Although it is not our primary concern, now we can find the explicit electromagnetic regularizer. Notice that expression (5.13) is identical in form to the symbol (5.10) of the original operator. This means that the operator corresponding to Φ^{-1} has the same form as the operator corresponding to Φ. Hence in the isotropic case the regularizer is

$$A^{\mathrm{r}}_{\mathrm{isotropic}} = \mathrm{d}\left(\mathbb{I} + \frac{1}{3}\chi'\right) - A^{\mathrm{s}}\mathrm{d}(\chi'), \tag{5.15}$$

with χ' given by (5.14).

The essential spectrum consists of the eigenvalues of the symbol matrix $\Phi(\mathbf{x},\tilde{\Theta})$ for all $\mathbf{x} \in \mathbb{R}^3$ and all $\tilde{\Theta}$ on the unit sphere $\mathbb{S}$. Direct computations show that in the anisotropic case these eigenvalues are $\lambda_1 = \lambda_2 = 1$ and $\lambda_3 = \tilde{\Theta}^T \eta_{\mathrm{r}}(\mathbf{x},\omega)\tilde{\Theta}$, and they depend on both $\mathbf{x}$ and $\tilde{\Theta}$, whereas in the isotropic case, where η_{r} is a scalar, the eigenvalues are $\lambda_1 = \lambda_2 = 1$ and $\lambda_3 = \eta_{\mathrm{r}}(\mathbf{x},\omega)$, and they depend on $\mathbf{x}$ only. Hence in general the essential spectrum is given by

$$\lambda_1^{\mathrm{ess}} = \lambda_2^{\mathrm{ess}} = 1, \qquad \lambda_3^{\mathrm{ess}} = \tilde{\Theta}^T \eta_{\mathrm{r}}(\mathbf{x},\omega)\tilde{\Theta}, \quad \mathbf{x} \in \mathbb{R}^3, \quad \tilde{\Theta} \in \mathbb{S}. \tag{5.16}$$

Notice that there is also a parametric dependence on the angular frequency ω in both isotropic and anisotropic cases, which matters if the scatterer is conductive and/or dispersive.

The object parameters are presumed to be Hölder continuous functions of $\mathbf{x}$ on $\mathbb{R}^3$. This means that even with a homogeneous scatterer, characterized by $\eta_{\mathrm{r}}(\mathbf{x},\omega) = \text{const}$, $\mathbf{x} \in D$, there exists a smooth transition between η_{r} and 1, the background medium parameter. Then, the essential spectrum must connect 1 and point η_{r} in the complex plane. Moreover, for any inhomogeneous scatterer the essential spectrum will emerge from point 1 on the real axis and continuously span all values admitted by $\tilde{\Theta}^T \eta_{\mathrm{r}}(\mathbf{x},\omega)\tilde{\Theta}$ for $\mathbf{x} \in D$ and $\tilde{\Theta} \in \mathbb{S}$.

Apart from the essential spectrum our operator may have discrete eigenvalues, which correspond to nontrivial solutions of the problem

$$\left[\mathrm{d}\left(\mathbb{I} + \frac{1}{3}\chi\right) - A^{\mathrm{s}}\mathrm{d}(\chi) + K\right] u - \lambda u = 0. \tag{5.17}$$

We shall consider here only the isotropic case. In this respect it is convenient to use the standard sufficient uniqueness condition for the original problem (5.7), which in terms of the admittance function $\eta(\mathbf{x},\omega)$ given by (5.3) can be written as

$$\mathrm{Re}\,[\eta(\mathbf{x},\omega)] > 0, \quad \mathbf{x} \in D. \tag{5.18}$$

Under this condition the null-space of the volume integral operator (operator in square brackets in (5.17)) is known to be trivial. Considering the case where $\lambda \neq 1$ we can rewrite (5.17) as

$$\left[\mathrm{d}\left(\mathbb{I} + \frac{1}{3}\chi'\right) - A^{\mathrm{s}}\mathrm{d}(\chi') + K'\right] u = 0, \tag{5.19}$$

where the only difference from the original operator is the new contrast function χ' given by

$$\chi'(\mathbf{x},\omega,\lambda)=\frac{\chi(\mathbf{x},\omega)}{1-\lambda}=\frac{\eta(\mathbf{x},\omega)-\lambda\eta_{\mathrm{b}}(\omega)}{\eta_{\mathrm{b}}(1-\lambda)}-1=\frac{\eta'(\mathbf{x},\omega,\lambda)}{\eta_{\mathrm{b}}(\omega)}-1. \tag{5.20}$$

And since the eigenvalue problem has been reduced to the problem about the non-trivial null-space of the original operator we can use an "inverse" of the condition (5.18), i.e.,

$$\mathrm{Re}\,[\eta'(\mathbf{x},\omega,\lambda)]\le 0,\quad \mathbf{x}\in D. \tag{5.21}$$

From here we derive the following bound on the eigenvalues:

$$\begin{aligned}\mathrm{Re}\,\eta(\mathbf{x},\omega)-[\mathrm{Re}\,\eta(\mathbf{x},\omega)+\mathrm{Re}\,\eta_{\mathrm{b}}(\omega)]\,\mathrm{Re}\lambda\\ -[\mathrm{Im}\,\eta(\mathbf{x},\omega)-\mathrm{Im}\,\eta_{\mathrm{b}}(\omega)]\,\mathrm{Im}\lambda+\mathrm{Re}\,\eta_{\mathrm{b}}(\omega)|\lambda|^2\le 0,\quad \mathbf{x}\in D.\end{aligned} \tag{5.22}$$

In addition we note that

$$|\lambda|\le\|A\|<\infty, \tag{5.23}$$

since A is bounded, and that $\lambda=0$ is not an eigenvalue if the scattering problem has a unique solution (which we presume from now on).

The only natural homogeneous background medium is a vacuum, where $\sigma_{\mathrm{b}}(\omega)=0$ and $\varepsilon_{\mathrm{b}}(\omega)=\varepsilon_0$. In particular cases, such as scattering from subsurface objects, other homogeneous backgrounds can be used as an approximation. We shall deal with those later. Let us first consider the natural case, and in addition presume that $\sigma(\mathbf{x},\omega)=\sigma(\mathbf{x})$ and $\varepsilon(\mathbf{x},\omega)=\varepsilon(\mathbf{x})$ and are real-valued functions. Further we also assume that the contrast in permittivity $\varepsilon(\mathbf{x})-\varepsilon_{\mathrm{b}}$ is positive for all $\mathbf{x}\in D$. These assumptions hold for a static model of a conducting dielectric, which is applicable at low frequencies where the dispersion of constitutive paremeters is insignificant. In this case the eigenvalue bound (5.22) reduces to

$$\sigma(\mathbf{x})-\sigma(\mathbf{x})\mathrm{Re}\lambda+\omega\,[\varepsilon(\mathbf{x})-\varepsilon_0]\,\mathrm{Im}\lambda\le 0,\quad \mathbf{x}\in D. \tag{5.24}$$

In Figures 5.1 and 5.2 (left) we present geometric estimates derived from this formula for the following three situations:

$$\sigma(\mathbf{x})=0,\qquad 1<\frac{\varepsilon(\mathbf{x})}{\varepsilon_0}\le M_0, \tag{5.25}$$

$$\sigma(\mathbf{x})=\mathrm{const}>0,\quad \varepsilon(\mathbf{x})=\mathrm{const}>\varepsilon_0, \tag{5.26}$$

$$\sigma(\mathbf{x})>0,\qquad \varepsilon(\mathbf{x})>\varepsilon_0, \tag{5.27}$$

where $\mathbf{x}\in D$. The other parameters in these figures are given by

$$M=\frac{\varepsilon}{\varepsilon_0}+i\frac{\sigma}{\omega\varepsilon_0},\quad N=-i\frac{\sigma}{\omega(\varepsilon-\varepsilon_0)}, \tag{5.28}$$

$$N_1=-i\max_{\mathbf{x}\in D}\frac{\sigma(\mathbf{x})}{\omega\,[\varepsilon(\mathbf{x})-\varepsilon_0]}, \tag{5.29}$$

$$N_2=-i\min_{\mathbf{x}\in D}\frac{\sigma(\mathbf{x})}{\omega\,[\varepsilon(\mathbf{x})-\varepsilon_0]}. \tag{5.30}$$

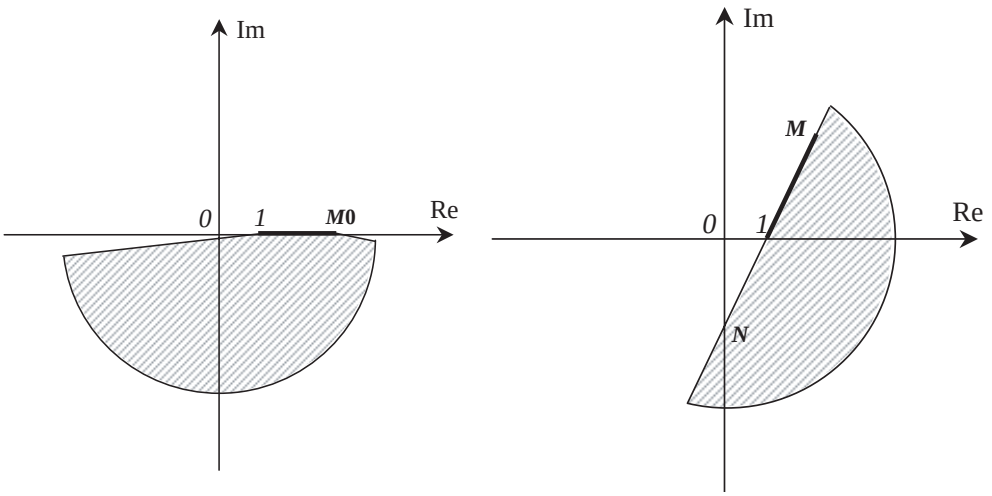

FIG. 5.1. *Location of the spectrum for a homogeneous object in a vacuum. Left: Nonconducting dielectric. Right: Conducting dielectric.*

Fat solid lines and curves schematically outline the essential part of the spectrum, which in the case of a homogeneous object we presume to be straight lines connecting the real 1 and the corresponding value of η/η_b. As one can see, in the natural (vacuum) background medium, the bounds are wedge shaped, as in [1]. In the case of an object with losses these bounds safely separate the domain of eigenvalues from the zero of the complex plane. This is important since the uniqueness condition can guarantee only that there are no eigenvalues [illegible] to zero but does not tell if there are any eigenvalues [illegible] to zero, and such eigenvalues may cause instabilities in the numerical solution and slow down the convergence of an iterative algorithm. From this point of view the worst case is the lossless object or an inhomogeneous object with lossless parts.

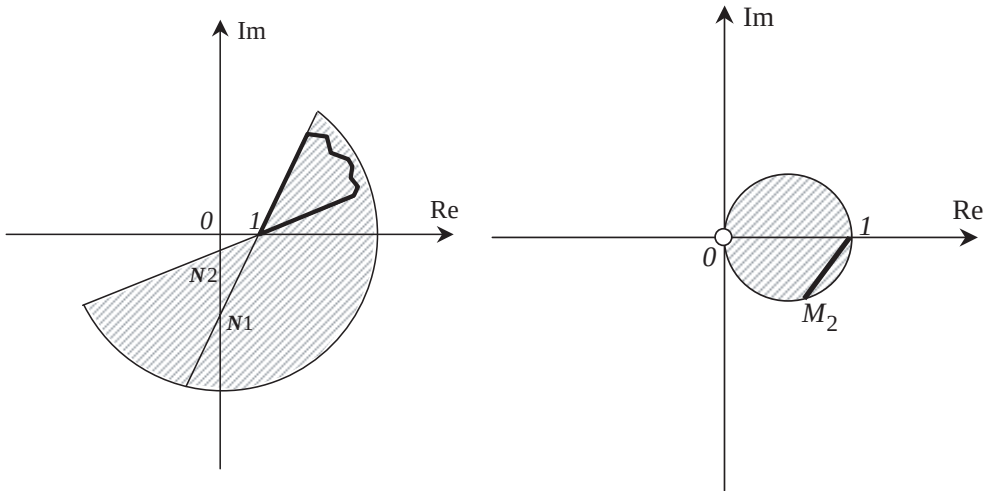

FIG. 5.2. *Location of the spectrum. Left: Inhomogeneous conducting dielectric in a vacuum. Right: Homogeneous nonconducting dielectric object in a conducting dielectric background (no contrast in permittivity).*

Now let us analyze the popular approximation, where the homogeneous background medium is considered to be conducting, i.e., $\sigma_\mathrm{b} > 0$, and/or has arbitrary constant permittivity $\varepsilon_\mathrm{b} > \varepsilon_0$. Such approximations are often used if a scatterer is located inside a large but finite and more or less homogeneous host medium, say, inside the Earth or a human body, and the reflections from the outer boundary of the host medium can be neglected. We again consider the static model of a dielectric and from (5.22) we derive the estimate

$$\left[\mathrm{Re}\lambda - \frac{A}{2}\right]^2 + \left[\mathrm{Im}\lambda + \frac{B}{2}\right]^2 < \left(\frac{D}{2}\right)^2, \tag{5.31}$$

which shows that all eigenvalues are situated inside a circle. Parameters of this circle's center are

$$A = \frac{\sigma(\mathbf{x})}{\sigma_\mathrm{b}} + 1, \quad B = \frac{\omega}{\sigma_\mathrm{b}}\left[\varepsilon(\mathbf{x}) - \varepsilon_\mathrm{b}\right], \tag{5.32}$$

and its diameter can be found from

$$D^2 = \left[\frac{\sigma(\mathbf{x})}{\sigma_\mathrm{b}} - 1\right]^2 + \omega^2\left[\frac{\varepsilon(\mathbf{x}) - \varepsilon_\mathrm{b}}{\sigma_\mathrm{b}}\right]^2. \tag{5.33}$$

Figure 5.2 (right) corresponds to a particular situation where a nonconducting object ($\sigma(\mathbf{x}) = 0$) with no contrast in permittivity ($\varepsilon(\mathbf{x}) = \varepsilon_\mathrm{b}$) is immersed in a conducting background. This can represent an air pocket or a low-contrast plastic landmine in wet soil. The constant M_2 is given by

$$M_2 = \frac{\eta}{\eta_\mathrm{b}} = \frac{\omega^2\varepsilon_\mathrm{b}^2}{\sigma_\mathrm{b}^2 + \omega^2\varepsilon_\mathrm{b}^2} - i\frac{\omega\varepsilon_\mathrm{b}\sigma_\mathrm{b}}{\sigma_\mathrm{b}^2 + \omega^2\varepsilon_\mathrm{b}^2}. \tag{5.34}$$

On one hand, the spectrum is now explicitly bounded, allowing, in particular, for a more precise convergence estimate when an iterative method is employed to solve the scattering problem. On the other hand, the circle extends toward the zero of the complex plane as in Figure 5.2 (right), meaning that, although there is no zero eigenvalue in the spectrum, some of the eigenvalues may get close to zero and render the scattering problem unstable.

The last point to note is about the relative weight of the compact and singular parts in the operator of (5.1) as a function of angular frequency ω. The coefficients α and β in (5.6) depend on the wavenumber $k_\mathrm{b}(\omega)$, which in its turn is proportional to ω. Hence, the kernel of the compact operator gets more "weight" as the frequency increases, and the norm of the operator increases as well. As the compact operator delivers only eigenvalues, we can expect that the eigenvalues will spread out at higher frequencies.

6. Numerical experiments. There is only a limited correspondence between the spectra of an integral operator and of its discretized (matrix) version. First, matrices do not have continuous spectra, but only discrete eigenvalues. Hence, we should not expect to see the lines and curves of the previous section. On the other hand, the continuous spectrum may serve as an accumulation area for the eigenvalues, as the latter should converge to the spectrum of an operator in the continuous limit. Let us first see if it is indeed so.

We discretize the operator of (5.1) using the standard collocation method (see, e.g., [6], [12]), which gives an order h^2 accuracy, where h is the size of an elementary

cubic cell. The scatterer is discretized on an N-point homogeneous grid, and the resulting matrix is $3N \times 3N$ and is completely filled with complex numbers. The matrix eigenvalues are computed using the standard MATLAB function `eig`.

According to our theoretical predictions the essential spectrum, continuous or not, dominates at lower frequencies (small objects). Therefore, we shall first consider an object whose extent is sufficiently small. The background medium is a vacuum and the frequency is set to $\omega/(2\pi) = 1$ GHz. The scatterer has the shape of a cube with side length $a \approx (\lambda_{\text{med}}/20)$, where λ_{med} is the medium wavelength; see Figure 6.1. According to the common ad hoc discretization rule such a small object can be modeled as a single cell (Figure 6.1, left). This, of course, would only give an order h^2 approximation of the field at the geometrical center of the scatterer. In an attempt to compute the field at other points inside the object one may wish to introduce a finer discretization. Then, if the object is homogeneous, i.e., $\eta(\mathbf{x}) = \text{const}$, the value of the constitutive parameter would be the same at all internal grid points (Figure 6.1, upper row). If, however, the object is inhomogeneous, then the matrix will include the new, refined, grid values of $\eta(\mathbf{x}_n)$, $n = 1, \ldots, N$ (Figure 6.1, middle and lower rows). Obviously, there is a link between the spatial discretization and the quantization of constitutive parameters, and we have observed an interesting phenomenon related to these two processes in our numerical experiments. Namely, if we refine the spatial discretization while keeping constitutive parameters constant, then the (low-frequency) spectrum converges to a set of very dense line segments connecting the real unit and the corresponding values of η/η_{b}. In this way we seem to model an object consisting of one or more homogeneous parts without really telling what the behavior of the constitutive parameter is across the interfaces. If, on the other hand, the quantization of the constitutive parameter results in new values at a finer level of discretization, then the line segments in the spectrum are less pronounced.

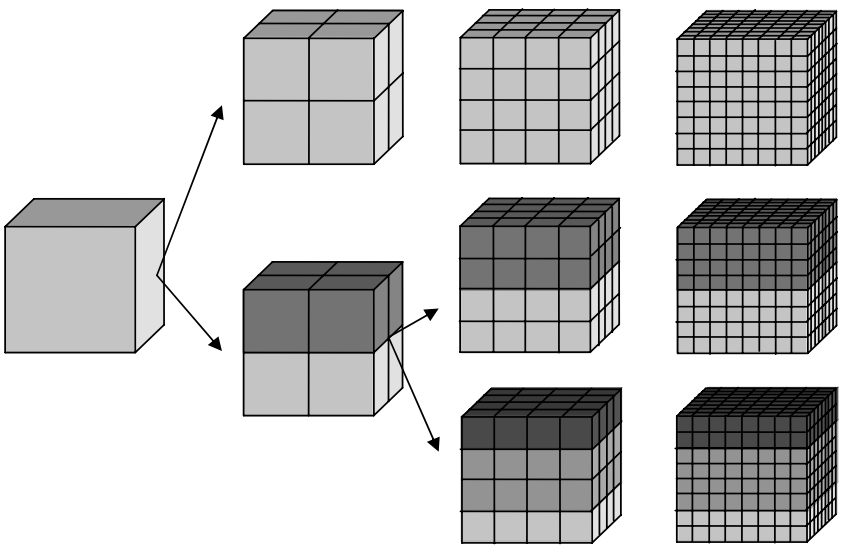

FIG. 6.1. *Different discretization (and quantization) levels for three cubes (homogeneous, two-layered, and three-layered). The side length of all cubes is* $a \approx \lambda_{\text{med}}/20$. *Inhomogeneity becomes "visible" only at an appropriate discretization level.*

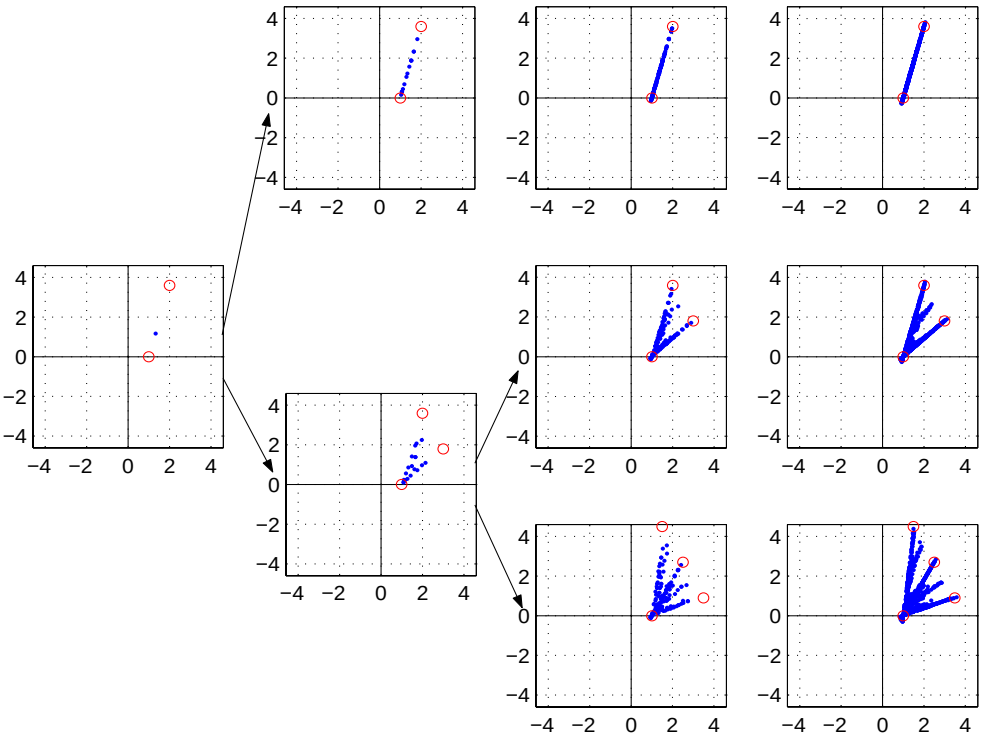

FIG. 6.2. *Effect of discretization (and quantization) refinement on the matrix eigenvalues in the low-frequency (small object) regime. Plots correspond to the objects shown in Figure* 6.1, *and constitutive parameters* η/η_{b} *are given as circles.*

Consider, for example, the case of three different cubes having the same size and the following sequence of grid steps: $h = a, a/2, a/4, a/8$. The matrix dimensions are then, correspondingly, 3×3, 24×24, 192×192, and 384×384. The objects and the eigenvalues are presented, respectively, in Figures 6.1 and 6.2. The upper row in both figures corresponds to the model of a completely homogeneous cube, the middle row models a cube consisting of two layers, and the bottom row corresponds to a three-layered cube. The layered structure becomes visible at $h = a/2$ (second column), and the difference between the two and the three layers is only seen at $h = a/4$ (third column). At $h = a/8$ (last column) we had no more changes in the constitutive parameters of all three objects. The constitutive parameters η/η_{b} are shown as circles in Figure 6.2. The dense lines appear as soon as we stop refining the quantization, but keep refining the spatial discretization.

Figure 6.3 illustrates the marginal influence of the object's geometry on the distribution of eigenvalues at low frequencies (the same frequency as before). Both objects (top and bottom row) consist of two homogeneous parts with constitutive parameters given by circles and have the same outer shape (long parallelepiped, roughly $\lambda/5 \times \lambda/42 \times \lambda/42$). The difference between the objects is in the geometry of the parts. The upper row in Figure 6.3 corresponds to the object consisting of two equal parts (roughly $\lambda/5 \times \lambda/42 \times \lambda/85$ each), which divide the parallelepiped [illegible] its longer dimension, whereas the lower row corresponds to the object consisting of two unequal parts (roughly $\lambda/21 \times \lambda/42 \times \lambda/42$ and $\lambda/7 \times \lambda/42 \times \lambda/42$) dividing the parallelepiped

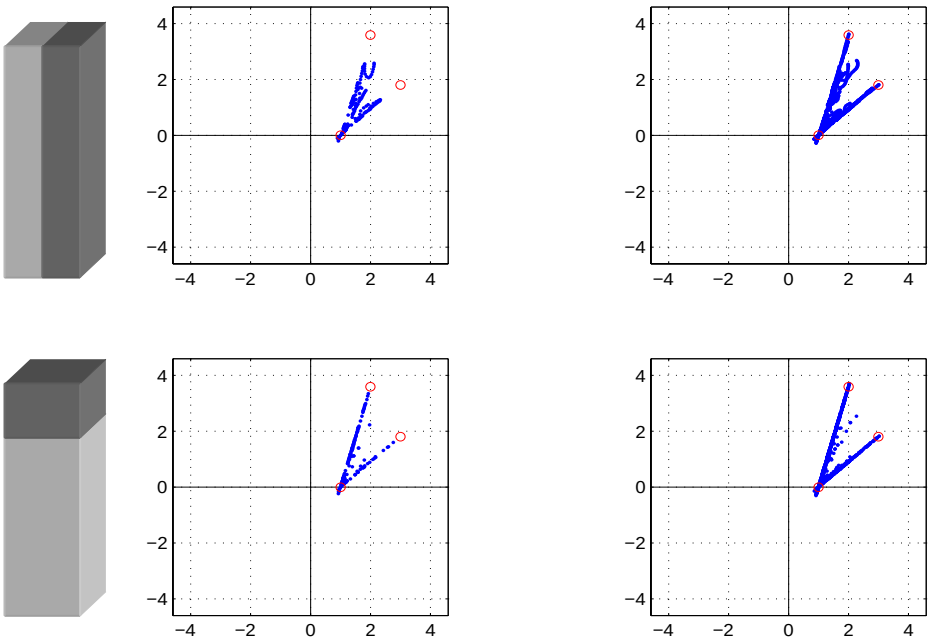

FIG. 6.3. *Effect of the object's shape on the matrix eigenvalues in the low-frequency (small object) regime: Same constitutive parameters* η/η_b *(circles), but different shapes. From left to right: Pictures of the objects, and eigenvalues for two discretization levels:* $h = \lambda_{\text{med}}/70$ *and* $\lambda_{\text{med}}/140$.

its longer dimension. From left to right two discretization levels are presented: $h = \lambda_{\text{med}}/70$ and $h = \lambda_{\text{med}}/140$. With both objects we notice the appearance of the line segments connecting the real unit and the values of η/η_b. The difference seems to be among the other eigenvalues situated between the line segments. These and many other low-frequency numerical experiments suggest that the line segments observed here and in [6] are the matrix analogue of the operator's essential spectrum and that they depend only on the grid values of $\eta(\mathbf{x})/\eta_b$.

Figure 6.4 gives the spectrum for a homogeneous cube at higher frequencies. The η/η_b of the object is shown as a circle. The length of the cube's side is chosen to coincide with the medium wavelength in this case, i.e., $a = \lambda_{\text{med}}$. One can see that now we have not only the dense line segment as in Figure 6.2 (top right), but also a few off-line eigenvalues, which appear within the predicted bounds of Figure 5.1 (right). Two discretizations are shown: $h = \lambda_{\text{med}}/5$ (Figure 6.4, left), and $h = \lambda_{\text{med}}/10$ (Figure 6.4, right). Normally, neither of these would be considered a "proper" level of discretization. However, here we observe an interesting phenomenon related to the essential spectrum, which partly justifies a much more relaxed attitude of practitioners to the discretization of the electromagnetic volume integral equation, as opposed to the tough requirements on the discretization of differential Maxwell's equations via the finite-difference approach. With $h = \lambda_{\text{med}}/5$ we have in total 375 eigenvalues, most of which are clustered along the line segment of the essential spectrum. With $h = \lambda_{\text{med}}/10$ we already have 3000 eigenvalues; however, all "new" 2625 eigenvalues keep filling the same line segment. Of course, the off-line eigenvalues do shift a little, but their number seems to remain the same for both discretization levels. This and similar experiments at higher (resonance) frequencies show that the refinement of

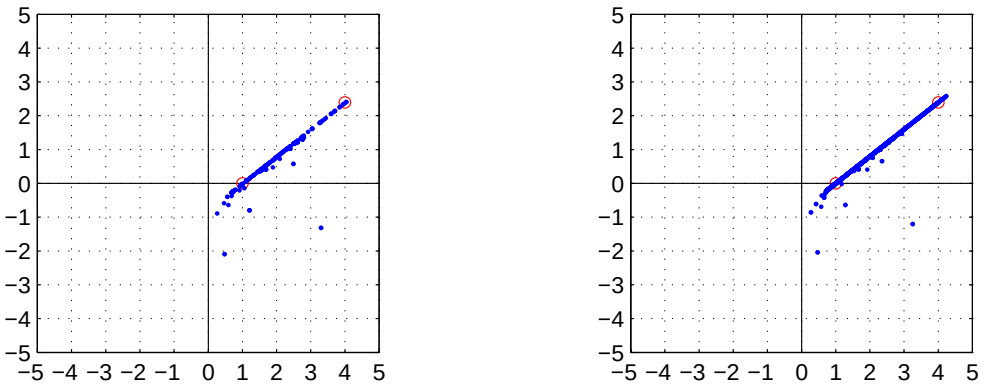

FIG. 6.4. *Effect of discretization on the matrix eigenvalues at higher frequencies. Object: Homogeneous cube. Left: Discretization level* $h = \lambda_{\text{med}}/5$. *Right: Discretization level* $h = \lambda_{\text{med}}/10$.

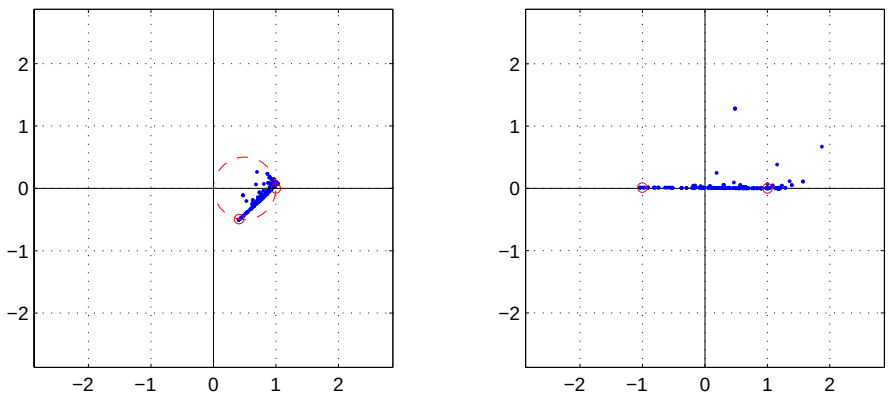

FIG. 6.5. *Spectrum in exotic cases. Left: Vacuum cube in a lossy background medium. Right: Cube with negative permittivity and small losses in vacuum background.*

discretization has no significant effect on the spectral radius of the matrix, which is what is expected from an integral equation formulation.

We conclude our numerical experiments with the result corresponding to the conductive background case described in Figure 5.2 (right). As one can see from Figure 6.5 (left) the matrix spectrum is, indeed, quite accurately described by the predicted circle.

7. Conclusions and applications. The spectrum of the volume integral operator of three-dimensional electromagnetic scattering contains both the essential continuous part and discrete eigenvalues. The apparent difference from the one- and two-dimensional electromagnetics, where the spectrum is purely discrete, stems from the presence of a strong singularity in the kernel of the integral operator in the three-dimensional case. We have shown that the essential spectrum is explicitly given by (5.16) for any anisotropic scatterer with Hölder continuous constitutive parameters.

Knowing the spectrum one can find a fixed iteration parameter which provides the optimal convergence for the Richardson's iteration scheme. In [13] we prove that the well-described essential spectrum dominates at lower frequencies and that all discrete eigenvalues are contained within the convex hull of the essential spectrum. We also

show in [13] how to employ this spectrum information to obtain the mentioned fixed optimal iteration parameter for low-frequency scattering problems.

At higher frequencies one should resort to more sophisticated iterative algorithms such as GMRES and BiCGStab. With large objects and objects with strong electromagnetic contrast GMRES may converge very slowly. In both cases this is probably caused by the increase in the spectral radius of the system matrix. However, now we understand that for the low-contrast large objects this is due to the discrete eigenvalues spreading out, whereas with small but strong-contrast objects the spectral radius will grow due to the stretching of the continuous spectrum. This suggests that two rather distinct preconditioning strategies are needed—an interesting topic for future research.

Information on the spatial spectrum can also be used in the analysis of electromagnetic resonances. Indeed, a resonance occurs at some angular frequency ω if the spatial spectrum either contains zero or is close to it at this frequency. In [14] we show that the spectral information obtained here and in [13] allows us to analyze electromagnetic resonances in arbitrarily inhomogeneous objects of finite extent. To date resonances are explicitly recovered only in infinite (unbounded) homogeneous or periodic media. Somewhat less explicit results can be derived for idealistic metallic and piecewise-homogeneous objects such as resonators, plane-layered media, and dielectric spheres. In [14] we suggest a novel approach to the problem of electromagnetic resonances based on the complex-plane dynamics of the spatial spectrum as a function of the angular frequency. We also show there that the modes associated with the essential spectrum are highly localized in space and are directly related to the so-called plasmons or polaritons.

Another related application area is the study of metamaterials. In particular, one can analyze materials with negative permittivity. Macroscopically these materials may be treated as highly dispersive media, such that for a certain range of ω's their dielectric permittivity and/or their magnetic permeability happen to have negative real parts. An immediate result which follows from our present study is that the spectrum for an object with a negative permittivity part will contain not only points in the left part of the complex plane but also lines or curves connecting these points with the real unit. For a low-loss material, which for obvious reasons is the ultimate goal of experimentalists, the lines of the essential spectrum may then proceed dangerously close to the zero of the complex plane as shown in Figure 6.5 (right), where $\epsilon/\epsilon_{\mathrm{b}} = -1$ and $\sigma = 0.001$ S/m. From the physical viewpoint this would mean that the electromagnetic field is unstable in such media. Without losses ($\sigma = 0$) the line would go right through the zero, meaning that the solution (electromagnetic field) does not exist at all. Perhaps that is the reason why we do not observe many left-handed substances in Nature. Yet another interesting application where the explicit knowledge of the essential spectrum may be of help is magnetically confined fusion plasma.

Acknowledgment. The authors wish to thank Dr. Rob Remis (Delft University of Technology) for his continuous support and encouragement and for pointing out the Cayley–Hamilton theorem.

SPACE-TIME APPROXIMATION WITH SPARSE GRIDS*

MICHAEL GRIEBEL†, DANIEL OELTZ†, AND PANAYOT VASSILEVSKI‡

Abstract. In this article we introduce approximation spaces, especially suited for the approximation of solutions of parabolic problems, which are based on the tensor product construction of a multiscale basis in space and a multiscale basis in time. Proper truncation then leads to so-called *space-time sparse grid spaces*. For a uniform discretization of the spatial space of dimension d with $O(N^d)$ degrees of freedom, these spaces involve for $d > 1$ also only $O(N^d)$ degrees of freedom for the discretization of the whole space-time problem. But they provide the same approximation rate as classical space-time finite element spaces which need $O(N^{d+1})$ degrees of freedoms. This makes these approximation spaces well suited for conventional parabolic and time-dependent optimization problems. We analyze the approximation properties and the dimension of these sparse grid space-time spaces for general stable multiscale bases. We then restrict ourselves to an interpolatory multiscale basis, i.e., a hierarchical basis. Here, to be able to handle also complicated spatial domains Ω, we construct the hierarchical basis from a given spatial finite element basis as follows: First we determine coarse grid points recursively over the levels by the coarsening step of the algebraic multigrid method. Then, we derive interpolatory prolongation operators between the respective coarse and fine grid points by a least squares approach. This way we obtain an algebraic hierarchical basis for the spatial domain which we then use in our space-time sparse grid approach. We give numerical results on the convergence rate of the interpolation error of these spaces for various space-time problems with two spatial dimensions. Implementational issues, data structures, and questions of adaptivity also are addressed to some extent.

1. Introduction.

The modeling of various phenomena in physics, chemistry, biology, and financial engineering leads to time-dependent partial differential equations (PDEs). In most cases there is no analytical solution available for these equations and hence they have to be solved approximately by an appropriate discretization scheme. If we employ, depending on the smoothness of the solution, a discretization scheme on a uniform grid in time and a uniform grid in d-dimensional space with an error of the order p in time and order q in space, we need $O(N^d)$ degrees of freedom for each time step and $O(N^{d+q/p})$ degrees of freedom for the whole approximate solution in space-time to obtain an $_{l'}$ $_{,,,}$ order of q. In particular, for a method which is second order in space and in time this would result in $O(N^{d+1})$ degrees of freedom. An approach which is only first order in time, e.g., the Euler methods, but second order in space needs $O(N^{d+2})$ degrees of freedom. The associated additional storage

requirements then fail to work for parabolic PDEs directly in space-time if $d = 3$ or larger, but enforce a time-slice approach, where only a few spatial grids at successive time points need to be stored.

In some applications it is necessary to solve a system of parabolic equations, where some of the equations are forward and the others are backward in time. Such systems typically arise in parabolic optimal control problems where the equations for the adjoint variables are backward in time but also involve the state variables for which forward equations have to be solved; see, e.g., [33]. Here, all values of the state variables in space $\cdot\, /$ time must be stored to be used for the solution of the adjoint. This is not computationally feasible for the case $d \geq 3$, however, due to the complexity of $O(N^{d+1})$ or $O(N^{d+2})$, even if N is moderately small.

One approach to overcoming this storage problem is the so-called reduced order method [34, 36]. Here, one tries to compute the most important spatial additional storage of the instationary solution from snapshots of the solution at different times. This results in (hopefully) only few spatial basis functions which approximate the given solution with sufficient accuracy over time. To this end, the instationary problem must, however, be approximately solved at the beginning to obtain the snapshots at certain time instances at all. Also, for any update of the reduced order model during an optimization it is necessary to compute an approximate solution to the actual full instationary problem again. Due to the above mentioned complexity orders this is still very expensive. Furthermore, the choice of the time points at which snapshots are taken strongly influences the reduced order model. To date, the question of how to choose the amount and the locations of the time points for the snapshots is not finally answered, and these topics are still a subject of current research.

Another approach is the so-called checkpointing [32]. Here, the solution of the state equation is stored only at some properly chosen time points, called checkpoints. Now, if the value of the state equation at a certain time is needed, the forward state equation is solved with the start time of the nearest checkpoint and the state variable at this point as initial value. Clearly, checkpointing leads to a further increase of computational time on the already expensive solution of the instationary problem.

In the present article we introduce new space-time sparse grid spaces which allow for complexity reduction of the space-time problem from $O(N^{d+q/p})$ to $O(N^d)$. If a slightly more involved regularity assumption is fulfilled, namely, if the mixed second derivative in space and time is bounded, the approximation rate for the space-time sparse grid space remains basically the same as for classical finite element spaces in space and time. Thus, the additional complexity stemming from the time part of a parabolic PDE is eliminated, and we obtain the same complexity order as for a stationary problem. Consequently, the memory and storage requirements are substantially reduced. These space-time sparse grid spaces are constructed from a d-dimensional multilevel basis in space and a one-dimensional multilevel basis in time via a tensor product approach. In this sense they are similar to classical sparse grid spaces; see, for example, [12], which are constructed via a tensor product approach from a one-dimensional multilevel basis for each coordinate direction. We, however, only use a d-dimensional isotropic multilevel basis in spatial space. For this purpose, any available stable multilevel basis in space can be employed. For ease of presentation, we restrict ourselves to an interpolatory multilevel basis, namely a hierarchical basis. To construct the necessary spatial multilevel basis from a given general finite element basis we proceed as follows: First we determine coarse grid points recursively over the levels by the coarsening step of an algebraic multigrid method (AMG). Then, to

assign hierarchical basis functions to these points, we use interpolatory prolongation operators between the respective coarse and fine grids which are derived by a least squares approach. We need higher accuracy of the prolongation operators than in the classical AMG methods in order to guarantee the desired approximation property of the hierarchical basis. In particular, by the least squares approach we employed, the linear functions are well represented on coarse levels. Note that the classical AMG methods have only a "weak approximation property" guaranteed; namely, only the constant function is well represented on coarse levels. Alternatives to the least squares approach could be the smoothed aggregation AMG [47] or the multiple vector preserving AMG interpolation proposed in [48]. These are not considered in the present paper but are worth pursuing in the future. The AMG approach in general allows us to employ any given finite element package on the finest level of the spatial discretization. Thus, we are able to deal also with complicated spatial domains Ω, where classical sparse grid spaces run into difficulties.

In the context of instationary control problems, these spaces can be used for an interpolant of the state variable which was solved with a classical discretization scheme. Then this cheap space-time sparse grid interpolant is employed in the adjoint equation. Alternatively, these spaces can be directly used for the discretization of both the state problem and the adjoint problem. Altogether, our approach overcomes the storage complexity in time-dependent two- and three-dimensional optimization problems and allows us to deal with quite complicated spatial geometries.

The remainder of this article is organized as follows.

In section 2 we describe the general construction of the proposed space-time sparse grid spaces from a multilevel basis in space and a multilevel basis in time. To this end, we simply use a tensor product and properly truncate the resulting multivariate series expansion. We then present results on the approximation rates for these spaces. Here, provided that a slightly stronger regularity assumption is fulfilled, it turns out that the approximation order of classical full grid spaces in space-time is preserved, while the overall complexity is significantly reduced.

In section 3 we discuss how a spatial hierarchical basis can be derived from a given nodal basis and a given sequence of prolongation operators. Here we use the classical coarsening scheme from AMG methods to obtain coarser grids and a least squares approach to compute the necessary interpolation operators.

In section 4 we address some implementational issues that arise for the proposed space-time sparse grid approach. We first describe the necessary operations which must be performed on the data to compute the space-time sparse grid interpolant for a given function. These insights are then used as guidelines for the development of efficient data structures for space-time sparse grids. Furthermore, we discuss additional requirements to take into account adaptivity in space and time.

In section 5 we consider numerical experiments with the proposed space-time sparse grid space. Here, we focus on the interpolation error. The results show that the approximation rates with respect to the L^2-norm deteriorate only slightly in comparison to those of classical finite element spaces in space and time. For the H^1-norm even the same rates are achieved. In addition, the results for an adaptive space-time sparse grid applied to a nonsmooth function indicate that singular functions also can be dealt with in an efficient manner.

Finally, in section 6 we draw some conclusions.

2. Space-time sparse grids. In this section we describe the general construction of space-time sparse grid spaces following the presentation in [29]. We discuss

their approximation properties as well as their cost complexity. It will turn out that these spaces provide the same approximation rate as classical finite element spaces in space-time under just slightly stronger regularity assumptions. The number of involved degrees of freedom, however, is significantly reduced, i.e., by a factor of $O(N^{q/p})$, where p denotes the order of the associated time discretization and q denotes the order of the space discretization, respectively.

For a d-dimensional spatial domain $\Omega \subset \mathbb{R}^d$ and $T > 0$ we define $\Omega_T := \Omega \times (0,T)$. In the following, let $H^m(\Omega)$, $m \in \mathbb{N}$, denote the usual Sobolev space on Ω with weak derivatives of order m. Now, for $m \in \mathbb{N}$, we define

$$H^{2m,m}(\Omega_T) := \big(H^{2m}(\Omega) \otimes L^2((0,T))\big) \cap \big(L^2(\Omega) \otimes H^m((0,T))\big) \tag{2.1}$$

with associated norm

$$\|u\|^2_{H^{2m,m}(\Omega_T)} := \sum_{2\cdot p + \|\mathbf{q}\|_1 \le 2m} \|\partial_t^p \partial_x^{\mathbf{q}} u\|^2_{L^2(\Omega_T)}. \tag{2.2}$$

Here and in the following we use boldface letters to denote multi-indices, i.e., $\mathbf{q} \in \mathbb{N}^d$. Function spaces with bounded mixed derivatives play an important role in the theoretical analysis of sparse grids; see [12, 44, 45]. For our space-time setting we define

$$H^{2m,m}_{mix}(\Omega_T) := H^{2m}(\Omega) \otimes H^m((0,T)) \tag{2.3}$$

with associated norm

$$\|u\|^2_{H^{2m,m}_{mix}(\Omega_T)} := \sum_{\substack{p \le m,\\ \|\mathbf{q}\|_1 \le 2m}} \|\partial_t^p \partial_x^{\mathbf{q}} u\|^2_{L^2(\Omega_T)}, \tag{2.4}$$

and

$$H^{m,m}_{mix}(\Omega_T) := H^m(\Omega) \otimes H^m((0,T)) \tag{2.5}$$

with associated norm

$$\|u\|^2_{H^{m,m}_{mix}(\Omega_T)} := \sum_{\substack{p \le m,\\ \|\mathbf{q}\|_1 \le m}} \|\partial_t^p \partial_x^{\mathbf{q}} u\|^2_{L^2(\Omega_T)}. \tag{2.6}$$

Note that the space $H^{2m,m}_{mix}(\Omega_T)$ has a structure similar to that of the space $H^{2m,m}$ which is usually employed in regularity estimates of parabolic problems; cf. [37]. Under regularity assumptions for the initial condition and right-hand side that are only slightly stronger than in classical regularity theory, the solution of the Cauchy problem can actually be shown to be in $H^{2m,m}_{mix}(\Omega_T)$; see [29] for details.

In the following we want to construct approximation spaces for the approximation of functions $u \in H^{2m,m}_{mix}(\Omega_T)$ and $u \in H^{m,m}_{mix}(\Omega_T)$, respectively. They will possess a substantially reduced number of overall degrees of freedom compared to a conventional finite element space on Ω_T without a change in the approximation order. Let us assume that there are finite-dimensional spaces V_j^Ω and V_j^T, $j \in \mathbb{N}$, such that

$$L^2(\Omega) = \sum_{j \ge 0} V_j^\Omega,$$
$$L^2((0,T)) = \sum_{j \ge 0} V_j^T,$$

and $V_j^\Omega \subset V_{j+1}^\Omega$, $V_j^T \subset V_{j+1}^T$. Furthermore, we define increment spaces W_j^Ω and W_j^T such that

$$V_j^\Omega = V_{j-1}^\Omega \oplus W_j^\Omega,\ j \geq 1,$$
$$V_j^T = V_{j-1}^T \oplus W_j^T,\ j \geq 1,$$

and $W_0^\Omega := V_0^\Omega$, $W_0^T := V_0^T$. Since $L^2(\Omega_T) = L^2(\Omega) \otimes L^2((0,T))$ (cf. [28]), we obtain

$$L^2(\Omega_T) = \bigoplus_{\mathbf{j}\in\mathbb{N}^2} V_{\mathbf{j}}, \quad V_{\mathbf{j}} = V_{j_1}^\Omega \otimes V_{j_2}^T.$$

In the following we identify the tensor product $\varphi^\Omega \otimes \varphi^T$ of two functions $\varphi^\Omega(x) \in L^2(\Omega)$ and $\varphi^T(t) \in L^2((0,T))$ with $\varphi^\Omega \cdot \varphi^T$. We define the hierarchical increment spaces $W_{\mathbf{j}}$, $\mathbf{j} \in \mathbb{N}^2$, as

$$W_{\mathbf{j}} = W_{(j_1,j_2)} := W_{j_1}^\Omega \otimes W_{j_2}^T. \tag{2.7}$$

To simplify notation we omit the domain of integration in the norms; e.g., we write $\|\cdot\|_{L^2}$ instead of $\|\cdot\|_{L^2(\Omega)}$. If not stated otherwise, we assume that the hierarchical increments W_j^T and W_j^Ω are L^2-stable; i.e.,[1]

$$\left\|\sum_j w_j\right\|_{L^2(\Omega)}^2 \simeq \sum_j \|w_j\|_{L^2(\Omega)}^2 \quad \forall \sum_j w_j \in L^2(\Omega),\ w_j \in W_j^\Omega,$$
$$\left\|\sum_j w_j\right\|_{L^2((0,T))}^2 \simeq \sum_j \|w_j\|_{L^2((0,T))}^2 \quad \forall \sum_j w_j \in L^2((0,T)),\ w_j \in W_j^T.$$

With this notation, we define the full grid spaces

$$V_\ell^\infty := \bigoplus_{\substack{2j_1\leq 2\ell,\\ j_2\leq 2\ell}} W_{(j_1,j_2)} \tag{2.8}$$

and

$$\tilde{V}_\ell^\infty := \bigoplus_{\|\mathbf{j}\|_\infty \leq \ell} W_{(j_1,j_2)} \tag{2.9}$$

as well as the sparse grid spaces

$$V_\ell^1 := \bigoplus_{2j_1+j_2\leq 2\ell} W_{(j_1,j_2)} \tag{2.10}$$

and

$$\tilde{V}_\ell^1 := \bigoplus_{\|\mathbf{j}\|_1 \leq \ell} W_{\mathbf{j}}. \tag{2.11}$$

Note that the space-time sparse grid spaces V_ℓ^1 and $\tilde{V}_\ell^1$ are similar to classical sparse grid spaces; see [10, 12, 28]. Now, however, the supports of the basis functions are

[1] Here, $A \simeq B \Leftrightarrow c_1 B \leq A \leq c_2 B$ with positive constants c_1, c_2.

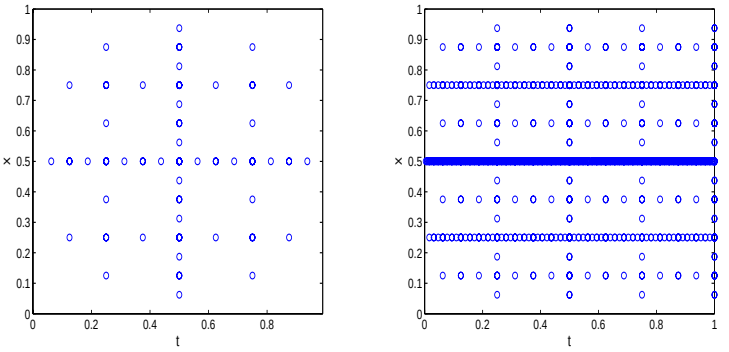

FIG. 2.1. *Grid points for the space* $\tilde{V}_4^1$ *(left) and* V_4^1 *(right) for the one-dimensional domain* $\Omega = (0,1)$ *and the time interval* $(0,1)$.

anisotropic with respect to space versus time but are isotropic in space. This results from our construction (2.7) which involves a tensor product between an (isotropic) multilevel basis in space and a one-dimensional multilevel basis in time, which is in contrast to the conventional sparse grid approach, where the basis in space is formed by a tensor product of a one-dimensional multiscale basis for each coordinate direction. Furthermore, the space V_ℓ^1 is twice as refined in the time direction as in the space direction. This can also be seen in Figure 2.1 (right) where sparse grids of level $\ell = 4$ on the domain $\Omega_T = (0,1)^2$ are shown. To this end, the one-dimensional piecewise linear hierarchical basis [22, 49, 50] was used for both space and time within the tensor product construction. The sparse grid points are the center points of the supports of the associated basis functions used for the respective spaces. Here we see that V_ℓ^1 involves more grid points in time than in the space direction, which results in a higher overall number of degrees of freedom than for $\tilde{V}_\ell^1$. As we will see later in Lemma 2.3, the sparse grid V_ℓ^1 is more suited to problems with lower regularity in time than in space, whereas $\tilde{V}_\ell^1$ is more efficient for problems with the same regularity in space and time.

To derive estimates of the approximation rates of the different spaces, we need the following lemma.

LEMMA 2.1. [illegible] $t \geq 0$ [illegible] $v^\Omega \in H^{2t}(\Omega)$ $v^\Omega = \sum_j w_j^\Omega$ $w_j^\Omega \in W_j^\Omega$

$$\|v^\Omega\|_{H^{2t}}^2 \simeq \sum_j 2^{2(2t)j} \|w_j^\Omega\|_{L^2}^2 \tag{2.12}$$

[illegible] $v^T \in H^t((0,T))$ $v^T = \sum_j w_j^T$ $w_j^T \in W_j^T$

$$\|v^T\|_{H^t}^2 \simeq \sum_j 2^{2tj} \|w_j^T\|_{L^2}^2. \tag{2.13}$$

[illegible] $u \in H^{2t,t}_{mix}(\Omega_T)$ $u = \sum_{\mathbf{j}} w_{\mathbf{j}}$ [illegible]

$$\|u\|_{H^{2t,t}_{mix}(\Omega_T)}^2 \simeq \sum_{\mathbf{j}} 2^{2t\|(2j_1,j_2)\|_1} \|w_{\mathbf{j}}\|_{L^2(\Omega_T)}^2. \tag{2.14}$$

(2.12)

$$\|v^{\Omega}\|_{H^t}^2 \simeq \sum_j 2^{2tj} \|w_j^{\Omega}\|_{L^2}^2, \tag{2.15}$$

(2.13) $u \in H^{t,t}_{mix}(\Omega_T)$ $u = \sum_{\mathbf{j}} w_{\mathbf{j}}$

$$\|u\|^2_{H^{t,t}_{mix}(\Omega_T)} \simeq \sum_{\mathbf{j}} 2^{2t\|(j_1,j_2)\|_1} \|w_{\mathbf{j}}\|^2_{L^2(\Omega_T)}. \tag{2.16}$$

The detailed proof of these norm equivalences can be found in [29]. Here, we restrict ourselves to (2.14) to show that the estimates follow directly from a proposition about additive subspace splittings taken from [30]. To this end we use the notation $\{V; a\}$ to denote a Hilbert space V which is equipped with the inner product $a(\cdot,\cdot)$. We now consider two Hilbert spaces H_1 and H_2 and a collection of closed subspaces $V_{1i} \subset H_1$ and $V_{2i} \subset H_2$, $i \in \mathbb{N}$, such that topologically

$$H_1 = \sum_i V_{1i} \quad \text{and} \quad H_2 = \sum_i V_{2i}.$$

For a sequence $b_{ki}(\cdot,\cdot)$ of bilinear forms on V_{ki}, $k \in \{1,2\}$, we call $\{H_k; a_k\} = \sum_i \{V_{ki}; b_k\}$ an additive subspace splitting which is stable if

$$a_k(u,u) \simeq |||u|||^2 \equiv \inf_{\substack{u_i \in V_{ki},\\ u=\sum_i u_i}} \sum_i b_{ki}(u_i,u_i) \tag{2.17}$$

holds true. From [30] we have the following proposition.

PROPOSITION 2.2. $\{H_k; a_k\} = \sum_i \{V_{ki}; b_{ki}\}$ $k = 1, 2$

$$\{H_1 \otimes H_2; a_1 \otimes a_2\} = \sum_{i_1} \sum_{i_2} \{V_{1i_1} \otimes V_{2i_2}; b_{1i_1} \otimes b_{2i_2}\}$$

Now we can start the proof of Lemma 2.1.

Here, we consider only (2.14); the other norm equivalences can be derived analogously. For $u \in H^{2t,t}_{mix}(\Omega_T)$, we obtain with Proposition 2.2 the stability of

$$\{H^{2t}(\Omega) \otimes H^t((0,T)); \|\cdot\|_{H^{2t}} \otimes \|\cdot\|_{H^t}\} = \sum_{\mathbf{j}} \{W_{\mathbf{j}}; 2^{2t\|(2j_1,j_2)\|_1} \|\cdot\|_{L^2} \otimes \|\cdot\|_{L^2}\}. \qquad \square$$

Now, we are in a position to state the approximation properties of the spaces $V_\ell^\infty, V_\ell^1, \tilde{V}_\ell^\infty$, and $\tilde{V}_\ell^1$.

LEMMA 2.3. (2.12) (2.13) s, t $t > s$ $u \in H^{2t,t}(\Omega_T)$

$$\inf_{v \in V_\ell^\infty} \|u - v\|^2_{H^{2s,s}(\Omega_T)} \le c \cdot 2^{4(s-t)\ell} \|u\|^2_{H^{2t,t}(\Omega_T)}. \tag{2.18}$$

$u \in H^{2t,t}_{mix}(\Omega_T)$

$$\inf_{v \in V_\ell^1} \|u - v\|^2_{H^{2s,s}(\Omega_T)} \le c \cdot 2^{4(s-t)\ell} \|u\|^2_{H^{2t,t}_{mix}(\Omega_T)} \tag{2.19}$$

... $u \in H^{t,t}(\Omega_T)$ ... (2.15) ... (2.13) ... s, t $t > s$ ...

$$\inf_{v \in \tilde{V}_\ell^\infty} \|u - v\|^2_{H^{s,s}(\Omega_T)} \leq c \cdot 2^{2(s-t)\ell} \|u\|^2_{H^{t,t}(\Omega_T)}, \tag{2.20}$$

... $u \in H^{t,t}_{mix}(\Omega_T)$ ...

$$\inf_{v \in \tilde{V}_\ell^1} \|u - v\|^2_{H^{s,s}(\Omega_T)} \leq c \cdot 2^{2(s-t)\ell} \|u\|^2_{H^{t,t}_{mix}(\Omega_T)}. \tag{2.21}$$

... We consider only the case (2.19). The other estimates follow in an analogous way. For $u \in H^{2t,t}_{mix}(\Omega_T)$, $u = \sum_{\mathbf{j}} w_{\mathbf{j}}$, $w_{\mathbf{j}} \in W_{\mathbf{j}}$, using the norm equivalences (2.12) and (2.13) we obtain

$$\begin{aligned}
\inf_{v \in V_\ell^1} \|u - v\|^2_{H^{2s,s}(\Omega_T)} &\leq \left\| u - \sum_{2j_1 + j_2 \leq 2\ell} w_{\mathbf{j}} \right\|^2_{H^{2s,s}(\Omega_T)} \\
&\leq c \cdot \sum_{2j_1 + j_2 > 2\ell} 2^{2s\|(2j_1, j_2)\|_\infty} \|w_{\mathbf{j}}\|^2_{L^2(\Omega_T)} \\
&= c \cdot \sum_{2j_1 + j_2 > 2\ell} 2^{2s\|(2j_1, j_2)\|_\infty - 2t\|(2j_1, j_2)\|_1} 2^{2t\|(2j_1, j_2)\|_1} \|w_{\mathbf{j}}\|^2_{L^2(\Omega_T)} \\
&\leq c \cdot \max_{2j_1 + j_2 > 2\ell} 2^{2s\|(2j_1, j_2)\|_\infty - 2t\|(2j_1, j_2)\|_1} \|u\|^2_{H^{2t,t}_{mix}(\Omega_T)} \\
&\leq c \cdot 2^{4(s-t)\ell} \|u\|^2_{H^{2t,t}_{mix}(\Omega_T)}. \qquad \square
\end{aligned}$$

The above lemma shows that the sparse grid spaces constructed with any multilevel basis which fulfills the norm equivalency (2.14) provide the same approximation rates for functions from $H^{2t,t}_{mix}(\Omega_T)$ as the full grid spaces. For a simple domain Ω which is (e.g., after a suitable differentiable mapping) a d-cube, there exist a variety of such bases like orthogonal wavelets, spline-wavelets, prewavelets, biorthogonal wavelets, lifting wavelets, and similar constructions which are constructed from a mother function by translation and dilation; see [13, 15, 19, 21, 43] and the references cited therein. Also a multilevel generating system, i.e., the collection of finite element bases for $V_j^\Omega, j \geq 0$, results in an estimate similar to (2.12) or (2.15).[2] The same holds for a domain Ω which is composed of simple nonoverlapping subdomains. Here, a wavelet-type basis or a multilevel basis is employed within each subdomain.[3] However, for a more complicated, general spatial domain Ω, the construction of a

[2] Here, the nonuniqueness of the representation $v^\Omega = \sum_j v_j^\Omega, v_j^\Omega \in V_j^\Omega$, is compensated by taking into account the prewavelets of all possible multilevel representations; i.e., instead of (2.15) we would have

$$\|v^\Omega\|^2_{H^t} \simeq \inf_{\substack{v^\Omega = \sum_j v_j^\Omega, \\ v_j^\Omega \in V_j^\Omega}} \sum_j 2^{2tj} \|w_j^\Omega\|^2_{L^2}. \tag{2.22}$$

[3] In these cases sparse grids can also be applied for the spatial discretization. This results in further substantial savings in cost provided that an additional smoothness prerequisite in space such as the boundedness of the second mixed derivatives is fulfilled. For details see the survey article [12] and the references cited therein.

multilevel basis which fulfills norm equivalencies like (2.12) or (2.15) can be quite difficult and demanding or even impossible. For wavelet-like approaches on polygonal domains, see [16, 20, 42, 41]. In view of the approximation properties, however, it is not really necessary that such norm equivalences are fulfilled. As the next lemma shows, we will need only upper bounds for the hierarchic increments $w_{\mathbf{j}} \in W_{\mathbf{j}}$ of a function $u = \sum_{\mathbf{j}} w_{\mathbf{j}}$ to obtain nearly the same rates of approximation.

LEMMA 2.4. [illegible] $t > s \geq 0$ [illegible] $c > 0$ [illegible]

$$\|w_{\mathbf{j}}\|_{H^{s,s}(\Omega_T)} \leq c 2^{s\|\mathbf{j}\|_\infty - t\|\mathbf{j}\|_1} \|u\|_{H^{t,t}_{mix}(\Omega_T)} \quad \forall \mathbf{j} \in \mathbb{N} \tag{2.23}$$

[illegible] $u \in H^{t,t}_{mix}(\Omega_T)$ $u = \sum_{\mathbf{j}} w_{\mathbf{j}}$ [illegible]

$$\inf_{v \in \tilde{V}_\ell^1} \|u - v\|^2_{H^{s,s}(\Omega_T)} \leq \begin{cases} c \cdot 2^{2(s-t)\ell} \cdot \ell^2 \|u\|^2_{H^{t,t}_{mix}(\Omega_T)} & \text{[illegible]} \ s = 0, t > 0, \\ c \cdot 2^{2(s-t)\ell} \|u\|^2_{H^{t,t}_{mix}(\Omega_T)} & \text{[illegible]} \ s > 0, t > 0. \end{cases} \tag{2.24}$$

This lemma is a simple generalization of Theorem 4 in [28].

The above lemma shows that it is possible to replace the norm equivalences (2.12) or (2.15) by simple upper bounds for the hierarchic increments of the type (2.23) while maintaining nearly the same approximation rates. As we will see in section 3 such upper bounds can easily be derived by tensor product arguments.

We are now interested in the dimension of the spaces $V_\ell^\infty, V_\ell^1, \tilde{V}_\ell^\infty$, and $\tilde{V}_\ell^1$.

LEMMA 2.5. [illegible] $\dim(W_j^\Omega) = O(2^{d \cdot j})$ [illegible] $\dim(W_j^T) = O(2^j)$ [illegible]

$$\dim(V_\ell^\infty) = O(2^{(d+2)\cdot \ell}), \tag{2.25}$$

$$\dim(V_\ell^1) = \begin{cases} O(2^{2d\ell}) & \text{[illegible]} \ d = 1, \\ O(2^{d\ell}\ell) & \text{[illegible]} \ d = 2, \\ O(2^{d\cdot\ell}) & \text{[illegible]} \ d > 2, \end{cases} \tag{2.26}$$

$$\dim(\tilde{V}_\ell^\infty) = O(2^{(d+1)\cdot \ell}), \tag{2.27}$$

$$\dim(\tilde{V}_\ell^1) = \begin{cases} O(2^\ell \ell) & \text{[illegible]} \ d = 1, \\ O(2^{d\cdot\ell}) & \text{[illegible]} \ d > 1. \end{cases} \tag{2.28}$$

[illegible] Since the estimates (2.25) and (2.27) for the full grid spaces are well known and the derivation of (2.26) can be found in [29], we will discuss only (2.28). We have

$$\begin{aligned} \tilde{V}_\ell^1 &= \bigoplus_{\|\mathbf{j}\|_1 \leq \ell} W_{\mathbf{j}} = \bigoplus_{j_1 \leq \ell} \bigoplus_{j_2 \leq \ell - j_1} W_{\mathbf{j}} \\ &= \bigoplus_{j_1 \leq \ell} W_{j_1}^T \otimes \left(\bigoplus_{j_2 \leq \ell - j_1} W_{j_2}^\Omega \right) \\ &= \bigoplus_{j_1 \leq \ell} W_{j_1}^T \otimes V_{\ell - j_1}^\Omega. \end{aligned}$$

Therefore, we get

$$\begin{aligned}\dim(\tilde{V}_\ell^1) &= \sum_{j_1=0}^{\ell} \dim(W_{j_1}^T) \cdot \dim(V_{\ell-j_1}^\Omega) \\ &\leq c \sum_{j_1=0}^{\ell} 2^{j_1} \cdot 2^{d\cdot(\ell-j_1)} \\ &= c \cdot 2^{d\cdot\ell} \sum_{j_1=0}^{\ell} 2^{(1-d)j_1},\end{aligned}$$

and (2.28) follows immediately. □

This lemma shows that the sparse grid spaces V_ℓ^1 and $\tilde{V}_\ell^1$ have a lower dimension than the full grid spaces V_ℓ^∞ and $\tilde{V}_\ell^\infty$. The overall complexity is reduced by one and two orders of magnitudes, respectively, where for the cases $d = 1$ and $d \leq 2$ the additional logarithmic factors ℓ and ℓ^{d-1} appear. The numerical results in section 5, furthermore, indicate that $\tilde{V}_\ell^1$ has just about four times as many degrees of freedom as the spatial multilevel basis alone; i.e.,

$$\dim(\tilde{V}_\ell^1) \approx 4 \cdot \dim(V_\ell^\Omega).$$

Taking the approximation results from Lemma 2.3 into account, we see that under some mild additional regularity assumptions we can approximate space-time functions by means of sparse grid spaces with basically the same complexity as functions stemming from stationary problems. The additional order of complexity due to time is no longer present, and therefore the associated problems discussed in the introduction are circumvented. Thus our sparse grid space-time spaces provide a powerful tool for a variety of instationary PDEs and parabolic optimal control problems.

3. A spatial multilevel basis. In this section we discuss the construction of a multilevel splitting and a simple hierarchical basis for the spatial discretization. In view of Lemma 2.4 it is sufficient to use a multilevel basis which just fulfills upper bounds of the type (2.23) within the sparse grid concept to obtain approximation properties similar to those of full grid spaces. To this end, we focus first on the hierarchical basis [49] constructed from a nested sequence of spatial finite element spaces in subsection 3.1. It turns out that, under suitable conditions on the sequence of the spatial finite element spaces, the use of the isotropic linear hierarchical basis in the spatial domain and the linear hierarchical basis in time results in sparse grid spaces which fulfill upper bounds of the type (2.23) for the L^2- and the energy-norm. Therefore, Lemma 2.4 can be applied, and thus estimates for the approximation rates of the resulting space-time sparse grids based on the spatial hierarchical basis are obtained.

But even for the simplest multiscale basis, i.e., the hierarchical basis, there is still the problem of the resolution of the boundary on all scales. The coarsest triangulation determines the domain from which the finer scale triangulations are derived by refinement. To overcome this problem we construct in subsection 3.2 a special spatial hierarchical basis from a finite element space given on the finest scale. Here, we determine so-called coarse grids by purely algebraic coarsening, i.e., following the approach of AMG [26, 39, 46] we use the AMG-coarsening scheme to create sets of coarse grid unknowns. Then, to assign hierarchical basis functions to these points,

we use prolongation operators between the respective coarse and fine grids which are derived from a least squares approach.

3.1. Multilevel subspace splitting, interpolation, and hierarchical basis. Let us assume that we have a sequence of nested triangulations/grids $\mathcal{T}_j$ on the domain Ω, $j \in \mathbb{N}$, $\mathcal{T}_j \subset \mathcal{T}_{j+1}$; i.e., the set of the nodes $\mathcal{N}_j$ of $\mathcal{T}_j$ is a subset of the set of nodes $\mathcal{N}_{j+1}$ of $\mathcal{T}_{j+1}$,

$$\mathcal{N}_j \subset \mathcal{N}_{j+1}.$$

As usual, we denote the diameter of $K \in \mathcal{T}_j$ with $h(K)$ and define

$$\rho(K) := \sup\{\operatorname{diam}(B) \mid B \subset K,\ B \text{ is a ball}\}.$$

Throughout this section we assume that $\mathcal{T}_j$ is a sequence of regular triangulations, i.e., that there is a constant σ such that

$$\frac{h(K)}{\rho(K)} \leq \sigma \ \forall j \text{ and } K \in \mathcal{T}_j,$$

and that there is a constant $c > 0$ such that

$$h_j := \max_{K \in \mathcal{T}_j} h(K) \leq c 2^{-j}.$$

We denote by V_j^Ω the associated finite element space of piecewise linear or d-linear functions, and define a mapping $P_j : C^1(\Omega) \to V_j^\Omega$. Then each $u_\ell \in V_\ell^\Omega$ has the representation

$$u_\ell = P_0 u_\ell + \sum_{j=0}^{\ell-1} (P_{j+1} u_\ell - P_j u_\ell), \tag{3.1}$$

with the increment spaces

$$W_{j+1}^\Omega := \operatorname{range}(P_{j+1} - P_j) \tag{3.2}$$

and $W_0^\Omega := V_0^\Omega$. For example, if we choose $P_j u$ as the interpolant of $u \in C^1(\Omega)$ in V_j^Ω, i.e.,

$$P_j u(x) = u(x) \ \forall x \in \mathcal{N}_j, \tag{3.3}$$

we obtain a splitting into increment spaces which are spanned by the hierarchical basis as described in [49]. For the choice $P_j u$ as the L^2-projection of u onto V_j we would obtain an L^2-orthogonal wavelet basis. Other choices of projection operators are discrete L^2-projections, approximate L^2-projections, quasi-interpolation or Clément-projections, which all lead to a stable multilevel basis.

In the following we focus on the choice of P_j as the interpolation operator (3.3) onto V_j. Since we are dealing with a regular triangulation, the classical interpolation theory of finite element spaces, (cf. [3, 14]) shows that

$$\|u - P_j u\|_{L^2(\Omega)} \leq c \cdot 2^{-2j} \|u\|_{H^2(\Omega)} \tag{3.4}$$

for all $u \in H^2(\Omega)$ with constant $c > 0$ independent of j. Therefore, using the hierarchical decomposition (3.1) we obtain for the parts w_j of the splitting $u = P_0 u + \sum_{j\in\mathbb{N}}(P_{j+1}u_\ell - P_j u_\ell) = \sum_{j\in\mathbb{N}} w_j$, $u \in H^2(\Omega)$, the estimate

$$\|w_j\|_{L^2(\Omega)} \le c \cdot 2^{-2j} \|u\|_{H^2(\Omega)} \tag{3.5}$$

with constant $c > 0$ independent of j. An analogous estimate follows directly for all $u \in H^2((0,T))$ with the linear interpolation operator and thus the linear hierarchical basis in time. Then, arguments on the tensor product of operators [31] lead, for the hierarchical increment spaces $W_{\mathbf{j}} = W_{j_1}^{\Omega} \otimes W_{j_2}^{T}$ with the splitting $u = \sum_{\mathbf{j}\in\mathbb{N}^2} w_{\mathbf{j}}$, to the estimate

$$\|w_{\mathbf{j}}\|_{L^2(\Omega_T)} \le c \cdot 2^{-2\cdot|\mathbf{j}|_1} \|u\|_{H^{2,2}_{mix}(\Omega)} \ \forall \mathbf{j} \in \mathbb{N}^2, \tag{3.6}$$

with c independent of $\mathbf{j}$ and independent of $u \in H^{2,2}_{mix}(\Omega_T)$. Here, $W_{j_2}^T$ are the one-dimensional linear increment spaces in time which result analogously to (3.2) from the differences of piecewise linear interpolation operators in time.

Now we can apply Lemma 2.4 and obtain the following result on the approximation rate of the space-time sparse grid space using a linear hierarchical basis in time and the isotropic d-dimensional hierarchical basis in space.

LEMMA 3.1. [illegible] V_j^{Ω} [illegible] (3.4) [illegible] c [illegible] j [illegible] $u \in H^2(\Omega)$ [illegible] (3.2) [illegible] $\tilde{V}_\ell^1$ [illegible]

$$\inf_{v\in\tilde{V}_\ell^1} \|u - v\|_{L^2(\Omega_T)} \le c \cdot 2^{-2\ell} \cdot \ell \cdot \|u\|_{H^{2,2}_{mix}(\Omega_T)} \tag{3.7}$$

[illegible] $u \in H^{2,2}_{mix}(\Omega_T)$

We define the energy norm $\|\cdot\|_E$ for $u \in H^{1,1}(\Omega_T)$ as usual by

$$\|u\|_E^2 = \int_0^T \int_\Omega (\partial_t u)^2 + \sum_{i=1}^{d} (\partial_{x_i} u)^2 \, dx \, dt.$$

Furthermore, analogous to the definition of $H^{2,2}_{mix}(\Omega_T)$, we now define

$$H^{2,2,\infty}_{mix}(\Omega_T) := H^{2,\infty}(\Omega) \otimes H^{2,\infty}((0,T)),$$

where $H^{2,\infty}(\Omega)$ and $H^{2,\infty}((0,T))$ denote the classical Sobolev spaces of functions $u \in L^\infty(\Omega)$ and $u \in L^\infty((0,T))$ with weak derivatives up to the order 2 which are contained in $L^\infty(\Omega)$, respectively. We then can state the following lemma.

LEMMA 3.2. [illegible] V_k [illegible] $\tilde{V}_\ell^1$ [illegible] (3.2) [illegible]

$$\inf_{v\in\tilde{V}_\ell^1} \|u - v\|_E \le c 2^{-\ell} \|u\|_{H^{2,2,\infty}_{mix}(\Omega_T)} \tag{3.8}$$

[illegible] $u \in H^{2,2,\infty}_{mix}(\Omega_T)$ [illegible] $c > 0$ [illegible] ℓ

For the proof of this lemma, one has to verify condition (2.23). Then the application of Lemma 2.4 leads to the estimate (3.8). The verification of (2.23) is quite technical; we therefore postpone it until the appendix.

The above discussion shows that it is sufficient to have a sequence of grids and linear or d-linear finite element spaces which induce the hierarchical increment spaces in the space-time sparse grid construction to maintain the approximation order of a full grid space in the energy norm. For the L^2-norm only an additional logarithmic factor comes into play. Now, the question is how such a sequence of grids and prolongation operators can be obtained. Quite a few finite element packages, meanwhile, use geometric multigrid methods for the solution of the linear systems which result from the discretization of a PDE. These codes then also provide in one way or another access to interpolation operators P_j which we can exploit.

However, for complicated geometries and unstructured grids it is difficult or even impossible to construct a sequence of nested subspaces and a hierarchy of grids which are needed for geometric multigrid methods. Here, a main problem is the resolution of the domain on coarser levels, which is one of the reasons AMG methods [4, 5, 6, 39] were developed. Here, given a matrix A stemming from a finite element discretization, AMG computes (among other things) a sequence of coarse grids, i.e., a set of unknowns, and a sequence of prolongation operators. Now, taking a closer look at the construction (3.2) of the hierarchical increment spaces W_j^Ω, we find that geometric information about the grids $\mathcal{T}_j$ is not necessary but that only the prolongation operators P_j are needed. Therefore, AMG offers a solution to the problem of the resolution of the geometry. We discuss in the next subsection how we use AMG ingredients to construct a sequence of prolongations which we will use in our space-time sparse grid construction.

3.2. Construction of algebraic prolongation operators. In this subsection we will focus on the construction of a sequence of prolongation operators P_j needed for the construction (3.2) of the hierarchic increment spaces W_j. Here, prolongation operators as well as sets C_j of coarse grid points are algebraically constructed using only the entries of the system matrix A^ℓ on the finest level of discretization.[4]

For most AMG methods, the set-up phase, i.e., the phase where the prolongation operators and the coarse grid operators are computed, can be divided into two parts. In the first step, the coarse grid, i.e., a subset $C_j \subset N_j$ of the set of all unknowns N_j on level j, is chosen. Then, given the set of coarse grid points which form the new set of unknowns of the next coarser level, the prolongation $P_j = (p_{kl}^j)$ is computed. Here, one usually requires that each unknown associated to a fine grid point which is also contained in the coarser grid is interpolated by the value of the respective coarse grid unknown; i.e., after reordering the fine and coarse grid unknowns, the prolongation operator P_j has the block-matrix representation

$$P_j = \begin{pmatrix} I_j \\ \tilde{P}_j \end{pmatrix}, \tag{3.9}$$

$n_j := |N_j| = |C_{j-1}|$, $I_j \in \mathbb{R}^{n_{j-1} \times n_{j-1}}$ is the identity, and $\tilde{P}_j \in \mathbb{R}^{(n_j - n_{j-1}) \times n_{j-1}}$.

For the coarsening process, i.e., the computation of C_j, we use the coarsening algorithm due to Ruge and Stüben as described in [39]. To derive $\tilde{P}_j$ we used in a first

[4] AMG needs to be given a fine grid stiffness matrix A^l to set up the interpolation operators and coarser grid matrices A^j via the Galerkin identity. But in our context we have no unique naturally given stiffness matrix A^l at our disposal. Since we are merely interested in the construction of a multilevel basis for the space part of a space-time sparse grid discretization by means of AMG, we used the stiffness matrix which stems from the discretization of the Laplacian in the given finite element space in the numerical experiments presented in section 5. For this choice AMG methods provide nearly the same hierarchy as geometric multigrid methods on structured uniform grids.

attempt some classical interpolation formulas, the so-called standard interpolation and the so-called direct interpolation; see [46]. These formulas involve the entries a_{kl}^j of the matrix A^j within the interpolation formulas. Numerical experiments showed, however, that, especially on unstructured grids, the resulting prolongations did not provide satisfying approximation rates when used in the sparse grid context. The reason is that the prolongation formulas in AMG are developed to interpolate algebraic smooth errors in as exact a manner as possible, i.e., errors which cannot efficiently be reduced by a given stationary linear iteration scheme. This requirement, however, does not have to lead to good approximation results when used in space-time sparse grids.

Therefore we use a least squares approach to compute interpolation formulas which are able to reproduce (global) linear or d-linear functions in as exact a manner as possible. We denote by $\bar{u}^j \in \mathbb{R}^{n_j}$ the vector of coefficients of the basis representation of $u_j \in V_j^\Omega$. We choose a basis $\{\zeta_i\}$ of the space of linear or, alternatively, d-linear functions, i.e., $\{1, x_i, i = 1, \ldots, d\}$ or $\{1, x_{i_1}, x_{i_1}x_{i_2}, \ldots, x_{i_1} \cdot \ldots \cdot x_{i_d}, i_j = 1, \ldots, d, i_1 < i_2, i_1 < i_2 < i_3, \ldots, i_1 < i_2 < \cdots < i_d\}$, and a norm $\|\cdot\|_\star$ on $\mathbb{R}^{n_j}$, and define the functional $J : \mathbb{R}^{(n_j - n_{j-1}) \times n_{j-1}} \mapsto \mathbb{R}$ as

$$J(\tilde{P}_j) := \sum_{\zeta_i} \|\bar{\zeta}_i^j - (\tilde{P}_j \bar{\zeta}_i^{j-1})\|_\star^2. \tag{3.10}$$

Now we compute the block $\tilde{P}_j$ in (3.9) as the solution of the constrained minimization problem

$$\min_{\tilde{P}_j \in \mathbb{R}^{(n_j - n_{j-1}) \times n_{j-1}}} J(\tilde{P}_j). \tag{3.11}$$

In general, this would lead to densely populated operators $\tilde{P}_j = (\tilde{p}_{kl}^j)$. Therefore, we impose a second constraint on the above minimization problem, namely

$$a_{kl}^j = 0 \Rightarrow \tilde{p}_{kl}^j = 0. \tag{3.12}$$

Loosely speaking, this constraint enforces that only neighboring grid points are used in the prolongation process to interpolate fine grid points. Note that due to the constraint (3.12) on the sparsity pattern of the prolongation operator, the overall constraint minimization (3.11) can be split into local small least squares problems which can be efficiently solved by simple LU-factorization.

For the choice of $\|\cdot\|_\star$ in (3.10) there are several possibilities. The norm induced by the coarse grid operators A^j which are set up from the AMG approach anyway, i.e.,

$$\|x\|_{A^j} := (x^T A^j x)^{1/2},$$

would lead to cost functionals similar to those used for the construction of prolongation operators in the context of AMG methods based on element interpolation (AMGe) [7]. In the following, we will use the Euclidean norm instead. It is easy to compute, and provided good results in our numerical experiments. Nevertheless, future research is needed to study in more detail the influence of the choice of the norm $\|\cdot\|_\star$ on the space-time sparse grid approach.

4. Data structures and adaptivity. In this section we will discuss the underlying data structure used to store the space-time sparse grid coefficients. The aim is

to obtain a storage format for the coefficients which allows for an efficient implementation of a sparse grid interpolant for given nodal values and vice versa; see [2, 40] for more details.

For classical sparse grids, there are several approaches [2, 11, 35, 40] to this topic which use hash maps or binary trees to manage the coefficients of the sparse grid basis. Note, however, that we are not dealing with classical sparse grids which are constructed by a tensor product from a purely one-dimensional multilevel basis. There, each basis function has a fixed number of hierarchical sons such that tree data structures can be efficiently applied. In our application the space part of the multilevel basis is allowed to stem from general unstructured grids instead. Therefore, the simple concept of recursively used binary trees is no longer efficiently applicable. Instead we use a slightly different approach, i.e., binary trees of hash maps, which is described in the following. The associated data structures allow for an efficient implementation of the operations that have to be performed on a space-time sparse grid, such as, e.g., the computation of the function values of the interpolant [40]. They are also well suited for adaptive refinement procedures on space-time sparse grids.

4.1. Algorithmic approach and data structures. Let $\mathcal{B}(V_\ell^T) = \{\psi_{j,i}^T\}$ be the piecewise linear hierarchical basis in time for V_ℓ^T, i.e., $\psi_{j,i}^T \in W_j^T$, where the index j indicates the level, $||\psi_{j,i}^T||_\infty = 1$, and

$$\operatorname{supp}(\psi_{j,i}^T) \cap \operatorname{supp}(\psi_{j,k}^T) = \emptyset \ \forall i \neq k. \tag{4.1}$$

Furthermore, let $\mathcal{B}(V_\ell^\Omega) = \{\psi_{j,i}^\Omega\}$ be the spatial algebraic hierarchical basis constructed from a finite element space as described in section 3.2. Then, we obtain a basis of the space-time sparse grid space $\tilde{V}_\ell^1$ by

$$\mathcal{B}(\tilde{V}_\ell^1) := \{\psi_{\mathbf{j},\mathbf{i}} := \psi_{j_1,i_1}^\Omega \cdot \psi_{j_2,i_2}^T \mid j_1 + j_2 \leq \ell\}. \tag{4.2}$$

For ease of presentation, we will use the set of multilevel indices $\mathcal{I}_{\tilde{V}_\ell^1}$ contained in the sparse grid $\tilde{V}_\ell^1$,

$$\mathcal{I}_{\tilde{V}_\ell^1} := \{(\mathbf{j},\mathbf{i}) \mid \ j_1 + j_2 \leq \ell,\ 0 \leq i_1 \leq \dim(W_{j_1}^\Omega),\ 0 \leq i_2 \leq \dim(W_{j_2}^T)\}.$$

Furthermore, to each multilevel index $(\mathbf{j},\mathbf{i})$ we associate a grid point $(x_{j_1,i_1}, t_{j_2,i_2})$ such that

$$\psi_{(\mathbf{j},\mathbf{i})}(x_{j_1,i_1}, t_{j_2,i_2}) = 1.$$

We define the usual hierarchical relation $>$ between two hierarchical indices (j_1,i_1) and $(\bar{j}_1,\bar{i}_1)$ of the multilevel basis in space as

$$(j_1,i_1) > (\bar{j}_1,\bar{i}_1) :\Leftrightarrow \operatorname{supp}\psi_{\bar{j}_1,\bar{i}_1}^\Omega \subset \operatorname{supp}\psi_{j_1,i_1}^\Omega \tag{4.3}$$

and we use the analogous definition for the hierarchical indices of the spatial multilevel basis. Now, given the nodal values $u(x_{j_1,i_1}, t_{j_2,i_2})$ of a continuous function u at the sparse grid points $(x_{j_1,i_1}, t_{j_2,i_2})$, we want to compute the coefficients $u_{\mathbf{j},\mathbf{i}}$ of the sparse grid interpolant u_ℓ^{sp},

$$u_\ell^{sp} = \sum_{(\mathbf{j},\mathbf{i}) \in \mathcal{I}_{\tilde{V}_\ell^1}} u_{\mathbf{j},\mathbf{i}} \psi_{\mathbf{j},\mathbf{i}}(x,t),$$

i.e.,

$$u_\ell^{sp}(x_{\tilde{j}_1,\tilde{i}_1}, t_{\tilde{j}_2,\tilde{i}_2}) = \sum_{(\mathbf{j},\mathbf{i})\in\mathcal{I}_{\tilde{V}_\ell^1}} u_{\mathbf{j},\mathbf{i}}\psi_{\mathbf{j},\mathbf{i}}(x_{\tilde{j}_1,\tilde{i}_1}, t_{\tilde{j}_2,\tilde{i}_2}),$$

for all sparse grid points $(x_{\tilde{j}_1,\tilde{i}_1}, t_{\tilde{j}_2,\tilde{i}_2})$. Using (4.1) we obtain

$$\begin{aligned} u(x_{\tilde{j}_1,\tilde{i}_1}, t_{\tilde{j}_2,\tilde{i}_2}) &= \sum_{(\mathbf{j},\mathbf{i})\in\mathcal{I}_{\tilde{V}_\ell^1}} u_{\mathbf{j},\mathbf{i}}\psi_{\mathbf{j},\mathbf{i}}(x_{\tilde{j}_1,\tilde{i}_1}, t_{\tilde{j}_2,\tilde{i}_2}) \\ &= \sum_{\substack{(j_2,i_2)\geq(\tilde{j}_2,\tilde{i}_2)\\(\mathbf{j},\mathbf{i})\in\mathcal{I}_{\tilde{V}_\ell^1}}} \psi_{j_2,i_2}^T(t_{\tilde{j}_2,\tilde{i}_2}) \left(\sum_{\substack{j_1,i_1\\(\mathbf{j},\mathbf{i})\in\mathcal{I}_{\tilde{V}_\ell^1}}} u_{\mathbf{j},\mathbf{i}}\psi_{j_1,i_1}^\Omega(x_{\tilde{j}_1,\tilde{i}_1}) \right). \end{aligned}$$

Therefore, to obtain the hierarchical coefficients we proceed in two steps. First, according to the second sum, we compute spatial multilevel coefficients $\hat{u}_{\mathbf{j},\mathbf{i}}$ such that for each time step $t_{\tilde{j}_2,\tilde{i}_2}$

$$u(x_{\tilde{j}_1,\tilde{i}_1}, t_{\tilde{j}_2,\tilde{i}_2}) = \sum_{\substack{j_1,i_1\\((\tilde{j}_1,j_2),(\tilde{i}_1,i_2))\in\mathcal{I}_{\tilde{V}_\ell^1}}} \hat{u}_{\mathbf{j},\mathbf{i}}\psi_{j_1,i_1}^\Omega(x_{\tilde{j}_1,\tilde{i}_1}) \quad \forall x_{\tilde{j}_1,\tilde{i}_1},\ (\tilde{\mathbf{j}},\tilde{\mathbf{i}})\in\mathcal{I}_{\tilde{V}_\ell^1}. \tag{4.4}$$

Then we apply a basis transformation from the nodal basis to the multilevel basis in time to transform $\hat{u}_{\mathbf{j},\mathbf{i}}$ to the sparse grid coefficients $u_{\mathbf{j},\mathbf{i}}$. Here, according to the first sum which involves all hierarchical ancestors, this can be done by a simple top-down tree traversal if the coefficients $\hat{u}_{\mathbf{j},\mathbf{i}}$ are stored in a binary tree.

Thus, this algorithm suggests the use of a binary tree for the multilevel basis in time, where each node contains an array for the coefficients which belong to the respective time step. However, we also want to be able to adaptively refine our space-time sparse grids, e.g., by starting with a regular sparse grid $\tilde{V}_\ell^1$ and locally inserting new grid points and associated basis functions according to certain error estimators or indicators. Therefore we use hash maps in each node instead of simple arrays. For a detailed discussion on the use of hash maps in the context of sparse grids and hierarchical bases, see [40, 27]. For a general introduction we refer to [38]. Here, a hash table M is used to store the data, and each data entry has to be uniquely identified by a key, for which we simply use the spatial hierarchical index (j_1, i_1). Now, we need a hash function h to compute the position $h((j,i))$ where the associated coefficient is stored in the hash table M. In each node of the binary tree which represents the time level j_2 we use a hash table with $\dim(V_{\ell-j_2}^\Omega)$ entries and define the hash map h by

$$h((j,i)) = (\dim(V_{j-1}^\Omega) + i) \mod \dim(V_{\ell-j_2}^\Omega),$$

where $V_0^\Omega := \emptyset$. Obviously, for a regular sparse grid $\tilde{V}_\ell^1$, there are exactly $\dim(V_{\ell-j_2}^\Omega)$ data entries in each node which belong to the time level j_2, and the above hash function h provides a mapping without collision. However, for adaptively refined sparse grids, different coefficients can result in the same hash values. Therefore, we use so-called [illegible] [25] where all coefficients with the same hash value are stored in a separate list. Then, to obtain the coefficient value for a given spatial index, we have to search the list which belongs to the hash value of the key. Numerical experiments showed that these lists are usually very small, so that the computational cost of this search is bounded by a small constant.

4.2. Adaptivity. Sparse grids can easily be refined adaptively; cf. [2, 8, 35]. This is necessary if the function to be approximated does not fulfill the smoothness requirements which are a prerequisite for regular sparse grids. This way singularities or strong variations in the function can be taken care of. It can be shown that the favorable approximation rates and complexities of regular sparse grids also can be obtained for nonsmooth functions provided that the right adaptivity scheme with a proper error estimator is used. Here one can derive classical error estimators involving residual- or duality-based error indicators in a way similar to classical finite elements; see [9, 12]. An alternative is the use of the size of the coefficients in a wavelet-like representation as indicators for local refinement along the lines of [17, 18, 19]. It can be shown that, for any stable multiscale basis, such an approach provides true error estimators, i.e., error indicators which are reliable and efficient. Note that there is an easy way to switch from our hierarchical basis representation to such a wavelet-type representation by means of the lifting scheme [35, 43].

In the following we simply use the weighted size of the coefficients in the hierarchical basis representation as an error indicator for local refinement. This approach was successfully used in several different application areas, e.g., in visualization [23], in numerical integration [24], and for the solution of PDEs [2, 8, 12, 35]. It results in a reliable but in general not perfectly efficient error estimator.[5] Nevertheless, numerical results show that the proposed adaptivity criterion provides quite good results.

We proceed as follows: For a basis function $\psi_{\mathbf{j},\mathbf{i}} = \psi^T_{j_1,i_i} \cdot \psi^\Omega_{j_2,i_2}$ we define the set $\mathcal{H}(\psi_{\mathbf{j},\mathbf{i}})$ of hierarchical sons, i.e.,

$$\mathcal{H}(\psi_{\mathbf{j},\mathbf{i}}) := \{\psi_{\bar{\mathbf{j}},\bar{\mathbf{i}}} \mid (\bar{j}_1,\bar{j}_2) = (j_1+1,j_2) \text{ or } (\bar{j}_1,\bar{j}_2) = (j_1,j_2+1), \tag{4.5}$$

$$\psi^T_{j_1,i_i} > \psi^T_{\bar{j}_1,\bar{i}_1} \text{ and } \psi^\Omega_{j_2,i_2} > \psi^\Omega_{\bar{j}_2,\bar{i}_2}\}, \tag{4.6}$$

using the $>$-relation from (4.3). Now, given the sparse grid approximation $u^{sp} = \sum_{(\mathbf{j},\mathbf{i})\in\Lambda} u_{\mathbf{j},\mathbf{i}} \cdot \psi_{\mathbf{j},\mathbf{i}}$, where Λ denotes the set of involved indices, we add $\mathcal{H}(\psi_{\mathbf{j},\mathbf{i}})$ to the actual sparse grid space[6] and thus the indices $(\tilde{\mathbf{j}},\tilde{\mathbf{i}})$ of the hierarchical sons to the actual set Λ whenever

$$|u_{\mathbf{j},\mathbf{i}}| > 2^{\frac{1}{2}(d\cdot j_1 + j_2)} \cdot \varepsilon \tag{4.7}$$

for a given threshold ε. Here, the factor $\frac{1}{2}$ in the exponent resembles a measurement of the error in the L^2-norm; for other norms, appropriate values have to be substituted. The term $d \cdot j_1 + j_2$ corresponds to an approximation scheme with the same order in space and time. Such a refinement strategy leads asymptotically to an equilibration of the error indicators in the sense of [1].

5. Numerical results. In this section we present some numerical results concerning the convergence rates of the space-time sparse grid interpolant in $\tilde{V}^1_\ell$ for the regular case and the adaptive refinement case. To this end, we use a bilinear finite element space V^Ω_ℓ, where $h := 2^{-\ell} > 0$ indicates the mesh width of the underlying grid, on the spatial domain $\Omega \subset \mathbb{R}^2$ to construct the spatial multilevel basis as described in section 3. Here we use the stiffness matrix of the Laplacian in the AMG coarsening algorithm.

[5] Note that the upper bound (which implies reliability) in the norm equivalency for the hierarchical basis is (after proper weighting) independent of the number of levels, whereas the lower bound (which relates to efficiency) depends slightly on the number of levels involved.

[6] Of course, this is done only for the indices which are "leaves" of the structure of Λ, i.e., for the indices $(\mathbf{j},\mathbf{i}) \in \Lambda$ with $\mathcal{H}(\psi_{\mathbf{j},\mathbf{i}}) \notin \Lambda$.

For $u \in C^1(\Omega_T)$ given, we set $h := 2^{-\ell}$ and denote by u_h the full grid interpolant of u and by u_ℓ^{sp} the sparse grid interpolant. We define the interpolation errors $e_h := u - u_h$ and $e_\ell^{sp} := u - u_\ell^{sp}$. Then obviously

$$\|e_\ell^{sp}\| \leq \|e_h\| + \|u_h - u_\ell^{sp}\| \tag{5.1}$$

for any given norm $\|\cdot\|$. In the following, we will use the norms

$$\begin{aligned}
\|u\|_{L^2\times L^\infty} &:= \operatorname{ess\,sup}_{t\in(0,T)} \|u(\cdot,t)\|_{L^2(\Omega)}, \\
\|u\|_{L^2\times L^2} &:= \left(\int_{0<t<T} \|u(\cdot,t)\|^2_{L^2(\Omega)}\, dt\right)^{1/2}, \\
\|u\|_{H^1\times L^\infty} &:= \operatorname{ess\,sup}_{t\in(0,T)} |u(\cdot,t)|_{H^1(\Omega)}, \\
\|u\|_{H^1\times L^2} &:= \left(\int_{0<t<T} |u(\cdot,t)|^2_{H^1(\Omega)}\, dt\right)^{1/2}.
\end{aligned}$$

For these norms, classical interpolation theory shows that the error e_h decreases with at least the same order as the error of the sparse grid interpolant e_ℓ^{sp} for decreasing mesh width. We are interested if the orders predicted by our theory in section 2 for the geometrically constructed hierarchical basis can also be achieved for the algebraically constructed increment spaces described in section 3.2. With (5.1) we see that it is sufficient to use $\tilde{e}_h := \|u_h - u_\ell^{sp}\|$, which is easier to compute. Therefore, we will present results in terms of $\tilde{e}_h$ only.

In all the following experiments we consider $T = 1.0$.

1. In our first example we examine the interpolation error for the space-time sparse grid space $\tilde{V}_\ell^1$ for the function

$$u(x,t) = t^2 \cdot (x_1^2 + x_2^2)$$

on the unit square $\Omega = [0,1]^2$. This function is just a product of a quadratic polynomial in time and in space. Here it serves as the simplest model problem for discussing the basic properties of our space-time sparse grid approach. We use a uniform rectangular grid with mesh width $h = 2^{-\ell}$ for the underlying finite element discretization from which the spatial multilevel basis is derived along the lines of subsection 3.2. In this case, the AMG coarsening algorithm of Ruge and Stüben leads to a sequence of coarse grids which is nearly identical to conventional geometric coarsening. Therefore, the constructed spatial multilevel basis is basically the usual isotropic hierarchical basis [49]. Note that the function is zero at the time point $t = 0$ and therefore all degrees of freedom at this time point can be eliminated.

Table 5.1 shows the error as well as the dimension of the space-time sparse grid space. First of all note that the number of degrees of freedom of the space-time sparse grid space $\tilde{V}_\ell^1$ increases with the same order, i.e., $O(h^{-2})$, as the degrees of freedom of the spatial grid as expected from (2.28) of Lemma 2.5. Moreover, the additional constant amount for the space-time sparse grid in comparison to the spatial grid is just a factor of three where we eliminated the degrees of freedom for $t = 0$ (it would be four including those degrees of freedom). Figure 5.1 shows the resulting space-time sparse grid of level $\ell = 5$. Here, one can clearly see the finest grids with $h = 1/32$ at the time points $t = 0.5$ and $t = 1.0$ which dominate the overall number of degrees of freedom.

Furthermore, from Lemma 3.1 in section 3 we expect a behavior of $O(2^{-2\ell}\ell)$ ($O(h^2 \log h)$) for the error in the $L^2 \times L^2$-norm on level ℓ ($h = 2^{-\ell}$). In fact, looking

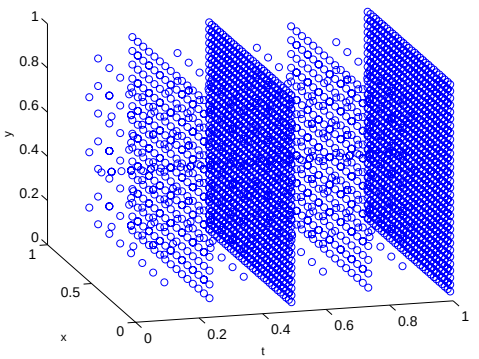

FIG. 5.1. *Space-time sparse grid associated to $\tilde{V}_\ell^1$ with two spatial dimensions for level $\ell = 5$ ($h = 1/32$).*

at the results in Table 5.1 we see that the quotient of the errors $\tilde{e}_h$ of two successive levels of discretization measured in $\|\cdot\|_{L^2\times L^2}$ and $\|\cdot\|_{L^\infty\times L^2}$ slowly approaches 0.25 from above for decreasing mesh width. This value would be the rate achieved with a full grid discretization. In more detail, from level $\ell = 5$ to level $\ell = 6$ the error is reduced by a factor of about 0.31 and decreases for growing ℓ. We finally obtain a factor of about 0.28 for the reduction from $\ell = 8$ to $\ell = 9$. This behavior accounts for the additional $\log h$-term in the convergence rate, which becomes more and more unimportant with growing number of levels in comparison to the exponential term. For the quotient of the error estimate of two consecutive levels we obtain $0.25\cdot(\ell+1)/\ell$, which is also an upper bound for the reduction factor. Moreover, using this formula, we get a theoretical estimate of about 0.28 for the reduction of the error from level $\ell = 8$ to $\ell = 9$, which is exactly the rate we observe in our experiment.

From Lemma 3.2 we would expect the same error reduction rate for the sparse grid interpolant as for the full grid interpolant if the H^1-norm were involved. Indeed, looking at the results in the $H^1 \times L^2$- and $H^1 \times L^\infty$-norms we observe a factor of 0.5 independent of the number of levels, which is just the same as that of a full grid interpolant.

2. We now present results for the more complicated function

$$u(x,t) = \sin(4\pi t x_1) + \sin(4\pi t x_2)$$

on the unit square, $\Omega = (0,1)^2$. Here, $u(x,t)$ is zero for $t = 0$ but develops more and more oscillations for $t \to 1.0$. A plot of the function at different time points is shown in Figure 5.2

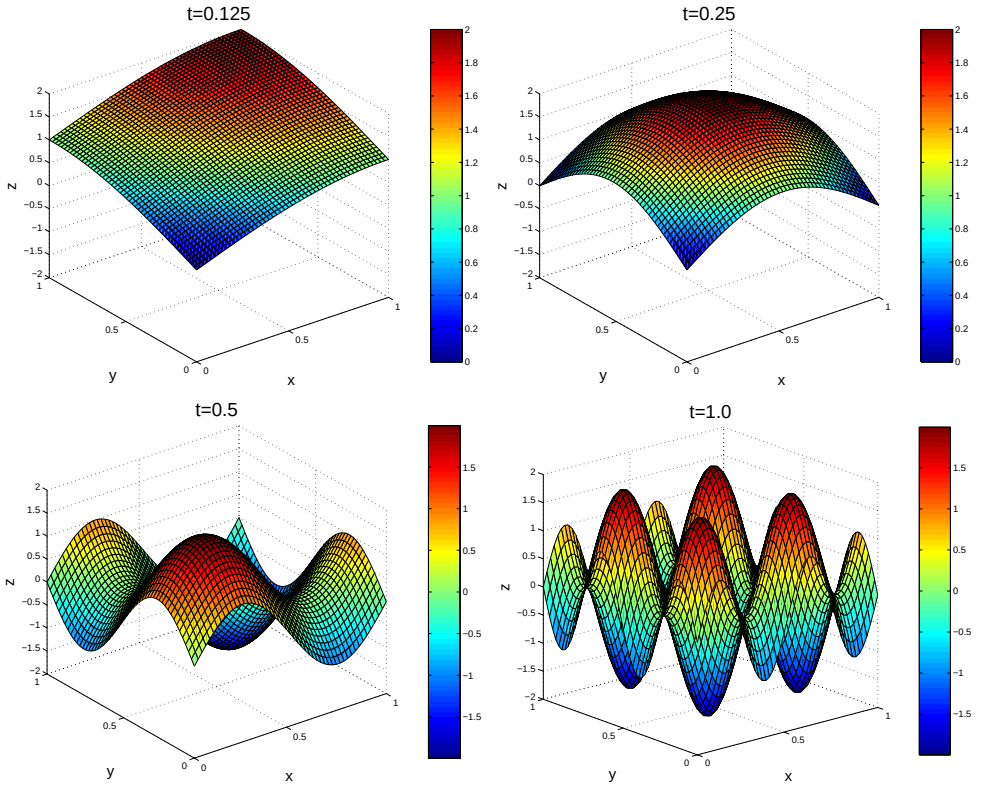

FIG. 5.2. *Plots of the function* $u(x,t) = \sin(4\pi t x_1) + \sin(4\pi t x_2)$ *of Example* 2 *at time points* $t = 0.125, 0.25, 0.5, 1.0$.

Although predicted by the theoretical results given in Lemmas 3.1 and 3.2, it is not directly obvious that the sparse grid approach still works well in practice for this case due to the oscillations in the function $u(x,t)$. Nevertheless, looking at the results in Table 5.2, we see that the behavior of the error measured in the $\|\cdot\|_{L^2\times L^2}$- and $\|\cdot\|_{L^2\times L^\infty}$-norms for increasing level number is the same as in the previous example. Here, the initial reduction rate from level $\ell = 5$ to $\ell = 6$ for the $\|\cdot\|_{L^2\times L^2}$-norm amounts to about 0.35, which is a little bit larger than in the previous example. On level $\ell = 9$ we obtain a reduction rate of about 0.30.

For the two norms involving the H^1-seminorm we expect from Lemma 3.2 an error reduction rate of about 0.5. In fact, the results of Table 5.2 clearly show that we achieve this predicted approximation rate.

3. In this example we show results for the proposed space-time sparse grid method for a slightly more complex geometry in space. We again consider the function

$$u(x,t) = t^2 \cdot (x_1^2 + x_2^2) \tag{5.2}$$

but choose now the unit circle

$$\Omega = \{x \,|\, \|x\| \le 1.0\}$$

as spatial domain. Note that for such a domain a sequence of geometric discretizations on different scales with piecewise linear finite elements no longer results in nested

TABLE 5.2

finite element spaces. This is due to the circular boundary, which is only linearly approximated on each level. Here, the algebraic coarsening by AMG sets in. Together with the prolongation operator constructed by (3.11) and the constraint (3.12), we obtain an algebraic hierarchical basis with good approximation properties also near the boundary. An example of a grid which is used for the finite element discretization of the Laplacian to obtain the initial system matrix for the AMG approach is given in Figure 5.3 (left); an associated space-time sparse grid is depicted in Figure 5.3 (right).

The results for three different space-time sparse grids are shown in Table 5.3. For the $H^1 \times L^2$- and the $H^1 \times L^\infty$-norms we obtain nearly the same approximation rate of about 0.5 as in the previous examples. For the $L^2 \times L^2$- and the $L^2 \times L^\infty$-norms the error is reduced by the factors 0.27 and 0.38, respectively. Here, the grids used for the construction of the spatial finite element spaces vary in their quality depending on their mesh width; i.e., the maximal and minimal interior angles of the rectangles vary between the different grids. This might influence the approximation property of the space-time sparse grid and, consequently, the error reduction rate to some extent.

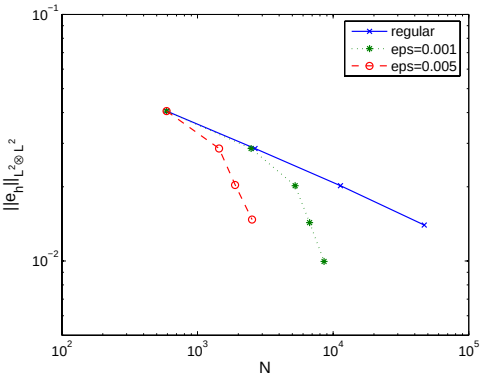

FIG. 5.4. *Interpolation error in the* $\|\cdot\|_{L^2\times L^2}$*-norm for the function* $\sqrt{(t\cdot x_1)}\cdot x_2$*, regular sparse grids for different levels, and adaptive refinement starting from level* $l = 4$ *with thresholds* $\varepsilon = 0.001$ *and* $\varepsilon = 0.005$ *versus overall degrees of freedom (N).*

4. In this example we present numerical results for the function

$$u(x,t) = \sqrt{(t\cdot x_1)}\cdot x_2,$$

which has a singularity on the edge $x_1 = 0$ for all times $t > 0$ and a singularity at $t = 0$. Note that this function is no longer in $H^{2,2}_{mix}(\Omega_T)$ as the functions of the previous examples are, and we therefore expect a decrease of the approximation rates. Furthermore, note that we would also obtain worse approximation results for a full grid approximation in space and time, since u is no longer in $H^{2,2}(\Omega_T)$ either. Therefore, using the error $\tilde{e}_h$ instead of e^{sp}_ℓ no longer provides reliable bounds for the space-time sparse grid approximation rates. Instead we use a very fine full grid ($\ell = 11$) as a reference solution, interpolate the adaptive sparse grid solution to this grid, and measure the error between the full grid and the sparse grid solution there.

To cope with the singularities in $u(x,t)$ we adaptively refine our sparse grids in space and time as described in section 4.2. We use the error indicator (4.7) with the thresholds $\varepsilon = 0.001$ and $\varepsilon = 0.005$. Figure 5.4 shows the error history in the $L^2\times L^2$-norm of the adaptive cycle when we apply the adaptive refinement starting on level $\ell = 4$ with the two different thresholds. For comparison the convergence result for regular sparse grids is given as well. We clearly see that the uniform refinement provides only a poor cost-benefit ratio. Here, starting with an error of about 0.02 for level $\ell = 4$ (i.e., 592 degrees of freedom), the space-time sparse grid results in an error of 0.0024 on level $\ell = 8$ (i.e., 46976 degrees of freedom). This leads to an error reduction rate with respect to the number of degrees of freedom N of 0.48, i.e., the error behaves as $O(N^{-0.48})$ which can be seen from the slope of the respective curve in Figure 5.4. Remember that for a smooth solution[7] we would obtain a behavior of nearly $O(N^{-1})$. Now, looking at the results for the adaptive cycles we see that we obtain a much higher accuracy with substantially fewer degrees of freedom. In the case of $\varepsilon = 0.001$ we obtain a final error of 0.0015 with only 8578 degrees of freedom, and the use of $\varepsilon = 0.005$ results in a final error of 0.0038 with 3286 degrees of freedom.

[7]In the previous examples the degrees of freedom grew roughly with a factor of 4 from level to level, and we gave the quotient of the error on two successive levels as reduction rate. Now we directly give the exponent of the error as a function of degrees of freedom, which is more appropriate in the adaptive case.

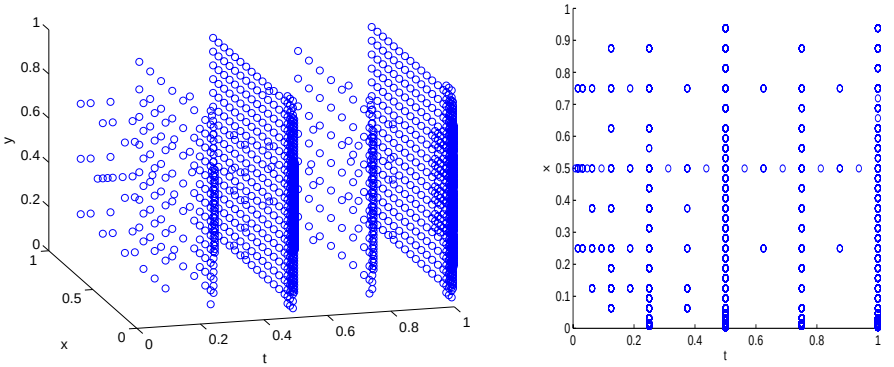

FIG. 5.5. *Adaptively refined space-time grid ($\varepsilon = 0.001$) after three refinement steps for the function $u(x,t) = \sqrt{(t \cdot x_1)} \cdot x_2$.*

Now, if we look at the cost-benefit ratio, i.e., if we compare the error and the degrees of freedom of the initial grid on level $\ell = 4$ and the grids obtained at the end of the adaptive cycles, we see that we get a rate of about 1.0 for both thresholds which is exactly the rate we would expect for a regular sparse grid and a smooth function. In Figure 5.5, we show the adaptive grid which results from the refinement process for $\varepsilon = 0.001$. Here we see that the nonsmoothness in space and time direction is detected by the error indicator and gets resolved by the insertion of additional points in [illegible]. This indicates that the proposed error indicator works well.

6. Conclusion. We presented a space-time sparse grid method for the approximation of functions which depend on space and time. It involves the tensor product of a multilevel basis in space and a multilevel basis in time. A proper truncation of the resulting series expansion then gives a space-time sparse grid. This approach reduces the number of degrees of freedom significantly in comparison to a conventional space-time finite element method.

Furthermore, we proposed a method to algebraically compute the spatial multilevel basis from a given finite element space. It involves AMG and special prolongation operators which are determined by a local minimization procedure. This allows us to also handle complex spatial geometries which pose a problem for classical sparse grid spaces. In the present paper we utilized a simple least squares approach to guarantee the approximation property of the coarse spaces. Other AMG interpolation procedures (i.e., [47] and [48]) are also feasible and worth pursuing in the future.

We showed that these space-time sparse grid spaces possess nearly the same approximation rates as classical finite element spaces if just slightly stronger regularity assumptions are fulfilled. Furthermore, it turned out that their number of degrees of freedom is of the same order as that of the spatial finite element space alone; i.e., the dimension of the space-time sparse grid spaces is one order of magnitude smaller than the dimension of conventional space-time finite element spaces. In addition numerical experiments showed that the approximation rates predicted by the theory really can be achieved in practice, even for complicated spatial geometries which do not allow for a sequence of nested finite element spaces. We also demonstrated for a problem with singularities in space and time that space-time adaptivity can easily be implemented and used. This results in adaptively refined space-time sparse grids which

resolve singularities and thus allow us to regain the superior convergence rates and complexities of space-time sparse grids also in the case of nonsmooth functions.

In this article we restricted ourselves to the hierarchical basis in space and in time as a special case of a multiscale basis. Note, however, that our approach is by no means confined to this type of basis. It works in the same (or an even better) way for any stable multiscale basis, such as wavelets or frames. However, to get rid of the relatively tight restriction on the spatial domain imposed by wavelet-like schemes due to translation and dilation, we opted for an AMG construction with associated algebraic hierarchical basis instead.

The proposed space-time sparse grid spaces can be efficiently used for the discretization of parabolic problems and related time-dependent control and optimization problems. To this end it is necessary to discretize and to apply the respective differential operator, e.g., in weak formulation, in space and time. The associated computational work should be proportional to the number of degrees of freedom. This is easily possible whenever the coefficient functions of the operator which belong to the spatial derivatives are constant in time. Then an algorithm which is based on the so-called unidirectional principle [8, 12] can be applied. Also the efficient solution of the arising linear system in optimal complexity is necessary by, e.g., a multilevel method which must be able to tackle the space-time discretized sparse grid problem directly. This, however, is future work.

7. Appendix. In this section, we give the proof of Lemma 3.2. Since the application of Lemma 2.4 shows the estimate, we just have to verify that inequality (2.23) holds true.

In the following, we denote a nodal basis of the spatial finite element space V_j^Ω by $\varphi_{j,i}^\Omega$, $1 \le i \le \dim(V_j^\Omega)$. Analogously, the hierarchical increment space W_j^Ω is spanned by a subset of the nodal basis of V_j^Ω. For ease of presentation we denote the basis elements of W_j^Ω by $\psi_{j,i}^\Omega$, $1 \le i \le \dim(W_j^\Omega)$. Furthermore (after reordering of the nodal set $\mathcal{N}_j$), we assume that the index i of the function $\psi_{j,i}^\Omega$ is associated to the nodal point where the basis function is equal to one; i.e., for every $n_j \in \mathcal{N}_j$ we have

$$\psi_{j,i}^\Omega(n_k) = \begin{cases} 1 & \text{if } k = i, \\ 0 & \text{otherwise.} \end{cases}$$

Using the definition (3.2) of W_j^Ω and the interpolation property of the prolongation operators P_j, we obtain the coefficients $w_{j,i}^\Omega$ of the basis representation $w_j^\Omega = \sum_{i=1}^{\dim(W_j)} w_{j,i}^\Omega \psi_{j,i}^\Omega$ of an element w_j^Ω, $w_j^\Omega \in W_j^\Omega$ by the formula

$$w_{j,i}^\Omega = (P_j u - P_{j-1} u)(n_i), \tag{7.1}$$

where $n_i \in \mathcal{N}_j$ is the nodal point with $\psi_{j,i}^\Omega(n_i) = 1.0$. Classical interpolation properties of finite element spaces (cf. [14]) show that

$$\|P_j u - P_{j-1} u\|_{L^\infty(\Omega)} \le \|P_j u - u\|_{L^\infty(\Omega)} + \|u - P_{j-1} u\|_{L^\infty(\Omega)} \le c \cdot 2^{-2j} \|u\|_{H^{2,\infty}},$$

and relation (7.1) leads to

$$|w_{j,i}^\Omega| \le \|P_j u - P_{j-1} u\|_{L^\infty(\Omega)} \le c \cdot 2^{-2j} \|u\|_{H^{2,\infty}(\Omega)}, \tag{7.2}$$

with $c > 0$ independent of u, j, and i. We denote by $\psi^T_{j,i}$ an element of the one-dimensional hierarchical basis on $(0,T)$ and derive the analogous estimate

$$|w^T_{j,i}| \le c \cdot 2^{-2j} \|u\|_{H^{2,\infty}((0,T))} \tag{7.3}$$

for $u \in H^{2,\infty}((0,T))$, with $u = \sum_j \sum_i w^T_{j,i} \psi^T_{j,i}$ and $c > 0$ independent of u, j, and i.

A basis of the increment space $W_{\mathbf{j}}$, $\mathbf{j} \in \mathbb{N}^2$, is given by $\{\psi_{\mathbf{j},\mathbf{i}}\}$, where $\psi_{\mathbf{j},\mathbf{i}} := \psi^\Omega_{j_1,i_1} \cdot \psi^T_{j_2,i_2}$, and we obtain the basis representation

$$w_{\mathbf{j}} = \sum_{\mathbf{i}} w_{\mathbf{j},\mathbf{i}} \psi_{\mathbf{j},\mathbf{i}} \tag{7.4}$$

for a function $w_{\mathbf{j}} \in W_{\mathbf{j}}$. Using (7.1) and (7.3) and a tensor product argument (cf. [31]), we obtain for $u \in H^{2,2,\infty}_{mix}(\Omega_T)$, $u = \sum_{\mathbf{j},\mathbf{i}} w_{\mathbf{j},\mathbf{i}} \psi_{\mathbf{j},\mathbf{i}}$, the estimate

$$|w_{\mathbf{j},\mathbf{i}}| \le c \cdot 2^{-2\|\mathbf{j}\|_1} |u|_{H^{2,2,\infty}_{mix}(\Omega)}$$

with $c > 0$ independent of u, $\mathbf{j}$ and $\mathbf{i}$.

Now we want to derive an estimate for the term $\|\psi_{\mathbf{j},\mathbf{i}}\|_E$. The tensor product structure of $\psi_{\mathbf{j},\mathbf{i}}$ leads to

$$\|\psi_{\mathbf{j},\mathbf{i}}\|_E = \|\psi^\Omega_{j_1,i_1}\|_{L^2(\Omega)} \cdot \|\psi^T_{j_2,i_2}\|_{E,(0,T)} + \|\psi^\Omega_{j_1,i_1}\|_{E,\Omega} \cdot \|\psi^T_{j_2,i_2}\|_{L^2((0,T))}. \tag{7.5}$$

Since we assume that the finite element spaces V^Ω_j are affine equivalent and we are dealing with a regular triangulation, classical finite element theory (cf. [14]) leads to

$$\|\psi^\Omega_{j_1,i_1}\|_{E,\Omega} \le c 2^{-(d-2)\cdot(j_1/2)}, \tag{7.6}$$

$$\|\psi^\Omega_{j_1,i_1}\|_{L^2(\Omega)} \le c 2^{-dj_1/2}. \tag{7.7}$$

For the one-dimensional hierarchical basis a straightforward calculation (see [12]) gives

$$\|\psi^T_{j_2,i_2}\|_{E,(0,T)} \le c 2^{j_2/2}, \tag{7.8}$$

$$\|\psi^T_{j_2,i_2}\|_{L^2((0,T))} \le c 2^{-j_2/2}. \tag{7.9}$$

This, together with (7.5), leads to

$$\|\psi_{\mathbf{j},\mathbf{i}}\|_E \le c \left(2^{-(d-2)\cdot(j_1/2)} \cdot 2^{-j_2/2} + 2^{-dj_1/2} \cdot 2^{j_2/2} \right) \tag{7.10}$$

$$\le c 2^{-dj_1/2} 2^{-j_2/2} \left(2^{j_1} + 2^{j_2} \right) \tag{7.11}$$

$$\le c 2^{-dj_1/2} 2^{-j_2/2} 2^{\|\mathbf{j}\|_\infty}. \tag{7.12}$$

Now, for $u \in H^{2,2,\infty}_{mix}(\Omega_T)$, $u = \sum_{\mathbf{j}} w_{\mathbf{j}}$, we obtain

$$\begin{aligned}
\|w_{\mathbf{j}}\|^2_{E,\Omega_T} &\le \sum_{\mathbf{i}} w^2_{\mathbf{j},\mathbf{i}} \|\psi_{\mathbf{j},\mathbf{i}}\|^2_{E,\Omega_T} \\
&\le \sum_{\mathbf{i}} 2^{-4\|\mathbf{j}\|_1} \cdot \|u\|^2_{H^{2,2,\infty}_{mix}(\Omega_T)} \cdot \|\psi_{\mathbf{j},\mathbf{i}}\|^2_{E,\Omega_T} \\
&\le c 2^{-4\|\mathbf{j}\|_1 + 2\|\mathbf{j}\|_\infty} \cdot 2^{-dj_1 - j_2} \sum_{\mathbf{i}} \|u\|^2_{H^{2,2,\infty}_{mix}(\Omega_T)} \\
&\le c 2^{-4\|\mathbf{j}\|_1 + 2\|\mathbf{j}\|_\infty} \|u\|^2_{H^{2,2,\infty}_{mix}(\Omega_T)}.
\end{aligned}$$

Therefore, we can apply Lemma 2.4, which then shows Lemma 3.2. ∎

EFFICIENT WEIGHTED LATTICE RULES WITH APPLICATIONS TO FINANCE*

XIAOQUN WANG† AND IAN H. SLOAN‡

Abstract. Good lattice rules are an important type of quasi-Monte Carlo algorithm. They are known to have good theoretical properties, in the sense that they can achieve an error bound (or optimal error bound) that is independent of the dimension for *weighted* function spaces with suitably decaying weights. To use the theory of weighted function spaces for practical applications, one has to determine *what weights should be used*. After explaining that lattice rules based on figures of merit with classical weights (classical lattice rules) may not give good results for high-dimensional problems, we propose a "matching strategy," which chooses the weights in such a way that the typical functions of a weighted Korobov space are similar (in the sense of similar relative sensitivity indices) to those of the given function. The matching strategy relates the weights of the spaces to the sensitivity indices of the given function. We apply the Korobov construction and the component-by-component construction of lattice rules with the suitably chosen weights to the valuation of high-dimensional financial derivative securities and find that such weighted lattice rules improve dramatically on the results for the classical lattice rules; moreover, they are competitive with other types of low discrepancy sequences. We also demonstrate that lattice rules combined with variance reduction techniques and dimension reduction techniques increase the efficiency significantly. We show that an acceptance-rejection approach to the construction of lattice rules can reduce the construction cost with almost no loss of accuracy.

Key words. quasi-Monte Carlo methods, lattice rules, multivariate integration, option pricing

DOI. 10.1137/S1064827502418197

1. Introduction.

High-dimensional integrals occur in various applications, such as physics, statistics, and financial mathematics. For example, from the theory of arbitrage-free pricing [13], the fair value of a European path-dependent option or multiasset option can be formulated as a multiple integral, with the dimension corresponding to the number of time steps in the time discretization or the number of assets. Monte Carlo (MC) and quasi-Monte Carlo (QMC) methods are now widely used for pricing complex financial derivatives (see [1, 2, 3, 21]). Consider the evaluation of a d-dimensional integral:

$$I_d(f) = \int_{[0,1]^d} f(\mathbf{x})\, d\mathbf{x}.$$

The MC estimate of the integral $I_d(f)$ takes the form

$$Q_{n,d}(f) = \frac{1}{n} \sum_{k=0}^{n-1} f(\mathbf{x}_k),$$

where the points $\mathbf{x}_0, \ldots, \mathbf{x}_{n-1}$ are independently and identically distributed (i.i.d.) random samples from the uniform distribution on $[0,1]^d$. It is well known that the MC method has a probabilistic convergence rate of order $O(n^{-1/2})$ independently of the dimension.

The QMC methods replace the random samples in MC by carefully chosen deterministic points, so as to yield better uniformity than the random samples. Let H be a Hilbert space of functions defined on $[0,1]^d$ with norm $||\cdot||_H$; then (see [9, 25])

$$|I_d(f) - Q_{n,d}(f)| \le e(Q_{n,d}; H)\, ||f||_H \qquad \forall f \in H,$$

where

$$e(Q_{n,d}; H) = \sup\{|I_d(f) - Q_{n,d}(f)| : f \in H,\ ||f||_H \le 1\} \tag{1.1}$$

is called the [illegible] of $Q_{n,d}(f)$ or the [illegible] of the point set $\{\mathbf{x}_k\}_{k=0}^{n-1}$.

To minimize the QMC error, one should construct a QMC algorithm such that its worst-case error in a suitable space H is as small as possible. There are two important classes of point sets that are well suited to multivariate integration: digital nets and good lattice rules [18, 22]. In general, the QMC methods have deterministic error bounds of the order $O(n^{-a}(\log n)^b)$ for functions satisfying some regularity conditions, where $a > 1/2$ and b is a constant in the order of d. This convergence is asymptotically better than that of MC. For weighted function spaces with fast decaying weights, it is possible to establish a QMC error bound that is independent of the dimension [11, 15, 23, 30].

Lattice rules (of rank 1) are QMC algorithms of the special form

$$Q_{n,d}(f) = \frac{1}{n} \sum_{k=0}^{n-1} f\left(\left\{\frac{k\mathbf{z}}{n}\right\}\right), \tag{1.2}$$

where $\mathbf{z} = (z_1, \ldots, z_d)$ is the generating vector of integers with no factor in common with n, and the braces around a vector indicate that each component of the vector is to be replaced by its fractional part. A central topic in the theory of lattice rules is to find a "good" generator $\mathbf{z}$. Several constructions are known, such as the Korobov construction [14] and the component-by-component (CBC) construction [24]. These constructions are considered in [illegible] function spaces, and some good theoretical properties of the resulting lattice rules have been revealed [15, 24, 35]. However, their usefulness for practical high-dimensional problems has not yet been established, the main difficulty being that these constructions depend on certain "weights." For practical applications, we need to know what weights should be used.

It has been observed that the functions in financial derivative pricing are often special, in that some variables are more important than others, and/or the lower-order "interactions" of the variables are more important than the higher-order ones (that is to say, the functions can often be well approximated by sums of low-dimensional functions); see [3, 34]. Many functions in other applications have similar properties. The classical lattice rules (i.e., the lattice rules with classical weights; see section 2) do not take advantage of such specific properties. While many high-dimensional financial problems have been successfully solved by digital nets (such as the Sobol points [28]; see [21]), the successful use of good lattice rules has been reported only in relatively low dimensions. In fact, in our experience (reported below) lattice rules based on figures of merit with classical weights may not give good results for high-dimensional

financial problems and indeed may give worse results than MC. By investigating the ANOVA decomposition, we shall see that the classical choice of weights not only treats all variables equally but also implicitly treats higher-order interactions between the variables as more important than the lower-order interactions. This unreasonable emphasis on the higher-dimensional interactions may lead to poor quality of low-dimensional projections of the lattice points, especially two-dimensional projections (see [31]), and is therefore inappropriate for the functions from finance. We believe that this is an important reason why classical lattice rules tend to fail for high-dimensional finance problems.

In this paper we make use of the so-called weighted spaces, introduced in [25] for Sobolev spaces and in [26] for (periodic) Korobov spaces. In weighted function spaces, the variables are associated with weights. These weights then enter the worst-case error, which is the criterion of goodness used to search for lattice rule generators. For this reason the determination of suitable weights is a central theme of this paper. Intuitively, for finance applications lattice rules need to concentrate on more important variables and on low-order interactions. Using different coordinate weights in the figure of merit was suggested in [7, 8].

The outline of this paper is as follows. In section 2, we introduce the weighted Korobov spaces and present the criterion of goodness for good lattice rules. In section 3, we propose a "matching strategy" to choose good weights, relating the weights to the sensitivity indices. In section 4, we present several constructions of lattice rules, including a variant of the constructive algorithm for finding the vector $\mathbf{z}$ in (1.2), that speeds the construction by introducing an acceptance-rejection technique. The effectiveness of various (weighted and unweighted) lattice rules for financial derivative pricing is investigated numerically in section 5. Section 6 presents the conclusions.

2. Weighted Korobov spaces and the quality measure for lattice rules. As in [26], we work in the framework of weighted Korobov spaces $H_{d,\alpha,\gamma}$ of functions defined in $[0,1)^d$. This is the Hilbert space of periodic integrable functions with absolutely convergent Fourier series and with the reproducing kernel $K_{d,\alpha,\gamma}$ given by

$$K_{d,\alpha,\gamma}(\mathbf{x},\mathbf{y}) = \prod_{j=1}^{d}\left(1+\gamma_j \sum_{h=-\infty}^{\infty}{}' \frac{e^{2\pi i h(x_j-y_j)}}{|h|^\alpha}\right), \quad i=\sqrt{-1}, \tag{2.1}$$

where $\{\gamma_j\}$ is a sequence of positive numbers (the weights). The prime on the sum indicates that the term $h=0$ is omitted. The smoothness parameter $\alpha > 1$ characterizes the rate of decay of the Fourier coefficients. If $\gamma_j = 1$, the space $H_{d,\alpha,\gamma}$ is the classical unweighted Korobov space. The space $H_{d,\alpha,\gamma}$ is equipped with the inner product

$$\langle f, g\rangle_{H_{d,\alpha,\gamma}} = \sum_{\mathbf{h}\in\mathbf{Z}^d}\prod_{j=1}^{d} r(\gamma_j,h_j)\ \hat{f}(\mathbf{h})\ \overline{\hat{g}(\mathbf{h})},$$

where $\mathbf{h}=(h_1,h_2,\ldots,h_d)$, $\mathbf{Z}=\{\ldots,-1,0,1,\ldots\}$,

$$r(\gamma,h) = \begin{cases} 1 & \text{if } h=0,\\ \gamma^{-1}|h|^\alpha & \text{if } h\neq 0,\end{cases}$$

and

$$\hat{f}(\mathbf{h}) = \int_{[0,1)^d} \exp(-2\pi i\mathbf{h}\cdot\mathbf{x}) f(\mathbf{x})\, d\mathbf{x}$$

is the Fourier coefficient of $f(\mathbf{x})$, with $\mathbf{h}\cdot\mathbf{x} = h_1x_1 + \cdots + h_dx_d$. Note that for a small weight γ_j, a function f with a norm at most 1 can depend only weakly on the jth variable. More general assumptions on the weights, and thus on the induced weighted spaces, have been studied; see [5, 6].

In the space $H_{d,\alpha,\gamma}$ the worst-case error defined by (1.1) is given by (see [26])

(2.2)
$$e_{n,d}(\mathbf{z}) := e(Q_{n,d}; H_{d,\alpha,\gamma}) = \left(-1 + \frac{1}{n}\sum_{k=0}^{n-1}\prod_{j=1}^{d}\left(1 + \gamma_j \sum_{h=-\infty}^{\infty}{}' \frac{e^{2\pi i h k z_j/n}}{|h|^\alpha}\right)\right)^{1/2}$$

for the case of the rank-1 lattice rule (1.2). The worst-case error $e_{n,d}(\mathbf{z})$ will be used as the criterion of goodness for lattice rules.

For the constructive algorithms to be discussed in section 4, it is important to be able to compute the worst-case error efficiently. For the case when α is an even integer, it is known that

$$\sum_{h=-\infty}^{\infty}{}' \frac{e^{2\pi i h x}}{|h|^\alpha} = \frac{(2\pi)^\alpha}{(-1)^{\frac{\alpha}{2}+1}\alpha!}\, B_\alpha(x), \quad x \in [0,1], \tag{2.3}$$

where $B_\alpha(x)$ is the Bernoulli polynomial of degree α. In particular, $B_2(x) = x^2 - x + 1/6$. Thus the infinite sum in the formula of the worst-case error (2.2) can be computed easily when $\alpha = 2$.

[illegible] 1. Note that if $\gamma_j = 1$ for all j, then $e^2_{n,d}(\mathbf{z})$ equals P_α, which is the classical criterion for lattice rules and is defined as (see [22])

$$P_\alpha = \sum_{\mathbf{h}\cdot\mathbf{z}\equiv 0 \bmod (n)}{}' \frac{1}{(\overline{h}_1 \cdots \overline{h}_d)^\alpha}, \tag{2.4}$$

where $\overline{h} := \max(1, |h|)$. In this paper, the term "classical lattice rules" is used to mean the lattice rules constructed by minimizing the classical quality measure P_α. Let $g(\mathbf{x}) = K_{d,\alpha,\gamma}(\mathbf{x}, \mathbf{0})$ with $\gamma_j = 1$ for all j; then P_α can be written as the quadrature error:

$$P_\alpha = Q_{n,d}(g) - I_d(g) = Q_{n,d}(g) - 1.$$

This observation is important for the analysis in section 3.

3. What weights should be used in practice? The construction of lattice rules in weighted Korobov spaces depends on the weights γ_j, since the weights enter the criterion of goodness. Such a situation is quite different from the constructions of digital sequences, such as the Sobol sequence [28] and the Niederreiter sequence [18]. However, the dependence of lattice rules on the weights is also good news: we have the possibility to control the weights based on information about the integrands, in order to make the constructed lattice rules more suited to our needs. An important question is, [illegible] Another is, [illegible]

The weights in a weighted Korobov space moderate the relative importance of successive variables and groups of variables. On the other hand, for a given function the relative importance of variables and groups of variables can be measured by Sobol's [illegible] [29], which are explained below. We shall relate the weights of the

space to the sensitivity indices of the given function, the basic idea being to choose the weights in such a way that "typical functions" (see section 3.2) of the weighted Korobov spaces have similar relative sensitivity indices to the given function. If this matching is successful, then we have good reason to expect that the resulting lattice rules will be suitable for the given function.

3.1. Sensitivity analysis for the given problems. The relative importance of each variable or group of variables can be measured by sensitivity indices, which are related to the ANOVA decomposition of functions. For any subset $u \subseteq \{1, \dots, d\}$, we use the notation $|u|$ for its cardinality and use $-u$ for its complementary set $\{1, \dots, d\} - u$. For $\mathbf{x} \in [0,1)^d$, let $\mathbf{x}_u$ be the $|u|$-dimensional vector containing the components of $\mathbf{x}$ whose indices are in u. Any square-integrable function $f(\mathbf{x})$ can be written as a sum of its ANOVA terms:

$$f(\mathbf{x}) = f_\emptyset + \sum_{j=1}^{d} f_{\{j\}}(x_j) + \sum_{1 \le i < j \le d} f_{\{i,j\}}(x_i, x_j) + \cdots + f_{\{1,\dots,d\}}(x_1, \dots, x_d), \tag{3.1}$$

where $f_\emptyset = I_d(f)$ and the terms $f_u(\mathbf{x})$ are defined recursively by

$$f_u(\mathbf{x}) = \int_{[0,1)^{d-|u|}} f(\mathbf{x}) d\mathbf{x}_{-u} - \sum_{v \subset u} f_v(\mathbf{x}),$$

where the sum in the last term is over strict subsets $v \neq u$. Each ANOVA term identifies the contribution of distinct group of variables to f. The ANOVA decomposition (3.1) is orthogonal, in that $\int_{[0,1]^d} f_u(\mathbf{x}) f_v(\mathbf{x}) d\mathbf{x} = 0$ whenever $u \neq v$. It follows that the variance of f can be expressed as

$$\sigma^2(f) = \sum_{\emptyset \neq u \subseteq \{1,\dots,d\}} \sigma_u^2(f),$$

where $\sigma_u^2(f) = \int_{[0,1]^d} [f_u(\mathbf{x})]^2 d\mathbf{x}$ for $|u| > 0$ is the variance of f_u, which indicates the contribution of the term f_u to the total variance $\sigma^2(f) = \int_{[0,1]^d} f^2(\mathbf{x}) d\mathbf{x} - f_\emptyset^2$.

[illegible] are defined as the ratios

$$S_u(f) = \frac{\sigma_u^2(f)}{\sigma^2(f)} \quad \text{for } \emptyset \neq u \subseteq \{1, \dots, d\}.$$

They are useful for measuring the relative importance of each ANOVA term. Clearly, $\sum_{\emptyset \neq u \subseteq \{1,\dots,d\}} S_u(f) = 1$. Letting u be a subset of $\{1, \dots, d\}$, the [illegible] corresponding to u is defined as

$$T_u(f) := \sum_{\emptyset \neq v \subseteq u} \sigma_v^2(f).$$

Writing $\mathbf{x} = (\mathbf{x}_u, \mathbf{x}_{-u})$ and $\mathbf{y} = (\mathbf{y}_u, \mathbf{y}_{-u})$, then it can be shown (see [29, 32]) that

$$T_u(f) = \int_{[0,1)^{2d-|u|}} f(\mathbf{x}) f(\mathbf{x}_u, \mathbf{y}_{-u}) d\mathbf{x} d\mathbf{y}_{-u} - [I_d(f)]^2. \tag{3.2}$$

This formula can be used to calculate numerically an approximation to the variance of each ANOVA term. Because our focus is on financial derivative pricing, where the corresponding functions are dominated by low-order ANOVA terms, we are mainly interested in the variances of low-order ANOVA terms. The variance of the first- and second-order ANOVA terms can be computed as follows:

- For $|u| = 1$, $\sigma_u^2(f) = T_u(f)$, so $\sigma_u^2(f)$ can be computed directly by (3.2).
- For $|u| = 2$, say, $u = \{i, j\}$, $\sigma_{\{i,j\}}^2(f)$ can be evaluated from

$$T_{\{i,j\}}(f) = \sigma_{\{i\}}^2(f) + \sigma_{\{j\}}^2(f) + \sigma_{\{i,j\}}^2(f),$$

where $T_{\{i,j\}}(f)$ can be computed by (3.2).

In this way, for a given function f one can calculate its sensitivity indices $S_u(f)$ for $|u| = 1, 2$ to obtain information about the relative importance of each variable and the pairwise interactions between variables. For our purpose we need only to compute several sensitivity indices.

3.2. ANOVA decomposition for weighted Korobov spaces. For a weighted reproducing kernel Hilbert space, it is also possible to obtain some information about the behavior of the functions of the space by analyzing typical functions in the space. Consider the weighted Korobov spaces with the smoothness parameter $\alpha = 2$. Based on (2.3), the reproducing kernel $K_{d,\alpha,\gamma}(\mathbf{x}, \mathbf{y})$ in (2.1) with $\alpha = 2$ can be written as

$$K_{d,2,\gamma}(\mathbf{x}, \mathbf{y}) = \prod_{j=1}^{d} \left[1 + 2\pi^2 \gamma_j B_2(\{x_j - y_j\})\right]. \tag{3.3}$$

For any fixed $\mathbf{y}^* = (y_1^*, \ldots, y_d^*) \in [0, 1)^d$, define a function of $\mathbf{x}$ by

$$f_{\mathbf{y}^*}(\mathbf{x}) := K_{d,2,\gamma}(\mathbf{x}, \mathbf{y}^*) = \prod_{j=1}^{d} \left[1 + 2\pi^2 \gamma_j B_2(\{x_j - y_j^*\})\right] =: \prod_{j=1}^{d} g_j(x_j). \tag{3.4}$$

We call $f_{\mathbf{y}^*}(\mathbf{x})$ a "typical function" of the weighted Korobov space $H_{d,2,\gamma}$ due to the following:

(1) Each $f_{\mathbf{y}^*}(\mathbf{x})$ belongs to the space $H_{d,2,\gamma}$ and has full dimension d.

(2) Any function of the space $H_{d,2,\gamma}$ is either a linear combination of the form $\sum a_k f_{\mathbf{y}_k^*}(\mathbf{x})$ for some choices of $\{a_k\}$ and $\{\mathbf{y}_k^*\}$ or the limit of a sequence of such combinations.

(3) The sensitivity indices for the function $f_{\mathbf{y}^*}(\mathbf{x})$ are independent of the choice of $\mathbf{y}^*$. (This fact, shown below, is a consequence of the translation invariance of the space.)

(4) The quadrature error of $f_{\mathbf{y}^*}(\mathbf{x})$ with the shifted lattice rule (see (5.3) below) with $\Delta = \mathbf{1} - \mathbf{y}^*$ is exactly the worst-case error in the space $H_{d,2,\gamma}$. This can be verified by using (2.2) and $I_d(f_{\mathbf{y}^*}) = 1$.

The function $f_{\mathbf{y}^*}(\mathbf{x})$ has a multiplicative structure. To exploit this, we note that, for any fixed $y_j^* \in [0, 1)$,

$$\int_0^1 B_2(\{x_j - y_j^*\}) dx_j = 0 \quad \text{and} \quad \int_0^1 B_2^2(\{x_j - y_j^*\}) dx_j = \frac{1}{180}.$$

Let

$$\mu_j := \int_0^1 g_j(x_j) dx_j = \int_0^1 \left[1 + 2\pi^2 \gamma_j B_2(\{x_j - y_j^*\})\right] dx_j = 1$$

and

$$\lambda_j^2 := \int_0^1 (g_j(x_j) - \mu_j)^2 dx_j = \int_0^1 4\pi^4 \gamma_j^2 B_2^2(\{x_j - y_j^*\}) dx_j = \frac{\pi^4}{45} \gamma_j^2.$$

Using the formulas in [32], the ANOVA terms of $f_{\mathbf{y}^*}(\mathbf{x})$ and the corresponding variances are

$$(f_{\mathbf{y}^*})_u = \prod_{j\in u}(g_j(x_j)-\mu_j)\prod_{j\notin u}\mu_j \quad \text{and} \quad \sigma_u^2(f_{\mathbf{y}^*}) = \left(\frac{\pi^4}{45}\right)^{|u|}\prod_{j\in u}\gamma_j^2. \tag{3.5}$$

The total variance of $f_{\mathbf{y}^*}(\mathbf{x})$ is

$$\sigma^2(f_{\mathbf{y}^*}) = \left[\prod_{j=1}^{d}\left(1+\frac{\pi^4\gamma_j^2}{45}\right)-1\right].$$

Therefore, the sensitivity indices of the typical function $f_{\mathbf{y}^*}$ can be computed easily. Note that all the variances $\sigma_u^2(f_{\mathbf{y}^*})$ and $\sigma^2(f_{\mathbf{y}^*})$ are independent of the point $\mathbf{y}^*$. Due to this fact, a typical function will also be denoted by $f^*(\mathbf{x})$. It is clear from (3.5) that the relative importance of the ANOVA terms strongly depends on the weights.

3.3. Why are classical lattice rules not suitable for high-dimensional financial problems? We explain why classical lattice rules may be [illegible] for high-dimensional financial problems. Consider the classical unweighted Korobov space with the weights $\gamma_j = 1$ for all j. For a typical function f^* in this space, from (3.5) we have

$$\sigma_u^2(f^*) = \left(\pi^4/45\right)^{|u|}.$$

Since $\pi^4/45 = 2.1646\cdots > 1$, the relative importance of a high-order ANOVA term of f^* is much more significant than that of a low-order term. Indeed, the sensitivity index of the ANOVA term f_u^*, namely

$$S_u(f^*) = \frac{1}{\sigma^2(f^*)}\left(\frac{\pi^4}{45}\right)^{|u|},$$

depends [illegible] on $|u|$ (with $\pi^4/45$ as the base). Moreover, the number of ANOVA terms with order $|u|$ is $\binom{d}{|u|}$, which is increasing for $|u| < d/2$. Thus a typical function f^* has large effective dimension in the superposition sense; see [32].

The classical quality measure of lattice rules P_α is the quadrature error of the lattice rule applied to a certain function; see (2.4). In particular, P_2 is the quadrature error of the function $K_{d,2,\gamma}(\mathbf{x},\mathbf{0}) = \prod_{j=1}^{d}\left[1+2\pi^2 B_2(x_j)\right]$ with all $\gamma_j = 1$ (see [22]), i.e.,

$$P_2 = Q_{n,d}(K_{d,2,\gamma}(\mathbf{x},\mathbf{0})) - I_d(K_{d,2,\gamma}(\mathbf{x},\mathbf{0})) = Q_{n,d}(K_{d,2,\gamma}(\mathbf{x},\mathbf{0})) - 1.$$

The function $K_{d,2,\gamma}(\mathbf{x},\mathbf{0})$ with all $\gamma_j = 1$ is a typical function in the space $H_{d,2,\gamma}$. As just shown, such a function has strong high-order ANOVA effects and relatively weak low-order ones (say the first- and second-order terms). Classical lattice rules are constructed by minimizing P_2. From the nature of the integrand $K_{d,2,\gamma}(\mathbf{x},\mathbf{0})$, by minimizing P_2 we are paying more attention to the high-order ANOVA terms and less attention to low-order terms. A lattice rule that minimizes P_2 may be the best one for the artificial space $H_{d,2,\gamma}$ (with all $\gamma_j = 1$), but the corresponding worst-case error is in general very large (see [22]). A recent investigation shows that the lattice rules found by minimizing P_2 have very bad two-dimensional projections [31]. (Note that all rank-1 lattices have the same one-dimensional projections.)

However, many practical problems have a quite different ANOVA structure from the function $K_{d,2,\gamma}(\mathbf{x},\mathbf{0})$. Quite commonly, the functions in finance are dominated by low-order ANOVA terms, often just the first- and second-order terms. While the third-order terms sometimes have a small influence on the function, higher-order terms are usually negligible. That is to say, an ANOVA expansion to the third-order

$$f(\mathbf{x}) \approx f_\emptyset + \sum_j f_{\{j\}}(x_j) + \sum_{i<j} f_{\{i,j\}}(x_i,x_j) + \sum_{i<j<k} f_{\{i,j,k\}}(x_i,x_j,x_k)$$

(or even to the second-order) often provides a quite satisfactory approximation of f (in the L_2-norm sense). It is therefore unreasonable to use the classical lattice rules for such financial problems. Indeed, it is quite possible that the classical lattice rules may lead to bad results, even worse than MC (see section 5 for examples). This is why it is important to choose more appropriate weights for practical applications in high dimensions.

