{1-\sqrt{4a_{k+1}+1}}{1+\sqrt{4a_{k+1}+1}}, \qquad w \in V_N.$$

When $\tilde{a} = 0$ this is very similar to the Gragg–Warner bound on the real line ($\phi = \arg(x) = 0$). Note that $w = 0$ is a valid choice if $\tilde{a} = 0$. This truncation error bound applies, for instance, to the function $f(x)$ given by

$$f(x) = \frac{x}{\tan(x)} - 1 = \sum_{n=1}^{\infty} \cfrac{-x^2/(4n^2-1)}{1}.$$

4.7. Conclusion. The truncation error bounds obtained here for $f_N(x;w)$ are more general than the ones given in [8] or [2] which contain more stringent conditions on the a_n that are not as easily satisfied for all n, and the ones found in [10] where $C_N = \tilde{w}$ with $\tilde{w}$ given by (7) is recommended for (9). Other truncation error bounds that can be found in the literature [7, 6] hold mainly for $w = 0$.

When classifying all these bounds with respect to sharpness, we have to distinguish between bounds for the unmodified approximant $f_N(x;0)$ and bounds for the modified approximant $f_N(x;w)$. As can be expected, the a posteriori error bounds, which take advantage of the information contained in continued fraction approximants computed for smaller values of N, are the most accurate truncation error bounds for $f_N(x;0)$. The newly developed a priori error bound is to the modified approximant $f_N(x;w)$ what the Gragg–Warner bound is to the unmodified approximant $f_N(x;0)$. Both are of comparable quality, which is precisely our goal.

An analysis of the complexity of the proposed implementation (counting additions/subtractions and multiplications/divisions) illustrates that the multiprecision continued fraction method presented here even compares well to the state-of-the-art fixed precision techniques which are in use. When choosing the radix $\beta = 2$ and the precision $t = 53$ (standard IEEE 754 double precision), the proposed continued fraction model allows one to evaluate the elementary functions in about 20 to 25 operations, including the computation of the square root modification $w = \tilde{w}$, which compares favorably to the current double-precision implementations. Moreover, the proposed technique is generic in the sense that it can be used for any user-definable precision.

Acknowledgments. Thanks are due to Stefan Becuwe and Johan Vervloet for implementing a lot of our ideas in either Maple or C++. The insight gained from the numerical illustrations guided us in the selection of the material for this paper and will assist us with the implementation of a reliable special function library in the future.

FREQUENCY DOMAIN OPTICAL TOMOGRAPHY BASED ON THE EQUATION OF RADIATIVE TRANSFER*

KUI REN†, GUILLAUME BAL†, AND ANDREAS H. HIELSCHER‡

Abstract. Optical tomography consists of reconstructing the spatial distribution of absorption and scattering properties of a medium from surface measurements of transmitted light intensities. Mathematically, this problem amounts to parameter identification for the equation of radiative transfer (ERT) with diffusion-type boundary measurements. Because they are posed in the phase-space, radiative transfer equations are quite challenging to solve computationally. Most past works have considered the steady-state ERT or the diffusion approximation of the ERT. In both cases, substantial cross-talk has been observed in the reconstruction of the absorption and scattering properties of inclusions. In this paper, we present an optical tomographic reconstruction algorithm based on the frequency-domain ERT. The inverse problem is formulated as a regularized least-squares minimization problem, in which the mismatch between forward model predictions and measurements is minimized. The ERT is discretized by using a discrete ordinates method for the directional variables and a finite volume method for the spatial variables. A limited-memory quasi-Newton algorithm is used to minimize the least-squares functional. Numerical simulations with synthetic data show that the cross-talk between the two optical parameters is significantly reduced in reconstructions based on frequency-domain data as compared to those based on steady-state data.

1. Introduction.

The inverse problem related to the equation of radiative transfer (ERT) has long been of interest in many fields of applied physics and mathematics. In this problem, one attempts to determine the spatial distribution of parameters (e.g., the spatial distribution of absorption and scattering coefficients) inside a medium from either transmission or reflectance data collected by illuminating the medium from many different directions. Applications include, for instance, astronomy [61], nuclear science [42, 43], and atmospheric science [12]; see the review [50]. Recent advances in this field have been fueled by an increased interest in medical applications. By performing optical measurements on the surface of the skin, optical tomographic techniques attempt to reconstruct the spatial distribution of absorption and scattering coefficients inside the body. These parameters can then be used for many diagnostic purposes [13].

Mathematically, optical tomography reduces to parameter identification problems (inverse problems) for the ERT, also referred to as the linear Boltzmann equation or the transport equation. Most early studies in the field deal with plane-parallel ge-

ometry [20, 24]. Inversion procedures were also developed in many more general yet still constrained geometries; see, for instance, [3, 42, 43, 61] and the review papers [49, 50]. Because of their geometrical specificities, most of these works do not directly apply to biomedical applications. In the mid-1990s several groups started developing schemes and algorithms that overcame these problems in the framework of the diffusion approximation to the ERT; see, for instance, [4, 34, 57, 63]. Many theoretical and experimental studies have shown that the diffusion approximation was valid only in specific contexts—for instance, when the scattering coefficient is sufficiently large and the absorption coefficient sufficiently small [16, 17, 23, 31]. While this is often the case in biomedical applications there remain many important applications, for which reconstructions based on the ERT are needed. Some examples include brain imaging, where the presence of low-absorbing and low-scattering cerebrospinal fluid leads to nondiffusive light propagation; imaging of joints, where clear synovial fluid has the same effects as cerebrospinal fluid in the brain; and small animal imaging, where small object dimensions (1–2 cm in diameter) invalidate the classical diffusion approximation [30, 32]; see, however, [6, 8] for ways to generalize the diffusion equation in certain situations.

Only quite recently have studies emerged that describe ERT-based reconstruction codes for use in biomedical optical tomography. First, a transport-backtransport method, a nonlinear inversion method, applied to the two-dimensional time-dependent equation of radiative transfer was reported in [18]. New algorithms were developed and experimentally tested for two- and three-dimensional cases using a time-independent ERT in [38, 39, 40, 41]. While these works, which address real-life three-dimensional problems, are an important step towards practical applications, they still suffer from considerable cross-talk between absorption and scattering reconstructions. What we mean by cross-talk is that purely scattering (or purely absorbing) inclusions are often reconstructed with unphysical absorption (or scattering) properties. This behavior is well-understood from the theoretical viewpoint: Different optical distributions inside the medium can lead to the same measurements collected at the surface of the medium [5, 33]. To avoid such cross-talk, which may lead to wrong diagnostics, we need different data. An experimental technique increasingly employed in recent years to obtain additional information is to use frequency domain measurements. In this case the source intensity is modulated (typically between 100–1000 MHz), leading to the propagation of so-called photon density waves. Since frequency domain measurements provide information about both the phase and the intensity of the waves (and not only the intensity as in steady-state measurements), it is expected that the frequency-domain techniques will allow for better separation of absorption and scattering effects [5, 48]. Numerical reconstructions based on the frequency-domain ERT, however, have not yet been developed in the literature. This is the major motivation for the present work.

We will propose in the following sections a numerical procedure that solves the frequency-domain optical tomography problem with angularly averaged measurement. The numerical procedure involves multiple techniques such as the finite volume method for transport discretization, limited memory BFGS for minimization, the adjoint state method for computing Fréchet derivatives, the matrix-free approach for evaluating matrix vector products, and the L-curve method for selecting regularization parameters. The combination of those techniques allows us to perform numerical reconstructions in geometrical settings that are of practical importance.

The remainder of the paper is organized as follows. In section 2 we formulate the inverse problem in frequency-domain optical tomography as a classical regularized

least-squares problem and describe the adjoint method for the computation of the gradient of the least-squares functional. In section 3 we present the details on the discretization of the forward and backward problems, which is based on using a discrete ordinates methods for the directional variables and a finite volume method for the spatial variables. The implementation of the minimization procedure, based on a quasi-Newton optimization algorithm, and the choice of the regularization parameter are described in section 4. Several numerical simulations illustrate the performance of the code in section 5. Reconstructions based on synthetic data indeed show a significant reduction of the cross-talk mentioned above when frequency-domain data are used. Concluding remarks are finally offered in section 6.

2. Problem formulation. We now formulate the optical tomography problem. Let $\mathcal{D} \subset \mathbb{R}^n$ be our domain of interest, with sufficiently regular boundary $\partial\mathcal{D}$. Then the frequency-domain equation of radiative transfer that describes the photon density in the phase space, i.e., as a function of position $\mathbf{x} \in \mathcal{D}$ and direction $\boldsymbol{\theta} \in S^{n-1}$ (unit sphere of $\mathbb{R}^n$) is given by [4]

$$\begin{aligned} \mathcal{T}u \equiv \Big(\frac{i\omega}{v} + \boldsymbol{\theta}\cdot\nabla + \sigma_a(\mathbf{x})\Big)u(\mathbf{x},\boldsymbol{\theta}) + Q(u)(\mathbf{x},\boldsymbol{\theta}) = 0 \qquad & \text{in } \mathcal{D}\times S^{n-1}, \\ u(\mathbf{x},\boldsymbol{\theta}) = f(\mathbf{x},\boldsymbol{\theta}) \qquad & \text{on } \Gamma_-, \end{aligned} \tag{2.1}$$

where $i = \sqrt{-1}$, $n = 2, 3$ is the space dimension, $v \in \mathbb{R}^+$ is the speed of light in the medium, and ω is the modulation frequency of the boundary source $f(\mathbf{x},\boldsymbol{\theta})$. The nonnegative function $\sigma_a(\mathbf{x}) \in L^\infty(\mathcal{D})$ is the absorption coefficient. The unknown quantity, $u(\mathbf{x},\boldsymbol{\theta})$, is the radiant power per unit solid angle per unit area perpendicular to the direction of propagation at $\mathbf{x}$ in the direction $\boldsymbol{\theta}$. Note that $u(\mathbf{x},\boldsymbol{\theta})$ depends also on ω although, for simplicity, we do not write this dependency explicitly. The boundary sets $\Gamma_\pm$ are defined as

$$\Gamma_\pm = \{(\mathbf{x},\boldsymbol{\theta}) \in \partial\mathcal{D}\times S^{n-1} \text{ s.t. } \pm\boldsymbol{\theta}\cdot\boldsymbol{\nu}(\mathbf{x}) > 0\},$$

with $\boldsymbol{\nu}(\mathbf{x})$ the outward unit normal to the domain at $\mathbf{x} \in \partial\mathcal{D}$. The scattering operator Q is defined as

$$Q(u)(\mathbf{x},\boldsymbol{\theta}) = \sigma_s(\mathbf{x})\Big(u(\mathbf{x},\boldsymbol{\theta}) - \int_{S^{n-1}} k(\boldsymbol{\theta}\cdot\boldsymbol{\theta}')u(\mathbf{x},\boldsymbol{\theta}')d\mu(\boldsymbol{\theta}')\Big). \tag{2.2}$$

Here, $\sigma_s(\mathbf{x}) \in L^\infty(\mathcal{D})$ is the scattering coefficient and $d\mu$ is the surface measure on S^{n-1} normalized so that $\int_{S^{n-1}} d\mu(\boldsymbol{\theta}) = 1$. The "collision" kernel $k(\boldsymbol{\theta}\cdot\boldsymbol{\theta}')$, which describes the probability that photons traveling in direction $\boldsymbol{\theta}'$ scatter into direction $\boldsymbol{\theta}$, is a positive function independent of $\mathbf{x}$ and satisfies the normalization condition:

$$\int_{S^{n-1}} k(\boldsymbol{\theta}\cdot\boldsymbol{\theta}')d\mu(\boldsymbol{\theta}') = 1. \tag{2.3}$$

The scattering kernel for light propagation in tissues is highly peaked forward and is chosen as the Henyey–Greenstein phase function [29, 62]

$$k(\boldsymbol{\theta}\cdot\boldsymbol{\theta}') = C\frac{1-g^2}{(1+g^2-2g\cos\phi)^{3/2}}, \tag{2.4}$$

where ϕ is the angle between $\boldsymbol{\theta}$ and $\boldsymbol{\theta}'$, i.e., $\boldsymbol{\theta}\cdot\boldsymbol{\theta}' = \cos\phi$, and where $g \in [0,1]$ is the anisotropy factor, which measures how peaked forward the phase function is.

The larger g is, the more forward the scattering. The anisotropy factor is often used to define the so-called effective scattering coefficient through $\sigma_s' = (1-g)\sigma_s$. C is a normalization constant such that (2.3) hold. We mention that scattering kernels other than (2.4) have also been used in some situations [36] and that simplified (Fokker–Planck) models can also be used to analyze highly peaked scattering in biological tissues [37].

The optical tomography problem thus consists of reconstructing $\sigma_a(\mathbf{x})$ and $\sigma_s(\mathbf{x})$ in (2.1) from boundary current measurements; see (2.6) below. Our objective in this work is to present a numerical scheme that performs the reconstruction.

2.1. Forward problem. The absorption and scattering coefficients σ_a and σ_s cannot take negative values and have to be bounded. We thus introduce the following parameter space $\mathcal{Q}$:

$$\mathcal{Q} := \{(\sigma_a, \sigma_s) \ : \ \sigma_a \geq 0, \ \sigma_s \geq 0, \ \text{ and } (\sigma_a, \sigma_s) \in L^\infty(\mathcal{D}) \times L^\infty(\mathcal{D})\}.$$

We also introduce the functional spaces [2, 16]:

$$L^2_{\boldsymbol{\theta}\cdot\nu}(\Gamma_\pm) := \Big\{u(\mathbf{x},\boldsymbol{\theta}) : \int_{\Gamma_\pm} |u(\mathbf{x},\boldsymbol{\theta})|^2 |\boldsymbol{\theta}\cdot\nu(\mathbf{x})| d\sigma(\mathbf{x}) d\mu(\boldsymbol{\theta}) < +\infty\Big\},$$
$$\mathcal{W}^2(\mathcal{D}\times S^{n-1}) := \big\{u(\mathbf{x},\boldsymbol{\theta}) : u \in L^2(\mathcal{D}\times S^{n-1}) \text{ and } \boldsymbol{\theta}\cdot\nabla u \in L^2(\mathcal{D}\times S^{n-1})\big\}.$$

Adapting well-known results [2, 16] with complex-valued absorption coefficient $\sigma_a + \frac{i\omega}{v}$ in $L^\infty(\mathcal{D})$, we have the following statement about the forward problem.

PROPOSITION 2.1. [illegible] $(\sigma_a, \sigma_s) \in \mathcal{Q}$ [illegible] $\omega < +\infty$ [illegible] $f \in L^2_{\boldsymbol{\theta}\cdot\nu}(\Gamma_-)$ [illegible] (2.1) [illegible] $u(\mathbf{x},\boldsymbol{\theta}) \in \mathcal{W}^2(\mathcal{D}\times S^{n-1})$

We can then define the following [illegible] operator (as well as its adjoint) [14, 51]:

$$\Lambda : \begin{array}{l} f \longmapsto u|_{\Gamma_+} \\ L^2_{\boldsymbol{\theta}\cdot\nu}(\Gamma_-) \longmapsto L^2_{\boldsymbol{\theta}\cdot\nu}(\Gamma_+). \end{array} \tag{2.5}$$

The albedo operator Λ maps the incoming flux on the boundary into the outgoing flux and is a functional of the optical parameters σ_a and σ_s.

A major difficulty in optical tomography comes from the fact that in practice only outgoing currents, which are angular averages of the outgoing flux and are similar to diffusion-type measurements, are available. This prevents us from using classical uniqueness and stability results in inverse transport theory [14]. In fact, the inverse problem we solve in this paper is very similar to the diffusion-based inverse problem [4], on which many more theoretical results exist. To date, we do not know of any theoretical result on the reconstruction of optical properties from outgoing currents for arbitrary geometries. This makes the development of numerical tools all the more important.

To be consistent with existing measurement technologies, we define the following "measurement operator":

$$\begin{aligned} \mathcal{G}u|_{\Gamma_+} &:= \int_{S^{n-1}_+} \boldsymbol{\theta}\cdot\boldsymbol{\nu}(\mathbf{x}) u|_{\Gamma_+} d\mu(\boldsymbol{\theta}) \equiv z(\mathbf{x}), \\ \mathcal{G} &: L^2_{\boldsymbol{\theta}\cdot\nu}(\Gamma_+) \longmapsto L^2(\partial\mathcal{D}) \equiv \mathcal{Z}, \end{aligned} \tag{2.6}$$

with $S_+^{n-1} := \{\boldsymbol{\theta} : \boldsymbol{\theta} \in S^{n-1} \text{ s.t. } \boldsymbol{\theta} \cdot \boldsymbol{\nu}(\mathbf{x}) > 0\}$. We will call $\mathcal{Z}$ the "measurement space." Now the composite operator $\mathcal{G}\Lambda : f \mapsto z$ maps the incoming flux into the tomographic measurements. The adjoint operator $\mathcal{G}^*$ of $\mathcal{G}$ is defined via the identity

$$\left\langle \overline{\mathcal{G}^* g_1}, g_2 \right\rangle_{L^2_{\boldsymbol{\theta}\cdot\boldsymbol{\nu}}(\Gamma_+)} = \left\langle \overline{g_1}, \mathcal{G} g_2 \right\rangle_{\mathcal{Z}} \tag{2.7}$$

for all $g_1 \in \mathcal{Z}$ and $g_2 \in L^2_{\boldsymbol{\theta}\cdot\boldsymbol{\nu}}(\Gamma_+)$, where the symbol $\overline{\mathscr{Y}_1}$ denotes the complex conjugate of $\mathscr{Y}_1$, and $\langle \cdot, \cdot \rangle_X$ is the usual inner product in a Hilbert space X. One observes that $\mathcal{G}^*$ is nothing but the operation of multiplication by $\boldsymbol{\theta} \cdot \boldsymbol{\nu}(\mathbf{x})$.

2.2. Least-squares formulation. The inverse problem of optical tomography can be formulated as follows: determine $(\sigma_a, \sigma_s) \in \mathcal{Q}$ such that

$$\mathcal{G}\Lambda f = z \tag{2.8}$$

holds for all possible source-measurement pairs (f, z). Here $z \in \mathcal{Z} \equiv L^2(\partial\mathcal{D})$ is the measured data corresponding to source f. This problem is in general severely ill-posed (assuming that uniqueness of reconstruction holds as in diffusion theory [4]) in the sense that when no regularization is applied, noise contained in the data z is more amplified during the inversion procedure than what would result from an arbitrary number of differentiations [21]. Another practical difficulty in solving (2.8) lies in the fact that the amount of available data may be quite limited [47]. For example, one may only be able to use a limited number (say, N_q) of light sources. After discretizing (2.8) on a reasonable mesh, we will end up with a very underdetermined nonlinear system. A classical way to resolve the lack of measurements is to turn to the following least-squares formulation: find (σ_a, σ_s) solving

$$\mathcal{F}(\sigma_a, \sigma_s) =: \frac{1}{2} \sum_{q=1}^{N_q} \left\| \mathcal{G}\Lambda f_q - z_q \right\|_{\mathcal{Z}}^2 \to \min . \tag{2.9}$$

Here, $1 \le q \le N_q$ denotes the light source number. For reasons we have mentioned earlier, the least-squares problem (2.9) is usually not stable [4]. To stabilize the problem, we impose additional smoothness restrictions on the coefficients we wish to reconstruct. In other words, we look for optical properties in a space that is much smaller than $\mathcal{Q}$. We call this space the space of admissible solutions:

$$\mathcal{Q}_{ad} := \{(\sigma_a, \sigma_s) \ : (\sigma_a, \sigma_s) \in [\sigma_a^l, \sigma_a^u] \times [\sigma_s^l, \sigma_s^u], \text{ and } (\sigma_a, \sigma_s) \in \mathcal{H}^1(\mathcal{D}) \times \mathcal{H}^1(\mathcal{D})\},$$

where σ_a^l (resp., σ_a^u) and σ_s^l (resp., σ_s^u) are lower (resp., upper) bounds of σ_a and σ_s, respectively, with $\sigma_a^l > 0$ and $\sigma_s^l > 0$. $\mathcal{H}^1(\mathcal{D})$ is the usual Hilbert space of $L^2(\mathcal{D})$ functions with first-order partial derivatives in $L^2(\mathcal{D})$:

$$\|\mathscr{Y}\|^2_{\mathcal{H}^1(\mathcal{D})} := \|\mathscr{Y}\|^2_{L^2(\mathcal{D})} + \|\nabla\mathscr{Y}\|^2_{L^2(\mathcal{D})} \quad \text{for } \mathscr{Y} \in \mathcal{H}^1(\mathcal{D}). \tag{2.10}$$

It is known that $\mathcal{Q}_{ad}$ is a closed and convex subset of $\mathcal{H}^1(\mathcal{D}) \times \mathcal{H}^1(\mathcal{D})$. We can thus introduce the following regularized least-squares functional:

$$\mathcal{F}_\beta(\sigma_a, \sigma_s) := \mathcal{F}(\sigma_a, \sigma_s) + \frac{\beta}{2} \mathcal{J}(\sigma_a, \sigma_s), \tag{2.11}$$

where the last term is a regularization term and β is the regularization parameter [21]. The method for choosing β will be described in section 4.3. We use the Tikhonov regularization functional in our problem:

$$\mathcal{J}(\sigma_a, \sigma_s) = \|\sigma_a - \sigma_a^0\|^2_{\mathcal{H}^1(\mathcal{D})} + \epsilon \|\sigma_s - \sigma_s^0\|^2_{\mathcal{H}^1(\mathcal{D})}, \tag{2.12}$$

where σ_a^0 and σ_s^0 are initial guesses for the σ_a and σ_s profiles, and ϵ is a small constant. The choice of ϵ is addressed in section 4.3. We thus formulate the optical tomography problem as the following regularized least-squares problem:

$$\text{(RLS)} \qquad \begin{aligned} &\min_{(\sigma_a,\sigma_s)} \mathcal{F}_\beta \\ &\sigma_a^l \le \sigma_a \le \sigma_a^u, \\ &\sigma_s^l \le \sigma_s \le \sigma_s^u. \end{aligned}$$

We first observe that problem (RLS) has at least one solution in the sense that the functional $\mathcal{F}_\beta(\sigma_a, \sigma_s)$ admits at least one minimizer. This existence result is classical and follows from the weak lower semicontinuity and coercivity of $\mathcal{F}_\beta(\sigma_a, \sigma_s)$ [46, 60]. However, we cannot show that $\mathcal{F}_\beta(\sigma_a, \sigma_s)$ is strictly convex and cannot conclude that the minimizer is unique [60].

Our implementation of the inverse problem of optical tomography is a gradient-based minimization approach. We thus need to compute the Fréchet derivative of the least-squares functional $\mathcal{F}_\beta(\sigma_a, \sigma_s)$. Direct estimates of the Fréchet derivatives being quite costly because the optical parameters are (at least at the continuous level) infinite-dimensional objects, we adopt the adjoint state (or costate) approach [60] to estimate the derivatives. We have the following result.

THEOREM 2.2 (Fréchet derivatives). [illegible] $\mathcal{F}_\beta(\sigma_a, \sigma_s)$ [illegible] σ_a [illegible] σ_s [illegible] (σ_a, σ_s) [illegible] $(h_a \ h_s)$ [illegible]

(2.13)
$$\begin{pmatrix} \mathcal{F}'_\beta h_a \\ \mathcal{F}'_\beta h_s \end{pmatrix} = \begin{pmatrix} \operatorname{Re} \sum_{q=1}^{N_q} \left\langle \varphi_q, \left(\dfrac{\partial \mathcal{T}}{\partial \sigma_a} h_a \right) u_q \right\rangle_{L^2(\mathcal{D}\times S^{n-1})} + \beta \left\langle \sigma_a - \sigma_a^0, h_a \right\rangle_{\mathcal{H}^1(\mathcal{D})} \\ \operatorname{Re} \sum_{q=1}^{N_q} \left\langle \varphi_q, \left(\dfrac{\partial \mathcal{T}}{\partial \sigma_s} h_s \right) u_q \right\rangle_{L^2(\mathcal{D}\times S^{n-1})} + \beta\epsilon \left\langle \sigma_s - \sigma_s^0, h_s \right\rangle_{\mathcal{H}^1(\mathcal{D})} \end{pmatrix},$$

[illegible] $\mathcal{T}$ [illegible] (2.1). u_q [illegible] φ_q [illegible] (2.1) [illegible] f_q [illegible] (2.16) [illegible] Re [illegible]. Let us denote by r_q the residual $\mathcal{G}\Lambda f_q - z_q = \mathcal{G}u_q|_{\Gamma_+} - z_q$. According to [18, 19], r_q is Fréchet differentiable with respect to both σ_a and σ_s. The L^2-norm is Fréchet differentiable as shown in [46]. By the chain rule, $\|r_q\|_{\mathcal{Z}}^2$ is Fréchet differentiable. Since the summation is finite, we deduce that $\mathcal{F}$ is differentiable. Together with the fact that $\mathcal{J}$ is differentiable, we conclude that $\mathcal{F}_\beta$ is Fréchet differentiable with respect to σ_a and σ_s.

We now compute these Fréchet derivatives. Let us compute the derivative with respect to σ_a:

$$\begin{aligned} \mathcal{F}'_\beta(\sigma_a, \sigma_s) h_a &= \operatorname{Re} \sum_{q=1}^{N_q} \left\langle \overline{r}_q, \mathcal{G} \left(\frac{\partial u_q|_{\Gamma_+}}{\partial \sigma_a} h_a \right) \right\rangle_{\mathcal{Z}} + \beta \left\langle \sigma_a - \sigma_a^0, h_a \right\rangle_{\mathcal{H}^1(\mathcal{D})} \\ &= \operatorname{Re} \sum_{q=1}^{N_q} \left\langle \overline{\mathcal{G}^* r_q}, \frac{\partial u_q|_{\Gamma_+}}{\partial \sigma_a} h_a \right\rangle_{L^2_{\boldsymbol{\theta}\cdot\nu}(\Gamma_+)} + \beta \left\langle \sigma_a - \sigma_a^0, h_a \right\rangle_{\mathcal{H}^1(\mathcal{D})}, \end{aligned} \tag{2.14}$$

where we have used the properties of the adjoint operator (2.7). On the other hand, differentiating the transport equation (2.1) for source f_q gives

$$\begin{aligned} \mathcal{T}\phi_q + \left(\frac{\partial \mathcal{T}}{\partial \sigma_a} h_a\right) u_q = 0 \quad &\text{in } \mathcal{D}\times S^{n-1}, \\ \phi_q = 0 \quad &\text{on } \Gamma_-, \end{aligned} \tag{2.15}$$

where $\phi_q \equiv \frac{\partial u_q}{\partial \sigma_a} h_a$, and $\mathcal{T}$ is the transport operator defined in (2.1). We need also to introduce an adjoint variable φ_q of u_q which is the solution of the following adjoint transport equation:

$$\begin{aligned} \mathcal{T}^*\varphi_q \equiv \Big(\frac{i\omega}{v} - \boldsymbol{\theta}\cdot\nabla + \sigma_a(\mathbf{x})\Big)\varphi_q(\mathbf{x},\boldsymbol{\theta}) + Q(\varphi_q)(\mathbf{x},\boldsymbol{\theta}) = 0 \quad &\text{in } \mathcal{D}\times S^{n-1}, \\ \varphi_q(\mathbf{x},\boldsymbol{\theta}) = -\overline{\mathcal{G}^* r_q} \quad &\text{on } \Gamma_+. \end{aligned} \tag{2.16}$$

Here we have used that $Q^* = Q$, which follows from the definition (2.2). Multiplying (2.15) by φ_q and (2.16) by ϕ_q, then integrating over $\mathcal{D}\times S^{n-1}$, we obtain

$$\langle \overline{\mathcal{G}^* r_q}, \phi_q \rangle_{L^2_{\boldsymbol{\theta}\cdot\nu}(\Gamma_+)} = \left\langle \varphi_q, \left(\frac{\partial \mathcal{T}}{\partial \sigma_a} h_a\right) u_q \right\rangle_{L^2(\mathcal{D}\times S^{n-1})}, \tag{2.17}$$

which leads to

$$\mathcal{F}'_\beta(\sigma_a,\sigma_s)h_a = \mathrm{Re}\sum_{q=1}^{N_q} \left\langle \varphi_q, \left(\frac{\partial \mathcal{T}}{\partial \sigma_a} h_a\right) u_q \right\rangle_{L^2(\mathcal{D}\times S^{n-1})} + \beta \left\langle \sigma_a - \sigma_a^0, h_a \right\rangle_{\mathcal{H}^1(\mathcal{D})}. \tag{2.18}$$

The derivative with respect to σ_s can be computed similarly. ∎

This result shows that in order to compute the Fréchet derivative of the objective functional $\mathcal{F}_\beta(\sigma_a,\sigma_s)$, we need to solve one forward transport problem (2.1) and one adjoint transport problem (2.16).

3. Discretization methods. There is a vast literature on the discretization of radiative transfer equations; see, for instance, [1, 25, 44]. In this paper, we have chosen to use the discrete ordinates method to discretize the directional variables and the finite volume method [22] to discretize the spatial variables.

3.1. The discrete ordinates formulation. In the discrete ordinates method [1, 44], we approximate the total scalar flux, defined as the integral of $u(\mathbf{x},\boldsymbol{\theta})$ over S^{n-1}, by the following quadrature rule:

$$\int_{S^{n-1}} u(\mathbf{x},\boldsymbol{\theta})\, d\mu(\boldsymbol{\theta}) \approx \sum_{j=1}^{J} \eta_j u(\mathbf{x},\boldsymbol{\theta}_j), \tag{3.1}$$

where $\boldsymbol{\theta}_j$ is the jth direction and η_j the associated weight for $1 \le j \le J$. Details on how to choose the set of directions $\{\boldsymbol{\theta}_j\}_{j=1}^J$ and the corresponding weights $\{\eta_j\}_{j=1}^J$ can be found in [44]. To ensure particle conservation, we impose that

$$\sum_{j=1}^{J} \eta_j = 1. \tag{3.2}$$

The equation of radiative transfer is now decomposed as a discrete set of J coupled differential equations that describe the photon flux field along J directions:

$$\nabla \cdot (\boldsymbol{\theta}_j u) + \left(\sigma_t + \frac{i\omega}{v}\right) u(\mathbf{x}, \boldsymbol{\theta}_j) = \sigma_s(\mathbf{x}) \sum_{j'=1}^{J} \eta_{j'} k_{jj'} u(\mathbf{x}, \boldsymbol{\theta}_{j'}) \tag{3.3}$$

for $j = 1, 2, \ldots, J$, where $k_{jj'} = k(\boldsymbol{\theta}_j \cdot \boldsymbol{\theta}_{j'})$, and where $\sigma_t = \sigma_a + \sigma_s$. We impose

$$\sum_{j=1}^{J} \eta_j k_{jj'} = 1, \qquad 1 \le j' \le J, \tag{3.4}$$

so that the number of photons in the system is preserved by the scattering process.

3.2. Spatial discretization. We use a finite volume method to perform the spatial discretization. Finite volume methods [22] ensure the conservation of mass (or momentum, energy) in a discrete sense, which is important in transport calculations. They also have the advantage of easily handling complicated geometries by arbitrary triangulations, which we need in tomographic applications.

We implement a cell-centered version of the finite volume methods. Consider a mesh of $\mathbb{R}^n$, $\mathcal{M}$, consisting of polyhedral bounded convex subsets of $\mathbb{R}^n$, which covers our computational domain $\mathcal{D}$. Let $\mathcal{C} \in \mathcal{M}$ be a [illegible], that is, an element of the mesh $\mathcal{M}$, $\partial\mathcal{C}$ its boundary, and $V_{\mathcal{C}}$ its Lebesgue measure. We assume that the unknown quantity, for example, $u(\mathbf{x}, \theta_j)$, takes its averaged value in $\mathcal{C}$ (and thus is constant). We denote this value by $u_j^{\mathcal{C}}$:

$$u_j^{\mathcal{C}} \equiv \frac{1}{V_{\mathcal{C}}} \int_{V_{\mathcal{C}}} u(\mathbf{x}, \boldsymbol{\theta}_j) d\mathbf{x}. \tag{3.5}$$

Integrating the above discrete ordinates equations (3.3) over cell $\mathcal{C}$ and using the divergence theorem on the first term, we obtain the equations

$$\int_{\partial\mathcal{C}} \boldsymbol{\theta}_j \cdot \mathbf{n}_{\mathcal{C}}(\mathbf{x}) u_j d\gamma(\mathbf{x}) + \left(\sigma_t^{\mathcal{C}} + \frac{i\omega}{v}\right) V_{\mathcal{C}} u_j^{\mathcal{C}} = V_{\mathcal{C}} \sigma_s^{\mathcal{C}} \sum_{j'=1}^{J} \eta_{j'} k_{jj'} u_{j'}^{\mathcal{C}} \tag{3.6}$$

for $1 \le j \le J$, where $\mathbf{n}_{\mathcal{C}}(\mathbf{x})$ denotes the outward normal to $\partial\mathcal{C}$ at point $\mathbf{x} \in \partial\mathcal{C}$, $d\gamma(\mathbf{x})$ denotes the surface Lebesgue measure on $\partial\mathcal{C}$, and $\sigma_s^{\mathcal{C}}$ ($\sigma_t^{\mathcal{C}}$) is the value of σ_s (σ_t) on cell $\mathcal{C}$.

Now we have to approximate the flux through the boundary of $\mathcal{C}$, i.e., the first integral term in (3.6). Let $\{\mathcal{C}_i\}_{i=1}^{I}$ be the set of neighboring cells of $\mathcal{C}$. We denote by $S_{\mathcal{C},i}$ the common edge of cell $\mathcal{C}$ and $\mathcal{C}_i$, i.e., $S_{\mathcal{C},i} = \partial\mathcal{C} \cap \partial\mathcal{C}_i$. We then have

$$\int_{\partial\mathcal{C}} \boldsymbol{\theta}_j \cdot \mathbf{n}_{\mathcal{C}}(\mathbf{x}) u_j d\gamma(\mathbf{x}) = \sum_i \int_{S_{\mathcal{C},i}} \boldsymbol{\theta}_j \cdot \mathbf{n}_{\mathcal{C}}(\mathbf{x}) u_j d\gamma(\mathbf{x}). \tag{3.7}$$

The flux $\int_{S_{\mathcal{C},i}} \boldsymbol{\theta}_j \cdot \mathbf{n}_{\mathcal{C}}(\mathbf{x}) u_j d\gamma(\mathbf{x})$ can be approximated by various numerical schemes. In this work, we take a first-order upwind scheme:

$$F_{j,i}^{\mathcal{C}} := \int_{S_{\mathcal{C},i}} \boldsymbol{\theta}_j \cdot \mathbf{n}_{\mathcal{C}}(\mathbf{x}) u_j d\gamma(\mathbf{x}) = \begin{cases} \boldsymbol{\theta}_j \cdot \mathbf{n}_{\mathcal{C}} |S_{\mathcal{C},i}| u_j^{\mathcal{C}} & \text{if } \boldsymbol{\theta}_j \cdot \mathbf{n}_{\mathcal{C}} \ge 0, \\ \boldsymbol{\theta}_j \cdot \mathbf{n}_{\mathcal{C}} |S_{\mathcal{C},i}| u_j^{\mathcal{C}_i} & \text{if } \boldsymbol{\theta}_j \cdot \mathbf{n}_{\mathcal{C}} < 0, \end{cases} \tag{3.8}$$

where $|S_{\mathcal{C},i}|$ is the Lebesgue measure of $S_{\mathcal{C},i}$. We then obtain a full discretization of the discrete ordinates equations

$$\sum_i F^{\mathcal{C}}_{j,i} + \left(\sigma^{\mathcal{C}}_t + \frac{i\omega}{v}\right) V_{\mathcal{C}} u^{\mathcal{C}}_j = V_{\mathcal{C}} \sigma^{\mathcal{C}}_s \sum_{j'=1}^{J} \eta_{j'} k_{jj'} u^{\mathcal{C}}_{j'} \tag{3.9}$$

for $j = 1, 2, \ldots, J$. Let N denote the total number of control cells. After collecting the discretized transport equation (3.9) on all control cells, we arrive at the following system of complex-valued algebraic equations:

$$\mathbf{AU} = \mathbf{SU} + \mathbf{G}, \tag{3.10}$$

where $\mathbf{A} \in \mathbb{C}^{NJ\times NJ}$ and $\mathbf{S} \in \mathbb{C}^{NJ\times NJ}$ are the discretized streaming-collision and scattering operators, respectively. The boundary source $f(\mathbf{x}, \boldsymbol{\theta})$, which comes into the discretized system via the flux approximation (3.8), is denoted by $\mathbf{G}$. The vector $\mathbf{U} \in \mathbb{C}^{NJ\times 1}$, which contains the values of $u(\mathbf{x}, \boldsymbol{\theta})$ on the cell $\mathcal{C}$ in the direction $\boldsymbol{\theta}_j$, is organized as

$$\mathbf{U} = \begin{pmatrix} \mathbf{U}_1 \\ \vdots \\ \mathbf{U}_J \end{pmatrix}, \text{ with } \mathbf{U}_j = \begin{pmatrix} u^1_j \\ \vdots \\ u^N_j \end{pmatrix} \in \mathbb{C}^N. \tag{3.11}$$

The matrices $\mathbf{A}$ and $\mathbf{S}$ have sparse structures. In fact, they are sparse block matrices. $\mathbf{A}$ is a block diagonal matrix that can be written as

$$\mathbf{A} = \begin{pmatrix} \mathbf{A}_1 & & \\ & \ddots & \\ & & \mathbf{A}_J \end{pmatrix} + \begin{pmatrix} \mathbf{C}_0 & & \\ & \ddots & \\ & & \mathbf{C}_0 \end{pmatrix}, \tag{3.12}$$

where $\mathbf{A}_j \in \mathbb{C}^{N\times N}$ is the discretization of the advection operator $\mathcal{A}$ defined by $\mathcal{A}u := \boldsymbol{\theta}_j \cdot \nabla u$. From (3.8) we can deduce that $\mathbf{A}_j$ has no more than $N \times N_E$ nonzero elements, where N_E is the total number of edges (surfaces in three dimensions) each control cell has.

Matrix $\mathbf{C}_0 \in \mathbb{C}^{N\times N}$ is diagonal:

$$\mathbf{C}_0 = \begin{pmatrix} V_1(\sigma^1_t + \frac{i\omega}{v}) & & \\ & \ddots & \\ & & V_N(\sigma^N_t + \frac{i\omega}{v}) \end{pmatrix},$$

where we recall $\sigma^i_t \equiv \sigma^i_a + \sigma^i_s$ $(i = 1, \ldots, N)$.

The matrix $\mathbf{S}$ can be expressed as the direct product of two smaller matrices:

$$\mathbf{S} = \mathbf{K} \otimes \mathbf{D}_0, \tag{3.13}$$

with $\mathbf{D}_0 \in \mathbb{C}^{N\times N}$ a diagonal matrix given by

$$\mathbf{D}_0 = \begin{pmatrix} V_1\sigma^1_s & & \\ & \ddots & \\ & & V_N\sigma^N_s \end{pmatrix},$$

and $\mathbf{K} \in \mathbb{C}^{J\times J}$ a dense matrix with component $(\mathbf{K})_{jj'} = \eta_{j'} k_{jj'}$. In practical applications, the number of directions is much smaller than the number of spatial mesh elements ($J \ll N$). So although $\mathbf{K}$ is dense, the scattering matrix $\mathbf{S}$ is sparse. However, in general the matrix $\mathbf{K}$ is not symmetric unless we choose η_j to be constant. The matrix $\mathbf{A} - \mathbf{S}$ is thus neither symmetric nor positive definite, which is the reason for us to choose a GMRES solver in section 4.2.

Let us remark here that our finite volume discretization reduces to an upwind finite difference scheme on usual finite difference grids. We refer to our earlier work [54] for some numerical tests on the finite volume discretization of the transport equation.

3.3. Discrete adjoint problem. We present in this section the numerical method we have employed to compute the gradient of discrete objective function with respect to the optical properties on each cell.

To simplify the notation, from now on we denote by $\sigma_a \in \mathbb{R}^{N\times 1}$ the absorption coefficient vector $(\sigma_a^1, \ldots, \sigma_a^{\mathcal{C}}, \ldots, \sigma_a^N)^T$ and by $\sigma_s \in \mathbb{R}^{N\times 1}$ the scattering coefficient vector $(\sigma_s^1, \ldots, \sigma_s^{\mathcal{C}}, \ldots, \sigma_s^N)^T$.

We want to minimize the discrepancy between model predictions and measurements over a set of source and detector pairs. Let N_q denote the number of sources used in an experiment, and let N_d denote the number of detectors used for each source. Then the following objective function we employed takes the form

$$\mathcal{F}_\beta(\sigma_a, \sigma_s) = \frac{1}{2}\sum_{q=1}^{N_q}\sum_{d=1}^{N_d} |\mathcal{P}_d \mathbf{U}^q - z_{q,d}^\delta|^2 + \frac{\beta}{2}\mathcal{J}(\sigma_a, \sigma_s), \tag{3.14}$$

where $z_{q,d}^\delta$ denote the dth measurement of the qth source. The superscript δ is used to denote the level of noise contained in the measurements. $\mathbf{U}^q$ is a solution of the transport equation for the qth source. $\mathcal{P}_d \in \mathbb{R}^{1\times N}$ is a discretized version of the measurement operator. It takes the outgoing flux at detector d and averages over S_+^{n-1}. The discretized regularization term is given by

$$\begin{aligned}\mathcal{J}(\sigma_a, \sigma_s) = \sum_{\mathcal{C}=1}^{N}\Big(\sum_{\kappa=\{x,y,z\}} [\mathcal{D}_\kappa^{\mathcal{C}}(\sigma_a - \sigma_a^0)]^2 + (\sigma_a^{\mathcal{C}} - \sigma_a^{0,\mathcal{C}})^2\Big) \\ + \epsilon\sum_{\mathcal{C}=1}^{N}\Big(\sum_{\kappa=\{x,y,z\}} [\mathcal{D}_\kappa^{\mathcal{C}}(\sigma_s - \sigma_s^0)]^2 + (\sigma_s^{\mathcal{C}} - \sigma_s^{0,\mathcal{C}})^2\Big),\end{aligned} \tag{3.15}$$

where $\mathcal{D}_\kappa^{\mathcal{C}} \in \mathbb{R}^{1\times N}$ denotes the discretized partial differential operator at cell $\mathcal{C}$ in the κ $(= x, y, z)$ direction.

We now start to compute the gradient of objective function (3.14) with respect to optical properties on each mesh element. It is straightforward to check that

$$\frac{\partial \mathcal{F}_\beta}{\partial \sigma_a^{\mathcal{C}}} = \Big[\sum_{q=1}^{N_q}\sum_{d=1}^{N_d} \overline{\mathbf{r}}_d^q \mathcal{P}_d \frac{\partial \mathbf{U}^q}{\partial \sigma_a^{\mathcal{C}}}\Big]_{\mathrm{Re}} + \frac{\beta}{2}\frac{\partial \mathcal{J}}{\partial \sigma_a^{\mathcal{C}}}, \tag{3.16}$$

with $\mathbf{r}_d^q = \mathcal{P}_d \mathbf{U}^q - z_{q,d}^\delta$, and $[\cdot]_{\mathrm{Re}}$ denotes the real part of $[\cdot]$.

At the same time, we notice from (3.10) that

$$\frac{\partial \mathbf{A}}{\partial \sigma_a^{\mathcal{C}}}\mathbf{U}^q + \mathbf{A}\frac{\partial \mathbf{U}^q}{\partial \sigma_a^{\mathcal{C}}} = \frac{\partial \mathbf{S}}{\partial \sigma_a^{\mathcal{C}}}\mathbf{U}^q + \mathbf{S}\frac{\partial \mathbf{U}^q}{\partial \sigma_a^{\mathcal{C}}} \tag{3.17}$$

for source $q = 1, \ldots, N_q$, which is equivalent to saying that

$$\frac{\partial \mathbf{U}^q}{\partial \sigma_a^{\mathcal{C}}} = -(\mathbf{A} - \mathbf{S})^{-1} \frac{\partial (\mathbf{A} - \mathbf{S})}{\partial \sigma_a^{\mathcal{C}}} \mathbf{U}^q, \tag{3.18}$$

since $\mathbf{A} - \mathbf{S}$ is invertible. It is very important to note that the matrices $\mathbf{A}$ and $\mathbf{S}$ are independent of the source used. Thus, there are no superscripts q associated with them. We thus have

$$\frac{\partial \mathcal{F}_\beta}{\partial \sigma_a^{\mathcal{C}}} = -\Big[\sum_{q=1}^{N_q} \sum_{d=1}^{N_d} \bar{\mathbf{r}}_d^q \mathcal{P}_d (\mathbf{A} - \mathbf{S})^{-1} \frac{\partial (\mathbf{A} - \mathbf{S})}{\partial \sigma_a^{\mathcal{C}}} \mathbf{U}^q \Big]_{\mathrm{Re}} + \frac{\beta}{2} \frac{\partial \mathcal{J}}{\partial \sigma_a^{\mathcal{C}}}. \tag{3.19}$$

We now introduce a new state variable $\mathbf{\Psi}^q \in \mathbb{C}^{N \times 1}$ (called the adjoint variable of $\mathbf{U}^q$) given by

$$-\sum_{d=1}^{N_d} \bar{\mathbf{r}}_d^q \mathcal{P}_d (\mathbf{A} - \mathbf{S})^{-1} = \mathbf{\Psi}^{qT}, \tag{3.20}$$

where $\mathbf{\Psi}^{qT}$ denotes the transpose of $\mathbf{\Psi}^q$. We then say that $\mathbf{\Psi}^q$ is the solution of the following [illegible] equation of (3.10):

$$(\mathbf{A} - \mathbf{S})^T \mathbf{\Psi}^q = -\sum_{d=1}^{N_d} \bar{\mathbf{r}}_d^q \mathcal{P}_d^T. \tag{3.21}$$

One then arrives at

$$\frac{\partial \mathcal{F}_\beta}{\partial \sigma_a^{\mathcal{C}}} = \Big[\sum_{q=1}^{N_q} \mathbf{\Psi}^{qT} \frac{\partial (\mathbf{A} - \mathbf{S})}{\partial \sigma_a^{\mathcal{C}}} \mathbf{U}^q \Big]_{\mathrm{Re}} + \frac{\beta}{2} \frac{\partial \mathcal{J}}{\partial \sigma_a^{\mathcal{C}}}, \tag{3.22}$$

with

$$\frac{\partial \mathcal{J}}{\partial \sigma_a^{\mathcal{C}}} = 2\Big(\sum_{\kappa = \{x,y,z\}} \mathcal{D}_\kappa^{\mathcal{C}} (\sigma_a - \sigma_a^0)(\mathcal{D}_\kappa^{\mathcal{C}} \mathcal{I}_{\mathcal{C}}) + (\sigma_a^{\mathcal{C}} - \sigma_a^{0,\mathcal{C}}) \Big),$$

where the unit direction vector $\mathcal{I}_{\mathcal{C}} \in \mathbb{R}^{N \times 1}$ is a vector whose $\mathcal{C}$th element is 1 and all other components are zero.

Very similar computation leads to the fact that the derivatives of the objective functional with respect to $\sigma_s^{\mathcal{C}}$ are given by

$$\frac{\partial \mathcal{F}_\beta}{\partial \sigma_s^{\mathcal{C}}} = \Big[\sum_{q=1}^{N_q} \mathbf{\Psi}^{qT} \frac{\partial (\mathbf{A} - \mathbf{S})}{\partial \sigma_s^{\mathcal{C}}} \mathbf{U}^q \Big]_{\mathrm{Re}} + \frac{\beta}{2} \frac{\partial \mathcal{J}}{\partial \sigma_s^{\mathcal{C}}}, \tag{3.23}$$

with

$$\frac{\partial \mathcal{J}}{\partial \sigma_s^{\mathcal{C}}} = 2\epsilon\Big(\sum_{\kappa = \{x,y,z\}} \mathcal{D}_\kappa^{\mathcal{C}} (\sigma_s - \sigma_s^0)(\mathcal{D}_\kappa^{\mathcal{C}} \mathcal{I}_{\mathcal{C}}) + (\sigma_s^{\mathcal{C}} - \sigma_s^{0,\mathcal{C}}) \Big).$$

Formulas (3.22) and (3.23) are what we used to compute the derivatives of objective function with respect to optical properties on each element. Note that we did not

form explicitly the matrix $\frac{\partial(\mathbf{A}-\mathbf{S})}{\partial\sigma_a^{\mathcal{C}}}$ (resp., $\frac{\partial(\mathbf{A}-\mathbf{S})}{\partial\sigma_s^{\mathcal{C}}}$) in the evaluations of $\mathbf{\Psi}^{qT}\frac{\partial(\mathbf{A}-\mathbf{S})}{\partial\sigma_a^{\mathcal{C}}}\mathbf{U}^q$ (resp., $\mathbf{\Psi}^{qT}\frac{\partial(\mathbf{A}-\mathbf{S})}{\partial\sigma_s^{\mathcal{C}}}\mathbf{U}^q$) because this matrix has a very simple sparse structure according to (3.12) and (3.13). Instead, a matrix-free method was adopted. In fact, since

$$\left[\frac{\partial(\mathbf{A}-\mathbf{S})}{\partial\sigma_a^{\mathcal{C}}}\right]_{ij} = \begin{cases} V_{\mathcal{C}}, & i=j \text{ and } \mod(i,N)=\mathcal{C}, \\ 0 & \text{otherwise}, \end{cases} \tag{3.24}$$

where we recall that N is the total number of volume cells that cover our computational domain, we have

$$\mathbf{\Psi}^{qT}\frac{\partial(\mathbf{A}-\mathbf{S})}{\partial\sigma_a^{\mathcal{C}}}\mathbf{U}^q = \sum_{j=1}^{J}\mathbf{\Psi}^q_{(j-1)\times N+\mathcal{C}}V_{\mathcal{C}}\mathbf{U}^q_{(j-1)\times N+\mathcal{C}}. \tag{3.25}$$

Note that here $\mathbf{\Psi}^q_{(j-1)\times N+\mathcal{C}}$ (resp., $\mathbf{U}^q_{(j-1)\times N+\mathcal{C}}$) denotes the $[(j-1)\times N+\mathcal{C}]$th element of $\mathbf{\Psi}^q$ (resp., $\mathbf{U}^q$).

The same observation on $\frac{\partial(\mathbf{A}-\mathbf{S})}{\partial\sigma_s^{\mathcal{C}}}$ leads to

$$\begin{aligned}\mathbf{\Psi}^{qT}\frac{\partial(\mathbf{A}-\mathbf{S})}{\partial\sigma_s^{\mathcal{C}}}\mathbf{U}^q = &\sum_{j=1}^{J}\mathbf{\Psi}^q_{(j-1)\times N+\mathcal{C}}V_{\mathcal{C}}\mathbf{U}^q_{(j-1)\times N+\mathcal{C}} \\ &- \sum_{j'=1}^{J}\sum_{j=1}^{J}(\mathbf{K})_{j'j}\mathbf{\Psi}^q_{(j'-1)\times N+\mathcal{C}}V_{\mathcal{C}}\mathbf{U}^q_{(j-1)\times N+\mathcal{C}},\end{aligned} \tag{3.26}$$

where the (j',j)th component of matrix $\mathbf{K}$, $(\mathbf{K})_{jj'}=\eta_{j'}k_{jj'}$, is given in (3.13). We can thus evaluate (3.22) and (3.23) without forming any intermediate matrices.

4. Numerical implementation. We have implemented the quasi-Newton optimization algorithm to solve the regularized least-squares problem (RLS) introduced in section 2.2. We have found in practice that this method converged much faster (in terms of function evaluations) than the nonlinear conjugate gradient method with either the Fletcher–Reeves or the Polak–Ribière updating formula [52]. This is expected from theory [52] and is consistent with practical applications tested in [41]. We have also implemented a Gauss–Newton method [52] to solve the least-squares problem (without the bounds constraints) and found that the method converges extremely slowly in our case. This is probably due to the fact that our problem is highly nonlinear and the Gauss–Newton method usually does not work well in this kind of situation [27, 52]. Detail comparison between various methods of solving the least-squares reconstruction problem is an ongoing project.

In this work, we employ the BFGS update rule [52] of the inverse Hessian matrix for our quasi-Newton method. The usual BFGS method, however, requires the explicit construction of the Hessian matrix, which is unrealistic for large problems. The memory size required to store the Hessian matrix is roughly proportional to the square of the memory used for the unknown parameters. We have thus resorted to a limited-memory version of the BFGS method which avoids the explicit construction of the inverse Hessian matrix.

4.1. Numerical optimization. The BFGS algorithm can be viewed as a special case of the quasi-Newton method [52]. With $\boldsymbol{\sigma}$ denoting the vector of discretized

optical properties, the quasi-Newton methods can be characterized by the following iterative process:

$$\boldsymbol{\sigma}_{k+1} = \boldsymbol{\sigma}_k + \alpha_k \mathbf{p}_k, \qquad k \in \mathbb{N}^+, \tag{4.1}$$

where $\mathbf{p}_k$ is a descent direction vector and α_k is the step length. The BFGS algorithm chooses $\mathbf{p}_k$ to be the solution of an approximated solution of Newton-type optimality equation, i.e.,

$$\mathbf{p}_k = H_k \mathbf{g}_k, \tag{4.2}$$

where $\mathbf{g}_k$ is the gradient of the least-squares functional, $\mathbf{g}_k = -\nabla_{\boldsymbol{\sigma}} \mathcal{F}_\beta(\boldsymbol{\sigma}_k)$. H_k is the inverse Hessian matrix of $\mathcal{F}_\beta$ at step k. Instead of computing real inverse Hessian matrices, which is very time consuming, the BFGS algorithm chooses to approximate H_k by the following updating rule:

$$H_{k+1} = W_k^T H_k W_k + \rho_k \mathbf{s}_k \mathbf{s}_k^T, \tag{4.3}$$

with $W_k = \mathbf{I} - \rho_k \mathbf{y}_k \mathbf{s}_k^T$, $\mathbf{s}_k = \boldsymbol{\sigma}_{k+1} - \boldsymbol{\sigma}_k$, $\mathbf{y}_k = \mathbf{g}_{k+1} - \mathbf{g}_k$, and $\rho_k = \frac{1}{\mathbf{y}_k^T \mathbf{s}_k}$. $\mathbf{I}$ is the identity matrix. As we mentioned above, forming (4.3) takes a tremendous amount of computer memory for large problems. To overcome this shortcoming, the limited-memory version of BFGS stores only the vectors $\mathbf{y}_k$ and $\mathbf{s}_k$ obtained in the last m ($3 \le m \le 7$ usually) iterations [35] and discards the rest. Thus after the first m iterations, (4.3) can be expressed as

$$\begin{aligned} H_{k+1} &= (W_k^T \cdots W_{k-m}^T) H_{k+1}^0 (W_{k-m} \cdots W_k) \\ &+ \rho_{k-m} (W_k^T \cdots W_{k-m+1}^T) \mathbf{s}_{k-m} \mathbf{s}_{k-m}^T \times (W_{k-m+1} \cdots W_k) \\ &+ \rho_{k-m+1} (W_k^T \cdots W_{k-m+2}^T) \mathbf{s}_{k-m+1} \mathbf{s}_{k-m+1}^T \times (W_{k-m+2} \cdots W_k) \\ &\vdots \\ &+ \rho_k \mathbf{s}_k \mathbf{s}_k^T, \end{aligned} \tag{4.4}$$

with the sparse initial guess H_{k+1}^0 given by $H_{k+1}^0 = \frac{\mathbf{y}_{k+1}^T \mathbf{s}_{k+1}}{\mathbf{y}_{k+1}^T \mathbf{y}_{k+1}} \mathbf{I}$.

We refer interested readers to [35, 52] for more details on the limited-memory BFGS algorithms, and to [41] for applications of those algorithms to optical tomographic problems. Convergence of BFGS algorithms has been proved under certain conditions and has been tested on many applications [11, 52].

To impose bounds on optical parameters, we have to modify the relation (4.2) slightly. We adopt a gradient projection method [11, 35, 52] to do this. At the beginning of each iteration, we use the gradient projection method to find a set of active bounds. We then solve a subminimization problem,

$$\min_{\boldsymbol{\sigma}} Q_k(\boldsymbol{\sigma}) \equiv \mathcal{F}_\beta(\boldsymbol{\sigma}_k) + \mathbf{g}_k^T (\boldsymbol{\sigma} - \boldsymbol{\sigma}_k) + \frac{1}{2} (\boldsymbol{\sigma} - \boldsymbol{\sigma}_k)^T H_k^{-1} (\boldsymbol{\sigma} - \boldsymbol{\sigma}_k), \tag{4.5}$$

on the set of free variables to find an approximation solution $\overline{\sigma}_{k+1}$, treating the active bounds as equality constraints by Lagrange multipliers. After we find an approximation solution $\overline{\boldsymbol{\sigma}}_{k+1}$, a line search along $\mathbf{p}_k = \overline{\boldsymbol{\sigma}}_{k+1} - \boldsymbol{\sigma}_k$ is done to find the step length α_k in (4.1). We use a line search method that enforces the Wolfe conditions [52]. That is, we look for an α_k that solves

$$\min_{\alpha_k > 0} \mathcal{F}_\beta(\boldsymbol{\sigma}_k + \alpha_k \mathbf{p}_k) \tag{4.6}$$

and satisfies

$$\mathcal{F}_\beta(\boldsymbol{\sigma}_k + \alpha_k \mathbf{p}_k) \le \mathcal{F}_\beta(\boldsymbol{\sigma}_k) + c_1 \alpha_k \nabla \mathcal{F}_\beta^T(\boldsymbol{\sigma}_k)\mathbf{p}_k, \tag{4.7}$$

$$\nabla \mathcal{F}_\beta^T(\boldsymbol{\sigma}_k + \alpha_k \mathbf{p}_k)\mathbf{p}_k \ge c_2 \nabla \mathcal{F}_\beta^T(\boldsymbol{\sigma}_k)\mathbf{p}_k, \tag{4.8}$$

where $c_1 = 10^{-4}$, $c_2 = 0.1$ in our case. More details on how to impose bound constraints in BFGS algorithms can be found in [35, sect. 5.5] and [11, 64].

4.2. Solving algebraic systems. As we have mentioned before, at each step of the minimization process, we have to solve both a discretized transport equation (3.10) and its adjoint problem (3.21) to compute the Fréchet derivatives (3.22) and (3.23) of the objective functional, forming the gradient vector $\mathbf{g}_k$ in (4.2). In fact, almost all of the computational time in the reconstruction process is devoted to the solution of these transport equations. In this work, instead of using the popular source iteration method, which converges very slowly in diffusive regimes unless it is properly accelerated [1], we choose to solve the forward problems by a preconditioned GMRES(n) algorithm [55, 56], where n denotes the number of iterative steps after which GMRES is restarted. Our general principle is to choose n large when the problem size is small and n small when the problem size is large. The implementation of the algorithm is based on the template provided in [9]. The preconditioner we employ is the zero fill-in incomplete LU factorization (ILU(0)) [53, 55] that has been proved to be efficient in transport calculations [53]. Details about this factorization can be found in [55]. In all of the numerical examples in section 5, we pick $n = 7$, and the GMRES algorithm is stopped if the relative residual is small enough. For example, the stopping criteria $\|\mathbf{G} - (\mathbf{A} - \mathbf{S})\mathbf{U}_k\|_{l^2}/\|\mathbf{G} - (\mathbf{A} - \mathbf{S})\mathbf{U}_0\|_{l^2} \le 10^{-10}$ is used to solve (3.10). Here $\mathbf{U}_0$ is the initial guess and $\mathbf{U}_k$ is the $\mathbf{U}$ value at the kth GMRES iteration.

4.3. Selecting regularization parameter. To choose the optimal regularization parameter β in (2.11), we adopt the L-curve method in this study. Although there exist proofs that the L-curve method fails to convergence for certain classes of inverse problems [59], we have observed satisfactory results in our applications. We plot the log of the regularization functional against the squared norm of the regularized residual, say, r_β, for a range of values of the regularization parameter. The right parameter β is the one at which the L-curve reaches the maximum of its curvature [28, 60]. One can show that the right β maximizes the curvature function [60]

$$\kappa(\beta) = -\frac{R(\beta)S(\beta)[\beta R(\beta) + \beta^2 S(\beta)] + [R(\beta)S(\beta)]/S'(\beta)}{[R^2(\beta) + \beta^2 S^2(\beta)]^{3/2}}, \tag{4.9}$$

where $R(\beta)$ and $S(\beta)$ are defined by

$$R(\beta) := \|r_\beta\|_{L^2}^2, \qquad S(\beta) := \mathcal{J}(\sigma_a, \sigma_s).$$

We recall that β is not included in $\mathcal{J}(\sigma_a, \sigma_s)$. One notices immediately that the L-curve method requires several reconstructions for any single problem, and thus is very time consuming. A simple [illegible] method is suggested in [27] to reduce the computational cost of regularization parameter selection. In this method, one starts the first reconstruction with a relatively large β. The result of this reconstruction is then taken to be the initial guess of next reconstruction with a smaller β. If the two

β are not dramatically different from each other, then the two reconstructions should converge to similar results. Thus, the reconstruction with smaller β is supposed to converge quickly since its initial guess is chosen to be close enough to its real solution. The process can be repeated to perform reconstructions with several values of β. In practice, this continuation method saves tremendous computational time for finding optimal regularization parameters. It now takes only about 80% extra work to find the optimal parameters in most cases. We adopt this continuation method in our three-dimensional numerical example (Example 4) in the next section. We present in Figures 5.2 (B) and 5.6 (B) the L-curve we have used in Examples 1 and 3, respectively, to choose the optimal regularization parameter β. Note that in the Figure 5.2 (B), $\mathcal{J}(\sigma_a, \sigma_s)$ simplifies to $\|\sigma_a\|^2_{\mathcal{H}^1}$ since we reconstruct only σ_a and have chosen $\sigma_a^0 = 0$ in that case.

Another important issue is to choose an appropriate weight ϵ in the regularization functional defined in (2.12). This weight is necessary because, in practice, σ_s takes values that are about two orders of magnitude larger than σ_a. The weight is used to bring the two terms in the regularization functional to the same level so that the regularization term has an effect on both σ_a and σ_s. In all our numerical simulations in section 5, we choose ϵ to be the ratio $(\sigma_a^b/\sigma_s^b)^2$, where σ_a^b and σ_s^b are optical properties of background media.

Note that the main purpose for introducing the scaling factor ϵ is to reduce computational complexity in choosing optimal regularization parameters. It is by no means the only way to perform regularizations on both absorption and scattering coefficients. For example, one can regularize σ_a and σ_s separately, which will involve selecting multiple regularization parameters such as those in [10, 26, 45].

We remark finally that the $\mathcal{H}^1$-norm we use in the regularization functional can be replaced by other norms or seminorms. For example, we have performed reconstructions on numerical Example 1 in section 5.3 with stricter bounds on σ_a and $\|\nabla\sigma_a\|_{L^2}$ (instead of $\|\sigma_a\|_{\mathcal{H}^1}$) as the regularization functional. We have obtained very similar results (although the optimal regularization parameter changes). The main reason for us to use the $\mathcal{H}^1$-norm is that in many practical applications, we want to find solutions near some reference (σ_a^0, σ_s^0), for example, some known background.

4.4. Cost of the numerical method. The computational cost of our method consists of two main parts. The first part is the evaluation of the objective function and its gradient in the optimization process. The second part is the updating of the BFGS matrices and vectors.

The costs of the function evaluation and of its gradient scale linearly with the number of optical sources N_q. Since each forward problem and its corresponding adjoint problem cost about the same, each gradient calculation (about $2N_q$ forward solves) is approximately twice as expensive as a function evaluation (about N_q forward solves). The cost in updating BFGS matrices and vectors can be neglected compared to function and gradient evaluations. The reason is that BFGS vectors (in $\mathbb{R}^{2N}$) are dramatically smaller than the vectors appearing in the forward and adjoint problems (in $\mathbb{C}^{JN}$).

In our computations, we store the nonzero elements of the matrix $\mathbf{A} - \mathbf{S}$ by using the compressed row storage scheme [9] whenever it is possible to do so. When it is not possible to store $\mathbf{A} - \mathbf{S}$, we store $\mathbf{A}$, $\mathbf{C}_0$, $\mathbf{K}$, and $\mathbf{D}_0$ defined in (3.12) and (3.13). This requires much less memory, but with the price that extra effort has to be paid to evaluate matrix vector products in GMRES. We use the following procedure to compute $\mathbf{Y} \equiv (\mathbf{A} - \mathbf{S})\mathbf{X}$ for any vector $\mathbf{X}$ with the same structure as $\mathbf{U}$ in (3.11):

1. For $j = 1, \ldots, J$,
   - Compute $\mathbf{X}'_j = \mathbf{D}_0 \mathbf{X}_j$;
   - Compute $\mathbf{X}''_j = \mathbf{C}_0 \mathbf{X}_j$;
   - Compute $\mathbf{X}''_j = \mathbf{X}''_j + \mathbf{A}_j \mathbf{X}_j$;
2. For $j = 1, \ldots, J$, $\mathbf{Y}_j = \mathbf{X}''_j - \sum_{j'} \mathbf{K}_{jj'} \mathbf{X}'_j$.

We prefer to store the matrix $\mathbf{A} - \mathbf{S}$ because it saves computational time when matrix-vector products are calculated. In all the numerical examples shown in the following section, we were able to store $\mathbf{A} - \mathbf{S}$. Note that the storage requirement does not increase with the number of sources (N_q) because we solve the transport equation (and its adjoint) with different sources sequentially. The storage cost of BFGS vectors can be neglected compared with the storage of the forward and adjoint matrices and vectors.

5. Numerical examples. We provide in this section four numerical examples that illustrate the performance of our numerical method. In the first example, we reconstruct the spatial distribution of the absorption coefficient while keeping the scattering coefficient fixed. In the second example, the spatially varying scattering coefficient is reconstructed, while the absorption coefficient is fixed. We then show an example in which both optical properties are reconstructed simultaneously. All the first three examples are done in two-dimensional settings. In the fourth example, we show three-dimensional simultaneous reconstructions of both optical properties.

5.1. Domain partition and measurement setup. For our two-dimensional simulations, we consider a computational domain of size 2×2 cm^2, denoted by $\overline{\mathcal{D}} \equiv \mathcal{D} \cup \partial\mathcal{D} = [0, 2] \times [0, 2]$. We cover the domain by 80×80 cells of uniform size whose nodes are given by

$$\mathcal{D}_h = \{\mathbf{x}_{i,j} = (x_i, y_j),\ x_i = i\Delta x,\ y_j = j\Delta y,\ i, j = 0, 1, \ldots, 80\},$$

with $\Delta x = \Delta y = 0.025$. The direction space is discretized into 128 uniformly distributed (over $[0, 2\pi)$) directions with identical quadrature weight:

$$S^1_{\Delta\theta} = \{\boldsymbol{\theta}_i : \boldsymbol{\theta}_i = (i-1) * \Delta\theta,\ i = 1, \ldots, 128\},$$

where $\Delta\theta = 2\pi/128$. The above discretizations yield a total number of 819,200 unknowns for one forward problem (solving for $\mathbf{U}$ in (3.10)), which is also true for the corresponding adjoint problem ($\boldsymbol{\Psi}$ in (3.21)). In all two-dimensional simulations, four sources ($N_q = 4$) are used. They are located at $(0, 1)$, $(1, 0)$, $(2, 1)$, and $(1, 2)$, respectively. For each sources, 20 detectors ($N_d = 20$) are used. The detectors are uniformly distributed along the sides of the square.

For the three-dimensional simulation, we consider a cylindrical domain given by

$$\overline{\mathcal{D}} := \{(x, y, z) : x^2 + y^2 \leq 1; 0 \leq z \leq 2\}.$$

We cover the domain by 22,022 tetrahedral elements. For the integration over S^2, we employ the full level symmetric S_8 discrete ordinate set of [44]. This set consists of 80 directions. A total number of 16 sources ($N_q = 16$) are used in the simulation. The sources are uniformly distributed on the two circles defined by $\Gamma^q_i = \{(x, y, z) : x^2 + y^2 = 1;\ z = z_i\}$ ($i = 1, 2$), where $z_1 = 0.5$, $z_2 = 1.5$. We arrange 8 layers of detectors on the boundary of the domain. Each layer has 16 detectors Those detectors are located at $\Gamma^d_j = \{(x, y, z) : x^2 + y^2 = 1;\ z = z_j\}$ ($j = 1, \ldots, 8$), with $z_j = 0.3 + (j-1) * 0.2$. Note that some detectors are placed on the same xy-plane as sources (but they do not overlap each other).

5.2. Generating synthetic data. In all the numerical reconstructions presented in section 5, the "measurements" are synthetic rather than obtained from real experimental data. A straightforward way of generating synthetic data is to use the same discretization for the forward model and for the inversion procedure. This may lead to somewhat simplified inversions of the finite-dimensional problem, which is often referred to as [illegible] in the inverse problems community [15, p. 133]. To avoid committing these "crimes," the data are generated with a discretization about twice as fine (in all variables) as the discretization used in the inversions.

In the following sections, our "exact data" will thus be those obtained from the fine mesh calculations. By noisy data, we mean the "exact data" polluted by additional multiplicative noise. Let z_d be the exact data; the "noisy" data are simulated according to the rule $z_d^\delta = (1 + \delta * \text{random}) z_d$, where "random" is a uniformly distributed random variable in $[-1, 1]$ and $\delta \geq 0$ will vary in our numerical simulations.

It should be noted that the "exact data" seen on the coarse grid used in the inversion actually already contain some "noise" because they were generated by the fine mesh calculations.

5.3. Single parameter reconstructions. We start with a simpler case where only one optical parameter needs to be reconstructed. Such reconstructions are often useful in practical applications. For example, it is generally believed that changes in the oxygenation of tissues correspond mainly to changes in the absorption property of tissues [58].

[illegible] 1: [illegible] σ_a. We first reconstruct a small absorbing disc centered at (1.15 cm, 1.15 cm) of radius 0.2 cm embedded in the two-dimensional computational domain. The optical parameters for the background and the disc are $\sigma_a = 0.1$ cm^{-1}, $\sigma_s = 80$ cm^{-1} and $\sigma_a = 0.2$ cm^{-1}, $\sigma_s = 80$ cm^{-1}, respectively. The anisotropy factor $g = 0.90$. Those are typical parameter values as they are encountered in biomedical applications. The modulation frequency of the source is $\omega = 600$ MHz. Each reconstruction here takes approximately 5 hours on a 2.4 GHz Pentium XEON processor.

Figure 5.1 shows the real absorption map and the reconstructed maps for different noise levels. We also provide in Figure 5.2 (A) (solid line) the evolution of the normalized objective function versus the iteration step in the case of reconstructions using noise-free synthetic data. Note that although the total number of BFGS iterations can be reduced by using a stricter line search scheme in the optimization algorithm, the total computational time remains almost constant. We have tested many classical line search algorithms. The results shown here use the one that works best for our application.

The quality of the reconstructions is measured as follows. Denote by $M^o \in \mathbb{R}^N$ ($M^r \in \mathbb{R}^N$) an exact (reconstructed) quantity, which can be either the absorption or the scattering map. We then define the relative l^2 error between M^o and M^r by

$$\mathcal{E}_{l^2} = \frac{\|M^r - M^o\|_{l^2}}{\|M^o\|_{l^2}} := \frac{\sqrt{\sum_{i=1}^N (M_i^r - M_i^o)^2}}{\sqrt{\sum_{i=1}^N (M_i^o)^2}}. \tag{5.1}$$

The quality of the reconstruction in the case of an absorbing disc is given by the parameters shown in the second column of Table 5.1. In Figure 5.2 (B), we display the L-curve we use to choose the optimal parameter β in the above reconstructions. We mention again that due to the acquisition of our data presented in section 5.2, the noise-free data actually contain "noise" on the coarse grid.

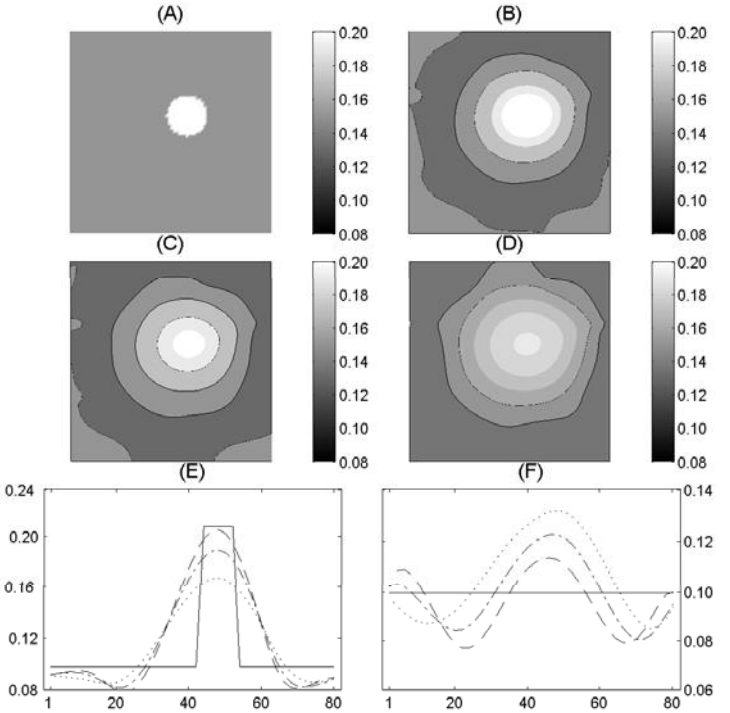

FIG. 5.1. *Maps of the reconstructed absorption coefficient* σ_a $[cm^{-1}]$ *in Example* 1. (A) *Real absorption map.* (B) *Reconstructed absorption map with exact synthetic data.* (C) *Reconstruction with* 10% *random noise.* (D) *Reconstruction with* 20% *random noise.* (E) *Cross sections of map* (A) *(solid line),* (B) *(dashed line),* (C) *(dash-dotted line), and* (D) *(dotted line) along the bottom left to top right diagonal.* (F) *Same as* (E) *except that the cross section is along* $y = 0.4$.

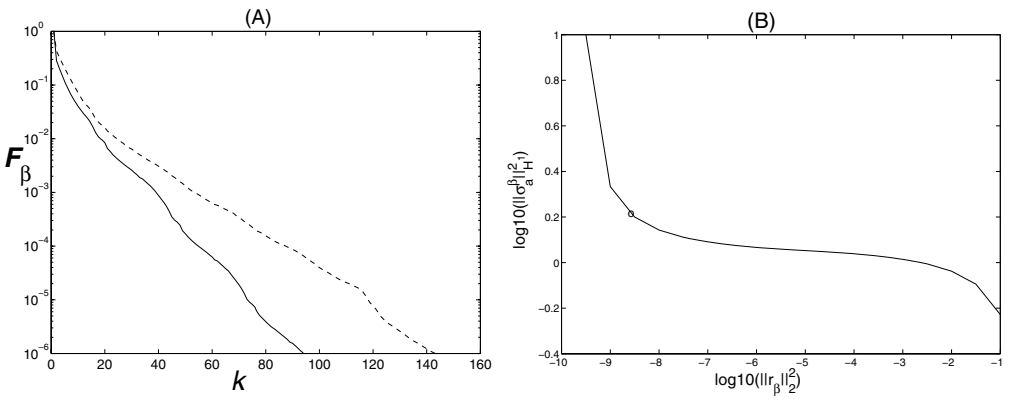

FIG. 5.2. (A) *Evolution of normalized objective functional* $\mathcal{F}_\beta$ *with respect to the number of iteration steps* k *for Example* 1. *Solid line: reconstruction of an absorbing disc; dashed line: reconstruction of a scattering disc.* (B) *L-curve used to choose optimal regularization parameter* β *for reconstruction with noise-free data in the reconstruction of an absorbing disc. The circle* (○) *denotes the place where* β *is chosen. Note that here* $\mathcal{J} = \|\sigma_a\|^2_{\mathcal{H}^1}$ *because we reconstruct only* σ_a *and we have set* $\sigma_a^0 = 0$.

TABLE 5.1
Optimal regularization parameters β and errors in reconstructions for different cases in Examples 1 *and* 2.

Cases	Absorbing disc			Scattering disc		
Noise level	0%	10%	20%	0%	10%	20%
$\beta \times 10^8$	1.0	2.8	4.6	1.3	2.9	5.7
$\mathcal{E}_{l^2}$	0.064	0.069	0.072	0.065	0.074	0.080

The reconstructions are classical examples of what we may expect in the field. Because of the severe ill-posedness of the inverse problem, it is difficult to reconstruct localized objects unless additional information is included in the reconstruction (which we do not want to do here). Note that the center and the integral of the absorption inclusion are more or less well reconstructed, even if the localized absorption map is somewhat smeared over a relatively large domain (whose size increases as the noise level, whence the regularization parameter β, increases). This is consistent with results obtained from asymptotic theories; see, for instance, [7].

2: σ_s. We now replace the highly absorbing disc in the previous case with a highly scattering disc in the same position and with the same size. The optical parameters for the background and the disc are $\sigma_a = 0.1$ cm^{-1}, $\sigma_s = 70$ cm^{-1} and $\sigma_a = 0.1$ cm^{-1}, $\sigma_s = 80$ cm^{-1}, respectively. Again, the anisotropy factor $g = 0.9$, and the modulation frequency $\omega = 600$ MHz. Each reconstruction here takes approximately 6 hours on a 2.4 GHz Pentium XEON processor. Figure 5.3 shows the exact scattering map and the reconstructed maps for different noise levels. Error estimates are presented in the third column of Table 5.1.

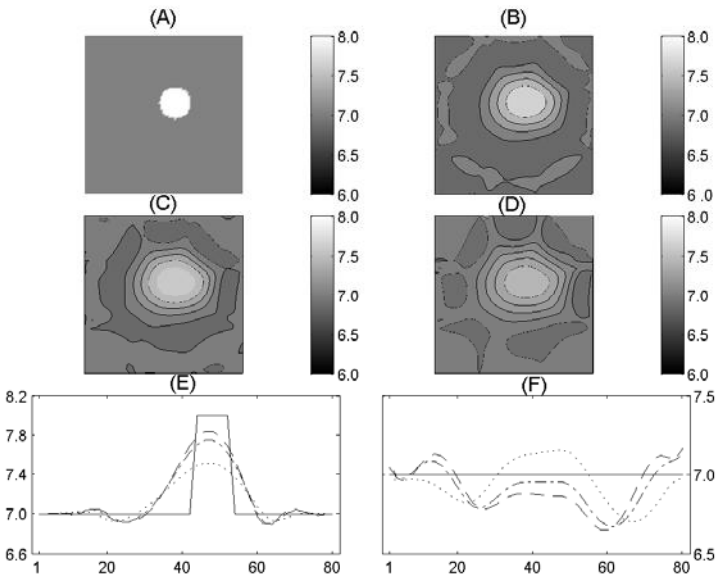

FIG. 5.3. *Maps of reconstructed reduced scattering coefficients $\sigma_s' = (1-g)\sigma_s$ [cm^{-1}] for Example* 1. (A) *Real scattering map.* (B) *Reconstructed scattering map with noise-free synthetic data.* (C) *Reconstruction with* 10% *random noise.* (D) *Reconstruction with* 20% *random noise.* (E) *Cross sections of map* (A) *(solid line),* (B) *(dashed line),* (C) *(dash-dotted line), and* (D) *(dotted line) along the bottom left to top right diagonal.* (F) *Same as* (E) *except that the cross section is along $y = 0.4$.*

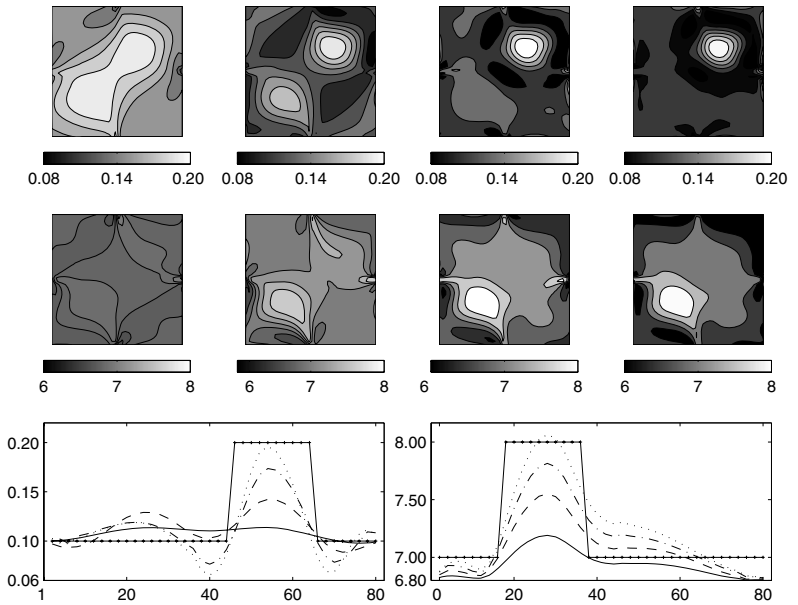

FIG. 5.4. *Top row: Maps of reconstructed absorption coefficients* σ_a $[cm^{-1}]$ *at BFGS iteration* $k = 40$, 80, 120, *and* 156 *(final), respectively, for the frequency domain reconstruction in Example* 3. *Middle row: same as the top row but for the reduced reconstructed scattering coefficients* $\sigma_s' = (1-g)\sigma_s$ $[cm^{-1}]$. *Bottom row: cross section of real (solid line with +) and reconstructed absorption maps (left), reduced scattering maps (right) along the diagonal at iterations* $k = 40$ *(solid line),* 80 *(dashed line),* 120 *(dash-dotted line), and* 156 *(dotted line). The reconstructions are done with noise-free synthetic data.*

The quality of the reconstructions is very similar in the above two examples and is quite satisfactory. In spite of the fact that stronger regularizations have to be imposed as the noise level increases, the localization and the estimate for the optical parameters in the presence of moderate noise indeed allow us to obtain reasonably accurate information toward diagnostic purposes.

5.4. Frequency-domain versus steady-state. One of the main reasons for introducing frequency-domain reconstructions is that they allow for a better separation between the scattering and absorption properties of the inclusions [48]. Diffusion-based theories show that both coefficients cannot be reconstructed simultaneously without additional geometrical hypotheses [5, 33]. We now show in two numerical examples that frequency-domain data indeed substantially improve the reconstruction of both coefficients.

[illegible] 3: [illegible]. We reconstruct here in the square domain two small discs of radius 0.2 cm and centered at (1.35 cm, 1.35 cm) and (0.65 cm, 0.65 cm), respectively. The first disc is highly absorbing and the second one is highly scattering. Optical properties for the two discs are $\sigma_a = 0.2$ cm^{-1}, $\sigma_s = 70$ cm^{-1} and $\sigma_a = 0.1$ cm^{-1}, $\sigma_s = 80$ cm^{-1}, respectively. The background parameters are $\sigma_a = 0.1$ cm^{-1} and $\sigma_s = 70$ cm^{-1}. As before, $g = 0.9$ and $\omega = 600$ MHz. Each reconstruction takes approximately 8 hours on a 2.4 GHz Pentium XEON processor.

We compare the reconstructions based on the frequency-domain ERT with those based on the steady-state ERT. The latter is obtained by setting the frequency $\omega = 0$

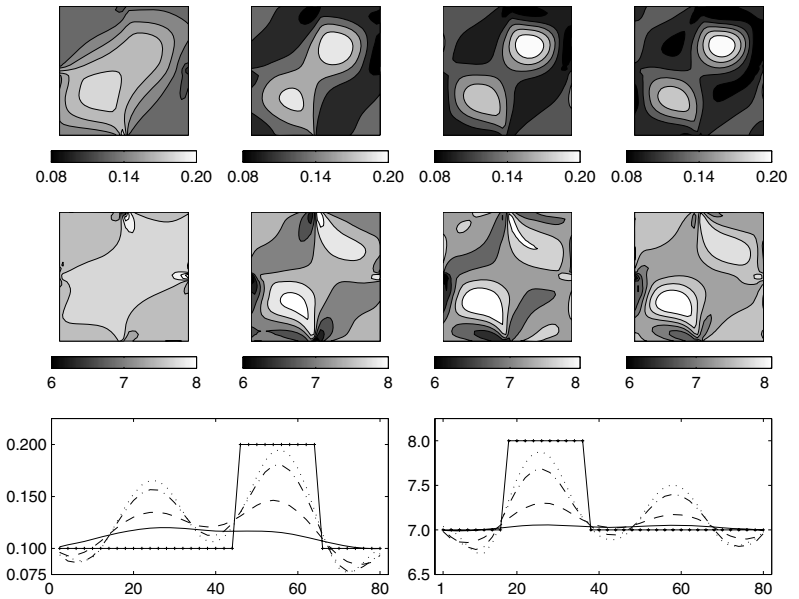

FIG. 5.5. *Top row: Maps of reconstructed absorption coefficients* σ_a $[cm^{-1}]$ *at BFGS iteration* $k = 40$, 80, 120, *and* 354 *(final), respectively, for the steady-state reconstruction in Example* 3. *Middle row: same as the top row but for the reduced reconstructed scattering coefficients* $\sigma_s' = (1-g)\sigma_s$ $[cm^{-1}]$. *Bottom row: cross section of real (solid line with +) and reconstructed absorption maps (left), reduced scattering maps (right) along the diagonal at iterations* $k = 40$ *(solid line),* 80 *(dashed line),* 120 *(dash-dotted line), and* 354 *(dotted line). The reconstructions are done with noise-free synthetic data.*

TABLE 5.2

Error estimates for the reconstructions of Example 3 (*E*3) *and Example* 4 (*E*4) *for several iteration steps* (k) *in the optimization process. Here, "f" refers to frequency-domain calculations and "s" to steady-state calculations.*

		$k = 40$		$k = 80$		$k = 120$		Final	
		σ_a	σ_s	σ_a	σ_s	σ_a	σ_s	σ_a	σ_s
*E*3	$\mathcal{E}_{l^2}(f)$	0.121	0.144	0.092	0.112	0.080	0.092	0.063	0.076
	$\mathcal{E}_{l^2}(s)$	0.181	0.224	0.127	0.132	0.113	0.112	0.094	0.106
*E*4	$\mathcal{E}_{l^2}(f)$	0.194	0.252	0.173	0.208	0.147	0.189	0.131	0.171
	$\mathcal{E}_{l^2}(s)$	0.342	0.422	0.287	0.366	0.245	0.322	0.210	0.292

in our formulation and keeping everything else the same. Note that we observe a slight difference (below 5%) in the computational times required for the case when $\omega = 0$ and the case when $\omega \neq 0$. We present in Figures 5.4 and 5.5 the reconstructions obtained by the frequency-domain method and the steady-state method, respectively. We also list the parameters which measure the quality of the reconstructions at different iteration steps in Table 5.2.

4: . In the last numerical test, we show simultaneous reconstructions of two optical properties in a three-dimensional setting. We try to reconstruct a small cylinder $\overline{\mathcal{D}}_s = \{(x, y, z) : (x - 0.5)^2 + y^2 \leq 0.2^2,\ 0 \leq z \leq 2\}$ embedded in the cylindrical domain defined in section 5.1. Both the absorption and the scattering coefficients of the small cylinder are

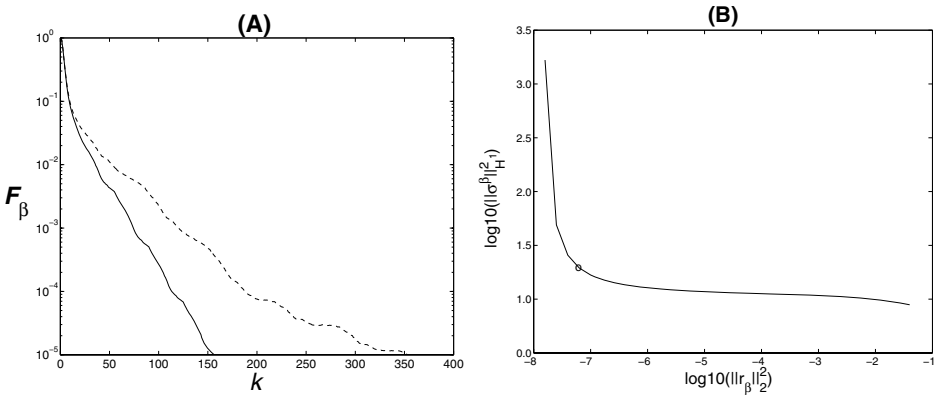

FIG. 5.6. (A) *Evolution of the normalized objective functional $\mathcal{F}_\beta$ with respect to the number of iteration steps k for Example* 3. *Solid line: frequency domain reconstruction of both coefficient simultaneously; dashed line: steady-state reconstruction of both coefficients simultaneously.* (B) *L-curve used to choose optimal regularization parameter β for reconstruction with noise-free data in the frequency domain simultaneous reconstruction of absorbing and scattering coefficients. The circle* ($\circ$) *denotes the place where β is chosen. Note that $\mathcal{J} \equiv \|\boldsymbol{\sigma}^\beta\|^2_{\mathcal{H}^1} := \|\sigma_a^\beta\|^2_{\mathcal{H}^1} + \epsilon\|\sigma_s^\beta\|^2_{\mathcal{H}^1}$ because we have set $\sigma_a^0 = \sigma_s^0 = 0$.*

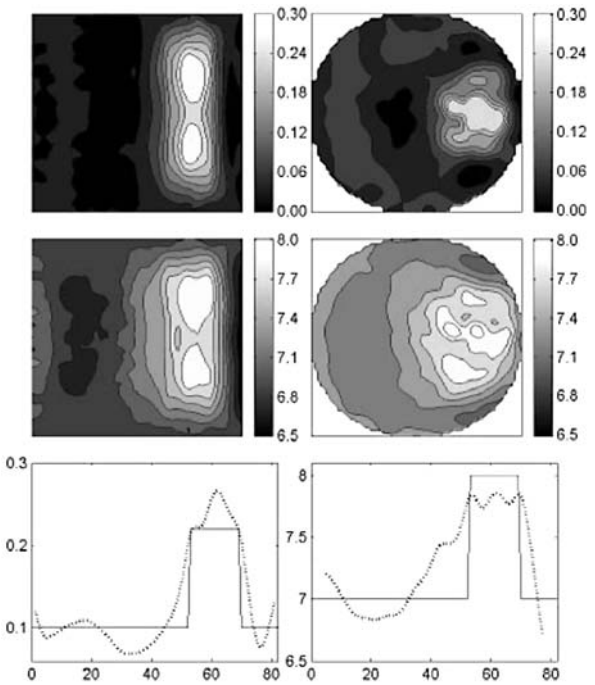

FIG. 5.7. *Top row: xy cross section (at $z = 1$) and xz cross section (at $y = 0$) of the reconstructed absorption coefficient σ_a $[cm^{-1}]$ for the frequency-domain reconstruction in Example* 4. *Middle row: same as the top row but for the reduced reconstructed scattering coefficients $\sigma_s' = (1-g)\sigma_s$ $[cm^{-1}]$. Bottom left: real (solid) and reconstructed (dotted) absorption coefficient along line $y = 0$, $z = 1$. Bottom right: same as bottom left but for reconstructed reduced scattering coefficient.*

different from those of the background. This is different from the case in Example 3 where absorption and scattering anomalies are located at different places. Optical properties for the small cylinder are $\sigma_a = 0.2$ cm^{-1} and $\sigma_s = 80$ cm^{-1}, while those for the background are $\sigma_a = 0.1$ cm^{-1} and $\sigma_s = 70$ cm^{-1}. The anisotropy factor $g = 0.9$ and the modulation frequency $\omega = 600$ MHz. Each reconstruction takes approximately 22 hours on a 3 GHz Pentium XEON processor. As in Example 3, we compare the frequency-domain reconstructions with the steady-state reconstructions. Cross sections of reconstructions obtained by the frequency-domain method and the steady-state method are presented in Figures 5.7 and 5.8, respectively. Qualities of the reconstructions at different iteration steps are again listed in Table 5.2.

We first observe that in both the two-dimensional (Example 3) and the three-dimensional (Example 4) reconstructions, the frequency-domain reconstruction converges faster (in terms of BFGS iterations) than the steady state reconstruction; see, for example, the results in Figure 5.6 (A) and Table 5.2. This has been confirmed in many other geometrical settings we have tested: the speed of convergence of the steady-state reconstruction presented here is one of the most favorable we have obtained, whereas the speed of convergence of the frequency-domain reconstructions was very often similar to what we have presented here.

As far as quality of the reconstruction is concerned, we observe a significant improvement in the frequency domain reconstructions compared to the steady-state

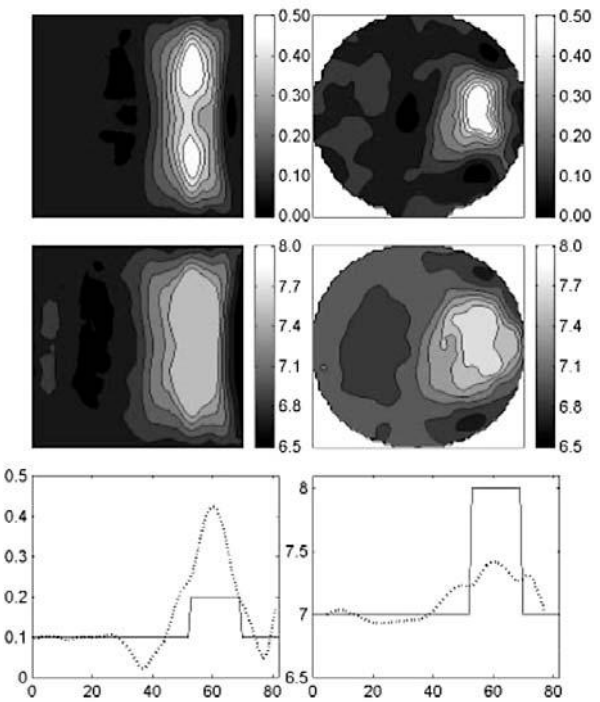

FIG. 5.8. *Top row: xy cross section (at $z = 1$) and xz cross section (at $y = 0$) of the reconstructed absorption coefficient σ_a $[cm^{-1}]$ for the steady-state reconstruction in Example 4. Middle row: same as the top row but for the reduced reconstructed scattering coefficients $\sigma_s' = (1-g)\sigma_s$ $[cm^{-1}]$. Bottom left: real (solid) and reconstructed (dotted) absorption coefficient along line $y = 0$, $z = 1$. Bottom right: same as bottom left but for reconstructed reduced scattering coefficient.*

reconstructions. In all simulations, the stopping criterion is the same:

$$\frac{\mathcal{F}_\beta^k(\sigma_a, \sigma_s)}{\mathcal{F}_\beta^0(\sigma_a, \sigma_s)} \leq 10^{-5}.$$

Although the L^2 errors may not enjoy a dramatic improvement (see Table 5.2), they are still significantly reduced. More importantly, the last rows in Figures 5.4 and 5.5 show dramatic reductions (at least by a factor of 2) of the cross-talk between the absorption and scattering reconstructions: the spurious bumps (left of the left picture on the bottom row and right of the right picture on the bottom row in Figures 5.4 and 5.5) are clearly much stronger in the steady-state calculations than in the frequency-domain calculations. This is the major advantage of the frequency-domain calculations. Very similar phenomena are observed in the three-dimensional simulations; see Figures 5.7 and 5.8. Although the absorption coefficient is still overestimated in the frequency-domain case (last row of Figure 5.7), it is better than the situation in the steady-state case (last row of Figure 5.8) where the absorption coefficient σ_a is severely overestimated, while the reduced scattering coefficient σ_s' is severely underestimated. As predicted by theory, we have observed that an increase in ω led to reduced cross-talk. How much this effect depends on the choice of the frequency (as well as on possible combinations of different frequencies) and on the geometrical setting will be explored in future works.

6. Concluding remarks. We have formulated an inverse problem in optical tomography as a regularized least-squares problem based on the frequency-domain equation of radiative transfer to model light propagation in biological tissues. In the inversion procedure, the forward model is discretized by using a finite volume method and a discrete ordinates method. We solve the regularized least-squares problem by using a limited-memory quasi-Newton method with BFGS-type updating rule for the Hessian matrix and have incorporated positivity constraints and L^∞ bounds on the optical parameters. Numerical reconstructions based on synthetic data provide results that are in agreement with the expected reconstructions. Notably, the crosstalk between the two optical parameters is significantly reduced in frequency-domain reconstructions.

The method presented here also overcomes several of the shortcomings of diffusion-equation-based optical tomography [4, 16], which provides a very useful tool in many problems but fails to adequately model strongly absorbing regions (e.g., large blood-filled spaces such as brain hematoma), low-scattering void-like inclusions (e.g., spaces filled with cerebrospinal fluid, amniotic fluid, or synovial fluid), and optically relatively thin media such as fingers and small animals. Main domains of application of the proposed method will be functional imaging of rheumatoid arthritis of human finger joints and small animal imaging [30, 32], where the diffusion equation typically fails to generate accurate forward predictions. Extensive numerical reconstructions in practically relevant geometries for these applications and based on possibly multifrequency experimental data will be performed in the near future.

Acknowledgment. We would like to thank the two anonymous referees for their many constructive comments and suggestions.

MOVING MESH METHODS FOR SINGULAR PROBLEMS ON A SPHERE USING PERTURBED HARMONIC MAPPINGS*

YANA DI†, RUO LI†, TAO TANG‡, AND PINGWEN ZHANG†

Abstract. This work is concerned with developing moving mesh strategies for solving problems defined on a sphere. To construct mappings between the physical domain and the logical domain, it has been demonstrated that harmonic mapping approaches are useful for a general class of solution domains. However, it is known that the curvature of the sphere is positive, which makes the harmonic mapping on a sphere not unique. To fix the uniqueness issue, we follow Sacks and Uhlenbeck [*Ann. of Math.* (2), 113 (1981), pp. 1–24] to use a perturbed harmonic mapping in mesh generation. A detailed moving mesh strategy including mesh redistribution and solution updating on a sphere will be presented. The moving mesh scheme based on the perturbed harmonic mapping is then applied to the moving steep front problem and the Fokker–Planck equations with high potential intensities on a sphere. The numerical experiments show that with a moderate number of grid points our proposed moving mesh algorithm can accurately resolve detailed features of singular problems on a sphere.

Key words. moving mesh methods, singularity, harmonic mapping, perturbed harmonic mapping, spherical domain

1. Introduction.

In this work, we will consider efficient moving mesh methods for solving singular problems on a sphere. Partial differential equations (PDEs) defined on a sphere are seen in many practical cases such as polymer rheological analysis, ocean modeling, and global climate simulation. The moving mesh technique is one of the natural choices for solving problems with localized moving singularities. Examples include moving internal boundaries or interfaces separating different regions which are present in many problems in nature, such as interfaces separating two different fluids in a multiphase flow, and between solid and liquid regions in a solidification process. Such interfaces are in general dynamic, i.e., they evolve in time. Moving mesh methods have been proved powerful for solving time-dependent PDEs in two-dimensional domains and simple three-dimensional domains [2, 3, 4, 5, 24, 30, 31, 34].

In general, a moving mesh method always involves a logical domain and a physical domain, together with a transformation between them. In [12], Dvinsky suggests that harmonic function theory may provide a general framework for developing useful mesh generators. His method can be viewed as a generalization and extension of Winslow's method [33]. However, unlike most other generalizations which add terms

or functionals to the basic Winslow grid generator, his approach uses a single functional to accomplish the adaptive mapping. The critical points of this functional are [illegible]. Meshes obtained by Dvinsky's method enjoy desirable properties of harmonic maps, particularly regularity, or smoothness [15, 27]. Motivated by the work of Dvinsky, a moving mesh finite element strategy based on harmonic mapping was proposed and studied by the authors in [21]. The key idea of this strategy is to construct the harmonic map between the physical space and a parameter space by an iteration procedure.

For two-dimensional domains or three-dimensional cubic domains as considered in [21, 22], the metric on the logical domain is Euclidean. Consequently, the construction of the harmonic mapping only solves some linear equations. However, this is not the case for spherical problems. In fact, if the physical domain is a sphere, then it is natural to set the logical domain as a sphere rather than a convex polygon as used in [21]. In this case, the fact that the curvature of a sphere is positive makes harmonic mappings on spheres not unique. Another difficulty is that the metric on the unit sphere is not an identity anymore, which is different from the cases considered before; see, e.g., [21]. Our goal is to construct a transformation which preserves the good properties of harmonic mappings such as smoothness and uniqueness. Moreover, a scheme for solving the nonlinear equation induced by the metric on a sphere will be designed.

Motivated by the work of Sacks and Uhlenbeck [26], we will use the so-called perturbed harmonic mapping to construct a unique mapping between the physical and logical spaces. It will be seen that perturbed harmonic mappings are useful for handling spherical domains. The nonlinear Euler–Lagrange equations from minimizing the mesh energy functional will be solved by a local Gauss–Seidel-like iterative method. The numerical experiments indicate that a satisfactory approximation to the perturbed harmonic mapping can be obtained using only a few iteration steps. Furthermore, a key step for the moving mesh method is to obtain an improved new mesh based on the underlying numerical solutions and the old meshes. With the spherical geometry, the mesh redistribution has to be designed carefully: efforts have to be made to ensure that the mesh movement occurs only on the sphere, and that all the grid points stay on the sphere during the whole process of mesh redistribution. In this work, appropriate mesh redistribution and solution updating strategies will be investigated.

The rest of the paper is arranged as follows. In section 2, the theory of the perturbed harmonic mapping on a sphere will be briefly reviewed. Section 3 describes the general framework of the moving mesh method on a sphere, including some details of the mesh-redistribution and solution-updating strategies. In section 4, the proposed moving mesh scheme will be applied to solve moving shocks on a sphere and the Fokker–Planck equations derived from liquid crystal simulations. For the latter problem, the solutions of the problem tend to a delta function when the strength of the excluded volume potential is large (see [20]). With a uniform mesh, an extremely fine mesh is required in order to obtain reasonable resolution, but the efficiency can be enhanced significantly by using moving mesh methods. Some concluding remarks will be given in the final section.

2. Perturbed harmonic mapping. Let Ω and Ω_c be compact Riemannian manifolds of dimension n with metric tensors d_{ij} and $r_{\alpha\beta}$ in some local coordinates $\vec{x}$ and $\vec{\xi}$, respectively. The energy density of a mapping $\vec{\xi}: \vec{x} \mapsto \vec{\xi}$ is defined by

$$e(\vec{\xi}) = G^{ij} g_{\alpha\beta} \frac{\partial \xi^\alpha}{\partial x^i} \frac{\partial \xi^\beta}{\partial x^j}, \tag{2.1}$$

where the standard summation convention is assumed. The corresponding energy functional is then defined by

$$E(\vec{\xi}) = \int_\Omega e(\vec{\xi})dx. \tag{2.2}$$

The harmonic mapping is the mapping which minimizes the above energy functional.

Existence and uniqueness of the harmonic map are guaranteed, provided the Riemannian curvature of Ω_c is nonpositive and its boundary convex (see Hamilton [15] and Schoen and Yau [27]). However, this result does not apply to the case when the physical and logical domains are spheres, i.e., $\Omega = \Omega_c = \mathcal{S}^2$; in this case, the Riemannian curvature of Ω_c is positive. In fact, the energy functional (2.2) has the conformal invariance [26], which leads to nonuniqueness of the harmonic mappings. To recover the uniqueness, we follow the work of Sacks and Uhlenbeck [26] to employ a so-called perturbed harmonic mapping approach. More precisely, let

$$E_\alpha(\vec{\xi}) = \int_\Omega (1 + e(\vec{\xi}))^\alpha dx, \tag{2.3}$$

with $\alpha > 1$. It is noted that when $\alpha = 1$ the functionals (2.3) and (2.2) are equivalent. It is known that the Sobolev space of mappings,

$$L_1^{2\alpha}(M, N) = \{\xi \in L_1^{2\alpha}(M, R^k) : \xi(x) \in N\} \subset C^0(M, N), \tag{2.4}$$

is a C^2 separable Banach manifold for $\alpha > 1$ [25]. In particular, it is shown in [26] that if $\alpha > 1$, then the critical mappings of E_α in $L_1^{2\alpha}(M, N)$ are C^∞ and are unique in the sense of isometric transformation. Such regularity and uniqueness results provide a sound theoretical background for the moving mesh method based on the perturbed harmonic mappings.

The Euler–Lagrange equation of the energy functional (2.3) is given by

$$-\Delta_{\mathrm{L-B}}\xi^l - (\alpha - 1)\frac{\nabla|\nabla\xi|^2 \cdot \nabla\xi^l}{|\nabla\xi|^2} + [A(\xi)(d\xi, d\xi)]^l = 0, \tag{2.5}$$

where $\Delta_{\mathrm{L-B}}$ stands for the Laplace–Beltrami operator,

$$\Delta_{\mathrm{L-B}} f = \frac{1}{\sqrt{G}} \sum_{i,j} \frac{\partial}{\partial x^i} \left(\sqrt{G} G^{ij} \frac{\partial f}{\partial x^j} \right),$$

and $A(\xi)$ is the second fundamental form of Ω_c. For a sphere, it is known that

$$A(\xi)(d\xi, d\xi) = -|\nabla\xi|^2 \xi. \tag{2.6}$$

Moreover, the derivatives in curvilinear coordinates are given by

$$(\nabla\xi^m)^j = G^{ij} \frac{\partial \xi^m}{\partial x^i},$$
$$\left(\nabla|\nabla\xi|^2\right)^j = G^{ij} \frac{\partial}{\partial x^i} \left(\sum_t G^{kl} \frac{\partial \xi^t}{\partial x^k} \frac{\partial \xi^t}{\partial x^l} \right).$$

Consequently, the Euler–Lagrange equation (2.5) can be written in the following divergence form:

$$-\nabla \cdot \left(\alpha |\nabla\xi|^{2(\alpha-1)} \nabla\xi^l \right) + \alpha |\nabla\xi|^{2(\alpha-1)} [A(\xi)(d\xi, d\xi)]^l = 0. \tag{2.7}$$

Using the Stokes law, we can get the weak form of the above equation:

$$\int_{\mathcal{S}^2} \left\{ \sum_l |\nabla\xi|^{2(\alpha-1)} \nabla\xi^l \cdot \nabla\lambda^l - \sum_l |\nabla\xi|^{2\alpha} \xi^l \lambda^l \right\} dV = 0 \qquad \forall \lambda \in L_1^{2\alpha}(M,N). \tag{2.8}$$

The way of obtaining the mapping for the perturbed equation (2.7) is similar to that used for obtaining the conventional harmonic mappings described in [21, 22]. It is shown that with the harmonic mappings the metric distortion can be minimized [13, 26]. Moreover, it is expected that the mesh associated with the mapping (2.7) has certain smoothness and uniqueness.

In this work, the perturbed harmonic mapping will be used to generate adaptive meshes for unstructured triangles in spherical domains. We point out that there are several other successful ways for adaptive remeshing also by minimizing the mesh energy function that depends on the local physical scales; see, e.g., Anderson, Zheng, and Cristini [1], Liao et al. [23], Sun and Huang [17], and Wang and Wang [32].

3. Moving mesh methods for spherical domain. Consider the time-dependent PDEs on a sphere $\Omega = \mathcal{S}^2$,

$$\Psi_t = \mathcal{L}(\Psi) \qquad \text{in } \Omega \times (0,T], \tag{3.1}$$

where $\mathcal{L}$ is some spatial partial differential operator, with initial value

$$\Psi|_{t=0} = \Psi_0 \qquad \text{in } \Omega. \tag{3.2}$$

Let us consider a moving mesh method based on the perturbed harmonic mappings to solve this time-dependent problem. We triangulate the domain Ω into a mesh $\mathcal{T}_h$ with spherical triangular elements. Equation (3.1) is discretized with finite element approximation on the mesh $\mathcal{T}_h$. Assume a PDE solver is given so that the numerical solution at time level t_{n+1} can be obtained by using the numerical approximation at $t = t_n$. Since our mesh varies with respect to time, we denote the mesh at time step t_n as $\mathcal{T}_h^{(n)}$. The procedure to combine the mesh motion and the PDE solutions is illustrated below:

- [illegible] 0. [illegible] Set $n = 0$ and $t_0 = 0$. Project the initial function on the initial mesh $\mathcal{T}_h^{(0)}$, which gives $\Psi_h^{(0)}$.
- [illegible] 1 [illegible] Obtain the numerical solutions at $t = t_{n+1}$ on the mesh $\mathcal{T}_h^{(n)}$ by an appropriate PDE solver to obtain $\Psi_h^{(n+1)}$.
- [illegible] 2. [illegible] Check the mesh quality by certain criteria; if satisfactory, set $\mathcal{T}_h^{(n+1)} = \mathcal{T}_h^{(n)}$, $n = n+1$, and go to Step 1.
- [illegible] 3. [illegible] Obtain a more appropriate mesh by some mesh moving techniques, as described later in this section.
- [illegible] 4. [illegible] Update the numerical solution $\Psi_h^{(n+1)}$ on the new mesh obtained in Step 3 and go to Step 2.

We point out that the mesh quality (mentioned in Step 2 above) takes into account the shape, alignment, and adaptation features of the elements. For example, the minimum angle, the maximum angle, and the aspect ratio have been used widely to characterize the mesh quality. More details can be found in Huang [18].

3.1. Finite element space on sphere. The sphere is triangulated into a mesh with spherical triangular elements. The Voronoi spherical geodesic grid (see, e.g., [11]) is used in our work. Here we give a finite element space for the discretization

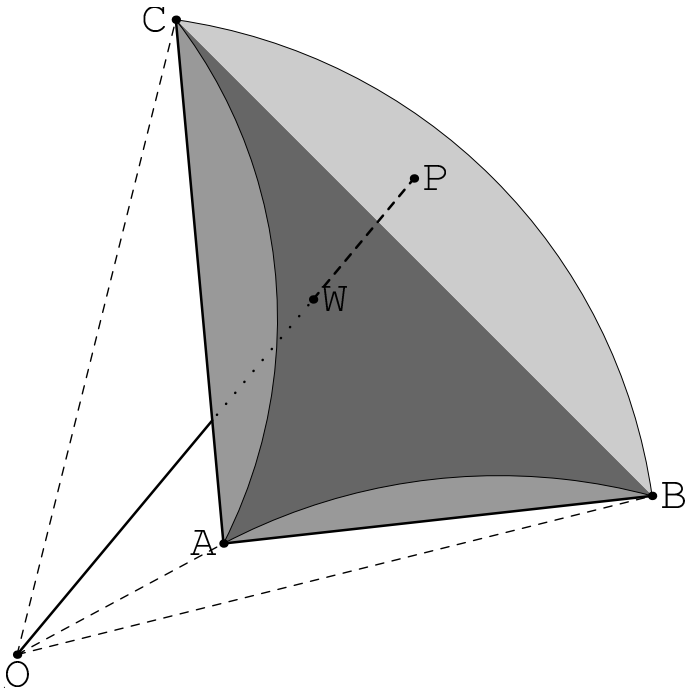

FIG. 1. *The shape function defined on a spherical triangle.*

of the problem (3.1)-(3.2). We will project the linear basis functions of the triangles on polyhedron onto the spherical geodesic triangles. The vertices (counter-clockwise) of a spherical geodesic triangle K are denoted by A, B, and C. The plane triangle K_p has the same vertices. For a point $P \in K$, the intersection point of line $\overrightarrow{OP}$ and K_p is denoted by W (see Figure 1). The three basis functions on spherical geodesic triangle K are defined by

$$\begin{aligned} \lambda_1(\vec{x}) &= \frac{1}{D}(\vec{w} \cdot \vec{a}_2 \times \vec{a}_3), \\ \lambda_2(\vec{x}) &= \frac{1}{D}(\vec{w} \cdot \vec{a}_3 \times \vec{a}_1), \\ \lambda_3(\vec{x}) &= \frac{1}{D}(\vec{w} \cdot \vec{a}_1 \times \vec{a}_2), \end{aligned} \tag{3.3}$$

where

$$\begin{aligned} &\overrightarrow{OA} = \vec{a}_1, \ \ \overrightarrow{OB} = \vec{a}_2, \ \ \overrightarrow{OC} = \vec{a}_3, \ \ \overrightarrow{OP} = \vec{x}, \\ &\overrightarrow{OW} = \vec{w}, \ \ D = (\vec{a}_1 \cdot \vec{a}_2 \times \vec{a}_3), \ \ \vec{w}(\vec{x}) = D\frac{\vec{x}}{\vec{x} \cdot \vec{d}}, \\ &\vec{d} = \vec{a}_1 \times \vec{a}_2 + \vec{a}_2 \times \vec{a}_3 + \vec{a}_3 \times \vec{a}_1. \end{aligned}$$

With this notation, a finite element space on sphere is presented:

$$H_h \triangleq \left\{ \Psi_h \in C^0(\Omega) : \ \Psi_h|_K \in \operatorname{span}\{\lambda_1, \lambda_2, \lambda_3\} \, \forall K \right\}. \tag{3.4}$$

3.2. Mesh redistribution on sphere. A key step for the moving mesh method is to obtain an improved new mesh based on the underlying numerical approximations. In our computations, we simply choose the given physical domain, i.e., the sphere, as the logical domain, and we use the Voronoi spherical geodesic grid (see, e.g., [11]) to generate a quasi-uniform mesh with triangular elements on the logical domain. Obviously, this also gives the initial partition for the physical domain. The nodes in the physical mesh are denoted by X_i, $1 \le i \le N$, and the nodes in the logical mesh by Ξ_i, $1 \le i \le N$. Initially, since we choose the logical mesh the same as the physical mesh, we have $\Xi_i = X_i$. The physical mesh will be redistributed at each time step, while the logical mesh will be kept unchanged during the entire process of the numerical computations. For each time step, by numerically solving the Euler–Lagrange equation (2.7), we can obtain a discrete transformation between the physical domain $\vec{x}_h$ and the logical domain $\vec{\xi}_h$. The logical mesh is then given such that $\Xi_i = \vec{\xi}_h(X_i)$. The metric on the physical domain is given according to the given PDEs and their numerical solution, which is called the [illegible].

On the sphere, there are no local coordinates to cover the whole domain $\mathcal{S}^2$. Therefore, we have to choose suitable local coordinates. The metric for the logical domain is the natural metric of sphere as a submanifold embedded in $\mathbb{R}^3$. Since the Euler–Lagrange equation (2.7) is nonlinear, it will be solved numerically by a point-by-point iterative approach. Assume that we are considering a node in the physical mesh, X_k, whose corresponding node in the logical mesh is denoted by Ξ_k. Denote the set of triangles in the physical domain with X_k as a vertex by $\mathbf{S}_k$ and the corresponding set in the physical domain by $\mathbf{S}_{c,k}$. We will set the local coordinate around X_k in the physical domain and the local coordinate around Ξ_k in the logical domain. It is natural to eliminate one component whose absolute value is the largest among the three components. This will give two-dimensional local coordinates. For example, for $X_k = (x_k^1, x_k^2, x_k^3)$ set, if $|x_k^1| \ge |x_k^2|$ and $|x_k^1| \ge |x_k^3|$, then we will let $(x_k^1, x_k^2) \leftarrow (x_k^2, x_k^3)$ to be the local coordinate around X_k. The same strategy is employed to choose the local coordinate around Ξ_k. We then have the Euler–Lagrange equation (2.7) around the node Ξ_k:

$$\begin{aligned} \nabla \cdot \left(|\nabla \xi|^{2(\alpha-1)} \nabla \xi^l \right) + |\nabla \xi|^{2\alpha} \xi^l = 0 \quad \text{for } l = 1, 2, 3, \\ \xi|_{\partial \mathbf{S}_k} = \xi_b. \end{aligned} \tag{3.5}$$

In the physical domain, around X_k the patch of surface on the unit sphere can be expressed as

$$\left(x^3\right)^2 = 1 - \left(x^1\right)^2 - \left(x^2\right)^2 , \tag{3.6}$$

and the metric of the physical domain is taken as a submanifold embedded in $\mathbb{R}^3$:

$$\tilde{G}^{ij}_{i,j=1,2} = \begin{pmatrix} 1 - \left(x^1\right)^2 & x^1 x^2 \\ x^1 x^2 & 1 - \left(x^2\right)^2 \end{pmatrix}. \tag{3.7}$$

The metric G^{ij} on the physical domain around X_k is then set as

$$G^{ij} = m(u_h)\tilde{G}^{ij}, \tag{3.8}$$

where $m(u_h)$ is the monitor function given for the problem under consideration. The choice of the monitor function m is very subtle, which is an indicator of the solution

singularity and is problem dependent. A general discussion of the monitor function can be found in [6, 29].

Now on the patch of triangles $\mathbf{S}_k$, we will solve a Dirichlet boundary-value problem for (3.5), with linear boundary mapping segmentwise on $\partial\mathbf{S}_k$ determined by the vertex mapping $\Xi_n = \vec{\xi}(X_n)\ \forall X_n \in \mathbf{S}_k, n \neq k$. The mapping in $\mathbf{S}_k$ is approximated by a piecewise linear mapping on every triangle in $\mathbf{S}_k$. Thus the mapping can be given only if $\vec{\xi}(X_k)$ is given. Using the standard Galerkin approximation for (3.5) in $\mathbf{S}_k$, we have only one test function, which is the pyramid-like basis function located at X_k. This gives

$$\int_{\mathbf{S}_k} \left\{ |\nabla\xi|^{2(\alpha-1)} \nabla\xi^l \cdot \nabla\lambda^k - |\nabla\xi|^{2\alpha} \xi^l \lambda^k \right\} dV = 0 \quad \text{for } l = 1,\, 2,\, 3, \tag{3.9}$$

where λ^k is the test function for X_k, which is an algebraic system with order $2\alpha + 1$ for three unknowns. We will solve (3.9) approximately. On $\mathbf{S}_k$, we denote $\vec{\xi}_h$ by

$$\vec{\xi}_h = \sum_n \Xi_n \lambda_h^n + \Xi_k \lambda^k\,, \tag{3.10}$$

where the summation for n is taken over all vertices in $\mathbf{S}_k$ except X_k. By taking $|\nabla\xi|$ in (3.9) explicitly, i.e., ξ_h in $|\nabla\xi|$ takes the currently available Ξ_k as its value at X_k, we then get an explicit approximation for (3.9):

$$\Xi_k^l \approx \frac{\int_{\mathbf{S}_k} \sum_n |\nabla\xi|^{2\alpha} \Xi_n^l \lambda^l \lambda^k dV - \sum_n \int_{\mathbf{S}_k} |\nabla\xi|^{2(\alpha-1)} G^{ij} \Xi_n^l \frac{\partial\lambda^n}{\partial x^i} \frac{\partial\lambda^k}{\partial x^j} dV}{\int_{\mathbf{S}_k} \big(- |\nabla\xi|^{2\alpha} \lambda^k \lambda^k + |\nabla\xi|^{2(\alpha-1)} G^{ij} \frac{\partial\lambda^k}{\partial x^i} \frac{\partial\lambda^k}{\partial x^j} \big) dV}. \tag{3.11}$$

Below we will describe the algorithm for mesh redistribution, which is similar to the one proposed in [21]. In the first step, we iterate for k from 0 to N, using (3.11) to update all logical nodes Ξ_k until convergence (i.e., the difference between the obtained Ξ_k and initial (fixed) $\Xi_k^{(0)}$ is smaller than a given tolerance). The tolerance for the convergence criteria is of the order $\mathcal{O}(h_l)$, where h_l is the typical element size in the logical mesh. The converged result is denoted by $\Xi_k^\star$, and we then get the difference between $\Xi_k^\star$ and the initial logical mesh as

$$\delta\Xi_k = \Xi_k^{(0)} - \Xi_k^\star. \tag{3.12}$$

In the second step, we use the above difference to obtain the mesh redistribution information in the physical mesh difference. Again we will choose the same local coordinate as described above. For a node X_k in the physical mesh, we first compute the mesh motion vector:

$$\delta X_k^l = \frac{\sum_{K\in\mathbf{S}_k} |E| \left.\frac{\partial x^l}{\partial\vec{\xi}}\right|_K \delta\Xi_k}{\sum_{K\in\mathbf{S}_k} |E|} \qquad \text{for } l = 1, 2, \tag{3.13}$$

where the Jacobian matrix $\partial\vec{x}/\partial\vec{\xi}\big|_K$ is computed by using the fact that the linear element is used (see also [21]):

$$\begin{pmatrix} \Xi_{E_1}^1 - \Xi_{E_0}^1 & \Xi_{E_2}^1 - \Xi_{E_0}^1 \\ \Xi_{E_1}^2 - \Xi_{E_0}^2 & \Xi_{E_2}^2 - \Xi_{E_0}^2 \end{pmatrix} \begin{pmatrix} \dfrac{\partial x^1}{\partial\xi^1} & \dfrac{\partial x^1}{\partial\xi^2} \\ \dfrac{\partial x^2}{\partial\xi^1} & \dfrac{\partial x^2}{\partial\xi^2} \end{pmatrix} = \begin{pmatrix} X_{E_1}^1 - X_{E_0}^1 & X_{E_2}^1 - X_{E_0}^1 \\ X_{E_1}^2 - X_{E_0}^2 & X_{E_2}^2 - X_{E_0}^2 \end{pmatrix}; \tag{3.14}$$

and E_0, E_1, and E_2 are the subscripts of the three vertices of the element K in the physical mesh. The coordinate in the third dimension is excluded, as explained earlier (i.e., with the way of choosing the local coordinate). On the other hand, to ensure that the mesh movement occurs only on the sphere, the third component can be recovered by using

$$\delta X_k^3 \to \operatorname{sgn}(X_k^3)\sqrt{1-\left(X_k^1+\delta X_k^2\right)^2-\left(X_k^2+\delta X_k^2\right)^2}-X_k^3. \tag{3.15}$$

In the third step, we will control the magnitude of each redistribution to avoid mesh tangling. For the element $K \in \mathcal{T}_h$ with vertices E_0, E_1, and E_2, we solve the cubic equation (in terms of μ)

$$\det\begin{pmatrix} X_{E_0}+\mu\cdot\delta X_{E_0} & X_{E_1}+\mu\cdot\delta X_{E_1} & X_{E_2}+\mu\cdot\delta X_{E_2} \end{pmatrix}=0, \tag{3.16}$$

where δX_{E_k} is determined by (3.13). Denote the smallest positive root of (3.16) by μ_K. The mesh motion parameter is then set as

$$\mu^\star = \min_{K\in\mathcal{T}_h}\left\{1;\, \mu_K/2\right\}. \tag{3.17}$$

It is obvious that the mesh tangling can be avoided if we move the mesh using the formula $X_k \leftarrow X_k + \mu^\star \delta X_k$.

In the last step, we update the mesh moving direction by

$$\delta X_k \leftarrow \frac{X_k+\mu^\star\delta X_k}{|X_k+\mu^\star\delta X_k|}-X_k\,. \tag{3.18}$$

This is to make sure that all the grid points are moving along the sphere. The new mesh nodes are then given by $X_k+\delta X_k$. It can be verified that the new nodes are all on the sphere.

3.3. Solution interpolation on the new mesh. After redistributing the mesh in the physical domain Ω, we need to transfer the solution information on the old mesh to the new mesh. Let $\delta\vec{x} := \sum_{i=1}^N \delta X_i \lambda^i$, where λ^i is the basis function of H_h. Assume that a finite element solution $\Psi_h^{(n)} = \sum_{i=1}^N \Psi_i^{(n)}\lambda^i$ is given at $t=t_n$. Let τ be a virtual time variable. We will regard the mesh motion from the old mesh to the new mesh as a linear homotopy for τ goes from 0 to 1. Consequently, the mesh flow with the virtual time τ is $\vec{x}(\tau) \triangleq \vec{x}_{\text{old}} + \tau\delta\vec{x}$. For an arbitrary point $\vec{x}_0 \in \mathcal{T}_h$, the basis function $\lambda^i(\vec{x})$ associated with $\vec{x_0}$ will be varying linearly with τ. Since $\lambda^i(\vec{x})$ is defined on the physical mesh, it is denoted by $\lambda^i(\vec{x};\tau)$. Direct calculation shows that

$$\frac{d\lambda^i(\vec{x};\tau)}{d\tau} = \delta\vec{x}\cdot\nabla_{\vec{x}}\lambda^i(\vec{x};\tau). \tag{3.19}$$

Assume that the numerical solution on mesh $\vec{x}(\tau)$ is of the form

$$\Psi_h(\vec{x};\tau) = \sum_{i=1}^N \Psi_i(\tau)\lambda^i(\vec{x};\tau), \tag{3.20}$$

which takes the starting value $\Psi_h(\cdot;0) = \Psi_h^{(n)}$. The main idea of the solution updating is to let the variation of $\Psi_h(\cdot;\tau)$ with respect to τ vanish in the test function space:

$$\left\langle \frac{d\Psi_h(\cdot;\tau)}{d\tau}, \Phi_h \right\rangle = 0 \quad \forall \Phi_h \in H_h. \tag{3.21}$$

Using (3.19) and (3.20) gives

$$\sum_{i=1}^{N}\int_{\Omega}\left\{\frac{d\Psi_i}{d\tau}\lambda^i(\cdot;\tau)\lambda^j(\cdot;\tau)+\Psi_i\delta\vec{x}\cdot\nabla_{\vec{x}}\lambda^i(\cdot;\tau)\lambda^j(\cdot;\tau)\right\}dx=0,\quad 1\le j\le N. \tag{3.22}$$

The above ODE system can be solved by some appropriate ODE solver, e.g., a three-step Runge–Kutta method [21, 22].

4. Numerical experiments. We first discuss the perturbation parameter α in (3.5): in the numerical computations reported in this section it is chosen as 1.5. It is known [25] that α must be larger than 1 in order to ensure the uniqueness of the mapping. If α is close to 1, the critical mapping of E_α is close to a harmonic mapping. This implies that α should be chosen to be approximately 1. On the other hand, it is found that larger values of α increase the solution efficiency for (2.8). In fact, larger values of α can speed up the convergence of the mesh movement: note that the nonlinear Euler–Lagrange equations are solved by a local Gauss–Seidel-like iterative method. With a few numerical tests, it is found that one of the good choices for the parameter α should be approximately 1.5.

Example 4.1 (moving steep front on a sphere). Our first example is to compute a moving steep front along the direction $\vec{b}:=(1,1,1)^T$ governed by the equation

$$\partial\Psi_t+\Psi\vec{b}\cdot\nabla^*\Psi=\epsilon\Delta_{L-B}\Psi, \tag{4.1}$$

which is defined on the unit sphere, where ∇^* is the surface gradient. The initial condition is given by

$$\Psi(x,y,z;0)=\left(1+\exp\left(\frac{x+y+z+1}{2\epsilon}\right)\right)^{-1}. \tag{4.2}$$

We first briefly discuss the PDE algorithm to be used. For this example, a simple finite element discretization as described in section 3.1 is employed. The weak formulation of (4.1) reads as follows: Find $\Psi\in H^1(\Omega)$ such that

$$\int_{\Omega}\frac{\partial\Psi}{\partial t}vdx+\int_{\Omega}\Psi\vec{b}\cdot\nabla^*\Psi vdx=-\epsilon\int_{\Omega}\nabla^*\Psi\cdot\nabla^*vdx\quad\forall v\in H^1(\Omega). \tag{4.3}$$

In the finite element space H_h, the above weak form can be approximated as follows: Find $\Psi_h\in H_h$, such that

$$\int_{\Omega}\frac{\partial\Psi_h}{\partial t}v_hdx+\int_{\Omega}\Psi_h\vec{b}\cdot\nabla^*\Psi_hv_hdx=-\epsilon\int_{\Omega}\nabla^*\Psi_h\cdot\nabla^*v_hdx\quad\forall v_h\in H_h(\Omega). \tag{4.4}$$

For the temporal approximation, an explicit three-step Runge–Kutta scheme is applied; see, e.g., [7].

In our computations, the viscosity coefficient ϵ is chosen as 0.01. For the convection dominant problem, more mesh points are required around the wave front, which makes the use of the moving mesh methods meaningful. The monitor function m defined in (3.8) is taken as the standard gradient-based one, i.e.,

$$m(\Psi)=\sqrt{1+\beta|\nabla\Psi|^2}. \tag{4.5}$$

For problems with a moving steep front, the parameter β has to be set as a large number, say between 10^2 to 10^3; see, e.g., [6]. A large value of β can usually cluster

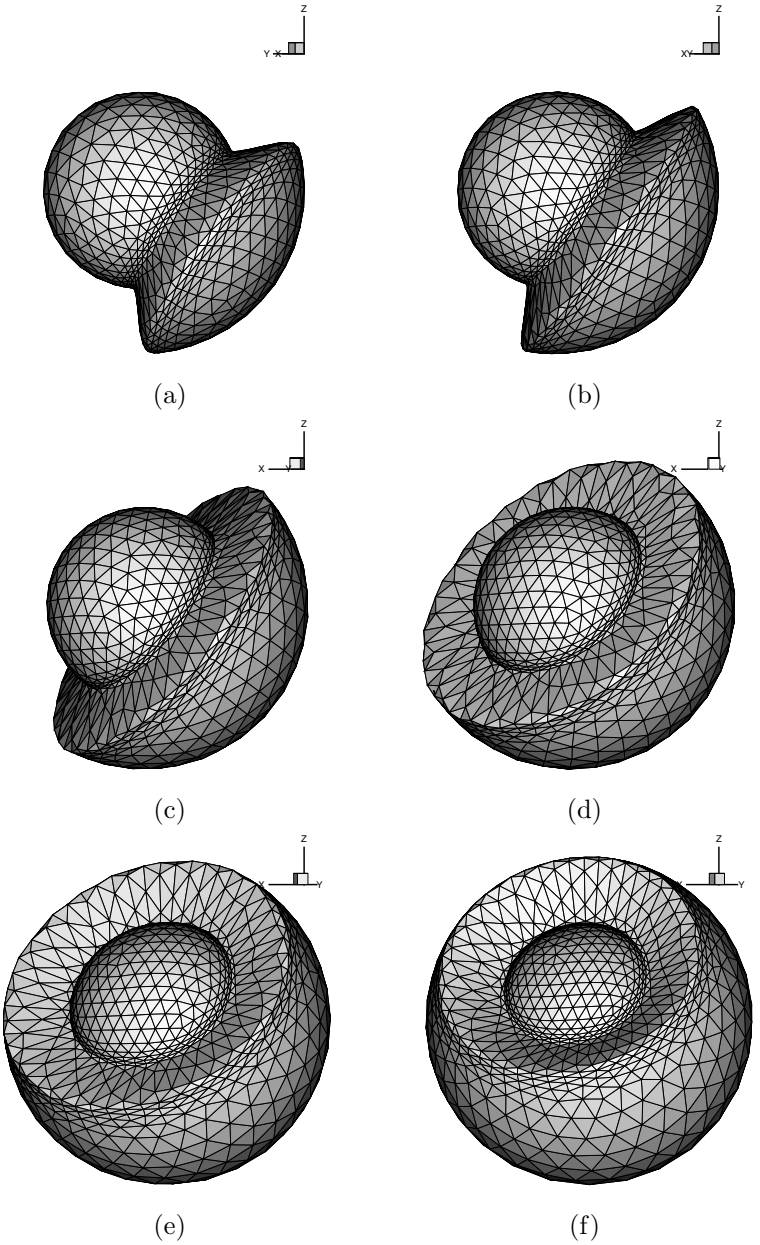

FIG. 2. *Example* 4.1. *The adaptive meshes on a sphere with* 800 *nodes from* $t = 0$ *to* $t = 1.5$.

more grid points around the steep front. On the other hand, if $|\nabla\Psi|$ in (4.5) is replaced by $|\nabla\Psi|/\max_\Omega|\nabla\Psi|$, then the parameter β can be chosen as an $\mathcal{O}(1)$ number; see, e.g., [7]. In our computations, the parameter β in (4.5) is chosen as 10^3.

In Figure 2, the moving meshes obtained by using our moving mesh scheme with 800 nodes (about 1600 triangular elements) are plotted. Together in this figure are the numerical solutions for Ψ at various time levels. Figure 2(a) shows the initial

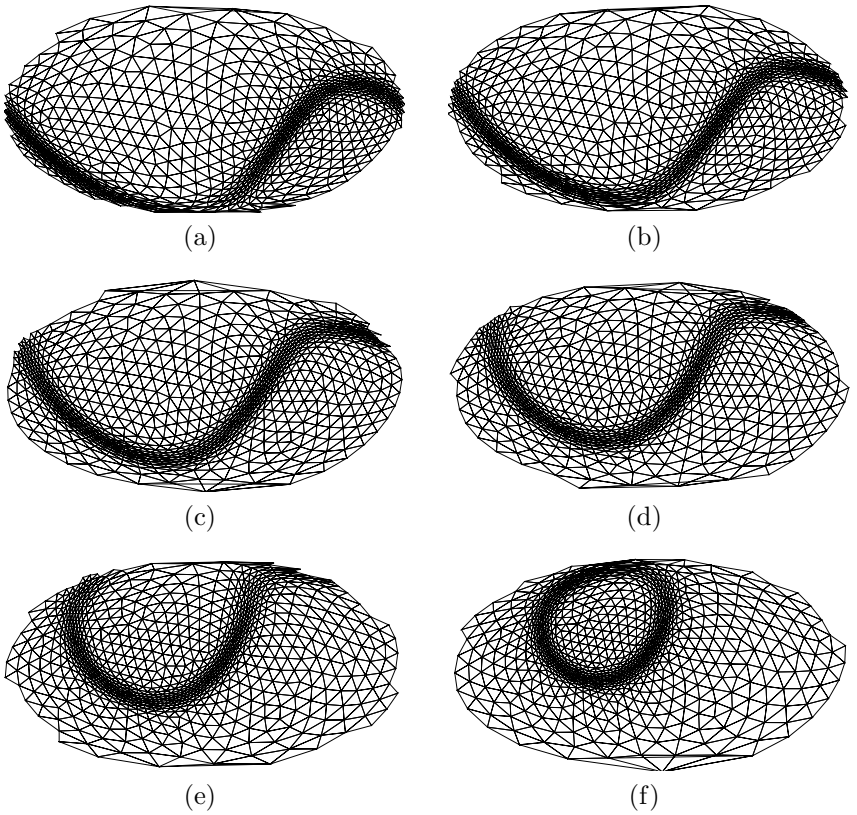

FIG. 3. *Example* 4.1. *The adaptive meshes on planisphere using* 800 *nodes from* $t = 0$ *to* $t = 1.5$.

state: the initial front is at $x+y+z+1 = 0$, where a stage can be seen. The solution is 0 on the top left side of the front and 1 on the bottom right side. It can be seen that the front moves along the direction $(1, 1, 1)^T$ on the sphere. In Figures 2(b)–(f), the area with solution value 1 becomes bigger, and the area of value 0 becomes smaller as time increases. At $t = 1.5$, the solution is mostly 1 on the sphere and is 0 only on a small concave area. In order to display the numerical solution more clearly, the figures are plotted from various visual angles at different time levels. Moreover, in order to have a better idea of the mesh distribution the meshes are projected to a planisphere and are plotted in Figure 3. It is seen that our moving mesh scheme adapts the mesh extremely well in the regions with large solution gradients.

Figure 4 shows the meshes and solutions obtained by the proposed moving mesh algorithm with 800 nodes (left) and by using a uniform mesh approach with 3200 nodes (right) at $t = 0.6$. It is observed from the figure that the moving mesh method with fewer nodes resolves the sharp front much more accurately than the corresponding uniform mesh approach with more nodes. Furthermore, the numerical oscillation in the uniform mesh solution is not seen in the moving mesh solution. In fact, it is found in our numerical computations that it requires more than 7000 nodes in a uniform mesh in order to obtain the same resolution of the moving mesh solution with 800 nodes.

4.2 (solution of the Fokker–Planck equation). The second example is

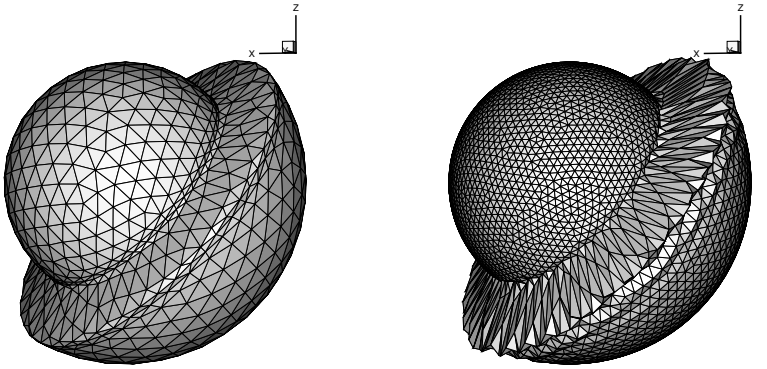

FIG. 4. *Example* 4.1. *The adaptive mesh on sphere with* 800 *nodes (left) and uniform mesh with* 3200 *nodes (right) at* $t = 0.6$.

concerned with the Doi model [9, 16], which is commonly used in studying rod-like polymer fluids. In this model, a homogeneous population of equal rods is described by an orientational distribution function $\Psi(\vec{x}, t)$. The evolution of $\Psi(\vec{x}, t)$ is modeled with the Smoluchowski equation or the Fokker–Planck equation [10]:

$$\frac{\partial \Psi}{\partial t} = \frac{1}{De}\mathcal{R} \cdot (\mathcal{R}\Psi + \Psi \mathcal{R} V_{ev}) \quad \text{on } \Omega = \mathcal{S}^2, \tag{4.6}$$

where De is the Deborah number, $\mathcal{R}$ is the rotational operator $\mathcal{R} \equiv \vec{x} \times \partial/\partial\vec{x}$, and V_{ev} is an effective excluded-volume potential which takes the Maier–Saupe form:

$$V_{ev}(\vec{x}) = \frac{3}{2} U \int_{\Omega} |\vec{x} \times \vec{x'}|^2 \Psi(\vec{x'}) dx'. \tag{4.7}$$

In (4.7), U is the nondimensional potential intensity which is proportional to the concentration of the polymers. The initial distribution function is taken as

$$\Psi(\vec{x}, 0) = \frac{1}{4\pi} + \frac{1}{16}\sqrt{\frac{5}{\pi}}\Big(3(\vec{x}_0 \cdot \vec{x})^2 - 1\Big),$$

where $\vec{x}_0$ is a constant unit vector.

As the potential intensity increases, the orientational distribution function becomes sharply peaked and behaves like a δ-function. To resolve the solutions in this case, it is necessary to use some adaptive grid methods. Here we will use the framework introduced in the last section, with a few additional details described below.

The weak formulation of (4.6) reads as follows: Find $\Psi \in H^1(\Omega)$, such that

$$\int_{\Omega} \frac{\partial \Psi}{\partial t} v dx + \frac{1}{De}\int_{\Omega} \mathcal{R}\Psi \cdot \mathcal{R} v dx = -\frac{1}{De}\int_{\Omega} \Psi \mathcal{R} V(\Psi) \cdot \mathcal{R} v dx \quad \forall v \in H^1(\Omega). \tag{4.8}$$

In the finite element space H_h, the above weak form can be approximated as follows: Find $\Psi_h \in H_h$, such that

$$\int_{\Omega} \frac{\partial \Psi_h}{\partial t} v_h dx + \frac{1}{De}\int_{\Omega} \mathcal{R}\Psi_h \cdot \mathcal{R} v_h dx = -\frac{1}{De}\int_{\Omega} \Psi_h \mathcal{R} V(\Psi_h) \cdot \mathcal{R} v_h dx \quad \forall v_h \in H_h(\Omega). \tag{4.9}$$

For the temporal approximation, similar to [7] we use a semi-implicit three-step Runge–Kutta scheme to solve (4.9): Find $\Psi_h^{n+1} \in H_h$, such that the following hold.

• , , 1.

$$\int_\Omega \frac{\Psi_h^{(1)}-\Psi_h^n}{\triangle t/3}v_h dx+\frac{1}{De}\int_\Omega \mathcal{R}\Psi_h^{(1)}\cdot\mathcal{R}v_h dx = -\frac{1}{De}\int_\Omega \Psi_h^n\mathcal{R}V(\Psi_h^n)\cdot\mathcal{R}v_h dx \quad \forall v_h\in H_h\,. \tag{4.10}$$

• , , 2.

$$\int_\Omega \frac{\Psi_h^{(2)}-\Psi_h^n}{\triangle t/2}v_h dx+\frac{1}{De}\int_\Omega \mathcal{R}\Psi_h^{(2)}\cdot\mathcal{R}v_h dx = -\frac{1}{De}\int_\Omega \Psi_h^{(1)}\mathcal{R}V(\Psi_h^{(1)})\cdot\mathcal{R}v_h dx \quad \forall v_h\in H_h\,. \tag{4.11}$$

• , , 3.

$$\int_\Omega \frac{\Psi_h^{n+1}-\Psi_h^n}{\triangle t}v_h dx+\frac{1}{De}\int_\Omega \mathcal{R}\Psi_h^{n+1}\cdot\mathcal{R}v_h dx = -\frac{1}{De}\int_\Omega \Psi_h^{(2)}\mathcal{R}V(\Psi_h^{(2)})\cdot\mathcal{R}v_h dx \quad \forall v_h\in H_h\,. \tag{4.12}$$

Note that in each step above the diffusion term is treated implicitly while the nonlinear term is treated explicitly. With this treatment, a standard stability criterion of CFL type applies; and in our computations a uniform time step is used. By doing this, it is well known that the moving mesh method does not gain much in time-stepping, since the time steps are controlled by the smallest size of the finite elements. One possible way of further speed-up in temporal discretization is to use the local time-stepping technique; see, e.g., [28].

For a piecewise linear approximation ϕ_h to a function ϕ, the following formula is adopted to approximate the computational error:

$$|\phi-\phi_h|_{1,\Omega}\sim\sqrt{\sum_{l\,:\,\text{interior edge}}\int_l\left[\mathcal{R}\phi_h\cdot\vec{t}_l\right]^2 dl}, \tag{4.13}$$

where $\vec{t}_l$ is the unit tangential vector of the edge l and $[\cdot]$ is the jump along the edge l; see, e.g., [7, 19]. With this a posteriori interpolant error estimator, a monitor function is proposed as

$$m(\Psi_h)|_K=\frac{1}{|K|}\sum_{l\subset\partial K}|l|\int_l\left[\mathcal{R}\Psi_h\cdot\vec{t}_l\right]^2 dl \quad \forall K\in\mathcal{T}_h\,. \tag{4.14}$$

The instantaneous average molecular orientation is quantified by the order parameter tensor

$$\mathbf{S}=\langle\mathbf{xx}\rangle-\frac{1}{3}\mathbf{I}. \tag{4.15}$$

The scalar order parameter $S=\frac{3}{2}\lambda$ represents the degree of molecular alignment, where λ is the eigenvalue with the largest absolute value for $\mathbf{S}$. It lies in the range $0\sim 1$ with $S=0$ for an isotropic phase and $S=1$ for rods that are all aligned in the same direction. Figure 5 shows the evolution of the scalar order parameter S

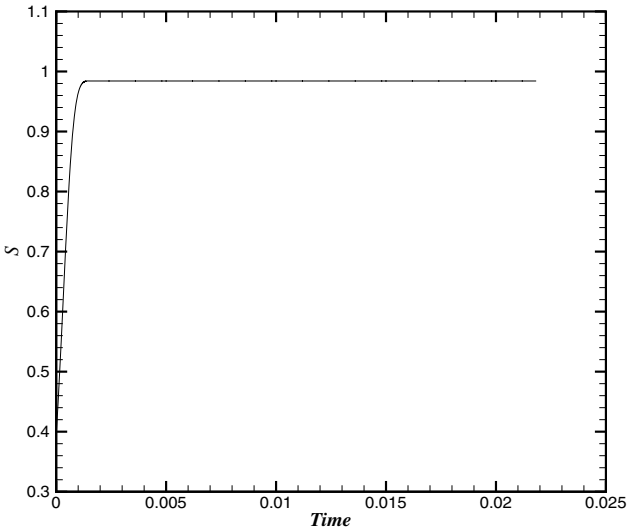

FIG. 5. *Example* 4.2. *Evolution of the scalar order parameter* S *with* $U = 1000$.

with $U = 100$. In this case, the stationary scalar order parameter S is very close to 1, indicating that all the molecular directions converge to one direction and the distribution function is very singular.

Figure 6 shows the meshes and the corresponding orientational distribution functions with $U = 100$ and 1000. To better demonstrate the singular behaviors of the solutions, the sphere is projected into a planisphere. The peak value of the distribution function with $U = 1000$ reaches $\Psi \sim 200$. Since the integral of the distribution function equals to 1, the area of nonzero Ψ is about $\frac{1}{200}$, where the solution has large gradients. Moreover, since the area of the unit sphere is equal to 4π, the compact support occupies only $\frac{1}{200}/(4\pi) \sim \frac{1}{2000}$ portion of the sphere. In order to put 25 $(= 5 \times 5)$ mesh points in such a small area, a uniform mesh requires a total of 50000 mesh points, while our moving mesh approach needs only 1600 points. By a close-up look of the mesh structure in Figure 7, it is seen that with the moving mesh approach more grid points are pushed into the (small) blow-up region.

More comparisons are made for Example 4.2 with $U = 1000$. In Figure 8, we compare the numerical solutions obtained by using the uniform mesh (nodes 12568, 25542, and 50266, respectively) and by using the adaptive moving mesh (1600 nodes). It is seen that the moving mesh solution with 1600 nodes is more accurate than the uniform mesh solution with 25542 nodes and is comparable to the uniform mesh solution with 50266 nodes. This is quite consistent with our estimate above.

Finally, it is necessary to compare the total CPU time usage for these computations. Table 1 gives the relevant CPU time usages with various numbers of nodes. The time step used is $\Delta t = 10^{-6}$ and the total time is $T = 2 \times 10^{-3}$. For this particular computation, the memory savings with the moving mesh method is about 1:30 and the speed-up is over 15.

5. Conclusions. In this paper, an effective moving mesh method is proposed to resolve steep solutions generated by PDEs on a sphere. The method exploits harmonic maps and invokes a regularization procedure to overcome the lack of convexity in the setup. Some special techniques for handling local coordinates on a sphere are also

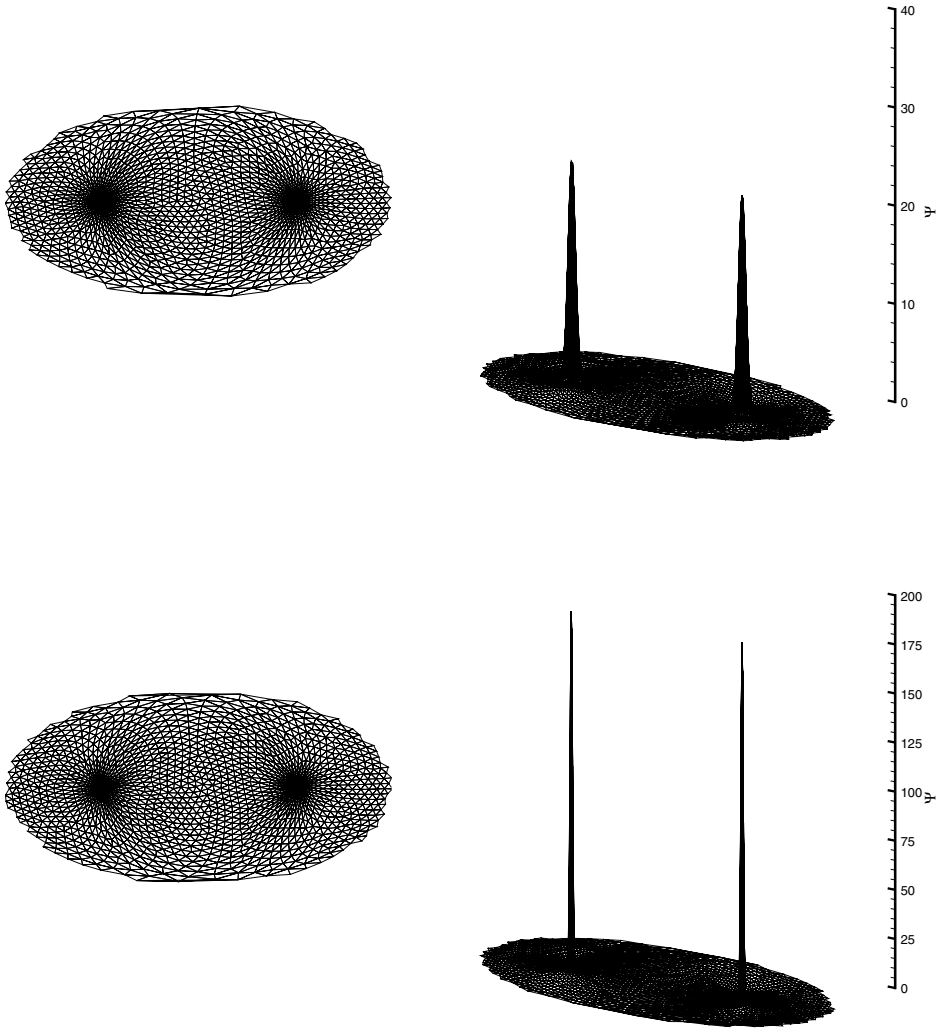

FIG. 6. *Example* 4.2. *The orientational distribution function obtained by using* 1600 *nodes and* 3196 *elements for* $U = 100$ *(top) and* $U = 1000$ *(bottom). The mesh on the sphere is projected to a disk (left) and the corresponding solution is shown on the right.*

designed. Efforts have been made to ensure that the mesh movement occurs only on the sphere and all the grid points remain on the sphere during the entire process of mesh redistribution. Two examples are given, one for a convection-dominated problem and the other for the Fokker–Planck equation on the sphere.

It is demonstrated that the moving mesh methods can not only enhance the solution , but can also substantially reduce the computational . The importance of increasing efficiency is obvious, but the latter part (of reducing storage) is also important for many practical problems, in particular higher-dimensional prob-

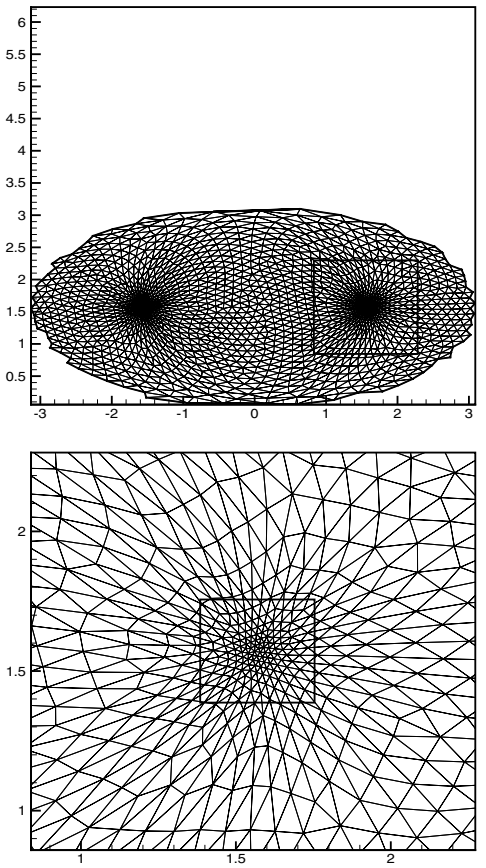

FIG. 7. *Example* 4.2. *Close-up of the adaptive mesh for* $U = 1000$ *(bottom figure of Figure* 6*).*

lems. For example, a large class of problems in complex fluid simulations are posed on spheres, for which Example 4.2 is a simple case. For the microscopic model of the polymer fluid, a well-known model is the rigid dumbbell model of Doi [9, 16]. In the Doi model, the orientation of a rod is determined by a pseudovector $\mathbf{u}$ on the unit sphere. The existing numerical schemes include a spectral-type method with spherical harmonic functions as basis functions (spherical harmonic expansion method); see, e.g., [14]; and a standard finite element approach; see, e.g., [20]. Since the underlying equations for the complex fluid models (such as the Fokker–Planck type) involve several dimensions in both physical and phase spaces, the required storage for the classical methods may be unrealistically large. It is seen that the moving mesh approach can use much less storage to obtain the required resolution. The numerical technique developed in this work is currently being used to study the rheological behavior of rod-like polymers governed by the Doi model; see, e.g., [8].

Finally, we point out that many important practical problems have been posed in spherical geometries, such as climate modeling and ocean modeling. One of our future projects is to extend the numerical techniques developed in this work to solve some practical problems defined on spheres with solution singularity.

EVALUATION OF THE BIOT–SAVART INTEGRAL FOR DEFORMABLE ELLIPTICAL GAUSSIAN VORTEX ELEMENTS*

LOUIS F. ROSSI†

Abstract. This paper introduces two techniques for approximating the Biot–Savart integral for deforming elliptical Gaussian functions. The primary motivation is to develop a high spatial accuracy vortex method. The first technique is a regular perturbation of the streamfunction in the small parameter $\epsilon = \frac{a-1}{a+1}$, where a^2 is the aspect ratio of the basis function. This perturbative technique is suitable for direct interactions. In the far field, this paper studies the applicability of the fast multipole method for deforming elliptical Gaussians since the multipole series are divergent. The noncompact basis functions introduce a new computational length scale that limits the efficiency of the multipole algorithm; however, by imposing a lower bound on the finest mesh size, one can approximate the far-field streamfunction to any specified tolerance.

Key words. computational fluid dynamics, vortex methods, deforming elements, elliptical Gaussians, fast summation

1. Introduction.

In this paper, we explore the calculation of Biot–Savart integrals for elliptical Gaussian basis functions,

$$\psi = -\frac{1}{4\pi} \iint_{-\infty}^{\infty} \log(|\vec{x} - \vec{s}|^2)\phi(\vec{s})d\vec{s}, \tag{1.1a}$$

$$\phi(\vec{s};\sigma,a) = \frac{1}{4\pi\sigma^2} \exp\left[\frac{-(x^2/a^2 + y^2a^2)}{4\sigma^2}\right], \tag{1.1b}$$

to determine the flow field and its derivatives induced by an elliptical Gaussian distribution of vorticity, or blob, in a two-dimensional incompressible fluid. The core size σ^2 and the aspect ratio a^2 are included as parameters. Translations and rotations of ϕ can be introduced through the symmetries in (1.1a), but we exclude them now for simplicity. There are two reasons for creating a robust and accurate approximation for the Biot–Savart integral of an elliptical Gaussian. The first reason, which is the impetus for this research, is the development of high spatial order vortex methods for two-dimensional, incompressible, viscous flows. For a vortex method, it is necessary to have a consistent description for the velocity field for it to be convergent. Recent results demonstrating that deforming elliptical Gaussian blobs can be used to achieve fourth order spatial accuracy for the convection and diffusion of passive scalars opened the door to high order viscous vortex methods [30, 31]. While not emphasized in this paper, the second reason for developing methods of approximating the Biot–Savart integral is that elliptical Gaussian vortices may be useful as modeling elements. That is, one could use a small number of elliptical Gaussians to model a more complex geophysical or laboratory system. To assess the interactions within the reduced system, one would need a means of evaluating the Biot–Savart integral of

each element. These reduced models yield helpful insights without resorting to specialized, large-scale simulations. For example, Knio, Collorec, and Juvé studied sound emissions from regular and chaotic systems of discrete vortices using three Gaussian vortices [18]. To understand the vortex core deformations, they refined their computation by using a large number of Gaussian elements to approximate the initial larger Gaussian. Deforming elliptical Gaussians offer more internal degrees of freedom for reduced models like these. Another use for exact solutions are as base states for stability studies. For instance, Sipp et al. recently studied the stability of a Gaussian vortex in an inhomogeneous fluid [37]. Similarly, a number of investigations have been conducted using interacting elliptical patches of constant vorticity (Kida vortices) to understand vortex mergers [26, 34, 45]. Elliptical Gaussian vortices in linear flow fields provides another family of base states for investigators to explore.

The primary purpose of this work is to the development of high accuracy viscous vortex methods. Vortex methods are a category of Lagrangian schemes long associated with successful computation of unsteady flow fields. For example, Rosenhead used eight-point vortices to compute the dynamics of an inviscid mixing layer in 1931 [27]. The common ingredient in all vortex methods is that the vorticity field of the flow is approximated by a linear combination of localized basis functions. These basis functions move with the local flow field, which must determined via a Biot–Savart integral over the basis functions. Overviews of a variety of vortex method techniques and applications can be found in [7, 20, 33] although new methods and techniques emerge regularly. Some more recent developments include large-scale engineering simulations of high Reynolds number flow past bluff bodies by Ploumhans et al. [25] and the use of radial basis functions for remeshing by Barba, Leonard, and Allen [4]. This paper focuses on deforming elliptical Gaussian basis functions because they provide a means of achieving high spatial accuracy for fully viscous flow. The use of deforming blobs for the two-dimensional, incompressible Navier–Stokes equations

$$\omega_t + \vec{u} \cdot \nabla\omega = \frac{1}{\mathrm{Re}} \nabla^2 \omega, \tag{1.2a}$$

$$\nabla \cdot \vec{u} = 0 \tag{1.2b}$$

(where $\vec{u}$ is the fluid velocity, $\omega = (\nabla \times \vec{u}) \cdot \widehat{z}$ is the fluid vorticity, and Re is the Reynolds number) is a natural extension of existing work both on core spreading techniques for Navier–Stokes and on the use of anisotropic elements to facilitate greater adaptivity and accuracy for Euler equations.

Core spreading has considerable appeal because it is deterministic, grid-free, and exact for uniform flow fields without operator splitting and the associated splitting errors. Furthermore, the uncorrected algorithm is easy to implement and computationally efficient. However, the spreading terms have an adverse effect on schemes using cores that satisfy the moment condition. For instance, Beale and Majda constructed a fourth order method for the Euler equation by superposing two Gaussian basis functions [5], but it drops to second order accuracy if one incorporates diffusion. To the knowledge of the author, core spreading was first proposed by Leonard [20], but concerns quickly arose over the consistency of this approach [13] because the simplest implementation of the scheme imposes a lower bound on the core size of the computational elements. The method was corrected in [28] with a consistent splitting algorithm and augmented with a merging algorithm [29]. Others have built upon these topics [16, 23, 35, 36]. Also, there have been engineering computations with core spreading methods (for example, [17, 41, 42, 43]), but the accuracy

of such methods is questionable in lieu of the finite core size issue as well as the lack of consistency in the core spreading formulation. Barba explores the numerical issues involved in [3]. While there is cause for concern about a lack of communication across disciplines, corrected core spreading is a strong and robust method for unsteady flows.

Still, core spreading is one of a small number of families of schemes featuring deforming blobs. There have been numerous efforts to use anisotropic elements for Euler and Navier–Stokes equations as a means of improving the efficiency of computations in large aspect ratio flows, a common situation in flows near solid boundaries. Teng used rigid and deforming elliptical patches to resolve boundary layers and vortex sheets more efficiently [38, 39, 40]. He establishes a theoretical $O(l^2 \log l)$ rate of convergence for his method where l is the core width of the computational elements. Marshall and Grant designed highly anisotropic elements to satisfy the no-slip, no normal flow boundary conditions [22]. Ojima and Kamemoto developed a scheme for large-scale simulations using deforming vortex elements that stretch with local flow deviations, but the resulting element is replaced with an isotropic element of equal volume at the end of each timestep to avoid having to calculate the Biot–Savart integral for anisotropic elements [24]. Rigorous convergence studies have not been reported for this method. Leonard used deforming elliptical Gaussian basis functions to simulate the convection of passive scalar quantities, (1.2a), but where $\vec{u}$ is specified, motivated by the fact that they remain self-similar under the linearized convection-diffusion equations [21]. Also, Moeleker and Leonard proposed using anisotropic elements with velocity field corrections based on subgrid scale for when computing Gaussian filtered scalar quantities, though they report modest gains in accuracy at a high computational cost [23].

This paper builds upon findings that fourth order spatial accuracy can be achieved with deforming elements when the basis functions advect with a velocity field given by the physical velocity field plus a velocity curvature correction [30]. These studies with an uncorrected method are limited to convection-diffusion equations. However, the analysis suggests that the same performance should be achieved for Navier–Stokes as long as the velocity field computed via the Biot–Savart integral and the exact field are close to one another because the errors are introduced through the nonlinear term at second order. In section 4, we shall see that this is the case. For convection-diffusion equations, the advantages of using more accurate but more computationally complex basis functions over less accurate simpler radial basis functions are realized at moderate problem sizes [31]. In short, deforming basis functions are better than axisymmetric basis functions in the sense that the former can compute a more accurate solution in the same amount of CPU time. This paper is a step in the same direction, building a better vortex method for Navier–Stokes. The vortex method described in this paper is an elliptical corrected core spreading vortex method, and for convenience it shall be termed ECCSVM. It is beyond the scope of this paper to explore corrections (the first "C"), but techniques such as remeshing, splitting, and merging are applicable to deformable blobs as well as axisymmetric blobs.

For a vortex method to be viable for scientific computation, it is not enough to evaluate the Biot–Savart integral directly to find the velocity field at each basis function location. If this were the case, the computational complexity of determining the velocity field at N blob positions would be $O(N^2)$. A number of fast summation algorithms have been developed over the past two decades that are capable of reducing certain particle computations from $O(N^2)$ to $O(N \log N)$ or even $O(N)$. These methods all hinge upon a separation of length scales. For instance, the Greengard–Rohklin algorithm uses Laurent expansions of complex Coulomb potentials to collect far-field

influences. The effects of distant elements are approximated as an aggregate, while velocity contributions from nearby elements are computed directly. The Greengard–Rohklin fast multipole method (FMM) has demonstrably reduced the computational complexity from $O(N^2)$ to $O(N)$ for potential kernels [14]. The multipole coefficients for the Laurent series can be collected on a hierarchy of meshes over the domain, so that the separation of near and far fields can be nested. There have been many extensions and augmentations to the FMM (for instance, [1, 2, 6, 15, 44]). The original FMM concepts have also been extended for fast polynomial interpolation and differentiation [11] and for a much broader class of velocity kernels [12]. An alternative to this algorithm based on Taylor series expansions has been analyzed and demonstrated by Draghicescu and Draghicescu [8, 9, 10]. This technique requires that one be able to Taylor expand the core shape function, and it achieves $O(N \log N)$ complexity. While the Draghicescu algorithm offers more flexibility in the types of core shapes one could use, the method requires that all elements have the same shape, so the Draghicescu method would not be suitable for the evolving anisotropic elements that are the focus of this paper. One of several difficulties in using the FMM under these circumstances is that the Biot–Savart integral (i.e., the velocity kernel) cannot be written in terms of elementary functions. The approach developed in this paper is to expand the Coulomb potential inside the integral (1.1a) as a Laurent series, and then perform the integration term by term. We shall see later that the resulting series is divergent but useful as an approximation and will yield an accurate $O(N)$ algorithm for finding the velocity field induced by a distant collection of elliptical Gaussian basis functions.

This paper has a simple organizational structure. This section reviewed different perspectives and contributions in the use of anisotropic elements for particle computations. Section 2 derives and demonstrates how one can approximate the streamfunction and its derivatives for an elliptical Gaussian basis function for direct pairwise interactions. In section 3, the fast multipole method is modified for use with anisotropic elliptical Gaussians. In that section, we rely heavily on the work of Greengard and Rohklin [14]. Finally in section 4, we certify these methods by approximating solutions to the Navier–Stokes for the Lamb–Oseen vortex and compare the numerical solutions with an exact solution.

2. Asymptotic evaluations for direct interactions in the near field. The evolution equations for the elliptical Gaussian basis functions (1.1b) depend upon $\vec{u}$ and $D\vec{u}$,[1] but unlike basis functions commonly used for vortex methods, there is no known elementary formula for these induced fields. A standard approach to problems of this type is to apply a quadrature method. Quadratures are accurate for this problem, but not effective relative to commonly used basis functions. The quadrature is computationally nontrivial for two reasons. First, there are at least two and as many as three relevant length scales (1, σa, σ/a) involved. (If a is close to unity, the last two collapse to one.) Second, numerical integration over two dimensions does not look promising in comparison with the single function evaluation required when the velocity kernel can be expressed in terms of elementary functions. In this section, we will see that the dimensionality can be reduced by one using Lamb's solution for a elliptical patch of constant vorticity. Rather than applying a quadrature to the resulting one-dimensional integral, we will use a regular perturbation so that the resulting one-dimensional integral can be evaluated analytically. This yields a series

[1] See [30] for the dynamics, and fourth order accuracy also requires knowing the second partial derivatives of the velocity components.

approximation written in terms of elementary functions, so that we are trading a two-dimensional quadrature for a few elementary function evaluations.

The induced velocity and velocity derivatives can be written as a regular perturbation in the small parameter

$$\epsilon = \frac{a-1}{a+1}. \tag{2.1}$$

For simplicity, we let $R^2 = x^2/a^2 + y^2a^2$, so that (1.1b) becomes

$$\phi(R;\sigma,a) = \frac{1}{4\pi\sigma^2} e^{-R^2/4\sigma^2}. \tag{2.2}$$

The variable R is a continuous index of level sets of the elliptical Gaussian element. To avoid an expensive two-dimensional quadrature of the Biot–Savart integral (1.1b), one can use the fact that the streamfunction (and therefore all derivatives) of an elliptical patch of vorticity with unit density and semimajor and minor axes of l_1 and l_2 can be determined using elliptical coordinates [19]:

$$\psi = \begin{cases} \frac{1}{2\pi(l_1+l_2)} \left(\frac{x^2}{l_1} + \frac{y^2}{l_2} \right), & (x,y) \in \mathcal{E}(l_1,l_2), \\ \frac{1}{2\pi} \left[\ln\left(\frac{\alpha+\beta}{l_1+l_2} \right) + \frac{\frac{x^2}{\alpha} + \frac{y^2}{\beta}}{\alpha+\beta} \right], & (x,y) \notin \mathcal{E}(l_1,l_2), \end{cases} \tag{2.3a}$$

$$\alpha = \sqrt{l_1^2 + \xi}, \tag{2.3b}$$

$$\beta = \sqrt{l_2^2 + \xi}, \tag{2.3c}$$

$$1 = \left(\frac{x^2}{l_1^2 + \xi} \right) + \left(\frac{y^2}{l_2^2 + \xi} \right), \tag{2.3d}$$

where $\mathcal{E}(l_1,l_2)$ is the support of the ellipse and

$$\vec{u} = \begin{bmatrix} u \\ v \end{bmatrix} = \begin{bmatrix} -\frac{\partial\psi}{\partial y} \\ \frac{\partial\psi}{\partial x} \end{bmatrix}.$$

The streamfunction induced by an elliptical blob can be expressed as an infinite sum of uniform elliptical patches. For each value of R in (2.2), the constituent patch would have density $\pi R^2(-\partial_R\phi)dR$ and axes $l_1 = Ra$ and $l_2 = R/a$. Adding all these patches together to form an elliptical Gaussian blob, one can calculate the value of the streamfunction at a point (x_*, y_*):

$$\psi(x_*,y_*) = -\int_0^{R_*} \psi_1 \partial_R\phi R^2 dR - \int_{R_*}^{\infty} \psi_2 \partial_R\phi dR, \tag{2.4a}$$

$$\psi_1 = \frac{1}{2} \left[\frac{\left(\frac{{x_*}^2}{\alpha} + \frac{{y_*}^2}{\beta} \right)}{\alpha+\beta} + \ln\left(\frac{\alpha+\beta}{Ra + R/a} \right) \right], \tag{2.4b}$$

$$\psi_2 = \frac{1}{2} \frac{\frac{{x_*}^2}{a} + {y_*}^2 a}{a + 1/a}, \tag{2.4c}$$

$$\alpha = \sqrt{R^2a^2 + \xi}, \tag{2.4d}$$

$$\beta = \sqrt{\frac{R^2}{a^2} + \xi}. \tag{2.4e}$$

Rather than using the implicit relation in (2.3d), we can use the quadratic solution

(2.5)
$$\xi = \frac{1}{2}\left\{ {\rho_*}^2 - R^2\left(a^2 + \frac{1}{a^2}\right) + \sqrt{\left[R^2\left(a^2 + \frac{1}{a^2}\right) - {\rho_*}^2\right]^2 + 4R^2({R_*}^2 - R^2)}\right\},$$

where ${\rho_*}^2 = {x_*}^2 + {y_*}^2$ and ${R_*}^2 = \frac{{x_*}^2}{a^2} + {y_*}^2 a^2$. Important limits to be used later are $\xi \to {\rho_*}^2$ as $R \to 0$ and $\xi \to 0$ as $R \to R_*$.

The second term on the right side of (2.4a) is elementary to integrate because ψ_2 does not vary with R. ψ_1 is not readily expressed in terms of the variable R, making the first term problematic. However, one can expand ψ_1 in powers of the small parameter ϵ. Expanding in ϵ rather than R has the advantage that, unlike R/σ, ϵ is a small number that is less than 1. The variable R is not guaranteed to be small relative to σ since one may wish to use the streamfunction anywhere in the domain. Thus, expanding in ϵ will yield a uniformly valid approximation of ψ_1 over the entire domain. The elliptical radius, R, is the natural variable of integration. At the same time, R_* is a parameter representing one possible combination of x_* and y_*. One possible complement is T_*, where ${T_*}^2 = {x_*}^2/a^2 - {y_*}^2 a^2$. Combined with the fact that the streamfunction must retain symmetries about the major and minor axes, the streamfunction can be expressed as a function of R_* and T_*. One could use radially symmetric coordinates such as ${x_*}^2 + {y_*}^2$ and ${x_*}^2 - {y_*}^2$, but it was found that these parameters yield a less accurate streamfunction approximation.

To perform an expansion of ψ_1, we make the substitutions

$$ {x_*}^2 = \frac{a^2}{2}\left({R_*}^2 + {T_*}^2\right), \tag{2.6a}$$

$$ {y_*}^2 = \frac{1}{2a^2}\left({R_*}^2 - {T_*}^2\right), \tag{2.6b}$$

$$ a = \frac{1+\epsilon}{1-\epsilon}, \tag{2.6c}$$

the latter arising from (2.1). Thus, it follows that

$$ {\rho_*}^2 = {R_*}^2 + 4\epsilon {T_*}^2 + 8\epsilon^2 {R_*}^2 + 12\epsilon^3 {T_*}^2 + 16\epsilon^4 {R_*}^4 + O(\epsilon^5). \tag{2.7}$$

Substituting this expression into the streamfunctions (2.4e) and (2.5), one can obtain an asymptotic expression for the streamfunction of the elliptical patch. If one expands these expressions out to a power of ϵ^n, then one obtains a polynomial in R of order $2n$. For example, if we expand in powers of ϵ for $n = 4$, we capture the following approximation for the streamfunction:

$$\begin{aligned}
\psi_1 = {} & \frac{1}{4}\left[1 + \ln\left(\frac{{R_*}^2}{R^2}\right)\right] + \epsilon\left(\frac{{T_*}^2}{{R_*}^2} - \frac{1}{2}\frac{{T_*}^2 R^2}{{R_*}^4}\right) \\
& + \epsilon^2\left[1 - 2\frac{{T_*}^4}{{R_*}^4} + \left(-2 + 4\frac{{T_*}^4}{{R_*}^4}\right)\frac{R^2}{{R_*}^2} + \left(1 - 2\frac{{T_*}^4}{{R_*}^4}\right)\frac{R^4}{{R_*}^4}\right] \\
& + \epsilon^3\left[\frac{16}{3}\frac{{T_*}^6}{{R_*}^6} - 5\frac{{T_*}^2}{{R_*}^2} + \left(\frac{37}{2}\frac{{T_*}^2}{{R_*}^2} - 24\frac{{T_*}^6}{{R_*}^6}\right)\frac{R^2}{{R_*}^2} + \left(-24\frac{{T_*}^2}{{R_*}^2} + 32\frac{{T_*}^6}{{R_*}^6}\right)\frac{R^4}{{R_*}^4}\right. \\
& \left. + \left(10\frac{{T_*}^2}{{R_*}^2} - \frac{40}{3}\frac{{T_*}^6}{{R_*}^6}\right)\frac{R^6}{{R_*}^6}\right]
\end{aligned}$$

$$
\begin{aligned}
&+\epsilon^4\left[-4+20\frac{{T_*}^4}{{R_*}^4}-16\frac{{T_*}^8}{{R_*}^8}+\left(20-136\frac{{T_*}^4}{{R_*}^4}+128\frac{{T_*}^8}{{R_*}^8}\right)\frac{R^2}{{R_*}^2}\right.\\
&+\left(-42+324\frac{{T_*}^4}{{R_*}^4}-320\frac{{T_*}^8}{{R_*}^8}\right)\frac{R^4}{{R_*}^4}+\left(40-320\frac{{T_*}^4}{{R_*}^4}+320\frac{{T_*}^8}{{R_*}^8}\right)\frac{R^6}{{R_*}^6}\\
&\left.+\left(-14+112\frac{{T_*}^4}{{R_*}^4}-112\frac{{T_*}^8}{{R_*}^8}\right)\frac{R^8}{{R_*}^8}\right]+O(\epsilon^5),
\end{aligned}
\tag{2.8}
$$

$$
\psi_2=\frac{1}{2}\left[\frac{1}{2}{R_*}^2+\left(\epsilon-\epsilon^3\right){T_*}^2\right]+O(\epsilon^5).
\tag{2.9}
$$

Using this expansion, the calculation of an approximate streamfunction together with its derivatives reduces to computing moments of elliptical Gaussians. Since ψ_2 does not vary with R, the second term of (2.4a) can be evaluated with the exact form of ψ_2 from (2.4e) or with the approximate form from (2.9). The advantage to using the approximation is that it makes the integrand and one derivative of the integrand continuous across R_*, so that one need not use Leibniz's rule when calculating velocities, but this is a minor consideration.

Next, we would like to calculate the derivatives of ψ. To be more precise, knowing the nth derivatives of ψ, we would like to be able to quickly compute the $(n+1)$st derivatives. While these operations can be performed using finite differences, the cost is high because ψ would have to be evaluated many times over a stencil near the origin. Instead, we shall determine the derivatives exactly from the asymptotic expression.

The regular perturbation in ϵ approximates ψ_1 as a polynomial in R whose coefficients depend upon ratios of powers T_* and R_*. Using the polynomial approximation, finding ψ in (2.4a) reduces to summing moments of the Gaussian. Differentiation of ψ reduces to a transformation of the polynomial coefficients in (2.8) followed by the summation of all the resulting moments. For instance, we can rewrite (2.8) as

$$
\begin{aligned}
\psi_1=&\frac{1}{4}\left[1+\ln\left(\frac{{R_*}^2}{R^2}\right)\right]\\
&+\left(\epsilon^2-4\epsilon^4\right)+\left(\epsilon-5\epsilon^3\right)\frac{{T_*}^2}{{R_*}^2}+\left(-2\epsilon^2+20\epsilon^4\right)\frac{{T_*}^4}{{R_*}^4}+\frac{16}{3}\epsilon^3\frac{{T_*}^6}{{R_*}^6}-16\epsilon^4\frac{{T_*}^8}{{R_*}^8}\\
&+\left[\left(-2\epsilon^2+20\epsilon^4\right)+\left(-\frac{1}{2}\epsilon+\frac{37}{2}\epsilon^3\right)\frac{{T_*}^2}{{R_*}^2}\right.\\
&\left.+\left(4\epsilon^2-136\epsilon^4\right)\frac{{T_*}^4}{{R_*}^4}-24\epsilon^3\frac{{T_*}^6}{{R_*}^6}+128\epsilon^4\frac{{T_*}^8}{{R_*}^8}\right]\frac{R^2}{{R_*}^2}\\
&+\left[\left(\epsilon^2-42\epsilon^4\right)-24\epsilon^3\frac{{T_*}^2}{{R_*}^2}+\left(-2\epsilon^2+324\epsilon^4\right)\frac{{T_*}^4}{{R_*}^4}+32\epsilon^3\frac{{T_*}^6}{{R_*}^6}-320\epsilon^4\frac{{T_*}^8}{{R_*}^8}\right]\frac{R^4}{{R_*}^4}\\
&+\left(40\epsilon^4+10\epsilon^3\frac{{T_*}^2}{{R_*}^2}-320\epsilon^4\frac{{T_*}^4}{{R_*}^4}-\frac{40}{3}\epsilon^3\frac{{T_*}^6}{{R_*}^6}+320\epsilon^4\frac{{T_*}^8}{{R_*}^8}\right)\frac{R^6}{{R_*}^6}\\
&+\left(-14\epsilon^4+112\epsilon^4\frac{{T_*}^4}{{R_*}^4}-112\epsilon^4\frac{{T_*}^8}{{R_*}^8}\right)\frac{R^8}{{R_*}^8}+O(\epsilon^5).
\end{aligned}
\tag{2.10}
$$

If we terminate the expansion of ψ_1 after finding the coefficients for ϵ^n, the result will be a polynomial of order $2n$ in R.

Differentiating the approximate streamfunction with respect to position x_* or y_* reduces to differentiating ratios of the form $\frac{{T_*}^{2m}}{{R_*}^{2n}}$, where $m \le n$. For instance, if

$m > 0$,

$$\frac{\partial}{\partial x_*}\left(\frac{{T_*}^{2m}}{{R_*}^{2n}}\right) = \left(m\frac{{T_*}^{2(m-1)}}{{R_*}^{2n}} - n\frac{{T_*}^{2m}}{{R_*}^{2(n+1)}}\right)\frac{2x_*}{a^2}, \tag{2.11a}$$

$$\frac{\partial}{\partial y_*}\left(\frac{{T_*}^{2m}}{{R_*}^{2n}}\right) = -\left(m\frac{{T_*}^{2(m-1)}}{{R_*}^{2n}} + n\frac{{T_*}^{2m}}{{R_*}^{2(n+1)}}\right)2y_*a^2. \tag{2.11b}$$

Similarly, when $m > 0$, we find

$$\begin{aligned}\frac{\partial^2}{\partial {x_*}^2}\left(\frac{{T_*}^{2m}}{{R_*}^{2n}}\right) &= \left(m\frac{{T_*}^{2(m-1)}}{{R_*}^{2n}} - n\frac{{T_*}^{2m}}{{R_*}^{2(n+1)}}\right)\frac{2}{a^2} \\ &\quad + \left[m(m-1)\frac{{T_*}^{2(m-2)}}{{R_*}^{2n}} - 2mn\frac{{T_*}^{2(m-1)}}{{R_*}^{2(n+1)}} + n(n+1)\frac{{T_*}^{2m}}{{R_*}^{2(n+2)}}\right]\frac{4{x_*}^2}{a^4}.\end{aligned} \tag{2.12}$$

However, if we make the substitution $4{x_*}^2/a^4 = 2({R_*}^2 + {T_*}^2)/a^2$ and perform similar substitutions on terms involving ${y_*}^2 = ({R_*}^2 - {T_*}^2)/(2a^2)$, we determine the following relations:

$$\begin{aligned}\frac{\partial^2}{\partial {x_*}^2}\left(\frac{{T_*}^{2m}}{{R_*}^{2n}}\right) &= \frac{2}{a^2}\left[m(m-1)\frac{{T_*}^{2(m-2)}}{{R_*}^{2(n+1)}} + m(m-2n)\frac{{T_*}^{2(m-1)}}{{R_*}^{2n}}\right. \\ &\quad \left. + n(n-2m)\frac{{T_*}^{2m}}{{R_*}^{2(n+1)}} + n(n+1)\frac{{T_*}^{2(m+1)}}{{R_*}^{2(n+2)}}\right],\end{aligned} \tag{2.13a}$$

$$\begin{aligned}\frac{\partial^2}{\partial {y_*}^2}\left(\frac{{T_*}^{2m}}{{R_*}^{2n}}\right) &= 2a^2\left[m(m-1)\frac{{T_*}^{2(m-2)}}{{R_*}^{2(n+1)}} + m(2n-m)\frac{{T_*}^{2(m-1)}}{{R_*}^{2n}}\right. \\ &\quad \left. + n(n-2m)\frac{{T_*}^{2m}}{{R_*}^{2(n+1)}} - n(n+1)\frac{{T_*}^{2(m+1)}}{{R_*}^{2(n+2)}}\right],\end{aligned} \tag{2.13b}$$

$$\frac{\partial^2}{\partial x_*\partial y_*}\left(\frac{{T_*}^{2m}}{{R_*}^{2n}}\right) = 4x_*y_*\left[m(1-m)\frac{{T_*}^{2(m-2)}}{{R_*}^{2n}} + n(n+1)\frac{{T_*}^{2m}}{{R_*}^{2(n+2)}}\right]. \tag{2.13c}$$

Relations (2.11) and (2.13) create an opportunity to calculate the partial derivatives of ψ. If we represent the streamfunction as a vector of coefficients with indices m and p because $n = m+p$ for terms of the form $\frac{{T_*}^m}{{R_*}^n}R^{2p}$ as shown in (2.10), the coefficients of the partial derivatives of ψ_1 are linear combinations of the coefficients for ψ_1. Specific algorithms arising from these expressions are provided in the appendix.

Now we can approximate the Biot–Savart integral by calculating moments of the elliptical Gaussian. For instance, if $n = 4$, we calculate the elementary integral

$$\begin{aligned}I &= -\int_0^{R_*} R^2(C_0 + C_1R^2 + C_2R^4 + C_3R^6 + C_4R^8)\partial_R\phi dR - C_5\phi(R_*) \\ &= \frac{\gamma}{2\pi}\Bigg\{2C_0 + 16C_1\sigma^2 + 192C_2\sigma^4 + 3072C_3\sigma^6 + 61440C_4\sigma^8 \\ &\quad - \left[C_0\left(\frac{{R_*}^2}{2\sigma^2} + 2\right) + C_1\left(\frac{{R_*}^4}{2\sigma^2} + 4{R_*}^2 + 16\sigma^2\right)\right.\end{aligned}$$

$$
\begin{aligned}
&+ C_2 \left(\frac{{R_*}^6}{2\sigma^2} + 6{R_*}^4 + 48{R_*}^2\sigma^2 + 192\sigma^4 \right) \\
&+ C_3 \left(\frac{{R_*}^8}{2\sigma^2} + 8{R_*}^6 + 96\sigma^2{R_*}^4 + 768\sigma^4{R_*}^2 + 3072\sigma^6 \right) \\
&+ C_4 \left(\frac{{R_*}^{10}}{2\sigma^2} + 10{R_*}^8 + 160\sigma^2{R_*}^6 + 1920\sigma^4{R_*}^4 + 15360\sigma^6{R_*}^2 + 61440\sigma^8 \right) \\
&- \frac{C_5}{2\sigma^2} \Bigg] \exp\left(-\frac{{R_*}^2}{4\sigma^2} \right) \Bigg\}, \qquad (2.14)
\end{aligned}
$$

where I could approximate ψ_x, ψ_y, ψ_{xx}, etc., and the C_i are polynomials in $\frac{{T_*}^m}{{R_*}^n}$.

To assess the accuracy of these approximations, the errors associated with the approximate solutions are compared to a reference solution using finite differences on a precise double-exponential quadrature of (2.4e) with fourteen digits of precision so that the third order finite differences could be adequately resolved. The results of a typical calculation is shown in Figure 1. The displayed relative error e is

$$e = \frac{\|f(x,y) - f_{\text{ref}}(x,y)\|_{\sup}}{\|f_{\text{ref}}\|_{\sup}}, \qquad (2.15)$$

where $f(x,y)$ is the approximation, $f_{\text{ref}}(x,y)$ is the reference solution, and the supremum is taken over the displayed domain.

As computational elements grow more eccentric and ϵ grows closer to one, the approximation becomes less accurate. On the other hand, the regular perturbation can be expanded for any n. Thus, there are competing trends. Figure 2 is an exploration of variations in ϵ and n, and we see the predicted rates of convergences are realized in practice.

3. Far-field calculations using fast multipoles. Using fast summation, far-field calculations of anisotropic elements can be performed more efficiently than direct calculations. Fast summation algorithms all hinge upon a separation of length scales, either artificial or physical. For instance, the Greengard–Rohklin algorithm uses Laurent expansions for complex potentials to collect far-field influences where the series is guaranteed to converge. At first glance, the Greengard–Rokhlin scheme would appear to be unsuitable for this method because the basis functions have infinite support and the kernel is singular, so the Laurent series will not converge at any point in the domain. We shall see in this section that the lack of compact support does not sink the idea completely because the partial sums contain useful information. By necessity, some details of Greengard–Rokhlin summation will be presented, but other aspects not related to anisotropic elements will be omitted in the interest of brevity. For a complete discussion of this method, the reader is referred to Greengard and Rokhlin's original article [14] or its successors, some of which are cited in section 1.

To begin, we will express positions in the domain (x,y) as a complex variable $z = x+iy$. Then the complex potential for a point vortex at the origin with circulation γ will be

$$\varphi(z) = -\frac{i\gamma}{2\pi} \ln z. \qquad (3.1)$$

If the velocity field has horizontal and vertical components u and v, respectively, then $\varphi' = u - iv$. Velocity derivatives in the far field can be computed by repeated

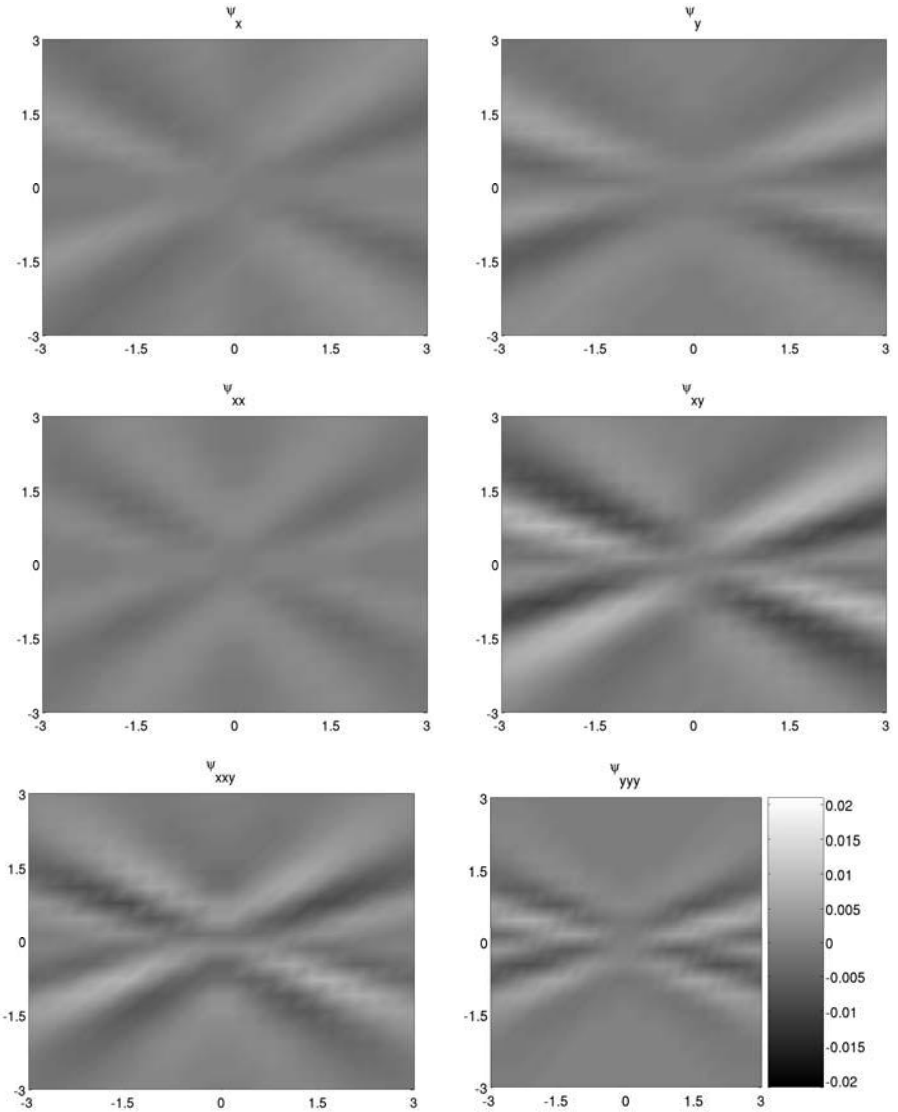

FIG. 1. *Relative field errors for the fourth order approximation of ψ for $\epsilon = 0.20$ (aspect ratio 2.25) and $\sigma = 1/4$. The relative error is calculated using (2.15) where the reference solution is calculated using a high precision quadrature. The scale as shown in the grayscale gradation bar on the ψ_{yyy} plot spanning an relative error of $\pm 2\%$ is used for all the plots.*

differentiation of φ. If the point vortex were at a point z_*, the complex potential could be evaluated relative to the origin using a power series expansion:

$$\begin{aligned}\varphi(z) &= -\frac{i\gamma}{2\pi}\ln(z - z_*) \\ &= -\frac{i\gamma}{2\pi}\left[\ln z + \ln\left(1 - \frac{z_*}{z}\right)\right] \\ &= -\frac{i\gamma}{2\pi}\left[\ln z - \sum_{j=1}^{\infty}\frac{1}{j}\left(\frac{z_*}{z}\right)^j\right].\end{aligned} \tag{3.2}$$

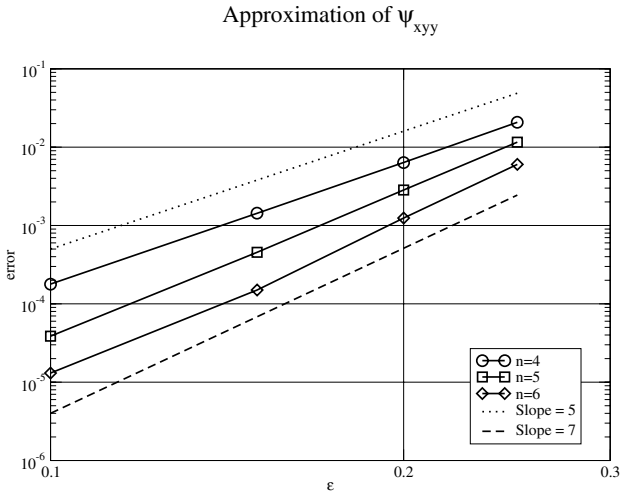

FIG. 2. *Behavior of asymptotic approximation for the streamfunction and its derivatives as one varies ϵ and n. The graph presents the absolute error versus ϵ on logarithmic axes along with reference slopes to show that the predicted convergence rates are realized.*

Thus, a singular potential displaced from the origin can be represented through a multipole expansion relative to the origin. The power series for $\ln(1-z)$ has a radius of convergence of 1, so that as long as the point of evaluation is further from the origin than the point vortex, the series will converge. In fact, one could design a simple algorithm where one uses direct velocity calculations if, say, $|z_*/z| > 1/2$ and use the series approximation otherwise. In the latter case, one could compute enough terms of the series to satisfy any desired error tolerance. The precise ratio $1/2$ is not so important, but it is crucial that one define the far field. For the remainder of this paper, we shall fix a parameter $\delta_1 < 1$ and define what is far from the origin as $|z_*/z| \leq \delta_1$. Contributions to the velocity field from elements that are not deemed far from the point of measurement will be computed directly as described in section 2, but for elements that are far from the point of measurement, we shall take advantage of the series solutions described in this section. When the point of measurement z is far from the point vortex z_*, series (3.2) converges.

One can [illegible] φ when $|z_*/z| \leq \delta_1$ by truncating the convergent power series,

$$\varphi(z) = -\frac{i\gamma}{2\pi}\left[\ln z - \sum_{j=1}^{p}\frac{1}{j}\left(\frac{z_*}{z}\right)^j - \frac{1}{p+1}\left(\frac{w}{z}\right)^{p+1}\right], \tag{3.3}$$

where w is a point on the line segment connecting 0 and z_* in the complex plane. If we consider p to be a controllable parameter in a calculation, we can choose p large enough to guarantee that the multipole approximation is as close as one would like to the exact potential.

Next, we can think about many elements with circulation γ_k and position z_k clustered near the origin. Following the same procedure as (3.2), we can find the

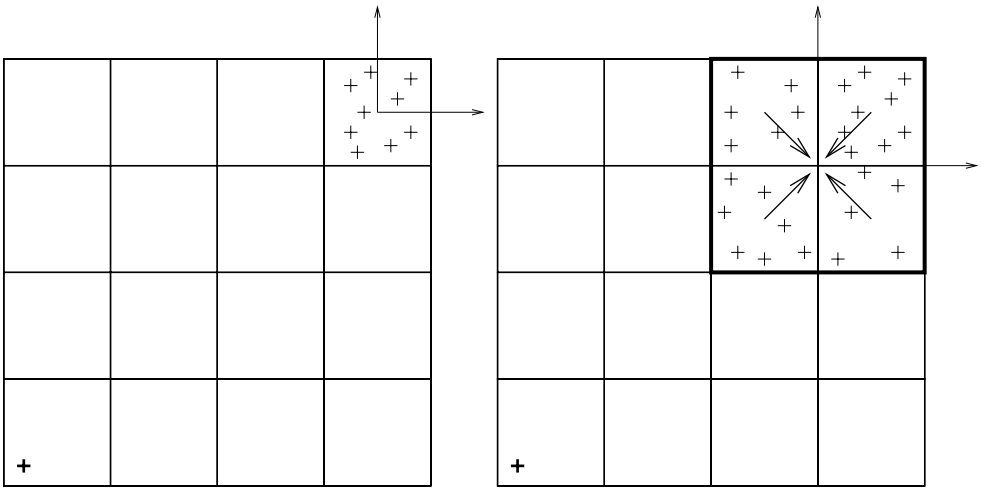

FIG. 3. *Overview of fast multipole summation. At left, we can see how a simple cluster can speed a calculation. If we seek to calculate the streamfunction and its derivatives for the computational element (shown in bold) at the bottom left box, we can treat distant elements in the upper right box as an aggregate rather than through individual interactions. Once one calculates the multipole coefficients for all the elements in the upper right box relative to the origin labeled with axes in the figure,* (3.4) *can be used anywhere in the far field, including the position of the basis function in the bottom left box. At right, we can see how one can save more computational effort by shifting multipole coefficients from the four small boxes in the upper right to the larger superbox by performing multipole expansion about the new origin labeled in the figure. The shifts are indicated by the bold arrows.*

complex potential at some point z relative to the origin:

$$\begin{aligned}\varphi &= -\sum_k \frac{i\gamma_k}{2\pi} \ln(z - z_k) \\ &= -\sum_k \frac{i\gamma_k}{2\pi} \left[\ln z - \sum_{j=1}^{p} \frac{1}{j} \left(\frac{z_k}{z}\right)^j - \frac{1}{p+1} \left(\frac{w_k}{z}\right)^{p+1} \right] \\ &= a_0 \ln z - \sum_{j=1}^{p} \frac{a_j}{j z^j} + R_{p+1}, \qquad \text{(3.4a)}\end{aligned}$$

where w_k is on the line segment connecting 0 and z_k in the complex plane and

$$a_0 = -\sum_k \frac{i\gamma_k}{2\pi}, \qquad a_j = -\sum_k \frac{i\gamma_k}{2\pi} z_k^j, \qquad |R_{p+1}| \le \frac{\delta_1^{p+1}}{2\pi(p+1)} \sum_k |\gamma_k|. \qquad \text{(3.4b)}$$

Thus, one can calculate the multipole coefficients a_j once for a cluster of elements grouped near the origin, and use (3.4) many times in the far field, as shown in Figure 3.

Substantial economy is added to the technique if one shifts multipole expansions relative to one another. That is, one can expand (3.2) or (3.4a) about another point (not the origin) and combine it with other clusters. In Figure 3, we see an example where four localized clusters can be combined into a single larger cluster when calculating distant interactions. The original Greengard–Rokhlin algorithm nests clusters in this arrangement to an arbitrarily fine level. The finest level can be defined as a

mesh where no box has more than k elements in it, so there are no more than Nk direct interactions.

Applying multipole summation to elliptical Gaussian basis functions poses a challenge because the basis functions have infinite support, so the Laurent series will not be convergent anywhere. However, even divergent series can provide useful information. In fact, one can use the leading partial sums to compute a useful approximation for the streamfunction and its derivatives.

We begin by calculating a multipole expansion for an elliptical Gaussian basis function that is displaced from the origin to some point (x_0, y_0), with circulation γ, aspect ratio a^2, width σ, and orientation θ. The complex potential would be the superposition

$$\varphi(z) = -\frac{i}{2\pi} \iint_{-\infty}^{\infty} \ln(z - z_*) \frac{\gamma}{4\pi\sigma^2} \exp\left[-\frac{\tilde{x}^2/a^2 + \tilde{y}^2 a^2}{4\sigma^2}\right] dx_* dy_*, \tag{3.5}$$

where $z = x + iy$, $z_* = x_* + iy_*$, and

$$\tilde{x} = \cos(\theta)(x_* - x_0) + \sin(\theta)(y_* - y_0), \quad \tilde{y} = -\sin(\theta)(x_* - x_0) + \cos(\theta)(y_* - y_0). \tag{3.6}$$

Writing the truncated multipole expansion inside the integral, interchanging the summation and integration, and changing variables, we obtain

$$\begin{aligned}
\varphi(z) &= -\frac{i\gamma}{2\pi} \iint_{-\infty}^{\infty} \left[\ln(z) - \sum_{j=1}^{p} \frac{1}{j} \left(\frac{z_*}{z}\right)^j - \frac{1}{p+1} \left(\frac{w_*}{z}\right)^{p+1}\right] \\
&\quad \times \frac{1}{4\pi\sigma^2} \exp\left[-\frac{\tilde{x}^2/a^2 + \tilde{y}^2 a^2}{4\sigma^2}\right] dx_* dy_* \\
&= -\frac{i\gamma}{2\pi} \left\{ \ln z - \sum_{j=1}^{p} \frac{1}{jz^j} \iint_{-\infty}^{\infty} (z_*)^j \frac{1}{4\pi\sigma^2} \exp\left[-\frac{\tilde{x}^2/a^2 + \tilde{y}^2 a^2}{4\sigma^2}\right] dx_* dy_* + R_{p+1} \right\} \\
&= -\frac{i\gamma}{2\pi} \left\{ \ln z - \sum_{j=1}^{p} \frac{1}{jz^j} \iint_{-\infty}^{\infty} \eta^j \frac{1}{4\pi\sigma^2} \exp\left[-\frac{\tilde{x}^2/a^2 + \tilde{y}^2 a^2}{4\sigma^2}\right] d\tilde{x} d\tilde{y} + R_{p+1} \right\},
\end{aligned} \tag{3.7}$$

where

$$\eta = (x_0 + iy_0) + (\cos\theta + i\sin\theta)\tilde{x} + (-\sin\theta + i\cos\theta)\tilde{y} \tag{3.8}$$

and

$$R_{p+1} = -\frac{1}{4\pi\sigma^2} \iint_{-\infty}^{\infty} \frac{1}{p+1} \left(\frac{w_*}{z}\right)^{p+1} \exp\left[-\frac{\tilde{x}^2/a^2 + \tilde{y}^2 a^2}{4\sigma^2}\right] dx_* dy_*. \tag{3.9}$$

The R_{p+1} determines the accuracy of the truncated series, so we will compute an upper bound on this quantity. Without loss of generality, we assume that $a > 1$ and that p is odd. Then, from (3.8) and (3.9), we can apply the triangle inequality and

change to polar coordinates to find that

$$
\begin{aligned}
|R_{p+1}| &\leq \frac{1}{p+1}\frac{1}{4\pi\sigma^2}\iint_{-\infty}^{\infty}\frac{|z_0|^{p+1}+|\tilde{z}|^{p+1}}{|z|^{p+1}}\exp\left[-\frac{\tilde{x}^2/a^2+\tilde{y}^2a^2}{4\sigma^2}\right]d\tilde{x}d\tilde{y} \\
&\leq \frac{1}{p+1}\left[\left(\frac{|z_0|}{|z|}\right)^{p+1}+\frac{2\pi}{4\pi\sigma^2}\int_0^{\infty}\frac{r^{p+2}}{|z|^{p+1}}\exp\left(-\frac{r^2}{4a^2\sigma^2}\right)dr\right] \\
&\leq \frac{1}{p+1}\left[\left(\frac{|z_0|}{|z|}\right)^{p+1}+\frac{2\pi}{4\pi\sigma^2}\int_0^{\infty}\frac{r^{p+2}}{|z|^{p+1}}\exp\left(-\frac{r^2}{4a^2\sigma^2}\right)dr\right]. \qquad (3.10)
\end{aligned}
$$

If we let

$$
C_{p+2} = \frac{2\pi}{4\pi\sigma^2}\int_0^{\infty}\frac{r^{p+2}}{|z|^{p+1}}\exp\left(-\frac{r^2}{4a^2\sigma^2}\right)dr, \qquad (3.11)
$$

then integrating by parts, we find that

$$
C_{p+2} = (p+1)\frac{2\sigma^2a^2}{|z|^2}C_p. \qquad (3.12)
$$

Since $C_1 = a^2$,

$$
C_{p+2} = a^2((p+1)/2)!\left(\frac{4\sigma^2a^2}{|z|^2}\right)^{(p+1)/2}. \qquad (3.13)
$$

Therefore,

$$
|R_{p+1}| \leq \frac{1}{p+1}\left[\left(\frac{|z_0|}{|z|}\right)^{p+1}+a^2\left(\frac{p+1}{2}\right)!\left(\frac{4\sigma^2a^2}{|z|^2}\right)^{(p+1)/2}\right]. \qquad (3.14)
$$

From this expression, we see two dominant mechanisms controlling the error of the multipole series. The first term inside the brackets is the traditional ratio discussed earlier requiring that $\frac{|z_0|}{|z|} < 1$. In other words, the singular potential has no natural length scale. In the second term, we see that that core size of the anisotropic element imposes a characteristic length scale $2\sigma a$ based on the computational resolution of the basis functions. If $\frac{|z|^2}{4\sigma^2a^2} < 1$, the upper bound on R_p in the multipole series grows without bound. However, if $\frac{|z|^2}{4\sigma^2a^2} > 1$, the upper bound on R_p decreases initially and then grows. For fast multipole summation with point vortices, one can fix δ_1 and compute a p that makes R_{p+1} smaller than any desired tolerance, and one can set the finest mesh level for direct interactions based on memory and computational performance criteria. In other words, with point vortices, the investigator can control the number of computational elements per box at the finest mesh level and then carry out the multipole expansion as far as needed to achieve a specified tolerance. However, for elements with finite cores, this is not the case because the number of terms in the multipole series that are guaranteed to be accurate depends upon the distance to the point of measurement $|z|$ relative to the numerical length scale $2\sigma a$. So, we must define a new parameter δ_2 that characterizes the far field as $\frac{|z|^2}{4\sigma^2a^2} > \delta_2$. One can estimate the number of useful terms by finding the value of p for which the ratio of consecutive upper bounds (3.14) is approximately one in the special case when $z_0 = 0$. This turnaround point is when

$$
\left(\frac{p-1}{2}\right)\left(\frac{4\sigma^2a^2}{|z|^2}\right) \approx 1,
$$

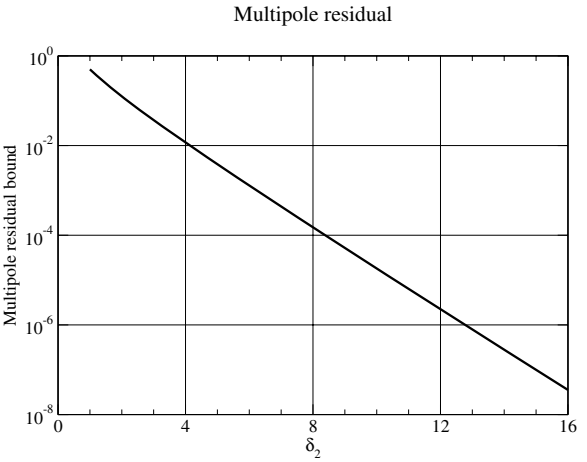

FIG. 4. *Exponential decay of multipole residual. This curve represents* (3.16) *for* $a^2 = 1$ *and* $\delta_1 = 0$. *Other values of* a^2 *will simply translate the curve vertically by* a^2. *The number of multipole terms required varies linearly with* δ_2 *as in* (3.15). *For instance, at* $\delta_2 = 8$ *we can expect* 17 *useful terms in the multipole series.*

$$p \approx \frac{|z|^2}{2\sigma^2 a^2} + 1. \tag{3.15}$$

This suggests a practical value for p would be $\bar{p} = 2\delta_2 + 1$. If we substitute (3.15) into (3.14) and apply the bounds δ_1 and δ_2 judiciously, we can obtain a useful estimate for the upper bound on $|R_{\bar{p}+1}|$ in (3.14),

$$|R_{\bar{p}+1}| \leq \frac{1}{2(\delta_2+1)} \left[\delta_1^{2(\delta_2+1)} + a^2 \Gamma(\delta_2+2)\, \delta_2^{-(\delta_2+1)} \right], \tag{3.16}$$

which is plotted in Figure 4. In practice, p is a discrete variable, but we have extended it as a continuum value and replaced the factorial with a gamma function. By inspection, the contributions from δ_2 dominate this expression.

While the convergence rate is exponential, accuracy requirements place a lower bound on the size of the finest mesh level via the parameter δ_2. When $\frac{|z|^2}{2\sigma^2 a^2}$ is too small, one must calculate the potential and its derivatives directly using the methods described in section 2.

Fixing $\bar{p}$ to achieve a desire accuracy, we calculate the multipole coefficients,

$$a_n = \frac{1}{4\pi\sigma^2} \iint_{-\infty}^{\infty} \eta^n \exp\left[-\frac{\tilde{x}^2/a^2 + \tilde{y}^2 a^2}{4\sigma^2} \right] d\tilde{x} d\tilde{y}, \tag{3.17}$$

where from (3.7),

$$\varphi(z) = -\frac{i\gamma}{2\pi} \left(\ln z - \sum_{j=1}^{p} \frac{a_j}{j z^j} + R \right). \tag{3.18}$$

Integrating directly, we see that $a_1 = x_0 + iy_0 = z_0$. If $n > 1$, we develop a recurrence

relation for the a_n's:

$$\begin{aligned}
a_n &= \frac{1}{4\pi\sigma^2}\iint_{-\infty}^{\infty}\eta^n \exp\left[-\frac{\tilde{x}^2/a^2+\tilde{y}^2a^2}{4\sigma^2}\right]d\tilde{x}d\tilde{y}\\
&= \frac{1}{4\pi\sigma^2}\iint_{-\infty}^{\infty}\left[x_0+iy_0+(\cos\theta+i\sin\theta)\tilde{x}+(-\sin\theta+i\cos\theta)\tilde{y}\right]\eta^{n-1}\\
&\quad\times\exp\left[-\frac{\tilde{x}^2/a^2+\tilde{y}^2a^2}{4\sigma^2}\right]d\tilde{x}d\tilde{y}\\
&= z_0a_{n-1}\\
&\quad+\frac{1}{4\pi\sigma^2}\iint_{-\infty}^{\infty}\eta^{n-1}\big[(\cos\theta+i\sin\theta)\tilde{x}\\
&\qquad\qquad+(-\sin\theta+i\cos\theta)\tilde{y}\big]\exp\left[-\frac{\tilde{x}^2/a^2+\tilde{y}^2a^2}{4\sigma^2}\right]d\tilde{x}d\tilde{y}.
\end{aligned}$$

Integrating by parts once, we obtain the relationship

$$\begin{aligned}
a_n &= z_0a_{n-1}\\
&\quad+\frac{1}{4\pi\sigma^2}(n-1)2\sigma^2\left[a^2(\cos\theta+i\sin\theta)^2+(-\sin\theta+i\cos\theta)^2/a^2\right]\\
&\quad\times\iint_{-\infty}^{\infty}\eta^{n-2}\exp\left[-\frac{\tilde{x}^2/a^2+\tilde{y}^2a^2}{4\sigma^2}\right]d\tilde{x}d\tilde{y}\\
&= z_0a_{n-1}+2(n-1)\sigma^2\left[a^2(\cos\theta+i\sin\theta)^2+(-\sin\theta+i\cos\theta)^2/a^2\right]a_{n-2}\\
&= z_0a_{n-1}+2(n-1)\sigma^2e^{2i\theta}\left(a^2-a^{-2}\right)a_{n-2}. \qquad (3.19)
\end{aligned}$$

If one is differentiating to find the velocity field, one finds that $a_0 = -1$ from the logarithmic term. With (3.19), one can quickly generate the multipole coefficients for an elliptical Gaussian.

To summarize, the essential difference between the classic FMM and fast summation of anisotropic Gaussians is that the latter requires that one impose a numerical length scale on the finest mesh level to achieve a specified accuracy via the partial summation of a divergent series. The accuracy limitations discussed in section 2 apply only to direct interactions amongst elements at the finest mesh level, but the far-field calculation enjoys exponential accuracy. After finding the finest mesh level, one applies the classic FMM using (3.19) as coefficients. The computational expense of determining or manipulating the multipole coefficients for an elliptical Gaussian is no different than it would be for any other basis function.

4. Sample calculations. To verify that the method actually achieves the predicted fourth order convergence rate, we apply the full vortex method to a standard problem with a known analytic solution. The initial vorticity distribution is

$$\omega(\vec{x},0) = 4\exp\left(4|\vec{x}|^2\right). \qquad (4.1)$$

The exact solution is

$$\omega(\vec{x},t) = \frac{1}{\frac{1}{4}+4t/\mathrm{Re}}\exp\left(\frac{|\vec{x}|^2}{\frac{1}{4}+4t/\mathrm{Re}}\right), \qquad (4.2)$$

where Re is the Reynolds number of the flow.

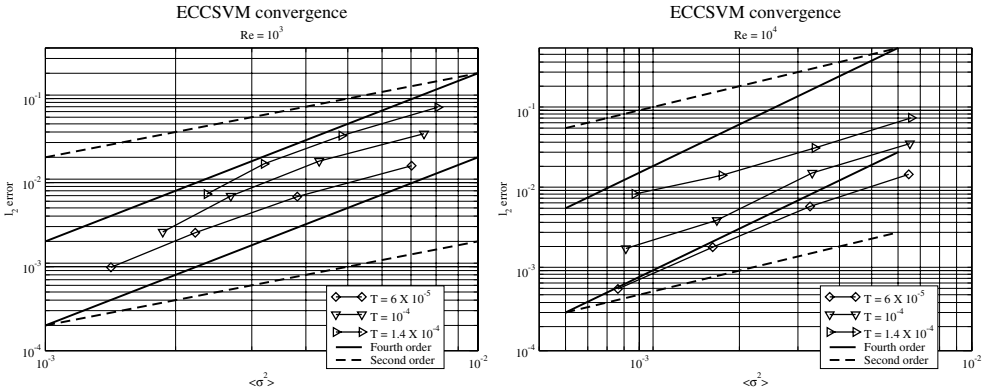

FIG. 5. *Convergence of ECCSVM at different Reynolds numbers with order* 4 *streamfunctions. As time grows, computational elements become more elongated and the Biot–Savart approximation becomes less accurate. Eventually, the velocity corrections break down, and the method reverts to second order spatial accuracy. The effective core* $\langle\sigma^2\rangle$ *is a circulation-weighted average over all elements.*

To generate the initial conditions, computational elements are laid down in a regular grid within a disk of radius 5/4 to approximate (4.1). This initial distribution can be constructed using initially isotropic or anisotropic basis functions using exact deregularization as explained in [32]. In these examples, the calculations always begin with isotropic basis functions. For all sample calculations, N/σ_0^2 remains constant where σ_0 is the initial core width and N is the number of computational elements used in the calculation. In other words, the initial overlap between computational elements is constant, $\frac{\sigma}{h} = 2$, where h is the initial grid width, as we refine the method. The initial core sizes were selected to be $\sigma_0^2 = 6.4 \times 10^{-3}$, 3.2×10^{-3}, 1.6×10^{-3}, and 8.0×10^{-4}. The vortex method uses the dynamic equations provided in [30] including curvature corrections to describe the movement and deformation of the elliptical Gaussian basis functions. The velocity field and its derivatives are computed using the methods described in this paper.

The results of these calculations at different Reynolds numbers are shown in Figure 5. For larger times in the simulation, the aspect ratios grow large in the domain, and the streamfunction approximation degrades to a point where the method falls back to second order spatial accuracy. The circulation weighted mean aspect ratio at $T = 1.4\times10^{-4}$ is approximately 2.8 (varying slightly from 2.7 to 2.9 depending upon σ_0^2 and the order of the streamfunction) with some aspect ratios in excess of 4.0 so that computations involve highly anisotropic elements in later phases of each calculation. The impact of using higher accuracy streamfunction calculations is shown in Figure 6. In this case, high order spatial accuracy is maintained throughout the interval shown even when basis functions are substantially elongated. Calculations were performed with and without the FMM discussed in this paper using $\delta_2 = 16$, but there is no noteworthy difference save that the former is substantially faster. For a single velocity evaluation on a single AMD Opteron CPU with a small problem size of $N = 1741$ ($\sigma = 6.4 \times 10^{-3}$), direct evaluation required 151 CPU seconds, while the multipole computation required only 55 CPU seconds. At a problem size of $N = 13{,}909$ ($\sigma_0^2 = 8.0 \times 10^{-4}$), direct evaluation required 9720 seconds, while the multipole computation required 496 CPU seconds.

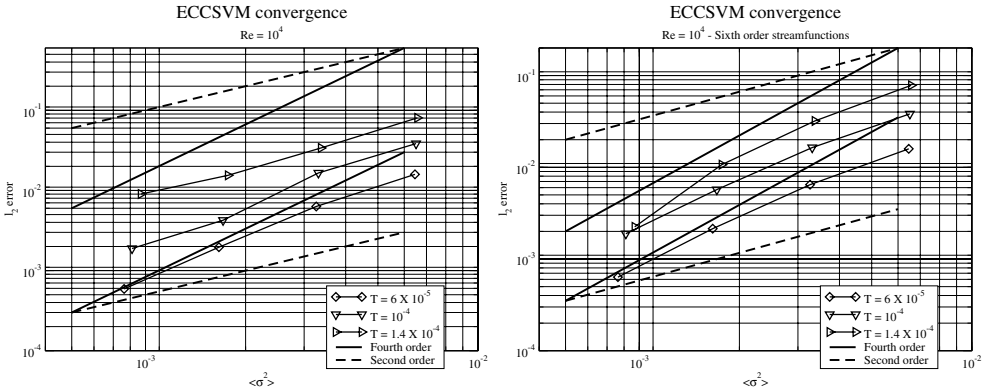

FIG. 6. *Convergence of ECCSVM with order* 4 *and* 6 *streamfunctions. The sixth order streamfunction permits more accurate velocity and velocity curvature computations than the forth order one as the aspect ratios grow. Thus, we see the anticipated fourth order spatial accuracy is sustained longer for the calculation using the sixth order calculation. The lower order behavior for small time is a result of interpolation error when setting the initial conditions for the computation.*

5. Conclusions. In this paper, we have explored a direct and far-field approximation to the Biot–Savart integral for elliptical Gaussian basis functions with the purpose of developing a high spatial accuracy vortex method. The direct method uses regular perturbations and yields a consistent means of producing uniformly valid estimates of the streamfunction and its derivatives for any order of accuracy. We have shown that Greengard and Rohklin's FMM algorithm is applicable to deforming Gaussians as long as care is taken when choosing the finest mesh size, but this paper also presents a means for calculating a fine mesh size that will meet specified accuracy requirements while reducing the operation count to $O(N)$. The result is a vortex method for the two-dimensional incompressible Navier–Stokes equations with fourth order spatial accuracy.

As discussed in the introduction, this paper has not addressed corrections, the first "C" in ECCSVM, since it is beyond the scope of the central problem. For large-scale computations, there is a need for remeshing or splitting/merging techniques. Furthermore, splitting, merging, and remeshing may serve the additional need to replace large aspect ratio elements with lower aspect ratio elements to retain accuracy in the Biot–Savart computation. Deformable elements introduce more internal degrees of freedom and so may offer some advantages inaccessible to rigid or axisymmetric elements. This remains fertile ground for future investigation.

Appendix. Algorithms for calculation of velocities and derivatives. We represent the approximation to the kernel of the streamfunction as a combination of terms:

$$\psi_1 = \frac{1}{4}\ln\left(\frac{{R_*}^2}{R^2}\right) + \sum_{p=0}^{N}\sum_{m=0}^{N} c_{m,p}^{\psi_1}\frac{{T_*}^{2m}}{{R_*}^{2(m+p)}}R^{2p}. \tag{A.1}$$

Knowing ϵ, all the c^{ψ_1}'s can be calculated.

To calculate the vector, $c^{\partial_{x_*}\psi_1}$, we represent the function as

$$\frac{\partial\psi_1}{\partial x_*} = \sum_{p=0}^{N}\sum_{m=0}^{N+1} c_{m,p}^{\partial_{x_*}\psi_1} x_* \frac{{T_*}^{2m}}{{R_*}^{2(m+p+1)}}R^{2p}, \tag{A.2}$$

and apply the following algorithm to determine $c^{\partial_{x_*}\psi_1}$ from the c^{ψ_1}.

Algorithm for $\frac{\partial}{\partial x_*}$.

1. Initialize the vector for $c^{\partial_{x_*}\psi_1}$ to zero.
2. $c_{0,0}^{\partial_{x_*}\psi_1} = \frac{1}{2a^2}$ from the logarithmic term in ψ_1.
3. $p \leftarrow 0$ to N.
4. $m \leftarrow 0$ to $N+1$.
5. If $m > 0$, then
$$c_{m,p}^{\partial_{x_*}\psi_1} = c_{m,p}^{\partial_{x_*}\psi_1} + \frac{2}{a^2} m c_{m,p}^{\psi_1}.$$
6.
$$c_{m,p}^{\partial_{x_*}\psi_1} = c_{m,p}^{\partial_{x_*}\psi_1} - \frac{2}{a^2}(m+p) c_{m,p}^{\psi_1}.$$
7. Next m.
8. Next p.

Both the first and second derivatives increase the number of $\frac{{T_*}^{2m}}{{R_*}^{2n}}$ terms in each power of R as seen in (2.11) and (2.13), so the upper limit on the m loop is $N+1$.

Similarly, to calculate the vector, $c^{\partial_{y_*}\psi_1}$, we represent the function as

$$\frac{\partial \psi_1}{\partial y} = \sum_{p=0}^{N} \sum_{m=0}^{N+1} c_{m,p}^{\partial_{x_*}\psi_1} y_* \frac{{T_*}^{2m}}{{R_*}^{2(m+p+1)}} R^{2p} \tag{A.3}$$

and apply the following algorithm to determine $c^{\partial_{y_*}\psi_1}$ from the c^{ψ_1}.

Algorithm for $\frac{\partial}{\partial y_*}$.

1. Initialize the vector for $c^{\partial_{y_*}\psi_1}$ to zero.
2. $c_{0,0}^{\partial_{y_*}\psi_1} = \frac{a^2}{2}$ from the logarithmic term in ψ_1.
3. $p \leftarrow 0$ to N.
4. $m \leftarrow 0$ to $N+1$.
5. If $m > 0$, then
$$c_{m,p}^{\partial_{y_*}\psi_1} = c_{m,p}^{\partial_{y_*}\psi_1} - 2a^2 m c_{m,p}^{\psi_1}.$$
6.
$$c_{m,p}^{\partial_{y_*}\psi_1} = c_{m,p}^{\partial_{y_*}\psi_1} - 2a^2(m+p) c_{m,p}^{\psi_1}.$$
7. Next m.
8. Next p.

Approximations for second derivatives can be computed directly from ψ_1 rather than using the first derivatives as a bootstrap.

We can calculate the vector $c^{\partial_{x_*x_*}\psi_1}$ for the representation

$$\frac{\partial^2\psi_1}{\partial {x_*}^2} = \sum_{p=0}^{N}\sum_{m=0}^{N+1} c_{m,p}^{\partial_{x_*x_*}\psi_1} \frac{{T_*}^{2m}}{{R_*}^{2(m+p+1)}} R^{2p} \tag{A.4}$$

using the following algorithm to determine $c^{\partial_{x_*x_*}\psi_1}$ from the c^{ψ_1}.

Algorithm for $\frac{\partial^2}{\partial {x_*}^2}$.

1. Initialize the vector for $c^{\partial_{x_*x_*}\psi_1}$ to zero.
2. $c_{1,0}^{\partial_{x_*x_*}\psi_1} = -\frac{1}{2a^2}$ from the logarithmic term in ψ_1. (This step would not be included for general polynomials in $\frac{{T_*}^{2m}}{{R_*}^{2n}}$.)
3. $p \leftarrow 0$ to N.
4. $m \leftarrow 0$ to $N+1$.
5. If $m > 0$,
$$c_{m-1,p}^{\partial_{x_*x_*}\psi_1} = c_{m-1,p}^{\partial_{x_*x_*}\psi_1} + \frac{2}{a^2}(m+p)(2p-m)c_{m,p}^{\psi_1}.$$
6. If $m > 1$,
$$c_{m-2,p}^{\partial_{x_*x_*}\psi_1} = c_{m-2,p}^{\partial_{x_*x_*}\psi_1} + \frac{2}{a^2}m(m-1)c_{m,p}^{\psi_1}.$$
7. $$c_{m,p}^{\partial_{x_*x_*}\psi_1} = c_{m,p}^{\partial_{x_*x_*}\psi_1} + \frac{2}{a^2}(p+m)(p-m)c_{m,p}^{\psi_1}.$$
8. If $m < N-1$,
$$c_{m+1,p}^{\partial_{x_*x_*}\psi_1} = c_{m+1,p}^{\partial_{x_*x_*}\psi_1} + \frac{2}{a^2}(p+m)c_{m,p}^{\psi_1}.$$
9. Next m.
10. Next p.

We can calculate the vector $c^{\partial_{y_*y_*}\psi_1}$ for the representation

$$\frac{\partial^2\psi_1}{\partial {y_*}^2} = \sum_{p=0}^{N}\sum_{m=0}^{N+1} c_{m,p}^{\partial_{y_*y_*}\psi_1} \frac{{T_*}^{2m}}{{R_*}^{2(m+p+1)}} R^{2p} \tag{A.5}$$

using the following algorithm to determine $c^{\partial_{y_*y_*}\psi_1}$ from the c^{ψ_1}.

Algorithm for $\frac{\partial^2}{\partial y_*^2}$.

1. Initialize the vector for $c^{\partial_{y_*y_*}\psi_1}$ to zero.
2. $c_{1,0}^{\partial_{y_*y_*}\psi_1} = \frac{1}{2}a^2$ from the logarithmic term in ψ_1. (This step would not be included for general polynomials in $\frac{{T_*}^{2m}}{{R_*}^{2n}}$.)
3. $p \leftarrow 0$ to N.
4. $m \leftarrow 0$ to $N+1$.
5. If $m > 0$,
$$c_{m-1,p}^{\partial_{y_*y_*}\psi_1} = c_{m-1,p}^{\partial_{y_*y_*}\psi_1} + 2a^2(m+p)(2p-m)c_{m,p}^{\psi_1}.$$
6. If $m > 1$,
$$c_{m-2,p}^{\partial_{y_*y_*}\psi_1} = c_{m-2,p}^{\partial_{y_*y_*}\psi_1} + 2a^2 m(m-1)c_{m,p}^{\psi_1}.$$
7. $$c_{m,p}^{\partial_{y_*y_*}\psi_1} = c_{m,p}^{\partial_{y_*y_*}\psi_1} + 2a^2(p+m)(p-m)c_{m,p}^{\psi_1}.$$
8. If $m < N-1$,
$$c_{m+1,p}^{\partial_{y_*y_*}\psi_1} = c_{m+1,p}^{\partial_{y_*y_*}\psi_1} - 2a^2(p+m)c_{m,p}^{\psi_1}.$$
9. Next m.
10. Next p.

We can calculate the vector $c^{\partial_{x_*y_*}\psi_1}$ for the representation

$$\frac{\partial^2\psi_1}{\partial x_*\partial y_*} = \sum_{p=0}^{N}\sum_{m=0}^{N+1} c_{m,p}^{\partial_{x_*y_*}\psi_1} x_* y_* \frac{{T_*}^{2m}}{{R_*}^{2(m+p+2)}} R^{2p} \tag{A.6}$$

using the following algorithm to determine $c^{\partial_{y_*y_*}\psi_1}$ from the c^{ψ_1}.

Algorithm for $\frac{\partial^2}{\partial x_*\partial y_*}$.

1. Initialize the vector for $c^{\partial_{y_*y_*}\psi_1}$ to zero.
2. $c_{0,0}^{\partial_{x_*y_*}\psi_1} = -1$ from the logarithmic term in ψ_1. (This step would not be included for general polynomials in $\frac{{T_*}^{2m}}{{R_*}^{2n}}$.)
3. $p \leftarrow 0$ to N.
4. $m \leftarrow 0$ to $N+1$.
5. If $m > 1$,
$$c_{m-2,p}^{\partial_{x_*y_*}\psi_1} = c_{m-2,p}^{\partial_{x_*y_*}\psi_1} - 4m(m-1)c_{m,p}^{\psi_1}.$$
6. $$c_{m,p}^{\partial_{x_*y_*}\psi_1} = c_{m,p}^{\partial_{x_*y_*}\psi_1} + 4(m+p)(m+p+1)c_{m,p}^{\psi_1}.$$
7. Next m.
8. Next p.

Higher order derivatives are calculated using first and second derivatives as building blocks and using these building blocks in the proper order. For instance, to calculate $\frac{\partial^3 \psi_1}{\partial {x_*}^3}$, we would begin with ψ_1 and calculate $\frac{\partial^2 \psi_1}{\partial {x_*}^2}$, which has the form given in (A.4). Then, we can apply the same $\frac{\partial}{\partial x_*}$ operation given before but without step 2 because there is no logarithmic term and the index on the $\frac{{T_*}^{2m}}{{R_*}^{2n}}$ terms is shifted by one. Therefore, we develop the representation

$$\frac{\partial \psi_1}{\partial {x_*}^3} = \sum_{p=0}^{N} \sum_{m=0}^{N+1} c_{m,p}^{\partial_{x_* x_* x_* x_*} \psi_1} x_* \frac{{T_*}^{2m}}{{R_*}^{2(m+p+2)}} R^{2p} \tag{A.7}$$

using the algorithm below.

Algorithm for $\frac{\partial}{\partial x_*}$.

1. Initialize the vector for $c^{\partial_{x_* x_* x_* x_*} \psi_1}$ to zero.
2. $p \leftarrow 0$ to N.
3. $m \leftarrow 0$ to $N+1$.
4. If $m > 0$, then
$$c_{m,p}^{\partial_{x_* x_* x_* x_*} \psi_1} = c_{m,p}^{\partial_{x_* x_* x_* x_*} \psi_1} + \frac{2}{a^2} m c_{m,p}^{\partial_{x_* x_* x_*} \psi_1}.$$
5.
$$c_{m,p}^{\partial_{x_* x_* x_* x_*} \psi_1} = c_{m,p}^{\partial_{x_* x_* x_* x_*} \psi_1} - \frac{2}{a^2} (m+p+1) c_{m,p}^{\partial_{x_* x_* x_*} \psi_1}.$$
6. Next m.
7. Next p.

AN ALGORITHM FOR TWO-DIMENSIONAL MESH GENERATION BASED ON THE PINWHEEL TILING*

PRITAM GANGULY†, STEPHEN A. VAVASIS‡, AND KATERINA D. PAPOULIA§

Abstract. We propose a new two-dimensional meshing algorithm called PINW able to generate meshes that accurately approximate the distance between any two domain points by paths composed only of cell edges. This technique is based on an extension of pinwheel tilings proposed by Radin and Conway (see [C. Radin, *Ann. of Math.* (2), 139 (1994), pp. 661–702]). We prove that the algorithm produces triangles of bounded aspect ratio. This kind of mesh would be useful in cohesive interface finite element modeling when the crack propagation path is an outcome of a simulation process.

Key words. pinwheel tiling, mesh generation, isoperimetric, cohesive interface finite element

AMS subject classifications. 52C23, 68U05

DOI. 10.1137/040611343

1. Introduction.

One of the most widely used techniques to simulate fracture is cohesive interface finite element modeling. In this kind of model, the area or volume under consideration is subdivided into bulk elements, which are typically triangles or quadrilaterals in two dimensions and tetrahedra or hexahedra in three dimensions. Next, interfacial elements, which are edge elements in two dimensions or surface elements in three dimensions, are placed between some or all pairs of adjacent bulk elements. The cohesive model prescribes a relationship relating traction to relative displacement on the interfacial elements. There is an abundance of literature that deals with the nature of this relationship; e.g., see [5] and the references therein. A widely accepted modeling assumption is that the total energy needed to create the crack is proportional to its surface area (or length in two dimensions). In fact, the critical energy release rate G_c per unit surface area or length of crack is often a parameter of the cohesive model.

In a finite element model, the energy release rate is associated with surface area or length of interfacial elements composing the crack being modeled. If the discrepancy between the "true" crack path (i.e., the path the crack would follow if it were not for the finite element constraint that the crack path must lie on predetermined interfacial elements) and the path of the simulated crack is large for certain paths, then nonphysical preferred crack directions can exist. In other words, the results of the simulation would depend upon how well the boundaries of the mesh cells are aligned along the true crack path. In this paper, we propose a meshing technique that approximates the true path with the path along mesh boundaries with high accuracy even though the true path is unknown to the mesh generation algorithm. In particular, meshes generated by this technique have the property that for any crack path, the simulated

and true crack path lengths converge to each other upon refining the mesh, which is a property not possessed by other simpler families of meshes. We call this algorithm the PINW mesh generator because it is based on an extension of the 1:2 pinwheel tiling described in the next section.

In section 3 we define "deviation ratio" and consider a simple experiment to test the properties of the 1:2 pinwheel mesh. The 1:2 pinwheel tiling seems to be too restricted to be useful for a general-purpose algorithm, so we explain how to generalize it to arbitrary triangles in section 4. This generalization is the basis for our meshing algorithm PINW. In section 5 we prove that our generalization still has the isoperimetric property. Then in section 6 we describe the algorithm. The main new ingredient introduced in that section is a procedure to convert a tiling to a mesh. The aspect ratio of the resulting mesh is analyzed in section 7.

The aspect ratio of the mesh is important for the cohesive fracture application because the bulk elements (e.g., triangles in two dimensions) are used to model a continuum mechanical theory such as linear elasticity. It is well known (see, e.g., Theorem 4.4.4 of [2], in which aspect ratio is called "chunkiness") that poorly shaped elements can lead to substantial errors in the elasticity solution.

2. Pinwheel tilings. In this section, we provide a brief introduction to the properties of pinwheel tilings. Tilings are a covering of Euclidean 2-space, $\mathcal{E}^2$, starting with a finite number of shapes called [illegible]. The tilings are constructed by translated and rotated copies of the prototiles that intersect each other only along the boundaries. The tilings were proposed to model crystallographic structures in the physics community.

The pinwheel tilings [6] are classified as [illegible]. In $\mathcal{E}^2$ this is equivalent to saying that no translation of the tiling leaves it invariant. The basic pinwheel tiling as developed by Radin and Conway (see [6]) has a hierarchical structure and is constructed by successive operations of subdivisions and expansions.

Consider a right triangle P with legs of length 1 and 2 referred to as the [illegible] and [illegible] sides. The hypotenuse is thus of length $\sqrt{5}$ and will be called the [illegible] side. The vertices will be named similarly; that is, the [illegible], and [illegible] vertices are opposite the corresponding sides. For brevity, we will call a right triangle with the ratio of its short to medium edge equal to 1/2 a "1:2 right triangle." This single tile is subdivided into five triangles that are all congruent to each other as shown in Figure 2.1. We call this subdivision into five triangles the "1:2 pentasection."

If one dilates the configuration in Figure 2.1 by a factor of $\sqrt{5}$ and then rotates and translates the resulting figure so that the dilated copy of C ends up coincident with the original tile P, then a larger subset of $\mathcal{E}^2$ is now tiled. Then 1:2 pentasection is applied to each of the five copies of P, and then another dilation followed by rotation and translation is carried out. Continuing this process infinitely would lead to a tiling of the plane. Thus, in the case of the standard pinwheel tilings, P and P_R (where P_R denotes the reflection of P about the x-axis) form the set of fixed prototiles, and the tiling uses translations and rotations of this set.

For our purposes, however, we will concentrate just on the repeated application of the 1:2 pentasection and omit the dilation, translation, and rotation steps, leading to the "subdivision pinwheel tiling" in which the cell diameter tends to zero and the area of the plane covered by the mesh does not expand from step to step. This is because we are interested in generating a mesh with varying amounts of refinement for a fixed region rather than a mesh that ultimately covers $\mathcal{E}^2$. In the subdivision pinwheel tiling, one starts with a fixed 1:2 triangle and then repeatedly subdivides

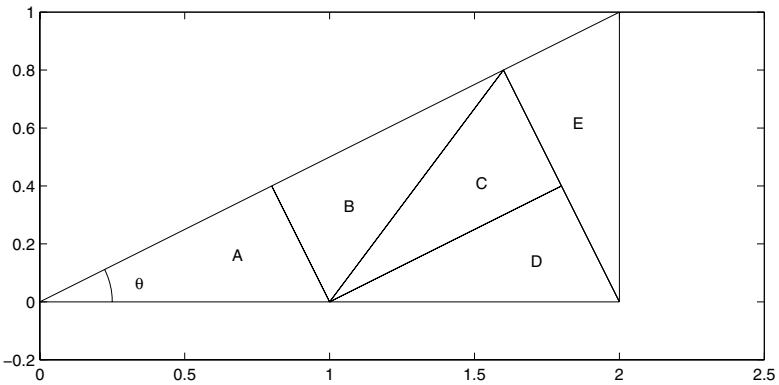

FIG. 2.1. *Basic pinwheel subdivision proposed by Radin.*

first the initial triangle and then each subtriangle into five congruent subtriangles using the 1:2 pentasection.

One can enumerate the rotation angles of the child triangles with respect to P and P_R as $R_\theta P_R$, $R_{\pi+\theta}P$, $R_\theta P$, $R_\theta P_R$, $R_{\frac{\pi}{2}+\theta}P$ corresponding to A, B, C, D, E in Figure 2.1, respectively. Here R_θ is rotation by θ in the counterclockwise direction. For a 1:2 right triangle, $\theta = \arctan(1/2)$, and θ/π in this case is irrational. The significance of this is as follows. As the number of subdivisions goes to infinity, so do the distinct orientations of the triangles. For example, suppose we keep track of the orientation of all triangles of type C with respect to the parent triangle in the subdivisions. As can be seen in Figure 2.1, the angle made by a triangle of type C with respect to the parent in the nth subdivision is $n\theta$. Since θ/π is irrational, $n\theta$ will represent a different angle for each n.

This presence of an infinite number of orientations leads to a special property known as the isoperimetric property [7]. For a tiling of $\mathcal{E}^2$, [illegible] means that given an $\epsilon > 0$, there exists a ρ such that for any two points p and q on the boundaries of the triangles with $\|p - q\| > \rho$, the shortest path from p to q that uses only tile edges has length at most $(1 + \epsilon)\|p - q\|$. Here $\|p - q\|$ denotes the Euclidean distance from p to q, which will also be denoted as $|pq|$, i.e., the length of edge pq.

There is an analogous property for the subdivision pinwheel tiling. In this case, let p, q be two points on the boundary of the initial triangle. Then for every $\epsilon > 0$, there exists an n such that after n recursive subdivisions of the initial triangle, the shortest path from p to q using only triangle edges is at most $\|p - q\|(1 + \epsilon)$. This theorem can be generalized so that p and q do not have to be on the boundary of the initial triangle but may be any two distinct boundary or interior points.