3.4. Determining the weights by a matching strategy. We show how to determine empirical weights by matching the relative sensitivity indices of a typical function of a weighted Korobov space to the given function. Assuming that the variables $x_1, x_2, \ldots, x_d$ are labelled in the order of decreasing importance, for the given function we compute the approximate values of the variances of some ANOVA terms using the method in section 3.1:

$$v_{\{1\}}(f) \approx \sigma^2_{\{1\}}(f), \quad v_{\{2\}}(f) \approx \sigma^2_{\{2\}}(f), \quad v_{\{1,2\}}(f) \approx \sigma^2_{\{1,2\}}(f).$$

The relative sensitivities can then be obtained from

$$\frac{S_{\{2\}}(f)}{S_{\{1\}}(f)} = \frac{\sigma^2_{\{2\}}(f)}{\sigma^2_{\{1\}}(f)} \approx \frac{v_{\{2\}}(f)}{v_{\{1\}}(f)} \quad \text{and} \quad \frac{S_{\{1,2\}}(f)}{S_{\{1\}}(f)} = \frac{\sigma^2_{\{1,2\}}(f)}{\sigma^2_{\{1\}}(f)} \approx \frac{v_{\{1,2\}}(f)}{v_{\{1\}}(f)}. \tag{3.6}$$

The first ratio indicates the relative importance of x_1 and x_2, and the second ratio indicates the relative importance of the joint interaction of x_1 and x_2 to that of x_1 alone.

On the other hand, suppose that f^* is a "typical function" in the weighted Korobov space $H_{d,2,\gamma}$ and that the weights have the two-parameter form

$$\gamma_j = a\tau^j, \quad j = 1,2,\ldots,d, \tag{3.7}$$

where a and τ are parameters to be determined. Then from (3.5) the variance of the ANOVA term of f^* is

$$\sigma^2_u(f^*) = \left(\frac{\pi^4}{45}\right)^{|u|} \prod_{j\in u} \gamma_j^2 = \left(\frac{a^2\pi^4}{45}\right)^{|u|} \prod_{j\in u} \tau^{2j}. \tag{3.8}$$

From (3.8), we have

$$\frac{S_{\{2\}}(f^*)}{S_{\{1\}}(f^*)} = \frac{\sigma^2_{\{2\}}(f^*)}{\sigma^2_{\{1\}}(f^*)} = \tau^2 \quad \text{and} \quad \frac{S_{\{1,2\}}(f^*)}{S_{\{1\}}(f^*)} = \frac{\sigma^2_{\{1,2\}}(f^*)}{\sigma^2_{\{1\}}(f^*)} = \frac{\pi^4}{45}a^2\tau^4. \tag{3.9}$$

In the two-parameter [illegible] we choose the parameters a and τ, and hence the weights, by equating the respective ratios in (3.6) and (3.9). This yields

$$\tau = \sqrt{\frac{v_{\{2\}}(f)}{v_{\{1\}}(f)}}, \quad a = \frac{3}{\pi^2\tau^2}\sqrt{\frac{5v_{\{1,2\}}(f)}{v_{\{1\}}(f)}}. \tag{3.10}$$

The weights γ_j are then determined by $\gamma_j = a\tau^j$, $j = 1, \ldots, d$. For functions whose successive variables become less and less important and the interactions between variables are weaker than the main effects, one has $v_{\{2\}}(f) < v_{\{1\}}(f)$ and $v_{\{1,2\}}(f) < v_{\{1\}}(f)$, and thus one must have $\tau < 1$ and $a \le 3\sqrt{5}/\pi^2 \approx 0.68$ (implying the classical weights are much too large).

We can verify whether the weights determined in this way are reasonable for a given problem by comparing "predicted" sensitivity indices with the actual values. For example, for the particular problem, given $S_{\{1\}}(f)$ and the weights determined by $\gamma_j = a\tau^j$ we can predict the sensitivity indices of all ANOVA terms from the theory. Indeed, from (3.8) we have

$$S_{\{j\}}(f) = \sigma^2_{\{j\}}(f)/\sigma^2(f) = \tau^{2(j-1)} S_{\{1\}}(f), \quad j = 1, 2, \ldots, d, \tag{3.11}$$

and similarly

$$S_{\{i,j\}}(f) = \frac{\pi^4}{45} a^2 \tau^{2i+2j-2} S_{\{1\}}(f), \quad i = 1, \ldots, d-1; \quad j = i+1, \ldots, d. \tag{3.12}$$

On the other hand, we can compute their actual values for the given problem by the method given in section 3.1:

$$S_{\{j\}}(f) = \frac{\sigma^2_{\{j\}}(f)}{\sigma^2(f)} \approx \frac{v_{\{j\}}(f)}{\hat{\sigma}^2(f)}, \quad j = 1, \ldots, d,$$

and

$$S_{\{i,j\}}(f) = \frac{\sigma^2_{\{i,j\}}(f)}{\sigma^2(f)} \approx \frac{v_{\{i,j\}}(f)}{\hat{\sigma}^2(f)}, \quad i = 1, \ldots, d-1; \quad j = i+1, \ldots, d,$$

where $\hat{\sigma}^2(f) \approx \sigma^2(f)$. If the predicted values fit the actual values well, we have good reason to expect that the typical functions of the weighted Korobov space (with the weights so determined) match the given function well and that it is reasonable to use these weights for constructing lattice rules. We describe an experiment of this kind in section 5.

2. The use of the weights in the form (3.7) is motivated by the observation that in some financial problems [32, 34], the variances captured by the successive variables are naturally ordered and decrease approximately exponentially (we use τ to characterize this); moreover, the high-order interactions are weaker than the low-order interactions (here a characterizes the relative importance of ANOVA terms of different orders: small a means that only low-order terms are important). Such weights are easy to work with, since only two parameters, a and τ, need to be determined. Note that it would be more robust to base the estimation of the parameters on $v_u(f)$ for all u of cardinality one and two, but this would require much more computation.

The matching strategy can also be used to determine more general weights γ_j. Define the relative weights $\tau_j := \gamma_j/\gamma_1$. It is then convenient to write the weights as

$$\gamma_j = a\,\tau_j, \quad j = 1, \ldots, d, \quad \text{with} \quad \tau_1 = 1.$$

The parameters a and τ_j $(j = 2, \ldots, d)$ can also be determined by a matching strategy:

$$\tau_j = \sqrt{\frac{v_{\{j\}}(f)}{v_{\{1\}}(f)}}, \quad j = 2, \ldots, d; \quad a = \frac{3\sqrt{5}}{\pi^2} \sqrt{\frac{\sum_{i<j} v_{\{i,j\}}(f)}{\sum_j v_{\{j\}}(f)} \, \frac{\sum_j \tau_j^2}{\sum_{i<j} \tau_i^2 \tau_j^2}},$$

where $v_{\{j\}}(f)$ and $v_{\{i,j\}}(f)$ are the approximate values of $\sigma_j^2(f)$ and $\sigma_{\{i,j\}}^2(f)$, respectively.

A simplification of (3.7) is the one-parameter form of weights: $\gamma_j = a$ for $j = 1, \ldots, d$ (obtained by letting $\tau = 1$). This choice is suitable for functions with (nearly) equally important variables. At the other extreme, one could associate each "important" ANOVA term with its own weight and associate the unimportant terms with the weight 0. The weights are then of the nonproduct form studied in [6].

3. If we are completely successful with the matching, i.e., if the weights γ_j are such that all the sensitivity indices $S_u(f^*)$ for $u \subseteq \{1, \ldots, d\}$ of the typical functions f^* of the form (3.4) are the same as those of the given function f or, at the extreme, that the given f is actually one function of the form (3.4), for example, $f(\mathbf{x}) = \prod_{j=1}^{d}[1 + 2\pi^2\gamma_j B_2(x_j)]$, then the lattice rule constructed by minimizing the worst-case error of the corresponding weighted Korobov space with the weights γ_j is the best choice for the given f. This is because, as mentioned earlier, the worst-case error for that weighted Korobov space is exactly the quadrature error for the given function f.

4. Typically, accurate estimation of the sensitivity indices for a practical problem is no easier than the original integration problem, because the formula (3.2) involves high-dimensional integrals. For practical use, we can take a "simpler" problem which is similar to the original one but with the property that computation of the corresponding sensitivity indices is easier, or even analytically tractable. It then seems plausible that the weights and the lattice rules found for the simpler problem will be useful for the original problem (this is seen to be the case for the examples in section 5). Another situation is that we have many integrals of a similar type to compute, with these integrals often differing from each other by differing values of some parameters. If we can show that the choice of weights or the quality of the resulting lattice rules is not very sensitive to the parameters lying in some ranges, then the weights (and the lattice rules) found for one particular integral may be useful for other integrals in the class. In our experience, even a rough estimation of good weights can bring a large benefit. See Remark 5 below for more discussion.

3.5. Nonperiodic function spaces. The functions encountered in practice are generally not periodic, and hence do not lie in the weighted Korobov spaces. However, it is known that when dealing with randomly shifted lattice rules in nonperiodic reproducing kernel Hilbert spaces, it is the "shift-invariant" kernel that is relevant to the error analysis (see [23]). For a reproducing kernel $K(\mathbf{x}, \mathbf{y})$, the shift-invariant kernel K^{sh} associated with K is defined by (see [12])

$$K^{\mathrm{sh}}(\mathbf{x}, \mathbf{y}) := \int_{[0,1]^d} K(\{\mathbf{x} + \Delta\}, \{\mathbf{y} + \Delta\})\, d\Delta.$$

An important property of the shift-invariant kernel is

$$\int_{[0,1]^d} e^2(Q_{n,d}(f, \Delta); H(K))\, d\Delta = e^2(Q_{n,d}; H(K^{\mathrm{sh}})),$$

where $H(K)$ and $H(K^{\mathrm{sh}})$ are the reproducing kernel Hilbert spaces with kernels K and K^{sh}, respectively. Therefore, a good lattice rule for $H(K^{\mathrm{sh}})$ corresponds to a good randomly shifted lattice rule for the space $H(K)$.

In some important cases, the shift-invariant kernel is a weighted Korobov kernel. Consider the Sobolev space of nonperiodic functions with the reproducing kernel

(see [27])

$$K(\mathbf{x},\mathbf{y})=\prod_{j=1}^{d}\left[1+w_j\left(\frac{1}{2}B_2(\{x_j-y_j\})+\left(x_j-\frac{1}{2}\right)\left(y_j-\frac{1}{2}\right)\right)\right].$$

Its shift-invariant kernel can be obtained by direct computation

$$K^{\rm sh}(\mathbf{x},\mathbf{y})=\prod_{j=1}^{d}[1+2\pi^2\gamma_j B_2(\{x_j-y_j\})],\quad \gamma_j=\frac{w_j}{2\pi^2},$$

which is exactly the kernel $K_{d,2,\gamma}(\mathbf{x},\mathbf{y})$ in (3.3). Next, consider the Sobolev space used in [25]:

$$K(\mathbf{x},\mathbf{y})=\prod_{j=1}^{d}(1+w_j\min(1-x_j,1-y_j)). \tag{3.13}$$

In [26] it is shown that its shift-invariant kernel is

$$K^{\rm sh}(\mathbf{x},\mathbf{y})=\prod_{j=1}^{d}\left(1+\frac{w_j}{3}\right)\prod_{j=1}^{d}[1+2\pi^2\gamma_j B_2(\{x-y\})]$$

with

$$\gamma_j=\frac{w_j}{2\pi^2(1+w_j/3)}.$$

Once more, apart from a constant factor, the shift-invariant kernel is just $K_{d,2,\gamma}(\mathbf{x},\mathbf{y})$ in (3.3) with γ_j given as above. That constant factor is irrelevant for our present purpose. Therefore, by estimating γ_j (using the matching strategy) we may, for example, take the point of view that we are simultaneously estimating the weights

$$w_j=\frac{2\pi^2\gamma_j}{1-2\pi^2\gamma_j/3}$$

in the setting of [25], i.e., for the Sobolev space kernel (3.13).

4. Constructing the lattice rules. In dimension $d\ge 3$ one normally finds lattice rules by computer searches based on a certain criterion of goodness, say the worst-case error. In this section, we present several constructions, including the Korobov construction [14, 35], the CBC construction [15, 23, 24], and a cheaper modification of the CBC construction. We consider the case when n is prime. In this case, each component of the generating vector $\mathbf{z}$ of the lattice rule (1.2) can be chosen from the restricted set

$$\mathbf{Z}_n=\{1,2,\ldots,n-1\}.$$

ALGORITHM 1 (Korobov construction).

Suppose n is prime. For each fixed dimension d and given weights $\{\gamma_j\}$, the optimal Korobov generator is found by minimizing

$$e^2_{n,d}(\mathbf{z}(a))=-1+\frac{1}{n}\sum_{k=0}^{n-1}\prod_{j=1}^{d}\left(1+\gamma_j\sum_{h=-\infty}^{\infty}{}'\,\frac{\exp\left(2\pi ikha^{j-1}/n\right)}{|h|^{\alpha}}\right)$$

with respect to $a \in \mathbf{Z}_n$, where $\mathbf{z}(a)$ is a vector in Korobov form $\mathbf{z}(a) = (1, a, \ldots, a^{d-1}) \bmod (n)$.

ALGORITHM 2 (CBC full search algorithm).

Suppose n is prime and the weights are given. The generator $\mathbf{z}$ is found as follows:

1. Set the first component z_1 of the generator $\mathbf{z}$ to 1.
2. For $t = 2, 3, \ldots, d$, find $z_t \in \mathbf{Z}_n$ such that

$$e_{n,t}^2(z_1, \ldots, z_t) = -1 + \frac{1}{n} \sum_{k=0}^{n-1} \prod_{j=1}^{t} \left(1 + \gamma_j \sum_{h=-\infty}^{\infty}{}' \frac{e^{2\pi i h k z_j/n}}{|h|^\alpha}\right)$$

is minimized.

It is proved in [15] that the resulting lattice rule satisfies

$$e_{n,d}(\mathbf{z}) \le C(d,\delta)\, n^{-\alpha/2+\delta}, \quad 0 < \delta \le (\alpha-1)/2,$$

where $C(d,\delta)$ depends on d and δ. Moreover, if $\sum_{j=1}^{\infty} \gamma_j^{\frac{1}{\alpha-2\delta}} < \infty$, then $C(d,\delta)$ is uniformly bounded in d. The good theoretical properties indicate the potential superiority of such lattice rules. A disadvantage of Algorithm 2 is its full search character in finding each component. It is desirable to speed up the construction. Here we take an approach which allows an incomplete search at some steps.

4.1. Acceptance-rejection control algorithm. Given a d-dimensional generator $\mathbf{z} = (z_1, \ldots, z_d)$, Algorithm 2 indicates a way of finding the next component by full search. We give here a more flexible way. For any $z_{d+1} \in \mathbf{Z}_n$, we have

$$e_{n,d+1}^2(\mathbf{z}, z_{d+1}) = -1 + \frac{1}{n} \sum_{k=0}^{n-1} \prod_{j=1}^{d+1} \left(1 + \gamma_j \sum_{h=-\infty}^{\infty}{}' \frac{e^{2\pi i h k z_j/n}}{|h|^\alpha}\right).$$

Define the mean of $e_{n,d+1}^2(\mathbf{z}, z_{d+1})$ over $z_{d+1} \in \mathbf{Z}_n$ as

$$M_{n,d,\alpha}(\mathbf{z}) := \frac{1}{n-1} \sum_{z_{d+1} \in \mathbf{Z}_n} e_{n,d+1}^2(\mathbf{z}, z_{d+1}).$$

An explicit formula for $M_{n,d,\alpha}(\mathbf{z})$ can be derived by using a similar method to that in [15, 23, 24]. The proof is omitted.

LEMMA 4.1. [illegible] $\alpha > 1$ [illegible] $\mathbf{z} = (z_1, \ldots, z_d) \in \mathbf{Z}_n^d$ [illegible] n[illegible]

$$M_{n,d,\alpha}(\mathbf{z}) = e_{n,d}^2(\mathbf{z}) + \frac{2\gamma_{d+1}\zeta(\alpha)}{n} \prod_{j=1}^{d}(1 + 2\gamma_j\zeta(\alpha)) + \gamma_{d+1} T^* \left(e_{n,d}^2(\mathbf{z}) + 1 - \frac{1}{n}\prod_{j=1}^{d}(1 + 2\gamma_j\zeta(\alpha))\right),$$

[illegible] ζ[illegible] $\zeta(\alpha) = \sum_{h=1}^{\infty} h^{-\alpha}$ [illegible] $T^* = -\frac{2\zeta(\alpha)(1-n^{1-\alpha})}{n-1}$

The mean $M_{n,d,\alpha}(\mathbf{z})$ can be used as a benchmark in searching the next component (see Algorithm 3). In our experience, an optimal component may be expensive to find, but nearly optimal components are not rare; indeed, they are quite common. Thus at least for some components (for example, the components associated with small weights), the full search is unnecessary. Instead, we can perform a random search.

In order to preserve as far as possible the good theoretical properties, we use an acceptance-rejection control search.

ALGORITHM 3 (acceptance-rejection control search algorithm).

Suppose n is prime and the weights γ_j are given. Set two integer parameters $2 \le d^* \le d$ and $1 \le m^* \le n-1$. The generator $(z_1, \ldots, z_d)$ is found as follows:

1. Set the first component z_1 of the generator $\mathbf{z}$ to 1.
2. For $t = 2, \ldots, d^* - 1$, find $z_t \in \mathbf{Z}_n$, such that $e^2_{n,t}(z_1, \ldots, z_t)$ is minimized.
3. For $t = d^*, \ldots, d$, the component z_t is found in the following way:
   (a) Randomly generate $z_t \in \mathbf{Z}_n$. If $e^2_{n,t}(z_1, \ldots, z_t) \le M_{n,t-1,\alpha}(z_1, \ldots, z_{t-1})$, accept this z_t as one candidate; otherwise, reject it.
   (b) Repeat step (a) until the number of acceptances is m^* or all possible values of $z_t \in \mathbf{Z}_n$ are exhausted.
   (c) Choose the best one from the accepted z_t's in the sense of smallest $e_{n,t}(z_1, \ldots, z_t)$.

The search is controlled by two parameters d^* and m^*. The first $d^* - 1$ components are found in the same way as in Algorithm 2. The remaining components are found by using the acceptance-rejection search; m^* is the maximum number of acceptances. We have the flexibility to choose these parameters according to the computing resource or the problem at hand. By choosing $d^* = d + 1$ or m^* sufficiently large, Algorithm 3 becomes equivalent to Algorithm 2. The lattice rules generated by Algorithm 3 partially preserve the good theoretical properties of the rules generated by Algorithm 2. We have convergence order $O(n^{-1/2})$, the same as MC, but the practical performance can be much better than MC.

THEOREM 4.2. [illegible] 3

$$e^2_{n,d}(\mathbf{z}) \le \frac{1}{n} \prod_{j=1}^{d} (1 + 4\gamma_j \zeta(\alpha)). \tag{4.1}$$

[illegible] $\sum_{j=1}^{\infty} \gamma_j < \infty$ [illegible] $O(n^{-1/2})$ [illegible]

The result follows easily by proving recursively that at each step the squared worst-case error $e^2_{n,d}(z_1, \ldots, z_t)$ is no worse than the average $M_{n,t-1,\alpha}(z_1, \ldots, z_{t-1})$ and that

$$M_{n,t-1,\alpha}(z_1, \ldots, z_{t-1}) \le \frac{1}{n} \prod_{j=1}^{t} (1 + 4\gamma_j \zeta(\alpha)).$$

The error bound (4.1) then follows.

Among the three algorithms, Algorithm 1 (the Korobov construction) is the cheapest one, while Algorithm 2 (full CBC construction) is the most expensive. The cost of Algorithm 1 for a fixed dimension d is $O(n^2 d)$, while the costs of the obvious implementations of Algorithms 2 and 3 for all dimensions up to d are $O(n^2 d^2)$ and $O(n^2 d d^* + n m^* d^2)$, respectively. (Note added in proof: Since this paper was written, Nuyens and Cools [19] have shown that there is an algorithm equivalent to Algorithm 2 whose cost is reduced to $O(n \log n\, d^2)$.) Although the theoretical properties of the lattice rules generated by Algorithm 1 (see also [35]) and Algorithm 3 are not as good as those of the lattice rules from Algorithm 2, their practical performance is similar (see section 5).

5. Financial derivative pricing.

5.1. Path-dependent options. Consider the problem of pricing path-dependent options with terminal payoff $g(S_{t_1}, \ldots, S_{t_d})$, where $S_{t_1}, \ldots, S_{t_d}$ are the prices of the underlying asset at times $t_1, \ldots, t_d$. For simplicity, assume the prices are sampled at equally spaced times $t_0 = 0$, $t_j = t_{j-1} + \Delta t$, $j = 1, \ldots, d$, $\Delta t = T/d$, where T is the expiration date. Assume that under the risk-neutral measure the underlying asset follows geometric Brownian motion (Black–Scholes model):

$$dS_t = rS_t dt + \sigma S_t dB_t, \tag{5.1}$$

where r is the risk-free interest rate, σ is the volatility, and B_t is the standard Brownian motion. The analytical solution to (5.1) is

$$S_t = S_0 \exp((r - \sigma^2/2)t + \sigma B_t). \tag{5.2}$$

Thus simulating values of S_t reduces to simulating values of B_t. Based on the risk-neutral valuation principle [13], the value of the option at time $t = 0$ is

$$C_0 = E_Q[e^{-rT} g(S_{t_1}, \ldots, S_{t_d})],$$

where $E_Q[\cdot]$ is the expectation under the risk-neutral measure Q.

Note that the random vector $(B_{t_1}, \ldots, B_{t_d})^T =: (y_1, \ldots, y_d)^T$ is normally distributed with mean zero and covariance matrix $\mathbf{V} = (\min(t_i, t_j))_{i,j=1}^d$. Defining $\mu_j = \log S_0 + (r - \sigma^2/2)t_j$, $j = 1, \ldots, d$, from (5.2) we have $S_{t_j} = \exp(\mu_j + \sigma y_j)$. The payoff can then be written as

$$g(S_{t_1}, \ldots, S_{t_d}) = g(e^{\mu_1 + \sigma y_1}, \ldots, e^{\mu_d + \sigma y_d}) =: H(\mathbf{y}).$$

The value of the option at time 0 can be written as

$$\begin{aligned} E_Q[e^{-rT} g(S_{t_1}, \ldots, S_{t_d})] &= \frac{e^{-rT}}{(2\pi)^{d/2}\sqrt{\det V}} \int_{R^d} H(\mathbf{y}) e^{-\frac{1}{2}\mathbf{y}^T \mathbf{V}^{-1} \mathbf{y}} d\mathbf{y} \\ &= \frac{e^{-rT}}{(2\pi)^{d/2}} \int_{R^d} H(A\mathbf{z}) e^{-\frac{1}{2}\mathbf{z}^T \mathbf{z}} d\mathbf{z}, \end{aligned}$$

where in the second step a linear transformation $(y_1, \ldots, y_d)^T = A(z_1, \ldots, z_d)^T$ is performed using an arbitrary $d \times d$ matrix A satisfying $AA^T = \mathbf{V}$. The change of variables can also be interpreted as a covariance matrix decomposition or a way of generating the Brownian motion:

$$(B_{t_1}, \ldots, B_{t_d})^T = A(z_1, \ldots, z_d)^T,$$

where $z_1, \ldots, z_d$ are i.i.d. standard normal variables. The standard construction generates the Brownian motion sequentially in time: given $B_0 = 0$,

$$B_{t_j} = B_{t_{j-1}} + \sqrt{\Delta t}\, z_j, \quad j = 1, \ldots, d.$$

In this case, the corresponding matrix A is the Cholesky decomposition of $\mathbf{V}$.

Now consider Asian call options based on the arithmetic average of the underlying asset. The terminal payoff is

$$g_A(S_{t_1}, \ldots, S_{t_d}) = \max\left(0, \frac{1}{d}\sum_{j=1}^{d} S_{t_j} - K\right),$$

where K is the strike price at time T. To improve the efficiency, as an option in our calculations we take the payoff of the corresponding geometric average Asian call option as a control variate: $g_G(S_{t_1},\dots,S_{t_d}) = \max(0, \prod_{j=1}^{d} S_{t_j}^{1/d} - K)$. An analytical expression can be easily derived for $E_Q[g_G(S_{t_1},\dots,S_{t_d})]$. Writing

$$E_Q[g_A(S_{t_1},\dots,S_{t_d})] = E_Q[g_A(S_{t_1},\dots,S_{t_d}) - bg_G(S_{t_1},\dots,S_{t_d})] + bE_Q[g_G(S_{t_1},\dots,S_{t_d})]$$

for some multiplier b, the optimal b in the MC setting, in the sense of minimizing the variance of $g_A - bg_G$, is $b^* = \mathrm{Cov}(g_A, g_G)/\sigma^2(g_G)$, which can be estimated numerically. The same multiplier b^* will also be used in the QMC setting (see [10] for the possible dangers). We will also use optionally antithetic variates and their combinations with control variates.

To reduce the effective dimension, we use the Brownian bridge (BB) [3, 17] or principal component analysis (PCA); see [1]. The advantage of BB and PCA is that they will match the most significant parts of the Brownian motion with the coordinates of the QMC points that have the highest quality. See [32] on the determination of the effective dimension and the extent to which the effective dimension can be reduced by BB and PCA.

We divide our experiments into two parts: one is to determine suitable weights; the other is to construct the corresponding lattice rules and compare their performance to other methods. In our calculations, we use the following parameters:

$$S_0 = 100, \quad \sigma = 0.2, \quad r = 0.1, \quad T = 1 \text{ year}, \quad K = 100.$$

The exact estimation of the sensitivity indices for the arithmetic average Asian option problem is not easier than the original problem, due to the high dimensionality of the integrals involved (see (3.2)). Thus to estimate the sensitivity indices, we take the simpler problem of the geometric average Asian option. The sensitivity indices can be computed easily as shown in [34]. For the standard construction they are

$$S_{\{1\}} = 1.44 \times 10^{-1}, \ S_{\{2\}} = 1.26 \times 10^{-1}, \ S_{\{1,2\}} = 8.85 \times 10^{-3} \quad \text{for } d = 16,$$

$$S_{\{1\}} = 3.76 \times 10^{-2}, \ S_{\{2\}} = 3.64 \times 10^{-2}, \ S_{\{1,2\}} = 7.42 \times 10^{-4} \quad \text{for } d = 64.$$

The parameters a, τ are determined by (3.10), resulting in $\tau = 0.93$ and $a = 0.20$ for $d = 16$ and $\tau = 0.98$ and $a = 0.098$ for $d = 64$. The weights γ_j can be determined by (3.7). Tables 5.1 and 5.2 present the comparison of the predicted sensitivity indices (computed by (3.11) and (3.12)) and the actual values of the sensitivity indices of some first- and second-order ANOVA terms for $d = 64$. The predicted values fit the actual ones surprisingly well (both the predicted and the actual values for higher-order terms are very small; we do not list them).

We will use the obtained weights to construct lattice rules by Algorithms 1–3 (setting $d^* = 10$ and $m^* = 200$ in Algorithm 3) and use the resulting lattice rules for arithmetic average Asian option problems. We compare their performance with MC and QMC based on the Sobol sequence [28]. The performance of the unweighted lattice rules (i.e., with all $\gamma_j = 1$) will also be compared. In order to get an error estimate for each method, the standard deviations are computed. We use random shifts for lattice rules and the digit-scrambling method [20, 33] for the Sobol sequence. A randomly shifted lattice rule takes the form (see [4])

$$Q_{n,d}(f, \Delta) = \frac{1}{n} \sum_{k=0}^{n-1} f\left(\left\{ \frac{k\mathbf{z}}{n} + \Delta \right\} \right), \tag{5.3}$$

TABLE 5.1

The sensitivity indices $S_{\{j\}} \times 100$, $j = 1, \ldots, 32$, of some first-order ANOVA terms for geometric average Asian option pricing problem ($d = 64$): predicted values vs. actual values (the actual values are in parentheses). The predicted values are computed by (3.11) *and* (3.12)*, using the values of a and τ from* (3.10) *and the computed value of $S_{\{1\}}$.*

where Δ is chosen from a uniform distribution on $[0,1)^d$. We take m replications of $Q_{n,d}(f,\Delta)$ and compute

$$\overline{Q}_{n,d}(f) = \frac{1}{m}\sum_{j=1}^{m} Q_{n,d}(f,\Delta_j),$$

where $\Delta_1, \ldots, \Delta_m$ are i.i.d. samples. The square root of the sample variance

$$\mathrm{Var}[\overline{Q}_{n,d}(f)] = \frac{1}{m(m-1)}\sum_{j=1}^{m}[Q_{n,d}(f,\Delta_j) - \overline{Q}_{n,d}(f)]^2$$

provides an estimation of the standard deviation of $\overline{Q}_{n,d}(f)$. The relative efficiency ratio of $\overline{Q}_{n,d}(f)$ with respect to crude MC is defined by $\mathrm{Eff}\,[\overline{Q}_{n,d}(f)] := \mathrm{Var}(Q_{\mathrm{MC}})/\mathrm{Var}[\overline{Q}_{n,d}(f)]$, where $\mathrm{Var}(Q_{\mathrm{MC}})$ is the sample variance of the crude MC estimate based on mn random points. The relative efficiency ratio is the factor by which the number of points in crude MC would need to be multiplied to achieve the same accuracy. Tables 5.3 and 5.4 show the standard deviations and relative efficiency ratios of various estimates with respect to crude MC. The results are discussed in section 5.3.

TABLE 5.3

Comparison of the standard deviations and relative efficiency ratios with respect to crude MC (relative efficiency ratios are in parentheses) for the arithmetic average Asian option with 30 *replications (*$d = 16$*,* $n = 4001$*; for the Sobol sequence* $n = 4096$*). For weighted lattice rules, the weights are* $\gamma_j = a\tau^j$ *with* $\tau = 0.93$ *and* $a = 0.20$*. The optimal multiplier* b^* *in the control variate is* $b^* \approx 1.034$*. The abbreviations are as follows: KBV—Korobov lattice rules; CBC—full search component-by-component construction; ARC—acceptance-rejection control search algorithm. The three blocks of rows correspond to different methods of path generation: Std—standard construction of Brownian motion; BB—Brownian bridge construction; PCA—principal component analysis. In the finer stratification by rows are the methods of variance reduction: Crude—crude estimate without variance reduction; AV—antithetic variates; CV—control variates; ACV—combination of AV and CV.*

5.2. Pricing multiasset options. Consider a European-style multiasset derivative whose terminal payoff is $\phi(S_T^1, \dots, S_T^d)$, where $S_T^1, \dots, S_T^d$ are the prices of d risky assets at time T. Assume that in the risk-neutral measure the prices $(S_t^1, \dots, S_t^d)$ of the assets satisfy

$$dS_t^j = rS_t^j dt + \sigma_j S_t^j dB_t^j, \quad j = 1, \dots, d,$$

where $\sigma_1, \dots, \sigma_d$ are volatility parameters and $B_t^1, \dots, B_t^d$ are correlated Brownian motions with correlations ρ_{ij} (each B_t^j has drift 0 and variance 1). The solutions to the stochastic differential equations are given by

$$S_t^j = S_0^j \exp\left(\left(r - \frac{1}{2}\sigma_j^2\right)t + \sigma_j B_t^j\right). \tag{5.4}$$

TABLE 5.4

The same as Table 5.3 but for the number of time steps $d = 64$. For weighted lattice rules, the weights are $\gamma_j = a\tau^j$ with $a = 0.098$ and $\tau = 0.98$. The optimal multiplier b^* in the control variate is $b^* \approx 1.037$.

		(2109)	(574710)	(72)	(13887)	(12743)	(38576)	(55668)	(59735)

Note that the random vector $(B_T^1, \ldots, B_T^d)^T =: (y_1, \ldots, y_d)^T$ is normally distributed with mean zero and covariance matrix $\Sigma = (\rho_{ij}T)_{i,j=1}^d$. Put $\nu_j := \log S_0^j + (r - \frac{1}{2}\sigma_j^2)T$. From (5.4), we have $S_T^j = e^{\nu_j + \sigma_j y_j}$. The payoff $\phi(S_T^1, \ldots, S_T^d)$ can be written as

$$\phi(S_T^1, \ldots, S_T^d) = \phi(e^{\nu_1+\sigma_1 y_1}, \ldots, e^{\nu_d+\sigma_d y_d}) =: G(\mathbf{y}).$$

Therefore, the current price of the derivative security can be written as

$$E_Q[e^{-rT}\phi(S_T^1, \ldots, S_T^d)] = \frac{e^{-rT}}{(2\pi)^{d/2}} \int_{R^d} G(A\mathbf{z}) e^{-\frac{1}{2}\mathbf{z}^T\mathbf{z}} d\mathbf{z},$$

where A is any real $d \times d$ matrix satisfying $AA^T = \Sigma$. The matrix A characterizes the method of generating the Brownian motions.

Consider a call option on the arithmetic average prices of the d assets. The payoff is

$$\phi_A(S_T^1, \ldots, S_T^d) = \max\left(0, \frac{1}{d}\sum_{j=1}^d S_T^j - K\right).$$

TABLE 5.5

The control variate is chosen to be the payoff of the corresponding call option on the geometric average price of the d assets: $\phi_G(S_T^1, \ldots, S_T^d) = \max(0, (\prod_{j=1}^d S_T^j)^{1/d} - K)$. An analytical expression can be easily derived for $E_Q[\phi_G(S_T^1, \ldots, S_T^d)]$. The following parameters will be used:

$$S_0^j = 100, \quad \sigma_j = 0.2, \quad \rho_{ij} = 0.3, \quad r = 0.1, \quad T = 1 \text{ year}, \quad K = 100.$$

We use the same strategy as above. We find suitable weights for the standard construction and the geometric average multiasset option and use them to construct lattice rules for the arithmetic average multiasset option. (For the model parameters given above, the parameters which determine the weights in the form (3.7) are $a = 0.25$ and $\tau = 0.75$ for both $d = 16$ and $d = 64$.) Variance reduction and dimension reduction techniques will also be used. The computational results are given in Tables 5.5 and 5.6.

5.3. Summary of the computational experiments. The computational results in sections 5.1 and 5.2 show the following:

- The weights γ_j have a strong influence on the efficiency for all types of lattice rules, not only for CBC lattice rules but also for Korobov lattice rules. Without weights (i.e., all weights are taken to be 1), all three types of lattice rules behave very badly: their performance is not only much worse than that of the Sobol sequence but also worse than that of MC. However, with the suitably chosen weights, the efficiency of all types of lattice rules is dramatically improved. In many cases (especially in the standard construction of Brownian motion), they are more efficient than the Sobol sequence.

TABLE 5.6
The same as Table 5.5 but with $d = 64$. For weighted lattice rules, the weights are $\gamma_j = a\tau^j$ with $a = 0.25$ and $\tau = 0.75$. The optimal multiplier b^* in the control variate is $b^* \approx 1.042$.

- The lattice rule constructed by the acceptance-rejection control algorithm is as efficient as the full search CBC lattice rule. But the former can be constructed faster, and thus is more suitable for practical use. In the weighted case, both types of CBC lattice rules are in general more efficient than Korobov lattice rules.
- Dimension reduction and variance reduction techniques can increase the efficiency of lattice rules considerably (there is no advantage in using antithetic variates in QMC without BB or PCA, but there is some advantage for QMC in conjunction with BB or PCA). Their combinations lead to extremely efficient estimates. However, the unweighted lattice rules in conjunction with these techniques lead to results that are worse than MC. This means that even the control variates or dimension reduction techniques cannot rescue the unweighted lattice rules. In other words, the potential efficiency of dimension reduction and variance reduction techniques also depends on the quality of the point set.
- For the standard construction the full CBC lattice rules seem to perform better than the Sobol method. For the BB and PCA constructions the contest is more even. It should be noted that our matching strategy was carried out for the standard construction only, so a reduction in quality when applied to the BB and PCA constructions is not unexpected. (Therefore there is still room to improve the efficiency of lattice rules in the context of the BB or PCA constructions.)
- The weights $\gamma_j = a\tau^j$ found for our examples are quite different from the classical ones ($\gamma_j = 1$ for all j). The matching strategy of choosing weights for these problems is both practical and well suited to the finance problems considered here. Even a rough estimation of weights can offer a large improvement in efficiency.

5. To see how "robust" the parameters a and τ are, we selected several sets of model parameters (σ, K, r) for the case of the Asian option and determined a and τ by the method discussed in sections 4 and 5.1. Surprisingly, given the dimension d, the value of τ remained almost constant, while the parameter a changed slightly with a very clear trend: it increases as the strike price K and/or the volatility σ increases (and/or as the interest rate r decreases). The same phenomenon was observed for a multiasset option for fixed correlations ρ_{ij}.

The values of a have a common feature in all our examples: they are much smaller than 1. Such values of a capture the essential characteristics of finance problems. Small values of a guarantee that more attention is put on low-order ANOVA terms and less attention on high-order terms. The resulting lattice rules are guaranteed to have good low-dimensional projections, especially two-dimensional projections. Therefore, the lattice rules are robust in some sense. This makes it sensible to use the weights and the lattice rules found for one set of model parameters for other sets of model parameters without significant changes. In our experience, small changes of weights have no significant influence on the quality of the lattice rules. We omit the computational results relating to these aspects.

In general, lattice rules constructed with small a and small τ are well suited to functions with small superposition dimension (d_{su}) and small truncation dimension (d_{tr}), while lattice rules constructed with small a but with $\tau \approx 1$ are well suited to functions with small d_{su} but not necessarily small d_{tr}. Since finance problems often have small d_{su} (or even small d_{tr}), any constructions (based on any criterion, not just the one we used in this paper), which generate lattice rules with good low-dimensional projections (especially two-dimensional projections), may work well for such problems; see [16, 31].

6. Concluding remarks. This paper investigated lattice rules for certain high-dimensional problems in finance, concentrating on the problem of what weights should be used in practice for constructing lattice rules. We explained why the classical lattice rules may be inefficient for high-dimensional finance problems. Consistently with this, the computational results show that blind use of lattice rules may lead to estimates that are worse than the MC estimate. Exploiting information about the problem, we choose suitable weights by a matching strategy, which relates the weights to the sensitivity indices. The lattice rules constructed with the suitably chosen weights improve the performance significantly over the usual unweighted lattice rules. The computational experiments are quite encouraging. More complicated finance problems need to be investigated empirically, and more research is needed into the construction of robust efficient lattice rules.

COMPUTATIONAL MODELING OF UNCERTAINTY IN TIME-DOMAIN ELECTROMAGNETICS*

C. CHAUVIÈRE†, J. S. HESTHAVEN‡, AND L. LURATI‡

Abstract. We discuss computationally efficient ways of accounting for the impact of uncertainty, e.g., lack of detailed knowledge about sources, materials, shapes, etc., in computational time-domain electromagnetics. In contrast to classic statistical Monte Carlo–based methods, we explore a probabilistic approach based on high-order accurate expansions of general stochastic processes. We show this to be highly efficient and accurate on both one- and two-dimensional examples, enabling the computation of global sensitivities of measures of interest, e.g., radar-cross-sections (RCS) in scattering applications, for a variety of types of uncertainties.

Key words. Maxwell's equations, discontinuous Galerkin methods, uncertainty quantification, chaos expansion

1. Introduction.

While computational methods have become increasingly refined and accurate, their reliance on exact data, e.g., complete descriptions of geometries, materials, sources, etc., is emerging as a bottleneck in the modeling of problems of realistic complexity. For instance, if one attempts to model an experiment, a classic computational approach would require knowledge of a degree of detail which is unrealistic and often impossible to obtain, e.g., one cannot hope to control all elements of an experiment, measure all details of an initial condition or geometry, know the microstructure of all materials, etc.

The usual approach to dealing with this lack of knowledge or uncertainty is to simply assume some mean parameters and compute the corresponding solution. If the solution is robust to parameter variation, this is indeed a reasonable approach. However, for general problems, where the sensitivity of parts of the solution can be significant, a solution based on mean parameters is not likely to match very well with experiments and, thus, is not a good predictive tool. An experimentalist would naturally deal with this exact problem by repeating the experiments and, subsequently, compute not only mean results but also error bars—reflecting, at least partly, the sensitivity of the solution.

It is natural to strive to achieve similar abilities in computational modeling effort, e.g., compute solutions or measures of interest and their associated sensitivities. Clearly, if a particular measured entity is highly sensitive there is no reason to expect that this matches experiments exactly. Thus, we would like to be able to model the impact of the uncertainty, assumed to have certain properties derived from experiments or otherwise, on the computed results, essentially resulting in an ensample of

possible solution values with an associated probability. This would immediately enable the computation of statistical moments, e.g., means and variances, and of other valuable information about the sensitivity of solutions and derived quantities.

In this paper we pursue this goal and present a systematic, accurate, and efficient way of addressing this type of problem, essentially enabling one to compute with an ensample of data and, subsequently, obtain a full space-time ensample of solutions with an associated probability density. It is important to realize that is this not a simple situation, since solutions may vary nonlinearly in the uncertainty due to stochastic correlations even if the deterministic problem is linear, e.g., Maxwell's equations.

A standard way of addressing problems of the type mentioned in the above is through Monte Carlo sampling [13], e.g., run a deterministic code a large number of times and, subsequently, extract the statistics of interest. The main problem with this approach is the very slow convergence rate, $\mathcal{O}(N^{-1/2})$, with N being the number of samples, which makes even the computation of mean solutions expensive and accurate recovery of higher moments, e.g., variances, prohibitive. As we shall see through examples, the techniques proposed here suggests that a very considerable reduction is possible without impacting the accuracy.

Our platform on which to demonstrate this approach is the time-domain Maxwell's equations, solved using a high-order accurate discontinuous Galerkin method [9]. However, the basic elements of the formulation are general and can be used with any computational kernel.

What remains of the paper is organized as follows. In the next two sections, we recall the deterministic Maxwell's equations in the time domain and we give some details of its space discretization using a high-order discontinuous Galerkin method. In section 4 we continue with an introduction to homogeneous chaos and stochastic collocation methods, enabling the transition from deterministic to stochastic modeling. In the same section, we explain how to model uncertainties and how to extract statistics of interest (i.e., mean and variance) from the computed stochastic solution. This sets the stage for numerous examples presented in section 5, comparing the two approaches and validating the general approach. In section 6 we conclude and offer some suggestions for continued research in this direction.

2. Maxwell's equations. Let us consider a general domain Ω and let $\mathbf{E}^s$ and $\mathbf{H}^s$ denote the scattered electric and magnetic fields, respectively. With $\varepsilon(\mathbf{x})$ and $\mu(\mathbf{x})$ being the local permittivity and permeability, and $\sigma(\mathbf{x})$ the conductivity of the media, the time-dependent Maxwell's equations in the scattered field formulation are given as

$$\epsilon \frac{\partial \mathbf{E}^s}{\partial t} = \nabla \times \mathbf{H}^s + \sigma \mathbf{E}^s + \mathbf{S}^E, \tag{2.1}$$

$$\mu \frac{\partial \mathbf{H}^s}{\partial t} = -\nabla \times \mathbf{E}^s + \mathbf{S}^H, \tag{2.2}$$

where, as is common in time-domain schemes, we have neglected divergence constraints, assuming that these amount to constraints on the initial conditions.

The source terms, $\mathbf{S}^E$ and $\mathbf{S}^H$, appearing on the right-hand side of (2.1)–(2.2), take the form

$$\mathbf{S}^E = -(\epsilon - \epsilon^i)\frac{\partial \mathbf{E}^i}{\partial t} + (\sigma - \sigma^i)\mathbf{E}^i, \tag{2.3}$$

$$\mathbf{S}^H = -(\mu - \mu^i)\frac{\partial \mathbf{H}^i}{\partial t}, \tag{2.4}$$

where the incident field $(\mathbf{E}^i, \mathbf{H}^i)$ is a solution to Maxwell's equations in a media of permittivity, permeability, and conductivity—$\varepsilon^i(\mathbf{x})$, $\mu^i(\mathbf{x})$, $\sigma^i(\mathbf{x})$, respectively.

We now turn our attention to boundary conditions. Along a perfect electric conductor (PEC), the boundary conditions on the electric field are

$$\hat{\mathbf{n}} \times \mathbf{E}^t = \mathbf{0}, \tag{2.5}$$

where $\hat{\mathbf{n}}$ is the outward pointing normal vector at the surface and $\mathbf{E}^t = \mathbf{E}^i + \mathbf{E}^s$ is the total field. For the total magnetic field $\mathbf{H}^t$, the condition is

$$\mathbf{H}^t \cdot \hat{\mathbf{n}} = 0. \tag{2.6}$$

Along the interface of two dielectric bodies, denoted by the subscripts 1 and 2, we have

$$\hat{\mathbf{n}} \times (\mathbf{E}_1^s - \mathbf{E}_2^s) = \mathbf{0} \text{ and } \hat{\mathbf{n}} \times (\mathbf{H}_1^s - \mathbf{H}_2^s) = \mathbf{0}; \tag{2.7}$$

i.e., all tangential components are continuous.

3. Numerical scheme for the deterministic case. Before turning our attention to the case including uncertainties, let us briefly describe the computational methods used for solving Maxwell's equations in the physical space. We use a discontinuous Galerkin formulation; the solution will be discontinuous between elements. This offers a number of advantages over widely used alternative techniques, e.g., geometric flexibility through fully unstructured grids, high-order accuracy to enable accurate wave propagation over long distance with a coarse resolution, and very high computational efficiency through explicit time stepping and high parallel performance. The method has been discussed, analyzed, and validated extensively [9, 10, 11, 12], and we shall simply sketch its main components.

We rewrite Maxwell's equations (2.1)–(2.2) in conservation form

$$Q\frac{\partial \mathbf{q}}{\partial t} + \nabla \cdot \mathbf{F}(\mathbf{q}) = \mathbf{S}, \tag{3.1}$$

where $\mathbf{q}$ is the state vector formed by the scattered electric field and the magnetic field

$$\mathbf{q} = \begin{pmatrix} \mathbf{E} \\ \mathbf{H} \end{pmatrix}, \tag{3.2}$$

and the components of the tensor $\mathbf{F}$ are defined by

$$\mathbf{F}_i(\mathbf{q}) = \begin{pmatrix} -\mathbf{e}_i \times \mathbf{H} \\ \mathbf{e}_i \times \mathbf{E} \end{pmatrix}, \tag{3.3}$$

where $\mathbf{e}_i$ denotes the Cartesian unit vectors. On the right-hand side of (3.1), $\mathbf{S} = [\mathbf{S}^E, \mathbf{S}^H]$ is the source term, which depends on the incident field, and the material matrix Q is a diagonal matrix with values $(\epsilon, \epsilon, \epsilon, \mu, \mu, \mu)$ on its diagonal.

We assume that the computational domain, Ω, is tessellated by triangles or tetrahedrons, D, and we represent the local solution $\mathbf{q}_N$ as

$$\mathbf{q}_N(\mathbf{x}, t) = \sum_{i=1}^{N} \widetilde{\mathbf{q}}_i(t) L_i(\mathbf{x}), \tag{3.4}$$

where $\widetilde{\mathbf{q}}_i$ reflects nodal values, defined on the element, and $L_i(\mathbf{x})$ signifies an nth order Lagrange polynomial, associated with grid points; see [9, 10, 11, 12] for details.

The discrete solution, $\mathbf{q}_N$, of Maxwell's equations is required to satisfy

$$\int_D \left(Q\frac{\partial \mathbf{q}_N}{\partial t} + \nabla \cdot \mathbf{F}(\mathbf{q}_N) - \mathbf{S}_N \right) L_i(\mathbf{x}) d\mathbf{x} = \oint_{\partial D} \hat{\mathbf{n}} \cdot [\mathbf{F}(\mathbf{q}_N) - \mathbf{F}^*] L_i(\mathbf{x}) d\mathbf{x}. \tag{3.5}$$

In (3.5), $\mathbf{F}^*$ denotes a numerical flux and $\hat{\mathbf{n}}$ is an outward pointing unit vector defined at the boundary ∂D of the element D. Note that this is an entirely local formulation, and relaxing the continuity of the elements decouples the elements, resulting in a block-diagonal global mass matrix which can be trivially inverted in preprocessing. The price to pay for this is the additional degrees of freedom needed to support the local basis functions. For high-order elements, this is, however, only a small fraction of the total number of degrees of freedom. Given the linearity of Maxwell's equations, and for stability reasons, it is natural to use an upwinding flux which takes the form [9]

$$\hat{\mathbf{n}} \cdot [\mathbf{F}(\mathbf{q}_N) - \mathbf{F}^*] = \begin{pmatrix} \overline{Z}^{-1} \hat{\mathbf{n}} \times (\hat{\mathbf{n}} \times [\mathbf{E}_N] - Z^+ [\mathbf{H}_N]) \\ \overline{Y}^{-1} \hat{\mathbf{n}} \times (\hat{\mathbf{n}} \times [\mathbf{E}_N] - Z^+ [\mathbf{H}_N]) \end{pmatrix}, \tag{3.6}$$

where the bracket $[\mathbf{q}] = \mathbf{q}^- - \mathbf{q}^+$ denotes the jump in the field values ($\mathbf{q}^-$ is the local value and $\mathbf{q}^+$ is the neighboring value) across an interface, $Z^\pm$ is the local impedance, and $Y^\pm$ is the local conductance,

$$Z^\pm = \frac{1}{Y^\pm} = \sqrt{\frac{\mu^\pm}{\epsilon^\pm}}. \tag{3.7}$$

$\overline{Z}$ and $\overline{Y}$ in (3.6) are the sums

$$\overline{Z} = Z^+ + Z^-, \quad \overline{Y} = Y^+ + Y^-. \tag{3.8}$$

After discretization of the operators and evaluation of the integrals appearing in (3.5), the problem can be rewritten in matrix-vector form (see [10] for details)

$$QM\frac{d\mathbf{q}_N}{dt} + S \cdot \mathbf{F}_N - M\mathbf{S}_N = F\hat{\mathbf{n}} \cdot [\mathbf{F}_N - \mathbf{F}^*]. \tag{3.9}$$

The matrices M, S, and F represent the local mass-, stiffness-, and face-integration matrices, respectively, the exact entries of which can be found in [9], where it is also discussed how to compute these local operators efficiently and accurately. Note that the local nature of the scheme allows for the use of an explicit solver for the time discretization of (3.9). This is traditionally done using an explicit Runge–Kutta method, although suitable alternatives are plentiful.

4. Accounting for the uncertainty. To deal with the actual lack of detailed knowledge leading to the uncertainty, we must make some educated guesses—a model—about the nature of the possible variations in the data. These models can be based on pure speculation, on measured data, or on other available information. Once this is done, however, we must introduce this into the computational approach in an efficient, accurate, and robust manner.

Consider, as a simple example, the wave equation

$$\frac{\partial u}{\partial t} + a(\theta)\frac{\partial u}{\partial x} = 0, \tag{4.1}$$

where θ is a random parameter with some associated probability density function (PDF). Thus, this represents an ensemble of wave problems, each with an individual phase speed occurring with a probability given by the PDF; i.e., the solution u is not only a function of (x,t) but also of θ, and the equation is a stochastic wave equation.

The actual form of $a(\theta)$ may not be known, causing the introduction of the uncertainty. However, it seems quite reasonable that in many situations one can measure or conjecture the average of a and perhaps its variation; i.e., one can reasonably assume that $a(\theta)$ varies in a certain way related to a normal distribution with a given mean and variance.

The question remains, however, how this uncertainty will affect the solution, $u(x,t,\theta)$, and, more often, its moments such as the mean and the variance. This is not a trivial question, as the uncertainty essentially renders the simple linear problem considerably more complex due to possible stochastic dependence between a and u.

One could naturally solve the above problem for a large number of values of θ, taken from a proper distribution, and, subsequently, compute the appropriate moments. This is the essence of a Monte Carlo method and suffers from a very slowly converging result as $1/\sqrt{N}$, with N being the number of samples. If higher-order moments, e.g., the variance or sensitivity of the result, are required, this is often prohibitive.

In the above example, the uncertainty enters through the phase speed. However, as we shall see shortly, dealing with uncertainty in initial conditions, boundary conditions, sources, or computational domain/geometries can be done in an entirely similar fashion.

In this section, we shall discuss two variations, referred to as stochastic Galerkin and collocation, respectively, of the same underlying result. This enables one to discretize stochastic partial differential equations (SPDEs) to recover systems of deterministic problems which we can subsequently solve with the methods discussed in section 3. As we shall experience through examples, both techniques offer excellent accuracy at a severely reduced computational cost as compared to straightforward Monte Carlo methods.

4.1. The homogeneous chaos expansion. The key result on which we shall rely is due to Wiener [16] (see also Cameron and Martin [3], Schoutens [14], and Ghanem and Spanos [7]) and shows that the chaos expansion can be used to approximate any functional in $L^2(\Omega,\mathcal{P})$, where $\mathcal{P}$ is a Gaussian measure on Ω. For such a random variable $X(\theta)$, the chaos expansion is written as

$$
\begin{aligned}
X(\theta) = a_0 H_0 &\\
&+ \sum_{i_1=1}^{d} a_{i_1} H_1(\xi_{i_1}(\theta)) \\
&+ \sum_{i_1=1}^{d} \sum_{i_2=1}^{i_1} a_{i_1 i_2} H_2(\xi_{i_1}(\theta), \xi_{i_2}(\theta)) \\
&+ \sum_{i_1=1}^{d} \sum_{i_2=1}^{i_1} \sum_{i_3=1}^{i_2} a_{i_1 i_2 i_3} H_3(\xi_{i_1}(\theta), \xi_{i_2}(\theta), \xi_{i_3}(\theta)) \\
&+ \cdots,
\end{aligned}
\tag{4.2}
$$

where $\xi = (\xi_1(\theta), \ldots, \xi_d(\theta))$ represents d independent Gaussian variables with zero mean and unit variance, each depending on the random event θ, and H_n are the

multivariate Hermite polynomials defined as

$$H_n(\xi_{i_1}(\theta),\dots,\xi_{i_n}(\theta)) = e^{\frac{1}{2}\xi^T\xi}(-1)^n \frac{\partial^n}{\partial\xi_{i_1},\dots,\partial\xi_{i_n}} e^{-\frac{1}{2}\xi^T\xi}. \tag{4.3}$$

The number of terms in the expansion (4.2) grows as

$$P = \frac{(n+d)!}{n!d!}, \tag{4.4}$$

where n is the length of the Hermite expansion and d is the dimension of the Gaussian random space. The polynomial homogeneous chaos expansion forms a complete orthogonal basis in the space of Gaussian variables, i.e.,

$$\begin{aligned}\langle H_i(\xi_{i_1}(\theta),\dots,\xi_{i_n}(\theta)), H_j(\xi_{j_1}(\theta),\dots,\xi_{j_n}(\theta))\rangle \\ = \int_{R^d} \frac{H_i(\xi_{i_1}(\theta),\dots,\xi_{i_n}(\theta))H_j(\xi_{j_1}(\theta),\dots,\xi_{j_n}(\theta))}{\sqrt{(2\pi)^d}} e^{-\frac{1}{2}\xi^T\xi} d\xi = i!\delta_{ij},\end{aligned} \tag{4.5}$$

where i denotes the multi-index $(i_1,\dots,i_n)$ and $i! = i_1!,\dots,i_n!$. Thus there is an intimate relation between the Hermite polynomials, orthogonal under the Gaussian weight, and the representation of random variables taken from a Gaussian distribution. One way of interpreting the homogeneous chaos expansion is that a general random variable can be expressed in terms of simpler Gaussian variables for which we can construct an efficient computational approach. Clearly, if the random variable is far from Gaussian, many terms in the expansion will be needed; i.e., n must be large. An alternative is to use an expansion in terms of other random variables with an associated distribution closer to what is expected at input or output (see [14] for generalizations). For notational convenience, we can rewrite (4.2) in the form

$$X(\theta) = \sum_{j=1}^{P} b_j \Psi_j(\xi), \tag{4.6}$$

where there is a one-to-one correspondence between the functions H_i and Ψ_j and also between the coefficients $a_{i_1,\dots,i_p}$ and b_j. In the case of a general stochastic process, these coefficients will be time dependent.

To model the impact of uncertainty on the propagation of electromagnetic waves, we include the randomness in the usual spatial-temporal dimensions; i.e., the electric field and the magnetic field become $\mathbf{E}(\mathbf{x},t,\theta)$ and $\mathbf{H}(\mathbf{x},t,\theta)$, reflecting that the fields are functions of d independent random variables, $(\xi_{i_1}(\theta),\dots,\xi_{i_d}(\theta))$.

In the following we shall discuss in some detail how this can be utilized to construct an efficient computational method. For simplicity of the discussion, we assume in what follows that one Gaussian variable suffices to represent the process (i.e., $d = 1$). However, the formulation is general and applies to problems requiring many random variables to describe the stochastic processes.

4.2. Stochastic Galerkin formulation. Using the chaos expansion, we can express $\mathbf{q}(\mathbf{x},t,\theta) = (\mathbf{E}(\mathbf{x},t,\theta),\mathbf{H}(\mathbf{x},t,\theta))^T$ as

$$\mathbf{q}(\mathbf{x},t,\theta) = \sum_{i=1}^{P} \mathbf{q}^i(\mathbf{x},t)\Psi_i(\theta). \tag{4.7}$$

We can write the computational scheme, which takes into account randomness in a general setting, as

$$\left\{ \begin{array}{l} Q(\theta) M \dfrac{d\mathbf{q}_N}{dt} + S \cdot \mathbf{F}_N - M\mathbf{S}(\theta)_N = F\hat{\mathbf{n}} \cdot [\mathbf{F}_N - \mathbf{F}^*], \\ \mathbf{q}_N(\mathbf{x}, t = 0, \theta) = \mathbf{f}(\mathbf{x}, \theta), \end{array} \right. \tag{4.8}$$

where the initial conditions are given by the function $\mathbf{f} = \mathbf{f}(\mathbf{x}, \theta)$ and the unknown vector $\mathbf{q}_N$ is given by (4.7). As a first step, we discretize (4.8) in the random space using a Galerkin approach. Multiplying (4.8) by a test function $\Psi_k(\theta)$, replacing $\mathbf{q}_N$ by its chaos expansion, and using the scalar product defined by (4.5), we obtain

$$\forall k \in [1, P] \, : \, \sum_{i=1}^{P} \langle Q\Psi_i, \Psi_k \rangle \, M \frac{d\mathbf{q}_N^i}{dt} + k! S \cdot \mathbf{F}_N^k - M\mathbf{S}_N^k = F \sum_{i=1}^{P} \hat{\mathbf{n}} \cdot [\mathbf{F}_N^i - \mathbf{F}^{i*}], \tag{4.9}$$

where we have used property (4.5). The detailed expression of the terms on the right-hand side is

$$\hat{\mathbf{n}} \cdot [\mathbf{F}_N^i - \mathbf{F}^{i*}] = \left(\begin{array}{l} \left\langle \overline{Z}^{-1} \Psi_i, \Psi_k \right\rangle \hat{\mathbf{n}} \times \hat{\mathbf{n}} \times [\mathbf{E}^i] - \left\langle Z^+ \overline{Z}^{-1} \Psi_i, \Psi_k \right\rangle \hat{\mathbf{n}} \times [\mathbf{H}^i] \\ \left\langle \overline{Y}^{-1} \Psi_i, \Psi_k \right\rangle \hat{\mathbf{n}} \times \hat{\mathbf{n}} \times [\mathbf{H}^i] + \left\langle Y^+ \overline{Y}^{-1} \Psi_i, \Psi_k \right\rangle \hat{\mathbf{n}} \times [\mathbf{E}^i] \end{array} \right). \tag{4.10}$$

Recall that Z and Y may depend on the material properties and, thus, may include uncertainty/randomness.

The initial conditions in (4.8) also need to be projected onto the chaos basis to give an initial condition for each mode of $\mathbf{q}_N^i$ in the chaos expansion, i.e.,

$$\forall i \in [1, P] \, : \, \mathbf{q}_N^i(\mathbf{x}, t = 0) = \frac{1}{i!} \langle \mathbf{f}(\mathbf{x}, \theta), \Psi_i \rangle. \tag{4.11}$$

Once the vectors $\{\mathbf{q}_N^i\}_{1 \le i \le P}$ of the system (4.9) have been computed, we have available at every point in space an approximation to the probability density of the solution to the system.

Considering (4.9), we observe that we have managed to recast the general stochastic problem into a system of P coupled deterministic problems which we can now discretize in space/time exactly as discussed in section 3—or in any other preferred way.

4.3. Stochastic collocation formulation. The idea of the stochastic collocation formulation is to replace the expression of the electric and magnetic fields (4.7) in the polynomial chaos expansion with a Lagrangian polynomial basis; i.e., we would have

$$\mathbf{q}(\mathbf{x}, t, \theta) = \sum_{i=1}^{P} \mathbf{q}^i(\mathbf{x}, t) L_i(\theta), \tag{4.12}$$

where $\{L_i(\theta)\}_{1 \le i \le P}$ forms a Lagrangian polynomial basis of degree $(P - 1)$. In the deterministic community, (4.7) would be referred to as a modal expansion and (4.12) as a nodal expansion. Since θ in (4.12) is a Gaussian variable with zero mean and

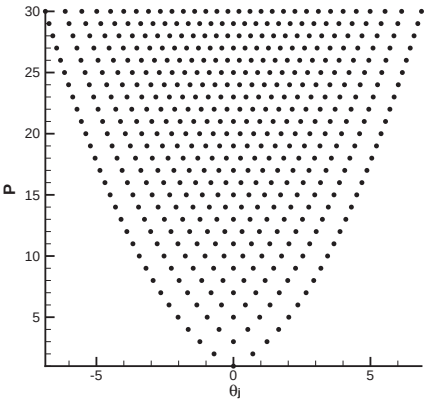

FIG. 4.1. *Distribution of Gauss–Hermite collocation points for* $P = 1, \ldots, 30$.

unit variance, it seems natural to use Gauss–Hermite collocation points as the basis for the Lagrange polynomials, as that also enables accurate evaluation of integrals. Figure 4.1 shows the collocation $\{\theta_j\}_{1\le j\le P}$ points for $P = 1, \ldots, 30$. It should be noted that those points are more concentrated near zero, where the probability of the normal law is highest.

For reasons to be explained shortly, the Lagrange polynomials of (4.12) will not be based on θ_j but on $\sqrt{2}\theta_j$. Therefore, by the property of Lagrange polynomials $L_i(\sqrt{2}\theta_j) = \delta_{ij}$, (4.12) gives

$$\mathbf{q}(\mathbf{x}, t, \sqrt{2}\theta_j) = \mathbf{q}^j(\mathbf{x}, t). \tag{4.13}$$

In the collocation formulation, we require that the residual of (4.8) be zero at collocation points $\{\sqrt{2}\theta_j\}_{1\le j\le P}$, i.e.,

$$\forall j \in [1, P] : \begin{cases} Q^j M \dfrac{d\mathbf{q}_N^j}{dt} + S \cdot \mathbf{F}_N^j - M\mathbf{S}_N^j = F\hat{\mathbf{n}} \cdot [\mathbf{F}_N^j - \mathbf{F}^{j*}], \\ \mathbf{q}_N^j(\mathbf{x}, t = 0) = \mathbf{f}(\mathbf{x}, \sqrt{2}\theta_j). \end{cases} \tag{4.14}$$

The stochastic collocation method is essentially a deterministic or lattice Monte Carlo method with samples $\{\sqrt{2}\theta_j\}_{1\le j\le P}$. The crucial difference is that a typical Monte Carlo simulation consisting of P realizations will converge at the slow rate $1/\sqrt{P}$, whereas the convergence of the stochastic collocation method is much faster, as will be shown by numerical examples (the interested reader can also refer to [17] for classical results in approximation theory). A simple analogy is that the approximation of a smooth function, the PDF, is done most efficiently by representing it by smooth polynomials based on points well suited for interpolation. In a simple Monte Carlo approach, the interpolation points are random, leading to a poor convergence rate.

We presented the stochastic collocation method for a random space of size $d = 1$. The generalization to higher random spaces is straightforward, using tensor products of quadrature points. Note that for higher random spaces and for purposes of efficiency, it might be necessary to use sparse grid methods (see [17] for details).

4.4. A brief comparison and discussion of the two techniques. It is worth highlighting a few essential differences between the two ways of introducing the uncertainty into the model. Although both rely on the use of the chaos expansion, the

two formulations lead to computationally different methods. In the Galerkin method, one recovers a system of P coupled equations, even if a scalar equation is considered initially. While the coupling coefficients can be precomputed, thus reducing the cost, essential questions, such as well-posedness of the system, do not follow trivially from the well-posedness of the scalar equation. However, analysis confirming the well-posedness of the system can be found in [5].

For the collocation approach, however, these problems never arise as one solves P decoupled problems, all of a type similar to that of the original problem. Thus, in terms of computational efficiency, the stochastic collocation method compares favorably to the stochastic Galerkin formulation.

On the other hand, there are situations in which the Galerkin formulation is superior to the collocation approach in terms of accuracy. To appreciate this, consider again (4.1) and assume, for simplicity, that the spatial direction is periodic. We use a Fourier spectral method in this direction; i.e., we assume

$$u(x,t,\theta) = \sum_{|n|\le N} \hat{u}_n(\theta,t)\exp(inx).$$

This yields the semidiscrete scheme

$$\forall |n| \le N \,:\, \frac{d\hat{u}_n(\theta,t)}{dt} + \tilde{a}(\theta)\hat{u}_n = 0,$$

with $\tilde{a}(\theta) = ina(\theta)$.

If we now represent the orthogonal projection of u onto the space spanned by the Hermite polynomial by $\mathcal{P}_P u$, we recover the error equation

$$\frac{d}{dt}\varepsilon + \tilde{a}(\theta)\hat{u}_n - \mathcal{P}_P(\tilde{a}(\theta)\hat{u}_n) = 0,$$

where $\varepsilon(t) = \hat{u}_n - \mathcal{P}_P\hat{u}_n$ with

$$\mathcal{P}_P\hat{u}_n = \sum_{i=1}^{P} \hat{u}_{ni}(t)H_i(\theta).$$

From classic approximation results for orthogonal polynomials [6], we recall

$$\|u - \mathcal{P}_P u\|_w \le P^{-k}\|u^{(k)}\|_w, \quad P > k \ge 0.$$

Here $\|\cdot\|_w$ is the Gaussian weighted inner product and $u^{(k)}$ reflects the kth derivative of u, i.e., it is a simple measure of the smoothness of the probability density associated with u.

Integration in θ and in time immediately yields the error bound

$$\|\varepsilon(t)\|_w \le \|\varepsilon(0)\|_w + tP^{-k}\max_{s\in[0,t]}\|(\tilde{a}\hat{u}_n)^{(k)}(s)\|_w$$

or

$$\|\varepsilon(t)\|_w \le P^{-k}\left(\|\hat{u}_n^{(k)}(0)\|_w + t\max_{s\in[0,t]}\|(\tilde{a}\hat{u}_n)^{(k)}(s)\|_w\right). \tag{4.15}$$

Thus, if $\hat{u}_n^{(k)}(0)$ and $(a\hat{u}_n)^{(k)}$ are well behaved, i.e., reasonably smooth, the scheme converges, although the details naturally depend on $\tilde{a}$ and the initial conditions.

If we now consider the collocation formulation in exactly the same way, we shall need the interpolation estimate [6]

$$\|u - \mathcal{I}_P u\|_w \leq P^{-k+1} \|u^{(k)}\|_w, \quad P > k \geq 1,$$

where

$$\mathcal{I}_P \hat{u}_n = \sum_{i=1}^{P} \hat{u}_n(\theta_i, t) L_i(\theta)$$

is the Lagrange form of the chaos expansion as discussed above. This immediately yields the estimate

$$\|\varepsilon(t)\|_w \leq P^{-k+1} \left(\|\hat{u}_n^{(k)}(0)\|_w + t \max_{s\in[0,t]} \|(\tilde{a}\hat{u}_n)^{(k)}(s)\|_w \right), \tag{4.16}$$

provided $k \geq 1$.

Comparing the bounds in (4.15) and (4.16) highlights several properties of the two different formulations. We notice, as mentioned above, that the Galerkin formulation in general is more accurate than the collocation approach, in particular for problems of low regularity (small k); i.e., for problems with very low regularity ($k \leq 1$) the collocation approach may well fail. Thus, for problems in which the probability density of $\hat{u}_n$ develops kinks or cusps, a Galerkin approach is likely to be advantageous. However, for problems in which both $a(\theta)$ and the probability density of the solution, u, are smooth in θ, the two methods are essentially equivalent in terms of accuracy. As we shall see shortly, for the different types of applications considered here, the two methods behave in very similar ways in terms of accuracy.

The analysis also shows that the error grows linearly in time—at least for problems of simple wave type (4.1). We can obtain a further appreciation of the impact of this by considering the exact solution

$$\hat{u}_n(\theta, t) = \hat{u}_n(\theta, 0) \exp(ina(\theta)t).$$

The length, P, of the chaos expansion must naturally be chosen to represent this solution adequately at all times. While this is easily accomplished for the initial conditions, $\hat{u}_n(\theta, 0)$, the other term reflects a wave, where the wavenumber, $a(\theta)nt$, grows with time. Again borrowing from classic results in approximation theory [8], we know that if we consider

$$\exp(ikx) = \sum_{l=0}^{L} \hat{u}_l H_l(x),$$

then exponential accuracy requires that

$$\frac{2^l (l/2)!}{k^l} \exp\left(\frac{l^2}{4}\right) > \exp\left(\frac{1}{2}\left(\frac{l\pi}{kp}\right)^2\right)$$

at a fixed value of x. Here

$$p = \frac{\lambda}{2x/l}$$

reflects the number of degrees of freedom used to represent the wave of wavelength λ.

Thus, if we want to accurately resolve waves within $x \in [-\pi, \pi]$, we find that $lp^{-1} = 1$, and the requirement above is fulfilled for $l = p > 6$. However, if we are interested in resolving the problem in $x \in [-2\pi, 2\pi]$, then $lp^{-1} = 2$, and we obtain $l = 2p > 15$, while $x \in [-4\pi, 4\pi]$ implies $lp^{-1} = 4$ and the bound $l = 4p > 44$.

These simple estimates have a few consequences for the methods discussed here. In particular, we find in the above that the effective wavenumber will grow linearly with time. This means that if we want to ensure an accurate representation of the local (in space) probability density, we shall generally expect that P, the number of terms in the chaos expansion, must grow linearly.

This requires, however, that the local PDF does not change too much over time; i.e., if it expands significantly in θ space beyond the initial range, we must ensure that it is well represented within a larger range of θ values, which requires, as seen above, a faster than linear growth. These arguments are independent of whether we consider the Galerkin or the collocation approach.

4.5. Computation of statistics. In practice, an expression of the stochastic fields in the form (4.7) or (4.12), containing a full space-time approximation to the local PDF, is of little use and often contains too much information. Quantities of interest—observables—are often macroscopic quantities, i.e., averages or variances of the fields. The way to extract those quantities depends on whether we have used a collocation formulation or a Galerkin formulation, and the procedure will also be different depending on whether we are interested in the statistics of linear or nonlinear functions of the electric or magnetic field. We shall sketch the different procedures in the next subsections, as this is an important component of the complete algorithm.

4.5.1. Statistics of linear quantities. As the treatment of the two methods is slightly different, we shall discuss each separately.

[illegible]. We assume that the solution $\mathbf{q}(\mathbf{x}, t, \theta)$ is available in the form (4.7), and we wish to extract some statistical information such as the average solution or its variance.

Let us first assume that we seek the moments of the solutions or a linear combination of them. Taking the average of (4.7), we get

$$\begin{aligned}\langle \mathbf{q}(\mathbf{x}, t, \theta), 1\rangle &= \sum_{i=1}^{P} \mathbf{q}^i(\mathbf{x}, t)\, \langle 1, \Psi_i(\theta)\rangle = \sum_{i=1}^{P} \mathbf{q}^i(\mathbf{x}, t)\, \langle \Psi_1(\theta), \Psi_i(\theta)\rangle \\ &= \sum_{i=1}^{P} \mathbf{q}^i(\mathbf{x}, t)\delta_{1i} = \mathbf{q}^1(\mathbf{x}, t). \end{aligned} \tag{4.17}$$

Thus, the average is simply the first mode in the chaos expansion. In a similar way, we can obtain the variance by first computing

$$\begin{aligned}\langle \mathbf{q}(\mathbf{x}, t, \theta), \mathbf{q}(\mathbf{x}, t, \theta)\rangle &= \sum_{i=1}^{P}\sum_{j=1}^{P} \mathbf{q}^i(\mathbf{x}, t)\mathbf{q}^j(\mathbf{x}, t)\, \langle \Psi_i(\theta), \Psi_i(\theta)\rangle \\ &= \sum_{i=1}^{P}\sum_{j=1}^{P} \mathbf{q}^i(\mathbf{x}, t)\mathbf{q}^j(\mathbf{x}, t) i!\delta_{ij} = \sum_{i=1}^{P} i!\mathbf{q}^i(\mathbf{x}, t)^2. \end{aligned} \tag{4.18}$$

The variance of the solution is then

$$
\begin{aligned}
var &= \langle \mathbf{q}(\mathbf{x},t,\theta), \mathbf{q}(\mathbf{x},t,\theta)\rangle - \langle \mathbf{q}(\mathbf{x},t,\theta), 1\rangle^2 \\
&= \sum_{i=1}^{P} i!\mathbf{q}^i(\mathbf{x},t)^2 - \mathbf{q}^1(\mathbf{x},t)^2 = \sum_{i=2}^{P} i!\mathbf{q}^i(\mathbf{x},t)^2.
\end{aligned} \tag{4.19}
$$

. We now assume that the solution $\mathbf{q}(\mathbf{x},t,\theta)$ is available in the form (4.12). First, we start by recalling that we have chosen to use the Gauss–Hermite collocation points $\{\theta_j\}_{1\le j\le P}$; i.e., we have a quadrature formula that is exact for all polynomial $f(x)$ of degree at most $2P-1$,

$$
\int_{-\infty}^{+\infty} e^{-\theta^2} f(\theta) d\theta = \sum_{j=1}^{P} \omega_j f(\theta_j), \tag{4.20}
$$

where $\{\omega_j\}_{1\le j\le P}$ are the integration weight [4]. This formula can be used to compute the average of $\mathbf{q}(\mathbf{x},t,\theta)$ given by (4.12):

$$
\langle \mathbf{q}(\mathbf{x},t,\theta)\rangle = \sum_{i=1}^{P} \mathbf{q}^i(\mathbf{x},t) \int_{-\infty}^{+\infty} \frac{1}{\sqrt{2\pi}} e^{-\frac{\theta^2}{2}} L_i(\theta) d\theta. \tag{4.21}
$$

After a simple change of variable and using (4.20), we get

$$
\langle \mathbf{q}(\mathbf{x},t,\theta)\rangle = \sum_{i=1}^{P} \mathbf{q}^i(\mathbf{x},t) \sum_{j=1}^{P} \frac{1}{\sqrt{\pi}} \omega_j L_i\left(\sqrt{2}\theta_j\right). \tag{4.22}
$$

This equation shows why we have decided to define Lagrange polynomials based on the collocation points $\sqrt{2}\theta_j$ instead of θ_j. Indeed, using the fact that $L_i(\sqrt{2}\theta_j) = \delta_{ij}$, the above equation simplifies as

$$
\langle \mathbf{q}(\mathbf{x},t,\theta)\rangle = \sum_{j=1}^{P} \frac{1}{\sqrt{\pi}} \omega_j \mathbf{q}^j(\mathbf{x},t). \tag{4.23}
$$

The procedure to compute the variance is similar, leading to

$$
var = \sum_{j=1}^{P} \frac{1}{\sqrt{\pi}} \omega_j \left(\mathbf{q}^j(\mathbf{x},t)\right)^2 - \langle \mathbf{q}(\mathbf{x},t,\theta)\rangle^2. \tag{4.24}
$$

It is important to emphasize that the simple, and most expensive, approach of using a tensor product grid of Gauss quadratures is only one among many alternatives. This is discussed in detail in [17], where special attention is given to methods of relevance to problems discussed here.

4.5.2. Statistics of nonlinear quantities. Often, however, we are interested in the statistics of some derived, possibly nonlinear, functional, $F(\mathbf{q})$ of $\mathbf{q}(\mathbf{x},t,\theta)$, e.g., computation of the impact on the RCS of the uncertainty in the scattering problem.

Let us utilize the idea behind the collocation approach and write

$$
F(\mathbf{q}(\theta)) = \sum_{j=1}^{P} F(\mathbf{q}(\theta_j)) L_j(\theta).
$$

Thus, we simply need to evaluate the general functionals at the values of θ_j. However, since we have already obtained full probabilistic information in the expansions, (4.7) or (4.12), we can use these results directly to obtain the required information and, thus, the probabilistic information on $F(\mathbf{q})$. All informations of interest, e.g., moments, can now be extracted from this in the same way as for the simple variables. Naturally, one can evaluate the integrals using a classic Monte Carlo approach. This can be done at little cost since it requires only evaluation of the expansions and not solution of Maxwell's equations.

For the Galerkin method, one just needs an extra step to express the fields from a modal polynomial basis (4.7) to a nodal polynomial basis (4.12), where the coefficients $\mathbf{q}^j(\mathbf{x},t)$ are computed by simple evaluation of $\mathbf{q}^j(\mathbf{x},t) = \sum_{i=1}^{P} \mathbf{q}^i(\mathbf{x},t)\Psi_i(\sqrt{2}\theta_j)$. Then, the procedure is the same as that for the collocation method.

5. Numerical examples. In the following we shall discuss a few examples used to validate the approach discussed above. These results are chosen largely to be simple enough to enable rigorous testing as well as to expose the generality and strength of the proposed technique.

5.1. One-dimensional material loaded cavity. As a first simple test case, we consider a one-dimensional PEC cavity loaded with two media, with a material interface at $x^{mat} = 0$ and perfectly conducting walls at $x_1^{pec} = -L$ and $x_2^{pec} = L$, as shown in Figure 5.1. The aim of the test is to compute the first few resonance frequencies of the cavity. For the simple case considered here, these frequencies are given as

$$\sqrt{\epsilon_1}\tan(\omega\sqrt{\epsilon_2}(L - x^{mat})) = -\sqrt{\epsilon_2}\tan(\omega\sqrt{\epsilon_1}(L + x^{mat})), \tag{5.1}$$

where ϵ_k reflects the two different permittivities. We assume for simplicity that the materials are nonmagnetic, i.e., $\mu_k = 1$, and solve on each domain D_k the equations

$$Q\frac{\partial \mathbf{q}}{\partial t} + \frac{\partial}{\partial x}\mathbf{F}(\mathbf{q}) = 0, \tag{5.2}$$

where

$$\mathbf{q} = \begin{pmatrix} \mathbf{E}_k^y \\ \mathbf{H}_k^z \end{pmatrix}, \quad \mathbf{F}(\mathbf{q}) = \begin{pmatrix} \mathbf{H}_k^z \\ \mathbf{E}_k^y \end{pmatrix}, \quad Q = \begin{pmatrix} \epsilon_k & 0 \\ 0 & \mu_k \end{pmatrix}. \tag{5.3}$$

To compute the resonant frequencies, we solve the one-dimensional Maxwell's equations in the time-domain, subject to a broadband initial condition, and collect one or several time-traces at various points in the cavity. The spectrum of the time-series yields the resonant frequencies as strong peaks which are found automatically.

5.1.1. Uncertainty in material. In this first test we assume an uncertainty or randomness in the permittivity of the material in domain D_2 of the form

$$\varepsilon(\mathbf{x},\theta) = \begin{cases} 1 & \text{if } \mathbf{x} \notin D_2, \\ 2.25\left(1 + 0.1\dfrac{\theta^2}{1+\theta^2}\right) & \text{otherwise,} \end{cases} \tag{5.4}$$

where, as everywhere else, θ is a Gaussian variable with zero mean and unit variance. This model ensures that the permittivity will remain positive in the domain D_2. Other parameters were fixed as $L = 1$ and $\mu_1 = \mu_2 = 1$.

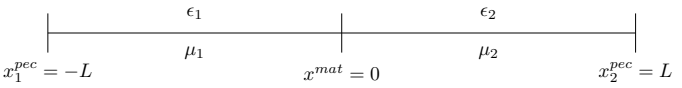

FIG. 5.1. *Illustration of one-dimensional loaded cavity.*

TABLE 5.1

Numerical mean and variance of resonance frequencies for cavity with random material. The discrepancy in the variance for ω_1 is caused by quantization errors in the frequency identification approach and is not related to the accuracy of the modeling of the uncertainty. This is confirmed by having an identical error in the Monte Carlo model.

For the stochastic Galerkin method with random permittivity, the terms Q, Z, $\overline{Z}$, Y, $\overline{Y}$ in the semidiscrete equation are all dependent on $\varepsilon(\mathbf{x}, \theta)$ so that the equations are given by (4.9). The case of random permittivity gives rise to a coupled system of P deterministic equations, where the coupling is through the many scalar products defined in (4.9). These scalar products are computed in the preprocessing stage and stored.

[illegible]. We evaluate the technique by computing the mean and variance of the resonance frequencies of the loaded cavity. In Table 5.1 we show values computed by three different methods. The results labeled "Exact Formula" are obtained by performing Monte Carlo sampling on the equation that describes the resonance frequencies (5.1). As a benchmark, we show results obtained using a standard Monte Carlo method on (5.2) with up to 1200 samples. The frequencies in the stochastic Galerkin method are computed using the method described in section 4.5.1. Results for two values of P, 40 and 100, are shown. The results show good agreement between the stochastic Galerkin approach and the statistics of the exact solution as well as the Monte Carlo method, although it is not clear that the latter results are

converged. The tables also show that while increasing P does increase the accuracy of the data, the gain in accuracy is not significant. Note that the iteration in the Monte Carlo solutions amounts to actually solving the Maxwell's equations, i.e., the computational time scales with the number of iterations. For the chaos expansion method, the computational work scales with P as the iterations simply amount to summing the final chaos expansions. Thus, the cost of the Monte Carlo approach is many times larger than the cost of using the techniques discussed here.

5.1.2. Uncertainty in boundary position. Let us now consider the case when the length of the cavity is unknown, i.e., when there is uncertainty associated with the position of the boundary. We choose to have uncertainty in the right boundary position so that the domain D_2 is of variable length. The position of the right boundary is assumed to be $x_2^{pec} = L + g(\theta)$, where

$$g(\theta) = 0.1\left(\frac{\theta}{1+\theta^2}\right). \tag{5.5}$$

All other parameters are fixed as $L = 1$, $\mu_1 = \mu_2 = 1$, $\epsilon_1 = 1$, and $\epsilon_2 = 2.25$.

For the stochastic Galerkin method with a random boundary position, we introduce a linear mapping from the variable x into the new variable $\xi \in [-1, 1]$, i.e., it is of fixed length. The mapping of the variable domain D_2 into a fixed domain of length L is

$$\xi = x^{mat} + (L - x^{mat})\frac{x - x^{mat}}{(L + g(\theta) - x^{mat})}. \tag{5.6}$$

We can then express (5.2) in the new variable ξ by

$$Q\frac{\partial \mathbf{q}}{\partial t} + \frac{\partial \xi}{\partial x}\frac{\partial \mathbf{F}(\mathbf{q})}{\partial \xi} = 0, \tag{5.7}$$

which is stated in a fixed computational domain. Note that this transformation should also be applied to the initial conditions. As the equations have changed only by the multiplication of the additional term $\frac{\partial \xi}{\partial x}$, and we now have a deterministic Q, the computational scheme is expressed as

$$\forall k \in [1, P] \,:\, QMk!\frac{d\mathbf{q}_N^k}{dt} + S\sum_{i=1}^{P}\left\langle \frac{\partial \xi}{\partial x}\Psi_i, \Psi_k \right\rangle \cdot \mathbf{F}_N^i = F\sum_{i=1}^{P}\hat{\mathbf{n}} \cdot [\mathbf{F}_N^i - \mathbf{F}^{i*}], \tag{5.8}$$

$$\hat{\mathbf{n}} \cdot [\mathbf{F}_N^i - \mathbf{F}^{i*}] = \left\langle \frac{\partial \xi}{\partial \mathbf{x}}\Psi_i, \Psi_k \right\rangle \begin{pmatrix} \overline{Z}^{-1}\hat{\mathbf{n}} \times \hat{\mathbf{n}} \times [\mathbf{E}^i] - Z^+\overline{Z}^{-1}\hat{\mathbf{n}} \times [\mathbf{H}^i] \\ \overline{Y}^{-1}\hat{\mathbf{n}} \times \hat{\mathbf{n}} \times [\mathbf{H}^i] + Y^+\overline{Y}^{-1}\hat{\mathbf{n}} \times [\mathbf{E}^i] \end{pmatrix}. \tag{5.9}$$

Thus, the random domain problem has been transformed into a random coefficient problem similar to the one discussed previously. Note that we apply this method in both domains, although in domain D_1, which is already of fixed length, the value of $\frac{\partial \xi}{\partial \mathbf{x}}$ is one.

. We compute again the mean and variance of the resonance frequencies of the loaded cavity. Since the boundary moves only in a small region of the domain $D_2 = [x^{mat}, x_2^{pec}]$, we split the domain D_2 into two artificial subdomains $D_{21} = [x^{mat}, x^{split}]$, $D_{22} = [x^{split}, x_2^{pec}]$ such that $D_2 = D_{21} \cup D_{22}$ and x^{split} is chosen depending on how far the boundary can move inward. Then we can apply the

transformation described in the previous section only to the subdomain D_{22}. This matches the physical properties of the case of an uncertain boundary more closely than mapping the entire domain D_2.

Table 5.2 shows statistics of the resonance frequencies computed by the stochastic Galerkin method and sampling of the exact solution. Since the Monte Carlo method is computationally far more expensive, we do not repeat the tests for all cases. The results again indicate that the stochastic Galerkin approach is in excellent agreement with the exact solution.

5.1.3. Uncertainty in the interface position. In this last example, we focus on the cavity where the position of an interface is uncertain, such that both domains are of variable length. We define the position of the material interface as $x^{mat} = 0 + g(\theta)$, where

$$g(\theta) = 0.1\left(\frac{\theta}{1+\theta^2}\right). \tag{5.10}$$

This allows the material interface to be positioned on both sides of the mean position. We fix other parameters as $L = 1$, $\mu_1 = \mu_2 = 1$, $\epsilon_1 = 1$, and $\epsilon_2 = 2.25$.

For the stochastic Galerkin method with random position of the interface, we proceed in a manner similar to that for the random boundary case and introduce a mapping of both domains from the variable x to the new variable ξ. The mapping of the variable domains D_1 and D_2 into domains of fixed length L is defined as

$$\xi = \begin{cases} -L + L\dfrac{(x+L)}{(g(\theta)+L)} & \text{if } x \in D_1, \\ L\dfrac{(x-g(\theta))}{(L-g(\theta))} & \text{if } x \in D_2. \end{cases} \tag{5.11}$$

The rest follows from (5.7)–(5.9).

. We split the domains into smaller regions, as described in the previous case, in order to match the physical properties of the cavity. In this case, the mapping is applied only to the two subdomains adjacent to the material interface. Table 5.3 shows statistics of the resonance frequencies computed by the stochastic Galerkin method and sampling of the exact solution. The quality of the results are similar to those of the previous test cases.

5.2. Two-dimensional circular cylinder. As a second and more advanced test, we consider plane wave scattering by a two-dimensional circular cylinder of radius unity. The measure of interest is the RCS, defined as

$$RCS_{db}(\phi) = 10 \log \left(2\pi \frac{|\mathbf{F}(\phi)|^2}{|\mathbf{E}_i|^2} \right), \tag{5.12}$$

where $\mathbf{E}_i$ is the incident field and $\mathbf{F}(\phi)$ is a nonlinear function of $\mathbf{E}(\mathbf{x}, t, \theta)$ and $\mathbf{H}(\mathbf{x}, t, \theta)$, computing the scattered far field as a function of the polar angle, ϕ. In this particular case, $\mathbf{F}(\phi)$ is the near-to-far-field transformation along some closed contour [15].

Typical meshes are represented in Figure 5.2, where the number of elements is 1141. The domain extends from -6 to $+6$, and a perfectly matched layer (PML) of width 1 is used to truncate the domain (see [1] for details). Degree five polynomials are enough to ensure that convergence is achieved in the physical space, and six modes in the chaos expansion (or six nodes for the collocation formulation, i.e., $P = 6$) are also enough for good convergence in probability space.

5.2.1. Uncertainty in the source term. Let us denote by Γ the boundary of a PEC two-dimensional circular cylinder contained in the domain Ω. In this first example, we consider the following model for the uncertainty in the source term appearing in (2.1):

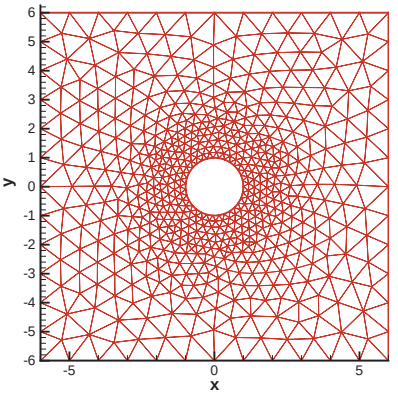

FIG. 5.2. *Typical mesh using* 1141 *spectral elements.*

$$\mathbf{S}^E = \begin{cases} \mathbf{E}_0 \sin(2\pi\omega(\mathbf{k}(\theta).\mathbf{x} - t) & \text{if } \mathbf{x} \in \Gamma, \\ \mathbf{0} & \text{otherwise,} \end{cases} \tag{5.13}$$

where $\mathbf{k}(\theta)$ is an uncertain wave vector. We assume that the value of the wave vector $\mathbf{k}(\theta)$ is subject to a small random perturbation from its deterministic value $\mathbf{k}_0 = (r_0\cos(\alpha_0), r_0\sin(\alpha_0))$. More precisely, we assume that this vector can vary in one of the following two ways:

1. Randomness in the direction of $\mathbf{k}$:

$$\mathbf{k}(\theta) = \begin{pmatrix} r_0\cos(\alpha_0 + 0.1\theta) \\ r_0\sin(\alpha_0 + 0.1\theta) \end{pmatrix}. \tag{5.14}$$

2. Randomness in the modulus of $\mathbf{k}$:

$$\mathbf{k}(\theta) = \begin{pmatrix} r_0(1 + 0.1\theta)\cos(\alpha_0) \\ r_0(1 + 0.1\theta)\sin(\alpha_0) \end{pmatrix}. \tag{5.15}$$

The latter case mimics a slight variation in the frequency of the source.

. For the stochastic Galerkin method, the source term in the semidiscrete equation (4.9) becomes

$$\mathbf{S}_N^k = \begin{cases} \mathbf{E}_0\langle \sin(2\pi\omega(\mathbf{k}(\theta)\cdot\mathbf{x} - t)), \Psi_k\rangle & \text{if } \mathbf{x} \in \Gamma, \\ \mathbf{0} & \text{otherwise,} \end{cases} \tag{5.16}$$

or, after a simple trigonometric manipulation,

$$\mathbf{S}_N^k = \begin{cases} \mathbf{E}_0\Big(\langle \sin(2\pi\omega\mathbf{k}(\theta)\cdot\mathbf{x}), \Psi_k\rangle \cos(2\pi\omega t) \\ \qquad\qquad - \langle \cos(2\pi\omega\mathbf{k}(\theta)\cdot\mathbf{x}), \Psi_k\rangle \sin(2\pi\omega t)\Big) & \text{if } \mathbf{x} \in \Gamma, \\ \mathbf{0} & \text{otherwise.} \end{cases} \tag{5.17}$$

The coefficients $\langle \sin(2\pi\omega\mathbf{k}(\theta)\cdot\mathbf{x}), \Psi_k\rangle$ and $\langle \cos(2\pi\omega\mathbf{k}(\theta)\cdot\mathbf{x}), \Psi_k\rangle$ in the above expression can be precomputed, stored, and then used to impose the boundary conditions at any subsequent time steps. Furthermore, by assuming that the permittivity ϵ and the permeability μ are deterministic, using the orthogonality of Hermite polynomials (4.5), equation (4.9) simplifies to

$$\forall k \in [1, P] \,:\, k!QM\frac{d\mathbf{q}_N^k}{dt} + k!S\cdot\mathbf{F}_N^k - M\mathbf{S}_N^k = F\hat{\mathbf{n}}\cdot[\mathbf{F}_N^k - \mathbf{F}^{k*}]. \tag{5.18}$$

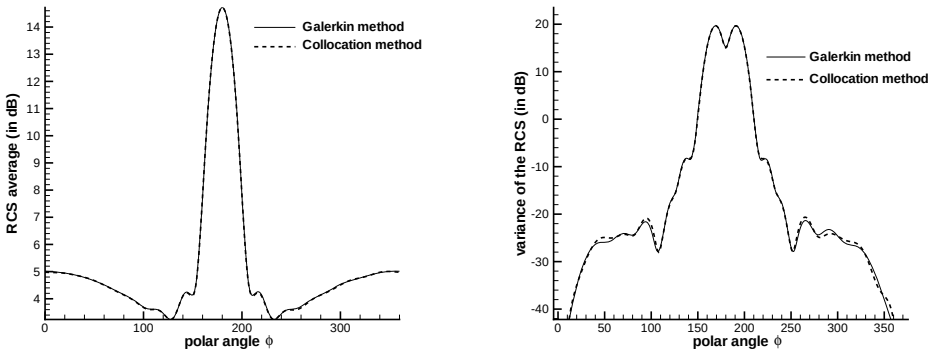

FIG. 5.3. *Comparison of the stochastic Galerkin method and the stochastic collocation method. Left: Average of the RCS for the randomness in the angle of the wave. Right: Variance of the RCS for the randomness in the angle of the wave vector.*

The above equation highlights that for this test case, all the modes are decoupled, and that the cost of solving it, compared to a deterministic simulation, is simply proportional to the number of modes in the chaos expansion. For this particular case, the costs of the Galerkin and collocation methods are the same.

. For the stochastic collocation method, the source term in the semidiscrete equation (4.14) becomes

$$\mathbf{S}_N^j = \begin{cases} \mathbf{E}_0 \sin(2\pi\omega(\mathbf{k}(\sqrt{2}\theta_j)\cdot\mathbf{x} - t)) & \text{if } \mathbf{x}\in\Gamma, \\ \mathbf{0} & \text{otherwise.} \end{cases} \tag{5.19}$$

As always for the stochastic collocation technique, the nodal solutions $\mathbf{q}_N^j$ are decoupled from each other and are obtained by solving P independent systems of the form

$$\forall j \in [1,P] \,:\, QM\frac{d\mathbf{q}_N^j}{dt} + S\cdot\mathbf{F}_N^j - M\mathbf{S}_N^j = F\hat{\mathbf{n}}\cdot[\mathbf{F}_N^j - \mathbf{F}^{j*}]. \tag{5.20}$$

. We conduct the first test to compare the results of the average and variance of the RCS computed by the stochastic collocation method and the stochastic Galerkin method. For the numerical experiments, we set $r_0 = 1$ and $\alpha_0 = \pi$ in (5.14)–(5.15). Figure 5.3 shows the average and the variance of the RCS, and it can be seen that for the same discretization, they give identical results in agreement with the discussion in section 4.4. This case corresponds to uncertainty in the angle of the wave vector, and similar results are obtained for uncertainty in the norm of the wave vector. Figure 5.4 shows the average of the RCS and its possible variations for the randomness in the angle of $\mathbf{k}$ and in the modulus of $\mathbf{k}$. It appears that the uncertainty in the angle of $\mathbf{k}$ primarily affects the RCS in the forward scatter, whereas the uncertainty in the norm of $\mathbf{k}$ mainly affects the RCS in the sidebands.

5.2.2. Uncertainty in materials. We now assume that the permittivity inside a cylindrical domain D is unknown, whereas the permittivity outside this domain is deterministic, e.g.,

$$\varepsilon(\mathbf{x},\theta) = \begin{cases} 1 & \text{if } \mathbf{x}\notin D, \\ 2.25e^{0.1\theta} & \text{otherwise.} \end{cases} \tag{5.21}$$

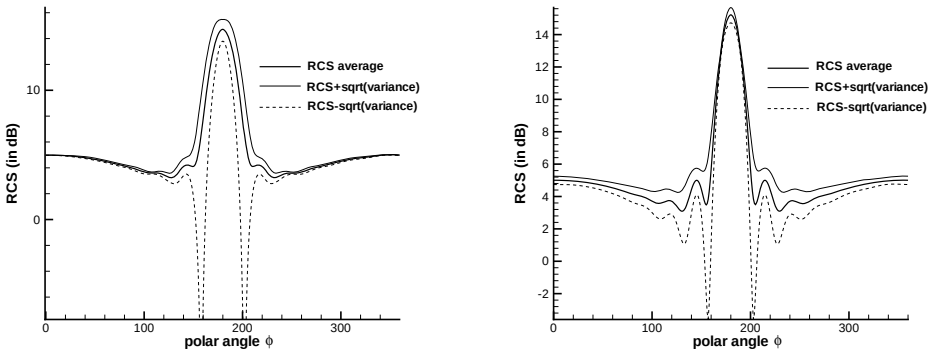

FIG. 5.4. *Left: RCS for the randomness in the angle of the wave vector. Right: RCS for the randomness in the norm of the wave vector. Results are shown with the mean RCS as well as* ± 1 *standard deviation.*

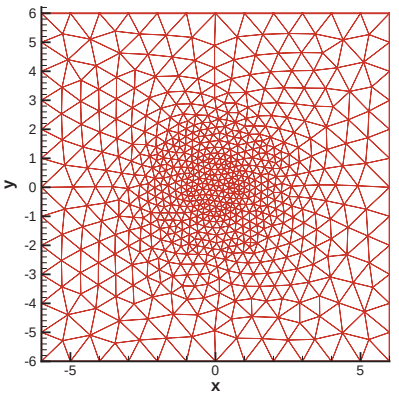

FIG. 5.5. *Typical mesh using* 1318 *spectral elements.*

Here again, our concern is not the correctness of the probabilistic law chosen in (5.21) for the uncertainty of the permittivity $\varepsilon(\mathbf{x}, \theta)$, since for any reasonable law, the techniques presented in this paper should work equally well. With an uncertainty of the form $e^{0.1\theta}$ (which is a log-normal law), the permittivity is guaranteed to remain positive. For uncertainty in the permittivity of the material, the source term of (2.1) takes the form

$$\mathbf{S}^E = -(\epsilon(\mathbf{x}, \theta) - \epsilon^i)\frac{\partial \mathbf{E}^i}{\partial t}, \tag{5.22}$$

where $(\mathbf{E}^i, \mathbf{H}^i)$ denotes the incident field which is a solution to Maxwell's equations. For that test case, it is necessary to mesh the entire domain, as shown in Figure 5.5 (here 1318 spectral elements are represented).

. Projecting the source term using the chaos basis, we obtain

$$\forall k \in [1, P] \ : \ \mathbf{S}_N^k = -\left(\langle \epsilon(\mathbf{x}, \theta), \Psi_k \rangle - \epsilon^i\right) \frac{\partial \mathbf{E}^i}{\partial t}. \tag{5.23}$$

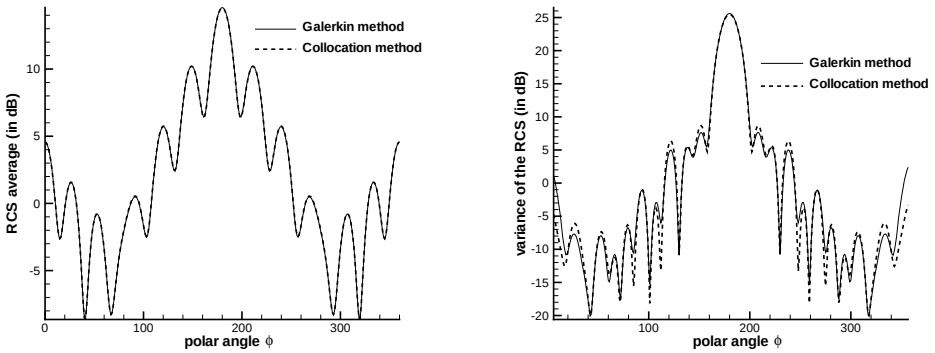

FIG. 5.6. *Comparison of the stochastic Galerkin method and the stochastic collocation method. Left: Average of the RCS for the randomness in material. Right: Variance of the RCS for the randomness in material.*

In this case, the equation to be solved is (4.9) and the source term is given by (5.23). Note that in this case, the size of the coupled system to be solved is P times the size of the system coming from a deterministic simulation.

. For the stochastic collocation method, the source term of (4.14) is simply

$$\mathbf{S}_N^j = -\left(\epsilon(\mathbf{x}, \sqrt{2}\theta_j) - \epsilon^i\right) \frac{\partial \mathbf{E}^i}{\partial t}. \tag{5.24}$$

In that case, the stochastic collocation method is cheaper than the stochastic Galerkin method since it only requires one to solve P decoupled systems of the size of a deterministic problem.

. Here we again compare the results of the RCS for both the stochastic collocation method and the stochastic Galerkin method. Figure 5.6 shows the average and the variance of the RCS. Although the results are not strictly identical, the small differences can be attributed to the nonsmooth nature of the RCS for this problem, which makes convergence more difficult to achieve. Figure 5.7 shows the average of the RCS and the possible variations around its average value. Note that for this test case, and contrary to the previous case, the whole RCS is affected by the uncertainty.

5.2.3. Uncertainty in shape. For this last example, the exact location of the boundary of an object is assumed to be unknown. One way to solve this problem is to generate different meshes for different radii of the cylinder and to perform a Monte Carlo simulation with those meshes. Since this cannot be achieved in an automatic and efficient way, in this paper we proceed differently, inspired by the one-dimensional approach based on mappings.

The idea is to keep the same mesh, the mean mesh, and to randomly move one side of the triangles sitting on the cylinder surface. For example, the triangle $(\mathbf{u}_1, \mathbf{u}_2, \mathbf{u}_3)$ has the side $(\mathbf{u}_1, \mathbf{u}_3)$ sitting on the cylinder surface (see Figure 5.8). For the deterministic case, the physical element is mapped into the parent element $\mathcal{T}$ and the transformation is written as

$$\mathbf{x}(\xi, \eta) = (1 - \xi - \eta)\mathbf{u}_1 + \xi\mathbf{u}_2 + \eta\mathbf{u}_3 \quad \text{for } (\xi, \eta) \in \mathcal{T}. \tag{5.25}$$

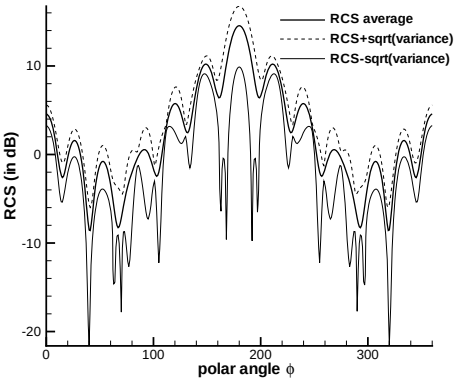

FIG. 5.7. *RCS for uncertainty in the material. Results are shown with the mean RCS as well as* ± 1 *standard deviation.*

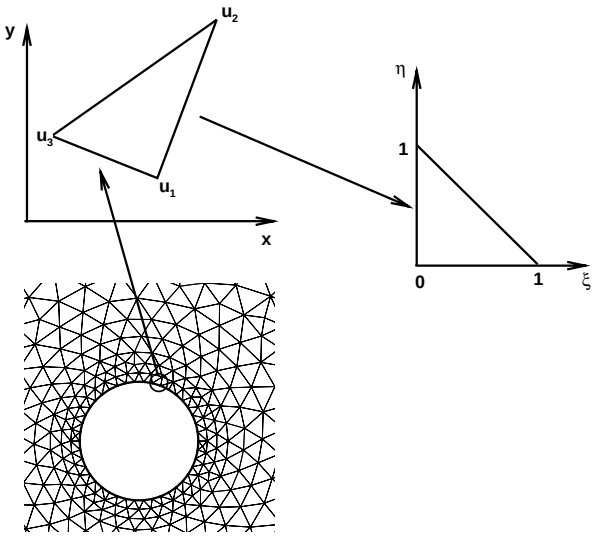

FIG. 5.8. *Illustration for the randomness in shape.*

Note that the Jacobian $J(\xi,\eta) = (\frac{\partial \mathbf{x}}{\partial \eta}, \frac{\partial \mathbf{x}}{\partial \xi})^T$ of transformation (5.25) is only a function of (ξ,η). Assuming randomness of the form $e^{0.1\theta}$, the points $\mathbf{u}_1$ and $\mathbf{u}_3$ take a new position $e^{0.1\theta}\mathbf{u}_1$ and $e^{0.1\theta}\mathbf{u}_3$, respectively, and the mapping (5.25) becomes

$$\mathbf{x}(\xi,\eta) = (1-\xi-\eta)e^{0.1\theta}\mathbf{u}_1 + \xi e^{0.1\theta}\mathbf{u}_2 + \eta \mathbf{u}_3 \quad \text{for } (\xi,\eta) \in \mathcal{T}. \tag{5.26}$$

The Jacobian of transformation (5.26) is now a function of (ξ,η,θ). The determinant of the Jacobian, which appears as a multiplicative coefficient in Maxwell's equations, is random, and this makes Maxwell's equation a stochastic PDE, which can be solved with the techniques described above (collocation or Galerkin stochastic method). The advantage of the procedure lies in the fact that one need only generate a single mesh, the randomness being modeled by the Jacobian of the transformation.

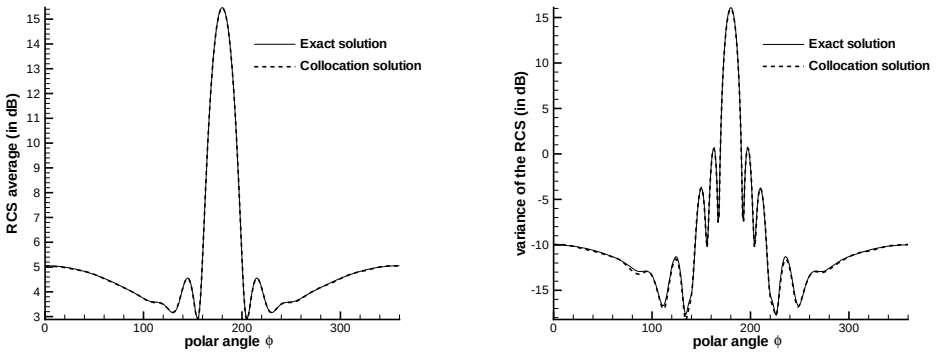

FIG. 5.9. *Comparison of the stochastic collocation solution with the exact solution. Left: Average of the RCS for the uncertainty in shape. Right: Variance of the RCS for uncertainty in shape.*

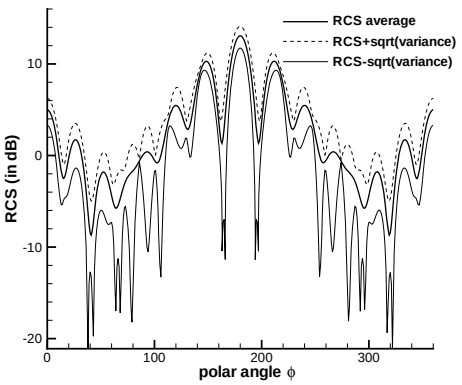

FIG. 5.10. *RCS for material cylinder with uncertain radius. Results are shown with the mean RCS as well as* ± 1 *standard deviation.*

. We test the approach by considering a PEC cylinder with an uncertain radius, the randomness being described by (5.26). For the deterministic problem, an exact RCS is available [2]. Therefore, the coefficients in (5.3) can be computed exactly and an exact stochastic solution for the RCS is available for the random radius problem. This enables us to compare the statistics of the numerical stochastic collocation solution with the exact one. This is what is done in Figure 5.9, which represents the average and the variance of the RCS (the mesh used for the numerical results is the same as in the previous section). We can see that the two solutions match very well.

. For this last example, the exact radius of the cylindrical boundary of a cylinder with a permittivity ϵ_1 is uncertain and is assumed to be described by (5.26). We also assume that outside the object, the relative permittivity is equal to one. Figure 5.10 shows the average of the RCS for this problem and the possible variations around its average value.

6. Concluding remarks. In this paper we discussed the use of probabilistic methods, rather than more traditional statistical methods such as Monte Carlo, to

enable the computation of quantitative measures for the impact of uncertainties on computational results, exemplified by the solution of the time-domain Maxwell's equations. These uncertainties can be due to a lack of knowledge, or lack of control over variations, or can simply be used as a model to compute the mean and variances over an ensemble of data, e.g., to compute the RCS of a fleet of aircraft, all of the same type but with minor differences.

The approach, based on chaos expansions, has the following significant advantages:

- It is simple, systematic, and accurate, and can be used in connection with existing validated codes with only minimal changes.
- The representation of probability distributions, which are most often smooth, by using high-order polynomials can be expected to be close to optimal and leads to a need for very few terms, i.e., few samples, without sacrificing the accuracy.
- It enables the computation of an ensample of solutions in space and time with an associated probability measure. It can handle large degrees of uncertainty simply by increasing the length of the expansion.
- It is flexible enough to handle a large variety of different types of uncertainty, e.g., materials, initial conditions, and shapes.

The computational results validate these claims and show the potential of computing high-order moments, in particular variances/sensitivities, thus enabling the computation of numerical error bars.

Throughout this paper, the dimension of the random space d is set to 1, and for the stochastic collocation method, the computational cost is proportional to P, where P is the number of collocation points. For more general problems with random dimensions $d > 1$, the computational cost of the collocation method would be proportional to P^d (for Galerkin polynomial chaos, it could be P^{2d}, where, in that case, P denotes the number of modes). This means that for problems where the correlation length is very small compared to the size of the problem, this method becomes more expensive, as a significant number of independent random variables is needed. For such cases requiring high-dimensional random spaces, the stochastic collocation methods discussed in [17] hold significant promise, as one can choose to limit the attention to high-dimensional integration formulas, thus dramatically reducing the number of samples even for high-dimensional randomness. As we have discussed in section 4.4, however, there is significant potential for reducing the computational cost by developing a theory that offers insight into how uncertainty can propagate through dynamical systems and what regularity one can expect for the underlying probability densities.

PRECONDITIONING MARKOV CHAIN MONTE CARLO SIMULATIONS USING COARSE-SCALE MODELS*

Y. EFENDIEV†, T. HOU‡, AND W. LUO‡

Abstract. We study the preconditioning of Markov chain Monte Carlo (MCMC) methods using coarse-scale models with applications to subsurface characterization. The purpose of preconditioning is to reduce the fine-scale computational cost and increase the acceptance rate in the MCMC sampling. This goal is achieved by generating Markov chains based on two-stage computations. In the first stage, a new proposal is first tested by the coarse-scale model based on multiscale finite volume methods. The full fine-scale computation will be conducted only if the proposal passes the coarse-scale screening. For more efficient simulations, an approximation of the full fine-scale computation using precomputed multiscale basis functions can also be used. Comparing with the regular MCMC method, the preconditioned MCMC method generates a modified Markov chain by incorporating the coarse-scale information of the problem. The conditions under which the modified Markov chain will converge to the correct posterior distribution are stated in the paper. The validity of these assumptions for our application and the conditions which would guarantee a high acceptance rate are also discussed. We would like to note that coarse-scale models used in the simulations need to be inexpensive but not necessarily very accurate, as our analysis and numerical simulations demonstrate. We present numerical examples for sampling permeability fields using two-point geostatistics. The Karhunen–Loève expansion is used to represent the realizations of the permeability field conditioned to the dynamic data, such as production data, as well as some static data. Our numerical examples show that the acceptance rate can be increased by more than 10 times if MCMC simulations are preconditioned using coarse-scale models.

DOI. 10.1137/050628568

1. Introduction.

Uncertainties on the detailed description of reservoir lithofacies, porosity, and permeability are major contributors to uncertainty in reservoir performance forecasting. Reducing this uncertainty can be achieved by integrating additional data in subsurface modeling. With the increasing interest in accurate prediction of subsurface properties, subsurface characterization based on dynamic data, such as production data, becomes more important.

To predict future reservoir performance, the reservoir properties, such as porosity and permeability, need to be conditioned to dynamic data, such as production data. In general it is difficult to calculate this probability distribution, because the process of predicting flow and transport in petroleum reservoirs is nonlinear. Instead, this probability distribution is estimated from the outcomes of flow predictions for a large number of realizations of the reservoir. It is essential that the permeability (and porosity) realizations adequately reflect the uncertainty in the reservoir properties; i.e., the probability distribution is sampled correctly. This problem is challenging because the permeability field is a function defined on a large number of grid blocks.

The Markov chain Monte Carlo (MCMC) method and its modifications have been used previously to sample the posterior distribution. In this paper, we design a two-stage MCMC method which employs coarse-scale models based on multiscale finite volume methods.

The direct MCMC simulations are generally very CPU demanding because each proposal requires solving a forward coupled nonlinear PDE over a large time interval. The forward fine-scale problem is usually formulated on a large number of grid blocks, which makes it prohibitively expensive to perform a sufficient number of MCMC simulations. There have been a few attempts to propose MCMC methods with high acceptance rates, for example, the randomized maximum likelihood method [19, 20]. This approach uses unconditional realizations of the production and permeability data and solves a deterministic gradient-based inverse problem. The solution of this minimization problem is taken as a proposal, and is accepted with probability 1, because the rigorous acceptance probability is very difficult to estimate. In addition to the need of solving a gradient-based inverse problem, this method does not properly sample the posterior distribution. Thus, developing efficient rigorous MCMC calculations with high acceptance rates remains a challenging problem.

In this paper, we show that using inexpensive coarse-scale computations one can increase the acceptance rate of MCMC calculations. Here the acceptance rate refers to the ratio between the number of accepted permeability samples and the number of times of solving the fine-scale nonlinear PDE system. The method consists of two stages. At the first stage, using coarse-scale runs we determine whether or not to run the fine-scale simulations. If the proposal is accepted at the first-stage, then a fine-scale simulation is performed at the second stage to determine the acceptance probability of the proposal. The first stage of the MCMC method modifies the proposal distribution. We show that the modified Markov chain satisfies the detailed balance condition for the correct distribution. Moreover, we point out that the chain is ergodic and converges to the correct posterior distribution under some technical assumptions. The validity of the assumptions for our application is discussed in the paper. We would like to note that two-stage MCMC algorithms have been used previously (e.g., [2, 15, 21, 10]) in different situations.

In this paper, we use a coarse-scale model based on multiscale finite volume methods. Note that it is essential that these coarse-scale models are inexpensive but not necessarily very accurate. The main idea of multiscale finite volume methods is to construct multiscale basis functions that contain the small scale information. Constructing these basis functions based on the single-phase flow is equivalent to single-phase flow upscaling, provided the transport equation is solved on a coarse grid. This method is inexpensive, since the basis functions are constructed only once, and the transport equation is solved on the coarse grid. The use of multiscale finite volume methods has another advantage: it can be further used as an accurate approximation for the production data if the transport equation is solved on the fine grid. For this purpose, one needs to compute the fine-scale velocity fields from the precomputed multiscale basis functions and solve the saturation on the fine grid. This provides an accurate approximation for the production data [12, 13, 1]. Since one can reuse the basis functions from the first stage, the resulting method is very efficient. We would like to note that upscaled models are used in MCMC simulations in previous findings. In an interesting work [9], the authors employ error models between coarse- and fine-scale simulations to quantify the uncertainty.

Numerical results for permeability fields generated using two-point geostatistics are presented in the paper. Using the Karhunen–Loève expansion, we can represent

the high dimensional permeability field by a small number of parameters. Furthermore, static data (the values of permeability field at some sparse locations) can be easily incorporated into the Karhunen–Loève expansion to further reduce the dimension of the parameter space. Numerical results are presented for both single-phase and two-phase flows for side-to-side and corner-to-corner flows. In all the simulations, we observe more than 10 times an increase in the acceptance rate. In other words, the preconditioned MCMC method can accept the same number of samples with much fewer fine-scale runs.

The paper is organized in the following way. In the next section, we briefly describe the model equations and their upscaling. Section 3 is devoted to the analysis of the preconditioned MCMC method and its relevance to our particular application. Numerical results are presented in section 4.

2. Fine and coarse models. We consider two-phase flows in a domain Ω under the assumption that the displacement is dominated by viscous effects. We neglect the effects of gravity, compressibility, and capillary pressure. The two phases are referred to as water (aqueous phase) and oil (nonaqueous phase liquid), designated by subscripts w and o, respectively. We write Darcy's law, with all quantities dimensionless, for each phase as follows:

$$\boldsymbol{v}_j = -\frac{k_{rj}(S)}{\mu_j}\boldsymbol{k}\cdot\nabla p, \tag{2.1}$$

where $\boldsymbol{v}_j$, $j = w, o$, is the phase velocity, $\boldsymbol{k}$ is the permeability tensor, k_{rj} is the relative permeability of the phase j, S is the water saturation (volume fraction), and p is the pressure. In this work, a single set of relative permeability curves is used and $\boldsymbol{k}$ is taken to be a diagonal tensor. Combining Darcy's law with a statement of conservation of mass allows us to express the governing equations in terms of the so-called pressure and saturation equations:

$$\nabla\cdot(\lambda(S)\boldsymbol{k}\nabla p) = q, \tag{2.2}$$

$$\frac{\partial S}{\partial t} + \boldsymbol{v}\cdot\nabla f(S) = -q_w, \tag{2.3}$$

where $\lambda(S)$ is the total mobility, q and q_w are the source terms, $\boldsymbol{v}$ is the total velocity, and $f(S)$ is the flux function, which are, respectively, given by

$$\lambda(S) = \frac{k_{rw}(S)}{\mu_w} + \frac{k_{ro}(S)}{\mu_o}, \tag{2.4}$$

$$\boldsymbol{v} = \boldsymbol{v}_w + \boldsymbol{v}_o = -\lambda(S)\boldsymbol{k}\,\nabla p, \tag{2.5}$$

$$f(S) = \frac{k_{rw}(S)/\mu_w}{k_{rw}(S)/\mu_w + k_{ro}(S)/\mu_o}. \tag{2.6}$$

The above description is referred to as the fine model of the two-phase flow problem. For the single-phase flow, we have $\lambda(S) = 1$ and $f(S) = S$. Throughout, the porosity is assumed to be constant and the permeability is assumed to have the form $\boldsymbol{k}(\boldsymbol{x}) = k(\boldsymbol{x})\boldsymbol{I}$, where $\boldsymbol{I}$ is a unit matrix and $k(\boldsymbol{x})$ is a scalar function.

The proposed coarse-scale model consists of upscaling the pressure equation (2.2) to obtain the velocity field on the coarse grid and then using it in (2.3) to resolve the

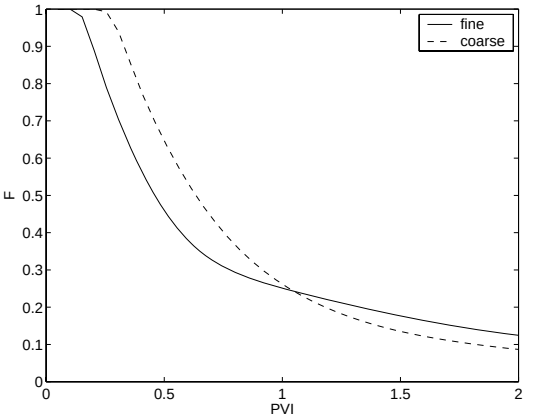

FIG. 2.1. *Typical fine- and coarse-scale fractional flows.*

saturation on the coarse grid. The pressure equation is upscaled using the multiscale finite volume method. The details of the method are presented in Appendix A. Using the multiscale finite volume method, we obtain the coarse-scale velocity field, which is used in solving the saturation equation on the coarse grid. Since no subgrid modeling is performed for the saturation equation, this upscaling procedure introduces errors. In Figure 2.1, we present a comparison of the typical fractional flows computed by fine- and coarse-scale models. The fractional flows are plotted against the dimensionless time "pore volume injected." The pore volume injected (PVI) at time T is defined as $\frac{1}{V_p}\int_0^T q_t(\tau)d\tau$, where q_t is the combined flow rates of water and oil at the production edge, and V_p is the total pore volume of the system. PVI provides the dimensionless time for the flow displacement. The fractional flow $F(t)$ (denoted simply by F thereafter) is the fraction of oil in the produced fluid and is defined as $F = q_o/q_t$, where $q_t = q_o + q_w$, with q_o and q_w denoting the flow rates of oil and water at the production edge of the model. More specifically,

$$F(t) = 1 - \frac{\int_{\partial\Omega^{out}} f(S)\, v_n\, dl}{\int_{\partial\Omega^{out}} v_n\, dl},$$

where $\partial\Omega^{out}$ is the outflow boundary and $v_n = \boldsymbol{v}\cdot\boldsymbol{n}$ is the normal velocity on the boundary. In future analysis, the notations q_o, q_w, or q_t will not be used, and q will be reserved for the proposal distributions. The proposed coarse-scale model is somewhat similar to the single-phase flow upscaling [4]. One can improve the accuracy of the above coarse model by solving the transport equation on the fine grid using the fine-scale velocity field which can be computed employing precomputed multiscale basis functions. This makes solving the coarse model more expensive because the transport update is performed on the fine grid with smaller time steps. However, it can provide an efficient numerical solver for the second stage of the preconditioned MCMC method, as we will discuss later.

3. Preconditioning MCMC simulations using coarse-scale models.

3.1. Problem setting. The problem under consideration consists of sampling the permeability field given fractional flow measurements. Typically, the permeability field is known at some sparse locations. This information should be incorporated into

the prior models (distributions) of the permeability. Since the fractional flow is an integrated response, the map from the permeability field to the fractional flow is not one-to-one. Hence this problem is ill-posed in the sense that there exist many different permeability realizations for the given production data.

From the probabilistic point of view, this problem can be regarded as sampling the permeability field conditioning on the fractional flow data with measurement errors. Consequently, our goal is to sample from the conditional distribution $P(k|F)$, where k is the fine-scale permeability field and F is the fractional flow curve measured from the production data. Using the Bayes theorem we can write

$$P(k|F) \propto P(F|k)P(k). \tag{3.1}$$

In the above formula, $P(k)$ is the prior distribution of the permeability field, which is assumed to be log-normal. The prior distribution $P(k)$ will also incorporate the additional information of the permeability field at the sparse locations. The likelihood function $P(F|k)$ denotes the conditional probability that the outcome of the measurement is F when the true permeability is k.

In practice, the measured fractional flow F contains measurement errors. Denote the fractional flow for a given k as F_k. F_k can be computed by solving the model equation (2.1)–(2.3) on the fine grid. The computed F_k will contain a modeling error as well as a numerical error. In this paper, we assume that the combined errors from the measurement, modeling, and numerics satisfy a Gaussian distribution. That is, the likelihood function $P(F|k)$ takes the form

$$P(F|k) \propto \exp\left(-\frac{\|F - F_k\|^2}{\sigma_f^2}\right), \tag{3.2}$$

where F is the observed fractional flow, F_k is the fractional flow computed by solving the model equations (2.1)–(2.3) on the fine grid for a given k, and σ_f is the precision associated with the measurement F and the numerical solution F_k. Since both F and F_k are functions of t, $\|F - F_k\|^2$ denotes the L_2 norm

$$\|F - F_k\|^2 = \int_0^T [F(t) - F_k(t)]^2 \, dt.$$

It is worth noting that the method discussed in this paper does not depend on the specific form of the error functions. A more general error model can be used in the simulations. We would like to emphasize that different permeability fields may produce the same fractional flow curve. Thus, the likelihood distribution $P(F|k)$ is a multimodal function of k with multiple local maxima.

Denote the posterior distribution as

$$\pi(k) = P(k|F) \propto \exp\left(-\frac{\|F - F_k\|^2}{\sigma_f^2}\right) P(k). \tag{3.3}$$

Sampling from the distribution $\pi(k)$ can be accomplished by using the MCMC method. The main idea of the MCMC method is to generate a Markov chain with $\pi(k)$ as its stationary distribution. A key step to this approach is to construct the desired transition kernel for the Markov chain. In this paper, we use the Metropolis-Hasting algorithm. Suppose $q(y|x)$ is a general transitional probability distribution, which is

easy to sample and has an explicit form. The Metropolis-Hasting MCMC algorithm (see, e.g., [22]) consists of the following steps.

ALGORITHM (METROPOLIS-HASTING MCMC [22]).

- Step 1. At state k_n generate k from $q(k|k_n)$.
- Step 2. Accept k as a sample with probability

$$p(k_n, k) = \min\left(1, \frac{q(k_n|k)\pi(k)}{q(k|k_n)\pi(k_n)}\right); \tag{3.4}$$

  i.e., take $k_{n+1} = k$ with probability $p(k_n, k)$ and $k_{n+1} = k_n$ with probability $1 - p(k_n, k)$.

Starting with an arbitrary initial permeability sample k_0, the MCMC algorithm generates a Markov chain $\{k_n\}$. At each iteration, the probability of moving from state k_n to a next state k is $q(k|k_n)p(k_n, k)$, so the transition kernel for the Markov chain $\{k_n\}$ is

$$K(k_n, k) = p(k_n, k)q(k|k_n) + \left(1 - \int p(k_n, k)q(k|k_n)dk\right)\delta_{k_n}(k).$$

Using the explicit formula of the transition kernel, it is not difficult to prove that the target distribution $\pi(k)$ is indeed the stationary distribution of the Markov chain $\{k_n\}$. As a result, we can take k_n as samples of the distribution $\pi(k)$ after the chain reaches the steady state.

3.2. The preconditioned MCMC method. In the above Metropolis-Hasting MCMC algorithm, the major computational cost is to compute F_k in the target distribution $\pi(k)$, which involves solving the coupled nonlinear PDE system (2.1)–(2.3) on the fine grid. Generally, the MCMC method requires thousands of iterations before it converges to the steady state. To quantify the uncertainty of the permeability field accurately, one also needs to generate a large number of different samples. However, the acceptance rate of the direct MCMC method is very low, due to the large dimensionality of the permeability field. The algorithm needs to test many proposals to accept only a few permeability samples. Most of the CPU time is spent on simulating the rejected samples. That makes the direct (full) MCMC simulations prohibitively expensive in practice.

One way to improve the direct MCMC method is to increase its acceptance rate by modifying the proposal distribution $q(k|k_n)$. In this paper, we propose an algorithm in which the proposal distribution $q(k|k_n)$ is adapted to the target distribution using the coarse-scale model. Instead of testing each proposal by fine-scale computations directly, the algorithm first tests the proposal by the coarse-scale model. This is achieved by comparing the fractional flow curves on the coarse grid first. If the proposal is accepted by the coarse-scale test, then a full fine-scale computation will be conducted and the proposal will be further tested as in the direct MCMC method. Otherwise, the proposal will be rejected by the coarse-scale test and a new proposal will be generated from $q(k|k_n)$. The coarse-scale test filters the unacceptable proposals and avoids the expensive fine-scale tests for those proposals. The filtering process essentially modifies the proposal distribution $q(k|k_n)$ by incorporating the coarse-scale information of the problem. That is why the modified method is called a

Recall that the fine-scale target distribution is given by (3.3). We approximate

the distribution $\pi(k)$ on the coarse scale by

$$\pi^*(k) \propto \exp\left(-\frac{\|F - F_k^*\|^2}{\sigma_c^2}\right) P(k), \tag{3.5}$$

where F_k^* is the fractional flow computed by solving the coarse-scale model of (2.1)–(2.3) for the given k, and σ_c is the precision associated with the coarse-scale model. The parameter σ_c plays an important role in improving the acceptance rate of the preconditioned MCMC method. The optimal value of σ_c depends on the correlation between $\|F - F_k\|$ and $\|F - F_k^*\|$, which can be estimated by numerical simulations. (cf. Figure 3.1 and later discussion). Using the coarse-scale distribution $\pi^*(k)$ as a filter, the preconditioned MCMC method can be described as follows.

Algorithm (preconditioned MCMC).

- Step 1. At k_n, generate a trial proposal k' from distribution $q(k'|k_n)$.
- Step 2. Take the real proposal as

$$k = \begin{cases} k' & \text{with probability } g(k_n, k'), \\ k_n & \text{with probability } 1 - g(k_n, k'), \end{cases}$$

  where

$$g(k_n, k') = \min\left(1, \frac{q(k_n|k')\pi^*(k')}{q(k'|k_n)\pi^*(k_n)}\right). \tag{3.6}$$

  Therefore, the final proposal k is generated from the effective instrumental distribution

$$Q(k|k_n) = g(k_n, k)q(k|k_n) + \left(1 - \int g(k_n, k)q(k|k_n)dk\right)\delta_{k_n}(k). \tag{3.7}$$

- Step 3. Accept k as a sample with probability

$$\rho(k_n, k) = \min\left(1, \frac{Q(k_n|k)\pi(k)}{Q(k|k_n)\pi(k_n)}\right); \tag{3.8}$$

  i.e., take $k_{n+1} = k$ with probability $\rho(k_n, k)$ and $k_{n+1} = k_n$ with probability $1 - \rho(k_n, k)$.

In the above algorithm, if the trial proposal k' is rejected by the coarse-scale test (Step 2), k_n will be passed to the fine-scale test as the proposal. Since $\rho(k_n, k_n) \equiv 1$, no further (fine-scale) computation is needed. Thus, the expensive fine-scale computations can be avoided for those proposals which are unlikely to be accepted. In comparison, the regular MCMC method requires a fine-scale simulation for every proposal k, even though most of the proposals will be rejected at the end.

It is worth noting that there is no need to compute $Q(k|k_n)$ and $Q(k_n|k)$ in (3.8) by the integral formula (3.7). The acceptance probability (3.8) can be simplified as

$$\rho(k_n, k) = \min\left(1, \frac{\pi(k)\pi^*(k_n)}{\pi(k_n)\pi^*(k)}\right). \tag{3.9}$$

In fact, (3.9) is obviously true for $k = k_n$ since $\rho(k_n, k_n) \equiv 1$. For $k \neq k_n$,

$$Q(k_n|k) = g(k, k_n)q(k_n|k) = \frac{1}{\pi^*(k)} \min\Big(q(k_n|k)\pi^*(k),\ q(k|k_n)\pi^*(k_n)\Big)$$

$$= \frac{q(k|k_n)\pi^*(k_n)}{\pi^*(k)} g(k_n, k) = \frac{\pi^*(k_n)}{\pi^*(k)} Q(k|k_n).$$

Substituting the above formula into (3.8), we immediately get (3.9).

Since the computation of the coarse-scale solution is very cheap, Step 2 of the preconditioned MCMC method can be implemented very quickly to decide whether or not to run the fine-scale simulation. The second step of the algorithm serves as a filter that avoids unnecessary fine-scale runs for the rejected samples. It is possible that the coarse-scale test may reject an individual sample which will otherwise have a (small) probability to be accepted in the fine-scale test. However, that does not play a crucial role, since we are interested only in the statistical property of the samples. We will show later that the preconditioned MCMC algorithm converges under some mild assumptions.

We would like to note that the Gaussian error model for the coarse-scale distribution $\pi^*(k)$ is not very accurate. We use it only in the filtering stage to decide whether or not to run the fine-scale simulations. The choice of the coarse-scale precision parameter σ_c is important for increasing the acceptance rate. If σ_c is too large, then too many proposals can pass the coarse-scale tests and the filtering stage will become less effective. If σ_c is too small, then eligible proposals may be incorrectly filtered out, which will result in biased sampling. Our numerical results show that the acceptance rate is optimal when σ_c is of the same order as σ_f. The optimal value of σ_c can be estimated based on the correlation between $\|F - F_k\|$ and $\|F - F_k^*\|$ (cf. Figure 3.1).

Based on the Gaussian precision models (3.3) and (3.5), the acceptance probability (3.9) has the form

$$\rho(k_n, k) = \min\left(1, \frac{\pi(k)\pi^*(k_n)}{\pi(k_n)\pi^*(k)}\right) = \min\left(1, \frac{\exp\left(-\frac{E_k - E_{k_n}}{\sigma_f^2}\right)}{\exp\left(-\frac{E_k^* - E_{k_n}^*}{\sigma_c^2}\right)}\right), \tag{3.10}$$

where

$$E_k = \|F - F_k\|^2, \qquad E_k^* = \|F - F_k^*\|^2.$$

If E_k^* is strongly correlated with E_k, then the acceptance probability (3.10) could be close to 1 for certain choice of σ_c. Hence a high acceptance rate can be achieved at Step 3 of the preconditioned MCMC method. To demonstrate that E_k^* is indeed strongly correlated with E_k, we compute E_k and E_k^* for many different permeability samples k (see the second example of section 4, Figure 4.7, for details of the permeability field) and plot E_k against E_k^* in Figure 3.1. We find that the correlation coefficient between E_k^* and E_k is approximately 0.9. If the correlation between E_k and E_k^* is strong, we can write

$$E_k \simeq \alpha E_k^* + \beta.$$

Substituting this into (3.10) and choosing $\sigma_c^2 = \sigma_f^2/\alpha$, we can obtain the acceptance rate close to 1 in Step 3. In practice, however, one does not know a priori the correlation constant α. The approximate value of α can be estimated by a priori numerical simulations where E_k and E_k^* are computed for a number of permeability samples.

The preconditioned MCMC method uses the coarse-scale distribution (3.5) with the reference fractional flow being the observed fine-scale fractional flow. One can also use a different reference fractional flow curve in Step 2 of the preconditioned MCMC method to improve the acceptance rate. In our numerical simulations (not presented here), we have used the coarse-scale fractional flow corresponding to the

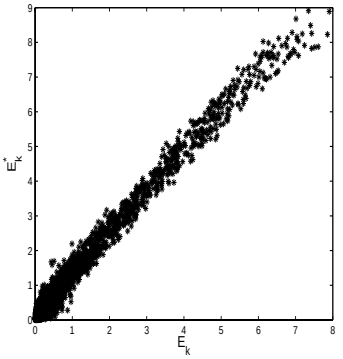

FIG. 3.1. *Cross-plot between* $E_k = \|F - F_k\|^2$ *and* $E_k^* = \|F - F_k^*\|^2$.

observed fractional flow as the reference fractional flow in the preconditioned MCMC simulations. We have observed similar numerical results. Since the coarse-scale fractional flow corresponding to the observed fractional flow is generally not known, we do not present these numerical results here. However, we note that one can possibly improve the preconditioning by a careful choice of the reference fractional flow.

The preconditioned MCMC method employs multiscale finite volume methods in the preconditioning step. If a proposal is accepted by the coarse-scale test (Step 2), one can use the precomputed multiscale basis functions to reconstruct the velocity field on the fine scale. Then the transport equation can be solved on the fine grid coupled with the coarse-grid pressure equation [6, 12, 13, 1]. This approach provides an accurate approximation to the production data on the fine grid and can be used to replace the fine-scale computation in the second stage (Step 3). In this procedure, the basis functions are not updated in time, or updated only in a few coarse blocks. Thus the fine-scale computation in the second stage of the preconditioned MCMC method (Step 3) can also be implemented quickly. Since the basis functions from the first-stage are reused for the fine-scale computation, this combined multiscale approach can be very efficient for our sampling problem.

3.3. Analysis of the preconditioned MCMC method. Next we will analyze the preconditioned MCMC method in more details. Denote

$$\begin{aligned} &\mathcal{E} = \big\{k;\ \pi(k) > 0\big\}, \\ &\mathcal{E}^* = \big\{k;\ \pi^*(k) > 0\big\}, \\ &\mathcal{D} = \big\{k;\ q(k|k_n) > 0 \text{ for some } k_n \in \mathcal{E}\big\}. \end{aligned} \tag{3.11}$$

The set $\mathcal{E}$ is the support of the posterior (target) distribution $\pi(k)$. $\mathcal{E}$ contains all the permeability field k which has a positive probability of being accepted as a sample. Similarly, $\mathcal{E}^*$ is the support of the coarse-scale distribution $\pi^*(k)$, which contains all the k acceptable by the coarse-scale test. $\mathcal{D}$ is the set of all the proposals which can be generated by the instrumental distribution $q(k|k_n)$. For the preconditioned MCMC method to work properly, the conditions $\mathcal{E} \subseteq \mathcal{D}$ and $\mathcal{E} \subseteq \mathcal{E}^*$ must hold (up to a zero measure set) simultaneously. If one of these conditions is not true, say, $\mathcal{E} \not\subseteq \mathcal{E}^*$, then

there will exist a subset $A \subset (\mathcal{E} \setminus \mathcal{E}^*)$ such that

$$\pi(A) = \int_A \pi(k)dk > 0 \qquad \text{and} \qquad \pi^*(A) = \int_A \pi^*(k)dk = 0,$$

which means no element of A can pass the coarse-scale test and A will never be visited by the Markov chain $\{k_n\}$. Thus, $\pi(k)$ cannot be sampled properly.

For most practical proposals $q(k|k_n)$, such as the random walk samplers and independent samplers, the conditions $\mathcal{E}, \mathcal{E}^* \subset \mathcal{D}$ can be naturally satisfied. By choosing the parameter σ_c in $\pi^*(k)$ properly, the condition $\mathcal{E} \subset \mathcal{E}^*$ can also be satisfied (see the discussion below). As a result, we have $\mathcal{E} \subset \mathcal{E}^* \subset \mathcal{D}$. In this case, $\mathcal{E}^*$ is identical to the support of the effective proposal $Q(k|k_n)$:

$$\mathcal{E}^* = \big\{k;\ Q(k|k_n) > 0 \text{ for some } k_n \in \mathcal{E}\big\}.$$

Due to the high dimension of the permeability field k, the support $\mathcal{E}$ of the target distribution $\pi(k)$ is much smaller than the support $\mathcal{D}$ of the proposal $q(k|k_n)$ distribution. For all the proposals $k \in (\mathcal{D} \setminus \mathcal{E})$, they will never be accepted as samples in the MCMC method since $\pi(k) = 0$. In the preconditioned MCMC algorithm, the effective proposal distribution $Q(k|k_n)$ samples from a much smaller support $\mathcal{E}^*$, and hence avoids solving the fine-scale problems for all $k \in (\mathcal{D} \setminus \mathcal{E}^*)$. Suppose that we sample the posterior distribution $\pi(k)$ by both the regular MCMC method and preconditioned MCMC method. For each proposal k generated from $q(k|k_n)$, the regular MCMC method accepts it as a sample with probability $p(k_n, k)$ as defined by (3.4), while the preconditioned MCMC method accepts it with probability $g(k_n, k)\rho(k_n, k)$, where $g(k_n, k)$ is the acceptance probability (3.6) of the coarse-scale test and $\rho(k_n, k)$ is the acceptance probability (3.8) of the fine-scale test. When $g(k_n, k) < 1$ and $\rho(k_n, k) < 1$, which is true for most proposals k, it is easy to show that $g(k_n, k)\rho(k_n, k) = p(k_n, k)$. That is, the two methods accept k as an example with the same probability. In numerical experiments, both methods indeed accept approximately the same amount of proposals for a fixed number of iterations. However, the regular MCMC method needs to solve a fine-scale problem for each MCMC iteration, while the preconditioned MCMC method solves only the fine-scale problem when the proposal passes the coarse-scale test. For all the proposals $k \in (\mathcal{D} \setminus \mathcal{E}^*)$, they will be rejected directly by the coarse-scale criteria and do not require fine-scale computations. For each iteration, the preconditioned MCMC solves only the fine-scale problem r time in average, where

$$r = \int_{\mathcal{E}^*} g(k_n, k)q(k|k_n)dk < 1.$$

Note that $\int_{\mathcal{D}} q(k|k_n)dk = 1$ and $g(k_n, k) \le 1$. If $\mathcal{E}^*$ is close to $\mathcal{E}$, and hence much smaller than $\mathcal{D}$, then $r \ll 1$. Therefore, the preconditioned MCMC method requires much less fine-scale simulation while still accepting approximately the same amount of proposals. In other words, the preconditioned MCMC method can achieve a much higher acceptance rate for each fine-scale computation.

Next we will discuss the stability property of the preconditioned MCMC method. We shall show that the preconditioned MCMC method shares the same convergence property as the regular MCMC method. Denote by K the transition kernel of the Markov chain $\{k_n\}$ generated by the preconditioned MCMC method. Since its effec-

tive proposal is $Q(k|k_n)$ as defined by (3.7), we get

$$K(k_n, k) = \rho(k_n, k)Q(k|k_n) \qquad \text{for } k \neq k_n, \tag{3.12}$$

$$K(k_n, \{k_n\}) = 1 - \int_{k \neq k_n} \rho(k_n, k)Q(k|k_n)dk. \tag{3.13}$$

That is, the transition kernel $K(k_n, \cdot)$ is continuous when $k \neq k_n$ and has a positive probability for the event $\{k = k_n\}$.

As in the regular MCMC method, it is easy to show that $K(k_n, k)$ satisfies the detailed balance condition

$$\pi(k_n)K(k_n, k) = \pi(k)K(k, k_n) \tag{3.14}$$

for any $k, k_n \in \mathcal{E}$. In fact, the equality (3.14) is obviously true when $k = k_n$. If $k \neq k_n$, then from (3.12) we have

$$\pi(k_n)K(k_n, k) = \pi(k_n)\rho(k_n, k)Q(k|k_n) = \min\Big(Q(k|k_n)\pi(k_n),\ Q(k_n|k)\pi(k)\Big)$$

$$= \min\left(\frac{Q(k|k_n)\pi(k_n)}{Q(k_n|k)\pi(k)},\ 1\right) Q(k_n|k)\pi(k) = \rho(k, k_n)Q(k_n|k)\pi(k) = \pi(k)K(k, k_n).$$

So the detailed balance condition (3.14) is always satisfied. Using (3.14), we can easily show that $\pi(A) = \int K(k, A)dk$ for any $A \in \mathcal{B}(\mathcal{E})$, where $\mathcal{B}(\mathcal{E})$ denotes all the measurable subsets of $\mathcal{E}$. Thus, $\pi(k)$ is indeed the stationary distribution of the transition kernel $K(k_n, k)$.

In the regular MCMC method, the proposal $q(k|k_n)$ is usually chosen to satisfy

$$q(k|k_n) > 0 \text{ for any } (k_n, k) \in \mathcal{E} \times \mathcal{E}, \tag{3.15}$$

which guarantees that the resulting regular MCMC method is irreducible. A similar statement is true for the preconditioned MCMC method.

LEMMA 3.1. [illegible] $q(k|k_n)$ [illegible] (3.15) [illegible] $\mathcal{E} \subset \mathcal{E}^*$ [illegible] $\{k_n\}$ [illegible] π [illegible].

[illegible]. According to the definition of strong irreducibility, we need only to show that $K(k_n, A) > 0$ for all $k_n \in \mathcal{E}$ and any measurable set $A \subset \mathcal{E}$ with $\pi(A) > 0$. Note that

$$K(k_n, A) \geq \int_{A \setminus k_n} K(k_n, k)dk = \int_{A \setminus k_n} \rho(k_n, k)Q(k_n, k)dk$$

$$= \int_{A \setminus k_n} \rho(k_n, k)g(k_n, k)q(k|k_n)dk.$$

In the above inequality, the equal sign holds when $k_n \notin A$. Since $\pi(A) = \int_A \pi(k)dk > 0$, it follows that $m(A) = m(A \setminus k_n) > 0$, where $m(A)$ is the Lebesgue measure. Since $A \subset \mathcal{E}$ and $\mathcal{E} \subset \mathcal{E}^*$, both $\rho(k_n, k)$ and $g(k_n, k)$ are positive for $k \in A$. Combining the positivity assumption (3.15), we can easily conclude that $K(k_n, A) > 0$. □

Most practical proposal distributions, such as random walk samplers or independent samplers, satisfy the positivity condition (3.15). Thus condition (3.15) poses only a mild restriction in practice. As we will see later, the proposals used in our numerical experiment naturally satisfy the condition (3.15).