The isoperimetric property is the reason that pinwheel tilings are attractive for cohesive interface modeling. Consider a finite region $\Omega \subset \mathcal{E}^2$ tiled with an infinite sequence of pinwheel tilings $\mathcal{M}_1, \mathcal{M}_2, \ldots$ in which the triangles in $\mathcal{M}_i$ all have side lengths η_i, $2\eta_i$, $\sqrt{5}\eta_i$, and $\eta_i \to 0$ as $i \to \infty$. Then for an arbitrary straight segment of length λ connecting $p \in \Omega$ to $q \in \Omega$, and for an arbitrary $\epsilon > 0$, there exists an i such that in each of the tilings $\mathcal{M}_i, \mathcal{M}_{i+1}, \ldots$, there is a path from p to q using only mesh edges (except for initial and ending segments to connect p and q to the boundaries of the triangles that contain them) such that the length of the path is $\lambda(1 + \epsilon)$. We will give a proof of this result in a more general setting in section 5.

Since an arbitrary line segment can be well approximated by mesh edges, so can any piecewise smooth curve or network of such curves. The reason is that a network of piecewise smooth curves can be approximated arbitrarily accurately with a network of line segments. Then each line segment can be approximated arbitrarily accurately with a path from the pinwheel tiling.

Thus, when used for cohesive fracture, the pinwheel tiling has the property that all possible crack paths are approximated as accurately as desired (in terms of their length) by paths that use only mesh edges, as the mesh diameter tends to zero. As we shall see in the next section, more common mesh generation techniques do not have this property.

3. A computational experiment. In this section we carry out some simple experiments to quantify the isoperimetric property of the 1:2 tiling. Since our interest here is in meshes, we first explain how to convert the 1:2 pinwheel tiling to a mesh. It is apparent from Figure 2.1 that the pinwheel tiling is almost a triangulation except for the hanging node bisecting the medium side of triangle E. (Recall our terminology from the previous section that the short, medium, and long sides of a 1:2 right triangle are the edges of length 1, 2, and $\sqrt{5}$, respectively; the short vertex is opposite from the short side; the medium and long vertices are defined analogously.) We define a [illegible] of a planar subdivision into triangles to be a point that is a vertex of one triangle but lies on the strict relative interior of an edge of another triangle.

It is fairly simple to make the pinwheel tiling a mesh [6]: We divide every triangle into two by joining its medium vertex to the midpoint of its medium edge. In fact, it is not necessary to split all the triangles, and in our example we have obtained a mesh by splitting a certain subset of the tiles. This splitting is done only on the finest level of the pinwheel subdivision.

Our computational experiment is as follows. Starting from a 1:2 rectangle, we divide it into two 1:2 triangles and then apply the 1:2 pentasection n times to each of the 1:2 triangles. Thus, the final pinwheel tiling has $2 \cdot 5^n$ triangles. The resulting tiling of the original rectangle is then converted to a mesh using the technique in the previous paragraph.

Given a tiling $\mathcal{T}$ of a domain Ω, let $\mathrm{Skel}(\mathcal{T})$ be the 1-skeleton of $\mathcal{T}$, that is, the union of all edges of all triangles, and let $V(\mathcal{T})$ be the set of all vertices of $\mathcal{T}$. Let ρ be a positive parameter chosen small enough so that Ω contains a disk of diameter ρ. We propose to evaluate isoperimetric quality of the triangulation with the following quantity, which we refer to as the ρ [illegible]:

$$\operatorname*{dev}_{\rho}(\mathcal{T}) = \max\left\{ \frac{\mathrm{dist}_{\mathrm{Skel}(\mathcal{T})}(p,q)}{\|p-q\|_{\Omega}} : p,q \in V(\mathcal{T}) \text{ and } \|p-q\| \geq \rho \right\}.$$

Here, $\mathrm{dist}_{\mathrm{Skel}(\mathcal{T})}(\cdot,\cdot)$ means the shortest distance among paths restricted to $\mathrm{Skel}(\mathcal{T})$. The notation $\|p-q\|_{\Omega}$ means the geodesic distance from p to q, i.e., the shortest path among paths lying in Ω. Thus, this quantity measures the maximum ratio between the paths in the mesh versus geodesic paths. Clearly for any mesh $\mathcal{T}$ of any polygon, $\mathrm{dev}_{\rho}(\mathcal{T}) > 1$. The pinwheel mesh of the 1:2 rectangle has the property that for any $\rho \in (0,1)$, $\mathrm{dev}_{\rho}(\mathcal{PT}_m) \to 1$ as $m \to \infty$, where $\mathcal{PT}_m$ is the pinwheel tiling of the 1:2 rectangle after m levels of refinement.

Our experiment is to evaluate $\mathrm{dev}_1(\mathcal{PT}_m)$ for $\mathcal{PT}_1, \ldots, \mathcal{PT}_5$. The results are depicted in Table 3.1. The worst-case shortest path is shown in Figure 3.1.

In contrast, consider the meshes in Figure 3.2. The deviation ratios of these meshes have lower bounds greater than 1 irrespective of the number of subdivisions.

TABLE 3.1
Direct computation of deviation ratios for the first five levels of pinwheel subdivision.

n	$\mathrm{dev}_1(\mathcal{PT}_n)$
1	1.3416
2	1.1948
3	1.1843
4	1.1264
5	1.0831

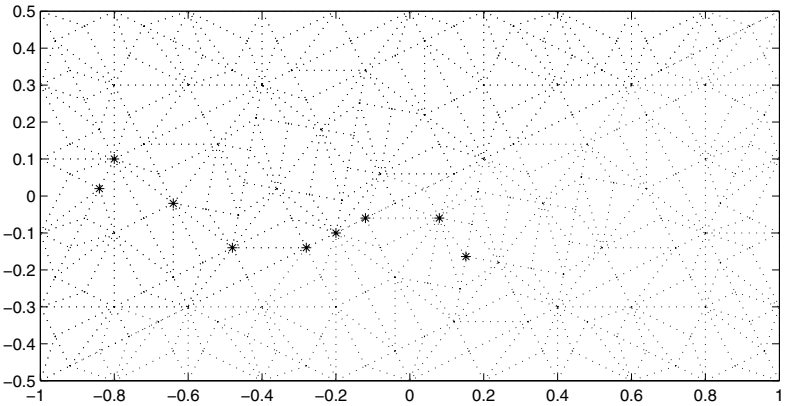

FIG. 3.1. *The path with the largest deviation ratio in $\mathcal{PT}_4$ is marked with asterisks.*

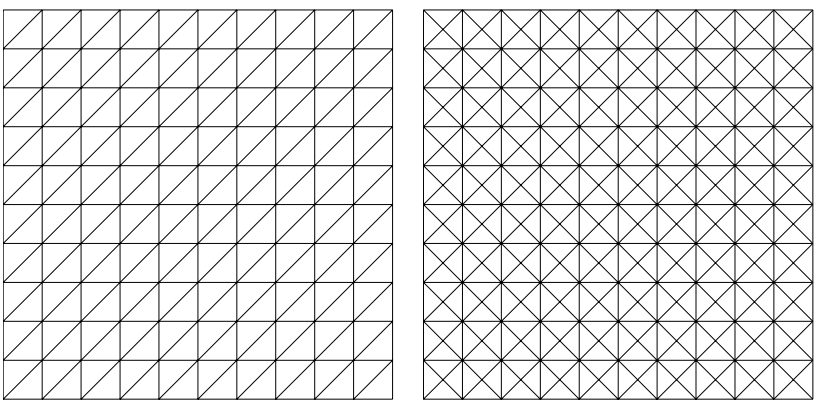

FIG. 3.2. *Two regular meshes of a square.*

In particular, the lower bound is $\sqrt{2} \approx 1.414$ for the mesh in Figure 3.2(a). For the mesh that was used by Xu and Needleman [10] (one of the first papers on cohesive finite element modeling), which is shown in Figure 3.2(b) and is sometimes called a "cross-triangle quadrilateral" mesh, the worst-case deviation ratio can be shown to be approximately equal to 1.082 in the limit as the mesh cell size tends to 0.

4. Generalization of pinwheel tilings. Pinwheel tiling based on 1:2 pentasection was extended to a tiling using an arbitrary right triangle and its reflection

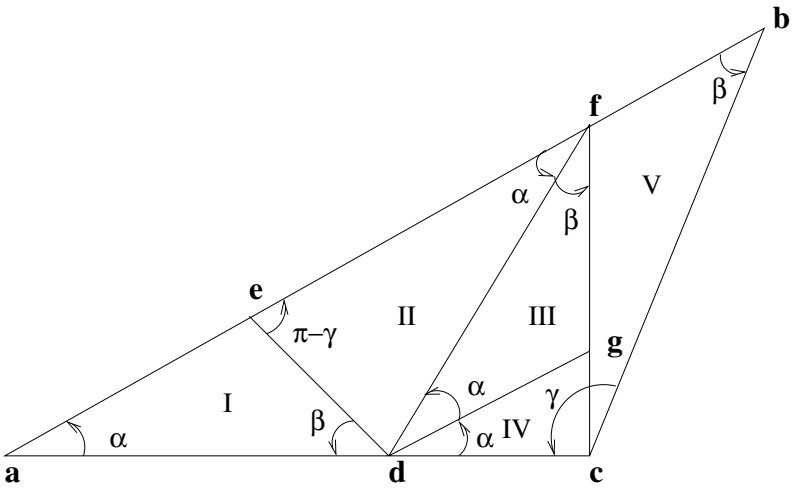

FIG. 4.1. *Our ATP subdivision of a triangle into five subtriangles, which generalizes* 1:2 *pinwheel subdivision.*

as prototiles by Sadun [8]. We now describe our approach to extend the pinwheel subdivision to arbitrary (nonright) triangles.

First, we propose a way of subdividing a general triangle and show that any number of subdivisions would produce triangles similar to a finite set of prototiles. Consider the triangle shown in Figure 4.1. We denote the vertices by a, b, and c and the included angles at these vertices by α, β, and γ, respectively, and assume that $\alpha < \gamma$. All angles are measured in radians unless otherwise noted. For the purpose of the ensuing description of our subdivision scheme, assume that abc are in clockwise order as in Figure 4.1. First, draw the segment cf such that f is a point on ab and $\angle fcb = \alpha$ measured counterclockwise from cb. From f draw fd such that d is on ac and $\angle dfc = \beta$ measured clockwise from fc. From d draw e and g such that e is on ab and g is on cf and $\angle ade = \beta$ clockwise from da and $\angle gdc = \alpha$ counterclockwise from dc. Thus, we have a subdivision of a general triangle $\triangle abc$ into five triangles of which I, III, and V are similar to the parent and the remaining two, II and IV, are similar to each other but not to the parent. Note that we required $\alpha < \gamma$ to make this construction. Let us call this procedure for subdividing a triangle into five subtriangles [illegible] subdivision or ATP subdivision for short. A different subdivision will result if the three nodes are reordered. Therefore, we assume that when ATP subdivision is applied, the nodes are specified in a certain sequence a, b, c. We assume also that the sequence is [illegible] for ATP, meaning that $\alpha < \gamma$.

THEOREM 4.1. [illegible] $\triangle abc$ [illegible] $\angle a, \angle b, \angle c$ [illegible] α, β, γ [illegible] $A_1 = \{\alpha, \beta, \gamma\}$ [illegible] $A_2 = \{\alpha, \gamma - \alpha, \pi - \gamma\}$ [illegible]. This is obvious by simply checking all the angles in Figure 4.1 and using the fact that angles of a triangle sum to π. Observe that triangles I, III, and V in Figure 4.1 are similar to $\triangle abc$ while triangles II and IV have angles from A_2. □

Let us assume that the vertices of triangles I, III, and V are sequenced according to their similarity with $\triangle abc$. Let us assume that triangles II and IV have angles sequenced $\alpha, \gamma - \alpha, \pi - \gamma$. Call these the [illegible] sequences of the vertices of the

subtriangles (inherited from $\triangle abc$). Note that the inherited sequence is feasible: $\alpha < \pi - \gamma$ since $\alpha + \beta + \gamma = \pi$.

THEOREM 4.2. [illegible] A_1 [illegible] A_2 [illegible]. One checks that if we define $\alpha' = \alpha$, $\beta' = \gamma - \alpha$, and $\gamma' = \pi - \gamma$, then $(\alpha', \gamma' - \alpha', \pi - \gamma') = (\alpha, \beta, \gamma)$. □

For the rest of this paper, we say that a triangle with angles α, β, γ is [illegible] to a triangle with angles $\alpha, \gamma - \alpha, \pi - \gamma$. The point of Theorem 4.2 is that conjugacy is a symmetric relationship. We remark that if the original triangle is a right triangle, i.e., $\gamma = \pi/2$, then this triangle is similar to its conjugate. This is the case considered by [8].

Starting from an arbitrary nonequilateral triangle $T_1 = \triangle abc$, let us assume that its nodes are sequenced a, b, c according to $\alpha \le \beta \le \gamma$. One can produce a tiling of T_1 by applying ATP to T_1 and then recursively applying ATP to subtriangles according to some scheme. The previous theorem implies that all the resulting subtriangles are congruent either to T_1 or its conjugate. We call the resulting subdivision of T_1 a [illegible], GPT for short, of T_1.

This procedure runs into a difficulty when $\gamma \approx \alpha$ (i.e., the initial triangle is close to equilateral) because in this case the conjugate triangle will have poor aspect ratio. We define the [illegible] of a triangle to be the square of the longest side length of the triangle divided by its area. An angle close to 0 automatically implies poor (large) aspect ratio as proved later in Lemma 7.8.

If an initial triangle is close to equilateral and therefore has $\gamma \approx \alpha$, we first subdivide it into three about its in-center; that is, we join the in-center to the vertices of the original triangle to form three subtriangles. We use a cutoff K_s in our algorithm: If $\gamma - \alpha < K_s$, then the preliminary tripartition is carried out. Parameter K_s is chosen to optimize the smallest angle. In other words, a parent is divided about the in-center if the smallest angle in $A_1 \cup A_2$ without preliminary tripartition is smaller than the smallest angle among the three sets $A_1 \cup A_2$ (one A_1 and one A_2 for each subtriangle) after tripartition. It can be shown that with the best choice of cutoff K_s, it is guaranteed that $\gamma - \alpha > 0.4$.

5. Isoperimetric property. This section is devoted to showing the result that the GPT introduced in the previous section obeys an isoperimetric inequality. The analysis and proof technique in this section closely follow the proof from [7]. The following is the key lemma in the proof of isoperimetry.

LEMMA 5.1. [illegible] $T = \triangle abc$ [illegible] T [illegible] α, β, γ [illegible] a, b, c, [illegible] $\alpha < \gamma$ [illegible] α/π [illegible] $\theta \in [0, \pi)$ [illegible] $\epsilon > 0$ [illegible] T [illegible] E [illegible] E [illegible] x [illegible] $(\theta - \epsilon, \theta + \epsilon)$ [illegible] θ [illegible] $\theta + \pi$ [illegible] x [illegible] E [illegible] $\zeta(\alpha, \beta, \gamma, \epsilon)\lambda$ [illegible] ϵ [illegible] $\zeta()$ [illegible] λ [illegible] T [illegible]. Observe that Triangle III in ATP subdivision is similar to the initial triangle T but is rotated by α. Call this triangle T'. If this triangle is subdivided by ATP, there will be another smaller copy of T, say T'', rotated by 2α, etc. The infinite sequence $\alpha, 2\alpha, 3\alpha, \ldots$ taken mod π is dense in the interval $[0, \pi)$ by the assumption that α/π is irrational. Therefore, for some sufficiently fine tiling, there is an edge E of triangle $T^{(k)}$ in the interval $(\theta - \epsilon, \theta + \epsilon)$.

For the second part of the lemma, observe that for any $\epsilon > 0$ there is an $n \equiv n(\epsilon, \alpha)$ such that every point in $[0, \pi]$ is distance (mod π) at most ϵ from at least one point in the set $\{\alpha, 2\alpha, 3\alpha, \ldots, n\alpha\}$. Therefore, one of $T, T', \ldots, T^{(n)}$ described in the last paragraph will have the desired edge E. The longest side length of T is λ; the longest side length of T' is $q(\alpha, \beta, \gamma)\lambda$, where q is some universal function (not depending on anything other than α, β, γ) derived from our construction. By similarity, the longest edge of $T^{(2)}$ has length $q(\alpha, \beta, \gamma)^2\lambda$. Thus, if we define $\zeta(\alpha, \beta, \gamma, \epsilon) \equiv \phi(\alpha, \beta, \gamma)q(\alpha, \beta, \gamma)^{n(\epsilon,\alpha)}$, where $\phi(\alpha, \beta, \gamma)$ is the ratio of the shortest to longest side length of T, then the length of E is at least $\zeta(\alpha, \beta, \gamma, \epsilon)\lambda$. This proves the second part of the lemma. □

For the first main theorem of this section, we need more definitions. We say that a GPT $\mathcal{T}'$ of a triangle T [illegible] another GPT $\mathcal{T}$ of T provided that for each tile U of $\mathcal{T}$, either U appears in $\mathcal{T}'$ or a subdivision of U appears in $\mathcal{T}'$. This definition implies that $V(\mathcal{T}) \subset V(\mathcal{T}')$ and $\mathrm{Skel}(\mathcal{T}) \subset \mathrm{Skel}(\mathcal{T}')$. If T is a triangle, we use the words [illegible] and [illegible] of T synonymously. The [illegible] of T is the length of its longest side, and the [illegible] of a tiling is the maximum over all tiles of triangle side lengths.

The first main theorem for this section is as follows.

THEOREM 5.2. [illegible] $T = \triangle abc$ [illegible] α, β, γ [illegible] a, b, c, [illegible] $\alpha < \gamma$ [illegible] α/π [illegible] $\mathcal{T}^0, \mathcal{T}^1, \ldots$ [illegible] T [illegible] i [illegible] η_i [illegible] $\mathcal{T}^i$ [illegible] (a) $\mathcal{T}^{i+1}$ [illegible] $\mathcal{T}^i$ [illegible] (b) $\eta_i \to 0$ [illegible] $i \to \infty$ [illegible] p, q [illegible] T [illegible]

$$\lim_{i\to\infty} \operatorname*{dist}_{\mathrm{Skel}(\mathcal{T}^i)}(p, q) = |pq|.$$

In other words, every straight-line path connecting two points (p, q) on the boundary of T is approximated with arbitrary accuracy by a path of edges of the tiling.

[illegible]. In order to prove this theorem, we require a simultaneous analysis of tilings of a conjugate triangle. Therefore, let us change notation so that the original triangle is T_1, its conjugate is T_2, and there are two sequences of generalized pinwheel tilings: $\mathcal{T}_1^0, \mathcal{T}_1^1, \mathcal{T}_1^2, \ldots$, which are tilings of T_1, and $\mathcal{T}_2^0, \mathcal{T}_2^1, \mathcal{T}_2^2, \ldots$, which are tilings of T_2.

Without loss of generality, let us further assume that $\mathcal{T}_\nu^0$ for $\nu \in \{1, 2\}$ is simply $\{T_\nu\}$, and that each subsequent $\mathcal{T}_\nu^i$ is obtained from $\mathcal{T}_\nu^{i-1}$ by applying ATP to exactly one tile (so that $\mathcal{T}_\nu^i$ has exactly $4i + 1$ tiles). This assumption is without loss of generality because we can take the original given sequence $\mathcal{T}_\nu^1, \mathcal{T}_\nu^2$, etc., and insert all intermediate tilings (i.e., if the original $\mathcal{T}_\nu^i$ was obtained from T_ν^{i-1} via l ATP operations, then we can insert $l - 1$ intermediate tilings in the sequence). If we prove that the limiting property holds for the augmented sequence, then it certainly also holds for the original sequence.

We make the following preliminary observation about GPTs. If $\mathcal{S}$ is any tiling of T_ν for $\nu = 1$ or 2 obtained by repeated ATP subdivision, then there exists an i such that $\mathcal{T}_\nu^i$ refines $\mathcal{S}$.

We use the following additional definitions and notation to prove the theorem.

- Let ∂T_ν denote the boundary of T_ν, $\nu = 1, 2$. Thus ∂T_1 and ∂T_2 are each unions of three segments. As noted above, these segments are called either [illegible] or [illegible] of T_ν.
- Define $X_\nu = \partial T_\nu \times \partial T_\nu$ for $\nu = 1, 2$, that is, the set of ordered pairs of boundary points.

- For any $(p,q) \in X_\nu$, let $f_\nu((p,q),n)$ denote $\mathrm{dist}_{\mathrm{Skel}(\mathcal{T}_\nu^n)}(p,q)$.
- For $(p,q) \in X_\nu$, let $g_\nu((p,q),n) = f_\nu((p,q),n)/\|p-q\|$, $\nu = 1,2$. If we took the maximum of this quantity over choices of (p,q), we would arrive at a quantity analogous to the "deviation ratio" introduced in section 3. Clearly $g_\nu((p,q),n) \geq 1$ for all p,q,n. If $p = q$, then define $g_\nu((p,p),n)$ to be 1.
- Let $f_\nu^*(p,q) = \inf_{n\geq 0} f_\nu((p,q),n)$. Note that $f_\nu((p,q),n)$ is a nonincreasing function of n (because every edge of $\mathcal{T}_\nu^n$ is covered by edges of $\mathcal{T}_\nu^{n+1}$ for all n), so this inf is also the limit of the sequence.
- Let $g_\nu^*(p,q) = \inf_{n\geq 0} g_\nu((p,q),n)$. Clearly $g_\nu^*(p,q) \geq 1$ for all p,q. For the same reason as above, g^* is also the limit of the sequence.

  The main theorem now reduces to showing that $g_1^*(p,q) = 1$ for all $(p,q) \in X_1$. Our proof technique requires us to claim more strongly that $g_\nu^*(p,q) = 1$ for all $(p,q) \in X_\nu$ for $\nu = 1$ and $\nu = 2$.
- Let η_ν be the length of the shortest edge of T_ν for $\nu = 1,2$. Let χ_ν be the length of the shortest edge among the five triangles that result from one application of ATP to T_ν, and let $\rho_\nu = \eta_\nu/\chi_\nu$.
- Let $X_\nu' \subset X_\nu$ denote ordered pairs (p,q) such that $p,q \in \partial T_\nu$ and such that $\mathrm{dist}_{\partial T_\nu}(p,q) \geq \chi_\nu$. Note that X_ν' is a compact set under usual product topology.

The reason for introducing X_ν' is that g_ν^* is continuous on X_ν' as we now proceed to show. (Once the main theorem is proved, we will have shown that g_ν^* is identically 1 and hence obviously continuous on all of X_ν, but continuity is not so easy to prove at this stage of the argument.) Observe that for $(p,q) \in X_\nu'$, $g_\nu^*(p,q) = f_\nu^*(p,q)/\|p-q\|$. We start with the following lemma.

LEMMA 5.3. [illegible] f_ν^* [illegible] X_ν

[illegible]. Let μ be the scalar such that $\mathrm{dist}_{\partial T_\nu}(p,q) \leq \mu\|p-q\|$ for all $(p,q) \in X_\nu$. This scalar depends on the sharpest angle of T_ν. Given two pairs $(p,q),(p',q') \in X_\nu$, and given $n > 0$, observe that $f_\nu((p,q),n) \leq f_\nu((p',q'),n) + \mu\|p-p'\| + \mu\|q-q'\|$. This follows because a possible path from p to q in $\mathrm{Skel}(\mathcal{T}_\nu^n)$ would follow p to p' along the outer boundary of T_ν (a distance of at most $\mu\|p-p'\|$), then p' to q' along the shortest path in $\mathrm{Skel}(\mathcal{T}_\nu^n)$ (a distance of $f_\nu((p',q'),n)$), followed by a path from q' to q along the outer boundary of T_ν. This argument is symmetric in (p,q) and (p',q'), so therefore we can combine the directions to claim

$$|f_\nu((p,q),n) - f_\nu((p',q'),n)| \leq \mu\|p-p'\| + \mu\|q-q'\|.$$

This inequality must hold in the limit of $n \to \infty$, thus proving that f_ν^* is continuous. □

This shows that the numerator in the formula $g_\nu^*(p,q) = f_\nu^*(p,q)/\|p-q\|$ is continuous. The denominator $\|p-q\|$ is also continuous and bounded away from 0 on X_ν'; hence g_ν^* is continuous on this set.

The following lemma shows that it suffices to analyze X_ν' rather than all of X_ν.

LEMMA 5.4. [illegible] $\nu = 1,2$

$$\sup\{g_\nu^*(p,q) : (p,q) \in X_\nu\} \leq \max(\sup\{g_1^*(p,q) : (p,q) \in X_1'\}, \sup\{g_2^*(p,q) : (p,q) \in X_2'\}).$$

[illegible]. Choose an arbitrary $(p,q) \in X_\nu$. This proof will show that

$$g_\nu^*(p,q) \leq \max(\sup\{g_1^*(p,q) : (p,q) \in X_1'\}, \sup\{g_2^*(p,q) : (p,q) \in X_2'\}).$$

Taking the supremum on the left will prove the result. If $(p,q) \in X_\nu'$, then the result is immediate since that value appears in one of the two terms in the right-hand side.

So assume for the rest of the proof that $(p,q) \in X_\nu - X'_\nu$. If p,q lie on the same side of T_ν, then the left-hand side is 1 because $f_\nu((p,q),n) = \|p-q\|$ for all n in this case since the boundaries of T_ν are covered by the edges of $\mathcal{T}_\nu^n$ for each n. Since the right-hand side is greater than or equal to 1, the result follows immediately.

The last case is that p,q are on distinct sides (and in particular, are not vertices of T_ν). In this case they must be less than distance χ_ν of the same vertex by definition of X'_ν. For the rest of the proof of this lemma, consider only the $\nu = 1$ case since the $\nu = 2$ case is similar.

First, suppose that p,q are both within distance χ_1 of vertex a of T_1. Without loss of generality, p lies on ab and q lies on ac. Consider the sequence of tiles $H_0 = T_1, H_1, H_2, \ldots$ such that H_i is the tile from $\mathcal{T}_\nu^i$ that contains vertex a. Each of these tiles is similar to T_1. The diameter of the H_i's tends to 0 as $i \to \infty$ by assumption. Thus, there is a k such that H_k contains both p and q but H_{k+1} fails to contain one or both of p or q. Let τ be the length of the shortest side of H_k. We claim that either $\|a-p\| \geq \tau/\rho_1$ or $\|a-q\| \geq \tau/\rho_1$. The reason is that if both $\|a-p\| < \tau/\rho_1$ and $\|a-q\| < \tau/\rho_1$, then p,q would both lie on the boundaries of H_{k+1} since the side lengths of H_{k+1} are all at least τ/ρ_1 by definition of ρ_1. This would contradict the choice of k.

As mentioned above, H_k is similar to T_1, and the constant of proportionality is τ/η_1. Note that H_k could be either a dilation of T_1 with no reflection or a dilation of T_1 with a reflection. Assume the former case since the latter is similar. There exist $\bar{p}$ and $\bar{q}$ lying on sides ab, ac of T_1 whose positions with respect to ab, ac are proportional to the positions of p,q with respect to the two sides of H_k. Refer to Figure 5.1. Since either $\|a-p\| \geq \tau/\rho_1$ or $\|a-q\| \geq \tau/\rho_1$ and the scaling factor between H_k and T_1 is τ/η_1, this means that at least one of $\bar{p}$, $\bar{q}$ is distance from a greater than or equal to $(\tau/\rho_1)/(\tau/\eta_1) = \chi_1$. Hence $(\bar{p},\bar{q}) \in X'_1$. For an arbitrary $n > 0$, consider the tiling $\mathcal{T}_*^n$ of H_k that is obtained by shrinking $\mathcal{T}_1^n$ by a factor of τ/η_1 and translating it so that it lies on top of H_k. The shortest path between p and q in this tiling is $f_1((\bar{p},\bar{q}),n)\tau/\eta_1$ by scaling. Also, there is an n' such that the portion of $\mathcal{T}_1^{n'}$ lying in H_k is strictly a refinement of $\mathcal{T}_*^n$ by the observation made at the beginning of the proof. The distance between p and q in this tiling is $f_1((p,q),n')$, and since $\mathcal{T}_1^{n'}$ refines $\mathcal{T}_*^n$, $f_1((p,q),n') \leq f_1((\bar{p},\bar{q}),n)\tau/\eta_1$. Note that $\tau/\eta_1 = \|p-q\|/\|\bar{p}-\bar{q}\|$ by similarity, so the previous inequality implies $g_1((p,q),n') \leq g_1((\bar{p},\bar{q}),n)$. Take the infimum over all n of both sides to conclude that $g_1^*(p,q) \leq g_1^*(\bar{p},\bar{q})$, thus establishing the lemma in this case.

In case that p,q are both within distance χ_1 from vertex b, the lemma follows by the same argument since the triangles containing b in all subdivisions of T_1 are similar to T_1.

The last case is that p,q are both within distance χ_1 of vertex c. Say, e.g., that p lies on ac and q on bc. In this case, the argument is slightly more complicated since there are two triangles containing c in the next level of subdivision. Let cf be the segment that is the common boundary to the two triangles of the next level of subdivision that meet vertex c. (Refer to Figure 4.1.) Let r be the point where segment pq crosses edge cf. Then the argument above shows that the infimum over n of the distance between p and r using edges from $\mathcal{T}_1^n$ is less than or equal to $|pr| \cdot g_2^*(\bar{p},\bar{r})$, where $(\bar{p},\bar{r}) \in X'_2$. Similarly, the infimum over n of the distance between r and q using edges from $\mathcal{T}_1^n$ is less than or equal to $|rq| \cdot g_1^*(\bar{r},\bar{q})$, where $(\bar{r},\bar{q}) \in X'_1$. Therefore, $f_1^*(p,q) \leq |pq| \cdot \max(\sup\{g_1^*(p,q) : (p,q) \in X'_1\}, \sup\{g_2^*(p,q) : (p,q) \in X'_2\})$ and thus the result follows. ∎

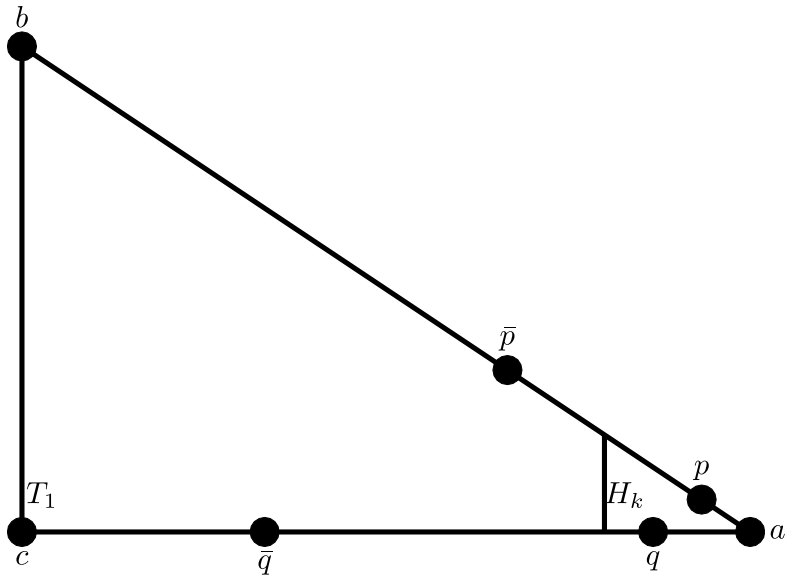

FIG. 5.1. *Construction in the proof of Lemma* 5.4. *The idea of the proof is that* $g_1^*(p,q)$ *cannot exceed* $g_1^*(\bar{p},\bar{q})$, *where* $\bar{p}$ *and* $\bar{q}$ *have positions in* T_1 *that are proportional to the positions of* p, q *in* H_k, *since any* (p,q) *path of tile edges in* H_k *for any particular tiling will eventually also occur (scaled up) as a* $(\bar{p},\bar{q})$ *path of tile edges in* T_1.

Finally, we conclude the proof of the main theorem by showing that $\sup\{g_\nu^*(p,q) : (p,q) \in X_\nu'\} = 1$ for $\nu = 1, 2$. To this end, choose the ν (either 1 or 2) that maximizes $\sup\{g_\nu^*(p,q) : (p,q) \in X_\nu'\}$. Without loss of generality, say $\nu = 1$ is chosen.

Since X_1' is a compact set and g_1^* is continuous on this set, there exists a (p^*, q^*) in X_1' that maximizes $g_1^*(p,q)$. If p^*, q^* lie on the same side of T_1, then $g_1^*(p^*, q^*) = 1$; thus the proof is finished. Else assume (for a contradiction) that $g_1^*(p^*, q^*) = \sigma > 1$. Let H^* be the line segment joining p^* and q^*.

Choose n_1 large enough so that there exists a tile T' in $\mathcal{T}_1^{n_1}$ such that $T' \cap H^*$ has positive length and is contained in the middle third H^*. Let the longest edge of T' be ω. For reasons to be explained below, we also choose n_1 large enough so that

$$\omega < \frac{(\sqrt{\sigma} - 1)\zeta(\alpha, \beta, \gamma, \arccos(1/\sqrt{\sigma}))}{6\sigma} |p^* q^*|, \tag{5.1}$$

where $\zeta()$ is the function defined by Lemma 5.1. Continue splitting until we reach split number $n_2 \geq n_1$ so that within $\mathcal{T}_1^{n_2}$, there exists a tile T'' in $\mathcal{T}_1^{n_2}$ lying inside in T' that has an edge making an angle θ with H^*, with $\cos\theta > 1/\sqrt{\sigma}$. This is possible by Lemma 5.1. See Figure 5.2. Let κ_2 be the length of this edge. By the second part of the lemma, we may assume $\kappa_2 \geq \zeta(a, b, c, \iota)\omega$, where $\iota = \arccos(1/\sqrt{\sigma})$.

Let v_1, v_2 be the endpoints of this edge with v_1 being the vertex near p^* and v_2 near q^*. Observe that $p^* v_1$, $v_1 v_2$, and $v_2 q^*$ make up a three-segment path from p^* to q^*. The length of this path is $\kappa_1 + \kappa_2 + \kappa_3$, where $\kappa_1 = |p^* v_1|$ and $\kappa_3 = |v_2 q^*|$. (We have already defined $\kappa_2 = |v_1 v_2|$.) Let λ_1, λ_2, and λ_3 be the lengths of the projections of $p^* v_1$, $v_1 v_2$, $v_2 q^*$, respectively, onto H^*. Because v_1 lies within T' while H^* crosses through T', the distance from v_1 to H^* is at most ω; hence

$$\kappa_1 \leq \sqrt{\lambda_1^2 + \omega^2} = \lambda_1 \sqrt{1 + \omega^2/\lambda_1^2}$$

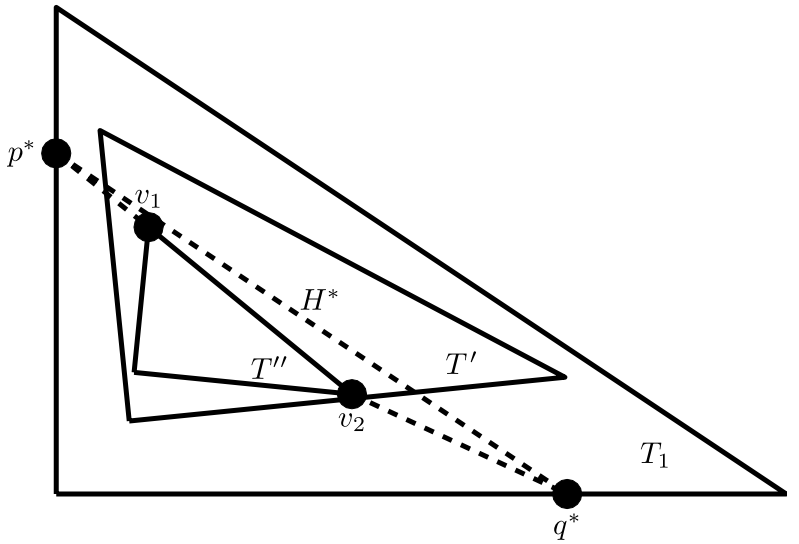

FIG. 5.2. *Construction for the proof of Theorem* 5.2. *In this figure,* $(p^*, q^*) \in X_1'$ *is the maximizer of* g_1^*. *Points* p^*, q^* *are connected by line segment* H^*. *Edge* v_1v_2 *of triangle* T'' *is very closely aligned with (i.e., makes a small angle with respect to)* H^*. *The assumption that* $g_1^*(p^*, q^*) > 1$ *leads to a contradiction because a path whose length relative to* H^* *is shorter than* $g_1^*(p^*, q^*)$ *is found by using tile edges to connect* p^* *to* v_1, *then the* v_1v_2 *line segment is followed, and then tile edges are used to connect* v_2 *to* q^*.

$$\begin{aligned} &\leq \lambda_1 \left(1 + \omega^2/\lambda_1^2\right) \\ &= \lambda_1 + \frac{\omega^2}{\lambda_1} \end{aligned}$$

and hence

$$\kappa_1 - \lambda_1 \leq \frac{\omega^2}{\lambda_1} \leq \frac{3\omega^2}{|p^*q^*|}. \tag{5.2}$$

(The factor of 3 arises because $\|p^* - v_1\| \geq \|p^* - q^*\|/3$ as assumed earlier.) Similarly,

$$\kappa_3 - \lambda_3 \leq \frac{3\omega^2}{|p^*q^*|}. \tag{5.3}$$

Next, because $\cos\theta > \frac{1}{\sqrt{\sigma}}$, where θ is the angle between H^* and v_1v_2, we have $\sqrt{\sigma}\lambda_2 > \kappa_2$. Therefore,

$$\sigma\lambda_2 - \kappa_2 > (\sqrt{\sigma} - 1)\kappa_2. \tag{5.4}$$

Next, note that

$$f_1^*(p^*, q^*) \leq \sigma\kappa_1 + \kappa_2 + \sigma\kappa_3, \tag{5.5}$$

thanks to the existence of the three-edge path $p^*v_1v_2q^*$. The reasoning is as follows. From p^* to v_1 there is a straight-line path of length κ_1. This path cuts through a finite list of triangles, say l triangles, within the tiling $\mathcal{T}_1^{n_2}$, since p^* and v_1 both lie on triangle edges of this tiling. Let the individual segments within these triangles be

of length $\mu_1, \ldots, \mu_l$. By construction, these quantities sum to κ_1. Then by further refinement, we can find paths within the tiling with lengths less than or arbitrarily close to $\mu_1\sigma$, $\mu_2\sigma$, etc., since σ is the factor that is the maximum amount longer that an edge path in refinements of either T_1 or T_2 can be versus the straight-line path. So the infimum of the lengths of these paths added up is at most $\sigma\kappa_1$. The same reasoning accounts for the term $\sigma\kappa_3$ in (5.5). Finally, the edge v_1v_2 is length κ_2 and is already in the tiling.

Use (5.2), (5.3), (5.4) and the equality $|p^*q^*| = \kappa_1 + \kappa_2 + \kappa_3$ to bound the right-hand side of (5.5):

$$\begin{aligned} f_1^*(p^*, q^*) &\leq \sigma\kappa_1 + \sigma\kappa_3 + \kappa_2 \\ &= \sigma(\kappa_1 - \lambda_1) + \sigma(\kappa_3 - \lambda_3) - (\sigma\lambda_2 - \kappa_2) + \sigma(\lambda_1 + \lambda_2 + \lambda_3) \\ &< 6\omega^2 \frac{\sigma}{|p^*q^*|} - (\sqrt{\sigma} - 1)\kappa_2 + \sigma|p^*q^*|. \end{aligned} \tag{5.6}$$

Multiply (5.1) by ω on both sides and use the fact that $\kappa_2 \geq \zeta(\alpha, \beta, \gamma, \iota)\omega$ to obtain

$$\omega^2 < \frac{(\sqrt{\sigma} - 1)\kappa_2}{6\sigma}|p^*q^*|. \tag{5.7}$$

Substituting (5.7) in (5.6) shows that $f_1^*(p^*, q^*) < \sigma|p^*q^*|$. But this is a contradiction, because the hypothesis of this analysis was that $g_1^*(p^*, q^*) = \sigma$; i.e., $f_1^*(p^*, q^*) = \sigma|p^*q^*|$. □

The preceding theorem has the drawback that it pertains only to paths starting and ending on the boundary of the root triangle. For isoperimetry, we would like to generalize the result to paths with arbitrary interior p and q. Since the nodes of the pinwheel tiling are dense in the interior (in the limit as the mesh size is refined), the following theorem provides a suitable generalization and will be taken as our definition of the isoperimetric property.

THEOREM 5.5. $\mathcal{T}^0, \mathcal{T}^1, \ldots$ $T = \triangle abc$ $\alpha < \gamma$ α/π $\mathcal{T}^{i+1}$ $\mathcal{T}^i$ $i = 0, 1, 2, \ldots$. p, q $\mathrm{Skel}(\mathcal{T}^n)$ n

$$\lim_{\substack{m \to \infty \\ m \geq n}} \operatorname{dist}_{\mathrm{Skel}(\mathcal{T}^m)}(p, q) = \|p - q\|.$$

. Consider the segment pq lying in T. Let $\epsilon > 0$ be given. Make a list $U_1, \ldots, U_l$ of tiles in $\mathcal{T}^n$ traversed by this segment. Since pq crosses U_i, define p_iq_i to be $U_i \cap pq$. Observe that p_i, q_i both lie on the boundary of U_i. By the preceding theorem, after a sufficient number of further subdivisions (say s), there exists a path in $\mathrm{Skel}(\mathcal{T}^{n+s})$ between p_i and q_i of length $|p_iq_i|(1 + \epsilon)$. This choice of s depends on i, so take the maximum such value of s (maximum over all $i = 1, \ldots, l$). Then there is a path in $\mathrm{Skel}(\mathcal{T}^{n+s})$ from p to q of length at most

$$|p_1q_1|(1 + \epsilon) + |p_2q_2|(1 + \epsilon) + \cdots + |p_rq_r|(1 + \epsilon),$$

i.e., at most $|pq|(1 + \epsilon)$. □

Algorithm PINW 1.0—Tiling Phase

1. Generate a mesh for Ω with bounded aspect ratio using Triangle.
2. Split triangles too close to equilateral at their in-centers.
3. Split triangles whose smallest angle is a rational multiple of π at a point near the in-center.
4. Let the set of triangles obtained after steps 1–3 be called $\mathcal{T}_0$.
5. Initialize a heap containing triangles that need splitting. The triangles are ordered so that the one whose minimum altitude is maximum is at the top of the heap. Initially the heap contains all triangles from $\mathcal{T}_0$.
6. Repeatedly remove a triangle from the heap and split it with ATP until the size of the top element of the heap is sufficiently small according to the user's specification.

FIG. 6.1. *Summary of first phase of Algorithm PINW in which a tiling of the input region is generated.*

Algorithm PINW 1.0—Simplicial Complex Phase

7. Let $\mathcal{T}_*$ be the set of tiles including those in $\mathcal{T}_0$ and all their descendants obtained by subdivision. Let $\mathcal{T}_f \subset \mathcal{T}_*$ be the set of leaf tiles.
8. Loop over all tiles in $\mathcal{T}_*$ starting from the coarsest to determine the value of big(E) for each edge E of any tile.
9. For each big edge (i.e., each edge in the image of the "big" operator), select one side as [illegible] and the other as [illegible]. Sort the list of nodes lying on the staying side of each such edge.
10. Loop over tiles in $\mathcal{T}_* - \mathcal{T}_f$ starting from the coarsest. For each such tile T and for each of its vertices d, e, f as labeled in Figure 4.1, let E be the big edge containing the particular vertex. If this vertex d, e, or f is on the moving side of E and is very close to a vertex v' on the staying side, then displace it to coincide with v' and apply the induced affine transformation to subtriangles of T.
11. Apply Delaunay triangulation to each leaf tile. The leaf tiles have been distorted by the affine transformations in the previous step. Their edges are subdivided because of the presence of hanging nodes. The collection of triangles output from this step is a simplicial mesh of Ω.

FIG. 6.2. *Summary of second phase of Algorithm PINW in which the tiling from the first phase is converted to a simplicial complex; i.e., hanging nodes are eliminated.*

6. Meshing an arbitrary region. In this section we present our algorithm PINW to mesh a region Ω with arbitrary polygonal boundary. The algorithm has two phases: generation of a tiling, which is summarized in Figure 6.1, and conversion of the tiling to a simplicial mesh, which is summarized in Figure 6.2. The steps in these summaries are described in more detail in the remainder of this section. The current version of PINW is 1.0 and has been coded in MATLAB. An example output from this algorithm is shown in Figure 6.3.

We first start with a coarse triangulation of the domain. We use the [illegible] package [9] developed by Shewchuk, which uses Delaunay triangulation. The triangles

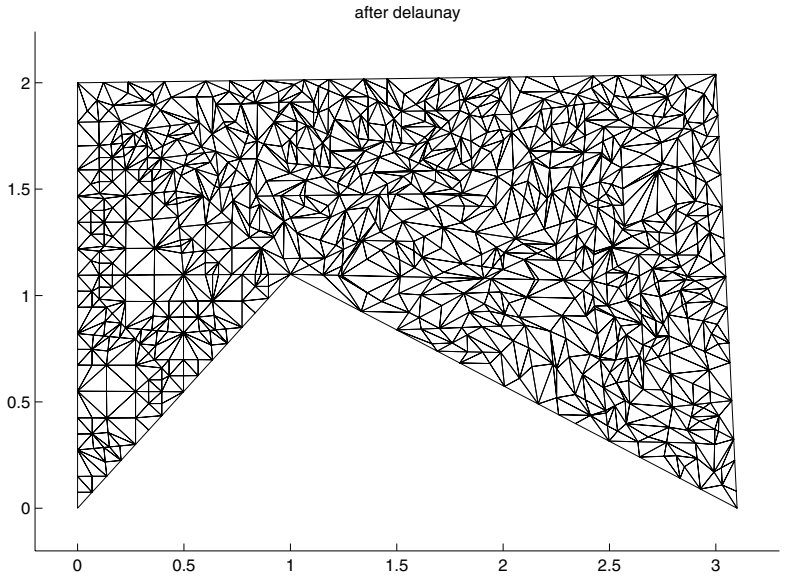

FIG. 6.3. *The coarse mesh for this figure had three triangles. The final mesh after pinwheel tiling, collapse-node operations, and Delaunay triangulation is shown.*

produced have bounded aspect ratio. The second preliminary step, as mentioned in section 4, locates triangles too close to equilateral and splits them at their in-centers.

A third preliminary step is to identify and split triangles whose smallest angle α is a rational multiple of π. (As noted above, the proof of isoperimetry requires that α/π be irrational.) In principle, this test could be conducted exactly using number-theoretic methods since the coordinates of the vertices of each triangle, being floating-point numbers, are rational numbers and can be treated with integer algorithms by clearing common denominators. Modifying a triangle in which α is a rational multiple of π is trivial in principle because any small random perturbation of a node of such a triangle will lead to an angle that is not a rational multiple of π with probability 1.

In practice, this exact test and solution are both undesirable. For practical use of the algorithm, we would like to avoid the case when α is close to a rational multiple of π of the form $m\pi/n$, where n is a small integer. The reason is that the presence of such a triangle in which α/π is irrational but is close to m/n implies that, although the isoperimetric property is asymptotically valid, the available angles will be badly distributed (clustered around multiples of π/n) for modest levels of refinement.

Therefore, a more practical heuristic is to check each smallest angle against a finite list of the form $m\pi/n$, where m, n range over a preselected set of small integers. If a triangle's smallest angle comes too close to a member of this list, then the triangle is either split into three using a point near its in-center or is perturbed. (The exact in-center obviously should not be used since this would replace each angle by half its previous value, and hence will still be close to a rational multiple of π.) This step has not been implemented in the current version of our code PINW 1.0 because we are still seeking the best practical heuristic. (Indeed, in Figure 6.3, one coarse triangle is close to a 45° right triangle, and hence one part of the subdivision exhibits a shortage of possible directions.)

Let $\mathcal{T}_0$ be the list of triangles that are produced by these preliminary steps. Thus, the triangles in $\mathcal{T}_0$ form a simplicial triangulation of the input set Ω. We call these

triangles the [illegible]. The generalized pinwheel subdivision is then performed on the root tiles to obtain a refined tiling. The procedure to refine the mesh used in PINW 1.0 is based on a simple heap [1]. The heap is initialized with all triangles in $\mathcal{T}_0$, which are ordered in the heap according to length of the minimum altitude. The main loop for the subdivision is to remove the top member of the heap (i.e., the unsubdivided tile with the largest value of minimum altitude), apply ATP to it, replace it with its five children. The procedure terminates when the top triangle in the heap is smaller than the user-specified mesh size requirement.

From this description, it is apparent that PINW 1.0 supports a single global user-specified mesh size requirement. For many applications of mesh generation, it is useful to have a finer mesh in one part of the domain versus another. This can also be implemented in the framework of generalized pinwheel subdivision but is not available in PINW 1.0. In addition, several aspects of our analysis that follows below would have to be generalized to cover graded meshes.

Once the subdivision procedure is complete, the resulting tiling must be converted to a simplicial mesh. For the 1:2 pinwheel triangulation, this step is quite straightforward as mentioned in section 3. In the generalized case, however, it is much more complicated and involves several steps that we shall now describe.

Let $\mathcal{T}_*$ be the list of all tiles in the hierarchy: It includes the tiles in $\mathcal{T}_0$ and all their descendants from the subdivision procedure. The tiles in $\mathcal{T}_*$ naturally have a forest structure associated with them in which the forest roots are root tiles. Let [illegible] denote a triangle in $\mathcal{T}_*$ that is not further subdivided during the generalized pinwheel subdivision phase. Let $\mathcal{T}_f$ be the set of leaf tiles.

The first step in converting the tiling to a mesh is to identify for each edge E of each tile $T \in \mathcal{T}_*$ the edge that we denote big(E). This is defined as follows. For the edges of a root tile, big() is the identity operator; i.e., for each edge E of a root tile, big(E) = E. Every nonroot tile arises from ATP subdivision, and hence each of its edges can be identified with one of the labeled edges in Figure 4.1. For the interior edges labeled de, df, dg, and cf in the figure, big() is taken to be the identity operator. For the interior edges labeled cg and gf, big(cg) = big(gf) = cf. For exterior edges ad, dc, cb, bf, fe, and ea, big() is inherited from the edge of $\triangle abc$ that contains this edge; i.e., big(ad) and big(dc) are defined to be big(ac), etc.

This definition implies in all cases that big(E) for an edge E of triangle T is the edge E' of an ancestor triangle T' in the subdivision hierarchy (i.e., T is derived from T' via a sequence of zero or more ATP operations) such that $E \subset E'$, and such that E' is maximal with this property. In other words, there is no other ancestor of T with an edge E'' that strictly contains E'.

If T is a nonroot triangle in the hierarchy and its parent's edges have already been labeled with their values of big(), then the edges of T can be labeled in a constant number of operations. Thus, assuming big() is determined starting from the root tiles and working downward, the total number of operations to determine big() for all edges is proportional to $|\mathcal{T}_*|$.

Next, for each "big" edge E (that is, an edge such that big(E) = E), identify a [illegible] and a [illegible] side. This choice can be arbitrary except for two stipulations. The moving side of an edge E that lies on the exterior boundary of Ω should be facing the exterior of Ω, which implies that no tiles lie on its moving side. The moving side of an edge in correspondence with cf in Figure 4.1 should be facing vertex b. PINW now identifies all the nodes on the staying side of E, i.e., nodes that are vertices of tiles adjacent to E and lying on its staying side. These nodes are sorted in order of occurrence on E. This sorted list is saved for the next step of the algorithm.

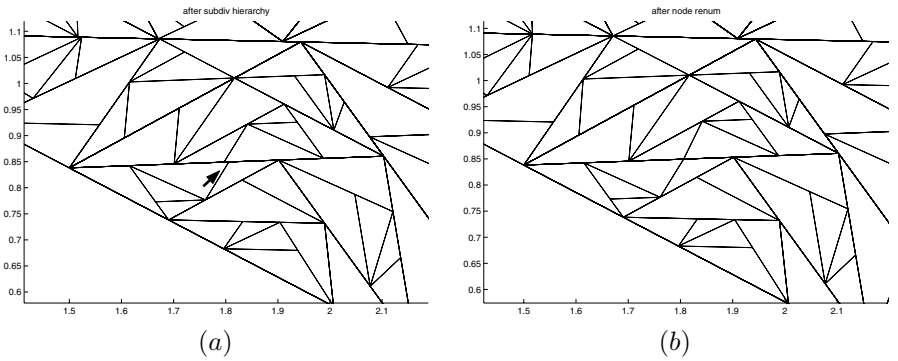

FIG. 6.4. *Example of a collapse-node operation is shown. A node on one side of a "big" edge that lies within the tolerance of a node on the other side is moved and merged with the nearby node on the other side.*

In the next step, PINW loops over triangles in $\mathcal{T}_* - \mathcal{T}_f$ starting from the coarsest and performs collapse-node operations on each. Let T be a tile in $\mathcal{T}_* - \mathcal{T}_f$. Let the four vertices of T introduced when it is subdivided be labeled d, e, f, g as in Figure 4.1. No operation is performed for g since it is on the staying side of edge cf. The big edge containing d is big(ac); call this $B(d)$. The big edge containing e and f is big(ab); call this $B(e)$ and also call it $B(f)$. Let v stand for one of d, e, f. PINW checks whether v (i.e., tile T) is on the moving side of $B(v)$. If it is on the staying side, then no further operation is performed. If it is on the moving side, then PINW finds the vertex v' taken from the staying side of $B(v)$ that is closest to v. This v' can be found efficiently using binary search on the precomputed sorted lists described in the previous paragraph. If $\|v - v'\| \le \delta$, nodes v and v' are collapsed by displacing v to v'. Here δ is a tolerance defined by (7.9) below.

This displacement induces uniquely determined affine transformations on triangles contained in T as follows. If v is the vertex labeled d in Figure 4.1, then there is a unique affine transformation on $\triangle adf$ that leaves a and f fixed and moves d to v'. A second affine transformation of $\triangle cdf$ leaves f and c fixed and moves d to v'. If v is the vertex labeled e, then there are unique affine transformations determined for $\triangle ade$ and $\triangle def$. Finally, if v is the vertex labeled f, then there are transformations for each of $\triangle def$, $\triangle cdf$, and $\triangle bcf$. The algorithm applies all the relevant affine transformations caused by motion of the node. Note that the affine transformations agree on the boundaries between these triangles, so there is no consistency issue regarding which transformation to apply. These transformations move the triangle, including every node at deeper levels of the hierarchy contained in it. This concludes the description of the operation. See Figure 6.4 for an illustration of this operation.

Note that a single tolerance δ is used to determine motion. The theoretical value for δ is given by (7.9) below. We will verify later that this value of δ is sufficiently small so that two important properties hold:

1. If a vertex v' is the target of a collapse-node move, then it should be uniquely determined; i.e., there should not be two vertices v' and v'' on the staying side of $B(v)$ that are both within distance δ of v.
2. No two vertices on the moving side of big(E) for any E should be collapsed to the same node on the staying side.

In a future extension of PINW to handle graded meshes, presumably the value of δ would not be a single global value.

The affine transformations described above have the property that all of the segments illustrated in Figure 4.1 remain straight (collinear) segments after the transformation. It is apparent that each collapse-node operation could cause many nodes to move. We will say that the one node v that is displaced to match v' is [illegible] displaced. The nodes moved by virtue of an affine transformation induced by moving v are said to be [illegible] displaced.

A collapse-node operation, once executed, cannot be undone by future collapse-node operations. The reason is that v is never moved again. It is never moved again directly since it can be moved directly only when the tile $T = \triangle abc$ that caused its creation is processed. It can also never be moved again indirectly since there is no tile in lower levels of the hierarchy that contains it except as a corner vertex, and corner vertices of a triangle T' are not moved when T' is processed. Similarly, v' can never be moved again. The reason is that v' is never moved directly (since it is on the staying side of its big edge). Any transformation that might move v' indirectly takes place at a level of the hierarchy higher than the level of T.

We carry out all available collapse-node operations for all triangles in the order described. Once all collapse-node operations are complete, we are left with the collection of distorted leaf tiles, each of which may have one or more hanging nodes. These hanging nodes are collinear with the endpoints of the edges on which they hang because, as noted above, we do not disturb any collinearity relationships with collapse-node operations. The hanging nodes are all at least δ apart from the corners and from each other.

For each of these distorted tiles, we compute its Delaunay triangulation (including the hanging nodes). The collection of all of these Delaunay triangles forms a simplicial mesh that is the final output of PINW.

The running time of PINW is analyzed as follows. Let n be the number of leaf tiles. Then the total number of tiles is $O(n)$, as is the total number of vertices, edges, and triangles of the final simplicial mesh. The heap insertions and deletions require $O(n \log n)$ total operations. Sorting all the lists associated with big edges requires $O(n \log n)$ operations. Looking up a vertex in a sorted list requires $O(\log n)$ operations for binary search; hence all of the lookups to see if a node should be collapsed require $O(n \log n)$ operations.

The recursive application of affine transformations requires $O(nd)$ operations since each vertex is transformed at most d times, where d is the maximum depth of the forest associated with $\mathcal{T}^*$. We claim $d = O(\log n)$. It follows from Lemmas 7.4 and 7.5 in the next section that the minimum altitude of a triangle at depth k lies between $\mu_0 \xi_1^k$ and $\mu_1 \xi_2^k$, where μ_0, μ_1 are lower and upper bounds on the minimum altitudes among root tiles, ξ_2 is an absolute constant, and ξ_1 is a scalar depending on the worst aspect ratio among root tiles. This means that a leaf tile can be at most a factor $\log \xi_2 / \log \xi_1$ (asymptotically) deeper in the forest than any other leaf tile. Thus, all leaves have depth $O(\log n)$.

Finally, the Delaunay triangulation operations in the last step of the algorithm also require $O(n \log n)$ operations total. Overall, we see that PINW requires $O(n \log n)$ operations.

7. Analysis of aspect ratio. In this section we analyze the aspect ratios of triangles produced by PINW, showing that they are bounded above by a number that depends only on the sharpest angle in the original polygon Ω. The first part

of this section obtains lower and upper bounds on the minimum altitudes of the five subtriangles resulting from ATP with respect to the initial triangle. We then explain how to choose δ, the tolerance parameter of algorithm PINW described in the previous section, which will be proportional to the minimum altitude among leaf tiles. Finally, we analyze the aspect ratio of the triangles produced by PINW. Let $\text{minalt}(T)$ denote the minimum altitude of triangle T.

LEMMA 7.1. [illegible] $\mu = \text{minalt}(T)$ [illegible] T [illegible] μ [illegible] T [illegible] μ [illegible] $\text{minalt}(T) \le \mu$

[illegible]. The first part of the lemma is quite trivial: Draw a line through the longest side length of T and a parallel line through the opposite vertex. These lines are distance μ apart. The argument for the converse is as follows. Without loss of generality, let the two lines be parallel to the x-axis. Let the vertices of T be numbered v_1, v_2, v_3 such that v_1 is closest to the bottom line (i.e., has minimal y-coordinate among the three vertices) and v_2 is closest to the top line. By reflecting if necessary, assume also that the x-coordinate of v_1 is less than or equal to the x-coordinate of v_2. Now draw the line v_1v_2, which is a transverse to the two parallel lines. If v_3 is below (to the right of) this line, then it is easy to see that the entire triangle T may be rotated clockwise about v_1 until v_1v_3 becomes horizontal, and during this whole rotation, all three vertices remain between the lines. On the other hand, if v_3 is above (to the left of) the line, then rotate T clockwise about v_2 until v_2v_3 becomes horizontal.

Once T has been reoriented so that one of its edges is horizontal, the claim is trivial since the altitude to the horizontal edge is a vertical line segment and hence must have length no more than μ. □

COROLLARY 7.2. [illegible] T_1, T_2 [illegible] $T_1 \subset T_2$ [illegible] $\text{minalt}(T_1) \le \text{minalt}(T_2)$

[illegible]. Draw the two parallel lines for T_2 as in the previous theorem; clearly T_1 also lies between them. □

LEMMA 7.3. [illegible] T [illegible] v_1, v_2, v_3 [illegible] T' [illegible] v_1', v_2, v_3 [illegible] A [illegible] T [illegible] T' [illegible] L [illegible]

$$1 - \eta/\mu \le \frac{\text{length}(A(L))}{\text{length}(L)} \le 1 + \eta/\mu, \tag{7.1}$$

[illegible] $\eta = |v_1v_1'|$ [illegible] μ [illegible] v_1 [illegible] v_2v_3

[illegible]. Without loss of generality, assume μ is 1 and η is replaced by $\iota = \eta/\mu$. Furthermore, without loss of generality, let T be positioned so that its v_2v_3 edge is a subsegment of the x-axis and v_1 lies on the y-axis (hence $v_1 = (0, 1)$ by the previous assumption). With these assumptions, the affine tranformation A in the question becomes a linear transformation (i.e., no additive term) since the x-axis (and the origin in particular) is invariant. The transformation maps $(1, 0)^T$ to $(1, 0)^T$ and $(0, 1)^T = v_1$ to v_1'. Let $r = v_1' - v_1$, and let r be written as $(\rho_1, \rho_2)^T$ so that $\rho_1^2 + \rho_2^2 = \iota^2$. Then A corresponds to the matrix

$$A = \begin{pmatrix} 1 & \rho_1 \\ 0 & 1 + \rho_2 \end{pmatrix}.$$

The minimum and maximum distortion of a line segment under a linear transformation is governed by the minimum and maximum singular values of the transformation.

Thus, the question now hinges on the two singular values of A. Notice that A may be regarded as a perturbation of the identity matrix, which has two singular values equal to 1. Therefore, by Corollary 8.6.2 of [3], the largest singular value of A is at most $1+\iota$, and the smallest singular value is at least $1-\iota$. These values are attainable by taking $\rho_1 = 0$ and $\rho_2 = \pm\iota$. □

LEMMA 7.4. [illegible] 4.1 [illegible] T [illegible] $\beta \geq \min(.4, \alpha)$ [illegible] $\gamma - \alpha \geq \min(.4, \alpha)$ [illegible] T' [illegible] [illegible] $\text{minalt}(T') \leq 0.9725\,\text{minalt}(T)$

[illegible] 1. The assumptions are valid for all tiles produced by PINW. For root tiles, we have ordered the angles $\alpha \leq \beta \leq \gamma$, and we know $\gamma - \alpha \geq .4$ because of the preliminary step of splitting near-equilateral triangles. For conjugates of root triangles, say $\alpha = \alpha'$, $\beta = \gamma' - \alpha'$, and $\gamma = \pi - \gamma'$, where α', β', γ' are the angles of a root tile, we also know that $\gamma - \alpha = \pi - \gamma' - \alpha' = \beta' \geq \alpha$ and that $\beta = \gamma' - \alpha' \geq .4$.

[illegible] 2. The factor 0.9725 is due to our proof technique and appears to be an overestimate. A search over a fairly dense grid of possible angles satisfying the hypotheses of the theorem indicates that the true bound is closer to 0.92.

[illegible]. We start by observing that $|bc|/|ab| = \sin\alpha/\sin\gamma$ by the law of sines. We know that either $\gamma \geq 2\alpha$ or $\gamma \geq \alpha + .4$. Furthermore, we know that either $\pi - \gamma \geq 2\alpha$ or $\pi - \gamma \geq \alpha + .4$ since $\pi - \gamma = \alpha + \beta$. Therefore, if we define $\bar{\gamma} = \min(\gamma, \pi - \gamma)$, then we can claim (a) either $\bar{\gamma} \geq 2\alpha$ or $\bar{\gamma} \geq \alpha + .4$, (b) $\bar{\gamma} \leq \pi/2$, and (c) $\sin\bar{\gamma} = \sin\gamma$, implying (d) $|bc|/|ab| = \sin\alpha/\sin\bar{\gamma}$. On the interval $[0, \pi/2]$, the sine is increasing. In the case that $\bar{\gamma} \geq 2\alpha$, we have $\sin\bar{\gamma} \geq \sin 2\alpha = 2\sin\alpha\cos\alpha \geq \sqrt{2}\sin\alpha$. The last inequality follows because $\alpha \leq \pi/4$ (by assumptions that $\bar{\gamma} \leq \pi/2$ and $\bar{\gamma} \geq 2\alpha$) so $\cos\alpha \geq 1/\sqrt{2}$. The other case is that $\bar{\gamma} \geq \alpha + .4$. Since sine is concave and increasing on $[0, \pi/2]$ the maximum value for $\sin\alpha/\sin\bar{\gamma}$ is attained at $(\alpha, \bar{\gamma}) = (\pi/2 - .4, \pi/2)$; hence $\sin\alpha/\sin\bar{\gamma} \leq .9211$. Thus,

$$|bc|/|ab| \leq .922. \tag{7.2}$$

Observe that subtriangle V, which is denoted T_{V}, is similar to T except scaled by a factor $|bc|/|ab|$. This proves $\text{minalt}(T_{\text{V}}) \leq .9211\,\text{minalt}(T)$.

Next, by similarity, $|bf|/|bc| = |bc|/|ab|$; hence, squaring (7.2) yields $|bf|/|ab| \leq .849$. This means

$$|af|/|ab| \geq .151. \tag{7.3}$$

Since $\triangle adf$ is isosceles, $|ad|/|af| \geq .5$ and $|df|/|af| \geq .5$; hence

$$|ad|/|ab| \geq .075 \tag{7.4}$$

and

$$|df|/|ab| \geq .075. \tag{7.5}$$

Next, by the law of sines applied to $\triangle cdf$, $|dc|/|df| = \sin\beta/\sin(\gamma - \alpha)$. We now take three cases: either $\beta < .4$, $\beta \in [.4, \pi/2]$, or $\beta > \pi/2$. In the first case $\beta \geq \alpha$ since the assumption in the lemma is $\beta \geq \min(.4, \alpha)$. Also, $\gamma - \alpha \geq \pi/2$ since $\gamma - \alpha + 2\alpha + \beta = \pi$ and $2\alpha + \beta < 1.2$ by the assumption for this case, so $\gamma - \alpha \geq \pi - 1.2$. This means $\sin(\gamma - \alpha) = \sin(\pi - (\gamma - \alpha)) = \sin(2\alpha + \beta)$, with $2\alpha + \beta \leq \pi/2$. Next, $2\alpha + \beta \leq 3\beta$, so $\sin(\gamma - \alpha) = \sin(2\alpha + \beta) \leq \sin(3\beta)$ (since $2\alpha + \beta \leq 3\beta$ and sine is increasing on $[0, \pi/2]$); thus $\sin\beta/\sin(\gamma - \alpha) \geq \sin\beta/\sin(3\beta)$. Now $\sin(3\beta) = \sin\beta(3\cos^2\beta - \sin^2\beta)$. Thus,

$\sin\beta/\sin(\gamma-\alpha) \geq 1/(3\cos^2\beta - \sin^2\beta)$. Since $\sin^2$ is increasing while $\cos^2$ is decreasing on $[0, .4]$, the minimum value of this fraction is when $\beta = 0$, so $\sin\beta/\sin(\gamma-\alpha) \geq 1/3$. In the second case, $\beta \in [.4, \pi/2]$. This means $\sin\beta \in [\sin(.4), 1]$ and in particular, $\sin\beta \geq .389$ so $\sin\beta/\sin(\gamma-\alpha) \geq .389$. The last case is $\beta > \pi/2$, which implies $\sin\beta = \sin(\pi-\beta) = \sin(\gamma+\alpha)$. So the quantity to analyze is $\sin(\gamma+\alpha)/\sin(\gamma-\alpha)$. Since the angles in the numerator and denominator are both less than $\pi/2$ (because $\beta > \pi/2$) and since $\gamma+\alpha > \gamma-\alpha$, we conclude that $\sin\beta/\sin(\gamma-\alpha) \geq 1$.

Thus, in all cases, we conclude that $|dc|/|df| \geq 1/3$. Combining this with (7.5) implies

$$|dc|/|ab| \geq .025. \tag{7.6}$$

Next, observe that $|ef|/|df| = \sin(\gamma-\alpha)/\sin\gamma$ by the law of sines applied to $\triangle def$. Again, we take three cases. If $\gamma - \alpha < .4$ (and hence $\gamma - \alpha \geq \alpha$; i.e., $\gamma \geq 2\alpha$, and $\alpha \leq \gamma/2$), then $2\alpha - \alpha < .4$; i.e., $\alpha \leq .4$, so $\gamma \leq \alpha + .4 \leq .8$. Since all these angles are in $[0, \pi/2]$, $\sin(\gamma-\alpha) \geq \sin(\gamma-\gamma/2) = \sin(\gamma/2)$ by monotonicity of sin in this range, and $\sin(\gamma/2)/\sin(\gamma) \geq 1/2$ by concavity of sin. The second case is $\gamma - \alpha \in [.4, \pi/2]$. In this case, $\sin(\gamma-\alpha) \geq .389$ so $\sin(\gamma-\alpha)/\sin\gamma \geq .389$. The last case is $\gamma - \alpha \geq \pi/2$. This implies that $\sin(\gamma-\alpha) = \sin(\pi-\gamma+\alpha) = \sin(2\alpha+\beta)$. The denominator becomes $\sin(\gamma) = \sin(\pi-\gamma) = \sin(\alpha+\beta)$. So we are analyzing $\sin(2\alpha+\beta)/\sin(\alpha+\beta)$, which exceeds 1 since all the angles in question are in $[0, \pi/2]$. Thus, in all cases, $|ef|/|df| \geq .389$; thus, combining with (7.5) yields

$$|ef|/|ab| \geq .0292. \tag{7.7}$$

Now we have enough inequalities to analyze $\text{minalt}(T_{\text{I}})$ where T_{I} denotes $\triangle ade$. Observe that this triangle is similar to T. Its longest side is either ae or ad (but not de, since $\alpha < \gamma$). If its longest side is ad, then we see that $|ad| = |ac| - |dc| \leq |ac| - .025|ab| \leq |ab| - .025|ab| = .9725|ab|$. (Here we use (7.6) plus the fact that $|ab| \geq |ac|$, which follows from the hypothesis of this case that $|ad| \geq |ae|$ together with the similarity of $\triangle ade$ to $\triangle abc$.) Thus, $\triangle ade$ is similar to $\triangle abc$ and is scaled down by a factor of .9725 or less.

The other case is when the longest side of $\triangle ade$ is ae. In this case, we can apply (7.7) to obtain $|ae| = |ab| - |eb| \leq |ab| - |ef| \leq (1 - .0292)|ab| \leq (1 - .0292)|ac|$. The inequality $|ab| \leq |ac|$ follows from the assumption that $|ad| \leq |ae|$ and from similarity. Thus, $\triangle ade$ is similar to $\triangle abc$ but is scaled down by a factor of less than .9708. This concludes the analysis of $\text{minalt}(T_{\text{I}})$. This same analysis applies to T_{III}, since T_{III} is congruent to T_{I} (because $\triangle adf$ is isosceles).

Next, observe that $|ae|/|ad| = \sin\beta/\sin\gamma$ by the law of sines applied to $\triangle ade$. Again, we take three cases. If $\beta < .4$ (and hence $\beta \geq \alpha$), then $\gamma > \pi/2$ as above so $\sin\gamma = \sin(\pi-\gamma) = \sin(\alpha+\beta)$; thus the quantity to analyze is $\sin\beta/\sin(\alpha+\beta)$. Using analysis as before, including steps like $\sin(\alpha+\beta) \leq \sin(2\beta) = 2\sin\beta\cos\beta \leq 2\sin\beta$, we conclude that $\sin\beta/\sin\gamma \geq 1/2$ in this case. If $\beta \in [.4, \pi/2]$, then we conclude again that $\sin\beta/\sin\gamma \geq .389$. Finally, if $\beta > \pi/2$, then $\sin\beta = \sin(\pi-\beta) = \sin(\gamma+\alpha)$, so again $\sin\beta/\sin\gamma > 1$. Thus, in all cases, $|ae|/|ad| \geq .389$. Since $|ad|/|ab| \geq .075$, we conclude that

$$|ae|/|ab| \geq .029. \tag{7.8}$$

Next, we analyze T_{II}, that is, $\triangle def$. Observe that this triangle is similar to $\triangle cfa$, and $\text{minalt}(\triangle cfa) \leq \text{minalt}(\triangle abc)$ by Corollary 7.2. The corresponding side to af is

fe. Applying (7.8) yields $|fe| = |af| - |ae| \le |af| - .029|ab| \le |af| - .029|af|$. Thus, $\text{minalt}(T_{\text{II}}) \le 0.971\,\text{minalt}(T)$.

Finally, we analyze T_{IV}, which is $\triangle cgd$. This triangle is also similar to $\triangle cfa$. Combining (7.4) with the fact that $|ab| \ge 0.5|ac|$ (since $|ab|$ is not the shortest side of $\triangle abc$ because $\gamma > \alpha$) yields $|ad| \ge .037|ac|$; thus $|cd| \le .963|ac|$. Observe that $|cd|/|ac|$ is the ratio of similarity between T_{IV} and $\triangle cfa$. ∎

The following lemma is like the previous one except with an inequality in the opposite direction.

LEMMA 7.5. [illegible] 4.1 [illegible] T [illegible] $\beta \ge \min(.4, \alpha)$ [illegible] $\gamma - \alpha \ge \min(.4, \alpha)$ [illegible] T' [illegible] $\text{minalt}(T') \ge \sigma\,\text{minalt}(T)$ [illegible] $\sigma = 0.0044$ [illegible] $\sigma = \sin\alpha$ [illegible] 3. The factor 0.0044 is due to our proof technique and appears to be an underestimate. A search over a fairly dense grid of possible angles satisfying the hypotheses of the theorem indicates that the true bound is closer to 0.125.

[illegible]. Again, we consider the five subtriangles and reuse some of the inequalities in the preceding proof. Observe that T_{I} is similar to $\triangle abc$, with ad corresponding to ab. By (7.4), $\text{minalt}(\triangle ade) \ge .075\,\text{minalt}(\triangle abc)$. The same bound applies to T_{III}, which is congruent to T_{I}.

For T_{V}, by the law of sines $|bc|/|ab| = \sin\alpha/\sin\gamma \ge \sin\alpha$. Thus, by similarity, $\text{minalt}(T_{\text{V}}) \ge \text{minalt}(T) \cdot \sin\alpha$.

Next, consider triangle $\triangle acf$. Equation (7.3) implies that if $\triangle acf$ were dilated by $1/.151$, it would completely cover $\triangle abc$. Therefore, by Corollary 7.2, $\text{minalt}(\triangle acf) \ge .151\,\text{minalt}(\triangle abc)$. Equation (7.7) implies that $|ef|/|af| \ge .0292$. Since T_{II} is similar to $\triangle acf$, we conclude that $\text{minalt}(T_{\text{II}}) \ge .0292\,\text{minalt}(\triangle acf) \ge .0292 \cdot .151\,\text{minalt}(\triangle abc)$. Note that $.0292 \cdot 0.151 \ge 0.0044$.

Finally, to analyze T_{IV}, we need to develop a new inequality. Observe that $\triangle dgf$ is similar to $\triangle acb$ and the scaling is at least .075 by (7.5); hence $|dg| \ge .075|ac|$. Meanwhile, we know $|ac| \ge 0.5|af|$ since $|ac|$ is not the shortest side of $\triangle acf$ (because it is opposite an angle of size $\alpha + \beta$, which is greater than α). Thus, $|dg| \ge .037|af|$. This means by similarity of T_{IV} to $\triangle acf$ that $\text{minalt}(T_{\text{IV}}) \ge .037\,\text{minalt}(\triangle acf) \ge .037 \cdot .151\,\text{minalt}(\triangle abc)$. ∎

LEMMA 7.6. [illegible] σ τ [illegible] $\sigma < 1$ [illegible] $\tau < 1$ [illegible] k [illegible]

$$\prod_{i=0}^{\infty}(1 - \sigma\tau^i)^k \ge 1 - k\sigma/(1-\tau)$$

[illegible]

$$\prod_{i=0}^{\infty}(1 + \sigma\tau^i)^k \le \exp(k\sigma/(1-\tau)).$$

[illegible]. The first inequality follows because $(1-a)(1-b) \ge 1-a-b$ for $a, b \in [0,1]$. Applying this repeatedly, k times for each factor in the product, $(1-\sigma)^k(1-\sigma\tau)^k \cdots (1-\sigma\tau^n)^k \ge 1 - k\sigma - k\sigma\tau - \cdots - k\sigma\tau^n \ge 1 - k\sigma\sum_{i=0}^{\infty}\tau^i = 1 - k\sigma/(1-\tau)$.

The second inequality follows by taking logs and using the inequality $\log(1+x) \le x$:

$$\log((1+\sigma)^k \cdots (1+\sigma\tau^n)^k) = k\log(1+\sigma) + k\log(1+\sigma\tau) + \cdots + k\log(1+\sigma\tau^n)$$

$$\begin{aligned}&\le k\sigma + k\sigma\tau + \cdots + k\sigma\tau^n\\ &\le k\sigma\sum_{i=0}^{\infty}\tau^i\\ &= k\sigma/(1-\tau). \qquad \square\end{aligned}$$

We now explain how to choose δ for the main algorithm. We set it to be

$$\delta = \frac{\min\{\text{minalt}(T) : T \in \mathcal{T}_*\}}{1460}. \tag{7.9}$$

The minimum altitudes in this definition are measured before any collapse-node operations begin. This choice of δ makes all the theorems work but leads to poorer aspect ratio (by a constant factor) than seems necessary. So instead, PINW 1.0 chooses δ dynamically based on the singular values of the affine transformations that could be applied during collapse-node operations. This heuristic seems to work well in practice.

The following theorem bounds the effect of all collapse-node operations, both direct and indirect.

THEOREM 7.7. [illegible] T [illegible] A [illegible] T [illegible] $\mu = \text{minalt}(T)$ [illegible] L [illegible] T [illegible] δ [illegible] (7.9) [illegible] $\text{length}(A(L))/\text{length}(L)$ [illegible]

$$\left(1-\frac{\delta}{0.75\mu}\right)^3\cdot\left(1-\frac{0.9725\delta}{0.75\mu}\right)^3\cdot\left(1-\frac{0.9725^2\delta}{0.75\mu}\right)^3\cdots$$

[illegible]

$$\left(1+\frac{\delta}{0.75\mu}\right)^3\cdot\left(1+\frac{0.9725\delta}{0.75\mu}\right)^3\cdot\left(1+\frac{0.9725^2\delta}{0.75\mu}\right)^3\cdots.$$

[illegible]. The proof of this theorem is by induction on the depth of the tile in hierarchy. The induction base is that for a root tile, there are no collapse-node operations; thus $A(L) = L$.

For a nonroot tile T, let T' be its parent triangle. By the induction hypothesis, the total distortion of a segment in T' prior to the processing of the vertices created within T' is between

$$\left(1-\frac{\delta}{0.75\mu'}\right)^3\cdot\left(1-\frac{0.9725\delta}{0.75\mu'}\right)^3\cdot\left(1-\frac{0.9725^2\delta}{0.75\mu'}\right)^3\cdots$$

and

$$\left(1+\frac{\delta}{0.75\mu'}\right)^3\cdot\left(1+\frac{0.9725\delta}{0.75\mu'}\right)^3\cdot\left(1+\frac{0.9725^2\delta}{0.75\mu'}\right)^3\cdots,$$

where $\mu' = \text{minalt}(T')$ (with minalt measured prior to any node movement). Referring to Figure 4.1 and regarding $T' = abc$ and T as one of I, II, III, IV, or V, we consider next the direct displacements of d, e, f due to collapse-node operations.

By Lemma 7.4, $0.9725\mu' \ge \mu$. Thus, for tile T, the distortion prior to the three direct displacements of d, e, f is bounded between

$$\left(1-\frac{0.9725\delta}{0.75\mu}\right)^3\cdot\left(1-\frac{0.9725^2\delta}{0.75\mu}\right)^3\cdot\left(1-\frac{0.9725^3\delta}{0.75\mu}\right)^3\cdots \tag{7.10}$$

and

$$\left(1+\frac{0.9725\delta}{0.75\mu}\right)^3\cdot\left(1+\frac{0.9725^2\delta}{0.75\mu}\right)^3\cdot\left(1+\frac{0.9725^3\delta}{0.75\mu}\right)^3\cdots. \tag{7.11}$$

By Lemma 7.6 with $k=3$, $s=\delta/(0.75\mu)$, and $t=0.9725$, infinite product (7.10) is greater than or equal to $1-3\delta/(0.75\mu(1-0.9725))$, which simplifies to $1-146\delta/\mu$. If we assume that δ satisfies (7.9), then this quantity is greater than 0.9. We now apply the three collapse-node operations of d, e, f to T, say in this order. (Not all three necessarily affect T; for example, if T is I in Figure 4.1, then moving f does not affect T.) To compute the distortion of L requires knowledge of the minimum altitude of T at the point of the algorithm when the collapse-node operation is applied. However, because the distortion so far is greater than 0.9, we know that the altitude at this step is at least 0.9μ for movement of d, which is of size δ. Therefore, the movement of d applies a new distortion between $1-\delta/(0.9\mu)$ and $1+\delta/(0.9\mu)$ by Lemma 7.3. By (7.9), this quantity is bounded between 0.95 and 1.05. Therefore, the minimum altitude of T when the collapse-node operation for e is applied is at least $0.9\mu\cdot 0.95=0.855\mu$. Thus, the collapse-node operation on e applies another distortion between $1-\delta/(0.855\mu)$ and $1+\delta/(0.855\mu)$. Again, by (7.9), this quantity is bounded between 0.95 and 1.05. So after the collapse-node operation on f, the minimum altitude of T is at least $0.855\mu\cdot 0.95=0.812\mu$. Combining these three distortions with the distortions from higher-level collapse-node operations given by (7.10) and (7.11) shows that the value of the distortion of a segment after the collapse-node operations involving T and its ancestors lies between

$$\begin{aligned}&(1-\delta/(0.9\mu))(1-\delta/(0.855\mu))(1-\delta/(0.812\mu))\\&\cdot\left(1-\frac{0.9725\delta}{0.75\mu}\right)^3\cdot\left(1-\frac{0.9725^2\delta}{0.75\mu}\right)^3\cdot\left(1-\frac{0.9725^3\delta}{0.75\mu}\right)^3\cdots\end{aligned}$$

and

$$\begin{aligned}&(1+\delta/(0.9\mu))(1+\delta/(0.855\mu))(1+\delta/(.812\mu))\\&\cdot\left(1+\frac{0.9725\delta}{0.75\mu}\right)^3\cdot\left(1+\frac{0.9725^2\delta}{0.75\mu}\right)^3\cdot\left(1+\frac{0.9725^3\delta}{0.75\mu}\right)^3\cdots.\end{aligned}$$

We can underestimate the first factor and overestimate the second by replacing 0.9, 0.855, and 0.812 all with 0.75. This proves the theorem. ∎

We now consider Properties 1 and 2 in section 6. Since the minimum altitude of a triangle is less than or equal to its shortest side length, and since the minimum altitude of any tile decreases by at most 0.75, the previous result shows that δ is sufficiently small so that no two nodes can be collapsed to the same node, and no node can have more than one choice of where it should be collapsed.

Furthermore, when we are finished with collapse-node operations, all hanging nodes are at least δ apart and at least δ from corners. Again, this is because the shortest side length is bounded below by the smallest altitude, and the smallest altitude is bounded below by a large constant multiple of δ.

We now consider the aspect ratio of the triangles in the mesh produced by PINW. As mentioned earlier, we define the [illegible] of a triangle T to be the square of the longest side length of the triangle divided by its area. Let maxside(T), area(T), and aspect(T) stand for the maximum side, area, and aspect ratio, respectively. We have

also already introduced minalt(T). Then the previous definition says that

$$\text{aspect}(T) = \text{maxside}(T)^2 / \text{area}(T).$$

Since the area is half the product of the longest side length and the minimum altitude, an equivalent definition is

$$\text{aspect}(T) = 2\,\text{maxside}(T) / \text{minalt}(T).$$

The following lemma gives another characterization of aspect ratio equivalent up to a constant factor as well as a useful property of aspect ratios.

LEMMA 7.8. [illegible] T [illegible]

(a) [illegible] θ [illegible] T [illegible] κ_1, κ_2 [illegible] $\kappa_1\,\text{aspect}(T) \le 1/\theta \le \kappa_2\,\text{aspect}(T)$ [illegible] $\kappa_1\,\text{aspect}(T) \le 1/\sin(\theta) \le \kappa_2\,\text{aspect}(T)$

(b) [illegible] λ_1, λ_2 [illegible] T [illegible] $\lambda_1/\lambda_2 \le \text{aspect}(T)/2$

[illegible]. Because both parts of this lemma are well known (see, e.g., [4]), we omit the full proof. □

We now establish via a sequence of lemmas followed by a theorem that the triangles produced by PINW have bounded aspect ratio, where the bound depends only on the sharpest angle in the input domain. For the remainder of the section, let

$$\rho^* = \max\{\text{aspect}(T) : T \in \mathcal{T}_0 \text{ or conjugate}(T) \in \mathcal{T}_0\}. \tag{7.12}$$

The first lemma relates ρ^* to the original input domain.

LEMMA 7.9. [illegible] θ [illegible] Ω [illegible] $\rho^* \le \kappa/\theta$ [illegible] κ [illegible]

[illegible]. For root tiles, this follows from the properties of the Triangle mesh generator: It is guaranteed that all triangles will have aspect ratio bounded by κ/θ. The preliminary splitting for angles too close to equilateral can decrease the sharpest angle by at most a constant factor, For a conjugate T' of a root tile T whose angles are α, β, γ in order, either its sharpest angle is α, in which case they satisfy the same bound (because α is also an angle of a root tile; Lemma 7.8(a) applies). The other case is that the sharpest angle in the conjugate is $\gamma - \alpha$, but because of the primary tripartition, this angle is no smaller than .4. □

The following lemma follows trivially from the fact that in the recursive application of ATP, all subsequent tiles are congruent either to a root tile or to its conjugate.

LEMMA 7.10. [illegible] $T \in \mathcal{T}_*$ [illegible] $\text{aspect}(T) \le \rho^*$

The next lemma shows that a leaf tile cannot be much larger than any other leaf tile.

LEMMA 7.11. [illegible] $\mathcal{T}_f$ [illegible] $\mathcal{T}_0$ [illegible]

$$\max\{\text{minalt}(T) : T \in \mathcal{T}_f\} \le \kappa\rho^* \min\{\text{minalt}(T) : T \in \mathcal{T}_f\},$$

[illegible] κ [illegible]

[illegible]. Recall that the tile selected for splitting at any given step is the one with the maximum minimum altitude. Thus, when the subdivision procedure terminates, the tile at the top of the heap will be the leaf tile with the maximum minimum altitude among all leaf tiles. Say this tile is T and its minimum altitude is μ. Now consider any

other leaf tile $T' \in \mathcal{T}_f$. Because of the assumption that no tile from $\mathcal{T}_0$ is a leaf tile, this tile T' must have arisen from ATP subdivision of some other tile T''. Because of the heap order, the minimum altitude μ'' of T'' exceeds μ. By Lemma 7.5, this means that the minimum altitude μ' of T' is at least $\min(0.0044, \sin\alpha)\mu''$. Note that $\sin\alpha \geq \kappa/\rho^*$ since α is an angle of a root tile or conjugate by Lemma 7.10. Thus, $\mu' \geq (\kappa/\rho^*)\mu'' \geq (\kappa/\rho^*)\mu$. □

Now, we consider the effect of collapse-node operations.

LEMMA 7.12. 1.22

. As explained in the proof of Theorem 7.7, the lowest possible contraction due to all collapse-node operations for any segment in any leaf tile is 0.90 or greater. Pick a tile T and let μ be the initial altitude. Applying the second part of Lemma 7.6 to the bound in the theorem shows that the maximum distortion of T is $\exp(3\delta/(0.9\mu(1-0.9725)))$, which by (7.9) is at most 1.09. Since the aspect ratio is the twice the longest side length divided by the minimum altitude, and the longest side went up by at most 1.09 while the minimum altitude changed by a factor of at least 0.90, the new aspect ratio is bounded by 1.22 times the old. □

We now come to the main result for this section about the aspect ratio of the triangles generated by PINW.

THEOREM 7.13. $\mathcal{T}_f$ $\kappa(\rho^*)^3$ κ ρ^* (7.12)

. In this proof, κ denotes a universal constant that takes on a different value for each inequality where it appears. Let $\bar{T}$ be a leaf tile. Let $\mu = \text{minalt}(\bar{T})$ and $\lambda = \text{maxside}(\bar{T})$, both measured prior to any collapse-node operations. Let T be the result of PINW's collapse-node operations applied to $\bar{T}$. As already observed in the proof of Theorem 7.7, $\text{minalt}(T) \geq 0.9\mu$ and $\text{maxside}(T) \leq 1.09\lambda$. The edges of T may contain hanging nodes. The distance between any pair of adjacent hanging nodes or between a hanging node and corner is at least δ. A node on the moving side could not be less than δ away from a node on the staying side, since in this case they would be collapsed. Also, two nodes on the staying side or two nodes on the moving side are at least distance 1460δ apart by (7.9), so even after collapse-node operations no leaf tile edge could ever shrink below δ.

Recall from (7.9) that δ is a constant multiple of $\mu_{\min}$, the minimum altitude among all leaf tiles. By Lemma 7.11, this implies

$$\delta \geq \kappa\mu/\rho^*, \tag{7.13}$$

where κ is a universal constant.

Now, let U be a triangle output by the Delaunay triangulation of T and consider the sharpest angle of U. Let $E = v_1v_2$ be the edge of U opposite the sharpest angle. There are two cases: Either v_1, v_2 lie on the same edge of T (i.e., they are consecutive hanging nodes or a hanging node and a corner node), or they are on different edges.

Start with first case. Let $E = v_1v_2$ be the edge of U lying on an edge of T. For the rest of this case, let the corners of T be a, b, c such that $v_1v_2 \subset bc$ and such that the order of these vertices is b, v_1, v_2, c. Let p be the vertex of U opposite E. Refer to Figure 7.1(a). By definition of the Delaunay triangulation, p is the first vertex hit by an expanding circle that contains both endpoints of E. This circle, if expanded farther, will eventually hit a. Either $\angle av_1v_2$ is acute or $\angle av_2v_1$ is acute; without loss

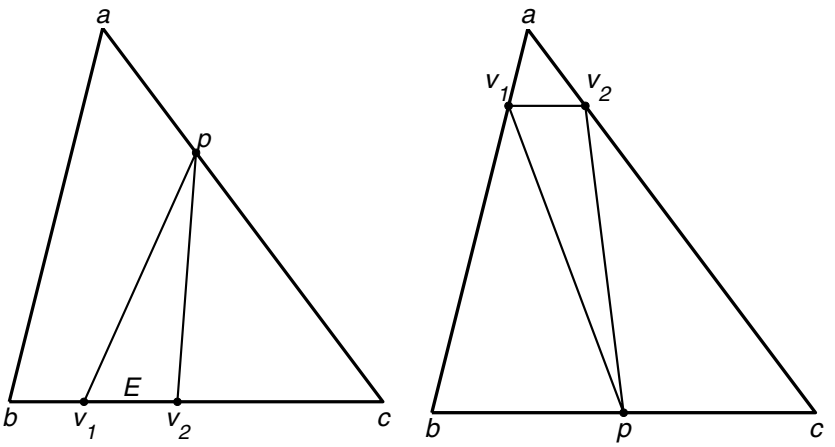

FIG. 7.1. *Constructions used in the proof of Theorem* 7.13. *Triangle v_1v_2p results from the Delaunay triangulation of tile T whose vertices are a, b, c and whose hanging nodes include v_1, v_2, p. Nodes are numbered so that v_1v_2 is the shortest side of $\triangle v_1v_2p$. Either* (a) *edge $E = v_1v_2$ lies on a single edge of T, or* (b) *v_1v_2 is interior to T.*

of generality, assume the former. The angle $\angle v_1av_2$ is at least $\kappa|E|/(\rho^*\lambda)$ by the law of sines: $\sin\angle v_1av_2 = \sin\angle av_1v_2|E|/|av_2| \geq \sin\angle av_1v_2|E|/(1.09\lambda)$. Meanwhile, $\sin\angle av_1v_2$ is bounded below by κ/ρ^* since $\angle av_1v_2$ is bounded below by $\angle abc$ but is less than $\pi/2$. Thus, $\sin\angle v_1av_2 \geq \kappa|E|/(\rho^*\lambda)$. Next, $\lambda \leq \mu\rho^*$ so $\sin\angle v_1av_2 \geq \kappa|E|/(\mu(\rho^*)^2)$. Finally, since $|E| \geq \delta$ because all hanging nodes are at least δ apart, it follows from (7.13) that $|E|/\mu \geq \kappa/\rho^*$. Therefore, $\sin\angle v_1av_2 \geq \kappa/(\rho^*)^3$. This is the angle formed by v_1av_2. The actual angle of U opposite E is v_1pv_2. But this angle is greater than or equal to v_1av_2, since the expanding Delaunay circle encounters p before it encounters a (or else $p = a$).

Next, let us consider the case that v_1 and v_2, the endpoints of the edge of U opposite its sharpest angle, do not lie on the same edge of T. Let the three vertices of T be a, b, c and let a be the T-vertex that is the common endpoint of the two T edges that contain v_1 and v_2 respectively, while we let b be the T-vertex such that ab contains v_1 and we let c be the T-vertex such that ac contains v_2. Refer to Figure 7.1(b). Consider $\angle v_1bv_2$. Since a, v_1, and b are collinear, this angle is equal to $\angle abv_2$. By the law of sines applied to $\triangle abv_2$, we have $\sin\angle abv_2 = |av_2|\sin\angle a/|bv_2|$. Now we apply the inequalities $|av_2| \geq \delta$, $\sin\angle a \geq \kappa/\rho^*$, and $|bv_2| \leq \lambda$ to conclude that $\sin\angle abv_2 = \sin\angle v_1bv_2 \geq \kappa\delta/(\rho^*\lambda)$. This is the same inequality derived in the previous case and yields the conclusion that $\sin\angle v_1bv_2 \geq \kappa/(\rho^*)^3$. Arguing again as in the previous case, the actual Delaunay triangle containing v_1v_2 may not have b as its third vertex, but if it has another vertex p, then $\angle v_1pv_2$ is greater than $\angle v_1bv_2$ by considering the expanding circle property. □

8. Isoperimetry of the final mesh. We have already proved in Theorem 5.2 that the tiling of a triangle by our generalized pinwheel subdivision has the isoperimetric property. It is straightforward to extend this result to the collection of all leaf tiles.

THEOREM 8.1. $\mathcal{T}_0, \mathcal{T}_1, \ldots$ Ω n $\mathcal{T}_n$ Ω δ_n $\delta_n \to 0$ $n \to \infty$ p, q $P, Q \in \text{Skel}(\mathcal{T}_k)$ k

$$\lim_{\substack{n\to\infty \\ n\geq k}} \operatorname{dist}_{\text{Skel}(\mathcal{T}_n)}(p,q) = \|p-q\|_\Omega.$$

. This theorem follows from Theorem 5.5 and uses the same proof technique. Let Π be the geodesic path from p to q of length $\|p-q\|_\Omega$. Since Ω is a polygon, Π is composed of a finite number of line segments. For each tile T_i in $\mathcal{T}_k$ that meets Π, consider the small segment p_iq_i that is $T_i \cap \Pi$. Then we use Theorem 5.2 to argue that this small segment p_iq_i can be approximated arbitrarily accurately. ∎

This theorem can now be extended to the final mesh output by PINW by analyzing the effect of collapse-node operations on the isoperimetric number. (The Delaunay operations do not disturb the isoperimetry result, since adding edges could only make the isoperimetric number decrease.)

The definition of isoperimetry implicit in Theorems 5.5 and 8.1 is not suitable for analyzing the output of PINW because the meshes produced by PINW are not refinements of their predecessors as the mesh size decreases. This is because the collapse-node operations move nodes differently depending on the size of the leaf tiles.

Therefore, we use the following definition. An infinite sequence of simplicial meshes $\mathcal{M}_1, \mathcal{M}_2, \ldots$ for a domain Ω has the if for each $\mathcal{M}_i$ there is a subset L_i of its vertices such that the following two properties hold. First, L_i is asymptotically dense in Ω as $i \to \infty$; i.e., for any $\epsilon > 0$, there is an i^* such that for any $x \in \Omega$ and any $i > i^*$, there exists a $v \in L_i$ such that $\|x - v\| \leq \epsilon$. Second,

$$\limsup_{i\to\infty} \left\{ \frac{\operatorname{dist}_{\text{Skel}(\mathcal{M}_i)}(x,y)}{\|x-y\|_\Omega} : x, y \in L_i; x \neq y \right\} = 1.$$

THEOREM 8.2.

. To show that PINW has this property, take a sequence of ϵ_i's tending to zero. For each i, let $\mathcal{T}_i$ be a generalized pinwheel subdivision of Ω such that each leaf cell has diameter less than $\epsilon_i/2$. Then let $\mathcal{T}_i'$ be a further subdivision of $\mathcal{T}_i$ such that for any two distinct vertices of $\mathcal{T}_i$, $\operatorname{dist}_{\text{Skel}(\mathcal{T}_i')}(x,y) \leq (1+\epsilon_i/4)\|x-y\|_\Omega$. The existence of such a $\mathcal{T}_i'$ is established by Theorem 8.1. Let μ' be the minimum altitude among leaf tiles in $\mathcal{T}_i'$. Next, further refine $\mathcal{T}_i'$ to yield a tiling $\mathcal{T}_i''$ with the property that when δ is defined by (7.9) for $\mathcal{T}_i''$ (i.e., the $\mathcal{T}_*$ appearing in (7.9) pertains to $\mathcal{T}_i''$), then this δ is sufficiently small so that

$$\exp(3\delta/(0.75\mu'(1-0.9725))) \leq 1+\epsilon_i/4 \tag{8.1}$$

and

$$1-\epsilon_i/4 \leq 1-3\delta/(0.75\mu'(1-0.9725)). \tag{8.2}$$

Now finally, take $\mathcal{M}_i$ to be the simplicial mesh output by PINW based on $\mathcal{T}_i''$, and take L_i to be the set of nodes of $\mathcal{M}_i$ that are displaced copies of the nodes of $\mathcal{T}_i$.

First, we have to show that L_i defined in this manner is asymptotically dense. The nodes of L_i are the same as the nodes of $\mathcal{T}_i$ after small displacements. Since every

cell of $\mathcal{T}_i$ has diameter less than $\epsilon_i/2$, this means that any point $x \in \Omega$ is distance at most $\epsilon_i/2$ from a vertex of $\mathcal{T}_i$. The vertices of L_i are slightly displaced, but no distance λ decreases below 0.9λ or increases to more than 1.09λ. Therefore, for any $x \in \Omega$ the perturbed set L_i contains a point v within distance $1.09 \cdot \epsilon_i/2 < \epsilon_i$ of x.

Let x, y be two distinct points in L_i. The next task is to show that $\operatorname{dist}_{\mathrm{Skel}(\mathcal{M}_i)}(x, y) \leq \|x-y\|_\Omega(1+\epsilon_i)$. Let x_0, y_0 be the positions of x, y in $\mathcal{T}_i''$ prior to all distortions caused by collapse-node operations. Note that x_0, y_0 are vertices of $\mathcal{T}_i'$ and also of $\mathcal{T}_i$ by construction. Therefore, by construction of $\mathcal{T}_i'$, there is a path P_0 in $\mathrm{Skel}(\mathcal{T}_i')$ connecting x_0 and y_0 such that $\operatorname{length}(P_0) \leq \|x_0 - y_0\|_\Omega \cdot (1 + \epsilon_i/4)$. Let the segments of P_0 be $E_1, E_2, \ldots, E_m$. Let the image of P_0 after all the collapse-node operations with their attendant distortions are applied be P, and let the images of $E_1, \ldots, E_m$ be $F_1, \ldots, F_m$. Recall that the distortions that affect a node v of a tile T in the hierarchy are those distortions associated with T and its ancestor tiles, but descendant tiles cannot move T. Therefore, by Theorem 7.7, all of the quantities $\|x - y\|/\|x_0 - y_0\|_\Omega$, $\operatorname{length}(F_i)/\operatorname{length}(E_i)$, and $\operatorname{length}(P)/\operatorname{length}(P_0)$ lie between

$$\left(1 - \frac{\delta}{0.75\mu'}\right)^3 \cdot \left(1 - \frac{0.9725\delta}{0.75\mu'}\right)^3 \cdot \left(1 - \frac{0.9725^2\delta}{0.75\mu'}\right)^3 \cdots$$

and

$$\left(1 + \frac{\delta}{0.75\mu'}\right)^3 \cdot \left(1 + \frac{0.9725\delta}{0.75\mu'}\right)^3 \cdot \left(1 + \frac{0.9725^2\delta}{0.75\mu'}\right)^3 \cdots,$$

where the δ in this formula is given by (7.9) associated with $\mathcal{T}_i''$. By Lemma 7.6, this interval is bracketed by

$$1 - 3\frac{\delta}{0.75\mu'(1 - 0.9725)}$$

and

$$\exp(3\delta/(0.75\mu'(1 - 0.9725))).$$

Then by (8.1) and (8.2), this interval is bracketed by $[1 - \epsilon_i/4, 1 + \epsilon_i/4]$. Thus,

$$\begin{aligned}\operatorname*{dist}_{\mathrm{Skel}(\mathcal{M}_i)}(x, y) &\leq (1 + \epsilon_i/4) \operatorname*{dist}_{\mathrm{Skel}(\mathcal{T}_i')}(x_0, y_0) \\ &\leq (1 + \epsilon_i/4)^2 \|x_0 - y_0\|_\Omega \\ &\leq (1 + \epsilon_i/4)^2 \|x - y\|_\Omega/(1 - \epsilon_i/4).\end{aligned}$$

Note that $(1 + \epsilon_i/4)^2/(1 - \epsilon_i/4) \leq 1 + \epsilon_i$ as long as $\epsilon_i \leq 1/2$. Thus, we have shown that for all $x, y \in L_i$, $\operatorname{dist}_{\mathrm{Skel}(\mathcal{M}_i)}(x, y) \leq (1 + \epsilon_i)\|x - y\|_\Omega$. □

9. Conclusions. We believe that this generalization of pinwheel tiling to meshing polygonal regions would aid in modeling arbitrary crack paths more accurately than the current meshing techniques. Also, this kind of substitutive mechanism for subdivision makes it easy for adaptive meshing. This work raises a number of interesting directions for future research. Among them are the following:

1. The transformation of the tiling to the mesh had the effect of increasing the aspect ratio significantly. Is there a better way to carry out this transformation to reduce the impact on aspect ratio?

2. The convergence rate of the isoperimetric number of the pinwheel tiling to 1, which was not analyzed here, is known to be extremely slow even in the case of the 1:2 tiling. Is there another approach to isoperimetry that converges faster?
3. Consider a mesh generated by placing random points in the domain under consideration and joining them with a Delaunay triangulation. Is there a limiting isoperimetric number for this family of meshes (with high probability)?
4. Another way to construct a mesh of an arbitrary polygon with limiting isoperimetric number equal to 1 is to use the 1:2 pinwheel subdivision for every coarse triangle after subjecting it to a (potentially large) affine transformation. This approach is simpler in certain respects than PINW. For example, the collapse-node operations for this algorithm need to be done only at the boundaries of the coarse triangles. The difficulty with this approach is that it spoils the "statistical rotational invariance" of the pinwheel tiling. The statistical rotational invariance property states that the set of possible directions is covered at a uniform rate as subdivision proceeds. We are unclear whether statistical rotational invariance is important for cohesive interface modeling. We suspect that our construction of generalized pinwheels has statistical rotational invariance but have no proof of this. Is a simplification of our algorithm such as this one possible?
5. Can any of this work be extended to three dimensions?

Acknowledgments. We are grateful to Marshall Bern for originally telling us about Radin's paper. We also thank the two reviewers of the short version of this paper submitted to the 2004 International Meshing Roundtable for their helpful comments. We thank the two referees of the first draft of the journal version of this paper for additional helpful comments.

A NEW KIND OF ACCURATE NUMERICAL METHOD FOR BACKWARD STOCHASTIC DIFFERENTIAL EQUATIONS*

WEIDONG ZHAO†, LIFENG CHEN†, AND SHIGE PENG†

Abstract. In this paper, we propose a new kind of numerical simulation method for backward stochastic differential equations (BSDEs). We discretize the continuous BSDEs on time-space discrete grids, use the Monte Carlo method to approximate mathematical expectations, and use space interpolations to compute values at nongrid points. To demonstrate the accuracy and the effectiveness of our method, several numerical examples are given.

Key words. backward stochastic differential equations, Monte Carlo method, time-space discretization

AMS subject classifications. 60H35, 65C05

DOI. 10.1137/05063341X

1. Introduction.

In this paper, we consider the numerical solutions for the backward stochastic differential equations (BSDEs)

$$\begin{aligned} -dy_t &= f(t, y_t, z_t)dt - z_t \mathrm{d}W_t, \quad t \in [0, T), \\ y_T &= \xi, \end{aligned} \tag{1.1}$$

where $W_t = (W_t^1, \ldots, W_t^d)^*$ is a d-dimensional Brownian motion defined on some complete, filtered probability space $(\Omega, \mathcal{F}, P, \{\mathcal{F}_t\}_{0 \le t \le T})$, and $\xi \in \mathcal{F}_T$, and the notation * is the transpose operator for matrix or vector.

In 1990, Pardoux and Peng in [26] obtained the unique solvability results for the nonlinear BSDEs under some standard conditions. Since then, the BSDEs have been extensively studied [28, 29, 30, 18, 1, 11, 33, 24, 25] by many researchers. In [18], the properties of the solutions of the BSDEs and their important applications in mathematical finance were discussed. Some fine properties of the BSDEs by using Malliavin derivatives [14, 15] under weaker conditions were studied in the Ph.D. thesis [33] of Zhang. The applications of the BSDEs now cover many scientific fields, such as stochastic control, turbulence fluid flow, biology, stock markets, radiation, chemical reactions, and PDEs. However, it is often difficult to solve the BSDEs analytically, even the linear BSDEs.

Many efforts have been made in the numerical methods for BSDEs [2, 3, 4, 6, 9, 12, 22, 23, 24, 25, 30, 33, 34, 35]. By using the relations between the BSDEs and the PDEs [28, 17], a four step scheme for solving the BSDEs was developed in [23, 24]. Based on the four step scheme, a characteristic difference method was proposed to solve forward-backward SDEs (FBSDEs) in [12]. These two methods depend on the numerical schemes for PDEs and for the related ordinary SDEs. In [3], Bally and Pagès studied an optimal discrete quantization method designed to compute the solution of a certain kind of reflected BSDE, and the error analysis was given in [4]. In his Ph.D. thesis [9], Chevance proposed a numerical method for BSDEs by using binomial approach to approximate the process y_t. Peng proposed an iterative

linearization procedure to solve BSDEs in [30]. In [6], the time discrete approximation and the Monte Carlo method for solving BSDEs were studied by Bounchard and Touzi. In [34], Zhang studied a numerical approximation to the solution of the BSDEs under some weaker conditions.

Compared with the development of the numerical methods for the ordinary stochastic differential equations (SDEs) [5, 19, 20, 21, 32], the numerical methods for solving the solution of the BSDEs are far undeveloped, and effective and efficient methods are urgently needed.

In this paper, we study the numerical methods for the BSDEs (1.1). Based on the properties of the BSDEs, we propose a new accurate numerical method for the BSDEs. We fully discretize the time-space continuous problems and use the Monte Carlo method to approximate the mathematical expectations in our method. The space interpolation is used when the values at nongrid points are needed. The unknowns on each time level are totally uncoupled among the space grids, and the used data can be local for each space grid. Thus our method can be used to solve the general BSDEs in high performance parallel computers. To demonstrate the efficiency of our method, we use our method to solve some model BSDEs, and the results show that our method is efficient and is of high order.

We organize this paper as follows. In section 2, some basic notation and definitions are given. In section 3, we outline our solution procedure for one-dimensional BSDEs. Then, we generalize it and propose the numerical scheme for the general BSDEs (1.1) in section 4. Numerical experiments for some BSDE models are given in section 5. Finally, we draw some conclusions in section 6.

2. Notation and definitions. Let $(\Omega, \mathcal{F}, P, \{\mathcal{F}_t\}_{0\le t\le T})$ be a complete, filtered probability space on which a standard d-dimensional Brownian motion $W_t (0 \le t \le T)$ is defined with a finite terminal time T. Let the filtration $\{\mathcal{F}_t\}_{0\le t\le T}$ be the σ-field generated by the Brownian motion W_t, i.e., $\mathcal{F}_t = \sigma\{W_s, 0 \le s \le t\}$. All the P-null sets are augmented to each σ-field $\mathcal{F}_t$. Denote $L^2 = L^2_{\mathcal{F}}(0, T; \mathbb{R}^d)$ to be the set of all $\mathcal{F}_t$-adapted and mean-square-integrable processes valued in $\mathbb{R}^d$.

A process $(y_t, z_t) : [0, T] \times \Omega \to \mathbb{R}^m \times \mathbb{R}^{m\times d}$ is called an L^2-adapted solution of the BSDEs (1.1) if it is $\{\mathcal{F}_t\}$-adapted and square integrable and satisfies (1.1) in the sense of

$$y_t = \xi + \int_t^T f(s, y_s, z_s)ds - \int_t^T z_s \mathrm{d}W_s, \quad t \in [0, T), \tag{2.1}$$

where $f(t, y, z) : [0, T] \times \Omega \times \mathbb{R}^m \times \mathbb{R}^{m\times d} \to \mathbb{R}^m$, and $f(t, y, z)$ is an adapted stochastic process with respect to $\{\mathcal{F}_t\}(0 \le t \le T)$ for each (y, z).

Under some conditions for $f(t, y, z)$, Pardoux and Peng in [26] obtained the uniqueness solvability results for the BSDE (2.1). Properties and applications of BSDEs can be found in [18]. In our paper, we are interested in the numerical solution of the BSDE (2.1). We assume that the BSDE (2.1) admits a unique L^2-adapted solution (y_t, z_t).

Let $\mathcal{F}_s^{t,x}(t \le s \le T)$ be a σ-field generated by the Brownian motion $\{x + W_v - W_t, t \le v \le s\}$ starting from the time-space point (t, x), and let $\mathcal{F}^{t,x} = \mathcal{F}_T^{t,x}$. We use $\mathbb{E}[X]$ to denote the mathematical expectation of the random variable X and $\mathbb{E}_s^{t,x}[X]$ to denote the conditional mathematical expectation of the random variable X under the σ-field $\mathcal{F}_s^{t,x}(t \le s \le T)$; that is, $\mathbb{E}_s^{t,x}[X] = \mathbb{E}[X|\mathcal{F}_s^{t,x}]$. If $X = (X_{ij})_{m\times n}$ is a matrix or vector stochastic variable, we define the conditional mathematical expectation $\mathbb{E}_s^{t,x}[X]$ by $\mathbb{E}_s^{t,x}[X] = (\mathbb{E}_s^{t,x}[X_{ij}])_{m\times n}$.

3. Development of the numerical method. For simplicity, in this section, we start with the one-dimensional BSDE to develop our numerical method for the BSDE (2.1)

For the real axis $\mathbb{R}$, we introduce a space partition $\mathfrak{R}_h$ as

$$\mathfrak{R}_h = \{x_i | x_i \in \mathbb{R}, i \in \mathbb{Z}, x_i < x_{i+1}, \lim_{i\to+\infty} = +\infty, \lim_{i\to-\infty} = -\infty\}, \tag{3.1}$$

where $\mathbb{Z}$ is the set of all integer numbers, and all x_i's are deterministic. We use $h_i = x_{i+1} - x_i$ to denote the space step and $h = \max_{i\in\mathbb{Z}} h_i$ to denote the maximum space step.

For the time interval $[0, T]$, we introduce the time partition

$$\mathfrak{R}_{th} = \{t_i | t_i \in [0, T], i = 0, 1, \ldots, N_T, t_i < t_{i+1}, t_0 = 0, t_{N_T} = T\}, \tag{3.2}$$

where all t_n's are deterministic. Let $\Delta t_n = t_{n+1} - t_n$ be the time step, and let $\Delta t = \max_{0\le n<N_T} \Delta t_n$ be the maximum time step.

3.1. Reference equations. Let (y_t, z_t) be the adapted solution of the BSDE (2.1); then we have

$$y_t = \quad y_{t+\delta} + \int_t^{t+\delta} f(s, y_s, z_s)ds - \int_t^{t+\delta} z_s dW_s, \quad t \in [0, T), \tag{3.3}$$

where δ is a deterministic nonnegative number with $t + \delta \le T$. Taking the conditional mathematical expectation $\mathbb{E}_t^{t,x}$ on the two sides of (3.3), we deduce

$$y_t^{t,x} = \quad \mathbb{E}_t^{t,x}[y_{t+\delta}] + \int_t^{t+\delta} \mathbb{E}_t^{t,x}[f(s, y_s, z_s)]ds, \tag{3.4}$$

where $y_t^{t,x} = \mathbb{E}[y_t | \mathcal{F}_t^{t,x}]$; that is, $y_t^{t,x}$ is the value of y_t at the time-space point (t, x). With respect to the filtration $\mathcal{F}_t$, the integrand on the right-hand side of (3.4) is deterministic. We write the integral term in (3.4) in the form

$$\begin{aligned}\int_t^{t+\delta} \mathbb{E}_t^{t,x}[f(s, y_s, z_s)]ds = \quad & \delta\{(1-\theta_1)\mathbb{E}_t^{t,x}[f(t+\delta, y_{t+\delta}, z_{t+\delta})] \\ & +\theta_1 f(t, y_t^{t,x}, z_t^{t,x})\} + R_y,\end{aligned} \tag{3.5}$$

where R_y is defined by

$$R_y = \quad \int_t^{t+\delta} \{\mathbb{E}_t^{t,x}[f(s, y_s, z_s)] - (1-\theta_1)\mathbb{E}_t^{t,x}[f(t+\delta, y_{t+\delta}, z_{t+\delta})] - \theta_1 f(t, y_t^{t,x}, z_t^{t,x})\}ds$$

with the parameter $\theta_1 \in [0, 1]$. Inserting (3.5) into (3.4) leads to

$$\begin{aligned}y_t^{t,x} = \quad & \mathbb{E}_t^{t,x}[y_{t+\delta}] + \delta\{(1-\theta_1)\mathbb{E}_t^{t,x}[f(t+\delta, y_{t+\delta}, z_{t+\delta})] \\ & +\theta_1 f(t, y_t^{t,x}, z_t^{t,x})\} + R_y.\end{aligned} \tag{3.6}$$

Let $\Delta W_s = W_s - W_t$ for $t \le s \le t + \delta$; then ΔW_s is a standard Brownian motion with mean zero and variance $\sqrt{s-t}$. Now multiplying the two sides of (3.3) by $\Delta W_{t+\delta}$, and taking the mathematical expectation $\mathbb{E}_t^{t,x}$ to the two sides of the derived equation, by using Itô isometry formula we obtain

$$-\mathbb{E}_t^{t,x}[y_{t+\delta}\Delta W_{t+\delta}] = \quad \int_t^{t+\delta} \mathbb{E}_t^{t,x}[f(s, y_s, z_s)\Delta W_s]ds - \int_t^{t+\delta} \mathbb{E}_t^{t,x}[z_s]ds. \tag{3.7}$$

The two integral terms on the right-hand side of (3.7) are two standard integrals with respect to time under the filtration $\mathcal{F}_t$. We decompose the two terms on the right-hand side of (3.7) by

$$\int_t^{t+\delta} \mathbb{E}_t^{t,x}[f(s,y_s,z_s)\Delta W_s]ds$$

$$= \delta(1-\theta_2)\mathbb{E}_t^{t,x}[f(t+\delta,y_{t+\delta},z_{t+\delta})\Delta w_{t+\delta}] + R_{z1}, \tag{3.8}$$

$$-\int_t^{t+\delta} \mathbb{E}_t^{t,x}[z_s]ds = -\delta\left\{(1-\theta_2)\mathbb{E}_t^{t,x}[z_{t+\delta})] + \theta_2 z_t^{t,x}\right\} + R_{z2}, \tag{3.9}$$

where $z_t^{t,x}$ is the value of z_t at the time-space point (t,x) under the filtration $\mathcal{F}_t$, and

$$\begin{aligned} R_{z1} = &\int_t^{t+\delta} \{\mathbb{E}_t^{t,x}[f(s,y_s,z_s)\Delta W_s] - (1-\theta_2)\mathbb{E}[f(t+\delta,y_{t+\delta},z_{t+\delta})\Delta W_{t+\delta}]\}ds, \\ R_{z2} = &-\int_t^{t+\delta} \{\mathbb{E}_t^{t,x}[z_s] - (1-\theta_2)\mathbb{E}_t^{t,x}[z_{t+\delta}] - \theta_2 z_t^{t,x}\}\}ds \end{aligned}$$

with $\theta_2 \in [0,1]$. Combining the (3.7), (3.8), and (3.9), we obtain

$$\begin{aligned} -\mathbb{E}_t^{t,x}[y_{t+\delta}\Delta W_{t+\delta}] = &\quad \delta(1-\theta_2)\mathbb{E}_t^{t,x}[f(t+\delta,y_{t+\delta},z_{t+\delta})\Delta w_{t+\delta}] \\ &-\delta\left\{(1-\theta_2)\mathbb{E}_t^{t,x}[z_{t+\delta})] + \theta_2 z_t^{t,x}\right\} + R_z \end{aligned} \tag{3.10}$$

with $R_z = R_{z1} + R_{z2}$.

The equations (3.6) and (3.10) are the two fundamental reference equations obtained from (2.1). They are held for the deterministic time variable t and the deterministic parameters δ, θ_1, and θ_2. Based on these two reference equations, we then propose our numerical method in the following sections.

3.2. Discrete scheme.

3.2.1. Semidiscrete θ-scheme. In the reference equations (3.6) and (3.10), let $t = t_n$, $\delta = \Delta t_n$. Take $(y^n, z^n)(n = N_T, N_T - 1, \ldots, 0)$ as the approximations to the analytic solution (y_t, z_t) of the BSDE (2.1) at time levels $t_n(n = N_T, N_T - 1, \ldots, 0)$. Let $(y^n, z^n)(n = N_T, N_T - 1, \ldots, 0)$ satisfy (3.6) and (3.10) without terms R_y and R_z; that is, (y^n, z^n) satisfies

$$\begin{aligned} y^n = &\mathbb{E}_{t_n}^{t_n,x}[y^{n+1}] + \Delta t_n[(1-\theta_1^n)\mathbb{E}_{t_n}^{t_n,x}[f(t_{n+1},y^{n+1},z^{n+1})] \\ &+\theta_1^n f(t_n,y^n,z^n)], \end{aligned} \tag{3.11}$$

$$\begin{aligned} 0 = &\mathbb{E}_{t_n}^{t_n,x}[y^{n+1}\Delta W_{t_{n+1}}] + \Delta t_n(1-\theta_2^n)\mathbb{E}_{t_n}^{t_n,x}[f(t_{n+1},y^{n+1},z^{n+1})\Delta W_{t_{n+1}}] \\ &-\Delta t_n\{(1-\theta_2^n)\mathbb{E}_{t_n}^{t_n,x}[z^{n+1}] + \theta_2^n z^n\} \end{aligned} \tag{3.12}$$

for $n = N_T - 1, N_T - 2, \ldots, 2, 1, 0$ with the parameters θ_1^n and θ_2^n in $[0,1]$.

The equations (3.11) and (3.12) are a semidiscrete θ-scheme for the BSDE (2.1). The semidiscrete θ-scheme is nonlinear in the random variables y^n and z^n. So for the general nonlinear BSDE problems, some methods for finding (y^n, z^n) are needed. In this paper, we use Newton's method to solve (y^n, z^n). The procedure to solve (y^n, z^n) is as follows:

1. Let $y^{N_T} = \xi$.
2. If $n = N_T - 1$, let $\theta_2^n = 1$, and use (3.11) and (3.12) to solve (y^n, z^n).
3. If $0 \le n < N_T - 1$, use (3.11) and (3.12) to solve (y^n, z^n).

1. By choosing θ_1^n and θ_2^n in (3.11) and (3.12), we can obtain different methods. When we choose $\theta_1^n = \theta_2^n = 0$, we get the explicit Euler scheme. When $\theta_1^n = \theta_2^n \neq 0$, the θ-scheme is implicit. The implicit Euler scheme is the case $\theta_1^n = \theta_2^n = 1$, and the implicit Crank–Nicolson (CN) scheme is the case $\theta_1^n = \theta_2^n = \frac{1}{2}$. Our implicit θ-scheme for the BSDE (2.1) is different from the implicit schemes for solving ODEs and PDEs in that our θ-scheme is always explicit for solving z^n.

3.2.2. Fully discrete θ-scheme. To simulate (y^n, z^n) based on the semidiscrete θ-scheme (3.11) and (3.12), two more numerical approximations must be done; these are the approximation of the conditional mathematical expectation and the space approximation of (y^n, z^n). To do these, we take $x = x_i \in \mathfrak{R}_h$ in (3.11) and (3.12), and let $\hat{x}_i = x_i + \Delta W_{t_{n+1}}$. Then there is an integer $\hat{i} \in \mathbb{Z}$ such that $\hat{x}_i \in [x_{\hat{i}}, x_{\hat{i}+1}]$. Let $I_h u(\hat{x}_i)$ be an interpolation approximation of the function $u(x)$ at the space point $\hat{x}_i$ by using the values of $u(x)$ at a finite number of the space points x_j's in $\mathfrak{R}_h$ near the space point $\hat{x}_i$. The more accurate the simulations are required to be, the more points in $\mathfrak{R}_h$ near $\hat{x}_i$ need be used. For some complicated problems, some special interpolations may be taken.

For each $x = x_i \in \mathfrak{R}_h$ in (3.11) and (3.12), let $\Delta_h^k W_{t_{n+1}} (k = 1, 2, \ldots, N_E)$ be the N_E times realizations of $\sqrt{\Delta t_n} N(0,1)$, where $N(0,1)$ is a standard normal distribution with mean zero and variance 1, and let $\hat{x}_i^k = x_i + \Delta_h^k W_{t_{n+1}}$.

To approximate the conditional mathematical expectations, we use the Monte Carlo method. We write the first term on the right-hand side of (3.11) in the following form:

$$\mathbb{E}_{t_n}^{t_n,x_i}[y^{n+1}] = \mathbb{E}_{h,t_n}^{t_n,x_i}[y^{n+1}] + Err_y, \tag{3.13}$$

where

$$\mathbb{E}_{h,t_n}^{t_n,x_i}[y^{n+1}] = \frac{\sum_{k=1}^{N_E} I_h y^{n+1}(\hat{x}_i^k)}{N_E}, \quad \mathbb{E}rr_y = \mathbb{E}_{t_n}^{t_n,x_i}[y^{n+1}] - \frac{\sum_{k=1}^{N_E} I_h y^{n+1}(\hat{x}_i^k)}{N_E}.$$

The first term on the right-hand side of (3.13) is the Monte Carlo approximation to the mathematical expectation $\mathbb{E}_{t_n}^{t_n,x_i}[y^{n+1}]$, and the second term is the Monte Carlo approximation error.

Similarly we write the second term on the right-hand side of (3.11) as

$$\mathbb{E}_{t_n}^{t_n,x_i}[f(t_{n+1}, y^{n+1}, z^{n+1})] = \mathbb{E}_{h,t_n}^{t_n,x_i}[f(t_{n+1}, y^{n+1}, z^{n+1})] + Err_f \tag{3.14}$$

with the Monte Carlo approximation

$$\mathbb{E}_{h,t_n}^{t_n,x_i}[f(t_{n+1}, y^{n+1}, z^{n+1})] = \frac{\sum_{k=1}^{N_E} f(t_{n+1}, I_h y^{n+1}(\hat{x}_i^k), I_h z^{n+1}(\hat{x}_i^k))}{N_E}$$

and the corresponding approximation error

$$Err_f = \mathbb{E}_{t_n}^{t_n,x_i}[f(t_{n+1}, y^{n+1}, z^{n+1})] - \mathbb{E}_{h,t_n}^{t_n,x_i}[f(t_{n+1}, y^{n+1}, z^{n+1})].$$

Combining (3.11), (3.13), and (3.14), we obtain

$$\begin{aligned} y_i^n = \; & \mathbb{E}_{h,t_n}^{t_n,x_i}[y^{n+1}] + \Delta t_n[(1-\theta_1^n)\mathbb{E}_{h,t_n}^{t_n,x_i}[f(t_{n+1}, y^{n+1}, z^{n+1})] \\ & + \theta_1^n f(t_n, y_i^n, z_i^n)] + \Delta t_n(1-\theta_1^n) Err_f + Err_y, \end{aligned} \tag{3.15}$$

where (y_i^x, z_i^n) is the value of (y^n, z^n) at the space point x_i with respect to the filtration $\mathcal{F}_{t_n}$, and $\Delta t_n(1-\theta_1^n)Err_f + Err_y$ is the Monte Carlo approximation error.

Now, let us turn to approximate the three conditional mathematical expectations in (3.12). We write the first term on the right-hand side of (3.12) as

$$\mathbb{E}_{t_n}^{t_n,x_i}[y^{n+1}\Delta W_{t_{n+1}}] = \mathbb{E}_{h,t_n}^{t_n,x_i}[y^{n+1}\Delta W_{t_{n+1}}] + Err_{yw}, \tag{3.16}$$

where

$$\begin{aligned}\mathbb{E}_{h,t_n}^{t_n,x_i}[y^{n+1}\Delta W_{t_{n+1}}] &= \frac{\sum_{k=1}^{N_E} I_h y^{n+1}(\hat{x}_i^k)\Delta_h^k W_{t_{n+1}}}{N_E},\\ Err_{yw} &= \mathbb{E}_{t_n}^{t_n,x_i}[y^{n+1}\Delta W_{t_{n+1}}] - \mathbb{E}_{h,t_n}^{t_n,x_i}[y^{n+1}\Delta W_{t_{n+1}}],\end{aligned}$$

we write the second term on the right-hand side of (3.12) as

$$\mathbb{E}_{t_n}^{t_n,x_i}[f(t_{n+1},y^{n+1},z^{n+1})\Delta W_{t_{n+1}}] = \mathbb{E}_{h,t_n}^{t_n,x_i}[f(t_{n+1},y^{n+1},z^{n+1})\Delta W_{t_{n+1}}] + Err_{fw}, \tag{3.17}$$

where

$$\begin{aligned}\mathbb{E}_{h,t_n}^{t_n,x_i}[f(t_{n+1},y^{n+1},z^{n+1})\Delta W_{t_{n+1}}] &= \frac{\sum_{k=1}^{N_E} f(t_{n+1}, I_h y^{n+1}(\hat{x}_i^k), I_h z^{n+1}(\hat{x}_i^k))\Delta_h^k W_{t_{n+1}}}{N_E},\\ Err_{fw} &= \mathbb{E}_{t_n}^{t_n,x_i}[f(t_{n+1},y^{n+1},z^{n+1})\Delta W_{t_{n+1}}]\\ &\quad -\mathbb{E}_{h,t_n}^{t_n,x_i}[f(t_{n+1},y^{n+1},z^{n+1})\Delta W_{t_{n+1}}],\end{aligned}$$

and we write the third term on the right-hand side of (3.12) as

$$\mathbb{E}_{t_n}^{t_n,x_i}[z^{n+1}] = \mathbb{E}_{h,t_n}^{t_n,x_i}[z^{n+1}] + Err_z, \tag{3.18}$$

where

$$\mathbb{E}_{h,t_n}^{t_n,x_i}[z^{n+1}] = \frac{\sum_{k=1}^{N_E} I_h z^{n+1}(\hat{x}_i^k)}{N_E}, \quad Err_z = \mathbb{E}_{t_n}^{t_n,x_i}[z^{n+1}] - \mathbb{E}_{h,t_n}^{t_n,x_i}[z^{n+1}].$$

Now combining (3.12), (3.16), (3.17), and (3.18), we get

$$\begin{aligned}&\mathbb{E}_{h,t_n}^{t_n,x_i}[y^{n+1}\Delta W_{t_{n+1}}] + \Delta t_n(1-\theta_2^n)\mathbb{E}_{h,t_n}^{t_n,x_i}[f(t_{n+1},y^{n+1},z^{n+1})\Delta W_{t_{n+1}}]\\ &\quad -\Delta t_n\{(1-\theta_2^n)\mathbb{E}_{h,t_n}^{t_n,x_i}[z^{n+1}] + \theta_2^n z_i^n\}\\ &\quad +Err_{yw} + \Delta t_n(1-\theta_2^n)Err_{fw} - \Delta t_n(1-\theta_2^n)Err_z = 0,\end{aligned} \tag{3.19}$$

where $Err_{yw}+\Delta t_n(1-\theta_2^n)Err_{fw}-\Delta t_n(1-\theta_2^n)Err_z$ is the Monte Carlo approximation error.

From probability theory, we know that the Monte Carlo approximation errors Err_y in (3.13), Err_z in (3.18), Err_f in (3.14), Err_{yw} in (3.16), and Err_{fw} in (3.17) converge to 0 with the convergence rate $\frac{1}{\sqrt{N_E}}$ as $N_E \to \infty$. So we can choose a proper integer N_E in the Monte Carlo method to approximate the mathematical expectations with the required accuracy.

Now we take (y_i^n, z_i^n) as the approximation of the solution (y_t, z_t) at the time-space point (t_n, x_i) with $t_n \in \mathfrak{R}_{th}$ and $x_i \in \mathfrak{R}_h$. Based on the two equations (3.15) and (3.19), by omitting the Monte Carlo error terms, we propose a fully time-space discrete θ-scheme to solve (y_t, z_t), the solution of the BSDE (2.1), as for the given terminal values $y_i^{N_T} (i \in \mathfrak{R}_h)$, select θ_1^n and θ_2^n in [0,1], and find (y_i^n, z_i^n) that satisfies

$$y_i^n = \mathbb{E}_{h,t_n}^{t_n,x_i}[y^{n+1}] + \Delta t_n\{(1-\theta_1^n)\mathbb{E}_{h,t_n}^{t_n,x_i}[f(t_{n+1}, y^{n+1}, z^{n+1})] + \theta_1^n f(t_n, y_i^n, z_i^n)\}, \tag{3.20}$$

$$0 = \mathbb{E}_{h,t_n}^{t_n,x_i}[y^{n+1}\Delta W_{t_{n+1}}] + \Delta t_n(1-\theta_2^n)\mathbb{E}_{h,t_n}^{t_n,x_i}[f(t_{n+1}, y^{n+1}, z^{n+1})\Delta W_{t_{n+1}}] - \Delta t_n\{(1-\theta_2^n)\mathbb{E}_{h,t_n}^{t_n,x_i}[z^{n+1}] + \theta_2^n z_i^n\} \tag{3.21}$$

for $i \in \mathbb{Z}$ and $n = N_T - 1, N_T - 2, \ldots, 2, 1, 0$ with $\theta_2^{N_T-1} = 1$.

In the fully discrete θ-scheme (3.20) and (3.21), for each point (t_n, x_i), the (y_i^n, z_i^n) is unknown. Here we suggest a procedure to solve (y_i^n, z_i^n) from the two equations (3.20) and (3.21) for $i \in \mathbb{Z}$ and $n = N_T - 1, N_T - 2, \ldots, 2, 1, 0$. The procedure is as follows:

1. Given $y_i^{N_T}, \quad i \in \mathbb{Z}$.
2. For $n = N_T - 1$, let $\theta_2^n = 1$ in (3.21), and solve (y_i^n, z_i^n) from the two equations (3.20) and (3.21) for each $i \in \mathbb{Z}$.
3. For $0 \le n < N_T - 1$, solve (y_i^n, z_i^n) from the two equations (3.20) and (3.21) for each $i \in \mathbb{Z}$.

. . . . 2.

1. In the fully discrete θ-scheme (3.20) and (3.21), in order to solve z_i^n, it is necessary for θ_2^n not to be zero. And solving z_i^n is always explicit from (3.21). For the linear BSDE, solving y_i^n is explicit. For the nonlinear BSDE, some numerical methods to solve y_i^n are needed if $\theta_1^n \neq 0$.
2. Solving (y_i^n, z_i^n) with different $i \in \mathbb{Z}$ is totally uncoupled. We can solve $(y_i^n, z_i^n)(i \in \mathbb{Z})$ in parallel.
3. In practical applications, we are often interested in the values of (y_0, z_0) in a bounded domain. Thus from the Brownian motion theory, the data of $(y_i^{N_T}, z_i^{N_T})$ on some bounded domain is needed under some required accuracy.
4. The terminal condition is y_T. In the first computing step, we set $\theta_2^{N_T-1} = 1$ for solving $z_i^{N_T-1}$. For $\theta_2^{N_T-1} = 1$, the accuracy of the scheme is not high. To achieve the high accuracy, a special time partition step Δt_{N_T-1} is needed. For example, we can choose $\theta_1^n = \theta_2^n = \frac{1}{2}$ for $n < N_T - 1$ and choose $\theta_2^n = 1$ and let $\Delta t_n = (\Delta t_{n-1})^2$ for $n = N_T - 1$.

4. Discrete θ-scheme for general BSDEs. Based on the method of constructing the discrete θ-scheme (3.20) and (3.21) in section 3, in this section, we generalize the scheme and propose a new numerical scheme for the general BSDEs (2.1) driven by a standard d-dimensional Brownian motion $W_t = (W_t^1, W_t^2, \ldots, W_t^d)^*$, where $W_t^i (i = 1, 2, \ldots, d)$ are the independent standard one-dimensional Brownian motions, and the notation * is the transpose operator for matrix or vector.

We use $\mathbb{R}^d$ to denote the d-dimensional Euclidean space. $x \in \mathbb{R}^d$ means $x = (x^1, x^2, \ldots, x^d)$ with $x^i \in \mathbb{R} (i = 1, 2, \ldots, d)$. Let $\mathbb{Z}^d = \{i | i = (i_1, i_2, \ldots, i_d), i_k \in \mathbb{Z}, k = 1, 2, \ldots, d\}$ and $x_i = (x_{i_1}^1, x_{i_2}^2, \ldots, x_{i_d}^d)$ for $i = (i_1, i_2, \ldots, i_d) \in \mathbb{Z}^d$.

Let $(y_t, z_t) : (t, \Omega) \to \mathbb{R}^m \times \mathbb{R}^{m \times d}$ be the solution of the BSDE (2.1), where

$y_t = (y_t^1, y_t^2, \ldots, y_t^m)^*$ and $z_t = (z_t^{i,j})_{m\times d}$. Similarly to obtaining (3.3), we have

$$y_t^k = y_{t+\delta}^k + \int_t^{t+\delta} f^k(s, y_s, z_s)ds - \int_t^{t+\delta} \sum_{j=1}^{d} z_s^{k,j} dW_s^j, \quad t \in [0, T), \tag{4.1}$$

where f^k is the kth component of the vector function f. Taking the conditional mathematical expectation $\mathbb{E}_t^{t,x}$ on the two sides of (4.1), we obtain

$$y_t^{k,t,x} = \mathbb{E}_t^{t,x}[y_{t+\delta}^k] + \int_t^{t+\delta} \mathbb{E}_t^{t,x}[f^k(s, y_s, z_s)]ds, \quad t \in [0, T), t+\delta \in [0, T] \tag{4.2}$$

for $k = 1, 2, \ldots, m$. We rewrite (4.2) in the following vector form:

$$y_t^{t,x} = \mathbb{E}_t^{t,x}[y_{t+\delta}] + \int_t^{t+\delta} \mathbb{E}_t^{t,x}[f(s, y_s, z_s)]ds, \quad t \in [0, T), t+\delta \in [0, T]. \tag{4.3}$$

As we did for $m = d = 1$ in section 3, for $t \le s \le t+\delta$, we let $\Delta W_s^l = W_s^l - W_t^l (l = 1, 2, \ldots, d)$, which are the independent standard one-dimensional Brownian motions with mean zero and variance $\sqrt{s-t}$. Multiplying the two sides of (4.1) by $\Delta W_{t+\delta}^l$ and taking the conditional mathematical expectation $\mathbb{E}_t^{t,x}$ on the two sides of the derived equation, by the Itô isometry formula we then obtain

$$-\mathbb{E}_t^{t,x}[y_{t+\delta}^k \Delta W_{t+\delta}^l] = \int_t^{t+\delta} \mathbb{E}_t^{t,x}[f^k(s, y_s, z_s)\Delta W_s^l]ds - \int_t^{t+\delta} \mathbb{E}_t^{t,x}[z_s^{k,l}]ds \tag{4.4}$$

for $k = 1, 2, \ldots, m$ and $l = 1, 2, \ldots, d$, or in the matrix form

$$-\mathbb{E}_t^{t,x}[y_{t+\delta}\Delta W_{t+\delta}^*] = \int_t^{t+\delta} \mathbb{E}_t^{t,x}[f(s, y_s, z_s)\Delta W_s^*]ds - \int_t^{t+\delta} \mathbb{E}_t^{t,x}[z_s]ds. \tag{4.5}$$

Here for a matrix random variable $X = (X_{lk})_{m\times d}$, the conditional mathematical expectation $\mathbb{E}_t^{t,x}[X]$ is defined by

$$\mathbb{E}_t^{t,x}[X] = (\mathbb{E}_t^{t,x}[X^{l,j}])_{m\times d}. \tag{4.6}$$

We now introduce the partitions of the Euclidean space $\mathbb{R}^d$ and the time interval $[0, T]$. The partition of the Euclidean space $\mathbb{R}^d$ is

$$\mathfrak{R}_h^d = \overbrace{\mathfrak{R}_h \times \mathfrak{R}_h \times \cdots \times \mathfrak{R}_h}^{d \ times}, \tag{4.7}$$

where $\mathfrak{R}_h$ is defined in section 3. The partition of the time interval $[0, T]$ is $\mathfrak{R}_{th}$ defined in section 3.

Let the approximations of the conditional mathematical expectations in (4.3) and (4.5) be defined as those in (3.13), (3.14), (3.16), (3.18), and (3.17); that is,

$$\mathbb{E}_{h,t_n}^{t_n,x_i}[X] = (\mathbb{E}_{h,t_n}^{t_n,x_i}[X^{l,j}]). \tag{4.8}$$

In the computation of $\mathbb{E}_{h,t_n}^{t_n,x_i}[X^{l,j}]$, the random variable $\hat{x}_i = x_i + \Delta W_{t_{n+1}}$ for $x_i \in \mathbb{R}_h^d$ and the d-dimensional interpolation operator I_h are used.

The number of the d-dimensional interpolation points near the space point $\hat{x}_i$ depends on the required accuracy. For the high-dimensional problems, the space interpolations may be expensive. It is still a challenging problem to propose an efficient high-dimensional interpolation method. In this paper, we focus our attention

on the numerical methods for the BSDE (2.1) and use the bilinear polynomial, bicubic polynomial, and bicubic spline interpolations to solve the two-dimensional BSDE (2.1) in Example 3 in section 5.

Now let (y_i^n, z_i^n) be an approximation of (y_t, z_t) at the time-space point (t_n, x_i) with $t_n \in \mathfrak{R}_{th}$ and $x_i \in \mathfrak{R}_h^d$. Based on the two equations (4.2) and (4.5), by using the same procedure of getting the fully discrete θ-scheme (3.20) and (3.21) in section 3, we propose a new fully discrete θ-scheme for the general BSDE (2.1) as follows: Given $y_i^{N_T} (i \in \mathbb{Z}^d)$, find $(y_i^n, z_i^n) \in \mathbb{R}^m \times \mathbb{R}^{m\times d}$ that satisfies

$$y_i^n = \mathbb{E}_{h,t_n}^{t_n,x_i}[y^{n+1}] + \Delta t_n\{(1-\theta_1^n)\mathbb{E}_{h,t_n}^{t_n,x_i}[f(t_{n+1}, y^{n+1}, z^{n+1})] + \theta_1^n f(t_n, y_i^n, z_i^n)\}, \tag{4.9}$$

$$0 = \mathbb{E}_{h,t_n}^{t_n,x_i}[y^{n+1}(\Delta W_{t_{n+1}})^*] + \Delta t_n(1-\theta_2^n)\mathbb{E}_{h,t_n}^{t_n,x_i}[f(t_{n+1}, y^{n+1}, z^{n+1})(\Delta W_{t_{n+1}})^*] - \Delta t_n\{(1-\theta_2^n)\mathbb{E}_{h,t_n}^{t_n,x_i}[z^{n+1}] + \theta_2^n z_i^n\} = 0 \tag{4.10}$$

for $i \in \mathbb{Z}^d$ and $n = N_T - 1, N_T - 2, \ldots, 2, 1, 0$, where θ_1^n and θ_2^n are two parameters in [0,1] with $\theta_2^{N_T-1} = 1$.

A solution procedure for the scheme (4.9) and (4.10) can be described as follows:

1. given $y_i^{N_T}$, $i \in \mathbb{Z}^d$, $n = N_T - 1$;
2. solve $z_i^n (i \in \mathbb{Z}^{m\times d})$ from (4.10);
3. solve $y_i^n (i \in \mathbb{Z}^d)$ from (4.9);
4. if $n = 0$, stop; else let $n \leftarrow n - 1$; goto step 2.

Remark 3. Like the one-dimensional fully discrete θ-scheme, in the fully discrete θ-scheme (4.9) and (4.10), the unknowns are y_i^n and z_i^n. Solving z_i^n is explicit from (4.10). For $\theta_1^n \neq 0$, solving y_i^n is implicit. At each time level $t = t_n$, $y_l^n (l \in \mathbb{Z}^d)$ are totally uncoupled among the space grids and can be solved parallelly.

5. Numerical experiments. The aim of this section is to use some numerical examples to demonstrate the effectiveness and accuracy of our method for solving the BSDE (2.1). In the examples, the time and space step sizes are Δt and h, respectively. The positive integer N_T is the total discrete time steps $N_T = \frac{T}{\Delta t}$ with the finite terminal time T. In the tables, the notations of $|\cdot|$, CR, EMC, HS, and Scheme$^\alpha (\alpha = L, C, S)$ represent, respectively, the standard Euclidean norm in the Euclidean space $\mathbb{R}^m$ or $\mathbb{R}^{m\times d}$, the convergence rate with respect to the time step sizes, the implicit Euler Monte Carlo method related to our scheme with $\theta_1^n = \theta_2^n = 1$, the Heun's method in which the cubic polynomial interpolation operator I_h is used, and our method in which the linear polynomial, cubic polynomial, and cubic spline interpolation operators I_h are used with $\theta_1^n = \theta_2^n = \frac{1}{2}$ for $\alpha = L, C, S$, respectively.

To obtain the convergence rates for the different interpolations, we adjust the space partition step h to the time partition step Δt. As we know, for ordinary differential equations, the CN scheme is a second order method. In our method, the time discretization is based on the integral approximations with the deterministic functions, which are the conditional mathematical expectations. The details of the approximations are described in section 3. If the functions $f(t, y, z)$ and $\Phi(x)$ are sufficiently smooth, the discrete approximation errors in the time direction are $C_t \Delta t$ for $\theta_1^n \neq \frac{1}{2}$ or $\theta_2^n \neq \frac{1}{2}$, and $C_t(\Delta t)^2$ for $\theta_1^n = \theta_2^n = \frac{1}{2}$. The space interpolation error is $I_h u - u = C_h h^r$ with a positive number r, which depends on the interpolation operator I_h and the regularity of the function u with respect to the space variables. For the linear polynomial interpolation operator I_h, $r = 2$. For the cubic polynomial and cubic spline interpolation operators I_h, $r = 4$. In numerical simulations, the time

errors and the space errors should be balanced, so the space discrete step h and the time discrete step Δt should be chosen to satisfy the equality $C_h h^r = C_t(\Delta t)^2$. In our numerical experiments, we use $h = \Delta t$ when the linear polynomial interpolation is used, and use $h = (\Delta t)^{\frac{1}{2}}$ when the cubic polynomial and cubic spline interpolations are used. If the order of the accuracy in the time direction is α, then the order of the accuracy in the space is α for the linear interpolation and 2α for the cubic polynomial and cubic spline interpolations.

In the Monte Carlo approximations, we use different random sampling numbers N_E for different time partitions. The sampling numbers N_E are listed in the corresponding tables.

It is well known that the random number generator is very important for Monte Carlo method and that the accuracy of the Monte Carlo method depends not only on the sampling number N_E but also on the quality of the random number generator. In this paper, we choose the software SPRNG (Scalable Parallel Random Number Generators Library) as our random number generator. We use SPRNG to generate uniform distribution samples and then use the well-known Box–Muller method [7] to transform these samples into the ones with normal distributions. The software SPRNG and its details can be found on the website http://sprng.cs.fsu.edu/.

To compare our method with other ones, we also use the Euler method and the Heun's method [8] combined with the Monte Carlo method to solve the BSDEs in the following numerical examples, and list their errors and their convergence rates in the corresponding tables.

Example 1. Consider the following nonlinear BSDE:

$$\begin{cases} -dY_t = \lambda(Y_t)|Z_t|^2 dt - Z_t dW_t, 0 \le t \le T, \\ Y_T = \Phi(W_T), \end{cases} \tag{5.1}$$

where $\Phi(x)$ and $\lambda(x)$ are two deterministic functions of x, and W_T is the Brownian motion at time T. The analytic solution of the problem (5.1) is in the form

$$Y_0 = h^{-1}(\mathbb{E}(h(\Phi(X_T)))) \tag{5.2}$$

where the function $h(x)$ is the solution of the following ordinary differential equation:

$$-h'(x)\lambda(x) + \frac{1}{2}h''(x) = 0. \tag{5.3}$$

When $\lambda(x) = ax$, the analytic solution of (5.1) is

$$Y_0 = \frac{-C_2\sqrt{C_1 a} + \tan^{-1}(\mathbb{E}[\tan(\Phi(X_T)\sqrt{C_1 a} + C_2\sqrt{C_1 a})])}{\sqrt{C_1 a}}, \tag{5.4}$$

where a, C_1, and C_2 are parameters, $\tan(\cdot)$ is the triangle function *tangent*, and $\tan^{-1}(\cdot)$ is the inverse of the function $\tan(\cdot)$.

In this numerical example, we take $a = 0.01$, $C_1 = 1$, and $C_2 = 0$ in (5.4). We choose the terminal time $T = 1$ and the terminal function $\Phi(x) = |\cos(x)|$. The solution of (5.1) at time $t = 0$ is $Y_0 = 0.6943$ from (5.4). We list the absolute errors between the analytic solution Y_0 and the numerical solution y_0^0 and list the convergence rates in Table 5.1. The plots of $\log_2(|Y_0 - y_0^0|)$ with respect to $\log_2(N_T)$ are drawn in Figure 5.1.

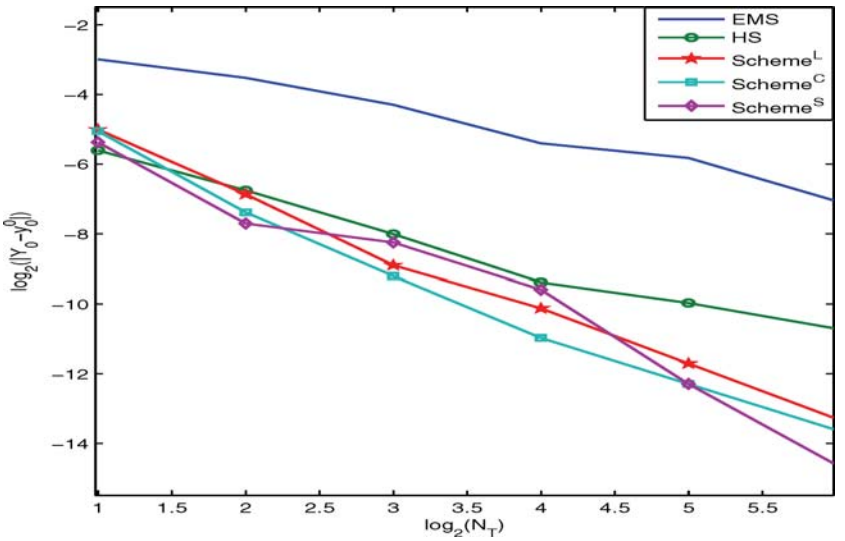

FIG. 5.1. *The plots of* $\log_2(|Y_0 - y_0^0|)$ *with respect to* $\log_2(N_T)$.

2. The BSDE is

$$\begin{cases} -dY_t = \left(\dfrac{Y_t}{2} - Z_t\right) dt - Z_t dW_t, \ 0 \le t \le T, \\ Y_T = \sin(W_T + T). \end{cases} \tag{5.5}$$

The analytic solution of (5.5) is

$$(Y_t, Z_t) = (\sin(W_t + t), \cos(W_t + t)), \tag{5.6}$$

where W_t is a standard Brownian motion. In this example, we take $T = 1$. The solution at $t = 0$ is $(Y_t, Z_t)|_{t=0} = (Y_0, Z_0) = (0, 1)$. The errors $|Y_0 - y_0^0|$ and $|Z_0 - z_0^0|$ and their convergence rates are listed in Table 5.2. We plot the lines of $\log_2(|Y_0 - y_0^0|)$ with respect to $\log_2(N_T)$ in Figure 5.2.

3. Let $\mathbf{W}_t = (W_t^1, W_t^2)^*$ be a two-dimensional Brownian motion, W_t^1 and W_t^2 independent standard one-dimensional Brownian motions. The BSDE driven by $\mathbf{W}_t$ is

$$-dY_t = \left(\frac{Y_t - d}{2}(b^2 + c^2) - Z_t \cdot \mathbf{A}\right) dt - Z_t \cdot d\mathbf{W}_t, \quad 0 \le t \le T, \tag{5.7}$$

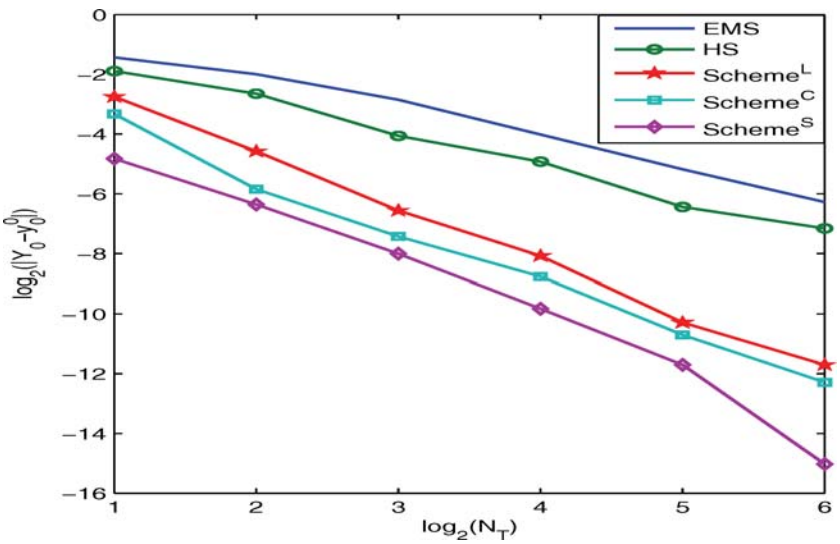

FIG. 5.3. *The plots of* $\log_2(|Y_0 - y_0^0|)$ *with respect to* $\log_2(N_T)$.

In this example, we take $T = 1$, $a = b = c = 1$, and $d = 0$. The solution at $t = 0$ is $(y_0, z_0) = (0, [1, 1])$. The absolute errors $|Y_0 - y_0^0|$ and $|Z_0 - z_0^0|$ and their convergence rates are listed in Table 5.3. The plots of $\log_2(|Y_0 - y_0^0|)$ with respect to $\log_2(N_T)$ are in Figure 5.3.

4. In this example, we use our method to solve one-dimensional evaluation problems in the stock market. Here we briefly describe the mathematical models in the BSDE form for these problems.

Consider a bond and a stock traded in a stock market. The bond price p_t and the stock price S_t, respectively, obey

$$\begin{cases} dp_t = r_t p_t dt, & t \geq 0, \\ p_0 = p, \end{cases} \tag{5.9}$$

and

$$\begin{cases} dS_t = & b_t S_t dt + \sigma_t S_t dW_t, \quad t \geq 0, \\ S_0 = & x, \end{cases} \tag{5.10}$$

where $\{W_t\}_{t\geq 0}$ is a standard Brownian motion, r_t is the return rate of the bond, b_t is the expected return rate of the stock, $\sigma_t > 0$ is the volatility of the stock, and r_t, b_t, σ_t, and ${\sigma_t}^{-1}$ are all bounded.

An investor with wealth Y_t at time t uses π_t money to buy stock and uses $Y_t - \pi_t$ to buy bond. Suppose that the stock pays dividends continuously with a bounded dividend rate $d(t, S_t)$ at the time t. Then the processes Y_t and π_t satisfy the following SDE [26, 18, 24, 25]:

$$-dY_t = -(r_t Y_t + (b_t - r_t + d(t, S_t))\pi_t)dt - \sigma_t \pi_t dW_t. \tag{5.11}$$

Let $Z_t = \sigma_t \pi_t$. Then (Y_t, Z_t) satisfies

$$-dY_t = -(r_t Y_t + (b_t - r_t + d(t, S_t))\sigma_t^{-1} Z_t)dt - Z_t dW_t. \tag{5.12}$$

When the money $Y_t - \pi_t \geq 0$, the investor invests $Y_t - \pi_t$ in the bond with the rate r_t. Otherwise, he will borrow $(Y_t - \pi_t)^- = \min\{0, Y_t - \pi_t\}$ money at the rate R_t. As we obtained (5.12), we have that (Y_t, Z_t) satisfies

$$\begin{aligned} -dY_t = \quad & -(r_t Y_t + (b_t - r_t + d(t, S_t)){\sigma_t}^{-1} Z_t \\ & +(R_t - r_t)(Y_t - \sigma_t^{-1} Z_t)^-)dt - Z_t dW_t \end{aligned} \tag{5.13}$$

for $t \in [0, T)$ with Z_t defined as the one in (5.12).

For the European call option, the terminal condition is given at the mature time T for (5.12) and (5.13) by

$$Y_T = \max\{S_T - K, 0\}, \tag{5.14}$$

where S_T is the solution S_t of the problem (5.10) at the mature time T, and K is the strike price.

When $r_t = r$, $b_t = b$, and $\sigma_t = \sigma$, and $d(t, S_t) = d$ are constants in (5.12) and (5.13), we can obtain their analytic solutions in closed forms. The analytic solution of the BSDE (5.12) with the terminal condition (5.14) is

$$\begin{cases} Y_t = V(t, S_t) = S_t e^{-d(T-t)} N(d_1(S_t)) - K e^{-r(T-t)} N(d_0(S_t)), \\ Z_t = \dfrac{\partial V}{\partial S}\sigma = S_t e^{-d(T-t)} N(d_1(S_t))\sigma, \\ d_0(S_t) = \dfrac{1}{\sigma\sqrt{T-t}} \ln\left(\dfrac{S_t}{K e^{(r-d)(T-t)}}\right) - \dfrac{1}{2}\sigma\sqrt{T-t}, \\ d_1(S_t) = d_0(S_t) + \sigma\sqrt{T-t}, \end{cases} \tag{5.15}$$

and the analytic solution of the BSDE (5.13) with the terminal condition (5.14) is

$$\begin{cases} Y_t = S_t e^{-d(T-t)} N(d_1(S_t)) - K e^{-R(T-t)} N(d_0(S_t)), \\ Z_t = S_t e^{-d(T-t)} N(d_1(S_t))\sigma, \\ d_0(S_t) = \dfrac{1}{\sigma\sqrt{T-t}} \ln\left(\dfrac{S_t}{K e^{(R-d)(T-t)}}\right) - \dfrac{1}{2}\sigma\sqrt{T-t}, \\ d_1(S_t) = d_0(S_t) + \sigma\sqrt{T-t}, \end{cases} \tag{5.16}$$

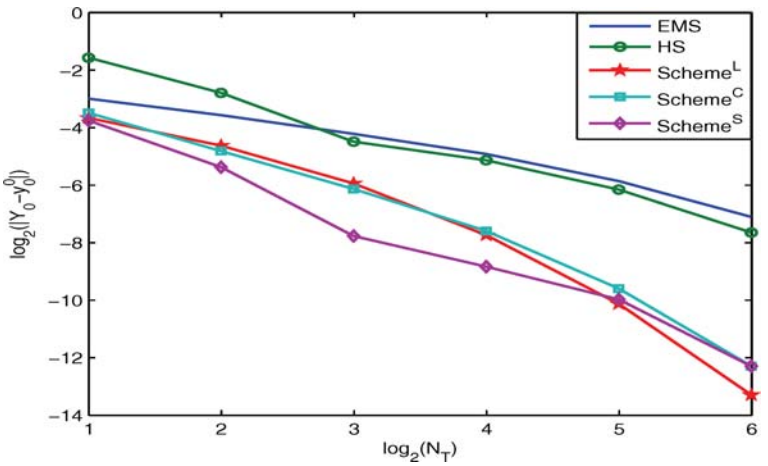

FIG. 5.5. *The plots of* $\log_2(|Y_0 - y_0^0|)$ *with respect to* $\log_2(N_T)$.

We summarize all numerical experiments as follows:

1. The accuracy of our method depends on the following:
   (a) Parameters θ_n^1 and θ_n^2. The accuracy of our method depends on the parameters θ_n^1 and θ_n^2, and if we choose them properly, the accuracy of our method can be high. Our numerical results show that the accuracy of our method is high when we choose $\theta_n^1 = \theta_n^2 = 0.5$.
   (b) Random sampling number N_E. It is known that the approximation error of the Monte Carlo method is approximately $\frac{1}{\sqrt{N_E}}$. Theoretically, if we want to obtain the accuracy ϵ, the random sampling number should approximately be $\left(\frac{1}{\epsilon}\right)^2$. For instance, when $\epsilon = (\Delta t)^2 = (\frac{T}{64})^2$, the sampling number is approximately $(64)^4$, which is a very big integer. In our simulations, for the time step $\Delta t = \frac{T}{64}$, the sampling number we used is 40000, which is much less than $(64)^4$. Even though we use the random samples much less than those needed theoretically, the accuracy

of our method is still high for solving (Y_t, Z_t) with $\theta_n^1 = \theta_n^2 = 0.5$.

(c) Space interpolations. In our method, we use the Monte Carlo method to approximate the conditional mathematical expectations and the space interpolations to compute the values at nongrid points. The accuracy of our method in space depends on the space interpolation operators and the regularity of the solutions. Our numerical results show that the higher the accuracy of the interpolation operators is, the higher the accuracy of our method is. The equidistant grid is far from optimal, especially for nonsmooth problems. To solve practical problems, some adaptive methods and some more efficient special grid interpolation operators may be used. All these will be our study projects on numerical methods for BSDEs in our future works.

(d) The regularity of the functions $f(t, y, z)$ and $\Phi(x)$. From the relation between BSDEs and PDEs [28], we know $Y_t = V(t, X_t)$ and $Z_t = \frac{\partial V(t,X_t)}{\partial x}$, where $V(t, x)$ is the solution of the PDEs, X_t is W_t in Examples 1–3, and $X_t = S_t$ in Example 4. The regularity of the solution (Y_t, Z_t) of the BSDE (2.1) depends on the regularity of the functions $f(t, y, z)$ and $\Phi(x)$. From PDE theory [31, 13], we know that the solutions of Examples 2 and 3 have smooth fourth order derivatives, and in Example 4, the solution Y_t has continuous second order derivatives with respect to S_t, and Z_t has only continuous first order derivatives. Our numerical results in Example 4 show that for nonsmooth data, the high-order interpolations cannot improve the approximate accuracy.

2. By comparison, we also solve the BSDEs in the examples by using Heun's method, in which the cubic polynomial interpolation is used in space. It is well known that Heun's method is a second order method for solving ODEs. But when used to solve the BSDEs, its accuracy is at most first order from our numerical results.

It is well known that the accuracy of the Monte Carlo method depends not only on the sampling number but also on the random number generator. We have tried several random number generators in C, Fortran, MATLAB, and the software SPRNG which is free and can be downloaded from the website http://sprng.cs.fsu.edu.

We found from our numerical experiments that the accuracy of our method depends on the random number generators, especially for solving Z_t. The high order accuracy was obtained for solving Y_t by using all the random number generators mentioned above in our numerical examples, but for solving Z_t, only by using the SPRNG random number generator was high order accuracy obtained. Since, in this paper, our aim is on the accuracy of our method, we list only the numerical results for EMC, HS and $Scheme^{\alpha}(\alpha = L, C, S)$ by using the software SPRNG to generate the random numbers. Better results may be obtained if some other better random number generators are used.

6. Conclusions. In this paper, we have proposed a new accurate numerical method to solve BSDEs at time-space grids. We use the Monte Carlo method to approximate the conditional mathematical expectations, and use local space interpolation to approximate the values of the solutions at nongrid points. Our numerical method is uncoupled not only between y_t and z_t, but also among the space grids at each time level. The data used to simulate the numerical solutions at each time-space point can be local. At the same time, the accuracy of our method can be improved

by better choosing the space interpolation operator and the parameters θ_1^n and θ_2^n. So there are large capacities of our method to solve the high-dimensional BSDEs with high accuracy by using parallel computers. To demonstrate the robustness of our methods, we performed some numerical experiments, and the results showed that our method is very effective and accurate for solving the BSDEs.

Acknowledgment. The authors would like to thank the referees for their valuable suggestions which greatly improved the paper.

DISCRETE-VELOCITY MODELS AND RELAXATION SCHEMES FOR TRAFFIC FLOWS*

MICHAEL HERTY†, LORENZO PARESCHI‡, AND MOHAMMED SEAID†

Abstract. We present simple discrete-velocity models for traffic flows. The novel feature in the corresponding relaxation system is the presence of nonnegative velocities only. We show that in the small relaxation limit the discrete models reduce to the Lighthill–Whitham–Richards equation. In addition we propose second order schemes combined with implicit-explicit time integrators as proper discretization of the relaxation-type system. Numerical tests are carried out on various situations in traffic flow. The results show that the proposed models are able to describe correctly the formation of backward waves induced by traffic jam.

Key words. discrete-velocity models, relaxation schemes, IMEX schemes, ENO schemes, Lighthill–Whitham–Richards equation

DOI. 10.1137/04061982X

1. Introduction.

Macroscopic modeling of vehicular traffic started with the work of Lighthill and Whitham [12]. They considered the continuity equation for the density ρ and approximated the mean velocity u by an equilibrium value $u^e(\rho)$:

$$\partial_t \rho + \partial_x(\rho u^e(\rho)) = 0. \tag{1.1}$$

The function $u^e(\rho)$ is also called a fundamental diagram, and $\rho u^e(\rho)$ is the flux. For a comparison with experimental data we refer the reader to [13]. More realistic effects are studied, for example, in [4], and among the models trying to include those effects, there are the "higher order" models by, e.g., [19, 3, 1].

In this paper we focus on simple discrete-velocity models of traffic flows which share the common properties that in the small relaxation limit reduce to a macroscopic description of traffic flow by the single conservation law (1.1).

In [8], Jin and Xin proposed the relaxation system

$$\begin{aligned} &\partial_t \rho + \partial_x q = 0, \\ &\partial_t q + a^2 \partial_x \rho = -\frac{1}{\varepsilon}\Big(q - F(\rho)\Big) \end{aligned} \tag{1.2}$$

as an approximation to the scalar hyperbolic equation

$$\partial_t \rho + \partial_x F(\rho) = 0. \tag{1.3}$$

Formally, solution of the relaxation system (1.2) approximates solution of the original equation (1.3) by order $\mathcal{O}(\varepsilon)$ if the constant a satisfies the so-called [illegible] condition [8, 7, 2, 14]

$$a^2 - F'(\rho)^2 \geq 0 \qquad \forall\ \rho, \tag{1.4}$$

which means that the kinetic wave speed $F'(\rho)$ is between the two characteristic speeds. At a numerical level, the main advantage in considering a relaxation system is the fact that the nonlinear conservation law (1.3) is replaced by a semilinear system (1.2) with linear characteristic variables given by $q \pm a\rho$. Consequently, nonlinear Riemann problems, characteristic decompositions, and linear iterations are avoided in its numerical solution. We refer the reader to [10, 8, 6, 20] and references therein. All of these methods are easy to formulate and implement. Moreover, there are strong links between relaxation methods and central schemes; see, for instance, [22, 16]. Of course, for scalar conservation laws there also exist other methods using exact or approximate Riemann solvers; see, for example, [25, 26, 27].

The relaxation system (1.2) is strongly connected to discrete-velocity models in kinetic theory. In fact, it can be reformulated by considering "kinetic" variables f and g as follows:

$$\begin{aligned} \partial_t f + a\partial_x f &= -\frac{1}{\varepsilon}\left(f - \frac{1}{2}\left(\rho + \frac{q}{a}\right)\right), \\ \partial_t g - a\partial_x g &= -\frac{1}{\varepsilon}\left(g - \frac{1}{2}\left(\rho - \frac{q}{a}\right)\right), \end{aligned} \tag{1.5}$$

where $\rho = f + g$ and $q = a(f - g)$. The equations (1.5) can be viewed as an evolution system of particles with speeds $\pm a$ and interaction terms given by the right-hand side; compare [15, 9, 17].

Note that in (1.5) the kinetic variables f and g propagate with positive and negative speed, respectively. This fits well with the fact that gas particles can move in either direction. However, if we restrict our discussion to a situation where all particles have the same (nonnegative) propagation direction, then the above formulation will not describe the correct dynamics of the relaxed flow. If we consider the case of particles travelling with speeds $b > a \geq 0$, easy computations lead to the subcharacteristic condition $(F'(\rho) - a)\,(b - F'(\rho)) \geq 0$, which is not satisfied unless $a \leq F'(\rho) \leq b$. A physical field where such a situation takes place is the case of traffic flow models where cars can have only positive velocities, but a traffic jam also moves backwards. Therefore, it is our goal here to derive simple relaxation-type models with a clear "kinetic" interpretation since we allow cars to propagate only with nonnegative speeds but are still able to capture the backward propagation of the solution.

In the following section, we present the traffic flow equations used in the paper to develop a relaxation-type model. In section 3, the relaxation scheme for the model problem is detailed. This includes the space and time discretizations. The numerical results are presented in section 4. We apply our scheme to common situations like free flow, bottleneck, and traffic jam. In section 5, some concluding remarks are listed.

2. Discrete-velocity models of traffic flows. In traffic flow theory the time evolution of a vehicle density in a freeway is governed by the Lighthill–Whitham–Richards model [12]

$$\partial_t \rho + \partial_x V(\rho) = 0, \tag{2.1}$$

where $\rho(t, x)$ is the vehicle density at location x and time t, and $V(\rho)$ is the flow function given by

$$V(\rho) = \rho \max\{u_0, u_e(\rho)\}, \tag{2.2}$$

where $u_e(\rho)$ is the fundamental diagram, i.e., an equilibrium velocity, and u_0 is the minimum speed. A typical choice for $u_e(\rho)$ is, for example,

$$u_e(\rho) = u_m \left(1 - \frac{\rho}{\rho_m}\right), \tag{2.3}$$

where ρ_m and u_m are the maximum density and the maximum speed, respectively.

Remark 1. More general flux functions as well as general traffic flow models have been considered in the literature; see [1, 4]. For inhomogeneous traffic flow situations we may have an additional dependence on x, i.e., $V(\rho) = V(x, \rho)$.

2.1. Two-speed models. Let us consider the following simple discrete-velocity model:

$$\partial_t f + v_1 \partial_x f = -\frac{K(\rho)}{\varepsilon}\Big(v_1 f + v_2 g - V(\rho)\Big), \tag{2.4}$$

$$\partial_t g + v_2 \partial_x g = \frac{K(\rho)}{\varepsilon}\Big(v_1 f + v_2 g - V(\rho)\Big), \tag{2.5}$$

where $K(\rho)$ is a suitable function such that

$$\begin{cases} K(\rho) \geq 0 & \text{if} \quad \rho \leq \rho_*, \\ K(\rho) < 0 & \text{if} \quad \rho > \rho_*, \end{cases}$$

where $0 < \rho_* < \rho_m$ is a constant.

The system (2.4)–(2.5) offers the following interpretation. We have two types of cars driving with velocity $v_2 > v_1 \geq 0$. The functions f and g are probability distributions of cars with speeds v_1 and v_2, respectively. Depending on the density, $K(\rho)$ changes sign. Usually in traffic flow models, the flux function $V : \rho \to \rho u_e(\rho)$ is a concave function. Hence $K(\rho) \geq 0$ in low density regimes, whereas $K(\rho)$ should become large and negative in high density regimes so that there is a gain for f and a loss for g by the interaction terms. Therefore, more cars will attain the speed v_1. This fits well with the observation that in areas of high densities, the cars tend to slow down. The opposite phenomena is also governed by (2.4)–(2.5).

In what follows we assume that

$$K(\rho) = H\left(V'(\rho) - v_1\right), \tag{2.6}$$

where $H(\cdot)$ is a function that preserves the sign of the argument, for example, a Heaviside or a hyperbolic tangent function.

Introducing the density and the flux of cars defined as

$$\rho = f + g \qquad \text{and} \qquad J = v_1 f + v_2 g, \tag{2.7}$$

we obtain the following macroscopic system:

$$\partial_t \rho + \partial_x J = 0, \tag{2.8}$$

$$\partial_t J + (v_1 + v_2)\partial_x J - v_1 v_2 \partial_x \rho = -\frac{K(\rho)}{\varepsilon}\left(v_2 - v_1\right)\Big(J - V(\rho)\Big). \tag{2.9}$$

In the small relaxation limit ($\varepsilon \to 0$), equation (2.9) gives to leading order

$$J = V(\rho) + \frac{\varepsilon}{K(\rho)\left(v_2 - v_1\right)}\Big(\left(V'(\rho) - v_1\right)\left(V'(\rho) - v_2\right)\partial_x \rho\Big).$$

By using this variable in (2.8) we obtain

$$\partial_t \rho + \partial_x V(\rho) + \partial_x \left(\frac{\varepsilon}{K(\rho)\,(v_2 - v_1)} \left(V'(\rho) - v_1\right)\left(V'(\rho) - v_2\right) \partial_x \rho \right) = 0. \tag{2.10}$$

To ensure the dissipative nature of (2.10), it is necessary that

$$\frac{\left(V'(\rho) - v_1\right)\left(V'(\rho) - v_2\right)}{K(\rho)\,(v_2 - v_1)} \leq 0. \tag{2.11}$$

This condition is satisfied by the assumption (2.6) on the kernel $K(\rho)$ if $v_1 \leq u_m \leq v_2$. Formally, when $\varepsilon \to 0$, the relaxation system (2.8)–(2.9) converges to the original equation (2.1) provided the [illegible] condition (2.11) is satisfied.

Note that the equilibrium states for f and g can be obtained by the equalities $f + g = \rho$ and $v_1 f + v_2 g = J$ and are given by

$$E_f(\rho) = \frac{\rho}{v_2 - v_1}\left(v_2 - \frac{V(\rho)}{\rho}\right), \qquad E_g(\rho) = \frac{\rho}{v_2 - v_1}\left(\frac{V(\rho)}{\rho} - v_1\right). \tag{2.12}$$

Nonnegativity of the equilibrium states is guaranteed if

$$v_1 \leq \frac{V(\rho)}{\rho} \leq v_2, \tag{2.13}$$

which is satisfied under the natural requirements $u_0 \geq v_1$ and $u_m \leq v_2$.

[illegible] 2. It is noteworthy that when the density in the system becomes critical, i.e., $\rho \to \rho_m$, a desirable feature would be that all cars reduce their speed to the lowest speed v_1 without allowing $f + g > \rho_m$. This behavior is obtained naturally for small values of ε in agreement with the kinetic interpretation of ε as the mean free path between car particles.

As an alternative, in order to have this feature even for large values of ε we can ask that $K(\rho) \to -\infty$ as $\rho \to \rho_m$ to recover the critical equilibrium states

$$f = \frac{\rho_m}{v_2 - v_1}\left(v_2 - u_0\right), \qquad g = \frac{\rho_m}{v_2 - v_1}\left(u_0 - v_1\right), \tag{2.14}$$

which correspond to a traffic jam situation. Clearly by taking $u_0 = v_1$ we have $f = \rho_m$ and $g = 0$.

[illegible] 3. Similarly one can derive discrete-velocity models with speeds $v_i, i = 1, 2, \ldots, n$ and kinetic variables f_i. For example, if one considers the Aw–Rascle model [1] written in conservative form as

$$\partial_t \rho + \partial_x \left(\rho v(\rho, y)\right) = 0, \tag{2.15}$$

$$\partial_t y + \partial_x \left(y v(\rho, y)\right) = 0, \tag{2.16}$$

where $v(\rho, y) = (y/\rho - p(\rho))$, ρ is the total density of cars and y is the density of cars with a given "quality" (typically a subset of the total number of cars). The pressure term $p(\rho)$ is an anticipation factor that takes into account drivers' reactions to the state of traffic in front of them.

We can consider the four-speed kinetic model

$$\partial_t f + v_1 \partial_x f = -\frac{K(\rho,y)}{\varepsilon}\Big(v_1 f + v_2 g - v(\rho,y)(f+g)\Big), \tag{2.17}$$

$$\partial_t g + v_2 \partial_x g = \frac{K(\rho,y)}{\varepsilon}\Big(v_1 f + v_2 g - v(\rho,y)(f+g)\Big), \tag{2.18}$$

$$\partial_t h + v_3 \partial_x h = -\frac{K(\rho,y)}{\varepsilon}\Big(v_3 h + v_4 k - v(\rho,y)(h+k)\Big), \tag{2.19}$$

$$\partial_t k + v_4 \partial_x k = \frac{K(\rho,y)}{\varepsilon}\Big(v_3 h + v_4 k - v(\rho,y)(h+k)\Big), \tag{2.20}$$

with $v_4 > v_3 \geq 0$ and $v_2 > v_1 \geq 0$, which in macroscopic form reads

$$\partial_t \rho + \partial_x J = 0, \tag{2.21}$$

$$\partial_t y + \partial_x W = 0, \tag{2.22}$$

$$\partial_t J + (v_1+v_2)\partial_x J - v_1 v_2 \partial_x \rho = -\frac{K(\rho,y)}{\varepsilon}(v_2 - v_1)\Big(J - \rho v(\rho,y)\Big), \tag{2.23}$$

$$\partial_t W + (v_3+v_4)\partial_x W - v_3 v_4 \partial_x y = -\frac{K(\rho,y)}{\varepsilon}(v_4 - v_3)\Big(W - y v(\rho,y)\Big), \tag{2.24}$$

where

$$\rho = f + g, \qquad y = h + k, \qquad \text{and} \qquad J = v_1 f + v_2 g, \qquad W = v_3 h + v_4 k. \tag{2.25}$$

Suitable conditions must be imposed on $K(\rho, y)$ in order to satisfy the subcharacteristic condition as $\varepsilon \to 0$.

3. Relaxation schemes. We present a numerical method of approximating the discrete-velocity models in such a way that the resulting scheme is asymptotic preserving (AP) and high order accurate in space and time (we refer to [16] for more details on AP schemes).

The numerical method we construct is based on the method of lines approach. We use a high order central weighted essentially nonoscillatory (WENO) scheme as space discretization of the kinetic system. The necessity of using a central scheme comes from the fact that the limiting equation (2.1) allows solutions $\rho(t,x)$ which can propagate with either positive or negative speed (see the appendix). For the time integration we apply a third order implicit-explicit (IMEX) Runge–Kutta method.

For simplicity we will describe the numerical schemes for the two-speed discrete-velocity model. The extension to the three-speed model is straightforward.

3.1. Space discretization. Let the spatial interval be discretized in equally spaced grids with stepsize Δx, and let w_i denote the point-value of an arbitrary function w at gridpoint x_i. Then a semidiscretization of (2.4) can be written as

$$\frac{df_i}{dt} + v_1 \frac{f_{i+\frac{1}{2}} - f_{i-\frac{1}{2}}}{\Delta x} = G_i^+. \tag{3.1}$$

For simplicity in presentation and to show how a space discretization can be reconstructed we consider only the Lax–Friedrichs method. Extension to higher order reconstructions can be developed using a similar formulation. Thus, the first order Lax–Friedrichs numerical flux $f_{i+\frac{1}{2}}$ is given by

$$f_{i+\frac{1}{2}} = \frac{1}{2}\left(f_{i+1} + f_i - \frac{\Delta x}{v_1 \Delta t}(f_{i+1} - f_i)\right). \tag{3.2}$$

Similarly, the semidiscretization of (2.5) can be written as

$$\frac{dg_i}{dt} + v_2 \frac{g_{i+\frac{1}{2}} - g_{i-\frac{1}{2}}}{\Delta x} = G_i^-, \tag{3.3}$$

where $g_{i+\frac{1}{2}}$ is defined analogously by

$$g_{i+\frac{1}{2}} = \frac{1}{2}\left(g_{i+1} + g_i - \frac{\Delta x}{v_2 \Delta t}\,(g_{i+1} - g_i)\right). \tag{3.4}$$

The source terms $G_i^{\pm}$ are given by

$$G_i^{\pm} = \pm \frac{K(\rho_i)}{2\varepsilon}\Big(v_1 f_i + v_2 g_i - V(\rho_i)\Big). \tag{3.5}$$

Using (2.12) in (3.1) and (3.3) gives a first order semidiscretization of the relaxation system (2.8)–(2.9):

$$\begin{aligned} &\frac{d\rho_i}{dt} + \frac{J_{i+\frac{1}{2}} - J_{i-\frac{1}{2}}}{\Delta x} = 0, \\ &\frac{dJ_i}{dt} + (v_1 + v_2)\frac{J_{i+\frac{1}{2}} - J_{i-\frac{1}{2}}}{\Delta x} - v_1 v_2 \frac{\rho_{i+\frac{1}{2}} - \rho_{i-\frac{1}{2}}}{\Delta x} = -\frac{K(\rho_i)}{2\varepsilon}\,(v_2 - v_1)\Big(J_i - V(\rho_i)\Big), \end{aligned} \tag{3.6}$$

where

$$\rho_{i+\frac{1}{2}} = f_{i+\frac{1}{2}} + g_{i+\frac{1}{2}} \qquad \text{and} \qquad J_{i+\frac{1}{2}} = v_1 f_{i+\frac{1}{2}} + v_2 g_{i+\frac{1}{2}},$$

with $f_{i+\frac{1}{2}}$ and $g_{i+\frac{1}{2}}$ given by (3.2) and (3.4), respectively.

Next, we discuss some properties of the semidiscrete first order relaxation scheme. We split the scheme (3.1)–(3.3) and give additional conditions on $|K(\rho)|$, which guarantee positivity. We consider the system

$$\partial_t f_i = G_i^+ = \frac{K(\rho)(v_2 - v_1)}{\varepsilon}\,(E_f(\rho_i) - f_i)\,, \tag{3.7}$$

$$\partial_t g_i = G_i^- = -\frac{K(\rho)(v_2 - v_1)}{\varepsilon}\,(E_g(\rho_i) - g_i) \tag{3.8}$$

for some initial data $f_0, g_0 \geq 0$. If $f_0 \geq E_f(\rho_i)$, then $K(\rho)(E_f - f)$ in (3.7) acts as reaction term and $f_i(t) \to E_f(\rho_i) \geq 0$. For $f_0 < E_f(\rho_i)$, the solution $f(t)$ to (3.7) is monotonic decreasing. In fact $f(t) = \exp(-K(\rho_i)(v_2 - v_1)t/\varepsilon)\,(f_0 - E_f(\rho_i)) + E_f(\rho_i)$. Hence, if $K(\rho_i)$ satisfies the assumption

$$|K(\rho_i)| \leq \frac{\varepsilon}{\Delta t (v_2 - v_1)} \max\left\{\frac{E_f(\rho_i)}{E_f(\rho_i) - f_0}, \frac{E_g(\rho_i)}{E_g(\rho_i) - g_0}\right\}, \tag{3.9}$$

then $f(t)$ and $g(t)$ remain nonnegative for all $t \in (0, \Delta t)$. This gives the positivity of the semidiscrete scheme (3.1)–(3.3). The positivity is inherited by the relaxed scheme in the limit $\varepsilon \to 0$; see below.

Higher order spatial discretizations can be derived following the essentially nonoscillatory (ENO) reconstructions; compare [21, 22, 11] among others. For instance, a second order reconstruction is obtained by substituting the numerical fluxes $f_{i+\frac{1}{2}}$ and $g_{i+\frac{1}{2}}$ using the convex ENO scheme [11]. Thus,

$$f_{i+\frac{1}{2}} = R\left(v_1, f_{i+\frac{1}{2}}\right) \qquad \text{and} \qquad g_{i+\frac{1}{2}} = R\left(v_2, g_{i+\frac{1}{2}}\right), \tag{3.10}$$

where the reconstruction flux function R is defined as

$$
\begin{aligned}
R\left(\alpha, w_{i+\frac{1}{2}}\right) = & \frac{1}{2}\left(w_{i+1} + w_i - \frac{\Delta x}{\alpha \Delta t}\left(w_{i+1} - w_i\right)\right) \\
& + \frac{1}{4}\left(w_{i+1} - w_i + \frac{\Delta x}{\alpha \Delta t}\left(w_{i+1} - w_i\right)\right) \phi\left(\theta_+^\alpha\right) \\
& - \frac{1}{4}\left(w_{i+2} - w_{i+1} - \frac{\Delta x}{\alpha \Delta t}\left(w_{i+2} - w_{i+1}\right)\right) \phi\left(\theta_-^\alpha\right),
\end{aligned} \tag{3.11}
$$

with the slopes θ_+^α and θ_-^α given by

$$
\theta_+^\alpha = \frac{w_i - w_{i-1} + \frac{\Delta x}{\alpha \Delta t}\left(w_i - w_{i-1}\right)}{w_{i+1} - w_i + \frac{\Delta x}{\alpha \Delta t}\left(w_{i+1} - w_i\right)}, \qquad \theta_-^\alpha = \frac{w_{i+1} - w_i - \frac{\Delta x}{\alpha \Delta t}\left(w_{i+1} - w_i\right)}{w_{i+2} - w_{i+1} - \frac{\Delta x}{\alpha \Delta t}\left(w_{i+2} - w_{i+1}\right)},
$$

and ϕ is a slope limiter function. A simple choice is the minmod limiter

$$
\phi(\theta) = \max\bigl(0, \min\left(1, \theta\right)\bigr).
$$

Note that if we set $\phi = 0$ in (3.11), the reconstruction (3.10) reduces to the first order Lax–Friedrichs discretization (3.2) and (3.4). We should mention that any discretization that requires characteristics information will generate instabilities in the computed solution. This is due to the structure of the relaxation system which allows propagation along the characteristics in one direction only.

3.2. Time integration. The full discretization of system (2.8)–(2.9) can be obtained by the well-established IMEX methods; see, for instance [16, 5]. The method applied here is the third order TVD time splitting scheme of [10]. The details can be found in the cited reference. We only mention that the special structure of the nonlinear terms in (3.6) makes it trivial to evolve the flux terms explicitly and the source term implicitly. Neither linear algebraic equations nor nonlinear source terms arise. In addition, the obtained relaxation scheme is stable independent of ε provided that the usual CFL condition

$$
\mathrm{CFL} = \max\left\{v_1, v_2\right\} \frac{\Delta t}{\Delta x} \leq 1 \tag{3.12}
$$

holds.

3.3. Relaxed schemes. Using a Hilbert expansion for (3.6) and neglecting terms of higher order in ε, we obtain

$$
J_i = V(\rho_i)
$$

and

$$
J_{i+\frac{1}{2}} = \frac{1}{2}\left(V(\rho_{i+1}) + V(\rho_i) - \frac{\Delta x}{\Delta t}\bigl(V(\rho_{i+1}) - V(\rho_i)\bigr)\right).
$$

This yields a first order Lax–Friedrichs discretization of the flux for the semidiscrete scheme

$$
\frac{d\rho_i}{dt} + \frac{J_{i+\frac{1}{2}} - J_{i-\frac{1}{2}}}{\Delta x} = 0. \tag{3.13}
$$

Similarly, when $\varepsilon \longrightarrow 0$, the reconstruction (3.10) yields to the second order convex ENO scheme for the relaxed equation (3.13) with

$$\begin{aligned} J_{i+\frac{1}{2}} = & \frac{1}{2}\left(V(\rho_{i+1}) + V(\rho_i) - \frac{\Delta x}{\Delta t}\big(V(\rho_{i+1}) - V(\rho_i)\big)\right) \\ & + \frac{1}{4}\left(V(\rho_{i+1}) - V(\rho_i) + \frac{\Delta x}{\Delta t}\big(V(\rho_{i+1}) - V(\rho_i)\big)\right)\phi\left(\theta_+\right) \\ & - \frac{1}{4}\left(V(\rho_{i+2}) - V(\rho_{i+1}) - \frac{\Delta x}{\Delta t}\big(V(\rho_{i+2}) - V(\rho_{i+1})\big)\right)\phi\left(\theta_-\right), \end{aligned}$$

where

$$\theta_+ = \frac{V(\rho_i) - V(\rho_{i-1}) + \frac{\Delta x}{\Delta t}\left(V(\rho_i) - V(\rho_{i-1})\right)}{V(\rho_{i+1}) - V(\rho_i) + \frac{\Delta x}{\Delta t}\left(V(\rho_{i+1}) - V(\rho_i)\right)},$$

$$\theta_- = \frac{V(\rho_{i+1}) - V(\rho_i) - \frac{\Delta x}{\Delta t}\left(V(\rho_{i+1}) - V(\rho_i)\right)}{V(\rho_{i+2}) - V(\rho_{i+1}) - \frac{\Delta x}{\Delta t}\left(V(\rho_{i+2}) - V(\rho_{i+1})\right)}.$$

For equilibrium initial data the leading behavior of the relaxation scheme is governed by the associated relaxed scheme. Hence, one can recover all physical properties of the full conservation law (2.1) by our relaxation-type system with positive velocities (2.4)–(2.5). In addition, at the limit when $\varepsilon \to 0$, the time integration converges to an explicit TVD Runge–Kutta scheme, and we refer to [10] for details.

In the relaxation limit ($\varepsilon \to 0$) the first order semidiscrete limit scheme is the Lax–Friedrichs scheme. Therefore, positivity, TVD, and the discrete entropy inequality are satisfied in the limit.

4. Numerical examples. In this section we illustrate the performance of our relaxation method for different test cases on traffic flow. Throughout the numerical tests the relaxation rate is $\varepsilon = 10^{-1}$ or $\varepsilon = 10^{-10}$ and the time step Δt is chosen according to the CFL condition (3.12). The kernel $K(\rho)$ and the characteristic speeds v_1 and v_2 are chosen as

$$K(\rho) = \tanh\left(5\left(V'(\rho) - v_1\right)\right), \qquad v_1 = 0.1, \qquad v_2 = 1 \tag{4.1}$$

for the two-speed model. In all the results reported in this section for traffic flow, the spatial domain is the road interval $[0, 1]$ discretized into 200 gridpoints, and a CFL $= 0.5$ is used. We display results for the two-speed model at $\varepsilon = 10^{-1}$ and $\varepsilon = 10^{-10}$. The following examples (subsections 4.1–4.3) are selected.

4.1. Free-flow traffic situation. We turn to the traffic flow model (2.1)–(2.3) in the simplest case where cars moves freely without jams. Here we assume that $\rho_m = u_m = 1$ and that initially the cars are normally distributed around the point $x = 0.4$ (Gaussian-like initial data). The propagation of the density in the space-time domain for $\varepsilon = 10^{-1}$ and $\varepsilon = 10^{-10}$ is given in Figure 1, whereas Figure 2 shows the contour lines of density ρ. As expected, the relaxation scheme evolves the free traffic in the correct way. In Figure 3 we plot the density at $t = 0.6$ for different relaxation limits. The asymptotic convergence of the solution as $\varepsilon \to 0$ is clearly preserved by our discretizations. All of these results are computed using the second order ENO reconstruction.

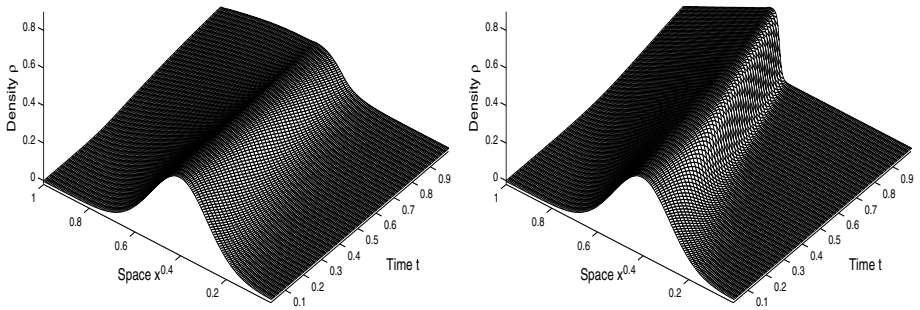

FIG. 1. *Density evolution for the free-flow traffic situation at* $\varepsilon = 10^{-1}$ *(left plot) and* $\varepsilon = 10^{-10}$ *(right plot).*

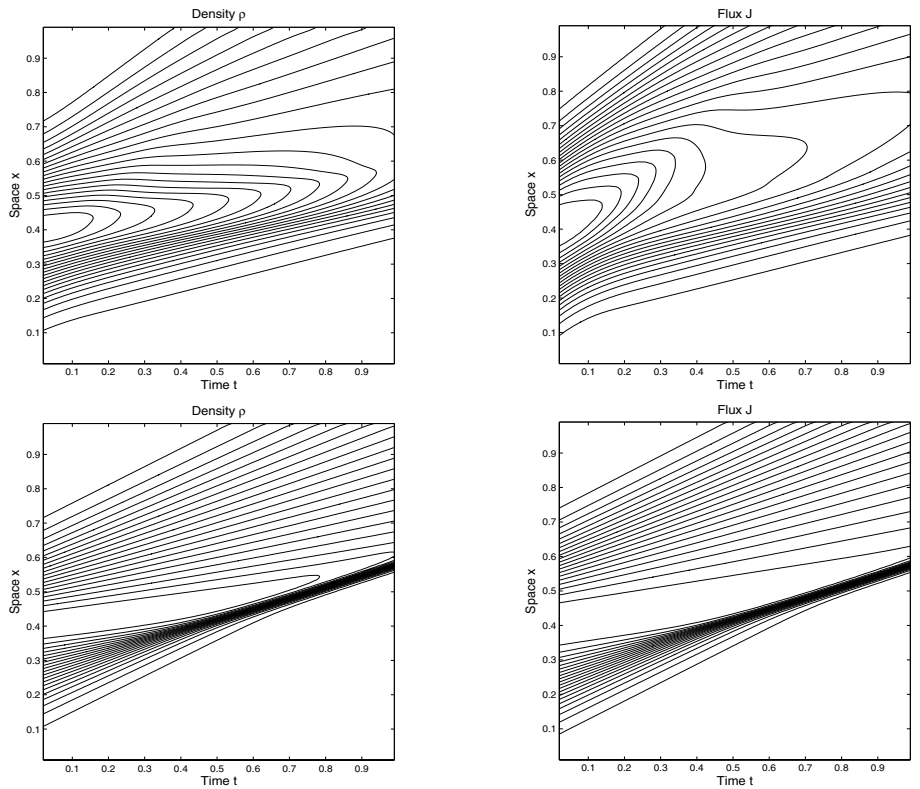

FIG. 2. *Contour plots of density* ρ *and flux* J *for the free-flow traffic situation at* $\varepsilon = 10^{-1}$ *(top) and* $\varepsilon = 10^{-10}$ *(bottom).*

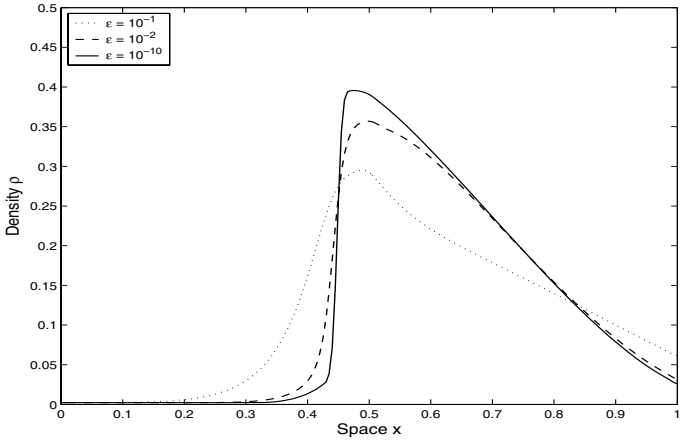

FIG. 3. *Plots of density for the free-flow traffic situation at* $t = 0.6$ *using different values of* ε.

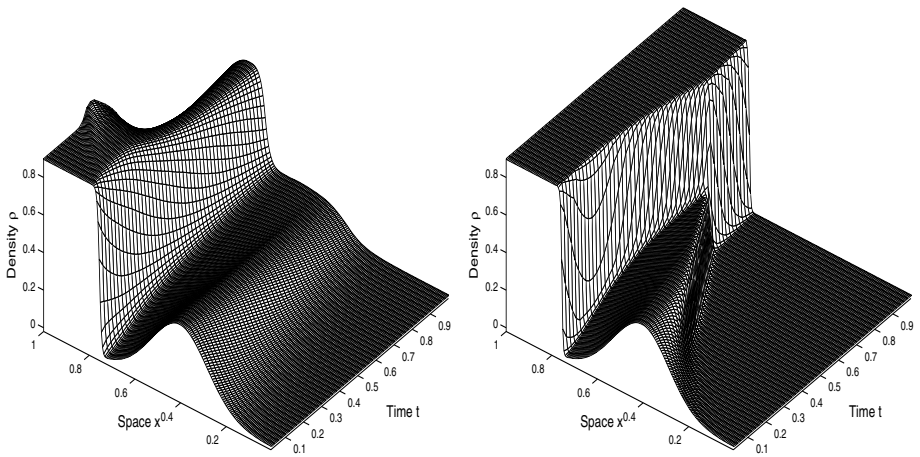

FIG. 4. *Density evolution for the jam traffic situation at* $\varepsilon = 10^{-1}$ *(left plot) and* $\varepsilon = 10^{-10}$ *(right plot).*

4.2. Jam situation. Next we consider a similar situation but with a traffic jam at $x = 0.75$. In realistic vehicular traffic flow this is equivalent to relaxed traffic upstream ($x < 0.75$) and crowded traffic downstream ($x \geq 0.75$). In such a situation one expects that the cars which are in a Gaussian-like distribution start moving into the jam, and that once they reach the jam a backwards wave should be formed. By examining the evolution of the density in Figure 4 for $\varepsilon = 10^{-10}$, we can observe that the mentioned physical features are well captured by our relaxation scheme. The contour plots of density ρ and flux J are displayed in Figure 5. It is clear that the Gaussian density distribution is moving into the jam and then propagates backwards. In the two-speed model there is an overshoot of the density at the jam due to the large value of ε. This suggests taking ε small when the value of the density is close to critical.

All of these results are computed using the second order ENO reconstruction. Figure 6 represents a comparison of density plots at $t = 0.6$ using the first order

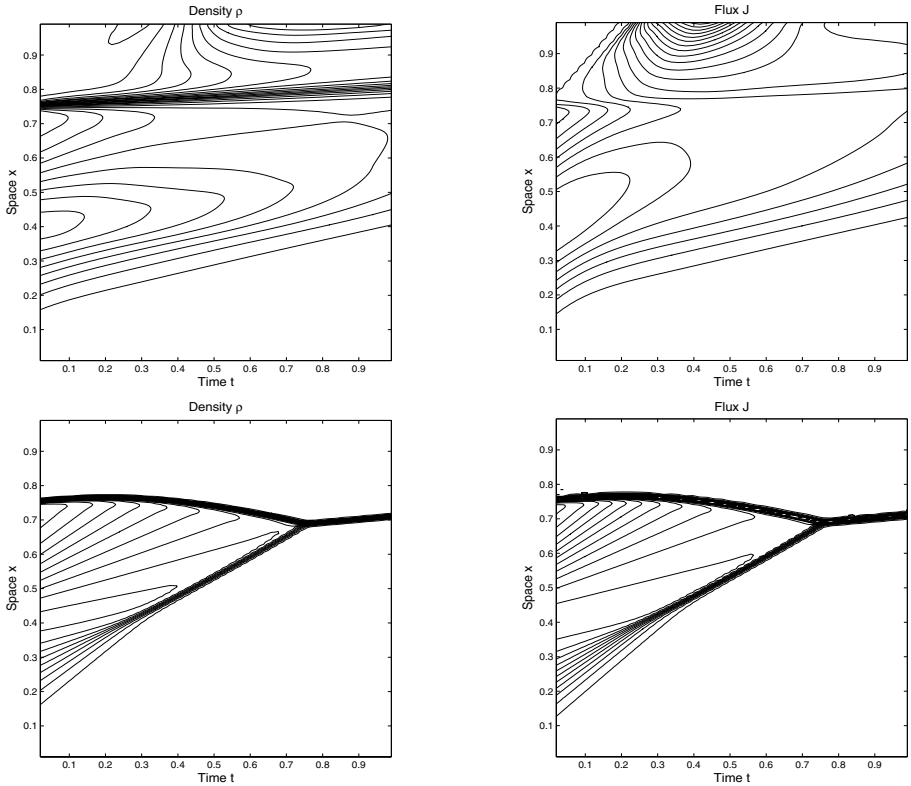

FIG. 5. *Contour plots of density ρ and flux J for the jam traffic situation at $\varepsilon = 10^{-1}$ (top) and $\varepsilon = 10^{-10}$ (bottom).*

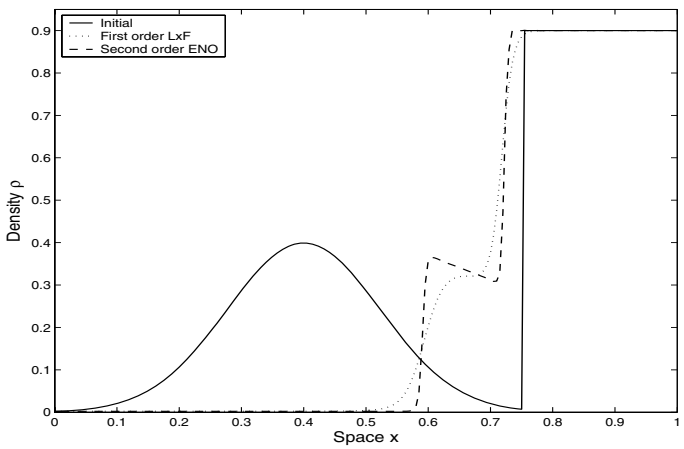

FIG. 6. *Plots of density for the jam traffic situation at $t = 0.6$ and $\varepsilon = 10^{-10}$ using the first order Lax–Friedrichs and the second order ENO discretizations.*

Lax–Friedrichs and the second order ENO discretizations. It is clear that excessive diffusion was introduced by the first order Lax–Friedrichs discretization, while the second order ENO reconstruction sharply captures the shock.

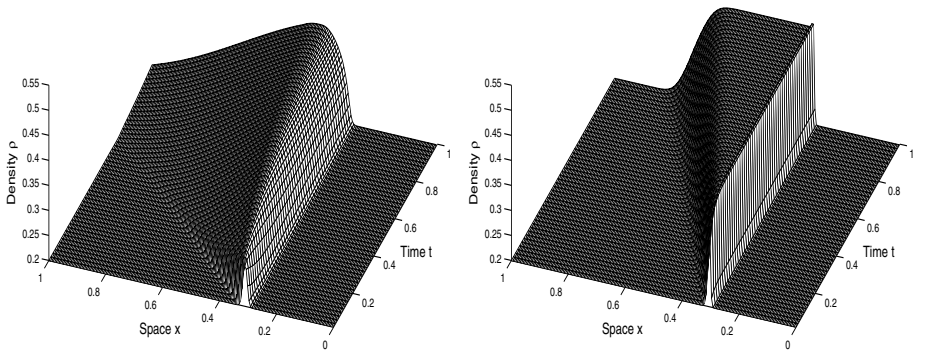

FIG. 7. *Density evolution for the bottleneck traffic situation with* $\bar{\rho} = 4$ *at* $\varepsilon = 10^{-1}$ *(left plot) and* $\varepsilon = 10^{-10}$ *(right plot).*

4.3. Bottleneck situation. Our final example is the bottleneck traffic taken from [24]. The problem statement is given by (2.1)–(2.3), where the flux function $V(\rho, x)$ also depends on the space coordinate x subject to discontinuous maximum density and velocity

$$V(x, \rho) = u_m(x)\rho\left(1 - \frac{\rho}{\rho_m(x)}\right),$$

with

$$\rho_m(x) = \begin{cases} \bar{\rho} & \text{if} \quad x < 0.3, \\ 2 & \text{if} \quad x \geq 0.3 \end{cases} \qquad \text{and} \qquad u_m(x) = \begin{cases} 1 & \text{if} \quad x < 0.3, \\ 0.6 & \text{if} \quad x \geq 0.3. \end{cases}$$

Initially the road has a constant density $\rho(x, 0) = 0.2$. We use two different values of $\bar{\rho}$, namely, $\bar{\rho} = 4$ and $\bar{\rho} = 8$. The evolution of density is given in Figure 7, and the contour plots of density ρ and flux J are given in Figure 8 at $\varepsilon = 10^{-1}$ and $\varepsilon = 10^{-10}$ using $\bar{\rho} = 4$. The results obtained for $\bar{\rho} = 8$ are shown in Figure 9. Our relaxation scheme performs well for this discontinuous situation in traffic flow.

5. Conclusions. We have presented a relaxation-type formulation for hyperbolic traffic flow problems. The advection part of these relaxation systems has only nonnegative velocities so that they can be interpreted as simple discrete-velocity models for traffic flow problems. We showed that high order central discretizations are an essential feature in order to also simulate backward traffic waves. The numerical results show that the performance of our second order numerical schemes is very attractive without solving Riemann problems or requiring special front tracking. More general relaxation systems which may be able to provide multivalued fundamental diagrams and detect stop and go waves, for example, taking the kernel $k = k(\rho, J)$ as in [23], are actually under study.

Appendix: Instability of upwind schemes. In this short appendix we show that the most natural approach for the discretization of a system like (2.4)–(2.5) becomes unstable in the small relaxation limit due to the presence of backward waves. Similar arguments can be extended to higher order upwind methods.

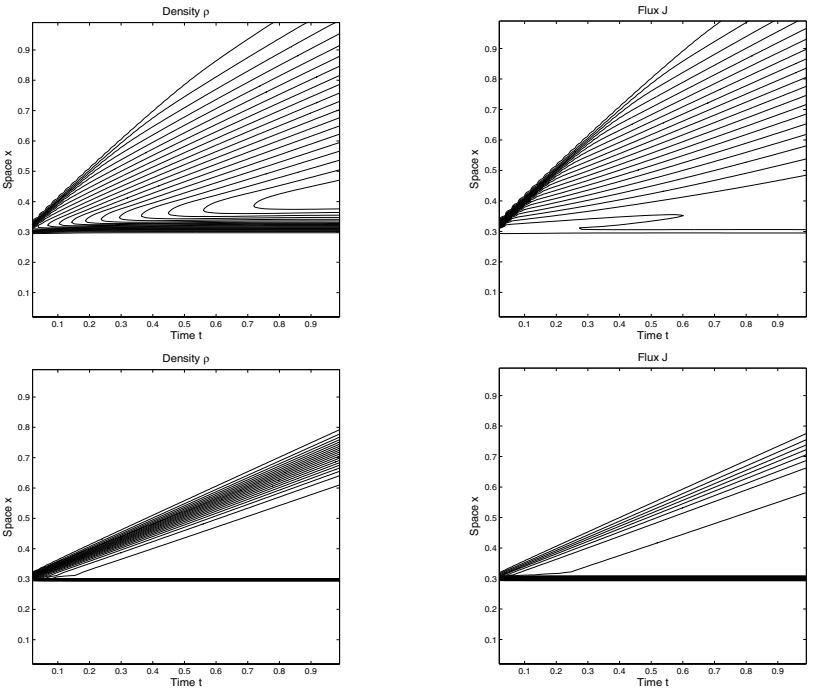

FIG. 8. *Contour plots of density ρ and flux J for the bottleneck traffic situation with $\bar{\rho} = 4$ at $\varepsilon = 10^{-1}$ (top) and $\varepsilon = 10^{-10}$ (bottom).*

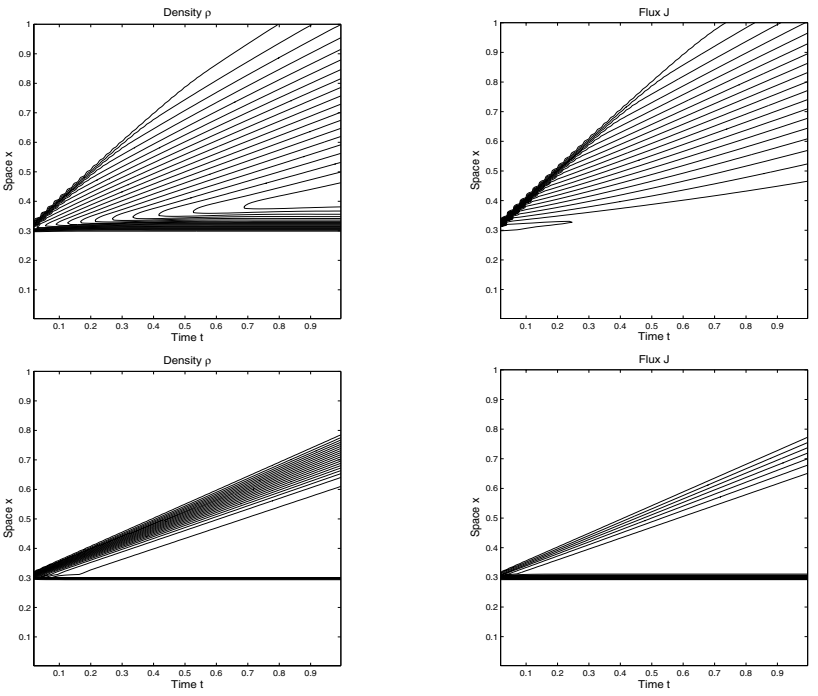

FIG. 9. *Contour plots of density ρ and flux J for the bottleneck traffic situation with $\bar{\rho} = 8$ at $\varepsilon = 10^{-1}$ (top) and $\varepsilon = 10^{-10}$ (bottom).*

The most popular way to solve system (2.4)–(2.5) is to consider, in two separate steps, an advection problem

$$\begin{aligned} &\partial_t f + v_1 \partial_x f = 0, \\ &\partial_t g + v_2 \partial_x g = 0, \end{aligned} \tag{5.1}$$

and a stiff relaxation problem

$$\begin{aligned} &\partial_t f = -\frac{K(\rho)}{2\varepsilon}\Big(v_1 f + v_2 g - V(\rho)\Big), \\ &\partial_t g = \frac{K(\rho)}{2\varepsilon}\Big(v_1 f + v_2 g - V(\rho)\Big). \end{aligned} \tag{5.2}$$

Since the advection part contains only nonnegative speeds, we can apply a simple first order upwind scheme. If we write the upwind scheme in terms of the macroscopic variables, we get

$$\begin{aligned} \rho_i^{n+1} &= \rho_i^n - \frac{\Delta t}{\Delta x}\left(J_i^n - J_{i-1}^n\right), \\ J_i^{n+1} &= J_i^n - \frac{\Delta t}{\Delta x}\left(v_1 + v_2\right)\left(J_i^n - J_{i-1}^n\right) + \frac{\Delta t}{\Delta x} v_1 v_2 \left(\rho_i^n - \rho_{i-1}^n\right). \end{aligned} \tag{5.3}$$

For small values of ε the relaxation step yields the equilibrium projections

$$f_i^n = \frac{\rho_i^n}{v_2 - v_1}\left(v_2 - \frac{V(\rho_i^n)}{\rho_i^n}\right), \qquad g_i^n = \frac{\rho_i^n}{v_2 - v_1}\left(\frac{V(\rho_i^n)}{\rho_i^n} - v_1\right), \tag{5.4}$$

corresponding to $J_i^n = V(\rho_i^n)$ which when substituted into the first equation in (5.3) gives

$$\rho_i^{n+1} = \rho_i^n - \frac{\Delta t}{\Delta x}\left(V(\rho_i^n) - V(\rho_{i-1}^n)\right). \tag{5.5}$$

Clearly (5.5) is an unstable numerical method for the Lighthill–Whitham–Richards equation when $\rho > \rho_m/2$ and thus $V'(\rho) < 0$.

A NUMERICAL STUDY OF THE PROBE METHOD*

KLAUS ERHARD† AND ROLAND POTTHAST†

Abstract. The goal of this work is the numerical realization of the *probe method* suggested by Ikehata for the detection of an obstacle D in inverse scattering. The main idea of the method is to use probes in the form of point source $\Phi(\cdot, z)$ with source point z to define an indicator function $\hat{I}(z)$ which can be reconstructed from Cauchy data or far field data. The indicator function $\hat{I}(z)$ can be shown to blow off when the source point z tends to the boundary ∂D, and this behavior can be used to find D. To study the feasibility of the probe method we will use two equivalent formulations of the indicator function. We will carry out the numerical realization of the functional and show reconstructions of a sound-soft obstacle.

Key words. inverse scattering, integral equations, obstacle reconstruction, probe method, point source method, sampling methods

1. Introduction.

The central task of the discipline of inverse scattering is to extract information about scattering objects from the scattered fields u^s or their far field patterns u^∞ of acoustic, electromagnetic, or elastic waves. Here, we will restrict our attention to acoustic scattering by a scatterer $\mathcal{D}$ for a set of incident plane waves $\{u^i(\cdot, d) : d \in \mathbb{S}\}$, where $\mathbb{S}$ is the unit sphere in two or three dimensions.

Several approaches have been introduced to solve different inverse problems. Distinguishing three categories as in [9], we mention iterative algorithms, decomposition or analytic extension methods, and sampling/probe methods. For iterative algorithms we refer to [2] and the literature cited therein. Decomposition methods, such as the Kirsch–Kress scheme or the point source method, have been extensively studied in [9] and [2]. Sampling and probe methods have been suggested since 1996 by Colton, Kirsch, Potthast, Ikehata, and many others; see [10] for a recent survey.

Ikehata [4] suggested using an indicator function $\hat{I}(z)$, which is based on the behavior of the integral

$$\int_{\Omega \setminus D} |\nabla \Phi^s(\cdot, z)|^2 dx \tag{1.1}$$

and related terms in the form of point source $\Phi(\cdot, z)$ with source point z (cf. (2.6)), and on its scattered field $\Phi^s(\cdot, z)$. When z tends to the boundary, the integral will diverge. This function is calculated using Cauchy data on the boundary of the domain Ω, which can be reconstructed from the far field patterns. So far, this method has not been numerically realized. The realization is the main task of this paper.

Our main goal is to employ the techniques of the point source and singular sources method [9] to numerically realize Ikehata's probe method. To this end, we will first summarize results about the forward problem in section 2. In section 3 we summarize

Ikehata's approach to the probe method. Section 4 serves to formulate a practical realization of the probe method with the help of the techniques developed in the framework of the point source method. In section 5 we present a numerical study of the probe method and its functional. In particular, we provide two equivalent formulations for the indicator function of the probe method. The goal of these formulations is to obtain a well-posed scheme for the calculation of the indicator function and to study its behavior.

2. The solution of the boundary value problem and the Dirichlet to Neumann map. The starting points of Ikehata's probe method are the Dirichlet to Neumann (D-t-N) maps Λ for the direct obstacle boundary value problem and Λ_0 for the obstacle-free boundary value problem. In practice, the D-t-N map is often available via physical measurements. For our numerical study we simulate the D-t-N maps by solving their underlying boundary value problems explicitly. Therefore, we will first introduce both the direct obstacle boundary value problem and the obstacle-free boundary value problem and briefly present a way of solving them numerically.

The following direct obstacle boundary value problem has its origin in the acoustic scattering theory of sound-soft obstacles; see, for example, [2]. We consider a bounded domain $\Omega \subset \mathbb{R}^m$, $m = 2, 3$, with a boundary $\partial\Omega$ of class C^2 and a normal derivative ν oriented into the exterior of Ω. Then, the obstacle $D \subset \Omega$ is modeled as a domain with a boundary ∂D of class C^2 with a normal vector ν oriented into the interior of D. Therefore, the boundary of the annular region $\Omega_D := \Omega \backslash \overline{D}$ is given by $\partial\Omega_D = \partial\Omega \cup \partial D$ with a normal vector ν, which is oriented into the exterior of Ω_D; see Figure 1. With κ, we denote the complex wave number, for which $\mathrm{Re}(\kappa) > 0$ and $\mathrm{Im}(\kappa) \geq 0$ hold.

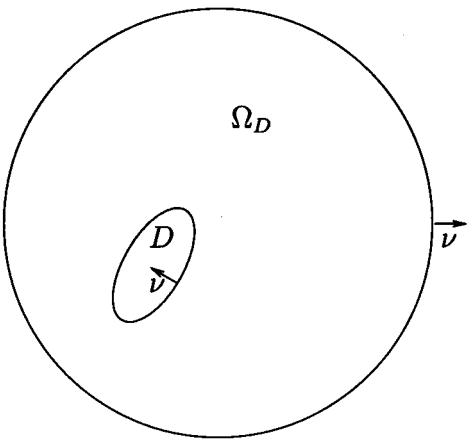

FIG. 1. *The normal ν to the boundary of the domain Ω_D.*

With this notation the direct obstacle boundary value problem and the obstacle-free boundary value problem read as follows.

Direct obstacle boundary value problem. For a given differentiable function $f \in C^{1,\alpha}(\partial\Omega)$, $0 < \alpha < 1$, with a Hölder continuous derivative and a continuous function $g \in C(\partial D)$, we want to find a function $u \in C^2(\Omega_D) \cap C(\overline{\Omega_D})$ such that

$$\Delta u + \kappa^2 u = 0 \quad \text{in } \Omega_D, \tag{2.1}$$

$$u = f \quad \text{on } \partial\Omega, \tag{2.2}$$

$$u = g \quad \text{on } \partial D. \tag{2.3}$$

. . . . . The assumption of Hölder differentiability will be needed for the evaluation of the normal derivative of the fields under consideration.

Obstacle-free boundary value problem. For a given continuous function $f \in C(\partial\Omega)$ we want to find a function $v \in C^2(\Omega) \cap C(\overline{\Omega})$ such that

$$\Delta v + \kappa^2 v = 0 \quad \text{in } \Omega, \tag{2.4}$$

$$v = f \quad \text{on } \partial\Omega. \tag{2.5}$$

We tacitly assume in the following that $-\kappa^2$ is not an eigenvalue of the Laplacian in Ω_D or in Ω. Then, the direct obstacle boundary value problem has a unique solution, which can be represented with a combined layer potential; see [3]. An analogous result holds for the obstacle-free boundary value problem, but since we do not need its numerical solution for our study of the probe method we will omit it here.

For $x, y \in \mathbb{R}^m$, we denote by

$$\Phi(x,y) = \begin{cases} \frac{i}{4} H_0^{(1)}(\kappa|x-y|), & m = 2, \\ \frac{1}{4\pi} \frac{\exp(i\kappa|x-y|)}{|x-y|}, & m = 3, \end{cases} \tag{2.6}$$

the fundamental solution of the Helmholtz equation, where $H_0^{(1)}$ is the Hankel function of first kind and order zero. Then the solution to the direct obstacle boundary value problem can be represented by the combined layer potential

$$u(x) = \int_{\partial\Omega_D} \Big(\frac{\partial\Phi(x,y)}{\partial\nu(y)} - i\eta\Phi(x,y) \Big) \varphi(y)\, ds(y), \quad x \in \Omega_D, \tag{2.7}$$

with a positive number η and a density $\varphi \in C(\partial\Omega) \times C(\partial D)$. In order for the combined layer potential (2.7) to admit the boundary values

$$b(x) := \begin{cases} f(x), & x \in \partial\Omega, \\ g(x), & x \in \partial D, \end{cases} \tag{2.8}$$

the density φ has to be a solution of the integral equation

$$(K - i\eta S)\varphi - \frac{1}{2}\varphi = b \tag{2.9}$$

on $\partial\Omega_D$, where the integral operators K and S are defined via

$$(K\varphi)(x) := \int_{\partial\Omega_D} \frac{\partial\Phi(x,y)}{\partial\nu(y)} \varphi(y)\, ds(y), \quad x \in \partial\Omega_D, \tag{2.10}$$

and

$$(S\varphi)(x) := \int_{\partial\Omega_D} \Phi(x,y)\varphi(y)\, ds(y), \quad x \in \partial\Omega_D. \tag{2.11}$$

Hence, solving the integral equation (2.9) yields a representation of the solution to the direct obstacle boundary value problem (2.1)–(2.3) in the form of (2.7); see [3] for details. We remark that due to the mapping properties of the integral operators S and K from C into $C^{0,\alpha}$ and from $C^{0,\alpha}$ into $C^{1,\alpha}$ using (2.9) and the regularity of the functions f and g on the boundary we obtain $\varphi \in C^{1,\alpha}(\partial\Omega) \times C(\partial D)$.

Next, we consider the D-t-N maps Λ and Λ_0 of the direct obstacle and obstacle-free boundary value problems.

D-t-N map Λ. The D-t-N map Λ of the direct obstacle boundary value problem maps a Hölder continuously differentiable function $f \in C^{1,\alpha}(\partial\Omega)$ to the continuous function $h \in C^{0,\alpha}(\partial\Omega)$ defined by

$$h(x) := \frac{\partial u}{\partial \nu}(x) \tag{2.12}$$

for $x \in \partial\Omega$, where u solves the direct obstacle boundary value problem (2.1)–(2.3) with a sound-soft boundary condition on ∂D, i.e., with u equal to $g \equiv 0$ on ∂D.

D-t-N map Λ_0. The D-t-N map Λ_0 of the obstacle-free boundary value problem maps a continuous function $f \in C(\partial\Omega)$ to the continuous function $h_0 \in C(\partial\Omega)$ given by

$$h_0(x) := \frac{\partial v}{\partial \nu}(x) \tag{2.13}$$

for $x \in \partial\Omega$, where v solves the obstacle-free boundary value problem (2.4)–(2.5).

As mentioned before, to implement the probe method we have to simulate the D-t-N map Λ in our numerical studies. We realize this in the following way: For a given Hölder continuously differentiable function f we solve the direct obstacle boundary value problem (2.1)–(2.3) with a sound-soft boundary condition $g \equiv 0$ on ∂D using the combined layer approach (2.7) by solving the integral equation (2.9). Then, we calculate the normal derivative of u at the boundary $\partial\Omega$ numerically in order to obtain $h = \Lambda f$.

The behavior of the layer potentials K and S at the boundary $\partial\Omega$ forbids us to apply a simple difference quotient for calculating h. Instead, we differentiate the combined layer potential (2.7) analytically to get the expression

$$h(x) = (T\varphi)(x) - i\eta(K'\varphi)(x) - i\eta\frac{1}{2}\varphi(x), \quad x \in \partial\Omega, \tag{2.14}$$

for the normal derivative on the boundary $\partial\Omega$. Here, T denotes the hypersingular integral operator

$$(T\varphi)(x) := \frac{\partial}{\partial\nu(x)} \int_{\Omega_D} \frac{\partial\Phi(x,y)}{\partial\nu(y)}\varphi(y)\, ds(y), \quad x \in \partial\Omega, \tag{2.15}$$

and K' is the adjoint operator of K, namely,

$$(K'\varphi)(x) := \int_{\Omega_D} \frac{\partial\Phi(x,y)}{\partial\nu(x)}\varphi(y)\, ds(y), \quad x \in \partial\Omega. \tag{2.16}$$

For the numerical evaluation of the hypersingular integral operator T, we consider the hypersingular part T_Ω of T, which is defined as

$$(T_\Omega\varphi_\Omega)(x) := \frac{\partial}{\partial\nu(x)} \int_{\partial\Omega} \frac{\partial\Phi(x,y)}{\partial\nu(y)}\varphi_\Omega(y)\, ds(y), \quad x \in \partial\Omega, \tag{2.17}$$

with a Hölder continuously differentiable density $\varphi_\Omega \in C^{1,\alpha}(\partial\Omega)$. The integral operator T_D is defined analogously for continuous densities $\varphi_D \in C(\partial D)$ on the interior boundary ∂D. Since the integral operator $T_D : C(\partial D) \to C(\partial\Omega)$ has an analytic

kernel, it can easily be evaluated by a numerical differentiation of the contribution $K_D\varphi_D$ from the interior boundary to the double layer potential $K\varphi$.

Next, the hypersingular operator T_Ω can be written as

$$T_\Omega\varphi_\Omega = \frac{d}{ds}S_\Omega\frac{d\varphi_\Omega}{ds} + \kappa^2\nu\cdot S_\Omega(\nu\varphi_\Omega) \tag{2.18}$$

due to Maue's identity [8] with the contribution S_Ω from the outer boundary $\partial\Omega$ to the single-layer operator S. After parametrizing (2.18) and integrating by parts, we obtain

$$\begin{aligned}&\left(\frac{d}{ds}S_\Omega\frac{d\varphi_\Omega}{ds}\right)(x(t))\\ &= \frac{1}{|x'(t)|}\int_0^{2\pi}\left\{\frac{1}{2\pi}\cot\frac{\tau-t}{2}\frac{d\varphi_\Omega(x(\tau))}{d\tau} - N(t,\tau)\varphi_\Omega(x(\tau))\right\}d\tau\end{aligned}$$

with

$$N(t,\tau) = N_1(t,\tau)\ln\left(4\sin^2\frac{t-\tau}{2}\right) + N_2(t,\tau) \tag{2.19}$$

and analytic functions $N_1(t,\tau)$ and $N_2(t,\tau)$. For the integration of these terms, we use the interpolatory quadrature rules

$$\frac{1}{2\pi}\int_0^{2\pi}\cot\frac{\tau-t}{2}f'(\tau)\,d\tau \approx \sum_{j=0}^{2n-1}T_j^{(n)}(t)f(t_j^{(n)}) \tag{2.20}$$

and

$$\int_0^{2\pi}\ln\left(4\sin^2\frac{t-\tau}{2}\right)f(\tau) \approx \sum_{j=0}^{2n-1}R_j^{(n)}(t)f(t_j^{(n)}) \tag{2.21}$$

with the weights

$$T_j^{(n)}(t) = -\frac{1}{n}\sum_{m=1}^{n-1}m\cos m(t-t_j^{(n)}) - \frac{1}{2}\cos n(t-t_j^{(n)}) \tag{2.22}$$

and

$$R_j^{(n)}(t) = -\frac{2\pi}{n}\sum_{m=1}^{n-1}\frac{1}{m}\cos m(t-t_j^{(n)}) - \frac{\pi}{n^2}\cos n(t-t_j^{(n)}). \tag{2.23}$$

Here, $t_j^{(n)} = \frac{j\pi}{n}$, $j = 0,\dots,2n-1$, are $2n$ equidistant sampling points of the interval $[0,2\pi]$. For details, we refer to the work of Kress [7].

3. The probe method. For the reconstruction of the obstacle D, the probe method uses the [illegible]

$$I(f) := \int_{\partial\Omega}\overline{(\Lambda-\Lambda_0)f(y)}\cdot f(y)\,ds(y), \tag{3.1}$$

with $f\in C^{1,\alpha}(\partial\Omega)$, and given D-t-N maps Λ and Λ_0. For any $z\in\Omega$, we will choose a domain of approximation $G(z)$ with $z\notin G(z)$ and find a sequence $(v_{n,z})_{n\in\mathbb{N}}$ of

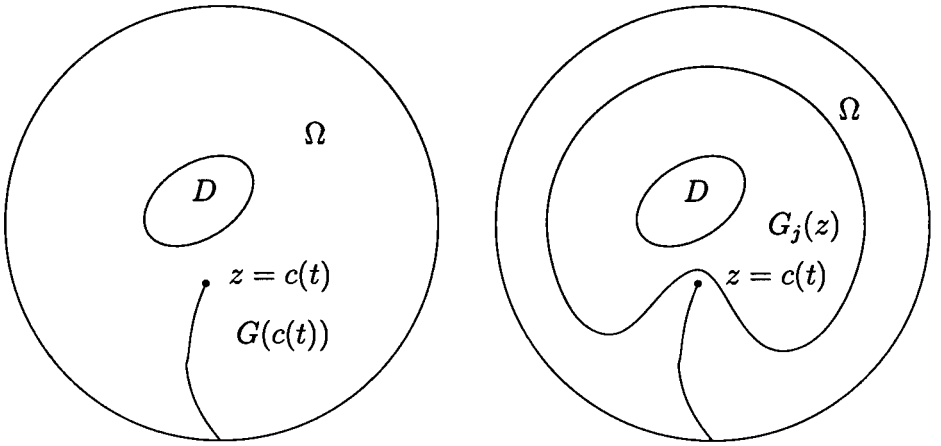

FIG. 2. *The needle domain $G(c(t))$ (left) and an approximation $G_j(z)$ (right) to the needle domain $G(c(t))$. Here, the index j indicates that we can choose a sequence of such approximation domains to successively fill the set $G(z)$. In this sense our approach can be viewed as a numerical realization of the needle approach.*

solutions $v_{n,z} \in C^2(\Omega) \cap C^{1,\alpha}(\overline{\Omega})$ to the Helmholtz equation in Ω, which approximates the point source $\Phi(\cdot, z)$ on the approximation domain $G(z)$, i.e., with

$$\lim_{n\to\infty} \|\Phi(\cdot, z) - v_{n,z}\|_{L^2(G(z))} = 0. \tag{3.2}$$

Given a point $z \in \Omega$ with $\overline{D} \subset G(z)$, $z \notin G(z)$, we use the notation

$$\hat{I}(z) := \lim_{n\to\infty} I(f_{n,z}), \tag{3.3}$$

where $f_{n,z} := v_{n,z}|_{\partial\Omega}$ and I is defined in (3.1). The function $\hat{I}$ is well defined in view of the following theorem.

THEOREM 1. [illegible] $z \in \Omega$ [illegible] $\overline{D} \subset G(z)$ $z \notin G(z)$ [illegible] $\hat{I}(z)$ [illegible] z_j [illegible] $\overline{D} \subset G(z_j)$ $z_j \notin G(z_j)$ [illegible] $j \in \mathbb{N}$, $z_j \to \partial D$, $j \to \infty$ [illegible]

$$|\mathrm{Re}\hat{I}(z_j)| \to \infty, \quad j \to \infty. \tag{3.4}$$

[illegible]. The proof can be adapted easily from Theorem 3.1 in [1]. □

In the work [1], which is based upon the work of Ikehata (see, for example, [4], [5], and [6]), a needle approach is proposed to reconstruct the obstacle D. The authors define a needle as a continuous function $c : [0,1] \longrightarrow \overline{\Omega}$ with $c(0), c(1) \in \partial\Omega$, and $c(t) \in \Omega$ for $0 < t < 1$; i.e., a needle is a path in Ω for a probe starting and ending at the boundary. Then, the function $\hat{I}$ is evaluated for the points $z = c(t)$ on the needle; cf. Figure 2. In [1] they choose the domains

$$G(z) = G(c(t)) = \Omega \setminus \{c(\tau) | 0 < \tau \leq t\} \tag{3.5}$$

for the approximation of the point source $\Phi(\cdot, c(t))$ in a Sobolev space setting under some additional constraints. In [4] the existence of such an approximating function is proved with Runge's approximation theorem, which uses the Hahn–Banach theorem and leads, therefore, to a nonconstructive approximation method.

The approximation domains (3.5) are very suitable for theoretical reasons, since the boundary can then be described easily by the set

$$\partial D = \{c(t) | t = T(c), c \text{ is a needle with } T(c) < 1\}, \tag{3.6}$$

with the impact parameter

$$T(c) = \sup \left\{ 0 < t < 1 \left\| \sup_{0 \le s \le t} |\mathrm{Re}\hat{I}(c(s))\right\| < \infty \right\}. \tag{3.7}$$

Note that $T(c) > 0$. Further, we remark that $T(c) = 1$ if and only if the needle c does not intersect $\overline{D}$.

In this paper, we will provide an explicit approximate function $v_{n,z}$ to the fundamental solution $\Phi(\cdot, z)$ on a particular class of domains $G(z)$ in terms of a Herglotz wave function without using Runge's approximation theorem. Together with the proper choice of the approximation domain G, this will be one of the key steps in the reconstruction algorithm. Figure 2 illustrates this special choice of approximation domains.

4. Numerics for the probe method.

4.1. Point source approximation by integral equations. For every $z \in \Omega$ with a corresponding approximation domain $G(z)$ having a sufficiently smooth boundary such that $z \notin G(z)$ and $-\kappa^2$ is not a Dirichlet eigenvalue for the Laplacian in $G(z)$, we can find a sequence of Herglotz wave functions

$$v_{n,z}(x) := \int_{\mathbb{S}} e^{i\kappa x \cdot d} g_{n,z}(d)\, ds(d) \tag{4.1}$$

with density functions $g_{n,z} \in L^2(\mathbb{S})$ such that the sequence $(v_{n,z})_n$ fulfills (3.2). The justification of this statement is provided by the following theorem.

THEOREM 2. [illegible] $G \subset \mathbb{R}^2$ [illegible] C^2 [illegible] $-\kappa^2$ [illegible] G [illegible] $H : L^2(\mathbb{S}) \longrightarrow L^2(\partial G)$, [illegible]

$$(Hg)(x) = \int_{\mathbb{S}} e^{i\kappa x \cdot d} g(d)\, ds(d), \tag{4.2}$$

[illegible] $L^2(\partial G)$ [illegible]. The proof can be found in the book [9, Lemma 3.1.2]. ∎

We mention (see [3]) that the point source $\Phi(\cdot, z)$ is not in the range of the compact operator H, and since H has no bounded inverse we have to apply a regularization scheme to obtain the densities $g_{n,z}$. The assumption on κ, together with the unique continuation principle and Theorem 3.15 in [2], proves the injectivity of G. Hence, we can apply a Tikhonov regularization scheme to substitute the ill-posed integral equation

$$Hg = \Phi(\cdot, z) \tag{4.3}$$

of the first kind with its regularized version

$$(\alpha I + H^* H) g = H^* \Phi(\cdot, z). \tag{4.4}$$

The operator

$$R_\alpha := (\alpha I + H^* H)^{-1} H^*, \quad \alpha > 0, \tag{4.5}$$

applied to H converges pointwise to the identity on $L^2(\mathbb{S})$,

$$\lim_{\alpha \to 0} R_\alpha H g = g, \tag{4.6}$$

for all $g \in L^2(\mathbb{S})$, and its norm satisfies $\|R_\alpha\| \leq \frac{1}{2\alpha}$. The main focus of this work is on the feasibility of the probe method, rather than the choice of α. Hence, we will choose by trial and error a fixed regularization parameter for our numerical examples.

4.2. Choice of the approximation domains. In principle, the approximation procedure of the last section can be used to construct the approximations of the point source needed for the probe method. This can be carried out by using a family of approximation domains $G_j(z)$, $j = 1, 2, 3, \ldots$, which fill step-by-step the whole approximation domain $G(z)$, as defined in (3.5). Then, for every compact subset M of $G(z)$ we can find $j \in \mathbb{N}$ such that $M \subset G_j(z)$, and on M we obtain an approximation of $\Phi(\cdot, z)$ by $v_{n,z} = H g_{\alpha,z}$ from the solution $g_{\alpha,z}$ to (4.4). However, we experienced the following instability phenomenon. The better the approximation domain $G_j(z)$ approximates the needle domain $G(z)$, the worse is the quality of the point source approximation on $G_j(z)$. For the needle domain, a numerical approximation becomes impossible. Therefore, we need to restrict our numerics to some simple approximation domains $G_j(z)$ and we do not carry out the limit $j \to \infty$; see Figure 2.

For the approximation of a point source $\Phi(\cdot, z)$ on some appropriately chosen approximation domains $G(z)$ by the Herglotz wave operator (4.2), the density $g_{\alpha,z}$ can be calculated as the approximate solution of the integral equation of the first kind (4.3) via (4.4). Hence, for each $z \in \Omega$, it is necessary to solve and regularize an ill-posed integral equation. This can be made efficient by using translation and rotations as follows. Consider approximation domains with a fixed shape, i.e.; approximation domains of the form

$$G(z) = \{M(z)x + z : x \in G_0, M(z) \in \mathrm{SO}(2, \mathbb{R})\} \tag{4.7}$$

with a fixed approximation domain $G_0 := G(0)$, corresponding to the point $z = 0$, where we assume $0 \in \Omega$ w.l.o.g.. Here $\mathrm{SO}(2, \mathbb{R})$ is the set of real, orthogonal 2×2 matrices with $\det(M) = 1$. We remark that $G(z)$ emerges from G_0 by first rotating the domain G_0 and then translating it by the vector z; i.e., the relative position of the source point z to the approximation domain $G(z)$ remains fixed for all $z \in \Omega$ with corresponding domains $G(z)$. In this case, it is sufficient to solve the ill-posed integral equation only once—for example, for the point $z = 0$—as stated by the following theorem.

THEOREM 3. [illegible] $\varepsilon > 0$ $0 \in \Omega$ [illegible] $g_{\alpha,0} \in L^2(\mathbb{S})$ [illegible]

[illegible]

$$(\alpha I + H^* H) g = H^* \Phi(\cdot, 0) \tag{4.8}$$

[illegible] ∂G_0 [illegible]

$$\|H g_{\alpha,0} - \Phi(\cdot, 0)\|_{L^2(\partial G_0)} < \varepsilon. \tag{4.9}$$

$z \in \Omega$ $G(z)$ (4.7)

$$g_{\alpha,z}(d) = e^{-i\kappa z\cdot d} g_{\alpha,0}(M(z)^t d) \tag{4.10}$$

$$\|Hg_{\alpha,z} - \Phi(\cdot, z)\|_{L^2(\partial G(z))} < \varepsilon. \tag{4.11}$$

We define

$$G'(z) := \{M(z)x : x \in G_0\}. \tag{4.12}$$

Then, we obtain for the left-hand side of (4.11) with fixed $z \in \Omega$

$$\begin{aligned}
&\left\| \int_{\mathbb{S}} e^{i\kappa x\cdot d} g_{\alpha,z}(d)\, ds(d) - \Phi(x,z) \right\|_{L^2(\partial G(z))} \\
&= \left\| \int_{\mathbb{S}} e^{i\kappa (x+z)\cdot d} g_{\alpha,z}(d)\, ds(d) - \Phi(x+z,z) \right\|_{L^2(\partial G'(z))} \\
&= \left\| \int_{\mathbb{S}} e^{i\kappa z\cdot d} e^{i\kappa x\cdot d} g_{\alpha,z}(d)\, ds(d) - \Phi(x,0) \right\|_{L^2(\partial G'(z))}.
\end{aligned} \tag{4.13}$$

With $\det(M(z)) = 1$ and $\Phi(M(z)x, 0) = \Phi(x, 0)$, (4.13) simplifies to

$$\begin{aligned}
&\left\| \int_{\mathbb{S}} e^{i\kappa z\cdot d} e^{i\kappa (M(z)x)\cdot d} g_{\alpha,z}(d)\, ds(d) - \Phi(x,0) \right\|_{L^2(\partial G_0)} \\
&= \left\| \int_{\mathbb{S}} e^{i\kappa z\cdot d} e^{i\kappa x\cdot \left(M(z)^t d\right)} g_{\alpha,z}(d)\, ds(d) - \Phi(x,0) \right\|_{L^2(\partial G_0)} \\
&= \left\| \int_{\mathbb{S}} e^{i\kappa z\cdot \left(M(z)\tilde{d}\right)} e^{i\kappa x\cdot \tilde{d}} g_{\alpha,z}(M(z)\tilde{d})\, ds(\tilde{d}) - \Phi(x,0) \right\|_{L^2(\partial G_0)}.
\end{aligned} \tag{4.14}$$

Inserting the definition of $g_{\alpha,z}$ into (4.14) ends the proof. □

The previous theorem reduces the complexity of calculating the densities $g_{\alpha,z}$ from solving a linear system to a simple pointwise vector multiplication. Choosing a fixed base domain G_0, from which all approximation domains $G(z)$ arise by a rotation and a translation by the vector z, the reconstruction algorithm for the probe method using Herglotz wave functions for approximating $\Phi(\cdot, z)$ can be written as follows.

Reconstruction algorithm for the probe method.

1. Choose a test domain G_0 such that $0 \notin G_0$ large enough.
2. For a proper choice of the regularization parameter α, calculate $g_{\alpha,0}$ by solving the regularized boundary integral equation (4.8).
3. For some evaluation points $z_j \in \Omega$, $j = 1, \ldots, N$, calculate the densities g_{α,z_j} $j = 1, \ldots, N$, via (4.10) by rotation of the argument on the unit circle and multiplication with a complex factor.
4. Calculate $f_j := v_{z_j}|_{\partial\Omega}$ and $\Lambda_0 f_j$ for $j = 1, \ldots, N$ by evaluating the Herglotz wave function (4.1) and its normal derivative, respectively.
5. (a) Solve the direct obstacle boundary value problem (2.1)–(2.3) with $f = f_j$ and $g = 0$ for $j = 1, \ldots, N$. Then, calculate Λf_j with (2.14), (simulation of the D-t-N map).
   or

(b) Calculate Λf_j by some externally given D-t-N map for $j = 1, \ldots, N$.

6. Calculate the approximation $I(f_j) \approx \hat{I}(z_j)$ for $j = 1, \ldots, N$ by evaluating the boundary integral (3.1) with the ingredients given by the previous steps. Calculate $|\mathrm{Re}(I(f_j))|$ for every $j = 1, \ldots, N$.
7. Choose some suitable cutoff constant $C > 0$ and decide if
   (a) $z_j \in D$ if $|\mathrm{Re}(I(f_j))| > C$, or
   (b) $z_j \in \mathbb{R}^m \setminus \overline{D}$ if $|\mathrm{Re}(I(f_j))| \leq C$
   for every $j = 1, \ldots, N$.

We remark here that the decision criterion is justified only in the case when $D \subset G(z_j)$. In contrast to the limiting case of the needle approach, where $D \subset G(c(t))$ is always satisfied as long as $t < T(c)$, we do not have information about whether $D \subset G(z_j)$ or not. Therefore, the decision criterion given in the reconstruction algorithm is based on heuristics. Nevertheless, in our numerical examples this decision criterion led to satisfactory results.

5. Numerical study for the probe method.

5.1. Two equivalent forms of the Ikehata functional. In this section, we want to give an equivalent formulation of the Ikehata functional (3.1) without using the D-t-N maps. To this end, we define with u_n the solution to the direct obstacle boundary value problem (2.1)–(2.3) with boundary values $f = f_n$ on $\partial\Omega$ and $g \equiv 0$ on ∂D. Furthermore v_n denotes the solution to the obstacle-free boundary value problem (2.4)–(2.5) with boundary data $f = f_n$ on $\partial\Omega$. Then, we have the following reformulation for the Ikehata functional for a sound-soft obstacle.

LEMMA 4. [illegible]

$$I(f_n) = \int_{\Omega_D} \left(|\nabla w_n|^2 - \kappa^2 |w_n|^2 \right) dx + \int_D \left(|\nabla v_n|^2 - \kappa^2 |v_n|^2 \right) dx \,, \tag{5.1}$$

[illegible] $w_n := u_n - v_n$ [illegible]. The proof can be found in [6]. For the convenience of the reader, and since we numerically study the above integrals, here we present the calculations. From Green's formula, together with $u_n = 0$ on ∂D, we obtain

$$\begin{aligned} \int_{\Omega_D} |\nabla(u_n - v_n)|^2 \, dx &= \int_{\partial\Omega} u_n \frac{\partial(\overline{u}_n - \overline{v}_n)}{\partial\nu} \, ds + \kappa^2 \int_{\Omega_D} u_n(\overline{u}_n - \overline{v}_n) \, dx \\ &\quad - \int_{\Omega_D} \nabla v_n \nabla(\overline{u}_n - \overline{v}_n) \, dx \\ &= \langle (\Lambda_D - \Lambda_0)\overline{f}_n, f_n \rangle + \kappa^2 \int_{\Omega_D} u_n(\overline{u}_n - \overline{v}_n) \, dx \\ &\quad - \int_{\Omega_D} \nabla v_n \nabla \overline{u}_n \, dx + \int_{\Omega_D} |\nabla v_n|^2 \, dx \,. \end{aligned} \tag{5.2}$$

Using $\nabla v_n \cdot \nabla \overline{u}_n = \nabla \cdot (\overline{u}_n \nabla v_n) - \overline{u}_n \Delta v_n$ and the Gaussian divergence theorem we get

$$\begin{aligned} - \int_{\Omega_D} \nabla v_n \nabla \overline{u}_n \, dx + \int_{\Omega_D} |\nabla v_n|^2 \, dx &= - \int_{\partial\Omega} \overline{u}_n \frac{\partial v_n}{\partial\nu} \, ds - \kappa^2 \int_{\Omega_D} \overline{u}_n v_n \, dx \\ &\quad + \int_{\Omega} |\nabla v_n|^2 \, dx - \int_D |\nabla v_n|^2 \, dx \,, \end{aligned}$$

and again with $\nabla v_n \cdot \nabla \overline{v}_n = \nabla \cdot (\overline{v}_n \nabla v_n) - \overline{v}_n \Delta v_n$ we observe

$$-\int_{\Omega_D} \nabla v_n \nabla \overline{u}_n \, dx + \int_{\Omega_D} |\nabla v_n|^2 \, dx = -\kappa^2 \int_{\Omega_D} \overline{u}_n v_n \, dx + \kappa^2 \int_{\Omega} |v_n|^2 \, dx - \int_D |\nabla v_n|^2 \, dx \,,$$

since $u_n - v_n = 0$ on $\partial\Omega$. With this expression we can reformulate (5.2) to

$$\begin{aligned} I_n(c(t)) &= \langle (\Lambda_D - \Lambda_0)\overline{f}_n, f_n \rangle \\ &= \int_{\Omega_D} \left(|\nabla w_n|^2 - \kappa^2 u_n(\overline{u}_n - \overline{v}_n) + \kappa^2 \overline{u}_n v_n \right) dx \\ &\quad -\kappa^2 \int_{\Omega} |v_n|^2 \, dx + \int_D |\nabla v_n|^2 \, dx \\ &= \int_{\Omega_D} \left(|\nabla w_n|^2 - \kappa^2 (u_n - v_n)(\overline{u}_n - \overline{v}_n) \right) dx + \kappa^2 \int_{\Omega_D} |v_n|^2 \, dx \\ &\quad -\kappa^2 \int_{\Omega} |v_n|^2 \, dx + \int_D |\nabla v_n|^2 \, dx \\ &= \int_{\Omega_D} \left(|\nabla w_n|^2 - \kappa^2 |w_n|^2 \right) dx + \int_D \left(|\nabla v_n|^2 - \kappa^2 |v_n|^2 \right) dx \,, \end{aligned}$$

which ends the proof. □

Since the domain of integration is unknown for both integrals, this formulation of the Ikehata functional cannot be used for reconstructions. Nevertheless, it will serve as a comparison with the D-t-N formulation (3.1) of the Ikehata functional in two ways. First, with the help of Lemma 4 we can calculate the Ikehata functional for all $z \in \Omega_D$ without any approximation of the point source $\Phi(\cdot, z)$. To this end, we replace v_n and w_n in (5.1) with $v_{\infty,z} = \Phi(\cdot, z)$ and $w_{\infty,z}$, which denotes the solution to the boundary value problem

$$\Delta w + \kappa^2 w = 0 \quad \text{in } \Omega_D, \tag{5.3}$$

$$w = 0 \quad \text{on } \partial\Omega, \tag{5.4}$$

$$w = -\Phi(\cdot, z) \quad \text{on } \partial D. \tag{5.5}$$

Second, we can also evaluate the Ikehata functional (5.1) with approximate functions to illustrate the influence of the approximation of the point source function on the Ikehata functional. For this purpose we substitute v_n and w_n in (5.1) with $v_{\alpha,z} \approx \Phi(\cdot, z)$, which is defined by (4.1) and (4.10), and with $w_{\alpha,z}$, which is the solution to the boundary value problem

$$\Delta w + \kappa^2 w = 0 \quad \text{in } \Omega_D, \tag{5.6}$$

$$w = 0 \quad \text{on } \partial\Omega, \tag{5.7}$$

$$w = -v_{\alpha,z}|_{\partial D} \quad \text{on } \partial D. \tag{5.8}$$

Both domain integrals in (5.1) can be numerically evaluated with the rectangle rule. The second integral can be easily calculated for any point $z \in \Omega_D$ with both the approximate function $v_{\alpha,z}$ (4.1) and the point source function $v_{\infty,z} = \Phi(\cdot, z)$ itself. The gradients of these functions are given by

$$\nabla v_{\alpha,z}(x) = i\kappa \int_{\mathbb{S}} d \, e^{i\kappa x \cdot d} g_{\alpha,z}(d) \, ds(d) \tag{5.9}$$

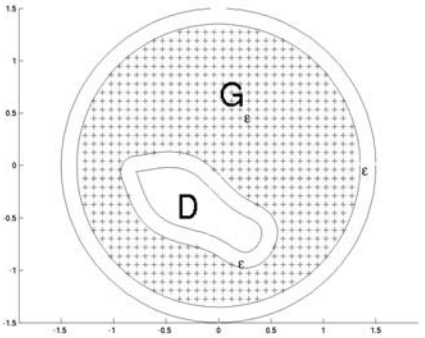

FIG. 3. *The integration domain $G_{0.15}$ for a nonconvex object.*

and

$$\nabla v_{\infty,z}(x) = -\frac{i\kappa}{4} H_1^{(1)}(\kappa|x-z|)\,\frac{x-z}{|x-z|}\,. \tag{5.10}$$

For the first integral, we have to solve the direct obstacle boundary value problem (2.1)–(2.3) with boundary values $f = 0$, $g = -v_{n,z}|_{\partial D}$ to obtain $w_{n,z}$ and with boundary data $f = 0$, $g = -\Phi(\cdot, z)|_{\partial D}$ to obtain $w_{\infty,z}$. In order to avoid numerical difficulties near the boundaries $\partial\Omega$ and ∂D, which arise from the representation of the function w by a combined layer potential, we choose an integration domain G_ε with $\varepsilon > 0$, as shown in Figure 3. Here G_ε is defined as the domain bounded by the surfaces

$$\partial D_\varepsilon := \{x - \varepsilon\nu(x) : x \in \partial D\}, \quad \varepsilon > 0, \tag{5.11}$$

and

$$\partial\Omega_\varepsilon := \{x - \varepsilon\nu(x) : x \in \partial\Omega\}, \quad \varepsilon > 0; \tag{5.12}$$

i.e., we exclude the "near-boundary" region around ∂D and $\partial\Omega$ for integration. Then, we can calculate the gradient of u in G_ε by applying the ∇ operator to the kernel functions of the integral operators S and K of the combined layer potential. In the 2D case, we obtain with $\Phi(x,y) = \frac{i}{4}H_0^{(1)}(\kappa|x-y|)$ and

$$\frac{d}{dz}H_n^{(1)}(z) = \frac{1}{2}\left(H_{n-1}^{(1)}(z) - H_{n+1}^{(1)}(z)\right) \tag{5.13}$$

the gradient

$$\begin{aligned}\nabla u(x) &= \int_{\partial\Omega_D} \nabla_x \frac{\partial\Phi(x,y)}{\partial\nu(y)}\varphi(y)\,ds(y) - i\eta\int_{\partial\Omega_D}\nabla_x\Phi(x,y)\varphi(y)\,ds(y)\\ &= \int_{\partial\Omega_D} k_1(x,y)\varphi(y)\,ds(y) - i\eta\int_{\partial\Omega_D} k_2(x,y)\varphi(y)\,ds(y),\end{aligned} \tag{5.14}$$

of u for all $x \in G_\varepsilon$ with the two kernel functions

$$\begin{aligned}k_1(x,y) = \frac{i\kappa}{4}\Bigg(&\frac{\kappa}{2}\left(H_0^{(1)}(\kappa|x-y|) - H_2^{(1)}(\kappa|x-y|)\right)(x-y)\cdot\nu(y)\frac{x-y}{|x-y|^2}\\ &+H_1^{(1)}(\kappa|x-y|)\frac{|x-y|^2\nu(y) - (x-y)\cdot\nu(y)(x-y)}{|x-y|^3}\Bigg)\end{aligned} \tag{5.15}$$

and

$$k_2(x,y) = -\frac{i\kappa}{4} H_1^{(1)}(\kappa|x-y|)\frac{x-y}{|x-y|}. \tag{5.16}$$

In the next section we give numerical examples, where we have evaluated the Ikehata functional (5.1) both with and without an approximation for the point source function $\Phi(\cdot,z)$ with the rectangular rule over the domains G_ε and D.

5.2. Numerical study of the Ikehata functional. In our numerical examples we will use a circular domain Ω of radius $r_\Omega = 2$ and a kite–shaped object D_K with boundary

$$\partial D_K := \{(-0.4\cos t - 0.3\cos 2t + 0.3, 0.6\sin t) : t \in [0,2\pi)\}, \tag{5.17}$$

as well as a boat-like obstacle D_B with boundary

$$\partial D_B := \{(0.25\cos t - 0.05\sin 4t, -0.75\sin t) : t \in [0,2\pi)\}. \tag{5.18}$$

Furthermore we will consider the translated versions

$$D_{K,v} := v + D_K = \{x + v : x \in D_K\} \tag{5.19}$$

and

$$D_{B,v} := v + D_B = \{x + v : x \in D_B\}, \tag{5.20}$$

with the translation vector $v = (-0.4, -0.7)$. The wave number will be either $\kappa = 1.0$ or $\kappa = 2.5$.

As described in the previous section, we will have to omit the "near-boundary" region around ∂D and $\partial\Omega$ when integrating $|w|^2$ and $|\nabla w|^2$ over Ω_D. For the proper choice of the parameter ε for the integration domain $G_\varepsilon \subset \Omega_D$, we first investigate the error between the true solution (and its gradient) of the direct obstacle boundary value problem and the solution (and gradient) given by the forward solver. To this end, we define with $x_i = (0,0) \in D$ and $x_e = (0,2.5) \in \mathbb{R}^2 \setminus \overline{\Omega}$ the solution

$$u_{\text{test}}(x) := \Phi(x,x_i) + \Phi(x,x_e) \tag{5.21}$$

to the Helmholtz equation in Ω_D, which satisfies the direct obstacle boundary value problem (2.1)–(2.3) with $f = u_{\text{test}}|_{\partial\Omega}$ and $g = u_{\text{test}}|_{\partial D}$. Tables 1 and 2 show the maximal error between the true solution u_{test} and the calculated solution u_{calc} on parallel surfaces $\partial\Omega_\varepsilon$ and ∂D_ε with distance $\varepsilon = 0.03$, n sampling points on the interior curve ∂D, and $3n$ sampling points on the exterior curve $\partial\Omega$ for the kite- and boat-shaped obstacles, respectively. The wave number for this numerical experiment is $\kappa = 1.0$.

Following this numerical example, we chose $n = 200$ sampling points on the interior and $3n = 600$ points on the exterior boundary of the domain Ω_D in the combined layer approach of the forward solver. Then, we can calculate the Ikehata functional with formula (5.1), where we substitute the integration domain Ω_D by G_ε with $\varepsilon = 0.03$. Figure 4 compares the Ikehata functional for the boat-shaped domain D_B and $D_{B,v}$ with the translation vector $v = (-0.4, -0.7)$ via three different calculations. First, the Ikehata functional is calculated with the D-t-N formulation (3.1), as described in sections 2–4. Second, to validate these results we calculated the

BENEFITS OF IEEE-754 FEATURES IN MODERN SYMMETRIC TRIDIAGONAL EIGENSOLVERS*

OSNI A. MARQUES†, E. JASON RIEDY‡, AND CHRISTOF VÖMEL†

Abstract. Bisection is one of the most common methods used to compute the eigenvalues of symmetric tridiagonal matrices. Bisection relies on the *Sturm count*: For a given shift σ, the number of negative pivots in the factorization $T - \sigma I = LDL^T$ equals the number of eigenvalues of T that are smaller than σ. In IEEE-754 arithmetic, the value ∞ permits the computation to continue past a zero pivot, producing a correct Sturm count when T is unreduced. Demmel and Li showed [*IEEE Trans. Comput.*, 43 (1994), pp. 983–992] that using ∞ rather than testing for zero pivots within the loop could significantly improve performance on certain architectures. When eigenvalues are to be computed to high relative accuracy, it is often preferable to work with LDL^T factorizations instead of the original tridiagonal T. One important example is the MRRR algorithm. When bisection is applied to the factored matrix, the Sturm count is computed from LDL^T which makes differential stationary and progressive qds algorithms the methods of choice. While it seems trivial to replace T by LDL^T, in reality these algorithms are more complicated: In IEEE-754 arithmetic, a zero pivot produces an overflow followed by an invalid exception (NaN, or "Not a Number") that renders the Sturm count incorrect. We present alternative, safe formulations that are guaranteed to produce the correct result. Benchmarking these algorithms on a variety of platforms shows that the original formulation without tests is always faster provided that no exception occurs. The transforms see speed-ups of up to 2.6× over the careful formulations. Tests on industrial matrices show that encountering exceptions in practice is rare. This leads to the following design: First, compute the Sturm count by the fast but unsafe algorithm. Then, if an exception occurs, recompute the count by a safe, slower alternative. The new Sturm count algorithms improve the speed of bisection by up to 2× on our test matrices. Furthermore, unlike the traditional tiny-pivot substitution, proper use of IEEE-754 features provides a careful formulation that imposes no input range restrictions.

1. Introduction.

In the early 1990s, Demmel and Li demonstrated that handling exceptions carefully can improve the performance of certain numerical algorithms [8]. One such algorithm is bisection using Sturm counts to compute the eigenvalues of a symmetric tridiagonal matrix T. A Sturm count finds the number of eigenvalues less than a given shift parameter σ. Sturm count calculations can encounter a zero pivot while factoring $T - \sigma I = LDL^T$. A conventional bisection

implementation such as LAPACK's DSTEBZ substitutes a small number for zero and continues the computation [3]. This procedure has two disadvantages. Testing imposes a performance penalty, and ensuring correctness requires a range restriction on the input data.

IEEE-754 arithmetic [4, 21] provides the [illegible] ∞ (infinity) to continue past the exceptions of overflow and division by zero. This quantity propagates like any other floating-point value, ideally at full speed. In [8], this capability of IEEE-754 arithmetic allows a faster Sturm count and hence a faster implementation of tridiagonal bisection. The faster algorithm also avoids the input restrictions, removing both disadvantages.

Since [8], there has been significant progress in algorithms for the symmetric eigenvalue problem. In particular, LAPACK now includes DSTEGR, an implementation of the MRRR algorithm [23, 24, 25, 26, 9]. Two key concepts of MRRR are its use of shifted LDL^T factorizations instead of the original tridiagonal matrix T, and the [illegible] that transform one shifted factorization into another. The MRRR algorithm applies these transformations to produce a suitable relatively robust representation (RRR) for each eigenvalue. This RRR is an appropriately shifted LDL^T factorization from which the MRRR algorithm computes a corresponding eigenvector with guaranteed small residual and numerical orthogonality. In this process, the algorithm also refines some eigenvalues by bisection, again using the differential qds algorithms.

This paper focuses on using the qds algorithms in bisection. Originally, the differential qd (dqd) algorithm was proposed by Rutishauser [28, 29]. Parlett and Fernando [14, 15, 22] discovered the shifted variant (dqds) as an improvement to Demmel and Kahan's zero shift QR [7] for computing singular values of a bidiagonal matrix to high relative accuracy; see also [27].

Applying bisection to the factored matrix LDL^T using the stationary and progressive differential qds transformations is more complicated than traditional bisection directly applied to the tridiagonal T. A qds implementation in IEEE-754 arithmetic can encounter not only ∞ but also an invalid operation ∞/∞ (producing NaN, or "Not a Number") that renders the Sturm count invalid. Demmel and Li [8] suggest a paradigm for algorithms where exceptions may invalidate the results of calculations that otherwise appear simple:

(i) Use a fast (but possibly incorrect) algorithm to compute a result.
(ii) Assess the correctness of the computed result.
(iii) If the answer is not correct, use a slower and more careful algorithm to recompute the result.

This paper applies this exception-handling paradigm to qds transformations and quantifies the resulting performance on today's computer architectures. This allows us to select the best performing and most robust implementation of qds transformations for use in bisection and the MRRR algorithm.

The paper is organized as follows. Section 2 gives an overview of the various formulations of Sturm counts via qds transformations. We analyze three always correct alternatives to the basic version. One of the alternative formulations computes a correct Sturm count without any additional input range restrictions.

Section 3 is the heart of this paper. We benchmark our algorithms for input data that results in both exceptional and unexceptional execution to quantify the benefits of using IEEE-754 features and the penalties for encountering exceptions. As long as no exception occurs, the basic version is always faster. Overall, the careful variants' times are around 1.12× the time of the basic version. We refer to this as a speed-

up of 1.12 when comparing the faster basic version with the slower careful variants. When an exception occurs, the combined plain/careful computation times are about 1.63× that of the careful loop alone, which we call a slow-down of 1.63. There is one remarkable exception, the Pentium 4 Xeon, whose performance drops by factors of 18–60× in the exceptional case.

Section 4 compares these formulations when applied within bisection on real world test examples. The median speed-up of the fast algorithm when running bisection to determine the eigenvalues fairly accurately is moderate, around 1.08. The Cray X1 greatly benefits from moving exceptional tests out of the inner loop, seeing speed-ups from 1.2 to almost 2.

The potential for huge slow-downs on aberrant architectures implies that our paradigm may not be suitable for portable code. However, section 5 describes a technique to limit the penalty on almost all cases: blocking. The Sturm count computation can be divided into blocks, and the NaN test is performed on each block. Thus, if an NaN occurs, only the computation of the previous block need be repeated.

The appendix gives a short overview of important implementation details in our algorithms.

2. Sturm counts with and without IEEE-754 arithmetic. Bisection is one of the most popular methods for computing the eigenvalues of a symmetric tridiagonal matrix. It can be used to find k selected eigenvalues with $\mathcal{O}(kn)$ work given a tridiagonal matrix of dimension n. Furthermore, it is easily parallelizable.

Bisection is based on Sturm counts. This section presents various methods for computing Sturm counts. We require that the input matrix be unreduced; that is, no entry on the super- or subdiagonal is zero. This implies that the eigenvalues are simple. Additionally, we assume no input is NaN or $\pm\infty$.

2.1. Sturm counts for a tridiagonal matrix. Sylvester's law of inertia states that the (shifted) symmetric tridiagonal matrix $T - \sigma I = LDL^T$, with L being unit-bidiagonal and D being diagonal, has the same number of positive, negative, and zero eigenvalues as D; see, for example, [16].

This result can be used to find, by suitable variation of the shifts, small enclosing intervals for each eigenvalue of T. Starting with an initial interval $[V_L, V_U]$ containing the eigenvalue, we compute the number of negative pivots at the midpoint $(V_L+V_U)/2$. If this number is smaller than the index of the wanted eigenvalue, the eigenvalue lies in the right half of the interval; otherwise it lies in the left half. This bisection process can be repeated until an interval of suitably small size is found. Its implementation in finite precision arithmetic is correct provided that the Sturm count is monotonic with σ; see [19, 6].

The well-known recurrence for the pivots in D is given by

$$d(i) = (T(i,i) - \sigma) - \frac{T(i,i+1)^2}{d(i-1)}. \tag{2.1}$$

In finite precision arithmetic, the pivot $d(i-1)$ may be tiny or exactly zero. In this case, the succeeding pivot $d(i)$ overflows (provided that $T(i,i+1) \neq 0$).

A possible cure to this situation was first developed in [19]. At the beginning of the algorithm, a minimum pivot threshold [illegible] is computed. It represents the smallest divisor so that $T(i,i+1)^2/\text{pivmin}$ does not overflow. Then, whenever $|d(i-1)| <$ pivmin, the algorithm replaces $d(i-1)$ by pivmin. (The convention in LAPACK's DSTEBZ is actually to replace the pivot by negative pivmin.) This substitution limits

the input range. To prevent overflows, the inputs must satisfy $|T(i,j)| \leq \Omega^{1/2}\eta^{1/4}$, where Ω is the arithmetic's overflow threshold and η is the smallest positive normalized number.

IEEE-754 arithmetic allows us to avoid the pivmin threshold [8]. With $d(i-1) = 0$, the next pivot becomes $-\infty$, and the computation continues normally afterwards with $d(i+1) = T(i+1, i+1) - \sigma$. In [8], the authors report a speed-up of 1.2 to 1.3 of Sturm counts using the IEEE-754 version over the version based on the pivmin threshold. The impact on bisection is reported to be a speed-up of 1.14 to 1.24. Also, the IEEE-754 version does not impose any range restrictions.

2.2. Sturm counts for a tridiagonal matrix in factored form LDL^T. Instead of applying Sylvester's law of inertia to a tridiagonal matrix T, it also can be applied to its LDL^T factorization. This idea leads to differential qds transformations that are introduced in the following. They are of great importance to the MRRR algorithm [23, 24, 25, 26, 9] that requires the reliable computation of Sturm counts from shifted LDL^T factorizations instead of the original tridiagonal matrix.

In order to compute Sturm counts, MRRR uses two principal algorithms, the stationary factorization $LDL^T - \sigma I = L_+ D_+ L_+^T$ and the progressive factorization $LDL^T - \sigma I = U_- D_- U_-^T$. These are variants of an algorithm originally proposed by Rutishauser [28, 29] and are stable in a mixed sense; see [26].

While a Sturm count on T does not look very different from one on LDL^T, there are subtle and important differences between the two approaches that are summarized in the following table.

	Tridiagonal T	Factored $T = LDL^T$
Sturm sequence algorithm	$T - \sigma I = LDL^T$	Differential qds algorithms
Possible exceptional values	∞	∞, NaN
Is the final Sturm count valid?	Always	If NaN has not occurred

Algorithm 2.1 presents both the stationary (a) and progressive (b) algorithms. The variable count holds the Sturm count. Note the following:

(i) Both algorithms use the quantities $d(i)$ and $l(i)^2 d(i)$. If the Sturm count is repeated several times as in bisection, precomputing $lld(i) \equiv l(i)^2 d(i)$ is more efficient than repeatedly computing $l(i)^2 d(i)$. We use $lld(i)$ throughout the rest of the paper.

(ii) For the purposes of the Sturm sequence, it is not necessary to store the pivots $d_+(i)$ and $d_-(i)$.

(iii) The division in both algorithms is probably the most costly operation. We place the sign tests after the division to encourage optimizations that overlap the two operations.

Sturm counts on the factored matrix LDL^T via differential stationary or progressive qds transforms can produce an NaN during the computation. In the case of differential stationary qds, if $d_+(i-1) = 0$, then $|d_+(i)| = \infty$ and $d_+(i+1) = \text{NaN}$; see also Table 1(a). For the differential progressive qds, if $d_-(i+1) = 0$, then $|d_-(i)| = \infty$ and $d_-(i-1) = \text{NaN}$; see also Table 1(b).

If an NaN occurs, that NaN propagates through all subsequent computations. The resulting Sturm count is invalid in this case; the computation needs to be repeated with an NaN-free variant of the respective algorithm. This is in contrast to a Sturm sequence using T that is robust even when ∞ occurs.

TABLE 1
Variable values after a zero pivot is encountered in step $i-1$ of the stationary and the progressive variants of Algorithm 2.1.

	$i-1$	i	$i+1$
t	$-d(i-1)$	$\pm\infty$	NaN
d_+	0	$\pm\infty$	NaN

(a) Stationary qds

	$i-1$	i	$i+1$
d_-	0	$\pm\infty$	NaN
p	$\pm\infty$	NaN	NaN

(b) Progressive qds

TABLE 2
Range restrictions and possible exceptional values for the alternative formulations of the differential qds algorithms. The quantity Ω is the overflow threshold, η is the smallest positive, normalized number, and ε denotes the smallest positive number such that $1+\varepsilon$ does not evaluate to 1.

Algorithm	Exceptional values	Range restrictions
2.2: pivmin	*none*	$\lvert T(i,j)\rvert \le \Omega^{1/2}\eta^{1/4}$
2.3: $\infty/\infty \Rightarrow 1$	$\pm\infty$	*none*
2.4: $\pm\infty \Rightarrow \pm\Omega$	$\pm\infty$	$\lvert d(i)\rvert < \Omega\,\varepsilon$

ALGORITHM 2.1. The differential stationary and progressive qds algorithms compute $L_+D_+L_+^T$(stationary) $= U_-D_-U_-^T$(progressive) $= LDL^T - \sigma I$ and count the number of negative pivots. The diagonal elements of D are $d(1),\ldots,d(n)$, and the products $D(i,i)L(i,i+1)^2$ are $lld(1),\ldots,lld(n-1)$. (The off-diagonal entries of L are not used explicitly; they occur only in the products $D(i,i)L(i,i+1)^2$.) The quantity [illegible] denotes the number of eigenvalues of LDL^T that are less than σ.

```
negcount = 0
p = d(n) - σ
for i = n - 1 : 1 do
   d-(i + 1) = lld(i) + p
   p = (p/d-(i + 1)) * d(i) - σ
   Increase negcount if d-(i + 1) < 0
end for
d-(1) = p
Increase negcount if d-(1) < 0
```

(b) Progressive qds

2.3. NaN-free variants of differential qds transforms. There are different possible approaches to avoiding invalid operations in the differential stationary and progressive qds algorithms. In this section, we discuss three such variants of Algorithm 2.1 that are based on appropriate substitutions. A summary of the possible exceptional values and range restrictions of the various alternative formulations is given in Table 2. These are explained in the later sections.

2.3.1. Substitution of pivmin for tiny pivots. The first approach mimics the tridiagonal Sturm count procedure presented in section 2.1. Algorithm 2.2 replaces tiny and zero pivots with a minimum threshold [illegible] to prevent division by a zero pivot. It entirely avoids exceptional values. The choice of [illegible] is justified by [19] and used in LAPACK. In our tests, we use pivmin $= \eta \cdot \max_{i=1,\ldots,n-1} T(i,i+1)^2$. To avoid overflows, the initial data must satisfy $|T(i,j)| \le \Omega^{1/2}\eta^{1/4}$.

ALGORITHM 2.2. Substituting pivmin for very small pivots.

```
negcount = 0
t = -σ
for i = 1 : n - 1 do
   d+(i) = d(i) + t
   if |d+(i)| < pivmin then
      d+(i) = -pivmin
   end if
   t = (t/d+(i)) * lld(i) - σ
   Increase negcount if d+(i) < 0
end for
d+(n) = d(n) + t
Increase negcount if d+(n) < 0
```

(a) Stationary qds

```
negcount = 0
p = d(n) - σ
for i = n - 1 : 1 do
   d-(i + 1) = lld(i) + p
   if |d-(i + 1)| < pivmin then
      d-(i + 1) = -pivmin
   end if
   p = (p/d-(i + 1)) * d(i) - σ
   Increase negcount if d-(i + 1) < 0
end for
d-(1) = p
Increase negcount if d-(1) < 0
```

(b) Progressive qds

2.3.2. Substitution of ∞/∞ by 1. The second approach mimics the tridiagonal Sturm count by allowing ∞ but preventing the subsequent NaN. For the differential stationary qds algorithm (Algorithm 2.1(a)), substituting an alternate value for ∞/∞ can avoid producing an NaN. Using l'Hôpital's limit formula, we find $\lim_{t\to\infty} t/d_+(i) = \lim_{t\to\infty} t/(d(i)+t) = 1$. The same argument holds for the quotient $p/d_-(i+1)$ in the differential progressive qds algorithm (Algorithm 2.1(b)). The qds variants in Algorithm 2.3 explicitly substitute 1 for ∞/∞. Note that the infinite t (or p) from a tiny or zero pivot produces a pivot d_+ (or d_-) with the same sign; thus the substitution is always 1. This variant does not restrict the input range but does produce $\pm\infty$ values.

ALGORITHM 2.3. Substituting 1 for ∞/∞.

```
negcount = 0
t = -σ
for i = 1 : n - 1 do
   d+(i) = d(i) + t
   if |t| = ∞ and |d+(i)| = ∞ then
      q = 1
   else
      q = (t/d+(i))
   end if
   t = q * lld(i) - σ
   Increase negcount if d+(i) < 0
end for
d+(n) = d(n) + t
Increase negcount if d+(n) < 0
```

(a) Stationary qds

```
negcount = 0
p = d(n) - σ
for i = n - 1 : 1 do
   d-(i + 1) = lld(i) + p
   if |p| = ∞ and |d-(i + 1)| = ∞ then
      q = 1
   else
      q = (p/d-(i + 1))
   end if
   p = q * d(i) - σ
   Increase negcount if d-(i + 1) < 0
end for
d-(1) = p
Increase negcount if d-(1) < 0
```

(b) Progressive qds

2.3.3. Substitution of overflow and divide-by-zero by $\pm\Omega$. Following a suggestion of Kahan [19, 20], we present an alternative version which emulates saturation arithmetic, an arithmetic where all overflows produce the largest representable

number rather than ∞. Algorithm 2.4 replaces an infinite t or p with the correctly signed largest representable number $\pm\Omega$. As long as the subsequent addition in the next iteration does not overflow, division with the new pivot evaluates to 1 as in Algorithm 2.3.

In true saturation arithmetic, all overflows would produce a correctly signed Ω as a result. Because we emulate saturation arithmetic only when calculating t (or p), the subsequent addition overflows and yields an incorrect pivot $d_+(i+1)$ (or $d_-(i+1)$) if $d(i+1) \geq \Omega\varepsilon$. Thus we must restrict the input range slightly or add additional tests to fully implement saturation arithmetic. We chose the former because practical examples do not approach the input restriction $d(i) < \Omega\varepsilon$. This variant also produces infinities as intermediate values. The function application sign(t) in Algorithm 2.4 returns 1 if $t = +\infty$ and -1 if $t = -\infty$.

ALGORITHM 2.4. Substituting the largest magnitude, finite number Ω for infinite quotients (correctly signed).

```
negcount = 0
t = -σ
for i = 1 : n - 1 do
   d+(i) = d(i) + t
   t = (t/d+(i)) * lld(i) - σ
   if |t| = ∞ then
      t = sign(t) * Ω
   end if
   Increase negcount if d+(i) < 0
end for
d+(n) = d(n) + t
Increase negcount if d+(n) < 0
```

(a) Stationary qds

```
negcount = 0
p = d(n) - σ
for i = n - 1 : 1 do
   d-(i + 1) = lld(i) + p
   p = (p/d-(i + 1)) * d(i) - σ
   if |p| = ∞ then
      p = sign(p) * Ω
   end if
   Increase negcount if d-(i + 1) < 0
end for
d-(1) = p
Increase negcount if d-(1) < 0
```

(b) Progressive qds

3. A benchmark of the various differential qds algorithms. We devise two benchmarks to compare the various algorithms. For a given tridiagonal matrix V_n in factored form LDL^T, both benchmarks compute differential qds factorizations of $LDL^T - \sigma I$. In the first case, we choose σ such that no zero pivot (and hence no IEEE exception) occurs. In the second case, we choose σ to force an exception. These benchmarks allow us to compare the performance of the algorithms in the unexceptional case and to quantify the penalties when an IEEE exception occurs. For a given dimension n, the matrix V_n is a tridiagonal with all off-diagonal entries equal to one; its diagonal consists of the vector $1 : n$.

3.1. Benchmark details. The occurrence of NaN always follows a zero (or tiny) pivot in $LDL^T - \sigma I$; see Table 1(a) and (b). Furthermore, a pivot can be zero only when the shift is chosen as an eigenvalue of a leading submatrix in the stationary case, and as an eigenvalue of a trailing submatrix in the progressive case.

For the first benchmark, the shift σ is chosen well outside the Gershgorin bounds. This guarantees that no exceptional operation occurs.

The second benchmark must induce an invalid operation. For the differential stationary qds algorithms, we choose as the shift the first diagonal element $d(1)$, and an NaN occurs in step 2. For the differential progressive qds algorithm, setting

TABLE 3

Opteron	2200	Linux	Pathscale pathf90 2.1 -O3	`cpu_time`

$lld(n-1) = -(d(n) - \sigma)$ forces the pivot $d_-(n)$ to zero for any shift σ. However, in order to prevent the matrix from becoming reducible, we must choose $\sigma \neq d(n)$. A reducible matrix would produce NaNs even in the alternative formulations of the progressive algorithm. The choices $\sigma = d(n)/2.0$ and $lld(n-1) = -d(n)/2.0$ produce an NaN regardless of any compiler optimizations or rounding settings.

We run each benchmark in double precision for matrices of dimensions from 500 to 6000 by steps of 500. Individual Sturm counts compute very quickly, so we time a loop of 50000 Sturm counts on the same data. Table 3 summarizes the architectures, compilers, and timers used for our experiments.

All tested platforms support the default IEEE-754 execution mode, producing and propagating ∞ and NaN without user-visible traps. We tested both the Pentium 4 Xeon's 80-bit x87 floating-point unit and its 64-bit SSE3 floating-point unit. We tested only the SSE2 unit on the Opteron. SSE2 and SSE3 floating-point units can perform vector operations where each operand is a pair of double-precision values. The Intel and Pathscale compilers did not vectorize the Sturm counting loops and used only the first 64-bit entry in each vector register. The Athlon platform tested supports only SSE1, and thus our tests use its x87 floating-point unit.

3.2. Benchmark results. Both benchmarks time the same Sturm count routines. Algorithms 2.2, 2.3, and 2.4 each are applied to $T = LDL^T$ for the two shifts above. To test the paradigm of computing quickly and fixing failures, we time three additional versions. Each runs the basic qds loop in Algorithm 2.1, tests the final pivot for NaN, and recomputes with runs of Algorithms 2.2, 2.3, or 2.4 if the pivot is NaN.

Figures 1, 2, and 3 present the timings for every algorithm and platform. The times are normalized into CPU cycles per entry examined by

$$\text{CPU cycles per entry} = \frac{\text{total time}}{50000 \text{ iterations} \cdot n \text{ entries}} \cdot \text{clock speed in Hz} \tag{3.1}$$

given the CPU clock speeds in Table 3. Note that the figures have different horizontal scales, and that Figure 3 provides two views of the Pentium 4 Xeon's performance when using the x87 floating-point unit. The markers have different shapes to distinguish both between progressive and stationary loops and between plain and exceptional execution. The dashed vertical lines denote the range of division latencies given in platform documentation and tuning guides [1, 17, 18, 30, 32, 31, 2]. No such

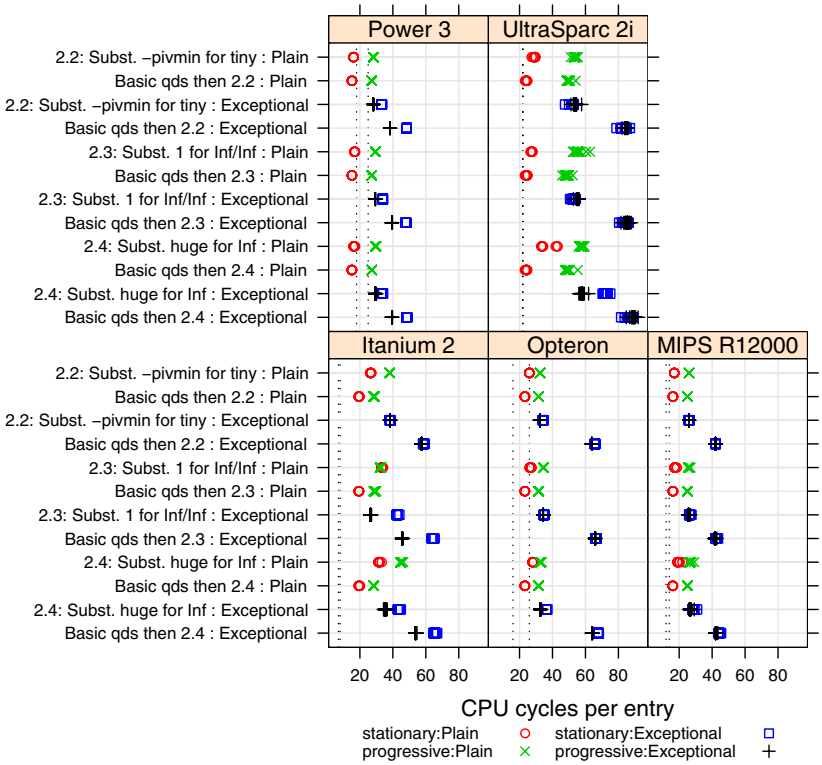

FIG. 1. *CPU cycles per entry for each qds algorithm. Vertical dashed lines show the range of documented division latencies, if known.*

information is available for the Cray X1.

3.3. Examining the benchmark results. On an unexceptional run, a basic qds Sturm count achieves a speed-up of 1.12 over the careful algorithms of section 2, where speed-up is measured by the time of the careful algorithm divided by the time of the basic qds algorithm on the same inputs. When exceptions occur, the median slow-down of the combined basic/careful qds loops over the careful loop alone is 1.63. We measure slow-down as the time of the combined loop divided by the time of the careful loop on the same inputs. The only slow-downs over 2 occur for the x87 unit on the Pentium 4 Xeon, which drastically penalizes exceptional values and suffers slow-downs from 18.93 to 66.53. No one careful algorithm's performance dominates the others, but we recommend that implementors use Algorithm 2.3 ($\infty/\infty \Rightarrow 1$) because it imposes no special range restrictions on the input data.

. Figure 4 compares the basic qds loops' times to the times of their careful counterparts when no exceptions occur. As expected, the basic qds loop runs faster. The speed-up of the basic qds loop over the corresponding careful algorithms across all platforms is given in Table 4.

Note that the stationary loops sometimes run more slowly than the progressive loops; some platforms appear to prefer sequential forward memory access over sequential reverse access. And the x87 unit on the Pentium 4 Xeon prefers Algorithm 2.2

(pivmin) over Algorithm 2.1's simple qds loop.

. Figure 5 shows the slow-downs from attempting a basic qds Sturm count, finding an exception, and recounting with a careful loop. The x87 unit on the Xeon processors shows an excessive slow-down, detailed in Figure 6. This is evidence that the Xeon implements IEEE-754 special values in microcode for its x87 unit. In other words, every time the Xeon's x87 unit encounters an ∞ or NaN , it flushes its internal pipelines and jumps to a special handler program inside the processor. In contrast, the Athlon's x87 unit processes these special values at full speed.

Assuming exceptions occur rarely in practice, most slow-downs in Figure 5 and Table 5 are acceptable. The median is 1.63, less than the factor of 2 that we expected. Section 5 details how breaking the loops into shorter blocks can limit impact of the worst slow-downs.

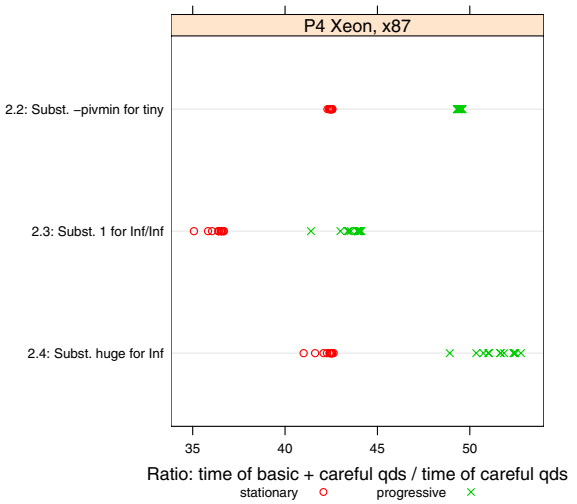

FIG. 6. *The* x87 *unit on Xeons suffers an extreme penalty for computing with NaNs, from over* 18× *to almost* 70× *slow-down.*

TABLE 5

Ratio of the failed basic loop plus the careful loop's times to the corresponding careful loops' times, or the slow-down of the attempted basic loop over the careful variants, for exceptional inputs across all platforms and both progressive and stationary qds.

Variant	Min	1st Quartile	Median	Mean	3rd Quartile	Max
All variants	1.088	1.526	1.634	6.417	1.963	52.77
2.2: pivmin	1.356	1.566	1.708	6.660	1.972	49.60

2.4: $\pm\infty \Rightarrow \pm\Omega$	1.088	1.493	1.569	6.636	1.960	52.77

. To help choose one among the careful qds loops to support the basic loop, Figure 7 and Table 6 compare times of the basic loop followed by the two algorithms with range restrictions, Algorithms 2.2 and 2.4, to the time of the same loop followed by the algorithm without range restrictions, Algorithm 2.3. No algorithm completely dominates the performance of the others. We suggest that users adopt Algorithm 2.3 because it imposes no range restrictions on the data.

4. Impact on bisection. Does performance of the Sturm count impact eigensolvers? We answer this question in part by using section 2.3's algorithms in bisection. We apply bisection to the tridiagonal matrices from matrix collections and applications described in section 4.1. The bisection routine tested is a modification of the auxiliary routine DLARRB from LAPACK. We test each version of our Sturm counts individually by computing the eigenvalues to within a relative error of 4ε. Overall, the basic qds loop provides a median speed-up of only 1.08. Particular platforms such as the Cray X1 see significant improvements.

4.1. Test matrices. The symmetric tridiagonal matrices used in our experiments come from a wide range of real applications, as follows:

1. Applications in chemistry. The matrices are related to the modeling of biphenyl using the Moller–Plesset theory, the density functional theory applied to

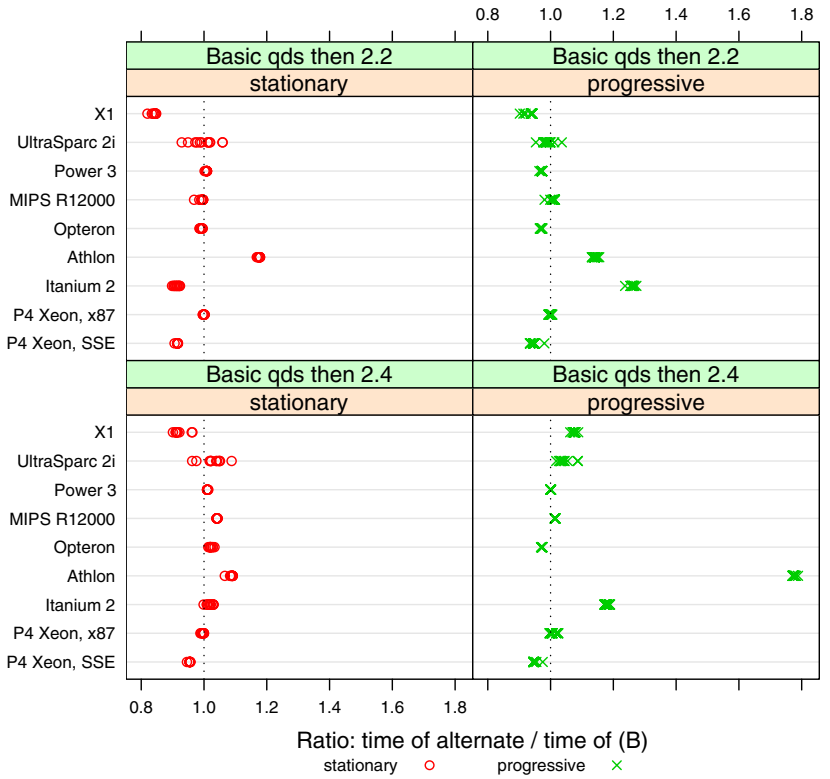

FIG. 7. *Comparing Algorithms* 2.2 *and* 2.4*, those with input range restrictions, to Algorithm* 2.3 *shows no all-around performance winner.*

TABLE 6

Ratio of the listed careful loops' times to the corresponding times for variant B ($\infty/\infty \Rightarrow 1$) *for exceptional inputs across all platforms and both progressive and stationary qds. To evaluate performance as a "backup" method, the times compared are those of the basic qds loop followed by the careful loop. We attribute the wide spread to wide architectural and compiler differences.*

matrices are related to finite element problems.

The matrices from 2 and 3 were tridiagonalized by means of LAPACK's DSYTRD or a simple MATLAB implementation of the Lanczos algorithm, with a starting vector filled with ones and no reorthogonalization, so as to provoke the appearance of very close eigenvalues in the resulting tridiagonal. In this case, Lanczos was run for $N \cdot k$ steps, where N is the dimension of the problem and k an integer at most 4. Table 7 gives more information about the matrices used in the tests.

4.2. Bisection performance results. Figures 8 and 9 show the CPU cycles per entry for each qds algorithm and platform. Because bisection does not run a fixed number of Sturm counts, calculating the cycles per entry requires replacing the 50000 in (3.1) with the number of calls to the qds routine in each individual execution. Section 4.1's test matrices generated no exceptions. Figure 10 provides the speed-ups for each algorithm and platform, and Table 8 summarizes those speed-ups across all platforms.

The median improvement of the basic qds loop over the careful algorithms is a modest 1.08, with a few notable slow-downs using the P4 Xeon's x87 unit. However, some platforms see substantial speed-ups. The Itanium 2 and Cray X1 both see speed-ups of at least 1.2. The Cray X1 benefits the most, achieving a maximum speed-up of 1.98 and a median speed-up of 1.66.

5. Blocking. For larger matrix sizes, the potential slow-downs shown in section 3.3 become unacceptable. Blocking the loops limits the slow-down for most cases without surrendering the basic loop's performance.

The idea is simple: Instead of performing the whole computation with the fast algorithm for the full loop, the computation is split into blocks $1 : n_1$, $n_1 + 1 : n_2$, and so forth. After the computation for the current block has finished, its correctness is assessed immediately. Thus, in the case of an invalid result, only the computation of the current block is repeated.

In our context of computing the Sturm count from a differential qds factorization,

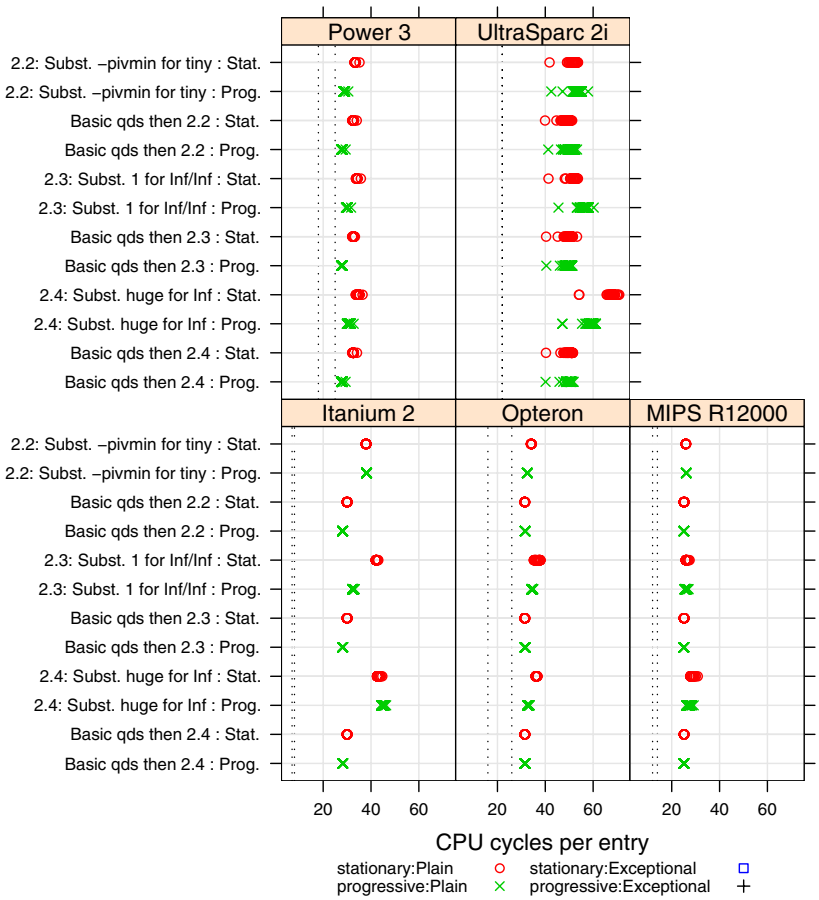

FIG. 8. *CPU cycles per entry for each qds algorithm during bisection. Vertical dashed lines show the range of documented division latencies, if known.*

blocking results in an outer loop over the blocks, and an inner loop that computes the Sturm count , the number of negative pivots in the factorization of the current block. The increment is added to the count if the factorization encounters no exceptions. Otherwise, the increment is recomputed with a careful algorithm.

The block size is a tuning parameter. Its setting has to address the trade-off between the cost for assessing the correctness of the intermediate solution, in our case the NaN test, and the potential overhead for redoing the computation. The optimal block size may depend not only on the computation costs but also on caching effects.

The benchmark test from section 3 motivates the blocking approach. The basic stationary differential qds algorithm produces an NaN in step 2 when the shift is chosen to be $d(1)$. Once that exception is handled, no further exceptions occur. Thus, the earlier the NaN is detected, the fewer unnecessary operations are performed. At the end of the first block, the NaN is detected, and only the first block's contribution is recomputed. The remainder of the blocks will proceed at full speed.

Blocking has no benefits in those very rare cases in which the computation has to be redone for block. One such example is an LDL^T factorization of a symmetric

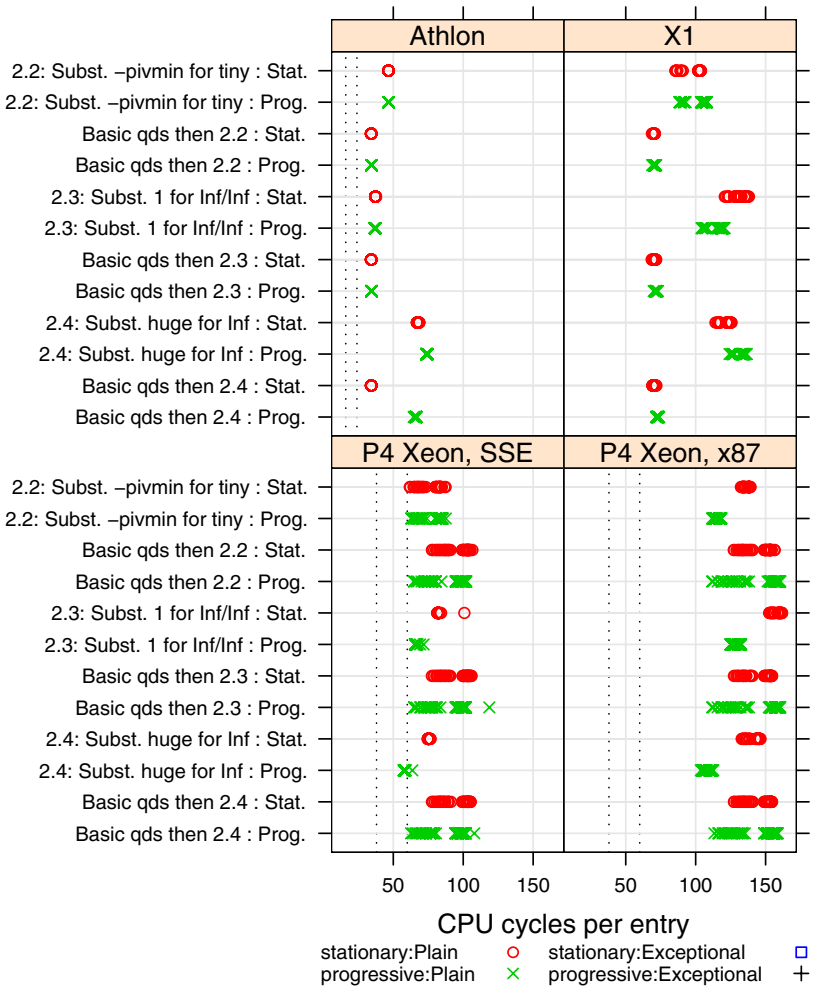

FIG. 9. *CPU cycles per entry for each qds algorithm during bisection for platforms needing a wider scale than Figure* 8. *Xeon values with the* x87 *unit are clipped to fit. Vertical dashed lines show the range of documented division latencies, if known.*

diagonally dominant tridiagonal Toeplitz matrix (e.g., the 1-2-1 matrix). We leave it to the reader to verify that for any shift in the stationary dqds algorithm and for each block size greater than two, the first pivot d_+ in each block is zero. Thus an NaN occurs in every block.

6. Conclusion. Evaluating the Sturm count with a qds factorization risks failure when a tiny or zero pivot causes an overflow, but avoiding those rare failures exacts a cost in performance. Following the example of Demmel and Li [8], we achieve better performance by attempting a fast but potentially erroneous qds factorization, testing for failure afterwards, and recomputing the factorization more carefully only when necessary. As shown in section 3.3, that strategy typically yields benchmark speed-ups over careful factorizations of around 1.12 across many platforms. However,

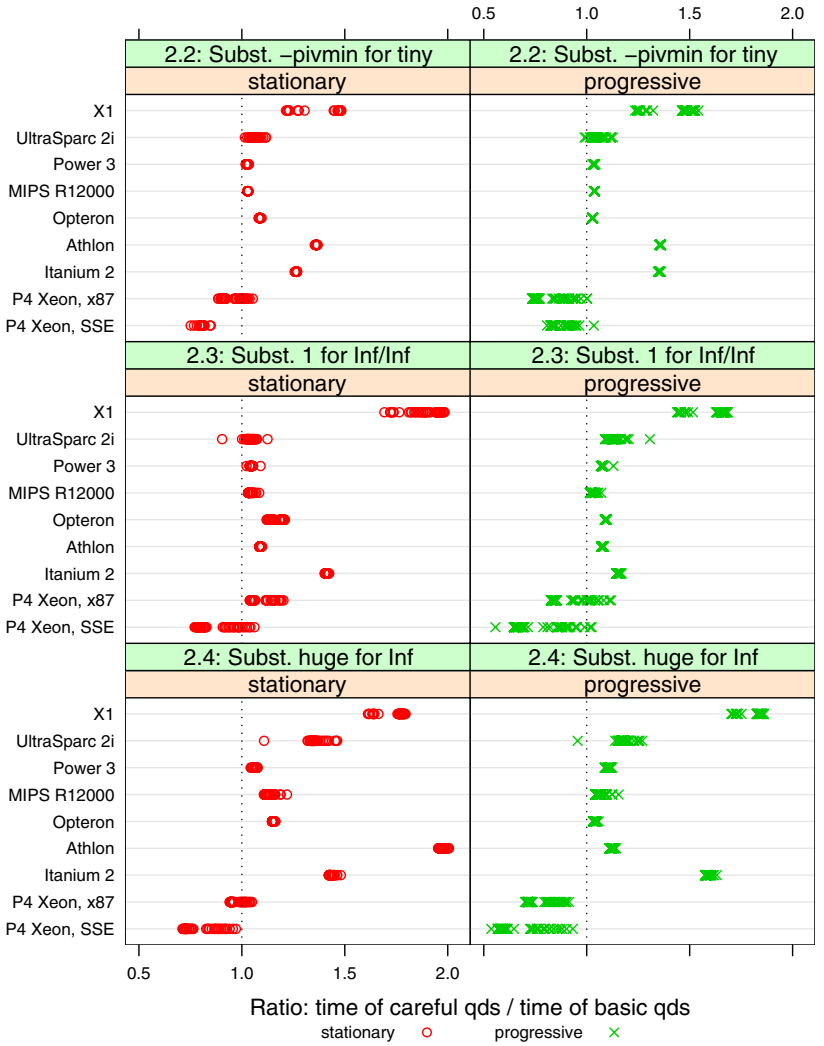

FIG. 10. *Similar improvements occur for bisection. A point at* 1.2 *means that bisection running time using the careful loop is* 1.2 *times as long as bisection time using the basic loop.*

a remarkable slow-down of up to 66× can occur for the x87 unit on the Pentium 4 Xeon in exceptional cases. For bisection on the matrices in section 4.1, we find the speed-ups vary greatly by platform and algorithm. While the median is a modest 1.08, some platforms benefit greatly. For example, bisection on the Cray X1 improves by factors of 1.2 to 2.

This paper has focused on the performance benefits of IEEE-754 features in the context of bisection. However, there are other interesting applications. We mention two related examples which should find similar benefits.

First, consider the dqds algorithm for computing the singular values of a bidiagonal matrix [14, 15, 22, 27]. There an invalid operation signals that stability has been lost. The shift to accelerate the convergence has been chosen too aggressively and

needs to be replaced by a more prudent shift.

Second, consider the MRRR algorithm's method of computing eigenvectors [23, 24, 25, 26, 9]. An invalid operation during the twisted factorization indicates that an eigenvector entry is tiny or zero. In this case, the fast product formula used to compute the eigenvector yields an incorrect result and must be replaced by a more careful formula.

Appendix A. Important implementation details. This section briefly describes important implementation details for our benchmark of the qds variants.

We describe the effort needed to test for NaNs to ensure a valid Sturm count from the unsafe loops in Algorithm 2.1. Only recently have language systems provided portable tests for NaNs. Since we cannot yet rely on those systems' availability, we provide our own test described in section A.1.

Also, Algorithms 2.3 and 2.4 must test for infinite values. Thankfully such tests can be implemented portably; see section A.2

Section A.3 discusses possible tests for the sign of a pivot.

And finally, section A.4 discusses the potential benefits and unfortunate drawbacks of using system trap handlers to treat exceptions when they occur.

A.1. Testing for NaNs. While NaN is the only IEEE-754 value for which X.EQ.X is false, many compilers in higher optimization levels replace this logical expression by a true value. In such circumstances, we have no in-line, reliable test for the presence of an NaN at run time.

For this reason, our experiments use a function of the form

```
LOGICAL FUNCTION DISNAN( DIN1, DIN2 )
DOUBLE PRECISION DIN1, DIN2
DISNAN = (DIN1.NE.DIN2)
END FUNCTION
```

that is compiled separately. Baring interprocedural analysis, the compiler must assume DIN1 and DIN2 are not related. DISNAN(X,X) thus returns true if and only if X is NaN.

Future languages will provide better support for IEEE-754 facilities. For example, the Fortran 2003 standard provides an NaN test with the IEEE_IS_NAN() function in the IEEE_ARITHMETIC module.

There is a trade-off in to test for NaNs. We could detect an NaN early by investigating the pivot in every step of the Sturm count, or we could use NaN propagation and wait and test only the final pivot. Including a test in every iteration penalizes unexceptional instances, while testing only after the loop requires loading all the data twice. Between these two extremes lies a range of blocking approaches; see section 5.

A.2. Testing for ∞. The substitutions in Algorithms 2.3 and 2.4 require a test for the presence of ∞. This can be done portably by the following code:

```
OMEGA = DLAMCH('Overflow')
ABS(X).GT.OMEGA
```

Here OMEGA (also Ω in the text) represents the overflow threshold. LAPACK provides Ω through _LAMCH('Overflow'). In Fortran 90, the enquiry function HUGE(X) returns the overflow threshold for the precision of its argument X. And Fortran 2003 provides IEEE_IS_FINITE() in the IEEE_ARITHMETIC module to test for nonfinite IEEE-754 values directly.

A.3. Testing the sign of a pivot. The straightforward way to count negative pivots in Fortran is to compare the pivot to zero, as in the following:

```
IF( PIVOT.LT.ZERO ) NEGCOUNT = NEGCOUNT + 1
```

The Cray compiler recognizes the sign test inside the inner loop and performs an interesting optimization to partially vectorize it. The pivots from a portion of the loop are copied into the intermediate vector. Then the entire vector is tested and converted into mask bits, and those mask bits are counted to provide a NEGCOUNT increment.

Another possible implementation copies the sign bit of PIVOT to an integer as 0 or 1, then adds that integer to NEGCOUNT. We lack a clear, direct way of expressing that implementation in Fortran.

A.4. Handling exceptional cases through traps. Algorithms 2.3 and 2.4 both explicitly test for exceptional operations. However, many platforms support implicit tests through ... A trap in this context is an implicit transfer of control from the exceptional operation to a ... The handler examines the exceptional operation and its operands and then returns a new result for the exceptional operation.

Trapping allows algorithms to run without explicit branches to test for exceptional cases; the tests are performed in hardware during floating-point operations. However, traps are only an optional feature in IEEE-754 [4]. While being widely implemented, each operating system and processor combination uses a different programming interface. This makes trap-handling nonportable. Furthermore, invoking a floating-point trap usually incurs expensive bookkeeping in both the processor and the operating system.

We experimented with trap handlers on three platforms with reasonable but very different interfaces: Solaris on an UltraSparc 2i, AIX on a Power3, and Linux on a Pentium 3. A single exceptional operation on any of these platforms increased the running time by a factor of at least 1000.

Acknowledgments. We would like to thank Prof. Kahan for Algorithm 2.4 and many comments. The anonymous reviewers provided very valuable advice and perspectives.

A CACHE-AWARE ALGORITHM FOR PDES ON HIERARCHICAL DATA STRUCTURES BASED ON SPACE-FILLING CURVES*

FRANK GÜNTHER†, MIRIAM MEHL‡, MARKUS PÖGL§, AND CHRISTOPH ZENGER‡

Abstract. Competitive numerical algorithms for solving partial differential equations have to work with the most efficient numerical methods like multigrid and adaptive grid refinement and thus with hierarchical data structures. Unfortunately, in most implementations, hierarchical data—typically stored in trees—cause a nonnegligible overhead in data access. To overcome this quandary—numerical efficiency versus efficient implementation—our algorithm uses space-filling curves to build up data structures which are processed linearly. In fact, the only kind of data structure used in our implementation is stacks. Thus, data access becomes very fast—even faster than the common access to nonhierarchical data stored in matrices—and, in particular, cache misses are reduced considerably. Furthermore, the implementation of multigrid cycles and/or higher order discretizations as well as the parallelization of the whole algorithm become very easy and straightforward on these data structures.

Key words. partial differential equations, space-tree, space-filling curves, cache-awareness

1. Introduction.

Most of the computing time in the numerical solution of partial differential equations (PDEs) is usually spent for the multiplication of a sparse matrix, representing the discrete operator, with a vector, representing the approximate solution. The amount of computing time and also the amount of memory heavily depend on the data structure used to represent the matrix and the solution vector. Many clever approaches are known, but it is usually impossible to access the memory in the course of the computation in such a way that the addresses do not "jump." As modern computer architectures use one or more cache-levels for the access of memory, jumps in the address space may cause cache misses, leading to a sometimes dramatic slow down of the computation. This fact is actually one of the most serious bottlenecks in high performance computing.

It seems to be very difficult to avoid these jumps in general. Therefore, we restrict our attention to a more special situation which is nevertheless general enough to be useful in many applications. The grid in our context is restricted to grids associated with space-trees [2], but we allow local (adaptive) refinement because adaptivity is crucial for the efficient solution of many problems. Moreover, space-trees allow a simple implementation of modern multilevel methods (additive or multiplicative) using appropriate hierarchical bases or generating systems [14], as we shall see in what follows. Hierarchical bases or generating systems also allow the simple handling of hanging nodes appearing in cases of local refinement. Complicated geometries can also be described easily by space-trees if some care is taken with a reasonably accurate discretization near the boundary.

As a main result of this paper, we show that in this restricted context we can avoid random access in the memory almost completely by using only a fixed and

small number of stacks independent of the number of nodes in the grid. Stacks can be considered as the most simple data structures used in computer science. The two basic operations allowed on stacks are push and pop, where push puts data on top of a pile and pop takes data from the top of a pile. It is immediately clear that subsequent accesses to memory can move only from one memory location to the previous or next location, and thus stacks can be implemented very efficiently on modern computer architectures.[1] As a consequence, the organization of our algorithms has to be done in such a way that the data needed in the sequence of operations are always on top of one of the stacks, avoiding transports from one stack to another to get access to elements deeper in the stack.

The present algorithm described in this paper is based on a standard finite element discretization, but the principle behind it can be adapted to other discretization schemes as well. The leaves of the space-tree describe the finite elements and, during the accumulation process for the operator matrix, which is not explicitly stored but instead directly applied to the approximate solution, these elements are visited in an order described by a space-filling curve, the so-called Peano curve.

Space-filling curves are a well-known device for designing efficient algorithms in computer graphics (see, e.g., [35, 37]). In the context of numerical simulations based on space-trees, space-filling curves are already an established tool for some key-based addressing of grid elements and/or nodes and, in particular, data parallel implementations (see, e.g., [28, 40, 41, 15, 16, 23, 24, 25, 32, 34, 18, 27, 26, 9]). The grid partitioning algorithm defined by space-filling curves can be shown to have linear complexity and to give quasi-optimal partitions with respect to cut-sizes [40]. In addition, the partitioning is well suited for multilevel grids [40, 41, 15, 16, 24, 32, 18, 27].

It is also known that—due to locality properties of the curves—reordering grid cells according to the numbering induced by a space-filling curve improves cache-efficiency (see, e.g., [1]). Similar benefits of reordering data along space-filling curves can also be observed for other applications such as matrix transposition [7] or matrix multiplication [8]. We go one step further and, in addition to the reordering of cells, construct stacks for which we do not need any addressing and/or hashing, as we always know that all data needed lie on top of one of the stacks and can thus be accessed in an even more cache-efficient way.

In contrast to other approaches to cache-optimizations for PDE solvers that work with some hardware-oriented strategies like specialized data padding [20], the efficiency of our algorithm does not depend on the particular setting of cache parameters like cache-line length, associativity, etc. In the literature, such algorithms which are cache-aware by concept without detailed knowledge of the cache parameters are also called cache-oblivious [6, 12, 31]. The general need for cache-optimization on the software side can easily be deduced from the impossibility of the implementation of an optimal replacement strategy for the cache-lines on the hardware side [36].

Section 2 gives some basic background information on the operator evaluation during a run along a space-filling curve; in section 3, the essence of our algorithm, the construction of stacks with the help of the Peano curve, is described. Section 4 describes the realization of some numerical algorithms like multigrid and evaluation of the operator matrix on adaptively refined grids. Finally, in section 5, we give some results—processing times, number of cache misses, etc.—for some test examples. Section 6 briefly describes the extension to the three-dimensional case including numerical results.

[1] Conflicts in the cache between different stacks are minimal due to the small number of stacks, as we could show by the extremely high cache hit-rates achieved (see section 5).

2. Operator accumulation along space-filling curves. In the mathematical definition, a space-filling curve is a surjective continuous mapping of the unit interval $[0;1]$ to a compact d-dimensional domain Ω with positive measure. In our context, Ω is always the unit square, or the unit cube in three dimensions. As we look at multilevel adaptive rectangular grids, we restrict ourselves to recursively defined, self-similar space-filling curves with rectangular recursive decomposition of the domain. These curves are given by a simple generating template and a recursive refinement procedure which describes the (rotated or mirrored) application of the generating template in subcells of the domain to be covered [33]. Prominent representatives of this class of space-filling curves are the Hilbert curve and the Peano curve. See Figure 2.1 for some iterates of the two-dimensional curves.

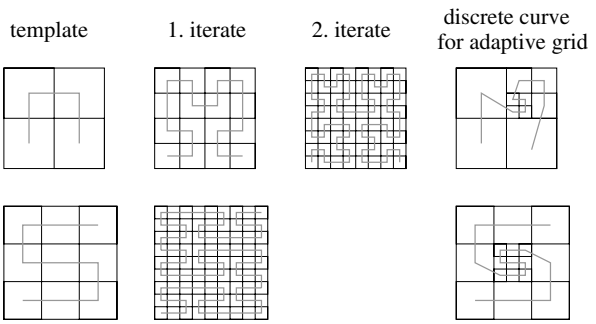

FIG. 2.1. *Generating templates, first iterates, and discrete curve on an adaptively refined grid for two-dimensional Hilbert and Peano curves.*

In fact, as our grids have finite resolution, the iterates—so-called discrete space-filling curves—are what we need (instead of the continuous space-filling curves). If we work with adaptively refined grids, the iterate that we use in a particular part of our domain depends on the local resolution (see also Figure 2.1 for some examples).

In our algorithm, this discrete space-filling curve defines the processing order of grid cells, corresponding to the leaves of our space-tree in a single-level context or to all nodes of the space-tree in a multilevel context. The application of the operator-matrix to the vector of data is done in a strictly cell-oriented way. For this, we decompose the discrete operator into parts per cell, which accumulate to the result of the operator evaluation after one run over all grid cells. This method is standard for finite element methods (see, e.g., [5]) but can be generalized to "local" discrete operators, which means that for the evaluation in one grid point, only direct neighbors are needed. In some cases—if the operator can be composed of a small number of local operators—this restriction can even be weakened. To illustrate the cell-oriented operator decomposition, we look at the one-dimensional three-point stencil

$$\begin{bmatrix} 1 & -2 & 1 \end{bmatrix}.$$

This simple stencil can be decomposed into a cell-part

$$\begin{bmatrix} 1 & -1 \end{bmatrix}$$

for the grid cell at the left-hand side of the respective point and

$$\begin{bmatrix} -1 & 1 \end{bmatrix}$$

for the grid cell at the right-hand side.

Thus, if we look at a space-tree with function values located at the vertices of cells, we have to construct our stacks such that all data from the respective cell-vertices lie on top of the stacks when we enter the cell during our run along the discrete space-filling curve.

3. Construction of stacks.

3.1. Regular grids with nodal data. To show the interaction of discrete space-filling curves and data stacks, we will start with a simple regular two-dimensional grid and nodal data. Figure 3.1 shows a grid where the processing order of grid cells is given by a discrete Peano curve.

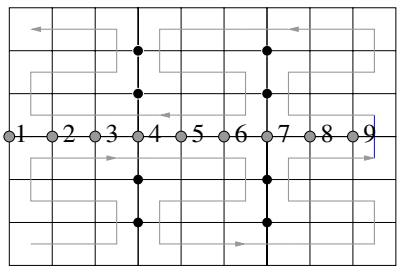

FIG. 3.1. *Example in two dimensions using the Peano curve.*

Let us have a closer look at data points on the middle line marked by 1 to 9. In the lower part of the domain, these data are processed linearly from 1 to 9; in the upper part, vice versa from 9 to 1. For the Peano curve and a regular grid, this linear forward and backward processing of the middle line can be shown for arbitrarily fine grids as well. Analogously, all other grid points can be organized on lines which are processed linearly forward and backward if we use the Peano curve to define the processing order of cells. Therefore, we organize all data within the well-known concept of stacks where we only have two possibilities of data access:

- push(data,number): write data on top of stack number,
- pop(number): read uppermost element of stack number.

Here, data is a structure in which all physical information of a grid point is held—for example the velocity vector and the type of boundary conditions.

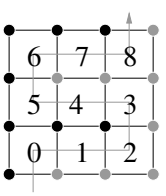

FIG. 3.2. *Stacks resulting from the usage of the Peano curve.*

A closer look at the two-dimensional example in Figure 3.2 shows that it is sufficient to have two stacks: $1D_{black}$ for the points on the right-hand side of the curve and $1D_{grey}$ for the points on the left-hand side of the curve. These stacks represent the evolving lines of points along the curve as described above. The behavior of a point concerning read and write operations on stacks can be predicted in a locally

deterministic way. We only have to classify the points as "inner points" or "boundary points" and respect the progression of the curve.

If we have a closer look at the example for the Peano curve, we can already extract two important properties that our space-filling curves have to fulfil: First, the processing order of grid points on a line has to be inverted if on our way along the Peano curve we switch from the domain on the right-hand side of the line to the domain on the left-hand side. This is quite easy to fulfill in the two-dimensional case, but in the three-dimensional case the same has to hold for grid points on planes (parallel to the coordinate planes). Second, a refinement of the grid must not destroy the order of existing points, but insert new points only between existing points. We could not find any Hilbert curve in three dimensions fulfilling these two properties, and there are good reasons to assume that this is not possible at all. Thus, we restrict our attention to Peano curves in the following. For the Peano curve even generalizations to four or more dimensions are straightforward.

It is a disadvantage of the Peano curve that in the refinement process each side of a cube is partitioned into three equal parts, leading to ternary trees instead of the standard binary trees used for quad-trees or octrees. This implies that the number of grid points grows like 3^d instead of 2^d in d-dimensional space from level to level. This implies that for a three-dimensional problem the number of grid points is multiplied by a factor of 27 if we add another refinement level.

An efficient algorithm deduced from the concepts described above passes the grid cell-by-cell and pushes/pops data to/from stacks deterministically and automatically. It will be cache-aware by design (independent of the actual cache-parameters such as cache-line-length, cache-size, etc.) because using linear stacks is a good idea in conjunction with caches that always load a whole block of neighboring data (cache-line) at once and, in addition, with modern processors using prefetching techniques.

3.2. Iterations on data. In the previous section, we have talked only about the intermediate storage of data within one solver iteration, but we have not yet mentioned where data come from when they are needed for the first time during a solver iteration and where we put them when they are "ready" (that is, when all work for the current situation is done at the corresponding point). For this purpose, we have to enhance our stack system by some input and output stacks to store all data between iterations. For this, we use so-called $2D$- or plane-stacks (as they include all data of the whole two-dimensional computational domain). The input stack contains all vertex data in the order of their first usage during one iteration. In fact, it acts as an input stream rather than a stack. Analogously, to store the output of the iteration, we again write all points to a $2D$-stack—the output stack or output stream—as soon as they are ready. It can easily be seen that, if we process the grid cells in the opposite direction in the next iteration, we can directly use the output stack as an input stream again. We apply this repeatedly and thus change the processing direction of grid cells after each iteration.

3.3. Extension to adaptive grids and hierarchical data. Up to this point, we have restricted our considerations to regular grids to explain the general idea of our algorithm, but the full potential of our approach becomes obvious only when we look at adaptively refined grids and, in the general case, hierarchical data in connection with generating systems [14]. This leads to more than one degree of freedom per grid point and function on coarse grid levels.

Before we can define our stacks for this case, we need an algorithm which now recursively visits the cells of different grid levels in a top-down depth-first process.

Since the discrete space-filling curve is defined by a recursion itself, this order can be deduced directly from the space-filling curve of the respective level. Figure 3.3 shows an example for such an order. The first cell visited is the coarsest cell, containing the whole domain. Next, the cells of the first refinement level are processed according to the first iterate of the Peano curve. As soon as we reach a cell which is further refined (in this example the middle cell), we process all "sons" of this cell according to the respective part of the next iterate of the Peano curve before we return to the next cell of the first refinement level.

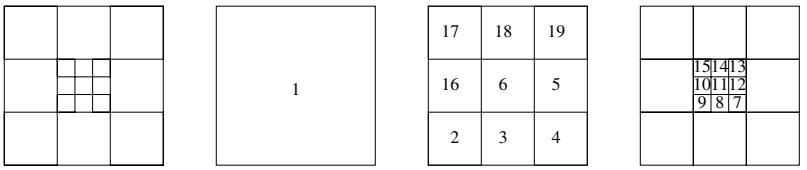

FIG. 3.3. *Example for the order of hierarchical cells defined by the discrete Peano curve.*

In our stack context, we have to assure even then that predictable and linear data access to and from stacks is possible. As points are visited on different grid levels now, we have to assure that grid points of coarser grid levels lie above those of finer levels in our stacks. Therefore, we have to change two basic properties of the concept described above: First, we have to realize restrictions and interpolations in addition to the pure evaluation of difference stencils, and thus we have to consider cells consisting of 3×3 finer cells and thus containing 16 grid points instead of single cells with only 4 grid points. Second, we have to introduce four "colors" instead of two (in Figure 3.4, the four colors are marked by crosses, circles, triangles, and squares) and a second type of stacks, so-called $0D$-stacks, in addition to the $1D$-stacks. The $0D$-stacks can be interpreted as an intermediate storage for vertex data to avoid the hiding of information associated with different levels, whereas the $1D$-stacks represent certain grid lines or parts of them, respectively. Again, we have a small and fixed number of stacks which is, in particular, independent of the problem size: four $1D$-stacks and four $0D$-stacks transporting hierarchical data over grid levels.

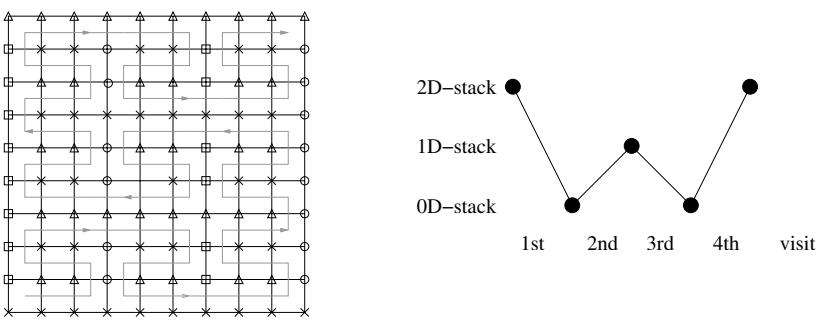

FIG. 3.4. *Left: recursive assignment of vertices to four "colors" and eight stacks; right: "way" of vertex data over the different stack types during one iteration of a two-dimensional solver visiting each vertex four times (corresponding to the four neighboring cells).*

For the formal construction of these stacks, we start with the one-dimensional case with nodal data, extend it to the one-dimensional case with hierarchical data (generating system), and finally generalize the concept to the two-dimensional case.

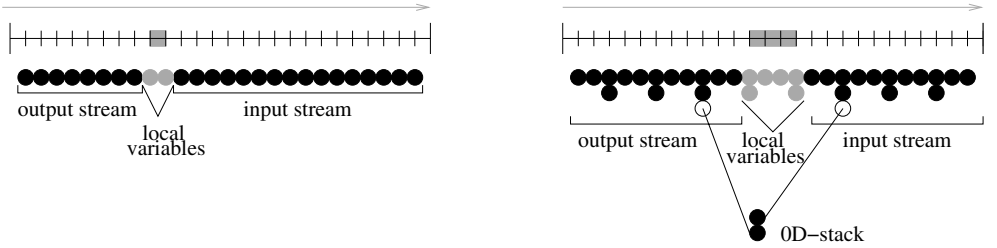

FIG. 3.5. *Illustration of the function and usage of stacks in the one-dimensional case (left: nodal data on a regular grid, right: hierarchical data (generating system)).*

The one-dimensional case with nodal data on a regular grid is trivial to handle: We process the grid cells from the left to the right (or vice versa) and, thus, do not need any stacks for the intermediate storage of points during one solver iteration. If we now introduce hierarchical data in the sense of a generating system, we cannot put every data point directly from the input- to the output-stream, since data points (degrees of freedom) associated with coarser grid levels are used once during the descend phase in the cell tree (to perform the interpolation to finer grids, e.g.) and a second time during the ascend phase (to restrict fine grid data to the respective points, e.g.). In between, we do (and finish) the work on all finer cells that are children (grandchildren, ...) of the respective coarse grid cell. Thus, to be able to access coarse grid points in the ascent phase again, we have to provide an intermediate data structure which we call the $0D$-stack (compare Figure 3.5). In fact, the two stack-operations `put` a datum on top of the stack and `pop` a datum from the top of the stack are sufficient, since at each point in time during a solver iteration, the $0D$-stack contains all vertex data of father (grandfather, ...) cells of the current cells in a top-down order and thus in just the correct order to find the currently needed data on top of the stack during the subsequent ascent of the cell tree.

For the extension to the two-dimensional case, we first reduce the two-dimensional data set to one-dimensional structure, and second reduce the handling of these structures to the one-dimensional case described above. As described in section 3.1, we can identify two lines of vertices processed in one direction during the first pass of the Peano curve and in the opposite direction during the second pass of the curve. If we now decompose those two lines into vertical and horizontal parts each (see Figure 3.4),[2] we end up with lines of vertices completely analogous to the one-dimensional lines considered above. The only difference is that they are not processed once but twice (once in each direction) during one solver iteration. Thus, one iteration of the two-dimensional solver corresponds to two iterations (with alternating processing directions) over the one-dimensional line. Altogether, we end up with eight stacks: one so-called $1D$-stack each for the vertical and the horizontal components of the two vertex groups from section 3.1, and one $0D$-stack for each of the $1D$-stacks. This results in the following "way" over the stacks for each data point associated with the grid vertices. At the beginning of a solver iteration, data are all stored in the $2D$-stack in the order of their first occurrence (like for the simple case of regular grids and nodal data). After their first usage, they are treated like vertices of a one-dimensional grid; that is, we move them to the $0D$-stack corresponding to the associated line (Figure 3.4) and, after the second usage, to the $1D$-stack, replacing the output stack

[2] [13] gives an example showing that the decomposition into vertical and horizontal parts is necessary to avoid a hiding of data between vertical and horizontal lines.

from the one-dimensional case. Subsequently, they are visited yet another two times in the opposite direction; that is, they are again first moved to the $0D$-stack and subsequently to the output stack, and then finally to the output stack (this time the $2D$ output stack; see Figure 3.4).[3]

With the ideas described above, we can now define numerical algorithms suited to adaptively refined grids, hierarchical data, and generating systems in the following section.

4. Numerical algorithms. As mentioned above, our data structures are very well suited for highly efficient numerical methods such as multigrid, adaptive grid refinement, and higher order discretizations. In this section, we will describe the concrete algorithmic realization of these methods.

We assume that we have to solve a system of linear equations

$$L_h u_h = f_h, \tag{4.1}$$

where h indicates the (locally defined) width of the square/cubic grid cells and the discrete operator L_h results from some "local" (see above) discretization of a differential operator.

4.1. Relaxation methods. Before we describe the implementation of a multigrid method, we will briefly mention the realization of relaxation methods with the help of our stacks and the cell-oriented evaluation of operators: The only thing special in comparison to standard implementations is that we do not compute the residual components $r_h^{(i)} = f_h^{(i)} - (L_h u_h)^{(i)}$ in one step per point, but accumulate them while visiting neighboring cells (as described above when we explained the cell-oriented evaluation of operators). For this, we need an appropriate decomposition of the right-hand side into cell-parts, which can easily be achieved, for example, by dividing f_h into four equal parts, which are assigned to the four neighboring cells. As soon as a grid point is visited the last time, we have computed the whole residual, and the respective value is updated according to the iteration scheme used.

4.2. Multigrid. As, in our stack, we store data of all refinement levels of the grid, the algorithm works on a generating system (in the context of finite elements) instead of a basis only. A multigrid cycle corresponds to a single run over all data. Thus, multigrid does not worsen the performance, in terms of runtime efficiency, of our program. In the following, we will briefly describe the basic ingredients of our additive multigrid algorithms, which turn out to perform well for adaptively refined grids in [4].

In contrast to relaxation methods, the multigrid method works on the whole set of hierarchical data, not only on the finest level. As described in the previous section, data are processed in a top-down, depth-first order (see also Figure 3.3 for an example of the processing order of cells). Thus, we cannot finish one step (smoothing, interpolation, or restriction) at all grid points of a level before we proceed to the next level. The cycle function is called recursively for all (nine in the case of two-dimensional Peano curves) subcells of a coarse cell, and thus, whenever we enter a cell, the whole work for one multigrid cycle within this cell has to be finished before we enter the next cell of the same level. Therefore, the natural choice in terms of our algorithm is an additive multigrid method where smoothing is done simultaneously

[3] Vertices visited directly consecutively are, of course, not moved to a stack in between but are kept as local variables.

on all levels.[4] Descending the space-tree[5] within the top-down depth-first run over the grid along the Peano curve, we interpolate coarse grid values to the finer grids in order to achieve nodal values on the finest grid. At the finest level we compute the residual and apply the smoother. Ascending the space-tree, we restrict the residual to the coarse levels and apply the smoother on the coarse levels.

1. We have to take care that residuals are correctly transported from fine to coarse grid points: Since we restrict the residual each time we visit a fine grid point (and only when the whole residual is computed), we may restrict only the cell-part of the respective residual and not the accumulated residual. This complication requires some additional local variables for the cell-parts of the residual.

2. As we use a generating system for u_h instead of nodal values, coarse grid corrections are simply done by smoothing the coarse-grid coefficients of the function representations. The transport to fine grid values is done implicitly during dehierarchization of u_h.

4.3. Adaptively refined grids. If we use the processing order of cells and the construction of stacks described in the previous section, adaptively refined grids can also be handled in a very natural way without any further complications, like, for example, special difference stencils at borders between differently refined areas.

Like for regular grids, we compute all operators in a cell-oriented way. Thus, the stencils used look the same for each cell (up to a potential scaling with the cell width h). Thus, in a first step, we end up with contributions to operators at all vertices of cells at the locally finest level. In particular, hanging nodes also have to carry function values and contributions to the operators. To eliminate hanging nodes from the system of equations (hanging nodes may not be considered as degrees of freedom!) we have to compute interpolated function values at hanging nodes before the operator evaluation and distribute the respective cell-part of the operators to the neighboring coarse grid points by some suitable restriction. With this restriction, we automatically get correct operator values at all coarse grid points. From the algorithmic point of view, this interpolation and restriction works completely analogously to the multigrid interpolation and restriction.

5. Examples. To point out the potential of our algorithm, we show some simple examples and the achieved results and make some remarks on the efficiency of our program concerning storage requirements, processing time, and cache behavior. Note that at this stage we are working with an experimental code which is not yet optimized at all. Thus, absolute values like computing time will be improved further, and our focus here is only on the cache behavior and the qualitative dependencies between the number of unknowns and the performance values like computing times.

5.1. Poisson equation on the unit square. As a first test, we solve the two-dimensional Poisson equation on the unit square with homogeneous Dirichlet boundary conditions:

$$\triangle u(\mathbf{x}) = -2\pi^2 \sin(\pi x)\sin(\pi y) \quad \forall\, \mathbf{x} = (x,y)^T \in \Omega =]0,1[\times]0,1[\,, \tag{5.1}$$

$$u(\mathbf{x}) = 0 \quad \forall\, \mathbf{x} \in \partial\Omega. \tag{5.2}$$

[4]The implementation of a multiplicative multigrid method is possible but requires additional techniques to outsource fine grid data currently not needed on coarser grid levels to separate data structures and to afterwards insert them into the input-stream again. The algorithmic methods needed are similar to those used for dynamical adaptivity [10] and currently in the implementation phase.

[5]In contrast to "descending" in the common context of multigrid methods, descending in our context means proceeding from the coarsest level to the finest.

The exact solution of this problem is given by $u(\mathbf{x}) = \sin(\pi x) \cdot \sin(\pi y)$. To discretize the Laplace operator, we use the common finite element stencil

$$\begin{bmatrix} 1 & 1 & 1 \\ 1 & -8 & 1 \\ 1 & 1 & 1 \end{bmatrix}.$$

The resulting system of linear equations is solved by an additive multigrid method with bilinear interpolation and full-weighting as restriction operator. As criteria for termination of the iteration loop we take a value of $r_{max} = 10^{-5}$, where r_{max} is the maximum (in magnitude) of all corrections over all levels. Table 5.1 shows performance values obtained on a dual Intel XEON 2.4 GHz with 4 GB of RAM for regular grids with growing resolution. All measurements of the cache-performance were realized with the help of the tools , or , which are based on [19] by Hewlett-Packard and which allow access to the hardware performance counters of the respective processors.

TABLE 5.1
Performance values for the two-dimensional Poisson equation on the unit square solved on a dual Intel XEON 2.4 GHz with 4 GB of RAM.

Resolution	Variables over all levels	Iterations	MFLOPS	CPU time (s)	L2 cache misses per iteration	#real misses / #minimal misses
243×243	65,708	39	354.55	5.800	134,432	1.09
729×729	595,692	39	360.20	52.130	1,246,949	1.12
2187×2187	5,374,288	39	359.65	472.410	11,278,058	1.12

Note that the number of iterations until convergence is independent of the resolution, which one would have expected for a multigrid method.

Table 5.1 shows very high L2 hit-rates of at least 99.13% measured on an Intel XEON, which is a very high value for "real" algorithms beyond simple programs for testing performance of a given architecture. Even more significant for the efficiency of our algorithm is the result of a comparison of the minimal number of necessary cache misses and actually measured cache misses: With the size s of a stack element, the number n of degrees of freedom, and the size cl of an L2 cache line on the architecture used, we can guess a minimum $cm_{min} = \frac{n \cdot s}{cl}$ of cache misses per iteration, which has to occur if we read each grid point once per iteration, producing $\frac{s}{cl}$ cache misses per point. In fact, grid points are typically used several times (in our case once by each of the four neighboring cells) in our algorithm, as well as in most FEM-algorithms. Thus, even this minimum guess is assumed to be too low. The entries of the last column in Table 5.1 are defined as $\frac{cm_{real}}{cm_{min}}$, where cm_{real} are the L2 cache misses per iteration simulated with `calltree`. As this rate is nearly 1 in our algorithm, we produce hardly more cache misses than if we used every grid point only once per iteration.

5.2. Poisson equation on a disk. The examples above show a very high performance on the L2 cache for full grids, but the major advantage of our method is that this holds also for adaptive grids and for more complicated geometries. To show this at least for a simple example, we consider the two-dimensional Poisson equation with inhomogeneous Dirichlet boundary conditions on a disk with radius one:

$$\triangle u(\mathbf{x}) = -2\pi^2 \sin(\pi x) \sin(\pi y) \quad \forall\, \mathbf{x} = (x, y)^T \text{ with } \|\mathbf{x}\| < 1, \tag{5.3}$$

$$u(\mathbf{x}) = \sin(\pi x) \cdot \sin(\pi y) \quad \forall\, \mathbf{x} \in \partial\Omega. \tag{5.4}$$

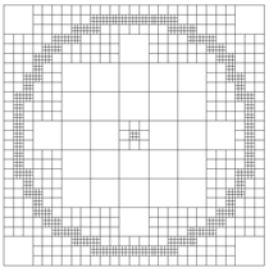

FIG. 5.1. *Representation of the disk with the help of an adaptive grid gained by a geometry-oriented coarsening of a* 81×81 *grid.*

TABLE 5.2
Performance values for the two-dimensional Poisson equation on a disk solved on a dual Intel XEON 2.4 GHz with 4 GB of RAM. "Iter" is the number of iterations.

Variables	% full grid	Computing time (s)	L2 hit-rate	Iter	time per iteration (ms)	time per variable and iteration (ms)
66220	15.094%	39.68	99.28%	287	138.26	0.002088
101146	23.055%	58.95	99.26%	287	205.40	0.002031
175578	40.021%	97.10	99.20%	286	339.51	0.001934
438719	100.00%	250.23	99.16%	281	890.50	0.002030

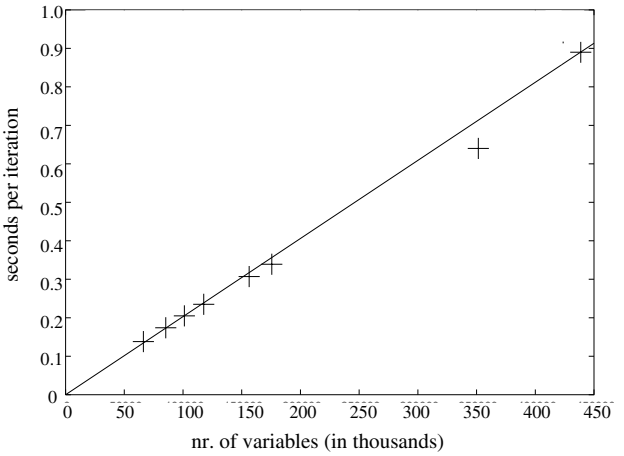

FIG. 5.2. *Linear dependency: number of variables versus computing time.*

Figure 5.1 shows the representation of the disk with the help of an adaptive grid gained by a geometry-oriented coarsening of an initial grid with 81×81 cells.

For our numerical tests, we used different adaptive grids gained by local coarsening strategies starting from an initial grid with 729×729 cells. To get sufficient accuracy near the boundary, we did not allow any coarsening of boundary cells.

The stopping criterion for the iterative solver was again $|r_{max}| < 10^{-5}$. In Table 5.2, the last column shows the amount of time needed per variable and per iteration. These values are nearly constant or even better for some adaptive grids than for the full grid. In Figure 5.2 you see the value "seconds per iteration" plotted against

the number of variables with crosses. The solid line is the corresponding line from the origin through the full grid point $(438719, 768.934)$. We see that we have a linear dependency between the number of variables/grid points and the computing time, no matter whether we have a regular full grid or an adaptively refined grid. This is a remarkable result, as we can conclude from this correlation that in our method variables on coarser grids do not have higher costs than those on the finest level.

6. Extension to three dimensions. In the previous sections we considered only the two-dimensional case. However, as mentioned in the introduction, our concepts can be generalized in a very natural way to three or even more dimensions. In this section, we want to give a few preliminary results on the three-dimensional case. The basic concepts are the same as in the two-dimensional case, but to achieve an efficient implementation, we introduce some changes and/or enhancements in the concrete realization.

The first, and obvious, change is that we need $3D$ in- and output stacks and $2D$-, $1D$-, and $0D$-stacks (corresponding to faces, edges, and vertices of a cube) during our run through the space tree instead of $1D$- and $0D$-stacks only. In addition, we use twelve $0D$- and $1D$-stacks each and six $2D$-stacks. These results can be deduced in a recursive way from the two-dimensional case (similarly as we deduced the two-dimensional case from the one-dimensional case): We decompose the set of vertices into "planes," distinguishing between the three possible orientations of a plane and the side of the curve (left, right) on which they are situated. Each of these six types of planes (corresponding to the six $2D$-stacks) can be handled like a two-dimensional set of vertices, again with the only difference that a solver iteration in three dimensions corresponds to two iterations over the respective planes. Since several planes can share the same $1D$- and $0D$-stacks, we need only twelve types of them instead of 24. The proof for the correctness of this concept can be found in [22]. Figure 6.1 shows the "way" of a data point over the stacks in the three-dimensional way.

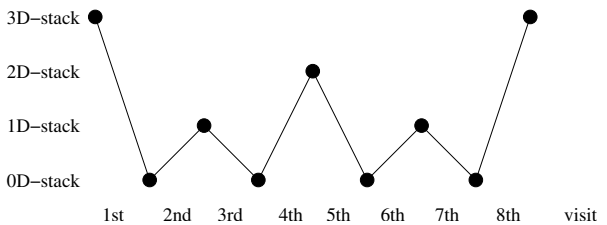

FIG. 6.1. *Way of data points over the different types of stacks in the three-dimensional case.*

Another interesting aspect in three dimensions is that we replace the direct refinement of a cell by the introduction of 27 subcells through a dimension recursive refinement: A cell is cut into three "plates" in a first step, each of these plates is cut into three "bars," and finally, each bar is cut into three "cubes" (see Figure 6.2). This reduces the number of different cases dramatically and can even be generalized to arbitrary dimensions [17]. Detailed descriptions of the three-dimensional implementations, including dynamical adaptivity, higher order discretizations, and full multigrid methods, are given in [30, 22, 10].

As can be seen from the following example, the performance of our algorithm carries over from two to three dimensions. The L2 hit-rates even get better by an order of magnitude (from 99% in the two-dimensional case to 99.99% in the three-

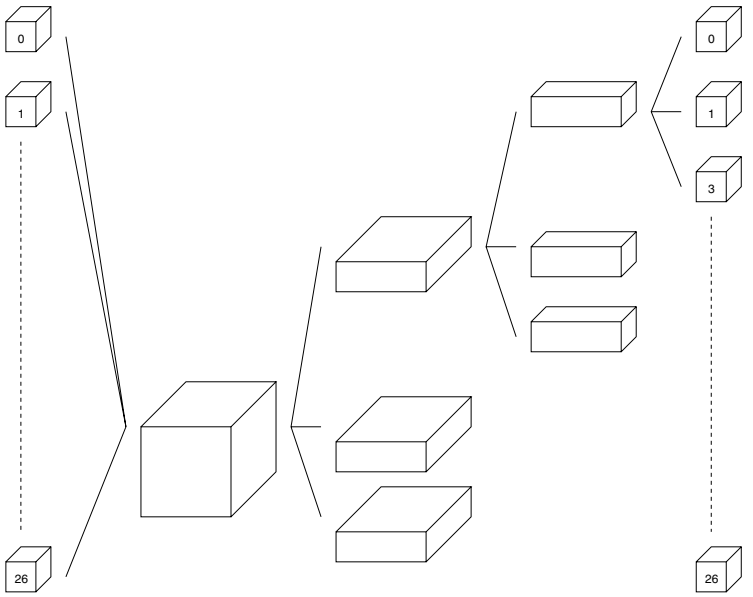

FIG. 6.2. *Dimension recursive refinement of a cell.*

TABLE 6.1
Performance values for the three-dimensional Poisson equation on a star-shaped domain solved on a dual Intel XEON 2.4 GHz with 4 GB of RAM. Abbreviations as in Table 5.2.

Resolution of the full grid	Variables	Storage requirements	Computing time (s)	L2 hit-rate	Iter	time per variable per iteration (ms)
$243 \times 243 \times 243$	508,528	9MB	2,405.86	99.99%	103	0.0459
$729 \times 729 \times 729$	13,775,328	230MB	63,502.14	99.98%	103	0.0448

dimensional case). Only the absolute computing time per variable and per iteration become worse. Both phenomena can easily be explained for the most part by the more complicated discretization stencil, with more nonzero entries which cause bigger computational cost, on the one hand, but also a larger number of operations performed per data point.

We solve the three-dimensional Poisson equation

$$\triangle u((\mathbf{x})) = 1 \tag{6.1}$$

on a star-shaped domain (see Figure 6.3), a sphere, and the unit cube with homogeneous boundary conditions. The Laplace operator is discretized by the common finite difference stencil, and—analogously to the two-dimensional case—we use an additive multigrid method with trilinear interpolation and full weighting as restriction operator. The termination criterion was $|r_{max}| \leq 10^{-5}$. Tables 6.1 and 6.2 show performance values obtained on a dual Intel XEON 2.4 GHz with 4 GB of RAM for adaptive grids (see also Figure 6.3 for a part of the (adaptively coarsened) $243 \times 243 \times 243$ grid for the star-shaped domain). For the star-shaped domain, the grid-coarsening was restricted to the portion of the domain outside the computational domain. Table 6.3 shows another important advantage of our algorithm—that we could handle a huge number of degrees of freedom with the same performance (e.g., over 400,000,000

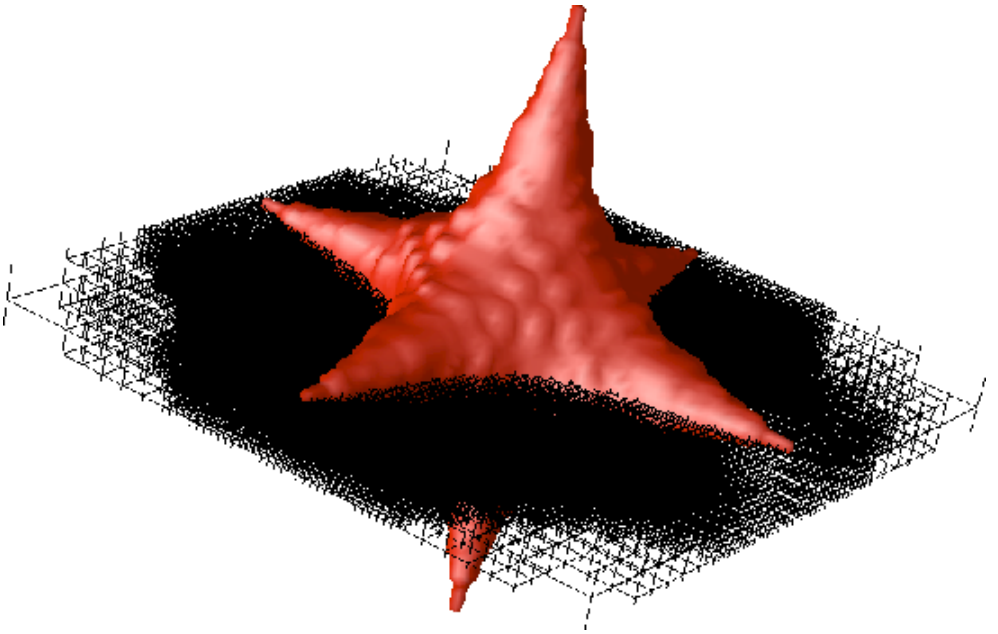

FIG. 6.3. *Representation of the star-shaped domain with the help of an adaptive grid gained by a geometry-oriented coarsening of a* $243 \times 243 \times 243$ *grid.*

variables) and with a very small amount of memory. The high number of iterations needed for the star-shaped domain, in particular, can be ascribed first to the worse performance of additive multigrid schemes in comparison to multiplicative ones, especially as tuning the relaxation parameter becomes more and more tricky for complicated problems, and second to the relatively bad approximation of complicated geometries on the coarse grid levels. Both problems, the switch to multiplicative multigrid methods and the better approximation of complicated geometries on coarse grids, are subjects of our current work.

7. Conclusion. In this paper we have presented a method combining several features for the solution of PDEs:

- adaptivity,
- efficient multilevel algorithm,
- geometrical flexibility,
- suitability for modern computer architectures (cache-awareness and parallelizability combined with load balancing),
- suitability for general discretized systems of PDEs.

The present implementations include the first three of these aspects and part of the fourth aspect. However, the implementation of the other features is not difficult. The parallelization of the method follows step-by-step the approach of Zumbusch [40], who has already successfully used space-filling curves for the parallelization of PDE-solvers. The generalization to systems of PDEs is also straightforward. [38] implemented a version solving the two-dimensional Navier–Stokes equations, and [29] presents results for problems with nonconstant coefficients.

All codes used here are still in an experimental state, in particular without any runtime optimization. Optimization is one of the main tasks of our current work, where we concentrate on testing the applicability of different methods like exploiting locally regular grid parts for a better vectorization, or methods similar to those used in [11, 20, 21, 39] or with the help of streaming SIMD[6] extensions (SSE).

As a further remark we want to mention that space-filling curves can also be used, e.g., for the computation of the product of a full matrix with a full vector, or a full matrix with a full matrix, where we also obtain a reduction of cache misses [3].

RECYCLING KRYLOV SUBSPACES FOR SEQUENCES OF LINEAR SYSTEMS*

MICHAEL L. PARKS†, ERIC DE STURLER‡, GREG MACKEY§, DUANE D. JOHNSON¶, AND SPANDAN MAITI‖

Abstract. Many problems in science and engineering require the solution of a long sequence of slowly changing linear systems. We propose and analyze two methods that significantly reduce the total number of matrix-vector products required to solve all systems. We consider the general case where both the matrix and right-hand side change, and we make no assumptions regarding the change in the right-hand sides. Furthermore, we consider general nonsingular matrices, and we do not assume that all matrices are pairwise close or that the sequence of matrices converges to a particular matrix. Our methods work well under these general assumptions, and hence form a significant advancement with respect to related work in this area. We can reduce the cost of solving subsequent systems in the sequence by recycling selected subspaces generated for previous systems. We consider two approaches that allow for the continuous improvement of the recycled subspace at low cost. We consider both Hermitian and non-Hermitian problems, and we analyze our algorithms both theoretically and numerically to illustrate the effects of subspace recycling. We also demonstrate the effectiveness of our algorithms for a range of applications from computational mechanics, materials science, and computational physics.

1. Introduction.

We consider the solution of a long sequence of general linear systems

$$A^{(i)}x^{(i)} = b^{(i)}, \qquad i = 1, 2, \ldots, \tag{1.1}$$

where the matrix $A^{(i)} \in \mathbb{C}^{n\times n}$ and right-hand side $b^{(i)} \in \mathbb{C}^n$ change from one system to the next, and the systems are typically not available simultaneously. Such sequences arise in many problems.

One important class of applications that we consider occurs in modeling fatigue and fracture via finite element analysis. These analyses use dynamic loading, requiring many loading steps, and rely on implicit solvers [13]. Generally, several thousand loading increments, each corresponding to a linear system, are required to resolve the fracture progression. The matrix and right-hand side, at each loading step, depend on the previous solution, so that only one linear system is available at a time. Further, the solution vectors are updates to a displacement vector and are therefore uncorrelated. Although the change from one linear system to the next is small, the cumulative change after many loading increments is significant. Rather than discarding the Krylov space generated when solving a linear system, we judiciously select a subspace and use it to reduce the number of iterations for solving the next system. We refer to this process as [illegible]. Clearly, similar sequences of linear systems arise from other (nonlinear) time-dependent applications. Another important source of such sequences of linear systems are Newton or Broyden-type methods for solving nonlinear equations and optimization problems.

We consider methods for the solution of sequences of general matrices, and do not assume that all matrices are pairwise close or that the sequence of matrices converges to a particular matrix. In addition, we make no assumptions on the right-hand-side vectors. A method that is effective under these assumptions must satisfy a number of properties. First, the method must be able to identify and converge to an effective subspace for recycling (the [illegible]) in a reasonable number of iterations, and it must be able to converge to an effective recycle space over the solution of multiple linear systems. Otherwise, a good recycle space may never be found for a sequence of changing matrices. Second, for efficiency a significant convergence improvement for the linear solver must be obtained with a relatively small recycle space. Third, the method must be able to converge quickly to an effective [illegible] recycle space for an updated matrix, and it must provide an inexpensive mechanism for regularly updating the recycle space to reflect the changes in the linear systems. As we will show, our proposed methods satisfy these properties, and they are effective under these general assumptions. As such, they form a significant advancement with respect to related work in this area.

We consider two approaches for the solution of (1.1) which are related to two existing truncated and restarted solvers. These solvers, GMRES-DR [21] and GCROT [7], were developed for solving single linear systems; both recycle a judiciously selected subspace between restarts to maintain good convergence. In the following, we define a [illegible] in the sense used by GCROT, wherein the iteration is restarted with a selected subspace and each new vector generated is orthogonalized against this subspace. We define a [illegible] as the computation between truncations or restarts. The first approach is to recycle an approximate invariant subspace and use it for deflation, following the GMRES-DR method. Since GMRES-DR cannot be adapted for recycling, we propose a more general method, GCRO-DR. The work by Rey and Risler [25, 26] has a similar motivation as that for GMRES-DR; see below. However, our implementation is cheaper, more effective, and more adaptive. An alternative idea is to recycle a subspace that minimizes the loss of orthogonality with the Krylov subspace from the previous system [7]. In either case, the recycled subspace will be utilized by first minimizing the residual over this subspace and then maintaining orthogonality with the image of this space in the Arnoldi recurrence. We will show that subspaces that are useful to retain for a subsequent cycle when solving a single linear system are also useful for the next linear system in a sequence if the matrix does

not change significantly. The proposed methods can be tuned to recycle a variety of subspaces based on computed information from the matrix, background knowledge of the application, and other information; this is discussed in [15]. However, for a first evaluation, it is reasonable to analyze the effectiveness of these existing methods appropriately modified for solving (1.1). The application of these methods to sequences of linear systems where both matrix and right-hand side change is new and provides a significant advance on related methods discussed below. Our proposed methods offer an efficient mechanism for continuous updating of the recycled subspace. As a result, they quickly adapt to gradual changes in matrices. Further, they make few assumptions on the linear systems and are applicable to general matrices. In addition, we provide theoretical motivation and careful experimental analysis of these methods. Our results show that significant convergence improvements are obtained using recycled subspaces of a small dimension. The application of an early version of GCROT to multiple right-hand sides was briefly discussed in [5]. The tuning of subspace recycling for diffuse optical tomography, leading to further convergence improvements, is discussed and relevant theory presented in [15].

We discuss the basic derivation of our methods from Morgan's GMRES-DR and de Sturler's GCROT in section 2. We modify GCROT to recycle subspaces between linear systems. GMRES-DR cannot be modified to do this, so we introduce GCRO-DR, a more general variant of GMRES-DR, capable of Krylov subspace recycling. In section 3, we discuss two important theorems and their consequences to explain why GCRO-DR satisfies the three essential properties for an effective recycling method. A similar convergence theory for GCROT is a topic of future research. This analysis is complemented by careful experimentation in section 4, where we provide an extensive experimental analysis to illustrate the behavior of both proposed methods and how well they satisfy the required properties. Particular examples from section 4.4 suggest that further improvements are possible in the subspace selection process, which is a subject of future research. Finally, we discuss conclusions and future work in section 5.

To conclude this section, we discuss a number of related approaches. For the Hermitian positive definite case, Rey and Risler have proposed reducing the effective condition number by either explicitly retaining all converged Ritz vectors from previous CG iterations or implicitly approximating the dominant invariant subspace by retaining all previously generated complete Krylov spaces [25, 26]. Moreover, both approaches use full recurrences, so the CG iteration is really a FOM (full orthogonalization method) iteration [27]. Clearly, both in memory and floating point operations, these methods are very expensive. This drawback is somewhat alleviated as the methods are presented in the context of the finite element tearing and interconnecting (FETI) method [10], which operates on a reduced-size problem. However, for general problems the approach would appear impractical. Furthermore, both approaches lack the possibility to gradually improve the recycle space. Instead, the recycle space is computed once and periodically replaced by starting from scratch. There is no effective mechanism for adapting this space for a sequence of linear systems that change gradually but substantially over many steps. For this reason, the authors make the explicit assumption that all matrices remain close. Although the approaches are motivated by well-known properties of CG, no theoretical or quantitative analysis is provided of the quality of the approximate invariant subspaces or the convergence rate for CG with recycling. Finally, the reported reductions in the number of iterations are modest at about 20%, even though large recycle spaces are used (e.g., of dimension 100 in [25]). In [26] the authors report about a 20% reduction in CPU-time with respect to CG with a full recurrence.

Another interesting approach for solving a sequence, or better a collection, of linear systems was proposed by Chan and Ng [3] developing two related Galerkin projection methods. Unfortunately, these methods require all systems to be available simultaneously, or at least the right-hand sides. They do not recycle subspaces that arise in the iteration, but instead use all vectors arising in the iteration immediately for all systems. Therefore, they focus on situations where all the matrices are close. However, this is generally not the case for the problems we target. Although the matrices change slowly, the cumulative change over many steps is usually significant.

Solving a sequence of linear systems where the matrix is fixed is a special case of (1.1). When all right-hand sides are available simultaneously, block methods are often suitable, such as block CG [22], block GMRES [37], and the family of block EN-like methods [39]. However, block methods do not generalize to the case (1.1). If only one right-hand side is available at a time, the method of Fischer [11], the deflated CG method [29], or the hybrid method of Simoncini and Gallopoulos [30] may be employed. Fischer's method looks for a starting vector in the space spanned by the previous solution vectors in the sequence, which is helpful if the solution vectors are correlated. The method does not maintain orthogonality to this subspace, and so no further speed-up is obtained. In deflated CG, only a small number of the initial Lanczos vectors for every system is used to update the approximate invariant subspace. This is efficient in computation and memory use, but the convergence to an invariant subspace is slow. Hence, the improvement in iterations is modest. The hybrid method of Simoncini and Gallopoulos is most effective when the right-hand sides share common spectral information.

2. Recycling Krylov methods. Restarting GMRES [28] may lead to poor convergence and even stagnation. Therefore, recent research has focused on truncated methods that improve convergence by retaining a judiciously selected subspace between cycles. A taxonomy of popular choices is given in [9]. In this section, we discuss two choices and solvers implementing them. We then modify those solvers to recycle subspaces between linear systems. Although these linear solvers are not new, their extension to sequences of linear systems has not been discussed and analyzed before.

One strategy for subspace selection was proposed in [7] for the GCROT method. We discuss this approach and its modification for solving (1.1) in section 2.2.

We discuss Morgan's GMRES-DR, which retains an approximate invariant subspace between cycles, in section 2.3. In particular, it focuses on removing the eigenvalues of smallest magnitude by recycling an approximate invariant subspace associated with those eigenvalues. Note that GMRES-DR must use only harmonic Ritz vectors, and that it cannot be modified for Krylov subspace recycling even when the matrix does not change. Therefore, we combine ideas from GCRO [6] and GMRES-DR to produce a new linear solver, GCRO-DR, which is suitable for the solution of individual linear systems as well as sequences of them, and is more flexible than GMRES-DR. We discuss GCRO-DR in section 2.4.

2.1. Definitions. The Arnoldi recurrence in GMRES leads to the following relation, which we denote as the Arnoldi relation:

$$AV_m = V_{m+1}\underline{H}_m, \tag{2.1}$$

where $V_m \in \mathbb{C}^{n\times m}$ and $\underline{H}_m \in \mathbb{C}^{(m+1)\times m}$ is upper Hessenberg. Let $H_m \in \mathbb{C}^{m\times m}$ denote the first m rows of $\underline{H}_m$.

For any subspace $S \subseteq \mathbb{C}^n$, $y \in S$ is a Ritz vector of A with Ritz value θ if

$$Ay - \theta y \perp w \qquad \forall w \in S. \tag{2.2}$$

Frequently, we choose $S = K^{(j)}(A, r)$, the jth Krylov subspace associated with the matrix A and the starting vector r. In this case the eigenvalues of H_m are the Ritz values of A. Ritz values tend to approximate the extremal eigenvalues of A well, but can give poor approximations to the interior eigenvalues. Likewise, the Ritz values of A^{-1} tend to approximate the interior eigenvalues of A. We define harmonic Ritz values as the Ritz values of A^{-1} with respect to the space AS,

$$A^{-1}\widetilde{y} - \widetilde{\mu}\widetilde{y} \perp w \qquad \forall w \in AS, \tag{2.3}$$

where again $S = K^{(j)}(A, r)$ and $\widetilde{y} \in AS$. We call $\widetilde{\theta} = 1/\widetilde{\mu}$ a harmonic Ritz value. In this case, we have approximated the eigenvalues of A^{-1}, but using a Krylov space generated with A. In GCRO-DR, we construct harmonic Ritz vectors using a modified operator rather than A.

2.2. GCROT. GCROT is a truncated minimum residual Krylov method that retains a subspace between cycles such that the loss of orthogonality with respect to the discarded space is minimized [7]. This process is called [illegible]. We discuss optimal truncation in the context of restarted GMRES, although it can be described in more general terms, independently of any specific linear solver [7, 18]. Consider solving $Ax = b$ with initial residual r_0. At the end of the first cycle of GMRES, starting with $v_1 = r_0/\|r_0\|_2$, we have the Arnoldi relation (2.1).

Let r_1 denote the residual vector after m iterations. Consider some iteration $s < m$. For s iterations of GMRES, we have the Arnoldi relation

$$AV_s = V_{s+1}\underline{H}_s. \tag{2.4}$$

Let r denote the residual after s iterations. Now suppose that we had restarted after iteration s, with initial residual r, and made $m - s$ iterations, yielding residual r_2. The optimal residual after m iterations is r_1. At best, we may have $\|r_2\|_2 = \|r_1\|_2$, but in general, $\|r_2\|_2 > \|r_1\|_2$, because GMRES restarted after iteration s ignores orthogonality to the Krylov subspace $AK^{(s)}(A, r_0)$. The deviation from optimality incurred by restarting after iteration s is $e = r_2 - r_1$, which we call the [illegible]. The residual error e depends on the [illegible] [12, pp. 603–604] between the subspaces $AK^{(s)}(A, r_0)$ and $AK^{(m-s)}(A, r)$. Instead of completely discarding the space $AK^{(s)}(A, r_0)$, suppose we had maintained orthogonality to a k-dimensional subspace ($k < s$) of $AK^{(s)}(A, r_0)$ for the remaining $m - s$ iterations to produce a new residual vector r_3. If we chose our k-dimensional subspace of $AK^{(s)}(A, r_0)$ to correspond to the k largest principal angles, we would minimize the norm of the new residual error $\|e'\|_2 = \|r_1 - r_3\|_2$. This process is what is meant by optimal truncation. Since the Krylov space generated with r contained vectors close to the recycled subspace, this is likely to happen again after restarting with r_1. Therefore, we retain the selected k-dimensional subspace for the next cycle.

GCROT maintains matrices $U_k, C_k \in \mathbb{C}^{n\times k}$ satisfying the relations

$$AU_k = C_k, \tag{2.5}$$

$$C_k^H C_k = I_k. \tag{2.6}$$

The minimum residual solution over range(U_k) is known from the previous cycle. In the following cycle, we carry out the Arnoldi recurrence while maintaining orthogonality to C_k. This corresponds to an Arnoldi recurrence with the operator $(I - C_k C_k^H)A$.

Then, we compute the update to the solution as in GMRES, taking the singularity of the operator into account using the relation $A^{-1}(I - C_k C_K^H)A = I - U_k C_k^H A$ [6]. The correction to the solution vector and other vectors selected via optimal truncation of the Krylov subspace are appended to U_k, and then U_k and C_k are updated such that (2.5)–(2.6) again hold. At the end of each cycle, only the matrices U_k and C_k are carried over to the next cycle. Each cycle of GCROT requires approximately $m-k$ matrix-vector products and $O(nm^2+nkm)$ other floating point operations. For details, see [7].

GCROT can be modified to solve (1.1) by carrying over U_k from the ith system to the $(i+1)$st system. We have the relation $A^{(i)}U_k = C_k$. We modify U_k and C_k to satisfy (2.5)–(2.6) with respect to $A^{(i+1)}$ as follows:

$$[Q, R] = \text{reduced QR decomposition of } A^{(i+1)}U_k^{old}, \tag{2.7a}$$

$$C_k^{new} = Q, \tag{2.7b}$$

$$U_k^{new} = U_k^{old} R^{-1}. \tag{2.7c}$$

[1]

Now, $A^{(i+1)}U_k^{new} = C_k^{new}$, and we can proceed with GCROT on the $(i+1)$st linear system. Note that in many cases computing $A^{(i+1)}U_k^{old} = C_k^{old} + \Delta A^{(i)}U_k^{old}$ is much cheaper than k matrix-vector products, because $\Delta A^{(i)}$ is considerably sparser than $A^{(i)}$ or has a special structure. See our example problem in section 4.1. Moreover, even if we were to compute $A^{(i+1)}U_k^{old}$ directly, this can be faster than k separate matrix-vector multiplications [8]. So long as $A^{(i+1)}$ has not changed significantly from $A^{(i)}$, the use of U_k^{new} should accelerate the solution of the $(i+1)$st linear system.

2.3. GMRES-DR. GMRES-DR [21] recycles an approximate invariant subspace to deflate eigenvalues of smallest magnitude. Deflating these eigenvalues can greatly improve convergence in certain circumstances.

In each cycle, GMRES-DR carries forward k harmonic Ritz vectors $\widetilde{Y}_k \in \mathbb{C}^{n\times k}$ computed at the end of the previous cycle. For the first cycle, the harmonic Ritz vectors can be computed from H_m in (2.1). It can be shown that these harmonic Ritz vectors fit naturally into a Krylov subspace [20]. In each cycle, GMRES-DR proceeds by first orthogonalizing $\widetilde{Y}_k$ to give $\widetilde{\Upsilon}_k$. GMRES-DR then carries out the Arnoldi recurrence for $m-k$ iterations while maintaining orthogonality to $\widetilde{\Upsilon}_k$. This gives the Arnoldi-like relation

$$A[\widetilde{\Upsilon}_k \;\; V_{m-k}] = [\widetilde{\Upsilon}_k \;\; V_{m-k+1}]\underline{H}_m, \tag{2.8}$$

where $\underline{H}_m$ is upper Hessenburg, except for a leading dense $(k+1)\times(k+1)$ submatrix. GMRES-DR updates the solution and residual as in GMRES. It then computes the harmonic Ritz vectors associated with the k smallest harmonic Ritz values using (2.8), and finally restarts with those vectors.

GMRES-DR cannot be used to solve (1.1) directly, even if the matrix is fixed. The harmonic Ritz vectors of A in $\widetilde{Y}_k$ do not form a Krylov subspace for another matrix or even just another starting vector. These and other reasons lead us to develop GCRO-DR, a generalization of GMRES-DR capable of solving (1.1).

2.4. GCRO-DR. We introduce a new Krylov method that uses recycling. We call this method GCRO-DR because it uses deflated restarting within the framework of GCRO [6]. The method is a generalization of GMRES-DR to solve (1.1). GCRO-DR is more flexible because any subspace may be recycled for subsequent cycles or

[1] For efficiency, U_k^{new} need not be computed explicitly.

linear systems. In the pseudocode given in the appendix, the harmonic Ritz vectors corresponding to the harmonic Ritz values of smallest magnitude have been chosen. However, any combination of k vectors may be selected. An interesting possibility would be to select a few [illegible] corresponding to the harmonic Ritz values of smallest magnitude, and a few [illegible] corresponding to the Ritz values of largest magnitude. This would allow simultaneous deflation of eigenvalues of both smallest and largest magnitude using the better approximation for each.

When solving a single linear system, GCRO-DR and GMRES-DR are algebraically equivalent. The primary advantage of GCRO-DR is its capability for solving sequences of linear systems.

GCRO-DR is a combination of GMRES-DR and GCRO. Suppose that we have solved the ith system of (1.1) with GCRO-DR, and we retain k approximate eigenvectors, $\widetilde{Y}_k = [\widetilde{y}_1, \widetilde{y}_2, \ldots, \widetilde{y}_k]$. Then, GCRO-DR computes matrices $U_k, C_k \in \mathbb{C}^{n\times k}$ from $\widetilde{Y}_k$ and $A^{(i+1)}$ such that $A^{(i+1)}U_k = C_k$ and $C_k^H C_k = I_k$, in the same manner as in (2.7). In the remainder of this section we drop the superscript in $A^{(i+1)}$ for notational convenience.

We find the optimal solution over the subspace range(U_k) as $x = x_0 + U_k C_k^H r_0$, and set $r = r_0 - C_k C_k^H r_0$ and $v_1 = r/\|r\|_2$. Next, we generate a Krylov space of dimension $m-k+1$ with $(I - C_k C_k^H)A$, which produces the Arnoldi relation

$$(I - C_k C_k^H)AV_{m-k} = V_{m-k+1}\underline{H}_{m-k}. \tag{2.9}$$

Since $V_{m-k+1} \perp C_k$, we have

$$A[U_k \;\; V_{m-k}] = [C_k \;\; V_{m-k+1}] \begin{bmatrix} I_k & B_k \\ 0 & \underline{H}_{m-k} \end{bmatrix}, \tag{2.10}$$

where $B_k = C_k^H A V_{m-k}$. To reduce unnecessary ill-conditioning of the rightmost matrix in (2.10) we proceed as follows. We compute the diagonal matrix D_k such that $\widetilde{U}_k = U_k D_k$ has unit columns, and we define

$$\widehat{V}_m = [\widetilde{U}_k \;\; V_{m-k}], \quad \widehat{W}_{m+1} = [C_k \;\; V_{m-k+1}], \quad \underline{G}_m = \begin{bmatrix} D_k & B_k \\ 0 & \underline{H}_{m-k} \end{bmatrix}.$$

We rewrite (2.10) as

$$A\widehat{V}_m = \widehat{W}_{m+1}\underline{G}_m, \tag{2.11}$$

where the columns of $\widehat{V}_M$ and $\widehat{W}_{m+1}$ have unit norm. Note that $\underline{G}_m = \widehat{W}_{m+1}^H A\widehat{V}_m$ is upper Hessenberg, with D_k diagonal. The columns of $\widehat{W}_{m+1}$ are orthogonal, but this is not true for the columns of $\widehat{V}_m$.

At the end of each cycle, GCRO-DR solves the minimization problem

$$t = \arg \min_{z \in \text{ range}(\widehat{V}_m)} \|r - Az\|_2, \tag{2.12}$$

which reduces to the $(m+1)\times m$ least squares problem

$$\underline{G}_m y \approx \widehat{W}_{m+1}^H r = \|r\|_2 e_{k+1}, \tag{2.13}$$

with $t = \widehat{V}_m y$. The residual and solution are given by

$$r = r - A\widehat{V}_m y = r - \widehat{W}_{m+1}\underline{G}_m y, \tag{2.14}$$

$$x = x + \widehat{V}_m y. \tag{2.15}$$

Next, the method solves the generalized eigenvalue problem

$$\underline{G}_m^H \underline{G}_m \widetilde{z}_i = \widetilde{\theta}_i \underline{G}_m^H \widehat{W}_{m+1}^H \widehat{V}_m \widetilde{z}_i, \tag{2.16}$$

derived from (2.3), and recovers the harmonic Ritz vectors as $\widetilde{y}_i = \widehat{V}_m \widetilde{z}_i$. In general, (2.16) will have complex eigenvalues. When storing the harmonic Ritz vectors in GCRO-DR, we use a real representation of a complex conjugate pair. To ensure that we retain both complex conjugate harmonic Ritz vectors associated with a selected eigenvalue, it is sometimes necessary to store $k+1$ vectors rather than k vectors per cycle.

GCRO-DR and GMRES-DR have about the same computational cost per cycle. In particular, they have the same number of matrix-vector products and orthogonalizations per cycle. GCRO-DR stores k additional vectors. If the new U_k is computed explicitly (which is not necessary), GCRO-DR has a modest additional computational cost of about $nk^2/2$. Given U_k and C_k, generating (2.11) with GCRO-DR(m,k) requires approximately $2kn\,(1+k)$ floating point operations than generating (2.1) with GMRES(m), although GMRES(m) stores k fewer vectors. The number of dot-products and vector updates per cycle is of the same order for GCRO-DR(m,k) and GMRES(m); the cost savings in GCRO-DR(m,k) arise because (2.5) and (2.6) are already satisfied.

3. Convergence analysis for deflation-based Krylov subspace recycling. Recent work on the convergence of GMRES [31] together with the theory on invariant subspaces and their perturbations [34] provides a good framework for analyzing the GCRO-DR method. Unfortunately, a similar convergence theory for the GCROT method is still lacking. However, in section 4 we show by numerical experiment that, regarding recycling, GCROT shares many of the properties of GCRO-DR. A full theoretical analysis of GCRO-DR is beyond the scope of the present paper; instead we discuss two main theoretical results and their implications and demonstrate these numerically in section 4. For more details on these theoretical results we refer to [15, 23, 24].

The first result concerns the convergence of GCRO-DR; see [23, 24]. We show that the recycle space need not approximate an invariant subspace accurately to improve the rate of convergence significantly.

Let $\mathcal{Q}$ be an ℓ-dimensional invariant subspace of A, and let $\mathcal{C} = \text{range}(C_k)$ be a k-dimensional space ($k \geq \ell$) selected to approximate $\mathcal{Q}$, where C_k is defined in section 2.4. We define $\Pi_{\mathcal{C}}$ to be the orthogonal projector onto $\mathcal{C}$, and we define $\Pi_{\mathcal{Q}}$ similarly. Furthermore, we define $P_{\mathcal{Q}}$ to be the spectral projector onto $\mathcal{Q}$. Finally, we define the from the subspace $\mathcal{Q}$ to the subspace $\mathcal{C}$ as

$$\delta(\mathcal{Q},\mathcal{C}) \equiv \|(I-\Pi_{\mathcal{C}})\,\Pi_{\mathcal{Q}}\|_2, \tag{3.1}$$

which is equal to the sine of the largest principal angle between $\mathcal{Q}$ and $\mathcal{C}$ [1]. This means that any unit vector in $\mathcal{Q}$ has a component of at most length δ orthogonal to $\mathcal{C}$.

THEOREM 3.1. $\mathcal{C}$ $\mathcal{V} = \text{range}\left(V_{m-k+1}\underline{H}_{m-k}\right)$ $(m-k)$ (2.9) $r_0 \in \mathbb{C}^n$ $r_1 = (I-\Pi_{\mathcal{C}})\,r_0$ $\mathcal{Q}$ $\delta(\mathcal{Q},\mathcal{C}) < 1$

$$\min_{d_1 \in \mathcal{V}\oplus\mathcal{C}} \|r_0 - d_1\|_2 \leq \min_{d_2 \in (I-P_{\mathcal{Q}})\mathcal{V}} \|(I-P_{\mathcal{Q}})\,r_1 - d_2\|_2 + \frac{\gamma}{1-\delta}\|P_{\mathcal{Q}}\|_2 \cdot \|(I-\Pi_{\mathcal{V}})\,r_1\|_2,$$

$\gamma = \|(I-\Pi_{\mathcal{C}})P_{\mathcal{Q}}\|_2$

A

$$\min_{d_1 \in \mathcal{V} \oplus \mathcal{C}} \|r_0 - d_1\|_2 \leq \min_{d_2 \in (I - \Pi_{\mathcal{Q}})\mathcal{V}} \|\,(I - \Pi_{\mathcal{Q}})\, r_1 - d_2\|_2 + \frac{\delta}{1-\delta} \cdot \|\,(I - \Pi_{\mathcal{V}})\, r_1\|_2.$$

. For the proof, see [23, Chapter 3] or [24]. □

Theorem 3.1 was inspired by a related theorem in [31] used to explain superlinear convergence in GMRES. In the two bounds above, the left-hand side represents the residual norm after $m-k$ iterations of GCRO-DR with the recycled subspace $\mathcal{C}$. On the right-hand sides, the first term represents the convergence of a deflated problem where all components in the subspace $\mathcal{Q}$ have been removed, which typically leads to an improved rate of convergence [21, 31, 36]. The second term in the right-hand sides represents a constant times the residual of $m-k$ iterations of GCRO-DR, solving for r_1. If the recycle space $\mathcal{C}$ contains an invariant subspace $\mathcal{Q}$, then $\delta = \gamma = 0$ for this $\mathcal{Q}$, and GCRO-DR converges at least as fast as the deflated problem. In our numerical experiments we demonstrate that the method fairly quickly gets to values of $\delta = O(10^{-2})$. In that case, we still obtain the convergence rate of the deflated problem, so long as $\|P_{\mathcal{Q}}\|_2$ is not large in the non-Hermitian case. Notice that for $\delta = O(10^{-2})$ the invariant subspace $\mathcal{Q}$ is not approximated very accurately, and that such values of δ are relatively easily obtained. Finally, we point out that for a given subspace $\mathcal{C}$, Theorem 3.1 is applicable to any invariant subspace $\mathcal{Q}$ such that $\delta(\mathcal{Q}, \mathcal{C}) < 1$. Hence, the sharpest bound for any $\mathcal{Q}$ applies, and the result appears to be fairly insensitive to conditioning issues of invariant subspaces for non-Hermitian A.

The second result concerns the perturbation of invariant subspaces associated with the smallest eigenvalues when the change in the matrix is concentrated in an invariant subspace corresponding to large eigenvalues. When the magnitude of the change is smaller than the gap between smallest and large eigenvalues, then the invariant subspace associated with the smallest eigenvalues is not significantly altered. As we aim to recycle exactly this subspace, this is a desirable property.

For simplicity we deal specifically with a Hermitian positive definite matrix A and a corresponding Hermitian perturbation E, as in our main numerical example in section 4. Following the discussion in [15], let A have the eigendecomposition

$$A = [Q_1\ Q_2\ Q_3]\, \mathrm{diag}(\Lambda_1, \Lambda_2, \Lambda_3)\, [Q_1\ Q_2\ Q_3]^H, \tag{3.2}$$

where $Q = [Q_1\ Q_2\ Q_3]$ is an orthogonal matrix, $\Lambda_1 = \mathrm{diag}(\lambda_1^{(1)}, \ldots, \lambda_{j1}^{(1)})$, and Λ_2 and Λ_3 are defined analogously. Furthermore, let

$$\lambda_1^{(1)} \leq \cdots \leq \lambda_{j1}^{(1)} < \lambda_1^{(2)} \leq \cdots \leq \lambda_{j2}^{(2)} < \lambda_1^{(3)} \leq \cdots \leq \lambda_{j3}^{(3)}.$$

Now we consider the change in the invariant subspace range(Q_1) under a symmetric perturbation E of A. Let $\theta_1(.,.)$ denote the largest canonical angle between two spaces. We do not require that $\|E\|_F$ be small, but we assume that the projection of E onto the subspace range$([Q_1\ Q_2])$ is small. We assume that $\|[Q_1\ Q_2]^H E\|_F \leq \varepsilon$ and that ε is small relative to $\lambda_1^{(2)} - \lambda_{j1}^{(1)}$. We also assume that $\eta \equiv \|Q_3^H E\|_F$ is small relative to $\lambda_1^{(3)} - \lambda_{j1}^{(1)}$. Note that we do not need to assume that $\lambda_1^{(2)} - \lambda_{j1}^{(1)}$ is large.

Also, let

$$\mu \equiv \min(\lambda_1^{(2)} - \varepsilon, \lambda_1^{(3)} - \eta) - 2\varepsilon - (\lambda_{j1}^{(1)} + \varepsilon) > 2\varepsilon,$$

$$\hat{\mu} \equiv \mu \left(1 - \frac{2\varepsilon^2}{\mu^2}\right) + \lambda_{j1}^{(1)} + \varepsilon.$$

THEOREM 3.2. A [illegible] (3.2), [illegible] E ε η μ $\hat{\mu}$ [illegible] $\hat{Q}_1$ [illegible] Q_1 [illegible] range$(\hat{Q}_1)$ [illegible] $A + E$

$$\tan\theta_1\left(\text{range}(Q_1), \text{range}(\hat{Q}_1)\right) \leq \frac{\varepsilon}{\hat{\mu}}.$$

[illegible]. For the proof, see [15]. □

A similar bound holds for the perturbation of the eigenvalues associated with Q_1.

In relation to Theorem 3.1 and GCRO-DR, Q_1 corresponds to $\mathcal{Q}$, whereas Q_2 and Q_3 can be chosen to fit the theorem. We need a specialized perturbation result of this kind, because in general the changes in the matrices are too large to show by standard perturbation theory that the invariant subspaces of interest remain intact. This perturbation theorem is of general importance, as there are many applications that involve a sequence of problems that undergo small local changes. In a problem like crack propagation we do not expect the smooth global modes associated with the smallest eigenvalues to change much from one system to the next, but only gradually over many systems as the crack propagates over some distance. We show experimentally that this is the case in section 4. The continual adaptation of the recycle space needs to track only these gradual changes. Another example is given in [15], where we optimize a parameterized medium in a tomography application to fit measured data.

Finally, we note that GCRO-DR uses more or less the Arnoldi method with dense restarting for approximating an invariant subspace [33, 38]. This method generally offers fast convergence for the exterior components of the spectrum. This fast convergence together with Theorems 3.1 and 3.2 indicates that GCRO-DR satisfies the three important properties mentioned in the introduction, especially for problems such as crack propagation.

The perturbation result indicates that if the recycle space provides a reasonable approximation to an invariant subspace, then it will also provide a reasonable approximation to the slightly perturbed invariant subspace of the updated matrix. The convergence result indicates that GCRO-DR will have fast convergence as the method does not require an accurate approximation to the invariant subspace. Moreover, Arnoldi's method with dense restarting will quickly improve the approximation to the invariant subspace of the perturbed matrix. In general, it is not hard to get a reasonable approximation to an invariant subspace corresponding to the outermost eigenvalues [34]. We will demonstrate this behavior of GCRO-DR using numerical experiments in the next section.

4. Test problems and numerical results. We discuss our main example in section 4.1, a problem from fracture mechanics that produces a long sequence of linear systems. The matrices are symmetric positive definite (SPD), and both the matrix and right-hand side change from one system to the next. For this problem we also provide a more detailed experimental analysis of the GCRO-DR and GCROT methods following the theory described in section 3. In addition, we provide results for

three problems that involve real nonsymmetric matrices and complex non-Hermitian matrices. We consider two examples from physics to illustrate the effectiveness of our approach for the case of a fixed matrix. We discuss electronic structure calculations in section 4.2, and a problem from lattice quantum chromodynamics in section 4.3. Finally, in section 4.4, we apply GCROT and GCRO-DR to a simple convection-diffusion problem to evaluate the effects of subspace recycling in the nonsymmetric case, independent from perturbations in the matrix or right-hand side.

In the following sections, GMRES(m) indicates restarted GMRES with a maximum subspace of dimension m, and GMRES(∞) indicates full GMRES. CG refers to the conjugate gradient method. For GMRES-DR(m,k) and GCRO-DR(m,k), m is the maximum subspace size, and k is the dimension of the recycle space. For GCROT(m,k_{max},k_{min},s,p_1,p_2), m is the maximum subspace size over which we optimize. The maximum number of column vectors stored in U_k and C_k (as described in section 2.2) is k_{max}. The argument k_{min} indicates the number of column vectors retained in U_k and C_k after truncation to make room for new vectors. The argument s indicates the dimension of the Krylov subspace from which we select p_1 vectors to place in U_k. We also include in U_k the last p_2 orthogonal basis vectors generated in the Arnoldi process. See [7, 18] for more discussion regarding the choice of parameters. At each restart for GCROT, the GMRES part is run for $m - k_{min}$ steps.

In comparing restarted GMRES, GCROT, GMRES-DR, and GCRO-DR, we decided to make the solvers minimize over a subspace of the same dimension. An alternative choice would be to provide the same amount of memory to each solver, but we felt that our choice would provide a more informative comparison.

4.1. Fatigue and fracture of engineering components. Research on failure mechanisms (e.g., fatigue and fracture) of engineering components often focuses on modeling complex, nonlinear response. Finite element methods for quasi-static and transient responses over longer time scales generally adopt an implicit formulation. Together with a Newton scheme for the nonlinear equations, such implicit formulations require the solution of linear systems, thousands of times, to accomplish a realistic analysis [13].

We study a sequence of linear systems taken from a finite element code developed by Philippe Geubelle and Spandan Maiti (both Aerospace Engineering, University of Illinois at Urbana-Champaign (UIUC)). In our example, the code simulates crack propagation in a metal plate using so-called [illegible]. The plate mesh is shown in Figure 4.1. The problem is symmetric about the x-axis, and the crack propagates exactly along this symmetry axis. The cohesive elements act as nonlinear springs connecting the surfaces that will define the crack location. As the crack propagates, the cohesive elements deform following a nonlinear yield curve and eventually break. The element stiffness is set to zero for a broken cohesive element. These elements are usually inserted dynamically, but that is not the case here. This simulation results in a sequence of sparse, symmetric, positive definite stiffness matrices that change slowly from one system to the next. Each stiffness matrix can be expressed as $A^{(i+1)} = A^{(i)} + \Delta A^{(i)}$. Although $\Delta A^{(i)}$ is considerably more sparse than $A^{(i)}$, it is not low-rank, as the terms in the update $\Delta A^{(i)}$ come from all nonbroken cohesive elements. The other finite elements model linear elasticity and have constant stiffness matrices. The matrices produced in our examples are 3988×3988, and have a condition number on the order of 10^4 before preconditioning. They have an average of 13.4 nonzero entries per row. Over 2000 linear systems must be solved to capture the fracture progression.

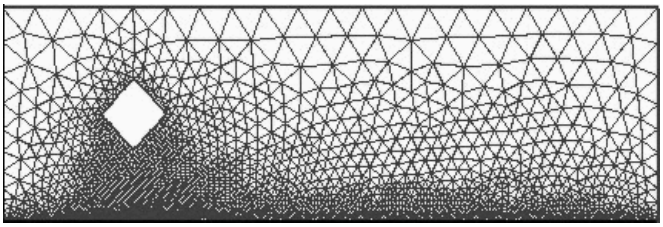

FIG. 4.1. *Two-dimensional plate mesh for the crack propagation problem.*

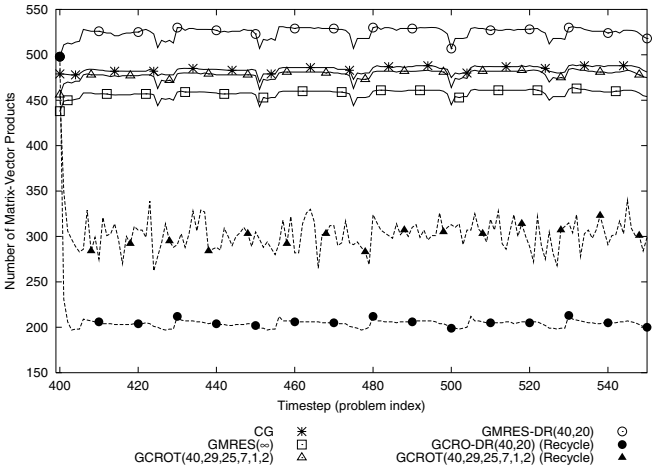

FIG. 4.2. *Number of matrix-vector products versus timestep for various solvers for the crack propagation problem without preconditioning. All solvers use a recurrence of at most* 40 *vectors, except GMRES*(∞) *and CG.*

We examine the 151 linear systems 400–550, representing a typical subset of the fracture progression in which many cohesive elements break. We start with a straightforward comparison of GCRO-DR and GCROT with subspace recycling with CG, restarted GMRES, GMRES(∞), GMRES-DR, and GCROT without subspace recycling. We always start with a zero initial guess, since we solve for the incremental displacement associated with the loading increment. We give both preconditioned and nonpreconditioned convergence results. All solvers are required to reduce the relative residual to 1.0×10^{-10}. In Figure 4.2 we give the number of matrix-vector products needed to solve each of these systems without preconditioning for GMRES(∞), CG, GMRES-DR(40,20), GCRO-DR(40,20), and GCROT(40,34,30,5,1,2), both with and without subspace recycling. Except for GMRES(∞) and CG, all methods in Figure 4.2 minimize over a subspace of dimension 40 in each cycle. GMRES(40) is not shown, because it required too many matrix-vector products. In Figure 4.3 we give results for the same sequence of problems and the same methods but with incomplete Cholesky (IC(0)) preconditioning. A new preconditioner was computed for each matrix, which is not the most efficient approach. The total number of matrix-vector products needed to solve all 151 preconditioned linear systems is given in Table 4.1.

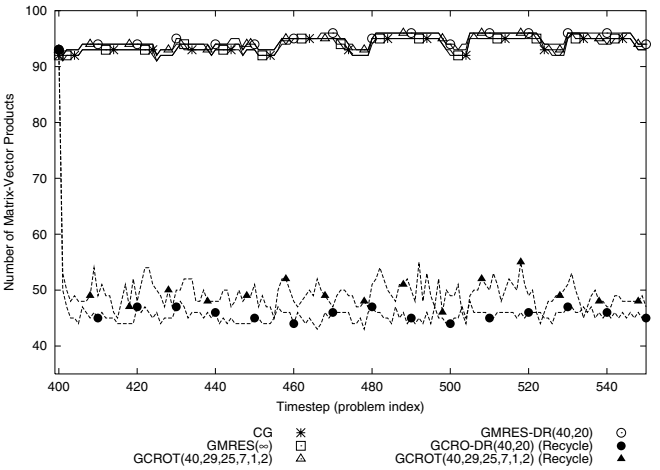

FIG. 4.3. *Number of matrix-vector products versus timestep for various solvers for the crack propagation problem with incomplete Cholesky preconditioning. All solvers use a recurrence of at most* 40 *vectors, except GMRES*(∞) *and CG.*

TABLE 4.1
The total number of iterations required to solve 151 *consecutive IC*(0) *preconditioned linear systems. Only GCRO-DR and GCROT(recycle) exploit subspace recycling.*

Method	Matrix-vector products
GMRES(40)	27188
GMRES-DR(40,20)	14305
GCROT(40,34,30,5,1,2)	14277
CG	14162
GMRES(∞)	14142
GCROT(40,34,30,5,1,2) (recycle)	**7482**
GCRO-DR(40,20) (recycle)	**6901**

We see in Figure 4.2 that GCRO-DR requires the fewest matrix-vector products, except for the first system in the sequence when no recycle space is available. For the first system, GCROT outperforms GCRO-DR. For all but the first system, GCRO-DR and GCROT with recycling require significantly fewer matrix-vector products than the solvers without subspace recycling. Furthermore, GCROT without recycling and CG show about the same convergence. GMRES(∞) outperforms CG, indicating that the convergence of CG is delayed due to effects of finite-precision arithmetic.

For the preconditioned case shown in Figure 4.3, GCRO-DR performs best, with GCROT with subspace recycling a close second. All the other solvers cluster near GMRES(∞).

Comparing GMRES-DR and GCRO-DR, we see a significant difference in convergence, even though both methods aim to retain the same approximate invariant subspace. This difference is due solely to subspace recycling. Without the space recycled from previous linear systems, GCRO-DR is algebraically equivalent to GMRES-DR. The results indicate that the invariant subspace associated with the smallest eigenvalues is hard to estimate accurately. GCRO-DR exhibits superior performance, because it does not have to compute that space from scratch for each new linear system. Indeed, we show below that after solving only three linear systems, GCRO-DR has computed a reasonable approximation to the invariant subspace associated with

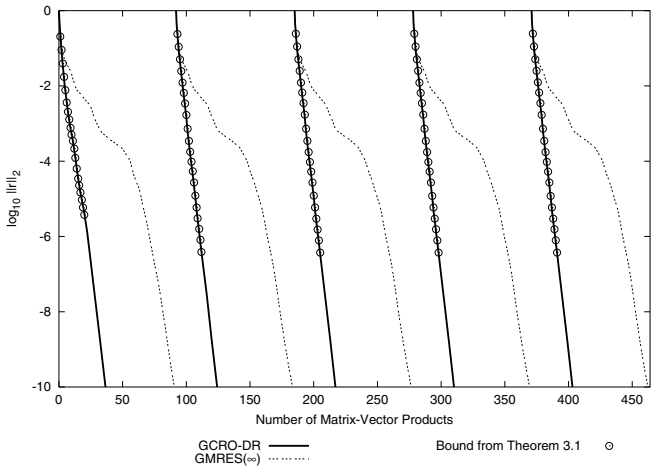

FIG. 4.4. *Convergence curves for GCRO-DR on five consecutive linear systems from the preconditioned crack propagation problem, along with the bound described in Theorem* 3.1. *The bound was computed with* $\mathcal{Q}$ *the eigenspace corresponding to the* 20 *smallest eigenvalues of the preconditioned operator. Since the bound is tight and* δ *is small, GCRO-DR achieved the convergence rate of the deflated problem in Theorem* 3.1.

TABLE 4.2

The decrease of* δ *within a column indicates the improvement of the approximation to* $\mathcal{Q}$ *for a particular system. The small perturbation of the invariant subspace is reflected in the minor increase in* δ *from the last cycle of one system to before the first of the next system. At each cycle, GCRO-DR updates its approximate invariant subspace.*

Linear system	401	402	403	404	405
Before cycle 1	0.9994	0.2380	0.0464	0.0607	0.0794
After cycle 1	0.9180	0.1448	0.0463	0.0606	0.0787
After cycle 2	0.2446	0.0302	0.0416	0.0568	0.0690
After cycle 3	0.2331	0.0302	0.0415	0.0567	0.0684

the fifteen smallest eigenvalues; GMRES-DR cannot do this.

Next, we evaluate some of the properties of GCRO-DR related to the two theoretical results in section 3 and the three properties mentioned in the introduction.

As GCRO-DR approximates an invariant subspace better, it gets closer to the convergence rate of a deflated problem, as described in Theorem 3.1. The convergence curves for five consecutive systems from the preconditioned crack propagation problem are shown in Figure 4.4, along with the bound described in Theorem 3.1. The bound was computed with the invariant subspace, $\mathcal{Q}$, corresponding to the 20 smallest eigenvalues of the preconditioned matrix. We see that the bound is sharp. Additionally, note that for each problem the initial convergence rate for GCRO-DR is approximately the same as the final convergence rate of GMRES(∞).

In Table 4.2, for the preconditioned example we show how the one-sided distance δ, defined in (3.1), from the invariant subspace associated with the 15 smallest eigenvalues to the recycle space evolves over multiple cycles and multiple linear systems. This table illustrates a number of important issues.

The first system solved in this experiment is system 400, and so system 401 is the first system that starts with a recycle space. For the chosen invariant subspace δ is

quite poor at the start, but δ improves quickly over the next two linear systems, and after cycle 2 for system 402, δ has taken a reasonably small value. So, GCRO-DR is able to compute from scratch increasingly good approximations to invariant subspaces that change slightly from system to system. Note that GMRES-DR starts from scratch for every new system. Therefore, it never obtains a sufficiently good approximation, and hence requires many additional iterations per linear system. Any other method that cannot continually update the approximation to the invariant subspace will suffer from the same problem.

Next, note how δ improves during the solution of a single linear system, whereas the small perturbation of the invariant subspace for the next linear system is reflected in the minor increase in δ from the last cycle of one system to before the first cycle of the next system. This confirms our earlier statement, based on Theorem 3.2, that the invariant subspace associated with the smallest eigenvalues and smooth global modes changes little under small local changes in the model. We have also verified this explicitly by computing the principal angles between invariant subspaces of successive matrices. However, in the next experiment we show that the cumulative change over a larger number of loading steps requires the continual or at least periodic updating of the recycle space to keep the number of iterations small.

Finally, this particular $\mathcal{Q}$ was chosen to illustrate the role and behavior of δ, not to get the best bound from Theorem 3.1. Initially, a smaller invariant subspace might have a much smaller δ and may lead to a tighter bound. The bound holds for any invariant subspace with $\delta < 1$, and so the [illegible] bound is the effective one.

Next, we provide a number of experiments that illustrate how quickly GCRO-DR and GCROT learn and adapt to an updated linear system, and how the convergence rate deteriorates if we stop updating the recycle space.

Figure 4.5 shows the results for three variants of GCRO-DR applied to the non-preconditioned problem. Standard GCRO-DR, as discussed so far, updates the recycle space every cycle, as this update is generally quite cheap. We also show a GCRO-DR variant that runs standard GCRO-DR for the first five linear systems in the sequence, but after that never updates the approximate invariant subspace. This also means that it makes no updates while solving each single system. In this case, convergence deteriorates slowly for the first few linear systems but then more rapidly as the gradual changes in the matrices accumulate. Eventually, the number of iterations per linear system exceeds that of GMRES-DR (cf. Figure 4.2). The third variant of GCRO-DR runs normal GCRO-DR for the first five linear systems in the sequence, then stops updating, except that it runs a standard GCRO-DR every 250th linear system. This frequency was chosen solely for the purpose of demonstration. Clearly, for this problem, the recycled subspace must be updated more frequently for good convergence, say every 25 or 50 systems. Note how, despite the significant deterioration in the number of iterations per system, GCRO-DR recovers the rate of convergence of standard GCRO-DR over the solution of a single system. This shows how quickly the method is able to recover (learn) a sufficiently accurate approximation to the invariant subspace. This example also suggests that the convergence is quite sensitive to the δ values for the relevant invariant subspaces. For this example, the average value of $\|A^{(i)}\|_2$ is 3.1357×10^{10}, and the average value of $\|\Delta A^{(i)}\|_2$ is 2.9076×10^8. In a relative sense, the change from one matrix to the next is small, but the cumulative change over many linear systems can be quite large. As mentioned before, $\|\Delta A^{(i)}\|_2$ is larger than the smallest eigenvalues. However, the values of δ in Table 4.2 show that the perturbation of the corresponding invariant subspace is quite small, as suggested

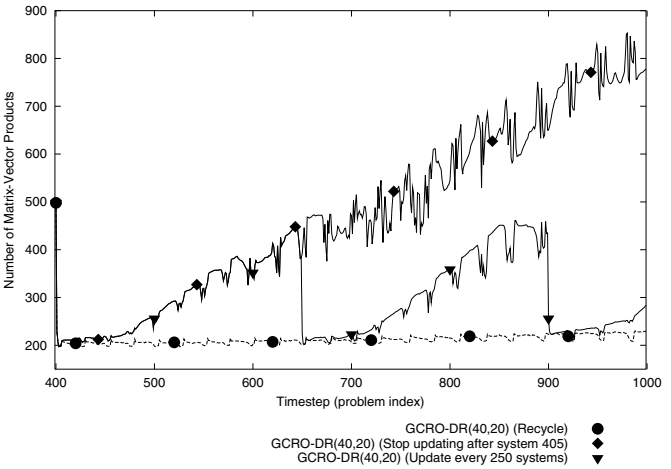

FIG. 4.5. *Number of matrix-vector products versus timestep for GCRO-DR*$(40, 20)$ *with subspace recycling on the nonpreconditioned crack propagation problem. We also show a modified version of GCRO-DR*$(40, 20)$ *that stops updating the recycled subspace after linear system* 405*, and a version that stops updating after linear system* 405 *but does update every* 250 *systems thereafter. Convergence quickly deteriorates in the latter two cases, showing the importance of updating the approximate invariant subspace regularly.*

by the discussion in section 3 regarding small localized changes in the problem and by Theorem 3.2. Figure 4.5 shows that GCRO-DR can adapt to the slow change of the invariant subspace. Finally, it would not be hard to dynamically balance the cost of updating the recycle space with the improved rate of convergence.

In Figure 4.6, we give the results for a similar experiment with GCROT. We show results for standard GCROT with recycling, a GCROT variant that stops updating the recycle space after the first five linear systems, and for a variant that stops updating after the first five linear systems except that it runs a standard GCROT every 100th system. Without the continual updating of the recycle space, the convergence of GCROT degrades more severely than that of GCRO-DR. After each linear system solved by standard GCROT, the number of iterations per system remains small for four or five subsequent systems, but then increases rapidly. This is likely caused by two factors. Since GCROT recycles a subspace that is important for maintaining orthogonality for the current iterations, the recycled space may have a more temporary relevance than an invariant subspace. If we stop updating, then GCROT more or less reduces to restarted GMRES after a number of updates to the matrix when the recycle space is no longer relevant. In addition, after solving a linear system, standard GCROT recycles a subspace that was relevant at the end of that iteration, which may not be the best recycle space for the start of the iteration for the next system. Note that solving a single linear system with standard GCROT restores the convergence rate to that for using standard GCROT for each system. This shows that the method is able to , , , quickly.

These experiments demonstrate that GCRO-DR and GCROT are able to make the small changes to the recycle space necessitated by small localized changes in the problem. For GCRO-DR this is explained by the perturbation result from Theorem 3.2 in combination with the convergence predicted by Theorem 3.1 for small enough δ (say, $\delta = O(10^{-2})$).

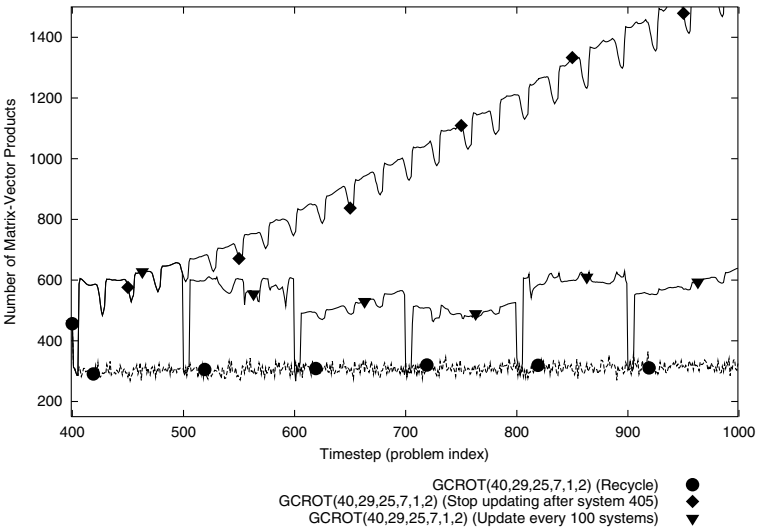

FIG. 4.6. *Number of matrix-vector products versus timestep for* $GCROT(40, 29, 25, 7, 1, 2)$ *with subspace recycling on the nonpreconditioned crack propagation problem. We also show a modified version of* $GCROT(40, 29, 25, 7, 1, 2)$ *that stops updating the recycled subspace after linear system* 405*, and a version that stops updating after linear system* 405 *but runs standard GCROT every* 100*th system thereafter. In the latter case, convergence remains small for about four or five systems after using standard GCROT, but then quickly deteriorates, showing the importance of updating the approximate invariant subspace regularly. Note that GCROT, too, is able to restore rapid convergence in the course of a single linear system.*

4.2. Electronic structure. First-principles, electronic-structure calculations based on the Schrödinger equation are used to predict key physical properties of materials systems with a large number of atoms. We consider systems arising in the KKR (Korringa–Kohn–Rostoker) method [16, 17] and seek to compute entries in the inverse of the matrix

$$G = (I - (t - t_{\text{ref}})G_{\text{ref}})^{-1}(t - t_{\text{ref}}),$$

where G_{ref} is a sparse and easily invertible matrix and t and t_{ref} are block-diagonal matrices. G is a sparse, complex, non-Hermitian matrix whose relative number of nonzeros decreases with the number of atoms [14, 40, 32].

Only the block-diagonal elements of G^{-1} are needed to calculate physical properties, such as charge densities, total energy, force, and formation and defect energies. As such, we solve $GX = I$, column-by-column. Iterative methods offer the advantage of storing only those components of the inverse that we need. Standard direct inversion methods are infeasible for large numbers of atoms ($N \geq 500$) on regular workstations, because the memory and computational costs grow as $O(N^2)$ and $O(N^3)$, respectively.

We consider a small model problem provided by Duane Johnson (Materials Science and Engineering, UIUC) and Andrei Smirnov (Oak Ridge National Laboratory). The problem involves the simulation of a cubic lattice of 54 copper atoms (treated as inequivalent) for a complex energy point close to the real axis. This is the key physical regime for metals and leads to problems that converge poorly. The matrix is 864×864 and has about 300,000 nonzeros. However, for increasingly larger systems the matrix

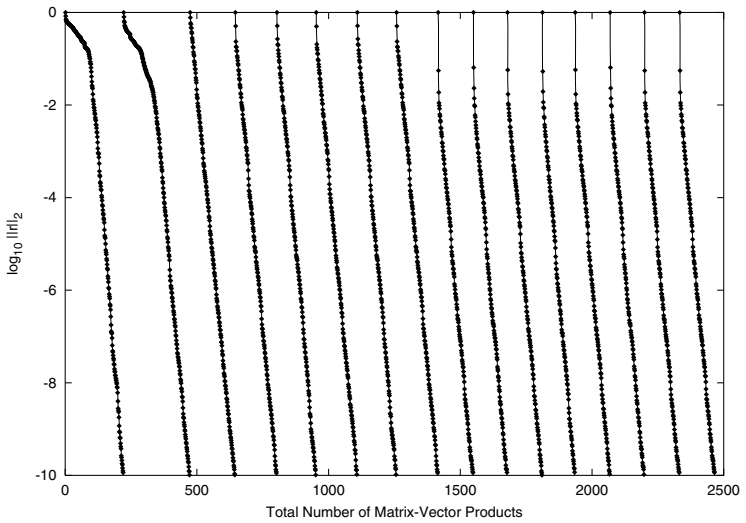

FIG. 4.7. *Convergence for* 16 *consecutive right-hand sides for a small electronic structure problem. Each distinct curve gives the convergence for a subsequent right-hand side, plotted against the total number of matrix-vector products. The first two right-hand sides together take about* 500 *iterations, while the remaining right-hand sides take about* 140 *iterations each, a reduction of almost* 50*%.*

becomes more sparse; the number of nonzeros grows roughly linearly with the size of the matrix. We solved this problem using GCRO-DR(50,25) with subspace recycling for 32 consecutive right-hand sides (the first 32 unit Cartesian basis vectors). We give the convergence history for the first atom in Figure 4.7. Note that the first two right-hand sides together take about 500 iterations; the remaining right-hand sides take approximately 140 iterations each, a reduction of almost 50%. Each right-hand side for the second atom (not shown) also takes approximately 140 iterations. Although for problems of this size iterative methods are not competitive with direct solvers, we have observed this convergence behavior for larger problems, in particular the immediate acceleration in convergence for subsequent right-hand sides.

4.3. QCD. Quantum chromodynamics (QCD) is the fundamental theory describing the strong interaction between quarks and gluons. Numerical simulations of QCD on a four-dimensional space-time lattice are considered the only way to solve QCD ab initio [4, 35]. As the problem has a 12×12 block structure, we are often interested in solving for 12 right-hand sides related to a single lattice site. The linear system to be solved is $(I - \kappa D)x = b$ with $0 \leq \kappa < \kappa_c$, where D is a sparse, complex, non-Hermitian matrix representing periodic nearest neighbor coupling on the four-dimensional space-time lattice [19]. For $\kappa = \kappa_c$ the system becomes singular. The physically interesting case is for κ slightly smaller than κ_c; κ_c depends on D.

As a model problem we use the matrix `conf5.0_0014x4.1000.mtx` downloaded from the Matrix Market website at NIST [2]. The model problems were submitted by Medeke [19]. For this problem we have $\kappa_c = 0.20611$, and we used $\kappa = 0.202$.

We solve for 12 consecutive right-hand sides (the first 12 Cartesian basis vectors) using the GCROT method with subspace recycling. The results are presented in Figure 4.8.

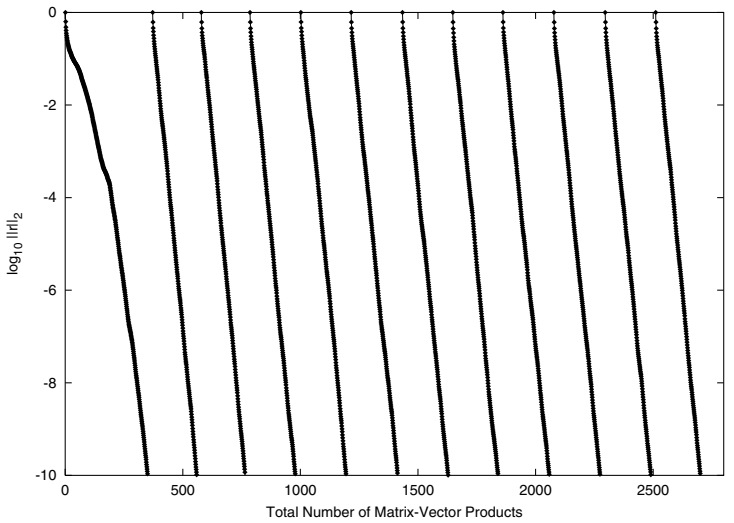

FIG. 4.8. *Convergence for* 12 *consecutive right-hand sides for a model QCD problem from the NIST Matrix Market. Each distinct curve gives the convergence for a subsequent right-hand side, plotted against the total number of matrix-vector products. Note that the final convergence rate for the first system is the starting convergence rate for the rest of the systems.*

4.4. Convection-diffusion. We consider the finite difference discretization of the partial differential equation

$$u_{xx} + u_{yy} + cu_x = 0$$

on $(0,1) \times (0,1)$ with boundary conditions

$$u(x,0) = u(0,y) = 0,$$
$$u(x,1) = u(1,y) = 1.$$

Central differences are used, and we set the mesh width to be $h = 1/41$ in both directions, which results in a 1600×1600 matrix. We consider the symmetric case, $c = 0$, and a nonsymmetric case for $c = 40$. The eigenvalues are real for both these examples. In order to study how a recycled subspace affects convergence, we will consider the "ideal" situation for subspace recycling by solving a linear system , , with GCRO-DR and GCROT, recycling the subspace generated from the first run.

In this example, we consider GMRES(∞), GMRES(25), GMRES-DR(25,10), GCRO-DR(25,10), and GCROT(25,18,15,5,1,1). To explore the effects of subspace recycling on this example problem, we , , GCRO-DR and GCROT on the same linear system, and recycle the subspace from the first run. We do this to exclude the effects of right-hand sides having slightly different eigenvector decompositions. In a sense, this is the ideal case for subspace recycling. The first run for GCRO-DR is the same as GMRES-DR. The results for the $c = 40$ (nonsymmetric) case are quite interesting and counterintuitive. In particular, this example suggests that there are better choices for a recycle space than approximate invariant subspaces. This topic is discussed further in [23]. We give the results for the symmetric case, $c = 0$, in Figure 4.9 and for the nonsymmetric case with $c = 40$ in Figure 4.10. In the legend for each of these figures, , , , denotes the second run of a solver that was run twice. All solvers were required to reduce the relative residual to 1.0×10^{-10}.

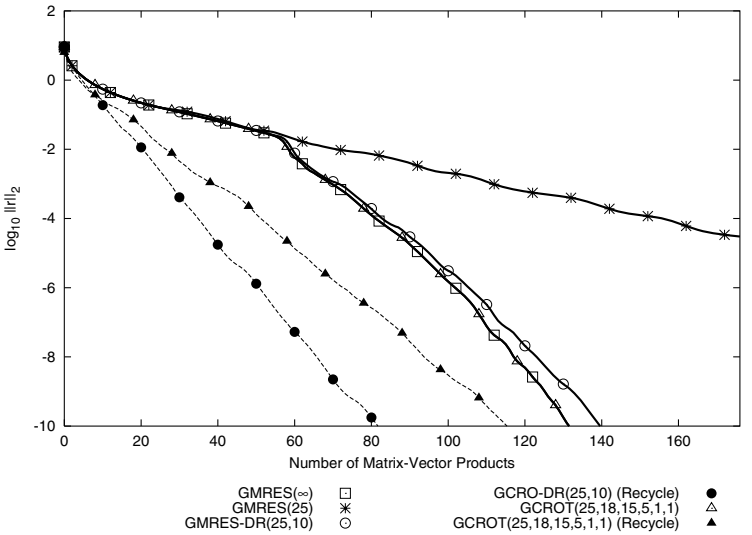

FIG. 4.9. *Residual norm versus number of matrix-vector products for various solvers for the convection-diffusion problem with* $c = 0$.

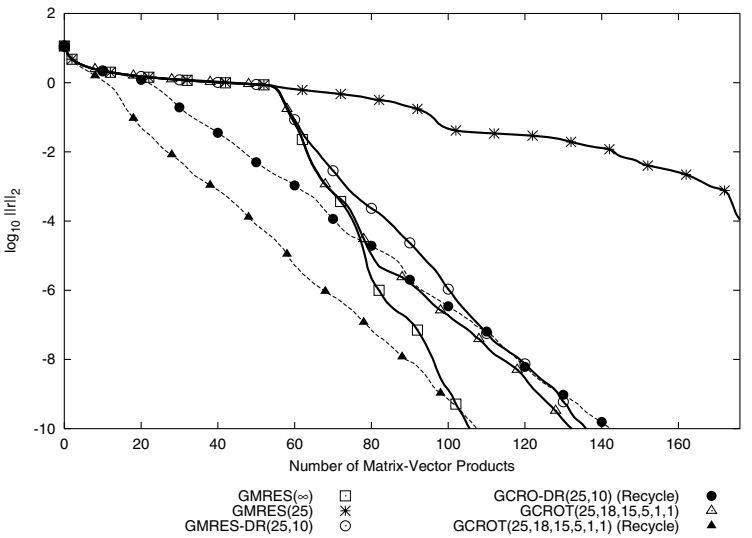

FIG. 4.10. *Residual norm versus number of matrix-vector products for various solvers for the convection-diffusion problem with* $c = 40$.

For the $c = 0$ case, we see that the second runs of GCRO-DR and GCROT both converged faster than GMRES(∞). Note that on its first run GCROT converges as fast as full GMRES and slightly faster than GCRO-DR/GMRES-DR. On the rerun, however, GCRO-DR is faster than GCROT, suggesting a more effective recycle space. Clearly, GCRO-DR and GCROT recycled a small subspace from their first run that improved convergence significantly. For the $c = 40$ case, GMRES(∞) and the second run of GCROT terminate in about the same number of iterations, but the second run of GCROT had a significantly smaller residual for almost the entire run. Only near

the end, with a much larger search space, does GMRES(∞) catch up. The second run of GCROT also does better than its first run, indicating that it recycled a subspace useful for convergence. However, GCRO-DR performed initially somewhat better on the second run than the first, but the overall iteration count was approximately the same for both runs. This means that the subspace it recycled failed to improve convergence. For more analysis on the selection of good recycle spaces, see [23, 15, 24].

Table 4.3 shows the cosines of the principal angles between the subspace recycled by GCRO-DR and the invariant subspaces associated with the 10 and 21 eigenvalues of smallest magnitude, respectively, for the $c = 0$ and $c = 40$ cases. For the comparison with 10 eigenvectors, we see that the recycle space for the $c = 0$ case captures only 5 eigenvectors. We compare with the space spanned by 21 eigenvectors because it captures the entire recycled subspace for the $c = 0$ case. This means that GCRO-DR does not select the invariant subspace spanned by the eigenvectors for the 10 smallest eigenvalues, but rather selects some subspace of the space spanned by the 21 smallest. The table also shows that the approximation of an invariant subspace for the $c = 40$ case is nearly as good as for $c = 0$. However, this does not lead to similar convergence.

5. Conclusions and future work. We have presented an overview of Krylov subspace recycling for sequences of linear systems, where both the matrix and right-hand side change. Different choices for subspace selection and recycling have been shown, as well as methods implementing those choices. We propose the new solver GCRO-DR to implement Krylov subspace recycling of approximate invariant subspaces for Hermitian and non-Hermitian systems. We provide two important theoretical results complemented by a set of experiments to analyze the convergence of GCRO-DR for a typical application generating a long sequence of linear systems. GCROT has convergence behavior similar to GCRO-DR regarding recycling, but theoretical results for this method are a topic of future research. When solving a sequence of linear systems, methods employing Krylov subspace recycling frequently outperformed GMRES(∞) while recycling a subspace of only small dimension and minimizing over a small subspace. However, as particular examples in section 4.4 show, it is not completely clear how subspace selection affects convergence, so further theory is needed. Short recurrence methods for the Hermitian case have been developed [15].

ON MASS-CONSERVING LEAST-SQUARES METHODS*

J. J. HEYS†, E. LEE‡, T. A. MANTEUFFEL‡, AND S. F. MCCORMICK‡

Abstract. Least-squares variational methods have several practical and theoretical advantages for solving elliptic partial differential equations, including symmetric positive definite discrete operators and a sharp error measure. One of the potential drawbacks, especially in three dimensions, is that mass conservation is achieved only in a least-squares sense, and underresolved solutions are especially vulnerable to poor conservation. For the stationary Navier–Stokes equations, which are typically rewritten as a larger system of first-order equations, the loss of mass in the approximate solution is strongly dependent upon the boundary conditions used. A new first-order system reformulation of the Navier–Stokes equations is presented that admits a wider range of mass-conserving boundary conditions. This new formulation is shown to provide both excellent mass conservation and excellent algebraic multigrid performance for three different problems, a square channel, backward-facing step, and branching tubes with two generations of bifurcations.

Key words. Navier–Stokes, conservation, finite elements, least squares, multigrid

1. Introduction.

Least-squares variational principles have been repeatedly recognized as a new tool to solve elliptic partial differential equations [6]. For the Stokes and Navier–Stokes equations in particular, a number of advantages are present [3, 4, 24], including the following:

- the weak formulations are associated with a minimization problem, resulting in several computational advantages;
- the finite element spaces for each variable may be chosen independently because the inf-sup (or LBB) stability condition does not apply; and
- the functional provides a sharp, local error measure at no additional computational cost.

However, these benefits do not come without some drawbacks. In our experience, the following two are the most significant:

- when popular C^0 finite elements are used, the number of dependent variables typically increases over the original formulation (by a factor of 2 to 3 in many cases); and
- a lack of conservation of mass resulting in "ugly" solutions.

The computational advantages associated with least-squares finite element methods (LSFEM) are usually sufficient to overcome the first drawback, especially as problems become larger due to the scalability of multigrid solvers [9], which are often used in

conjunction with least-squares methods [12]. Further, in many cases, the additional variables are physically important quantities that must be calculated at some point, regardless of the discretization method being used. It is the second drawback, the lack of conservation of mass, that is the focus of this paper.

Mass conservation between any inflow surface, Γ_i, and an outflow surface, Γ_o, which are possibly connect with impermeable boundaries, is typically measured in terms of the fractional change of mass flow, defined as

$$\frac{\int_{\Gamma_i}(\mathbf{n}\cdot\mathbf{v})d\Gamma_i - \int_{\Gamma_o}(\mathbf{n}\cdot\mathbf{v})d\Gamma_o}{\int_{\Gamma_i}(\mathbf{n}\cdot\mathbf{v})d\Gamma_i},$$

where $\mathbf{v}$ is the velocity of an incompressible fluid. The mass conservation can be measured either globally over the entire domain or locally over smaller subdomains. If the velocity is completely specified over all boundaries, it must be set to satisfy the global mass-conservation constraint, and only local mass conservation will not be exactly satisfied. Published computational results [16] and our own experience show that when global mass conservation is enforced through boundary conditions, LSFEM give approximate solutions with acceptable local mass conservation. However, a common flow problem involves the velocity being completely specified only along the inflow and wall regions but not completely specified along the outflow regions. In this case, the error in global mass conservation is approximately the accumulation of errors in local mass conservation between the inlet and outlet. It is these types of flow problems, where the outlet velocity is not fully specified, that are the subject of this paper. The goal is to improve global mass conservation while maintaining the strengths of LSFEM, specifically the multigrid convergence rates. This is in contrast to many of the existing methods to improve mass conservation, which result in slower convergence rates for standard multigrid.

Mass conservation in Galerkin formulations of the Navier–Stokes equations is enforced by the divergence-free constraint on the velocity field, which essentially uses pressure as a Lagrange multiplier. With least-squares formulations, the objective is to minimize, in a least-squares sense, the value of a functional. For example, the stationary Navier–Stokes equations in dimensionless form are

$$-Re\,(\mathbf{v}\cdot\nabla\mathbf{v}) - \nabla p + \Delta\mathbf{v} = 0 \quad \text{in } \Omega, \tag{1.1}$$

$$\nabla\cdot\mathbf{v} = 0 \quad \text{in } \Omega, \tag{1.2}$$

where p is the pressure normalized by viscosity, Re is the Reynolds number, and $\mathbf{v} = (v_x, v_y, v_z)$ is the dimensionless velocity. Equations (1.1) and (1.2) may be combined in a least-squares sense into a single functional given by

$$G(\mathbf{v},p) := \alpha\| - Re\,(\mathbf{v}\cdot\nabla\mathbf{v}) - \nabla p + \Delta\mathbf{v}\|^2_{0,\Omega} + \beta\|\nabla\cdot\mathbf{v}\|^2_{0,\Omega}\,. \tag{1.3}$$

In practice, $G(\mathbf{v},p)$ would never be minimized because it exhibits behavior similar to a biharmonic, but it is shown to illustrate that there is always a balance between equations. The first term in G represents conservation of momentum, and the second represents conservation of mass. One of the potential strengths of least-squares methods is that, by adjusting the values of constants α and β, the error can be distributed between mass and momentum conservation in a controlled manner. However, changing the values of α and β almost always affects solver performance. For example, making β larger (i.e., less error in conservation of mass) can result in faster or slower multigrid convergence, depending on the Reynolds number, Re, and the actual

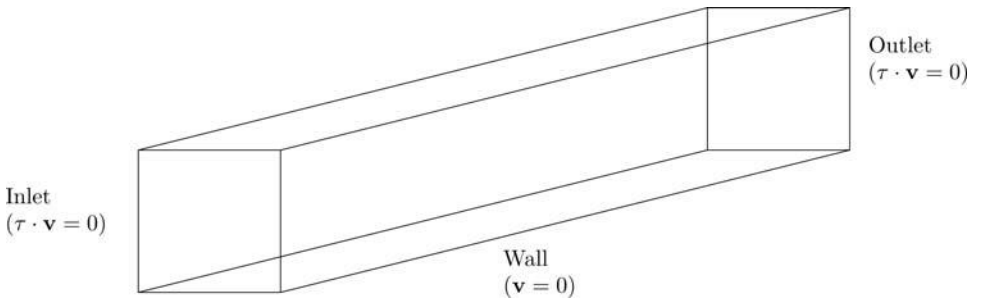

FIG. 1.1. *The test problem domain consisting of a brick with an aspect ratio of* 4:1:1.

functional used (G is not a computationally practical functional and is rarely used). The effects of weighting the functional are demonstrated later in this paper, but, even though this can be beneficial in some situations, it should not be considered a universal solution [8].

The focus in this paper is on stationary or steady-state Navier–Stokes equations, although some general statements can be made about the extension to nonstationary Navier–Stokes using implicit time stepping. The additional terms in the functional due to the discrete approximation of the time derivative makes the diagonal of the operator larger and, hence, it is usually more efficiently solved by a multigrid algorithm. Further acceleration is realized by the fact that the previous time step solution provides a good initial guess to the new time step. As a result, the methods proposed in this paper are also good methods for solving the nonstationary problem if implicit time stepping is desired.

1.1. Model problem and loss of mass conservation. We introduce a simple test problem to illustrate the mass-conservation issue associated with existing least-squares methods. The test problem was chosen to be as simple as possible while still capturing the key mass-conservation issues. Initially, the Reynolds number is set to zero because the important mass conservation issues exist in Stokes flow as well as laminar Navier–Stokes flow. Later, results using nonzero Reynolds numbers are given. While it is possible to demonstrate some of the mass-conservation issues in two dimensions, Pontaza and Reddy [24] recently showed that using higher-order finite elements largely alleviates the problems in two dimensions. Our own experiences agree with this finding, but, as we show, moving to higher-order elements is not as effective in addressing the mass-conservation issues in three dimensions. Therefore, the domain for the test problem is the simple "brick" shown in Figure 1.1 with an aspect ratio of 4:1:1. The long sides of the brick are walls upon which the no-slip boundary condition is imposed. Along the inlet and outlet, the tangential velocity is set to zero, and an additional boundary condition to be chosen later must also be set.

The functional, G, given by (1.3) has a higher regularity requirement and cannot be used with practical C^0 finite element spaces. Typically, the governing equations are transformed into an equivalent system of first-order equations. A number of different methods exist for generating a first-order system for the Navier–Stokes equations [3, 4]. One approach is based on defining a matrix of new variables, $\mathbf{V}$, equal to the gradient of the velocity vector. The first-order system for Navier–Stokes equations is then written as

$$\begin{aligned} &\mathbf{V} - \nabla \mathbf{v} = 0 && \text{in } \Omega, \\ &-Re(\mathbf{v} \cdot \mathbf{V}) - \nabla p + \nabla \cdot \mathbf{V} = 0 && \text{in } \Omega, \\ &\nabla \cdot \mathbf{v} = 0 && \text{in } \Omega. \end{aligned} \tag{1.4}$$

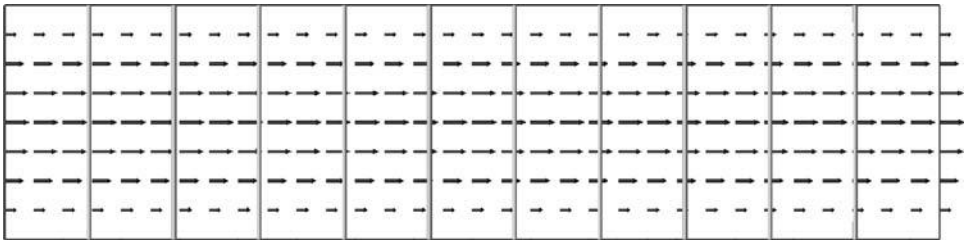

FIG. 1.2. *Cross-section of flow through the brick domain using the velocity-flux formulation of the Navier–Stokes equations. The pressure is set to* 1 *at the inlet and* 0 *at the outlet, and the contour bars represent evenly spaced pressure lines.*

Because $\mathbf{V}$ is the gradient of $\mathbf{v}$ and we are solving a minimization problem, we can augment the first-order system of equations by the following consistent equations:

$$\begin{aligned} \nabla(\mathrm{tr}(\mathbf{V})) &= 0 \quad \text{in } \Omega, \\ \nabla \times \mathbf{V} &= 0 \quad \text{in } \Omega, \end{aligned} \tag{1.5}$$

where $\mathrm{tr}(\mathbf{V}) = V_{11} + V_{22} + V_{33}$. This first-order formulation of the Navier–Stokes equations is often called the "velocity-flux" formulation, and it has a number of theoretical and practical advantages, including optimal error estimates in the H^1 norm for each variable and optimal multigrid convergence estimates [7, 4]. The corresponding functional for the velocity-flux formulation is

$$\begin{aligned} G_{v.f.}(\mathbf{V},\mathbf{v},p) := \|\mathbf{V} - \nabla\mathbf{v}\|^2_{0,\Omega} + \| - Re\,(\mathbf{v}\cdot\mathbf{V}) - \nabla p + \nabla\cdot\mathbf{V}\|^2_{0,\Omega} \\ + \|\nabla\cdot\mathbf{v}\|^2_{0,\Omega} + \|\nabla(\mathrm{tr}(\mathbf{V}))\|^2_{0,\Omega} + \|\nabla\times\mathbf{V}\|^2_{0,\Omega}. \end{aligned} \tag{1.6}$$

To minimize the functional $G_{v.f.}$ over the test domain shown in Figure 1.1, additional boundary conditions must be defined along the inlet and outlet. A common boundary condition is to set the normal stress on the normal face (i.e., the natural boundary condition) equal to a constant. For this domain with no tangential velocity at the inlet and outlet, setting the normal stress to a constant is equivalent to setting the pressure to a constant. The results of setting the inlet pressure (i.e., the normal stress) to 1 along the inlet and 0 along the outlet are shown in Figure 1.2. To generate this result, a hexahedral (cubic) mesh of $32 \times 8 \times 8$ elements was used ($h = 1/8$), the Reynolds number was set to zero (i.e., Stokes flow), and a trilinear finite element basis was used. Even though Figure 1.2 only shows the central cross-section of the brick, it is clear that there is good mass conservation based on a visual inspection. In fact, integrating the velocity field along the inlet and outlet (or any other cross-section orthogonal to the flow) shows perfect mass conservation up to 5 digits. The value of the functional at the approximate solution is 4.0×10^{-3}. If we look at the size of different terms in the functional, the divergence term, $\nabla\cdot\mathbf{v}$, is very small at 5.8×10^{-9}, and the error is largely in the momentum term, $-Re\,(\mathbf{v}\cdot\mathbf{V}) - \nabla p + \nabla\cdot\mathbf{V}$, with a value of 1.6×10^{-3}.

At this point, the least-squares formulation appears to provide excellent mass conservation. However, a change in the inlet boundary condition can have a dramatic effect. For example, the result of replacing the natural inlet condition, $p = 1$, with an essential one, in which the normal velocity is set to $v_x = y(1-y)z(1-z)$, is shown in Figure 1.3. It is important to note that the inlet condition is not set to the steady flow profile, but it is a valid boundary condition. The total value of the functional

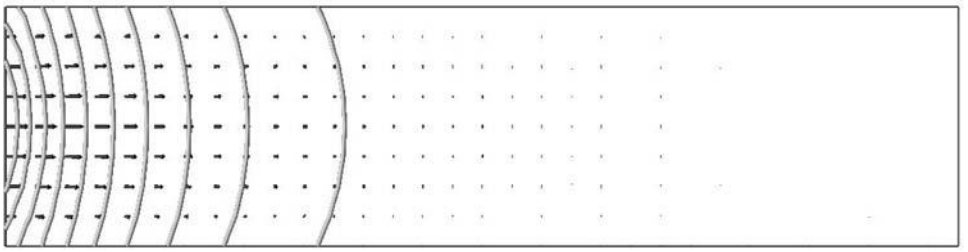

FIG. 1.3. *Cross-section of flow through the brick domain using the velocity-flux formulation of the Navier–Stokes equations. The normal velocity is set to* $v_x = y(1-y)z(1-z)$ *at the inlet and the pressure to* 0 *at the outlet, and the contour bars represent evenly spaced pressure lines.*

at the minimum is 6.0×10^{-3}, and the divergence term in the functional (5×10^{-4}), representing conservation of mass, is now nearly the same size as the momentum term (1×10^{-3}). The total flow rate into the domain is 2.7×10^{-2} and the outflow rate is 5.0×10^{-5}, a 99.8% loss of mass. The key to understanding this mass loss is to look at the pressure, which should be decreasing nearly linearly except for some small entrance effects near the inlet. Instead, the functional is a minimum when both the pressure and the flow rate are approximately zero for two-thirds of the domain lying downstream. Clearly, the functional is approximately zero for the downstream portion of the domain, which helps keep the functional small. The larger error at the entrance is not sufficient to make the overall functional value large. Remember, this method finds the solution that [illegible] the functional over all possible solutions in the finite element space. In other words, if we do not like the solution, we asked the method to minimize a functional that does not capture our requirements for the solution.

1.2. Possible remedies. Several approaches can be taken to "fix" the conservation of mass problem illustrated in the previous example (i.e., Figure 1.3), including the following:

- reducing the mesh size, h;
- weighting the velocity-divergence term in the functional;
- using higher-order elements or some other finite element space (e.g., [10]); and
- using a different first-order system of equations that is still equivalent to the Navier–Stokes equations.

Other, more complex remedies can be used, including norms other than L^2 norms or using a FOSLL* approach [11], but only the approaches listed above are explored here. Below, each of these options is individually explored using the previous test problem. In most cases, mass conservation is improved at the cost of multigrid performance, making the remedy unacceptable.

Reducing the mesh size has the advantage that it should improve mass conservation and not make the problem worse. As the mesh size approaches zero, the approximate solution approaches the true solution at the expected rate, which depends on the finite element basis. However, because conservation of mass is currently far from being acceptable, significant refinement is required before the approximation becomes acceptable. For example, if the previous mesh ($32 \times 8 \times 8$) is refined to ($64 \times 16 \times 16$), the loss of mass is only reduced from 99.8% to 98.8%.

As mentioned previously, weighting the divergence of velocity term in the functional can also improve conservation [16]. If the divergence term in the velocity-flux

formulation (i.e., $G_{v.f.}$) is weighted by 100, the mass loss is reduced from 99.8% to 0.7%. However, the multigrid convergence factor, defined as

$$\rho \approx \sqrt[m]{\frac{\|res^{(m)}\|_2}{\|res^{(0)}\|_2}}, \tag{1.7}$$

where $res^{(m)}$ is the residual (or defect) after the mth V-cycle, is increased from 0.74, with a weight of 1.0, to 0.87, with a weight of 100.0. To put that change into perspective, reducing the residual norm by a factor of 1.0×10^{-8} requires 62 V-cycles when the convergence factor is 0.74, and 132 V-cycles when the convergence factor is 0.87, a doubling of the total computational cost. Further, in our experience, larger weights are required as the domain becomes more complex, especially domains with high aspect ratios. Multigrid methods that perform well on this class of problems exist, but require special elements and special relaxation techniques (cf. [2]). A similar idea to weighting the divergence term is to enforce it through a Lagrange multiplier strategy [13]. In this case, the operator is still symmetric, but the now indefinite operator is not effectively solved using a standard multigrid method.

It has been shown by both Pontaza and Reddy [24] and Deang and Gunzburger [16] that higher-order (or spectral) elements can produce very accurate results with least-squares formulations. This has been shown extensively in two dimensions, but it has not been demonstrated in three dimensions. Further, the computational costs associated with least-squares formulations in three dimensions with high-order elements can become prohibitive. For example, in the velocity-flux formulation there are 13 variables per node in three dimensions. Taking the tensor product of 3 eighth-order nodal basis functions results in an element with 729 nodes. The cost of storing a single element stiffness matrix with double precision variables approaches 1 gigabyte. If eighth-order basis functions are too expensive to store, one may ask what is the benefit of simply refining from trilinear elements to triquadratic elements. For the test problem above with the essential condition on velocity along the inlet, the mass loss is decreased from 99.8% to 64%, a significant improvement. However, even the improved mass conservation is still not acceptable, and it came at a increased computational cost (e.g., if the one-dimensional polynomial order is p, then computational costs scale as $O(p^6)$ if exact integration is used).

Related to the idea of using alternative finite element spaces is the idea of using reduced integration methods [21, 26]. Often, the use of reduced integration results in a collocation solution [6, 24]. The net effect of using reduced integration on most problems, including the test problem, is excellent conservation of mass, loss of the functional as an error measure because it is zero at the minimum, and poor multigrid performance. For example, when using reduced integration on the brick test problem, mass was conserved up to at least 5 digits of accuracy, but thousands of algebraic multigrid V-cycles were required for marginal convergence. In this case, a direct solver would have been much more effective, but our desire is to find a solution to the mass conservation problem that maintains the optimal computational scalability of standard multigrid.

The final approach we mention is to change the form of the functional (i.e., to use a different first-order system of equations). This approach is attractive due to our previous observation that if we do not like the approximate solution that minimizes the functional, then we are using the wrong functional. The most popular first-order system that is equivalent to the Navier–Stokes equations is the vorticity system, given

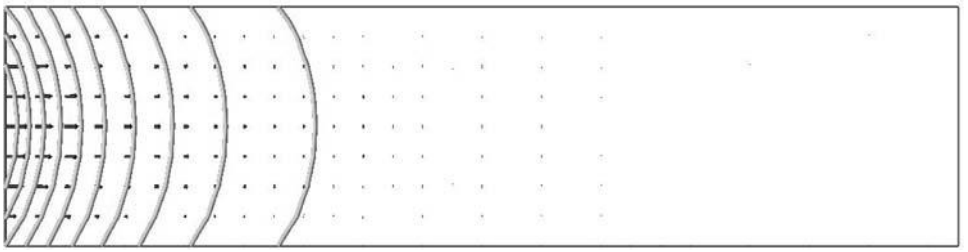

FIG. 1.4. *Cross-section of flow through the brick domain using the vorticity formulation of the Navier–Stokes equations. The normal velocity is set to* $v_x = y(1-y)z(1-z)$ *at the inlet and the pressure to* 0 *at the outlet, and the contour bars represent evenly spaced pressure lines.*

by

$$\begin{aligned} &\omega + \nabla \times \mathbf{v} = 0 && \text{in } \Omega, \\ &-Re(\mathbf{v}\cdot\nabla)\mathbf{v} - \nabla p + \nabla \times \omega = 0 && \text{in } \Omega, \\ &\nabla \cdot \mathbf{v} = 0 && \text{in } \Omega. \end{aligned} \tag{1.8}$$

Because ω, the vorticity, is the negative curl of $\mathbf{v}$ and we are solving a minimization problem, we can augment this first-order system by the following consistent equation:

$$\nabla \cdot \omega = 0 \quad \text{in } \Omega. \tag{1.9}$$

The corresponding functional for the vorticity formulation is

$$\begin{aligned} G_\omega(\omega, \mathbf{v}, p) := \|\omega + \nabla \times \mathbf{v}\|^2_{0,\Omega} + \| - Re\,(\mathbf{v}\cdot\nabla)\,\mathbf{v} - \nabla\, p + \nabla \times \omega\|^2_{0,\Omega} \\ + \|\nabla \cdot \mathbf{v}\|^2_{0,\Omega} + \|\nabla \cdot \omega\|^2_{0,\Omega}. \end{aligned} \tag{1.10}$$

One advantage of this formulation is that it contains only 7 dependent variables in three dimensions, almost half the number of the velocity-flux formulation; however, since it is not a fully H^1-coercive system [6], optimal multigrid convergence cannot be proven. Nevertheless, since the focus here is on mass conservation, we examine the effects of this formulation on mass loss through the brick domain using the same boundary conditions as Figure 1.2 (i.e., $v_x = y(1-y)z(1-z)$ along the inlet). The results are summarized by the cross-section shown in Figure 1.4, and they demonstrate extensive mass loss similar to the velocity-flux formulation. In this case, the mass loss is 99.9%, even worse than the 99.8% previously observed, and the multigrid convergence factor was significantly worse, requiring approximately twice the number of V-cycles. The final value of the functional, G_ω, was 2.7×10^{-3}, but most of the error was in the divergence-of-velocity term (1.1×10^{-3}). Clearly, the two first-order systems for the stationary Navier–Stokes equations commonly found in the literature do not provide acceptable mass conservation for this set of boundary conditions in three dimensions.

In summary, even though some of the remedies tested improved mass conservation, they did so at the cost of multigrid performance. Since the goal is to improve mass conservation without an appreciable decline in multigrid performance, none of these remedies is acceptable. The only solution shown to improve mass conservation without a decline in multigrid performance is setting boundary conditions on pressure for both the inlet and outlet. This observation first provoked an effort to find a new formulation that allows pressure boundary conditions to be set in a more flexible way.

During this effort, we developed a formulation that not only allowed new boundary conditions to be set that incorporated pressure, but the new formulation also achieves better computational performance (i.e., multigrid convergence rates) at the same. In this way, it satisfies our goal of improving mass conservation while maintaining the strengths of the LSFEM methodology.

2. New formulation. Before defining the new formulation, we need the identity

$$\nabla \times (\mathbf{v} \cdot \nabla)\mathbf{v} = (\mathbf{v} \cdot \nabla)\omega - (\omega \cdot \nabla)\mathbf{v}, \tag{2.1}$$

and we define a new variable $\mathbf{r}$ as

$$\mathbf{r} = \nabla p + Re(\mathbf{v} \cdot \nabla)\mathbf{v} \ . \tag{2.2}$$

The new variable is equal to the pressure gradient plus the convective term. We now introduce the following first-order system to replace the Navier–Stokes equations:

$$\begin{array}{ll} \nabla \times \mathbf{v} + \omega = 0 & \text{in } \Omega, \\ \nabla \cdot \mathbf{v} = 0 & \text{in } \Omega, \\ \nabla \times \omega - \mathbf{r} = 0 & \text{in } \Omega, \\ \nabla \cdot \omega = 0 & \text{in } \Omega, \\ \nabla \times \mathbf{r} - Re(\mathbf{v} \cdot \nabla\omega - \omega \cdot \nabla\mathbf{v}) = 0 & \text{in } \Omega, \\ \nabla \cdot \mathbf{r} = 0 & \text{in } \Omega. \end{array} \tag{2.3}$$

The first two equations in system (2.3) are the same as those previously used in the vorticity formulation. The third equation is the momentum balance, rewritten in terms of $\mathbf{r}$ and the curl of vorticity. The fourth equation is derived by taking the divergence of the first equation. The fifth equation comes from taking the curl of (2.2), and the final equation is the result of taking the divergence of the momentum balance. The corresponding functional for the new formulation is

$$\begin{aligned} G_{new}(\omega, \mathbf{v}, \mathbf{r}) := & \|\omega + \nabla \times \mathbf{v}\|^2_{0,\Omega} + \|\nabla \cdot \mathbf{v}\|^2_{0,\Omega} \\ & + \|\mathbf{r} + \nabla \times \omega\|^2_{0,\Omega} + \|\nabla \cdot \omega\|^2_{0,\Omega} \\ & + \|\nabla \times \mathbf{r} - Re(\mathbf{v} \cdot \nabla\omega - \omega \cdot \nabla\mathbf{v})\|^2_{0,\Omega} + \|\nabla \cdot \mathbf{r}\|^2_{0,\Omega} \ . \end{aligned} \tag{2.4}$$

To further analyze this system of equations, it is useful to rewrite the system using slack variables, α, β, and δ, and moving subprincipal terms to the right-hand side, giving:

$$\begin{array}{cccccccc} \nabla \times \mathbf{v} & -\nabla\alpha & & & & & = & -\omega, \\ \nabla \cdot \mathbf{v} & & & & & & = & 0, \\ & & \nabla \times \omega & -\nabla\beta & & & = & \mathbf{r}, \\ & & \nabla \cdot \omega & & & & = & 0, \\ & & & & \nabla \times \mathbf{r} & -\nabla\delta & = & Re(\mathbf{v} \cdot \nabla\omega - \omega \cdot \nabla\mathbf{v}), \\ & & & & \nabla \cdot \mathbf{r} & & = & 0. \end{array} \tag{2.5}$$

Here, the slack variables are included to help analyze the new formulation, but the boundary conditions are set so that the slack variables, α, β, and δ, are equal to zero everywhere and, hence, are not necessary in the computation. The system of equations given by (2.5) contain a block diagonal operator with three blocks. Each block consists of a curl and divergence of a variable we are interested in approximating. With the proper boundary conditions on each block (specifically, one condition on the

slack variable and one on the original variable in the normal direction or, alternatively, conditions on the original variable in the two tangential directions), it is easy to show that the functional associated with (2.5) and $Re = 0$ is continuous and coercive in the $(H(\text{div}) \cap H(\text{curl})) \times H^1$ norm for each block of variables. The results are obtained by using a standard compactness argument. For the lowest block, containing the curl and divergence of $\mathbf{r}$, boundary conditions are typically set on $\mathbf{n} \cdot \mathbf{r}$, where $\mathbf{n}$ is the normal vector, and on slack variable δ. For the central block, boundary conditions are set on the normal vorticity and on slack variable β. For the upper block, boundary conditions only need to be set on the normal velocity and α because the tangential velocity is related to the normal vorticity, but, in practice, boundary conditions are set on two or all three of the velocity components.

If the Reynolds number is set to zero, the system of equations (2.5) can be solved by inverting the individual blocks of the matrix. First, the bottom block is inverted to calculate $\mathbf{r}$, then $\mathbf{r}$ is used on the right-hand side of the central block, which is inverted to calculate ω. Finally, ω is used to calculate the velocity, $\mathbf{v}$. In this way, storage costs can be reduced by requiring only that the blocks of the operator be stored. Further, these div/curl blocks are solved very efficiently by multigrid solvers. If the Reynolds number is not equal to zero, the block strategy can still be used, but an initial guess for $\mathbf{v}$ and ω is required followed by multiple iterations. In practice, we assemble the full operator because it is efficiently handled by multigrid and makes the implementation more straightforward.

The boundary conditions for the new formulation are similar to those typically used for the traditional vorticity formulation except for those on $\mathbf{r}$. An excellent description and classification of possible boundary conditions on $\mathbf{v}$ and ω can be found in the work of Bochev [3]. Fully specifying the velocity along all boundaries is sufficient to obtain a well-posed problem having a unique solution. However, the inclusion of boundary conditions on $\mathbf{n}\cdot\omega$ and $\mathbf{n}\cdot\mathbf{r}$ results in the operator being coercive in H^1 and optimal multigrid performance on the linear system. Before the boundary conditions are described in detail, it is important to note that all boundary conditions can be imposed either strongly on the finite element space or weakly by including the boundary conditions in the least-squares functional. This flexibility is useful since we want to strongly impose some boundary conditions, like the no-slip condition on velocity, while others are typically imposed weakly.

Along the walls or the no-slip boundaries, all velocity components are set to zero, the normal vorticity is set to zero, and $\mathbf{n} \cdot \mathbf{r}$ is set to zero (see Table 2.1). The last boundary condition, which is set on $\mathbf{r}$, can be explained by the equation

$$\mathbf{n} \cdot \mathbf{r} = \mathbf{n} \cdot \nabla p + \mathbf{n} \cdot (Re(\mathbf{v} \cdot \nabla)\mathbf{v}) = \mathbf{n} \cdot \Delta\mathbf{v}, \tag{2.6}$$

where $\Delta\mathbf{v} \equiv (\nabla \cdot \nabla)\mathbf{v}$. Therefore, setting $\mathbf{n} \cdot \mathbf{r}$ to zero along the wall can be viewed physically in two different ways. First, it is equivalent to setting the second derivative of the normal velocity in the normal direction to zero (i.e., the normal velocity must be zero near the wall as well as at the wall). Second, since the normal velocity is zero at the wall, it is equivalent to setting the normal derivative on pressure to zero, and this is consistent with the basic assumptions of Prandtl's boundary layer theory [28].

Inflow and outflow boundary conditions are a well-known difficulty in computational fluid dynamics [18]. For the new formulation, boundary conditions are typically set on two or three of the velocity components (see Table 2.1), although it is possible to set a condition on just the normal velocity. A condition should be set only on the normal vorticity because fully specifying the vorticity usually results in a problem

TABLE 2.1
Boundary conditions used for the the new formulation. τ_1 and τ_2 are the two tangential vectors along the inlet and c is an unknown constant that approximates $\frac{\partial^2 \mathbf{v}_n}{\partial \mathbf{n}^2}$.

Boundary	Condition	Enforcement
Wall	$\mathbf{v} = 0$	strong
	$\mathbf{n} \cdot \omega = 0$	weak
	$\mathbf{n} \cdot \mathbf{r} = 0$	weak
Inflow	$\mathbf{n} \cdot \mathbf{v} = g$	strong
	$\mathbf{n} \times \mathbf{v} = 0$	strong
	$\mathbf{n} \cdot \omega = 0$	weak
	$\mathbf{n} \cdot \mathbf{r} = \frac{\partial^2 \mathbf{v}_n}{\partial \tau_1^2} + \frac{\partial^2 \mathbf{v}_n}{\partial \tau_2^2} + c$	weak
Outflow	$\mathbf{n} \times \omega = 0$	strong
	$\mathbf{n} \cdot \omega = 0$	weak
	$\mathbf{n} \times \mathbf{r} = 0$	weak

that is not well posed [3]. The final boundary condition to be set is on $\mathbf{r}$. In the test problem, for example, a boundary condition setting the pressure equal to zero was used. An equivalent boundary condition here would be to set the value of $\mathbf{r}$ in the tangential direction(s) to zero, assuming that the tangential velocity is zero. If a steady flow boundary condition is desired, then $\mathbf{n} \cdot \mathbf{r}$ is set to $\mathbf{n} \cdot \Delta\mathbf{v}$, which is fully known since the second derivative in the normal direction is zero under steady flow conditions. The most difficult boundary condition to handle is when the velocity is fully specified, but the velocity profile is not equal to the steady profile, i.e., $\mathbf{n} \cdot \Delta\mathbf{v}$ is not fully known. Clearly, we know the second derivatives of the normal velocity in the tangential directions, but the second derivative in the normal direction of the normal velocity is not known and it is generally nonzero. One possible mechanism for solving for this unknown is to (1) assume the unknown is zero, (2) impose the boundary condition weakly, (3) solve the minimization problem, (4) check the value of the unknown quantity, and (5) repeat using the new value until convergence. This method has potentially slow convergence, and we have developed an alternative approach. Recalling that one of our primary goals is global mass conservation, we propose setting the second derivative of $\mathbf{n} \cdot \mathbf{v}$ in the normal direction equal to an unknown constant and solving for the constant using the constraint of global mass conservation.

Solving for the unknown constant in the $\mathbf{n} \cdot \mathbf{r}$ boundary condition can be accomplished easily if the Reynolds number is zero. In this case, two different guesses of the value of the constant are made, and the problem is solved with each guess. Unless one of the guesses is exact, the inflow rate will not exactly equal the outflow rate. However, based on the different mass conservation results, linear interpolation can be used to determine the correct value of the unknown constant, and a linear combination of the two solutions gives the final solution. For the case of the nonlinear Navier–Stokes equations, the same basic procedure of guessing different values of the constant may be used. In this case, however, more than two solutions may be required to get acceptably close to global conservation. This process often does not add any additional computational cost, in the case of a nonzero Reynolds number, because multiple iterations are already required by the nonlinear operator.

To solve the least-squares problem, the equations that are used in the functional (G_{new}) are first linearized so that the solution can be found using a Gauss–Newton approach. The value of the nonlinear functional is calculated after each Gauss–Newton step to ensure that the nonlinear functional is decreasing to a minimum. A line search in the direction of the Gauss–Newton step could be used to ensure that the nonlinear

functional decreases at each step. However, for all the problems that we tested, no line search was necessary. The functional for the linearized equations is minimized using standard techniques from the calculus of variations to obtain the weak form (e.g., [5, 3]). A finite element basis is then chosen so that the weak form generates a matrix problem. An alternative approach is to linearize the weak form instead of linearizing the original equations [14, 15], but we found better convergence by first linearizing the equations. All of the simulations presented in the results section utilized a trilinear finite element basis for all of the variables unless otherwise noted. The FOSLS formulation allows the solution spaces for the variables to be chosen independently, and there is no restrictive stability condition (i.e., inf-sup condition) to satisfy. As a result, both the pressure and velocity in the Navier–Stokes equations can be approximated with the same basis.

All simulations, including those in the introduction section, were performed using the ParaFOS code, written by the authors. The code imports hexahedral meshes from the Cubit mesh generation package (Sandia National Laboratory). The finite element meshes are then partitioned using the Metis graph partitioning library [23]. The software is designed to run on distributed memory clusters using the MPI library for communication. The linear matrix problem generated during each Gauss–Newton step is solved using the .,. library of solvers ([17], Center for Applied Scientific Computing, Lawrence Livermore National Laboratory). Specifically, the Boomer-AMG parallel algebraic multigrid (AMG) solver is used as a preconditioner for a conjugate gradient solver. Most of the solver parameters used were the default settings except for the coarse grid selection algorithm, which was set to the parallel modified independent set algorithm. This algorithm was chosen because it chooses coarse grids with fewer nodes, thus reducing storage requirements.

3. Results. The brick test problem with all components of the inlet velocity specified ($v_x = y(1-y)z(1-z)$, $v_y = 0$, $v_z = 0$) is complicated because the value of $\mathbf{n} \cdot \Delta\mathbf{v}$ is not completely known over the inlet. Specifically, the value of $\frac{\partial^2 v_x}{\partial x^2}$, which we refer to as C_1, is unknown. While this value may be a function of (y, z) along the inlet, we assume it is a constant and solve for it using the constraint of global mass conservation. Since the Reynolds number is also set to zero, this constant is equal to the deviation of the normal pressure gradient from the steady flow value. In other words, if the inlet velocity profile was the steady velocity profile, the pressure gradient would be a constant (i.e., a linear pressure drop), and the value of C_1 would be zero. The appropriateness of our assumption that C_1 is a constant and not a function of (x, y) is going to depend upon how close the specified inlet velocity profile is to the steady velocity profile. If the specified profile is close in some regions and deviates greatly in other regions, the assumption will not be appropriate. If the specified profile is close to the steady profile, the assumption is not a considerable source of error. A more detailed analysis of the error resulting from this assumption is the subject of a future paper. For now, we just show numerically that setting C_1 to a constant is acceptable for the chosen test problems.

We begin by setting $C_1 = 0$ and minimizing the functional, G_{new}, over the brick-shaped domain. Clearly, $C_1 \neq 0$ and the result is that the inflow rate is 2.7×10^{-2} and the outflow rate is 1.9×10^{-2}. It is well known from computational and experimental fluid dynamics that the pressure drop in the normal direction at the inlet must be larger than the steady-state pressure drop due to entrance effects. In other words, $C_1 > 0$ due to the extra pressure drop to rearrange the flow profile into the steady-state profile. For the second run, we set $C_1 = 1$ and minimize the functional again.

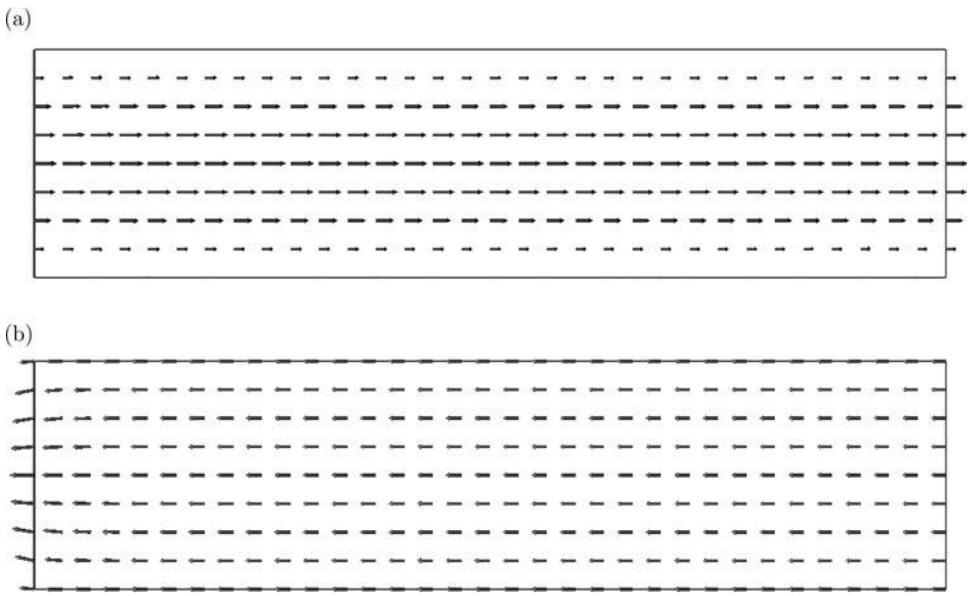

FIG. 3.1. *Central cross-section of flow through the brick domain using the new formulation of the Navier–Stokes equations. The normal velocity is set to* $v_x = y(1-y)z(1-z)$ *at the inlet and the pressure to* 0 *at the outlet. Velocity vectors are shown in* (a) *and the pressure gradient is shown in* (b).

The inflow rate remains unchanged at 2.7×10^{-2} (this essential boundary condition was strongly enforced), but now the outflow rate is 4.8×10^{-2}. Instead of losing mass, we are now "creating" mass. The true value for C_1 can be determined by linear interpolation to be 0.28 to give discrete mass conservation. To get the final solution shown in Figure 3.1, we can either use the appropriate linear combination of previous solutions or simply resolve the problem using $C_1 = 0.28$. Both the global and local conservation of mass using the final value of C_1 are excellent as mass is conserved exactly to the 5 digits calculated for any cross-section. Further, the average AMG convergence factor is also excellent at 0.3, indicating that only 15 V-cycles are required to reduce the residual by a factor of 1×10^{-8}. A comparison of the 3 different functionals, $G_{v.f.}$, G_ω, and G_{new}, is given in Table 3.1. The new formulation provides excellent global mass conservation and significantly better computational performance while maintaining computational scalability. It is not appropriate to compare the minimums of the different functionals, and they are only given for reference. Under steady flow conditions, the pressure drop in the normal direction is 1.0 and, now, for this inlet flow profile, the pressure drop at the center of the entrance is approximately 1.28. Figure 3.1(b) shows the pressure gradient throughout the domain. Note that it is constant at the outlet, but there are some entrance effects near the inlet.

Similar results can be achieved for problems with nonzero Reynolds number. Repeating the previous problem with $Re = 40$ results in $C_1 = 0.46$ being required for global mass conservation. In this case, the average AMG convergence factor deteriorates slightly to between 0.36 and 0.5, depending on the Gauss–Newton step, but it remains much improved over the factors of the other two formulations, which are between 0.9 and 0.95. As the Reynolds number becomes larger and larger, the entrance effects extend further downstream. For laminar flow into a round pipe, the

TABLE 3.1
Comparison of the different functionals for solving Stokes flow through the brick-shaped domain with the velocity fully specified along the inlet.

Method	Mesh	Mass loss	Functional	Avg. C.F.	CPU time
Velocity-flux	$32 \times 8 \times 8$	99.8%	6×10^{-3}	0.74	60 sec.
Vorticity	$32 \times 8 \times 8$	99.9%	2.7×10^{-3}	0.88	16 sec.
New	$16 \times 4 \times 4$	$< 0.01\%$	2.3×10^{-1}	0.25	1.6 sec.
New	$32 \times 8 \times 8$	$< 0.01\%$	9.6×10^{-2}	0.3	15 sec.
New	$64 \times 16 \times 16$	$< 0.01\%$	3.0×10^{-2}	0.36	150 sec.

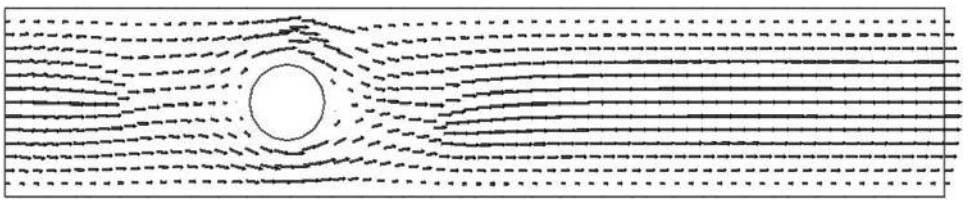

FIG. 3.2. *Central cross-section of flow through the brick domain* $(5 \times 1 \times 1)$ *with a cylindrical obstruction with a diameter of* 0.4. *The normal velocity is set to* $v_x = y(1-y)z(1-z)$ *at the inlet, and the nodal velocity vectors are shown.*

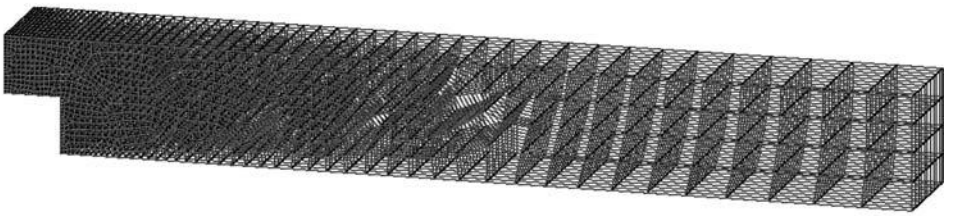
accepted correlation [27] is $L \approx 0.06 \cdot Re \cdot d$, where d is the diameter and L is the length of the entrance effects. The current assumption of steady flow at the outlet is probably appropriate since the inlet profile is close to the steady profile, but the assumption will break down at higher Reynolds numbers.

An obstruction can be included in this first test problem by removing a cylindrical portion of the domain. The results for $Re = 100$ and an obstruction with a diameter of 0.4 are shown in Figure 3.2. The boundary conditions along the walls of the obstruction are the same as those along the outer walls of the domain (i.e., $\mathbf{v} = 0$, $\mathbf{n} \cdot \omega = 0$, and $\mathbf{n} \cdot \mathbf{r} = 0$), and, in this case, a triquadratic finite element basis is used to more accurately capture the cylindrical geometry. Interestingly, to achieve global mass conservation C_1 is set to 0.20, a smaller value than the unobstructed case, but this is likely due to the more accurate triquadratic basis. The finite element mesh for this problem contains 1290 hexahedral elements and is unstructured, which contributes to some of the deterioration in the average AMG convergence factor to 0.74. For this problem, the domain was extended to a dimensionless length of 5 to ensure that the outlet profile is the steady profile.

The geometry and boundary conditions for the second test problem are somewhat similar to the first. In this case, however, the domain is longer, having an aspect ratio of 8:1:1, and there is a 0.5:0.5:1 notch removed from the lower half of the inlet. In other words, this is the classic flow over a backward-facing step in three dimensions. The inlet velocity is once again set to a tensor product of one-dimensional parabolas, $v_x = y(0.5-y)(0.5+z)(0.5-z), v_y = 0, v_z = 0$, and the tangential velocity is set to zero along the outlet. Along the inlet, $\mathbf{n} \cdot \mathbf{r} = -2(0.5+z)(0.5-z) - 2y(0.5-y) - C_2$, where C_2 is a constant that is set so that global conservation of mass is achieved, and $\tau \cdot \mathbf{r}$ is set to zero along the outlet. Finally, the no-slip boundary conditions along the wall are set the same as before, with the notable exception of the condition on $\mathbf{n} \cdot \mathbf{r} = \mathbf{n} \cdot \Delta\mathbf{v}$, which is set to zero near the reentrant corner of the step. This is because the physical assumption that allowed us to set this to zero along a smooth wall

(a)



(b)

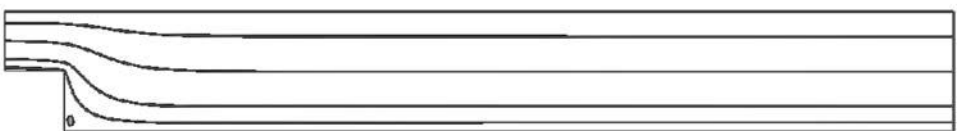


FIG. 3.3. *Central cross-section of flow through the backward-facing step domain using the new formulation of the Navier–Stokes equations at* $Re = 50$. *The finite element mesh are shown in* (a) *and streamlines are shown in* (b).

no longer holds. In this problem, there is a boundary layer separation at the corner, and there is an infinite number of normal vectors at the corner. Numerical experiments were performed on different methods for removing this boundary condition from the corner. First, the $\mathbf{n}\cdot\mathbf{r}$ condition, which is typically enforced weakly, can be completely removed from the functional along the two walls that contact at the corner. Second, the $\mathbf{n}\cdot\mathbf{r}$ term can be multiplied by a weight function that is zero at the corner and one at some radius away from the corner [19]. A typical weight function has the form $w(r) = (r/R)^n$, where r is the distance from the corner, R is the radius of the weight function (typically $O(0.1)$), and n is the polynomial order of the weight function (typically 3 or 4). Acceptable (and indistinguishable) results were obtained with either method as long as the radius of the weight function was sufficiently large.

The finite element mesh used for the backward-facing step geometry is shown in Figure 3.3(a). The mesh is unstructured and consists of 6510 elements. A triquadratic finite element basis was used to improve the accuracy of the method. An analysis of the accuracy of LSFEM for the two-dimensional backward-facing step problem can be found in Röhrle [25] and for the three-dimensional problem in Jiang et al. [22]. A Reynolds number of 50 was used to obtain the streamlines in a central cross-section of the approximate solution shown in Figure 3.3(b). At this low Reynolds number, only a small recirculation is found downstream of the step; this is consistent with the two-dimensional experimental results of Armaly et al. [1]. The global conservation of mass was exact, since it was enforced by setting C_2, and the behavior of the pressure field was also consistent with experimental predictions in that the pressure gradient in the flow direction was greater for the small channel, upstream from the step, than for the larger channel downstream from the step. The AMG convergence factor was 0.49 for a trilinear basis and 0.72 for a triquadratic basis. Both factors are acceptable considering the higher-order finite element basis, the partitioning of the problem among 16 processors, and absence of a boundary condition on $\mathbf{r}$ along the step.

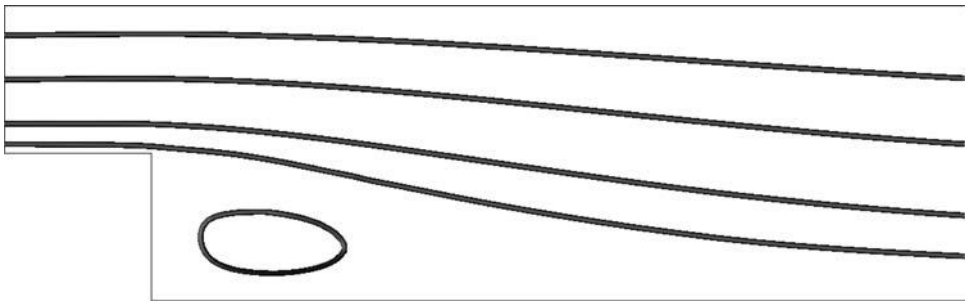

FIG. 3.4. *Central cross-section of flow through the backward-facing step domain using the functional $G_{new,b}$ at $Re = 200$. Only the upstream half of the total domain is shown for clarity.*

For greater values of Re, it is potentially helpful to rescale the momentum equation by dividing by Re, giving a new functional

$$
\begin{aligned}
G_{new,b}(\omega, \mathbf{v}, \mathbf{r}) := {} & \|\omega + \nabla \times \mathbf{v}\|_{0,\Omega}^2 + \|\nabla \cdot \mathbf{v}\|_{0,\Omega}^2 \\
& + \|\mathbf{r} + \frac{1}{Re}\nabla \times \omega\|_{0,\Omega}^2 + \|\nabla \cdot \omega\|_{0,\Omega}^2 \\

\end{aligned} \tag{3.1}
$$

in which the diffusive term becomes small instead of the convective term becoming large and dominating the other terms in the functional. Figure 3.4 shows streamlines in the upstream half of the domain for flow over the backward-facing step at a Reynolds number of 200. Interestingly, when triquartic elements were used, excellent conservation ($> 99\%$ of mass was conserved) is achieved even though the boundary conditions on $\mathbf{n} \cdot \mathbf{r}$ were not set along the inflow. Consequently, in this case, we did not have to solve for the value of an unknown constant. Unfortunately, the lack of a boundary condition on $\mathbf{r}$ means that the operator is no longer elliptic, and the convergence rate of the linear solver is slower. The excellent conservation without a boundary condition on $\mathbf{r}$ along the inlet and outlet is not observed if a trilinear basis is used or if the Reynolds number is small (i.e., less than approximately 100 in this case). Regardless, this is an encouraging result because the requirement of an inflow boundary condition on $\mathbf{n} \cdot \mathbf{r}$ is one of the few drawbacks of the new formulation.

The final test problem is flow with $Re = 40$ through a series of bifurcations, as shown in Figure 3.5. The inlet is the single tube at the top, and the flow into the initial tube is the steady flow profile, which has a known analytic form. Boundary conditions along the inlet are very straightforward as a result of the steady profile. Velocity is set to $v_x = 0$, $v_y = 0$, and $v_z = -1 + (x^2 + y^2)$, normal vorticity is set to zero, and $\mathbf{n} \cdot \mathbf{r} = \frac{\partial^2 v_z}{\partial x^2} + \frac{\partial^2 v_z}{\partial y^2} = 4$. Because we wish to accurately capture the inflow boundary condition on velocity, a [illegible] finite element basis is used for this problem. The no-slip conditions, specified previously, are set along the walls. The main inlet tube branches into two tubes, and each of these tubes branch, giving a total of four outlet surfaces. The outflow boundary condition is, as always in computational fluid dynamics, difficult to determine. We begin by setting the tangential velocity to zero, which implies that the normal vorticity is also zero. Another potential boundary condition is setting the pressure to a constant by setting $\tau \cdot \mathbf{r} = 0$. However, better accuracy is usually found by setting a boundary condition on $\mathbf{n} \cdot \mathbf{r}$. If the flow is steady (i.e., fully developed), then $\mathbf{n} \cdot \mathbf{r} = \textit{constant}$, and the value of the *constant* can

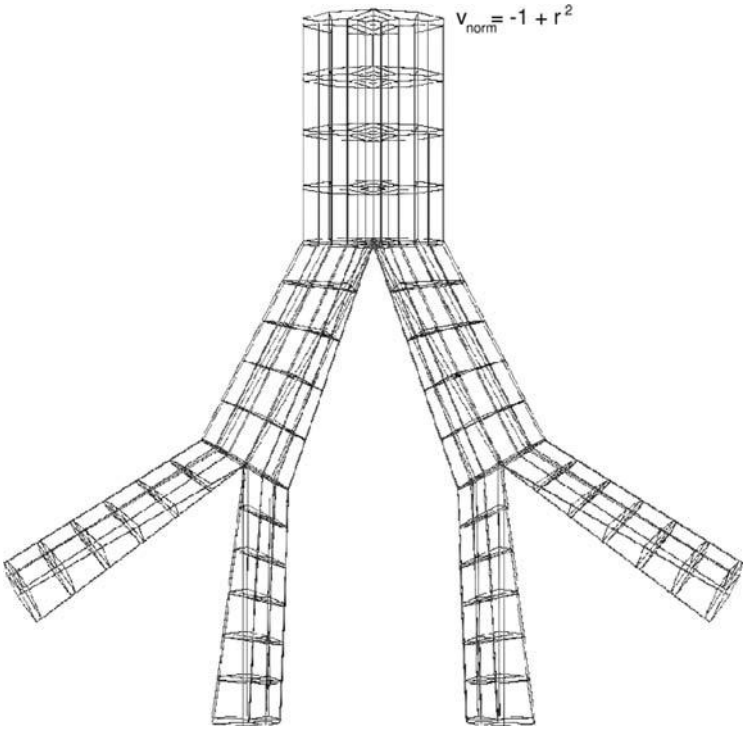

FIG. 3.5. *The hexahedral mesh used for the bifurcating flow domain. The inlet is the single tube at the top, and the four tubes at the bottom contain the outflow surfaces.*

be determined based on the geometry and setting the inflow rate equal to the outflow rate. However, because the tubes are not exact cylinders due to the bifurcations, it is unlikely that the outflow is fully developed. A third possibility is to assume that the flow has not developed fully (i.e., $\frac{\partial^2 v_n}{\partial n^2} \neq 0$), but well enough that it is a paraboloid at the outlet, albeit an unsteady one due to small changes in tube geometry. In this case, $\mathbf{n} \cdot \mathbf{r}$ is equal to an unknown constant, C_3. We solve for this unknown constant using the constraint that mass be conserved globally.

Figure 3.6 shows streamlines for the central cross-section of the bifurcating tubes domain. Also shown in the inset images are velocity vectors for specific branches. Because the triquartic finite element basis was based on Chebyshev–Lobatto node positions, which have been previously shown to work well with AMG solvers [20], the nodes are not evenly distributed but are somewhat clustered near the corners of elements. The global conservation of mass is approximately exact because C_3 was set to enforce this condition, but it is useful to examine the pressure gradient to determine the accuracy of the solution. For laminar flow in a straight, cylindrical tube, the relationship between the pressure gradient, flow rate (Q), and tube radius (R) is given by [27]

$$\frac{\partial p}{\partial n} \propto \frac{Q}{R^4}. \tag{3.2}$$

If the flow rate into the domain is Q, the flow rate through each of the outlets is approximately $Q/4$ due to symmetry. Further, for this geometry, the radius of the inlet is R, and the radius of each outlet tube is $R/2$. Combining these relationships

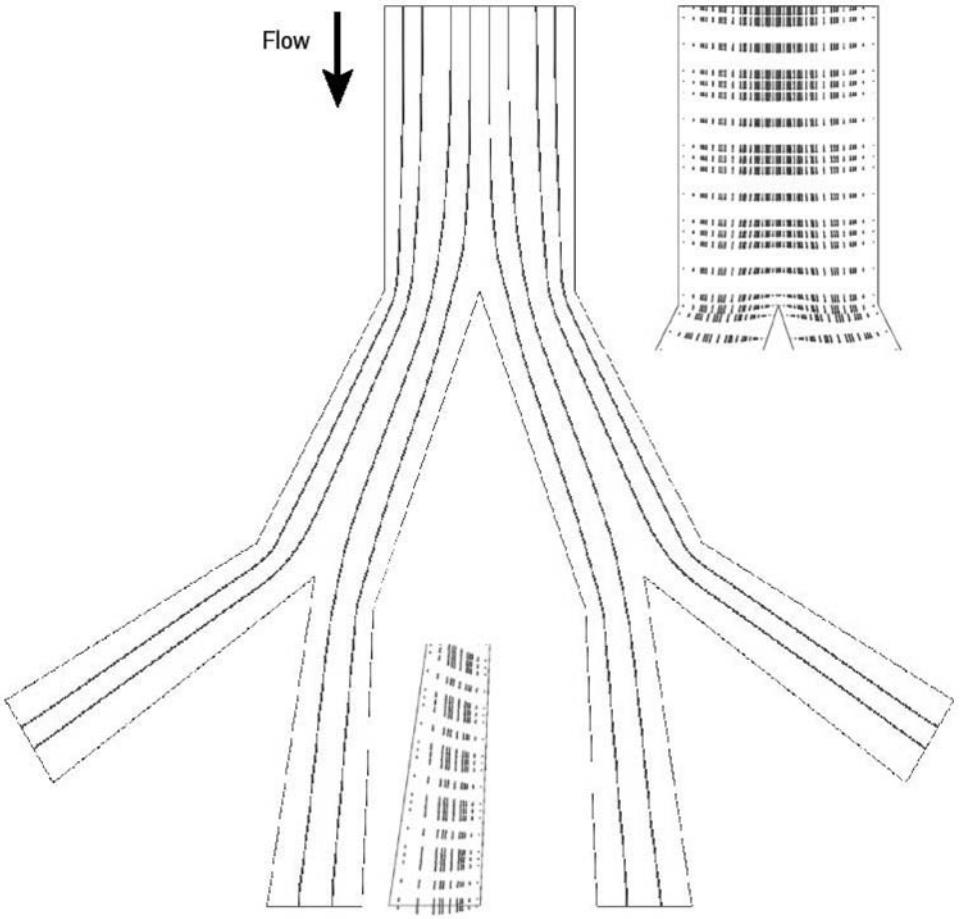

FIG. 3.6. *The central cross-section of the bifurcating tube domain showing streamlines through the bifurcations. The inset images show velocity vectors for the nearby tubes. The inlet is the single tube at the top, and the four tubes at the bottom contain the outflow surfaces.*

and using (3.2) results in the prediction that the normal pressure gradient at the outlet is roughly 4 times the normal pressure gradient at the inlet. Since the normal pressure gradient at the inlet is equal to 4, we expect that the normal pressure gradient at the outlet is roughly 16, but probably slightly higher due to the multiple bifurcations and entrance effects. For the result shown in Figure 3.6, the normal pressure gradient at the outlet was 17.4, indicating good agreement with our straight tube heuristic. Further, the approximation just presented can be used to obtain a good initial guess for the value of C_3.

Conclusions. Poor mass conservation can be observed when reformulating the Navier–Stokes equations as a first-order system using either the velocity-flux or vorticity formulations. The problem occurs primarily when the pressure (or normal stress) is not specified on both ends of the domain. To help address this problem, we are proposing a new first-order system of equations that allows boundary conditions to be set on the pressure gradient. In many cases, it is easier to specify boundary conditions on the pressure gradient because much of the information can be obtained from the

boundary conditions on velocity. Further, when using the new formulation in conjunction with AMG, significant computational improvements can also be observed. In this way, the new formulation achieves the objective of improved mass conservation on coarse grids while maintaining AMG convergence rates. The new formulation achieves only local mass conservation asymptotically as the mesh size goes to zero, like other least-squares formulations, but overall conservation is much improved for coarser meshes due to the boundary condition on $\mathbf{n}\cdot\mathbf{r}$. For each of the three test problems presented here—the square channel, the backward-facing step, and the series of bifurcations—excellent mass conservation was possible for both Stokes flow and low to moderate Reynolds numbers. Traditionally, high Reynolds number flows have been a strength of least-squares methods because of their excellent stability properties. However, high Reynolds numbers also imply that flow through the outflow boundary is unlikely to be steady, a difficult condition to handle with the new formulation. However, we are confident that as experience is gained with the new formulation, the proper boundary conditions can be found for a much wider set of problems.

A VARIATIONAL APPROACH TO MODELING AND SIMULATION OF GRAIN GROWTH*

DAVID KINDERLEHRER†, IRENE LIVSHITS‡, AND SHLOMO TA'ASAN†

Abstract. Most technologically useful materials arise as polycrystalline microstructures, composed of a myriad of small crystallites, called grains, separated by their interfaces, called grain boundaries. The orientations and arrangements of the grains and their network of boundaries are implicated in many properties across wide scales, for example, functional properties, like conductivity in microprocessors, and lifetime properties, like fracture toughness in structures. Simulation is becoming an important tool for understanding both materials properties and their processing requirements. Here we offer a consistent variational approach to the mesoscale simulation of these systems subject to the Mullins equation of curvature-driven growth in a two-dimensional setting. The main objective is to provide a calibration for future two-dimensional and three-dimensional efforts. We discuss several novel features of our approach, which we anticipate will render it a flexible, scalable, and robust tool to aid in microstructural prediction. Simulation results offer compelling evidence of the predictability and robustness of statistical properties of large systems, such as grain size distribution and texture, that are of immediate interest in materials science.

1. Introduction.

A central problem in materials science is the understanding and control of microstructure, the ensemble of grains that comprise polycrystalline materials. The orientations and arrangements of the grains and their network of boundaries are implicated in many properties across wide scales, for example, functional properties, like conductivity in microprocessors, and lifetime properties, like fracture toughness in structures. As discussed below, these mesoscale properties are necessarily interpreted by means of statistical measures, especially grain size statistics and texture, or grain orientation, statistics. Most tantalizing is the grain boundary character distribution (GBCD), a five-dimensional distribution function of grain misorientation and interface normals. Modeling and simulation of the grain evolution at the mesoscale plays an increasingly important role in resolving these central problems. Indeed, the grain boundary character distribution owes much of its discovery to the very simulation we are presenting here.

With the implementation of automated data acquisition, based on orientation imaging microscopy, in the Mesoscale Interface Mapping Project, a strategy has emerged for determining interfacial energy and mobility in polycrystals [1]. Simulation with such energy and mobility functions offers the promise of understanding these properties and satisfying processing requirements. Here we exhibit a consistent variational approach to the mesoscale simulation of large systems of grain boundaries sub-

ject to the Mullins equations of curvature-driven growth [31], [32] in a two-dimensional setting. We illustrate this with the simulation of a polycrystalline system with constant energy and mobility. This serves as a calibration for future two-dimensional and three-dimensional efforts. This paradigm system is the most studied in theory and corresponds in experiment to a columnar "fiber texture." We discuss several novel features of our approach, which we anticipate will render it a flexible, scalable, and robust tool to aid in microstructural prediction. We offer compelling evidence of the predictability and robustness of statistical properties of large systems, such as grain size distribution and texture, that are of immediate interest in materials science. As a consequence, the simulation technique enters the arena of being useful. For example: How important is anisotropy? How prominent are low angle boundaries in various textures? Or (see below) are there general laws of evolution for ensembles of grains? Such questions become accessible now that we are in possession of a reliable and accurate approach to simulation.