Based on the stability property of Markov chains [22, 18], the following convergence result is readily available.

THEOREM 3.2 (see [22]). [illegible] (3.15) [illegible] $\mathcal{E} \subset \mathcal{E}^*$ [illegible] $\{k_n\}$ [illegible] $h(k)$

$$\lim_{N\to\infty} \frac{1}{N} \sum_{n=1}^{N} h(k_n) = \int h(k)\pi(k)dk. \tag{3.16}$$

[illegible] $\{k_n\}$ [illegible] k_n [illegible] $\pi(k)$ [illegible]

$$\lim_{n\to\infty} \sup_{A\in\mathcal{B}(\mathcal{E})} \left|K^n(k_0, A) - \pi(A)\right| = 0 \tag{3.17}$$

[illegible] k_0

To get the convergence property (3.17), we need to show that the Markov chain $\{k_n\}$ generated by the preconditioned MCMC method is aperiodic. Recall that a simple sufficient condition for aperiodicity is that $K(k_n, \{k_n\}) > 0$ for some $k_n \in \mathcal{E}$. In other words, the event $\{k_{n+1} = k_n\}$ happens with a positive probability in the preconditioned MCMC method. From the definition (3.13), we have

$$K(k_n, \{k_n\}) = 1 - \int_{k\neq k_n} \rho(k_n, k)Q(k|k_n)dk = 1 - \int_{k\neq k_n} \rho(k_n, k)g(k_n, k)q(k|k_n)dk.$$

Consequently, $K(k_n, \{k_n\}) \equiv 0$ requires $g(k_n, k) = 1$ and $\rho(k_n, k) = 1$ for almost all $k \in \mathcal{D}$, which means that all the proposals generated by $q(k|k_n)$ are correct samples of distributions $\pi(k)$ and $\pi^*(k)$. This is obviously not true in practice. Thus, the practical preconditioned MCMC method is always aperiodic and converges to the target distribution $\pi(k)$ in the sense of (3.17).

Next we discuss the necessary condition $\mathcal{E} \subseteq \mathcal{E}^*$, which is essential to guarantee the convergence of the preconditioned MCMC method. Due to the Gaussian form of the posterior distribution, $\pi(k)$ and $\pi^*(k)$ do not have a compact support and the domain $\mathcal{E}$ (or $\mathcal{E}^*$) is the whole space spanned by all k. However, if the precision parameters σ_f and σ_c are relatively small, then $\pi(k)$ and $\pi^*(k)$ are very close to zero for most proposals. From the numerical point of view, the proposal k is very unlikely to be accepted if $\pi(k)$ or $\pi^*(k)$ is close to zero. Consequently, the support of the distributions should be interpreted as $\mathcal{E} = \{k; \pi(k) > \delta\}$ and $\mathcal{E}^* = \{k; \pi^*(k) > \delta\}$, where δ is a small positive number.

If $k \in \mathcal{E}$, then $\pi(k) > \delta$ and $\|F_k - F\|^2/\sigma_f^2$ is not very large. To make $k \in \mathcal{E}^*$, $\|F_k^* - F\|^2/\sigma_c^2$ should not be very large either. If $\|F_k^* - F\|^2$ is bounded by $\|F_k - F\|^2$ up to a multiplicative constant, then the condition $\mathcal{E} \subseteq \mathcal{E}^*$ can be satisfied by choosing the parameter σ_c properly. For most upscaled models, the coarse-scale quantity is indeed bounded by the corresponding fine-scale quantity. For example, the upscaled velocity $\boldsymbol{v}^*$ in the saturation equation is obtained by averaging the fine-scale velocity $\boldsymbol{v}$ over the coarse-grid blocks

$$\boldsymbol{v}^*(x) = \sum_i \left(\frac{1}{|\Omega_i|} \int_{\Omega_i} \boldsymbol{v}(y)dy\right) 1_{\Omega_i}(x),$$

where $\Omega_i \subset \Omega$ are the coarse blocks. It is easy to show that

$$\begin{aligned} \|\boldsymbol{v}^*\|^2_{L^2(\Omega)} &= \sum_i \frac{1}{|\Omega_i|} \left(\int_{\Omega_i} \boldsymbol{v}(y) dy \right)^2 \\ &\leq \sum_i \frac{1}{|\Omega_i|} \left(\int_{\Omega_i} 1(y)^2 dy \right) \left(\int_{\Omega_i} \boldsymbol{v}^2(y) dy \right) = \|\boldsymbol{v}\|^2_{L^2(\Omega)}. \end{aligned} \tag{3.18}$$

Thus, the coarse-scale velocity is bounded by the corresponding fine-scale velocity. We would like to remark that for some nonlinear averaging operators, one can also show that the coarse-scale quantities are bounded by the corresponding fine-scale quantities. One of the examples is the homogenization operator for linear elliptic equations.

In general, it is difficult to carry out such estimates for fractional flows. However, coarse-scale fractional flows can be interpreted as some type of average of the corresponding fine-scale fractional flows. Indeed, the fine-scale fractional flow curve can be regarded as the travel times along the characteristics of the particles that start at the inlet. The coarse-scale fractional flow, on the other hand, represents an average of these travel times over characteristics within the coarse domain. In general, the estimation similar to (3.18) does not hold for fractional flow curves, as our next counterexample shows. For simplicity, we present the counterexample for the single-phase flow in porous media with four layers. This example can be easily generalized. Denote by t_i, $i = 1, 2, 3, 4$, the breakthrough times for the layers. Consider two fine-scale (with four layers) permeability fields with breakthrough times $t_1 = T_1$, $t_2 = T_2$, $t_3 = T_1$, $t_4 = T_2$ and $t_1 = T_1$, $t_2 = T_1$, $t_3 = T_2$, $t_4 = T_2$, respectively. These two fine-scale permeability fields will give the same fractional flows, since the times of the flights are the same up to a permutation. Now we consider the upscaling of these two fine scale permeability fields to two-layered media. Upscaling is equivalent to averaging the breakthrough times. Consequently, the breakthrough times for the corresponding upscaled models are $t_1^* = 0.5(T_1 + T_2)$, $t_2^* = 0.5(T_1 + T_2)$ and $t_1^* = 0.5(T_1 + T_1) = T_1$, $t_2^* = 0.5(T_2 + T_2) = T_2$, respectively. Thus, the coarse-scale models give different fractional flows, even though the fractional flows are identical for the fine-scale models. However, this type of counterexample can be avoided in practice, because the near-well values of the permeability are known, and consequently, permutation of the layers can be avoided.

4. Numerical results. In this section we discuss the implementation details of the preconditioned MCMC method and present some representative numerical results. Suppose the permeability field $k(\boldsymbol{x})$, where $\boldsymbol{x} = (x, z)$, is defined on the unit square $\Omega = [0, 1]^2$. We assume that the permeability field $k(\boldsymbol{x})$ is a log-normal process and its covariance function is known. The observed data include the fractional flow curve F and the values of the permeability at sparse locations. We discretize the domain Ω by a rectangular mesh, and the permeability field k is represented by a matrix (thus k is a high dimensional vector). As for the boundary conditions, we have tested various boundary conditions and observed similar results for the preconditioned MCMC method. In the following numerical experiments we assume $p = 1$ and $S = 1$ on $x = 0$ and $p = 0$ on $x = 1$ and no flow conditions on the lateral boundaries $z = 0$ and $z = 1$. We call this type of boundary condition side-to-side. We have chosen this type of boundary condition because they provide large deviations between coarse- and fine-scale simulations for the permeability fields considered in the paper. The other

type of boundary condition is set by specifying $p = 1$, $S = 1$ along the $x = 0$ edge for $0.5 \le z \le 1$ and $p = 0$ along the $x = 1$ edge for $0 \le z \le 0.5$. On the rest of the boundaries, no-flow boundary conditions are assumed. We call this type of boundary condition corner-to-corner. We will consider both single-phase and two-phase flow displacements.

Using the Karhunen–Loève expansion [17, 23], the permeability field can be expanded in terms of an optimal L^2 basis. By truncating the expansion we can represent the permeability matrix by a small number of random parameters. To impose the hard constraints (the values of the permeability at prescribed locations), we will find a linear subspace of the random parameter space (a hyperplane) which yields the desired permeability fields satisfying the hard constraints.

We first briefly recall the basic idea of the Karhunen–Loève expansion. Denote $Y(\boldsymbol{x}, \omega) = \log[k(\boldsymbol{x}, \omega)]$, where the sample variable ω is included to remind us that k is a random field. Suppose $Y(\boldsymbol{x}, \omega)$ is a second order stochastic process; that is, $Y(\boldsymbol{x}, \omega) \in L^2(\Omega)$ with probability 1. Without loss of generality, we assume that $E[Y(\boldsymbol{x}, \omega)] = 0$. Given an arbitrary orthonormal basis $\{\phi_k\}$ in $L^2(\Omega)$, we can expand $Y(\boldsymbol{x}, \omega)$ in Fourier series

$$Y(\boldsymbol{x}, \omega) = \sum_{k=1}^{\infty} Y_k(\omega)\phi_k(\boldsymbol{x}),$$

where

$$Y_k(\omega) = \int_\Omega Y(\boldsymbol{x}, \omega)\, \phi_k(\boldsymbol{x}) d\boldsymbol{x}, \qquad k = 1, 2, \ldots,$$

are random variables with zero means. We are interested in the special L^2 basis $\{\phi_k\}$ which makes Y_k uncorrelated: $E(Y_i Y_j) = 0$ for all $i \ne j$. Denote the covariance function of Y as $R(\boldsymbol{x}, \boldsymbol{y}) = E[Y(\boldsymbol{x})Y(\boldsymbol{y})]$. Then such basis functions $\{\phi_k\}$ satisfy

$$E[Y_i Y_j] = \int_\Omega \phi_i(\boldsymbol{x}) d\boldsymbol{x} \int_\Omega R(\boldsymbol{x}, \boldsymbol{y})\phi_j(\boldsymbol{y}) d\boldsymbol{y} = 0, \qquad i \ne j.$$

Since $\{\phi_k\}$ is complete and orthonormal in $L^2(\Omega)$, it follows that $\phi_k(\boldsymbol{x})$ are eigenfunctions of $R(\boldsymbol{x}, \boldsymbol{y})$:

$$\int_\Omega R(\boldsymbol{x}, \boldsymbol{y})\phi_k(\boldsymbol{y}) d\boldsymbol{y} = \lambda_k \phi_k(\boldsymbol{x}), \qquad k = 1, 2, \ldots, \tag{4.1}$$

where $\lambda_k = E[Y_k^2] > 0$. Furthermore, we have

$$R(\boldsymbol{x}, \boldsymbol{y}) = E[Y(\boldsymbol{x})Y(\boldsymbol{y})] = \sum_{k=1}^{\infty} \lambda_k \phi_k(\boldsymbol{x})\phi_k(\boldsymbol{y}). \tag{4.2}$$

Denote $\theta_k = Y_k/\sqrt{\lambda_k}$; then θ_k satisfy $E(\theta_k) = 0$ and $E(\theta_i \theta_j) = \delta_{ij}$. It follows that

$$Y(\boldsymbol{x}, \omega) = \sum_{k=1}^{\infty} \sqrt{\lambda_k}\theta_k(\omega)\phi_k(\boldsymbol{x}), \tag{4.3}$$

where ϕ_k and λ_k satisfy (4.1). We assume that the eigenvalues λ_k are ordered $\lambda_1 \ge \lambda_2 \ge \cdots$. The expansion (4.3) is called the Karhunen–Loève expansion (KLE) of

the stochastic process $Y(\boldsymbol{x},\omega)$. For finite discrete processes, the KLE reduces to the principal component decomposition.

In (4.3), the L^2 basis functions $\phi_k(\boldsymbol{x})$ are deterministic and resolve the spatial dependence of the permeability field. The randomness is represented by the scalar random variables θ_k. Generally, we need only to keep the leading order terms (quantified by the magnitude of λ_k) and still capture most of the energy of the stochastic process $Y(\boldsymbol{x},\omega)$. For a N-term KLE approximation $Y_N = \sum_{k=1}^{N} \sqrt{\lambda_k}\theta_k\phi_k$, we define the energy ratio of the approximation as

$$e(N) := \frac{E\|Y_N\|^2}{E\|Y\|^2} = \frac{\sum_{k=1}^{N}\lambda_k}{\sum_{k=1}^{\infty}\lambda_k}.$$

If $\lambda_k, k = 1, 2, \ldots$, decay very fast, then the truncated KLE would be good approximations of the stochastic process in the L^2 sense.

Suppose the permeability field $k(\boldsymbol{x},\omega)$ is a log-normal homogeneous stochastic process. Then $Y(\boldsymbol{x},\omega)$ is a Gaussian process and θ_k are independent standard Gaussian random variables. We assume that the covariance function of $Y(\boldsymbol{x},\omega)$ has the form

$$R(\boldsymbol{x},\boldsymbol{y}) = \sigma^2 \exp\left(-\frac{|x_1-y_1|^2}{2L_1^2} - \frac{|x_2-y_2|^2}{2L_2^2}\right). \tag{4.4}$$

In the above formula, L_1 and L_2 are the correlation lengths in each dimension, and $\sigma^2 = E(Y^2)$ is a constant. In our first example, we set $L_1 = 0.2$, $L_2 = 0.2$, and $\sigma^2 = 2$. We first solve the eigenvalue problem (4.1) numerically and obtain the eigenpairs $\{\lambda_k, \phi_k\}$. In Figure 4.1 the first 50 eigenvalues are plotted. As we can see, the eigenvalues of the KLE decay very fast. It has been shown in [8] that the eigenvalues decay exponentially fast for the covariance function (4.4). Therefore, only a small number of terms need to be retained in the truncated expansion (4.3). We can sample $Y(\boldsymbol{x},\omega)$ easily from the truncated KLE (4.3) by generating independent Gaussian random variables θ_k.

It is worth noting that for a different covariance function such as $R(\boldsymbol{x},\boldsymbol{y}) = \sigma^2 \exp\left(-\frac{|x_1-y_1|}{L_1} - \frac{|x_2-y_2|}{L_2}\right)$, the eigenvalues of the integral equation (4.1) may decay slowly (only algebraically [8]). To achieve the same accuracy, more terms should be retained in the truncated expansion (4.3), which will increase the dimension of the parameter space to represent the permeability. As a result, sampling the permeability from the distribution will be more expensive for both the direct MCMC method and the preconditioned MCMC method. However, small parameter space does not favor the preconditioned MCMC method, and the preconditioning technique is applicable independent of the problem dimension. For permeabilities with higher dimensional parameters, the acceptance rates of the direct MCMC method will be even lower. Consequently, the preconditioned MCMC method will be more preferable since its filtering procedure can increase the acceptance rates dramatically. Note that if the permeability field is not a log-normal process, then θ_k in the expansion (4.3) are not necessarily Gaussian random variables. However, we can still sample the permeability field from the truncated expansion (4.3) by sampling the random variables θ_k.

In the numerical experiments, we first generate a reference permeability field using all eigenvectors and compute the corresponding fractional flows. To propose permeability fields from the prior (unconditioned) distribution, we keep 20 terms in the KLE. Suppose the permeability field is known at eight distinct points. This

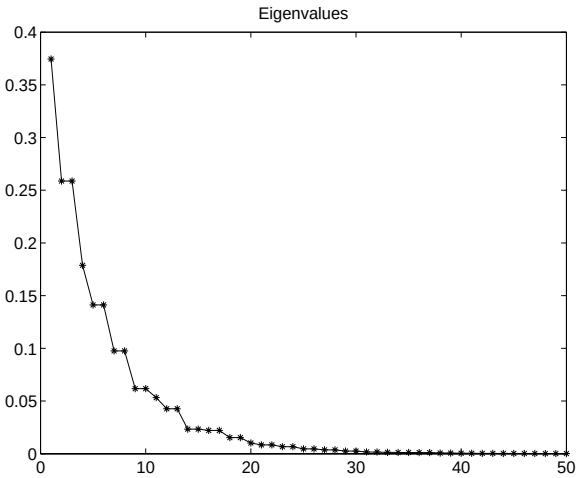

FIG. 4.1. *Eigenvalues of the KLE for the Gaussian covariance with $L_1 = L_2 = 0.2$. The eigenvalues decay very fast.*

condition is imposed by setting

$$\sum_{k=1}^{20} \sqrt{\lambda_k}\theta_k\phi_k(\boldsymbol{x}_j) = \alpha_j, \tag{4.5}$$

where α_j $(j = 1, \ldots, 8)$ are prescribed constants. For simplicity, we set $\alpha_j = 0$ for all $j = 1, \ldots, 8$. In the simulations we propose 12 θ_i and calculate the rest of θ_i by solving the linear system (4.5). In all the simulations, we test 50000 proposals and iterate the Markov chain 50000 times. Because the direct MCMC computations are expensive, we do not select the large model problems and consider only 40×40 and 60×60 fine-scale models. However, the preconditioned MCMC method is applicable independent of the size of the permeability field.

We have considered two types of instrumental proposal distributions $q(k|k_n)$: the independent sampler and the random walk sampler. In the case of the independent sampler, the proposal distribution $q(k|k_n)$ is chosen to be independent of k_n and equal to the prior (unconditioned) distribution. In the random walk sampler, the proposal distribution depends on the previous value of the permeability field and is given by

$$k = k_n + \epsilon_n, \tag{4.6}$$

where ϵ_n is a random perturbation with prescribed distribution. If the variance of ϵ_n is chosen to be very large, then the random walk sampler becomes similar to the independent sampler. Although the random walk sampler allows us to accept more realizations, it often gets stuck in the neighborhood of a local maximum of the target distribution. For both proposal distributions, we have observed consistently more than 10 times an increase in the acceptance rate when the preconditioned MCMC method is used.

For the first set of numerical tests, we use a 40×40 fine-scale permeability field and 10×10 coarse-scale models. The permeability field is assumed to be log-normal, with $L_1 = L_2 = 0.2$ and $\sigma^2 = 2$ for the covariance function (4.4). In Figure 4.2, the acceptance rates are plotted against different coarse-scale precisions, σ_c. Here

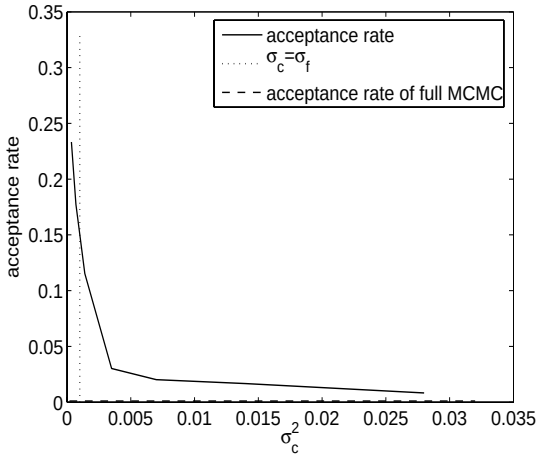

FIG. 4.2. *Acceptance rate versus different coarse-scale precisions for the preconditioned MCMC method. Single-phase flow and* $\sigma_f^2 = 0.001$.

the acceptance rate refers to the ratio between the number of accepted permeability samples and the number of fine-scale simulations that are performed. The acceptance rate for the direct (full) MCMC method is plotted using the dashed line, and it is equal to 0.001. The vertical dotted line marks the coarse-scale precision $\sigma_c = \sigma_f$. If σ_c is very small, then the total number of accepted realizations is also small, even though the acceptance rate is higher. We have found that if σ_c is of the same order as σ_f, then the preconditioned MCMC method accepts almost the same number of proposals as the direct MCMC method but requires only 10% of the fine-scale runs. Note that as σ_c increases the acceptance rate decreases and reaches the acceptance rate of the full MCMC method. Indeed, if σ_c is very large, then all the proposals will be accepted by the coarse-scale test, and there is no gain in preconditioning. In general, one can estimate the optimal σ_c based on a limited number of simulations, prior to the full simulations as described above.

In Figure 4.3 we plot the fractional flows of the accepted permeability realizations. On the left plot, the cross-plot between the reference fractional flow and the sampled fractional flows (of accepted realizations) is plotted. Since the reference fractional flow is the same for every accepted sample, the curve has jumps in the vertical direction. On the right plot, fractional flows of accepted samples are plotted using dotted lines. The bold solid line is the reference fractional flow curve. As we can see from these figures, the fractional flows of accepted realizations are very close to the observed fractional flow, because the precision is taken to be $\sigma_f^2 = 0.001$. In Figure 4.4, we plot the fractional flow error $E_k = \|F - F_k\|^2$ of the accepted samples for both the direct and preconditioned MCMC methods. We observe that the errors of both of the Markov chains converge to a steady state within 20 accepted iterations (corresponds to 20000 proposals). Note that we can assess the convergence of the MCMC methods based on the fractional flow errors. This is a reasonable indicator for the convergence and is frequently used in practice. Given the convergence result of the MCMC method, a longer chain can be easily generated when it is needed. We present a few accepted permeability realizations generated by the preconditioned MCMC method in Figure 4.5. The first plot is the reference (true) permeability field and the others are the last

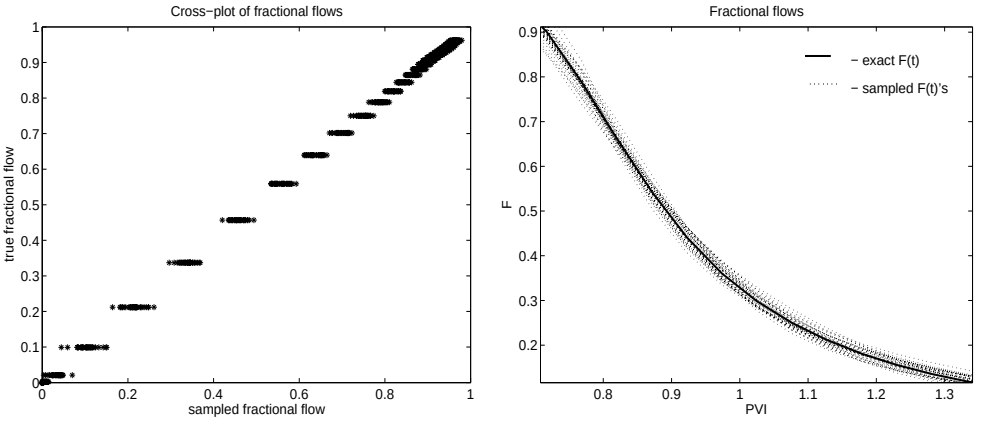

FIG. 4.3. *Fractional flow comparisons. Left: Cross-plot between the reference fractional flow and sampled fractional flows. Right: the solid line designates the fine-scale reference fractional flow, and dotted lines designate fractional flows corresponding to sampled permeability fields.*

five accepted permeability realizations. Some of these realizations closely resemble the true permeability field. Note that the fractional flows of these accepted realizations are in good agreements with the reference (true) fractional flow. One can use these samples for the uncertainty estimation.

For the next set of numerical examples, we consider an anisotropic permeability field with $L_1 = 0.4$, $L_2 = 0.05$, and $\sigma^2 = 2$ defined on a 60×60 fine grid. As in the previous example, we use eight conditioning points and truncate the KLE expansion of the permeability field with 20 terms to maintain a sufficient accuracy. In Figure 4.6, we plot the acceptance rates for 6×6 and 10×10 coarse-scale models against different choices of σ_c^2. The acceptance rate for the direct (full) MCMC method is 0.0008, and it is designated by the dashed line. The acceptance rate is increased by more than 10 times in the preconditioned MCMC method when σ_c is slightly larger than σ_f (the vertical dotted line marks the choice $\sigma_c = \sigma_f$). We also observe a higher acceptance

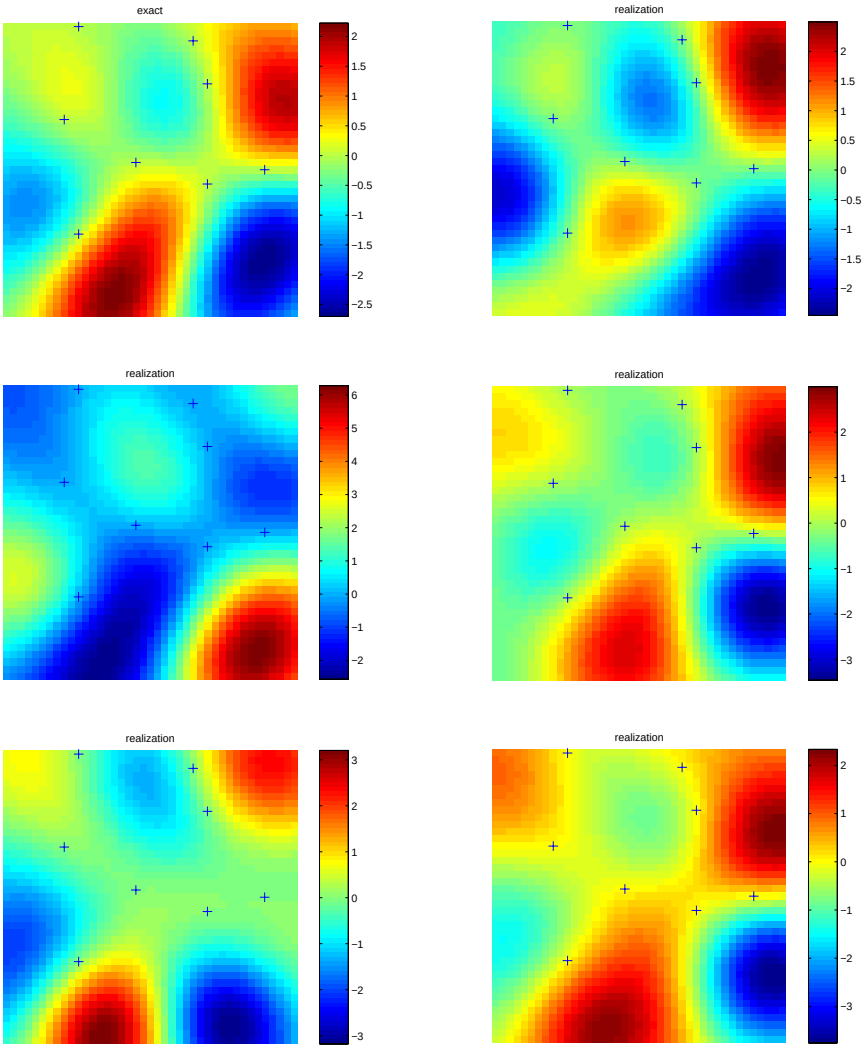

FIG. 4.5. *The last five accepted realizations of the log permeability field. The "+" sign marks the locations of the hard data.*

rate for the 10×10 coarse-scale model than for the 6×6 coarse-scale model. This is because the 10×10 coarse-scale model provides more accurate predictions of the fine-scale results compared to the 6×6 coarse-scale model. As in the previous cases, when the σ_c is slightly larger than σ_f, the preconditioned MCMC method can accept the same number of samples as the underlying full MCMC method but performs only 10% of the fine-scale simulations. Moreover, we have observed that both the direct (full) MCMC method and the preconditioned MCMC method converge to the steady state within 20 accepted iterations, which indicates that both chains have similar convergence properties. In Figure 4.7, we plot the last five accepted samples of the permeability field generated by the preconditioned MCMC method using the 6×6 coarse-scale model. Some of these samples closely resemble the reference (true)

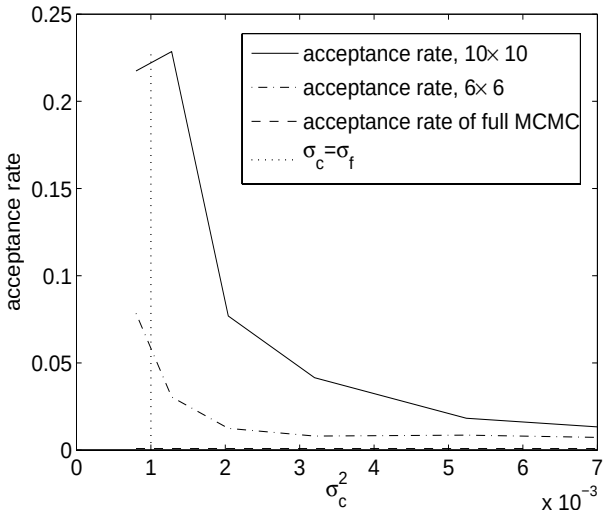

FIG. 4.6. *Acceptance rate versus different coarse-scale precisions of the MCMC method using* 6×6 *and* 10×10 *coarse-scale models. Anisotropic single-phase flow and* $\sigma_f^2 = 0.001$.

permeability field.

Our next set of numerical experiments are for the two-phase flow simulations. We have observed very similar results for two-phase flow simulations, and thus restrict our numerical results to only a few examples. We consider $\mu_w/\mu_o = 5$ and $k_{rw}(S) = S^2$, $k_{ro}(S) = (1-S)^2$. Typically, one observes similar behavior between the upscaling errors for single- and two-phase flows. We consider a 40×40 fine-scale log-normal permeability field with $L_1 = L_2 = 0.2$ and 10×10 coarse-scale models. In Figure 4.8, the acceptance rate for $\sigma_f^2 = 0.001$ is plotted. As in the case of the single-phase flow simulations, we observe more than 10 times an increase in the acceptance rate. The preconditioned MCMC method accepts the same amount of samples as in the full MCMC method with less than 10% of the fine-scale runs. To study the relative convergence of the preconditioned MCMC method, we plot the fractional flow error for both full and preconditioned MCMC simulations in Figure 4.9. It can be seen from this figure that both the full and preconditioned MCMC methods reach the steady state within 20 accepted iterations. This indicates that the direct and preconditioned MCMC methods have similar convergence properties. The typical samples for the two-phase flow are very similar to those for the single-phase flow, and we do not present them here.

Next we present some numerical results using the random walk sampler (4.6) as the instrumental proposal distribution. The random walk sampler proposes new permeability fields in a neighborhood of the previously accepted permeability field. This improves the acceptance rate in general, though the random walk sampler can get stuck in the neighborhood of the local maxima of the distribution. As a result, the MCMC method will accept a large number of realizations, but it takes a long time for the Markov chain to go from one local maxima to another local maxima. We consider 60×60 fine-scale permeability fields, with $L_1 = 0.4$, $L_2 = 0.05$, and $\sigma^2 = 2$ for the covariance function (4.4). In the preconditioning step, 10×10 and 6×6 coarse-scale models are used. In Figure 4.10, we present the acceptance rates for

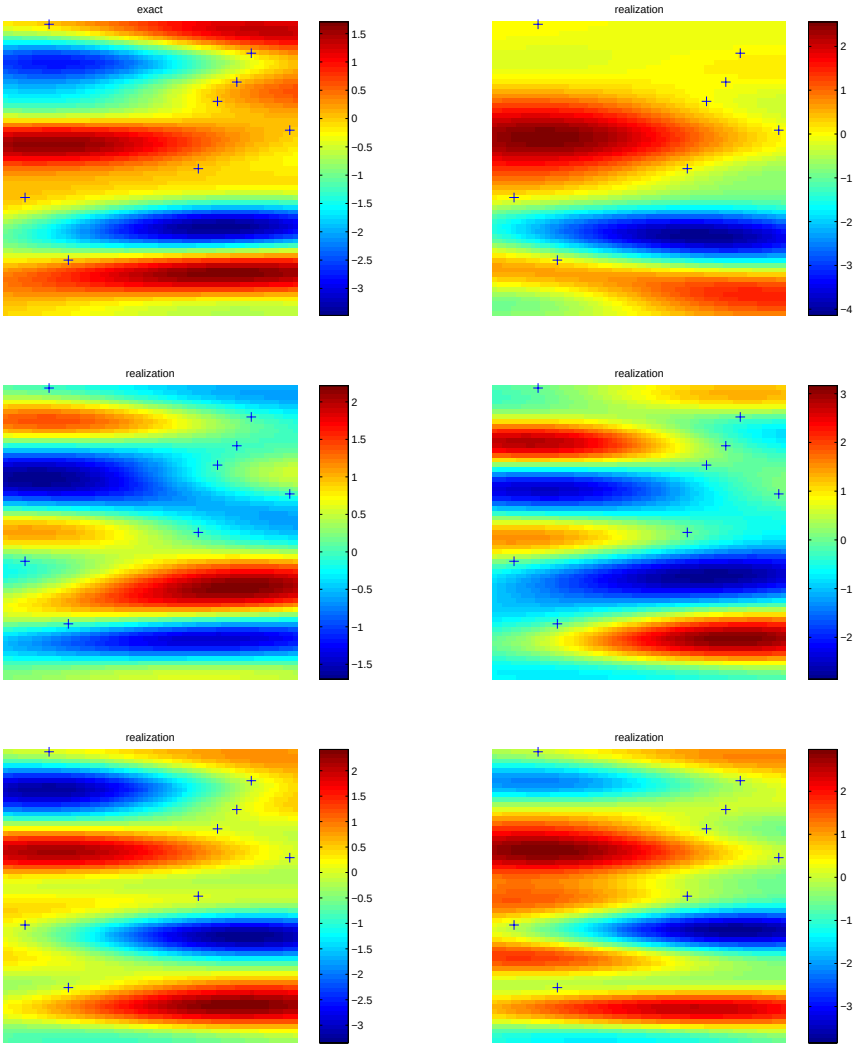

FIG. 4.7. *The last five accepted realizations of the log permeability field for the anisotropic case. The "+" sign marks the locations of the hard data.*

both coarse-scale models when the side-to-side boundary condition is used. In both cases, the acceptance rates are increased several times. In particular, the acceptance rate reaches its peak for σ_c close to σ_f and decreases as σ_c increases. We find that the generated chain k_n has a long correlation length and the nearby accepted permeability realizations are similar to each other. This indicates that the permeability realizations are sampled from a neighborhood of a local maxima, and consequently many proposals are required for a proper sampling. Next we study the convergence of the direct (full) and preconditioned MCMC methods using the random walk sampler (4.6). Figure 4.11 is the plot of the fractional flow errors against accepted iterations. As we can see from this figure, both the full MCMC method and the preconditioned MCMC method converge within 20 accepted iterations.

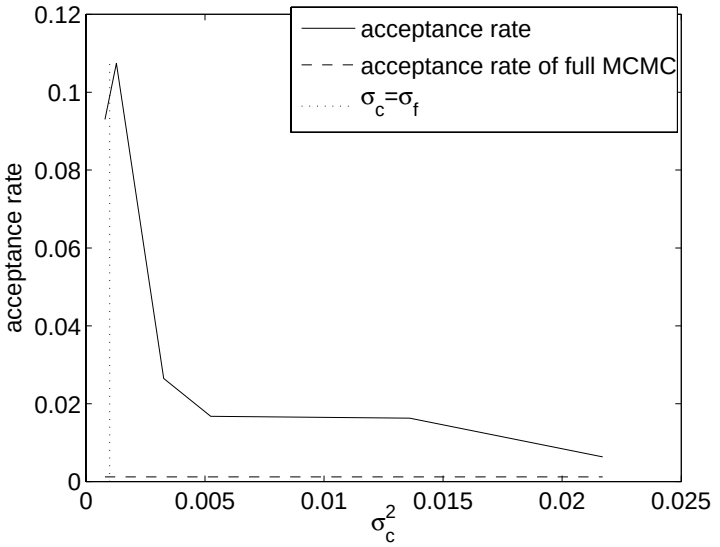

FIG. 4.8. *Acceptance rate versus coarse-scale precision of the MCMC method. Two-phase flow and* $\sigma_f^2 = 0.001$.

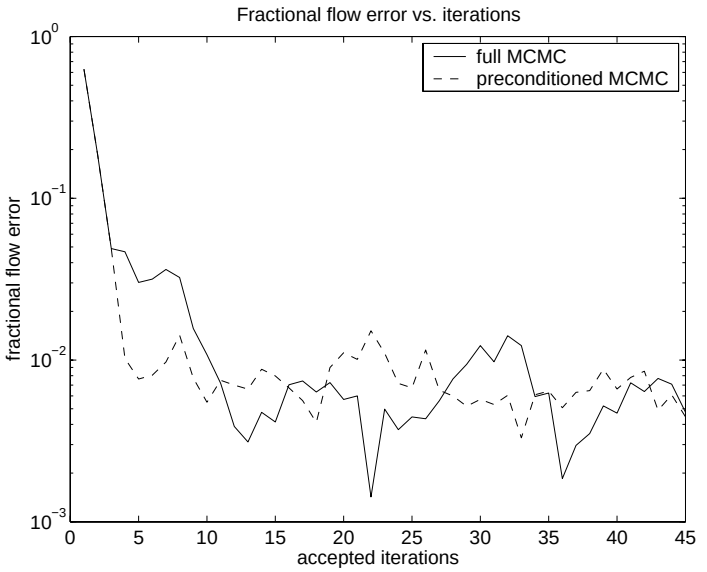

FIG. 4.9. *Fractional flow errors vresus accepted iterations in two phase-flow.*

Finally, we test the preconditioned MCMC method when different boundary conditions are used. In Figure 4.12, we compare the acceptance rates using 10×10 and 6×6 coarse-scale models for the side-to-side and the corner-to-corner boundary conditions. We obtain similar increases of the acceptance rates in the preconditioned MCMC method for the different boundary conditions. We have tested the preconditioned MCMC algorithm with more complicated boundary conditions involving mul-

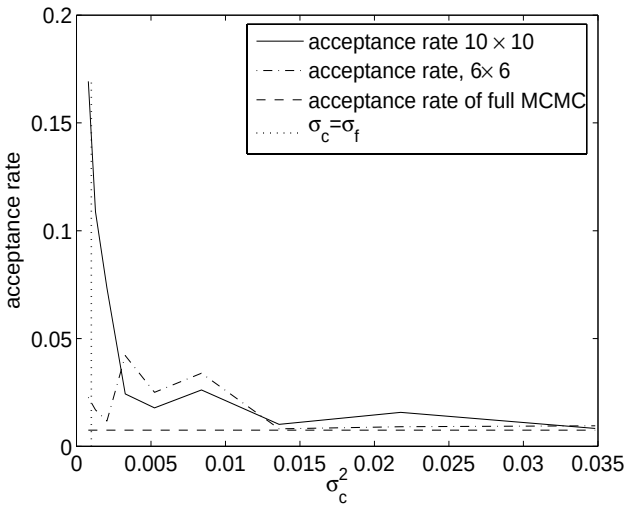

FIG. 4.10. *Acceptance rate versus coarse-scale precision of the MCMC method using* 6×6 *and* 10×10 *coarse-scale models. Single-phase flow and* $\sigma_f^2 = 0.001$. *The random walk sampler is used as the proposal distribution.*

tiple wells (source terms) that arise in petroleum applications (see [5]). In these numerical tests, the single-phase flow upscaling is used (as in [4]) since the multiscale finite volume methods require additional modifications to take into account the well information. The resulting preconditioned MCMC method can increase the acceptance rates by several times. In general, we have found the multiscale finite volume methods to be more accurate for coarse-scale simulations, and they can be further used for efficient and robust fine-scale simulations.

As we mentioned earlier, the full MCMC method and the preconditioned MCMC method accept approximately the same amount of samples for a fixed number of tested proposals. Denote N as the total number of tested proposals; then the direct MCMC method requires exactly N number of fine-scale simulations. Suppose $M < N$ is the number of fine-scale simulations conducted in the preconditioned MCMC method. Denote t_f and t_c as the CPU times for a single fine-scale and coarse-scale forward simulation. Then the computational costs for the direct MCMC method and the preconditioned MCMC method would be Nt_f and $Nt_c + Mt_f$, respectively. Therefore, the CPU cost for the preconditioned MCMC method is only $\frac{t_c}{t_f} + \frac{M}{N}$ that of the direct MCMC method. The coarse-scale computational cost t_c is usually much smaller than the fine-scale computational cost t_f. Suppose the fine-scale model is upscaled 5 times in each direction. Then solving the pressure equation at each time step is about 25 times faster on the coarse grid than on the fine grid. Moreover, the saturation equation is also solved on the [illegible] and with [illegible]. This makes the overall coarse-scale computations of the two-phase flow equation at least 25 times faster than the fine-scale computations, i.e., $t_c \approx 0.04 t_f$. If the acceptance rate is increased by more than 10 times in the preconditioned MCMC method, as in our numerical experiments, then $\frac{M}{N} < 0.1$, and the overall CPU cost of the preconditioned MCMC method would be only 10% of the CPU costs of the direct MCMC method. Note that using very coarse-scale models (fewer coarse blocks) reduces t_c but increases the

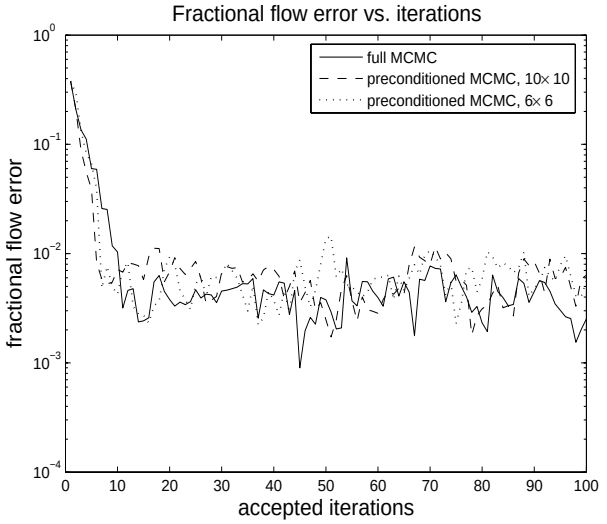

FIG. 4.11. *Fractional flow errors versus accepted iterations for* 6×6 *and* 10×10 *coarse-scale models. Single-phase flow and* $\sigma_f^2 = 0.001$. *The random walk sampler is used as the proposal distribution.*

fine-scale run ratio $\frac{M}{N}$. On the other hand, using finer coarse-scale models reduces the ratio $\frac{M}{N}$ but increases t_c. Consequently, a somewhat moderate coarsening (5–10 times coarsening in each direction for large-scale fine models) can provide an optimal choice in the preconditioning of the MCMC simulations.

One can use cruder approximation methods instead of physics-based upscaling methods in preconditioning the MCMC simulations. Next we discuss applying simple

averaging methods in the preconditioned MCMC method. Suppose that the proposal $k(\boldsymbol{x})$ can be represented by the KLE $\log(k(\boldsymbol{x})) = \sum_{k=1}^{n} c_k \phi_k(\boldsymbol{x})$. Denote $\phi_k^*(\boldsymbol{x})$ as the spatial average of $\phi_k(\boldsymbol{x})$ on the coarse grid

$$\phi_k^*(\boldsymbol{x}) = \sum_i \left(\frac{1}{|\Omega_i|} \int_{\Omega_i} \phi_k(\boldsymbol{x})\, d\boldsymbol{x} \right) 1_{\Omega_i}(\boldsymbol{x}),$$

where Ω_i are the coarse blocks. Then $k^*(\boldsymbol{x}) = \exp(\sum_{k=1}^{n} c_k \phi_k^*(\boldsymbol{x}))$ is a coarse-scale approximation of $k(\boldsymbol{x})$. We can use $k^*(\boldsymbol{x})$ in the coarse-scale simulations to determine whether or not to run the fine-scale simulations. We would like to note that this type of averaging is less expensive compared to the upscaling method used in the paper because it involves only volume average and it is performed only once. However, in general this type of averaging does not represent the correct average flow properties, and consequently the strong correlation between the fine-scale and coarse-scale quantities is not guaranteed. Our numerical results show that using simple averaging methods, such as the one presented here, can give an incorrect sampling. We have observed that averaging the KLE eigenfunctions leads to more uniform permeability fields. Consequently, the first stage of the preconditioned MCMC method restricts the proposal permeability to the more uniform fields and leads to incorrect sampling of the multimodal target distribution.

Finally, we would like to point out that the coarse-scale approximation techniques can also be efficiently used for other instrumental distributions. In our recent work [3], we have used coarse-scale approximations based on the multiscale finite volume methods in Langevin MCMC algorithms. In the Langevin MCMC algorithms, the gradient of the posterior distribution is used in the instrumental proposal distribution. The computation of the gradient of the posterior distribution is very expensive. We have employed the coarse-scale model in approximating the gradient and used a two-stage MCMC method in filtering these proposals. We have shown that one can achieve the acceptance rate comparable to the fine-scale Langevin MCMC with much less CPU time.

5. Conclusion. In this paper, we study the preconditioning of MCMC simulations using inexpensive coarse-scale runs in inverse problems related to subsurface characterization. For each MCMC proposal, a coarse-scale simulation is performed to decide whether or not to run the fine-scale simulations. The coarse scale simulation, which is based on the multiscale finite volume methods, filters unlikely acceptable proposals and avoids expensive fine-scale simulations for them. The filtering process takes into account the coarse-scale information of the problem and modifies the Markov chain generated by the MCMC method. We formulate the conditions which guarantee that the modified chain will converge to the correct posterior distribution. We also discuss the applicability of these conditions to the commonly used upscaling methods. Numerical examples show that we can achieve more than 10 times an increase in the acceptance rate if the MCMC simulations are preconditioned using coarse-scale models. The sampled realizations of the permeability field can be used in uncertainty quantification.

Appendix A. Coarse-scale models using multiscale finite volume methods. In this appendix, we discuss the details of the upscaled model used in the paper. The key idea of the method is the construction of the finite element basis functions on the coarse grids, such that these basis functions capture the small scale information on each coarse block. The method we will use follows its finite element counterpart

presented in [11]. The basis functions are constructed from the solution of the leading order homogeneous elliptic equation on each coarse element with carefully chosen boundary conditions. For a coarse element K with d vertices, the local basis functions $\phi^i, i = 1, \ldots, d$, satisfy the following elliptic problem:

$$\begin{aligned} -\nabla \cdot (k \cdot \nabla \phi^i) &= 0 \quad \text{in } K, \\ \phi^i &= g^i \quad \text{on } \partial K \end{aligned} \tag{A.1}$$

for some functions g^i defined on the boundary of the coarse element K. Hou and Wu [11] have demonstrated that a careful choice of the boundary condition would guarantee that the basis functions capture the local information of the solution, and hence improve the accuracy of the method. The function g^i for each i varies linearly along ∂K. Thus, ϕ^i will reduce to a standard linear/bilinear basis function for a constant diagonal tensor. Note that as usual we require $\phi^i(\xi_j) = \delta_{ij}$. Finally, a nodal basis function associated with each vertex ξ is constructed from the combination of the local basis functions that share this ξ. These nodal basis functions are denoted by $\{\psi_\xi\}_{\xi \in Z_h^0}$.

Denote by V^h the space for the approximate pressure solution which is spanned by the basis functions $\{\psi_\xi\}_{\xi \in Z_h^0}$. Based on (2.2), a statement of mass conservation is formed on each control volume V_ξ, where the approximate solution is expressed as a linear combination of the basis functions. Assembly of this mass conservation statement on all control volumes would give rise to a linear system of equations that can be solved accordingly. The resulting linear system has incorporated the fine-scale information through the involvement of the nodal basis functions on the approximate solution. To be more specific, the problem now is to seek $p^h \in V^h$ with $p^h = \sum_{\xi \in Z_h^0} p_\xi \psi_\xi$ such that

$$\int_{\partial V_\xi} \lambda(S) k \cdot \nabla p^h \cdot \vec{n}\, dl = \int_{V_\xi} f\, dA \tag{A.2}$$

for every control volume $V_\xi \subset \Omega$. Here $\vec{n}$ denotes the unit normal vector on the boundary ∂V_ξ of the control volume, and S is the fine-scale saturation field at this point. We note that concerning the basis functions, a vertex-centered finite volume difference is used to solve (A.1).

Once the pressure solution is available, it can be used to compute the total velocity field at the coarse-scale level, denoted by $\overline{\boldsymbol{v}} = (\overline{v}_x, \overline{v}_z)$ via (2.5). In general, the following formulas are used to compute the velocities in the horizontal and vertical directions, respectively:

$$\overline{v}_x = -\frac{1}{h_z} \sum_{\xi \in Z_h^0} p_\xi \left(\int_E \lambda(S) k_x \frac{\partial \psi_\xi}{\partial x} dz \right), \tag{A.3}$$

$$\overline{v}_z = -\frac{1}{h_x} \sum_{\xi \in Z_h^0} p_\xi \left(\int_E \lambda(S) k_z \frac{\partial \psi_\xi}{\partial z} dx \right), \tag{A.4}$$

where E is the edge of V_ξ. Furthermore, for the control volumes V_ξ adjacent to the Dirichlet boundary (which are half control volumes), we can derive the velocity approximation using the conservation statement derived from (2.2) on V_ξ. One of the terms involved is the integration along part of the Dirichlet boundary, while the other

three terms are known from the adjacent internal control volumes calculations. The analysis of the two-scale finite volume method can be found in [7].

As for the upscaling of the saturation equation, we use the coarse-scale velocity to update the saturation field on the coarse grid, i.e.,

$$\frac{\partial \overline{S}}{\partial t} + \overline{\boldsymbol{v}} \cdot \nabla f(\overline{S}) = 0, \tag{A.5}$$

where $\overline{S}$ denotes the saturation on the coarse grid. In this case the upscaling of the saturation equation does not take into account the subgrid effects. As we mentioned above, one can reconstruct the velocity field and solve the saturation equation on the fine grid. The latter, though more expensive, provides an accurate approximation of the production data.

Acknowledgments. The authors would like to thank the referees for valuable comments and suggestions and Victor Ginting for his help in preparing this manuscript.

RKDG FINITE ELEMENT METHOD COMBINED WITH BGK SCHEME FOR SOLVING FLUID DYNAMICS SYSTEM*

QINGFANG DAI† AND XIJUN YU†

Abstract. This paper presents a new type of second-order scheme for solving the system of Euler equations, which combines the Runge–Kutta discontinuous Galerkin (RKDG) finite element method and the Bhatnagar–Gross–Krook (BGK) scheme. We first discretize the Euler equations in space with the DG method, and then the resulting system will be discretized using an RK method. Finally, a second-order BGK method is used to construct the numerical flux. The proposed scheme keeps the main advantages of the DG finite element method, including its flexibility in handling irregular solution domains and in parallelization. Moreover, with the BGK approach the proposed schemes avoid using Riemann solvers. The efficiency and effectiveness of the proposed method are illustrated by several numerical examples in one- and two-dimensional spaces.

Key words. Runge–Kutta method, discontinuous Galerkin method, Bhatnagar–Gross–Krook method, Euler equations

1. Introduction.

In the past few years, there has been much important progress in constructing and analyzing high-resolution schemes for solving the hydromechanical Euler equations. Several high-order nonoscillatory schemes have been proposed, including TVD schemes [3], ENO schemes [4], NND schemes [38], and MmB schemes [33]. In the existing schemes, the upwinding-type schemes are very popular, partly because their dissipation is lower than that of many other types of schemes and they are very robust. However, upwinding schemes require computing exact or approximate Riemann solvers when being applied for solving hyperbolic conservation laws, which increases the numerical complexity and computational time. To overcome this difficulty, several methods have been investigated, including the flux vector splitting (FVS) scheme which splits the macroscopic flux vector directly. The first FVS scheme based on the gas-kinetic theory is the beam scheme which was proposed by Sanders and Prendergast [30]. Since the construction of the beam scheme uses three delta functions to approximate the equilibrium Maxwellian distribution function, the numerical dissipation is still high. The kinetic flux vector splitting (KFVS) method, which is similar to the beam scheme, splits the macroscopic flux vector based on the transport velocity symbol of the microcosmic molecule or particle. The KFVS scheme has been extensively studied in recent years, including by Pullin [14], Reitz [29], Deshpande [31], Macrossan [26], Perthame [12], and Eppard and Grossman [32]. Since the KFVS method is based on the collisionless Boltzmann equation, which ignores the particle collisions, the numerical dissipation of this method is higher than that of those classical high-resolution schemes. To include the real particle collisions in reducing the overdissipation in the KFVS scheme, a more accurate physical model

to approximate the particle collisions is needed. A good candidate for this purpose is the Bhatnagar–Gross–Krook (BGK) model. In 1990 [17], the BGK method based on the BGK model was developed. The BGK model is a microcosmic dynamical model raised by the concept of collision interval τ. The collision interval theory assumes that during a time dt, a fraction of dt/τ of molecules in a given small volume undergoes collision, which alters the velocity-distribution function from f to g (Maxwellian distribution function g is corresponding to the local values of ρ, u and T). This is equivalent to assuming that the rate of changes of f due to collisions is $(g - f)/\tau$, so the Boltzmann equation becomes

$$f_t + v \cdot \nabla_x f = \frac{g - f}{\tau}, \tag{1.1}$$

where $v = (v_x, v_y, v_z)$ is particle velocity and $u = (u_x, u_y, u_z)$ is macroscopic flow velocity. The earliest results were published in papers [16, 18]. This scheme has been further studied and simplified [19, 20, 21]. At the same time, the BGK method has been extended to multicomponent flow calculation [22] and the Euler equations with heat transfer [24]. In recent years, the BGK method has found its way into many applications, including astrophysics [15], aerodynamics [13], hydraulic engineering [25], and physical science [1, 2]. It has been demonstrated that the BGK scheme is robust and accurate in simulating various unsteady compressible flows. Both KFVS and BGK methods do not require computing Riemann solvers.

The discontinuous Galerkin (DG) finite element method was first introduced by Reed and Hill [34] to solve the neutron transport equation. The DG method has several advantages, including its flexibility in handling irregular solution domain, the requirement of fewer adjacent gridding points, and its highly self-adaptive and parallelization properties. Therefore, the DG finite element method has been developed rapidly in the past two decades. In particular, Cockburn and Shu successfully used the Runge–Kutta discontinuous Galerkin (RKDG) method and nonlinear limiters in solving hyperbolic conversation laws and the convection-dominated problems [5, 6, 7, 8, 9, 10, 11]. However, their schemes require using the Riemann solver, and it is difficult to distinguish the shock waves on the adjacent element interface. The main purpose of this work is to overcome these difficulties by improving the RKDG methods. To this end, we will apply the BGK flux constructing techniques based on the Boltzmann equation with collision term to RKDG methods. This work is to continue an earlier effort of the authors in [28, 35], where the RKDG methods were combined with the KFVS and the first-order BGK flux constructing techniques to solve the Euler equations. This work will make the scheme second-order accurate, which will be used to solve one-dimensional (1D) and two-dimensional (2D) Euler equations.

The organization of this paper is as follows. A class of second-order schemes obtained by combining the RKDG method with BGK numerical flux will be designed for 1D Euler equations in section 2 and 2D equations in section 3. Section 4 is devoted to the numerical experiments, which demonstrate the efficiency and effectiveness of the proposed schemes. The final section gives some concluding remarks.

2. Second-order scheme in one dimension. We consider the initial value problem for 1D hyperbolic conservation laws [37]:

$$\begin{cases} \dfrac{\partial U}{\partial t} + \dfrac{\partial F(U)}{\partial x} = 0 & \forall (x,t) \in R \times (0,T), \\ U(x,0) = U_0(x) & \forall x \in R, \end{cases} \tag{2.1}$$

where

$$U = (\rho, \rho u, E)^T, \quad F(U) = (\rho u, \rho u^2 + p, u(E + p))^T,$$

ρ is the density, u is the velocity, E is the total energy, and p is the pressure.

2.1. The DG finite element space discretization. For a partition of the interval R, $R = \cup_j^{\infty} I_j$, we set $I_j = (x_{j-1/2}, x_{j+1/2})$ and $\Delta x_j = x_{j+1/2} - x_{j-1/2}$ and use the piecewise interpolation polynomials to approximate U on I_j. The space of interpolated functions is

$$V_h = V_h^k = \{v_h \in L^{\infty}(R) : v_h \in P^k(I_j)\ \forall I_j\},$$

where $P^k(I_j)$ is a polynomial space of degree not exceeding k on I_j. Choose

$$P^k(I_j) = span\{v_i^{(j)}(x)\}_{i=0}^k,$$

where $v_i^{(j)}(x)$ is the Legendre polynomial over I_j,

$$v_0^{(j)}(x) = 1, v_1^{(j)}(x) = x - x_j, v_2^{(j)}(x) = (x - x_j)^2 - \frac{1}{12}\Delta x_j^2, \ldots. \tag{2.2}$$

Then the approximate solution of (2.1), $U_h \in V_h$, is defined by

$$U_h(x,t) = \sum_{l=0}^{k} a_l U_j^{(l)}(t) v_l^{(j)}(x)\ \forall x \in I_j, \tag{2.3}$$

where the coefficients a_l are given by

$$a_l = \frac{\Delta x_j^{l+1}}{\int_{I_j} (v_l^j(x))^2 dx}. \tag{2.4}$$

In particular, the first three coefficients are given by

$$a_0 = 1, \quad a_1 = 12/\Delta x_j, \quad a_2 = 180/\Delta x_j^2.$$

The degree of freedom in (2.3), $U_j^{(l)}(t)$, is defined by

$$U_j^{(l)} = U_j^{(l)}(t) = \frac{1}{\Delta x^{l+1}} \int_{I_j} U(x,t) v_l^{(j)}(x) dx, \quad l = 0, 1, \ldots, k. \tag{2.5}$$

To determine $U_j^{(l)}(t)$, we multiply (2.1) by $v_h \in V_h^k$ and integrate the resulting equation over I_j. Using integration by parts gives

$$\begin{aligned} &\frac{d}{dt} \int_{I_j} U(x,t) v_h(x) dx + [\Delta_+(v_h(x_{j-1/2}) F(U(x_{j-1/2}, t)))] \\ &\quad - \int_{I_j} F(U(x,t)) \frac{d}{dx} v_h(x) dx = 0\ \forall v_h \in V_h^k,\ \forall j \geq 1, \end{aligned} \tag{2.6}$$

where $\Delta_{\pm} a_j = \pm(a_{j\pm1} - a_j)$. In (2.6), the exact solution U will be replaced by its approximation, U_h, and $F(U(x_{j+1/2}, t))$ will be approximated by some monotone

numerical fluxes, $H_{j+1/2} = H(U_j, U_{j+1})$, where U_j is the average value of U_h over I_j. Then we obtain

$$\begin{aligned}(2.7)\qquad &\frac{d}{dt}U_j^{(l)}(t) + \frac{1}{\Delta x_j^{l+1}}[\Delta_+(v_l^{(j)}(x_{j-1/2})H_{j-1/2})] \\ &- \frac{1}{\Delta x_j^{l+1}}\int_{I_j} F(U_h(x,t))\frac{d}{dx}v_l^{(j)}(x)dx = 0, \quad l = 0, 1, \ldots, k, \quad j = 1, 2, \ldots.\end{aligned}$$

Note that the choice of numerical flux has no relation to the choice of finite element space. Therefore, if we choose $k = 0$, then the finite element space is a piecewise constant space. In this case, (2.7) can be rewritten as follows:

$$(2.8)\qquad \frac{d}{dt}U_j^{(0)}(t) + (H_{j+1/2} - H_{j-1/2})/\Delta x_j = 0 \ \forall j \geq 1.$$

This indicates that the first-order method above is a finite volume-type method and can also be regarded as a finite difference method when a uniform mesh is used.

It is known that properly constructing numerical fluxes is a key to the numerical methods for hyperbolic conservation laws. If (2.8) is a monotone scheme, then the numerical flux $H(a, b)$ has to satisfy the following conditions:

(1) $H(a, b)$ is locally Lipschitz continuous and consistent with the flux F, i.e.,

$$H(U, U) = F(U).$$

(2) $H(a, b)$ is a nondecreasing function of its first argument and a nonincreasing function of its second argument.

2.2. The RK time discretization. It is noted that (2.7) leads to an ODE system

$$(2.9)\qquad \frac{d}{dt}U_h = L_h(U_h, t).$$

In order to obtain high-order accuracy in time, we use the RK formula to solve the ODE system (2.9). The $(k + 1)$th order accuracy in space can be achieved in smooth regions when the kth order polynomials are chosen (see, e.g., [5, 7]). Thus, to unify the accuracy in space and time, we use an $(k + 1)$th order time discretization. Similar to the finite difference theory, for the RKDG method the numerical solution at each time step also needs to be limited (only for the polynomials of degree ≥ 1) to enhance the nonlinear stability of the numerical method.

Let $\{t^n\}_0^N$ be a partition for $[0, T]$ and $\Delta t^n := t^{n+1} - t^n, 0 \leq n \leq N - 1$, be the time step. Below we briefly describe the $(k + 1)$th order RK time discretization for (2.9).

1. $U_h^0 = P(U_0)$.
2. For $n = 0, \ldots, N - 1$ compute U_h^{n+1} as follows:
   a. set $U_h^{(0)} = U_h^n$.
   b. for $i = 1, \ldots, k + 1$ compute the intermediate functions:

$$U_h^{(i)} = \sum_{l=0}^{i-1} [\alpha_{il}U_h^{(l)} + \beta_{il}\Delta t^n L_h(U_h^{(l)}, t^n + d_l\Delta t^n)].$$

3. Set $U_h^{n+1} = U_h^{(k+1)}$.

After a local slope limiter operator $\Lambda\Pi_h$ is introduced, the above algorithm becomes the following.

1. $U_h^0 = \Lambda\Pi_h P(U_0)$.
2. For $n = 0, \ldots, N-1$ compute U_h^{n+1} as follows:
   a. set $U_h^{(0)} = U_h^n$.
   b. for $i = 1, \ldots, k+1$ compute the intermediate functions:

$$U_h^{(i)} = \Lambda\Pi_h \left\{ \sum_{l=0}^{i-1} [\alpha_{il} U_h^{(l)} + \beta_{il} \Delta t^n L_h(U_h^{(l)}, t^n + d_l \Delta t^n)] \right\}. \tag{2.10}$$

3. Set $U_h^{n+1} = U_h^{(k+1)}$.

Some detailed analysis for the limiter $\Lambda\Pi_h$ can be found in [5]. The parameters in the above formula are as follows.

• Second-order accuracy (i.e., $k+1=2$):

$$\alpha_{10} = \beta_{10} = 1; \quad \alpha_{20} = \alpha_{21} = \beta_{21} = \tfrac{1}{2}$$
$$\beta_{20} = 0; \quad d_0 = 0; \quad d_1 = 1.$$

• Third-order accuracy (i.e., $k+1=3$):

$$\alpha_{10} = \beta_{10} = 1; \quad \alpha_{20} = \tfrac{3}{4}; \quad \beta_{20} = 0;$$
$$\alpha_{21} = \beta_{21} = \tfrac{1}{4}; \quad \alpha_{30} = \tfrac{1}{3}; \quad \beta_{30} = \alpha_{31} = \beta_{31} = 0;$$
$$\alpha_{32} = \beta_{32} = \tfrac{2}{3}; \quad d_0 = 0; \quad d_1 = 1, \quad d_2 = \tfrac{1}{2}.$$

The numerical scheme (2.7) with (2.10) is the RKDG finite scheme for solving the 1D hyperbolic equation (2.1).

2.3. Second-order BGK numerical flux. For scheme (2.7) with (2.10), if the linear finite element method is used, then the accuracy is of second order on the spatial direction. In this case, for the numerical flux in (2.7), we need to solve Riemann problems when it is across the cell interface. To preserve the second-order accuracy in space and avoid using the Riemann solvers, we will construct second-order accurate numerical fluxes $H_{j+1/2}$ by using the relation between the Euler equations and the Boltzmann equation. In particular, we will construct a second-order BGK numerical flux.

In Boltzmann equation (1.1), due to the mass, momentum, and energy conservations in the process of particle collisions, the collision term satisfies the following compatibility condition:

$$\iint \frac{g-f}{\tau} \psi dv d\xi = 0. \tag{2.11}$$

Here the molecular equilibrium velocity distribution function g is taken for the Maxwell–Boltzmann distribution

$$g = \rho \left(\frac{\lambda}{\pi}\right)^{\frac{k+3}{2}} e^{-\lambda[(v-u)^2+\xi^2]}$$

and the moment vector function ψ,

$$\psi = (1, v_x, v_y, v_z, \tfrac{1}{2}(v^2+\xi^2))^T,$$

where $(v-u)^2=(v_x-u_x)^2+(v_y-u_y)^2+(v_z-u_z)^2$, $\xi^2=\xi_1^2+\cdots+\xi_K^2$, $\lambda=\rho/2p$, $K=2/(\gamma-1)-d$ is the internal freedom degree of particle, and d is the dimension of space. Equations (1.1) and (2.11) are the famous BGK model.

To construct a second-order BGK numerical flux, we need to reconstruct the initial data. In one dimension, for uniform partition, the conservation variables in $I_j=(x_{j-1/2},x_{j+1/2})$ and $U_j=(\rho_j,\rho_j u_j,E_j)$ can be reconstructed as follows:

$$\bar{U}_j(x)=U_j+L(s_{j+},s_{j-})(x-x_j)$$

by using the Van Leer limiter

$$L(s_{j+},s_{j-})=S(s_{j+},s_{j-})\frac{|s_{j+}||s_{j-}|}{|s_{j+}|+|s_{j-}|}$$

or the MUSCL limiter

$$L(s_{j+},s_{j-})=S(s_{j+},s_{j-})\min\left(\frac{1}{2}|s_{j+}+s_{j-}|,2|s_{j+}|,2|s_{j-}|\right), \tag{2.12}$$

where

$$S(s_{j+},s_{j-})=sign(s_{j+})+sign(s_{j-}),$$

$$s_{j+}=\frac{(U_{j+1}-U_j)}{\Delta x},\quad s_{j-}=\frac{(U_j-U_{j-1})}{\Delta x},$$

$sign(\cdot)$ being the sign function. In our numerical experiments (section 4), the Van Leer limiter was used.

From the above formula, the flow variables $\bar{U}_j(x)$ at the cell interface $x_{j-1/2}$ and $x_{j+1/2}$ of I_j are given by

$$\bar{U}_j(x_{j-1/2})=U_j-\frac{\Delta x}{2}L(s_{j+},s_{j-}),\quad \bar{U}_j(x_{j+1/2})=U_j+\frac{\Delta x}{2}L(s_{j+},s_{j-})$$

and $\bar{U}_j(x_j)=U_j$ at the cell center x_j.

For the BGK model (1.1) and (2.11), the equivalent integral solution of f at the cell interface $x_{j+1/2}$ and time t is [23]

$$f(x_{j+1/2},t,v,\xi)=\frac{1}{\tau}\int_0^t g(x',t',v,\xi)e^{\frac{-(t-t')}{\tau}}dt'+e^{\frac{-t}{\tau}}f_0(x_{j+1/2}-vt), \tag{2.13}$$

where $x'=x_{j+1/2}-v(t-t')$ is the trajectory of a particle motion, f_0 is the initial distribution function at the beginning of each time step, and g is the corresponding equilibrium function to the point $(x_{j+1/2},t^n)$. To obtain the solution f, both f_0 and g must be specified in the above equation.

For the second-order scheme, f_0 and g around the cell interface $x_{j+1/2}$ are given by

$$f_0=\begin{cases} g_l[1+a_l(x-x_{j+1/2})], & x<x_{j+1/2},\\ g_r[1+a_r(x-x_{j+1/2})], & x>x_{j+1/2}, \end{cases} \tag{2.14}$$

and

$$g=g_0[1+(1-H(x-x_{j+\frac{1}{2}}))\bar{a}_l(x-x_{j+\frac{1}{2}})+H(x-x_{j+\frac{1}{2}})\bar{a}_r(x-x_{j+\frac{1}{2}})+\bar{A}t], \tag{2.15}$$

where g_l and g_r are local Maxwellian distribution functions located to the left and to the right, g_0 is the local Maxwellian distribution function at the center of a cell interface, and $H(\mathrm{x})$ is a Heaviside function,

$$H(x) = \begin{cases} 0, & x < x_{j+1/2}, \\ 1, & x \geq x_{j+1/2}, \end{cases}$$

and $a_l, a_r, \bar{a}_l, \bar{a}_r$, and $\bar{A}$ depend on the particle velocity v and the internal variable ξ. Using the second-order Taylor expansion gives

$$\begin{aligned} a_l &= a_{1l} + a_{2l}v + a_{3l}\frac{1}{2}(v^2 + \xi^2), \\ a_r &= a_{1r} + a_{2r}v + a_{3r}\frac{1}{2}(v^2 + \xi^2), \\ \bar{a}_l &= \bar{a}_{1l} + \bar{a}_{2l}v + \bar{a}_{3l}\frac{1}{2}(v^2 + \xi^2), \\ \bar{a}_r &= \bar{a}_{1r} + \bar{a}_{2r}v + \bar{a}_{3r}\frac{1}{2}(v^2 + \xi^2), \\ \bar{A} &= \bar{A}_1 + \bar{A}_2 v + \bar{A}_3\frac{1}{2}(v^2 + \xi^2). \end{aligned}$$

Using the relationship between the macroscopic variables and the velocity distribution function

$$\int f_0 \psi dv d\xi = \bar{U}_j(x), \quad x_{j-1/2} \leq x \leq x_{j+1/2},$$

we have

$$\int \psi g_l dv d\xi = \begin{pmatrix} \bar{\rho}_j(x_{j+1/2}) \\ \bar{\rho}_j \bar{u}_j(x_{j+1/2}) \\ \bar{E}_j(x_{j+1/2}) \end{pmatrix}, \quad \int \psi g_r dv d\xi = \begin{pmatrix} \bar{\rho}_{j+1}(x_{j+1/2}) \\ \bar{\rho}_{j+1}\bar{u}_{j+1}(x_{j+1/2}) \\ \bar{E}_{j+1}(x_{j+1/2}) \end{pmatrix}, \tag{2.16}$$

$$\int \psi a_l g_l dv d\xi = \begin{pmatrix} \dfrac{\bar{\rho}_j(x_{j+1/2}) - \bar{\rho}_j(x_j)}{\Delta x^-} \\ \dfrac{\bar{\rho}_j \bar{u}_j(x_{j+1/2}) - \bar{\rho}_j \bar{u}_j(x_j)}{\Delta x^-} \\ \dfrac{\bar{E}_j(x_{j+1/2}) - \bar{E}_j(x_j)}{\Delta x^-} \end{pmatrix},$$

$$\int \psi a_r g_r dv d\xi = \begin{pmatrix} \dfrac{\bar{\rho}_{j+1}(x_{j+1}) - \bar{\rho}_{j+1}(x_{j+1/2})}{\Delta x^+} \\ \dfrac{\bar{\rho}_{j+1}\bar{u}_{j+1}(x_{j+1}) - \bar{\rho}_{j+1}\bar{u}_{j+1}(x_{j+1/2})}{\Delta x^+} \\ \dfrac{\bar{E}_{j+1}(x_{j+1}) - \bar{E}_{j+1}(x_{j+1/2})}{\Delta x^+} \end{pmatrix}, \tag{2.16$'$}$$

where $\Delta x^- = x_{j+1/2} - x_j$, $\Delta x^+ = x_{j+1} - x_{j+1/2}$. With the definition of the Maxwellian distribution functions

$$g_l = \rho_l \left(\frac{\lambda_l}{\pi}\right)^{\frac{K+1}{2}} e^{-\lambda_l[(v-u_l)^2+\xi^2]}, \quad g_r = \rho_r \left(\frac{\lambda_r}{\pi}\right)^{\frac{K+1}{2}} e^{-\lambda_r[(v-u_r)^2+\xi^2]}$$

and from equations (2.16), we obtain ρ, u, λ in both equilibrium states g_l and g_r, respectively:

$$\begin{pmatrix} \rho_l \\ u_l \\ \lambda_l \end{pmatrix} = \begin{pmatrix} \bar{\rho}_j(x_{j+1/2}) \\ \bar{u}_j(x_{j+1/2}) \\ \dfrac{(K+1)\bar{\rho}_j(x_{j+1/2})}{4(\bar{E}_j(x_{j+1/2}) - \frac{1}{2}\bar{\rho}_j\bar{u}_j^2(x_{j+1/2}))} \end{pmatrix},$$

$$\begin{pmatrix} \rho_r \\ u_r \\ \lambda_r \end{pmatrix} = \begin{pmatrix} \bar{\rho}_{j+1}(x_{j+1/2}) \\ \bar{u}_{j+1}(x_{j+1/2}) \\ \dfrac{(K+1)\bar{\rho}_{j+1}(x_{j+1/2})}{4(\bar{E}_{j+1}(x_{j+1/2}) - \frac{1}{2}\bar{\rho}_{j+1}\bar{u}_{j+1}^2(x_{j+1/2}))} \end{pmatrix}.$$

It follows from (2.16)′ that

$$\frac{1}{\rho_l}\begin{pmatrix} \dfrac{\bar{\rho}_j(x_{j+1/2}) - \bar{\rho}_j(x_j)}{\Delta x^-} \\ \dfrac{\bar{\rho}_j\bar{u}_j(x_{j+1/2}) - \bar{\rho}_j\bar{u}_j(x_j)}{\Delta x^-} \\ \dfrac{\bar{E}_j(x_{j+1/2}) - \bar{E}_j(x_j)}{\Delta x^-} \end{pmatrix} \equiv \frac{1}{\rho_l}\begin{pmatrix} \left(\dfrac{\partial \rho}{\partial x}\right)^l \\ \left(\dfrac{\partial \rho u}{\partial x}\right)^l \\ \left(\dfrac{\partial E}{\partial x}\right)^l \end{pmatrix} = M^l_{\alpha\beta}\begin{pmatrix} a_{1l} \\ a_{2l} \\ a_{3l} \end{pmatrix},$$

$$\frac{1}{\rho_r}\begin{pmatrix} \dfrac{\bar{\rho}_{j+1}(x_{j+1}) - \bar{\rho}_{j+1}(x_{j+1/2})}{\Delta x^+} \\ \dfrac{\bar{\rho}_{j+1}\bar{u}_{j+1}(x_{j+1}) - \bar{\rho}_{j+1}\bar{u}_{j+1}(x_{j+1/2})}{\Delta x^+} \\ \dfrac{\bar{E}_{j+1}(x_{j+1}) - \bar{E}_{j+1}(x_{j+1/2})}{\Delta x^+} \end{pmatrix} \equiv \frac{1}{\rho_r}\begin{pmatrix} \left(\dfrac{\partial \rho}{\partial x}\right)^r \\ \left(\dfrac{\partial \rho u}{\partial x}\right)^r \\ \left(\dfrac{\partial E}{\partial x}\right)^r \end{pmatrix} = M^r_{\alpha\beta}\begin{pmatrix} a_{1r} \\ a_{2r} \\ a_{3r} \end{pmatrix},$$

(2.17)

where the symmetric matrices $M^l_{\alpha\beta}$ and $M^r_{\alpha\beta}$ are given by

$$M^l_{\alpha\beta} = \begin{pmatrix} 1 & u_l & \dfrac{1}{2}\left(u_l^2 + \dfrac{K+1}{2\lambda_l}\right) \\ u_l & u_l^2 + \dfrac{1}{2\lambda_l} & \dfrac{1}{2}\left(u_l^3 + \dfrac{(K+3)u_l}{2\lambda_l}\right) \\ \dfrac{1}{2}\left(u_l^2 + \dfrac{K+1}{2\lambda_l}\right) & \dfrac{1}{2}\left(u_l^3 + \dfrac{(K+3)u_l}{2\lambda_l}\right) & \dfrac{1}{2}\left(u_l^4 + \dfrac{(K+3)u_l^2}{\lambda_l} + \dfrac{(K^2+4K+3)}{4\lambda_l^2}\right) \end{pmatrix},$$

$$M^r_{\alpha\beta} = \begin{pmatrix} 1 & u_r & \dfrac{1}{2}\left(u_r^2 + \dfrac{K+1}{2\lambda_r}\right) \\ u_r & u_r^2 + \dfrac{1}{2\lambda_r} & \dfrac{1}{2}\left(u_r^3 + \dfrac{(K+3)u_r}{2\lambda_r}\right) \\ \dfrac{1}{2}\left(u_r^2 + \dfrac{K+1}{2\lambda_r}\right) & \dfrac{1}{2}\left(u_r^3 + \dfrac{(K+3)u_r}{2\lambda_r}\right) & \dfrac{1}{2}\left(u_r^4 + \dfrac{(K+3)u_r^2}{\lambda_r} + \dfrac{(K^2+4K+3)}{4\lambda_r^2}\right) \end{pmatrix}.$$

(2.18)

Using (2.17) and (2.18) gives

$$
\begin{aligned}
a_{3m} &= \frac{4\lambda_m^2}{K+1}\left(2\left(\frac{\partial \varepsilon}{\partial x}\right)^m - 2u_m\left(\frac{\partial u}{\partial x}\right)^m\right),\\
a_{2m} &= 2\lambda_m\left(\left(\frac{\partial u}{\partial x}\right)^m - \frac{u_m}{2\lambda_m}a_{3m}\right),\\
a_{1m} &= \frac{1}{\rho_m}\left(\frac{\partial \rho}{\partial x}\right)^m - a_{2m}u_m - a_{3m}\left(\frac{u_m^2}{2} + \frac{K+1}{4\lambda_m}\right),
\end{aligned}
\tag{2.19}
$$

where

$$
\begin{aligned}
\left(\frac{\partial u}{\partial x}\right)^m &= \frac{1}{\rho_m}\left(\left(\frac{\partial(\rho u)}{\partial x}\right)^m - u_m\left(\frac{\partial \rho}{\partial x}\right)^m\right),\\
\left(\frac{\partial \varepsilon}{\partial x}\right)^m &= \frac{1}{\rho_m}\left(\left(\frac{\partial E}{\partial x}\right)^m - \frac{1}{2}\left(u_m^2 + \frac{K+1}{2\lambda_m}\right)\left(\frac{\partial \rho}{\partial x}\right)^m\right), \quad m = l, r.
\end{aligned}
$$

Thus the initial distribution function after reconstruction is obtained. To determine g_0, we take the limit $t \to 0$ in (2.13) and substitute the result into (2.11) to have

$$
\iint g_0 \psi dv d\xi = \iint_{v>0} g_l \psi dv d\xi + \iint_{v<0} g_r \psi dv d\xi. \tag{2.20}
$$

Since

$$
\lambda_0 = \frac{(K+1)\rho_0}{4(E_0 - \frac{1}{2}\rho_0 u_0^2)},
$$

we need only to know $(\rho_0, \rho_0 u_0, E_0)^T$, which can be expressed as moments of g_l and g_r. From (2.20), we have

$$
\begin{pmatrix} \rho_0 \\ \rho_0 u_0 \\ E_0 \end{pmatrix} = \begin{pmatrix} \rho_l \langle v^0 \rangle_{v>0} + \rho_r \langle v^0 \rangle_{v<0} \\ \rho_l \langle v^1 \rangle_{v>0} + \rho_r \langle v^1 \rangle_{v<0} \\ \frac{1}{2}\rho_l \langle v^2 + \xi^2 \rangle_{v>0} + \frac{1}{2}\rho_r \langle v^2 + \xi^2 \rangle_{v<0} \end{pmatrix},
$$

where

$$
\rho_l \langle \cdots \rangle_{v>0} = \iint_{v>0} (\cdots) g_l dv d\xi,
$$

$$
\rho_r \langle \cdots \rangle_{v<0} = \iint_{v<0} (\cdots) g_r dv d\xi.
$$

After obtaining g_0, $\bar{a}_l$ and $\bar{a}_r$ in (2.15) can be computed through the relation

$$
\frac{1}{\rho_0}\begin{pmatrix} \dfrac{\bar{\rho}_{j+1}(x_{j+1}) - \rho_0}{\Delta x^+} \\ \dfrac{\bar{\rho}_{j+1}\bar{u}_{j+1}(x_{j+1}) - \rho_0 u_0}{\Delta x^+} \\ \dfrac{\bar{E}_{j+1}(x_{j+1}) - E_0}{\Delta x^+} \end{pmatrix} = \bar{M}^0_{\alpha\beta}\begin{pmatrix} \bar{a}_{1r} \\ \bar{a}_{2r} \\ \bar{a}_{3r} \end{pmatrix} \tag{2.21}
$$

and

$$\frac{1}{\rho_0}\begin{pmatrix} \dfrac{\rho_0-\bar{\rho}_j(x_j)}{\Delta x^-} \\ \dfrac{\rho_0 u_0-\bar{\rho}_j\bar{u}_j(x_j)}{\Delta x^-} \\ \dfrac{E_0-\bar{E}_j(x_j)}{\Delta x^-} \end{pmatrix} = \bar{M}^0_{\alpha\beta}\begin{pmatrix} \bar{a}_{1l} \\ \bar{a}_{2l} \\ \bar{a}_{3l} \end{pmatrix}, \tag{2.21}'$$

where the matrix $\bar{M}^0_{\alpha\beta}=\frac{1}{\rho_0}\int g_0\psi_\alpha\psi_\beta dvd\xi$ has the same form as $M^r_{\alpha\beta}$, that is,

$$\bar{M}^0_{\alpha\beta}=\begin{pmatrix} 1 & u_0 & \frac{1}{2}\left(u_0^2+\frac{K+1}{2\lambda_0}\right) \\ u_0 & u_0^2+\frac{1}{2\lambda_0} & \frac{1}{2}\left(u_0^3+\frac{(K+3)u_0}{2\lambda_0}\right) \\ \frac{1}{2}\left(u_0^2+\frac{K+1}{2\lambda_0}\right) & \frac{1}{2}\left(u_0^3+\frac{(K+3)u_0}{2\lambda_0}\right) & \frac{1}{2}\left(u_0^4+\frac{(K+3)u_0^2}{\lambda_0}+\frac{(K^2+4K+3)}{4\lambda_0^2}\right) \end{pmatrix}.$$

Therefore, $(\bar{a}_{1l},\bar{a}_{2l},\bar{a}_{3l})^T$ and $(\bar{a}_{1r},\bar{a}_{2r},\bar{a}_{3r})^T$ can be found through the procedure similar to (2.19).

Substituting (2.14) and (2.15) into (2.13), the final gas distribution function at a cell interface can be written as

$$\begin{aligned} f(x_{j+1/2},t,v,\xi) &= (1-e^{-t\tau})g_0 \\ &\quad +(\tau(-1+e^{-t/\tau})+te^{-t/\tau})(\bar{a}_lH(v)+\bar{a}_r(1-H(v)))vg_0 \\ &\quad +\tau(t/\tau-1+e^{-t/\tau})\bar{A}g_0 \\ &\quad +e^{-t/\tau}((1-vta_l)H(v)g_l+(1-vta_r)(1-H(v))g_r). \end{aligned} \tag{2.22}$$

To determine the only unknown term $\bar{A}$ in the above expression, using the relation (2.11) at the cell interface $x_{j+1/2}$ and integrating it over the whole time step Δt, we have

$$\int_0^{\Delta t}\int((g_0+\bar{A}g_0t)-f)\psi dvd\xi dt=0.$$

Substituting (2.22) into the above equation gives

$$\int_0^{\Delta t}\int(\tau-\tau e^{-t/\tau})\bar{A}g_0\psi dvd\xi dt=\int_0^{\Delta t}\int\eta\psi dvd\xi dt,$$

where

$$\begin{aligned} \eta &= -e^{-t/\tau}g_0 \\ &\quad +(\tau(-1+e^{-t/\tau})+te^{-t/\tau})(\bar{a}_lH(v)+\bar{a}_r(1-H(v)))vg_0 \\ &\quad +e^{-t/\tau}((1-vta_l)H(v)g_l+(1-vta_r)(1-H(v))g_r). \end{aligned}$$

With the integrating relations

$$\int_0^{\Delta t}(\tau-\tau e^{-t/\tau})dt=\tau(\Delta t-\tau(1-e^{-\Delta t/\tau})),$$
$$\int_0^{\Delta t}e^{-t/\tau}dt=\tau(1-e^{-\Delta t/\tau}),$$
$$\int_0^{\Delta t}(\tau(-1+e^{-t/\tau})+te^{-t/\tau})dt=-\tau\Delta t+2\tau^2(1-e^{-\Delta t/\tau})-\tau\Delta te^{-\Delta t/\tau},$$
$$\int_0^{\Delta t}te^{-t/\tau}dt=-\tau\Delta te^{-\Delta t/\tau}+\tau^2(1-e^{-\Delta t/\tau}),$$

we obtain

$$\begin{aligned}\int\bar{A}g_0\psi dvd\xi dt=\int&[\gamma_1 g_0+\gamma_2 v(\bar{a}_l H(v)+\bar{a}_r(1-H(v)))g_0\\&+\gamma_3(H(v)g_l+(1-H(v))g_r)\\&+\gamma_4 v(a_l H(v)g_l+a_r(1-H(v))g_r)]\psi dvd\xi,\end{aligned}\tag{2.23}$$

where

$$\begin{aligned}\gamma_0&=\Delta t-\tau(1-e^{-\Delta t/\tau}),\\\gamma_1&=-(1-e^{-\Delta t/\tau})/\gamma_0,\\\gamma_2&=(-\Delta t+2\tau(1-e^{-\Delta t/\tau})-\Delta te^{-\Delta t/\tau})/\gamma_0,\\\gamma_3&=(1-e^{-\Delta t/\tau})/\gamma_0,\\\gamma_4&=(\Delta te^{-\Delta t/\tau}-\tau(1-e^{-\Delta t/\tau}))/\gamma_0.\end{aligned}$$

Equation (2.23) gives $(\bar{A}_1,\bar{A}_2,\bar{A}_3)$ by following the same procedure as evaluating $\bar{a}_l$.

Up to this point, we have obtained the distribution function $f(x_{j+1/2},t,v,\xi)$ at the cell interface $x_{j+1/2}$, and the numerical fluxes can subsequently be obtained as follows:

$$\begin{pmatrix}H_\rho\\H_{\rho u}\\H_E\end{pmatrix}_{j+1/2}=\int v\begin{pmatrix}1\\v\\\frac{1}{2}(v^2+\xi^2)\end{pmatrix}f(x_{j+1/2},t,v,\xi)dvd\xi.\tag{2.24}$$

Combining formulas (2.7), (2.24), and (2.10), we have obtained a second-order RKDG finite element method which is Riemann solver-free.

3. Second-order scheme in two dimensions. We consider 2D hyperbolic conservation laws:

$$\frac{\partial U}{\partial t}+\frac{\partial F(U)}{\partial x}+\frac{\partial F(U)}{\partial y}=0\quad\forall(x,y)\in\Omega,\quad t\in(0,T),\tag{3.1}$$

where $U=(\rho,\rho u,\rho v,E)^T$, $F(U)=(\rho u,\rho u^2+p,\rho uv,u(E+p))^T$, $G(U)=(\rho v,\rho uv,\rho v^2+p,v(E+p))^T$, ρ is the flow density, u and v are velocity components in the x- and y-directions, respectively, E is the total energy, and p is the flow pressure.

3.1. The DG finite element method space discretization. Assume Γ_h is a partition of the domain Ω. Let $K \in \Gamma_h$ and $V(K)$ be a finite element space on K. In practice, $V(K)$ is often taken as mth ($m \geq 0$) order polynomial space. Given $t \in [0, T]$, we look for the approximate solution $U_h(t)$ in the finite element space

$$V_h = \{v_h \in L^\infty(\Omega) : v_h|_K \in V(K) \ \forall K \in \Gamma_h\}.$$

For any smooth function $v(x)$, we have

(3.2)
$$\frac{d}{dt}\int_K U(x,t)v(x)dx + \sum_{e\in\partial K}\int_e \vec{f}(U(x,t))\cdot n_{e,K}v(x)d\Gamma - \int_K \vec{f}(U(x,t))\cdot\nabla v(x)dx = 0,$$

where $n_{e,K}$ denotes the unit outward normal of the edge e, $\vec{f}(U) = (F(U), G(U))$, and $x = (x, y)$. The following numerical quadrature rules will be employed to approximate the integrals in (3.2):

$$\int_e \vec{f}(U(x,t))\cdot n_{e,K}v(x)d\Gamma \approx \sum_{l=1}^{L}\omega_l\vec{f}(U(x_{el},t))\cdot n_{e,K}v(x_{el})\,|e|, \tag{3.3}$$

$$\int_K \vec{f}(U(x,t))\cdot\nabla v(x)dx \approx \sum_{j=1}^{M}\underline{\omega}_j\vec{f}(U(x_{Kj},t))\cdot\nabla v(x_{Kj})\,|K|. \tag{3.4}$$

Replacing the exact solution U by U_h, the smooth function v by $v_h \in V(K)$, and the flux $\vec{f}(U(x,t))\cdot n_{e,K}$ in the boundary integrals by the numerical flux $H_{e,K}(x,t)$, we obtain

$$\begin{aligned}&\frac{d}{dt}\int_K U_h(x,t)v_h(x)dx + \sum_{e\in\partial K}\sum_{l=1}^{L}\omega_l H_{e,K}(x_{el},t)v_h(x_{el})|e|\\ &-\sum_{j=1}^{M}\underline{\omega}\vec{f}(U_h(x_{kj},t))\cdot\nabla v_h(x_{kj})|K| \ \forall v_h \in V(K),\ \forall K \in \Gamma_h,\end{aligned} \tag{3.5}$$

$$\int_K U_h(x,0)v_h dx = \int_K U_0(x)v_h dx,$$

where

$$H_{e,K} = H_{e,K}(U_h(x^{int(K)},t), U_h(x^{ext(K)},t)),$$

$$U_h(x^{int(K)},t)) = \lim_{y\to x, y\in K} U_h(y,t),$$

$$U_h(x^{ext(K)},t) = \begin{cases}\gamma_h(x,t), & x \in \partial\Omega,\\ \lim\limits_{y\to x, y\notin K} U_h(y,t) & \text{otherwise.}\end{cases}$$

Above, $\gamma_h(x,t)$ is the trace function and $H_{e,K}$ satisfies the following conditions:

(1) $H_{e,K}(U,U)$ is locally Lipschitz continuous and is consistent with $\vec{f}(U)\cdot n_{e,K}$ in the following sense:

$$H_{e,K}(U,U)=\vec{f}(U)\cdot n_{e,K}.$$

(2) $H_{e,K}(U,U)$ is a nondecreasing function of its first argument and a nonincreasing function of its second argument.

(3) $H_{e,K}(U,U)$ satisfies the conservation laws in the following sense:

$$H_{e,K}(U_h(x^{int(K)},t),U_h(x^{ext(K)},t))+H_{e,K}(U_h(x^{int(K')},t),U_h(x^{ext(K')},t))=0, \tag{3.6}$$

$$K\cap K'=e.$$

3.2. The RK time discretization. The semidiscrete scheme (3.5) yields the following ODE system:

$$\frac{d}{dt}U_h=L_h(U_h,\gamma_h), \tag{3.7}$$

which is solved by using the RK method similar to that described in the 1D case; see also [7]. Therefore, the RKDG finite element scheme is obtained by combining (3.5) with (2.10).

3.3. Second-order BGK numerical flux. Again, to avoid solving Riemann problems, we use the second-order BGK method to construct the numerical fluxes $H_{i+1/2,j}$ and $H_{i,j+1/2}$ in (3.5). More precisely, consider the 2D element $K=[x_{i-1/2}, x_{i+1/2}]\times[y_{j-1/2},y_{j+1/2}]$, where (i,j) denotes the cell K with the boundary $i\pm 1/2$ and $j\pm 1/2$, $(x_{i+1/2,j},y_{i+1/2,j})$ denotes the center of the cell boundary between cells (i,j) and $(i+1,j)$. For simplicity, $(x_{i+1/2,j}=0,y_{i+1/2,j}=0)$ is assumed.

Consider the 2D BGK model

$$f_t+uf_x+vf_y=\frac{g-f}{\tau}, \tag{3.8}$$

$$\iint\frac{g-f}{\tau}\psi_\alpha dudvd\xi=0,\quad \alpha=1,2,3,4, \tag{3.9}$$

where $\psi=(\psi_1,\psi_2,\psi_3,\psi_4)=(1,u,v,\frac{1}{2}(u^2+v^2+\xi^2))^T$, which gives the integral solution of f at $(x_{i+1/2,j},y_{i+1/2,j})$:

$$\begin{aligned}f(x_{i+1/2,j},y_{i+1/2,j},t,u,v,\xi)=&\frac{1}{\tau}\int_0^t g(x',y',t',u,\xi)e^{\frac{-(t-t')}{\tau}}dt'\\&+e^{\frac{-t}{\tau}}f_0(x_{i+1/2,j}-ut,y_{i+1/2,j}-vt),\end{aligned} \tag{3.10}$$

where $x'=x_{i+1/2,j}-u(t-t')$ and $y'=y_{i+1/2,j}-v(t-t')$ are the trajectory of a particle motion, f_0 is the initial distribution function, and g is the equilibrium state around the cell interface $(x_{i+1/2,j},y_{i+1/2,j})$. With the definition $(x_{i+1/2,j}=0,y_{i+1/2,j}=0)$, f goes to

$$f(0,0,t,u,v,\xi)=\frac{1}{\tau}\int_0^t g(x',y',t',u,\xi)e^{\frac{-(t-t')}{\tau}}dt'+e^{\frac{-t}{\tau}}f_0(-ut,-vt). \tag{3.11}$$

To obtain the solution f, both f_0 and g must be specified in (3.11).

Similar to the 1D case, the reconstructed initial data in the cell (i,j) at the beginning of each time step can be expressed as

$$\bar{U}_{i,j}(x,y) = U_{i,j} + L_x(s^+_{i,j}, s^-_{i,j})(x - x_{i,j}) + L_y(\delta^+_{i,j}, \delta^-_{i,j})(y - y_{i,j}),$$

where $U_{i,j}$ is the cell averaged initial data and $L_x(s_1, s_2)$, $L_y(\delta_1, \delta_2)$ are the nonlinear limiters,

$$s^+_{i,j} = (U_{i+1,j} - U_{i,j})/(x_{i+1,j} - x_{i,j}), \quad s^-_{i,j} = (U_{i,j} - U_{i-1,j})/(x_{i,j} - x_{i-1,j}),$$
$$\delta^+_{i,j} = (U_{i,j+1} - U_{i,j})/(x_{i,j+1} - x_{i,j}), \quad \delta^-_{i,j} = (U_{i,j} - U_{i,j-1})/(x_{i,j} - x_{i,j-1}).$$

For the second-order scheme, f_0 and g after the initial data reconstruction are given by

$$\begin{aligned} f_0(x,y,0) &= \begin{cases} g_l[1 + a_l x + b_l y], & x < 0, \\ g_r[1 + a_r x + b_r y], & x > 0, \end{cases} \\ &= g_l(1 + a_l x + b_l y)(1 - H(x)) + g_r(1 + a_r x + b_r y)H(x), \end{aligned} \tag{3.12}$$

and

$$g(x,y,t) = g_0[1 + (1 - H(x))\bar{a}_l x + H(x)\bar{a}_r x + \bar{b}y + \bar{A}t], \tag{3.13}$$

where

$$\begin{aligned} g_l &= \rho_l\left(\tfrac{\lambda_l}{\pi}\right)^{\frac{k+2}{2}} e^{-\lambda_l[(u-v_l)^2 + (v-v_l)^2 + \xi^2]}, \\ g_r &= \rho_r\left(\tfrac{\lambda_r}{\pi}\right)^{\frac{k+2}{2}} e^{-\lambda_r[(u-v_r)^2 + (v-v_r)^2 + \xi^2]}, \\ g_0 &= \rho_0\left(\tfrac{\lambda_0}{\pi}\right)^{\frac{k+2}{2}} e^{-\lambda_0[(u-v_0)^2 + (v-v_0)^2 + \xi^2]}, \end{aligned}$$

$$H(x) = \begin{cases} 0, & x < 0, \\ 1, & x \geq 0. \end{cases} \tag{3.14}$$

The parameters a_l, a_r, b_l, and b_r in (3.12) and $\bar{a}_l$, $\bar{a}_r$, $\bar{b}$, and $\bar{A}$ in (3.13) depend on the particle velocity (u,v) and the internal variable ξ. By the second-order Taylor expansion, we have

$$\begin{aligned} a_l &= a_{1l} + a_{2l}u + a_{3l}v + a_{4l}\tfrac{1}{2}(u^2 + v^2 + \xi^2), \\ a_r &= a_{1r} + a_{2r}u + a_{3r}v + a_{4r}\tfrac{1}{2}(u^2 + v^2 + \xi^2), \\ b_l &= b_{1l} + b_{2l}u + b_{3l}v + b_{4l}\tfrac{1}{2}(u^2 + v^2 + \xi^2), \\ b_r &= b_{1r} + b_{2r}u + b_{3r}v + b_{4r}\tfrac{1}{2}(u^2 + v^2 + \xi^2), \\ \bar{a}_l &= \bar{a}_{1l} + \bar{a}_{2l}u + \bar{a}_{3l}v + \bar{a}_{4l}\tfrac{1}{2}(u^2 + v^2 + \xi^2), \\ \bar{a}_r &= \bar{a}_{1r} + \bar{a}_{2r}u + \bar{a}_{3r}v + \bar{a}_{4r}\tfrac{1}{2}(u^2 + v^2 + \xi^2), \\ \bar{b} &= \bar{b}_1 + \bar{b}_2 u + \bar{b}_3 v + \bar{b}_4\tfrac{1}{2}(u^2 + v^2 + \xi^2), \\ \bar{A} &= \bar{A}_1 + \bar{A}_2 u + \bar{A}_3 v + \bar{A}_4\tfrac{1}{2}(u^2 + v^2 + \xi^2). \end{aligned} \tag{3.15}$$

Similar to (2.19), a_l, a_r, b_l, b_r can be computed. Thus the initial distribution function f_0 is obtained. To determine g_0, we take the limit $t \to 0$ in (3.10); then g_0 can be obtained from g_l and g_r of f_0 by using the compatibility condition

$$\int g_0 \psi du dv d\xi = \iint_{u>0} \psi g_l du dv d\xi + \iint_{u<0} \psi g_r du dv d\xi.$$

More specifically, we have

$$\begin{aligned} U_0 = \begin{pmatrix} \rho_0 \\ \rho_0 u_0 \\ \rho_0 v_0 \\ E_0 \end{pmatrix} &= \rho_l \begin{pmatrix} \langle u^0 v^0 \rangle_{u>0} \\ \langle u^1 v^0 \rangle_{u>0} \\ \langle u^0 v^1 \rangle_{u>0} \\ \frac{1}{2}(\langle u^2 v^0 \rangle_{u>0} + \langle u^0 v^2 \rangle_{u>0} + \langle u^0 v^0 \xi^2 \rangle_{u>0}) \end{pmatrix} \\ &+ \rho_r \begin{pmatrix} \langle u^0 v^0 \rangle_{u<0} \\ \langle u^1 v^0 \rangle_{u<0} \\ \langle u^0 v^1 \rangle_{u<0} \\ \frac{1}{2}(\langle u^2 v^0 \rangle_{u<0} + \langle u^0 v^2 \rangle_{u<0} + \langle u^0 v^0 \xi^2 \rangle_{u<0}) \end{pmatrix}, \end{aligned} \tag{3.16}$$

$$\lambda_0 = \frac{(K+2)\rho_0}{4(E_0 - \frac{1}{2}\rho_0(u_0^2 + v_0^2))}. \tag{3.17}$$

Up to this point, g_0 is totally determined. $\bar{a}_l$ and $\bar{a}_r$ terms in (3.13) can be obtained by using the similar techniques (2.21) and (2.21)′. The term $\bar{b}$ in (3.13) can be obtained from the following compatibility condition:

$$\frac{\partial}{\partial y} \int (g - f_0) \psi du dv d\xi = 0,$$

which gives

$$\frac{1}{\rho_0} \int_{-\infty}^{\infty} \psi \bar{b} g_0 du dv d\xi = M^0_{\alpha\beta} \begin{pmatrix} \bar{b}_1 \\ \bar{b}_2 \\ \bar{b}_3 \\ \bar{b}_4 \end{pmatrix} = \frac{1}{\rho_0} \Big(\iint_{u>0} \psi b_l g_l du dv d\xi + \iint_{u<0} \psi b_r g_r du dv d\xi \Big), \tag{3.18}$$

where the matrix

$$M^0_{\alpha\beta} = \frac{1}{\rho_0} \int \psi_\alpha \psi_\beta g_0 du dv d\xi$$

has the same form as the matrix in section 2. So, $(\bar{b}_1, \bar{b}_2, \bar{b}_3, \bar{b}_4)$ can be obtained by using similar methods of obtaining (a_{1m}, a_{2m}, a_{3m}) in (2.19).

Substituting both the expression (3.12) of f_0 and the expression (3.13) of g into the integral solution (3.11) of the BGK model, we have

$$\begin{aligned} f(0,0,t,u,v,\xi) &= (1-e^{-t/\tau})g_0 \\ &\quad + (\tau(-1+e^{-t/\tau}) + te^{-t/\tau})((\bar{a}_l H(u) + \bar{a}_r(1-H(u)))u + \bar{b}v)g_0 \\ &\quad + \tau(t/\tau - 1 + e^{-t/\tau})\bar{A}g_0 \\ &\quad + e^{-t/\tau}((1-uta_l - vtb_l)H(u)g_l + (1-uta_r - vtb_r)(1-H(u))g_r). \end{aligned} \tag{3.19}$$

To determine the only unknown term $\bar{A}$ in the above expression, using the compatibility condition at the point $(x=0, y=0)$ and integrating it over the whole time step Δt, we have

$$\int_0^{\Delta t} \int \begin{pmatrix} 1 \\ u \\ v \\ \frac{1}{2}(u^2+v^2+\xi^2) \end{pmatrix} (g(0,0,t) - f(0,0,t,u,v,\xi))dudvd\xi dt = 0, \tag{3.20}$$

which gives

$$\begin{aligned} M^0_{\alpha\beta}(\bar{A}_1,\bar{A}_2,\bar{A}_3,\bar{A}_4)^T &= \frac{1}{\rho_0}\int [\gamma_1 g_0 + \gamma_2(u(\bar{a}_l H(u) + \bar{a}_r(1-H(u))) + \bar{b}v)g_0 \\ &\quad + \gamma_3(H(u)g_l + (1-H(u))g_r) \\ &\quad + \gamma_4((a_l u + b_l v)H(u)g_l + (a_r u + b_r v)(1-H(u))g_r)]\psi dudvd\xi, \end{aligned} \tag{3.21}$$

where the parameters $\gamma_1, \gamma_2, \gamma_3, \gamma_4$ have the same values as those in the 1D case. Then $\bar{A} = (\bar{A}_1, \bar{A}_2, \bar{A}_3, \bar{A}_4)$ can be obtained from (3.21).

Up to this point, we have obtained the explicit distribution function $f(0,0,t,u,v,\xi)$ in (3.19), and the numerical fluxes across the cell interface between cells (i,j) and $(i+1,j)$ can subsequently be obtained as

$$H_{i+1/2,j} = \begin{pmatrix} H_\rho \\ H_{\rho u} \\ H_{\rho v} \\ H_E \end{pmatrix}_{i+1/2,j} = \int u \begin{pmatrix} 1 \\ u \\ v \\ \frac{1}{2}(u^2+v^2+\xi^2) \end{pmatrix} f(0,0,t,u,v,\xi)dudvd\xi. \tag{3.22}$$

Similar techniques can be developed to construct the numerical fluxes $H_{i,j+1/2}$ across the cell interface between cells (i,j) and $(i,j+1)$. Replacing the numerical fluxes in (3.5) by formula (3.22) and combining the resulting equation with (2.10), we obtained a second-order RKDG finite element method which is Riemann solver-free.

4. Numerical experiment. In this section, we apply the methods developed in section 2 and section 3 to some benchmark problems. Among them Examples 1–4 are 1D problems and Examples 5–6 are 2D ones.

4.1. 1D examples. For 1D problems, the domain $[-0.5, 0.5]$ is divided by 100 cells and 200 cells, respectively, and the CFL number is taken to be 0.1.

Example 1. The first example is the standard Sod test problem, which uses the following initial conditions:

$$(\rho, u, p)_L = (1.0, 0.0, 1.0), \quad (\rho, u, p)_R = (0.125, 0.0, 0.1).$$

The exact and approximate solutions are plotted in Figure 1. The problem was computed in [6] using the TVB RKDG method. It is found that our 100-cell results are more accurate than those obtained by using the componentwise limiter (Figures 1–3 in [6]) and are almost the same as the results obtained by using the characteristicwise limiter (Figures 7–9 in [6]). There is some instability in the back of the shock wave of the velocity. But, this instability does not spread when the meshes are refined.

Example 2. The second example is the Lax problem which uses the following initial conditions:

$$(\rho, u, p)_L = (0.445, 0.698, 3.528), \quad (\rho, u, p)_R = (0.5, 0.0, 0.571).$$

The results are displayed in Figure 2. Compared to the results in [6], 100-cell results are almost the same as those with second-order accuracy and more accurate than those with third-order accuracy obtained by using characteristicwise limiter.

Example 3. The third example uses the following initial conditions:

$$(\rho, u, p)_L = (5.99924, 19.5975, 460.894), \qquad (\rho, u, p)_R = (5.99242, -6.19633, 46.0950).$$

The results are plotted in Figure 3. We can find that there are some instabilities in the density, velocity, and pressure. It may be due to the BGK assumption made in section 1 that during a time dt, a fraction of dt/τ of molecules in a given small volume undergoes collision, which alters the velocity-distribution function from f to g. If the collision interval τ taken is not good, the instabilities appear in the back of the shock wave. Example 4 is similar.

Example 4. The fourth example uses the following initial conditions:

$$(\rho, u, p)_L = (1, 0, 1.0), \quad (\rho, u, p)_R = (0.125, 0, 0.2).$$

The results are displayed in Figure 4.

4.2. 2D examples. Two well-known 2D test problems, namely the double-Mach reflection problem and the forward-facing step problem, will be used to test the method proposed in section 3. Compared with [27], the numerical results showed the favorable shock resolution and computational accuracy of our methods.

Example 5 (The double-Mach reflection problem). The problem involves a Mach 10 shock that initially makes a 60° angle with a reflecting wall. The state ahead of the shock is $(\rho, u, v, p) = (1.4, 0, 0, 1)$. The initial value for numerical calculation is taken to be the preshock condition and the postshock condition, where the postshock condition is obtained by the following Hoguniot formula of the positive shock:

$$\frac{u - u_0}{C_0} = \frac{2}{\gamma + 1}\left(M - \frac{1}{M}\right), \quad \frac{p}{p_0} = \frac{2\gamma}{\gamma + 1}\left(M^2 - \frac{\gamma - 1}{\gamma + 1}\right), \quad \frac{\rho}{\rho_0} = \frac{(\gamma + 1)M^2}{(\gamma - 1)M^2 + 2},$$

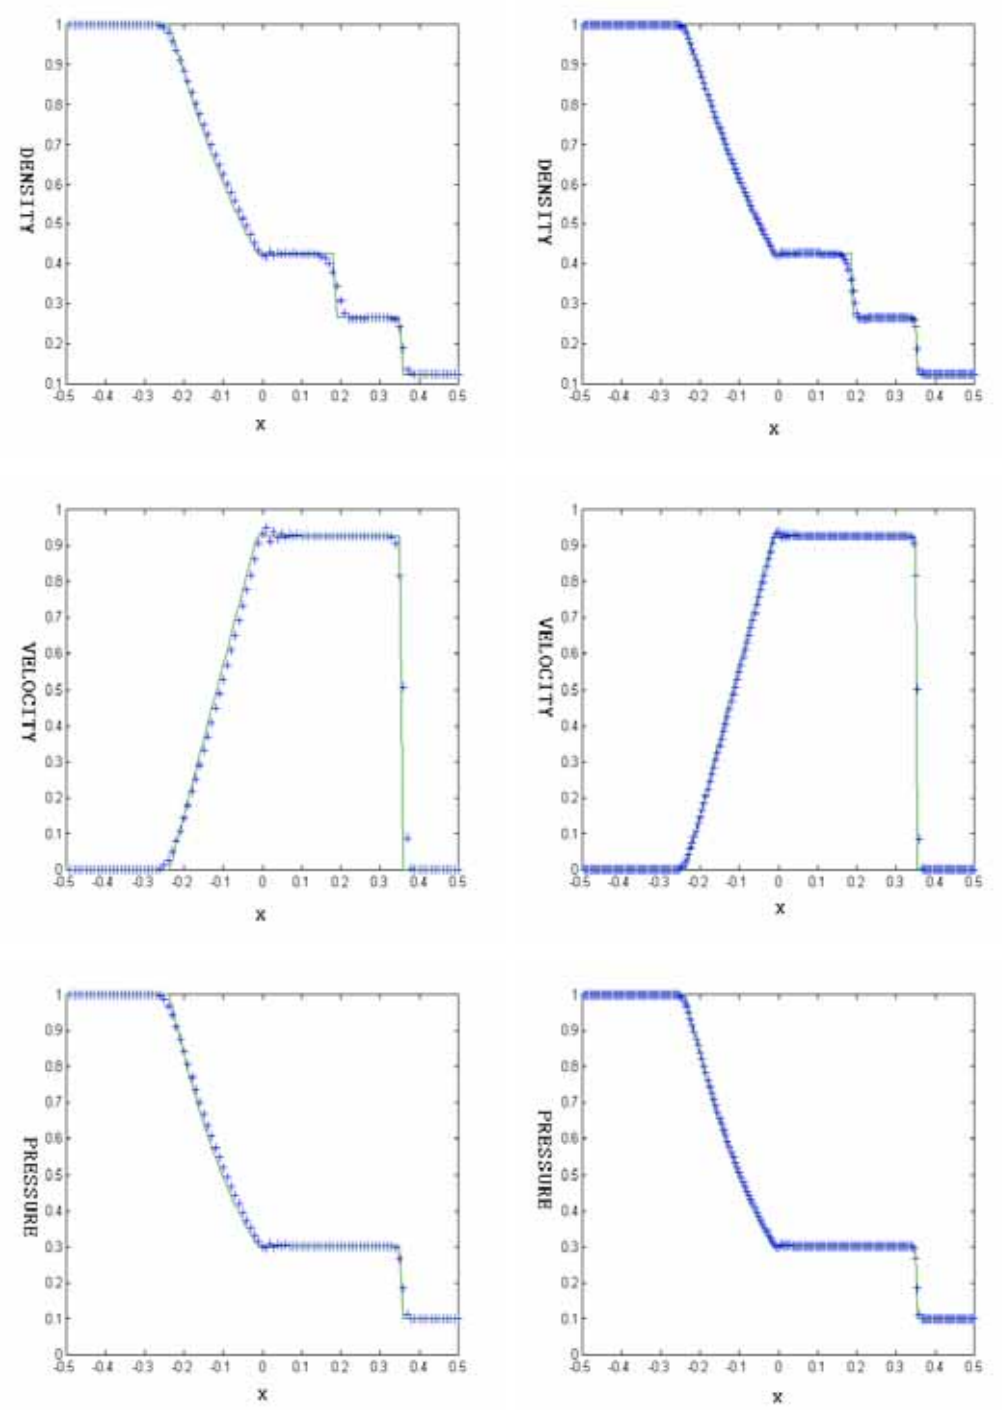

FIG. 1. *Example* 1. *Comparison between numerical solutions* (+) *and exact solutions* (*solid line*)*:* 100 *cells* (*left*) *and* 200 *cells* (*right*) *at* $t = 0.2$.

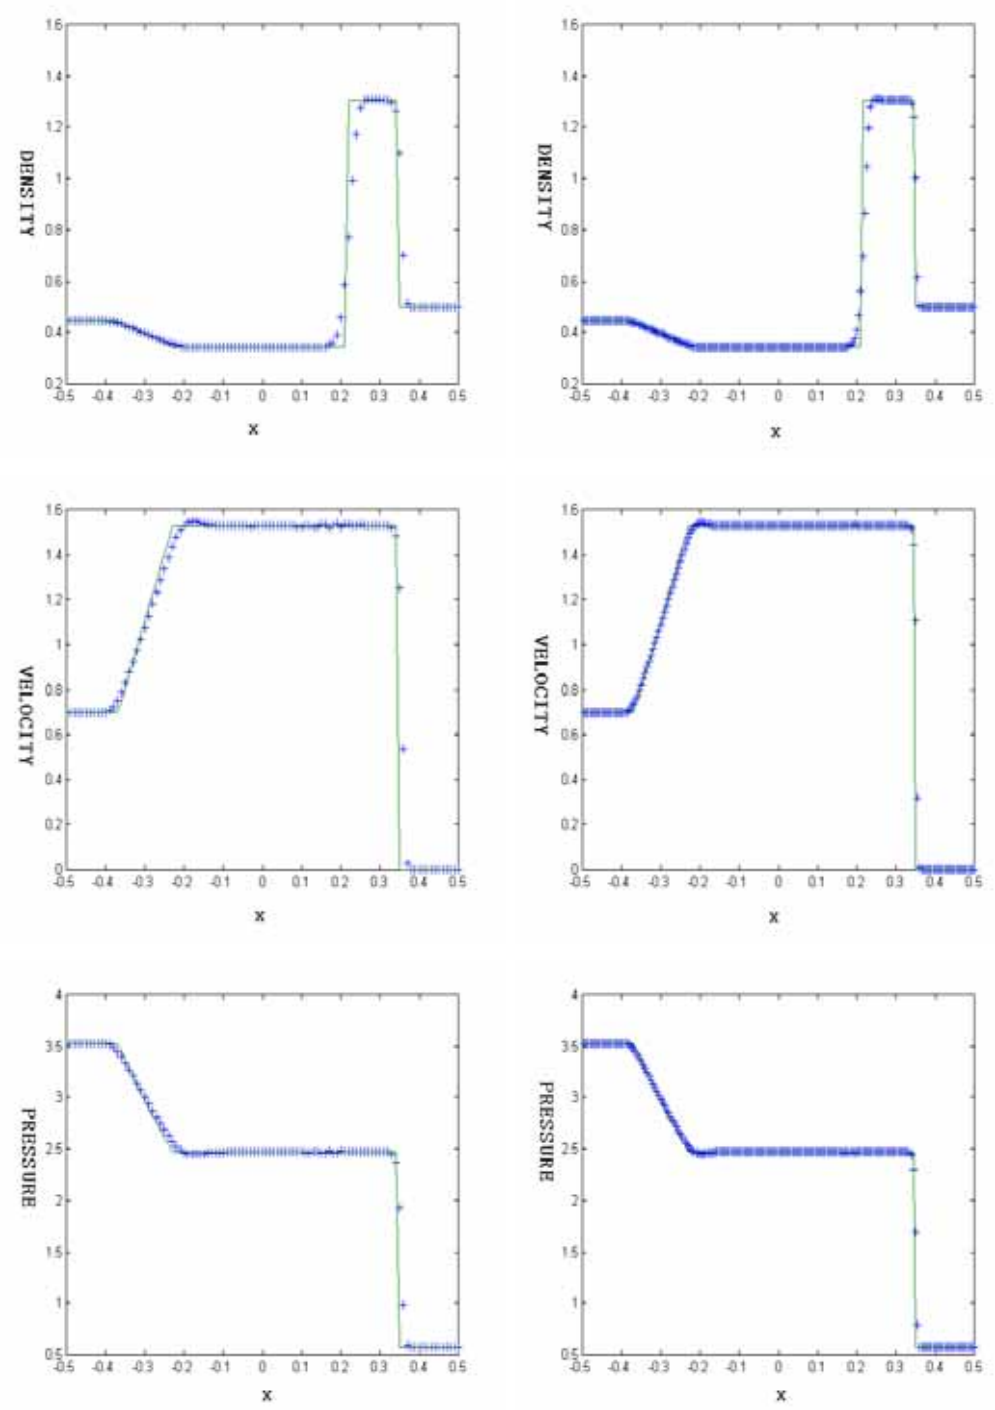

FIG. 2. *Example* 2. *Comparison between numerical solutions* (+) *and exact solutions* (*solid line*)*:* 100 *cells* (*left*) *and* 200 *cells* (*right*) *at* $t = 0.14$.

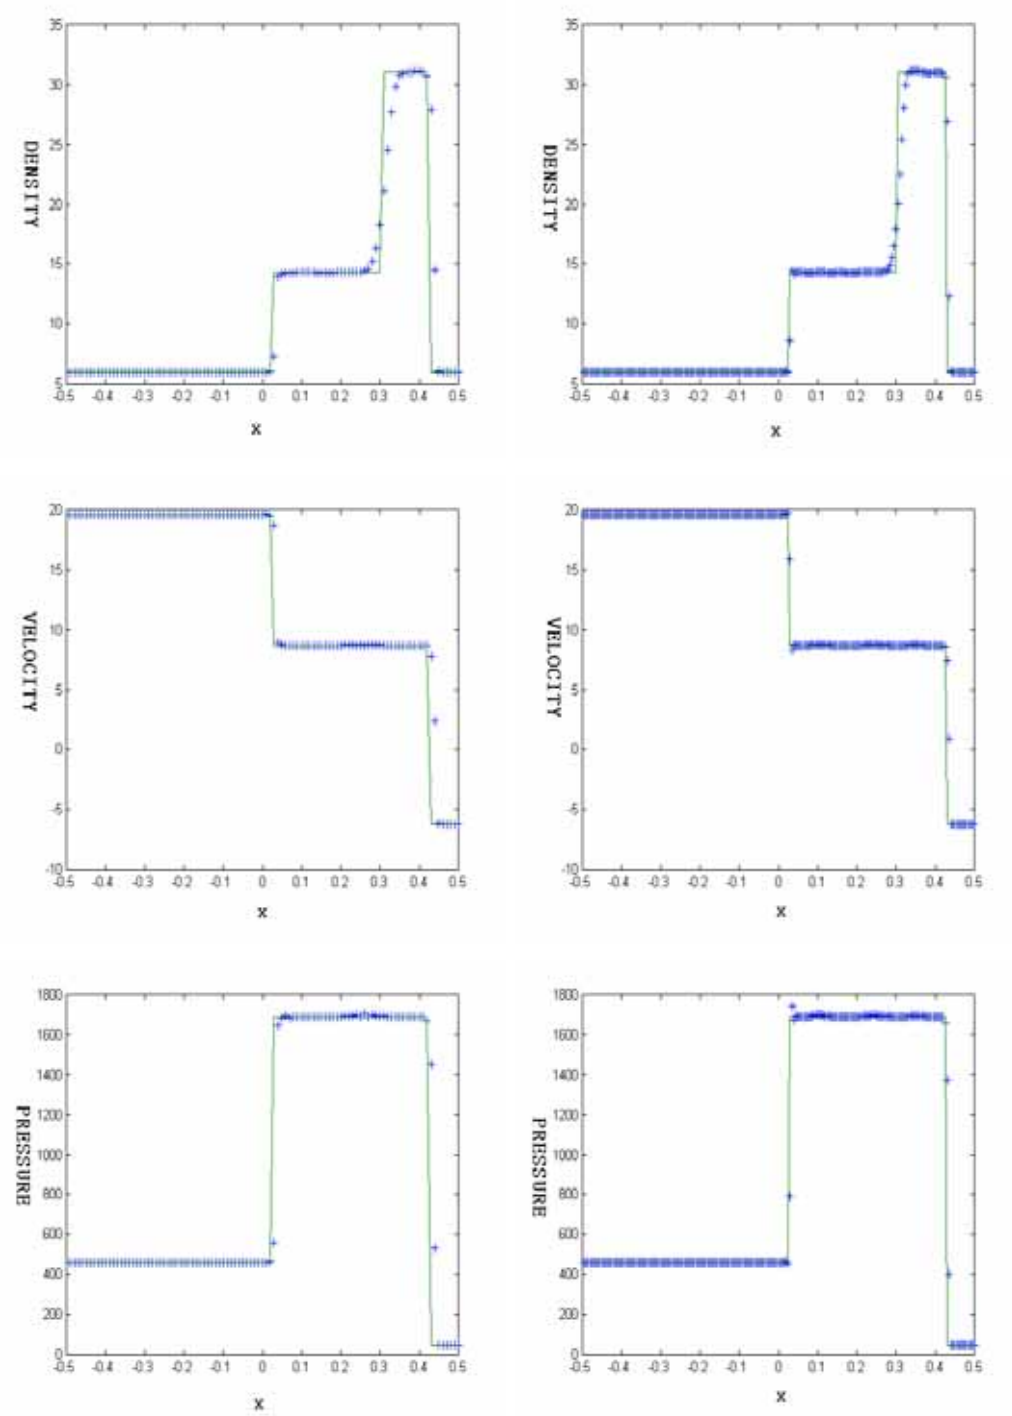

FIG. 3. *Example* 3. *Comparison between numerical solutions* (+) *and exact solutions* (*solid line*)*:* 100 *cells* (*left*) *and* 200 *cells* (*right*) *at* $t = 0.035$.

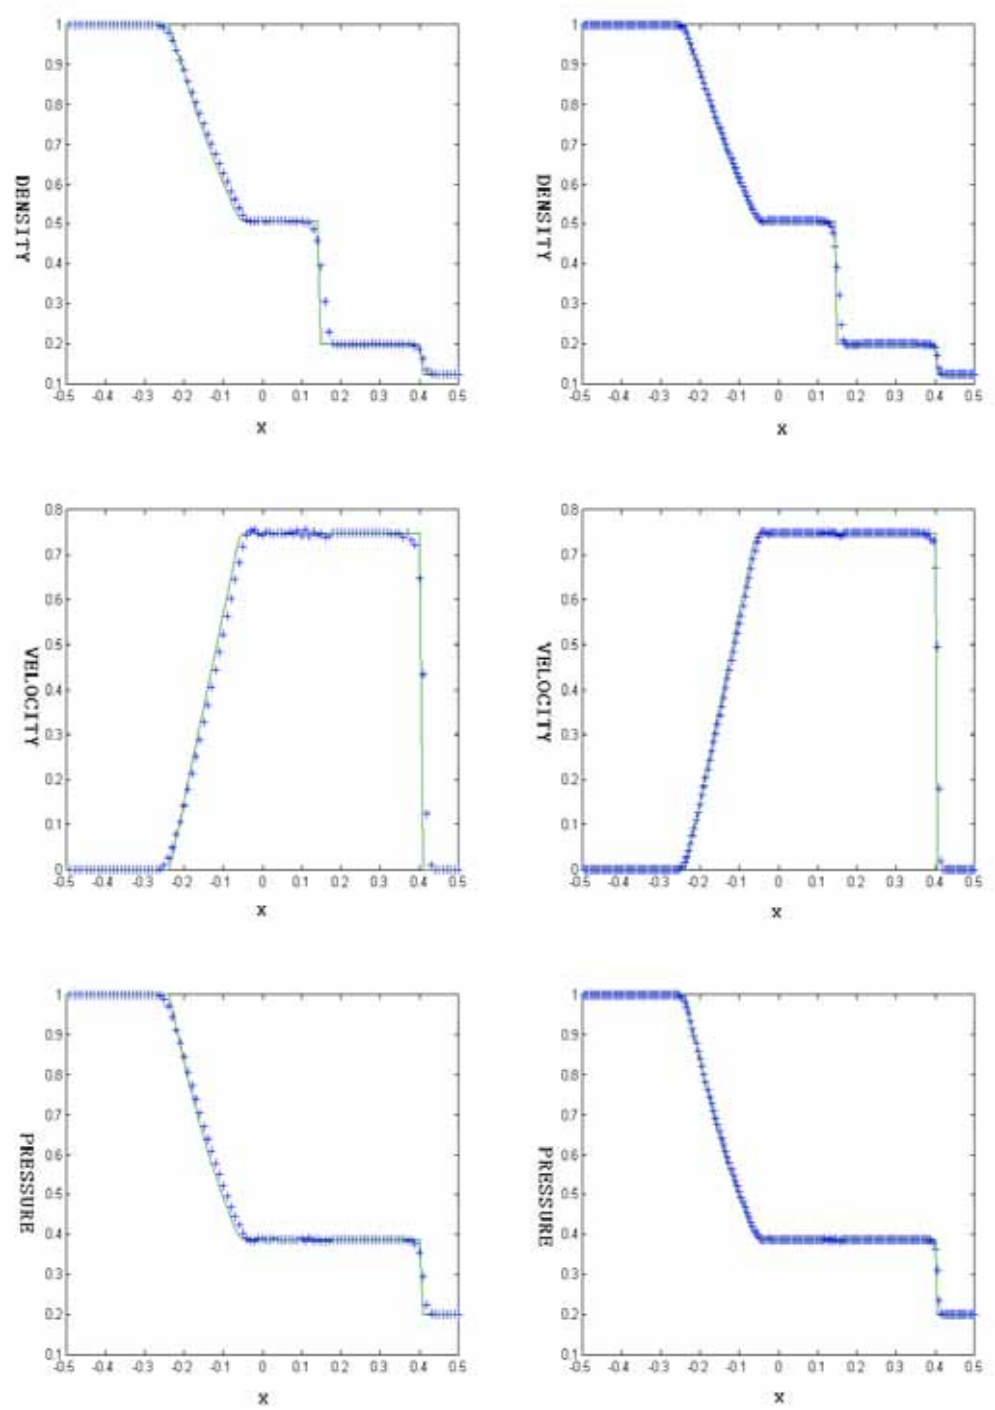

FIG. 4. *Example* 4. *Comparison between numerical solutions* (+) *and exact solutions* (*solid line*)*:* 100 *cells* (*left*) *and* 200 *cells* (*right*) *at* $t = 0.2$.

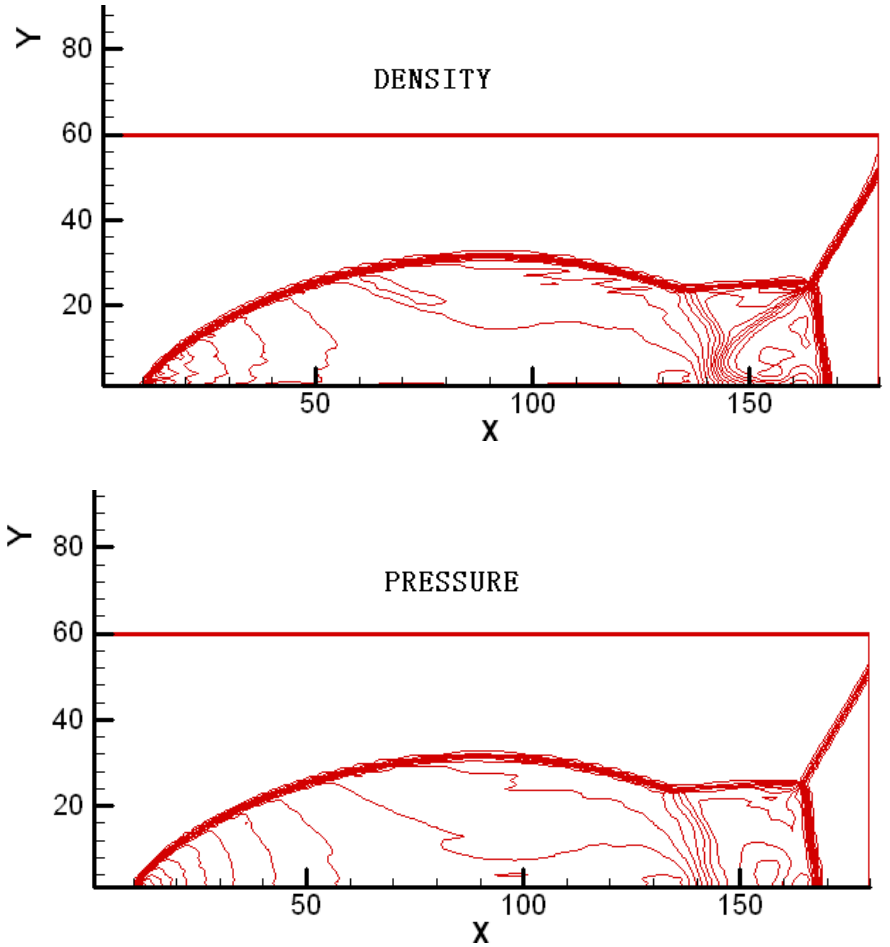

FIG. 5. *Example* 5. *Density and pressure distributions at* $t = 0.2$ *with a* 240×60 *mesh.*

where $M = (D - u_0)/C_0$, D is the Mach number of the shock, u_0 is a composition velocity consisting of the two velocity components in the normal direction of the preshock, and the variables with subscript 0 denote the preshock physical quantities.

This numerical example was studied extensively by Woodward and Colella [27], which is a standard test model in designing high-resolution schemes. In this numerical experiment, the computational domain is taken to be $[0, 4] \times [0, 1]$ and divided by the rectangular elements. The CFL number used is 0.18. The left and right boundaries use inflow and outflow boundary conditions, respectively, and the top boundary uses the exact boundary condition. The left side of the shock takes the postshock condition and the right side takes the preshock condition. For the bottom boundary, the exact postshock condition is imposed for the part $0 \le x \le 1/6$ and the rest uses the reflection boundary condition.

Figures 5 and 6 display the results in $[0, 3] \times [0, 1]$. Compared to the results in [8, 27, 35], our numerical results are found to be acceptable with good approximation accuracy.

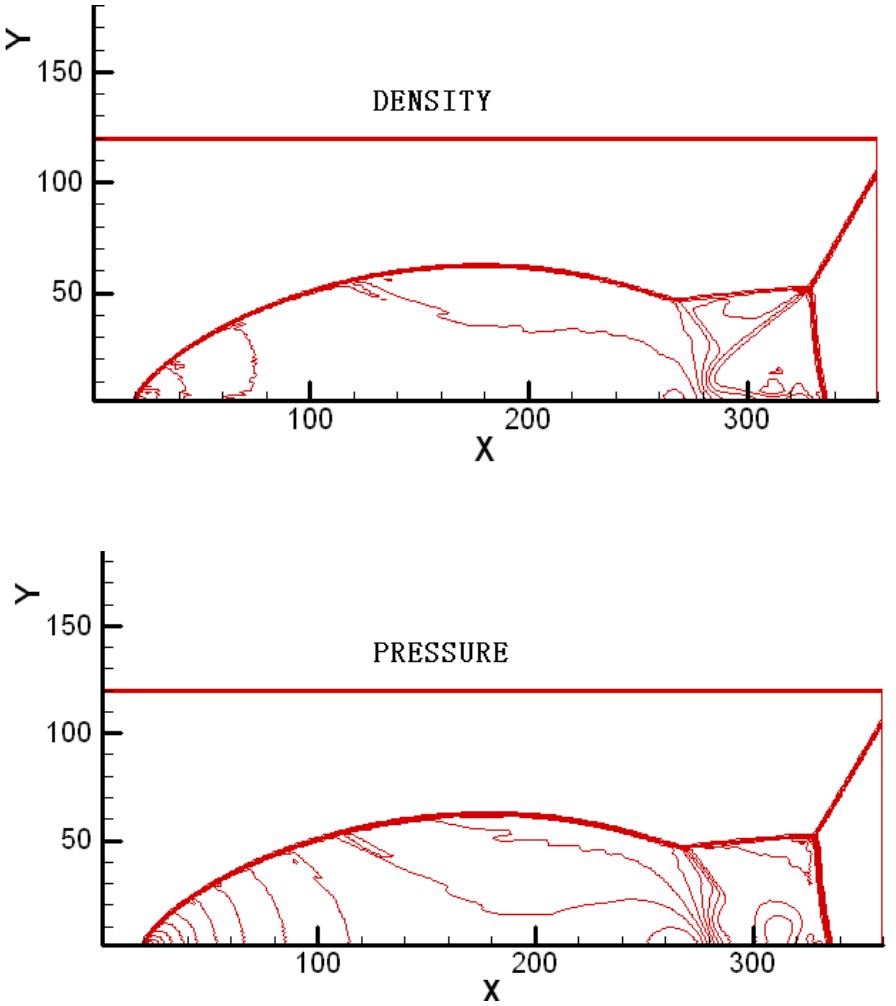

FIG. 6. *Example* 5. *Density and pressure distributions at* $t = 0.2$ *with a* 480×120 *mesh.*

6 (forward-facing step problem). In this example, the top and bottom boundaries are the reflective boundary condition. The left boundary uses an inflow boundary condition. For the right boundary, the reflective boundary condition is imposed for the part $x = 0.6$ and $0 \le y \le 0.2$, and the rest uses an outflow boundary condition.

The computational domain is taken to be $[0, 3] \times [0, 1]$ and divided by the rectangular elements. The CFL number used is 0.95. Observe that the corner of the face step is a singular point. In [27], a special corner treatment is made which improved the numerical results substantially. In [8], a local refining is used near the corner to enhance the overall numerical accuracy. In this work, we did not make any special efforts to handle the corner singularity.

Figures 7 and 8 display the computational results for Example 6. Compared to the results in [27], it is found that our numerical results are acceptable.

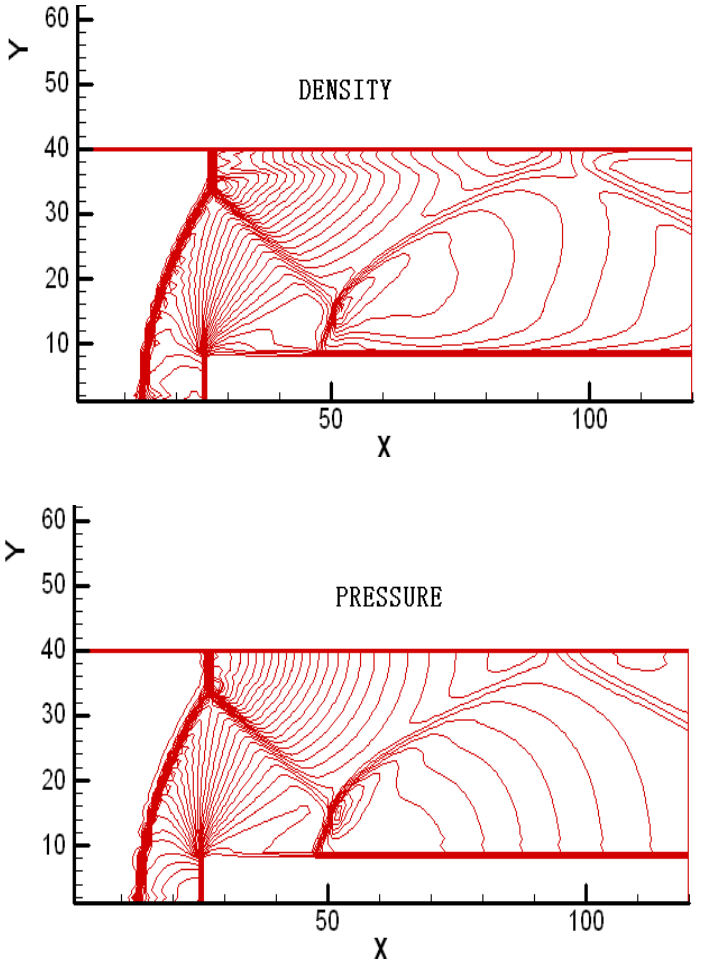

FIG. 7. *Example* 6. *Density and pressure distributions at* $t = 4.0$ *with a* 120×40 *mesh.*

In the above calculations, the collision time τ was taken to be

$$\tau = c_1 \Delta t + \Delta t \min(1, c), \tag{4.1}$$

where

$$c = c_2 \frac{|\rho_l/\lambda_l - \rho_r/\lambda_r|}{|\rho_l/\lambda_l + \rho_r/\lambda_r|},$$

and Δt is the CFL time step. c_1 and c_2 are positive constants. $c_1 = 0.01$ and $c_2 = 5$ are chosen in our numerical experiments.

We conclude this section by pointing out that the results presented in this section are more accurate than those obtained in our earlier work [35, 36].

5. Concluding remarks. In this paper, we have proposed a class of numerical schemes which combines the RKDG finite element scheme method and the second-order BGK scheme. The main advantage of this approach is that it is Riemann

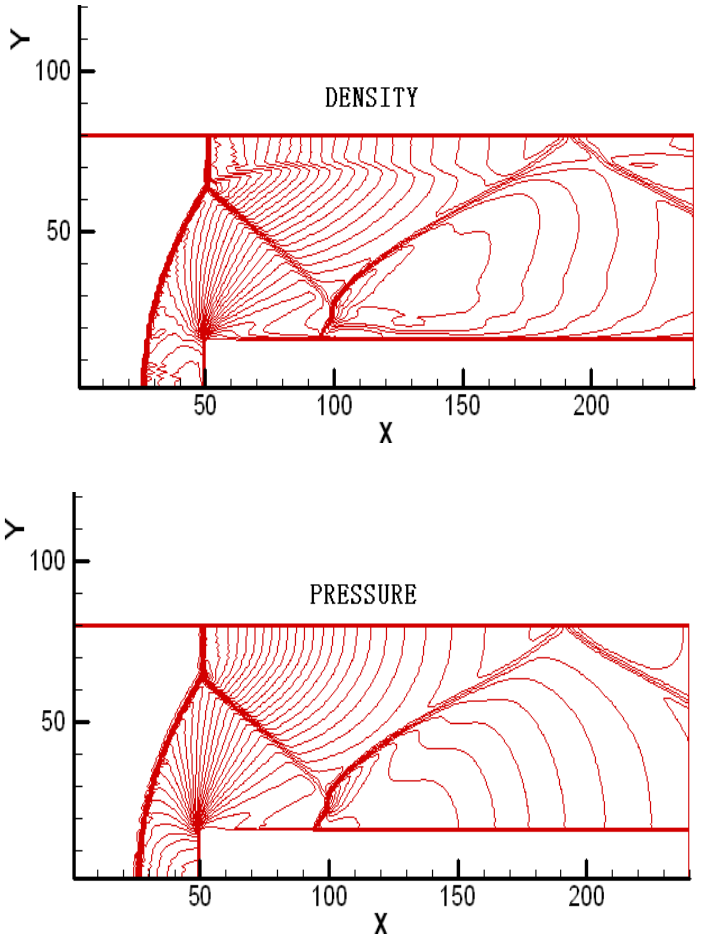

FIG. 8. *Example* 6. *Density and pressure distributions at* $t = 4.0$ *with a* 240×80 *mesh.*

solver-free when solving the Euler equations. The method also keeps the main advantages of the discontinuous Galerkin methods in solving the Euler equations. Further research of this scheme will be presented in future work.

MODELING TEST RESPONSES BY MULTIVARIABLE POLYNOMIALS OF HIGHER DEGREES*

JIGUAN G. LIN†

Abstract. Engineering tests generally acquire a large set of response data at once while focusing on a small number of variables. Higher-order response models are better for capturing and displaying the characteristics such data can reveal, but response surface models traditionally are linear or quadratic (first or second order) only. If attempted for a higher order, the matrix X of the test inputs formed for fitting the test responses often immediately stops satisfying the full-rank assumption on X traditionally made for computing the regression coefficients. The resulting product matrix X^TX is singular and hence cannot be inverted, directly or indirectly, for obtaining the desired least-squares regression coefficients from the system of normal equations. Ill-conditioning of X when near rank deficiency, not unusual even in the traditional second-order response modeling, can also render the computed coefficients unreliable. This paper incorporates singular value decomposition (SVD) to handle the rank deficiency and ill-conditioning problems directly. The proposed SVD-based fitting algorithm enables response modeling to the desirable high-order reliably and efficiently with no difficulty despite rank deficiency in X. Two proposed trimming algorithms enable reduction of redundant terms or insignificant coefficients of the fitted polynomials on a sound mathematical base.

Key words. polynomial approximation, regression, number of terms, response surface, least squares, rank deficiency, singular value decomposition, higher-order response modeling, subset selection

DOI. 10.1137/040603954

1. Introduction.

Engineers have recently started to adopt the response surface methodology (RSM) [MyersM95, KhuriC96, HinkeK94] for various analysis, design, and optimization purposes (e.g., see [ChenGM01, SteffSY00, GiuntBH97, ChenAT96]). After making quantitative examination of their response surface model, the authors of [SteffSY00] analyzed the effects of six independent parameters on system performance using various three-dimensional response surface plots and wrote that "graphical interpretation was far more useful for exploring the results." Engineering test results usually become easier to understand or interpret when they are put into a graphic form. The graphics used in presenting the test results still are predominantly x-y curves with the response variable plotted against the test variable. They remain curves in a plane even when there are two or more test variables. In the case of two variables, for instance, one of them is treated as a parameter, and multiple parameterized curves are overlaid in a single x-y plane. Figure 1 is a typical traditional example, where 21 pressure measurements of an air-fuel-mixing stream by three rakes of seven probes are presented in three parameterized curves using rake position as the parameter [KamhaKT03]. Can one see as the authors of [KamhaKT03] claimed that near the top of the rakes the centerline pressure distribution shows separation of the flow, i.e., that some flow migrates to the outboard rakes? A single response surface in a three-dimensional space could make it easier than multiple overlaid parameterized curves in a plane to understand, interpret, or even visualize the same test results.

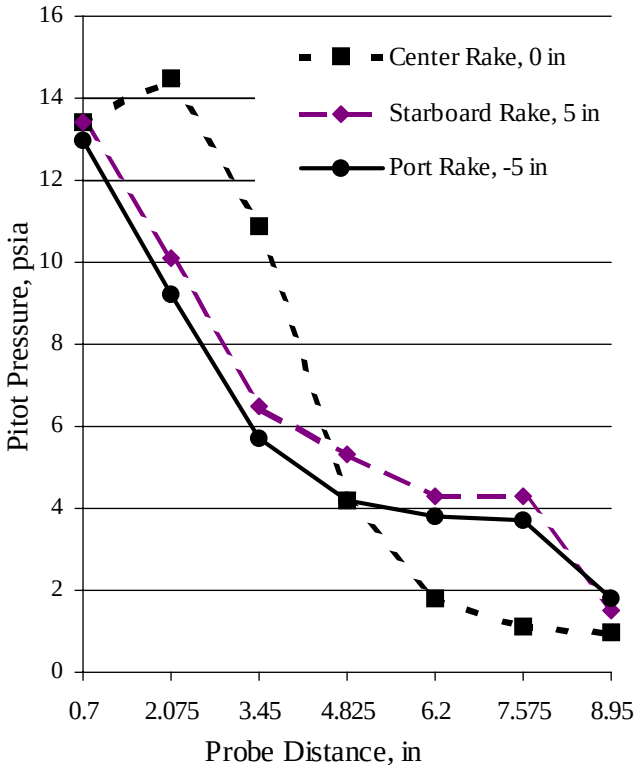

FIG. 1. *Pressure measurements by* 3 *rakes of* 7 *probes.*

A second-order response model obviously will not fit the pressure data of Figure 1 well, judging by the highly nonlinear sine-wave-like pressure profile along the center rake. We may consider building a higher-order response model. To build a model by RSM is to form a (test) matrix X first, using the specific values of the test variables. Then the resulting system of normal equations is solved for the unknown coefficients with the conventional assumption that the matrix X has full column rank [MyersM95, KhuriC96, Myers71], and hence the product matrix X^TX is nonsingular and invertible. We cannot build any higher-order response model for the pressure data this way because the matrix X stops having full column rank even for the third order.

We may seek D-optimal design of experiments [MyersM95, KhuriC96] for help, because it will maximize the determinant of the product matrix X^TX [BoxD71] and hence make X^TX most invertible. This would mean, for instance in using an algorithm such as proposed in [Mitch74], eliminating (or replacing) linearly dependent rows of matrix X and hence all the corresponding response data. Neglecting test results, especially those acquired with great effort and expense, such as from complex engineering or wind-tunnel tests or from flight experiments, however, would be impractical or unwise. Deleting rows from the matrix X for a third-order model of the pressure data actually cannot make the shrunk matrix X full column rank, 10, at all. Should we just give up and be content with a plainly flat second-order response surface?

Traditionally, response surface models are linear or quadratic (i.e., of first or second order). Recently, there have been some interesting advances to higher-order data or response fitting. The following are two examples.

(1) The problem of fitting scattered data is encountered frequently in many scientific disciplines. A variety of (quadratic) surface fitting methods are used in global methods, in which each interpolated value is influenced by all of the data, and in local methods, which are capable of treating much larger data sets. The most accurate local methods in earlier survey papers included a modified Shepard's method. Renka [Renka88] improved both efficiency and accuracy of this modified quadratic Shepard's method further by clever modification and enhancement.

Recently, Renka extended the modified quadratic Shepard method [Renka88] to a cubic Shepard method [Renka99] for constructing a smooth two-variable cubic function C that interpolates given data values y_i at given scattered points (nodes) in a two-dimensional plane for $i = 1, \ldots, N$, where N is a given large number. Accordingly, the accuracy is greatly improved further. The interpolating function C is defined as a weighted sum of N nodal functions C_j. At each node j, the nodal function C_j is a two-variable cubic polynomial that not only interpolates the data value y_j at node j but also fits the data values on a set of N_j nearby nodes in a weighted least-squares sense. The system of normal equations for each nodal function is solved for the regression coefficients. In both quadratic and cubic versions, when N_j nearby nodes have been incorporated for the least-squares fitting, the system is tested for ill-conditioning, and more nodes and data values are added if necessary, up to a limit that is arbitrarily set at $\min\{40, N-1\}$. In case the limit is exceeded, see [Renka88, Renka99] for more details.

(2) The drive for efficient methods of testing engineering design ideas and prototypes has led to a rapid increase in the field of numerical simulation using computers, which in turn has fueled the need for empirical models that interpolate data collected from these simulations. The data generated from computer code contain no measurement error, and models that are exact interpolators are desirable. Because engineering analysis, design, and optimization would be too slow if conducted on the simulator directly, these interpolators are used as fast approximations to the slow simulators. Traditional response surface methods are not sufficiently flexible to accurately model data from computer experiments. Bates, Giglio, and Wynn [BatesGW03] thus propose using a wider class of polynomial models and to take advantage of the lack of measurement error to develop a methodology for finding good interpolators. They propose a two-stage process. First, a search is conducted to find the smoothest (in the sense of minimum curvature) interpolating model from the set of "complete" models. Then backward stepwise regression is carried out on the chosen interpolator to reduce the number of terms in the polynomial according to a combination of model curvature and fitting residuals.

A model for which the number of terms in the polynomial is equal to the number of observations is an (exact) interpolator, provided that certain nonsingularity conditions on the (design) matrix X hold. Given a set of observations without error, in general there is no unique polynomial interpolator. When the number of variables and observations increases, the number of possible interpolators grows rapidly. Thus, in applications where a class of interpolators needs to be searched to find the best model for a given data set, the problem can become too complex. Instead, they consider the subclass C called "complete" models and present an algorithm that combines global and local search strategies within C for the efficient identification of interpolating

polynomials. A polynomial model is said to be complete if for each term in the model all of the terms that divide it are also included in the model. For example, with 2 variables (x_1, x_2) and 6 observations, there are four possible 6-term complete models:

$$\begin{aligned}
&\text{highest-order term is } x_1^5(\text{no } x_2) : 1, x_1, x_1^2, \ldots, x_1^5;\\
&\text{highest-order term is } x_2^5(\text{no } x_1) : 1, x_2, x_2^2, \ldots, x_2^5;\\
&\text{highest-order term is } x_1^2x_2 : 1, x_1, x_2, x_1^2, x_1x_2, x_1^2x_2;\\
&\text{highest-order term is } x_1x_2^2 : 1, x_1, x_2, x_1x_2, x_2^2, x_1x_2^2.
\end{aligned}$$

With 18 observations, there are six possible 18-term complete models, each having $x_1^{17}x_2^0, x_1^0x_2^{17}, x_1^8x_2, x_1x_2^8, x_1^5x_2^2$, or $x_1^2x_2^5$ as the highest-order term.

They must apply a matrix rank test to any interpolator considered during the search stage to prevent any model with singular design matrix X from being fitted. See [BatesGW03] for more details.

What if, in many other data or response fitting problems, adding more nodes or points with response data is hardly feasible? What if the matrix X^TX (or X if square) is nearly singular (i.e., ill-conditioned) because its computed determinant or one of its computed eigenvalues is nearly zero? How does one compute reliably for determining matrix rank, especially when the matrix is nearly rank deficient? In general, when the test or design matrix X, though still having full column rank, is near rank deficiency, the inverse of X^TX may have an excessively large magnitude erroneously, and any error in the response data will be magnified undesirably. What if one cannot simply give up such an ill-conditioned matrix?

Difficulties with solving ill-conditioned systems of linear equations have been actively addressed in the field of numerical algebra for a long time already, and reliable and efficient computational techniques have been developed (see, e.g., [GolubV83, LawsoH74, Stewa73, Wilki68]). In order to enable RSM to handle general test or design matrix X, for higher order or not, we propose that problems with rank deficiency and near rank deficiency in the matrix be dealt with directly by using the singular value decomposition (SVD) techniques and algorithms. Thus, the main effort in this paper is to incorporate SVD appropriately into conventional first/second-order and unconventional higher-order response modeling. Three associated issues are also addressed.

1. While developing and advocating SVD for solving general ill-conditioned systems of linear equations, Golub has persistently argued against the RSM-conventional normal-equation method of solving least-squares (LS) fitting problems. Should the normal-equation method be abandoned?

2. When the matrix X has full column rank, as in the traditional case, we may want to lop off some of the fitted coefficients if they are considered insignificant. Student's t-statistic and the F-statistic are commonly used for such a significance test. They are based on the assumption that the uncertainties in the response data are normally distributed. There are cases, such as numerical experiments using the computer, where normal distribution of the uncertainties or random errors is not justifiable and may be purely an arbitrary assumption for analytical convenience. What is a reasonable mathematical alternative to such statistical tests as a truncation criterion?

3. After having successfully modeled with a rank-deficient matrix X, there are more coefficients than the matrix rank, and we may want to reduce the redundant coefficients. The usual t- and F-statistical tests are not applicable if the matrix X does not have full column rank [Searl71]. What is a reasonable analytical way to truncate

such a fitted polynomial to a full-rank state without causing excessive increase in the residuals?

In section 2, first we formulate higher-order response modeling as a linear regression problem in the standard general form. Then we address major issues with solving the resulting, possibly ill-conditioned, system of normal equations. We also discuss whether we can simply turn the crank of a generalized inverse or pseudoinverse algorithm for the desired LS solution when the rank of the matrix X^TX (or X) is not known a priori. In section 3, we propose that the SVD of the matrix X be calculated first and then used for computing the desired solution. Key SVD properties, particularly the rank of a rank-deficient matrix, are introduced. We then derive the SVD-based solution from three different viewpoints and address the associated Issue 1. In section 4, we propose a specific computational formula for the desired SVD-based solution plus two new, intuitively meaningful fitness measures. Then Algorithm 1 is formulated for computing the LS fitting coefficients in the general case where the matrix X may or may not have full rank.

Now that Algorithm 1 handles rank deficiency effectively, we can model given responses with a higher order. An interesting question is, How high? In section 5, we derive some formulas for calculating the number of coefficients in higher-degree polynomials and discuss practical limitations on model order. On the other hand, after having modeled given responses with a desirable high order, we may want to reduce the model complexity by trimming off redundant terms or insignificant coefficients. Section 6 thus addresses the associated Issues 2 and 3 and develops two unconventional trimming algorithms. Finally, in section 7, demonstrations and applications are given. First, we use published results of two well-executed or well-illustrated examples of conventional RSM application for apples-to-apples comparison of the proposed SVD approach on the same conventional ground. Then we use two hypothetical examples to validate the proposed computational technique by demonstrating that if the response is actually a polynomial, the proposed technique can model it accurately whether the matrix X has full rank or has a large rank deficiency. Then an example of real hardware tests with a truly unknown response function is given to demonstrate the application of three proposed algorithms. There we show that the proposed SVD approach enables us to model the pressure responses of Figure 1 to a desirable higher order without difficulty. We can therefore obtain an interesting three-dimensional response surface plot that makes it rather simple to see and interpret the flow separation and the outward flow migration.

2. Higher-order regression. Given values of k independent test variables, $x_1, \ldots, x_k$, and the associated values of response variable, y, the general response modeling problem is to find a polynomial P_m of degree m that agrees with response y as well as possible at the given test points. To build a third-order response model, for instance, is to postulate a (full) cubic polynomial,

$$P_3(x_1, \ldots, x_k) = \beta_0 + \sum_{j_1=1}^{k} \beta_{j_1} x_{j_1} + \sum_{j_1=1}^{k} \sum_{j_2 \geq j_1} \beta_{j_1 j_2} x_{j_1} x_{j_2} + \sum_{j_1=1}^{k} \sum_{j_2 \geq j_1} \sum_{j_3 \geq j_2} \beta_{j_1 j_2 j_3} x_{j_1} x_{j_2} x_{j_3},$$

with undetermined coefficients (also called model parameters) $\beta_0, \beta_1, \ldots, \beta_k, \ldots, \beta_{kk}, \ldots, \beta_{kkk}$). We may occasionally see in design-of-experiment literature (e.g., [BoxD71])

that a polynomial basically of degree 2 includes a couple of two- or three-variable interactions. Here we start with full-order modeling since in general, the empirical models that are most sensible in practical situations are those that contain all terms up to a given order [BoxD71]. Suppose there are N observations or, equivalently, N test points at which responses are available. Let $x_{i1}, \ldots, x_{ik}$ represent specifically the inputs at test point i and y_i the corresponding response. Then the given test data can be expressed as

$$y_i = P_3(x_{i1}, \ldots, x_{ik}) + \varepsilon_i, \qquad i = 1, \ldots, N, \tag{1}$$

with ε_i representing the associated uncertainties. Denote by X the test matrix having

$$(1, x_{i1}, \ldots, x_{ik}; x_{i1}^2, x_{i1}x_{i2}, \ldots, x_{ik}^2; x_{i1}^3, x_{i1}^2 x_{i2}, \ldots, x_{ik}^3)$$

as the ith row and by $\boldsymbol{\beta}$ the coefficient vector

$$(\beta_0, \beta_1, \ldots, \beta_k; \beta_{11}, \beta_{12}, \ldots, \beta_{kk}; \beta_{111}, \beta_{112}, \ldots, \beta_{kkk}).$$

Also, denote by $\boldsymbol{y}$ the response vector $(y_1, \ldots, y_N)$ and by $\boldsymbol{\varepsilon}$ the uncertainty vector $(\varepsilon_1, \ldots, \varepsilon_N)$. Then (1) can be recast in the standard matrix form as

$$\boldsymbol{y} = X\boldsymbol{\beta} + \boldsymbol{\varepsilon}. \tag{2}$$

Similarly, to build a higher, mth-order response model is to postulate a polynomial of degree m and express the given test data in a form similar to (2), except that as a result of including higher-power products of the test inputs, the matrix X has additional columns and the vector $\boldsymbol{\beta}$ has additional components. In other words, X is an $N \times p$ matrix and $\boldsymbol{\beta}$ is a p-component vector, where p denotes the number of the terms in the polynomial.

In the following, consider the fitting of N response data by a generic mth-order model and use (2) as the general form with matrix X having p columns and vector $\boldsymbol{\beta}$ having p components. This general full-order formulation applies to all special cases where specific terms are omitted. (In such cases, delete the corresponding columns of the matrix X and the corresponding components of the vector $\boldsymbol{\beta}$.) To fit by a polynomial P_m is as usual to find a particular vector $\boldsymbol{\beta}$ that minimizes the sum of squared deviations

$$\sum_{i=1}^{N} [y_i - P_m(x_{i1}, \ldots, x_{ik})]^2 = (\boldsymbol{y} - X\boldsymbol{\beta})^T (\boldsymbol{y} - X\boldsymbol{\beta}).$$

Differentiating the right-hand side with respect to vector $\boldsymbol{\beta}$ and setting the result to zero, we readily obtain the following necessary and sufficient condition for vector $\boldsymbol{b}$ to be a LS solution:

$$X^T X\boldsymbol{b} = X^T \boldsymbol{y}. \tag{3}$$

It is the system of [illegible] in the matrix form. A common practice in the first- and second-order cases is to invert the product $X^T X$ and obtain a solution from (3) simply as

$$\boldsymbol{b} = (X^T X)^{-1} X^T \boldsymbol{y} \tag{4}$$

with the traditional assumption [Myers71, MyersM95, KhuriC96] that $N > p$ and the matrix X has full column rank, p. The matrix X, however, does not necessarily have full rank, and hence the product X^TX does not always have inverse, even when N is much larger than p. Solving (3) indirectly as usual by applying Cholesky factorization, Householder orthogonalization, Gram–Schmidt orthonormalization, or Givens rotations will lead to various numerical difficulties when X^TX, though nonsingular, is near rank deficiency.

An overdetermined system of linear equations is generally known to have no solution and an underdetermined or rank-deficient system to have infinitely many solutions. A rank-deficient system, even not overdetermined, such as the following, also may have no solution:

$$\begin{aligned} z_1 + 2z_2 &= 1, \\ 2z_1 + 3z_2 &= 2, \\ 3z_1 + 4z_2 &= 3, \\ 4z_3 + 5z_4 &= 4. \end{aligned}$$

Fortunately, we can assert, as it would likely have been taken for granted, that the normal equations always have solutions even when X is rank deficient.

THEOREM 1. For any vector $\boldsymbol{y}$, the system of normal equations (3) has a solution $\boldsymbol{b}$.

PROOF. All we need is to prove that the augmented matrix $[X^TX, X^T\boldsymbol{y}]$ has the same rank as X^TX. First of all, denote the rank of matrix X by r. Arrange the columns of X such that the first r columns are linearly independent. Denote by $X_R = [X_1, X_2, \ldots, X_r]$ the corresponding submatrix of matrix X, where X_j represents the jth column of X. Then any other column of X, represented by X_{r+1}, must be a linear combination of these r columns; that is, $X_{r+1} = X_R\boldsymbol{c}$ for some nonzero vector $\boldsymbol{c}$.

The first r rows of product X^TX are $X_1^TX, X_2^TX, \ldots, X_r^TX$. The corresponding submatrix of X^TX is X_R^TX. It has rank r. Let X_{r+1}^TX represent any other row of X^TX. Then it must be a linear combination of these rows because $X_{r+1}^TX = \boldsymbol{c}^TX_R^TX$.

The first r rows of the augmented matrix $[X^TX, X^T\boldsymbol{y}]$ are $[X_1^TX, X_1^T\boldsymbol{y}]$, $[X_2^TX, X_2^T\boldsymbol{y}], \ldots, [X_r^TX, X_r^T\boldsymbol{y}]$. The submatrix of $[X^TX, X^T\boldsymbol{y}]$ corresponding to these rows is $[X_R^TX, X_R^T\boldsymbol{y}]$. It has rank r. Likewise, let $[X_{r+1}^TX, X_{r+1}^T\boldsymbol{y}]$ represent any other row of the augmented matrix. Then it must be a linear combination of these r rows because $[X_{r+1}^TX, X_{r+1}^T\boldsymbol{y}] = [\boldsymbol{c}^TX_R^TX, \boldsymbol{c}^TX_R^T\boldsymbol{y}] = \boldsymbol{c}^T[X_R^TX, X_R^T\boldsymbol{y}]$. This means that product X^TX augmented by vector $X^T\boldsymbol{y}$ gets no increase in rank.

Consequently, given any vector $\boldsymbol{y}$, $X^T\boldsymbol{y}$ is a linear combination of the columns of X^TX. The combination coefficients thus provide a solution vector $\boldsymbol{b}$ to the system of normal equations. □

Theorem 1 implies that the system of normal equations is always consistent and that when X is rank deficient, the system may have multiple solutions. Theoretically, any consistent system of equations can be solved by using a generalized inverse of either the weakest kind, the weak or normalized kind, or the Moore–Penrose kind [Rohde66, Searl71]. In statistical analysis of unbalanced data [Searl71], the matrix X for first-order regression is a sparse incidence matrix, consisting only of 1's and 0's ("yes" or "no" it is a type considered), which rarely has full column rank, even though N is much greater than p. The product X^TX has no inverse, and a generalized inverse is computed. Given a matrix A, such as $A = X^TX$, a generalized inverse is any matrix G satisfying $AGA = A$. An algorithm for computing G is described essentially as follows [Searl71, pp. 5–6]. In matrix A, of rank r, find a nonsingular minor of

order r and bring it to the leading position. Let P and Q be the elementary row and column operations such that

$$PAQ = \begin{bmatrix} B_{11} & B_{12} \\ B_{21} & B_{22} \end{bmatrix} \quad \text{and} \quad \text{define } C = \begin{bmatrix} B_{11}^{-1} & 0 \\ 0 & 0 \end{bmatrix},$$

where B_{11} is nonsingular of order r. Then $G = QCP$ is a generalized inverse of A. Mentioned explicitly in [Searl71, pp. 6–7] are that the computation is based on knowing the rank of matrix A and that most methods involve the same kind of numerical problems as are incurred in calculating the regular inverse B_{11}^{-1} of a nonsingular matrix B_{11}. Numerical difficulties are frequently encountered in situations where near rank deficiency prevails; rounding errors and fuzzy data make rank determination a nontrivial exercise. One of the most valuable aspects of SVD is that it enables us to deal sensibly with the concept of matrix rank [GolubV83, p. 19].

The unique solution obtainable by using the pseudoinverse [Grevi59] is the smallest of all kinds of generalized inverses, having the least Euclidean norm. Computing the pseudoinverse of a matrix numerically has not been without complications and difficulties. It not only has four different conditions to satisfy but also has to assess the matrix rank from, for instance, extremely small computed eigenvalues, many of which are essentially zero in the finite-precision, floating-point computer operations. The development of reliable SVD calculation [GolubK69, GolubR70] started to greatly simplify it. Even then, no SVD subroutines for calculating pseudoinverses or solving LS solutions, such as the Golub–Reinsch algorithm [GolubR70] or Chan's improved algorithm [Chan82], produce a pseudoinverse automatically. They leave it to their user to decide the rank of the specific matrix after the subroutines have terminated before composing the desired pseudoinverse of X or X^TX. The SVD algorithms can compute all the singular values precisely and reliably, but the user has to decide how small a computed singular value is to be considered negligible (and thus treated as zero). This is important, since the pseudoinverse is essentially obtained from inverting each nonzero singular value deemed significant and retained. Small changes in matrix X or in vector $\boldsymbol{y}$ can induce undesirably large changes in solution $\boldsymbol{b}$ if an extremely small computed singular value is retained for inversion.

Therefore, instead of computing and applying pseudoinverses of X^TX formally, we propose that the following SVD-based solution of the normal equations be computed directly. It is simpler and more efficient, avoiding unnecessary matrix formation and multiplication.

3. Solution via SVD. We propose that the system of normal equations be solved for LS solution $\boldsymbol{b}$ by performing the SVD of the matrix X first. The following are some useful properties associated with SVD. See [GolubV83, pp. 16–20; KlemaL80, LawsoH74, Golub69].

LEMMA 1 (see [GolubV83, pp. 16–17; LawsoH74]). [illegible] $N \times p$, [illegible] X [illegible] [illegible] $N \times N$, [illegible] $U = [\boldsymbol{u}_1, \ldots, \boldsymbol{u}_N]$ [illegible] [illegible] $p \times p$, [illegible] $V = [\boldsymbol{v}_1, \ldots, \boldsymbol{v}_p]$ [illegible]

$$U^TXV = S \quad \text{and hence} \quad X = USV^T, \tag{5}$$

[illegible] S [illegible] $N \times p$ [illegible] [illegible] [illegible]

square roots of the eigenvalues of X^TX or XX^T [LawsoH74; GolubV83, p. 285], but to compute them by first finding the eigenvalues of either product matrix is not a reliable approach (for an illustration, see [KlemaL80]). Columns $\boldsymbol{u}_j$ are the jth left singular vector and columns $\boldsymbol{v}_j$ the jth right singular vectors. Golub and Reinsch [GolubR70] have developed a very efficient and stable algorithm for calculating the SVD, fairly sophisticated and reliable implementation of which can be found in LINPACK or EISPACK; see, e.g., [KlemaL80, GolubV83] for more discussions. The Golub–Reinsch algorithm is made further efficient by Chan's improvement [Chan82, GolubV83].

1 (see [GolubV83, p. 18]). The rank of X is r if (a) all but the first r singular values of matrix X are zero, i.e., $s_1 \geq \cdots \geq s_r > s_{r+1} = \cdots = 0$, and $r < \min\{N, p\}$, or (b) all singular values of X are positive, i.e., $s_1 \geq \cdots \geq s_r > 0$, and $r = \min\{N, p\}$.

2 (see [GolubV83, p. 19]). Denote the rank of matrix X by r and the diagonal matrix of order r consisting of all r nonzero singular values of X by $S_r = \operatorname{diag}\{s_1, \ldots, s_r\}$. Partition the orthogonal matrix U into two parts, $U = [U_r, U_z]$, with $U_r = [\boldsymbol{u}_1, \ldots, \boldsymbol{u}_r]$ consisting of its first r columns. Also partition the orthogonal matrix V into two parts, $V = [V_r, V_z]$, with $V_r = [\boldsymbol{v}_1, \ldots, \boldsymbol{v}_r]$ consisting of its first r columns. Then

$$U_r^T U_r = I_r, \quad V_r^T V_r = I_r, \quad X = U_r S_r V_r^T, \tag{6}$$

and I_r denotes the identity matrix of order r.

Now we are ready to derive the SVD-based solution by three approaches.

3.1. Solving the normal equations.

THEOREM 2. SVD X U, V S X r SVD X r (3)

$$V_r^T \boldsymbol{b} = S_r^{-1} U_r^T \boldsymbol{y} \tag{7}$$

$\boldsymbol{y}$ LS

$$\boldsymbol{b} = V_r S_r^{-1} U_r^T \boldsymbol{y}. \tag{8}$$

. It follows from (5) and orthogonality of U and V that $X^TX = VS^TSV^T$ and $X^T\boldsymbol{y} = VS^TU^T\boldsymbol{y}$. Then the necessary and sufficient condition, (3), is equivalent to $S^TSV^T\boldsymbol{b} = S^TU^T\boldsymbol{y}$ because V is nonsingular. Upon partitioning the matrices with respect to rank r of X as described above, the necessary and sufficient condition is equivalent to

$$\begin{bmatrix} S_r^2 & 0 \\ 0 & 0 \end{bmatrix} \begin{bmatrix} V_r^T \\ V_z^T \end{bmatrix} \boldsymbol{b} = \begin{bmatrix} S_r & 0 \\ 0 & 0 \end{bmatrix} \begin{bmatrix} U_r^T \\ U_z^T \end{bmatrix} \boldsymbol{y},$$

which, in turn, is equivalent to (7) as claimed because S_r is nonsingular.

Now, given any $\boldsymbol{y}$, vector $\boldsymbol{b}$ defined by (8) is obviously an LS solution because by the second identity in (6), it satisfies an equivalent form of the normal equations, (7). Moreover, $V_rS_r^{-1}U_r^T\boldsymbol{y}$ is also the solution of the following minimum-norm problem constrained by this SVD form of the normal equations:

$$\begin{aligned} &\text{minimize} && \boldsymbol{\beta}^T\boldsymbol{\beta} \\ &\text{subject to} && V_r^T\boldsymbol{\beta} = S_r^{-1}U_r^T\boldsymbol{y}. \end{aligned}$$

To see that define Lagrangian $L = \boldsymbol{\beta}^T\boldsymbol{\beta} + \boldsymbol{\lambda}^T(V_r^T\boldsymbol{\beta} - S_r^{-1}U_r^T\boldsymbol{y})$ with vector $\boldsymbol{\lambda}$ of Lagrange multipliers. Differentiating it with respect to vector $\boldsymbol{\beta}$ and setting the result to zero gives $\boldsymbol{\beta} = -V_r\boldsymbol{\lambda}/2$. Substituting it into the equality constraint and using the second identity in (6) yields $-\boldsymbol{\lambda}/2 = S_r^{-1}U_r^T\boldsymbol{y}$. Thus, we have $\boldsymbol{\beta} = V_rS_r^{-1}U_r^T\boldsymbol{y}$ as the constrained minimum-norm solution. □

3.2. Pseudoinverting $\boldsymbol{X^TX}$. The pseudoinverse of a matrix A is a unique matrix Z that satisfies the following four Moore–Penrose conditions [Grevi59, LawsoH74, GolubV83]:

(i) $AZA = A$,
(ii) $ZAZ = Z$,
(iii) $(AZ)^T = AZ$, and
(iv) $(ZA)^T = ZA$.

In the case of product X^TX with SVD of X, we have a specific closed-form expression.

THEOREM 3. [illegible] X^TX, $V_rS_r^{-2}V_r^T$ [illegible]. Take $A = X^TX = V_rS_r^2V_r^T$ by the third identity in (6). Then $Z = V_rS_r^{-2}V_r^T$ satisfies all four Moore–Penrose conditions by the second identity in (6) as follows:

(a) $AZA = V_rS_r^2V_r^T(V_rS_r^{-2}V_r^T)V_rS_r^2V_r^T = V_rS_r^2(V_r^TV_r)S_r^{-2}(V_r^TV_r)S_r^2V_r^T = V_rS_r^2V_r^T = A$.
(b) $ZAZ = (V_rS_r^{-2}V_r^T)V_rS_r^2V_r^T(V_rS_r^{-2}V_r^T) = V_rS_r^{-2}(V_r^TV_r)S_r^2(V_r^TV_r)S_r^{-2}V_r^T = V_rS_r^{-2}V_r^T = Z$.
(c) $AZ = V_rS_r^2V_r^T(V_rS_r^{-2}V_r^T) = V_rV_r^T$ [illegible], $(AZ)^T = AZ$).
(d) $ZA = (V_rS_r^{-2}V_r^T)V_rS_r^2V_r^T = V_rV_r^T$ [illegible], $(ZA)^T = ZA$). □

It is interesting to see that $(V_rS_r^{-2}V_r^T)$ is an inverse of $X^TX = V_rS_r^2V_r^T$ in the sense of (squares of the nonzero singular values) S_r^2 being inverted inside the same wrap by V_r.

Now define $(X^TX)^+ = V_rS_r^{-2}V_r^T$ as the pseudoinverse of X^TX. Then a solution of normal equations can be conveniently written as

$$\boldsymbol{b} = (X^TX)^+X^T\boldsymbol{y}, \tag{8a}$$

just as (4). In fact, it is easy to prove that (8a) is actually the general form, taking (4) as the special case where pseudoinverse becomes regular inverse because of nonsingularity of X^TX. Also, writing it out in the SVD form, we have

$$\boldsymbol{b} = (X^TX)^+X^T\boldsymbol{y} = (V_rS_r^{-2}V_r^T)\ V_rS_rU_r^T\boldsymbol{y} = V_rS_r^{-1}U_r^T\boldsymbol{y},$$

which is the same as (8).

3.3. Pseudoinverting $\boldsymbol{X}$. Define S^+, a $p \times N$ matrix having reciprocals of the r nonzero singular values (i.e., $1/s_1, \ldots, 1/s_r$) in the leading diagonal positions but zeros elsewhere, as the pseudoinverse of the $N \times p$ singular-value matrix S. Define $X^+ = VS^+U^T$ as the pseudoinverse of X. Then, as stated in [GolubV83, p. 139],

$$\boldsymbol{b} = X^+\boldsymbol{y} \tag{8b}$$

is the minimum-norm LS solution of the system

$$X\boldsymbol{\beta} = \boldsymbol{y}. \tag{9}$$

Upon partitioning the SVD matrices according to rank r of matrix X, the pseudoinverse of X readily becomes $X^+ = VS^+U^T = V_rS_r^{-1}U_r^T$. Consequently, solution (8b) also becomes identical to solution (8).

The method of normal equations has traditionally been most commonly used to solve LS problems. Since X is conventionally presumed to have full column rank, the product matrix X^TX is both symmetric and positive definite and thus naturally suitable for applying Cholesky factorization algorithms, which not only run to completion but also are extremely stable [GolubV83, pp. 85, 89]. Nonetheless, Golub [Golub69, GolubV83] has persistently argued, with good reasons based on Wilkinson's extensive studies on Cholesky algorithms [Wilki68], against using Cholesky algorithms with the method of normal equations particularly when matrix X is nearly rank deficient. It is asserted in [GolubV83, p. 170] that the only fully reliable way to treat rank deficiency is to compute the SVD. What we have shown above is that if SVD is performed on X first, then solving the normal equations in the SVD form, (7), for LS solution (8) is the same, and equally reliable, as solving the system of equations, (9), for LS solution (8b) with the pseudoinverse of X. The associated Issue 1 is thus resolved.

4. Proposed computational technique. RSM has rarely made use of polynomials of degree higher than 2, and we suggest that one should try if it would fit and characterize the test results better. If one decides to try for a higher-order model and applies the method of normal equations as usual, one may likely encounter difficulties with rank deficiency or near rank deficiency of the resulting matrix X, difficulties that one generally need not deal with in the conventional first- or second-order modeling. Here we propose that SVD, a mathematical technique well-developed for treating ill-conditioned systems, be employed right away in the numerical computation so that one can easily succeed in the modeling whether or not the resulting matrix X has full rank. A major advantage of the proposed SVD approach is that the rank of any matrix X can be determined appropriately, reliably, and efficiently before computing the LS solution.

4.1. Computational formula. Lawson and Hanson [LawsoH74] pointed out that the inverse matrix is a very useful mathematical concept even though efficient and reliable methods for computing the solution of, say, system (9) when X is nonsingular do not involve explicit computation of an inverse matrix. Likewise, the pseudoinverse is also a very useful mathematical concept, but one would not usually compute it explicitly in computing a minimum-norm LS solution. Thus, (8) is more suitable for numerical computation than (8a) and (8b). Furthermore, it is more efficient to compute directly by the following expanded form, saving all the wasting operations of multiplying with the zero off-diagonal elements of the sparse S_r^{-1}:

$$\boldsymbol{b} = \sum_{j=1}^{r} (\boldsymbol{u}_j^T \boldsymbol{y}/s_j)\boldsymbol{v}_j. \tag{10}$$

4.2. Measures of fitness. The modeling errors minimized with LS solution $\boldsymbol{b}$ are the residuals: $\boldsymbol{e} = \boldsymbol{y} - X\boldsymbol{b}$. The sum of squared modeling errors, SSE $= \boldsymbol{e}^T\boldsymbol{e}$, is useful for assessing the accuracy, or measuring the fitness, of the model. Another measure is the spread of the uncertainties. A conventional convenient practice [MyersM95, KhuriC96] is to assume that all the uncertainties are independent and have zero mean and identical variance, σ^2. An estimate of the variance, hence the spread, is then derivable from the residuals.

THEOREM 4. [illegible] $E(\boldsymbol{\varepsilon}) = 0, E(\boldsymbol{\varepsilon}\boldsymbol{\varepsilon}^T) = \sigma^2 I_N$ [illegible] E [illegible] X [illegible] r [illegible] SVD [illegible]

[illegible] 2 [illegible]

$$E(\text{SSE}) = \sigma^2(N - r). \tag{11}$$

[illegible]. Relate the residuals to the uncertainties $\boldsymbol{\varepsilon}$ through (6) and (8) as follows:

$$\begin{aligned}\boldsymbol{e} &= \boldsymbol{y} - U_r S_r V_r^T V_r S_r^{-1} U_r^T \boldsymbol{y} \\ &= \boldsymbol{y} - U_r U_r^T \boldsymbol{y} \\ &= (I_N - U_r U_r^T) X\boldsymbol{\beta} + (I_N - U_r U_r^T)\boldsymbol{\varepsilon} \\ &= (I_N - U_r U_r^T)\boldsymbol{\varepsilon},\end{aligned}$$

where $(I_N - U_r U_r^T)X = X - U_r U_r^T (U_r S_r V_r^T) = X - U_r S_r V_r^T = 0$. Then

$$\text{SSE} = \boldsymbol{e}^T\boldsymbol{e} = \boldsymbol{\varepsilon}^T(I_N - U_r U_r^T)(I_N - U_r U_r^T)\boldsymbol{\varepsilon} = \boldsymbol{\varepsilon}^T(I_N - U_r U_r^T)\boldsymbol{\varepsilon} = tr[(I_N - U_r U_r^T)\boldsymbol{\varepsilon}\boldsymbol{\varepsilon}^T],$$

where tr denotes the trace of the matrix. Taking the expected value, we have

$$\begin{aligned}E(\text{SSE}) &= tr[(I_N - U_r U_r^T)E(\boldsymbol{\varepsilon}\boldsymbol{\varepsilon}^T)] = \sigma^2 tr(I_N - U_r U_r^T) \\ &= \sigma^2[N - tr(U_r^T U_r)] = \sigma^2(N - r). \qquad \square\end{aligned}$$

Therefore, for $N > r$, an unbiased estimator of variance σ^2 is

$$\hat{\sigma}^2 = \text{SSE}/(N - r). \tag{12}$$

Vector $\boldsymbol{e}$ represents the deviations from the responses by the fitted polynomial, and so does vector $\boldsymbol{\varepsilon}$ but by the underlying unknown polynomial. When would both deviations $\boldsymbol{e}$ and $\boldsymbol{\varepsilon}$ have the same spread, i.e., $E(\text{SSE}) = \sigma^2$? By (11), it would happen only if $N - r = 1$ when SSE $\neq 0$. In general, $E(\text{SSE}) \geq \sigma^2$; that is, for $N - r \geq 1$, we should not (and cannot) expect the residuals to be contained within the unknown uncertainties. Therefore, each can be a different fitness measure in its own right.

Define the root-mean-square (RMS) modeling error as RMSE $= \sqrt{(\text{SSE}/N)}$, evaluated over the N responses as usual in engineering (but not over the "degrees of freedom" in the statistical analysis of variance). We prefer the intuitive meaning of average individual size conveyed by RMS to the concept of root-sum-square, which increases with the group size (i.e., the number of residuals in the summation). Define the estimated standard deviation by (12) as StDev $= \sqrt{[\text{SSE}/(N - r)]}$, provided $N > r$.

Relative errors generally are more meaningful than absolute errors in accuracy assessment. Since both represent deviations from the same responses, we use the RMS value of the responses, RMSY $= \sqrt{(\text{SSY}/N)}$, as the common reference, where $SSY = \sum_{i=1}^{N} y_i^2$. Then define the relative RMS error (expressed in percentage) as

$$\text{RMSE}\% = 100(\text{RMSE}/\text{RMSY}). \tag{13}$$

Similarly, define the relative estimated standard deviation (also expressed in percentage) as

$$\text{StDev}\% = 100(\text{StDev}/\text{RMSY}). \tag{14}$$

Both RMSE% and StDev% indicate the goodness of the fit: the smaller the better. The former always decreases as the model order increases, but the latter may not. The latter is useful for helping one determine whether or not raising the order is necessary. Example 2 in section 7 shows that StDev% is a good alternative to the conventional statistical counterpart in discriminating fitness of models of different orders. Because they are normalized with respect to the response data, both RMSE% and StDev% are good to be universal fitness measures for general performance assessment when comparing across different sets of response data or even different response modeling situations.

These new definitions are compatible, respectively, with the R^2 and R^2_{adj} statistics used in the conventional response surface methodology [MyersM95, KhuriC96]. The square of the coefficient of correlation, also known as coefficient of multiple determination, $R^2 = 1 - \text{SSE}/\text{SST}$, is used as a measure of the amount of reduction in the variability of response obtained by regression [MyersM95], where $\text{SST} = \sum_{i=1}^{N}(y_i - \bar{y})^2$ is the total sum of squares (of responses $\boldsymbol{y}$) corrected for the mean $\bar{y} = \sum_{i=1}^{N} y_i$. The square of RMSE% essentially is a complement of R^2, since SST and SSY differ only by a constant, the mean $\bar{y}$.

Some model builders prefer the adjusted R^2 statistic,

$$R^2_{adj} = 1 - [\text{SSE}/(N-p)]/[\text{SST}/(N-1)],$$

because adding variables to the model will always increase R^2 regardless of whether or not the addition is statistically significant, whereas adding variables in general will not increase the adjusted R^2 statistic [MyersM95]. First, note that in analysis of variance, the SSE is considered to have $N-p$ "degrees of freedom" and the SST to have $N-1$ "degrees of freedom." Thus, $\text{SSE}/(N-p)$ and $\text{SST}/(N-1)$ are the so-called sums of squares in statistics. Next, note that this adjusted statistic is defined only for the conventional case of matrix X having full column rank p. Nevertheless, because of (12), we can extend it to the general case where X has rank r, full or not. Then the square of StDev% is essentially a complement of such a yet-to-be-extended R^2_{adj} statistic if it has to lose the mean $\bar{y}$ and one degree of freedom from its SSY. Moreover, StDev% is much closer to common sense, having a much more intuitively obvious meaning.

4.3. Computing steps. By SVD Property 1, the number of nonzero singular values determines the rank. It is not nearly as clear-cut in the context of computation on a digital computer, though, because zero singular values may actually appear as small nonzero numbers due to finite precision of the floating-point operations. (Bounded by finite precision, computation must be done in the presence of rounding or truncation error at each stage.) One approach, adapted from [GolubV83, p. 176; KlemaL80], is to have a parameter $\zeta > 0$ and a convention that the $N \times p$ matrix X has "numerical rank" r if the computed singular values are such that $s_1 \geq \cdots \geq s_r > \zeta \geq s_{r+1} \geq \cdots$ or has "numerical rank" $r = \min\{N, p\}$ if all the computed singular values are greater than ζ. The parameter ζ should be chosen consistent with both the precision of the specific machine and the numerical magnitude of the specific test matrix. After having gotten some experience, we have no difficulty setting such a parameter for automatic determination of the appropriate numerical rank.

In summary, we propose the following procedure for computing the LS fitting coefficients in the general case where the test matrix X may or may not have full rank.

ALGORITHM 1.

1. Form the matrix X as usual.
2. Perform SVD of X and obtain matrices U, V, and S.
3. Determine the numerical rank r of X based on the computed singular values.
4. Determine the first (largest) r computed singular values s_j, the first r columns $\boldsymbol{u}_j$ of U, and the first r columns $\boldsymbol{v}_j$ of V.
5. Compute the regression coefficients: $\boldsymbol{b} = \sum_{j=1}^{r} (\boldsymbol{u}_j^T \boldsymbol{y}/s_j)\boldsymbol{v}_j$.
6. Check if RMSE% and StDev% are small and acceptable. If not, repeat the procedure for a higher order.

Though not required by this algorithm, it is a good common RSM practice to convert natural variables ξ_j in natural units of measurement to "coded" variables—each being dimensionless with zero mean and same standard deviation—and use the coded variables as test variables x_j to form the matrix X. A standard procedure is to shift each natural variable ξ_j to the center between its maximum and minimum (in the N observations) and then scale it by half of the range between its maximum and minimum.

5. Number of coefficients. The (total) number of coefficients in a k-variable quadratic polynomial is well known to be $(k+1)(k+2)/2$. In this section, we derive similar general expressions for higher degrees and discuss how model order is limited by given numbers of test variables and test responses through the number of coefficients. That these formulas are useful to making D-optimal design of experiments is self-evident. First, we cite four known summation formulas.

LEMMA 2 (see [KornK68]).

(a) $\sum_{j=1}^{k} j = k(k+1)/2$.
(b) $\sum_{j=1}^{k} j^2 = k(k+1)(2k+1)/6$.
(c) $\sum_{j=1}^{k} j^3 = k^2(k+1)^2/4$.
(d) $\sum_{j=1}^{k} j^4 = k(k+1)(2k+1)(3k^2+3k-1)/30$.

Then we derive five new useful formulas.

THEOREM 5. Let p_m denote the number of coefficients in a k-variable polynomial of degree m. Then

(a) $p_3 = (k+1)(k^2+5k+6)/6$;
(b) $p_4 = (k+1)(k^3+9k^2+26k+24)/24$;
(c) $p_5 = (k+1)(k^4+14k^3+71k^2+154k+120)/120$.
(d) $p_m = (k+1)(k+2)\dots(k+m)/m!$
(e) $p_m = p_{m-1}(k+m)/m$.

PROOF. First of all, a polynomial of degree 2 can be reexpressed as follows:

$$\begin{aligned} P_2(x_1, \dots, x_k) &= \beta_0 + \sum_{j_1=1}^{k} \beta_{j_1} x_{j_1} + \sum_{j_1=1}^{k} \sum_{j_2 \le j_1} \beta_{j_1 j_2} x_{j_1} x_{j_2} \\ &= \beta_0 + \sum_{j_1=1}^{k} x_{j_1} \left[\beta_{j_1} + \sum_{j_2 \le j_1} \beta_{j_1 j_2} x_{j_2} \right] \\ &= \beta_0 + \sum_{j_1=1}^{k} x_{j_1} P_{1:j_1}(x_1, \dots, x_k), \end{aligned}$$

where $P_{1:j_1}$ denotes a polynomial of degree 1 having the first j_1 of the k variables.

This linear polynomial, $P_{1:j_1}$, obviously has $(1+j_1)$ terms. Therefore, the number of coefficients in polynomial P_2 is

$$p_2 = 1 + \sum_{j_1=1}^{k} (1+j_1) = 1 + k + k(k+1)/2 = (k+1)(k+2)/2,$$

as is well known.

A polynomial of degree 3 can be reexpressed in a similar manner:

$$\begin{aligned} P_3(x_1, \ldots, x_k) &= \beta_0 + \sum_{j_1=1}^{k} \beta_{j_1} x_{j_1} + \sum_{j_1=1}^{k} \sum_{j_2 \le j_1} \beta_{j_1 j_2} x_{j_1} x_{j_2} \\ &\quad + \sum_{j_1=1}^{k} \sum_{j_2 \le j_1} \sum_{j_3 \le j_2} \beta_{j_1 j_2 j_3} x_{j_1} x_{j_2} x_{j_3} \\ &= \beta_0 + \sum_{j_1=1}^{k} x_{j_1} \left[\beta_{j_1} + \sum_{j_2 \le j_1} \beta_{j_1 j_2} x_{j_2} + \sum_{j_2 \le j_1} \sum_{j_3 \le j_2} \beta_{j_1 j_2 j_3} x_{j_2} x_{j_3} \right] \\ &= \beta_0 + \sum_{j_1=1}^{k} x_{j_1} P_{2:j_1}(x_1, \ldots, x_k), \end{aligned}$$

where $P_{2:j_1}$ denotes a polynomial of degree 2 in the first j_1 of the k variables. By the quadratic formula, polynomial $P_{2:j_1}$ has $(j_1+1)(j_1+2)/2$ terms. Thus, the number of coefficients in polynomial P_3 is

$$p_3 = 1 + \sum_{j_1=1}^{k} (j_1+1)(j_1+2)/2 = 1 + \sum_{j_1=1}^{k} (j_1^2 + 3j_1 + 2)/2 = (k+1)(k^2+5k+6)/6,$$

where Lemma 2(a) and (b) were applied. This proves part (a) of this theorem.

Similarly, a polynomial of degree 4 can be expressed in terms of polynomials of degree 3:

$$\begin{aligned} P_4(x_1, \ldots, x_k) &= \beta_0 + \sum_{j_1=1}^{k} \beta_{j_1} x_{j_1} + \sum_{j_1=1}^{k} \sum_{j_2 \le j_1} \beta_{j_1 j_2} x_{j_1} x_{j_2} \\ &\quad + \sum_{j_1=1}^{k} \sum_{j_2 \le j_1} \sum_{j_3 \le j_2} \beta_{j_1 j_2 j_3} x_{j_1} x_{j_2} x_{j_3} \\ &\quad + \sum_{j_1=1}^{k} \sum_{j_2 \le j_1} \sum_{j_3 \le j_2} \sum_{j_4 \le j_3} \beta_{j_1 j_2 j_3 j_4} x_{j_1} x_{j_2} x_{j_3} x_{j_4} \\ &= \beta_0 + \sum_{j_1=1}^{k} x_{j_1} P_{3:j_1}(x_1, \ldots, x_k) \end{aligned}$$

with $P_{3:j_1}$ being a polynomial of degree 3 in first j_1 of the k variables. By the cubic

formula, the number of coefficients in polynomial P_4 is therefore

$$\begin{aligned} p_4 &= 1 + \sum_{j_1=1}^{k} (j_1 + 1)(j_1^2 + 5j_1 + 6)/6 \\ &= 1 + \sum_{j_1=1}^{k} (j_1^3 + 6j_1^2 + 11j_1 + 6)/6 \\ &= (k + 1)(k^3 + 9k^2 + 26k + 24)/24 \end{aligned}$$

after applying Lemma 2(a), (b), and (c). This proves part (b) of the theorem.

Reexpressing a polynomial of degree 5 in terms of polynomials of degree 4 likewise and using the quartic formula, we have its number of coefficients as

$$\begin{aligned} p_5 &= 1 + \sum_{j_1=1}^{k} (j_1 + 1)(j_1^3 + 9j_1^2 + 26j_1 + 24)/24 \\ &= 1 + \sum_{j_1=1}^{k} (j_1^4 + 10j_1^3 + 35j_1^2 + 50j_1 + 24)/24 \\ &= (k + 1)(k^4 + 14k^3 + 71k^2 + 154k + 120)/120 \end{aligned}$$

by using all parts of Lemma 2. Part (c) of the theorem is thus proved. Parts (d) and (e) are readily evident by induction after factorizing the expressions in parts (a) to (c). □

Flight experiments, wind-tunnel tests, and many complex or large-scale engineering experiments cannot afford frequent reruns, or modified reruns, because their setup and execution usually require commitment and consumption of a great deal of material and human resources. To be cost, time, and resource effective, sufficient and even redundant data often are obtained at once. Such tests tend to be thorough on certain few crucial variables so as to get as clear a picture of their impact as possible. When building regression models to fit those response data, higher-order models naturally are more appropriate for capturing or reflecting the characteristics better. How high order can a model be? It depends on both the number of responses and the number of test variables. As an extended conventional rule of thumb, the number of coefficients (i.e., model parameters) should be less than the number of responses. Now Theorem 5 indicates that the number of coefficients increases rapidly as the number of test variables, k, increases (see also Table 1) essentially at the rate of power k^m, given the order of the response model, m. Thus, given the number of test variables, the order of the response model is severely limited by the number of responses, N, given. With three test variables, for instance, the highest should be second order for 11 up to 20 responses, third order for 21 up to 35 responses, and so on; see Table 1. The test matrix X formed by specific values of the test variables may further dictate that the highest order be even lower to ensure it has full column rank.

Not all terms are equally needed for modeling a specific set of responses. Nevertheless, we can first build up to a desirable highest order and then trim off the redundant or insignificant terms afterward. Because Algorithm 1 handles rank deficiency effectively, a response model actually can be, unconventionally, of a few orders higher than both the number of responses and the rank of the test matrix would dictate (see Examples 4 and 6 in section 7). Suppose we want to use no more terms than the full rank of the test matrix while using important higher-order terms. We

TABLE 1
Number of coefficients.

k	p_2	p_3	p_4	p_5
1	3	4	5	6
2	6	10	15	21
3	*10*	*20*	*35*	*56*
4	15	35	70	126
5	21	56	126	252
6	28	84	210	462
7	36	120	330	792
8	45	165	495	1,287
9	55	220	715	2,002
10	66	286	1,001	3,003

can use Algorithm 2A (in section 6) to trim the terms of a rank-deficient higher-order model down to a full-rank state while keeping whatever higher-order terms that are highly important (see Example 6).

6. Trimming fitted polynomials. We often do not know what factors (powers or cross-products of the test variables) would actually contribute significantly in approximating the responses. Some model builders may toss in a few trial factors at a time; some others may simply include all possible factors for a given order. In any way, we may want to truncate the resulting polynomial afterward if we wish to use fewest possible terms, especially when some are insignificant or redundant. In the extended RSM, there are two trimming phases, full rank and rank deficient, each with a different intent. These are the associated Issues 2 and 3, respectively.

6.1. Trimming in rank-deficient or near rank-deficient phase. Suppose the matrix X is rank deficient or nearly rank deficient. Denote by r the empirical, numerical rank and by $s_r(X)$ the corresponding smallest computed singular value. (This means that there are possibly more than r computed singular values but that all that are smaller than $s_r(X)$ are regarded as being zero.) Rank deficiency implies redundancy among the terms that compose the approximating polynomial. If a coefficient is zero, the corresponding term obviously is redundant, but redundant terms may have nonzero coefficients. Nevertheless, we may not be interested in a polynomial that involves all of the redundant terms. We may instead seek a polynomial that has at most r nonzero coefficients. The position of the nonzero coefficients in the polynomial determines which columns of matrix X are to be used to approximate the responses.

A procedure proposed by Golub, Klema, and Stewart is, after the numerical rank of X is determined through SVD of X, as follows [GolubV83, p. 415]. (a) Calculate a permutation matrix P such that the columns of the $N \times r$ submatrix Z_1 in the partition $XP = [Z_1, Z_2]$ are sufficiently independent. (b) Approximate the responses with $Z_1\boldsymbol{\gamma}$, where $\boldsymbol{\gamma}$ is an r-vector of coefficients to be determined. Step (a) needs elaboration. The selection of r columns from matrix X should be best if they align with response vector $\boldsymbol{y}$ the closest possible because the LS criterion is to minimize deviations from the responses. Such a subset of columns, however, may be very weakly independent, if not linearly dependent. The resulting submatrix Z_1 may therefore be nearly rank deficient, or even rank deficient. Thus, there should be a trade-off between the independence of the chosen columns and the smallness of the residuals they render. Golub, Klema, and Stewart then proposed the following algorithm. Use QR factorization with column pivoting to compute $Q^T[V_{11}^T, V_{21}^T]P = [R_{11}, R_{12}]$, where V_{ij} are blocks of orthogonal matrix V. Then pick the first r columns of X

according to the resulting permutation matrix P as Z_1. Golub, Klema, and Stewart's procedure is particularly suitable for rank-deficient and nearly rank-deficient matrices. See [LawsoH74] for discussions on many other earlier methods of subset selection. The problem of subset selection is to delete some variables β_j from system (9), or select a subset of columns of matrix X, to find the smallest number of variables that can be used in the LS solution and still give acceptably small residuals.

The use of QR with column pivoting is to choose such a permutation P that will produce a matrix $\hat{V}_{11}$ (an upper principal block of product P^TV) as well conditioned as possible [GolubV83, p. 416] so that Z_1 would not be rank deficient (see related discussion shortly). Observe, however, that the choice of r columns of X this way clearly has no connection whatsoever to response vector $\boldsymbol{y}$ so as to lead to any such trade-off. Nevertheless, we can improve their algorithm for our trimming purpose as follows.

Suppose the responses have been fitted with $X\boldsymbol{b}$ and we wish to eliminate $p-r$ terms of the resulting approximating polynomial. Note that it is the whole term—the coefficient together with the self- or cross-product of the variables—that participates as a part of the polynomial in minimizing deviations from the responses. Thus, the columns X_j of matrix X alone do not adequately represent the terms in the approximating polynomial. Those columns of the matrix modified by the appropriate coefficients, namely, $b_1X_1, \ldots, b_jX_j, \ldots, b_pX_p$, do. For these particular, LS fitted, coefficients b_j connect the columns of X to the responses (through the normal equations, of course). Thus, we let diagonal matrix D of order r represent these coefficients, $D = \operatorname{diag}\{b_1, \ldots, b_j, \ldots, b_p\}$, and develop the following improved mathematical machinery.

THEOREM 6. $N \times r$ $\hat{Z}_1$ $XDP = [\hat{Z}_1, \hat{Z}_2]$ P r P^TDP $\hat{D}_1 = \operatorname{diag}\{\hat{b}_1, \ldots, \hat{b}_r\}$ $p \times p$ P^TV $\hat{V}_{11}$ r, P^TV $\begin{bmatrix} \hat{V}_{11} & \hat{V}_{12} \\ \hat{V}_{21} & \hat{V}_{22} \end{bmatrix}$ $\hat{V}_{11}$ $\hat{D}_1$ $s_r(\hat{Z}_1)$ $\hat{Z}_1$ $s_r(\hat{Z}_1) \geq s_r(X) \min\{|\hat{b}_1|, \ldots, |\hat{b}_r|\}/\|\hat{V}_{11}^{-1}\|$

. Let $\boldsymbol{w}$ be a unit r-vector such that $\|\hat{Z}_1\boldsymbol{w}\| = s_r(\hat{Z}_1)$. First, by definition of $\hat{Z}_1$ and $\hat{D}_1$,

$$\hat{Z}_1\boldsymbol{w} = [\hat{Z}_1, \hat{Z}_2] \begin{bmatrix} \boldsymbol{w} \\ 0 \end{bmatrix} = XDP \begin{bmatrix} \boldsymbol{w} \\ 0 \end{bmatrix} = XP(P^TDP) \begin{bmatrix} \boldsymbol{w} \\ 0 \end{bmatrix} = XP \begin{bmatrix} \hat{D}_1\boldsymbol{w} \\ 0 \end{bmatrix}.$$

Then, by (5) and the partitioning of P^TV,

$$\begin{aligned} \hat{Z}_1\boldsymbol{w} &= USV^TP \begin{bmatrix} \hat{D}_1\boldsymbol{w} \\ 0 \end{bmatrix} = US \begin{bmatrix} \hat{V}_{11}^T & \hat{V}_{21}^T \\ \hat{V}_{12}^T & \hat{V}_{22}^T \end{bmatrix} \begin{bmatrix} \hat{D}_1\boldsymbol{w} \\ 0 \end{bmatrix} \\ &= U \begin{bmatrix} S_r & 0 \\ 0 & S_z \end{bmatrix} \begin{bmatrix} \hat{V}_{11}^T\hat{D}_1\boldsymbol{w} \\ \hat{V}_{12}^T\hat{D}_1\boldsymbol{w} \end{bmatrix} = U \begin{bmatrix} S_r\hat{V}_{11}^T\hat{D}_1\boldsymbol{w} \\ S_z\hat{V}_{12}^T\hat{D}_1\boldsymbol{w} \end{bmatrix}, \end{aligned}$$

where S_z is the diagonal matrix of the remaining $p-r$ computed singular values. Because U is orthogonal,

$$\|\hat{Z}_1\boldsymbol{w}\|^2 = \|S_r\hat{V}_{11}^T\hat{D}_1\boldsymbol{w}\|^2 + \|S_z\hat{V}_{12}^T\hat{D}_1\boldsymbol{w}\|^2 \geq s_r(X)^2\|\hat{V}_{11}^T\hat{D}_1\boldsymbol{w}\|^2.$$

Now, because both $\hat{V}_{11}$ and $\hat{D}_1$ are nonsingular, first we can write

$$\boldsymbol{w} = (\hat{V}_{11}^T\hat{D}_1)^{-1}\hat{V}_{11}^T\hat{D}_1\boldsymbol{w}.$$

Taking the norm,

$$1 = \|\boldsymbol{w}\|^2 = \|(\hat{V}_{11}^T \hat{D}_1)^{-1}\, \hat{V}_{11}^T \hat{D}_1 \boldsymbol{w}\|^2 \le \|(\hat{V}_{11}^T \hat{D}_1)^{-1}\|^2\, \|\hat{V}_{11}^T \hat{D}_1 \boldsymbol{w}\|^2.$$

Since

$$\begin{aligned}\|(\hat{V}_{11}^T \hat{D}_1)^{-1}\| \le \|\hat{V}_{11}^{-1}\| \cdot \|\hat{D}_1^{-1}\| &\le \|\hat{V}_{11}^{-1}\| \max\{1/|\hat{b}_1|, \ldots, 1/|\hat{b}_r|\} \\ &= \|\hat{V}_{11}^{-1}\| / \min\{|\hat{b}_1|, \ldots, |\hat{b}_r|\},\end{aligned}$$

then we have

$$\|\hat{V}_{11}^T \hat{D}_1 \boldsymbol{w}\| \ge 1/\|(\hat{V}_{11}^T \hat{D}_1)^{-1}\| \ge \min\{|\hat{b}_1|, \ldots, |\hat{b}_r|\}/\|\hat{V}_{11}^{-1}\|.$$

Consequently,

$$s_r(\hat{Z}_1) = \|\hat{Z}_1 \boldsymbol{w}\| \ge s_r(X) \|\hat{V}_{11}^T \hat{D}_1 \boldsymbol{w}\| \ge s_r(X) \min\{|\hat{b}_1|, \ldots, |\hat{b}_r|\}/\|\hat{V}_{11}^{-1}\| \qquad \square$$

Theorem 6 implies that in order for the smallest singular value $s_r(\hat{Z}_1)$ to be bounded significantly above zero, the permutation matrix P needs not only to make $\hat{V}_{11}$ as well conditioned as possible (so that its inverse does not have a very large norm) but also to get each of the new leading r coefficients $\hat{b}_1, \ldots, \hat{b}_r$ as large as possible. Accordingly, we trade off some linear independence among the selected columns in some implicit favor (conveyed via the permuted coefficients) of participation in minimizing the deviations, $\boldsymbol{y} - \hat{Z}_1 \boldsymbol{\gamma}$, by incorporating the fitted coefficients into the choice for permutation P. Then those coefficients that correspond to the columns in $\hat{Z}_1$ chosen from according to P are retained. Others are lopped off (or set to zero).

It is a good idea to obtain an adjustment factor for each retained coefficient so that the loss of minimality in the residuals due to truncation can be made up as much as possible by the retained. Packing all above into a simple procedure, we propose the following trimming algorithm.

ALGORITHM 2A.

(a) Use QR factorization with column pivoting to compute $Q^T[V_{11}^T, V_{21}^T]DP = [R_{11}, R_{12}]$.
(b) Pick the first r columns of X according to the resulting permutation matrix P and form Z_1.
(c) Refit the responses with matrix Z_1 by applying Algorithm 1.

6.2. Trimming in full-rank phase. The conventional approach is to drop those factors whose coefficients are tested statistically insignificant. The tests—Student's t-test on individual coefficients and the F-test on groups of coefficients—are based on the assumption that the uncertainties are normally distributed. For illustrations and more details, see RSM texts [MyersM95, KhuriC96]. If we can hardly justify even the basic assumption that the uncertainties have zero mean and zero correlation, additional assumptions such as their normal distribution will be harder still to justify.

An alternative is to base the trimming on mathematical properties of the approximating polynomial. One obvious approach is to judge by the magnitude of the coefficients. This is not a good general idea, however, because it is not the coefficient alone but rather the whole term—the product of the coefficient with the corresponding factor—that participates in the polynomial approximation. Instead, we propose that those terms having low percentage of usage be trimmed off. Compute the norm of vector $b_j X_j$ (i.e., column j of matrix X multiplied by the corresponding coefficient

b_j) and then trim it off if the norm is less than a certain small percentage of the norm of the response vector $\boldsymbol{y}$.

Specifically, define the utility of term j by $u_j = 100\|b_j X_j\|/\|\boldsymbol{y}\|$. Assume that all terms with utility less than $u_t\%$ are trimmed off. Denote by $\boldsymbol{e}_t$ the residuals after the trimming. Then $\boldsymbol{e} = \boldsymbol{y} - X\boldsymbol{b} = \boldsymbol{e}_t - \sum_{u_j<u_t} b_j X_j$. Hence,

$$\|\boldsymbol{e}_t\| = \|\boldsymbol{e} + \sum_{u_j<u_t} b_j X_j\| \le \|\boldsymbol{e}\| + \left\| \sum_{u_j<u_t} b_j X_j \right\| \le \|\boldsymbol{e}\| + \sum_{u_j<u_t} \|b_j X_j\|.$$

Let $\mathrm{RMSE}_t\%$ represent the relative error corresponding to $\boldsymbol{e}_t$ by the same definition, (13). Then the increase in the relative modeling error due to truncation is

$$\begin{aligned} \mathrm{RMSE}_t\% - \mathrm{RMSE}\% &= 100(\|\boldsymbol{e}_t\|/\|\boldsymbol{y}\| - \|\boldsymbol{e}\|/\|\boldsymbol{y}\|) \\ &\le 100 \left\| \sum_{u_j<u_t} b_j X_j \right\| /\|\boldsymbol{y}\| \\ &\le \sum_{u_j<u_t} 100\|b_j X_j\|/\|\boldsymbol{y}\| = \sum_{u_j<u_t} u_j. \end{aligned}$$

It means that the increase is smaller than the sum of the utility of all the lopped-off terms. It also implies that the actual increase can even be substantially smaller since components of the dropped vectors $b_j X_j$ may have cancelled each other out, leaving a much smaller net effect than estimated by the sum of their individual norms.

Again, it is a good idea to refit the truncated polynomial to adjust the coefficients of the retained factors so that what has been trimmed off can be made up as much as possible. Therefore, we propose the following algorithm.

ALGORITHM 2B.

(a) Compute utility $u_j = 100\|b_j X_j\|/\|\boldsymbol{y}\|$ of each term j.
(b) Trim off all terms with utility less than $u_t\%$.
(c) Form submatrix Z_1 by deleting the corresponding columns of X.
(d) Refit the responses with matrix Z_1 by applying Algorithm 1.

7. Examples of application. We demonstrate by examples that the proposed SVD technique works as well as the current RSM while expanding and enabling the RSM to handle reliably and efficiently (a) any test or design matrix X that is rank deficient or nearly so and (b) unconventional higher-order response modeling. Examples 1 and 2 are "apples-to-apples" comparisons of the proposed technique on the conventional ground with existing results of other methods. Examples 2 and 3 also show how the new fitness measure StDev% is useful for judging whether adding higher-order terms is necessary, just as the adjusted R^2 statistic is in the conventional RSM applications. Two hypothetical cases (Examples 4 and 5) show that if the unknown response function is actually a polynomial, the proposed technique can determine accurately both the degree and the coefficients whether the matrix X has full column rank or a large rank deficiency. Example 6 is a real hardware test case with a truly unknown response function, the case that produced the pressure profiles of Figure 1. It shows that by using the proposed technique, we are able to model the pressure responses to a desirable higher order without difficulty and that the predictive capability is confirmed by three responses set aside. In addition, we get an interesting three-dimensional response surface representation that makes the flow separation and outward flow migration rather obvious.

Example 1. This is an apples-to-apples comparison with existing results of a conventional method to show that the proposed SVD technique produces computed coefficients and prediction results essentially the same as the conventional results even not using the same computer. It also shows that the coefficients trimmed by the proposed mathematical alternative criterion yield good results.

[SteffSY00] is a good documentary reference for its careful, comprehensive application of the conventional RSM to a complex engineering problem. In particular, it contains numerical details we can use directly for the comparison. They applied RSM designs and Navier–Stokes calculations to analyze the nozzle efficiency of rocket-based combined-cycle (RBCC) systems operating in an all-rocket mode over a broad range of parameters. They varied six independent parameters (four geometric and two flow field variables) simultaneously to study their effects upon system performance. A full parametric study of these six variables, each at three levels, would necessitate an enormous computational effort, a total of 729 possible computational fluid dynamics (CFD) simulation runs. Through a D-optimal design strategy, only 36 separate CFD solutions are required for developing a full response surface (RS) model of conventionally the highest (i.e., second) order.

Their RS model contained initially an intercept, six linear, 15 bilinear or interaction, and six square terms. Of the 28 coefficients, only 13 were retained in the final form because of statistical significance. Their final step in the design of experiments involved confirmation tests with eight new cases (37 to 44). All but case 37 were well within the approximate uncertainty band of $+/-1\%$ in the specific-impulse efficiency; case 37 results lay just outside the uncertainty band. Their D-optimal design construction and RSM model analyses were executed with the RS/1 software of Bolt, Beranek, and Newman, Inc.

The test points are the 36 cases of settings in their Table 3 for independent (natural) variables $x_1, \ldots, x_6$. The response variable y is the vacuum specific impulse efficiency, η_{Isp}, calculated with the S-A turbulence model in the CFD simulations. Its 36 response values are in the rightmost column of their Table 5. As in [SteffSY00], we convert each of the six independent variables to take on values only between -1 and +1 as a coded variable. Then we form the 36x28 matrix X for second-order regression, apply the SVD technique (Algorithm 1), and compute the 28 coefficients that fit the 36 responses.

(a) Conventional trimming. Not all terms in the full model are significant in fitting the responses, especially those with negligible coefficients. A conventional approach uses Student's t-statistic to test the hypothesis that an individual coefficient is zero. Accordingly, they determined with the RS/1 software that 15 of the 28 coefficients failed to reject the null-hypothesis with a certain level of confidence. They lopped off these 15 terms of their polynomial. First, we similarly lop off these 15 terms of ours by t-statistic. Then we drop those columns of the matrix X that correspond to the 15 lopped-off coefficients. We treat the thinned matrix as if it were a new 36x13 matrix X, apply the SVD technique again, and compute new 13 coefficients that fit the same 36 responses. In other words, our truncated polynomial is refitted to the 36 responses. The retained 13 coefficients of theirs and of ours are listed next to each other in Table 2. They are essentially identical to each other.

They used eight additional cases (37 to 44) for confirming the predicative capability of their truncated polynomial. We likewise subject our truncated polynomial to the same confirmation tests. The results are listed next to theirs in Table 3, where y^{CFD} stands for the vacuum specific impulse efficiency they calculated in the CFD

simulations and y^{RS} the response they predicted using their RS model. The Dif% at the bottom represents the RMS value of the eight prediction differences (Dif) relative to the RMS value of the eight CFD responses (y^{CFD}) and is expressed in percentage. Our prediction results are headed by SVD (t-statistic) with y^P standing for the predicted response by our SVD model. The comparison shows that the proposed SVD approach is at least as good as the conventional one, having the same good performance that all but one case are within the $+/-1\%$ uncertainty band.

Both our computed coefficients and our prediction results are essentially the same as theirs in [SteffSY00]. What this means is that the SVD approach is at least as good as the conventional on the same ground.

(b) Unconventional truncation. They made a conscious effort—an unusually good engineering practice—to control the sources of computational bias and defend their assumed uncertainty estimate, but still nowhere in their paper, not unusual in application papers (not their fault, either), does it show that it is valid to assume that the uncertainties are normally distributed. Instead of using t-statistic, which is based on such a normality assumption, an alternative is to truncate the polynomial according to the mathematical utility of the terms. We apply Algorithm 2B and truncate 28 coefficients also down to 13. These 13 coefficients also are listed in Table 2 but headed by SVD (utility). The main difference from the conventionally truncated counterpart is the replacement of three bilinear terms involving x_3 (i.e., x_1x_3, x_2x_3, x_3x_5) by three square terms (x_2^2, x_3^2, x_5^2).

The corresponding prediction results are listed in the last two columns of Table 3, headed by SVD (utility). Observe that such coefficients yield better results: All prediction differences (Dif) are within the $+/-1\%$ uncertainty band!

Example 2. A regression model need not be of a higher order to be better. The transistor example used throughout the textbook [MyersM95] is one that first order is superior to second order in fitting the transistor responses. The matrix X has full

column rank for both orders, and the conventional RS method is well demonstrated in the book. Here we apply the SVD technique for another apples-to-apples comparison.

The 14 responses (transistor gain in an integrated circuit device) to two variables (emitter drive-in time and emitter dose) are given in their Table 2.2. They formed the 14x3 matrix X for the first-order regression, multiplied the normal equations by the inverse of product X^TX, and thereby obtained the coefficients $\boldsymbol{b} = (1242.3057, 323.4366, -54.7691)$ and the estimated variance $\hat{\sigma}^2 = 1,220.1$. We form the same 14x3 matrix X but apply the proposed SVD technique and obtain the coefficients $\boldsymbol{b} = (1242.314755, 323.434737, -54.773595)$ and the estimated variance $\hat{\sigma}^2 = 1,220.101394$, which are virtually identical to what they obtained by the conventional method.

They added quadratic terms (x_1^2, x_1x_2, and x_2^2) and then fitted the same responses with a second-order model. The new estimated variance was larger: $\hat{\sigma}^2 = 1,559.975$. They regarded it as "suggesting that the first order model is superior in that there is less unexplained variability." Likewise, we fit the same responses with a second-order model by the SVD technique. Since the estimated variance we produced, $\hat{\sigma}^2 = 1,559.9785$, is also virtually identical to theirs, the conclusion is the same: the first-order model is superior to the second-order model.

They also demonstrated the above conclusion by using the adjusted R^2 statistic on both models. The statistic we computed with the SVD models is exactly the same as theirs when also rounded to 4 digits:

$$R^2_{adj} = 0.9762(\text{1st order}); \qquad R^2_{adj} = 0.9695(\text{2nd order}).$$

The decrease in R^2_{adj}, from first order to second order, is as stated in their text: "a strong indication that the quadratic terms are unnecessary."

The fitness measure StDev% of the SVD models is 0.735932 for first order but 0.832145 for second order. It is intuitively obvious that the increase in the spread (i.e., StDev%) indicates correctly that the quadratic terms are unnecessary.

Example 3. The curious reader may wonder if second order is superior to first order in the case of Example 1. Here we also form the 36x7 matrix X for first-order regression in addition to the previous 36x28 matrix X, apply the SVD technique, and obtain the following fitness measures and adjusted R^2 statistic on both orders:

[illegible]: RMSE% = 1.470005, StDev% = 0.272973, $R^2_{adj} = 0.893149$
[illegible]: RMSE% = 0.408067, StDev% = 0.144274, $R^2_{adj} = 0.970152$

The second-order model is clearly both necessary and superior because it essentially halves the spread (StDev%) of the first-order model to nearly perfect 0.14%, in addition to having a very impressive 0.41% RMS error, almost four times smaller than that of the first-order model. Correspondingly in the conventional front, the relatively large increase in the adjusted R^2 statistic from the first to the second order also indicates strongly that quadratic terms are necessary.

Example 4. This example illustrates how given responses are modeled from a full-rank first-order case through a rank-deficient fifth-order case of test matrix X. Suppose there are 18 test points in two variables with 7 levels in variable ξ_1, starting from $\xi_1 = 0.70$ and stepping up by 1.375, and 3 levels in variable ξ_2, starting from $\xi_2 = -5$ and stepping up by 5. (Three points, (2.075, 5), (3.45, −5), and (6.2, 5), are not included.) The natural variables are converted to coded variables and used as x_1

and x_2 in the regression:

$$x_1 = (\xi_1 - 4.825)/4.125, \qquad x_2 = \xi_2/5.$$

Assume that the unknown response function is actually a two-variable polynomial of degree 5 with known coefficients:

$$\begin{aligned} P_5(x_1, x_2) = {} & 5.186855 - 13.933827x_1 + 0.135362x_2 + 7.685090x_1^2 - 0.019777x_1x_2 \\ & - 0.388437x_2^2 + 8.458755x_1^3 + 0.109929x_1^2x_2 + 5.363036x_1x_2^2 \\ & + 0.135362x_2^3 - 5.503517x_1^4 - 0.150153x_1^3x_2 + 0.741562x_1^2x_2^2 \\ & - 0.019777x_1x_2^3 - 0.388437x_2^4 - 0.681754x_1^5 - 0.593747x_1^4x_2 \\ & - 10.365834x_1^3x_2^2 + 0.109929x_1^2x_2^3 + 5.363036x_1x_2^4 + 0.135362x_2^5 \end{aligned} \tag{15}$$

Suppose 18 responses are thereby generated. Then we treat both the degree and the coefficients as if they were unknown and conduct the response modeling by the proposed SVD technique (Algorithm 1).

Table 4(a) summarizes the results with the fitness measures RMSE% and StDev%, where #Coef denotes the number of regression coefficients (i.e., p) and Rank the numerical rank of the matrix X (i.e., r). Table 4(b) lists the computed singular values of the matrix X for each order up to the fifth. First, observe that from the third order on, matrix X starts to have one or more nearly zero singular values, and the product X^TX therefore starts to have less than full rank. Note in particular that for the fifth order, $N < p$ (unconventionally) and the column-rank deficiency is large: $21 - 15 = 6$. Then observe that measure RMSE% decreases continuously until it suddenly becomes "zero" (0.000002) at the fifth order. In other words, the degree of the response polynomial is correctly indicated to be 5 despite rank deficiency in the corresponding matrix X.

Notice, however, that StDev% stops decreasing momentarily at fourth order, which might suggest that the fourth-order model is not really much better, but becomes "zero" (0.000001) at fifth order with a very large drop, which suggests (correctly) that it is worth continuing until fifth order. This also reflects (correctly) that an odd order fits these responses much better.

TABLE 4(c)
Computed coefficients—Example 4.

Order	1	x_1	x_2	x_1^2	x_1x_2	x_2^2	x_1^3	$x_1^2x_2$	$x_1x_2^2$	x_2^3	
1	6.549223	-6.176864	0.168112

	x_1^4	$x_1^3x_2$	$x_1^2x_2^2$	$x_1x_2^3$	x_2^4	x_1^5	$x_1^4x_2$	$x_1^3x_2^2$	$x_1^2x_2^3$	$x_1x_2^4$	x_2^5
4	-6.741169	0.622442	0.803713	-0.420243	-0.356290						
5	-5.503518	-0.150153	0.741562	-0.019777	-0.388437	-0.681753	-0.593747	-10.365834	0.109929	5.363036	0.135362

Table 4(c) lists the computed coefficients for all these models. Notice that the computed coefficients for the fifth-order model are the same as assumed in (15) except some that are somewhat different in the sixth decimal place. (The SVD matrices computed and used in the third-order modeling are listed in the appendix.)

Example 5. A simple question of curiosity with regard to Example 4 is, What if there are more than 21 test points so that the resulting matrix X has full column rank for the fifth order? In this example, the number of data points is thus increased from 18 to 37. Before proceeding, it is worth mentioning that rank deficiency in matrix X is not unusual at all when increasing the 18 data points step by step. Near the end, after having additional two full columns of 7 points in the middle (i.e., at $\xi_2 = \pm 2.5$), the rank of the resulting 35x21 matrix X was 20, still one short of being full. Finally, after another two additional data points (rather arbitrarily at $\xi_1 = 0.70, \xi_2 = \pm 1.25$), the resulting 37x21 matrix X attained, marginally, its full column rank.

Now assume the same polynomial as in Example 4, (15), and suppose 37 responses are thereby generated. Again, we treat both the degree and the coefficients as if they were unknown and conduct the same response modeling as before. Table 5(a) summarizes the results with fitness measures RMSE% and StDev% for each model order up to fifth, whereas Table 5(b) lists the computed singular values of the matrix X for the fifth order. Both RMSE% and StDev% steadily decrease until suddenly dropping to "zero" (0.000002 and 0.000001, respectively) at the fifth order. Just as in Example 4, the computed coefficients for the fifth-order model (listed in Table 5(c)) are the same as the assumed except some that are slightly different in the sixth decimal place. Therefore, we conclude that if the unknown response is actually a polynomial of degree 5, the proposed SVD technique can model the responses as accurately when the corresponding matrix X is greatly rank deficient as when it has full column rank.

To summarize, this example shows that many more test points may be needed for the matrix X to have full column rank, but the full-rank results, when they fit the responses well, may have no noticeable difference from rank-deficient results for the same order.

Example 6. Here we use a set of real hardware test results [KamhaKT03] as an example. NASA Glenn Research Center (GRC) has been developing a hydrogen-fueled single-thruster RBCC semiaxisymmetric propulsion system for single-stage-to-orbit vehicles [Trefn99]. For flight from lift-off to Mach 2.5, the propulsion system can operate in two different schemes: the simultaneous mixing and combustion (SMC) and the independently fueled ramjet stream. In the SMC scheme, the excess fuel from the rocket thruster mixes and burns with the unfueled air stream. Tests were conducted at the direct-connect facility of the GRC to determine the extent of mixing between the primary (rocket) stream and the secondary (unfueled air) stream to assess the feasibility of the SMC scheme in a short single-thruster flowpath.

Three vertical rakes (port, center, and starboard) with seven probes per rake were mounted at the end of the mixer-combustor for pressure measurements. The port and starboard rakes were 5 in. off the center rake. The seven probes are equally spaced 1.375 in. apart beginning with a probe 0.70 in. up from the mixer-combustor floor. There are totally 21 responses, each being the pitot-pressure reading of a probe. The three parametric curves in Figure 11 of [KamhaKT03] (see our Figure 1) represent the mixer-combustor exit pressure profiles of one of the tests with the rocket turned on. The profiles reveal a complex flow pattern. Near the floor, the rocket directly influences all rakes with similar high pressure; but near the cowl surface (i.e., top of the rakes), "the centerline distribution shows separation of the flow: some flow migrates to the outboard rakes" [KamhaKT03].

Generally speaking, it is desirable for systems evaluation and technology analysis of the RBCC engine, and eventually for design optimization of the space vehicle, if performance-related test results can be modeled analytically. More specifically, the engineers may like to visualize or get some idea of how the pressure might be distributed between the rakes if they would place more columns of such probes there. Since the test variables are spatial coordinates (height and side of the test location) on the exit plane, if the test results could be represented by a three-dimensional response surface over such physical two-dimensional domain, it would provide a realistic visualization and a particularly intuitive realization of the flow separation.

For this example, we take the probe distance as ξ_1 (starting from $\xi_1 = 0.70$) and the rake distance as ξ_2 (starting from $\xi_2 = -5$) and convert them to coded variables x_1 and x_2 just as described in Example 4. We read the parametric pressure-profile curves (Figure 11 in [KamhaKT03]) manually for the 21 pressure responses (subject to possible visual round-off errors) and "reproduced" the curves shown in Figure 1. (See Table 6(a) for the read response data.)

TABLE 6(b)
Modeling summary—Example 6.

Order	#Coef	Rank	Full?	RMSE%	StDev%
1	3	3	yes	22.930659	5.920671
2	6	6	yes	19.750396	5.701448
3	10	9	No	16.047028	5.349009
4	15	12	No	13.652458	5.573593
5	21	15	No	4.535100	2.618341

Before fitting the responses, we set aside three of them so as to have a token confirmation test on the predictive capability of the resulting model later. There are only 21 responses, and we cannot afford not to use as many as there are, because one of the parametric curves is highly nonlinear, indicating very clearly a strong need for a fairly high order if the responses are to be fitted with reasonably small residuals. We certainly would not ignore any of the responses along the center rake by setting aside for the confirmation purpose. We choose to set aside one point on the port rake ($\xi_1 = 3.45,\ \xi_2 = -5$) and two on the starboard rake ($\xi_1 = 2.075$ and $\xi_1 = 6.2$, both with $\xi_2 = 5$).

(a) Full-order models. We apply Algorithm 1 and model the pressure responses just as we did in Example 4, except that the response function is now truly unknown. Table 6(b) summarizes the results with the fitness measures. The computed singular values are exactly the same as in Example 4 (see Table 4(b)), but it is worth repeatedly mentioning here, because this example is a real test case, that the matrix X stops having full column rank at the third order.

As expected, the residuals (RMSE%) decrease as the order increases. Although zero was not reached at the fifth order, a sharp drop by more than 3 times from the fourth order was attained. It is a rather clear indication that fifth order is most desirable, even though 4.54% RMS error is still large.

TABLE 6(c)
Computed coefficients—Example 6.

Order	1	x_1	x_2	x_1^2	x_1x_2	x_2^2	x_1^3	$x_1^2x_2$	$x_1x_2^2$	x_2^3

4	-6.741168	0.622441	0.803712	-0.420243	-0.356290						
5	-5.503517	-0.150153	0.741562	-0.019777	-0.388437	-0.681754	-0.593747	-10.365834	0.109929	5.363036	0.135362

On the other hand, the estimated uncertainty spread (StDev%) stops decreasing momentarily at fourth order. Thus, it appears that third order might be a reasonable stop, if one is particularly concerned with increase in model complexity. Nevertheless, the uncertainty spread at the fifth order has a big drop from the fourth (and even from the third) order down to more than 2 times smaller. It means that there are definitely some significant, characteristic fifth- (or higher-) order terms that deserve attention if one does not mind the additional model complexity or the extra effort in seeking such particular fifth-order terms.

In light of Example 4, we can readily recognize that if fifth order were already higher enough for fitting the responses, both fitness measures should have dropped to zero at fifth order. Besides, judging by the still very large size of the residuals, 4.54% RMS, especially compared to the 2.62% estimated uncertainty spread, we hardly can regard this fifth-order model as overfitting (or mistaking noises as) the pressure responses.

Table 6(c) lists the computed coefficients for each of the five orders. Compare with Table 4(c) and observe that the coefficients for each order have essentially no difference between these two examples (only some differ at the sixth digit below the decimal point). The observant reader may have recognized that we use the fifth-order coefficients for (15) in Example 4 to investigate the rank-deficient response modeling and validate the SVD technique. The conclusion of Example 4 also has effectively ascertained the validity of the regression coefficients computed here for fitting the 18 pressure responses with a fifth-order model.

(b) Trimming. Full-order regression has the convenience of not having to guess first what the significant terms to include are, but if we also want to use as few terms as possible, generally we need to trim the polynomial afterward. If the matrix X is rank deficient or nearly rank deficient, trimming first to a full-rank state is desirable. [illegible]. Consider specifically the fifth-order model computed above. The polynomial has 21 coefficients, but the 18x21 matrix X is only of rank 15. We apply Algorithm 2A to trim it down to 15 coefficients while at the same time trying to minimize possible increase in the residuals due to trimming. First, define diagonal matrix D by the 21 computed coefficients. Next, use the 21x21 orthogonal matrix V in the SVD of the matrix X and apply QR factorization with column pivoting to compute $Q^T[V_{11}^T, V_{21}^T]DP = [R_{11}, R_{12}]$ for a permutation matrix P. Pick the first 15 columns of X according to the resulting permutation matrix P to form 18x15 submatrix Z_1. Then refit the 18 responses by repeating Algorithm 1 with Z_1 as if it were a new, 18x15 matrix X. (The refitting effectively adjusts the retained coefficients that correspond to the 15 chosen columns.) The results are shown in Tables 7(a) (summary, measures) and 7(b) (coefficients), all with #Coef "15." Observe that six out of originally 21 coefficients are zeroed but both RMSE% and StDev%

TABLE 7(a)

	x_1^4	$x_1^3x_2$	$x_1^2x_2^2$	$x_1x_2^3$	x_2^4	x_1^5	$x_1^4x_2$	$x_1^3x_2^2$	$x_1^2x_2^3$	$x_1x_2^4$	x_2^5
15	-5.503517	-0.150153	0.741562	0	0	-0.68175	-0.593747	-10.365834	0.219858	0	0
12	-5.366035	0	0.738064	0	0	-0.95108	-0.386094	-10.433512	0	0	0

remain unchanged.

[illegible] We may trim the polynomial further depending on the utility of each term. We apply Algorithm 2B. First, compute and rank the utility. Then trim off three terms of utility less than, say, 1.5% and refit the 18 responses with 12 retained terms . The results also are shown in Tables 7(a) and 7(b) but with #Coef "12." Observe that eight out of 21 coefficients are now zeroed but RMSE% increases just a little and StDev% continues to decrease.

This trimmed fifth-order model has 2 fourth-order and 3 fifth-order terms and yet has a total of 12 terms, only 2 more than the total number of terms in a full third-order model.

(c) Confirmation. Response data not involved in fitting an approximating polynomial should not be expected to be predicted by the very polynomial with a given accuracy. Nevertheless, common intention of regression is to predict new responses by interpolating with the fitted approximating polynomial. Recall that we set aside responses at three test points to be used for confirmation. First, we predict these responses by using each of the four full-order models, second through fifth orders. The results are given in Table 8(a), where y^P stands for the predicted response and Dif% represents the RMS of the three prediction differences (Dif) relative to the RMS of the three responses and is expressed in percentage. (It is defined exactly in the same way as RMSE% in the fitting, except that only the three reserved responses are involved.) It is interesting to observe that prediction uncertainty (Dif%) exhibits the same trend as StDev% in the fitting (see Table 6(b)) and that the fifth-order model predicts the best even though the relative prediction "error" 3.46% is not as small as commonly acceptable. It is also interesting to notice that of all but the fourth-order models the prediction accuracy (Dif%) is better than the fitting accuracy (RMSE%).

Next, we predict the three responses by using the trimmed versions of the fifth-order model. Recall that we trimmed the fifth-order model first to a full-rank state (the 15-term version) by applying Algorithm 2A and then trimmed off three low-utility terms of the 15-term version by Algorithm 2B. The prediction results by these two trimmed versions are similarly given in Table 8(b). The prediction accuracy remains unchanged, just as the fitting accuracy, in the case of the 15-term version but improves slightly, unlike the fitting accuracy (see Table 7(a)), in the case of the 12-term version.

TABLE 8(a)

			Dif%:	3.462		3.114

(d) Three-dimensional graphic representation. Having computed the coefficients for various model orders, we are ready to plot the pressure response surfaces. Although response surfaces in current engineering applications commonly mean those of the second-order models, the second-order response surface for the test results, such as shown in Figure 2, clearly is inadequate compared to Figure 1. It is inadequate not because it is an elementary graphic made simply by connecting the adjacent fitted responses with straight lines but because it is simply too flat to capture even an obvious characteristic of the centerline pressure distribution. (In Figure 2 and the subsequent response surface plots, imagine that we are standing inside the rocket on the combustor floor just like the rakes but with our back against the rakes, looking outward just as the flow presses out, and feeling the outward pressure of the air-fuel-exhaust flow on our back.) It is understandable because the second-order model has very large residuals (nearly 20% RMS), even though they were already minimized. Connecting the actual pressure responses likewise by straight lines will depict the pressure profiles like a shattered mirror (see Figure 3), but even such a simplistic graphic looks more inspiring, more revealing, or at least more expressive of the responses than Figure 2. (The second-order response surface remains equally plain, flat, and unexpressive even after including many interpolated responses between the test points in the connection.)

The third-order plot, Figure 4, is slightly better, but the fifth-order version, Figure 5, is clearly much better. First, residuals of the fifth order are more reasonable in size (4.54% versus 16.05% in RMS). Second, the centerline and the two edges of the response surface in Figure 5 resemble the three pressure profiles very well—capturing the basic characteristics shown in Figure 3, the simplistic three-dimensional graphic representation of the pressure responses.

After viewing Figure 5, one might wonder what the pressure distribution would look like if more columns of such probes were placed between the existent rakes. We can duly imagine it by interpolating the response since we have a reasonably well-fitted approximating polynomial in closed form. Suppose there were a 13x11 array of such

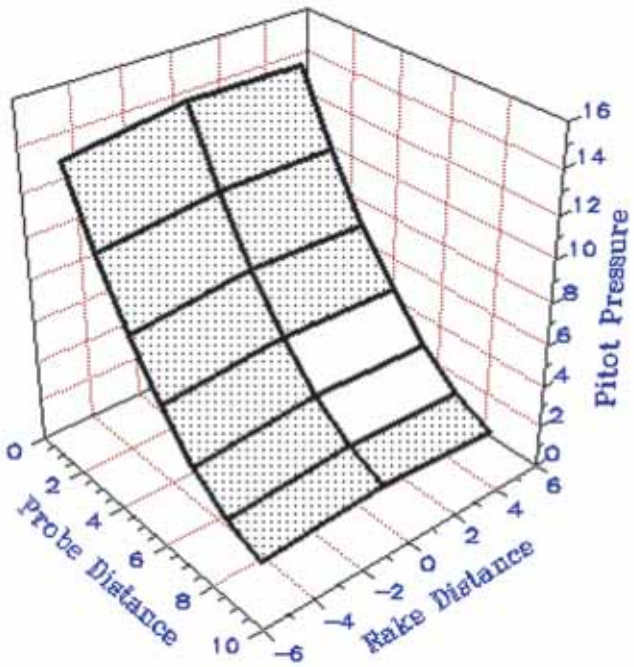

FIG. 2. *Second-order fitted responses connected with lines.*

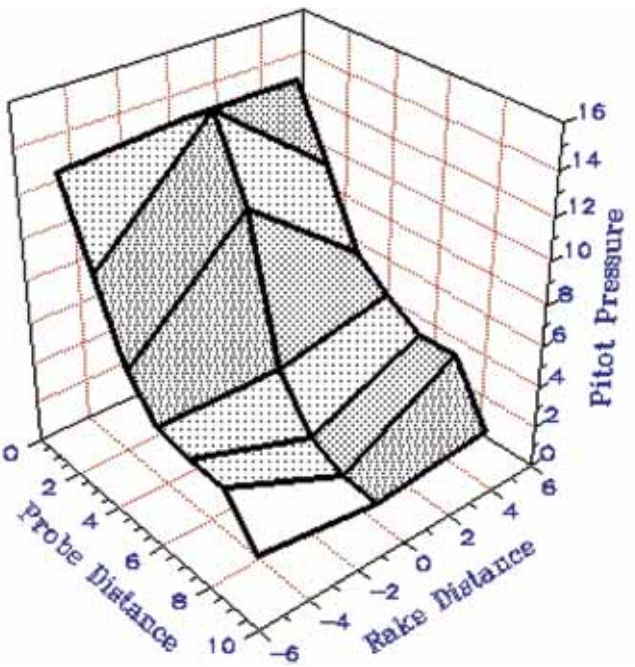

FIG. 3. *Pressure responses connected with lines.*

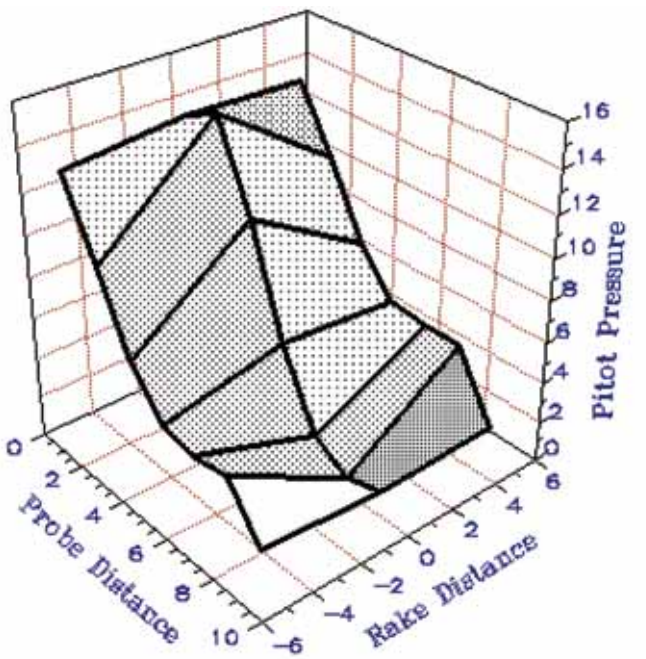

FIG. 5. *Fifth-order fitted responses connected with lines.*

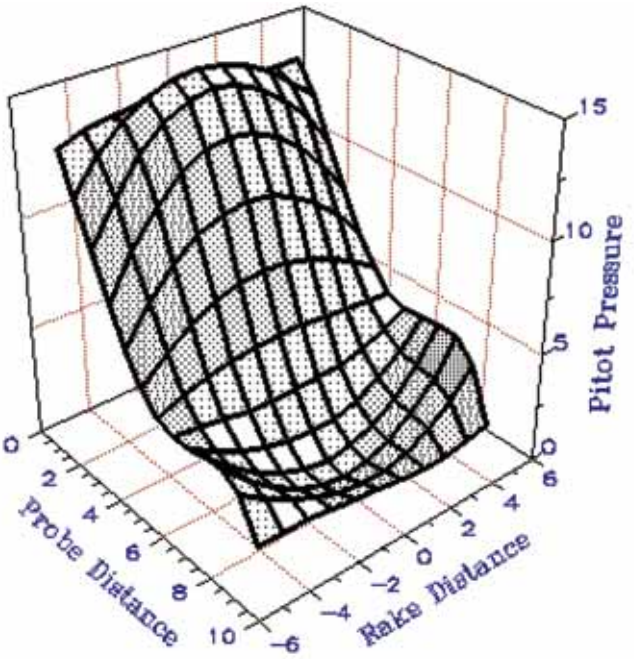

FIG. 6. *Fifth-order* 13x11 *interpolated responses connected with lines.*

probes evenly placed along and between the rakes. The swelling in Figure 6, big near the bottom center and relatively small on the upper port and starboard edges, may be a surprise to many, since conventional response surfaces would never show anything other than extremely flattened or forcibly smoothed. These small lifts on the edges suggest rather clearly that the flow does not mix uniformly but rather separates and some migrates to the outboard rakes. These lifts, in the semiaxisymmetric path of the entrained air stream, might help visualizing (and realizing) that a portion of the air (secondary) stream on the sides remains essentially separated from the rocket (primary) stream in the lower center. Without an expert's well-trained eyes, the flow separation and migration are not really easy to visualize or realize from just looking at the overlaid parameterized plane curves of the pressure profiles. After viewing the illuminating revelations by this response surface plot, Figure 6, it may become much easier to interpret or comprehend the parameterized pressure curves in Figure 1 as indicating flow separation and outward migration.

By the way, the 13x11 third-order response surface plot (Figure 7) is hardly adequate, let alone the corresponding second-order plot (not shown).

8. Conclusion. Instead of being unable to build a higher-order response model for the test results on hand because the product matrix X^TX is not invertible, we can now model the responses to a desirable higher order, despite rank deficiency in X, by using the proposed SVD technique, namely, Algorithm 1. RMSE% and StDev% provide new, intuitively meaningful, universal measures of fitness, whether or not matrix X has full rank. Algorithms 2A and 2B offer two good mathematical alternatives to statistics-based truncation of the fitted polynomials.

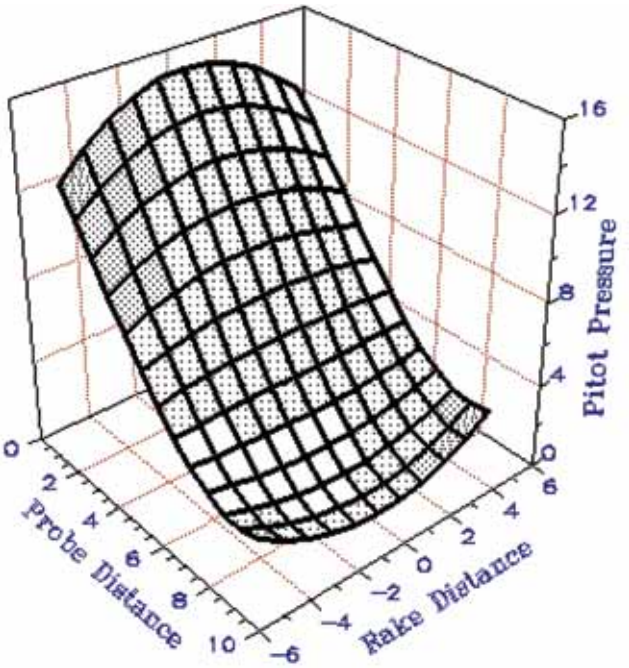

FIG. 7. *Third-order* 13x11 *interpolated responses connected with lines.*

9. Appendix. SVD matrices of a rank-deficient test matrix. A reviewer suggested that an interested reader (e.g., a discipline specialist seeking to apply the proposed SVD approach to physical test data) would be well served by seeing the full matrices (i.e., the U, S, and V) of the SVD result for the third-order model in Example 4. For computing LS solutions, all right singular vectors may be used (depending on the number of singular values accepted as being nonzero), but at most $\min\{N, p\}$ left singular vectors are useful. Since $N = 18$ and $p = 10$ for this model, only 10 columns of U (i.e., 10 left singular vectors) are listed below. To conserve space further, all numbers are rounded to the third decimal place.

Except the diagonal, zero is everywhere in the 18x10 "diagonal" S. On the diagonal $(S_{ii}, i = 1, \ldots, 10)$ are 10 computed singular values, the same as listed in the row of Table 4(b) for order "3."

ON THE PRESERVATION OF INVARIANTS BY EXPLICIT RUNGE–KUTTA METHODS*

M. CALVO†, D. HERNÁNDEZ-ABREU‡, J. I. MONTIJANO†, AND L. RÁNDEZ†

Abstract. A new strategy to preserve invariants in the numerical integration of initial value problems with explicit Runge–Kutta methods is presented. It is proved that this technique retains the order of the original method, has an easy and cheap implementation, and can be used in adaptive Runge–Kutta codes. Some numerical experiments with the classical code of Dormand and Prince, DoPri5(4), based on a pair of embedded methods with orders 5 and 4, are presented to show the behavior of the new method for several problems which possess invariants.

Key words. initial value problems, explicit Runge–Kutta methods, numerical geometric integration, preservation of invariants, variable step-size codes

1. Introduction and basic definitions.

First integrals and invariants of (autonomous) differential systems

$$y' = f(y), \tag{1}$$

where $f : \mathcal{D} \subset \mathbb{R}^m \to \mathbb{R}^m$ is a sufficiently smooth function, play an important role both in qualitative and quantitative studies of the flow of (1). These invariants allow us to describe the geometry of the orbits and also to check the accuracy of numerical integrators of the corresponding differential equation.

A function $G = G(y) : \widehat{\mathcal{D}} \subset \mathbb{R}^m \to \mathbb{R}^l$ of class $\mathcal{C}^1(\widehat{\mathcal{D}})$, $\widehat{\mathcal{D}} \subset \mathcal{D}$, is called an l-invariant system of (1) in $\widehat{\mathcal{D}}$ (see [15, p. 61]) if

(i) there exists some $y^0 \in \widehat{\mathcal{D}}$ such that $G(y^0) = 0$,
(ii) for all solutions $y = y(t)$ of (1), $G(y(t)) = 0$ holds either for every t or for no t in the interval of definition of $y(t)$.

In such a case we may consider the flow defined by (1) restricted to the $(m-l)$-dimensional manifold $\mathcal{M} = \{y \in \widehat{\mathcal{D}}; G(y) = 0\}$ as a differential equation on $\mathcal{M}$. In the case $l = 1$, the invariant system is called an invariant relation. In connection with the above concept, it is worth remarking that for $l > 1$ the l scalar relations which constitute the invariant system need not be invariant relations. An l-invariant system is also called a weak invariant (see [5]), and it is not difficult to see that $G(y)$ is a weak invariant of (1) if and only if there exists some $y^0 \in \widehat{\mathcal{D}}$ such that $G(y^0) = 0$, and $\nabla G(y)^T f(y) = 0$ for all $y \in \mathcal{M}$.

On the other hand, a scalar function $F : \widehat{\mathcal{D}} \subset \mathbb{R}^m \to \mathbb{R}$ of class $C^1(\widehat{\mathcal{D}}), \widehat{\mathcal{D}} \subset \mathcal{D}$, is a first integral (or a conserved quantity) of (1) if $F(y(t))$ is a constant along any

solution path $y = y(t)$ of (1). In such a case, since

$$0 = \frac{dF(y(t))}{dt} = \nabla F(y(t))^T \cdot f(y(t)) \qquad \text{for all } t,$$

it follows that $\nabla F(y)^T \cdot f(y) = 0$ for all $y \in \widehat{\mathcal{D}}$. Now, for all $y^0 \in \widehat{\mathcal{D}}$ the solution $y = y(t)$ of (1) such that $y(0) = y^0$ is contained in the hypersurface $\mathcal{M}_{y^0} = \{y \in \mathbb{R}^m \,;\, F(y) = F(y^0)\}$. First integrals are also called strong invariants (see [5, 7]) and quadratic integrals $G(y) = y^T S y$, where $S \in \mathbb{R}^{m\times m}$ is a constant symmetric matrix, are strong invariants of (1) if and only if $y^T\, S\, f(y) = 0$ for all $y \in \mathcal{D}$.

In order to simplify the presentation, we will use in the following the term invariant of the differential system (1) for either a first integral or an invariant system (or relation) of (1).

Since many general numerical integrators do not preserve first integrals or invariants of their corresponding differential systems, these functions have been widely used as a tool to measure the accuracy and the long-term behavior of these integrators. As a matter of fact, in the last two decades there has been an increasing interest in numerical integrators that preserve as far as possible the qualitative properties of the underlying differential systems. In particular, a natural requirement is to consider those numerical Runge–Kutta (RK) methods that preserve first integrals or invariants. It was proved by Cooper [3] that all RK methods conserve linear invariants. However, an irreducible RK method preserves all quadratic invariants $G(y) = y^T S y + \mu^T y + \nu$ with constants $S \in \mathbb{R}^{m\times m}, \mu \in \mathbb{R}^m, \nu \in \mathbb{R}$, if and only if their coefficients ($A \in \mathbb{R}^{s\times s}, b \in \mathbb{R}^s$) satisfy $m_{ij} \equiv b_i a_{ij} + b_j a_{ji} - b_i b_j = 0$, $1 \le i \le j \le s$. These conditions, which also imply that (A, b) is a symplectic method, pose strong requirements on the coefficients of the method which are satisfied only by some implicit RK methods and have been extensively studied in connection with symplectic methods. Moreover, it can be seen (see, e.g., [5, Thm. 3.3, p. 102]) that for $n \ge 3$ no RK method can conserve all polynomial invariants of degree n. Further studies on the preservation of invariants by numerical methods have been carried out in [7, 9, 11].

An alternative attempt to preserve invariants in numerical integrations is proposed by Schropp [10]. This author modifies the original flow of (1) by stabilizing the invariant set $\mathcal{M}_{y^0} = \{y \in \mathbb{R}^m \,;\, G(y) = G(y^0)\}$ and considers the modified problem

$$y' = f(y) - \nabla G(y)\; a(y)(G(y) - G(y^0)),$$

where $a(y)$ is a suitably chosen smooth function so that $\mathcal{M}_{y^0}$ is an exponentially attracting set for the modified problem. In view of this, the numerical solutions generated by the method are expected to approach this attracting set; however, the modified problem may become very stiff depending on the choice of $a(y)$.

In view of the above limitations several techniques have been proposed to preserve invariants in practical numerical integrators. Thus, del Buono and Mastroserio in [1], starting with an explicit s-stage RK method ($A = (a_{ij}), b = (b_i)$) given by the equations

$$\varphi_h(y_n) = y_n + h \sum_{j=1}^{s} b_j f(Y_{n,j}), \tag{2}$$

with

$$Y_{n,1} = y_n, \quad Y_{n,i} = y_n + h\sum_{j=1}^{i-1} a_{ij} f(Y_{n,j}) \quad (2 \le i \le s), \tag{3}$$

modify the advancing solution (2) by introducing at each step a scalar $\gamma_n = \gamma_n(y_n, h)$, so that the new method $\widehat{\varphi}_h$ defined by (3) and

$$\widehat{\varphi}_h(y_n) = y_n + h\gamma_n \sum_{j=1}^{s} b_j f(Y_{n,j}) \tag{4}$$

preserves a given invariant of (1). Clearly, this requirement implies that γ_n will be a problem-dependent scalar such that $\gamma_n \to 1$ when $h \to 0$ and may vary from step to step. These authors [1] have proved that for all differential systems (1) possessing a quadratic invariant $G(y) = y^T S y$ with a symmetric S, there exist fourth-order explicit RK methods φ_h with four stages such that the modified methods $\widehat{\varphi}_h$ given by (3) and (4) preserve the quadratic invariant and have order three for a suitable value γ_n. Further, $\widehat{\varphi}_h$ attains order four at $t_n + h\gamma_n$, and therefore $\widehat{\varphi}_h$ would get (global) order four at the nonuniform grid $\{\widehat{t}_n\}_{n=0}^N$ with $\widehat{t}_0 = t_0$ and $\widehat{t}_{n+1} = \widehat{t}_n + h\gamma_n$. To compute γ_n at each step, the authors [1] use the formula $\gamma_n = 1 - (\delta_n/\eta_n)$ with

$$\eta_n = \sum_{i,j=1}^{4} b_i b_j \langle f(Y_{n,i}), f(Y_{n,j})\rangle, \quad \delta_n = \eta_n - 2\sum_{i=2}^{4}\sum_{j=1}^{i-1} b_i a_{ij} \langle f(Y_{n,i}), f(Y_{n,j})\rangle,$$

where $\langle u, v\rangle \equiv u^T S v$ for $u, v \in \mathbb{R}^m$ is the bilinear form associated to the invariant $G(y) = y^T S y$. This means that the computational cost of $\widehat{\varphi}_h$ at each step includes $s(s-1)/2 = 6$ bilinear forms $\langle f(Y_{n,i}), f(Y_{n,j})\rangle$, apart from the function evaluations of (3). Note that $\widehat{\varphi}_h(y_n) = \varphi_h(y_n) + (\gamma_n - 1)(\varphi_h(y_n) - y_n)$ can be considered as the projection of $\varphi_h(y_n)$ onto the invariant manifold $\mathcal{M}_{y_n} = \{y \ ; \ G(y) = G(y_n)\}$ along the direction $\varphi_h(y_n) - y_n$. In the remainder of this paper this technique will be called the incremental direction technique.

An alternative technique (see [5, p. 106]), known as the standard projection method, consists of combining a standard RK method φ_h (or any one-step method) together with an orthogonal projection P onto the invariant manifold $\mathcal{M}_{y_n}$ at each step $(t_n, y_n) \to (t_{n+1} = t_n + h, y_{n+1})$. For the Euclidean norm, it would be given by $y_{n+1} = (P \cdot \varphi_h)(y_n)$, with y_{n+1} defined by $y_{n+1} = \varphi_h(y_n) + \nabla G(y_{n+1})\ \lambda_n$, with $G(y_{n+1}) = G(y_n)$. Due to the implicitness, this system is replaced in [5] by

$$y_{n+1} = \varphi_h(y_n) + \nabla G(\varphi_h(y_n))\ \lambda_n \quad \text{with} \quad G(y_{n+1}) = G(y_n), \tag{5}$$

and the calculation of λ_n at each step is carried out by applying a simplified Newton iteration to the corresponding nonlinear equation. As remarked in [5], since λ_n is small, taking the starting value $\lambda_{n,0} = 0$, one simplified Newton iteration is usually enough for practical purposes. It can be proved that (5) preserves the order of the original method $\varphi_h(y_n)$ but requires us to provide an analytical expression of the gradient $\nabla G(y)$ that will be evaluated at each step and also will be used to obtain λ_n by a simplified Newton iterative scheme in the solution of the implicit equations $G(y_{n+1}) = G(y_n)$. On the other hand, although RK methods preserve linear invariants and are affine invariant, the standard projection method (5) in general does

not preserve these properties, and this fact may be inconvenient for the qualitative behavior of the integrator.

As follows from (4) and (5), the above projection techniques can be included in the general form

$$\widehat{\varphi}_h(y_n) = \varphi_h(y_n) - \lambda_n \Phi_n, \tag{6}$$

where the vector $\Phi_n \in \mathbb{R}^m$ defines the direction of projection and λ_n is a scalar chosen so that $\widehat{\varphi}_h(y_n)$ belongs to the invariant manifold. In the case (4) the direction $\Phi_n = \varphi_h(y_n) - y_n$ is defined by the original method and a zero-order method, whereas in the case (5) of the simplified projection, Φ_n is orthogonal to the invariant at $\varphi_h(y_n)$. Clearly, other possible directions Φ_n may be considered. In particular, taking into account that for many explicit RK methods several low order embedded approximations of type

$$\widetilde{\varphi}_h(y_n) = y_n + h \sum_{j=1}^{s} \widetilde{b}_j f(Y_{n,j}) \tag{7}$$

are usually available without additional cost, one is tempted to take $\Phi_n = \varphi_h(y_n) - \widetilde{\varphi}_h(y_n)$, and then the resulting projected method (6)

$$\widehat{\varphi}_h(y_n) = y_n + h \sum_{j=1}^{s} ((1-\lambda_n) b_j + \lambda_n \widetilde{b}_j) f(Y_{n,j}) \tag{8}$$

has the form of an RK method with (variable) weights $\widehat{b}_j = (1-\lambda_n) b_j + \lambda_n \widetilde{b}_j$ and retains important properties of these methods, such as the preservation of linear invariants, the affine invariance, and a low computational cost.

The aim of this paper is to study projected explicit RK methods of type (8) that preserve general invariants with the purpose of being used in numerical integrators based on adaptive RK methods. In section 2, a revision of the case $\widetilde{\varphi}_h(y_n) = y_n$, in which the companion method has order zero, is presented with the purpose of generalizing the results given in [1] and also of showing a more efficient way of computing λ_n. In section 3, a general study for quadratic invariants and embedded methods $\widetilde{\varphi}_h$ with order q $(1 \le q < p)$ is carried out. In section 4 this study is generalized to nonquadratic scalar invariants and to the case of several scalar invariants. Further, some remarks on how to include the proposed schemes in adaptive RK codes are also given. Finally, in section 5, some numerical experiments with the classical embedded pair of explicit RK methods of orders five and four, DoPri5(4) [4], are shown in order to make clear how our technique performs on several test problems.

2. The incremental direction technique revisited. In [1] del Buono and Mastroserio propose to advance the integration $t_n \to t_{n+1} = t_n + h$ of (1) with the RK method $\widehat{\varphi}_h$ given by (4), where γ_n is properly chosen so that the method preserves a fixed quadratic invariant $G(y) = y^T S\, y = \langle y, y \rangle$. Here we will write $\widehat{\varphi}_h$ in the equivalent form

$$\widehat{\varphi}_h(y_n) = \varphi_h(y_n) - \lambda_n(\varphi_h(y_n) - y_n) = (1-\lambda_n)\varphi_h(y_n) + \lambda_n y_n, \tag{9}$$

so that the scalar $\lambda_n = 1 - \gamma_n$ will be a small quantity at each step.

Next it will be seen that for all RK methods φ_h with order $p \ge 2$ the projected method $\widehat{\varphi}_h$ has order $p - 1$. This result generalizes Proposition 4 of [1] in two

directions: First, it extends the statement on fourth-order RK methods to any order $p \geq 2$; second, there are no restrictions on the coefficients of the method φ_h in contrast with the situation in [1]. Finally, we will show that for any order p, λ_n (or γ_n) can be computed with two bilinear form evaluations $\langle \cdot, \cdot \rangle$ per step.

With the notation (9) and putting $\varphi_h(y_n) - y_n = h\Delta_n$, the preservation of the quadratic invariant $G(y) = y^T S y = \langle y, y \rangle$ holds if and only if λ_n satisfies

$$2\langle y_n, h\Delta_n \rangle + (1 - \lambda_n)\langle h\Delta_n, h\Delta_n \rangle = 0. \tag{10}$$

If $\langle y_n, h\Delta_n \rangle = \langle h\Delta_n, h\Delta_n \rangle = 0$, then $\langle \widehat{\varphi}_h(y_n), \widehat{\varphi}_h(y_n) \rangle = \langle y_n, y_n \rangle$ for all λ_n, and therefore it would be enough to take $\lambda_n = 0$ (i.e., the original method φ_h) to preserve the invariant. If either $\langle y_n, h\Delta_n \rangle = 0$ or else $\langle h\Delta_n, h\Delta_n \rangle = 0$, equation (10) cannot be satisfied by $\lambda_n \neq 1$ (note that $\lambda_n = 1$ leads to the method $\widehat{\varphi}_h(y_n) = y_n$ producing a constant output) and therefore it is not possible to preserve the invariant. Hence the condition

$$\langle y_n, \Delta_n \rangle \, \langle \Delta_n, \Delta_n \rangle \neq 0 \tag{11}$$

must be satisfied in order to make (10) solvable. Observe that if φ_h is Euler's method, since $\Delta_n = f(y_n)$, condition (11) does not hold. Thus, only methods with order $p \geq 2$ will be considered.

THEOREM 2.1. [illegible] φ_h [illegible] $p \geq 2$ [illegible] (11) [illegible]

(i) [illegible] $\widehat{\varphi}_h$ [illegible] (9) [illegible] $G(y) = \langle y, y \rangle$ [illegible] λ_n [illegible]

$$\lambda_n = \frac{\langle 2y_n + h\Delta_n, h\Delta_n \rangle}{\langle h\Delta_n, h\Delta_n \rangle} = \frac{\langle \varphi_h(y_n), \varphi_h(y_n) \rangle - \langle y_n, y_n \rangle}{\langle \varphi_h(y_n) - y_n, \varphi_h(y_n) - y_n \rangle}. \tag{12}$$

(ii) [illegible] $\langle f(y_n), f(y_n) \rangle \neq 0$, [illegible] $\widehat{\varphi}_h$ [illegible] $p - 1$ [illegible]. Under the assumption (11), equation (10) has the solution λ_n given by (12), and therefore the method $\widehat{\varphi}_h$ preserves the quadratic invariant. On the other hand, since φ_h has order p, we have

$$\varphi_h(y_n) = y_n + h\Delta_n = y(t_n + h) + \epsilon_{n+1},$$

where $\epsilon_{n+1} = C_{p+1}h^{p+1} + \mathcal{O}(h^{p+2})$ is the local error of φ_h at y_n with step size h and $y(t_n + t)$ is the local solution of (1) at (t_n, y_n); i.e., it satisfies $y(t_n) = y_n$ and

$$\langle y(t_n + h), y(t_n + h) \rangle = \langle y(t_n), y(t_n) \rangle = \langle y_n, y_n \rangle$$

for all h. Then, for the numerator and denominator of λ_n in (12) we have

$$\begin{aligned} \langle \varphi_h(y_n), \varphi_h(y_n) \rangle - \langle y_n, y_n \rangle &= 2\langle y_n, C_{p+1} \rangle h^{p+1} + \mathcal{O}(h^{p+2}), \\ \langle h\Delta_n, h\Delta_n \rangle &= h^2 \langle y'(t_n), y'(t_n) \rangle + \mathcal{O}(h^3), \end{aligned}$$

and λ_n behaves like $O(h^{p-1})$ providing that $\langle y'(t_n), y'(t_n) \rangle = \langle f(y_n), f(y_n) \rangle \neq 0$, and, according to (9), this implies that $\widehat{\varphi}_h$ is a method of order $p - 1$. □

To end this section, observe that it follows from (12) that the computation of λ_n requires only two bilinear forms per step in contrast with [1] which needs six bilinear forms for $s = 4$. Moreover, since the two required bilinear forms are $\langle \varphi_h(y_n), \varphi_h(y_n) \rangle, \langle \varphi_h(y_n), y_n \rangle$, only one matrix-vector product is necessary.

3. A general projection technique for quadratic invariants. Let φ_h be an explicit s-stage RK method (A, b) with order p defined by equations (2)–(3), and let $\widetilde{\varphi}_h$ be an embedded method (7) with order q $(1 \le q < p)$ defined by the weights $\widetilde{b}_i,\ i = 1, \ldots, s$. As remarked above, practical RK methods possess embedded methods with several orders $(1 \le q \le p-1)$, so that we have wide freedom in the choice of $\widetilde{\varphi}_h$ and the computation of the embedded method does not require additional function evaluations. Suppose that (1) possesses a quadratic invariant $G(y) = y^T S y = \langle y, y\rangle$. We propose to complete the step $t_n \to t_{n+1}$, projecting $\varphi_h(y_n)$ onto the manifold defined by the invariant $\mathcal{M}_{y_n} = \{y \in \mathbb{R}^m; \langle y, y\rangle = \langle y_n, y_n\rangle\}$ along the direction given by the unit vector

$$w_n = w(y_n, h) = \frac{\varphi_h(y_n) - \widetilde{\varphi}_h(y_n)}{\|\varphi_h(y_n) - \widetilde{\varphi}_h(y_n)\|_2}, \tag{13}$$

where $\|\cdot\|_2$ is the Euclidean norm.

Then the projected method $\widehat{\varphi}_h$ is given by

$$\widehat{\varphi}_h(y_n) = \varphi_h(y_n) - \lambda_n w_n, \tag{14}$$

with the scalar $\lambda_n = \lambda(y_n, h)$ such that

$$G(\widehat{\varphi}_h(y_n)) - G(y_n) \equiv \langle \widehat{\varphi}_h(y_n), \widehat{\varphi}_h(y_n)\rangle - \langle y_n, y_n\rangle = 0. \tag{15}$$

Substituting (14) into (15), λ_n must satisfy

$$\alpha_n \lambda_n^2 - 2\beta_n \lambda_n + \delta_n = 0, \tag{16}$$

with

$$\begin{aligned} \alpha_n &= \alpha(y_n, h) = \langle w_n, w_n\rangle, \\ \beta_n &= \beta(y_n, h) = \langle \varphi_h(y_n), w_n\rangle, \\ \delta_n &= \delta(y_n, h) = \langle \varphi_h(y_n), \varphi_h(y_n)\rangle - \langle y_n, y_n\rangle. \end{aligned} \tag{17}$$

Given $h > 0$ and y_n, if $\delta(y_n, h) = 0$, the original method $\varphi_h(y_n)$ preserves the quadratic invariant in this step and in such a case we would take $\lambda_n = 0$.

If $\delta_n \neq 0$, let us suppose $\beta_n^2 - \alpha_n \delta_n > 0$; then we take for λ_n the real root of (16) closest to $\lambda = 0$ given by

$$\lambda_n = \begin{cases} \dfrac{\delta_n}{\beta_n + \operatorname{sign}\beta_n \sqrt{\beta_n^2 - \alpha_n \delta_n}} & \text{if} \quad \beta_n \neq 0, \\ (-\delta_n/\alpha_n)^{1/2} & \text{if} \quad \beta_n = 0. \end{cases} \tag{18}$$

To study the order of the projected method (14), (15), observe that denoting by $C_{q+1}(y_n)h^{q+1}$ the leading term of the local error of the embedded method $\widetilde{\varphi}_h(y_n)$, $w_n = C_{q+1}/\|C_{q+1}\|_2 + \mathcal{O}(h)$ and then

$$\beta(y_n, 0) = \langle \varphi_h(y_n), w(y_n, h)\rangle|_{h=0} = \left\langle y_n, \frac{C_{q+1}}{\|C_{q+1}\|_2} \right\rangle. \tag{19}$$

Now we have the following theorem.

THEOREM 3.1. [illegible] φ_h [illegible] $\widetilde{\varphi}_h$ [illegible] RK [illegible] p [illegible] q $(1 \le q \le p-1)$.

(i) [illegible] $\langle y_n, C_{q+1}(y_n)\rangle \neq 0$ [illegible] $h^* > 0$ [illegible] $\widehat{\varphi}_h$ [illegible] (14) [illegible] $\lambda_n = \lambda(y_n, h)$ [illegible] (18) [illegible] $\widehat{p} \ge p$ [illegible] $h \in (0, h^*]$

(ii) [illegible] β_n [illegible] (17) [illegible] $\beta_n = B(y_n)h^r + \mathcal{O}(h^{r+1})$ [illegible] $B(y_n) \neq 0$ $r \ge 1$ [illegible] $p - 2r + 1 > 0$, [illegible] $\widehat{\varphi}_h$ [illegible] $\widehat{p} \ge p - r$ [illegible] $h \in (0, h^*]$

[illegible]. (i) Since $\beta(y_n, 0) \neq 0$ and by (17) we have $\alpha_n = \mathcal{O}(1)$, $\delta_n = \mathcal{O}(h^{p+1})$, there exist some $h^* > 0$ such that $\beta_n^2 - \alpha_n\delta_n > 0$ for $h \in (0, h^*]$. Then λ_n is well defined by (18) and $\lambda_n = \mathcal{O}(h^{p+1})$, which implies that the projected method (14) has order $\widehat{p} \ge p$.

(ii) Now, since $\beta_n = \mathcal{O}(h^r)$, $\alpha_n = \mathcal{O}(1)$, $\delta_n = \mathcal{O}(h^{p+1})$, and $2r < p+1$, $\beta_n^2 - \alpha_n\delta_n > 0$ also holds for $h \in (0, h^*]$. Further it follows from (18) that $\lambda_n = \mathcal{O}(h^{p+1-r})$ and now the order $\widehat{p}$ of the projected method is $\ge p - r$. ∎

In practical application of (14), given an explicit RK method φ_h of order p, we usually have the freedom to choose several embedded methods $\widetilde{\varphi}_h$ with different orders $(1 \le q \le p-1)$. Then the question is how to choose $\widetilde{\varphi}_h$. It will be seen that the simplest choice, namely Euler's method, in general provides a projected method with order $\ge p$. In fact, for $\widetilde{\varphi}_h(y_n) = y_n + hf(y_n)$, we have $q = 1$ and $C_2 = y_n''(t_n)/2 = f'(f(y_n))/2$, and the condition

$$\beta(y_n, 0) = \left\langle y_n, \frac{f'(f(y_n))}{\|f'(f(y_n))\|_2} \right\rangle \neq 0$$

implies that the projected method has order $\ge p$.

Finally, observe that $\langle y_n(t+h), y_n(t+h)\rangle - \langle y_n, y_n\rangle = 0$ along the local solution $y_n(t)$ at (t_n, y_n) for all h sufficiently small implies $\langle y_n, f'(f(y_n))\rangle = -\langle f(y_n), f(y_n)\rangle$ and the above condition can be easily checked.

[illegible]. The above theory extends easily to more general invariants which include both quadratic and linear terms with the form $G(y) = y^T S y + d^T y$, where S is a symmetric constant matrix and d a constant vector. In fact, for $\widehat{\varphi}_h$ given by (14), (15) holds if and only if λ_n satisfies

$$\alpha_n\lambda_n^2 - 2\beta_n'\lambda_n + \delta_n' = 0, \tag{20}$$

with $\beta_n' = \beta_n + (1/2)d^T w_n$ and $\delta_n' = \delta_n + d^T\varphi_h(y_n) - d^T y_n$. If $\delta_n' = 0$, for a given h, the original method φ_h preserves the invariant and we take $\lambda_n = 0$. Otherwise, the existence of a real solution of the quadratic equation (20) depends on the sign of $(\beta_n')^2 - \alpha_n\delta_n'$, and sufficient conditions similar to those in Theorem 3.1 can be given in order to guarantee the solvability.

4. General invariants. In this section we extend our technique to nonquadratic scalar invariants and to the case of several scalar invariants.

For a general scalar invariant given by a smooth function $G = G(y) : \widehat{\mathcal{D}} \subset \mathbb{R}^m \to \mathbb{R}$ the proposed projection technique reduces to the solution of the nonlinear scalar equation

$$G\Big(\varphi_h(y_n) - \lambda_n w_n\Big) - G(y_n) = 0, \tag{21}$$

where $w_n = w_n(y_n, h)$ is given by (13). In this case, the existence of solution λ_n is guaranteed under the conditions of the following theorem.

THEOREM 4.1. φ_h $\widetilde{\varphi}_h$ p q $(1 \le q \le p-1)$, $C_{q+1}(y_n)h^{q+1}$ $\widetilde{\varphi}_h(y_n)$

(i) $\nabla G(y_n)^T C_{q+1}(y_n) \neq 0$ $h^* > 0$ (21) $\lambda_n = \lambda(y_n, h)$ $h \in [0, h^*]$ $\widehat{\varphi}(y_n)$ $\hat{p} \ge p$

(ii) $\nabla G(\varphi_h(y_n))^T w_n = B(y_n)h^r + \mathcal{O}(h^{r+1})$ $r \ge 1$ $B(y_n) \neq 0$ $2r \le p$ $h^* > 0$ (21) $\lambda_n = \lambda(y_n, h)$ $h \in (0, h^*]$ $\widehat{\varphi}(y_n)$ $\hat{p} \ge p - r$

Proof. (i) For λ, h in a neighborhood of the origin let us define the real function $g(\lambda, h) \equiv G(\varphi_h(y_n) - \lambda w_n) - G(y_n)$. Taking into account the smoothness of G and φ_h and that

$$g(0,0) = G(y_n) - G(y_n) = 0, \quad \frac{\partial g}{\partial \lambda}(0,0) = -\nabla G(y_n)^T \frac{C_{q+1}(y_n)}{\|C_{q+1}(y_n)\|_2} \neq 0,$$

the implicit function theorem ensures the existence of a neighborhood $[0, h^*]$ and a unique smooth function $\lambda_n = \lambda_n(h)$ satisfying $\lambda_n(0) = 0$ and $g(\lambda_n(h), h) = 0$ for all $h \in [0, h^*]$.

Moreover, we can expand

$$g(\lambda_n, h) = g(0, h) + \frac{\partial g}{\partial \lambda_n}(0, h)\lambda_n + \mathcal{O}(\lambda_n^2),$$

with

$$g(0,h) = G(\varphi_h(y_n)) - G(y_n) = \mathcal{O}(h^{p+1}),$$
$$\frac{\partial g}{\partial \lambda_n}(0,h) = \frac{\partial g}{\partial \lambda_n}(0,0) + \mathcal{O}(h).$$

Then $\lambda_n = \lambda_n(h) = \mathcal{O}(h^{p+1})$ and the projected method has order $\hat{p} \ge p$.

(ii) Now we consider the real function $z(\mu, h)$ defined in the neighborhood of the origin by

$$z(\mu, h) = h^{-2r}\left[G(\varphi_h(y_n) - \mu h^r w_n) - G(y_n)\right] \quad \text{for } h \neq 0, \tag{22}$$

where $z(\mu, 0)$ is given by the corresponding limit

$$\lim_{h \to 0} z(\mu, h) = -B(y_n)\mu + \frac{1}{2\|C_{q+1}(y_n)\|_2^2} C_{q+1}(y_n)^T \frac{\partial^2 G}{\partial y^2}(y_n) C_{q+1}(y_n)\mu^2. \tag{23}$$

Clearly z is continuous for all $h > 0$. To check the continuity of z at $h = 0$ note that by the mean value theorem,

$$G(\varphi_h(y_n) - \mu h^r w_n) = G(\varphi_h(y_n)) - \mu h^r \int_0^1 \nabla G(\varphi_h(y_n) - \theta \mu h^r w_n)^T w_n \mathrm{d}\theta;$$

then for $h \neq 0$ we have

$$z(\mu, h) = -\mu h^{-r} \int_0^1 \nabla G(\varphi_h(y_n) - \theta \mu h^r w_n)^T w_n \mathrm{d}\theta + h^{-2r}\big(G(\varphi_h(y_n)) - G(y_n)\big).$$

Let us consider the smooth function defined as $\varsigma(y) := \nabla G(y)^T w_n$. By considering again the mean value theorem applied to ς, we can write

$$\varsigma(\varphi_h(y_n) - \theta\mu h^r w_n) = \varsigma(\varphi_h(y_n)) - \theta\mu h^r \int_0^1 \nabla\varsigma(\varphi_h(y_n) - \rho\theta\mu h^r w_n)^T w_n \mathrm{d}\rho.$$

Thus, we have that

$$\begin{aligned} z(\mu,h) = {} & h^{-2r}(G(\varphi_h(y_n)) - G(y_n)) - \mu h^{-r}\varsigma(\varphi_h(y_n)) \\ & + \mu^2 \int_0^1 \int_0^1 \theta\nabla\varsigma(\varphi_h(y_n) - \rho\theta\mu h^r w_n)^T w_n \mathrm{d}\rho\mathrm{d}\theta. \end{aligned} \tag{24}$$

Since $p+1 > 2r$, we deduce (23) from (24), and then $z(\mu,h)$ is a continuous function at $h = 0$.

Moreover, $\partial z/\partial\mu$ is also a continuous function in a neighborhood of the origin, and $\partial z/\partial\mu(0,0) = -B(y_n) \neq 0$; therefore by the implicit function theorem there exist $h^* > 0$ and a continuous $\mu = \mu(h)$ such that $z(\mu(h),h) = 0$ for all $h \in [0,h^*]$.

Taking into account (22), for all $h \in (0,h^*]$, $\lambda_n(h)$ given by $\lambda_n(h) = h^r\mu(h)$ is the unique solution of $G(\varphi_h(y_n) - \lambda_n w_n) - G(y_n) = 0$.

Finally, by considering the expansion

$$z(\mu,h) = z(0,h) + \frac{\partial z}{\partial\mu}(0,h)\mu + \mathcal{O}(\mu^2),$$

with

$$\begin{aligned} z(0,h) &= h^{-2r}\big(G(\varphi_h(y_n)) - G(y_n)\big) = \mathcal{O}(h^{p+1-2r}), \\ \frac{\partial z}{\partial\mu}(0,h) &= \frac{\partial z}{\partial\mu}(0,0) + \mathcal{O}(h) = -B(y_n) + \mathcal{O}(h), \end{aligned}$$

it follows that $\mu = \mathcal{O}(h^{p+1-2r})$ and therefore $\lambda_n = \mathcal{O}(h^{p+1-r})$, which implies that the projected method has order $\hat{p} \geq p - r$. □

1. Since w_n is a unit vector in the direction of the local error of the embedded method $\widetilde{\varphi}_h(y_n)$ and $w_n = C_{q+1}(y_n)/\|C_{q+1}(y_n)\|_2 + \mathcal{O}(h)$, $C_{q+1}(y_n) \neq 0$, condition $\nabla G(y_n)^T C_{q+1}(y_n) \neq 0$ of Theorem 4.1(i) is equivalent to the nonvanishing of the derivative of $G(y)$ in the direction of the leading error term $C_{q+1}(y_n)$ of w_n at y_n. Geometrically it means that $C_{q+1}(y_n)$ is not tangent to the level surface $G(y) - G(y_n) = 0$ at y_n. Further, if the leading term of $\nabla G(\varphi_h(y_n))^T w_n$ given by $\nabla G(y_n)^T C_{q+1}(y_n)$ vanishes for some y_n, but $\nabla G(\varphi_h(y_n))^T w_n = \mathcal{O}(h^r)$ with $1 \leq r \leq p/2$, it is possible to ensure the preservation of the invariant at the cost of an order reduction ($\hat{p} \geq p - r$) of the projected numerical solution.
2. Theorem 4.1 can also be applied to prove that the standard orthogonal projection of an RK method of order p has order $\geq p$. In fact (5) has the form (14) with $w_n = -\nabla G(\varphi_h(y_n))$, and in this case since $\nabla G(y_n)^T w_n = \|\nabla G(y_n)\|_2^2 + \mathcal{O}(h)$, the method (5) has order $\geq p$. If $\nabla G(y_n) = 0$, the standard projection cannot be applied, but in such a case if $\nabla G(\varphi_h(y_n))^T w_n = \mathcal{O}(h^r)$, our projection technique could be applied. Note also that the standard orthogonal projection requires having an analytical expression of $\nabla G(y)$, whereas in our approach the gradient is not necessary.

3. Recall that for all affine transformations $z \to y = Pz + q$ with constant $P \in \mathbb{R}^{m\times m}$, $q \in \mathbb{R}^m$, if we denote by $\psi_{f,t}$ the flow map of $y' = f(y)$ and by $\psi_{\tilde{f},t}$ the corresponding flow map to the transformed system $z' = \tilde{f}(z) = P^{-1}f(Pz+q)$, they are affine invariants in the sense that $\psi_{f,t}(y_0) = P\psi_{\tilde{f},t}(z_0) + q$ whenever $y_0 = Pz_0+q$. It can be seen that this property holds for RK methods and also for the proposed methods (14). However, the standard projection preserves the affine invariance only for orthogonal P.

4.1. Implementation in adaptive RK codes. To use our technique in adaptive codes based on an embedded pair of RK formulas with orders p and $p-1$, recall that the step size $t_n \to t_{n+1} = t_n + h_n$ is chosen so that a norm of the local error estimator $\mathrm{EST} = y_{n+1} - y_{n+1}^{(p-1)}$ given by the difference between the solutions y_{n+1} and $y_{n+1}^{(p-1)}$ of orders p and $p-1$, respectively, is lower than a given error tolerance TOL. For the new projected solution $\widehat{y}_{n+1} = y_{n+1} - \lambda_n w_n$ one is tempted to use the new estimator $\widehat{\mathrm{EST}} = \widehat{y}_{n+1} - y_{n+1}^{(p-1)}$, but $\widehat{y}_{n+1}$ could lose (at some isolated times) one or more orders of accuracy and then this is not a reliable estimate. Thus we propose a more conservative policy in which we check both EST and the correction of projection $\|\lambda_n w_n\| = |\lambda_n|$ and accept a step whenever $\max\{\|\mathrm{EST}\|, |\lambda_n|\} \le \mathrm{TOL}/2$.

Observe that $\|\mathrm{EST}\| = \mathcal{O}(h^p)$ and that if the projected solution has no order reduction, then $|\lambda_n| = \mathcal{O}(h^{p+1})$. Hence the above step-size control will be usually governed by EST.

Then for a rejected step h_n' or the new step h_{n+1} we propose the new step size given by the modified standard formula

$$\mathrm{fac} * \left(\frac{\mathrm{TOL}}{2\max\{\|\mathrm{EST}\|, \lambda_n\}}\right)^{1/p} * h_n,$$

with the security factor fac of the original code.

On the other hand, note that in the projected method $\widehat{y}_{n+1} = \widehat{\varphi}_h(y_n)$ can be rewritten as

$$\widehat{y}_{n+1} = y_{n+1} - \lambda_n w_n = y_{n+1} - \frac{\lambda_n}{\|y_{n+1} - \widetilde{y}_{n+1}\|}\,(y_{n+1} - \widetilde{y}_{n+1})$$

and is an RK type method whenever $\lambda_n \|y_{n+1} - \widetilde{y}_{n+1}\|^{-1}$ is bounded. Since $\lambda_n = \mathcal{O}(h^{p+1-r})$ and $\|y_{n+1} - \widetilde{y}_{n+1}\| = \mathcal{O}(h^{q+1})$, the above quotient is $\mathcal{O}(h^{p-q-r})$; then for a strong order reduction ($r > p-q$) the projected method would lose its reliability. To protect the code from such eventual strong order reductions we propose to include the additional control $|\lambda_n| < \|y_{n+1} - \widetilde{y}_{n+1}\|$. If this condition does not hold at some step, we would take another $\widetilde{\varphi}_h$ method that would change the direction of the projected method. In our numerical experiments we have not detected such a strong order reduction that this control has been necessary.

Finally, in practical application of our technique with one scalar nonquadratic invariant we must solve at each step the (nonquadratic) equation $g(\lambda, h) = 0$. Many iterative methods have been proposed to solve nonlinear equations: In Newton-type methods we need to approximate the gradient of G (either analytically or numerically) one or more times per step depending on the convergence of the iteration. In our numerical experiments with the modified Newton, convergence was attained with 1–2 iterations. However, other iterative schemes that require only evaluations of G may be used. We have found that the secant method, with starting values $\lambda = 0$ and the

value λ obtained in the previous step, requires 1–2 iterations to attain convergence to the round-off level in the tested problems. Thus, we have used this iterative scheme because its convergence is similar to that of the modified Newton and it has a lower computational cost.

4.2. Several invariants. Suppose now that the differential system (1) possesses $l \geq 1$ smooth invariants $G_1(y), \ldots, G_l(y)$ defined in $\mathcal{D} \subset \mathbb{R}^m$, and let $G = (G_1, \ldots, G_l)^T : \mathcal{D} \subset \mathbb{R}^m \to \mathbb{R}^l$. Together with the starting method φ_h of order p we consider l linearly independent embedded methods $\widetilde{\varphi}_h^{(1)}, \ldots, \widetilde{\varphi}_h^{(l)}$ with orders $q_1 \leq q_2 \leq \cdots \leq q_l < p$. Then, generalizing (14), the projected method $\widehat{\varphi}_h$ will be defined by

$$\widehat{\varphi}_h(y_n) = \varphi_h(y_n) - \sum_{i=1}^{l} \lambda_n^{(i)} w_n^{(i)}, \tag{25}$$

where

$$w_n^{(i)} = \frac{\varphi_h(y_n) - \widetilde{\varphi}_h^{(i)}(y_n)}{\|\varphi_h(y_n) - \widetilde{\varphi}_h^{(i)}(y_n)\|}$$

and $\lambda_n^{(i)} = \lambda^{(i)}(y_n, h)$, $i = 1, \ldots, l$, are problem-dependent scalars that will be chosen so that

$$G\left(\varphi_h(y_n) - \sum_{i=1}^{l} \lambda_n^{(i)} w_n^{(i)}\right) = G(y_n). \tag{26}$$

We also introduce the $m \times l$ matrix T_n defined by its column vectors $T_n = [w_n^{(1)} | \ldots | w_n^{(l)}]$, and then

$$(\nabla G(\varphi_h(y_n)))^T \; T_n = M(y_n) + \mathcal{O}(h), \tag{27}$$

with $M(y_n) \in \mathbb{R}^{l \times l}$. With this notation we have the following theorem.

THEOREM 4.2. [illegible] (27) [illegible] $M(y_n)$ [illegible] $h^* > 0$ [illegible] $(\lambda^{(1)}(y_n, h), \ldots, \lambda^{(l)}(y_n, h))$ [illegible] $\widehat{\varphi}_h$ [illegible] (25) [illegible] l [illegible] $G_i, i = 1, \ldots, l$ [illegible] $h \in [0, h^*]$ [illegible] $\geq p$ [illegible]. Consider $\lambda = (\lambda^{(1)}, \ldots, \lambda^{(l)})^T$ and $g(\lambda, h) : \mathbb{R}^l \times \mathbb{R} \to \mathbb{R}$ defined by

$$g(\lambda, h) = G\left(\varphi_h(y_n) - \sum_{i=1}^{l} \lambda^{(i)} w_n^{(i)}\right) - G(y_n). \tag{28}$$

The proof follows in a way similar to that of statement (i) of Theorem 4.1. ∎

To end this section, the following result is given in order to ensure that Newton-type iterations applied to (26) provide numerical sequences which converge in small neighborhoods of the origin. In fact, we have the following corollary.

COROLLARY 4.1. [illegible] 4.2 [illegible] $h^* > 0$ [illegible] $0 < h < h^*$ [illegible] (26), [illegible] $\lambda := 0$ [illegible]

Considering, as in Theorem 4.2 above, the function $g(\lambda, h)$ (28), it is not difficult to see that

$$\gamma := \sup_{\substack{\eta,\mu\in\Lambda_0 \\ \eta\neq\mu}} \frac{\| \nabla_\lambda g(\eta, h) - \nabla_\lambda g(\mu, h) \|}{\| \eta - \mu \|} = \mathcal{O}(1),$$

$$\alpha := \| \nabla_\lambda g(0, h)^{-1} g(0, h) \| = \mathcal{O}(h^{p+1}),$$

$$\beta := \| \nabla_\lambda g(0, h)^{-1} \| = \mathcal{O}(1),$$

where $\Lambda_0 \subset \mathbb{R}^l$ stands for a sufficiently small neighborhood of $\lambda = 0$. Thus, there exists $h^* > 0$ such that for all $0 < h < h^*$, $\tau := \gamma\alpha\beta = \mathcal{O}(h^{p+1}) \leq 1/2$ is fulfilled. Then, the statement follows from the Newton–Kantorovich theorem (see, e.g., Theorem 5.3.6 in [14]). □

Concerning the implementation of the new projection technique with several invariants, it is straightforward to extend the step-size control of subsection 4.1 to several invariants.

5. Numerical experiments. Here we present some numerical experiments with the purpose of showing some features of the new projection technique. First of all we want to make clear that it is possible to include in any adaptive RK code the new projection technique in a simple way. Further, the resulting code retains its reliability and accuracy and has a low additional computational cost. For comparison we have also included the standard orthogonal projection technique which also preserves the order of the original method but requires explicit expressions of the gradients ∇G and in general has a higher computational cost. In our experiments we have employed as adaptive RK code the pair of Dormand and Prince, DoPri5(4) (see, e.g., [4] for details on the coefficients of this method). Some practical examples have been considered in order to illustrate how the projection technique performs on this kind of problem with invariants. For the sake of brevity, we will show here some results related to the following three problems. Further numerical examples can be found in [2].

1. A problem of micromagnetism [12].

$$f(y) := H_{eff} \times y + \lambda y \times (H_{eff} \times y),$$

with $\lambda = 1/20.1$ and $H_{eff}, y \in \mathbb{R}^3$. We have chosen the initial value $y(0) = (y_0[1], y_0[2], y_0[3]) = (\sin\theta_0 \cos\varphi_0, -\sin\theta_0 \sin\varphi_0, \cos\theta_0)^T$, where $\varphi_0 = \pi/4$ and $\theta_0 = \pi/3$.

This kind of equation appears in micromagnetism problems when solving the Landau–Lifshitz–Gilbert equation (see, e.g., [8, 12, 13]). Since $y'(t)$ is orthogonal to the exact solution $y(t)$, it is clear that $G(y) = y^T y$ is a quadratic invariant. In case of $H_{eff} := (1, 0, 0)^T$, the exact solution is given by

$$y(t) = \left(\frac{a(t)}{b(t)}, \frac{2}{b(t)}(y_0[2]\cos t - y_0[3]\sin t), \frac{2}{b(t)}(y_0[2]\sin t + y_0[3]\cos t) \right)^T,$$

with

$$a(t) = e^{\lambda t}(1 + y_0[1]) - e^{-\lambda t}(1 - y_0[1]),$$
$$b(t) = e^{\lambda t}(1 + y_0[1]) + e^{-\lambda t}(1 - y_0[1]).$$

2. The restricted three body problem (see, e.g., [6, pp. 129–130]). Here $F : \mathbb{R}^4 \to \mathbb{R}^4$ is given by

$$f(y) := \left(y_3, y_4, y_1 + 2y_4 - \bar{\mu}\frac{y_1+\mu}{D_1^{3/2}} - \mu\frac{y_1-\bar{\mu}}{D_2^{3/2}}, y_2 - 2y_3 - \bar{\mu}\frac{y_2}{D_1^{3/2}} - \mu\frac{y_2}{D_2^{3/2}} \right)^T,$$

with $D_1 := (y_1+\mu)^2 + y_2^2$, $D_2 := (y_1-\bar{\mu})^2 + y_2^2$, $y = (y_1, y_2, y_3, y_4)^T$, and $y(0) = (0.994, 0, 0, -2.00158510637908252240537862224)^T$, where $\bar{\mu} = 1-\mu$ and $\mu = 0.012277471$. For this initial condition we get a periodic solution with a minimal period $T_2 := 17.06521656015796255889172062 49$. Now the total energy

$$G(y) = \frac{1}{2}(y_3^2 + y_4^2 - y_1^2 - y_2^2) - \bar{\mu}D_1^{-1/2} - \mu D_2^{-1/2}$$

is a nonquadratic first integral.

3. Euler equations (see, e.g., [1] and [5, pp. 95–96]).

$$f(y) := \big((\alpha-\beta)y_2y_3,\ (1-\alpha)y_3y_1,\ (\beta-1)y_1y_2\big)^T,$$

with $y = (y_1, y_2, y_3)^T$ and $y(0) = (0, 1, 1)^T$, where $\alpha = 1 + \frac{1}{\sqrt{1.51}}$ and $\beta = 1 - \frac{0.51}{\sqrt{1.51}}$. In these equations the exact solution can be written as

$$y(t) = \left(\sqrt{1.51}\ \mathrm{sn}(t, 0.51), \mathrm{cn}(t, 0.51), \mathrm{dn}(t, 0.51) \right)^T,$$

where sn, cn, dn stand for the elliptic Jacobi functions. This problem has two quadratic integrals:

$$\text{(i)}\ \ G_1(y) = y_1^2 + y_2^2 + y_3^2, \qquad \text{(ii)}\ \ G_2(y) = y_1^2 + \beta y_2^2 + \alpha y_3^2.$$

These problems have been integrated with the following three methods: DoPri5(4) (the classical pair of Dormand and Prince [4]), DoPri5(4)+SP (the pair of Dormand and Prince with the standard projection technique), and DoPri5(4)+DP (the same pair with the proposed directional projection technique). To define the directional projection we have used the Euler method as embedded method $\widetilde{y}_{n+1}$ (of order $q = 1$) when only one scalar invariant must be preserved (Problems 1 and 2). For Problem 3, which posses two invariants, we need two "independent" embedded methods of orders q_1 and q_2 to define the projected method. We have used the Euler method ($q_1 = 1$) and a second-order embedded method ($q_2 = 2$).

For a quadratic invariant $G(y) = y^T Sy$, since the gradient $\nabla G = 2Sy$ is immediately available, we compute λ_n from the quadratic equation (12). For nonquadratic invariants λ_n is computed by a modified Newton iteration in the case of orthogonal projection and by a secant iterative scheme for our projected solution. For several invariants we have used modified Newton for both projection techniques (in the case of our projected solution Broyden's iteration is under consideration).

The first problem has been integrated with several fixed step sizes in the interval $[0, T_{end} = 16\pi]$. The global and invariant errors (i.e., *ge* and *ie*, resp.) for DoPri5(4) and DoPri5(4)+DP and the different step sizes have been plotted in Figure 1. It can be observed that the projected method preserves the invariant and also provides a numerical solution with the same order (the slopes of the global error curves are the same) but with a smaller global error than classical Dopri5(4).