The Mullins equations, discussed below, are a system of evolution parabolic partial differential equations for each grain boundary curve. Grain boundaries meet, typically, at triple junctions, where an additional condition is required. We enforce the Herring force balance condition, which is the natural boundary condition for equilibrium, at these triple junctions [17], [18]. The resulting system is then dissipative for the energy [22]. The evolution of grain boundaries using the above model can be viewed as a steepest descent method for the total grain boundary energy, where natural boundary conditions are imposed. This observation serves as the basis for our discretization method and leads to stable schemes. Our method begins by discretizing the grain boundaries, which are curves in two dimensions, using linear elements. We then form the discrete energy by numerical integration (using the midpoint rule) of the grain boundary energy density along the network of grains. The gradient of this functional gives the velocity of the curves, and the discretized Herring condition is given as the discrete natural boundary condition for that functional. The resulting semidiscrete system (continuous time) satisfies a dissipation estimate analogous to that of the original problem. This guarantees the stability for small time steps of the whole network. The Herring condition at the discrete level provides us with a nonlinear set of equations that the triple junctions must satisfy. These are solved approximately using a fixed point method. Time stepping uses a first order discretization. The scheme here is explicit, so there is the usual time stepping restriction of $\triangle t = O(h^2)$, where h is a parameter describing the grain boundary discretization. One of the features of this approach is that the data structure consists of curves only and does not require the discretization of the grains. In this way we deal with discretized systems that are of lower dimension than the physical space. This permits us to have very large configurations: initial configurations typically consist of 25,000 grains.

In addition to using the gradient of the above functional to determine the grain boundary evolution, we had to implement treatment of certain critical events. During evolution, a grain boundary or a grain may shrink and disappear. This creates multiple junctions that are unstable. Such multiple junctions split into triple junctions in a way that is consistent with energy reduction. Thus, we introduce, one at a time, new edges, in a way that the energy will result in maximum reduction.

Convergence of approximation schemes, of which this is one, is a standard problem in numerical analysis. Usually there is a natural topology associated with a problem; for example, when we deal with solution of the Poisson equation, we examine convergence in H^1. The situation here is more complex since it is not clear that the network as a whole has convergence of the same type as the curves (network links). In any

event, we may not have convergence of the configuration of the network, but only of certain statistical properties. As an analogy consider a large system of interacting particles, say with a Lennard–Jones interaction force. Individual trajectories are not predictable for large times, but statistical properties, such as temperature, density, and average velocity, are predictable. In the present context many theoretical questions remain open. We are faced with a vast number of solutions of time dependent partial differential equations which satisfy relations among themselves, like being boundaries of the same grain. There need not be any characterizing statistical properties. If there are, we are faced with understanding the meaning of "convergence" for such properties.

The numerical approach described here aims at large networks of grains, with emphasis toward distribution functions such as grain size, numbers of edges, and orientations. We succeed in showing that these distribution functions are robust from a computational standpoint. We verify some elementary diagnostics, for example, the von Neumann–Mullins $(n-6)$ rule for area evolution of individual grains [31], [38], as explained later.

Essentially, we are faced with a large metastable system. Ideally, one would like to have an evolution equation for such distribution functions, so that the simulation of the quantities of interest for scientific and engineering purposes will be as efficient as possible. This would constitute a coarse graining of the system in a dynamic fashion analogous to the way in which the equations of fluid dynamics describe the interacting particles mentioned above when large temporal and spatial scales are considered. We discuss the use of this simulation to derive stochastic models for grain growth that are valid for large time scales (cf. [5] for a preliminary version). In [24], a first attempt to understand the evolution of grain growth statistics derived from this simulation is discussed.

There is an extensive and distinguished literature in the simulation of grain growth. These models can be divided into the following major groups: molecular dynamics (MD) [8], [16], [33], [34], [35], [19], [37], [39], [40], [42], Monte-Carlo (MC) [2], [3], [28], [29], [41], [42], front tracking [14], [15], vertex models [43], [44], [45], phase field models [6], [7], [25], [26], [42], partial differential equations (PDE) [9], [24], [27], and distribution function models [10], [11], [12], [13]. Each modeling approach is appropriate in studying grain growth on a particular length or time scale. For instance, understanding local topological changes occurring during grain growth can be best achieved using MD models, while studying abnormal grain growth is more appropriate by MC or PDE models.

2. Theory. In preparation for discussing our grain growth algorithm, we briefly review the elements of the theory of curvature-driven growth developed by Herring [17], [18] and Mullins [32]. This theory is based on thermodynamic considerations. In this paper we consider two-dimensional grain growth; an extension of the theory to three dimensions for most parts is rather straightforward [20], [21]. (This is not true for the simulation, of course!) Different viewpoints are possible for the description of the Mullins curvature-driven growth theory; here we present it in a form a best suited for subsequent discretization purposes.

Let us consider a collection of grain boundaries, which are smooth curves, meeting at triple junctions. The dynamics are governed by a given energy density function σ and a given mobility function μ. Consider a set of smooth curves, i.e., the grain boundaries

$$\mathbf{\Gamma} = \mathbf{\Gamma}(t) = \{\Gamma^1, \Gamma^2, \ldots, \Gamma^K\}, \quad K = K(t), \tag{2.1}$$

where each curve is given in a parametrized form

$$\Gamma^k(t) = \{x = \xi^k(s,t), 0 \le s \le 1\}. \tag{2.2}$$

The curves are assumed to form a network, meeting at triple junctions or fixed points, for example the points on the outside border of the configuration.

We consider the set of triple junctions

$$\mathbf{\Lambda} = \mathbf{\Lambda}(t) = \{z^1, z^2, \dots, z^M\}, \quad M = M(t), \tag{2.3}$$

consisting of all points that belong to three grain boundaries simultaneously; namely,

$$z^m(t) = \xi^{k_1}(s_{k_1}, t) = \xi^{k_2}(s_{k_2}, t) = \xi^{k_3}(s_{k_3}, t)$$

for $s_{k_i} = 0$ or $s_{k_i} = 1$; k_1, k_2, k_3 being distinct integers in $\{1, \dots, K(t)\}$.

We assume that the grain boundary energy density function, σ, is given in terms of misorientation angle α and θ, the angle that the normal makes with the x-axis. Each grain boundary Γ^k is associated with a grain boundary energy, σ^k. The total grain boundary energy of the network can then be written as

$$E(t) = \sum_{k=1}^{K} \int_0^1 \sigma^k(\theta^k(s,t), \alpha^k)|l^k(s,t)|ds, \qquad l^k = \frac{d\xi^k}{ds}. \tag{2.4}$$

This energy is equal to the amount of work required to create an infinitesimal amount of new surface. The next step is to describe grain boundary motion that leads to energy dissipation. For an arbitrary motion of the grain boundaries, specified by $\xi^k(s,t)$, $0 \le s \le 1$, the rate of change in energy is

$$\frac{d}{dt}E(t) = \sum_{k=1}^{K} \int_0^1 \left(\frac{\partial \sigma}{\partial \theta}^k \frac{d\theta^k}{dt}|l^k| + \sigma^k \frac{l^k}{|l^k|} \cdot \frac{dl^k}{dt} \right) ds. \tag{2.5}$$

We now define a unit tangent vector $b^k = l^k/|l^k|$ and a unit normal vector n^k given by $n^k = Rb^k$, where R is rotation through $\pi/2$. With v denoting the velocity of the curve Γ, using the obvious relations

$$\frac{dl^k}{dt} = \frac{d}{dt}\frac{d\xi^k}{ds} = \frac{d}{ds}\frac{d\xi^k}{dt} = \frac{dv^k}{ds} \tag{2.6}$$

and

$$\frac{d\theta^k}{dt} = \frac{1}{|l^k|}\frac{dl^k}{dt} \cdot n^k, \tag{2.7}$$

we find that (2.5) reads as

$$\frac{d}{dt}E(t) = \sum_{k=1}^{N} \int_0^1 \left(\frac{\partial \sigma}{\partial \theta}^k n^k + \sigma^k b^k \right) \cdot \frac{dv^k}{ds} ds. \tag{2.8}$$

Then (2.8) can be rewritten as

$$\frac{d}{dt}E(t) = \sum_{k=1}^{N} \int_0^1 T^k \cdot \frac{dv^k}{ds} ds, \tag{2.9}$$

where vector T^k,

$$T^k = \frac{\partial \sigma^k}{\partial \theta} n^k + \sigma^k b^k, \tag{2.10}$$

is the line tension or capillary stress vector, and dT^k/ds is the line force per unit length. Integration by parts in (2.9) leads to

$$\frac{d}{dt}E(t) = -\sum_{k=1}^{K} \int_0^1 \frac{dT^k}{ds} \cdot v^k ds + \sum_{m=1}^{M} v^m \cdot \sum_{l=1}^{3} T^{m,l}, \tag{2.11}$$

where $T^{m,l}$ is the line stress vector on grain boundary Γ^l that ends at the triple junction z^m. The grain growth process entails several possible mechanisms which, at the mesoscale, amount to consideration of exchange of matter across the curve. This results in the creation of a new area on one side. Mullins' theory is that the normal velocity v_n of a grain boundary (the rate of creation of area), is proportional to the line force (the rate at which work is done), through the factor of the mobility μ:

$$v_n = \mu \frac{dT}{ds}. \tag{2.12}$$

From the equation above we conclude that the Mullins theory can be viewed as evolution resulting in steepest descent for the energy,

$$\frac{d}{dt}E(t) = -\sum_{k=1}^{K} \int_0^1 \frac{1}{\mu^k} |v_n^k|^2 ds + \sum_{m=1}^{M} v^m \cdot \sum_{l=1}^{3} T^{m,l}. \tag{2.13}$$

The Herring condition,

$$\sum_{l=1}^{3} T^{m,l} = 0, \qquad m = 1, \ldots, M, \tag{2.14}$$

is the natural boundary condition for this problem, and it, together with (2.12), leads to the energy dissipation:

$$\frac{d}{dt}E(t) = -\sum_{k=1}^{K} \int_0^1 \frac{1}{\mu^k} |v_n^k|^2 ds \le 0. \tag{2.15}$$

From the Frenet formulas, for a grain boundary Γ we conclude that

$$\frac{dT}{ds} = \left(\frac{d^2\sigma}{d\theta^2} + \sigma \right) \kappa n \qquad \text{on } \Gamma, \tag{2.16}$$

where κ is the curvature of Γ. The evolution equations then take the form

$$v_n = \mu \left(\frac{d^2\sigma}{d\theta^2} + \sigma \right) \kappa n \qquad \text{on } \Gamma. \tag{2.17}$$

At equilibrium

$$\frac{dT^k}{ds} = 0,$$

or, equivalently,

$$\left(\frac{d^2\sigma}{d\theta^2}+\sigma\right)\kappa = 0 \qquad \text{on } \Gamma. \tag{2.18}$$

Thus we recover that in equilibrium the mean curvature, $\kappa = 0$, or the grain boundaries are straight segments.

This theory is applicable to most of the process of grain growth. However, grains do not necessarily always retain their integrity. Two types of major network changes, different from a regular grain boundary and triple junction evolution, occur occasionally during grain growth. We name such events , , , and we distinguish between two main events.

When the length of a grain boundary becomes 0, it disappears, and its two triple junctions become one quadruple-junction, a point where four grain boundaries meet. Triple junctions are typically the only stable junctions, and therefore the quadruple-junction instantly splits into two new triple junctions connected by an infinitesimally small new grain boundary. The split is energy decreasing, and the dissipative quality of the evolution is maintained.

As a small grain shrinks, it eventually becomes a point at which three, four, or five grain boundaries meet. The area of a grain with six or more grain boundaries either does not change or increases. This conclusion comes from the von Neumann–Mullins $(n-6)$ rule [31], [38]. In a system with σ and μ constant and satisfying the Herring condition, the area $A(t)$ of a grain with n sides satisfies

$$\frac{d}{dt}A(t) = \frac{\pi}{3}\sigma\mu(n-6). \tag{2.19}$$

We shall employ this as a diagnostic for numerical simulations.

The newly formed multijunction then instantly splits into triple junctions, one after the other. (In other words, quadruple junctions split into two triple junctions, the junctions with five incoming grain boundaries first split into a triple junction and a quadruple junction, and the latter immediately splits into two triple junctions.)

3. Semidiscrete formulation. Our approach for discretizing the problem is to start by defining a discrete version of the total energy, analogous to (2.4). The evolution in the continuous case was shown to be related to the gradient of the energy, and this is the path we follow for the discretized energy. In this semidiscrete formulation we assume space discretization, keeping time a continuous variable.

We begin by considering a network of grain boundaries

$$\mathbf{\Gamma} = \mathbf{\Gamma}(t) = \{\Gamma^1, \Gamma^2, \ldots, \Gamma^K\}, \quad K = K(t), \tag{3.1}$$

where each grain boundary is a piecewise linear curve represented by a set of its nodal points

$$\Gamma^k(t) = \{x_j^k(t) | j = 1, \ldots, N_k(t)\}.$$

The set of triple junctions is the set of all nodal points that belong to exactly three grain boundaries,

$$\mathbf{\Lambda} = \mathbf{\Lambda}(t)\{z^1, \ldots, z^M\}, \quad M = M(t), \tag{3.2}$$

where each $z^m(t)$ is defined as

$$z^m = x_{l_1}^{k_1}(t) = x_{l_2}^{k_2}(t) = x_{l_3}^{k_3}(t) \quad \text{for} \quad l_n \in \{1, N_{k_n}\},\ n = 1, 2, 3,$$

with $k_1, k_2, k_3 \in \{1, \dots, K(t)\}$ being distinct. In the algorithm description we also allow quadruple junctions in $\mathbf{\Lambda}$. They appear as a result of the disappearance of grains and grain boundaries, and they split into two triple junctions within the same time step. In addition, we consider a set of all grains

$$\mathbf{\Omega} = \{G^1, \dots, G^N\}, \qquad N = N(t). \tag{3.3}$$

Our approximation for the total energy uses the midpoint rule for approximating integrals. Thus, we need to evaluate different quantities at the midpoints of the segments connecting successive nodal points. We introduce notation $x^k_{j-1/2} = (x^k_j + x^k_{j-1})/2$ and $\theta^k_{j-1/2} = \theta(x^k_{j-1/2})$, the angle that the vector normal to $[x^k_{j-1}, x^k_j]$ makes with the x-axis. The unit normal and unit tangent vectors for the linear segment $[x^k_{j-1}, x^k_j]$ are given by $n^k_{j-1/2} = (\cos\theta^k_{j-1/2}, \sin\theta^k_{j-1/2})$ and $b^k_{j-1/2} = (x^k_j - x^k_{j-1})/|x^k_j - x^k_{j-1}|$, respectively. The energy density function is evaluated at midpoints and is denoted by $\sigma^{k,j-1/2}$.

The discrete energy E^h, approximating (2.4) by the midpoint rule, reads as

$$E^h(t) = \sum_{k=1}^{K} \sum_{j=1}^{N_k} \sigma^{k,j-1/2} |x^k_j(t) - x^k_{j-1}(t)|, \tag{3.4}$$

with a discretization parameter $h = \max_j |x^k_j(t) - x^k_{j-1}(t)|$.

Following the continuous derivation, we compute the rate of change of the semidiscrete energy,

$$\begin{aligned} \frac{d}{dt}E^h(t) = &\sum_k \sum_j \sigma^{k,j-1/2} \frac{d}{dt}|x^k_j(t) - x^k_{j-1}(t)| \\ &+ \sigma^{k,j-1/2}_\theta \frac{d}{dt}\theta^{j-1/2}(t)|x^k_j(t) - x^k_{j-1}(t)|. \end{aligned} \tag{3.5}$$

To simplify (3.5), we will use

$$\frac{d}{dt}|x^k_j(t) - x^k_{j-1}| = \langle \dot{x}^k_j(t) - \dot{x}^k_{j-1}, b^k_{j-1/2}(t)\rangle \tag{3.6}$$

and

$$\frac{d}{dt}\theta^k_{j-1/2}(t) \approx \frac{1}{|x^k_j(t) - x^k_{j-1}|}\langle \dot{x}^k_j - \dot{x}^k_{j-1}, n^k_{j-1/2}(t)\rangle. \tag{3.7}$$

Equality (3.7) follows from the relation

$$\delta\theta_{j-1/2} \approx \tan\delta\theta_{j-1/2} = \frac{1}{|x^k_j(t) - x^k_{j-1}|}\langle \delta x_j - \delta x_{j-1}, n_{j-1/2}\rangle, \tag{3.8}$$

which can be easily verified.

Next, for each triple junction, z_m, we define the integers $k_1(m), k_2(m), k_3(m)$, the indices of the three grain boundaries that meet at this triple junction; and $p_l(m)$, $l = 1, 2, 3$, the indices of the intervals that connect the triple junction with the nearest nodal point on the grain boundary $k_l(m)$. The expression for $p_l(m)$ is then given by

$$p_l(m) = \begin{cases} 1\frac{1}{2}, & x^{k_l(m)}_1 = z^m, \\ N_{k_l(m)} - \frac{1}{2}, & x^{k_l(m)}_{N_{k_l(m)}} = z^m, \end{cases} \qquad l = 1, 2, 3. \tag{3.9}$$

Substitution of (3.6) and (3.7) into (3.5) leads to

$$\frac{d}{dt}E^h(t) = -\sum_{k=1}^{K}\sum_{j=2}^{N_k-1}\langle \dot{x}_j^k(t), T^{k,j+1/2} - T^{k,j-1/2}\rangle + \sum_{m=1}^{M}\left\langle \dot{z}^m(t), \sum_{l=1}^{3} T^{k_l(m),p_l(m)}\right\rangle, \tag{3.10}$$

where

$$T^{k,j\pm1/2} = \frac{\partial\sigma}{\partial\theta}^{k,j\pm1/2} n^{k,j\pm1/2} + \sigma^{k,j\pm1/2} b^{k,j\pm1/2}. \tag{3.11}$$

This is in complete analogy to (2.11) of the continuous case. As a result, the motion of interior nodal points is given by

$$v_j^k(t) = \frac{2\mu_j^k}{|x_{j+1}^k - x_{j-1}^k|}(T^{k,j+1/2} - T^{k,j-1/2}), \tag{3.12}$$

where scaling by $2/|x_{j+1}^k - x_{j-1}^k|$ makes the correspondence to the continuous velocity, $v_n^k(t)$. The resulting scheme is a central difference scheme approximation to (2.17).

A discrete Herring condition at the triple junction z_m is given as

$$\sum_{l=1}^{3} T^{k_l(m),p_l(m)} = 0, \qquad m = 1,\dots,M(t). \tag{3.13}$$

It is easy to see that the semidiscrete problem has the same dissipative property as the continuous problem.

4. Numerical implementation. The data structure for execution of the simulation consists of grain boundaries, triple junctions, and grains, and is managed using standard linked lists. Each grain boundary Γ^k has pointers to the two grains sharing it as a boundary, G_0^k and G_1^k ($G(\Gamma^k) = \{G_0^k, G_1^k\}$). Each grain boundary Γ^k also has pointers to its end points, triple junctions z_0^k and z_1^k ($Z(\Gamma^k) = \{z_0^k, z_1^k\}$) . Each triple junction z_m has pointers to three grain boundaries, Γ_0^m, Γ_1^m, and Γ_2^m, that meet at that point ($\Gamma(z^m) = \{\Gamma_0^m, \Gamma_1^m, \Gamma_2^m\}$). Each grain G^n has pointers to a list of its grain boundaries, $\Gamma(G^n)$.

In this numerical implementation, grain boundaries are defined by the set of nodal points and are approximated using linear elements. Evolution is done by moving nodal points according to (3.12)–(3.13).

In our experiments, we specified a global mesh size, h, and uniformly discretized grain boundaries with local mesh size (distance between neighboring nodal points) satisfying

$$\frac{3}{4}h < |x_j^k - x_{j-1}^k| < \frac{3}{2}h. \tag{4.1}$$

The mesh size h, the typical distance defined at the beginning of the simulation, remains constant through the simulation. The number of nodal points for each grain boundary is updated, and the points are redistributed in order to keep the distance between each pair of neighboring nodal points in the range (4.1).

The simulation was done by first evolving the grain boundaries, according to Mullin's equation, and then updating the triple points according to Herring's condition, as explained in what follows.

Triple junction motion. To satisfy the Herring condition (2.14), one needs to solve a nonlinear equation for triple junctions z. In the simulation, an iterative process

$$z^{n+1} = \frac{\sum_{j=1}^{3} x_{l_j}^{k_j} / |z^n - x_{l_j}^{k_j}|}{\sum_{j=1}^{3} 1/|z^n - x_{l_j}^{k_j}|} \tag{4.2}$$

is used to find a new position of a triple junction. Points $x_{l_j}^{k_j}$ are the nearest to the triple junction inner nodal points of grain boundaries that met at z. (Under the assumption of isotropic grain boundary energy, the term that contains a grain boundary energy derivative disappears.) The process stops when

$$\left| \sum_{j=1}^{3} \frac{z - x_{l_j}^{k_j}}{|z - x_{l_j}^{k_j}|} \right| < \epsilon, \tag{4.3}$$

where ϵ is a small number (10^{-6} in our simulation.) For some triple junction configurations, however, (4.3) is impossible to satisfy (it happens when process (4.2) forces z to take the place of one of $x_{l_j}^{k_j}$). In such cases the new position of the triple junction is calculated as follows:

$$z \leftarrow z + dt \sum_{j=1}^{3} \frac{z - x_{l_j}^{k_j}}{|z^k - x_{l_j}^{k_j}|}; \tag{4.4}$$

namely, it is moved a little in the right direction.

Grain growth. As grain growth proceeds, two types of critical events occur. Short grain boundaries and small grains shrink below a certain size, triggering two processes called grain boundary flipping and grain disappearance.

Grain boundary removal. In the numerical simulation the grain boundary is assumed to be too short if its length is less than $1.5h$. This condition is related to the fact that the minimal number of nodal points for a grain boundary must be three to guarantee at least one interior (nonjunction) nodal point. When the grain boundary becomes short enough so that in order to satisfy condition (4.1) the interior nodal points must be eliminated, this grain boundary becomes subject for removal, if it is growing (e.g., it is longer than at the previous time step).

When a small grain boundary is removed, a temporary quadruple junction is created and then splits into a pair of new triple junctions (as depicted in Figure 4.1) connected by a new small (with length $h/4$) grain boundary. This new grain boundary will most likely grow during the next time step and, therefore, will not disappear in flipping events. The old grain boundaries that meet at each of two new triple junctions most likely did not have a common triple junction in the configuration prior to the grain boundary disappearance.

Grain boundary flipping (Figure 4.1) consists of the following stages. I. The short horizontal grain boundary is a subject to removal. II. After its disappearance two triple junctions are shut into a quadruple junction. III. The quadruple junction splits into two different (from the previous configuration) triple junctions connected by a short vertical grain boundary. IV. After the Herring condition is satisfied for the two new triple junctions, the new grain boundary grows.

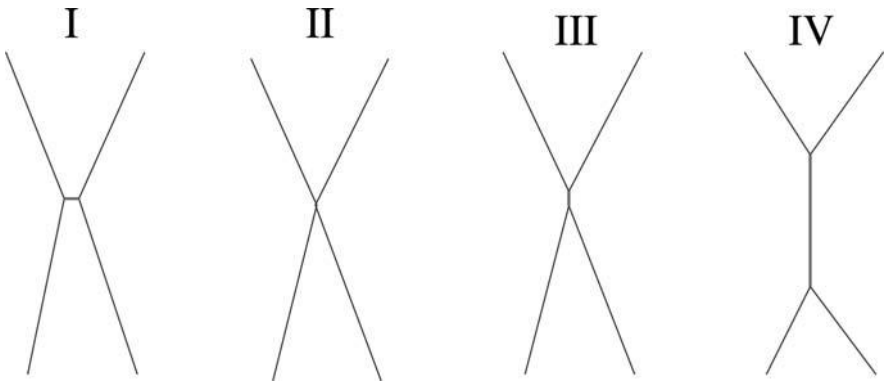

FIG. 4.1. *Critical event: a grain boundary flipping.*

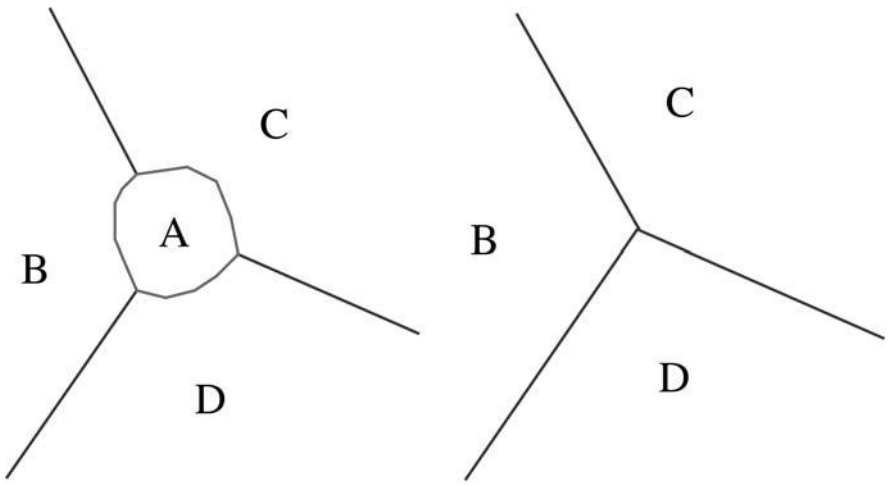

FIG. 4.2. *Critical event: a grain disappearance.*

According to the $(n-6)$ rule, a grain with less than six sides shrinks and will eventually disappear (unless the number of its boundary segments increases as a result of topological changes). Our numerical implementation removes grains when their area becomes smaller than a minimal area ($4h^2$ in our experiments). The actual process of grain disappearance involves an instantaneous shrinking of a three- and a four-sided grain with minimal area into triple or quadruple junctions, correspondingly. As the results of the numerical simulations show, a five-sided grain is more likely to first lose a grain boundary, i.e., become a four-sided grain, and only then disappear. Therefore, to avoid the technicalities that appear in evolving a junction with five incoming grain boundaries, the disappearance of such grains is performed in two time steps. At the first time step, the shortest grain boundary flips, leaving a four-sided small grain, which disappears during the next time step.

The disappearance of a grain with three grain boundaries (grain A in Figure 4.2) leads to the following local changes: the grain shrinks into one point, and each of its immediate neighbors loses one grain boundary. All grain boundaries of A and the triple junctions that were connected to these grain boundaries are erased. One new triple junction and no new grain boundaries are added to the network.

Forward Euler time discretization is employed in the algorithm, posing a strong limitation on time stepping, $\triangle t = O(h^2)$. The discrete times are denoted by $t_p,\ p = 0, 1, \ldots$, where $t_{p+1} = t_p + \triangle t,\ p = 1, \ldots,$.

5. Numerical results.

5.1. Single grain. We begin by demonstrating the accuracy of the scheme using a single grain simulation. First, we show results related to curvature and its effect on accuracy. For that purpose, we take a circular grain for which an analytic solution exists. The rate of area change must be constant for this case. In Table 5.1 we monitor the short term evolution ($t = 1$, 400 time steps) of a discrete circle of radius 1. The circle is discretized by n uniformly distributed points, $n = 4, 8, 16, 32, 64, 128$, and the distance between the neighboring points is h_n, $h_{2n}/h_n \approx 2$. The measured parameter is the area change $\delta A_n = A_n(t = 0) - A_n(t = 1)$. (The time interval is short enough to assure that the change in h during the evolution is insignificant and can be ignored.) The area change depends on the accuracy of discretization, h_n. To determine the order of accuracy, we computed successive differences $\delta A_{2n}(t = 1) - \delta A_n(t = 1)$. The results clearly show a quadratic dependence of the error on the mesh size.

In Table 5.2 we monitor a short term evolution (= 0.5, 50 unit time steps) of discrete circles with different radii r, $r = 0.25, 0.5, 1.0, 2.0, 4.0, 8.0$. The circles are discretized by n uniformly distributed points; each time n is chosen to provide the same discretization size h. The measured parameter is the area change $\delta A_r = A_r(t = 0) - A_r(t = 0.5)$. (The size of the time interval is short enough to assure that the changes in r during the evolution are insignificant and can be ignored.) The area change depends on the curvature of the circle, $\kappa = 1/r$. To determine the order of accuracy we computed successive differences, $\delta A_{2r} - \delta A_r$. The results clearly show a quadratic dependence of the error on the curvature.

In Figure 5.1 we represent the accuracy in triple junction evolution as a function of the mesh size, h. A single triple junction was considered. The incoming arcs at the initial configurations meet at angles $2\pi/3$; the grain boundaries near the triple junction were straight lines, continued later by $\mathbf{C}^2$ curves. The results shown in the figure are ratios $\|x^h(t) - x^{2h}(t)\|/\|x^{2h}(t) - x^{4h}(t)\|$, where $x(t)$ is the x coordinate of

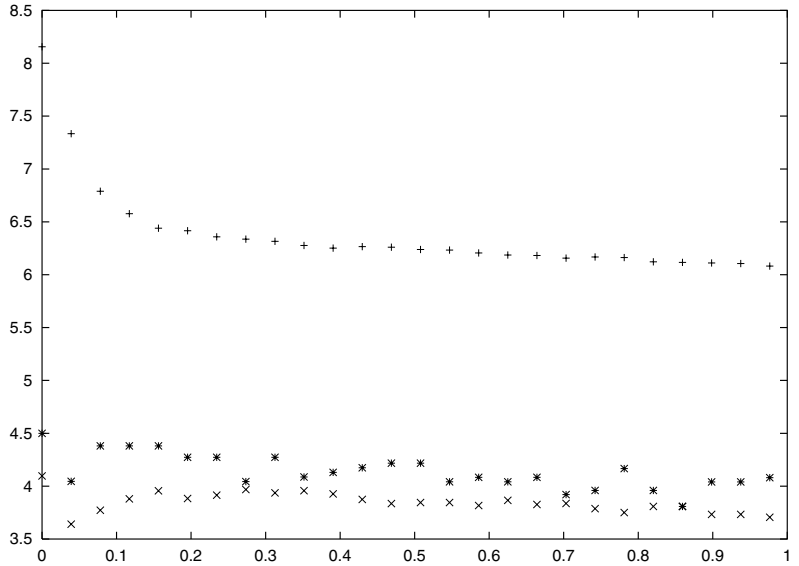

FIG. 5.1. *Triple junction: a mesh size dependence.* $\|x^h(t) - x^{2h}(t)\|/\|x^{2h}(t) - x^{4h}(t)\|$ *as a function of time. A value of* 4 *indicates a second order convergence.*

TABLE 5.3

0.025	0.0130660	0.0120707	0.0120725
0.0125	0.0116220	0.0112152	0.0112345

the triple junction at time t. (If $\|x^h(t) - x^{2h}(t)\| = Ch^p$, then these ratios converge as $h \to 0$ to 2^p.) We have tracked the evolution of a triple junction for different mesh sizes $h, h = 0.1, 0.05, 0.025, 0.0125, 0.00625$. The top dotted line is for $h = 0.25$, the bottom one is for $h = 0.125$, and the middle one is for $h = 0.00625$. The results in Figure 5.1 clearly show quadratic ($p = 2$) convergence.

In Table 5.3 we verify the $n - 6$ rule. We present results for individual grains with different number of grain boundaries n, $n = 3, 4, 7$, and different mesh sizes $h, h = 0.1, 0.05, 0.025, 0.0125$. In this experiment grain boundary grid points are subject to redistribution, in order to keep the distance between neighboring grid points approximately constant. This is done in order to keep the time step as well as the number of grid points under control. The results show that as h decreases, the quantity $\delta A_n/(n-6)$ approaches a constant independent of n. The table does not show exactly $O(h^2)$ convergence. This is due to slightly different initial configurations for different values of h.

6. Simulation of a bamboo structure. In this section we discuss simulations with isotropic grain boundary energy and mobility, $\sigma = \mu = 1$. The initial configurations for these simulations were obtained using a Voronoi algorithm. Grain boundary end points at the border of the computational domain are held fixed to represent the

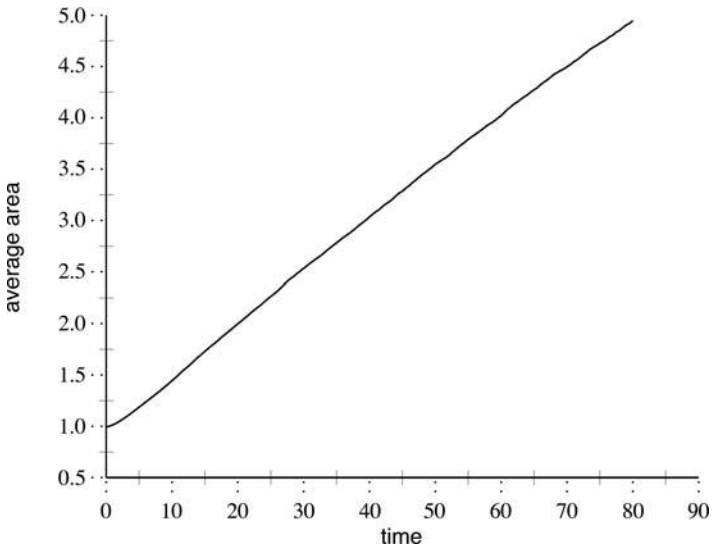

FIG. 6.1. *The average area evolution.*

presence of typical defect structures. Numerical simulations were performed to study basic properties of grain growth and stability of simple distribution functions.

As in any numerical model, to verify its reliability we would like to verify that the numerical simulations show the results predicted by, for instance, analytical considerations. Some analytical results are suggested for two-dimensional grain growth in an isotropic setting. One of them is a linearity, as a function of time, of the average area. The average area, $\langle a \rangle$, is calculated as

$$\langle a \rangle = A/N(t), \tag{6.1}$$

where A is the total area and is time independent and $N(t)$ is the total number of grains at time t. As Figure 6.1 shows, after a short relaxation time, a linear behavior prevails.

Another test to validate our simulations was the $(n-6)$ rule for a network of grains. Figure 6.2 shows the result of area change for each class of grains, e.g., grains with the same number of grain boundaries. In the figure the rates of area changes δA_n were calculated as an average area change in grains that had n grain boundaries at the beginning and the end of the statistical time interval $[t, t+0.5]$. The results are almost indistinguishable for different values of t. The $(n-6)$ rule is clearly obeyed for the network.

While the configuration does not converge to a steady state, certain distribution functions reach equilibrium, particularly the relative grain area distribution and number of edges distribution function. We define $g(n,t)$ and $f(\xi,t)$ as follows: $g(n,t)$ is the number of grains with n grain boundaries at time t, and $f(\xi,t)d\xi$ is the number of grains with relative area in $x \in [\xi, \xi+d\xi]$ at time t, and $\xi = a/\langle a \rangle$. The corresponding distribution functions are

$$G(n,t) = g(n,t)/N(t) \to G_0(n) \quad \text{as } t \text{ grows}$$

and

$$F(\xi,t) = f(\xi,t)/N(t) \to F_0(\overline{a}) \quad \text{as } t \text{ grows},$$

where $N(t)$ is the total number of grains at time t.

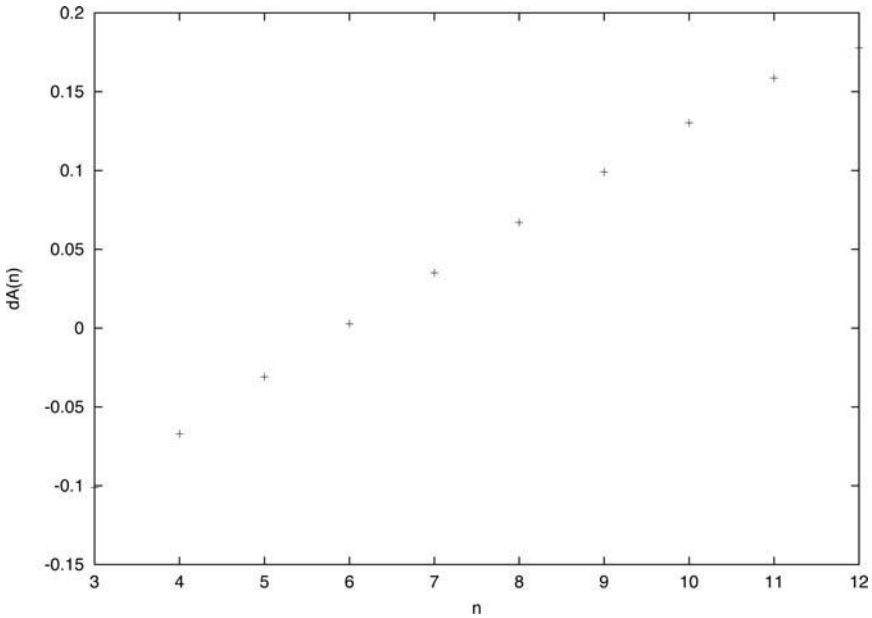

FIG. 6.2. *Verification of the* $(n-6)$ *rule for a network of grains.*

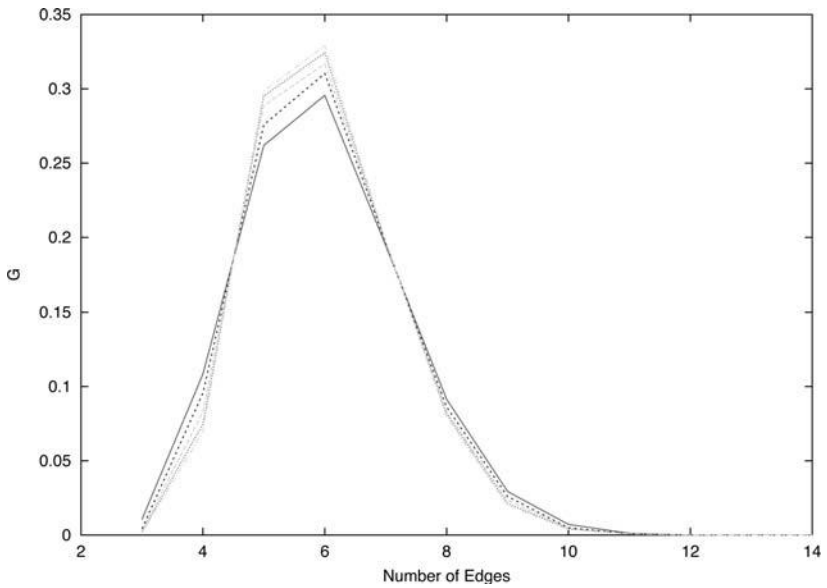

FIG. 6.3. *Evolution: the number of grain boundaries distribution function.*

Numerical studies shows that both $F(\xi, t)$ and $G(n, t)$ reach equilibrium.

In Figure 6.3, $G(n, t)$ is displayed at times $t = 0$ (initial configuration, the graph with lowest peak), $t = 2$, $t = 3$, $t = 4$, and $t = 5$. In Figure 6.4, $G(n, t)$ is displayed at times $t = 4, 6, 8, 10$. The curves are almost indistinguishable.

In Figure 6.5, $F(\xi, t)$ is displayed at times $t = 0$ (initial configuration, the graph with highest peak), $t = 1$ (graph with second highest peak), $t = 2$ (graph with next to

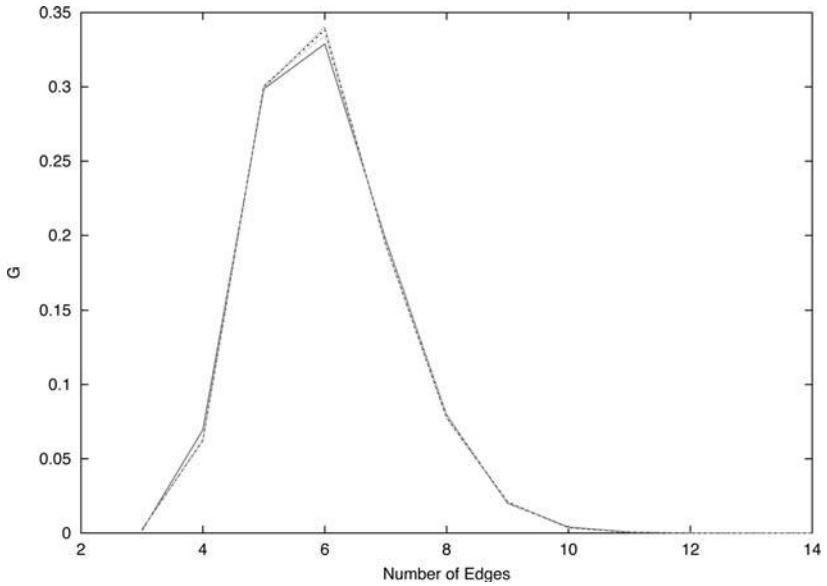

FIG. 6.4. *Steady state: the number of grain boundaries distribution function.*

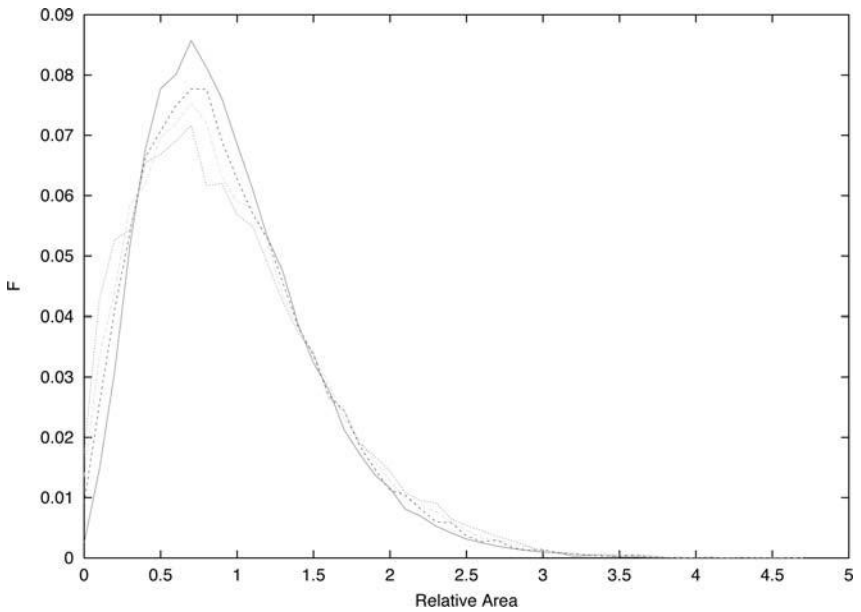

FIG. 6.5. *Evolution: the relative area distribution function.*

lowest peak), and $t = 4$ (the graph with lowest peak). In Figure 6.6 the relative area distribution function is displayed at times $t = 4, 6, 8, 10$, and the curves are almost indistinguishable.

These results demonstrate the convergence toward equilibrium of these distribution functions. This agrees with other numerical results such as MC simulations. The question of agreement with experiment is problematic [4], [5].

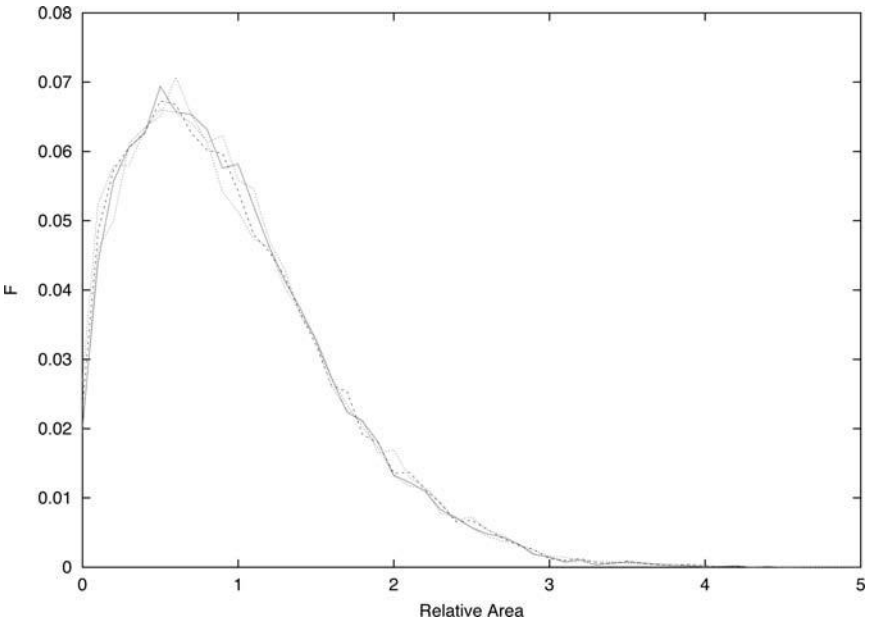

FIG. 6.6. *Steady state: the relative area distribution function.*

7. Simulation with anisotropic energies. A few preliminary results about simulations with anisotropic energies are briefly presented here to illustrate the flexibility of the method. This is part of an extensive project presently underway. For a general energy of this nature, the diagnostics presented in the last two sections no longer apply. But in this new context we have the opportunity to examine the development of texture, albeit in a reduced two-dimensional mode. For the present, let us ask for the [illegible], the distribution of grain boundary as a function of lattice misorientation. We consider first a density $\sigma(\alpha)$, which depends only on the lattice misorientation α but not on the normal angle θ. We choose cubic symmetry, which means that $\sigma(\alpha)$ is periodic of period $\pi/2$. For the convenience of the reader, we recall that in this context the Mullins equation and Herring condition take the form

$$v_n = \sigma(\alpha)\kappa \qquad \text{on } \Gamma, \tag{7.1}$$

$$\sum_{l=1}^{3} \sigma(\alpha_l) b_l = 0 \qquad \text{at a triple junction,} \tag{7.2}$$

where the triple junction involves the three curves $\{\Gamma_l\}$ with lattice misorientations $\{\alpha_l\}$. In this situation, the Herring condition reduces to Young's Law,

$$\frac{\sigma(\alpha_1)}{\sin\beta_1} = \frac{\sigma(\alpha_2)}{\sin\beta_2} = \frac{\sigma(\alpha_3)}{\sin\beta_3}, \tag{7.3}$$

where β_l is the angle subtended by the arcs opposite Γ_l. We now execute a simulation, starting from about 50,000 grains. When the relative area histogram reaches stationarity, we form the new grain boundary character distribution, the histogram of relative boundary length with respect to lattice misorientation $\alpha, -\pi/2 \le \alpha \le \pi/2$.

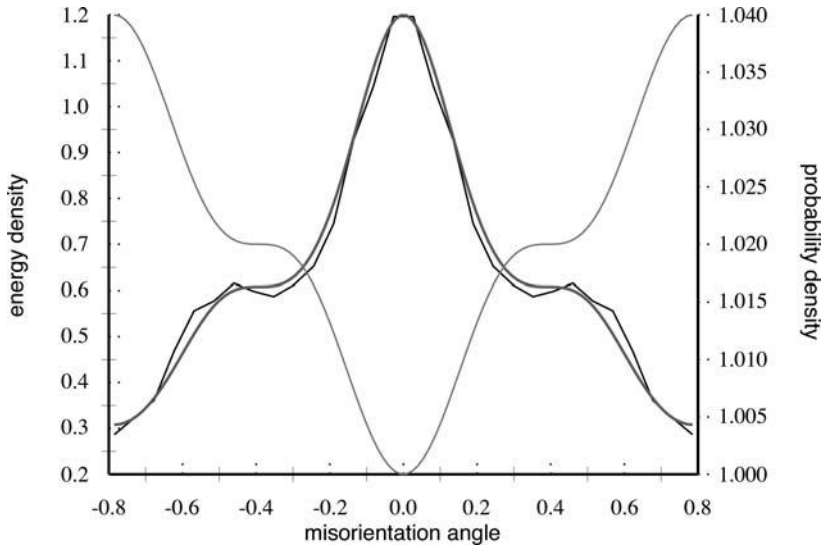

FIG. 7.1. *A simple anisotropic energy density σ,* (7.4)*, graph with minimum at zero with scale on left, and the computed grain boundary character density in graph with three maxima with Boltzmann comparison graph with a single maximum, scale on right.*

In Figure 7.1 are the resulting plots for

$$\sigma(\alpha) \;=\; 1 + \frac{\epsilon}{2}(1 - \cos^3(4\alpha)), \qquad \epsilon = 0.02. \tag{7.4}$$

This σ is very regular, with equal minima at multiples of $\pi/2$ and an inflection point between its maxima and its minima, as shown in Figure 7.1. The result has been smoothly interpolated and shows a distribution f which is compared with a Boltzmann distribution for the energy σ. This result has been found for simulations of (7.1), (7.2) for all choices of $\sigma(\alpha)$. It confirms that the thermodynamic theory of Mullins and Herring admits the statistic and thus ought to be observable as well in experiment; for a preliminary discussion, see [23]. As a check, we also executed the simulation with

$$v_n = \sigma(\alpha)\kappa \qquad \text{on } \Gamma, \tag{7.5}$$

$$\sum_{l=1}^{3} b_l = 0 \qquad \text{at a triple junction,} \tag{7.6}$$

which means that triple junctions meet at angles of $2\pi/3$. In this case the realized grain boundary character distribution is random, as it should be. It is extremely important to keep in mind that this demonstrates conclusively the role of the Herring condition in the theory.

To conclude we present the result of the simulation of a network where the energy density depends on both normal angle θ and lattice misorientation α. The simplest such energy densities consistent with the thermodynamical requirement of frame indifference may be constructed from σ of (7.4) by the expression

$$\begin{aligned} \hat{\sigma}(\theta, \alpha) &= \frac{1}{2}(\sigma(\theta - \omega) + \sigma(\theta - \omega')) \\ &= \frac{1}{2}(\sigma(\theta - \omega) + \sigma(\theta - \alpha - \omega)), \quad \alpha = \omega - \omega', \end{aligned} \tag{7.7}$$

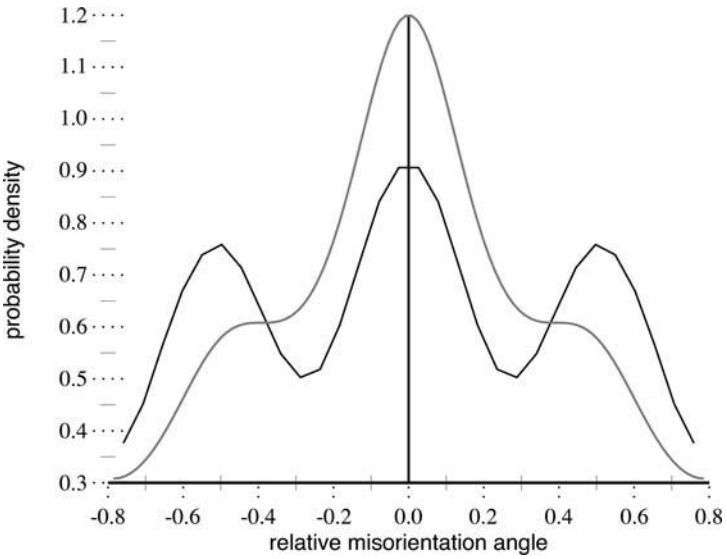

FIG. 7.2. *Histogram f of grain boundary character density (graph with three peaks) compared with Boltzmann distribution (graph with a single peak) for the energy $\hat{\sigma} = \hat{\sigma}(\theta, \alpha)$; see* (7.7).

where ω and ω' are the orientations of the grains neighboring the curve. This represents the energy of the interface as the sum of the energies of the two free interfaces which comprise it, a reasonable assumption in view of recent work by Saylor, Morawiec, and Rohrer [36]. The realized grain boundary energy distribution is shown in Figure 7.2 (three peak graph) and clearly is not a Boltzmann distribution.

8. Conclusion. In this paper we have exhibited a consistent variational approach to the mesoscale simulation of grain growth in two dimensions, and illustrated its application to a "bamboo structure," a system with constant energy and mobility, and a sample "fiber texture," where anisotropy is present. The method accurately computes curvature-driven growth with the Herring condition imposed at triple junctions. The issues we had to resolve to accomplish this include the correct discretization scheme and the treatment of critical events, and will arise in three-dimensional simulations. An important feature of the mesoscale approach is that it respects the thermodynamic formulation given by Mullins and Herring. The reduced dimensionality of its data structure permits simulation of large scale systems, indeed, systems sufficiently larg e that we may inquire about their statistics. We found that the statistics produced by our simulation are very robust. The last section, where we described sample simulations with anisotropic energy densities, illustrates the flexibility of our formulation and shows how it can be employed to discover the grain boundary character distribution, a new statistic with significant promise for predicting material properties. of We hope that the advantages will become even more pronounced for three-dimensional grain growth, which is work in progress, where the description is reduced to evolution of two-dimensional surfaces.

Future work can exploit this method to investigate interface dominated properties, for example, questions about anisotropy, texture, and abnormal grain growth, as mentioned in the Introduction. As a first step previewed in section 7, we are exploring the role of anisotropy; cf. also [9], [23].

A PSEUDOSPECTRAL FICTITIOUS POINT METHOD FOR HIGH ORDER INITIAL-BOUNDARY VALUE PROBLEMS*

BENGT FORNBERG†

Abstract. When pseudospectral approximations are used for space derivatives, one often encounters spurious eigenvalues. These can lead to severe time stepping difficulties for PDEs. This is especially the case for equations with high order derivatives in space, requiring multiple conditions at one or both boundaries. We note here that a very simple-to-implement fictitious point approach circumvents most of these difficulties. The new approach is tested on the Kuramoto–Sivashinsky equation and on a dispersive linear PDE featuring a time-space corner singularity.

Key words. spurious eigenvalues, PDE, pseudospectral method, Kuramoto–Sivashinsky equation, time-space corner singularities

AMS subject classification. 65M70

DOI. 10.1137/040611252

1. Introduction.

PDEs with high derivatives in space typically require multiple conditions at one or more of its boundaries, as noted in Table 1.1. Implementation of one Dirichlet condition at a boundary is straightforward when using a Chebyshev-type spectral method. This paper discusses how to best implement additional conditions.

The third order linear initial-boundary value (IBV) problem

$$\begin{cases} \text{PDE} & u_t = u_{xxx}, \\ \text{IC} & u(x,0) = f(x), \\ \text{BC} & u(\pm L, t) = 0,\ u_x(-L,t) = 0 \end{cases} \tag{1.1}$$

can be used to illustrate this topic. A numerical methods-of-lines (MOL) time stepping method for (1.1) will be stable if and only if the spatial differentiation operator is such that, when instead applied to the eigenvalue problem

$$\begin{cases} \text{ODE} & u_{xxx} = \lambda u, \\ \text{BC} & u(\pm L) = 0,\ u_x(-L) = 0, \end{cases} \tag{1.2}$$

the quantity $\xi = \lambda \Delta t$ for all the eigenvalues λ fall within the time stepping method's stability domain.

For the problem (1.2), the true eigenvalues are all real and negative. They are given by the roots to

$$e^{3L\lambda^{1/3}} - 2\sin\left(\sqrt{3}L\lambda^{1/3} + \frac{\pi}{6}\right) = 0 \tag{1.3}$$

(omitting $\lambda = 0$), and can be approximated very closely by

$$\lambda_k \approx -\left[\frac{\left(k+\frac{1}{6}\right)\pi}{\sqrt{3}L}\right]^3, \quad k = 1, 2, \ldots. \tag{1.4}$$

TABLE 1.1
Number of conditions needed at each boundary for some time dependent PDEs in order to form well-posed IBV problems.

PDE		Number of conditions needed	
		Left side	Right side
$u_t = u_x$		0	1
$u_t = u_{xx}$		1	1
$u_t = u_{xxx}$		2	1
$u_t = u_{xxxx}$		2	2
$u_t = u_{xxxxx}$		2	3
$u_t + uu_x + u_{xxx} = 0$	KdV	1	2
$u_t + uu_x + u_{xx} + u_{xxxx} = 0$	KS	2	2

The challenge thus lies in approximating (1.2) so that (i) as many of the leading eigenvalues (and eigenvectors) as possible become accurately approximated, and (ii) the remaining (spurious) numerical eigenvalues are all located far out in the left half-plane, so as not to damage either the accuracy or the stability when using the MOL approach with a stiff ODE solver.

When using Galerkin (or tau) spectral methods—working with expansion coefficients rather than with node values as in the present pseudospectral (PS) approach—remedies have been discussed numerous times in the literature, e.g., [15], [23], and the references therein. However, especially in contexts involving variable coefficients and nonlinearities, the PS approach tends to be a lot more convenient.

In the next two sections of this paper, we summarize some approaches for resolving the problem with spurious eigenvalues when using the PS approach. We will note that an approach based on fictitious points (previously introduced for spectral methods in [13], in a slightly different context) is particularly effective, flexible, and simple to implement. In section 4, we discuss the same issues for some more general PDEs, in particular for the Kuramoto–Sivashinsky (KS) equation, and for some linearized versions of it. We note in section 5 that the issue of time-space corner singularities still needs more investigation, especially in the presence of nonlinearities. The example in section 6 illustrates this singularity issue, and also shows that the application of inhomogeneous boundary conditions (BCs) causes no further difficulties. Section 7 contains some concluding remarks.

2. Differentiation matrix (DM) approaches. With the node points denoted by $x_k,\ k = 0, 1, \ldots, n$, and the corresponding function values by u_k, the first derivative values u'_k can be approximated by means of a matrix×vector product

$$\begin{bmatrix} & & \\ & D^1 & \\ & & \end{bmatrix} \begin{bmatrix} u_0 \\ u_1 \\ \vdots \\ u_n \end{bmatrix} = \begin{bmatrix} u'_0 \\ u'_1 \\ \vdots \\ u'_n \end{bmatrix}.$$

Requiring that this formula becomes exact for all polynomials of degree n determines the differentiation matrix D^1 uniquely. This matrix can be computed at a cost of only four operations per entry by means of the explicit formula [27]

$$D^1_{j,k} = \begin{cases} \dfrac{a_j}{a_k(x_j - x_k)} & \text{if } j \neq k, \\ \displaystyle\sum_{\substack{i=0 \\ i\neq k}}^{n} \dfrac{1}{x_k - x_i} & \text{if } j = k, \end{cases} \qquad \text{where } a_k = \prod_{\substack{i=0 \\ i\neq k}}^{n} (x_k - x_i).$$

For higher derivatives, the corresponding DMs can be obtained by immediate matrix multiplication, i.e., $D^p = (D^1)^p$. However, several direct recursions have been found which give the entries of D^p both faster and in a more numerically stable manner. For different methods and/or variations, see, for example, [12], [14], [19], [35], [36], [37], [38]. In all the following discussions, we have used Chebyshev distributed nodes, i.e., $x_k = -L\ \cos\frac{\pi k}{n},\ k = 0, 1, 2, \ldots, n,$ in case of the interval $[-L, L]$. However, the results and conclusions become the same for similar choices, such as Legendre, Gegenbauer, or Jacobi distributions.

The immediate numerical discretization of (1.2) can be written as

$$\text{ODE:} \qquad \begin{bmatrix} & D^3 & \end{bmatrix}_{n+1,n+1} \begin{bmatrix} u \end{bmatrix}_{n+1} = \lambda \begin{bmatrix} u \end{bmatrix}_{n+1}, \tag{2.1}$$

with

$$\text{BC:} \qquad \begin{bmatrix} 1 & 0 & \ldots & 0 & 0 \\ 0 & 0 & \ldots & 0 & 1 \\ d_0 & d_1 & \ldots & d_{n-1} & d_n \end{bmatrix}_{3,n+1} \begin{bmatrix} u \end{bmatrix}_{n+1} = \begin{bmatrix} 0 \\ 0 \\ 0 \end{bmatrix}_3. \tag{2.2}$$

We have here also marked the sizes of the matrices and vectors. The most natural way to incorporate the first two BCs would be to simply remove the first and last rows and columns from D^3 and the first and last elements of u, leading to the eigenvalue problem $\widehat{D^3}\hat{u} = \lambda\hat{u}$ of size $(n-1) \times (n-1)$. Had there been no more BCs (as in the case for second derivatives using one condition at each end), this would have been fully satisfactory. However, we have here also a third BC. Its implementation is much less apparent, and forms the main topic of this present study.

Trefethen notes in [32, page 135] "There are two basic approaches to boundary conditions for spectral collocation methods: (I) [illegible]; or (II) [illegible]." We describe this second approach first, in subsection 2.1. Most recent work has concentrated on the first approach, discussed in subsection 2.2. We introduce then, in section 3, the fictitious point (FP) approach. This is very simple to implement and, as will be shown, lends itself especially well to the time stepping of PDEs with either homogeneous or inhomogeneous BCs.

2.1. Approach II: Elimination of an additional row and column. Merryfield and Shizgal [24] consider the possibility of adding suitable multiples of the last BC in (2.2) to the different rows in the ODE, so that also the second column of D^3 gets eliminated. The second unknown u_1 can, from this BC, be expressed in terms of the remaining unknowns:

$$u_1 = -\frac{1}{d_1} \sum_{i \neq 1} d_i u_i. \tag{2.3}$$

In order not to impose more relations than there are unknowns, we would then omit imposing the ODE at this second grid point location. The eigenvalue problem has then been reduced to size $(n-2) \times (n-2)$. We write this as

$$\widetilde{D_1^3} = \lambda\check{u}, \tag{2.4}$$

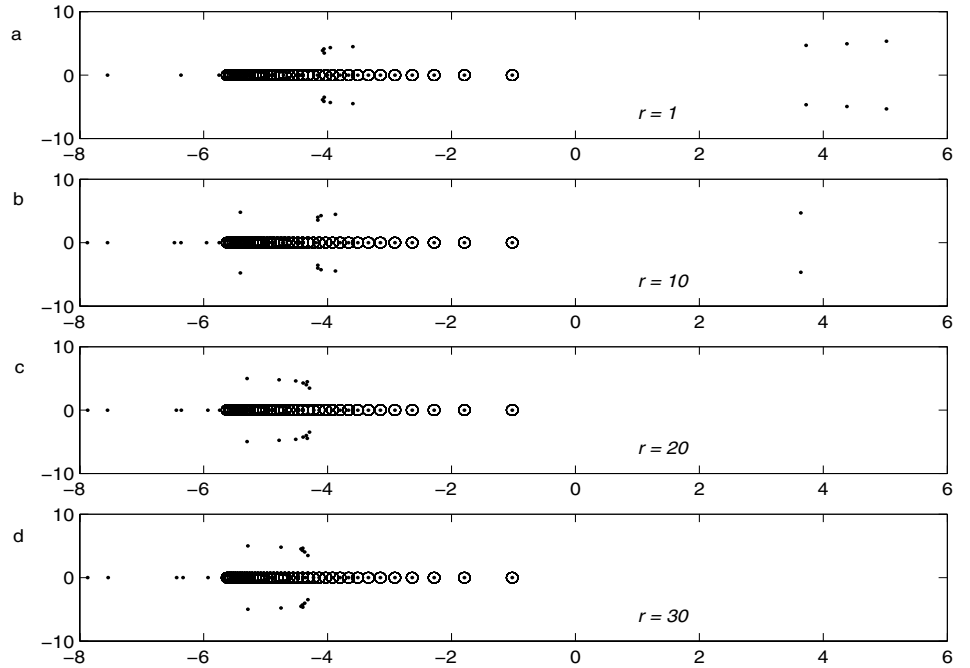

FIG. 2.1. *Complex spectra for the reduced matrix* $\check{D}_1^3$ *in the Mulholland approach, when the first and last row and column and also row and column* r, $r = 1, 10, 20, 30$, *have been eliminated. The axes have been scaled by* $x \to sign(x)\ \log_{10}(1 + |x|)$ *and similarly for* y (*in order to keep signs but compress large arguments*).

where the subscript "1" denotes that the second row and column are also eliminated (recalling that we count rows and columns starting with zero). Figure 2.1(a) (labeled $r = 1$) compares, in the case of $n = 40$ and $L = 1$, the eigenvalue distribution for (2.4) (marked by dots) against the first $n + 1$ analytic eigenvalues (marked by circles). As Merryfield and Shizgal first noted, the presence of several spurious eigenvalues far out in the right half-plane rules out this approach in the context of MOL time stepping.

Mulholland [26] generalized the approach of eliminating row 1 and column 1 to instead eliminating row r and column r, where $1 \le r \le n - 1$. Since the extra boundary condition appears at the left boundary, Merryfield and Shizgal's choice $r = 1$ is what first comes to mind. However, it transpires that the stability situation improves very much when r is increased. Figures 2.1(b), (c), (d) show the results with $r = 10, 20, 30$, respectively. Although the situation with r approaching n might appear satisfactory in the present case, there is something strange about eliminating a node in the Chebyshev grid far away from the boundary at which the extra condition had to be imposed. In fact, the generalization

$$u_r = -\frac{1}{d_r} \sum_{i \ne r} d_i u_i \tag{2.5}$$

of (2.3) becomes problematic because the weights d_i are oscillatory and decay rapidly in magnitude with increasing r. Figure 2.2 shows these in the case of $L = 1$ and $n = 20$. Some coefficients d_i/d_r in (2.5) become much larger than one, and small oscillations in u_i, $i < r$, get strongly amplified in the computed value of u_r. The

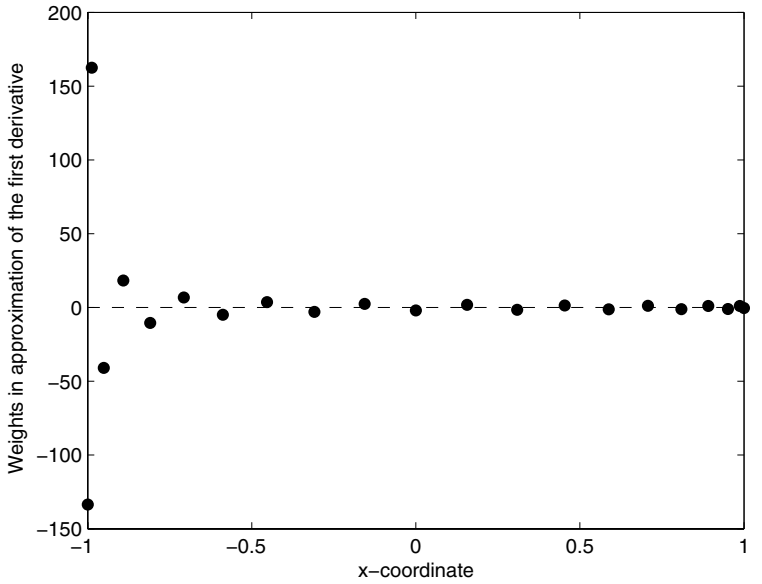

FIG. 2.2. *Weights d_i when the first derivative is approximated at the left boundary of a* 21*-node Chebyshev-spaced grid.*

reason the methodology still works, even as r is increasing, is that the resulting errors in u_r occur close to the right boundary, and the general character of solutions to (1.1) is that all modes are transported towards this right boundary and become completely absorbed there—the faster the higher the mode is. It thus would appear that the Mulholland approach will work only for very special PDEs. In fact, it fails entirely for the KS equation, which we will consider in section 4.

2.2. Approach I: Modify the DM to incorporate the boundary information. Determining the DM for collocation at $x_0,\ x_1, \ldots, x_n$ with a polynomial $p_n(x)$ over $[-1, 1]$ and then enforcing $u(-1) = u(1) = 0$ leads to the same DM as one would get if one considered only polynomials of the form $(x + 1)(x - 1)p_{n-2}(x)$ and collocated only over the internal nodes $x_1, \ldots, x_{n-1}$. In order to also enforce $u_x(-1) = 0$, we can collocate over the interior nodes with a polynomial of the form $(x+1)^2(x-1)p_{n-2}(x)$. This type of approach was taken by Funaro and Heinrichs [16], later independently by Huang and Sloan [18], and again by Heinrichs [17]. In these cases, closed form expressions for the resulting DMs were obtained. Trefethen [32, page 146] describes another approach which, for arbitrary node distributions, gives the desired DM from standard ones in just a few matrix operations. Figure 2.3(a), showing its eigenvalues, should be compared to Figure 2.1. The spurious eigenvalues are located as advantageously as in any of the previous cases from Mulholland's method, but without the need to discard the governing equation at any one of the interior grid points. One of the referees of the present paper proposed the following procedure: with $\underline{u} = [u(-1), u_1, u_2, \ldots, u_{n-1}, u(1)]^T$, form $D^1\underline{u}$, set its first component to $u'(-1)$, and then apply D^2 to get an approximation for u_{xxx} that incorporates the given values of $u(-1)$, $u(1)$, and $u'(-1)$. This procedure, which is particularly simple to implement in case of nonhomogeneous BC, gives results that are only very slightly

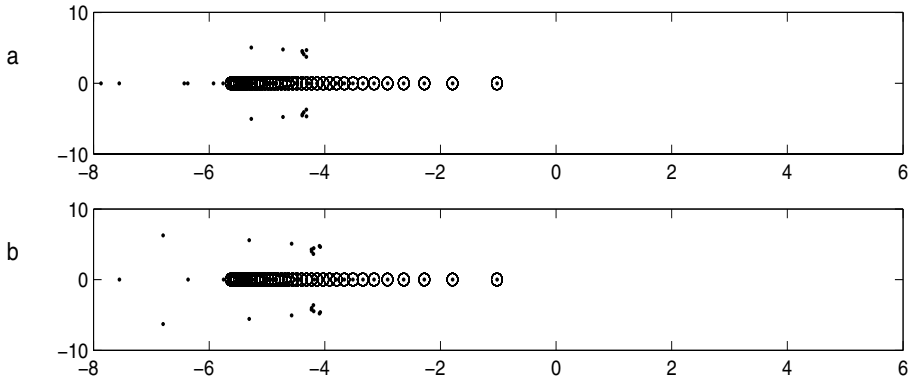

FIG. 2.3. *Complex spectrum for the same test case as in Figure* 2.1. (a) *Collocation with a polynomial of the form* $(x+1)^2(x-1)p_{n-2}(x)$. *This will agree with the FP method described in section* 3. (b) *Last method described in section* 2.2.

different from the method just mentioned (as seen in Figure 2.3(b)).

None of the methods/implementations that have just been mentioned combine all of the following desirable features:

(i) easy implementation;

(ii) easy generalization to nonhomogeneous cases;

(iii) ability to handle Robin-type BCs (involving linear combinations of values and derivatives, in place of values and/or derivatives);

(iv) ability to impose BCs on staggered-type grids (where the actual boundary location does not coincide with a grid point).

3. Fictitious point approach. Although for simplicity, our description will not be the most general, the FP approach will be seen to meet all the four criteria that were just noted.

Since we in our model problem (1.2) have one more BC than can be imposed by just fixing the values for $u(x_0)$ and $u(x_n)$, we introduce an additional grid point at some arbitrary location x_{FP}. When evaluating the matrix D^3, for example, by the algorithm in [37], this point is included just like $x_0, \ldots, x_n$. The extra BC can be expressed as a linear combination of node values:

$$\begin{bmatrix} d_{FP} & d_0 & d_1 & \ldots & d_{n-1} & d_n \end{bmatrix}_{n+2} \begin{bmatrix} u \end{bmatrix}_{n+2} = 0.$$

Since finding these weights requires the computation of only one global FD stencil (rather than a full DM), the algorithm in [12] is particularly suitable for this task. Multiples of $[d_{FP}\ d_0\ d_1\ \ldots\ d_{n-1}\ d_n]$ are next subtracted from D^3 in order to eliminate all weights at x_{FP}. The two BCs for $u(x_0)$ and $u(x_n)$ are implemented as before, i.e., we omit the first and last row and column of D^3. The key to this approach is that, apart from possible rounding errors, the resulting $\widetilde{D^3}$ matrix becomes completely independent of our choice for x_{FP}. The reason for this is that introducing this point and then eliminating all weights at it can be seen as a particularly convenient way to find the same DM as before, i.e., corresponding to collocating with polynomials of

the form

$$P(x) = (x+1)^2(x-1)p_{n-2}(x). \tag{3.1}$$

The equivalence just mentioned can be explained in more detail as follows: Data values $u_0 = 0,\ \{u_i, i = 1, 2, \ldots, n-1\},\ u_n = 0$ at node locations $x_0 = -1,\ \{x_i, i = 1, 2, \ldots, n-1\},\ x_n = 1$ determine uniquely the polynomial $P(x)$ in (3.1). We next choose an additional point x_{FP} and evaluate $u_{FP} = P(x_{FP})$. If we extend the data set above with the value u_{FP} at location x_{FP}, it will then consist of $n+2$ points, and it therefore determines a unique interpolating polynomial of degree $n+1$. This polynomial must be identical to $P(x)$. The FP approach provides the exact value for any derivative of this polynomial, at any location, i.e., its results must agree exactly with those obtained by immediate use of (3.1). The value we happened to have chosen for x_{FP} did not affect $P(x)$ (which was determined before x_{FP} was introduced), and it could therefore not in any way have influenced the outcome of the FP method.

The general idea of introducing one (or more) temporary grid points outside an interval is not new. It has long been used to implement Neumann conditions in connection with low order FD methods (e.g., [30, page 32]); other contexts include domain decomposition, block-PS methods [7], [8], and the "enslaving" idea for FD schemes [21]. In all these cases, the final computational result will depend on where the extra point(s) are located. The expression "fictitious point" was first used in [13], in a situation where the point truly vanished in the sense that not even its temporary location left any remaining trace behind. We use here the term FP in that sense. These points can just as well be placed inside a computational domain as outside it.

4. The Kuramoto–Sivashinsky equation. The KS equation can be written

$$u_t = -u\, u_x - u_{xx} - u_{xxxx}. \tag{4.1}$$

It features some similarities with Burgers' equation

$$u_t = -u\, u_x + u_{xx} \tag{4.2}$$

but is more interesting in several respects. In (4.2), the dissipative term u_{xx} counteracts the effects of steepening caused by the nonlinear term uu_x, and solutions typically evolve into pulses which travel while decaying. In (4.1), the u_{xx} term (in conjunction with the time derivative) amounts to the backwards heat equation, which is unstable for all modes. Inclusion of the u_{xxxx} term causes high modes to become dampened while low modes remain unstable. The uu_x term causes again a steepening of waves, with the effect that unstable modes of sufficient height get brought over to the stable higher-frequency regime. The KS equation models numerous phenomena in physics [34] and is a frequently used model equation for chaotic dynamics [20], [29].

A very brief Fourier-PS MATLAB code, slightly modified from [33], has been used to produce Figure 4.1. This shows how the small initial disturbance

$$u(x,0) = \begin{cases} 0.1\, \sin^2(x/2), & -12\pi < x < -10\pi, \\ 0 & \text{otherwise} \end{cases} \tag{4.3}$$

over the periodic domain $[-16\pi, 16\pi]$ causes chaotic structures to emerge.

4.1. A linear model equation. In preparation for introducing a nonperiodic PS code for the KS equation, we next consider the linear problem

$$u_t = -u_{xx} - u_{xxxx} \tag{4.4}$$

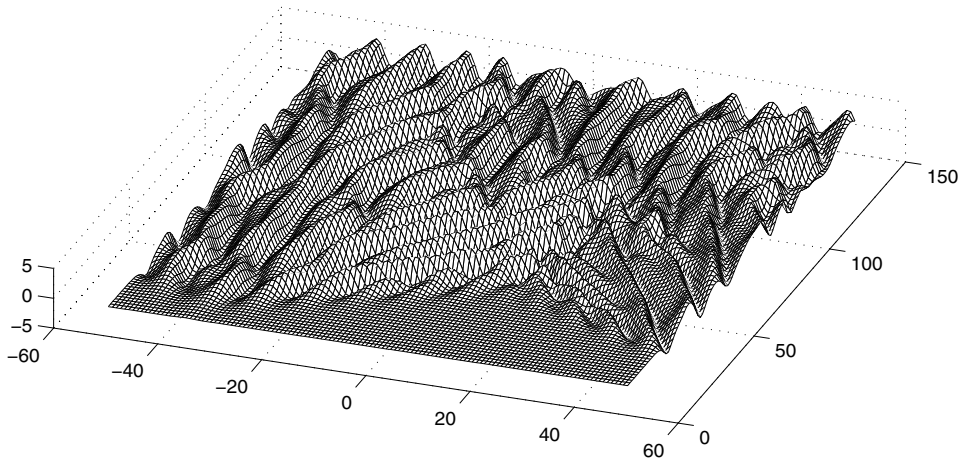

FIG. 4.1. *Periodic solution to the KS equation* (4.1) *with initial condition* (*IC*) (4.3) *computed with a periodic PS method using* 128 *points in space.*

with BCs

$$u(\pm L, t) = 0,\ u_x(\pm L, t) = 0. \tag{4.5}$$

If we at first limit ourselves still further to

$$u_t = -u_{xx} \tag{4.6}$$

with BC $u(\pm L) = 0$, the corresponding eigenvalues become

$$\lambda_k = \left[\frac{k\pi}{2L}\right]^2, \quad k = 1, 2, 3, \ldots,$$

and for

$$u_t = -u_{xxxx} \tag{4.7}$$

with BC (4.5), they become $\lambda_k = -\left(\frac{\rho_k}{2L}\right)^4$, where ρ_k is the kth positive root to $\cos(\rho) \cdot \cosh(\rho) = 1$, i.e.,

$$\lambda_k \approx -\left[\frac{(k + \frac{1}{2})\pi}{2L}\right]^4, \quad k = 1, 2, 3, \ldots .$$

The PS approach to (4.6) features all real and positive eigenvalues, as seen in Figure 4.2(a) for the case of $L = 20$ and $n = 10, 20, 30, \ldots, 80$. The lowest eigenvalues are very accurate, whereas the higher (spurious) ones become very large. Figure 4.2(b) shows similarly the FP PS method's eigenvalues for (4.7). These are all negative—again with spurious ones far away. One might have guessed that the FP-computed eigenvalues to the combined equation (4.4) would feature spurious eigenvalues both to the right and to the left (and, if so, causing maybe insurmountable time stepping difficulties). However, as Figure 4.2(c) shows, they are all far out in the left half-plane. Although the equation that gives the exact eigenvalues to (4.4) is too complicated to be practical to work with, they can nevertheless be computed accurately. The lower eigenvalues appear in close pairs, as can be seen in the tabulation along the top edge of Figure 4.3. The figure also shows graphically the errors in FP-type PS approximations based on increasingly fine Chebyshev distributions.

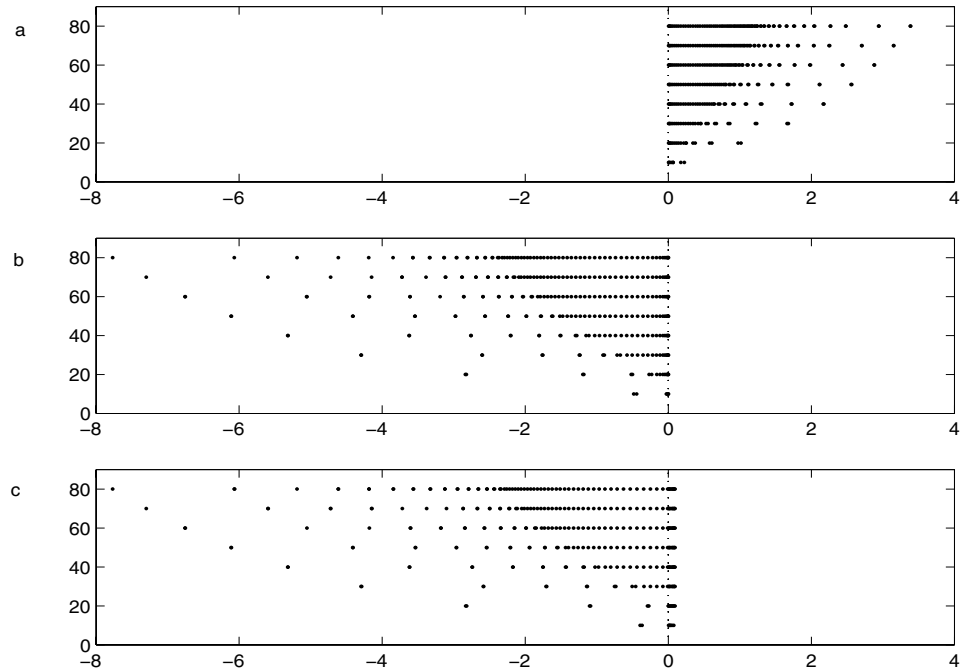

FIG. 4.2. *Eigenvalues* (*all real*) *in cases of* $N = 10, 20, 30, \ldots, 80$ *for* (a) *equation* (4.6), (b) *equation* (4.7), *and* (c) *equation* (4.4). *The scaling in the horizontal direction is the same as described in the caption for Figure* 2.1.

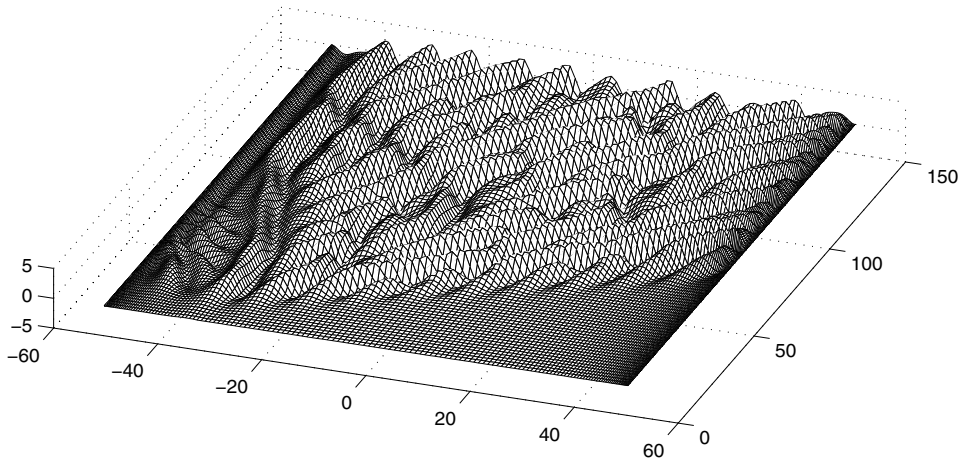

FIG. 4.4. *Nonperiodic solution to the KS equation* (4.1)*, computed by the FP PS method.*

4.2. Numerical solution of the nonperiodic KS equation. The FP PS method, as just described, has been implemented for solving the KS equation (4.1) with the nonperiodic BC $u(\pm L, t) = 0,\ u_x(\pm L, t) = 0$. With again $L = 16\pi$ and the IC (4.3), Figure 4.4 shows the resulting time evolution.

In this calculation, the time stepping (again over $0 \le t \le 150$) was performed with the 2-stage fourth order accurate Hammer–Hollingsworth implicit Runge–Kutta scheme. However, any standard stiff ODE solver should also have worked perfectly well. According to comparisons in [22], an LI (linearly implicit) scheme or an ETD (exponential time differencing) scheme would likely have been a more effective choice. The former have a long history, and were recently surveyed, for example, in [1] and [5], while Runge–Kutta-based LI schemes are considered in [28]. It should, however, be noted that Boyd [3, pages 267–269] warns against their use for certain nonlinear wave equations. ETD schemes were introduced independently several times [31], [2], [25], and [6], with a stability problem resolved in [22]. In Figure 4.4, we see again a chaotic solution that reaches approximately the same amplitude as in the periodic case. However, both quantitative and qualitative differences can be spotted compared to the periodic case that was previously displayed in Figure 4.1.

5. Time-space corner singularities. In applications leading to IBV problems, ICs and BCs typically come from different physical considerations. In order for the solutions to the PDE not to feature singularities in the time-space corners where ICs and BCs meet, an infinite number of compatibility conditions need to hold, as explored by Flyer and collaborators [4], [9], [10], [11]. For (1.1), these were analyzed in detail in [10]. Figure 5.1 shows for $k = 1$ and $k = 2$ the structure of the solutions

(5.1)
$$u_k(x,t) = t^k \left\{ {}_1F_2\left(-k, \left\{\frac{1}{3}, \frac{2}{3}\right\}, -\frac{x^3}{27t}\right) - \frac{x^2}{2t^{2/3}} \frac{\Gamma(k+1)}{\Gamma(k+\frac{1}{3})}\ {}_1F_2\left(\frac{2}{3} - k, \left\{\frac{4}{3}, \frac{5}{3}\right\}, -\frac{x^3}{27t}\right)\right\}$$

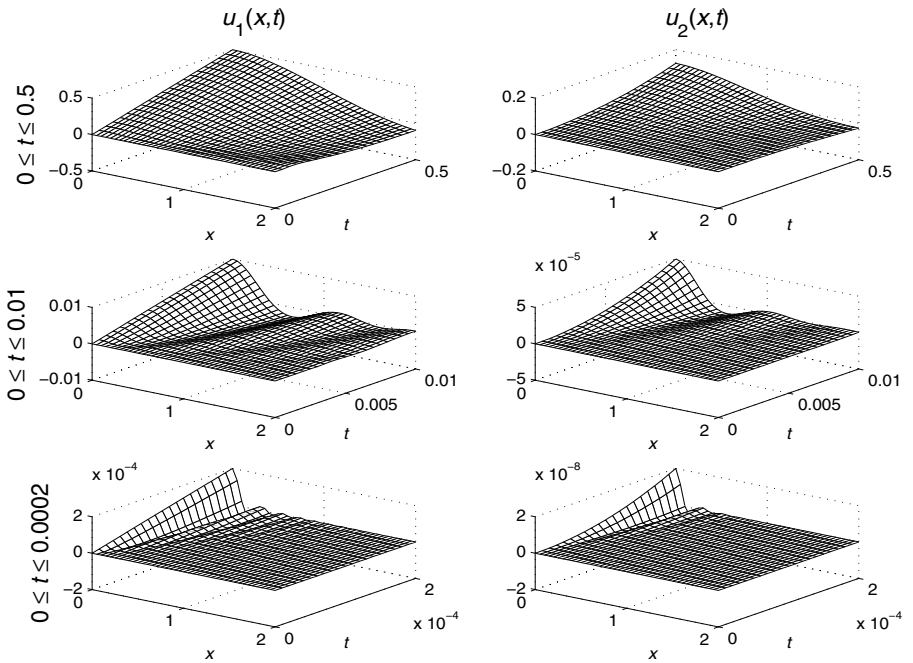

FIG. 5.1. *The corner functions $u_1(x,t)$ and $u_2(x,t)$ for* (5.2)*, displayed over progressively shorter initial time intervals.*

near the origin for the quarter-plane problems

$$
\text{(5.2)} \qquad \begin{cases} \text{PDE} & u_t = u_{xxx}, \\ \text{IC} & u(x,0) = 0, \\ \text{BC} & \begin{cases} u(t,0) &= t^k, \\ u_x(t,0) &= 0, \end{cases} \quad k = 0,1,2,\ldots; \;\; u(t,\infty) = 0, \end{cases}
$$

$x \geq 0$, $t \geq 0$. For the BCs $u(t,0) = 0, \;\; u_x(t,0) = t^k$, we denote the corresponding quarter-plane solutions by $v_k(x,t)$:

$$
v_k(x,t) = t^{k+\frac{1}{3}} \left\{ {}_1F_2\left(-k, \left\{\frac{2}{3}, \frac{4}{3}\right\}, -\frac{x^3}{27t}\right) - \frac{x^2}{2t^{2/3}} \frac{\Gamma(k+1)}{\Gamma(k+\frac{2}{3})} \, {}_1F_2\left(\frac{1}{3} - k, \left\{\frac{4}{3}, \frac{5}{3}\right\}, -\frac{x^3}{27t}\right) \right\}.
$$

The top row of subplots in Figure 5.1 shows seemingly very smooth analytic solutions, for which one would not expect any numerical difficulties. No amount of "zooming in" (uniformly in x and t) near the origin in the (x,t)-plane will visually reveal any irregularities. However, if we increase the graphical resolution in time only, the lower subplots reveal the presence of transient fine structures which accurate numerics would also need to resolve. A typical numerical approach, as explained in some detail for convective-diffusive equations in [9], would be to subtract an appropriate combination of different [illegible] before an FP PS numerical method is applied to the remaining problem.

The issue of corner singularities in the time-space domain was little noted before the advent of spectral methods, since the truncation errors of finite difference and finite element methods tended to dominate over them. However, when using PS methods,

corner-induced errors can easily dominate over other errors with many orders of magnitude. In the present test case for the KS equation (4.1), all space derivatives of the IC (4.3) and time derivatives of the BC (4.5) are zero in the corners, and this issue did not arise. However, it needs to be noted that it is one that has to be considered in most spectral IBV calculations. The precise form of the corner singularity functions for most higher order PDEs (such as (4.4) and (4.1)) remains to be investigated. For cases when they cannot be obtained in convenient closed form, it was noted in [9] that a simple change of variables makes their numerical computation straightforward.

6. Inhomogeneous boundary conditions. The description of the FP approach in section 3 applies entirely unchanged also to the case of inhomogeneous BCs. As an example, we consider the case illustrated in the center left subplot of Figure 5.1, i.e., we use the FP method to numerically solve

$$\text{(6.1)} \qquad \begin{cases} \text{PDE} & u_t = u_{xxx}, \\ \text{IC} & u(x,0) = 0, \\ \text{BC} & u(0,t) = t,\ u_x(0,t) = 0,\ u(2,t) = \left\{ \begin{array}{c} \text{values from the ana-} \\ \text{lytic solution (5.1)} \end{array} \right\} \end{cases}$$

for $0 \le t \le 0.01$. The resulting solution should agree exactly with the $k = 1$ case of (5.1). Figure 6.1(a) shows the result on a 20-node Chebyshev grid with the time stepping, this time carried out with one of MATLAB's standard stiff ODE solvers (ode15s). Part (b) of the figure shows the error compared to the analytic solution. At the very first moments, extremely high frequency transients emerge from the origin (where the ICs and BCs meet) and then race to the right across the spatial domain. After they have done so, and have "died down" at the right boundary, the numerical solution features a very high accuracy. As we noted above, these initial transients at first contain frequencies that are too high for any computational grid, and the error they cause

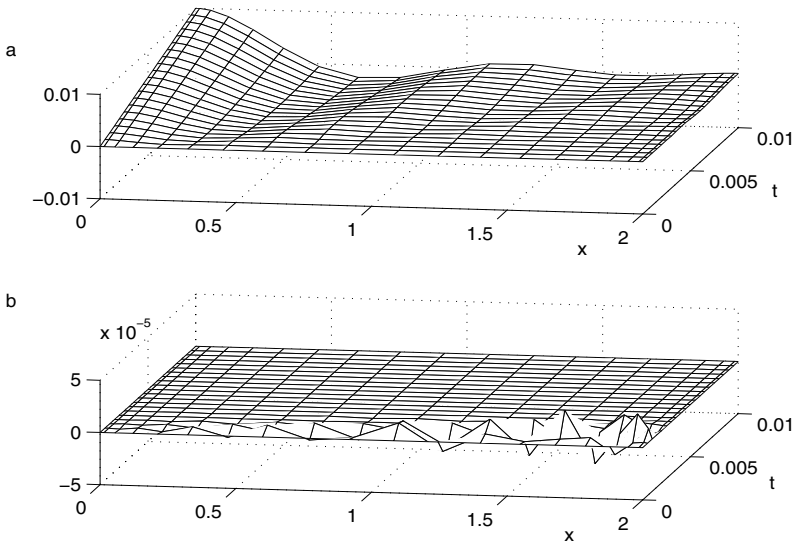

FIG. 6.1. *The $u_1(x,t)$ corner function for $u_t = u_{xxx}$.* (a) *Numerical FP solution on a* 20*-node Chebyshev grid.* (b) *The error compared to the analytic solution.*

can easily dominate all other errors by several orders of magnitude. It depends on the application whether or not accurate resolution of initial transients is important.

7. Conclusions. High order IBV problems can require several conditions at each boundary. When using Chebyshev-type PS approximations in space, it has in the past not been clear how best to implement these conditions in order to obtain good accuracy, stability, flexibility, and simplicity. The present FP approach has been shown to meet such requirements. Demonstration cases have included the KS equation as well as the dispersive wave equation $u_t = u_{xxx}$ with inhomogeneous boundary conditions. As with other Chebyshev-type PS methods, the DMs in the FP approach are not particularly close to being normal matrices. However, they are close enough that eigenvalue analysis accurately describes actual stability under time stepping. With the very high accuracy that is now easily reachable also for high order IBV problems, the singularities that such equations generally have at time-space corners (where ICs and BCs meet) will need to be taken into account, especially in computations over short times.

A HIGH-ORDER ACCURATE PARALLEL SOLVER FOR MAXWELL'S EQUATIONS ON OVERLAPPING GRIDS*

WILLIAM D. HENSHAW†

Abstract. A scheme for the solution of the time-dependent Maxwell's equations on composite overlapping grids is described. The method uses high-order accurate approximations in space and time for Maxwell's equations written as a second-order vector wave equation. High-order accurate symmetric difference approximations to the generalized Laplace operator are constructed for curvilinear component grids. The modified equation approach is used to develop high-order accurate approximations that use only three time levels and have the same time-stepping restriction as the second-order scheme. Discrete boundary conditions for perfect electrical conductors and for material interfaces are developed and analyzed. The implementation is optimized for component grids that are Cartesian, resulting in a fast and efficient method. The solver runs on parallel machines with each component grid distributed across one or more processors. Numerical results in two and three dimensions are presented for the fourth-order accurate version of the method. These results demonstrate the accuracy and efficiency of the approach.

Key words. Maxwell's equations, overlapping grids, high-order accurate, symmetric finite difference

1. Introduction.

A numerical scheme is described for the fast and accurate solution of the time-dependent Maxwell's equations in complex geometry. Maxwell's equations are solved as a second-order vector wave equation rather than the more common approach of treating the equations as a first-order system. The governing equations are discretized to high-order accuracy in space and time on domains that are represented with composite overlapping grids. High-order accurate symmetric finite difference discretizations of the generalized Laplace operator are devised for use on curvilinear grids. High-order accurate centered approximations to boundary conditions are developed and analyzed. The three-level time-stepping scheme is based on the modified equation approach and achieves high-order accuracy through a Taylor series in time that uses the differential equations to replace time derivatives by space derivatives. The time-step restriction, as dictated by stability, is the same as that used with the second-order version of the method. The interface between materials with different electric and magnetic properties is treated using component grids that align with the interface. High-order accurate centered approximations to the interface jump conditions are developed that maintain the full accuracy of the scheme at the interface. The numerical approach presented here is particularly fast and efficient on Cartesian component grids. A typical overlapping grid for a region Ω will consist of body fitted curvilinear grids near the boundaries together with one or more background Cartesian grids covering most of the domain. For sufficiently fine grids, the majority of the grid

points will reside on the Cartesian grids. In this case, the efficiency of the scheme approaches that of a single Cartesian grid.

The time-dependent Maxwell's equations for linear, isotropic, and nondispersive materials are

$$\partial_t \mathbf{E} = \frac{1}{\epsilon}\nabla \times \mathbf{H} - \frac{1}{\epsilon}\mathbf{J}, \tag{1.1}$$

$$\partial_t \mathbf{H} = -\frac{1}{\mu}\nabla \times \mathbf{E}, \tag{1.2}$$

$$\nabla \cdot (\epsilon \mathbf{E}) = \rho, \quad \nabla \cdot (\mu \mathbf{H}) = 0. \tag{1.3}$$

Here $\mathbf{E} = \mathbf{E}(\mathbf{x}, t)$ is the electric field, $\mathbf{H} = \mathbf{H}(\mathbf{x}, t)$ is the magnetic field, $\rho = \rho(\mathbf{x}, t)$ is the electric charge density, $\mathbf{J} = \mathbf{J}(\mathbf{x}, t)$ is the electric current density, $\epsilon = \epsilon(\mathbf{x})$ is the electric permittivity, and $\mu = \mu(\mathbf{x})$ is the magnetic permeability. This first-order system for Maxwell's equations can also be written in a second-order form. By taking the time derivatives of (1.2) and (1.1) and using (1.3) it follows that

$$\epsilon\mu\ \partial_t^2 \mathbf{E} = \Delta \mathbf{E} + \nabla\Big(\nabla \ln \epsilon\ \cdot \mathbf{E}\Big) + \nabla \ln \mu \times \Big(\nabla \times \mathbf{E}\Big) - \nabla\left(\frac{1}{\epsilon}\rho\right) - \mu \partial_t \mathbf{J}, \tag{1.4}$$

$$\epsilon\mu\ \partial_t^2 \mathbf{H} = \Delta \mathbf{H} + \nabla\Big(\nabla \ln \mu\ \cdot \mathbf{H}\Big) + \nabla \ln \epsilon \times \Big(\nabla \times \mathbf{H}\Big) + \epsilon \nabla \times \left(\frac{1}{\epsilon}\mathbf{J}\right). \tag{1.5}$$

It is evident that the equations for the electric and magnetic field are decoupled with each satisfying a vector wave equation with lower-order terms. In the case of constant μ and ϵ and no charges, $\rho = \mathbf{J} = 0$, the equations simplify to the classical second-order wave equations,

$$\partial_t^2 \mathbf{E} = c^2\ \Delta \mathbf{E}, \qquad \partial_t^2 \mathbf{H} = c^2\ \Delta \mathbf{H}, \tag{1.6}$$

where $c^2 = 1/(\epsilon\mu)$. There are some advantages to solving the second-order form of the equations rather than the first-order system. One advantage is that in some cases it is necessary only to solve for one of the variables, say $\mathbf{E}$. If the other variable, $\mathbf{H}$, is required, it can be determined by integrating (1.2) as an ordinary differential equation with known $\mathbf{E}$. Alternatively, as a postprocessing step $\mathbf{H}$ can be computed from an elliptic boundary value problem formed by taking the curl of (1.1). Another advantage of the second-order form, which simplifies the implementation on an overlapping grid, is that there is no need to use a staggered grid formulation. Many schemes approximating the first-order system (1.2)–(1.3) rely on a staggered arrangement of the components of $\mathbf{E}$ and $\mathbf{H}$ such as the popular Yee scheme [44] for Cartesian grids. From a numerical point of view, there is an advantage in that the principal part of the spatial operator of the second-order system (1.4) is the Laplace operator Δ, which is a strongly elliptic operator and thus amenable to the discretization through compact difference approximations. The corresponding operator $-\nabla \times \nabla$ for the first-order system (1.1)–(1.2), on the other hand, has a large null space consisting of all functions that are a gradient of a scalar field, and requires more care in discretizing. The development of appropriate boundary conditions is sometimes cited as a disadvantage of solving the second-order form of the equations. The second-order continuous formulation requires additional boundary conditions as discussed in section 2, as well as additional numerical boundary conditions for higher-order accurate discretizations. A primary purpose of this work is to show how to define accurate centered approximations to the boundary conditions that are based upon compatibility conditions consistent with the governing equations.

There have been a variety of numerical approaches developed for solving the Maxwell's equations in the time domain, and there is extensive literature on the subject including the books by Cohen [4] and Taflove and Hagness [41]. Some references to the different approaches will now be given. One of the most popular approaches is the staggered grid scheme of Yee [44], commonly known as the finite-difference time-domain (FDTD) method. For complex geometry, a [illegible] approximation to the boundary is often used with the scheme. Improvements to the accuracy of the basic stair-step technique have been considered by, for example, Dey and Mittra [7], Ditkowski, Dridi, and Hesthaven [9], and Kreiss and Petersson [27]. The Yee scheme has been extended to curvilinear grids (see, for example, Lee, Palendech, and Mittra [30]) and to unstructured grids such as in the discrete surface-integral (DSI) scheme originally developed by Madsen [32] and extended by Gedney, Lansing, and Rascoe [13]. Finite volume methods have been applied to the solution of Maxwell's equations as discussed, for example, in Holland [24]. Jurgens and Zingg [26] used high-order finite-difference approximations on block-structured grids for the equations written as a first-order system. Schemes based on the finite element method (FEM) have been developed to solve Maxwell's equations; see, for example, Nédélec [33], Jin [25], and Rodrigue and White [37]. The spectral element method has been used by a variety of authors including Yang, Gottlieb, and Hesthaven [43]. High-order spectral penalty methods and discontinuous Galerkin-type approaches have also been successful; see, for example, Hesthaven and Warburton [23]. Use of hybrid grids, part structured and part unstructured, has become increasingly popular. Rylander and Bondeson [38], for example, presented a hybrid FEM-FDTD method that retains the symmetry of the discrete operators, even at the interface between the FEM and FDTD methods. Yee, Chen, and Chang [45] considered the solution of Maxwell equations on overlapping grids using a second-order accurate method. Driscoll and Fornberg [10, 11] developed a block pseudospectral method for Maxwell's equations on two-dimensional overlapping grids. They solved the equations as a first-order system using a high-order difference method on the Cartesian background grid and a pseudospectral method on the boundary fitted curvilinear grids.

2. Governing equations and boundary conditions. The numerical scheme is based upon the solution of the second-order form of Maxwell's equations. To begin with, the material properties $\epsilon(\mathbf{x})$ and $\mu(\mathbf{x})$ are assumed to be constant. The case of multiple materials will be treated in section 7. In three space dimensions, the initial boundary value problem for Maxwell's equations on a domain Ω is given by

$$\partial_t^2 \mathbf{E} = c^2 \, \Delta \mathbf{E}, \qquad \mathbf{x} \in \Omega, \tag{2.1}$$

$$\mathbf{n} \times \mathbf{E} = 0, \;\; \nabla \cdot \mathbf{E} = 0, \qquad \mathbf{x} \in \partial\Omega_E \quad \text{(PEC BCs)}, \tag{2.2}$$

$$\mathcal{B}_F(\mathbf{E}) = 0, \;\; \nabla \cdot \mathbf{E} = 0, \qquad \mathbf{x} \in \partial\Omega_F \quad \text{(far field BCs)}, \tag{2.3}$$

$$\mathbf{E}(\mathbf{x},0) = \mathbf{E}^{(0)}(\mathbf{x}), \quad \mathbf{E}_t(\mathbf{x},0) = \mathbf{E}_t^{(0)}(\mathbf{x}) \qquad \text{(initial conditions)}, \tag{2.4}$$

where $\mathbf{E} = (E_x, E_y, E_z)$ and $c = 1/\sqrt{\epsilon\mu}$. The outward normal to the boundary $\partial\Omega$ is $\mathbf{n}$. At a boundary, $\partial\Omega_E$, next to a perfect electrical conductor (PEC), the boundary condition (BC) is that the tangential components of the field are zero; i.e., $\mathbf{n} \times \mathbf{E} = 0$. For boundaries where the computational domain is truncated, i.e., $\partial\Omega_F$, appropriate far-field boundary conditions are applied. These are denoted by $\mathcal{B}_F(\mathbf{E}) = 0$. The initial conditions should satisfy the constraints $\nabla \cdot \mathbf{E}^{(0)} = 0$ and $\nabla \cdot \mathbf{E}_t^{(0)} = 0$. Note that the second-order formulation requires the additional boundary condition $\nabla \cdot \mathbf{E} = 0$. The fact that the Gauss law, $\nabla \cdot \mathbf{E} = 0$, holds everywhere can be seen by noting that

the divergence of the electric field, $\delta = \nabla \cdot \mathbf{E}$, satisfies a second-order wave equation, $\delta_{tt} = c^2\Delta\delta$, with zero initial conditions and zero boundary conditions, and thus δ will remain identically zero.

In two space dimensions the so-called $\mathrm{TE_Z}$ mode (transverse electric mode with respect to z) is considered. Let $\mathbf{w} = (u, v, w) = (E_x, E_y, H_z)$ denote the vector holding the x- and y-components of the electric field and the z-component of the magnetic field. In addition, let $\mathbf{u} = (u, v) = (E_x, E_y)$. The initial boundary value problem for Maxwell's equations in this case is

$$\partial_t^2 \mathbf{w} = c^2 \Delta \mathbf{w}, \qquad \mathbf{x} \in \Omega, \tag{2.5}$$

$$\mathbf{u}(\mathbf{x},0) = \mathbf{u}^{(0)}(\mathbf{x}), \quad \mathbf{u}_t(\mathbf{x},0) = \mathbf{u}_t^{(0)}(\mathbf{x}), \quad t = 0 \qquad \text{(initial conditions)}, \tag{2.6}$$

$$w(\mathbf{x},0) = w^{(0)}(\mathbf{x}), \quad w_t(\mathbf{x},0) = w_t^{(0)}(\mathbf{x}), \quad t = 0 \qquad \text{(initial conditions)}, \tag{2.7}$$

$$\mathbf{n} \times \mathbf{u} = 0, \quad \nabla \cdot \mathbf{u} = 0, \quad \partial_n w = 0, \qquad \mathbf{x} \in \partial\Omega_{\mathrm{E}} \quad \text{(PEC BCs)}, \tag{2.8}$$

$$\mathcal{B}_F(\mathbf{w}) = 0, \quad \nabla \cdot \mathbf{u} = 0, \qquad \mathbf{x} \in \partial\Omega_F \quad \text{(far field BCs)}. \tag{2.9}$$

As in three dimensions, the initial conditions should satisfy the Gauss law, $\nabla\cdot\mathbf{u}^{(0)} = 0$, $\nabla \cdot \mathbf{u}_t^{(0)} = 0$. In two dimensions it may be possible to solve for just one component, $w = H_z$, or the two components, $\mathbf{u} = (E_x, E_y)$. However, all three components will be considered here in order to develop the numerical scheme for either case.

3. Summary of the numerical scheme. Consider the second-order wave equation with a forcing function, $u_{tt} = c^2\Delta u + f$. An attractive time-stepping method to solve this second-order wave equation is the [illegible] approach based on the Taylor series

$$u(\mathbf{x}, t+\Delta t) - 2u + u(\mathbf{x}, t-\Delta t) = 2\tfrac{\Delta t^2}{2!}\partial_t^2 u + 2\tfrac{\Delta t^4}{4!}\partial_t^4 u + 2\tfrac{\Delta t^6}{6!}\partial_t^6 u + \cdots .$$

Using the wave equation to eliminate even numbers of time derivatives in terms of space derivatives gives

$$\begin{aligned} u(\mathbf{x}, t+\Delta t) - 2u + u(\mathbf{x}, t-\Delta t) = {} & 2\tfrac{\Delta t^2}{2!}\big(c^2\Delta u + f\big) \\ & + 2\tfrac{\Delta t^4}{4!}\Big\{(c^2\Delta)^2 u + c^2\Delta f + f_{tt}\Big\} + \cdots . \end{aligned} \tag{3.1}$$

This last expansion can be used to derive an approximation of any order that uses only three time levels. Letting $U_{\mathbf{i}}^n \approx u(\mathbf{x}_{\mathbf{i}}, t^n)$ denote a discrete approximation to u at the grid point $\mathbf{x}_{\mathbf{i}}$ and time $t^n = n\Delta t$, a fourth-order accurate approximation is

$$U_{\mathbf{i}}^{n+1} - 2U_{\mathbf{i}}^n + U_{\mathbf{i}}^{n-1} = \Delta t^2\big(c^2\Delta_{4h}U_{\mathbf{i}}^n + f\big) + \tfrac{\Delta t^4}{12}\big(c^4(\Delta^2)_{2h}U_{\mathbf{i}}^n + c^2\Delta_{2h}f + f_{tt}\big), \tag{3.2}$$

where Δ_{mh} denotes some mth-order approximation to the Laplace operator Δ and $(\Delta^2)_{mh}$ denotes an mth-order approximation to the square of the Laplace operator. The precise form of these approximations will be given in section 5. Using a second-order approximation for Δ^2 prevents the discrete stencil from becoming wider than that of the fourth-order approximation for Δ, while retaining the order of accuracy. Higher-order approximations follow easily. The modified equation time-stepping approach is related to the Numerov and Stoermer methods for ODEs [29], and for the second-order wave equation it has been considered by numerous authors, including Dablain [6] and Shubin and Bell [39]. Anné, Joly, and Tran [1] showed that in one

space dimension the time-step restriction required for stability is independent of the order of accuracy. Gustafsson and Mossberg [15] used a similar approach for treating the equations written as a first-order system.

The time-stepping scheme is not restricted to the modified equation approach. The spatial discretization and boundary conditions can be employed in a method-of-lines approach and used with any number of time-stepping schemes for the second-order ODE $u_{tt} = F(u,t)$. High-order Stoermer approximations [29] have been implemented and used with success. Although these schemes require a smaller time step as the order of accuracy increases, the approach may be attractive to simplify the implementation details for the case of when $\epsilon(\mathbf{x})$ and $\mu(\mathbf{x})$ vary in space.

High-order accurate finite difference approximations that use wide stencils require special treatment at boundaries. One common approach for treating approximations near boundaries is to use one-sided difference approximations. Another approach, the one primarily taken here, is to use high-order accurate centered approximations to boundary conditions that use compatibility conditions derived from the continuous formulation [20, 14]. In particular, appropriate compatibility conditions for a PEC boundary are now given. The essential boundary conditions for a PEC are given by (2.2). By taking $2m$-time derivatives of these boundary conditions and using (2.1) it follows that

$$\mathbf{n} \times (\Delta^m \mathbf{E})(\mathbf{x},t) = 0, \qquad \nabla \cdot (\Delta^m \mathbf{E})(\mathbf{x},t) = 0, \qquad \mathbf{x} \in \partial\Omega_E, \tag{3.3}$$

for $m = 0, 1, 2, \ldots$. In the two-dimensional case, taking $2m$-time derivatives of the Neumann boundary condition for H_z leads to the compatibility conditions

$$\partial_n \Delta^m H_z(\mathbf{x},t) = 0, \qquad \mathbf{x} \in \partial\Omega_E, \tag{3.4}$$

for $m = 0, 1, 2, \ldots$. Discrete approximations to the compatibility conditions (3.3)–(3.4) can be used as numerical boundary conditions. In general, the use of centered boundary conditions such as those based on these compatibility conditions will be more stable and more accurate than boundary conditions based on one-sided differences.

In summary, the proposed scheme for Maxwell's equations uses the modified equation time-stepping approximation based on (3.1), such as (3.2) for a fourth-order scheme, together with discrete approximations to the boundary conditions (2.2) and compatibility conditions (3.3) or (3.4). These equations are discretized on an overlapping grid. Symmetric difference approximations to the equations are developed in section 5. The solution values at the overlapping grid interpolation points are obtained using high-order accurate interpolation as described in section 4. On a Cartesian grid the basic scheme is neutrally stable and nondissipative. From an analysis of similar problems [35], it can be expected that such a scheme may develop some weak instabilities near boundaries of curvilinear grids and near interpolation points of the overlapping grid. These instabilities are easily dealt with, however, by the addition of a high-order spatial dissipation. This dissipation does not change the accuracy of the scheme and can be added locally in regions near boundaries and interpolation points. Computational results show that this dissipation generally has a negligible effect on the overall accuracy of the solution, even for long times.

4. Overlapping grids. The governing equations for Maxwell's equations are discretized on an overlapping grid $\mathcal{G}$ (see Figures 7 and 10). The overlapping grid consists of a set of component grids, $\mathcal{G} = \{G_g\}$. The component grids overlap and

cover the domain Ω. Typically, body fitted curvilinear grids are used near the boundaries, while one or more background Cartesian grids are used in the remainder of the domain. Each component grid G_g is a logically rectangular, curvilinear grid in d space dimensions defined by a smooth mapping $\mathbf{x} = \mathbf{G}_g(\mathbf{r})$, from parameter space $\mathbf{r} \in [0,1]^d$ (the unit-square or unit-cube) to physical space $\mathbf{x} \in \mathbb{R}^d$. This mapping is used to define the location of grid points at any desired resolution. Derivatives of the mapping, $\partial\mathbf{x}/\partial\mathbf{r}$, will appear as coefficients in the discrete approximations, as shown in section 5. Thus, for high-order approximations it is important that the mapping $\mathbf{G}_g(\mathbf{r})$ be sufficiently smooth to avoid numerical artifacts such as spurious reflections. Points on a grid are classified as discretization points (where the PDE or boundary conditions are discretized), unused points, and interpolation points (where the solution is interpolated from a different grid). The values of the solution at interpolation points are determined by a tensor-product Lagrange interpolant, using w points in each direction. For a pth-order approximation to the second-order wave equation, $p = 2, 4, \ldots$, the width of the interpolation stencil is taken as $\mathrm{w} = p + 1$, following the analysis in [3]. Let $N_m^{(g)}$ grid denote the number of grid cells on grid G_g in each coordinate direction, $m = 1, 2, \ldots, d$. Let $\mathbf{i} = (i_1, i_2, i_3)$ denote a multi-index, and let $\mathbf{x}_\mathbf{i} = \mathbf{G}(\mathbf{r}_\mathbf{i})$ denote the grid point corresponding to the unit-square coordinate $\mathbf{r}_\mathbf{i} = (i_1\Delta r_1, i_2\Delta r_2, i_3\Delta r_3)$, where $i_m = 0, 1, \ldots, N_m$ and $\Delta r_m = 1/N_m$. Ghost points will correspond to $i_m = -1, -2, \ldots$ and $i_m = N_m + 1, N_m + 2, \ldots$. For more details on the discretization of problems on overlapping grids, see [3, 21, 22].

Introduce a time step Δt, and let $U_\mathbf{i}^n$ denote a grid function at time $t^n = n\Delta t$, representing an approximation to $E_x(\mathbf{x}_\mathbf{i}, t^n)$, for example. Introduce the standard forward, backward, and centered divided difference operators in the r_1 direction by

$$D_{+r_1}U_\mathbf{i} = (U_{i_1+1,i_2,i_3} - U_\mathbf{i})/(\Delta r_1), \quad D_{-r_1}U_\mathbf{i} = (U_\mathbf{i} - U_{i_1-1,i_2,i_3})/(\Delta r_1),$$
$$D_{0r_1}U_\mathbf{i} = (U_{i_1+1,i_2,i_3} - U_{i_1-1,i_2,i_3})/(2\Delta r_1).$$

Similar definitions hold for difference operators in the other coordinate directions, D_{+r_m}, D_{-r_m}, and D_{0r_m} for $m = 2, 3$. On a Cartesian grid, the grid spacings will be denoted by Δx, Δy, and Δz with corresponding difference operators D_{+x}, D_{+y}, D_{+z}, etc. The difference operators in time are D_{+t}, D_{-t}, and D_{0t}, where, for example, $D_{+t}U_\mathbf{i}^n = (U_\mathbf{i}^{n+1} - U_\mathbf{i}^n)/\Delta t$.

5. High-order accurate symmetric difference approximations on curvilinear grids. In some applications, such as long time integrations, it can be advantageous to use methods that are both high-order accurate and have low dissipation. To achieve these goals it will be helpful to use symmetric difference approximations to the discrete operators that are used in the solution of Maxwell's equations. Standard finite-difference approximations to the Laplace operator on curvilinear grids will not in general be symmetric. This section develops high-order accurate symmetric difference approximations for general logically rectangular curvilinear grids.

To understand the relationship between symmetric approximations and low dissipation schemes, consider the solution of the second-order wave equation,

$$w_{tt} = \nabla \cdot (c^2 \nabla w), \tag{5.1}$$

for the function $w = w(\mathbf{x}, t)$ on a periodic domain $\Omega = [0, 2\pi]^d$. Let $(u, v) = \int_\Omega u^* v \, d\mathbf{x}$ and $\|u\| = (u, u)^{1/2}$ denote the usual L_2 inner product and norm on this domain. The wave equation (5.1) has no dissipation, and there is an "energy" that remains

constant over time. This energy can be determined by multiplying the equation by w_t, integrating over the domain, and using integration by parts, giving

$$\tfrac{1}{2}\partial_t \left\{ \|w_t\|^2 + \|c\nabla w\|^2 \right\} = 0.$$

The "energy" $\mathcal{E} = \|w_t\|^2 + \|c\nabla w\|^2$ is thus constant on a periodic domain. Discrete approximations to the wave equation (5.1) will not in general have a discrete energy that remains constant. For stability reasons many approximations will have some dissipation built into the spatial approximation or into the time-stepping method. There is, however, a class of stable methods with no dissipation. Consider, for example, the second-order accurate centered approximation

$$D_{+t}D_{-t}W^n_{\mathbf{i}} = c^2(D_{+,x}D_{-,x} + D_{+,y}D_{-,y})W^n_{\mathbf{i}} \tag{5.2}$$

for use on a Cartesian grid, where $W^n_{\mathbf{i}} \approx w(\mathbf{x}_i, t^n)$. Let $(U,V)_h = \sum_{\mathbf{i}} U^*_{\mathbf{i}} V_{\mathbf{i}}\, \Delta x_1 \Delta x_2$ and $\|U\|_h = (U,U)_h^{1/2}$ denote the discrete L_2 inner product and norm on the Cartesian grid where the sum is over the grid points $i_m = 0, 1, \ldots, N_m - 1$. Equation (5.2) has a discrete "energy"

$$\mathcal{E}_h = \|D_{-t}W^n\|_h^2 + c^2(D_{-x}W^n, D_{-x}W^{n-1})_h + c^2(D_{-y}W^n, D_{-y}W^{n-1})_h$$

that is conserved, as will be shown below. Equation (5.2) is a special case of the more general discrete approximation

$$D_{+t}D_{-t}W^n = AW^n, \qquad n = 2, 3, 4, \ldots, \tag{5.3}$$

$$W^0 = W^{(0)}, \quad W^1 = W^{(1)} \quad \text{(initial conditions)}, \tag{5.4}$$

where $W^n \in \mathbb{R}^N$ is the vector of all N grid point values $W^n_{\mathbf{i}}$, and $A \in \mathbb{R}^{N\times N}$ is the matrix representing the spatial discretization (including eliminated boundary conditions). The three-level time-stepping schemes used in this paper are of this form (although for solutions on general overlapping grids a high-order dissipation is also added; see section 9.2). The following lemma indicates the conditions on A so that all solutions to (5.3) remain uniformly bounded in time.

LEMMA 5.1. [illegible] (5.3)–(5.4) [illegible] n [illegible] A [illegible] λ [illegible] A [illegible] Δt [illegible] $-4 < \lambda\Delta t^2 < 0$ [illegible] λ [illegible]. Suppose that $\widehat{V}$ is an eigenvector of A corresponding to the eigenvalue λ. Looking for a solution of the form $V^n = \kappa^n \widehat{V}$ implies that κ satisfies the characteristic equation $\kappa - 2 + \kappa^{-1} = \lambda\Delta t^2$ with

$$\kappa = 1 + \tfrac{1}{2}\lambda\Delta t^2 \pm \sqrt{(1 + \tfrac{1}{2}\lambda\Delta t^2)^2 - 1}. \tag{5.5}$$

When $\lambda = 0$ ($\kappa = 1$) or $\lambda\Delta t^2 = -4$ ($\kappa = -1$) there is a double root and the solutions can grow linearly in time, with $V^n = (c_0 + c_1(n\Delta t))\widehat{V}$ for $\lambda = 0$, and $V^n = (-1)^n\ (c_0 + c_1(n\Delta t))\widehat{V}$ for $\lambda\Delta t^2 = -4$. Therefore in these two cases the solutions will not be uniformly bounded for general initial conditions. A root, κ, of the characteristic equation will be a simple root and satisfy $|\kappa| = 1$ if and only if λ is real and $-4 < \lambda\Delta t^2 < 0$. In this case the solution will be of the form $V^n = (c_0\kappa^n + c_1\kappa^{-n})\widehat{V}$ and will remain uniformly bounded. If λ is not real or $\lambda > 0$ or $\lambda\Delta t^2 < -4$, there will be one root with $|\kappa| > 1$ and the approximation (5.3)

is not uniformly bounded. If all λ satisfy $-4 < \lambda\Delta t^2 < 0$ and there is a complete set of eigenvectors, then the general solution can be represented as a linear combination of the eigenvectors and this solution will remain uniformly bounded. If there is not a complete set of eigenvectors, then the Jordan normal form of A has a Jordan block of size larger than 1. In this case there are solutions of the form $V^n = (n\Delta t)\kappa^n$, and hence the solutions do not remain bounded in this case. □

The conditions of Lemma 5.1 will be satisfied when A is symmetric and the eigenvalues of A are less than zero. In this case a discrete energy estimate can be obtained as follows: Taking the inner product of $W^{n+1} - W^{n-1}$ with (5.3) and rearranging terms gives

$$\tfrac{1}{\Delta t^2}|W^{n+1} - W^n|^2 - \langle W^{n+1}, AW^n\rangle = \tfrac{1}{\Delta t^2}|W^n - W^{n-1}|^2 - \langle W^n, AW^{n-1}\rangle.$$

Here $\langle W, V\rangle = \sum_{i=1}^N W_i^* V_i$ and $|W| = \langle W, W\rangle^{\frac{1}{2}}$. It follows that the quantity

$$\mathcal{E}_h^n = \tfrac{1}{\Delta t^2}|W^n - W^{n-1}|^2 - \langle W^n, AW^{n-1}\rangle \tag{5.6}$$

$$= \tfrac{1}{\Delta t^2}\left\langle D_{+t}W^{n-1}, \left(I + \tfrac{\Delta t^2}{4}A\right)D_{+t}W^{n-1}\right\rangle - \langle W^{n-\frac{1}{2}}, AW^{n-\frac{1}{2}}\rangle \tag{5.7}$$

remains constant for all time, where $W^{n-\frac{1}{2}} := (W^n + W^{n-1})/2$. Note that two different time levels of the solution appear in the last term of (5.6). However, it can be seen from the alternative form (5.7) that $\mathcal{E}_h^n$ is positive provided Δt satisfies $-4 < \lambda\Delta t^2 < 0$ for all eigenvalues of A (see Kreiss, Petersson, and Ysström [28] or Cohen [4] for further details).

The above results provide a motivation for developing symmetric difference approximations for discretizations of Maxwell's equations. To this end, consider the generalized Laplace operator, L, defined by

$$Lw = \nabla \cdot (k\nabla w). \tag{5.8}$$

A straightforward approach to discretizing L on a curvilinear grid is to use the mapping method, as follows. Using the chain rule, the operator L can be written in general curvilinear coordinates (with summation convention) as

$$Lw = k(\mathbf{r})\frac{\partial r_n}{\partial x_i}\frac{\partial r_m}{\partial x_i}\frac{\partial^2 w}{\partial r_m \partial r_n} + \frac{\partial r_n}{\partial x_i}\left\{k(\mathbf{r})\frac{\partial}{\partial r_n}\left(\frac{\partial r_m}{\partial x_i}\right) + \frac{\partial k}{\partial r_n}\frac{\partial r_m}{\partial x_i}\right\}\frac{\partial w}{\partial r_m}. \tag{5.9}$$

The metric terms $\partial r_m/\partial x_n$ are computed from the mapping that defines the grid and are thus assumed to be known. The derivatives with respect to the parameter space coordinates r_m can be approximated with central difference approximations. Standard finite difference approximations, FDm, of order m for $m = 2, 4, 6, \ldots$, can be defined in this way. The resulting approximations will not, however, be symmetric on general curvilinear grids. High-order accurate symmetric approximations on rectangular grids and unstructured grids have been developed for this type of operator by various authors; see, for example, [4, 16]. The remainder of this section will show how to construct high-order accurate symmetric approximations to L for arbitrary curvilinear grids.

The operator L can be written in [illegible] form, or [illegible] form, in general curvilinear coordinates as

$$Lw = \tfrac{1}{J}\sum_{m=1}^{d}\sum_{n=1}^{d}\tfrac{\partial}{\partial r_m}\left(A^{mn}\tfrac{\partial w}{\partial r_n}\right), \quad A^{mn} = kJ\sum_{\mu=1}^{d}\tfrac{\partial r_m}{\partial x_\mu}\tfrac{\partial r_n}{\partial x_\mu}, \tag{5.10}$$

where J denotes the determinant of the Jacobian matrix $[\partial x_i/\partial r_j]$. To improve readability in the subsequent discussion, let $(r,s)=(r_1,r_2)$ and $(h_r,h_s)=(\Delta r_1,\Delta r_2)$. The discrete inner product on a curvilinear grid is defined as

$$(U_{\mathbf{i}},V_{\mathbf{i}})_h=\sum_{\mathbf{i}} U^*_{\mathbf{i}}V_{\mathbf{i}}\ J_{\mathbf{i}}\ h_rh_s. \tag{5.11}$$

Consider approximations to the two operators, $\mathcal{L}_{rr}=J^{-1}\partial_r(a\partial_r)$ and $\mathcal{L}_{rs}=J^{-1}\partial_r(b\partial_s)$, that are representative of the terms appearing in the expression (5.10) for L. The operator $\mathcal{L}_{rr}$ will be approximated in the discrete form $\mathcal{L}_{rr}w=J^{-1}\partial_r(a\partial_r w)\approx J^{-1}\mathcal{D}_+(a_{i-\frac12}\mathcal{D}_-)w(\mathbf{r_i})$, where $\mathcal{D}_+\approx\partial_r w(r+h_r/2)$ and $\mathcal{D}_-\approx\partial_r w(r-h_r/2)$ are some appropriately defined high-order accurate approximations to the derivatives at locations midway between grid points and $a_{i-\frac12}\approx a(r-h_r/2)$. If the adjoint of $J^{-1}\mathcal{D}_+$ with respect to (5.11) is $-J^{-1}\mathcal{D}_-$, then a symmetric approximation will result since

$$(v,J^{-1}\mathcal{D}_+(a_{i-\frac12}\mathcal{D}_-)w)_h=-(J^{-1}\mathcal{D}_-,a_{i-\frac12}\mathcal{D}_-w)_h=(J^{-1}\mathcal{D}_+(a_{i-\frac12}\mathcal{D}_-)v,w)_h.$$

To simplify notation let $D_+=D_{+,r}$ and $D_-=D_{-,r}$. An order $2m+2$ approximation for $\mathcal{D}_+$ is obtained from the expansion

$$\tfrac{\partial w}{\partial r}(r+h_r/2)=D_+\left[1+\sum_{n=1}^{m}\alpha_n h_r^{2n}(D_+D_-)^n\right]w(r+h_r/2)+\mathcal{O}(h_r^{2m+2}),$$

where the coefficients α_i can be determined from equating coefficients in the expression $y=\sin(y)\left[1+\sum_{n=1}^{\infty}\alpha_n(-4\sin^2(y))^n\right]$ (see, for example, [12] or [14]). The first four values of α_i are given by $\alpha_1=-\frac16$, $\alpha_2=\frac{3}{640}$, $\alpha_3=-\frac{5}{7168}$, and $\alpha_4=\frac{35}{294912}$. Assuming that the coefficient $a(r)$ is given at the grid points, a_i, approximations to $a_{i-1/2}$ will be needed. These approximations can be obtained by interpolation in a straightforward fashion and, to orders $m=2$ and $m=4$, are given by

$$a^{(2)}_{i-1/2}=\tfrac12(a_i+a_{i-1}),\quad a^{(4)}_{i-1/2}=\tfrac{9}{16}(a_i+a_{i-1})-\tfrac{1}{16}(a_{i+1}+a_{i-2}),$$

where $a^{(m)}_{i-1/2}=a_{i-1/2}+O(h_r^m)$. Note that other forms of interpolation may be appropriate when the coefficient k is discontinuous. Define $\mathcal{D}_+$ and $\mathcal{D}_-$ as

$$\mathcal{D}_\pm=D_\pm\left[1+\sum_{n=1}^{\infty}\alpha_n h_r^{2n}(D_+D_-)^n\right].$$

Expanding the expression $\mathcal{D}_+(a\mathcal{D}_-)$ in powers of h_r^2 leads to

$$\begin{aligned}\tfrac{\partial}{\partial r}\left(a\tfrac{\partial}{\partial r}\right)&=D_+(a^{(m)}_{i-1/2}D_-)-\tfrac{h_r^2}{24}\left[D_+(a^{(m-2)}_{i-1/2}D_+D_-^2)+D_+^2D_-(a^{(m-2)}_{i-1/2}D_-)\right]\\&+\tfrac{h_r^4}{24^2}\left[D_+^2D_-(a^{(m-4)}_{i-1/2}D_+D_-^2)\right]+\tfrac{3h_r^4}{640}\left[D_+(a^{(m-4)}_{i-1/2}D_+^2D_-^3)+D_+^3D_-^2(a^{(m-4)}_{i-1/2}D_-)\right]\\&-\tfrac{5h_r^6}{7168}\left[D_+^4D_-^3(a^{(m-6)}_{i-1/2}D_-)+D_+(a^{(m-6)}_{i-1/2}D_+^3D_-^4)\right]\\&-\tfrac{3h_r^6}{640\cdot24}\left[D_+^2D_-(a^{(m-6)}_{i-1/2}D_+^2D_-^3)+D_+^3D_-^2(a^{(m-6)}_{i-1/2}D_+D_-^2)\right]+O(h_r^8).\end{aligned} \tag{5.12}$$

Note that different orders of approximation for $a_{i-1/2}$ are used, so that the difference stencil for an mth-order formulation is no larger than $m+1$ points wide in each direction. Equation (5.12) can be used to generate symmetric approximations of

order m by involving terms up to and including those of order h_r^m. For example, a fourth-order symmetric approximation to $J^{-1}\partial_r(a\partial_r)$ is

$$\mathcal{L}_{rr}^{(4)}[a]w := J_{\mathbf{i}}^{-1}\Big\{D_+(a_{i-1/2}^{(4)}D_-) - \tfrac{h_r^2}{24}\big[D_+(a_{i-1/2}^{(2)}D_+D_-^2) + D_+^2D_-(a_{i-1/2}^{(2)}D_-)\big]\Big\}w.$$

It is easy to show that the approximation $\mathcal{L}_{rr}^{(4)}[a]$ is symmetric since the adjoint of $J^{-1}D_+$ is $-J^{-1}D_-$ with respect to the discrete inner product (5.11).

The operator $\mathcal{L}_{rs} = J^{-1}\partial_r(b\partial_s)$ for the mixed derivative terms is approximated using

(5.13)
$$\mathcal{L}_{rs} \approx J^{-1}D_{0r}\left[1 + \sum_{n=1}^{\infty}\beta_n h_r^{2n}(D_{+r}D_{-r})^n\right]\left\{bD_{0s}\left[1 + \sum_{n=1}^{\infty}\beta_n h_s^{2n}(D_{+s}D_{-s})^n\right]\right\},$$

where $D_{+r} = D_{+,r_1}$, $D_{+s} = D_{+,r_2}$, etc. and where $b = b_{\mathbf{i}}$ denotes the value of b at a grid point. In this case the values of b that appear are located at the grid points and no interpolation is needed. From the expansion of (5.13), a fourth-order approximation to $J^{-1}\partial_r(b\partial_s)$ is

$$\mathcal{L}_{rs}^{(4)}[b]w := J_{\mathbf{i}}^{-1}\Big\{D_{0r}(bD_{0s}) - \tfrac{1}{6}\big[h_s^2D_{0r}(bD_{+s}D_{-s}D_{0s}) + h_r^2D_{0r}D_{+r}D_{-r}(bD_{0s})\big]\Big\}w.$$

This operator is not symmetric, but the combination $\mathcal{L}_{rs}^{(4)}[b]+\mathcal{L}_{sr}^{(4)}[b]$ will be symmetric. A fourth-order symmetric approximation to $L = \nabla\cdot(k\nabla)$ denoted by $\mathcal{L}^{(4)}$ is thus

$$\mathcal{L}^{(4)} = \sum_{m=1}^{d}\sum_{n=1}^{d}\mathcal{L}_{r_mr_n}^{(4)}[A^{mn}],$$

where the coefficients A^{mn} are defined by (5.10). The symmetric approximation can be easily generalized to the case where $k(\mathbf{x})$ is replaced by a symmetric tensor; this only changes the definition of A^{mn}.

The symmetric approximations have been implemented in two and three space dimensions for orders $m = 2$, 4, 6, and 8. Figure 1 compares the accuracy of the symmetric difference operators of order m, denoted by SDm, to those of the standard finite-difference operators of order m, denoted by FDm. The maximum-norm errors in computing the Laplacian of a trigonometric function on a smooth nonorthogonal grid are presented in the figure for a sequence of grids of increasing resolution. The estimated convergence rate for each approximation is also indicated. These estimated rates are computed from a least squares fit to the log of the error versus the log of the grid spacing. The results show that the symmetric schemes, SDm, have similar errors to the finite-difference schemes, FDm. The convergence rates are reasonably close to the expected values. Note that the numerical values of the computed rates are sensitive to small changes in the data.

To illustrate that the discrete operators SDm are indeed symmetric on arbitrary logically rectangular grids, a computation was performed on the grid shown in Figure 2. The grid for the unit square, with periodic boundary conditions, is obtained by randomly perturbing the grid points of a Cartesian grid. The grid points are defined as $\mathbf{x}_{\mathbf{i}} = ((i_1+\mathcal{R}^{(x)}/4)\Delta x, (i_2+\mathcal{R}^{(y)}/4)\Delta y)$, where $\mathcal{R}^{(x)}$ and $\mathcal{R}^{(y)}$ are pseudorandom numbers uniformly distributed in $[-1, 1]$. Figure 2 shows the results from computations solving Maxwell's equations with $c = 1$ on a two-dimensional perturbed

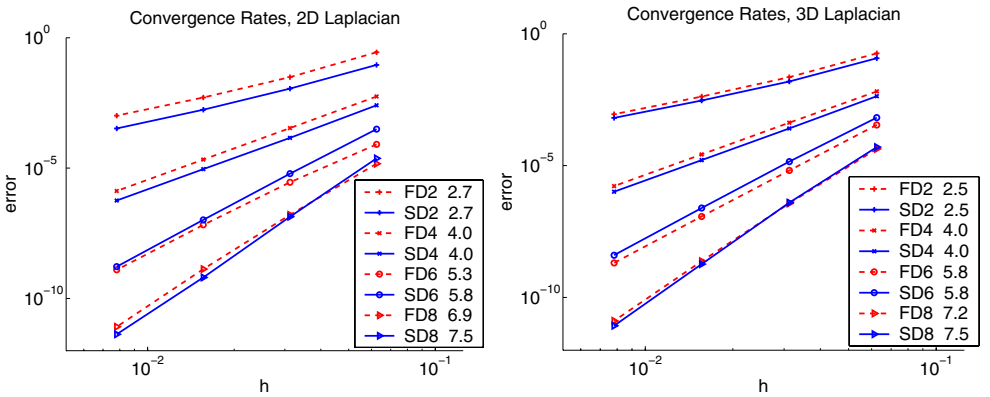

FIG. 1. *Convergence rates for the maximum-norm errors in computing the Laplacian on a smooth nonorthogonal grid. FDm denotes the standard finite-difference approximations of order m, while SDm denotes the symmetric difference approximations of order m. The estimated convergence rate for each approximation is indicated in the legend.*

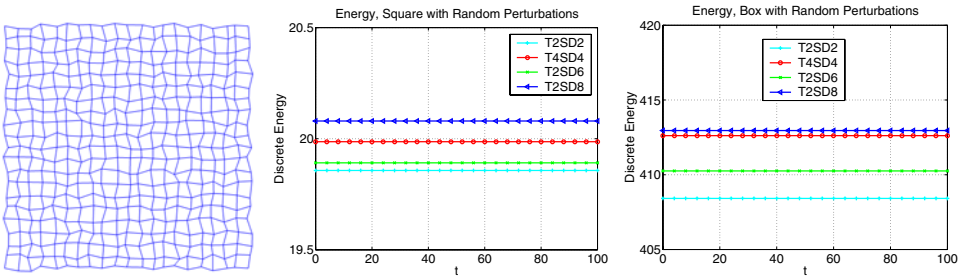

FIG. 2. *The computation of Maxwell's equations on a randomly perturbed Cartesian grid using the symmetric approximations. The discrete energy remains almost constant (to a relative error of about 10^{-10} in double precision) using the symmetric difference approximations, even on a non-smooth, nonorthogonal grid. Results for a perturbed grid for a square and a perturbed grid for a box are shown for the various schemes TmSDn of order of accuracy n in time and m in space.*

square. The discrete energy (5.6) for the component E_x (other components are similar) is plotted for different schemes for $t \in [0, 100]$. Let the symmetric time-stepping schemes be denoted by TnSDm, where n is the order of accuracy in time and m is the order of accuracy in space. Figure 2 presents results for the methods T2SD2, T4SD4, T2SD6, and T2SD8. The scheme T4SD4 is given by (3.2). The schemes T2SDm use second-order accurate time stepping with an mth order accurate approximation to the Laplacian, $U_{\mathbf{i}}^{n+1} - 2U_{\mathbf{i}}^{n} + U_{\mathbf{i}}^{n-1} = \Delta t^2 c^2 \Delta_{mh} U_{\mathbf{i}}^{n}$. The discrete energy is essentially constant over the computation (to within a relative error of about 10^{-10} in 64 bit double precision) for all schemes that use the symmetric operators. By comparison, schemes using the standard finite-difference approximations, denoted by TmFDn, are not energy preserving. These schemes are not stable for this grid without the addition of some dissipation. Figure 2 also shows the corresponding results for a perturbed three-dimensional box.

6. Analysis of the scheme. In this section the stability of the fourth-order accurate time-stepping scheme and boundary conditions is analyzed for a model problem. The analysis considers the solution to Maxwell's equations on the unit

square, $\Omega = [0,1]^2$, with PEC boundary conditions at $x = 0$ and $x = 1$ and periodic boundary conditions in y. A Cartesian grid is introduced with mesh points $\mathbf{x_i} = (x_i, y_j) = (i\Delta x, j\Delta y)$, where $\mathbf{i} = (i,j)$ and $i = -2, 1, 0, 1, 2, \ldots, N_1, N_1+1, N_1+2$ with $\Delta x = 1/N_1$, and $j = 0, 1, 2, \ldots, N_2 - 1$ with $\Delta y = 1/N_2$. Two lines of ghost points have been introduced outside the boundaries at $x = 0$ and $x = 1$. Discrete approximations to $E_x(\mathbf{x_i}, t^n)$ and $E_y(\mathbf{x_i}, t^n)$ are given by U_{ij}^n and V_{ij}^n, respectively, with $\mathbf{U_i^n} = (U_{\mathbf{i}}^n, V_{\mathbf{i}}^n)$. For this two-dimensional example the discretization for the magnetic field will not be presented since it is the same as the discretization for E_x. The interior equations (2.5) are discretized in a fourth-order manner using the modified equation approximation (3.2)

$$\mathbf{U_i^{n+1}} - 2\mathbf{U_i^n} + \mathbf{U_i^{n-1}} = (c\Delta t)^2 \Delta_{4h} \mathbf{U_i^n} + \tfrac{(c\Delta t)^4}{12} \Delta_{2h}^2 \mathbf{U_i^n} \quad \text{for} \quad i = 0, 1, \ldots, N_1, \quad j = 0, 1, \ldots, N_2 - 1. \tag{6.1}$$

Here Δ_{4h} is a fourth-order approximation to Δ, and Δ_{2h}^2 is a second-order approximation to Δ^2 given by

$$\Delta_{4h} \equiv D_{+x}D_{-x}\big(1 - \tfrac{\Delta x^2}{12} D_{+x}D_{-x}\big) + D_{+y}D_{-y}\big(1 - \tfrac{\Delta y^2}{12} D_{+y}D_{-y}\big),$$
$$\Delta_{2h}^2 \equiv \big(D_{+x}D_{-x} + D_{+y}D_{-y}\big)^2.$$

The divided difference operators D_{+x}, D_{-x}, D_{0x}, etc. were defined in section 4. The boundary conditions at $x = 0$ ($i = 0$) and $x = 1$ ($i = N_1$) are discretized as

$$V_{\mathbf{i}}^n = 0 \qquad \text{for } i = 0, N_1, \tag{6.2}$$

$$D_{0x}\big(1 - \tfrac{\Delta x^2}{6} D_{+x}D_{-x}\big) U_{\mathbf{i}}^n = 0 \qquad \text{for } i = 0, N_1, \tag{6.3}$$

$$D_{+x}D_{-x}\big(1 - \tfrac{\Delta x^2}{12} D_{+x}D_{-x}\big) V_{\mathbf{i}}^n = 0 \qquad \text{for } i = 0, N_1, \tag{6.4}$$

$$D_{0x}D_{+x}D_{-x} U_{\mathbf{i}}^n = 0 \qquad \text{for } i = 0, N_1, \tag{6.5}$$

$$\big(D_{+x}D_{-x}\big)^2 V_{\mathbf{i}}^n = 0 \qquad \text{for } i = 0, N_1, \tag{6.6}$$

where three additional [illegible] have been introduced. The boundary conditions (6.2)–(6.6) are, respectively, approximations to $E_y = 0$, fourth-order approximations to $\nabla \cdot \mathbf{E} = 0$, $\Delta E_y = 0$, and second-order approximations to $\nabla \cdot \Delta \mathbf{E} = 0$ and $\Delta^2 E_y = 0$. The latter three equations arise from the compatibility conditions (3.3). The scheme is completed by specifying initial values for two time levels, for example,

$$\mathbf{U_{ij}^0} = \mathbf{E}^{(0)}(\mathbf{x}_{ij}), \tag{6.7}$$

$$\mathbf{U_{ij}^1} = \mathbf{E}^{(0)}(\mathbf{x}_{ij}) + \Delta t \mathbf{E}_t^{(0)}(\mathbf{x}_{ij}) + \tfrac{\Delta t^2}{2} \Delta_{2h} \mathbf{E}^{(0)}(\mathbf{x}_{ij}) + \tfrac{\Delta t^3}{3!} \Delta_{2h} \mathbf{E}_t^{(0)}(\mathbf{x}_{ij}). \tag{6.8}$$

LEMMA 6.1. [illegible] (6.1) [illegible] (6.2)–(6.6) [illegible]

$$\Delta t < c^{-1} \left(\Delta x^{-2} + \Delta y^{-2}\right)^{-1/2}. \tag{6.9}$$

[illegible]. Making the ansatz $\widetilde{U}_{\mathbf{i}}^n = \kappa^n \cos(\alpha\pi x_i) e^{i2\pi\beta y_j}$ and $\widetilde{V}_{\mathbf{i}}^n = \kappa^n \sin(\alpha\pi x_i) e^{i2\pi\beta y_j}$, it follows that $\widetilde{U}_{\mathbf{i}}^n$ and $\widetilde{V}_{\mathbf{i}}^n$ satisfy (6.1) and boundary conditions (6.2)–(6.6) provided that κ satisfies the characteristic equation

$$\kappa - 2 + \kappa^{-1} = -4G, \tag{6.10}$$

where $\xi_x = \pi\alpha\Delta x$, $\xi_y = 2\pi\beta\Delta y$, $\sigma_x = \sin^2(\xi_x/2)$, $\sigma_y = \sin^2(\xi_y/2)$, $\lambda_x = c\frac{\Delta t}{\Delta x}$, $\lambda_y = c\frac{\Delta t}{\Delta y}$, and

$$G = \lambda_x^2\sigma_x[1+\tfrac{1}{3}\sigma_x] + \lambda_y^2\sigma_y[1+\tfrac{1}{3}\sigma_y] - \tfrac{1}{3}[\lambda_x^2\sigma_x + \lambda_y^2\sigma_y]^2,$$
$$\alpha = 0,1,2,\ldots,N_1, \quad \beta = 0,1,2,\ldots,N_2-1.$$

The two roots of the characteristic equation (6.10) are $\kappa_\pm = (1-2G)\pm\sqrt{(1-2G)^2-1}$, where $\kappa_+ = \kappa_-^{-1}$. The roots will satisfy $|\kappa_\pm| = 1$, and the solutions will remain uniformly bounded provided that $0 < G < 1$ (following the argument in the proof of Lemma 5.1). Letting $\gamma = \lambda_x^2\sigma_x + \lambda_y^2\sigma_y$, it follows that G can be written in the form

$$\begin{aligned} G &= \gamma - \tfrac{1}{3}\gamma^2 + \tfrac{1}{3}(\lambda_x^2\sigma_x^2 + \lambda_y^2\sigma_y^2) \\ &\le \gamma - \tfrac{1}{3}\gamma^2 + \tfrac{1}{3}(\lambda_x^2\sigma_x + \lambda_y^2\sigma_y) = \gamma + \tfrac{1}{3}\gamma(1-\gamma). \end{aligned}$$

The function G is always positive for $0 < \gamma < 1$. The function $\widetilde{G}(\gamma) = \gamma + \frac{1}{3}\gamma(1-\gamma)$ is less than 1 for $0 < \gamma \le 1$, and thus $0 < G < 1$ provided that $\gamma < 1$. Therefore the condition that $\widetilde{U}_{\mathbf{i}}^n$ and $\widetilde{V}_{\mathbf{i}}^n$ remain uniformly bounded is

$$\lambda_x^2\sigma_x + \lambda_y^2\sigma_y \le \lambda_x^2 + \lambda_y^2 < 1. \tag{6.11}$$

Let $\kappa_{\alpha,\beta}$ and $G_{\alpha,\beta}$ denote the values of κ_+ and G as functions of α and β. The general solution can be written as

$$U_{\mathbf{i}}^n = \sum_\alpha\sum_\beta (A_{\alpha,\beta}\kappa_{\alpha,\beta}^n + B_{\alpha,\beta}\kappa_{\alpha,\beta}^{-n})\cos(\alpha\pi x_{\mathbf{i}})e^{i2\beta\pi y_{\mathbf{i}}},$$
$$V_{\mathbf{i}}^n = \sum_\alpha\sum_\beta (C_{\alpha,\beta}\kappa_{\alpha,\beta}^n + D_{\alpha,\beta}\kappa_{\alpha,\beta}^{-n})\sin(\alpha\pi x_{\mathbf{i}})e^{i2\beta\pi y_{\mathbf{i}}},$$

where the values of $A_{\alpha,\beta}$, $B_{\alpha,\beta}$, $C_{\alpha,\beta}$, and $D_{\alpha,\beta}$ are determined by the initial conditions. The solution will be stable provided that $0 < G_{\alpha,\beta} < 1$ for all permissible α,β. It follows from the stability condition (6.11) and the definitions of λ_x and λ_y that the solution to the model problem is stable provided that the time step satisfies (6.9). □

Note that

$$\kappa_{\alpha,\beta} = 1 + ik\Delta t + \tfrac{1}{2}(ik\Delta t)^2 + \tfrac{1}{3!}(ik\Delta t)^3 + \tfrac{1}{4!}(ik\Delta t)^4 + O(\Delta t h^4, \Delta t^3 h^2, \Delta t^5),$$

where $h = \sqrt{\Delta x^2 + \Delta y^2}$, $k = \sqrt{k_x^2 + k_y^2}$, $k_x = \pi\alpha$, and $k_y = 2\pi\beta$. This shows that κ_{mn} is a fourth-order accurate approximation to $e^{ik\Delta t}$. The discrete eigenfunctions $\widetilde{U}_{\mathbf{i}}^n$ and $\widetilde{V}_{\mathbf{i}}^n$ are thus fourth-order accurate approximations to the eigenfunctions of the continuous problem, and it is apparent that the discrete approximation to the model problem is fourth-order accurate.

In three dimensions an argument similar to that used for the two-dimensional case shows that the stability condition is $\Delta t < c^{-1}\left(\Delta x^{-2} + \Delta y^{-2} + \Delta z^{-2}\right)^{-1/2}$.

6.1. Relationship to the Yee scheme. The current approach can be compared to the classic Yee scheme [44]. For the two-dimensional TE_Z system

$$u_t = w_y, \quad v_t = -w_x, \quad w_t = u_y - v_x,$$

the Yee scheme can be written as

$$D_{+t}U^n_{i+\frac{1}{2},j} = D_{+y}W^{n+\frac{1}{2}}_{i+\frac{1}{2},j-\frac{1}{2}}, \tag{6.12}$$

$$D_{+t}V^n_{i,j+\frac{1}{2}} = -D_{+x}W^{n+\frac{1}{2}}_{i-\frac{1}{2},j+\frac{1}{2}}, \tag{6.13}$$

$$D_{+t}W^{n-\frac{1}{2}}_{i+\frac{1}{2},j+\frac{1}{2}} = D_{-y}U^n_{i+\frac{1}{2},j} - D_{-x}V^n_{i,j+\frac{1}{2}}, \tag{6.14}$$

where the subscripts denote the staggering of the variables with $W^{n+\frac{1}{2}}_{i+\frac{1}{2},j+\frac{1}{2}}$, for example, being cell-centered. It is also true that $D_{+x}U^n_{i+\frac{1}{2},j} + D_{+y}V^n_{i,j+\frac{1}{2}} = 0$ (assuming the initial conditions satisfy this). A discrete second-order form for these equations can be found by first applying the operator D_{-t} to (6.12). Combining this with the other equations gives

$$\begin{aligned} D_{+t}D_{-t}U^n_{i+\frac{1}{2},j} &= D_{+y}D_{-y}U^n_{i+\frac{1}{2},j} - D_{+y}D_{+x}V^n_{i-\frac{1}{2},j+\frac{1}{2}} \\ &= (D_{+x}D_{+x} + D_{+y}D_{-y})U^n_{i+\frac{1}{2},j}, \end{aligned}$$

and similarly for the other variables. Thus each component satisfies the second-order wave equation discretized with the standard central difference operators. Neglecting boundaries, the Yee scheme therefore effectively uses the same discretization as the second-order accurate version of the current scheme.

7. Boundary conditions at material interfaces. In this section the propagation of electromagnetic waves through different dielectric (insulating) materials will be considered. The domain Ω is partitioned into a set of subdomains, $\Omega = \bigcup_k \Omega_k$, with each Ω_k representing a region with different material properties,

$$\epsilon(\mathbf{x}) = \epsilon_k, \quad \mu(\mathbf{x}) = \mu_k \quad \text{for } \mathbf{x} \in \Omega_k.$$

The assumption is made that ϵ and μ are constant within each subdomain (although this restriction is not essential). The boundaries of each subdomain, $\partial\Omega_k$, are assumed to be sufficiently smooth so that normal and tangent vectors to the interface can be defined. Overlapping grids will be used to discretize each subdomain separately. The subdomain boundaries will be represented with boundary fitted grids (see, for example, Figure 7). Maxwell's equations in second-order form are discretized in each subdomain using the high-order accurate difference approximations discussed in previous sections. Ghost points are used on the grids on both sides of the interface as shown in the one-dimensional overlapping grid of Figure 3. Boundary conditions at the interface are required for the numerical approximation. These boundary conditions are used to determine the solution values at the ghost points. As in the case of the PEC boundary, centered numerical boundary conditions are developed from compatibility conditions consistent with the governing equations. The compatibility conditions are based on interface jump conditions derived from the first-order form of Maxwell's equations. For $\rho = 0$, with spatially variable ϵ and μ, these are

$$\epsilon(\mathbf{x})\mathbf{E}_t = \nabla \times \mathbf{H}, \qquad \mu(\mathbf{x})\mathbf{H}_t = -\nabla \times \mathbf{E}, \tag{7.1}$$

$$\nabla \cdot (\epsilon(\mathbf{x})\mathbf{E}) = 0, \qquad \nabla \cdot (\mu(\mathbf{x})\mathbf{H}) = 0. \tag{7.2}$$

Under the assumption that $\mathbf{E}$ and $\mathbf{H}$ remain bounded, the basic jump conditions at a material interface $\mathcal{I}$ are derived by integrating each of the equations (7.1)–(7.2) over

an appropriate control volume that spans the interface (see, for example, [2]), and the result is

$$[\epsilon \mathbf{n}\cdot\mathbf{E}]_{\mathcal{I}}=0, \qquad [\mu \mathbf{n}\cdot\mathbf{H}]_{\mathcal{I}}=0, \tag{7.3}$$

$$[\boldsymbol{\tau}_m\cdot\mathbf{E}]_{\mathcal{I}}=0, \qquad [\boldsymbol{\tau}_m\cdot\mathbf{H}]_{\mathcal{I}}=0. \tag{7.4}$$

Here $[\mathbf{f}]_{\mathcal{I}}$ denotes the jump in $\mathbf{f}$ across the interface, $\mathbf{n}=\mathbf{n}(\mathbf{x})$ is the unit normal vector to the interface, and $\boldsymbol{\tau}_m=\boldsymbol{\tau}_m(\mathbf{x})$ is a unit tangent vector to the material interface. Since there are two linearly independent tangents in three dimensions, there will be two linearly independent conditions $[\boldsymbol{\tau}_m\cdot\mathbf{E}]=0$, $m=1,2$ (or just one condition in two dimensions). Jump conditions on the first spatial derivatives of the solution follow directly from equations (7.2), and also by taking one time derivative of (7.4) and combining with equations (7.1):

$$[\nabla\cdot\mathbf{E}]_{\mathcal{I}}=0, \qquad [\nabla\cdot\mathbf{H}]_{\mathcal{I}}=0, \tag{7.5}$$

$$[\mu^{-1}\boldsymbol{\tau}_m\cdot\nabla\times\mathbf{E}]_{\mathcal{I}}=0, \qquad [\epsilon^{-1}\boldsymbol{\tau}_m\cdot\nabla\times\mathbf{H}]_{\mathcal{I}}=0. \tag{7.6}$$

Note that $[\nabla\cdot(\epsilon\mathbf{E})]_{\mathcal{I}}=0$ can be replaced by $[\nabla\cdot\mathbf{E}]_{\mathcal{I}}=0$ since $\nabla\cdot\mathbf{E}$ is identically zero on either side of the interface. A similar remark applies to the condition $[\nabla\cdot\mathbf{H}]_{\mathcal{I}}=0$. Additional compatibility conditions can be derived by taking an even number of time derivatives of the four conditions (7.3)–(7.6) and using the vector wave equation (1.6) to transform the time derivatives into space derivatives. This gives the complete set of interface conditions

$$[\epsilon \mathbf{n}\cdot\Delta^n\mathbf{E}/(\epsilon\mu)^n]_{\mathcal{I}}=0, \qquad [\mu \mathbf{n}\cdot\Delta^n\mathbf{H}/(\epsilon\mu)^n]_{\mathcal{I}}=0, \tag{7.7}$$

$$[\boldsymbol{\tau}\cdot\Delta^n\mathbf{E}/(\mu\epsilon)^n]_{\mathcal{I}}=0, \qquad [\boldsymbol{\tau}\cdot\Delta^n\mathbf{H}/(\mu\epsilon)^n]_{\mathcal{I}}=0, \tag{7.8}$$

$$[\nabla\cdot(\Delta^n\mathbf{E})]_{\mathcal{I}}=0, \qquad [\nabla\cdot(\Delta^n\mathbf{H})]_{\mathcal{I}}=0, \tag{7.9}$$

$$[\mu^{-1}\boldsymbol{\tau}\cdot\nabla\times\Delta^n\mathbf{E}/(\mu\epsilon)^n]_{\mathcal{I}}=0, \qquad [\epsilon^{-1}\boldsymbol{\tau}\cdot\nabla\times\Delta^n\mathbf{H}/(\mu\epsilon)^n]_{\mathcal{I}}=0 \tag{7.10}$$

for $n=0,1,2,3,\ldots$. These interface jump conditions impose constraints on each spatial derivative of the solution.

Discrete versions of the jump conditions are used as numerical boundary conditions in the following manner. First consider the case of a second-order accurate approximation that uses one ghost line on each side of the interface. Let $\mathbf{U}^{(k)}_{\mathbf{i}}$ denote the discrete approximation to the electric field where $k=1,2$ denotes the solution on each side of the material interface. The dependence of the solution on time is suppressed for this discussion. To be specific, let the interface correspond to the value of $i_1=0$ and the ghost line values correspond to $i_1=-1$. The values $\mathbf{U}^{(1)}_{-1,i_2,i_3}$ and $\mathbf{U}^{(2)}_{-1,i_2,i_3}$ of the solution on the ghost lines (one ghost line value on each side of the interface) are determined by imposing the following centered interface conditions at $i_1=0$:

$$[\epsilon \mathbf{n}\cdot\Delta_{2h}\mathbf{U}^{(k)}_{\mathbf{i}}/(\epsilon\mu)]_{\mathcal{I}}=0, \qquad [\boldsymbol{\tau}_m\cdot\Delta_{2h}\mathbf{U}^{(k)}_{\mathbf{i}}/(\mu\epsilon)]_{\mathcal{I}}=0, \tag{7.11}$$

$$[\nabla_{2h}\cdot(\mathbf{U}^{(k)}_{\mathbf{i}})]_{\mathcal{I}}=0, \quad [\mu^{-1}\boldsymbol{\tau}_m\cdot\nabla_{2h}\times\mathbf{U}^{(k)}_{\mathbf{i}}]_{\mathcal{I}}=0. \tag{7.12}$$

Here $\nabla_{2h}\cdot$, $\nabla\times_{2h}$, and Δ_{2h} are some appropriate second-order accurate centered difference approximations. Equations (7.11)–(7.12) implicitly specify that the time derivatives of the jump conditions (7.3)–(7.4) are zero (to second-order accuracy). Therefore, by imposing the conditions (7.11)–(7.12) the basic jump conditions (7.3)–(7.4)

should also be approximately satisfied (assuming they are satisfied at the initial time). Therefore it may not be essential to explicitly impose the conditions (7.3)–(7.4). In practice, however, the solution values on the interface itself are constrained to satisfy the basic jump conditions,

$$[\epsilon \mathbf{n}\cdot \mathbf{U}_{\mathbf{i}}^{(k)}]_{\mathcal{I}}=0, \quad [\boldsymbol{\tau}_m\cdot \mathbf{U}_{\mathbf{i}}^{(k)}]_{\mathcal{I}}=0, \tag{7.13}$$

by setting the solution values on the side of the interface with the larger value of ϵ in terms of the values on the other side. For example, if $\epsilon_2 \le \epsilon_1$, then

$$\mathbf{U}^{(1)}_{0,i_2,i_3}=\frac{\epsilon_2}{\epsilon_1}\Big(\mathbf{n}\cdot \mathbf{U}^{(2)}_{0,i_2,i_3}\Big)\mathbf{n}+\sum_{m=1}^{2}\Big(\boldsymbol{\tau}_m\cdot \mathbf{U}^{(2)}_{0,i_2,i_3}\Big)\boldsymbol{\tau}_m. \tag{7.14}$$

A fourth-order accurate approximation will use two ghost lines on each side of the interface. The values at the ghost points are determined using fourth-order accurate approximations to the interface conditions for the first and second derivatives,

$$[\epsilon \mathbf{n}\cdot \Delta_{4h}\mathbf{U}_{\mathbf{i}}^{(k)}/(\epsilon\mu)]_{\mathcal{I}}=0, \qquad [\boldsymbol{\tau}_m\cdot \Delta_{4h}\mathbf{U}_{\mathbf{i}}^{(k)}/(\mu\epsilon)]_{\mathcal{I}}=0, \tag{7.15}$$

$$[\nabla_{4h}\cdot (\mathbf{U}_{\mathbf{i}}^{(k)})]_{\mathcal{I}}=0, \quad [\mu^{-1}\boldsymbol{\tau}_m\cdot \nabla_{4h}\times \mathbf{U}_{\mathbf{i}}^{(k)}]_{\mathcal{I}}=0, \tag{7.16}$$

together with second-order accurate approximations to the interface conditions for the third and fourth derivatives,

$$[(\nabla\cdot\Delta)_{2h}(\mathbf{U}_{\mathbf{i}}^{(k)})]_{\mathcal{I}}=0, \quad [\mu^{-1}\boldsymbol{\tau}_m\cdot (\nabla\times\Delta)_{2h}\mathbf{U}_{\mathbf{i}}^{(k)}/(\epsilon\mu)]_{\mathcal{I}}=0, \tag{7.17}$$

$$[\epsilon \mathbf{n}\cdot (\Delta^2)_{2h}\mathbf{U}_{\mathbf{i}}^{(k)}/(\epsilon\mu)^2]_{\mathcal{I}}=0, \qquad [\boldsymbol{\tau}_m\cdot (\Delta^2)_{2h}\mathbf{U}_{\mathbf{i}}^{(k)}/(\epsilon\mu)^2]_{\mathcal{I}}=0. \tag{7.18}$$

The fourth-order approximation will also impose equations (7.13). The accuracy and stability of these conditions for a model problem are considered in section 8.

A complicating factor in applying these interface boundary conditions is that the discrete equations couple the unknown values of $\mathbf{U}_{\mathbf{i}}^{(k)}$ at all ghost points on both sides of the interface. Therefore, the solution to these equations requires the solution of a system of equations with the number of unknowns proportional to the number of points on the interface. In practice, it has been found that these equations can be approximately solved using an iterative technique (see section 9.3 for further details).

8. Analysis of the material interface conditions. The accuracy and stability of the centered boundary conditions for material interfaces are considered in this section. A semidiscrete one-dimensional model problem is studied using the Laplace transform in time and mode analysis in space. Second-order accurate and fourth-order accurate interface conditions are analyzed.

A one-dimensional model problem for $u=u(x,t)$ and $v=v(x,t)$ on the interval $[a,b]$ with a material interface at $x=0$, $a<x<b$, is

$$\epsilon(x)u_{tt}=u_{xx}, \quad \epsilon(x)v_{tt}=v_{xx}, \tag{8.1}$$

$$[\epsilon u]_{\mathcal{I}}=0, \qquad [v]_{\mathcal{I}}=0, \tag{8.2}$$

$$[u_x]_{\mathcal{I}}=0, \qquad [v_x]_{\mathcal{I}}=0, \tag{8.3}$$

where $\epsilon(x)=\epsilon_1$ for $x<0$ and $\epsilon(x)=\epsilon_2$ for $x>0$. The variable u represents the normal component of the field (say, E_x), while the variable v represents one of the

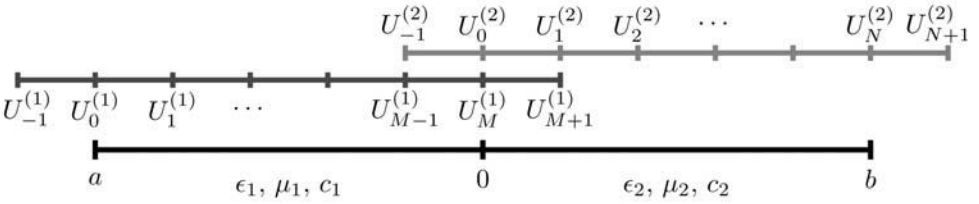

FIG. 3. *The overlapping grids for a one-dimensional material interface located at $x = 0$. Ghost points are introduced on the two grids at the interface.*

tangential components of the field (say E_y). Note that for this model problem the equations for the normal and tangential components are decoupled.

Introduce a one-dimensional overlapping grid as shown in Figure 3. A (formally) second-order accurate semidiscrete approximation is

$$\epsilon_1 U^{(1)}_{tt} = D_+D_-U^{(1)}_j, \quad \epsilon_1 V^{(1)}_{tt} = D_+D_-V^{(1)}_j \quad \text{for } j = M, M-1, M-2, \dots, \tag{8.4}$$

$$\epsilon_2 U^{(2)}_{tt} = D_+D_-U^{(2)}_j, \quad \epsilon_2 V^{(2)}_{tt} = D_+D_-V^{(2)}_j \quad \text{for } j = 0, 1, 2, \dots \tag{8.5}$$

with interface conditions

$$D_0U^{(1)}_M = D_0U^{(2)}_0, \qquad D_0V^{(1)}_M = D_0V^{(2)}_0, \tag{8.6}$$

$$D_+D_-U^{(1)}_M = D_+D_-U^{(2)}_0, \quad D_+D_-V^{(1)}_M/\epsilon_1 = D_+D_-V^{(2)}_0/\epsilon_2. \tag{8.7}$$

Here $U^{(k)}_i(t)$ and $V^{(k)}_i(t)$ denote the approximations to u and v on the grids while $D_+ = D_{+x}$, $D_- = D_{-x}$, and $D_0 = D_{0x}$. The grid points are denoted by $\mathbf{x}^{(k)}_i$. Approximations to the jump conditions $[u_{xx}]_{\mathcal{I}} = 0$ and $[v_{xx}/\epsilon]_{\mathcal{I}}$ have been imposed in place of (8.2); these follow from (8.1)–(8.2). The interface equations (8.6) and (8.7) can be solved for the values at the ghost points, $U^{(1)}_{M+1}, U^{(2)}_{-1}$, in terms of interior values:

$$U^{(1)}_{M+1} = U^{(2)}_1 + (U^{(1)}_M - U^{(2)}_0) = U^{(2)}_1 + (\epsilon_2/\epsilon_1 - 1)U^{(2)}_0, \tag{8.8}$$

$$U^{(2)}_{-1} = U^{(1)}_{M-1} - (U^{(1)}_M - U^{(2)}_0) = U^{(1)}_{M-1} - (1 - \epsilon_1/\epsilon_2)U^{(1)}_M, \tag{8.9}$$

$$V^{(1)}_{M+1} = \frac{2\epsilon_1}{\epsilon_1+\epsilon_2}\, V^{(2)}_1 + \frac{\epsilon_2-\epsilon_1}{\epsilon_1+\epsilon_2}\big(2V^{(1)}_M - V^{(1)}_{M-1}\big), \tag{8.10}$$

$$V^{(2)}_{-1} = \frac{2\epsilon_2}{\epsilon_1+\epsilon_2}\, V^{(1)}_{M-1} + \frac{\epsilon_1-\epsilon_2}{\epsilon_1+\epsilon_2}\big(2V^{(2)}_0 - V^{(2)}_1\big). \tag{8.11}$$

The interface boundary conditions have the useful property that when $\epsilon_1 = \epsilon_2$, the solution to the interface problem is the same as if there were no interface at all.

The stability of the discrete approximations to the interface problem will now be analyzed. A necessary condition for stability is the Godunov–Ryabenkii condition, which requires that there be no solutions to the following eigenvalue problem for $\mathrm{Re}(s) > 0$:

$$\epsilon_1 s^2 W^{(1)}_j = D_+D_-W^{(1)}_j \qquad \text{for } j = M, M-1, M-2, \dots, \tag{8.12}$$

$$\epsilon_2 s^2 W^{(2)}_j = D_+D_-W^{(2)}_j \qquad \text{for } j = 0, 1, 2, \dots, \tag{8.13}$$

$$D_0W^{(1)}_M = D_0W^{(2)}_0, \qquad (D_+D_-W^{(1)}_M)/\epsilon^{\alpha}_1 = (D_+D_-W^{(2)}_0)/\epsilon^{\alpha}_2, \tag{8.14}$$

$$\|W^{(1)}\|_h < \infty, \qquad \|W^{(2)}\|_h < \infty. \tag{8.15}$$

Here $\alpha = 0$ corresponds to the problem for the normal component $U_i^{(k)}$, while $\alpha = 1$ corresponds to the problem for the tangential component $V_i^{(k)}$. The discrete norms of the grid functions are defined from $\|W^{(1)}\|_h^2 = \sum_{j=-\infty}^{M} |W_j^{(1)}|^2\ h$ and $\|W^{(2)}\|_h^2 = \sum_{j=0}^{\infty} |W_j^{(2)}|^2\ h$. If this problem (8.12)–(8.15) were to have a solution, there would be a solution to (8.4)–(8.7) of the form $U_i^{(k)}(t) = e^{st} W_i^{(k)}$ that would grow arbitrarily fast in time as $h \to 0$, and the scheme would not be stable.

LEMMA 8.1. [illegible] (8.4)–(8.7) [illegible]. The solution to the eigenvalue problem (8.12)–(8.15) is of the form

$$W_j^{(1)} = A\kappa_1^{M-j}, \quad W_j^{(2)} = B\kappa_2^j,$$

where $\kappa_k = 1 + s_k/2 - \sqrt{s_k}\sqrt{1 + s_k/4}$ is a root of the characteristic equation $\kappa - 2 + \kappa^{-1} = s_k$, with $s_k = \epsilon_k s^2 h^2$, for $k = 1, 2$. The branch of the square root is taken so that $|\kappa_1| < 1$ and $|\kappa_2| < 1$ for $\mathrm{Re}(s) > 0$. Applying the interface conditions (8.8) and (8.9) implies

$$\begin{aligned} A(\kappa_1^{-1} - \kappa_1) &= B(\kappa_2 - \kappa_2^{-1}), \\ A(\kappa_1^{-1} - 2 + \kappa_1)/\epsilon_1^{\alpha} &= B(\kappa_2 - 2 + \kappa_2^{-1})/\epsilon_2^{\alpha}. \end{aligned}$$

For the case $\alpha = 0$ the determinant condition for nontrivial solutions is

$$(\kappa_1^{-1} - \kappa_1)(\kappa_2 - 2 + \kappa_2^{-1}) = (\kappa_2 - \kappa_2^{-1})(\kappa_1^{-1} - 2 + \kappa_1),$$

which simplifies to $\kappa_1\kappa_2 = 1$. This contradicts the fact that $|\kappa_1\kappa_2| < 1$ and thus there can be no nontrivial solutions. For $\alpha = 1$ it follows that $A = B$ and for a nontrivial solution, $-(\kappa_1 - \kappa_1^{-1}) = \kappa_2 - \kappa_2^{-1}$. From the definitions of κ_1 and κ_2 it follows that $\sqrt{s_1}\sqrt{1 + s_1/4} = -\sqrt{s_2}\sqrt{1 + s_2/4}$. The solution to the last equation is $s_1 = -s_2 - 4$ (the other possible solution $s_1 = s_2$ is on the wrong branch of the square root), which implies $s = \pm i/(h\sqrt{\epsilon_1 + \epsilon_2})$. This contradicts the assumption that $Re(s) > 0$, and thus there are no nontrivial solutions for $\alpha = 1$. It thus follows that the Godunov–Ryabenkii condition is satisfied. □

The accuracy of the approximation can be determined by examining the problem for the error, $E_i^{(k)} = U_i^{(k)} - u(\mathbf{x}_i^{(k)}, t)$:

$$\begin{aligned} \epsilon_1 s^2 E_j^{(1)} &= D_+ D_- E_j^{(1)} + h^2 F_1 \qquad \text{for } j = M, M-1, M-2, \ldots, \\ \epsilon_2 s^2 E_j^{(2)} &= D_+ D_- E_j^{(2)} + h^2 F_2 \qquad \text{for } j = 0, 1, 2, \ldots, \\ D_0 E_M^{(1)} - D_0 E_0^{(2)} &= h^2 G_1, \qquad (D_+ D_- E_M^{(1)})/\epsilon_1^{\alpha} - (D_+ D_- E_0^{(2)})/\epsilon_2^{\alpha} = h^2 G_2, \end{aligned}$$

where the terms h^2F_1, h^2F_2, h^2G_1, and h^2G_2 are the truncation errors. In the usual manner (for example, see [14]), by subtracting out a solution to the Cauchy problem it may be assumed that $F_1 = F_2 = 0$. The solution to the error equations is then of the form

$$E_j^{(1)} = A\kappa_1^{M-j}, \quad E_j^{(2)} = B\kappa_2^j,$$

and applying the interface conditions gives the equations for A and B,

$$\begin{bmatrix} (\kappa_1^{-1} - \kappa_1)/(2h) & -(\kappa_2 - \kappa_2^{-1})/(2h) \\ \epsilon_1^{1-\alpha} s^2 & -\epsilon_2^{1-\alpha} s^2 \end{bmatrix} \begin{bmatrix} A \\ B \end{bmatrix} = \begin{bmatrix} h^2 G_1 \\ h^2 G_2 \end{bmatrix}.$$

Using $\kappa_k - \kappa_k^{-1} = -2\sqrt{s_k}\sqrt{1+s_k/4}$, it follows that

$$A = \frac{\epsilon_1^{1-\alpha} s G_1 + \epsilon_2^{1/2} G_2}{\epsilon_1^{1-\alpha}(\epsilon_1^{1/2}+\epsilon_2^{1/2})s^2}\, h^2 + O(h^4), \quad B = \frac{\epsilon_1^{1-\alpha} s G_1 - \epsilon_1^{1/2} G_2}{\epsilon_1^{1-\alpha}(\epsilon_1^{1/2}+\epsilon_2^{1/2})s^2}\, h^2 + O(h^4).$$

Therefore the solution to the semidiscrete problem is second-order accurate.

Now consider the fourth-order accurate approximation

$$\epsilon_1 U_{tt}^{(1)} = D_+D_-(1 - \tfrac{h^2}{12}D_+D_-)U_j^{(1)} \quad \text{for } j = M, M-1, M-2, \dots, \tag{8.16}$$

$$\epsilon_2 U_{tt}^{(2)} = D_+D_-(1 - \tfrac{h^2}{12}D_+D_-)U_j^{(2)} \quad \text{for } j = 0, 1, 2, \dots, \tag{8.17}$$

$$D_0(1 - \tfrac{h^2}{6}D_+D_-)U_M^{(1)} = D_0(1 - \tfrac{h^2}{6}D_+D_-)U_0^{(2)}, \tag{8.18}$$

$$D_+D_-(1 - \tfrac{h^2}{12}D_+D_-)U_M^{(1)}/\epsilon_1^{\alpha} = D_+D_-(1 - \tfrac{h^2}{12}D_+D_-)U_0^{(2)}/\epsilon_2^{\alpha}, \tag{8.19}$$

$$D_0D_+D_-U_M^{(1)}/\epsilon_1 = D_0D_+D_-U_0^{(2)}/\epsilon_2, \tag{8.20}$$

$$(D_+D_-)^2U_M^{(1)}/\epsilon_1^{1+\alpha} = (D_+D_-)^2U_0^{(2)}/\epsilon_2^{1+\alpha}, \tag{8.21}$$

where $\alpha = 0$ corresponds to the interface conditions for the normal component and $\alpha = 1$ corresponds to the conditions for the tangential component. Two ghost points have been added to the grids on each side of the interface. Appropriate initial conditions are also required to complete the specification of the problem; their precise form is not germane to the following discussion. When $\epsilon_1 = \epsilon_2$, the solution to the interface problem reduces to the solution of the equations with no interface present since in this case $U_{M+m}^{(1)} = U_m^{(2)}$ and $U_{-m}^{(2)} = U_{M+m}^{(1)}$ for $m = 1, 2$.

The Godunov–Ryabenkii condition, necessary for the stability of solutions to these difference equations, requires that there be no solutions with $\mathrm{Re}(s) > 0$ to the eigenvalue problem

$$\epsilon_1 s^2 W_j^{(1)} = D_+D_-(1 - \tfrac{h^2}{12}D_+D_-)W_j^{(1)} \quad \text{for } j = M, M-1, M-2, \dots,$$

$$\epsilon_2 s^2 W_j^{(2)} = D_+D_-(1 - \tfrac{h^2}{12}D_+D_-)W_j^{(2)} \quad \text{for } j = 0, 1, 2, \dots,$$

$$D_0(1 - \tfrac{h^2}{6}D_+D_-)W_M^{(1)} = D_0(1 - \tfrac{h^2}{6}D_+D_-)W_0^{(2)},$$

$$D_+D_-(1 - \tfrac{h^2}{12}D_+D_-)W_M^{(1)}/\epsilon_1^{\alpha} = D_+D_-(1 - \tfrac{h^2}{12}D_+D_-)W_0^{(2)}/\epsilon_2^{\alpha},$$

$$D_0D_+D_-W_M^{(1)}/\epsilon_1 = D_0D_+D_-W_0^{(2)}/\epsilon_2,$$

$$(D_+D_-)^2W_M^{(1)}/\epsilon_1^{1+\alpha} = (D_+D_-)^2W_0^{(2)}/\epsilon_2^{1+\alpha},$$

$$\|W^{(1)}\|_h < \infty, \qquad \|W^{(2)}\|_h < \infty.$$

LEMMA 8.2. [illegible] (8.16)–(8.21) [illegible] $sh \ll 1$ [illegible]. For $\mathrm{Re}(s) > 0$ the bounded solutions may be written as

$$W_j^{(1)} = A_1\kappa_1^{M-j} + B_1\widetilde{\kappa}_1^{M-j}, \quad W_j^{(2)} = A_2\kappa_2^{j} + B_2\widetilde{\kappa}_2^{j},$$

where κ_k are the roots approximating the solution to the continuous problem and $\widetilde{\kappa}_k$ are the spurious roots.[1] These are roots of the characteristic equation

$$(\kappa - 2 + \kappa^{-1})(1 - \tfrac{1}{12}(\kappa - 2 + \kappa^{-1})) = s_k,$$

[1] This form must be modified to use $j\kappa_k^j$ instead of $\widetilde{\kappa}^j$ when there is a double root, $\kappa_k = \widetilde{\kappa}_k$.

where $s_k = \epsilon_k s^2 h^2$. In particular

$$\kappa_k = 1 + z_k/2 - \sqrt{z_k}\sqrt{1 + z_k/4}, \quad \widetilde{\kappa}_k = 1 + \widetilde{z}_k/2 - \sqrt{\widetilde{z}_k}\sqrt{1 + \widetilde{z}_k/4},$$
$$z_k = 6(1 - \sqrt{1 - s_k/3}), \qquad \widetilde{z}_k = 6(1 + \sqrt{1 - s_k/3}),$$

where the branch of the square root is chosen so that $|\kappa_k| < 1$ and $|\widetilde{\kappa}_k| < 1$ for $Re(s) > 0$. Note that for $s_k = 3$ there is a double root $\kappa_k = \widetilde{\kappa}_k$, but this occurs when sh is order 1 and thus will not be considered. For $sh \ll 1$, the roots take the form

$$\kappa_k = 1 - \sqrt{\epsilon_k} sh + \epsilon_k (sh)^2/2 - (\sqrt{\epsilon_k} sh)^3/6 + (\sqrt{\epsilon_k} sh)^4/24 + O((sh)^5),$$
$$\widetilde{\kappa}_k = \frac{1}{7 + 4\sqrt{3}} + O(sh).$$

It can be seen that κ_k is a fourth-order approximation to $e^{-\sqrt{\epsilon_k} sh}$. Substitution of $W_j^{(1)}$ and $W_j^{(1)}$ into the four boundary conditions implies

$$\begin{bmatrix} \mathcal{D}_1(\kappa_1) & \mathcal{D}_1(\widetilde{\kappa}_1) & \mathcal{D}_1(\kappa_2) & \mathcal{D}_1(\widetilde{\kappa}_2) \\ s_1/\epsilon_1^{\alpha} & s_1/\epsilon_1^{\alpha} & -s_2/\epsilon_2^{\alpha} & -s_2/\epsilon_2^{\alpha} \\ \mathcal{D}_3(\kappa_1)/\epsilon_1 & \mathcal{D}_3(\widetilde{\kappa}_1)/\epsilon_1 & \mathcal{D}_3(\kappa_2)/\epsilon_2 & \mathcal{D}_3(\widetilde{\kappa}_2)/\epsilon_2 \\ \mathcal{D}_4(\kappa_1)/\epsilon_1^{1+\alpha} & \mathcal{D}_4(\widetilde{\kappa}_1)/\epsilon_1^{1+\alpha} & -\mathcal{D}_4(\kappa_2)/\epsilon_2^{1+\alpha} & -\mathcal{D}_4(\widetilde{\kappa}_2)/\epsilon_2^{1+\alpha} \end{bmatrix} \begin{bmatrix} A_1 \\ B_1 \\ A_2 \\ B_2 \end{bmatrix} = \mathbf{0}, \tag{8.22}$$

where $\mathcal{D}_1(\kappa) = \frac{1}{2}(\kappa - \kappa^{-1})(1 - \frac{1}{6}(\kappa - 2 + \kappa^{-1}))$, $\mathcal{D}_3(\kappa) = \frac{1}{2}(\kappa - \kappa^{-1})(\kappa - 2 + \kappa^{-1})$, and $\mathcal{D}_4(\kappa) = (\kappa - 2 + \kappa^{-1})^2$. Let $\mathcal{M}$ denote the matrix appearing in equation (8.22). Note that $\kappa_k - \kappa_k^{-1} = -2\sqrt{z_k}\sqrt{1 + z_k/4}$ and $\kappa_k - 2 + \kappa_k^{-1} = z_k$, which can be used to simplify the entries in $\mathcal{M}$. For stability there should be no values of s with $Re(s) > 0$ when the determinant of $\mathcal{M}$ is zero. This condition is difficult to prove for general values of sh. For $sh \ll 1$, corresponding to the resolved modes in the discrete solution, the elements of the determinant can be expanded in powers of sh and one finds that for $sh \to 0$,

$$\det(\mathcal{M}) \sim -2^9 3^3 \sqrt{3}(\epsilon_1^{-1/2} + \epsilon_2^{-1/2})\ (sh)^3 \qquad \text{for } \alpha = 0, \tag{8.23}$$

$$\det(\mathcal{M}) \sim -2^8 3^3 \sqrt{3} \frac{1}{\epsilon_1^2 \epsilon_2^2}(\epsilon_1^{1/2} + \epsilon_2^{1/2})(\epsilon_1 + \epsilon_2)\ (sh)^3 \quad \text{for } \alpha = 1. \tag{8.24}$$

Therefore there are no unstable modes for $sh \ll 1$ with $Re(s) > 0$. This proves the lemma. □

The stability of the interface boundary conditions was investigated further by computing the reflection and transmission of an electromagnetic wave from a straight interface. The computational domain is the region $\Omega = [-1, 1] \times [0, 1]$, with the interface located at $x = 0$. A Cartesian grid, $\mathcal{G}_1$, with $N_1 \times M_1$ grid cells covers the left half of the domain, $\Omega_1 = [-1, 0] \times [0, 1]$, where the material properties are ϵ_1 and μ_1. Another Cartesian grid, $\mathcal{G}_2$, with $N_2 \times M_2$ grid cells covers the right half of the domain, $\Omega_2 = [0, 1] \times [0, 1]$, where the material properties are ϵ_2 and μ_2. The incident field was chosen to be $(E_x, E_y) = (-k_2, k_1)/|\mathbf{k}| \exp(2\pi i(\mathbf{k}\cdot\mathbf{x} - \omega t))$, where $\mathbf{k} = (k_1, k_2)$ and $\omega/|\mathbf{k}| = c_1$. The reflected and transmitted fields are easily determined [2]. The solution was evaluated using the fourth-order modified equation method (6.1) and the fourth-order accurate interface boundary conditions (7.15)–(7.18). See section 9.3 for further details of the implementation. Periodic boundary conditions were chosen at $y = 0$ and $y = 1$, and the exact solution was given as a boundary condition at $x = -1$ and $x = 1$. Figure 4 shows results for the case $\epsilon_1 = 1$, $\mu_1 = 1$ ($c_1 = 1$), $\epsilon_2 = 4$, $\mu_2 = 1$

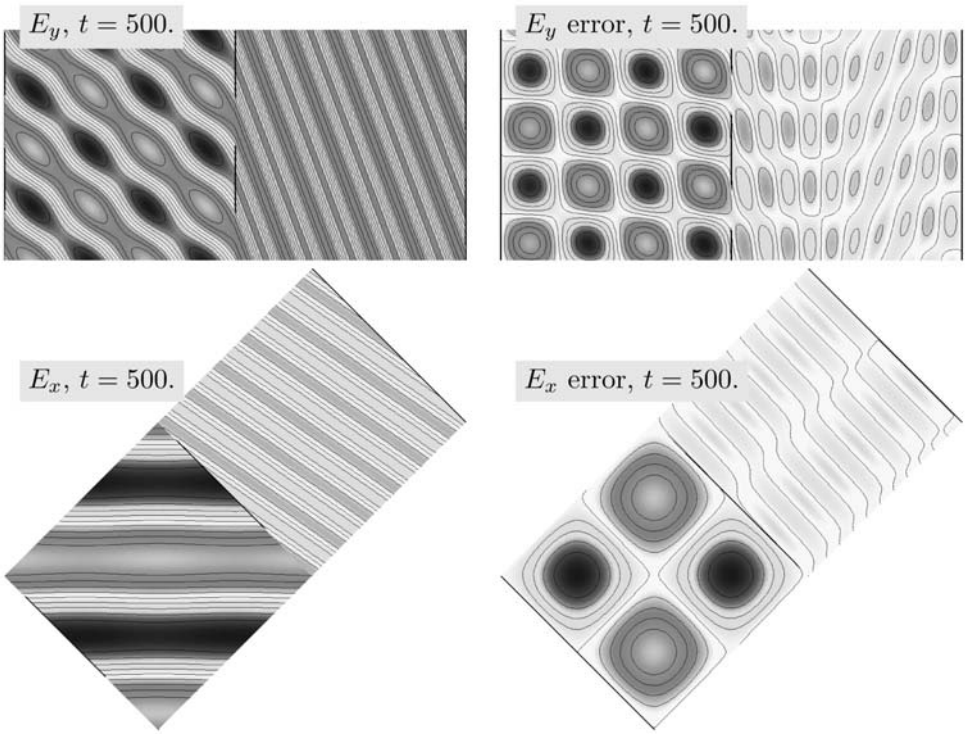

FIG. 4. *The reflection and transmission of a plane wave by a straight interface computed with the fourth-order accurate method. Top left: contours of* E_y *at* $t = 500$. *Top right: the error in* E_y *at* $t = 500$ *(the maximum error is* .01*). Bottom: the domain is rotated by* 45°. *Bottom left: contours of* E_x *at* $t = 500$. *Bottom right: the error in* E_x *at* $t = 500$ *(the maximum error is* .05*).*

$(c_2 = 1/2)$, $\mathbf{k} = (2, 2)$, and $N_1 = M_1 = N_2 = M_2 = 80$. The solution was computed to time $t = 500$ (approximately 60000 time steps). The solution remained stable as evidenced by the smooth behavior of the solution and error. Figure 4 shows similar results for a domain rotated by 45 degrees using $\mathbf{k} = (1, 1)$, $\epsilon_1 = 1$, $\mu_1 = 1$ $(c_1 = 1)$, $\epsilon_2 = 16$, $\mu_2 = 1$ $(c_2 = 1/4)$, and $N_1 = M_1 = N_2 = M_2 = 80$. The solution remained stable in this case as well.

For the long-time nondissipative calculations of Figure 4, the material interface conditions must be solved accurately to avoid a late time instability. More accuracy is required the larger the number of time steps. For accuracy reasons alone, only a few iterations are needed. For the problem of scattering by a dielectric cylinder of section 10.3, when dissipation is added to the equations, only a few iterations are needed to solve the interface conditions since the dissipation suppresses this weak instability. If the need arises, the interface equations should be amenable to solution by a Krylov-based method.

9. Implementation of the scheme. Some aspects of the implementation of the discrete approximations to the differential operators and boundary conditions will be considered in this section. The intent of these remarks is to give a basic outline of the implementation; a more detailed description is left for a future report. In typical cases the majority of grid points on an overlapping grid belong to Cartesian grids where the discrete approximations are straightforward to implement. The Cartesian

grid approximations are very fast to evaluate and use little memory. The majority of the programming effort, however, is concerned with implementing the approximations to the boundary conditions and material interface conditions on curvilinear grids.

9.1. Solving the PEC boundary conditions. The solution of the discrete approximations to the boundary conditions for a PEC are based upon the boundary conditions $\mathbf{n}\times\mathbf{E}=0$ and $\nabla\cdot\mathbf{E}=0$, together with the compatibility conditions (3.3). To simplify the implementation, some approximations are made that do not seem to affect the overall accuracy, as evidenced by the numerical results from section 10. The divergence of $\mathbf{E}$ can be written in general curvilinear coordinates as

$$\nabla\cdot\mathbf{E}=J^{-1}\sum_{m=1}^{d}\tfrac{\partial}{\partial r_m}(\mathbf{a}_m\cdot\mathbf{E}),\quad \mathbf{a}_m=J\nabla_{\mathbf{x}}r_m=J(\partial_x r_m,\partial_y r_m,\partial_z r_m).$$

For a PEC boundary, corresponding to the parameter space line $r_1=0$, the boundary condition $\nabla\cdot\mathbf{E}=0$ becomes a condition relating the r_1-derivative of $\mathbf{a}_1\cdot\mathbf{E}=-J\|\nabla_{\mathbf{x}}r_1\|\mathbf{n}\cdot\mathbf{E}$ to tangential derivatives of the components $\mathbf{a}_2\cdot\mathbf{E}_2$ and $\mathbf{a}_3\cdot\mathbf{E}$, $\partial_{r_1}(\mathbf{a}_1\cdot\mathbf{E})=-\partial_{r_2}(\mathbf{a}_2\cdot\mathbf{E}_2)-\partial_{r_3}(\mathbf{a}_3\cdot\mathbf{E})$. For an orthogonal grid, $\mathbf{a}_2\cdot\mathbf{E}(0,r_2,r_3)=0$ and $\mathbf{a}_3\cdot\mathbf{E}(0,r_2,r_3)=0$ on the boundary since $\mathbf{a}_2$ and $\mathbf{a}_3$ are in the tangent plane. In addition, $\mathbf{a}_1\cdot\mathbf{E}$ is (always) proportional to the normal component of $\mathbf{E}$, and thus the $\nabla\cdot\mathbf{E}=0$ boundary condition reduces to a normal derivative of this component:

$$J\ \nabla\cdot\mathbf{E}=\partial_{r_1}(\mathbf{a}_1\cdot\mathbf{E})\quad\text{for } r_1=0\quad\text{(orthogonal grid)}.$$

For general grids, $\mathbf{a}_2\cdot\mathbf{E}_2$ and $\mathbf{a}_3\cdot\mathbf{E}$ are not zero. A second-order accurate approximation to the boundary conditions at $i_1=0$ is

$$\boldsymbol{\tau}_m\cdot\mathbf{U}_{\mathbf{i}}=0, \tag{9.1}$$

$$D_{0,r_1}(\mathbf{a}_1\cdot\mathbf{U}_{\mathbf{i}})=-D_{0,r_2}(\mathbf{a}_2\cdot\mathbf{U}_{\mathbf{i}})-D_{0,r_3}(\mathbf{a}_3\cdot\mathbf{U}_{\mathbf{i}}), \tag{9.2}$$

$$\boldsymbol{\tau}_m\cdot D_{+r}D_{-r}\mathbf{U}_{\mathbf{i}}=0, \tag{9.3}$$

where $\boldsymbol{\tau}_m$, $m=1,2$, are tangent vectors to the boundary (there is only one in two dimensions). The equations (9.2)–(9.3) determine the solution on the ghost point, $\mathbf{U}_{-1,i_2,i_3}$. Equation (9.3) approximates the more accurate compatibility condition $\boldsymbol{\tau}_m\cdot\Delta\mathbf{E}=0$. These equations can be solved without iteration since the terms appearing on the right-hand side of (9.2) involve known values on the boundary once (9.1) is applied.

Let $D^{(4)}_{r_m}=D_{0,r_m}(1-\frac{1}{12}\Delta {r_1}^2 D_{+,r_m}D_{-,r_m})$ denote the fourth-order accurate approximation to $\partial/\partial r_m$. A fourth-order accurate approximation to the boundary conditions at $i_1=0$ is

$$\boldsymbol{\tau}_m\cdot\mathbf{U}_{\mathbf{i}}=0, \tag{9.4}$$

$$D^{(4)}_{r_1}(\mathbf{a}_1\cdot\mathbf{U})_{\mathbf{i}}=-D^{(4)}_{r_2}(\mathbf{a}_2\cdot\mathbf{U}_{\mathbf{i}})-D^{(4)}_{r_3}(\mathbf{a}_3\cdot\mathbf{U}_{\mathbf{i}}), \tag{9.5}$$

$$\boldsymbol{\tau}_m\cdot(\Delta_{4h}\mathbf{U}_{\mathbf{i}})=0, \tag{9.6}$$

$$D_{0,r_1}(\mathbf{a}_1\cdot\Delta_{2h}\mathbf{U}_{\mathbf{i}})=-D_{0,r_2}(\mathbf{a}_2\cdot\Delta_{2h}\mathbf{U}_{\mathbf{i}})-D_{0,r_3}(\mathbf{a}_3\cdot\Delta_{2h}\mathbf{U}_{\mathbf{i}}), \tag{9.7}$$

$$(D_{+,r_1}D_{-,r_1})^2(\boldsymbol{\tau}_m\cdot\mathbf{U}_{\mathbf{i}})=0. \tag{9.8}$$

Equations (9.5)–(9.8) will determine the solution at the two ghost lines, $\mathbf{U}_{-1,i_2,i_3}$ and $\mathbf{U}_{-2,i_2,i_3}$. Condition (9.8) is an approximation to the more accurate compatibility

condition $\Delta_{2h}^2(\boldsymbol{\tau}_m \cdot \mathbf{U}_\mathbf{i}) = 0$. Δ_{4h} is the fourth-order accurate FD4 approximation, and Δ_{2h} is the second-order accurate FD2 approximation to the Laplacian as defined in section 5. Equations (9.6)–(9.7) couple the unknown values at the ghost points with neighboring points. These equations can be solved by iterating on the unknown values using an appropriate initial guess; only one or two iterations are normally required.

9.2. Numerical dissipation. A high-order dissipation is added to the scheme to stabilize the approximation from weak, high-frequency (with respect to the grid) instabilities that may develop near interpolation points and boundaries. The most unstable modes tend to be the [illegible] that oscillate in sign from one grid point to the next. The appearance of an instability can be explained in the following way (see Reyna [35] for a careful analysis for the scalar wave equation on an overlapping grid). Except for simple cases of a single Cartesian grid or multiple matching Cartesian grids, the discrete operator for the method, including interpolation and boundary conditions, will not be exactly symmetric. As a result it can be expected that some of the eigenvalues of the discrete system will have a nonzero imaginary part. It follows from Lemma 5.1 that the corresponding eigenvectors will be unstable. Since the scheme is accurate, one can expect that the well-resolved modes will have accurate eigenvalues. The most unstable modes are likely associated with high-frequency modes that are not well resolved on the grid. The high-order dissipation is added to suppress these unstable modes. The dissipation is particularly effective for modes that vary rapidly in space. By default the dissipation is always added to the method.

At the continuous level, the dissipation of the second-order wave equation takes the form $u_{tt} = c^2\Delta u - \alpha\, h^{2p}(-\Delta)^p u_t$, where h is a measure of the local grid spacing. For the fourth-order accurate scheme a fourth-order dissipation with $p = 2$ is typically used,

$$U_\mathbf{i}^{n+1} - 2U_\mathbf{i}^n + U_\mathbf{i}^{n-1} = (c\Delta t)^2\Delta_{4h}U_\mathbf{i}^n + \tfrac{(c\Delta t)^4}{12}(\Delta^2)_{2h}U_\mathbf{i}^n - \alpha_d(c\Delta t)^2\sum_{m=1}^{d}(\Delta r_m)^4(D_{+r_m}D_{-r_m})^2(U_\mathbf{i}^n - U_\mathbf{i}^{n-1})/\Delta t. \tag{9.9}$$

The coefficient α_d is typically chosen to be about 1. The scheme remains fourth-order accurate provided that $\alpha_d = O(1)$. The damping acts as a low pass filter, having little effect on the waves that are well resolved on the grid but rapidly damping the modes that are not resolved on the grid. It is also possible to use a sixth-order dissipation with the fourth-order scheme, but this does not seem to provide any significant advantage.

9.3. Material interfaces. The boundary conditions for material interfaces have been implemented in two dimensions. Both second- and fourth-order accurate approximations have been developed; see sections 8 and 10.3 for some fourth-order accurate computations. The implementation is currently restricted to the case when the grids that meet at the interface have matching grid points (as shown, for example, in the grid in Figure 7). Currently only a simple iteration is used to solve the coupled interface equations. A more sophisticated solution scheme could be useful, but this option has not been investigated.

The solution of the fourth-order accurate approximations in two dimensions will be discussed here; the second-order accurate case is similar. Assume, as in section 7, that the interface corresponds to the line $i_1 = 0$, with the unknown ghost point values being $\mathbf{U}^{(k)}_{-m,i_2,i_3}$ for the ghost lines $m = 1, 2$ on the two sides of the interface, $k = 1, 2$. As a first step, the basic jump conditions (7.3)–(7.4) for the electric field are imposed.

These conditions are used to assign the values of the electric field $\mathbf{U}^{(k)}_{0,i_2,i_3}$ for the side of the interface with the larger value of ϵ. The interface compatibility conditions are given by (7.15)–(7.18). The solution to these equations will determine the values at the ghost points on both sides of the interface. Approximations for Δ_{4h}, ∇_{4h}, $(\nabla\cdot\Delta)_{2h}$, etc. are obtained with the mapping method (section 5). Three of the conditions (7.15), (7.17), (7.18) cause the equations to be coupled between adjacent points along the boundary, although on an orthogonal grid only the higher-order correction conditions (7.17), (7.18) lead to coupling. At the start of the iteration the values on the ghost points on both sides of the interface are given initial values by extrapolation. Then, at each step in the iteration, a small system of equations is solved at each point, $(0, i_2)$, along the boundary for the 8 unknown values $\mathbf{U}^{(k)}_{-m,i_2,i_3}$, $m = 1, 2$, $k = 1, 2$, using the 8 equations (7.15)–(7.18). There will be 12 unknowns and 12 equations in three dimensions. When solving these equations the values at adjacent points are kept fixed at their most recent values.

For the long-time computations presented at the end of section 8, which included no dissipation, it was found necessary to solve the interface equations very accurately (approximately 30 iterations) to avoid the development of late time instabilities. With the addition of a small fourth-order dissipation the number of iterations can be reduced to just a few. For the computations presented in section 10.3, which included a small fourth-order dissipation, it was found sufficient to use only one or two iterations to approximately solve the interface equations.

9.4. Parallel implementation. The algorithms described here have been implemented in the computer code **mx**. The **mx** solver is implemented at a high level in C++. It is based upon the Overture class library.[2] Most of the numerically intensive kernels are written in Fortran77. The overhead in using C++ is found to be negligible for any reasonable size problem (see section 10.5). The computer code **mx** runs on both serial and distributed memory parallel computers.

In a distributed parallel computing environment, the grid functions on each component grid (representing the solution variables such as E_x, E_y, E_z) are represented as multidimensional arrays. These arrays can be distributed across one or more processors. The grid functions are implemented using parallel distributed arrays from the P++ array class library [34]. Each P++ array can be independently distributed across the available processors. The distributed array consists of a set of serial arrays, one serial array for each processor. Each serial array is a multidimensional array that can be operated on using array operations. The data from the serial array can also be passed to a Fortran function, for example. When running in parallel, the serial arrays contain extra ghost lines that hold copies of the data from the serial arrays on neighboring processors. P++ is built on top of the Multiblock PARTI parallel communication library [40], which is used for ghost boundary updates and copying blocks of data between arrays with possibly different parallel distributions.

A special parallel overlapping grid interpolation routine has been developed for updating the points on grids that interpolate from other grids. Overlapping grid interpolation is based on a multidimensional tensor product Lagrange interpolant. In parallel, the Lagrange formula is evaluated on the processor that owns the data in the stencil (the donor points); the resulting sums are collected into a message and then sent to the processor that owns the interpolation points. There is at most one message that needs to be sent between any two processors. In this way, the number

of messages and the size of the messages that need to be passed between processors are quite small.

Figure 5 shows some results from solving Maxwell's equations with the **mx** solver on a distributed memory Linux cluster (with 2.4 GHz Zeon processors). The equations are solved to fourth-order accuracy. In these examples the number of grid points remains fixed as the number of processors is increased. The figure compares two-dimensional results for a square with 1024^2 $(1.1e6)$ grid points to that of a circle-in-channel overlapping grid with $3.8e6$ grid points. The parallel scaling is very good in two dimensions for these problems since the number of computational points is large compared to the number of points where communication is required. Also shown are three-dimensional results for a box with 256^3 $(1.78e7)$ grid points compared to a grid for a pill-box with about $3.2e6$ grid points (the pill-box appears in Figure 10). In the three-dimensional cases, there are relatively many more points where communication is required since for N^3 grid points in three-dimensions there are $O(N^2)$ points on the interprocessor boundaries. The parallel scaling is still reasonable with the results for the overlapping grid being comparable to that for the box.

10. Numerical results. Numerical results will now be presented that demonstrate the accuracy and efficiency of the fourth-order accurate version of the scheme. The scheme has also been verified on a number of other problems including the scattering of a plane wave by a two-dimensional cylinder and the computation of eigenmodes of a three-dimensional cylindrical cavity.

10.1. The method of analytic solutions. The [illegible] is an extremely useful technique for constructing exact solutions to check the accuracy of a computer program. This method, also sometimes known as the [illegible] [36], or [illegible] [3], adds forcing functions to the governing equations and boundary conditions. These forcing functions are determined so that some given functions, $\mathbf{E}^{\text{true}}(\mathbf{x},t)$, will be the exact solution to the forced equations. With this approach, the error in the discrete solution can be easily determined. Two common choices for exact solutions are low-degree polynomials or trigonometric functions. The polynomial solutions are useful for checking that the

fourth-order scheme can exactly solve a problem on a Cartesian grid, or overlapping Cartesian grids, when the degree of the polynomials is less than or equal to four. The trigonometric functions will be used in the convergence results given in this section. The exact solutions are chosen to be divergence free. In two and three dimensions the functions are

$$(E_x^{\text{true}}, E_y^{\text{true}}, H_z^{\text{true}}) = \left(\tfrac{1}{2}c_x c_y, \tfrac{1}{2}s_x s_y, c_x s_y\right)\cos(\pi t),$$
$$(E_x^{\text{true}}, E_y^{\text{true}}, E_z^{\text{true}}) = \left(c_x c_y c_z, \tfrac{1}{2}s_x s_y c_z, \tfrac{1}{2}s_x c_y s_z\right)\cos(\pi t),$$

where $c_x = \cos(\pi x)$, $s_y = \sin(\pi x)$, etc. Define the error in the discrete approximation $U_{\mathbf{i}}^n$ to E_x at a given time t^n by

$$\mathrm{e}_{\mathbf{i}}^{E_x} = U_{\mathbf{i}}^n - E_x^{\text{true}}(\mathbf{x}_{\mathbf{i}}, t^n), \tag{10.1}$$

with similar definitions for $\mathrm{e}_{\mathbf{i}}^{E_y}$, $\mathrm{e}_{\mathbf{i}}^{E_z}$, and $\mathrm{e}_{\mathbf{i}}^{H_z}$. Define the discrete max-norm by

$$\|U_{\mathbf{i}}^n\|_\infty = \max_{\mathbf{i}} |U_{\mathbf{i}}^n|, \tag{10.2}$$

where the maximum is taken over all valid points in the overlapping grid.

Table 1 shows convergence results for a two-dimensional cylinder in a channel. The coarse grid, $\mathcal{G}_1$, for this case consists of a Cartesian grid for the square $[-2,2]^2$ with 61×61 grid points, and an annular grid centered at the origin with inner radius $\frac{1}{2}$, with outer radius $\frac{3}{4}$, and containing 81×5 grid points. The grids $\mathcal{G}_2$ and $\mathcal{G}_4$ are, respectively, two and four times finer in each direction. PEC boundary conditions are taken on all boundaries. The results in the table show that the solution is converging at a rate close to 4 in the maximum norm. The nondimensionalized divergence in $\mathbf{E}$, defined as $\delta_{\mathbf{E}} = \|\nabla \cdot \mathbf{E}\|_\infty / \|\nabla \mathbf{E}\|_\infty$, is small and also converging at a rate close to 4. The convergence rate σ was estimated by assuming an error of the form $E = Ch^\sigma$ and making a least squares fit for σ to the equation $\log(E) = \sigma \log(h) + \log(C)$.

TABLE 1

Convergence rates for a two-dimensional cylinder in a channel grid. The maximum errors in E_x, E_y, H_z and $\delta_{\mathbf{E}} = \|\nabla \cdot \mathbf{E}\|_\infty / \|\nabla \mathbf{E}\|_\infty$ are shown at $t = 1$ for a trigonometric exact solution. The estimated convergence rate, $E \propto h^\sigma$, is also indicated.

Table 2 shows convergence results for solutions computed on a sphere in a box domain. The coarse grid, $\mathcal{G}_1$, in this case consists of three grids. A Cartesian grid covers the cube $[-2,2]^3$ with 41^3 grid points. The sphere of radius $\frac{1}{2}$ is covered with two overlapping orthographic patches, each with $33 \times 33 \times 13$ grid points. The grids $\mathcal{G}_2$ and $\mathcal{G}_4$ are, respectively, two and four times finer in each direction. The fine grid $\mathcal{G}_4$ has about 6.4 million grid points. PEC boundary conditions are taken on all boundaries. The results in the table show the maximum errors and estimated convergence rates. The convergence rates for the errors in $\mathbf{E}$ are close to 4. The convergence rate for $\delta_{\mathbf{E}}$ is approximately 3.5, which is still reasonable considering that this quantity is derived from derivatives of the computed variables.

TABLE 2

Convergence rates for a three-dimensional sphere in a box domain. The maximum errors in E_x, E_y, E_z and the nondimensionalized divergence $\delta_{\mathbf{E}}$ are shown at $t = 1$ for a trigonometric exact solution. The estimated convergence rate, $E \propto h^{\sigma}$, is also indicated.

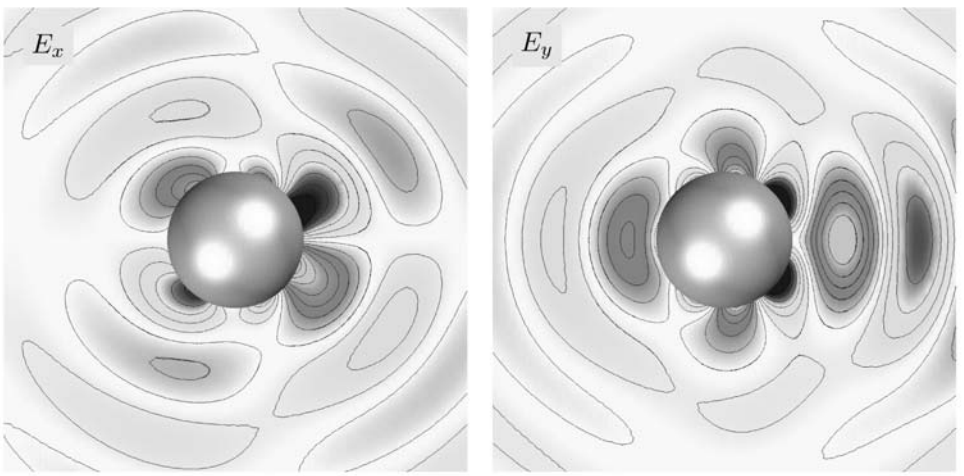

FIG. 6. *Scattering of a plane wave by a perfectly conducting sphere. The scattered fields for E_x and E_y are shown.*

10.2. Scattering by a PEC sphere. The scattering of an incident plane wave $\mathbf{E}^I = \left(e^{i(kx-\omega t)}, 0, 0\right)$ by a sphere of radius a is considered. The exact Mie series solution is well known [42]. The given incident field can be subtracted out, leaving the solution to the scattered field to be determined. A PEC boundary condition is imposed on the surface of the sphere, taking into account the incident field that has been removed. The initial conditions are taken as the exact solution for the scattered field at times $t = -\Delta t$ and $t = 0$. The exact solution is imposed on the outer boundaries of the domain. The solution is integrated to time $t = 3$. The grids, $\mathcal{G}_1$, $\mathcal{G}_2$, and $\mathcal{G}_4$, used for the sphere in a box are the same as those described in section 10.1. Table 3 presents the maximum errors and estimated convergence rates. The computed values of $\mathbf{E}$ are converging at rates close to 4. Figure 6 shows the scattered field for an incident wave with $ka = \pi$.

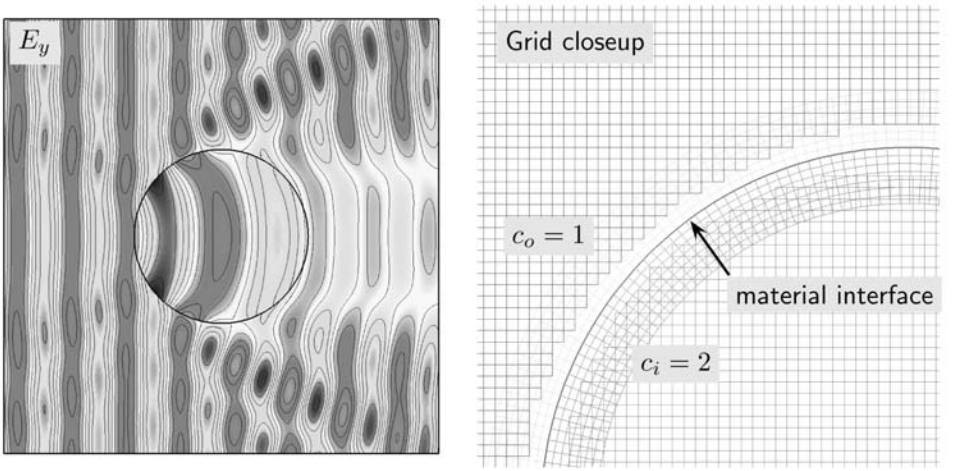

FIG. 7. *Scattering of a plane wave by a dielectric cylinder for* $ka = 4\pi$, $c_o = 1$, *and* $c_i = 2$. *The field component* E_y *is shown for the solution computed on grid* $\mathcal{G}_4$. *A closeup of the grid* $\mathcal{G}_2$ *near the interface is shown.*

10.3. Scattering of a plane wave by a dielectric cylinder. The two-dimensional computation of a plane wave hitting a dielectric (insulating) cylindrical disk possessing different material properties is used to test the accuracy of the material interface conditions presented in section 7. Consider a plane wave, $(E_x^I, E_y^I, H_z^I) = (0, \frac{\omega}{k}e^{i(kx-\omega t)}, e^{i(kx-\omega t)})$, incident upon a dielectric cylinder of radius a. Let ϵ_i be the electric permittivity for the region interior to the cylinder, let ϵ_o be the electric permittivity for the region outside the cylinder, and let $m = \sqrt{\epsilon_i/\epsilon_o} = c_o/c_i$ be the relative index of refraction for the dielectric. (The magnetic permeability μ is assumed to be the same in both materials.) The solution for the magnetic field in terms of the incident, scattered field and dielectric field is known as a series solution; see Balanis [2] or van de Hulst [42]. A closeup of the grid used in this computation is shown in Figure 7. The coarse grid, $\mathcal{G}_1$, for this domain consists of four component grids. A Cartesian grid covers the domain $[-1,1]^2$ with 81×81 grid points. An annular grid of inner radius $a = \frac{1}{2}$ and radial width .0875 covers the region immediately adjacent and exterior to the circle of radius $\frac{1}{2}$, centered at the origin. A second annular grid with the same radial width and grid spacing covers the region just inside the circle, and a second Cartesian grid lies in the central region. The refined versions of the grids are $\mathcal{G}_2$ and $\mathcal{G}_4$. The width of the annular grids are decreased by the same factor of 2 as the grids are refined so that 6 grid points remain in the radial direction. The initial conditions at $t = 0$ and $t = -\Delta t$ are taken as the exact solution. The boundary condition on the outer boundaries is also taken as the exact solution.

Table 4 shows convergence results for the scattering of a plane wave by the dielectric cylinder for an incident wave number of $ka = 4\pi$ with $c_o = 1$ and $c_i = 2$. The fourth-order accuracy of the method is evident. The E_y component of the computed solution is shown in Figure 7. Note that the tangential component of the field is continuous at the interface, but there is a jump in the normal component.

10.4. Computing eigenvalues of a disk and an L-shaped domain. The main focus of this paper has been on the solution of the time domain equations. In

TABLE 4
Maximum errors at $t = 1$ in computing the scattering of a plane wave by a dielectric cylinder. The incident wave number was $ka = 4\pi$, with $\epsilon = 1/4$ inside the cylinder and $\epsilon = 1$ in the region exterior to the cylinder.

this section the computation of the frequency domain eigenvalues and eigenvectors will be briefly considered. Of particular interest will be the behavior of the scheme in computing approximations to the highly singular solutions of a problem with a reentrant corner.

The eigenvalue problem for Maxwell's equations is posed as

$$-\Delta \mathbf{E} = \lambda \mathbf{E}, \qquad \mathbf{x} \in \Omega, \tag{10.3}$$

$$\mathbf{n} \times \mathbf{E} = 0, \quad \nabla \cdot \mathbf{E} = 0, \qquad \mathbf{x} \in \partial\Omega. \tag{10.4}$$

This formulation is sometimes called the "regularized" eigenvalue problem [18, 8] since the operator $\nabla \times \nabla$ has been replaced by the more [illegible] operator $-\Delta$. This problem is discretized following the approximations and boundary conditions given in section 9, resulting in the generalized matrix eigenvalue problem $Ax = \lambda Mx$. The smallest eigenvalues of this system are determined using ARPACK [31]. Note that the eigenvalue problem (10.3)–(10.4) admits solutions with nonzero $\nabla \cdot \mathbf{E}$ (corresponding to the Dirichlet eigenvalues of the $-\Delta$ operator). These eigenvalues are removed as a postprocessing step. Alternatively the original formulation (10.3)–(10.4) can be altered to eliminate these eigenvalues [17].

As a first example, consider the computation of the eigenvalues for the domain consisting of the unit disk, $\Omega = \{\mathbf{x} \in \mathbb{R}^2 \mid |\mathbf{x}| \le 1\}$. The exact eigenvalues and eigenvectors for this problem are easily determined. The coarse grid, $\mathcal{G}_1$, for this case consists of a Cartesian grid for the square $[-.7, .7]^2$ with 25×25 grid points, and an annular grid centered at the origin with inner radius $\frac{3}{4}$ and outer radius 1 and containing 61×7 grid points. Grids $\mathcal{G}_2$ and $\mathcal{G}_4$ have two and four times as many points in each direction. Figure 8 shows the coarse grid $\mathcal{G}_1$, the E_y component of the eigenvector for the smallest eigenvalue, and the relative errors in the first five eigenvalues for the three different grids. The relative error is defined as the difference between the computed value and the true value, divided by the true value. It is seen that the eigenvalues are computed very accurately with the values converging at a rate close to fourth-order.

As a second problem, the eigenvalues will be computed for the L-shaped domain $\Omega = [-1, 1]^2 - [-1, 0]^2$. This problem is quite difficult due to the highly singular nature of some of the eigenfunctions. The eigenfunction corresponding to the smallest eigenvalue, for example, becomes unbounded at the corner. It is known [8] that many straightforward finite-difference and finite element approximations to the eigenvalue problem for a problem with a reentrant corner will fail to approximate some of the singular eigenfunctions (those that become unbounded), and the corresponding eigenvalues will be missing entirely from the discretized equations. There are a number of proposed fixes to this problem including adding new degrees of freedom based on singular functions [8] or the use of a weighted regularization [5]. Note that both of

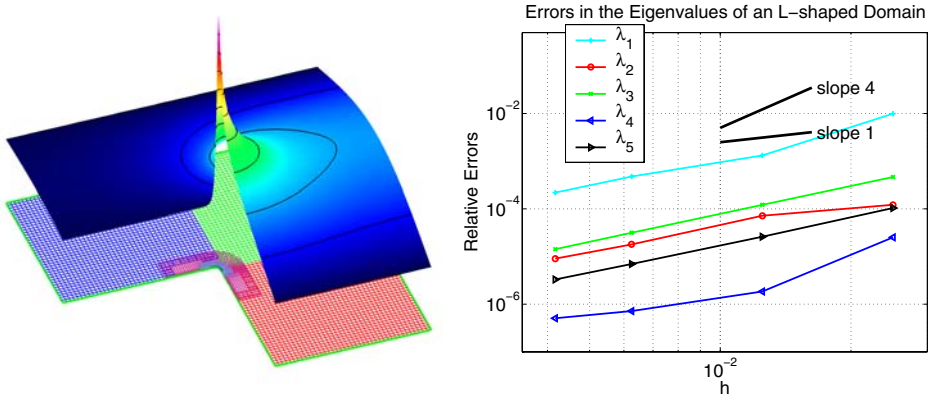

FIG. 9. *Solving the eigenvalue problem for an L-shaped domain. Left: the coarse grid $\mathcal{G}_1$ and the component E_x of the eigenvector for the smallest eigenvalue. The reentrant corner is rounded off slightly and refined. Right: the relative errors in the smallest five eigenvalues for three different grid spacings.*

these latter approaches could likely be adapted to the current discretization if so desired. The use of edge elements [33] and a sufficiently fine grid will not have these difficulties.

For the case here using overlapping grids, the corner problem will be dealt with by introducing a domain with a slightly rounded corner as shown in Figure 9. The radius of curvature of the rounded corner can be made as small as desired, given a sufficiently fine grid. This use of smooth boundary approximations to corners with large opening angles is one that the author generally recommends for other classes of problems as well. The coarse grid, $\mathcal{G}_1$, for the L-shaped domain consists of a total of six grids. There are three Cartesian grids for the three square domains $[-1,0]\times[0,1]$, $[0,1]^2$, and $[0,1]\times[-1,0]$, each with 41×41 points. A small boundary fitted grid with 64×14 points is added to define a smooth rounded corner. Two additional nested refinement grids with 80×17 and 100×21 are added to this boundary fitted grid (see

Figure 9). The boundary fitted grid is defined by an analytic function involving the logarithm of hyperbolic cosine functions [19]. Finer grids $\mathcal{G}_2$, $\mathcal{G}_4$, and $\mathcal{G}_6$ have two, four, and six times as many points in each direction.

Figure 9 shows the relative errors in computing the first 5 of the smallest eigenvalues for the L-shaped domain. The coarse grid $\mathcal{G}_1$ is shown along with the E_x component of the eigenvector corresponding to the smallest eigenvalue. The eigenvalues for the L-shaped domain correspond to the eigenvalues of the Neumann problem for the $-\Delta$ operator and have been computed very accurately[3] (see Table 5). The relative errors shown in the figure and table are for the computed eigenvalues of the rounded domain compared to these accurate values for the domain with a sharp corner. The results from Figure 9 indicate that all of the smallest eigenvalues can be computed with reasonable accuracy. The convergence rates are between first- and second-order accurate rather than fourth-order. This might be expected since the solutions and gradients are very large and not fully resolved. The eigenvalues of the rounded domain will also be slightly different from the domain with a sharp corner. It may be possible to improve the convergence rates by a more careful choice of grid or by incorporating knowledge of the singularity, following the approaches mentioned earlier.

The numerical values of the computed eigenvalues for the rounded corner are compared to the "exact" values for a sharp corner in Table 5. Note that the imaginary parts of these computed eigenvalues are all found to be zero (to double precision accuracy). The matrix system $Ax = \lambda Mx$ for the generalized eigenvalue problem will not in general be completely symmetric on an overlapping grid, and thus there may be some eigenvalues with an imaginary part. It is expected that some high-frequency eigenvalues will have an imaginary part; these will correspond to the weakly unstable modes for the time-dependent problem. A high-order dissipation is added to the time domain algorithm to remove this instability (discussed in section 9.2).

10.5. Serial performance and memory usage. The performance of the **mx** solver on two problems, one two-dimensional and one three-dimensional, is given in Table 6. The two-dimensional problem is for a circle in a channel grid. The three-dimensional problem considered the computation in the pill-box geometry shown in Figure 10. The table indicates the amount of time that is spent in various parts of the code. In the two-dimensional case, close to 70% of the time is spent in the Fortran kernel that advances the solution on the interior points of the Cartesian grid. Advancing the solution on the curvilinear grids takes about 14%, while applying the boundary conditions on all grids takes about 11%. These results show that the overall

performance of the code is approaching that of a purely Cartesian grid solver, provided that a sufficiently high percentage of the grid points are Cartesian grid points.

In three dimensions, the advancement of the curvilinear grids takes the most time at about 48% with the Cartesian grids taking 28% and boundary conditions and interpolation taking a total of about 22%. In three dimensions the cost of advancing the curvilinear grid with a fourth-order approximation is on the order of 10 times slower per grid point than for a Cartesian grid. As the grids are refined the percentage of Cartesian grid points will increase since the number of Cartesian grid points scales like N^3, while the number of curvilinear grid points grows like N^2 (assuming that the curvilinear boundary fitted grids retain a fixed number of grid points in the normal direction as the grids are refined). Thus for sufficiently fine grids in three dimensions it can be expected that the time will be dominated by the work done on Cartesian grids.

Table 7 gives the computer memory usage of the **mx** code for solving Maxwell's equations, to fourth-order accuracy, on the three-dimensional pill-box example of Figure 10. The table indicates the amount of memory required in MBytes for a double precision (64-bit) computation and the number of double precision floating point numbers required per grid point, denoted by reals/point. The number of reals/point for this computation was about 12.6. Only the **E** field was computed in this case. About 18% of the memory was dedicated to the storage of the overlapping grid (grid metrics, masks, etc.). To put these numbers in context, note that if the Cartesian grids were treated as general curvilinear grids, then the storage of the Jacobian matrix $\partial\mathbf{x}/\partial\mathbf{r}$ on the entire grid would itself require 9 reals/point. The **mx** solver is therefore seen to be quite memory efficient.

TABLE 7

Memory usage for the three-dimensional pill-box problem solved in double precision with the fourth-order accurate approximation. The grid for this problem contained about 10.2 *million grid points with about* 4.2e5 *interpolation points. The number of double precision floating point numbers required per grid point was about* 12.6 *(reals/pt). About* 17.8% *of the memory was dedicated to the storage of the overlapping grid (grid metrics, masks, etc.).*

11. Conclusions. A scheme has been presented for the solution of the time-dependent Maxwell equations in complex geometries. The approach uses overlapping grids with a typical grid consisting of one or more background Cartesian grids overlapping body fitted curvilinear grids. Maxwell's equations are solved as a second-order vector wave equation. A three-level time-stepping scheme is used that can generate methods of orders 2, 4, 6, and higher. High-order accurate symmetric finite-difference approximations to the generalized Laplace operator have been developed. These approximations are symmetric on arbitrary logically rectangular curvilinear grids. Implementations of these operators in two and three dimensions for orders 2, 4, 6, and 8 are shown to give energy-preserving results when solving Maxwell's equations on a square and a box with randomly perturbed grid points. High-order accurate centered boundary conditions for PEC boundaries have been devised. High-order accurate centered boundary conditions have also been developed for material interfaces that

separate regions with constant values of the material properties. The interfaces are represented with overlapping grids, using boundary fitted grids on each side of the interface. These centered boundary conditions are based on compatibility conditions derived from the governing equations. The stability and accuracy of the fourth-order accurate PEC approximations are analyzed for a model problem on a periodic strip. The stability of the material interface conditions are analyzed for a one-dimensional model problem for a second- and a fourth-order approximation.

The approach has been implemented for computations on distributed memory multiprocessor machines. The arrays holding the solution variables and grid metrics on each component grid are distributed across one or more processors. An efficient parallel interpolation scheme has been developed for communicating the interpolation information where component grids overlap. Results from some parallel computations show that the algorithm scales well.

Numerical results for a number of two- and three-dimensional problems are used to verify the accuracy of the fourth-order accurate version of the method. The method of analytic solutions is used to generate [illegible] solutions to the forced equations and verify the convergence rates. The scattering of a plane wave by a three-dimensional sphere is computed and shown to converge to fourth-order accuracy compared to the exact series solution. The material interface boundary conditions are verified to be fourth-order accurate for the scattering of a plane wave by a dielectric cylinder. The frequency domain eigenvalue problem is discretized using the fourth-order accurate approximations. Eigenmodes and eigenvalues of a two-dimensional disk and an L-shaped domain are determined. By rounding the sharp reentrant corner of the L-shaped domain, the method is able to compute accurate approximations to the eigenvalues of the highly singular eigenmodes. Statistics presented from some representative computations show that the method is very efficient in both speed and memory, especially when the overlapping grid for the domain consists mainly of Cartesian grid points. In that case the performance of the method can approach that of a Cartesian grid solver.

The **mx** Maxwell solver has been implemented using the Overture framework that has support for adaptive mesh refinement, moving grids and fast multigrid solvers for elliptic equations [22, 21]. These capabilities of Overture may be useful for future extensions of the Maxwell solver. Far-field radiation conditions for boundaries of the computational domain that have been artificially truncated are an important consideration. The treatment of these far-field boundary conditions in conjunction with the present approach is left to a future publication. The general approach developed here can also be applied to other systems that take the form of a second-order wave equation, such as the equations of elasticity.

Acknowledgments. The author would like to thank Professor Heinz-Otto Kreiss for many useful discussions. Thanks also to Kyle Chand for help with the **mx** solver.

AN UNSTAGGERED, HIGH-RESOLUTION CONSTRAINED TRANSPORT METHOD FOR MAGNETOHYDRODYNAMIC FLOWS*

JAMES A. ROSSMANITH†

Abstract. The ideal magnetohydrodynamic (MHD) equations are important in modeling phenomena in a wide range of applications, including space weather, solar physics, laboratory plasmas, and astrophysical fluid flows. Numerical methods for the MHD equations must confront the challenge of producing approximate solutions that remain accurate near shock waves and that satisfy a divergence-free constraint on the magnetic field. Failure to accomplish this often leads to unphysical solutions. In this paper, a high-resolution wave propagation method is developed that utilizes a novel constrained transport technique to keep the magnetic field divergence-free. This approach is based on directly solving the magnetic potential equation in conjunction with a new limiting strategy to obtain a nonoscillatory magnetic field. It is demonstrated in this work that an unstaggered definition of the divergence is the correct one to use in the case of wave propagation methods. Therefore, we solve the magnetic potential equation on the same grid as the MHD equations; hence the usual grid staggering that is found in constrained transport methods is eliminated. We demonstrate through truncation error analysis and direct numerical simulation that the resulting method is second order accurate in space and time for smooth solutions and nonoscillatory near shocks and other discontinuities. The resulting numerical method has been implemented as an extension to the CLAWPACK software package and can be freely downloaded from the Web.

1. Introduction.

The ideal magnetohydrodynamic (MHD) equations model the dynamics of an electrically conducting fluid. In conservation form, the MHD system can be written as

$$\frac{\partial}{\partial t}\begin{bmatrix}\rho\\ \rho\vec{u}\\ \mathcal{E}\\ \vec{B}\end{bmatrix} + \vec{\nabla}\cdot\begin{bmatrix}\rho\vec{u}\\ \rho\vec{u}\otimes\vec{u} + \left(p+\frac{1}{2}|\vec{B}|^2\right)\mathcal{I} - \vec{B}\otimes\vec{B}\\ \vec{u}\left(\mathcal{E}+p+\frac{1}{2}|\vec{B}|^2\right) - \vec{B}(\vec{u}\cdot\vec{B})\\ \vec{u}\otimes\vec{B} - \vec{B}\otimes\vec{u}\end{bmatrix} = 0, \tag{1.1}$$

$$\vec{\nabla}\cdot\vec{B} = 0\,, \tag{1.2}$$

where

$$p = (\gamma-1)\left(\mathcal{E} - \frac{1}{2}\rho|\vec{u}|^2 - \frac{1}{2}|\vec{B}|^2\right). \tag{1.3}$$

Here ρ is the mass density, $\vec{u} = (u_1, u_2, u_3)^t$ is the velocity field, $\mathcal{E}$ is the total energy, $\vec{B} = (B_1, B_2, B_3)^t$ is the magnetic field, p is the thermal pressure, $(1/2)|\vec{B}|^2$ is the magnetic pressure, and γ is the ideal gas constant. Equation (1.3) is the [illegible] for an ideal gas and closes the system by relating the pressure to the other

unknowns. See, for example, Chapter 4 of Gombosi [19] for a detailed derivation of these equations.

The ideal MHD equations form a system of hyperbolic conservation laws, (1.1), with a constraint, (1.2). Furthermore, any [illegible] solution to (1.1) automatically satisfies (1.2) provided that the initial magnetic field obeys the divergence-free constraint (see, for example, [24]). Most numerical discretizations of (1.1), however, can guarantee only that the divergence of the magnetic field is of the order of the numerical truncation error:

$$\vec{\nabla} \cdot \vec{B} = \mathcal{O}(\Delta x^p, \Delta y^p). \tag{1.4}$$

Furthermore, across shock waves the discrete divergence may become very large:

$$\vec{\nabla} \cdot \vec{B} = \mathcal{O}(\Delta x^{-1}, \Delta y^{-1})\,. \tag{1.5}$$

Brackbill and Barnes [8] showed that this error can lead to spurious solutions. It has been shown several times in the literature that for shock-capturing schemes, failure to satisfy the divergence-free constraint can lead to unphysical oscillations near shocks and other discontinuities. These oscillations can in turn lead to the production of negative pressures. See Tóth [38] for a review.

In order to overcome the difficulty associated with the divergence error, several methods have been introduced. The first approach used was the projection method of Brackbill and Barnes [8], which makes use of a Poisson solver in each time step in order to project a predicted magnetic field down to its divergence-free subspace. For example, this approach was recently used by Balbas, Tadmor, and Wu [2] in conjunction with various central schemes to evolve the fluid variables. Zachary, Malgolin, and Collela [43] proposed a method that splits the MHD equations into a conservative and an advective part; the advective part is moved to the right-hand side and treated as a source term. In Powell's method [34, 35] a source term proportional to the divergence of the magnetic field is added, which causes any divergence error to propagate with the fluid velocity. This source term was first used by Godunov [18] to symmetrize the MHD system. Dedner et al. [11] introduced an additional hyperbolic equation with damping in order to control the divergence error. Yee and Sjögreen [41] introduced a high-order method with special divergence filtering. Fey and Torrilhon [14] and Torrilhon [40] developed a multidimensional limiting procedure that selects which discrete divergence is satisfied in each grid cell. Aslan [1] introduced a fluctuation splitting scheme for MHD on unstructured grids; the divergence-free condition is handled through the same source term as in Powell's approach. In this work we focus on the [illegible] (CT) framework of Evans and Hawley [13], which is based on the method of Yee [42] for Maxwell's equations. In this approach the numerical discretization is carefully chosen so that a divergence-free constraint is automatically satisfied to machine precision. The overall method is based on modifying a cell-centered finite volume method (called the [illegible]) in such a way that it satisfies a divergence-free constraint. The base scheme we will use is the Riemann solver–based wave propagation method [27].

The CT method of Evans and Hawley [13] provides a general framework for solving the ideal MHD equations so that the magnetic field satisfies a discrete divergence-free condition. The basic idea of their approach is to introduce a staggered magnetic field at cell faces (edges in two dimensions) and a staggered electric field at cell edges (corners in two dimensions) in such a way that the overall update for the magnetic field conserves a discrete definition of the divergence. The framework has built into it some

degrees of freedom that can be exploited in order to devise a specific numerical update. Several such methods have been proposed in the literature [5, 6, 10, 32, 33, 36, 12]. Furthermore, unstaggered variants of some of these methods were introduced by Tóth [38].

In this work we present a new CT scheme that updates the magnetic potential in a fundamentally different way than that of existing methods. In line with the methods of Balsara [5] and Londrillo and Del Zanna [33], the method proposed here tries to achieve an update for the magnetic field that preserves not only a divergence-free property, but also a quantifiable measure of the total variation. The basic features of the proposed method are summarized below:

1. The evolution equation for the magnetic potential is written as a system of first order hyperbolic equations. This system reduces to a scalar advection equation in two space dimensions.
2. The magnetic potential is updated with a high-resolution upwind method modified from the method of LeVeque [26].
3. Limiters are applied in such a way as to minimize the oscillations in both the magnetic potential and the magnetic field. Mathematical justification is provided for the choice of this limiting procedure.
4. The method is completely unstaggered; this makes the method simpler and reduces the amount of averaging in the numerical scheme. Analysis of the Lorentz force is provided that gives mathematical justification for the choice of the discrete divergence that is conserved.

2. The 8-wave Riemann solver. The numerical methods considered in this paper are based on the solution of one-dimensional (1D) [illegible]. In particular, we make use of [illegible], Roe-type Riemann solvers [30], which require us to compute wave decompositions. The specific Riemann solvers we consider in this paper are based on the 8-wave Riemann solver of Powell [34, 35]. Note that we are only using the wave decomposition of Powell and are not including the source terms of [34, 35] in our evolution equations.

For smooth solutions, the MHD equations can be rewritten in the following quasi-linear form:

$$\frac{\partial U}{\partial t} + A_1 \frac{\partial U}{\partial x} + A_2 \frac{\partial U}{\partial y} = 0\,,$$

where $U = (\rho, u_1, u_2, u_3, p, B_1, B_2, B_3)$ is the vector of primitive variables. The matrices A_1 and A_2 are 8×8 diagonalizable matrices with real eigenvalues:

$$A_m = R_m \Lambda_m L_m\,,$$

where $m = 1, 2$. R_m is the matrix of right eigenvectors, Λ_m is the diagonal matrix of eigenvalues, and $L_m = R_m^{-1}$ is the matrix of left eigenvectors. The exact form of A_1 and A_2 as well as their right and left eigenvectors can be found in [35]. The matrices A_m are related to the flux Jacobians, $\partial f^m/\partial q$, through a similarity transform:

$$\frac{df^m}{dq} = S A_m S^{-1},$$

where $S = \frac{dq}{du}$ [35].

The eigenvalues of A_m represent the wave speeds of the eight waves present in the MHD system,

$$\begin{aligned}
\lambda^{1,8} &= u_m \mp c_f &&: \text{fast magnetosonic waves,}\\
\lambda^{2,7} &= u_m \mp c_a &&: \text{Alfvén waves,}\\
\lambda^{3,6} &= u_m \mp c_s &&: \text{slow magnetosonic waves,}\\
\lambda^{4} &= u_m &&: \text{entropy wave,}\\
\lambda^{5} &= u_m &&: \text{divergence wave,}
\end{aligned}$$

where

$$\begin{aligned}
a &\equiv \sqrt{\frac{\gamma p}{\rho}},\\
c_a &\equiv \sqrt{\frac{B_m^2}{\rho}},\\
c_f &\equiv \left\{ \frac{1}{2}\left[a^2 + \frac{|\vec{B}|^2}{\rho} + \sqrt{\left(a^2 + \frac{|\vec{B}|^2}{\rho} \right)^2 - 4a^2 \frac{B_m^2}{\rho}} \right] \right\}^{1/2},\\
c_s &\equiv \left\{ \frac{1}{2}\left[a^2 + \frac{|\vec{B}|^2}{\rho} - \sqrt{\left(a^2 + \frac{|\vec{B}|^2}{\rho} \right)^2 - 4a^2 \frac{B_m^2}{\rho}} \right] \right\}^{1/2}.
\end{aligned}$$

The eigenvalues are well ordered in the sense that

$$\lambda^1 \le \lambda^2 \le \lambda^3 \le \lambda^4 \le \lambda^5 \le \lambda^6 \le \lambda^7 \le \lambda^8 .$$

The fast and slow magnetosonic waves are genuinely nonlinear, while the remaining waves are linearly degenerate.

Although it is possible to compute the Roe averages for the ideal MHD equations using the strategy of Cargo and Callice [9], we will instead base our approximate Riemann solver on simple arithmetic averages of the primitive variables. These are computationally less expensive to evaluate than the Roe averages presented in [9] and give good accuracy in practice (see section 7).

3. The high-resolution wave propagation method. The CT schemes that will be discussed in sections 4 and 5 all require an underlying [illegible] for solving the ideal MHD equations. The base scheme considered in this work is the high-resolution wave propagation method of LeVeque [27] in conjunction with the flux-based wave decomposition approach of [4]. The wave propagation method is based on solving 1D Riemann problems and then using the solutions from these Riemann problems to obtain an update that is second order accurate for smooth solutions, numerically conservative, shock-capturing, and stable up to a CFL number of one. This method has in the past been successfully applied to several application problems, including acoustics [15, 17], linear elasticity [16], nonlinear elasticity [29], shallow water waves [28], incompressible fluid dynamics [25], combustion and detonation waves [22, 23], relativistic hydrodynamics [3], and numerical relativity [7]. We should note that although we make use of this particular base scheme, we argue in section 5 that the CT method proposed in this work can be used independent of this choice.