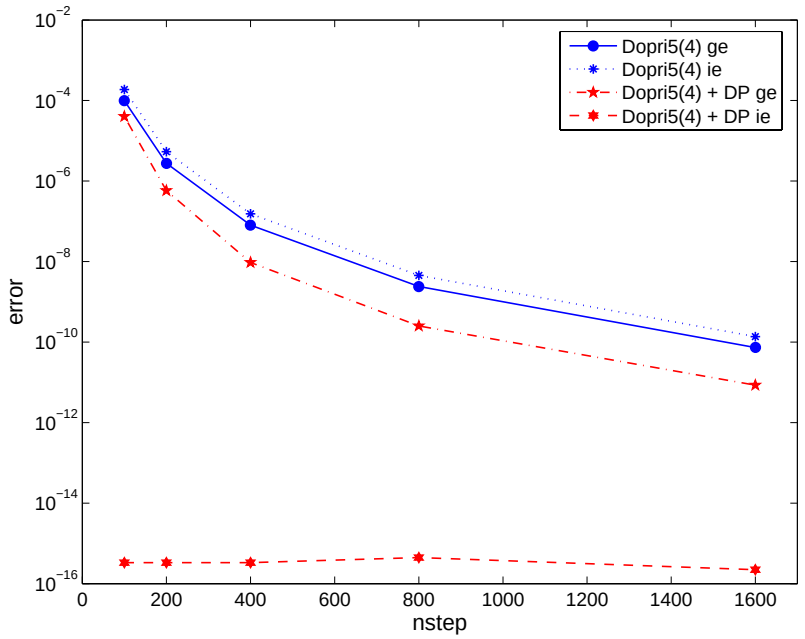

FIG. 1. *Problem* 1 *integrated with DoPri*5(4) *and DoPri*5(4)+*DP.*

On the other hand, Problems 2 and 3 have been integrated with variable step size using the technique proposed in subsection 4.1, with values $ATOL = 10^{-6}$ and $RTOL = ATOL/10$ representing the absolute and relative tolerance errors, respectively. The fourth-order embedded method was considered in order to estimate the local error at each point in the nonuniform grid. The end point was taken in each problem as $T_{end} = 3T_2$ and $T_{end} = 100$, respectively.

Figures 2 and 3 show the numerical orbits in the (y_1, y_2)-plane when Problem 2 is integrated with DoPri5(4) and DoPri5(4)+DP, respectively (the figure for DoPri5(4)+SP is very similar to the one corresponding to DoPri5(4)+DP). It is seen that both projected methods give a better qualitative behavior than DoPri5(4) because they preserve the corresponding first integral, as shown in Figure 4. It must be remarked that some round-off errors came up when solving the nonlinear equations defining the projected methods in neighborhoods of the singularities of the underlying problem, and this is the reason the projected methods do not preserve properly the invariant in neighborhoods of the singularities. Efficiency curves have not been presented for this problem because they show a similar behavior to those in Problems 1 and 3.

Figures 5 and 6 correspond to Problem 3, integrated with variable step size. In this case, we have displayed in Figure 5 the global error produced by the three methods in relation to the number of function evaluations, whereas Figure 6 plots the error in both invariants. Again, the projected methods provide numerical solutions with a smaller global error than the classical pair 5(4) for a similar number of derivative function evaluations.

6. Conclusions. A projection technique to preserve invariants by means of explicit RK methods has been proposed. The projected methods preserve both the order

of consistency of the original methods and the selected invariants of the problem under consideration. A study of the order of consistency has been carried out.

The main advantages of the new approach over the standard projection technique are as follows: The gradient of the invariants is not required. The approach preserves linear invariants and affine invariance. Further, the new projection methods are well suited for use in adaptive RK methods with a low extra cost.

Finally the new technique and the standard projection have been implemented in the code DoPri5(4), and the results of some numerical experiments are presented.

SPECTRAL METHODS FOR PARTIAL DIFFERENTIAL EQUATIONS IN IRREGULAR DOMAINS: THE SPECTRAL SMOOTHED BOUNDARY METHOD*

ALFONSO BUENO-OROVIO†, VÍCTOR M. PÉREZ-GARCÍA†, AND FLAVIO H. FENTON‡

Abstract. In this paper, we propose a numerical method to approximate the solution of partial differential equations in irregular domains with no-flux boundary conditions. The idea is to embed the domain into a box and use a smoothing term to encode the boundary conditions into a modified equation that can be approached by standard spectral methods. The main features of this method are its capability to deal with domains of arbitrary shape and its easy implementation via fast Fourier transform routines. We discuss several examples of practical interest and test the results against standard numerical methods.

Key words. spectral methods, irregular domains, phase field methods, reaction-diffusion equations

1. Introduction.

Spectral methods [1, 2, 3] are among the most extensively used methods for the discretization of spatial variables in partial differential equations and have been shown to provide very accurate approximations of sufficiently smooth solutions. Because of their high-order accuracy, spectral methods have become widespread over the years in various fields, including fluid dynamics, quantum mechanics, heat conduction, and weather prediction [4, 5, 6, 7, 8]. However, these methods have some limitations which have prevented them from being extended to many problems, where finite-difference and finite-element methods continue to be used predominantly. One limitation is that the discretization of partial differential equations by spectral methods leads to the solution of large systems of linear or nonlinear equations involving full matrices. Finite-difference and finite-element methods, on the other hand, lead to systems involving sparse matrices that can be handled by appropriate methods to reduce the complexity of the calculations substantially. Another drawback of spectral methods is their inability to handle irregularly shaped domains, which is why these methods have had limited use in many engineering problems, where finite-element methods are preferred because of their flexibility in describing complex geometries despite the computational costs associated with constructing an appropriate solution grid. Although there have been attempts to use spectral methods in irregular domains [9, 10], these approaches usually involve either incorporating finite-element preconditioning or using the so-called spectral elements. We are not aware of any

previous study in which purely spectral methods, particularly those involving fast Fourier transforms (FFTs), have been used to obtain solutions in complex irregular geometries.

In this paper we present an easy-to-use method for approximating the solution of partial differential equations in irregular domains with no-flux boundary conditions using spectral methods. The idea is based on what, in dendritic solidification, is known as the phase-field method [11]. This method is used to locate and track the interface between the solid and liquid states and has been applied to a wide variety of problems including viscous fingering [12, 13], crack propagation [14], and the tumbling of vesicles [15]. For a comprehensive review see [16].

In what follows we use the idea behind phase-field methods to illustrate how the solution of several partial differential equations can be obtained in irregular domains using spectral methods, understanding for irregular any arbitrarily shaped domain beyond the standard rectangular or circular geometries. Throughout, for simplicity, we will refer to the combination of the phase-field and spectral methods as the spectral smoothed boundary (SSB) method. Our approach consists of two steps. First, the idea of the phase-field method is formalized and its convergence analyzed for the case of homogeneous Neumann boundary conditions. Then we discuss how the new formulation is useful for the direct use of spectral methods, specifically those based on trigonometric polynomials. This formulation makes the problem suitable for efficient solution using FFTs [17]. Since it is our intention that the resulting methodology be used in a variety of problems in engineering and applied science, we have concentrated on the important underlying concepts, reserving some of the more formal questions related to these methods for a subsequent analysis.

2. The phase-field (smoothed boundary) method. In this work we focus on applying the phase-field method to partial differential equations of the form

$$\nabla(\boldsymbol{D}^{(j)}\nabla u_j) + f(u_1, \ldots, u_N, t) = \partial_t u_j \tag{2.1a}$$

for N unknown real functions u_j defined on an irregular domain $\Omega \subset \mathbb{R}^n$, where $n = 1, 2, 3$ is the spatial dimensionality of the problem, together with appropriate initial conditions $u_j(x, 0) = u_{j0}(x)$ and subject to Neumann boundary conditions

$$\vec{\boldsymbol{n}} \cdot \boldsymbol{D}^{(j)}\nabla u_j = 0 \tag{2.1b}$$

on $\partial\Omega$, where $\boldsymbol{D}^{(j)}(x)$ is a family of $n \times n$ matrices that may depend on the spatial variables. Equations (2.1a) and (2.1b) include many reaction-diffusion models, such as those describing population dynamics or cardiac electrical activity. Here we will restrict the analysis to equations of the form (2.1a), although the idea behind the method can be extended to many other problems involving complex boundaries and different types of partial differential equations.

Instead of discretizing (2.1a), the smoothed boundary method (SBM) relies on considering the auxiliary problem

$$\nabla(\phi^{(\xi)}\boldsymbol{D}^{(j)}\nabla u_j^{(\xi)}) + \phi^{(\xi)} f(u_1^{(\xi)}, \ldots, u_N^{(\xi)}, t) = \partial_t(\phi^{(\xi)} u_j^{(\xi)}) \tag{2.2}$$

for the unknown functions $u_j^{(\xi)}$ on an enlarged domain Ω' satisfying the following conditions: (i) $\Omega \subset \Omega'$ and (ii) $\partial\Omega \cap \partial\Omega' = \emptyset$. The function $\phi^{(\xi)}$ is continuous in Ω' and has the value one inside Ω and smoothly decays to zero outside Ω, with ξ

identifying the width of the decay. That is, if χ_Ω is the characteristic function of the set Ω defined as

$$\chi_\Omega = \begin{cases} 1, & x \in \Omega, \\ 0, & x \in \Omega' \backslash \Omega, \end{cases} \tag{2.3}$$

then $\phi^{(\xi)} : \Omega' \to \mathbb{R}$ is a regularized approximation to χ_Ω such that $\lim_{\xi \to 0} \phi_\xi = \chi_\Omega$.

The key idea of the SBM is that when $\xi \to 0$, the solutions $u_j^{(\xi)}$ of (2.2) on any domain Ω' with arbitrary boundary conditions on $\partial\Omega'$ satisfy $u_j^{(\xi)} \to u_j$; in other words, they tend pointwise to the solution of (2.1a), automatically incorporating the boundary conditions (2.1b). To see why, let us first realize that inside Ω the statement is inmediate since $\phi^{(\xi)} \to 1$ in Ω as $\xi \to 0$ and (2.2) becomes (2.1a). At the boundary, we consider for simplicity the situation with $n = 2$ (the extension to $n = 3$ is immediate). Assuming smoothness of $\partial\Omega$ (which in this case will be a curve) and choosing any connected curve $\Gamma \subset \partial\Omega$, we define two families of differentiable curves $\Gamma_{\delta(+)} \subset \Omega' \backslash \Omega$ and $\Gamma_{\delta(-)} \subset \Omega$ whose ends coincide with those of Γ and which tend uniformly to Γ following the parameter δ. The curves $\Gamma_{\delta(+)}$ and $\Gamma_{\delta(-)}$ are then the boundaries of a region A_δ whose boundary $\partial A_\delta = \Gamma_{\delta(+)} \cup \Gamma_{\delta(-)}$ (see Figure 2.1).

We now integrate (2.2) over A_δ:

$$\int\int_{A_\delta} \left[\nabla(\phi^{(\xi)} \boldsymbol{D}^{(j)} \nabla u_j^{(\xi)}) + \phi^{(\xi)} f(u,t) \right] dx = \int\int_{A_\delta} \partial_t(\phi^{(\xi)} u_j^{(\xi)}) dx. \tag{2.4}$$

Using the Gauss (or Green) theorem for the first term of (2.4), we obtain

$$\oint_{\partial A_\delta} \vec{\boldsymbol{n}} \cdot \phi^{(\xi)} \boldsymbol{D}^{(j)} \nabla u_j^{(\xi)} dx + \int\int_{A_\delta} \phi^{(\xi)} f(u,t) dx = \int\int_{A_\delta} \partial_t(\phi^{(\xi)} u_j^{(\xi)}) dx, \tag{2.5}$$

where $\oint$ denotes a line integral over ∂A_δ.

Now we take the limit $\xi \to 0$ in (2.5) to obtain

$$\begin{aligned} \lim_{\xi \to 0} \oint_{\partial A_\delta} \vec{\boldsymbol{n}} \cdot \phi^{(\xi)} \boldsymbol{D}^{(j)} \nabla u_j^{(\xi)} dx &= -\lim_{\xi \to 0} \int\int_{A_\delta} \phi^{(\xi)} f(u,t) dx \\ &\quad + \lim_{\xi \to 0} \int\int_{A_\delta} \partial_t(\phi^{(\xi)} u_j^{(\xi)}) dx \\ &= m(A_\delta) \left[-\phi^{(\xi)} f(u,t) + \partial_t(\phi^{(\xi)} u_j^{(\xi)}) \right]_{x=\zeta}, \end{aligned} \tag{2.6}$$

where the last equality comes from the mean value theorem for integrals and $m(A_\delta)$ is the measure of the set A_δ. Here we assume that the solutions to (2.2) and its time derivatives are bounded so that the right-hand side of (2.6) is finite. On the left-hand side we decompose $\oint_{\partial A_\delta}$ as $\int_{\Gamma_{\delta(+)}} + \int_{\Gamma_{\delta(-)}}$. It is straightforward that $\lim_{\xi \to 0} \int_{\Gamma_{\delta(+)}} \vec{\boldsymbol{n}} \cdot \phi^{(\xi)} \boldsymbol{D}^{(j)} \nabla u_j^{(\xi)} dx = 0$, since in this limit $\phi^{(\xi)} = 0$ over all $\Gamma_{\delta(+)}$ and $\phi^{(\xi)} = 1$ on $\Gamma_{\delta(-)}$. As we were interested in proving that the boundary conditions are satisfied, we now make the width of the integration region A_δ tend to zero. Since $\Gamma_{\delta(-)} \to \Gamma$ as $\delta \to 0$, and $\lim_{\delta \to 0} m(A_\delta) = 0$, we obtain

$$\begin{aligned} \lim_{\delta \to 0} \lim_{\xi \to 0} \oint_{\partial A_\delta} \vec{\boldsymbol{n}} \cdot \phi^{(\xi)} \boldsymbol{D}^{(j)} \nabla u_j^{(\xi)} dx &= \lim_{\delta \to 0} \int_{\Gamma_{\delta(-)}} \vec{\boldsymbol{n}} \cdot \boldsymbol{D}^{(j)} \nabla u_j^{(\xi)} dx \\ &= \int_\Gamma \vec{\boldsymbol{n}} \cdot \boldsymbol{D}^{(j)} \nabla u_j^{(\xi)} dx = 0. \end{aligned} \tag{2.7}$$

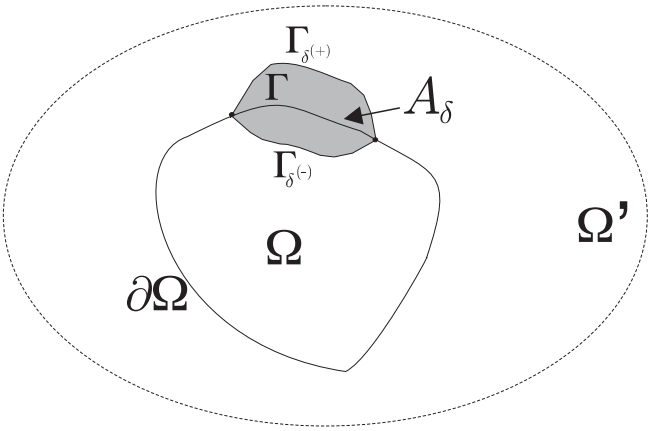

FIG. 2.1. *Illustration of an irregular domain* Ω *with an example of the connected curve* Γ *and the domain* A_δ *used in the proof of convergence of the method.*

Since (2.7) is true for any boundary segment Γ, we obtain the final result that, in the limit $\xi \to 0$, (2.2) satisfies $\vec{\boldsymbol{n}} \cdot \boldsymbol{D}^{(j)} \nabla u_j^{(\xi)} = 0$ for $j = 1, \ldots, N$, i.e., the boundary conditions.

The idea of the SBM is then to consider (2.2) for a small but finite ξ and to discretize this problem instead of (2.1a) and (2.1b). The main advantage is that one can search for the approximation $u^{(\xi)}$ on any enlarged domain Ω' such that $\Omega \subset \Omega'$. The enlarged discrete problem can then be solved with any proper boundary conditions on $\partial\Omega'$, since the fulfillment of the boundary conditions for u on $\partial\Omega$ is guaranteed in the limit $\xi \to 0$.

3. The SSB method. We want to discretize (2.2) on an enlarged domain Ω', chosen to be a rectangular region containing Ω, and we will expand $u^{(\xi)}$ in the basis of Cartesian products of trigonometric polynomials $e^{ik_x x} e^{ik_y y}$. Thus, we will seek an extension of the solution u of (2.1a) and (2.1b) that is periodic on the enlarged region Ω'.

Note that since $\phi^{(\xi)}$ is located inside the time derivative of the right term of (2.2), it is possible for the integration domain itself to evolve in time, and thus this method could be used to solve moving boundary problems once a coupling equation is added for the movement of $\phi^{(\xi)}$. However, here we will deal only with stationary integration domains; thus, $\partial_t \phi^{(\xi)} = 0$ and the right side of (2.2) can be simplified as $\phi^{(\xi)} \partial_t u_j^{(\xi)}$. Dividing (2.2) by $\phi^{(\xi)}$, we get

$$\nabla \log \phi^{(\xi)} \cdot \boldsymbol{D^{(j)}} \nabla u_j^{(\xi)} + \nabla(\boldsymbol{D^{(j)}} \nabla u_j^{(\xi)}) + f(u^{(\xi)}, t) = \partial_t u_j^{(\xi)}, \tag{3.1}$$

which is an easier version of the equation of the SBM that we will use here to perform the numerical simulations.

To implement numerically any solution method for (3.1), we need to make a specific choice for $\phi^{(\xi)}$. In practice, any method that produces a smooth characteristic function can be used. In the context of phase-field methods, the standard procedure for obtaining the values of $\phi^{(\xi)}$ (which is called the "phase-field") is to integrate an auxiliary diffusion equation of the form $\partial_t \phi = \xi^2 \Delta\phi + (2\phi - 1)/2 - (2\phi - 1)^3/2$, with initial conditions $\phi^{(\xi)}(t = 0) = \chi_\Omega$, until a steady state is reached [16, 18]. Alternatively, since we seek only a smoothed boundary, we choose to obtain $\phi^{(\xi)}$ from

χ_Ω using a convolution of the form

$$\phi^{(\xi)} = \chi_\Omega * G^{(\xi)}, \tag{3.2}$$

where $G^{(\xi)}$ is any family of functions such that $\lim_{\xi\to 0} G^{(\xi)}(x) = \delta(x)$, with $\delta(x)$ being the Dirac delta function. In particular, Gaussian functions of the form

$$G^{(\xi)}(x) = \prod_{k=1}^{n} \exp(-x_k^2/\xi^2) \tag{3.3}$$

can be chosen. In this paper, all the functions $\phi^{(\xi)}$ have been obtained using this n-dimensional discrete convolution given by (3.3), which also have the advantage of being efficiently computed using FFTs. An example of the creation of $\phi^{(\xi)}$ is shown in Figure 3.1, where it can be seen that the width of the interface in which $\phi^{(\xi)}$ changes from zero to one depends on the value used for ξ (in fact, it is of order ξ).

To avoid computational difficulties for very small values of $\phi^{(\xi)}$, we approximate $\log\phi^{(\xi)} \approx \log(\phi^{(\xi)} + \epsilon)$, where ϵ is the machine precision. Numerically, $\phi^{(\xi)}$ and $(\phi^{(\xi)} + \epsilon)$ are equal up to roundoff errors, but this correction bounds the value of $\log\phi^{(\xi)}$ as $\phi^{(\xi)} \to 0$. Due to the effect of the boundaries in the numerical stability of the scheme, we also need a reasonable margin between the boundaries of the physical and the enlarged domains. We found that a margin of value $M = 10\xi$ is sufficient for all the simulations to be stable [19]. Finally, all the spatial derivatives of $u^{(\xi)}$ in (3.1) are computed in Cartesian coordinates using differentiation in Fourier space, which as mentioned previously implicitly assumes periodic boundary conditions on $\partial\Omega'$. It is significant that only Fourier transforms are used for these calculations instead of differentiation matrices, thereby avoiding the generation and storage of these matrices and yielding more efficient codes and shorter execution times, especially when FFT routines are used.

In this paper, we are not concerned with designing the most efficient implementation of the SSB method, but only with proving that such a method can be used to integrate partial differential equations in irregular domains. Thus, for time integration we use a simple second-order explicit method. In the particular case when all the coefficients of the diffusion tensor $\boldsymbol{D}^{(j)}$ are constants, we can write (3.1) in the form

$$\mathcal{L}u^{(\xi)} + \mathcal{N}(u^{(\xi)}, t) = \partial_t u^{(\xi)}, \tag{3.4}$$

where $\mathcal{L}u^{(\xi)} = \nabla(\boldsymbol{D}^{(j)}\nabla u_j^{(\xi)})$ is the linear part of the equation, while the nonlinear term is represented by $\mathcal{N}(u^{(\xi)}, t) = \nabla\log\phi^{(\xi)} \cdot \boldsymbol{D}^{(j)}\nabla u_j^{(\xi)} + f(u^{(\xi)}, t)$. Then a second-order in time operator splitting scheme of the form

$$U^{(\xi)}(t + \Delta t) = e^{\mathcal{L}\Delta t/2} e^{\mathcal{N}\Delta t} e^{\mathcal{L}\Delta t/2} U^{(\xi)}(t) \tag{3.5}$$

can be used to solve the equation in time [20]. For the examples to be presented later, we solve the nonlinear term by a second-order (half-step) explicit method and integrate the linear part exactly in Fourier space by exponential integration, which reduces the stiffness of the problem considerably and allows for the use of larger time steps.

4. Examples of the methodology.

4.1. The heat equation. As a first example, we will consider a simple linear heat equation. This first case will allow us to make a quantitative study of the errors of the SSB method. Specifically, we are interested in solving the following heat equation with sources:

$$\partial_t u = D\Delta u - r\cos(2\theta) \tag{4.1}$$

in the annulus Ω defined by $1 \le r \le 2$ with homogeneous Neumann boundary conditions on $\partial\Omega$, $\partial_r u|_{r=1} = \partial_r u|_{r=2} = 0$. The diffusion coefficient is taken to be constant with value $D = 1$. Figure 4.1 shows one example of the generation of the smoothed boundary for this domain.

Equation (4.1) in this geometry has an explicit steady state solution of the form

$$u_{st}(r,\theta) = \left(\frac{1}{5}r^3 - \frac{31}{50}r^2 - \frac{8}{25}\frac{1}{r^2}\right)\cos(2\theta), \tag{4.2}$$

which can be used to determinate the contribution to the error introduced by the smoothing term in (2.2). Thus, (4.1) is evolved in time using the SSB method and this explicit steady state as initial data until the new steady state is reached and deviations from the initial condition are measured. Figure 4.2 (left) shows the L^2-norm of the error of several simulations for different values of ξ and grid resolutions. Note that in general these maximum errors decrease as the thickness of the interface is reduced. The left and right interior plots show the log-log plots of the L^2-norm of the error versus ξ (values at $\eta = 5$, see below), indicating an $O(\xi^2)$ accuracy of the method as $\xi \to 0$ when the integration domain Ω does not have sharp corners.

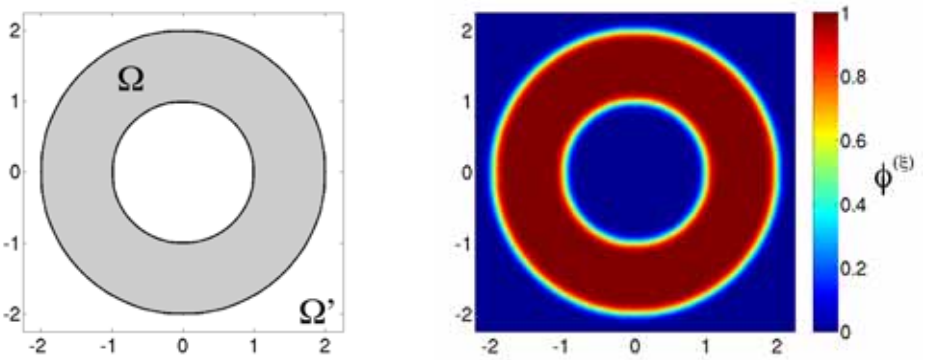

FIG. 4.1. *Left: The rectangular domain Ω' in which* (4.1) *is solved using the SSB method, with the irregular domain Ω (an annulus) shown in gray. Right: Smoothed boundary function $\phi^{(\xi)}$ given by* (3.2) *for $\xi = 0.10$.*

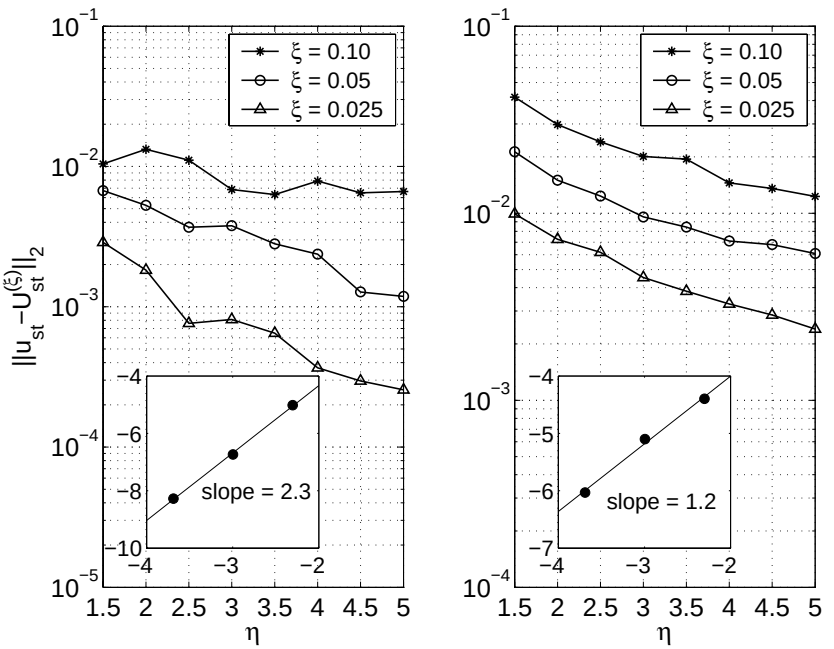

FIG. 4.2. *Left: L^2-error of the numerical steady state solution of* (4.1) *in the annulus compared to the exact steady solution as a function of the parameter $\eta = \xi/\Delta x$. Right: Same as left but for the quarter-annulus geometry. See text for details.*

Although $\phi^{(\xi)}$ is a continuous function, it is necessary to have a grid fine enough to properly resolve the boundary layers in which it quickly changes from zero to one. For this reason, errors are represented in Figure 4.2 not as a function of the number of grid points but as a function of the parameter $\eta = \xi/\Delta x$, which gives an idea of the number of points that lie in the interface (with number of points varying in this case from 90 to 300 points for $\xi = 0.10$, from 150 to 500 points for $\xi = 0.05$, and from 270 to 900 points for $\xi = 0.025$). To ensure that this error is produced only by the spatial

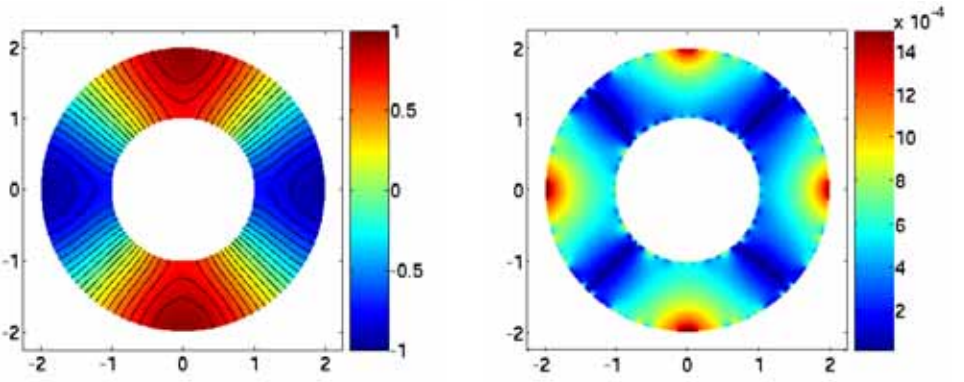

FIG. 4.3. *Left: Solution of* (4.1) *obtained with the SSB method at steady state in the annulus* $1 \leq r \leq 2$. *Grid size is* 540×540 *with* $\xi = 0.025$. *Right: Spatial distribution of the absolute error* $|u_{st} - U_{st}^{(\xi)}|$ *over the annulus for the simulation solution compared to the analytical steady solution.*

discretization and is not due to the order of the method chosen to perform the time integration, we have also run the simulations with a first-order explicit (Euler) time-integration method and obtained errors of the same order of magnitude. Figure 4.3 shows the solution to (4.1) obtained at stationary state with the SSB method. Contour lines are also included to illustrate that the no-flux boundary conditions at $r = 1$ and $r = 2$ are satisfied.

The analytical steady state solution of (4.1) also satisfies homogeneous Neumann boundary conditions on the quarter-annulus delimited by $1 \leq r \leq 2$, $0 \leq \theta \leq \pi/2$ (see Figure 4.4), which also allows us to use this related geometry to show how the SSB method performs when sharp corners are present in a given geometry. As before, the L^2-norms of the deviations from the analytical steady state are shown in Figure 4.2 (right) for the simulations on the quarter-annulus. Both geometries show similar convergence properties. However, errors are slightly larger than for the full annulus due to the presence of the sharp corners, which become slightly blunted when the smoothed boundary is generated. This is translated into a loss of accuracy of the method from $O(\xi^2)$ to $O(\xi)$ for regions with sharp corners (see interior plot in Figure 4.2, right). This can also be seen in Figure 4.4, which shows the error distribution $|u_{st} - U_{st}^{(\xi)}|$ at steady state over the domain Ω, along with the corresponding solution. See how errors are larger when close to the corners of the domain.

In Figures 4.3 and 4.4, we have shown the solutions of (4.1) within the physical domains of interest, Ω. However, solutions $U^{(\xi)}$ are calculated over the entire extended domain Ω'. Figure 4.5 shows the solutions over Ω' in the full and quarter-annulus examples. While no-flux boundary conditions are implemented along $\partial\Omega$, the overall solution has periodic boundary conditions. Note that, as the solution $U^{(\xi)}$ is not discontinuous on $\partial\Omega$, solutions do not present Gibbs phenomena due to the irregular boundaries.

An important advantage of the SSB method is that when the new formulation given by (3.1) is used, separate equations are not written for the boundaries, as the solution automatically adapts to satisfy the boundary conditions on $\partial\Omega$, which results in a very simple computational implementation. Alterations to the domain geometry therefore can be handled straightforwardly, without generating and implementing additional boundary condition equations. As an example, we present in Figure 4.6

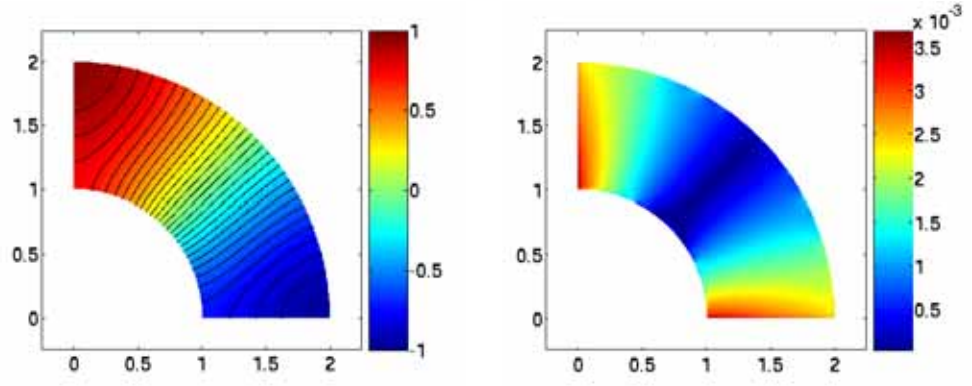

FIG. 4.4. *Left: Solution to* (4.1) *in the quarter-annulus* $1 \leq r \leq 2$, $0 \leq \theta \leq \pi/2$ *at steady state using the SSB method. the solution to (4.1) in a more complicated geometry that combines both polar and Cartesian coordinates. As an analytic steady solution to the equation cannot be easily obtained in this domain, we evolve it until time $t = 5$ and compare our solution to the one obtained using finite elements in the finest mesh that our machine could handle (P1-Lagrangian elements, mesh made of 31152 nodes and 61440 triangles). At this resolution, and as shown in Figure 4.6, maximum differences between the solutions obtained by both methods are small.

4.2. The Allen–Cahn equation. An important partial differential equation which arises in the modeling of the formation and motion of phase boundaries is the Allen–Cahn [21] equation

$$\begin{aligned} \partial_t u &= \epsilon^2 \Delta u - f(u), && x \text{ in } \Omega, \\ \vec{n} \cdot \nabla u &= 0, && x \text{ on } \partial\Omega, \end{aligned} \tag{4.3}$$

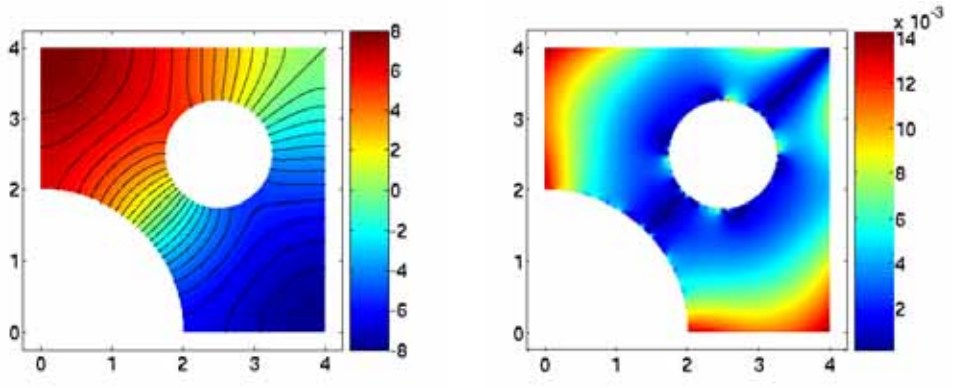

FIG. 4.6. *Solution to* (4.1) *at time* $t = 5$ *in a more complicated domain (left) and spatial distribution of the difference between the solutions obtained by the SSB method and using finite elements (right). Grid resolution is* 400×400 *and* $\xi = 0.05$.

where ϵ is a small positive constant and $f(u)$ is the derivative of a potential function $W(u)$ that has two wells of equal depth. For simplicity, we will assume that $W(u) = (u^2-1)^2/4$, which makes $f(u) = u^3-u$. In this manner, the Allen–Cahn equation may be seen as a simple example of a nonlinear reaction-diffusion equation. As explained in [2], this equation has three fixed-point solutions, $u = -1$, $u = 0$, and $u = 1$. The middle state is unstable, but the states $u = \pm 1$ are attracting, and solutions tend to exhibit flat areas close to these values separated by interfaces of increasing sharpness as the control parameter ϵ is reduced to zero. Figure 4.7 shows the solution of the Allen–Cahn equation at $t = 25$ solved with Neumann boundary conditions on an annulus with a z-shaped hole using the SSB method, with $\epsilon = 0.1$. The annulus structure is given by $1 \le r \le 5$ and the z-hole is formed using radii at 2, 3, and 4 and angles in steps of 15 degrees (15, 30, 60, and 75 degrees). As an initial condition, two positive and two negative Gaussian functions located in different parts of the domain were chosen:

$$u(r,\theta,0) = \sum_{i=1}^{n=4} (-1)^{n+1} \exp(-20((x - r_i\cos\theta_i)^2 + (y - r_i\sin\theta_i)^2)), \tag{4.4}$$

where pairs $(r_1,\theta_1) = (1.5,\pi/6)$, $(r_2,\theta_2) = (4,\pi/12)$, $(r_3,\theta_3) = (4.5,\pi/3)$, and $(r_4,\theta_4) = (4,11\pi/24)$ represent the positions of the Gaussians in polar coordinates.

For comparison we also solved the Allen–Cahn equation using finite elements in space as in the previous example (P2-Lagrangian elements, mesh made of 8304 elements and 348 boundary elements, 16956 degrees of freedom) and implicit backward differentiation formula for time integration. Due to the sharp transition of the solution between -1 and 1, a slight difference in the position of the interfaces can be seen as a significant error when comparing the solutions obtained by the two methods, but as shown in Figure 4.7 (right) both the SSB and finite elements solutions are in good agreement.

4.3. Reaction-diffusion equations and excitable media. Models of excitable media form another significant class of nonlinear parabolic partial differential equations and describe systems as diverse as chemical reactions [22, 23], aggregation of amoebae in the cellular slime mold [illegible] [24], calcium waves

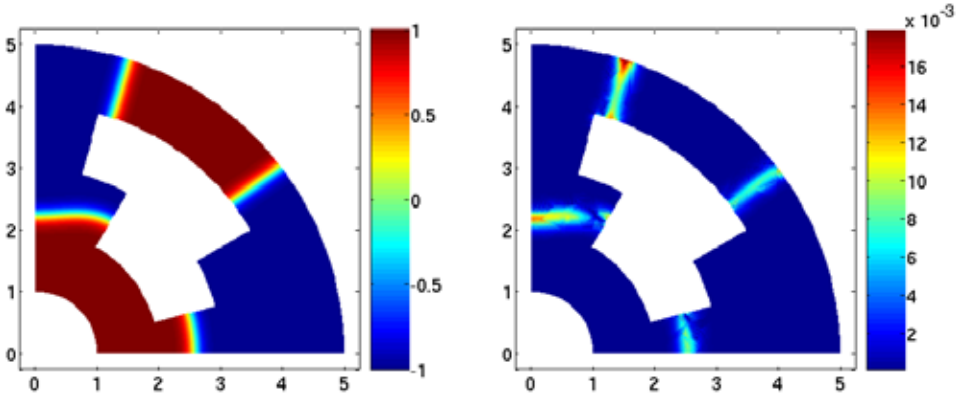

FIG. 4.7. *Solution of the Allen–Cahn equation* (4.3) *at time* $t = 25$ *using the SSB method (left) and errors when compared to the solution obtained using* P2*-Lagrangian finite elements (right). Grid size is* 360×360 *with* $\xi = 0.025$ *for the SSB method.*

[25], and the electrical properties of neural [26] and cardiac cells [27, 28], among others. The equations of excitable systems extend the Allen–Cahn equation by including one or more additional variables that govern growth and decay of the waves. Solutions of excitable media consist of excursions in state space from a stable rest state and a return to rest, with the equations describing the additional variables determining the time courses of excitation and recovery. In spatially extended systems, diffusive coupling allows excitation to propagate as nonlinear waves, and in multiple dimensions complex patterns can be formed, including two-dimensional spiral waves [22, 23, 24, 25, 29] and their three-dimensional analogues, scroll waves [30, 31]. Well-known examples of excitable media equations include the Hodgkin–Huxley [26] model of cells and its generalized simplification, the FitzHugh–Nagumo [32] model.

The dynamics of wave propagation in excitable media has been studied extensively in regular domains. However, the complex geometry inherent to some systems, such as the heart, often can have a significant influence on wave stability and dynamics [33]. This fact, combined with the need for high-order accuracy to resolve the sharp wave fronts characteristic of cardiac models, should make the SSB method a useful tool for studying electrical waves in realistic heart geometries. Figure 4.8 shows an example of a propagating wave of action potential in both an idealized (left) and a realistic (right) slice [34] of ventricular tissue using the SSB method and a phenomenological ionic cell model [31, 33] with equations of the form

$$\partial_t u(\mathbf{x},t) = \nabla\cdot(\boldsymbol{D}\nabla u) - J_{fi}(u,v) - J_{so}(u) - J_{si}(u,w), \tag{4.5a}$$

$$\partial_t v(\mathbf{x},t) = \Theta(u_c-u)(1-v)/\tau_v^-(u) - \Theta(u-u_c)v/\tau_v^+, \tag{4.5b}$$

$$\partial_t w(\mathbf{x},t) = \Theta(u_c-u)(1-w)/\tau_w^- - \Theta(u-u_c)w/\tau_w^+, \tag{4.5c}$$

$$J_{fi}(u,v) = -\frac{v}{\tau_d}\Theta(u-u_c)(1-u)(u-u_c), \tag{4.5d}$$

$$J_{so}(u) = \frac{u}{\tau_0}\Theta(u_c-u) + \frac{1}{\tau_r}\Theta(u-u_c), \tag{4.5e}$$

$$J_{si}(u,w) = -\frac{w}{2\tau_{\mathrm{si}}}(1+\tanh[k(u-u_c^{\mathrm{si}})]), \tag{4.5f}$$

$$\tau_v^-(u) = \Theta(u-u_v)\tau_{v1}^- + \Theta(u_v-u)\tau_{v2}^-, \tag{4.5g}$$

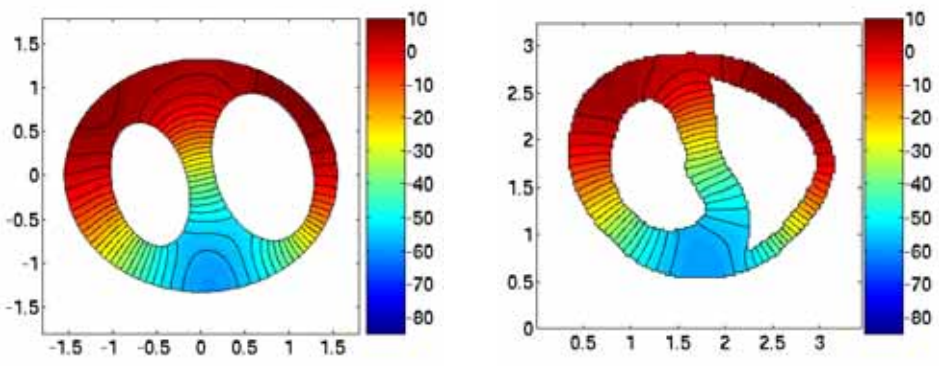

FIG. 4.8. *Propagating wave of electrical potential in an idealized (left) and a realistic (right) slice of ventricular tissue using the SSB method. Grid size is* 400×400 *and* $\xi = 0.025$ *in both cases. where u is the membrane potential; J_{fi}, J_{so}, and J_{si} are phenomenological currents; v and w are ionic gate variables; and $\boldsymbol{D}$ is the diffusion tensor (isotropic for these simulations, with value $D = 1$ cm^2/s). In all these formulas, $\Theta(x)$ is the standard Heaviside step function defined by $\Theta(x) = 1$ for $x \geq 0$ and $\Theta(x) = 0$ for $x < 0$, and the set of parameters of the model is chosen to reproduce different cellular dynamics measured experimentally (for simulations presented here, $\tau_d = 0.25$, $\tau_r = 50$, $\tau_{\mathrm{si}} = 45$, $\tau_0 = 8.3$, $\tau_v^+ = 3.33$, $\tau_{v1}^- = 1000$, $\tau_{v2}^- = 19.2$, $\tau_w^+ = 667$, $\tau_w^- = 11$, $u_c = 0.13$, $u_v = 0.055$, and $u_c^{\mathrm{si}} = 0.85$). Contour lines demonstrate that boundary conditions are correctly approximated by the method in both geometries.

Finally, Figure 4.9 illustrates the application of the proposed method to realistic three-dimensional geometries, using for that purpose the full anatomical model of rabbit heart ventricles. All the information in the ventricular model originally digitalized in a finite elements mesh, including fiber orientation, was interpolated and mapped onto a regular Cartesian grid slightly larger than the structure, of sizes $L_x = 3.4$, $L_y = 3.2$, and $L_z = 3.7$ cm and $150 \times 150 \times 160$ grid points, and smoothed with a value of $\xi = 0.05$. The simulation shows the creation of a spiral wave of electrical activity in the rabbit ventricles, solutions to the reaction-diffusion equations that are

closely related to the development of arrhythmias [29, 31, 33]. In the left image, a second excitation shock is applied in the wake of the preceding excitation wave to initiate the spiral wave. In the first moments the second shock cannot move upwards (central panel) since the tissue has not yet recovered excitability, but starts curving at the bottom of the heart. The right image of Figure 4.9 shows the evolution of the self-maintained spiral wave in the tissue. The simulation is perfectly handled by the SSB method, and the extension of the algorithm is absolutely straightforward from two to three dimensions.

5. Discussion and future work. In this paper, we have presented a new method for implementing homogeneous Neumann boundary conditions using spectral methods for several problems of general interest. The SSB method offers several advantages over finite-difference and finite-element alternatives. Because ghost cells are not needed, the implementation of boundary conditions requires less coding than finite-difference stencils. The use of simple Cartesian grids also makes the SSB method easier to use than finite elements with multiple domain shapes, since [illegible]. Furthermore, the use of FFT routines in the SSB method ensures efficiency and also makes extension of the method to three dimensions straightforward using well-established routines. Since the method is directly based on the FFT, it is very simple to implement on high performance computers by using native parallel or vector FFT libraries.

The most significant limitation of the SSB method is that its accuracy is directly controlled by the value of parameter ξ, and therefore it will be more moderate than the accuracy achieved by any spectral method in a typical rectangular domain. The error of the method also depends directly on the ratio of the width of the smoothed boundary ξ to the spatial step Δx; this implies that when using uniform grids the number of points in the discretization needs to be large. This limitation is perhaps not important for certain classes of problems in which the solution contains steep wavefronts or other sharp features that require a fine spatial resolution to correctly reproduce the dynamics of the system, such as electrical waves in cardiac tissue or shock waves in fluid mechanics. However, for problems with smooth behavior, such as the heat equation with slowly varying sources, the adequate reduction of error in domains with irregular boundaries using this method may require an increase in spatial resolution of a factor of 10 or 20 in each direction of the mesh when compared to what is typically needed to obtain the same accuracy using a spectral method in a rectangular domain. This need for a large number of points is also a clear disadvantage in terms of computational efficiency, and since the accuracy of the method is controlled more by the width of the smoothed boundary rather than by the order of the method used to compute the spatial derivatives, an implementation of the method using a lower order scheme in space, such as the one presented in [18] using finite differences, can be significantly more efficient than the implementation presented here using spectral methods.

Thus, an important future extension of this work is to try to improve the performance of the SSB method for problems that do not track features with sharp spatial gradients. For instance, if the boundary is stationary, it could be useful to compute the spatial derivatives using any numerical scheme featuring adaptability, such as a combination of a nonuniform grid with extra resolution along the boundaries and a nonuniform fast Fourier transform (NFFT), or the use of wavelets [35]. However, if the boundary moves over time, it might be more efficient to use a fine spatial discretization than to keep track of the boundary for such problems. Other planned

future work includes properly handling complex anisotropies in the diffusion matrices, such as those found in cardiac muscle, examining whether the method can be used to satisfy other types of boundary conditions including Dirichlet and Robin, and implementing nonstationary boundaries.

In conclusion, we have presented a new numerical method which imposes homogeneous Neumann boundary conditions in complex geometries using spectral methods. We have used this method to solve various partial differential equations in domains with irregular boundaries and have found good agreement between our solutions and the ones obtained by standard numerical methods. Along with the overall advantage of allowing domains of different shapes to be considered with spectral methods in a very simple way, this method also offers highly accurate discretizations of spatial derivatives, ease of implementation, straightforward extension to three dimensions, and applicability to a wide variety of equations. Moreover, SSB codes need not change to implement different geometries since all the information on the geometry is contained in the function $\phi^{(\xi)}$, with the additional advantage that this function is easy to generate and, unlike finite-element methods, does not require the use of special software for grid generation.

MULTI-ELEMENT GENERALIZED POLYNOMIAL CHAOS FOR ARBITRARY PROBABILITY MEASURES*

XIAOLIANG WAN† AND GEORGE EM KARNIADAKIS†

Abstract. We develop a multi-element generalized polynomial chaos (ME-gPC) method for arbitrary probability measures and apply it to solve ordinary and partial differential equations with stochastic inputs. Given a stochastic input with an arbitrary probability measure, its random space is decomposed into smaller elements. Subsequently, in each element a new random variable with respect to a conditional probability density function (PDF) is defined, and a set of orthogonal polynomials in terms of this random variable is constructed numerically. Then, the generalized polynomial chaos (gPC) method is implemented element-by-element. Numerical experiments show that the cost for the construction of orthogonal polynomials is negligible compared to the total time cost. Efficiency and convergence of ME-gPC are studied numerically by considering some commonly used random variables. ME-gPC provides an efficient and flexible approach to solving differential equations with random inputs, especially for problems related to long-term integration, large perturbation, and stochastic discontinuities.

1. Introduction.

(PC) has been used extensively recently to model uncertainty in physical applications. It originated from first defined by Wiener as the span of Hermite polynomial functionals of a Gaussian process [31]. Other names, such as Wiener-chaos and Hermite-chaos, are also used in literature. Ghanem and Spanos first combined Hermite-chaos with a finite element method to model uncertainty in solid mechanics [14, 12, 13]. A more general extension, termed (gPC), was proposed in [32] by Xiu and Karniadakis based on the correspondence between the probability density functions (PDFs) of certain random variables and the weight functions of orthogonal polynomials of the Askey scheme. The family of gPC includes Hermite-chaos as a subset and supplies optimal bases for stochastic processes represented by random variables of commonly used distributions, such as uniform distribution and Beta distribution. In [18, 19], PC was combined with wavelets to deal with discontinuities for uniform random inputs for which standard PC or gPC fails to converge.

To solve differential equations with stochastic inputs following the procedure established by Ghanem and Spanos, the random solution is expanded spectrally by PC, and a Galerkin projection scheme is subsequently used to transform the original stochastic problem into a deterministic one with a larger dimensional parameter [14, 32, 7, 21, 20]. On the other hand, Deb, Babuška, and Oden have proposed employing finite elements in the random space to approximate the stochastic dependence of the solution [4]; this approach also reduces a stochastic differential equation to a high-dimensional deterministic one. This method was later studied theoretically within the framework of a deterministic finite element method in [1]. Since a finite

†Division of Applied Mathematics, Brown University, Providence, RI 02912 (xlwan@dam.brown.edu, gk@dam.brown.edu).

element method is generally used to solve the obtained deterministic PDE system, the above methods are called [illegible] in [1], while the scheme in [14, 32] is classified as the $p \times h$ version and the scheme in [4] as the $k \times h$ version, where p denotes the polynomial order of PC, k the element size in the random space, and h the element size in the physical space. Both schemes use finite elements in the physical space. The $p \times h$ version relies on the spectral representation in the entire random space by PC, while the $k \times h$ version is based on the discretization of the random space using the same basis as the deterministic finite element method to approximate the random field locally. For simplicity, here we refer to the scheme in [14, 32] as a PC method of p-version and the scheme in [4] as a k-version. Both the concepts and the terminology introduced here share similarities with those of the spectral/[illegible] element method for deterministic problems [17, 25].

In this work, we present a multi-element generalized polynomial chaos (ME-gPC) method, which can deal with stochastic processes represented by random variables of arbitrary distributions and achieve kp-convergence in the random space. In the ME-gPC method, we discretize the random space and use a spectral expansion locally to represent the desired random field. However, the PC basis is, in general, not orthogonal in a random element since the PDF is also discretized simultaneously. The only exception is the uniform distribution which has been considered so far in previous works [14, 4, 32, 28]. To overcome this difficulty, we reconstruct the orthogonal basis numerically in each random element. From the practical standpoint, it is more effective to employ a relatively low polynomial order ($p = 5$ to $p = 8$) for the ME-gPC method. Thus, we can do this reconstruction [illegible] with high accuracy for most continuous or discrete arbitrary probability measures.

In certain nonlinear stochastic differential equations, random inputs can give rise to singularities as discussed in [18, 19] or the Kraichnan–Orszag problem [24], where the gPC method may converge very slowly or even fail to converge. By noting that singularities usually occur at a lower-dimensional manifold in the random space for such problems, we aim to "capture" the singular region by random elements related to a very small probability measure, and implement the gPC method in the regular region. Hence, the error in the singular region will be dominated by the size (k-convergence) of the random elements, while the error in the regular region decreases fast (p-convergence)—possibly exponentially fast. To reduce the total computational cost, we also present a criterion to implement the decomposition of random space adaptively.

2. Multi-element generalized polynomial chaos (ME-gPC) method.

2.1. Overview. The original PC was first proposed by Wiener [31]. It employs the Hermite polynomials in terms of Gaussian random variables as the trial basis to expand stochastic processes in the random space. According to the theorem by Cameron and Martin [3] such expansion converges for any second-order processes in the L_2 sense. gPC was proposed in [33] and employs more types of orthogonal polynomials from the Askey family. It is a generalization of the original Wiener's Hermite-chaos and can deal with non-Gaussian random inputs more efficiently.

Let $(\Omega, \mathcal{F}, P)$ be a probability space, where Ω is the sample space, $\mathcal{F}$ is the σ-algebra of subsets of Ω, and P is a probability measure. Let

$$\boldsymbol{\xi} = (\xi_1, \ldots, \xi_d) : (\Omega, \mathcal{F}) \to (\mathbb{R}^d, \mathcal{B}^d) \tag{2.1}$$

be an $\mathbb{R}^d$-valued continuous random variable, where $d \in \mathbb{N}$ and $\mathcal{B}^d$ is the σ-algebra of Borel subsets of $\mathbb{R}^d$. A general second-order random process $R(\omega) \in {}_2(\Omega, \mathcal{F}, P)$ can

be expressed by gPC as

$$R(\omega) = \sum_{i=0}^{\infty} \hat{a}_i \Phi_i(\boldsymbol{\xi}(\omega)), \tag{2.2}$$

where ω is the random event and $\Phi_i(\boldsymbol{\xi}(\omega))$ denotes the gPC basis of degree p in terms of the random variable $\boldsymbol{\xi}$. The family $\{\Phi_i\}$ is an orthogonal basis in $L_2(\Omega, \mathcal{F}, P)$ with orthogonality relation

$$\mathbb{E}[\Phi_i \Phi_j] = \mathbb{E}[\Phi_i^2]\delta_{ij}, \tag{2.3}$$

where δ_{ij} is the Kronecker delta and $\mathbb{E}$ denotes the expectation with respect to the probability measure $\mathrm{d}P(\omega) = f(\boldsymbol{\xi}(\omega))\mathrm{d}\omega$. The index in (2.2) and $d \in \mathbb{N}$ are, in general, infinite. In practice, both limits will be truncated at a certain level. For example, the dimension d of the stochastic input is usually determined by the Karhunen–Loeve (K-L) expansion based on the decay rate of eigenvalues [14].

For a certain random variable $\boldsymbol{\xi}$, the orthogonal gPC basis $\{\Phi_i\}$ can be chosen in such a way that its weight function has the same form as the PDF $f(\boldsymbol{\xi})$ of $\boldsymbol{\xi}$. The corresponding types of classical orthogonal polynomials $\{\Phi_i\}$ and their associated random variable $\boldsymbol{\xi}$ can be found in [32]. In this paper we generalize the idea of gPC and construct numerically the orthogonal polynomials with respect to an arbitrary probability measure.

2.2. ME-gPC formulation. We next present the scheme of an adaptive ME-gPC method, which consists of the decomposition of random space, the construction of orthogonal polynomials, and an adaptive procedure.

2.2.1. Decomposition of random space. We assume that $\boldsymbol{\xi}$ is a random variable defined on $B = \times_{i=1}^{d}[a_i, b_i]$, where a_i and b_i are finite or infinite in $\mathbb{R}$ and the components of $\boldsymbol{\xi}$ are independent identically-distributed (i.i.d.) random variables. We define a decomposition $\mathbf{D}$ of B as

$$\mathbf{D} = \begin{cases} B_k = [a_{k,1}, b_{k,1}) \times [a_{k,2}, b_{k,2}) \times \cdots \times [a_{k,d}, b_{k,d}], \\ B = \bigcup_{k=1}^{N} B_k, \\ B_{k_1} \bigcap B_{k_2} = \emptyset \text{ if } k_1 \neq k_2, \end{cases} \tag{2.4}$$

where $k, k_1, k_2 = 1, 2, \ldots, N$. Based on the decomposition $\mathbf{D}$, we define the following indicator random variables:

$$I_{B_k} = \begin{cases} 1 & \text{if } \boldsymbol{\xi} \in B_k, \\ 0 & \text{otherwise.} \end{cases} \qquad k = 1, 2, \ldots, N. \tag{2.5}$$

Thus, $\Omega = \cup_{k=1}^{N} I_{B_k}^{-1}(1)$ is a decomposition of the sample space Ω, where

$$I_{B_i}^{-1}(1) \cap I_{B_j}^{-1}(1) = \emptyset \text{ for } i \neq j. \tag{2.6}$$

Given any point $\boldsymbol{q} = (q_1, q_2, \ldots, q_d)$, we use $\boldsymbol{\xi} \leq \boldsymbol{q}$ to denote $\xi_i \leq q_i$ for $i = 1, 2, \ldots, d$. According to the law of total probability, we can obtain

$$\Pr(\boldsymbol{\xi} \leq \boldsymbol{q}) = \sum_{k=1}^{N} \Pr(\boldsymbol{\xi} \leq \boldsymbol{q} | I_{B_k} = 1) \Pr(I_{B_k} = 1). \tag{2.7}$$

Using Bayes's rule, (2.7) implies that we can define a new random variable $\boldsymbol{\xi}_k : I_{B_k}^{-1}(1) \mapsto B_k$ on the probability space $(I_{B_k}^{-1}(1), \mathcal{F} \cap I_{B_k}^{-1}(1), P(\cdot|I_{B_k}=1))$ subject to a conditional PDF

$$\hat{f}_k(\boldsymbol{\xi}_k|I_{B_k}=1) = \frac{f(\boldsymbol{\xi}_k)}{\Pr(I_{B_k}=1)} \tag{2.8}$$

in each random element B_k, where $\Pr(I_{B_k}=1) > 0$.

Let $u(\boldsymbol{x},t;\boldsymbol{\xi}) \in L_2(\Omega,\mathcal{F},P)$ denote a space-time related random field. For simplicity, we may drop $\boldsymbol{x}$ and t.

PROPOSITION 2.1. $\mathcal{P}_M u(\boldsymbol{\xi})$ $u(\boldsymbol{\xi})$ $\{\Phi_i(\boldsymbol{\xi})\}$ M $i=1,2,\ldots,M$ $\mathcal{P}_M u(\boldsymbol{\xi})$ $u(\boldsymbol{\xi})$ L_2 $f(\boldsymbol{\xi})$ $\mathcal{P}_M u(\boldsymbol{\xi}_k)$ $u(\boldsymbol{\xi}_k)$ L_2 $\hat{f}_k(\boldsymbol{\xi}_k|I_{B_k}=1)$ $k=1,2,\ldots,N$

. According to the assumption, we know that

$$\mathbb{E}[(u(\boldsymbol{\xi})-\mathcal{P}_M u(\boldsymbol{\xi}))^2] = \int_B (u(\boldsymbol{\xi})-\mathcal{P}_M u(\boldsymbol{\xi}))^2 f(\boldsymbol{\xi})\mathrm{d}\boldsymbol{\xi} \to 0 \quad \text{as } M \to \infty.$$

By noting

$$\mathbb{E}[(u(\boldsymbol{\xi})-\mathcal{P}_M u(\boldsymbol{\xi}))^2] = \sum_{k=1}^{N} \Pr(I_{B_k}=1) \int_{B_k} (u(\boldsymbol{\xi}_k)-\mathcal{P}_M u(\boldsymbol{\xi}_k))^2 \hat{f}_k(\boldsymbol{\xi}_k|I_{B_k}=1)\mathrm{d}\boldsymbol{\xi}_k, \tag{2.9}$$

we obtain

$$\int_{B_k} (u(\boldsymbol{\xi}_k)-\mathcal{P}_M u(\boldsymbol{\xi}_k))^2 \hat{f}_k(\boldsymbol{\xi}_k|I_{B_k}=1)\mathrm{d}\boldsymbol{\xi}_k \to 0 \quad \text{as } M \to \infty,$$

since both $\Pr(I_{B_k}=1)$ and the integrand on the right-hand side of (2.9) are positive for $k=1,2,\ldots,N$. □

To this end, we know that there exists a local polynomial approximation for each random element B_k, which converges in the L_2 sense with respect to the local conditional PDF. For the orthogonal basis $\{\Phi_i(\boldsymbol{\xi})\}$ on the entire random space, $u(\boldsymbol{\xi}) - \mathcal{P}_M u(\boldsymbol{\xi})$ is orthogonal to the space $V(M,\boldsymbol{\xi}) := \mathrm{span}\{\Phi_i(\boldsymbol{\xi}) : i \le M\}$. We note here that although $\mathcal{P}_M u(\boldsymbol{\xi}_k)$ converges to $u(\boldsymbol{\xi}_k)$ in the L_2 sense within random element B_k, $u(\boldsymbol{\xi}_k) - \mathcal{P}_M u(\boldsymbol{\xi}_k)$ is not orthogonal to the space $V(M,\boldsymbol{\xi}_k)$ with respect to the conditional PDF $\hat{f}_k(\cdot|I_{B_k}=1)$, since the orthogonality $\mathbb{E}[\Phi_i\Phi_j] = \delta_{ij}$ is, in general, valid only on the entire random space of $\boldsymbol{\xi}$ with respect to the PDF $f(\boldsymbol{\xi})$. Due to the efficiency of orthogonal polynomials in representing stochastic processes, we will reconstruct the local polynomial chaos modes numerically to make them mutually orthogonal with respect to the local conditional PDF $\hat{f}(\boldsymbol{\xi}_k|I_{B_k}=1)$. According to [26, theorem 2.1.1], such an orthogonal polynomial system $\{\Phi_{k,i}(\boldsymbol{\xi}_k)\}$ always exists. Since in each random element we perform a spectral expansion as in gPC, we call this method " " (ME-gPC).

To approximate a random field $u(\boldsymbol{\xi})$ using ME-gPC, we expand the random field spectrally in each element B_k, then reconstruct the entire random field by the following proposition.

PROPOSITION 2.2. $\hat{u}_k(\boldsymbol{\xi}_k)$ [illegible] B_k [illegible]

$$u^r(\boldsymbol{\xi}) = \sum_{k=1}^{N} \hat{u}_k(\boldsymbol{\xi}) I_{B_k} = \sum_{k=1}^{N} \sum_{j=0}^{M} \hat{u}_{k,j} \Phi_{k,j}(\boldsymbol{\xi}) I_{B_k}, \tag{2.10}$$

[illegible] $u(\boldsymbol{\xi})$ [illegible] L_2 [illegible]

$$\int_B (u^r(\boldsymbol{\xi}) - u(\boldsymbol{\xi}))^2 f(\boldsymbol{\xi}) \mathrm{d}\boldsymbol{\xi} \to 0 \quad \text{[illegible]} \quad M \to \infty. \tag{2.11}$$

[illegible]. It is easy to see that

$$\begin{aligned} &\int_B (u^r(\boldsymbol{\xi}) - u(\boldsymbol{\xi}))^2 f(\boldsymbol{\xi}) \mathrm{d}\boldsymbol{\xi} \\ &= \sum_{k=1}^{N} \Pr(I_{B_k} = 1) \int_{B_k} (u^r(\boldsymbol{\xi}_k) - u(\boldsymbol{\xi}_k))^2 \hat{f}_k(\boldsymbol{\xi}_k | I_{B_k} = 1) \mathrm{d}\boldsymbol{\xi}_k. \end{aligned}$$

Since $u^r(\boldsymbol{\xi}_k) = \hat{u}_k(\boldsymbol{\xi}_k)$ and the spectral expansion $\hat{u}_k(\boldsymbol{\xi}_k)$ converges locally in the L_2 sense with respect to $\hat{f}(\boldsymbol{\xi}_k | I_{B_k} = 1)$, it is clear that the right-hand side of the above equation goes to zero as $M \to \infty$. The conclusion follows immediately. □

By Bayes's rule and the law of total probability, any statistics can be obtained as

$$\int_B g\left(u(\boldsymbol{\xi})\right) f(\boldsymbol{\xi}) \mathrm{d}\boldsymbol{\xi} \approx \sum_{k=1}^{N} \Pr(I_{B_k} = 1) \int_{B_k} g\left(\hat{u}_k(\boldsymbol{\xi}_k)\right) \hat{f}_k(\boldsymbol{\xi}_k | I_{B_k} = 1) \mathrm{d}\boldsymbol{\xi}_k, \tag{2.12}$$

where $g(\cdot) \in L_1(\Omega, \mathcal{F}, P)$ is a functional of random field $u(\boldsymbol{\xi})$.

In the appendix, we demonstrate for the interested reader some details on how to solve PDEs with stochastic coefficients using ME-gPC.

2.2.2. Construction of orthogonal polynomials. We next discuss the numerical construction of orthogonal polynomials with respect to a conditional PDF $\hat{f}_k(\cdot | I_{B_k} = 1)$. For simplicity, here we discuss only the construction of one-dimensional orthogonal polynomials, since the high-dimensional basis can be obtained using tensor products of one-dimensional basis.

It is a distinctive feature of orthogonal polynomials, compared to other orthogonal systems, that they satisfy a three-term recurrence relation,

$$\begin{aligned} &\pi_{i+1}(\tau) = (\tau - \alpha_i)\pi_i(\tau) - \beta_i \pi_{i-1}(\tau), \quad i = 0, 1, \ldots, \\ &\pi_0(\tau) = 1, \quad \pi_{-1}(\tau) = 0, \end{aligned} \tag{2.13}$$

where $\{\pi_i(\tau)\}$ is a set of (monic) orthogonal polynomials,

$$\pi_i(\tau) = \tau^i + \text{lower-degree terms}, \quad i = 0, 1, \ldots, \tag{2.14}$$

and the coefficients α_i and β_i are uniquely determined by a positive measure, which corresponds to a probability measure in the construction we propose herein.

For a continuous measure $m(\tau)$ there are two classical methods to compute the recurrence coefficients α_i and β_i: the Stieltjes procedure and the modified Chebyshev

algorithm [8]. The Stieltjes procedure uses the fact that the coefficients α_i and β_i can be expressed by the following simple formulas:

$$\alpha_i = \frac{(\tau\pi_i, \pi_i)}{(\pi_i, \pi_i)}, \quad i = 0, 1, 2, \dots \tag{2.15}$$

and

$$\beta_0 = (\pi_0, \pi_0), \quad \beta_i = \frac{(\pi_i, \pi_i)}{(\pi_{i-1}, \pi_{i-1})}, \quad i = 1, 2, \dots, \tag{2.16}$$

where $(\cdot, \cdot)$ denotes the inner product in terms of the measure $m(\tau)$. The above two formulas together with the recurrence relation (2.13) can be used to calculate recursively as many coefficients α_i and β_i as desired.

The modified Chebyshev algorithm is a generalization of the Chebyshev algorithm [8]. The Chebyshev algorithm relies on the fact that the first n pairs of recurrence coefficients α_i and β_i, $i = 0, 1, \dots, n-1$, can be uniquely determined by the first $2n$ moments μ_i:

$$\mu_i = \int_B \tau^i \mathrm{d}m(\tau), \quad i = 0, 1, \dots, 2n-1. \tag{2.17}$$

Analytical formulas are known which express α_i and β_i in terms of Hankel determinants in these moments. However, this algorithm is not reliable for a big n due to the increasing sensitivity of these formulas to small errors. The modified Chebyshev algorithm replaces the power τ^i with a properly chosen polynomial $h_i(\tau)$ of degree i:

$$\nu_i = \int_B h_i(\tau) \mathrm{d}m(\tau), \quad i = 0, 1, \dots, 2n-1. \tag{2.18}$$

Generally, we can assume that $h_i(\tau)$ are monic orthogonal polynomials satisfying a three-term relation

$$\begin{aligned} h_{i+1}(\tau) &= (\tau - \hat{\alpha}_i) h_i(\tau) - \hat{\beta}_i h_{i-1}(\tau), \quad i = 0, 1, \dots, \\ h_0(\tau) &= 1, \quad h_{-1}(\tau) = 0. \end{aligned} \tag{2.19}$$

Using the $2n$ modified moments in (2.18) and the $2n-1$ pairs of recurrence coefficients $\hat{\alpha}_i$ and $\hat{\beta}_i$, $i = 0, 1, \dots, 2n-2$, in (2.19), the first n desired pairs of recurrence coefficients α_i and β_i, $i = 0, 1, \dots, n-1$, can be generated [8].

For a discrete measure

$$\mathrm{d}m_M(\tau) = \sum_{i=1}^{M} w_i \delta(\tau - \tau_i) \mathrm{d}\tau, \quad i = 0, 1, \dots, M \tag{2.20}$$

with δ being the Dirac delta function, we have another choice: the Lanczos algorithm [2, 8]. Given (2.20), there exists an orthogonal matrix $Q^{(M+1)\times(M+1)}$ with the first column being $[1, 0, \dots, 0]^T \in \mathbb{R}^{(M+1)\times 1}$ such that

$$Q^T A_M Q = J_M, \tag{2.21}$$

where

$$A_M = \begin{bmatrix} 1 & \sqrt{w_1} & \sqrt{w_2} & \cdots & \sqrt{w_M} \\ \sqrt{w_1} & \tau_1 & 0 & \cdots & 0 \\ \sqrt{w_2} & 0 & \tau_2 & \cdots & 0 \\ \vdots & \vdots & \vdots & \vdots & \vdots \\ \sqrt{w_M} & 0 & 0 & \cdots & \tau_M \end{bmatrix}, \tag{2.22}$$

and J_M is the Jacobian matrix

$$J_M = \begin{bmatrix} 1 & \sqrt{\beta_0} & 0 & \cdots & 0 \\ \sqrt{\beta_0} & \alpha_0 & \sqrt{\beta_1} & \cdots & 0 \\ 0 & \sqrt{\beta_1} & \alpha_1 & \cdots & 0 \\ \vdots & \vdots & \vdots & \vdots & \vdots \\ 0 & 0 & 0 & \cdots & \alpha_{M-1} \end{bmatrix}. \tag{2.23}$$

The above algorithms were presented in [8], and a Fortran package based on these algorithms was proposed in [9]. To implement the Stieltjes procedure and the modified Chebyshev algorithm we need to evaluate the inner product with high precision. In practice, we usually employ a Gauss-type quadrature rule. Such a quadrature rule can be regarded as a discrete measure that yields the corresponding discrete versions of these two methods [8]. The stability of the Stieltjes procedure is not completely clear. One interesting aspect about this procedure is that it is reliable in many cases where a discretization for the inner product of a continuous measure is employed, while it breaks down in some cases where the measure itself is discrete. In [6], the Stieltjes procedure for discrete measures is discussed and improved. The stability of the modified Chebyshev algorithm is determined by the condition of the map from the $2n$ modified moments to the n pairs of recurrence coefficients. Such a condition was studied in [8, 5]. The Lanczos algorithm has good stability properties but it may be considerably slower than the Stieltjes procedure. In this work, we use the Stieltjes procedure and the Lanczos algorithm.

It can be seen that the basic operation in the above procedures is the inner product with respect to a given measure $m(\tau)$. Since an explicit formula is generally unavailable, we discretize the inner product using an appropriate quadrature rule. We know that an n-point Gauss-type quadrature rule can reach the highest algebraic accuracy of order $2n-1$. However, such quadrature points and the corresponding weights are not in general explicitly known. In this work, we use the interpolatory quadrature rule [23] relative to the Legendre weight function on $[-1,1]$. An n-point interpolatory quadrature rule has an algebraic precision $n-1$. Compared to the Gauss–Legendre quadrature rule, the advantage of the interpolatory quadrature rule is that the nodes and weights are explicitly known; thus the expensive Newton–Raphson iterations are avoided.

Using the Stieltjes procedure or the Lanczos algorithm, the recurrence coefficients α_i and β_i are computed iteratively using the following stopping criterion [8]:

$$|\beta_i^s - \beta_i^{s-1}| \le \epsilon \beta_i^s, \quad i = 0, 1, \ldots, n-1, \tag{2.24}$$

where s is the iteration step and ϵ is the relative error.

If a measure $m(\tau)$ is given and orthogonal polynomials up to pth order are needed, we first compute the recurrence coefficients α_i and β_i, $i = 0, 1, \ldots, p-1$. Once the recurrence coefficients are obtained, the orthogonal polynomials are uniquely determined. From the recurrence coefficients, the Gauss-type quadrature points and the corresponding integration weights can be efficiently derived [9].

It is well known that the gPC method usually relies on a three-dimensional table $\mathbb{E}[\pi_l \pi_m \pi_n]$ for the Galerkin projection [14]. Here we use the notation $\mathbb{E}[\cdot]$ freely to denote the ensemble average with respect to a given measure $m(\tau)$ since $m(\tau)$ can be regarded as a probability measure in this work. If the recurrence coefficients are obtained—in other words, the orthogonal polynomials are uniquely determined—we

can use any numerical integration formula to calculate the table $\mathbb{E}[\pi_l \pi_m \pi_n]$. Here we consider the quadrature rule. We know that for the measure $m(\tau)$ there exists, for each $M \in \mathbb{N}$, a quadrature rule

$$\int_B f(\tau) \mathrm{d}\sigma(\tau) = \sum_{i=1}^{M} w_i f(\tau_i) + R_M(f), \tag{2.25}$$

where $R_M(f) = 0$ if f is a polynomial of degree $\leq 2M - c$. The value of c is determined by the type of quadrature used, which can be either classical Gauss ($c = 1$), Gauss–Radau ($c = 2$), or Gauss–Lobatto ($c = 3$). If we do not consider the numerical accuracy of the recurrence coefficients, we need

$$M = \left\lceil \frac{3p + c}{2} \right\rceil \tag{2.26}$$

quadrature points to get the three-term integration $\mathbb{E}[\pi_l \pi_m \pi_n]$ with zero error, where $\lceil * \rceil$ denotes the smallest integer no less than $*$. Thus, we need to compute all the recurrence coefficients α_i and β_i with $i \leq M - 1$ although we employ polynomials only up to order p.

2.2.3. An adaptive procedure. Adaptivity is necessary for many cases, such as problems related to long-term integration or discontinuity. In this work we present a heuristic adaptivity criterion based on the relative local errors similar to the adaptivity criteria employed in the spectral element method for deterministic problems [22, 15].

We assume that the gPC expansion of a random field in element k is

$$\hat{u}_k(\boldsymbol{\xi}_k) = \sum_{j=0}^{N_p} \hat{u}_{k,j} \Phi_{k,j}(\boldsymbol{\xi}_k), \tag{2.27}$$

where p is the highest order of PC and N_p denotes the total number of basis modes given by

$$N_p = \frac{(p + d)!}{p! d!} - 1, \tag{2.28}$$

where d is the dimension of $\boldsymbol{\xi}_k$. From the orthogonality of gPC we can easily obtain the local variance given by PC with order p:

$$\sigma_{k,p}^2 = \sum_{j=1}^{N_p} \hat{u}_{k,j}^2 \mathbb{E}[\Phi_{k,j}^2]. \tag{2.29}$$

The [illegible] global mean $\bar{u}$ and variance $\bar{\sigma}^2$ can be expressed as

$$\bar{u} = \sum_{k=1}^{N} \hat{u}_{k,0} \Pr(I_{B_k} = 1), \quad \bar{\sigma}^2 = \sum_{k=1}^{N} \left[\sigma_{k,p}^2 + (\hat{u}_{k,0} - \bar{u})^2 \right] \Pr(I_{B_k} = 1). \tag{2.30}$$

Compared to the error of variance, the error of mean is usually much smaller in the gPC method. Thus, we can express the [illegible] global variance as

$$\sigma^2 \approx \bar{\sigma}^2 + \sum_{k=1}^{N} \gamma_k \Pr(I_{B_k} = 1), \tag{2.31}$$

where γ_k denotes the error of local variance. We define the decay rate of relative error of PC in each element as follows:

$$\eta_k = \frac{\sum_{i=N_{p-1}+1}^{N_p} \hat{u}_{k,i}^2 \mathbb{E}[\Phi_{k,i}^2]}{\sigma_{k,p}^2}. \tag{2.32}$$

Based on η_k and the scaled parameter $\Pr(I_{B_k} = 1)$, we implement k-[illegible], in other words, decompose the current random element into smaller ones, if the criterion

$$\eta_k^\gamma \Pr(I_{B_k} = 1) \geq \theta_1, \quad 0 < \gamma < 1, \tag{2.33}$$

is satisfied, where γ and θ_1 are prescribed constants. A discussion about γ and θ_1 can be found in [28] for random inputs with [illegible] distributions.

The error of the variance should decrease exponentially (for continuous random inputs) given sufficient smoothness of the solutions; furthermore, the error of $\hat{u}_{k,0}$ is usually much smaller than the error of local variance. Thus, we can use η_k as an indicator of the true error for any orthogonal chaos basis, and the criterion (2.33) is a general one. For high-dimensional random inputs, we can choose the most sensitive random dimensions for refinement. We define the sensitivity for each random dimension as

$$r_i = \frac{(\hat{u}_{i,p})^2 \, \mathbb{E}[\Phi_{i,p}^2]}{\sum_{j=N_{p-1}+1}^{N_p} \hat{u}_j^2 \mathbb{E}[\Phi_j^2]}, \qquad i = 1, 2, \ldots, d, \tag{2.34}$$

where we drop the subscript k for clarity and the subscript $*_{i,p}$ denotes the one-dimensional mode of ξ_i with polynomial order p. Let us consider a d-dimensional mode $\phi_{(j_1,j_2,\ldots,j_d)}(\boldsymbol{\xi}) = \phi_{j_1}(\xi_1)\phi_{j_2}(\xi_2)\cdots\phi_{j_d}(\xi_d)$ with $\sum_{n=1}^d j_n \leq p$, which is a tensor product of one-dimensional modes $\phi_{j_n}(\xi_n)$, $n = 1, 2, \ldots, d$. The subscript $*_{i,p}$ means that $\phi_{i,p}(\boldsymbol{\xi}) = \phi_p(\xi_i)$, $i = 1, 2, \ldots, d$. All random dimensions which satisfy

$$r_i \geq \theta_2 \cdot \max_{j=1,\ldots,d} r_j, \quad 0 < \theta_2 < 1, \quad i = 1, 2, \ldots, d \tag{2.35}$$

will be split into two [illegible] random elements in the next time step while all other random dimensions will remain unchanged. Hence, we can reduce the total element number while gaining efficiency.

2.2.4. Implementation. Next we discuss issues related to the numerical implementation. Based on the decomposition of random space, it is straightforward to reconstruct orthogonal polynomials with respect to the conditional PDFs of the local random variables $\boldsymbol{\xi}_k$. However, such a procedure is not robust in practice because (π_i, π_i) may decay fast and cause a potential problem of overflow or underflow in the computer.

PROPOSITION 2.3. [illegible] $[a, b]$ [illegible] a [illegible] b [illegible]

$$(\pi_{i+1}, \pi_{i+1}) \leq (b - a)^2 (\pi_i, \pi_i). \tag{2.36}$$

[illegible]. From (2.15), we can obtain that $a \leq \alpha_i \leq b$. Using (2.13) and the Cauchy–Schwarz inequality, we know that

$$(\pi_{i+1}, \pi_{i+1}) = ((\tau - \alpha_i)\pi_i, \pi_{i+1}) \leq ((\tau - \alpha_i)\pi_i, (\tau - \alpha_i)\pi_i)^{1/2} (\pi_{i+1}, \pi_{i+1})^{1/2}, \tag{2.37}$$

which yields that

$$(\pi_{i+1}, \pi_{i+1}) \leq ((\tau - \alpha_i)\pi_i, (\tau - \alpha_i)\pi_i). \tag{2.38}$$

The proof concludes by noting that $a \leq \alpha_i \leq b$. □

Thus, if the element is small, the L_2 norm of π_i will lead to underflow quickly. In practice, we rescale the random elements with [illegible] boundaries by the following linear transformation:

$$\xi_{k,i} = \frac{b_{k,i} - a_{k,i}}{2} Y_{k,i} + \frac{b_{k,i} + a_{k,i}}{2}, \tag{2.39}$$

where we map the random variable $\boldsymbol{\xi}_k$ defined in element k to a random variable $\boldsymbol{Y}_k$ defined in $[-1, 1]^d$. The PDF of $\boldsymbol{Y}_k$ can be obtained as

$$\bar{f}(\boldsymbol{y}_k) = \det \left| \frac{\partial \boldsymbol{\xi}_k}{\partial \boldsymbol{y}_k} \right| \hat{f}(\boldsymbol{\xi}_k(\boldsymbol{y}_k)) = \frac{f(\boldsymbol{\xi}_k(\boldsymbol{y}_k))}{\Pr(I_{B_k} = 1)} \prod_{i=1}^{d} \frac{b_{k,i} - a_{k,i}}{2}. \tag{2.40}$$

Compared to $\boldsymbol{\xi}_k$, $\boldsymbol{Y}_k$ are much more tractable for the numerical construction of orthogonal polynomials as demonstrated in section 3.1.1. After such a transformation is employed, we can apply the ME-gPC scheme with respect to the new random variable $\boldsymbol{Y}_k$ instead of the random variable $\boldsymbol{\xi}_k$. Note that such a mapping is usually unnecessary for random elements with at least one [illegible] boundary because these elements can be related to a small probability $\Pr(I_{B_k} = 1)$.

We now summarize the overall ME-gPC algorithm.

ALGORITHM 2.1 (ME-gPC).

3. [illegible]

2.1 (C^0 continuity in random space). In the ME-gPC scheme, we deal with the stochastic problem locally without considering the interface between two random elements; in other words, we split the original problem into N independent ones. The reason is that all the statistics are in L_q sense, which means that the statistics are determined by up to qth moments of the desired random field. Thus, the continuity

$$u_{B_1}(\boldsymbol{\xi}) = u_{B_2}(\boldsymbol{\xi}), \quad \boldsymbol{\xi} \in \bar{B}_1 \cap \bar{B}_2, \tag{2.41}$$

where $\bar{B}_1$ and $\bar{B}_2$ indicate the closure of two adjacent random elements, respectively, is not required since the measure of the interface is zero.

Remark 2.2 (construction cost of π_i). In practice, the K-L decomposition related to a random variable $\boldsymbol{\xi}$ is often used to reduce the dimensionality of colored noise. Since all the components of $\boldsymbol{\xi}$ are assumed to have identical distributions, we can maintain a table for one-dimensional orthogonal polynomials which have already been constructed. When the decomposition of random space is activated, we first look up the table to check if the edges of new random elements are in the table or not and construct orthogonal polynomials only for the missing edges. This way, the time cost for construction of orthogonal polynomials is almost independent of the random dimension.

Remark 2.3 (complexity of ME-gPC). In Algorithm 2.1, we decompose a stochastic problem into N independent ones, since C^0 continuity is unnecessary in random space. Thus, if polynomials of the same order are used in both gPC and ME-gPC, the cost of ME-gPC will increase linearly by a factor N compared to the cost of gPC, since the cost of numerical orthogonal polynomials is negligible as demonstrated in section 3.1.4.

3. Numerical results.

3.1. Construction of orthogonal polynomials. We first discuss the construction of orthogonal polynomials for random variables with some commonly used distributions. Due to the nice properties of uniform distribution, the orthogonality of Legendre-chaos can be naturally inherited in the decomposition of random space, which means that the polynomial construction is unnecessary for the uniform distribution. Here we focus on the Beta and Gaussian distributions, for which we need the on-the-fly polynomial construction.

3.1.1. Problem of overflow and underflow. We consider a random variable defined in $[-1, 1]$ with the following Beta distribution:

$$f(x) = \frac{(1-x)^\alpha (1+x)^\beta}{2^{\alpha+\beta+1} B(\alpha+1, \beta+1)}, \quad -1 \le x \le 1. \tag{3.1}$$

In a random element $[0, 0.001]$, we define a random variable X with a conditional PDF

$$\hat{f}(x) = \frac{f(x)}{\int_0^{0.001} f(x)\mathrm{d}x}, \tag{3.2}$$

and map X to another random variable Y defined in $[-1, 1]$ with a PDF

$$\bar{f}(y) = \frac{0.0005 f(x(y))}{\int_0^{0.001} f(x)\mathrm{d}x}, \tag{3.3}$$

where

$$x(y) = 0.0005y + 0.0005. \tag{3.4}$$

Here we let $\alpha = 1$ and $\beta = 4$. In Figure 3.1, we show the orthogonal polynomials for random variable X from first order up to fourth order. We can see that the maximum values of these polynomials decrease very quickly approaching the machine accuracy. In Figure 3.2, the corresponding orthogonal polynomials for random variable Y are shown. It can be seen that their shapes are the same as those of the orthogonal polynomials for X but are well scaled.

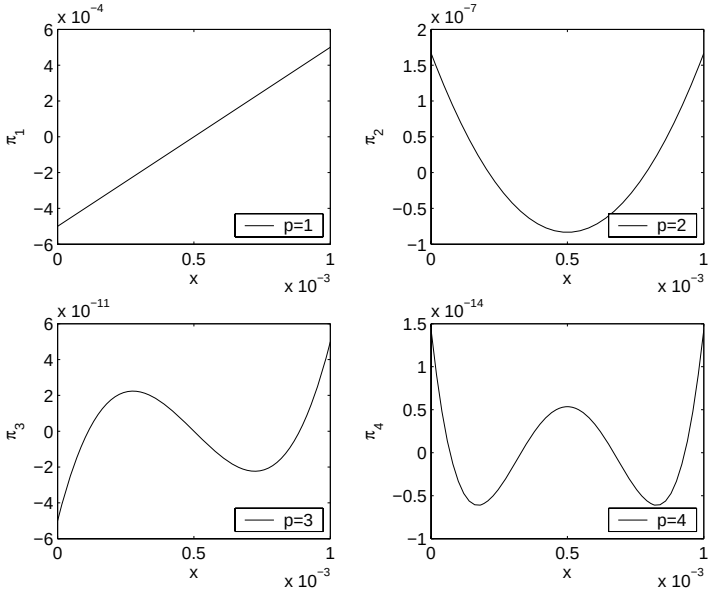

FIG. 3.1. *Orthogonal polynomials for random variable X, π_1 to π_4.*

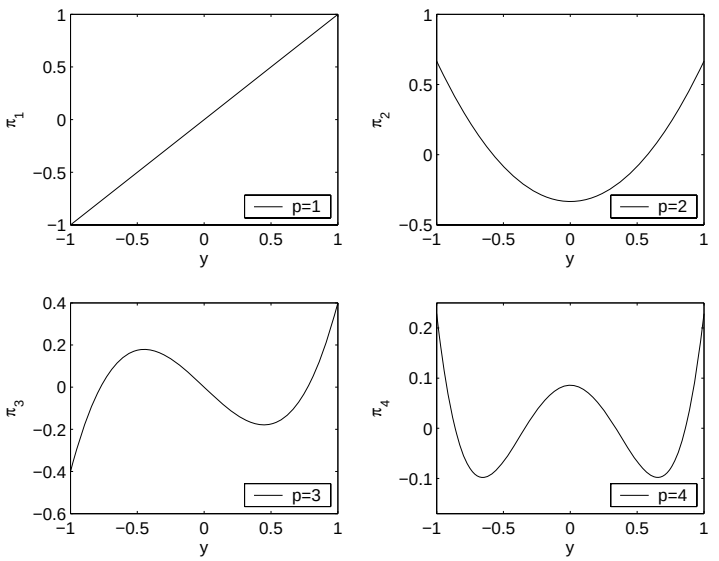

FIG. 3.2. *Orthogonal polynomials for random variable Y, π_1 to π_4.*

3.1.2. Orthogonal polynomials for Beta distribution. From the ME-gPC scheme, we know that the orthogonal basis in each random element depends on a particular part of the PDF of the random inputs. We now demonstrate such a dependence using a Beta-type random variable X with $\alpha = 1$ and $\beta = 4$. For simplicity, we consider only two random elements: $[-1, 0]$ and $[0, 1]$. We define a random variable

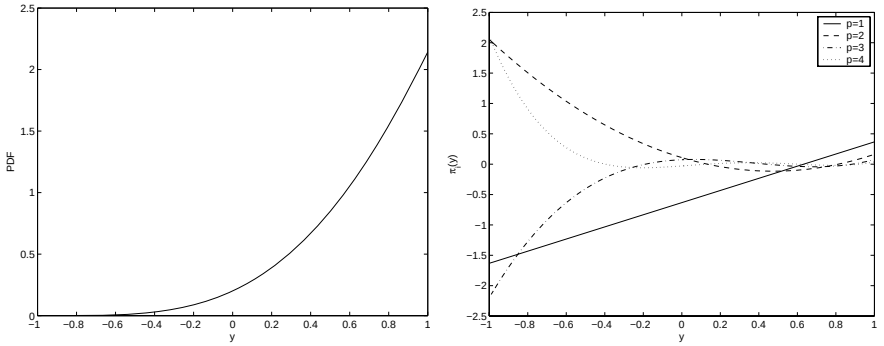

FIG. 3.3. *Left: PDF of random variable Y_l induced by Beta distribution with $\alpha = 1$ and $\beta = 4$. Right: orthogonal polynomials for Y_l.*

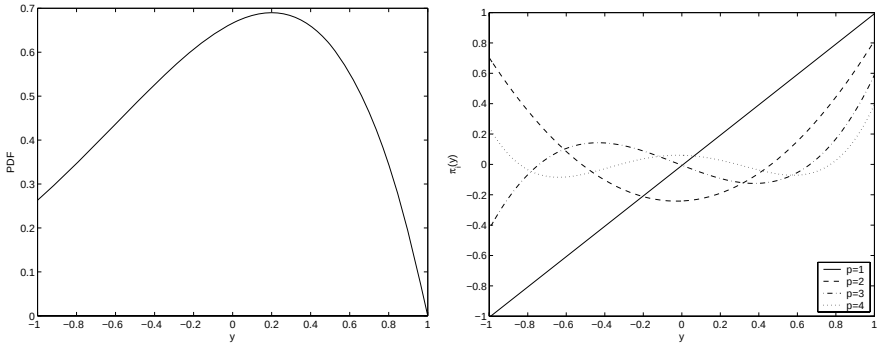

FIG. 3.4. *Left: PDF of random variable Y_r induced by Beta distribution with $\alpha = 1$ and $\beta = 4$. Right: orthogonal polynomials for Y_r.*

X_l in $[-1, 0]$ with a conditional PDF

$$f_l(x_l) = \frac{f(x_l)}{\int_{-1}^{0} f(x)\mathrm{d}x} \tag{3.5}$$

and another random variable X_r in $[0, 1]$ with a conditional PDF

$$f_r(x_r) = \frac{f(x_r)}{\int_{0}^{1} f(x)\mathrm{d}x}, \tag{3.6}$$

where $f(x)$ is the PDF of X. Due to the potential problem of overflow (underflow), we will not construct the orthogonal basis according to the above two conditional PDFs, but first map X_l and X_r to Y_l and Y_r, respectively, using the transformation

$$X_l = \frac{1}{2}Y_l - \frac{1}{2}, \quad Y_r = \frac{1}{2}Y_r + \frac{1}{2}, \tag{3.7}$$

and then construct orthogonal polynomials in terms of Y_l and Y_r. In Figures 3.3 and 3.4, we show the PDFs of Y_l and Y_r on the left and the corresponding orthogonal polynomials on the right. It is clear that these two sets of orthogonal polynomials are quite different due to their different weight functions (i.e., local PDFs).

3.1.3. Orthogonal polynomials for Gaussian distribution. Some random distributions, e.g., Gaussian distribution and Gamma distribution, have long tails. Next, we demonstrate the decomposition of random space and the corresponding orthogonal polynomials for this type of random variable. Given a Gaussian random variable $X \sim N(0,1)$, we decompose the random space into three random elements $(-\infty, -a]$, $[-a, a]$, and $[a, +\infty)$, where a is a positive constant. In the middle element $[-a, a]$, we define a random variable X_m with a conditional PDF

$$f_m(x_m) = \frac{e^{-\frac{1}{2}x_m^2}}{\int_{-a}^{a} e^{-\frac{1}{2}x^2}\mathrm{d}x}. \tag{3.8}$$

In one of the tail elements, say, $[a, +\infty)$, we define a random variable X_∞ with a conditional PDF

$$f_\infty(x_\infty) = \frac{e^{-\frac{1}{2}x_\infty^2}}{\int_{a}^{\infty} e^{-\frac{1}{2}x^2}\mathrm{d}x}. \tag{3.9}$$

We choose a in such a way that $\Pr(X \geq a) < \epsilon$, where ϵ is a small positive constant. From (2.31), we know that the error contribution of tail elements can be effectively weakened by the small value of $\Pr(X \geq a)$; thus we usually do not decompose the tail elements in applications, but rather the middle element $[-a, a]$. Furthermore, there is no overflow or underflow problem for the tail elements due to the infinite boundary. Here we take $a = 5$, which yields $\Pr(X \geq 5) = 2.87 \times 10^{-7}$. In Figure 3.5, we show the PDF of the rescaled random variable $Y_m = X_m/a$ on the left and the corresponding orthogonal polynomial basis on the right. The orthogonal polynomials have similar shapes with Hermite polynomials; however, they are bounded now. In Figure 3.6, the conditional PDF of X_∞ is shown on the left and the corresponding orthogonal basis on the right. Due to the infinite boundary the orthogonal polynomials look almost like Laguerre polynomials.

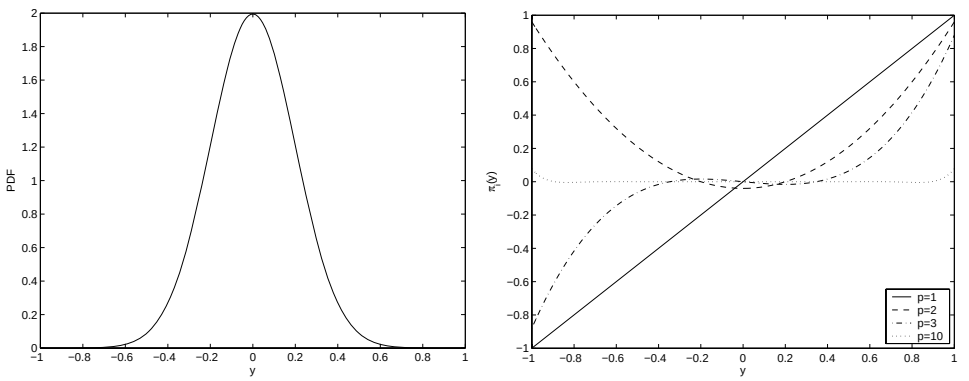

FIG. 3.5. *Left: PDF of random variable Y_m induced by Gaussian distribution. Right: orthogonal polynomials for Y_m.*

3.1.4. Efficiency of the solver for numerical orthogonal polynomials. It is clear that the ME-gPC method relies heavily on the numerical orthogonal polynomials. We now test the solver for the recurrence coefficients, quadrature points, and integration weights. Due to the absence of explicit formulas, we use the following

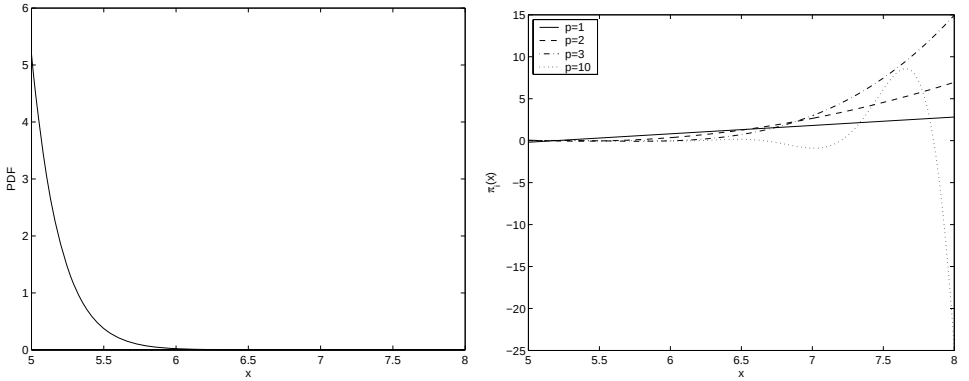

FIG. 3.6. *Left: PDF of random variable X_∞ induced by Gaussian distribution. Right: orthogonal polynomials for X_∞.*

example. Given a weight function $w(x)$ defined in $[a, b]$, we decompose $[a, b]$ into small elements and construct numerical orthogonal polynomials in these elements. Then we map a simple function $g(x) = c_1 x^p + c_2$ onto such elements numerically and compute the errors on the quadrature points in each element. In the kth element $[a_k, b_k]$, $g(x) = c_1 x^p + c_2$ should have the form

$$g_k(\tau) = c_1 \left(\frac{b_k - a_k}{2} \tau + \frac{b_k + a_k}{2} \right)^p + c_2, \tag{3.10}$$

since all the orthogonal polynomials in element k are defined in $[-1, 1]$. Expressed by the numerical orthogonal polynomials, $g_k(\tau)$ has another form:

$$\hat{g}_k(\tau) = \sum_{i=0}^{p} \nu_{k,i} \pi_{k,i}(\tau), \tag{3.11}$$

where the coefficients $\nu_{k,i}$ can be obtained by the inner product

$$\nu_{k,i} = (g_k(\tau), \pi_{k,i})/(\pi_{k,i}, \pi_{k,i}). \tag{3.12}$$

Next, we define the L_∞ error on the quadrature points over all the elements

$$\epsilon_{max} = \max \left| \frac{g_k(\tau_j) - \hat{g}_k(\tau_j)}{g_k(\tau_j)} \right|, \quad k = 1, 2, \ldots, N, \quad j = 1, 2, \ldots, n, \tag{3.13}$$

where N is the number of elements and n is the number of quadrature points in each element. In Table 3.1, we show ϵ_{max} and the time cost for different uniform meshes. We record the time used for the computation of recurrence coefficients, quadrature points, integration weights, and the table $\mathbb{E}[\pi_{k,i}\pi_{k,j}\pi_{k,m}]$, which represents the total set-up requirement for the standard Galerkin gPC method. We can see that the biggest error ϵ_{max} occurs in a one-element mesh. As the number of elements increases, ϵ_{max} is almost of the same order as the relative error of recurrence coefficients, which implies that the numerical polynomials can achieve good orthogonality and high accuracy. Furthermore, numerical experiments show that the time cost for the numerical polynomials is very small. For example, 10^5 sets of orthogonal polynomials up to 10th order can be computed within less than one-and-a-half minutes on a 1.5GHz

TABLE 3.1

Error ϵ_{max} and time cost for a uniform mesh with N elements. $p = 10$ and $g(x) = x^{10} + 1$. The relative error for the recurrence coefficients was set to be 10^{-13}. $\alpha = 1$ and $\beta = 4$ for Beta distribution. The middle element $[-6, 6]$ was used for Gaussian distribution. The computations were performed on a 1.5GHz AMD CPU.

	Beta distribution		Gaussian distribution

10^5	9.28e-13	76.43	4.09e-13	78.74

AMD CPU. In practice, we do not need so many elements and the time cost for the construction of orthogonal polynomials actually can be ignored compared to the time used by the gPC solver.

3.2. Accuracy and convergence of ME-gPC. We next show the accuracy and convergence of ME-gPC by several numerical examples. We use a simple stochastic ODE model to demonstrate the *kp*-convergence of the ME-gPC method and the Kraichnan–Orszag problem to show how to deal with discontinuities introduced by random inputs using the ME-gPC method.

3.2.1. Basic stochastic ODE model. We consider the performance of the ME-gPC method for the following simple ODE equation studied with the original gPC in [32]:

$$\frac{\mathrm{d}u}{\mathrm{d}t} = -\lambda h(\zeta(\omega))u, \qquad u(0;\omega) = u_0, \tag{3.14}$$

where $\zeta(\omega)$ is a random variable, h is a function of $\zeta(\omega)$, and λ is constant. The exact solution can be easily found as

$$u(t;\omega) = u_0 e^{-\lambda h(\zeta(\omega))t}. \tag{3.15}$$

Using ME-gPC with uniform meshes, we study the following two cases:

(i) ζ is a Beta-type random variable. $\alpha = 1$, $\beta = 4$, and $h(\zeta(\omega)) = \zeta(\omega)$.

(ii) ζ is a Gaussian random variable. $h(\zeta(\omega)) = \zeta(\omega)$.

In Figure 3.7, we show the convergence of ME-gPC at $t = 5$ for case (i) with p-convergence on the left and k-convergence on the right. It can be seen that ME-gPC exhibits exponential convergence while the index of algebraic convergence goes asymptotically to a constant. The convergence of the ME-gPC method at $t = 5$ for case (ii) is shown in Figure 3.8. Note here for the Gaussian random variable we start with a three-element mesh: $(-\infty, -6]$, $[-6, 6]$, and $[6, +\infty)$. We refine only the middle element $[-6, 6]$ because the error contribution of the tail elements is very small compared with that of the middle element. We can see that the error curve of such a three-element mesh matches exactly with that given by the Hermite-chaos. The plot of p-convergence also shows that the four-element mesh works better than

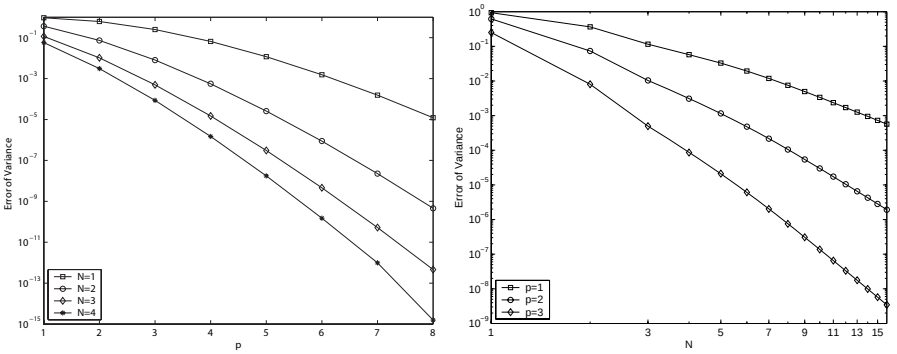

FIG. 3.7. *Convergence of ME-gPC for the simple ODE with ζ being a Beta-type random variable. $\lambda = 1$. Left: p-convergence. Right: k-convergence.*

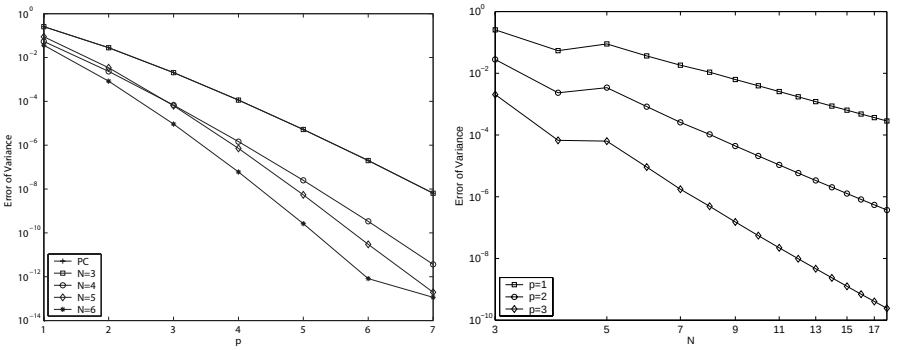

FIG. 3.8. *Convergence of ME-gPC for the simple ODE with ζ being a Gaussian random variable. $\lambda = 0.1$. Left: p-convergence. Right: k-convergence.*

the five-element mesh when $p < 3$. The behavior of (3.14) may be very different if $\zeta(\omega)$ is located in different random elements, which gives rise to a nonuniform error distribution in each element. For instance, when $p = 2$, $\zeta(\omega) < 0$ in element $[-6, 0]$ and the error of local variance is $\epsilon_{[-6,0]} = 5.06 \times 10^{-3}$; $\zeta(\omega) > 0$ in element $[0, 6]$ and $\epsilon_{[0,6]} = 2.48 \times 10^{-3}$.

From (2.31), we know that the error of global variance is of $O((\epsilon_{[-6,0]} + \epsilon_{[0,6]})/2)$, where we neglect the error contribution of the tail elements. For a five-element mesh the error contribution comes mainly from element $[-2, 2]$ in which $\Pr(I_{[-2,2]} = 1) = 0.95$. Thus, the error of global variance is of $O(\epsilon_{[-2,2]})$, where $\epsilon_{[-2,2]} = 5.39 \times 10^{-3}$. It can be seen that $\epsilon_{[-2,2]} > (\epsilon_{[-6,0]} + \epsilon_{[0,6]})/2$, which corresponds to the behavior of p-convergence and k-convergence in Figure 3.8. As the polynomial order p or the number N of the random elements increases, p-convergence or k-convergence will be dominant and such a phenomenon will disappear. In Table 3.2, we present the estimated indices of algebraic convergence for both case (i) and case (ii). It can be seen that for both mean and variance the index of algebraic convergence is close to $-2(p + 1)$, which is consistent with the error estimate given in [4]. From the theory of the deterministic finite element method [4], it can be shown that the index of algebraic convergence will go to $-2(p+1)$ for any PDF. When computing the recurrence coefficients α_i and β_i iteratively, a relative error 10^{-13} is imposed for both case (i) and case (ii). From the plots of p-convergence, it can be seen that the maximum accuracy ME-gPC can

achieve is of $O(10^{-13})$, which implies that the constructed orthogonal polynomials are very accurate.

An obvious question that arises here is how well the *kp*-convergence of ME-gPC compares with the *k*-convergence or *p*-convergence. The answer is very dependent on the problem under consideration, since the properties of the solution, such as smoothness, may be significantly different. Given enough smoothness in the random space and a fixed time cost, *p*-convergence is usually a better choice than *k*-convergence or *kp*-convergence; however, *kp*-converge can be better than *p*-convergence for many cases. In the following we will measure computational complexity through n that indicates the number of operations. Using a standard gPC procedure with a Galerkin projection, we obtain the following deterministic equations for the coefficients of the polynomial chaos expansion of $u(\zeta)$:

$$\frac{\mathrm{d}u_i}{\mathrm{d}t} = \frac{1}{\mathbb{E}[\Phi_i^2(\zeta)]} \sum_{j=0}^{p_h} \sum_{k=0}^{p} h_j u_k \mathbb{E}[\Phi_i(\zeta)\Phi_j(\zeta)\Phi_k(\zeta)], \quad i = 0, 1, \ldots, p,$$

where p_h and p indicate the highest polynomial orders of polynomial chaos expansions for $h(\zeta)$ and $u(\zeta)$, respectively. Then we can use $n = N(p_h+1)(p+1)^2$ to measure the cost of ME-gPC, which is proportional to the number of operations of each time step if the Runge–Kutta method is employed for the integration in time. In Table 3.3 we present the accuracy of ME-gPC for different k and p while the cost is fixed ($n = 200$). We note that $p_h = 1$. It can be seen that *p*-convergence is superior for the case $\lambda = 1.0$. However, for a larger perturbation $\lambda = 1.5$, the ME-gPC with $N = p = 4$ achieves a better accuracy of the variance than gPC. This implies that for a large perturbation the *kp*-convergence of ME-gPC can enhance the accuracy and efficiency significantly. From (2.39), it can be seen that the degree of perturbation is reduced in ME-gPC from (λ) to $(\frac{b_i-a_i}{2}\lambda)$. Due to the fast (exponential) convergence of local gPC in each random element B_k, the overall performance of ME-gPC can be more efficient than that of gPC. We also expect that ME-gPC should be more robust than gPC for a large perturbation due to the decomposition of the random space. Furthermore, if

the solution is not smooth in the random space, the p-convergence may be destroyed and we need to resort to the (adaptive) kp-convergence, as demonstrated in the next section.

3.2.2. Kraichnan–Orszag (K-O) problem (stochastic discontinuity). It is well known that gPC fails for the K-O problem [24]. The K-O problem with uniform random inputs was studied in [28]. We now reconsider this problem with random inputs of Beta and Gaussian distributions. The transformed K-O problem can be expressed as [28]

$$\begin{aligned} \frac{\mathrm{d}y_1}{\mathrm{d}t} &= y_1 y_3, \\ \frac{\mathrm{d}y_2}{\mathrm{d}t} &= -y_2 y_3, \\ \frac{\mathrm{d}y_3}{\mathrm{d}t} &= -y_1^2 + y_2^2 \end{aligned} \tag{3.16}$$

subject to initial conditions

$$y_1(0) = y_1(0;\omega), \quad y_2(0) = y_2(0;\omega), \quad y_3(0) = y_3(0;\omega). \tag{3.17}$$

The deterministic solutions of this problem are periodic, and the period will go to infinity if the initial points are located at the planes $y_1 = 0$ and $y_2 = 0$. It was shown in [28] that gPC fails if the initial random inputs can pass through these two planes. We study the following three different kinds of initial conditions:

(i) $y_1(0) = 1$, $y_2(0) = 0.1\xi_1$, and $y_3(0) = 0$;
(ii) $y_1(0) = 1$, $y_2(0) = 0.1\xi_1$, and $y_3(0) = 0.1\xi_2$;
(iii) $y_1(0) = c\xi_1$, $y_2(0) = c\xi_2$, and $y_3(0) = c\xi_3$,

where c is constant and ξ_i are random variables of Beta or Gaussian distribution.

For all three cases, the relative error of recurrence coefficients α_i and β_i is set to be 10^{-12}. For case (i) we show the convergence of adaptive ME-gPC in Tables 3.4 and 3.5, where ξ_1 is of Beta distribution and Gaussian distribution, respectively. It can be seen that ME-gPC converges as θ_1 decreases. For all the cases in Tables 3.4 and 3.5, we have recorded the time used for the construction of orthogonal PC, which is less than 0.15% of the time used by the ME-gPC solver. Thus, the cost of the polynomial construction can be ignored compared with the total cost. In Figure 3.9, we show the adaptive meshes for Beta distribution and Gaussian distribution. Due to the symmetry of distribution, the mesh for Gaussian distribution is symmetric in contrast to the unsymmetric one for Beta distribution with $\alpha = 1$ and $\beta = 4$. From the adaptive criterion (2.33), we know that the element size is controlled by two factors: the relative error η_k and $\Pr(I_{B_k} = 1)$. We can see that around the discontinuity region ($\xi_1 = 0$) the mesh is refined because the error of gPC goes to $O(1)$, and the mesh is coarser where $\Pr(I_{B_k} = 1)$ is smaller. For the Gaussian distribution we refine only the middle element $[-6, 6]$ as before. In Figure 3.10 we show the speedup of ME-gPC for case (i) compared to the Monte Carlo (MC) method; n is defined as the number of operations. If the data in Figure 3.10 are approximated by a first-order polynomial in a least-squares sense, the accuracy of ME-gPC can be obtained as $(n^{-3.23})$, $(n^{-3.85})$, and $(n^{-5.55})$, corresponding to $p = 3$, $p = 4$, and $p = 5$, respectively, for Beta distribution and $(n^{-3.07})$, $(n^{-5.16})$, and $(n^{-6.33})$ for Gaussian distribution. It can be seen that the adaptive ME-gPC converges much faster than the Monte Carlo method and the speedup increases with the polynomial

order. However, since the error of gPC increases with time, the above speedups will decrease with time. The long-term behavior of gPC and ME-gPC was studied in [29].

In Figure 3.11, we show the adaptive meshes of case (ii) for Beta and Gaussian distributions. Since the discontinuity occurs at the line $\xi_1 = 0$ in the random space for this case, it can be seen that the meshes are well refined along the line $\xi_1 = 0$. It is not surprising that the random elements are bigger where the PDF is smaller because $\Pr(I_{B_k} = 1)$ is relatively smaller in these elements. In Figure 3.12, the speedup for case (ii) is shown. We can see that the Monte Carlo method is competitive for low accuracy and ME-gPC can achieve a good speedup for high accuracy.

In Figure 3.13, the evolution of y_1 in case (iii) is shown. We take $c = 1$ for the Beta distribution and 0.3 for the Gaussian distribution. For the purpose of comparison, we include the results of gPC. For both cases, gPC with $p = 3$ begins to fail at $t \approx 1$. Since increasing polynomial order does not improve gPC [28], the results of gPC with a higher order are not shown. ME-gPC can maintain convergence by increasing random elements adaptively. However, for a comparable accuracy of $O(10^{-3})$, the Monte Carlo method is about twice as fast as ME-gPC for the Beta distribution and about four times as fast as ME-gPC for the Gaussian distribution. This is mainly due to two factors. First, the discontinuity for case (iii) is strong because the discontinuity

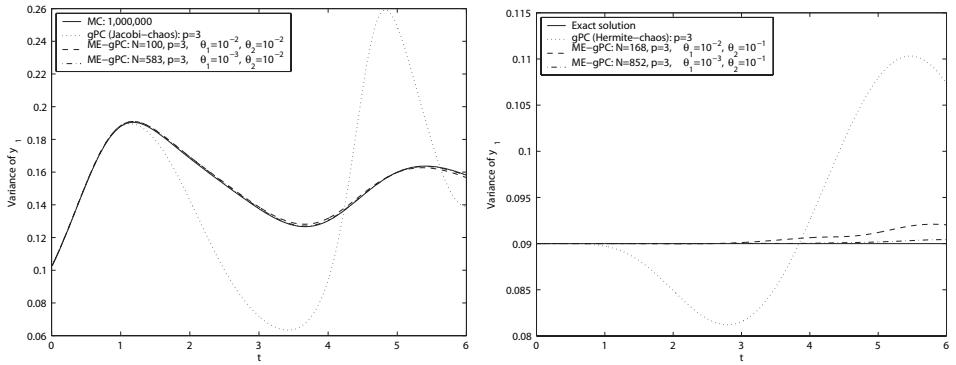

FIG. 3.13. *Evolution of the variance of* y_1 *for case* (iii) *of K-O problem. Left: Beta distribution with* $\alpha = 1$ *and* $\beta = 4$. $c = 1$. *Right: Gaussian distribution.* $c = 0.3$.

region consists of two planes: $\xi_1 = 0$ and $\xi_2 = 0$. Second, the cost of gPC increases very quickly with the random dimension. Since ME-gPC is a dimension dependent method, its efficiency decreases as the random dimension increases. The Monte Carlo method is still a better choice for obtaining a moderate accuracy for high-dimensional cases unless a high accuracy is really required.

3.2.3. ME-gPC for PDEs: Heat transfer in a grooved channel. Next, we demonstrate the use of ME-gPC to engineering applications, by simulating the heat transfer enhancement in a two-dimensional grooved channel subjected to stochastic excitation. The phenomenon of heat transfer enhancement in a grooved channel has been widely studied numerically and experimentally (see [11, 16] and references therein). The geometry to be considered is depicted in Figure 3.14. We use exactly the same geometry as in [11], which corresponds to $L = 6.6666$, $l = 2.2222$, and $a = 1.1111$.

The flow is assumed to be fully developed in the x (flow) direction. For the velocity field we have the incompressible Navier–Stokes equations

$$\frac{\partial \boldsymbol{v}}{\partial t} + (\boldsymbol{v} \cdot \nabla)\boldsymbol{v} = -\nabla \Pi + \nu \nabla^2 \boldsymbol{v}, \tag{3.18a}$$

$$\nabla \cdot \boldsymbol{v} = 0, \tag{3.18b}$$

where $\boldsymbol{v}(\boldsymbol{x}, t; \omega)$ is the stochastic velocity, Π is the pressure, and ν is the kinematic viscosity. The fully developed boundary conditions for the velocity are

$$\boldsymbol{v}(\boldsymbol{x}, t; \omega) = 0 \qquad \text{on } \partial D, \tag{3.19a}$$

$$\boldsymbol{v}(x + L, y, t; \omega) = \boldsymbol{v}(x, y, t; \omega), \tag{3.19b}$$

corresponding to no-slip and periodicity, respectively. The uncertainty is introduced by the following imposed flow-rate condition:

$$Q(t; \omega) = \int_{\partial D_B}^{\partial D_T} u(x, y, t; \omega) \mathrm{d}y = \frac{4}{3}(1 + 0.2\xi_H(\omega) \sin 2\pi \Omega_F t), \tag{3.20}$$

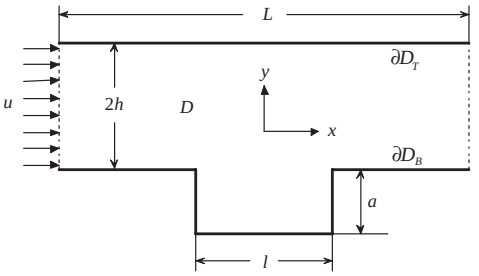

FIG. 3.14. *Schematic of the geometry of a grooved channel.*

where $\xi_H(\omega)$ is a random variable and Ω_F is a prescribed frequency. Due to the periodic boundary condition for the velocity, we require

$$\Pi(\boldsymbol{x}, t; \omega) = -h(t; \omega)x + \tilde{\Pi}(\boldsymbol{x}, t; \omega), \tag{3.21a}$$

$$\tilde{\Pi}(x, y, t; \omega) = \tilde{\Pi}(x + L, y, t; \omega) \tag{3.21b}$$

for the pressure; otherwise, a trivial solution for the velocity will be obtained. The convection equation for the temperature $T(\boldsymbol{x}, t)$ is given as

$$\frac{\partial T}{\partial t} + (\boldsymbol{v} \cdot \nabla)T = \alpha_t \nabla^2 T, \tag{3.22}$$

where α_t is the assumed constant thermal diffusivity. For the temperature boundary conditions on the top and bottom walls we have

$$\kappa \nabla T \cdot \boldsymbol{n} = 0 \quad \text{on } \partial D_T, \tag{3.23a}$$

$$\kappa \nabla T \cdot \boldsymbol{n} = 1 \quad \text{on } \partial D_B, \tag{3.23b}$$

where κ is the thermal conductivity of the fluid and $\boldsymbol{n}$ refers to the outward normal on the boundary. As for the inlet and outlet thermal boundary conditions, we first subtract a linear term from T and use a periodic boundary condition for the other contribution

$$T(\boldsymbol{x}, t; \omega) = \theta(\boldsymbol{x}, t; \omega) + \phi(\omega)x, \tag{3.24a}$$

$$\theta(x, y, t; \omega) = \theta(x + L, y, t; \omega), \tag{3.24b}$$

where the coefficient $\phi(\omega)$ can be determined by the global energy balance [10]. The numerical schemes for the aforementioned equations, which can be found in [27], are based on the deterministic splitting schemes for the Navier–Stokes equations [17, 10].

In this work we demonstrate only the k-convergence of ME-gPC by the computation of an averaged global Nusselt number. Using the same notation as in [11], we define a Nusselt number Nu as

$$Nu = L\left(1 + \frac{2a}{L}\right)^2 \Bigg/ \int_0^{L+2a} \langle \theta - \theta_b \rangle \mathrm{d}s|_{\partial D_B}, \tag{3.25}$$

TABLE 3.6
k-convergence of the ME-gPC method in terms of the variance of the Nusselt number in a grooved channel. Uniform meshes are used in the random space. The reference variance of the Nusselt number is 0.0394*, which is given by the ME-gPC method with* $N = 10$ *and* $p = 6$.

gPC	Variance	Δ_{var}	ME-gPC	Variance	Δ_{var}
$p = 1$, $n_p = 2$	0.0719	8.26e-1	$N = 1$, $p = 1$, $n_p = 2$	0.0719	8.26e-1
$p = 3$, $n_p = 4$	0.0617	5.67e-1	$N = 3$, $p = 1$, $n_p = 6$	0.0325	1.75e-1
$p = 5$, $n_p = 6$	0.0435	1.06e-1	$N = 5$, $p = 1$, $n_p = 10$	0.0355	9.84e-2
$p = 7$, $n_p = 8$	0.0430	8.41e-2	$N = 7$, $p = 1$, $n_p = 14$	0.0402	4.82e-3

where θ_b is a reference temperature taken to be the mixed-mean temperature at $x = 0$,

$$\theta_b = \left\langle \frac{3}{4} \int_{-1}^{1} u(x = 0, y, t; \omega)\theta(x = 0, y, t; \omega) \mathrm{d}y \right\rangle, \tag{3.26}$$

and $\langle \cdot \rangle$ refers to the time average over one period of the flow, $t < t' < +\Omega_F^{-1}$.

The Reynolds number is defined as $Re = 3\langle Q(t) \rangle / 4\nu$, and the Prandtl number as $Pr = \nu/\alpha$. We take $Re = 525$ and $Pr = 1$ in this work. We let $\Omega_F = 0.15$ and let ξ_H be a random variable of Beta distribution with $\alpha = 1$ and $\beta = 4$.

The convergence of gPC for the Navier–Stokes equation and the advection-diffusion equation has been studied and verified in [34, 30]. The solution of (3.18) and (3.22) converges to a steady state. We use the variance obtained by the ME-gPC method with $N = 10$, $p = 6$, and $t = 4000$ as the reference R^*. We define a relative normalized error for the variance as

$$\Delta_{var} = \left| \frac{R - R^*}{R^*} \right|, \tag{3.27}$$

where R is the variance given by gPC or ME-gPC. Let $n_p = N(p + 1)$ indicate the number of unknowns in the PC expansion. In Table 3.6, we show the k-convergence of the ME-gPC method. We note that both the mean and the variance obtained from a low-order ME-gPC are converging to the reference results as the number of elements N increases, which yields a k-convergence. The decomposition of random space accelerates the convergence significantly, but at this (relatively low) Reynolds number we need a slightly larger n_p for ME-gPC to obtain comparable accuracy with gPC. However, at higher Reynolds numbers we have larger stochastic perturbations and ME-gPC is more efficient than gPC; this is consistent with the cost comparison results of the first example presented earlier. In fact, for large values of the polynomial order p, gPC yields stochastic solutions that exhibit artificial oscillations at the tails of the corresponding PDFs; such artifacts are not present with ME-gPC [27]. Finally, compared to high-order gPC, an important cost advantage of ME-gPC for large-scale numerical simulations in fluid mechanics is that it can be easily parallelized as the local problems in each random element are independent.

In Figure 3.15, we show the standard deviation of the temperature at $t = 4000$. It can be seen that the standard deviation increases from the channel region to the groove part of the domain. The local maxima are inside the cavity and close to the top right corner of the cavity, which reflects the established flow communication between the groove and the channel. This, in turn, is the reason that gives rise to enhanced heat transfer [11].

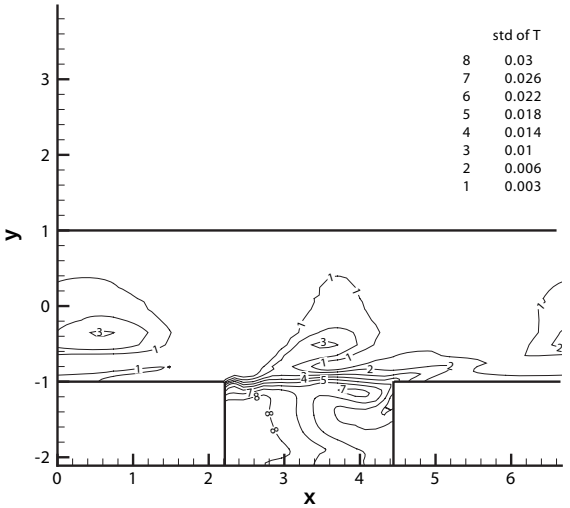

FIG. 3.15. *Standard deviation of T at $t = 4000$ obtained by ME-gPC with $N = 10$ and $p = 6$.*

4. Summary. In this paper we present an ME-gPC method for stochastic processes represented by random variables of arbitrary distributions. The ME-gPC method combines the two PC schemes of k-version and p-version by the numerical reconstruction of orthogonal polynomials, which yields a $k \times p$ version. Numerical experiments show that the numerical reconstruction of high accuracy can be obtained with negligible cost. Hence, the ME-gPC method inherits the advantages of previous PC methods and can efficiently achieve kp-convergence for stochastic differential equations. This is shown by a simple ODE model and a heat transfer problem in a grooved channel. The application of ME-gPC depends on the smoothness of the solution in the random space. Due to the fast (exponential) convergence, gPC is preferred if the p-convergence can be achieved; otherwise, the convergence can be improved by the kp-convergence of ME-gPC. The adaptive ME-gPC scheme shows a good performance in convergence for problems related to discontinuities induced by random inputs because it can weaken the influence of discontinuities by small random elements and maintain the fast (exponential) convergence of gPC in regular elements, which is clearly shown by the adaptive meshes for the K-O problem. Thus, the ME-gPC method is more flexible and efficient than previous polynomial chaos schemes in many cases.

In [1], the asymptotic numerical complexity of stochastic Galerkin finite element methods of $k \times h$ version and $p \times h$ version is compared with the Monte Carlo method. Note that the comparison is valid only for the optimal case. For some cases, especially when the random dimension is high and the desired accuracy is moderate, the Monte Carlo method is still preferred in practice because it is random dimension independent while all PC methods including the ME-gPC method depend on the random dimension. If strong discontinuities exist together with a high random dimension as shown in case (iii) of section 3.2.2, polynomial chaos methods can lose efficiency further or even fail to converge. However, if the required error is sufficiently small, the PC method, especially the ME-gPC method, will be more efficient than the Monte

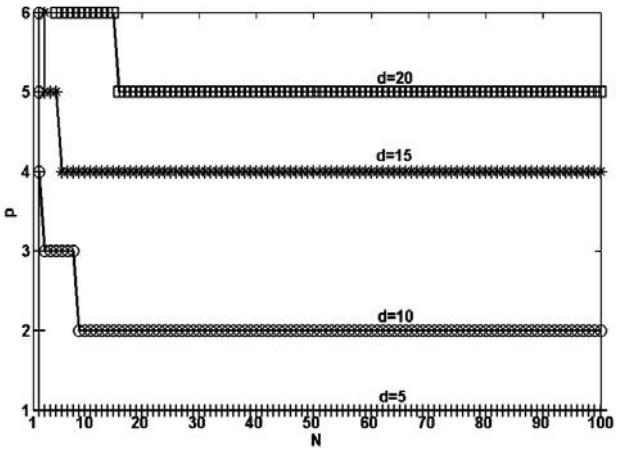

FIG. 4.1. *Cost comparison between ME-gPC and the standard Monte Carlo method for fixed accuracy. Here p is the order of gPC in each element, N is the number of elements and d is the number of dimensions. The symbol-lines are iso-cost lines.*

Carlo method due to the k-p convergence as shown in cases (i) and (ii) of section 3.2.2. In Figure 4.1, we present a comparison between the k-convergence $(N^{-2(p+1)})$ of ME-gPC and the convergence $(n^{-1/2})$ of the standard Monte Carlo method; see [1]. For the same accuracy and different random dimension numbers, the lines show the cases where the cost of the standard Monte Carlo method is equal to that of ME-gPC. For a certain random dimension number (denoted by "d"), the region below the line is where MC is more efficient; the region above the line is where ME-gPC is more efficient.

In this work we use heuristically the decay rate of relative error of variance as the indicator for the k-type refinement. A more rigorous a posteriori error estimate is still needed for the kp-adaptivity. These issues will be addressed in future publications.

Appendix (application of ME-gPC to a stochastic elliptic problem). Here we briefly elaborate on how to apply ME-gPC to solve differential equations with stochastic coefficients using the following stochastic linear boundary value problem: Find a stochastic function, $u : \overline{D} \times \Omega \to \mathbb{R}$, such that almost surely the following equation holds:

$$\begin{aligned} -\nabla \cdot (a(\boldsymbol{x};\omega)\nabla u(\boldsymbol{x};\omega)) &= f(\boldsymbol{x};\omega) \quad \text{on } D, \\ u(\boldsymbol{x};\omega) &= 0 \quad \text{on } \partial D, \end{aligned} \tag{4.1}$$

where D is an open domain in the physical space with Lipschitz boundaries, $a(\boldsymbol{x};\omega)$ and $f(\boldsymbol{x};\omega)$ are second-order random processes. We assume $0 < \alpha_1 \le a(\boldsymbol{x};\omega) \le \alpha_2 < \infty$ almost everywhere on $\overline{D} \times \Omega$. Using the K-L expansion and following the procedure in [1], we assume that $a(\boldsymbol{x};\omega) \approx a(\boldsymbol{x};\boldsymbol{\xi}(\omega))$ and $f(\boldsymbol{x};\omega) \approx f(\boldsymbol{x};\boldsymbol{\xi}(\omega))$, where the same $\mathbb{R}^d$-valued random variable $\boldsymbol{\xi}$ with i.i.d. components is used for both $a(\boldsymbol{x};\omega)$ and $f(\boldsymbol{x};\omega)$ in their K-L expansions. We note here that the "i.i.d." assumption is strong since it is sufficient for the random variables in a K-L expansion to be mutually uncorrelated.

In each random element B_k we naturally have the following problem:

$$\begin{aligned} -\nabla \cdot (a(\boldsymbol{x};\boldsymbol{\xi}_k)\nabla u(\boldsymbol{x};\boldsymbol{\xi}_k)) &= f(\boldsymbol{x};\boldsymbol{\xi}_k) \quad \text{on } D, \\ u(\boldsymbol{x};\boldsymbol{\xi}_k) &= 0 \quad \text{on } \partial D. \end{aligned} \tag{4.2}$$

All previous assumptions on $a(\boldsymbol{x};\boldsymbol{\xi}_k)$ and $f(\boldsymbol{x};\boldsymbol{\xi}_k)$ are satisfied with respect to a conditional PDF $\hat{f}_k(\boldsymbol{\xi}_k|I_{B_k}=1)$. We note that such a system is complete on each random element B_k.

We define a bilinear form $\mathscr{B}(\cdot,\cdot)$ as

$$\mathscr{B}(u,v) = \int_{B_k} \hat{f}_k(\boldsymbol{\xi}_k|I_{B_k}=1) \int_D a(\boldsymbol{x};\boldsymbol{\xi}_k)\nabla u(\boldsymbol{x};\boldsymbol{\xi}_k)\cdot\nabla v(\boldsymbol{x};\boldsymbol{\xi}_k)\mathrm{d}\boldsymbol{x}\mathrm{d}\boldsymbol{\xi}_k \tag{4.3}$$

and a linear form $\mathscr{L}(\cdot)$ as

$$\mathscr{L}(v) = \int_{B_k} \hat{f}_k(\boldsymbol{\xi}_k|I_{B_k}=1) \int_D f(\boldsymbol{x};\boldsymbol{\xi}_k)v(\boldsymbol{x};\boldsymbol{\xi}_k)\mathrm{d}\boldsymbol{x}\mathrm{d}\boldsymbol{\xi}_k. \tag{4.4}$$

Due to the assumption on $a(\boldsymbol{x};\boldsymbol{\xi}_k)$ the space

$$W(D,B_k,\hat{f}_k) = \left\{v(\boldsymbol{x};\boldsymbol{\xi}_k)|\mathscr{B}(v,v) = \|v\|_W^2 < \infty \quad \forall v \in L_2(B_k)\otimes H_0^1(D)\right\} \tag{4.5}$$

is a Hilbert space. Using the Lax–Milgram theorem, we can claim that a unique solution $\hat{u}_k(\boldsymbol{x};\boldsymbol{\xi}_k)$ exists for the problem

$$\mathscr{B}(u,v) = \mathscr{L}(v) \quad \forall v \in W. \tag{4.6}$$

To this end, the gPC procedure can be readily employed in each element B_k on a truncated subspace $V^r \otimes V^p \subset W$to solve (4.2) [14, 32], where V^r indicates the local orthogonal basis $\{\Phi_{k,i}(\boldsymbol{\xi}_k)\}$ in the random space and V^p denotes the piecewise polynomial basis in the physical space. Once the local approximation is obtained, the global approximation can be constructed by Proposition 2.2.

Using a similar procedure ME-gPC can be readily applied to any differential equations with stochastic coefficients.

NUMERICAL SIMULATIONS IN 3D HEAT CONDUCTION: MINIMIZING THE QUADRATIC MEAN TEMPERATURE GRADIENT BY AN OPTIMALITY CRITERIA METHOD*

ALBERTO DONOSO†

Abstract. We analyze an optimal design problem in three-dimensional (3D) heat conduction: Given fixed amounts of two isotropic conducting materials, decide how we are to mix them in a 3D domain to minimize the quadratic mean temperature gradient. By using an optimality criteria method, we provide some numerical evidence that Tartar's result (see [in *Calculus of Variations, Homogenization and Continuum Mechanics*, G. Buttazzo, G. Bouchitte, and P. Suquet, eds., World Scientific, River Edge, NJ, 1994, pp. 279–296]) is verified in three dimensions when the target vector field is zero.

1. Introduction.

We consider the following optimal design problem in heat conduction: Given two isotropic conducting materials, with thermal conductivities α and β, $0 < \alpha < \beta$, decide on the best way to mix them in a simply connected design domain $\Omega \subset \mathrm{R}^3$ (and the emphasis is placed on the three-dimensional (3D) situation), so as to minimize the temperature gradient, ∇u, when the amounts of both materials are fixed and the body is subjected to the thermal load, f, and the temperature boundary condition, u_0.

Let us denote by (VP) the following problem:
Minimize

$$I(\chi) = \frac{1}{2}\int_\Omega |\nabla u(x)|^2\, dx$$

subject to

$$\begin{aligned} -\mathrm{div}((\alpha\chi(x) + \beta(1-\chi(x)))\nabla u(x)) &= f(x) \quad \text{in } \Omega, \\ u &= u_0 \quad \text{on } \partial\Omega, \\ \frac{1}{|\Omega|}\int_\Omega \chi(x)\, dx &= V_0, \quad 0 < V_0 < 1. \end{aligned}$$

Here $\Omega \subset \mathrm{R}^3$ is a simply connected regular domain. Typically, the characteristic function χ indicates where the α-material is to be placed, and V_0 is the relative volume fraction of the α-material, which is given.

It is well known that such problems lack optimal solutions within the class of characteristic functions [9]. In such cases, the optimal design is obtained by placing a graded material, that is to say, a two-component composite characterized by a gradual variation from the α-material to the β-material. The analysis when the cost functional

does not explicitly depend on derivatives of the temperature has been carried out by means of the theory of homogenization. Some recent nice accounts are [1] and [4]. Another interesting reference in the context of elastic structures is [2], where both problems, the minimization of the compliance for multiple surface loadings (in two and three dimensions) and the maximization of the first eigenfrequency, are addressed. Quadratic functionals on ∇u, like the one above, have been explored (see [7], [8], [11]), trying to extend the ideas of homogenization and H-convergence to treat this more general situation.

There exists another recent perspective to tackle the design problem. The idea is based on introducing a suitable potential to reformulate the problem as a vector variational problem and, afterwards, relax the reformulated problem by computing the explicit quasi convexification. For the 3D case we present, explicit formulae of the relaxed integrand have been recently computed in [5], and it has also been possible for a general quadratic functional in two dimensions (see [10]). In all of these cases, the relaxed integrands take the value $+\infty$ in a certain domain. This makes us think that it could complicate the numerical treatment of the relaxed problem. On the other hand, we also think it could be interesting to develop a tool which allow us to analyze in a systematic way this kind of design problem under this approach.

The pioneering work [11] addressed for the first time this optimal design problem. One of the main achievements was to conclude that for F in a dense G_δ, but unknown set of L^2, the optimization problem, $(\widetilde{VP})$,

Minimize:

$$I(t) = \frac{1}{2}\int_\Omega |\nabla u(x) - F(x)|^2 \, dx$$

subject to

$$\begin{aligned} -\mathrm{div}((\alpha t(x) + \beta(1-t(x)))\nabla u(x)) &= f(x) \quad \text{in } \Omega, \\ u &= u_0 \quad \text{on } \partial\Omega, \\ \frac{1}{|\Omega|}\int_\Omega t(x)\, dx &= V_0, \quad 0 < V_0 < 1, \end{aligned}$$

where the function $t(x)$ is now constrained by

$$0 \le t(x) \le 1,$$

admits optimal solutions. Moreover, if the pair $(\tilde{u},\tilde{t})$ is an optimal solution for $(\widetilde{VP})$, optimal structures for (VP) (when a target vector field, F, is considered) are locally first-order laminates with local volume fraction $\tilde{t}(x)$, the temperature gradient, $\nabla\tilde{u}$, is perpendicular to the direction of lamination, and all minimizing sequences of temperature gradients converge strongly in L^2.

Our approach has consisted of obtaining and solving optimality conditions for $(\widetilde{VP})$ when $F \equiv 0$. We have not been able to show that $(\widetilde{VP})$ has optimal solutions. This is essentially Tartar's result in [11] for such a G_δ set as explained before, but for that particular case ($F \equiv 0$) we provide some numerical evidence that the zero field belongs to that G_δ set. In all experiments we have conducted the convergence was fine and the simulations stable and robust. Under these circumstances, we suspect that the infima of $(\widetilde{VP})$ are, in fact, minima. This is our main contribution with this paper. In fact this same evidence also holds for a general quadratic functional. All

these numerical experiments have been carried out for the two-dimensional (2D) case in [6].

It is worth emphasizing that in this paper, the 3D case of a variational problem in the presence of gradients in the objective function is treated for the first time, as far as the author knows.

The motivation for solving (VP) is the design of macroscopic thermal conducting devices, made up of graded materials with desired properties under the action of the thermal load, f, and the value of the temperature, u_0, on the boundary. In this case, we measure the dissipated energy by means of minimizing the quadratic mean temperature gradient.

The work is organized as follows. We begin obtaining optimality conditions for $(\widetilde{VP})$. Later, we explain how to solve the nonlinear resulting system and, finally, show different numerical examples, changing the source term, f, the relative volume fraction, V_0, and the contrast ratio (β/α).

2. Numerical approach: Optimality conditions. There are mainly two types of iterative methods [1] in optimal design, both of which alternate evaluations of the state and the adjoint state and also update the design parameters. The first type is the so-called . Its principle is to use optimality conditions to update the design parameters. This is a very popular method commonly used in the structural engineering community (see [4] and the references therein). The second method is more classical and is based on gradient information. Although it can include several variants to improve properties concerning convergence, it is well known as the . There is a vast literature on this kind of descent method (see, for instance, [3] and the references therein). It is important to notice that in [8] a gradient-based optimization scheme was developed for the same design problem considered here but in the 2D context. In that work it is shown that the numerically optimized designs support Tartar's result [11] in two dimensions when the target vector field is zero. In this work an optimality criteria method is used to solve the design problem in the 3D situation.

Looking back to the design problem, we can state that if $(\widetilde{VP})$ admits optimal solutions, they can be approximated by using the necessary conditions of optimality.

PROPOSITION 2.1. f u_0 α β V_0 $\widetilde{VP}$

$$
\begin{aligned}
-\operatorname{div}((\alpha t(x)+\beta(1-t(x)))\nabla u(x)) &= f(x) \quad \Omega,\\
u &= u_0 \quad \partial\Omega,\\
-\operatorname{div}((\alpha t(x)+\beta(1-t(x)))\nabla p(x)) &= -\Delta u(x) \quad \Omega,\\
p &= 0 \quad \partial\Omega,\\
(\beta-\alpha)\nabla u(x)\nabla p(x) &= \lambda_1(x)-\lambda_2(x)+\lambda_3,\\
\lambda_1(x)t(x) &= 0, \quad \lambda_1(x)\geq 0, \quad t(x)\geq 0,\\
\lambda_2(x)(t(x)-1) &= 0, \quad \lambda_2(x)\geq 0, \quad t(x)\leq 1,\\
\frac{1}{|\Omega|}\int_\Omega t(x)\,dx &= V_0.
\end{aligned}
$$

The numerical algorithm used works in a simple way: Given an admissible control t_k at iteration step k, we solve the state equation to obtain the gradient ∇u_k and, using both, we get ∇p_k. Having in mind that for intermediate controls[1] $(0<t_k<1)$,

[1] In fact, the control can be as close to either of the extreme values, 0 and 1, as we wish.

$\lambda_1 = \lambda_2 = 0$ and hence

$$\frac{(\beta-\alpha)\nabla u \nabla p}{\lambda_3} = 1,$$

we choose as the iterative sequence a heuristic updating scheme [4], $t_{k+1} = 1 - G_k(1 - t_k)$ to update[2] the control, where $G_k = \frac{(\beta-\alpha)\nabla u_k \nabla p_k}{\lambda_{3,k}}$ (notice that when $G_k \to 1$, then $t_{k+1} \to t_k$). Since the update t_{k+1} depends on the present value of the Lagrange multiplier $\lambda_{3,k}$, then $\lambda_{3,k}$ must be adjusted in an inner iteration loop by using, for example, a bisection method, to ensure that since t_{k+1} verifies the volume constraint at iteration step $k+1$. In this case since

$$\int_\Omega t_{k+1}\, dx = \int_\Omega (1 - G_k(1-t_k))\, dx = \int_\Omega \left(1 - \frac{(\beta-\alpha)\nabla u_k \nabla p_k}{\lambda_{3,k}}(1-t_k)\right)\, dx = V_0|\Omega|,$$

we arrive at

$$\frac{1}{\lambda_{3,k}} \int_\Omega (\beta-\alpha)\nabla u_k \nabla p_k (1-t_k)\, dx = (1-V_0)|\Omega| > 0 \tag{1}$$

and find that

$$\lambda_{3,k} = \frac{\int_\Omega (\beta-\alpha)\nabla u_k \nabla p_k (1-t_k)\, dx}{(1-V_0)|\Omega|}.$$

As we mentioned, there are several type of gradient algorithms. The simplest would be a fixed step-size descent method. In such a case the control must be updated by (in a compacted way)

$$t_{k+1} = \max(0, \min(1, t_k - I'(t_k) s_k)),$$

where s_k is a small step such that $I(t_{k+1}) < I(t_k)$, and $I'(t_k)$ is the gradient of the objective function with respect to the control, easily computed as

$$I'(t_k) = (\alpha - \beta)\nabla u_k \nabla p_k + \lambda_{3,k}.$$

Therefore, when $G_k \to 1$, this in fact means that $I'(t_k) \to 0$, and we have converged, at least, to a local minimum. Moreover, having in mind that $I'(t_k) = \lambda_{3,k}(1 - G_k)$, it is easy to prove that the heuristic updating scheme, $t_{k+1} = 1 - G_k(1-t_k)$, and the fixed step-size descent method, $t_{k+1} = t_k - I'(t_k)s_k$, are identically the same by taking $s_k = \frac{(t_k - 1)}{\lambda_{3,k}}$.

The general iteration scheme used for obtaining all numerical results presented in this work has the following form.

START At iteration k, take an admissible control t_k, such as $0 < t_k < 1$, and let $\int_\Omega t_k\, dx = V_0|\Omega|$.

Step 1: Given t_k, obtain ∇u_k by solving the state equation,

$$\begin{aligned} -\mathrm{div}((\alpha t_k + \beta(1-t_k))\nabla u_k) &= f \quad \text{in } \Omega, \\ u_k &= u_0 \quad \text{on } \partial\Omega. \end{aligned}$$

[2]Notice that in the design problems addressed in [4] under optimality criteria the law used to update the control is $t_{k+1} = G_k t_k$, and the control t corresponds to the β-material property in the state equation. Following the same idea, we have chosen the law $1 - t_{k+1} = G_k(1-t_k)$ because $(1-t)$ now accompanies the β-material property in the state equation.

Step 2: Get ∇p_k by solving the adjoint state equation,

$$\begin{aligned} -\mathrm{div}((\alpha t_k + \beta(1-t_k))\nabla p_k) &= -\mathrm{div}(\nabla u_k) \quad \text{in } \Omega, \\ p_k &= 0 \quad \text{on } \partial\Omega. \end{aligned}$$

Step 3: Compute the Lagrange multiplier, $\lambda_{3,k}^j$, as

$$\lambda_{3,k}^j = \frac{\int_\Omega (\beta-\alpha)\nabla u_k \nabla p_k (1-t_k^j)\, dx}{(1-V_0)|\Omega|},$$

in such a way that $t_k^{j+1} = 1 - G_k^j(1-t_k^j)$ verifies the volume constraint.