The wave propagation of LeVeque [27] is a numerical method for approximately solving hyperbolic conservation laws of the form

$$\frac{\partial q}{\partial t} + \frac{\partial}{\partial x} f^1(q) + \frac{\partial}{\partial y} f^2(q) = 0. \tag{3.1}$$

The method can be obtained by first constructing a second order accurate Taylor series in time,

$$\begin{aligned} q(x,y,t+\Delta t) &= q(x,y,t) + \Delta t \frac{\partial q}{\partial t}(x,y,t) + \frac{1}{2}\Delta t^2 \frac{\partial^2 q}{\partial t^2}(x,y,t) + \mathcal{O}(\Delta t^3) \\ &= q - \Delta t \left(f^1_x + f^2_y\right) + \frac{1}{2}\Delta t^2 \Big\{ \left(A f^1_x\right)_x + \left(B f^2_y\right)_y \\ &\quad + \left(A f^2_y\right)_x + \left(B f^1_x\right)_y \Big\} + \mathcal{O}(\Delta t^3), \end{aligned} \tag{3.2}$$

where $A = \partial f^1/\partial q$, $B = \partial f^2/\partial q$, and we have used the evolution equation to turn time derivatives into spatial derivatives. After discretizing in space, the general update in two dimensions is

$$\begin{aligned} Q^{n+1}_{ij} = Q^n_{ij} &- \frac{\Delta t}{\Delta x}\left[\mathcal{A}^-_1 \Delta Q_{i+1/2,j} + \mathcal{A}^+_1 \Delta Q_{i-1/2,j}\right] \\ &- \frac{\Delta t}{\Delta y}\left[\mathcal{A}^-_2 \Delta Q_{i,j+1/2} + \mathcal{A}^+_2 \Delta Q_{i,j-1/2}\right] \\ &- \frac{\Delta t}{\Delta x}\left[\tilde{F}^1_{i+1/2,j} - \tilde{F}^1_{i-1/2,j}\right] - \frac{\Delta t}{\Delta y}\left[\tilde{F}^2_{i,j+1/2} - \tilde{F}^2_{i,j-1/2}\right], \end{aligned} \tag{3.3}$$

where $\mathcal{A}^-\Delta Q$ and $\mathcal{A}^+\Delta Q$ are [illegible] and $\tilde{F}^1$ and $\tilde{F}^2$ are [illegible]. The wave propagation method is constructed so that the fluctuations contain corrections needed for a first order upwind update (approximates terms with one x or one y derivative) and $\tilde{F}^1$ and $\tilde{F}^2$ contain higher-resolution (approximates terms with two x or two y derivatives) and multidimensional corrections (approximates terms with cross derivatives) [27, 30].

3.1. First order upwind update. The fluctuations are constructed by solving locally linearized Riemann problems. At each cell interface $(x_{i-1/2}, y_j)$ we have to solve a 1D Riemann problem of the form

$$\frac{\partial q}{\partial t} + \tilde{A}_{i-1/2,j} \frac{\partial q}{\partial x} = 0, \tag{3.4}$$

$$q(x,0) = \begin{cases} Q_{i-1,j} & \text{if } x < x_{i-1/2}, \\ Q_{ij} & \text{if } x > x_{i-1/2}, \end{cases} \tag{3.5}$$

$$f^1(q,x) = \begin{cases} f^1_{i-1,j}(q) & \text{if } x < x_{i-1/2}, \\ f^1_{ij}(q) & \text{if } x > x_{i-1/2}, \end{cases} \tag{3.6}$$

where

$$\tilde{A}_{i-1/2,j} \approx \frac{\partial f^1}{\partial q}\left(q(\vec{x}_{i-1/2,j}, t), x_{i-1/2}, y_j\right) \tag{3.7}$$

is an approximate flux Jacobian that is considered to be constant in the Riemann problem. We denote the eigenvalues, right eigenvectors, and left eigenvectors of $\tilde{A}_{i-1/2,j}$ by $s^p_{i-1/2,j}$, $r^p_{i-1/2,j}$, and $\ell^p_{i-1/2,j}$.

In order to solve Riemann problem (3.4)–(3.5), the flux difference is decomposed along the eigenvectors of $\tilde{A}_{i-1/2,j}$. Based on these eigenvectors and eigenvalues, the fluctuations $\mathcal{A}_1^- \Delta Q_{i-1/2,j}$ and $\mathcal{A}_1^+ \Delta Q_{i-1/2,j}$ in (3.3) are assembled by summing all the components of the flux that are left- and right-going, respectively. Mathematically, we write

$$\Delta F^1_{i-1/2,j} = f^1_{ij}(Q_{ij}) - f^1_{i-1,j}(Q_{i-1,j}), \tag{3.8}$$

$$\mathcal{Z}^p_{i-1/2,j} = \left[\ell^p_{i-1/2,j} \cdot \Delta F^1_{i-1/2,j}\right] r^p_{i-1/2,j}, \tag{3.9}$$

$$\mathcal{A}_1^+ \Delta Q_{i-1/2,j} = \sum_{p:\, s^p_{i-1/2,j} > 0} \mathcal{Z}^p_{i-1/2,j} + \frac{1}{2} \sum_{p:\, s^p_{i-1/2,j} = 0} \mathcal{Z}^p_{i-1/2,j}, \tag{3.10}$$

$$\mathcal{A}_1^- \Delta Q_{i-1/2,j} = \sum_{p:\, s^p_{i-1/2,j} < 0} \mathcal{Z}^p_{i-1/2,j} + \frac{1}{2} \sum_{p:\, s^p_{i-1/2,j} = 0} \mathcal{Z}^p_{i-1/2,j}, \tag{3.11}$$

where we refer to $\mathcal{Z}^p_{i-1/2}$ as a [illegible] and $s^p_{i-1/2,j}$ as a [illegible]. An analogous procedure is carried out in the 2-direction in order to obtain $\mathcal{A}_2^- \Delta Q_{i,j-1/2}$ and $\mathcal{A}_2^+ \Delta Q_{i,j-1/2}$.

It is well known that linearized Riemann solvers can fail in the case where the exact solution to the Riemann problem is a transonic rarefaction (see [30] for more discussion). In order to avoid this difficulty we make use of an entropy fix similar to the one introduced by Harten and Hyman [21].

3.2. Correction fluxes. To obtain second order accuracy for smooth flows, [illegible] corrections of the following form are constructed:

$$\tilde{F}^1_{i-1/2,j} = \frac{1}{2} \sum_{p=1}^{M} \operatorname{sign}(s^p_{i-1/2,j}) \left(1 - \frac{\Delta t}{\Delta x} \left| s^p_{i-1/2,j} \right| \right) \mathcal{Z}^p_{i-1/2}\, \phi_{i-1/2,j}\,, \tag{3.12}$$

where ϕ is a total variation diminishing (TVD) wave limiter function. The wave limiter allows the method to switch between a second order method in smooth regions of the solution and a first order method near discontinuities [30]. To make this method stable up to a CFL number of one without dimensional splitting, [illegible] corrections based on solving transverse Riemann problems are added to the numerical fluxes. For more details on these corrections, we refer the reader to [26, 27, 30].

4. Constrained transport. Because the magnetic field satisfies a divergence-free condition, it can always be written as the curl of a magnetic potential:

$$\vec{B} = \vec{\nabla} \times \vec{\mathbb{A}}. \tag{4.1}$$

Using the magnetic potential, the evolution equations for the magnetic field in (1.1), this can be rewritten as follows:

$$\frac{\partial \vec{\mathbb{A}}}{\partial t} + \vec{\Omega} = 0, \tag{4.2}$$

where $\vec{\Omega}$ is the electric field, and

$$\vec{\Omega} = \vec{B} \times \vec{u} \tag{4.3}$$

is Ohm's law for a perfect conductor [19].

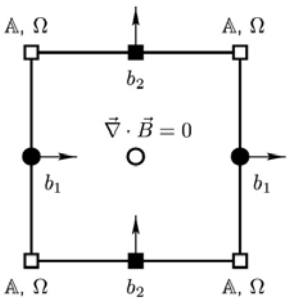

FIG. 4.1. *Grid staggering for the CT framework of Evans and Hawley* [13].

In 2 or 2.5 dimensions[1] we need only keep track of the z-components of the magnetic potential, $\mathbb{A}$, and the electric field, Ω, such that

$$\Omega = (\vec{B}\times\vec{u})\cdot\hat{k} = -u_1B_2 + u_2B_1, \tag{4.4}$$

and

$$B_1 = \frac{\partial\mathbb{A}}{\partial y} \qquad \text{and} \qquad B_2 = -\frac{\partial\mathbb{A}}{\partial x}.$$

Note that in 2.5 dimensions, the B_3 component of the magnetic field does not need to be computed from a potential, since the divergence of $\vec{B}$ in 2.5 dimensions involves only B_1 and B_2.

Independent of the dimension, the key property of the magnetic potential is that if it is known, a divergence-free magnetic field can be directly computed from it. The constrained transport method introduced by Evans and Hawley [13] tries to take advantage of this property on a discrete numerical grid.

4.1. Staggered constrained transport. Evans and Hawley [13] introduced the following numerical grid staggering (see Figure 4.1):

$$\begin{aligned}
\text{at cell centers:} &\quad \rho_{ij},\ \rho\vec{u}_{ij},\ \mathcal{E}_{ij},\ \vec{B}_{ij},\\
\text{at cell corners:} &\quad \mathbb{A}_{i-1/2,j-1/2},\ \Omega_{i-1/2,j-1/2},\\
\text{at left/right edges:} &\quad [b_1]_{i-1/2,j},\\
\text{at top/bottom edges:} &\quad [b_2]_{i,j-1/2}\,.
\end{aligned}$$

If the magnetic potential is known, then the magnetic field at the cell edges can be computed in the following way:

$$[b_1]_{i-1/2,j} = \frac{1}{\Delta y}\Big(\mathbb{A}_{i-1/2,j+1/2} - \mathbb{A}_{i-1/2,j-1/2}\Big), \tag{4.5}$$

$$[b_2]_{i,j-1/2} = \frac{1}{\Delta x}\Big(\mathbb{A}_{i-1/2,j-1/2} - \mathbb{A}_{i+1/2,j-1/2}\Big). \tag{4.6}$$

It can be easily shown that with this definition of the magnetic field, the following discrete divergence-free condition is satisfied to machine precision:

$$\Big[\vec{\nabla}\cdot\vec{B}\Big]_{ij} \equiv \frac{[b_1]_{i+1/2,j} - [b_1]_{i-1/2,j}}{\Delta x} + \frac{[b_2]_{i,j+1/2} - [b_2]_{i,j-1/2}}{\Delta y} = 0. \tag{4.7}$$

[1]By 2.5 dimensions we mean that all three components of $\vec{u}$ and/or $\vec{B}$ are nonzero, but that all these components are functions of only x, y, and t.

In order to update the fluid variables, however, we also need a cell-centered representation of the magnetic field. This can be obtained through simple linear interpolation:

$$[B_1]_{ij} = \frac{1}{2}\Big([b_1]_{i+1/2,j} + [b_1]_{i-1/2,j}\Big), \tag{4.8}$$

$$[B_2]_{ij} = \frac{1}{2}\Big([b_2]_{i,j+1/2} + [b_2]_{i,j-1/2}\Big). \tag{4.9}$$

Tóth [38] showed that with these definitions, the cell-centered magnetic field also satisfies a discrete divergence-free condition:

$$\begin{aligned}\Big[\vec{\nabla}\cdot\vec{B}\Big]_{i+1/2,j+1/2} &\equiv \frac{[B_1]_{i+1,j} + [B_1]_{i+1,j+1} - [B_1]_{ij} - [B_1]_{i,j+1}}{2\Delta x} \\ &+ \frac{[B_2]_{i,j+1} + [B_2]_{i+1,j+1} - [B_2]_{ij} - [B_2]_{i+1,j}}{2\Delta y} = 0.\end{aligned} \tag{4.10}$$

In order to obtain a complete numerical method for the MHD equations, an update for the magnetic potential that couples to the other variables must be provided.

The full constrained transport algorithm can be summarized as follows:

Step 0. Primary quantities: $\rho^n,\ \rho\vec{u}^{\,n},\ \mathcal{E}^n,\ b_1^n,\ b_2^n,\ B_3^n,\ \mathbb{A}^n$.

Step 1. Average edge magnetic field:

$$\Longrightarrow [B_1]_{ij}^n = \tfrac{1}{2}\Big([b_1]_{i-1/2,j}^n + [b_1]_{i+1/2,j}^n\Big),$$
$$\Longrightarrow [B_2]_{ij}^n = \tfrac{1}{2}\Big([b_2]_{i,j-1/2}^n + [b_2]_{i,j+1/2}^n\Big).$$

Step 2. Solve the MHD equations using the base scheme:

$$\Longrightarrow \rho^{n+1},\ \rho\vec{u}^{\,n+1},\ \mathcal{E}^{n+1},\ \vec{B}^{\star}.$$

Step 3. Construct electric field at cell corners: $\Omega_{i-1/2,j-1/2}^{n+1/2}$.

Step 4. Update the magnetic potential:

$$\Longrightarrow \mathbb{A}_{i-1/2,j-1/2}^{n+1} = \mathbb{A}_{i-1/2,j-1/2}^{n} - \Delta t\,\Omega_{i-1/2,j-1/2}^{n+1/2}.$$

Step 5. Compute $\vec{\nabla}\times\vec{\mathbb{A}}$:

$$\Longrightarrow [b_1]_{i-1/2,j}^{n+1} = \tfrac{1}{\Delta y}\Big(\mathbb{A}_{i-1/2,j+1/2}^{n+1} - \mathbb{A}_{i-1/2,j-1/2}^{n+1}\Big),$$
$$\Longrightarrow [b_2]_{i,j-1/2}^{n+1} = \tfrac{1}{\Delta x}\Big(\mathbb{A}_{i-1/2,j-1/2}^{n+1} - \mathbb{A}_{i+1/2,j-1/2}^{n+1}\Big).$$

In other words, the algorithm says that we begin with cell-centered quantities ρ^n, $\rho\vec{u}^n$, b_1^n, b_2^n, B_3^n, and $\mathbb{A}^n$. The magnetic field is averaged to cell centers so that the ideal MHD equations can be solved with a high-resolution finite volume method. After updating the cell-centered quantities, an electric field at cell corners is constructed. This electric field is then used to update the magnetic potential. Finally, the magnetic potential is differenced and we obtain the updated magnetic field values.

In the above description of CT each step is clearly defined, with the exception of Step 3; in this step there are many options for how the electric field is constructed. Several methods have been proposed in the literature [6, 10, 36]. See Tóth [38] for a review. Additional staggered CT methods that are closely related to these methods but do not conform to the algorithm as described above were developed by De Sterck [12], Londrillo and Del Zanna [32, 33], and Balsara [5].

4.2. Unstaggered CT. One of the main drawbacks of the Evans and Hawley [13] formulation coupled to a cell-centered finite volume method is that one needs a dual representation of the magnetic field. In an adaptive mesh refinement framework, especially in three space dimensions, this makes the method somewhat cumbersome. In order to overcome this, Tóth [38] introduced fully cell-centered versions of the Evans and Hawley approach. These approaches do not require a cell edge magnetic field, and instead of conserving the divergence defined as in (4.7) they conserve the following cell-centered definition of the divergence:

$$\left[\vec{\nabla}\cdot\vec{B}\right]_{ij} \equiv \frac{[B_1]_{i+1,j}-[B_1]_{i-1,j}}{2\Delta x}+\frac{[B_2]_{i,j+1}-[B_2]_{i,j-1}}{2\Delta y}=0. \tag{4.11}$$

This is accomplished through the following definition of the magnetic field:

$$[B_1]_{ij}=\frac{1}{2\Delta y}\Big(\mathbb{A}_{i,j+1}-\mathbb{A}_{i,j-1}\Big), \tag{4.12}$$

$$[B_2]_{ij}=\frac{1}{2\Delta x}\Big(\mathbb{A}_{i-1,j}-\mathbb{A}_{i+1,j}\Big). \tag{4.13}$$

In this case, Step 1 in the constrained algorithm described in section 4.1 is completely eliminated. The modified algorithm can be written as follows:

Step 0. Primary quantities: $\rho^n,\ \rho\vec{u}^{\,n},\ \mathcal{E}^n,\ B_1^n,\ B_2^n,\ B_3^n,\ \mathbb{A}^n$.

Step 1. Solve the MHD equations using the base scheme:
$\Longrightarrow \rho^{n+1},\ \rho\vec{u}^{\,n+1},\ \mathcal{E}^{n+1},\ \vec{B}^{\star}$.

Step 2. Construct electric field at cell centers: $\Omega_{ij}^{n+1/2}$.

Step 3. Update the magnetic potential:
$\Longrightarrow \mathbb{A}_{ij}^{n+1}=\mathbb{A}_{ij}^{n}-\Delta t\,\Omega_{ij}^{n+1/2}$.

Step 4. Compute $\vec{\nabla}\times\vec{\mathbb{A}}$:
$$\Longrightarrow [B_1]_{ij}^{n+1}=\tfrac{1}{2\Delta y}\Big(\mathbb{A}_{i,j+1}^{n+1}-\mathbb{A}_{i,j-1}^{n+1}\Big),$$
$$\Longrightarrow [B_2]_{ij}^{n+1}=\tfrac{1}{2\Delta x}\Big(\mathbb{A}_{i-1,j}^{n+1}-\mathbb{A}_{i+1,j}^{n+1}\Big).$$

Tóth [38] introduced two separate techniques for constructing the electric field in Step 3; one is a variant of Balsara and Spicer [6], the other a variant of Dai and Woodward [10]. Tóth [38] found that the variant of Balsara and Spicer [6] is less accurate than the original method, because it introduces additional averaging of the numerical fluxes. The variant of Dai and Woodward [10] has less averaging than the original method and was therefore found to be more accurate.

4.3. Computing the initial potential. CT schemes require an initial magnetic potential. In many cases, however, the initial conditions will only be given in terms of the magnetic field, and it may be difficult to obtain an analytic form for the initial $\mathbb{A}$. In this case, we can compute the magnetic potential by solving a Poisson equation of the form [24]

$$\vec{\nabla}\times\vec{B}=\vec{\nabla}\times\vec{\nabla}\times\vec{\mathbb{A}}=\vec{\nabla}\left(\vec{\nabla}\cdot\vec{\mathbb{A}}\right)-\nabla^2\vec{\mathbb{A}},$$
$$\Longrightarrow\quad \nabla^2\vec{\mathbb{A}}=-\vec{\nabla}\times\vec{B},$$

where we have assumed, without loss of generality, that the initial magnetic potential is solenoidal. Note that the magnetic potential at later times will in general not satisfy $\vec{\nabla} \cdot \vec{\mathbb{A}} = 0$. Once the initial magnetic potential has been determined, the initial magnetic field should be redefined as a finite difference of the magnetic potential so that it satisfies the discrete divergence-free condition.

5. A new CT method. The advantage of the CT framework is that it allows one to control the divergence of the magnetic field, which results in control over the Lorentz force along the magnetic field. This makes CT much more robust than standard cell-centered finite volume methods for the ideal MHD equations. The drawback of CT methods is that by constructing the electric field in the various ways proposed in the literature and then applying centered differences to compute the magnetic fields, one is not guaranteed that the resulting magnetic field satisfies any kind of TVD property. The staggered methods of Londrillo and Del Zanna [32, 33] and Balsara [5] address this issue through more careful reconstructions of the electric field. In this section we develop an alternative to these methods. The proposed method has the following basic features:

1. The evolution equation for the magnetic potential is written as a system of first order hyperbolic equations.
2. The magnetic potential is updated with a high-resolution upwind method.
3. Limiters are applied in such a way as to minimize the oscillations in both the magnetic potential and the magnetic field.
4. The method is naturally unstaggered.

5.1. The magnetic potential equation. The equation for the magnetic potential, (4.2), can be rewritten as a partial differential equation (PDE) by applying Ohm's law (4.3) and the definition of the magnetic potential (4.1). In two dimensions this PDE is a scalar advection equation of the form

$$\frac{\partial \mathbb{A}}{\partial t} + u_1 \frac{\partial \mathbb{A}}{\partial x} + u_2 \frac{\partial \mathbb{A}}{\partial y} = 0\,. \tag{5.1}$$

In three dimensions the magnetic potential satisfies a system of PDEs:

$$\frac{\partial \vec{\mathbb{A}}}{\partial t} + N_1(\vec{u}) \frac{\partial \vec{\mathbb{A}}}{\partial x} + N_2(\vec{u}) \frac{\partial \vec{\mathbb{A}}}{\partial y} + N_3(\vec{u}) \frac{\partial \vec{\mathbb{A}}}{\partial z} = 0, \tag{5.2}$$

where N_1, N_2, and N_3 are 3×3 matrices that depend only on the fluid velocity $\vec{u}$. If we assume that the fluid velocity is given, then both (5.1) and (5.2) are linear, variable coefficient, hyperbolic PDEs.

5.2. The MPACT scheme. In this section we propose a new CT scheme that is based on directly solving (5.1) or (5.2) with a properly chosen high-resolution method. It is natural to solve the magnetic potential equation on the same numerical grid as the MHD equations, and therefore we will use an unstaggered representation of the magnetic field. The proposed CT scheme can be summarized as follows:

Step 0. Primary quantities: $\rho^n,\ \rho\vec{u}^{\,n},\ \mathcal{E}^n,\ \vec{B}^{\,n},\ \mathbb{A}^n$.

Step 1. Solve the MHD equations using the base scheme:
$\Longrightarrow \rho^{n+1},\ \rho\vec{u}^{\,n+1},\ \mathcal{E}^{n+1},\ \vec{B}^{\star}$.
(NOTE: $\vec{B}^{\star}$ is discarded and need not be stored.)

Step 2. Time average the velocity field:
$$\Longrightarrow \vec{u}^{\,n+1/2} = \tfrac{1}{2}\left(\vec{u}^{\,n} + \vec{u}^{\,n+1}\right).$$

Step 3. Solve the magnetic potential equation (5.1) using $\vec{u}^{\,n+1/2}$: $\mathbb{A}^{n+1}$.

Step 4. Compute $\vec{\nabla} \times \vec{\mathbb{A}}$:
$$\Longrightarrow [B_1]_{ij}^{n+1} = \tfrac{1}{2\Delta y}\left(\mathbb{A}_{i,j+1}^{n+1} - \mathbb{A}_{i,j-1}^{n+1}\right),$$
$$\Longrightarrow [B_2]_{ij}^{n+1} = \tfrac{1}{2\Delta x}\left(\mathbb{A}_{i-1,j}^{n+1} - \mathbb{A}_{i+1,j}^{n+1}\right).$$

In other words, this algorithm tells us that in Step 1 all of the primitive variables are updated self-consistently. The only problem is that the resulting magnetic field is not divergence-free. In order to correct this problem, we also advance the magnetic potential forward in time (Step 3). When we advance the magnetic potential forward in time, the new velocity field is no longer an unknown since we have already computed it self-consistently. Therefore, we can solve for the magnetic potential simply by advecting it along the computed velocity field. Once we have the magnetic potential at the new time level, a new magnetic field is computed from the potential in such a way that it satisfies a discrete divergence-free condition (Step 4). The coupling between the fluid variables and the magnetic potential comes from the fact that in the update for the fluid variables we need to use the magnetic field, which comes from the potential.

We refer to this method as the MPACT (magnetic potential advection constrained transport) scheme. Definition (4.11) of the divergence of the magnetic field is exactly conserved by this method. Note that we must use the intermediate value of the velocity, $\vec{u}^{\,n+1/2}$, in Step 3 in order to guarantee full second order accuracy. Also note that the only step in the above algorithm that requires further explanation is Step 3.

In section 5.3 we explain how one can solve the magnetic potential equation (5.1) to second order accuracy in the wave propagation framework. In section 5.4 we devise a new limiting strategy in order to obtain both a magnetic potential and a magnetic field that remains approximately TVD. In section 6 quantitative arguments are presented that explain why this method produces better approximations to the ideal MHD equations than the base scheme alone. This method is tested on several two-dimensional (2D) examples in section 7.

5.3. A modified wave propagation method. Although the magnetic potential equation is not a conservation law, it can still be solved using the wave propagation method of LeVeque [27]. However, LeVeque [27] showed that the wave propagation method is only formally first order accurate for variable coefficient problems written in quasilinear form—the standard wave program method is second order accurate for conservation laws. We present in this section a modified wave propagation method that is formally second order for variable coefficient, linear advection. Extension to linear hyperbolic systems and to three dimensions is straightforward.

In Step 3 of the MPACT scheme we are faced with solving the following equation:

$$\frac{\partial q}{\partial t} + u_1(x,y)\,\frac{\partial q}{\partial x} + u_2(x,y)\,\frac{\partial q}{\partial y} = 0\,, \tag{5.3}$$

where u_1 and u_2 are time averaged onto time level $t = t^{n+1/2}$. Just as in the wave

propagation method, we construct a second order Taylor expansion in time:

$$\begin{aligned} q(x,y,t+\Delta t) &= q(x,y,t) + \Delta t \frac{\partial q}{\partial t}(x,y,t) + \frac{1}{2}\Delta t^2 \frac{\partial^2 q}{\partial t^2}(x,y,t) + \mathcal{O}(\Delta t^3) \\ &= q - \Delta t \left(u_1 q_x + u_2 q_y\right) + \frac{1}{2}\Delta t^2 \Big\{ u_1 \left(u_1 q_x\right)_x + u_2 \left(u_2 q_y\right)_y \\ &\quad + u_1 \left(u_2 q_y\right)_x + u_2 \left(u_1 q_x\right)_y \Big\} + \mathcal{O}(\Delta t^3), \end{aligned} \tag{5.4}$$

where we have used the evolution equation to turn time derivatives into spatial derivatives. We will try to approximate the terms in this expansion with a modified wave propagation method of the form

$$\begin{aligned} Q_{ij}^{n+1} = Q_{ij}^n &- \frac{\Delta t}{\Delta x}\left[\mathcal{A}_1^- \Delta Q_{i+1/2,j} + \mathcal{A}_1^+ \Delta Q_{i-1/2,j}\right] \\ &- \frac{\Delta t}{\Delta y}\left[\mathcal{A}_2^- \Delta Q_{i,j+1/2} + \mathcal{A}_2^+ \Delta Q_{i,j-1/2}\right] \\ &- \frac{\Delta t}{\Delta x}\left[\tilde{F}^{1-}_{i+1/2,j} - \tilde{F}^{1+}_{i-1/2,j}\right] - \frac{\Delta t}{\Delta y}\left[\tilde{F}^{2-}_{i,j+1/2} - \tilde{F}^{2+}_{i,j-1/2}\right], \end{aligned} \tag{5.5}$$

where the $\mathcal{A}^{\pm}\Delta Q$ terms contain first order upwind corrections (approximates terms with one x or one y derivative) and the $\tilde{F}$ terms contain high-resolution (approximates terms with two x or two y derivatives) and multidimensional corrections (approximates terms with cross derivatives). What distinguishes this method from the wave propagation method of [27] is that for each cell interface, $(x_{i-1/2}, y_j)$, we define two distinct correction fluxes, $\tilde{F}^{1-}_{i-1/2,j}$ and $\tilde{F}^{1+}_{i-1/2,j}$. $\tilde{F}^{1-}_{i-1/2,j}$ is associated with the solution in grid cell (x_{i-1}, y_j), while $\tilde{F}^{1+}_{i-1/2,j}$ is associated with the solution in grid cell (x_i, y_j).

In the modified method, we take first order corrections of the form

$$\mathcal{A}_1^- \Delta Q_{i-1/2,j} = [s_{i-1,j}]^- \, \mathcal{W}_{i-1/2,j}, \tag{5.6}$$

$$\mathcal{A}_1^+ \Delta Q_{i-1/2,j} = [s_{ij}]^+ \, \mathcal{W}_{i-1/2,j}, \tag{5.7}$$

where

$$[s]^- = \begin{cases} s & \text{if} \quad s < 0, \\ 0 & \text{otherwise,} \end{cases} \qquad [s]^+ = \begin{cases} s & \text{if} \quad s > 0, \\ 0 & \text{otherwise,} \end{cases} \tag{5.8}$$

$$s_{i-1/2,j} = [u_1]_{i-1/2,j}\,, \tag{5.9}$$

$$\mathcal{W}_{i-1/2,j} = (Q_{ij} - Q_{i-1,j})\,. \tag{5.10}$$

We refer to $\mathcal{W}$ as a [illegible] and s as a [illegible]. The high-resolution correction fluxes are given by

$$\tilde{F}^{1-}_{i-1/2,j} = \frac{1}{2}\left|s_{i-1,j}\right|\left(1 - \frac{\Delta t}{\Delta x}\frac{s_{i-1/2,j}}{\left|s_{i-1,j}\right|}\, s_{i-1,j}\right)\mathcal{W}_{i-1/2,j}, \tag{5.11}$$

$$\tilde{F}^{1+}_{i-1/2,j} = \frac{1}{2}\left|s_{ij}\right|\left(1 - \frac{\Delta t}{\Delta x}\frac{s_{i-1/2,j}}{\left|s_{ij}\right|}\, s_{ij}\right)\mathcal{W}_{i-1/2,j}\,, \tag{5.12}$$

where $s_{i-1/2,j}$ can be taken as the arithmetic average of s_{ij} and $s_{i-1,j}$. Finally, in order to achieve full second order accuracy and stability up to a CFL number of one,

multidimensional corrections must be included. These multidimensional corrections can be written as

$$\begin{aligned}\tilde{F}^{1-}_{i+1/2} = \tilde{F}^{1-}_{i+1/2} - \frac{1}{2}\frac{\Delta t}{\Delta y}\Big(& [u_1]^+_i \left(u_2^+ \Delta Q - 2\tilde{F}^{2+}\right)_{i,j-1/2} \\ & + [u_1]^-_i \left(u_2^+ \Delta Q - 2\tilde{F}^{2+}\right)_{i+1,j-1/2} \\ & + [u_1]^+_i \left(u_2^- \Delta Q + 2\tilde{F}^{2-}\right)_{i,j+1/2} \\ & + [u_1]^-_i \left(u_2^- \Delta Q + 2\tilde{F}^{2-}\right)_{i+1,j+1/2}\Big),\end{aligned} \tag{5.13}$$

where $\tilde{F}^{2-}$ are the high-resolution fluxes in the 2-direction.

CLAIM. [illegible] $\Delta t = c_1 \Delta x = c_2 \Delta y$ [illegible] c_1 [illegible] c_2 [illegible] $q(x,y,t)$ [illegible] (x,y,t) [illegible] $\mathcal{O}(\Delta t^2)$

This claim is proved in the appendix.

5.4. A new limiting strategy for obtaining a nonoscillatory magnetic field. The aim of this paper is to develop a CT method that produces a nonoscillatory magnetic field. The modified wave propagation method developed so far offers a new approach for updating the magnetic potential. However, if standard wave limiters are applied to the magnetic potential, unphysical oscillations can still be introduced into the magnetic field. In order to overcome this problem we must introduce a new limiting strategy.

The [illegible] limiting strategy of LeVeque [27], adapted to the modified wave propagation method presented in this work, results in the following correction fluxes.

[illegible] "

$$\tilde{F}^{1-}_{i-1/2} = \frac{1}{2}\left|s_{i-1}\right|\left(1 - \frac{\Delta t}{\Delta x}\frac{s_{i-1/2}}{\left|s_{i-1}\right|}\, s_{i-1}\right)\mathcal{W}_{i-1/2}\,\phi_{i-1/2}, \tag{5.14}$$

$$\tilde{F}^{1+}_{i-1/2} = \frac{1}{2}\left|s_{i}\right|\left(1 - \frac{\Delta t}{\Delta x}\frac{s_{i-1/2}}{\left|s_{i}\right|}\, s_{i}\right)\mathcal{W}_{i-1/2}\,\phi_{i-1/2}, \tag{5.15}$$

$$\phi_{i-1/2} = \phi\left(\frac{\mathcal{W}_{I-1/2}\cdot\mathcal{W}_{i-1/2}}{\mathcal{W}_{i-1/2}\cdot\mathcal{W}_{i-1/2}}\right), \tag{5.16}$$

where $\phi(\theta)$ is a TVD limiter function and $\mathcal{W}_{I-1/2}$ is chosen from the upwind direction based on $s_{i-1/2}$ [30]. This approach has the following effect:

[illegible] $\Longrightarrow$ [illegible]

Since we are more concerned with obtaining a nonoscillatory derivative, we propose the following approach:

[illegible] $\Longrightarrow$ [illegible]

We note that such a procedure will yield accurate results only if the variable that is being updated remains continuous. If the variable is discontinuous, then limiting based on the first derivative will be too aggressive, yielding an overly diffusive approximation. Such a limiting strategy may work in our case, however, since the magnetic

potential is always continuous, while the magnetic field is discontinuous wherever the potential fails to be differentiable.

Applying the wave-difference limiting strategy results in the following correction fluxes.

$$\tilde{F}^{1-}_{i-1/2} = \frac{1}{2}\left|s_{i-1}\right|\left(1 - \frac{\Delta t}{\Delta x}\frac{s_{i-1/2}}{\left|s_{i-1}\right|}\, s_{i-1}\right)\mathcal{W}_{i-1/2}\,\phi_{i-1}, \tag{5.17}$$

$$\tilde{F}^{1+}_{i-1/2} = \frac{1}{2}\left|s_{i}\right|\left(1 - \frac{\Delta t}{\Delta x}\frac{s_{i-1/2}}{\left|s_{i}\right|}\, s_{i}\right)\mathcal{W}_{i-1/2}\,\phi_{i}, \tag{5.18}$$

$$\phi_i = \phi\left(\frac{\Delta\mathcal{W}_I \cdot \Delta\mathcal{W}_i}{\Delta\mathcal{W}_i \cdot \Delta\mathcal{W}_i}\right), \tag{5.19}$$

where $\Delta\mathcal{W}_i = \mathcal{W}_{i+1/2} - \mathcal{W}_{i-1/2}$ and $\Delta\mathcal{W}_I$ is chosen from the upwind direction based on s_i. As we demonstrate in an example below, this approach has the desired property of adding numerical diffusion whenever there is a "large" change in $\Delta\mathcal{W}$ even if there is a "small" change in $\mathcal{W}$. In particular, we can prove the following result.

CLAIM.

$$\frac{\partial q}{\partial t} + \frac{\partial q}{\partial x} = 0,$$

1.

$$B^n_{i+1/2} \equiv \frac{Q^n_{i+1} - Q^n_i}{\Delta x},$$

$$\text{TV}(B^{n+1}_{i+1/2}) \equiv \sum_{i=-\infty}^{\infty} |B^{n+1}_{i+1/2} - B^{n+1}_{i-1/2}| \le \text{TV}(B^n_{i+1/2}) \le \cdots \le \text{TV}(B^0_{i+1/2}).$$

2.

$$B^n_i \equiv \frac{1}{2}\left(B^n_{i+1/2} + B^n_{i-1/2}\right) = \frac{Q^n_{i+1} - Q^n_{i-1}}{2\Delta x},$$

$$\text{TV}(B^{n+1}_i) \equiv \sum_{i=-\infty}^{\infty} |B^{n+1}_{i+1} - B^{n+1}_i| \le \text{TV}(B^0_{i+1/2}).$$

The numerical update using the wave propagation method with the wave-difference limiting approach takes the following form for the simple constant coefficient advection equation:

$$Q^{n+1}_i = Q^n_i - \nu\left(Q^n_i - Q^n_{i-1}\right) - \frac{1}{2}\nu(1-\nu)\phi\left(\theta^n_i\right)\left(Q^n_{i+1} - 2Q^n_i + Q_{i-1}\right),$$

where

$$\theta^n_i = \frac{Q^n_i - 2Q^n_{i-1} + Q^n_{i-2}}{Q^n_{i+1} - 2Q^n_i + Q^n_{i-1}}.$$

1. If we take the above numerical update for Q_{i+1} and Q_i, subtract them from each other, and divide by Δx, we obtain the following update for $B_{i+1/2}$:

$$B^{n+1}_{i+1/2} = B^n_{i+1/2} - \nu\left(B^n_{i+1/2} - B^n_{i-1/2}\right) - \frac{1}{2}\nu(1-\nu)\left[\phi\left(\theta^n_i\right)\left(B^n_{i+3/2} - B^n_{i+1/2}\right) - \phi\left(\theta^n_{i-1}\right)\left(B^n_{i+1/2} - B^n_{i-1/2}\right)\right],$$

where

$$\theta^n_{i+1} = \frac{B^n_{i+1/2} - B^n_{i-1/2}}{B^n_{i+3/2} - B^n_{i+1/2}}.$$

This update can be rewritten in the following form:

$$B^{n+1}_{i+1/2} = B^n_{i+1/2} - C^n_{i-1/2}\left(B^n_{i+1/2} - B^n_{i-1/2}\right),$$

where

$$C^n_{i-1/2} = \nu + \frac{1}{2}\nu(1-\nu)\left(\frac{\phi(\theta^n_{i+1})}{\theta^n_{i+1}} - \phi(\theta^n_i)\right).$$

We know from the theorem of Harten [20] that the total variation of $B_{i+1/2}$ is nonincreasing if $0 \le C^n_{i-1/2} \le 1$ for all i. We know from the work of Sweby [37] that the standard TVD limiters (i.e., minmod, superbee, monotonized centered, and van Leer) satisfy this constraint. Therefore, we have shown part (1) of the claim.

2. We note that

$$\begin{aligned}\mathrm{TV}(B^{n+1}_i) &\equiv \sum_{i=-\infty}^{\infty} |B^{n+1}_{i+1} - B^{n+1}_i| \\ &= \frac{1}{2}\sum_{i=-\infty}^{\infty} |B^{n+1}_{i+3/2} + B^{n+1}_{i+1/2} - B^{n+1}_{i+1/2} - B^{n+1}_{i-1/2}| \\ &\le \frac{1}{2}\sum_{i=-\infty}^{\infty} |B^{n+1}_{i+3/2} - B^{n+1}_{i+1/2}| + \frac{1}{2}\sum_{i=-\infty}^{\infty} |B^{n+1}_{i+1/2} - B^{n+1}_{i-1/2}| = \mathrm{TV}(B^{n+1}_{i+1/2}).\end{aligned}$$

Using the result from part (1) it follows that

$$\mathrm{TV}(B^{n+1}_i) \le \mathrm{TV}(B^{n+1}_{i+1/2}) \le \mathrm{TV}(B^n_{i+1/2}) \le \cdots \le \mathrm{TV}(B^0_{i+1/2}). \qquad \square$$

In order to test this new limiting strategy, let us consider the linear advection equation,

$$\frac{\partial q}{\partial t} + \frac{\partial q}{\partial x} = 0, \tag{5.20}$$

on the interval $0 \le x \le 1$ with periodic boundary conditions. We take as initial conditions the following continuous and piecewise linear function:

$$q(x,0) = \begin{cases} 0 & \text{if} \quad x \le 0.25, \\ (x - 0.25)/0.075 & \text{if} \quad 0.25 \le x \le 0.4, \\ 2 & \text{if} \quad 0.4 \le x \le 0.6, \\ (0.75 - x)/0.075 & \text{if} \quad 0.6 \le x \le 0.75, \\ 0 & \text{if} \quad 0.75 \le x. \end{cases} \tag{5.21}$$

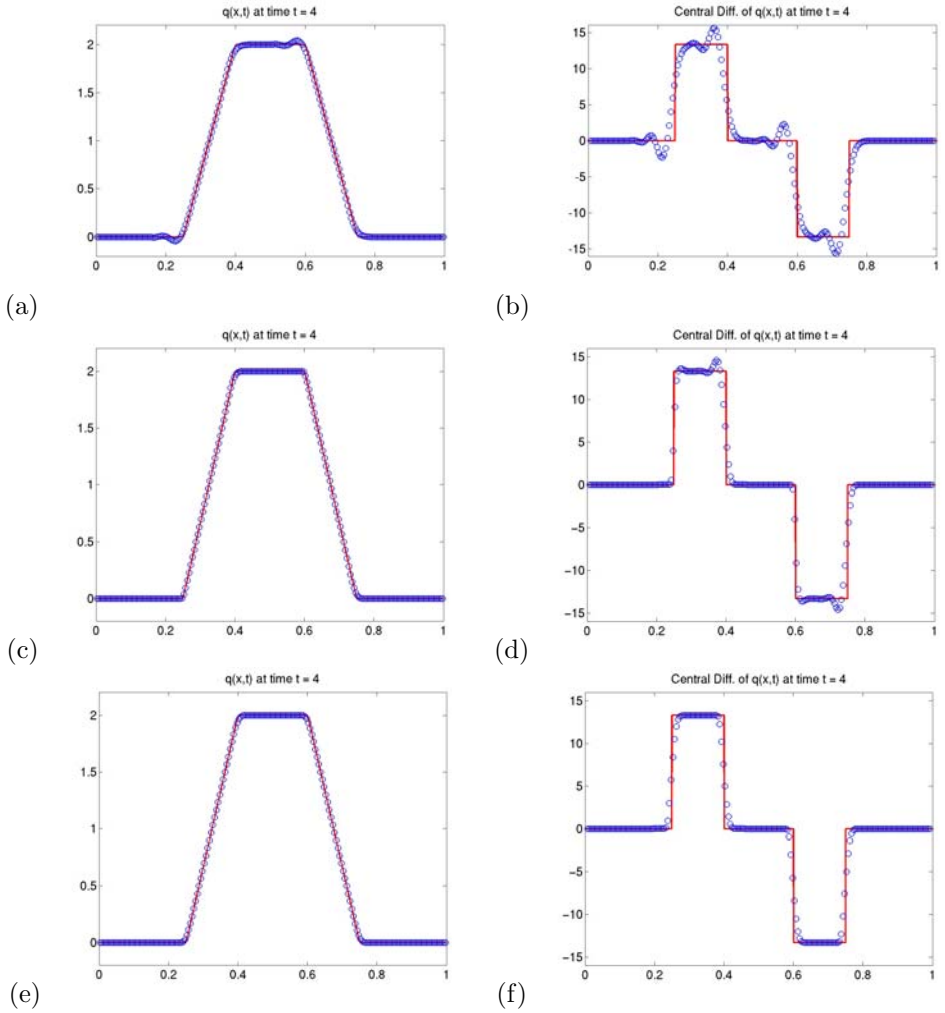

FIG. 5.1. *The solution to the* 1*D advection equation and its derivative on a periodic domain after four revolutions; the derivative is computed using a centered finite difference. In plots* (a) *and* (b) *no limiters are used (Lax–Wendroff method). In plots* (c) *and* (d) *the monotonized centered (MC) limiter is applied to the waves, while in plots* (e) *and* (f) *the MC limiter is applied to wave differences.*

Because the boundary conditions are periodic the solution returns to its initial state whenever t is an integer. The quantity that we would like to compute is the derivative of q, which we approximate using centered differences:

$$\frac{dq}{dx}(x_i, t^n) \approx \frac{Q^n_{i+1} - Q^n_{i-1}}{2\Delta x}. \tag{5.22}$$

In Figure 5.1 we plot $q(x,t)$ and the central difference of $q(x,t)$ after four full revolutions on a grid with 200 points using (a)–(b) no limiters, (c)–(d) the standard wave limiting, and (e)–(f) the new wave-difference limiting. As expected, the wave limiting approach does not limit the oscillations in the x-derivative of $q(x,t)$, while the wave-difference limiting approach produces a sharp and oscillation-free profile. Both limiting strategies produce sharp and oscillation-free $q(x,t)$ profiles.

5.5. Conservation of magnetic field. It is clear that the method we are proposing conserves mass, momentum, and energy, since these quantities are updated via flux differencing. In order to have confidence that our method produces correct jump conditions across shock waves, we should also verify that the magnetic field is conserved (as it would be in the base scheme). In order to show this we note that the total amount of $B_1(x,y,t)$ in the computational domain at time $t=t^n$ is given by

$$\begin{aligned} T_1^n &= \Delta x \Delta y \sum_{i=1}^{N}\sum_{j=1}^{M} [B_1]_{ij}^n = \frac{\Delta x}{2}\sum_{i=1}^{N}\sum_{j=1}^{M}\left(\mathbb{A}_{i,j+1}^n - \mathbb{A}_{i,j-1}^n\right) \\ &= \frac{\Delta x}{2}\sum_{i=1}^{N} \mathbb{A}_{i,M+1}^n + \mathbb{A}_{i,M}^n - \mathbb{A}_{i,1}^n - \mathbb{A}_{i,0}^n \\ &\equiv \Delta x \sum_{i=1}^{N} \mathbb{A}_{i,M+1/2}^n - \Delta x \sum_{i=1}^{N} \mathbb{A}_{i,1/2}^n, \end{aligned} \tag{5.23}$$

where N and M are the number of computational grid cells in the x- and y-directions, respectively. Similarly, the total amount of $B_2(x,y,t)$ in the computational domain at time $t=t^n$ is given by

$$T_2^n = \Delta x \Delta y \sum_{j=1}^{M}\sum_{i=1}^{N} [B_2]_{ij}^n = \cdots \equiv \Delta y \sum_{j=1}^{M} \mathbb{A}_{1/2,j}^n - \Delta y \sum_{j=1}^{M} \mathbb{A}_{N+1/2,j}^n. \tag{5.24}$$

Therefore, the only way to modify the total amount of B_1 and B_2 in the computational domain is through loss/gain across the boundary; B_1 and B_2 are numerically conserved. In other words, the central differencing of the magnetic potential that is used to obtain the magnetic field acts to produce an update for the magnetic field that is in flux differencing form.

5.6. Boundary conditions for the magnetic potential. In the examples we present in section 7, we will use two types of boundary conditions: (1) extrapolation to model inflow/outflow and (2) periodic boundary conditions. In both cases we add to the computational domain two layers of ghost cells, which are used to construct numerical fluxes on the computational boundaries. For conserved variables, it will suffice in our examples to use zeroth order extrapolation (i.e., simply copying solution values from the outermost computational cells into the neighboring ghost cells). In order to specify a magnetic potential that is consistent with a zeroth order extrapolated magnetic field, we must in fact apply linear extrapolation to the magnetic potential; for example, on the left boundary we take

$$\mathbb{A}_{0,j} = 2\mathbb{A}_{1,j} - \mathbb{A}_{2,j} \quad \text{and} \quad \mathbb{A}_{-1,j} = 3\mathbb{A}_{1,j} - 2\mathbb{A}_{2,j},$$

where $j=-1,0,1,2,\ldots,M,M+1,M+2$ and M is the number of regular grid cells in the x-direction. This is simply due to the fact that a constant potential means a zero strength magnetic field, while a linear potential means a constant strength magnetic field.

Periodic boundary conditions on the conserved variable can again be handled by copying the appropriate computational grid values into the ghost cells; for example, on the left boundary we take

$$Q_{0,j} = Q_{N,j} \quad \text{and} \quad Q_{-1,j} = Q_{N-1,j},$$

where $j = -1, 0, 1, 2, \ldots, M, M+1, M+2$ and N and M are the number of regular grid points in the x- and y-directions, respectively. If the magnetic field is periodic, then the potential will in general be comprised of a linear part corresponding to the mean magnetic field plus a periodic part corresponding to the zero-mean part of the magnetic field:

$$\mathbb{A}(x, y) = \langle B_1 \rangle y - \langle B_2 \rangle x + \bar{\mathbb{A}}(x, y),$$

where $\vec{B} = (\langle B_1 \rangle, \langle B_2 \rangle)$ is the mean magnetic field. For periodic boundary conditions, the linear part is linearly extrapolated, while the periodic part is handled using the same boundary conditions as the conserved variables.

6. Analysis of the Lorentz force. In this section we take a closer look at the Lorentz force in both the base scheme and the newly proposed MPACT scheme. The idea here is to be able to quantify the improvements that the cell-centered CT method provides over those of just the base scheme. The analysis presented here is based on the work of Tóth [39]; a similar analysis was carried out by Londrillo and Del Zanna [33] for their scheme.

In the conservative form of the ideal MHD equations (1.1), the Lorentz force shows up as part of the momentum flux:

$$\vec{F} \equiv \vec{\nabla} \cdot \left(\frac{1}{2} |\vec{B}|^2 \mathcal{I} - \vec{B} \otimes \vec{B} \right) \equiv \vec{\nabla} \cdot \overleftrightarrow{T}. \tag{6.1}$$

If the magnetic field satisfies the divergence-free condition (1.2), then one can easily show that the projection of the Lorentz force along the magnetic field must identically vanish for all space and time:

$$\vec{F} \cdot \vec{B} \equiv 0. \tag{6.2}$$

Numerical discretizations of the ideal MHD equations in general only satisfy constraint (6.2) to the truncation error of the method. Across shocks this can mean that $\vec{F} \cdot \vec{B}$ is very large, which in turn can lead to the production of unphysical oscillations and the eventual failure of the method.

6.1. Estimating $\vec{F} \cdot \vec{B}$. We now try to quantify the magnitude of the projection of the Lorentz force along the magnetic field in the context of the methods discussed in this work. The wave propagation method can be rewritten in standard finite volume form:

$$Q_{ij}^{n+1} = Q_{ij}^n - \frac{\Delta t}{\Delta x} \left(F^1_{i+1/2,j} - F^1_{i-1/2,j} \right) - \frac{\Delta t}{\Delta y} \left(F^2_{i,j+1/2} - F^2_{i,j-1/2} \right), \tag{6.3}$$

where

$$F^1_{i-1/2,j} = \frac{1}{2} \left(f^1(Q^n_{ij}) + f^1(Q^n_{i-1,j}) \right) + \Phi^1_{i-1/2,j}, \tag{6.4}$$

$$F^2_{i,j-1/2} = \frac{1}{2} \left(f^2(Q^n_{ij}) + f^2(Q^n_{i,j-1}) \right) + \Phi^2_{i,j-1/2}. \tag{6.5}$$

In fact, the above formula is not restricted to the wave propagation method; for example, the corrections could have the following form (see LeVeque [30]):

$$\text{Godunov:} \quad \Phi^1_{i-1/2,j} \equiv \frac{1}{2} \left(\mathcal{A}_1^- \Delta Q_{i-1/2,j} - \mathcal{A}_1^+ \Delta Q_{i-1/2,j} \right),$$

$$\text{Lax–Friedrichs:} \quad \Phi^1_{i-1/2,j} \equiv \frac{1}{2} \frac{\Delta x}{\Delta t} \left(Q^n_{ij} - Q^n_{i-1,j} \right).$$

Independent of the choice of these corrections, the discrete projection of the Lorentz force along the magnetic field can be written as

$$\begin{aligned}\left[\vec{F}\cdot\vec{B}\right]_{ij} \equiv\ & [B_1]_{ij}\left(\frac{T^{11}_{i+1/2,j}-T^{11}_{i-1/2,j}}{\Delta x}+\frac{T^{12}_{i,j+1/2}-T^{12}_{i,j-1/2}}{\Delta y}\right)\\ &+\ [B_2]_{ij}\left(\frac{T^{21}_{i+1/2,j}-T^{21}_{i-1/2,j}}{\Delta x}+\frac{T^{22}_{i,j+1/2}-T^{22}_{i,j-1/2}}{\Delta y}\right).\end{aligned}$$

If we use in the above formula the full numerical construction of the fluxes, T^{ab}, according to formulas (6.4) and (6.5), the analysis of the Lorentz force becomes rather complicated. Instead, we note that in order to compute the dominant contributions in the discrete form of $\vec{F}\cdot\vec{B}$, using only the first terms in the numerical fluxes suffices and the corrections Φ may be omitted:

$$T^{ab}_{i-1/2,j} \approx \frac{1}{2}\left(T^{ab}(\vec{B}^n_{ij})+T^{ab}(\vec{B}^n_{i-1,j})\right), \tag{6.6}$$

$$T^{ab}_{i,j-1/2} \approx \frac{1}{2}\left(T^{ab}(\vec{B}^n_{ij})+T^{ab}(\vec{B}^n_{i,j-1})\right), \tag{6.7}$$

where

$$\overleftrightarrow{T} = \begin{bmatrix}\frac{1}{2}\left(B_2^2-B_1^2\right) & -B_1B_2\\ -B_1B_2 & \frac{1}{2}\left(B_1^2-B_2^2\right)\end{bmatrix}. \tag{6.8}$$

The omission of Φ is justified, because for first order schemes Φ acts to add numerical diffusion to numerical flux that would otherwise be unstable (see, for example, Chapter 4 of [30]). Therefore, the dominant contribution to $\vec{F}\cdot\vec{B}$ will come from the "uncorrected" fluxes. Furthermore, we are concerned only with first order schemes since we would like to understand the behavior of $\vec{F}\cdot\vec{B}$ across shocks.

Having made this simplification, we are now ready to compute a discrete form of $\vec{F}\cdot\vec{B}$. Following Tóth [39], we define the following quantities:

$$\begin{aligned}[\mu_x U]_{ij} &\equiv \frac{1}{2}\left(U_{i+1,j}+U_{i-1,j}\right),\\ [\mu_y U]_{ij} &\equiv \frac{1}{2}\left(U_{i,j+1}+U_{i,j-1}\right),\\ [\delta_x U]_{ij} &\equiv U_{i+1,j}-U_{i-1,j},\\ [\delta_y U]_{ij} &\equiv U_{i,j+1}-U_{i,j-1}.\end{aligned} \tag{6.9}$$

Using these definitions along with the simplified definitions (6.6)–(6.8), one can show that

$$\begin{aligned}\vec{F}\cdot\vec{B} \approx & -\left(B_1\mu_xB_1+B_2\mu_yB_2\right)\left[\frac{\delta_xB_1}{2\Delta x}+\frac{\delta_yB_2}{2\Delta y}\right]\\ &+B_2\left(\mu_yB_2-\mu_xB_2\right)\frac{\delta_xB_1}{2\Delta x}+B_1\left(\mu_xB_1-\mu_yB_1\right)\frac{\delta_yB_2}{2\Delta y}\\ &+\left(B_1\mu_xB_2-B_2\mu_xB_1\right)\frac{\delta_xB_2}{2\Delta x}+\left(B_2\mu_yB_1-B_1\mu_yB_2\right)\frac{\delta_yB_1}{2\Delta y},\end{aligned} \tag{6.10}$$

where we have dropped all ij subscripts. We note that this is the same expression that Tóth [39] derived, except that our expression has an extra factor of $1/2$ in each term and our definitions (6.9) are fully cell-centered versions of those given by Tóth.

TABLE 6.1

Numerical evaluation of the projection of the Lorentz force along the magnetic field. This data shows that for the base scheme $\vec{F}\cdot\vec{B}$ is relatively large and $\mathcal{O}\left(\Delta x^{-1}, \Delta y^{-1}\right)$, while for the MPACT *scheme this quantity is much smaller and $\mathcal{O}(1)$.*

	Base		MPACT

Across a shock, we can estimate $\vec{F}\cdot\vec{B}$ as follows:

$$\vec{F}\cdot\vec{B} \sim \mathcal{O}(1)\left[\frac{\delta_x B_1}{2\Delta x} + \frac{\delta_y B_2}{2\Delta y}\right] + \mathcal{O}(\Delta x, \Delta y)\cdot\left\{\frac{\delta_x B_1}{2\Delta x}, \frac{\delta_x B_2}{2\Delta x}, \frac{\delta_y B_1}{2\Delta y}, \frac{\delta_y B_2}{2\Delta y}\right\}.$$

Furthermore, finite difference approximations to the derivatives of $\vec{B}$ across a shock will in general be of the order $\mathcal{O}\left(\Delta x^{-1}, \Delta y^{-1}\right)$. This implies that we can further estimate $\vec{F}\cdot\vec{B}$ as follows:

$$\vec{F}\cdot\vec{B} \sim \begin{cases} \mathcal{O}(1) & \text{if} \quad \frac{\delta_x B_1}{2\Delta x} + \frac{\delta_y B_2}{2\Delta y} = 0, \\ \mathcal{O}\left(\Delta x^{-1}, \Delta y^{-1}\right) & \text{otherwise.} \end{cases} \tag{6.11}$$

Therefore, in both the base scheme and the MPACT scheme, $\vec{F}\cdot\vec{B} \neq 0$. However, in the MPACT scheme the projection of the Lorentz force is always bounded independent of the grid resolution, while in the base scheme this term blows up like $1/(\Delta x, \Delta y)$. For a fixed resolution one would expect the MPACT scheme to have a much smaller $\vec{F}\cdot\vec{B}$ error, since the first term in (6.10) vanishes.

Finally, we would like to point out that Tóth [39] introduced a scheme for which $\vec{F}\cdot\vec{B} \equiv 0$ on the discrete level. The main difficulty with that scheme is that it is fully second order and has no mechanism for flux limiting. Although the MPACT scheme presented in this work only satisfies $\vec{F}\cdot\vec{B} \sim \mathcal{O}(1)$ for discontinuous data, we believe that for many problems this is good enough. As evidence for this we note that for standard 1D high-resolution schemes, which are known to work well for 1D ideal MHD, expression (6.10) also does not identically vanish:

$$\vec{F}\cdot\vec{B} \approx B_1\left(\mu_x B_2 - B_2\right)\frac{\delta_x B_2}{2\Delta x}.$$

For discontinuous data this expression is again $\mathcal{O}(1)$.

6.2. Numerical example. In order to numerically verify the above statements, we consider the 30° rotated Riemann problem that is described in detail in section 7.2. At $t = 0.3$ and $y = \Delta y/2$ (the $y =$ constant slice nearest the center), the 1-norm of the cell-centered divergence and the 1-norm of $\vec{F}\cdot\vec{B}$ as defined in (6.10) are computed for various values of $\Delta x = \Delta y$. Both the base scheme and the MPACT scheme are tested. The results of this computation are shown in Table 6.1; the numerical calculations validate the conclusions of formula (6.11).

7. MHD examples. In this section the MPACT method is applied to six separate 2D test problems for the ideal MHD equations. The first example is used to test

TABLE 7.1
Convergence study on a smooth Alfvén wave problem. Note that the errors shown here are truncated to three significant digits for the sake of brevity; however, the R_N values are computed with the full errors.

	Base		MPACT	
N	δ_N	R_N	δ_N	R_N
16	5.58e−2	–	1.48e−1	–
32	1.41e−2	1.98	3.80e−2	1.96
64	3.71e−3	1.93	9.60e−3	1.99
128	9.36e−4	1.99	2.34e−3	2.00

the order of accuracy, the second examines the shock-capturing ability, and the third examines the numerical dissipation of the MPACT method. The final three examples test the MPACT scheme on fully 2D problems. Unless otherwise noted, all computations are run with a CFL number of 0.95, the MC limiter (see [30]), and a gas constant of $\gamma = 5/3$.

7.1. Smooth Alfvén wave problem. We begin by numerically verifying the order of accuracy of the base scheme and the MPACT scheme on the smooth Alfvén problem proposed in [38]. This problem consists of a circularly polarized Alfvén wave that propagates at angle $\alpha = \tan^{-1}(0.5) \approx 25.5651^\circ$ relative to the horizontal axis. The computational domain is $(x, y) \in [0, 1/\cos\alpha] \times [0, 1/\sin\alpha]$ with double-periodic boundary conditions. The initial Alfvén wave propagates at a constant speed towards the origin and returns to its initial state whenever t is an integer.

Each method is run on grids of size $N \times 2N$, where $N = 16, 32, 64$, and 128. These grid resolutions are chosen so that $\Delta x/\Delta y = 1$. All of these simulations are run out to $t = 2$. As in [38], for each value of N we compute a relative error, δ_N, and an approximation to the order of accuracy, R_N, using the following definitions:

$$\begin{aligned} \delta_N &= \frac{1}{4}(E_N(u_\perp) + E_N(u_3) + E_N(B_\perp) + E_N(B_3)), \\ E_N(v) &= \frac{\sum_{i=1}^{N}\sum_{j=1}^{2N} |v_{ij} - v_{\text{exact}}|}{\sum_{i=1}^{N}\sum_{j=1}^{2N} |v_{\text{exact}}|}, \\ R_N &= \log_2\left(\delta_{N/2}/\delta_N\right). \end{aligned}$$

The results of these simulations are summarized in Table 7.1. Both methods are second order accurate; the MPACT scheme is slightly less accurate due to the additional step in computing the magnetic field.

7.2. Rotated Riemann problem. Next we test the constrained transport methods on a problem with discontinuities. In particular, we consider a 1D shock tube problem that has been rotated by an angle of $\alpha = 30^\circ$. The computational domain is $(x, y) \in [-1.2, 1.2] \times [-1, 1]$ with extrapolation boundary conditions on all conserved variables on all sides. On the top and bottom boundaries we don't extrapolate in the direction normal to the boundary (as is customary); instead, we extrapolate in the direction parallel to the shock interface. The initial data is

$$\left[\rho, u_\perp, u_{||}, u_3, p, B_\perp, B_{||}, B_3\right] = \begin{cases} \left[1, -0.4, 0, 0, 1, 0.75, 1, 0\right] & \text{if} \quad \xi < 0, \\ \left[0.2, -0.4, 0, 0, 0.1, 0.75, -1, 0\right] & \text{if} \quad \xi > 0, \end{cases}$$

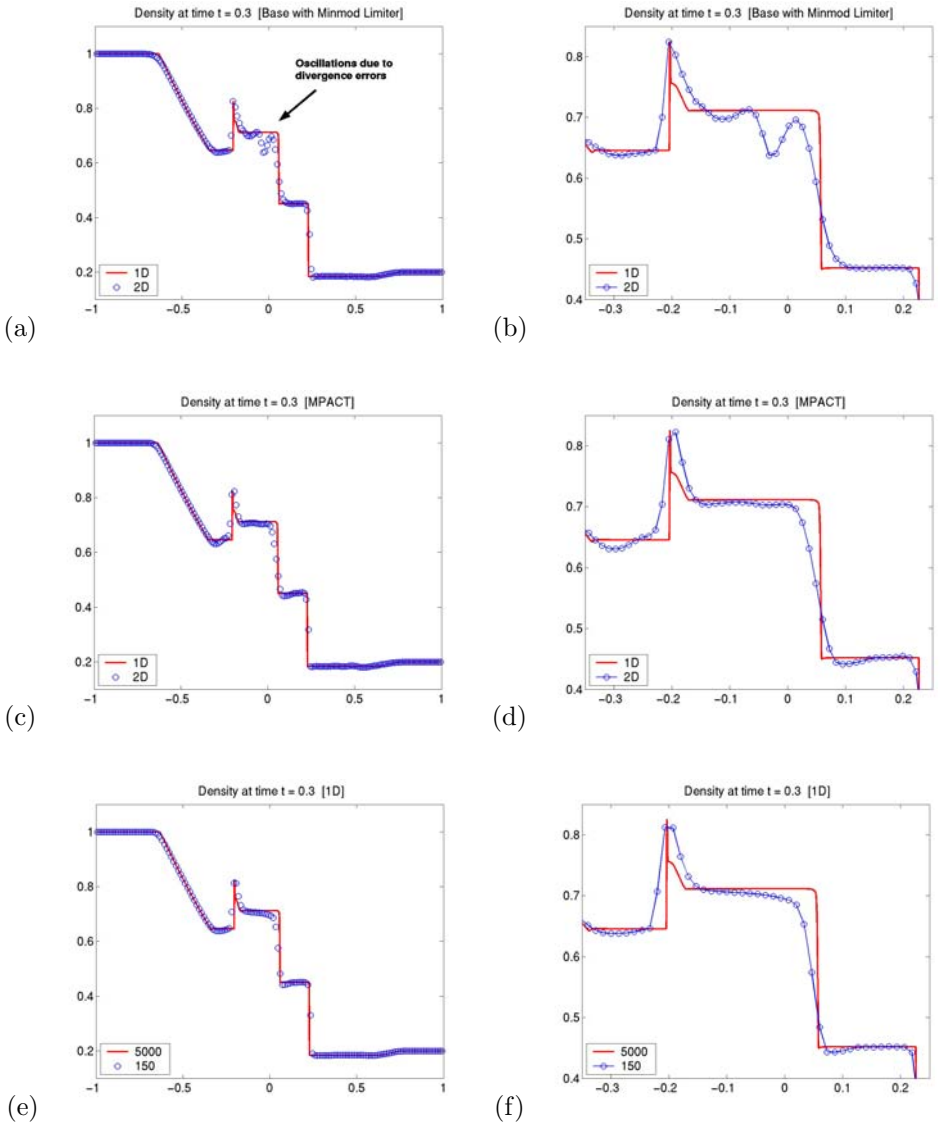

FIG. 7.1. *Solution to a* 30° *rotated Riemann problem. The solutions are obtained using* (a)–(b) *the base scheme,* (c)–(d) *the* MPACT *scheme, and* (e)–(f) *the* 1*D wave propagation method. The solid line in each plot is a highly resolved (*5000 *points) solution of the* 1*D MHD equations. For each method we plot both the entire solution from* −1 *to* 1 *as well as a blowup of the solution near the origin.*

where $\xi = x\cos\alpha + y\sin\alpha$, $u_\perp$ is the component of the velocity perpendicular to the shock interface, and $u_{||}$ is the component of velocity parallel to the shock interface.

The results on a 180×150 grid are shown in Figures 7.1 and 7.2. In these figures we plot the density at $j = 75$, which corresponds to $y = -0.066\bar{6}$. Also shown in all of these plots is a highly resolved (5000 grid points) solution of the 1D MHD equations. We see in panels (a)–(b) of Figure 7.1 that the base scheme produces oscillations because it fails to satisfy a discrete divergence-free condition. In order to be sure that these oscillations are due to divergence errors and not inadequate

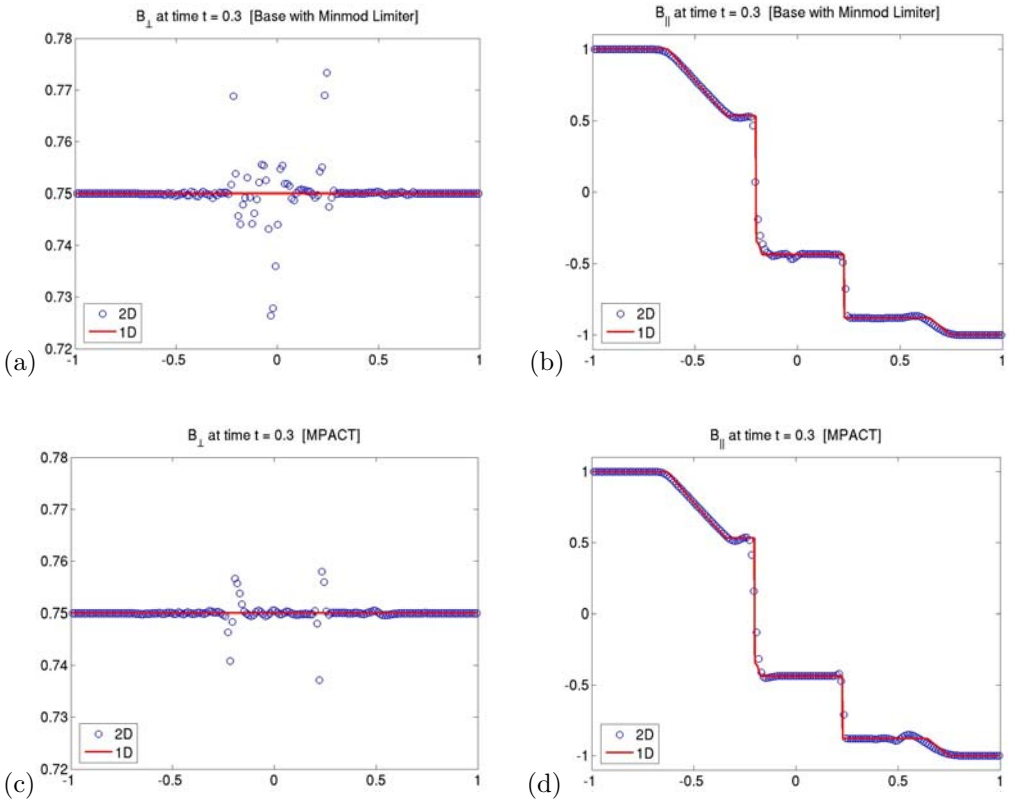

FIG. 7.2. *Magnetic field solutions to a* 30° *rotated Riemann problem (the corresponding density plots are shown in Figure* 7.1*). The solutions are obtained using* (a)–(b) *the base scheme and* (c)–(d) *the* MPACT *scheme. limiting, the diffusive minmod limiter was used. Very similar results, which are not shown here, were also obtained with the base scheme using other standard limiters. As shown in panels (c)–(d), the MPACT scheme produces much cleaner results. In the MPACT scheme we have used the MC limiter for all conserved variables and the van Leer limiter for the magnetic potential. In this same figure we also show in (e)–(f) a truly 1D calculation with the same resolution as the other two schemes and the MC limiter; we note that both the 1D approach and the MPACT scheme produce very similar results. We note that the largest unphysical oscillations occur near the origin (where the initial discontinuity is placed); this is due to the fact that the ideal MHD equations produce the following "evolution" equation for the divergence of the magnetic field:

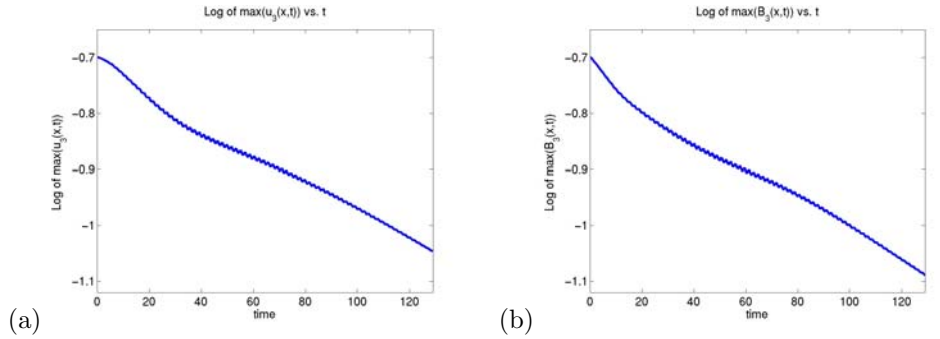
$$\frac{\partial}{\partial t}\left(\vec{\nabla}\cdot\vec{B}\right) = 0.$$

Finally, in Figure 7.2 we show the corresponding magnetic field components for this rotated Riemann problem. In these plots it is again evident that the base scheme produces larger errors near the origin than the MPACT scheme.

7.3. Numerical dissipation and long-term decay of Alfvén waves. Next we consider a problem proposed by Balsara [5], which tries to quantify the amount of



(a) (b)

FIG. 7.3. *Log-linear plot of the maximum value of the z-components of* (a) *velocity and* (b) *magnetic fields. In the exact solution the maximum value should remain constant, but numerical dissipation causes the amplitude to decay. The numerical dissipation produced by the* MPACT *scheme on the linearly degenerate Alfvén waves is comparable to several of the schemes tested by Balsara* [5].

numerical dissipation introduced by a numerical scheme for ideal MHD. Specifically, the test problem measures the decay of the amplitude of a linearly degenerate Alfvén wave that propagates at a shallow angle to the grid ($\tan(1/6) \approx 9.462°$). See Balsara [5] for a description of the initial conditions.

The MPACT scheme was run on the computational domain $[-3,3] \times [-3,3]$ on a 120×120 grid until time $t = 129$. The maximum values of u_3 and B_3 should remain constant in time for the exact solution, but decay due to numerical dissipation. These quantities are plotted versus time in Figure 7.3. The numerical dissipation produced by the MPACT scheme on the linearly degenerate Alfvén waves is comparable to several of the schemes tested by Balsara [5].

7.4. Rotor problem. The first truly multidimensional problem we attempt is the rotor problem considered in both [6] and [38]. The computational domain is $(x, y) \in [0, 1] \times [0, 1]$ with zeroth order extrapolation boundary conditions on all four sides. We make use of the MC limiter with a CFL number of 0.85.

The results of a computation using the MPACT scheme on a 256×256 grid are shown in Figure 7.4. We plot contour lines of the (a) density, (b) thermal pressure, (c) Mach number, and (d) magnetic pressure. These results are in good agreement with the computations of Balsara and Spicer [6] and Tóth [38].

7.5. Orszag–Tang vortex. Next we consider a problem that appears several times in the literature, including [10, 38, 43]. The computational domain in this case is $(x, y) \in [0, 2\pi] \times [0, 2\pi]$ with double-periodic boundary conditions. In this problem we again use the MC limiter, but with a reduced CFL number of 0.75. This slightly reduced CFL number is required because in the solution shock waves propagate along the boundary; however, in CLAWPACK [31] the computed CFL number does not include the tangential wave speed directly on the boundaries.

A Schlieren plot of the thermal pressure at time $t = 3.14$ predicted by the MPACT scheme on a 256×256 grid is shown in Figure 7.5(a). A slice of this solution at $y = 1.9321$ is shown in Figure 7.5(b). Although each paper displays the solution at slightly different times and resolutions, our results compare well with those given in [10, 38, 43].

Let us also take this opportunity to show what can go wrong if no CT is used. With a grid resolution of 256×256, the wave propagation method without CT (i.e., the base scheme) produces a negative pressure at time $t = 0.633$. The solution at

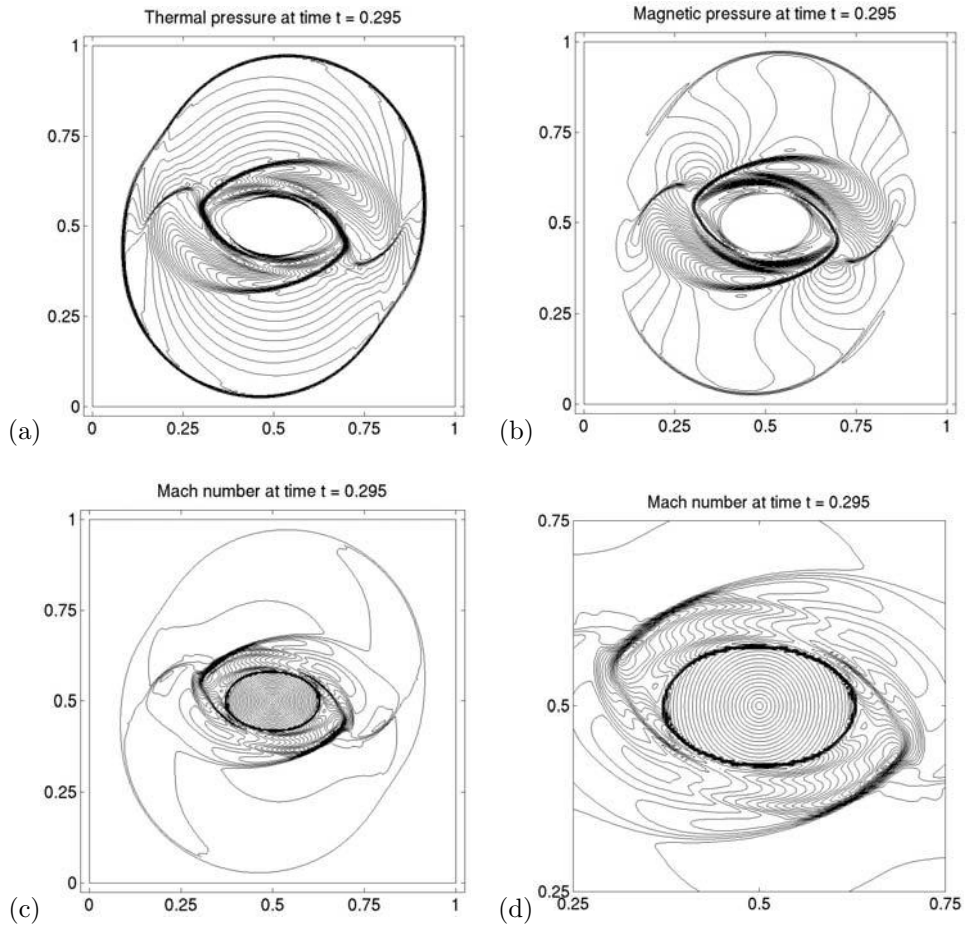


FIG. 7.4. *The* (a) *thermal pressure,* (b) *magnetic pressure,* (c) *Mach number, and* (d) *close-up view of the Mach number at* $t = 0.295$ *for the rotor problem. The solution was obtained with the* MPACT *scheme on a* 256×256 *grid. In following with Tóth* [38]*,* 30 *contour lines are shown for each graph in the ranges* $0.007 < p < 0.776$*,* $0 < |\vec{u}|/c_s < 3.64$*, and* $0.007 < |\vec{B}|^2/2 < 0.702$*.*

this time is shown in Figure 7.6 along with the CT solution at the same time. One clearly sees from these plots that keeping the divergence small is crucial for numerical stability. Note that we are using the same limiters, CFL numbers, etc., in these two calculations.

7.6. Cloud-shock interaction. Finally, we consider a slight modification of the cloud-shock interaction problem from Tóth [38] and Dai and Woodward [10]. In their formulation, the cloud is propagating at a constant speed toward the shock, while in our setup the bubble is initially stationary. The computational domain is $(x, y) \in [0, 1] \times [0, 1]$ with constant inflow conditions at the left boundary and outflow boundary conditions on the three remaining sides. In this problem we use the more diffusive minmod limiter [30] and a slightly reduced CFL number of 0.75. Here we have to use a slightly reduced CFL number in order to avoid producing negative pressures when the shock and cloud first come into contact. The initial conditions

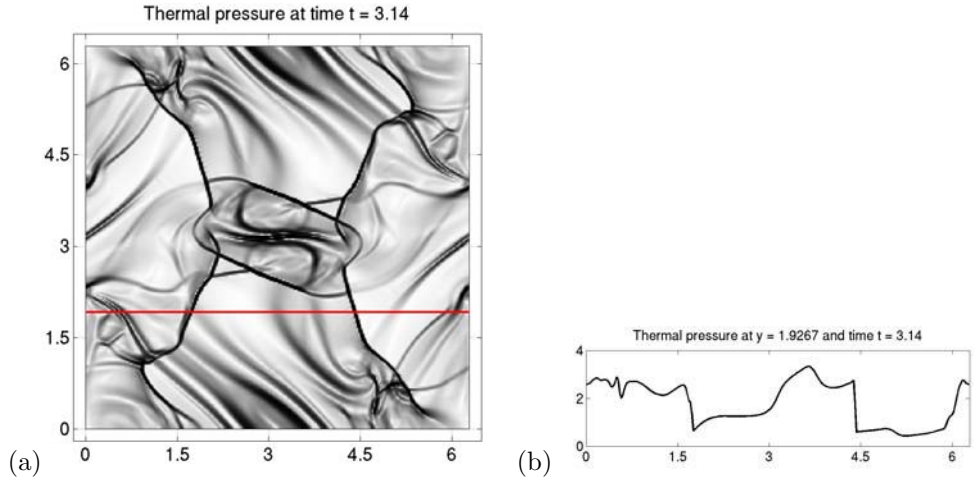

FIG. 7.5. *The thermal pressure at* $t = 3.14$ *for the Orszag–Tang vortex. Shown are* (a) *a Schlieren plot over the entire domain and* (b) *a horizontal slice at* $y = 1.9267$. *The solution was obtained with the* MPACT *scheme on a* 256×256 *grid.*

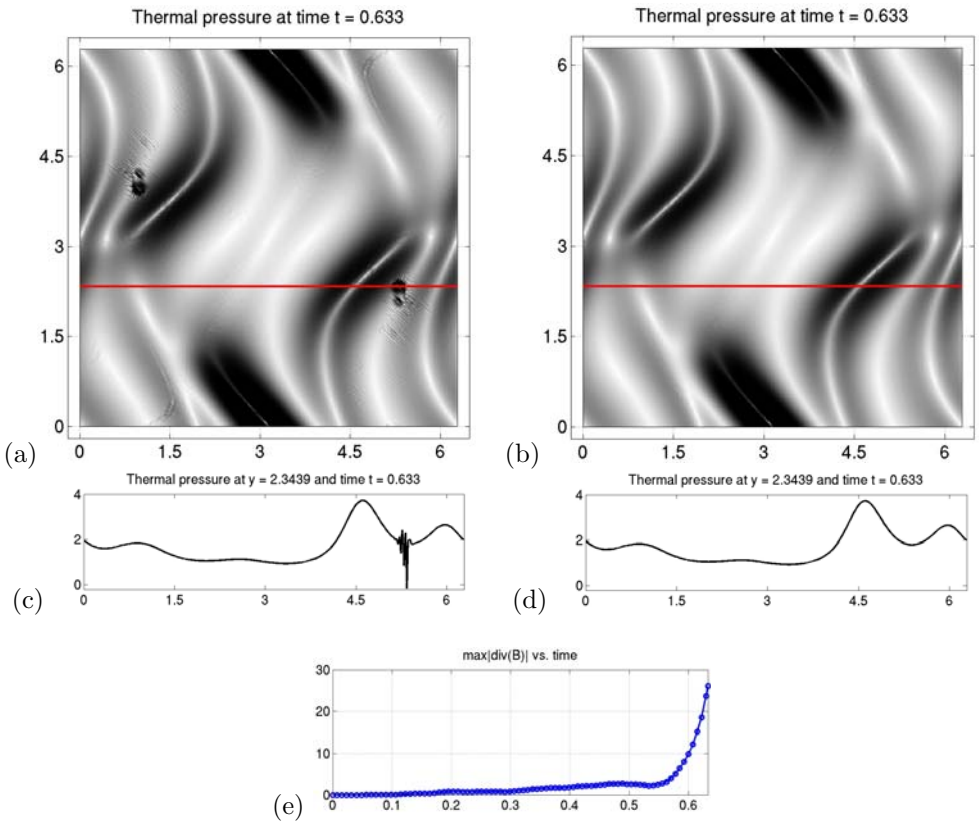

FIG. 7.6. *The thermal pressure at* $t = 0.633$ *for the Orszag–Tang vortex on a* 256×256 *grid. Plots* (a) *and* (c) *show the solution computed with the wave propagation method without CT (i.e., the base scheme). Plots* (b) *and* (d) *show the solution computed with the proposed CT method. Shown in* (e) *is* $\max |\vec{\nabla} \cdot \vec{B}|$ *as a function of time for the base scheme calculation—note the sharp increase in the divergence near* $t = 0.633$. *These plots demonstrate how unphysical oscillations can appear in calculations that do not explicitly control the divergence of the magnetic field.*

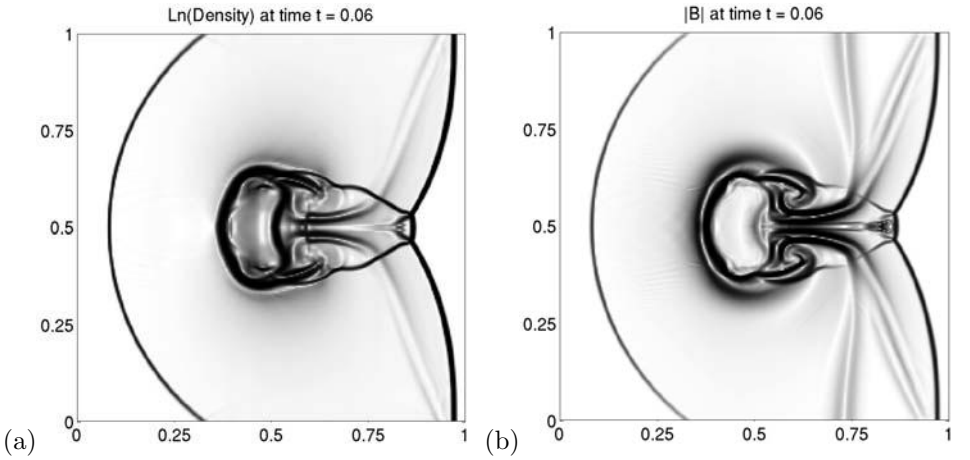

FIG. 7.7. *Schlieren plots of the* (a) *natural log of the density and* (b) *magnetic field at* $t = 0.06$ *for the cloud-shock interaction problem. The solution was obtained with the* MPACT *scheme on a* 256×256 *grid.*

consist of a shock located at $x = 0.05$,

$$\Big[\rho, u_1, u_2, u_3, p, B_1, B_2, B_3\Big]_{t=0} = \begin{cases} \Big[3.86859, 11.2536, 0, 0, 167.345, 0, 2.1826182, -2.1826182\Big] & \text{if } x < 0.05, \\ \Big[1, 0, 0, 0, 1, 0, 0.56418958, 0.56418958\Big] & \text{if } x > 0.05, \end{cases}$$

and a circular cloud of density $\rho = 10$ and radius $r = 0.15$ centered at $(x, y) = (0.25, 0.5)$. The cloud is in hydrostatic equilibrium with the fluid to the right of the shock. The initial magnetic potential is given by

$$\mathbb{A}(x, y, 0) = \begin{cases} -2.1826182x + 0.080921431 & \text{if} \quad x \leq 0.05, \\ -0.56418958x & \text{if} \quad x \geq 0.05. \end{cases}$$

The results of a computation using the MPACT scheme on a 256×256 grid are shown in Figure 7.7. We show Schlieren plots of the (a) log of the density and (b) magnetic field lines. Our results compare well with the solutions presented in [38]. With this test problem we are able to demonstrate the robustness of the MPACT scheme on a violent shock-cloud interaction.

8. Conclusions. We have introduced a new CT method for solving the ideal MHD equations. This method is comprised of four steps which must be carried out during each computational time step:

1. Solve the ideal MHD equations in conservative form using a high-resolution finite volume method.
2. Compute an intermediate time velocity field through linear interpolation in time.
3. Solve the magnetic potential equation.
4. Compute a divergence-free magnetic field from the magnetic potential using centered finite differences.

In this paper, the ideal MHD equations in Step 1 are solved using the wave propagation of LeVeque [27] with normal and transverse Riemann solvers based on the 8-wave decomposition described by Powell [34]. The magnetic potential equation in Step 3 is solved using a modified wave propagation method that ensures that smooth magnetic potentials are computed to second order accuracy. The centered finite differences in Step 4 of this method can introduce spurious oscillations in the magnetic field even if standard TVD limiters are applied in the magnetic potential update. To overcome this difficulty, a novel limiting strategy based on applying TVD limiters to [illegible] was introduced. The resulting MPACT scheme has all of the following properties:

1. Smooth solutions are approximated to second order accuracy in space and time.
2. The method is numerically conservative.
3. The magnetic field satisfies a discrete divergence-free condition.
4. Shock waves and other discontinuities are accurately captured.

This approach was successfully tested on several 2D problems.

The numerical method proposed in this work has been implemented as an extension to the CLAWPACK software package [31] and can be freely downloaded from the Web.

Appendix. Proof of second order accuracy for the modified WP method.

CLAIM. [illegible] $\Delta t = c_1 \Delta x = c_2 \Delta y$ [illegible] c_1 [illegible] c_2 [illegible] $q(x, y, t)$ [illegible] (x, y, t) [illegible] 5.3 [illegible] $\mathcal{O}(\Delta t^2)$ [illegible]. Under the assumption that $q(x, y, t)$ is smooth in x, y, and t, the quantity $q(x, y, t + \Delta t)$ can be expanded in a Taylor series in the following way:

$$
\begin{aligned}
q(x, y, t + \Delta t) &= q + \Delta t\, q_t + \frac{\Delta t^2}{2}\, q_{tt} + \mathcal{O}(\Delta t^3) \\
&= q - \Delta t\, u_1\, q_x + \frac{\Delta t^2}{2} \left[u_1 \left(u_1\, q_x + u_2\, q_y \right)_x \right] \\
&\quad - \Delta t\, u_2\, q_y + \frac{\Delta t^2}{2} \left[u_2 \left(u_2\, q_y + u_1\, q_x \right)_y \right] + \mathcal{O}(\Delta t^3)\,,
\end{aligned}
\tag{A.1}
$$

where $q = q(x, y, t)$, $u_1 \equiv u_1(x, y, t + \Delta t/2)$, and $u_2 \equiv u_2(x, y, t + \Delta t/2)$. In the above expression, derivatives in time were replaced by derivatives in space through the use of (5.3). Showing that the modified wave propagation method is $\mathcal{O}(\Delta t^2)$ accurate becomes equivalent to showing that each term in (A.1) is approximated to $\mathcal{O}(\Delta t^2)$. Furthermore, through symmetry this is equivalent to showing that the terms

$$
q^\star = q - \Delta t\, u_1\, q_x + \frac{\Delta t^2}{2} \left[u_1 \left(u_1\, q_x + u_2\, q_y \right)_x \right] \tag{A.2}
$$

are approximated to $\mathcal{O}(\Delta t^2)$ by the part of the algorithm that is responsible for constructing fluctuations and fluxes in the x-direction.

The part of the algorithm that is responsible for modeling the terms in expression (A.2) can be written as

$$
Q_i^\star = Q_i^n - \frac{\Delta t}{\Delta x} \left[\mathcal{A}_1^- \Delta Q_{i+1/2} + \mathcal{A}_1^+ \Delta Q_{i-1/2} \right] - \frac{\Delta t}{\Delta x} \left[\tilde{F}^{1-}_{i+1/2} - \tilde{F}^{1+}_{i-1/2} \right]. \tag{A.3}
$$

We now plug in definitions (5.6), (5.7), (5.11), and (5.12) to obtain that

$$\begin{aligned} Q_i^\star = Q_i^n &- \frac{1}{2}\frac{\Delta t}{\Delta x}\left[\left(2\left[s_i\right]^- + |s_i|\right)\mathcal{W}_{i+1/2} + \left(2\left[s_i\right]^+ - |s_i|\right)\mathcal{W}_{i-1/2}\right] \\ &+ \frac{1}{2}\frac{\Delta t^2}{\Delta x^2}\left[u_1\right]_i\left[s_{i+1/2}\mathcal{W}_{i+1/2} - s_{i-1/2}\mathcal{W}_{i-1/2}\right] - \frac{\Delta t}{\Delta x}\left[\tilde{\tilde{F}}^{1-}_{i+1/2} - \tilde{\tilde{F}}^{1+}_{i-1/2}\right], \end{aligned} \tag{A.4}$$

where the $\tilde{\tilde{F}}$'s contain the transverse corrections. We now make use of the identities

$$\left[s_i\right]^+ + \left[s_i\right]^- = s_i, \tag{A.5}$$

$$\left[s_i\right]^+ - \left[s_i\right]^- = |s_i|, \tag{A.6}$$

$$s_{i+1/2}\mathcal{W}_{i+1/2} = \left[u_1\right]_{i+1/2}\left(Q_{i+1} - Q_i\right) \tag{A.7}$$

and reduce (A.4) to

$$\begin{aligned} Q_i^\star = Q_i^n &- \frac{1}{2}\frac{\Delta t}{\Delta x}s_i\left(\mathcal{W}_{i+1/2} + \mathcal{W}_{i-1/2}\right) \\ &+ \frac{1}{2}\frac{\Delta t^2}{\Delta x^2}\left[u_1\right]_i\left(\left[u_1\right]_{i+1/2}\left(Q_{i+1} - Q_i\right) - \left[u_1\right]_{i-1/2}\left(Q_i - Q_{i-1}\right)\right) \\ &- \frac{\Delta t}{\Delta x}\left[\tilde{\tilde{F}}^{1-}_{i+1/2} - \tilde{\tilde{F}}^{1+}_{i-1/2}\right], \end{aligned} \tag{A.8}$$

$$\begin{aligned} \implies Q_i^\star = Q_i^n &- \frac{1}{2}\frac{\Delta t}{\Delta x}\left[u_1\right]_i\left(Q_{i+1} - Q_{i-1}\right) \\ &+ \frac{1}{2}\frac{\Delta t^2}{\Delta x^2}\left[u_1\right]_i\left(\left[u_1\right]_{i+1/2}\left(Q_{i+1} - Q_i\right) - \left[u_1\right]_{i-1/2}\left(Q_i - Q_{i-1}\right)\right) \\ &- \frac{\Delta t}{\Delta x}\left[\tilde{\tilde{F}}^{1-}_{i+1/2} - \tilde{\tilde{F}}^{1+}_{i-1/2}\right] + \mathcal{O}\left(\Delta t^3\right), \end{aligned} \tag{A.9}$$

$$\begin{aligned} \implies Q_i^\star = Q_i^n &- \Delta t\left[u_1 q_x\right]_i + \frac{\Delta t^2}{2}\left[u_1\left(u_1 q_x\right)_x\right]_i \\ &- \frac{\Delta t}{\Delta x}\left[\tilde{\tilde{F}}^{1-}_{i+1/2} - \tilde{\tilde{F}}^{1+}_{i-1/2}\right] + \mathcal{O}\left(\Delta t^3\right). \end{aligned} \tag{A.10}$$

Finally, we turn our attention to the transverse corrections. After collecting contributions from all the necessary grid cells, the transverse flux correction can be written as

$$\begin{aligned} \tilde{\tilde{F}}^{1-}_{i+1/2} = -\frac{1}{2}\frac{\Delta t}{\Delta y}\Bigg(&\left[u_1\right]_i^+\left(u_2^+\Delta Q - 2\tilde{F}^{2+}\right)_{i,j-1/2} \\ &+ \left[u_1\right]_i^-\left(u_2^+\Delta Q - 2\tilde{F}^{2+}\right)_{i+1,j-1/2} \\ &+ \left[u_1\right]_i^+\left(u_2^-\Delta Q + 2\tilde{F}^{2-}\right)_{i,j+1/2} \\ &+ \left[u_1\right]_i^-\left(u_2^-\Delta Q + 2\tilde{F}^{2-}\right)_{i+1,j+1/2}\Bigg). \end{aligned} \tag{A.11}$$

We note that

$$\begin{aligned} u_2^+\Delta Q - 2\tilde{F}^{2+} &= u_2^-\Delta Q + \mathcal{O}(\Delta t^2), \\ u_2^-\Delta Q + 2\tilde{F}^{2-} &= u_2^+\Delta Q + \mathcal{O}(\Delta t^2) \end{aligned}$$

through the application of identities (A.5) and (A.6). Using this result in conjunction with a Taylor expansion, the terms in expression (A.11) can be rewritten as follows:

$$\begin{aligned}
\left(u_2^+ \Delta Q - 2\tilde{F}^{2+}\right)_{i,j-1/2} &= u_2^- \Delta Q_{i+1/2,j} + \mathcal{O}(\Delta t^2), \\
\left(u_2^+ \Delta Q - 2\tilde{F}^{2+}\right)_{i+1,j-1/2} &= u_2^- \Delta Q_{i+1/2,j} + \mathcal{O}(\Delta t^2), \\
\left(u_2^- \Delta Q + 2\tilde{F}^{2-}\right)_{i,j+1/2} &= u_2^+ \Delta Q_{i+1/2,j} + \mathcal{O}(\Delta t^2), \\
\left(u_2^- \Delta Q + 2\tilde{F}^{2-}\right)_{i+1,j+1/2} &= u_2^+ \Delta Q_{i+1/2,j} + \mathcal{O}(\Delta t^2)\,.
\end{aligned}$$

Note that the error here is $\mathcal{O}(\Delta t^2)$ because the Taylor expansions are accurate to $\mathcal{O}(\Delta t)$ and $u_2^{\pm}\Delta Q \mp 2\tilde{F}^{2\pm} = \mathcal{O}(\Delta t)$. Using these results, the transverse flux correction (A.11) can be rewritten as

$$\begin{aligned}
\tilde{\tilde{F}}^{1-}_{i+1/2} &= -\frac{1}{2}\frac{\Delta t}{\Delta y}\left([u_1]_i^- + [u_1]_i^+\right)\left(u_2^- \Delta Q_{i+1/2,j} + u_2^+ \Delta Q_{i+1/2,j}\right) + \mathcal{O}(\Delta t^2) \\
&= -\frac{1}{2}\frac{\Delta t}{\Delta y}\,[u_1]_i\, u_2 \Delta Q_{i+1/2,j} + \mathcal{O}(\Delta t^2)\,.
\end{aligned}$$

Similarly,

$$\tilde{\tilde{F}}^{1+}_{i-1/2} = -\frac{1}{2}\frac{\Delta t}{\Delta y}\,[u_1]_i\, u_2 \Delta Q_{i-1/2,j} + \mathcal{O}(\Delta t^2)\,.$$

Plugging these results into (A.10) yields

$$\begin{aligned}
Q_i^\star &= Q_i^n - \Delta t\,[u_1 q_x]_i + \frac{\Delta t^2}{2}\,[u_1\,(u_1 q_x)_x]_i \\
&\quad + \frac{1}{2}\frac{\Delta t^2}{\Delta x \Delta y}\,[u_1]_i\left(u_2 \Delta Q_{i+1/2,j} - u_2 \Delta Q_{i-1/2,j}\right) + \mathcal{O}\left(\Delta t^3\right) \\
&= Q_i^n - \Delta t\,[u_1 q_x]_i + \frac{\Delta t^2}{2}\left[u_1\,(u_1 q_x + u_2 q_y)_x\right]_i + \mathcal{O}\left(\Delta t^3\right)\,.
\end{aligned} \tag{A.12}$$

Comparing expressions (A.12) and (A.1) shows that the 1-step error of the modified wave propagation method is $\mathcal{O}\left(\Delta t^3\right)$, and therefore the local truncation error is $\mathcal{O}\left(\Delta t^2\right)$. ∎

A RATIONAL SPECTRAL COLLOCATION METHOD WITH ADAPTIVELY TRANSFORMED CHEBYSHEV GRID POINTS*

T. W. TEE† AND LLOYD N. TREFETHEN†

Abstract. A spectral collocation method based on rational interpolants and adaptive grid points is presented. The rational interpolants approximate analytic functions with exponential accuracy by using prescribed barycentric weights and transformed Chebyshev points. The locations of the grid points are adapted to singularities of the underlying solution, and the locations of these singularities are approximated by the locations of poles of Chebyshev–Padé approximants. Numerical experiments on two time-dependent problems, one with finite time blow-up and one with a moving front, indicate that the method far outperforms the standard Chebyshev spectral collocation method for problems whose solutions have singularities in the complex plane close to $[-1, 1]$.

Key words. rational spectral collocation method, adaptive grid points, barycentric interpolation formula, complex singularities, Chebyshev–Padé approximation, blow-up problem, the Burgers equation

1. Introduction.

The Chebyshev spectral method (the phrase spectral method is synonymous with spectral collocation method in this article) is a method for the numerical solution of differential equations on a bounded nonperiodic interval, which may be assumed without loss of generality to be $[-1, 1]$. The basis of the method is to approximate the solution of a differential equation by a polynomial which interpolates data u_k at Chebyshev points $x_k = \cos(k\pi/N)$, $k = 0, 1, \ldots, N$, where the data $\{u_k\}$ are determined by requiring that the polynomial interpolant satisfy the differential equation exactly at the points $\{x_k\}$. As N increases, the approximation error decays at a rate which depends on the smoothness of the underlying solution. If the solution can be continued as an analytic function in a closed ellipse with foci ± 1, semimajor axis length L, and semiminor axis length l, then the error decays exponentially at the rate $O((L+l)^{-N})$ [29]. However, if the solution has singularities in the complex plane close to $[-1, 1]$, so that $L + l \approx 1$, then this convergence rate will be too slow for the method to be effective.

One cannot simply alter the points and expect a better convergence rate, because polynomials which interpolate at Chebyshev points already give near best polynomial approximations. Instead, one must consider spectral methods based on other types of global interpolants, such as rational functions. Unlike polynomials, rational functions can interpolate at any set of points without the drawback of the Runge phenomenon.

The purpose of this article is to present a new spectral method based on rational interpolants and adaptive grid points, and to show that this method far outperforms the Chebyshev spectral method for problems whose solutions have singularities in the complex plane close to $[-1, 1]$.

Spectral methods based on rational interpolants have been developed by Berrut, Baltensperger, and Mittelmann [12]. A common feature of their methods is the rep-

resentation of rational interpolants in barycentric form. The barycentric form of a rational function r which interpolates data $f_0, f_1, \ldots, f_N$ at points $x_0, x_1, \ldots, x_N$ is

$$r(x) = \frac{\displaystyle\sum_{k=0}^{N} \frac{w_k}{x - x_k} f_k}{\displaystyle\sum_{k=0}^{N} \frac{w_k}{x - x_k}}, \tag{1.1}$$

where $w_0, w_1, \ldots, w_N$ are called barycentric weights. An advantage of representing a rational interpolant in barycentric form is that its derivatives can be evaluated easily using differentiation formulae derived by Baltensperger and Berrut [1, 2], instead of using the quotient rule repeatedly. The pth derivative of r evaluated at x_j can be written in the form $r^{(p)}(x_j) = \sum_{k=0}^{N} D_{jk}^{(p)} u_k$, where the entries of $D^{(1)}$ and $D^{(2)}$, the first and second order differentiation matrices, are given by

$$D_{jk}^{(1)} = \begin{cases} \dfrac{w_k}{w_j(x_j - x_k)} & \text{if } j \neq k, \\ -\displaystyle\sum_{i=0,\ i\neq k}^{N} D_{ji}^{(1)} & \text{if } j = k, \end{cases} \tag{1.2}$$

$$D_{jk}^{(2)} = \begin{cases} 2D_{jk}^{(1)} \left(D_{jj}^{(1)} - \dfrac{1}{x_j - x_k} \right) & \text{if } j \neq k, \\ -\displaystyle\sum_{i=0,\ i\neq k}^{N} D_{ji}^{(2)} & \text{if } j = k \end{cases} \tag{1.3}$$

for $j, k = 0, 1, \ldots, N$. For every set of points $\{x_k\}$, there is a unique set of barycentric weights $\{w_k\}$, up to a multiplicative constant, for which (1.1) represents a polynomial interpolant. For example, if $\{x_k\}$ are the Chebyshev points, then (1.1) represents a polynomial interpolant if and only if $w_0 = c/2$, $w_k = (-1)^k c$, $k = 1, \ldots, N-1$, and $w_N = (-1)^N c/2$ for some nonzero constant c [17]. Thus,

Baltensperger, Berrut, and Noël exploited this property, modifying a polynomial which interpolates at Chebyshev points into a rational interpolant which approximates analytic functions with exponential accuracy, by applying a conformal map to the points and leaving the barycentric weights unchanged [4]. Baltensperger and Berrut developed a spectral method based on that rational interpolant, in which they used the conformal map of Kosloff and Tal-Ezer [24] to distribute grid points more evenly over the computational interval [3, 11]. Berrut had shown in earlier work that if that rational interpolant has arbitrary points, then it cannot have poles in the interpolation interval, which is a crucial property for approximating continuous functions [9].

Berrut and Mittelmann took the alternative approach, modifying a polynomial which interpolates at Chebyshev points into a rational interpolant with preassigned poles, by changing the barycentric weights using a formula discovered by Berrut [10] and leaving the points unchanged [13]. They developed a spectral method based on that rational interpolant, in which they computed the locations of preassigned poles by minimizing a residual error iteratively [14, 15].

Berrut and Mittelmann also developed a spectral method based on a combination of the two previous rational interpolants, in which they used a modified version of the conformal map of Bayliss and Turkel [8] to adapt grid points to multiple fronts, and computed the parameters of the map and the locations of poles simultaneously by minimizing a residual error iteratively [16]. However, this computationally expensive optimization step renders their method inefficient for time-dependent problems.

Spectral methods based on adaptive grid points have, so far, required that the underlying problem be transformed into new coordinates, where the transformation maps predefined grid points in a transformed coordinate into irregular grid points in a physical coordinate. The aim is to transform a problem which has a rapidly varying solution into one which has a slowly varying solution. The transformation is usually achieved by means of a parametrized map whose parameters are chosen to minimize an error functional [6, 7, 22]. A related method is that of an adaptive finite difference method coupled with a spectral method, in which a transformation serving the same purpose as that just described is constructed from the grid points of an adaptive finite difference solution [26, 27].

In this article, we present a new adaptive rational spectral method which, unlike existing adaptive spectral methods, does not require that the underlying problem be transformed into new coordinates, and unlike existing rational spectral methods, takes into account and locates a priori unknown singularities of the underlying solution. In section 2, we explain how a conformal map which maps the singularities of a function farther into the complex plane can be used to improve the Chebyshev spectral method. In section 3, we explain how Chebyshev–Padé approximation can be used to approximate the locations of these singularities. In section 4, we explain how the new method can be implemented from ideas discussed in sections 2 and 3. In section 5, we present the results of numerical experiments on two time-dependent problems. Finally in section 6, we present some conclusions.

2. Enlarging the ellipse of analyticity. The basis of our adaptive rational spectral method is the following theorem, which was proved in [4], on the exponential convergence of rational functions which interpolate at transformed Chebyshev points.

THEOREM 1. D_1 D_2 $\mathbb{C}$ $J = [-1, 1]$ I $g : D_1 \to D_2$ $g(J) = I$ E_ρ ± 1 ρ $f : D_2 \to \mathbb{C}$ $f \circ g : D_1 \to \mathbb{C}$ E_ρ g $E_\sigma \supseteq E_\rho$

$$r_N(x) = \frac{\displaystyle\sum_{k=0}^{N}{}' \frac{(-1)^k}{x - x_k} f(x_k)}{\displaystyle\sum_{k=0}^{N}{}' \frac{(-1)^k}{x - x_k}}, \qquad x_k = g(\cos(k\pi/N)), \tag{2.1}$$

$k = 0$ $k = N$

$$|r_N(x) - f(x)| = O((L + l)^{-N}) \tag{2.2}$$

$x \in [-1, 1]$

If the solution u of a differential equation can be continued as an analytic function in a neighborhood of $[-1, 1]$ in the complex plane, then the error in approximating u by the Chebyshev spectral method will decay exponentially at a rate which depends

on the size of the largest ellipse with foci ± 1 in which u is analytic. To be brief, this largest ellipse will be called the [illegible] of u.

Theorem 1 suggests that one should choose a conformal map g for which the ellipse of analyticity of $u \circ g$ is larger than the ellipse of analyticity of u, and apply g in a spectral method based on rational interpolants of the form (2.1), to obtain an approximation of u which is more accurate than that obtained using the Chebyshev spectral method with the same number of grid points. Alternatively, one can obtain an equally accurate approximation of u by using the Chebyshev spectral method to approximate $u \circ g$ directly, but this approach requires the tedious transformation of the underlying differential equation into new coordinates. To be precise, if x is the physical coordinate and $y = g^{-1}(x)$ is the transformed coordinate, where g^{-1} is the inverse of g, then the first few derivatives of u have to be transformed according to

$$\frac{du}{dx} = \frac{1}{g'(y)} \frac{du}{dy}, \tag{2.3}$$

$$\frac{d^2u}{dx^2} = \frac{1}{[g'(y)]^2} \frac{d^2u}{dy^2} - \frac{g''(y)}{[g'(y)]^3} \frac{du}{dy}, \tag{2.4}$$

$$\frac{d^3u}{dx^3} = \frac{1}{[g'(y)]^3} \frac{d^3u}{dy^3} - \frac{3g''(y)}{[g'(y)]^4} \frac{d^2u}{dy^2} - \frac{g'''(y)g'(y) - 3[g''(y)]^2}{[g'(y)]^5} \frac{du}{dy}, \tag{2.5}$$

and similarly for higher derivatives. These transformations are not required when one approximates u by a spectral method based on rational interpolants of the form (2.1).

How do we choose g? If only real solutions are of interest, then we should choose g such that g^{-1} maps the two complex conjugate singularities lying on the ellipse of analyticity of u farther away from $[-1, 1]$. There are many possibilities, but for the time being, consider the case where u is analytic everywhere in the complex plane except along two lines extending from $0 \pm \varepsilon \mathrm{i}$ to $0 \pm \infty \mathrm{i}$, as shown in the region I_1 of Figure 1. Then

1. $h_1(z) = -z\varepsilon^{-1}\mathrm{i}$ rotates and scales I_1 to produce I_2,
2. $h_2(z) = \sin^{-1}(z)$ maps I_2 to the vertical strip I_3, and
3. $h_3(z) = -z/\sin^{-1}(\varepsilon^{-1}\mathrm{i})$ rotates and scales I_3 to produce I_4.

The conformal map g which maps I_4 to I_1 is the inverse of $h_3 \circ h_2 \circ h_1$ and due to the identity $\sin^{-1}(z) = -\mathrm{i}\sinh^{-1}(\mathrm{i}z)$, can be written in the form

$$g(z) = \varepsilon \sinh(z \sinh^{-1}(\tfrac{1}{\varepsilon})). \tag{2.6}$$

Figure 1 shows the adaptive nature of g, in that it maps points which are clustered near the boundaries of $[-1, 1]$ into points which are clustered near the singular lines of u. Table 1 shows that as ε decreases geometrically, the number of grid points required for the Chebyshev spectral method to approximate u to 10 digits of accuracy increases geometrically, whereas for a spectral method based on rational interpolants of the form (2.1) and the conformal map (2.6), this number increases only algebraically.

The derivation of (2.6) can be generalized to cases where the two singular lines begin at $\delta \pm \varepsilon \mathrm{i}$ instead of $0 \pm \varepsilon \mathrm{i}$. The conformal map g becomes

$$g(z) = \delta + \varepsilon \sinh\left[\left(\sinh^{-1}(\tfrac{1-\delta}{\varepsilon}) + \sinh^{-1}(\tfrac{1+\delta}{\varepsilon})\right)\tfrac{z-1}{2} + \sinh^{-1}(\tfrac{1-\delta}{\varepsilon})\right]. \tag{2.7}$$

The derivation of (2.7) makes no assumptions about the type of singularities of u, so (2.7) is applicable for all types of singularities, such as poles and branch points, as long as they are confined to the two singular lines.

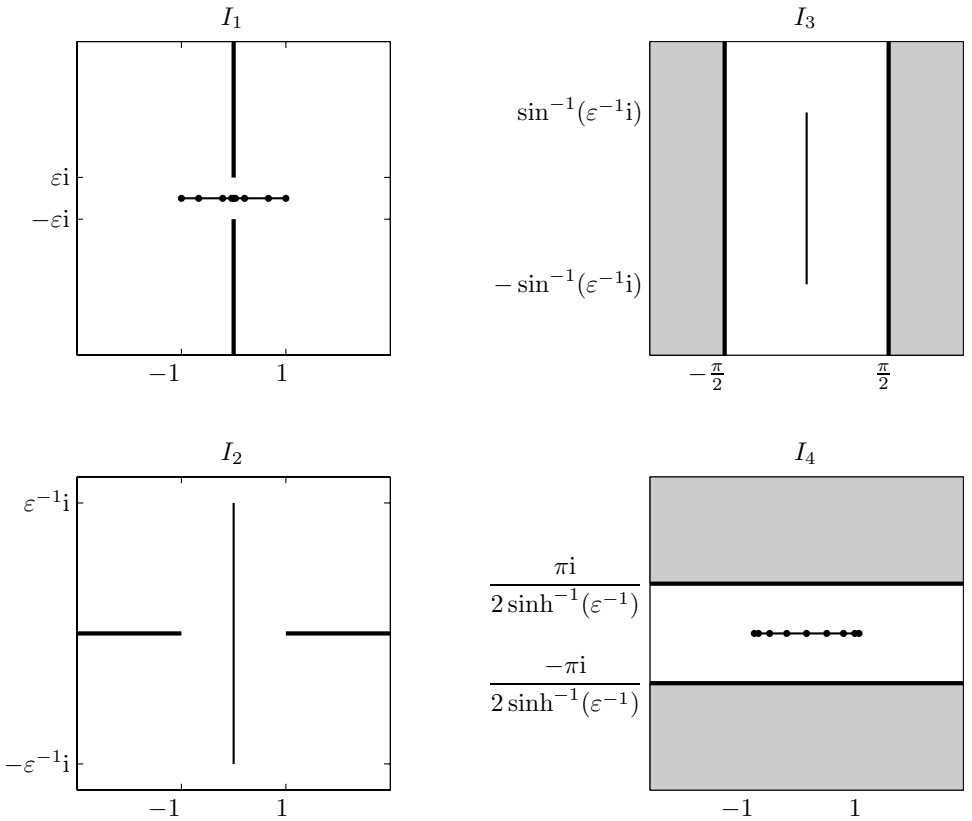

FIG. 1. *Sequence of transformation images to be read from top to bottom, then from left to right. In the first panel, the thick lines represent singular lines, the thin line represents* $[-1, 1]$*, and the white background represents the region of analyticity* I_1*. In the fourth panel, the dots represent Chebyshev points.*

TABLE 1

ε	Chebyshev spectral method		Adaptive rational spectral method	
	Convergence rate	$N_{\min}$	Convergence rate	$N_{\min}$
1	$O(2.4142^{-N})$	27	$O(3.8258^{-N})$	18
0.1	$O(1.1050^{-N})$	231	$O(1.6528^{-N})$	46
0.01	$O(1.0100^{-N})$	2303	$O(1.3395^{-N})$	79
0.001	$O(1.0010^{-N})$	23026	$O(1.2277^{-N})$	113
0.0001	$O(1.0001^{-N})$	230259	$O(1.1711^{-N})$	146

3. Locating the singularities. The parameters δ and ε required in (2.7) are usually not known analytically, so it is necessary to approximate them using some singularity location technique. The technique must be computationally cheap for our adaptive rational spectral method to be more efficient than existing rational spectral methods. The technique which we chose is based on Chebyshev–Padé approximation. It is conceptually similar to the technique presented by Weideman in [30], where the locations of singularities are approximated by the locations of poles of Fourier–Padé approximants.

If f is Lipschitz continuous on $[-1,1]$, then it has a Chebyshev expansion

$$f(x) = \sum_{k=0}^{\infty} a_k T_k(x), \tag{3.1}$$

where $a_k = \frac{2}{\pi}\int_{-1}^{1}(1-x^2)^{-\frac{1}{2}} f(x)\,T_k(x)\,dx$ (a_0 is half the value given by this formula) and $T_k(x) = \cos(k\cos^{-1}(x))$. The scalars $\{a_k\}$ are called Chebyshev coefficients and the functions $\{T_k\}$ are the Chebyshev polynomials. The linear $[m,n]$ Chebyshev–Padé approximation of f is defined as the rational function

$$r_{m,n}(x) \equiv \frac{p(x)}{q(x)} = \frac{\displaystyle\sum_{k=0}^{m} b_k T_k(x)}{1 + \displaystyle\sum_{k=1}^{n} c_k T_k(x)} \tag{3.2}$$

of numerator degree at most m and denominator degree at most n, such that the Chebyshev expansion of $fq - p$ satisfies

$$f(x)q(x) - p(x) = O(T_{m+n+1}(x)). \tag{3.3}$$

The coefficients $\{b_k\}$ and $\{c_k\}$ can be determined by substituting (3.1) and (3.2) into (3.3), matching terms with Chebyshev polynomials of equal degree, and finally solving the system of linear equations

$$\begin{pmatrix} 1 & & & -d_{0,1} & \cdots & -d_{0,n} \\ & \ddots & & \vdots & \vdots & \vdots \\ & & 1 & -d_{m,1} & \cdots & -d_{m,n} \\ & & & -d_{m+1,1} & \cdots & -d_{m+1,n} \\ & & & \vdots & \vdots & \vdots \\ & & & -d_{m+n,1} & \cdots & -d_{m+n,n} \end{pmatrix} \begin{pmatrix} b_0 \\ \vdots \\ b_m \\ c_1 \\ \vdots \\ c_n \end{pmatrix} = \begin{pmatrix} a_0 \\ \vdots \\ a_m \\ a_{m+1} \\ \vdots \\ a_{m+n} \end{pmatrix}, \tag{3.4}$$

where $\sum_{j=0}^{\infty} d_{j,k}T_j(x) = \sum_{j=0}^{\infty} a_j T_j(x)T_k(x)$ for $\{b_k\}$ and $\{c_k\}$ as required. It should be noted that $\{c_k\}$ can be computed independently of $\{b_k\}$, in which case the system of linear equations to be solved is only of size n. The poles of $r_{m,n}$ can be determined by computing the eigenvalues of the companion matrix [5, 18]

$$C = \begin{pmatrix} 0 & 1 & & & & \\ \frac{1}{2} & 0 & \frac{1}{2} & & & \\ & \ddots & \ddots & \ddots & & \\ & & \ddots & \ddots & \ddots & \\ & & & \frac{1}{2} & 0 & \frac{1}{2} \\ \dfrac{c_0}{-2c_n} & \dfrac{c_1}{-2c_n} & \cdots & \dfrac{c_{n-3}}{-2c_n} & \dfrac{c_{n-2}}{-2c_n} + \dfrac{1}{2} & \dfrac{c_{n-1}}{-2c_n} \end{pmatrix}, \tag{3.5}$$

where $c_0 = 1$. This is a matrix eigenvalue problem of size n. It can be deduced from (3.4) that $r_{m,n}$ always exists and is unique provided that $c_n \neq 0$.

How do we determine δ and ε? The aim is to approximate them by the real and imaginary parts of the poles of a Chebyshev–Padé approximant. If we can evaluate

or approximate the solution u of a differential equation at $M+1$ Chebyshev points, typically scaled and translated to a subinterval of $[-1,1]$ rather than $[-1,1]$ itself, then we can compute approximations to the Chebyshev coefficients $a_0,\dots,a_M$ of u by applying the fast Fourier transform to these values of u. The poles of an $[m,2]$ Chebyshev–Padé approximation of u, where m is a small integer which we take to be $M/2$ rounded to the nearest integer, can then be computed by applying the techniques described in the preceding paragraph. The locations of these poles approximate the locations of the two complex conjugate singularities lying on the ellipse of analyticity of u [28], and hence δ and ε. The overall work involves solving a 2×2 system of linear equations and computing the eigenvalues of a 2×2 matrix, both of which are trivial computationally. In practice, the ill-conditioning of (3.4) is not a problem, because we need only know δ and ε to one or two digits of accuracy.

4. Implementation. How do we put together a spectral method based on the ideas discussed in sections 2 and 3? If we can evaluate or approximate the solution u of a differential equation at grid points $x_0^n, x_1^n, \dots, x_N^n$ and time t^n, then we approximate u by the rational interpolant

$$r_N^n(x,t) = \frac{\displaystyle\sum_{k=0}^{N}{}' \frac{(-1)^k}{x-x_k^n}\, r_N^n(x_k^n,t)}{\displaystyle\sum_{k=0}^{N}{}' \frac{(-1)^k}{x-x_k^n}}, \tag{4.1}$$

where $r_N^n(x_k^n,t^n)\approx u(x_k^n,t^n)$. The data $\{r_N^n(x_k^n,t^{n+1})\}$ approximating $\{u(x_k^n,t^{n+1})\}$ can be determined by discretizing the underlying differential equation using a temporal discretization method of choice and requiring that r_N^n satisfy the discretized equation exactly at the grid points $\{x_k^n\}$ and at any intermediate time steps, where the spatial derivatives of r_N^n can be evaluated as the product of differentiation matrices and data vectors, as mentioned in section 1. In MATLAB, the first and second order differentiation matrices can be constructed by calling `bcmatrix`:

```
% BCMATRIX constructs the first and second order differentiation matrices, D1
% and D2, corresponding to the barycentric weights w and grid points x. Note
% that w and x must be column vectors of the same size.
function [D1,D2] = bcmatrix(w,x)
  N = length(x)-1; ii = (1:N+2:(N+1)^2)';
  Dw = repmat(w',N+1,1) ./ repmat(w,1,N+1) - eye(N+1);
  Dx = repmat(x ,1,N+1) - repmat(x',N+1,1) + eye(N+1);
  D1 = Dw ./ Dx;
  D1(ii) = 0; D1(ii) = - sum(D1,2);
  D2 = 2*D1 .* (repmat(D1(ii),1,N+1) - 1./Dx);
  D2(ii) = 0; D2(ii) = - sum(D2,2);
```

There is no difference between what we have done so far and what we would do with the Chebyshev spectral method. The difference arises when we adapt grid points for the next time step, for which we do the following.

ALGORITHM 1. [illegible]

1. [illegible] $r_N^n(x,t^{n+1})$ [illegible] $M+1$ [illegible] $[-1,1]$ [illegible] δ
2. [illegible] $r_N^n(x,t^{n+1})$ [illegible] 1 [illegible]
3. [illegible] δ [illegible] ε [illegible] 2 [illegible]

4. [illegible] $x_k^{n+1} = g(\cos(k\pi/N)) \quad k = 0, 1, \ldots, N$ [illegible] g [illegible] (2.7) [illegible] δ [illegible] ε
5. [illegible] $r_N^n(x, t^{n+1})$ [illegible] $\{x_k^{n+1}\}$ [illegible]

In practice, we start with a grid of Chebyshev points and only begin adapting the grid points when ε falls below a threshold indicating how close the true singularities of u in the complex plane are to $[-1, 1]$. In our numerical experiments, we take this threshold to be 0.5. It is necessary to make a few remarks about steps 1–3.

The number $M+1$ of Chebyshev points in step 1 should be enough for $r_N^n(x, t^{n+1})$ to be approximated to a prescribed accuracy in the subinterval centered at δ. The width of the subinterval should be sufficiently small for M to be small, too, and yet sufficiently large for the real part of the true singularities of $u(x, t^{n+1})$ to lie within it. In our numerical experiments, we take M to be the smallest power of 2 for which the Chebyshev coefficient of largest subindex in step 2 is less than 10^{-6} in absolute value and we take the subinterval to be $[\delta - \zeta, \delta + \zeta]$, where $\zeta = \min(10\varepsilon, 1 - |\delta|)$. A typical value of M is 128. In MATLAB, step 1 (and step 5) can be implemented by calling `bcinterp`:

```
% BCINTERP evaluates the barycentric interpolation formula to find the values
% ff of a rational interpolant with barycentric weights w, grid points x, and
% grid data f, at the points xx. Note that w, x, and f must be column vectors
% of the same size.
function ff = bcinterp(w,x,f,xx)
  [mask,index] = ismember(xx,x);
  invmask = (mask==0);
  xxx = xx(invmask);
  ff = zeros(length(xx),1);
  numer = zeros(length(xxx),1);
  denom = zeros(length(xxx),1);
  for i=1:length(x)
    temp = w(i)./(xxx-x(i));
    numer = numer + temp*f(i);
    denom = denom + temp;
  end
  ff(invmask) = numer./denom;
  ff(mask) = f(index(mask));
```

and step 2 can be implemented by calling `chebpoly`:

```
% CHEBPOLY uses the fast Fourier transform to find M+1 Chebyshev coefficients
% A of a function, given its values U at M+1 Chebyshev points. The operation
% is applied to each column of U.
function A = chebpoly(U)
  M = size(U,1)-1;
  U(M+2:2*M,:) = U(M:-1:2,:);
  A = real(ifft(U)); A = A(1:M+1,:); A(2:M,:) = 2*A(2:M,:);
```

The new ε in step 3 should be multiplied by a safety factor to ensure that (2.7) accounts for the true singularities of $u(x, t^{n+1})$. In our numerical experiments, we take this safety factor to be 0.75. In MATLAB, step 3 can be implemented by calling `chebpade`, which in turn calls `chebeval` and `chebpoly`:

```
% CHEBPADE computes the poles z of an [m,n] Chebyshev-Pade approximation of a
% function with Chebyshev coefficients a. Note that a must be a column vector
% with the coefficients in the order a0, a1, a2, ...
function z = chebpade(m,n,a)
  N = length(a)-1;                          % number of coefficients less one
  E = chebeval([zeros(1,n);eye(N+n,n)]);
```

```
  F = repmat(chebeval([a;zeros(n,1)]),1,n);
  D = -chebpoly(E.*F);
  c = [1;D(m+2:m+n+1,:)\a(m+2:m+n+1)];     % denominator coefficients
  if (n > 1)                               % denominator is at least quadratic
    C = diag(0.5*ones(n-1,1),-1);          % companion matrix
    C = C + diag([1;0.5*ones(n-2,1)],1);
    C(n,1:n) = -0.5*c(1:n)'/c(n+1);
    C(n,n-1) = C(n,n-1) + 0.5;
    z = eig(C);                            % poles
  else                                     % denominator is linear
    z = -c(1)/c(2);                        % poles
  end

% CHEBEVAL uses the fast Fourier transform to find the values U of a function
% at N+1 Chebyshev points, given its N+1 Chebyshev coefficients A. The
% operation is applied to each column of A.
function U = chebeval(A)
  N = size(A,1)-1;
  A(2:N,:) = A(2:N,:)/2; A(N+2:2*N,:) = A(N:-1:2,:);
  U = real(fft(A)); U = U(1:N+1,:);
```

5. Numerical experiments. We now present the results of numerical experiments on two time-dependent problems. The problems are discretized temporally using the adaptive Runge–Kutta 5(4) method of Dormand and Prince [20] with an error tolerance of 10^{-10} (we did not use the `ode45` solver of MATLAB, even though it implements the same method, because it does not give us the option of pausing at the end of each time step to adapt the grid points), and solutions are computed using the Chebyshev spectral method and our adaptive rational spectral method with various $N < 128$. The approximation errors are calculated as the maximum absolute value of the difference between the various approximations and their $N = 128$ counterparts evaluated at 10001 equispaced points.

5.1. Blow-up problem. The first problem is the Frank–Kamenetskii or Gelfand equation

$$\frac{\partial u}{\partial t} = \frac{\partial^2 u}{\partial x^2} + e^u, \quad -1 < x < 1, \tag{5.1}$$

with the initial condition $u(x, 0) = 0$ and boundary conditions $u(-1, t) = u(1, t) = 0$. The equation arises in mathematical models of exothermic chemical reactions in solids [25]. The solution of this problem is symmetric with a peak at $x = 0$ which blows up to infinity in finite time due to the nonlinear exponential term, a phenomenon known in the literature as thermal runaway. The solution has logarithmic singularities along the line $\mathrm{Re}(x) = 0$ near the blow-up time T [19], but this time is not known to high precision. The numerical experiment was run until $t = 3.544664598$. The results are summarized in Figure 2.

The first row of the figure shows the solution u approximated using the adaptive rational spectral method with $N = 56$. The grid points are shown as dots. The logarithmic blow-up effect can be seen in the fact that when time moves forward by two digits, the height of u increases by almost a fixed amount. The equidistribution of grid points along the approximation curves enables the method to resolve the tall sharp peak.

The second row shows the poles whose locations approximate the locations of the two complex conjugate singularities lying on the ellipse of analyticity of u. The poles

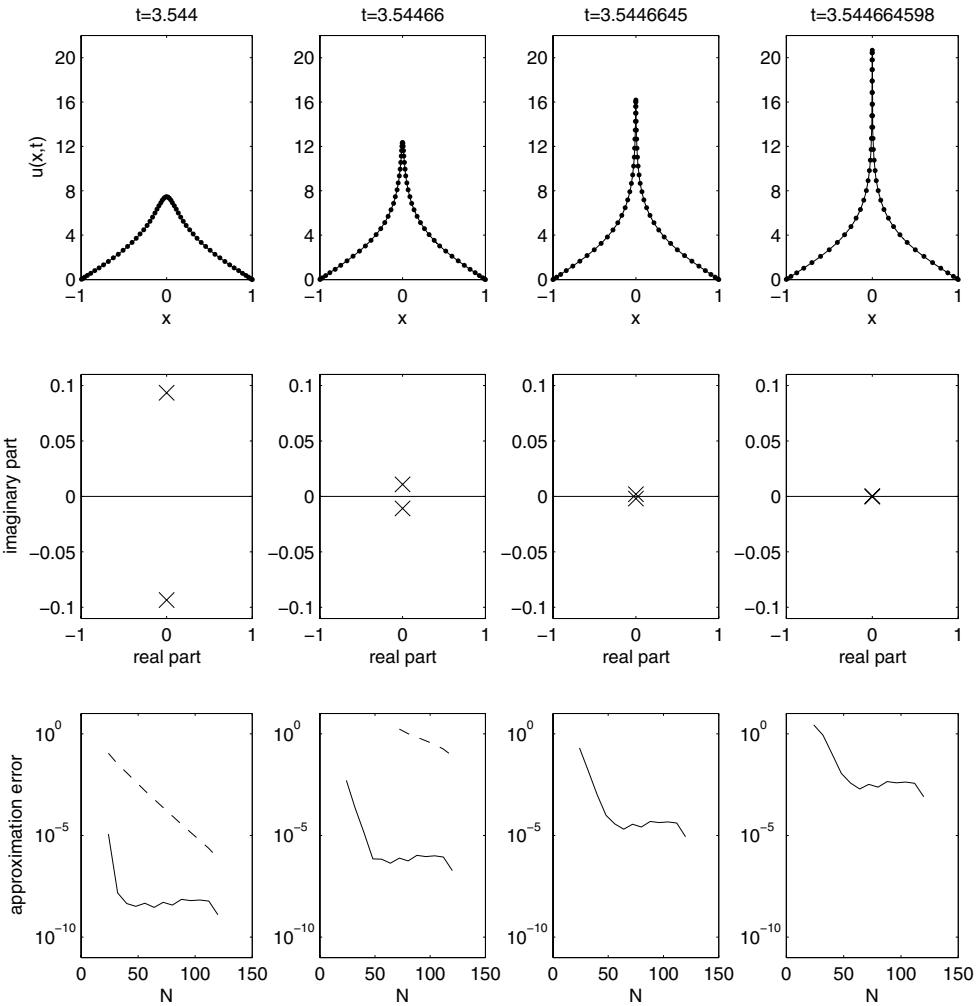

FIG. 2. *The first row shows approximations of the solution of* (5.1) *computed using the adaptive rational spectral method with* $N = 56$. *Dots represent grid points. The second row shows the poles computed using the Chebyshev–Padé singularity location technique. The third row shows log-linear plots of approximation error against* N. *Dashed lines correspond to the Chebyshev spectral method and solid lines to the adaptive rational spectral method. Dashed lines are absent where the Chebyshev spectral method failed to produce a result.*

appear along the line $\mathrm{Re}(x) = 0$ in agreement with the theory. They move closer to each other as the peak grows taller and coalesce at the blow-up time [30].

The third row shows plots of approximation error against N on a log-linear scale for the Chebyshev spectral method and the adaptive rational spectral method. As the height of u increases from about 8 to 20, the maximum number of accurate digits for the adaptive rational spectral method decreases in steps of about 2, reflecting the loss of absolute accuracy in the evaluation of e^u as its magnitude grows in steps of about 2 digits and its relative accuracy remains at about 16 digits. Apart from this quirk, the method requires about 50 grid points to produce results which are accurate to the limit of temporal errors. In contrast, the Chebyshev spectral method fails to produce any result beyond $t = 3.54466$ for $N \leq 128$.

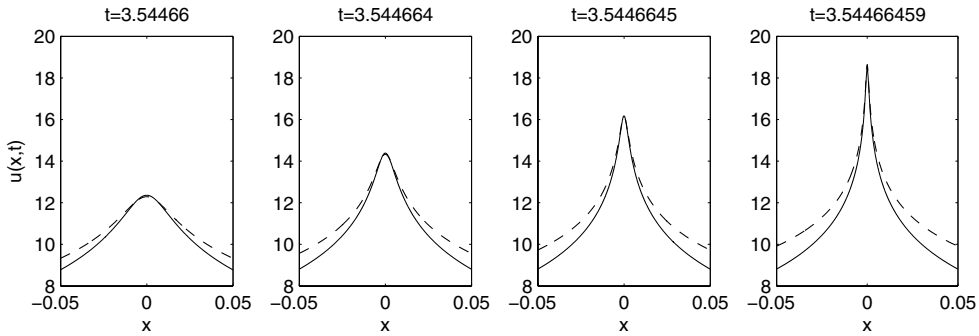

FIG. 3. *Shapes of the solution of* (5.1) *near the blow-up point and blow-up time. Dashed curves correspond to the asymptotic approximation* (5.2)*, and solid curves to the adaptive rational spectral method with* $N = 56$.

TABLE 2
The solution of (5.1) *evaluated at* $x = 0$ *approximated using the adaptive rational spectral method.*

N	$t = 3.544$	$t = 3.54466$	$t = 3.5446645$	$t = 3.544664598$
32	7.460488435	12.36019369	16.16163618	19.81771341
48	7.460488439	12.36040241	16.17636012	20.65913394
64	7.460488439	12.36040263	16.17643386	20.66847337
80	7.460488439	12.36040250	16.17642809	20.66802983
96	7.460488436	12.36040214	16.17641126	20.66650626
112	7.460488436	12.36040219	16.17641359	20.66671875

We also include Figure 3, which compares shapes of a computed approximation of u near the blow-up time with the asymptotic approximation [19]

$$u(x,t) = \xi - \log(1+\eta^2) - \frac{5}{2}\frac{\log(\xi)}{\xi}\frac{\eta^2}{1+\eta^2} + O\Big(\frac{1}{\xi}\Big), \tag{5.2}$$

where $\xi = -\log(T-t)$, $\eta = x/\sqrt{4\xi(T-t)}$, and $T = 3.544664598$. The shapes match only near $x = 0$, because (5.2) is valid only as $x \to 0$ and $t \to T$. In addition, we include Table 2, which lists the height of u approximated using the adaptive rational spectral method with various N, and hope that it will serve as a reference for further study of this blow-up problem.

5.2. Moving front problem. The second problem is the Burgers equation

$$\frac{\partial u}{\partial t} = \nu\frac{\partial^2 u}{\partial x^2} - u\frac{\partial u}{\partial x}, \quad 0 < x < 1, \tag{5.3}$$

with the initial condition $u(x,0) = \sin(2\pi x) + \frac{1}{2}\sin(\pi x)$ and boundary conditions $u(0,t) = u(1,t) = 0$. This problem serves as a common test problem for adaptive grid methods (see [23] and the references therein). Its solution develops a steep front which moves towards $x = 1$ but, due to the homogeneous boundary conditions, also decays with time. The width of the front is $O(\nu)$. The numerical experiment was run until $t = 0.90$ with $\nu = 10^{-3}$. The results are summarized in Figure 4.

The first row of the figure shows the solution u approximated using the adaptive rational spectral method with $N = 56$. The grid points are shown as dots. The clustering of grid points where the approximation curves have steep gradients enables the method to resolve the thin steep front.

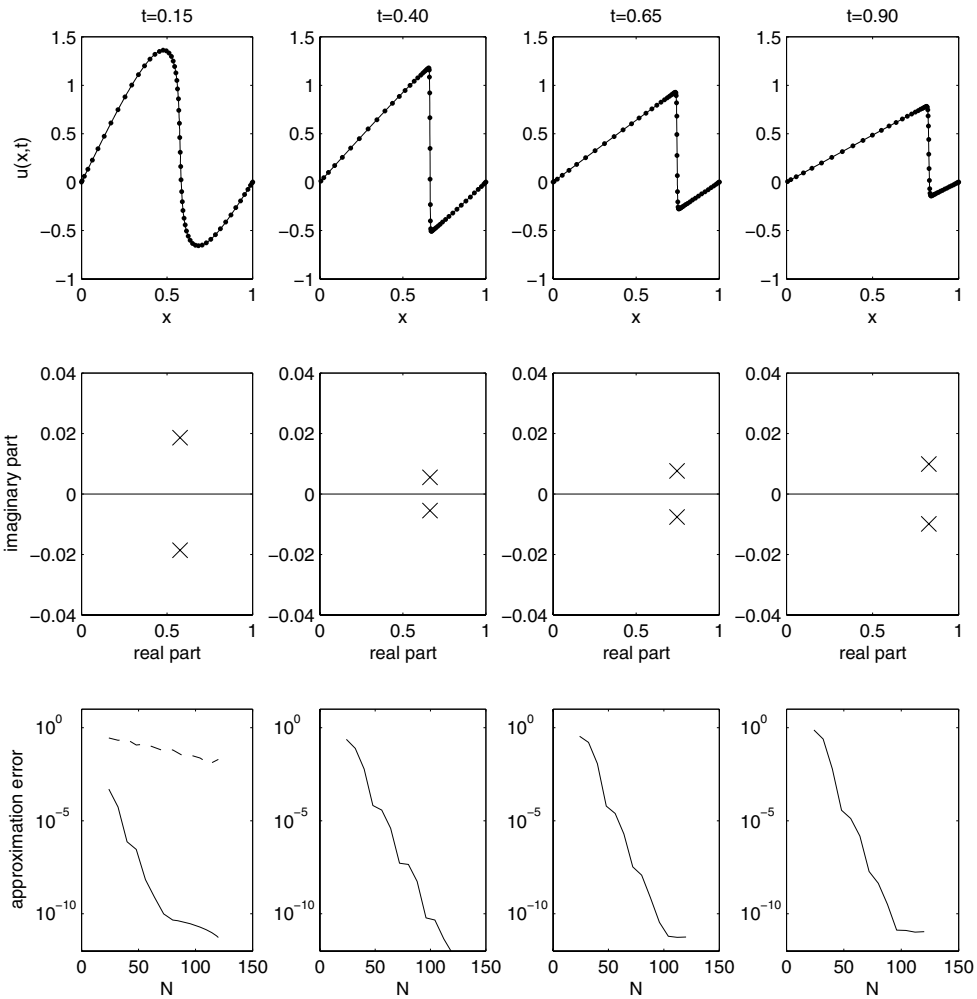

FIG. 4. *Like Figure* 2 *but for* (5.3) *with* $\nu = 10^{-3}$.

The second row shows the poles whose locations approximate the locations of the two complex conjugate singularities lying on the ellipse of analyticity of u. The poles move closer to each other when the front steepens, and apart again when the front decays. They also move towards $\mathrm{Re}(x) = 1$ in accordance with the front. In the absence of viscosity, they would coalesce when a shock is formed [30].

The third row shows plots of approximation error against N on a log-linear scale for the Chebyshev spectral method and the adaptive rational spectral method. The latter requires about 100 grid points to produce results which are accurate to the limit of temporal errors. In contrast, the Chebyshev spectral method fails to produce any result beyond $t = 0.15$ for $N \leq 128$.

We also vary ν and include Figure 5, which shows plots of approximation error against N on a log-linear scale for the adaptive rational spectral method with various ν. Each time ν decreases geometrically by a factor of 10, the number of grid points required for the method to produce results accurate to the limit of temporal errors increases by an approximately constant amount of 50.

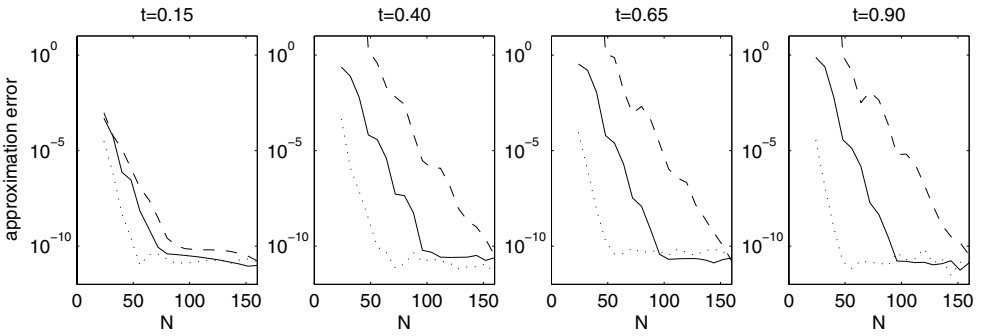

FIG. 5. *Log-linear plots of approximation error against N for the solution of* (5.3) *approximated using the adaptive rational spectral method. Dotted lines correspond to* $\nu = 10^{-2}$*, solid lines to* $\nu = 10^{-3}$*, and dashed lines to* $\nu = 10^{-4}$*.*

6. Conclusion. We have presented an adaptive rational spectral method which far outperforms the Chebyshev spectral method for problems whose solutions have singularities in the complex plane close to $[-1, 1]$. It combines ideas from existing rational spectral methods [3, 11] with an adaptive technique for locating singularities [30] using Chebyshev–Padé approximation. The method can be improved in various ways. For example, one can derive maps analogous to (2.7) for problems on periodic intervals or problems with multiple complex conjugate singularities. We are in the process of doing this using the framework of Schwarz–Christoffel mapping [21]. We are also studying the maps used in other adaptive spectral methods and hope to compare the effectiveness of those maps with ours. In addition, we are investigating further improvements and applications to some of the innumerable problems of scientific computing whose solutions involve fronts, boundary layers, or other singularities.

EFFICIENT COMPUTATION OF ISOMETRY-INVARIANT DISTANCES BETWEEN SURFACES*

ALEXANDER M. BRONSTEIN†, MICHAEL M. BRONSTEIN†, AND RON KIMMEL†

Abstract. We present an efficient computational framework for isometry-invariant comparison of smooth surfaces. We formulate the Gromov–Hausdorff distance as a multidimensional scaling–like continuous optimization problem. In order to construct an efficient optimization scheme, we develop a numerical tool for interpolating geodesic distances on a sampled surface from precomputed geodesic distances between the samples. For isometry-invariant comparison of surfaces in the case of partially missing data, we present the partial embedding distance, which is computed using a similar scheme. The main idea is finding a minimum-distortion mapping from one surface to another, while considering only relevant geodesic distances. We discuss numerical implementation issues and present experimental results that demonstrate its accuracy and efficiency.

Key words. generalized multidimensional scaling, isometric embedding, Gromov–Hausdorff distance, intrinsic geometry, isometry-invariant surface matching, iterative optimization, multiresolution methods

1. Introduction.

Many objects in nature can be described as nonrigid deformable (or bendable) surfaces. Often, the metric and the topological properties of the surface are preserved during bending. For example, most human organs bend without significantly stretching or tearing their surfaces. Study of living organs done through medical imaging often puts forth the challenge of comparing two deformable surfaces, which in turn requires identifying surface properties invariant to deformations. This paper addresses the problem of bending-invariant comparison between surfaces. More formally, we distinguish between the *extrinsic* and the *intrinsic* geometry of a surface. *Extrinsic* properties describe the way a surface is immersed into the ambient space. These properties are subject to changes while the surface bends. *Intrinsic* properties, on the other hand, are associated with the internal metric structure of the surface. Most natural deformations preserve, at least approximately, the intrinsic properties. Such deformations are called *inelastic deformations*. Our goal is therefore to define an efficiently computable *inelastic deformation invariant* measure of similarity between surfaces.

Going back to the human organs example, an interesting application for such a measure of similarity is expression-invariant three-dimensional face recognition. In [6], we showed that facial expressions can be modeled as near-isometric deformations of the facial surface. Thus, an isometry-invariant similarity measure between faces would be a good candidate for face recognition insensitive to facial expressions.

1.1. Prior work.

The case of Euclidean-isometry matching of surfaces was intensively explored. A classical result for rigid surface matching is the *Cohn-Vossen rigidity*

(ICP) method [27], finding a Euclidean transformation between two discrete surfaces represented as point clouds.

A near-isometry-invariant comparison of surfaces based on Euclidean embeddings was presented by Elad and Kimmel in [13] as a generalization of [23]. The main idea is to map the intrinsic (metric) structure of the surfaces to a low-dimensional space and compare the resulting images in this space. The numerical core of the Elad–Kimmel approach is based on a multidimensional scaling (MDS) algorithm [3], whose numerical solutions can be computed efficiently. It is also related to dimensionality reduction [22, 12, 25] and to texture mapping [28, 17]. Similar problems are analyzed in graph theory in the context of representation of discrete metric spaces [20]. Yet, when dealing with abstract metric spaces like graphs, or even point clouds with local distances, smoothness of the underlying geometry cannot be assumed, and thus embedding is a much harder problem.

One of the caveats of the Euclidean embedding approach is the fact that usually a Riemannian surface cannot be perfectly represented in a finite-dimensional Euclidean space, thus inevitably introducing a metric distortion. It was argued and proved empirically in [5, 4] that using a two-dimensional or a three-dimensional sphere instead of the Euclidean space results in smaller embedding error for certain types of objects, and consequently the recognition results get better. In [26], embedding into a space with hyperbolic geometry was shown.

In [16], Gromov introduced the Gromov–Hausdorff distance, which in a sense measures the metric distortion between metric spaces. Such a distance is invariant to isometries. In their recent fundamental paper [21], Mémoli and Sapiro adopted the Gromov–Hausdorff distance to the problem of deformable shape recognition. They considered a discrete setting in which surfaces are given as point clouds. In this case the computation of the Gromov–Hausdorff distance requires evaluating all the permutations between the samples. Such a combinatorial optimization problem appears to be computationally prohibitive. Mémoli and Sapiro showed a theoretical probabilistic framework and a practical procedure, which allowed them to formulate an approximation of the Gromov–Hausdorff distance between two point clouds without computing all the permutations.

1.2. Main contribution. In many applications, like computer graphics, surfaces are represented as triangulated meshes that capture the local smoothness properties of the underlying surface. One contribution of our paper is the derivation of an MDS-like formulation for the Gromov–Hausdorff distance between surfaces. This results in a continuous nonconvex optimization problem, which lends itself to a numerically exact computation of the Gromov–Hausdorff distance between surfaces.

In many practical cases, where surfaces are given only partially, the Gromov–Hausdorff distance cannot be used. For this purpose we introduced in [7] the , which can handle isometry-invariant partial surface matching. The key idea is to embed one surface into another and measure the minimal possible distortion of such a mapping. A numerical procedure devised in [7] for this purpose is similar in nature to MDS and therefore has been named or GMDS. GMDS can be thought of as a natural extension of previous works on isometric embedding into non-Euclidean spaces [26, 5, 4], as visualized in Figure 1. Here we provide the formal support for the framework presented in [7] and show the relationship between our partial embedding distance and the Gromov–Hausdorff distance.

Our paper comprises five sections. Section 2 provides the theoretical foundations of isometry-invariant surface matching. There, we define the Gromov–Hausdorff dis-

TABLE 1
Notation and symbols.

$\mathbb{R}$; $\mathbb{R}^+$	Real numbers; nonnegative real numbers
$\mathbb{R}^m$	m-dimensional Euclidean space
$\mathbb{R}^{M\times N}$	Space of $M \times N$ matrices
$\mathbb{M}$	Set of compact metric spaces
$(\mathcal{S}, d_{\mathcal{S}})$; $\mathcal{S}$	Metric space $\mathcal{S}$ with metric $d_{\mathcal{S}}$ arising from a Riemannian surface
s ; $\mathbf{s}$	A point on $\mathcal{S}$; extrinsic coordinates of s
$d_{\mathcal{S}}\vert_{\mathcal{S}'}$	Restriction of $d_{\mathcal{S}}$ to $\mathcal{S}'$
$\mathcal{S}_N$	Finite sampling of $\mathcal{S}$ consisting of N points
$\mathbf{D}_{\mathcal{S}}$	Matrix of geodesic distances on $\mathcal{S}_N$
$T_{\mathcal{S}}$; t^k	Triangulation of $\mathcal{S}_N$; kth triangle in $T_{\mathcal{S}}$
$\mathcal{S}^r$; $\mathcal{S}^r_N$	r-covering; finite r-covering of $\mathcal{S}$
$B_{\mathcal{S}}(s_0, r)$	Open ball of radius r in the metric space $\mathcal{S}$ around s_0
$\operatorname{diam}\mathcal{S}$	Diameter of metric space $\mathcal{S}$
$\operatorname{dis}\psi$	Distortion of the mapping ψ
$d_{\mathrm{H}}^{\mathcal{Z}}$	Hausdorff metric in the metric space $\mathcal{Z}$
d_{GH}	Gromov–Hausdorff metric between metric spaces
d_{P}	Permutation distance
d_{PE}	Partial embedding distance
Π_N ; π	Permutations of the set $\{1, \ldots, N\}$; a permutation in Π_N
$\mathbf{1}_{N\times N}$	$N \times N$ matrix of ones

tance and review previous attempts for its approximation. We also describe the partial embedding distance and summarize its properties. In section 3, we introduce an efficient algorithm for our isometry-invariant distance computation. We address the problem of geodesic distance interpolation, a vital component of our numerical algorithm. We also discuss the question of GMDS convergence and show a multiresolution optimization approach as a means to overcome convergence to local minima. Section 4 presents an experimental validation of the proposed framework. Finally, section 5 concludes the paper. Proofs and technical details can be found in the appendices. Notation and symbols used throughout the paper are summarized in Table 1.

2. Theoretical background. The objects we deal with are surfaces. We use $\mathcal{S}$ to denote a surface, and assume it to be modeled as a smooth connected complete Riemannian 2-manifold. We denote by $d_{\mathcal{S}} : \mathcal{S} \times \mathcal{S} \mapsto \mathbb{R}^+$ the geodesic distance function induced by the Riemannian metric. For simplicity, hereafter we say [illegible] $\mathcal{S}$, implying the underlying metric space $(\mathcal{S}, d_{\mathcal{S}})$. We assume, without loss of generality, that $\mathcal{S}$ is immersed into $\mathbb{R}^3$ and denote the extrinsic coordinates of a point $s \in \mathcal{S}$ by $\mathbf{s} = (s^1, s^2, s^3)$.

In practice, we work with sampled surfaces represented by finite metric spaces. To this end, we use the following definition: a subset $\mathcal{S}^r \subset \mathcal{S}$ is called an r-[illegible] of $\mathcal{S}$ (or an r-[illegible] in $\mathcal{S}$) if

$$\mathcal{S} = \bigcup_{s \in \mathcal{S}^r} B_{\mathcal{S}}(s, r). \tag{1}$$

Here $B_{\mathcal{S}}(s_0, r) = \{s \in \mathcal{S} : d_{\mathcal{S}}(s, s_0) < r\}$ is an open ball of radius r around s in $\mathcal{S}$. A finite r-covering of $\mathcal{S}$ consisting of N points is denoted by $\mathcal{S}^r_N$. The space $(\mathcal{S}^r_N, d_{\mathcal{S}}|_{\mathcal{S}^r_N})$ constitutes a finite metric space, where the metric $d_{\mathcal{S}}|_{\mathcal{S}^r_N}$ is obtained by restricting the original metric $d_{\mathcal{S}}$ to the subset $\mathcal{S}^r_N$. An arbitrary finite sampling of $\mathcal{S}$ consisting of N points (a[illegible]) is denoted by $\mathcal{S}_N = \{s_1, \ldots, s_N\}$. In order to make a distinction between the original and the sampled surfaces, we refer to $\mathcal{S}$ as a [illegible] surface and to $\mathcal{S}_N$ as a [illegible] surface.

A sampled surface can be represented as a cloud of points $\mathcal{S}_N$ and an $N \times N$ matrix $\mathbf{D}_{\mathcal{S}} = (d_{\mathcal{S}_N}(s_i, s_j))$ of the corresponding geodesic distances. In addition, we assume that a triangulation $T_{\mathcal{S}}$ capturing the local geometry of the surface is given (here $T_{\mathcal{S}} = \{(t_{11}, t_{12}, t_{13}), \ldots, (t_{K,1}, t_{K,2}, t_{K,3})\}$ is a list of K triangles, where each triangle is a triplet of sample indices, $t_{ki} \in \{1, \ldots, N\}$). The resulting triangulated mesh can be thought of as a polyhedral approximation of the smooth surface $\mathcal{S}$.

Surface $\mathcal{S}$ is called [illegible] if $\operatorname{diam}\mathcal{S} = \sup_{s,s' \in \mathcal{S}} d_{\mathcal{S}}(s, s')$ is finite. $\mathcal{S}$ is said to be [illegible] if all its open covers have a finite subcover. If $\mathcal{S}$ is compact, it is necessarily bounded. This will be our tacit assumption, as surfaces encountered in practical applications are compact. We use $\mathbb{M}$ to denote the set of all such surfaces.

Given two surfaces $\mathcal{S}$ and $\mathcal{Q}$ in $\mathbb{M}$, a transformation $\varphi : \mathcal{S} \mapsto \mathcal{Q}$ is said to have a [illegible] or distort the metric by

$$\operatorname{dis}\varphi \equiv \sup_{s,s' \in \mathcal{S}} \left| d_{\mathcal{S}}(s, s') - d_{\mathcal{Q}}(\varphi(s), \varphi(s')) \right|. \tag{2}$$

If in addition for every $q \in \mathcal{Q}$ there exists $s \in \mathcal{S}$ such that $d_{\mathcal{Q}}(q, \varphi(s)) \leq \epsilon$ (we call this property ϵ-[illegible]), φ is called an ϵ-[illegible] and the spaces $\mathcal{S}$ and $\mathcal{Q}$ are termed ϵ-[illegible]. The image of $\mathcal{S}$, $\varphi(\mathcal{S})$ is called an ϵ-[illegible] of $\mathcal{S}$ in $\mathcal{Q}$. A transformation $\varphi : \mathcal{S} \mapsto \mathcal{Q}$ with $\operatorname{dis}\varphi = 0$ is called an [illegible], and $\mathcal{S}$ and $\mathcal{Q}$ admitting such a transformation are called [illegible]. Unlike ϵ-isometries, an isometry is always bijective and bi-Lipschitz continuous.

In this paper, we address the question of matching between two surfaces, insensitively to their isometries. More formally, we study a [illegible] $d : \mathbb{M} \times \mathbb{M} \mapsto \mathbb{R}^+$, which assigns a nonnegative number to every pair of surfaces, measuring the degree of their similarity. The basic property we require is that for all isometries f of $\mathcal{S}$ and g of $\mathcal{Q}$, $d(f(\mathcal{S}), g(\mathcal{Q})) = d(\mathcal{S}, \mathcal{Q})$.

2.1. Gromov–Hausdorff distance. Mémoli and Sapiro in [21] introduced the Gromov–Hausdorff distance into the deformable surface matching arena. Here we use this powerful theory and present numerical methods for its consistent computation

subject to the disclaimer that we cannot guarantee completely avoiding the intrinsic local minima of the associated measure. Our starting point is the classical Hausdorff distance. Assume that the surfaces $\mathcal{S}$ and $\mathcal{Q}$ are subsets of some larger metric space $(\mathcal{Z}, d_{\mathcal{Z}})$. Then the [illegible] can be defined in the following way:

$$d_{\mathrm{H}}^{\mathcal{Z}}(\mathcal{S},\mathcal{Q}) \equiv \max\left\{\sup_{s\in\mathcal{S}} d_{\mathcal{Z}}(s,\mathcal{Q}), \sup_{q\in\mathcal{Q}} d_{\mathcal{Z}}(q,\mathcal{S})\right\}. \tag{3}$$

Here for notational simplicity we use $d_{\mathcal{Z}}(s,\mathcal{Q}) = \inf_{q\in\mathcal{Q}} d_{\mathcal{Z}}(s,q)$, implying a point-to-set distance. It can be shown that $d_{\mathrm{H}}^{\mathcal{Z}}$ is a metric on all the subsets of $\mathcal{Z}$. Versions of the Hausdorff distance are often used to measure similarity between rigid surfaces in $\mathbb{R}^3$, which give birth to a family of algorithms known as [illegible], or ICP [2, 27, 11]. Yet, while being a good match for comparison of extrinsic geometries, the Hausdorff distance is not isometry-invariant.

In order to overcome this problem, Mémoli and Sapiro [21] adopted an extension of the Hausdorff distance introduced by Gromov [16]. The [illegible] is defined by

$$d_{\mathrm{GH}}(\mathcal{S},\mathcal{Q}) \equiv \inf_{\substack{\mathcal{Z}\\ \rho:\mathcal{S}\mapsto\mathcal{Z}\\ \sigma:\mathcal{Q}\mapsto\mathcal{Z}}} d_{\mathrm{H}}^{\mathcal{Z}}(\rho(\mathcal{S}),\sigma(\mathcal{Q})), \tag{4}$$

where $\rho : \mathcal{S} \mapsto \mathcal{Z}$ and $\sigma : \mathcal{Q} \mapsto \mathcal{Z}$ are isometric embeddings into the metric space $\mathcal{Z}$. The Gromov–Hausdorff distance is invariant to isometries and thus allows a comparison between two surfaces in a truly intrinsically geometric way. In addition, d_{GH} has several nice properties, which we summarize here.

1. [illegible] d_{GH} is a finite metric on the space of compact surfaces $\mathbb{M}$, in which a point is defined as an equivalence class of a surface and its isometries [15, 10]. In other words, d_{GH} satisfies the following axioms: (i) $d_{\mathrm{GH}}(\mathcal{S},\mathcal{Q}) \geq 0$; (ii) $d_{\mathrm{GH}}(\mathcal{S},\mathcal{Q}) = 0$ if and only if $\mathcal{S}$ and $\mathcal{Q}$ are isometric; (iii) $d_{\mathrm{GH}}(\mathcal{S},\mathcal{Q}) = d_{\mathrm{GH}}(\mathcal{Q},\mathcal{S})$; and (iv) $d_{\mathrm{GH}}(\mathcal{R},\mathcal{Q}) \leq d_{\mathrm{GH}}(\mathcal{R},\mathcal{S}) + d_{\mathrm{GH}}(\mathcal{S},\mathcal{Q})$, also known as the [illegible].
2. [illegible] (i) If $d_{\mathrm{GH}}(\mathcal{S},\mathcal{Q}) \leq \epsilon$, then there exists a 2ϵ-Hausdorff approximation of $\mathcal{S}$ in $\mathcal{Q}$; (ii) if there exists an ϵ-Hausdorff approximation of $\mathcal{S}$ in $\mathcal{Q}$, then $d_{\mathrm{GH}}(\mathcal{S},\mathcal{Q}) \leq 2\epsilon$. This property can be thought of as an extension of the second metric axiom to ϵ-isometries (see [10] for details).
3. [illegible] Given $\mathcal{S}^r$ an r-covering of $\mathcal{S}$ and $\mathcal{Q}^{r'}$ and r'-covering of $\mathcal{Q}$, $|d_{\mathrm{GH}}(\mathcal{S},\mathcal{Q}) - d_{\mathrm{GH}}(\mathcal{S}^r,\mathcal{Q}^{r'})| \leq r + r'$. In other words, the Gromov–Hausdorff distance between sampled versions of two surfaces is close to the Gromov–Hausdorff distance between the original ones, and the discrepancy vanishes as the sample radius decreases.

The main disadvantage of $d_{\mathrm{GH}}(\mathcal{S},\mathcal{Q})$ according to definition (4) is its computational intractability.

Fortunately, for bounded metric spaces, the Gromov–Hausdorff distance can be translated to comparison of distances within $\mathcal{S}$ and $\mathcal{Q}$ to each other, thus avoiding the cumbersome construction of the metric space $\mathcal{Z}$. Formally, the Gromov–Hausdorff distance can be redefined as follows [18, 21]:

$$d_{\mathrm{GH}}(\mathcal{S},\mathcal{Q}) = \frac{1}{2}\inf_{\substack{\varphi:\mathcal{S}\mapsto\mathcal{Q}\\ \psi:\mathcal{Q}\mapsto\mathcal{S}}} \max\left\{\operatorname{dis}\phi, \operatorname{dis}\psi, \operatorname{dis}(\varphi,\psi)\right\}, \tag{5}$$

where $\operatorname{dis}\varphi$ and $\operatorname{dis}\psi$ defined in (2) measure the metric distortion of the mappings φ and ψ, respectively, and

$$\operatorname{dis}(\varphi,\psi) \equiv \sup_{\substack{s\in\mathcal{S}\\ q\in\mathcal{Q}}} \left| d_{\mathcal{S}}(s,\psi(q)) - d_{\mathcal{Q}}(q,\varphi(s)) \right| \tag{6}$$

measures how far φ and ψ are from being the inverse of each other. This reformulation, as we will show, allows us an efficient computation of the Gromov–Hausdorff distance between surfaces.

2.2. Mémoli–Sapiro approximation of d_{GH}. In [21], Mémoli and Sapiro considered the approximation of the Gromov–Hausdorff distance between point clouds by dropping the term $\operatorname{dis}(\varphi,\psi)$ in the definition of d_{GH} in (5) and bounding its contribution probabilistically. Given two bounded surfaces $\mathcal{S}$ and $\mathcal{Q}$, both sampled at N points ($\mathcal{S}_N$ and $\mathcal{Q}_N$, respectively), they defined the

$$d_{\mathrm{P}}(\mathcal{S}_N,\mathcal{Q}_N) \equiv \frac{1}{2}\min_{\pi\in\Pi_N}\max_{1\le i,j\le N}\left| d_{\mathcal{S}}(s_i,s_j) - d_{\mathcal{Q}}(q_{\pi_i},q_{\pi_j}) \right|,$$

where Π_N denotes all the permutations of $\{1,\dots,N\}$. d_{P} is not the exact Gromov–Hausdorff distance but a different measure of surface similarity related to d_{GH}. Obviously, $d_{\mathrm{GH}}(\mathcal{S}_N,\mathcal{Q}_N) \le d_{\mathrm{P}}(\mathcal{S}_N,\mathcal{Q}_N)$, since d_{P} can be considered a particular discrete case of d_{GH}, in which the correspondences between the two metric spaces are restricted only to the bijective ones. The upper bound is much more complicated and is derived in a probabilistic setting [21]. Based on these results, Mémoli and Sapiro described an algorithm for the approximation of d_{GH}. The key idea is to select subsamplings of the given point clouds, the distance between which can be related to the Gromov–Hausdorff distance. Alternative, more practical estimation methods of the distance between point clouds, motivated by the Gromov–Hausdorff distance, were also presented in [21].

Mémoli and Sapiro also noted that by restricting the $\mathcal{Z}$ space in definition (4) of d_{GH}, the metric actually boils down to the canonical form distance proposed in [13]. The canonical form distance is computed by first finding the best representation of $\mathcal{S}$ and $\mathcal{Q}$ in $\mathcal{Z}$ (in the sense of lowest metric distortion). Let $\rho : \mathcal{S} \mapsto \mathcal{Z}$ be the lowest distortion embedding of $\mathcal{S}$ in $\mathcal{Z}$; the image $\mathcal{S}_{\mathrm{can}} = \rho(\mathcal{S})$ is referred to as the canonical form of $\mathcal{S}$. Similarly, the canonical form of $\mathcal{Q}$ is computed. Once $\mathcal{S}_{\mathrm{can}}$ and $\mathcal{Q}_{\mathrm{can}}$ are available, the canonical form distance is computed according to

$$d_{\mathrm{CF}}(\mathcal{S},\mathcal{Q}) = d^{\mathcal{Z}}(\mathcal{S}_{\mathrm{can}},\mathcal{Q}_{\mathrm{can}}), \tag{7}$$

where $d^{\mathcal{Z}}$ is some distance between two sets in $\mathcal{Z}$ (e.g., the Hausdorff distance or its variant). The typical choice of $\mathcal{Z}$ is $\mathbb{R}^3$.

2.3. Partial embedding distance. The main drawback of the Gromov–Hausdorff distance and its approximate version is the fact that it compares two metric spaces as a whole, which is inappropriate for partial matching. One of the most significant differences of partial matching compared to its "full" counterpart is the lack of symmetry. We therefore address the problem of finding a match between a surface $\mathcal{S}$ and a $\mathcal{Q}$, which is a deformed version of the model. In practice, one is often required to find whether a $\mathcal{Q}' \subset \mathcal{Q}$ is similar to $\mathcal{S}$.

In [7] we defined the nonsymmetric [illegible] as

$$d_{\mathrm{PE}}(\mathcal{S},\mathcal{Q}') \equiv \frac{1}{2}\inf_{\psi:\mathcal{Q}\mapsto\mathcal{S}} \sup_{(q,q')\in P} \left|d_{\mathcal{Q}}(q,q') - d_{\mathcal{S}}(\psi(q),\psi(q'))\right|, \tag{8}$$

where $P = \{(q,q') : d_{\mathcal{Q}'}(q,q') = d_{\mathcal{Q}}(q,q')\} \subseteq \mathcal{Q}\times\mathcal{Q}$. In other words, we define the distortion only on pairs of points for which the metric on the patch $\mathcal{Q}'$ is consistent with that on $\mathcal{Q}$. Such a restriction is necessary because the assumption $d_{\mathcal{Q}'} = d_{\mathcal{Q}}|_{\mathcal{Q}'}$ (i.e., that $d_{\mathcal{Q}'}(q,q') = d_{\mathcal{Q}}(q,q')$ for all $q,q' \in \mathcal{Q}'$) holds only in particular cases, e.g., when $\mathcal{Q}'$ is a convex subset of the surface $\mathcal{Q}$. In general, minimal geodesics on $\mathcal{Q}$ that cross the boundary $\partial\mathcal{Q}'$ change in $\mathcal{Q}'$, and therefore the geodesic distances between the corresponding points in $\mathcal{Q}$ and $\mathcal{Q}'$ may differ. Note that when $P = \mathcal{Q}\times\mathcal{Q}$, we have $\sup_{(q,q')\in P}|d_{\mathcal{Q}}(q,q') - d_{\mathcal{S}}(\psi(q),\psi(q'))| = \operatorname{dis}\psi$ and the partial embedding distance becomes

$$d_{\mathrm{PE}}(\mathcal{S},\mathcal{Q}) = \frac{1}{2}\inf_{\psi:\mathcal{Q}\mapsto\mathcal{S}} \operatorname{dis}\psi. \tag{9}$$

A comment about the potential usefulness of (9) for partial matching was made in [21].

The properties of d_{PE} resemble those of d_{GH}. We summarize them here; for proofs, see Appendix A.

1. [illegible] d_{PE} satisfies some of the metric axioms: (i) $d_{\mathrm{PE}}(\mathcal{S},\mathcal{Q}) \geq 0$; (ii) $d_{\mathrm{PE}}(\mathcal{S},\mathcal{Q}) = 0$ if and only if $\mathcal{Q}$ is isometrically embeddable into $\mathcal{S}$; (iii) $d_{\mathrm{PE}}(\mathcal{S},\mathcal{Q}) \leq d_{\mathrm{PE}}(\mathcal{S},\mathcal{R}) + d_{\mathrm{PE}}(\mathcal{R},\mathcal{Q})$, which is a nonsymmetric version of the triangle inequality.
2. [illegible] (i) If there exists an ϵ-Hausdorff approximation of $\mathcal{S}$ in $\mathcal{Q}$, then $d_{\mathrm{PE}}(\mathcal{S},\mathcal{Q}) \leq 2\epsilon$. (ii) The converse appears to be true under some more restrictive assumptions (the proof is to be published elsewhere).
3. [illegible] Given $\mathcal{S}^r$ an r-covering of $\mathcal{S}$ and $\mathcal{Q}^{r'}$ an r'-covering of $\mathcal{Q}$, $d_{\mathrm{PE}}(\mathcal{S},\mathcal{Q}) - r' \leq d_{\mathrm{PE}}(\mathcal{S}^r,\mathcal{Q}^{r'}) \leq d_{\mathrm{PE}}(\mathcal{S},\mathcal{Q}) + r$.
4. [illegible] Given $\mathcal{Q}^{r'}$ an r'-covering of $\mathcal{Q}$, $d_{\mathrm{PE}}(\mathcal{Q}^{r'},\mathcal{Q}) = 0$.

First, we see that, though not a metric in the strict sense, d_{PE} satisfies some important properties of a metric: isometry invariance and an asymmetric version of the triangle inequality. Second, by virtue of property 4 (unlike the corresponding property $d_{\mathrm{GH}}(\mathcal{Q},\mathcal{Q}^r) \leq r$ of the Gromov–Hausdorff distance, as mentioned above) d_{PE} can be used for partial matching. Third, note that a particular case of property 3 is $d_{\mathrm{PE}}(\mathcal{S},\mathcal{Q}) - r \leq d_{\mathrm{PE}}(\mathcal{S},\mathcal{Q}^r) \leq d_{\mathrm{PE}}(\mathcal{S},\mathcal{Q})$. When r is too large, the lower bound makes little sense, and one can obtain $d_{\mathrm{PE}}(\mathcal{S},\mathcal{Q}^r) \approx 0$ while $d_{\mathrm{PE}}(\mathcal{S},\mathcal{Q})$ is large. This reveals a potential danger in partial matching: when the patch $\mathcal{Q}^r$ is too small, such a comparison is liable to be meaningless, since a sufficiently small patch can be embedded with low metric distortion into every surface.

3. Efficient computation of the partial embedding and the Gromov–Hausdorff distances. We now address a practical question of efficiently computing the Gromov–Hausdorff and the partial embedding distances between two polyhedral surfaces. For clarity, we start with the computation of the simpler $d_{\mathrm{PE}}(\mathcal{S},\mathcal{Q})$, of which the computation of $d_{\mathrm{GH}}(\mathcal{S},\mathcal{Q})$ will be a straightforward generalization. As input, let us be given the following:

1. A discretization of the continuous surface $\mathcal{Q}$, defined by the point cloud $\mathcal{Q}_M^r = \{q_i\}_{i=1}^M$.
2. A polyhedral approximation of the continuous surface $\mathcal{S}$ defined by the point cloud $\mathcal{S}_N^r = \{s_i\}_{i=1}^N$ and a triangulation $T_\mathcal{S} = \{(m_{11}, m_{12}, m_{13}), \ldots, (m_{N_T,1}, m_{N_T,2}, m_{N_T,3})\}$. In our notation, the polyhedron $\mathcal{S}_N^r$ consists of N_T triangular faces, where the tth face is described by the vertices $s_{m_{t1}}, s_{m_{t2}}, s_{m_{t3}}$.
3. Two distance matrices $\mathbf{D}_\mathcal{S} = (d_\mathcal{S}(s_i, s_j))$ and $\mathbf{D}_\mathcal{Q} = (d_\mathcal{Q}(q_i, q_j))$, representing the geodesic distances between the samples of $\mathcal{S}$ and $\mathcal{Q}$, respectively. In practice, only an approximation of these distances can be computed numerically, e.g., using the fast marching method [24].

Using the triangulated surface $\mathcal{S}_N^r$ as a polyhedral r approximation of $\mathcal{S}$, we parameterize the points on $\mathcal{S}$ in local [illegible] derived from the triangulation. Let s be a point on $\mathcal{S}_N^r$ belonging to some triangle $t \in \{1, \ldots, N_T\}$; the Euclidean coordinates $\mathbf{s}$ of s can be represented as a convex combination of the triangle vertices $\mathbf{s}_{m_{t1}}, \mathbf{s}_{m_{t2}}, \mathbf{s}_{m_{t3}}$:

$$\mathbf{s} = \sum_{i=1}^{3} \mathbf{s}_{m_{ti}} u_i. \tag{10}$$

Hence, every point on $\mathcal{S}_N^r$ can be identified with a vector of barycentric coordinates $(t, \mathbf{u}) = (t, u_1, u_2, u_3)$, where $u_i \geq 0$, $u_1 + u_2 + u_3 = 1$. We will freely switch between s and its barycentric representation.

The partial embedding distance between $\mathcal{S}_N^r$ and $\mathcal{Q}_M^r$ can be formulated as the following constrained minimization problem:

$$\min_{s_i', \epsilon \geq 0} \epsilon \quad \text{s.t.} \quad \left| d_\mathcal{S}(s_i', s_j') - d_\mathcal{Q}(q_i, q_j) \right| \leq \epsilon, \tag{11}$$

where $(i, j) \in P \subseteq \{1, \ldots, M\} \times \{1, \ldots, M\}$ (for the time being we assume P to be given; a way to find it is shown in section 3.4). Once the minimal ϵ is found, our approximation to the partial embedding distance is $\hat{d}_{\mathrm{PE}}(\mathcal{S}_N^r, \mathcal{Q}_M^r) = \epsilon/2$.

Note that we use the images $s_i' = \psi(q_i)$ (in their barycentric coordinates) directly as the optimization variables, which frees us from the need to optimize over all possible permutations of s_i and q_j. In fact, the problem above is a modest-sized constrained minimization problem with $M + 1$ variables and at most $\frac{1}{2}M(M-1)$ inequality constraints. Also note that the points s_i are given, and so are the distances $d_\mathcal{Q}(q_i, q_j)$, which are the elements of the matrix $\mathbf{D}_\mathcal{Q}$. On the other hand, the distances $d_\mathcal{S}(s_i', s_j')$ have to be approximated numerically (see section 3.3); in the meantime, we assume them to be computable exactly. The reason is that the images s_i' [illegible] with the vertices of $\mathcal{S}_N^r$, respectively, and can fall inside any triangle on the latter polyhedron.

Theoretically, our computation is accurate up to the sampling radius, i.e., $|\hat{d}_{\mathrm{PE}}(\mathcal{S}_N^r, \mathcal{Q}_M^r) - d_{\mathrm{PE}}(\mathcal{S}, \mathcal{Q})| \leq 2r$. If in addition we take into account that the distances $d_\mathcal{S}$ and $d_\mathcal{Q}$ are computed with accuracy δ, we have $|\hat{d}_{\mathrm{PE}}(\mathcal{S}_N^r, \mathcal{Q}_M^r) - d_{\mathrm{PE}}(\mathcal{S}, \mathcal{Q})| \leq 2(r + \delta)$. In practice, a finer grid is used to approximate the distances, and therefore $\delta \ll r$. Sampling the surfaces sufficiently densely (r sufficiently small), we can compute d_{PE} with any desired accuracy. In other words, our approach is numerically [illegible].[1]

[1] Note that since our optimization problem is nonconvex, no practical optimization algorithm guarantees convergence to the global minimum. Yet, in section 3.2 we show that, in practice, local convergence can be avoided using multiresolution methods.

Problem (11) can be viewed as a minimization of maximum distortion, or a minmax (ℓ_∞ norm) problem. Practical considerations may favor the choice of norms other than ℓ_∞. In order to handle them numerically, we abandon the constrained minimization formulation with the artificial variable ϵ, and minimize

$$F(s'_1,\ldots,s'_M)=\sum_{i,j} w_{ij}\eta\left(d_{\mathcal{S}}(s'_i,s'_j)-d_{\mathcal{Q}}(q_i,q_j)\right) \tag{12}$$

with respect to s'_i, where $w_{ij}=1$ for $(i,j)\in P$ and zero otherwise are weights representing the set of "consistent pairs" P, and $\eta(x)$ is some nonlinear function (e.g., the choices $\eta(x)=x^2$ and $\eta(x)=|x|$ yield the ℓ_2 and the ℓ_1 norms, respectively). Note the resemblance of F to the [illegible] used in the MDS problems.

Though the properties of $\operatorname{argmin}_{s'_i} F$ are dramatically different from those of d_{PE}, it is a good measure of surface similarity with most of the important properties of the true partial embedding distance, yet less susceptible to noise and numerical errors. We will henceforth denote the ℓ_p version of d_{PE} as d^p_{PE}.

The Gromov–Hausdorff distance is computed essentially in the same way as $\hat{d}_{\mathrm{PE}}$ by solving

$$\min_{s'_i,q'_k,\epsilon\geq 0}\epsilon \quad \text{s.t.} \quad \begin{aligned} &\left|d_{\mathcal{Q}}(q'_i,q'_j)-d_{\mathcal{S}}(s_i,s_j)\right|\leq\epsilon,\\ &\left|d_{\mathcal{S}}(s'_k,s'_l)-d_{\mathcal{Q}}(q_k,q_l)\right|\leq\epsilon,\\ &\left|d_{\mathcal{S}}(s_i,s'_k)-d_{\mathcal{Q}}(q_k,q'_i)\right|\leq\epsilon, \end{aligned} \tag{13}$$

where $j>i$, $l>k$. Here two additional terms standing for dis φ and $\operatorname{dis}(\varphi,\psi)$ are added. As in the case of $\hat{d}_{\mathrm{PE}}$, it might be advantageous to replace the ℓ_∞ norm with some more robust nonlinearity, yielding the stress

$$\begin{aligned} F=&\sum_{i,j=1}^{N}\eta\left(d_{\mathcal{Q}}(q'_i,q'_j)-d_{\mathcal{S}}(s_i,s_j)\right)+\sum_{k,l=1}^{M}\eta\left(d_{\mathcal{S}}(s'_k,s'_l)-d_{\mathcal{Q}}(q_k,q_l)\right)\\ &+\sum_{i,j}\eta\left(d_{\mathcal{S}}(s_i,s'_k)-d_{\mathcal{Q}}(q_k,q'_i)\right). \end{aligned} \tag{14}$$

3.1. Iterative minimization algorithm. We now present a practical numerical algorithm for computation of $\hat{d}_{\mathrm{PE}}$. For clarity, we will henceforth consider only the unconstrained minimization of (12); in order to handle the constrained problem (13), it is first converted to an unconstrained one using the [illegible] [1], which is then solved in an essentially similar way. The same technique can be used to compute the Gromov–Hausdorff distance.

Our goal is to bring $F(s'_1,\ldots,s'_M)$ to a (possibly local) minimum over $s'_i=(t_i,\mathbf{u}_i)$ by starting with some initial guess $s'^{(0)}_i=(t^{(0)}_i,\mathbf{u}^{(0)}_i)$ of the points and proceeding by iteratively updating their locations, producing a decreasing sequence of function values. Let $s'^{(k)}_i=(t^{(k)}_i,\mathbf{u}^{(k)}_i)$ be the optimization variables at kth iteration and let there be a set of directions $\mathbf{d}^{(k)}_i$ such that displacement of $\mathbf{u}^{(k)}_i$ along them by some step size $\alpha^{(k)}$ decreases the value of F (for convenience, we omit the iteration index k wherever possible). The simplest way to select the directions is $\mathbf{d}_i=-\nabla_{\mathbf{u}_i}F$, which yields a family of algorithms usually termed as [illegible] or [illegible]. There exist a variety of more efficient strategies for selecting $\mathbf{d}_i$, including conjugate gradients and quasi-Newton methods, just to name a few [1].

The step size α has to be chosen to guarantee a sufficient decrease of F. When constant step is used, there is generally a tradeoff between too small steps, which result in slow convergence, and too large steps, which are liable to increase the value of F. To provide guaranteed decrease of F, we adaptively select the step size at every iteration using the [illegible], which first sets $\alpha = \alpha_0$ and then successively reduces it by some factor $\beta \in (0,1)$ until

$$F(s'_1,\dots,s'_M) - F(s''_1,\dots,s''_M) \geq -\sigma\alpha \sum_i \mathbf{d}_i^{\mathrm{T}} \nabla_{\mathbf{u}_i} F(s'_1,\dots,s'_M), \tag{15}$$

where $\sigma \in (0,1)$ and s''_i represent the points s'_i displaced by α along $\mathbf{d}_i$. In our implementation, we used $\sigma = 0.3$, $\beta = 0.5$. The initial value α_0 is first selected to be large, and gradually refined at each iteration. A similar rule can be applied when the update is performed for a single point per iteration, yielding a block-coordinate descent algorithm.

Note that unlike common optimization problems, here, in order to displace s'_i, one cannot simply add $\alpha\mathbf{d}_i$ to $\mathbf{u}_i$, since the latter might leave the triangle t_i, thus invalidating the barycentric representation. Instead, the displacement is performed by following a polylinear path starting at $\mathbf{u}_i$, propagating along a straight line in the direction $\mathbf{d}_i$ until the first intersection with the triangle boundary, then proceeding along a line inside the triangle adjacent to the intersected edge, and so on until the total length of the path is α (see Figure 2).

The computation is carried out by the following algorithm, which accepts an initial point $s = (t, \mathbf{u})$, a direction $\mathbf{d}$, and a step size α and returns the displaced point $s' = (t', \mathbf{u}')$:

1. Compute $\mathbf{u}' = \mathbf{u} + \alpha\mathbf{d}$. If $\mathbf{u}'$ is inside the triangle t, return $s' = (t, \mathbf{u}')$ and stop.
2. Find $\alpha' < \alpha$, for which $\mathbf{u}' = \mathbf{u} + \alpha'\mathbf{d}$ lies on the boundary of t.
3. Otherwise, if there is no triangle adjacent to the edge on which $\mathbf{u}'$ lies, we can proceed no further, since the shape boundary is reached. Return $s' = (t, \mathbf{u}')$ and stop.
4. Otherwise, let t' be a triangle sharing the edge on which $\mathbf{u}'$ lies. Transform $\mathbf{u}'$ and $\mathbf{d}$ to the barycentric coordinates of t', replace α with $\alpha - \alpha'$ and $(t, \mathbf{u}) \leftarrow (t', \mathbf{u}')$, and go to step 1.

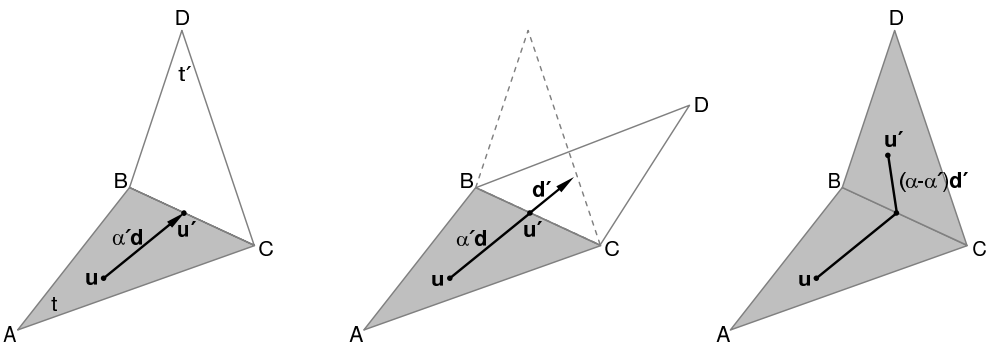

FIG. 2. *Displacement of the point* $\mathbf{u}$ *in the triangle* $t = ABC$ *along the direction* $\mathbf{d}$. *From left to right: the point is displaced along* $\mathbf{d}$ *until the triangle edge* BC *is reached; the adjacent triangle* $t' = BCD$ *is rotated about* BC *and the direction vector* $\mathbf{d}$ *is transformed to the barycentric coordinates of* t', $\mathbf{d}'$; *the final point* $\mathbf{u}'$ *is distant* α *from* $\mathbf{u}$ *along a polylinear path.*

The transformation of $\mathbf{u}'$ from barycentric coordinates in t to those in t' carried out in step 4 is trivial, since $\mathbf{u}'$ is located on the edge shared by the two triangles and thus has the same barycentric representation in t' up to vertex numbering. In order to transform $\mathbf{d}$, we rotate the triangle t' about the edge shared with t so that both triangles lie in the same plane, and we find such $\mathbf{d}'$ in the coordinate system of t', which defines the same planar direction as $\mathbf{d}$ in t.

Since at each iteration the Armijo rule produces a decreasing sequence of step sizes, it is sufficient to compute the displacement of $s_i'^{(k)}$ by $\alpha_0\mathbf{d}_i$ and cache the entire path; this allows us to save path computations for subsequent smaller steps.

3.2. Multiresolution minimization. GMDS, similarly to MDS algorithms in general [3], is liable to local convergence, since the objective function involved in the computation of $\hat{d}_{\mathrm{GH}}$ and $\hat{d}_{\mathrm{PE}}$ is nonconvex. Here we propose multiresolution optimization schemes as a practical remedy for this problem, in light of the results obtained in [9] for traditional MDS. An additional advantage of multiresolution optimization is a significant speedup of convergence.

The key idea of a multiresolution optimization scheme is to work with a hierarchy of problems, starting from a coarse version of the problem containing a small number of variables (points). The coarse level solution is interpolated to the next resolution level and is used as an initialization for the optimization at that level. The process is repeated until the finest level solution is obtained. Such a multiresolution scheme can be thought of as a smart way of initializing the optimization problem. Small local minima tend to disappear at coarse resolution levels, thus reducing the risk of local convergence, which is more probable when working at a single resolution.

The main components of a multiresolution scheme are the hierarchy of data which defines optimization problems at different resolution levels and the interpolation procedure, which allows to pass from coarse level to a finer one. Formally, let us denote by $\mathcal{Q}_{M_1} \subset \mathcal{Q}_{M_2} \subset \cdots \subset \mathcal{Q}_{M_L} = \mathcal{Q}_M$ an L-level hierarchy of data. The points on the $(l-1)$st resolution level are obtained by removing part of the points on the lth level. The corresponding distance matrices $\mathbf{D}_1, \ldots, \mathbf{D}_L = \mathbf{D}_{\mathcal{Q}}$ are created as submatrices of $\mathbf{D}_{\mathcal{Q}}$.

One possible means of constructing such a hierarchy is the farthest point sampling (FPS) strategy [14]. At the coarsest resolution level $\mathcal{Q}_{M_1}$, we select M_1 points. In practical problems, a few landmark points can be selected on the surface (e.g., in the face recognition problem, it is usually easy to roughly locate points such as the nose and the eyes); otherwise, these points can be chosen randomly. At the next resolution level, we add points in the following manner: q_{M_1+1} is selected as the most distant point from $\mathcal{Q}_{M_1}$, and so on, $q_{M_1+k} = \mathrm{argmax}_{q_i \in \mathcal{Q}_M} d_{\mathcal{Q}_M}(q_i, \{q_1, \ldots, q_{M_1+k-1}\})$. Taking the first M_l points from the sequence produced in this manner, we obtain $\mathcal{Q}_{M_l}$ (see the example in Figure 3).

Let us assume that at the lth resolution level, $\mathcal{Q}_{M_l} = \{q_1, \ldots, q_{M_l}\}$ were embedded into $\mathcal{S}_N^r$ using the iterative minimization algorithm outlined in section 3.1. As a result, the set of images $\psi(\mathcal{Q}_{M_l}) = \{s_1', \ldots, s_{M_l}'\}$ on the polyhedron $\mathcal{S}_N^r$ was obtained. At the next resolution level, we have to embed a larger set $\mathcal{Q}_{M_{l+1}}$ into $\mathcal{S}_N^r$, solving the minimization problem for $\psi(\mathcal{Q}_{M_{l+1}}) = \{s_1', \ldots, s_{M_{l+1}}'\}$. The initialization for the first M_l points is readily available from the solution at the previous level. The initial locations for the remaining points s_i' for $i = M_l + 1, \ldots, M_{l+1}$ have to be interpolated.

It is reasonable to initialize s_i' with such a point on S_N^r that the geodesic distances from it to the points $s_1', \ldots, s_{M_l}'$ are as close as possible to the geodesic distances

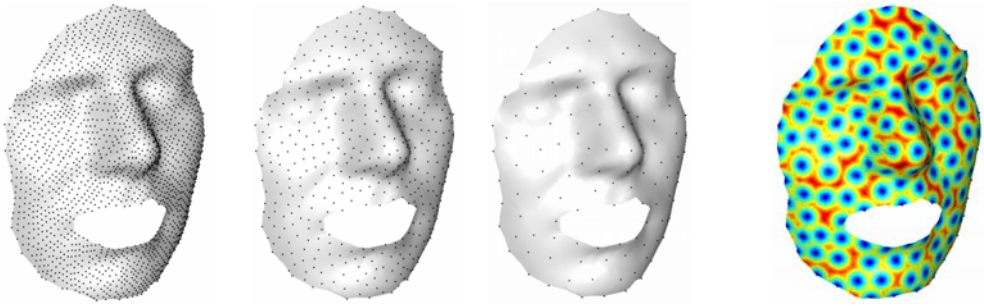

FIG. 3. *Example of data hierarchy construction for multiresolution optimization. Left: three resolution levels constructed using the farthest point sampling algorithm. Right: Geodesic distances from the coarsest grid points.*

from q_i to $q_1, \ldots, q_{M_l}$. Formally, s'_i can be expressed as

$$s'_i = \arg\min_{s} \sum_{j=1}^{M_l} \left(d_{\mathcal{S}}(s, s'_j) - d_{\mathcal{Q}}(q_i, q_j) \right)^2 . \tag{16}$$

Note that practically the minimum can be found by exhaustively searching over all $s_1, \ldots, s_N$ or even a coarser subset of $\mathcal{S}^r_N$. The complexity of such a search is negligible compared to the complexity of the iterative minimization process.

3.3. Interpolation of geodesic distances. So far, we considered the distance terms in (11) readily available, though it is obvious that only the distances between the surface samples, namely, $d_{\mathcal{S}}(s_i, s_j)$, are available, whereas distances between two arbitrary points in $\mathcal{S}^r_N$ have to be computed. Let us now devise a numerical procedure for computation of the geodesic distances between a pair of points on the polyhedron $\mathcal{S}^r_N$. As an input, we are given the following:

1. Euclidean coordinates $\{\mathbf{s}_i\}_{i=1}^N$ of the polyhedron vertices s_i.
2. The distance matrix $\mathbf{D}$, with elements $d_{ij} = d_{\mathcal{S}}(s_i, s_j)$.
3. Two arbitrary points $s = (t, \mathbf{u})$, $s' = (t', \mathbf{u}')$ in barycentric coordinates.

The output of our numeric procedure is the approximate geodesic distance $\hat{d}_{\mathcal{S}}(s, s') \approx d_{\mathcal{S}}(s, s')$.

Although the geodesic distance between two arbitrary points s, s' is generally unavailable, each point lies inside a triangle with vertices on the grid. Let s_1, s_2, s_3 and $s'_1, s\prime_2, s\prime_3$ be the vertices of the triangles t and t' enclosing s and s', respectively. Note that the mutual geodesic distances $d_{\mathcal{S}}(s_i, s'_j)$ are known. A naïve approach is to use the average of the above distances as $\hat{d}_{\mathcal{S}}(s, s')$, i.e.,

$$\hat{d}_{\mathcal{S}}(s, s') = \frac{1}{3} \sum_{i=1}^{3} d_{\mathcal{S}}(s_i, s'_i) . \tag{17}$$

By the triangle inequality, the approximation error has the order of the radius of the largest triangle, that is, $\mathcal{O}(r)$. In order to make the interpolant $\hat{d}_{\mathcal{S}}(s, s')$ smooth as a function $\mathbf{u}$ and $\mathbf{u}'$, the average is replaced by a weighted sum, where the weights are chosen according to proximity of $\mathbf{u}$ and $\mathbf{u}'$ to each of the enclosing triangle vertices. Such an interpolation procedure has very low computational complexity; yet its main disadvantage is the fact that it ignores the underlying geometry. Here we develop

an alternative geometric interpolation approach, which is a bit more elaborate, yet provides significantly more accurate approximation of the geodesic distances.

The basic idea of our interpolator is to compute first an approximation to the geodesic distances $d_{\mathcal{S}}(s, s'_i)$ between the point s and each of the three vertices s'_i of t'. Computation of each of these distances can be regarded as the problem of finding an approximation to $d_{\mathcal{S}}(s, s'_1)$ given $d_{\mathcal{S}}(s_i, s'_1)$. We handle the solution of this problem by a numerical procedure that we named the [illegible], which is detailed in Appendix B. Once the approximate $d_{\mathcal{S}}(s, s'_i)$ are available, we invoke again the three-point geodesic distance approximation, this time to compute the desired distance $d_{\mathcal{S}}(s, s')$ from $d_{\mathcal{S}}(s'_i, s)$.

3.4. Selection of weight for partial matching. So far, we have assumed that the set P of the consistent pairs of points in (11) or, alternatively, the weights w_{ij} in (12) are given. Here we show a way to find it in practice. Let $\mathcal{S}$ be the model surface and let $\mathcal{Q}$ be the probe surface. We denote by $\mathcal{Q}'$ a patch of $\mathcal{Q}$ and assume that its sampled version is $\mathcal{Q}'_{M'}$. The question is how to find the indices $(i, j) \in \{1, \ldots, M'\} \times \{1, \ldots, M'\}$ of pairs of points for which $d_{\mathcal{Q}'_{M'}}(q_i, q_j) \neq d_{\mathcal{Q}}(q_i, q_j)$, and thus must be excluded from P.

If a sampled version $\mathcal{Q}_M$ of $\mathcal{Q}$ is given (this is a common situation in face recognition, where one has the full probe surface but wishes to deliberately remove some parts of it [7]), the solution is straightforward: we remove the pairs of points (i, j) for which $|d_{\mathcal{Q}'_{M'}}(q_i, q_j) - d_{\mathcal{Q}_M}(q_i, q_j)| < \delta$, where δ is some small threshold, related to distance approximation accuracy. In the case when only the patch $\mathcal{Q}'$ is available, we note that the minimal geodesics may change due to the change in the boundary of $\mathcal{Q}$. We therefore remove pairs of points (i, j) for which $d_{\mathcal{Q}'}(q_i, \partial\mathcal{Q}') + d_{\mathcal{Q}'}(q_j, \partial\mathcal{Q}') < d_{\mathcal{Q}'}(q_i, q_j)$. Here $\partial\mathcal{Q}'$ denotes the boundary of $\mathcal{Q}'$. Since in practice a sampled version $\mathcal{Q}'_{M'}$ is given, this criterion must be discretized, and the distances approximated numerically.

4. Numerical results. We now present numerical experiments that assess the validity of our theoretical and computational framework. In the first experiment, we show the performance of the partial embedding distance in matching between spheres with different radii. In the second experiment, matching of articulated objects is performed using the Gromov–Hausdorff distance. The Elad–Kimmel canonical form distance [13] is used as the baseline reference in the two experiments. In the third experiment, we show matching of partially missing objects using the partial embedding distance. Additional numerical evaluations of the partial embedding distance can be found in [7, 8].

4.1. Partial embedding distance between spherical patches. In the first experiment, we measured the distance between a unit two-dimensional sphere sampled at 3200 points, and spheres with radii in the range $R = [0.5, 2.5]$ sampled at a smaller number of points according to the farthest point sampling strategy with a random seed. Ten random samplings were used for each radius. Two distance measures were compared: d^2_{PE} with $M = 100$ points and d_{CF} with $M = 100$, 250, and 500 points. d^2_{PE} was computed using the multiresolution minimization algorithm.

Figure 4 presents the normalized distances as a function of the sphere radius. In Figure 5, a close-up look is shown for radii in the range of $R = [0.88, 1.1]$. The gray areas represent the variance of the distance computed for the ten different samplings of the spheres. This variance makes spheres within a certain interval of radii around $R = 1$ indistinguishable by the distance function. The partial embedding distance appears to be extremely sensitive to the geometry of the surfaces. A change as small

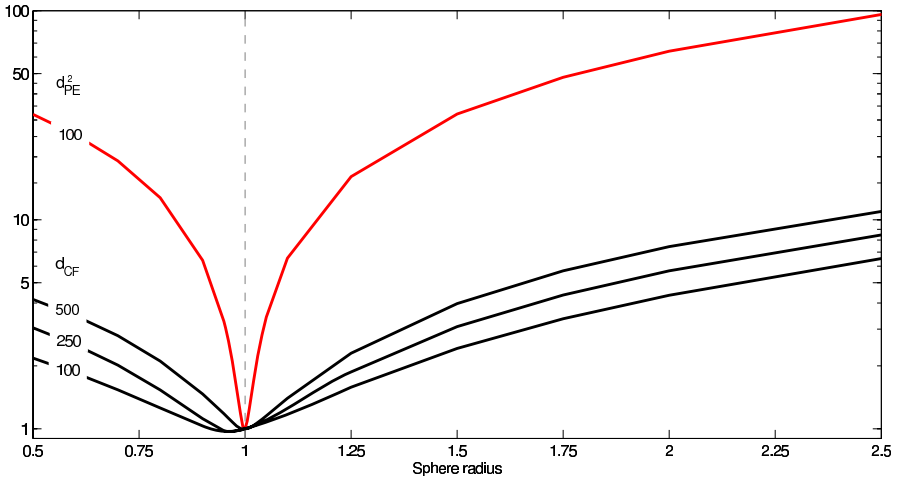

FIG. 4. *Normalized distance between a densely sampled unit sphere and spheres of different radii measured using the ℓ_2 approximation of the partial embedding distance (top line), and the canonical form distance (three bottom lines). The numbers on the plot stand for the number of points used for distance computation.*

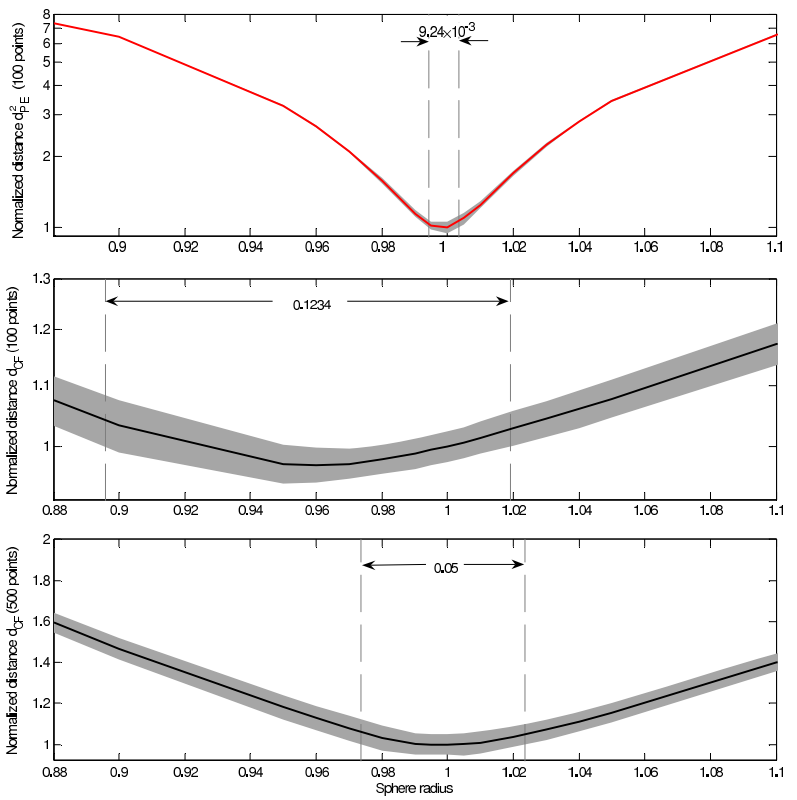

FIG. 5. *A close-up look at the normalized distance between a unit sphere and spheres of different radii measured using d^2_{PE} with 50 points (top) and d_{CF} with 100 and 500 points (middle and bottom plots). Gray areas denote the variance measured over ten random furthest point samplings. Intervals of sphere radii that fall below the sensitivity threshold of the distance measure are indicated.*

as 0.1% in the spherical patch radius (from 1.000 to 0.999) increases d^2_{PE} by a value exceeding the variance due to sampling. Similar results are achieved using d^1_{PE}, and with d_{PE} results are slightly inferior. For comparison, with the same number of points (100), d_{CF} is unable to discern between spheres differing in radius by more than 10%. Increasing the number of points to 500 makes d_{CF} sensitive to radius differences of about 2.64%, which is still one order of magnitude below the sensitivity of d^2_{PE}. From these results, d_{PE} appears to be a promising tool for very accurate comparison of surfaces.

Reasonable execution times were observed. The generalized stress function (12) and its gradient implemented in C are evaluated in about 40 msec on a Pentium IV PC for $M = 100$ points. The entire computation of d_{PE} using nonoptimized MATLAB and C code took about 10–60 sec.[2]

4.2. Gromov–Hausdorff distance between isometric surfaces. In the second experiment, we evaluated the performance of the Gromov–Hausdorff distance on six articulated objects and their approximate isometries. The ℓ_2 and ℓ_∞ approximations of d_{GH} were used. All surfaces were represented as triangulated polyhedral meshes (see Figure 6). The embedding spaces consisted of the full-density meshes, whereas the embedded meshes were sampled at $M = N = 50$ points. Optimization was performed using the multiresolution scheme. Geodesic distances were computed using the fast marching method for triangulated domains [19]. As a reference, the canonical form distance was computed between the surfaces by comparing a full-density canonical form to canonical forms sampled at $M = 100$, 250, and 600 points as well as to full-density canonical forms. Moment signatures and an iterative closest point algorithm were used to compare the canonical forms.

Figure 7 presents the distance matrices obtained using the ℓ_2 and ℓ_∞ approximations of d_{GH}. As few samples as 50 give perfect recognition of all the objects using both d^2_{GH} and d_{GH}. For comparison, the best result of d_{CF} with full-density canonical forms and ICP (Figure 7, bottom right) yielded about 11% equal error rate. Figure 8 depicts Euclidean representations of the dissimilarities between the objects measured using d^2_{GH} and d_{CF}. Note the tight clusters produced by d^2_{GH} compared to looser clusters obtained from d_{CF}. The dog and paper objects exhibit larger intracluster dissimilarities, which we attribute to larger deviations from isometricity.

In order to accurately quantify the discriminative power of the compared distances, we measured the [illegible] as

$$\sigma = \min_n \left\{ \frac{\min_{i,j,m\neq n} d(\mathcal{S}_{mi}, \mathcal{S}_{mj})}{\max_{i,j} d(\mathcal{S}_{ni}, \mathcal{S}_{nj})} \right\}, \tag{18}$$

where S_{ni} denotes the ith instance of the nth object. In simple words, σ expresses the worst-case ratio between the intercluster and the intracluster distances. The higher σ, the better the discrimination between the objects. d^2_{GH} yielded $\sigma = 3.47$, which is a manifest of excellent separation; slightly inferior results were exhibited by d_{GH}. For comparison, the best result obtained by d_{CF} was $\sigma = 0.58$.

Increasing the number of points from 100 to 600 in d_{CF} increases the computational complexity with small or no benefit in accuracy. We also noted that starting from about 250 points, the use of ICP in the computation of the canonical form distance gives negligible accuracy improvement compared to the faster moment signature comparison. This leads us to the conclusion that in this experiment, the discrimina-

[2]The codes and datasets used in this paper will be published at http://tosca.cs.technion.ac.il.

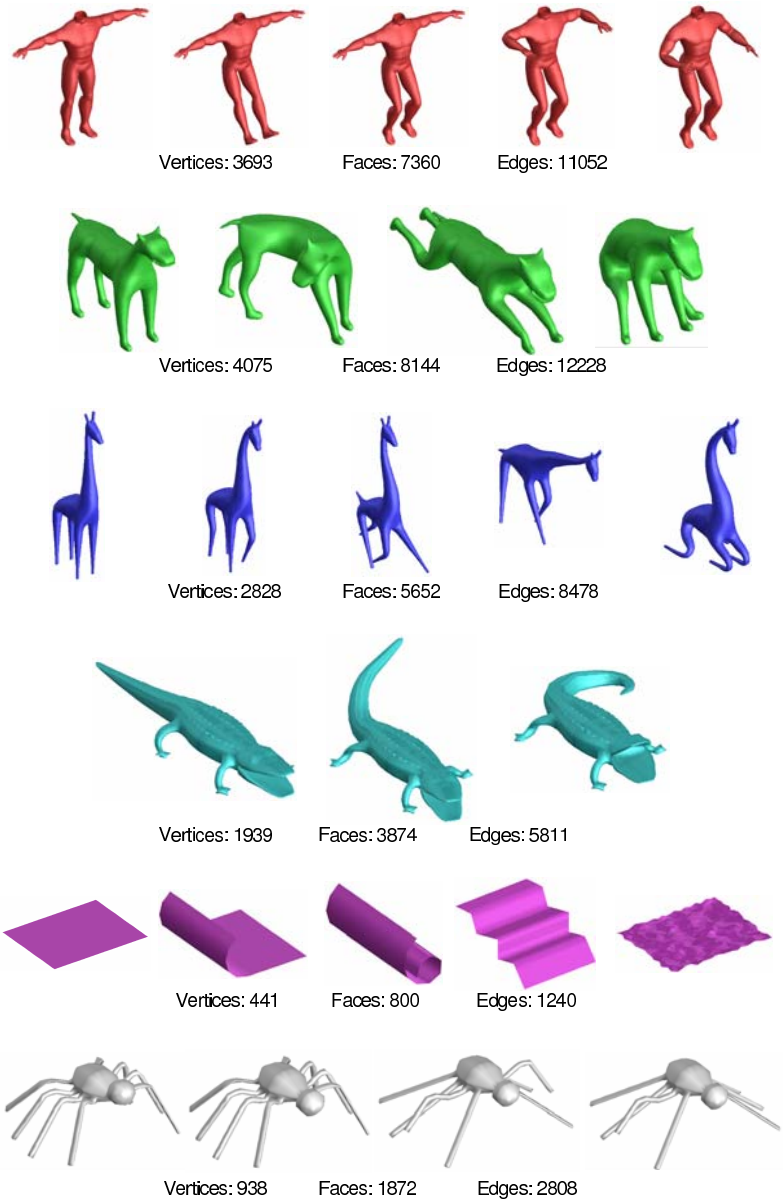

FIG. 6. *Six objects (human, dog, giraffe, crocodile, paper, and spider) with their approximate isometries.*

tive power of the canonical form distance is essentially limited by metric distortion introduced by embedding the surface into $\mathbb{R}^3$.

4.3. Partial matching of isometric surfaces. In the third experiment, six partial probes (Figure 9) were matched against the objects from the previous experiment using the ℓ_2 and ℓ_∞ approximations of d_{PE}. As before, the embedding spaces consisted of full-density meshes, whereas the partial probes were sampled at $M = N = 50$ points. Optimization was performed using the multiresolution scheme.

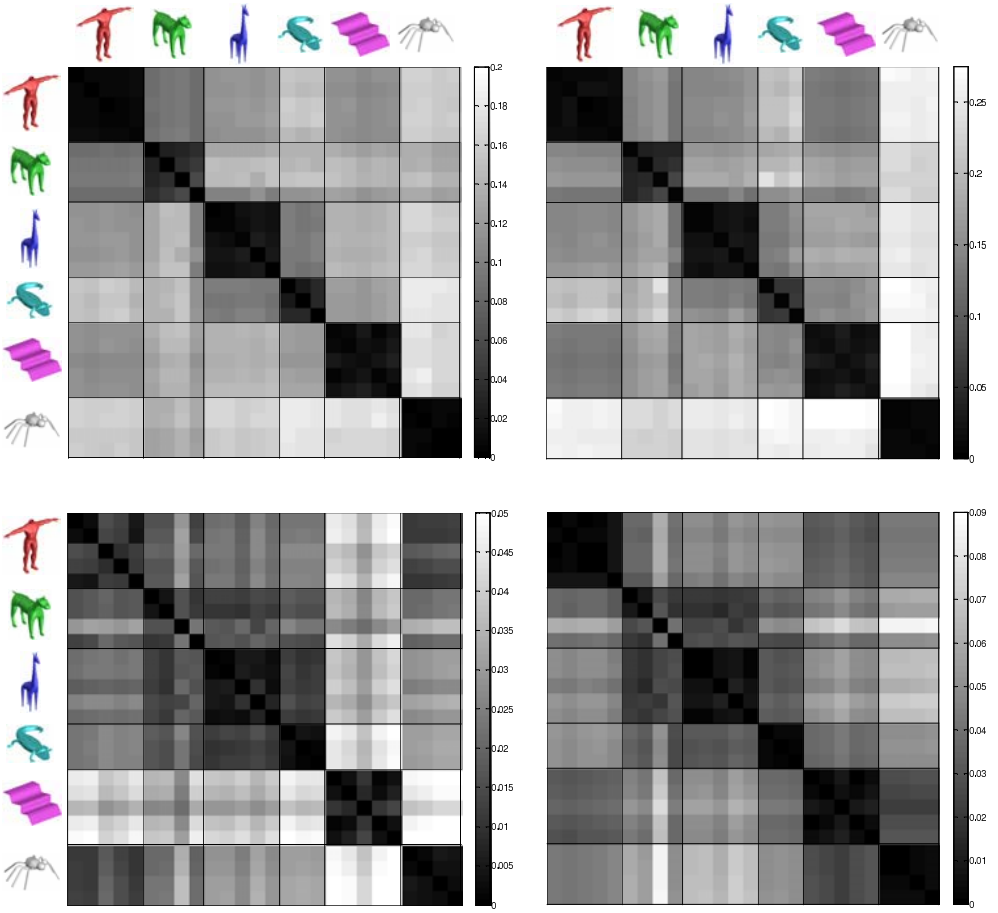

FIG. 7. *Matrices of distances (dissimilarities) between the objects obtained using* d^2_{GH} *(top left) and* d_{GH} *(top right) with* $M = N = 50$*; and* d_{CF} *with* $M = 600$ *(bottom left) and full-density canonical forms (bottom right).*

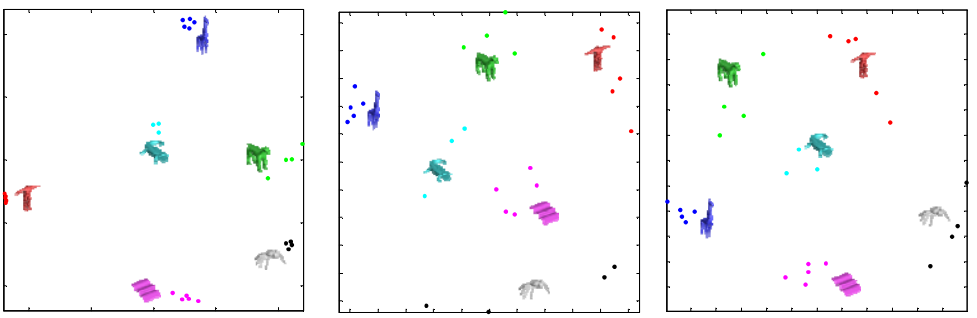

FIG. 8. *Euclidean proximity pattern representing the distances between different objects measured according to* d^2_{GH} *with* $M = N = 50$ *(left) and* d_{CF} *with* $M = 600$ *and full-density canonical forms (middle and right, respectively). Each point represents an object; Euclidean distance between two points represents dissimilarity between the corresponding objects.*

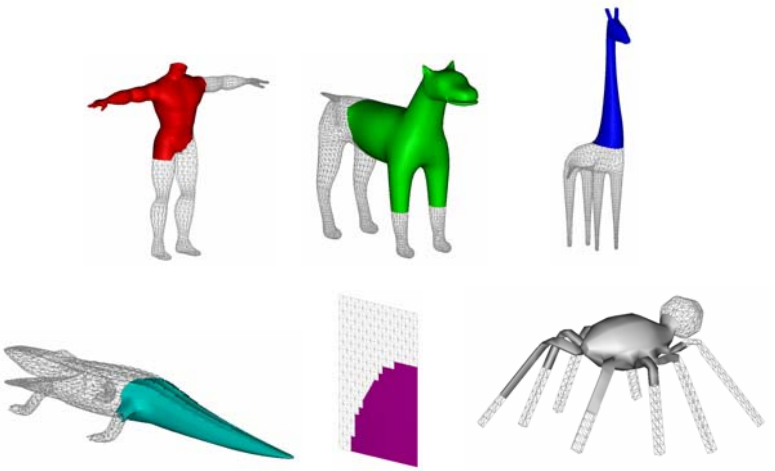

FIG. 9. *Parts of the human, dog, giraffe, crocodile, paper, and spider objects used as probes in the third experiment.*

Perfect matching was achieved by both distance functions, yielding the separability of $\sigma = 1.62$ and 1.29 for d^2_{PE} and d_{PE}, respectively.

Additional numerical assessment of the partial embedding distance was presented in [8], where it was used for face recognition from partially occluded data.

5. Conclusions. In this paper, we introduced a new computational framework for isometry-invariant surface matching. This framework allowed us to formulate the Gromov–Hausdorff distance between two surfaces as a solution of the generalized MDS problem. We also mentioned that the same numerical framework can be used to perform isometry-invariant matching of partially missing surfaces [7]. The GMDS problem is posed as a continuous optimization problem and is solved efficiently using the proposed iterative optimization algorithm. A multiresolution scheme can be a practical means of avoiding convergence to local minima. In light of recent results [9], we foresee that further performance boosting can be obtained using multigrid optimization methods.

Appendix A. Proofs of properties of the partial embedding distance.

1 (i) is trivial since $\operatorname{dis}\psi \geq q$.

The first direction of (ii) is straightforward, since if $\mathcal{Q}$ is isometrically embeddable into $\mathcal{S}$, there exists $\psi : \mathcal{Q} \mapsto \mathcal{S}$ with $\operatorname{dis}\psi = 0$. The second direction is more elaborate; our proof closely follows the proof of Theorem 7.3.30 in [10]. From $d_{\mathrm{PE}}(\mathcal{S}, \mathcal{Q}) = 0$ it follows that there exists a sequence of mappings $\{\psi_n : \mathcal{Q} \mapsto \mathcal{S}\}$ satisfying $\operatorname{dis}\psi_n \leq \frac{1}{n}$. Fix a countable dense set $\mathcal{Q}' \subset \mathcal{Q}$. Using the Cantor diagonalization procedure, one can choose a subsequence $\{\psi_{n_k}\}$, such that for every $q' \in \mathcal{Q}'$ the sequence $\{\psi_{n_k}(q')\}$ converges in $\mathcal{S}$. Let us assume without loss of generality that such a sequence is $\{\psi_n\}$ itself. We define a map $\psi : \mathcal{Q}' \mapsto \mathcal{S}$ as the pointwise limit of $\{\psi_n\}$, namely, $\psi(q') = \lim_{n\to\infty} \psi_n(q')$ for every $q' \in \mathcal{Q}'$. Since $|d_{\mathcal{S}}(\psi_n(q''), \psi_n(q')) - d_{\mathcal{Q}}(q'', q')| \leq \operatorname{dis}\psi_n \to 0$, we have

$$d_{\mathcal{S}}(\psi(q''), \psi(q')) = \lim_{n\to\infty} d_{\mathcal{S}}(\psi_n(q''), \psi_n(q')) = d_{\mathcal{Q}}(q'', q')$$

for all $q', q'' \in \mathcal{Q}'$, i.e., ψ is a distance preserving embedding of $\mathcal{Q}'$ into $\mathcal{S}$. Since

$\mathcal{Q}'$ is dense, by Proposition 1.5.9 in [10], ψ can be extended to a distance preserving embedding of the entire $\mathcal{Q}$ into $\mathcal{S}$.

To prove (iii), let $d_{\mathrm{PE}}(\mathcal{R},\mathcal{Q}) = \delta_1$ and $d_{\mathrm{PE}}(\mathcal{S},\mathcal{R}) = \delta_2$. Then there exist two sequences of mappings $\{\varphi_n : \mathcal{Q} \mapsto \mathcal{R}\}$ and $\{\psi_n : \mathcal{R} \mapsto \mathcal{S}\}$ satisfying $\operatorname{dis}\varphi_n < 2\delta_1 + \frac{1}{n}$ and $\operatorname{dis}\psi_n < 2\delta_2 + \frac{1}{n}$. Denote by $\{\zeta_n : \mathcal{Q} \mapsto \mathcal{S}\}$ the sequence of the compositions $\zeta_n = \psi_n \circ \varphi_n$. Invoking the triangle inequality for real numbers, one has

$$\begin{aligned}|d_{\mathcal{S}}(\zeta_n(q),\zeta_n(q')) - d_{\mathcal{Q}}(q,q')| &\le |d_{\mathcal{S}}(\zeta_n(q),\zeta_n(q')) - d_{\mathcal{R}}(\varphi_n(q),\varphi_n(q'))| \\ &\quad + |d_{\mathcal{R}}(\varphi_n(q),\varphi_n(q')) - d_{\mathcal{Q}}(q,q')| \\ &\le \operatorname{dis}\varphi_n + \operatorname{dis}\psi_n < 2(\delta_1+\delta_2) + \frac{2}{n}\end{aligned}$$

for all $q, q' \in \mathcal{Q}'$. Hence, $\operatorname{dis}\zeta_n \le 2(\delta_1+\delta_2) + \frac{2}{n}$ and $d_{\mathrm{PE}}(\mathcal{S},\mathcal{Q}) \le \delta_1 + \delta_2$. □

Proof of property 2 (i) This property follows straightforwardly from the fact that $d_{\mathrm{PE}}(\mathcal{S},\mathcal{Q}) \le d_{\mathrm{GH}}(\mathcal{Q},\mathcal{S})$. □

Proof of property 3 We divide the proof into the following two separate statements:

(i) $d_{\mathrm{PE}}(\mathcal{S},\mathcal{Q}) - r \le d_{\mathrm{PE}}(\mathcal{S},\mathcal{Q}^r) \le d_{\mathrm{PE}}(\mathcal{S},\mathcal{Q})$.
(ii) $d_{\mathrm{PE}}(\mathcal{S},\mathcal{Q}) \le d_{\mathrm{PE}}(\mathcal{S}^{r'},\mathcal{Q}) \le d_{\mathrm{PE}}(\mathcal{S},\mathcal{Q}) + r'$.

The combination of (i) and (ii) gives property 3.

The right side of inequality (i) is straightforward, since $\sup_{q,q'\in\mathcal{Q}} |d_{\mathcal{Q}^r}(q,q') - d_{\mathcal{S}}(\psi(q),\psi(q'))| \le \sup_{q,q'\in\mathcal{Q}} |d_{\mathcal{Q}}(q,q') - d_{\mathcal{S}}(\psi(q),\psi(q'))|$. To show the left side, we invoke property 1(ii), which yields $d_{\mathrm{PE}}(\mathcal{S},\mathcal{Q}) \le d_{\mathrm{PE}}(\mathcal{S},\mathcal{Q}^r) + d_{\mathrm{PE}}(\mathcal{Q}^r,\mathcal{Q})$. It remains to show that $d_{\mathrm{PE}}(\mathcal{Q}^r,\mathcal{Q}) \le r$. Let the mapping $\psi : \mathcal{Q} \mapsto \mathcal{Q}^r$ be defined in the following way: for $q \in \mathcal{Q}^r$, $\psi(q) = q$; and for $q \in \mathcal{Q}\backslash\mathcal{Q}^r$, $\psi(q) = \arg\min_{q'\in\mathcal{Q}^r} d_{\mathcal{Q}}(q,q')$ (the minimum exists, since $\mathcal{Q}^r$ can be replaced by its finite subcovering). From the fact that $\mathcal{Q}^r$ is an r-covering, it follows that $d_{\mathcal{Q}}(q,\psi(q)) \le r$. Let q_1, q_2 be two points in $\mathcal{Q}$; if both are in $\mathcal{Q}^r$, then $|d_{\mathcal{Q}}(q_1,q_2) - d_{\mathcal{Q}}(\psi(q_1),\psi(q_2))| = 0$. If both q_1 and q_2 are in $\mathcal{Q}^r$, invoking the triangle inequality, one has $|d_{\mathcal{Q}}(q_1,q_2) - d_{\mathcal{Q}}(\psi(q_1),\psi(q_2))| \le d_{\mathcal{Q}}(q_1,\psi(q_1)) + d_{\mathcal{Q}}(q_2,\psi(q_2)) \le 2r$. Similarly, when only q_1 is in $\mathcal{Q}^r$, $|d_{\mathcal{Q}}(q_1,q_2) - d_{\mathcal{Q}}(\psi(q_1),\psi(q_2))| \le r$. Hence, $\operatorname{dis}\psi \le 2r$.

The left side of inequality (ii) is straightforward. To show the right side, let us be given some $\psi : \mathcal{Q} \to \mathcal{S}$. We define a new mapping $\tilde{\psi} : \mathcal{Q} \to \mathcal{S}^{r'}$ in the following way:

$$\tilde{\psi}(q) = \begin{cases} \psi(q), & \psi(q) \in \mathcal{S}^{r'}, \\ \operatorname{argmin}_{s\in\mathcal{S}^{r'}} d_{\mathcal{S}}(s,\psi(q)) & \text{else.} \end{cases}$$

Since $\mathcal{S}^{r'}$ is an r'-covering of $\mathcal{S}$, $\sup_{q,q'\in\mathcal{Q}} |d_{\mathcal{Q}}(q,q') - d_{\mathcal{S}}(\tilde{\psi}(q),\tilde{\psi}(q'))| \le \sup_{q,q'\in\mathcal{Q}} |d_{\mathcal{Q}}(q,q') - d_{\mathcal{S}}(\psi(q),\psi(q'))| + 2r'$ for all ψ, and consequently $d_{\mathrm{PE}}(\mathcal{S}^{r'},\mathcal{Q}) \le d_{\mathrm{PE}}(\mathcal{S},\mathcal{Q}) + r'$. □

Proof of property 4 The right side of the inequality follows from the combination of properties 3 and 1(ii), $d_{\mathrm{PE}}(\mathcal{S}_M^{r'},\mathcal{Q}_N^r) \le d_{\mathrm{PE}}(\mathcal{S}_M^{r'},\mathcal{Q}) + d_{\mathrm{PE}}(\mathcal{Q},\mathcal{Q}_N^r) \le d_{\mathrm{PE}}(\mathcal{S},\mathcal{Q}) + r'$. The left side of the inequality follows from property 3, $d_{\mathrm{PE}}(\mathcal{S},\mathcal{Q}) \le d_{\mathrm{PE}}(\mathcal{S},\mathcal{Q}_N^r) + r \le d_{\mathrm{PE}}(\mathcal{S}_M^{r'},\mathcal{Q}_N^r) + r$. □

Appendix B. Three-point geodesic distance approximation. We now outline a numerical scheme for interpolation of geodesic distance $d_{\mathcal{S}}(s,s')$ between two arbitrary points $s = (t,\mathbf{u})$ and $s' = (t',\mathbf{u}')$ on a polyhedral surface $\mathcal{S}_N$ from the matrix $\mathbf{D}_{\mathcal{S}}$ of geodesic distances between all s_i and s_j. Let us denote the vertices of

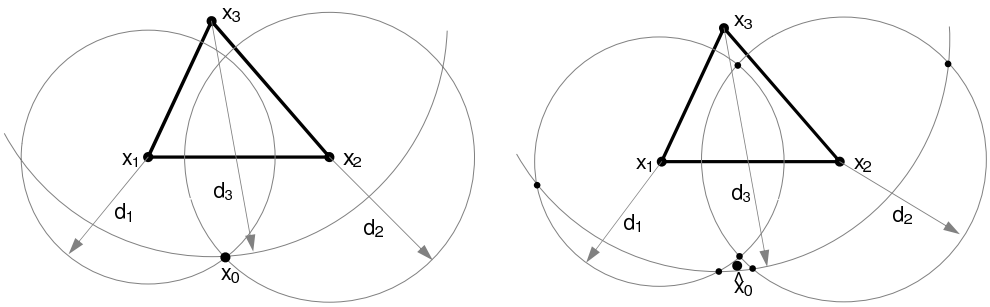

FIG. 10. *Geodesic distances associated with the triangle vertices* $\mathbf{x}_1$, $\mathbf{x}_2$, $\mathbf{x}_3$ *are used to find a virtual "source" point, distant* d_1, d_2, *and* d_3 *from the corresponding vertices. When the surface is a plane, the three circles intersect at one point* $\mathbf{x}_0$ *and such a source exists (left); in the general case, only an approximate source* $\hat{\mathbf{x}}_0$ *can be found, yet every pair of circles usually intersects at two distinct points (right).*

the triangle t, in which the point s lies, as $s_1, s_2, s_3 \in \mathcal{S}_N$. Similarly, the vertices of t' will be denoted by s'_1, s'_2, s'_3.

As a starting point, let us consider the particular case where s' is one of the polyhedron vertices. In this case, the distances $d_j = d_{\mathcal{S}}(s_i, s')$ for $i = 1, 2, 3$ can be obtained from the matrix $\mathbf{D}_{\mathcal{S}}$. We will assume without loss of generality that the triangle s_1, s_2, s_3 lies in $\mathbb{R}^2$ with s_1 at the origin and s_2 on the horizontal axis, denoting by $\mathbf{x}_1 = (0,0)^{\mathrm{T}}$, $\mathbf{x}_2 = (x_2, 0)^{\mathrm{T}}$, and $\mathbf{x}_3 = (x_3, y_3)^{\mathrm{T}}$ the planar coordinates of the corresponding vertices. The original triangle can always be brought to this coordinate system by a simple precomputed transformation. In other words, the actual vertex coordinates $\mathbf{s}_i$ in a triangle are not required by the algorithm.

Let us assume that there exists a (virtual) source point $\hat{\mathbf{x}}_0 = (\hat{x}_0, \hat{y}_0)^{\mathrm{T}}$ in the plane of the triangle, whose distance from $\mathbf{x}_i$ is d_i. When the surface $\mathcal{S}$ is planar, there indeed exists such a point consistent with the data, and it can be found by computing the intersection of three circles of radii d_i centered at the corresponding triangle vertices $\mathbf{x}_i$ (Figure 10, left). This gives rise to the following system of quadratic equations:

$$\begin{aligned} \hat{x}_0^2 + \hat{y}_0^2 &= d_1^2, \\ (\hat{x}_0 - x_2)^2 + \hat{y}_0^2 &= d_2^2, \\ (\hat{x}_0 - x_3)^2 + (\hat{y}_0 - y_3)^2 &= d_3^2. \end{aligned} \tag{19}$$

Once $\hat{\mathbf{x}}_0$ is determined, the Euclidean distance $\|\hat{\mathbf{x}}_0 - \mathbf{x}\|$ serves as the approximation to the geodesic distance $d_{\mathcal{S}}(\mathbf{x}_0, \mathbf{x})$. In the above particular case, the two coincide.

However, in the general case when the surface has nonzero Gaussian curvature, the Euclidean distances $\|\hat{\mathbf{x}}_0 - \mathbf{x}_i\|$ will be inconsistent with the geodesic distances d_i, and thus the three circles will not generally intersect at a single point (Figure 10, right). Even if $\hat{\mathbf{x}}_0$ can be found to satisfy (19) in the "best possible way," the Euclidean distance $\|\hat{\mathbf{x}}_0 - \mathbf{x}\|$ will not generally coincide with the true geodesic distance $d_{\mathcal{S}}(\mathbf{x}, \mathbf{x}_0)$. Yet this scheme still gives a good approximation to $d_{\mathcal{S}}(\mathbf{x}, \mathbf{x}_0)$.[3]

[3]Theoretically, the scheme is first order, but in practice we observed that its accuracy is often superior by about two orders of magnitude compared to the straightforward "nongeometric" linear interpolation of geodesic distances on articulated objects.

Here, we find the virtual source $\hat{\mathbf{x}}_0$ by a weighted least-squares solution of (19), namely,

$$\hat{\mathbf{x}}_0\left(\mathbf{X},\mathbf{d},\mathbf{w}\right)=\arg\min_{\mathbf{x}_0}\ell\left(\mathbf{x}_0;\mathbf{X},\mathbf{d},\mathbf{w}\right), \tag{20}$$

where

$$\ell(\mathbf{x}_0;\mathbf{X},\mathbf{d},\mathbf{w})=\sum_{i=1}^{3}w_i\big(\left\|\mathbf{x}_0-\mathbf{x}_i\right\|^2-d_i^2\big)^2, \tag{21}$$

$\mathbf{X}=(\mathbf{x}_1,\mathbf{x}_2,\mathbf{x}_3)$, $\mathbf{d}=(d_1^2,d_2^2,d_3^2)^{\mathrm{T}}$, and $\mathbf{w}=(w_1,w_2,w_3)^{\mathrm{T}}$ is a vector of weights controlling the influence of each of the vertices. For a moment, we assume that the weights are given; later we will discuss their choice.

In our implementation, the minimization is carried out using Newton steps [1]. The gradient $\mathbf{g}$ and the Hessian matrix $\mathbf{H}$ of $\ell(\mathbf{x}_0;\mathbf{X},\mathbf{d},\mathbf{w})$ with respect to $\mathbf{x}_0$, required by the Newton method, are given by

$$\mathbf{g}=4\left(\mathbf{w}^{\mathrm{T}}\mathbf{f}\cdot\mathbf{x}-\mathbf{X}\cdot\mathbf{w}\odot\mathbf{f}\right), \tag{22}$$

$$\mathbf{H}=4\ \mathbf{w}^{\mathrm{T}}\mathbf{f}\cdot\mathbf{I}+8\sum_{i=1}^{3}w_i\left(\mathbf{x}_0-\mathbf{x}_i\right)\left(\mathbf{x}_0-\mathbf{x}_i\right)^{\mathrm{T}}, \tag{23}$$

where $(\mathbf{f})_i=\left\|\mathbf{x}_0-\mathbf{x}_i\right\|^2-d_i^2$, and $\mathbf{w}\odot\mathbf{f}$ denotes the elementwise (Hadamard) product. When the vertices $\mathbf{x}_i$ are not collinear, which normally happens in a valid triangulation, the Hessian is full rank for $w_i\neq 0$. When one of the weights, say w_3, is zero, the first two equations in (19) are satisfied and hence the first terms of $\mathbf{f}$ vanish. Consequently, the first term in the Hessian is zero, whereas the second term is a sum of two outer products of linearly independent vectors, which is full rank. When only one weight, say w_1, is nonzero, the Hessian assumes the form $\mathbf{H}=8w_1\left(\mathbf{x}_0-\mathbf{x}_1\right)\left(\mathbf{x}_0-\mathbf{x}_1\right)^{\mathrm{T}}$, which is a rank one matrix. Since in this case the solution $\hat{\mathbf{x}}_0$ admits only the first equation in (19), the minimum of $\ell(\mathbf{x}_0;\mathbf{X},\mathbf{d},\mathbf{w})$ is achieved on the circle described by the said equation, and the null vector of $\mathbf{H}$ corresponds to the tangential direction, in which the function does not change.

Due to the lack of convexity of $\ell(\mathbf{x}_0;\mathbf{X},\mathbf{d},\mathbf{w})$, we need to pay attention to the initialization. In our implementation, we first find simultaneous solutions of different pairs of equations from (19), giving at most six different points, and then initialize the minimization algorithm by the one yielding the smallest value of ℓ. The solution of a pair of quadratic equations has an analytic expression; for example, the first two equations yield

$$\hat{x}_0=\frac{d_1^2-d_2^2+x_2^2}{2x_2},$$

$$\hat{y}_0=\pm\sqrt{d_1^2-\hat{x}_0^2} \tag{24}$$

wherever two, one, or none of the solutions exist. Since by its virtue such an initialization is sufficiently close to the optimal $\hat{\mathbf{x}}_0$, the algorithm converges in about two or three iterations.

LEMMA B.1. $\mathbf{x}_i$ $\mathbf{w}$ $\hat{\mathbf{x}}_0(\mathbf{X},\mathbf{d},\mathbf{w})$ $\mathbf{d}$ $\mathbf{w}$

$$\mathbf{J}_{\mathbf{w}} = \nabla_{\mathbf{w}}\hat{\mathbf{x}}_0^{\mathrm{T}} = -\mathbf{G}_{\mathbf{w}}\mathbf{H}^{-1},$$

$$\mathbf{J}_{\mathbf{d}} = \nabla_{\mathbf{d}}\hat{\mathbf{x}}_0^{\mathrm{T}} = -\mathbf{G}_{\mathbf{d}}\mathbf{H}^{-1}, \tag{25}$$

$\mathbf{G}_{\mathbf{w}} = \nabla_{\mathbf{w}}\mathbf{g}^{\mathrm{T}}$ $\mathbf{G}_{\mathbf{d}} = \nabla_{\mathbf{d}}\mathbf{g}^{\mathrm{T}}$

$$\mathbf{G}_{\mathbf{w}} = 4\mathbf{F}\left(\mathbf{x}_0\mathbf{1}^{\mathrm{T}} - \mathbf{X}\right),$$

$$\mathbf{G}_{\mathbf{d}} = -4\mathbf{W}\left(\mathbf{x}_0\mathbf{1}^{\mathrm{T}} - \mathbf{X}\right). \tag{26}$$

$\mathbf{W}$ $\mathbf{F}$ $\mathbf{w}$ $\mathbf{f}$ $\mathbf{1} = (1,1,1)^{\mathrm{T}}$. Let us start with the derivative with respect to $\mathbf{w}$. By (20), $\hat{\mathbf{x}}_0$ is a local minimum of $\ell(\mathbf{x}_0;\mathbf{X},\mathbf{d},\mathbf{w})$, hence $\mathbf{g}(\hat{\mathbf{x}}_0;\mathbf{X},\mathbf{d},\mathbf{w}) = 0$, where $\mathbf{g}$ stands for the gradient $\nabla_{\mathbf{x}_0}\ell$. Adding an infinitesimal perturbation to $\mathbf{w}$ results in $\mathbf{g}(\hat{\mathbf{x}}_0;\mathbf{X},\mathbf{d},\mathbf{w}+d\mathbf{w}) \neq 0$, yet there exists an infinitesimal perturbation $d\hat{\mathbf{x}}_0$, such that $\mathbf{g}(\hat{\mathbf{x}}_0 + d\hat{\mathbf{x}}_0;\mathbf{X},\mathbf{d},\mathbf{w}+d\mathbf{w}) = 0$. From the first order Taylor expansion,

$$\begin{aligned}\mathbf{g}(\hat{\mathbf{x}}_0 + d\hat{\mathbf{x}}_0;\mathbf{X},\mathbf{d},\mathbf{w}+d\mathbf{w}) &\approx \mathbf{g}(\hat{\mathbf{x}}_0;\mathbf{X},\mathbf{d},\mathbf{w}) \\ &\quad + \mathbf{H}(\hat{\mathbf{x}}_0;\mathbf{X},\mathbf{d},\mathbf{w})\,d\hat{\mathbf{x}}_0 + \mathbf{G}_{\mathbf{w}}^{\mathrm{T}}(\hat{\mathbf{x}}_0;\mathbf{X},\mathbf{d},\mathbf{w})\,d\mathbf{w},\end{aligned} \tag{27}$$

where $\mathbf{H}$ stands for the Hessian matrix of ℓ with respect to $\mathbf{x}_0$ given in (23). Substituting $\mathbf{g}(\hat{\mathbf{x}}_0;\mathbf{X},\mathbf{d},\mathbf{w}) = 0$ and neglecting second order terms, we obtain

$$\mathbf{H}d\hat{\mathbf{x}}_0 + \mathbf{G}_{\mathbf{w}}^{\mathrm{T}}d\mathbf{w} = 0. \tag{28}$$

Since for noncollinear $\mathbf{x}_i$ and at most one zero weight the Hessian is invertible,

$$d\hat{\mathbf{x}}_0 = -\mathbf{H}^{-1}\mathbf{G}_{\mathbf{w}}^{\mathrm{T}}d\mathbf{w}, \tag{29}$$

from which $\mathbf{J}_{\mathbf{w}}$ is straightforwardly obtained. In the same way, $\mathbf{J}_{\mathbf{d}}$ is derived. □

Having the approximant of the virtual source $\hat{\mathbf{x}}_0(\mathbf{X},\mathbf{d},\mathbf{w})$ and its first order derivatives, we can construct the three-point geodesic distance approximant,

$$\hat{d}_{\mathcal{S}}^2(\mathbf{x};\mathbf{X},\mathbf{d},\mathbf{w}) = \left\|\mathbf{x} - \hat{\mathbf{x}}_0(\mathbf{X},\mathbf{d},\mathbf{w})\right\|^2, \tag{30}$$

and it derivatives,

$$\begin{aligned}\nabla_{\mathbf{x}}\hat{d}_{\mathcal{S}}^2(\mathbf{x};\mathbf{X},\mathbf{d},\mathbf{w}) &= 2\left(\mathbf{x} - \hat{\mathbf{x}}_0\right), \\ \nabla_{\mathbf{w}}\hat{d}_{\mathcal{S}}^2(\mathbf{x};\mathbf{X},\mathbf{d},\mathbf{w}) &= 2\mathbf{J}_{\mathbf{w}}\left(\hat{\mathbf{x}}_0 - \mathbf{x}\right), \\ \nabla_{\mathbf{d}}\hat{d}_{\mathcal{S}}^2(\mathbf{x};\mathbf{X},\mathbf{d},\mathbf{w}) &= 2\mathbf{J}_{\mathbf{d}}\left(\hat{\mathbf{x}}_0 - \mathbf{x}\right),\end{aligned} \tag{31}$$

where for convenience we use the squared distance. Assuming that $s = (t,\mathbf{u})$ is given in normalized barycentric coordinates $u_1 + u_2 + u_3 = 1$, one has $\mathbf{x} = \mathbf{X}\mathbf{u} = u_1\mathbf{x}_1 + u_2\mathbf{x}_2 + u_3\mathbf{x}_3$, where $\mathbf{X}$ is a precomputed matrix defining the geometry of the triangle t.

Hence, we have a tool to compute the approximate geodesic distance $\hat{d}^2_{\mathcal{S}}(s,s')$ given $\mathbf{d} = (d^2_{\mathcal{S}}(s_1,s'), d^2_{\mathcal{S}}(s_2,s'), d^2_{\mathcal{S}}(s_3,s'))^{\mathrm{T}}$ and a vector of weights $\mathbf{w}$. The derivatives of $\hat{d}^2_{\mathcal{S}}$ with respect to $\mathbf{u}$ are obtained using the chain rule, $\nabla_{\mathbf{u}} \hat{d}^2_{\mathcal{S}} = \mathbf{X}^{\mathrm{T}} \nabla_{\mathbf{x}} \hat{d}^2_{\mathcal{S}}(\mathbf{X}\mathbf{u})$.

Let us now address the issue of weights. We fix s' to be a point on $\mathcal{S}_N$ and assume that the vector $\mathbf{d} = (d^2_1, d^2_2, d^2_3)^{\mathrm{T}}$ of the geodesic distances $d_{\mathcal{S}}(s', s_i)$ for $i = 1,2,3$ is known. It is straightforward that for nonzero weights $\mathbf{w}$ and $s = (t, \mathbf{u})$ belonging to the interior of the triangle s_1, s_2, s_3 (i.e., $u_i > 0$), the function $\hat{d}^2_{\mathcal{S}}(\mathbf{u})$ is $\mathcal{C}^1$. However, the transition of s to an adjacent triangle, say s_4, s_3, s_2, will cause the vector of distances to change to $\mathbf{d} = (d^2_4, d^2_2, d^2_3)^{\mathrm{T}}$. As a result, $\hat{d}^2_{\mathcal{S}}(\mathbf{u})$ is liable to be discontinuous along the triangle edges. This complicates the numerical solution of (13). Therefore, our goal is to achieve at least $\mathcal{C}^1$ continuity for $\hat{d}^2_{\mathcal{S}}$ on all of $\mathcal{S}_N$.

In order to handle this problem, we set the weights $\mathbf{w}$ proportional to the barycentric coordinates of s, $\mathbf{u}$. Inside the triangle one has $u_i > 0$ and, consequently, the weights are set to some positive values inside the triangle. For s located on the edge $\overline{s_2 s_3}$, one has $w_1 = u_1 = 0$, which cancels the influence of the vertex s_1 in the least squares problem. Hence, the same vertices participate with the same weights when $\hat{d}^2_{\mathcal{S}}$ is computed from both triangles s_1, s_2, s_3 and s_2, s_3, s_4, yielding a continuous transition of $\hat{d}^2_{\mathcal{S}}$ across the edge. In order to enforce $\mathcal{C}^1$ continuity for $\hat{d}^2_{\mathcal{S}}$, a change of $\mathbf{u}$ by a unit vector $\Delta\mathbf{u}$ and of $\mathbf{u}'$ by a unit vector $\Delta\mathbf{u}'$ must displace the point $\mathbf{x}$ inside the triangles t and t' by the same Euclidean distance. Since barycentric coordinates are defined up to scale, this can be enforced by selecting an appropriate scaling for $\mathbf{u}$ in each triangle.

Since the least-squares problem (20) is underdetermined when one of the weights is set to zero and generally yields two distinct solutions, one has to select the solution consistent with the case when the weight is slightly larger than zero. In practice, it is easier to avoid the second inconsistent solution by setting the weight to some small positive constant ϵ rather than strictly to zero. At the triangle vertices two weights vanish, which makes the least-squares problem underdetermined. In this case, however, there is no need for the least-squares solution, since the geodesic distances between the triangle edges to s' are assumed to be known.

Our final step is to put everything together to obtain the approximant $d^2_{\mathcal{S}}(s,s')$ of the geodesic distance between two arbitrary points $s = (t, \mathbf{u})$ and $s' = (t', \mathbf{u}')$ on $\mathcal{S}_N$, given the mutual geodesic distances $d_{\mathcal{S}}(s_i, s'_j)$ between the vertices s_1, s_2, s_3 of t and s'_1, s'_2, s'_3 of t'. We first compute the approximate geodesic distances from s to s'_i, $\hat{d}^2_{\mathcal{S}}(s, s'_i) = \hat{d}^2_{\mathcal{S}}(\mathbf{u}; \mathbf{X}, \mathbf{d}_i, \mathbf{w} = \mathbf{u})$ for $i = 1,2,3$, where $\mathbf{X}$ is the matrix with the canonical coordinates of s_1, s_2, s_3 and $\mathbf{d}_i = (d^2_{\mathcal{S}}(s_1, s'_i), d^2_{\mathcal{S}}(s_2, s'_i), d^2_{\mathcal{S}}(s_3, s'_i))^{\mathrm{T}}$. Using the vector of distances $\hat{\mathbf{d}} = (\hat{d}^2_{\mathcal{S}}(s, s'_1), \hat{d}^2_{\mathcal{S}}(s, s'_2), \hat{d}^2_{\mathcal{S}}(s, s'_3))^{\mathrm{T}}$ and operating in the triangle t', we compute the approximate geodesic distance between s and s', $\hat{d}^2_{\mathcal{S}}(s, s') = \hat{d}^2_{\mathcal{S}}(\mathbf{u}'; \mathbf{X}', \hat{\mathbf{d}}, \mathbf{w} = \mathbf{u}')$, where $\mathbf{X}'$ are the canonical coordinates of s'_1, s'_2, s'_3.

Using the chain rule, it is straightforward to show that the derivatives of $\hat{d}^2_{\mathcal{S}}(s, s')$ with respect to $\mathbf{u}$ and $\mathbf{u}'$ are given by

$$\nabla_{\mathbf{u}'} \hat{d}^2_{\mathcal{S}}(s,s') = \nabla_{\mathbf{u}} \hat{d}^2_{\mathcal{S}}\big(\mathbf{u}'; \mathbf{X}', \hat{\mathbf{d}}, \mathbf{u}'\big) + \nabla_{\mathbf{w}} \hat{d}^2_{\mathcal{S}}\big(\mathbf{u}'; \mathbf{X}', \hat{\mathbf{d}}, \mathbf{u}'\big),$$

$$\nabla_{\mathbf{u}} \hat{d}^2_{\mathcal{S}}(s,s') = \big(\nabla_{\mathbf{u}} \hat{d}^2_1, \nabla_{\mathbf{u}} \hat{d}^2_2, \nabla_{\mathbf{u}} \hat{d}^2_3\big)^{\mathrm{T}} \nabla_{\mathbf{d}} \hat{d}^2_{\mathcal{S}}\big(\mathbf{u}'; \mathbf{X}', \hat{\mathbf{d}}, \mathbf{u}'\big), \tag{32}$$

where

$$\nabla_{\mathbf{u}} \hat{d}^2_i = \nabla_{\mathbf{u}} \hat{d}^2_{\mathcal{S}}(\mathbf{u}; \mathbf{X}, \mathbf{d}_i, \mathbf{u}) + \nabla_{\mathbf{w}} \hat{d}^2_{\mathcal{S}}(\mathbf{u}; \mathbf{X}, \mathbf{d}_i, \mathbf{u}).$$

EXTENSIONS OF PRIEST'S DOUBLE-PRECISION SUMMATION*

YVES NIEVERGELT†

Abstract. From single-precision summands sorted in nonincreasing exponents, extended-precision faithful additions with any radix yield an extended-precision sum, which, rounded back to single-precision, suffers from a roundoff smaller than one unit in the penultimate significant digit. Such provable accuracy holds only if the radix-based logarithm of the number of summands does not exceed the difference between the number of digits in extended and single precisions.

Key words. accuracy, extended precision, faithful floating-point addition, rounding

AMS subject classification. 65G50

DOI. 10.1137/040617005

1. Introduction.

This work resolves an issue raised by Demmel and Hida [6, p. 1247] about extensions of Priest's double-precision summation [26, pp. 62–63]. Priest's double-precision summation sorts single-precision floating-point summands in nonincreasing , then adds them with -precision floating-point arithmetic using radix. Demmel and Hida's extended-precision summation sorts single-precision binary floating-point summands in nonincreasing , then adds them with -precision floating-point arithmetic properly rounding to the even floating-point number.

Adding first the summands with the largest magnitudes (or exponents) allows for exact partial sums of summands that might have nearly equal magnitudes but opposite signs. The cap on the number of summands then prevents roundoffs from compounding to a size affecting more than the penultimate digit of the rounded sum.

The issue, affirmatively settled here, is whether Priest's and Demmel and Hida's results both generalize to -precision summations using radix.

2. Notation.

The set $\mathtt{F}(B, n, E_{\min}, E_{\max})$, abbreviated by $\mathtt{F}_n$, of with n significant digits with radix B consists of all numbers of the form

$$d = (-1)^s * B^{\mathtt{E}(d)} * d_0.d_1 \dots d_{n-1}, \tag{1}$$

which is if $d_0 > 0$. Here $s \in \{0, 1\}$ is the , $\mathtt{E}(d)$ is an integer in a range $E_{\min} \le \mathtt{E}(d) \le E_{\max}$, and $d_0, \dots, d_{n-1} \in \{0, \dots, B-1\}$ are the . If $0 < |d| < B^{E_{\min}}$, but despite a leading zero d has the form

$$d = (-1)^s * B^{E_{\min}} * 0.d_1 \dots d_{n-2}d_{n-1}, \tag{2}$$

then d is called a , or , or number. For every floating-point number $d \ne 0$, a (ulp) is defined by

$$\mathtt{ulp}_n(d) := B^{\mathtt{E}(d)} * 0.0 \dots 000 \dots 01 = B^{\mathtt{E}(d)+1-n}. \tag{3}$$

Let $\Omega_n := \max(\mathtt{F}_n) = B^{E_{\max}} \cdot (B - B^{1-n})$ denote the largest magnitude in $\mathtt{F}_n$, and define the set of floating-point numbers by $\overline{\mathtt{F}}_n := \mathtt{F}_n \cup \{-\infty, +\infty\}$.

A function denoted by $\mathtt{float}_n$ or by $\mathtt{round}_n : \mathbb{R} \to \overline{\mathtt{F}}_n$ approximates each real number $x \in \mathbb{R}$ by an extended floating-point number $\mathtt{round}_n(x) \in \overline{\mathtt{F}}_n$.

Each arithmetic operation $\circ \in \{+, -, *, /\}$ is a function $\circ : \mathbb{R}^2 \to \mathbb{R}$ (with exceptions for divisions by zero), which a floating-point computer approximates by a function $\circledcirc_n$ or $\circledcirc : \mathtt{F}_n^2 \to \overline{\mathtt{F}}_n$ (with corresponding exceptions for divisions by zero).

More generally, a floating-point computer can approximate a function $\mathrm{S} : \mathbb{R}^\ell \to \mathbb{R}$ or $\mathrm{S} : \mathtt{F}_n^\ell \to \mathbb{R}$ by a function $Ⓢ : \mathbb{R}^\ell \to \overline{\mathtt{F}}_n$ or $Ⓢ : \mathtt{F}_n^\ell \to \overline{\mathtt{F}}_n$. The difference $\mathrm{S} - Ⓢ$ is a or . Thus, if $\mathrm{S} : \mathbb{R} \to \mathbb{R}$ is the "identity" function, defined by $\mathrm{S}(r) := r$ for every $r \in \mathbb{R}$, then $Ⓢ : \mathbb{R} \to \overline{\mathtt{F}}_n$ can be $Ⓢ := \mathtt{round}_n$. Similarly, if $\mathrm{R} : \mathbb{R}_+ \to \mathbb{R}_+$ is the square root function, with $\mathrm{R}(r) := \sqrt{r}$ for every $r \in \mathbb{R}_+ = \{r \in \mathbb{R} : r \geq 0\}$, then Ⓡ is a floating-point square root.

Two extended floating-point numbers $p, q \in \overline{\mathtt{F}}_n$ are if and only if $\overline{\mathtt{F}}_n$ does not contain any element x such that $p < x < q$ or $q < x < p$. For each function $\mathrm{c} : \mathbb{R}^\ell \to \mathbb{R}$ and each point $\vec{\mathbf{r}} \in \mathtt{F}^\ell$ such that $\mathrm{c}(\vec{\mathbf{r}}) \in \mathbb{R}$, denote by $p, q \in \overline{\mathtt{F}}_n$ the two extended floating-point numbers with the $\mathrm{c}(\vec{\boldsymbol{r}})$ and

$$|p| \leq |\mathrm{c}(\vec{\mathbf{r}})| < |q|.$$

A floating-point approximation $ⓒ : \mathtt{F}_n^\ell \to \overline{\mathtt{F}}_n$ is if and only if

$$ⓒ(\vec{\mathbf{r}}) := \begin{cases} p & \text{if } p = \mathrm{c}(\vec{\mathbf{r}}), \text{ else} \\ \text{either } p \text{ or } q & \text{if } p \neq \mathrm{c}(\vec{\mathbf{r}}) \text{ and } |\mathrm{c}(\vec{\mathbf{r}})| < \Omega_n + \mathtt{ulp}(\Omega_n), \text{ else} \\ q & \text{if } |\mathrm{c}(\vec{\mathbf{r}})| \geq \Omega_n + \mathtt{ulp}(\Omega_n). \end{cases}$$

For $p \neq \mathrm{c}(\vec{\mathbf{r}})$, a faithful approximation $-\infty$ if $ⓒ(\vec{\mathbf{r}}) := \min\{p, q\}$, $+\infty$ if $ⓒ(\vec{\mathbf{r}}) := \max\{p, q\}$, ( ) if $ⓒ(\vec{\mathbf{r}}) := p$, or if $ⓒ(\vec{\mathbf{r}}) := q$. A faithful approximation if and only if

$$ⓒ(\vec{\mathbf{r}}) := \begin{cases} p & \text{if } |p| \leq |\mathrm{c}(\vec{\mathbf{r}})| < (|p| + |q|)/2 < +\infty, \text{ else} \\ \text{either } p \text{ or } q & \text{if } (p+q)/2 = \mathrm{c}(\vec{\mathbf{r}}), \text{ else} \\ q & \text{if } (|p| + |q|)/2 < |\mathrm{c}(\vec{\mathbf{r}})| < |q|. \end{cases}$$

For instance, ⓒ if and only if it is properly rounding and rounds $(p+q)/2 = \mathrm{c}(\vec{\mathbf{r}})$ to whichever value p or q has an even last digit. Thus,

$$|\mathrm{c}(\vec{\mathbf{r}}) - ⓒ(\vec{\mathbf{r}})| \leq \begin{cases} \frac{1}{2}\mathtt{ulp}_n\left[ⓒ(\vec{\mathbf{r}})\right] & \text{for properly rounding arithmetic, or} \\ \mathtt{ulp}_n\left[ⓒ(\vec{\mathbf{r}})\right] & \text{for faithful arithmetic for } ⓒ(\vec{\mathbf{r}}) \neq \pm\infty. \end{cases}$$

If $|\mathrm{c}(\vec{\mathbf{r}})| < B^{E_{\min}}$, then ⓒ may either represent $\mathrm{c}(\vec{\mathbf{r}})$ by a subnormal number $ⓒ(\vec{\mathbf{r}})$ as in (2), or may round $\mathrm{c}(\vec{\mathbf{r}})$ to either 0 or $\pm B^{E_{\min}}$, which can be accompanied by an exception flag called an . In particular, the floating-point number, $\iota_n := \min\{d \in \mathtt{F}_n : d > 0\}$, is $B^{E_{\min}}$ in the first case, or $B^{E_{\min}+1-m}$ in the second case. Therefore, if $\mathrm{c}(\vec{\mathbf{r}}) = 0$, then the foregoing definitions of faithfulness apply, with $p = 0$ and $q = \iota_n$. If $|\mathrm{c}(\vec{\mathbf{r}})| \geq \Omega_n + \mathtt{ulp}_n(\Omega_n)$, then ⓒ represents $\mathrm{c}(\vec{\mathbf{r}})$ by $\pm\infty$, which can be accompanied by an exception flag called an . The result of $0 \oslash 0$ can be yet another exception flag, $\mathtt{NaN} \notin \overline{\mathtt{F}}_n$, called . If $s = 0$ but $r \neq 0$, then $r \oslash 0$ can be either NaN, or $+\infty$ for $r > 0$, or $-\infty$ for $r < 0$.

A ($\mathtt{uls}$) is defined by

$$\mathtt{uls}(d) := B^{\mathtt{E}(d)} * 0.0\ldots010\ldots00 = B^{\mathtt{E}(d)-\ell} \tag{4}$$

if $d_\ell > 0$ but $d_i = 0$ for each $i > \ell$. The number of [illegible] of d is

$$\mathtt{Z}(d) := \mathtt{E}[\mathtt{uls}(d)] - \mathtt{E}[\mathtt{ulp}(d)],$$

while the [illegible] of d is then

$$\mathtt{L}(d) := \ell.$$

A "k-digit multiple of $\mathtt{ulp}_i(p)$" will mean a number of the form $j \cdot \mathtt{ulp}_i(p)$ with an integer $j \in \mathbb{Z}$ with [illegible] k nonzero digits, so that $0 \le |j| < B^k$.

Finally, if $m < n$, then the exponent ranges are assumed so that $\mathtt{F}_m \subset \mathtt{F}_n$.

[illegible] 1. Some faithful floating-point operations $\circledcirc$ do [illegible] factor as the composition of a real arithmetic operation $\circ$ followed by a rounding [illegible] $\mathtt{round}$. Indeed, $r \circledcirc s \ne \mathtt{round}(r \circ s)$ if $r \circledcirc s$ depends on factors other than r, s, and $r \circ s$.

[illegible] 1. Random rounding [23] is faithful yet pseudorandom.

The phenomenon in Remark 1 occurs for [illegible] floating-point addition with at least one [illegible] digit, which is faithful [24, eqn. (8), p. 403], [29, sect. 1.8, pp. 22–20].

[illegible] 2. The IBM System/360/370/390 and the space shuttle's IBM AP-101 [illegible] single-precision floating-point additions with six hexadecimal digits using one hexadecimal [illegible] digit [18, pp. 45–46], [19, p. 160], [21, pp. 18-8–18-9, pp. A-5–A-6], [30, Chap. 4]. With $B = 16$ and $n = 6$, let $\mathrm{A}_{\mathrm{hex}} := 10_{\mathrm{ten}}, \ldots, \mathrm{F}_{\mathrm{hex}} := 15_{\mathrm{ten}}$.

If $u = 123456$ and $v = 0.\mathrm{F8}$, then aligning u and v with only one guard digit chops the last digit of v and gives $123456 + 0.\mathrm{F}$, which is chopped to $u \oplus v = 123456$.

If $r = 123457$ and $s = -0.08$, then aligning r and s with only one guard digit chops the last digit of s and gives $123457 - 0.0$, which is chopped to $r \oplus s = 123457$.

Thus $u + v = 123456.\mathrm{F8} = r + s$ but $u \oplus v = 123456 \ne 123457 = r \oplus s$. Therefore, there is no function $\mathtt{round} : \mathbb{R} \to \overline{\mathtt{F}}_n$ such that $z \oplus w = \mathtt{round}(z + w)$ for all $z, w \in \mathtt{F}_n$.

[illegible] 3. For contrast with Example 4, the IBM 7090 & 7094 store binary floating-point numbers in the form $d = \pm 2^{\mathtt{E}(d)} * .d_1 \ldots d_n$ with $n = 27$, and [illegible] additions using 27 [illegible] digits. For all $s, u \in \mathtt{F}_{27}$ such that $\mathtt{E}(s) \ge \mathtt{E}(u)$, they compute $v', w' \in \mathtt{F}_{27}$ so that $s + u = v' + w' +$ lower-order bits, with $\mathrm{sign}(w') = \mathrm{sign}(v')$ and $\mathtt{E}(w') = \mathtt{E}(v') - 27$, and then set $s \oplus u := v'$ [16, pp. 32–33], [17, pp. 26–27]. The double word (v', w')—not in $\overline{\mathtt{F}}_n$ but accessible to the programmer [16, p. 43], [17, p. 33]—is yet another type of floating-point sum, described by Brown [1], [26, p. 28].

The phenomenon in Remark 1 also occurs with Dekker's and Priest's "properly truncating" addition [4, def. (3.5), p. 227], [25, p. 134], [26, p. 17], which is faithful but may have been confused with "correctly chopping" addition [22], [25, p. 134].

Definition 1. [illegible] properly truncating [illegible] $r, s \in \mathtt{F}_n$ [illegible] $|r| \ge |s|$ [illegible] $p, q \in \mathtt{F}_n$ [illegible] $p < r + s < q$ [illegible]

$$r \oplus s = \begin{cases} p & \text{if } s > 0, \\ q & \text{if } s < 0. \end{cases}$$

[illegible] 4. The IBM 704 stores binary floating-point numbers in the form $d = \pm 2^{\mathtt{E}(d)} * .d_1 \ldots d_n$ with $n = 27$ [15, pp. 8–9, 21–22]. To add $s, u \in \mathtt{F}_n$ ranked so that $\mathtt{E}(s) \ge \mathtt{E}(u)$, it aligns the digits of u into two floating-point numbers $v, w \in \mathtt{F}_n$ with $\mathrm{sign}(v) = \mathrm{sign}(u) = \mathrm{sign}(w)$, $\mathtt{E}(v) = \mathtt{E}(s)$, and $\mathtt{E}(w) = \mathtt{E}(s) - 27$, so that $u = v + w +$ chopped lower digits of u. The adder computes $v' := s + v$, and adds (or subtracts) (signed) bits from w until v' is normalized, so that $s + v + w = v' + w' +$ dropped bit in case of a carry, but $\mathrm{sign}(w') = \mathrm{sign}(u)$ regardless of $\mathrm{sign}(v')$, in contrast to Example 3.

If $s = +2^{-1} * (1 - 2^{-27})$ and $u = 2^{-29} > 0$, then $v = +2^0 * .0$ and $w = +2^{-28} * .01$. Hence $v' = s + v = s$ and $w' = w$, whence $s \oplus u = s$ is rounded with $u > 0$.

If $b = +2^{-1} = +2^0 * .1$ and $d = -2^{-29}$, then $v = +2^0 * .0$ and $w = -2^{-27} * .01$. Hence $v' = b + v = b$ and $w' = w$, whence $b \oplus d = b$ is rounded with $d < 0$.

Thus $s + u = b + d$ but $s \oplus u = s \neq b = b \oplus d$, and both are

2. If $\textcircled{c}_1$ and $\textcircled{c}_2$ are two faithful approximations of a function c, and if $\textcircled{c}_3(\vec{\mathbf{r}}) \in \{\textcircled{c}_1(\vec{\mathbf{r}}), \textcircled{c}_2(\vec{\mathbf{r}})\}$ for every $\vec{\mathbf{r}}$, then $\textcircled{c}_3$ is also a faithful approximation of c.

Remark 2 will simplify the proof of Corollary 3 below. In contrast, the assumption that $\textcircled{c}(\vec{\mathbf{r}}) = \mathtt{round}\,[\mathrm{c}(\vec{\mathbf{r}})]$ would not substantially simplify any of the proofs. Another reason for including the full generality of faithful arithmetic is to allow for all currently available faithful arithmetic, for instance, toggling between various rounding modes in interval arithmetic [28], [31], [32]. Yet another reason is to demonstrate by comparison and contrast the advantages and disadvantages of various faithful arithmetic, be they historical, available, or merely contemplated for future design.

In what follows, a function $\mathtt{round}_m : \mathtt{F}_n \to \overline{\mathtt{F}}_m$ will serve only to round an extended-precision sum $s_N \in \mathtt{F}_n$ to a single-precision value $\mathtt{round}_m(s_N) \in \mathtt{F}_m$ with $m < n$.

3. Analysis. Priest's double-precision summation adds N single-precision summands $x_1, \ldots, x_N \in \mathtt{F}_m$ sorted by nonincreasing using at least -precision faithful additions $\oplus_n$ in $\mathtt{F}_n$, with $n \geq 2m$. In contrast, following Demmel and Hida, Algorithm 1 adds N single-precision summands $r_1, \ldots, r_N \in \mathtt{F}_m$ sorted by nonincreasing $\mathtt{E}(r_1) \geq \cdots \geq \mathtt{E}(r_N)$ using -precision faithful additions $\oplus_n$ in $\mathtt{F}_n$, with any $n > m$. Following Priest, however, Algorithm 1 does not yet round the final sum to m digits.

Algorithm 1 (exponent-sorted extended-precision summation).
Data: single-precision numbers $r_1, \ldots, r_N \in \mathtt{F}_m$ such that
$\mathtt{E}(r_1) \geq \cdots \geq \mathtt{E}(r_N)$,
$2 \leq m < n$,
$N \leq 2 + B^{n-m}(1 - B^{-1})/(1 - B^{-m})$.
Result: an extended-precision sum $s_N \in \mathtt{F}_n$ approximating $s := r_1 + \cdots + r_N$.
Start
Let $s_1 := r_1$;
for each $k \in \{2, \ldots, N\}$, add with extended-precision
$s_k := s_{k-1} \oplus_n r_k \in \mathtt{F}_n$;
next k;
return s_N.
Stop.

The analysis examines the differences between the sum $s := \sum_{k=1}^{N} r_k \in \mathbb{R}$, the extended-precision sum $s_N \in \mathtt{F}_n$, and the single-precision value $\mathtt{round}_m(s_N) \in \mathtt{F}_m$.

In their analysis of Algorithm 1, Demmel and Hida compare the last bit of the current summand r_k and the last bit of the current partial sum s_{k-1}. In contrast, Priest compares the last bit of the current summand r_k and the last bit of the partial sum $s_k := r_k + s_{k-1}$. Priest's method is also the basis of the present analysis, which reveals that, starting from the first occurrence of a nonzero roundoff, the exponents of all the subsequent partial sums remain within one unit of one another (Lemmas 6, 7, and 8). The crux of the analysis weakens Priest's condition $\mathtt{ulp}_m(r_i) > \mathtt{ulp}_n(r_i \oplus_n s_{i-1})$ under which the first partial sums are exact [26, line 5, p. 63] and, instead, characterizes the conditions for $s_k = r_k \oplus_n s_{k-1}$ to equal $r_k + s_{k-1}$, as done in Theorem 2 and Corollary 3.

THEOREM 2. [illegible] $m < n$ [illegible] $\mathtt{F}_m \subset \mathtt{F}_n$ [illegible] $p \in \mathtt{F}_m$ [illegible] $q \in \mathtt{F}_n$ [illegible] q [illegible] $\mathtt{uls}(p)$ [illegible] $p \oplus_n q = p + q$ [illegible]

- $\mathtt{uls}(p) \geq \mathtt{ulp}_n(p \oplus_n q)$ [illegible]
- $\mathtt{uls}(p) = B^{-1}\mathtt{ulp}_n(p \oplus_n q)$ [illegible] $\mathtt{uls}(p) = \mathtt{ulp}_n(q)$ [illegible] $p_{\mathtt{L}(p)} + q_{n-1} = B$

[illegible]. Either $\mathtt{ulp}_n(q) < \mathtt{uls}(p)$, or $\mathtt{ulp}_n(q) = \mathtt{uls}(p)$, or $\mathtt{uls}(p) < \mathtt{ulp}_n(q)$.

(2.1) If $\mathtt{ulp}_n(q) < \mathtt{uls}(p)$, then p is an m-digit multiple of $\mathtt{uls}(p)$ while q is an $(n-1)$-digit multiple of $\mathtt{uls}(p)$. Hence $p+q$ is an n-digit multiple of $\mathtt{uls}(p)$, whence $p \oplus_n q = p + q \in \mathtt{F}_n$ by faithfulness.

(2.2) If $\mathtt{uls}(p) = \mathtt{ulp}_n(q)$, then two cases can arise.

(2.2.1) If $\operatorname{sign}(p) \neq \operatorname{sign}(q)$, then $|p|$ and $|q|$ are n-digit multiples of $\mathtt{uls}(p)$, and hence so is their difference, whence $p \oplus_n q = \pm(|p| - |q|) \in \mathtt{F}_n$, so that again $p \oplus_n q = \pm(|p| - |q|) = p + q \in \mathtt{F}_n$ by faithfulness.

(2.2.2) Alternatively, if $\operatorname{sign}(p) = \operatorname{sign}(q)$, then two subcases can occur.

(2.2.2.1) If $|p| + |q|$ is also an n-digit multiple of $\mathtt{uls}(p) = \mathtt{ulp}_n(q)$, then $|p+q| = |p| + |q| \in \mathtt{F}_n$, whence $p \oplus_n q = p + q \in \mathtt{F}_n$ by faithfulness.

(2.2.2.2) In contrast, if $|p| + |q|$ is [illegible] an n-digit multiple of $\mathtt{uls}(p)$, then $|p| + |q|$ is an $(n+1)$-digit multiple of $\mathtt{uls}(p) = \mathtt{ulp}_n(q)$, whose last digit is $p_{\mathtt{L}(p)} + q_{n-1}$, so that $p+q \neq p \oplus_n q$ if and only if the last digit of $p + q$ differs from 0, in other terms, $p_{\mathtt{L}(p)} + q_{n-1} \neq B$, but then rounding to the most significant n digits gives $\mathtt{ulp}_n(p \oplus_n q) > \mathtt{uls}(p)$.

(2.3) If $\mathtt{uls}(p) < \mathtt{ulp}_n(q)$, then $|p| < |q|/B \leq |q|/2$, and $p+q$ is a multiple of $\mathtt{uls}(p)$ whose last nonzero significant digit is either $0 + p_{\mathtt{L}(p)} = p_{\mathtt{L}(p)}$ or $B - p_{\mathtt{L}(p)}$, so that $\mathtt{uls}(p+q) = \mathtt{uls}(p)$; two cases can arise.

(2.3.1) If $\operatorname{sign}(p) = \operatorname{sign}(q)$, then $|p+q| = |p|+|q| \geq |q| \in \mathtt{F}_n$, whence $|p \oplus_n q| \geq |q|$ by faithfulness, and hence $\mathtt{uls}(p) < \mathtt{ulp}_n(q) \leq \mathtt{ulp}_n(p \oplus_n q)$, but then $p \oplus_n q \neq p + q$ because $\mathtt{uls}(p+q) = \mathtt{uls}(p)$ by item (2.3).

(2.3.2) Alternatively, if $\operatorname{sign}(p) \neq \operatorname{sign}(q)$, then $|q| \geq |p+q| = |q| - |p| > |q|/2 > |p|$, and again two subcases can arise.

(2.3.2.1) If $p + q$ is an n-digit multiple of $\mathtt{uls}(p)$, then $p \oplus_n q = p + q$ by faithfulness, but $\mathtt{uls}(p) = \mathtt{uls}(p+q) = \mathtt{ulp}_n(q \oplus_n p)$ by item (2.3).

(2.3.2.2) In contrast, if $p + q$ has more than n significant digits, then after rounding to n digits, $p + q \neq p \oplus_n q$, but then $\mathtt{uls}(p) < \mathtt{ulp}_n(q \oplus_n p)$. □

Corollary 3 extends Theorem 2 where q is an integer multiple of $\mathtt{ulp}_m(p)$.

COROLLARY 3. [illegible] $m < n$ [illegible] $\mathtt{F}_m \subset \mathtt{F}_n$ [illegible] $p \in \mathtt{F}_m$ [illegible] $q \in \mathtt{F}_n$ [illegible] q [illegible] $\mathtt{ulp}_m(p)$ [illegible] $t := p \oplus_n q \neq p + q$ [illegible]

$$|p| \leq B^{\mathtt{E}(t)+(m-n)-1}(B - B^{1-m}) < B^{\mathtt{E}(t)+m-n}.$$

[illegible]. If q is an integral multiple of $\mathtt{uls}(p)$, then Corollary 3 is the contraposition of Theorem 2, with

$$\begin{aligned} |p| &\leq B^{\mathtt{E}(p)}(B - B^{1-m}) = B^{\mathtt{E}(p)+1-m}(B^m - 1) = \mathtt{ulp}_m(p)(B^m - 1) \\ &\leq B^{-1}\mathtt{ulp}_n(t)(B^m - 1) = B^{-1}B^{\mathtt{E}(t)+1-n}(B^m - 1) < B^{\mathtt{E}(t)+m-n} \end{aligned}$$

following from $\mathtt{ulp}_m(p) \leq \mathtt{uls}(p) < \mathtt{ulp}_n(t)$ and (1), (3), (4).

If q is an integral multiple of $\mathtt{ulp}_m(p)$ but [illegible] an integral multiple of $\mathtt{uls}(p)$, then $\mathtt{ulp}_m(p) \leq \mathtt{uls}(q) < \mathtt{uls}(p)$, whence p and q are n-digit multiples of $\mathtt{uls}(q)$. If p and q have opposite signs, then $p \oplus_n q = p + q \in \mathtt{F}_n$ by integer arithmetic and faithfulness.

If p and q have the same sign, then let $k := \mathtt{E}[\mathtt{uls}(p)] - \mathtt{E}[\mathtt{uls}(q)] \le \mathtt{Z}(p)$, so that

$$\begin{array}{rlllll} p &= (-1)^s \cdot B^{\mathtt{E}(p)} \cdot p_0.p_1 \ldots p_{\mathtt{L}(p)} & 0 & \ldots & 0, \\ q &= (-1)^s \cdot B^{\mathtt{E}(q)} \cdot q_0.q_1 \ldots q_{\mathtt{L}(q)-k} & q_{\mathtt{L}(q)-(k-1)} & \ldots & q_{\mathtt{L}(q)}. \end{array}$$

Transferring the k least significant digits of q to p (for the purpose of this proof, not in the computations) yields floating-point numbers

$$\begin{array}{rlllll} p' &:= (-1)^s \cdot B^{\mathtt{E}(p)} \cdot p_0.p_1 \ldots p_{\mathtt{L}(p)} & q_{\mathtt{L}(q)-(k-1)} & \ldots & q_{\mathtt{L}(q)}, \\ q' &:= (-1)^s \cdot B^{\mathtt{E}(q)} \cdot q_0.q_1 \ldots q_{\mathtt{L}(p)} & 0 & \ldots & 0. \end{array}$$

In particular, $p+q = p'+q'$, with $q' \in \mathtt{F}_n$ and still $p' \in \mathtt{F}_m$, because p was an m-digit multiple of $\mathtt{ulp}_m(p)$ and hence of $\mathtt{uls}(q)$. Here $t' := p' \oplus_n q'$ need not equal $t = p \oplus_n q$, but t is a faithful floating-point sum of p' and q' by Remarks 1 and 2. Also, q' is an integral multiple of $\mathtt{uls}(p')$. Consequently, if $p+q \notin \mathtt{F}_n$, then $p'+q' \notin \mathtt{F}_n$, whence $t \ne p'+q'$, and hence $\mathtt{E}(p) = \mathtt{E}(p') < \mathtt{E}(t) + m - n$ by the first part of the proof. ∎

Lemmas 4 and 5 establish inequalities used repeatedly in Lemmas 6, 7, and 8.

LEMMA 4. [illegible] $\mathtt{E}(r_i) \le \mathtt{E}(s_i) + (m-n) - 1$ [illegible]

$$\mathtt{E}(r_{i+j}) \le \mathtt{E}(r_i) \le \mathtt{E}(s_i) + (m-n) - 1, \tag{5}$$

$$|r_{i+j}| \le B^{\mathtt{E}(s_i)+(m-n)-1}(B - B^{1-m}) < B^{\mathtt{E}(s_i)+(m-n)} \tag{6}$$

[illegible] $j \ge 0$ [illegible] $\mathtt{E}(r_i) \le \mathtt{E}(s_i) + (m-n) - 1$ [illegible] $\mathtt{E}(s_{i+j}) \ne \mathtt{E}(s_i)$ [illegible] $2 \le i < N$ [illegible]. If $\mathtt{E}(r_i) \le \mathtt{E}(s_i) + (m-n) - 1$, then $i \ge 2$, because $r_1 = s_1$ for $i = 1$.

If $j \ge 0$ and $\mathtt{E}(s_{i+j}) \ne \mathtt{E}(s_i)$, then $j > 0$, whence $i < N$.

Inequalities (5) and (6) follow from the ordering $\mathtt{E}(r_{i+j}) \le \mathtt{E}(r_i)$. ∎

LEMMA 5. [illegible] $B \ge 2$ [illegible] $n > m \ge 1$ [illegible]

$$2 + B^{n-m} \cdot \frac{1 - B^{-1}}{1 - B^{-m}} \le 1 + B^{1+n-m} \cdot (B-1). \tag{7}$$

[illegible] $B \ge 2$ [illegible] $n > m \ge 2$ [illegible] $0 \le k \le N-2$ [illegible]

$$N \le 1 + B^{1+n-m} \cdot (B-1),$$

[illegible] $1 + k \cdot B^{(m-n)-1} \in \mathtt{F}_n$ [illegible]

$$1 + k \cdot B^{(m-n)-1} \le B - B^{1-n}. \tag{8}$$

[illegible] $B \ge 2$ $n > m \ge 2$ [illegible] $0 \le k \le N-2$ [illegible]

$$N \le 2 + B^{n-m} \cdot \frac{1 - B^{-1}}{1 - B^{-m}}, \tag{9}$$

[illegible] $1 - k \cdot B^{-n} \cdot (B^m - 1) \in \mathtt{F}_n$ [illegible]

$$1 - k \cdot B^{-n} \cdot (B^m - 1) \ge B^{-1}. \tag{10}$$

[illegible] (9) [illegible] $0 \le k \le N-3$ [illegible] $1 + k \cdot B^{m-n} \in \mathtt{F}_n$ [illegible]

$$1 + k \cdot B^{m-n} \le B - B^{1-n}. \tag{11}$$

If $B \geq 2$ and $n > m \geq 1$, then $B - B^{1-m} \geq 2 - B^0 = 1$ and also $B^{n-m} \cdot (1 - B^{-1}) = B^{(n-m)-1} \cdot (B-1) \geq B - 1 \geq 1 \geq 1 - B^{-m}$, whence

$$\begin{aligned} B^{1+n-m} \cdot (B-1) \cdot (1 - B^{-m}) &= B^{n-m} \cdot (B-1) \cdot (B - B^{1-m}) \\ &\geq B^{n-m} \cdot \left[(1 - B^{-1}) \cdot B\right] \cdot 1 \\ &\geq B^{n-m} \cdot \left[(1 - B^{-1}) \cdot 2\right] \\ &\geq B^{n-m} \cdot (1 - B^{-1}) + (1 - B^{-m}). \end{aligned}$$

Dividing by $1 - B^{-m} > 0$ and then adding 1 yields inequality (7).

If $m \geq 2$, then $B^{2-m} \leq 1$ and $B^{(m-1)-n}$ is a multiple of $\mathtt{ulp}_n(1)$. If also $k \leq N - 2 \leq B^{1+n-m} \cdot (B-1) - 1$, then $k \leq B^{1+n-m} \cdot (B-1) - B^{2-m}$, whence

$$\begin{aligned} 1 + k \cdot B^{(m-n)-1} &\leq 1 + \left[B^{1+n-m} \cdot (B-1) - B^{2-m}\right] \cdot B^{(m-n)-1} \\ &= 1 + (B-1) - B^{2-m} \cdot B^{(m-n)-1} \\ &= B - B^{1-n}, \end{aligned}$$

proving (8). Moreover, if $k \leq N - 2 \leq B^{n-m}(1 - B^{-1})/(1 - B^{-m})$, then (10) holds:

$$1 - k \cdot B^{-n} \cdot (B^m - 1) \geq 1 - \left(B^{n-m} \cdot \frac{1 - B^{-1}}{1 - B^{-m}}\right) \cdot B^{-n} \cdot (B^m - 1) = B^{-1}.$$

Furthermore, if $k \leq N - 3 \leq B^{n-m} \cdot (1 - B^{-1})/(1 - B^{-m}) - 1$, then (11) holds:

$$\begin{aligned} 1 + k \cdot B^{m-n} &\leq 1 + \left(B^{n-m} \cdot \frac{1 - B^{-1}}{1 - B^{-m}} - 1\right) \cdot B^{m-n} \\ &= \frac{(1 - B^{-m}) + (1 - B^{-1}) - (B^{m-n} - B^{-n})}{1 - B^{-m}} \\ &= \frac{2 + (B^{-n} - B^{-m}) - (B^{-1} + B^{m-n})}{1 - B^{-m}} \\ &\leq \frac{B + B^{(1-m)-n} - (B^{1-m} + B^{1-n})}{1 - B^{-m}} \\ &= B - B^{1-n}, \end{aligned}$$

because $B^{-n} - B^{-m} < 0 < B^{(1-m)-n}$ and $B^{1-m} < B^{-1}$ with $B^{1-n} < B^{m-n}$. □

Lemma 6 shows that if the summand r_i is sufficiently smaller than the ith partial sum s_i in magnitude, then the exponents of all of the subsequent partial sums can drop by at most one unit below—in which case they never again exceed—that of s_i.

LEMMA 6. If $\mathtt{E}(r_i) \leq \mathtt{E}(s_i) + (m-n) - 1$, $B \geq 2$, and $2 \leq m < n$, and

$$N \leq 2 + B^{n-m}(1 - B^{-1})/(1 - B^{-m}), \tag{12}$$

then $\mathtt{E}(s_i) - 1 \leq \mathtt{E}(s_{i+j})$ for $0 \leq j \leq N - i$. Moreover, if $\ell > i$ and $\mathtt{E}(s_\ell) = \mathtt{E}(s_i) - 1$, then $\mathtt{E}(s_i) - 1 \leq \mathtt{E}(s_{\ell+j}) \leq \mathtt{E}(s_i)$ for $0 \leq j \leq N - \ell$.

PROOF. Assume (13) for some i and j with $0 \leq j \leq N - i \leq N - 2$:

$$|s_{i+j}| \geq B^{\mathtt{E}(s_i)-1}\left\{B - j\left[B^{1+(m-n)} - B^{1-n}\right]\right\}. \tag{13}$$

For instance, (13) holds for $j = 0$ and every $i \leq N$. If $i + j = N$, then $j = N - i$ reaches its upper bound, which does not require any further induction, because $i + (j+1) > N$. Hence assume that $i + j < N$, whence $j + 1 \leq N - i \leq N - 2$.

Combining (13) with (6) from Lemma 4 gives

$$|s_{i+j}| - |r_{i+j+1}| \geq B^{\mathtt{E}(s_i)-1} \left\{ B - (j+1) \left[B^{1+(m-n)} - B^{1-n} \right] \right\}.$$

The reverse triangle inequality, inequality (10) from Lemma 5, and faithfulness yield

$$|s_{i+j+1}| \geq B^{\mathtt{E}(s_i)-1} \left\{ B - (j+1) \left[B^{1+(m-n)} - B^{1-n} \right] \right\}.$$

Thus (13) holds for $j+1$ instead of j. Consequently, $\mathtt{E}(s_{i+j}) \geq \mathtt{E}(s_i) - 1$ for every j such that $0 \leq j \leq N - i$.

Moreover, if there exists $\ell > i$ such that equality holds, $\mathtt{E}(s_\ell) = \mathtt{E}(s_i) - 1$, then $|s_\ell| \leq B^{\mathtt{E}(s_i)-1} \cdot (B - B^{1-n})$. However, $\ell > i \geq 2$ by Lemma 4, whence $\ell \geq 3$, so that there remain at most $N - 3$ summands $r_{\ell+j}$ for $1 \leq j \leq N - \ell \leq N - 3$, with $|r_{\ell+1+j}| \leq B^{\mathtt{E}(s_i)+(m-n)-1} \cdot (B - B^{1-m}) < B^{\mathtt{E}(s_i)} \cdot B^{m-n}$, by hypothesis on $\mathtt{E}(r_i)$.

Hence, assume (14) for some index j with $0 \leq j \leq N - \ell \leq N - 3$:

$$|s_{\ell+j}| \leq B^{\mathtt{E}(s_i)} \cdot \left(1 + j \cdot B^{m-n}\right). \tag{14}$$

For instance, (14) holds for $j = 0$. If also $j + 1 \leq N - \ell$, then

$$|s_{\ell+j}| + |r_{\ell+j+1}| \leq B^{\mathtt{E}(s_i)} \cdot \left(1 + j \cdot B^{m-n}\right) + B^{\mathtt{E}(s_i)} \cdot B^{m-n},$$

by hypothesis on $\mathtt{E}(r_i)$. Consequently, the triangle inequality gives

$$|s_{\ell+j+1}| \leq B^{\mathtt{E}(s_i)} \cdot \left[1 + (j+1) \cdot B^{m-n}\right],$$

by faithfulness and (11) in Lemma 5. Thus (14) also holds for $j + 1$. Therefore, $\mathtt{E}(s_i) - 1 \leq \mathtt{E}(s_{\ell+j}) \leq \mathtt{E}(s_i)$ for every j with $0 \leq j \leq N - \ell$. □

Lemma 7 shows that if the summand r_i is sufficiently smaller than the i-th partial sum s_i in magnitude, then the exponents of all of the following partial sums can jump by at most one unit above—in which case they never drop back below—that of s_i.

Lemma 7. If $\mathtt{E}(r_i) \leq \mathtt{E}(s_i) + (m-n) - 1$, $B \geq 2$, $2 \leq m < n$, and

$$N \leq 1 + B^{1+n-m}(B-1),$$

then $\mathtt{E}(s_{i+j}) \leq \mathtt{E}(s_i) + 1$ for every j with $0 \leq j \leq N - i$.

If $N \leq 2 + B^{n-m}(1 - B^{-1})/(1 - B^{-m})$, then for every $\ell > i$ with $\mathtt{E}(s_\ell) = \mathtt{E}(s_i) + 1$ one has $\mathtt{E}(s_i) \leq \mathtt{E}(s_{\ell+j}) \leq \mathtt{E}(s_i) + 1$ for every j with $0 \leq j \leq N - \ell$.

Proof. Assume (15) for some i and j with $0 \leq j \leq N - i \leq N - 2$:

$$|s_{i+j}| \leq B^{\mathtt{E}(s_i)+1} \left[1 + jB^{(m-n)-1}\right]. \tag{15}$$

For instance, (15) holds for $j = 0$ and every $i \leq N$. If $i+j = N$, then $j = N-i$ reaches its upper bound, which does not require any further induction, because $i+(j+1) > N$. Hence assume that $i + j < N$, whence $j + 1 \leq N - i \leq N - 2$.

Combining (15) with (6) from Lemma 4 gives

$$|s_{i+j}| + |r_{i+j+1}| \leq B^{\mathtt{E}(s_i)+1} \left[1 + (j+1)B^{(m-n)-1}\right].$$

The triangle inequality, inequality (8) from Lemma 5, and faithfulness then give

$$|s_{i+j+1}| \leq B^{\mathtt{E}(s_i)+1} \left[1 + (j+1)B^{(m-n)-1}\right].$$

Thus (15) also holds for $j+1$, whence $\mathtt{E}(s_{i+j}) \le \mathtt{E}(s_i)+1$ for every $j \ge 0$.

Moreover, if $N \le 2 + B^{n-m}(1-B^{-1})/(1-B^{-m})$ and if there exists $\ell > i$ such that equality holds, $\mathtt{E}(s_\ell) = \mathtt{E}(s_i)+1$, then $\mathtt{E}(r_\ell) \le \mathtt{E}(r_i) \le \mathtt{E}(s_i) + (m-n) - 1 < \mathtt{E}(s_\ell) + (m-n) - 1$, whence Lemma 6 holds for ℓ instead of i, which states that $\mathtt{E}(s_i) = \mathtt{E}(s_\ell) - 1 \le \mathtt{E}(s_{\ell+j})$ for every j with $0 \le j \le N-\ell$. □

Hence, Lemma 8 shows that after the first occurrence of a nonzero roundoff, where $s_k \ne s_{k-1} + r_k$, the exponents of all of the subsequent partial sums differ from one another by at most one unit: $|\mathtt{E}(s_{k+i}) - \mathtt{E}(s_{k+j})| \le 1$ for all $i, j \ge 0$.

LEMMA 8. [illegible] $s_i = s_{i-1} + r_i$ [illegible] $i < k$ [illegible] $s_k \ne s_{k-1} + r_k$ [illegible] $N \le 2 + B^{n-m}(1-B^{-1})/(1-B^{-m})$ [illegible] $B \ge 2$ [illegible] $2 \le m < n$ [illegible]

- $\mathtt{E}(s_k) - 1 \le \mathtt{E}(s_{k+j}) \le \mathtt{E}(s_k)$ [illegible] j [illegible] $0 \le j \le N-k$ [illegible]
- $\mathtt{E}(s_k) \le \mathtt{E}(s_{k+j}) \le \mathtt{E}(s_k)+1$ [illegible] j [illegible] $0 \le j \le N-k$

[illegible]. Thanks to the ordering of the summands, s_{k-1} is an integral multiple of $\mathtt{ulp}_m(r_k)$. From $s_k = s_{k-1} \oplus_n r_k \ne s_{k-1} + r_k$, Corollary 3 yields

$$|r_k| \le B^{\mathtt{E}(s_k)+(m-n)-1}(B - B^{1-m}).$$

Hence Lemmas 5, 6, and 7 show that $\mathtt{E}(s_k) - 1 \le \mathtt{E}(s_{k+j}) \le \mathtt{E}(s_k)+1$ for every $j \ge 0$.

Consequently, if there does [illegible] exist any $\ell > k$ such that $\mathtt{E}(s_\ell) = \mathtt{E}(s_k)+1$, then $\mathtt{E}(s_k) - 1 \le \mathtt{E}(s_{k+j}) \le \mathtt{E}(s_k)$ for every $j \ge 0$.

In contrast, if there exists $\ell > k$ such that $\mathtt{E}(s_\ell) = \mathtt{E}(s_k)+1$, so that $\mathtt{E}(s_\ell) > \mathtt{E}(s_k)$, then the contraposition of Lemma 6 with k instead of i shows that $\mathtt{E}(s_\ell) \ne \mathtt{E}(s_k) - 1$, whence $\mathtt{E}(s_\ell) > \mathtt{E}(s_k) - 1$ and hence $\mathtt{E}(s_\ell) \ge \mathtt{E}(s_k)$ for every $\ell \ge k$, or, equivalently, $\mathtt{E}(s_k) \le \mathtt{E}(s_{k+j})$ for every $j \ge 0$, whence Lemma 7 shows that $\mathtt{E}(s_k) \le \mathtt{E}(s_{k+j}) \le \mathtt{E}(s_k)+1$ for every $j \ge 0$. □

Theorem 9 shows the accuracy of Algorithm 1 for faithful addition with any radix.

THEOREM 9. [illegible] B, m, n, N [illegible] $B \ge 2$ [illegible] $n > m \ge 2$ [illegible] $N \le 2 + B^{n-m} \cdot (1-B^{-1})/(1-B^{-m})$ [illegible]

$$|s_N - s| \le [1 + (N-2)B] \cdot \mathtt{ulp}_n(s_N); \tag{16}$$

$$|\mathtt{round}_m(s_N) - s| < B \cdot \mathtt{ulp}_m\left[\mathtt{round}_m(s_N)\right]. \tag{17}$$

[illegible]. By hypothesis, s_{k-1} is exact. By faithfulness, the magnitude of the first roundoff does not exceed $B^{\mathtt{E}(s_k)+1-n}$. Hence, by Lemma 8, two cases can occur.

(9.1) If $\mathtt{E}(s_k) - 1 \le \mathtt{E}(s_\ell) \le \mathtt{E}(s_k)$ for each $\ell \ge k$, then the $N-1$ subsequent roundoffs are bounded by $B^{\mathtt{E}(s_k)+1-n}$, and two subcases can arise.

(9.1.1) If there does [illegible] exist any $\ell \ge k$ such that $\mathtt{E}(s_\ell) = \mathtt{E}(s_k) - 1$, then $\mathtt{E}(s_N) = \mathtt{E}(s_k)$, whence the total error is bounded by

$$\begin{aligned} |s - s_N| &\le (N-1)B^{\mathtt{E}(s_k)+1-n} \\ &= (N-1)\mathtt{ulp}_n(s_N) \\ &\le [1 + (N-2)B]\,\mathtt{ulp}_n(s_N), \end{aligned}$$

which proves (16) in this subcase.

(9.1.2) If there exists some $\ell \ge k$ such that $\mathtt{E}(s_\ell) = \mathtt{E}(s_k) - 1$, then at least one roundoff (namely that of s_ℓ) is bounded by $B^{\mathtt{E}(s_k)-n}$, whence

$$\begin{aligned} |s - s_N| &\le [1 + (N-2)B]\,B^{\mathtt{E}(s_k)-n} \\ &\le [1 + (N-2)B]\,\mathtt{ulp}_n(s_N), \end{aligned}$$

because $\mathtt{E}(s_k) - 1 \le \mathtt{E}(s_N) \le \mathtt{E}(s_k)$, which proves (16).

(9.2) In contrast, if $\mathtt{E}(s_k) \le \mathtt{E}(s_\ell) \le \mathtt{E}(s_k)+1$ for every $\ell \ge k$, then each roundoff after that of s_k is bounded by $B^{\mathtt{E}(s_k)+2-n}$, whence

$$\begin{aligned} |s - s_N| &\le [1+(N-2)B]\, B^{\mathtt{E}(s_k)+1-n} \\ &\le [1+(N-2)B]\, \mathtt{ulp}_n(s_N), \end{aligned}$$

because $\mathtt{E}(s_k) \le \mathtt{E}(s_N) \le \mathtt{E}(s_k)+1$, which proves (16).

Rounding $s_N \in \mathtt{F}_n$ to $\mathtt{round}_m(s_N) \in \mathtt{F}_m$ either truncates or rounds up magnitudes, which does not decrease the exponent, so that $\mathtt{E}\,[\mathtt{round}_m(s_N)] \ge \mathtt{E}(s_N)$. Therefore,

$$\begin{aligned} \mathtt{ulp}_m\,[\mathtt{round}_m(s_N)] &= B^{\mathtt{E}[\mathtt{round}_m(s_N)]+1-m} \\ &\ge B^{\mathtt{E}(s_N)+1-m} \\ &= B^{n-m} \cdot B^{\mathtt{E}(s_N)+1-n} \\ &= B^{n-m} \cdot \mathtt{ulp}_n(s_N). \end{aligned} \tag{18}$$

The roundoff from $\mathtt{round}_m : \mathtt{F}_n \to \overline{\mathtt{F}}_m$ is at most $\mathtt{ulp}_m\,[\mathtt{round}_m(s_N)] \cdot (1-B^{m-n})$, barring overflow. Hence (12), (16), and (18) lead to (17):

$$\begin{aligned} |s - \mathtt{round}_m(s_N)| &\le \left\{(1-B^{m-n}) + [1+B(N-2)]\, B^{m-n}\right\} \cdot \mathtt{ulp}_m\,[\mathtt{round}_m(s_N)] \\ &\le \left(1 + B \cdot \frac{1-B^{-1}}{1-B^{-m}} \cdot B^{m-n}\right) \cdot \mathtt{ulp}_m\,[\mathtt{round}_m(s_N)] \\ &< B \cdot \mathtt{ulp}_m\,[\mathtt{round}_m(s_N)]\,, \end{aligned}$$

because $(B-1)\cdot B^{m-n} < (B-1)\cdot(1-B^{-m})$ for all $B \ge 2$ and $n > m \ge 2$. □

THEOREM 10. [illegible] (16) [illegible] (17) [illegible] 9 [illegible] $m \ge 2$ [illegible] $\mathtt{F}(B, n, E_{\min}, E_{\max})$ [illegible] $E_{\min} < -2m < -n < 0 \le E_{\max}$ [illegible]

$$N := 2 + B^{n-m}(1-B^{-1}) \tag{19}$$

[illegible] N [illegible] $(r_1, \ldots, r_N) = \vec{r}(m, B, n, E_{\min}, E_{\max}) \in \mathtt{F}_n^N$ [illegible]

$$\lim_{E_{\min}\to-\infty} |s - s_N| = \left[1 + B(N-2) - B^{1+n-2m}\right] \mathtt{ulp}_n(s_N), \tag{20}$$

[illegible] m [illegible] n [illegible] $n-m$ [illegible]

$$\lim_{\substack{m,n,n-m\to\infty \\ E_{\min}+n\to-\infty}} \frac{|s - \mathtt{round}_m(s_N)|}{\mathtt{ulp}_m\,[\mathtt{round}_m(s_N)]} = B. \tag{21}$$

[illegible]. For any m and n with $2 \le m < n < 2m$, define $r_1, r_2 \in \mathtt{F}_m$ by

$$\begin{aligned} r_1 &:= 1 + B^{1-m} \in \mathtt{F}_m, \\ r_2 &:= -B^{-m}(1+B^{1-m}) \in \mathtt{F}_m. \end{aligned}$$

Then $r_1 + r_2 = 1 + B^{1-m} - (B^{-m} + B^{1-2m})$ takes the algebraically equivalent form

$$r_1 + r_2 = 1 + \left[B^{n-m}(1-B^{-1}) - 1\right] B^{1-n} + (B^{1-n} - B^{1-2m}),$$

where $1 + B^{1-m} - (B^{-m} + B^{1-n}) \in \mathtt{F}_n$ and $B^{1-n} - B^{1-2m}$ gets truncated. Hence

$$s_2 = r_1 \oplus_n r_2 = 1 + \left[B^{n-m}(1-B^{-1}) - 1\right] B^{1-n}$$

if $\oplus_n$ rounds faithfully toward zero (truncates). Then let

$$L := B^{n-m}(1 - B^{-1}) - 1,$$
$$N := 2 + B^{n-m}(1 - B^{-1}),$$

and for each $i \in \{1, \ldots, N-2\}$, define the next summands

$$r_{2+i} := -B^{E_{\min}}.$$

Hence truncating subtractions gives

$$\begin{aligned} s_{2+i} &= 1 + (L - i)B^{1-n}, \\ s_{2+L} &= 1, \\ s_N &= 1 - B^{-n}, \\ \texttt{round}_m(s_N) &= 1 - B^{-m}. \end{aligned} \tag{22}$$

However, the exact sum of all the summands is

$$s = 1 + LB^{1-n} + (B^{1-n} - B^{1-2m}) - (N-2)B^{E_{\min}}.$$

Consequently, before the final rounding, the total error amounts to

$$\begin{aligned} s - s_N &= LB^{1-n} + (B^{1-n} - B^{1-2m}) + B^{-n} - (N-2)B^{E_{\min}} \\ &= \left[B(N-2) + 1 - B^{1+n-2m}\right] \cdot \texttt{ulp}_n(s_N) - (N-2)B^{E_{\min}}. \end{aligned} \tag{23}$$

Formula (23) establishes (20), and also yields

$$B(N-2) \cdot \texttt{ulp}_n(s_N) \le \lim_{E_{\min} \to -\infty} (s - s_N) \le [1 + B(N-2)] \cdot \texttt{ulp}_n(s_N),$$

which corroborates the sharpness of (16). After the final rounding,

$$\begin{aligned} s - \texttt{round}_m(s_N) &= LB^{1-n} + (B^{1-n} - B^{1-2m}) + B^{-m} - (N-2)B^{E_{\min}} \\ &= B(1 - B^{-m})B^{-m} - (N-2)B^{E_{\min}} \\ &= B(1 - B^{-m}) \cdot \texttt{ulp}_m\left[\texttt{round}_m(s_N)\right] - (N-2)B^{E_{\min}}. \end{aligned}$$

Yet $\texttt{ulp}_m\left[\texttt{round}_m(s_N)\right] = B^{-m}$ by (22), whence (19) gives

$$\frac{|s - \texttt{round}_m(s_N)|}{\texttt{ulp}_m\left[\texttt{round}_m(s_N)\right]} = B(1 - B^{-m}) - (1 - B^{-1})B^{n+E_{\min}}. \tag{24}$$

Equation (24) shows that (17) is sharp in the sense of the limit (21).

The conditions for this limit ($m \to \infty$ and $n \to \infty$, with $n - 2m \to -\infty$ and also $E_{\min} + n \to -\infty$) hold, for instance, with $n = m + \lfloor m/2 \rfloor$ and $E_{\min} \le -2n$. □

5. This example shows that if the number of summands exceeds the upper bound (12), then all the significant digits in the rounded sum can be inaccurate. To this end, let $B := 2$, $m := 2$, $n := 3$, $E_{\min} \ll -n$, and

$$N := 4 = 3 + 2^{3-2}(1 - 2^{-1}) = \left\lceil 2 + 2^{3-2}(1 - 2^{-1})/(1 - 2^{-2}) \right\rceil.$$

With binary notation, define $r_1 := 1.1$, $r_2 := -0.001$, and $r_3 := r_4 := -2^{E_{\min}}$. If $\oplus_3$ rounds toward zero, then $s_2 = 1.01$ because $r_1 + r_2 = 1.011$, whence $s_3 = 1.00$ and

TABLE 1

[a] The precision name used in the cited source.
[b] Abbreviation in this table for "single extended" in [14].
[c] Abbreviation in this table for "double extended" in [14].
[d] Variable number of digits, chopped, or faithfully rounded, up from trailing 0001.
[e] Minimum number of digits.
[f] Maximum number of digits.
[g] Variable number of digits, chopped, or properly rounded, "traditionally" up from trailing 5.
[h] s_N is not available, but $\texttt{round}_m(s_N) := \vec{\mathbf{r}} \odot \vec{\mathbf{1}}$ with a built-in extend-precision dot-product $\odot$.

$s_4 = 0.111$ similarly. If $\texttt{round}_2$ also rounds toward zero, then $\texttt{round}_2(s_4) = 0.11$ has no accurate significant digit, because $s = 1.011 - 2^{1-E_{\min}}$, whence $s - \texttt{round}_2(s_4) = 0.101 - 2^{1-E_{\min}}$, with $0.101 = (2 + 2^{-1})\texttt{ulp}_2\,[\texttt{round}_2(s_4)]$.

Table 1 lists maximum values of the number N of summands (computed with [illegible] [33]) for systems spanning decades of multiple-precision floating-point arithmetic. Because of faithful—instead of proper—rounding, the values are about an order of magnitude below those listed by Demmel and Hida [5, Table 1, p. 1222].

4. Conclusions. Any extended precision, by any number of additional digits, with any radix and any faithful rounding mode, can increase the accuracy of floating-point sums by several additional correct significant digits.

Acknowledgment. I thank the referees for suggestions that vastly improved the manuscript.

WAVELET FILTERING FOR EXACT CONTROLLABILITY OF THE WAVE EQUATION*

M. NEGREANU†, A.-M. MATACHE‡, AND C. SCHWAB‡

Abstract. In this paper we propose and analyze a wavelet-based numerical method for exact controllability of the one-dimensional wave equation, concentrating on the particular case of *Dirichlet* controls. We use the Hilbert uniqueness method (HUM) and prove this result in the context of the finite element space semidiscretization with spline wavelet basis functions. The algorithm for the numerical construction of the controls is based on a conjugate gradient method proposed by Glowinski [*J. Comput. Phys.*, 103 (1992), pp. 189–221] and a two-grid filtering technique in the wavelet basis. We show that wavelet filtering yields numerically exact controllability in the optimal time of the continuous problem and the convergence of the numerical controls using a multilevel discretization filtering technique. Classical arguments then allow proving the uniform boundedness of the numerical controls and passing to the limit as the mesh size tends to zero. We prove that the condition number of the discretized HUM operator Λ with wavelet filtering is uniformly bounded with respect to the mesh width and prove convergence of the numerical controls obtained with the two-grid filtering technique. Numerical experiments show that wavelet filtering yields numerical controls with the same control time T as in the continuous case.

Key words. boundary controllability, uniform observability, multigrid algorithm, finite element discretization, wavelet filtering, wave equation

1. Introduction.

In the present paper, we consider the numerically exact controllability of wave equations, the simplest example of which is the constant coefficient one-dimensional wave equation:

$$\begin{cases} u_{tt} - u_{xx} = 0, & 0 < x < 1, \quad 0 < t < T, \\ u(0,t) = 0, \quad u(1,t) = v(t), & 0 < t < T, \\ u(x,0) = u^0(x), \qquad u_t(x,0) = u^1(x), & 0 < x < 1. \end{cases} \tag{1.1}$$

In (1.1), $u = u(x,t)$ describes the displacement of a vibrating string occupying the interval $(0,1)$, (u^0, u^1) is the given initial state, and v is an unknown control function that acts on the system through the end point $x = 1$. System (1.1) is well posed in appropriate functional spaces.

When no control acts on the boundary $x = 1$, i.e., $v = 0$, the total energy

$$E(t) = \frac{1}{2} \int_0^1 \left(|u_x(x,t)|^2 + |u_t(x,t)|^2 \right) dx \tag{1.2}$$

of the solution is conserved, i.e.,

$$\frac{dE(t)}{dt} = E'(t) = 0 \quad \forall t \in [0,T].$$

The following exact controllability result is well known (see, e.g., [7]): [illegible] $T \geq 2$ [illegible] $(u^0, u^1) \in L^2(0,1) \times H^{-1}(0,1)$ [illegible] $v \in L^2(0,T)$ [illegible] $u = u(x,t)$ [illegible] (1.1) [illegible]

$$u(T) = u_t(T) = 0, \quad 0 < x < 1. \tag{1.3}$$

The goal in this control problem is therefore to drive solutions to equilibrium at time $t = T$. Once the equilibrium configuration is reached at time $t = T$, by taking null controls for $t \geq T$, i.e., $v = 0$ for $t \geq T$, the solution remains at rest for all $t \geq T$.

Let us now introduce the homogeneous system

$$\begin{cases} \phi_{tt} - \phi_{xx} = 0, & 0 < x < 1, \quad 0 < t < T, \\ \phi(0,t) = \phi(1,t) = 0, & 0 < t < T, \\ \phi(x,0) = \phi^0(x), \qquad \phi_t(x,0) = \phi^1(x), & 0 < x < 1. \end{cases} \tag{1.4}$$

It admits a unique solution $\phi = \phi(x,t) \in \mathcal{C}^0\left([0,T], H_0^1(0,1)\right) \cap \mathcal{C}^1\left([0,T], L^2(0,1)\right)$ when $(\phi^0, \phi^1) \in H_0^1(0,1) \times L^2(0,1)$. This system is the adjoint of (1.1) up to an inversion in time.

The exact controllability of (1.1) is reduced to the study of the observability properties of the adjoint system: [illegible] $T \geq 2$ [illegible] $C(T) > 0$ [illegible]

$$E(0) \leq C(T) \int_0^T \left| \frac{\partial \phi(1,t)}{\partial x} \right|^2 dt \tag{1.5}$$

[illegible] $\phi = \phi(x,t)$ [illegible]. We refer to Lions [7] for a detailed analysis of the equivalence between controllability and observability through the [illegible] (HUM).

For any given $(u^0, u^1) \in L^2(0,1) \times H^{-1}(0,1)$, $T > 0$, there may exist many controls v with (1.3). Among all controls with the property (1.3) there exists a unique control of minimal L^2-norm, the so-called HUM control. Note that (1.3) makes sense, since in these conditions (1.1) admits a unique solution $u \in \mathcal{C}([0,T]; L^2(0,1)) \cap \mathcal{C}^1([0,T]; H^{-1}(0,1))$. Once we know that such a control exists, it is natural to try to construct this control numerically. A possible procedure is to approximate the wave operator by some sequence of discrete or semidiscrete operators and to obtain the control of system (1.1) as the limit of the sequence of controls of the approximating equations.

It is a well-known fact that the interaction of waves with the numerical mesh produces dispersion phenomena and spurious high-frequency oscillations [15, 16]. The observation and control properties of the discrete model eventually disappear. This has some impact when computing the control for the continuous model.

The goal of this paper is to obtain a convergent numerical approximation of the exact control.

For the space semidiscrete system, one method for constructing a convergent sequence of computed controls consists in filtering the high frequencies by truncating

the Fourier series of the solution. This method is natural from a theoretical point of view, but rather hard to implement in numerical simulations [6, 17].

Another method was proposed by Glowinski et al. in [4, 5]. They employ a Tychonoff regularization procedure which allows one to uniformly control the semidiscrete system at the price of adding an extra internal control such that the boundary component of the controls converges to the boundary control of the continuous wave equation. This method is efficient to compute.

Glowinski in [4] introduced a two-grid algorithm that also allows one to compute efficiently the control of the continuous model. It consists in using a coarse and a fine grid, and to project the initial data from the fine grid to the coarse grid. With that strategy, the highest frequencies cannot exist alone. The convergence of this method has been proved in [10, 11] for $T = 4$ for the finite difference and finite element semidiscrete approximation in one space dimension with a discrete multiplier approach. In [8], Loreti and Mehrenberger have proposed a new proof of this fact thanks to an Ingham-type approach. This leads to the critical time $T \geq 2$.

In the full one-dimensional space-time discretization with equal space and time step, the high-frequency pathologies no longer arise and the HUM controls for the discrete model (with finite difference and finite element approximation) converge to the control of the continuous wave equation. The detailed proof of these results is given in [9, 11]. When $\Delta t/\Delta x = \alpha < 1$, or in the semidiscrete case, it is easy to check that both the observability constant and the computed controls diverge [6, 12, 13].

In this paper we propose an algorithm to approximate the HUM control based on the conjugate gradient method proposed by Glowinski [4] and multilevel filtering in a hierarchical spline wavelet basis. We obtain convergence of the numerical controls computed by the multilevel filtering. In Theorem 3.4 we prove the convergence of the numerical controls computed by the multigrid filtering.

This paper is organized as follows: In section 2 we recall the HUM algorithm and discuss its application to the exact boundary controllability of the wave equation (1.1). In section 3 we discuss the application of this algorithm in the semidiscrete case using finite element spaces of spline wavelets as approximating spaces. Moreover, we analyze the conjugate gradient method with multigrid filtering and obtain the convergence of this procedure for the finite element controls. We also prove that the condition number of the discretized HUM operator corresponding to wavelet filtering is uniformly bounded with respect to the mesh width. In section 4 we present some numerical results.

2. The HUM method and the operator Λ. We describe briefly a method due to Lions called HUM (the Hilbert uniqueness method) for control of a wave equation from a part of the boundary $x = 1$; for more details see [1, 4, 5].

2.1. Operator Λ. Let us denote by $E = H_0^1(0,1) \times L^2(0,1)$ the space of initial states for the homogeneous wave equation. Further let $E' = H^{-1}(0,1) \times L^2(0,1)$ be the dual space of E, and define the operator

$$\Lambda : E \to E'$$

as follows:

- Given $e = \{\phi^0, \phi^1\} \in E$, let ϕ be the solution of the uncontrolled wave equation (1.4) from $t = 0$ to $t = T$ with initial state e.
- Let ψ be the solution of the backward controlled system from $t = T$ to $t = 0$

with boundary data $\frac{\partial\phi(1,t)}{\partial x}$ at the end point $x = 1$:

$$\text{(2.1)}\quad \begin{cases} \psi_{tt} - \psi_{xx} = 0, & 0 < x < 1, \quad 0 < t < T, \\ \psi(0,t) = 0 \qquad \psi(1,t) = \dfrac{\partial\phi(1,t)}{\partial x}, & 0 < t < T, \\ \psi(x,T) = \psi_t(x,T) = 0, & 0 < x < 1. \end{cases}$$

- Define $\Lambda\, e$ as

$$\text{(2.2)}\qquad \Lambda\, e = \{\psi_t(0), -\psi(0)\}\,.$$

Using the HUM approach, the original control problem (1.3) is transformed into an identification of initial conditions problem, and the linear problem (2.2) is in duality with a minimization problem,

$$\min_{\mathcal{U}} \int_0^T v^2 dt$$

(see [7, 4] for more details), where the set of admissible controls is given by

$$\mathcal{U} = \{v \in L^2(0,T) \,|\, y_{tt} - y_{xx} = 0 \,\text{in}\, (0,1)\times(0,T),\ y(0,t) = 0,\ y(1,t) = v \,\text{in}\, (0,T),$$
$$y(x,0) = u^0(v),\ y_t(x,0) = u^1(x),\ y(x,T) = y_t(x,T) = 0\}.$$

The HUM control is the unique solution of this minimization problem.

Following this systematic way for constructing such control v provided by the HUM approach, the original exact controllability problem (1.3) is transformed into the problem of identifying initial values for an associated adjoint wave equation.

2.2. HUM algorithm. We discuss now an application to the exact boundary controllability of the wave equation (1.1) for the initial conditions (u^0, u^1). To this end, $f = \{u^1, -u^0\} \in E'$ and let $e = \{\phi^0, \phi^1\} \in E$ be such that

$$\text{(2.3)}\qquad \Lambda\, e = f.$$

The linear problem (2.3) admits a unique solution, provided that T is sufficiently large [7]. The optimal control v is then obtained as follows: take $e = \{\phi^0, \phi^1\}$ as the initial state in (1.4) and define v as $v = \partial\phi(1,t)/\partial x$. This yields the HUM control v which satisfies the exact controllability property. Indeed, solving the wave equation (2.1) backward in time using v as the boundary data in $x = 1$ and denoting by ψ its solution, $u = \psi$ satisfies the following by the definition of the operator Λ: $u(0,x) = u^0(x)$, $u_t(0,x) = u^1(x)$, and $u(x,T) = u_t(x,T) = 0$ for all $x \in (0,1)$.

We can rewrite (2.3) in the following symmetric variational form [1, 5]: given $f \in E'$,

$$\text{(2.4)}\qquad \text{find } e \in E \text{ such that } \langle \Lambda\, e, \bar{e}\rangle = \langle f, \bar{e}\rangle \quad \forall\, \bar{e} \in E,$$

where $\langle\cdot,\cdot\rangle$ denotes the duality pairing between E and E'.

Integrating by parts in time and space, the following representation of the form $\langle \Lambda\, e, \bar{e}\rangle$ is obtained (see [7, Chapter 1, section 2]):

$$\text{(2.5)}\qquad \langle \Lambda\, e, \bar{e}\rangle = \int_0^1 \left[\psi_t(x,0)\bar{\phi}(x,0) - \psi(x,0)\bar{\phi}_t(x,0)\right] dx = \int_0^T \left[\frac{\partial\phi}{\partial x}(1,t)\frac{\partial\bar{\phi}}{\partial x}(1,t)\right] dt$$

for all e, $\bar{e} \in E$, where $\int_0^1$ is understood as an extension of duality pairing, and $\{\phi, \psi\}$, $\{\bar{\phi}, \bar{\psi}\}$ are the solutions of (1.4)–(2.1) with initial states e and $\bar{e}$, respectively.

2.3. Properties of Λ. We collect here some properties of the operator Λ. It is proved in [7, Chapter 1, section 2] that Λ is a linear and continuous operator from E into E'; moreover, if T is sufficiently large ($T \geq T_{\min} = 2$), Λ is an isomorphism from E onto E'. If $T \geq T_{\min} = 2$, it follows from (2.5) that Λ is coercive, and symmetric, i.e., there exist constants $C > 0$ and $\gamma > 0$ such that

$$|\langle \Lambda e, \bar{e} \rangle| \leq C \|e\|_E \|\bar{e}\|_E \quad \forall\, e, \bar{e} \in E, \tag{2.6}$$

$$\langle \Lambda e, e \rangle \geq \gamma \|e\|_E^2 \quad \forall\, e \in E, \tag{2.7}$$

where for $e = \{\phi^0, \phi^1\} \in E$

$$\|e\|_E := \left(\int_0^1 (|\nabla \phi^0|^2 + |\phi^1|^2)\, dx \right)^{1/2}. \tag{2.8}$$

The combination of coercivity with the symmetry is of fundamental importance, since it implies that (2.3) can be solved by a conjugate gradient algorithm operating in the space E.

The operator Λ is composed of the solution of the two wave equations (1.4) and (2.1). From the analysis given in [5], after discretization of these equations, one in general does not end up with a positive definite matrix: it appears that the approximation of $\partial\phi(1,t)/\partial x$, which is used to construct the discrete operator Λ_h, introduces a very strong damping of the large wave number components of discrete initial data e_h (parameter h describes the size of the space mesh). This is related to the fact that the velocity of propagation of solutions tends to zero as the size of the mesh tends to zero and the wavelength of solutions is of the same order as the size of the mesh (see [12, 13]).

2.4. Conjugate gradient implementation of HUM. The outline of this section is as follows: after a short recapitulation of the conjugate gradient algorithms for the numerical solution of linear variational problems we specify its application to the boundary control of the wave equation.

2.4.1. Conjugate gradient algorithm: Generalities. As we have seen in section 2.1, the original control problem is transformed into a resolution of the equation $\Lambda e = f$, which is a particular case of the abstract linear variational problems,

$$u \in V, \qquad a(u, v) = L(v) \qquad \forall v \in V, \tag{2.9}$$

where in (2.9) the following hold:

1. V is a real Hilbert space for the scalar product $(\cdot, \cdot)$ and the corresponding norm $\|\cdot\|$.
2. $a : V \times V \to V$ is bilinear, symmetric, continuous, and V-elliptic.
3. $L : V \to \mathbb{R}$ is linear and continuous.

With the above hypotheses, problem (2.9) has a unique solution, which can be computed by the following conjugate gradient algorithm (see [5] for more details).

- Step 0. Initialization.

  With $u^0 \in V$ given (2.10)

  solve

  $$g^0 \in V, \ \ (g^0, v) = a(u^0, v) - L(v) \quad \forall v \in V. \tag{2.11}$$

If $g^0 = 0$ or is [illegible], take $u = u^0$; if not, set

$$w^0 = g^0. \tag{2.12}$$

Then for $n \geq 0$, assuming that u^n, g^n, w^n are known, compute u^{n+1}, g^{n+1}, w^{n+1} as follows.

- Step 1. [illegible] Compute

$$\rho_n = \frac{\|g^n\|^2}{a(w^n, w^n)}, \tag{2.13}$$

and then

$$u^{n+1} = u^n - \rho_n w^n. \tag{2.14}$$

- Step 2. [illegible]
Solve

$$g^{n+1} \in V,$$

$$(g^{n+1}, v) = (g^n, v) - \rho_n a(w^n, v) \quad \forall v \in V; \tag{2.15}$$

if $g^{n+1} = 0$ or is [illegible], take $u = u^{n+1}$; if not, compute

$$\gamma_n = \frac{\|g^{n+1}\|^2}{\|g^n\|^2}, \tag{2.16}$$

and define the new descent direction by

$$w^{n+1} = g^{n+1} + \gamma_n w^n. \tag{2.17}$$

Take $n = n + 1$ and go to (2.13).

If u is the solution of problem (2.9), we also have (see [5])

$$\|u^n - u\| \leq C\|u^0 - u\| \left(\frac{\sqrt{\nu_a} - 1}{\sqrt{\nu_a} + 1}\right)^n, \tag{2.18}$$

where the [illegible] ν_a of $a(\cdot, \cdot)$ is defined by

$$\nu_a = \sup_{v \in V - \{0\}} \frac{a(v, v)}{\|v\|^2} : \inf_{v \in V - \{0\}} \frac{a(v, v)}{\|v\|^2}.$$

Back to the practical implementation of algorithm, by g^0 and g^{n+1} [illegible] we mean that g^0 and g^{n+1} satisfy

$$\frac{\|g^0\|}{\|u^0\|} \leq \varepsilon, \quad \frac{\|g^{n+1}\|}{\|g^0\|} \leq \varepsilon,$$

where ε is a small positive number depending upon the floating point arithmetic used by the computer (see [5] for more details).

2.4.2. Conjugate gradient solution of $\Lambda e = f$. The HUM reduces the calculation of the control of minimal L^2-norm for the continuous problem (1.1) to the resolution of $\Lambda e = f$, with $f = \{-u^1, u^0\}$ given and $e \in E = H_0^1(0,1) \times L^2(0,1)$.

Application of the general conjugate gradient algorithm (2.10)–(2.17) to the solution of $\Lambda e = f$ is possible if $T \geq 2$; indeed, we take

$$V = E,$$

$$a(\cdot,\cdot) = \langle \Lambda \cdot, \cdot \rangle, \qquad L : \check{e} \to \langle \{u^1, -u^0\}, \check{e} \rangle.$$

We obtain then the following conjugate gradient algorithm.

- Step 0.

(2.19) With $e_0^0 \in H_0^1(0,1)$ and $e_0^1 \in L^2(0,1)$ given,

solve

$$\text{(2.20)} \qquad \begin{cases} (\phi_0)_{tt} - (\phi_0)_{xx} = 0, & 0 < x < 1, \quad 0 < t < T, \\ \phi_0 = 0, & 0 < t < T, \\ \phi_0(0) = e_0^0, \qquad (\phi_0)_t(0) = e_0^1 \end{cases}$$

and

$$\text{(2.21)} \qquad \begin{cases} (\psi_0)_{tt} - (\psi_0)_{xx} = 0, & 0 < x < 1, \quad 0 < t < T, \\ \psi_0(0) = 0, \quad \psi_0(1) = (\phi_0)_x(1,t), & 0 < t < T, \\ \psi_0(T) = (\psi_0)_t(T) = 0, & 0 < x < 1. \end{cases}$$

Compute $g_0 = \{g_0^0, g_0^1\} \in E$,

$$\text{(2.22)} \qquad -(g_0^0)_{xx} = (\psi_0)_t(0) - u^1 \text{ in } (0,1), \quad g_0^0(0) = g_0^0(1) = 0,$$

$$\text{(2.23)} \qquad g_0^1 = u^0 - \psi_0(0),$$

respectively. Then set

$$\text{(2.24)} \qquad w_0 = g_0.$$

Now, for $n \geq 0$, assuming that e_n, g_n, w_n, ϕ_n, ψ_n are known, compute e_{n+1}, g_{n+1}, w_{n+1}, ϕ_{n+1}, ψ_{n+1} as follows:

- Step 1. Solve the systems

$$\text{(2.25)} \qquad \begin{cases} (\phi_n)_{tt} - (\phi_n)_{xx} = 0, & 0 < x < 1, \quad 0 < t < T, \\ \phi_n = 0, & 0 < t < T, \\ \phi_n(0) = w_n^0, \qquad (\phi_n)_t(0) = w_n^1 \end{cases}$$

and

$$\text{(2.26)} \qquad \begin{cases} (\psi_n)_{tt} - (\psi_n)_{xx} = 0, & 0 < x < 1, \quad 0 < t < T, \\ \psi_n(0) = 0, \quad \psi_n(1) = (\phi_n)_x(1,t), & 0 < t < T, \\ \psi_n(T) = (\psi_n)_t(T) = 0, & 0 < x < 1, \end{cases}$$

$$-(g_n^0)_{xx} = (\psi_n)_t(0) \text{ in } (0,1), \quad g_n^0(0) = g_n^0(1) = 0 \tag{2.27}$$

and set

$$g_n^1 = -\psi_n(0). \tag{2.28}$$

Now compute

$$\rho_n = \frac{\int_0^1 (|(g_n^0)_x|^2 + |g_n^1|^2)dx}{\int_0^1 ((g_n^0)_x (w_n^0)_x + g_n^1 w_n^1)dx}, \tag{2.29}$$

$$e_{n+1} = e_n - \rho_n w_n, \tag{2.30}$$

$$\phi_{n+1} = \phi_n - \rho_n \phi_n, \tag{2.31}$$

$$\psi_{n+1} = \psi_n - \rho_n \psi_n, \tag{2.32}$$

$$g_{n+1} = g_n - \rho_n g_n. \tag{2.33}$$

- Step 2. [illegible]
  If $g_{n+1} = 0$ or is [illegible], take $e = e_{n+1}$, $\phi = \phi_{n+1}$, $\psi = \psi_{n+1}$; if not, compute

$$\gamma_n = \frac{\int_0^1 (|(g_{n+1}^0)_x|^2 + |g_{n+1}^1|^2)dx}{\int_0^1 (|(g_n^0)_x|^2 + |g_n^1|^2)dx}, \tag{2.34}$$

  and define the new descent direction by

$$w_{n+1} = g_{n+1} + \gamma_n w_n. \tag{2.35}$$

  Set $n := n + 1$ and go to (2.29).

3. Wavelet HUM. We compute numerical solutions to (2.4) by Galerkin approximation: we restrict trial and test space E in (2.4) to finite-dimensional subspaces $E_h \subset E$ of finite element type. This procedure was proposed by Glowinski and Lions in [5]. It will lead to convergent approximations if (a) the sequence $\{E_h\}_h$ of subspaces is dense in E, and (b) if the operator Λ is realized exactly on E_h.

In practice, however, Λ [illegible] be realized exactly for two reasons: (a) the forward/backward wave equations (1.4), (2.1) must be integrated numerically by a suitable time stepping scheme, and (b) if (1.4), (2.1) are solved with initial data in the finite element space E_h, the exact solution does [illegible] belong to E_h: (1.4), (2.1) must be solved with a higher spatial resolution than the given initial data and must be projected back into E_h. As observed in [4], this projection back into the "coarse" space of initial data amounts to a filtering.

Various filtering techniques were proposed in [4]. The key requirement of uniform in h stability in the topology of E for the filtering is difficult to satisfy. For various choices proposed in [4], discrete controls with an exact controllability time $T_{\min} = 4 > T = 2$ result for (1.1) (see [10, 11] for more details).

Here, we propose space discretization of (1.4), (2.1) in a hierarchical spline wavelet basis. While this yields the usual finite spaces for Galerkin approximation of (2.1), in this basis an E-stable filtering is immediately obtained by truncating the wavelet expansion, respectively, by the quasi-interpolation operator corresponding to this truncation. The efficiency of this computational methodology is illustrated by the numerical experiments below in which we obtain the optimal observability time $T \geq T_{\min} = 2$ also for the numerical controls.

3.1. Space discretization. Given $\Omega = (0,1)$, $N \in \mathbb{N}$, we set $h = 1/(N+1)$ and consider the mesh $\mathcal{T}_h$

$$0 = x_0 < x_1 < \cdots < x_{N+1} = 1,$$

with $x_j = jh$, $j = 0, \ldots, N+1$.

Let V_h be the finite element space of continuous, piecewise linear functions on $\mathcal{T}_h$ vanishing at end points. Let $\phi_h(t) \in V_h$ denote the solution of the semidiscrete problem

$$\begin{cases} \dfrac{d^2}{dt^2}\left(\phi_h(t),\, v\right)_{L^2(\Omega)} + \left(\dfrac{\partial \phi_h(t)}{\partial x},\, \dfrac{dv}{dx}\right)_{L^2(\Omega)} = 0 \qquad \forall v \in V_h, \\ \phi_h(0) = \phi_h^0 \in V_h, \\ \phi_h'(0) = \phi_h^1 \in V_h, \end{cases} \tag{3.1}$$

with ϕ_h^0, ϕ_h^1 being the L^2-projections into V_h of ϕ^0, ϕ^1, respectively:

$$(\phi^0 - \phi_h^0, v)_{L^2(\Omega)} = (\phi^1 - \phi_h^1, v)_{L^2(\Omega)} = 0 \quad \forall\, v \in V_h.$$

If we expand both $\phi_h(t)$ and the test function v with respect to a basis $\mathcal{B} = \{\Phi_j\}_{j=1}^N$ of $V_h = \operatorname{span} \mathcal{B}$, (3.1) can be rewritten in matrix form as

$$\begin{cases} \mathbf{M} \dfrac{d^2}{dt^2} \underline{\phi}_h(t) + \mathbf{A} \underline{\phi}_h(t) = 0, \qquad 0 < t < T, \\ \underline{\phi}_h(0) = \underline{\phi}_h^0, \\ \underline{\phi}_h'(0) = \underline{\phi}_h^1. \end{cases} \tag{3.2}$$

Here we denote by $\underline{v}$ the coefficient vector of the function $v \in V_h$ with respect to the basis $\mathcal{B}$, $\mathbf{A}$ represents the stiffness matrix, and $\mathbf{M}$ is the mass matrix:

$$A_{i,j} := (\Phi_j', \Phi_i')_{L^2(\Omega)}, \quad M_{i,j} := (\Phi_i, \Phi_j)_{L^2(\Omega)} \quad \forall\, i,j = 1, \ldots, N.$$

The simplest choice for the basis $\{\Phi_i\}_{i=1}^N$ is to take the so-called hat functions $\Phi_i = \max(1 - |x - x_i|/h, 0)$. The standard hat functions do not build a hierarchical basis.

The hierarchical hat functions are obtained as follows: for $\Omega = (0,1)$, let ϕ be the hat function taking values $0, 1, 0$ at $0, 1/2, 1$, respectively, and vanishing outside Ω. We set $\mathcal{I}_l := \{0, 1, \ldots, 2^l - 1\}$, $\psi_j^l(x) := 2^{-l/2}\phi(2^l x - j)$, $j \in \mathcal{I}_l$, $x \in \Omega$, and denote $\mathcal{B}_L := \left\{\psi_j^l\right\}_{l=0,\ldots,L\ j \in \mathcal{I}_l}$. Then $\mathcal{B}_L$ is a basis of V_h for $h = 2^{-L}$, which is [illegible]:

$$\mathcal{B}_0 \subset \mathcal{B}_1 \subset \cdots \subset \mathcal{B}_L \subset \cdots.$$

The total energy of the space-semidiscrete problem (3.2) is given by

$$E_h(t) = \frac{1}{2}\left[\underline{\phi}_h'^{\top} \mathbf{M} \underline{\phi}_h' + \underline{\phi}_h^{\top} \mathbf{A} \underline{\phi}_h\right]. \tag{3.3}$$

PROPOSITION 3.1. [illegible] (3.3) [illegible] (3.2) [illegible]. Similarly to the continuous case, we multiply (3.2) by $\underline{\phi}_h' = \frac{d}{dt}\phi_h(t)$ and obtain that

$$\underline{\phi}_h'^{\top} \mathbf{M} \underline{\phi}_h'' = -\underline{\phi}_h'^{\top} \mathbf{A} \underline{\phi}_h.$$

Equivalently,

$$\frac{d}{dt}\left(\underline{\phi}_h'^{\top}\,\mathbf{M}\underline{\phi}_h' + \underline{\phi}_h^{\top}\,\mathbf{A}\underline{\phi}_h\right) = 0,$$

and therefore $\frac{dE_h(t)}{dt} = 0$ for all $t \in (0,T)$. ∎

3.2. Wavelet basis. For filtering and preconditioning purposes in a numerical version of HUM, it will be essential to employ a wavelet basis of V_h, which we now describe.

In the interval $\Omega = (0,1)$ we create a sequence $\{\mathcal{T}^l\}$ of meshes by $\mathcal{T}^0 = \{\Omega\}$ and by halving the elements $I_j^{l-1} \in \mathcal{T}^{l-1}$ to get $\mathcal{T}^l$. To make level dependence explicit, we denote by $\mathcal{V}_l$ the space of continuous, piecewise linears on $\mathcal{T}^l$ that vanish at the end points. The mesh width of $\mathcal{T}^l$ is $h_l = 2^{-l}$, and we write $N_l = \dim\mathcal{V}_l$, $M_l := N_l - N_{l-1}$, $N_{-1} := 0$. Then $N_l = 2^{l+1} - 1$, $l = 0, 1, 2, \ldots$.

We assume we are given a spline wavelet basis ψ_j^l, $j = 1, \ldots, M_l$, $l = 0, 1, 2, \ldots, L$, of

$$V_h := \mathcal{V}_L$$

with the properties

$$\mathcal{V}_L = \operatorname{span}\left\{\psi_j^l \mid 0 \le l \le L;\ 1 \le j \le M_l\right\}, \quad \operatorname{diam}\operatorname{supp}\,(\psi_j^l) \le C\,2^{-l}, \tag{3.4}$$

such that ψ_j^l for $l \ge l_0$ are obtained by scaling and translation of the function $\psi_j^{l_0}$.

Any function $v \in V_h = \mathcal{V}_L$ has the representation

$$v = \sum_{l=0}^{L}\sum_{j=1}^{M^l} v_j^l \psi_j^l, \tag{3.5}$$

with wavelet coefficients $v_j^l \in \mathbb{R}$. For $v \in H_0^1(\Omega)$ one obtains the series

$$v = \sum_{l=0}^{\infty}\sum_{j=1}^{M_l} v_j^l \psi_j^l, \tag{3.6}$$

which converges in $L^2(\Omega)$ and in $H_0^1(\Omega)$. Moreover, we assume that in the scale of spaces

$$H_\theta = \left(L^2(\Omega),\, H_0^1(\Omega)\right)_{\theta,2}$$

the following [illegible] holds:

$$\forall\, v \in H_\theta,\ c_1\|v\|_{H_\theta}^2 \le \sum_{l=0}^{\infty}\sum_{j=1}^{M_l} |v_j^l|^2 2^{2l\theta} \le c_2\|v\|_{H_\theta}^2, \quad 0 \le \theta \le 1. \tag{3.7}$$

We define the projector $P_L : L^2(\Omega) \to \mathcal{V}_L$ by truncating (3.6):

$$P_L\, v := \sum_{l=0}^{L}\sum_{j=1}^{M_l} v_j^l \psi_j^l,\ P_{-1} := 0. \tag{3.8}$$

The increment or detail spaces $\mathcal{W}^l$ are defined by

$$\mathcal{W}_l := \operatorname{span}\left\{\psi_j^l : \ 1 \le j \le M_l\right\}, \ l = 1, 2, \ldots, \quad \mathcal{W}_0 := \mathcal{V}_0. \tag{3.9}$$

Then it holds that

$$\mathcal{V}_l = \mathcal{V}_{l-1} \oplus \mathcal{W}_l \text{ for } l \ge 1 \quad \text{and} \quad \mathcal{V}_l = \mathcal{W}_0 \oplus \cdots \oplus \mathcal{W}_l, \ l \ge 0, \tag{3.10}$$

and $Q_l := P_l - P_{l-1}$ is a projection from $L^2(\Omega)$ to $\mathcal{W}_l$ (see [2, 3]).

1 (spline prewavelet basis). A wavelet basis is a prewavelet basis if $\mathcal{W}_l$ is orthogonal in $L^2(0,1)$ to $\mathcal{V}_{l-1}$, i.e.,

$$\forall\, l \ge 1, \ \forall\, j \in \{1, \ldots, M_l\}, \quad (\psi_j^l, \phi)_{L^2(0,1)} = 0 \quad \forall\, \phi \in \mathcal{V}_{l-1}.$$

In this case, P_L in (3.8) is the L^2-projection. Prewavelets are functions with small support in $\mathcal{V}_l$ which are L^2-orthogonal on $\mathcal{V}_{l-1}$. The interior wavelet functions are obtained as a linear combination of fine scaling functions with coefficients $(1/10, -6/10, 1, -6/10, 1/10)$.

For the boundary wavelets the coefficients are $(9/10, -6/10, 1/10)$ for the left boundary and $(1/10, -6/10, 9/10)$ for the right boundary.

2 (spline biorthogonal wavelet basis). Another family of wavelets are so-called biorthogonal wavelets, which need not be orthogonal on $\mathcal{V}_{l-1}$.

Let $\Omega = (0,1), \mathcal{I}^l := \{0, 1, \ldots, 2^l - 1\}$, and let ϕ be the hat function taking values 0, 1, 0 at 0, 1/2, 1, respectively, and vanishing outside $\Omega = (0,1)$. We define ψ as the continuous, piecewise linear function taking values $(0, -1/2, 1, -1/2, 0)$ at $(0, 1/4, 1/2, 3/4, 1)$ and vanishing outside $(0,1)$. Similarly, $\psi^\star$ takes values $(0, 1, -1/2, 0)$ at $(0, 1/4, 1/2, 3/4)$ and $\psi_\star$ assumes values $(0, -1/2, 1, 0)$ at $(1/4, 1/2, 3/4, 1)$. Further, we define $\psi_0^0 := \phi$ (scaling function), $\psi_0^l(x) := \psi^\star(2^{l-1}x)$, $\psi_{2^l-1}^l := \psi_\star(2^{l-1}x - 2^{l-1} + 1)$, $x \in I$, for $l \ge 1$ (boundary wavelets).

The interior wavelets are given by $\psi_j^l(x) := \psi(2^{l-2}x - 2^{-2}j + 2^{-2})$, $x \in \Omega$, for $1 \le j \le 2^l - 2$ and $l \ge 2$. These boundary wavelets are suitable to accommodate zero Dirichlet boundary conditions. In the case of Neumann boundary conditions the wavelet at the left boundary has values $-2, 2, -1, 0, \ldots, 0$ (and similarly at the right boundary); see Figure 3.1.

3.3. Two-grid space discretization. We will discuss two different choices for the system of shape functions $\{\Phi_j\}_{j=1}^N$. The standard hat functions are given by

$$\varphi_i(x) = \max(1 - |x - x_i|/h, 0), \quad i = 1, \ldots, N. \tag{3.11}$$

The second choice is the hierarchical spline wavelets basis from Example 2 (see also Figure 3.1) or the prewavelet basis from Example 1.

The direct discretization of the HUM algorithm leads to an discrete problem leading to the oscillatory results described in [4, 5]. With f_h a convenient approximation of $f = \{u^1, -u^0\}$, they approximate problem $\Lambda e = f$ by

$$\Lambda_h e_h = f_h.$$

From the numerical results discussed in detail in [4], we see that when h decreases to zero, the of the discrete problem is getting worse. From the oscillatory results it is quite clear that the trouble lies with the of the discrete solution or, to be more precise, with the way the discrete operator Λ_h acts

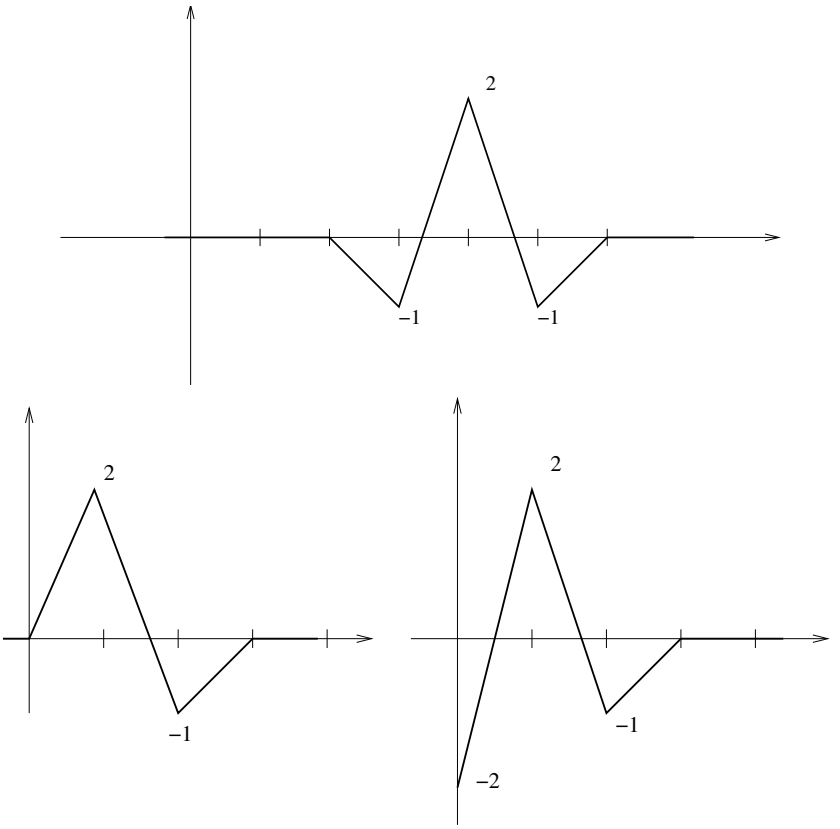

FIG. 3.1. *Generating wavelets: interior wavelets (top) and boundary wavelets for Dirichlet boundary conditions (bottom left) and Neumann boundary conditions (bottom right).*

on the [illegible] component of e_h, i.e., small perturbations of the right-hand side of the discrete problem, $\Lambda_h e_h = f_h$, can produce very large variations of the corresponding solution.

Our implementation of the HUM algorithm is based on the hierarchical spline wavelet basis and a two-grid filtering technique. The idea is to eliminate the high-frequency components of the initial conditions $\underline{\phi}_h^0$ and $\underline{\phi}_h^1$ by defining them on a finer grid with mesh size $h/2$. To this end, we take

$$N = N_L = 2^L - 1, \quad h = h_L = 2^{-L}.$$

The interpolation operator $I_L^{L+1} : \mathbb{R}^{N_L} \to \mathbb{R}^{N_{L+1}}$ maps coarse grid functions onto fine grid functions

$$I_L^{L+1} \underline{v}_w^L := \underline{v}_w^{L+1}, \tag{3.12}$$

where

$$\underline{v}_w^L = \{v_{(j,l)}^L\}_{\substack{l=0,\dots,L \\ j\in\mathcal{I}_l}}, \qquad \underline{v}_w^{L+1} = \{v_{(j',l')}^{L+1}\}_{\substack{l'=0,\dots,L+1 \\ j'\in\mathcal{I}_{l'}}},$$

with

$$v_{(j,l)}^{L+1} = \begin{cases} v_{(j,l)}^L, & l = 0,\dots,L, \quad j \in \mathcal{I}_l, \\ 0, & l = L+1, \qquad j \in \mathcal{I}_{L+1}, \end{cases}$$

and $\mathcal{I}_l := \{0, 1, \ldots, 2^l - 1\}$. The restriction operator $I_{L+1}^L : \mathbb{R}^{N_{L+1}} \to \mathbb{R}^{N_L}$ maps fine grid functions into coarse grid functions as follows:

$$\underline{v}_w^{L+1} = \{v_{(j',l')}^{L+1}\}_{\substack{l'=0,\ldots,L+1 \\ j' \in \mathcal{I}_{l'}}} \mapsto \underline{v}_w^L = \{v_{(j,l)}^{L+1}\}_{\substack{l=0,\ldots,L \\ j \in \mathcal{I}_l}}. \tag{3.13}$$

3.2. In the hat function basis, the analogous interpolation operator $J_L^{L+1} : \mathbb{R}^{N_L} \to \mathbb{R}^{N_{L+1}}$ is defined as

$$\underline{v}_{hat}^L = \{v_j^L\}_{j=1,\ldots,N_L} \mapsto \underline{v}_{hat}^{L+1} = \{v_{j'}^{L+1}\}_{j'=1,\ldots,N_{L+1}},$$

with

$$v_{2j}^{L+1} = v_j^L, \quad v_{2j+1}^{L+1} = \frac{1}{2}\left(v_j^L + v_{j+1}^L\right)$$

(see [1] for more details).

Let $v \in V_L$ be a coarse grid function. We denote by $\underline{v}_w^L$ and $\underline{v}_{hat}^L$ the coefficient vectors of v in the wavelet basis and in the hat function basis, respectively. With $\underline{v}_w^{L+1} = I_L^{L+1}\underline{v}_w^L$ and $\underline{v}_{hat}^{L+1} = J_L^{L+1}\underline{v}_{hat}^L$ it holds that

$$\sum_{l=0}^{L+1}\sum_{k=0}^{2^l-1} v_{k,l}^{L+1}\psi_k^l = \sum_{j=0}^{N_{L+1}} v_j^{L+1}\varphi_j^{L+1}, \tag{3.14}$$

i.e., the fine grid interpolation function is the same if we use the extension operator I_L^{L+1} in the hierarchical wavelet basis, which acts by adding zeros on the finest level, or if we employ the natural extension operator J_L^{L+1} in the two-grid system of hat function bases.

3.4. Wavelet filtering approximation of $\Lambda e = f$. In this section we describe a method based on two-grid algorithm wavelet filtering to approximate (2.3), i.e., $\Lambda e = f$. Let us denote by Λ_L the operator that acts as follows: given $e_L := \{\phi_L^0, \phi_L^1\} \in (V_L)^2$ as the initial condition for the homogeneous wave equation (3.2), we solve (3.2) exactly in time, and by the finite element method in x based on the finite element space V_L, find $\phi_L(t) \in V_L$ such that

$$\begin{aligned} &\frac{d^2}{dt^2}\left(\phi_L(t),\, v\right)_{L^2(\Omega)} + \left(\frac{\partial\phi_L(t)}{\partial x},\, \frac{dv}{dx}\right)_{L^2(\Omega)} = 0 \qquad \forall v \in V_L, \\ &(\phi_L(0), \phi_L'(0)) = e_L. \end{aligned}$$

Likewise, one solves backward in time the controlled system continuous in time and space semidiscrete with finite element space V_L, with terminal data $(0, 0)$ and Dirichlet control at $x = 1$ given by $\partial_x^h\phi_L(1, t)$, where the finite difference operator ∂_x^h is defined by

$$\partial_x^h\phi_L(1, t) = -\phi_{N_L}^L/h_L, \tag{3.15}$$

with $\underline{\phi}^L = \{\phi_i^L\}_{i=1}^{N_L}$ being the coefficient vector of ϕ_L in the hat function basis. Let ψ_L denote the solution of the discrete controlled system. The operator Λ_L is then defined as follows:

$$\Lambda_L e_L := \{\partial_t\psi_L(0), -\psi_L(0)\}. \tag{3.16}$$

Heuristically, $\Lambda_\infty = \Lambda$.

We define next the two-grid filtering operator $\Lambda_{L,\tilde{L}}$. For any $\tilde{L} > L$ denote by $I_L^{\tilde{L}} = I_{\tilde{L}-1}^{\tilde{L}} \circ \cdots \circ I_L^{L+1}$ the extension operator and by $I_{\tilde{L}}^{L} = I_{L+1}^{L} \circ \cdots \circ I_{\tilde{L}}^{\tilde{L}-1}$ the restriction operator acting between V_L and $V_{\tilde{L}}$.

ALGORITHM 3.3.

- Step 1. Given initial state $e_L = (\phi_L^0, \phi_L^1) \in (V_L)^2$, solve the uncontrolled wave equation (3.2) in $V_{\tilde{L}}$ with $\tilde{L} > L$. Denote by $\phi_{\tilde{L}}$ the corresponding solution.
- Step 2. Next solve backward in time the controlled system with terminal data $(0,0)$ and Dirichlet control at $x = 1$ given by $\partial_x^h \phi_{\tilde{L}}(1,t)$ with ∂_x^h defined as in (3.15), and denote by $\psi_{\tilde{L}}$ the corresponding solution.

  Note that we use here the wavelet basis for the finite element space discretization. Unlike in the case when hat shape functions are employed where the stiffness and mass matrices have a three diagonal structure, these matrices in the wavelet basis have rather $\mathcal{O}(N_L \log N_L)$ nonzero entries. They are, however, still sparse matrices, and the matrix-vector multiplication is realized in $\mathcal{O}(N_L \log N_L)$ floating point operations.

  Denote $\psi_{\tilde{L}}^0 = \psi(\cdot,0)$, $\psi_{\tilde{L}}^1 = \frac{\partial \psi}{\partial t}(\cdot,0)$ and let $\underline{\psi}_w^{0,\tilde{L}}$, $\underline{\psi}_w^{1,\tilde{L}}$ denote the coefficient vectors in the hierarchical wavelet basis.
- Step 3 (filtering). Restrict $(\underline{\psi}_w^{0,\tilde{L}}, \underline{\psi}_w^{1,\tilde{L}})$ to the coarse space as follows: let

$$\left(\underline{\psi}_w^{0,L}, \underline{\psi}_w^{1,L}\right) = I_{\tilde{L}}^{L}\left(\underline{\psi}_w^{0,\tilde{L}}, \underline{\psi}_w^{1,\tilde{L}}\right)$$

  and denote by (ψ_L^0, ψ_L^1) the corresponding finite element functions.
- Step 4. Finally, the operator $\Lambda_{L,\tilde{L}}$ acts as follows:

$$\langle \Lambda_{L,\tilde{L}}\{\phi_L^0, \phi_L^1\}, \{\bar{\phi}_L^0, \bar{\phi}_L^1\}\rangle = \left(\underline{\bar{\phi}}_w^{0,L}\right)^{\top} \mathbf{M}_w \underline{\psi}_w^{1,L} - \left(\underline{\bar{\phi}}_w^{1,L}\right)^{\top} \mathbf{M}_w \underline{\psi}_w^{0,L}.$$

  We observe that

$$\Lambda_{L,\tilde{L}} = P_L \Lambda_{\tilde{L}}.$$

- Step 5. Denote by $\mathbf{\Lambda}_{L,\tilde{L}}$ the wavelet basis matrix corresponding to $\Lambda_{L,\tilde{L}}$.

As an approximation of $\partial_x \phi(1,t)$ in $V_{\tilde{L}}$ below we take $\partial_x^h \phi_h(1,t)$ with $h = h_{\tilde{L}}$ as in (3.15):

$$\partial_x^h \phi_{\tilde{L}}(1,t) = -\frac{\phi_{N_{\tilde{L}}}^{\tilde{L}}}{h_{\tilde{L}}}(t).$$

In the hierarchical wavelet basis from Example 2 (see also Figure 3.1) $\underline{\partial}_x \phi_{\tilde{L}}(1,t)$ is given by

$$\partial_x^h \phi_{\tilde{L}}(1,t) = -\sum_{l=0}^{\tilde{L}} 2^{l-\tilde{L}} \frac{\phi_{N_{\tilde{L}}-1,l}^{\tilde{L}}}{h_{\tilde{L}}}(t), \tag{3.17}$$

with $\underline{\phi}_w^{\tilde{L}} = \{\phi_{j,l}^{\tilde{L}}\}$ being the coefficient vector with respect to the wavelet basis $\{\psi_j^l\}$.

3.5. Conjugate gradient solution of $\mathbf{\Lambda_{L,\tilde{L}} e_L = f_L}$, $\mathbf{\tilde{L} > L}$. The conjugate gradient algorithm for finding an approximate solution of the equation $\Lambda_{L,\tilde{L}} e_L = f_L$ with space discretization level $\tilde{L} > L$ for the wave equation is a Galerkin discretization of algorithm (2.19)–(2.35).

First of all, let us consider the systems obtained by a wavelet approximation of the semidiscretization of (1.1) and (2.1) in $V_{\tilde{L}}$.

We obtain the following conjugate gradient algorithm for the application of HUM based on hierarchical wavelet bases and a multigrid filtering technique.

- Step 0.
  (a)

$$\text{Given } e_0^0 \in V_L \text{ and } e_0^1 \in V_L \tag{3.18}$$

solve the homogeneous semidiscrete system

$$\mathbf{M}\phi_{0,\tilde{L}}''(t) + \mathbf{A}\phi_{0,\tilde{L}}(t) = 0, \qquad 0 < t < T, \tag{3.19}$$

in $V_{\tilde{L}}$, initialized by

$$\phi_{0,L}(0) = e_0^0, \quad \partial_t \phi_{0,L}(0) = e_0^1, \tag{3.20}$$

$$\phi_{0,\tilde{L}}(0) = I_L^{\tilde{L}} \phi_{0,L}(0), \quad \partial_t \phi_{0,\tilde{L}}(0) = I_L^{\tilde{L}} \partial_t \phi_{0,L}(0), \tag{3.21}$$

and denote by $\phi_{0,\tilde{L}}$ the corresponding solution.

  (b) Solve the backward wave equation in $V_{\tilde{L}}$,

$$\mathbf{M}\psi_{0,\tilde{L}}''(t) + \mathbf{A}\psi_{0,\tilde{L}}(t) = 0, \qquad 0 < t < T, \tag{3.22}$$

with terminal data $(0,0)$ in $t = T$ and Dirichlet control at $x = 1$ given by $\partial_x^h \phi_{0,\tilde{L}}(1,t)$, with ∂_x^h defined as in (3.17), and denote by $\psi_{0,\tilde{L}}$ the corresponding solution.

  (c) (Filtering.)
  Restrict $\psi_{0,\tilde{L}}$ to the coarse space,

$$\psi_{0,L} = I_{\tilde{L}}^{L} \psi_{0,\tilde{L}},$$

and denote by $\psi_{0,L}$ the restricted functions.

  (d) Compute $g_0 = \{g_0^0, g_0^1\} \in V_L \times V_L$, solving the discrete problem

$$\mathbf{A}(g_0^0) = (\partial_t \psi_{0,L})(0) - u^1 \text{ in } (0,1), \quad g_0^0 \in V_L, \tag{3.23}$$

and set

$$g_0^1 = u^0 - \psi_{0,L}(0), \quad g_0^1 \in V_L, \tag{3.24}$$

If $g_0 = 0$ or is , take $e_L = e_0$; if not, set

$$w_0 = g_0. \tag{3.25}$$

- Step 1.
  Then, for $k \geq 0$, assuming that e_k, g_k, w_k, $\phi_{k,L}$, $\psi_{k,L}$ are known, compute e_{k+1}, g_{k+1}, w_{k+1}, $\phi_{k+1,L}$, $\psi_{k+1,L}$ as follows:
  Solve

$$\mathbf{M}\phi_{k,\tilde{L}}''(t) + \mathbf{A}\phi_{k,\tilde{L}}(t) = 0, \qquad 0 < t < T, \tag{3.26}$$

in $V_{\tilde{L}}$ with sufficiently large $\tilde{L} > L$, initialized by

$$\phi_{k,L}(0) = w_k^0, \quad \partial_t \phi_{k,L}(0) = w_k^1, \tag{3.27}$$

$$\phi_{k,\tilde{L}}(0) = I_L^{\tilde{L}} \phi_{k,L}(0), \quad \partial_t \phi_{k,\tilde{L}}(0) = I_L^{\tilde{L}} \partial_t \phi_{k,L}(0), \tag{3.28}$$

and denote by $\phi_{k,\tilde{L}}$ the corresponding solution; solve in $V_{\tilde{L}}$ the backward time system

$$\mathbf{M}\psi''_{k,\tilde{L}}(t) + \mathbf{A}\psi_{k,\tilde{L}}(t) = 0, \qquad 0 < t < T, \tag{3.29}$$

with final data $(0,0)$ in $t = T$ and with Dirichlet control at $x = 1$ given by $\partial_x^h \phi_{k,\tilde{L}}(1,t)$ with ∂_x^h defined as in (3.17) and with L in place of $\tilde{L}$. This corresponds to truncation of the high-frequency components in the calculation of the numerical control. We denote by $\psi_{k,\tilde{L}}$ the corresponding solution.

Restrict $\psi_{k,\tilde{L}}$ to the coarse space: take

$$\psi_{k,L} = I_{\tilde{L}}^L \psi_{k,\tilde{L}}$$

and denote by $\psi_{k,L}$ the resulting functions.

Compute $g_k = \{g_k^0, g_k^1\} \in V_L \times V_L$, solving the discrete problem

$$A(g_k^0) = (\partial_t \psi_{k,L})(0) \text{ in } (0,1), \quad g_k^0 \in V_L, \tag{3.30}$$

and then

$$g_k^1 = -\psi_{k,L}(0), \quad g_k^1 \in V_L. \tag{3.31}$$

Compute

$$\rho_k = \frac{(|g_k^0|^2_{\hbar^{-1}} + |g_k^1|^2_{\ell^2})}{(g_k^0, w_k^0)_{\hbar^{-1} \times \hbar^1} + (g_k^1, w_k^1)_{\ell^2}}, \tag{3.32}$$

and

$$e_{k+1} = e_k - \rho_k w_k, \tag{3.33}$$

$$\phi_{k+1,L} = \phi_{k,L} - \rho_k \phi_{k,L}, \tag{3.34}$$

$$\psi_{k+1,L} = \psi_{k,L} - \rho_k \psi_{k,L}, \tag{3.35}$$

$$g_{k+1} = g_k - \rho_k g_k. \tag{3.36}$$

- Step 2. [illegible]
If $g_{k+1} = 0$ or is [illegible], take $e_L = e_{k+1}$, $\phi_L = \phi_{k+1,L}$, $\psi_L = \psi_{k+1,L}$; otherwise, compute

$$\gamma_n = \frac{(|g_{k+1}^0|^2_{\hbar^{-1}} + |g_{k+1}^1|^2_{\ell^2})}{(|g_k^0|^2_{\hbar^{-1}} + |g_k^1|^2_{\ell^2})}, \tag{3.37}$$

and set the new descent direction by

$$w_{k+1} = g_{k+1} + \gamma_k w_k. \tag{3.38}$$

Set $k := k + 1$ and go to (3.26).

3.6. Matrix representation of Λ. By (2.6) and (2.7), for $T \geq T_{\min} = 2$ the operator Λ is continuous and coercive in the $\|\cdot\|_E$-norm (2.8). If we expand both ϕ^0 and ϕ^1 in the wavelet series

$$\phi^0 = \sum_{l=0}^{\infty} \sum_{j=0}^{2^l-1} \phi^0_{j,l} \psi^l_j, \quad \phi^1 = \sum_{l=0}^{\infty} \sum_{j=0}^{2^l-1} \phi^1_{j,l} \psi^l_j$$

(prewavelet basis or the wavelets as in Example 2) and exploit the norm equivalencies as in (3.7), then (2.6)–(2.7) become

$$|\langle \Lambda\{\phi^0, \phi^1\}, \{\hat{\phi}^0, \hat{\phi}^1\}\rangle| \leq C \left[\sum_{l=0}^{\infty} \sum_{k=0}^{2^l-1} \left(\phi^0_{k,l}\right)^2 2^l + \sum_{l=0}^{\infty} \sum_{k=0}^{2^l-1} \left(\phi^1_{k,l}\right)^2 2^{-l} \right]^{1/2} \times \left[\sum_{l=0}^{\infty} \sum_{k=0}^{2^l-1} \left(\hat{\phi}^0_{k,l}\right)^2 2^l + \sum_{l=0}^{\infty} \sum_{k=0}^{2^l-1} \left(\hat{\phi}^1_{k,l}\right)^2 2^{-l} \right]^{1/2} \tag{3.39}$$

and

$$\langle \Lambda\{\phi^0, \phi^1\}, \{\phi^0, \phi^1\}\rangle \geq \gamma \left[\sum_{l=0}^{\infty} \sum_{k=0}^{2^l-1} \left(\phi^0_{k,l}\right)^2 2^l + \sum_{l=0}^{\infty} \sum_{k=0}^{2^l-1} \left(\phi^1_{k,l}\right)^2 2^{-l} \right]. \tag{3.40}$$

Denote by $\mathbf{\Lambda}_{L,\tilde{L}}$ the matrix corresponding to the wavelet representation of $\Lambda_{L,\tilde{L}}$. This matrix is an $\mathbb{R}^{2N_L \times 2N_L}$ block matrix of the form

$$\mathbf{\Lambda}_{L,\tilde{L}} = \begin{pmatrix} \mathbf{\Lambda}_1 & \mathbf{\Lambda}_2 \\ \mathbf{\Lambda}_3 & \mathbf{\Lambda}_4 \end{pmatrix},$$

with

$$(\mathbf{\Lambda}_1)_{(j,l),(\hat{\jmath},\hat{l})} = \langle \mathbf{\Lambda}_{L,\tilde{L}}\{\psi^l_j, 0\}, \{\psi^{\hat{l}}_{\hat{\jmath}}, 0\}\rangle, \quad (\mathbf{\Lambda_2})_{(j,l),(\hat{\jmath},\hat{l})} = \langle \mathbf{\Lambda}_{L,\tilde{L}}\{\psi^l_j, 0\}, \{0, \psi^{\hat{l}}_{\hat{\jmath}}\}\rangle,$$

$$(\mathbf{\Lambda}_3)_{(j,l),(\hat{\jmath},\hat{l})} = \langle \mathbf{\Lambda}_{L,\tilde{L}}\{0, \psi^l_j\}, \{\psi^{\hat{l}}_{\hat{\jmath}}, 0\}\rangle, \quad (\mathbf{\Lambda}_4)_{(j,l),(\hat{\jmath},\hat{l})} = \langle \mathbf{\Lambda}_{L,\tilde{L}}\{0, \psi^l_j\}, \{0, \psi^{\hat{l}}_{\hat{\jmath}}\}\rangle.$$

To simplify the notation we omit the level L (or $\tilde{L}$) and the index $_w$, unless necessary. By $\sum_{j,l}$ we will always understand $\sum_{l=0}^{L} \sum_{j \in \mathcal{I}_l}$, with $\mathcal{I}_l = \{0, 1, \ldots, 2^l - 1\}$. Then we have

$$\begin{aligned} \Lambda_{L,\tilde{L}}\{\phi^0, \phi^1\} &= \Lambda_{L,\tilde{L}} \left\{ \sum_{j,l} \phi^0_{j,l} \psi^l_j, \sum_{p,q} \phi^1_{p,q} \psi^q_p \right\} \\ &= \Lambda_{L,\tilde{L}} \left\{ \sum_{j,l} \phi^0_{j,l} \psi^l_j, 0 \right\} + \Lambda_{L,\tilde{L}} \left\{ 0, \sum_{p,q} \phi^1_{p,q} \psi^q_p \right\} \\ &= \sum_{j,l} \phi^0_{j,l} \Lambda_{L,\tilde{L}}\{\psi^l_j, 0\} + \sum_{p,q} \phi^1_{p,q} \Lambda_{L,\tilde{L}}\{0, \psi^q_p\}. \end{aligned}$$

Therefore,

(3.41)

$$= \begin{pmatrix} \underline{\hat{\phi}}^0 \\ \\ \underline{\hat{\phi}}^1 \end{pmatrix}^\top \mathbf{\Lambda}_{L,\tilde{L}} \begin{pmatrix} \underline{\phi}^0 \\ \\ \underline{\phi}^1 \end{pmatrix} = \langle \Lambda_{L,\tilde{L}}\{\phi^0,\phi^1\},\{\hat{\phi}^0,\hat{\phi}^1\}\rangle$$

$$= \left\langle \Lambda_{L,\tilde{L}} \left\{ \sum_{j,l} \phi^0_{j,l}\psi^l_j, \sum_{p,q} \phi_{p,q}\psi^q_p \right\}, \left\{ \sum_{\hat{j},\hat{l}} \hat{\phi}^0_{\hat{j},\hat{l}}\psi^{\hat{l}}_{\hat{j}}, \sum_{\hat{p},\hat{q}} \hat{\phi}^1_{\hat{p},\hat{q}}\psi^{\hat{q}}_{\hat{p}} \right\} \right\rangle$$

$$= \left\langle \sum_{j,l} \phi^0_{j,l}\Lambda_{L,\tilde{L}}\{\psi^l_j,0\} + \sum_{p,q} \phi^1_{p,q}\Lambda_{L,\tilde{L}}\{0,\psi^q_p\}, \sum_{\hat{j},\hat{l}} \hat{\phi}^0_{\hat{j},\hat{l}}\{\psi^{\hat{l}}_{\hat{j}},0\} + \sum_{\hat{p},\hat{q}} \hat{\phi}^1_{\hat{p},\hat{q}}\{0,\psi^{\hat{q}}_{\hat{p}}\} \right\rangle$$

$$= \sum_{j,l}\sum_{\hat{j},\hat{l}} \phi^0_{j,l}\hat{\phi}^0_{\hat{j},\hat{l}}\langle \Lambda_{L,\tilde{L}}\{\psi^l_j,0\},\{\psi^{\hat{l}}_{\hat{j}},0\}\rangle + \sum_{p,q}\sum_{\hat{j},\hat{l}} \phi^1_{p,q}\hat{\phi}^0_{\hat{j},\hat{l}}\langle \Lambda_{L,\tilde{L}}\{0,\psi^q_p\},\{\psi^{\hat{l}}_{\hat{j}},0\}\rangle$$

$$+ \sum_{j,l}\sum_{\hat{p},\hat{q}} \phi^0_{j,l}\hat{\phi}^1_{\hat{p},\hat{q}}\langle \Lambda_{L,\tilde{L}}\{\psi^l_j,0\},\{0,\psi^{\hat{q}}_{\hat{p}}\}\rangle + \sum_{p,q}\sum_{\hat{p}\hat{q}} \phi^1_{p,q}\hat{\phi}^1_{\hat{p},\hat{q}}\langle \Lambda_{L,\tilde{L}}\{0,\psi^q_p\},\{0,\psi^{\hat{q}}_{\hat{p}},\}\rangle$$

$$= \begin{pmatrix} \underline{\hat{\phi}}^0 \\ \\ \underline{\hat{\phi}}^1 \end{pmatrix}^\top \begin{pmatrix} \mathbf{\Lambda}_1 & \mathbf{\Lambda}_2 \\ \\ \mathbf{\Lambda}_3 & \mathbf{\Lambda}_4 \end{pmatrix} \begin{pmatrix} \underline{\phi}^0 \\ \\ \underline{\phi}^1 \end{pmatrix}.$$

We note that the matrix corresponding to $\Lambda_{L,\infty}$ is a finite section of the matrix $\mathbf{\Lambda}$.

3.7. Convergence of the discrete controls. In this section we prove the convergence of the two-grid filtering procedure for finite element controls.

THEOREM 3.4. [illegible] $\{\psi^l_j\}$ [illegible] $e_L := \{\phi^0_L,\phi^1_L\}$ $\bar{e}_L := \{\bar{\phi}^0_L,\bar{\phi}^1_L\} \in E$ [illegible] $L > 0$

$$|\langle (\Lambda_{L,\tilde{L}} - \Lambda)e_L,\bar{e}_L\rangle| \le o(1)\|e_L\|_E\|\bar{e}_L\|_E, \tag{3.42}$$

[illegible] $o(1)$ [illegible] $\tilde{L} \to \infty$ [illegible]. For every $\tilde{L} > L > 0$ we have

$$\begin{aligned} \langle (\Lambda_{L,\tilde{L}} - \Lambda)e_L,\bar{e}_L\rangle &= \langle (P_L\Lambda_{\tilde{L}} - \Lambda_{\tilde{L}} + \Lambda_{\tilde{L}} - \Lambda_\infty)e_L,\bar{e}_L\rangle \\ &= \langle (P_L\Lambda_{\tilde{L}} - \Lambda_{\tilde{L}})e_L,\bar{e}_L\rangle + \langle (\Lambda_{\tilde{L}} - \Lambda_\infty)e_L,\bar{e}_L\rangle. \end{aligned} \tag{3.43}$$

We discuss the two terms separately.

For the first term, we use the first representation in (2.5) of the inner product $\langle\cdot,\cdot\rangle$. We note that for every $e_L \in (V_L)^2$, $\Lambda_{\tilde{L}}e_L \in (V_{\tilde{L}})^2$. More precisely, the solution $\psi_{\tilde{L}}(x,t)$ of the backward controlled, space semidiscrete wave equation can be written as

$$\psi_{\tilde{L}}(x,t) = \sum_{l=0}^{\tilde{L}} \sum_{j\in\mathcal{I}_l} c^l_j(t)\psi^l_j(x),$$

where the $c_j^l(t)$ are obtained by solving the ODEs for the space semidiscrete wave equation in the definition of the operator $\Lambda_{\tilde{L}}$. By (3.16), we then find

$$\Lambda_{\tilde{L}} e_L = \left\{ \sum_{l=0}^{\tilde{L}} \sum_{j\in\mathcal{I}_l} (c_j^l)'(0)\psi_j^l(x),\ -\sum_{l=0}^{\tilde{L}} \sum_{j\in\mathcal{I}_l} c_j^l(0)\psi_j^l(x) \right\},$$

and by the $L^2(0,1)$-orthogonality of the prewavelets between scales,

$$\langle \Lambda_{\tilde{L}} e_L - P_L \Lambda_{\tilde{L}} e_L, \bar{e}_L \rangle = 0, \tag{3.44}$$

and by the L^2-orthogonality of the prewavelets,

$$\langle (P_L \Lambda_{\tilde{L}} - \Lambda_{\tilde{L}}) e_L, \bar{e}_L \rangle \le o(1) \|e_L\|_E \|\bar{e}_L\|_E. \tag{3.45}$$

$o(1)$ tends to 0 when $\tilde{L} \to \infty$ and it is independent of e_L and $\bar{e}_L$.

Let $T > 0$. Denote by $\phi^L(x,t)$, $\bar{\phi}^L(x,t)$ the solutions of the continuous wave equation (1.4) with initial data $e_L := \{\phi_L^0, \phi_L^1\}$, $\bar{e}_L := \{\bar{\phi}_L^0, \bar{\phi}_L^1\} \in E$, respectively. By definition we have $\Lambda_\infty = \Lambda$ and

$$\langle \Lambda e_L, \bar{e}_L \rangle = \int_0^T \frac{\partial \phi^L}{\partial x}(1,t) \frac{\partial \bar{\phi}^L}{\partial x}(1,t) dt.$$

Let $\phi^{L,\tilde{L}}(h,t)$, $\bar{\phi}^{L,\tilde{L}}(h,t) \in V_{\tilde{L}}$ be the solutions of the semidiscrete homogeneous wave equation by finite element method in the fine space $V_{\tilde{L}}$ with initial data e_L, $\bar{e}_L \in (V_L)^2 \subset (V_{\tilde{L}})^2$, $N_{\tilde{L}} = 2^{\tilde{L}} - 1$, and $h = 2^{-\tilde{L}}$. The corresponding coefficient vectors in the hat basis are $\underline{\phi}^{L,\tilde{L}}(h,t) = (\phi_j^{L,\tilde{L}}(h,t))_{j=1,\dots,N_{\tilde{L}}}$, $\underline{\bar{\phi}}^{L,\tilde{L}}(h,t) = (\bar{\phi}_j^{L,\tilde{L}}(h,t))_{j=1,\dots,N_{\tilde{L}}}$, respectively. Following [4, section 6] the operator $\Lambda_{\tilde{L}}$ satisfies

$$\langle \Lambda_{\tilde{L}} e_L, \bar{e}_L \rangle = \int_0^T \frac{\phi_{N_{\tilde{L}}}^{L,\tilde{L}}(h,t)}{h} \frac{\bar{\phi}_{N_{\tilde{L}}}^{L,\tilde{L}}(h,t)}{h} dt.$$

Therefore we get

$$\begin{aligned}
\langle (\Lambda_{\tilde{L}} - \Lambda_\infty) e_L, \bar{e}_L \rangle &= \int_0^T \frac{\phi_{N_{\tilde{L}}}^{L,\tilde{L}}(h,t)}{h} \frac{\bar{\phi}_{N_{\tilde{L}}}^{L,\tilde{L}}(h,t)}{h} dt - \int_0^T \frac{\partial \phi^L(1,t)}{\partial x} \frac{\partial \bar{\phi}^L(1,t) dt}{\partial x} dt \\
&= \int_0^T \frac{\phi_{N_{\tilde{L}}}^{L,\tilde{L}}(h,t)}{h} \left(\frac{\bar{\phi}_{N_{\tilde{L}}}^{L,\tilde{L}}(h,t)}{h} + \frac{\partial \bar{\phi}^L(1,t) dt}{\partial x} \right) dt \\
&\quad - \int_0^T \frac{\partial \bar{\phi}^L(1,t) dt}{\partial x} \left(\frac{\phi_{N_{\tilde{L}}}^{L,\tilde{L}}(h,t)}{h} + \frac{\partial \phi^L(1,t)}{\partial x} \right) dt.
\end{aligned}$$

On the other hand, for every $T > 0$ we have

$$\int_0^T \left| \frac{\phi_{N_{\tilde{L}}}^{L,\tilde{L}}(h,t)}{h} \right|^2 dt \le C(T) \|e_L\|_E, \qquad \int_0^T \left| \frac{\partial \bar{\phi}^L(1,t) dt}{\partial x} \right|^2 dt \le C(T) \|\bar{e}_L\|_E$$

(see inequality (2.72) in [6] and Corollaire 4.1. in [7]).

Clearly, to obtain (3.42) it suffices to prove that for every e_L and $\bar{e}_L$ with $\|e_L\|_E = \|\bar{e}_L\|_E = 1$, as $\tilde{L} \to \infty$,

(3.46)
$$\int_0^T \left| \frac{\phi_{N_{\tilde{L}}}^{L,\tilde{L}}(h,t)}{h} + \frac{\partial \phi^L(1,t)}{\partial x} \right|^2 dt \le o(1), \qquad \int_0^T \left| \frac{\bar{\phi}_{N_{\tilde{L}}}^{L,\tilde{L}}(h,t)}{h} + \frac{\partial \bar{\phi}^L(1,t)}{\partial x} \right|^2 dt \le o(1).$$

Since $\dim V_L < \infty$, it suffices to prove the strong convergence in $L^2(0,T)$ of the discrete controls

$$-\frac{\phi_{N_{\tilde{L}}}^{L,\tilde{L}}(h,t)}{h} \underset{\tilde{L}\to\infty}{\to} \frac{\partial \phi^L(1,t)}{\partial x}, \qquad -\frac{\bar{\phi}_{N_{\tilde{L}}}^{L,\tilde{L}}(h,t)}{h} \underset{\tilde{L}\to\infty}{\to} \frac{\partial \bar{\phi}^L(1,t)}{\partial x} \tag{3.47}$$

for every fixed e_L and $\bar{e}_L$, respectively. This fact is a consequence of the following theorem.

THEOREM 3.5. [illegible] L

$$-\frac{\phi_{N_{\tilde{L}}}^{L,\tilde{L}}(h,t)}{h} \to \frac{\partial \phi^L(1,t)}{\partial x} \quad \text{[illegible]} \quad L^2(0,T) \tag{3.48}$$

[illegible] $\tilde{L} \to \infty$

The proof of Theorem 3.5 is given in the appendix. As an immediate consequence of (3.48) we deduce that

$$\forall L, \quad \forall \tilde{e}_L, e_L \in V_L, \quad |\langle (\Lambda_{\tilde{L}} - \Lambda)\, e_L, \bar{e}_L \rangle| \le o(1) \|e_L\|_E \|\bar{e}_L\|_E \quad \text{as } \tilde{L} \to \infty. \tag{3.49}$$

Therefore, combining (3.44) and (3.49) we deduce that (3.42) holds with $o(1)$ tending to 0 when $\tilde{L} \to \infty$, it is independent of e_L and $\bar{e}_L$, and the proof of Theorem 3.4 is now complete. ∎

3.8. Multilevel preconditioning of $\mathbf{\Lambda_{L,\tilde{L}}}$. Since the HUM algorithm is essentially a conjugate gradient iteration on the operator $\Lambda_{L,\tilde{L}}$, with each iteration amounting to the solution of two wave equations, the number of iteration steps should be kept small. We will precondition the discretized operator Λ by a diagonal wavelet preconditioner of the form $\mathbf{D}_L^{-1/2} \mathbf{\Lambda}_{L,\tilde{L}} \mathbf{D}_L^{-1/2}$. Based on the continuity and coercivity of Λ, (2.6) and (2.7), and using the norm equivalence (3.7), the preconditioned matrix $\mathbf{\Lambda}_{L,\tilde{L}}$ is given by

$$\mathbf{D}_L = \begin{pmatrix} \mathbf{D}_L^1 & 0 \\ 0 & \mathbf{D}_L^2 \end{pmatrix}, \tag{3.50}$$

where $\mathbf{D}_L^1 = \mathrm{diag}(1 : 2^l,\, l = 0, \ldots, L)$ and $\mathbf{D}_L^2 = \mathrm{diag}(1 : 2^{-l},\, l = 0, \ldots, L)$. Based on the norm equivalences, we obtain the following.

THEOREM 3.6. [illegible] $\mathbf{D}_L^{-1/2} \mathbf{\Lambda}_{L,\tilde{L}} \mathbf{D}_L^{-1/2}$ [illegible] L [illegible]. The proof is a direct consequence of (2.6)–(2.7), of the norm equivalence (3.7) as expressed in (3.39)–(3.40), and of the approximation result of Theorem 3.4. Indeed, given $C, \gamma > 0$, and given L, by (3.42) there exists $\tilde{L} > L$ (see the uniform observability inequality in [8] and [11] for every $T \ge 2$) such that

$$|\langle (\Lambda_{L,\tilde{L}} - \Lambda) e_L, \bar{e}_L \rangle| \le C \|e_L\|_E \|\bar{e}_L\|_E \quad \forall\, e_L, \bar{e}_L \in (V_L)^2,$$
$$\langle (\Lambda_{L,\tilde{L}} - \Lambda) e_L, e_L \rangle \ge \frac{\gamma}{2} \|e_L\|_E^2 \quad \forall\, e_L \in (V_L)^2.$$

With the constants $C > 0$, $\gamma > 0$ being now as in (3.39)–(3.40) (in particular, C, γ are independent of L) we infer

$$|\langle \Lambda_{L,\tilde{L}} e_L, \bar{e}_L \rangle| \le 2C \|e_L\|_E \|\bar{e}_L\|_E \quad \forall\, e_L, \bar{e}_L \in (V_L)^2, \tag{3.51}$$

$$\langle \Lambda_{L,\tilde{L}} e_L, e_L \rangle = \langle \Lambda e_L, e_L \rangle + \langle (\Lambda_{L,\tilde{L}} - \Lambda) e_L, e_L \rangle \ge \frac{\gamma}{2} \|e_L\|_E^2 \quad \forall\, e_L \in (V_L)^2. \tag{3.52}$$

By the norm equivalence (3.7), there exist constants C_1, $C_2 > 0$ independent of L such that

$$C_1 \|\mathbf{D}_L^{1/2} \begin{pmatrix} \underline{\phi}^0 \\ \underline{\phi}^1 \end{pmatrix} \|_{\ell^2}^2 \le \|e_L\|_E^2 \le C_2 \|\mathbf{D}_L^{1/2} \begin{pmatrix} \underline{\phi}^0 \\ \underline{\phi}^1 \end{pmatrix} \|_{\ell^2}^2 \quad \forall\, e_L = (\phi_L^0, \phi_L^1) \in (V_L)^2, \tag{3.53}$$

where we denoted by $\underline{\phi}^0$, $\underline{\phi}^1$ the wavelet coefficients of ϕ_L^0, ϕ_L^1 in the prewavelet basis. By (3.51)–(3.52) and from inequality (3.53) we conclude that the condition number of $\mathbf{D}_L^{-1/2} \mathbf{\Lambda}_{L,\tilde{L}} \mathbf{D}_L^{-1/2}$ is bounded independent of L. □

4. Numerical results. From the theoretical point of view, it is convenient to choose $\tilde{L}$ possibly much larger than L since $\tilde{L} = \infty$ corresponds to an exact solution of the wave equations. In this case the operator Λ is linear, continuous, and coercive and bounded uniformly with respect to L. If the time-stepping scheme used for the numerical solution of the wave equations is convergent (i.e., in particular, consistent and stable as $\tilde{L} \to \infty$ and as $\Delta t \to 0$), a Strang-type perturbation argument will yield smallness of the resulting perturbation of Λ_L so that $\Lambda_{L,\tilde{L}}$ will also be uniformly bounded with respect to L [illegible] $\tilde{L}$ [illegible] L. This will imply in particular the convergence of the HUM controls as $\tilde{L} \to \infty$ under the condition that $\tilde{L}/L > 1$ be fixed sufficiently large, independently of L.

In this section, we present numerical results of the wavelet-based HUM applied to (1.1). For this example, we found $\tilde{L} = L + 1$ to be sufficient for stability and convergence (with the controllability time $T \ge 2$).

4.1. Wavelet preconditioning and compression of Λ. First we study numerically wavelet preconditioning, the sparsity pattern of the matrix $\mathbf{\Lambda}_{L,\tilde{L}}$, and the sparsity pattern of the matrix $\mathbf{\Lambda}_{L,\tilde{L}}$.

In Figures 4.1 and 4.2 we present the sparsity pattern of the matrix $\mathbf{\Lambda}_{L,L+1}$ for the case when $L \in \{6, 7\}$ and $\alpha = \Delta t/\Delta x \in \{1, 1/5\}$, respectively. Notice that the "off-diagonal" blocks in the first case ($\alpha = 1$) are zeros, as expected from theoretical considerations.

[illegible] 4.1. In the continuous case, the solution of (1.4) admits a Fourier development on the basis of eigenvectors $\{\sin(k\pi x)\}_k$. More precisely, every solution $\phi = \phi(x,t)$ can be written as

$$\phi(x,t) = \sum_{k=0}^{\infty} \left(a_k \cos(k\pi t) + \frac{b_k}{k\pi} \sin(k\pi t) \right) \sin(k\pi x) \tag{4.1}$$

for suitable coefficients a_k, $b_k \in \mathbb{R}$, $k > 0$, that can be computed explicitly in terms of the initial data:

$$\phi^0(x) = \phi(x,0) = \sum_{k=0}^{\infty} a_k \sin(k\pi x), \quad \phi^1(x) = \phi_t(x,0) = \sum_{k=0}^{\infty} b_k \sin(k\pi x).$$

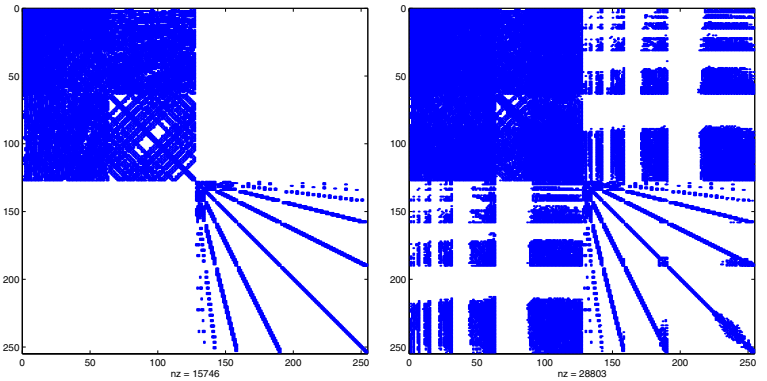

FIG. 4.1. *Sparsity pattern of the matrix* $\mathbf{\Lambda}_{L,L+1}$ *with* $L = 6$, $\alpha = \Delta t/\Delta x = 1$ (*left*) *and* $\alpha = \Delta t/\Delta x = 1/5$ (*right*)*; truncation threshold* $\epsilon = 10^{-10}$.

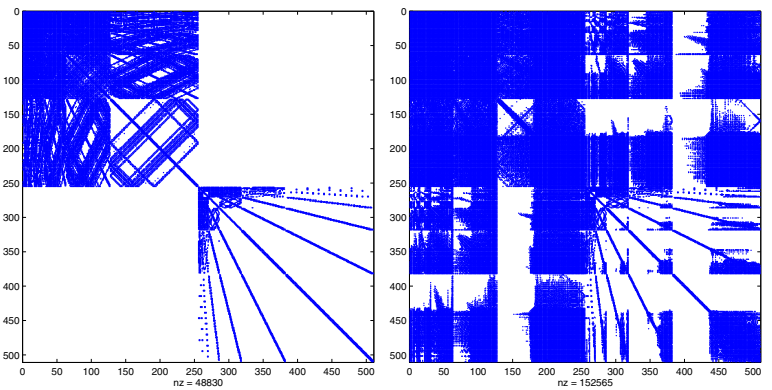

FIG. 4.2. *Sparsity pattern of the matrix* $\mathbf{\Lambda}_{L,L+1}$ *with* $L = 7$, $\alpha = \Delta t/\Delta x = 1$ (*left*) *and* $\alpha = \Delta t/\Delta x = 1/5$ (*right*)*; truncation threshold* $\epsilon = 10^{-10}$.

To define $\mathbf{\Lambda}_2$, we use the solutions

$$\phi(x,t) = \sum_{k=0}^{\infty} a_k \cos(k\pi t)\sin(k\pi x), \quad \hat{\phi}(x,t) = \sum_{k=0}^{\infty} \frac{\hat{b}_k}{k\pi}\sin(k\pi t)\sin(k\pi x)$$

corresponding to the initial data $(\phi^0, 0)$ and $(0, \hat{\phi}^1)$, respectively.

In this case we have

$$\begin{aligned}\int_0^T \frac{\partial\phi(1,t)}{\partial x}\frac{\partial\hat{\phi}(1,t)}{\partial x}dt &= \int_0^T \left(\sum_k k\pi(-1)^k a_k\cos(k\pi t)\right)\left(\sum_l (-1)^l \hat{b}_l \sin(l\pi t)\right)dt \\ &= \sum_{k,l} k\pi(-1)^{k+l} a_k \hat{b}_l \int_0^T \cos(k\pi t)\sin(l\pi t)dt.\end{aligned}$$

For $T = T_{\min} = 2$ it holds that $\int_0^T \cos(k\pi t)\sin(l\pi t)dt = 0$ for all k, l. Consequently, $\mathbf{\Lambda}_2 = 0$.

On the other hand, according to (4.1), the solutions of the homogeneous wave

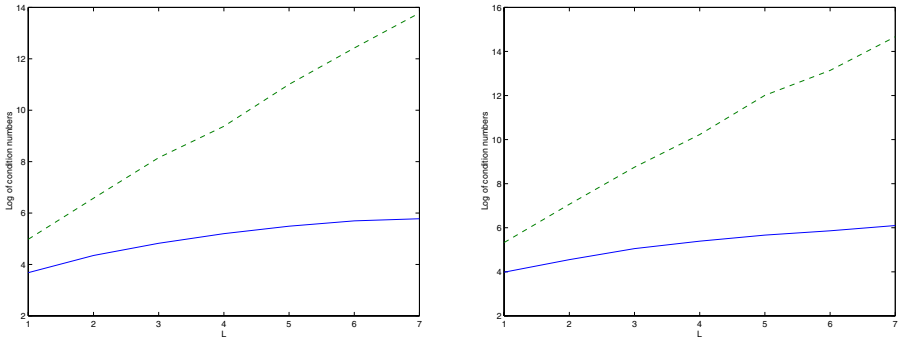

FIG. 4.3. *Natural logarithm of condition numbers of* $\mathbf{\Lambda}_{L,L+1}$ *versus* L *for* $\alpha = 1$ (*left*) *and* $\alpha = 1/5$ (*right*) *with* (*solid line*) *and without* (*dashed line*) *wavelet preconditioner.*

equation with initial data $(0, \phi^1)$ and $(\hat{\phi}^0, 0)$ are

$$\phi(x,t) = \sum_{k=0}^{\infty} \frac{b_k}{k\pi} \sin(k\pi t) \sin(k\pi x), \quad \hat{\phi}(x,t) = \sum_{k=0}^{\infty} \hat{a}_k \cos(k\pi t) \sin(k\pi x),$$

respectively. We deduce that

$$\int_0^T \frac{\partial \phi(1,t)}{\partial x} \frac{\partial \hat{\phi}(1,t)}{\partial x} dt = \sum_{k,l} l\pi(-1)^{k+l} b_k \hat{a}_l \int_0^T \sin(k\pi t) \cos(l\pi t) dt = 0$$

for all $k, l > 0$ and $T = T_{\min} = 2$. Thus, the other off-diagonal block $\mathbf{\Lambda}_4$ satisfies $\mathbf{\Lambda}_4 = 0$.

In Figure 4.3 we illustrate the effect of the wavelet preconditioners on the condition numbers of the matrix $\mathbf{\Lambda}_{L,L+1}$ for the values $\alpha = 1$ and $\alpha = 1/5$ for $L = 1, \ldots, 7$: the diagonal wavelet preconditioner reduces the condition of $\mathbf{\Lambda}_{L,L+1}$ by several orders of magnitude. We have used in our computations the spline-wavelet basis of Example 2; see Figure 3.1.

4.2. Numerical convergence study of the controls. We present here numerical experiments in which we analyze the convergence of the numerical control in conjugate gradient iterations versus L.

The above numerical experiments have been done with $T = 2$. In Table 4.1 ($\alpha = 1$) and in Table 4.2 ($\alpha = 1/5$), $L =$ level and it$(\cdot)$ is the number of conjugate gradient iterations necessary to achieve convergence with

$$(1) \begin{cases} u^0(x) = \sin(5\pi x), \\ u^1(x) = \begin{cases} x, & x \in [0, 1/2), \\ 0, & x \in (1/2, 1], \end{cases} \end{cases}$$

for it(1) and with

$$(2) \begin{cases} u^0(x) = \begin{cases} 0, \\ \text{for } i = 1:10,\ u^0(x) = u^0(x) + \sin(i\pi x), \\ u^0(x) = u^0(x)/10, \end{cases} \\ u^1(x) = 0 \end{cases}$$

for it(2).

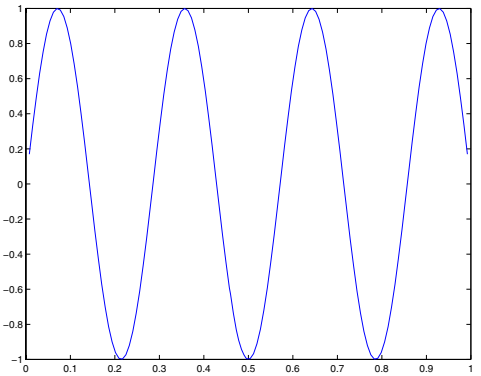
4.3. Numerically exact controllability. To obtain a fully discrete realization of Algorithm 3.3, we have to discretize with respect to time in (3.2). Perhaps the most widely used family of direct methods for solving (3.2) is that of Newmark [14]. By this way, the evolution equations are solved exactly in time. The convergence analysis of the Newmark family of methods is similar to the classical convergence analysis. CFL-type stability conditions must be satisfied for each mode in the discretized system: $\Delta t = \alpha\, h_L$, $\alpha \leq 1$, where the time step is Δt.

We implement this algorithm with $\tilde{L} = L+1$ and test the efficiency of the discrete HUM control v by visualizing and checking how far $u(\cdot, T)$ and $u_t(\cdot, T)$ differ from $(0, 0)$.

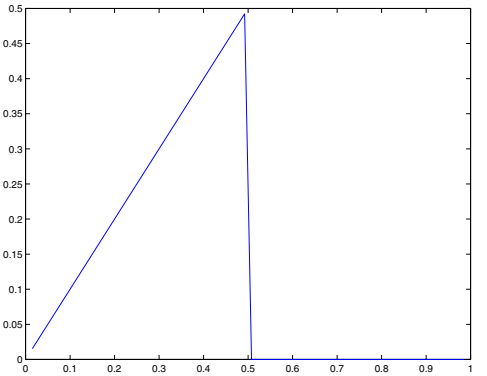
In Figures 4.4 and 4.5 we present two examples corresponding to (1) and (2) with $L = 7$. In each example, (a)–(b) describe the initial data (u^0, u^1) to be controlled along the mesh, (c) and (c′) correspond to the numerical solution u and derivative u' with numerical control which confirm the efficiency of the numerical control, and (d) shows the computed control.

4.4. Further comments and conclusions. We have discussed the numerical implementation of HUM, introduced in [7], applied to the exact controllability of the one-dimensional wave equation when the control is achieved by appropriate Dirichlet boundary conditions. It has been shown that, combining a multilevel finite element discretization and a two-grid filtering technique in the spline wavelet basis, we obtain quite effective numerical methods for approximating the boundary control. The results of Tables 4.1 and 4.2 compare favorably with those obtained using the Tychonoff regularization procedure in [5].

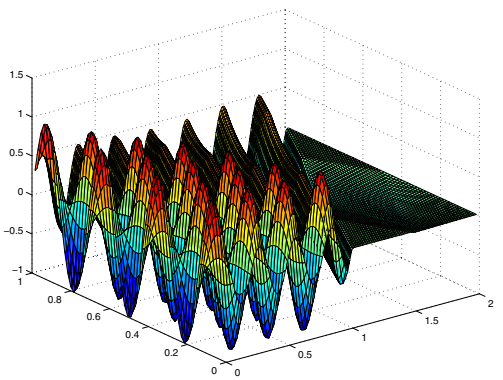
The following facts appear quite clearly: (a) the filtering method described in section 3.4 has been a very effective cure to the ill-posedness of the approximate problem (3.16); (b) as in [4, 5], the number of conjugate gradient iterations necessary to achieve the convergence in the optimal time $T = 2$ is essentially independent of Δx (and L).



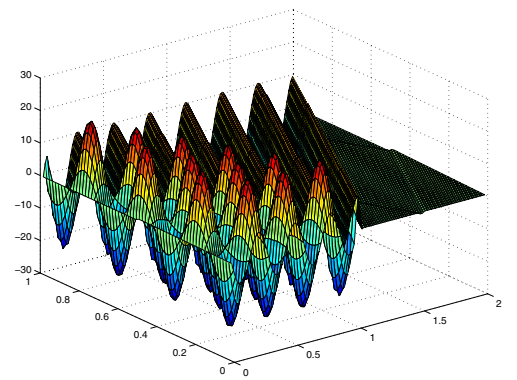
(a) Initial position (u^0).



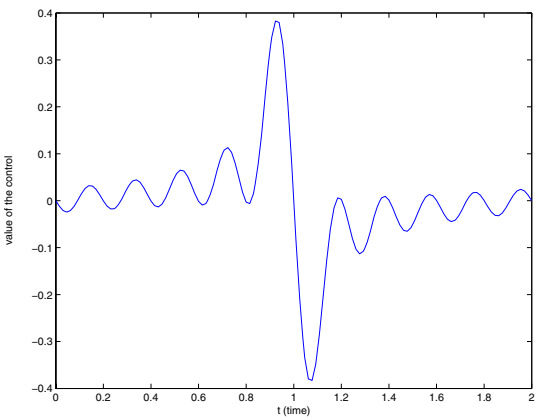
(b) Initial velocity (u^1).



(c) Numerical displacement (u).



(c′) Numerical velocity (u').

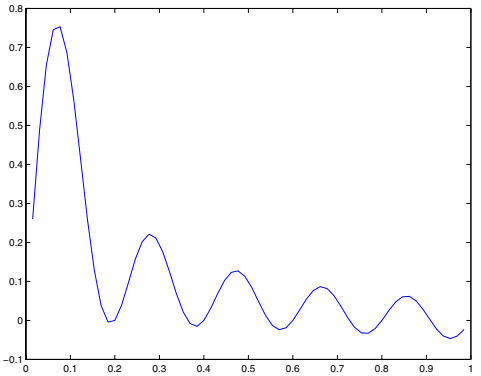


(d) Numerical control.

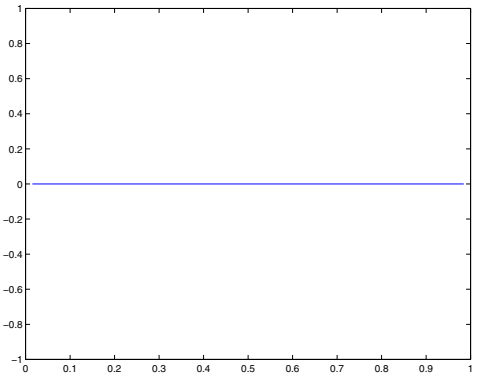
FIG. 4.4. (a)–(b) *Variation of initial data corresponding to* (1). (c)–(c′) *Variation of numerical displacement and numerical velocity with* (d) *numerical control.*

The numerical experiments presented are in very good agreement with the theory [8, 9, 10, 11]. Concerning the CPU time, the scheme appears comparable to the Tychonoff regularization method.

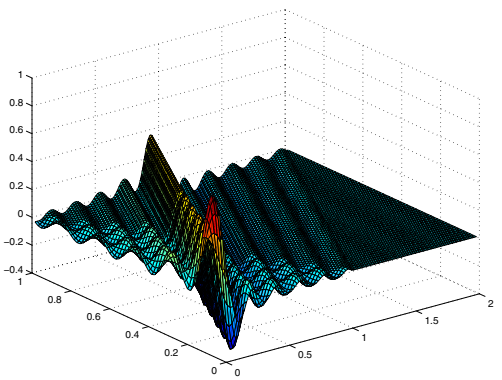
It is the intention of the authors to study whether or not it is possible to extend



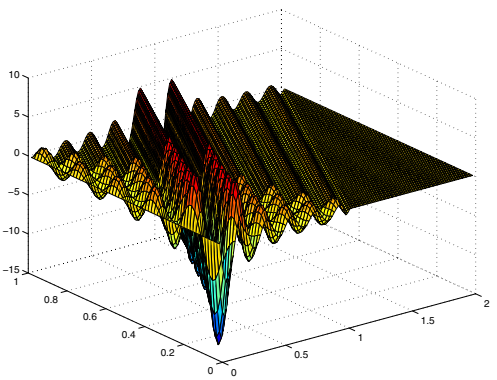
(a) Initial position (u^0).



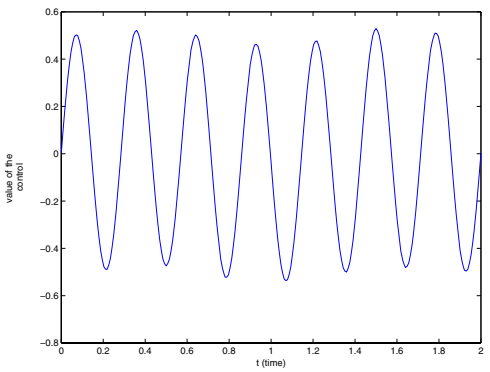
(b) Initial velocity (u^1).



(c) Numerical displacement (u).



(c′) Numerical velocity (u').



(d) Numerical control.

FIG. 4.5. *Variation of initial data* (a)–(b) *corresponding to* (2). (c)–(c′) *Variation of numerical displacement and numerical velocity with* (d) *numerical control.*

or adapt the present analysis to other types of boundary controls, to more complicated and complex time-dependent multidimensional models, such as, for instance, the equations modeling the vibrations of elastic plates. Indeed there are many ways to include multigrid procedures, and investigating them could in itself be an interesting study.

Appendix. Proof of Theorem 3.5. In this part we prove some general results. The convergences obtained in Lemmas A.1 and A.2 were proved in [17] for any bounded family of finite difference space semidiscretization solutions of the two-dimensional uncontrolled wave equation in the square. Here we prove similar results for the finite element method.

Given $\Omega = (0,1)$, $N \in \mathbb{N}$, we set $h = 1/(N+1)$ and denote by $\phi(h,t)$ the solution of the finite element space semidiscretization of the uncontrolled wave equation (3.1).

Let $\varphi_i(x) = \max(1 - |x - x_i|/h, 0)$ denote the hat function basis of V_h, and let $\underline{\phi}(h,t) = \{\phi_i(h,t)\}_{i=1}^N$ be the coefficient vector of $\phi(h,t)$ with respect to $\{\varphi_i\}$. The space semidiscrete wave equation (3.1) can be rewritten as

$$\mathbf{M}\frac{d^2}{dt^2}\underline{\phi}(h,t) + \mathbf{A}\underline{\phi}(h,t) = 0, \qquad 0 < t < T. \tag{A.1}$$

We adopt $\partial_x^h \phi(1,t) = -\frac{\phi_N(h,t)}{h}$ as an approximation of the normal derivative $\partial_x \phi(1,t)$. We consider the family $\{\phi(h,t)\}_h$ of solutions of (3.1) depending on the parameter h and study their limit behavior as $h \to 0$. The solution of (3.1) admits the Fourier expansion

$$\underline{\phi}(h,t) = \sum_{k \geq 1} m_k(h,t)\bar{\varphi}^k(h), \tag{A.2}$$

where $\bar{\varphi}^k(h) = (\varphi_1^k, \dots, \varphi_N^k)$ are the discrete eigenvectors $\varphi_j^k(h) = \sin(jk\pi h)$ and $m_k(h,t)$ are the time-dependent Fourier coefficients: $m_k(h,t) = 0$ for all $t > 0$ and $k \geq N+1$. In particular,

$$m_k(h,t) = m_k(h)e^{i\sqrt{\mu_k(h)}t},$$

with $\mu_k(h)$ being the discrete eigenvalues: $\mu_k(\mathbf{M}^{-1}\mathbf{A}) = \frac{6}{h^2}\frac{1-\cos(k\pi h)}{2+\cos(k\pi h)}$.

The conserved energy of system (3.1) is given by

$$E_h(0) = \frac{h}{6}\sum_{j=1}^{N}\left|\phi_j'(h,t)\right|^2 + \frac{h}{12}\sum_{j=0}^{N}\left|\phi_j'(h,t) + \phi_{j+1}'(h,t)\right|^2 + \frac{h}{2}\sum_{j=0}^{N}\left|\frac{\phi_j(h,t) - \phi_{j+1}(h,t)}{h}\right|^2. \tag{A.3}$$

In the following lemmas we prove that the bounded family of solutions of (3.1) weakly converges as $h \to 0$ to a solution of the continuous homogeneous wave equation (Lemma A.1). Moreover we analyze the behavior of the normal derivative of the solution of the semidiscrete problem (Lemma A.2).

LEMMA A.1. [illegible] $\{\phi(h,t)\}_h$ [illegible] (3.1) [illegible] h $h = 1/(N+1)$ $N \in \mathbb{N}$ [illegible] E_h [illegible]

$$E_h(0) \leq C \quad \forall h > 0. \tag{A.4}$$

[illegible]

$$m_k(h,\cdot) \underset{h\to 0}{\rightharpoonup} m_k(\cdot) \text{ [illegible] } H^1(0,T) \text{ [illegible] } h \to 0 \quad \forall k \in \mathbb{N}. \tag{A.5}$$

[illegible]

$$\phi = \sum_{k \geq 1} m_k(t)\sin(k\pi x), \tag{A.6}$$

[illegible] ϕ [illegible]

$$\phi \in \mathcal{C}([0,T]; H_0^1(0,1)) \cap \mathcal{C}^1([0,T]; L^2(0,1)), \tag{A.7}$$

$$E(0) \le \liminf_{h\to 0} E_h(0); \tag{A.8}$$

$$h\sum_{j=1}^{N} |\phi_j(h,t)|^2 \underset{h\to 0}{\to} \|\phi(t)\|^2_{L^2(0,1)} \text{ [illegible] } L^\infty(0,T). \tag{A.9}$$

[illegible]. Let us introduce the Hilbert spaces ℓ^2, $\hbar^1$, and $\hbar^{-1}$:

$$\ell^2 = \left\{ \{m_k\} \ : \ \|m_k\|^2_{\ell^2} = \sum_{k\in\mathbb{N}} |m_k|^2 < \infty \right\}, \tag{A.10}$$

$$\hbar^1 = \left\{ \{m_k\} \in \ell^2 \ : \ \|m_k\|^2_{\hbar^1} = \sum_{k\in\mathbb{N}} k^2 |m_k|^2 < \infty \right\}, \tag{A.11}$$

$$\hbar^{-1} = \left\{ \{m_k\} \in \ell^2 \ : \ \|m_k\|^2_{\hbar^{-1}} = \sum_{k\in\mathbb{N}} k^{-2} |m_k|^2 < \infty \right\}, \tag{A.12}$$

endowed with their canonical norms.

Due to the fact that the eigenvectors $\bar{\varphi}^k$ are orthogonal in the discrete L^2-norm, for all $k \in \{1, \dots, N\}$, we have

$$\begin{aligned} E_h(t) &= \frac{1}{2}\sum_k \left[|m_k'(h,t)|^2 + \mu_k(h) |m_k(h,t)|^2 \right] \frac{1 + 2\cos^2 \frac{k\pi h}{2}}{6} \\ &\ge \frac{1}{12} \left[\sum_k |m_k'(h,t)|^2 + k^2 |m_k(h,t)|^2 \right]. \end{aligned} \tag{A.13}$$

Then, from the uniform boundedness estimate (A.4) and the conservation of the energy, we deduce that

$$\vec{m}\,(h,\cdot) = \{m_k(h,\cdot)\}_{k\in\mathbb{N}} \text{ is uniformly bounded in } W^{1,\infty}(0,T;\ell^2) \text{ as } h \to 0. \tag{A.14}$$

Thus, extracting subsequences, it follows that

$$\vec{m}\,(h,t) \rightharpoonup \vec{m}\,(t) = \{m_k(t)\}_{k\ge 1} \text{ weakly in } H^1(0,T;\ell^2) \text{ as } h \to 0. \tag{A.15}$$

It is easy to see that $\hbar^1 \hookrightarrow \ell^2$ with compact embedding. According to (A.13) and (A.4) we have

$$\left\{ \vec{m}\,(h,\cdot) \right\} \text{ is uniformly bounded in } \text{[illegible]}\,([0,T];\hbar^1). \tag{A.16}$$

Using the classical Lions–Aubin compactness lemma, we deduce that

$$\left\{ \vec{m}\,(h,\cdot) \right\} \text{ is relatively compact in } \text{[illegible]}\,([0,T];\ell^2), \tag{A.17}$$

$$\vec{m}\,(h,\cdot) \rightharpoonup \vec{m}\,(\cdot) \quad \text{weakly in } H^1(0,T;\ell^2) \cap L^2(0,T;\hbar^1) \text{ as } h \to 0, \tag{A.18}$$

and

$$\vec{m}\,(h,\cdot) \rightharpoonup \vec{m}\,(\cdot) \quad \text{strongly in } \mathcal{C}([0,T];\ell^2). \tag{A.19}$$

We now observe that

$$h\sum_{j=0}^{N+1} |\phi_j(h,t)|^2 = \frac{1}{2}\sum_k |m_k(h,t)|^2 \tag{A.20}$$

($\bar{\varphi}^k$ is orthogonal to $\bar{\varphi}^{k'}$ in the discrete L^2-norm when $k \neq k'$) and therefore

$$h\sum_{j=1}^{N} |\phi_j(h,t)|^2 \underset{h\to 0}{\rightharpoonup} \|\phi(t)\|^2_{L^2(0,1)} \quad \text{in } L^\infty(0,T) \tag{A.21}$$

follows immediately from (A.19), since $\vec{m}\,(\cdot) = \{m_k(\cdot)\}_{k\in\mathbb{N}}$ are precisely the Fourier coefficients of ϕ (A.6) in the basis $\{\sin(k\pi x)\}_k$ of $L^2(0,1)$.

Observe that according to the bounds (A.14) and (A.16) the subsequence may be extracted so that

$$\vec{m}\,(h,0) \rightharpoonup \vec{m}^0 \quad \text{weakly in } \hbar^1, \tag{A.22}$$

$$\vec{m}'\,(h,0) \rightharpoonup \vec{m}^1 \quad \text{weakly in } \ell^2 \tag{A.23}$$

for some $(\vec{m}^0, \vec{m}^1) \in \hbar^1 \times \ell^2$. In view of (A.19) we have

$$\vec{m}\,(0) = \vec{m}^0\,. \tag{A.24}$$

We use the fact that

$$m_k''(h,t) + \mu_k(h) m_k(h,t) = 0,$$

which combined with

$$\mu_k(h) \leq 3k^2\pi^2 \quad \forall h, k > 0$$

implies that

$$\vec{m}''\,(h,\cdot) \text{ is uniformly bounded in } \mathcal{C}([0,\mathrm{T}];\hbar^{-1}). \tag{A.25}$$

Combining (A.14), (A.25), and the compactness results mentioned above we deduce that

$$\vec{m}'\,(h,\cdot) \rightharpoonup \vec{m}'\,(\cdot) \quad \text{strongly in } \mathcal{C}([0,\mathrm{T}],\hbar^{-1}), \tag{A.26}$$

and therefore by (A.23)

$$\vec{m}'\,(0) = \vec{m}^1\,. \tag{A.27}$$

$(\vec{m}^0, \vec{m}^1) \in \hbar^1 \times \ell^2$ is equivalent to saying that the limit initial data are of finite energy. Then ϕ, defined as in (A.6), is the solution of the continuous wave equation with initial data:

$$\phi^0 = \sum_k m_k^0 \sin(k\pi x) \in H_0^1(0,1), \quad \phi^1 = \sum_k m_k^1 \sin(k\pi x) \in L^2(0,1).$$

By uniqueness of solutions we deduce that (A.7) holds. On the other hand,

$$h\sum_{j=1}^{N}|\phi_j(h,t)|^2 \;=\frac{1}{2}\sum_k|m_k(h,t)|^2\to\frac{1}{2}\sum_k|m_k(t)|^2 \;=\|\phi(t)\|^2_{L^2(0,1)}\ \text{in}\,\mathcal{C}(0,T).$$

We conclude the proof by checking the property of lower semicontinuity of the energy (A.8).

In view of (A.22) and (A.23) we deduce that

$$\sum_k|m_k'(0)|^2+\sum_k k^2\pi^2|m_k(0)|^2\le\liminf_{h\to0}\left[\sum_k|m_k'(h,0)|^2+\sum_k\mu_k(h)|m_k(h,0)|^2\right].$$

Obviously

$$E(0)=\frac{1}{2}\sum_k\left[k^2\pi^2|m_k(0)|^2+|m_k'(0)|^2\right].$$

Thus, we deduce (A.8). ∎

In the following lemma we study the convergence of the normal derivatives of the solutions of the semidiscrete system.

LEMMA A.2. $\{\phi(h,t)\}_h$ [illegible] $h\to0$ [illegible] (A.4) [illegible] ϕ [illegible] $h\to0$ [illegible] $\{\phi(h,t)\}_h$ [illegible] A.1 [illegible]

$$\int_0^T|\partial_x\phi(1,t)|^2dt\le\liminf_{h\to0}\int_0^T\left|\frac{\phi_N(h,t)}{h}\right|^2dt, \tag{A.28}$$

[illegible]

$$-\frac{\phi_N(h,t)}{h}\rightharpoonup\partial_x\phi(1,t)\ \text{[illegible]}\ h\to0\ \text{[illegible]}\quad L^2(0,T).$$

[illegible]. Let $\phi(h,t)$ be a solution of (A.1) as in (A.2). In view of the decomposition (A.2) we have

$$\int_0^T\left|\frac{\phi_N(h,t)}{h}\right|^2dt=\left|\sum_k m_k(h,t)\frac{\sin(Nk\pi h)}{h}\right|^2_{L^2(0,T)}. \tag{A.29}$$

For all the solutions of the semidiscrete system, it holds that

$$C(h)\int_0^T\left|\frac{\phi_N(h,t)}{h}\right|^2dt\le E_h(0)\quad\forall h\in(0,1), \tag{A.30}$$

with $C(h)$ uniformly bounded from below with respect to h. Recall that

$$\frac{\sin(Nk\pi h)}{h}=\frac{\sin(k\pi-k\pi h)}{h}=-\cos(k\pi)\frac{\sin(k\pi h)}{h}\to-k\pi\cos(k\pi)$$

as $h\to0$ for all $k\ge0$.

We prove now that

(A.31)
$$-\sum_k m_k(h,t)\frac{\sin(Nk\pi h)}{h} \underset{h\to 0}{\rightharpoonup} \sum_k k\pi\cos(k\pi)m_k(t) \quad \text{weakly in } L^2(0,T) \text{ as } h\to 0.$$

In view of (A.30) we have

$$\sum_k m_k(h,t)\frac{\sin(Nk\pi h)}{h} \quad \text{is bounded in } L^2(0,T). \tag{A.32}$$

For any function $\psi \in \quad (0,T)$ we set

$$v_h = \sum_{k=1}^{N} \langle m_k(h),\psi\rangle_{D'(0,T)\times D(0,T)}\,\varphi^k(h), \tag{A.33}$$

$$v = \sum_{k\in\mathbb{N}} \langle m_k,\psi\rangle_{D'(0,T)\times D(0,T)}\,\varphi^k(x), \quad \varphi^k(x)=\sin(k\pi x). \tag{A.34}$$

For the semidiscrete problem we have

$$-\mathbf{A}\phi_h = \mathbf{M}\phi_h'' = \sum_{k=1}^{N} h\frac{2+\cos(k\pi h)}{3} m_k''(h,t)\bar{\varphi}^k(h), \tag{A.35}$$

and for the continuous problem we have

$$\partial_x^2\phi = \sum_{k\in\mathbb{N}} m_k''(t)\varphi^k = \sum_{k\in\mathbb{N}} m_k(t)(\varphi^k)''. \tag{A.36}$$

As a consequence of Lemma A.1 we have that

$$m_k''(h,t)+\mu_k(h)m_k(h,t) \rightharpoonup m_k''(t)+k^2\pi^2 m_k(t) \tag{A.37}$$

weakly in $H^{-1}(0,T;\ell^2)$ as $h\to 0$. We have

$$\begin{aligned} -(\mathbf{A}v_h)_j &= -\sum_{k=1}^{N} \langle m_k(h),\psi\rangle_{D'(0,T)\times D(0,T)} \left(\mathbf{A}\bar{\varphi}^k(h)\right)_j \\ &= \sum_{k=1}^{N} h\left\langle \frac{2+\cos(k\pi h)}{3} m_k''(h),\psi\right\rangle_{D'(0,T)\times D(0,T)} \varphi_j^k(h) \end{aligned} \tag{A.38}$$

and

$$v'' = \sum_{k\in\mathbb{N}} \langle m_k,\psi\rangle_{D'(0,T)\times D(0,T)}\,(\varphi^k)'' = \sum_{k\in\mathbb{N}} \langle m_k'',\psi\rangle_{D'(0,T)\times D(0,T)}\,\varphi^k. \tag{A.39}$$

Therefore, v_h and v satisfy the elliptic problems

$$\begin{cases} -\left(\mathbf{A}v_h\right)_j = f_j(h), & j=1,\dots,N,\\ v_{h,0}=v_{h,N+1}=0, \end{cases} \tag{A.40}$$

with $f_j(h)=\sum_{k=1}^{N} f_h^k\varphi_j^k(h)$ and $f_h^k = h\left\langle \frac{2+\cos(k\pi h)}{3} m_k''(h,\cdot),\psi(\cdot)\right\rangle_{D'(0,T)\times D(0,T)}$ and

$$\begin{cases} v''=f,\\ v(0)=v(1)=0, \end{cases} \tag{A.41}$$

with $f = \sum_{k\geq 1} f^k \varphi^k = \sum_{k\geq 1} f^k \sin(k\pi x)$ and $f^k = \langle m_k''(\cdot), \psi(\cdot)\rangle_{D'(0,T)\times D(0,T)}$.

Statement (A.31) is equivalent to showing that

$$-\frac{v_{h,N}(h)}{h} \underset{h\to 0}{\to} \frac{\partial v}{\partial x}(1,t). \tag{A.42}$$

We obtained in Lemma A.1

$$\vec{m}''(h,\cdot) \underset{h\to 0}{\rightharpoonup} \vec{m}''(\cdot) \text{ weakly in } H^{-1}(0,T;\ell^2) \text{ as } h\to 0, \tag{A.43}$$

and therefore

$$\left\{\frac{1}{h} f_h^k\right\}_{k=1}^N \underset{h\to 0}{\rightharpoonup} \left\{f^k\right\}_{k\in\mathbb{N}} \text{ weakly in } \ell^2 \text{ as } h\to 0. \tag{A.44}$$

The solutions of the elliptic problems can be written explicitly as

$$v_{h,j} = -\sum_{k=1}^{N} \frac{f_h^k}{h} \sin(k\pi h j) \frac{1}{\lambda_k(h)} \tag{A.45}$$

and

$$v(x) = -\sum_{k\geq 1} \frac{f^k \sin(k\pi x)}{k^2\pi^2}, \tag{A.46}$$

respectively, ($\lambda_k(h) = \frac{4}{h^2}\sin^2\frac{k\pi h}{2}$).

Thus, statement (A.42) is equivalent to

$$\sum_{k=1}^{N} \frac{f_h^k}{\lambda_k(h)} \frac{\sin(Nk\pi h)}{h^2} \to -\sum_{k\geq 1} \frac{f^k}{k\pi}\cos(k\pi) \text{ as } h\to 0. \tag{A.47}$$

In view of (A.44) it is easy to see that for any $M>0$ fixed

$$\sum_{k=1}^{M} \left[\frac{f_h^k}{\lambda_k(h)} \frac{\sin(k\pi h)}{h^2} - \frac{f^k}{k\pi}\right]\cos(k\pi) \to 0 \quad \text{as } h\to 0 \tag{A.48}$$

and

$$f_h^k = 0 \quad \forall\, k \geq N+1.$$

(Note that $\sin(Nk\pi h) = -\sin(k\pi h)\cos(k\pi)$.)

Taking into account that the convergence of each term of the series for k fixed holds, it is enough to prove that for every $\epsilon>0$, there exists $M(\epsilon)>0$ such that

$$\left|\sum_{k\geq M(\epsilon)+1} \left[\frac{f_h^k}{\lambda_k(h)} \frac{\sin(k\pi h)}{h^2} - \frac{f^k}{k\pi}\right]\cos(k\pi)\right| \leq \epsilon \tag{A.49}$$

uniformly as $h\to 0$.

Taking into account that $\left\{f^k\right\}_{k\in\mathbb{N}} \in \ell^2$, it is easy to see that

$$\left|\sum_{k\geq M(\epsilon)+1} f^k \frac{\cos(k\pi)}{k\pi}\right| \leq \frac{\epsilon}{2} \tag{A.50}$$

for $M(\epsilon) > 0$ large enough.

Let us analyze the remainder

(A.51)
$$\left| \sum_{k \geq M(\epsilon)+1} \frac{f_h^k}{\lambda_k(h)} \frac{\sin(k\pi h)}{h^2} \cos(k\pi) \right| \leq \sum_{k \geq M(\epsilon)+1} \frac{|f_h^k|}{h\,\lambda_k(h)} k\pi$$
$$\leq \left(\sum_{k \geq M(\epsilon)+1} \left| \frac{f_h^k}{h} \right|^2 \right)^{\frac{1}{2}} \left(\sum_{k \geq M(\epsilon)+1} \left| \frac{k\pi}{\lambda_k(h)} \right|^2 \right)^{\frac{1}{2}}.$$

In view of (A.44) and (A.51) we observe that it is sufficient to show that

$$\sum_{k \geq M(\epsilon)+1} \left| \frac{k\pi}{\lambda_k(h)} \right|^2 \to 0 \tag{A.52}$$

as $M(\epsilon) \to \infty$ uniformly on h (we take into account that $\lambda_k(h) \geq ck^2$ for some $C > 0$ for all $h > 0$ and $k = 1, \ldots, N$).

This completes the proof of Lemma A.2. □

The following result provides the strong convergence of the normal derivative under suitable assumptions on the initial data.

LEMMA A.3. [illegible] $T > 0$ [illegible] $h \in (0,1)$ [illegible] $(\phi_h^0, \phi_h^1) \in \hbar^1 \times \ell^2$ [illegible] $(\phi^0, \phi^1) \in H_0^1(0,1) \times L^2(0,1)$ [illegible] (A.1) ([illegible]) [illegible] [illegible]

$$(\phi_h^0, \phi_h^1) = \sum_{k=1}^{N} (m_k^0(h), m_k^1(h)) \bar{\varphi}^k(h),$$
$$(\phi^0, \phi^1) = \sum_{k \in \mathbb{N}} (m_k^0, m_k^1) \varphi^k.$$

[illegible] $m_k^0(h) = m_k^1(h) = 0$ [illegible] $k \geq N+1$ [illegible]

$$\left\{ m_k^0(h) \right\}_{k \in \mathbb{N}} \underset{h \to 0}{\to} \left\{ m_k^0 \right\}_{k \in \mathbb{N}} \quad \text{[illegible]} \quad \hbar^1, \tag{A.53}$$

$$\left\{ m_k^1(h) \right\}_{k \in \mathbb{N}} \underset{h \to 0}{\to} \left\{ m_k^1 \right\}_{k \in \mathbb{N}} \quad \text{[illegible]} \quad l^2, \tag{A.54}$$

[illegible]

$$-\frac{\phi_N(h,t)}{h} \underset{h \to 0}{\to} \partial_x \phi(1,t) \quad \text{[illegible]} \quad h \to 0 \quad \text{[illegible]} \quad L^2(0,T). \tag{A.55}$$

[illegible]. As a consequence of Lemma A.2 we have

$$-\frac{\phi_N(h,t)}{h} \rightharpoonup \partial_x \phi(1,t) \ \text{ weakly as } \ h \to 0 \ \text{ in } \ L^2(0,T),$$

where

$$\frac{\phi_N(h,t)}{h} = -\sum_{k=1}^{N} m_k(h,t) \frac{\sin(k\pi h)}{h} \cos(k\pi)$$

and

$$\partial_x \phi(1,t) = \sum_{k\in\mathbb{N}} k\pi\, m_k(t)\cos(k\pi).$$

To conclude the proof of (A.55) it is sufficient to show that the following holds:

$$\int_0^T \left| \sum_{k=1}^{N} m_k(h,t)\frac{\sin(k\pi h)}{h}\cos(k\pi) - \sum_{k\in\mathbb{N}} m_k(t) k\pi \cos(k\pi)\right|^2 dt \to 0 \ \text{ as } \ h\to 0.$$

Thus, it is sufficient to check, for every $\varepsilon > 0$, that there exists $M_\varepsilon > 0$ such that

$$\int_0^T \left| \sum_{k\geq M_\varepsilon} \left(m_k(h,t)\frac{\sin(k\pi h)}{h} - m_k(t)k\pi\right)\cos(k\pi)\right|^2 dt \leq \varepsilon. \tag{A.56}$$

In view of the convergences (A.53)–(A.55) and the conservation of the energies E_h, we deduce that

$$\overrightarrow{m}(h,t) = \{m_k(h,t)\}_{k\in\mathbb{N}} \underset{h\to 0}{\to} \overrightarrow{m}(t) = \{m_k(t)\}_{k\in\mathbb{N}} \quad \text{strongly in } \ \hbar^1 \tag{A.57}$$

for all $0 \leq t \leq T$. Moreover, for $m_k(h,t) = m_k(h)e^{i\sqrt{\mu_k(h)}t}$ and $m_k(t) = m_k e^{ik\pi t}$, as a consequence of inequality (A.30) (see [17]), we deduce that

$$\int_0^T \left| \sum_{k\geq M} m_k(h,t)\frac{\sin(k\pi h)}{h}\cos(k\pi)\right|^2 dt \leq A\sum_{k\geq M} |m_k(h)|^2 k^2\pi^2 \quad \forall M \geq 1. \tag{A.58}$$

Due to the conservation of energy and taking hypotheses (A.53)–(A.54) into account, we have that

$$\sum_{k\geq M_\varepsilon} |m_k(h)|^2 k^2\pi^2 \leq \frac{\varepsilon}{2} \quad \text{for } M_\varepsilon \text{ large enough.} \tag{A.59}$$

On the other hand, by the same argument [7]

$$\int_0^T \left| \sum_{k\geq M_\varepsilon} m_k(t) k\pi\cos(k\pi)\right|^2 dt \leq \hat{A}\sum_{k\geq M_\varepsilon} |m_k|^2 k^2\pi^2 \leq \frac{\varepsilon}{2}. \tag{A.60}$$

Combining inequality (A.60) with (A.58)–(A.59), the convergence (A.55) follows immediately. □

In what follows we obtain the convergence results which have been used in the paper.

3.5. For every $e_L = (\phi_L^0, \phi_L^1) \in H_0^1(0,1)\times L^2(0,1)$ fixed, we denote by (m_k^0, m_k^1) the Fourier coefficients and by $(m_{k,\tilde{L}}^0, m_{k,\tilde{L}}^1)$ the Fourier coefficients in every $V_{\tilde{L}}$ of $e_L \in (V_L)^2 \subset (V_{\tilde{L}})^2$. Trivially we have

$$\left(m_{k,\tilde{L}}^0, m_{k,\tilde{L}}^1\right) \underset{\tilde{L}\to\infty}{\to} \left(m_k^0, m_k^1\right) \ \text{ strongly in } \ \hbar^1\times l^2,$$

and therefore, by Lemma A.3, we obtain the strong convergence (3.48). □

A PARALLEL IMPLEMENTATION OF DUAL-PRIMAL FETI METHODS FOR THREE-DIMENSIONAL LINEAR ELASTICITY USING A TRANSFORMATION OF BASIS*

AXEL KLAWONN† AND OLIVER RHEINBACH†

Abstract. Dual-primal FETI methods for linear elasticity problems in three dimensions are considered. These are nonoverlapping domain decomposition methods where some primal continuity constraints across subdomain boundaries are required to hold throughout the iterations, whereas most of the constraints are enforced by Lagrange multipliers. An algorithmic framework for dual-primal FETI methods is described together with a transformation of basis to implement the primal constraints. Numerical results obtained from a parallel implementation of these algorithms applied to a model benchmark problem with structured meshes and to problems with more complicated geometries from industrial and biological applications using unstructured meshes are provided. These results show that the presented dual-primal FETI algorithms are numerical and parallel scalable.

Key words. domain decomposition, Lagrange multipliers, FETI, preconditioners, elliptic systems, elasticity, finite elements, parallel computing

1. Introduction.

Dual-primal FETI (FETI-DP) methods are the most recent members of the family of finite element tearing and interconnecting (FETI) domain decomposition methods. The FETI methods, introduced by Farhat and Roux [18], are all dual iterative substructuring methods for partial differential equations. In these methods the original domain, on which the given partial differential equation has to be solved, is decomposed into nonoverlapping subdomains. The intersubdomain continuity is then enforced by Lagrange multipliers across the interface defined by the subdomain boundaries. For further results and references, see, e.g., [17, 13, 5, 34, 24, 41]. In FETI-DP methods, some continuity constraints on the primal displacement variables are forced to hold throughout iterations, as in primal substructuring algorithms, while the other constraints are enforced by the use of Lagrange multipliers, as in standard one-level FETI methods. The primal constraints have to be chosen such that the local subproblems become invertible and such that a parallel scalable method is obtained; the primal constraints provide a coarse problem for these domain decomposition methods. Different choices of primal constraints are possible; see the discussion below. Each of these choices defines a different coarse space and thus a different member of the family of FETI-DP algorithms.

FETI-DP algorithms were introduced by Farhat et al. in [14] for linear elasticity problems in the plane and then extended by Farhat, Lesoinne, and Pierson [15] to three-dimensional elasticity problems; see also Pierson [37]. The first theoretical analysis for two-dimensional, scalar elliptic partial differential equations of second and fourth order with only small coefficient jumps across the subdomain boundaries was given by Mandel and Tezaur [35]; it was shown that the condition number is bounded polylogarithmically as a function of the dimension of the individual subregion

problems. The family of FETI-DP algorithms for scalar, second order elliptic problems in three dimensions was extended by Klawonn and Widlund [23] and Klawonn, Widlund, and Dryja [27, 28]; see also [41]. There, constraints on averages over subdomain edges and faces are used to obtain algorithms with an improved scalability for three-dimensional problems. We note that such averages were already used in Dryja, Sarkis, and Widlund [11] and Dryja, Smith, and Widlund [12] to construct primal iterative substructuring methods which are scalable in three dimensions. In [15, 37] similar constraints on averages are used to define FETI-DP methods which are scalable for three-dimensional linear elasticity problems, although the definition of subdomain edges is different from the one used in [23, 27, 28]; see also the discussion at the end of section 2. We also note that an important feature of the algorithms presented in [23, 27, 28] was to develop variants of FETI-DP with smaller coarse problems while still maintaining scalability and a good convergence bound. In fact, in [27, 28] a theory was provided which shows that the condition number in three dimensions can again be bounded polylogarithmically as a function of the dimension of the individual subdomain problems and that the bounds can otherwise be made independent of the number of subdomains, the mesh size, and the jumps in the coefficients.

More recently, new variants of FETI-DP for three-dimensional, linear elasticity problems were provided by Klawonn and Widlund [25, 26] together with a theoretical analysis proving a polylogarithmic condition number estimate as in the scalar case, which is also robust with respect to discontinuities in the material coefficients. For benign elasticity problems, it is shown that selecting an appropriate set of edge averages as primal constraints is sufficient for obtaining good polylogarithmic bounds. For arbitrary coefficient distributions, certain first order moments on selected edges have to be added as primal constraints as well as constraints at some of the vertices in order to obtain robust, polylogarithmic bounds. An implementational variant of FETI-DP is presented in [25], using a transformation of basis for the primal edge averages and first order moments. Originally, optional Lagrange multipliers are used for the implementation of constraints of this type; cf. [15].

Strongly related to FETI-DP methods are the more recently developed Neumann–Neumann methods with constraints, also known as balancing domain decomposition methods by constraints (BDDC); cf. [10, 32, 33]. Neumann–Neumann methods with primal vertex constraints were also developed independently by Cros [7] and Fragakis and Papadrakakis [19]; in the latter, this approach is called P-FETIDP. In [19], it was also experimentally observed that for the balancing Neumann–Neumann and one-level FETI methods, the eigenvalues, which are different from one and zero, are the same. It was first proved in Mandel, Dohrmann, and Tezaur [33] that the eigenvalues of BDDC and FETI-DP, which are not one or zero, are the same; see also Li and Widlund [31] for another approach.

Recently, new results for inexact FETI-DP and BDDC algorithms have been obtained for the inexact solution of the subdomain or coarse problems. For inexact BDDC methods, see Tu [42, 43], Dohrmann [9], and Li and Widlund [30], and for inexact FETI-DP algorithms, see Klawonn and Rheinbach [22].

The purpose of this article is to present results obtained from a parallel implementation of some of the algorithms developed in Klawonn and Widlund [25] using only average constraints over selected edges and to show numerical and parallel scalability of these algorithms in three dimensions. Here, we restrict ourselves to homogeneous elasticity problems without any jumps in the material coefficients; numerical experiments for heterogeneous problems are part of ongoing research; see Klawonn and

Rheinbach [21]. We note that the implementation using a transformation of basis leads to a symmetric, positive definite coarse problem in contrast to the approach using optional Lagrange multipliers, where the coarse problem is symmetric and indefinite; cf. [15, 25]. Another interesting feature is the fact that for homogeneous problems, no vertex constraints have to be used and only edge averages over selected edges are needed. Our experiments show that using a transformation of basis for the implementation of the primal edge average constraints leads to a parallel scalable domain decomposition method. We first report on experiments for model benchmark problems with structured meshes. It is shown that the experimental results confirm the theory in [25] in the case of structured domain decompositions using cubic subdomains. In scientific computing, solving real-world, three-dimensional problems from structural mechanics applications, usually unstructured meshes occur and the decomposition into subdomains is obtained by using automatic graph partitioners. In general, this leads to irregularly shaped subdomains with jagged boundaries. To be of relevance in scientific computing, it is of utmost importance for a domain decomposition method to show applicability to and scalability in such situations. We note that such a situation is not covered by theory anymore. Thus, it is important to provide numerical results showing scalability experimentally. We see that our algorithms can also be successfully applied to cases which are not covered by the theory anymore, such as unstructured domain decompositions using mesh partitioners or faces, edges, and vertices defined by equivalence classes, which can, e.g., lead to curved or jagged edges. We also show that the parallel implementation of our FETI-DP method applied to some three-dimensional, industrial applications, in almost all cases, shows better scalability and uses less CPU time compared to a parallel direct solver. Furthermore, we successfully considered an elasticity problem from a biological application. We note that the bone structure considered in this example is a very difficult and challenging domain since it contains many holes and thin bridges. We also carried out numerical experiments which show the robustness of our method with respect to reduction of the relative residual; it is shown that it can be reduced to 10^{-14} without stagnation of the method.

The remainder of this article is organized as follows. In section 2, we introduce the equations of linear elasticity in three dimensions, the discretization by finite elements and the partition of the domain into substructures. In section 3, we present the algorithmic framework for our FETI-DP methods and in section 4 we describe how to perform the transformation of basis to implement the primal constraints. Finally, in section 5 we present the numerical results obtained from a parallel implementation of our methods. First, we apply it to a benchmark problem on the unit cube, testing for numerical and parallel scalability, confirming the theoretical findings in [25]. We then show the parallel performance of our algorithms applied to geometries obtained from industrial and biological applications. Finally, we show that the approach presented in this article is very stable with respect to the residual reduction.

2. The equations of linear elasticity, finite elements, and geometry. The equations of linear elasticity model the displacement of a linear elastic material under the action of external and internal forces. The elastic body occupies a domain $\Omega \subset \mathbb{R}^3$, which is assumed to be polyhedral and of diameter one. We denote its boundary by $\partial\Omega$ and assume that one part of it, $\partial\Omega_D$, is clamped, i.e., with homogeneous Dirichlet boundary conditions, and that the rest, $\partial\Omega_N := \partial\Omega \setminus \partial\Omega_D$, is subject to a surface force $\mathbf{g}$, i.e., a natural boundary condition. We can also introduce a body force $\mathbf{f}$, e.g., gravity. With $\mathbf{H^1}(\Omega) := (H^1(\Omega))^3$, the appropriate space for a variational

formulation is the Sobolev space $\mathbf{H_0^1}(\Omega, \partial\Omega_D) := \{\mathbf{v} \in \mathbf{H^1}(\Omega) : \mathbf{v} = \mathbf{0} \text{ on } \partial\Omega_D\}$. The linear elasticity problem consists in finding the displacement $\mathbf{u} \in \mathbf{H_0^1}(\Omega, \partial\Omega_D)$ of the elastic body Ω, such that

(2.1)
$$\int_\Omega G(\mathbf{x})\varepsilon(\mathbf{u}) : \varepsilon(\mathbf{v})d\mathbf{x} + \int_\Omega G(\mathbf{x})\,\beta(\mathbf{x})\,\mathrm{div}\,\mathbf{u}\,\mathrm{div}\,\mathbf{v}\,d\mathbf{x} = \langle \mathbf{F}, \mathbf{v}\rangle \quad \forall \mathbf{v} \in \mathbf{H_0^1}(\Omega, \partial\Omega_D).$$

Here G and β are material parameters which depend on the Young modulus $E > 0$ and the Poisson ratio $\nu \in (0, \frac{1}{2}]$; we have $G = E/(1+\nu)$ and $\beta = \nu/(1-2\nu)$. In this article, we consider only the case of compressible elasticity, which means that the Poisson ratio ν is bounded away from $\frac{1}{2}$. Furthermore, $\varepsilon_{ij}(\mathbf{u}) := \frac{1}{2}(\frac{\partial u_i}{\partial x_j} + \frac{\partial u_j}{\partial x_i})$ is the linearized strain tensor, and

$$\varepsilon(\mathbf{u}) : \varepsilon(\mathbf{v}) = \sum_{i,j=1}^{3} \varepsilon_{ij}(\mathbf{u})\varepsilon_{ij}(\mathbf{v}), \quad \langle \mathbf{F}, \mathbf{v}\rangle := \int_\Omega \mathbf{f}^T\mathbf{v}\,d\mathbf{x} + \int_{\partial\Omega_N} \mathbf{g}^T\mathbf{v}\,d\sigma.$$

For convenience, we also introduce the notation

$$(\varepsilon(\mathbf{u}), \varepsilon(\mathbf{v}))_{L_2(\Omega)} := \int_\Omega \varepsilon(\mathbf{u}) : \varepsilon(\mathbf{v})d\mathbf{x}.$$

The bilinear form associated with linear elasticity is then

$$a(\mathbf{u}, \mathbf{v}) = (G\,\varepsilon(\mathbf{u}), \varepsilon(\mathbf{v}))_{L_2(\Omega)} + (G\,\beta\,\mathrm{div}\,\mathbf{u}, \mathrm{div}\,\mathbf{v})_{L_2(\Omega)}.$$

The wellposedness of the linear system (2.1) follows immediately from the continuity and ellipticity of the bilinear form $a(\cdot,\cdot)$, where the first follows from elementary inequalities and the latter from Korn's first inequality; see, e.g., Ciarlet [6].

The null space $\mathbf{ker}\,(\varepsilon)$ of ε is the space of rigid body motions which is spanned by the three translations

$$\mathbf{r}_1 := \begin{bmatrix} 1 \\ 0 \\ 0 \end{bmatrix}, \quad \mathbf{r}_2 := \begin{bmatrix} 0 \\ 1 \\ 0 \end{bmatrix}, \quad \mathbf{r}_3 := \begin{bmatrix} 0 \\ 0 \\ 1 \end{bmatrix} \tag{2.2}$$

and the three rotations

$$\mathbf{r}_4 := \begin{bmatrix} x_2 - \hat{x}_2 \\ -x_1 + \hat{x}_1 \\ 0 \end{bmatrix}, \quad \mathbf{r}_5 := \begin{bmatrix} -x_3 + \hat{x}_3 \\ 0 \\ x_1 - \hat{x}_1 \end{bmatrix}, \quad \mathbf{r}_6 := \begin{bmatrix} 0 \\ x_3 - \hat{x}_3 \\ -x_2 + \hat{x}_2 \end{bmatrix}. \tag{2.3}$$

Here $\hat{\mathbf{x}} \in \Omega$ to shift the origin to a point in Ω.

We will consider only compressible elastic materials. It is therefore sufficient to discretize our elliptic problem (2.1) by low order, conforming finite elements, e.g., linear or trilinear elements.

Let us assume that a triangulation τ^h of Ω is given which is shape regular and has a typical diameter of h. We denote by $\mathbf{W}^h := \mathbf{W}^h(\Omega) \subset \mathbf{H_0^1}(\Omega, \partial\Omega_D)$ the corresponding conforming finite element space of finite element functions. The corresponding discrete problem is then

$$a(\mathbf{u}_h, \mathbf{v}_h) = \langle \mathbf{F}, \mathbf{v}_h\rangle \quad \forall \mathbf{v}_h \in \mathbf{W}^h. \tag{2.4}$$

When there is no risk of confusion, we will drop the subscript h.

Let the domain $\Omega \subset \mathbb{R}^3$ be decomposed into nonoverlapping subdomains $\Omega_i, i = 1, \ldots, N$, each of which is the union of finite elements with matching finite element nodes on the boundaries of neighboring subdomains across the interface Γ. The interface Γ is the union of three different groups of open sets, namely, subdomain faces, edges, and vertices. We denote individual faces, edges, and vertices by $\mathcal{F}, \mathcal{E}$, and $\mathcal{V}$, respectively. To define faces, edges, and vertices, we introduce certain equivalence classes. Let us denote the sets of nodes on $\partial\Omega$, $\partial\Omega_i$, and Γ by $\partial\Omega_h$, $\partial\Omega_{i,h}$, and Γ_h, respectively. For any interface nodal point $x \in \Gamma_h$, we define

$$\mathcal{N}_x := \{j \in \{1, \ldots, N\} : x \in \partial\Omega_j\},$$

i.e., $\mathcal{N}_x$ is the set of indices of all subdomains with x in the closure of the subdomain. For a node x we define the multiplicity as $|N_x|$.

Associated with the nodes of the finite element mesh, we have a graph, the nodal graph, which represents the node-to-node adjacency. For a given node $x \in \Gamma_h$, we denote by $\mathcal{C}_{con}(x)$ the connected component of the nodal subgraph, defined by $\mathcal{N}_x$, to which x belongs. For two interface points $x, y \in \Gamma_h$, we introduce an equivalence relation by

$$x \sim y :\Longleftrightarrow \mathcal{N}_x = \mathcal{N}_y \quad \text{and} \quad y \in \mathcal{C}_{con}(x).$$

We can now describe faces, edges, and vertices using their equivalence classes. Here, $|G|$ denotes the cardinality of the set G. We define the following.

Definition 2.1.

$$\begin{aligned} x \in \mathcal{F} &:\Longleftrightarrow |\mathcal{N}_x| = 2. \\ x \in \mathcal{E} &:\Longleftrightarrow |\mathcal{N}_x| \geq 3 \quad \exists y \in \Gamma_h, y \neq x, \quad y \sim x. \\ x \in \mathcal{V} &:\Longleftrightarrow |\mathcal{N}_x| \geq 3 \quad \nexists y \in \Gamma_h, \quad x \sim y. \end{aligned}$$

In the case of a decomposition into regular substructures, e.g., cubes or tetrahedrons, our definition of faces, edges, and vertices conforms to our basic geometric intuition; see Figure 2.2. On the other hand, for subdomains generated by an automatic mesh partitioner, the situation can be quite complicated. We can, e.g., have several edges with the same index set $\mathcal{N}_x$ or an edge and a vertex with the same $\mathcal{N}_x$. In practice, we can also have situations when there are not enough edges and potential edge constraints for some subdomains. Then we have to use constraints on some extra edges on $\partial\Omega_N$, which otherwise would be regarded as part of a face. A similar problem might occur for flat structures for which additional constraints might be required for each subdomain. Therefore, we introduce an alternative definition of edges.

Definition 2.2. N_x $|N_x| \geq 3$ $|N_x| \geq 2$ x $\partial\Omega_N$

If needed, we will increase the number of edges in unstructured cases by switching locally from the definition of edges given in Definition 2.1 to Definition 2.2 and by splitting edges into several edges.

Let us note that sometimes the term is used differently in the literature; cf., e.g., [15, 37]. Also, instead of vertices, the term is often used although usually with a different meaning than vertices in our terminology; cf. [15, 37, 29]. A simple choice is to define corners in three dimensions as nodes which either belong to more than three subdomains (see Pierson [37, p. 24]) or to more than four subdomains (see Lesoinne [29]). A more elaborate algorithmic choice, which can reduce the number

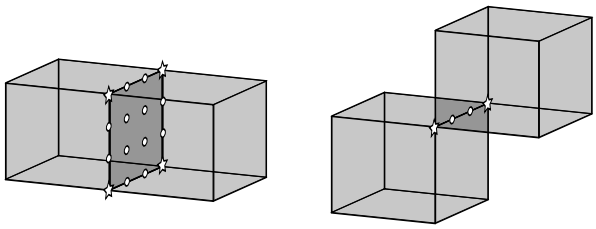

FIG. 2.1. *Definition of edges in* [15, 36, 37]. *When the nodes, denoted by stars, are selected as corners, the set of edge nodes is given by those nodes denoted by circles. Left: The intersection of the closure of the two subdomains consists of one edge (which looks like a geometric face) and four corners based on this definition of edges. Right: The intersection of the closure of the two subdomains consists of one edge and two corners.*

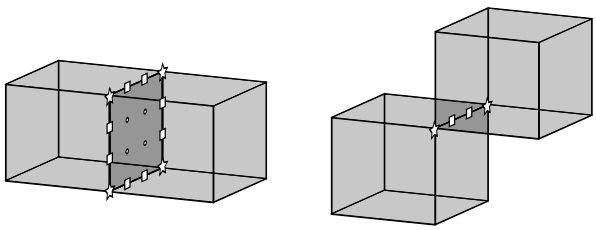

FIG. 2.2. *Definition* 2.1 *of vertices, edges, and faces. Vertices are denoted by stars, edge nodes by squares, and face nodes by small circles. Left: The intersection of the closure of the two subdomains consists of one face, four edges, and four vertices. Right: The intersection of the closure of the two subdomains consists of one edge and two vertices.*

of corners, is given in [29]. For completeness, we also give the definition of edges in three dimensions as used in [15, 37]; see Pierson [36]. There, an edge between two subdomains is the set of interface nodes, excluding corners, which is common to the boundaries of both subdomains. To illustrate the subtle difference between this and our definition, we consider a structured decomposition of the unit cube into cubic subdomains. For two different situations of interior neighboring subdomains, we illustrate the different definitions in Figures 2.1 and 2.2. Here, an edge in Figure 2.1 can be, for example, either an edge as in Definition 2.1 or the union of, in our terminology, a face with the edges belonging to its closure; cf. also Figure 2.2.

Let us note that in the algorithms in this article, we exclusively use constraints over edges; no vertices or faces are needed.

3. The FETI-DP algorithms. In this section, we introduce a matrix formulation of the FETI-DP algorithms considered in this article. For each subdomain Ω_i, $i = 1, \ldots, N$, we assemble local stiffness matrices K_i and local load vectors $\mathbf{f}_i$ of the elasticity problem (2.4). Furthermore, we denote by $\mathbf{u}_i$ the local solution vectors of nodal values. In the dual-primal FETI methods, we distinguish between dual and primal displacement variables according to the way the continuity of the solution in those variables is established. Dual displacement variables are those for which the continuity is enforced by a continuity constraint and Lagrange multipliers $\boldsymbol{\lambda}$, and thus continuity is not established until convergence of the iterative method is reached, as in the classical one-level FETI methods. On the other hand, continuity of the primal displacement variables is enforced explicitly in each iteration step by subassembly of the local stiffness matrices K_i at the primal displacement variables. This subassembly yields a symmetric, positive definite stiffness matrix $\widetilde{K}$ which is not block diagonal

anymore but is coupled at the primal displacement variables. Let us note that this coupling yields a global problem which is necessary to obtain a parallel and numerical scalable algorithm. An obvious choice of primal variables are (selected) vertices for which a partial assembly is then carried out. We will see in section 4 that there are other possible choices, such as edge averages over selected edges; cf. Klawonn and Widlund [25] for other possible choices. If a transformation of basis is used, then the edge average constraints can be treated algorithmically exactly in the same way as primal vertices; cf. section 4.

We will use the subscripts I, Δ, and Π to denote the interior, dual, and primal displacement variables, respectively, and obtain for the local stiffness matrices, load vectors, and solution vectors of nodal values

$$K^{(i)} = \begin{bmatrix} K_{II}^{(i)} & K_{\Delta I}^{(i)T} & K_{\Pi I}^{(i)T} \\ K_{\Delta I}^{(i)} & K_{\Delta\Delta}^{(i)} & K_{\Pi\Delta}^{(i)T} \\ K_{\Pi I}^{(i)} & K_{\Pi\Delta}^{(i)} & K_{\Pi\Pi}^{(i)} \end{bmatrix}, \quad \mathbf{u}^{(i)} = \begin{bmatrix} \mathbf{u}_I^{(i)} \\ \mathbf{u}_\Delta^{(i)} \\ \mathbf{u}_\Pi^{(i)} \end{bmatrix}, \quad \mathbf{f}^{(i)} = \begin{bmatrix} \mathbf{f}_I^{(i)} \\ \mathbf{f}_\Delta^{(i)} \\ \mathbf{f}_\Pi^{(i)} \end{bmatrix}.$$

By subassembly in the primal displacement variables, we obtain

$$\widetilde{K} = \begin{bmatrix} K_{BB} & \widetilde{K}_{\Pi B}^T \\ \widetilde{K}_{\Pi B} & \widetilde{K}_{\Pi\Pi} \end{bmatrix},$$

where a tilde indicates the subassembled matrices and where

$$K_{BB} = \begin{bmatrix} K_{BB}^{(1)} & O & \cdots & O \\ O & \ddots & \ddots & \vdots \\ \vdots & \ddots & \ddots & O \\ O & \cdots & O & K_{BB}^{(N)} \end{bmatrix}, \quad K_{BB}^{(i)} = \begin{bmatrix} K_{II}^{(i)} & K_{\Delta I}^{(i)T} \\ K_{\Delta I}^{(i)} & K_{\Delta\Delta}^{(i)} \end{bmatrix},$$

and

$$\widetilde{K}_{\Pi B} = [\widetilde{K}_{\Pi B}^{(1)} \cdots \widetilde{K}_{\Pi B}^{(N)}].$$

Introducing local assembly operators $R_\Pi^{(i)T}$ which map from the local primal displacement variables $\mathbf{u}_\Pi^{(i)}$ to the global, assembled $\widetilde{\mathbf{u}}_\Pi$, we have

$$\widetilde{K}_{\Pi B}^{(i)} = R_\Pi^{(i)T} K_{\Pi B}^{(i)}, \qquad \mathbf{u}_\Pi^{(i)} = R_\Pi^{(i)} \widetilde{\mathbf{u}}_\Pi, \quad i = 1, \ldots, N,$$

and

$$\widetilde{K}_{\Pi\Pi} = \sum_{i=1}^{N} R_\Pi^{(i)T} K_{\Pi\Pi}^{(i)} R_\Pi^{(i)}.$$

We also introduce the notation

$$\mathbf{u}_B^T = [\mathbf{u}_I^T \ \mathbf{u}_\Delta^T], \quad \mathbf{f}_B^T = [\mathbf{f}_I^T \ \mathbf{f}_\Delta^T], \mathbf{u}_B^{(i)T} = [\mathbf{u}_I^{(i)T} \ \mathbf{u}_\Delta^{(i)T}], \quad \mathbf{f}_B^{(i)T} = [\mathbf{f}_I^{(i)T} \ \mathbf{f}_\Delta^{(i)T}].$$

To guarantee continuity at the dual displacement variables, we introduce a jump operator B, which is constructed from $\{0, 1, -1\}$, in such a way that the values of the solution $\mathbf{u}_\Delta$, associated with more than one subdomain, coincide when $B\mathbf{u}_B = 0$; the

interior variables $\mathbf{u}_I$ remain unchanged and thus the corresponding entries in B are zero. These constraints are very simple and just express that the nodal values coincide across the interface; clearly, we do not need any constraints associated with the primal displacement variables. However, we will otherwise use all possible constraints and thus work with a fully redundant set of Lagrange multipliers as in [24, section 5]; cf. also [38]. Thus, for an edge node common to four subdomains, we will use six constraints rather than choosing as few as three.

We can now reformulate the finite element discretization of (2.4) as

$$\begin{bmatrix} K_{BB} & \widetilde{K}_{\Pi B}^T & B^T \\ \widetilde{K}_{\Pi B} & \widetilde{K}_{\Pi\Pi} & O \\ B & O & O \end{bmatrix} \begin{bmatrix} \mathbf{u}_B \\ \widetilde{\mathbf{u}}_\Pi \\ \boldsymbol{\lambda} \end{bmatrix} = \begin{bmatrix} \mathbf{f}_B \\ \widetilde{\mathbf{f}}_\Pi \\ \mathbf{0} \end{bmatrix}.$$

Elimination of the interior and dual displacement variables $\mathbf{u}_B$ and of the primal displacement variables $\widetilde{\mathbf{u}}_\Pi$ leads to

$$\begin{bmatrix} K_{BB} & \widetilde{K}_{\Pi B}^T & B^T \\ O & \widetilde{S}_{\Pi\Pi} & -\widetilde{S}_{\Lambda\Pi}^T \\ O & O & -F \end{bmatrix} \begin{bmatrix} \mathbf{u}_B \\ \widetilde{\mathbf{u}}_\Pi \\ \boldsymbol{\lambda} \end{bmatrix} = \begin{bmatrix} \mathbf{f}_B \\ \widetilde{\mathbf{f}}_\Pi - \widetilde{K}_{\Pi B} K_{BB}^{-1} \mathbf{f}_B \\ -\mathbf{d} \end{bmatrix}$$

with

$$\begin{aligned} \widetilde{S}_{\Pi\Pi} &= \widetilde{K}_{\Pi\Pi} - \widetilde{K}_{\Pi B} K_{BB}^{-1} \widetilde{K}_{\Pi B}^T, \qquad \widetilde{S}_{\Lambda\Pi}^T = \widetilde{K}_{\Pi B} K_{BB}^{-1} B^T, \\ F &= B K_{BB}^{-1} B^T + B K_{BB}^{-1} \widetilde{K}_{\Pi B}^T \widetilde{S}_{\Pi\Pi}^{-1} \widetilde{K}_{\Pi B} K_{BB}^{-1} B^T, \\ \mathbf{d} &= B K_{BB}^{-1} \mathbf{f}_B + B K_{BB}^{-1} \widetilde{K}_{\Pi B}^T \widetilde{S}_{\Pi\Pi}^{-1} \left(\widetilde{\mathbf{f}}_\Pi - \widetilde{K}_{\Pi B} K_{BB}^{-1} \mathbf{f}_B \right). \end{aligned}$$

Since K_{BB} is a block-diagonal matrix, we obtain

$$\begin{aligned} F = &\sum_{i=1}^{N} B^{(i)} \left(K_{BB}^{(i)} \right)^{-1} B^{(i)T} \\ &+ \left(\sum_{i}^{N} B^{(i)} (K_{BB}^{(i)})^{-1} \widetilde{K}_{\Pi B}^{(i)T} \right) \widetilde{S}_{\Pi\Pi}^{-1} \left(\sum_{j}^{N} \widetilde{K}_{\Pi B}^{(j)} (K_{BB}^{(j)})^{-1} B^{(j)T} \right). \end{aligned} \tag{3.1}$$

We see that in a matrix-vector multiplication with F, we only need to solve local linear systems in the first sum. To apply the second term in (3.1) to a vector, we first apply the right sum in it to that vector; this represents a gather operation. Next, we have to solve a linear system with the matrix $\widetilde{S}_{\Pi\Pi}$, which yields our global problem needed for scalability. Finally, we apply the left sum of the second term in (3.1) to the result; this represents a scatter operation. A similar form can be derived for the right-hand side $\mathbf{d}$.

To define the FETI-DP Dirichlet preconditioner M^{-1}, we first need to introduce a scaled jump operator B_D; this is done by scaling the contributions of B associated with the dual displacement variables from individual subdomains. We can write

$$B_D = [B_D^{(1)}, \ldots, B_D^{(N)}],$$

where the $B_D^{(i)}$ are defined as follows: Each row of $B^{(i)}$ with a nonzero entry corresponds to a Lagrange multiplier connecting the subdomain Ω_i with a neighboring

subdomain Ω_j at a point $x \in \partial\Omega_{i,h} \cap \partial\Omega_{j,h}$. We obtain $B_D^{(i)}$ by multiplying each such row of $B^{(i)}$ with $G_j(x)/\sum_{k\in\mathcal{N}_x} G_k(x)$, where $G_l(x) := G(x)$ for $x \in \partial\Omega_l, l = 1, \ldots, N$. In the homogeneous case, this results in scaling each such row with the reciprocal of the multiplicity $|\mathcal{N}_x|$ of the node $x \in \partial\Omega_{i,h} \cap \partial\Omega_{j,h}$; thus it is also called multiplicity scaling.

Let us now consider the matrix representation of our preconditioner M^{-1}. For this, we need certain Schur complement matrices $S^{(i)}$, $i = 1, \ldots, N$. Each $S^{(i)}$ is obtained from the local stiffness matrices $K^{(i)}$ by eliminating the interior displacement variables. Denoting the displacement variables on the local interface $\partial\Omega_i$ by the subscript Γ, we then have

$$K^{(i)} = \begin{bmatrix} K_{II}^{(i)} & K_{\Gamma I}^{(i)T} \\ K_{\Gamma I}^{(i)} & K_{\Gamma\Gamma}^{(i)} \end{bmatrix}$$

and the local Schur complements $S^{(i)}$ are obtained as

$$S^{(i)} = K_{\Gamma\Gamma}^{(i)} - K_{\Gamma I}^{(i)}(K_{II}^{(i)})^{-1}K_{\Gamma I}^{(i)T}.$$

We now define the block-diagonal Schur complement matrix S as

$$S = \begin{bmatrix} S^{(1)} & & O \\ & \ddots & \\ O & & S^{(N)} \end{bmatrix}.$$

Our preconditioner is then given in matrix form by

$$M^{-1} = B_D R_\Gamma^T S R_\Gamma B_D^T = \sum_{i=1}^{N} B_D^{(i)} R_\Gamma^{(i)T} S^{(i)} R_\Gamma^{(i)} B_D^{(i)T}. \tag{3.2}$$

Here, $R_\Gamma^{(i)}$ are restriction matrices that restrict the degrees of freedom of a subdomain to its interface and $R_\Gamma = \operatorname{diag}_i(R_\Gamma^{(i)})$.

Let us note that generally the local Schur complements $S^{(i)}$ are never built explicitly; instead, in each iteration step and each application of M^{-1} to a vector, local linear systems with $K^{(i)}$ are solved. This corresponds to the solution of local Dirichlet problems; thus, this preconditioner is also known as the Dirichlet preconditioner. Clearly, a matrix-vector multiplication with M^{-1} requires only the solution of local linear systems and can be carried out completely in parallel. The Dirichlet preconditioner without scaling was first introduced in Farhat, Mandel, and Roux [16]. For early references to the scaled version used in (3.2), see, e.g., Rixen and Farhat [39] and Klawonn and Widlund [24]. Let us note that appropriate scaling can be important to obtain convergence results which are independent of jumps in the coefficients of the partial differential equation; see [24, 27, 25]. But also for homogeneous problems, scaling can be important to improve convergence and also in order to obtain a condition number result for the one-level FETI method which is of the order of $(1+\log(H/h))^2$ instead of $(1+\log(H/h))^3$, where H is the subdomain diameter; cf. [34] and [24].

The FETI-DP method can now be described as the standard preconditioned conjugate gradient (pcg) method for solving the preconditioned linear system

$$M^{-1}F\boldsymbol{\lambda} = M^{-1}\mathbf{d}.$$

4. Primal constraints and a change of basis. We have to decide how to choose the primal displacement variables. The simplest choice is to choose them as certain selected primal vertices of the subdomains; see Farhat et al. [14], where this approach was first considered. In this section, we show that edge average constraints can be treated the same way by using a transformation of basis. In the following, we will denote the FETI-DP algorithm which exclusively uses selected vertices as primal displacement constraints as Algorithm A; cf. Klawonn, Widlund, and Dryja [27], where this notation was introduced. In Lesoinne [29], an algorithm for the choice of selected vertices as primal variables is suggested in the context of choosing a relatively small number of vertices to guarantee invertibility of the subproblems and otherwise enhance the coarse problem by face averages using optional Lagrange multipliers.

For scalar, second order, elliptic differential equations in three dimensions, certain edge and face averages were suggested in [23, 27] as additional primal constraints. For linear elasticity problems in three dimensions, Farhat, Lesoinne, and Pierson [15] considered similar averages as primal constraints. Let us note that there, edges (faces) are defined differently from our definition; cf. the discussion at the end of section 2. In Klawonn and Widlund [25], edge averages and first order edge moments were introduced and analyzed in order to obtain scalable algorithms which are also robust for arbitrarily large jumps of the material coefficients across the subdomain interface. The algorithms described in this article are based on [25].

There are two different approaches to implement the edge and face constraints: one using optional Lagrange multipliers, which form a part of the global, coarse problem; cf. [15] and [25, section 6.1]; and the other using a change of basis; cf. [25, section 6.2]. The latter approach generally leads to smaller and computationally more efficient coarse problems. In our transformation of basis, we introduce edge averages explicitly as new (primal) variables into the FETI-DP system. Then we subassemble in these degrees of freedom. This leads to a symmetric, positive definite coarse problem. Using this approach, the invertibility of the local problems and the positive definiteness of the entire problem can be guaranteed without any vertex constraints; the rigid body modes of a subdomain can be controlled if a sufficient number of edge averages is chosen. For homogeneous materials or problems with only small jumps in the material coefficients across the interface, this approach is scalable without any vertex constraints; see [25] for a theoretical analysis and section 5 for numerical results. In fact, vertex constraints are needed only for problems with very special distributions of the material coefficients and large jumps of these coefficients across the interface; they are necessary to obtain a convergence rate which is uniformly bounded with respect to these jumps. A complete theoretical treatment of these cases is given in Klawonn and Widlund [25, section 8.3]; experimental results which confirm these theoretical considerations are presented in Klawonn and Rheinbach [21].

We now describe the approach using an explicit change of basis. As a result, the finite element functions associated with dual displacement vectors will have zero edge averages over primal edges. In addition, we introduce these averages as primal variables. Here and in the following, we define an edge as primal if at least one component of the displacements has the same edge average across the interface on this edge.

The transformation matrix T_E performs the desired change of basis from the new basis to the original nodal basis, and we then iterate in the space defined by the new basis. Denoting the edge unknowns in the new basis by $\widehat{\mathbf{u}}_E$, we have

$$\mathbf{u}_E = T_E \widehat{\mathbf{u}}_E.$$

Such a transformation matrix T_E can be constructed separately for each edge with three primal edge constraints. Ordering the three edge averages last, a possible choice of T_E is

$$T_E = \begin{bmatrix} I_3 & & O & I_3 \\ & \ddots & & \vdots \\ O & & I_3 & I_3 \\ -I_3 & \cdots & -I_3 & I_3 \end{bmatrix}, \tag{4.1}$$

where I_3 is the 3×3 identity matrix. We denote the resulting transformation, which operates on all relevant edges of $\partial\Omega_i$, by $T_E^{(i)}$. The transformation for all variables of one subdomain Ω_i is then of the form

$$T^{(i)} = \begin{bmatrix} I_I & O & O \\ O & I_{\overline{\Gamma}} & O \\ O & O & T_E^{(i)} \end{bmatrix},$$

where I_I and $I_{\overline{\Gamma}}$ are identity matrices. Here, we assume that the variables are ordered interior variables first, interface variables not related to the primal edges second, and the variables on the primal edges last, i.e., a typical vector of nodal unknowns is of the form $[\mathbf{u}_I^{(i)T}, \mathbf{u}_{\overline{\Gamma}}^{(i)T}, \mathbf{u}_E^{(i)T}]^T$. Here, we denote the interface variables not related to a primal edge by the subscript $\overline{\Gamma}$. We note that $T_E^{(i)}$ is a direct sum of the relevant transformation matrices associated with the primal edges of that subdomain; $T_E^{(i)}$ is a block-diagonal matrix where each block represents the transformation of a component of a primal edge.

Decomposing the subdomain stiffness matrices $K^{(i)}$ in the same manner, we obtain

$$K^{(i)} = \left[\begin{array}{cc|c} K_{II}^{(i)} & K_{I\overline{\Gamma}}^{(i)} & K_{IE}^{(i)} \\ K_{\overline{\Gamma}I}^{(i)} & K_{\overline{\Gamma}\overline{\Gamma}}^{(i)} & K_{\overline{\Gamma}E}^{(i)} \\ \hline K_{EI}^{(i)} & K_{E\overline{\Gamma}}^{(i)} & K_{EE}^{(i)} \end{array}\right].$$

Using the transformation $\mathbf{u}^{(i)} = T^{(i)}\widehat{\mathbf{u}}^{(i)}$, we obtain

$$T^{(i)T}K^{(i)}T^{(i)} = \left[\begin{array}{cc|c} K_{II}^{(i)} & K_{I\overline{\Gamma}}^{(i)} & K_{IE}^{(i)}T_E^{(i)} \\ K_{\overline{\Gamma}I}^{(i)} & K_{\overline{\Gamma}\overline{\Gamma}}^{(i)} & K_{\overline{\Gamma}E}^{(i)}T_E^{(i)} \\ \hline T_E^{(i)T}K_{EI}^{(i)} & T_E^{(i)T}K_{E\overline{\Gamma}}^{(i)} & T_E^{(i)T}K_{EE}^{(i)}T_E^{(i)} \end{array}\right], \tag{4.2}$$

where the upper left 2×2 block matrix is not affected by the basis transformation. The primal variables in the new basis consist now of averages, but we note that we might also have selected primal vertices as additional primal variables. The primal variables belonging to Ω_i are denoted by $\mathbf{u}_\Pi^{(i)}$ and the remaining, dual displacement variables by $\mathbf{u}_\Delta^{(i)}$. By construction, the basis functions associated with the new dual displacement variables have zero edge average over primal edges.

In the same manner the indices Δ_E and Π_E indicate the dual and primal displacement variables associated with the primal edge constraints. Denoting the transformed

matrices by an overline and ordering the primal edge variables last, we obtain

$$T^{(i)T}K^{(i)}T^{(i)} = \left[\begin{array}{cc|cc} K_{II}^{(i)} & K_{I\overline{\Gamma}}^{(i)} & \overline{K}_{I\Delta_E}^{(i)} & \overline{K}_{I\Pi_E}^{(i)} \\ K_{\overline{\Gamma}I}^{(i)} & K_{\overline{\Gamma}\overline{\Gamma}}^{(i)} & \overline{K}_{\overline{\Gamma}\Delta_E}^{(i)} & \overline{K}_{\overline{\Gamma}\Pi_E}^{(i)} \\ \hline \overline{K}_{\Delta_E I}^{(i)} & \overline{K}_{\Delta_E\overline{\Gamma}}^{(i)} & \overline{K}_{\Delta_E\Delta_E}^{(i)} & \overline{K}_{\Delta_E\Pi_E}^{(i)} \\ \overline{K}_{\Pi_E I}^{(i)} & \overline{K}_{\Pi_E\overline{\Gamma}}^{(i)} & \overline{K}_{\Pi_E\Delta_E}^{(i)} & \overline{K}_{\Pi_E\Pi_E}^{(i)} \end{array}\right].$$

Denoting the primal vertices by a subscript Π_V and the remaining dual displacement variables by a subscript Δ, we can then write $\mathbf{u}_{\overline{\Gamma}}^{(i)} = [\mathbf{u}_{\Delta}^{(i)T}\ \mathbf{u}_{\Pi_V}^{(i)T}]^T$. Using this splitting for the local stiffness matrices $K^{(i)}$ accordingly, ordering the primal variables $\mathbf{u}_{\Pi_V}^{(i)}$ and $\mathbf{u}_{\Pi_E}^{(i)}$ last, and combining them as primal variables $\mathbf{u}_{\Pi}^{(i)} = [\mathbf{u}_{\Pi_V}^{(i)T}, \mathbf{u}_{\Pi_E}^{(i)T}]^T$, we obtain

$$T^{(i)T}K^{(i)}T^{(i)} = \left[\begin{array}{ccc} K_{II}^{(i)} & \overline{K}_{\Delta I}^{(i)T} & \overline{K}_{\Pi I}^{(i)T} \\ \overline{K}_{\Delta I}^{(i)} & \overline{K}_{\Delta\Delta}^{(i)} & \overline{K}_{\Pi\Delta}^{(i)T} \\ \overline{K}_{\Pi I}^{(i)} & \overline{K}_{\Pi\Delta}^{(i)} & \overline{K}_{\Pi\Pi}^{(i)} \end{array}\right].$$

Assembling the primal contributions of each transformed $K^{(i)}$ and ordering the primal variables last, we obtain

$$\widetilde{K} := \left[\begin{array}{ccccccc} K_{II}^{(1)} & \overline{K}_{I\Delta}^{(1)} & & & & & \widetilde{K}_{\Pi I}^{(1)T} \\ \overline{K}_{\Delta I}^{(1)} & \overline{K}_{\Delta\Delta}^{(1)} & & & & & \widetilde{K}_{\Pi\Delta}^{(1)T} \\ & & \ddots & & & & \vdots \\ & & & K_{II}^{(N)} & \overline{K}_{I\Delta}^{(N)} & & \widetilde{K}_{\Pi I}^{(N)T} \\ & & & \overline{K}_{\Delta I}^{(N)} & \overline{K}_{\Delta\Delta}^{(N)} & & \widetilde{K}_{\Pi\Delta}^{(N)T} \\ \widetilde{K}_{\Pi I}^{(1)} & \widetilde{K}_{\Pi\Delta}^{(1)} & \cdots & \widetilde{K}_{\Pi I}^{(N)} & \widetilde{K}_{\Pi\Delta}^{(N)} & & \widetilde{K}_{\Pi\Pi} \end{array}\right] =: \left[\begin{array}{cc} \overline{K}_{BB} & \widetilde{K}_{\Pi B}^T \\ \widetilde{K}_{\Pi B} & \widetilde{K}_{\Pi\Pi} \end{array}\right].$$

The transformation of basis changes the sparsity pattern of the transformed matrices $T^{(i)T}K^{(i)}T^{(i)}$ compared to that of the original local stiffness matrices $K^{(i)}$, but only the matrix blocks related to the edge degrees of freedom are affected; cf. (4.2). We note that the set of edge degrees of freedom is only a small subset of the overall set of interface degrees of freedom. Thus, the transformation of basis only slightly affects the sparsity pattern. Using local Lagrange multipliers, the sparsity of the transformed matrices can be further improved; cf. [25, section 6.2]. To illustrate the change of sparsity of our local, transformed matrices $T^{(i)T}K^{(i)}T^{(i)}$ using the transformation (4.1), we compared the increase of nonzero entries in $T^{(i)T}K^{(i)}T^{(i)}$ to that of $K^{(i)}$ for the problems in Tables 5.1 and 5.2 in section 5. We found an increase between 4 and 12 percent of nonzero entries compared to the original local matrices $K^{(i)}$.

In our FETI-DP algorithm described in section 3, we always assume that we have performed an appropriate change of basis. If there is no danger of confusion, we will drop the overline notation which indicates the dual displacement variables in the transformed basis.

Using the transformation of basis, we again obtain

$$\left[\begin{array}{ccc} K_{BB} & \widetilde{K}_{\Pi B}^T & B^T \\ \widetilde{K}_{\Pi B} & \widetilde{K}_{\Pi\Pi} & O \\ B & O & O \end{array}\right] \left[\begin{array}{c} \mathbf{u}_B \\ \tilde{\mathbf{u}}_{\Pi} \\ \boldsymbol{\lambda} \end{array}\right] = \left[\begin{array}{c} \mathbf{f}_B \\ \tilde{\mathbf{f}}_{\Pi} \\ \mathbf{0} \end{array}\right].$$

We note that after the change of basis has been carried out, we can always use the same implementation as for Algorithm A since the algorithmic description in section 3 does not depend on a specific choice of primal and dual variables. Note that the local problems as well as the Schur complement $\tilde{S}_{\Pi\Pi}$ remain symmetric positive definite.

The following condition number estimate for FETI-DP algorithms using edge averages on selected edges and/or selected vertices as primal constraints can be deduced from Klawonn and Widlund [25, Theorem 1].

THEOREM 4.1.

$$\kappa(M^{-1}F) \leq C\,(1+\log(H/h))^2,$$

H h C h H

For homogeneous materials or problems with discontinuities of the material coefficients which are not very large, it follows from the results in Klawonn and Widlund [25] that primal vertices are not needed to obtain a good condition number bound. We thus introduce a new notation and denote the algorithm using edge averages on selected primal edges as the only primal constraints by Algorithm D_E.

We note that in [25] a variant of Algorithm D_E is considered which in addition uses first order moments on selected edges and possibly selected primal vertices. In this case, a condition number estimate is shown which is also independent of discontinuities of the material coefficients across the interface.

5. Numerical results. We apply our new implementation of FETI-DP using a basis transformation to different problems. First, we consider the standard benchmark problem of an elastic cube divided into smaller regular cubes as subdomains; as a second example we consider three different mechanical parts from an industrial application; and finally, we apply our algorithm to a cancellous bone geometry; see subsections 5.1, 5.2, and 5.3. The domains considered in the second and third subsections are decomposed in irregularly shaped substructures by using ParMetis [20]. In all problems, we use linear tetrahedral finite elements and, for simplicity, a Young modulus of $E = 210$ and a Poisson ratio of $\nu = 0.29$ throughout. In all of our experiments we use Algorithm D_E, i.e., our choice of primal constraints is given by edge averages on selected edges, without any primal vertices. Here, we always constrain all three averages on a primal edge. In all of our computations, we make all edges obtained by Definition 2.1 primal; additionally, in subsections 5.2 and 5.3, we add some edges obtained by Definition 2.2. All computations of subsections 5.1 and 5.2 were carried out on , a 350-node computing cluster operated by the Mathematics and Computer Science Division at Argonne National Laboratory. The cluster consists of 2.4 GHz Xeon processors with 1 or 2 GBytes of memory each and uses a Myrinet connection. The numerical results given in Table 5.1, Figure 5.6, and in subsection 5.3 have been carried out on a 16-processor computing cluster in Essen with eight dual 2.2 GHz Opteron nodes and 4 GBytes of memory for each processor. This cluster uses a Gigabit ethernet connection.

5.1. Model problem. In this section, as a benchmark model problem, we consider a homogeneous, isotropic, linearly elastic cube which is clamped at one side, while all other parts of the boundary have homogeneous natural boundary conditions. A volume force is applied which defines the right-hand side.

In order to analyze the numerical and parallel scalability of our FETI-DP algorithm we report on two different series of experiments. In our first set of runs, we

keep the dimension of the local problems, and H/h, fixed and increase the number N of subdomains and thus the overall problem size; see Tables 5.1 and 5.2. In a second series of experiments, we keep a fixed number N of subdomains and increase the size of the local problems, and H/h, resulting in a smaller h and thus a larger overall problem size. The results of these experiments are given in Table 5.3 and Figure 5.1. In all sets of experiments, we use as a stopping criterion the relative reduction of the preconditioned dual residual by 10^{-7}.

In the numerical results obtained for a fixed subdomain size, reported in Tables 5.1 and 5.2, the cube is partitioned into smaller cubes with $H/h = 13$ which results in 8 232 degrees of freedom for each subdomain. In Tables 5.1 and 5.2, we denote the degrees of freedom of the original, assembled problem by "d.o.f." and those of the coarse problem by "Coarse". We first present results using the sparse direct solver built into PETSc [3, 2, 4] for solving the coarse problem and the local problems; cf. Table 5.1. Next, we present a set of experiments using the sparse direct solver package MUMPS 4.3.2 [1] together with the optimized BLAS libraries for the Xeon architecture to solve the coarse problem and the local problems; cf. Table 5.2. Both sets of experiments show that our FETI-DP algorithm using only edge averages as primal constraints yields a numerical and parallel scalable domain decomposition method. As a further result of this comparison, we see that using MUMPS as a direct solver accelerates our method by almost a factor of three in terms of CPU time.

The numerical results for a fixed number of subdomains with increasing size are obtained for the unit cube divided into $N = 4 \times 4 \times 4 = 64$ subdomains. We keep $H = 1/4$ fixed and vary H/h between 3 and 23. Algorithm D_E has a coarse problem size of 324. The growth of the number of iterations and of the largest eigenvalue of Algorithms D_E are shown in Figure 5.1.

All of the numerical results in this subsection confirm the theoretical condition number estimate given in Theorem 4.1; cf. also [25, Theorem 1].

5.2. Industrial applications. In this section, we apply our FETI-DP algorithm to three different industrial finite element problems, denoted by mechanical parts A, B, and C.

The direct subdomain solves as well as the coarse problem solve are performed by again using the sparse direct solver MUMPS and the optimized BLAS libraries for the Xeon architecture. To compare the parallel performance of our FETI-DP domain decomposition method Algorithm D_E to that of the parallel sparse direct solver provided by MUMPS, we also provide CPU timings for MUMPS applied to the assembled and undecomposed problem on the same machine.

The first problem, mechanical part A (cf. Figure 5.2) has been discretized by 208 536 linear tetrahedral finite elements yielding a global number of 187 539 degrees of freedom. In the reported experiments the mechanical part A is partitioned into $N = 16$ subdomains using ParMetis. The FETI-DP algorithm using only edge averages as primal constraints needed 29 iterations for a relative reduction of the preconditioned dual residual by 10^{-7}. The size of the coarse problem is 393 degrees of freedom. The smallest and largest eigenvalues are $\lambda_{\min} = 1.02$ and $\lambda_{\max} = 19.63$, respectively. The parallel scalability results on 2 to 16 processors are given in Table 5.4.

The second problem in this subsection, mechanical part B (cf. Figure 5.3) is discretized by 581 394 linear tetrahedral finite elements resulting in a global number of 380 709 degrees of freedom. It is partitioned into $N = 64$ subdomains using ParMetis. In all of the experiments reported in Table 5.5, our FETI-DP algorithm using only edge averages as primal constraints needed 29 iterations for a relative reduction of the preconditioned dual residual by 10^{-7}. The size of the coarse problem is 1 020. The

smallest and largest eigenvalues are $\lambda_{\min} = 1.03$ and $\lambda_{\max} = 33.85$, respectively. The parallel scalability results on 4 to 64 processors are given in Table 5.5.

The third problem in this subsection, mechanical part C (cf. Figure 5.4) is discretized by 1 291 933 linear tetrahedral finite elements yielding a global number of 841 836 degrees of freedom. It is partitioned into $N = 64$ subdomains using ParMetis. In all of the experiments reported in Table 5.6, the number of iterations is 32 for a relative reduction of the preconditioned dual residual by 10^{-7}. The size of the coarse problem is 957 degrees of freedom. The smallest and largest eigenvalues are $\lambda_{\min} = 1.03$ and $\lambda_{\max} = 27.77$, respectively. The parallel scalability results on 16 to 64 processors are given in Table 5.6.

In Table 5.7 we also report results for mechanical part C decomposed into 512 subdomains. In these experiments the largest eigenvalue is $\lambda_{\max} = 21.36$ and the smallest eigenvalue $\lambda_{\min} = 1.03$. The coarse problem size was chosen as 7 500 degrees

of freedom. The number of iterations is 32 for a relative reduction of the preconditioned dual residual of 10^{-7}.

From our numerical experiments we see that the FETI-DP algorithms using edge averages only as primal constraints yield a parallel scalable domain decomposition method also for problems from industrial applications using irregularly shaped substructures. The FETI-DP algorithm is, in terms of CPU time, always faster than the sparse direct solver applied to the undecomposed problem, except for the smallest problem, mechanical part A, and there only for 2 and 4 processors.

5.3. A cancellous bone geometry. In this subsection, we present results of our FETI-DP algorithm applied to a linearly elastic domain which has a cancellous bone geometry. We show that our method is robust also for complicated geometries with many holes and thin structures, as usually appear in cancellous/trabecular bone; see Figure 5.5. For simplicity, we consider only isotropic linear elasticity. For a full study of cancellous bone, we should use linearly elastic orthotropic or even nonlinear material models; this will be considered in forthcoming work. The bone geometry is discretized by 907 609 linear tetrahedral finite elements resulting in a global number of 620 730 degrees of freedom. The mesh is obtained using a marching cubes algorithm to generate a surface mesh and Netgen [40] to produce a volume mesh from it. It is partitioned into $N = 96$ subdomains using ParMetis. In all of our experiments reported in Table 5.8, the number of iterations is 51 for a relative reduction of the

preconditioned dual residual by 10^{-10}. The size of the coarse problem is 1 602 degrees of freedom. The smallest and largest eigenvalues are $\lambda_{\min} = 1.02$ and $\lambda_{\max} = 43.57$, respectively. The parallel scalability results on 1 to 16 processors are given in Table 5.8. As sparse direct solvers for the coarse and the local problems, we use UMFPACK 4.3 [8].

In Figure 5.6 we show the convergence history for the cancellous bone geometry as well as for mechanical parts A and B and for the cube benchmark problem with $H/h = 14$ and $h = 1/105$. We compute the true relative residual $\|F\boldsymbol{\lambda}^n - \mathbf{d}\|_2/\|F\boldsymbol{\lambda}^0 - \mathbf{d}\|_2$ explicitly in each step. Let us note that the true residual is only used in the experiments for the results shown in Figure 5.6. Here, we use the true residual for the computation of the results to avoid possible inaccuracies in the recursive computation used in the conjugate gradient algorithm when the residual is approaching machine precision.