Step 4: Update t_k^{j+1} as

$$t_k^{j+1} = \begin{cases} 1 - \frac{1-t_k^j}{2} & \text{if} \quad G_k^j(1-t_k^j) \le \frac{1-t_k^j}{2}, \\ 1 - G_k^j(1-t_k^j) & \text{if} \quad \frac{1-t_k^j}{2} \le G_k^j(1-t_k^j) \le \frac{1+(1-t_k^j)}{2}, \\ 1 - \frac{1+(1-t_k^j)}{2} & \text{if} \quad \frac{1+(1-t_k^j)}{2} \le G_k^j(1-t_k^j). \end{cases}$$

Step 5: Ensure that $\int_\Omega t_k^{j+1}\, dx = V_0|\Omega|$. If the volume constraint is verified, go to **Step 6** and $t_{k+1} = t_k^{j+1}$. Otherwise, go to **Step 3** ($j \leftarrow j+1$) and calculate the new $\lambda_{3,k}^{j+1}$.

Step 6: Stopping criteria: $|I(t_{k+1}) - I(t_k)| \le tol$. If it is not verified, go to **Step 1** ($k \leftarrow k+1$).

END

We have solved both the state equation and the adjoint one (Steps 1 and 2) by minimizing their associated energy functional and have approached them by using piecewise linear basis functions and finite differences.

By using the fixed point scheme for the control (Step 4), each design variable is updated independently of the update of the other design variables, except for the rescaling (Step 5) that has to take place to satisfy the volume constraint [4]. Instead of using the ("more natural") updating $t_{k+1} = \max(0, \min(1, 1 - G_k(1-t_k)))$, the adjustment process of Step 4 allows the control to converge in a more gradual way, ensuring that at iteration step $k+1$, $0 < t_{k+1} < 1$. In the inner loop (Steps 2, 3, and 4), $\lambda_{3,k}$ is adjusted in order to satisfy the volume constraint.

Finally, it is not hard to realize that the function used to adjust the volume constraint, $g(\lambda_{3,k}) = \int_\Omega t_{k+1}(\lambda_{3,k})\, dx - V_0|\Omega|$, has a continuous monotone dependence on the Lagrange multiplier, $\lambda_{3,k}$. We can convince ourselves by taking into account the expression (1). If $\int_\Omega (\beta-\alpha)\nabla u_k \nabla p_k (1-t_k)\, dx > 0$, then $\lambda_{3,k} > 0$, and the function g is strictly decreasing. By contrast, when $\int_\Omega (\beta-\alpha)\nabla u_k \nabla p_k (1-t_k)\, dx < 0$, then $\lambda_{3,k} < 0$ and the function g is strictly increasing; thus we can use the bisection method to determine when the function becomes zero in both situations (see Figure 1).

The stability and robustness of the algorithm have been tested by running the same numerical examples with different mesh sizes and different starting points, respectively, obtaining very similar results. This let us conclude that $(\widetilde{VP})$ admits, first, optimal solutions (this indicates existence) and, second, uniqueness. Concerning the convergence, it has been checked that the objective function slightly changes its value and therefore, the L^∞-norm of the difference $I(t_{k+1}) - I(t_k)$ reduces to zero, as we approach the minimum. All numerical examples belonging to this work, with the

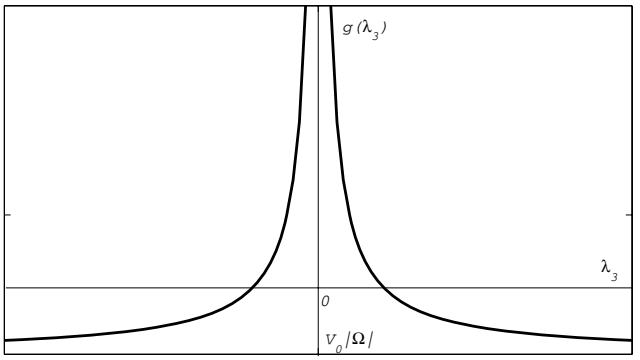

FIG. 1. *Volume adjustment using the bisection method.*

exception of the first one, have been obtained under the stopping criteria, $tol = 10^{-4}$, requiring for convergence about 100 iterations of the algorithm, on average. However, when plotting the density map, a "visual" convergence is reached long before this, in about 40 iterations.

3. Numerical examples. We illustrate our approach through several numerical examples. In all of them, the design domain is chosen to be the cube $\Omega = [0,1]^3$ which is subdivided into 125,000 tetrahedric subdomains (a mesh of $50 \times 50 \times 50$ nodes). Although it is known that the optimal solution is given by a locally first-order laminate, in some areas the best choice is to place a pure phase, as we will see later. The following numerical simulations show optimal layouts when the value of the temperature is fixed on the boundary and also constant, $u_0 = 0$, and the thermal load applied over the body is always positive. Therefore, intuition tells us that the material with higher conductivity should be placed where the outward heat flux is also higher in order to drain the energy away and hence minimize the temperature gradient inside the body.

In the first example the source term is uniform in Ω, for example, $f(x) = 1$, and the material properties take the values $\alpha = 1$ and $\beta = 2$. We have constrained the amount of β (best conductor) to be 40% of the design domain (it corresponds to taking $V_0 = 0.6$). A graded scale has been used to represent the optimal solution (see Figure 2(a)) where aqua would correspond to the α-material and pink to the β-material. The regions of graded properties are given by intermediate shades. In such zones, it is necessary to know the direction of the laminates. This information is provided by Figure 2(c), where the contours are the level surfaces of the temperature. Note that the direction of the laminates is tangential to the level surfaces, hence perpendicular to the temperature gradient. Contrary to what happened in two dimensions [6], now the direction of lamination, n, is contained in the manifold of normal ∇u, so, at first, we have infinite possibilities, that is, first-order laminates with different n but with the same functional value. We have tried to indicate this microstructural behavior in the two points A and B in Figure 2(b).

In Figure 2(a) a half-section of the body is depicted in order to see the internal details. In Figures 2(d), 2(e), and 2(f), some sections are also shown in order to understand better what happens as we look inside. For this example, the i-level indicates the i-slice in any characteristic direction because of the symmetry in the input data. The convergence history for the objective function and for the residual term is also included in Figures 3(a) and 3(b), respectively ($tol = 10^{-5}$).

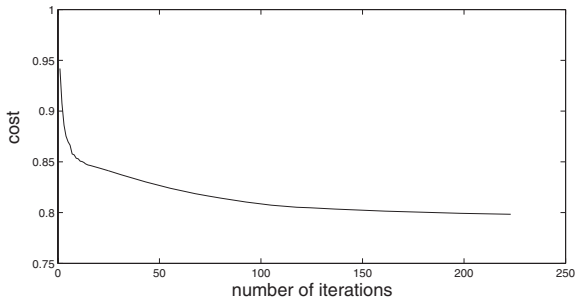
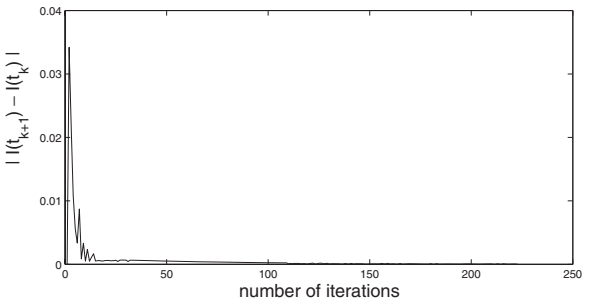
FIG. 2. *Optimal solution of Example* 1.



(a) Objective function



(b) Residual term

FIG. 3. *Convergence history of Example* 1.

As commented before, very similar results are obtained when different mesh sizes and different starting points are used. Although this numerical analysis has been carried out for all examples included in this work, we show such comparisons only for the previous example (Example 1 but now with $V_0 = 0.5$), while in the following examples, only the optimal design (obtained for the homogeneous distribution as a starting point and for a mesh size of $50 \times 50 \times 50$) is shown.

Concerning the existence of solutions, we run the same example for three different mesh sizes. The numerical simulations are shown in Figure 4. Judging from the numerical results, there exists clear numerical evidence that the design problem has optimal solutions.

Now we run the same example by using different starting points, verifying the volume constraint (at starting point 1 there is a homogeneous distribution (Figure 5(a)), at 2 the β-material occupys the upper half of the body (Figure 5(b)), and at 3 the β-material is in a centered cube (Figure 5(c))). Judging from their respective numerical results (Figures 5(d), 5(e), and 5(f)), we can state that there exists clear numerical evidence about the uniqueness of the optimal solution. The convergence plots for the objective function and for the three starting points are shown in Figure 6.

In the second example we have taken $f(x) = e^{-100|x-\frac{1}{2}|^2}$, $V_0 = 0.6$, $\alpha = 1$, $\beta = 2$. As before, a half-section (Figure 7(a)) and the isosurfaces of temperature (Figure 7(b)) are included to understand the internal layout of the body and how the

optimal graded material must be built. Again, due to the symmetry of the example, the i-level indicates the i-slice in any characteristic direction (see Figures 7(c), 7(d), and 7(e)).

Now we see the influence of changing the relative volume fraction V_0 when heat is generated only in a centered cube; namely, the thermal load is given by

$$f(x) = \begin{cases} 1 & \text{if } x \in \left(\frac{1}{4}, \frac{3}{4}\right)^3, \\ 0 & \text{else.} \end{cases}$$

We maintain the same values in the material properties, $\alpha = 1$, $\beta = 2$. As we can ap-

preciate for this particular example, less graded areas appear as the relative volume fraction decreases (see Figure 8).

Finally we see the influence of varying the contrast ratio (β/α). The source term is the same as that used in the first example. In this case, more graded areas appear as the ratio increases (see Figure 9).

ADAPTIVITY IN SPACE AND TIME FOR REACTION-DIFFUSION SYSTEMS IN ELECTROCARDIOLOGY*

PIERO COLLI FRANZONE†, PETER DEUFLHARD‡, BODO ERDMANN‡, JENS LANG§, AND LUCA F. PAVARINO¶

Abstract. The paper introduces and studies numerical methods that are fully adaptive in both three-dimensional (3D) space and time to challenging multiscale cardiac reaction-diffusion models. In these methods, temporal adaptivity comes via stepsize control in function space oriented linearly implicit time integration, while spatial adaptivity is realized within multilevel finite element methods controlled by a posteriori local error estimators. In contrast to other recent adaptivity approaches to cardiac modeling that discretize first in space and then in time (so-called method of lines), our method discretizes first in time and then in space (so-called Rothe method)—an approach that has already proven to be highly efficient in a number of challenging multiscale problems in science and technology (KARDOS code library). With this method, the evolution of a complete heartbeat, from the excitation to the recovery phase, is simulated both in the frame of the anisotropic monodomain models and in the more realistic anisotropic bidomain models, coupled with either a variant of the simple FitzHugh–Nagumo model or the more complex phase-I Luo–Rudy ionic model. The numerical results exhibit a rather satisfactory performance of our adaptive method for complex cardiac reaction-diffusion models on 3D domains up to moderate sizes. In particular, the method accurately resolves the evolution of the intra- and extracellular potentials, gating variables, and ion concentrations during the excitation, plateau, and recovery phases.

Key words. reaction-diffusion equations, cardiac bidomain and monodomain models, adaptive finite elements, multilevel methods, error estimates, adaptive time integration, adaptive Rothe method

1. Introduction.

Recent advances in contemporary cardiac electrophysiology are progressively revealing the complex multiscale structure of the bioelectrical activity of the heart, from the microscopic activity of ion channels of the cellular membrane to the macroscopic properties of the anisotropic propagation of excitation and recovery fronts in the whole heart; see, e.g., Zipes and Jalife [59], Kléber and Rudy [31], and Panfilov and Holden [43]. In recent years, the experimental study of these complex phenomena has been accompanied by mathematical and physical modeling and numerical simulation. The most complete of these models describes the cardiac tissue by a reaction-diffusion system of PDEs (the bidomain model), coupled with a system of ODEs (e.g., Luo–Rudy ionic models) modeling the ionic currents associated with the reaction terms.

Due to their inherent multiscale structure in both time and space, the numerical simulation of such models will be quite expensive. In space, meaningful portions of

cardiac tissue have sizes in the cm regime, while the steep excitation front requires discretizations of the order of 0.1 mm—which results in a spatial scale spread factor of up to 10^3. In time, a normal heartbeat takes about 1 sec, while the time constants of the involved rapid kinetics range from 0.1 to 500 msec, requiring in some phases computational time steps of about 0.001 msec (or even less when currents or shocks are applied); we thus have a temporal scale spread factor of up to 10^6. Hence, realistic three-dimensional (3D) models employing , , grids will give rise to discrete problems with $\mathcal{O}(10^7)$ unknowns per time step—with simulations running over a huge number of time steps. As a remedy for the spatial spreading, algorithmic speedup by parallelism, domain decomposition, or adaptive mesh refinement is in the toolbox; for the time spreading, adaptive time-step control must be implemented. For large scale , , simulations, see, e.g., Colli Franzone and Pavarino [11], Pavarino and Colli Franzone [44], and Colli Franzone, Pavarino, and Taccardi [12]; for the use of some in parabolic reaction-diffusion systems, see, e.g., Cherry, Greenside, and Henriquez [8], Yu [57], and Trangenstein and Kim [53] in two space dimensions and Moore [40] or Lines, Grøttum, and Tveito [37] in two and three dimensions. All of these papers use a (discretization first in space and then in time). In contrast, the present authors have strong arguments, both theoretical and practical, to favor a (discretization first in time and then in space) within a multilevel finite element setting. As for the Rothe approach, see the first pioneering paper [6] by Bornemann for linear parabolic equations and its generalization to realistic nonlinear parabolic systems of PDEs by Lang [32], where the efficient solution of an impressive number of challenging problems from science and technology has also been documented. As for a detailed computational comparison between both approaches (including adaptivity), see, e.g., the survey paper [17] by Deuflhard, Lang, and Nowak. It is the purpose of the present paper to apply this elsewhere rather successful kind of method to the challenging class of cardiac models. For the mere purpose of just evaluating the algorithms in this special PDE context, we decided to start with quite simple 3D geometries. Clearly, once the method has proven to be useful, we will turn to real-world geometries from medical imaging input—see, e.g., work by the ZIB group in other fields of computational medicine [19, 33, 21, 58].

We consider both the anisotropic monodomain and bidomain models, coupled with either a variant of the simple FitzHugh–Nagumo model or the more complex phase-I Luo–Rudy ionic model. We simulate the evolution of a complete heartbeat, from the excitation (depolarization) phase to the following plateau and recovery (repolarization) phases. Our simulations are performed with the KARDOS code library [20, 2] that realizes the above Rothe method in an adaptive multilevel finite element setting. Note that most simulations in computational electrocardiology are based on the simpler monodomain model, while here we also consider the full bidomain system in three dimensions. The few other bidomain simulations presented in the literature often employ simplifications of the model, such as two-dimensional (2D) domains, simpler ionic models, operator splitting of the elliptic-parabolic formulation of the bidomain system, coarser time or space mesh size for the elliptic subproblem, etc.; out of the bulk of literature we mention Colli Franzone, Guerri, and Rovida [10], Colli Franzone and Guerri [9], Roth [48], Hooke et al. [28], Pormann [46], Henriquez [25], Henriquez, Muzikant, and Smoak [26], and Muzikant et al. [42], Vigmond, Aguel, and Trayanova [55], Sambelashvili and Efimov [49], Ashihara et al. [3], Dos Santos et al. [56], Murillo and Cai [41], Pennacchio and Simoncini [45], and Sundnes et al. [52].

The paper is organized as follows. In section 2, we introduce the standard model of cardiac tissue, including its fiber structure and conductivity tensors, the anisotropic

bidomain model for the intra- and extracellular potentials, and the simpler anisotropic monodomain model. Moreover, the basic ideas of cellular ionic models of Hodgkin–Huxley type are reviewed, focusing on a FitzHugh–Nagumo variant and the phase-I Luo–Rudy model that will be employed in our cardiac model. In section 3, we describe the adaptive numerical discretization of our models as realized within the KARDOS code library, focusing on the adaptive time discretization by linearly implicit methods and the adaptive multilevel finite elements employed in the space discretization. Finally, in section 4, we present the results of several numerical experiments in three space dimensions and discuss the gain due to adaptivity. All 3D visualizations in this paper have been created using Amira—a system for advanced visual data analysis; see [1, 50].

2. Cardiac reaction-diffusion models. In this section, we collect details about the cardiac models, including the membrane models as far as we have chosen them for our simulations.

2.1. Cardiac fibers and conductivity tensors. The cardiac ventricular tissue can be modeled as an arrangement of cardiac fibers which rotate counterclockwise from epi- to endocardium (Streeter [51]) and which has a laminar organization modeled as a set of muscle sheets running radially from epi- to endocardium (LeGrice, Smaill, and Hunter [36]). Therefore, at every point $\mathbf{x}$ it is possible to identify a triplet of orthonormal principal axes $\mathbf{a}_l(\mathbf{x})$, $\mathbf{a}_t(\mathbf{x})$, $\mathbf{a}_n(\mathbf{x})$, with $\mathbf{a}_l(\mathbf{x})$ parallel to the local fiber direction, $\mathbf{a}_t(\mathbf{x})$ and $\mathbf{a}_n(\mathbf{x})$ tangent and orthogonal to the radial laminae, respectively, and both being transversal to the fiber axis.

The macroscopic bidomain model represents the cardiac tissue as the superposition of two anisotropic continuous media, the intra- (i) and extra- (e) cellular media, coexisting at every point of the tissue and separated by a distributed continuous cellular membrane; see, e.g., Henriquez [25] and Keener and Sneyd [30]. Denoting by $\sigma_l^{i,e}$, $\sigma_t^{i,e}$, $\sigma_n^{i,e}$ the conductivity coefficients in the intra- and extracellular media measured along the corresponding directions $\mathbf{a}_l, \mathbf{a}_t, \mathbf{a}_n$, the anisotropic conductivity tensors $D_i(\mathbf{x})$ and $D_e(\mathbf{x})$ related to [illegible] of the media are given by

$$D_{i,e}(\mathbf{x}) = \sigma_l^{i,e}\, \mathbf{a}_l(\mathbf{x})\mathbf{a}_l^T(\mathbf{x}) + \sigma_t^{i,e}\, \mathbf{a}_t(\mathbf{x})\mathbf{a}_t^T(\mathbf{x}) + \sigma_n^{i,e}\, \mathbf{a}_n(\mathbf{x})\mathbf{a}_n^T(\mathbf{x}). \tag{2.1}$$

For [illegible] anisotropic media, $\sigma_n^{i,e} = \sigma_t^{i,e}$, we have

$$D_{i,e}(\mathbf{x}) = {\sigma_t}^{i,e} I + ({\sigma_l}^{i,e} - {\sigma_t}^{i,e})\mathbf{a}_l(\mathbf{x})\mathbf{a}_l^T(\mathbf{x}).$$

2.2. Anisotropic bidomain (B) model. The intra- and extracellular electric potentials u_i, u_e in the anisotropic bidomain model are described by a reaction-diffusion system coupled with a system of ODEs for ionic gating variables w and for ion concentrations c. We denote by $v = u_i - u_e$ the transmembrane potential and by

$$I_m = c_m \frac{\partial v}{\partial t} + I_{ion}(v, w, c)$$

the membrane current per unit volume, where $c_m = \chi * C_m$, $I_{ion} = \chi * i_{ion}$, with χ the ratio of membrane area per tissue volume, C_m the surface capacitance, and i_{ion} the ionic current of the membrane per unit area. Let I_{app}^e be an applied extracellular current per unit volume, satisfying the compatibility condition $\int_\Omega I_{app}^e \,\mathrm{dx} = 0$, and $\mathbf{j}_{i,e} = -D_{i,e}\nabla u_{i,e}$ the intra- and extracellular current density. Due to the current conservation law, we have

$$\operatorname{div} \mathbf{j}_i = -I_m, \qquad \operatorname{div} \mathbf{j}_e = I_m - I_{app}^e.$$

Then the anisotropic bidomain model in the unknown potentials $(u_i(\mathbf{x},t), u_e(\mathbf{x},t))$ and $v(\mathbf{x},t) = u_i(\mathbf{x},t) - u_e(\mathbf{x},t)$, gating variables $w(\mathbf{x},t)$, and ion concentrations $c(\mathbf{x},t)$ can be written as

$$
\begin{aligned}
& c_m \partial_t v - \operatorname{div}(D_i \nabla u_i) + I_{ion}(v,w,c) = 0 && \text{in } \Omega \times (0,T),\\
& -c_m \partial_t v - \operatorname{div}(D_e \nabla u_e) - I_{ion}(v,w,c) = -I^e_{app} && \text{in } \Omega \times (0,T),\\
& \partial_t w - R(v,w) = 0, \quad \partial_t c - S(v,w,c) = 0 && \text{in } \Omega \times (0,T),\\
& \mathbf{n}^T D_{i,e} \nabla u_{i,e} = 0 && \text{in } \partial\Omega \times (0,T),\\
& v(\mathbf{x},0) = v_0(\mathbf{x}), \quad w(\mathbf{x},0) = w_0(\mathbf{x}), \quad c(\mathbf{x},0) = c_0(\mathbf{x}) && \text{in } \Omega,
\end{aligned}
\tag{2.2}
$$

where we have imposed insulated boundary conditions. The system uniquely determines v, while the potentials u_i and u_e are defined only up to a same additive time-dependent constant relating to the reference potential. This potential is chosen to be the average extracellular potential in the cardiac volume by imposing $\int_\Omega u_e \, \mathrm{dx} = 0$. We refer the reader to [13] for a mathematical analysis of the bidomain model. In the following, we will consider as ionic membrane models some Luo–Rudy models which are briefly recalled in section 2.4; (see Luo and Rudy [39]). These models specify the reaction term I_{ion} and the functions $R(v,w)$ and $S(v,w,c)$ determining the evolution of the gating variables w and the ion concentrations c.

In terms of the transmembrane and extracellular potentials $v(\mathbf{x},t)$ and $u_e(\mathbf{x},t)$, we obtain the following equivalent formulation of the reaction-diffusion equations of the anisotropic bidomain model:

$$
\begin{aligned}
& c_m \partial_t v + I_{ion}(v,w,c) + \operatorname{div}(D_e \nabla u_e) = I^e_{app} && \text{in } \Omega \times (0,T),\\
& -\operatorname{div}((D_i + D_e)\nabla u_e) = \operatorname{div}(D_i \nabla v) - I^e_{app} && \text{in } \Omega \times (0,T).
\end{aligned}
\tag{2.3}
$$

2.3. Anisotropic monodomain (M) model. If we assume equal anisotropy ratio of the two media, it is well known that the bidomain system reduces to the monodomain model. We shall mention here another interesting derivation of a reduced bidomain model which does not make such an assumption and that we will still call monodomain model. Denoting by $J_{tot} = \mathbf{j}_i + \mathbf{j}_e$ the total current flowing in the two media, since $J_{tot} = -D_i \nabla u_i - D_e \nabla u_e$, substituting $u_i = v + u_e$, we get

$$
\nabla u_e = -D^{-1} D_i \nabla v - D^{-1} J_{tot}, \tag{2.4}
$$

with $D = D_i + D_e$. Therefore, the first equation in the bidomain system can be written as

$$
-c_m \partial_t v + \operatorname{div}(D_e D^{-1} D_i \nabla v) + \operatorname{div}(D_e D^{-1} J_{tot}) - I_{ion}(v,w) = -I^e_{app}. \tag{2.5}
$$

Since the tensors (2.1) can be written as

$$
D_{i,e}(\mathbf{x}) = \sigma_l^{i,e} I + (\sigma_t^{i,e} - \sigma_l^{i,e}) \mathbf{a}_t(\mathbf{x}) \mathbf{a}_t^T(\mathbf{x}) + (\sigma_n^{i,e} - \sigma_l^{i,e}) \mathbf{a}_n(\mathbf{x}) \mathbf{a}_n^T(\mathbf{x}),
$$

then

$$
D_e D^{-1} = \mu_l^e I + (\mu_t^e - \mu_l^e) \mathbf{a}_t(\mathbf{x}) \mathbf{a}_t^T(\mathbf{x}) + (\mu_n^e - \mu_l^e) \mathbf{a}_n(\mathbf{x}) \mathbf{a}_n^T(\mathbf{x}), \tag{2.6}
$$

with $\mu^e_{l,t,n} = \sigma^e_{l,t,n}/(\sigma^e_{l,t,n} + \sigma^i_{l,t,n})$. Assuming constant conductivity coefficients and taking into account that $\operatorname{div} J_{tot} = -I^e_{app}$, we have

$$\begin{aligned}\operatorname{div}(D_e D^{-1} J_{tot}) &= \mu^e_l \operatorname{div} J_{tot} + (\mu^e_t - \mu^e_l)\operatorname{div}(\mathbf{a}_t(\mathbf{x})\mathbf{a}^T_t(\mathbf{x})J_{tot}) \\ &\quad + (\mu^e_n - \mu^e_l)\operatorname{div}(\mathbf{a}_n(\mathbf{x})\mathbf{a}^T_n(\mathbf{x})J_{tot}) \\ &= -\mu^e_l I^e_{app} + (\mu^e_t - \mu^e_l)\operatorname{div}(\mathbf{a}_t(\mathbf{x})\mathbf{a}^T_t(\mathbf{x})J_{tot}) \\ &\quad + (\mu^e_n - \mu^e_l)\operatorname{div}(\mathbf{a}_n(\mathbf{x})\mathbf{a}^T_n(\mathbf{x})J_{tot}.\end{aligned} \tag{2.7}$$

From (2.4) it follows that $-D_e D^{-1} D_i \nabla v = D_e D^{-1} J_{tot} + D_e \nabla u_e$, and hence the flux relationship

$$\mathbf{n}^T D_e D^{-1} D_i \nabla v = \mathbf{n}^T D_e D^{-1} J_{tot} + \mathbf{n}^T D_e \nabla u_e. \tag{2.8}$$

Using (2.6), the first term on the right-hand side can be written as

$$\mathbf{n}^T (D_e D^{-1} J_{tot}) = \mu^e_l \mathbf{n}^T J_{tot} + (\mu^e_t - \mu^e_l)(\mathbf{n}^T \mathbf{a}_t)(\mathbf{a}^T_t J_{tot}) + (\mu^e_\nu - \mu^e_l)(\mathbf{n}^T \mathbf{a}_\nu)(\mathbf{a}^T_\nu J_{tot}).$$

The insulating conditions $\mathbf{n}^T \mathbf{j}_i = \mathbf{n}^T \mathbf{j}_e = 0$ imply $\mathbf{n}^T J_{tot} = 0$, i.e., J_{tot} is tangent to $\partial\Omega$, and assuming that the fibers are also tangent to $\partial\Omega$, we have $\mathbf{n}^T \mathbf{a}_\nu = 0$ and $\mathbf{a}^T_t J_{tot} = 0$. Substituting these conditions into (2.8) it follows the monodomain boundary condition

$$\mathbf{n}^T D_e D^{-1} D_i \nabla v = 0. \tag{2.9}$$

Disregarding the two additional terms in (2.7) related to the projections of J_{tot} onto the directions across fiber $\mathbf{a}_t$ and $\mathbf{a}_n$ (which disappear for media having equal anisotropic ratio $\mu^e_l = \mu^e_t = \mu^e_n$), it results that $\operatorname{div}(D_e D^{-1} J_{tot}) \approx -\mu^e_l I^e_{app}$. Substituting this approximation into (2.5) and considering the boundary condition (2.9), we obtain the anisotropic monodomain model consisting of a single parabolic reaction-diffusion equation for v with the conductivity tensor $D_m = D_e D^{-1} D_i$, $I^m_{app} = I^e_{app}\sigma^i_l/(\sigma^e_l + \sigma^i_l)$ and coupled with the same gating system

$$\begin{aligned}&c_m \partial_t v - \operatorname{div}(D_m \nabla v) + I_{ion}(v, w, c) = I^m_{app} && \text{in } \Omega \times (0,T), \\ &\partial_t w - R(v, w) = 0, \quad \partial_t c - S(v, w, c) = 0 && \text{in } \Omega \times (0,T), \\ &\mathbf{n}^T D_m \nabla v = 0 && \text{in } \partial\Omega \times (0,T), \\ &v(\mathbf{x}, 0) = v_0(\mathbf{x}), \quad w(\mathbf{x}, 0) = w_0(\mathbf{x}), \quad c(\mathbf{x}, 0) = c_0(\mathbf{x}) && \text{in } \Omega.\end{aligned} \tag{2.10}$$

From the knowledge of the distribution of $v(\mathbf{x}, t)$ the extracellular potential distribution u_e is derived by solving the elliptic boundary value problem

$$-\operatorname{div}(D\nabla u_e) = \operatorname{div}(D_i \nabla v), \qquad -\mathbf{n}^T D \nabla u_e = \mathbf{n}^T D_i \nabla v.$$

2.4. Membrane models and ionic currents. Following the celebrated work by Hodgkin and Huxley [27] (1963 Nobel Prize in Medicine) on nerve action potential, many models of Hodgkin–Huxley type have later been developed for the cardiac action potential. In these models, the ionic current through channels of the membrane, due to the transmembrane potential v and the M gating and Q ionic concentration variables $w := (w_1, \ldots, w_M), c := (c_1, \ldots, c_Q)$, is given by

$$I_{ion}(v, w, c) = \sum_{k=1}^{N} G_k(v, c) \prod_{j=1}^{M} w_j^{p_{j_k}} (v - v_k(c)) + H(v, c),$$

where $G_k(v,c)$ is the membrane conductance, $H(v,c)$ accounts for pump and exchanger currents, v_k is the Nernst equilibrium potential for the kth current, and p_{j_k} are integers. The dynamics of the gating and concentration variables is described by a system of ODEs as in (2.2); when w_j is a gating variable ($0 \le w_j \le 1$) these equations have the form

$$\partial_t w_j = \alpha_j(v)(1-w_j) - \beta_j(v) w_j, \tag{2.11}$$

with coefficients $\alpha_j > 0$ and $\beta_j > 0$ and appropriate initial conditions.

Many refinements of the original Hodgkin–Huxley model have been proposed by fitting improved experimental data with more complex models; for example, we recall here the following models: Beeler–Reuter (1977, N = 4, M = 6, Q = 1), phase-I Luo–Rudy (1991, N = 6, M = 6, Q = 1), phase-II Luo–Rudy (1994, N = 10, M = 6, Q = 5); see Hund and Rudy [29] for current developments.

Simplified models of lower complexity (with 1 or 2 gating variables) have been proposed too. The simplest and most used is the FitzHugh–Nagumo (FHN) model (N = 1, M = 1), which yields only a coarse approximation of a typical cardiac action potential, particularly in the plateau and repolarization phases. A better approximation is given by the following FHN variant by Rogers and McCulloch [47]:

$$\begin{aligned} I_{ion}(v,w) &= Gv(1-v/v_{th})(1-v/v_p) + \eta_1 v w, \\ \partial_t w &= \eta_2 \left(v/v_p - \eta_3 w\right), \end{aligned}$$

where $G, \eta_1, \eta_2, \eta_3$ are positive real coefficients, v_{th} is a threshold potential, and v_p is the peak potential. The gating variable w satisfies

$$\partial_t w = \eta v - \gamma w,$$

with $\eta, \gamma > 0$. We will consider this FHN variant as our simplest gating model.

In this paper, we will also consider the more detailed phase-I Luo–Rudy (LR1) model (see [39]), where I_{ion} is the sum of $N = 6$ currents

$$I_{ion} = I_{Na} + I_{si} + I_K + I_{K1} + I_{Kp} + I_b,$$

two inwards (I_{Na} and I_{si}) and four outwards (I_K, I_{K1}, I_{Kp}, I_b). The first three currents depend on $M = 6$ gating variables satisfying differential equations of the form (2.11) and $Q = 1$ ion (calcium) concentration c satisfying a different differential equation. The last three currents are time-independent. For the detailed equations of this model, we refer the reader to [39].

3. Adaptive Rothe method (code KARDOS). The code family KARDOS [20, 2] is characterized by a combination of discretization in time with finite elements in space in the setting of a , i.e., first time discretization and then spatial discretization. In this setting, both time-step control and dynamic mesh refinement on the basis of a posteriori error estimation can be simultaneously realized. For linear parabolic scalar PDEs, this so-called adaptive Rothe method has been suggested, theoretically investigated, and worked out in algorithmic detail by Bornemann [6]. On this basis, Lang and Walter [35] have generalized the approach to systems of reaction-diffusion equations. A rigorous analysis for nonlinear parabolic systems has been given by Lang [32], where challenging examples

from other fields of science and technology are also included. For a detailed comparison with an adaptive method of lines (first in space and then time discretization), we refer the reader to Deuflhard, Lang, and Nowak [17]. In what follows, we want to collect the main ingredients of the adaptive Rothe method as needed for the above described anisotropic monodomain and bidomain cardiac models.

Throughout this section, our reaction-diffusion problems will be written as

$$B(x,t,u,\nabla u)\partial_t u = \nabla \cdot (D(x,t,u,\nabla u)\nabla u) + F(x,t,u,\nabla u), \tag{3.1}$$

supplemented with suitable boundary and initial conditions. For simplicity of the presentation, we assume that the vector-valued solution $u = (u_1, \ldots, u_m)^T$ is unique.

3.1. Linearly implicit methods. Mathematically speaking, the above cardiac models are nonlinear parabolic PDEs, with the bidomain model even degenerate. The additional mildly stiff ODEs stemming from the membrane models (FHN or LR1) are naturally treated within the frame of the Rothe approach. This means that after discretization we are faced with a large scale [illegible] or even [illegible] system. From an ODE point of view, an optimal treatment of this stiffness structure would mean to apply some L-stable implicit time discretization; for general reference, see the textbooks by Hairer and Wanner [24] or by Deuflhard and Bornemann [16]. From the PDE point of view, however, the avoidance of order reduction (which occurs above order 2) is even more important for the overall efficiency of the time integrator. As shown in [34], the time discretization behind the code ROS3P is a good compromise which avoids order reduction, exhibits [illegible] A [illegible] (with $R(\infty) \sim 0.7$ instead of $R(\infty) = 0$ as for L-stability), and damps higher frequency oscillations to a sufficient extent. Note that the popular Crank–Nicolson scheme is not strongly A-stable (it goes with $R(\infty) = -1$), which results in an insufficient filtering of spurious modes. Fully implicit schemes require the iterative solution of finite dimensional [illegible] systems of algebraic equations by some Newton-like method. In contrast, as pointed out by Deuflhard [14, 15], linearly implicit methods realize a (simplified) Newton method in function space and require only one or a few [illegible] systems per time step. The code KARDOS contains linearly implicit methods of Rosenbrock type. According to their one-step nature, they allow for a rapid change of step sizes and an efficient adaptation of the spatial discretization in each time step. Moreover, a simple embedding technique can be used to estimate the error part arising from time discretization.

In order to give a rough idea of this kind of time discretization, we set $B = I$ in (3.1) and consider only the autonomous case. In the Rothe approach, we look at (3.1) as an abstract Cauchy problem of the form

$$\partial_t u = f(u), \quad u(t_0) = u_0, \quad t > t_0, \tag{3.2}$$

where the differential operators and the boundary conditions are incorporated into the nonlinear function $f(u)$. Its time discretization by an s-stage Rosenbrock method has the recursive form

$$(I - \tau\gamma_{ii}\, J_n)\, K_{ni} = \tau f\left(u_n + \sum_{j=1}^{i-1} \alpha_{ij}\, K_{nj}\right) + \tau J_n \sum_{j=1}^{i-1} \gamma_{ij}\, K_{nj},\ i = 1(1)s, \tag{3.3}$$

$$u_{n+1} = u_n + \sum_{i=1}^{s} b_i K_{ni}, \tag{3.4}$$

where the step number s and the defining formula coefficients b_i, α_{ij}, and γ_{ij} are chosen such that a desired order of consistency and good stability properties for stiff equations (see, e.g., [24, Chapter IV.7]) are obtained. We assume $\gamma_{ii}=\gamma>0$ for all i, which is the standard simplification to derive Rosenbrock methods with one and the same operator on the left-hand side of (3.3). The simplest candidate of this class of methods is the linearly implicit Euler method ($s=1$ and $\gamma=1$).

For the general system

$$B(t,u)\partial_t u = f(t,u), \quad u(t_0)=u_0, \quad t>t_0, \tag{3.5}$$

an efficient implementation that avoids matrix-vector multiplications with the Jacobian was given by Lubich and Roche [38]. In the case of a time- or solution-dependent matrix B, an approximation of $\partial_t u$ has to be taken into account, leading to the generalized Rosenbrock method of the form

$$\begin{aligned}\left(\frac{1}{\tau\gamma}B(t_n,u_n)-J_n\right)U_{ni} &= f(t_i,U_i)-B(t_n,u_n)\sum_{j=1}^{i-1}\frac{c_{ij}}{\tau}U_{nj}+\tau\gamma_i C_n \\ &\quad + \left(B(t_n,u_n)-B(t_i,U_i)\right)Z_i, \quad i=1(1)s,\end{aligned} \tag{3.6}$$

where the internal values are given by

$$t_i=t_n+\alpha_i\tau, \quad U_i=u_n+\sum_{j=1}^{i-1}a_{ij}\,U_{nj}, \quad Z_i=(1-\sigma_i)z_n+\sum_{j=1}^{i-1}\frac{s_{ij}}{\tau}\,U_{nj},$$

and the Jacobians are defined by

$$\begin{aligned}J_n &:= \partial_u\left(f(t,u)-B(t,u)z\right)\big|_{u=u_n,t=t_n,z=z_n},\\ C_n &:= \partial_t\left(f(t,u)-B(t,u)z\right)\big|_{u=u_n,t=t_n,z=z_n}.\end{aligned}$$

This yields the new solution

$$u_{n+1}=u_n+\sum_{i=1}^{s}m_i\,U_{ni}$$

and an approximation of the temporal derivative $\partial_t u$

$$z_{n+1}=z_n+\sum_{i=1}^{s}m_i\left(\frac{1}{\tau}\sum_{j=1}^{i}(c_{ij}-s_{ij})U_{nj}+(\sigma_i-1)z_n\right).$$

The new coefficients can be derived from α_{ij}, γ_{ij}, and b_i [38]. In the special case $B(t,u)=I$, we get (3.3) by setting $U_{ni}=\tau\sum_{j=1,\dots,i}\gamma_{ij}K_{nj}$, $i=1,\dots,s$.

Among the many Rosenbrock solvers suitable to integrate index-1 systems of the form (3.5) we selected the code ROS3P that has been constructed recently by Lang and Verwer [34]. This choice had also turned out to be favorable in preliminary tests on the monodomain model.

For linearly implicit methods of Rosenbrock type a second solution of inferior order, say $\hat{p}$, can be computed by a so-called embedded formula

$$\hat{u}_{n+1} = u_n + \sum_{i=1}^{s} \hat{m}_i U_{ni},$$

$$\hat{z}_{n+1} = z_n + \sum_{i=1}^{s} \hat{m}_i \left(\frac{1}{\tau} \sum_{j=1}^{i} (c_{ij} - s_{ij}) U_{nj} + (\sigma_i - 1) z_n \right),$$

where the original weights m_i are simply replaced by $\hat{m}_i$. If p is the order of u_{n+1}, we call such a pair of formulas to be of order $p(\hat{p})$. Introducing an appropriately scaled norm $\|\cdot\|$, the local error estimator

$$r_{n+1} = \|u_{n+1} - \hat{u}_{n+1}\| + \|\tau(z_{n+1} - \hat{z}_{n+1})\| \tag{3.7}$$

can be used to propose a new time step by

$$\tau_{n+1} = \frac{\tau_n}{\tau_{n-1}} \left(\frac{TOL_t \, r_n}{r_{n+1} \, r_{n+1}} \right)^{1/(\hat{p}+1)} \tau_n. \tag{3.8}$$

Here TOL_t is a desired tolerance prescribed by the user. This formula is related to a discrete PI controller first established in the pioneering papers [23, 22] by Gustafsson, Lundh, and Söderlind.

Note that the above time discretization scheme has been applied to the abstract Cauchy problem (3.2), i.e., to the initial value problem in function space. This means that the Rosenbrock discretization scheme (3.3) is a sequence of linear elliptic PDE boundary value problems. The evaluation of the terms used in the time-step control (3.8) is done via a finite element approximation to be discussed next.

3.2. Multilevel finite elements. In section 4, we show only results for rather simple geometries, which would well permit the use of spectral methods for spatial discretization. However, since the whole scheme is intended to work for realistic geometries of individual patients' hearts, a choice of linear finite elements within the multilevel scheme seems to be in order. The main idea of multilevel techniques consists of replacing the solution space, an infinite dimensional function space, by a (nested) sequence of finite dimensional spaces with successively increasing dimension—see, e.g., Bank and Smith [5], Deuflhard, Leinen, and Yserentant [18], and Bornemann, Erdmann, and Kornhuber [7].

For the construction of the adaptive multilevel mesh, the edge-oriented hierarchical error estimator from [18] is used in the form extended to Rosenbrock schemes in [32]. Such estimators are well established to control the adaptive multilevel process producing successively finer meshes and, in spatial multiscale cases, drastically reducing the size of the arising linear algebraic systems with respect to a prescribed tolerance.

For a more formal description, let T_h be an admissible finite element mesh at $t = t_n$ and S_h^q be the associated finite dimensional space consisting of all continuous functions which are polynomials of order q on each finite element $T \in T_h$. Then the standard Galerkin finite element approximation $U_{ni}^h \in S_h^q$ of the intermediate values U_{ni} satisfies the equation

$$(L_n \, U_{ni}^h, \phi) = (r_{ni}, \phi) \quad \text{for all } \phi \in S_h^q, \tag{3.9}$$

where L_n is the weak representation of the differential operator on the left-hand side in (3.6) and r_{ni} stands for the entire right-hand side in (3.6). Since the operator L_n is independent of i, its calculation is required only once within each time step.

The resulting linear systems can be solved by either direct or iterative methods. While direct methods work quite satisfactorily in 1D and even 2D applications, iterative solvers such as Krylov subspace methods perform considerably better with respect to CPU time and memory requirements for large 2D and 3D problems. For the problem class in question here, i.e., the cardiac models, we mainly used the BI-CGSTAB algorithm [54] with ILU preconditioning.

After computing the approximate intermediate values U_{ni}^h, a posteriori error estimates can be used to give specific assessment of the error distribution. Consider a hierarchical decomposition

$$S_h^{q+1} = S_h^q \oplus Z_h^{q+1}, \tag{3.10}$$

where Z_h^{q+1} is the subspace that corresponds to the span of additional basis functions, typically of higher order. Defining an a posteriori error estimator $E_{n+1}^h \in Z_h^{q+1}$ by

$$E_{n+1}^h = E_{n0}^h + \sum_{i=1}^{s} m_i E_{ni}^h, \tag{3.11}$$

with E_{n0}^h approximating the projection error of the initial value u_n in Z_h^{q+1} and E_{ni}^h estimating the spatial error of the intermediate value U_{ni}^h, the local spatial error for a finite element $T \in T_h$ can be estimated by $\eta_T := \|E_{n+1}^h\|_T$. The error estimator E_{n+1}^h is computed by linear systems which can be derived from (3.9). We get for $i = 1, \ldots, s$

$$(L_n\, E_{ni}^h, \phi) = (r_{ni}(E_{n1}^h + U_{n1}^h, \ldots, E_{n,i-1}^h + U_{n,i-1}^h), \phi) - (L_n\, U_{ni}^h, \phi) \quad \text{for all } \phi \in Z_h^{q+1}.$$

With linear finite elements as approximation space, quadratic bubble functions living on edges are used for local error estimation. The scaling of the solution components is specified in [32, page 66]. The whole process of multilevel mesh adaptation is controlled by a local extrapolation technique due to Babuška and Rheinboldt [4].

The authors are well aware of the fact that in the field of numerical cardiac modeling other spatial adaptivity techniques are also in use, but none of them use a posteriori error estimators as the ones we advocate here. As an example, Tveito and his group use wave front tracking [37], a method well known from [illegible] PDEs and based on monitoring local gradients (or a finite difference approximation of them). Such techniques may be less costly (depending on the necessary overhead for the mesh data structure) but are typically regarded as less reliable in nonlinear [illegible] PDEs.

4. Numerical simulations. In order to study the performance of our adaptive Rothe method, we have performed various simulations on the simple 3D test domain $\Omega = [1, 2] \times [1, 2] \times [1, 1.1]$ of size $1 * 1 * 0.1$ cm^3, including both the monodomain (M) and the bidomain (B) model. Results are presented for the FHN and the LR1 ionic models. The parameters used in our computations are listed in Table 4.1—for details compare to section 2 above. The fibers lie in the (x, y)-plane and have constant direction, forming a $-45°$ angle with the [illegible]-axis.

TABLE 4.1
Parameters chosen in the cardiac (M, B) and membrane (FHN, LR1) models.

(3.5) For the (M) we set

$$B(t,u) = \begin{pmatrix} c_m & 0 \\ 0 & I \end{pmatrix}, \qquad f(t,u) = \begin{pmatrix} I_{app} - I_{ion}(u) + \nabla \cdot (D_m \nabla u_1) \\ P(u) \end{pmatrix},$$

where

$$u = (v, w)^T, \quad I = 1, \quad P = \eta_2 \left(\frac{v}{v_p} - \eta_3 w \right)$$

for the ( ) and

$$u = (v, h, j, m, d, f, X, [C_a]_i)^T, \quad I = \mathrm{diag}(1,1,1,1,1,1,1,1),$$
$$P = (R_1, \ldots, R_6, S)^T, \quad R_k = \alpha_k(u_1)(1 - u_{k+1}) - \beta_k(u_1) u_{k+1}, \quad k = 1, \ldots, 6,$$
$$S = 0.07(10^{-4} - u_8) - 10^{-4} I_{si}(u)$$

for the (1). In this case, the matrix B is so that (under mild additional conditions) the solution is unique.

For the ( ), we have

$$B(t,u) = \begin{pmatrix} c_m & -c_m & 0 \\ -c_m & c_m & 0 \\ 0 & 0 & I \end{pmatrix}, \qquad f(t,u) = \begin{pmatrix} -I_{ion} + \nabla \cdot (D_m \nabla u_1) \\ -I_{app} + I_{ion} + \nabla \cdot (D_m \nabla u_2) \\ P(u) \end{pmatrix},$$

where

$$u = (u_i, u_e, w)^T, \quad I = 1, \quad v = u_1 - u_2, , \quad P = \eta_2 \left(\frac{v}{v_p} - \eta_3 w \right)$$

for the ( ) and

$$u = (u_i, u_e, h, j, m, d, f, X, [C_a]_i)^T, \quad v = u_1 - u_2, I = \mathrm{diag}(1,1,1,1,1,1,1,1),$$
$$P = (R_1, \ldots, R_6, S)^T, \quad R_k = \alpha_k(v)(1 - u_{k+2}) - \beta_k(v) u_{k+2}, \ k = 1, \ldots, 6,$$
$$S = 0.07(10^{-4} - u_9) - 10^{-4} I_{si}(u)$$

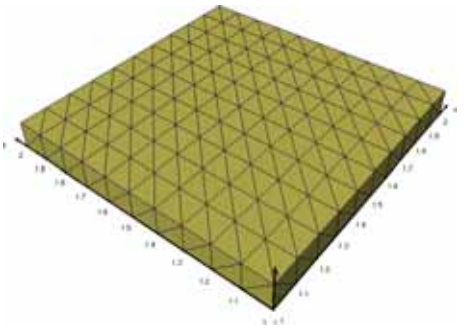

FIG. 4.1. *Initial mesh on simple test domain* Ω.

for the [illegible] ([illegible] 1).

In this case, the matrix B is [illegible], due to the rank-1 upper 2×2 diagonal block, thus exhibiting the already mentioned [illegible] character of the bidomain model. As a consequence, special attention towards a possible uniqueness of the solution must be paid. For μ constant, the vector $(\mu, \mu, 0)^T$ is an eigenfunction corresponding to the zero eigenvalue of B and of $\mathcal{M} := B/(\tau\gamma) - J(u)$ as well. Therefore, the solvability of the bidomain problem is assured for right-hand sides orthogonal to this eigenfunction, i.e., for $(\mu, \mu, 0)f(t, u) = 0$. It is easy to verify that for (3.6) the orthogonality condition holds. Thus, whenever $\int_\Omega I_{app}\, dx = 0$, the system has a unique solution up to an additive constant in the components u_i and u_e. Throughout the computation, we fixed this constant by imposing the condition $\int_\Omega u_e\, dx = 0$.

In all models, the Jacobians C_n and J_n reduce to

$$C_n = 0, \qquad J_n = \partial_u f(u)_{|u=u_n}.$$

Setting $u = (u_1, u_2, q)^T$ the nonlinear terms I_{ion} and P depend only on the difference $v = u_1 - u_2$, which means

$$I = I_{ion}(u_1 - u_2, q), \qquad P = P(u_1 - u_2, q).$$

In our simulations documented here, we present the results for a complete heartbeat in its three main phases at each point $\mathbf{x} \in \Omega$:

(a) the excitation phase (depolarization), where the potential v undergoes an abrupt temporal change within 2 msec, followed by an exponential decay; in our numerical simulations we applied a stimulus of 200 $\mu A/\text{cm}^3$ for 1 msec in a small area close to the center of the domain;
(b) the plateau phase, lasting from $40 - 50$ msec to about 400 msec according to the ionic model chosen and the type of normal and pathological heartbeat considered; v varies very little and slowly compared to the excitation phase, and the cardiac tissue is refractory; i.e., any applied stimulus does not elicit another action potential;
(c) the recovery phase (repolarization), where v returns to the rest value during a period of 20–50 msec, after which the tissue becomes excitable again.

Throughout the computations, we used an initial coarse mesh consisting of 600 tetrahedral finite elements; see Figure 4.1. As tolerances for the accuracies in time and in space we normally chose $TOL_t = TOL_x = 0.01$. This sometimes led to an overflow of our memory resources. Therefore, we restricted mesh refinement to level 3 or 4 (where level 0 was the coarse initial grid).

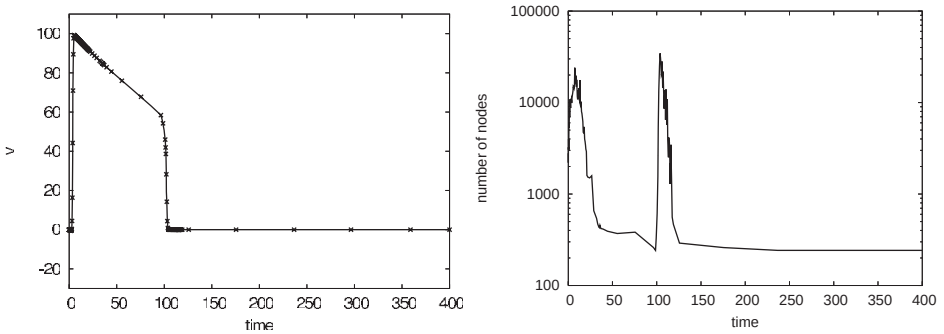

FIG. 4.2. *M-FHN model: Left: potential v at point* $(1.65, 1.65, 1.10)$ *versus time. Right: dynamically adapted number of spatial nodes.*

4.1. Monodomain model. We start with results for the M-FHN model.

In Figure 4.2(left), a typical profile of the solution component v observed at the spatial point $\mathbf{x} = (1.65, 1.65, 1.10)$ is presented. The automatically chosen time integration points nicely condense at sharp changes (exponential increase and decrease of the potential) and relax in the plateau and the recovery phases.

The time steps selected by the stepsize control in the code ROS3P range between the maximum $\tau_{\max} = 62.52$ and the minimum $\tau_{\min} = 0.0548$ msec, which means a spreading factor of about 10^3. Overall, only 130 time integration points were needed. Figure 4.2(right) documents the dynamically varying number of spatial nodes. Figure 4.3 shows the adaptive movement of the spatial grid as a whole.

For the M-LR1 model, Figure 4.4 presents plots of the action potential, the gating variables, and the calcium concentration as a function of time. Again, small time steps arise only in the depolarization and repolarization phases.

In order to illustrate the performance of our spatial adaptation procedure, we present in Figure 4.5 temporal evolutions of the action potential and of one of the gating variables for two different spatial tolerances $TOL_x = 0.02, 0.01$ using a common time tolerance $TOL_t = 0.01$. The maxima of achieved numbers of nodes at intermediate time steps were 41,156 versus 160,047 with four additional refinement steps. For $TOL_x = 0.03$, which is not depicted here, unphysical oscillations around the steep solution fronts would occur.

4.2. Bidomain model. We start with the B-FHN model.

Figure 4.6 plots the intra- and extracellular electric potentials u_i, u_e at two different points as a function of time. Observe that there is not only a moving front but a much more complex dynamics. In particular, the extracellular potentials vary a lot depending on the spatial position, both in the first wave complex (the QRS) and the last little wave (the T wave).

Next, we present the results for the B-LR1 model. Even in this most complex of our selected models the adaptive strategy of the code KARDOS works properly: the adaptivity devices both in time and in space cope nicely with the scale spreading. Figure 4.7 shows the extra- and intracellular electric potentials u_e and u_i over the whole period of 400 msec. Here the time steps selected by the stepsize control in the code ROS3P range between the maximum $\tau_{\max} = 38.60$ and the minimum $\tau_{\min} = 0.0334$ msec, which means a spreading factor of about 10^3 as in the simpler models. Overall, only 195 time integration points were needed.

4.3. Adaptivity gain. Within our code KARDOS, we realize adaptivity both in time and in space. In , , any constant time stepping procedure would need to select a time step $\sim \tau_{\min}$ as suggested from the time-step control. In the simulations over a time span of 400 msec, this would lead to roughly $\sim 10,000$ integration steps to be compared with ~ 200 steps in the adaptive code. This gain factor is expected if the same integrator is used. However, quite often, strongly A-stable integrators are not applied (e.g., Crank–Nicolson or even explicit schemes). This might increase the number of necessary integration points even further.

As for the , , adaptation, the construction principle within KARDOS is to equilibrate the discretization errors at each time step. To be more precise, let $\tilde{v}(x,t)$, $t \in [t_n, t_{n+1}]$, be the , solution of (3.2) with initial values taken from the approximate solution $v_h(x,t)$, i.e., $\tilde{v}(x,t_n) = v_h(x,t_n)$. Using variable time-step sizes and adaptive mesh refinement as described in section 3, we obtain an error estimate Est as the sum of temporal and spatial error estimates. From theory [32], we get the error bounds

$$c\,Est \le \|(\tilde{v} - v_h)(x,t_{n+1})\| \le C\,Est,$$

where $0 < c < C$ are unknown, problem-dependent constants. In this way, local errors are kept at moderate size if $Est \le TOL$, which can be guaranteed by our adaptive method. This technique also controls the growth of global errors for dynamically unstable systems.

We illustrate the effect of spatial adaptivity by comparing uniform versus adaptive meshes, both within the time integrator ROS3P. As a simpler test example, we solve the Nagumo equation with a diffusion operator and a cubic reaction term $I(v)$, which reads

$$\partial_t v - \sum_{i=1}^{3} \sigma_i \partial_{x_i} \partial_{x_i} v(x,t) + I(v(x,t)) = f(x,t,v(x,t)),$$

$$I(v) = 1.5v\left(1 - \frac{v}{13}\right)\left(1 - \frac{v}{100}\right),$$

where $\sigma_1 = 1.2 \cdot 10^{-5}$ and $\sigma_2 = \sigma_3 = 2.556 \cdot 10^{-4}$. The function f and the boundary conditions are determined so that the travelling wave reference solution is

$$v(x,t) = w(\alpha(t - \phi(x)))$$

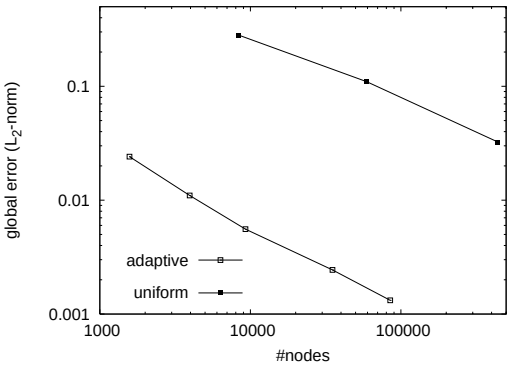

FIG. 4.8. *Impact of adaptive refinement in space at time* $t = 38$.

with

$$w(\tau) = \frac{100}{1 + e^{-6.85\tau}}, \qquad \phi = \sqrt{\Big(\frac{x_1}{0.0616}\Big)^2 + \Big(\frac{x_2}{0.0284}\Big)^2}.$$

The constant fibers are assumed to be parallel to the x_1- and the x_2-axis. The computational domain is the same as for the previous examples. Note that the solution v has the same structure of action potential during the excitation phase as the potentials in the bioelectrical models.

Figure 4.8 shows the relative global L_2-error $\|v - v_h\|/\|v\|$ at time $t = 38$ achieved for a varying number of spatial nodes. At this point in time the early excitation occurs which is crucial for the travelling wave front later on. For the uniform meshes, we chose successive mesh sizes $h = 1/40, 1/80,$ and $1/160$, whereas the adaptive meshes were obtained automatically. Obviously, for finer and finer meshes, both approaches reduce the global error, but uniform meshes need about 200 times more nodes for a comparable accuracy in the depicted L_2-norm. In the maximum norm, this factor would even be about 400.

For realistic heart geometries, the impact of spatial adaptivity is expected to play an even stronger role. In view of future computations with real life patient data, we here did not include any comparisons in terms of CPU time, since a comparison on the chosen simple geometry would not be meaningful.

Conclusion. We have presented a fully adaptive approach to solve various 3D reaction-diffusion models arising in computational electrocardiology. The model complexity ranged from the simple monodomain model coupled with a FitzHugh–Nagumo ionic membrane model (M-FHN) to the quite complex bidomain model coupled with the phase-I Luo–Rudy ionic membrane model (B-LR1). Due to the arising steep solution gradients and travelling fronts, an automatic local adaptation of spatial and temporal discretizations appeared to be crucial—not only to save computing time and storage but also to obtain accurate solutions with tolerable effort. The computations in this paper have concentrated on adaptivity and models and chosen a simple geometry. Future work will have to focus on more realistic geometries and to compare the efficiency of the advocated method with other computational approaches.

Acknowledgments. We want to thank Rainer Roitzsch (ZIB) for providing a lot of ideas to improve the code and the layout of the paper. We also are grateful to

Ulrich Nowak (ZIB) for fruitful discussions about questions of stable integration of the LR1 model.

ON LARGE-SCALE DIAGONALIZATION TECHNIQUES FOR THE ANDERSON MODEL OF LOCALIZATION*

OLAF SCHENK†, MATTHIAS BOLLHÖFER‡, AND RUDOLF A. RÖMER§

Abstract. We propose efficient preconditioning algorithms for an eigenvalue problem arising in quantum physics, namely the computation of a few interior eigenvalues and their associated eigenvectors for large-scale sparse real and symmetric indefinite matrices of the Anderson model of localization. We compare the Lanczos algorithm in the 1987 implementation by Cullum and Willoughby with the shift-and-invert techniques in the implicitly restarted Lanczos method and in the JACOBI–DAVIDSON method. Our preconditioning approaches for the shift-and-invert symmetric indefinite linear system are based on maximum weighted matchings and algebraic multilevel incomplete LDL^T factorizations. These techniques can be seen as a complement to the alternative idea of using more complete pivoting techniques for the highly ill-conditioned symmetric indefinite Anderson matrices. We demonstrate the effectiveness and the numerical accuracy of these algorithms. Our numerical examples reveal that recent algebraic multilevel preconditioning solvers can accelerate the computation of a large-scale eigenvalue problem corresponding to the Anderson model of localization by several orders of magnitude.

1. Introduction.

One of the hardest challenges in modern eigenvalue computation is the numerical solution of large-scale eigenvalue problems, in particular those arising from quantum physics such as, e.g., the Anderson model of localization (see section 3 for details). Typically, these problems require the computation of some eigenvalues and eigenvectors for systems which have up to several million unknowns due to their high spatial dimensions. Furthermore, their underlying structure involves random perturbations of matrix elements which invalidates simple preconditioning approaches based on the graph of the matrices. Moreover, one is often interested in finding some eigenvalues and associated eigenvectors in the interior of the spectrum. The classical Lanczos approach [51] has led to eigenvalue algorithms [16, 17] that are, in principle, able to compute these eigenvalues using only a small amount of memory. More recent work on implicitly restarted Lanczos techniques [42] has accelerated these methods significantly, yet to be fast one needs to combine this approach with shift-and-invert techniques; i.e., in every step one has to solve a shifted system of type $A - \sigma I$, where σ is a shift near the desired eigenvalues and $A \in \mathbb{R}^{n,n}$,

$A = A^T$ is the associated matrix. In general, shift-and-invert techniques converge rather quickly, which is in line with the theory [51]. Still, a linear solver is required to solve systems $(A - \sigma I)x = b$ efficiently with respect to time and memory. While implicitly restarted Lanczos techniques [42] usually require the solution of the system $(A - \sigma I)x = b$ to maximum precision, and thus are mainly suited for sparse direct solvers, the JACOBI–DAVIDSON method has become an attractive alternative [61], in particular when dealing with preconditioning methods for linear systems.

Until recently, sparse symmetric indefinite direct solvers were not as efficient as symmetric positive definite solvers, and this might have been one major reason why shift-and-invert techniques were not able to compete with traditional Lanczos techniques [27], in particular because of memory constraints. With the invention of fast matchings-based algorithms [49], which improve the diagonal dominance of linear systems, the situation has dramatically changed and the impact on preconditioning methods [7], as well as the benefits for sparse direct solvers [58], has been recognized. Furthermore, these techniques have been successfully transferred to the symmetric case [22, 24], allowing modern state-of-the-art direct solvers [57] to be orders of magnitudes faster and more memory efficient than ever, finally leading to symmetric indefinite sparse direct solvers that are almost as efficient as their symmetric positive definite counterparts. Recently this approach has also been utilized to construct incomplete factorizations [38] with similar dramatic success. For a detailed survey on preconditioning techniques for large symmetric indefinite linear systems, the interested reader should consult [5, 6].

2. Numerical approach for large systems. In the present paper we combine the above mentioned advances with inverse-based preconditioning techniques [8]. This allows us to find interior eigenvalues and eigenvectors for the Anderson problem several orders of magnitudes faster than traditional algorithms [16, 17] while still keeping the amount of memory reasonably small.

Let us briefly outline our strategy. We will consider recent novel approaches in preconditioning methods for symmetric indefinite linear systems and eigenvalue problems and apply them to the Anderson model. Since the Anderson model is a large-scale sparse eigenvalue problem in three spatial dimensions, the eigenvalue solvers we deal with are designed to compute only a few interior eigenvalues and eigenvectors, thus avoiding a complete factorization. In particular we will use two modern eigenvalue solvers, which we will briefly introduce in section 5. The first one is ARPACK [42], which is a Lanczos-type method using implicit restarts (cf. section 5.1). We use this algorithm together with a shift-and-invert technique; i.e., eigenvalues and eigenvectors of $(A - \sigma I)^{-1}$ are computed instead of those of A. ARPACK is used in conjunction with a direct factorization method and a multilevel incomplete factorization method for the shift-and-invert technique.

First, we use the shift-and-invert technique with the novel symmetric indefinite sparse direct solver that is part of PARDISO [57], and we report extensive numerical results on the performance of this method. Section 6 will give a short overview of the main concepts that form the PARDISO solver. Second, we use ARPACK in combination with the multilevel incomplete LU factorization package ILUPACK [9]. Here we present a new version of this preconditioner that is devoted to symmetric indefinite problems and combines two basic ideas, namely (i) symmetric maximum weighted matchings [22, 24] and (ii) inverse-based decomposition techniques [8]. These will be described in sections 6.2 and 8.

As a second eigenvalue solver we use the symmetric version of the JACOBI–

DAVIDSON method, in particular the implementation JDBSYM [32]. This Newton-type method (see section 5.2) is used together with ILUPACK [9]. As we will see in several further numerical experiments, the synergy of both approaches will form an extremely efficient preconditioner for the Anderson model that is memory efficient while at the same time accelerates the eigenvalue computations significantly; i.e., system sizes that resulted in weeks of computing time [27] can now be computed within an hour.

3. The Anderson model of localization. The Anderson model of localization is a paradigmatic model describing the electronic transport properties of disordered quantum systems [41, 54]. It has been used successfully in amorphous materials such as alloys [52], semiconductors, and even DNA [53]. Its hallmark is the prediction of a spatial confinement of the electronic motion upon increasing the disorder—the so-called Anderson [illegible] [2]. When the model is used in three spatial dimensions, it exhibits a metal-insulator transition in which the disorder strength w mediates a change of transport properties from metallic behavior at small w via critical behavior at the transition w_c to insulating behavior and strong localization at larger w [41, 54]. Mathematically, the quantum problem corresponds to a Hamilton operator in the form of a real symmetric matrix A, with quantum mechanical energy levels given by the eigenvalues $\{\lambda\}$, and the respective wave functions are simply the eigenvectors of A, i.e., vectors x with real entries. With $N = M \times M \times M$ sites, the quantum mechanical (stationary) Schrödinger equation is equivalent to the eigenvalue equation $Ax = \lambda x$, which in site representation reads as

(3.1)
$$x_{i-1;j;k} + x_{i+1;j;k} + x_{i;j-1;k} + x_{i;j+1;k} + x_{i;j;k-1} + x_{i;j;k+1} + \varepsilon_{i;j;k} x_{i;j;k} = \lambda x_{i;j;k},$$

with $i, j, k = 1, 2, \ldots, M$, denoting the Cartesian coordinates of a site. The disorder enters the matrix on the diagonal, where the entries $\varepsilon_{i;j;k}$ correspond to a spatially varying disorder potential and are selected randomly according to a suitable distribution [40]. Here, we shall use the standard box distribution $\varepsilon_{i;j;k} \in [-w/2, w/2]$ such that the w parameterizes the aforementioned disorder strength. Clearly, the eigenvalues of A then lie within the interval $[-6 - w/2, 6 + w/2]$ due to the Gershgorin circle theorem. In most studies of the disorder-induced metal-insulator transition, w ranges from 1 to 30 [54]. But these values also depend on whether generalizations to random off-diagonal elements [26, 63] (the so-called random-hopping problem), anisotropies [44, 47], or other lattice graphs [36, 60] are being considered.

The intrinsic physics of the model is quite rich. For disorders $w \ll 16.5$, the eigenvectors are extended, i.e., $x_{i;j;k}$ is fluctuating from site to site, but the envelope $|x|$ is approximately a nonzero constant. For large disorders $w > 16.5$, all eigenvectors are localized such that the envelope $|x_n|$ of the nth eigenstate may be approximately written as $\exp -|\vec{r} - \vec{r}_n|/l_n(w)$ with $\vec{r} = (i, j, k)^T$ and $l_n(w)$ denoting the [illegible] of the eigenstate. In Figure 1, we show examples of such states. Note that $|x|^2$ and not x corresponds to a physically measurable quantity and is therefore the observable quantity of interest to physicists. Directly at $w = w_c \approx 16.5$, the extended states at $\lambda = 0$ vanish and no current can flow. The wave function vector x appears simultaneously extended and localized, as shown in Figure 2.

In order to numerically distinguish these three regimes, namely, localized, critical, and extended behaviors, one needs to (i) go to extremely large system sizes of order 10^6 to 10^8 and (ii) average over many different realizations of the disorder, i.e., compute eigenvalues or eigenvectors for many matrices with different diagonals. In the present paper, we concentrate on the computation of a few eigenvalues and corresponding

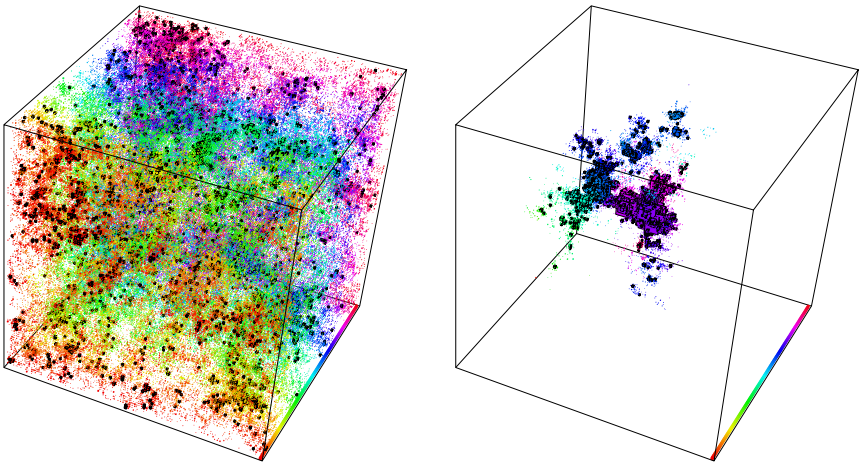

FIG. 1. *Extended (left) and localized (right) wave function probabilities for the 3D Anderson model with periodic boundary conditions at $\lambda = 0$ with $N = 100^3$ and $w = 12.0$ and 21.0, respectively. Every site with probability $|x_j|^2$ larger than the average $1/N^3$ is shown as a box with volume $|x_j|^2 N$. Boxes with $|x_j|^2 N > \sqrt{1000}$ are plotted with black edges. The color scale distinguishes between different slices of the system along the axis into the page. eigenvectors for the physically most interesting case of critical disorder w_c and in the center of $\sigma(A)$, i.e., at $\lambda = 0$, for large system sizes [3, 10, 46, 64]. Since there is a high density of states for $\sigma(A)$ at $\lambda = 0$ in all cases, we have the further numerical challenge of clearly distinguishing the eigenstates in this high density region.

4. The Lanczos algorithm and the Cullum–Willoughby implementation. Since the mid 1980s, the preferred numerical tool for studying the Anderson matrix and computing a selected set of eigenvectors, e.g., as needed for a multifractal analysis at the transition, was the Cullum–Willoughby implementation (CWI) [16, 17, 18] of the Lanczos algorithm. Since both CWI and the algorithm itself are well known, let us here just briefly recall the algorithm's main benefits, mostly to define our notation. The algorithm iteratively generates a sequence of orthogonal vectors v_i, $i = 1, \ldots, K$, such that $V_K^T A V_K = T_K$, with $V = [v_1, v_2, \ldots, v_K]$ and T_K a symmetric tridiagonal $K \times K$ matrix. The recursion $\beta_{i+1} v_{i+1} = A v_i - \alpha_i v_i - \beta_i v_{i-1}$ defines the diagonal and subdiagonal entries of T_K, $\alpha_i = v_i^T A v_i$, and $\beta_{i+1} = v_{i+1} A v_i$, respectively. Its associated (Ritz) eigenvalues and eigenvectors then yield those for the A's.

The CWI avoids reorthogonalization of the v_i's and hence is very memory efficient. The sparsity of the matrix A can be used to full advantage. However, one needs to construct many Ritz vectors of T_K, which is computationally intensive. Nevertheless, in 1999 CWI was still significantly faster than more modern iterative schemes [27]. The main reason for this surprising result lies in the indefiniteness of the sparse matrix A, which led to severe difficulties with solvers more accustomed to standard Laplacian-type problems.

5. Modern approaches for solving symmetric indefinite eigenvalue problems. When dealing with eigenvalues near a given real shift σ, the Lanczos algorithm [51] is usually accelerated when being applied to the shifted inverse $(A - \sigma I)^{-1}$

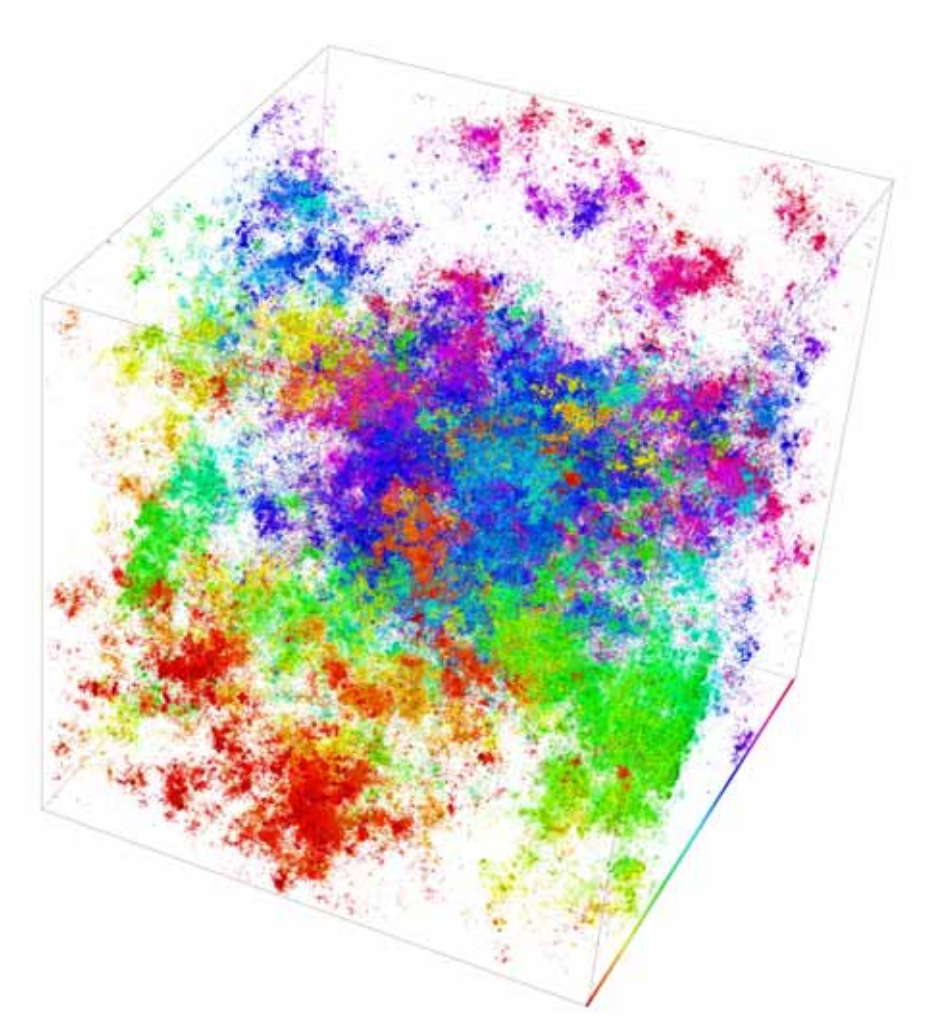

FIG. 2. *Plot of the electronic eigenstate at the metal-insulator transition with* $\lambda = 0$, $w = 16.5$, *and* $N = 350^3$. *The box-and-color scheme is as in Figure* 1. *Note how the state* extends *nearly everywhere while at the same time exhibiting certain* localized *regions of higher* $|x_j|^2$ *values. instead of A directly. This approach relies on the availability of a fast solution method for linear systems of type $(A - \sigma I)x = b$. However, the limited amount of available memory allows only for a small number of solution steps, and sparse direct solvers also need to be memory efficient to turn this approach into a practical method.

The limited number of Lanczos steps has led to modern implicitly restarted methods [42, 62] which ensure that the information about the desired eigenvalues is inherited when being restarted. With an increasing number of preconditioned iterative methods for linear systems [55], Lanczos-type algorithms have become less attractive mainly because in every iteration step the systems of type $(A - \sigma I)x = b$ have to be solved to „ ,, accuracy in order to avoid false eigenvalues. In contrast to this, JACOBI–DAVIDSON-like methods [61] allow using a crude approximation of the under-

lying linear system. From the point of view of linear solvers as part of the eigenvalue computation, modern direct and iterative methods need to inherit the symmetric structure $A = A^T$ while maintaining both time and memory efficiency. Symmetric matching algorithms [22, 24, 57] have significantly improved these methods.

5.1. The shift-and-invert mode of the restarted Lanczos method. The Lanczos method for real symmetric matrices A near a shift σ is based on computing successively orthonormal vectors $[v_1, \ldots, v_k, v_{k+1}]$ and a tridiagonal $(k+1) \times k$ matrix

$$\underline{T_k} = \left(\begin{array}{cccc} \alpha_1 & \beta_1 & & \\ \beta_1 & \alpha_2 & \ddots & \\ & \ddots & \ddots & \beta_{k-1} \\ & & \beta_{k-1} & \alpha_k \\ \hline & & & \beta_k \end{array} \right) \equiv \left(\begin{array}{c} T_k \\ \hline \beta_k e_k^T \end{array} \right), \tag{5.1}$$

where e_k is the kth unit vector in $\mathbb{R}^k$, such that

$$(A - \sigma I)^{-1}[v_1, \ldots, v_k] = [v_1, \ldots, v_k, v_{k+1}]\underline{T_k}. \tag{5.2}$$

Since only a limited number of Lanczos vectors $v_1, \ldots, v_k$ can be stored, and since this Lanczos sequence also consists of redundant information about undesired small eigenvalues, implicitly restarted Lanczos methods have been proposed [62, 42] that use implicitly shifted QR [35], exploiting the small eigenvalues of T_k to remove them from this sequence without ever forming a single matrix vector multiplication with $(A - \sigma I)^{-1}$. The new transformed Lanczos sequence

$$(A - \sigma I)^{-1}[\tilde{v}_1, \ldots, \tilde{v}_l] = [\tilde{v}_1, \ldots, \tilde{v}_l, \tilde{v}_{l+1}]\underline{\tilde{T}_l} \tag{5.3}$$

with $l \ll k$ then allows one to compute further $k - l$ approximations. This approach is at the heart of the symmetric version of ARPACK [42].

5.2. The symmetric JACOBI–DAVIDSON method. One of the major drawbacks of shift-and-invert Lanczos algorithms is the fact that the multiplication with $(A - \sigma I)^{-1}$ requires solving a linear system to full accuracy. In contrast to this, JACOBI–DAVIDSON-like algorithms [61] are based on a Newton-like approach to solve the eigenvalue problem. Like the Lanczos method, the search space is expanded step by step, solving the correction equation

$$(I - uu^T)(A - \theta I)(I - uu^T)z = -r \quad \text{such that} \quad z = (I - uu^T)z, \tag{5.4}$$

where (u, θ) is the given approximate eigenpair and $r = Au - \theta u$ is the associated residual. Then the search space based on $V_k = [v_1, \ldots, v_k]$ is expanded by reorthogonalizing z with respect to $[v_1, \ldots, v_k]$, and a new approximate eigenpair is computed from the Ritz approximation $[V_k, z]^T A[V_k, z]$. When computing several right eigenvectors, the projection $I - uu^T$ has to be replaced with $I - [Q, u][Q, u]^T$ using the already computed approximate eigenvectors Q. This ensures that the new approximate eigenpair is orthogonal to those that have already been computed.

The most important part of the JACOBI–DAVIDSON approach is to construct an approximate solution for (5.4) such that

$$(I - uu^T)K(I - uu^T)c = d \quad \text{with} \quad u^T z = 0 \tag{5.5}$$

and $K \approx A - \theta I$ that allows for a fast solution of the system $Kx = b$. Here, there is a strong need for robust preconditioning methods that preserve symmetry and efficiently solve sequences of linear systems with K. If K is itself symmetric and indefinite, then the simplified QMR method [29, 30] using the preconditioner $\left(I - \frac{uw^T}{w^T u}\right) K^{-1}$, where $Kw = u$ and the system matrix $\left(I - uu^T\right)(A - \theta I)$, can be used as an iterative method. Note that here the accuracy of the solution of (5.4) is uncritical until the approximate eigenpair converges [28]. This fact has been exploited in JDBSYM [4, 32]. For an overview on JACOBI–DAVIDSON methods for symmetric matrices see [33].

6. On recent algorithms for solving symmetric indefinite systems of equations. We now report on recent improvements in solving symmetric indefinite systems of linear equations that have significantly changed sparse direct as well as preconditioning methods. One key to the success of these approaches is the use of symmetric matchings, which we review in section 6.2.

6.1. Sparse direct factorization methods. For a long time, dynamic pivoting has been a central tool by which nonsymmetric sparse linear solvers gain stability. Therefore, improvements in speeding up direct factorization methods were limited to the uncertainties that have arisen from using pivoting. Certain techniques, like the column elimination tree [19, 34], have been useful for predicting the sparsity pattern despite pivoting. However, in the symmetric case the situation becomes more complicated since only symmetric reorderings, applied to both columns and rows, are required, and no a priori choice of pivots is given. This makes it almost impossible to predict the elimination tree in a sensible manner, and the use of cache-oriented level-3 BLAS [20, 21] is impossible.

With the introduction of symmetric maximum weighted matchings [22] as an alternative to complete pivoting, it is now possible to treat symmetric indefinite systems similarly to how we treat symmetric positive definite systems. This allows us to predict fill using the elimination tree [31], and thus allows us to set up the data structures that are required to predict dense submatrices (also known as supernodes). This in turn means that one is able to exploit level-3 BLAS applied to the supernodes. Consequently, the classical Bunch–Kaufman pivoting approach [12] needs to be performed only inside the supernodes.

This approach has recently been successfully implemented in the sparse direct solver PARDISO [57]. As a major consequence of this novel approach, the sparse indefinite solver has been improved to become almost as efficient as its symmetric positive analogy. Certainly for the Anderson problem studied here, PARDISO is about two orders of magnitude more efficient than previously used direct solvers [27]. We also note that the idea of symmetric weighted matchings can be carried over to incomplete factorization methods with similar success [38].

6.2. Symmetric weighted matchings as an alternative to complete pivoting techniques. Symmetric weighted matchings [22, 24], which will be explained in detail in section 7.2, can be viewed as a preprocessing step that rescales the original matrix and at the same time improves the block diagonal dominance. By this strategy, all entries are at most one in modulus, and, in addition, the diagonal blocks are either 1×1 scalars a_{ii} such that $|a_{ii}| = 1$ (in exceptional cases we will have $a_{ii} = 0$) or 2×2 blocks

$$\begin{pmatrix} a_{ii} & a_{i,i+1} \\ a_{i+1,i} & a_{i+1,i+1} \end{pmatrix} \text{ such that } |a_{ii}|, |a_{i+1,i+1}| \leqslant 1, \text{ and } |a_{i+1,i}| = |a_{i,i+1}| = 1.$$

Although this strategy does not necessarily ensure that symmetric pivoting, as in [12], is unnecessary, it is nevertheless likely to waive dynamic pivoting during the factorization process. It has been shown in [24] that, based on symmetric weighted matchings, the performance of the sparse symmetric indefinite [illegible] direct solver MA57 is improved significantly, although a dynamic pivoting strategy by Duff and Reid [25] was still present. Recent results in [57] have shown that the absence of dynamic pivoting does not harm the method anymore and that, therefore, symmetric weighted matchings can be considered as an alternative to complete pivoting.

7. Symmetric reorderings to improve the results of pivoting on restricted subsets. In this section we will discuss weighted graph matchings as an additional preprocessing step. The motivation for weighted matching approaches is to identify large entries in the coefficient matrix A that, if permuted close to the diagonal, permit the factorization process to identify more acceptable pivots and proceed with fewer pivot perturbations. These methods are based on maximum weighted matchings $\mathcal{M}$ and improve the quality of the factor in a way complementary to the alternative idea of using more complete pivoting techniques. The idea of using a permutation $P_{\mathcal{M}}$ associated with a weighted matching $\mathcal{M}$ as an approximation of the pivoting order for nonsymmetric linear systems was first introduced by Olschowka and Neumaier [49] and extended by Duff and Koster [23] to the sparse case. Permuting the rows $A \leftarrow P_{\mathcal{M}}A$ of the sparse system to ensure a zero-free diagonal or to maximize the product of the absolute values of the diagonal entries are techniques that are now often regularly used for nonsymmetric matrices [7, 45, 58, 59].

7.1. Matching algorithms for nonsymmetric matrices. Let $A = (a_{ij}) \in \mathbb{R}^{n\times n}$ be a general matrix. The nonzero elements of A define a graph with edges $\mathcal{E} = \{(i,j) : a_{ij} \neq 0\}$ of ordered pairs of row and column indices. A subset $\mathcal{M} \subset \mathcal{E}$ is called a matching, or a transversal, if every row index i and every column index j appears at most once in $\mathcal{M}$. A matching $\mathcal{M}$ is called perfect if its cardinality is n. For a nonsingular matrix, at least one perfect matching exists and can be found with well known algorithms. With a perfect matching $\mathcal{M}$, it is possible to define a permutation matrix $P_{\mathcal{M}} = (p_{ij})$ with

$$p_{ij} = \begin{cases} 1 & (j,i) \in \mathcal{M}, \\ 0 & \text{otherwise.} \end{cases} \tag{7.1}$$

As a consequence, the permutation matrix $P_{\mathcal{M}}A$ has nonzero elements on its diagonal. This method takes only the nonzero structure of the matrix into account. There are other approaches which maximize the diagonal values in some sense. One possibility is to look for a matrix $P_{\mathcal{M}}$ such that the product of the diagonal values of $P_{\mathcal{M}}A$ is maximal. In other words, a permutation σ has to be found, which maximizes

$$\prod_{i=1}^{n} |a_{\sigma(i)i}|. \tag{7.2}$$

This maximization problem is solved indirectly. It can be reformulated by defining a matrix $C = (c_{ij})$ with

$$c_{ij} = \begin{cases} \log a_i - \log |a_{ij}| & a_{ij} \neq 0, \\ \infty & \text{otherwise,} \end{cases} \tag{7.3}$$

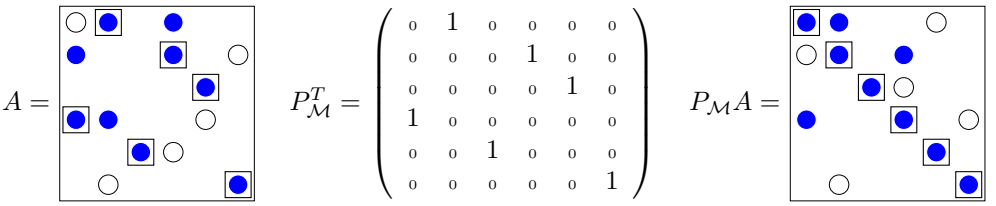

FIG. 3. *Illustration of the row permutation. A small numerical value is indicated by ∘ and a large numerical value by •. The matched entries $\mathcal{M}$ are marked with squares, and* $P_{\mathcal{M}} = (e_4; e_1; e_5; e_2; e_3; e_6)$.

where $a_i = \max_j |a_{ij}|$, i.e., the maximum element in row i of matrix A. A permutation σ, which minimizes $\sum_{i=1}^{n} c_{\sigma(i)i}$, also maximizes the product (7.2).

The minimization problem is known as the linear sum assignment problem or the bipartite weighted matching problem in combinatorial optimization. The problem is solved by a sparse variant of the Kuhn–Munkres algorithm. The complexity is $O(n^3)$ for full $n \times n$ matrices and $O(n\tau \log n)$ for sparse matrices with τ entries. For matrices whose associated graph fulfills special requirements, this bound can be reduced further to $O\left(n^{\alpha}(\tau + n \log n)\right)$ with $\alpha < 1$. All graphs arising from finite-difference or finite-element discretizations meet these conditions [37]. As before, we finally get a perfect matching $\mathcal{M}$ that in turn defines a nonsymmetric permutation $P_{\mathcal{M}}$.

The effect of nonsymmetric row permutations using a permutation associated with a matching $\mathcal{M}$ is shown in Figure 3. It is clearly visible that the matrix $P_{\mathcal{M}}A$ is now nonsymmetric, but has the largest nonzeros on the diagonal.

7.2. Symmetric 1×1 and 2×2 block weighted matchings. In the case of symmetric indefinite matrices, we are interested in symmetrically permuting PAP^T. The problem is that zero or small diagonal elements of A remain on the diagonal when we use a symmetric permutation PAP^T. Alternatively, instead of permuting a large[1] off-diagonal element a_{ij} nonsymmetrically to the diagonal, we can try to devise a permutation $P_{\mathcal{S}}$ such that $P_{\mathcal{S}}AP_{\mathcal{S}}^T$ permutes this element close to the diagonal. As a result, if we form the corresponding 2×2 block to $\left[\begin{smallmatrix} a_{ii} & a_{ij} \\ a_{ij} & a_{jj} \end{smallmatrix}\right]$, we expect the off-diagonal entry a_{ij} to be large, and thus the 2×2 block would form a suitable 2×2 pivot for the supernode Bunch–Kaufman factorization. An observation on how to build $P_{\mathcal{S}}$ from the information given by a weighted matching $\mathcal{M}$ was presented by Duff and Gilbert [22]. They noticed that the cycle structure of the permutation $P_{\mathcal{M}}$ associated with the nonsymmetric matching $\mathcal{M}$ can be exploited to derive such a permutation $P_{\mathcal{S}}$. For example, the permutation $P_{\mathcal{M}}$ from Figure 3 can be written in cycle representation as $P_{\mathcal{C}} = (e_1; e_2; e_4)(e_3; e_5)(e_6)$. This is shown in the upper graphics in Figure 4. The left graphic displays the cycles (1 2 4), (3 5), and (6). If we modify the original permutation $P_{\mathcal{M}} = (e_4; e_1; e_5; e_2; e_3; e_6)$ into this cycle permutation $P_{\mathcal{C}} = (e_1; e_2; e_4)(e_3; e_5)(e_6)$ and permute A symmetrically with $P_{\mathcal{C}}AP_{\mathcal{C}}^T$, it can be observed that the largest elements are permuted to diagonal blocks. These diagonal blocks are shown by filled boxes in the upper right matrix. Unfortunately, a long cycle would result in a large diagonal block, and the fill-in of the factor for $P_{\mathcal{C}}AP_{\mathcal{C}}^T$ may be prohibitively large. Therefore, long cycles corresponding to $P_{\mathcal{M}}$ must be broken down into disjoint 2×2 and 1×1 cycles. These smaller cycles are used to define a symmetric permutation $P_{\mathcal{S}} = (c_1, \ldots, c_m)$, where m is the total number of 2×2 and

[1] Large in the sense of the weighted matching $\mathcal{M}$.

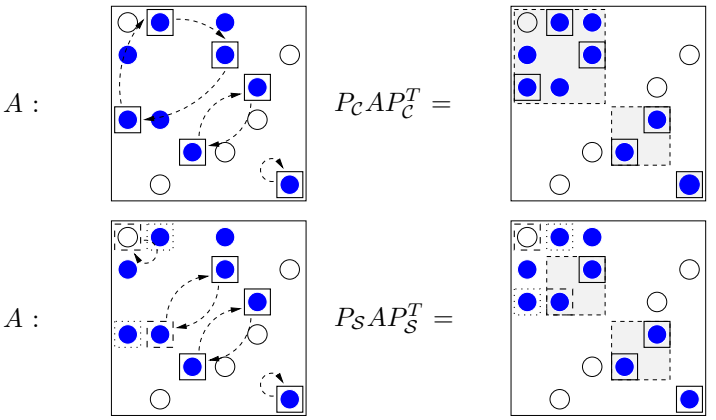

FIG. 4. *Illustration of a cycle permutation with* $P_C = (e_1; e_2; e_4)(e_3; e_5)(e_6)$ *and* $P_{\mathcal{S}} = (e_1)(e_2; e_4)(e_3; e_5)(e_6)$. *The symmetric matching* $P_{\mathcal{S}}$ *has two additional elements (indicated by dashed boxes), while one element of the original matching fell out (dotted box). The two* 2*-cycles are permuted into* 2×2 *diagonal blocks to serve as initial* 2×2 *pivots.*

1×1 cycles.

The rule for choosing the 2×2 and 1×1 cycles from $P_{\mathcal{C}}$ to build $P_{\mathcal{S}}$ is straightforward. One has to distinguish between cycles of even and odd length. It is always possible to break down even cycles into cycles of length 2. For each even cycle, there are two possible ways to break it down. We use a structural metric [24] to decide which one to take. The same metric is also used for cycles of odd length, but the situation is slightly different. Cycles of length $2l + 1$ can be broken down into l cycles of length 2 and one cycle of length 1. There are $2l + 1$ possible ways to do this. The resulting 2×2 blocks will contain the matched elements of $\mathcal{M}$. However, there is no guarantee that the remaining diagonal element corresponding to the cycle of length 1 will be nonzero. Our implementation will randomly select one element as a 1×1 cycle from an odd cycle of length $2l + 1$.

A selection of $P_{\mathcal{S}}$ from a weighted matching $P_{\mathcal{M}}$ is illustrated in Figure 4. The permutation associated with the weighted matching, which is sorted according to the cycles, consists of $P_{\mathcal{C}} = (e_1; e_2; e_4)(e_3; e_5)(e_6)$. We now split the full cycle of odd length 3 into two cycles (1)(24)—resulting in $P_{\mathcal{S}} = (e_1)(e_2; e_4)(e_3; e_5)(e_6)$. If $P_{\mathcal{S}}$ is symmetrically applied to $A \leftarrow P_{\mathcal{S}} A P_{\mathcal{S}}^T$, we see that the large elements from the nonsymmetric weighted matching $\mathcal{M}$ will be permuted close to the diagonal, and these elements will have more chances to form good initial 1×1 and 2×2 pivots for the subsequent (incomplete) factorization.

Good fill-in reducing orderings P_{Fill} are equally important for symmetric indefinite systems. The following section introduces two strategies for combining these reorderings with the symmetric graph matching permutation $P_{\mathcal{S}}$. This will provide good initial pivots for the factorization as well as a good fill-in reduction permutation.

7.3. Combination of orderings P_{Fill} for fill reduction with orderings $P_{\mathcal{S}}$ based on weighted matchings. In order to construct the factorization efficiently, care has to be taken that not too much fill-in is introduced during the elimination process. We now examine two algorithms for the combination of a permutation $P_{\mathcal{S}}$ based on weighted matchings to improve the numerical quality of the coefficient matrix A with a fill-in reordering P_{Fill} based on a nested dissection from METIS [39]. The first method is based on compressed subgraphs and has also been used by Duff and

Pralet in [24] in order to find good scalings and orderings for symmetric indefinite systems.

In order to combine the permutation $P_{\mathcal{S}}$ with a fill-in reducing permutation, we compress the graph of the reordered system $P_{\mathcal{S}}AP_{\mathcal{S}}^T$ and apply the fill-in reducing reordering to the compressed graph. In the compression step, the union of the structure of the two rows and columns corresponding to a 2×2 diagonal block is built and used as the structure of a single, compressed row and column representing the original ones.

If $G_A = (V; E)$ is the undirected graph of A and a cycle consists of two vertices $(s, t) \in V$, then graph compression will be done on the 1×1 and 2×2 cycles, which have been found using a weighted matching $\mathcal{M}$ on the graph. The vertices (s, t) are replaced with a single supervertex $u = \{s, t\} \in V_c$ in the compressed graph $G_c = (V_c, E_c)$. An edge $e_c = (s, t) \in E_c$ between two supervertices $s = \{s_1, s_2\} \in V_c$ and $t = \{t_1, t_2\} \in V_c$ exists if at least one of the following edges exists in E: (s_1, t_1), (s_1, t_2), (s_2, t_1), or (s_2, t_2). The fill-in reducing ordering is found by applying METIS on the compressed graph $G_c = (V_c, E_c)$. Expansion of P_{Fill} to the original numbering yields the final permutation. Hence all 2×2 cycles that correspond to a suitable 2×2 pivot block are reordered consecutively in the factor.

8. Symmetric multilevel preconditioning techniques. We now present a new symmetric indefinite approximate multilevel factorization that is mainly based on three parts which are repeated in a multilevel framework in each subsystem. The components consist of (i) reordering of the system, (ii) approximate factorization using inverse-based pivoting, and (iii) recursive application to the system of postponed updates.

8.1. Reordering the given system. The key ingredient for turning this approach into an efficient multilevel solver consists of the symmetric maximum weight matching presented in section 6.2. After the system is reordered into a representation

$$P_s^T DADP_s = \hat{A}, \tag{8.1}$$

where $D, P_s \in \mathbb{R}^{n,n}$, D is a diagonal matrix, and P_s is a permutation matrix, $\hat{A}$ is expected to have many diagonal blocks of size 1×1 or 2×2 that are well conditioned. Once the diagonal blocks of size 1×1 and 2×2 are built, the associated block graph of $\hat{A}$ is reordered by a symmetric reordering, e.g., AMD [1] or METIS [39], i.e.,

$$\Pi^T P_s^T DADP_s \Pi = \tilde{A}, \tag{8.2}$$

where $\Pi \in \mathbb{R}^{n,n}$ refers to the associated symmetric block permutation.

8.2. Inverse-based pivoting. Given $\tilde{A}$ we compute an incomplete factorization $LDL^T = \tilde{A} + E$ of $\tilde{A}$. To do this at step k of the algorithm we have

$$\tilde{A} = \begin{pmatrix} B & F^T \\ F & C \end{pmatrix} = \begin{pmatrix} L_B & 0 \\ L_F & I \end{pmatrix} \begin{pmatrix} D_B & 0 \\ 0 & S_C \end{pmatrix} \begin{pmatrix} L_B^T & L_F^T \\ 0 & I \end{pmatrix}, \tag{8.3}$$

where $L_B \in \mathbb{R}^{k-1,k-1}$ is lower triangular with unit diagonal and $D_B \in \mathbb{R}^{k-1,k-1}$ is block diagonal with diagonal blocks of sizes 1×1 and 2×2. Also, $S_C = C - L_F D_B L_F^T = (s_{ij})_{i,j}$ denotes the approximate Schur complement. To proceed with the incomplete factorization we perform either a 1×1 update or a 2×2 block update. One possible choice could be to use Bunch's algorithm [11]. This approach has been used in [38].

Here we use a simple criterion based on block diagonal dominance of the leading block column. Depending on the values

$$d_1 = \sum_{j>1} \frac{|s_{j1}|}{|s_{11}|}, \quad d_2 = \sum_{j>2} \left\| (s_{j1}, s_{j2}) \begin{pmatrix} s_{11} & s_{12} \\ s_{12} & s_{22} \end{pmatrix}^{-1} \right\|, \tag{8.4}$$

we perform a 2×2 update only if $d_2 < d_1$. The two leading columns of S_C can be efficiently computed using linked lists [43], and it is not required to have all entries of S_C available.

When applying the (incomplete) factorization LDL^T to $\tilde{A}$ we may still encounter a situation where at step k either $1/|s_{11}|$ or $\|(s_{ij})^{-1}_{i,j\leqslant 2}\|$ is large or even infinite. Since we are dealing with an incomplete factorization we propose to use inverse-based pivoting [8]. Therefore, we require in every step that

$$\left\| \begin{pmatrix} L_B & 0 \\ L_F & I \end{pmatrix}^{-1} \right\| \leqslant \kappa \tag{8.5}$$

for a prescribed bound κ. If after the update using a 1×1 pivot (or 2×2 pivot) the norm of the inverse lower triangular factor fails to be less than κ, the update is postponed and the leading rows/columns of L_F are permuted to the end of S_C. Otherwise, depending on whether a 1×1 or a 2×2 pivot has been selected, the entries

$$(s_{j1}/s_{11})_{j>1}, \quad \left((s_{j1},\ s_{j2}) \begin{pmatrix} s_{11} & s_{12} \\ s_{12} & s_{22} \end{pmatrix}^{-1} \right)_{j>2} \tag{8.6}$$

become the next (block) column of L, and we drop these entries whenever their absolute value is less than ε/κ for some threshold ε. For a detailed description see [8]. The norm of the inverse can be cheaply estimated using a refined strategy of [15] and is part of the software package ILUPACK that is now extended to the symmetric indefinite case [9].

8.3. Recursive application. After the inverse-based ILU we have an approximate factorization

$$Q^T \tilde{A} Q = \begin{pmatrix} L_{11} & 0 \\ L_{21} & I \end{pmatrix} \begin{pmatrix} D_{11} & 0 \\ 0 & S_{22} \end{pmatrix} \begin{pmatrix} L_{11}^T & L_{21}^T \\ 0 & I \end{pmatrix}, \tag{8.7}$$

and it typically does not pay off to continue the factorization for the remaining matrix S_{22} which consists of the previously postponed updates. Thus S_{22} is now explicitly computed and the strategies for reordering, scaling, and factorization are recursively applied to S_{22}, leading to a multilevel factorization.

Note that in order to save memory, L_{21} is not stored but implicitly approximated by $\tilde{A}_{21}(L_{11}D_{11}L_{11}^T)^{-1}$. In addition we use a technique called [illegible] that sparsifies the triangular factor L a posteriori. To do this observe that when applying a perturbed triangular factor $\tilde{L}^{-1}$ for preconditioning, instead of L^{-1} we have

$$\tilde{L}^{-1} = (I + E_L)L^{-1}, \text{ where } E_L = \tilde{L}^{-1}(L - \tilde{L}).$$

We can expect that $\tilde{L}^{-1}$ serves as a good approximation to L^{-1} as long as $\|E_L\| \ll 1$. If we obtain $\tilde{L}$ from L by dropping some entry, say l_{ij} from L, then we have to ensure that

$$\|\tilde{L}^{-1}e_i\| \cdot |l_{ij}| \leqslant \tau \ll 1$$

for some moderate constant $\tau < 1$, e.g., $\tau = 0.1$. To do this requires having a good estimate for $\nu_i \approx \|\tilde{L}^{-1}e_i\|$ available for any $i = 1, \ldots, n$. In principle it can be computed [8, 15] using $\tilde{L}^T$ instead of $\tilde{L}$. Finally, knowing how many entries exist in column j, we could drop any l_{ij} such that

$$|l_{ij}| \leqslant \tau/(\nu_i \cdot \#\{l_{kj} : \ l_{kj} \neq 0, k = j+1, \ldots, n\}).$$

8.4. Iterative solution. By construction, the computed incomplete multilevel factorization is symmetric but indefinite. For the iterative solution of linear systems using the multilevel factorization, in principle different Krylov subspace solvers could be used, such as general methods that do not explicitly use symmetry (e.g., GMRES [56]) or methods like SYMMLQ [50] which preserve the symmetry of the original matrix but which are devoted only to symmetric positive definite preconditioners. To fully exploit both symmetry and indefiniteness at the same time, here the simplified QMR method [29, 30] is chosen.

9. Numerical experiments. Here we present numerical experiments that show that the previously outlined advances in symmetric indefinite sparse direct solvers as well as in preconditioning methods significantly accelerate modern eigenvalue solvers and allow us to gain orders of magnitude in speed compared to more conventional methods.

9.1. Computing environments and software. All large-scale numerical experiments for the Anderson model of localization were performed on an SGI Altix 3700/BX2 with 56 Intel Itanium2 1.6 GHz processors and 112 GB of memory. If not explicitly stated, we always used only one processor of the system and all algorithms were implemented in either C or Fortran77. All codes were compiled by the Intel V8.1 compiler suite using [illegible] and [illegible] with the `-O3` optimization option and linked with basic linear algebra subprograms optimized for Intel architectures. The computations for $M = 250,350$ and $w = 16.5$ required 64-bit long integers and `-i8` flag for [illegible]. From comparison with smaller examples we observed an overhead of approximately 30% with respect to memory and computation time. For completeness, let us recall the main software packages used:

- ARPACK is a collection of Fortran77 subroutines designed to solve large-scale eigenvalue problems. The eigenvalue solver has been developed at the Department of Computational and Applied Mathematics at Rice University. It is available at http://www.caam.rice.edu/software/ARPACK.
- JDBSYM is a C library implementation of the JACOBI–DAVIDSON method optimized for symmetric eigenvalue problems. It solves eigenproblems of the form $Ax = \lambda x$ and $Ax = \lambda Bx$ with or without preconditioning, where A is symmetric and B is symmetric positive definite. It has been developed at the Computer Science Department of the ETH Zürich. It is available at http://people.web.psi.ch/geus/software.html.
- PARDISO is a fast direct solver package, developed at the Computer Science Department of the University of Basel. It is available at http://www.computational.unibas.ch/cs/scicomp/software/pardiso.
- ILUPACK is an algebraic multilevel preconditioning software package. This iterative solver has been developed at the Mathematics Department of the Technical University of Berlin. It is available at http://www.math.tu-berlin.de/ilupack.

9.2. CWI compared to shift-and-invert Lanczos with implicit restarts and PARDISO as direct solver. Let us first briefly compare the classical CWI with the shift-and-invert Lanczos method using implicit restarts. The latter is part of ARPACK [42]. For the solution of the symmetric indefinite system $A - \theta I$ we use the most recent version of sparse direct solver PARDISO [57]. This version is based on symmetric weighted matchings and uses METIS as a symmetric reordering strategy. The numerical results deal with the computation of five eigenvalues of the Anderson matrix A near $\lambda = 0$. Here we state the results for the physically most interesting critical disorder strength $w_c = 16.5$. We have measured the CPU times in seconds and memory requirements in GB to compute five eigenvalues closest to $\lambda = 0$ of an Anderson matrix of size $N = M^3 \times M^3$ up to $M = 100$ with CWI and ARPACK–PARDISO. We observe from this initial numerical experiment that the combination of the shift-and-invert Lanczos with PARDISO is faster when compared to the CWI by about a factor of 10 for systems with $M > 50$. Despite this success, with increasing problem size the amount of memory consumed by the sparse direct solver becomes significant[2] and numerical results with N larger than 1000000 are skipped. Figure 1 shows two different eigenstates computed with the help of PARDISO.

9.3. Using the ILUPACK-based preconditioner. We now switch to the ILUPACK-based preconditioner that is also based on symmetric weighted matchings and in addition uses inverse-based pivoting. In particular, for our experiments we use $\kappa = 5$ as a bound for the norm $\|L^{-1}\|$ of the inverse triangular factor and AMD for the symmetric reordering. We also tried to use METIS, but for this particular matrix problem we find that AMD is clearly more memory efficient. Next we compare the shift-and-invert Lanczos (ARPACK) with ILUPACK and the simplified QMR as the inner iterative solver. Here we use $\varepsilon = 1/\sqrt{N}$ with aggressive dropping, and the QMR method is stopped once the norm of residual satisfies $\|Ax - b\| \leqslant 10^{-10}\|b\|$. In order to illustrate the benefits of using symmetric weighted matchings we also tried ILUPACK without matching, but the numerical results are disappointing, as can be seen from the †'s in Table 9.1. We emphasize that the multilevel approach is crucial; a simple use of incomplete factorization methods without multilevel preconditioning [38] does not give the desired results. Besides the effect of matchings we also compare how the performance of the methods changes when varying the value w from the critical value $w = w_c = 16.5$ to $w = 12.0$ and $w = 21.0$. We find that these changes do not affect the sparse direct solver at all while the multilevel ILU significantly varies in its performance. Up to now our explanation for this effect is the observation that with increasing w the diagonal dominance of the system also increases and the ILUPACK preconditioner gains from higher diagonal dominance. As we can see from Table 9.1, ILUPACK still uses significantly less memory than the direct solver PARDISO for all values of w, and it is the only method we were able to use for larger N due to the memory constraints. Also, the computation time is best.

9.4. Using JACOBI–DAVIDSON. When using preconditioning methods inside shift-and-invert Lanczos we usually have to solve the inner linear system for $A - \theta I$ up to machine precision to make sure that the eigenvalues and eigenvectors are sufficiently correct. In contrast to this the JACOBI–DAVIDSON method allows us to solve the associated correction equation less accurately, and only when convergence takes place is a more accurate solution required. In order to show the significant

[2]The current standard memory of 2GB RAM for a desktop computer is exceeded for sizes beyond $M > 64$.

difference between the iterative parts of ARPACK and JACOBI–DAVIDSON we state the number of iteration steps in Table 9.2. If we were to aim for more eigenpairs, we would expect that eventually the JDBSYM would become less efficient and should again be replaced by ARPACK. As stopping criteria for the inner iteration inside the JACOBI–DAVIDSON method we use recent results from [48, 65]. Given the eigenvector residual

$$r_{eig} = Au - u\lambda, \text{ where } \|u\| = 1,\ \lambda = u^T Au,$$

and given an approximate solution z of the correction equation (5.4) with the associated linear system residual

$$r_{lin} = -r_{eig} - (I - uu^T)(A - \theta I)(I - uu^T)z,$$

one could define a new approximate eigenvector via $u_{eignew} = (u + z)/\|u + z\|$. Following [48] the associated new eigenvector residual r_{eignew} can be bounded by

$$\frac{|\|r_{lin}\| - \beta\|z\||}{1 + \|z\|^2} \leqslant \|r_{eignew}\| \leqslant \frac{\sqrt{(\|r_{lin}\| + \beta\|z\|)^2 + \|r_{lin}\|^2\|z\|^2}}{1 + \|z\|^2},$$

where $\beta = |\lambda - \theta + r_{eig}^T z|$. Numerical experiments in [48] indicate that initially

$$\beta\|z\| \ll \|r_{lin}\| \Rightarrow \|r_{eignew}\| \approx \frac{\|r_{lin}\|}{\sqrt{1 + \|z\|^2}},$$

while asymptotically we expect r_{lin} to converge to zero leading to

$$\beta\|z\| \gg \|r_{lin}\| \Rightarrow \|r_{eignew}\| \approx \frac{\beta\|z\|}{1 + \|z\|^2}.$$

When z is obtained from the simplified QMR algorithm as in our case, it has been shown in [65] that $\|r_{eignew}\|$ and $r_{eig}^T z$ can be cheaply computed as a by-product of the simplified QMR algorithm. In addition, in practice $\|z\|$ need not be recomputed throughout the iteration, since after a few steps, $\|z\|$ typically does not vary too much anymore [48]. This motivates our stopping criterion, where we stop the inner iteration inside QMR whenever

$$\frac{\|r_{lin}\|}{\sqrt{1 + \|z\|^2}} \leqslant \min\left\{\|r_{eignew}\|, \frac{\beta\|z\|}{1 + \|z\|^2}, \frac{\tau}{2}\right\}.$$

Here τ is the desired tolerance of the eigenvector residual (10^{-10} in our experiments). Note also that $\|r_{lin}\|$ is not explicitly available in the QMR method. Thus we use the quasi residual as an estimate and check only the true residual on exit to safeguard the process.

In what follows we compare the traditional CWI method with the JACOBI–DAVIDSON code JDBSYM [33] using ILUPACK as a preconditioner. Table 9.3 shows that switching from ARPACK to JACOBI–DAVIDSON in this case improves the total time by another factor of 6 or greater. For this reason JACOBI–DAVIDSON together with ILUPACK will be used as a default solver in the following. The numerical results in Table 9.3 show a dramatic improvement in the computation time by using ILUPACK-based JACOBI–DAVIDSON. Although this new method slows down for smaller w due to poorer diagonal dominance, a gain by orders of magnitude can still be observed. For $w = 16.5$ and larger, even more than three orders of magnitude in the computation time can be observed. Hence the new method drastically outperforms the CWI method while the memory requirement is still moderate. Figure 2 shows an eigenstate computed within three days with the help of the ILUPACK-based JACOBI–DAVIDSON. The construction of the ILUPACK preconditioner needed 14 hours at a fill-in factor of 18 compared with the fill of the original matrix.

One key to the success of the preconditioner is based on the threshold κ which bounds the growth of L^{-1}. Already, for a small example such as $M = 70$ significant differences can be observed. As we show in Table 9.4, increasing the bound by a factor of 2 from $\kappa = 5$ up to $\kappa = 10$ and $\kappa = 20$ leads to an enormous increase in fill. Here we measure the fill of the incomplete LDL^T factorization relative to the nonzeros of the original matrix. By varying the drop tolerance ε we also see that the dependence

on κ is much more significant than the dependence on ε. Roughly speaking, the ILU decomposition becomes twice as expensive when κ is replaced with 2κ, as does the fill-in. The latter is crucial since memory constraints severely limit the size of the application that can be computed.

9.5. Hard wall boundaries and randomness in the off-diagonal matrix elements. In Table 9.5 we show how JDBSYM and ILUPACK–SYMMATCH perform when, instead of periodic boundary conditions, we use hard wall boundaries, i.e., $x_{0;j;k} = x_{i;0;k} = x_{i;j;0} = x_{M+1;j;k} = x_{i;M+1;k} = x_{i;j;M+1} = 0$ for all i, j, k. This is sometimes of interest in the Anderson problem, and, generally, it is expected that for large M, the difference in eigenvalues and eigenvectors becomes small when compared to the standard periodic boundaries. In addition, we also show results for the so-called off-diagonal Anderson problem [14]. Here, we shift the diagonal to a constant $\sigma = 1.28$ and incorporate the randomness by setting the off-diagonal elements of

70	161	0.3	169	0.3	251	0.2
100	661	1.0	704	0.9	1055	0.8
130	2000	2.4	1566	2.4	3203	1.8
160	3961	4.8	4078	4.6	11614	3.3
190	10955	8.1	10922	7.8	29455	6.5

A to be uniformly distributed in $[-1/2, 1/2]$. The graph of the matrix A remains the same. These values correspond—similarly to $w_c = 16.5$ used before for purely diagonal randomness—to the physically most interesting localization transition in this model [14]. We note that using hard wall boundary conditions instead of periodic boundary conditions leads to slightly less fill but increases the number of iteration steps, as can be seen in Table 9.5. This conclusions carries over to the off-diagonal Anderson problem, where the memory consumption is less but the iterative part takes even longer. In principle our results could be improved if we were to switch to a smaller threshold ε than the uniformly applied $\varepsilon = 1/\sqrt{N}$ here.

10. Conclusion. We have shown that modern approaches to preconditioning based on symmetric matchings and multilevel preconditioning methods lead to an astonishing increase in performance and available system sizes for the Anderson model of localization. This approach is not only several orders of magnitudes faster than the traditional CWI approach, but it also consumes only a moderate amount of memory, thus allowing us to study the Anderson eigenproblem for significantly larger scales than ever before.

Let us briefly recall the main ingredients necessary for this progress. At the heart of the new approach lies the use of symmetric matchings [38] in the preconditioning stage of the inverse-based incomplete factorization preconditioning iterative method [9]. Furthermore, the preconditioning itself is of a multilevel type, complementary to the often used full-pivoting strategies. Next, the inverse-based approach is also of paramount importance to keep the fill-in at a manageable level (see Table 9.4). Finally, we emphasize that these results, of course, reflect our selected problem class: to compute a few of the interior eigenvalues and associated eigenvectors for a highly indefinite symmetric matrix defined by the Anderson model of localization.

The performance increase by several orders of magnitude (see Table 9.3) is solely due to our use of new and improved algorithms. Combined with advances in the performance-to-cost ratio of computing hardware during the past six years, current preconditions methods make it possible to solve those problems quickly and easily, which have been considered by far too large until recently [13].

Even for $N \times N$ matrices as large as $N = 64 \cdot 10^6$, it is now possible to compute within a few days the interior eigenstates of the Anderson problem.

The success of this method indicates that it might also be successfully applied to other large-scale problems arising in (quantum) physics.

Acknowledgments. We gratefully acknowledge discussions with and implementation help from A. Croy and C. Sohrmann in the initial stages of the project.

COMBINED COMPLEX RIDGELET SHRINKAGE AND TOTAL VARIATION MINIMIZATION*

JIANWEI MA† AND MARKUS FENN‡

Abstract. A new algorithm for the characterization of engineering surface topographies with line singularities is proposed. It is based on thresholding complex ridgelet coefficients combined with total variation (TV) minimization. The discrete ridgelet transform is designed by first using a discrete Radon transform based on the nonequispaced fast Fourier transform (NFFT) and then applying a dual-tree complex wavelet transform (DT CWT). The NFFT-based approach of the Radon transform completely avoids linear interpolations of the Cartesian-to-polar grid and requires only $\mathcal{O}(n^2 \log n)$ arithmetic operations for n by n arrays, while its inverse preserves the good reconstruction quality of the filtered backprojection. The DT CWT in the second step of the ridgelet transform provides approximate shift invariance on the projections of the Radon transform. After hard thresholding the ridgelet coefficients, they are restored using TV minimization to eliminate the pseudo-Gibbs artifacts near the discontinuities. Numerical experiments demonstrate the remarkable ability of the methodology to extract line scratches.

Key words. nonequispaced fast Fourier transform, ridgelets, complex wavelets, shift invariance, total variation minimization, detection of line singularities, surface characterization

1. Introduction.

Surface topography is one of the most important factors affecting the functional performance of components. The functional topographical features such as peaks/pits and ridges/valleys impact directly on mechanical and physical properties of the whole system such as wear, friction, lubrication, corrosion, fatigue, coating, paintability, etc. For instance, during the functional operation of interacting surfaces, peaks and ridges will act as sites of high contact stresses and abrasion, and consequently, wear particles and debris will be generated by such surface topographical features, whereas the pits and valleys will affect the lubrication and fluid retention properties. Therefore, a highly accurate separation and extraction of different topographical features from surfaces for corresponding functional analysis is an important issue in the initial stages of engineering systems.

Over the past few years, wavelet methods have been applied for the analysis of functional surfaces including nanosurfaces. Unfortunately, the usual discrete wavelet transform (DWT) suffers from shift sensitivity, poor directionality, and pseudo-Gibbs artifacts. Recently, a dual-tree complex wavelet transform (DT CWT) combined with total variation (TV) minimization has been applied by Ma [23] and Ma, Jiang, and Blunt [24] to solve the above problems. However, wavelet-based techniques perform poorly when representing line singularities. In this paper, we pay attention to extract line scratches from engineering surfaces by applying the discrete ridgelet transform.

Ridgelets have been designed by Candès [3] and Candès and Donoho [5] to deal

with line singularities effectively by mapping them into point singularities using the Radon transform. It should be noted that several other geometric multiresolution structures such as curvelets by Candès and Donoho [6], bandelets by LePennec and Mallat [22], or contourlets by Do and Vetterli [9] have been proposed to restore local image features in a different way. Moreover, these methods have to compete with anisotropic diffusion filtering [37].

When implementing a discrete ridgelet transform one has to cope with certain technical difficulties. The basic strategy of the ridgelet transform is an application of the wavelet transform on the projections of the Radon transform. The Radon transform seems natural and simple on the continuum, but it is a challenging problem for discrete data.

Do and Vetterli [10] proposed an orthonormal version of the ridgelet transform based on a discrete Radon transform defined on the finite grid $\mathbb{Z}_p^2$, where p is a prime number. Unfortunately, the $\mathbb{Z}_p^2$ Radon transform integrates over "lines" which are defined algebraically—due to the arithmetic modulo p—rather than geometrically. This causes a wrap-around effect, i.e., texture-like artifacts in reconstructions.

Carré and Andres [7] presented a so-called discrete analytical ridgelet transform (DART) with a flexible redundancy factor based on discrete analytical lines, which cause only a limited wrap-around effect. By using an arithmetical thickness they choose the best discrete approximation of the Euclidean line for each line direction. The innovative step of this transform is the construction of discrete analytical lines in the Fourier domain, which allows a fast perfect backprojection without interpolation or iteration.

Other discrete ridgelet transforms have been also explored by Donoho et al. In [33], they offer a discrete transform with exact reconstruction, stability against perturbations, and low computational complexity. It uses a pseudopolar sampling grid based on concentric squares by means of a simple nearest-neighbor interpolation scheme. In [11], an effective discrete ridgelet transform based on so-called true ridge functions was proposed using the fast slant stack (FSS) in [1], a pseudopolar FFT-based discrete Radon transform, followed by fast one-dimensional (1-D) wavelet transforms. The essential part of the FSS-based "true" ridgelet transform is an interpolation performed using a Dirichlet kernel, which leads to a transform that is geometrically faithful and has no wrap-around effect. But an iterative approximation process is required for the inverse transform.

In this paper, we develop a discrete complex ridgelet transform based on the nonequispaced fast Fourier transform (NFFT). This ridgelet transform uses the NFFT for the computation of the discrete Radon transform. As for the FSS, this approach completely avoids linear interpolations and requires only $\mathcal{O}(n^2 \log n)$ arithmetic operations. Then 1-D DT CWTs are applied to the projections of the Radon transform. The DT CWT was introduced by Kingsbury [19, 20] to cope with the lack of translation and rotation invariance of the (decimated) wavelet transform in an efficient way. For a mathematical treatment of the DT CWT, see also [32, 28]. Replacing the DWT by the approximate shift invariant DT CWT improves the quality of ridgelet denoising remarkably.

For denoising or feature extraction, a shrinkage function is applied to the ridgelet coefficients. However, this usual shrinkage is far from optimal and leads to blurred edges and pseudo-Gibbs artifacts. Therefore, we combine thresholding with TV minimization in order to reduce these artifacts.

TV minimization was first introduced by Rudin, Osher, and Fatemi [31] for denoising, and then was widely studied in image processing and computer vision

(e.g., restoration, inpainting, blind deconvolution). Recently, the TV model has been combined with computational harmonic analysis (e.g., wavelets, wavelet packets, curvelets, etc.) to reduce both the pseudo-Gibbs and staircasing artifacts [26, 8, 12, 23, 35]. The idea of coupled TV minimization used in this paper is similar to [12, 23] but applied for complex ridgelet coefficients and in two dimensions. The ridgelet transform combined with TV minimization attempts to give a better restoration of ridgelet coefficients. In particular, the oscillations (pseudo-Gibbs artifacts) near discontinuities are eliminated while the strong edges and shapes of the features of surfaces are preserved.

This paper is organized as follows. First, we explain the continuous setting of ridgelets in section 2. In section 3, we introduce our NFFT-based discrete complex ridgelet transform and its inverse. Then we explain hard thresholding and combine it with TV minimization in section 4. Numerical experiments show the good performance of our new method for feature extraction and denoising in section 5.

2. Continuous ridgelet transform. Let $\psi \in L^2(\mathbb{R})$ be a wavelet; i.e., it fulfills the admissibility condition

$$\int_{\mathbb{R}} \frac{|\hat{\psi}(\omega)|^2}{|\omega|}\,\mathrm{d}\omega < \infty.$$

A ridgelet $\psi_{\theta,a,b}$ with orientation parameter $\theta \in [0, 2\pi)$, scale parameter $a > 0$, and location parameter $b \in \mathbb{R}$ is defined by

$$\psi_{\theta,a,b}(x) := a^{-1/2}\psi\big((x_1\cos\theta + x_2\sin\theta - b)/a\big).$$

This function is constant along lines $x_1\cos\theta + x_2\sin\theta = \text{const}$, and transverse it is a wavelet. The continuous ridgelet transform for $f \in L^2(\mathbb{R}^2)$ is defined as

$$\mathfrak{R}_f(\theta,a,b) := \int_{\mathbb{R}^2} f(x)\psi_{\theta,a,b}(x)\,\mathrm{d}x. \tag{2.1}$$

For $f \in \mathcal{S}(\mathbb{R}^2)$, where $\mathcal{S}(\mathbb{R}^2)$ denotes the Schwartz space, the reconstruction formula is given as

$$f(x) = \int_0^{2\pi}\int_{-\infty}^{\infty}\int_0^{\infty} \mathfrak{R}_f(\theta,a,b)\psi_{\theta,a,b}(x)\,\frac{\mathrm{d}a}{a^3}\,\mathrm{d}b\,\frac{\mathrm{d}\theta}{4\pi}.$$

We introduce the vectors $\Theta := (\cos\theta, \sin\theta)^t$ and $\Theta^\perp := (\sin\theta, -\cos\theta)^t$. Now we can rewrite (2.1) by a change of the integration variable $x = s\Theta + t\Theta^\perp$ as

$$\begin{aligned}\mathfrak{R}_f(\theta,a,b) &= \int_{\mathbb{R}}\int_{\mathbb{R}} f(s\Theta + t\Theta^\perp)a^{-1/2}\psi\big((s-b)/a\big)\,\mathrm{d}s\,\mathrm{d}t\\ &= a^{-1/2}\int_{\mathbb{R}} R_f(\theta,s)\psi\big((s-b)/a\big)\,\mathrm{d}s,\end{aligned} \tag{2.2}$$

where the Radon transform $R_f(\theta, s)$ is defined as

$$\begin{aligned}R_f(\theta,s) &:= \int_{\mathbb{R}} f(s\Theta + t\Theta^\perp)\,\mathrm{d}t\\ &= \int_{\mathbb{R}^2} f(x)\delta(s - x_1\cos\theta - x_2\sin\theta)\,\mathrm{d}x\end{aligned} \tag{2.3}$$

with the Dirac delta distribution δ. Thus, ridgelet analysis can be seen as a form of wavelet analysis in the Radon domain.

For $f \in \mathcal{S}(\mathbb{R}^2)$, Radon transform and Fourier transform are related by the so-called projection theorem or Fourier slice theorem

$$\int_{\mathbb{R}} R_f(\theta, s) \mathrm{e}^{-2\pi \mathrm{i} s\sigma} \, \mathrm{d}s = \int_{\mathbb{R}^2} f(x) \, \mathrm{e}^{-2\pi \mathrm{i}\sigma(x_1 \cos\theta + x_2 \sin\theta)} \, \mathrm{d}x; \tag{2.4}$$

see, e.g., [27].

3. NFFT-based discrete complex ridgelet transform. Following (2.2), the basic strategy for the computation of the discrete ridgelet transform is to calculate the Radon transform R_f and then to compute the 1-D wavelet transform of $R_f(\theta, \cdot)$ for every direction θ.

3.1. Discrete radon transform. In this subsection, we are interested in an efficient discrete Radon transform based on the NFFT, e.g., applied in [29]. First, we sketch the NFFT, and then we explain how to apply it to compute the Radon transform.

Let $n \in \mathbb{N}$ be even, $I_n := \{-\frac{n}{2}, \ldots, \frac{n}{2} - 1\}$, and $\mathbb{T}^2 := [-\frac{1}{2}, \frac{1}{2})^2$. The bivariate NFFT computes approximations $\tilde{F}$ of the trigonometric polynomial

$$F(x) = \sum_{(\mu,\nu) \in I_n^2} f_{\mu,\nu} \, \mathrm{e}^{-2\pi \mathrm{i}(\mu x_1 + \nu x_2)} \tag{3.1}$$

at arbitrary knots $x^{(\ell)} := \big(x_1^{(\ell)}, x_2^{(\ell)}\big)^t \in \mathbb{T}^2$, $\ell = 1, \ldots, M$. Straightforward computation of (3.1) requires $\mathcal{O}(n^2 M)$ arithmetical operations, too much for practical purposes. For equispaced knots $x^{(\mu,\nu)} = (\mu/n, \nu/n)^t$, $(\mu, \nu) \in I_n^2$, the arithmetic complexity can be reduced to $\mathcal{O}(n^2 \log n)$ operations by applying the well-known FFT.

The main idea of the NFFT consists in the approximation of F by linear combinations of translates of a window function. Original approaches used Gaussian bells [13], B-splines [2], or Kaiser–Bessel functions [16, 17] as window functions. A general approach to NFFTs can be found in [34, 30, 18]. Free NFFT software packages are available [21, 15].

The fast computation of (3.1) by the NFFT requires

$$\mathcal{O}(\alpha^2 n^2 \log n + m^2 M)$$

arithmetic operations. Both parameters, the oversampling factor α and the cut-off parameter m, have to be chosen in accordance with the desired accuracy of the fast algorithm. In general the approximation error introduced by the NFFT decays exponentially in m, where the basis of the exponent depends on α. In our numerical experiments, we will use the Gaussian window function. Then the error can be estimated by [14] as

$$\frac{|F(x^{(\ell)}) - \tilde{F}(x^{(\ell)})|}{\sum\limits_{(\mu,\nu) \in I_n^2} |f_{\mu,\nu}|} \leq 16 \mathrm{e}^{-m\pi(1 - 1/(2\alpha - 1))}. \tag{3.2}$$

Next, we want to couple the NFFT with the computation of the Radon transform. Let $f_{\mu,\nu}$, $(\mu, \nu) \in I_n^2$, be given discrete data. For a line $x_1 \cos\theta + x_2 \sin\theta = s$ we discretize the Radon transform (2.3) as

$$R_f(\theta, s) := \sum_{(\mu,\nu) \in I_n^2} f_{\mu,\nu} K(s - \mu\cos\theta - \nu \sin\theta), \tag{3.3}$$

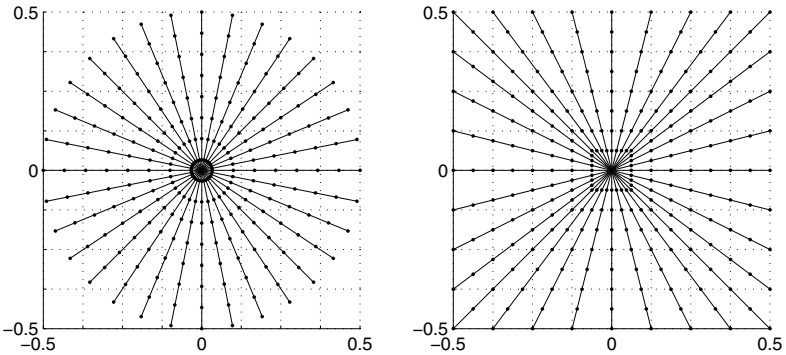

FIG. 3.1. *Polar grid (left) and pseudopolar grid (right).*

where the kernel function

$$K(x) := \sum_{r=-n}^{n-1} \alpha_r \, \mathrm{e}^{2\pi \mathrm{i} r x/(2n)} \tag{3.4}$$

is used as an approximation of the Dirac delta distribution.

We now discretize the parameter domain as $\theta_t = \frac{\pi}{2n} t$ $(t = 0, \ldots, 2n-1)$ and $s = -n, \ldots, n-1$. Together with (3.4), equation (3.3) yields

$$R_f(\theta_t, s) = \sum_{r=-n}^{n-1} \alpha_r \sum_{(\mu,\nu)\in I_n^2} f_{\mu,\nu} \mathrm{e}^{-2\pi \mathrm{i}(\mu \frac{r\cos\theta_t}{2n} + \nu \frac{r\sin\theta_t}{2n})} \mathrm{e}^{2\pi \mathrm{i} r s/(2n)}. \tag{3.5}$$

Note that (3.5) can be seen as a discrete analogue of the Fourier slice theorem (2.4).

Obviously, a fast algorithm for the computation of the discrete Radon transform is given by computing the inner sum in (3.5) by a two-dimensional (2-D) NFFT at the $M = 4n^2$ knots $\left(\frac{r\cos\theta_t}{2n}, \frac{r\sin\theta_t}{2n}\right)_{t,r}$ of the polar grid (see Figure 3.1(left)) followed by multiplication with the kernel coefficients α_r and ends with the computation of the outer sum by 1-D inverse FFTs (iFFTs) for every direction θ_t.

By choosing $\alpha_n = 0$ and $\alpha_{-r} = \alpha_r$ $(r = -n+1, \ldots, n-1)$ in (3.5), we can ensure real values for the discrete Radon transform. In our numerical examples, we will use the (modified) [illegible] $K(x) = \sum_{r=-n+1}^{n-1} \left(1 - \frac{|r|}{n}\right) \mathrm{e}^{2\pi \mathrm{i} r x/(2n)}$.

[illegible] Using in our definition of the discrete Radon transform (3.5) a (modified) Dirichlet kernel $K(x) = \sum_{r=-n}^{n-1} \mathrm{e}^{2\pi \mathrm{i} r x/(2n)}$ together with the pseudopolar grid (see Figure 3.1(right)) leads essentially to the same notion of discrete Radon transform as proposed by Averbuch et al. [1] and Donoho and Flesia [11]. They call their transform [illegible] (FSS). For the computation of the inner sum in (3.5), these authors use the so-called pseudopolar FFT based on the chirp-z transform as an alternative for the NFFT.

3.2. Dual-tree complex wavelet transform. To obtain the ridgelet transform, we have to apply fast 1-D orthogonal wavelet transforms in the Radon domain. Let the projection $R_f(\theta, \cdot)$ in direction θ be represented by a wavelet decomposition of the form

$$R_f(\theta, \cdot) = \sum_{k\in\mathbb{Z}} c_{\theta,j_0,k} \phi_{j_0,k} + \sum_{j\le j_0} \sum_{k\in\mathbb{Z}} d_{\theta,j,k} \psi_{j,k}, \tag{3.6}$$

where $\phi_{j_0,k}$ denotes the scaling function at the coarsest level j_0 associated with the orthogonal wavelet basis $\{\psi_{j,k} := \psi\big((x-b)/a\big) : a = 2^{-j},\ b = k2^{-j},\ k,j \in \mathbb{Z}\}$. Then the coefficients $c_{\theta,j_0,k} = \langle R_f(\theta,\cdot), \phi_{j_0,k}\rangle$ and $d_{\theta,j,k} = \langle R_f(\theta,\cdot), \psi_{j,k}\rangle$ refer to the smooth components at level j_0 and the detail components at level j in direction θ, respectively.

The discrete wavelet transform (DWT) suffers from shift sensitivity, which is caused by aliasing due to the transform having maximal decimation at each level. Many wavelet techniques, including undecimated wavelet transform and complex wavelet transform, have been explored to solve this problem, but they either require highly redundant computational cost or they do not have perfect reconstruction or good filter characteristics. Based on the z-transform theory of linear time invariant systems, Kingsbury [19, 20] proposed the dual-tree complex wavelet transform (DT CWT), which adds perfect reconstruction to approximate shift invariance of complex wavelets. In contrast to the $\mathcal{O}(n \log n)$ undecimated DWT, which is $\log n$ times redundant in one dimension and $3 \log n$ times redundant in two dimensions, the DT CWT is only slightly redundant by a factor of 2 in one dimension and 4 in two dimensions. Thus, the computational complexity of the DT CWT remains $\mathcal{O}(n)$, the same as for the decimated DWT.

Furthermore, the complex ridgelet transform can provide better phase information, a useful property for many applications. In [25], one of us showed that the ridgelet transform can achieve approximate shift invariance by the use of the DT CWT. Unfortunately, textural artifacts are still unavoidable since the finite $\mathbb{Z}_p^2$ Radon transform is used as a building block in [25]. However, the DT CWT used in this paper is well motivated by this prior attempt.

The DT CWT is a special discrete complex wavelet transform, which is essentially a combination of two different real wavelet transforms by a sophisticated dual tree. More precisely, we have two wavelet decompositions of the form (3.6) with scaling functions $\phi^r_{j_0,k}$, $\phi^i_{j_0,k}$ and wavelets $\psi^r_{j,k}$, $\psi^i_{j,k}$, respectively. We set $\phi_{j_0,k} := \frac{1}{\sqrt{2}}(\phi^r_{j_0,k} - \mathrm{i}\phi^i_{j_0,k})$ and $\psi_{j,k} := \frac{1}{\sqrt{2}}(\psi^r_{j,k} - \mathrm{i}\psi^i_{j,k})$. Then the DT CWT can be seen as the real part of a decomposition of the form (3.6) with the outputs of the dual tree interpreted as the real and imaginary parts of the complex coefficients

$$c_{\theta,j_0,k}(f) := \tfrac{1}{\sqrt{2}}\langle R_f(\theta,\cdot), \phi^r_{j_0,k}\rangle + \mathrm{i}\tfrac{1}{\sqrt{2}}\langle R_f(\theta,\cdot), \phi^i_{j_0,k}\rangle,$$
$$d_{\theta,j,k}(f) := \tfrac{1}{\sqrt{2}}\langle R_f(\theta,\cdot), \psi^r_{j,k}\rangle + \mathrm{i}\tfrac{1}{\sqrt{2}}\langle R_f(\theta,\cdot), \psi^i_{j,k}\rangle.$$

Therefore, we will call the proposed ridgelets [illegible]. Note that the filter/wavelet design for the DT CWT is rather sophisticated. In our experiments, we will use the nearly orthogonal (13,19)-tap filters at level 1 and the 18-tap Q-shift filters constructed in [20] for the higher levels.

In summary, we obtain the following algorithm for the fast computation of the discrete complex ridgelet transform.

ALGORITHM 3.1 (discrete complex ridgelet transform).

[illegible] $f := (f_{\mu,\nu})_{(\mu,\nu)\in I_n^2}$

1. [illegible] $\theta_t = \frac{\pi}{2n}t$ $(t = 0,\dots,2n-1)$ [illegible] $r = -n,\dots,n-1$ [illegible]

$$\hat{f}_{\theta_t,r} := \sum_{(\mu,\nu)\in I_n^2} f_{\mu,\nu}\, \mathrm{e}^{-2\pi\mathrm{i}\left(\mu\frac{r\cos\theta_t}{2n} + \nu\frac{r\sin\theta_t}{2n}\right)}$$

[illegible] 2 [illegible]

2. [illegible] $s = -n, \dots, n-1$ [illegible]

$$R_f(\theta_t, s) = \sum_{r=-n}^{n-1} \hat{f}_{\theta_t,r}\, \mathrm{e}^{2\pi \mathrm{i} rs/(2n)}$$

[illegible] 1 [illegible] $\hat{f}_{\theta_t,r}$ [illegible] θ_t

3. [illegible]

$$c_{\theta_t,j_0,k}(f) \quad [\text{illegible}] \quad d_{\theta_t,j,k}(f)$$

[illegible] 1 [illegible] $R_f(\theta_t, \cdot)$ [illegible] θ_t
[illegible] $c_{\theta_t,j_0,k}(f)$ $d_{\theta_t,j,k}(f)$

3.3. The inverse complex ridgelet transform. The inverse discrete complex ridgelet transform can be achieved by inverting the steps of Algorithm 3.1 one after the other in reverse order.

Inverting the 2-D NFFT (3.1) in the first step needs more attention. We consider the following reconstruction or recovery problem. Given the values $F^{(\ell)} \in \mathbb{C}$ of a trigonometric polynomial at nonequispaced knots $x^{(\ell)} \in \mathbb{T}^2$ $(\ell = 1, \dots, M)$, the aim is to reconstruct its Fourier coefficients $f_{\mu,\nu}$, $(\mu, \nu) \in I_n^2$, i.e., to solve the linear system of equations

$$\sum_{(\mu,\nu)\in I_n^2} f_{\mu,\nu} \mathrm{e}^{-2\pi \mathrm{i}(\mu x_1^{(\ell)} + \nu x_2^{(\ell)})} = F^{(\ell)} \qquad (\ell = 1, \dots, M). \tag{3.7}$$

In our case, the number of knots is larger than the dimension of the space of trigonometric polynomials, i.e., $M > n^2$, so that the linear system (3.7) is overdetermined and can thus only be solved approximately. A standard method is to use the least squares approximation. For its numerical solution, the free NFFT software package [21] provides fast iterative CG-type algorithms (iNFFTs) which involve the NFFT for the fast matrix-vector multiplications occurring in the CG steps. The approximation error remains the same as for the NFFT estimated by inequality (3.2).

Since the second step of Algorithm 3.1 can be easily inverted by 1-D FFTs and the first step can be inverted (approximately to arbitrary accuracy) by a 2-D iNFFT, we also have a fast algorithm for the inverse discrete Radon transform. The algorithm possesses low arithmetic costs and leads to a good reconstruction quality similar to that of filtered backprojection.

ALGORITHM 3.2 (inverse discrete complex ridgelet transform).

[illegible] $c_{\theta_t,j_0,k}(f)$ $d_{\theta_t,j,k}(f)$

1. [illegible] $s = -n, \dots, n-1$ [illegible] $\theta_t = \frac{\pi}{2n} t$ $(t = 0, \dots, 2n-1)$ [illegible]

$$R_f(\theta_t, s)$$

2. [illegible] $r = -n, \dots, n-1$ [illegible]

$$\hat{f}_{\theta_t,r} = \sum_{s=-n}^{n-1} R_f(\theta_t, s)\, \mathrm{e}^{-2\pi \mathrm{i} rs/(2n)}$$

[illegible] 1 [illegible] θ_t

3. [illegible] $(\mu,\nu) \in I_n^2$ [illegible] $f_{\mu,\nu}$ [illegible]

$$\hat{f}_{\theta_t,r} = \sum_{(\mu,\nu)\in I_n^2} f_{\mu,\nu}\, \mathrm{e}^{-2\pi \mathrm{i}\left(\mu \frac{r\cos\theta_t}{2n} + \nu \frac{r\sin\theta_t}{2n}\right)}$$

[illegible] 2 [illegible] $f := (f_{\mu,\nu})_{(\mu,\nu)\in I_n^2}$

4. Combination of hard thresholding with TV minimization. The combination of ordinary wavelet shrinkage with TV minimization was successfully applied in various papers [8, 12, 23, 26]. In this paper we apply the technique with respect to our ridgelet coefficients. We mainly follow the approach in [12].

Many problems such as denoising and feature extraction can be written as the model

$$f = f_{\text{true}} + \varepsilon,$$

where f is the observed function, f_{true} is the function (or component) to estimate, and ε is white Gaussian noise or, more generally, an unwanted component. Our aim is to restore f_{true} without artifacts, i.e., recover the smooth parts of f_{true} while preserving the discontinuities.

The [illegible] τ is defined for $x \in \mathbb{C}$ as

$$\tau(x) := \begin{cases} x, & |x| \geq \sigma, \\ 0, & |x| < \sigma. \end{cases}$$

We restrict our attention to hard thresholding, although other thresholding functions such as soft thresholding or garotte thresholding can also be used. Applying hard thresholding with some fixed threshold σ to the complex ridgelets coefficients $d_{\theta_t,j,k}(f)$ of our discrete function f and applying the inverse discrete complex ridgelet transform of Algorithm 3.2 results in a function $f^{(0)}$. The indices of the ridgelet coefficients retained after hard thresholding are recorded in Λ, i.e.,

$$\Lambda := \big\{(\theta_t, j, k) : |d_{\theta_t,j,k}(f)| \geq \sigma\big\}.$$

Unfortunately, wavelet thresholding produces artificial oscillations near discontinuities, a phenomenon known as "pseudo-Gibbs phenomenon" or "side-band effect." To lower the pseudo-Gibbs artifacts we will use TV minimization. For a function $f : \mathbb{R}^2 \supseteq \Omega \to \mathbb{R}$ with $|\nabla f(x)| \in L^1(\mathbb{R}^2)$ the TV functional is defined by

$$TV(f) = \int_\Omega \big|\nabla f(x)\big|\, \mathrm{d}x. \tag{4.1}$$

TV functionals as regularizing terms became very popular in image processing. Meanwhile, there exists a broad literature on this topic. In particular, relations between TV regularization and wavelet shrinkage were examined in [35, 38].

To circumvent computational difficulties arising from the nondifferentiability of the modulus at zero, the TV functional is often replaced by

$$TV(f) = \int_\Omega \sqrt{\big|\nabla f(x)\big|^2 + \beta^2}\, \mathrm{d}x \tag{4.2}$$

with a small parameter $\beta > 0$; see [36]. In the following, we restrict our attention to (4.2) and use the following discrete version for $f := \big(f_{\mu,\nu}\big)_{(\mu,\nu)\in I_n^2}$:

$$TV(f) = \sum_{\mu,\nu} \sqrt{\big|(\delta_1 f)_{\mu,\nu}\big|^2 + \big|(\delta_2 f)_{\mu,\nu}\big|^2 + \beta^2}, \tag{4.3}$$

where $(\delta_1 f)_{\mu,\nu} = f_{\mu+1,\nu} - f_{\mu,\nu}$, $(\delta_2 f)_{\mu,\nu} = f_{\mu,\nu+1} - f_{\mu,\nu}$. More precisely, for our given f let

$$U := \Big\{ u := \big(u_{\mu,\nu}\big)_{(\mu,\nu)\in I_n^2} : c_{\theta_t,j_0,k}(u) = c_{\theta_t,j_0,k}(f) \quad \forall(\theta_t,k), \\ d_{\theta_t,j,k}(u) = d_{\theta_t,j,k}(f) \quad \forall(\theta_t,j,k)\in\Lambda \Big\}.$$

Then we are looking for the solution of the constrained minimization problem

$$\min_{u\in U} TV(u). \tag{4.4}$$

Let the linear subspace V of functions on I_n^2 be given by

$$V := \Big\{ v := \big(v_{\mu,\nu}\big)_{(\mu,\nu)\in I_n^2} : c_{\theta_t,j_0,k}(v) = 0 \quad \forall(\theta_t,k), \\ d_{\theta_t,j,k}(v) = 0 \quad \forall(\theta_t,j,k)\in\Lambda \Big\}.$$

Then it holds that $U = f^{(0)} + V$; i.e., U is an affine and hence convex space. Since the TV functional is convex, too, problem (4.4) has a solution. Given a positive sequence $(t_\ell)_{\ell=0}^\infty$ with $\lim_{\ell\to\infty} t_\ell = 0$ and $\sum_{\ell=0}^\infty t_\ell = \infty$, it was shown in [12] that a solution of (4.4) can be computed by the following [illegible] (using subgradients for the nonmodified TV functional (4.1)):

$$f^{(\ell+1)} = f^{(\ell)} - t_\ell P_V\big(\nabla_f TV(f^{(\ell)})\big)$$

with our hard-thresholded function $f^{(0)}$ as initial guess. Here $P_V(g)$ denotes the projection of g onto V, i.e., the inverse discrete complex ridgelet transform of

$$c_{\theta_t,j_0,k}(v) := 0, \qquad d_{\theta_t,j,k}(v) := \begin{cases} 0 & \text{for } (\theta_t,j,k)\in\Lambda, \\ d_{\theta_t,j,k}(g) & \text{else.} \end{cases}$$

It is applied to the gradient ∇_f of the discrete TV functional (4.3) given by

$$\begin{aligned} \nabla_f TV(f) := {} & (2f_{\mu,\nu} - f_{\mu,\nu+1} - f_{\mu+1,\nu})\big[(f_{\mu,\nu+1} - f_{\mu,\nu})^2 + (f_{\mu+1,\nu} - f_{\mu,\nu})^2 + \beta^2\big]^{-1/2} \\ & + (f_{\mu,\nu} - f_{\mu-1,\nu})\big[(f_{\mu-1,\nu+1} - f_{\mu-1,\nu})^2 + (f_{\mu-1,\nu} - f_{\mu,\nu})^2 + \beta^2\big]^{-1/2} \\ & + (f_{\mu,\nu} - f_{\mu,\nu-1})\big[(f_{\mu+1,\nu-1} - f_{\mu,\nu-1})^2 + (f_{\mu,\nu} - f_{\mu,\nu-1})^2 + \beta^2\big]^{-1/2} \end{aligned} \tag{4.5}$$

for the inner points $(\mu,\nu)\in I_n^2$ and corresponding modifications at the boundary ∂I_n^2.

Algorithm 4.1 (TV minimization of complex ridgelet coefficients).

5. Experiments. Some abbreviations used in this section should be declared. Nridgelet-c denotes the discrete complex ridgelet transform of Algorithm 3.1 and Nridgelet-c-tv is the proposed Algorithm 4.1. We always use the Gaussian window function with cut-off parameter $m = 4$ and oversampling factor $\alpha = 2$ for the NFFT [21]. The DT CWT is due to Kingsbury [20] and applied with the near-symmetry (13,19)-tap biorthogonal filters at level 1 and 18-tap Q-shift filters in a cascaded way at levels beyond level 1. Other abbreviations are Nridgelet for the NFFT-based real ridgelet transform, in which we use DWT (Sym4 wavelets) in the second step instead of the DT CWT and FRIT for Do and Vetterli's finite $\mathbb{Z}_p^2$ ridgelet transform.

In the first test, we show the inverse Nridgelet-c of a point (all ridgelet coefficients are zero but one). In Figures 5.1(a) and (b) the obtained 2-D (resp., three-dimensional (3-D)) surface is depicted. Unlike FRIT, it can be seen that the Nridgelet-c is free from wrap-around artifacts. The similar sample was given using the recent discrete analytical ridgelet transform (DART) in [7]. Our method is also better than the DART in terms of the influence of the wrap-around artifacts in comparison to the displayed illustrations. However, we note that it is nonsmooth along the ridge shown in Figure 5.1(b). The proposed Nridgelet-c in this paper is not based on true ridge function, because the polar grid is adopted.

Our next test shows the good performance of the proposed method for denoising an image with line singularities. An image (256×256) of an object used in [10] is considered in order to compare with other methods conveniently. Figure 5.2(a) shows the object contaminated with additive zero-mean Gaussian white noise of variance σ^2. A universal hard thresholding is applied to denoising. Figure 5.2(b) shows the result obtained using the (9,7)-tap DWT. As we know, it causes nonsmoothness along the edges. Figure 5.2(c) shows the result obtained using FRIT. It suffers from strongly textural artifacts. Figure 5.2(d) shows the result obtained using the Nridgelet. Figure 5.2(e) shows the result obtained using the Nridgelet-c. It can be seen from Figures 5.2(d) and (e) that the proposed framework is effective in recovering straight edges, even with such heavy background noise. The Nridgelet-c shows a better result with fewer line-like artifacts, as well as in terms of the signal to noise ratio (SNR). Generally speaking, a more oscillating wavelet basis used in the second step produces fewer

artifacts, as mentioned in [10], but causes more computational burden because of its larger support. A similar denoising sample using the FSS-based ridgelet transform and DART with a very oscillating wavelet basis (Daubechies20) is depicted in [7, Fig. 3]. There seem to be fewer disturbing artifacts than in the Nridgelet result, but the edges are not very clear. Figure 5.2(f) in this paper shows the result obtained using the Nridgelet-c-tv with $t_\ell = 0.1$ ($\ell = 1, \ldots, 120$). It is much more effective in reducing undesirable artifacts, including the pseudo-Gibbs artifacts, while preserving the edges.

Figure 5.3 shows a comparison of the center profile taken across the original object and Figures 5.2(e) and (f), respectively. The effectivity of Nridgelet-c-tv can be seen

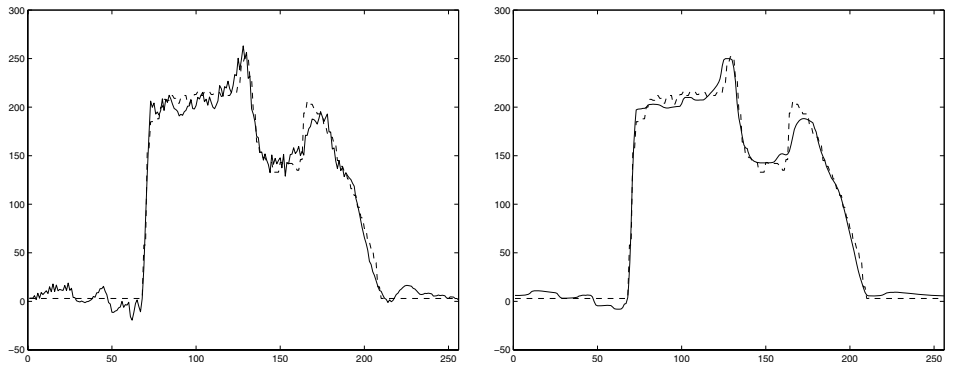

FIG. 5.3. *The center profile taken across the original object (shown as the dashed line) and the reconstruction by* (a) *the Nridgelet-c (shown in Figure* 5.2(e)*) and* (b) *the Nridgelet-c-tv (shown in Figure* 5.2(f)*), respectively.*

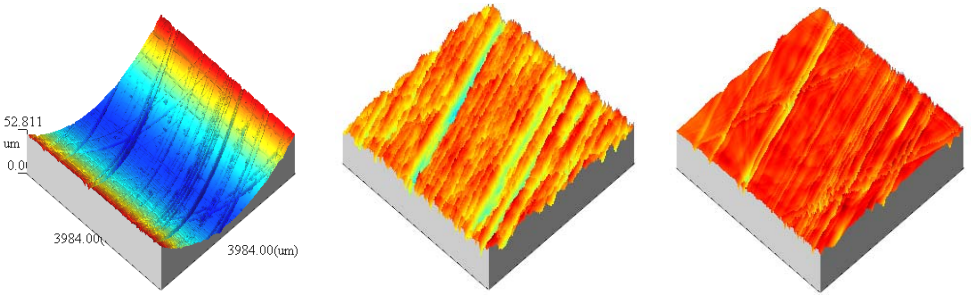
more clearly from these profiles.

The simple thresholding scheme is effective for the ridgelet methods in denoising the piecewise smooth image with line singularities, because the line singularities are represented by a few large coefficients while noise unlikely generates significant coefficients. From the view of the hybrid approach, the Nridgelet-c combines just the multiresolution analysis of the DT CWT with the anisotropy of the Radon transform. Nridgelet-c-tv offers an optimal choice of reconstructed coefficients in the procedure of thresholding.

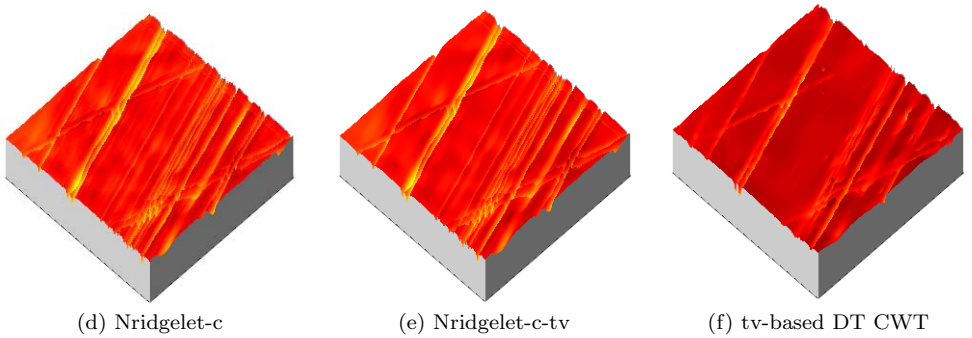
In our third test, we apply the proposed method to extract straight scratches in the bands of roughness and waviness in order to study the functional performance of the 3-D surface topography of systems according to different applications. The extracted information could be fed back to monitor and manufacturing processes or to study actual contact stress, loaded area, asperity volume, and lubrication regimes occurring during the initial stages of wear of surfaces in service.

Figure 5.4 shows a typical engineering surface: a honed surface from an automotive engine cylinder. This kind of surface includes the form, waviness, and roughness components that almost submerge the main features of the deep valleys/scratches. Usually, the most important features that affect the performance of the cylinder are scratches whose distribution and amplitude will considerably influence the flow of gas or air in a pressure balance of an engine.

Figure 5.4(a) is the raw measured surface including the form, waviness, and roughness components. Figure 5.4(b) is the extracted surface using FRIT followed by removing form error. It is far way from satisfaction because of the strongly texture-like artifacts. Figure 5.4(c) is the extracted surface using the Nridgelet. As we supposed, the DWT suffers from shift aliasing, which leads to the line-like artifacts in the extracted surface by Nridgelet. Figure 5.4(d) is the extracted surface using Nridgelet-c. The edge-preserving scratches are nicely restored. But the pseudo-Gibbs artifacts resulting from the aberrant ridgelet coefficients are still visible. Figure 5.4(e) is the extracted surface using the Nridgelet-c-tv with $t_\ell = 0.001$ ($\ell = 1, \ldots, 100$). The nonsmooth artifacts are reduced remarkably. This is due to the fact that Nridgelet-c-tv allows the reconstruction of some small ridgelet coefficients, which are canceled by thresholding. Furthermore, the elimination of pseudo-Gibbs artifacts can be seen more clearly from their center profiles shown in Figure 5.5, in which Figures 5.5(a)



(a) raw measured surface (b) FRIT (c) Nridgelet



(d) Nridgelet-c (e) Nridgelet-c-tv (f) tv-based DT CWT

FIG. 5.4. *Extraction of scratches from a honed surface of an automotive engine cylinder.*

FIG. 5.5. *The center profiles taken across* (a) *the Nridgelet-c extracted surface (shown in Figure* 5.4(d)*) and* (b) *the Nridgelet-c-tv extracted surface (shown in Figure* 5.4(e)*), respectively.*

and (b) are taken across the extracted surfaces using Nridgelet-c and Nridgelet-c-tv, as shown in Figures 5.4(d) and (e), respectively. The experiments show that the method is more efficient in removing the pseudo-Gibbs oscillations when the DT CWT and TV are joined. As to the method when one uses TV minimization only, i.e., combining TV with Nridgelet instead of Nridgelet-c, one needs many more iterations than with Nridgelet-c-tv in order to eliminate the strong line-like artifacts caused by shift variance of the DWT. In such a case, the intrinsic scratches will be smoothed over to some extent.

Figure 5.4(f) shows the extracted surface using the TV-based DT CWT method with 500 iterations proposed in [23]. The method has a good performance, but in

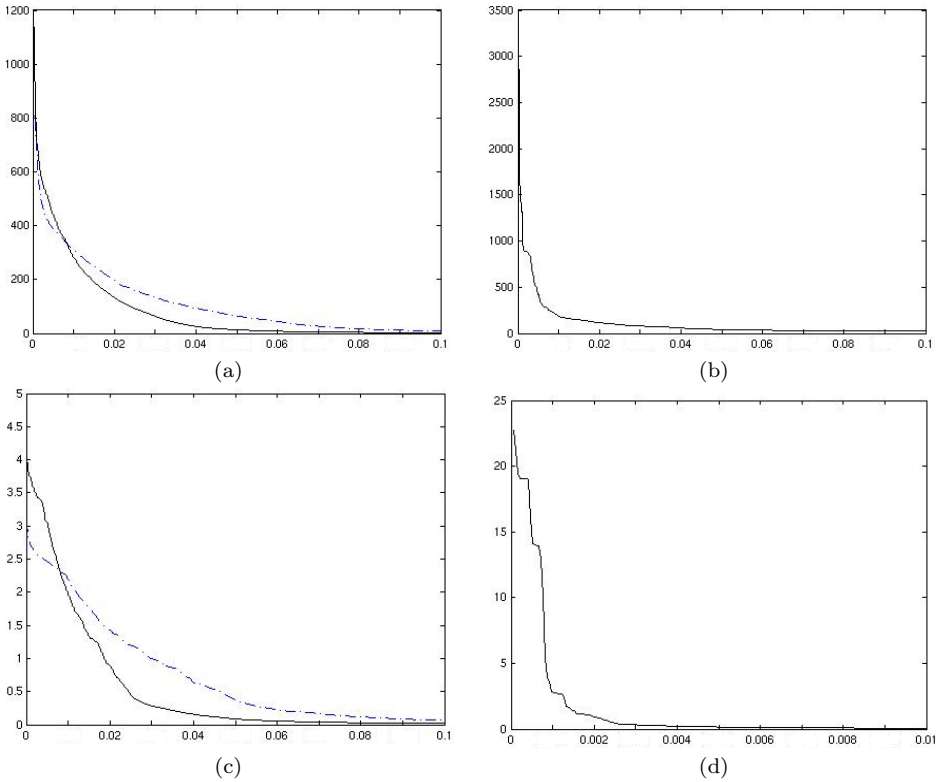

FIG. 5.6. *Decreasing rearrangement of ridgelet coefficients of object (upper) and HalfDome (lower).* (a) *and* (c): *the real line denotes Nridgelet coefficients and the dotted-dashed line denotes Nridgelet-c coefficients;* (b) *and* (d): *FRIT coefficients. Note the difference of the horizontal coordinate in* (d).

terms of the extraction of scratches, setting a high threshold to kick out the point-like features causes the intrinsic features to be destroyed and some shallow scratches to be missed. This is because wavelets lack line sensitivity.

In our last test, we examine the decay of the ridgelet coefficients. The proposed method in this paper is an overcomplete system. Although it shows good performance for denoising and feature extraction, the main disappointment is the relatively slow decay of the coefficients in the ridgelet domain. Figure 5.6 gives two examples to show the decreasing rearrangement of the ridgelet transform coefficients, in comparison to the orthogonal FRIT. The upper line shows the rearrangement of the object used in the second test. The object cannot be represented as a summation of a few global linear singularities, and thus it is not in the optimal class of the ridgelet transform [10]. The lower line shows those of a typically optimal class: HalfDome, i.e., the mutilated Gaussian $g(x_1, x_2) = 1_{\{x_2>0\}} e^{-x_1^2-x_2^2}$. The decay of coefficients of the proposed ridgelet transform is much slower than that of FRIT, especially for the optimal class.

However, leaving out the captious criticism, the proposed ridgelet transform is very effective to sparsely represent line singularities. Figure 5.7 shows the histogram of the coarsest subband $d_{\theta,j_0,k}$ of HalfDome. The distribution is characterized by a very sharp peak (at zero) with an extended tail. The highly non-Gaussian distribution

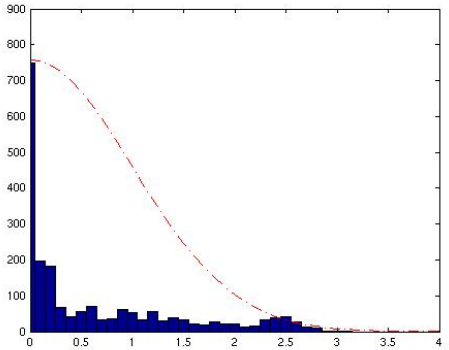

FIG. 5.7. *Histogram of the coarsest subband* $d_{\theta,j_0,k}$ *of HalfDome. The dotted-dashed line denotes the sketch of normal distribution.*

implies that the transform is very spare. Other experiments of real surfaces with line scratches display similar distributions. It is rare to meet natural images with global linear singularities, but for engineering surfaces, many kinds of these images belong to the optimal class of ridgelet transform. So, application of ridgelets to this field is of practical interest.

We remark that visual similar result can be obtained with the pseudopolar grid. Using the Dirichlet kernel instead of the Fejér kernel in (3.5) yields slightly worse results.

6. Conclusions. Based on the requirements of highly accurate functional analysis of engineering surfaces, a new method for line-feature extraction has been proposed by designing a NFFT-based discrete complex ridgelet transform with TV-minimization synthesis. The transform is achieved by taking 1-D DT CWTs (to achieve approximate shift invariance) on the projections of the NFFT-based discrete Radon transform, which identifies the polar grid as a nonequispaced data grid in Cartesian coordinates and thus avoids linear interpolations. This method can be easily modified to incorporate the pseudopolar grid. We remark that the pseudopolar grid together with unequispaced FFT was recently also applied by Candès et al. for the efficient computation of the curvelet transform [4]. TV minimization does not set the nonsignificant ridgelet coefficients simply to zero but typically inputs optimal small values to cancel the pseudo-Gibbs oscillation in the vicinity of discontinuities and eliminates the ripples while perfectly preserving the strong edges and shapes of features. Although the NFFT-based Radon transform, the DT CWT, and TV minimization are not new, they are combined for the first time in this paper. Numerical experiments show that this method performs an almost artifact-free denoising and feature extraction for surfaces with line singularities. It is very significant for ongoing applications on precision engineering involving the steel, pump, and biomedical industries.

NEUMANN–NEUMANN DOMAIN DECOMPOSITION PRECONDITIONERS FOR LINEAR-QUADRATIC ELLIPTIC OPTIMAL CONTROL PROBLEMS*

MATTHIAS HEINKENSCHLOSS† AND HOANG NGUYEN‡

Abstract. We present a class of domain decomposition (DD) preconditioners for the solution of elliptic linear-quadratic optimal control problems. Our DD preconditioners are extensions of Neumann–Neumann DD preconditioners, which have been successfully applied to the solution of single PDEs. The DD preconditioners are based on a decomposition of the optimality conditions for the elliptic linear-quadratic optimal control problem into smaller subdomain optimality conditions with Dirichlet boundary conditions for the states and the adjoints on the subdomain interfaces. These subdomain optimality conditions are coupled through Neumann interface conditions for the states and the adjoints. This decomposition leads to a Schur complement system in which the unknowns are the state and adjoint variables on the subdomain interfaces. The Schur complement operator is the sum of subdomain Schur complement operators, the application of which is shown to correspond to the solution of subdomain elliptic linear-quadratic optimal control problems, which are essentially smaller copies of the original optimal control problem. We show that, under suitable conditions, the application of the inverse of the subdomain Schur complement operators requires the solution of a subdomain elliptic linear-quadratic optimal control problem with Neumann interface conditions for the state. The subdomain Schur complement operators are analyzed in the variational setting of the problem as well as the algebraic setting obtained after a finite element discretization of the problem. Definiteness properties of the algebraic form of the (subdomain) Schur complement operator(s) are studied. Numerical tests show that the dependence of these preconditioners on mesh size and subdomain size is comparable to its counterpart applied to elliptic equations only. These tests also show that the preconditioners are insensitive to the size of the control regularization parameter.

1. Introduction.

This paper is concerned with a class of nonoverlapping domain decomposition (DD) preconditioners for linear-quadratic elliptic optimal control problems. The solution of linear-quadratic elliptic optimal control problems arises in many applications, either directly or as subproblems in Newton or sequential quadratic programming methods for the solution of nonlinear elliptic optimal control problems. After a finite element discretization, convex linear-quadratic elliptic optimal control problems lead to large-scale symmetric indefinite linear systems. The solution of these large systems is a very time consuming step and must be done iteratively, typically with a preconditioned Krylov subspace method. Developing good preconditioners for these linear systems is an important part of improving the overall performance of the solution method.

To illustrate our ideas, we consider the example problem

$$\text{(1.1a)} \qquad \text{minimize} \quad \frac{1}{2}\int_{\Omega_o}(y(x)-\hat{y}(x))^2dx+\frac{\alpha}{2}\int_{\partial\Omega}u^2(x)dx,$$

$$\text{(1.1b)} \qquad \text{subject to} \quad -\Delta y(x)+\sigma y(x)=\widehat{f}(x) \qquad \text{in } \Omega,$$

$$\text{(1.1c)} \qquad \frac{\partial}{\partial n}y(x)=u(x) \qquad \text{on } \partial\Omega,$$

where $\hat{y}, \widehat{f}$ are given functions and $\alpha > 0$ and $\sigma \geq 0$ are given parameters. The problem (1.1) has to be solved for y and u. Detailed model problem assumptions will be introduced in section 3. While (1.1) is used to illustrate the DD preconditioners introduced in this paper, their formulation and many of their properties carry over to more general linear-quadratic elliptic optimal control problems.

Our DD preconditioners for linear-quadratic elliptic optimal control problems such as (1.1) are based on a decomposition of the system of necessary and sufficient optimality conditions. We decompose Ω into nonoverlapping subdomains. We then introduce state and adjoint variables on the subdomain interfaces and formulate subdomain optimality conditions with Dirichlet boundary conditions for states and adjoints on the subdomain interfaces. These subdomain optimality conditions are coupled by requiring continuity of normal derivatives of subdomain state and adjoints, defined as solutions of the local optimality conditions, on the subdomain interfaces. This leads to subdomain Schur complement operators that map Dirichlet interface data into Neumann interface data. The original optimality conditions are equivalent to an optimality Schur complement system in which the operator is given by the sum of subdomain Schur complements. The properties of the subdomain Schur complements allow the construction of preconditioners for the optimality condition Schur complement system that are extensions of the Neumann–Neumann methods, which have been successfully applied to single elliptic PDEs [13, 14, 24, 26, 33, 34, 36, 38].

We will show that the application of subdomain Schur complements corresponds to the solution of subdomain optimal control problems that are essentially smaller copies of the original optimal control problem but impose Dirichlet boundary conditions for the state on the subdomain interface and include an objective function term that implies Dirichlet boundary conditions for the adjoint on the subdomain interface. Under suitable conditions, these subdomain Schur complements are invertible. The application of the inverses of local Schur complement operators corresponds to the solution of subdomain optimal control problems that are also essentially smaller copies of the original optimal control problem but impose Neumann boundary conditions on the subdomain interfaces.

The paper is organized as follows. In the next section, we give a brief overview of other DD approaches to solve linear-quadratic optimal control problems and describe how our approach differs from existing ones.

In section 3 we study the model problem (1.1) with emphasis on the case $\sigma = 0$. In this case, the state equation (1.1b), (1.1c) has a solution if and only if the control satisfies a certain compatibility condition; the solution of (1.1b), (1.1c), if it exists, is not unique. In section 3 we will show that the optimal control problem (1.1) has a unique solution. However, the issues outlined above regarding the existence and uniqueness of the solution of the state equation (1.1b), (1.1c) later may lead to singularities in the subproblems arising in our DD methods. This is one reason for choosing the model problem (1.1).

Our DD approach is introduced in section 4. This section introduces the Schur complement formulation of the optimality system and investigates properties of the subdomain Schur complement. The presentation in section 4 is based on the variational form of the optimal control problem (1.1).

The algebraic view of our DD approach is presented in section 5. This view emphasizes the formal similarity between the Neumann–Neumann methods for single elliptic PDEs and our approach. In section 5 we will also investigate the inertia of the Schur complements arising in our DD preconditioners. We will see that the Schur complements arising in the optimal control context are highly indefinite; the number of positive and negative eigenvalues is essentially the same and is equal to the number of discrete state variables on the subdomain interfaces.

Numerical results for our (balancing) Neumann–Neumann preconditioners applied to the model problem (1.1) are given in section 6. The results indicate that the numerical performance of our (balancing) Neumann–Neumann DD methods applied to linear-quadratic elliptic optimal control problems is similar to that of their counterparts applied to single elliptic PDEs. We also observe that the performance of our preconditioners applied to the model problem (1.1) is largely independent of the size of the regularization parameter.

This work significantly expands the material in [20] in which an additional numerical example may be found.

2. Comparison with other domain decomposition approaches. DD-based iterative methods for the solution of linear-quadratic elliptic optimal control problems such as (1.1) can be split into three categories, depending on how the DD is integrated with the optimization. In all cases DD introduces parallelism into the optimization but affects the (outer) iteration differently. We give an outline and refer to [32, sect. 1.2] for more details.

1. The methods in the first category apply preconditioned Krylov subspace methods to the system of discretized optimality conditions (also known as the KKT system) for (1.1). This system has a 3×3 block structure, and the preconditioners for the system matrix (also known as the KKT matrix) are obtained from approximate block factorizations. DD methods are used for the approximate solution of systems involving the stiffness matrix and its transpose. DD is used at the PDE level. These methods require a good preconditioner for the so-called reduced Hessian, which can be difficult to obtain. The methods in [9, 10] belong to this category.

2. The methods in the second category use DD to reformulate the optimization problem (1.1) or its discretization [11, 28]. For example, a reformulation may eliminate state variables in the interior of subdomains by viewing them as functions of the controls in that subdomain as well as state variables on the subdomain interfaces. The optimization variables visible to the outer iteration then consist of the control variables and the state variables restricted to the subdomain interfaces. The optimality conditions for the reformulated problem can be viewed as a Schur complement of the KKT matrix corresponding to the original problem (1.1). This Schur complement involves the state and adjoint variables on the subdomain interfaces as well as all control variables. In contrast, the Schur complement formulation introduced in this paper involves only the state and adjoint variables on the subdomain interfaces. The application of the Schur complement arising in the DD methods in category 2 to a vector requires the solution of subdomain PDEs. Typically, the Schur complements arising in the methods in category 2 are better conditioned than the original KKT matrix, but additional preconditioners are required, especially when α or the mesh

size h is small (see [32, sect. 1.2] for an example). The approach in [12] for a nonlinear parameter identification problem also falls into this category.

3. In [5, 6, 7] DD methods for linear-quadratic elliptic optimal control problems are introduced that are based on a decomposition of the optimality conditions. The resulting iterative method requires the solution of KKT-type systems restricted to smaller domains, and the variables in the iteration are related to states and adjoints on the subdomain interfaces. In [5, 6, 7] Robin-Robin-type transmission conditions are used to connect the subdomain problems. Convergence of the method is proved in [6, 7], but no convergence rates are given. No results regarding the dependence of the convergence on mesh size, subdomain size, and regularization parameter α are given. The KKT-type systems restricted to smaller domains are related to subdomain optimal control problems, but these optimal control problems have a structure different from that of the original ones. In particular, the state space for the subdomain optimal control problems in [6, p. 2411] is twice as large as that of the original optimal control problems restricted to the same subdomain.

DD methods for a class of nonlinear parameter identification problems are investigated in [25, 37]. The augmented Lagrangian method is used for the solution of the nonlinear optimization problem, and DD approaches for unconstrained minimization are used to solve the subproblems within the augmented Lagrangian method.

The methods proposed in this paper, like those in [5, 6, 7], are based on a decomposition of the optimality conditions but use different transmission conditions. One consequence is that the DD methods proposed in this paper require the solution of KKT systems restricted to smaller subdomains, which are related to smaller copies of the original linear-quadratic elliptic optimal control problem. Hence existing code can be reused for subproblem solves. The DD methods proposed in this paper are extensions of the Neumann–Neumann methods, which have been successfully applied to single elliptic PDEs [13, 14, 24, 26, 33, 34, 36, 38]. The numerical performance of our (balancing) Neumann–Neumann DD methods applied to the model problem (1.1) indicates that their performance is similar to that of their counterparts applied to single elliptic PDEs. We also observe that their performance on the model problem (1.1) is largely independent of the size of the regularization parameter. This is important since the condition numbers of the KKT matrix corresponding to (1.1) and of the reduced Hessian grow linearly with α^{-1} (see [32, Chap. 1] for an example). The subdomain problems that need to be solved in our (balancing) Neumann–Neumann DD methods are essentially smaller subdomain copies of (1.1), and state and adjoint variables restricted to subdomain interfaces have to be communicated between adjacent subdomains. Hence our methods, like those in [5, 6, 7], involve more computations per communication than those in categories 1 and 2 sketched above.

The DD preconditioners proposed in this paper complement existing preconditioners for KKT systems, such as those in [1, 3, 4, 8, 9, 10, 21, 15, 16, 18, 19, 23, 29, 31], which can be used as subproblem solvers within our DD preconditioners. Such a combination introduces parallelism. For some applications, such a combination may make existing preconditioners that rely on sparse matrix factorizations feasible, since they now are applied to smaller subproblems.

3. The example problem. In this section, we define the setting for the model problem (1.1), establish existence and uniqueness of its solution, and derive necessary and sufficient optimality conditions. If $\sigma > 0$, the state equation (1.1b) has a unique solution y for given control u. In this case existence and uniqueness of solutions as well as derivation of necessary and sufficient optimality conditions are standard (see,

e.g., [27]). The case $\sigma = 0$ is more interesting and is the focus of this section. In the case $\sigma = 0$, the state equation (1.1b) is solvable if and only if the control satisfies a certain compatibility condition; if (1.1b) is solvable, the solution is not unique.

Let $\Omega \subset \mathbb{R}^d$, $d = 2, 3$, be an open, bounded set with Lipschitz boundary, let $\Omega_o \subset \Omega$ be measurable with $\operatorname{meas}(\Omega_o) > 0$, let $\hat{y} \in L^2(\Omega_0)$, $\widehat{f} \in L^2(\Omega)$ be given functions, and let $\alpha > 0$, $\sigma \geq 0$ be given parameters. We define the (bi)linear forms

$$a : H^1(\Omega) \times H^1(\Omega) \to \mathbb{R}, \qquad a(y, \psi) = \int_\Omega \nabla y(x) \nabla \psi(x) + \sigma y(x) \psi(x) dx,$$

$$b : L^2(\partial\Omega) \times H^1(\Omega) \to \mathbb{R}, \qquad b(u, \psi) = -\int_{\partial\Omega} u(x) \psi(x) dx,$$

$$m : H^1(\Omega) \times H^1(\Omega) \to \mathbb{R}, \qquad m(y, \psi) = \int_{\Omega_o} y(x) \psi(x) dx,$$

$$q : L^2(\partial\Omega) \times L^2(\partial\Omega) \to \mathbb{R}, \qquad q(u, \mu) = \alpha \int_{\partial\Omega} u(x) \mu(x) dx,$$

$$f : H^1(\Omega) \to \mathbb{R}, \qquad f(\psi) = \int_\Omega \widehat{f}(x) \psi(x) dx.$$

We are interested in the solution $y \in H^1(\Omega)$, $u \in L^2(\partial\Omega)$ of the optimal control problem

$$\text{minimize} \quad \tfrac{1}{2} m(y - \hat{y}, y - \hat{y}) + \tfrac{1}{2} q(u, u), \tag{3.1a}$$

$$\text{subject to} \quad a(y, \phi) + b(u, \phi) = f(\phi) \quad \forall \phi \in H^1(\Omega). \tag{3.1b}$$

THEOREM 3.1. [illegible] $\sigma \geq 0$ [illegible] (3.1) [illegible] $(u_*, y_*) \in L^2(\partial\Omega) \times H^1(\Omega)$ [illegible] $p_* \in H^1(\Omega)$ [illegible]

$$a(\psi, p) + m(y, \psi) = m(\hat{y}, \psi) \qquad \forall \psi \in H^1(\Omega), \tag{3.2a}$$

$$q(u, \mu) + b(\mu, p) = 0 \qquad \forall \mu \in L^2(\partial\Omega), \tag{3.2b}$$

$$a(y, \phi) + b(u, \phi) = f(\phi) \qquad \forall \phi \in H^1(\Omega). \tag{3.2c}$$

[illegible] (3.2) [illegible] $y_* \in H^1(\Omega)$ $u_* \in L^2(\partial\Omega)$ $p_* \in H^1(\Omega)$ [illegible]. For $\sigma > 0$ the state equation (3.1b) has a unique solution y for any $u_* \in L^2(\partial\Omega)$ and $f \in (H^1(\Omega))'$. In this case, the assertion of the theorem is well known and a proof can be found, e.g., in [27] or by a modification of the arguments below.

Let $\sigma = 0$. We recall that for given $l \in (H^1(\Omega))'$ the equation

$$a(y, \phi) = l(\phi)$$

has a solution if and only if $l(1) = 0$. If $l(1) = 0$ and if y_0 is a solution, then the set of solutions is given by $y_0 + \gamma$, $\gamma \in \mathbb{R}$.

(i) [illegible] We define

$$Y = \left\{ y \in H^1(\Omega) \ : \ \int_\Omega y(x)dx = 0 \right\}.$$

By the second Poincaré inequality (see, e.g., [35, Cor. 6.100], [39, Thm. 7.7]),

$$\|y\|_Y = \|\nabla y\|_{L^2(\Omega)}$$

defines a norm on Y which on Y is equivalent to $\|\cdot\|_{H^1(\Omega)}$. Moreover, Y equipped with $\|\cdot\|_Y$ is a Hilbert space. Standard arguments can be used to show that if $u \in L^2(\partial\Omega)$ satisfies $f(1) = b(u,1)$, then (3.1b) has a unique solution $y \in Y$ and there exists $\kappa > 0$, independent of u and f such that

$$\|y\|_Y \le \kappa(\|u\|_{L^2(\partial\Omega)} + \|f\|_{(H^1(\Omega))'}).$$

The problem (3.1), which is an optimization problem in $u \in L^2(\partial\Omega)$, $y \in H^1(\Omega)$, can be written as an optimization problem in $u \in L^2(\partial\Omega)$, $y_0 \in Y$, $\gamma \in \mathbb{R}$ given by

$$\text{(3.3a)} \qquad \text{minimize} \quad \tfrac{1}{2}m(y_0 + \gamma - \hat{y}, y_0 + \gamma - \hat{y}) + \tfrac{1}{2}q(u,u),$$

$$\text{(3.3b)} \qquad \text{subject to} \quad a(y_0,\psi) + b(u,\psi) = f(\psi) \quad \forall \psi \in H^1(\Omega).$$

Using the affine linear map $u \mapsto y_0(u)$ that maps $u \in L^2(\partial\Omega)$ with $b(u,1) = f(1)$ to the solution $y_0(u) \in Y$ of (3.3b), we can write (3.3) as

$$\text{(3.4a)} \qquad \text{minimize} \quad \tfrac{1}{2}m(y_0(u) + \gamma - \hat{y}, y_0(u) + \gamma - \hat{y}) + \tfrac{1}{2}q(u,u),$$

$$\text{(3.4b)} \qquad \text{subject to} \quad b(u,1) = f(1).$$

For fixed u satisfying (3.4b), the unique solution of

$$\min_\gamma \tfrac{1}{2}m(y_0(u) + \gamma - \hat{y}, y_0(u) + \gamma - \hat{y})$$

is given by

$$\gamma(u) = -\int_{\Omega_o} y_0(u;x) - \hat{y}(x)dx \Big/ \int_{\Omega_o} dx. \tag{3.5}$$

Note that

$$\int_{\Omega_o} y_0(u;x) + \gamma(u) - \hat{y}(x)dx = 0. \tag{3.6}$$

Using the definition (3.5) of $\gamma(u)$, (3.4) can be written as the following optimization problem in u only:

$$\text{(3.7a)} \qquad \text{Minimize} \quad \tfrac{1}{2}m(y_0(u) + \gamma(u) - \hat{y}, y_0(u) + \gamma(u) - \hat{y}) + \tfrac{1}{2}q(u,u),$$

$$\text{(3.7b)} \qquad \text{subject to} \quad b(u,1) = f(1).$$

Since $u \mapsto y_0(u)$ is an affine linear map, $u \mapsto y_0(u) + \gamma(u)$ is affine linear and (3.7a) is strictly convex. The existence and uniqueness of the optimal control u_* follows by standard arguments (see, e.g., [22]). The unique corresponding state is given by $y_* = y_0(u_*) + \gamma(u_*)$.

(ii) [illegible]. The optimality conditions follow from an application of the Lagrange multiplier theorem (see, e.g., [22]). First, we show that the linear constraints are surjective. Let $f \in (H^1(\Omega))'$ be arbitrary. If we define $u = -\|f\|_{(H^1(\Omega))'}/\int_{\partial\Omega} dx$, then the state equation (3.2c) has a solution $y \in H^1(\Omega)$. This proves the surjectivity of the constraints.

Since the constraints are surjective, there exists $p \in H^1(\Omega)$ such that the partial Fréchet derivatives of

$$L(y,u,p) = \tfrac{1}{2}m(y-\hat{y},y-\hat{y}) + \tfrac{1}{2}q(u,u) + a(y,p) + b(y,p) - f(p)$$

with respect to y, u, and p are equal to zero. This gives (3.2). Since the optimal control problem (3.1) is convex, the necessary optimality conditions are also sufficient.

(iii) [illegible]. In part (i) we have already shown the uniqueness of the optimal state and control. The uniqueness of the associated adjoint p_* remains to be shown. We write the optimal state, control, and adjoint as

$$y_* = y_0 + \gamma, \quad u_* = u_0 + u_f, \quad p_* = p_0 + \eta,$$

where $y_0, p_0 \in Y$, $u_0 \in \{u \in L^2(\partial\Omega) \,:\, b(u,1) = 0\}$, $u_f = -\|f\|_{(H^1(\Omega))'}/\int_{\partial\Omega} dx$, and $\gamma, \eta \in \mathbb{R}$. The function y_0 is the unique solution (in Y) of the state equation (3.2c), and γ is given by (3.5). Since the optimal state $y_* = y_0 + \gamma$ satisfies (3.6), the adjoint equation (3.2a) has a solution $p_* = p_0 + \eta$, where $p_0 \in Y$ is unique. Using the representation of u_* and p_* as well as the decomposition $L^2(\partial\Omega) = \{u \in L^2(\partial\Omega) \,:\, b(u,1) = 0\} \oplus \operatorname{span}\{1\}$ (by definition of b, $\{u \in L^2(\partial\Omega) \,:\, b(u,1) = 0\}$ is the orthogonal complement of $\operatorname{span}\{1\}$ in $L^2(\partial\Omega)$), we can write condition (3.2b) equivalently as

$$\begin{aligned} &q(u_0 + u_f, 1) + b(1, p_0 + \eta) = 0, \\ &q(u_0 + u_f, \mu) + b(\mu, p_0 + \eta) = 0, \quad \mu \in \{u \in L^2(\partial\Omega) \,:\, b(u,1) = 0\}. \end{aligned}$$

The first condition implies

$$\eta = -(q(u_0 + u_f, 1) + b(1, p_0))/b(1,1),$$

and the second condition characterizes $u_0 \in \{u \in L^2(\partial\Omega) \,:\, b(u,1) = 0\}$. ∎

Note that in the case $\sigma = 0$, adjoint equation (3.2a) alone does not have a unique solution, but because the optimal state $y_* = y_0(u_*) + \gamma(u_*)$ satisfies (3.6), the adjoint equation (3.2a) is solvable. The entire optimality system (3.2) specifies optimal state, control, and adjoint uniquely.

4. Domain decomposition Schur complement formulation of the example problem.

4.1. Domain decomposition of the example problem. We discretize (3.1) using conforming linear finite elements. Let $\{T_l\}$ be a triangulation of Ω. We divide Ω into nonoverlapping subdomains Ω_i, $i = 1, \ldots, s$, such that each T_l belongs to exactly one $\overline{\Omega}_i$.

We define

$$\Gamma_i = \partial\Omega_i \setminus \partial\Omega$$

and

$$\Gamma = \bigcup_{i=1}^{s} \Gamma_i.$$

The unit outward normal of Ω_i is denoted by n_i. By Tr_{Γ_i} we denote the trace on Γ_i.

We split the subdomains into no-control subdomains

$$\mathcal{N} = \{i \ : \ \mathrm{int}(\partial\Omega_i \cap \partial\Omega) = \emptyset\}$$

and control subdomains

$$\mathcal{C} = \{i \ : \ \mathrm{int}(\partial\Omega_i \cap \partial\Omega) \neq \emptyset\}.$$

Here int denotes the relative interior.

The state y is approximated using piecewise linear functions. We define the finite dimensional spaces

$$\begin{aligned} V^h &= \left\{v \in H^1(\Omega) \ : \ v|_{T_l} \in P^1(T_l) \ \forall l\right\}, \\ V_i^h &= \left\{v \in H^1(\Omega_i) \ : \ v|_{T_l} \in P^1(T_l) \ \forall T_l \subset \overline{\Omega}_i\right\}, \qquad i = 1, \ldots, s, \\ V_{i,0}^h &= \left\{v \in V_i^h \ : \ v = 0 \text{ on } \Gamma_i\right\}, \qquad i = 1, \ldots, s. \end{aligned} \tag{4.1}$$

We can identify $v_i \in V_{i,0}^h$ with a function in V^h if we extend v_i by zero onto Ω. Furthermore, we introduce the "trace" space V_{i,Γ_i}^h of functions in V_i^h that are zero at vertices in $\overline{\Omega}_i \setminus \Gamma_i$ and the "trace" space V_Γ^h of functions in V^h that are zero at vertices in $\overline{\Omega} \setminus \Gamma$. Hence, each function $v^h \in V^h$ can be written as

$$V^h = \bigoplus_{i=1}^{s} V_{i,0}^h \oplus V_\Gamma^h. \tag{4.2}$$

For our discretization of the control, we use piecewise linear functions on $\partial\Omega$. However, our discretization of the control is somewhat nonstandard. Typically, one would choose the space of discretized controls to be

$$U^h = \left\{u \in C^0(\partial\Omega) \ : \ u \text{ is linear on } \partial\Omega \cap \partial T_l \ \forall T_l \subset \overline{\Omega}\right\}. \tag{4.3}$$

A DD formulation based on such a discretization would introduce "interface controls" (dotted hat function in the left-hand plot in Figure 4.1) defined on a "band" of width $O(h)$ around $\partial\Omega \cap \partial\Omega_i \cap \partial\Omega_j$, $i \neq j$. See the left-hand plot in Figure 4.1. Since the evaluation of $u \in L^2(\partial\Omega)$ on $\partial\Omega \cap \partial\Omega_i \cap \partial\Omega_j$ does not make sense, we avoid interface controls.

We discretize the control u by a function which is continuous on each $\partial\Omega_i$, $i = 1, \ldots, s$, and linear on each $\partial\Omega \cap \partial\Omega_i \cap T_l$. The discretized control is not assumed to be continuous at $\partial\Omega \cap \partial\Omega_i \cap \partial\Omega_j$, $i \neq j$. In particular, for each point $x_k \in \partial\Omega \cap \partial\Omega_i \cap \partial\Omega_j$, $i \neq j$, there are two discrete controls u_{k_i}, u_{k_j} belonging to subdomains Ω_i and Ω_j, respectively (see the right-hand plot in Figure 4.1). Hence, our control discretization depends on the partition $\{\Omega_i\}_{i=1}^d$ of the domain Ω. We define the discrete control spaces

$$U_i^h = \left\{u \in C^0(\partial\Omega \cap \partial\Omega_i) \ : \ u \text{ is linear on } \partial\Omega \cap \partial\Omega_i \cap \partial T_l \ \forall T_l \subset \overline{\Omega}_i\right\}. \tag{4.4}$$

We identify U_i^h with a subspace of $L^2(\partial\Omega)$ by extending functions $u_i \in U_i^h$ by zero onto $\partial\Omega$. We define

$$U^h = \bigcup_{i=1}^{s} U_i^h \subset L^2(\partial\Omega).$$

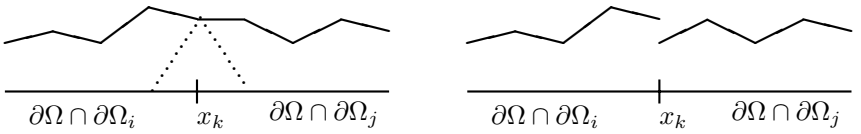

FIG. 4.1. *Sketch of the control discretization for the case* $\Omega \subset \mathbb{R}^2$.

In particular,

$$U^h = \bigoplus_{i=1}^{s} U_i^h. \tag{4.5}$$

Our discretization of (3.2) is given by

$$a(\psi, p) + m(y, \psi) = m(\hat{y}, \psi) \qquad \forall \psi \in V^h, \tag{4.6a}$$

$$q(u, \mu) + b(\mu, p) = 0 \qquad \forall \mu \in U^h, \tag{4.6b}$$

$$a(y, \phi) + b(u, \phi) = f(\phi) \qquad \forall \phi \in V^h. \tag{4.6c}$$

The system (4.6) is also the system of necessary and sufficient optimality conditions for the discretization of (3.1) using piecewise linear finite elements for the state and controls, as described above.

We decompose the optimality system (4.6) using (4.2), (4.5). For this purpose, we introduce the following (bi)linear forms. Let

$$a_i : V_i^h \times V_i^h \to \mathbb{R}, \qquad a_i(y, \psi) = \int_{\Omega_i} \nabla y(x) \nabla \psi(x) + \sigma y(x) \psi(x) dx,$$

$$m_i : V_i^h \times V_i^h \to \mathbb{R}, \qquad m_i(y, \psi) = \int_{\Omega_i \cap \Omega_o} y(x) \psi(x) dx,$$

$$f_i : V_i^h \to \mathbb{R}, \qquad f_i(\psi) = \int_{\Omega_i} \widehat{f}(x) \psi(x) dx,$$

and, if Ω_i is a control subdomain,

$$b_i : U_i^h \times V_i^h \to \mathbb{R}, \qquad b_i(u, \psi) = -\int_{\partial\Omega_i \cap \partial\Omega} u(x) \psi(x) dx,$$

$$q_i : U_i^h \times U_i^h \to \mathbb{R}, \qquad q_i(u, \mu) = \alpha \int_{\partial\Omega_i \cap \partial\Omega} u(x) \mu(x) dx.$$

The parameters $\alpha > 0$ and $\sigma \geq 0$ as well as $\widehat{f} \in L^2(\Omega)$ are given as in section 3.

Now we write $y = y_\Gamma + \sum_{i=1}^s y_i$, $p = p_\Gamma + \sum_{i=1}^s p_i$, and $u = \sum_{i=1}^s u_i$, where $y_\Gamma, p_\Gamma \in V_\Gamma^h$, $y_i, p_i \in V_{i,0}^h$, $i = 1, \ldots, s$, and $u_i \in U_i^h$, $i = 1, \ldots, s$ (cf. (4.2) and (4.5)), and insert these representations into (4.6). Using an analogous decomposition of the test functions, this leads to the systems

$$a_i(\psi, p_i) + m_i(y_i, \psi) = m_i(\hat{y}, \psi) \qquad \forall \psi \in V_{i,0}^h, \tag{4.7a}$$

$$b_i(\mu, p_i) + q_i(u_i, \mu) = 0 \qquad \forall \mu \in U_i^h, \tag{4.7b}$$

$$a_i(y_i, \psi) + b_i(u_i, \psi) = f_i(\psi) \qquad \forall \psi \in V_{i,0}^h, \tag{4.7c}$$

$$y_i = y_\Gamma, \quad p_i = p_\Gamma \qquad \text{on } \Gamma_i \tag{4.7d}$$

for $i \in \mathcal{C}$,

$$a_i(\psi, p_i) + m_i(y_i, \psi) = m_i(\hat{y}, \psi) \qquad \forall \psi \in V_{i,0}^h, \tag{4.8a}$$

$$a_i(y_i, \psi) = f_i(\psi) \qquad \forall \psi \in V_{i,0}^h, \tag{4.8b}$$

$$y_i = y_\Gamma, \quad p_i = p_\Gamma \qquad \text{on } \Gamma_i \tag{4.8c}$$

for $i \in \mathcal{N}$, and

$$\sum_{i=1}^{s} a_i(y_i, q_\Gamma) + b_i(u_i, q_\Gamma) + a_i(v_\Gamma, p_i) + m_i(y_i, v_\Gamma) = \sum_{i=1}^{s} f_i(q_\Gamma) + m_i(\hat{y}_i, v_\Gamma) \quad \forall\, v_\Gamma, q_\Gamma \in V_\Gamma^h. \tag{4.9}$$

The next theorem states that solving the optimality conditions (4.6) is equivalent to finding $(y_\Gamma, p_\Gamma) \in V_\Gamma^h \times V_\Gamma^h$ such that the solutions $(y_i, u_i, p_i) \in V_i^h \times U_i^h \times V_i^h$, $i \in \mathcal{C}$, and $(y_i, p_i) \in V_i^h \times V_i^h$, $i \in \mathcal{N}$, of (4.7) and (4.8), respectively, satisfy the interface conditions (4.9).

THEOREM 4.1. [illegible] $(y, u, p) \in V^h \times U^h \times V^h$ [illegible] (4.6) [illegible] $y_i = y|_{\Omega_i}$ $p_i = p|_{\Omega_i}$ $i = 1, \ldots, s$ $u_i = u|_{\Omega_i}$ $i \in \mathcal{C}$ [illegible] (4.7) (4.9) [illegible] $(y_\Gamma, p_\Gamma) \in V_\Gamma^h \times V_\Gamma^h$ [illegible] $(y_i, u_i, p_i) \in V_i^h \times U_i^h \times V_i^h$ $i \in \mathcal{C}$ [illegible] $(y_i, p_i) \in V_i^h \times V_i^h$ $i \in \mathcal{N}$ [illegible] (4.7) [illegible] (4.8) [illegible] (4.9) [illegible] $(y, u, p) \in V^h \times U^h \times V^h$ [illegible] $y_i = y|_{\Omega_i}$ $p_i = p|_{\Omega_i}$ $i = 1, \ldots, s$ $u_i = u|_{\Omega_i}$ $i \in \mathcal{C}$ [illegible] (4.6)

The proof of this theorem is analogous to the proof of [34, Lem. 1.2.1] and is omitted.

Our next goal is to view the solution of (4.7), (4.8) as an affine linear function of (y_Γ, p_Γ) and then consider (4.9) as a linear equation in (y_Γ, p_Γ). This Schur complement system will be solved using a preconditioned Krylov subspace method. To derive this Schur complement system, however, we first have to investigate the solvability of (4.7) and (4.8).

4.2. The subdomain optimality systems. We investigate the solvability of the systems (4.7) and (4.8). These are the weak forms of

$$-\Delta y_i(x) + \sigma y_i(x) = f(x) \qquad \text{in } \Omega_i, \tag{4.10a}$$

$$\frac{\partial}{\partial n} y_i(x) = u_i(x) \qquad \text{on } \partial\Omega \cap \partial\Omega_i, \tag{4.10b}$$

$$y_i(x) = y_\Gamma(x) \qquad \text{on } \Gamma_i, \tag{4.10c}$$

$$-\Delta p_i(x) + \sigma p_i(x) = -(y_i(x) - \hat{y}(x))|_{\Omega_o} \qquad \text{in } \Omega_i, \tag{4.10d}$$

$$\frac{\partial}{\partial n} p_i(x) = 0 \qquad \text{on } \partial\Omega \cap \partial\Omega_i, \tag{4.10e}$$

$$p_i(x) = p_\Gamma(x) \qquad \text{on } \Gamma_i, \tag{4.10f}$$

$$\alpha u_i(x) - p_i(x) = 0 \qquad \text{on } \partial\Omega \cap \partial\Omega_i \tag{4.10g}$$

and

$$-\Delta y_i(x) + \sigma y_i(x) = f(x) \qquad \text{in } \Omega_i, \tag{4.11a}$$

$$y_i(x) = y_\Gamma(x) \qquad \text{on } \Gamma_i, \tag{4.11b}$$

$$-\Delta p_i(x) + \sigma p_i(x) = -(y_i(x) - \hat{y}(x))|_{\Omega_o} \qquad \text{in } \Omega_i, \tag{4.11c}$$

$$p_i(x) = p_\Gamma(x) \qquad \text{on } \Gamma_i, \tag{4.11d}$$

respectively.

We will show that (4.7), (4.8) have unique solutions, even if $\sigma = 0$ (see Theorems 4.3 and 4.4 below). This is due to the presence of Dirichlet boundary conditions, which ensure that the state equations (4.7c) and (4.8b) have a unique solution for each $u_i \in U_i^h$ and that the adjoint equations (4.7a) and (4.8a) have a unique solution for each $y_i \in V_i^h$.

LEMMA 4.2. [illegible] $\sigma \geq 0$ [illegible] $l_i \in (V_{i,0}^h)^*$ [illegible]

$$a_i(y_i, \psi) = l_i(\psi) \quad \forall \psi \in V_{i,0}^h.$$

[illegible] $\kappa_i > 0$ [illegible] l_i [illegible] $\|y_i\|_{V_i^h} \leq \kappa_i \|l_i\|_{(V_i^h)^*}$ [illegible]. By the Poincaré inequality there exists $c_i > 0$ such that $c_i \|y_i\|_{V_i^h}^2 \leq a_i(y_i, y_i)$ for all $y_i \in V_{i,0}^h$. The lemma now follows from a standard application of the Lax–Milgram theorem. □

The system (4.8) is a system of elliptic differential equations in triangular form that can be easily solved by first determining $y_i \in V_i^h$ from the second equation in (4.8) and then $p_i \in V_i^h$ from the first equation in (4.8). The unique solvability of the two elliptic PDEs follows from the definition of V_{i,Γ_i}^h and from Lemma 4.2.

THEOREM 4.3. [illegible] (4.8) [illegible] $(y_i, u_i, p_i) \in V_i^h \times U_i^h \times V_i^h$

Next we will show that (4.7) are the optimality conditions for a convex linear-quadratic optimal control problem restricted to the subdomain Ω_i. Let Ω_i be a control subdomain. Formally the system (4.7) (or its corresponding strong form (4.10)) may be viewed as the necessary and sufficient optimality conditions for

(4.12a)
$$\text{minimize } \frac{1}{2}\int_{\Omega_o \cap \Omega_i} (y_i(x) - \hat{y}(x))^2 dx + \frac{\alpha}{2}\int_{\partial\Omega_i} u_i^2(x) dx + \int_{\Gamma_i} \frac{\partial}{\partial n_i} y_i(x) p_\Gamma(x) dx,$$

(4.12b)
$$\text{subject to } -\Delta y_i(x) + \sigma y_i(x) = \widehat{f}(x) \text{ in } \Omega_i,$$

(4.12c)
$$\frac{\partial}{\partial n} y_i(x) = u_i(x) \text{ on } \partial\Omega_i \cap \partial\Omega,$$

(4.12d)
$$y_i(x) = y_\Gamma(x) \text{ on } \Gamma_i.$$

The local optimal control problem (4.12) is an optimization problem in the variables u_i, y_i; all other quantities in (4.12) are given.

To rigorously establish a relationship between (4.7) and (4.12) we have to make precise the meaning of the state equation (4.12b)–(4.12d) and of the objective function (4.12a). The state equation (4.12b)–(4.12d) is understood in the weak sense (4.7c), (4.7d). Concerning the objective function (4.12a) we note that equations (4.12b), (4.12c) imply

$$\begin{aligned}
&\int_{\Gamma_i} \frac{\partial}{\partial n} y_i(x) \psi(x) dx \\
&= \int_{\Omega_i} \nabla y_i(x) \nabla \psi(x) + \sigma y_i(x) \psi(x) dx - \int_{\partial\Omega \cap \partial\Omega_i} u(x) \psi(x) dx - \int_{\Omega_i} \widehat{f}(x) \psi(x) dx, \\
&= a_i(y_i, \psi) + b_i(u_i, \psi) - f_i(\psi).
\end{aligned}$$

Thus, in (4.12a) we set

$$\int_{\Gamma_i} \frac{\partial}{\partial n} y_i(x) p_\Gamma(x) dx = a_i(y_i, \mathcal{R}_i p_\Gamma) + b_i(u_i, \mathcal{R}_i p_\Gamma) - f_i(\mathcal{R}_i p_\Gamma),$$

where $\mathcal{R}_i : V_{i,\Gamma_i}^h \to V_i^h$, is a continuous linear extension operator satisfying $\mathrm{Tr}_{\Gamma_i}(\mathcal{R}_i v_\Gamma) = v_\Gamma$ for all $v_\Gamma \in V_{i,\Gamma_i}^h$. To summarize, the problem (4.12) is understood as follows:

$$\begin{aligned} &\text{Minimize} && \frac{1}{2} m_i(y_i - \hat{y}, y_i - \hat{y}) + \frac{\alpha}{2} q_i(u_i, u_i) \\ &&& + a_i(y_i, \mathcal{R}_i p_\Gamma) + b_i(u_i, \mathcal{R}_i p_\Gamma) - f_i(\mathcal{R}_i p_\Gamma), && \text{(4.13a)} \\ &\text{subject to} && a_i(y_i, \psi) + b_i(u_i, \psi) = f_i(\psi) \quad \forall \psi \in V_{i,0}^h, && \text{(4.13b)} \\ &&& y_i = y_\Gamma \quad \text{on } \Gamma_i. && \text{(4.13c)} \end{aligned}$$

THEOREM 4.4. [illegible] (4.13) [illegible] (4.7) [illegible] (4.13)

[illegible]. (i) By definition of V_{i,Γ_i}^h and Lemma 4.2, the state equations (4.13b), (4.13c) have a unique solution $y_i(u_i) \in V_i^h$ for every $u_i \in U_i^h$. Moreover, $u_i \mapsto y_i(u_i)$ is a continuous affine linear map. Thus, the presence of $\frac{\alpha}{2} q_i(u_i, u_i)$ in the objective ensures that (4.13) is strictly convex and has a unique solution.

(ii) Since (4.13) is a convex linear-quadratic optimal control problem, $y_i \in V_i^h, u_i \in U_i^h$ is a solution of (4.13) if and only if (4.13b), (4.13c) are satisfied and the Fréchet derivative of (4.13a) applied to all vectors in the null-space of the constraints (4.13b), (4.13c) is zero, i.e., if

$$m_i(y_i - \hat{y}, z_i) + q_i(u_i, v_i) + a_i(z_i, \mathcal{R}_i p_\Gamma) + b_i(v_i, \mathcal{R}_i p_\Gamma) = 0 \tag{4.14a}$$

for all $v_i \in U_i^h$ and all $z_i \in V_{i,0}^h$ satisfying the homogeneous linear state equation

$$a_i(z_i, \psi) + b_i(V_i^h, \psi) = 0 \quad \forall \psi \in V_{i,0}^h. \tag{4.14b}$$

Let $y_i \in V_i^h, u_i \in U_i^h$ be a solution of (4.13). Let p_i solve (4.7a) and $p_i = p_\Gamma$ on Γ_i, and define $p_i^0 = p_i - \mathcal{R}_i p_\Gamma \in V_{i,0}^h$. Let $v_i \in U_i^h$ be arbitrary and let $z_i \in V_{i,0}^h$ be the corresponding solution of (4.14b). Using (4.14b) with $\psi = p_i^0$, (4.7a) with $\phi = z_i$, and (4.14a) implies that

$$\begin{aligned} 0 &= m_i(y_i - \hat{y}, z_i) + q_i(u_i, v_i) + a_i(z_i, \mathcal{R}_i p_\Gamma) + b_i(v_i, \mathcal{R}_i p_\Gamma) \\ &\quad + a_i(z_i, p_i^0) + b_i(v_i, p_i^0) \\ &= m_i(y_i - \hat{y}, z_i) + q_i(u_i, v_i) + a_i(z_i, p_i) + b_i(v_i, p_i) \\ &= q_i(u_i, v_i) + b_i(v_i, p_i) \end{aligned}$$

for all $V_i^h \in U_i^h$. Hence, if $y_i \in V_i^h, u_i \in U_i^h$ is a solution of (4.13), then (4.7) is satisfied.

On the other hand, let $y_i, p_i \in V_i^h, U_i^h \in U_i^h$ solve (4.7). Define $p_i^0 = p_i - \mathcal{R}_i p_\Gamma \in V_{i,0}^h$. Let $v_i \in U_i^h, z_i \in V_{i,0}^h$ satisfy the homogeneous linear state equation (4.14b). If we use (4.7a) with $\phi = z_i$, (4.7b) with $\mu = v_i$, and (4.14b) with $\psi = p_i^0$, we obtain

$$\begin{aligned} 0 &= m_i(y_i - \hat{y}, z_i) + q_i(u_i, v_i) + a_i(z_i, p_i) + b_i(v_i, p_i) - a_i(z_i, p_i^0) + b_i(v_i, p_i^0) \\ &= m_i(y_i - \hat{y}, z_i) + q_i(u_i, v_i) + a_i(z_i, \mathcal{R}_i p_\Gamma) + b_i(v_i, \mathcal{R}_i p_\Gamma). \end{aligned}$$

Thus, (4.14a) is satisfied and, therefore, $y_i \in V_i^h, u_i \in U_i^h$ solve (4.13). ∎

4.3. Schur complement formulation. Now we formulate the Schur complement system; i.e, we view the solution of (4.7), (4.8) as an affine linear function of (y_Γ, p_Γ) and then consider (4.9) as a linear equation in (y_Γ, p_Γ).

For $i \in \mathcal{C}$ we define the operator

$$\mathcal{H}_i^h \in \mathcal{L}(V_\Gamma^h \times V_\Gamma^h, V_i^h \times U_i^h \times V_i^h) \tag{4.15a}$$

with

$$\mathcal{H}_i^h(y_\Gamma, p_\Gamma) = \begin{pmatrix} (\mathcal{H}_i^h)^y(y_\Gamma, p_\Gamma) \\ (\mathcal{H}_i^h)^u(y_\Gamma, p_\Gamma) \\ (\mathcal{H}_i^h)^p(y_\Gamma, p_\Gamma) \end{pmatrix} = \begin{pmatrix} y_i^0 \\ u_i^0 \\ p_i^0 \end{pmatrix}, \tag{4.15b}$$

where (y_i^0, u_i^0, p_i^0) is the solution of (4.7) with $f = 0$ and $\hat{y} = 0$. For $i \in \mathcal{N}$ we define the operator

$$\mathcal{H}_i^h \in \mathcal{L}(V_\Gamma^h \times V_\Gamma^h, V_i^h \times V_i^h) \tag{4.16a}$$

with

$$\mathcal{H}_i^h(y_\Gamma, p_\Gamma) = \begin{pmatrix} (\mathcal{H}_i^h)^y(y_\Gamma, p_\Gamma) \\ (\mathcal{H}_i^h)^p(y_\Gamma, p_\Gamma) \end{pmatrix} = \begin{pmatrix} y_i^0 \\ p_i^0 \end{pmatrix}, \tag{4.16b}$$

where (y_i^0, p_i^0) is the solution of (4.8) with $f = 0$ and $\hat{y} = 0$. The linear operators (4.15), (4.16) may be viewed as generalizations of the harmonic extension used in DD methods for linear elliptic PDEs to elliptic linear-quadratic optimal control problems.

THEOREM 4.5. [illegible] $0 < c < C$ [illegible] h [illegible]

$$c\|(y_\Gamma, p_\Gamma)\|_{(V_{i,\Gamma_i}^h)^2} \le \|\mathcal{H}_i^h(y_\Gamma, p_\Gamma)\|_{V_i^h \times U_i^h \times V_i^h} \le C\|(y_\Gamma, p_\Gamma)\|_{(V_{i,\Gamma_i}^h)^2} \tag{4.17}$$

[illegible] $y_\Gamma, p_\Gamma \in (V_{i,\Gamma_i}^h)^2$

[illegible]. We consider the case that Ω_i is a control subdomain, i.e., that (y_i^0, u_i^0, p_i^0) in (4.15b) is the solution of (4.7) with $f = 0$ and $\hat{y} = 0$. The other case can be proved similarly.

(i) Let $y_\Gamma, p_\Gamma \in (V_{i,\Gamma_i}^h)^2$ be arbitrary and let (y_i^0, u_i^0, p_i^0) be the corresponding solution of (4.7) with $f = 0$ and $\hat{y} = 0$. By the trace theorem, there exist constants $c_1, c_2 > 0$, independent of $y_\Gamma, p_\Gamma \in (V_{i,\Gamma_i}^h)^2$, such that

$$\|y_\Gamma\|_{V_{i,\Gamma_i}^h} \le c_1\|y_i^0\|_{V_i^h}, \quad \|p_\Gamma\|_{V_{i,\Gamma_i}^h} \le c_2\|p_i^0\|_{V_i^h},$$

where (y_i^0, u_i^0, p_i^0) is the solution of (4.7) with $f = 0$ and $\hat{y} = 0$. This implies the left-hand inequality in (4.17).

(ii) Let $\mathcal{R}_i : V_{i,\Gamma_i}^h \to V_i^h$ be a continuous linear extension operator satisfying $\mathrm{Tr}_{\Gamma_i}(\mathcal{R}_i v_\Gamma) = v_\Gamma$ for all $v_\Gamma \in V_{i,\Gamma_i}^h$.

The y, p component of the solution (y_i^0, u_i^0, p_i^0) of (4.7) with $f = 0$ and $\hat{y} = 0$ can be written as $y_i^0 = \mathcal{R}_i y_\Gamma + \tilde{y}_i$, $p_i^0 = \mathcal{R}_i p_\Gamma + \tilde{p}_i$, where $\tilde{y}_i, \tilde{p}_i \in V_{i,0}^h$, and $(\tilde{y}_i, u_i^0, \tilde{p}_i) \in V_{i,0}^h \times U_i^h \times V_{i,0}^h$ solve

$$a_i(\psi, \tilde{p}_i) + m_i(\tilde{y}_i, \psi) = -a_i(\psi, \mathcal{R}_i p_\Gamma) - m_i(\mathcal{R}_i y_\Gamma, \psi) \qquad \forall \psi \in V_{i,0}^h, \tag{4.18a}$$

$$b_i(\mu, \tilde{p}_i) + q_i(u_i^0, \mu) = -b_i(\mu, \mathcal{R}_i p_\Gamma) \qquad \forall \mu \in U_i^h, \tag{4.18b}$$

$$a_i(\tilde{y}_i, \phi) + b_i(u_i^0, \phi) = -a_i(\mathcal{R}_i y_\Gamma, \phi) \qquad \forall \phi \in V_{i,0}^h. \tag{4.18c}$$

The properties of the bilinear forms a_i, b_i, equation (4.18c), and the continuity of $\mathcal{R}_i$ imply the existence of $c_3, c_4 > 0$ independent of $\tilde{y}_i, u_i^0, y_\Gamma$ such that

$$\begin{aligned} \|\tilde{y}_i\|_{V_i^h} &\le c_3\Big(\|u_i^0\|_{U_i^h} + \|\mathcal{R}_i y_\Gamma\|_{V_i^h}\Big) \\ &\le c_4\Big(\|u_i^0\|_{U_i^h} + \|y_\Gamma\|_{V_{i,\Gamma_i}^h}\Big). \end{aligned} \tag{4.19}$$

Similarly, properties of the bilinear forms a_i, m_i, equation (4.18a), the continuity of $\mathcal{R}_i$, and (4.19) imply the existence of $c_5, c_6 > 0$ independent of $\tilde{y}_i, u_i^0, y_\Gamma, \tilde{p}_i, p_\Gamma$ such that

$$\begin{aligned} \|\tilde{p}_i\|_{V_i^h} &\le c_5\Big(\|\tilde{y}_i\|_{V_i^h} + \|\mathcal{R}_i y_\Gamma\|_{V_i^h} + \|\mathcal{R}_i p_\Gamma\|_{V_i^h}\Big) \\ &\le c_6\Big(\|u_i^0\|_{U_i^h} + \|y_\Gamma\|_{V_{i,\Gamma_i}^h} + \|p_\Gamma\|_{V_{i,\Gamma_i}^h}\Big). \end{aligned} \tag{4.20}$$

If we set $\psi = \tilde{y}_i$, $\mu = u_i^0$, $\phi = -\tilde{p}_i$ in (4.18) and add the equations, we obtain

$$m_i(\tilde{y}_i, \tilde{y}_i) + q_i(u_i^0, u_i^0) = -a_i(\tilde{y}_i, \mathcal{R}_i p_\Gamma) - m_i(\mathcal{R}_i y_\Gamma, \tilde{y}_i) - b_i(u^0, \mathcal{R}_i p_\Gamma) + a_i(\mathcal{R}_i y_\Gamma, \tilde{p}_i).$$

The properties of the bilinear forms a_i, b_i, q_i, m_i, the continuity of $\mathcal{R}_i$, and the inequalities (4.19), (4.20) guarantee the existence of $c_7, c_8 > 0$ independent of $\tilde{y}_i, u_i^0, y_\Gamma, p_\Gamma$ such that

$$\begin{aligned} \alpha\|u_i^0\|_{U_i^h}^2 &\le m_i(\tilde{y}_i, \tilde{y}_i) + q_i(u_i^0, u_i^0) \\ &\le c_7\Big(\|\tilde{y}_i\|_{V_i^h}\|p_\Gamma\|_{V_{i,\Gamma_i}^h} + \|\tilde{y}_i\|_{V_i^h}\|y_\Gamma\|_{V_{i,\Gamma_i}^h} + \|u_i^0\|_{U_i^h}\|p_\Gamma\|_{V_{i,\Gamma_i}^h} \\ &\qquad + \|\tilde{p}_i\|_{V_i^h}\|y_\Gamma\|_{V_{i,\Gamma_i}^h}\Big) \\ &\le c_8\Big(\|y_\Gamma\|_{V_{i,\Gamma_i}^h} + \|p_\Gamma\|_{V_{i,\Gamma_i}^h}\Big)\|u_i^0\|_{U_i^h} + c_8\Big(\|y_\Gamma\|_{V_{i,\Gamma_i}^h} + \|p_\Gamma\|_{V_{i,\Gamma_i}^h}\Big)^2 \\ &\le \frac{\alpha}{2}\|u_i^0\|_{U_i^h}^2 + \frac{c_8^2}{2\alpha}\Big(\|y_\Gamma\|_{V_{i,\Gamma_i}^h} + \|p_\Gamma\|_{V_{i,\Gamma_i}^h}\Big)^2 + c_8\Big(\|y_\Gamma\|_{V_{i,\Gamma_i}^h} + \|p_\Gamma\|_{V_{i,\Gamma_i}^h}\Big)^2. \end{aligned}$$

Hence,

$$\|u_i^0\|_{U_i^h} \le c_9\Big(\|y_\Gamma\|_{V_{i,\Gamma_i}^h} + \|p_\Gamma\|_{V_{i,\Gamma_i}^h}\Big), \tag{4.21}$$

where $c_9 = \sqrt{2c_8/\alpha + c_8^2/\alpha^2}$. The right-hand inequality in (4.17) now follows from (4.19), (4.20), (4.21). ∎

Let $\langle\!\langle \cdot, \cdot \rangle\!\rangle$ denote the duality pairing between $(V_\Gamma^h)^2$ and $((V_\Gamma^h)^*)^2$. We define the subdomain Schur complement operator

$$\mathcal{S}_i^h \in \mathcal{L}((V_\Gamma^h)^2, ((V_\Gamma^h)^*)^2), \tag{4.22a}$$

$i = 1, \ldots, s$, with

$$\begin{aligned} &\langle\!\langle \mathcal{S}_i^h(y_\Gamma, p_\Gamma), (v_\Gamma, q_\Gamma) \rangle\!\rangle \\ &= a_i((\mathcal{H}_i^h)^y(y_\Gamma, p_\Gamma), (\mathcal{H}_i^h)^p(v_\Gamma, q_\Gamma)) + b_i((\mathcal{H}_i^h)^u(y_\Gamma, p_\Gamma), (\mathcal{H}_i^h)^p(v_\Gamma, q_\Gamma)) \\ &\quad + a_i((\mathcal{H}_i^h)^y(v_\Gamma, q_\Gamma), (\mathcal{H}_i^h)^p(y_\Gamma, p_\Gamma)) + m_i((\mathcal{H}_i^h)^y(y_\Gamma, p_\Gamma), (\mathcal{H}_i^h)^y(v_\Gamma, q_\Gamma)) \end{aligned} \tag{4.22b}$$

for $i \in \mathcal{C}$, and

$$\begin{aligned}
&\langle\!\langle \mathcal{S}_i^h(y_\Gamma, p_\Gamma), (v_\Gamma, q_\Gamma) \rangle\!\rangle \\
&= a_i((\mathcal{H}_i^h)^y(y_\Gamma, p_\Gamma), (\mathcal{H}_i^h)^p(v_\Gamma, q_\Gamma)) \\
&\quad + a_i((\mathcal{H}_i^h)^y(v_\Gamma, q_\Gamma), (\mathcal{H}_i^h)^p(y_\Gamma, p_\Gamma)) + m_i((\mathcal{H}_i^h)^y(y_\Gamma, p_\Gamma), (\mathcal{H}_i^h)^y(v_\Gamma, q_\Gamma))
\end{aligned} \tag{4.22c}$$

for $i \in \mathcal{N}$. The definition of $\mathcal{H}_i^h$ implies that for $i \in \mathcal{C}$,

$$\begin{aligned}
&\langle\!\langle \mathcal{S}_i^h(y_\Gamma, p_\Gamma), (v_\Gamma, q_\Gamma) \rangle\!\rangle \\
&= a_i((\mathcal{H}_i^h)^y(y_\Gamma, p_\Gamma), (\mathcal{H}_i^h)^p(v_\Gamma, q_\Gamma)) + b_i((\mathcal{H}_i^h)^u(y_\Gamma, p_\Gamma), (\mathcal{H}_i^h)^p(v_\Gamma, q_\Gamma)) \\
&\quad + b_i((\mathcal{H}_i^h)^u(v_\Gamma, q_\Gamma), (\mathcal{H}_i^h)^p(y_\Gamma, p_\Gamma)) + q_i((\mathcal{H}_i^h)^u(y_\Gamma, p_\Gamma), (\mathcal{H}_i^h)^u(v_\Gamma, q_\Gamma)) \\
&\quad + a_i((\mathcal{H}_i^h)^y(v_\Gamma, q_\Gamma), (\mathcal{H}_i^h)^p(y_\Gamma, p_\Gamma)) + m_i((\mathcal{H}_i^h)^y(y_\Gamma, p_\Gamma), (\mathcal{H}_i^h)^y(v_\Gamma, q_\Gamma)).
\end{aligned} \tag{4.22d}$$

We define $r_i \in ((V_\Gamma^h)^*)^2$, $i = 1, \ldots, s$, as follows. If $i \in \mathcal{C}$, then

$$\begin{aligned}
\langle\!\langle r_i, (v_\Gamma, q_\Gamma) \rangle\!\rangle &= f_i((\mathcal{H}_i^h)^p(v_\Gamma, q_\Gamma)) + m_i(\hat{y}_i, (\mathcal{H}_i^h)^y(v_\Gamma, q_\Gamma)) \\
&\quad - a_i(y_i, (\mathcal{H}_i^h)^p(v_\Gamma, q_\Gamma)) - b_i(u_i, (\mathcal{H}_i^h)^p(v_\Gamma, q_\Gamma)) \\
&\quad - a_i((\mathcal{H}_i^h)^y(v_\Gamma, q_\Gamma), p_i) - m_i(y_i, (\mathcal{H}_i^h)^y(v_\Gamma, q_\Gamma)),
\end{aligned} \tag{4.23}$$

where (y_i, u_i, p_i) is the solution of (4.7) with $y_\Gamma = 0$ and $p_\Gamma = 0$. If $i \in \mathcal{N}$, then

$$\begin{aligned}
\langle\!\langle r_i, (v_\Gamma, q_\Gamma) \rangle\!\rangle &= f_i((\mathcal{H}_i^h)^p(v_\Gamma, q_\Gamma)) + m_i(\hat{y}_i, (\mathcal{H}_i^h)^y(v_\Gamma, q_\Gamma)) - a_i(y_i, (\mathcal{H}_i^h)^p(v_\Gamma, q_\Gamma)) \\
&\quad - a_i((\mathcal{H}_i^h)^y(v_\Gamma, q_\Gamma), p_i) - m_i(y_i, (\mathcal{H}_i^h)^y(v_\Gamma, q_\Gamma)),
\end{aligned} \tag{4.24}$$

where (y_i, p_i) is the solution of (4.8) with $y_\Gamma = 0$ and $p_\Gamma = 0$.

Theorem 4.1 implies that the system (4.6) of optimality conditions is equivalent to the Schur complement system

$$\sum_{i=1}^{s} \mathcal{S}_i^h(y_\Gamma, p_\Gamma) = \sum_{i=1}^{s} r_i \quad \text{in } ((V_\Gamma^h)^*)^2. \tag{4.25}$$

From (4.22c) and (4.22d) it is easy to see that the subdomain Schur complement operator is symmetric; i.e.,

$$\langle\!\langle \mathcal{S}_i^h(y_\Gamma, p_\Gamma), (v_\Gamma, q_\Gamma) \rangle\!\rangle = \langle\!\langle \mathcal{S}_i^h(v_\Gamma, q_\Gamma), (y_\Gamma, p_\Gamma) \rangle\!\rangle \quad \forall y_\Gamma, v_\Gamma, p_\Gamma, q_\Gamma \in V_{i,\Gamma_i}^h.$$

However, unlike subdomain Schur complement operators arising in DD methods for elliptic PDEs, the subdomain Schur complement operator $\mathcal{S}_i^h$ is not positive definite. The inertia will be investigated in Theorem 5.5 and we will show that the Schur complement operator essentially has the same number of positive and negative eigenvalues.

Remark 4.6. If Ω_i is a control subdomain, Theorem 4.4 states that the evaluation of $\mathcal{S}_i(y_\Gamma, p_\Gamma)$ requires the solution of a linear-quadratic elliptic optimal control problem (4.13). If Ω_i is a no-control subdomain, the evaluation of $\mathcal{S}_i(y_\Gamma, p_\Gamma)$ requires the solution of a triangular system of elliptic PDEs (4.8).

We will solve (4.25) using a preconditioned Krylov subspace method. Our preconditioner is constructed using the inverses of the subdomain Schur complement operators $\mathcal{S}_i^h(y_\Gamma, p_\Gamma)$, $i = 1, \ldots, s$. Their existence and computation will be studied next.

4.4. The inverse subdomain Schur complement. The next result establishes the invertibility of the subdomain Schur complement operator $\mathcal{S}_i^h$ in the case that $\sigma > 0$.

THEOREM 4.7. [illegible] $\sigma > 0$ [illegible] $r_i = (r_i^y, r_i^p) \in ((V_{i,\Gamma_i}^h)^*)^2$

(i) [illegible] Ω_i [illegible] $(y_\Gamma, p_\Gamma) \in (V_{i,\Gamma_i}^h)^2$ [illegible]

$$\mathcal{S}_i^h(y_\Gamma, p_\Gamma) = r_i \quad \text{[illegible]} \quad ((V_{i,\Gamma_i}^h)^*)^2 \tag{4.26}$$

[illegible]

$$(y_\Gamma, p_\Gamma) = (\ \cdot_{\Gamma_i} y_i, \ \cdot_{\Gamma_i} p_i),$$

[illegible] $(y_i, u_i, p_i) \in V_i^h \times U_i^h \times V_i^h$ [illegible]

$$a_i(\psi, p_i) + m_i(y_i, \psi) = \langle r_i^y, \ \cdot_{\Gamma_i}\psi\rangle \qquad \forall \psi \in V_i^h, \tag{4.27a}$$

$$b_i(\mu, p_i) + q_i(u_i, \mu) = 0 \qquad \forall \mu \in U_i^h, \tag{4.27b}$$

$$a_i(y_i, \psi) + b_i(u_i, \psi) = \langle r_i^p, \ \cdot_{\Gamma_i}\psi\rangle \qquad \forall \psi \in V_i^h, \tag{4.27c}$$

[illegible] $\langle\cdot,\cdot\rangle$ [illegible] V_{i,Γ_i}^h [illegible] $(V_{i,\Gamma_i}^h)^*$

(ii) [illegible] Ω_i [illegible] $(y_\Gamma, p_\Gamma) \in (V_{i,\Gamma_i}^h)^2$ [illegible] (4.26) [illegible]

$$(y_\Gamma, p_\Gamma) = (\ \cdot_{\Gamma_i} y_i, \ \cdot_{\Gamma_i} p_i),$$

[illegible] $(y_i, u_i, p_i) \in V_i^h \times U_i^h \times V_i^h$ [illegible]

$$a_i(\psi, p_i) + m_i(y_i, \psi) = \langle r_i^y, \ \cdot_{\Gamma_i}\psi\rangle \qquad \forall \psi \in V_i^h, \tag{4.28a}$$

$$a_i(y_i, \psi) = \langle r_i^p, \ \cdot_{\Gamma_i}\psi\rangle \qquad \forall \psi \in V_i^h. \tag{4.28b}$$

[illegible] (i) By definition (4.22) of $\mathcal{S}_i^h$, the equality (4.26) can be written as

$$\begin{aligned} &a_i((\mathcal{H}_i^h)^y(y_\Gamma, p_\Gamma), (\mathcal{H}_i^h)^p(v_\Gamma, q_\Gamma)) + b_i((\mathcal{H}_i^h)^u(y_\Gamma, p_\Gamma), (\mathcal{H}_i^h)^p(v_\Gamma, q_\Gamma)) \\ &\quad + a_i((\mathcal{H}_i^h)^y(v_\Gamma, q_\Gamma), (\mathcal{H}_i^h)^p(y_\Gamma, p_\Gamma)) + m_i((\mathcal{H}_i^h)^y(y_\Gamma, p_\Gamma), (\mathcal{H}_i^h)^y(v_\Gamma, q_\Gamma)) \\ &= \langle r_i^y, v_\Gamma\rangle + \langle r_i^p, q_\Gamma\rangle \end{aligned} \tag{4.29}$$

for all $v_\Gamma, q_\Gamma \in V_{i,\Gamma_i}^h$. Using the definition (4.15) of $\mathcal{H}_i^h(y_\Gamma, p_\Gamma)$ together with (4.29), we see that (4.26) is equivalent to

$$\begin{aligned} &a_i(y_i, (\mathcal{H}_i^h)^p(v_\Gamma, q_\Gamma)) \\ &+ b_i(u_i, (\mathcal{H}_i^h)^p(v_\Gamma, q_\Gamma)) \\ &+ a_i((\mathcal{H}_i^h)^y(v_\Gamma, q_\Gamma), p_i) \\ &+ m_i(y_i, (\mathcal{H}_i^h)^y(v_\Gamma, q_\Gamma)) = \langle r_i^y, V_\Gamma^h\rangle + \langle r_i^p, q_\Gamma\rangle \qquad \forall v_\Gamma, q_\Gamma \in V_{i,\Gamma_i}^h, \end{aligned} \tag{4.30a}$$

$$a_i(\psi^0, p_i) + m_i(y_i, \psi^0) = 0 \qquad \forall \psi^0 \in V_{i,0}^h, \tag{4.30b}$$

$$b_i(\mu, p_i) + q_i(u_i, \mu) = 0 \qquad \forall \mu \in U_i^h, \tag{4.30c}$$

$$a_i(y_i, \phi^0) + b_i(u_i, \phi^0) = 0 \qquad \forall \phi^0 \in V_{i,0}^h, \tag{4.30d}$$

$$y_i = y_\Gamma, \quad p_i = p_\Gamma \qquad \text{on } \Gamma. \tag{4.30e}$$

If we set $\psi = \psi^0 + (\mathcal{H}_i^h)^p(v_\Gamma, q_\Gamma) \in V_i^h$ and $\phi = \phi^0 + (\mathcal{H}_i^h)^y(v_\Gamma, q_\Gamma) \in V_i^h$, then (4.30) is equivalent to

$$a_i(\psi, p_i) + m_i(y_i, \psi) = \langle r_i^y, \mathrm{Tr}_{\Gamma_i}\psi\rangle \qquad \forall \psi \in V_i^h, \tag{4.31a}$$

$$b_i(\mu, p_i) + q_i(u_i, \mu) = 0 \qquad \forall \mu \in U_i^h, \tag{4.31b}$$

$$a_i(y_i, \phi) + b_i(u_i, \phi) = \langle r_i^p, \mathrm{Tr}_{\Gamma_i}\phi\rangle \qquad \forall \phi \in V_i^h, \tag{4.31c}$$

$$y_i = y_\Gamma, \quad p_i = p_\Gamma \qquad \text{on } \Gamma. \tag{4.31d}$$

The assertion follows if we prove that (4.27) has a unique solution $(y_i, u_i, p_i) \in V_i^h \times U_i^h \times V_i^h$. Let $(y_i^1, u_i^1, p_i^1), (y_i^2, u_i^2, p_i^2) \in V_i^h \times U_i^h \times V_i^h$ be solutions of (4.27). Then $(e_i^y, e_i^u, e_i^p) = (y_i^1 - y_i^2, u_i^1 - u_i^2, p_i^1 - p_i^2) \in V_i^h \times U_i^h \times V_i^h$ satisfies

$$a_i(\psi, e_i^p) + m_i(e_i^y, \psi) = 0 \qquad \forall \psi \in V_i^h, \tag{4.32a}$$

$$b_i(\mu, e_i^p) + q_i(e_i^u, \mu) = 0 \qquad \forall \mu \in U_i^h, \tag{4.32b}$$

$$a_i(e_i^y, \phi) + b_i(e_i^u, \phi) = 0 \qquad \forall \phi \in V_i^h. \tag{4.32c}$$

If we set $\psi = e_i^y$, $\mu = e_i^u$, and $\phi = -e_i^p$ in (4.32) and add the resulting equations, we obtain

$$0 = m_i(e_i^y, e_i^y) + q_i(e_i^u, e_i^u) \geq \alpha \|e_i^u\|^2_{U_i^h}.$$

Hence $e_i^u = 0$. Equation (4.32c) implies $e_i^y = 0$ and, finally, (4.32a) implies $e_i^p = 0$.

(ii) The second statement can be proved analogously. ∎

REMARK 4.8. Equations (4.27) can be interpreted as the weak form of

$$-\Delta y_i(x) + \sigma y_i(x) = 0 \qquad \text{in } \Omega_i, \tag{4.33a}$$

$$\frac{\partial}{\partial n} y_i(x) = U_i^h(x) \qquad \text{on } \partial\Omega \cap \partial\Omega_i, \tag{4.33b}$$

$$\frac{\partial}{\partial n} y_i(x) = r_i^y(x) \qquad \text{on } \Gamma, \tag{4.33c}$$

$$-\Delta p_i(x) + \sigma p_i(x) = -y_i(x) \qquad \text{in } \Omega_i, \tag{4.33d}$$

$$\frac{\partial}{\partial n} p_i(x) = 0 \qquad \text{on } \partial\Omega \cap \partial\Omega_i, \tag{4.33e}$$

$$\frac{\partial}{\partial n} p_i(x) = r_i^p(x) \qquad \text{on } \Gamma, \tag{4.33f}$$

$$\alpha u_i(x) - p_i(x) = 0 \qquad \text{on } \partial\Omega \cap \partial\Omega_i. \tag{4.33g}$$

REMARK 4.9. If $\sigma = 0$, then the subdomain Schur complement operator $\mathcal{S}_i$ may no longer be invertible. In this case we define

$$\widehat{a}_i : V_i^h \times V_i^h \to \mathbb{R}, \qquad \widehat{a}_i(y, \psi) = \int_{\Omega_i} \nabla y(x) \nabla \psi(x) + \varepsilon y(x)\psi(x) dx,$$

where $\varepsilon > 0$ and we introduce the perturbed subdomain Schur complement operator $\widehat{\mathcal{S}}_i$, which is defined as in (4.22) but with a_i replaced by $\widehat{a}_i$. Theorem 4.7 implies that $\widehat{\mathcal{S}}_i$ is continuously invertible. A situation somewhat comparable to the case $\sigma = 0$ arises in so-called Neumann–Neumann DD methods for the Laplace equation. Following, e.g., [36, p. 175], we use $\widehat{a}_i$ with $\varepsilon = 1/H_i^2$, where H_i is the diameter of Ω_i.

5. Algebraic formulation. In this section we present the matrix view of the DD Schur complement formulation introduced in the previous section and introduce the Neumann–Neumann preconditioners for the Schur complement. Furthermore, we study some properties of the Schur complement matrix arising in the optimal control context and discuss the numerical solution of the preconditioned Schur complement system.

5.1. Matrix representation of the discretized optimal control problem. A finite element discretization of the optimal control problem (3.1) leads to a large-scale linear-quadratic problem of the form

$$\text{minimize } \frac{1}{2}\mathbf{y}^T\mathbf{M}\mathbf{y} + \mathbf{c}^T\mathbf{y} + \mathbf{y}^T\mathbf{N}\mathbf{u} + \frac{\alpha}{2}\mathbf{u}^T\mathbf{Q}\mathbf{u} + \mathbf{d}^T\mathbf{u}, \tag{5.1a}$$

$$\text{subject to } \mathbf{A}\mathbf{y} + \mathbf{B}\mathbf{u} + \mathbf{b} = \mathbf{0}, \tag{5.1b}$$

with $\mathbf{A} \in \mathbb{R}^{m\times m}$, $\mathbf{B} \in \mathbb{R}^{m\times n}$, $\mathbf{N} \in \mathbb{R}^{m\times n}$, $\mathbf{M} \in \mathbb{R}^{m\times m}$, $\mathbf{Q} \in \mathbb{R}^{n\times n}$, $\mathbf{b} \in \mathbb{R}^m$, $\mathbf{c} \in \mathbb{R}^m$, $\mathbf{d} \in \mathbb{R}^n$, $\mathbf{y} \in \mathbb{R}^m$, $\mathbf{u} \in \mathbb{R}^n$, and $\alpha > 0$.

For our model problem the matrices and vectors $\mathbf{A}, \dots$ are given as follows. Let $\{x_j\}_{j=1}^{n_v}$ be the set of vertices of $\{T_l\}$ and let $\{\phi_j\}_{j=1}^{n_v}$ be the piecewise linear nodal basis for V^h defined in (4.1). Furthermore, let $\{\mu_j^i\}_{j=1}^{n_{bv}^i}$ be the piecewise linear nodal basis for U_i^h defined in (4.4), where n_{bv}^i is the number of vertices on $\partial\Omega \cap \partial\Omega_i$. We identify μ_j^i with a function in $L^2(\partial\Omega)$ by extending μ_j^i by zero outside $\partial\Omega_i$. We set

$$\mu_1 = \mu_1^1, \dots, \mu_{n_{bv}^i} = \mu_{n_{bv}^1}^1,\ \mu_{n_{bv}^1+1} = \mu_1^2, \dots, \mu_{n_{bv}^1+n_{bv}^2} = \mu_{n_{bv}^2}^2, \dots.$$

Then $m = n_v$, $n = \sum_{i=1}^s n_{bv}^i$, and

$$\mathbf{A}_{jk} = a(\phi_k, \phi_j), \quad \mathbf{M}_{jk} = m(\phi_k, \phi_j), \quad \mathbf{c}_j = -m(\hat{y}, \phi_j), \quad \mathbf{b}_j = f(\phi_j)$$

for $j, k = 1, \dots, m$, and

$$\mathbf{B}_{jk} = b(\mu_k, \phi_j), \quad \mathbf{Q}_{jk} = q(\mu_k, \mu_j)$$

for $j, k = 1, \dots, n$, and $\mathbf{N} = \mathbf{0}$, $\mathbf{d} = \mathbf{0}$.

LEMMA 5.1. [illegible] $\sigma \geq 0$ [illegible]

$$\text{range}(\mathbf{A} \mid \mathbf{B}) = \mathbb{R}^m \tag{5.2}$$

[illegible] $\mathbf{M}, \mathbf{Q}$ [illegible] (5.1a) [illegible] [illegible] (5.1b).

$$\begin{pmatrix} \mathbf{z} \\ \mathbf{v} \end{pmatrix}^T \begin{pmatrix} \mathbf{M} & \mathbf{N} \\ \mathbf{N}^T & \alpha\mathbf{Q} \end{pmatrix} \begin{pmatrix} \mathbf{z} \\ \mathbf{v} \end{pmatrix} > 0 \quad \forall\, \mathbf{z} \in \mathbb{R}^m, \mathbf{v} \in \mathbb{R}^n \text{ [illegible] } \mathbf{A}\mathbf{z} + \mathbf{B}\mathbf{v} = 0. \tag{5.3}$$

[illegible]. If $\sigma > 0$, then $\mathbf{A}$ is symmetric positive definite and (5.2) follows immediately. It holds that

$$\text{null}(\mathbf{A} \mid \mathbf{B}) = \left\{ \begin{pmatrix} -\mathbf{A}^{-1}\mathbf{B}\mathbf{v} \\ \mathbf{v} \end{pmatrix} \,:\, \mathbf{v} \in \mathbb{R}^n \right\}$$

and (5.3) is equivalent to

$$\mathbf{v}^T(\alpha\mathbf{Q} + \mathbf{B}^T\mathbf{A}^{-T}\mathbf{M}\mathbf{A}^{-1}\mathbf{B})\mathbf{v} > 0 \quad \forall\, \mathbf{v} \in \mathbb{R}^n, \tag{5.4}$$

where we have used the fact that in the model problem $\mathbf{N} = \mathbf{0}$. Condition (5.4) follows, since in our model problem $\mathbf{M}$ is symmetric positive semidefinite and $\mathbf{Q}$ is symmetric positive definite.

If $\sigma = 0$, then $\mathbf{A}$ is symmetric positive semidefinite and $\text{null}(\mathbf{A}) = \text{span}\{\mathbf{e}\}$, where $\mathbf{e} \in \mathbb{R}^m$ is the vector of all ones. If $(\mathbf{z}^T, \mathbf{v}^T)^T \in \text{null}(\mathbf{A} \mid \mathbf{B})$, then $0 = \mathbf{e}^T(\mathbf{A}\mathbf{z} + \mathbf{B}\mathbf{v}) = \mathbf{e}^T\mathbf{B}\mathbf{v}$. Hence, $\mathbf{v} \in \text{span}\{\mathbf{B}^T\mathbf{e}\}^\perp$. Moreover, for each $\mathbf{v} \in \text{span}\{\mathbf{B}^T\mathbf{e}\}^\perp$, the equation $\mathbf{A}\mathbf{z} = -\mathbf{B}\mathbf{v}$ has a solution and the minimum norm solution of this equation is characterized by $\mathbf{e}^T\mathbf{z} = 0$. This implies that

$$\text{null}(\mathbf{A} \mid \mathbf{B}) = \text{span}\left\{\begin{pmatrix}\mathbf{e}\\ \mathbf{0}\end{pmatrix}\right\} + \left\{\begin{pmatrix}-\mathbf{A}^\dagger\mathbf{B}\mathbf{v}\\ \mathbf{v}\end{pmatrix} \;:\; \mathbf{v} \in \text{span}\{\mathbf{B}^T\mathbf{e}\}^\perp\right\},$$

where $\mathbf{A}^\dagger$ denotes the pseudoinverse of $\mathbf{A}$, and $\dim(\text{null}(\mathbf{A} \mid \mathbf{B})) = n$. Consequently, $\dim(\text{range}(\mathbf{A} \mid \mathbf{B})) = m$, which implies (5.2). Condition (5.3) follows, since in our model problem $\mathbf{M}$ is symmetric positive semidefinite with $\mathbf{e}^T\mathbf{M}\mathbf{e} = \int_{\Omega_o} 1 dx > 0$, $\mathbf{Q}$ is symmetric positive definite, and $\mathbf{N} = \mathbf{0}$. □

The following result is known, and it is stated here for completeness. A proof can be found in [17].

THEOREM 5.2. (i) [illegible] (5.2) [illegible] (5.3) [illegible] (5.1) [illegible]

$$\begin{pmatrix}\mathbf{M} & \mathbf{N} & \mathbf{A}^T\\ \mathbf{N}^T & \alpha\mathbf{Q} & \mathbf{B}^T\\ \mathbf{A} & \mathbf{B} & \mathbf{0}\end{pmatrix}\begin{pmatrix}\mathbf{y}\\ \mathbf{u}\\ \mathbf{p}\end{pmatrix} = -\begin{pmatrix}\mathbf{c}\\ \mathbf{d}\\ \mathbf{b}\end{pmatrix}. \tag{5.5}$$

(ii) [illegible] (5.2) [illegible] (5.3) [illegible] (5.5) [illegible] $m + n$ [illegible] m [illegible]

The equation (5.5) is the matrix representation of the discretized optimality conditions (4.6).

5.2. Domain decomposition Schur complement formulation. We can use the decomposition of Ω to decompose the matrices $\mathbf{A}$, etc. Let the local (bi)linear forms $a_i, \ldots$ be defined as in section 4.

Let $\tilde{\mathbf{R}}_i^y$, $i = 1, \ldots, s$, be the restriction operator which maps from the vector of coefficient unknowns on the artificial boundary, $\mathbf{y}_\Gamma$, to only those associated with the boundary of Ω_i, and define

$$\tilde{\mathbf{R}}_i = \begin{pmatrix}\tilde{\mathbf{R}}_i^y & \\ & \tilde{\mathbf{R}}_i^p\end{pmatrix}, \quad \tilde{\mathbf{R}}_i^p = \tilde{\mathbf{R}}_i^y. \tag{5.6}$$

For $i = 1, \ldots, s$, we define the submatrices

$$\begin{aligned}(\mathbf{A}_{II}^i)_{jk} &= a_i(\phi_k, \phi_j), \quad x_j, x_k \in \Omega_i,\\ (\mathbf{A}_{I\Gamma}^i)_{jk} &= a_i(\phi_k, \phi_j), \quad x_j \in \Omega_i,\ x_k \in \partial\Omega_i \setminus \partial\Omega,\\ (\mathbf{A}_{\Gamma\Gamma}^i)_{jk} &= a_i(\phi_k, \phi_j), \quad x_j, x_k \in \partial\Omega_i \setminus \partial\Omega,\end{aligned}$$

$\mathbf{A}_{\Gamma I}^i = (\mathbf{A}_{I\Gamma}^i)^T$, and we define $\mathbf{A}_{\Gamma\Gamma} = \sum_{i=1}^s (\tilde{\mathbf{R}}_i^y)^T \mathbf{A}_{\Gamma\Gamma}^i \tilde{\mathbf{R}}_i^y$. After a suitable reordering of rows and columns, the stiffness matrix can be written as

$$\mathbf{A} = \begin{pmatrix}\mathbf{A}_{II}^1 & & & \mathbf{A}_{I\Gamma}^1\tilde{\mathbf{R}}_1^y\\ & \ddots & & \vdots\\ & & \mathbf{A}_{II}^s & \mathbf{A}_{I\Gamma}^s\tilde{\mathbf{R}}_s^y\\ (\tilde{\mathbf{R}}_1^y)^T\mathbf{A}_{\Gamma I}^1 & \cdots & (\tilde{\mathbf{R}}_s^y)^T\mathbf{A}_{\Gamma I}^s & \mathbf{A}_{\Gamma\Gamma}\end{pmatrix}.$$

Similar decompositions can be introduced for $\mathbf{M}$ and $\mathbf{c}$, as well as $\mathbf{y}, \mathbf{p}$.

For $i = 1, \ldots, s$, we define the submatrices

$$(\mathbf{B}_{II}^i)_{jk} = b_i(\mu_k, \phi_j), \quad x_j \in \Omega_i, x_k \in \partial\Omega_i \cap \partial\Omega,$$
$$(\mathbf{B}_{\Gamma I}^i)_{jk} = b_i(\mu_k, \phi_j), \quad x_j \in \partial\Omega_i \setminus \partial\Omega, x_k \in \partial\Omega_i \cap \partial\Omega.$$

After a suitable reordering of rows and columns, the matrix $\mathbf{B}$ can be written as

$$\mathbf{B} = \begin{pmatrix} \mathbf{B}_{II}^1 & & \\ & \ddots & \\ & & \mathbf{B}_{II}^s \\ (\tilde{\mathbf{R}}_1^y)^T \mathbf{B}_{\Gamma I}^1 & \cdots & (\tilde{\mathbf{R}}_s^y)^T \mathbf{B}_{\Gamma I}^s \end{pmatrix}.$$

Note that in our particular control discretization, all basis functions μ_k^i for the discretized control u_h have support in only one subdomain boundary $\partial\Omega_i$ (see the right-hand plot in Figure 4.1). Consequently, there is no $\mathbf{B}_{\Gamma\Gamma}^i$. The matrix $\mathbf{Q}$ and the vector $\mathbf{u}$ can be decomposed analogously. Note that there is no $\mathbf{u}_\Gamma$.

We can now insert the DD structure of the matrices $\mathbf{A}, \mathbf{M}, \mathbf{B}, \mathbf{Q}$ into (5.5). After a symmetric permutation, (5.5) can be written as

$$\begin{pmatrix} \mathbf{K}_{II}^1 & & & (\mathbf{K}_{\Gamma I}^1)^T \tilde{\mathbf{R}}_1 \\ & \ddots & & \vdots \\ & & \mathbf{K}_{II}^s & (\mathbf{K}_{\Gamma I}^s)^T \tilde{\mathbf{R}}_s \\ \tilde{\mathbf{R}}_1^T \mathbf{K}_{\Gamma I}^1 & \cdots & \tilde{\mathbf{R}}_s^T \mathbf{K}_{\Gamma I}^s & \mathbf{K}_{\Gamma\Gamma} \end{pmatrix} \begin{pmatrix} \mathbf{x}_I^1 \\ \vdots \\ \mathbf{x}_I^d \\ \mathbf{x}_\Gamma \end{pmatrix} = \begin{pmatrix} \mathbf{g}_I^1 \\ \vdots \\ \mathbf{g}_I^d \\ \mathbf{g}_\Gamma \end{pmatrix}, \tag{5.7}$$

where

$$\mathbf{K}_{\Gamma\Gamma}^i = \begin{pmatrix} \mathbf{M}_{\Gamma\Gamma}^i & (\mathbf{A}_{\Gamma\Gamma}^i)^T \\ \mathbf{A}_{\Gamma\Gamma}^i & \end{pmatrix}, \ i = 1, \ldots, s, \quad \mathbf{K}_{\Gamma\Gamma} = \sum_{i=1}^s \tilde{\mathbf{R}}_i^T \mathbf{K}_{\Gamma\Gamma}^i \tilde{\mathbf{R}}_i,$$

$$\mathbf{K}_{II}^i = \begin{pmatrix} \mathbf{M}_{II}^i & \mathbf{N}_{II}^i & (\mathbf{A}_{II}^i)^T \\ (\mathbf{N}_{II}^i)^T & \alpha \mathbf{Q}_{II}^i & (\mathbf{B}_{II}^i)^T \\ \mathbf{A}_{II}^i & \mathbf{B}_{II}^i & \end{pmatrix}, \quad \mathbf{K}_{\Gamma I}^i = \begin{pmatrix} \mathbf{M}_{\Gamma I}^i & \mathbf{N}_{\Gamma I}^i & (\mathbf{A}_{I\Gamma}^i)^T \\ \mathbf{A}_{\Gamma I}^i & \mathbf{B}_{\Gamma I}^i & \end{pmatrix}, \quad i \in \mathcal{C},$$

and

$$\mathbf{K}_{II}^i = \begin{pmatrix} \mathbf{M}_{II}^i & (\mathbf{A}_{II}^i)^T \\ \mathbf{A}_{II}^i & \end{pmatrix}, \quad \mathbf{K}_{\Gamma I}^i = \begin{pmatrix} \mathbf{M}_{\Gamma I}^i & (\mathbf{A}_{I\Gamma}^i)^T \\ \mathbf{A}_{\Gamma I}^i & \end{pmatrix}, \quad i \in \mathcal{N}.$$

Furthermore,

$$\mathbf{x}_\Gamma = \begin{pmatrix} \mathbf{y}_\Gamma \\ \mathbf{p}_\Gamma \end{pmatrix}, \quad \mathbf{g}_\Gamma = \begin{pmatrix} \mathbf{c}_\Gamma \\ \mathbf{b}_\Gamma \end{pmatrix}, \quad \mathbf{x}_I^i = \begin{pmatrix} \mathbf{y}_I^i \\ \mathbf{u}_I^i \\ \mathbf{p}_I^i \end{pmatrix}, \quad \mathbf{g}_I^i = \begin{pmatrix} \mathbf{c}_I^i \\ \mathbf{d}_I^i \\ \mathbf{b}_I^i \end{pmatrix}, \quad i \in \mathcal{C},$$

and

$$\mathbf{x}_I^i = \begin{pmatrix} \mathbf{y}_I^i \\ \mathbf{p}_I^i \end{pmatrix}, \quad \mathbf{g}_I^i = \begin{pmatrix} \mathbf{c}_I^i \\ \mathbf{b}_I^i \end{pmatrix}, \quad i \in \mathcal{N}.$$

Frequently, we use the compact notation

$$\begin{pmatrix} \mathbf{K}_{II} & \mathbf{K}_{\Gamma I}^T \\ \mathbf{K}_{\Gamma I} & \mathbf{K}_{\Gamma\Gamma} \end{pmatrix} \begin{pmatrix} \mathbf{x}_I \\ \mathbf{x}_\Gamma \end{pmatrix} = \begin{pmatrix} \mathbf{g}_I \\ \mathbf{g}_\Gamma \end{pmatrix} \tag{5.8}$$

or even $\mathbf{K}\mathbf{x} = \mathbf{g}$ instead of (5.7).

The matrix representation of the operators $\mathcal{H}_i^h$ defined in (4.15) and (4.16) is given by

$$\mathbf{H}_i = \begin{pmatrix} -(\mathbf{K}_{II}^i)^{-1}\mathbf{K}_{I\Gamma}^i \\ \mathbf{I} \end{pmatrix}.$$

The matrix representation of the local Schur complement operators $\mathcal{S}_i^h$ defined in (4.22) is given by

$$\mathbf{S}_i = \mathbf{K}_{\Gamma\Gamma}^i - \mathbf{K}_{\Gamma I}^i(\mathbf{K}_{II}^i)^{-1}(\mathbf{K}_{\Gamma I}^i)^T. \tag{5.9}$$

The matrix

$$\mathbf{K}^i = \begin{pmatrix} \mathbf{K}_{II}^i & (\mathbf{K}_{\Gamma I}^i)^T \\ \mathbf{K}_{\Gamma I}^i & \mathbf{K}_{\Gamma\Gamma}^i \end{pmatrix}$$

plays an important role in the computation of the inverse of $\mathbf{S}_i$ (assuming it exists). In fact, if $\mathbf{K}_{II}^i$ is invertible,

$$\mathbf{K}^i = \begin{pmatrix} \mathbf{I} & \mathbf{0} \\ \mathbf{K}_{\Gamma I}^i(\mathbf{K}_{II}^i)^{-1} & \mathbf{I} \end{pmatrix} \begin{pmatrix} \mathbf{K}_{II}^i & \mathbf{0} \\ \mathbf{0} & \mathbf{S}_i \end{pmatrix} \begin{pmatrix} \mathbf{I} & (\mathbf{K}_{II}^i)^{-1}(\mathbf{K}_{\Gamma I}^i)^T \\ \mathbf{0} & \mathbf{I} \end{pmatrix}, \tag{5.10}$$

and $\mathbf{S}_i$ is invertible if and only if $\mathbf{K}^i$ is invertible. In this case,

$$\mathbf{S}_i^{-1}\mathbf{v} = (\mathbf{0} \quad \mathbf{I})\,(\mathbf{K}^i)^{-1} \begin{pmatrix} \mathbf{0} \\ \mathbf{I} \end{pmatrix} \mathbf{v}$$

(see, e.g., [36, p. 113]).

The following theorem is concerned with the invertibility of the submatrices $\mathbf{K}_{II}^i$, which is important for the computation of $\mathbf{S}_i$, and with the invertibility of the submatrices $\mathbf{K}^i$, which is important for the computation of $(\mathbf{S}_i)^{-1}$.

THEOREM 5.3.

(i) $\sigma \geq 0$

a. $\mathbf{A}_{II}^i \in \mathbb{R}^{m_i^I \times m_i^I}$ $\mathbf{M}_{II}^i \in \mathbb{R}^{m_i^I \times m_i^I}$ $i = 1, \ldots, s$

b. $i \in \mathcal{C}$

$$\begin{pmatrix} \mathbf{z}_{II}^i \\ \mathbf{v}_{II}^i \end{pmatrix}^T \begin{pmatrix} \mathbf{M}_{II}^i & \mathbf{N}_{II}^i \\ (\mathbf{N}_{II}^i)^T & \alpha\mathbf{Q}_{II}^i \end{pmatrix} \begin{pmatrix} \mathbf{z}_{II}^i \\ \mathbf{v}_{II}^i \end{pmatrix} > 0 \tag{5.11}$$

$\mathbf{z}_{II}^i \in \mathbb{R}^{m_i^I}, \mathbf{v}_{II}^i \in \mathbb{R}^{n_i^I}$ $\mathbf{A}_{II}^i\mathbf{z}_{II}^i + \mathbf{B}_{II}^i\mathbf{v}_{II}^i = 0$

c. $\mathbf{K}_{II}^i$ $i = 1, \ldots, s$

(ii) $\sigma > 0$

a. $\mathbf{A}^i \in \mathbb{R}^{m_i \times m_i}$ $\mathbf{M}^i \in \mathbb{R}^{m_i \times m_i}$ $i = 1, \ldots, s$

b. [illegible] $i \in \mathcal{C}$

$$\begin{pmatrix} \mathbf{z}^i \\ \mathbf{v}^i \end{pmatrix}^T \begin{pmatrix} \mathbf{M}^i & \mathbf{N}^i \\ (\mathbf{N}^i)^T & \alpha \mathbf{Q}^i \end{pmatrix} \begin{pmatrix} \mathbf{z}^i \\ \mathbf{v}^i \end{pmatrix} > 0 \tag{5.12}$$

[illegible] $\mathbf{z}^i \in \mathbb{R}^{m_i}, \mathbf{v}^i \in \mathbb{R}^{n_i}$ [illegible] $\mathbf{A}^i \mathbf{z}^i + \mathbf{B}^i \mathbf{v}^i = 0$

c. [illegible] $\mathbf{K}^i$ $i = 1, \ldots, s$ [illegible]

(iii) [illegible] $\sigma = 0$ [illegible] $\text{null}(\mathbf{A}^i) = \text{span}\{\mathbf{e}\}$ [illegible] $\mathbf{e} \in \mathbb{R}^{m_i}$ [illegible]

$\mathbf{M}^i \in \mathbb{R}^{m_i \times m_i}$ [illegible] $i = 1, \ldots, s$

[illegible] $i \in \mathcal{C}$ [illegible] (5.12) [illegible] $\mathbf{z}^i \in \mathbb{R}^{m_i}, \mathbf{v}^i \in \mathbb{R}^{n_i}$

[illegible] $\mathbf{A}^i \mathbf{z}^i + \mathbf{B}^i \mathbf{v}^i = 0$ [illegible] $\mathbf{e}^T \mathbf{M}^i \mathbf{e} > 0$

[illegible] The matrices $\mathbf{A}^i_{II} \in \mathbb{R}^{m_i \times m_i}$ and $\mathbf{A}^i \in \mathbb{R}^{m_i \times m_i}$ are the stiffness matrices corresponding to the problems

$$-\Delta y + \sigma y = f \text{ in } \Omega_i, \quad y = 0 \text{ on } \partial\Omega_i,$$

and

$$-\Delta y + \sigma y = f \text{ in } \Omega_i, \quad \partial y / \partial n = 0 \text{ on } \partial\Omega_i,$$

respectively. This implies (a) that $\mathbf{A}^i_{II}$ is symmetric positive definite, (b) that $\mathbf{A}^i$ is symmetric positive definite if $\sigma > 0$, and (c) that $\text{null}(\mathbf{A}^i) = \text{span}\{\mathbf{e}\}$ if $\sigma = 0$.

The proof of assertions (i)–(iii) is identical to the proof of Theorem 5.2. ∎

[illegible] 5.4. Consider the model problem with $\sigma = 0$.

For $i \in \mathcal{N}$, the matrix $\mathbf{K}^i$ is singular. After a symmetric permutation, $\mathbf{K}^i$ is given by

$$\widetilde{\mathbf{K}^i} = \begin{pmatrix} \mathbf{M}^i & \mathbf{A}^i \\ \mathbf{A}^i & \mathbf{0} \end{pmatrix},$$

where

$$\mathbf{A}^i = \begin{pmatrix} \mathbf{A}^i_{II} & (\mathbf{A}^i_{\Gamma I})^T \\ \mathbf{A}^i_{\Gamma I} & \mathbf{A}^i_{\Gamma\Gamma} \end{pmatrix}, \quad \mathbf{M}^i = \begin{pmatrix} \mathbf{M}^i_{II} & (\mathbf{M}^i_{\Gamma I})^T \\ \mathbf{M}^i_{\Gamma I} & \mathbf{M}^i_{\Gamma\Gamma} \end{pmatrix}.$$

The vector $(\mathbf{0}^T, \mathbf{e}^T)^T \in \mathbb{R}^{2m_i}$ is in the null-space of $\widetilde{\mathbf{K}^i}$ and, if $\mathbf{M}^i \mathbf{e} = 0$, so is the vector $(\mathbf{e}^T, \mathbf{0}^T) \in \mathbb{R}^{2m_i}$.

If $i \in \mathcal{C}$ and $\mathbf{M}^i \mathbf{e} = 0$, the matrix $\mathbf{K}^i$ is singular. In fact, after a symmetric permutation, $\mathbf{K}^i$ is given by

$$\widetilde{\mathbf{K}^i} = \begin{pmatrix} \mathbf{M}^i & \mathbf{0} & \mathbf{A}^i \\ \mathbf{0} & \mathbf{Q}^i_{II} & (\mathbf{B}^i)^T \\ \mathbf{A}^i & \mathbf{B}^i & \mathbf{0} \end{pmatrix},$$

where $\mathbf{A}^i, \mathbf{M}^i$ are defined as before and

$$\mathbf{B}^i = \begin{pmatrix} \mathbf{B}^i_{II} \\ \mathbf{B}^i_{\Gamma I} \end{pmatrix}.$$

The vector $(\mathbf{e}^T, \mathbf{0}^T, \mathbf{0}^T)^T \in \mathbb{R}^{2m_i + n_i}$ is in the null-space of $\widetilde{\mathbf{K}^i}$.

By definition of $\mathbf{M}^i$,

$$\mathbf{e}^T \mathbf{M}^i \mathbf{e} = \sum_{x_j, x_k \in \Omega_i} \int_{\Omega_o} \phi_j(x) \phi_k(x) dx.$$

Hence $\mathbf{M}^i \mathbf{e} = \mathbf{0}$ if and only if $\Omega_i \cap \Omega_o = \emptyset$.

Theorem 5.3(i) guarantees that $\mathbf{K}_{II}$ is invertible. Hence, we can form the Schur complement system

$$\mathbf{S}\mathbf{x}_\Gamma = \mathbf{r}, \tag{5.13}$$

where

$$\mathbf{S} = \mathbf{K}_{\Gamma\Gamma} - \mathbf{K}_{\Gamma I}\mathbf{K}_{II}^{-1}\mathbf{K}_{\Gamma I}^T \tag{5.14}$$

and

$$\mathbf{r} = \mathbf{g}_\Gamma - \mathbf{K}_{\Gamma I}\mathbf{K}_{II}^{-1}\mathbf{g}_I.$$

The Schur complement matrix $\mathbf{S}$ can be written as a sum of subdomain Schur complement matrices,

$$\mathbf{S} = \sum_{i=1}^{s} \tilde{\mathbf{R}}_i^T \mathbf{S}_i \tilde{\mathbf{R}}_i, \tag{5.15}$$

where $\mathbf{S}_i$, $i = 1, \ldots, s$, is defined in (5.9).

THEOREM 5.5. (i) [illegible] $\sigma \geq 0$ [illegible] $\mathbf{S}$ [illegible] $m - \sum_{i=1}^{s} m_i^I$ [illegible] $m - \sum_{i=1}^{s} m_i^I$ [illegible] m_i^I [illegible] $\overline{\Omega}_i \setminus \Gamma$

(ii) [illegible] $\sigma > 0$ [illegible] $\mathbf{S}_i$ $i = 1, \ldots, s$ [illegible] $m_i - m_i^I$ [illegible] $m_i - m_i^I$ [illegible] m_i [illegible] $\overline{\Omega}_i$ [illegible] m_i^I [illegible] $\overline{\Omega}_i \setminus \Gamma$

(iii) [illegible] $\sigma = 0$ $i \in \mathcal{N}$ $i \in \mathcal{C}$ $\mathbf{e}^T\mathbf{M}^i\mathbf{e} = 0$ [illegible] $\mathbf{S}_i$ [illegible] $\mathbf{S}_i$ [illegible].

(i) Recall (5.14). It is easy to verify that

$$\begin{pmatrix} \mathbf{K}_{II} & \mathbf{K}_{\Gamma I}^T \\ \mathbf{K}_{\Gamma I} & \mathbf{K}_{\Gamma\Gamma} \end{pmatrix} = \begin{pmatrix} \mathbf{K}_{II} & 0 \\ \mathbf{K}_{\Gamma I} & \mathbf{I} \end{pmatrix} \begin{pmatrix} \mathbf{K}_{II}^{-1} & 0 \\ 0 & \mathbf{S} \end{pmatrix} \begin{pmatrix} \mathbf{K}_{II} & \mathbf{K}_{\Gamma I}^T \\ 0 & \mathbf{I} \end{pmatrix}.$$

The matrix $\mathbf{K}$ is a symmetric permutation of the system matrix in (5.5) and, hence, both matrices have the same eigenvalues. By Theorem 5.2, the system matrix in (5.5), and hence $\mathbf{K}$, both have $m + n$ positive and m negative eigenvalues.

Let m_i^I be the number of finite element nodes in Ω_i and let n_i^I be the number of finite element nodes in $\partial\Omega_i \setminus \partial\Omega$. Applying the same arguments used to analyze the inertia of $\mathbf{K}$ to $\mathbf{K}_{II}$, one can show that the matrix $\mathbf{K}_{II}$ has $\sum_{i=1}^{s} m_i^I + n_i^I$ positive and $\sum_{i=1}^{s} m_i^I$ negative eigenvalues. By Sylvester's law of inertia, the number of positive (negative) eigenvalues of $\mathbf{K}$ is equal to the number of positive (negative) eigenvalues of $\mathbf{K}_{II}^{-1}$ plus the number of positive (negative) eigenvalues of $\mathbf{S}$. Since $n = \sum_{i=1}^{s} n_i^I$, this implies that $\mathbf{S}$ has $m - \sum_{i=1}^{s} m_i^I$ positive and $m - \sum_{i=1}^{s} m_i^I$ negative eigenvalues.

(ii) The second assertion can be proved using arguments analogous to those applied in (i). We omit the details.

(iii) By Lemma 5.4, $\mathbf{K}_{II}^i$ is invertible. In Remark 5.4 we have shown that $\mathbf{K}^i$ is singular if $i \in \mathcal{N}$ or if $i \in \mathcal{C}$ and $\mathbf{e}^T\mathbf{M}^i\mathbf{e} = 0$. In these cases the zero eigenvalue of $\mathbf{K}^i$ has mutiplicity one or two. Hence, the assertion follows from (5.10). ∎

5.3. The Neumann–Neumann preconditioners. It is now relatively easy to generalize the Neumann–Dirichlet and Neumann–Neumann preconditioners used in the context of elliptic PDEs (see, e.g., [36, Chap. 4] for an overview) to the optimal control context. We focus on Neumann–Neumann preconditioners.

Let $\mathbf{D}_i^y$ be the diagonal matrix whose entries are computed as follows. If $x_k \in \Gamma_i$, then $(\mathbf{D}_i^y)_{kk}^{-1}$ is the number of subdomains that share node x_k. Note that $\sum_i \mathbf{D}_i^y = \mathbf{I}$. Furthermore, let $\tilde{\mathbf{D}}_i^p = \tilde{\mathbf{D}}_i^y$ and

$$\mathbf{D}_i = \begin{pmatrix} \mathbf{D}_i^y & \\ & \mathbf{D}_i^p \end{pmatrix}.$$

By Theorem 5.3(i), $\mathbf{S}_i$, $i = 1, \ldots, s$, is well defined. If $\sigma > 0$, then Theorem 5.5(ii) guarantees the existence of $\mathbf{S}_i^{-1}$, $i = 1, \ldots, s$. The one-level Neumann–Neumann preconditioner is given by

$$\mathbf{P} = \sum_i \mathbf{D}_i \tilde{\mathbf{R}}_i^T \widehat{\mathbf{S}}_i^{-1} \tilde{\mathbf{R}}_i \mathbf{D}_i, \tag{5.16}$$

where $\widehat{\mathbf{S}}_i^{-1}$ is equal to $\mathbf{S}_i^{-1}$ if $\mathbf{S}_i$ is invertible and otherwise $\widehat{\mathbf{S}}_i^{-1}$ is the inverse of the Schur complement matrix $\widehat{\mathbf{S}}_i$ obtained by adding a positive multiple of $\int_{\Omega_i} \psi_k, \psi_j$ to the bilinear form a_i (cf. Remark 4.9). (With this modified bilinear form Theorem 5.5(ii) guarantees the invertibility of $\widehat{\mathbf{S}}_i$.)

It is well known that the performance of one-level Neumann–Neumann preconditioners for elliptic PDEs deteriorates quickly as the number of subdomains increases. The same is observed for the Neumann–Neumann preconditioner (5.16) in the optimal control context (see section 6). To avoid this, we include a coarse grid. More precisely, we adapt the balancing Neumann–Neumann preconditioner proposed in [30] to the optimal control context. Following the description in [36, sect. 4.3.3], the balancing Neumann–Neumann preconditioner for the optimal control problem is given by

$$\mathbf{P} = \left(\mathbf{I} - \tilde{\mathbf{R}}_0^T \mathbf{S}_0^{-1} \tilde{\mathbf{R}}_0 \mathbf{S}\right) \left(\sum_{i=1}^{s} \mathbf{D}_i \tilde{\mathbf{R}}_i^T \widehat{\mathbf{S}}_i^{-1} \tilde{\mathbf{R}}_i \mathbf{D}_i\right) \left(\mathbf{I} - \mathbf{S}\tilde{\mathbf{R}}_0^T \mathbf{S}_0^{-1} \tilde{\mathbf{R}}_0\right) + \tilde{\mathbf{R}}_0^T \mathbf{S}_0^{-1} \tilde{\mathbf{R}}_0, \tag{5.17}$$

where $\widehat{\mathbf{S}}_i^{-1}$ is defined as in (5.16), and where $\mathbf{S}_0 = \tilde{\mathbf{R}}_0 \mathbf{S} \tilde{\mathbf{R}}_0^T$ and $\tilde{\mathbf{R}}_0$ is defined as in (5.6) with $\tilde{\mathbf{R}}_0^y$ being the restriction operator which returns for each subdomain the weighted sum of the values of all the nodes on the boundary of that subdomain. The weight corresponding to an interface node is one divided by the number of subdomains in which the node is contained.

6. Numerical results. We consider the model problem (1.1) with $\Omega = \Omega_o = (-1, 1)^2$, $\sigma = 0$, $\widehat{f}(x) = (2\pi^2 + 1)\sin(\pi x_1)\sin(\pi x_2)$, and $\hat{y}(x) = \sin(\pi x_1)\sin(\pi x_2)$.

Additional numerical results for the model problem (1.1) with $\sigma = 1$ can be found in [20], and results using a problem with distributed control are given in [32, Chap. 4].

The domain $\Omega = (-1, 1)^2$ was partitioned into equal-sized square subdomains in a checkerboard pattern. The side length of each subdomain was denoted by H. Regular meshes consisting of triangular elements of various widths (denoted as h) were generated. The preconditioned KKT system was solved using symmetric QMR (sQMR) with the Neumann–Neumann and the balancing Neumann–Neumann preconditioners. In all cases, the stopping criteria was 10^{-8} for the ℓ_2-norm of the preconditioned residual.

TABLE 6.1

Number of iterations for the sQMR method with Neumann–Neumann and balancing Neumann–Neumann preconditioners for varying mesh sizes h, subdomain sizes H, and regularization parameters α.

The subdomain Schur complements are well defined, but for $\sigma = 0$ subdomain Schur complements corresponding to no-control subdomains are not invertible (see Theorem 5.5 and Remark 5.4 and recall that $\Omega = \Omega_o$). In this case we construct $\widehat{\mathbf{S}}_i$, where $\widehat{\mathbf{S}}_i$ is computed as $\mathbf{S}_i$ but with the bilinear form a_i replaced by

$$\widehat{a}_i : V_i \times V_i \to \mathbb{R}, \qquad \widehat{a}_i(y, \psi) = \int_{\Omega_i} \nabla y(x) \nabla \psi(x) + H^{-2} y(x) \psi(x) dx;$$

cf. Remark 4.9. The subproblem solves involving $\mathbf{K}_{II}^i$ and $\mathbf{K}^i$ (the latter constructed with bilinear form $\widehat{a}_i$) were performed using a sparse LU decomposition.

Table 6.1 summarizes the sQMR iteration counts for both preconditioners. These numerical results show that both the Neumann–Neumann and the balancing Neumann–Neumann preconditioners grow worse slowly when the mesh size h is reduced while other parameters are kept constant. This behavior is consistent with the PDE version of these preconditioners. As expected, the Neumann–Neumann preconditioner grows

worse quickly as the number of subdomains increases while the balancing Neumann–Neumann preconditioner remains effective. A notable result is that both preconditioners depend only weakly on the regularization parameter α. As α is reduced from 1 to 10^{-8}, the iteration count for the balancing Neumann–Neumann preconditioner grows by only a factor of two or less in most cases. The one-level Neumman–Neumann preconditioner appeared to be even less sensitive to small α.

7. Conclusion. We have introduced Neumann–Neumann preconditioners for linear-quadratic elliptic optimal control problems, which are obtained by introducing auxiliary states and adjoints on the subdomain interfaces and formulating subdomain optimality conditions with Dirichlet boundary conditions for states and adjoints on the subdomain interfaces. These subdomain optimality conditions are coupled by requiring continuity of normal derivatives of subdomain states and adjoints, defined as solutions of the local optimality conditions, on the subdomain interfaces. This leads to subdomain Schur complement operators that map Dirichlet interface data into Neumann interface data. The original optimality conditions are equivalent to a Schur complement system in which the operator is given by the sum of subdomain Schur complements.

The application of subdomain Schur complements has been shown to correspond to the solution of subdomain optimal control problems with Dirichlet boundary conditions on the subdomain interfaces that are otherwise smaller copies of the original optimal control problem. Conditions are given that establish the invertibility of subdomain Schur complements. The application of the inverses of local Schur complement operators has been shown to correspond to the solution of subdomain optimal control problems with Neumann boundary conditions on the subdomain interfaces that are otherwise smaller copies of the original optimal control problem. For a finite element discretization, the inertia of the local Schur complement matrices as well as that of the sum of the local matrices has been analyzed.

Numerical results for our (balancing) Neumann–Neumann preconditioners applied to a model problem indicate that the numerical performance of our (balancing) Neumann–Neumann DD methods applied to linear-quadratic elliptic optimal control problems is similar to that of their counterparts applied to single elliptic PDEs. We also observe that the performance of our preconditioners applied to the model problem (1.1) is largely independent of the size of the regularization parameter. A convergence theory for Neumann–Neumann methods applied to elliptic optimal control problems comparable to the convergence theory for these methods applied to individual symmetric elliptic PDEs [13, 14] or to the Stokes equation [33] is still missing.

While we have used an elliptic model optimal control problem with Neumann boundary control to illustrate the preconditioners, they can be applied to many other elliptic model optimal control problems. For example, it is straightforward to admit state equations with nonconstant coefficient functions (although the scaling matrices $\mathbf{D}_i$ may have to be adjusted if there are large jumps in coefficients across subdomains [13, 14]). It is also easy to extend the methods to distributed controls (see [32, Chap. 4]). Recently, we have extended the approach in this paper to advection dominated optimal control problems [2]. This requires a careful adjustment of the interface conditions to account for advection terms.

Acknowledgment. The authors thank the anonymous referees for their careful reading and suggestions, which have led to an improvement in the presentation of the paper.

SOLVING THE BOLTZMANN EQUATION IN $N \log_2 N$*

FRANCIS FILBET†, CLÉMENT MOUHOT‡, AND LORENZO PARESCHI§

Abstract. In [C. Mouhot and L. Pareschi, "Fast algorithms for computing the Boltzmann collision operator," *Math. Comp.*, to appear; C. Mouhot and L. Pareschi, *C. R. Math. Acad. Sci. Paris*, 339 (2004), pp. 71–76], fast deterministic algorithms based on spectral methods were derived for the Boltzmann collision operator for a class of interactions including the *hard spheres model* in three dimensions. These algorithms are implemented for the solution of the Boltzmann equation in two and three dimensions, first for homogeneous solutions, then for general nonhomogeneous solutions. The results are compared to explicit solutions, when available, and to Monte Carlo methods. In particular, the computational cost and accuracy are compared to those of Monte Carlo methods as well as to those of previous spectral methods. Finally, for inhomogeneous solutions, we take advantage of the great computational efficiency of the method to show an oscillation phenomenon of the entropy functional in the trend to equilibrium, which was suggested in the work [L. Desvillettes and C. Villani, *Invent. Math.*, 159 (2005), pp. 245–316].

1. Introduction.

The construction of approximate methods of a solution for the Boltzmann equation has a long history and can be traced back to Hilbert, Chapmann, and Enskog [13] at the beginning of the last century. The mathematical difficulties related to the Boltzmann equation make it extremely difficult, if not impossible, to determine analytic solutions in most physically relevant situations. Only in recent years, starting in the 1970s with the pioneering works by Chorin [14] and Sod [46], has the problem been tackled numerically with particular care given to accuracy and computational cost. Even nowadays the deterministic numerical solution of the Boltzmann equation still represents a challenge for scientific computing.

Most of the difficulties are due to the multidimensional structure of the collisional integral, since the integration runs on a highly dimensional unflat manifold. In addition the numerical integration requires great care since the collision integral is at the basis of the macroscopic properties of the equation. Further difficulties are represented by the presence of stiffness, such as the case of small mean free path [24] or the case of large velocities [19].

For such reasons realistic numerical simulations are based on Monte Carlo techniques. The most famous examples are the direct simulation Monte Carlo (DSMC) methods by Bird [3] and Nanbu [36]. These methods guarantee efficiency and preservation of the main physical properties. However, avoiding statistical fluctuations in the results becomes extremely expensive in the presence of nonstationary flows or when close to continuum regimes.

Among deterministic approximations, perhaps the most popular method is represented by the so-called discrete velocity models (DVM) of the Boltzmann equation. These methods [29, 45, 6, 10, 39] are based on a Cartesian grid in velocity and on a discrete collision mechanism on the points of the grid that preserves the main physical properties. Unfortunately DVM are not competitive with Monte Carlo methods in terms of computational cost, and their accuracy seems to be less than first order [37, 38, 39]. In this work we are interested in high-order deterministic methods and therefore we shall not discuss algorithms based on DVM. We refer the reader to the work in preparation [34].

More recently a new class of numerical methods based on the use of spectral techniques in the velocity space has been developed. The methods were first derived in [40], inspired from spectral methods in fluid mechanics [11] and by previous works on the use of Fourier transform techniques for the Boltzmann equation (see [5], for instance). The numerical methods are based on approximating the distribution function by a periodic function in the phase space and on its representation by Fourier series. The resulting Fourier–Galerkin approximation can be evaluated with a computational cost of $O(n^2)$ (where n is the total number of discretization parameters in velocity), which is lower than that of previous deterministic methods (but still larger than that of Monte Carlo methods).

The new methods were further developed in [41, 43], where evolution equations for the Fourier modes were explicitly derived and spectral accuracy of the methods was proven. Strictly speaking these methods are not conservative, since they preserve mass, whereas momentum and energy are approximated with spectral accuracy. This trade-off between accuracy and conservation seems to be an unavoidable compromise in the development of numerical schemes for the Boltzmann equation (with the noticeable exception of [28]).

We recall here that the spectral method has been applied also to nonhomogeneous situations [20, 22]; to the Landau equation [19, 42], where fast algorithms can be readily derived; and to the case of granular gases [35, 21]. For a recent introduction to numerical methods for the Boltzmann equation and related kinetic equations we refer the reader to [15]. Finally, let us mention that Bobylev and Rjasanow [7, 8] have also constructed fast algorithms based on a Fourier transform approximation of the distribution function.

In [33, 32] a fast spectral method was proposed for a class of particle interactions, including pseudo-Maxwell molecules (in dimension 2) and hard spheres (in dimension 3), on the basis of the previous spectral method together with a suitable semidiscretization of the collision operator. This method permits us to reduce the computational cost from $O(n^2)$ to $O(n \log_2 n)$ without losing the spectral accuracy, and thus making the method competitive with Monte Carlo. The principles and basic features of this new method will be presented in the following sections.

The rest of the paper is organized as follows. Section 2 is devoted to a short introduction on the Boltzmann equation and its physical properties. In section 3 we explain the principles of the different spectral algorithms used to compute the collision operator. Several numerical results and comparisons to exact solutions as well as to Monte Carlo methods are given in section 4. An application to a challenging nonhomogeneous test case is finally given in section 5. Some final considerations close the paper in the last section.

2. The Boltzmann equation. The Boltzmann equation describes the behavior of a dilute gas of particles when the only interactions taken into account are binary

elastic collisions. It reads as $x \in \Omega$, $v \in \mathbb{R}^d$, where $\Omega \subset \mathbb{R}^d$ is the spatial domain ($d \geq 2$)

$$\frac{\partial f}{\partial t} + v \cdot \nabla_x f = Q(f, f),$$

where $f(t, x, v)$ is the time-dependent particles distribution function in the phase space. The Boltzmann collision operator Q is a quadratic operator local in (t, x). The time and position act only as parameters in Q and therefore will be omitted in its description

$$Q(f, f)(v) = \int_{v_* \in \mathbb{R}^d} \int_{\sigma \in \mathbb{S}^{d-1}} B(|v - v_*|, \cos\theta)\ (f'_* f' - f_* f)\ d\sigma\, dv_*. \tag{2.1}$$

In (2.1) we used the shorthand $f = f(v)$, $f_* = f(v_*)$, $f' = f(v')$, $f'_* = f(v'_*)$. The velocities of the colliding pairs (v, v_*) and (v', v'_*) are related by

$$v' = v - \frac{1}{2}\big((v - v_*) - |v - v_*|\,\omega\big), \qquad v'_* = v - \frac{1}{2}\big((v - v_*) + |v - v_*|\,\omega\big).$$

The collision kernel B is a nonnegative function which by physical arguments of invariance depends only on $|v - v_*|$ and $\cos\theta = \hat{g} \cdot \omega$ (where $\hat{g} = (v - v_*)/|v - v_*|$). In this work we are concerned with [illegible] models. More precisely we assume that B is locally integrable. This assumption is satisfied by the [illegible], which in dimension $d = 3$ is written as

$$B(|v - v_*|, \cos\theta) = |v - v_*| \tag{2.2}$$

and is known as [illegible] when it is (artificially) extended to interactions deriving from power-law potentials. As an important benchmark model for the numerical simulation we therefore introduce the so-called [illegible], which is written as

$$B(|v - v_*|, \cos\theta) = C_\gamma\, |v - v_*|^\gamma, \tag{2.3}$$

for some $\gamma \in [0, 1]$ and a constant $C_\gamma > 0$.

For this class of model, one can split the collision operator into

$$Q(f, f) = Q^+(f, f) - L(f)\, f,$$

with

$$Q^+(f, f) = \int_{\mathbb{R}^d} \int_{S^{d-1}} B(|v - v_*|, \cos\theta) f' f'_*\, d\sigma\, dv_*, \tag{2.4}$$

$$L(f) = \int_{\mathbb{R}^d} \int_{S^{d-1}} B(|v - v_*|, \cos\theta) f_*\, d\sigma\, dv_*. \tag{2.5}$$

Boltzmann's collision operator has the fundamental properties of conserving mass, momentum, and energy

$$\int_{v \in \mathbb{R}^d} Q(f, f)\, \phi(v)\, dv = 0, \qquad \phi(v) = 1, v, |v|^2,$$

and satisfies the well-known Boltzmann's H theorem

$$-\frac{d}{dt}\int_{v\in\mathbb{R}^d} f\log f\,dv = -\int_{v\in\mathbb{R}^d} Q(f,f)\log(f)\,dv \geq 0.$$

The functional $-\int f\log f$ is the [illegible] of the solution. Boltzmann's H theorem implies that any equilibrium distribution function, i.e., any function which is a maximum of the entropy, has the form of a locally Maxwellian distribution

$$M(\rho,u,T)(v) = \frac{\rho}{(2\pi T)^{d/2}}\exp\left(-\frac{|u-v|^2}{2T}\right), \tag{2.6}$$

where ρ, u, T are the [illegible], and [illegible] of the gas, defined, respectively, by

$$\rho = \int_{v\in\mathbb{R}^d} f(v)dv, \quad u = \frac{1}{\rho}\int_{v\in\mathbb{R}^d} vf(v)dv, \quad T = \frac{1}{d\rho}\int_{v\in\mathbb{R}^d} |u-v|^2 f(v)dv. \tag{2.7}$$

For further details on the physical background and derivation of the Boltzmann equation we refer to [13] and [49].

3. The spectral methods. In this section we shall explain the principles of the algorithms for computing the collision integral for a fixed value of the spatial variable x. Indeed, it is well known that one can reduce to this case by some splitting strategy (see [41, 20], for example).

3.1. A general framework. We consider the spatially homogeneous Boltzmann equation written in the general form

$$\frac{\partial f}{\partial t} = Q(f,f), \tag{3.1}$$

where Q is given by

$$Q(f,f) = \int_{\{(y,z)\in\mathcal{C}\}} \mathcal{B}(y,z)\big(f'f'_* - f_*f\big)\,dy\,dz, \quad v\in\mathbb{R}^d, \tag{3.2}$$

with

$$v' = v+\Theta'(y,z), \qquad v'_* = v+\Theta'_*(y,z), \qquad v_* = v+\Theta_*(y,z).$$

In the equations above, $\mathcal{C}$ is some given unbounded domain, and Θ, Θ', Θ'_* are suitable functions, to be defined later. This general framework emphasizes the translation invariance property of the collision operator, which is crucial for the spectral methods. We will explain more precisely in the next paragraphs some changes of variables which allow us to reduce the classical operator (2.1) to the form (3.2).

A problem associated with deterministic methods which use a fixed discretization in the velocity domain is that the velocity space is approximated by a finite region. Physically the domain for the velocity is $\mathbb{R}^d$, and the property of having compact support is not preserved by the collision operator. In general the collision process spreads the support by a factor of $\sqrt{2}$ in the elastic case (see [44, 31] and also [30] for similar properties in the inelastic case). As a consequence, for the continuous equation in time, the function f is immediately positive in the whole domain $\mathbb{R}^d$. Thus, at the numerical level, some nonphysical condition has to be imposed to keep the support of the function in velocity uniformly bounded. In order to do this there are two main strategies.

- One can remove the physical binary collisions that will lead outside the bounded velocity domain, which means a possible increase of the number of local invariants (that is, the functions φ such that $(\varphi'_* + \varphi' - \varphi_* - \varphi)$ is zero everywhere on the domain). If this is done properly (i.e., without removing too many collisions), the scheme remains conservative (and without spurious invariants). However, this truncation breaks down the convolution-like structure of the collision operator, which requires the translation invariance in velocity. Indeed, the modified collision kernel depends on v through the boundary conditions. This truncation is the starting point of most schemes based on DVM in a bounded domain.
- One can add some nonphysical binary collisions by periodizing the function and the collision operator. This implies the loss of some local invariants (some nonphysical collisions are added). Thus the scheme is no longer conservative, except for the mass if the periodization is done carefully. In this way the structural properties of the collision operator are maintained and thus they can be exploited to derive fast algorithms. This periodization is the basis of the spectral methods.

Therefore, we consider the space homogeneous Boltzmann equation in a bounded domain in velocity $\mathcal{D}_T = [T;T]^d$ $(0 < T < \infty)$. We need to truncate the integration in y and z, since periodization would yield an infinite result if not. Thus we set y and z to belong to some truncated domain $\mathcal{C}_R \subset \mathcal{C}$ (the parameter R refers to its size and will be defined later). For a compactly supported function with support included in B_S, the ball centered at 0 with radius $S > 0$, one has to prescribe suitable relations (depending on the precise change of variable and truncation chosen) between S, R, T in order to retain all possible collisions and at the same time prevent intersections of the regions, where f is different from zero (dealiasing condition). Then the [illegible] collision operator reads

$$Q^R(f,f) = \int_{\mathcal{C}_R} \mathcal{B}(y,z) \left(f'_* f' - f_* f\right) dy\, dz \tag{3.3}$$

for $v \in \mathcal{D}_T$ (the expression for $v \in \mathbb{R}^d$ is deduced by periodization). By making some changes of variable on v, one can easily prove for the two choices of variables y, z in the next subsections that for any function φ periodic on $\mathcal{D}_T$ the following weak form is satisfied:

$$\int_{\mathcal{D}_T} Q^R(f,f)\,\varphi(v)\,dv = \frac{1}{4}\int_{\mathcal{D}_T}\int_{\mathcal{C}_R} \mathcal{B}(y,z)\, f_* f\, (\varphi'_* + \varphi' - \varphi_* - \varphi)\, dy\, dz\, dv. \tag{3.4}$$

Now we use the representation Q^R to derive spectral methods. Hereafter we use just one index to denote the d-dimensional sums with respect to the vector $k = (k_1, \ldots, k_d) \in \mathbb{Z}^d$, and hence we set

$$\sum_{k=-N}^{N} := \sum_{k_1,\ldots,k_d=-N}^{N}.$$

The approximate function f_N is represented as the truncated Fourier series

$$f_N(v) = \sum_{k=-N}^{N} \hat{f}_k\, e^{i\frac{\pi}{T}k\cdot v}, \tag{3.5}$$

$$\hat{f}_k = \frac{1}{(2T)^d}\int_{\mathcal{D}_T} f(v)\, e^{-i\frac{\pi}{T}k\cdot v}\, dv.$$

In a Fourier–Galerkin method the fundamental unknowns are the coefficients $\hat{f}_k$, $k = -N, \dots, N$. We obtain a set of ODEs for the coefficients $\hat{f}_k$ by requiring that the residual of (3.3) be orthogonal to all trigonometric polynomials of degree less than N. Hence for $k = -N, \dots, N$

$$\int_{\mathcal{D}_T} \left(\frac{\partial f_N}{\partial t} - Q^R(f_N, f_N) \right) e^{-i\frac{\pi}{T}k\cdot v}\, dv = 0. \tag{3.6}$$

By substituting expression (3.5) in (3.4) we get

$$Q^R(f_N, f_N) = Q^{R,+}(f_N, f_N) - L^R(f_N)\, f_N,$$

with

$$L^R(f_N)\, f_N = \sum_{l=-N}^{N} \sum_{m=-N}^{N} \beta(m,m)\, \hat{f}_l\, \hat{f}_m e^{i\frac{\pi}{T}(l+m)\cdot v}, \tag{3.7}$$

$$Q^{R,+}(f_N, f_N) = \sum_{l=-N}^{N} \sum_{m=-N}^{N} \beta(l,m)\, \hat{f}_l\, \hat{f}_m e^{i\frac{\pi}{T}(l+m)\cdot v}, \tag{3.8}$$

where

$$\beta(l,m) = \int_{\mathcal{C}_R} \mathcal{B}(y,z) e^{i\frac{\pi}{T}(l\cdot\Theta'(y,z) + m\cdot\Theta'_*(y,z))}\, dy\, dz. \tag{3.9}$$

The [illegible] is the projection of the collision equation in $\mathbb{P}_N$, the $(2N+1)^d$-dimensional vector space of trigonometric polynomials of degree at most N in each direction, i.e.,

$$\frac{\partial f_N}{\partial t} = \mathcal{P}_N\, Q^R(f_N, f_N),$$

where $\mathcal{P}_N$ denotes the orthogonal projection on $\mathbb{P}_N$ in $L^2(\mathcal{D}_T)$. A straightforward computation leads to the following set of ODEs on the Fourier coefficients

$$\frac{\partial \hat{f}_k}{\partial t} = \sum_{\substack{l+m=k \\ l,m=-N}}^{N} \hat{\beta}(l,m)\, \hat{f}_l\, \hat{f}_m, \tag{3.10}$$

where $\hat{\beta}(l,m)$ are the so-called [illegible], given by

$$\hat{\beta}(l,m) = \beta(l,m) - \beta(m,m),$$

with the initial condition

$$\hat{f}_k(0) = \frac{1}{(2T)^d} \int_{\mathcal{D}_T} f_0(v)\, e^{-i\frac{\pi}{T}k\cdot v}\, dv. \tag{3.11}$$

3.2. Classical spectral methods. In the classical spectral method [41], a simple change of variables in (2.1) permits us to write

$$Q(f,f) = \int_{\mathbb{R}^d} \int_{S^{d-1}} \mathcal{B}^c(g,\omega)\big(f(v')f(v'_*) - f(v)f(v_*)\big)\, d\omega\, dg, \tag{3.12}$$

with $g = v - v_* \in \mathbb{R}^d$, $\omega \in \mathbb{S}^{d-1}$, and

$$\begin{cases} v' = v - \frac{1}{2}(g - |g|\omega) =: v + \Theta'(g,\omega), \\ v'_* = v - \frac{1}{2}(g + |g|\omega) =: v + \Theta'_*(g,\omega), \\ v_* = v + g =: v + \Theta_*(g,\omega). \end{cases} \tag{3.13}$$

Finally, $\mathcal{B}^c$ is defined by

$$\mathcal{B}^c(g,\omega) = 2^{d-1}\left(1 - (\hat{g}\cdot\omega)\right)^{d/2-1} B\big(|g|, 2(\hat{g}\cdot\omega)^2 - 1\big). \tag{3.14}$$

The Boltzmann operator (3.12) is now written in the form (3.2) with $(y,z) = (g,\omega) \in \mathbb{R}^d \times S^{d-1} =: \mathcal{C}$. Moreover, from the conservation of the momentum $v'_* + v' = v_* + v$ and the energy $|v'_*|^2 + |v'|^2 = |v_*|^2 + |v|^2$, we get the following results [40], assuming supp $f \subset B_S$:

- We have supp $Q(f,f) \subset B_{\sqrt{2}\,S}$;
- the collision operator is then given by

$$Q(f,f)(v) = \int_{B_{2S}} \int_{S^{d-1}} B(|g|, \cos\theta)\big(f(v')f(v'_*) - f(v_*)f(v)\big)\, d\omega\, dg,$$

with $v', v'_*, v_* \in B_{(2+\sqrt{2})R}$.