Acknowledgments. The authors gratefully acknowledge the use of , a 350-node computing cluster operated by the Mathematics and Computer Science Division at Argonne National Laboratory as part of its Laboratory Computing Resource Center. The authors also gratefully acknowledge the X-ray computer tomography cross sections which were obtained from Matthias Epple, Institute of Inorganic Chemistry, University of Duisburg-Essen, within a common research collaboration. The second author acknowledges many fruitful discussions with Barry Smith and Matthew Knepley while visiting the Mathematics and Computer Science Division at Argonne National Laboratory. The authors wish to thank Hans-Jürgen Philipsenburg, Holger Hein, and GETRAG FORD Transmissions GmbH, Cologne, Germany. For discussions on the revised version, the authors are grateful to Kendall Pierson, Sandia National Laboratories. Last but not least, the authors have had many interesting discussions with Olof Widlund, Courant Institute of Mathematical Sciences.

PARALLEL GUARANTEED QUALITY DELAUNAY UNIFORM MESH REFINEMENT*

ANDREY N. CHERNIKOV† AND NIKOS P. CHRISOCHOIDES†

Abstract. We present a theoretical framework for developing parallel guaranteed quality Delaunay mesh generation software that allows us to use commercial off-the-shelf sequential Delaunay meshers for two-dimensional geometries. In this paper, we describe our approach for constructing uniform meshes, that is, the meshes in which all elements have approximately the same size. Our uniform distributed- and shared-memory implementations are based on a simple (block) coarse-grained mesh decomposition. Our method requires only local communication, which is bulk and structured as opposed to fine and unpredictable communication of the other existing practical parallel guaranteed quality mesh generation and refinement techniques. Our experimental data show that on a cluster of more than 100 workstations we can generate about 0.9 billion elements in less than 5 minutes in the absence of work-load imbalances. Preliminary results for this paper were presented in [A. N. Chernikov and N. P. Chrisochoides, "Practical and efficient point insertion scheduling method for parallel guaranteed quality Delaunay refinement," in Proceedings of the 18th Annual International Conference on Supercomputing, ACM Press, New York, 2004, pp. 48–57]. Our work in progress includes extending the presented approach, which can efficiently generate only uniform meshes, to nonuniform graded meshes.

Key words. Delaunay triangulation, mesh generation, parallel refinement

DOI. 10.1137/050625886

1. Introduction.

With the development of very efficient sequential guaranteed quality mesh generators, e.g., the "Triangle" [33], the construction of very large meshes that cannot fit into the memory of a single machine still remains a challenging problem. These large meshes are required, for instance, to conduct direct numerical simulations of turbulence in cylinder flows with very large Reynolds numbers; see [14]. With the increase of the Reynolds number, the size of the mesh grows in the order of $Re^{9/4}$ (see [23]), which motivates the use of a parallel distributed-memory mesh generation algorithm.

There are four important requirements that are usually imposed on the parallel mesh generation algorithms: , , , and refers to the fact that distributed meshes retain the same quality of the elements and partition properties as the sequentially generated and partitioned meshes; see [10]. is understood as the ability of the algorithm and software to achieve the speedup proportional to the number of processors; see [25]. The can be measured in terms of its computation cost and the appropriateness of the resulting subdomains for the selected mesh generation algorithm. Finally, allows one to take advantage of the ever-evolving basic sequential meshing libraries which are now mature and highly optimized. In this

paper, we present an algorithm that conforms to all four of these requirements, while the previously published results address only some of them.

The sophisticated domain decomposition methods like the medial axis domain decomposition (MADD) [27] allow one to completely decouple the subproblems, and therefore eliminate the communication, but they are very expensive and difficult to construct for three-dimensional domains. In this paper, we settle for a simpler (block) domain decomposition at the cost of some bulk communication and work-load imbalances. Fortunately, the bulk communication in our method is structured and can be tolerated. To cope with the work-load imbalances, we developed a runtime system [2] that successfully addresses the dynamic load balancing problem for mesh generation.

Nave, Chrisochoides, and Chew [30] presented the first practical provably good parallel mesh refinement algorithm for polyhedral domains. They addressed the stability, and to some success the scalability, but not the code reuse requirement. The algorithm in [30] guarantees stability by simultaneously partitioning and refining the interface surfaces and the volumes of the subdomains—the changes caused by a point insertion can propagate across the processor boundaries—at the cost of high communication and of the restructuring of the Delaunay kernel. In [10], Chrisochoides and Nave restructured the sequential Bowyer–Watson (B-W) Delaunay kernel [5, 39] using the speculative execution model (see [20]) in order to tolerate high communication latencies. The speculative execution model allows setbacks to occur if the changes caused by the concurrent insertion of two or more points are incompatible. Although more than 80% of the overhead due to the remote data gather operations is masked, the experimental data in [10] suggest only $\mathcal{O}(\log P)$ speedup, P being the number of processors. In this paper, we provide a sufficient condition, which (in two dimensions) guarantees the independence of the simultaneously inserted points, eliminates the setbacks and the need to restructure the mesh generation kernel, and does not induce intensive communication. Moreover, our condition is not based on the coloring techniques, which require high preprocessing time, since they need first to construct a graph (cavity graph[1]).

Blelloch et al. [4] describe a divide-and-conquer projection-based algorithm for constructing Delaunay triangulations of predefined point sets in parallel. The work by Kadow [21] and Kadow and Walkington [22] extended [4] for parallel mesh generation and further eliminated the sequential step (contrary to our proposed method) for an initial mesh, but did not address the issue of code reuse.

An idea of updating partition boundaries when inserted points happen to be close to them was presented by Chew, Chrisochoides, and Sukup [8] as a parallel constrained Delaunay meshing (PCDM) algorithm. In PCDM, the edges on the boundaries of submeshes are fixed (constrained), and if a new point encroaches upon a constrained edge, another point is inserted in the middle of this edge instead. As a result, a "split" message is sent to the neighboring processor, notifying that it also has to insert the midpoint of the shared edge. This approach requires the construction of the separators that will not compromise the quality of the final mesh, and permits the reuse of sequential codes only to a limited degree, since one has to handle "split" messages and partial cavity expansions within the B-W kernel.

[1]When a new point is inserted, all tetrahedra that have this point within their circumspheres are eliminated. This creates a *cavity*. In the cavity graph each cavity is represented by a vertex and two adjacent cavities are represented by an edge. Chew et al. [9] presented a method to improve the efficiency of this method, but its computation requirements and possible optimizations are subject to additional research.

The theoretical analysis of the idea of the concurrent insertion of independent points has been started by several authors. Edelsbrunner and Guoy [15] define the prestar of point x as the difference between the closure of the set of tetrahedra whose circumspheres enclose x and the closure of the set of remaining tetrahedra. Further, they define the points x and y as independent if the closures of their prestars are disjoint. We prove a similar condition of point independence. The difference between the independence condition in [15] and in this paper is that our formulation is less restrictive: it allows the prestars (we use the word cavity) to share a point. However, computing the prestars (cavities) and their intersections for all candidate points is very expensive. That is why we do not use coloring methods that are based on the cavity graphs and continue by proving a theorem, which allows us to use only the distance between the points to check whether they are independent. The minimum separation distance argument in [15] is used to derive the upper bound on the number of inserted vertices and prove termination, but does not ensure point independence. In addition, we propose a simple block decomposition scheme for scheduling parallel point insertion for both the distributed- and the shared-memory implementations. In [15], a shared-memory algorithm based on finding the maximal independent set of points is used. Also, Spielman, Teng, and Üngör [36] presented the first theoretical analysis of the complexity of the parallel Delaunay refinement algorithms. However, the assumption is that the global mesh is completely retriangulated each time a set of independent points is inserted [38]. In [37] a more practical algorithm was developed.

Besides the Delaunay-based algorithms, a number of other parallel mesh generation algorithms have been published. De Cougny, Shephard, and Ozturan [12] base the parallel mesh construction on an underlying octree. Löhner and Cebral [28] and Ito et al. [19] developed parallel advancing front schemes. Globisch [17, 18] presented a parallel mesh generator which uses a sequential frontier algorithm. A detailed review of many more methods appears in [11].

The rest of the paper is organized as follows. Section 2 presents the theoretical framework for our parallel guaranteed quality Delaunay refinement algorithm. After introducing the notation, we describe the sequential Delaunay refinement algorithm and emphasize the Delaunay triangulation loop invariant, which has to be maintained in order to ensure the correctness of the result. In subsection 2.3.1, we show how the concurrent point insertion can violate this invariant and lead to either nonconforming or non-Delaunay mesh. We prove a theorem which states that if the distance between two points is greater than four times the upper bound on triangle circumradius, then these points can be safely inserted in parallel. We continue by proving in subsection 2.3.2 that the maximal circumradius is not increased in the course of the execution of the B-W algorithm, which makes our condition applicable at all times during the mesh refinement. Next, we show in subsection 2.3.3 how to select the preprocessing parameters so that we can efficiently use all processors and at the same time have minimal sequential overhead. Our coarse-grained partitioning scheme is described in section 3. Finally, in section 4 we present the implementation issues and the experimental results. We conclude with a summary of our results and future work directions.

2. Parallel Delaunay refinement.

2.1. Notation. We will denote a point with index i as p_i and the triangle with vertices p_i, p_j, and p_k as $\triangle p_i p_j p_k$. When the vertices of a triangle are irrelevant, we will denote such a triangle with a single letter t. We will use the small letters a, b, and c to refer to the side lengths of a triangle, adopting the convention $a \leq b \leq c$,

and the capital letters A, B, and C to represent the measures of the three angles in the triangle, where we suppose the relation $A \leq B \leq C$.

The term [illegible] p [illegible] r refers to the set of points in $\mathbb{R}^2$ whose Euclidean distance to p is exactly r. We will use the term [illegible] for the set of points in $\mathbb{R}^2$ whose distance from p is strictly less than r. The symbol $\|\cdot\|$ will represent the conventional Euclidean distance (the L_2 norm).

Let the [illegible] of triangle $\triangle p_i p_j p_k$ be the unique circle that passes through p_i, p_j, and p_k. The center and the radius of a triangle's circumcircle are called its [illegible] and [illegible], respectively. Let us call the open disk corresponding to a triangle's circumcircle its [illegible]. We will use the symbols $\bigcirc(t)$, $r(t)$, and $\odot(t)$ to represent the circumdisk, circumradius, and the circumcenter of the triangle t, respectively.

The input to a planar triangular mesh generation algorithm includes a description of [illegible] $\Omega \subset \mathbb{R}^2$, which is permitted to contain holes or have more than one connected component. We will use a [illegible] (PSLG) [33] to delimit Ω from the rest of the plane. A PSLG consists of a set P of points and a set S of segments connecting the points in P. The segments are not allowed to intersect in points that are not in P. Each segment in S is considered [illegible] and must appear (possibly as a union of smaller segments) in the final mesh.

DEFINITION 1. [illegible] V [illegible] $\Omega \subset \mathbb{R}^2$ [illegible] T [illegible] V [illegible] $\mathcal{T} = (V, T)$ [illegible] conformal[2] triangulation ([illegible] [16]) [illegible]

1. [illegible] T [illegible] V
2. [illegible] T [illegible] Ω
3. [illegible] ([illegible]) [illegible] T
4. [illegible]

We will use the terms [illegible] and [illegible] interchangeably, depending on the context.

Also, let $\bar{r}$, $\bar{\rho}$, and $\bar{\Delta}$ denote the upper bounds on the circumradius, the circumradius-to-shortest edge ratio, and the area of the triangles, respectively.

2.2. Sequential Delaunay refinement. The applications that use Delaunay meshes usually impose two constraints on the quality of the mesh elements: the upper bound $\bar{\Delta}$ on the element area and the lower bound $\bar{A}$ on the smallest angle. As shown by Miller et al. [29] and Shewchuk [34], in two dimensions the circumradius-to-shortest edge ratio ρ of a triangle can be expressed in terms of its minimal angle A as

$$\rho = \frac{1}{2 \sin A}. \tag{2.1}$$

As the circumradius-to-shortest edge ratio is the metric that is naturally optimized by the Delaunay refinement (see [29]), we will consider $\bar{\Delta}$ and $\bar{\rho}$, along with a PSLG $\mathcal{X}$, as the parameters to the mesh generation algorithm.

Typically, a mesh generation procedure starts by constructing an initial mesh which conforms to the input vertices and segments, and then refines this mesh until the constraints $\bar{\Delta}$ and $\bar{\rho}$ are met. For sufficiently small values of $\bar{\Delta}$, resulting in large fine meshes, most of the time is spent reducing the area of the triangles. Although

[2] A term which sounds similar, but has a different meaning, is *conforming triangulation*, which is used in the context of preserving constrained edges [32].

asymptotically $\mathcal{O}(n \log n)$ time is required to triangulate n points, while refining an existing mesh is on average linear in the number of the triangles produced, for fairly large final meshes the latter time significantly dominates. In this paper, we focus on parallelizing the Delaunay refinement stage, which is usually the most memory- and computation-expensive. The general idea of the Delaunay refinement is to insert points in the circumcenters of the triangles that violate the required bounds, until there are no such triangles left. There are two main variations of the point insertion procedure: Lawson's algorithm [26], which uses edge flips, and the B-W algorithm [5, 39], which is based on deleting the triangles that are no longer Delaunay and inserting new triangles that satisfy the Delaunay property. These algorithms produce equivalent results (see [34]); thus, we will use only the B-W algorithm for our analysis. The following definition, adapted from [16], plays a major role in the study of the B-W algorithm.

DEFINITION 2. [illegible] cavity $\mathcal{C}_{\mathcal{M}}(p)$ of point p with respect to mesh $\mathcal{M}$ [illegible] $\mathcal{M}$ [illegible] p. $\mathcal{C}_{\mathcal{M}}(p) = \{t \in \mathcal{M} \mid p \in \bigcirc(t)\}$

We will write simply $\mathcal{C}(p)$ when $\mathcal{M}$ is clear from the context. Also, we will denote $\mathcal{B}_{\mathcal{M}}(p)$ to be the set of the edges which belong to only one triangle in $\mathcal{C}_{\mathcal{M}}(p)$, i.e., the external edges of $\mathcal{C}_{\mathcal{M}}(p)$.

The sequential Delaunay algorithms treat constrained (boundary) segments differently from triangle edges in the interior of the mesh; see [31, 34]. For a segment s, the unique circle with s as a diameter is called the [illegible] of s. A vertex p is said to [illegible] s if it lies within the open diametral disk of s. When a new point is about to be inserted and it happens to encroach upon a constrained segment s, another point is inserted in the middle of s instead, and the cavity of the segment's midpoint is constructed and triangulated in a similar way.

For a thorough description of the sequential Delaunay refinement algorithms and the proofs of their termination, as well as the proofs of good grading and size optimality of the result, the reader can consult [16, 31, 34, 35] and the references therein. For our analysis, it is sufficient to consider the algorithm in Figure 1. The while-loop of the algorithm maintains the following invariant.

LOOP INVARIANT 1 (Delaunay triangulation). $\mathcal{M}$ [illegible] (i) [illegible] (ii) [illegible]

2.3. Theoretical framework. The parallelization of the sequential Delaunay refinement algorithm can be achieved by inserting the circumcenters of multiple triangles concurrently by several processors. In this subsection, we propose a theoretical framework which allows us to select the candidate circumcenters in such a way that the Delaunay triangulation loop invariant holds throughout the run of the parallel algorithm, and, thus, all the quality guarantees of the sequential algorithm remain valid.

2.3.1. Maintaining the Delaunay triangulation loop invariant. We expect a parallel Delaunay refinement algorithm to maintain Loop Invariant 1. The reason for a parallel algorithm to produce a nonconformal mesh can be a concurrent retriangulation of two or more cavities that have common triangles. Consider, for example, Figure 2(a). However, even if the cavities of two points do not have common triangles, Loop Invariant 1 can still be violated due to the creation of non-Delaunay triangles, i.e., triangles whose circumdisks include mesh vertices. This can happen if two cavities have common edges; see Figure 2(b). The following lemma provides a sufficient condition for the simultaneous retriangulation of two cavities to yield a conformal Delaunay mesh.

DelaunayRefinement($\mathcal{X}$, $\mathcal{M}$, $\bar{\Delta}$, $\bar{\rho}$)
Input: $\mathcal{X}$ is a PSLG which defines Ω
$\mathcal{M}$ is some Delaunay mesh over Ω
$\bar{\Delta}$ and $\bar{\rho}$ are desired upper bounds
Output: a conforming Delaunay mesh respecting $\bar{\Delta}$ and $\bar{\rho}$

```

FIG. 1. *The sequential Delaunay refinement algorithm. A more detailed description along with the segment splitting strategies, which always guarantee termination, can be found in* [35].

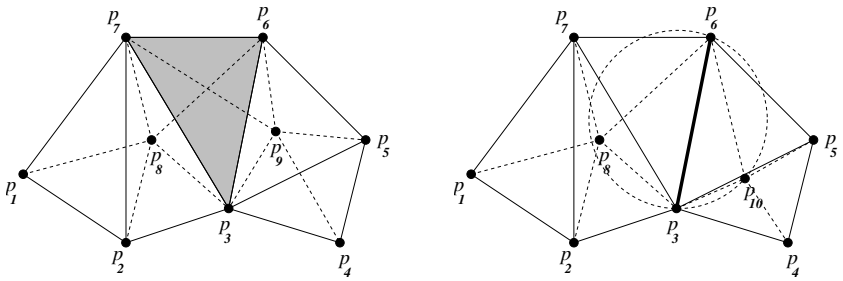

FIG. 2. (a) *If* $\triangle p_3p_6p_7 \in \mathcal{C}(p_8) \cap \mathcal{C}(p_9)$, *where* $\mathcal{C}(p_8) = \{\triangle p_1p_2p_7, \triangle p_2p_3p_7, \triangle p_3p_6p_7\}$ *and* $\mathcal{C}(p_9) = \{\triangle p_3p_6p_7, \triangle p_3p_5p_6, \triangle p_3p_4p_5\}$, *then the concurrent insertion of* p_8 *and* p_9 *results in a nonconformal mesh. The solid lines represent the edges of the initial triangulation, and the dashed lines represent the edges created by the insertion of* p_8 *and* p_9. (b) *If the edge* p_3p_6 *is shared by* $\mathcal{C}(p_8) = \{\triangle p_1p_2p_7, \triangle p_2p_3p_7, \triangle p_3p_6p_7\}$ *and* $\mathcal{C}(p_{10}) = \{\triangle p_3p_5p_6, \triangle p_3p_4p_5\}$, *then the new triangle* $\triangle p_3p_{10}p_6$ *can have point* p_8 *inside its circumdisk, thus violating the Delaunay property.*

LEMMA 1. $\mathcal{C}(p_i)$ $\mathcal{C}(p_j)$ p_i p_j . Since $\mathcal{C}(p_i)$ and $\mathcal{C}(p_j)$ do not intersect, the processors that are working independently on retriangulating $\mathcal{C}(p_i)$ and $\mathcal{C}(p_j)$ will not attempt to simultaneously delete the same triangles or create overlapping triangles, and thus the resulting mesh will be conformal.

To show that the mesh will also satisfy the Delaunay criterion, we need to recall the Delaunay lemma (see [13, 16]), which states that if the empty circumdisk criterion holds for every pair of adjacent triangles, the triangulation is globally Delaunay. The condition that $\mathcal{C}(p_i)$ and $\mathcal{C}(p_j)$ do not share any triangle edges implies that every

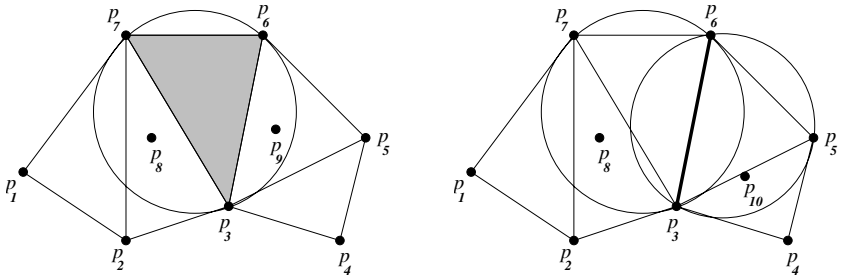

FIG. 3. (a) *If* $\triangle p_3p_6p_7 \in \mathcal{C}(p_8) \cap \mathcal{C}(p_9)$, *then* $\|p_8 - p_9\| < 2r(\triangle p_3p_6p_7) < 2\bar{r}$. (b) *If edge* p_3p_6 *is shared by* $\mathcal{C}(p_8) = \{\triangle p_1p_2p_7, \triangle p_2p_3p_7, \triangle p_3p_6p_7\}$ *and* $\mathcal{C}(p_{10}) = \{\triangle p_3p_5p_6, \triangle p_3p_4p_5\}$, *then* $\|p_8 - p_{10}\| < 2r(\triangle p_3p_6p_7) + 2r(\triangle p_3p_5p_6) < 4\bar{r}$.

external edge of $\mathcal{C}(p_i)$ and $\mathcal{C}(p_j)$ is incident upon some triangle which belongs neither to $\mathcal{C}(p_i)$ nor to $\mathcal{C}(p_j)$. These external triangles together with the ones created by the retriangulation of $\mathcal{C}(p_i)$ and $\mathcal{C}(p_j)$ will locally satisfy the Delaunay property; see [34]. Hence, the mesh will be globally Delaunay. ∎

In practice, though, this lemma may not be very useful, since it requires the construction and the comparison of the cavities for all candidate points. The next lemma achieves a more practical result.

LEMMA 2. $\bar{r}$ $\mathcal{M}$ $p_i, p_j \in \Omega$ Ω $\|p_i - p_j\| \geq 4\bar{r}$ $\mathcal{C}(p_i)$ $\mathcal{C}(p_j)$

We will prove this lemma by contradiction by considering two cases:

(i) Suppose $\|p_i - p_j\| \geq 4\bar{r}$ and $\mathcal{C}(p_i) \cap \mathcal{C}(p_j) \neq \emptyset$. Let $t \in \mathcal{C}(p_i) \cap \mathcal{C}(p_j)$; see Figure 3(a). By the definition of the cavity, $p_i \in \bigcirc(t)$ and $p_j \in \bigcirc(t)$, and hence $\|p_i - p_j\| < 2r(\triangle p_kp_lp_m) < 2\bar{r} < 4\bar{r}$, which contradicts our assumption.

(ii) Suppose $\|p_i - p_j\| \geq 4\bar{r}$ and there exists an edge p_kp_l which is shared by $\mathcal{C}(p_i)$ and $\mathcal{C}(p_j)$; see Figure 3(b). Let $\triangle p_kp_lp_m \in \mathcal{C}(p_i)$ and $\triangle p_kp_lp_n \in \mathcal{C}(p_j)$. Obviously, $\|p_k - p_i\| < 2r(\triangle p_kp_lp_m)$ and $\|p_k - p_j\| < 2r(\triangle p_kp_lp_n)$. From the triangle inequality it follows that $\|p_i - p_j\| < 2r(\triangle p_kp_lp_m) + 2r(\triangle p_kp_lp_n) < 4\bar{r}$, which again contradicts the assumption. ∎

Theorem 1 is the immediate consequence of Lemmas 1 and 2 and can be used for an efficient constant-time verification of whether two points are independent and, hence, can be inserted concurrently.

THEOREM 1. $\bar{r}$ $p_i, p_j \in \Omega$ $\|p_i - p_j\| \geq 4\bar{r}$ p_i p_j

2.3.2. The circumradius upper bound invariant. For Theorem 1 to be applicable throughout the run of the algorithm, we need to prove another invariant.

LOOP INVARIANT 2 (circumradius upper bound). $\bar{r}$

Next, we show that the execution of the B-W algorithm, either sequentially or in parallel, does not violate Loop Invariant 2.

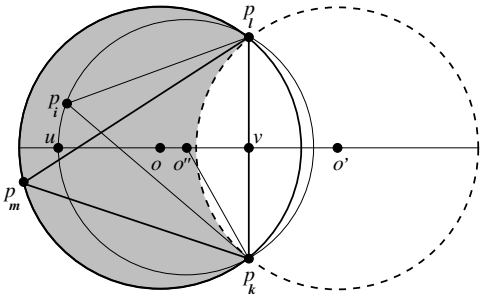

FIG. 4. *The solid circle corresponds to* $\bigcirc(\triangle p_k p_l p_m)$ *with the center in point* o*, and the dashed circle corresponds to* $\bigcirc'_{p_k p_l}(\triangle p_k p_l p_m)$ *with the center in point* o'*. Point* o'' *is the center of the variable-radius disk, whose circle passes through* p_k *and* p_l*. We prove that for any point* p_i *inside the shaded region,* $r(\triangle p_k p_l p_i) < r(\triangle p_k p_l p_m)$*.*

Let the [illegible] $\bigcirc(\triangle p_k p_l p_m)$ [illegible] $p_k p_l$ be the disk $\bigcirc'_{p_k p_l}(\triangle p_k p_l p_m)$ that has the same radius, whose circle passes through the points p_k and p_l, and whose center lies on the other side of edge $p_k p_l$ from point p_m. See Figure 4.

LEMMA 3. [illegible] p_i [illegible] $\bigcirc(\triangle p_k p_l p_m) \setminus \bigcirc'_{p_k p_l}(\triangle p_k p_l p_m)$ [illegible] 4. $r(\triangle p_k p_l p_i) < r(\triangle p_k p_l p_m)$

[illegible] Let o'' be the center of the disk $\bigcirc(\triangle p_k p_l p_i)$, where p_i is any point inside the shaded region $\bigcirc(\triangle p_k p_l p_m) \setminus \bigcirc'_{p_k p_l}(\triangle p_k p_l p_m)$. o'' has to lie on the straight line through o and o'. Let v be the point of intersection of this straight line with the edge $p_k p_l$ (i.e., the midpoint of $p_k p_l$), and let u be the point of intersection of the straight line with the circle of $\bigcirc(\triangle p_k p_l p_i)$ inside the shaded region. Let $x = \|u - v\|$. We will express the radius of $\bigcirc(\triangle p_k p_l p_i)$ as a function of x: $r(\triangle p_k p_l p_i) = f(x)$.

Let us consider the triangle $\triangle p_k v o''$ with the right angle at the vertex v. If we denote $\|p_k - p_l\| = a$, and $\|v - o\| = \|v - o'\| = b$, then by observing that $\|p_k - v\| = a/2$, $\|v - o''\| = x - f(x)$, and $\|o'' - p_k\| = f(x)$, we have

$$f^2(x) = \left(\frac{a}{2}\right)^2 + (x - f(x))^2 \quad \text{or} \quad f(x) = \frac{a^2}{8x} + \frac{x}{2}, \quad \text{where } 0 < x < \infty.$$

$f(x)$ is convex everywhere on $0 < x < \infty$ since its second derivative is positive:

$$f''(x) = \frac{a^2}{4x^3} > 0 \quad \text{for } 0 < x < \infty.$$

In addition,

$$\begin{aligned} f(x)|_{o''=o'} &= f(r(\triangle p_k p_l p_m) - b) = r(\triangle p_k p_l p_m), \\ f(x)|_{o''=o} &= f(r(\triangle p_k p_l p_m) + b) = r(\triangle p_k p_l p_m). \end{aligned}$$

Using Jensen's inequality (see [40]), for $0 \le \lambda \le 1$ and $r(\triangle p_k p_l p_m) - b < x < r(\triangle p_k p_l p_m) + b$, we can derive the following:

$$\begin{aligned} f(x) &< \lambda f(r(\triangle p_k p_l p_m) - b) + (1 - \lambda) f(r(\triangle p_k p_l p_m) + b) \\ &= \lambda r(\triangle p_k p_l p_m) + (1 - \lambda) r(\triangle p_k p_l p_m) \\ &= r(\triangle p_k p_l p_m). \qquad \square \end{aligned}$$

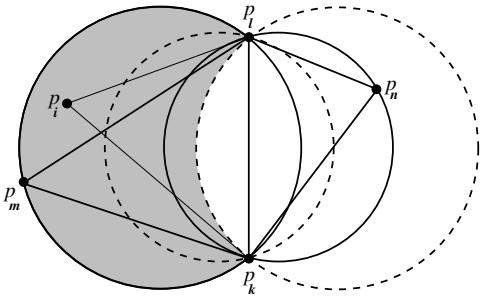

FIG. 5. $\triangle p_k p_l p_m \in \mathcal{C}(p_i)$, $\triangle p_k p_n p_l \notin \mathcal{C}(p_i)$, *and* $r(\triangle p_k p_l p_m) > r(\triangle p_k p_n p_l)$.

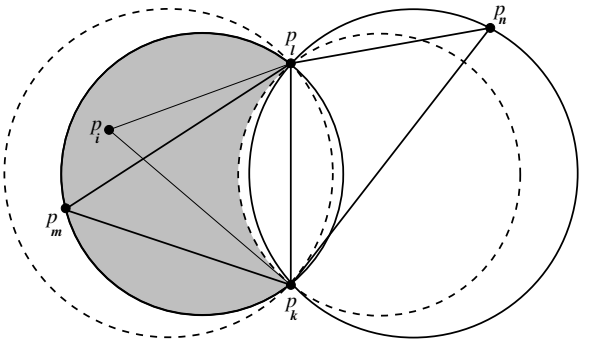

FIG. 6. $\triangle p_k p_l p_m \in \mathcal{C}(p_i)$, $\triangle p_k p_n p_l \notin \mathcal{C}(p_i)$, *and* $r(\triangle p_k p_l p_m) \leq r(\triangle p_k p_n p_l)$.

LEMMA 4. [illegible] $\triangle p_k p_l p_m \in \mathcal{C}(p_i)$ [illegible] $\triangle p_k p_n p_l \notin \mathcal{C}(p_i)$ [illegible] $r(\triangle p_k p_l p_i) < \max(r(\triangle p_k p_l p_m), r(\triangle p_k p_n p_l))$

[illegible] There are two cases:

(i) $r(\triangle p_k p_l p_m) > r(\triangle p_k p_n p_l)$; see Figure 5. In this case, p_i has to lie inside the region $\bigcirc(\triangle p_k p_l p_m) \setminus \bigcirc(\triangle p_k p_n p_l)$, which is a subset of the region $\bigcirc(\triangle p_k p_l p_m) \setminus \bigcirc'_{p_k p_l}(\triangle p_k p_l p_m)$, and, according to Lemma 3, $r(\triangle p_k p_l p_i) < r(\triangle p_k p_l p_m)$.

(ii) $r(\triangle p_k p_l p_m) \leq r(\triangle p_k p_n p_l)$; see Figure 6. Again, p_i has to lie in the region $\bigcirc(\triangle p_k p_l p_m) \setminus \bigcirc(\triangle p_k p_n p_l)$, which in this case is a subset of $\bigcirc'_{p_k p_l}(\triangle p_k p_n p_l) \setminus \bigcirc(\triangle p_k p_n p_l)$, and, by Lemma 3, $r(\triangle p_k p_l p_i) < r(\triangle p_k p_n p_l)$. □

Thus, we may state the following theorem.

THEOREM 2. [illegible] 2 [illegible]

[illegible] The B-W algorithm creates only triangles of the form $\triangle p_k p_l p_i$, where there exists $\triangle p_k p_l p_m \in \mathcal{M}$ such that $\triangle p_k p_l p_m \in \mathcal{C}(p_i)$. There are two cases:

(i) There exists $\triangle p_k p_n p_l \in \mathcal{M}$ such that $\triangle p_k p_n p_l \notin \mathcal{C}(p_i)$, in other words, $p_k p_l$ is not a boundary segment. In this case, by Lemma 4, $r(\triangle p_k p_l p_i) < \max(r(\triangle p_k p_l p_m), r(\triangle p_k p_n p_l))$.

(ii) $p_k p_l$ is a boundary segment. Then p_i must be outside the diametral circle of $p_k p_l$; otherwise, p_i wouldn't have been inserted. Consequently, p_i lies in the region $\bigcirc(\triangle p_k p_l p_m) \setminus \bigcirc'_{p_k p_l}(\triangle p_k p_l p_m)$, and, by Lemma 3, $r(\triangle p_i p_k p_l) < r(\triangle p_k p_l p_m)$. □

2.3.3. Adjusting the degree of concurrency. We have shown how with a simple and inexpensive test one can check whether two points (i.e., circumcenters) can be inserted independently. Now it remains to provide a way of finding enough independent circumcenters so that all processors can be kept busy inserting them. This task can be accomplished by decreasing all triangle circumradii below some value $\bar{r}$ with the purpose of increasing the number of pairwise independent circumcenters. Fortunately, this can be easily done by applying the sequential Delaunay refinement procedure as a preprocessing step. In this step, we use the initial parameter $\bar{\rho}$ and select parameter $\bar{\Delta}$ as

$$\bar{\Delta} = \frac{\bar{r}^2}{4\bar{\rho}^3}, \tag{2.2}$$

where $\bar{r}$ is computed based on the number of available processors and the size of the domain (see section 3).

Such preprocessing allows us to decrease the maximal circumradius of the triangles in a mesh automatically as a result of decreasing the maximal circumradius-to-shortest edge ratio and the maximal area. In the rest of this subsection, we prove (2.2).

We start by proving an auxiliary lemma, which relates the length of any side of a triangle to the sum of the cotangents of the adjacent angles and the triangle's area.

LEMMA 5. a b c A B C

$$a^2 = 2(\cot B + \cot C)\Delta, \tag{2.3}$$

Δ

. The cyclical application of the law of cosines,

$$\cos A = \frac{b^2 + c^2 - a^2}{2bc}, \tag{2.4}$$

coupled with the formula computing the area of the triangle,

$$\Delta = \frac{1}{2} bc \sin A, \tag{2.5}$$

allows us to obtain the following formula:

$$\cot A + \cot B + \cot C = \frac{a^2 + b^2 + c^2}{4\Delta}. \tag{2.6}$$

Rearranging (2.5) and substituting into (2.4) yields

$$\cot A = \frac{b^2 + c^2 - a^2}{4\Delta}. \tag{2.7}$$

Finally, by coupling (2.6) and (2.7), we obtain (2.3). ∎

Now, we show how an expression involving the smallest angle of a triangle bounds the sum of the cotangents of the other angles.

LEMMA 6. $A \le B \le C$

$$\cot B + \cot C \le \frac{1}{\sin A}.$$

Since A, B, C are positive summing themselves up to π, we can define the following function:

$$f(B) = \cot B + \cot C = \cot B + \cot(\pi - A - B) = \cot B - \cot(A + B),$$

where

$$0 < A \le B \le \frac{\pi - A}{2} \le C \le \pi - 2A, \quad \text{and} \quad A \le \frac{\pi}{3}. \tag{2.8}$$

$f(B)$ is continuous on $\left[A, \frac{\pi-A}{2}\right]$ and has no points of local maxima which satisfy (2.8); thus, it can reach its maxima only in the ends of the interval $\left[A, \frac{\pi-A}{2}\right]$. Direct substitution yields

$$f(A) = \frac{1}{2\sin A\cos A} \le \frac{1}{2\sin A \cdot \frac{1}{2}} = \frac{1}{\sin A}$$

and

$$f\left(\frac{\pi - A}{2}\right) = 2\frac{1 - \cos A}{\sin A} \le 2\frac{1 - \frac{1}{2}}{\sin A} = \frac{1}{\sin A}.$$

Hence,

$$f(B) \le \frac{1}{\sin A} \quad \forall B \in \left[A, \frac{\pi - A}{2}\right]. \qquad \square$$

Finally, assuming that the bounds $\bar{\rho}$ and $\bar{\Delta}$ on the triangle area and the circumradius-to-shortest edge ratio, respectively, hold for all triangles in the mesh, we find out the upper bound $\bar{r}$ on the circumradius of triangles.

LEMMA 7. [illegible] r [illegible] $a \le b \le c$ [illegible] ρ [illegible] $\bar{\rho}$ $\rho = r/a < \bar{\rho}$ [illegible] $\bar{\Delta}$ $\Delta < \bar{\Delta}$ [illegible]

$$r < 2(\bar{\rho})^{3/2}\sqrt{\bar{\Delta}}.$$

From $\rho = r/a$, or $r = \rho a$, using Lemma 5 it follows that

$$r = \rho a = \rho\sqrt{2(\cot B + \cot C)\Delta}$$

and Lemma 6 implies that

$$r \le \rho\sqrt{2\frac{1}{\sin A}\Delta} = \rho\sqrt{\frac{2\Delta}{\sin A}}. \tag{2.9}$$

By substituting $\sin A$ from (2.1) into (2.9), we have

$$r \le 2\rho^{3/2}\sqrt{\Delta} < 2(\bar{\rho})^{3/2}\sqrt{\bar{\Delta}}. \qquad \square$$

The following theorem directly follows from Lemma 7.

THEOREM 3. $\bar{\rho}$ $\bar{\Delta}$ [illegible] $\bar{r}$ [illegible]

$$\bar{r} = 2(\bar{\rho})^{3/2}\sqrt{\bar{\Delta}},$$

FIG. 7. *An augmented sequential Delaunay refinement algorithm.*

3. Coarse grain partitioning. One possible way to break the meshing problem of the entire domain up into smaller independent subproblems is to partition the domain into subdomains in such a way that the circumcenters of the triangles in each subdomain can be inserted concurrently with the circumcenters in any other subdomain.

If we consider a selected spatial region as a subdomain, which is refined sequentially by one processor, then the layer of triangles whose circumcenters are within $2\bar{r}$ from any circumcenter in the region forms the buffer zone of the entire region. The partitioning and the decoupling of the subdomains can be achieved by creating a special buffer zone around every subdomain, so that the insertion of a point in one subdomain can modify the triangles only inside this subdomain and its buffer zone, but the changes will not propagate to other subdomains and their buffer zones. After refining the subdomains, the buffer zones can be refined in a similar way.

We have chosen a simple and efficient way to partition the domain, which consists in dividing its bounding box into squares. One of the main advantages of this approach is the efficiency of assigning triangles to subdomains based on the coordinates of their circumcenters. A small adjustment (see Figure 7) to the sequential Delaunay refinement algorithm (Figure 1) allows the insertion of only those circumcenters which satisfy some user-defined condition (i.e., being inside a given rectangle). The drawback is that the amount of work assigned to different processors can vary significantly. However, we developed a runtime system [2] for dynamic load balancing which solves this problem, and thus we do not have to address it here.

The selection of subdomain box sizes is closely related to the scheduling of the refinement phases. First, Theorem 1 requires that the regions simultaneously refined by different processors are at least $4\bar{r}$ away. Second, the refinement of a region can

ParallelDelaunayMeshing($\mathcal{X}$, $\bar{\Delta}$, $\bar{\rho}$, P, p)
Input: $\mathcal{X}$ is a PSLG which defines Ω
$\bar{\Delta}$ and $\bar{\rho}$ are desired upper bounds
P is the total number of processors (we assume $\sqrt{P}$ is integer)
p is the index of the current processor, $0 \le p \le P-1$

FIG. 8. *A parallel Delaunay meshing algorithm. In order to simplify the presentation of the algorithm, we do not address the index out-of-range problems (e.g., d_{-1}), which we handle in the implementation.*

create poor quality triangles near the boundary in a neighboring region, which has been refined in a previous iteration (see Figure 8). To avoid performing multiple refinement iterations of the same region, some overlapping among the regions needs to be introduced. The degree of overlapping depends on the partitioning of Ω. We partition the domain Ω into a two-dimensional lattice of squares, arrange the processors into logical rows and columns, and assign to each processor a fraction (N/P) of the lattice, where N is the number of cells and P is the number of processors, which it is responsible to mesh. We ensure global mesh consistency by forcing each processor to

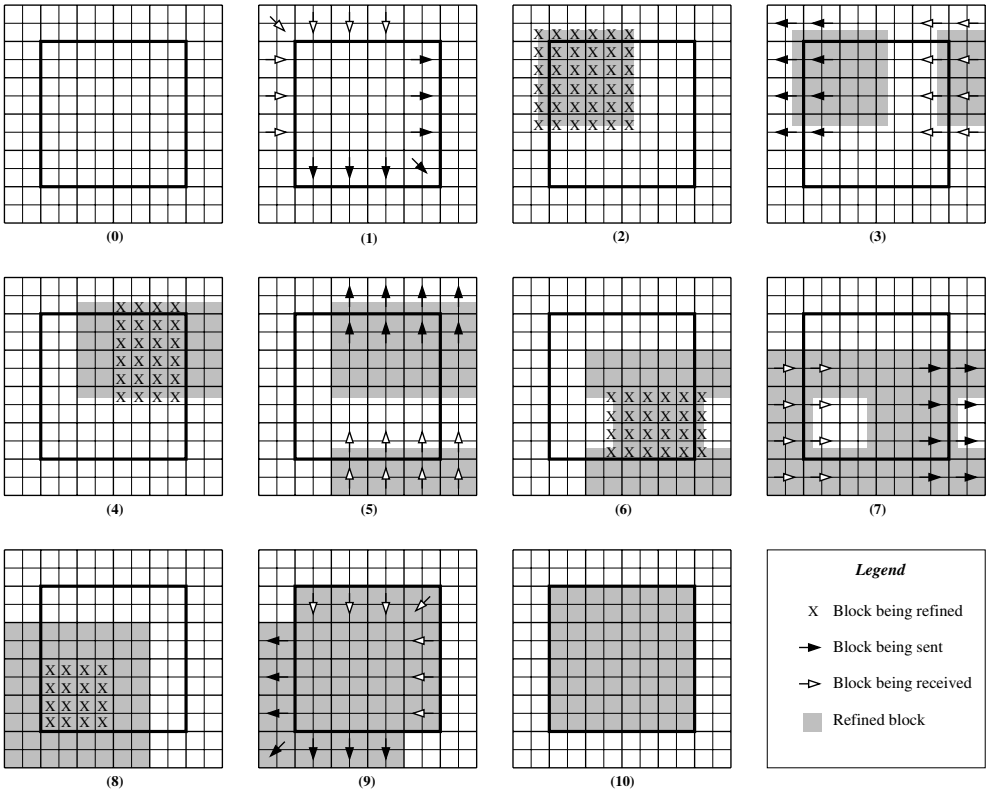

FIG. 9. *A schedule of the parallel Delaunay refinement and communication on distributed memory. Each phase* (0)–(10) *depicts the actions performed by a single processor. The smallest cells have side length* $2\bar{r}$*; they are the atomic units of refinement. Since the refinement may leave fractions of big triangles, whose circumcenters are outside the small cell, the refined cells sometimes are not completely shaded. The bigger cells, which consist of* 4 *small cells, are the atomic units of data migration. The thick lines outline the subdomain assigned to the given processor. A processor also holds parts of its neighbors' meshes. Arrows represent the direction of data migration.*

hold and exchange $(4\bar{r})$-wide layers of triangles near the boundaries of their assigned subdomains. Each processor in position (i, j) communicates only with its neighbors in positions (s, t), such that $|i - s| \leq 1$ and $|j - t| \leq 1$.

The entire parallel algorithm is summarized in Figure 8. The scheduling of the refinement and the communication phases is also schematically presented in Figure 9. A sequence of meshes created by four processors for the pipe cross-section model (Figure 10) is shown in Figure 11.

4. Parallel implementation. For the experimental evaluation of our method, we triangulated (i) 1000 random points uniformly distributed in a unit square and (ii) the pipe cross-section model (Figure 10). We used the "Triangle" [33] as a sequential mesher on each processor. The Triangle facilitates the use of a user-defined function for deciding which triangles should be considered "big" and queued for refinement. However, apparently, it doesn't provide a mechanism for the user to decide at run-time which triangles are "bad" in terms of the circumradius-to-shortest edge ratio or minimal angle. This fact caused us to insert a test for the triangle circumcenter position inside the Triangle code and recompile it. We believe that in future releases

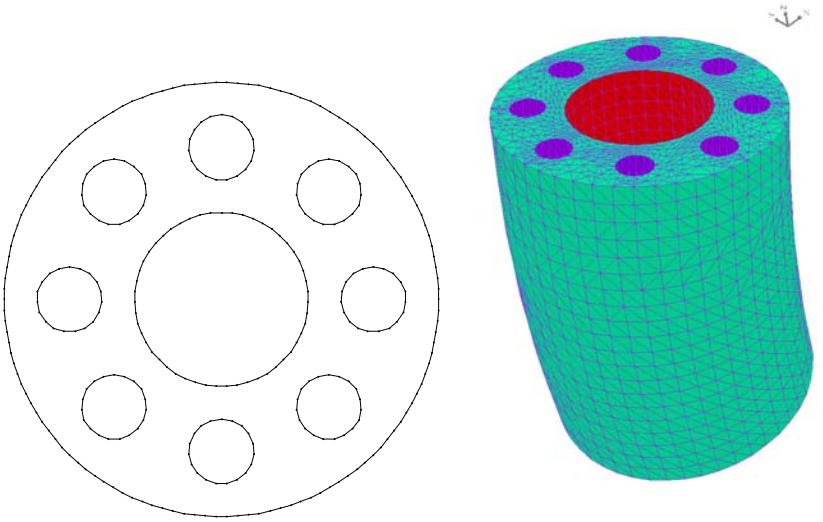

FIG. 10. *A cross section and a cartoon pipe of a regenerative cooled pipe geometry which came from the testing of a rocket engine at NASA Marshall. NASA had to slightly bend one of the regenerative cooled "pipes" that contained combustion gases in order to fit a rocket engine onto a test stand. In testing, this curved pipe failed due to an unanticipated increase of heating. Since this was a one-off design, NASA couldn't afford to do the extensive testing. The failure caused them to scrap that particular project since it destroyed the engine under test. This is an example of why simulation is useful in reducing the cost.*

of sequential mesh generation codes, the facility for defining user-supplied functions, which test the suitability of both types of triangles, can be easily provided.

Another technical detail that we ran into while running our tests is the substantial difference in time required by the Triangle to refine an existing mesh and to construct a fine mesh without taking advantage of a previously constructed coarser mesh. Contrary to our expectations, building a fine mesh anew turned out to be much faster. For example, in the case of the contour of the letter "A," which is included in the Triangle distribution, the Triangle is about six times faster in retriangulating a given set of points than in reconstructing the mesh data structure from a list of triangles. That is why, when moving a part of the mesh from one processor to another, we decided to migrate only the set of points and boundary edges and retriangulate them as necessary. Since the Delaunay triangulation of a given set of points is unique, provided that there are no four cocircular points [34], this process will not destroy the boundary conformity. In the presence of cocircular points near the boundary, the enforcement of boundary segments causes the required edge flips. The additional advantage of this optimization is the decrease of the network traffic.

We have conducted our experiments on the Sciclone cluster computing system at the College of William and Mary using its two tightly coupled subclusters: "whirlwind"—64 single-cpu Sun Fire V120 servers (650 MHz, 1 GB RAM)—and "twister"—32 dual-cpu Sun Fire 280R servers (900 MHz, 2 GB RAM). The scaled and the fixed work-load evaluation for a mesh of a unit square is shown in Table 1, with the breakdown of the total time in Table 2, and for the pipe model in Table 3. We can see that in the pipe case the algorithm performs slightly worse, which happens because of the load imbalance due to the empty space inside pipe holes. Table 4 shows a comparison of a distributed- and a shared-memory implementation on the

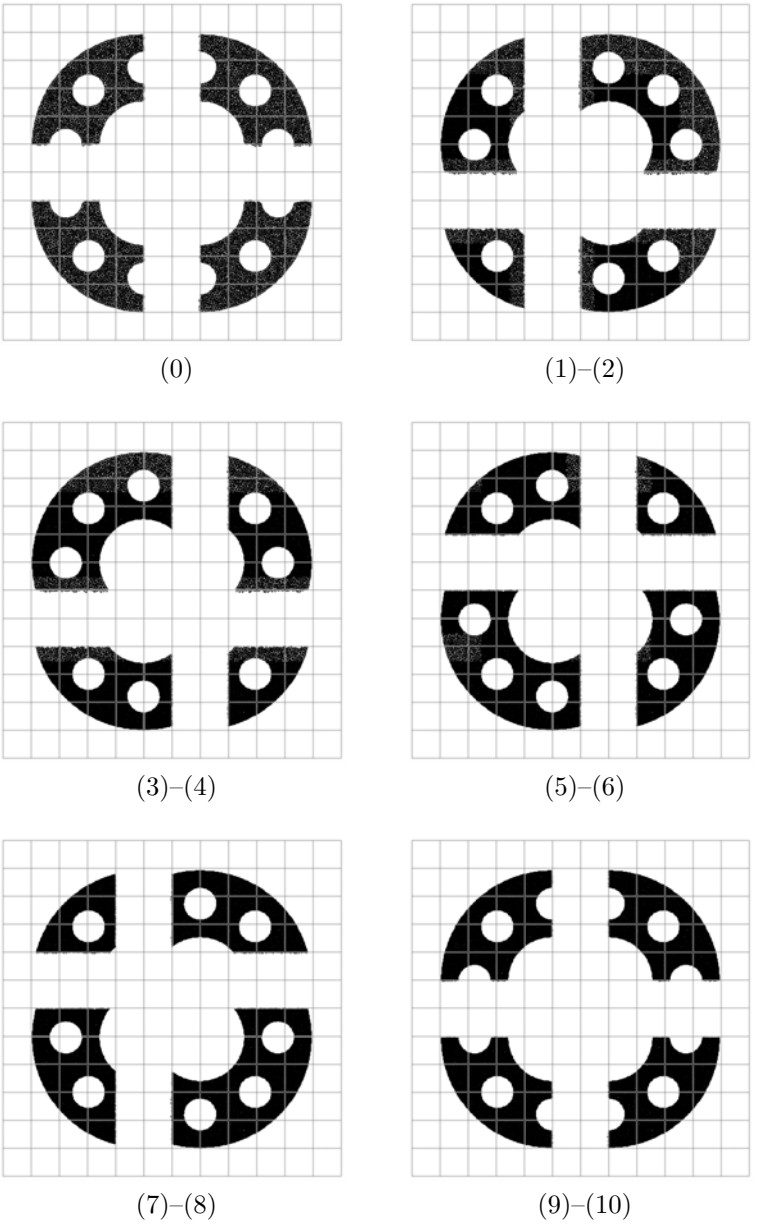

FIG. 11. *Snapshots of a mesh distributed among four processors. Each picture corresponds to the specified phases schematically shown in Figure* 9*. Dark areas are the parts of the mesh that have already been refined. Gray areas are those that have not been refined. Each processor starts with an initial coarse mesh and ends up with a refined mesh covering the same area.*

"hurricane" subcluster.

Finally, we didn't have to write any mesh generation code, since for both the preprocessing and the refinement it was sufficient to call the Triangle as a library.

5. Conclusions. We introduced a parallel coarse-grained mesh generation algorithm based on a block domain decomposition, which can be used in a variety of

contexts. First, as we showed, the parallel algorithm can be implemented efficiently on distributed- and shared-memory systems by exploiting the fact that only local communication between processors is necessary, the data can be sent in large blocks at the

TABLE 4

beginning of each computation phase, and the number of the communication phases is a small constant (five). In this paper, we addressed the code reuse issue from the viewpoint of concurrency; the design of the generic application programming interface is out of the scope; see, e.g., [3] for a discussion. Second, we designed an out-of-core algorithm [24] which utilizes the absence of communication during subdomain refinement phases. Third, a shared-memory implementation can use the sufficient condition of the circumcenter independence to guide the fine-grained parallelism. However, our experimental evaluation [1] of fine-grain parallelism in a B-W kernel showed that current simultaneous multithreaded processors (SMTs) are not capable of achieving performance improvement, while the experiments on a simulated SMT indicate that with modest hardware support it is possible to exploit fine-grain parallelism opportunities. Fourth, our future work includes the extension of the framework to the three-dimensional domains. We also plan to improve the performance of our parallel implementation, for more irregular geometries, by addressing the work-load balancing problem using our runtime system [2] and improving the memory management for a single processor. Finally, we are currently working on the extension of the theoretical framework for the construction of nonuniform (graded) meshes [7].

Acknowledgments. We thank Andriy Kot for the shared-memory implementation of the algorithm. We appreciate the very detailed comments from the anonymous reviewers which helped us improve the manuscript.

BEHAVIOR OF FINITE VOLUME SCHEMES FOR HYPERBOLIC CONSERVATION LAWS ON ADAPTIVE REDISTRIBUTED SPATIAL GRIDS*

CH. ARVANITIS† AND A. I. DELIS‡

Abstract. In this work we consider finite volume schemes combined with dynamic spatial mesh redistribution. We study whether appropriate mesh redistribution is a satisfactory mechanism for increasing the resolution of numerical solutions for problems of scalar and systems of conservation laws (CL) in one space dimension, while being at the same time a stabilization mechanism for selecting the appropriate entropy solution. In order to increase the resolution around shock areas and keep the computational cost low, our redistribution policy is to reconstruct spatially the numerical solution on a new mesh, where the solution's curvature is almost uniformly distributed, while the node's cardinality is kept constant. We examine the stabilization properties of that redistribution process by adding it as a substep on the time evolution step of some classical schemes with known (unstable) characteristics. Testing the resulting method for several such schemes and on a large number of CL problems that have solutions with special characteristics (shocks, rarefaction areas, steady states) and comparing the results with those produced by schemes with extra stabilization mechanisms (like slope/flux limiters, entropy corrections), we conclude that indeed the proposed redistribution adds such stabilization properties while at the same time increasing the resolution.

Key words. finite volume methods, adaptive grid redistribution, hyperbolic conservation laws

1. Introduction.

The application of finite volume schemes is a very popular choice for computing solutions of systems of conservation laws (CL) in the following context: $u : \mathbb{R}^d \times [0,T] \to \mathbb{R}^M$

$$\begin{aligned} u(\cdot,0) &= u_0 \\ \partial_t u + \sum_{i=1}^{d} \partial_{x_i} F_i(u) &= 0. \end{aligned} \tag{1.1}$$

Some classical schemes, of first or second order in space, when applied directly to this system will result in computational solutions with diffusive or oscillatory behavior, especially close to shocks. To overcome this difficulty several modifications of such schemes have been proposed in the literature where the necessary stability and viscosity mechanisms are imposed "by hand." Mesh adaptation is a main current stream to efficiently compute numerical solutions of complex systems by increasing the resolution of the essential solution. Several redistribution techniques have been introduced recently for solving the problem of proper mesh selection, starting with the self-adjusting method of Harten and Hyman [14] to the moving mesh methods of Azarenok et al., Fazio and LeVeque, Stockie et al., Tao Tang, Huazhong Tang, and

others (see [4], [5], [6], [8], [12], [17], [19], [20], [21], [23], [27], [28], [29], [30]). These methods calculate the spatial positions of the nodes of the new mesh, some of them by solving an Euler–Lagrange equation, others by optimizing proper energy metrics. All of them have as a common factor that they can be combined with any numerical scheme (making appropriate modifications) for increasing its resolution.

In this work the evolving mesh is constructed such that its spatial resolution is controlled via selective characteristics of the computed solution. Our main aim here is to experimentally study the behavior of finite difference-volume schemes, with or without stabilization mechanisms, but under the regime of this adaptively evolving mesh. Our choice of classical schemes includes, for example, the first order Roe scheme, the second order Lax–Wendroff and MacCormack schemes, and also some TVD schemes. The adaptive procedure studied in this work is based on a mesh redistribution policy that evolves within every computational time step. The basic principle of the suggested mesh redistribution is to (re)distribute the nodes of the generated partition with respect to geometrical characteristics of the solution. These characteristics are defined through a positive functional of the solution, the so-called [illegible] [1], [2], [3]. Among other estimator functions for evolution PDEs, like the arc-length and variance, we choose the curvature of the solution as such a function, for its diffuseless behavior. Experiments in [3] with Galerkin finite element schemes, which approximate CL solutions like central finite difference schemes, have shown that this redistribution procedure has stabilization properties of its own. For example, in this work we show that schemes like Lax–Wendroff combined with our redistribution policy provide surprisingly stable solutions free of oscillations. From the numerical experiments produced in the course of this work we concluded the following advantages of the use of this particular adaptive grid redistribution (AGR) method.

- The method when applied to classical second order schemes, which produce oscillating solutions, suppresses the oscillations, producing TVD-like approximations. Classical schemes like the Lax–Wendroff or the MacCormack scheme become stable and produce reliable solutions.
- When applied to numerical schemes that do not satisfy entropy conditions, for example, the original Roe scheme, the method approximates the entropy satisfying solution.
- The method works well for hyperbolic problems with source terms and produces stable solutions for first and second order balanced schemes and can converge to correct steady states.
- The method can automatically detect, resolve, and track steep wave fronts and discontinuities, without having to resort to finer grids.
- The AGR method is of linear complexity, as we will see in the next section (cf. Remark 3), and consequently its computational cost is in favor when compared, for example, to the stabilization mechanisms for high resolution TVD schemes, where we have to solve a number of Riemann problems in order to compute the corresponding stabilization limiters.
- The mechanism has been proved robust for all the applications presented and schemes used.

Following from the above, our main conclusion from the present work is that numerical schemes, when combined with the proposed mesh adaptation, yield stable solutions free of oscillations.

The paper is organized as follows. In the next section we define the AGR algorithm. In section 3 we present finite volume schemes for scalar CL, adjusted to nonuniform grids, which will be tested in the regime of the adaptive redistribution al-

gorithm. Section 4 is devoted to numerical results. In section 5 numerical schemes for systems of CL, with or without source terms, are detailed, and in section 6 numerical results for the shallow water system of equations are presented.

2. The AGR method in one dimension. Let X be a partition of a domain $[a,b]$ and $\{x_i\}_{i=0}^{N}$ the corresponding nodes in increasing order, i.e., $a = x_0 < x_1 < \cdots < x_{N-1} < x_N = b$. Then we introduce the following notation:

- With $\sigma(X)$ we denote the σ-algebra of X, which for finite partitions coincides with the superset of unions of sets from X.
- With **resolution** of X, we denote the measure which for any measurable set A is defined by

$$\mathbf{resolution}(A) = \operatorname{card}\{K \in X : K \subset A\},$$

  i.e., the resolution of the partition X over some set A is the number of partition elements that A contains.
- If $U = \{u_i\}_{i=0}^{N}$ is a vector of values defined on elements of the partition X, then it shall be notated as $U(X)$. For compatibility with approximations given from finite volume schemes, in the following we shall identify any vector of function values $\{u_i\}_{i=0}^{N}$ evaluated on partition nodes $\{x_i\}_{i=0}^{N}$, i.e., $U = U(X)$, with the locally constant function U, defined on $[a,b]$ by

$$U = \sum_{i=0}^{N} u_i \ \chi_{[x_{i-1}^+, x_i^+)} + u_N \ \chi_{\{x_N^+\}}, \tag{2.1}$$

  with χ_A denoting the characteristic function of the set A, and $\{x_i^+\}_{i=-1}^{N}$ denoting the points

$$x_{-1}^+ = x_0, \quad x_i^+ = x_{i+\frac{1}{2}}, \quad i = 0, 1, \ldots, N-1, \quad x_N^+ = x_N.$$

In the case of evolution PDEs, where the numerical solution is constructed like a sequence of spatial approximations of solutions instances, the redistribution process could be applied before every evolution step. Let **Solver** denote a (general) finite volume scheme for solving some evolution PDE. For $n = 1, 2, \ldots$ **Solver** gives sequentially the approximations U^n of the solution instances $u(t^n, \cdot)$ at given time moments $t^0 < t^1 < \cdots < t^n \in \mathbb{R}^+$, starting at $t^0 = 0$. The given initial data U^0 is defined on the uniform partition X^0 of the domain. In the case of uniform partition, the evolution step can be represented for $n = 1, 2, \ldots$ as an equation on the vector space $\mathbb{R}^{2(N+1)}$:

$$(X^n,\ U^n(X^n)) = (X^{n-1},\ \mathbf{Solver}(X^{n-1},\ U^{n-1}(X^{n-1}))).$$

On meshes generated by the AGR process, the evolution step can be represented by the system of vector equations:

$$\begin{aligned} (\tilde{X},\ \tilde{U}(\tilde{X})) &= \mathbf{AGR}(X^{n-1},\ U^{n-1}(X^{n-1})), \\ (X^n,\ U^n(X^n)) &= (\tilde{X},\ \mathbf{Solver}(\tilde{X},\ \tilde{U}(\tilde{X}))), \end{aligned} \tag{2.2}$$

where $\tilde{X}, \tilde{U}$ are temporal vectors. Observe that in the case where the AGR process returns the same vectors, i.e., the AGR coincides with the identity linear transformation, then (2.2) reduces to the uniform evolution step. The AGR procedure, for a

given vector of values $U = \{u_i\}_{i=0}^{N}$ defined on the nodes $\{x_i\}_{i=0}^{N}$ of the partition X, i.e., $U = U(X)$, is described by the following two sequential steps,

$$\begin{aligned} \tilde{X} &= \mathbf{GMesh}(X,\ U(X)), \\ \tilde{U}(\tilde{X}) &= \mathbf{Rec}(X,\ U(X),\ \tilde{X}). \end{aligned} \tag{2.3}$$

In what follows we describe in detail the two steps **GMesh**, **Rec** of our redistribution algorithm AGR.

2.1. The GMesh step. At the **GMesh** step of the AGR procedure (2.3), a new partition $\tilde{X}$ of spatial nodes $\{\tilde{x}_i\}_{i=0}^{N}$ is formed, with resolution controlled by selected characteristics of the numerical solution U. The step is accomplished in two phases.

At the [illegible] the selected characteristics are defined on the domain $[a, b]$ through a strictly positive functional g of the approximate solution, the [illegible]. Since we are mainly interested in increasing the resolution over areas with discontinuities, and taking into account the results in [3], in this work we will also use some power p of proper approximation of the solution's curvature defined by

$$(\mathrm{curv} \circ u)(x) = \frac{|u''(x)|}{(1 + u'(x)^2)^{\frac{3}{2}}}$$

as the estimator function for selecting the resolution's density of the new partition. For a given partition $\{x_i\}_{i=0}^{N}$, the solution's curvature at the node x_i can be approximated by

$$(\mathrm{curv}_h \circ u)(x_i) = \frac{\frac{2}{x_{i+1}-x_{i-1}} \left| \frac{u(x_i)-u(x_{i-1})}{x_i - x_{i-1}} - \frac{u(x_{i+1})-u(x_i)}{x_{i+1}-x_i} \right|}{\sqrt{1+\left(\frac{u(x_i)-u(x_{i-1})}{x_i-x_{i-1}}\right)^2}\sqrt{1+\left(\frac{u(x_{i+1})-u(x_i)}{x_{i+1}-x_i}\right)^2}\sqrt{1+\left(\frac{u(x_{i+1})-u(x_{i-1})}{x_{i+1}-x_{i-1}}\right)^2}},$$

which is the inverse outer radius of the plane points $A_j = (x_j, u(x_j))$, $j = i-1, i, i+1$, i.e.,

$$(\mathrm{curv}_h \circ u)(x_i) = 2\frac{\|(A_{i+1} - A_i) \times (A_i - A_{i-1})\|}{\|A_{i+1} - A_i\|\ \|A_{i+1} - A_{i-1}\|\ \|A_i - A_{i-1}\|},$$

where $\|\cdot\|$ denotes the Euclidean norm. Thus, at the discrete level, the values g_i of our estimator function on the node points $\{x_i\}_{i=0}^{N}$, are given by $g_0 = g_N = \delta^p$ and for $i = 1, \ldots, N-1$,

$$g_i = \left(\max\left\{ \delta,\ 2\frac{\|(A_{i+1} - A_i) \times (A_i - A_{i-1})\|}{\|A_{i+1} - A_i\|\ \|A_{i+1} - A_{i-1}\|\ \|A_i - A_{i-1}\|} \right\} \right)^p, \tag{2.4}$$

where the power p is left as a free parameter taking values in the range $[0, 1]$ and δ is a very small positive number which ensures that g_i is strictly positive. The constant δ must be chosen such that, at a computational level, g_i behaves monotonically as a function of p even for negligible values. In our experiments, where the calculations were performed with ANSI-C computational libraries of double precision, δ was fixed to the value 10^{-32}. In the case of vector solution $u = (u_1, \ldots, u_M)^{\mathrm{T}}$, we intend to use the average of the coordinate estimators as the uniform estimator function for all the coordinates of the solution. Therefore, in general, instead of the values g_i we keep the normalized version $g_i / \sum_{j=0}^{N} g_j$, $i = 0, 1, \ldots, N$.

At the [illegible], the partition $\tilde{X}$ is actually produced through $g_h \circ U$, the corresponding function of type (2.1) to values (2.4). Since we expect a new mesh $\tilde{X}$ with resolution that locally follows the function $g_h \circ U$, we conclude that the resolution measure must be distributed in space like the measure $G_U(A) = \int_A (g_h \circ U)\, d\mu$ introduced by the positive function $g_h \circ U$, at least for sets from $\sigma(\tilde{X})$. Therefore the new partition $\tilde{X}$ is defined such that

$$\forall A \in \sigma(\tilde{X}) \quad G_U(A) = C\ \mathbf{resolution}(A),\ \text{with } C = \frac{G_U([a,b])}{N}. \tag{2.5}$$

Applying sequentially (2.5) with the sets $A_i = [a, \tilde{x}_i]$, $i = 1, 2, \ldots, N$, where their indices declare also the resolution of the partition $\tilde{X}$ over them, we induce, as it is called in the literature of moving meshes, the [illegible]:

(2.6)

$$\tilde{x}_0 = a \text{ and for } i = 1, \ldots, N,\ \tilde{x}_i \text{ is such that } \int_a^{\tilde{x}_i} g_h(U(x))\, dx = \frac{i}{N} \int_a^b g_h(U(x))\, dx.$$

In the present work, the new mesh $\tilde{X}$ is defined through (2.6), but we note that other inverting algorithms could also be constructed through a more elegant treatment of the generic equidistribution principal (2.5). Let $G(x) = G_U([a,x])$ be the distribution function, which is an increasing local linear function defined on the grid X, since $g_h \circ U$ is a positive function of type (2.1). Thus, G is completely defined from the values $G_i = G(x_i)$ of the G_U measure of the intervals $[a, x_i]$, that is, $G_0 = 0$, and for $i = 1, \ldots, N$,

$$\begin{aligned} G_i = G_U([a,x_i]) &= \int_{[a,x_i]} (g_h \circ U)\, d\mu = G_{i-1} + \int_{x_{i-1}}^{x_i} g_h(U(x))\, dx \\ &\overset{(2.1)}{=} G_{i-1} + (g_{i-1} + g_i)(x_i - x_{i-1})/2. \end{aligned} \tag{2.7}$$

From (2.6) it follows that the $\tilde{x}_i$ node is given by inverting the equation $G(\tilde{x}_i) = \frac{i}{N} G(\tilde{x}_N)$, so the nodes of the new mesh $\tilde{X}$ are $\tilde{x}_0 = a$, $\tilde{x}_N = b$, and, for $i = 1, \ldots, N-1$, $k_0 := 0$,

(2.8)

$$\tilde{G}_i = \frac{i}{N} G_N, \quad k_i = \max_{k_{i-1} \le \ell \le N} \{\ell : G_\ell \le \tilde{G}_i\}, \quad \tilde{x}_i = x_{k_i} + \frac{x_{k_i+1} - x_{k_i}}{G_{k_i+1} - G_{k_i}} (\tilde{G}_i - G_{k_i}).$$

2.2. The Rec step. At the **Rec** step of the AGR procedure (2.3), a new numerical solution $\tilde{U} = \{\tilde{u}_i\}_{i=0}^N$ of type (2.1) is defined on the new grid $\tilde{X}$ by reconstructing U from the old grid X to the new one. Since the schemes used in this work produce conservative solutions, the reconstruction step is done so that it is locally conservative on each interval $[\tilde{x}_{i-1}^+, \tilde{x}_i^+]$ of the new mesh. That is, for $i = 0, \ldots, N$, we require

$$\int_{\tilde{x}_{i-1}^+}^{\tilde{x}_i^+} \tilde{U}(x)\, dx = \int_{\tilde{x}_{i-1}^+}^{\tilde{x}_i^+} U(x)\, dx.$$

Since the functions $U, \tilde{U}$ are of type (2.1) defined on the partitions $X, \tilde{X}$, respectively,

$$\tilde{u}_i(\tilde{x}_i^+ - \tilde{x}_{i-1}^+) = \int_{\tilde{x}_{i-1}^+}^{\tilde{x}_i^+} U(x)\, dx = \int_{x_{k_i}^+}^{\tilde{x}_i^+} U(x)\, dx + \int_{x_{k_{i-1}}^+}^{x_{k_i}^+} U(x)\, dx - \int_{x_{k_{i-1}}^+}^{\tilde{x}_{i-1}^+} U(x)\, dx,$$

where, using the real line ordering of the domain $[a,b]$, $x^+_{k_i}$ denotes the larger node from the old partition not exceeding the node $\tilde{x}^+_i$ of the new partition. Consequently, the new values $\tilde{U}$ are $\tilde{u}_0 = u_0$ and, for $i = 1, \ldots, N$, $k_0 := 0$,

(2.9)
$$k_i = \max_{k_{i-1} \le \ell \le N} \{\ell : x^+_\ell \le \tilde{x}^+_i\},$$

$$\tilde{u}_i = \left\{ (\tilde{x}^+_i - x^+_{k_i}) u_{k_i+1} + \sum_{\ell=k_{i-1}+1}^{k_i} (x^+_\ell - x^+_{\ell-1}) u_\ell - (\tilde{x}^+_{i-1} - x^+_{k_{i-1}}) u_{k_{i-1}+1} \right\} / \big(\tilde{x}^+_i - \tilde{x}^+_{i-1}\big).$$

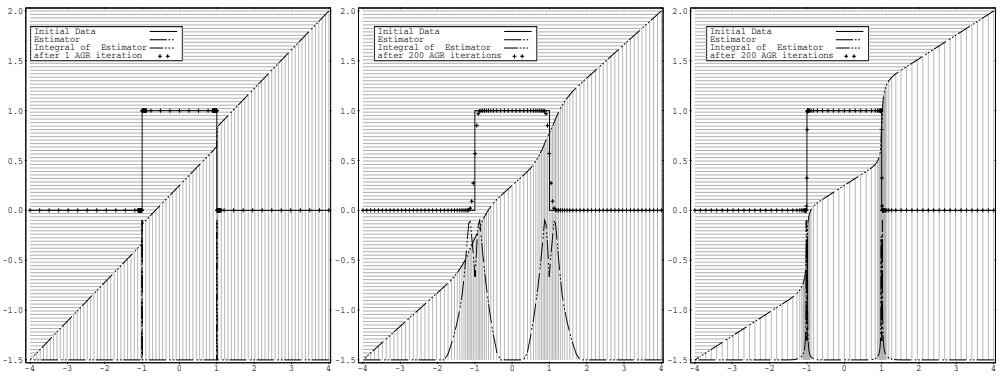

FIG. 1. *Iteration of the AGR procedure applied on Riemann data. After* 1 *iteration (left) and after* 200 *iterations for* $p = 0.023$ *(middle) and* $p = 0.1$ *(right).*

The **Gmesh** step of the AGR process can be graphically represented as in Figure 1. Starting with some initial data (solid line) we calculate the estimator function (dotted line) through (2.4) and then the corresponding distribution function (increasing dotted line) using (2.7). The proposed mesh (x position of the vertical lines, under the distribution function) is given by inverting a uniform mesh (y position of the horizontal lines, over the distribution function) through the distribution function using (2.8). Notice that y-coordinates are valid only for the data while either the estimator or its distribution function was scaled vertically to fit on the viewing graph area.

. . . . 1 (the action of the parameter p). Parameter p controls essentially the maximum density of the generated mesh $\tilde{X}$. Indeed, from relations (2.4), (2.6), we conclude that the corresponding nodes $\tilde{x}_i$, $i = 1, \ldots, N$, satisfy the equation

$$\frac{1}{N} \int_a^b \mathrm{curv}_h^p(U(x))\, dx = \int_{\tilde{x}_{i-1}}^{\tilde{x}_i} \mathrm{curv}_h^p(U(x))\, dx \le \max_{x \in [\tilde{x}_{i-1}, \tilde{x}_i]} \{\mathrm{curv}_h^p(U(x))\}\ (\tilde{x}_i - \tilde{x}_{i-1}),$$

and therefore

$$\frac{1}{N} \left(\frac{||\mathrm{curv}_h \circ U||_{L^p[a,b]}}{||\mathrm{curv}_h \circ U||_{L^\infty[a,b]}} \right)^p \le \min_i \{\tilde{x}_i - \tilde{x}_{i-1}\}.$$

Thus, choosing p appropriately, the resolution of the $\tilde{X}$ mesh respects an upper given bound. The action of the parameter p in the AGR procedure can also be seen in

Figure 1 (middle, right). For $p = 0$ observe from (2.7) that $G_i = x_i - x_0$, so the proposed partition from (2.8) coincides with the uniform partition of $[a, b]$. As the value of p increases, the proposed partition becomes more dense on the discontinuity areas, but over some value of p the process becomes unreliable because the partition lacks nodes over smooth areas. In our experiments with finite volume schemes an appropriate range for the parameter p was $[0.02, 0.10]$ for first order and $[0.04, 0.14]$ for second order schemes.

. . . . 2 (smoothing effect of the AGR process). Results in [3] show that the reconstructed function $\tilde{U}$ of the AGR procedure is more diffusive than the initial function U. Indeed this diffusive behavior can be observed by applying the AGR procedure iteratively on some initial data, i.e., starting with some initial data U^0 on the uniform partition X^0 of $[a, b]$, we define the sequence $(X^n, U^n(X^n)) = \mathbf{AGR}(X^{n-1}, U^{n-1}(X^{n-1}))$, $n = 1, 2, \ldots$. Experiments with Riemann initial data show that the above sequence attains a limit pair $(X, U(X))$. In Figure 1 (middle, right) we present the results after 200 iterations for $p = 0.023$ (middle) and for $p = 0.1$ (right). In Figure 2 (middle, right) we present the trajectories of the nodes for the above iterative process. Notice that after about 20 iterations for $p = 0.023$ and about 80 for $p = 0.1$ the position of all the nodes X stabilizes. But from (2.9) one can observe that reconstructing any function on the same grid leads to the same function, i.e., $U(X) = \mathbf{Rec}(X, U(X), X)$, so we conclude that also the reconstructed values $U(X)$ after the above iterations became constant. Figure 2 (left) shows the smoothing effect of the AGR process on the initial data after 200 iterations and for various values of p.

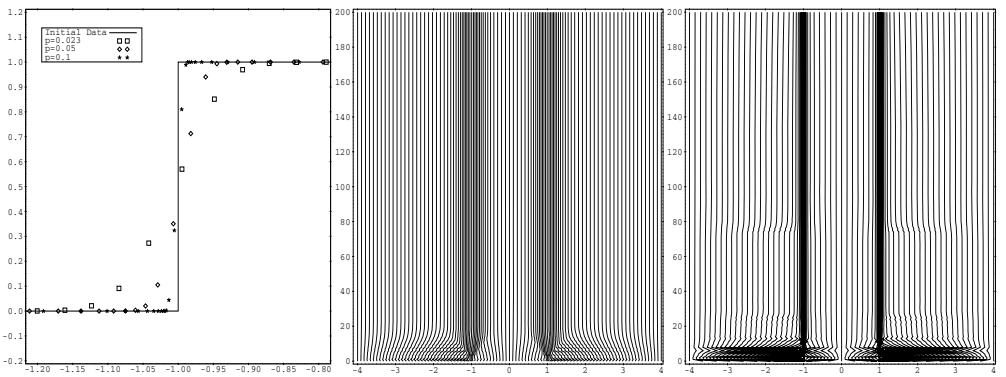

FIG. 2. *Focus in the shock area (left) after* 200 *iterations of the AGR procedure and for various values of parameter p. Trajectories of mesh nodes for* $p = 0.023$ *(middle) and for* $p = 0.1$ *(right).*

. . . . 3 (complexity of the AGR process). Observe that both the **Gmesh** step (2.7), (2.8) and the **Rec** step (2.9) of the AGR process are of linear complexity.

2.3. Redistribution in the steady state regime. The diffusive behavior of the AGR process might be one of the reasons that second order schemes, when combined with the redistribution step, produce nonoscillatory approximations; however, in the case where the current and the new mesh are almost the same the redistribution step should be avoided. In addition, in the case of very sensitive CL problems with steady states we noticed that the repeated application of the AGR process prevents the conservation of the steady states. Taking into account these observations, in the numerical experiments of this work we adopt a new version of the AGR process:

$$\begin{aligned} &\tilde{X} = \mathbf{GMesh}(X, U), \\ &\text{if } (|X - \tilde{X}| > D), \quad \tilde{U} = \mathbf{Rec}(X, U, \tilde{X}), \\ &\text{else} \qquad\qquad\quad \tilde{X} = X,\ \tilde{U} = U, \end{aligned}$$

where D is a "cutoff" level for the relative mean displacement $|X - \tilde{X}|$ between the current and the proposed meshes, under which the **Rec** step is avoided. The relative mean displacement is measured in the ℓ^1 vector norm, that is, $|X - \tilde{X}| = \frac{\frac{1}{N+1}\sum_{i=0}^{N}|x_i - \tilde{x}_i|}{b-a}$. Experiments show that, for first order schemes or those with extra stabilization mechanisms (like using slope/flux limiters), the AGR process produces results with higher resolution when the cutoff parameter D is of order 10^{-2}, whereas, due to the oscillatory behavior of second order schemes like the classical Lax–Wendroff, the cutoff level can be of order 10^{-3} or even less. In all cases, when the problem imposes steady states a nonzero value of D is crucial for the solving process in order to reach the time invariant solution for all schemes. The above observations become more pronounced for systems of conservation laws.

3. Numerical schemes on nonuniform grids (one-dimensional scalar equations). In this section we review some well-known classical numerical schemes, implemented at the **Solver** step, for the discretization of a scalar conservation law,

$$u_t + f(u)_x = 0, \tag{3.1}$$

and present them in their nonuniform grid formulation. We will also state some well-known disadvantages that these schemes exhibit.

We will approximate the solution $u(t, x)$, $x \in \mathbb{R}$, $t \geq 0$, of (3.1) by the discrete values u_i^n, $i \in \mathbb{Z}$, $n \in \mathbb{N}$, and in order to do so we consider a grid of points $x_{i+\frac{1}{2}}$ and define the computational cells and their lengths as

$$C_i = [x_{i-\frac{1}{2}}, x_{i+\frac{1}{2}}], \qquad \Delta x_i = x_{i+\frac{1}{2}} - x_{i-\frac{1}{2}} > 0.$$

We also denote by $x_i = (x_{i-\frac{1}{2}} + x_{i+\frac{1}{2}})/2$ the centers of the partition cells. The values u_i^n will be approximations of the averages of the exact solution over the cell

$$u_i^n \approx \frac{1}{\Delta x_i} \int_{C_i} u(t^n, x) dx,$$

with t^n the discrete time levels.

For consistency, we present the schemes in the usual conservative formulation with explicit time stepping,

$$u_i^{n+1} = u_i^n - \frac{\Delta t}{\Delta x_i} \left(f_{i+\frac{1}{2}}^n - f_{i-\frac{1}{2}}^n \right), \tag{3.2}$$

where $f_{i+\frac{1}{2}}^n$, $i = 1, 2, \ldots, N-1$, is the numerical flux function that determines the scheme.

. The numerical flux of the well-known first order upwind Roe scheme is given by (see [15])

$$f_{i+\frac{1}{2}}^{\mathrm{ROE}} = \frac{1}{2} \left(f_{i+1} + f_i - |a_{i+\frac{1}{2}}| \Delta u_{i+\frac{1}{2}} \right), \tag{3.3}$$

with $f_i = f(u_i)$, $\Delta u_{i+\frac{1}{2}} = u_{i+1} - u_i$ and $|a_{i+\frac{1}{2}}|$ the characteristic speed defined by

$$a_{i+\frac{1}{2}} = \begin{cases} \dfrac{f_{i+1} - f_i}{u_{i+1} - u_i}, & u_{i+1} \neq u_i, \\ a_i = \dfrac{\partial f}{\partial u}, & u_{i+1} = u_i. \end{cases} \tag{3.4}$$

A well-known drawback of Roe's scheme is that it may resolve nonphysical solutions by admitting stationary entropy-violating expansion shocks. Various [illegible] have been proposed; see [18]. For example, we can replace the moduli of a in (3.3) by

$$\psi(a) = \max(\delta, |a|)$$

or by the smoother form

$$\psi(a) = \begin{cases} |a|, & |a| \geq \delta, \\ (a^2 + \delta^2)/2\delta, & |a| < \delta, \end{cases}$$

with

$$\delta_{i+\frac{1}{2}} = \max\{0, a_{i+\frac{1}{2}} - a_i, a_{i+1} - a_{i+\frac{1}{2}}\}, \quad \delta_{i-\frac{1}{2}} = \max\{0, a_{i-\frac{1}{2}} - a_{i-1}, a_i - a_{i-\frac{1}{2}}\}.$$

The Roe numerical flux is then defined as

$$f^{\mathrm{ROE}}_{i+\frac{1}{2}} = \frac{1}{2}\left(f_{i+1} + f_i - \psi(a_{i+\frac{1}{2}})\Delta u_{i+\frac{1}{2}}\right). \tag{3.5}$$

In our numerical examples to follow we will see that when the adaptive mechanism is applied, the above entropy corrections are not necessary for the scheme to produce approximations of entropy solutions. This is a first order diffusive scheme, but it serves as a key ingredient in developing higher order methods.

[illegible]. A well-known first order scheme that produces approximations of entropy solutions is the local Lax–Friedrichs (LF) scheme. Its numerical flux function (see [18]) is given by

$$f^{\mathrm{LF}}_{i+\frac{1}{2}} = \frac{1}{2}\left(f_{i+1} + f_i - a_{max}\Delta u_{i+\frac{1}{2}}\right), \tag{3.6}$$

where $a_{max} = \max\{|f'(u_i)|, f'(u_{i+1})|\}$. This scheme produces diffusive numerical solutions and smears discontinuities and was used for comparison reasons only.

[illegible]. A natural generalization of the classical second order Lax–Wendroff (LW) scheme for nonuniform grids can be given as a combination of the first order Roe flux plus a correction flux (see [18]):

$$f^{\mathrm{LW}}_{i+\frac{1}{2}} = f^{\mathrm{ROE}}_{i+\frac{1}{2}} + \frac{1}{2}\left(\frac{\Delta x_i}{0.5\,(\Delta x_{i+1} + \Delta x_i)} - \frac{\Delta t}{0.5\,(\Delta x_{i+1} + \Delta x_i)}|a_{i+\frac{1}{2}}|\right)|a_{i+\frac{1}{2}}|\Delta u_{i+\frac{1}{2}}, \tag{3.7}$$

with $a_{i+\frac{1}{2}}$ as defined in (3.4). It is easy to see that for a uniform grid numerical flux (3.7) is reduced to the classical LW numerical flux. As for uniform grids this scheme has highly oscillatory behavior near discontinuities and without entropy correction cannot produce entropy solutions.

. One of the most classical second order schemes (see [15]) is the well-known two-step MacCormack scheme:

$$u_i^{(1)} = u_i^n - \frac{\Delta t}{\Delta x_i}\left(f_{i+1}^n - f_i^n\right), \tag{3.8}$$

$$u_i^{(2)} = u_i^n - \frac{\Delta t}{\Delta x_i}\left(f_{i+1}^{(1)} - f_i^{(1)}\right), \tag{3.9}$$

$$u_i^{n+1} = \frac{1}{2}\left(u_i^{(1)} + u_i^{(2)}\right). \tag{3.10}$$

This simple scheme also exhibits oscillatory behavior near discontinuities and cannot produce the correct entropy solutions.

. Here we present a second order slope-limiting scheme based on the MUSCL-TVD interpolation formula on nonuniform grids; see, for example, [22]. We define

$$u_{i+\frac{1}{2}}^{\mathrm{L}} = u_i + \frac{h_{i+1}}{2}\left(\frac{u_i - u_{i-1}}{h_i}\right)\Phi\left(\theta_i\right),$$

$$u_{i+\frac{1}{2}}^{\mathrm{R}} = u_{i+1} - \frac{h_{i+1}}{2}\left(\frac{u_{i+2} - u_{i+1}}{h_{i+2}}\right)\Phi\left(\frac{1}{\theta_{i+1}}\right),$$

with $h_i = x_i - x_{i-1}$ and θ_i given by

$$\theta_i = \frac{\left(u_{i+1} - u_i\right)/h_{i+1}}{\left(u_i - u_{i-1}\right)/h_i}.$$

The Φ is a limiter function, and there are several options from which to choose Φ; see, for example, [25]. Some of the most popular limiters are the MinMod (MM) limiter,

$$\Phi(\theta) = \max(0, \min(1, \theta)),$$

the Superbee (SB) limiter

$$\Phi(\theta) = \max(0, \min(2\theta, 1), \min(\theta, 2)),$$

the VanLeer (VL) limiter

$$\Phi(\theta) = \frac{|\theta| + \theta}{1 + |\theta|},$$

and the monotonized central (MC) limiter

$$\Phi(\theta) = \max(0, \min((1+\theta)/2, 2, 2\theta)).$$

The numerical flux for the MUSCL scheme can then be expressed, based on the Roe flux (without an entropy fix), as

$$f_{i+\frac{1}{2}}^{\mathrm{MUSCL}} = \frac{1}{2}\left(f(u_{i+\frac{1}{2}}^{\mathrm{R}}) + f(u_{i+\frac{1}{2}}^{\mathrm{L}}) - |a_{i+\frac{1}{2}}|(u_{i+\frac{1}{2}}^{\mathrm{R}} - u_{i+\frac{1}{2}}^{\mathrm{L}})\right), \tag{3.11}$$

where $a_{i+\frac{1}{2}}$ is evaluated as before, with u_{i+1} and u_i replaced by $u_{i+\frac{1}{2}}^R$ and $u_{i+\frac{1}{2}}^L$. In a similar way one can define a MUSCL flux based on the LF flux.

Second order TVD schemes reduce to first order at extrema, and there are also differences in the behavior for each limiter; for example, the last three limiters have been shown to exhibit sharper resolution of discontinuities, since they do not reduce the slope as severely as MM near a discontinuity.

4. Numerical examples for scalar conservation laws. Because all the schemes presented above are explicit in time, stability requires the time step Δt to satisfy the CFL condition, as to ensure that the time step is small enough that waves from neighboring cells do not interact, with CFL ≤ 1. Based on that we use a variable time step calculated from

$$\text{CFL} = \Delta t \max_i \left\{ \left| \frac{a^+_{i-\frac{1}{2}}}{\Delta x_i} \right|, \left| \frac{a^-_{i+\frac{1}{2}}}{\Delta x_i} \right| \right\}, \tag{4.1}$$

with $a^+ = \max(0, a)$ and $a^- = \min(0, a)$.

4.1. Burgers equation. We first consider numerical experiments for the Burgers equation in the inviscid limit,

$$u_t + \left(\frac{u^2}{2} \right)_x = 0. \tag{4.2}$$

The analytical solutions to this problem can be found, for example, in [15].

The first problem is an academic test case with initial conditions, for $x \in [-5, 5]$,

$$u(x,0) = \begin{cases} -1.0, & x < 0, \\ 1.0, & x \geq 0, \end{cases} \tag{4.3}$$

and has the following exact solution, also known as a [illegible]:

$$u(x,0) = \begin{cases} -1.0, & x < -t, \\ x/t, & -t \leq x \leq t, \\ 1.0, & x > t. \end{cases} \tag{4.4}$$

As pointed out in [18], dealing with transonic rarefactions properly is an important component in the development of successful methods. Results for this problem are presented in Figures 3 and 4 at $t = 2$s. A grid of 61 points was used for all schemes with CFL number equal to 0.9. All the schemes presented in the previous section, with the exception of the LF scheme, cannot produce the correct entropy solution. By the application of the adaptive mechanism all the schemes calculate the correct solution. The most accurate results were produced with the MUSCL adaptive scheme using the SB limiter. We note here that when the adaptive mechanism was applied to the MUSCL scheme, we were able to produce similar results for all limiters.

The second problem was presented in [22] and has initial conditions given by

$$u(x,0) = \begin{cases} 1.0, & x \in [0.2, 2.0], \\ -0.5, & x \in (2.0, 3.0], \\ -1.0, & x \in (3.0, 4.8], \\ 0.0 & \text{otherwise.} \end{cases} \tag{4.5}$$

The solution domain is for $x \in [0, 5]$ with homogeneous Dirichlet conditions. This problem includes two shocks initially at $x = 2$ and $x = 3$, moving to the right and left, respectively, and two expansion discontinuities at $x = 0.2$ and $x = 4.8$ also expanding to the right and left, respectively. The two shocks collide at time $t = 1$s and form a single shock moving to the left. The numerical results are presented in Figures 5 and 6 for $t = 2$s when the shocks have combined into a single one. A grid of 121 points was used for all schemes with CFL number equal to 0.9. All the schemes

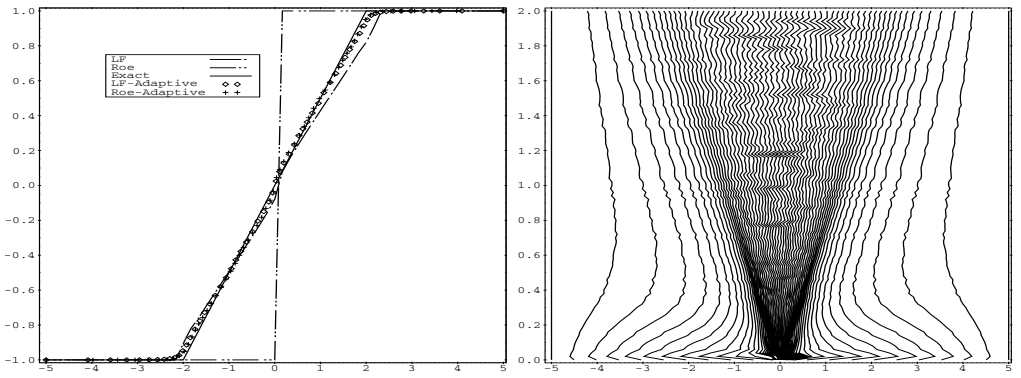

FIG. 3. *Transonic rarefaction problem: Numerical solution (left) and grid point trajectories (right) for the adaptive Roe scheme* ($p = 0.09$, $D = 0$).

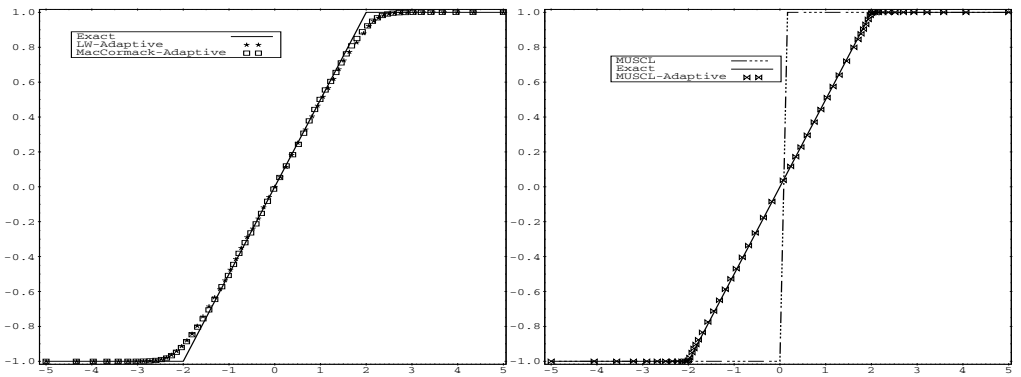

FIG. 4. *Transonic rarefaction problem: Numerical solution (left) for the LW and MacCormack schemes* ($p = 0.062$, $D = 0$) *and (right) for the MUSCL scheme* ($p = 0.10$, $D = 0$).

produce improved results when the adaptive mechanism is imposed, when compared to those produced in a uniform mesh. It is impressive that even the second order oscillatory LW and MacCormack schemes are now able to produce accurate solutions. The performance of the MUSCL using the MC limiter scheme is also greatly improved, since in the nonadaptive case the scheme fails to produce the entropy correct solution at expansions. Similar observations were made for the other limiters as well. In Figure 6 one can also see the ability of the mesh to capture and follow the evolution of the solution as demonstrated by the grid point trajectories.

The third problem has an initial profile of a smooth wave given by

$$u(x, 0) = 0.5 \sin(\pi x) + \sin(2\pi x), \qquad x \in [0, 1],$$

with periodic boundary conditions imposed. The solution propagates to the right, steepening until the singularity time $t_c = 64/(129\pi)$. Results are presented in Figures 7 and 8 for the second order schemes for a 61-point grid and with a CFL number of 0.6 at $t = 1$s, and verify the observations made for the second example. Considerably better results are obtained for the adaptive methods, compared to the ones in uniform grid, especially in shock resolution because of the clustering of grid points near the shock. Again the grid trajectories show the formation and following of the shock layer.

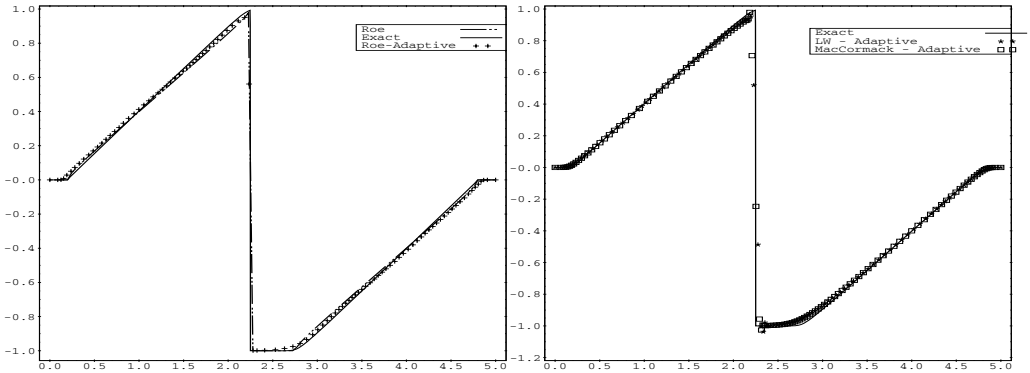

FIG. 5. *The second Burgers problem: Numerical solution Roe's scheme (left)* ($p = 0.079$, $D = 0.0224$) *and the LW and MacCormack schemes (right)* ($p = 0.10$, $D = 0$).

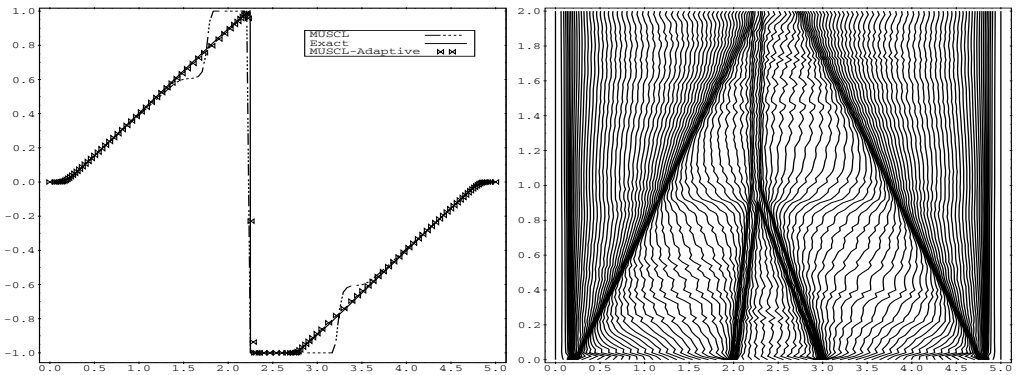

FIG. 6. *The second Burgers problem: Numerical solution (left) and grid point trajectories (right) for the adaptive MUSCL scheme* ($p = 0.09$, $D = 0$).

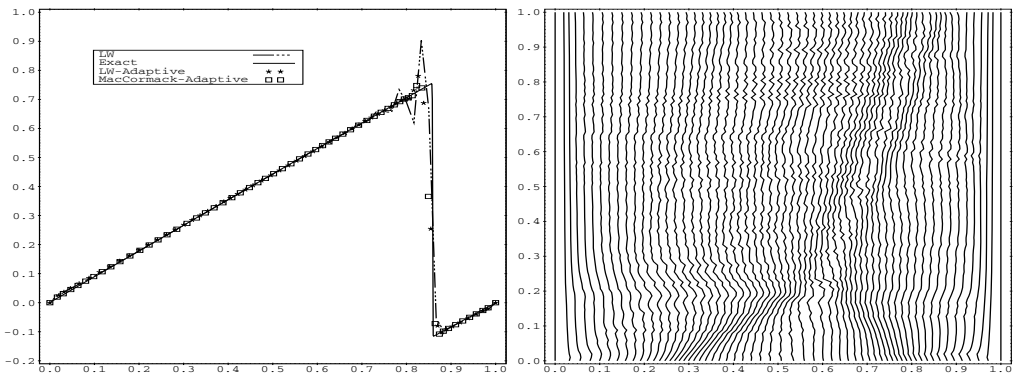

FIG. 7. *The third Burgers problem: Numerical solution for the LW and MacCormack schemes (left) and grid point trajectories (right) for the LW scheme* ($p = 0.06$, $D = 0$).

The fourth problem has initial condition

$$u(x, 0) = 1 - 0.02x, \qquad x \in [0, 100],$$

and has been selected to illustrate convergence to a discontinuous steady state. The

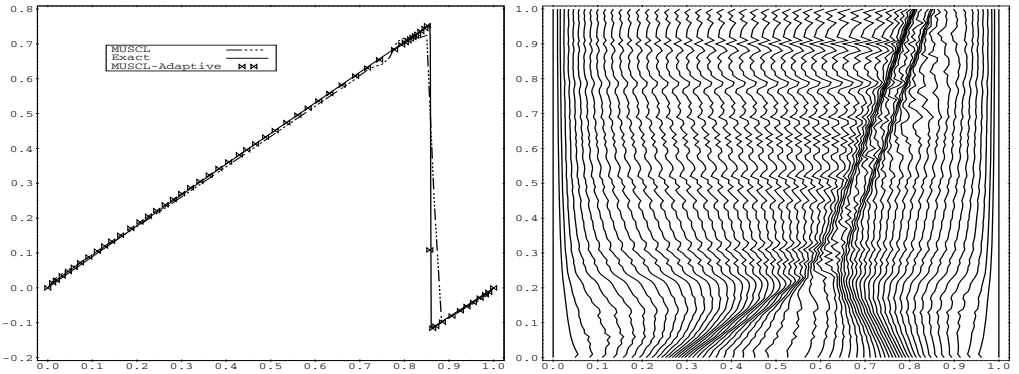

FIG. 8. *The third Burgers problem: Numerical solution (left) and grid point trajectories (right) for the MUSCL scheme* ($p = 0.118$, $D = 0$).

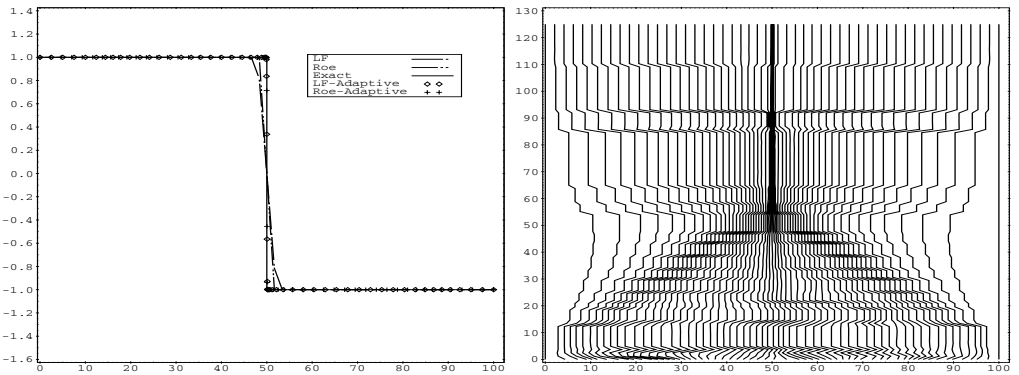

FIG. 9. *The fourth Burgers problem: Numerical solutions for the Roe and LF schemes (left) and grid point trajectories (right) for the adaptive Roe scheme* ($p = 0.10$, $D = 0.013$).

parameters for the calculations were 61 grid points and a CFL number equal to 0.9. The stabilizing tendency of the adaptive method can be clearly seen since it does not produce oscillatory results, as shown in Figures 9 and 10 for $t = 125$s. One can also observe the improvement in all the calculations when the adaptive mechanism is imposed. The effect in the grid movement of a zero and a nonzero value for the "cutoff" parameter D, for Roe's first order scheme, can be seen in Figure 11, following the remarks made in section 2.3.

4.2. Nonconvex conservation law and the Buckley–Leverett equation. In this section we first apply the adaptive grid method to the scalar conservation law with nonlinear nonconvex flux,

$$f(u) = (u^2 - 1)(u^2 - 4)/4 \quad \text{for} \quad x \in [0, 1]. \tag{4.6}$$

The initial profile is $u(x, 0) = -2\text{sign}(x)$. As pointed out in [29] solving this Riemann problem for a scalar conservation law with nonconvex flux leads to difficulties with some numerical schemes. Numerical solutions for all schemes are shown in Figure 12 at $t = 1.2$s, in a 101-point grid and for CFL number equal to 0.8. Again by imposing the adaptive mechanism we are able to produce quality results for all schemes.

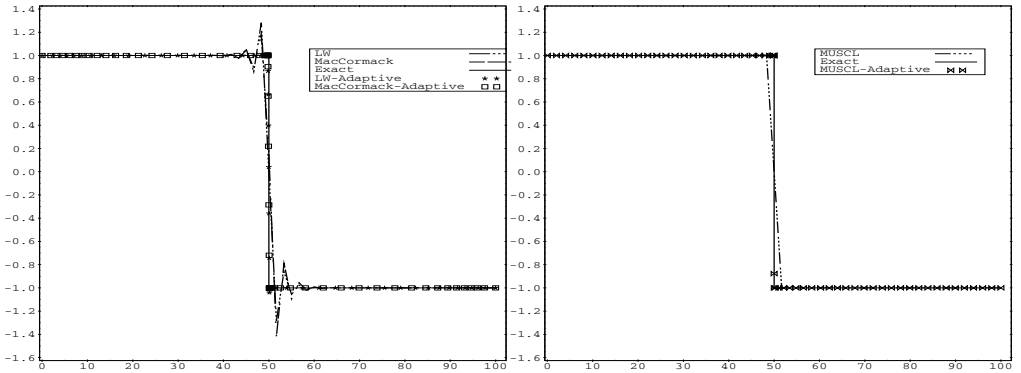

FIG. 10. *The fourth Burgers problem: Numerical solutions for the LW and MacCormack schemes (left) and MUSCL scheme (right)* ($p = 0.13$, $D = 0$).

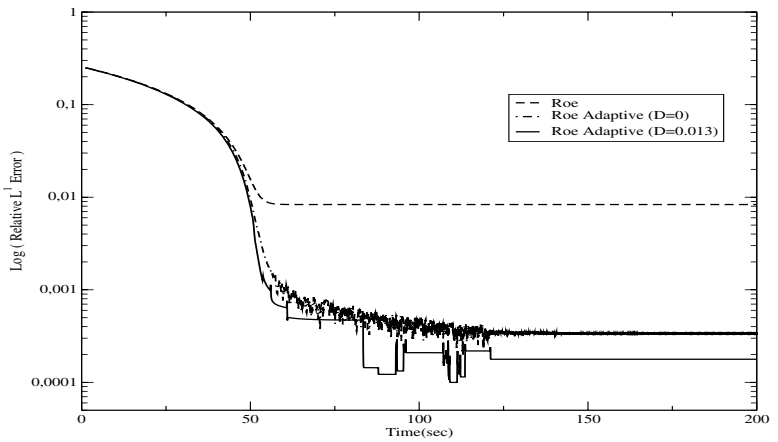

FIG. 11. *The fourth Burgers problem: convergence histories for the Roe scheme.*

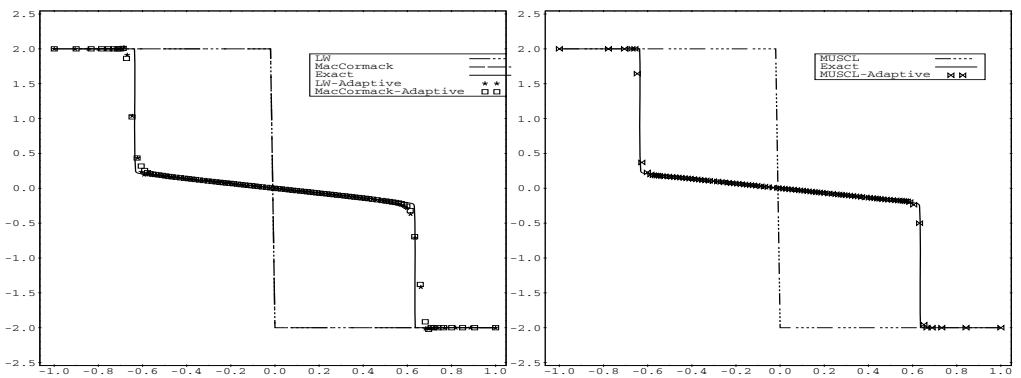

FIG. 12. *Nonconvex flux problem: Numerical solutions for the LW and MacCormack schemes (left) and MUSCL scheme (right)* ($p = 0.069$, $D = 0$).

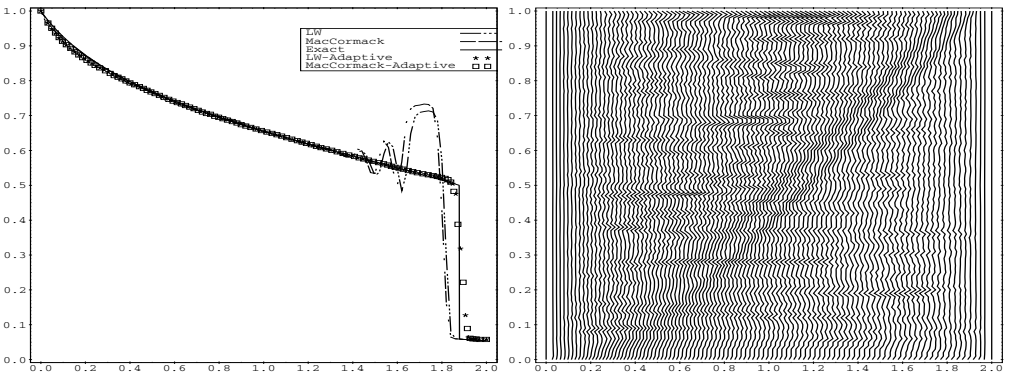

FIG. 13. *Buckley–Leverett problem: Numerical solutions for the LW and MacCormack schemes (left) and grid point trajectories for the adaptive LW scheme* ($p = 0.076$, $D = 0$).

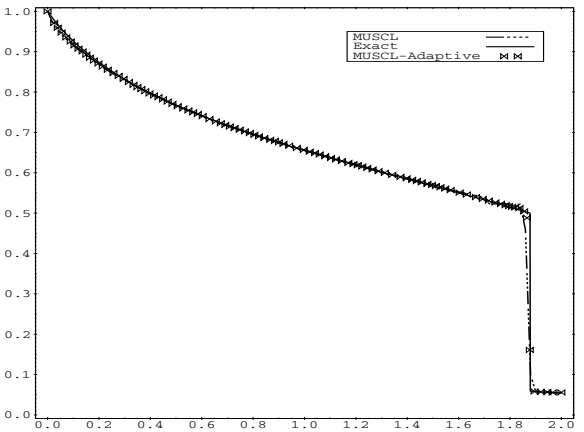

FIG. 14. *Buckley–Leverett problem: Numerical solutions for the MUSCL scheme* ($p = 0.10$, $D = 0.0088$).

Next we consider the scalar Buckley–Leverett equation with the flux function

$$f(u) = \frac{u^2}{u^2 + 0.5(1-u)^2},$$

with initial and boundary conditions for $x \in [0, 2]$,

$$u(x,0) = \frac{1}{1+10x}, \qquad u(0,t) = 1, \qquad u(1,t) = \frac{1}{21}.$$

The solution for the adaptive and uniform LW and MacCormack schemes is shown in Figure 13 in a 101-point grid. The highly oscillatory behavior of these schemes is totally suppressed by the adaptive mechanism resolving and following the shock layer much more accurately. Improvement in the shock resolution can also be observed for the MUSCL scheme in Figure 14.

. . . . 4 (a result on the smoothing effect of the AGR). As a final result for scalar CL we present a simple advection test (see [26]) of a contact discontinuity in order to measure the smoothing effect of the adaptive mechanism. We compute an

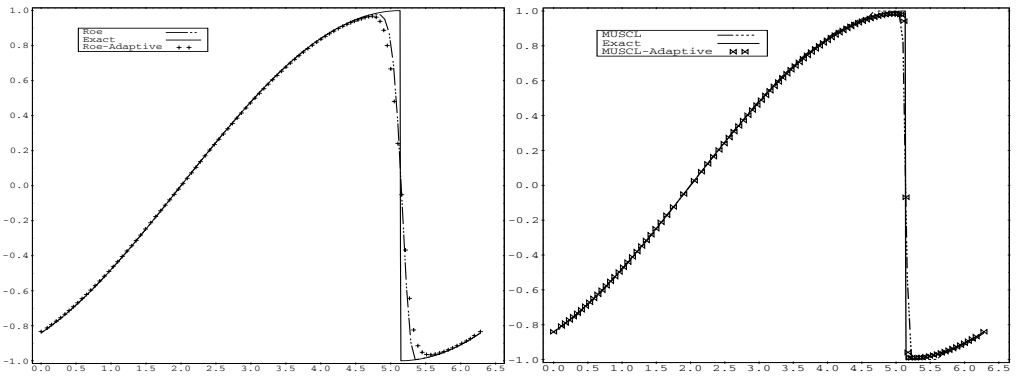

FIG. 15. *Linear advection of a contact discontinuity for the Roe scheme* ($p = 0.03$, $D = 0.004$) *and MUSCL scheme* ($p = 0.12$, $D = 0$).

approximate solution to the linear advection equation, $u_t + u_x = 0$, with periodic boundary conditions and initial condition

$$u(x,0) = \begin{cases} \sin(x/2), & x \in [0,\pi), \\ -\sin(x/2), & x \in [\pi, 2\pi), \end{cases}$$

that has a discontinuity at $x = \pi$ which at t = 2s is advected to $x = \pi + 2$. Results on a 101-point grid for the Roe and MUSCL schemes, with CFL = 0.95, are shown in Figure 15. The smoothing effect of the adaptive mechanism can be seen for the first order Roe scheme, but for the second order MUSCL scheme the results have been improved.

5. Numerical schemes for nonuniform grids (one-dimensional systems of equations). We consider the general system of conservation laws with a source term added, i.e.,

$$\mathbf{U}_t + \mathbf{F}(\mathbf{U})_x = \mathbf{G}(\mathbf{U}), \quad \mathbf{U} \in \mathbb{R}^M; \tag{5.1}$$

here $\mathbf{F}(\mathbf{U})$ is the flux function and $\mathbf{G}$ is the source term. We can numerically approximate system (5.1) by using the explicit conservative numerical scheme with a source term approximation within the finite difference-volume frame, as

$$\mathbf{U}_i^{n+1} = \mathbf{U}_i^n - \frac{\Delta t}{\Delta x_i}\left[\mathbf{F}^n_{i+\frac{1}{2}} - \mathbf{F}^n_{i-\frac{1}{2}}\right] + \frac{\Delta t}{\Delta x_i}\widetilde{\mathbf{G}}_i^n, \tag{5.2}$$

where again $\mathbf{F}^n_{i+\frac{1}{2}}$, $i = 1, 2, \ldots, N-1$, is the numerical flux function, and the approximation of the source term $\widetilde{\mathbf{G}}_i^n$ is considered as the cell average value (numerical source integral over the computational cell) satisfying the relationship

$$\widetilde{\mathbf{G}}_i^n = \frac{1}{\Delta x_i}\int_{x_{i-\frac{1}{2}}}^{x_{i+\frac{1}{2}}} \mathbf{G}(x, \mathbf{U}^n)dx, \tag{5.3}$$

and after choosing the numerical flux function it remains to choose an appropriate approximation (depending on the scheme used) for the numerical source integral $\widetilde{\mathbf{G}}_i^n$.

For the stationary case, $\mathbf{U}_t = 0$, the flux function and source term balance:

$$\mathbf{F}(\mathbf{U})_x = \mathbf{G}(\mathbf{U}).$$

Therefore, an accurate numerical scheme should also balance the numerical flux with the source term approximation,

$$\mathbf{F}^n_{i+\frac{1}{2}} - \mathbf{F}^n_{i-\frac{1}{2}} = \widetilde{\mathbf{G}}^n_i. \tag{5.4}$$

The numerical schemes presented next incorporate the numerical source integral in such a way that (5.4) is satisfied.

5.1. Roe's scheme for systems of conservation laws with source terms. The numerical flux for the Roe upwind scheme can be written in the form

$$\mathbf{F}^{\mathrm{ROE}}_{i+\frac{1}{2}} = \frac{1}{2}\left[\mathbf{F}_{i+1} + \mathbf{F}_i - \mathbf{J}_{i+\frac{1}{2}}(\mathbf{U}_{i+1} - \mathbf{U}_i)\right]. \tag{5.5}$$

The matrix $\mathbf{J}_{i+\frac{1}{2}}$ is the Roe-type linearization and satisfies

$$\mathbf{F}_{i+1} - \mathbf{F}_i = \mathbf{J}_{i+\frac{1}{2}}(\mathbf{U}_{i+1} - \mathbf{U}_i) \tag{5.6}$$

and has real eigenvalues $(\tilde{a}^k_{i+\frac{1}{2}})$, $k = 1, \ldots, M$, and a complete set of eigenvectors $(\tilde{\mathbf{e}}^k_{i+\frac{1}{2}})$. Representing now $\mathbf{U}_{i+1} - \mathbf{U}_i$ in terms of the eigenvectors of the Roe linearization, i.e.,

$$\mathbf{U}_{i+1} - \mathbf{U}_i = \sum_{k=1}^{M} \alpha^k_{i+\frac{1}{2}} \tilde{\mathbf{e}}^k_{i+\frac{1}{2}}, \tag{5.7}$$

we obtain from (5.6)

$$\mathbf{J}_{i+\frac{1}{2}}(\mathbf{U}_{i+1} - \mathbf{U}_i) = \sum_{k=1}^{M} \tilde{a}^k_{i+\frac{1}{2}} \alpha^k_{i+\frac{1}{2}} \tilde{\mathbf{e}}^k_{i+\frac{1}{2}}. \tag{5.8}$$

Then the Roe numerical flux can be written as

$$\mathbf{F}^{\mathrm{ROE}}_{i+\frac{1}{2}} = \frac{1}{2}\left[\mathbf{F}_{i+1} + \mathbf{F}_i - \sum_{k=1}^{M} |\tilde{a}^k_{i+\frac{1}{2}}| \alpha^k_{i+\frac{1}{2}} \tilde{\mathbf{e}}^k_{i+\frac{1}{2}}\right]. \tag{5.9}$$

The $\alpha_{i+\frac{1}{2}}$ (wave strengths) values follow from (5.7).

. The integral of $\mathbf{G}$, in relation (5.3), over the cell $[x_{i-\frac{1}{2}}, x_{i+\frac{1}{2}}]$ is first split into a sum of two integrals in the $[x_{i-\frac{1}{2}}, x_i]$, $[x_i, x_{i+\frac{1}{2}}]$ as

$$\frac{1}{\Delta x_i}\int_{x_{i-\frac{1}{2}}}^{x_{i+\frac{1}{2}}} \mathbf{G}(x, \mathbf{U}^n)dx = \frac{1}{\Delta x_i}\left[\int_{x_{i-\frac{1}{2}}}^{x_i} \mathbf{G}(x, \mathbf{U}^n)dx + \int_{x_i}^{x_{i+\frac{1}{2}}} \mathbf{G}(x, \mathbf{U}^n)dx\right]. \tag{5.10}$$

The upwind definition of the approximated source terms $\widetilde{\mathbf{G}}^n_i$ for nonuniform grids is given by

$$\widetilde{\mathbf{G}}^n_i = \frac{1}{\Delta x_i}\left[\frac{(x_i - x_{i-1})}{2}\widetilde{\mathbf{G}}^L(x_{i-1}, x_i, \mathbf{U}^n_{i-1}, \mathbf{U}^n_i) + \frac{(x_{i+1} - x_i)}{2}\widetilde{\mathbf{G}}^R(x_i, x_{i+1}, \mathbf{U}^n_i, \mathbf{U}^n_{i+1})\right], \tag{5.11}$$

where $\widetilde{\mathbf{G}}^L$ and $\widetilde{\mathbf{G}}^R$ are continuous functions, giving the averages of $\mathbf{G}(x, \mathbf{U}^n)$ on the subcells $[x_{i-\frac{1}{2}}, x_i]$, $[x_i, x_{i+\frac{1}{2}}]$, respectively. These functions give the upwind values of the source terms and following [7] can be defined as

$$\widetilde{\mathbf{G}}^L_{i-\frac{1}{2}} = \left[\mathbf{I} + |\mathbf{J}_{i-\frac{1}{2}}|\mathbf{J}^{-1}_{i-\frac{1}{2}}\right] \widetilde{\mathbf{G}}_{i-\frac{1}{2}}, \quad \widetilde{\mathbf{G}}^R_{i+\frac{1}{2}} = \left[\mathbf{I} - |\mathbf{J}_{i+\frac{1}{2}}|\mathbf{J}^{-1}_{i+\frac{1}{2}}\right] \widetilde{\mathbf{G}}_{i+\frac{1}{2}}. \tag{5.12}$$

The definition of the $\mathbf{J}_{i\pm\frac{1}{2}}$ and $|\mathbf{J}_{i\pm\frac{1}{2}}|$ matrices follow from (5.6) for the Roe linearization and are defined in the appendix. The terms $\widetilde{\mathbf{G}}_{i\pm\frac{1}{2}}$ represent approximations of $\mathbf{G}$ at cells $(i-1, i)$ and $(i, i+1)$, respectively.

Alternatively, we rewrite (5.12) in decomposed form,

$$\widetilde{\mathbf{G}}^L_{i-\frac{1}{2}} = \sum_{k=1}^{M} \beta^k_{i-\frac{1}{2}} \tilde{\mathbf{e}}^k_{i-\frac{1}{2}} \left(1 + \operatorname{sgn}(\tilde{a}^k_{i-\frac{1}{2}})\right), \quad \widetilde{\mathbf{G}}^R_{i+\frac{1}{2}} = \sum_{k=1}^{M} \beta^k_{i+\frac{1}{2}} \tilde{\mathbf{e}}^k_{i+\frac{1}{2}} \left(1 - \operatorname{sgn}(\tilde{a}^k_{i+\frac{1}{2}})\right), \tag{5.13}$$

with the values of $\beta^k_{i\pm\frac{1}{2}}$ determined from

$$\sum_{k=1}^{M} \beta^k_{i\pm\frac{1}{2}} \tilde{\mathbf{e}}^k_{i\pm\frac{1}{2}} = \widetilde{\mathbf{G}}_{i\pm\frac{1}{2}}. \tag{5.14}$$

5.2. The LW scheme. The numerical flux for the classical second order LW scheme for nonlinear systems, on nonuniform grids, can be written, following [18], as

$$\mathbf{F}^{\mathrm{LW}}_{i+\frac{1}{2}} = \mathbf{F}^{\mathrm{ROE}}_{i+\frac{1}{2}} + \frac{1}{2} \sum_{k=1}^{M} \left(\frac{\Delta x_i}{\Delta x_{i+\frac{1}{2}}} - \frac{\Delta t}{\Delta x_{i+\frac{1}{2}}} |\tilde{a}^k_{i+\frac{1}{2}}| \right) |\tilde{a}^k_{i+\frac{1}{2}}| \alpha^k_{i+\frac{1}{2}} \tilde{\mathbf{e}}^k_{i+\frac{1}{2}}, \tag{5.15}$$

where $\Delta x_{i+\frac{1}{2}} = (\Delta x_{i+1} + \Delta x_i)/2$.

A flux-limited second order TVD version of the LW scheme is then given by

$$\mathbf{F}^{\mathrm{LWTVD}}_{i+\frac{1}{2}} = \mathbf{F}^{\mathrm{ROE}}_{i+\frac{1}{2}} + \frac{1}{2} \sum_{k=1}^{M} \left(\frac{\Delta x_i}{\Delta x_{i+\frac{1}{2}}} - \frac{\Delta t}{\Delta x_{i+\frac{1}{2}}} |\tilde{a}^k_{i+\frac{1}{2}}| \right) \Phi(\theta^k_{i+\frac{1}{2}}) |\tilde{a}^k_{i+\frac{1}{2}}| \alpha^k_{i+\frac{1}{2}} \tilde{\mathbf{e}}^k_{i+\frac{1}{2}}, \tag{5.16}$$

where

$$\theta^k_{i+\frac{1}{2}} = \frac{\alpha^k_{I+\frac{1}{2}}}{\alpha^k_{i+\frac{1}{2}}} \qquad \text{with} \qquad I = \begin{cases} i-1 & \text{if} \quad \tilde{a}^k_{i+\frac{1}{2}} > 0, \\ i+1 & \text{if} \quad \tilde{a}^k_{i+\frac{1}{2}} < 0; \end{cases} \tag{5.17}$$

here Φ can be any of the limiter functions presented in section 3.

The Roe averaged values can be used for the source term approximations, and we obtain a flux-limited second order approximation of the source term in the numerical source term (5.10), similar to the one presented in [16], by setting

$$\widetilde{\mathbf{G}}^L_{i-\frac{1}{2}} = \sum_{k=1}^{M} \beta^k_{i-\frac{1}{2}} \tilde{\mathbf{e}}^k_{i-\frac{1}{2}} \left[1 + \operatorname{sgn}(\tilde{a}^k_{i-\frac{1}{2}}) \left(1 - \Phi(\theta^k_{i-\frac{1}{2}}) \left(\frac{\Delta x_i}{\Delta x_{i-\frac{1}{2}}} - \frac{\Delta t}{\Delta x_{i-\frac{1}{2}}} |\tilde{a}^k_{i-\frac{1}{2}}| \right)\right)\right],$$

$$\widetilde{\mathbf{G}}^R_{i+\frac{1}{2}} = \sum_{k=1}^{M} \beta^k_{i+\frac{1}{2}} \tilde{\mathbf{e}}^k_{i+\frac{1}{2}} \left[1 - \operatorname{sgn}(\tilde{a}^k_{i+\frac{1}{2}}) \left(1 - \Phi(\theta^k_{i+\frac{1}{2}}) \left(\frac{\Delta x_i}{\Delta x_{i+\frac{1}{2}}} - \frac{\Delta t}{\Delta x_{i+\frac{1}{2}}} |\tilde{a}^k_{i+\frac{1}{2}}| \right)\right)\right].$$

5.3. The MacCormack scheme. The MacCormack scheme adapted to approximate systems of conservation laws with a source term can be written as

$$\mathbf{U}_i^{n+1} = \frac{1}{2}\left(\mathbf{U}_i^n + \mathbf{U}_i^{(1)}\right) - \frac{\Delta t}{2\Delta x_i}\left(\mathbf{F}_i^{(1)} - \mathbf{F}_{i-1}^{(1)}\right) + \frac{\Delta t}{2\Delta x_i}\widetilde{\mathbf{G}}_{i-\frac{1}{2}}^{(1)}, \tag{5.18}$$

where

$$\mathbf{U}_i^{(1)} = \mathbf{U}_i^n - \frac{\Delta t}{\Delta x_i}\left(\mathbf{F}_{i+1}^n - \mathbf{F}_i^n\right) + \frac{\Delta t}{\Delta x_i}\widetilde{\mathbf{G}}_{i+\frac{1}{2}}^n.$$

This scheme is a predictor-corrector one and has the advantage that we do not need to approximate the eigenvalues and eigenvectors of the Jacobian matrix. However, spurious oscillations may occur in the solution, especially when discontinuities are present, even when we choose the $\widetilde{\mathbf{G}}$ discretizations in (5.18) in such a way as to satisfy (5.4).

6. The shallow water model. We consider the well-known one-dimensional shallow water system, with a geometrical source term (the bottom topography) added, written in differential conservation law form as a single vector equation:

$$\mathbf{U}_t + \mathbf{F}(\mathbf{U})_x = \mathbf{G}(\mathbf{U}), \tag{6.1}$$

with

$$\mathbf{U} = \begin{bmatrix} h \\ hu \end{bmatrix}, \qquad \mathbf{F}(\mathbf{U}) = \begin{bmatrix} hu \\ hu^2 + \frac{g}{2}h^2 \end{bmatrix}, \qquad \mathbf{G}(\mathbf{U}) = \begin{bmatrix} 0 \\ -ghZ' \end{bmatrix}.$$

System (6.1) describes the flow at time $t \geq 0$ at point $x \in \mathbb{R}$, where $h(x,t) \geq 0$ is the total water height above the bottom, $u(x,t)$ is the average horizontal velocity, $Z(x)$ is the bottom height function, and g the gravitational acceleration. In the following we will denote by $q = hu$ the water unit discharge.

An important property of system (6.1) is related to the source term: the shallow water system admits nontrivial steady states. They are characterized by

$$(hu)_x = 0, \tag{6.2}$$

$$\left(hu^2 + \frac{g}{2}h^2\right)_x = ghZ', \tag{6.3}$$

i.e.,

$$q = (hu) = \text{constant}, \tag{6.4}$$

$$hu^2 + g(h+Z) = \text{constant}. \tag{6.5}$$

A particular case that provides a benchmark for many approximating schemes is the still water steady state (flow at rest), i.e., when $u = 0$ and $h + Z = \text{constant}$.

In [7] the concept of Property C was introduced. A given scheme would satisfy Property C if, in the case of a flow at rest, there is an exact balance between the discrete components of the flux and a given source term treatment based on (5.4), approximating this stationary solution. Thus, when numerically treating the source terms, for Property C to be satisfied exactly or approximately (to order $O(\Delta x^2)$) one must ensure that this equilibrium solution would not be perturbed. The source term discretizations presented in the previous sections along with those presented in the appendix for the shallow water system satisfy this property.

In the numerical examples presented next we use again a variable time step as to satisfy the CFL ≤ 1 stability condition:

$$\text{CFL} = \Delta t \max_{i,k} \left\{ \left| \frac{\tilde{a}^{k^+}_{i-\frac{1}{2}}}{\Delta x_i} \right|, \left| \frac{\tilde{a}^{k^-}_{i+\frac{1}{2}}}{\Delta x_i} \right| \right\}, \tag{6.6}$$

where for the shallow water model values $\tilde{a}^{k^+}_{i-\frac{1}{2}}$ and $\tilde{a}^{k^-}_{i+\frac{1}{2}}$ are defined in the appendix.

6.1. Idealized dam-break flow. We first consider a nonstationary case, the dam-break problem in a rectangular channel with flat bottom, $Z = 0$. We computed the solution on a channel of length $L = 2000$m for time $t = 50$s and with initial conditions

$$u(x,0) = 0,$$
$$h(x,0) = \begin{cases} h_1, & x \leq 1000, \\ h_0, & x > 1000, \end{cases}$$

with $h_1 > h_0$. This is the corresponding Riemann problem for the homogeneous problem. The water depth ratio is given by h_0/h_1. The dam collapses at $t = 0$s and the resulting flow consists of a shock wave (bore) traveling downstream and a rarefaction wave (depression wave) traveling upstream. The upstream depth h_1 was set at 10m. When the depth ratio is greater than 0.5, the flow throughout the channel remains subcritical. For depth ratios smaller than 0.5, the flow downstream of the dam position is supercritical while remaining subcritical upstream. For very small values of the ratio h_0/h_1 the flow regime becomes strongly supercritical downstream and the shock wave can be difficult to capture; see [10], for example. Analytical solutions to this problem can be found, for example, in [24].

Comparative results are presented in a 101-point grid and depth ratio 0.005, for all schemes in Figures 16–18, using CFL = 0.9. All the results produced with the adaptive method are significantly better in terms of shock resolution and nonoscillatory behavior in both components of the solution. No entropy problems appeared for all adaptive schemes. The grid clustering and the close following of the downstream shocks can also be seen. It is impressive that the LW and MacCormack schemes are able to produce quality results with no extra dissipative mechanism imposed other than the adaptive one. The performance of the TVD scheme, using the VL limiter, was also improved.

A more quantitative comparison is afforded in Table 1, where we compare the adaptive and nonadaptive Roe and TVD schemes in terms of computational costs, reported as the CPU times, the number of time steps (NT), and the L^1 errors for h and q. It is clear that the adaptive schemes produce accurate results with fewer grid points than the nonadaptive schemes, and even though the total number of time steps is increased, for the adaptive schemes, CPU times are substantially smaller (since in nonadaptive schemes one has to obtain solutions to many more grid points). For example, the adaptive grid calculations with 101 grid points are as accurate as for a fixed grid with 401 points, and require less CPU time. The effect of the parameter D can also be seen in Table 1.

6.2. Flow at rest over topography. We consider system (6.1) with initial conditions

$$u(x,0) = 0 \quad \forall x \in \mathbb{R},$$
$$h(x,0) + Z(x) = H \quad \forall x \in \mathbb{R}.$$

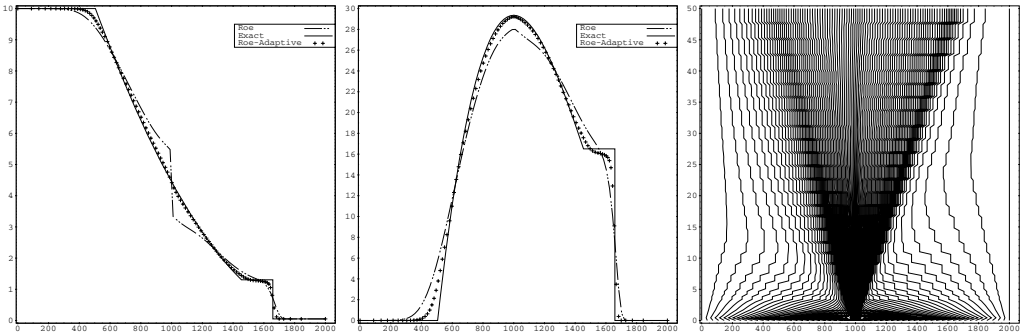

FIG. 16. *Idealized dam-break flow: results with Roe's scheme for h (left), q (middle), and grid point trajectories (right) for the adaptive Roe scheme* ($p = 0.0518$, $D = 0.0065$).

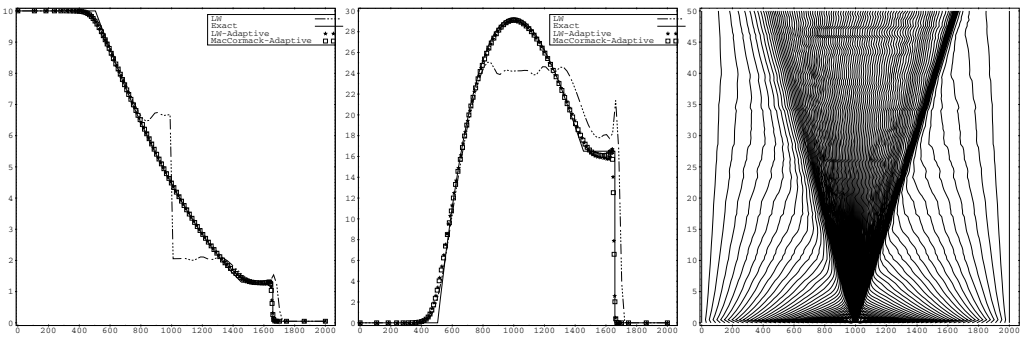

FIG. 17. *Idealized dam-break flow: results with the LW and MacCormack schemes for h (left), q (middle), and grid point trajectories (right) for the adaptive LW scheme* ($p = 0.10$, $D = 0$).

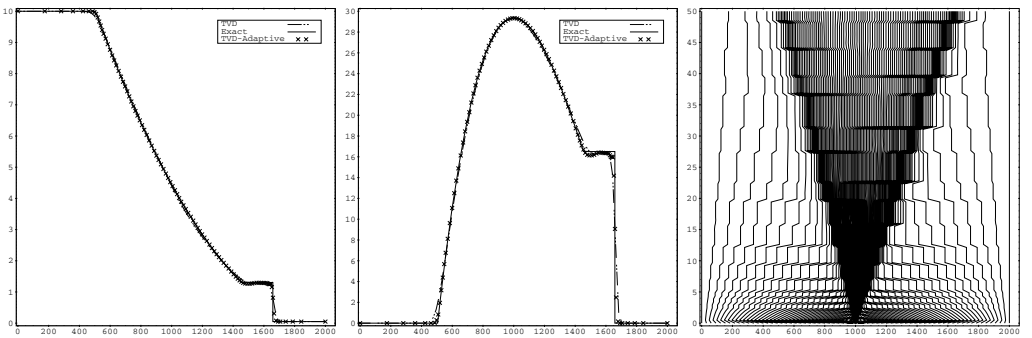

FIG. 18. *Idealized dam-break flow: results with the TVD scheme for h (left), q (middle), and grid point trajectories (right) for the adaptive TVD scheme* ($p = 0.10$, $D = 0.0125$).

Then, clearly,

$$u(x,t) = 0 \quad \forall x \in \mathbb{R}, t \geq 0,$$
$$h(x,t) + Z(x) = H \quad \forall x \in \mathbb{R}, t \geq 0$$

is a solution to (6.1).

We test the schemes with the adaptive mechanism in order to study their behavior

TABLE 1
Idealized dam-break flow: comparative performance of the Roe and TVD schemes.

Description	CPU time (sec)	NT	L^1 error (h)	L^1 error (q)

to this benchmark problem [13, 9, 11] with $Z(x)$ given by

$$Z(x) = \begin{cases} 0.2 - 0.05(x-10)^2, & 8 \le x \le 12, \\ 0 \quad \text{otherwise}, \end{cases} \tag{6.7}$$

in a channel of length $L = 25$m and $H = 2$m. Figures 19 and 20 display the final water level and the final unit discharge values, respectively, for the Roe and MacCormack schemes at time $t = 200$s and in a grid of 101 points. Both schemes with the adaptation method perfectly preserve this steady state, up to machine accuracy. Grid points are concentrated where most needed, in the topography area. The movement of the grid points is stopping much faster for the MacCormack scheme being a second order method in time. Similar results and observations were made for the TVD scheme that are not presented here for brevity.

6.3. Steady transcritical flow. In this case, and for the same initial conditions as in section 6.2, we impose an upstream boundary condition for the discharge $q = 1.53\text{m}^2/\text{s}$ and a downstream boundary condition for the water level $H_0 = 0.66$m only in the case where the flow is subcritical. If the flow becomes supercritical downstream, no condition for the water level is imposed. Results at $t = 250$s in a 51-point grid are presented in Figures 21 and 22 for the Roe and TVD schemes (using the MM limiter) and CFL = 0.9.

In Table 2 we quantify the errors and performance of the schemes for this test problem. Similar observations with those in section 6.1 can be deduced. The importance of using the parameter D for steady state problems can be clearly seen.

6.4. Steady transcritical flow with shock. The initial conditions in this case was taken to be as in the previous section, with H being the constant water level downstream provided by the boundary condition. In this test case the upstream boundary condition for the discharge was $q = 0.18\text{m}^2/\text{s}$ and the downstream boundary condition for the water level was $H = 0.33$m.

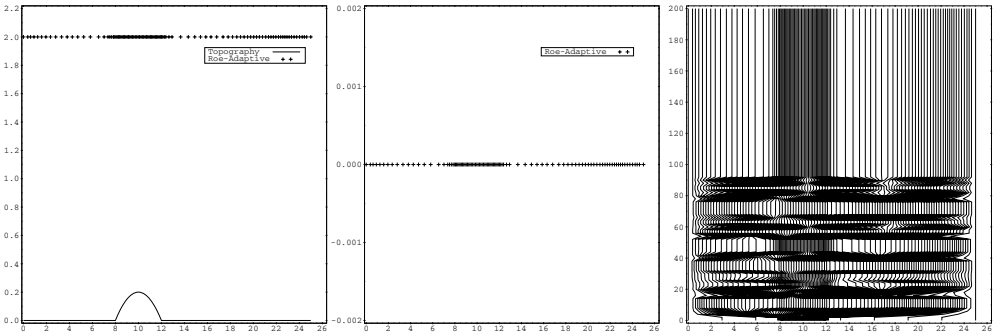

FIG. 19. *Flow at rest over topography: results with the adaptive Roe scheme for $h + Z$ (left), q (middle), and grid point trajectories (right)* ($p = 0.06$, $D = 0.0525$).

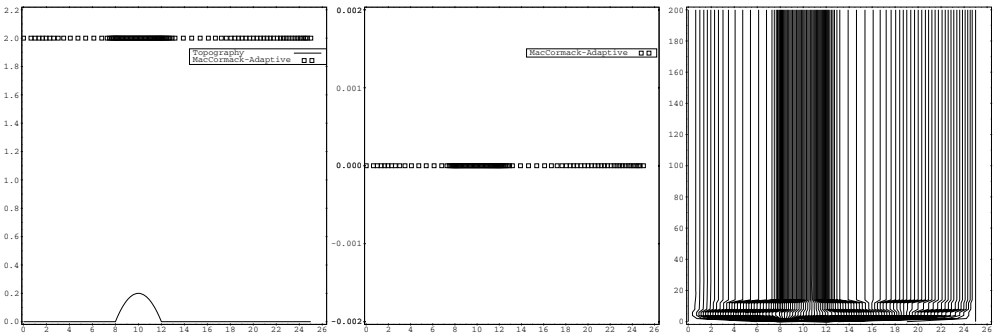

FIG. 20. *Flow at rest over topography: results with the adaptive MacCormack scheme for $h + Z$ (left), q (middle), and grid point trajectories (right)* ($p = 0.06$, $D = 0.0525$).

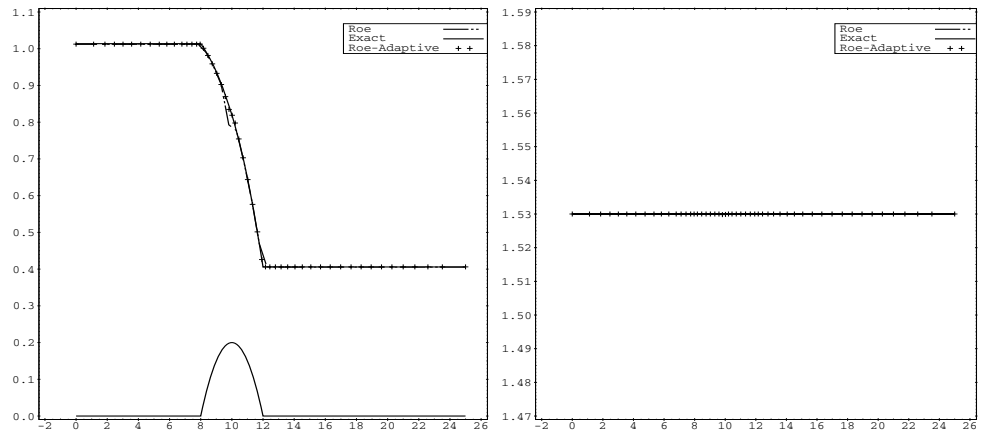

FIG. 21. *Steady transcritical flow: results with Roe's scheme for $h + Z$ (left), discharge (q) (right)* ($p = 0.075$, $D = 0.06$).

Results for a coarse 51-point grid for the Roe and TVD schemes and also on a 101-point grid for the TVD scheme with the MM limiter used are shown in Figures 23–25. The improvement in the results compared to the uniform grid results is clear. The shock resolution is very good and the steady state is perfectly preserved for a

long time calculation of $t = 800$s. The CFL value used in all tests was 0.8.

Finally in Figure 26 the numerical results for the depth are shown for the adaptive MacCormack scheme, where in spite of the formation of a strong shock the scheme can produce a nonoscillatory steady state solution, especially when applying the parameter D.

6.5. Dam-break flow over topography. In this example we solve the shallow water equations with a wavy bottom $Z(x)$,

$$Z(x) = \begin{cases} 0.3(\cos(\pi(x-1)/2))^{30}, & |x-1| \le 1, \\ 0 & \text{otherwise}, \end{cases} \tag{6.8}$$

and initial conditions

$$h(x,0) = \begin{cases} 2.0 - Z(x), & -10 \le x < 1, \\ .35 - Z(x), & 1 \le x < 10, \end{cases} \qquad u(x,0) = \begin{cases} 1, & -10 \le x < 1, \\ 0, & 1 \le x < 10, \end{cases} \tag{6.9}$$

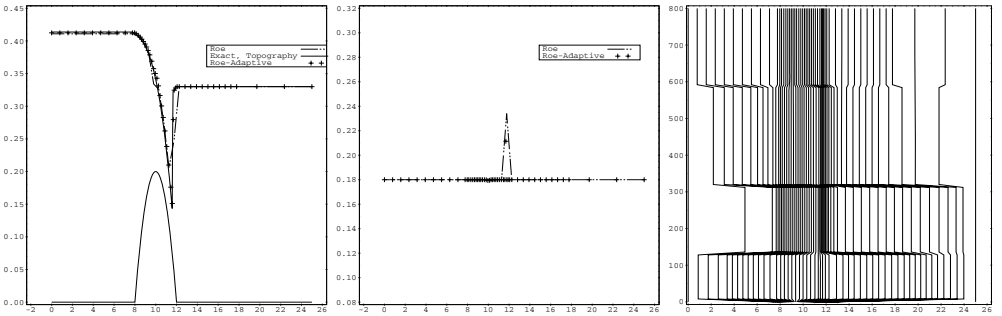

FIG. 23. *Steady transcritical flow with shock: results with Roe's scheme for $h + Z$ (left), q (middle), and grid point trajectories (right) for the adaptive Roe scheme* ($p = 0.08$, $D = 0.07$).

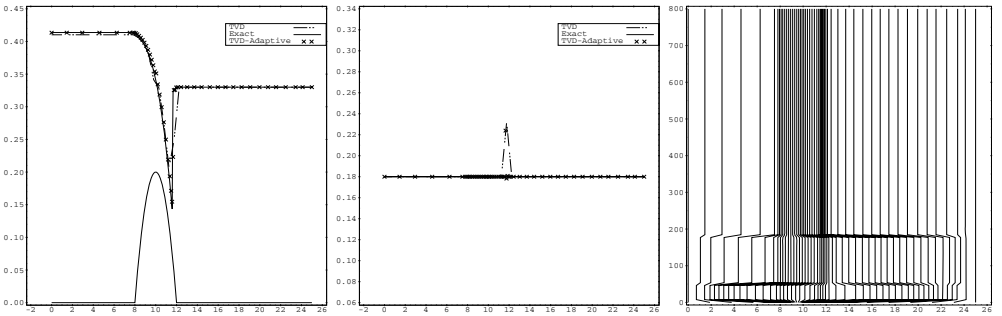

FIG. 24. *Steady transcritical flow with shock: results with the TVD scheme for $h + Z$ (left), q (middle), and grid point trajectories (right) for the adaptive TVD scheme on a* 51*-point grid* ($p = 0.08$, $D = 0.075$).

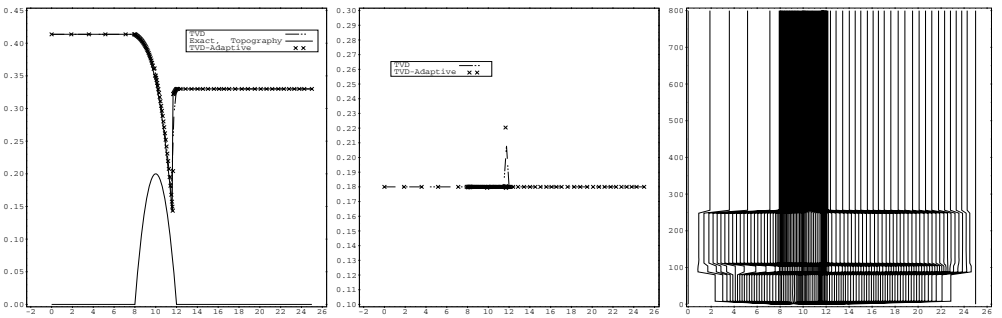

FIG. 25. *Steady transcritical flow with shock: results with the TVD scheme for $h + Z$ (left), q (middle), and grid point trajectories (right) for the adaptive TVD scheme on a* 101*-point grid* ($p = 0.08$, $D = 0.075$).

in order to test the adaptive behavior of the schemes in an unsteady flow over topography; this test was also presented in [28]. The solution profiles for the water depth and velocity profile at time $t = 1$s are shown in Figures 27–29. A grid of 101 points was used in all calculations. The exact solution for this problem is a reference solution calculated in a uniform grid with 4001 grid points. The improvements in the numerical solution can be observed for all the schemes; even the MacCormack scheme can produce a stable solution when compared with the one calculated in a uniform grid.

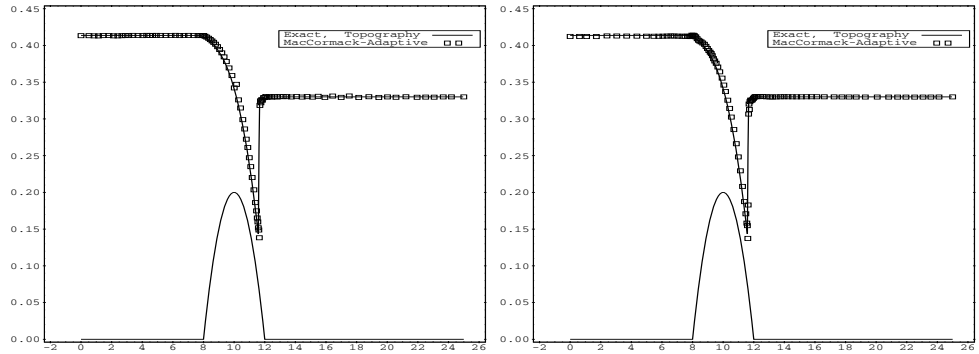

FIG. 26. *Steady transcritical flow with shock: results for $h + Z$ with the adaptive MacCormack scheme with $p = 0.12$, $D = 0$ (left) and with $p = 0.12$, $D = 0.003$ (right).*

7. Conclusions. In this work we have rigorously investigated, in a general framework, the numerical behavior of an adaptive grid redistribution (AGR) mechanism, when combined with classical finite volume numerical methods with well-known characteristics, for solving one-dimensional hyperbolic conservation laws. The evolving mesh is constructed such that its spatial resolution is controlled via selective geometrical characteristics of the numerical solution, by choosing some power of the curvature of the solution as the estimator function. A conservative reconstruction procedure for the numerical solution is also applied at each evolution step.

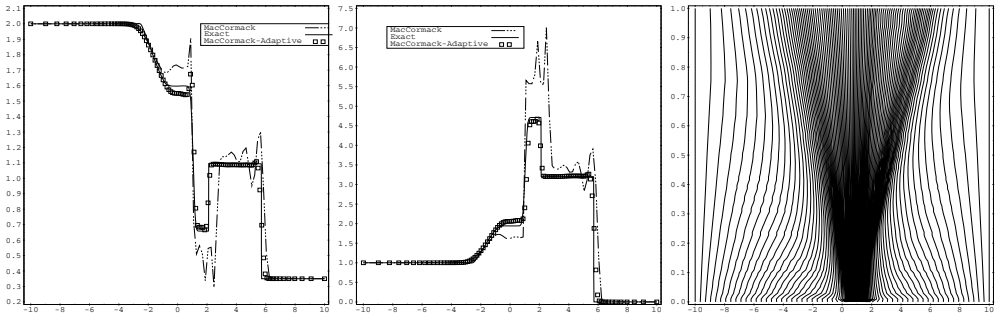

FIG. 29. *Dam-break flow over topography: results with the MacCormack scheme for h (left), u (middle), and grid point trajectories (right) for the adaptive MacCormack scheme* ($p = 0.0345$, $D = 0.001$).

From the numerical experiments produced in the course of this work we concluded the following advantages of the use of this particular AGR method. The method, when applied to classical second order schemes that compute oscillatory solutions, suppresses the oscillations produced, and as such, classical schemes like the Lax–Wendroff or the MacCormack scheme become stable and can produce reliable solutions. When applied to numerical schemes that do not satisfy entropy conditions, the mechanism can converge to the entropy satisfying solution. The method performs well with hyperbolic problems with source terms by producing stable solutions for first and second order balanced schemes that converge to the correct steady states. The method can automatically detect, resolve, and track steep wave fronts and discontinuities, without having to resort to finer grids. It can be combined with a high resolution flux or slope-limiting TVD scheme and improve the numerical solutions obtained. Only two computational parameters have to be tuned for each problem: the power of the estimator function and the tolerance that measures the relative mean displacement between two consecutive grid distributions, under which the reconstruction step is avoided. The mechanism has been proved robust for all applications presented and schemes used.

There is a need for further theoretical work and development of the method, as well as extension of the ideas presented in this work to higher dimensions. These will provide a more in-depth understanding of the method's behavior, the advantages gained when the adaptive mechanism is combined with existing numerical schemes, and, more generally, the influence of evolving adaptive grids to the numerical solution of evolution PDEs.

Appendix. Following [7] and [9] the average velocity and celerity, $\tilde{u}_{i+\frac{1}{2}}$ and $\tilde{c}_{i+\frac{1}{2}}$, for the eigenvalues $\tilde{a}^{1,2}_{i+\frac{1}{2}} = \tilde{u}_{i+\frac{1}{2}} \pm \tilde{c}_{i+\frac{1}{2}}$ and eigenvectors, and $\tilde{\mathbf{e}}^{1,2}_{i+\frac{1}{2}} = \left(1, \tilde{a}^{1,2}_{i+\frac{1}{2}}\right)^{\mathrm{T}}$ of Roe's linearized Jacobian $\mathbf{J}_{i+\frac{1}{2}}$ for the shallow water system, are calculated as

$$\tilde{u}_{i+\frac{1}{2}} = \frac{u_{i+1}\sqrt{h_{i+1}} + u_i\sqrt{h_i}}{\sqrt{h_{i+1}} + \sqrt{h_i}}, \qquad \tilde{c}_{i+\frac{1}{2}} = \sqrt{g\tilde{h}}, \tag{A.1}$$

with $\tilde{h} = (h_{i+1} + h_i)/2$.

The wave strengths $\alpha^{1,2}_{i+\frac{1}{2}}$ follow solving (5.7), and they are

$$\alpha^{1,2}_{i+\frac{1}{2}} = \frac{1}{2}\Delta_{i+\frac{1}{2}}h \pm \frac{1}{2\tilde{c}_{i+\frac{1}{2}}}(\Delta_{i+\frac{1}{2}}(uh) - \tilde{u}_{i+\frac{1}{2}}\Delta_{i+\frac{1}{2}}h), \tag{A.2}$$

where the operator $\Delta_{i+\frac{1}{2}}(\cdot) = (\cdot)_{i+1} - (\cdot)_i$.

For a general system of equations and temporarily dropping the subscript indices we define $\mathbf{\Lambda}$ to be the diagonal form of $\mathbf{J}$ given by its eigenvalues, with

$$\mathbf{J} = \mathbf{R}\mathbf{\Lambda}\mathbf{R}^{-1}, \tag{A.3}$$

where $\mathbf{R}$ is the matrix of the eigenvectors of $\mathbf{J}$. We can now define the $|\mathbf{\Lambda}|$, $\mathbf{\Lambda}^+$, and $\mathbf{\Lambda}^-$ matrices as

$$|\mathbf{\Lambda}| = \operatorname{diag}(|a^1|, \ldots, |a^M|), \quad \mathbf{\Lambda}^{\pm} = \operatorname{diag}(a^{1^{\pm}}, \ldots, a^{M^{\pm}}), \tag{A.4}$$

where $a^{k^+} = \max(0, a^k)$ and $a^{k^-} = \min(0, a^k)$. We can now define

$$|\mathbf{J}| = \mathbf{R}|\mathbf{\Lambda}|\mathbf{R}^{-1}, \tag{A.5}$$

$$\mathbf{J}^{\pm} = \mathbf{R}\mathbf{\Lambda}^{\pm}\mathbf{R}^{-1}. \tag{A.6}$$

Therefore,

$$|\mathbf{J}| = \mathbf{J}^+ - \mathbf{J}^-, \quad \mathbf{J}^{\pm} = \frac{1}{2}(\mathbf{J} \pm |\mathbf{J}|). \tag{A.7}$$

Now at the discrete level the $\mathbf{J}_{i+\frac{1}{2}}$ and $|\mathbf{J}_{i+\frac{1}{2}}|$ are defined as

$$\mathbf{J}_{i+\frac{1}{2}} = \mathbf{R}_{i+\frac{1}{2}}\mathbf{\Lambda}_{i+\frac{1}{2}}\mathbf{R}^{-1}_{i+\frac{1}{2}}, \tag{A.8}$$

$$|\mathbf{J}_{i+\frac{1}{2}}| = \mathbf{R}_{i+\frac{1}{2}}|\mathbf{\Lambda}_{i+\frac{1}{2}}|\mathbf{R}^{-1}_{i+\frac{1}{2}}. \tag{A.9}$$

Using the above formulation to calculate the upwind approximation of the source term $\mathbf{G}$, we need to evaluate $\widetilde{\mathbf{G}}_{i\pm\frac{1}{2}}$ approximations, that is, some average of the source term on the left and right of the cell interfaces. Then a well-balanced approximation of the source term, at each computational cell, is

$$\widetilde{\mathbf{G}}_{i\pm\frac{1}{2}} = \left[0, -\frac{g}{2}(h_{i+1} + h_i)(Z_{i+1} - Z_i)\right]^{\mathrm{T}}. \tag{A.10}$$

The values of $\beta^{1,2}_{i\pm\frac{1}{2}}$ in (5.14) are the components of $\mathbf{R}^{-1}_{i+\frac{1}{2}}\widetilde{\mathbf{G}}_{i\pm\frac{1}{2}}$, and for the shallow water system they are

$$\beta^{1,2}_{i\pm\frac{1}{2}} = \mp\frac{\tilde{c}_{i+\frac{1}{2}}(Z_{i+1} - Z_i)}{2}.$$

Acknowledgment. The authors wish to thank Prof. Ch. Makridakis for his helpful discussions during the course of this work.

SEGMENTATION WITH DEPTH: A LEVEL SET APPROACH*

WEI ZHU†, TONY CHAN‡, AND SELIM ESEDOĞLU‡

Abstract. Segmentation with depth is the challenging problem of obtaining three dimensional information from a single two dimensional image. Unlike the standard segmentation problem, the goal of segmentation with depth is to determine not only the boundaries of objects that appear in the image, but also their relative distances to the observer by making use of occlusion relations. Nitzberg, Mumford, and Shiota [*The* 2.1*D sketch*, in Proceedings of the Third International Conference on Computer Vision, Osaka, Japan, 1990; *Filtering, Segmentation, and Depth*, Lecture Notes in Comput. Sci. 662, Springer-Verlag, Berlin, 1993] proposed a variational formulation of this problem; according to their model, called the 2.1D sketch model, the regions that the objects occupy and their relative depth are to be extracted from the two dimensional image by minimizing a curvature based functional. Numerically, this is a highly nontrivial problem as the functional involves curvatures of the unknown contours. In this paper, we develop a level set based procedure for minimizing the Nitzberg–Mumford–Shiota energy. Unlike the minimization technique of Nitzberg–Mumford–Shiota [*Filtering, Segmentation, and Depth*, Lecture Notes in Comput. Sci. 662, Springer-Verlag, Berlin, 1993], our technique represents contours implicitly and thus allows for connections between T-junctions to take place automatically.

1. Introduction.

We develop level set methods [27, 29] to numerically minimize the Nitzberg–Mumford–Shiota (NMS) functional that was proposed for the segmentation with depth problem [26, 25]. Segmentation with depth fundamentally differs from standard segmentation [16, 23, 24, 21, 6, 7, 9, 10] (see Figure 1). Indeed, the typical goal of a standard segmentation procedure is to determine what parts of the image domain belong to distinct objects in the depicted scene. Segmentation with depth, on the other hand, refers to the difficult task of extracting three dimensional information from a single two dimensional image that depicts a scene with several objects in it. Unlike the standard segmentation problem, segmentation with depth attempts to reconstruct both the regions occupied by different objects in the given two dimensional image and their relative distances (depth) to the observer. Recovering depth information about objects contained in a scene is of course an important step toward understanding the three dimensional layout of the scene. In turn, information about the three dimensional layout of a scene is invaluable in many applications that require automatic interpretation of the environment, such as navigation. To accomplish this, the model of NMS tries to decompose the given image into regions that are allowed to overlap, and includes terms that depend on the curvature of these regions' boundaries. Because of its nonlinearity and the difficulty to express it effectively, the

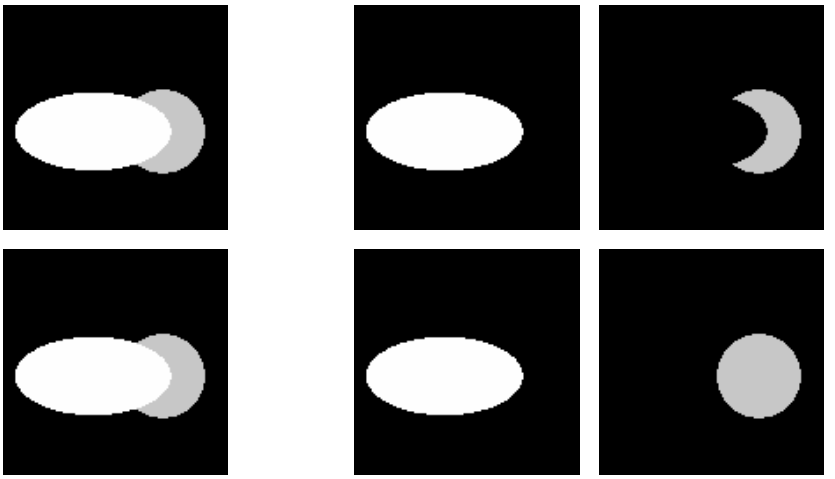

FIG. 1. *The first row contains the original image (left) with two regions (middle and right) given by any multiphase gray-scale intensity based segmentation method, and the second row illustrates the results from a segmentation with depth model. Besides the occlusion relation between the two objects ("Front" and "Behind" in this example), the missing boundary of the Behind object is also restored.*

curvature dependence of the functional involved is one of the most difficult aspects of the model. Specifically, the energy has terms of the form

$$\int_{\partial R} \phi(\kappa) ds, \tag{1}$$

where κ denotes the curvature of the boundary of the region R and ϕ is a particular function.

In [26], the authors avoid minimizing their functional directly. Instead, they propose a combinatorial algorithm that first detects edges and T-junctions in the given two dimensional image and then considers all possible ways of connecting the T-junctions by new edges that are consistent with a given ordering hypothesis. The ordering hypothesis with respect to which the detected T-junctions can be connected using the smallest amount of energy is found to be the correct depth relation between the (possibly overlapping) regions. This is thus a combinatorial technique with very high computational complexity. Moreover, it requires explicitly detecting T-junctions in the image as a preprocessing step, which can be a significant source of errors (in the form of false positives and misses). On the other hand, the model itself makes no explicit reference to T-junctions; therefore it should be possible to minimize the energy without detecting such features first.

In [11], Esedoḡlu and March propose a new, direct way of minimizing the NMS energy that is based on curve evolution and gradient descent. It works in much the same way that the Chan–Vese algorithm [9] minimizes the Mumford–Shah segmentation functional [23, 24]. Their technique makes essential use of Γ-convergence ideas [18] and a conjecture of De Giorgi [14] to approximate the NMS functional by elliptic ones which are numerically much more convenient; see also [1, 19, 20] for other related examples of such approximations in image processing. This approach avoids the need for detecting and connecting T-junctions explicitly; these happen automatically

as a consequence of the curve evolution (and involve changes in the topology of the curves). However, the approximation technique used by the authors forces them to consider only quadratic dependence on curvature (i.e., $\phi(x) = x^2$), which is an approximation to but is different from the correct choice prescribed by NMS in their original formulation. The difference is significant as explained by the authors in [11].

In this paper, we give a level set based formulation [27, 29, 28] to minimize the NMS functional that is also based on curve evolution and gradient descent. However, our techniques allow us to use the more general curvature dependence required by the original model of NMS. This way we get an implementation that remains faithful to the model and avoids the issues caused by using quadratic dependence as in [11]. However, we should point out that it is also possible to approximate via Gamma convergence the correct curvature dependence in the NMS model; see, for example, papers [2, 3, 4, 5] in this regard, which propose alternative methods to that of this paper.

The level set method of Osher and Sethian [27] is particularly well suited to handling curvature dependent functionals, since the curvature of a contour has a very simple expression in terms of the level set function that represents it. For example, let ψ be a level set function; then the curvature κ along any level curve $\psi = c$ (c is any real value) can be represented as

$$\kappa = \nabla \cdot \left(\frac{\nabla \psi}{|\nabla \psi|} \right). \tag{2}$$

With this representation, it is also straightforward to handle the absolute value of curvature that appears in the above functional. By using level set methods, the problem of minimizing the NMS functional turns out to be solving a system of fourth order partial differential equations. These kinds of equations were also solved by the first two authors in [32] for capturing illusory contours. In this paper, we also employ a semi-implicit discretization scheme due to Smereka [30] to solve the resulting fourth order equations. This method can speed up computations significantly, since explicit schemes for these equations are notoriously slow to converge to a stationary state.

The rest of this paper is organized as follows. In the next section, we introduce the background of segmentation with depth as well as the NMS functional. In section 3, we rewrite the functional in a level set formulation and derive the associated gradient descent flows. We then discuss numerical solution techniques including Smereka's semi-implicit scheme in the subsequent section 4. In section 5, we present some numerical experiments on synthetic images that appear in [11]. Section 6 is devoted to our conclusions.

2. NMS functional. In this section, we sketch the problem of segmentation with depth and present the NMS functional. Further details can be found in [26, 11].

The most important unknowns of the NMS model are the shapes of the objects that make up the scene and their relative distances to the observer (i.e., their depth). The relative distances of the objects can be described by an ordering between them. The shapes of the objects are described by subsets of the image domain. Since the model allows for occlusions, these regions need not be disjoint: Parts of regions in the back (further from the observer) might be blocked from view by parts of regions in front (closer to the observer). The model thus inevitably involves reconstructing invisible parts of the regions' boundaries. This calls for the notion of the "most likely completion" of a boundary contour. In the NMS model, the most likely completion of a curve is expressed as the minimizer of a curvature dependent functional.

The 2.1D model of NMS makes the following simplifying assumptions about the three dimensional scene:

- Objects in the scene are not entangled.
- There are no self-occlusions.
- Gray-scale intensities of different objects are approximately uniform and different from each other.

The first two assumptions can be summarized as follows: the 2.1D sketch model of NMS assumes that the objects making up the three dimensional scene live in distinct planes which are parallel to each other and which are perpendicular to the line of sight of the observer. The unknowns of the problem are

- the ordering relation between the regions (which is in front of which),
- the (unoccluded) shapes of the regions, and
- the approximate gray-scale intensity of the corresponding objects.

Let $f : \Omega \to R^1$ be a two dimensional image defined on $\Omega \subset R^2$, and $R_1, \ldots, R_n$ be the regions occupied by objects inside the image. Denote the visible parts of the above objects by $R_1^{'}, \ldots, R_n^{'}$, respectively.

Suppose the regions $R_1, \ldots, R_n$ are listed in order of increasing distance to the observer (i.e., depth), so that R_1, R_n are the nearest and farthest regions, respectively. Then the visible part $R_i^{'}$ of R_i is given by

$$R_1^{'} = R_1, \qquad R_i^{'} = R_i - \bigcup_{j<i} R_j \quad \text{for } i = 2, \ldots, n.$$

For simplicity, we denote $R_{n+1}^{'} = \Omega - \bigcup_{j<n+1} R_j$ as the background. Then the NMS functional reads

$$E = \sum_{i=1}^{n} \int_{\partial R_i \bigcap \Omega} [\alpha + \beta\phi(\kappa)]ds + \sum_{i=1}^{n+1} \int_{R_i^{'}} (f(x) - c_i)^2 dx, \tag{3}$$

where α, β are two nonnegative parameters, and the unknowns $c_i \in R^1$ denote the approximate gray-scale intensities (color) of the corresponding objects. An important point is that the contour integrals in energy (3) are taken along the entire boundaries of the regions inside the image domain Ω, not just the visible parts of these boundaries; i.e., instead of on the visible boundaries $\partial R_i^{'} \bigcap \Omega$, the contour integrals are taken on $\partial R_i \bigcap \Omega$. These terms therefore dictate how the occluded parts of boundary curves are best reconstructed. The area integrals in the energy (3) make up the "fidelity" terms in the model. They ensure that the reconstructed configuration of regions and their ordering in three dimensional space yield a two dimensional image that agrees with the observed one, namely, $f(x)$. The function ϕ determines how the curvature information will be incorporated in the functional. The authors in [25, 26] choose ϕ as follows:

$$\phi(x) = \begin{cases} x^2, & |x| \le 1, \\ |x|, & |x| > 1. \end{cases} \tag{4}$$

Corners are allowed when (4) is used because of the linear growth of ϕ at infinity. In [11], the authors select the quadratic dependence on curvature, i.e., $\phi(x) = x^2$, which inevitably smears corners. Furthermore, quadratic growth of ϕ at infinity leads to a stability issue as explained in that paper, where small disks are encouraged by the energy to grow. In [11], quadratic dependence on curvature is chosen because the approximation procedure used there requires it. In contrast, the techniques we use

in this paper allow for a more general dependence on curvature, including the choice (4), and hence allow us to avoid the stability and smearing drawbacks.

3. Level set method for minimizing the NMS functional. As noted in the introduction, the level set method of Osher and Sethian [27] is very well suited for the representation of functionals that involve geometric quantities such as curvature. In this section, we first rewrite the NMS functional in terms of level set functions that represent the unknown regions R_i. Subsequently, we derive the associated gradient descent flows in terms of the level set functions to minimize the NMS functional.

3.1. Level set formulation. The regions R_i are among the unknowns of the optimization problem (3) and therefore need to be updated during our iterative solution procedure. To represent them, we introduce the level set functions ψ_i so that $R_i = \{\psi_i\}$, $i = 1, \ldots, n$.

Then, the first sum of (3) can be rewritten as

$$\sum_{i=1}^{n} \int_{\Omega} [\alpha + \beta\phi(\kappa_i)]|\nabla\psi_i|\delta(\psi_i)dx, \tag{5}$$

where $\kappa_i = \nabla \cdot (\frac{\nabla\psi_i}{|\nabla\psi_i|})$ is the curvature of any level curve, and $\delta(x)$ is the derivative of the Heaviside function

$$H(x) = \begin{cases} 1, & , > 0, \\ 0, & , \leq 0, \end{cases} \tag{6}$$

in the distribution sense, or the Dirac delta function. Of course, both in the derivations below and in our numerical implementation, H and δ are taken to be smooth approximations to the Heaviside and delta functions.

On the other hand, since $R_i^{'} = R_i - \bigcup_{j<i} R_j$, i.e., $R_i^{'} = \{\psi_i > 0\} \bigcap (\bigcup_{j<i} \{\psi_j \leq 0\})$, and $R_{n+1}^{'} = \Omega - \bigcup_{j<n+1} R_j = \bigcap_{j=1}^{n} (\Omega - R_j)$, i.e., $R_{n+1}^{'} = \bigcap_{j=1}^{n} \{\psi_j < 0\}$, we may rewrite the second sum of (3) as

$$\sum_{i=1}^{n} \Big\{ \int_{\Omega} (f - c_i)^2 H(\psi_i) \prod_{j=1}^{i-1} (1 - H(\psi_j))dx \Big\} + \int_{\Omega} (f - c_{n+1})^2 \prod_{j=1}^{n} (1 - H(\psi_j))dx, \tag{7}$$

where H is the Heaviside function.

Combining (5) and (7), we obtain the NMS functional in a level set based formulation as follows:

$$\begin{aligned} E = & \sum_{i=1}^{n} \int_{\Omega} [\alpha + \beta\phi(\kappa_i)]|\nabla\psi_i|\delta(\psi_i)dx \\ & + \sum_{i=1}^{n} \Big\{ \int_{\Omega} (f - c_i)^2 H(\psi_i) \prod_{j=1}^{i-1} (1 - H(\psi_j))dx \Big\} \\ & + \int_{\Omega} (f - c_{n+1})^2 \prod_{j=1}^{n} (1 - H(\psi_j))dx. \end{aligned} \tag{8}$$

We remind the reader that here ψ_i are the level set functions describing the regions occupied by the n objects in the scene, κ_i are the curvatures of their boundaries, c_i are the (unknown) average gray-scale intensities within these regions, α and β are two positive parameters, Ω is the image domain, and f is the given image.

3.2. Derivation of the gradient descent flows. To derive the gradient descent flows for minimizing the functional (8), we here consider only the curvature related terms, since the fidelity terms are easy to handle. For simplicity, let us consider a functional $\widehat{E}(\psi) = \int_\Omega \Psi(\kappa_\psi)|\nabla\psi|\delta(\psi)dx$, where $\Psi(x)$ can be a general function. In this paper, $\Psi(x) = \alpha + \beta\phi(x)$ as in the functional (8). Derivations of gradient descent flows for some similar functionals can be found in [8, 12]. We emphasize that the functional we consider here is an integral along a contour instead of on the whole domain Ω.

Before deriving the gradient descent flows of ψ according to the minimization of $\widehat{E}(\psi)$, we use observations made in [8] in the following calculations. The authors of [8] computed gradient descent flows for minimizing similar functionals.

LEMMA 1. $\overrightarrow{n} \in R^2$ $I, P_{\overrightarrow{n}} : R^2 \to R^2$ $I(\overrightarrow{v}) = \overrightarrow{v}$ $P_{\overrightarrow{n}}(\overrightarrow{v}) = (\overrightarrow{v}\cdot\overrightarrow{n})\overrightarrow{n}$ $\overrightarrow{v} \in R^2$ $\psi : R^2 \times [0, +\infty) \to R^1$ $\kappa = \nabla\cdot(\frac{\nabla\psi}{|\nabla\psi|})$ $\frac{\partial\kappa}{\partial t} = \nabla\cdot[(I - P_{\overrightarrow{n}})\frac{\nabla\psi_t}{|\nabla\psi|}]$ $\overrightarrow{n} = \frac{\nabla\psi}{|\nabla\psi|}$

We simply compute

$$\frac{\partial\kappa}{\partial t} = \nabla\cdot\left(\frac{\partial}{\partial t}\frac{\nabla\psi}{|\nabla\psi|}\right) = \nabla\cdot\left[\frac{\nabla\psi_t}{|\nabla\psi|} - \left(\frac{\nabla\psi_t}{|\nabla\psi|}\cdot\frac{\nabla\psi}{|\nabla\psi|}\right)\frac{\nabla\psi}{|\nabla\psi|}\right] = \nabla\cdot\left[(I - P_{\overrightarrow{n}})\frac{\nabla\psi_t}{|\nabla\psi|}\right]. \qquad \square$$

LEMMA 2. 1 $(I - P_{\overrightarrow{n}})\overrightarrow{v}\cdot\overrightarrow{w} = (I - P_{\overrightarrow{n}})\overrightarrow{w}\cdot\overrightarrow{v}$ $\overrightarrow{v}, \overrightarrow{w} \in R^2$

We may thus obtain the following theorem.

THEOREM 1. $\widehat{E}(\psi) = \int_\Omega \Psi(\kappa)|\nabla\psi|\delta(\psi)dx$ $\Psi : R^1 \to R^1$ $\Psi'(0) = 0$ P $P_{\frac{\nabla\psi}{|\nabla\psi|}}$

$$\frac{\partial\psi}{\partial t} = |\nabla\psi|\nabla\cdot\left[\frac{\nabla\psi}{|\nabla\psi|}\Psi(\kappa) - \frac{1}{|\nabla\psi|}(I - P)(\nabla(\Psi'(\kappa)|\nabla\psi|))\right], \tag{9}$$

$\frac{\partial\psi}{\partial\overrightarrow{\nu}}|_{\partial\Omega} = 0$ $\kappa_\psi|_{\partial\Omega} = 0$ $\overrightarrow{\nu}$ $\partial\Omega$

To get the associated gradient descent flow, let us take the derivative of $\widehat{E}$ according to time t and then determine the derivative of ψ with respect to t by decreasing the functional $\widehat{E}$.

In fact, by Lemma 1, we have

$$\begin{aligned}
\frac{d\widehat{E}}{dt} &= \int_\Omega [\Psi'(\kappa)\kappa_t|\nabla\psi|\delta(\psi) + \Psi(\kappa)|\nabla(\psi)|_t\delta(\psi) + \Psi(\kappa)|\nabla(\psi)|\delta'(\psi)\psi_t]dx \\
&= \int_\Omega \left[\Psi'(\kappa)\nabla\cdot\left[(I - P)\left(\frac{\nabla\psi_t}{|\nabla\psi|}\right)\right]|\nabla\psi|\delta(\psi) + \Psi(\kappa)\nabla\psi_t\cdot\frac{\nabla\psi}{|\nabla\psi|}\delta(\psi)\right]dx \\
&\quad + \int_\Omega \Psi(\kappa)|\nabla(\psi)|\delta'(\psi)\psi_t dx \\
&= \int_\Omega \nabla\cdot\left[(I - P)\left(\frac{\nabla\psi_t}{|\nabla\psi|}\right)\Psi'(\kappa)|\nabla\psi|\delta(\psi)\right]dx + \int_\Omega \nabla\cdot\left[\psi_t\frac{\nabla\psi}{|\nabla\psi|}\Psi(\kappa)\delta(\psi)\right]dx \\
&\quad - \int_\Omega \left\{(I - P)\left(\frac{\nabla\psi_t}{|\nabla\psi|}\right)\cdot\nabla(\Psi'(\kappa)|\nabla\psi|\delta(\psi)) + \psi_t\nabla\cdot\left[\frac{\nabla\psi}{|\nabla\psi|}\Psi(\kappa)\delta(\psi)\right]\right\}dx \\
&\quad + \int_\Omega \Psi(\kappa)|\nabla(\psi)|\delta'(\psi)\psi_t dx. \qquad (10)
\end{aligned}$$

By the Neumann boundary condition, i.e., $\frac{\partial \psi}{\partial \overrightarrow{\nu}} = \nabla\psi \cdot \overrightarrow{\nu} = 0$, we see that $\nabla\psi_t \cdot \overrightarrow{\nu} = (\nabla\psi \cdot \overrightarrow{\nu})_t - \nabla\psi \cdot \overrightarrow{\nu}_t = 0$; therefore by applying the Green–Gauss theorem, we may drop the two divergence terms and get

$$\begin{aligned}\frac{d\widehat{E}}{dt} &= \int_\Omega -(I-P)\left(\frac{\nabla\psi_t}{|\nabla\psi|}\right)\cdot\nabla(\Psi'(\kappa)|\nabla\psi|\delta(\psi))dx \\ &\quad - \int_\Omega \left\{\psi_t\nabla\cdot\left[\frac{\nabla\psi}{|\nabla\psi|}\Psi(\kappa)\delta(\psi)\right] - \Psi(\kappa)|\nabla(\psi)|\delta'(\psi)\psi_t\right\}dx. \qquad (11)\end{aligned}$$

By Lemma 2, $(I-P)\overrightarrow{v}\cdot\overrightarrow{w} = \overrightarrow{v}\cdot(I-P)\overrightarrow{w}$, and we have

$$\begin{aligned}\frac{d\widehat{E}}{dt} &= \int_\Omega \Big\{ -\frac{\nabla\psi_t}{|\nabla\psi|}\cdot(I-P)\nabla(\Psi'(\kappa)|\nabla\psi|\delta(\psi)) \\ &\quad -\psi_t\nabla\cdot\left[\frac{\nabla\psi}{|\nabla\psi|}\Psi(\kappa)\delta(\psi)\right]\Big\}dx + \int_\Omega \Psi(\kappa)|\nabla(\psi)|\delta'(\psi)\psi_t dx \\ &= \int_\Omega \Big\{ -\nabla\cdot\left[\psi_t\frac{1}{|\nabla\psi|}(I-P)\nabla(\Psi'(\kappa)|\nabla\psi|\delta(\psi))\right] \\ &\quad +\psi_t\nabla\cdot\left[\frac{1}{|\nabla\psi|}(I-P)\nabla(\Psi'(\kappa)|\nabla\psi|\delta(\psi))\right]\Big\}dx \\ &\quad -\int_\Omega \psi_t\left[\nabla\cdot\left(\frac{\nabla\psi}{|\nabla\psi|}\Psi(\kappa)\right)\delta(\psi) + \frac{\nabla\psi}{|\nabla\psi|}\Psi(\kappa)\cdot\delta'(\psi)\nabla\psi\right]dx \\ &\quad +\int_\Omega \Psi(\kappa)|\nabla(\psi)|\delta'(\psi)\psi_t dx. \qquad (12)\end{aligned}$$

Notice that $\nabla(\Psi'(\kappa)|\nabla\psi|\delta(\psi)) = \nabla(\Psi'(\kappa)|\nabla\psi|)\delta(\psi) + \Psi'(\kappa)|\nabla\psi|\delta'(\psi)\nabla\psi$; then $(I-P)\nabla(\Psi'(\kappa)|\nabla\psi|\delta(\psi)) = \delta(\psi)(I-P)\nabla(\Psi'(\kappa)|\nabla\psi|)$, since $(I-P)\nabla\psi = 0$. Therefore, by applying the Green–Gauss theorem again and noting that $\Psi'(\kappa)|_{\partial\Omega} = 0$, we drop the divergence part in (12) and obtain

$$\begin{aligned}\frac{d\widehat{E}}{dt} &= \int_\Omega \psi_t\nabla\cdot\left[\frac{1}{|\nabla\psi|}(I-P)\nabla(\Psi'(\kappa)|\nabla\psi|)\delta(\psi)\right]dx - \int_\Omega \psi_t\nabla\cdot\left[\frac{\nabla\psi}{|\nabla\psi|}\Psi(\kappa)\right]\delta(\psi)dx \\ &= \int_\Omega \psi_t\Bigg\{\nabla\cdot\left[\frac{1}{|\nabla\psi|}(I-P)\nabla(\Psi'(\kappa)|\nabla\psi|)\right]\delta(\psi) \\ &\quad +\frac{1}{|\nabla\psi|}(I-P)\nabla(\Psi'(\kappa)|\nabla\psi|)\cdot\delta'(\psi)\nabla\psi\Bigg\}dx - \int_\Omega \psi_t\nabla\cdot\left[\frac{\nabla\psi}{|\nabla\psi|}\Psi(\kappa)\right]\delta(\psi)dx \\ &= \int_\Omega \psi_t\delta(\psi)\nabla\cdot\left[\frac{1}{|\nabla\psi|}(I-P)\nabla(\Psi'(\kappa)|\nabla\psi|) - \frac{\nabla\psi}{|\nabla\psi|}\Psi(\kappa)\right]dx. \qquad (13)\end{aligned}$$

Therefore, if we choose $\psi_t = -\delta(\psi)\nabla\cdot[\frac{1}{|\nabla\psi|}(I-P)(\nabla(\Psi'(\kappa)|\nabla\psi|)) - \frac{\nabla\psi}{|\nabla\psi|}\Psi(\kappa)]$, we see $\frac{d\widehat{E}}{dt} \le 0$. Moreover, by employing the standard technique which replaces $\delta(\psi)$ by $|\nabla\psi|$ in [31] (the factor $|\nabla\psi|$ also helps to accelerate the evolution process as discussed in [22]), we then have the gradient descent flow:

$$\frac{\partial\psi}{\partial t} = |\nabla\psi|\nabla\cdot\left[\frac{\nabla\psi}{|\nabla\psi|}\Psi(\kappa) - \frac{1}{|\nabla\psi|}(I-P)(\nabla(\Psi'(\kappa)|\nabla\psi|))\right]. \qquad (14)$$

□

Indeed, replacing $\delta(\psi)$ by $|\nabla\psi|$ does not change the property that the flow decreases the energy.

1. We do not know if there is a rigorous well posedness theory for the gradient flow equations obtained above. The factor $\delta(\psi)$ is replaced with $|\nabla\psi|$ mostly for numerical reasons, but this might also make the equations better behaved and perhaps theoretically more approachable. Nevertheless, in this paper we restrict ourselves to a numerical study of these flows. Some analytical results on related problems can be found in [13].

Let us turn to the original NMS functional (8). From Theorem 1, the system of the gradient flows reads

$$\begin{aligned}\frac{\partial\psi_i}{\partial t} &= |\nabla\psi_i|\nabla\cdot\left[\frac{\nabla\psi_i}{|\nabla\psi_i|}\Psi(\kappa_i) - \frac{1}{|\nabla\psi_i|}(I - P_{\frac{\nabla\psi_i}{|\nabla\psi_i|}})(\nabla(\Psi^{'}(\kappa_i)|\nabla\psi_i|))\right]\\ &\quad -|\nabla\psi_i|(f-c_i)^2\prod_{j=1}^{i-1}(1-H(\psi_j))\\ &\quad +|\nabla\psi_i|\sum_{s=i+1}^{n+1}\left\{(f-c_s)^2H(\psi_s)\prod_{j=1}^{i-1}(1-H(\psi_j))\prod_{j=i+1}^{s-1}(1-H(\psi_j))\right\},\end{aligned} \tag{15}$$

with the boundary conditions $\frac{\partial\psi_i}{\partial\overrightarrow{\nu}}|_{\partial\Omega} = 0$, $\kappa_i|_{\partial\Omega} = 0$, $i = 1,\ldots,n$, where $H(\psi_{n+1}) = 1$.

4. Numerical implementation. In this section, we show how to discretize each term in (15) and explain how to apply Smereka's semi-implicit method to solve the equations.

4.1. Discretization of the gradient descent flows. We first discuss the schemes for the fourth order terms in (15). The discretization is essentially the same as the one in [8]. We include its details for the sake of completeness of the present discussion.

As in [8], we rewrite them as follows:

$$\frac{\partial\psi}{\partial t} = |\nabla\psi|\nabla\cdot\overrightarrow{V}, \tag{16}$$

where $\overrightarrow{V} = (V_1, V_2) = \frac{\nabla\psi}{|\nabla\psi|}\Psi(\kappa) - \frac{1}{|\nabla\psi|}(I-P)(\nabla(\Psi^{'}(\kappa)|\nabla\psi|))$.

Then, denoting $\Psi^{'}(\kappa)|\nabla\psi|$ simply by A, we get

$$V_1 = \Psi(\kappa)\frac{\psi_x}{|\nabla\psi|} - \frac{\psi_y}{|\nabla\psi|^3}[A_x\psi_y - A_y\psi_x] \tag{17}$$

and

$$V_2 = \Psi(\kappa)\frac{\psi_y}{|\nabla\psi|} - \frac{\psi_x}{|\nabla\psi|^3}[A_y\psi_x - A_x\psi_y], \tag{18}$$

where $A_x = \partial A/\partial x$, $A_y = \partial A/\partial y$.

Let (i,j) denote the pixel locations, h be the spatial step size, and the time be discretized to be $\{ndt\}$, where $n = 0,1,2,\ldots$, and dt is the time step. Then $\psi^n_{i,j}$ refers to the value of ψ at pixel (i,j) at time ndt.

Let us discuss the discretization of each term in (16) to (18). In (16), we approximate $|\nabla\psi|$ by central difference as

$$|\nabla\psi|_{i,j} = \sqrt{\left[\frac{\psi_{(i+1,j)} - \psi_{(i-1,j)}}{2h}\right]^2 + \left[\frac{\psi_{(i,j+1)} - \psi_{(i,j-1)}}{2h}\right]^2}. \tag{19}$$

As for the terms in (17), (18), since

$$\begin{aligned}\nabla \cdot \overrightarrow{V}_{(i,j)} &= V_{1x(i,j)} + V_{2y(i,j)} \\ &= \frac{V_{1(i+1/2,j)} - V_{1(i-1/2,j)}}{h} + \frac{V_{2(i,j+1/2)} - V_{2(i,j-1/2)}}{h},\end{aligned} \tag{20}$$

we need to calculate the values of V_1 at the x-half-pixel $(i+1/2, j)$, while the values of V_2 at the y-half-pixel $(i, j+1/2)$.

We approximate the terms in (17) at $(i+1/2, j)$ as follows:

$$\begin{aligned}\kappa &= \text{minmod}(\kappa_{(i,j)}, \kappa_{(i+1,j)}), \\ \psi_x &= \frac{\psi_{(i+1,j)} - \psi_{(i,j)}}{h}, \\ \psi_y &= \text{minmod}\left(\frac{\psi_{(i+1,j+1)} - \psi_{(i+1,j-1)}}{2h}, \frac{\psi_{(i,j+1)} - \psi_{(i,j-1)}}{2h}\right), \\ |\nabla\psi| &= \sqrt{\psi_x^2 + \psi_y^2},\end{aligned} \tag{21}$$

$$\begin{aligned}A_x &= \frac{A_{(i+1,j)} - A_{(i,j)}}{h} \\ &= \frac{\Psi'(\kappa_{(i+1,j)})|\nabla\psi|_{(i+1,j)} - \Psi'(\kappa_{(i,j)})|\nabla\psi|_{(i,j)}}{h}, \\ A_y &= \text{minmod}\Bigg(\frac{\Psi'(\kappa_{(i+1,j+1)})|\nabla\psi|_{(i+1,j+1)} - \Psi'(\kappa_{(i+1,j-1)})|\nabla\psi|_{(i+1,j-1)}}{2h}, \\ &\qquad \frac{\Psi'(\kappa_{(i,j+1)})|\nabla\psi|_{(i,j+1)} - \Psi'(\kappa_{(i,j+1)})|\nabla\psi|_{(i,j-1)}}{2h}\Bigg),\end{aligned} \tag{22}$$

where

$$\text{minmod}(x, y) = \frac{\text{sgn}(x) + \text{sgn}(y)}{2}\min(|x|, |y|).$$

Of course, there are other ways to discretize the terms than using the minmod function (see Chapter 16 in [17]).

Similarly, we may approximate the terms in (18).

It is subtle to discretize the remaining terms in (15). Specifically, one should be careful to approximate $|\nabla\psi|$. In this paper, we use the technique that is discussed in [29] (see Chapter 6). The detail can be found in our previous work [32]. We omit them here.

Moreover, we approximate the Heaviside function $H(x)$ by a standard regularized function as in [9], which reads

$$H_\epsilon(x) = \frac{1}{2}\left(1 + \frac{2}{\pi}\arctan\left(\frac{x}{\epsilon}\right)\right),$$

where ϵ is a fixed small number. In the experiments, we choose ϵ as small as h^2, where h is the mesh size.

2. The gradient descent flow (15) is in essence a degenerate parabolic equation. It is like a higher order version of the more familiar mean curvature flow. Our discretization is similar to the ones used for this type of parabolic equations [8].

4.2. Smereka's semi-implicit method. Since the equations in (15) are fourth order and parabolic, we would expect the Courant–Friedrichs–Levy (CFL) condition (see, for instance, [15]) for an explicit scheme to require the time step size to be proportional to the fourth power of spatial step size, i.e., $dt \sim dx^4$. This restriction would result in an intolerably long time for the minimization process. To ease the time step restriction, we will apply a semi-implicit discretization method due to Smereka [30], which significantly accelerates the convergence of the gradient descent.

For simplicity, as in [30], let us denote the gradient descent flows as

$$\psi_t = S(\psi); \tag{23}$$

then, we can rewrite it as

$$\psi_t = -\lambda\Delta^2\psi + \lambda\Delta^2\psi + S(\psi), \tag{24}$$

where Δ^2 is a bi-Laplacian (since equations (15) are fourth order equations) and λ is a positive parameter. Then we may discretize (24) in time as

$$\psi^{n+1} - \psi^n = dt(-\lambda\Delta^2\psi^{n+1} + \lambda\Delta^2\psi^n + S(\psi^n)),$$

and then

$$\psi^{n+1} = \psi^n + dt(1 + dt\lambda\Delta^2)^{-1}S(\psi^n). \tag{25}$$

The operator $(1 + dt\lambda\Delta^2)$ is positive definite, and it can be efficiently inverted by the fast Fourier transform (FFT).

Therefore, in our case, we need only to calculate the values on the right side of (15) at time nh as $S(\psi^n)$ for each function ψ_i, and then we can get the values of ψ_i at the new time $(n+1)h$ by using FFT.

Smereka's semi-implicit method will relax the CFL condition considerably, since the operator Δ^2 helps to smooth possible high oscillating waves. Numerical experiments in the following section also show that we may choose a much larger time step size than what is required by CFL condition.

4.3. Procedure for minimizing NMS functional. During the evolution of the variables ψ_i according to (15), the unknown intensities c_i also need to be updated. Variations of the objective energy E with respect to the c_i yield the following optimality conditions:

$$c_i = \frac{\int_\Omega f H(\psi_i)\prod_{j=1}^{i-1}(1 - H(\psi_j))}{\int_\Omega H(\psi_i)\prod_{j=1}^{i-1}(1 - H(\psi_j))}, \qquad i = 1, \ldots, n, \tag{26}$$

and

$$c_{n+1} = \frac{\int_\Omega f \prod_{j=1}^{n}(1 - H(\psi_j))}{\int_\Omega \prod_{j=1}^{n}(1 - H(\psi_j))}. \tag{27}$$

They are just the averages of the gray-scale intensities on the appropriate unoccluded domains.

Then, given the initial guesses for the level set functions ψ_i and the intensity constants c_i, we iteratively solve the equations (15) and (26), (27).

Now, let us discuss how to choose the initial guesses. We first employ any multiphase segmentation method, for instance, Chan–Vese's method [10], to segment the

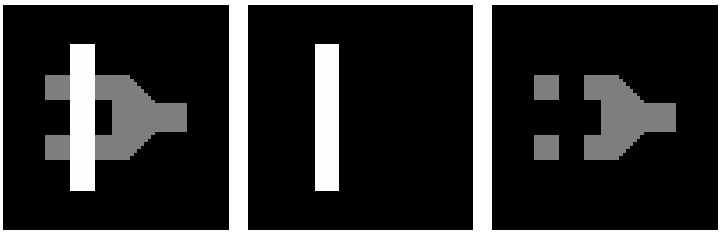

FIG. 2. *Bar and Fork. From left to right, these figures are the original image and the two regions obtained from standard segmentation model.*

image domain Ω into several regions in each of which the intensity is homogenous, and thus obtain the associated level set function and intensity constant for each region. Then, as in [11], we use these results as the initial guesses for solving (15) and (26), (27). Of course, there may be other and potentially better ways to choose initial conditions.

Moreover, as usual, during the gradient descent evolutions given above it becomes necessary to periodically reinitialize the level set functions so that they are close to being signed distance functions of the contours they represent (for reinitialization, see [29]). It is not necessary to do this very often, and in fact we observed that reinitializations, if done too frequently and not accurately enough, can interfere with the fourth order evolution.

5. Numerical experiments. In this section, we present numerical results of applying our technique on some synthetic images, including the typical example (Bar and Fork) that appears in [11].

5.1. Two regions and a background. We here show two examples: Bar and Fork, and Ellipse and Disk. For each example, the intensities for the two regions and the background are 1.0, 0.5, and 0, respectively.

The first example is an image with a bar and a broken fork inside a background (Figure 2). For this case, there are only two possible orderings: the bar is in front of the fork, or vice versa. We minimize the NMS functional under both of these order hypothesis separately. The way that we build the hypothesis into the computation is by the assignment of initial conditions for the regions, i.e., in one of the computations, we take the bar to be the initial guess for the region that is in front and the broken fork to be the initial guess for the region that is behind, and we switch them for the other case. The values are listed as follows:

- Bar front, Fork behind, the NMS functional = 0.1762.
- Fork front, Bar behind, the NMS functional = 0.2718.

This shows that the assumption that the bar is in front of the fork yields a smaller value of the NMS functional, the scene is made up of a fork that is behind and occluded by a vertical bar.

In Figure 3, we list the evolution process of the two regions under the assumption of the first ordering. From these groups of figures, one can see how the broken fork is connecting while the bar is kept stable; note especially the behavior of its corners. It

FIG. 3. *The evolution process under the assumption that the Bar is in front of the Fork. In the second and third row, the evolutions of the two regions by solving* (15) *are listed. The fourth row shows how the boundary of the Fork is growing. During the process, the front region occupied by the Bar is keeping stable while the region by the Fork is connecting behind the Bar. In this experiment, the parameters are* $\alpha = 0.00005$, $\beta = 0.005$, *and* $\lambda = 0.1$ *in Smereka's semi-implicit method.*

is the choice of $\phi(x) = |x|$ when $|x|$ big in (3) that preserves the corners. The choice $\phi(x) = x^2$ would inevitably smear those corners.

We omit the evolution process under the second assumption since the two regions are kept stable.

The restriction on the time step size has been obtained numerically, by checking whether energy is decreased or not. When Smereka's semi-implicit method is not used, the result is consistent with what one would expect, based on the fact that the gradient descent is given essentially by a fourth order (degenerate) parabolic PDE, namely, the step size has to be proportional to dx^4.

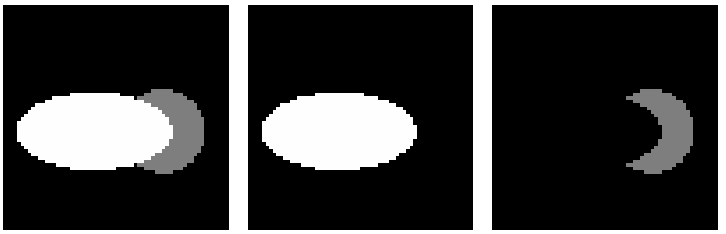

FIG. 4. *Ellipse and Crescent. From left to right, these figures are the original image, and the two regions obtained from standard segmentation model.*

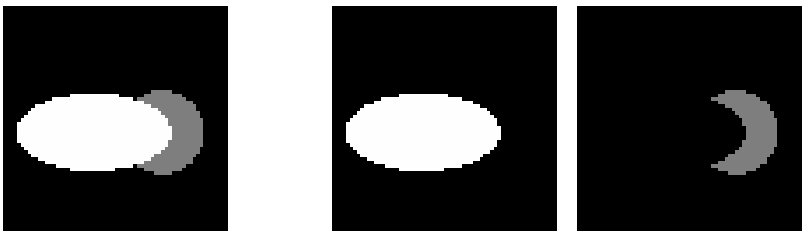

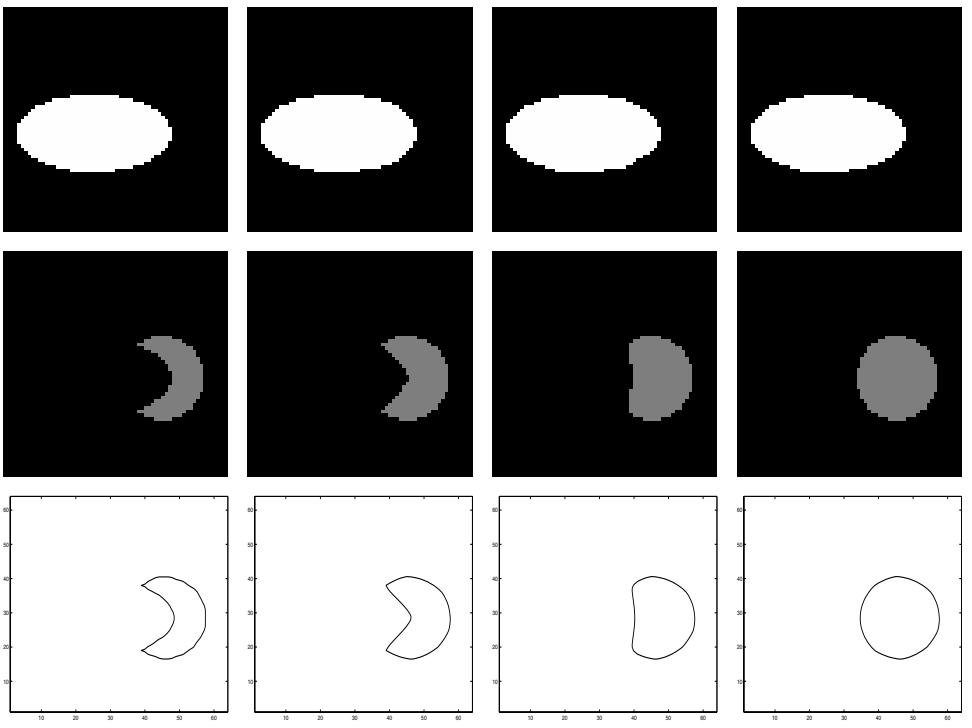

FIG. 5. *The evolution process under the assumption that the Ellipse is in front of the Crescent. In the second and third row, the evolutions of the two regions by solving* (15) *are listed. The fourth row shows how the boundary of the Crescent is growing. During the process, the front region occupied by the Ellipse is keeping stable while the region by the Crescent is connecting behind the Ellipse. In this experiment, the parameters are* $\alpha = 0.00005$, $\beta = 0.01$, *and* $\lambda = 0.1$ *in Smereka's semi-implicit method.*

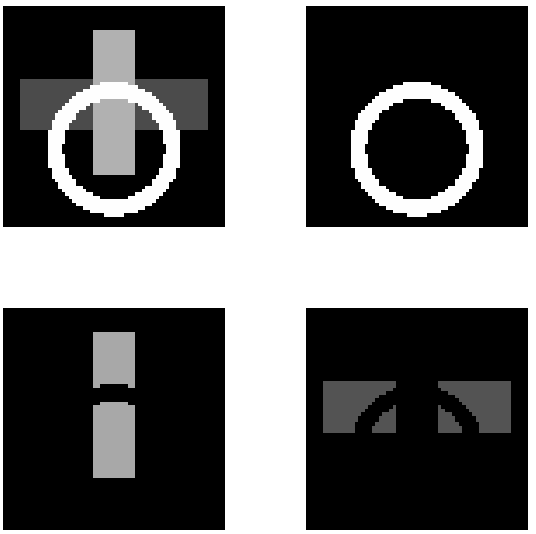

FIG. 6. *An annulus and two bars. The top left is the original image, and the other three figures show the regions obtained from the original image by standard segmentation model.*

The second example is an image with an ellipse and a crescent on top of a dark background (Figure 4). We calculate the values of the NMS functional for the two ordering as follows:

- Ellipse front, Crescent behind, the NMS functional = 0.1404.
- Crescent front, Ellipse behind, the NMS functional = 0.2812.

This shows that the ellipse is in front of the disk (instead of crescent!). In Figure 5, we list the evolution process of the two regions under the first assumption of ordering and we still omit the process under the second assumption. From these groups of figures, one can see how the crescent is growing to be a full moon while the front ellipse is kept stable.

5.2. Three regions and a background. We present here an example with an annulus and two bars inside a background (Figure 6). The intensities for them are 1.0, 0.9, 0.8, and 0, respectively.

Since there are three objects inside the image, $3! = 6$ cases of the ordering should be considered. Here we list the evolution process under the ordering assumption that the Annulus is in front of the vertical Bar while the horizontal Bar is behind the vertical Bar, which yields the smallest value of the NMS functional (Figure 7).

Of course, if there are more than just a few objects (n objects) in the given image, the number of minimizations ($n!$ cases of the ordering) that need to be done quickly becomes unrealistic. However, as pointed out in [11], it would be reasonable to localize the computation by restricting attention to smaller sections of the image at a time. If these sections are small enough, one would not expect to find more than a few objects present in them. But then it would be necessary to combine the results obtained from different sections in a suitable way.

6. Conclusion. In this paper, we develop a level set based technique to numerically minimize the NMS functional that appears in the variational formulation of the segmentation with depth problem. In contrast to [11], we can handle more general dependence of the functionals on curvature, which allows us to remain faithful to

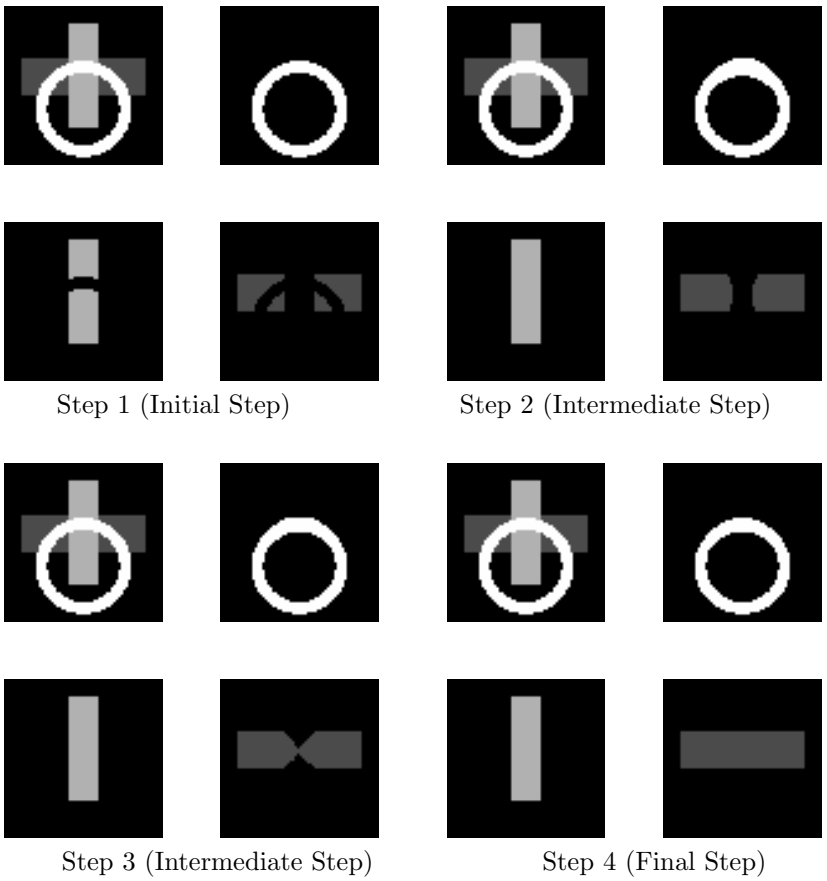

FIG. 7. *The evolution process under the ordering assumption that the Annulus, the vertical Bar, and the horizontal Bar are listed from the nearest to the farthest. In each group of figures, the left top is the original image while the others show the evolution of each region. During this process, the Annulus is almost keeping stable while the vertical Bar is connecting and then the horizontal Bar. In this experiment, the parameters are* $\alpha = 0.00005$, $\beta = 0.03$, *and* $\lambda = 0.1$ *in Smereka's semi-implicit method.*

the original functional of NMS, and therefore avoid the smearing and stability issues. Moreover, level set methods seem to provide better contour localization at the same spatial resolution than the phase-field method used in [11]. One disadvantage of our technique developed in this paper is that the resulting equations are more nonlinear, more degenerate, and therefore more difficult to solve than the ones that result from the phase-field approach based on De Giorgi's conjecture in [11]. However, there is progress in addressing the computational expense of level set methods in such higher order problems, such as Smereka's semi-implicit method, which we have utilized.

We study only some synthetic images in this paper. Our results on these images constitute a promising step toward effective minimization of those challenging functionals such as the NMS functional. In particular, based on our results, we would expect our algorithm to be successful with scenes that have a few large, distinct objects in them, such as the ones considered by Nitzberg, Mumford, and Shiota in [25, 26].

Acknowledgment. The authors thank Stanley Osher, who suggested to us the idea of a level set implementation of the NMS model.

ON THE ACOUSTIC SINGLE LAYER POTENTIAL: STABILIZATION AND FOURIER ANALYSIS*

A. BUFFA† AND S. SAUTER‡

Abstract. In this paper, we propose a general approach for stabilizing the single layer potential for the Helmholtz boundary integral equation and prove its stability. We consider Galerkin boundary element discretizations and analyze their convergence. Furthermore, we derive quantitative error bounds for the Galerkin discretization which are explicit with respect to the mesh width *and* the wave number for the special case that the surface is the unit sphere in $\mathbb{R}^3$. We perform then a qualitative analysis which allows us to choose the stabilization such that the (negative) influence of the wave number in the stability and convergence estimates attains its minumum.

Key words. acoustic scattering, Galerkin boundary element method, stabilization of Helmholtz equation, high wave number

DOI. 10.1137/040615110

1. Introduction. In this paper, we will address problems related to the discretization of boundary integral equations for the Helmholtz problem outside of a reflecting obstacle Ω^-, where $\Omega^- \subset \mathbb{R}^3$ is a bounded Lipschitz domain. Let $\Omega^+ = \mathbb{R}^3 \setminus \bar{\Omega}^-$ and $\mathcal{L}_k := -\Delta - k^2$. We consider the following problem: Find $u^+ \in H^1_{\mathrm{loc}}(\Omega^+)$ such that the Helmholtz problem

$$\begin{aligned} \mathcal{L}_k u^+ &= 0 && \text{in } \Omega^+, \\ u^+ &= g && \text{on } \Gamma := \partial\Omega^-, \\ \left| \frac{\partial u}{\partial r} - \mathrm{i}\, k u \right| &\le C \left\| \mathbf{x} \right\|^{-2} && \left\| \mathbf{x} \right\| \to \infty \end{aligned} \tag{1.1}$$

is satisfied in a weak sense (cf. [26]). Here, $\partial/\partial r$ denotes the derivative in radial direction $\mathbf{x}/\left\|\mathbf{x}\right\|$.

Our goal is to solve these equations by the method of integral equations. A potential ansatz leads to a boundary integral equation on Γ for the unknown density φ which is of the form $R_k \varphi = g$. Here, R_k is the trace V_k of the single layer potential associated to $\mathcal{L}_k$ on Γ or a stabilized version of it. We will consider the Galerkin boundary element method for its discretization. It is well known that the V_k is not invertible on a countable set of frequencies k (see, e.g., [11]) and we will introduce a class of stabilizations such that the boundary integral equation is well posed for all frequencies $k > 0$.

Alternatively, the Helmholtz equation (1.1) can be solved numerically by finite element discretizations where the problem related to the unbounded domain Ω^+ is treated either by [illegible] elements or by introducing an artificial outer boundary far away from the scatterer. It is well known (see, e.g., [3]) that finite element discretiza-

tions for the Helmholtz problem suffer from the [illegible]; i.e., the constants in the Galerkin error estimates deteriorate to infinity with increasing wave number $k > 0$. Hence, the question arises whether this pollution effect is possibly reduced by solving the boundary integral equation for the Helmholtz problem via the Galerkin boundary element method. In order to address this question, it is mandatory to first remove the forbidden frequencies of the single layer potential through a suitable stabilization.

In the literature, various approaches exist for stabilizing these integral equations (cf. [31], [4], [10], [2], [14], [20], [9]). Among them the so-called Brakhage–Werner formulation for the stabilization of the acoustic double layer potential is one of the most popular.

Here we introduce a class of stabilizations for the single layer potential for which the well-posedness of the resulting continuous and discrete equations (for mesh size sufficiently small) can be proved (a related work is [8]). The results can be summarized as follows:

a. The stabilized acoustic single layer potential, on the continuous level, admits a unique solution which depends continuously on the data for general Lipschitz surfaces. This is a strong advantage compared to the Brakhage–Werner stabilization, where the question of existence and uniqueness is open for general Lipschitz surfaces and even for piecewise smooth surfaces.
b. The Galerkin method converges for "sufficiently small" step size on general triangulated surfaces with optimal rate.

Indeed, as in all stabilization approaches, well-posedness and quasi-optimality can be proved provided the step size is "sufficiently small." More precisely, the threshold for the maximal step size such that the Galerkin discretization is stable depends on the wave number, and the "constant" in the quasi-optimality error estimate typically deteriorates to infinity as the wave number increases.

Consequently, in order to compare different approaches from the viewpoint of numerical efficiency the following questions have to be addressed:

1. How does the threshold for the stability of the Galerkin discretization quantitatively depend on the wave number?
2. How does the Galerkin error quantitatively depend on the mesh width [illegible] the wave number?
3. Can the stabilization approach be implemented efficiently in a boundary element code? What is the computational complexity?

These questions have been discussed for the Brakhage–Werner stabilization in [17] (see also [24]). Here, we analyze quantitatively the dependence of the constants entering the stability and convergence estimates for our class of stabilized single layer potentials, in the case that the surface is the unit sphere in $\mathbb{R}^3$. For this case, we obtain the following:

c. The condition for the stability of Galerkin method (related to the condition "the step size has to be sufficiently small") is slightly more restrictive as for the stabilization in the Brakhage–Werner approach.
d. The constant of quasi-optimality in the Galerkin error estimates which amplifies the error of the best approximation is $k^{1/3}$ for both the stabilized acoustic single layer potential and the Brakhage–Werner stabilization.

In this light, the Fourier analysis in this paper shows that, for the surface of the unit sphere, the stabilized acoustic single layer potential has similar convergence properties as the Brakhage–Werner stabilization.

However, we consider the result that the stabilized acoustic single layer potential is stable also on surfaces of general Lipschitz polyhedra as the essential advantage compared to the Brakhage–Werner formulation, where the stability on general Lipschitz polyhedra is still an open question.

The paper is organized as follows. In section 2, we will formulate the boundary integral equation for the Helmholtz problem and introduce our abstract stabilization approach. Concrete stabilization operators which satisfy the abstract assumptions will be presented as examples. As a side result, we will prove, for some sesquilinear forms associated to integral operators of general fractional order, continuity and ellipticity in appropriate Sobolev spaces.

In section 3, we will introduce the Galerkin boundary element method with piecewise constant boundary elements for the stabilized single layer integral equation.

In section 4, the stability and convergence of the Galerkin boundary element method will be analyzed. It will be proved that the discretization is stable on general Lipschitz polyhedrons and the Galerkin solution converges at an optimal rate, provided the step size is sufficiently small.

In section 5, we will employ Fourier analysis to explicitly analyze the dependence of the stability and convergence of the stabilized Galerkin method with respect to both the mesh size and the wave number. We will discuss three parameter constellations by asymptotic analysis in a rigorous way. The intermediate ranges of the parameters are studied by systematic computer experiments and show that the asymptotic cases are relevant for the estimates of the constants of interest. In this light, the asymptotic analysis [illegible] that the estimates of the constants of interest cannot be improved while the computer experiments [illegible] that these constants do not behave worse in the intermediate ranges of the parameters.

Section 6 briefly discusses the computational complexity of the proposed stabilization approaches.

2. Boundary integral formulation.

2.1. Sobolev spaces on Lipschitz manifolds and trace operators. In this section, we will introduce some notation related to Sobolev spaces and recall some of their properties. As before, Ω^- denotes a bounded Lipschitz domain in $\mathbb{R}^3$, Ω^+ its complement, and $\mathbf{n}$ the unit normal vector pointing from Ω^- to Ω^+.

We make use of standard complex Sobolev spaces in the whole space $H^s(\mathbb{R}^3)$, in the domains $H^s(\Omega^\pm)$, $s \in \mathbb{R}$, and on the boundary Γ, $H^\ell(\Gamma)$, $\ell \in [-1,1]$. On the boundary, $(\cdot,\cdot)_0$ is the $L^2(\Gamma)$ scalar product, i.e., $(u,v)_0 = \int_\Gamma u\bar{v}$, which is identified with its continuous extension to the duality pairing between $H^s(\Gamma)$ and $H^{-s}(\Gamma)$, $s \in (0,1]$.

Moreover, for any positive s, we denote by $H^s_{\mathrm{loc}}(\mathbb{R}^3)$, $H^s_{\mathrm{loc}}(\Omega^+)$ the space of functions which are locally in H^s and by $H^{-s}_{\mathrm{comp}}(\mathbb{R}^3)$, $H^{-s}_{\mathrm{comp}}(\Omega^+)$ their dual spaces. Furthermore, we introduce

$$H^{s+1}_\Delta(\Omega^\pm) := \{u \in H^{s+1}(\Omega^\pm) \ : \ \Delta u \in H^s(\Omega^\pm)\}. \tag{2.1}$$

The standard one-sided trace operators are denoted by γ_0^+, γ_0^- and they map $\gamma_0^\pm : H^s(\Omega^\pm) \to H^{s-1/2}(\Gamma)$ continuously for all $s \in (1/2, 3/2)$. The one-sided normal derivative trace operators associated to the mapping $u \mapsto \partial_{\mathbf{n}} u$ are denoted by γ_1^+, γ_1^- and they are continuous operators from $H^{s+1}_\Delta(\Omega^\pm)$ to $H^{s-1/2}(\Gamma)$ for $s \in [0, 1/2)$. Note that the ranges of $\gamma_0^\pm$ and $\gamma_1^\pm$ do not change if the spaces $H^s(\Omega^+)$ are replaced by $H^s_{\mathrm{loc}}(\Omega^+)$ everywhere.

For later use, we will define Sobolev spaces of order $H^{1+s}(\Gamma)$ for $s > 0$ as the ranges of the trace operator γ_0 applied to functions in $H^{3/2+s}(\Omega^-)$. More precisely, for $s \in (0, \frac{1}{2}]$, we define

$$H^{1+s}(\Gamma) := \gamma_0(H^{3/2+s}(\Omega^-)),$$

$$\|v\|_{H^{1+s}(\Gamma)} := \inf_{u \in H^{3/2+s}(\Omega^-), \gamma_0(u)=v} \|u\|_{H^{3/2+s}(\Omega^-)},$$

and we denote by $H^{-(1+s)}(\Gamma)$, $s \in (0, 1/2]$, the dual space of $H^{1+s}(\Gamma)$ with $L^2(\Gamma)$ as pivot space. The corresponding duality pairing is denoted again by $(\cdot, \cdot)_0$. We will often use the shorthand notation $\|\cdot\|_s$ for $\|\cdot\|_{H^s(\Gamma)}$.

Since we shall deal with the numerical discretization of boundary integral operators via the boundary element method, it is reasonable to assume that the Lipschitz surface Γ is piecewise smooth.

NOTATION 2.1. Γ Γ $\Gamma_j \subset \Gamma$ $1 \le j \le J < \infty$ $\Gamma = \bigcup_{j=1}^{J} \overline{\Gamma}_j$

PROPOSITION 2.2. Γ $H^{1+s}(\Gamma_j)$ $s \in (0, \frac{1}{2}]$ j

$$H^{1+s}(\Gamma) \equiv \{v \in H^1(\Gamma) \ : \ v_{|\Gamma_j} \in H^{1+s}(\Gamma_j)\}, \quad s \in (0, \tfrac{1}{2}]. \tag{2.2}$$

The proof can be found in, e.g., [13] or [7].

2.2. Boundary integral operators. For $z \in \mathbb{R}^3 \setminus \{0\}$, let $G_k(z) := \frac{e^{\mathrm{i}\, k \|z\|}}{4\pi \|z\|}$ and define the associated single layer and double potential by

$$(S_k \varphi)(x) := \int_\Gamma G_k(x-y)\, \varphi(y)\, ds_y, \qquad x \in \mathbb{R}^3 \setminus \Gamma,$$

$$(D_k \varphi)(x) := \int_\Gamma \left(\frac{\partial}{\partial n_y} G_k(x-y) \right) \varphi(y)\, ds_y, \qquad x \in \mathbb{R}^3 \setminus \Gamma.$$

The restrictions of these operators to Ω^+ (resp., Ω^-) are denoted by S_k^+, D_k^+ (resp., S_k^-, D_k^-).

The boundary integral operators associated with the single and double layer potentials are given by $V_k := \gamma_0 S_k$ and $K_k := \{\gamma_0\} D_k := \frac{1}{2}\left(\gamma_0^+ D_k + \gamma_0^- D_k\right)$.

It is well known that every solution $\varphi \in H^{-1/2}(\Gamma)$ of

$$V_k \varphi = g \tag{2.3}$$

has the property that $u^- = S_k^- \varphi$, respectively, $u^+ = S_k^+ \varphi$, satisfies the homogeneous interior, respectively, exterior, Helmholtz problem.

However, for countably many wave numbers k, the boundary integral equation (2.3) is not injective and, hence, does not admit a solution for all right-hand sides g (although, e.g., the exterior Helmholtz problem (1.1) admits a unique solution for all boundary data $g \in H^{1/2}(\Gamma)$).

Our goal is to modify the boundary integral equation so that the problem admits a unique solution for all wave numbers. Our approach follows the framework of [31].

We start with the formal ansatz

$$R_k = V_k + \mathrm{i}\,\eta(\tfrac{1}{2}I + K_k)\gamma_0 B, \tag{2.4}$$

where $B : H^{-1/2}(\Gamma) \to H^{1/2}(\mathbb{R}^3)$ is, for the moment, any linear and continuous operator. We consider the equation

$$R_k\varphi = g. \tag{2.5}$$

In Proposition 2.3, we will prove that, under suitable conditions on B, (2.5) admits a unique solution for all wave numbers, and the functions

$$u^+ = \left(S_k^+ + \mathrm{i}\,\eta D_k^+\gamma_0 B\right)\varphi, \quad \text{resp.,} \quad u^- = \left(S_k^- + \mathrm{i}\,\eta D_k^-\gamma_0 B\right)\varphi \tag{2.6}$$

satisfy the homogeneous exterior, respectively, interior, Helmholtz problem.

PROPOSITION 2.3. [illegible] $\gamma_0 B : H^{-1/2}(\Gamma) \to H^{1/2}(\Gamma)$ [illegible] $(\cdot, \gamma_0 B\cdot)_0 : H^{-1/2}(\Gamma) \times H^{-1/2}(\Gamma) \to \mathbb{C}$ [illegible] $\varphi \in H^{-1/2}(\Gamma)$ [illegible] $(\varphi, \gamma_0 B\varphi)_0 > 0 \Leftrightarrow \varphi \neq 0$ [illegible] (2.5) [illegible] $k \in \mathbb{R}_+$ [illegible] $\eta \in \mathbb{R} \setminus \{0\}$ [illegible] u^+ [illegible] u^- [illegible] (2.6) [illegible] Ω^+ [illegible] Ω^-

For the proof, see [11] or [8].

There are various ways of choosing an operator B in (2.4) satisfying the assumptions in Proposition 2.3. However, to obtain an efficient numerical scheme it is essential that the complexity of the numerical realization of B is moderate and the implementation does not cause too much extra work. We will present in section 2.3 some choices of B and will comment on the numerical complexity in section 6. All these choices will satisfy the following assumption.

[illegible] 2.4. There exists $0 < \varepsilon \leq 1$, such that the following hold:

1. The operator $\gamma_0 B : H^{-1/2-\varepsilon}(\Gamma) \to H^{1/2+\varepsilon}(\Gamma)$ is continuous.
2. The sesquilinear form $(\cdot, \gamma_0 B\cdot)_0 : H^{-1/2-\varepsilon}(\Gamma) \times H^{-1/2-\varepsilon}(\Gamma) \to \mathbb{C}$ is hermitian and $H^{-1/2-\varepsilon}(\Gamma)$-elliptic: There exists $\alpha_B > 0$ such that

$$(\varphi, \gamma_0 B\varphi)_0 \geq \alpha_B \|\varphi\|^2_{-1/2-\varepsilon} \qquad \forall \varphi \in H^{-1/2-\varepsilon}(\Gamma).$$

Note that Assumption 2.4 implies that the assumptions in Proposition 2.3 are satisfied.

2.3. Choices of B. In this section, we will present various choices for the operator B.

2.3.1. $B = S_0 V_0$. The single layer potential for the operator $-\Delta$ is given by

$$(S_0\varphi)(x) := \int_\Gamma \frac{\varphi(y)}{4\pi\|x-y\|} ds_y, \qquad x \in \mathbb{R}^3.$$

It is well known (see [12], [21]) that $V_0 := \gamma_0 S : H^{-1/2+s}(\Gamma) \to H^{1/2+s}(\Gamma)$ is a linear and continuous isomorphism for all $s \in \left[-\frac{1}{2}, \frac{1}{2}\right]$ and, for $s = 0$, the associated sesquilinear form $(\cdot, V_0\cdot)_0 : H^{-1/2}(\Gamma) \times H^{-1/2}(\Gamma) \to \mathbb{C}$ is elliptic. Hence,

$$V_0^2 : H^{-1}(\Gamma) \to H^1(\Gamma)$$

is continuous and

$$\left(\varphi, V_0^2\varphi\right)_0 = \|V_0\varphi\|_0^2 \geq c\|\varphi\|^2_{H^{-1}(\Gamma)},$$

where we have used that $V_0 : L^2(\Gamma) \to H^1(\Gamma)$ is an isomorphism.

Hence, the choice $B = S_0 V_0$ leads to $\gamma_0 B = V_0^2$ which satisfies Assumption 2.4 with $\varepsilon = 1/2$.

2.3.2. Single layer potential for $(I-\Delta)^{1+\varepsilon}$. The fundamental solution of the pseudodifferential operator $(I-\Delta)^{1+\varepsilon}$, $0 < \varepsilon \leq 1$, is given by (cf. [30, Example 2.2])

$$\mathcal{G}_\varepsilon(z) := \frac{2^{-\varepsilon}}{(2\pi)^{3/2}\,\Gamma(1+\varepsilon)}\,\|z\|^{\varepsilon-1/2}\,\mathrm{K}_{\varepsilon-1/2}(\|z\|)\,, \tag{2.7}$$

where K_ν is the modified Bessel function (cf. [1, sec. 9.6]) and $\Gamma(\cdot)$ denotes the Gamma function. The corresponding potential is given by

$$(B_\varepsilon \varphi)(x) := \int_\Gamma \mathcal{G}_\varepsilon(x-y)\,\varphi(y)\,ds_y, \qquad x \in \mathbb{R}^3. \tag{2.8}$$

Next, we will prove that the operator $\gamma_0 B_\varepsilon : H^{-1/2-\varepsilon}(\Gamma) \to H^{1/2+\varepsilon}(\Gamma)$ is continuous and the associated sesquilinear form $(\cdot, \gamma_0 B_\varepsilon \cdot)_0 : H^{-1/2-\varepsilon}(\Gamma) \times H^{-1/2-\varepsilon}(\Gamma) \to \mathbb{C}$ is hermitian and $H^{-1/2-\varepsilon}(\Gamma)$-elliptic, i.e., satisfies Assumption 2.4 for any chosen value of $\varepsilon \in]0,1] \setminus \{1/2\}$. (The case $\varepsilon = 1/2$ is exceptional only for nonsmooth surfaces and this problem is related to the mapping properties of γ_0 applied to functions in $H^{3/2}(\mathbb{R}^3)$.)

THEOREM 2.5 (mapping properties). [illegible] $1/2 < \ell \leq 2$ $\ell \neq 3/2$ [illegible] $\varepsilon \in]0,1]$ [illegible] $B_\varepsilon : H^{1/2-\ell}(\Gamma) \to H^{2+2\varepsilon-\ell}(\mathbb{R}^3)$ [illegible] $\varepsilon \in]0,1] \setminus \{1/2\}$ [illegible] $\gamma_0 B_\varepsilon : H^{-1/2-\varepsilon}(\Gamma) \to H^{1/2+\varepsilon}(\Gamma)$ [illegible] $\varepsilon = 1/2$

[illegible]. We introduce the Bessel potential for the operator $(I-\Delta)^{1+\varepsilon}$:

$$N_\varepsilon u(x) := \int_{\mathbb{R}^3} \mathcal{G}_\varepsilon(x-y)\,u(y)\,dy, \qquad x \in \mathbb{R}^3, \tag{2.9}$$

with the fundamental solution $\mathcal{G}_\varepsilon$ as in (2.7). Its symbol is given by $\sigma(\xi) = (\|\xi\|^2 + 1)^{m/2}$ with $m = -(2+2\varepsilon)$. Hence, Theorem 1.4' in [15] implies the mapping property $N_\varepsilon : H^s(\mathbb{R}^3) \to H^{s+2+2\varepsilon}(\mathbb{R}^3)$ for all $s \in \mathbb{R}$. Since, for all $1/2 < \ell \leq 2$, $\ell \neq 3/2$, the trace operator $\gamma_0 : H^\ell(\mathbb{R}^3) \to H^{-1/2+\ell}(\Gamma)$ is continuous, its dual $\gamma_0' := H^{1/2-\ell}(\Gamma) \to H^{-\ell}(\mathbb{R}^3)$ is continuous in the same range of ℓ. Thus, the representation $B_\varepsilon = N_\varepsilon \gamma_0'$ implies the continuity of

$$B_\varepsilon : H^{1/2-\ell}(\Gamma) \to H^{2+2\varepsilon-\ell}(\mathbb{R}^3)\,. \tag{2.10}$$

The mapping property of $\gamma_0 B_\varepsilon$ follows from this and the mapping properties of the trace operator γ_0. □

THEOREM 2.6. [illegible] $\varepsilon \in]0,1] \setminus \{1/2\}$ [illegible] $(\cdot, \gamma_0 B_\varepsilon \cdot)_0 : H^{-1/2-\varepsilon}(\Gamma) \times H^{-1/2-\varepsilon}(\Gamma) \to \mathbb{C}$ [illegible] $H^{-1/2-\varepsilon}(\Gamma)$ [illegible] $\varepsilon = 1/2$

[illegible]. Let $\varepsilon \in]0,1]$ with the exclusion of the case $\varepsilon = 1/2$ for nonsmooth surfaces. Let $(\cdot,\cdot)_{0,\mathbb{R}^3}$ denote the continuous extension of the $L^2(\mathbb{R}^3)$-scalar product to the duality pairing $H^{-1-\varepsilon}(\mathbb{R}^3) \times H^{1+\varepsilon}(\mathbb{R}^3)$. The relation $B_\varepsilon = N_\varepsilon \gamma_0'$ and the mapping properties of B_ε imply

$$(\varphi, \gamma_0 B_\varepsilon \varphi)_0 = (\varphi, \gamma_0 N_\varepsilon \gamma_0' \varphi)_0 = (\gamma_0' \varphi, N_\varepsilon \gamma_0' \varphi)_{0,\mathbb{R}^3} \qquad \forall \varphi \in H^{-1/2-\varepsilon}(\Gamma)\,. \tag{2.11}$$

Simple properties of the Fourier transform lead to

(2.12)
$$(\gamma_0'\varphi, N_\varepsilon\gamma_0'\varphi)_{0,\mathbb{R}^3} = \left(\widehat{\gamma_0'\varphi}, \frac{\widehat{\gamma_0'\varphi}}{\left(1+\|\cdot\|^2\right)^{1+\varepsilon}}\right)_{0,\mathbb{R}^3}$$
$$= \left(\frac{\widehat{\gamma_0'\varphi}}{\left(1+\|\cdot\|^2\right)^{\frac{1+\varepsilon}{2}}}, \frac{\widehat{\gamma_0'\varphi}}{\left(1+\|\cdot\|^2\right)^{\frac{1+\varepsilon}{2}}}\right)_{0,\mathbb{R}^3} \geq c\,\|\gamma_0'\varphi\|^2_{H^{-1-\varepsilon}(\mathbb{R}^3)}.$$

Let $R := \left\{\gamma_0'(\varphi) : \varphi \in H^{-1/2-\varepsilon}(\Gamma)\right\}$ denote the range of γ_0'. Next we will show that $\gamma_0' : H^{-1/2-\varepsilon}(\Gamma) \to R$ is an isomorphism.

It is well known that $\gamma_0 : H^{t+1/2}(\mathbb{R}^3) \to H^t(\Gamma)$ is surjective for $t \in (0, 3/2] \setminus \{1\}$, and hence, trivially, γ_0 has closed range. From the surjectivity of γ_0 we conclude the injectivity of γ_0' and the closed range theorem [34, sec. VII.5] implies that R is closed in $H^{-1-\varepsilon}\left(\mathbb{R}^3\right)$. Thus, $\gamma_0' : H^{-1/2-\varepsilon}(\Gamma) \to R$ is bijective and has closed range in $H^{-1-\varepsilon}\left(\mathbb{R}^3\right)$. The open mapping theorem implies that $\gamma_0' : H^{-1/2-\varepsilon}(\Gamma) \to R$ is an isomorphism. Thus,

$$\|\gamma_0'\varphi\|^2_{H^{-1-\varepsilon}(\mathbb{R}^3)} \geq c\,\|\varphi\|^2_{-1/2-\varepsilon} \qquad \forall\varphi \in H^{-1/2-\varepsilon}(\Gamma),$$

and this, in combination with (2.11) and (2.12), yields the $H^{-1/2-\varepsilon}(\Gamma)$-ellipticity of $(\cdot, \gamma_0 B_\varepsilon \cdot)_{0,\Gamma}$.

The sesquilinear form $(\cdot, \gamma_0 B_\varepsilon \cdot)_{0,\Gamma}$ is hermitian because the kernel function $\mathcal{G}_\varepsilon$ in (2.7) is real valued (cf. [1, sec. 9.6.1]) and symmetric; i.e., $\mathcal{G}_\varepsilon(x-y) = \mathcal{G}_\varepsilon(y-x)$. □

2.7. The choice $\varepsilon = 1$ in (2.3.2) yields that B_1 is the single layer potential for the biharmonic operator $\mathcal{L}_{\mathrm{i}}^2 = (-\Delta + I)(-\Delta + I)$, and in this case the fundamental solution becomes

$$\mathcal{G}_1(z) = \frac{e^{-\|z\|}}{8\pi}. \tag{2.13}$$

2.8. A further choice for the operator $\gamma_0 B$ in (2.4) is the inverse of the Laplace–Beltrami operator. This operator satisfies, as V_0^2, Assumption 2.4 with $\varepsilon = 1/2$ (cf. [9] and [8]).

3. Galerkin boundary element method. The continuous problem which we are going to solve numerically is given by seeking $\varphi \in H^{-1/2}(\Gamma)$ such that

$$(R_k\varphi, \psi)_0 = (g, \psi)_0 \qquad \forall\psi \in H^{-1/2}(\Gamma), \tag{3.1}$$

where R_k is as in (2.4) and $g \in H^{1/2}(\Gamma)$ is a given right-hand side.

Our goal is to solve the problem (3.1) by the Galerkin boundary element method and we start by defining the relevant boundary element space.

Let Γ be a polyhedral surface. Let $\mathcal{T} = \{\tau_1, \tau_2, \ldots, \tau_N\}$ denote a shape-regular triangulation of Γ, and let X_h be the boundary element space

$$X_h := \operatorname{span}\{b_\tau : \tau \in \mathcal{T}\} \tag{3.2}$$

with the indicator function $b_\tau : \Gamma \to \mathbb{R}$ for the triangle τ. The mesh width is denoted by

$$h := \max_{\tau \in \mathcal{T}} h_\tau \quad \text{with} \quad h_\tau := \operatorname{diam} \tau.$$

The discrete problem is given by seeking $\varphi_h \in X_h$ such that

$$(R_k \varphi_h, \psi)_0 = (g, \psi)_0 \qquad \forall \psi \in X_h. \tag{3.3}$$

4. Stability and error analysis for the Galerkin boundary element method. We start with the well-known approximation property of piecewise constant boundary elements on a shape-regular triangulation. In this light, we assume from now on that Γ is a polyhedral Lipschitz surface.

THEOREM 4.1. $\mathcal{T}$ Γ h C_A $\mathcal{T}$ $-1/2 \le s \le 0$ $s \le t \le 1$

$$\inf_{\psi \in X_h} \|\varphi - \psi\|_s \le C_A h^{t-s} \|\varphi\|_t \qquad \forall \varphi \in H^t(\Gamma).$$

We need now to recall the well-known mapping properties for the operators V_k and $\gamma_0^+ D_k$.

For polyhedral surfaces, we denote by s_Γ the regularity exponent associated with Γ such that for all s, $|s| < s_\Gamma$, the operators

$$V_k : H^{-1/2+s}(\Gamma) \to H^{+1/2+s}(\Gamma) \quad \text{and} \quad \gamma_0^+ D_k = \tfrac{1}{2} I + K_k : H^{1/2+s}(\Gamma) \to H^{1/2+s}(\Gamma) \tag{4.1}$$

are continuous. Note that, for polyhedral surfaces, we may choose $s_\Gamma = 1/2$. For smooth surfaces of class C^∞, the choice $s_\Gamma = \infty$ is allowed and, moreover, the operator K_k is of order -1, namely,

$$K_k : H^{1/2+s}(\Gamma) \to H^{3/2+s}(\Gamma) \quad \forall\, s \in \mathbb{R},\ \Gamma \text{ in } C^\infty. \tag{4.2}$$

As a consequence of these facts and of Proposition 2.3, the operator

$$R_k : H^{-1/2+s}(\Gamma) \to H^{1/2+s}(\Gamma) \text{ is an isomorphism } \forall |s| < s_\Gamma. \tag{4.3}$$

The stability and convergence analysis will be based on a splitting of R_k into its principal part $V_0 + \frac{\mathrm{i}\eta}{2}\gamma_0 B_\varepsilon$ and the compact perturbation $\tilde{R}_k := V_0 + \frac{\mathrm{i}\eta}{2}\gamma_0 B_\varepsilon - R_k$. It is well known that the boundary integral operator V_0 for the single layer potential of the Laplacian is coercive, i.e., there is a constant $\alpha_0 > 0$ such that

$$(V_0 \varphi, \varphi)_0 \ge \alpha_0 \|\varphi\|^2_{-1/2} \qquad \forall \varphi \in H^{-1/2}(\Gamma). \tag{4.4}$$

Assumption 2.4 implies that the sesquilinear form $\left(\cdot, \frac{1}{2}\gamma_0 B_\varepsilon \cdot\right)_0$ is hermitian and

$$\left(\varphi, \frac{1}{2}\gamma_0 B_\varepsilon \varphi\right)_0 \ge \alpha_B \|\varphi\|^2_{-1/2-\varepsilon} \ge 0 \qquad \forall \varphi \in H^{-1/2}(\Gamma).$$

We conclude that $V_0 + \frac{1}{2}\gamma_0 B_\varepsilon$ is $H^{-1/2}$-coercive

$$\operatorname{Re}\left(\left(V_0 + \frac{\mathrm{i}\eta}{2}\gamma_0 B_\varepsilon\right)\varphi, \varphi\right)_0 \ge \alpha_0 \|\varphi\|^2_{-1/2} \qquad \forall \varphi \in H^{-1/2}(\Gamma), \tag{4.5}$$

where α_0 is as in (4.4) and, in particular, independent of ε.

In order to describe the mapping properties of the compact perturbation $\tilde{R}_k$ we introduce the interval I_{shift} which depends on the smoothness of the surface by

$$I_{\text{shift}} := \begin{cases} [0, 2\varepsilon] \cap [0, s_\Gamma[& \text{if } \Gamma \text{ is a general polyhedral surface,} \\ \left[0, \min\left\{\tfrac{3}{2}, 1+2\varepsilon\right\}\right] & \text{if } \Gamma \text{ is of class } C^\infty. \end{cases} \tag{4.6}$$

PROPOSITION 4.2. [illegible] $\tilde{R}_k : H^{-1/2}(\Gamma) \to H^{1/2+\mu}(\Gamma)$ [illegible] $\mu \in I_{\text{shift}}$.

[illegible]. For polyhedral surfaces, the combination of (2.10) and (4.1) yields

$$K_k \gamma_0 B : H^{-1/2}(\Gamma) \to H^{1/2+\mu}\left(\mathbb{R}^3\right) \qquad \forall \mu \in I_{\text{shift}}, \tag{4.7}$$

whereas, for surfaces of class C^∞, the combination of (2.10) and (4.2) yields

$$K_k \gamma_0 B : H^{-1/2}(\Gamma) \to H^{1/2+\mu}\left(\mathbb{R}^3\right) \qquad \forall \mu \in [0, 1+2\varepsilon]. \tag{4.8}$$

The difference $V_0 - V_k$ can be written in the form $\gamma_0 \mathcal{N}_{0,k} \gamma_0'$, where $\mathcal{N}_{0,k} : H^s_{\text{comp}}\left(\mathbb{R}^3\right) \to H^{s+4}_{\text{loc}}\left(\mathbb{R}^3\right)$ is a pseudodifferential operator of order -4 (cf. [32, Bemerkung 3.1.3]). Hence, the mapping properties of the trace operator and its dual imply the continuity of

$$V_0 - V_k : H^{-1/2}(\Gamma) \to H^{1/2+s}(\Gamma) \qquad \forall s \ : \ s \le 2, s < s_\Gamma. \qquad \square \tag{4.9}$$

Note that the proof of Proposition 4.2 allows us to replace $\frac{3}{2}$ by 2 in (4.6) for smooth surfaces. However, the proof of Theorem 4.3 will further restrict the set of admissible shifts to $\mu \le 3/2$ and we have taken this fact into account already in (4.6).

We denote by C_X the continuity constant of R_k; i.e.,

$$C_X := \sup\left\{ |(\varphi, R_k \psi)_0| : \varphi, \psi \in H^{-1/2}(\Gamma) : \|\varphi\|_{-1/2} = \|\psi\|_{-1/2} = 1 \right\}. \tag{4.10}$$

The combination of (4.3) with Proposition 4.2 yields that

$$C_\mu := \left\| (R_k^\star)^{-1} \tilde{R}_k \right\|_{H^{-1/2+\mu}(\Gamma) \leftarrow H^{-1/2}(\Gamma)} \tag{4.11}$$

is bounded for all $\mu \in I_{\text{shift}}$. The operator R_k satisfies a Gårding inequality but is not coercive. Hence, we may expect the existence of a discrete solution of (3.3) only for sufficiently small mesh width h. In this light, we define h_0 depending on $\mu \in I_{\text{shift}}$ by

$$h_0 := \left(\frac{\alpha_0}{2C_A} \frac{1}{C_X C_\mu} \right)^{1/\mu}. \tag{4.12}$$

THEOREM 4.3. [illegible] 2.4 [illegible] $0 < h < h_0$ [illegible] h_0 [illegible] (4.12) [illegible] $\mu \in I_{\text{shift}}$ [illegible] (3.3) [illegible]

$$\|\varphi - \varphi_h\|_{-1/2} \le \frac{2C_X}{\alpha_0} \inf_{\psi \in X_h} \|\varphi - \psi\|_{-1/2}. \tag{4.13}$$

[illegible] $\bigcup X_h \hookrightarrow H^{-1/2}(\Gamma)$ [illegible] $h \to 0$

. This proof is inspired by the proof of the analogue theorem for elliptic partial differential equations (see, e.g., [6, sec. 5.7]).

(a) . Assume that a discrete solution φ_h exists. The error is denoted by $e := \varphi - \varphi_h$ and can be estimated by using the Galerkin orthogonality

$$\begin{aligned}(4.14)\quad \alpha_0 \|e\|_{-1/2}^2 &\le (R_k e, e)_0 + \left(\tilde{R}_k e, e\right)_0 \le |(R_k e, \varphi - \phi_h)_0| + \left|\left(\tilde{R}_k e, e\right)_0\right| \\ &\le C_X \|e\|_{-1/2} \|\varphi - \phi_h\|_{-1/2} + \left|\left(\tilde{R}_k e, e\right)_0\right|,\end{aligned}$$

where $\phi_h \in X_h$ is the best approximation of φ with respect to the $\|\cdot\|_{-1/2}$-norm. In order to estimate the modulus of $(\tilde{R}_k e, e)_0$ we use a duality argument. Let ψ_e be the solution of the adjoint problem:

$$R_k^\star \psi_e = \tilde{R}_k e \qquad \text{in } H^{1/2}(\Gamma).$$

By the definition of the constant C_μ, we conclude that

$$\|\psi_e\|_{-1/2+\mu} \le C_\mu \|e\|_{-1/2} \qquad \forall \mu \in I_{\text{shift}}$$

holds.

Let $\psi_h \in X_h$ denote the best approximation of ψ_e with respect to the $\|\cdot\|_{-1/2}$-norm. The approximation property of piecewise constant boundary elements yields

$$\|\psi_e - \psi_h\|_{-1/2} \le C_A C_\mu \|e\|_{-1/2} h^\mu \qquad \forall \mu \in I_{\text{shift}}.$$

Galerkin's orthogonality implies

$$\begin{aligned}\left|\left(\tilde{R}_k e, e\right)_0\right| &= |(R_k^\star \psi_e, e)_0| = |(\psi_e, R_k e)_0| = |(R_k e, \psi_e - \psi_h)_0| \\ &\le C_X \|e\|_{-1/2} \|\psi_e - \psi_h\|_{-1/2} \le C_A C_X C_\mu h^\mu \|e\|_{-1/2}^2 \qquad \forall \mu \in I_{\text{shift}}.\end{aligned}$$

Using this estimate in (4.14) we obtain

$$\alpha_0 \|e\|_{-1/2}^2 \le C_X \|e\|_{-1/2} \|\varphi - \phi_h\|_{-1/2} + C_A C_X C_\mu h^\mu \|e\|_{-1/2}^2.$$

Let h_0 be as in (4.12). Then, for $h < h_0$, the estimate (4.13) holds. Note that, when Γ is a C^∞-surface, the choice $\mu = \min\left\{\frac{3}{2}, 1 + 2\varepsilon\right\}$ is allowed.

(b) . Since the discrete problem is finite dimensional it suffices to prove uniqueness. For $g = 0$, Proposition 2.3 implies that the exact solution is $\varphi = 0$. Equation (4.13) implies $\varphi_h = 0$ and this proves the uniqueness. □

. 4.4. Theorem 4.3 provides convergence of the Galerkin method for polyhedral surfaces Γ. This is a much stronger result as for the Brakhage–Werner stabilization where the stability of the resulting method is still open for polyhedral surfaces.

. 4.5. In section 5 we will investigate the dependence of the maximal mesh width h_0 on the wave number k for the special case that Γ is the unit sphere. It turns out that the operator splitting

$$C_\mu \le \left\|(R_k^\star)^{-1}\right\|_{H^{-1/2+\mu}(\Gamma) \leftarrow H^{1/2+\mu}(\Gamma)} \left\|\tilde{R}_k\right\|_{H^{1/2+\mu}(\Gamma) \leftarrow H^{-1/2}(\Gamma)}$$

and the estimate of the two factors in the right-hand side lead to too pessimistic estimates of the dependence of C_μ on k. Thus, we estimate the constant C_μ directly.

In the following, we will analyze the dependence of the Galerkin error on the wave number k for the case, where we have full regularity. In this light, we introduce the set of functions having the property that the derivatives grow proportionally with respect to the wave number k.

DEFINITION 4.6. [illegible] $\rho > 0$ [illegible] $\mathcal{O}_{\rho,k}$ [illegible] $\varphi \in H^1(\Gamma)$ [illegible]

$$\|\varphi\|_1 \leq \rho k^{3/2} \|\varphi\|_{-1/2}. \tag{4.15}$$

THEOREM 4.7. [illegible] 2.4 [illegible] Γ [illegible] φ [illegible] (2.5) [illegible] $\mathcal{O}_{\rho,k}$ [illegible] $\rho > 0$ [illegible] $0 < h < h_0$ [illegible] h_0 [illegible] (4.12) [illegible] $\mu \in I_{\text{shift}}$ [illegible] $\varphi \neq 0$ [illegible]

$$\frac{\|\varphi - \varphi_h\|_{-1/2}}{\|\varphi\|_{-1/2}} \leq \left(\frac{2C_X}{\alpha_0}\right) C_A \rho (kh)^{3/2}.$$

[illegible]. Using (4.13) together with Theorem 4.1, we obtain

$$\|\varphi - \varphi_h\|_{-1/2} \leq \left(\frac{C_X}{2\alpha_0}\right) C_A h^{3/2} \|\varphi\|_1.$$

Taking into account the oscillation condition (4.15) yields the proof. ∎

In subsection 5.7 we will consider the question of under which conditions the solution of the integral equation (2.5) belongs to the set $\mathcal{O}_{\rho,k}$.

5. The special case of $\Gamma = \mathbb{S}^2$. In this section, we will investigate the dependence of the constant C_X and the minimal mesh width h_0 (see (4.12)) upon η and k for the special case that Ω is the unit ball

$$\Omega := \left\{x \in \mathbb{R}^3 : \|x\| < 1\right\}.$$

It is well known that for $\Gamma = \mathbb{S}^2$, the Sobolev spaces can be defined via the decay properties of the Fourier coefficients.

5.1. Spherical harmonics. For a function $f \in L^2(\mathbb{S}^2)$ the Fourier coefficients are defined by

$$f_n^m := \int_{\mathbb{S}^2} Y_n^m(\hat{x}) \overline{f(\hat{x})} ds_x, \tag{5.1}$$

where Y_n^m are the spherical harmonics. We defer the reader to [1].

DEFINITION 5.1. [illegible] $f \in L^2(\mathbb{S}^2)$ [illegible] $\mathcal{H}^s(\mathbb{S}^2)$ $s \geq 0$ [illegible]

$$\sum_{n=0}^{\infty} \sum_{m=-n}^{n} |f_n^m|^2 (1+n^2)^s < \infty. \tag{5.2}$$

[illegible]

$$\langle f, g \rangle_s := \sum_{n=0}^{\infty} (1+n^2)^s \sum_{m=-n}^{n} f_n^m \overline{g_n^m} \tag{5.3}$$

[illegible] $\mathcal{H}^s(\mathbb{S}^2)$ [illegible] $s < 0$ [illegible] $\mathcal{H}^s(\mathbb{S}^2)$ [illegible] $\mathcal{H}^{-s}(\mathbb{S}^2)$ [illegible] $F \in \mathcal{H}^s(\mathbb{S}^2)$ [illegible] (5.2), [illegible] f_n^m [illegible] $f_n^m := F(Y_n^m)$

The eigenfunctions of all arising boundary integral operator on $\mathbb{S}^2$ are given by the spherical harmonics. The eigenvalues can be expressed by Bessel and related functions. Let j_n, respectively, $h_n^{(1)}$, denote the spherical Bessel functions of first and third kind (cf. [1]).

LEMMA 5.2.

a. $\mathcal{H}^s\left(\mathbb{S}^2\right)$ $s \in \mathbb{R}$

$$\left\langle Y_n^m, Y_{n'}^{m'} \right\rangle_s = \delta_{n,n'}\delta_{m,m'}\left(1+n^2\right)^s$$

$n, n' \in \mathbb{N}$ $|m| \le n$ $|m'| \le n'$.

b. R_k

i.

$$V_k Y_n^m = \lambda_{n,k}^{(V)} Y_n^m \qquad \lambda_{n,k}^{(V)} := 2\,\mathrm{i}\,k h_n^{(1)}(k)\, j_n(k).$$

ii.

$$\left(\frac{1}{2}I + K_k\right) Y_n^m = \lambda_{n,k}^{(K)} Y_n^m \qquad \lambda_{n,k}^{(K)} := \mathrm{i}\,k^2 h_n^{(1)}(k)\, j_n'(k).$$

c. $\mathcal{H}^s\left(\mathbb{S}^2\right)$ $H^s\left(\mathbb{S}^2\right)$ $\varphi \in \mathcal{H}^s\left(\mathbb{S}^2\right)$ $\varphi := (\varphi_n^m)_{\substack{n\in\mathbb{N}_0 \\ -n\le m\le n}}$ $\mathbf{H}_s := \left(\operatorname{diag}\left(1+n^2\right)^s\right)_{n\in\mathbb{N}_0}$

$$\|\varphi\|_{H^s(\mathbb{S})}^2 \sim \left|\!\left|\!\left|(\varphi_n^m)_{n,m}\right|\!\right|\!\right|_s^2 := \sum_{n=0}^{\infty} (\mathbf{H}_s)_n \sum_{m=-n}^{n} |\varphi_n^m|^2. \tag{5.4}$$

. Ad a. The result follows by using the $L^2(\mathbb{S})$-orthogonality of the spherical harmonics (cf., e.g., [29, Theorem 2.4.1]) for $f = Y_{n'}^{m'}$ in (5.1) and the definition of the scalar product (5.3).

Ad b. See [22].

Ad c. See [28, Chapter X, Theorem 6.4]. □

In view of Lemma 5.2 (c), we will use the same notation $H^s(\mathbb{S})$ for both $H^s(\mathbb{S})$ and $\mathcal{H}^s(\mathbb{S})$.

The space of sequences $(\varphi_n^m)_{\substack{n\in\mathbb{N} \\ -n\le m\le n}}$ where the right-hand side in (5.4) is finite is denoted by $\mathbf{h}_s$ and the right-hand side in (5.4) defines (the square of) the norm in $\mathbf{h}_s$.

Assumption 2.4 implies that $\gamma_0 B : H^{-1/2-\varepsilon}(\Gamma) \to H^{1/2+\varepsilon}(\Gamma)$ is continuous and elliptic. In order to develop a spectral analysis of the operator R_k we furthermore assume that, for $\Gamma = \mathbb{S}^2$, the spherical harmonics are the eigenfunctions also for the operator $\gamma_0 B$.

. 5.3. Let $\Gamma = \mathbb{S}^2$ and let Assumption 2.4 be satisfied for some $0 < \varepsilon \le 1$. The spherical harmonics are the eigenfunctions of $\gamma_0 B$:

$$(\gamma_0 B)\, Y_n^m = \lambda_n^{(B)} Y_n^m \qquad \forall n \in \mathbb{N}, -m \le n \le m.$$

There exist constants $0 < c_1 \le C_1 < \infty$ independent of n such that

$$\frac{c_1}{(n+1)^{1+2\varepsilon}} \le \lambda_n^{(B)} \le \frac{C_1}{(n+1)^{1+2\varepsilon}} \qquad \forall n \in \mathbb{N}. \tag{5.5}$$

For the choice $\gamma_0 B = V_0^2$ (cf. subsection 2.3.1) Assumption 5.3 with $\varepsilon = 1/2$ simply follows from the well-known relation $V_0 Y_n^m = (2n+1)^{-1} Y_n^m$ (cf. [29]).

THEOREM 5.4. [illegible] $\varepsilon \in]0,1]$ [illegible] B_ε [illegible] (2.8) [illegible] 5.3.

[illegible]. First, we will prove that

$$\gamma_0 B_\varepsilon Y_n^m = \lambda_n Y_n^m$$

holds. Note that

$$\gamma_0 B_\varepsilon Y_n^m = \gamma_0 N_\varepsilon \left(Y_n^m \delta_\Gamma \right), \tag{5.6}$$

where N_ε denotes the Bessel potential (cf. (2.9)) and δ_Γ is the Dirac function concentrated on Γ. For $\xi \in \mathbb{S}^2$, we write for short $Y_n^m(\xi)$ instead of $Y_n^m(\alpha,\beta)$, where α,β are the spherical angles of ξ. We employ the Fourier transform to evaluate (5.6) and obtain

$$\begin{aligned}
\widehat{N_\varepsilon \left(Y_n^m \delta_\Gamma \right)}(\hat{x}) &= \frac{1}{\left(1+\|\hat{x}\|^2\right)^{1+\varepsilon} (2\pi)^{3/2}} \int_{\mathbb{R}^3} Y_n^m\left(\frac{x}{\|x\|}\right) \delta_\Gamma(x)\, e^{-i\langle \hat{x}, x\rangle} dx \\
&= \frac{1}{\left(1+\|\hat{x}\|^2\right)^{1+\varepsilon} (2\pi)^{3/2}} \int_{\mathbb{S}^2} Y_n^m(\xi)\, e^{-i\langle \hat{x}, \xi\rangle} d\xi.
\end{aligned}$$

We make use of the formula

$$\int_{\mathbb{S}^2} e^{-i\langle x, \hat{x}\rangle} Y_\ell^m(x)\, dx = g_\ell(\|\hat{x}\|)\, Y_\ell^m\left(\frac{\hat{x}}{\|\hat{x}\|}\right) \quad \text{with} \quad g_\ell(r) = (-i)^\ell 4\pi j_\ell(r)$$

which follows by a comparison of [29, section 3.2.4, formula (3.2.44)] and [29, section 3.2.4, formula (3.2.54)] . Let $\mathcal{F}^{-1}$ denote the inverse Fourier transform. Then

$$\begin{aligned}
N_\varepsilon \left(Y_n^m \delta_\Gamma \right)(x) &= \left(\mathcal{F}_{\hat{x}}^{-1} \frac{g_n(\|\hat{x}\|)\, Y_n^m\left(\frac{\hat{x}}{\|\hat{x}\|}\right)}{\left(1+\|\hat{x}\|^2\right)^{1+\varepsilon} (2\pi)^{3/2}} \right)(x) \\
&= \frac{1}{(2\pi)^{3/2}} \int_{\mathbb{R}^3} \frac{g_n(\|\hat{x}\|)\, Y_n^m\left(\frac{\hat{x}}{\|\hat{x}\|}\right)}{\left(1+\|\hat{x}\|^2\right)^{1+\varepsilon}} e^{i\langle x, \hat{x}\rangle} d\hat{x} \\
&\overset{\hat{x} \leftarrow r\zeta}{=} \frac{1}{(2\pi)^{3/2}} \int_0^\infty \frac{r^2 g_n(r)}{(1+r^2)^{1+\varepsilon}} \left(\int_{\mathbb{S}^2} Y_n^m(\zeta)\, e^{i\langle x, r\zeta\rangle} d\zeta \right) dr \\
&= Y_n^m\left(\frac{-x}{\|x\|}\right) \frac{1}{(2\pi)^{3/2}} \int_0^\infty \frac{r^2 g_n(r)\, g_n(-\|x\|\, r)}{(1+r^2)^{1+\varepsilon}} dr.
\end{aligned}$$

Note that $Y_n^m(-\xi) = (-1)^n Y_n^m(\xi)$. Applying the trace operator to this equation yields

$$\gamma_0 B_\varepsilon Y_n^m = \lambda_n Y_n^m \quad \text{with} \quad \lambda_n := \frac{(-1)^n}{(2\pi)^{3/2}} \int_0^\infty \frac{r^2 g_n(r)\, g_n(-r)}{(1+r^2)^{1+\varepsilon}} dr,$$

where the asymptotic behavior of the spherical Bessel functions (see [1, (10.1)]) implies that λ_n is finite.

In summary, we have proved that Y_n^m are the eigenfunctions of the operator $\gamma_0 B_\varepsilon$ with eigenvalues λ_n. We already proved (cf. Theorem 2.5) that $B_\varepsilon : H^{-1/2-\varepsilon}(\Gamma) \to H^{1/2+\varepsilon}(\Gamma)$ is continuous and (cf. Theorem 2.6) that the sesquilinear form associated with $\gamma_0 B_\varepsilon$ is $H^{-1/2-\varepsilon}(\Gamma)$-elliptic and, thus, $\lambda_n > 0$. Hence,

$$\frac{1}{C}\,\|Y_n^m\|^2_{H^{-1/2-\varepsilon}(\Gamma)} \le \underbrace{(\gamma_0 B_\varepsilon Y_n^m, Y_n^m)_{0,\Gamma}}_{=\lambda_n} \le C\,\|Y_n^m\|^2_{H^{-1/2-\varepsilon}(\Gamma)} \quad \forall n \in \mathbb{N},\ -n \le m \le n,$$

where $C > 0$ is independent of n, m. For $\Gamma = \mathbb{S}^2$, the $H^{-1/2-\varepsilon}(\Gamma)$-norm is equivalent to the Fourier norm (cf. Lemma 5.2) and the estimate

$$\tilde{c}\,(1+n)^{-1-2\varepsilon} \le \lambda_n \le \tilde{C}\,(1+n)^{-1-2\varepsilon} \qquad \forall n \in \mathbb{N}$$

directly follows. ∎

5.2. Evaluation of the constants of interest in terms of eigenvalues of the underlying integral operators. The eigenvalues of the operator R_k are given by

$$\lambda_{n,k}^{(R)} := \lambda_{n,k}^{(V)} + \mathrm{i}\,\eta \lambda_n^{(B)} \lambda_{n,k}^{(K)}. \tag{5.7}$$

Remark 5.5. Assumption 5.3 implies that the qualitative dependence of $\lambda_n^{(B)}$ on n can be studied by replacing $\lambda_n^{(B)}$ by $\tilde{\lambda}_n^{(B)} := (n+1)^{-1-2\varepsilon}$. For all numerical experiments, we have employed this simplification and indicated this by a superscript $\tilde{\lambda}$.

Since we are concerned in this section with the smooth surface of the unit ball we may choose the parameter μ in the definition of h_0 (cf. (4.12)) by

$$\mu := \min\left\{\frac{3}{2}, 1+2\varepsilon\right\}. \tag{5.8}$$

In view of Theorem 4.3, we see that the maximal mesh width h_0 which guarantees existence and uniqueness is given by (4.12) and depends on α_0, ε, C_μ, C_X, C_A. Our goal is to analyze the dependence of h_0 on k and h. Since α_0 and C_A (cf. (4.5), Theorem 4.1) are independent of k and h, we are left with the analysis of C_μ (cf. (4.11)), C_X (cf. (4.10)). Note that such estimates directly imply an estimate of the constant $2C_X/\alpha_0$ in the error estimate (4.13).

i. The continuity constant C_X can be estimated in terms of eigenvalues by

$$\begin{aligned} C_X = \|R_k\|_{H^{1/2}(\Gamma)\leftarrow H^{-1/2}(\Gamma)} &\le \sup_{n\in\mathbb{N}} \sqrt{1+n^2}\left|\lambda_{n,k}^{(R)}\right| \\ &\le \sup_{n\in\mathbb{N}} \sqrt{1+n^2}\left(\left|\lambda_{n,k}^{(V)}\right| + \eta\left|\lambda_n^{(B)}\lambda_{n,k}^{(K)}\right|\right). \end{aligned} \tag{5.9}$$

ii. The constant C_μ can be expressed in terms of the eigenvalues as follows. Let $\varphi = \sum_{n=0}^\infty \sum_{m=-n}^n \varphi_n^m Y_n^m$ be such that $\sum_{n=0}^\infty \sum_{m=-n}^n (1+n^2)^{-1/2}|\varphi_n^m|^2 = 1$; then $(R_k^\star)^{-1}\tilde{R}_k\varphi$ reads

$$(R_k^\star)^{-1}\tilde{R}_k\varphi = \sum_{n=0}^\infty \frac{1}{\overline{\lambda}_{n,k}^{(R)}}\left(\lambda_{n,k}^{(R)} - \frac{2}{2n+1} - \frac{\mathrm{i}\,\eta}{2}\lambda_n^{(B)}\right)\sum_{m=-n}^n \varphi_n^m Y_n^m$$

and C_μ can be expressed by

$$C_\mu = \sup_{n\in\mathbb{N}}\left\{\frac{\left(1+n^2\right)^{\frac{\mu+1}{2}}\left|\lambda_{n,k}^{(R)} - \frac{2}{2n+1} - \frac{\mathrm{i}\,\eta}{2}\lambda_n^{(B)}\right|}{|\lambda_{n,k}^{(R)}|\sqrt{1+n^2}}\right\}. \tag{5.10}$$

The rest of the section is structured as follows: In subsection 5.3 we will study the behavior (in k and n) of the eigenvalues in the asymptotic ranges of k and n; the choice of η in subsection 5.4 will be based on these asymptotics; in subsection 5.5 we will study the behavior of the eigenvalues in the nonasymptotic range of k and n via computer experiments. In subsection 5.6 we will derive bounds for the quantities C_X and h_0 which are [illegible] in the wave number k. Finally, in subsection 5.7 we will investigate the oscillation hypothesis made in Theorem 4.7.

5.3. Asymptotic analysis of the eigenvalues. The following lemma concerns the asymptotic behavior of the eigenvalues $\lambda_{n,k}^{(V)}$, $\lambda_n^{(B)}$, and $\lambda_{n,k}^{(K)}$. Let

$$\operatorname{trig}(k) := \begin{cases} \sin k & \text{if } n \text{ is even,} \\ \mathrm{i}\cos k & \text{if } n \text{ if odd,} \end{cases}$$

where we suppress the dependence on n in the notation of trig. Note that

$$\operatorname{trig}\left(k+\frac{\pi}{2}\right) = \operatorname{trig}'(k) = \begin{cases} \cos k & \text{if } n \text{ is even,} \\ -\mathrm{i}\sin k & \text{if } n \text{ if odd.} \end{cases}$$

LEMMA 5.6. [illegible] $\lambda_{n,k}^{(V)}$ $\lambda_{n,k}^{(K)}$ [illegible]

1. [illegible] n [illegible] $k \to \infty$ [illegible]

$$\lambda_{n,k}^{(V)} = 2\frac{e^{\mathrm{i}k}}{k}\operatorname{trig}(k) + O\left(\frac{1}{k^2}\right),$$

$$\lambda_{n,k}^{(K)} = e^{\mathrm{i}k}\operatorname{trig}'(k) + O\left(\frac{1}{k}\right).$$

2. [illegible] $k = n + 1/2$ [illegible]

$$\lambda_{n,k}^{(V)} = \pi\left(\frac{2^{1/3}}{3^{2/3}\Gamma\left(\frac{2}{3}\right)}\right)^2 k^{-2/3}\left(\sqrt{3}+\mathrm{i}\right)(1+o(1)),$$

$$\lambda_{n,k}^{(K)} = \frac{\mathrm{i}+\sqrt{3}}{2\sqrt{3}}(1+o(1)).$$

3. [illegible] k [illegible] $n \to \infty$ [illegible]

$$\lambda_{n,k}^{(V)} = \frac{2}{2n+1}\left(1+O\left(\frac{1}{n^2}\right)\right),$$

$$\lambda_{n,k}^{(K)} = \frac{1}{2} + O\left(\frac{1}{n}\right).$$

[illegible] Ad 1. The [illegible] Bessel functions j_n, h_n can be expressed via the Bessel functions of first and third kind J_n and H_n (cf. [1, (10.1.1)]):

$$j_n(z) = \sqrt{\frac{\pi}{2z}}J_{n+1/2}(z) \quad \text{and} \quad h_n(z) = \sqrt{\frac{\pi}{2z}}H_{n+1/2}^{(1)}(z). \tag{5.11}$$

We combine (5.11) with the asymptotic expansion (cf. [1, (9.2.1) and (9.2.3)]) to obtain

$$
\begin{aligned}
(5.12)\qquad h_n^{(1)}(k)\, j_n(k) &\overset{[1,\ (10.1.1)]}{=} \frac{\pi}{2k} J_{n+1/2}(k)\, H_{n+1/2}^{(1)}(k) \\
&\overset{[1,\ (9.2.1),\ (9.2.3)]}{\sim} \frac{1}{k^2} e^{\mathrm{i}\left(k-\frac{\pi}{2}(n+1)\right)} \cos\left(k-\frac{\pi}{2}(n+1)\right) + O\left(\frac{1}{k^3}\right) \\
&= \frac{e^{\mathrm{i}\,k}}{\mathrm{i}\,k^2}\,\mathrm{trig}(k) + O\left(\frac{1}{k^3}\right)
\end{aligned}
$$

and

$$
\begin{aligned}
h_n^{(1)}(k)\, j_n'(k) &\overset{[1,\ (10.1.20)]}{=} \sqrt{\frac{\pi}{2k}} H_{n+1/2}^{(1)}(k)\, \frac{\left(n j_{n-1}(k) - (n+1)\, j_{n+1}(k)\right)}{2n+1} \\
(5.13)\qquad &\overset{[1,\ (10.1.1)]}{=} \frac{\pi}{2k} H_{n+1/2}^{(1)}(k)\, \frac{\left(n J_{n-1/2}(k) - (n+1)\, J_{n+3/2}(k)\right)}{2n+1} \\
&\overset{[1,\ (9.2.1),\ (9.2.3)]}{\sim} \frac{e^{\mathrm{i}\,k}}{k^2} e^{-\mathrm{i}\,\frac{\pi}{2}(n+1)} \frac{n\cos\left(k-\frac{\pi n}{2}\right) - (n+1)\cos\left(k-\frac{\pi(n+2)}{2}\right)}{2n+1} \\
&\quad + O\left(\frac{1}{k^3}\right) \\
&= \frac{e^{\mathrm{i}\,k}}{\mathrm{i}\,k^2}\,\mathrm{trig}'(k) + O\left(\frac{1}{k^3}\right).
\end{aligned}
$$

Hence

$$
(5.14)\qquad \lambda_{n,k}^{(V)} = 2\,\mathrm{i}\,k h_n^{(1)}(k)\, j_n(k) = 2\frac{e^{\mathrm{i}\,k}}{k}\,\mathrm{trig}(k) + O\left(\frac{1}{k^2}\right),
$$

$$
(5.15)\qquad \lambda_{n,k}^{(K)} = \mathrm{i}\,k^2 h_n^{(1)}(k)\, j_n'(k) = e^{\mathrm{i}\,k}\,\mathrm{trig}'(k) + O\left(\frac{1}{k}\right).
$$

Ad 2. Let $k = n + 1/2$. Then,

$$
j_n\left(n+\frac{1}{2}\right) \overset{(5.11)}{=} \sqrt{\frac{\pi}{2k}} J_k(k) \quad \text{and} \quad h_n^{(1)}(k) = \sqrt{\frac{\pi}{2k}} H_k^{(1)}(k).
$$

We employ the asymptotics for $J_\nu(\nu)$ and $H_\nu(\nu)$ to obtain

$$
\begin{aligned}
\lambda_{n,k}^{(V)} &= 2\,\mathrm{i}\,k j_n\left(n+\frac{1}{2}\right) h_n^{(1)}\left(n+\frac{1}{2}\right) \\
&\overset{[1,\ (9.3.31),\ (9.3.32)]}{=} \pi\left(\frac{2^{1/3}}{3^{2/3}\Gamma\left(\frac{2}{3}\right)}\right)^2 k^{-2/3}\left(\sqrt{3}+\mathrm{i}\right)(1+o(1))
\end{aligned}
$$

and

$$
\begin{aligned}
\lambda_{n,k}^{(K)} &= \mathrm{i}\,k^2 h_n^{(1)}(k)\, j_n'(k) \overset{(5.13)}{=} \mathrm{i}\,k^2 \frac{\pi}{2k} H_k^{(1)}(k)\, \frac{\left(\left(k-\frac{1}{2}\right) J_{k-1}(k) - \left(k+\frac{1}{2}\right) J_{k+1}(k)\right)}{2k} \\
&\overset{[1,\ (9.1.27)(1)\text{-}(2)]}{=} \mathrm{i}\,k\frac{\pi}{2} H_k^{(1)}(k)\left(J_k'(k) - \frac{1}{2k} J_k(k)\right) \\
&\overset{[1,\ (9.3.31\text{-}34)]}{\sim} \frac{\mathrm{i}+\sqrt{3}}{2\sqrt{3}}(1+o(1)).
\end{aligned}
$$

Ad 3. Let k be fixed and $n \to \infty$.

The definition of the spherical Bessel and Hankel functions implies in that case

$$\lambda_{n,k}^{(V)} = \frac{2\,\mathrm{i}\,k \cdot k^n \left\{1 - \frac{k^2/2}{2n+3} + O\left(n^{-2}\right)\right\}}{1 \cdot 3 \cdot \cdots \cdot (2n+1)} \times \frac{1 \cdot 3 \cdot \cdots \cdot (2n-1)\left\{1 - \frac{k^2/2}{1-2n} + O\left(n^{-2}\right)\right\}}{\mathrm{i}\,k^{n+1}}$$
$$= \frac{2}{2n+1}\left(1 + O\left(n^{-2}\right)\right)$$

and

$$\lambda_{n,k}^{(K)} = \mathrm{i}\,k^2 h_n^{(1)}(k)\, j_n'(k) = \frac{n}{2n+1}\left(1 + O\left(\frac{1}{n}\right)\right) = \frac{1}{2} + O\left(\frac{1}{n}\right). \qquad \square$$

Lemma 5.6 leads to the following asymptotic behavior of the real and imaginary parts of the eigenvalues $\lambda_{n,k}^{(R)}$. We restrict ourselves to the case $k \geq k_0 > 0$. The "$\sim$"-notation indicates that we neglect the higher order terms in Lemma 5.6. The numbers $a_0, \ldots, a_4$ below are positive and may depend on k_0 but not on k.

- $n = 0$, $k \to \infty$:

  (5.16a)
  $$\operatorname{Re}\lambda_{0,k}^{(R)} \sim \sin k \cos k \left(\frac{2}{k} - a_0\eta\right) \quad \text{and} \quad \operatorname{Im}\lambda_{0,k}^{(R)} \sim 2\frac{\sin^2 k}{k} + a_0\eta\cos^2 k.$$

- $n + \frac{1}{2} = k$:

  (5.16b)
  $$\sqrt{1+n^2}\operatorname{Re}\lambda_{n,k}^{(R)} \sim a_1 k^{1/3} - \frac{a_2\eta}{k^{2\varepsilon}} \quad \text{and} \quad \sqrt{1+n^2}\operatorname{Im}\lambda_{n,k}^{(R)} \sim a_3 k^{1/3} + \frac{a_4\eta}{k^{2\varepsilon}}.$$

- k fixed and $n \to \infty$:

  (5.16c)
  $$\sqrt{1+n^2}\operatorname{Re}\lambda_{n,k}^{(R)} \sim 1 \quad \text{and} \quad \operatorname{Im}\lambda_{n,k}^{(R)} \to 0.$$

5.4. Choice of η. Our goal is to stabilize the single layer potential V_k such that the constant governing the convergence behavior, i.e., $2C_X/\alpha_0$, and the bound for the maximal step width h_0 are as close as possible to those of the pure single layer potential away from the forbidden frequencies. The asymptotic behavior of the eigenvalues in (5.16b) indicates that the continuity constant C_X in (5.9) cannot behave better than $O\left(k^{1/3}\right)$. This leads to the heuristics to choose the stabilization parameter η maximal under the side condition that C_X still is bounded by $Ck^{1/3}$. The asymptotics (5.16a)–(5.16c) show that the choice $\eta = k^{1/3}$ leads to the bound

$$\sqrt{1+n^2}\left|\lambda_{n,k}^{(R)}\right| \leq Ck^{1/3}$$

for the three asymptotic cases, while the choice $\eta = k^{1/3+\delta}$ for any $\delta > 0$ would lead to an increased constant $C_X = O\left(k^{1/3+\delta}\right)$; cf. (5.16a).

We have performed computer experiments to study the behavior of $\sqrt{1+n^2}|\lambda_{n,k}^{(R)}|$ in the intermediate ranges.

a. Figure 5.1 indicates that the case $n + \frac{1}{2} = k$ (Lemma 5.6(2)) is relevant for the upper bound of $\sqrt{1+n^2}|\lambda_{n,k}^{(V)}|$ and this choice leads to

(5.17)
$$\sqrt{1 + \left(k - \frac{1}{2}\right)^2}\left|\lambda_{k-1/2,k}^{(V)}\right| \overset{\text{Lemma 5.6(2)}}{\leq} C' k^{1/3}.$$

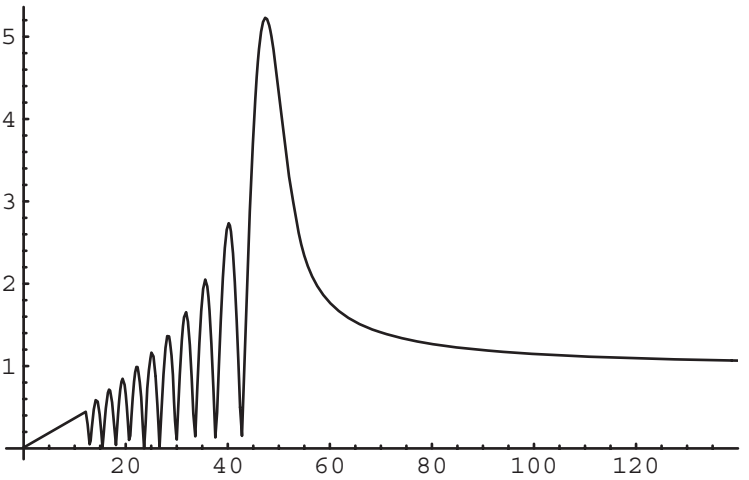

FIG. 5.1. *Plot of* $\sqrt{1+n^2}\left|\lambda_{n,k}^{(V)}\right|$ *for* $k = 50$ *in the range of* $1 \le n \le 300$. *The maximum is achieved at about* $n = k - 1/2$. *Pictures for different values of* k *show the same behavior.*

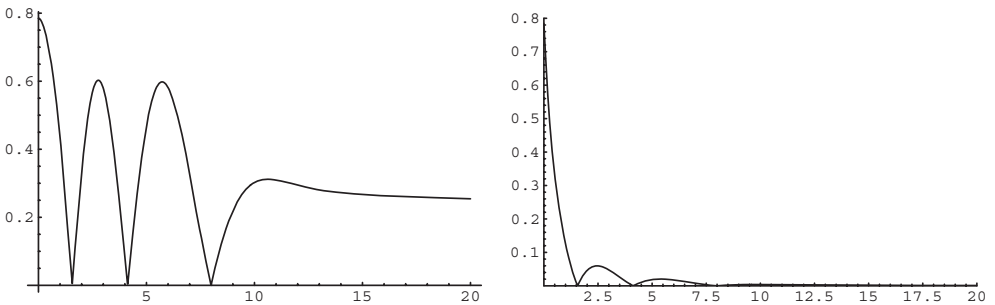

FIG. 5.2. *Plot of* $\sqrt{1+n^2}|\tilde{\lambda}_n^{(B)}\lambda_{n,k}^{(K)}|$ *for* $k = 10$ *and* $\varepsilon = \frac{1}{10}$ *(left picture),* $\varepsilon = 1$ *(right picture) in the range of* $0 \le n \le 20$. *The function decreases as* $n \to \infty$. *The maximum is achieved at* $n = 0$. *Pictures for different values of* k *show qualitatively the same behavior.*

b. We have plotted the upper bound of $|\sqrt{1+n^2}\tilde{\lambda}_n^{(B)}\lambda_{n,k}^{(K)}|$ for a small value $\varepsilon = 0.1$ and the maximal value $\varepsilon = 1$ to study its qualitative behavior. Figure 5.2 indicates that the case $n = 0$ is relevant for the upper bound and this choice leads to the (rough) estimate (cf. Lemma 5.2 (b.ii) for $n = 0$)

$$\left|\lambda_0^{(B)}\lambda_{0,k}^{(K)}\right| \le C\left|\cos k - \frac{\sin k}{k}\right| \le 2C. \tag{5.18}$$

Hence the estimates (5.17), (5.18) along with the asymptotics (5.16a)–(5.16c) suggest $\eta \le k^{1/3}$ in order not to destroy the upper bound for the continuity constant C_X.

DEFINITION 5.7. [illegible] η [illegible] (2.4) [illegible]

$$\eta := k^{1/3}.$$

5.5. Computer based analysis of the constant C_μ. Recall the choice of the shift parameter μ as in (5.8) and the formula (5.10) for the constant $C_\mu = \sup_{n\in\mathbb{N}} \frac{\beta_{n,k}}{\gamma_{n,k}}$,

where

$$\beta_{n,k} := \left(1+n^2\right)^{\frac{\mu+1}{2}} \left|\lambda_{n,k}^{(R)} - \frac{2}{2n+1} - \frac{\mathrm{i}\,\eta}{2}\lambda_n^{(B)}\right| \quad \text{and} \quad \gamma_{n,k} := \sqrt{1+n^2}\left|\lambda_{n,k}^{(R)}\right|.$$

First, we will estimate the behavior of $\beta_{n,k}$. The results of the asymptotic analysis (see Lemma 5.6 and (5.16)) together with (5.5) yield the following:

1. $n = 0$ and $k \to \infty$,

$$\left(1+n^2\right)^{\frac{\mu+1}{2}} \left|\lambda_{n,k}^{(R)} - \frac{2}{2n+1} - \frac{\mathrm{i}\,\eta}{2}\lambda_n^{(B)}\right| \le a_5 k^{1/3}; \tag{5.19a}$$

2. for $n + \frac{1}{2} = k$,

$$\left(1+n^2\right)^{\frac{\mu+1}{2}} \left|\lambda_{n,k}^{(R)} - \frac{2}{2n+1} - \frac{\mathrm{i}\,\eta}{2}\lambda_n^{(B)}\right| \le a_6 k^{\mu+1/3}; \tag{5.19b}$$

3. for k fixed and $n \to \infty$,

$$\left(1+n^2\right)^{\frac{\mu+1}{2}} \left|\lambda_{n,k}^{(R)} - \frac{2}{2n+1} - \frac{\mathrm{i}\,\eta}{2}\lambda_n^{(B)}\right| \le a_7 k^{1/3}. \tag{5.19c}$$

In Figure 5.3, the function $\left(1+n^2\right)^{\frac{\mu+1}{2}} |\lambda_{n,k}^{(R)} - \frac{2}{2n+1} - \frac{\mathrm{i}\,\eta}{2}\lambda_n^{(B)}|$ is depicted for $k = 20$ indicating that the bounds derived from asymptotic analysis are valid in neighborhoods of $n = 0$, $n = k - 1/2$ as well.

Next, we will investigate the behavior of $\gamma_{n,k}$. The asymptotic behavior of $\gamma_{n,k}$ as $n \to \infty$ is derived by using (5.16c)

$$\left|\gamma_{n,k}\right| \ge \sqrt{1+n^2}\left|\operatorname{Re}\lambda_{n,k}^{(R)}\right| \sim 1 \quad \text{for } k \text{ fixed and } n \to \infty.$$

By choosing $\eta = k^{1/3}$, the function $\operatorname{Re}\lambda_{n,k}^{(R)}$ is oscillating as a function of $n < k$ about zero and bounded from below properly away from zero for $n \ge k$ (cf. Figure 5.4). This supports the heuristics

$$\inf_{n\ge k} \gamma_{n,k} \ge \inf_{n\ge k} \left\{\sqrt{1+n^2}\operatorname{Re}\lambda_{n,k}^{(R)}\right\} \ge 1. \tag{5.20a}$$

The behavior of $\gamma_{n,k}$ in the range $0 \le n < k$ is more complicated.

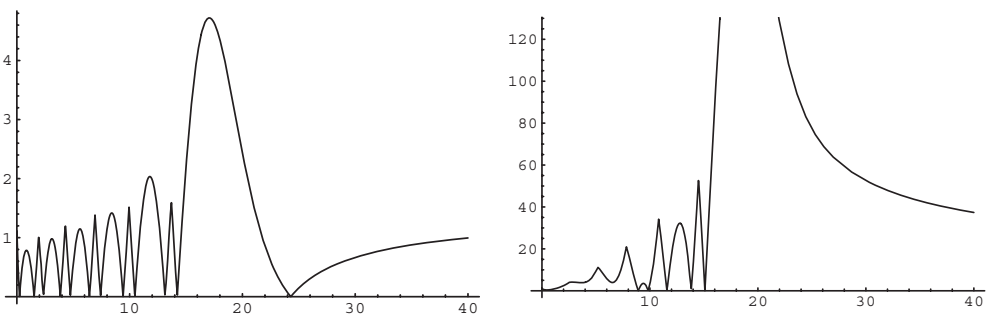

FIG. 5.3. *Plot of* $\left(1+n^2\right)^{\frac{s+1}{2}} |\lambda_{n,k}^{(R)} - \frac{2}{2n+1} - \frac{\mathrm{i}\,\eta}{2}\tilde{\lambda}_n^{(B)}|$ *for* $k = 20$ *and* $\varepsilon = \frac{1}{10}$ *(left),* $\varepsilon = 1$ *(right) in the range of* $n \in [0, 40]$.

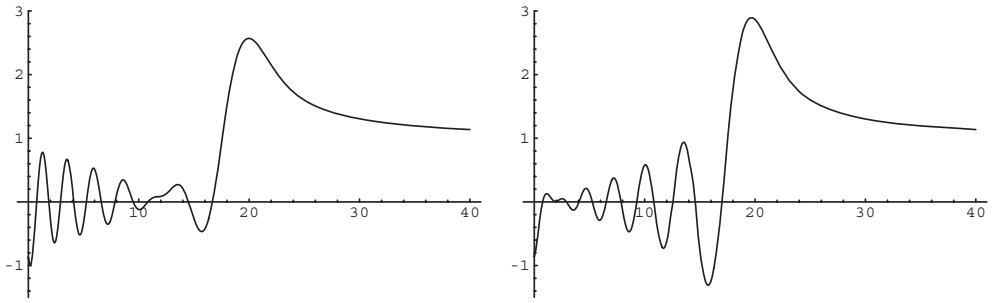

FIG. 5.4. *Function* $\sqrt{1+n^2}\,\mathrm{Re}\,\tilde{\lambda}_{n,k}^{(R)}$ *for fixed* $k = 20$ *and* $\varepsilon = \frac{1}{10}$ *(left picture),* $\varepsilon = 1$ *(right picture) in the range* $n \in [0, 40]$. *The function values are oscillating for* $n \in [0, k[$ *about zero and bounded from below away from zero in the range* $n \geq k$.

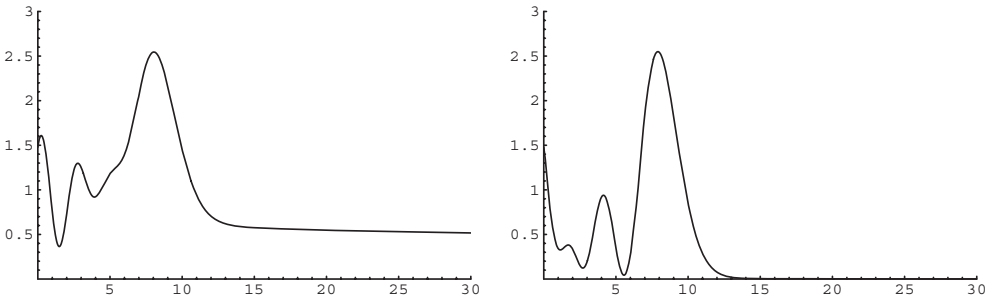

FIG. 5.5. *Plot of* $\sqrt{1+n^2}\,\mathrm{Im}\,\tilde{\lambda}_{n,k}^{(R)}$ *for* $k = 10$ *and* $\varepsilon = \frac{1}{10}$ *(left picture),* $\varepsilon = 1$ *(right picture) in the range* $0 \leq n \leq 30$. *The function values are all positive and decreasing as* $n \to \infty$.

By choosing $\eta = k^{1/3}$, the function $\mathrm{Im}\,\lambda_{n,k}^{(R)}$ is positive for all $n \geq 0$ and $k \geq 0$ (cf. Figure 5.5).

Since the quantities $\mathrm{Re}\,\lambda_{n,k}^{(R)}$ are oscillating in the range $0 \leq n \leq k$, we employ the imaginary part to bound $\gamma_{n,k}$ from below

$$\gamma_{n,k} \geq \sqrt{1+n^2}\,\mathrm{Im}\,\lambda_{n,k}^{(R)} = f_1(n,k) + f_2(n,k,\varepsilon)\,, \tag{5.21}$$

where

$$f_1(n,k) := \sqrt{1+n^2}\,\mathrm{Im}\,\lambda_{n,k}^{V} \quad \text{and} \quad f_2(n,k,\varepsilon) := \sqrt{1+n^2}\,\mathrm{Im}\left(\mathrm{i}\,\eta\lambda_n^{(B)}\lambda_{n,k}^{(K)}\right).$$

We have plotted both summands in the right-hand side of (5.21) for $\eta = k^{1/3}$ in the range $0 \leq n \leq k$ separately (cf. Figure 5.6).

In the range $0 \leq n \leq k$, the function f_1 is large when f_2 is zero or close to zero while, vice versa, f_2 is large when f_1 is zero or close to zero. The maxima of f_1 are monotonously increasing while the maxima of f_2 are monotonously decreasing. These observations lead to the following heuristics.

- If n is small, then

$$\gamma_{n,k} \geq \sqrt{1+n^2}\,\mathrm{Im}\,\lambda_{n,k}^{(R)} \geq a_8 f_1(n_0,k) \overset{(5.16a)}{\geq} a_9 k^{-1}, \tag{5.20b}$$

  where n_0 denotes the first local maximum of f_1 and a_8, a_9 depend only on k_0.

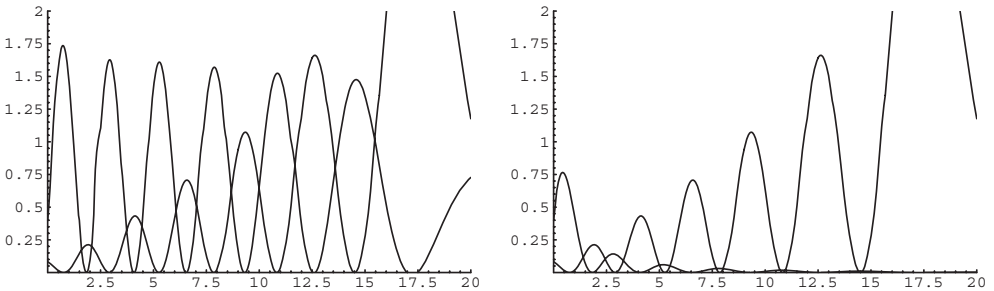

FIG. 5.6. *Functions* $\sqrt{1+n^2}\,\mathrm{Im}\,\lambda_{n,k}^V$ *and* $\sqrt{1+n^2}\,\mathrm{Im}(\mathrm{i}\,\eta\tilde{\lambda}_n^{(B)}\lambda_{n,k}^{(K)})$ *for* $k=20$ *and* $\varepsilon=\frac{1}{10}$ *(left picture),* $\varepsilon=1$ *(right picture) as a function of* n *in the range* $0\le n\le 20$. *The zeros and extrema are properly separated.*

- If n is close to k but smaller than k, then

  (5.20c)
  $$\gamma_{n,k}\ge\sqrt{1+n^2}\,\mathrm{Im}\,\lambda_{n,k}^{(R)}\ge a_{10}f_2\left(k-\frac{1}{2},k,\varepsilon\right)\overset{(5.5),\ \text{Lemma 5.6(2)},}{\ge}a_{11}k^{1/3-2\varepsilon},$$

  where a_{10}, a_{11} depend only on k_0.

We combine the estimates (5.19) and (5.20) and obtain the following heuristics.

- If n is small, then
  $$\beta_{n,k}/\gamma_{n,k}\le a_{12}k^{4/3}.$$
- If n is close to k but smaller than k, then
  $$\beta_{n,k}/\gamma_{n,k}\le a_{13}k^{\mu+2\varepsilon}.$$
- If k is fixed and n becomes large, then
  $$\beta_{n,k}/\gamma_{n,k}\le a_{14}k^{1/3}.$$

This leads to the heuristics

$$C_\mu=\sup_{n\ge0}\frac{\beta_{n,k}}{\gamma_{n,k}}\le a_{15}k^{\max\{4/3,\mu+2\varepsilon\}}. \tag{5.22}$$

To verify the qualitative dependence of C_μ on k numerically in the whole range of n we have evaluated the quantity $k^{-\max\{4/3,\mu+2\varepsilon\}}\beta_{n,k}/\gamma_{n,k}$ as a function of n for different values of k and ε by the software [illegible]. In Table 5.1, the results are depicted which strongly support the heuristics that the asymptotic behavior as in (5.22) is valid in the whole range of n.

5.6. Estimates on the constants of interest. We combine the general error estimate (cf. Theorem 4.3) with the estimate for the continuity constant C_X (cf. subsection 5.4) to obtain an estimate of the Galerkin error which is explicit with respect to the wave number k.

THEOREM 5.8. [illegible] h [illegible] $h<h_0$ h_0 [illegible] (4.12). [illegible] $\hat{C}$ $k_0>0$ [illegible] $k\ge k_0$

$$\frac{\|\varphi-\varphi_h\|_{H^{-1/2}(\Gamma)}}{\|\varphi\|_{H^{-1/2}(\Gamma)}}\le\hat{C}k^{1/3}\,(hk)^{3/2}. \tag{5.23}$$

TABLE 5.1
Numerical verification of the heuristics (5.22) *for the constant* C_μ. *The table lists the numerical determined value of* $k^{-\max\{4/3,\mu+2\varepsilon\}} \sup_{n\geq 0} \beta_{n,k}/\gamma_{n,k}$ *which we expect to be bounded by a constant independent of* k.

ε	$k=10$	$k=20$	$k=40$	$k=80$	$k=160$
$\frac{1}{20}$	0.307	0.301	0.284	0.258	0.240
$\frac{1}{5}$	0.251	0.278	0.268	0.238	0.201
1	0.0917	0.142	0.164	0.162	0.148

Finally, we will determine the dependence of the maximal step size h_0 on the wave number k such that existence and uniqueness of the Galerkin solution is guaranteed. The combination of (4.12) with the results of subsection 5.4 and (5.22) leads to the condition

$$h_0^\mu k^{1/3} k^{\max\{4/3,\mu+2\varepsilon\}} \leq C, \tag{5.24}$$

where the constant C is independent of k and ε. Recall that $\mu = \min\{3/2, 1+2\varepsilon\}$. We distinguish the following cases.

1. $0 \leq \varepsilon \leq \frac{1}{12}$. Condition (5.24) takes the form
$$h^{1+2\varepsilon} k^{5/3} \leq C.$$
2. $\frac{1}{12} \leq \varepsilon \leq \frac{1}{4}$. Condition (5.24) takes the form
$$h^{1+2\varepsilon} k^{4/3+4\varepsilon} \leq C.$$
3. $\frac{1}{4} \leq \varepsilon \leq 1$. Condition (5.24) takes the form
$$h^{3/2} k^{11/6+2\varepsilon} \leq C.$$

By inspecting these cases we derive that the choice $\varepsilon = 1/12$ is optimal and the condition

$$(hk)\, k^{\frac{3}{7}} \leq C$$

ensures existence and uniqueness. In Table 5.2, the Galerkin error estimate and the stability condition are listed for different choices of $\gamma_0 B$.

We finish this section by comparing these results with the quantitative analysis of the Brakhage–Werner stabilization which we briefly recall. For the solution of the Helmholtz problem, the ansatz

$$u_+ = D_k \psi - i\eta S_k \psi$$

TABLE 5.2
Stability condition and estimate of the relative Galerkin error for different choices of $\gamma_0 B$.

$\gamma_0 B$	ε	Stability condition	Rel. Galerkin error is smaller than
$(V_0)^2$	$\frac{1}{2}$	$hk^{1+8/9} \leq C$	$\hat{C} k^{1/3} (hk)^{3/2}$
B_1	1	$hk^{1+14/19} \leq C$	$\hat{C} k^{1/3} (hk)^{3/2}$
$B_{1/12}$	$\frac{1}{12}$	$hk^{1+3/7} \leq C$	$\hat{C} k^{1/3} (hk)^{3/2}$

is employed and the density ψ is determined by solving the following boundary integral equation:

Find $\psi \in L^2(\Gamma)$ such that

$$\left(\left(\frac{1}{2} I + K_k - i\eta V_k \right) \psi, \sigma \right)_{0,\Gamma} = (g, \sigma)_{0,\Gamma} \qquad \forall \sigma \in L^2(\Gamma).$$

Let ψ_h denote the corresponding Galerkin solution where $L^2(\Gamma)$ is replaced by the piecewise constant boundary element space S as in (3.2). By choosing $\eta \sim k/4$, it was proved in [17]—for Γ being the surface of the unit sphere—that the relative error can be estimated by

$$\frac{\|\psi - \psi_h\|_{L^2(\Gamma)}}{\|\psi\|_{L^2(\Gamma)}} \leq \hat{C} k^{1/3} (hk).$$

By comparing this result with Table 5.2 it is obvious that the pollution factor which amplifies the error of the best approximation is $k^{1/3}$ for both cases, the Brakhage–Werner approach and the stabilized acoustic single layer potential. On the other hand, the convergence rate $(hk)^{3/2}$ compared to (kh) is higher for the stabilized single layer ansatz. In addition, we emphasize that the stability behavior of the acoustic single layer potential can be proved for general Lipschitz polyhedra while the proof of the well-posedness of the Brakhage–Werner approach is restricted to smooth surfaces. For the special case of a sphere, the stability condition $hk \lesssim 1$ for the Brakhage–Werner formulation is better compared to the stability condition $hk^{1+3/7} \lesssim 1$ for the stabilized single layer potential.

5.7. Oscillation condition. In this subsection, we will investigate the oscillation condition (4.15) in the case of the unit sphere.

Any right-hand side $g \in H^{1/2}(\Gamma)$ in (2.5) has a Fourier representation

$$g = \sum_{n=0}^{\infty} \sum_{m=-n}^{n} g_n^m Y_n^m.$$

Due to the orthogonality of the spherical harmonics, the solution of (2.5) has the representation

$$\varphi = \sum_{n=0}^{\infty} \frac{1}{\lambda_{n,k}^{(R)}} \sum_{m=-n}^{n} g_n^m Y_n^m.$$

The ratio of the $H^1(\mathbb{S}^2)$- and the $H^{-1/2}(\mathbb{S}^2)$-norms takes the form

$$Q(g) := \frac{\displaystyle\sum_{n=0}^{\infty} \frac{1+n^2}{\left|\lambda_{n,k}^{(R)}\right|} |g_n|^2}{\displaystyle\sum_{n=0}^{\infty} \frac{|g_n|^2}{\sqrt{1+n^2}\left|\lambda_{n,k}^{(R)}\right|}} = \frac{\|\varphi\|_{H^1(\Gamma)}^2}{\|\varphi\|_{H^{-1/2}(\Gamma)}^2} \quad \text{with} \quad |g_n|^2 := \sum_{n=-m}^{m} |g_n^m|^2.$$

By the substitution $w_n := \frac{g_n}{(1+n^2)^{1/4} |\lambda_{n,k}^{(R)}|^{1/2}}$ we obtain

$$Q(g) = \left(\sum_{n=0}^{\infty} \left(1+n^2\right)^{3/2} |w_n|^2 \right) / \|w_n\|_0^2.$$

It is not our goal to derive sharp decay conditions for the Fourier coefficients of the right-hand side $g \in H^{1/2}(\Gamma)$ so that $Q(g)$ is bounded by $C\left(1+k^2\right)^{3/2}$ and the oscillation property (4.15) is valid with properly chosen $\rho = O(1)$. Instead we will discuss the characteristic case that all oscillations in g vanish starting from $n \geq k$; i.e., all oscillations in the solution stem from the boundary integral equation itself and not from the right-hand side.

PROPOSITION 5.9. [illegible] $\Gamma = \mathbb{S}^2$ [illegible] g_n^m [illegible] $g \in H^{1/2}(\Gamma)$ [illegible] (3.1) [illegible]

$$g_n^m = 0 \qquad \forall n > k \quad -n \leq m \leq n$$

[illegible]

$$Q(g) \leq \left(1+k^2\right)^{3/2}$$

[illegible] (4.15) [illegible] $\rho = O(1)$

6. Computational complexity. In this section, we will remark on the computational complexity related to the different choices of the operator B.

The computation of the Galerkin system matrix $\mathbf{R}_k$ for (3.3) requires the evaluation of the integrals $(R_k b_\tau, b_t)_{\tau,t\in\mathcal{T}}$. Besides the additive term $K_k\gamma_0 B$ in (2.4), the discretization of the arising integral operators is standard. The numerical treatment of the composition $K_k\gamma_0 B$ is discussed in the following remark.

[illegible] 6.1. In the context of the Galerkin boundary element method, the exact computation of the system matrix entries is not possible in general and, e.g., numerical quadrature and panel clustering have to be employed. This leads to a perturbed Galerkin method and the accuracy requirements are determined via Strang's lemma [18]. In this light, we recommend replacing the matrix entries $\mathbf{W}_{\tau,t} := (K_k\gamma_0 B b_\tau, b_t)_0$ by $\tilde{\mathbf{W}}_{\tau,t} := (K_k P\gamma_0 B b_\tau, b_t)_0$, where P denotes the L^2-orthogonal projection onto $\mathcal{S}$. The advantage is that $\tilde{\mathbf{W}}$ has the representation

$$\tilde{\mathbf{W}} = \mathbf{K}_k\mathbf{M}^{-1}\mathbf{B},$$

where $\mathbf{K}_k := \left((K_k b_\tau, b_t)_0\right)_{\tau,t\in\mathcal{T}}$, respectively, $\mathbf{B} := \left((\gamma_0 B b_\tau, b_t)_0\right)_{\tau,t\in\mathcal{T}}$, are the standard Galerkin system matrices of K_k, respectively, $\gamma_0 B$, or approximations to it. The mass matrix $\mathbf{M} = \left((b_\tau, b_t)_0\right)_{\tau,t\in\mathcal{T}}$ is diagonal and its inversion is trivial.

In other words, the Galerkin system matrix $\mathbf{R}_k$ for the operator R_k can be approximately computed from the system matrices $\mathbf{V}_k$, $\mathbf{K}_k$, $\mathbf{B}$ (or approximations thereof) via

$$\widehat{\mathbf{R}}_k := \mathbf{V}_k + \mathrm{i}\,\eta\left(\frac{1}{2}\mathbf{B} + \mathbf{K}_k\mathbf{M}^{-1}\mathbf{B}\right).$$

Some comments concerning the complexity are listed below.

- Since for large problems the linear system should be solved iteratively, the matrix entries of $\widehat{\mathbf{R}}_k$ need not be computed explicitly; only a procedure for a matrix-vector multiplication has to be provided. Hence, the matrix-matrix multiplication $\mathbf{K}_k\mathbf{M}^{-1}\mathbf{B}$ does not have to be carried out, but $\mathbf{K}_k\mathbf{M}^{-1}\mathbf{B}\mathbf{v}$ can be realized by a matrix-vector multiplication with $\mathbf{K}_k$, one diagonal scaling, and the evaluation of $\mathbf{B}\mathbf{v}$. Table 6.1 lists the different strategies for this evaluation.

TABLE 6.1
Evaluation of $\mathbf{Bv}$.

$\gamma_0 B$	Storage	Matrix-vector multiplication
$(V_0)^2$	$\mathbf{V}_0 = \big((V_0 b_\tau, b_t)_0\big)_{\tau,t\in\mathcal{T}}$	$\mathbf{Bv} = \mathbf{V}_0\mathbf{M}^{-1}\mathbf{V}_0\mathbf{v}$
B_1	$\mathbf{B}_1 := \big((B_1 b_\tau, b_t)_0\big)_{\tau,t\in\mathcal{T}}$	$\mathbf{Bv} = \mathbf{B}_1\mathbf{v}$
$B_{1/12}$	$\mathbf{B}_{1/12} := \Big(\big(B_{1/12} b_\tau, b_t\big)_0\Big)_{\tau,t\in\mathcal{T}}$	$\mathbf{Bv} = \mathbf{B}_{1/12}\mathbf{v}$

- Since $\mathbf{B}$ is independent of the possibly high wave number k, the accuracy requirements for numerical quadrature, panel-clustering, and iterative solution are reduced compared to $\mathbf{V}_k$, $\mathbf{K}_k$. Hence, we expect that the extra cost for the stabilization is moderate.
- The choices $\mathbf{V}_0$, $\mathbf{B}_1$, $\mathbf{B}_{1/12}$ correspond to the discretization of a boundary integral operator (such as $\mathbf{V}_k$ and $\mathbf{K}_k$). Hence, the numerical implementation does not require any new data structures. By using the blackbox quadrature methods (cf. [16]) and/or the panel-clustering based on interpolation (cf. [5], [25]) the discretization of $\gamma_0 B$ requires only a subroutine for the evaluation of the integral kernel in (2.13).

Acknowledgments. Thanks are due to Prof. Herbert Amann for fruitful discussions. Some of the results were achieved during the authors' stay at the Mathematische Forschungsinstitut Oberwolfach. This support is greatly acknowledged.

A FULLY MASS AND VOLUME CONSERVING IMPLEMENTATION OF A CHARACTERISTIC METHOD FOR TRANSPORT PROBLEMS*

TODD ARBOGAST† AND CHIEH-SEN HUANG‡

Abstract. The characteristics-mixed method considers the transport not of a single point or fluid particle, but rather the mass in an entire region of fluid. This mass is transported along the characteristic curves of the hyperbolic part of the transport equation, and the scheme thereby produces very little numerical dispersion, conserves mass locally, and can use long time steps. However, since the shape of a characteristic trace-back region must be approximated in numerical implementation, its volume may be incorrect, resulting in inaccurate concentration densities and, further, inaccurate reaction dynamics. We present a simple modification to the characteristics-mixed method that conserves both mass and volume of the transported fluid regions. Our algorithm also handles boundary conditions through a space-time change of variables in the trace-back routines, which allows the boundary to be treated as if it were interior to the domain. Nearly point sources, such as wells, present special difficulties, since characteristic trace-back curves converge in their vicinity. We also present techniques that allow one to conservatively implement wells. The techniques are illustrated in five numerical examples.

1. Introduction.

We consider in this paper the problem of tracer transport in a flow field, as might arise in a porous medium or a shallow water or atmospheric system. We concentrate on the problem as it arises in porous media simulation, though many of the ideas carry over to other contexts.

Let $\Omega \subset \mathbb{R}^2$ be our bounded domain, and consider an incompressible bulk fluid of velocity $\mathbf{u}(\mathbf{x}, t)$ satisfying the incompressibility condition

$$\nabla \cdot \mathbf{u} = q, \quad \Omega \times J, \tag{1.1}$$

where $q(\mathbf{x}, t)$ is a given external source or sink function, assumed smooth enough for our purposes, and $J = (0, \infty)$ is the time interval. Our interest lies in the transport of some dilute tracer or other solute species of concentration $c(\mathbf{x}, t)$ within the bulk fluid. We assume that it does not change the overall velocity $\mathbf{u}$. The concentration will generally satisfy an advection-diffusion equation of the form

$$(R\phi c)_t + \nabla \cdot (c\mathbf{u} - D\nabla c) = c_I q_+ + c q_- \equiv q_c(c), \quad \Omega \times J, \tag{1.2}$$

where $R(\mathbf{x})$ is the retardation factor, $\phi(\mathbf{x})$ is the storage factor of the medium called porosity, subscript t is time partial differentiation, $D(\mathbf{x}, t)$ is the diffusion/dispersion

coefficient (that may also depend on $\mathbf{u}$), $q_+(\mathbf{x},t) \geq 0$ is q when $q > 0$ and 0 otherwise, $q_-(\mathbf{x},t) = q - q_+ \leq 0$, and $c_I(\mathbf{x},t)$ is the given concentration of injected fluid.

To apply characteristic methods to (1.2), one generally uses an operator splitting technique to isolate the hyperbolic and parabolic parts of the equation. That is, over a time step, one approximates the hyperbolic part of the operator,

$$(R\phi c)_t + \nabla \cdot (c\mathbf{u}) = q_c(c), \quad \Omega \times J, \tag{1.3}$$

and the parabolic part,

$$(R\phi c)_t - \nabla \cdot (D\nabla c) = 0, \quad \Omega \times J, \tag{1.4}$$

in some order. We discuss neither the operator splitting nor the approximation of the parabolic part in this paper.

The hyperbolic part of (1.3) is the most delicate to approximate well. It models pure transport of the fluid particles, while the rest of the operator, $-\nabla \cdot (D\nabla c)$, is diffusive. In the absence of shocks and diffusion, fluid particles simply travel along the characteristics of (1.3) (see (2.2) below). The fluid must obey two principles: [illegible] and incompressibility, or, loosely speaking, [illegible] (i.e., mass conservation of the incompressible bulk fluid). The first principle is well known; we make the second precise in the next section, but basically, for an incompressible fluid, the volume occupied by a given amount of mass is fixed.

Numerical methods based on fixed grids, such as Godunov's method [15], are locally mass conservative by design. They are also automatically volume conserving, since the volumes of the fixed grid elements do not change in time.

Moving mesh and characteristic methods, however, do not automatically conserve volume. Characteristic methods became viable when Douglas and Russell described their [illegible] in 1982 [12]. In their method, one approximates the characteristic derivative by a finite difference in the characteristic direction; that is,

$$c_\tau(\mathbf{x},t) \equiv c_t(\mathbf{x},t) + \frac{\mathbf{u}(\mathbf{x},t)}{R\phi} \cdot \nabla c(\mathbf{x},t) \approx \frac{c(\mathbf{x},t+\Delta t) - c(\hat{\mathbf{x}},t)}{\Delta t} ,$$

where $\mathbf{x}$ is a grid point, $\Delta t > 0$, and $\hat{\mathbf{x}}$ is defined by tracing the point $(\mathbf{x}, t+\Delta t)$ backwards in time along the characteristics to $(\hat{\mathbf{x}}, t)$ (see section 2). This results in the approximation

$$R\phi \frac{c(\mathbf{x},t+\Delta t) - c(\hat{\mathbf{x}},t)}{\Delta t} = (c_I - c)q_+$$

of (1.3). Because the method is based on points, it violates [illegible] local mass and volume constraints. A subsequent modification produced a global mass balance [10], but not a local mass balance.

Various ELLAM [6] schemes have been developed based on the local mass constraint, including the characteristics-mixed method [2, 3] and its two-phase variant [11]. The basic idea is to trace back along the characteristics each entire grid element E to $\hat{E}$. In this way, all mass can be accounted for locally; that is, all the mass in $\hat{E}$ is numerically transported forward into E. In the absence of sources, sinks, and external boundaries, the volumes of E and $\hat{E}$ agree. However, to trace $\hat{E}$ back in time requires tracing each boundary point back, which can only be done in one space dimension (unless perhaps the velocity is particularly simple). So, in practice, one

must approximate $\hat{E}$ by some simpler shape $\tilde{E}$ by, say, tracing back only the vertices of the element. Almost assuredly the volumes of $\tilde{E}$ and $\hat{E}$ will disagree, violating the volume conservation principle.

Although mass is conserved locally, incorrect local volumes lead to incorrect concentrations, which measure mass per volume. That is, the density is incorrectly approximated and can lead to overshoot or undershoot and seriously degrade the quality of the solution over time, especially when reaction dynamics, based on densities, are also considered.

We present in this paper a simple and relatively computationally efficient method for adjusting the trace-back regions $\hat{E}$ to $\tilde{E}$. The difficulty, of course, is that the set of $\tilde{E}$ must tessellate the region (i.e., they must have no overlaps or gaps). For simplicity of exposition, we consider in this paper only a two-dimensional (2-D) domain and a rectangular grid of elements. In principle, our ideas should generalize to other grids and even to three dimensions, but we expect the difficulty of implementation to be considerable, and so we have no numerical experience to report for these cases at this time.

A more computationally expensive method was proposed by Chilakapati [7, 8]. He proposed a procedure that modifies the way in which the Darcy velocity itself is computed and then applies this to the advection equation.

An outline of this paper follows. We define the characteristics in the next section, and point out that our techniques cannot handle multiple characteristics as might arise in multiphase flow. In section 3, we then carefully derive the local mass and volume constraints. Since sources and sinks in porous media simulation arise from wells, which are very small, the source terms must be approximated carefully. Similar to sources are inflow boundaries, where $\mathbf{u}\cdot\nu < 0$ and points track out of the domain as time reverses. When the flow is not too strong, we have simple techniques for handling injection wells and inflow boundaries, as described in sections 4 and 5. Our trace-back point volume adjustment algorithm is described in section 6. For stronger flows, it is more effective to use a trace-forwarding technique to treat injection wells (and perhaps inflow boundaries), as presented in section 7. The final section is devoted to five numerical examples illustrating the need for volume adjustment and showing the efficacy of the proposed scheme.

2. Characteristic trace-back. In the absence of diffusion and dispersion (i.e., $D = 0$), fluid particles governed by (1.3) travel along paths called characteristics. In multiphase flow problems, there are multiple characteristics, as each phase flows at its own speed. We allow here only the relatively simple situation of linear adsorption, with a single fluid phase and a single incompressible solid phase. Assuming adsorption of the tracer but not the bulk fluid, the bulk and tracer fluid particles travel at different speeds. This can be seen more easily if the medium is considered as being compressible, i.e., ϕ depends also on time. Then (1.1) should be written as

$$\phi_t + \nabla \cdot \mathbf{u} = q, \quad \Omega \times J,$$

and we see that bulk fluid particles flow with velocity $\mathbf{u}/\phi$. However, tracer particles flow with velocity $\mathbf{u}/R\phi$, which is not the same if $R \neq 1$. Multiple characteristics cause difficulties, so we have assumed incompressibility of the medium (ϕ and R depend only on $\mathbf{x}$). Then (1.1) is equivalent to

$$(R\phi)_t + \nabla \cdot \mathbf{u} = q, \quad \Omega \times J, \tag{2.1}$$

with characteristic speed $\mathbf{u}/R\phi$. We remark that we could have instead assumed that $R = 1$ and allowed ϕ to depend on t. Our technique extends to this case.

We consider only flow during a time step, so let $\Delta t > 0$ be given and $t^n = n\Delta t$ for $n = 0, 1, \ldots$. As is usual, for a generic function φ, we denote $\varphi(t^n)$ by φ^n. The time interval of interest is $[t^n, t^{n+1}]$. The characteristic trace-back of the point $\mathbf{x} \in \Omega$ is denoted $\hat{\mathbf{x}} = \hat{\mathbf{x}}(\mathbf{x}; t)$, and it satisfies the (time backward) ordinary differential equation

$$\frac{d\hat{\mathbf{x}}}{dt} = \frac{\mathbf{u}(\hat{\mathbf{x}}, t)}{R(\hat{\mathbf{x}})\phi(\hat{\mathbf{x}})}, \quad t^n \le t < t^{n+1}, \tag{2.2}$$

$$\hat{\mathbf{x}}(t^{n+1}) = \mathbf{x}, \tag{2.3}$$

unless the particle traces to the boundary of the domain or is created at an external source. In either of these two exceptional cases, the particle arises from the outside world and must be treated accordingly.

3. The local mass and volume constraints. Let $\mathcal{T}$ be a finite partition of Ω into closed elements with disjoint interiors; that is, $\bar{\Omega} = \bigcup_{E\in\mathcal{T}} E$ and $\overset{\circ}{E}_i \cap \overset{\circ}{E}_j = \emptyset$ for all $i \ne j$. Often in our discussion $\mathcal{T}$ can be an arbitrary partition of Ω; however, sometimes we need more structure, so we tacitly assume that both Ω and the partition $\mathcal{T}$ are rectangular, with $\mathcal{T}$ having $M \times N$ elements. We use the usual Cartesian labeling of the grid points $\mathbf{x}_{i,j} = (x_i, y_j)$, where $i = 1, 2, \ldots, M+1$ and $j = 1, 2, \ldots, N+1$, and $x_i < x_{i+1}$ and $y_j < y_{j+1}$. Then rectangular element $E_{i,j} \in \mathcal{T}$ has vertices $\{\mathbf{x}_{i,j}, \mathbf{x}_{i+1,j}, \mathbf{x}_{i,j+1}, \mathbf{x}_{i+1,j+1}\}$. We also denote the midpoints of the element edges as $\mathbf{x}_{i+1/2,j} = (x_{i+1/2}, y_j)$ and $\mathbf{x}_{i,j+1/2} = (x_i, y_{j+1/2})$, where $x_{i+1/2} = (x_i + x_{i+1})/2$ and $y_{j+1/2} = (y_j + y_{j+1})/2$.

The key idea used to obtain mass conserving characteristic methods is to trace regions rather than points, an idea due to Arbogast and Wheeler [2, 3]. The particles in $E \in \mathcal{T}$ trace back to a region we call $\hat{E}$, defined by

$$\hat{E} = \{\hat{\mathbf{x}} \in \Omega : \hat{\mathbf{x}} = \hat{\mathbf{x}}(\mathbf{x}; t^n) \text{ for some } \mathbf{x} \in E\}.$$

In space and time, we actually trace a region $\mathcal{E} = \mathcal{E}(E)$ given by

$$\mathcal{E} = \{(\hat{\mathbf{x}}, t) \in \Omega \times [t^n, t^{n+1}] : \hat{\mathbf{x}} = \hat{\mathbf{x}}(\mathbf{x}; t) \text{ for some } \mathbf{x} \in E\}.$$

We decompose $\partial\mathcal{E}$ into three regions, viewing time as going "up." Then the "top" is E, where $t = t^{n+1}$; the "bottom" is $\hat{E}$, where $t = t^n$; and the "sides" we call $\mathcal{S}$. The sides come in two flavors. If particles trace back to the boundary of the domain, we have $\mathcal{S}_B = \partial\mathcal{E} \cap \partial\Omega \times (t^n, t^{n+1})$. Otherwise, we have the more usual interior side $\mathcal{S}_I = \partial\mathcal{E} \cap \Omega \times (t^n, t^{n+1})$. That is, we have the disjoint union

$$\partial\mathcal{E} = E \cup \hat{E} \cup \mathcal{S} = E \cup \hat{E} \cup \mathcal{S}_I \cup \mathcal{S}_B.$$

Local mass conservation of the tracer can be obtained over $E \in \mathcal{T}$ by integrating (1.3) in space-time over $\mathcal{E}$ and using the divergence theorem [3]. First, if $d\sigma$ is the space-time boundary differential on $\partial\mathcal{E}$, we compute

$$\begin{aligned}
\iint_{\mathcal{E}} q_c \, dx\, dt &= \iint_{\mathcal{E}} \nabla_{x,t} \cdot \begin{pmatrix} c\mathbf{u} \\ R\phi c \end{pmatrix} dx\, dt \\
&= \iint_{\partial\mathcal{E}} c \begin{pmatrix} \mathbf{u} \\ R\phi \end{pmatrix} \cdot \nu_{x,t} \, d\sigma \\
&= \int_E R\phi c^{n+1} \, dx - \int_{\hat{E}} R\phi c^n \, dx + \int_{\mathcal{S}} c \begin{pmatrix} \mathbf{u} \\ R\phi \end{pmatrix} \cdot \nu_{x,t} \, d\sigma,
\end{aligned}$$

since on the top and bottom of the domain $\nu_{x,t} = (0, \pm 1)$. The last term is integration on the space-time sides $\mathcal{S}$ of $\mathcal{E}$. Because the region $\mathcal{E}$ is defined by following characteristics, $\binom{\mathbf{u}}{R\phi}$ is orthogonal to $\nu_{x,t}$ on $\mathcal{S}_I$, that is, on $\mathcal{S}$ unless we have traced to the boundary of the domain. Thus the last term is

$$\int_{\mathcal{S}} c \begin{pmatrix} \mathbf{u} \\ R\phi \end{pmatrix} \cdot \nu_{x,t} \, d\sigma = \int_{\mathcal{S}_B} c\mathbf{u} \cdot \nu \, d\sigma,$$

since $\nu_{x,t} = \nu$ on $\mathcal{S}_B \subset \partial\Omega \times (t^n, t^{n+1})$.

The local mass constraint. Combining, we have the [illegible]

$$\int_E R\phi c^{n+1} \, dx - \int_{\hat{E}} R\phi c^n \, dx + \int_{\mathcal{S}_B} c\mathbf{u} \cdot \nu \, d\sigma = \iint_{\mathcal{E}} q_c \, dx \, dt. \tag{3.1}$$

This equation is the basis for approximation of (1.3) in the the characteristics-mixed method [2, 3], which uses piecewise discontinuous constant test functions defined over the space-time regions $\mathcal{E}$ (and the lowest order Raviart–Thomas mixed finite element [16] method for the parabolic part of the problem (1.4)).

The local volume constraint. A similar local mass constraint for the bulk fluid can also be derived analogously starting from the flow equation (1.1) or, equivalently, (2.1); that is, compute as above with $c \equiv 1$. Since we are dealing with incompressible fluids, we call this constraint the [illegible] and it is

$$\int_E R\phi \, dx - \int_{\hat{E}} R\phi \, dx + \int_{\mathcal{S}_B} \mathbf{u} \cdot \nu \, d\sigma = \iint_{\mathcal{E}} q \, dx \, dt. \tag{3.2}$$

As mentioned in the introduction, the reason why volume is not conserved locally is that the trace-back region $\hat{E}$ has an irregular shape, which must therefore be approximated by a simpler region $\tilde{E}$ so that the integrals in (3.1) can be evaluated. We propose to define $\tilde{E}$ as a simple octagonal shape that is approximately the original trace-back region $\hat{E}$. We do this by tracing back the four vertices and four midpoints of the edges of E and then adjusting the positions of these trace-back points locally until the volume constraint is satisfied (to some acceptably small tolerance). Recall that the characteristics are the solutions of a nonlinear ordinary differential equation (2.2)–(2.3), so these are approximated numerically. Thus the trace-back points $\hat{\mathbf{x}}$ are only approximately in the correct position to begin with, so some adjustment of them to maintain a system constraint seems quite reasonable.

4. Approximation of the integrals representing wells. We must approximate the integral of the source function in the volume balance equation (3.2). In porous medium applications, this function models wells, which have small scales that may require special consideration.

There is no need to treat the integral representing sink (i.e., production or extraction) wells in a special way, since they simply grow in size. If $q < 0$ on element E, the trace-back region $\hat{E}$ contains E. Thus

$$\iint_{\mathcal{E}} q \, dx \, dt = \int_{t^n}^{t^{n+1}} \int_E q \, dx \, dt \quad \text{and} \quad \iint_{\mathcal{E}} q_c \, dx \, dt = \int_{t^n}^{t^{n+1}} \int_E q_c \, dx \, dt,$$

and $\hat{E}$ can be adjusted as below in section 6 to satisfy (3.2). The only caveat is that we might choose to trace more than eight points on the boundary of E to obtain reasonable resolution of $\hat{E}$, since the trace-back points are diverging.

At an injection well ($q > 0$), fluid particles trace back into the well-bore where they arise. If we simply use the trapezoidal rule in time,

$$\iint_{\mathcal{E}} q\,dx\,dt \approx \frac{\Delta t}{2}\Big(\int_{\hat{E}} q^n\,dx + \int_E q^{n+1}\,dx\Big),$$

then if $\mathcal{S}_B$ is empty, the discrete volume constraint (3.2) becomes

$$\int_{\hat{E}} R\phi\,dx + \frac{\Delta t}{2}\int_{\hat{E}} q^n\,dx = \int_E R\phi\,dx - \frac{\Delta t}{2}\int_E q^{n+1}\,dx.$$

At injection, where $q > 0$, the left-hand side is positive, but the right-hand side could be [illegible] if Δt and/or q is large. Thus there is no adjustment of $\hat{E}$ that will result in local volume conservation. Since we desire to use large time steps with characteristic methods, simply restricting Δt is inappropriate.

Instead, we use a weighted trapezoidal rule with weight w between 0 and 1, as in

$$\iint_{\mathcal{E}} q\,dx\,dt \approx w\Delta t\int_{\hat{E}} q^n\,dx + (1-w)\Delta t\int_E q^{n+1}\,dx, \tag{4.1}$$

so that the volume constraint becomes

$$\int_{\hat{E}} R\phi\,dx + w\Delta t\int_{\hat{E}} q^n\,dx = \int_E R\phi\,dx - (1-w)\Delta t\int_E q^{n+1}\,dx. \tag{4.2}$$

We want to define w so that adjustment of $\hat{E} \subset E$ to $\tilde{E}$ results in volume conservation. We must adjust $\hat{E}$ to $\tilde{E}$ somewhere between the extreme cases of $\tilde{E} = E$ and $\tilde{E}$ being a point of size zero. That is, we need

$$\int_E R\phi\,dx + w\Delta t\int_E q^n\,dx \ge \int_E R\phi\,dx - (1-w)\Delta t\int_E q^{n+1}\,dx \ge 0, \tag{4.3}$$

so that we can define $\tilde{E}$ such that

$$\int_{\tilde{E}} R\phi\,dx + w\Delta t\int_{\tilde{E}} q^n\,dx = \int_E R\phi\,dx - (1-w)\Delta t\int_E q^{n+1}\,dx. \tag{4.4}$$

To determine an appropriate w, we argue as follows. Suppose that there is an injection well in element E. Since fluid is being injected, $q > 0$ and we expect trace-back[illegible] the element. Assume that $E = [-h/2, h/2]^2$ is square, q and $R\phi$ are constant on E, the solution is symmetric near the well, and the velocity is, say, approximated by a lowest order Raviart–Thomas mixed finite element [16]. With these assumptions, the solution is found as follows. First

$$qh^2 = \int_E q\,dx\,dy = \int_E \nabla\cdot\mathbf{u}\,dx\,dy = \int_{\partial E}\mathbf{u}\cdot\nu\,d\sigma = 4\mathbf{u}\cdot\nu h,$$

since $\mathbf{u}\cdot\nu$ is assumed constant on ∂E. Thus $\mathbf{u}\cdot\nu = qh/4$ and the corresponding Raviart–Thomas function in E is

$$\mathbf{u}(x,y) = \frac{q}{2}\begin{pmatrix} x \\ y \end{pmatrix}.$$

It is now easy to follow the characteristics (2.2)–(2.3). For $\mathbf{x} \in E$, we have that

$$\hat{\mathbf{x}}(x) = \mathbf{x}\exp\big(q(t-t^{n+1})/2R\phi\big),$$

and so $\hat{E} = [-e^{-\alpha/2}h/2, e^{-\alpha/2}h/2]^2$, where $\alpha = q\Delta t/R\phi \in (0,\infty)$. Thus the volume balance equation (3.2) is

$$R\phi h^2 - e^{-\alpha}R\phi h^2 = \int_{\mathcal{E}} q\,dx\,dt \approx [e^{-\alpha}w + (1-w)]q\Delta t\,h^2,$$

applying the weighted trapezoidal rule to the time integration. We choose the weight w so that this volume balance approximation is exact; that is,

$$w = w(\alpha) = \frac{1}{1-e^{-\alpha}} - \frac{1}{\alpha}. \tag{4.5}$$

Note that $w(0^+) = 1/2$, $w(+\infty) = 1$, and

$$w'(\alpha) = \frac{-e^{-\alpha}}{(1-e^{-\alpha})^2} + \frac{1}{\alpha^2} = \frac{1}{4\sinh^2(\alpha/2)}\left[\left(\frac{\sinh(\alpha/2)}{\alpha/2}\right)^2 - 1\right] \geq 0,$$

since $\sinh(\beta) \geq \beta$ for $\beta \geq 0$. It follows that

$$1/2 \leq w(\alpha) < 1 \quad \text{for all } \alpha > 0.$$

Now in the general case we should define w by (4.5) using

$$\alpha = \frac{\int_E q^{n+1}\,dx\,\Delta t}{\int_E R\phi\,dx}. \tag{4.6}$$

Since $w < 1$, we have the first inequality in (4.3), and the second follows easily. Adjustment of $\hat{E}$ in section 6 can then result in satisfaction of the volume constraint (4.2). Once this is done, the mass constraint (3.1) is then computed analogously from

$$\begin{aligned}\int_E R\phi c^{n+1}\,dx - \int_{\hat{E}} R\phi c^n\,dx + \int_{\mathcal{S}_B} c\mathbf{u}\cdot\nu\,d\sigma \\ = w\Delta t\int_{\hat{E}} q_c^n\,dx + (1-w)\Delta t\int_E q_c^{n+1}\,dx.\end{aligned} \tag{4.7}$$

We remark that the weighted trapezoidal rule is accurate to order Δt, which is the same rate of convergence in time expected of the characteristics-mixed method (see [3]). The trapezoidal rule itself is accurate to order Δt^2 but gives worse results over time because it leads to violation of local volume balance.

5. Approximation of inflow boundaries. Inflow boundaries are similar to internal sources in that particles trace to the boundary where they enter the system. Again, some care is needed to approximate this process. We use a technique that allows us to "trace out of the domain" in some sense. The term of concern in the volume balance equation (3.2) is

$$\int_{\mathcal{S}_B} \mathbf{u}\cdot\nu\,d\sigma,$$

which has an irregular shape on the space-time boundary $\partial\Omega\times(t^n, t^{n+1})$. The idea is to "fold" the time axis down to the xy-plane to create a "ghost region" (see Figure 5.1) by extending the spatial domain by an amount $t^{n+1} - t^n$ outside Ω across the inflow boundary. (The figure shows a relatively weak inflow for which no element is traced

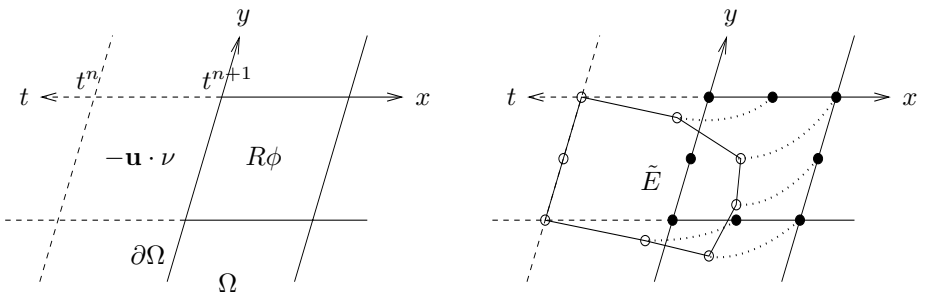

FIG. 5.1. *The inflow space-time boundary "folded" into the xy-plane, and the space-time trace-back region* $\tilde{E}$.

entirely into the folded region; however, it is possible to trace several layers of elements back into this region.)

Given an element E, one traces a vertex or midpoint from time t^{n+1} as usual. The only question is what velocity to use outside the domain Ω. One uses unit speed in the direction of ν, so that the points lying on the inflow boundary of Ω trace to the $t = t^n$ boundary of the folded domain.

This procedure defines the generalized space-time trace-back region $\tilde{E}$, which is decomposed into $\tilde{E} \cap \Omega$, the usual trace-back region, and a piece $\tilde{\mathcal{S}}_B = \tilde{E} \setminus \tilde{E} \cap \Omega$ which approximates $\mathcal{S}_B$. Thus the volume constraint is simply

$$\int_E R\phi \, dx - \int_{\tilde{E}\cap\Omega} R\phi \, dx + \int_{\tilde{\mathcal{S}}_B} \mathbf{u}\cdot\nu \, d\sigma = \int_E R\phi \, dx - \int_{\tilde{E}} R\phi \, dx = \iint_{\mathcal{E}} q \, dx \, dt, \tag{5.1}$$

wherein $R\phi$ is defined to be $\mathbf{u}\cdot\nu$ in the ghost region.

The local mass constraint defining the characteristics method is similarly computed by replacing the quantity $R\phi c^n$ by $c_I^n \mathbf{u}\cdot\nu$ in the ghost region, where c_I^n is the given inflow concentration; that is, we have simply

$$\int_E R\phi c^{n+1} \, dx - \int_{\tilde{E}} R\phi c^n \, dx = \iint_{\mathcal{E}} q_c \, dx \, dt. \tag{5.2}$$

In the way described in this section, we avoid explicit reference to the inflow boundary and reduce its computations to the same ones used in the interior of the domain. There is no need to treat outflow boundaries in a special way, since the trace-back region will remain within the spatial domain Ω. An alternative is to use the trace-forwarding idea of section 7, especially if the flow is quite strong.

6. Trace-back volume adjustment. We begin the process by tracing back the four vertices $\{\mathbf{x}_{i,j},\ \mathbf{x}_{i+1,j},\ \mathbf{x}_{i,j+1},\ \mathbf{x}_{i+1,j+1}\}$ and the four midpoints of the four edges $\{\mathbf{x}_{i+1/2,j},\ \mathbf{x}_{i+1/2,j+1},\ \mathbf{x}_{i,j+1/2},\ \mathbf{x}_{i+1,j+1/2}\}$ of $E_{i,j} \in \mathcal{T}$ to form an octagon $\tilde{E}$ approximating $\hat{E}$ with corner points $\{\hat{x}_{i,j},\ \hat{x}_{i+1,j},\ \hat{x}_{i,j+1},\ \hat{x}_{i+1,j+1},\ \hat{x}_{i+1/2,j},\ \hat{x}_{i+1/2,j+1},\ \hat{x}_{i,j+1/2},\ \hat{x}_{i+1,j+1/2}\}$. We continue to call the first four corner points "vertices," and the last four "midpoints." We adjust only these eight points to enforce the local volume constraint.

We assume in this section that every element traces back without hitting the boundary of the domain. This is always possible using the space-time "folding" technique presented in section 5. That is, we may trace an element E out of Ω as described,

and obtain what for algorithmic purposes looks like an octagon $\tilde{E}$ that can be adjusted as needed.

Our only restriction is related to external boundaries with no-flow, where we should respect this condition and disallow certain adjustments. If $\mathbf{x} \in \partial\Omega$ and the velocity field arises from the Stokes or Navier–Stokes equations with $\mathbf{u}(\mathbf{x}) = 0$, we should not allow any adjustment of the point $\hat{\mathbf{x}} = \mathbf{x}$. If only $\mathbf{u}(\mathbf{x}) \cdot \nu(\mathbf{x}) = 0$, we should not allow adjustment of $\hat{\mathbf{x}}$ in the normal direction (unless perhaps $\mathbf{x}$ traces back along $\partial\Omega$ to a point where the boundary condition changes to a type that allows such movement).

6.1. Trace-back point adjustment along characteristics. When adjusting trace-back points, care must be taken to avoid introducing systematic bias into the transport computation. We use an idea first described by Douglas, Huang, and Pereira [10], who achieved a [illegible] mass balance in the modified method of characteristics [12] by adjusting the trace-back points [illegible]. That is, the trace-back points are adjusted in the direction of the flow field, along the characteristics, so that no bias is introduced into the [illegible] of the flow. The effect is to convert spatial errors into time errors. Spatial errors tend to grow over time, but time errors are better behaved. However, Douglas, Huang, and Pereira applied their idea globally to all points simultaneously each time step. We will apply the idea locally in space.

To adjust a group of trace-back points, simultaneously adjust all of them by solving the characteristic governing equation (2.2) over a time interval $\tau^n \le t < t^{n+1}$ for some $\tau^n \approx t^n$. This changes each position along the characteristic by a small amount proportional to the local speed and the difference $\tau^n - t^n$.

We begin our trace-back point adjustment near external sources of bulk fluid, either injection wells or inflow boundaries, and proceed outward in "layers," as described subsequently.

6.2. Trace-backs near external sources. Using the integral approximation described in section 4, we adjust simultaneously each trace-back point of an injection well boundary until its volume is within tolerance of the target value given by (4.2). Consider now these trace-back points as being fixed in position.

For inflow boundaries, we fix the trace-back of the boundary points into the ghost region, as in section 5.

These techniques work well for milder flows. For stronger flow fields (or, equivalently, longer time steps), the trace-forwarding scheme of section 7 below is a better alternative.

6.3. Trace-back adjustment of layers away from sources. Once an external source has been treated, we proceed to adjust the layer of adjoining elements to obtain volume conservation in two steps, as illustrated in Figure 6.1. These adjustments are computationally quite fast.

First, simultaneously adjust all the trace-back points on the nonfixed boundary of the layer along the characteristics in time. That is, solve (2.2) over a time interval $\tau^n \le t < t^{n+1}$ for some $\tau^n \approx t^n$, so that the sum of the volumes of the elements in the layer meets the volume constraint (3.2), which in the absence of other sources, inflow boundaries, and sinks is simply

$$\sum_{E \text{ in the layer}} \int_E R\phi \, dx = \sum_{E \text{ in the layer}} \int_{\tilde{E}} R\phi \, dx.$$

We meet this constraint to some small tolerance using a type of "bisection" algorithm

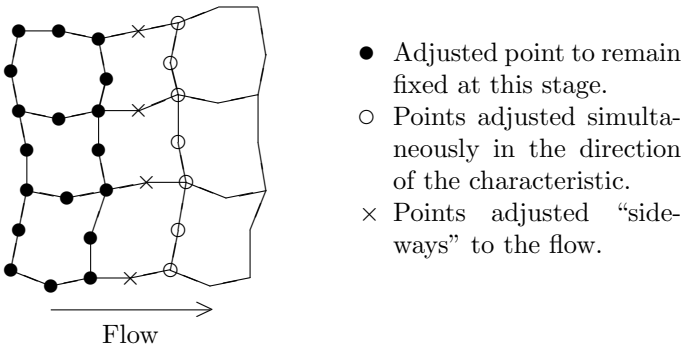

FIG. 6.1. *The adjustment of the trace-back regions. At each adjustment stage, the points marked with a solid dot remain fixed. In the first step, the points marked with a circle are simultaneously adjusted to obtain volume balance of the entire layer. In the second step, the points marked with a cross are adjusted to obtain volume balance for each element.*

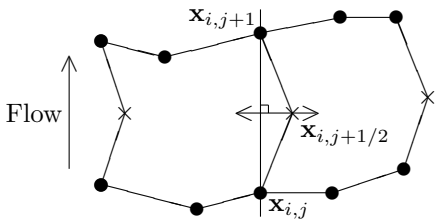

FIG. 6.2. *The adjustment of the interior midpoints. The points marked with a solid dot remain fixed, and the points marked with a cross are adjusted to obtain volume balance for each element.*

converging to the correct τ^n. This method works well since points trace toward the sources backward in time, and so $\tau^n < t^n$ adjusts the region to have less volume while $\tau^n > t^n$ gives more volume. At the conclusion of this step, we have volume balance for the layer, but not for each element.

The second step is to adjust the interior midpoints of the layer to obtain volume balance of each element. We choose to adjust in the direction of maximal change to the volume (so that points move minimally). As depicted in Figure 6.2, we adjust, e.g., $\mathbf{x}_{i,j+1/2} = (x_i, y_{j+1/2})$ along the line through its unadjusted position and perpendicular to the line adjoining vertices $\mathbf{x}_{i,j}$ and $\mathbf{x}_{i,j+1}$. On an exterior no-flow boundary where $\mathbf{u}(\mathbf{x}) \cdot \nu(\mathbf{x}) = 0$, points should not be adjusted, since they can move only tangentially along the boundary, and so do not change volumes.

The trace-back layers can be of several types. Around an injection well, we may have a closed ring, in which case we may fix one of the midpoints and adjust the rest in sequence around the ring. The volume of the entire ring is correct, so adjustment of the last point will correct the volumes of the final two elements. We may also have a simple layer which meets the external boundary on two ends. Even if we are not allowed to change the end trace-back midpoints (because of no-flow boundary conditions), again we can meet the volume constraint for each element since the entire layer has the proper volume.

Things get more complex with multiple injection wells and/or inflow boundaries, since these can produce multiple basins of attraction. In that case, care must be taken when multiple trace-back adjustment layers intersect. In principle this problem can be resolved, either through human intervention or automatically. Automatic handling

involves analyzing intricate topological complexities that are beyond the scope of this work and are left for future research.

For small times, the trace-back regions of elements are well defined. However, if the time step is too large, an approximate trace-back region $\tilde{E}$ might intersect itself. This is unacceptable, and it indicates that the boundary of the true trace-back region $\hat{E}$ is convoluted (we should conclude this also if $|\tau^n - t^n|/\Delta t$ is relatively large). In this case one should either increase the number of points traced per element edge or, more practically, reduce the time step. This is in principle the only limitation on the time step Δt. This problem is most prevalent near injection wells, and we present an alternative strategy in the next section.

7. Trace-forwarding of strong injection wells (and inflow boundaries). Near injection wells, we have observed that before adjustment, relative volume errors of the trace-back regions $\tilde{E}$ can easily exceed 100%; thus, we must handle these regions carefully. The basic problem is that, when tracing backward in time, regions trace [illegible] the very small well-bore, significantly distorting the boundary of the true trace-back regions $\hat{E}$ near the well. The natural solution is to trace forward in time instead of backward. This idea was first advocated by Healy and Russell [13].

We trace points forward in time by solving the time-forward equation for the characteristics

$$\frac{d\check{\mathbf{x}}}{dt} = \frac{\mathbf{u}(\check{\mathbf{x}}, t)}{R(\check{\mathbf{x}})\phi(\check{\mathbf{x}})}, \quad t^n < t \le t^{n+1}, \tag{7.1}$$

$$\check{\mathbf{x}}(t^n) = \mathbf{x}. \tag{7.2}$$

The time-forward local volume constraint for element E, analogous to (3.2), is

$$\int_{\check{E}} R\phi \, dx - \int_E R\phi \, dx + \int_{\mathcal{S}_{f,B}} \mathbf{u} \cdot \nu \, d\sigma = \iint_{\mathcal{E}_f} q \, dx \, dt, \tag{7.3}$$

where now

$$\mathcal{E}_f = \{(\check{\mathbf{x}}, t) \in \Omega \times [t^n, t^{n+1}] : \check{\mathbf{x}} = \check{\mathbf{x}}(\mathbf{x}; t) \text{ for some } \mathbf{x} \in E\}$$

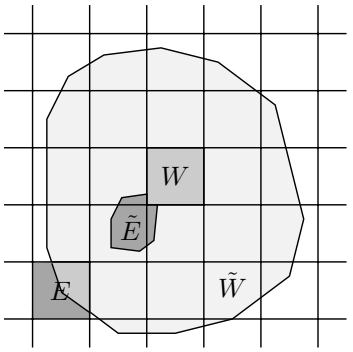
and $\mathcal{S}_{f,B} = \mathcal{E} \cap \partial\Omega \times [t^n, t^{n+1}]$.

We present now a technique for handling strong injection wells that replaces the ideas of section 4. It has four main steps, and is illustrated in Figure 7.1. Let W represent the element containing the well (we tacitly assume the well fills the element).

First, we define the initial region $\tilde{W}$. The region of space filled by fluid from the well, $\check{W}$, is defined by tracing each point on ∂W forward in time. This region is approximated by a polygon $\tilde{W}$, given by joining the traces of a finite number of boundary points. As mentioned in section 4, we might choose to trace more than our customary eight boundary points to obtain reasonable resolution of $\check{W}$, since now the trace-forward points diverge.

The second step is to adjust $\tilde{W}$ so that it satisfies the volume constraint. We simultaneously adjust the boundary points in time by solving (7.1) over the perturbed time interval $t^n < t \le \tau^{n+1} \approx t^{n+1}$ until the time-forward local volume constraint (7.3) is satisfied by the well, which is

$$\int_{\tilde{W}} R\phi \, dx = \int_W R\phi \, dx + \iint_{\mathcal{E}_f} q \, dx \, dt, \tag{7.4}$$



W is the injection well element.
$\tilde{W}$ is the approximation to the trace-forward of ∂W.
E is an element cut by $\partial\tilde{W}$.
$\tilde{E}$ is the approximation to the trace-back of $E \setminus \tilde{W}$.

FIG. 7.1. *Trace-forwarding around an injection well. Over the time step, part of the fluid that flows into E comes from $\tilde{E}$, and the rest comes from the well W.*

assuming no flow on $\mathcal{S}_{f,B}$, wherein, assuming q vanishes outside W, $\mathcal{E}_f$ can be replaced by $W \times [t^n, t^{n+1}]$.

Consider now an element E affected by the well, i.e., such that $E \cap \tilde{W} \neq \emptyset$. Our third step is to define $\tilde{E}$. Points within $\tilde{W}$ need not be traced back, since we know that they trace into the well. Thus, if $E \subset \tilde{W}$, $\tilde{E} = \emptyset$. So consider an E cut by $\partial\tilde{W}$ (i.e., $E \cap \partial\tilde{W} \neq \emptyset$). We trace back any of our usual eight points on ∂E that lie outside $\tilde{W}$. We also trace back the (most likely two) points $\partial E \cap \partial\tilde{W}$, which must trace to ∂W (if not, simply adjust the time interval so as to hit the well). Polygonal approximation defines a region $\tilde{E}$ outside W.

The fourth and final step is to adjust $\tilde{E}$ to satisfy the local volume constraint. We simultaneously adjust the points of $\partial\tilde{E}$ not on ∂W backward in time using (2.2) over a time interval $t^n \approx \tau^n \leq t < t^{n+1}$ to satisfy the local volume constraint outside the well, which is

$$\int_E R\phi \, dx = \int_{\tilde{E}} R\phi \, dx + \frac{|E \cap \tilde{W}|}{|\tilde{W}|} \iint_{W \times [t^n, t^{n+1}]} q \, dx \, dt,$$

since the region $E \cap \tilde{W}$ receives a proportional amount of fluid from the well.

We note that the transport itself, given above in the local mass constraint (3.1), is correspondingly modified as

$$\int_E R\phi c^{n+1} \, dx = \int_{\tilde{E}} R\phi c^n \, dx + \iint_{W \times [t^n, t^{n+1}]} q_c \, dx \, dt.$$

A similar construction can be applied near strong inflow boundaries. In that case, the construction of section 5 is not needed, since points no longer trace out of the domain.

8. Numerical experiments. In this section we illustrate the volume balance techniques in five examples. The last example has an analytic solution, but in the others, we determine the Darcy velocity $\mathbf{u}$ of the fluid in terms of the pressure p according to Darcy's law:

$$\mathbf{u} = -\frac{k}{\mu} \nabla p, \tag{8.1}$$

where μ is the viscosity and k is the permeability. We assume that the wells q are independent of time t, so that it suffices to solve for $\mathbf{u}$ once from the divergence constraint (1.1), subject to the boundary conditions, which vary with the example.

We assume that μ is constant (i.e., the concentrations of the components are too small to affect the viscosity of the fluid), and has the value 0.01 poise (i.e., water) in our examples. However, k varies with the example, and it is heterogeneous. A measure of the variability of k is given by the dimensionless coefficient of variation

$$C_v = \frac{1}{\mu_k}\left(\frac{1}{|\Omega|}\int_\Omega (k(x)-\mu_k)^2\,dx\right)^{1/2}, \tag{8.2}$$

which is the ratio of the standard deviation of k and its mean value

$$\mu_k = \frac{1}{|\Omega|}\int_\Omega k(x)\,dx. \tag{8.3}$$

Since the local volume constraint is really local conservation of the bulk fluid, we believe that it is important to use a locally conservative method to approximate the solution of (8.1). We use a standard lowest order Raviart–Thomas mixed method [16] implemented as cell-centered finite differences [17, 4].

We will be solving (1.2), wherein the diffusion/dispersion tensor D is given by the formula

$$D = \phi\, d_{\mathrm{mol}} I + |\mathbf{u}|[(d_{\mathrm{long}} E(\mathbf{u}) + d_{\mathrm{trans}} E^{\perp}(\mathbf{u}))], \tag{8.4}$$

where $E(\mathbf{u})$ denotes projection along the vector $\mathbf{u}$, $E^{\perp}(\mathbf{u})$ its orthogonal complement, and where the molecular diffusion coefficient $d_{\mathrm{mol}} = 10^{-7}$ cm^2/sec, the longitudinal dispersion coefficient $d_{\mathrm{long}} = 10^{-3}$ cm, and the transverse dispersion coefficient $d_{\mathrm{trans}} = 10^{-4}$ cm. Again we use Raviart–Thomas spaces to approximate this part of the operator (see [2, 3] for details).

In this section, we contrast our three schemes: the unmodified characteristics-mixed method (CMM) [2, 3], our volume conserving CMM without trace-forwarding of the well (VCCMM), and our volume conserving CMM with trace-forwarding of the well (VCCMM-TF).

8.1. A nuclear contamination problem. In our first example, we describe a nuclear contamination problem in a water saturated porous medium. The domain Ω is a square of size 256 m $\times$ 256 m. The permeability k is depicted in Figure 8.1. The

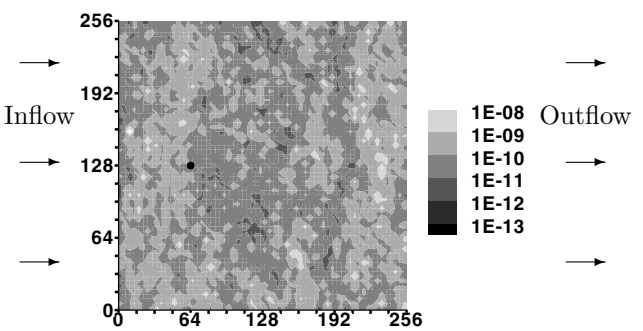


FIG. 8.1. *The nuclear contamination problem domain and permeability field, in cm^2. The location of the injection well is marked with a black dot at* $(64, 128)$.

permeability is log-normal and fractal, with mean 2×10^{-10} cm^2 (about 20 md) and a variation of over five orders of magnitude from around 10^{-13} to 10^{-8} cm^2 (about 0.01 md to 1 darcy). Its coefficient of variation (8.2) is $C_v = 0.522$.

Our assumption that μ is constant merely says that the concentrations of the nuclear components are too small to affect the viscosity of the fluid. We impose the boundary conditions of no normal flow $\mathbf{u}\cdot\nu = 0$ on the "top" and "bottom" faces of the domain ($y = 0$ m and $y = 256$ m, respectively), and a constant pressure at the left face of 5×10^5 g/cm·sec^2 and a constant pressure at the right face of -5×10^5 g/cm·sec^2, giving rise to a background flow from left to right. There is a single injection well covering 4 grid cells and placed at $(64, 128)$ m. We inject one pore volume every 50 years.

We transport a decaying nuclear component of concentration c. It satisfies the advection-diffusion equation (1.2), with a reaction term added in:

$$(R\phi c)_t + \nabla \cdot (c\mathbf{u} - D\nabla c) = -\lambda\phi R c + q_c(c), \quad \Omega \times J. \tag{8.5}$$

We take the porosity $\phi = 0.01$, the retardation factor $R = 12$, and the decay constant (for ^{234}U) $\lambda = 9 \times 10^{-14}$/sec. We inject into an initially clean aquifer a concentration c_I of 1×10^{-5} g/cm^2.

In the first set of runs, we consider a 64×64 rectangular grid and contrast four schemes: the unmodified characteristics-mixed method (CMM) [2, 3], a higher order Godunov method [18, 5, 9, 15, 1], and our volume conserving CMM with and without trace-forwarding near the well (VCCMM and VCCMM-TF).

Explicit methods in one dimension have a time step restriction [15], known as the CFL time-step, given by

$$\Delta t \le \Delta t_{\text{CFL,1-D}} = \max_{\mathbf{x}\in\Omega} \frac{hR\phi(x)}{|\mathbf{u}(\mathbf{x})|},$$

where h is the grid spacing. Since we are working in two dimensions, we should limit Δt to half this value,

$$\Delta t \le \Delta t_{\text{CFL,2-D}} = \max_{\mathbf{x}\in\Omega} \frac{hR\phi(x)}{2|\mathbf{u}(\mathbf{x})|},$$

for the Godunov method. For our 64×64 grid, the two-dimensional CFL limited time-step is 0.586 year, but we use a much larger time step for the VCCMM.

We obtain the trace-back regions by tracing back the corners and midpoints of each grid element, and connecting the points by straight lines. On the left side of Figure 8.2, we plot these trace-back regions near the injection well for the CMM and the corresponding volume (i.e., area) errors, using a time step of only 1.5 years, which is about 3 times the CFL limit. We see up to 292% volume balance error at the well. Most of the regions are beyond $\pm 1\%$, and many beyond $\pm 10\%$. Starting from these trace-back regions, the VCCMM adjustment algorithm (without trace-forwarding around the well) gives the trace-back regions on the right side of Figure 8.2, in which only floating point rounding error is observed (up to only about 10^{-9} volume balance error).

We show the contour plots of the contaminant concentration c at 30 years in Figures 8.3 and 8.4 for the four methods. The shape and sharpness of the front, and the presence of undershoot or overshoot, are to be noted. The CMM, while locally mass conservative, does not conserve volume, so the concentrations exhibit

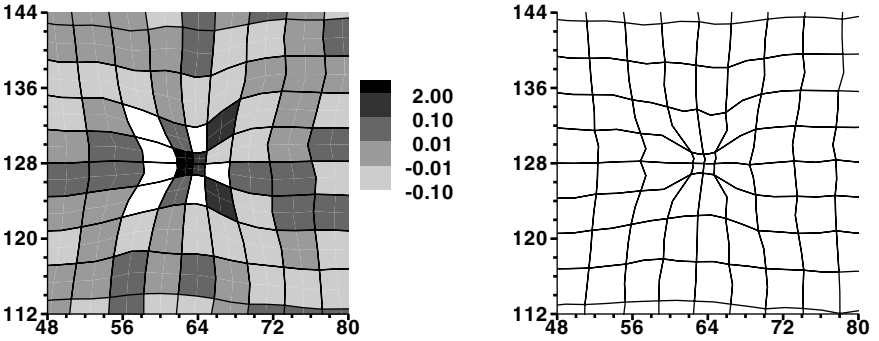

FIG. 8.2. *The nuclear contamination problem trace-back regions near the well, with CMM on the left and VCCMM (without trace-forwarding near the well) on the right. The relative volume errors are shown for CMM. The VCCMM volume errors are on the order of* 10^{-9}.

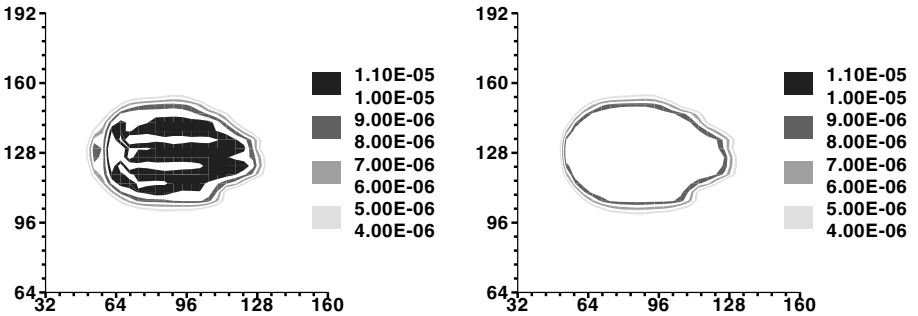

FIG. 8.3. *The nuclear contamination problem CMM (left) and VCCMM (right) concentration at* 30 *years on the* 64×64 *grid, in g/cm*^{2}*, using a time step of* 1.5 *years.*

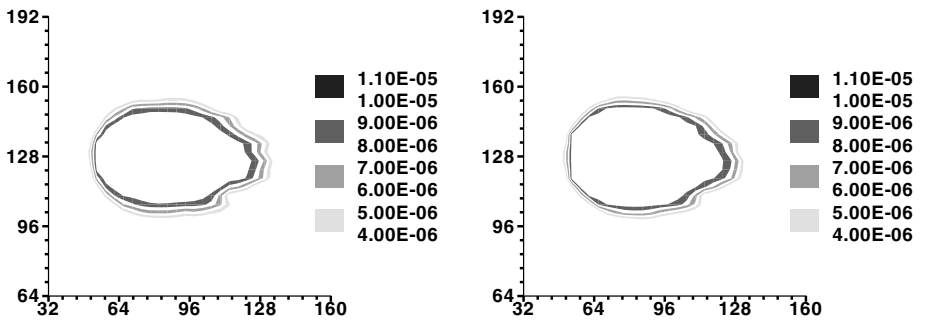

FIG. 8.4. *The nuclear contamination problem higher order Godunov (left) and VCCMM-TF (right) concentration at* 30 *years on the* 64×64 *grid, in g/cm*^{2}*. We used the CFL time step* 0.586 *year for Godunov and* 3 *years for VCCMM-TF.*

significant overshoot, reaching 134% of the maximum possible value near the well using a time step of 1.5 years. Moreover, volume nonconservation introduces many nonphysical local minima and maxima into the solution. The VCCMM corrects these problems and gives a solution very similar to the higher order Godunov method using $\Delta t = 0.586$ year. Moreover, attention to the well in the VCCMM-TF allows us to use a much larger time step of 6 years. These three methods exhibit no undershoot

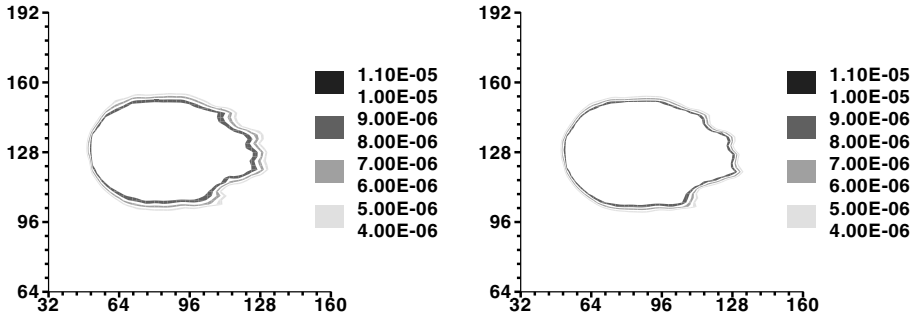

FIG. 8.5. *The nuclear contamination problem higher order Godunov (left) and VCCMM-TF (right) concentration at* 30 *years on the* 128×128 *grid, in g/cm*^{2}. *We used the CFL time step* 0.146 *years for Godunov and* 1 *year for VCCMM-TF.*

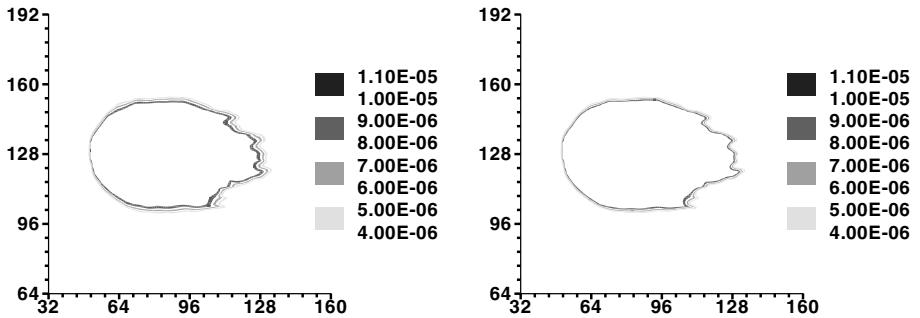

FIG. 8.6. *The nuclear contamination problem higher order Godunov (left) and VCCMM-TF (right) concentration at* 30 *years on the* 256×256 *grid, in g/cm*^{2}. *We used the CFL time step* 0.0366 *years for Godunov and* 0.5 *years for VCCMM-TF.*

or overshoot, and each predicts a similar front shape. However, the VCCMM and VCCMM-TF are less numerically diffuse, in that the front is sharper (due primarily to using a larger time step).

Finally, in Figures 8.5 and 8.6, we show the results of using finer grids: 128×128 and 256×256. The front sharpens under refinement, indicating that most of the spread is indeed due to the numerical methods and not the physical diffusion and dispersion. Again, the higher order Godunov and VCCMM-TF give comparable results, but the VCCMM-TF is somewhat less numerically diffusive and uses a much larger time step. The CFL step for the 128×128 grid is $\Delta t_{\text{CFL,2-D}} = 0.146$ years (205 steps to 30 years), but the VCCMM-TF used $\Delta t = 1$ year (30 steps), which is 6.8 times the CFL limit. For the 256×256 grid, $\Delta t_{\text{CFL,2-D}} = 0.0366$ years (820 steps), but the VCCMM-TF used $\Delta t = 0.5$ years (60 steps), which is 13.7 times the CFL limit.

8.2. A quarter five-spot flood. The second example is related to miscible flooding in a petroleum reservoir. We consider a quarter of a "five-spot" pattern of wells, which is a rectangular domain with an injection well in the lower left corner and a production well in the upper right corner, and no-flow (homogeneous Neumann) boundary conditions. Our domain is 40×40 meters square, and we impose an 80×80 grid over the domain. It is initially clean: $c(\mathbf{x}, 0) = 0$. The injector covers 4 cells near the corner $(0, 0)$ meters and has a rate of 1 pore volume every 5 years, injecting an inert tracer with concentration $c_I = 1$. The 4 cell comprising the producer are near the

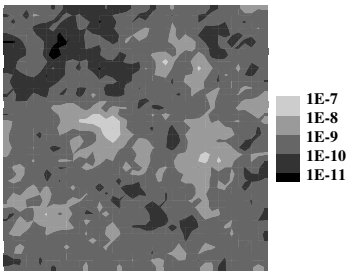

FIG. 8.7. *The quarter five-spot permeability field, in* cm^2.

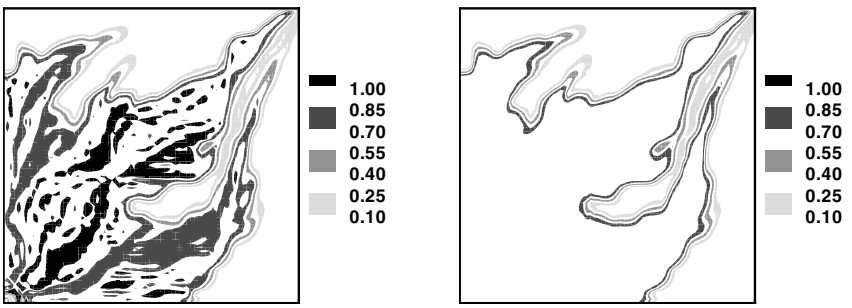

FIG. 8.8. *The quarter five-spot CMM (left) and VCCMM (right) concentration at* 3.36 *years.*

opposite corner $(40, 40)$ meters and its rate is opposite that of the injector. We solve (1.2) with no retardation (i.e., $R = 1$), no reactions, a constant porosity of 0.25, and the heterogeneous permeability k depicted in Figure 8.7, which was geostatistically generated and has mean 100 md (10^{-9} cm^2) and $C_v = 2.58$ and varies by about 4 orders of magnitude.

In Figure 8.8 we plot the results at 3.36 years using 280 steps of 0.012 year/step, which is 10.68 times the 2-D CFL number. The CMM shows both overshoot and undershoot in what should be the swept region, while the VCCMM shows no such artifacts. The poor performance of the CMM can be attributed to the extreme local heterogeneity of the permeability ($C_v = 2.58$), which produces large volume imbalances throughout the domain. In fact the field is so heterogeneous that a slightly larger time step of 0.0136 year/step (12.10 times the CFL number) initially creates degenerate trace-back regions, which cannot be used.

8.3. A fluvial domain. The third example is related to a fluvial geological environment that is correlated over large distances. The problem is taken from White and Horne [19], and the permeability is depicted in Figure 8.9, which clearly shows an ancient river bed with high permeability. We use only three values for the permeability, with mean 4.056 Darcy and $C_v = 1.15$. The domain is 600×600 feet squared and posed on a 30×30 grid. There is an injection well at grid cell $(1, 1)$ and a production well at grid cell $(30, 30)$. The injection concentration is $c_I = 1$, and the rate is 1 pore volume every 3 years. The production rate is opposite, and there are no-flow boundary conditions. The porosity is constant at 0.2, and c is initially set to zero. We solve the problem on a refined 60×60 computational grid to improve resolution (with wells now filling 4 cells). We use a time step of 0.015 years, which is 12.84 times the 2-D CFL limit.

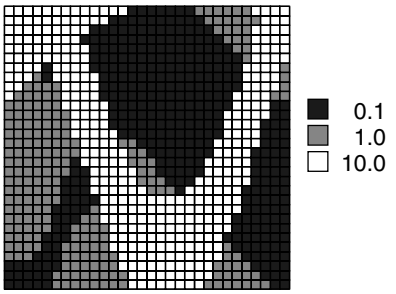

FIG. 8.9. *The fluvial domain example. The permeability field, in darcies, with the injector in the lower left and the producer in the upper right.*

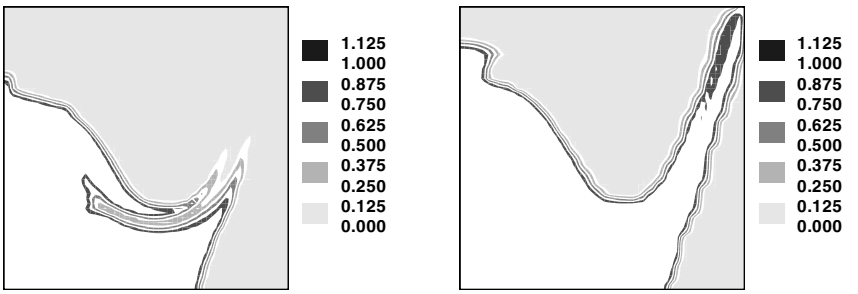

FIG. 8.10. *The fluvial domain VCCMM-TF concentration at* 1.05 *years (left) and* 1.65 *years (right).*

In Figure 8.10, we show results at 1.05 and 1.65 years (70th and 110th steps). Notice how the tracer follows the ancient river channel and avoids the lower permeability regions. The plume advances initially in time on both sides of the very low permeability region containing the well, as seen at 1.05 years, and reconnects further along in time within the very high permeability channel. As is evident at 1.65 years, within the high permeability channel, the top portion of the plume travels a greater distance, and so is retarded in position compared to the bottom half of the plume. Each half of the plume near the production well at 1.65 years is only a few grid elements in width. The plume is connected; however, the plotting routine cannot handle such a thin plume and shows some disconnection. We see a similar illusion at 1.05 years where the plume is very thin.

Serious relative volume errors are observed both at the wells and along the ancient riverbank, where a "stair-step" pattern of grid elements is used to approximate its shape. Using initial trace-back regions, the wells are so poorly approximated that the CMM actually produces negative concentrations on a 30×30 grid and time step of only 0.01 years, indicating a twisting of the trace-back regions so that they self intersect.

To isolate the riverbank errors, we applied only the trace-forwarding well adjustment to the injection well and adjusted volumes near the production well. The result of CMM using this partially processed trace-back mesh is depicted in Figure 8.11. We obtained significant improvement over straight CMM (not pictured), but the front is advanced in the CMM results compared to the VCCMM-TF, since the CMM with well adjustment simulation has average concentrations in the plume below 0.875. Thus the

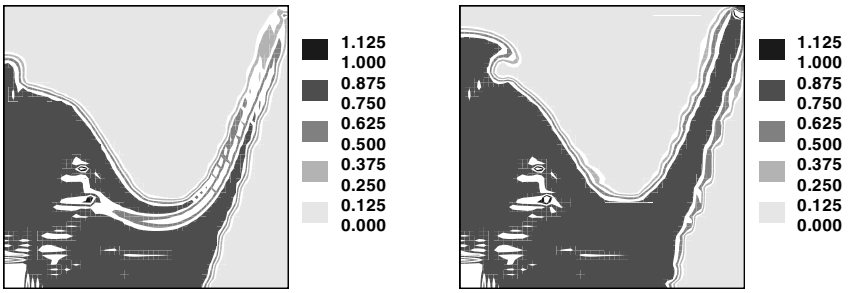

FIG. 8.11. *The fluvial domain CMM with well adjustments only. Concentration at* 1.05 *years (left) and* 1.65 *years (right).*

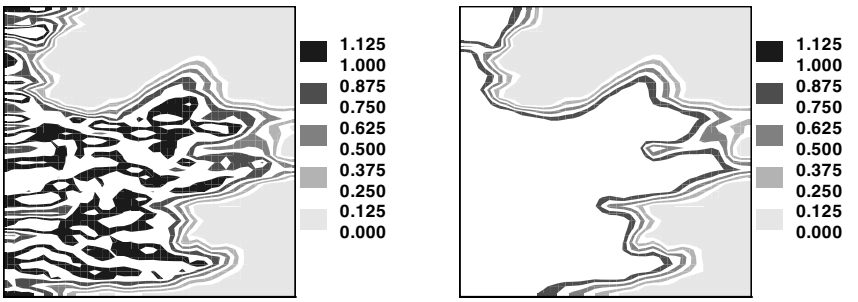

FIG. 8.12. *The linear flood CMM (left) and VCCMM (right) concentration at* 25 *years using time step* 0.18 *years. (The CFL time step is* 0.06 *years.)*

problem is not simply associated with the treatment of wells but also with treatment of trace-back regions throughout the domain. We note that the relative errors along the "stair-step" river bank reduce under grid refinement (as long as the refinement attempts to follow the true, smooth river bank).

8.4. A linear flood. Our fourth example tests the inflow boundary adjustment. We use the permeability field in the second example (see Figure 8.7). However, this time we assume no wells and instead impose a linear pressure drop across the domain in the x-direction (the pressure difference is about a tenth of that in the first example).

The time step is 0.18 years, which is three times the CFL time step. In Figure 8.12, we show results after 140 steps, or about 25 years. The CMM is very disappointing. It exhibits severe overshoots up to a concentration of 1.65 and volume errors exceed 10% in the interior of the domain. However, the VCCMM algorithm (using the ideas in section 5 to approximate the inflow boundary) was able to remove these severe volume errors, and we observe good results with mass and volume being strictly conserved.

In Figure 8.13 we show the corresponding results for the VCCMM-TF (using section 7 to treat the inflow boundary) for time steps 0.18 and 0.36 years (3 and 6 times the CFL step). As can be seen, the inflow is better approximated using VCCMM-TF. We might expect a thinner diffusion layer for the simulation using the larger time step, but evidently the grid is not fine enough to resolve this. We note that for this example, a time step 9 times CFL causes excessive initial relative volume errors inside the domain of around 25%.

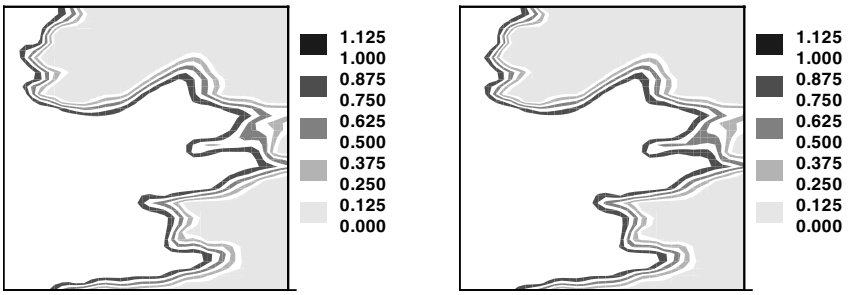

FIG. 8.13. *The linear flood VCCMM-TF concentration at* 25 *years for time steps* 0.18 *years (left) and* 0.36 *years (right). (The CFL time step is* 0.06 *years.)*

8.5. A comparison with an analytic solution. Our fifth and final example is to compare the VCCMM-TF to the results of an analytic solution due to Hsieh [14] involving radial flow out of a well in a horizontally infinite, uniform porous medium (effectively making the problem one dimensional). In radial coordinates, where r is the radial distance from the center line of the recharge well, we have

$$\begin{aligned} &c_t + \frac{A}{r}c_r = d_{\text{long}}\frac{A}{r}c_r r, && r > r_w,\ t > 0,\\ &c(r_w,t) = c_I \quad \text{and} \quad c(+\infty,t) = 0, && t > 0,\\ &c(r,0) = 0, && r > r_w, \end{aligned}$$

where $A = Q/(2\pi b\phi)$, Q is the volumetric rate of tracer injection, b is the vertical thickness of the formation, ϕ is the porosity, d_{long} is the longitudinal dispersivity, r_w is the radius of the injection well, and c_I is the concentration of the injected tracer. In dimensionless form, the equation is

$$G_\tau + \frac{1}{\rho}G_\rho = \frac{1}{\rho}G_{\rho\rho}, \quad \rho > \rho_w,\ \tau > 0,$$

where $G = c/c_I$, $\rho = r/d_{\text{long}}$, $\rho_w = r_w/d_{\text{long}}$, and $\tau = At/d_{\text{long}}^2$. Hsieh gave the analytic solution to this problem.

We mimic the same setting in a 2-D finite domain with the well in the center. The domain is 256 meters square and has a thickness of $b = 1$ m, porosity $\phi = 0.2$, and initial concentration $c = 0$. Fluid with a concentration $c_I = 1$ is injected into the center of the domain at the rate of $Q = 4369.06$ cubic meters per year (which is 1 pore-volume every 3 years). We also set $R = 1$ (i.e., no retardation).

We present two test cases, with either more or less dispersion. For the dispersion tensor (8.4), the less dispersive case has molecular diffusion $d_{\text{mol}} = 0.002$ cm^2/sec and longitudinal dispersion $d_{\text{long}} = 20$ cm. The more dispersive case is five times stronger: $d_{\text{mol}} = 0.01$ cm^2/sec and $d_{\text{long}} = 100$ cm.

In Figure 8.14 we show the comparison in the concentration along the radial direction away from the well. The analytic solution is derived from Hsieh's code [14]. We solve the full 2-D problem using our VCCMM-TF algorithm on a 128×128 grid and a time step of $\Delta t = 0.005$ years, which is 6.82 times the 2-D CFL limit, and report the concentration on the positive x-axis away from the well. On the left is the less diffusive case at time 0.2 years, and on the right is the more diffusive case at 0.1 years. As can be seen, the match is excellent.

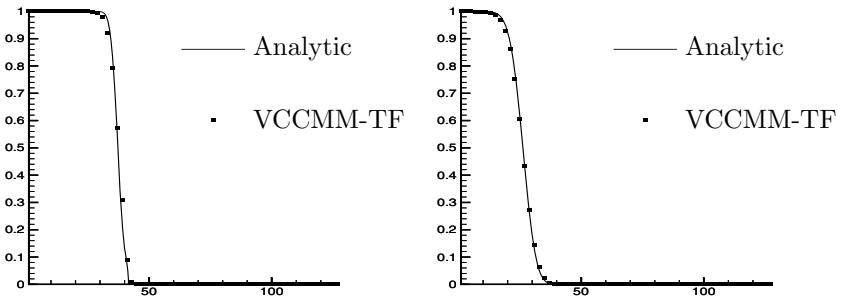

FIG. 8.14. *Comparison between the analytic and the VCCMM-TF concentration along the radial direction away from the well. On the left is the less diffusive case at time* 0.2 *years, and on the right is the more diffusive case at* 0.1 *years.*

9. Conclusions. A critical aspect of approximating hyperbolic transport problems is to conserve the mass of the tracer locally. As we saw in the numerical examples, it is just as critical to the conserve locally the mass of the bulk fluid. We have termed this constraint [illegible]. Incorrect densities, and therefore incorrect reaction dynamics, result from violation of the volume constraint. It can also lead to severe overshoot or undershoot, especially around injection wells, and even to incorrectly predicting the advancement of fronts.

We should remark that one can recover smooth densities by modifying the definition of the trace-back concentration. Simply multiply the concentration obtained for element E by the correction factor $|\tilde{E}|/|E|$. This results in volume conservation, and to the eye, all the plumes appear smooth (i.e., show no overshoot or undershoot) like the VCCMM results. However, this modification destroys mass conservation.

When adjusting trace-back points, care must be used to avoid introducing systematic bias into the transport computation. We presented algorithms that produce good trace-back regions. The key is to adjust the trace-back points "in time," i.e., along the characteristics, where possible. Weaker wells and inflow boundaries can be treated with simple techniques (wells by quadrature and inflow transparently through a space-time "fold-down" strategy). For stronger wells and inflow boundaries, one should use a trace-forwarding strategy.

We do not suggest that ours is the only reasonable adjustment strategy; it is merely one of many that could be implemented. The point of the paper has been to point out how critical this step is, and to present one practical solution to the problem. We saw that our algorithms produce accurate results when compared to Godunov's method and an analytical solution. Our method also allows us to take large time steps such as 3 to 14 times the two-dimensional CFL limited time step, which results in less numerical dispersion than do explicit differencing methods such as Godunov's method.

Trace-back adjustment requires a fair amount of computation. Thus characteristic methods such as ELLAM and CMM are perhaps best suited to steady or near steady flows and long time periods or perhaps when numerical diffusion simply cannot be tolerated. These situations arise, for example, in the modeling of geologic basin formation, long-lived radio-isotope decay, or miscible fingering.

ADAPTIVE FINITE ELEMENT METHODS FOR ELLIPTIC PDEs BASED ON CONFORMING CENTROIDAL VORONOI–DELAUNAY TRIANGULATIONS*

LILI JU†, MAX GUNZBURGER‡, AND WEIDONG ZHAO§

Abstract. A new triangular mesh adaptivity algorithm for elliptic PDEs that combines a posteriori error estimation with centroidal Voronoi–Delaunay tessellations of domains in two dimensions is proposed and tested. The ability of the first ingredient to detect local regions of large error and the ability of the second ingredient to generate superior unstructured grids result in a mesh adaptivity algorithm that has several very desirable features, including the following. Errors are very well equidistributed over the triangles; at all levels of refinement, the triangles remain very well shaped, even if the grid size at any particular refinement level, when viewed globally, varies by several orders of magnitude; and the convergence rates achieved are the best obtainable using piecewise linear finite elements. This methodology can be easily extended to higher-order finite element approximations or mixed finite element formulations although only the linear approximation is considered in this paper.

1. Introduction.

Adaptive grid generation techniques play an increasingly important role in the numerical solution of partial differential equations (PDEs). An essential ingredient of adaptive meshing techniques is a posteriori error estimators which are quantities that are computable once an approximate solution of the PDE has been determined. The key objectives in designing reliable and efficient a posteriori error estimators and mesh adaptivity techniques are that an existing mesh is refined in such a way that the errors in the approximate solution of the PDE on the new mesh are distributed as uniformly as possible, that those approximate solutions converge, as the mesh size decreases, to the exact solution as well as can be expected, and that the first two objectives are met with a relatively simple complexity. Both mesh adaptivity and a posteriori error estimators have been extensively studied, beginning in the late 1970s [4, 5, 6, 7] and followed by a vast literature. Here, we refer the reader to [2, 11, 31] for references on a posteriori error estimation and mesh adaptivity for elliptic PDEs.

The performance of adaptive methods for PDEs depends not only on the error estimators, but also on the techniques used for adaptively refining and generating meshes. In [14], a convergent adaptive algorithm was proposed for the linear finite element methods applied to the Poisson equation in two dimensions; a sequence of refined triangulations is defined based on an a posteriori error estimator and the

convergence is proved. Another new family of adaptive algorithms was given in [25, 26, 27] and the convergence of the algorithms was also proved.

In many if not most adaptive methods for PDEs, the meshes are refined locally whenever some criterion based on a local error estimator is not satisfied on some elements; the mesh elsewhere in the domain is not changed. However, in an unrefined region, the errors could be so small that, because one has too many grid nodes there, computational resources are wasted. Thus, to achieve some sort of mesh optimality, it is more reasonable to coarsen the meshes in regions where errors are relatively small in addition to refining in regions where the errors are relatively large. For example, in [8], by introducing a coarsening step to the algorithm proposed in [25], an adaptive method is defined that results in certain optimal convergence rates in the energy norm.

In this paper, we propose an adaptive algorithm for linear finite element methods that can distribute the nodes in some optimal way according to a posteriori error estimates, so that the error of the resulting approximate solution is distributed equally over the elements. To some extent, it is close to the mesh smoothing scheme proposed in [3]. We also would like to point out that the techniques described in this paper can be easily extended to higher-order finite element approximations or mixed finite element formulations. The plan of the rest of the paper is as follows. In sections 2 and 3, we respectively discuss the specific a posteriori error estimators and mesh generation and optimization methods that are used to define our mesh adaptivity algorithm. The mesh generation algorithm we use requires the definition of a density function which that algorithm uses to decide how grid points should be distributed. In section 4, we first show how that density function can be related to the a posteriori error estimators and then we provide the description of our mesh adaptation algorithm. In section 5, we use several computational experiments to demonstrate the effectiveness and efficiency of our mesh adaptation approach. Finally, some concluding remarks are given in section 6.

2. Error estimators for linear finite element methods. Let $\Omega \subset \mathbb{R}^2$ be a bounded domain with a Lipschitz boundary $\partial\Omega$. Consider the model elliptic PDE with homogeneous boundary condition

$$\begin{cases} -\nabla \cdot (a\nabla u) = f & \text{in } \Omega, \\ u = 0 & \text{on } \partial\Omega, \end{cases} \tag{2.1}$$

where $f \in L^2(\Omega)$ and $a \in C^1(\Omega)$ with $a(\mathbf{x}) \geq \widetilde{a} > 0$.

There are several types of a posteriori error estimators used in adaptive finite element methods, e.g., explicit error estimators, implicit error estimators, multilevel estimators, and averaging estimators. In this paper, we use only explicit a posteriori error estimators for adaptive mesh generation and refinement because they can be computed directly from the finite element approximate solution and the data of the problem. In the following, we first review some results about explicit a posteriori error estimators in the context of finite element methods for the model problem (2.1).

2.1. Finite element spaces and a priori error estimates. Assume that Ω is a polygonal domain with boundary $\partial\Omega$ and $\mathcal{T}$ is a conforming triangulation of Ω [13]. Denote by h_T the diameter of the triangle $T \in \mathcal{T}$ and by r_T the diameter of the largest circle that can be inscribed in T. Define the regularity ratio of the triangle T by $\kappa_T = h_T/r_T$. If there is a constant κ such that $\kappa_T \leq \kappa$ for all $T \in \mathcal{T}$, then we say that the triangulation $\mathcal{T}$ of Ω is regular. It is worth noting that the assumption of regularity permits partitions of the domain Ω into meshes that may contain elements

of quite different sizes. This observation is very important for adaptive refinement. In the following, we will assume that $\mathcal{T}$ is regular.

Let p denote a nonnegative integer and $\mathbb{P}_p$ the space of polynomials of degree less than or equal to p. The finite element space of degree p associated with the triangulation $\mathcal{T}$ is defined by $V_h = \{v \in C(\overline{\Omega}) \mid v|_T \in \mathbb{P}_p(T) \text{ for all } T \in \mathcal{T}\}$. In this paper, for simplicity, we consider the case $p = 1$; i.e., V_h is the continuous piecewise linear finite element space with respect to $\mathcal{T}$. But the techniques described in the remaining sections can be easily extended to other higher-order approximations.

In the a posteriori error analysis, it is also worthwhile to consider properties of certain patches of elements. Let the patch $\widetilde{T} \in \Omega$ be the union of the triangle T and the other triangles in $\mathcal{T}$ that share at least one common vertex with T. We define

$$h_{\widetilde{T}} = \max_{T' \subset \widetilde{T}} h_{T'} \qquad \text{and} \qquad r_{\widetilde{T}} = \max_{T' \subset \widetilde{T}} r_{T'};$$

then, the regularity of the patch $\widetilde{T}$ is measured by $\kappa_{\widetilde{T}} = h_{\widetilde{T}}/r_{\widetilde{T}}$. It is easy to see that the regularity of the triangulation $\mathcal{T}$ is inherited by each patch $\widetilde{T}$; see, e.g., [2].

Let V be the Hilbert space $H_0^1(\Omega)$. The weak form of problem (2.1) is to find $u \in V$ such that

$$B(u, v) = L(v) \qquad \forall\, v \in V,$$

where B is the bilinear form and L is the linear functional respectively defined by

$$B(u, v) = \int_\Omega a\nabla u \cdot \nabla v \, \mathrm{d}\mathbf{x} \qquad \text{and} \qquad L(v) = \int_\Omega fv \, \mathrm{d}\mathbf{x} \qquad \forall\, u, v \in V.$$

It is clear that $V_h \subset V$. Then, the finite element approximation $u_h \in V_h$ of the problem (2.1) is determined from the problem

$$B(u_h, v_h) = L(v_h) \qquad \forall\, v_h \in V_h.$$

For any $u \in V$, we define its energy norm $\|\cdot\|_E$ by $\|u\|_E = \big(B(u, u)\big)^{1/2}$. We denote by h the piecewise linear function with respect to $\mathcal{T}$ satisfying

$$h(\mathbf{x}) = \max_{T \in \mathcal{T} \text{ and } \mathbf{x} \in \overline{T}} h_T$$

for each vertex $\mathbf{x}$ of $\mathcal{T}$. We also assume that the exact solution $u \in H^2(\Omega)$. Let $e_h = u - u_h$ be the error of the approximate solution u_h; we then have the following classic results about a priori error estimates [13].

THEOREM 1. [illegible] C_1 [illegible] C_2 [illegible] a [illegible] h [illegible]

$$\|e_h\|_E \le C_1 \|\sqrt{a} h^{k-1} |\nabla_k u|\|_{L^2(\Omega)}, \quad k = 1, 2, \tag{2.2}$$

[illegible]

$$\|e_h\|_{L^2(\Omega)} \le C_2 \|\sqrt{a} h^2 |\nabla_2 u|\|_{L^2(\Omega)}. \tag{2.3}$$

2.2. An explicit H^1-type a posteriori error estimator. Let $v \in V$ be chosen arbitrarily; then writing the integral over the whole domain Ω as a sum of integrals over individual triangles gives

$$B(e_h, v) = \sum_{T \in \mathcal{T}} \left\{ \int_T fv \, \mathrm{d}\mathbf{x} - \int_T (a\nabla u_h) \cdot \nabla v \, \mathrm{d}\mathbf{x} \right\}.$$

Let $\mathcal{E}_I$ denote the set of interior edges of $\mathcal{T}$. If T and T' share the common edge $\gamma \in \mathcal{E}_I$, define the jump in the normal flux across the edge γ by

$$[(a\nabla u_h)\cdot \mathbf{n}_\gamma] = (a\nabla u_h)|_T \cdot \mathbf{n}_T + (a\nabla u_h)|_{T'} \cdot \mathbf{n}_{T'},$$

where $\mathbf{n}_T$ is the unit outward normal vector to ∂T. Applying integration by parts and rearranging terms, we then can get

$$B(e_h, v) = \sum_{T\in\mathcal{T}} \int_T rv \,\mathrm{d}\mathbf{x} + \sum_{\gamma\in\mathcal{E}_I} \int_\gamma Rv \,\mathrm{d}s, \tag{2.4}$$

where $r = f + \nabla\cdot(a\nabla u_h)$ and $R = -[(a\nabla u_h)\cdot \mathbf{n}_\gamma]$.

For given $v \in V$, let $I_h v$ be the interpolant of v in V_h. Then, by the orthogonality property $B(e_h, I_h v) = 0$ and (2.4), we have

$$B(e_h, v) = \sum_{T\in\mathcal{T}} \int_T r(v - I_h v) \,\mathrm{d}\mathbf{x} + \sum_{\gamma\in\mathcal{E}_I} \int_\gamma R(v - I_h v) \,\mathrm{d}s \qquad \forall\, v \in V. \tag{2.5}$$

The identity (2.5) plays an important role, indirectly or directly, throughout an a posteriori error analysis of finite element approximations. Due to the coercivity of the bilinear form B on V, the approximation theory, and some norm equivalences, by choosing $v = e_h$, we can obtain the first a posteriori error estimate

$$\begin{aligned} \|e_h\|_E^2 &\le C\bigg\{ \sum_{T\in\mathcal{T}} h_T^2 \|r\|_{L^2(T)}^2 + \sum_{\gamma\in\mathcal{E}_I} h_T \|R\|_{L^2(\gamma)}^2 \bigg\} \\ &= C \sum_{T\in\mathcal{T}} \bigg\{ h_T^2 \|r\|_{L^2(T)}^2 + \frac{1}{2} h_T \|R\|_{L^2(\partial T)}^2 \bigg\}. \end{aligned} \tag{2.6}$$

Except for the constant C, all of the quantities on the right-hand side of (2.6) can be computed explicitly from the finite element solution u_h. Then we obtain an H^1-type local error estimator η_{T,H^1} associated with the element $T \in \mathcal{T}$ defined by

$$\eta_{T,H^1}^2 = h_T^2 \|r\|_{L^2(T)}^2 + \frac{1}{2} h_T \|R\|_{L^2(\partial T)}^2. \tag{2.7}$$

The inequality (2.6) shows that the true error e_h can be bounded from above in terms of the local error estimator η_{T,H^1}; i.e., when η_{T,H^1} is small, the true error e_h must also be small. This property is referred to as the [illegible] of the error estimator η_{T,H^1}. However, we cannot discern anything about the true error e_h on any particular triangle $T \in \mathcal{T}$ from the stability estimate (2.6). Adaptive numerical methods generally also need the fact that the true error e_h is also locally bounded from below by the local error estimator η_{T,H^1}. This type of property is referred to as the [illegible] of the error estimator. By using properly chosen bubble functions, the efficiency of the explicit a posteriori error estimator η_{T,H^1} can also be proved. Details can be found in [2] and the references cited therein. We collect the stability and efficiency results for the error estimator η_{T,H^1} in the following theorem.

THEOREM 2. [illegible] η_{T,H^1} [illegible] (2.7) [illegible] $\eta_{H^1}^2 = \sum_{T\in\mathcal{T}} \eta_{T,H^1}^2$ [illegible] C_1 [illegible] C_2 [illegible] Ω [illegible] a [illegible] $\mathcal{T}$ [illegible]

$$C_1 \bigg\{ \|e_h\|_E^2 + \sum_{T\in\mathcal{T}} h_T^2 \|f - \bar{f}\|_{L^2(T)}^2 \bigg\} \le \|e_h\|_E^2 \le C_2 \eta_{H^1}^2, \tag{2.8}$$

$\bar{f}$ f T T_γ γ

$$\eta_{T,H^1}^2 \le C_2\Big\{\|e_h\|_{E,T_\gamma} + h_T^2\|f-\overline{f}\|_{L^2(T_\gamma)}\Big\}$$

2.3. An explicit L^2-type a posteriori error estimator. Duality arguments can be used to derive L^2-type a posteriori error estimators. The starting point for the application of this technique is the adjoint of the model problem: find $\phi_g \in V$ such that

$$B(v,\phi_g) = (g,v) \qquad \forall v \in V \tag{2.9}$$

with $g \in L^2(\Omega)$ and where $(\cdot,\cdot)$ denotes the $L^2(\Omega)$ inner product. It is assumed that this problem is regular in the sense that the solution $\phi_g \in H^2(\Omega)\cap V$ and there exists a constant C such that

$$\|\phi_g\|_{H^2(\Omega)} \le C\|g\|_{L^2(\Omega)}. \tag{2.10}$$

This assumption is known to hold, in particular, if the domain Ω is convex. The specific choice $g = e_h$ in (2.9) then gives

$$\|e_h\|_{L^2(\Omega)}^2 = B(e_h,\phi_{e_h}).$$

Then, we have

$$\begin{aligned}\|e_h\|_{L^2(\Omega)}^2 \le &\sum_{T\in\mathcal{T}} \|r\|_{L^2(T)}\|\phi_{e_h} - I_h\phi_{e_h}\|_{L^2(T)} \\ &+ \sum_{\gamma\in\mathcal{E}_I} \|R\|_{L^2(\gamma)}\|\phi_{e_h} - I_h\phi_{e_h}\|_{L^2(\gamma)}.\end{aligned} \tag{2.11}$$

By the approximation theory again, combining the inequalities (2.10) with $g = e_h$ and (2.11), we obtain

$$\|e_h\|_{L^2(\Omega)}^2 \le C\sum_{T\in\mathcal{T}}\Big\{h_T^4\|r\|_{L^2(T)}^2 + h_T^3\|R\|_{L^2(\partial T)}^2\Big\},$$

which is similar to (2.6), the only difference being a higher-order scaling in the mesh size; this reflects the expectation of a high-order rate of convergence with respect to the L^2 norm. Let η_{T,L^2} denote the L^2-type local error estimator defined by

$$\eta_{T,L^2}^2 = h_T^4\|r\|_{L^2(T)}^2 + h_T^3\|R\|_{L^2(\partial T)}^2. \tag{2.12}$$

We summarize the results about this local error estimator in the following theorem [2].

THEOREM 3. Ω η_{T,L^2} (2.12) $\eta_{L^2}^2 = \sum_{T\in\mathcal{T}}\eta_{T,L^2}^2$ C Ω a $\mathcal{T}$

$$\|e_h\|_{L^2(\Omega)}^2 \le C\eta_{L^2}^2. \tag{2.13}$$

3. Mesh generation and mesh optimization. There have been many good algorithms developed for mesh generation and mesh optimization; see, e.g., [12, 16, 19, 21, 28, 29]. In this paper, we focus on centroidal Voronoi tessellation based mesh generation as proposed in [15, 16, 19].

3.1. Conforming centroidal Voronoi–Delaunay triangulation. Given an open convex domain $\Omega \in \mathbb{R}^d$ and a set of distinct points $\{\mathbf{x}_i\}_{i=1}^n \subset \Omega$, define for each point $\mathbf{x}_i$, $i = 1, \ldots, n$, the corresponding Voronoi region V_i, $i = 1, \ldots, n$, by

$$V_i = \big\{\mathbf{x} \in \Omega \;\mid\; \|\mathbf{x} - \mathbf{x}_i\| < \|\mathbf{x} - \mathbf{x}_j\| \quad \text{for } j = 1, \ldots, n \quad \text{and} \quad j \neq i\big\}.$$

Clearly, we have $\mathbf{x}_i \in V_i$, $V_i \cap V_j = \emptyset$ for $i \neq j$, and $\cup_{i=1}^n \overline{V}_i = \overline{\Omega}$ so that $\{V_i\}_{i=1}^n$ is a tessellation of Ω. We refer to $\{V_i\}_{i=1}^n$ as the [illegible] of Ω associated with the point set $\{\mathbf{x}_i\}_{i=1}^n$. A point $\mathbf{x}_i$ is called a [illegible] and a subdomain $V_i \subset \Omega$ is referred to as the [illegible] corresponding to the generator $\mathbf{x}_i$.

It is well known that the dual tessellation (in a graph-theoretical sense) to a Voronoi tessellation of Ω is a [illegible]. It is easy to show that the vertices of the Voronoi regions V_i's are the circumcenters of the corresponding Delaunay triangles.

Given a density function $\rho(\mathbf{x})$ defined on Ω, for any region $V \subset \Omega$, we define the [illegible] $\mathbf{x}^*$ of V by

$$\mathbf{x}^* = \frac{\displaystyle\int_V \mathbf{y}\rho(\mathbf{y})\, d\mathbf{y}}{\displaystyle\int_V \rho(\mathbf{y})\, d\mathbf{y}}.$$

DEFINITION 1. [illegible] $\{(\mathbf{x}_i, V_i)\}_{i=1}^n$ [illegible] Ω [illegible] centroidal Voronoi tessellation (CVT) [15] [illegible] $\{\mathbf{x}_i\}_{i=1}^n$ [illegible] $\{V_i\}_{i=1}^n$ [illegible]

$$\mathbf{x}_i = \mathbf{x}_i^* \quad \text{[illegible]} \quad i = 1, \ldots, n.$$

[illegible] centroidal Voronoi–Delaunay triangulation (CVDT).

It is worth noting that a CVT/CVDT may not be unique; see [15]. The extension of CVTs and CVDTs to general surfaces is discussed in [17].

Given any set of points $\{\widetilde{\mathbf{x}}_i\}_{i=1}^n$ on Ω and any tessellation $\{\widetilde{V}_i\}_{i=1}^n$ of Ω, we define the corresponding [illegible] by

$$\mathcal{K}\big(\{(\widetilde{\mathbf{x}}_i, \widetilde{V}_i)\}_{i=1}^n\big) = \sum_{i=1}^n \int_{\widetilde{V}_i} \rho(\mathbf{y})\|\mathbf{y} - \widetilde{\mathbf{x}}_i\|^2\, d\mathbf{y}\,.$$

It has been shown that $\mathcal{K}$ is minimized only if $\{(\widetilde{\mathbf{x}}_i, \widetilde{V}_i)\}_{i=1}^n$ forms a CVT [15]. Although $\mathcal{K}$ may not be directly identified with an energy of some physical system, it is often naturally associated with quantities such as error distortion, variance, and cost in many practical applications.

An important and very useful property of CVTs is that the energy is equally distributed over the Voronoi regions V_i's in an asymptotic way. For example, it was shown in [15] that, in the one-dimensional case,

$$\mathcal{K}_{V_i} \approx \mathcal{K}/n \qquad \text{for } i = 1, \ldots, n,$$

where $\mathcal{K}_{V_i} = \int_{V_i} \rho(\mathbf{x})\|\mathbf{x} - \mathbf{x}_i\|^2 \, d\mathbf{x}$ and $\mathcal{K} = \sum_{i=1}^{n} \mathcal{K}_{V_i}$. For higher-dimensional cases, this property is only a conjecture but its validity has been verified through extensive numerical studies and is widely assumed in practical applications such as vector quantization. As a consequence of this equipartition property, CVTs have important geometric features, including the following.

- For a constant density function, the generators $\{\mathbf{x}_i\}_{i=1}^n$ are uniformly distributed; the Voronoi regions $\{V_i\}_{i=1}^n$ are all almost the same size, and, in the two-dimensional case, most of them are (nearly) congruent convex hexagons [15].
- For a nonconstant density function, the generators $\{\mathbf{x}_i\}_{i=1}^n$ are still locally uniformly distributed, and it is conjectured [15] that, asymptotically, for some constant C,

$$\mathcal{K}_{V_i} = C\rho(\mathbf{x}_i)h_{V_i}^{d+2} \qquad \text{and} \qquad \frac{h_{V_i}}{h_{V_j}} \approx \left(\frac{\rho(\mathbf{x}_j)}{\rho(\mathbf{x}_i)}\right)^{\frac{1}{d+2}}, \tag{3.1}$$

  where h_{V_i} denotes the diameter of V_i and d is the dimension of Ω.

Thus, in principle, one could control the distribution of generators to obtain an equal distribution of the error by connecting the density function $\rho(\mathbf{x})$ to an a posteriori error estimator.

An often used algorithm for constructing CVT/CVDT is the Lloyd method [15].

ALGORITHM 1 (Lloyd's method for CVT). [illegible] Ω [illegible] $\rho(\mathbf{x})$ [illegible] Ω [illegible] n

0. [illegible] n [illegible] $\{\mathbf{x}_i\}_{i=1}^n$ [illegible] Ω.
1. [illegible] $\{V_i\}_{i=1}^n$ [illegible] Ω [illegible] $\{\mathbf{x}_i\}_{i=1}^n$.
2. [illegible] $\{V_i\}_{i=1}^n$ [illegible] $\{\mathbf{x}_i\}_{i=1}^n$.
3. [illegible] $\{(\mathbf{x}_i, V_i)\}_{i=1}^n$ [illegible] 1.

An important property of Lloyd's algorithm is that the energy $\mathcal{K}$ of the Voronoi tessellation $\{(\mathbf{x}_i, V_i)\}_{i=1}^n$ decreases after each iteration [15]. A probabilistic version of Lloyd's method and its parallel implementation were suggested in [24].

If a CVDT mesh is to be used within a discretization method for a PDE, e.g., in a finite element method, some modifications are needed. An obvious one is that the CVDT mesh must conform with the boundary of the domain Ω; i.e., some of the CVDT nodes should be constrained to lie on the boundary so that the boundary conditions of the PDE problem can be enforced.[1]

One can, of course, predefine a set of boundary mesh points and then determine an interior mesh that in some sense "conforms" with the boundary mesh. We choose to instead amend the CVT definition and construction algorithm so that the boundary mesh points are automatically selected in conjunction with the interior mesh points. This results in a better "fit" of the boundary and interior meshes.

First, we generalize the CVT definition. Assume that Ω is compact and the domain boundary $\partial\Omega$ is piecewise smooth; the set of singular points, e.g., corners, is denoted by $P_S = \{\mathbf{z}_i\}_{i=1}^k$. Denote by $\mathbf{Proj}(\mathbf{x})$ the process that projects $\mathbf{x} \in \Omega$ to the closest point to $\mathbf{x}$ on the boundary $\partial\Omega$. Let

$$P_I = \{\mathbf{x}_i \mid \overline{V}_i \cap \partial\Omega = \emptyset\} \qquad \text{and} \qquad P_B = \{\mathbf{x}_i \mid \overline{V}_i \cap \partial\Omega \neq \emptyset\}$$

[1] If $\partial\Omega = \emptyset$, e.g., if Ω is the *surface* of a sphere, Voronoi-based discretizations of PDEs have been discussed in [18].

so that P_I, the set of [illegible], denotes the set of generators that have Voronoi regions that do not intersect the boundary and P_B, the set of [illegible], denotes the set of generators that have Voronoi regions that do intersect the boundary.

DEFINITION 2. [illegible] $\{(\mathbf{x}_i, V_i)\}_{i=1}^n$ [illegible] Ω [illegible] conforming centroidal Voronoi tessellation (CfCVT) [illegible]

- $P_S \subset \{\mathbf{x}_i\}_{i=1}^n$.
- $\mathbf{x}_i = \mathbf{x}_i^*$ *for* $\mathbf{x}_i \in P_I$.
- $\mathbf{x}_i = \mathbf{Proj}(\mathbf{x}_i^*)$ *for* $\mathbf{x}_i \in P_B - P_S$

[illegible] conforming centroidal Voronoi–Delaunay triangulation (CfCVDT).

It is noted that the meaning of singular (corner) points is trivial in two-dimensional space but may need to be more rigorously defined in spaces higher than two dimensions.

An algorithm for constructing a CfCVT/CfCVDT was given in [16, 19] and can be described as follows.[2] We follow Algorithm 1 except that in step 2 the new set of generators is given by

- the centers of mass of the interior Voronoi regions;
- the projections onto the boundary of the centers of mass of the boundary Voronoi regions except if the boundary Voronoi region contains a point in P_S, in which case the new generator is that point.

For this approach, both the number of mesh points on the boundary and their location are not predetermined. However, it is not difficult to show that the number of generators lying on the boundary will never decrease after the first iteration of Lloyd's method. The reason for this is that the nodes on the boundary cannot return to the interior of the domain since their Voronoi regions are obviously always boundary Voronoi regions. Thus, for this approach, the initial position of generators must be chosen well according to the density function ρ; for example, one could determine an ordinary CVT (with no points lying on the boundary) to use as an initial set of generators for the CfCVT construction algorithm.

In practical applications, the domain Ω is often nonconvex and is possibly very complicated [19], so that a main difficulty associated with Lloyd's method for constructing CfCVDTs is the construction of the Voronoi regions. For this reason, we next propose an algorithm for constructing approximate CfCVDTs in two dimensions that does not require the construction of exact Voronoi tessellations.

3.2. Approximate CfCVDT construction. In this section, we propose an algorithm to construct approximate CfCVDTs; we will later use this algorithm within our adaptive methods for mesh generation and optimization. We describe our approach for the two-dimensional case in detail; the generalization to higher dimensions follows similar lines.

Currently, for mesh generation with conforming boundary requirements, [illegible] (CDTs) have been widely used; see, e.g., [29, 30]. The main difference between CDTs and standard Delaunay triangulations is that some geometric constraints such as predetermined node position and node connectivities are added and strictly enforced during the CDT process. For example, the boundary of the domain can be triangulated first, and the resulting boundary triangulation is

[2] Other modified techniques for constructing CfCVTs are given in [16].

then used as a constraint on the conforming triangulation of the whole domain using a CDT. It is worth noting that the dual tessellations of the CDT generally is not an exact Voronoi tessellation, especially near the boundary.

Our algorithm for constructing approximate CfCVDTs is based on the CDT process. Assume that $\Omega \in \mathbb{R}^2$ is a domain with a polygonal boundary.[3] Denote by $P_S = \{\mathbf{z}\}_{i=1}^k$ its corner vertex set as before. An initial conforming triangulation $\mathcal{T}_0 = \{T_i\}_{i=1}^m$ of Ω is generated using the "TRIANGLE" software package [29] that uses the CDT process with a boundary mesh as a constraint and interior Delaunay refinement techniques, or by some other means. Denote by $P = \{\mathbf{x}_i\}_{i=1}^n$ the set of vertices of $\mathcal{T}_0$, by P_B the set of boundary vertices, and by P_I the set of interior vertices. The CDT process guarantees that $P_S \subset P_B$.

For each triangle $T_i = (\mathbf{x}_{i_1}, \mathbf{x}_{i_2}, \mathbf{x}_{i_3}) \in \mathcal{T}_0$, we define

$$\mathbf{x}_{T_i} = \begin{cases} \text{circumcenter of } T_i & \text{if } T_i \text{ is an acute triangle;} \\ \text{the middle point of the longest edge of } T_i & \text{otherwise.} \end{cases}$$

Clearly, $\mathbf{x}_{T_i} \in \overline{T}_i$. For each vertex $\mathbf{x}_i$, we denote by $\{T_{i_k}\}_{k=1}^{m_i} \subset \mathcal{T}_0$ the set of triangles for which $\mathbf{x}_i$ is a vertex, counting in the counterclockwise direction.

First, consider the case $\mathbf{x}_i \in P_I$, i.e., $\mathbf{x}_i$ is an interior vertex. Define U_i by

$$U_i = \text{the polygon formed by } \{\mathbf{x}_{T_{i_k}}\}_{k=1}^{m_i};$$

see Figure 3.1. The polygon U_i can be regarded as an approximation to the Voronoi region V_i associated with $\mathbf{x}_i$. Let $\overline{\mathbf{x}}_i$ denote the center of mass of the U_i with respect to the density function ρ. Denote by $\{\alpha_{i_k}\}_{k=1}^{m_i}$ the associated angles around $\mathbf{x}_i$ corresponding to $\{T_{i_k}\}_{k=1}^{m_i}$. Define

$$\alpha = \begin{cases} \max\{\alpha_{i_k} \mid \overline{T}_{i_k} \cap \partial\Omega \neq \emptyset\} & \text{if } \overline{T}_{i_k} \cap \partial\Omega \neq \emptyset \text{ for some } i_k; \\ 0 & \text{otherwise,} \end{cases}$$

and let $\mathbf{e}_i$ denote the corresponding boundary edge opposite to the angle α_{i_k} such that $\alpha_{i_k} = \alpha$; see Figure 3.1 for illustrations of some cases.

Now, select a parameter θ_{max} ($\pi > \theta_{max} > \pi/2$). Then, define

$$\mathbf{y}_i = \begin{cases} \overline{\mathbf{x}}_i & \text{if } \alpha < \theta_{max}; \\ \mathbf{Proj}_{\mathbf{e}_i}\mathbf{x}_i & \text{otherwise,} \end{cases} \tag{3.2}$$

where $\mathbf{Proj}_{\mathbf{e}_i}\mathbf{x}_i$ denotes the projection of $\mathbf{x}_i$ onto the boundary edge $\mathbf{e}_i$. It is clear that $\mathbf{y}_i$ is still an interior vertex if $\alpha < \theta_{max}$; otherwise, it is a boundary vertex although $\mathbf{x}_i$ is an interior node.

Next, consider the case $\mathbf{x}_i \in P_B$, i.e., $\mathbf{x}_i$ is a boundary vertex. Let $\mathbf{e}_1$ and $\mathbf{e}_2$ denote the two boundary edges having $\mathbf{x}_i$ as the common endpoint, and let $\mathbf{z}_1$ and $\mathbf{z}_2$ denote the midpoints of $\mathbf{e}_1$ and $\mathbf{e}_2$, respectively; see Figure 3.2. The approximate Voronoi region U_i of $\mathbf{x}_i$ is defined by

$$U_i = \text{the polygon formed by } \mathbf{z}_1, \{\mathbf{x}_{T_{i_k}}\}_{k=1}^{m_i}, \text{ and } \mathbf{z}_2;$$

see Figure 3.2. Let $\overline{\mathbf{x}}_i$ denote the center of mass of the U_i associated with the density function ρ.

[3] For domains with curved boundaries, the projection process **Proj** can be easily effected by a damped Newton method; see [28].

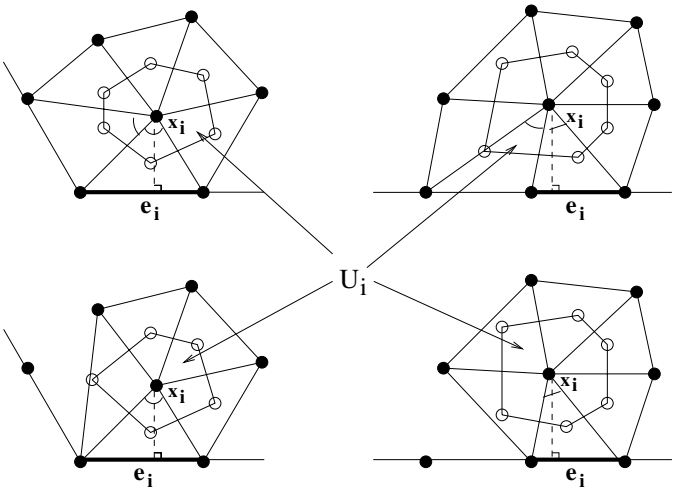

FIG. 3.1. *The approximate Voronoi region U_i for the interior vertex $\mathbf{x}_i$.*

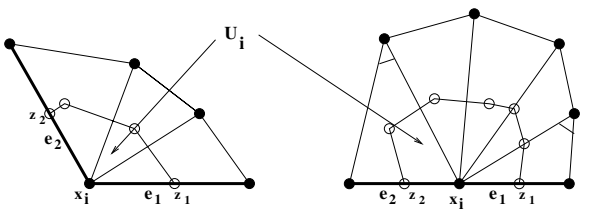

FIG. 3.2. *The approximate Voronoi region U_i for the boundary vertex $\mathbf{x}_i$. Left: Corner vertex. Right: Noncorner vertex.*

If $\mathbf{x}_i \in P_B - P_S$, denote by β_1 and β_2 the angles facing the boundary edges $\mathbf{e}_1$ and $\mathbf{e}_2$, respectively, in $\{T_{i_k}\}_{k=1}^{m_i}$; see Figure 3.2 (right). Let

$$\beta = \max(\beta_1, \beta_2)$$

and select a parameter θ_{min} ($\pi/3 > \theta_{min} > 0$). Then, define

$$\mathbf{y}_i = \begin{cases} \mathbf{x}_i & \text{if } \mathbf{x}_i \in P_S; \\ \mathbf{Proj}_{\overline{\mathbf{z}_1\mathbf{z}_2}}\overline{\mathbf{x}}_i & \text{if } \mathbf{x}_i \in P_B - P_S \text{ and } \beta > \theta_{min}; \\ \overline{\mathbf{x}}_i & \text{if } \mathbf{x}_i \in P_B - P_S \text{ and } \beta \le \theta_{min}, \end{cases} \tag{3.3}$$

where $\mathbf{Proj}_{\overline{\mathbf{z}_1\mathbf{z}_2}}\mathbf{x}_i$ denotes the projection of $\mathbf{x}_i$ onto the segment $\overline{\mathbf{z}_1\mathbf{z}_2}$. It is clear that $\mathbf{y}_i$ is also a boundary vertex if $\mathbf{x}_i$ is a corner vertex, or $\mathbf{x}_i$ is a noncorner vertex but $\beta > \theta_{min}$; otherwise, $\mathbf{y}_i$ becomes an interior vertex although $\mathbf{x}_i$ is on the boundary (We also call it a [illegible].)

[illegible] We can now describe an algorithm for constructing an approximate CfCVDT of the domain Ω.

ALGORITHM 2 (modified Lloyd method for approximate CfCVDT). [illegible] Ω [illegible] $\rho(\mathbf{x})$ [illegible] Ω [illegible] $\mathcal{T}_0$ [illegible] Ω [illegible] $\{\mathbf{x}_i\}_{i=1}^n$ [illegible]

1. [illegible] $\{\mathbf{y}_i\}_{i=1}^n$ [illegible] $\{\mathbf{x}_i\}_{i=1}^n$ [illegible] (3.2) [illegible] (3.3).
2. [illegible] $\{\mathbf{x}_i\}_{i=1}^n = \{\mathbf{y}_i\}_{i=1}^n$ [illegible] $\mathcal{E}_B$ [illegible] $\{\mathbf{x}_i\}_{i=1}^n$.
3. [illegible] Ω [illegible] $\{\mathbf{x}_i\}_{i=1}^n$ [illegible] $\mathcal{E}_B$ [illegible] $\mathcal{T}$.
4. [illegible] $\mathcal{T}$ [illegible] $\mathcal{T}$ [illegible] 1.

In the remainder of this paper, we will use the notation $\mathcal{T}$=CfCVDT($\mathcal{T}_0$,Ω,ρ) to represent the output of Algorithm 2.

Remark 1. To prevent some vertices from frequently jumping back and forth between the boundary and the interior of the domain, more sophisticated controls are needed; for the sake of simplicity, we omit some details in Algorithm 2.

Remark 2. Two user-defined parameters θ_{max} and θ_{min} corresponding respectively to the projection process and the lifting process are used to avoid badly shaped triangles in the region close to the boundary. In our computational experiments, we set $\theta_{max} = 5\pi/9$ and $\theta_{min} = \pi/6$. These are only empirical values, but many experiments lead us to believe they are good choices.

4. CfCVDT-based adaptive finite element methods. Adaptive meshing methods for solving PDEs often takes the following standard form:

0. generate a coarse mesh $\mathcal{T}^{(0)}$ of the domain Ω and set $\ell = 0$;
1. solve the system produced by discretizing the PDE based on $\mathcal{T}^{(\ell)}$ and calculate the local error estimators;
2. if some convergence criteria is satisfied, terminate; otherwise, go to step 3;
3. refine the mesh $\mathcal{T}^{(\ell)}$ based on the local error estimators to get the next level of mesh $\mathcal{T}^{(\ell+1)}$ and set $\ell = \ell + 1$; then go to step 1.

In our adaptive method, we use CfCVDTs to refine and optimize the mesh at each level, but first we need to determine, from the error estimators, the density function used in the CfCVDT algorithm.

4.1. Determination of the density function. Let $\mathcal{T}^{(\ell)}$ denote the triangulation of Ω with vertices $\{\mathbf{x}_i^{(\ell)}\}_{i=1}^{n^{(\ell)}}$ at the refinement level ℓ. Let $\eta_{T,H^1}^{(\ell)}$ and $\eta_{T,L^2}^{(\ell)}$ represent the corresponding local H^1-type and L^2-type error estimators on $T \in \mathcal{T}^{(\ell)}$ at level ℓ defined by (2.7) and (2.12), respectively. A comparison of (2.2) and (2.8) and of (2.3) and (2.13) reveals that it is reasonable to divide both $\eta_{T,H^1}^{(\ell)}$ and $\eta_{T,L^2}^{(\ell)}$ by $\sqrt{a}$ in order to reflect the local variations of true error more accurately. Thus, we define

$$(\xi_{T,H^1}^{(\ell)})^2 = \frac{(\eta_{T,H^1}^{(\ell)})^2}{a_T} \qquad \text{and} \qquad (\xi_{T,L^2}^{(\ell)})^2 = \frac{(\eta_{T,L^2}^{(\ell)})^2}{a_T}, \tag{4.1}$$

where a_T is the mean value of $a(\mathbf{x})$ on the triangle T, i.e., $a_T = \int_T a(\mathbf{x})\,d\mathbf{x}/\text{Area}(T)$. In order to minimize

$$(\xi_{H^1}^{(\ell)})^2 = \sum_{T\in\mathcal{T}^{(\ell)}} (\xi_{T,H^1}^{(\ell)})^2 \qquad \text{or} \qquad (\xi_{L^2}^{(\ell)})^2 = \sum_{T\in\mathcal{T}^{(\ell)}} (\xi_{T,H^1}^{(\ell)})^2,$$

we need to distribute $(\xi_{T,H^1}^{(\ell)})^2$ or $(\xi_{T,L^2}^{(\ell)})^2$ equally over all triangles of $\mathcal{T}^{(\ell)}$.

Set

$$\widetilde{\rho}_{T,H^1}^{(\ell)} = \frac{(\xi_{T,H^1}^{(\ell)})^2}{h_T^4} \qquad \text{and} \qquad \widetilde{\rho}_{T,L^2}^{(\ell)} = \frac{(\xi_{T,L^2}^{(\ell)})^{4/3}}{h_T^4}. \tag{4.2}$$

We then uniquely determine two piecewise linear functions (with respect to $\mathcal{T}^{(\ell)}$) $\rho_{H^1}^{(\ell+1)}$ and $\rho_{L^2}^{(\ell+1)}$ on Ω such that for any vertex $\mathbf{x}_i^{(\ell)}$ of $\mathcal{T}^{(\ell)}$,

$$\rho_{H^1}^{(\ell+1)}(\mathbf{x}_i^{(\ell)}) = \frac{\sum\limits_{T\in S_i} \widetilde{\rho}_{T,H^1}^{(\ell)}}{\mathrm{card}(S_i)} \qquad \text{and} \qquad \rho_{L^2}^{(\ell+1)}(\mathbf{x}_i^{(\ell)}) = \frac{\sum\limits_{T\in S_i} \widetilde{\rho}_{T,L^2}^{(\ell)}}{\mathrm{card}(S_i)}, \tag{4.3}$$

where

$$S_i = \{T \in \mathcal{T}^{(\ell)} \mid \mathbf{x}_i^{(\ell)} \in \overline{T}\}.$$

Note that, in some sense, if the solution $u \in H^2(\Omega)$, we have

$$(\xi_{T,H^1}^{(\ell)})^2 \approx a_T |\nabla_2 u|^2 h_T^4 \qquad \text{and} \qquad (\xi_{T,L^2}^{(\ell)})^2 \approx a_T |\nabla_2 u|^2 h_T^6. \tag{4.4}$$

Combining (4.4) with the CVT/CVDT property (3.1) for $d = 2$, i.e.,

$$\frac{h_{V_i}}{h_{V_j}} \approx \Big(\frac{\rho(\mathbf{x}_j)}{\rho(\mathbf{x}_i)}\Big)^{1/4}$$

for a CVT $\{(\mathbf{x}_i, V_i)\}_{i=1}^n$ of Ω with respect to the density function ρ, it is then not difficult to verify that the CfCVDT mesh $\mathcal{T}^{(\ell+1)}$ generated by the density function $\rho_{H^1}^{(\ell+1)}$ or $\rho_{L^2}^{(\ell+1)}$ will approximately have the property that

$$(\xi_{T_i,H^1}^{(\ell+1)})^2 \approx (\xi_{T_j,H^1}^{(\ell+1)})^2 \qquad \text{or} \qquad (\xi_{T_i,L^2}^{(\ell+1)})^2 \approx (\xi_{T_j,L^2}^{(\ell+1)})^2,$$

respectively, for any triangles $T_i, T_j \in \mathcal{T}^{(\ell+1)}$.

We will refer to the density functions $\rho_{H^1}^{(\ell+1)}$ and $\rho_{L^2}^{(\ell+1)}$ as the H^1-based and L^2-based density functions, respectively. From their defining formulas, it is easy to see that $\rho_{H^1}^{(\ell+1)}$ varies more rapidly than does $\rho_{L^2}^{(\ell+1)}$. We expect that CfCVDT meshes generated using $\rho_{H^1}^{(\ell+1)}$ will produce a finite element approximation with smaller H^1 norm or energy error while those generated using $\rho_{L^2}^{(\ell+1)}$ will tend to have smaller L^2 norm error.

The most time consuming step in the calculations of $\rho_{H^1}^{(\ell+1)}(\mathbf{x})$ and $\rho_{L^2}^{(\ell+1)}(\mathbf{x})$ for any $\mathbf{x} \in \Omega$ is the nearest neighbor search operation since they are defined by interpolation with respect to an unstructured mesh. However, this task can be effected efficiently using the software package "ANN" [1] that is based on the K-D tree algorithm.

Remark 3. In many practical applications, the coefficient in the model equation (2.1) is often a tensor product, i.e., a symmetric, positive definite matrix

$$A(\mathbf{x}) = \begin{pmatrix} a_{11}(\mathbf{x}) & a_{12}(\mathbf{x}) \\ a_{21}(\mathbf{x}) & a_{22}(\mathbf{x}) \end{pmatrix}$$

rather than a scalar-valued function $a(\mathbf{x})$. Under this situation, if the difference between $a_{11}(\mathbf{x})$ and $a_{22}(\mathbf{x})$ is not large locally, then it is still reasonable to scale these estimators by

$$(\xi_{T,H^1}^{(\ell)})^2 = \frac{(\eta_{T,H^1}^{(\ell)})^2}{A_T} \qquad \text{and} \qquad (\xi_{T,L^2}^{(\ell)})^2 = \frac{(\eta_{T,L^2}^{(\ell)})^2}{A_T}, \tag{4.5}$$

where $A_T = \int_T \sqrt{\det(A(\mathbf{x}))}\, d\mathbf{x}/\mathrm{Area}(T)$. If $A(\mathbf{x})$ is strongly anisotropic, then it could not be handled correctly in this framework; the anisotropic CVT meshes proposed in [20], perhaps with some variations, may be able to deal with this case.

. . . . 4. If a higher-order finite element approximation is used, for example, $V_h = \{v \in C(\overline{\Omega}) \mid v|_T \in \mathbb{P}_k(T) \text{ for all } T \in \mathcal{T}\}$, where $k > 1$, then the discrete solution u_h is of kth order convergence in the H^1 norm and $(k+1)$th order in the L^2 norm. Let $\eta^{(\ell)}_{T,H^1}$ and $\eta^{(\ell)}_{T,L^2}$ be the accordingly derived local H^1- and L^2-type error estimators for this approximation; then by similar analysis, it is better to replace (4.2) by

$$\widetilde{\rho}^{(\ell)}_{T,H^1} = \frac{(\xi^{(\ell)}_{T,H^1})^{\frac{4}{k+1}}}{h_T^4} \qquad \text{and} \qquad \widetilde{\rho}^{(\ell)}_{T,L^2} = \frac{(\xi^{(\ell)}_{T,L^2})^{\frac{4}{k+2}}}{h_T^4}. \tag{4.6}$$

. . . . 5. If the mixed finite element method is used, the density function can be determined similarly to the standard finite element approximation since all we need are just explicit a posteriori local error estimators and their orders with respect to the local mesh size h_T.

4.2. Adaptive algorithms based on CfCVDT. Let $\{E_i\}_{i=1}^{k^{(\ell)}}$ denote the set of edges of the ℓth level triangulation $\mathcal{T}^{(\ell)}$. Set $\rho_{E_i} = \rho(\mathbf{z}_i)$ for any density function ρ, where $\mathbf{z}_i$ denotes the midpoint of the edge E_i. We can now define our adaptive finite element method as follows.

Algorithm 3 (CfCVDT-based adaptive finite element method). . . . . Ω . . . . . $N_{max} > 0$ . . . . .

The parameter θ in Algorithm 3 is used here to control the refinement process [26]. The sorting procedure in step 4 can be implemented efficiently using a quick sorting algorithm.

5. Computational experiments. In this section, using computational experiments, we illustrate the effectiveness of CfCVDT-based adaptive finite element methods. Consider the problem

$$\begin{cases} -\nabla \cdot (a\nabla u) + bu = f & \text{in } \Omega, \\ u = g & \text{on } \partial\Omega, \end{cases} \tag{5.1}$$

where $b \in L^\infty(\Omega)$ with $b \geq 0$. Correspondingly, $r = f$ in (2.7) and (2.12) is changed to $r = f - bu_h$. Initial coarse meshes are either chosen to be a uniform Cartesian grid or are produced using the "TRIANGLE" package and are subsequently repeatedly refined by our adaptive methods, i.e., Algorithm 3. For the sake of having something to compare to, we also find finite element approximations of the problem (5.1) using uniform refinements of the initial meshes. We set $L_{max} = 15$, $N_{max} = 20{,}000$, and $\theta = 0.4$ for Algorithm 3. For our adaptive methods, the convergence rate CR with respect to the norm $\|\cdot\|$ at the refinement level ℓ is roughly computed by

$$\text{CR} = \frac{2\log(\|e_{h,\ell}\|/\|e_{h,\ell-1}\|)}{\log(n_{\ell-1}/n_\ell)}, \tag{5.2}$$

where n_ℓ denotes the number of nodes and $e_{h,\ell}$ denotes the error $u - u_h$ at the refinement level ℓ.

We apply the commonly used q measure [22] to evaluate the quality of triangular meshes, where, for any triangle T, q is defined to be twice the ratio of the radius R_T of the largest inscribed circle and the radius r_T of the smallest circumscribed circle, i.e.,

$$q(T) = 2\frac{R_T}{r_T} = \frac{(b+c-a)(c+a-b)+(a+b-c)}{abc},$$

where a, b, and c are side lengths of T. For a given triangulation $\mathcal{T}$, we define

$$q_{min} = \min_{T\in\mathcal{T}} q(T) \qquad \text{and} \qquad q_{avg} = \frac{1}{\text{card}(\mathcal{T})}\sum_{T\in\mathcal{T}} q(T); \tag{5.3}$$

q_{min} measures the quality of the worst triangle and q_{avg} measures the average quality of the mesh $\mathcal{T}$.

5.1. Smooth solution with large gradients. The first illustrative problem is given as follows.

1. Set $\Omega = [-1,1]\times[-1,1]$, $a(x,y) = 10.0\cos(y)$, and $b(x,y) = x^2 + y^2$. The exact solution u is chosen to be

$$u(x,y) = \frac{1.0}{(x-0.5)^2+(y-0.5)^2+0.01} - \frac{1.0}{(x+0.5)^2+(y+0.5)^2+0.01} \tag{5.4}$$

and f and g are determined from u so that (5.1) is satisfied.

It is easy to see that the exact solution u given in (5.4) is a smooth function, i.e., certainly, $u \in C^2(\Omega)$. Note that u achieves its maximum value $99\frac{101}{201}$ at the point $(0.5, 0.5)$ and its minimum value $-99\frac{101}{201}$ at the point $(-0.5, -0.5)$ but decays very

quickly away from its extrema and thus has large gradients near these two points. Note also that $a(x, y)$ and $f(x, y)$ also have relatively rapid variations over Ω.

The initial coarse mesh (the input for step 0 of Algorithm 3) used for the solution of Example 1 is a uniform Cartesian grid consisting of 81 nodes; see Figure 5.1. The corresponding CfCVDT meshes (the output of step 0) with the same number of nodes produced using the density functions ρ_{H^1} and ρ_{L^2} are also given in Figure 5.1. Figure 5.2 presents repeatedly refined meshes at some levels generated using Algorithm 3. The distributions of nodes in the CfCVDT-based adaptive meshes clearly show the accumulation of nodes in the vicinity of the two points near which large gradients in the solution occur. The CfCVDT-based adaptive meshes are "optimal" in the sense that all triangles remain well shaped at all refinement levels, an observation which is supported by the values of q_{min} and q_{avg} given in Table 5.1. It is also clear that the CfCVDT meshes generated using the density function ρ_{H^1} tend to distribute the nodes in a slightly less uniform manner than those generated using the density

function ρ_{L^2}; this observation, which is also verified by the values of h_{max}/h_{min} in Table 5.1, can be explained by the fact that ρ_{H^1} has larger variations than does ρ_{L^2}.

Table 5.1 contains information about mesh quality, solution errors, and convergence rates at all refinement levels for different refinement strategies for Example 1; the corresponding plots of the error norms ($\|e_h\|_{L^2(\Omega)}$ and $|e_h|_{H^1(\Omega)}$) versus the number of nodes are given in Figure 5.3 where $|e_h|_{H^1(\Omega)}$ denotes the semi-H^1 norm defined by $\|\nabla e_h\|_{L^2(\Omega)}$. One observes that the two CfCVDT-based adaptive methods and the uniform refinement strategy achieve almost perfect convergence rates, i.e., 2 and 1 for $\|e_h\|_{L^2(\Omega)}$ and $|e_h|_{H^1(\Omega)}$, respectively.[4] These, of course, are the expected rates since the exact solution u of Example 1 belongs to $H^2(\Omega)$. The values of q_{min} and q_{avg} given in Table 5.1 demonstrate that the shape quality of the meshes resulting from the CfCVDT-based adaptive strategy is always very good at all levels for both density functions ρ_{L^2} and ρ_{H^1}, although the mesh sizes vary a lot over the Ω, e.g., h_{max}/h_{min} reaches 176.3 at the last level when ρ_{H^1} is used. Note that h_{max}/h_{min} tends to converge for our adaptive methods since u is smooth. Also, as expected, the

[4]The convergence rate for $\|e_h\|_{L^2(\Omega)}$ for the adaptive method using ρ_{H^1} being a little erratic and slightly lower than 2.

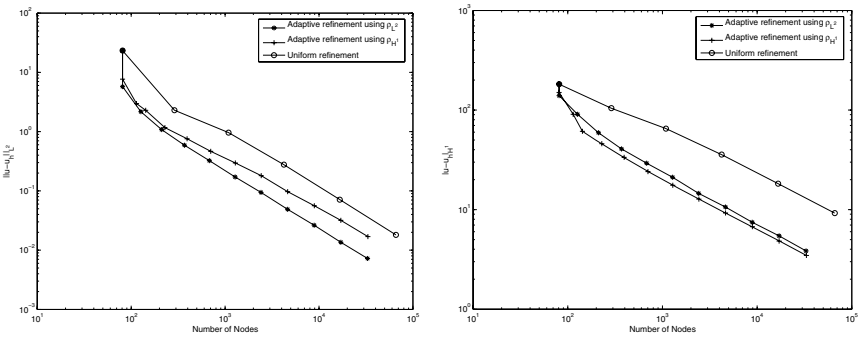

FIG. 5.3. *Error norms versus number of nodes for different refinement strategies for Example* 1. *Left:* $\|e_h\|_{L^2(\Omega)}$. *Right:* $|e_h|_{H^1(\Omega)}$.

adaptive method using ρ_{L^2} as the density function generated approximate solutions u_h having smaller $\|e_h\|_{L^2(\Omega)}$ relative to those obtained using ρ_{H^1}; on the other hand, the latter generated approximate solutions with (slightly) smaller $|e_h|_{H^1(\Omega)}$.

From Table 5.1 and Figure 5.3, one also observes that the CfCVDT-based adaptive methods are much more efficient relative to the uniform refinement strategy. For example, for the uniform refinement method, we have that $\|e_h\|_{L^2(\Omega)} = 1.8071\text{e-}02$ and $|e_h|_{H^1(\Omega)} = 9.2255\text{e+}00$ on the refined mesh with 66,049 nodes. However, for the adaptive methods, the values of these norms are 5.6155e-02 and 6.7420e+00, respectively, on the mesh with only 8,921 nodes when ρ_{H^1} is used as the density function, and 2.6327e-02 and 7.4636e+00, respectively, on the mesh with only 8,883 nodes when ρ_{L^2} is used as the density function. This means that, in the case of the $|e_h|_{H^1(\Omega)}$ norm, the CfCVDT-based adaptive methods are more than 8 times more efficient than the uniform refinement method if considering only the size of the resulting system.

An important optimal property of CfCVDT-based adaptive methods is the equidistribution of the errors over Ω. In order to verify this, we plot, in Figure 5.4, a representative approximate solution u_h and the errors e_h for different refinement methods. It is obvious that the adaptive methods do indeed distribute the errors much more equally than does the uniform refinement method; note that the same scale is used for e_h in Figure 5.4 for all the refinement methods.

5.2. Geometric singularity. The second illustrative problem is given as follows.

EXAMPLE 2. Let $\Omega = \Omega_{R_1} \cup \Omega_{R_2}$, where $\Omega_{R_1} = [-1, 0] \times [0, 1]$ and $\Omega_{R_2} = [0, 1] \times [-1, 1]$ so that Ω is a nonconvex, Γ-shaped region which induces a geometrically based singularity in the solution of the PDE at the origin $(0, 0)$. In (5.1), we set $a(x, y) = 1$ and $b(x, y) = 0$. We use the polar coordinates (r, θ) instead of the Cartesian coordinates $(x, y) = (r\cos\theta, r\sin\theta)$ to describe the exact solution u which is chosen to be

$$u(r,\theta) = s\left(\frac{r-\delta_1}{\delta_2-\delta_1}\right) r^{2/3}\sin\left(\frac{2}{3}\theta\right) + w(r\cos\theta, r\sin\theta) \tag{5.5}$$

with $\delta_1 = 0.02$ and $\delta_2 = 0.25$, where s is the cut-off function

$$s(t) = \begin{cases} 1, & t < 0, \\ -6t^5 + 15t^4 - 10t^3 + 1, & 0 \le t \le 1, \\ 0, & t > 1, \end{cases}$$

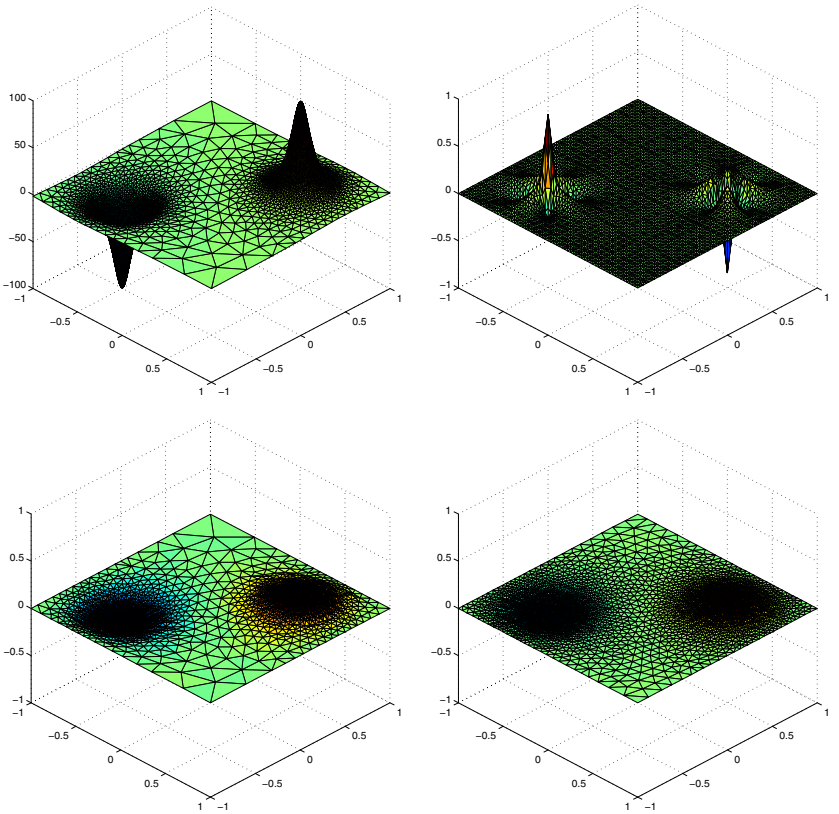

FIG. 5.4. *Plots of an approximate solution and error distributions for different refinement methods for Example* 1. *Top left: A representative approximate solution* u_h. *Top right: The error* e_h *on the mesh with* 4225 *nodes obtained using the uniform refinement method. Bottom left:* e_h *on the mesh with* 4644 *nodes obtained using the CfCVDT-based adaptive method using* ρ_{H^1}. *Bottom right:* e_h *on the mesh with* 4629 *nodes obtained using the CfCVDT-based adaptive method using* ρ_{L^2}.

and $w(x, y) = (x - x^3)(y^2 - y^4)$. Note that w is a smooth function with $w|_{\partial\Omega} = 0$. Then, f and g are again determined from u so that (5.1) is satisfied.

The exponent and angle factor $2/3$ in the exact solution (5.5) emulates the typical singular behavior of solutions of (5.1) in the Γ-shaped domain that has an interior angle equal to $3\pi/2$; see [23]. It is then easy to show that the exact solution u given in (5.5) belongs only to $H^{\frac{5}{3}-\epsilon}(\Omega)$ for any $\epsilon > 0$ and has a strong singularity at the origin. Again, this is the typical regularity one can expect for solutions of (5.1) in a Γ-shaped domain. Note that, in particular, $u \notin H^2(\Omega)$.

The initial coarse mesh (the input for step 0 of Algorithm 3) used for the solution of Example 2 is a uniform Cartesian grid consisting of 65 nodes; see Figure 5.5. The corresponding CfCVDT meshes (the output of step 0) with the same number of nodes produced using the density functions ρ_{H^1} and ρ_{L^2} are also given in Figure 5.5. Figure 5.6 presents repeatedly refined meshes at some levels generated using Algorithm 3. The distributions of nodes in the CfCVDT-based adaptive meshes clearly show the accumulation of nodes near the origin where the singularity in the solution occurs. In order to better visualize the extent of the accumulation, 16-fold magnifications of

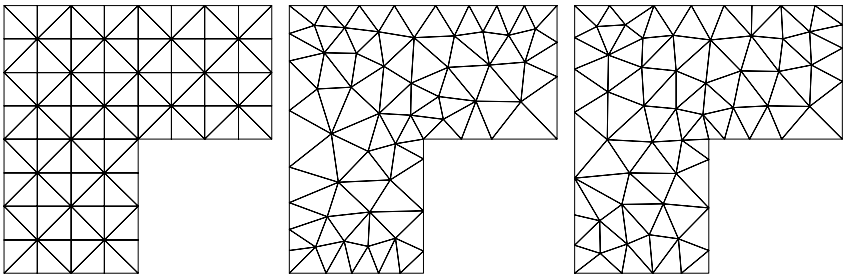

FIG. 5.5. *Initial meshes for Example* 2. *Left: A uniform Cartesian grid with* 65 *nodes. Middle and right: The corresponding CfCVDT meshes with the same number of nodes generated using the density functions* ρ_{H^1} *and* ρ_{L^2}, *respectively.*

the meshes near the origin are also included in Figure 5.6. It is easy to see that again CfCVDT meshes generated using the density function ρ_{H^1} have a little higher concentration of nodes near the singular point than the ones generated using ρ_{L^2}. Also, once again, all triangles remain well shaped at all refinement levels, an observation that is supported by the values of q_{min} and q_{avg} listed in Table 5.2.

Table 5.2 contains information about mesh quality, solution errors, and convergence rates at all refinement levels for different refinement strategies for Example 2; the corresponding plots of the error norms ($\|e_h\|_{L^2(\Omega)}$ and $|e_h|_{H^1(\Omega)}$) versus the number of nodes are given in Figure 5.7. The convergence rates for the uniform refinement method are about 1.48 and 0.85 for $\|e_h\|_{L^2(\Omega)}$ and $|e_h|_{H^1(\Omega)}$, respectively. These rates are a little better than the values 4/3 and 2/3, respectively, that finite element theory predicts for an exact solution $u \in H^{\frac{5}{3}-\epsilon}(\Omega)$; this behavior can possibly be explained

TABLE 5.2

by the superconvergence property of piecewise linear finite element approximations on uniform grids and by the fact that the mesh resolution may still not be fine enough to achieve asymptotic convergence rates; see [9]. However, one sees that the CfCVDT-based adaptive methods still achieve almost perfect convergence rates, i.e., 2 and 1 for $\|e_h\|_{L^2(\Omega)}$ and $|e_h|_{H^1(\Omega)}$, respectively. The values of q_{min} and q_{avg} given in Table 5.2 demonstrate that the quality of the meshes produced by the CfCVDT-based adaptive methods is always very good for both density functions ρ_{H^1} and ρ_{L^2}, even though the mesh sizes vary greatly over the Ω; e.g., h_{max}/h_{min} reaches 194.7 at the last level when the density function ρ_{H^1} is used. It is interesting to observe that, since u does not belong to $H^2(\Omega)$, h_{max}/h_{min} tends to monotonically increase for the adaptive methods. The CfCVDT adaptive method using the density function ρ_{L^2} generated approximate solutions with almost the same values of $\|e_h\|_{L^2(\Omega)}$ as that obtained using the density function ρ_{H^1}; on the other hand, the latter generated approximate solutions with (slightly) smaller values of $|e_h|_{H^1(\Omega)}$.

From Table 5.2 and Figure 5.7, one also observes that the CfCVDT-based adaptive methods are much more efficient relative to the uniform refinement strategy. For example, for the uniform refinement method, we have that $\|e_h\|_{L^2(\Omega)}$ =1.9910e-04 and

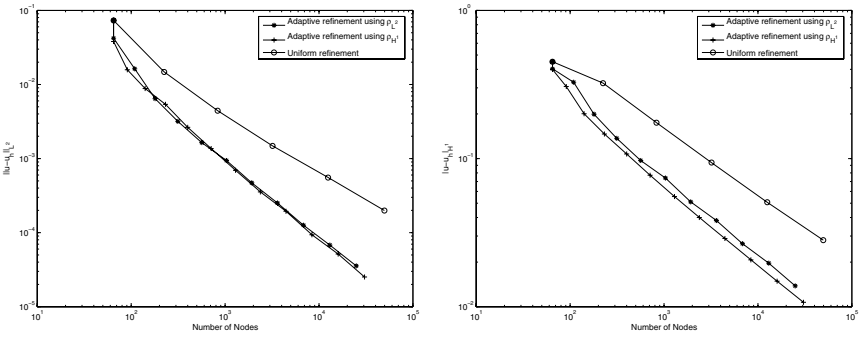

FIG. 5.7. *Error norms versus number of nodes for different refinement strategies for Example* 2. *Left:* $\|e_h\|_{L^2(\Omega)}$. *Right:* $|e_h|_{H^1(\Omega)}$.

$|e_h|_{H^1(\Omega)} = 2.8144\text{e-}02$ on the refined mesh with 49,665 nodes. However, for the adaptive methods, the values of these norms are 1.9454e-04 and 2.8889e-02, respectively, on the mesh with only 4,455 nodes when ρ_{H^1} is used as the density function, and 1.2593e-04 and 2.6637e-02, respectively, on the mesh with only 6,847 nodes when ρ_{L^2} is used as the density function. This means that, in the case of the $\|e_h\|_{H^1(\Omega)}$ norm, the CfCVDT-based adaptive methods are more than 10 times more efficient than the uniform refinement method if only considering the size of the resulting system.

We display a representative approximate solution u_h and the errors e_h for different refinement methods in Figure 5.8. It is again obvious that the CfCVDT-based adaptive methods distribute the errors much more equally over the triangles than does the uniform refinement method.

5.3. Interface singularity. The third illustrative problem is given as follows.

EXAMPLE 3. Let $\Omega = [-1,1] \times [-1,1]$, $b(x,y) = 0$, and

$$a(x,y) = \begin{cases} 1 & (x,y) \in \Omega_1 \cup \Omega_3, \\ 5 & (x,y) \in \Omega_2 \cup \Omega_4, \end{cases}$$

where $\Omega_1 = (0,1) \times (0,1)$, $\Omega_2 = (-1,0) \times (0,1)$, $\Omega_3 = (-1,0) \times (-1,0)$, and $\Omega_4 = (0,1) \times (-1,0)$; see the top left image in Figure 5.9. Note that the coefficient a is discontinuous across the two lines $x = 0$ and $y = 0$. This problem is thus an interface problem [10]. The exact solution u is chosen to be

$$u(r,\theta) = r^{\alpha}\big(p_i \cos(\alpha\theta) + q_i \sin(\alpha\theta)\big) \quad \text{in } \Omega_i, \tag{5.6}$$

with $0 < \alpha < 1$ and for $i = 1,2,3,4$. With a normalization condition such as

$$\sum_{i=1}^{4}(p_i + q_i) = 1,$$

we can easily solve a Sturm–Liouville problem to find that if $\alpha \approx 0.53544094560$ and

$$\{(p_i,q_i)\}_{i=1}^{4} \approx \big\{(14.535673, -0.839562),\ (0.429608, 1.621108),\ (-13.043759, 6.469236),\ (-0.478922, -0.693383)\big\},$$

then u given by (5.6) satisfies

$$\nabla \cdot (a \nabla u) = 0 \quad \text{in } \Omega_i$$

and

$$\lim_{\theta \to (i\pi/2)^+} a \frac{\partial u(r,\theta)}{\partial \theta} = \lim_{\theta \to (i\pi/2)^-} a \frac{\partial u(r,\theta)}{\partial \theta}$$

for $i = 1, 2, 3, 4$. Note that $u \in H^{1+\alpha-\epsilon}(\Omega)$ for any $\epsilon > 0$ and has a strong singularity at the origin.

The initial coarse mesh, i.e., the input for step 0 of Algorithm 2, used for the solution of Example 3 is the same as that used for Example 1, i.e., a uniform Cartesian grid consisting of 81 nodes; see Figure 5.9. For this interface problem, we need to impose a restriction on the computational meshes: no triangle at any refinement level can straddle the interface lines $x = 0$ and $y = 0$; i.e., the triangulations have to conform to the interfaces, so that the discontinuities of a occur only across mesh edges.

Uniformly refined grids automatically meet this constraint. Some modifications can be made to Algorithm 2 so that CfCVDT adapted meshes also satisfy this requirement. The initial CfCVDT meshes, i.e., the output of step 0 of Algorithm 2, determined using the density functions ρ_{H^1} and ρ_{L^2} are also given in Figure 5.9. Figure 5.10 displays refined meshes at some levels generated by the CfCVDT-based adaptive method. The

distributions of nodes in the CfCVDT-adapted meshes clearly show the accumulation of nodes near the origin. In order to better visualize the extent of the accumulation, a portion of the meshes near the origin, magnified 1024 times, are also included in Figure 5.10. It is easy to see that the CfCVDT-adapted meshes generated using the density function ρ_{H^1} have a much higher concentration of nodes near the singular point, i.e., the origin, than those generated using ρ_{L^2}. This observation is supported by the values of h_{max}/h_{min} listed in Table 5.3. Again, all triangles are well shaped at all refinement levels, an observation that is supported by the values of q_{min} and q_{avg} listed in Table 5.3.

Table 5.3 contains information about mesh quality, solution errors, and convergence rates at all refinement levels for different refinement strategies for Example 3; the corresponding plots of the error norms ($\|e_h\|_{L^2(\Omega)}$ and $|e_h|_{H^1(\Omega)}$) versus the number of nodes are given in Figure 5.11. The convergence rates for the uniform refinement method are about 1.08 and 0.53 for $\|e_h\|_{L^2(\Omega)}$ and $|e_h|_{H^1(\Omega)}$, respectively. These match very well with those predicted by finite element theory, i.e., 2α and α, respectively, for $u \in H^{\alpha-\epsilon}(\Omega)$. However, one sees that the CfCVDT-based adaptive methods still achieve almost perfect convergence rates, i.e., 1.0 and 1.8 for $|e_h|_{H^1(\Omega)}$ and $|e_h|_{L^2(\Omega)}$, respectively. The values of q_{min} and q_{avg} given in Table 5.3 demonstrate that the

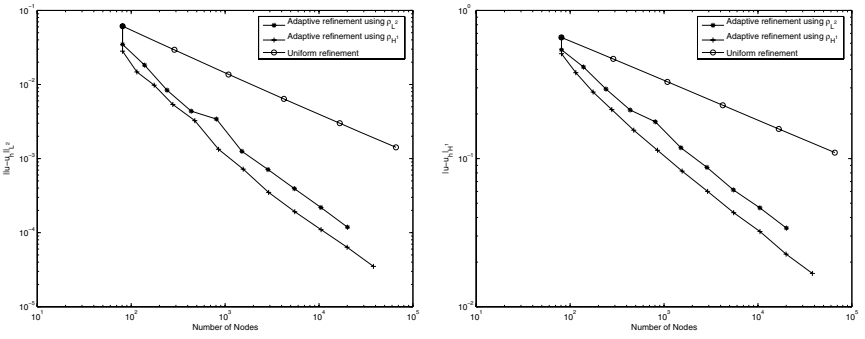

FIG. 5.11. *Error norms versus number of nodes for different refinement strategies for Example* 3. *Left:* $\|e_h\|_{L^2(\Omega)}$. *Right:* $|e_h|_{H^1(\Omega)}$.

quality of the meshes produced by the CfCVDT-based adaptive methods is always very good at all refinement levels and for both density functions ρ_{H^1} and ρ_{L^2}, although the mesh sizes vary greatly over the Ω; e.g., h_{max}/h_{min} reaches 53393.1 at the last level when the density function ρ_{H^1} is used. Again, since u is not in $H^2(\Omega)$, we see that h_{max}/h_{min} tends to monotonically increase for the adaptive methods. Note that in this case, the CfCVDT-based adaptive method using the density function ρ_{H^1} generated approximate solutions having both smaller $\|e_h\|_{L^2(\Omega)}$ and $\|e_h\|_{H^1(\Omega)}$ than using ρ_{L^2}. We believe this phenomenon is due to the strong singularity of the exact solution u while the density functions are constructed based on the assumption that $u \in H^2(\Omega)$.

From Table 5.3 and Figure 5.11, one also observes that the CfCVDT-based adaptive methods are much more efficient relative to the uniform refinement strategy. For example, for the uniform refinement method, we have that $\|e_h\|_{L^2(\Omega)} = 1.4193\text{e-}03$ and $|e_h|_{H^1(\Omega)} = 1.0975\text{e-}01$ on the refined mesh with $66,409$ nodes. However, for the adaptive methods, the values of these norms are 1.3335e-03 and 1.1379e-01, respectively, on the mesh with only 853 nodes when ρ_{H^1} is used as the density function, and 1.2532e-03 and 1.1830e-01, respectively, on the mesh with only $1,512$ nodes when ρ_{L^2} is used as the density function. This means that, in the case of the $|e_h|_{H^1(\Omega)}$ norm, the CfCVDT-based adaptive methods are more than 60 times more efficient than the uniform refinement method if considering only the size of the resulting system.

We display a representative approximate solution u_h and the errors e_h for different refinement methods in Figure 5.12. It is again obvious that the CfCVDT-based adaptive methods distribute the errors much more equally over the triangles than does the uniform refinement method.

5.4. More complicated geometries. Our last two examples involve more complicated geometries and serve to illustrate the robustness and effectiveness of our adaptive CfCVDT-based mesh generation algorithm.

EXAMPLE 4. Let $\Omega = \Omega_S - \Omega_{H^1} \cup \Omega_{H_2}$, where $\Omega_S = [0,1] \times [0,1]$ and Ω_{H^1} and Ω_{H_2} are two open hexagons formed by the set of vertices $\{0.25 + 0.1\cos(j-1)\theta,\ 0.75 + 0.1\sin(j-1)\theta)\}_{j=1}^{6}$ and $\{0.6 + 0.1\cos(j-1)\theta,\ 0.4 + 0.1\sin(j-1)\theta)\}_{j=1}^{6}$ with $\theta = \pi/3$, respectively. Clearly, Ω is a square domain having two hexagonal holes; see Figure 5.13. In general, solutions of (5.1) possess large geometric singularities at

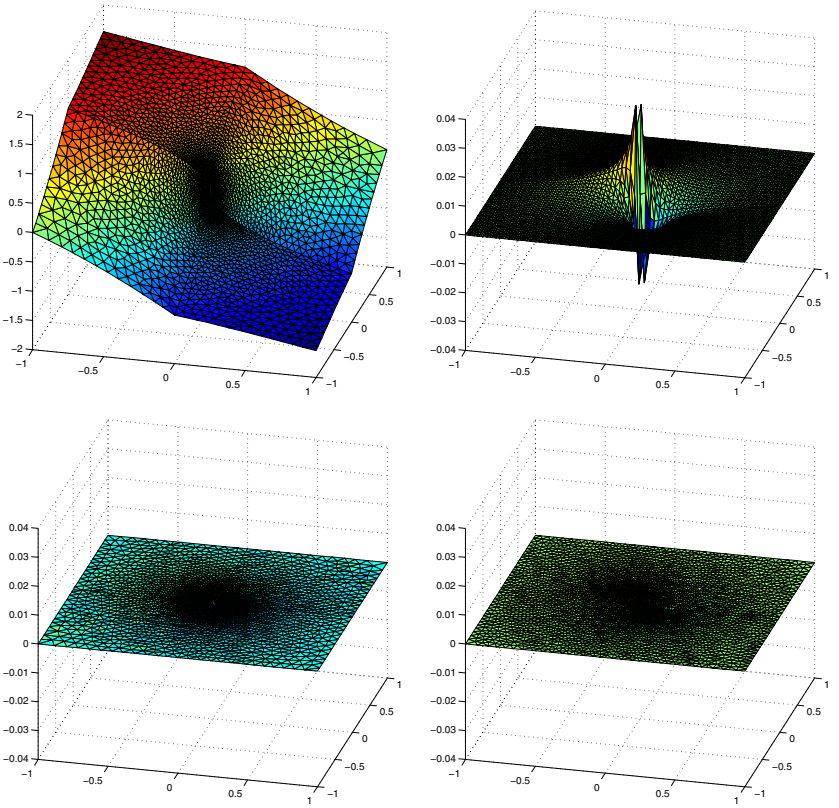

FIG. 5.12. *Plots of an approximate solution and error distributions for different refinement methods for Example* 3. *Top left: A representative approximate solution* u_h. *Top right: The error* e_h *on the mesh with* 4225 *nodes obtained using the uniform refinement method. the vertices of the two interior hexagons. Set

$$a(x,y) = 1 + 10x^2 + y^2, \quad b(x,y) = 1 + x^2, \quad f(x,y) = 1, \text{ and } \quad g(x,y) = 0. \tag{5.7}$$

Although an analytic form of the exact solution u of (5.1) with the data (5.7) is not known, it is known that u belongs only to $H^{\frac{7}{4}-\epsilon}(\Omega)$ for any $\epsilon > 0$ and not to $H^2(\Omega)$.

5. Let $\Omega = \Omega_{S_1} - \Omega_{S_2}$, where $\Omega_{S_1} = [-1,1] \times [-1,1]$ and $\Omega_{S_2} = (-0.5,0.5) \times (-0.5,0.5)$. Set

$$b(x,y) = 0, \quad f(x,y) = 1, \quad g(x,y) = 0 \tag{5.8}$$

and

$$a(x,y) = \begin{cases} 1 & (x,y) \in \Omega_1, \\ 20 & (x,y) \in \Omega_2, \\ 20 & (x,y) \in \Omega_3, \\ 400 & (x,y) \in \Omega_4, \end{cases} \tag{5.9}$$

where Ω_i for $i = 1, 2, 3, 4$ are defined in Figure 5.13. Note that a is discontinuous in Ω. We again do not know an analytic form of the exact solution u of (5.1) with the data (5.8) and (5.9), but we do know that globally u belongs only to $H^1(\Omega)$ (and not $H^2(\Omega)$), but $u|_{\Omega_i} \in H^2(\Omega_i)$ for $i = 1, 2, 3, 4$.

The initial coarse meshes used for the solution of Examples 4 and 5 are displayed in Figure 5.13. Figures 5.14 and 5.15 present repeatedly refined meshes at different levels

generated by the CfCVDT-based adaptive methods for Examples 4 and 5, respectively, for both density functions ρ_{H^1} and ρ_{L^2}. Information about mesh quality is given in Tables 5.4 and 5.5, respectively. Figure 5.16 displays approximate solutions u_h computed by our adaptive methods for the two examples.

6. Conclusions. In this paper, we presented an efficient adaptive mesh refining algorithm for elliptic PDEs that combines a posteriori error estimation with centroidal Voronoi–Delaunay tessellations of domains in two dimensions. The two ingredients are well linked together by the fact that the density function required by the second one is defined and computed from the first one with standard interpolations. Various numerical experiments were carried out and showed that our techniques always obtained optimal convergence rates for the piecewise linear finite elements with respect to both H^1 and L^2 norms and worked pretty robustly. This mesh adaptation strategy can be easily generalized and applied to higher-order finite element approximations or mixed finite element formulations. We also would like to remark that we are currently studying the extension of this methodology to problems in three dimensions and to time dependent problems.

Acknowledgment. The authors would like to thank the referees for their valuable suggestions which greatly improved the paper.

AN EMBEDDED BOUNDARY METHOD FOR THE WAVE EQUATION WITH DISCONTINUOUS COEFFICIENTS*

HEINZ-OTTO KREISS† AND N. ANDERS PETERSSON‡

Abstract. A second order accurate embedded boundary method for the two-dimensional wave equation with discontinuous wave propagation speed is described. The wave equation is discretized on a Cartesian grid with constant grid size and the interface (across which the wave speed is discontinuous) is allowed to intersect the mesh in an arbitrary fashion. By using ghost points on either side of the interface, previous embedded boundary techniques for the Neumann and Dirichlet problems are generalized to satisfy the jump conditions across the interface to second order accuracy. The resulting discretization of the jump conditions has the desirable property that each ghost point can be updated independently of all other ghost points, resulting in a fully explicit time-integration method. We prove that the one-dimensional restriction of the method is stable without damping for arbitrary locations of the interface relative to the grid. For the two-dimensional case, the previously developed fourth order A^TA-dissipation is generalized to handle jump conditions. We demonstrate that this operator provides sufficient stabilization to enable long-time simulations while being weak enough to preserve the accuracy of the solution. Numerical examples are given where the method is used to study electromagnetic scattering of a plane wave by a dielectric cylinder. The numerical solutions are evaluated against the analytical solution due to Mie, and pointwise second order accuracy is confirmed.

1. Introduction.

This paper describes a second order accurate Cartesian embedded boundary method for the two-dimensional wave equation with discontinuous wave propagation speed. Motivated by wave propagation problems from applications like seismology, acoustics, and general relativity, where the underlying differential equations are systems of second order hyperbolic partial differential equations, we develop a numerical method that directly discretizes the wave equation in second order formulation. This approach extends previous research [1, 2, 3] to the case of discontinuous coefficients.

For every second order hyperbolic system, there is an equivalent but larger first order system. For example, two-dimensional acoustic wave propagation is governed by a scalar second order wave equation for the pressure, or by a system of three first order hyperbolic equations governing the two velocity components and the pressure. Most previous numerical methods for this type of problem have focused on the first order formulation [4, 5, 6]. For linear wave propagation, a staggered grid is often used to avoid complications with stability of extra numerical boundary conditions [7] and spurious waves traveling in the wrong direction [8]. However, Cartesian staggered grid discretizations are difficult to generalize to handle complex geometries, that is, boundaries that intersect the grid in an arbitrary way.

The accuracy of a finite difference approximation of the wave equation with discontinuous coefficients was analyzed by Brown [9]. For the one-dimensional case, he proved that the amplitude error in reflected and transmitted waves is determined by the accuracy by which the jump conditions are discretized, while the phase error is determined by the accuracy of the discretization in the interior of the domain. In the one-dimensional case, Tikhonov and Samarskiĭ's [10] averaging formula was used to obtain a second order accurate approximation without explicitly discretizing the jump conditions. Numerical calculations indicated a significant benefit of combining the second order treatment of the jump conditions with a fourth order method in the interior of the domain. Unfortunately, it is not known how to generalize the averaging formula to the two-dimensional case when the discontinuity is not aligned with the grid, and the combinations of a first order treatment of the jump conditions with a second or fourth order formula away from the interface gave less impressive results than in the one-dimensional case.

A fully second order immersed interface method for solving the two-dimensional acoustic wave equation with discontinuous coefficients was developed by Zhang and LeVeque [11]. Here, the problem was written as a hyperbolic system of three first order equations and special difference formulas were developed near the interface, which take the location of the interface and the jump conditions into account to achieve second order accuracy. For each grid point next to the interface, a linear system with 54 equations for 54 unknowns had to be solved to find the values of the coefficients in the local difference formula. For more complicated hyperbolic systems (such as the elastic wave equation), even larger systems of equations must be solved to set up the coefficients.

Finite difference methods for the time-dependent Maxwell equations have been studied extensively, and a relatively recent overview of the field is provided by Hesthaven [12]. Maxwell's equations are usually written as a first order hyperbolic system and a Cartesian staggered grid is often employed to discretize the equations in space. Several second, fourth, and even higher order accurate schemes have been derived to handle embedded discontinuous coefficients in the one-dimensional case [13, 14, 15, 16], but these methods generalize only to the two-dimensional case when the material interface is parallel to a grid direction. A brief description of a compact fourth order accurate implicit staggered grid scheme based on Pade' approximations is presented by Turkel and Yefet [17]. Here the Dirichlet condition associated with a perfectly electric conducting boundary is satisfied on an embedded boundary by locally modifying the uniform mesh to make the nearest grid points fall on the boundary. However, it is not clear how this approach can be generalized to handle jump conditions across material interfaces. Furthermore, this approach can result in a severe time step restriction due to small cells at the boundary. An alternative to the staggered grid approach is presented by Cai and Deng [18], who solve the first order hyperbolic system on a node-based grid by combining a Lax–Wendroff scheme in the interior with an upwinding approach for satisfying jump conditions across an embedded material interface. However, solving a first order system on a node-based grid can lead to the aforementioned problem with spurious waves traveling in the wrong direction [8]. Furthermore, the mesh needs to be finer to achieve the same accuracy compared to when the wave equation is solved in second order formulation [1].

Higher order finite difference schemes for Maxwell's equations have also been extended to the curvilinear case [19] and to overlapping grids [20], but these approaches rely on the availability of a smooth mesh conforming to the interface. We also remark that there are many Cartesian embedded boundary methods for elliptic and parabolic

partial differential equations, e.g., [21, 22, 23, 24, 25, 26].

In this paper, we consider the scalar second order wave equation in a two-dimensional domain $\Omega = \Omega_I \cup \Omega_{II}$, with a piecewise constant coefficient $\rho(\boldsymbol{x}) > 0$,

$$\rho(\boldsymbol{x}) = \begin{cases} \rho_I, & \boldsymbol{x} \in \Omega_I, \\ \rho_{II}, & \boldsymbol{x} \in \Omega_{II}. \end{cases}$$

Let $u(\boldsymbol{x}, t)$ and $w(\boldsymbol{x}, t)$ denote the solutions in the subdomains Ω_I and Ω_{II}, satisfying

$$u_{tt} = \frac{1}{\rho_I}\Delta u + F(\boldsymbol{x}, t), \qquad \boldsymbol{x} \in \Omega_I, \quad t \geq 0, \tag{1}$$

$$w_{tt} = \frac{1}{\rho_{II}}\Delta w + F(\boldsymbol{x}, t), \quad \boldsymbol{x} \in \Omega_{II}, \quad t \geq 0, \tag{2}$$

$$u(\boldsymbol{x}, 0) = U_0(\boldsymbol{x}), \quad u_t(\boldsymbol{x}, 0) = U_1(\boldsymbol{x}), \qquad \boldsymbol{x} \in \Omega_I, \tag{3}$$

$$w(\boldsymbol{x}, 0) = W_0(\boldsymbol{x}), \quad w_t(\boldsymbol{x}, 0) = W_1(\boldsymbol{x}), \qquad \boldsymbol{x} \in \Omega_{II}. \tag{4}$$

Here, $F(\boldsymbol{x}, t)$ is a forcing function. Let Γ be the smooth interface between Ω_I and Ω_{II}, across which the solutions are coupled by the jump conditions

$$u = w, \qquad \boldsymbol{x} \in \Gamma, \quad t \geq 0, \tag{5}$$

$$\frac{1}{\rho_I}\frac{\partial u}{\partial n} = -\frac{1}{\rho_{II}}\frac{\partial w}{\partial n}, \quad \boldsymbol{x} \in \Gamma, \quad t \geq 0. \tag{6}$$

Note that the normal derivatives are taken outward from both Ω_I and Ω_{II}. Hence we have the minus sign in the latter equation.

For the purpose of our discussion, we assume that Ω_I is a bounded domain inside Ω_{II}, and that Ω_{II} has a rectangular outer boundary where Dirichlet or Neumann boundary conditions are enforced. The interface between Ω_I and Ω_{II} can however have an arbitrary smooth shape. As will be demonstrated below, the method can be generalized to several subdomains. Nonrectangular outer boundaries can be handled using the embedded boundary techniques in [2] and [3].

We discretize the two-dimensional wave equations on a Cartesian grid $\boldsymbol{x}_{i,j} = (ih, jh)$ in space, where $h > 0$ is the grid size, and let $t_n = n\delta_t$, $n = 0, 1, 2, \ldots$, denote the time-discretization with step size $\delta_t > 0$. We take $u^n_{i,j}$ and $w^n_{i,j}$ to be the difference approximations of $u(x_i, y_j, t_n)$ and $w(x_i, y_j, t_n)$, respectively. At all grid points interior to Ω_I, a second order accurate approximation of the Laplacian of u is given by

$$\Delta_h u^n_{i,j} =: \frac{1}{h^2}(u^n_{i+1,j} + u^n_{i-1,j} + u^n_{i,j+1} + u^n_{i,j-1} - 4u^n_{i,j}), \quad \boldsymbol{x}_{i,j} \in \Omega_I. \tag{7}$$

In order to form (7) at all grid points in Ω_I, we also define $u^n_{i,j}$ at the set of ghost points G_I:

$$G_I = \{(i, j),\ \boldsymbol{x}_{i,j} \notin \Omega_I,\ \text{but at least one of } \boldsymbol{x}_{i\pm1,j} \in \Omega_I \text{ or } \boldsymbol{x}_{i,j\pm1} \in \Omega_I\}.$$

A corresponding formula is used to approximate the Laplacian of w at all interior grid points of Ω_{II} using a corresponding set of ghost points G_{II}.

The solution at the ghost points are determined by the jump conditions (5) and (6). We start by considering the ghost point $u_{i,j}$; see Figure 1.

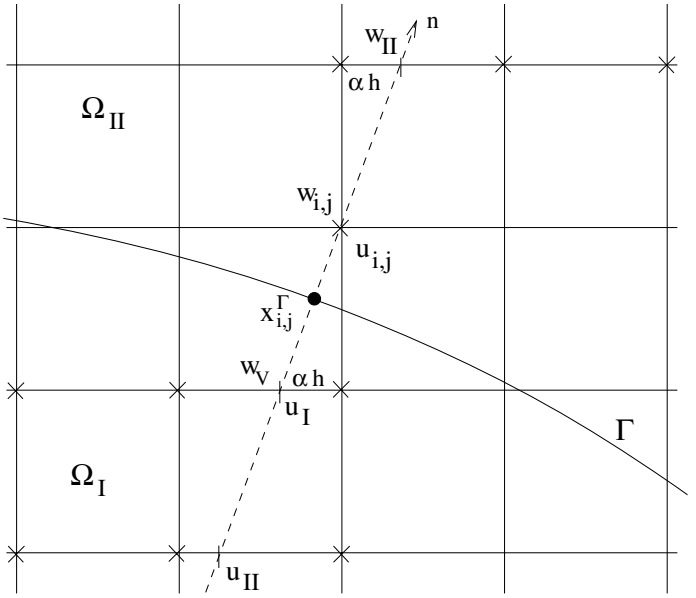

FIG. 1. *The points used for discretizing the jump conditions.*

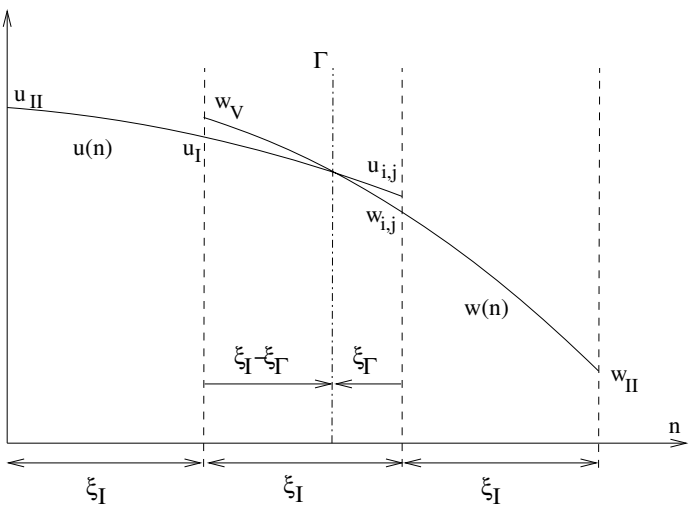

FIG. 2. *The solution along the normal to the interface is continuous, but its first derivative is discontinuous.*

We can derive second order approximations for the value and normal derivative on the boundary using Lagrange interpolation between $u_{i,j}$, u_I, and u_{II} (see Figure 2):

$$B^D_{i,j}u =: g^D_0(\xi_\Gamma)u_{i,j} + g^D_I(\xi_\Gamma)u_I + g^D_{II}(\xi_\Gamma)u_{II} = u(\boldsymbol{x}^\Gamma_{i,j}) + \mathcal{O}(h^2), \qquad (i,j) \in G_I, \tag{8}$$

$$B^N_{i,j}u =: g^N_0(\xi_\Gamma)u_{i,j} + g^N_I(\xi_\Gamma)u_I + g^N_{II}(\xi_\Gamma)u_{II} = \frac{\partial u}{\partial n}(\boldsymbol{x}^\Gamma_{i,j}) + \mathcal{O}(h^2), \quad (i,j) \in G_I. \tag{9}$$

The values u_I and u_{II} are obtained by Lagrange interpolation, in this case, along the

horizontal grid lines y_{j-1} and y_{j-2},

$$u_I^n = r_0 u_{i,j-1}^n + r_1 u_{i-1,j-1}^n + r_2 u_{i-2,j-1}^n, \tag{10}$$

$$u_{II}^n = r_3 u_{i,j-2}^n + r_4 u_{i-1,j-2}^n + r_5 u_{i-2,j-2}^n. \tag{11}$$

The coefficients g^D and g^N are given in section 4.

To derive corresponding formulas for w along the same normal, we introduce the virtual ghost point value w_v, defined at the same location as u_I; see Figure 1. Since w_v is outside Ω_{II} and it is in general located in between grid points, this value is only used to form the discrete jump conditions. Lagrange interpolation between w_v, $w_{i,j}$, and w_{II} (see Figure 2) gives for $(i,j) \in G_I$

$$\begin{aligned} V_{i,j}^D w &=: g_0^D(\xi_I - \xi_\Gamma) w_v + g_I^D(\xi_I - \xi_\Gamma) w_{i,j} + g_{II}^D(\xi_I - \xi_\Gamma) w_{II} \\ &= w(\boldsymbol{x}_{i,j}^\Gamma) + \mathcal{O}(h^2), \end{aligned} \tag{12}$$

$$\begin{aligned} V_{i,j}^N w &=: g_0^N(\xi_I - \xi_\Gamma) w_v + g_I^N(\xi_I - \xi_\Gamma) w_{i,j} + g_{II}^N(\xi_I - \xi_\Gamma) w_{II} \\ &= \frac{\partial w}{\partial n}(\boldsymbol{x}_{i,j}^\Gamma) + \mathcal{O}(h^2). \end{aligned} \tag{13}$$

Note that there is a symmetry between the interpolation formulas for u_I and w_{II} that simplifies the calculation of w_{II}. If the normal going through $\boldsymbol{x}_{i,j}$ intersects the horizontal grid line $y = y_{j-1}$ at $x = x_i - \alpha h$, the extension of the same normal will intersect the grid line $y = y_{j+1}$ at $x = x_i + \alpha h$. The Lagrange interpolation formula for w_{II}^n therefore becomes

$$w_{II}^n = r_0 w_{i,j+1}^n + r_1 w_{i+1,j+1}^n + r_2 w_{i+2,j+1}^n.$$

Inserting the discrete approximations of the value and normal derivatives of u and w into the jump conditions (5), (6) results in the discretized jump conditions

$$B_{i,j}^D u^n = V_{i,j}^D w^n, \tag{14}$$

$$\frac{1}{\rho_I} B_{i,j}^N u^n = -\frac{1}{\rho_{II}} V_{i,j}^N w^n. \tag{15}$$

Hence, we get a 2×2 linear system for the unknowns $(u_{i,j}^n, w_v^n)$:

$$\begin{aligned} &\begin{pmatrix} g_0^D(\xi_\Gamma) & -g_0^D(\xi_I - \xi_\Gamma) \\ g_0^N(\xi_\Gamma)/\rho_I & g_0^N(\xi_I - \xi_\Gamma)/\rho_{II} \end{pmatrix} \begin{pmatrix} u_{i,j}^n \\ w_v^n \end{pmatrix} \\ &= \begin{pmatrix} g_I^D(\xi_I - \xi_\Gamma) w_{i,j}^n + g_{II}^D(\xi_I - \xi_\Gamma) w_{II}^n - g_I^D(\xi_\Gamma) u_I^n - g_{II}^D(\xi_\Gamma) u_{II}^n \\ -(g_I^N(\xi_I - \xi_\Gamma) w_{i,j}^n + g_{II}^N(\xi_I - \xi_\Gamma) w_{II}^n)/\rho_{II} - (g_I^N(\xi_\Gamma) u_I^n + g_{II}^N(\xi_\Gamma) u_{II}^n)/\rho_I \end{pmatrix}. \end{aligned} \tag{16}$$

We solve this system for $u_{i,j}^n$ and ignore the virtual ghost point value w_v^n. A formula for the w-ghost points can be derived in a similar way.

Note that this discretization of the jump conditions has the desirable property that each ghost point can be updated independently of all other ghost points. Hence, there is no coupling along the boundary.

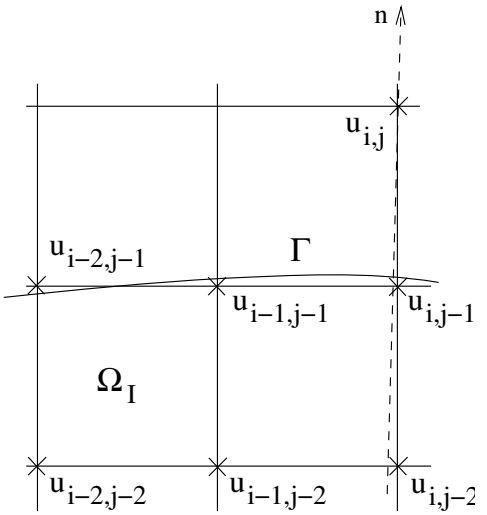

FIG. 3. *The Lagrange interpolation formula for u_I can in rare cases contain outside points.*

Our practical experience with the above interpolation procedure from previous work [2, 3] and the numerical examples in section 6 indicate that it is almost always possible to find enough interior points to compute u_I, u_{II}, and w_{II}, as long as the interface Γ is well resolved on the grid. However, there are rare cases when one or two of the points in the interpolation stencil for u_I can be outside the domain; see Figure 3. In this case, the interface curve has a local maxima just above y_{j-1}, between x_{i-1} and x_i, such that the normal going through $u_{i,j}$ has the form $\boldsymbol{n} = (\zeta, 1-\zeta^2/2)^T$, $\zeta > 0$, $\zeta \ll 1$. Since $\zeta > 0$, we choose to interpolate from $u_{i-2,j-1}$, $u_{i-1,j-1}$, and $u_{i,j-1}$ to obtain u_I. In this situation it is possible for $u_{i-2,j-1}$ to be outside the domain Ω_I, even though the interface is well resolved on the grid. Since the interpolation formula for updating $u_{i,j}$ contains an outside point, we call $u_{i,j}$ a coupled ghost point. However, $u_{i-2,j-1}$ is itself a ghost point which uses only interior points in its interpolation stencils. Such points are called uncoupled ghost points. Hence, if we first compute the uncoupled ghost point value $u_{i-2,j-1}$ we will have all values necessary for computing the coupled ghost point value $u_{i,j}$. In all smooth interface cases we have tried, any coupled ghost points have depended only on uncoupled ghost points, allowing us to use a pointwise procedure where we first update all uncoupled ghost points, followed by updating any coupled ghost points. Some attempts to treat boundaries with corners with the embedded boundary method were reported in [2]. However, the solution can exhibit singularities at the corners which present a more severe set of challenges than merely finding enough grid points to interpolate from. In the following we assume that the interface is smooth and well resolved on the grid.

The remainder of the paper is organized as follows. In section 2, we prove that the discretization of the jump conditions is stable in the one-dimensional case. A simplified stability argument, based on a modified equation model, is presented in section 3. The solvability of the discrete jump conditions in the two-dimensional setting is demonstrated in section 4. Section 5 discusses time-integration and a generalization of the A^TA-dissipation operator (see [2]), which is used to stabilize the scheme for long time-integrations. In section 6, we use the method to study electromagnetic scattering of a plane wave by a dielectric cylinder, where there is a century-old analytical

solution due to Mie [27]. The method is finally applied to two more complicated scattering problems: one including many subdomains and the other with a more irregular interface.

2. Stability. We start by considering the one-dimensional wave equation with discontinuous wave propagation speed,

$$u_{tt} = u_{xx}, \qquad x_{min} \le x \le 0, \quad t \ge 0, \tag{17}$$

$$w_{tt} = c^2 w_{xx}, \quad 0 \le x \le x_{max}, \quad t \ge 0, \tag{18}$$

$$u(x,0) = U_0(x), \quad u_t(x,0) = U_1(x), \qquad x_{min} \le x \le 0, \tag{19}$$

$$w(x,0) = W_0(x), \quad w_t(x,0) = W_1(x), \qquad 0 \le x \le x_{max}, \tag{20}$$

where $c^2 > 0$, $x_{min} < 0$, and $x_{max} > 0$, subject to the Dirichlet boundary conditions

$$u(x_{min}, t) = 0, \quad w(x_{max}, t) = 0, \quad t \ge 0. \tag{21}$$

At the interface, the jump conditions are

$$u(0,t) = w(0,t),$$

$$u_x(0,t) = c^2 w_x(0,t).$$

Using the notation in Figure 4, we discretize the problem in space on a uniform grid $x_\nu = -\alpha h + \nu h$, with grid size $h > 0$, and denote a grid function by $u_\nu(t) = u(x_\nu, t)$. Divided difference operators are defined by $D_+^x u_\nu = (u_{\nu+1} - u_\nu)/h$ and $D_-^x u_\nu = D_+^x u_{\nu-1}$. To model the two-dimensional case, we shift the grid so the discontinuity in the wave speed does not coincide with a grid point, i.e., $0 < \alpha < 1$. We want to focus the discussion on the stability of the discretization of the jump conditions, and we take x_{min} and x_{max} to coincide with grid points, i.e., $x_{min} = x_{-N}$ and $x_{max} = x_N$.

The semidiscrete problem becomes