As a consequence of this result, in order to write a spectral approximation to (3.1) we consider the distribution function f restricted on $[-T,T]^d$ $(0 < T < +\infty)$, assuming $f(v) = 0$ on $[-T,T]^d \setminus B_S$, and extend it by periodicity to a periodic function on $[-T,T]^d$. We truncate the domain for $(y,z) = (g,\omega)$ as $\mathcal{C}_R = B_R \times \mathbb{S}^{d-1}$ for $R > 0$ (thus defining Q^R). Following the previous discussion on the dealiasing condition, we take $R = 2S$, and the shortest period can be restricted to $[-T,T]^d$, with $T \geq (3+\sqrt{2})S/2$ (for a more detailed discussion see [41]).

Then we apply the spectral algorithm (3.7), (3.8) and get the coefficients $\beta^c(l,m)$

$$\beta^c(l,m) = \int_{B_R} \int_{S^{d-1}} B(|g|, \cos\theta)\, e^{-i\frac{\pi}{T}\left(g\cdot\frac{(l+m)}{2} - i|g|\omega\cdot\frac{(m-l)}{2}\right)}\, d\omega\, dg. \tag{3.15}$$

We refer to [41, 22] for the explicit computation of Fourier coefficients $\beta^c(l,m)$ in the VHS case, where B is given by (2.3). Now the evaluation of the right-hand side of (3.10) requires exactly $O(N^{2d})$ operations. We emphasize that the usual cost for a DVM method based on N^d parameters for f in the velocity space is $O(N^{2d}M)$, where M is the numbers of angle discretizations.

3.3. Fast spectral methods. Here we shall approximate the collision operator starting from a representation which conserves more symmetries of the collision operator when one truncates it in a bounded domain. This representation was used

in [7, 26] to derive finite differences schemes and is close to the classical Carleman representation (cf. [12]). The basic identity we shall need is (for $u \in \mathbb{R}^d$)

$$\frac{1}{2}\int_{S^{d-1}} F(|u|\sigma - u)\, d\sigma = \frac{1}{|u|^{d-2}}\int_{\mathbb{R}^d} \delta(2\, y\cdot u + |y|^2)\, F(y)\, dy. \tag{3.16}$$

Using (3.16) the collision operator (2.1) can be written as

$$\begin{aligned} Q(f,f)(v) = 2^{d-1}\int_{x\in\mathbb{R}^d}\int_{y\in\mathbb{R}^d} \mathcal{B}^f(y,z)\,\delta(y\cdot z) \\ \times\big(f(v+z)f(v+y) - f(v+y+z)f(v)\big)\, dy\, dz, \end{aligned} \tag{3.17}$$

with

$$\mathcal{B}^f(y,z) = 2^{d-1}\, B\left(|y+z|, -\frac{y\cdot(y+z)}{|y||y+z|}\right)\, |y+z|^{-(d-2)}.$$

Thus the collision operator is now written in the form (3.2), with $(y,z)\in\mathbb{R}^d\times\mathbb{R}^d =: \mathcal{C}$, $\mathcal{B}(y,z) = \mathcal{B}^f(y,z)\,\delta(y\cdot z)$, and $v'_* = v + z =: v + \Theta'_*(y,z)$, $v' = v + y =: v + \Theta'(y,z)$, $v_* = v + y + z =: v + \Theta_*(y,z)$.

Now we consider the bounded domain $\mathcal{D}_T = [T,T]^d$ $(0 < T < \infty)$ for the distribution f, and the bounded domain $B_R \times B_R$ for (y,z) (for some $R > 0$). If f has support included in B_S, $S > 0$, geometrical arguments similar to the one for the classical spectral methods (see [41, 33, 32]) show that we can take $R = 2S$ and $T \geq (1+3\sqrt{2})S/2$ to get all collisions and prevent intersections of the regions, where f is different from zero. The (truncated) operator now reads

$$Q^R(f,f)(v) = \int_{y\in B_R}\int_{z\in B_R} \mathcal{B}^f(y,z)\,\delta(y\cdot z)\,(f(v+z)f(v+y) - f(v+y+z)f(v))\, dy\, dz \tag{3.18}$$

for $v\in\mathcal{D}_T$. This representation of the collision kernel yields better decoupling properties between the arguments of the operator. From now on we can apply the spectral algorithm (3.7), (3.8) to this collision operator, and the corresponding kernel modes are given by

$$\beta^f(l,m) = \int_{y\in B_R}\int_{z\in B_R} \tilde{B}(y,z)\,\delta(y\cdot z)\, e^{i\frac{\pi}{T}(l\cdot y + m\cdot z)}\, dy\, dz.$$

In what follows we shall focus on β^f, and one easily checks that $\beta^f(l,m)$ depends only on $|l|$, $|m|$, and $|l\cdot m|$.

3.1. Note that the classical spectral method originates the following form of the kernel modes in the y, z notation:

$$\beta^c(l,m) = \int_{y\in B_R}\int_{z\in B_R} \mathcal{B}^f(y,z)\,\delta(y\cdot z)\,\chi_{|y+z|\leq R}\, e^{i\frac{\pi}{T}(l\cdot y + m\cdot z)}\, dy\, dz.$$

One can notice that the condition $|y+z|^2 = |y|^2 + |z|^2 \leq R^2$ couples the modulus of y and z such that the ball is not completely covered (for instance, if y and z are orthogonal both with modulus R, the condition is not satisfied, since $|y+z| = \sqrt{2R}$). This explains the better decoupling properties between the arguments of the collision operator of this representation.

4. Fast algorithms. The search for fast deterministic algorithms for the collision operator, i.e., algorithms with a cost lower than $O(N^{2d+\epsilon})$ (with typically $\epsilon = 1$ for DVM, or $\epsilon = 0$ for the classical spectral method), consists mainly of identifying some convolution structure in the operator (see, for example, [8, 42]). The aim is to approximate each $\beta^f(l,m)$ by a sum

$$\beta^f(l,m) = \sum_{p=1}^{A} \alpha_p(l)\alpha'_p(m). \tag{4.1}$$

This gives a sum of A discrete convolutions, and thus the algorithm can be computed in $O(A\,N^d \log_2 N)$ operations by means of standard fast Fourier transform (FFT) techniques [11]. To this purpose we shall use a further approximated collision operator, where the number of possible directions of collision is reduced to a finite set. We start from representation (3.18) and write y and z in spherical coordinates

$$Q^R(f,f)(v) = \frac{1}{4}\int_{e\in S^{d-1}}\int_{e'\in S^{d-1}} \delta(e\cdot e')\,de\,de'$$
$$\times\left[\int_{-R}^{R}\int_{-R}^{R} \rho^{d-2}(\rho')^{d-2}\mathcal{B}^f(\rho,\rho')\left(f(v+\rho' e')\,f(v+\rho e) - f(v+\rho' e'+\rho e)f(v)\right)d\rho\,d\rho'\right]$$

(note that thanks to the orthogonality condition imposed by the Dirac mass on y and z, $\mathcal{B}^f$ depends only on the modulus of y and z). Let us denote by $\mathcal{A}$ a discrete set of orthogonal couples of unit vectors (e,e'), which is even; i.e., $(e,e')\in\mathcal{A}$ implies that $(-e,e')$, $(e,-e')$, and $(-e,-e')$ belong to $\mathcal{A}$ (this property on the set $\mathcal{A}$ is required to preserve the conservation properties of the operator). Now we define $Q^{R,\mathcal{A}}$ to be

$$Q^{R,\mathcal{A}}(f,f)(v) = \frac{1}{4}\int_{(e,e')\in\mathcal{A}} d\mathcal{A}$$
$$\times\left[\int_{-R}^{R}\int_{-R}^{R} \rho^{d-2}(\rho')^{d-2}\mathcal{B}^f(\rho,\rho')\left(f(v+\rho' e')\,f(v+\rho e) - f(v+\rho' e'+\rho e)f(v)\right)d\rho\,d\rho'\right],$$

where $d\mathcal{A}$ denotes a discrete measure on $\mathcal{A}$, which is also even in the sense that $d\mathcal{A}(e,e') = d\mathcal{A}(-e,e') = d\mathcal{A}(e,-e') = d\mathcal{A}(-e,-e')$. It is easy to check that $Q^{R,\mathcal{A}}$ has the same conservation properties as Q^R. We make the decoupling assumption that

$$\forall\, y\perp z, \quad \mathcal{B}^f(y,z) = a(|y|)\,b(|z|). \tag{4.2}$$

This assumption is obviously satisfied if $\mathcal{B}^f$ is constant. This is the case of Maxwellian molecules in dimension $d=2$ and hard spheres in dimension $d=3$ (the most relevant kernel for applications). Extensions to more general interactions are discussed in [33].

Let us describe the method in dimension $d=3$ with $\mathcal{B}^f$ satisfying the decoupling assumption (4.2) (see [33] for other dimensions). First we change to spherical coordinates

$$\beta^f(l,m) = \frac{1}{4}\int_{e\in S^2}\int_{e'\in S^2}\delta(e\cdot e')$$
$$\times\left[\int_{-R}^{R}|\rho|\,a(\rho)\,e^{i\frac{\pi}{T}\rho(l\cdot e)}\,d\rho\right]\left[\int_{-R}^{R}|\rho'|\,b(\rho')\,e^{i\frac{\pi}{T}\rho'(m\cdot e')}\,d\rho'\right]de\,de'$$

and then we integrate first e' on the intersection of the unit sphere with the plane $e^\perp$

$$\beta^f(l,m) = \frac{1}{4}\int_{e\in S^2} \phi^3_{R,a}(l\cdot e)\,\left[\int_{e'\in S^2\cap e^\perp} \phi^3_{R,b}(m\cdot e')\,de'\right]\,de,$$

where

$$\phi^3_{R,a}(s) = \int_{-R}^{R} |\rho| a(\rho) e^{i\frac{\pi}{T}\rho s}\,d\rho, \quad \phi^3_{R,b}(s) = \int_{-R}^{R} |\rho| b(\rho) e^{i\frac{\pi}{T}\rho s}\,d\rho.$$

Thus we get the following decoupling formula with two degrees of freedom:

$$\beta_R(l,m) = \int_{e\in S^2_+} \phi^3_{R,a}(l\cdot e)\,\psi^3_{R,b}(\Pi_{e^\perp}(m))\,de,$$

where S^2_+ denotes the half-sphere and

$$\psi^3_{R,b}(\Pi_{e^\perp}(m)) = \int_0^\pi \phi^3_{R,b}\big(|\Pi_{e^\perp}(m)|\,\cos\theta\big)\,d\theta,$$

and $\Pi_{e^\perp}$ is the orthogonal projection on the plane $e^\perp$. In the particular case where $\mathcal{B}^f = 1$ (HS model), we can compute the functions ϕ^3_R and ψ^3_R

$$\phi^3_R(s) = R^2\big(2\,\mathrm{Sinc}(Rs) - \mathrm{Sinc}^2(Rs/2)\big), \quad \psi^3_R(s) = \int_0^\pi \phi^3_R\big(s\,\cos\theta\big)\,d\theta.$$

Now the function $e\mapsto \phi^3_{R,a}(l\cdot e)\,\psi^3_{R,b}(\Pi_{e^\perp}(m))$ is periodic on S^+_2. Taking a spherical parametrization (θ,φ) of $e\in S^2_+$ and taking for the set $\mathcal{A}$ uniform grids of respective size M_1 and M_2 for θ and φ we get

$$\beta^f(l,m) \simeq \frac{\pi^2}{M_1\,M_2}\sum_{p,q=0}^{M_1,M_2} \alpha_{p,q}(m)\,\alpha'_{p,q}(l),$$

where

$$\alpha_{p,q}(l) = \phi^3_{R,a}(l\cdot e_{\theta_p,\varphi_q}), \quad \alpha'_{p,q}(m) = \psi^3_{R,b}\left(\Pi_{e^\perp_{\theta_p,\varphi_q}}(m)\right)$$

and $(\theta_p,\varphi_q) = (p\pi/M_1, q\pi/M_2)$.

We consider this expansion with $M = M_1 = M_2$ to avoid anisotropy in the computational grid. By using the FFT algorithm, the computational cost of the algorithm is then $O(M^2N^3\log N)$ (compared to $O(M^2N^6)$ of a direct discretization on the grid for a DVM method, and to $O(N^6)$ of the classical spectral method).

Let us finally mention that the mathematical analysis of the fast algorithm in [33] provides the following results:

- It is spectrally accurate according to the parameters N and M;
- the error on the conservation laws of momentum and energy is spectrally small according to the parameter N, and no additional error (according to the speed-up parameter M) is made.

These two properties were the main motivations for the development of the method of [33] described above to obtain the decomposition (4.1). Other advantages of this particular decomposition is that it does not introduce instability in the equation (see [33, Theorem 3.1], for instance) and it is naturally adaptive (as it is based on the rectangular quadrature rule for approximating integrals of periodic functions). Finally, another advantage of the proposed method is that it is still easy to implement since it is based only on FFT.

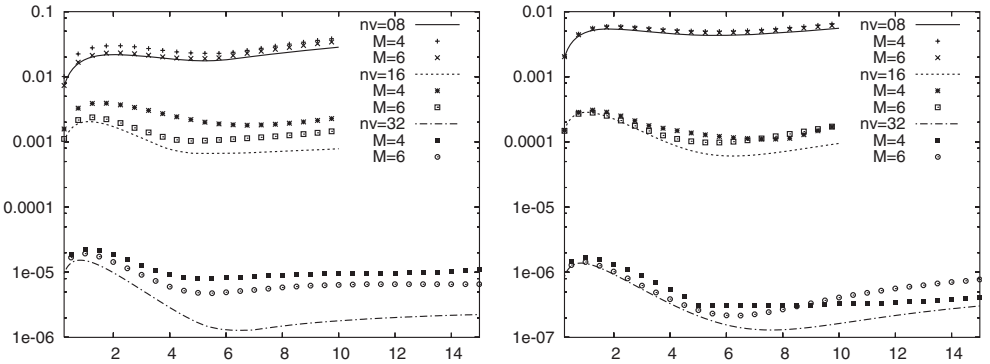

FIG. 1. *Two-dimensional homogeneous case: evolution of the numerical L^1 and L^∞ relative error of $f(t, v)$.*

5. Numerical results in the homogeneous case. In this section we will present several numerical results for the space homogeneous equation which show the improvement of the fast spectral algorithms with respect to the classical spectral methods and how they compare with Monte Carlo methods. The time discretization is performed by suitable Runge–Kutta methods.

5.1. Spatially homogeneous Maxwell molecules in dimension 2.

Comparison to exact solutions. We consider two-dimensional pseudo-Maxwell molecules (i.e., the VHS model with $\gamma = 0$). In this case we have an exact solution given by

$$f(t, v) = \frac{\exp(-v^2/2S)}{2\pi\, S^2} \left[2\, S - 1 + \frac{1 - S}{2\, S}\, v^2\right],$$

with $S = 1 - \exp(-t/8)/2$, which corresponds to the well-known exact solution [4]. This test is performed to check spectral accuracy, by comparing the error at a given time, when using $n_v = 8$, 16, and 32 Fourier modes for each coordinate. We present the results obtained by the classical spectral method and the fast spectral method with different numbers of discrete angles.

Figure 1 shows the relative L^∞, L^1, and L^2 norms of the difference between the numerical and exact solutions as functions of time. These errors are computed according to the formula

$$\mathcal{E}_p = \left(\frac{\sum_{i=-N}^{N} |f_i(t) - f(v_i, t)|^p}{\sum_{i=-N}^{N} |f(v_i, t)|^p} \right)^{1/p},$$

with $i = (i_1, i_2)$ and $N = n_v/2$ for $p = 1$ and $p = 2$. A similar expression is used for the L^∞ error. Note that the error increases initially and then decreases almost monotonically in time. After a long time the error starts increasing again. This effect is due to aliasing. Indeed, for a fixed computational domain, when the number of Fourier modes increases, the effect of aliasing becomes dominant over the error due to the spectral approximation. For this reason, the size of the domain is chosen in order to minimize the aliasing error. A trade-off should be obtained between aliasing and spectral error, which means that the size of the domain should be increased when

TABLE 1
Comparison of the L^1 error in two dimensions between the classical spectral method and the fast spectral method with different numbers of discrete angles and with a second-order Runge–Kutta time discretization at time $T_{end} = 1$.

8	0.02013	0.02778	0.02129	0.02112
16	0.00204	0.00329	0.00238	0.00224
32	1.405E-5	2.228E-5	1.861E-5	1.772E-5

increasing the number of Fourier modes. Roughly speaking, the period should be chosen in such a way that the two contributions of the error are of the same order of magnitude. In this test, the radius of the ball, which defines the computational domain, is $T = 4$ for $n_v = 8$, $T = 5$ for $n_v = 16$, and $T = 7$ for $n_v = 32$. We refer to [41] for a more detailed discussion about aliasing.

Concerning the comparison between the classical and fast spectral methods, we observe that for a fixed value of n_v, the numerical error of the classical spectral method and of the fast algorithm is of the same order. Moreover, the influence of the number of discrete angles is very weak. Indeed, with only $M = 4$, the results are quite similar even for large n_v and as expected the number of discrete angles does not affect the variations of energy, which are of the same order of magnitude as the numerical error (note that there is no variation for the momentum since in the special case of even solutions, it is preserved at 0 by the spectral scheme). In Table 1, we give a quantitative comparison of the numerical error $\mathcal{E}_1$ at time $T_{end} = 1$. We can also observe the spectral accuracy for the classical and fast methods: the order of accuracy is about 3 between 8 and 16 grid points, whereas it becomes 7 between 16 to 32 points.

Efficiency and accuracy. Now we still consider two-dimensional pseudo-Maxwell molecules (i.e., $\gamma = 0$) with the initial datum

$$f(0,v) = \frac{1}{4\,\pi}\left[\exp\left(-\frac{|v-v_0|^2}{2}\right) + \exp\left(-\frac{|v+v_0|^2}{2}\right)\right], \quad v \in \mathbb{R}^2,$$

where $v_0 = (1,2)$. In this case, we do not know the exact solution but we want to study the influence of the number of discrete angles on a nonisotropic solution. Thus, this test is used to check the energy conservation and the evolution of high-order moments of the solution.

The time step is chosen small enough to reduce the influence of the time discretization, i.e., $\Delta t = 0.025$. Moreover, the computational domain is taken large enough with respect to the number of grid points in order to reduce the aliasing error due to the periodization of the solution. Simulations are performed with $n_v = 16$, 32, and 64 points.

In Figure 2 the relaxation of the entropy and the temperature components for the fast and classical spectral methods is shown. The energy is conserved by the continuous collision operator, but when using the spectral method the total energy can change with time, which is a good indicator of the accuracy of the numerical solution. Indeed, the total discrete energy is not exactly conserved over time, but if the aliasing error is small, it is conserved within spectral accuracy; typically here the variations are about 10^{-4} when $n_v = 32$. Moreover, we observe that the number of discrete angles does not significantly affect the transient regime. For instance, with only four angles

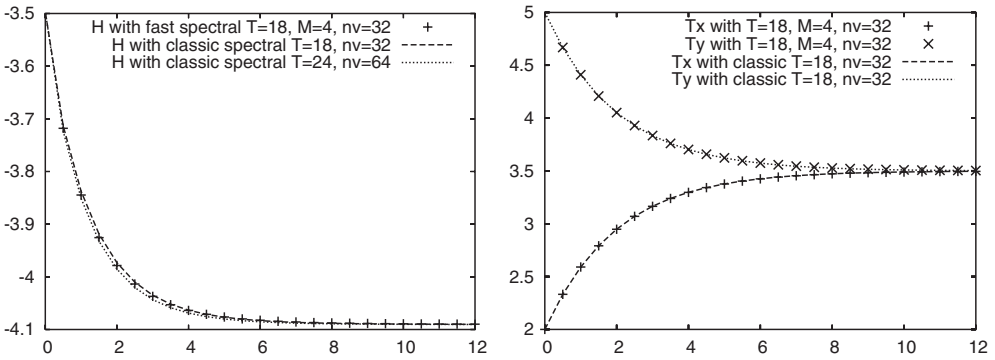

FIG. 2. *Two-dimensional homogeneous case: relaxation of the entropy and the temperature components for the fast and classical spectral methods with respect to the number of modes per direction n_v and the length box T.*

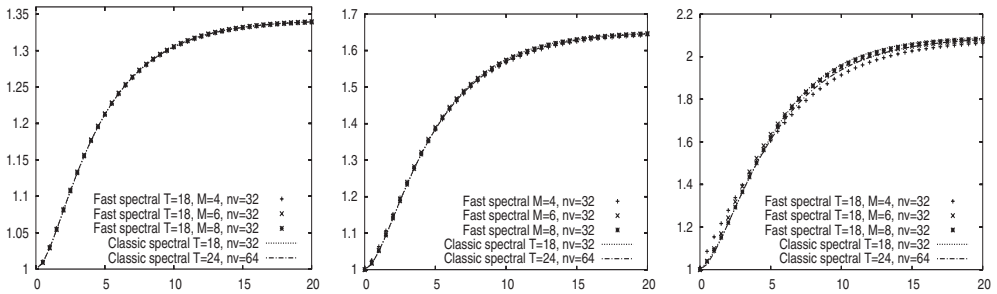

FIG. 3. *Two-dimensional homogeneous case: time evolution of the variations of high-order normalized moments $\mathcal{M}_4$, $\mathcal{M}_5$, and $\mathcal{M}_6$ of $f(t,v)$ for the fast and classical spectral methods with respect to the number of modes per direction n_v and the length box T.*

on the half-sphere, the relaxation of entropy and temperature components is very close to the numerical solution obtained by the classical spectral method. Finally, we plot in Figure 3 the time evolution of high-order moments of $f_N(t,v)$ given in discrete form by

$$\mathcal{M}_k(t) = \Delta v^2 \sum_{l=-N}^{N} |v_l|^k \, f_N(t, v_l).$$

High-order moments give information on the accuracy of the approximate distribution function tail. Once again, we observe that the number of angles does not affect the results even if the solution is nonisotropic.

To conclude, we observe that in dimension $d = 2$, the fast algorithm is really efficient in terms of accuracy and computational cost compared to the classical spectral method. In Table 2 we report the computational times of the methods which show a speed-up of the fast solver independently of the number of points used in our tests and with a maximum speed-up reached for $N = 64$, where the fast methods with $M = 4$ is more than 17 times faster than the classical method.

5.2. Spatially homogeneous hard spheres in dimension 3. In this section we consider the three-dimensional HS molecules model. The initial condition is chosen

as the sum of two Gaussians

$$f(v,0) = \frac{1}{2(2\pi\sigma^2)}\left[\exp\left(-\frac{|v-v_0|^2}{2\sigma^2}\right) + \exp\left(-\frac{|v+v_0|^2}{2\sigma^2}\right)\right],$$

with $\sigma = 1$ and $v_0 = (2,1,0)$. The final time of the simulation is $T_{end} = 3$ and corresponds approximately to the time for which the steady state of the solution is reached. The time step is $\Delta t = 0.1$ and the length box is taken as $T = 12$ when $n_v = 16$ and as $T = 15$ when $n_v = 32$.

This test is used to check the evolution of moments and particularly the stress tensor $P_{i,j}$, $i,j = 1,\dots,3$ defined as

$$P_{i,j} = \int_{\mathbb{R}^3} f(v)(v_i - u_i)\,(v_j - u_j)\,dv, \quad (i,j) \in \{1,2,3\}^2,$$

where $(u_i)_i$ are the components of the mean velocity. As in the previous case, we compare the classical and fast methods in terms of computational time (see Table 3) and accuracy. In Figure 4, we propose the evolution of the temperature for the two methods using 32 grid points in each direction. This solution is also compared with the solution obtained from the Monte Carlo method. The discrete temperatures agree well in this case and the efficiency of the fast algorithm is verified since the computational time is highly reduced using only $M_1 = M_2 = 4$ discrete angles without affecting the accuracy of the distribution function. We remark that in dimension $d = 3$ the speed-up of the methods becomes really evident for large values of N. Again for $N = 64$ and $M = 4$ the fast method is more than 14 times faster.

Comparison with Monte Carlo. Finally, we compare the results obtained with our spectral method with those obtained by a Monte Carlo scheme. We use a standard version of Monte Carlo, which may be referred to as the Nanbu–Babovsky scheme [36, 2].

In the case of Monte Carlo methods, the moments are computed by using unbiased estimators averaged over several runs. The number of runs N_{runs}, number of particles N_p, and the time step Δt, have been chosen in such a way to balance the time discretization error with statistical fluctuations.

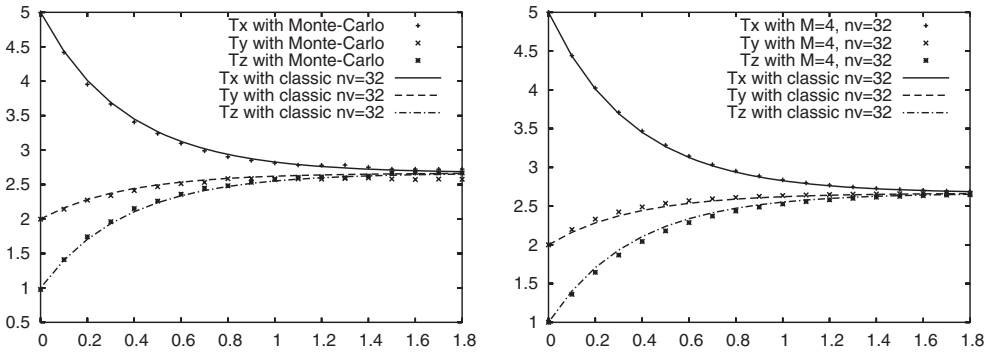

FIG. 4. *Three-dimensional homogeneous case: comparison between the fast and classical spectral methods and the Monte Carlo method for the temperature components relaxation.*

The first run consists of taking a large number of particles and making time averaging in order to minimize the fluctuation errors: $N_{\text{runs}} = 10^3$, $N_p = 10^4$, and $\Delta t = 0.01$. The total computational time for computing the evolution of moments in this case is 113 min. 23 sec. On the other hand we perform a second run, where we use more averaging to minimize fluctuation errors: $N_{\text{runs}} = 5.\,10^3$, $N_p = 5.\,10^3$, and $\Delta t = 0.01$. The computational time is now 100 min.

We remark that the computations have been obtained by using the HS model (VHS with $\gamma = 1$), which is the most realistic. In this case, the computational time of the Monte Carlo methods becomes larger than in the case when we consider pseudo-Maxwell molecules (VHS with $\gamma = 0$) for which the collision kernel is constant and no rejection is needed. For the spectral method the computational cost is independent of the collision kernel.

From the comparison, it is obvious that, for three-dimensional computations, the greater cost of the classical spectral scheme (with the same number of degrees of freedom) is compensated by a much greater accuracy, allowing for better results with the same computational cost. Moreover, with the fast algorithm, the spectral scheme really becomes competitive in terms of computational time since the accuracy is not affected when we use fewer discrete angles (for instance, $M = 4$). In Figure 5, we compare the accuracy on the evolution of high-order moments with the different methods: the fourth-order moments are very close, but the results obtained with the Monte Carlo methods are affected by fluctuations on the tail of the distribution function, which are difficult to remove (see the evolution of the eighth-order moment). Note that for two- and three-dimensional pseudo-Maxwell molecules, comparisons had also been performed between Monte Carlo methods and the classical spectral method in [41, section 6.3].

5.3. Stability of spectral methods with respect to nonsmooth data. In this subsection we perform some numerical simulations in order to study the behavior of the spectral methods when applied to nonsmooth data. We consider the distribution

$$f_0(v) = \begin{cases} 1 & \text{if } |v|^2 \leq 1, \\ 0 & \text{else} \end{cases}$$

and use a mollified initial datum, which suitably approximates moments. We perform two numerical simulations using the fast spectral method with 32^2 and 64^2 grid points and plot the evolution of the entropy and the fourth-order moment in Figure 6. Even

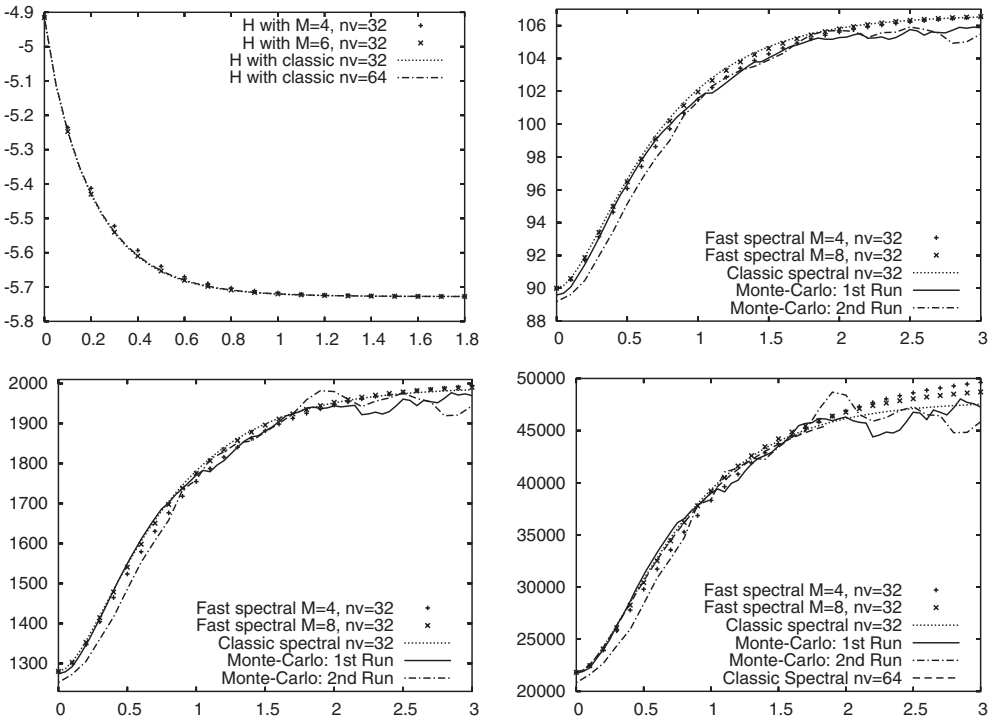

FIG. 5. *Three-dimensional homogeneous case: time evolution of the kinetic entropy H and high-order moments $\mathcal{M}_4$, $\mathcal{M}_6$, and $\mathcal{M}_8$ of $f(t,v)$ for the fast and classical spectral methods and the Monte Carlo methods.*

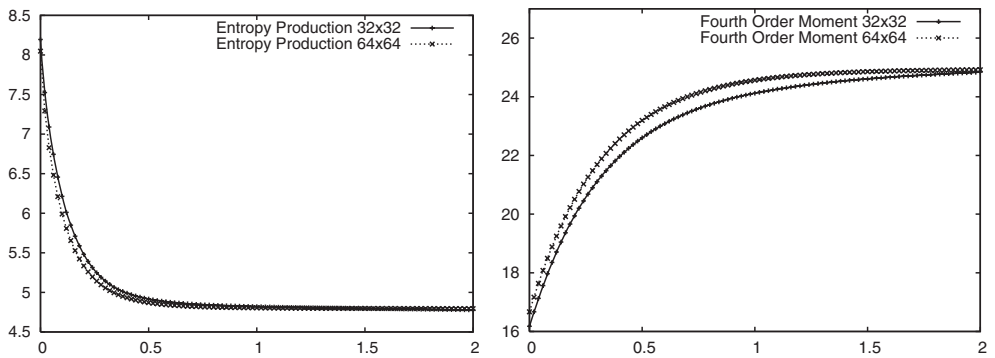

FIG. 6. *Time evolution of the kinetic entropy and the fourth-order moment with respect to the number of grid points 32^2 and 64^2.*

for this discontinuous initial datum, we observe that for the two configurations the numerical entropy is decreasing and both numerical solutions converge to the same steady state. Moreover, we plot the evolution of the distribution function with respect to time in Figure 7: the fast spectral method is very stable for this numerical test even if spurious oscillations are first generated; the distribution becomes smooth and converges to an approximated Maxwellian. As expected from a Fourier–Galerkin method, the accuracy degenerates in the discontinuity region. However, surprisingly the method seems to remain stable.

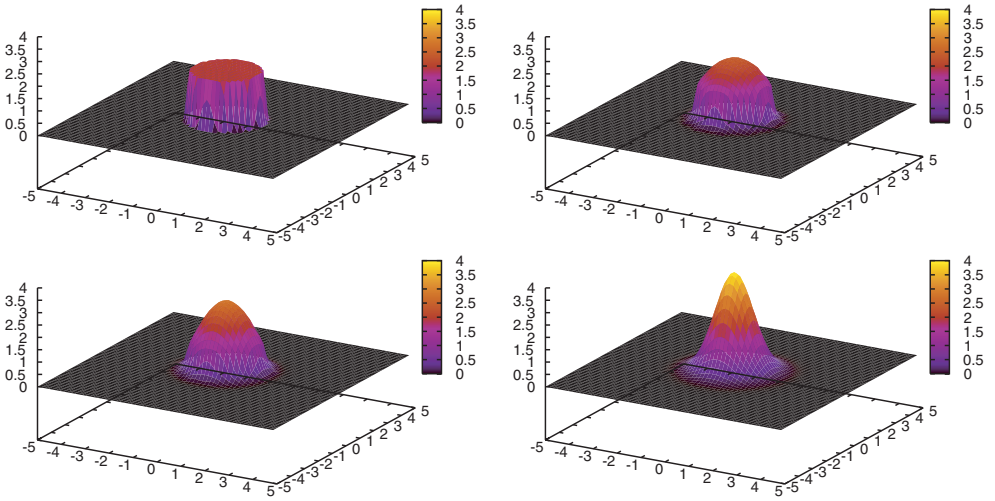

FIG. 7. *Time evolution of the distribution function for* 64×64 *grid points.*

Finally, let us mention that we have also performed some numerical tests when the initial datum approximates a Dirac distribution. The spectral method is still stable even if spurious oscillations are generated, but this problem is inherent to gridded methods and we refer to [23] for a rescaling method, which follows the variation of the distribution function and allows us to treat concentrated distributions.

6. Application to the nonhomogeneous case. In [20, 22], we performed several numerical simulations to compare the spectral scheme with Monte Carlo methods and showed that when we are interested in the transient regime, the deterministic method becomes very efficient. Obviously, the fast spectral method will still improve the computational cost.

In what follows, since we will be interested in the study of the trend to a global equilibrium state of the kinetic equation, we avoid the use of a splitting method by solving the whole nonhomogeneous equation in time by a second-order Runge–Kutta method. Clearly the spectral methods apply straightforwardly to the collision operator also in this situation. The transport part is treated by the positive flux conservative method (see [18, 21, 20] for further details).

6.1. Definition of the problem. We consider the full Boltzmann equation in dimension $d = 2$ on the torus

$$\frac{\partial f}{\partial t} + v \cdot \nabla_x f = Q(f, f), \qquad x \in [0, L]^2, \quad v \in \mathbb{R}^2,$$

with periodic boundary conditions in x. We first introduce the hydrodynamical fields associated with a kinetic distribution $f(t, x, v)$. These are the $(d + 2)$ scalar fields of density ρ (scalar), mean velocity u (vector valued), and temperature T (scalar) defined by the formulas (2.7). Whenever $f(t, x, v)$ is a smooth solution to the Boltzmann equation with periodic boundary conditions, one has the global conservation laws for

mass, momentum, and energy

$$\frac{d}{dt}\int_{[0,L]^2\times\mathbb{R}^2} f(t,x,v)\,dx\,dv = 0,$$
$$\frac{d}{dt}\int_{[0,L]^2\times\mathbb{R}^2} f(t,x,v)\,v\,dx\,dv = 0,$$
$$\frac{d}{dt}\int_{[0,L]^2\times\mathbb{R}^2} f(t,x,v)\,\frac{|v|^2}{2}\,dx\,dv = 0.$$

Therefore, without loss of generality we shall impose

$$\int_{[0,L]^2\times\mathbb{R}^2} f(t,x,v)\,dx\,dv = 1, \quad \int_{[0,L]^2\times\mathbb{R}^2} f(t,x,v)\,v\,dx\,dv = 0,$$

and

$$\int_{[0,L]^2\times\mathbb{R}^2} f(t,x,v)\,\frac{|v|^2}{2}\,dx\,dv = 1.$$

These conservation laws are then enough to uniquely determine the stationary state of the Boltzmann equation: the normalized global Maxwellian distribution

$$M_g(v) = \frac{1}{2\pi}\exp\left(-\frac{|v|^2}{2}\right). \tag{6.1}$$

We shall use the following terminology: a velocity distribution of the form (6.1) will be called a [illegible], whereas a distribution of the form

$$M_l(x,v) = \frac{\rho(x)}{2\pi T(x)}\exp\left(-\frac{|v-u(x)|^2}{2T(x)}\right) \tag{6.2}$$

will be called a [illegible] (in the sense that the constants ρ, u, and T appearing there depend on the position x). We also define the notion of [illegible] H_l, the entropy relative to the local Maxwellian, and the [illegible] H_g, the entropy relative to the global Maxwellian distribution, respectively, by

$$H_l(t) = \int f\,\log\left(\frac{f}{M_l}\right)\,dx\,dv, \quad H_g(t) = \int f\,\log\left(\frac{f}{M_g}\right)\,dx\,dv.$$

Our goal here is to investigate numerically the long-time behavior of the solution f. If f is any reasonable solution of the Boltzmann equation, satisfying certain a priori bounds of compactness (in particular, ensuring that no kinetic energy is allowed to leak at large velocities), then it is possible to prove that f does indeed converge to the global Maxwellian distribution M_g as t goes to $+\infty$. Of course, obtaining these a priori bounds is extremely difficult; as a matter of fact, they have been established only in the spatially homogeneous situation (which means that the distribution function does not depend on the position variable x; see the survey in [49]) or in a close-to-equilibrium setting (see in particular [25] for the torus), and it still constitutes a famous open problem for spatially inhomogeneous initial data far from equilibrium. More recently, Desvillettes and Villani [16] and Strain and Guo [47] were interested in the study of rates of convergence for the full Boltzmann equation. Roughly speaking,

in [16] it was proved that if the solution to the Boltzmann equation is smooth enough and satisfies bounds from below of the form

$$\forall\, t \geq 0,\ x \in [0, L]^2,\ v \in \mathbb{R}^2, \quad f(t, x, v) \geq K_0\, e^{-A_0\, |v|^{q_0}} \quad (A_0, K_0 > 0,\ q_0 \geq 2),$$

(although this bound can be shown to be a consequence of the regularity bounds; see [31]), then (with constructive bounds)

$$\|f(t) - M_g\| = O(t^{-\infty}),$$

which means that the solution converges almost exponentially fast to the global equilibrium (namely, with polynomial rate $O(t^{-r})$ with r as large as desired).

The solution f to the Boltzmann equation satisfies the formula of additivity of the entropy: the entropy can be decomposed into the sum of a purely hydrodynamic part and (by contrast) of a purely kinetic part. In terms of the H functional, one can write

$$H_g(t) = H_l(t) + \int_0^L \rho_l(t, x)\, \log\left(\frac{\rho_l(t, x)}{T_l(t, x)}\right) dx.$$

In fact, we can also show that

$$H_l(t) \leq H_g(t) \quad \forall t \geq 0.$$

Moreover, the Csiszár–Kullback–Pinsker inequality asserts that (when the total mass of the solution is normalized to 1)

$$H(f|M) \geq \frac{1}{2}\|f - M\|_{L^1}^2.$$

In other words, controlling the speed of convergence of the entropy to its equilibrium value is enough to control the speed of convergence of the solution to its equilibrium in a very strong sense.

Moreover, in [16] Desvillettes and Villani conjectured that time oscillations should occur on the evolution of the relative local entropy. In fact their proof does not rule out the possibility that the entropy production undergoes important oscillations in time, and actually most of the technical work is caused by this possibility.

6.2. Description and interpretation of the results. Here we performed simulations on the full Boltzmann equation in a simplified geometry (one dimension of space, two dimensions of velocity, periodic boundary conditions, fixed Knudsen number) with the fast spectral method to observe the evolution of the entropy and to check numerically if such oscillations occur. Clearly this test is challenging for a numerical method due to the high accuracy required to capture such oscillating behavior.

Then we considered an initial datum as a perturbation of the global equilibrium M_g

$$f_0(x, v) = \frac{1}{2\pi}\,(1 + A_0\, \cos(k_0\, x))\, \exp(-|v|^2/2), \qquad x \in [0, L], \quad v \in \mathbb{R}^2, \tag{6.3}$$

for some constants $A_0 > 0$ and $k_0 = 2\pi/L$.

In Figures 8 and 9, we are indeed able to observe oscillations in the entropy production and in the hydrodynamic entropy. The strength of the oscillations depends a lot on the length L of the domain, which is consistent with the fact that

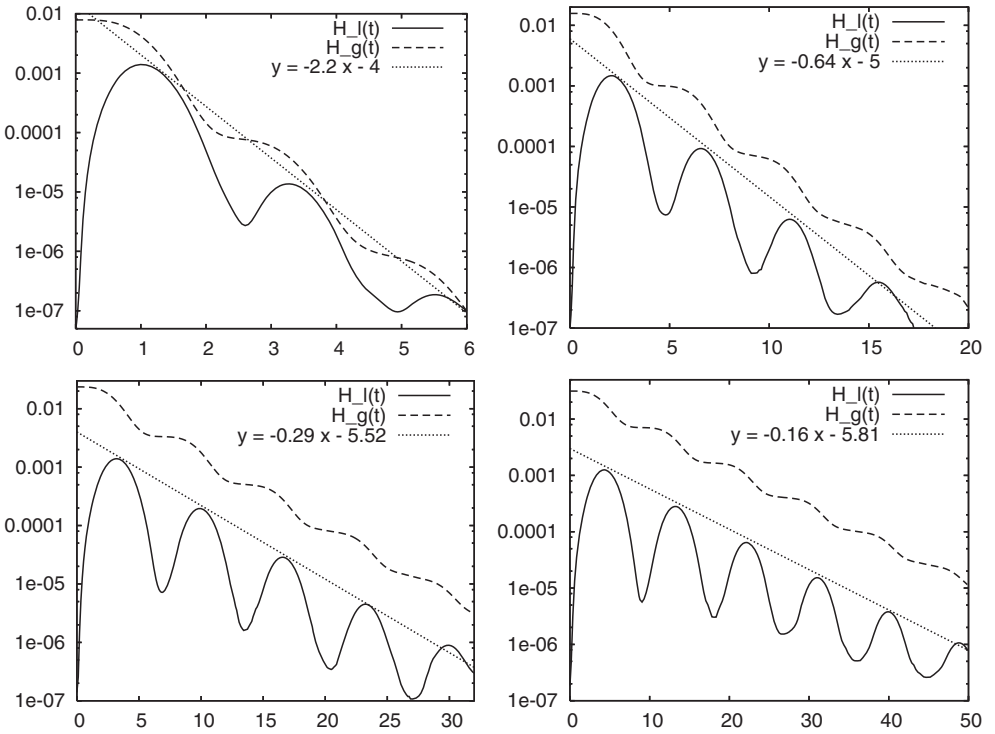

FIG. 8. *Influence of the length box: relative entropy with respect to the local Maxwellian* $H_l(t)$ *using* $64 \times 64 \times 64$ *for* $L = \pi$, 2π, 3π, *and* 4π *with* $A_0 = 0.1$ *in* (6.3).

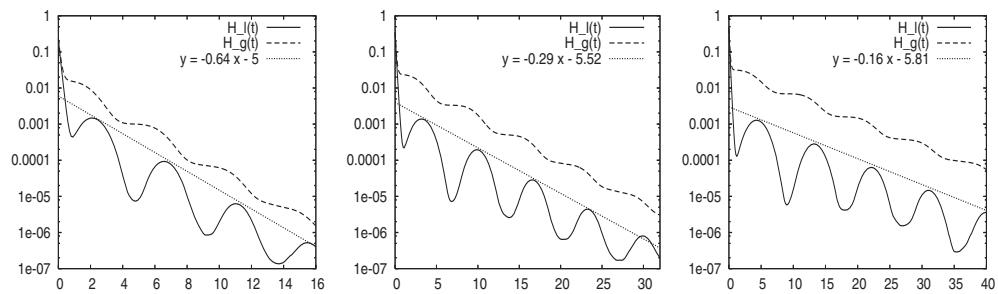

FIG. 9. *Influence of the length box: relative entropy with respect to the local Maxwellian* $H_l(t)$ *using* $64 \times 64 \times 64$ *for* $L = 2\pi$, 3π, *and* 4π *with* $A_0 = 0.1$ *in* (6.4).

such oscillations are never observed in the spatially homogeneous case ($L = 0$). The superimposed curves yield the time evolution of the total H functional and of its kinetic part, respectively. In all cases, a local Maxwellian distribution is chosen for the initial datum; the first plot corresponds to $L = 1$ and the second one to $L = 4$. Some slight oscillations can be seen in the case $L = 1$, but what is most striking is that after a short while, the kinetic entropy is very close to the total entropy, which is an indication that the solution evolves basically in a spatially homogeneous way (contrary to the intuition of the hydrodynamic regime). On the contrary, in the case $L = 4$, the oscillations are much more important in frequency and amplitude (note that this is a logarithmic plot): the solution "hesitates" between states in which it

TABLE 4
Influence of the length box: damping rate and oscillation frequency for the relative entropy with respect to the local Maxwellian $H_l(t)$ using $64 \times 64 \times 64$ with $A_0 = 0.1$ in (6.3).

Length box	Oscillation frequency ω	ω/L	Damping rate α	$-\alpha L^2$
$L = \pi/2$	01.10	0.701	-6.521	16.04
$L = \pi$	02.25	0.716	-2.202	21.71
$L = 2\pi$	04.50	0.716	-0.641	25.26
$L = 3\pi$	06.61	0.701	-0.285	25.31
$L = 4\pi$	08.78	0.699	-0.160	25.27
$L = 8\pi$	17.57	0.699	-0.040	25.35

is very close to hydrodynamic and states in which it is not at all. Further note that the equilibration is much more rapid when the box is small and that the convergence seems to be exponential.

It is in fact possible to give a simple interpretation of these oscillations thanks to the work [17]. Since this effect is observed near the global equilibrium one can replace the Boltzmann collision operator with the linearized Boltzmann collision operator (moreover, oscillation is effectively observed for the linearized Boltzmann collision operator as well). Then it is straightforward that the computations above correspond to observing the time evolution of one Fourier mode in x (here with frequency k_0 and amplitude A_0). Hence by an obvious rescaling, this evolution is given by the semigroup $\tilde{T}_{k_0/L}(t)$, where $\tilde{T}_k(t)$ is defined in [17] (this is the semigroup for the $\cdot$th Fourier mode in x for the linearized equation). An asymptotic study of the spectrum of its infinitesimal generator for small frequencies k was done in [17]. The dominant term in terms of long-time behavior (i.e., the one with the lower rate of decrease) is given by the $(d+2)$ "hydrodynamical eigenvalues." Moreover, explicit computations are available for the expansions of these eigenvalues according to $\varepsilon = |k|$ near $k = 0$.

At first order in ε, the eigenvalues vanish, except for two of them, which are purely imaginary. They are given by

$$\begin{cases} I_1 = i\,\varepsilon\,\sqrt{1+2/d} + O(\varepsilon^2), \\ I_2 = -i\,\varepsilon\,\sqrt{1+2/d} + O(\varepsilon^2), \\ I_3 = \cdots = I_{d+2} = 0. \end{cases}$$

Therefore for $|k_0|/L << 1$ (realized, for instance, when k_0 is fixed and L is large enough), this analysis gives us the dominant imaginary term in the eigenvalues. In this regime, one should thus observe oscillations with frequency $\sqrt{1+2/d}\,|k_0|/L$. Thus, the period of oscillations should be given by $2\pi(1+2/d)^{-1/2}\,L/|k_0|$, which can be checked with the numerical simulations. Indeed, in Table 4 we give the ratio of the period of oscillations ω with the length box L. The numerical results agree well with the analytical computations $\omega/L \simeq 1/\sqrt{2}$.

We also observe that the damping rate is related to the length box and is proportional to $1/L^2$ when L becomes large (see Table 4; $\alpha\,L^2 \simeq$ constant). This is coherent with the fact that no real value occurs in the hydrodynamical eigenvalues until the second order in $\varepsilon = |k|$. The coefficients for the order 2 in the expansion are computed in [17]; they are purely real and can be expressed simply in terms of the dimension d, the viscosity coefficient η, and the heat conductivity λ of the gas (indeed, these coefficients are related to the Navier–Stokes limit of the Boltzmann

equation). Namely, they are given by

$$\begin{cases} R_1 = R_2 = -\dfrac{\lambda}{d+2} - \dfrac{\eta}{2}, \\ R_3 = \cdots = R_{d+1} = -\dfrac{\eta\, d}{2(d-1)}, \\ R_{d+2} = -\dfrac{\lambda\, d}{d+2}. \end{cases}$$

Therefore for $|k_0|/L << 1$, the damping rate is given by the minimum among these values.

To conclude these tests, we performed a final numerical experiment to evaluate the robustness of the theory of the trend to equilibrium. We have chosen an initial datum which is far from the equilibrium

(6.4)
$$f_0(x,v) = \frac{1}{2\pi v_{th}^2}\,(1 + A_0\,\cos(k_0\,x))\,\left[\exp\left(-\frac{|v-v_0|^2}{2v_{th}^2}\right) + \exp\left(-\frac{|v+v_0|^2}{2v_{th}^2}\right)\right],$$

with $v_0 = (1/2, 1/2)$ and $v_{th} = \sqrt{3}/2$. We present the time evolution of the relative entropies H_l and H_g in log scale and observe that initially the entropy is strongly decreasing, and when the distribution function becomes close to a local equilibrium, some oscillations appear with the good frequency $\omega/L = 1/\sqrt{2}$ and damping rate α (see Figure 9).

1. Now numerical methods for the Boltzmann equation, such as the one presented in this paper, become able to provide very accurate simulations of the transient regime towards equilibrium with reasonable cost, even in the inhomogeneous case. This could be used to explore the spectrum of the linearized Boltzmann collision operator (in the homogeneous case), or, more interestingly, the spectrum of the linearized Boltzmann collision operator together with the transport term in the inhomogeneous case. For instance, the exponential rate of convergence is directly readable on the figures above and provides a numerical estimation of the (that is, the real part of the first nonzero eigenvalue) of this operator (it has been known since Ukai [48] that this operator has a spectral gap in the torus; see also [13]). Moreover, by a frequency analysis of the curve of the time evolution of the relative entropy or the L^1 distance to the equilibrium, it could be possible also to describe other eigenvalues; as long as they have a different imaginary part, it should be possible (in principle) to extract from the frequency analysis the curve corresponding to their contribution in the evolution semigroup, and then to compute their real part which corresponds to the exponential rate of decay of this curve.

2. A recent work [27] gave a detailed pointwise study of the Green function for the linearized Boltzmann equation in the domain $x \in \Omega = \mathbb{R}$. This particular study shows that the long-time behavior is governed by "fluid-like waves" (corresponding to the waves of the linearized Euler and Navier–Stokes equations) whose amplitude decreases polynomially, whereas the amplitude of the "kinetic part" of the Green function decreases exponentially. We think it is likely that this study could be extended to the torus, where the amplitude of both the fluid and the kinetic parts of the Green function should decrease exponentially. Moreover, the rate of decay of the kinetic part should not depend on the size of the box, whereas the rate of decay of the

fluid part should. Hence for a box small enough, the long-time behavior should be governed by the kinetic part of the Green function (that is, like the spatially homogeneous Boltzmann equation), whereas for a box big enough, the long-time behavior should be governed by the fluid-like waves. This is precisely what we observe numerically, and thus this theoretical study could provide a rigorous proof of the numerical observations above, at least in the linearized regime.

7. Conclusions. In this paper we have introduced and deeply tested a class of new fast algorithms for the computation of the Boltzmann collision operator. These methods allow us to reduce the computational cost from $O(n^2)$ to $O(n \log_2 n)$. We give computational evidence of the great performance of the schemes which can provide a dramatic speed-up in computing time of deterministic schemes by making them competitive with Monte Carlo methods, where higher accuracy is required. A first numerical application to a nontrivial problem in the space nonhomogeneous case confirms the strong computing potential of the new schemes.

Other methods such as singular value decomposition, fast multipole methods [9], separated representations in high-dimensional problems (see, for instance, [1]), wavelets, etc. could have been used to search for a decomposition of the form (4.1). However, to our knowledge it is not known at present how to obtain the properties described above for our decomposition with these methods.

Acknowledgment. We would like to thank Cédric Villani for suggesting the numerical study of possible oscillations in the relaxation to equilibrium.

AN ALTERNATING-DIRECTION IMPLICIT ORTHOGONAL SPLINE COLLOCATION SCHEME FOR NONLINEAR PARABOLIC PROBLEMS ON RECTANGULAR POLYGONS*

BERNARD BIALECKI† AND RYAN I. FERNANDES‡

Abstract. We consider a nonlinear parabolic initial-boundary value problem on a rectangular polygon with the solution satisfying Robin boundary conditions with variable coefficients. An approximation to the solution at the desired time value is obtained using an alternating-direction implicit extrapolated Crank–Nicolson scheme in which orthogonal spline collocation with piecewise polynomials of an arbitrary degree is used for spatial discretization. At each time level, the scheme determines the intermediate solution along horizontal lines and the approximate solution along vertical lines passing through the Gauss points. Only at the last time level is the approximate solution along vertical lines converted into the approximate solution defined on the entire rectangular polygon. This property of our approach leads to its efficient implementation and its applicability to rectangular polygons.

Key words. parabolic problems, alternating-direction implicit, extrapolation, orthogonal spline collocation, Gauss points, interpolants, implementation

1. Introduction.

We assume that Ω is a rectangular polygon, that is, a polygon whose sides are parallel to the x- and y-coordinate axes, and consider the numerical solution of the nonlinear parabolic initial-boundary value problem consisting of the differential equation

$$u_t + (L_1 + L_2)u = f(x, y, t, u, u_x, u_y), \qquad (x, y, t) \in \Omega \times [0, d], \tag{1.1}$$

the initial condition

$$u(x, y, 0) = g_0(x, y), \qquad (x, y) \in \overline{\Omega}, \tag{1.2}$$

and Robin boundary conditions on $\partial\Omega$. The differential operators L_1 and L_2 in (1.1) are given by

$$L_1 u = -p_1(x, y, t, u, u_x, u_y)u_{xx}, \qquad L_2 u = -p_2(x, y, t, u, u_x, u_y)u_{yy}, \tag{1.3}$$

where p_1, p_2 are assumed to be continuous functions for which there exist positive constants p_* and p^* so that

$$p_* \le p_i(x, y, t, v, w, z) \le p^*, \quad i = 1, 2, \quad (x, y) \in \Omega, \quad t \in (0, d], \quad v, w, z \in R.$$

In order to demonstrate numerically the expected convergence rates, we also assume that the solution u is sufficiently smooth. Although the paper is primarily concerned

with the development of a scheme for (1.1), we also discuss a simple extension of the scheme to the equation

$$\begin{aligned} &u_t + (L_1 + L_2)u - p(x,t,u,u_x,u_y)u_{xy} \\ &= f(x,y,t,u,u_x,u_y), \qquad (x,y,t) \in \Omega \times [0,d]. \end{aligned} \tag{1.4}$$

On page 11 of [24], (1.4) is called the quasi-linear equation of general form, while

$$\begin{aligned} &u_t - (q_1(x,y,t,u,u_x,u_y))_x - (q_2(x,y,t,u,u_x,u_y))_y \\ &= f(x,y,t,u,u_x,u_y), \qquad (x,y,t) \in \Omega \times [0,d], \end{aligned} \tag{1.5}$$

is called the quasi-linear equation with principal part in divergence form; see also section 30.4 of [28]. Assuming that q_1 and q_2 of (1.5) are continuously differentiable, we have (see the corresponding formula on page 3 of [24])

$$\begin{aligned} &(q_1(x,y,t,u,u_x,u_y))_x = (q_1)_x(x,y,t,u,u_x,u_y) + (q_1)_u(x,y,t,u,u_x,u_y)u_x \\ &+ (q_1)_{u_x}(x,y,t,u,u_x,u_y)u_{xx} + (q_1)_{u_y}(x,y,t,u,u_x,u_y)u_{xy}. \end{aligned} \tag{1.6}$$

Hence an equation of the form (1.5) can be transformed into an equation of the form (1.4). In the special case when

$$q_1(x,y,t,u,u_x,u_y) = p_1(x,y,t,u)u_x, \quad q_2(x,y,t,u,u_x,u_y) = p_2(x,y,t,u)u_y, \tag{1.7}$$

where p_1 and p_2 are continuously differentiable, (1.5) is transformed into an equation of the form (1.1). It is stated on page 417 of [24] that "all of the widely known equations of mechanics of parabolic type belong to the class (1.5)." Other applications of (1.5) can be found in magnetic fields, heat conduction processes, fluid mechanics, nuclear physics (see page 236 of [29]), and combustion theory (see page 438 of [22]). We consider equations of the form (1.4) since they are more natural for collocation spatial discretization than equations of the form (1.5). Of course, equations of the form (1.5) are more suitable for the finite element Galerkin (FEG) spatial discretization.

The first alternating-direction implicit (ADI) method was introduced in [25] for the finite difference (FD) spatial discretization of a simple linear parabolic problem on a rectangle. The development of ADI methods at that time (see [26]) was motivated by the need to solve multidimensional problems efficiently by reducing them to a collection of one-dimensional problems, each of which can be solved with an optimal cost proportional to the number of unknowns. Several first and second order in time ADI FEG schemes for linear and nonlinear parabolic problems on rectangles were introduced in [17]. The FEG schemes of [17] have direct ADI factorizations only in the case of a linear and separable parabolic operator. For general nonlinear parabolic problems, the ADI FEG methods of [17] are obtained from Laplace modified schemes which include additional truncation error terms and hence, in general, may be less accurate. Moreover, the ADI FEG schemes of [17] require stability parameters whose optimal selections for nonlinear parabolic problems in particular may not be easy. For nonlinear parabolic problems, the first and second order in time ADI schemes of [17] were extended in [12] to certain rectangular polygons. In some cases, implementations of the schemes in [12] were based on the ideas of [18] involving disintegrating difference operators. A generalization of the ADI FEG methods of [17] was carried out in [20] to general curved regions which can be mapped isoparametrically onto a rectangle or certain rectangular polygons. The first order in time ADI methods of [20] were based on the knowledge of the isoparametric mapping and approximation of its Jacobian. In [6], extrapolated backward differentiation formulas of orders 1, 2, and 3 for time

approximation and the FEG spatial discretization were used for nonlinear parabolic problems on rectangles. Since there are no direct ADI factorizations of the proposed perturbation schemes in [6], matrices from ADI schemes with constant coefficients were used as preconditioners at each time level.

In this paper, we use a two level ADI extrapolated Crank–Nicolson scheme for the second order discretization in time and orthogonal spline collocation (OSC) with piecewise polynomials of an arbitrary degree for spatial discretization to solve nonlinear parabolic problems on rectangular polygons. The present paper extends our previous work [4, 5] on ADI OSC schemes for linear parabolic problems on rectangles. For elliptic problems, OSC is based on replacing the exact solution by its piecewise polynomial approximation and on satisfying the partial differential equation at the Gauss points (see, e.g., [2] and references therein). There are several reasons for using OSC in place of FEG or FD for spatial discretization. First, since the idea behind ADI methods is to reduce the solution of a multidimensional problem to the solution of a collection of one-dimensional problems, it is natural to use a spatial discretization which is most efficient for solving one-dimensional problems. As it was shown in the computational study [21] of five finite element methods for the solution of second order, linear, two-point boundary value problems, OSC is the cheapest method for given accuracy and the easiest to implement. Second, in comparison to the FEG schemes in [17] and [6], which have direct ADI factorizations only for linear separable parabolic operators, our OSC scheme has a direct ADI factorization for nonlinear equation (1.1) and hence it does not require a stability parameter or preconditioning. While the FD scheme of [11] also has a direct ADI factorization for (1.1), it is only second order accurate in space and provides only approximations at discrete points of $\overline{\Omega}$. In comparison, our OSC scheme is of arbitrary order in space and yields an approximate solution defined on $\overline{\Omega}$. Third, in comparison to ADI FEG and ADI FD schemes, our ADI OSC scheme is easily applicable to arbitrary rectangular polygons.

Our ADI OSC scheme is most efficient for an equation of the form (1.1). In this case, at each time level, the scheme determines a piecewise polynomial intermediate solution along horizontal lines and a piecewise polynomial approximate solution along vertical lines passing through the Gauss points. Only at the last time level is the approximate solution along vertical lines converted into the approximate solution defined on $\overline{\Omega}$. It is this property of our approach that leads to its efficient implementation and its applicability to rectangular polygons. For an equation of the form (1.4), a modification of our scheme requires the computation, at each time level, of an extrapolated approximation of the mixed derivative. This, in turn, involves converting a function defined along vertical lines passing through the Gauss points into a function defined on $\overline{\Omega}$. If p_1 or p_2 of (1.7) were discontinuous along horizontal or vertical lines in Ω, then, as in the case of FD discretization, the corresponding interface conditions along these lines involving the solution and its flux would have to be incorporated into the definition of our OSC scheme.

If Ω is an arbitrary region, (1.5) can be solved using the extrapolated Crank–Nicolson FEG scheme; cf. (13.21) of [27]. At each time level, a linear elliptic FEG problem is usually solved by preconditioned iterative methods, with domain decomposition or multigrid preconditioners gaining in popularity in recent years. Of course, the smaller the number of iterations at each time level, the smaller the total cost of the scheme is. If Ω is a rectangle, the approach of [6] is based on a similar idea with the matrices from ADI schemes with constant coefficients being used as preconditioners at each time level. At each time level, the number of iterations in [6] is proportional to the logarithm of the number of all time levels. In comparison, our

ADI OSC scheme, applicable to a rectangular polygon Ω and equations of the form (1.1) or (1.4), does not involve iterations at any time level and, consequently, has the optimal cost proportional to the total number of unknowns.

The ADI FD and ADI FEG methods were developed and analyzed extensively in the 1960s, '70s, and '80s. However, even in recent years these methods have been used to solve specific problems [7, 8] or to derive more accurate schemes [23]. The general purpose of our paper is to draw attention to the fact that the ADI OSC methods offer some advantages over ADI FD and ADI FEG schemes in the solution of nonlinear parabolic problems.

A brief outline of the paper is as follows. Section 2 embodies the heart of the paper. While the purpose of this paper is to develop the ADI OSC scheme for any rectangular polygon, in the interest of giving a simple presentation of the scheme and its implementation, in section 2.1 we first formulate the ADI OSC scheme for a rectangle and then comment on its comparison with other schemes in [1, 4, 5, 11] and show how to extend it to solve (1.4). In section 2.2, we present an efficient implementation and give the computational cost of the scheme. Section 3 demonstrates how the ADI OSC scheme can be applied to an L-shaped region. Comparison of our scheme with other ADI FD and ADI FEG schemes on a rectangular polygon is discussed in section 4. Finally, section 5 contains numerical results obtained using our ADI OSC scheme.

2. The ADI OSC scheme for a rectangle. Assume that $\Omega = (a_1, b_1)\times(a_2, b_2)$ and consider the nonlinear parabolic initial-boundary value problem consisting of the differential equation (1.1), (1.3), the initial condition (1.2), Robin boundary conditions on the horizontal sides,

$$\begin{aligned} &\alpha_1(x,t)u(x,a_2,t) - \beta_1(x,t)u_y(x,a_2,t) = g_1(x,t),\\ &\alpha_2(x,t)u(x,b_2,t) + \beta_2(x,t)u_y(x,b_2,t) = g_2(x,t), \end{aligned} \qquad t \in (0,d], \tag{2.1}$$

where $x \in [a_1, b_1]$, and Robin boundary conditions on the vertical sides,

$$\begin{aligned} &\alpha_3(y,t)u(a_1,y,t) - \beta_3(y,t)u_x(a_1,y,t) = g_3(y,t),\\ &\alpha_4(y,t)u(b_1,y,t) + \beta_4(y,t)u_x(b_1,y,t) = g_4(y,t), \end{aligned} \qquad t \in (0,d], \tag{2.2}$$

where $y \in [a_2, b_2]$. The functions α_i and β_i, $i = 1, 2, 3, 4$, in (2.1) and (2.2) are assumed to be nonnegative and not simultaneously equal to zero.

2.1. The scheme. Let $\{x_k\}_{k=0}^{N_x}$ and $\{y_l\}_{l=0}^{N_y}$ be partitions (in general nonuniform) of $[a_1, b_1]$ and $[a_2, b_2]$, respectively, such that

$$a_1 = x_0 < x_1 < \cdots < x_{N_x-1} < x_{N_x} = b_1, \quad a_2 = y_0 < y_1 < \cdots < y_{N_y-1} < y_{N_y} = b_2.$$

Let r be an integer ≥ 3, and let $\mathcal{M}_x$ and $\mathcal{M}_y$ be spaces of piecewise polynomials defined by

$$\mathcal{M}_x = \{v \in C^1[a_1, b_1] : v|_{[x_{k-1},x_k]} \in P_r, k = 1, \ldots, N_x\},$$
$$\mathcal{M}_y = \{v \in C^1[a_2, b_2] : v|_{[y_{l-1},y_l]} \in P_r, l = 1, \ldots, N_y\},$$

where P_r denotes the set of polynomials of degree $\leq r$. The dimensions of $\mathcal{M}_x$ and $\mathcal{M}_y$ are $M_x = N_x(r-1)+2$ and $M_y = N_y(r-1)+2$, respectively. Let $\mathcal{M}$ be the space of piecewise polynomials in x and y given by

$$\mathcal{M} = \mathcal{M}_x \otimes \mathcal{M}_y.$$

($\mathcal{M}$ is the set of all functions that are finite linear combinations of products $v^x(x)v^y(y)$, where $v^x \in \mathcal{M}_x$ and $v^y \in \mathcal{M}_y$.) Let $\{\sigma_j\}_{j=1}^{r-1}$ be the nodes of the $(r-1)$-point Gauss–Legendre quadrature on $[0,1]$, and let $\mathcal{G}_x = \{\xi_k^x\}_{k=1}^{M_x-2}$, $\mathcal{G}_y = \{\xi_l^y\}_{l=1}^{M_y-2}$ be the collocation points defined by

$$\xi^x_{(k-1)(r-1)+j} = x_{k-1} + h^x_k\sigma_j, \qquad k = 1,\dots,N_x, \qquad j = 1,\dots,r-1,$$
$$\xi^y_{(l-1)(r-1)+j} = y_{l-1} + h^y_k\sigma_j, \qquad l = 1,\dots,N_y, \qquad j = 1,\dots,r-1,$$

where $h^x_k = x_k - x_{k-1}$, $h^y_l = y_l - y_{l-1}$. Let

$$\mathcal{G} = \{(x,y) : x \in \mathcal{G}_x, y \in \mathcal{G}_y\}.$$

Let $\{t_n\}_{n=0}^{N_t}$ be a partition of $[0,d]$ such that $t_n = n\tau$, where $\tau = d/N_t$, and let $t_{n+1/2} = (t_n + t_{n+1})/2$, $n = 0,\dots,N_t-1$. For $i = 1,2$, and given functions v and w, let $L_i^m(v,w)$ be the differential operators defined by

$$L_1^m(v,w)u = -p_1(x,y,t_m,v,w_x,v_y)u_{xx}, \qquad L_2^m(v,w)u = -p_2(x,y,t_m,v,w_x,v_y)u_{yy}.$$

In the following, $\phi^m(\cdot) = \phi(\cdot,t_m)$, and $g^m_{1,h}, g^m_{2,h} \in \mathcal{M}_x$ and $g^m_{3,h}, g^m_{4,h} \in \mathcal{M}_y$ are Hermite or Gauss interpolants of g_1^m, g_2^m and g_3^m, g_4^m, respectively. For $v \in C^1[a_1,b_1]$ its Hermite interpolant $v_h \in \mathcal{M}_x$ is defined by (cf. definition of $T_{r,\delta}v$ on page 9 of [15])

$$v_h^{(j)}(x_k) = v^{(j)}(x_k), \qquad j = 0,1, \qquad k = 0,\dots,N_x,$$
$$v_h(x_{k-1} + h^x_k\eta_j) = v(x_{k-1} + h^x_k\eta_j), \qquad k = 1,\dots,N_x, \qquad j = 1,\dots,r-1,$$

where $0 < \eta_1 < \eta_2 < \cdots < \eta_{r-3} < 1$ are the simple roots of $[x^{r-1}(x-1)^{r-1}]^{(r-3)}$. For $v \in C[a_1,b_1]$ its Gauss interpolant $v_h \in \mathcal{M}_x$ is defined by (cf. definition of $S_{r,\delta}v$ on page 10 of [15])

$$v_h(x) = v(x), \qquad x \in \mathcal{G}_x \cup \{a_1,b_1\}.$$

Our ADI OSC scheme to compute $u_h \in \mathcal{M}$ approximating the solution $u(x,y,t)$ of (1.1)–(1.3), (2.1), and (2.2) at $t = d$ consists of the following three stages.

In the first stage, we set up some initial approximations to the exact solution u on vertical and horizontal lines in $\overline{\Omega}$ passing through the points of $\mathcal{G}$. Specifically, for each $x \in \mathcal{G}_x$, the function $u_h^0(x,\cdot) \in \mathcal{M}_y$ approximating $u(x,y,0)$, $y \in [a_2,b_2]$, is obtained by collocating the initial condition; that is, we require that

$$u_h^0(x,y) = g_0(x,y), \qquad y \in \mathcal{G}_y \cup \{a_2,b_2\}. \tag{2.3}$$

Similarly, for each $y \in \mathcal{G}_y$, the function $\hat{u}_h^0(\cdot,y) \in \mathcal{M}_x$ approximating $u(x,y,0)$, $x \in [a_1,b_1]$, is determined using the collocation equations

$$\hat{u}_h^0(x,y) = g_0(x,y), \qquad x \in \mathcal{G}_x \cup \{a_1,b_1\}. \tag{2.4}$$

The functions $u_h^0(x,\cdot) \in \mathcal{M}_y$, $x \in \mathcal{G}_x$, and $\hat{u}_h^0(\cdot,y) \in \mathcal{M}_x$, $y \in \mathcal{G}_y$, are well defined since it can be shown that any $v^y \in \mathcal{M}_y$ and any $v^x \in \mathcal{M}_x$ are uniquely determined by their values at $\mathcal{G}_y \cup \{a_2,b_2\}$ and $\mathcal{G}_x \cup \{a_1,b_1\}$, respectively.

In order to begin advancing the ADI OSC procedure in the t direction, we also require, second order accurate in t, initial approximations to $u(x,y,t_{1/2})$ on vertical

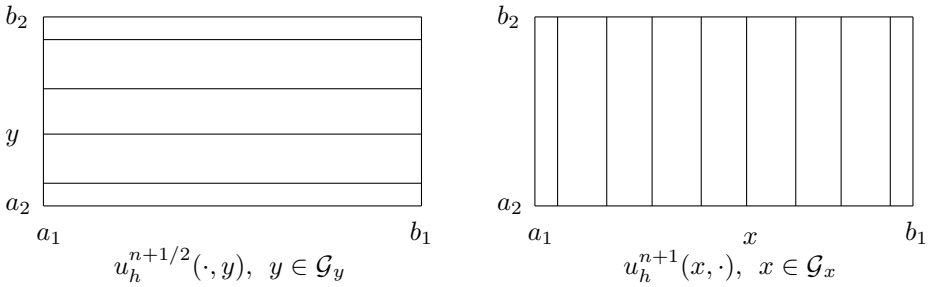

FIG. 2.1. *Rectangle.*

and horizontal lines in $\overline{\Omega}$ passing through the points of $\mathcal{G}$. Using Taylor's theorem, (1.1) with $t = 0$, (1.2), and (1.3), we have

$$u(x, y, t_{1/2}) = g_0(x, y) + \frac{\tau}{2}\left[f(x, y, 0, g_0(x, y), (g_0)_x(x, y), (g_0)_y(x, y)) - \sum_{i=1}^{2} L_i^0(g_0, g_0) g_0(x, y)\right] + O(\tau^2), \qquad (x, y) \in \Omega.$$

Replacing g_0, in the terms on the right-hand side enclosed in the brackets, with u_h^0 and $\hat{u}_h^0$, we introduce

$$g(x, y) = \frac{\tau}{2}\left[f(x, y, 0, u_h^0(x, y), (\hat{u}_h^0)_x(x, y), (u_h^0)_y(x, y)) - L_1^0(u_h^0, \hat{u}_h^0)\hat{u}_h^0(x, y) - L_2^0(u_h^0, \hat{u}_h^0)u_h^0(x, y)\right], \qquad (x, y) \in \mathcal{G}. \tag{2.5}$$

For each $x \in \mathcal{G}_x$, the function $\tilde{u}_h^{1/2}(x, \cdot) \in \mathcal{M}_y$ approximating $u(x, y, t_{1/2})$, $y \in [a_2, b_2]$, is determined using

$$\begin{aligned} &\tilde{u}_h^{1/2}(x, y) = g_0(x, y) + g(x, y), \quad y \in \mathcal{G}_y, \\ &\alpha_1^{1/2}(x)\tilde{u}_h^{1/2}(x, a_2) - \beta_1^{1/2}(x)(\tilde{u}_h^{1/2})_y(x, a_2) = g_1^{1/2}(x), \\ &\alpha_2^{1/2}(x)\tilde{u}_h^{1/2}(x, b_2) + \beta_2^{1/2}(x)(\tilde{u}_h^{1/2})_y(x, b_2) = g_2^{1/2}(x). \end{aligned} \tag{2.6}$$

In a similar manner, for each $y \in \mathcal{G}_y$, the function $\hat{u}_h^{1/2}(\cdot, y) \in \mathcal{M}_x$ approximating $u(x, y, t_{1/2})$, $x \in [a_1, b_1]$, is determined using

$$\begin{aligned} &\hat{u}_h^{1/2}(x, y) = g_0(x, y) + g(x, y), \quad x \in \mathcal{G}_x, \\ &\alpha_3^{1/2}(y)\hat{u}_h^{1/2}(a_1, y) - \beta_3^{1/2}(y)(\hat{u}_h^{1/2})_x(a_1, y) = g_3^{1/2}(y), \\ &\alpha_4^{1/2}(y)\hat{u}_h^{1/2}(b_1, y) + \beta_4^{1/2}(y)(\hat{u}_h^{1/2})_x(b_1, y) = g_4^{1/2}(y). \end{aligned} \tag{2.7}$$

In the second stage, we advance in the t direction. Corresponding to the time levels $t_{n+1/2}$ and t_{n+1}, we compute $u_h^{n+1/2}$ along horizontal lines and u_h^{n+1} along vertical lines, respectively, passing through the Gauss points (see Figure 2.1). Specifically, for $n = 0, \ldots, N_t - 1$ and $x \in \mathcal{G}_x$, we determine $u_h^{n+1}(x, \cdot) \in \mathcal{M}_y$ approximating

$u(x,y,t_{n+1})$, $y\in[a_2,b_2]$, using the scheme

$$\begin{aligned}&\left[\frac{u_h^{n+1/2}-u_h^n}{0.5\tau}+L_1^{n+1/2}(\tilde u_h^{n+1/2},\hat u_h^{n+1/2})u_h^{n+1/2}\right.\\&\qquad\left.+L_2^{n+1/2}(\tilde u_h^{n+1/2},\hat u_h^{n+1/2})u_h^n\right](x,y)\\&=f(x,y,t_{n+1/2},\tilde u_h^{n+1/2}(x,y),(\hat u_h^{n+1/2})_x(x,y),(\tilde u_h^{n+1/2})_y(x,y)),\quad (x,y)\in\mathcal{G},\end{aligned}\tag{2.8}$$

$$\begin{aligned}&\left[\frac{u_h^{n+1}-u_h^{n+1/2}}{0.5\tau}+L_1^{n+1/2}(\tilde u_h^{n+1/2},\hat u_h^{n+1/2})u_h^{n+1/2}\right.\\&\qquad\left.+L_2^{n+1/2}(\tilde u_h^{n+1/2},\hat u_h^{n+1/2})u_h^{n+1}\right](x,y)\\&=f(x,y,t_{n+1/2},\tilde u_h^{n+1/2}(x,y),(\hat u_h^{n+1/2})_x(x,y),(\tilde u_h^{n+1/2})_y(x,y)),\quad (x,y)\in\mathcal{G}.\end{aligned}\tag{2.9}$$

For $n=0$, $x\in\mathcal{G}_x$, and $y\in\mathcal{G}_y$, the functions $u_h^0(x,\cdot)$, $\tilde u_h^{1/2}(x,\cdot)\in\mathcal{M}_y$, and $\hat u_h^{1/2}(\cdot,y)\in\mathcal{M}_x$ are defined by (2.3), (2.6), and (2.7), respectively, and for $n=1,\dots,N_t-1$, $x\in\mathcal{G}_x$, and $y\in\mathcal{G}_y$, the functions $\tilde u_h^{n+1/2}(x,\cdot)\in\mathcal{M}_y$ and $\hat u_h^{n+1/2}(\cdot,y)\in\mathcal{M}_x$ are given by

$$\begin{aligned}&\tilde u_h^{n+1/2}(x,\cdot)=(3/2)u_h^n(x,\cdot)-(1/2)u_h^{n-1}(x,\cdot),\qquad n=1,\dots,N_t-1,\\&\hat u_h^{3/2}(\cdot,y)=3u_h^{1/2}(\cdot,y)-2\hat u_h^0(\cdot,y),\\&\hat u_h^{n+1/2}(\cdot,y)=2u_h^{n-1/2}(\cdot,y)-u_h^{n-3/2}(\cdot,y),\qquad n=2,\dots,N_t-1,\end{aligned}\tag{2.10}$$

where $\hat u_h^0(\cdot,y)\in\mathcal{M}_x$, $y\in\mathcal{G}_y$, is defined by (2.4). For each $y\in\mathcal{G}_y$, the function $u_h^{n+1/2}(\cdot,y)\in\mathcal{M}_x$ is determined using (2.8) and the boundary conditions

$$\begin{aligned}&\alpha_3^{n+1/2}(y)u_h^{n+1/2}(a_1,y)-\beta_3^{n+1/2}(y)(u_h^{n+1/2})_x(a_1,y)\\&=(1/2)(g_{3,h}^{n+1}+g_{3,h}^n)(y)+(\tau/4)L_2^{n+1/2}(\overline{u}_h^{n+1/2},\hat u_h^{n+1/2})(g_{3,h}^{n+1}-g_{3,h}^n)(a_1,y),\\&\alpha_4^{n+1/2}(y)u_h^{n+1/2}(b_1,y)+\beta_4^{n+1/2}(y)(u_h^{n+1/2})_x(b_1,y)\\&=(1/2)(g_{4,h}^{n+1}+g_{4,h}^n)(y)+(\tau/4)L_2^{n+1/2}(\overline{u}_h^{n+1/2},\hat u_h^{n+1/2})(g_{4,h}^{n+1}-g_{4,h}^n)(b_1,y),\end{aligned}\tag{2.11}$$

where for $\gamma=a_1,b_1$, the function $\overline{u}_h^{n+1/2}(\gamma,\cdot)\in\mathcal{M}_y$ is defined by

$$\begin{aligned}&\overline{u}_h^{n+1/2}(\gamma,y)=\hat u_h^{n+1/2}(\gamma,y),\qquad y\in\mathcal{G}_y,\\&\alpha_1^{n+1/2}(\gamma)\overline{u}_h^{n+1/2}(\gamma,a_2)-\beta_1^{n+1/2}(\gamma)(\overline{u}_h^{n+1/2})_y(\gamma,a_2)=g_1^{n+1/2}(\gamma),\\&\alpha_2^{n+1/2}(\gamma)\overline{u}_h^{n+1/2}(\gamma,b_2)+\beta_2^{n+1/2}(\gamma)(\overline{u}_h^{n+1/2})_y(\gamma,b_2)=g_2^{n+1/2}(\gamma).\end{aligned}\tag{2.12}$$

For each $x\in\mathcal{G}_x$, the function $u_h^{n+1}(x,\cdot)\in\mathcal{M}_y$ is determined using (2.9) and the boundary conditions

$$\begin{aligned}&\alpha_1^{n+1}(x)u_h^{n+1}(x,a_2)-\beta_1^{n+1}(x)(u_h^{n+1})_y(x,a_2)=g_{1,h}^{n+1}(x),\\&\alpha_2^{n+1}(x)u_h^{n+1}(x,b_2)+\beta_2^{n+1}(x)(u_h^{n+1})_y(x,b_2)=g_{2,h}^{n+1}(x).\end{aligned}\tag{2.13}$$

Since for $x \in \mathcal{G}_x$ and $y \in \mathcal{G}_y$, the functions $u_h^n(x,\cdot) \in \mathcal{M}_y$ and $u_h^{n-1/2}(\cdot,y) \in \mathcal{M}_x$ are expected to be second order accurate approximations in t to $u(x,y,t_n)$, $y \in [a_2,b_2]$, and $u(x,y,t_{n-1/2})$, $x \in [a_1,b_1]$, respectively, the extrapolation formulas of (2.10) are obtained from the Taylor expansions

$$u^{n+1/2}(x,y) = (3/2)u^n(x,y) - (1/2)u^{n-1}(x,y) + O(\tau^2),$$
$$u^{3/2}(x,y) = 3u^{1/2}(x,y) - 2u^0(x,y) + O(\tau^2),$$
$$u^{n+1/2}(x,y) = 2u^{n-1/2}(x,y) - u^{n-3/2}(x,y) + O(\tau^2).$$

In the third stage, we convert the computed functions $u_h^{N_t}(x,\cdot) \in \mathcal{M}_y$, $x \in \mathcal{G}_x$, into a piecewise polynomial defined on $\overline{\Omega}$. Specifically, the function $u_h \in \mathcal{M}$, approximating $u(x,y,d)$ for $(x,y) \in \overline{\Omega}$, is obtained from the conditions

$$u_h(x,y) = u_h^{N_t}(x,y), \qquad x \in \mathcal{G}_x, \qquad y \in [a_2,b_2], \tag{2.14}$$

and

$$\begin{aligned} &\alpha_3^{N_t}(y)u_h(a_1,y) - \beta_3^{N_t}(y)(u_h)_x(a_1,y) = g_{3,h}^{N_t}(y), \\ &\alpha_4^{N_t}(y)u_h(b_1,y) + \beta_4^{N_t}(y)(u_h)_x(b_1,y) = g_{4,h}^{N_t}(y), \end{aligned} \qquad y \in \mathcal{G}_y \cup \{a_2,b_2\}. \tag{2.15}$$

We now give several remarks concerning the scheme (2.8)–(2.9).

2.1. For nonlinear parabolic problems the scheme (2.8)–(2.9) is similar to the corresponding ADI FD scheme of [11].

2.2. It is possible to obtain the initial functions $u_h^0(x,\cdot) \in \mathcal{M}_y$ and $\hat{u}_h^0(\cdot,y) \in \mathcal{M}_x$ (see (2.3) and (2.4)) using Hermite interpolation rather than collocation.

2.3. For a linear parabolic problem, that is, a problem in which the given functions f and p_1, p_2 of (1.1) and (1.3) depend only on x, y, t, the scheme (2.8)–(2.9) coincides with the scheme (3.1) of [5]. The scheme of [5] is formulated for a linear parabolic problem with

$$L_1u = -p_1(x,y,t)u_{xx} + q_1(x,y,t)u_x + c(x,y,t)u, \quad L_2u = -p_2(x,y,t)u_{yy} + q_2(x,y,t)u_y,$$

and the solution u subject to Dirichlet boundary conditions. It follows from (3.2) of [5] that if, for the nonlinear parabolic problem, Robin boundary conditions on the vertical sides of $\overline{\Omega}$ reduce to Dirichlet boundary conditions, that is, $\alpha_3 = \alpha_4 = 1$ and $\beta_3 = \beta_4 = 0$ in (2.2), then (2.11) with $y \in \mathcal{G}_y$ can be replaced by

$$\begin{aligned} u_h^{n+1/2}(\gamma,y) &= [(1/2)(u_h^{n+1} + u_h^n) \\ &+ (\tau/4)L_2^{n+1/2}((u_h^{n+1} + u_h^n)/2, \hat{u}_h^{n+1/2})(u_h^{n+1} - u_h^n)](\gamma,y), \quad \gamma = a_1, b_1, \end{aligned}$$

where $u_h^n(\gamma,\cdot) \in \mathcal{M}_y$, $n = 0,\dots,N_t$, $\gamma = a_1, b_1$, are given by

$$u_h^n(a_1,\cdot) = g_{3,h}^n, \qquad u_h^n(b_1,\cdot) = g_{4,h}^n.$$

2.4. While the functions $\tilde{u}_h^{n+1/2}$, given by the first equation of (2.10), are defined on the vertical lines passing through the points of $\mathcal{G}$, the functions $\hat{u}_h^{n+1/2}$, given by the last two equations in (2.10), are defined on the horizontal lines passing through the points of $\mathcal{G}$. This is why the $\hat{u}_h^{n+1/2}$ are used at those places in (2.8)–(2.9) that require differentiation with respect to x. On the other hand, $\tilde{u}_h^{n+1/2}$ are used in

(2.8)–(2.9) at all remaining places, including those which involve differentiation with respect to y. It should be noted that for $n = 2, \dots, N_t - 1$ and $y \in \mathcal{G}_y$, the function $\hat{u}_h^{n+1/2}(\cdot, y) \in \mathcal{M}_x$ given by the last equation in (2.10) could be defined in terms of u_h^n and u_h^{n-1} rather than $u_h^{n-1/2}$ and $u_h^{n-3/2}$, using, for example, the equations

$$
\begin{aligned}
&\hat{u}_h^{n+1/2}(x,y) = (3/2)u_h^n(x,y) - (1/2)u_h^{n-1}(x,y), \qquad x \in \mathcal{G}_x,\\
&\alpha_3(y, t_{n+1/2})\hat{u}_h^{n+1/2}(a_1,y) - \beta_3(y, t_{n+1/2})(\hat{u}_h^{n+1/2})_x(a_1,y) = g_3(y, t_{n+1/2}),\\
&\alpha_4(y, t_{n+1/2})\hat{u}_h^{n+1/2}(b_1,y) + \beta_4(y, t_{n+1/2})(\hat{u}_h^{n+1/2})_x(b_1,y) = g_4(y, t_{n+1/2}),
\end{aligned}
\tag{2.16}
$$

the first of which is similar to the first equation of (2.10) defining $\tilde{u}_h^{n+1/2}$. However, we choose to use the last equation of (2.10) for the definition of $\hat{u}_h^{n+1/2}$ since its implementation is less expensive than that of (2.16) which requires solving a collection of independent one-dimensional OSC two-point boundary value problems.

REMARK 2.5. In (2.9), it seems natural to use the function $u_h^{n+1/2}$ determined from (2.8) and (2.11) in place of $\hat{u}_h^{n+1/2}$. However, such a modification of the scheme would require an additional evaluation of the function f and a more involved implementation than the one presented in this paper.

REMARK 2.6. The scheme (2.8)–(2.9) can be viewed as the one obtained from linearization of the nonlinear ADI OSC scheme

$$
\begin{aligned}
&\left[\frac{u_h^{n+1/2} - u_h^n}{0.5\tau} + L_1^{n+1/2}(u_h^{n+1/2}, u_h^{n+1/2})u_h^{n+1/2} \right.\\
&\qquad \left. + L_2^{n+1/2}(u_h^{n+1/2}, u_h^{n+1/2})u_h^n\right](x,y)\\
&= f(x, y, t_{n+1/2}, u_h^{n+1/2}(x,y), (u_h^{n+1/2})_x(x,y), (u_h^{n+1/2})_y(x,y)), \quad (x,y) \in \mathcal{G},\\
&\left[\frac{u_h^{n+1} - u_h^{n+1/2}}{0.5\tau} + L_1^{n+1/2}(u_h^{n+1/2}, u_h^{n+1/2})u_h^{n+1/2} \right.\\
&\qquad \left. + L_2^{n+1/2}(u_h^{n+1/2}, u_h^{n+1/2})u_h^{n+1}\right](x,y)\\
&= f(x, y, t_{n+1/2}, u_h^{n+1/2}(x,y), (u_h^{n+1/2})_x(x,y), (u_h^{n+1/2})_y(x,y)), \quad (x,y) \in \mathcal{G},
\end{aligned}
\tag{2.17}
$$

in which the unknown function $u_h^{n+1/2}$ in $L_1^{n+1/2}$, $L_2^{n+1/2}$, and f is replaced with its corresponding extrapolated approximations given in (2.10). In comparison to (2.8)–(2.9), the scheme (2.17) would require solving a collection of one-dimensional nonlinear, rather than linear, OSC two-point boundary value problems.

REMARK 2.7. An alternative to (2.8)–(2.9) is the scheme

$$
\begin{aligned}
&\left[\frac{u_h^{n+1/2} - u_h^n}{0.5\tau} + L_1^{n+1/2}(\tilde{u}_h^{n+1/2}, \hat{u}_h^{n+1/2})u_h^{n+1/2} + L_2^n(u_h^n, \hat{u}_h^n)u_h^n\right](x,y)\\
&= f(x, y, t_{n+1/2}, \tilde{u}_h^{n+1/2}(x,y), (\hat{u}_h^{n+1/2})_x(x,y), (\tilde{u}_h^{n+1/2})_y(x,y)), \quad (x,y) \in \mathcal{G},\\
&\left[\frac{u_h^{n+1} - u_h^{n+1/2}}{0.5\tau} + L_1^{n+1/2}(\tilde{u}_h^{n+1/2}, \hat{u}_h^{n+1/2})u_h^{n+1/2} + L_2^{n+1}(\tilde{u}_h^{n+1}, \hat{u}_h^{n+1})u_h^{n+1}\right](x,y)\\
&= f(x, y, t_{n+1/2}, \tilde{u}_h^{n+1/2}(x,y), (\hat{u}_h^{n+1/2})_x(x,y), (\tilde{u}_h^{n+1/2})_y(x,y)), \quad (x,y) \in \mathcal{G},
\end{aligned}
\tag{2.18}
$$

where the additional functions $\tilde{u}_h^{n+1}(x,\cdot)$ and $\hat{u}_h^{n+1}(x,\cdot)$ in L_2^{n+1} are given by

$$\tilde{u}_h^{n+1}(x,\cdot) = 2u_h^n(x,\cdot) - u_h^{n-1}(x,\cdot), \quad \hat{u}_h^{n+1}(x,\cdot) = (3/2)u_h^{n+1/2}(x,\cdot) - (1/2)u_h^{n-1/2}(x,\cdot).$$

The scheme (2.18) is also second order accurate in t and is obtained from (2.8)–(2.9) by replacing the operator $L_2^{n+1/2}(\tilde{u}_h^{n+1/2}, \hat{u}_h^{n+1/2})$ in (2.8) and (2.9) with the operators $L_2^n(u_h^n, \hat{u}_h^n)$ and $L_2^{n+1}(\tilde{u}_h^{n+1}, \hat{u}_h^{n+1})$, respectively. For a linear parabolic problem, the scheme (2.18) coincides with the scheme (3.41) of [4].

REMARK 2.8. For the operators L_1, L_2 in the divergence forms

$$L_1 u = -(p_1(x,y,t,u,u_x,u_y)u_x)_x, \qquad L_2 u = -(p_2(x,y,t,u,u_x,u_y)u_y)_y$$

and zero Neumann boundary conditions, an ADI OSC scheme similar to ours is discussed in [1]. The authors of [1] formulate (2.8)–(2.9) with $(1/2)(u_h^{n+1} + u_h^n)$ in place of $\tilde{u}_h^{n+1/2}$, $\hat{u}_h^{n+1/2}$ and suggest, but do not seem to carry out, the extrapolation procedure of [16] in the implementation of their scheme for nonlinear problems. The application of the extrapolation procedure of [16] in the formulation of the scheme yields the formula for $\tilde{u}_h^{n+1/2}$ in (2.10), which along with the other formulas of (2.10) leads to (2.8)–(2.9). The main difference between the two schemes is that in [1] the intermediate and approximate solutions $u_h^{n+1/2}$ and u_h^{n+1} are required to be piecewise Hermite bicubics defined on $\overline{\Omega}$, whereas in (2.8)–(2.9) they are, respectively, piecewise polynomials along horizontal and vertical lines passing through the points of $\mathcal{G}$. This property of our scheme leads to its efficient implementation and its generalization to rectangular polygons.

REMARK 2.9. Our ADI OSC scheme for (1.1) can be easily extended to (1.4) by extrapolating the term $p(x,y,t,u,u_x,u_y)u_{xy}$. Specifically, for $n = 0, \ldots, N_t - 1$, we include on the right-hand sides of (2.8) and (2.9) the additional term

$$p(x,y,t_{n+1/2},\tilde{u}_h^{n+1/2}(x,y),(\hat{u}_h^{n+1/2})_x(x,y),(\tilde{u}_h^{n+1/2})_y(x,y))(\tilde{u}_h^{n+1/2})_{xy}(x,y),$$

where, for each n, $\tilde{u}_h^{n+1/2}$ defined along vertical lines passing through the Gauss points is converted into a function defined on $\overline{\Omega}$. A similar modification is also made on the right-hand side of (2.5) by including the additional term

$$\frac{\tau}{2}p(x,y,0,u_h^0(x,y),(\hat{u}_h^0)_x(x,y),(u_h^0)_y(x,y))(u_h^0)_{xy}(x,y),$$

where u_h^0 defined along vertical lines passing through the Gauss points is converted into a function defined on $\overline{\Omega}$.

2.2. Implementation and cost. To discuss implementation of the ADI OSC scheme of section 2.1, we assume that $\{\phi_i^x\}_{i=1}^{M_x}$ and $\{\phi_j^y\}_{j=1}^{M_y}$ are B-spline basis functions for $\mathcal{M}_x$ and $\mathcal{M}_y$, respectively. This implies (see [10, page 445]), that

$$\begin{gathered}\phi_1^x(a_1) \neq 0, \quad [\phi_1^x]'(a_1) \neq 0, \qquad \phi_2^x(a_1) = 0, \quad [\phi_2^x]'(a_1) \neq 0,\\ \phi_i^x(a_1) = [\phi_i^x]'(a_1) = 0, \quad i = 3, \ldots, M_x,\end{gathered} \tag{2.19}$$

$$\begin{gathered}\phi_i^x(b_1) = [\phi_i^x]'(b_1) = 0, \quad i = 1, \ldots, M_x - 2,\\ \phi_{M_x-1}^x(b_1) = 0, \quad [\phi_{M_x-1}^x]'(b_1) \neq 0, \qquad \phi_{M_x}^x(b_1) \neq 0, \quad [\phi_{M_x}^x]'(b_1) \neq 0,\end{gathered} \tag{2.20}$$

and that $\{\phi_j^y\}_{j=1}^{M_y}$ have similar properties at a_2 and b_2.

Since for each ξ_k^x, $k = 1, \ldots, M_x - 2$, the functions $u_h^n(\xi_k^x, \cdot)$, $\tilde{u}_h^{n+1/2}(\xi_k^x, \cdot) \in \mathcal{M}_y$, and for each ξ_l^y, $l = 1, \ldots, M_y - 2$, the functions $\hat{u}_h^0(\cdot, \xi_l^y)$, $\hat{u}_h^{n+1/2}(\cdot, \xi_l^y)$, $u_h^{n+1/2}(\cdot, \xi_l^y) \in \mathcal{M}_x$, we have

$$u_h^n(\xi_k^x, y) = \sum_{j=1}^{M_y} u_{k,j}^n \phi_j^y(y), \tag{2.21}$$

$$\tilde{u}_h^{n+1/2}(\xi_k^x, y) = \sum_{j=1}^{M_y} \tilde{u}_{k,j}^{n+1/2} \phi_j^y(y), \tag{2.22}$$

$$\hat{u}_h^0(x, \xi_l^y) = \sum_{i=1}^{M_x} \hat{u}_{i,l}^0 \phi_i^x(x), \tag{2.23}$$

$$\hat{u}_h^{n+1/2}(x, \xi_l^y) = \sum_{i=1}^{M_x} \hat{u}_{i,l}^{n+1/2} \phi_i^x(x), \tag{2.24}$$

$$u_h^{n+1/2}(x, \xi_l^y) = \sum_{i=1}^{M_x} u_{i,l}^{n+1/2} \phi_i^x(x). \tag{2.25}$$

Implementation of the first stage of the scheme requires the computation of the expansion coefficients of the initial approximations $u_h^0(\xi_k^x, \cdot)$, $\hat{u}_h^0(\cdot, \xi_l^y)$, $\tilde{u}_h^{1/2}(\xi_k^x, \cdot)$, and $\hat{u}_h^{1/2}(\cdot, \xi_l^y)$. It follows from (2.3) and (2.21) that the coefficients $\{u_{k,j}^0\}_{j=1}^{M_y}$ of $u_h^0(\xi_k^x, \cdot)$ satisfy the equations

$$\sum_{j=1}^{M_y} \phi_j^y(\xi_l^y) u_{k,j}^0 = g_0(\xi_k^x, \xi_l^y), \qquad l = 0, \ldots, M_y - 1, \tag{2.26}$$

where

$$\xi_0^y = a_2, \qquad \xi_{M_y-1}^y = b_2.$$

Therefore, for fixed $k = 1, \ldots, M_x - 2$, the coefficients $\{u_{k,j}^0\}_{j=1}^{M_y}$ are obtained by solving a linear system with the matrix

$$C^y = (c_{l,j}^y)_{l=0,j=1}^{M_y-1,M_y}, \qquad c_{l,j}^y = \phi_j^y(\xi_l^y). \tag{2.27}$$

Similarly, it follows from (2.4) and (2.23) that for fixed $l = 1, \ldots, M_y - 2$, the coefficients $\{\hat{u}_{i,l}^0\}_{i=1}^{M_x}$ of $\hat{u}_h^0(\cdot, \xi_l^y)$ are determined by solving a linear system with the matrix

$$C^x = (c_{k,i}^x)_{k=0,i=1}^{M_x-1,M_x}, \qquad c_{k,i}^x = \phi_i^x(\xi_k^x), \tag{2.28}$$

where

$$\xi_0^x = a_1, \qquad \xi_{M_x-1}^x = b_1.$$

The matrices C^x and C^y have an almost block diagonal (ABD) structure [9]. It follows from (2.19) and (2.20) that the first element in the first rows of C_x and C_y is the only

nonzero element in these rows and that the last element in the last rows of C_x and C_y is the only nonzero element in these rows. The remaining nonzero elements of C^x and C^y are located along the diagonals in $(r-1)\times(r+1)$ blocks which overlap in two columns; there are N_x such blocks in C^x and N_y blocks in C^y. Linear systems with C^x and C^y can be solved efficiently using the package COLROW [13], [14] at costs $O(r^3N_x)$ and $O(r^3N_y)$, respectively.

Equations (2.6) and (2.22) imply that for fixed $k=1,\dots,M_x-2$, the coefficients $\{\tilde u^{1/2}_{k,j}\}_{j=1}^{M_y}$ of $\tilde u^{1/2}_h(\xi^x_k,\cdot)$ are computed by solving an ABD linear system with the matrix that differs from C^y in the first and last rows; the first two and, respectively, the last two elements being the only nonzero elements in these rows. Similarly, (2.7) and (2.24) imply that for fixed $l=1,\dots,M_y-2$, the coefficients $\{\hat u^{1/2}_{i,l}\}_{i=1}^{M_x}$ of $\hat u^{1/2}_h(\cdot,\xi^y_l)$ are obtained by solving an ABD linear system with the matrix that differs from C^x in the first and last rows. Again, with the use of COLROW, linear systems with the modified C^x and C^y are solved at costs $O(r^3N_x)$ and $O(r^3N_y)$, respectively. It follows from (2.6), (2.7), (2.5), (2.23), and (2.21) that the computation of the right-hand sides in the systems for $\{\tilde u^{1/2}_{k,j}\}_{j=1}^{M_y}$ and $\{\hat u^{1/2}_{i,l}\}_{i=1}^{M_x}$ involves, among other things, matrix-vector multiplications with the matrices

$$B^{1,l}=(b^{1,l}_{k,i})_{k=1,i=1}^{M_x-2,M_x},\qquad b^{1,l}_{k,i}=L^0_1(u^0_h,\hat u^0_h)\phi^x_i(\xi^x_k,\xi^y_l),\qquad l=1,\dots,M_y-2,$$

and

$$B^{2,k}=(b^{2,k}_{l,j})_{l=1,j=1}^{M_y-2,M_y},\qquad b^{2,k}_{l,j}=L^0_2(u^0_h,\hat u^0_h)\phi^y_j(\xi^x_k,\xi^y_l),\qquad k=1,\dots,M_x-2.$$

Since $B^{1,l}$ and $B^{2,k}$ are ABD matrices, multiplying $B^{1,l}$ and $B^{2,k}$ by a vector requires $O(r^2N_x)$ and $O(r^2N_y)$ operations, respectively.

To describe implementation of the second stage of the scheme, we first rewrite (2.8) in the form

$$\begin{aligned}&\left[I+0.5\tau L_1^{n+1/2}(\tilde u_h^{n+1/2},\hat u_h^{n+1/2})\right]u_h^{n+1/2}(x,y)\\&\qquad=\left[I-0.5\tau L_2^{n+1/2}(\tilde u_h^{n+1/2},\hat u_h^{n+1/2})\right]u_h^n(x,y)\\&+0.5\tau f(x,y,t_{n+1/2},\tilde u_h^{n+1/2}(x,y),(\hat u_h^{n+1/2})_x(x,y),(\tilde u_h^{n+1/2})_y(x,y)),\quad (x,y)\in\mathcal{G},\end{aligned}$$

where I is the identity operator. Subtracting (2.8) from (2.9) and multiplying by 0.5τ, we obtain

$$\begin{aligned}&\left[I+0.5\tau L_2^{n+1/2}(\tilde u_h^{n+1/2},\hat u_h^{n+1/2})\right]u_h^{n+1}(x,y)\\&\qquad=2u_h^{n+1/2}(x,y)-\left[I-0.5\tau L_2^{n+1/2}(\tilde u_h^{n+1/2},\hat u_h^{n+1/2})\right]u_h^n(x,y),\qquad (x,y)\in\mathcal{G}.\end{aligned}$$

Thus, for fixed $n=0,\dots,N_t-1$, the second stage of the scheme is implemented using equations

$$\begin{aligned}&\left[I+0.5\tau L_1^{n+1/2}(\tilde u_h^{n+1/2},\hat u_h^{n+1/2})\right]u_h^{n+1/2}(x,y)=v_h^n(x,y)\\&\qquad+0.5\tau f(x,y,t_{n+1/2},\tilde u_h^{n+1/2}(x,y),(\hat u_h^{n+1/2})_x(x,y),(\tilde u_h^{n+1/2})_y(x,y)),\end{aligned}\tag{2.29}$$

$$\left[I+0.5\tau L_2^{n+1/2}(\tilde u_h^{n+1/2},\hat u_h^{n+1/2})\right]u_h^{n+1}(x,y)=2u_h^{n+1/2}(x,y)-v_h^n(x,y),\tag{2.30}$$

$$v_h^n(x,y) = \left[I - 0.5\tau L_2^{n+1/2}(\tilde{u}_h^{n+1/2}, \hat{u}_h^{n+1/2})\right] u_h^n(x,y), \tag{2.31}$$

with $(x,y) \in \mathcal{G}$, where for $y \in \mathcal{G}_y$ and $x \in \mathcal{G}_x$, the functions $u_h^{n+1/2}(\cdot,y) \in \mathcal{M}_x$ and $u_h^{n+1}(x,\cdot) \in \mathcal{M}_y$ satisfy the boundary conditions (2.11) and (2.13), respectively. Using (2.25) and (2.21) in (2.29)–(2.31), and setting $(x,y) = (\xi_k^x, \xi_l^y)$, we obtain

$$\begin{aligned}
&\sum_{i=1}^{M_x} \left[\phi_i^x(\xi_k^x) + 0.5\tau L_1^{n+1/2}(\tilde{u}_h^{n+1/2}, \hat{u}_h^{n+1/2})\phi_i^x(\xi_k^x, \xi_l^y)\right] u_{i,l}^{n+1/2} = v_h^n(\xi_k^x, \xi_l^y) \\
&\quad + 0.5\tau f(\xi_k^x, \xi_l^y, t_{n+1/2}, \tilde{u}_h^{n+1/2}(\xi_k^x, \xi_l^y), (\hat{u}_h^{n+1/2})_x(\xi_k^x, \xi_l^y), (\tilde{u}_h^{n+1/2})_y(\xi_k^x, \xi_l^y)),
\end{aligned} \tag{2.32}$$

$$\begin{aligned}
&\sum_{j=1}^{M_y} \left[\phi_j^y(\xi_l^y) + 0.5\tau L_2^{n+1/2}(\tilde{u}_h^{n+1/2}, \hat{u}_h^{n+1/2})\phi_j^y(\xi_k^x, \xi_l^y)\right] u_{k,j}^{n+1} \\
&\qquad = 2\sum_{i=1}^{M_x} \phi_i^x(\xi_k^x) u_{i,l}^{n+1/2} - v_h^n(\xi_k^x, \xi_l^y),
\end{aligned} \tag{2.33}$$

$$v_h^n(\xi_k^x, \xi_l^y) = \sum_{j=1}^{M_y} \left[\phi_j^y(\xi_l^y) - 0.5\tau L_2^{n+1/2}(\tilde{u}_h^{n+1/2}, \hat{u}_h^{n+1/2})\phi_j^y(\xi_k^x, \xi_l^y)\right] u_{k,j}^n,$$

where $k = 1, \ldots, M_x - 2$ and $l = 1, \ldots, M_y - 2$. For fixed $k = 1, \ldots, M_x - 2$, the computation of $\{v_h^n(\xi_k^x, \xi_l^y)\}_{l=1}^{M_y-2}$ involves matrix-vector multiplication with the matrix

$$A^{2,k} = (a_{l,j}^{2,k})_{l=1,j=1}^{M_y-2,M_y}, \quad a_{l,j}^{2,k} = \phi_j^y(\xi_l^y) - 0.5\tau L_2^{n+1/2}(\tilde{u}_h^{n+1/2}, \hat{u}_h^{n+1/2})\phi_j^y(\xi_k^x, \xi_l^y). \tag{2.34}$$

Since $A^{2,k}$ is an ABD matrix, the cost of multiplying $A^{2,k}$ by a vector is $O(r^2 N_y)$. For fixed $l = 1, \ldots, M_y - 2$, (2.32) with $k = 1, \ldots, M_x - 2$ and both equations in (2.11) with $y = \xi_l^y$ involve solving an ABD linear system in the x-direction for the coefficients $\{u_{i,l}^{n+1/2}\}_{i=1}^{M_x}$ of $u_h^{n+1/2}(\cdot, \xi_l^y)$. Similarly, for fixed $k = 1, \ldots, M_x - 2$, (2.33) with $l = 1, \ldots, M_y - 2$ and both equations in (2.13) with $x = \xi_k^x$ involve solving an ABD linear system in the y-direction for the coefficients $\{u_{k,j}^{n+1}\}_{j=1}^{M_y}$ of $u_h^{n+1}(\xi_k^x, \cdot)$. The corresponding matrices in these systems are given by formulas similar to those for $A_{2,k}$ of (2.34). With the help of COLROW, the systems in the x- and y-directions are solved at costs $O(r^3 N_x)$ and $O(r^3 N_y)$, respectively. Setting up the matrix $A^{2,k}$ of (2.34), the matrix and right-hand side in the linear system corresponding to (2.32), and the matrix in the linear system corresponding to (2.33) involves multiplications of ABD matrices by the vectors $\{\tilde{u}_{k,j}^{n+1/2}\}_{j=1}^{M_y}$ and $\{\hat{u}_{i,l}^{n+1/2}\}_{i=1}^{M_x}$ whose components, according to (2.10) and (2.21)–(2.25), are computed using formulas

$$\begin{aligned}
\tilde{u}_{k,j}^{n+1/2} &= (3/2)u_{k,j}^n - (1/2)u_{k,j}^{n-1}, \qquad n = 1, \ldots, N_t - 1, \\
\hat{u}_{i,l}^{3/2} &= 3u_{i,l}^{1/2} - 2\hat{u}_{i,l}^0, \qquad \hat{u}_{i,l}^{n+1/2} = 2u_{i,l}^{n-1/2} - u_{i,l}^{n-3/2}, \qquad n = 2, \ldots, N_t - 1.
\end{aligned}$$

In the third phase of the ADI OSC scheme, the coefficients $u_{i,j}$ in

$$u_h(x,y) = \sum_{i=1}^{M_x} \sum_{j=1}^{M_y} u_{i,j}\phi_i^x(x)\phi_j^y(y), \qquad (x,y) \in \overline{\Omega}, \tag{2.35}$$

are determined using (2.14) and (2.15). It follows from (2.14) and (2.21) with $n = N_t$ that

$$u_h(\xi_k^x, y) = \sum_{j=1}^{M_y} u_{k,j}^{N_t} \phi_j^y(y), \qquad k = 1, \ldots, M_x - 2, \qquad y \in [a_2, b_2], \tag{2.36}$$

where for each $k = 1, \ldots, M_x - 2$, the coefficients $\{u_{k,j}^{N_t}\}_{j=1}^{M_y}$ are known. Setting $x = \xi_k^x$, $k = 1, \ldots, M_x - 2$, in (2.35) and equating the coefficients of ϕ_j^y in the resulting right-hand side with those on the right-hand sides in (2.36), we obtain

$$\sum_{i=1}^{M_x} \phi_i^x(\xi_k^x) u_{i,j} = u_{k,j}^{N_t}, \qquad k = 1, \ldots, M_x - 2, \tag{2.37}$$

for $j = 1, \ldots, M_y$. For fixed j, (2.37) forms a system of $M_x - 2$ equations in the unknown coefficients $\{u_{i,j}\}_{i=1}^{M_x}$. Since the number of the unknown coefficients is M_x, we require two additional equations or knowledge of two coefficients. In the following we show how to determine $\{u_{1,j}\}_{j=1}^{M_y}$ and $\{u_{M_x,j}\}_{j=1}^{M_y}$. (It follows from (2.37) and (2.28) that once $u_{1,j}$ and $u_{M_x,j}$ are known, the remaining unknown coefficients $\{u_{i,j}\}_{i=2}^{M_x-1}$ are obtained with cost $O(r^3 N_x)$ by solving, using COLROW, an ABD linear system with the matrix that differs from C^x in the first and last rows whose first and last elements, respectively, are set to 1.) Since $u_h(\cdot, y) \in \mathcal{M}_x$ for fixed $y \in [a_2, b_2]$, there are coefficients $\{z_{i,l}\}_{i=1}^{M_x}$, $l = 0, \ldots, M_y - 1$, such that

$$u_h(x, \xi_l^y) = \sum_{i=1}^{M_x} z_{i,l} \phi_i^x(x), \qquad x \in [a_1, b_1], \qquad l = 0, \ldots, M_y - 1. \tag{2.38}$$

Then it follows from (2.35) with $x = a_1, b_1$, $y = \xi_l^y$, $l = 0, \ldots, M_y - 1$, (2.38) with $x = a_1, b_1$, (2.19), and (2.20) that

$$\sum_{j=1}^{M_y} \phi_j^y(\xi_l^y) u_{1,j} = z_{1,l}, \qquad l = 0, \ldots, M_y - 1,$$

$$\sum_{j=1}^{M_y} \phi_j^y(\xi_l^y) u_{M_x,j} = z_{M_x,l}, \qquad l = 0, \ldots, M_y - 1.$$

Solving these two systems using COLROW with cost $O(r^3 N_y)$ (cf. definition (2.27) of the ABD matrix C^y), we obtain the required coefficients $\{u_{1,j}\}_{j=1}^{M_y}$ and $\{u_{M_x,j}\}_{j=1}^{M_y}$. Thus, it remains to show how $\{z_{1,l}\}_{l=0}^{M_y-1}$ and $\{z_{M_x,l}\}_{l=0}^{M_y-1}$ are computed.

It follows from (2.38) with $x = \xi_k^x$, $k = 1, \ldots, M_x - 2$, and (2.36) with $y = \xi_l^y$, $l = 0, \ldots, M_y - 1$, that

$$\sum_{i=1}^{M_x} \phi_i^x(\xi_k^x) z_{i,l} = \sum_{j=1}^{M_y} \phi_j^y(\xi_l^y) u_{k,j}^{N_t}, \qquad k = 1, \ldots, M_x - 2, \tag{2.39}$$

for $l = 0, \ldots, M_y - 1$. Substituting (2.38) into (2.15) with $y = \xi_l^y$ and using (2.19), (2.20), we also obtain

$$\left\{\alpha_3^{N_t}(\xi_l^y)\phi_1^x(a_1) - \beta_3^{N_t}(\xi_l^y)[\phi_1^x]'(a_1)\right\} z_{1,l} - \beta_3^{N_t}(\xi_l^y)[\phi_2^x]'(a_1) z_{2,l} = g_{3,h}^{N_t}(\xi_l^y) \tag{2.40}$$

and

$$\left\{\alpha_4^{N_t}(\xi_l^y)\phi_{M_x}^x(b_1)+\beta_4^{N_t}(\xi_l^y)[\phi_{M_x}^x]'(b_1)\right\}z_{M_x,l} + \beta_4^{N_t}(\xi_l^y)[\phi_{M_x-1}^x]'(b_1)z_{M_x-1,l}=g_{4,h}^{N_t}(\xi_l^y) \tag{2.41}$$

for $l=0,\dots,M_y-1$. Therefore, for fixed $l=0,\dots,M_y-1$, the coefficients $\{z_{i,l}\}_{i=1}^{M_x}$, and hence $z_{1,l}$ and $z_{M_x,l}$, are obtained by solving the ABD linear system consisting of (2.39), (2.40), and (2.41). By (2.39) and (2.28), the matrix in this system differs from C^x in the first and last rows. It follows from (2.39) and (2.27) that the right-hand sides in these systems are first computed by multiplying C^y by $\{u_{k,j}^{N_t}\}_{j=1}^{M_y}$ for $k=1,\dots,M_x-2$.

If the Dirichlet boundary conditions are imposed on the vertical sides of $\overline{\Omega}$, the systems (2.39)–(2.41) need not be solved since $z_{1,l}$ and $z_{M_x,l}$ are known explicitly. Indeed, it follows from (2.40) and (2.41) with $\alpha_3=\alpha_4=1$ and $\beta_3=\beta_4=0$ that

$$z_{1,l}=\frac{g_{3,h}^{N_t}(\xi_l^y)}{\phi_1^x(a_1)},\qquad z_{M_x,l}=\frac{g_{4,h}^{N_t}(\xi_l^y)}{\phi_{M_x}^x(b_1)},\qquad l=0,\dots,M_y-1.$$

Assume $N_x=N_y=N$. Since M_x and M_y are proportional to rN_x and rN_y, respectively, it follows that the costs of stages 1 and 3 and, for fixed n, stage 2 are $O(r^4N^2)$ each. Hence the total cost of computing the approximation u_h is $O(r^4N^2N_t)$.

3. The ADI OSC scheme for an *L*-shaped region. Assume $a_1<c_1<b_1$, $a_2<c_2<b_2$ and consider the L-shaped region $\Omega=\{(a_1,b_1)\times(a_2,b_2)\}\setminus\{[c_1,b_1)\times[c_2,b_2)\}$ (see Figure 3.1).

Consider problem (1.1)–(1.2) with L_1 and L_2 as in (1.3), the solution u subject to the conditions in (2.1) with $x\in[a_1,b_1]$, $x\in[a_1,c_1]$, respectively, the conditions in (2.2) with $y\in[a_2,b_2]$, $y\in[a_2,c_2]$, respectively, and the conditions

$$\begin{aligned}&\alpha_5(x,t)u(x,c_2,t)+\beta_5(x,t)u_y(x,c_2,t)=g_5(x,t),\quad x\in[c_1,b_1],\\ &\alpha_6(y,t)u(c_1,y,t)+\beta_6(y,t)u_x(c_1,y,t)=g_6(y,t),\quad y\in[c_2,b_2],\end{aligned}\qquad t\in(0,d]. \tag{3.1}$$

Let $\{x_k\}_{k=0}^{N_x}$ and $\{y_l\}_{l=0}^{N_y}$ of section 2 be such that

$$c_1=x_i,\qquad c_2=y_j$$

for some integers i and j. Let $\mathcal{M}_x$, $\mathcal{M}_y$, $\mathcal{G}_x$, $\mathcal{G}_y$, and $\mathcal{G}$ be as in section 2. Let $\mathcal{M}_x^{(1)}$, $\mathcal{M}_x^{(2)}$ be restrictions of $\mathcal{M}_x$ to $[a_1,c_1]$, $[c_1,b_1]$, respectively, and let $\mathcal{M}_y^{(1)}$, $\mathcal{M}_y^{(2)}$ be restrictions of $\mathcal{M}_y$ to $[a_2,c_2]$, $[c_2,b_2]$, respectively. Let $\mathcal{G}_x^{(1)}=\mathcal{G}_x\cap(a_1,c_1)$, $\mathcal{G}_x^{(2)}=\mathcal{G}_x\cap(c_1,b_1)$, $\mathcal{G}_y^{(1)}=\mathcal{G}_y\cap(a_2,c_2)$, and $\mathcal{G}_y^{(2)}=\mathcal{G}_y\cap(c_2,b_2)$. Let $g_{1,h}^m\in\mathcal{M}_x$, $g_{2,h}^m\in\mathcal{M}_x^{(1)}$, $g_{3,h}^m\in\mathcal{M}_y$, $g_{4,h}^m\in\mathcal{M}_y^{(1)}$, $g_{5,h}^m\in\mathcal{M}_x^{(2)}$, and $g_{6,h}^m\in\mathcal{M}_y^{(2)}$ be Hermite or Gauss interpolants of $g_1^m,\dots,g_6^m$, respectively.

In the first stage of the ADI OSC scheme, the functions $u_h^0(x,\cdot)\in\mathcal{M}_y$, $x\in\mathcal{G}_x^{(1)}$, and $\hat{u}_h^0(\cdot,y)\in\mathcal{M}_x$, $y\in\mathcal{G}_y^{(1)}$, are defined by (2.3) and (2.4), respectively. The functions $u_h^0(x,\cdot)\in\mathcal{M}_y^{(1)}$, $x\in\mathcal{G}_x^{(2)}$, and $\hat{u}_h^0(\cdot,y)\in\mathcal{M}_x^{(1)}$, $y\in\mathcal{G}_y^{(2)}$, are defined by

$$u_h^0(x,y)=g_0(x,y),\qquad y\in\mathcal{G}_y^{(1)}\cup\{a_2,c_2\},$$

and

$$\hat{u}_h^0(x,y)=g_0(x,y),\qquad x\in\mathcal{G}_x^{(1)}\cup\{a_1,c_1\}.$$

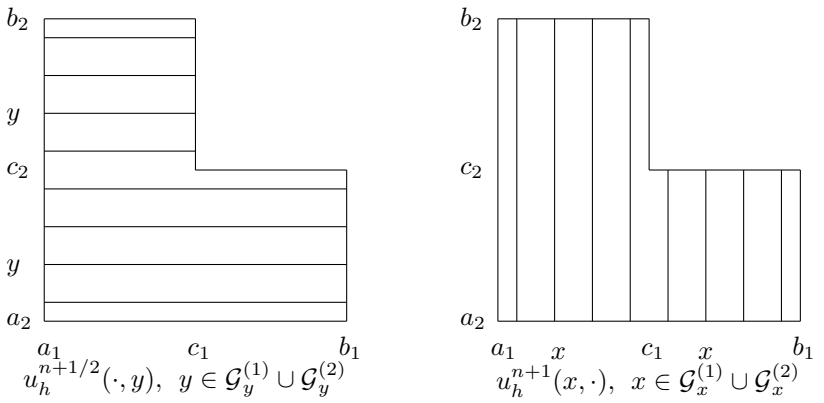

FIG. 3.1. *L-shaped region.*

The functions $\tilde{u}_h^{1/2}(x, \cdot) \in \mathcal{M}_y$, $x \in \mathcal{G}_x^{(1)}$, and $\hat{u}_h^{1/2}(\cdot, y) \in \mathcal{M}_x$, $y \in \mathcal{G}_y^{(1)}$, are defined by (2.6) and (2.7), respectively. The functions $\tilde{u}_h^{1/2}(x, \cdot) \in \mathcal{M}_y^{(1)}$, $x \in \mathcal{G}_x^{(2)}$, and $\hat{u}_h^{1/2}(\cdot, y) \in \mathcal{M}_x^{(1)}$, $y \in \mathcal{G}_y^{(2)}$, are defined by

$$\begin{aligned}
&\tilde{u}_h^{1/2}(x, y) = g_0(x, y) + g(x, y), \quad y \in \mathcal{G}_y^{(1)},\\
&\alpha_1^{1/2}(x)\tilde{u}_h^{1/2}(x, a_2) - \beta_1^{1/2}(x)(\tilde{u}_h^{1/2})_y(x, a_2) = g_1^{1/2}(x),\\
&\alpha_5^{1/2}(x)\tilde{u}_h^{1/2}(x, c_2) + \beta_5^{1/2}(x)(\tilde{u}_h^{1/2})_y(x, c_2) = g_5^{1/2}(x)
\end{aligned}$$

and

$$\begin{aligned}
&\hat{u}_h^{1/2}(x, y) = g_0(x, y) + g(x, y), \quad x \in \mathcal{G}_x^{(1)},\\
&\alpha_3^{1/2}(y)\hat{u}_h^{1/2}(a_1, y) - \beta_3^{1/2}(y)(\hat{u}_h^{1/2})_x(a_1, y) = g_3^{1/2}(y),\\
&\alpha_6^{1/2}(y)\hat{u}_h^{1/2}(c_1, y) + \beta_6^{1/2}(y)(\hat{u}_h^{1/2})_x(c_1, y) = g_6^{1/2}(y),
\end{aligned}$$

where g is given in (2.5).

In the second stage of the scheme, corresponding to the time levels $t_{n+1/2}$ and t_{n+1}, we compute, respectively, $u_h^{n+1/2}$ along horizontal lines and u_h^{n+1} along vertical lines passing through the Gauss points (see Figure 3.1). Specifically, for $n = 0, \ldots, N_t - 1$, we use (2.8)–(2.9) with $(x, y) \in \mathcal{G} \cap \Omega$ to determine $u_h^{n+1}(x, \cdot) \in \mathcal{M}_y$, $x \in \mathcal{G}_x^{(1)}$, and $u_h^{n+1}(x, \cdot) \in \mathcal{M}_y^{(1)}$, $x \in \mathcal{G}_x^{(2)}$. The functions $u_h^{n+1/2}(\cdot, y) \in \mathcal{M}_x$, $y \in \mathcal{G}_y^{(1)}$, satisfy the boundary conditions (2.11). The functions $u_h^{n+1/2}(\cdot, y) \in \mathcal{M}_x^{(1)}$, $y \in \mathcal{G}_y^{(2)}$, satisfy the first equation of (2.11) and

$$\begin{aligned}
&\alpha_6^{n+1/2}(y)u_h^{n+1/2}(c_1, y) + \beta_6^{n+1/2}(y)(u_h^{n+1/2})_x(c_1, y)\\
&= (1/2)(g_{6,h}^{n+1} + g_{6,h}^n)(y) + (\tau/4)L_2^{n+1/2}(\overline{u}_h^{n+1/2}, \hat{u}_h^{n+1/2})(g_{6,h}^{n+1} - g_{6,h}^n)(c_1, y).
\end{aligned}$$

The functions $u_h^{n+1}(x, \cdot) \in \mathcal{M}_y$, $x \in \mathcal{G}_x^{(1)}$, satisfy the boundary conditions (2.13). The functions $u_h^{n+1}(x, \cdot) \in \mathcal{M}_y^{(1)}$, $x \in \mathcal{G}_x^{(2)}$, satisfy the first equation in (2.13) and

$$\alpha_5^{n+1}(x)u_h^{n+1}(x, c_2) + \beta_5^{n+1}(x)(u_h^{n+1})_y(x, c_2) = g_{5,h}^{n+1}(x).$$

As in section 2, for $n = 1, \dots, N_t - 1$, the functions $\tilde{u}_h^{n+1/2}(x, \cdot) \in \mathcal{M}_y$, $x \in \mathcal{G}_x^{(1)}$; $\tilde{u}_h^{n+1/2}(x, \cdot) \in \mathcal{M}_y^{(1)}$, $x \in \mathcal{G}_x^{(2)}$; $\hat{u}_h^{n+1/2}(\cdot, y) \in \mathcal{M}_x$, $y \in \mathcal{G}_y^{(1)}$; and $\hat{u}_h^{n+1/2}(\cdot, y) \in \mathcal{M}_x^{(1)}$, $y \in \mathcal{G}_y^{(2)}$, are defined by (2.10), and $\overline{u}_h^{n+1/2}(a_1, \cdot) \in \mathcal{M}_y$ is defined by (2.12) with $\gamma = a_1$. The functions $\overline{u}_h^{n+1/2}(b_1, \cdot) \in \mathcal{M}_y^{(1)}$, $\overline{u}_h^{n+1/2}(c_1, \cdot) \in \mathcal{M}_y^{(2)}$ are defined by

$$\begin{aligned}
&\overline{u}_h^{n+1/2}(b_1, y) = \hat{u}_h^{n+1/2}(b_1, y), \qquad y \in \mathcal{G}_y^{(1)},\\
&\alpha_1^{n+1/2}(b_1)\overline{u}_h^{n+1/2}(b_1, a_2) - \beta_1^{n+1/2}(b_1)(\overline{u}_h^{n+1/2})_y(b_1, a_2) = g_1^{n+1/2}(b_1),\\
&\alpha_5^{n+1/2}(b_1)\overline{u}_h^{n+1/2}(b_1, c_2) + \beta_5^{n+1/2}(b_1)(\overline{u}_h^{n+1/2})_y(b_1, c_2) = g_5^{n+1/2}(b_1)
\end{aligned}$$

and

$$\begin{aligned}
&\overline{u}_h^{n+1/2}(c_1, y) = \hat{u}_h^{n+1/2}(c_1, y), \qquad y \in \mathcal{G}_y^{(2)},\\
&\alpha_5^{n+1/2}(c_1)\overline{u}_h^{n+1/2}(c_1, c_2) - \beta_5^{n+1/2}(c_1)(\overline{u}_h^{n+1/2})_y(c_1, c_2) = g_5^{n+1/2}(c_1),\\
&\alpha_2^{n+1/2}(c_1)\overline{u}_h^{n+1/2}(c_1, b_2) + \beta_2^{n+1/2}(c_1)(\overline{u}_h^{n+1/2})_y(c_1, b_2) = g_2^{n+1/2}(c_1).
\end{aligned}$$

In the third stage we convert $u_h^{N_t}(x, \cdot) \in \mathcal{M}_y$, $x \in \mathcal{G}_x^{(1)}$, and $u_h^{N_t}(x, \cdot) \in \mathcal{M}_y^{(1)}$, $x \in \mathcal{G}_x^{(2)}$, into $u_h^I \in \mathcal{M}_x^{(1)} \otimes \mathcal{M}_y^{(2)}$ and $u_h^{II} \in \mathcal{M}_x \otimes \mathcal{M}_y^{(1)}$ which are to be approximations to $u(x, y, d)$ on $\overline{\Omega}_I = [a_1, c_1] \times [c_2, b_2]$ and $\overline{\Omega}_{II} = [a_1, b_1] \times [a_2, c_2]$, respectively. Specifically we require that

$$\begin{aligned}
&u_h^I(x, y) = u_h^{N_t}(x, y), \qquad x \in \mathcal{G}_x^{(1)}, \qquad y \in [c_2, b_2],\\
&\alpha_3^{N_t}(y)u_h^I(a_1, y) - \beta_3^{N_t}(y)(u_h^I)_x(a_1, y) = g_{3,h}^{N_t}(y),\\
&\alpha_6^{N_t}(y)u_h^I(c_1, y) + \beta_6^{N_t}(y)(u_h^I)_x(c_1, y) = g_{6,h}^{N_t}(y),
\end{aligned} \qquad y \in \mathcal{G}_y^{(2)} \cup \{c_2, b_2\}, \tag{3.2}$$

and

$$\begin{aligned}
&u_h^{II}(x, y) = u_h^{N_t}(x, y), \qquad x \in \mathcal{G}_x, \qquad y \in [a_2, c_2],\\
&\alpha_3^{N_t}(y)u_h^{II}(a_1, y) - \beta_3^{N_t}(y)(u_h^{II})_x(a_1, y) = g_{3,h}^{N_t}(y),\\
&\alpha_4^{N_t}(y)u_h^{II}(b_1, y) + \beta_4^{N_t}(y)(u_h^{II})_x(b_1, y) = g_{4,h}^{N_t}(y),
\end{aligned} \qquad y \in \mathcal{G}_y^{(1)} \cup \{a_2, c_2\}.$$

We note that, in general, $u_h^I(c_1, c_2) \neq u_h^{II}(c_1, c_2)$, and hence u_h^I and u_h^{II} do not match in a continuous fashion along the line segment $\{(x, c_2) : x \in [a_1, c_1]\}$. This is a consequence of the fact that if $v_h \in \mathcal{M}_x$ is the Gauss interpolant of v, then, in general, $v(x_i) \neq v_h(x_i)$, even though $v(x_i) - v_h(x_i)$ is expected to be close to 0.

With $\overline{\Omega}_I$ and $u_h^I \in \mathcal{M}_x^{(1)} \otimes \mathcal{M}_y^{(2)}$ as above, we describe below an alternative to the above conversion of $u_h^{N_t}$ into u_h^{II}. With $\overline{\Omega}_{II} = [a_1, c_1] \times [a_2, c_2]$ and $\overline{\Omega}_{III} = [c_1, b_1] \times [a_2, c_2]$, we seek approximations $u_h^{II} \in \mathcal{M}_x^{(1)} \otimes \mathcal{M}_y^{(1)}$ and $u_h^{III} \in \mathcal{M}_x^{(2)} \otimes \mathcal{M}_y^{(1)}$ to $u(x, y, d)$ on $\overline{\Omega}_{II}$ and $\overline{\Omega}_{III}$, respectively. First, for each $y \in \mathcal{G}_y^{(1)} \cup a_2$, we determine $v_h(\cdot, y) \in \mathcal{M}_x$ such that

$$\begin{aligned}
&v_h(x, y) = u_h^{N_t}(x, y), \qquad x \in \mathcal{G}_x,\\
&\alpha_3^{N_t}(y)v_h(a_1, y) - \beta_3^{N_t}(y)(v_h)_x(a_1, y) = g_{3,h}^{N_t}(y),\\
&\alpha_4^{N_t}(y)v_h(b_1, y) + \beta_4^{N_t}(y)(v_h)_x(b_1, y) = g_{4,h}^{N_t}(y).
\end{aligned}$$

Then we compute $z_h \in \mathcal{M}_y^{(1)}$ such that

$$z_h(y) = v_h(c_1, y), \qquad y \in \mathcal{G}_y^{(1)} \cup a_2,$$
$$z_h(c_2) = u_h^I(c_1, c_2).$$

Finally, we obtain the desired u_h^{II} and u_h^{III} from

$$u_h^{II}(x, y) = u_h^{N_t}(x, y), \qquad x \in \mathcal{G}_x^{(1)}, \qquad y \in [a_2, c_2],$$
$$\left.\begin{aligned} \alpha_3^{N_t}(y) u_h^{II}(a_1, y) - \beta_3^{N_t}(y)(u_h^{II})_x(a_1, y) &= g_{3,h}^{N_t}(y), \\ u_h^{II}(c_1, y) &= z_h(y), \end{aligned}\right\} \quad y \in \mathcal{G}_y^{(1)} \cup \{a_2, c_2\},$$

and

$$u_h^{III}(x, y) = u_h^{N_t}(x, y), \qquad x \in \mathcal{G}_x^{(2)}, \qquad y \in [a_2, c_2],$$
$$\left.\begin{aligned} u_h^{III}(c_1, y) &= z_h(y), \\ \alpha_4^{N_t}(y) u_h^{III}(b_1, y) + \beta_4^{N_t}(y)(u_h^{III})_x(b_1, y) &= g_{4,h}^{N_t}(y), \end{aligned}\right\} \quad y \in \mathcal{G}_y^{(1)} \cup \{a_2, c_2\}.$$

This approach guarantees that

$$u_h^I(x, c_2) = u_h^{II}(x, c_2), \qquad x \in [a_1, c_1],$$
$$u_h^{II}(c_1, y) = u_h^{III}(c_1, y), \qquad y \in [a_2, c_2],$$

which means that u_h^I, u_h^{II} are continuous across the interface $\overline{\Omega}_I \cap \overline{\Omega}_{II}$ and that u_h^{II}, u_h^{III} are continuous across the interface $\overline{\Omega}_{II} \cap \overline{\Omega}_{III}$.

Implementation of the ADI OSC scheme for the L-shaped region is similar to that for a rectangular region (see section 2.2). For example, finding $u_h^{n+1/2}(\cdot, y) \in \mathcal{M}_x$, $y \in \mathcal{G}_y^{(1)}$, and $u_h^{n+1/2}(\cdot, y) \in \mathcal{M}_x^{(1)}$, $y \in \mathcal{G}_y^{(2)}$, amounts to solving a collection of independent two-point OSC boundary value problems in the x-directions. Similarly, $u_h^{n+1}(x, \cdot) \in \mathcal{M}_y$, $x \in \mathcal{G}_x^{(1)}$, and $u_h^{n+1}(x, \cdot) \in \mathcal{M}_y^{(1)}$, $x \in \mathcal{G}_x^{(2)}$, are obtained by solving a collection of independent two-point OSC boundary value problems in the y-directions. In our implementation of the third stage of the ADI OSC scheme we use the original conversion of $u_h^{N_t}$ into u_h^I, u_h^{II} since its implementation is simpler than that of converting $u_h^{N_t}$ into u_h^I, u_h^{II}, u_h^{III}. Computing u_h^I and u_h^{II} involves performing two independent conversions on rectangles $\overline{\Omega}_I$ and $\overline{\Omega}_{II}$.

4. ADI schemes for rectangular polygons. For parabolic problems on rectangular polygons, ADI FD methods were considered in [18] and [19], and ADI FEG methods were presented in [12]. It should be noted that for a nonlinear parabolic problem, the second order in time method (2.6) in [12] is the three level ADI Laplace-modified scheme. Implementation of the scheme for Dirichlet boundary conditions uses a technique similar to that of [18] involving disintegrating difference operators. To describe possible complications in ADI FD methods on polygons, we consider the rectangular polygon Ω depicted in Figure 4.1. Suppose that Ω is partitioned with a stepsize h in the x- and y-directions, and that $x_k = kh$, $y_l = lh$ for $k, l = 0, \pm 1, \pm 2, \ldots$. Let Ω_h be the collection of all (k, l) such that $(x_k, y_l) \in \Omega$ and let $\partial\Omega_h$ be the collection of all (k, l) such that $(x_k, y_l) \in \partial\Omega$. Let $\partial\Omega_h^x$ be the collection of all (k, l) such that (x_k, y_l) is a point on a vertical side of $\partial\Omega$, excluding vertices but including the reentrant corners B and C of Ω.

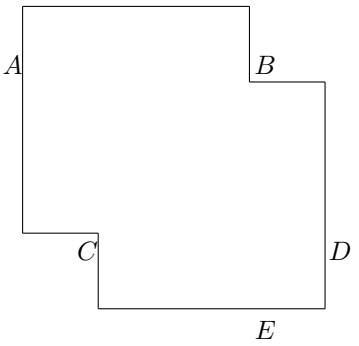

FIG. 4.1. *Rectangular polygon* Ω.

The ADI FD method for the linear problem

$$u_t - u_{xx} - u_{yy} = f(x,y,t), \qquad (x,y,t) \in \Omega \times [0,d],$$
$$u(x,y,0) = g_0(x,y), \quad (x,y) \in \overline{\Omega}, \qquad u(x,y,t) = g_1(x,y,t), \quad (x,y) \in \partial\Omega \times [0,d],$$

is defined for $n = 0, \ldots, N_t - 1$ and $(k,l) \in \Omega_h$ by

$$\frac{u_{k,l}^{n+1/2} - u_{k,l}^{n}}{0.5\tau} - \partial_x^2 u_{k,l}^{n+1/2} - \partial_y^2 u_{k,l}^{n} = f^{n+1/2}(x_k, y_l), \tag{4.1}$$

$$\frac{u_{k,l}^{n+1} - u_{k,l}^{n+1/2}}{0.5\tau} - \partial_x^2 u_{k,l}^{n+1/2} - \partial_y^2 u_{k,l}^{n+1} = f^{n+1/2}(x_k, y_l), \tag{4.2}$$

$$u_{k,l}^{n+1/2} = \frac{1}{2}\left(u_{k,l}^{n+1} + u_{k,l}^{n}\right) - \frac{\tau}{4}\partial_y^2\left(u_{k,l}^{n+1} - u_{k,l}^{n}\right), \qquad (k,l) \in \partial\Omega_h^x, \tag{4.3}$$

where

$$\partial_x^2 v_{k,l} = \frac{v_{k-1,l} - 2v_{k,l} + v_{k+1,l}}{h^2}, \qquad \partial_y^2 v_{k,l} = \frac{v_{k,l-1} - 2v_{k,l} + v_{k,l+1}}{h^2},$$
$$u_{k,l}^{0} = g_0(x_k, y_l), \qquad (k,l) \in \Omega_h \cup \partial\Omega_h,$$
$$u_{k,l}^{n} = g_1^n(x_k, y_l), \qquad n = 1, \ldots, N_t, \qquad (k,l) \in \partial\Omega_h. \tag{4.4}$$

Using (4.1), (4.3), and (4.4), we can compute $u_{k,l}^{n+1/2}$ along all horizontal partition lines except the lines AB and CD. We cannot compute $u_{k,l}^{n+1/2}$ along, for example, the line AB since we do not know u_{k^*,l^*}^{n+1} corresponding to the partition point directly below B and we cannot determine u_{k^*,l^*}^{n+1} by solving (4.2) along the line BE. (There is no such difficulty if Ω is an L-shaped region.) In contrast to the FD scheme, our ADI OSC scheme for Ω in Figure 4.1 does not have any such complications described above since it involves finding $u_h^{n+1/2}$ along horizontal lines passing through the Gauss points and since $L_2^{n+1/2}$ in (2.11) is a differential, rather than difference, operator.

For any rectangular polygon Ω, using our ADI OSC scheme, at each time level we can solve for $u_h^{n+1/2}$ along horizontal lines and then solve for u_h^{n+1} along vertical lines passing through the Gauss points as explained for an L-shaped region in section 3. Once the approximate solution at the final time level is obtained along vertical lines, it is converted into global piecewise polynomials on subrectangles in a similar way as described in section 3; for the polygon Ω in Figure 4.1, the subrectangles of $\overline{\Omega}$ would be $\overline{\Omega}_I$, $\overline{\Omega}_{II}$, and $\overline{\Omega}_{III}$ with the lines AB and CD as two interfaces.

5. Numerical results. For the rectangle Ω of section 2 with $a_1 = a_2 = 0$, $b_1 = b_2 = 1$, and the L-shaped region Ω of section 3 with $a_1 = a_2 = 0$, $b_1 = b_2 = 1$, and $c_1 = c_2 = 1/2$, we present numerical results obtained using our ADI OSC scheme. For $r = 3, 4, 5$ and several increasing values of integer N_i, we use the uniform partitions $\{x_k\}_{k=0}^{N_x^{(i)}} = \{y_l\}_{l=0}^{N_y^{(i)}}$ of $[0,1]$ with $N_x^{(i)} = N_y^{(i)} = N_i$. We give spatial errors in various norms and the corresponding convergence rates determined by the formula

$$\text{Convergence rate} \approx \frac{\log(\varepsilon_i/\varepsilon_{i+1})}{\log(h_i/h_{i+1})},$$

where the stepsize $h_i = 1/N_i$ and ε_i is the error corresponding to h_i. For the L-shaped region, $\epsilon_i = \max(\epsilon_i^I, \epsilon_i^{II})$, where ϵ_i^I and ϵ_i^{II} are the errors corresponding to $\Omega^I = [0, 0.5] \times [0.5, 1]$ and $\Omega^{II} = [0, 1] \times [0, 0.5]$, respectively. For all tests, we give the errors and the rates corresponding to the approximation of $u(\cdot, \cdot, d)$.

For the rectangle and the L-shaped region, we solve problem (1.1)–(1.3), (2.1), (2.2), (3.1), with $d = 1$, the exact solution

$$u(x, y, t) = e^{(1+t)^{-1}+xy}, \tag{5.1}$$

$$\begin{aligned}
&\alpha_1(x,t) = x + t + 2, && \beta_1(x,t) = x^2 + t^2,\\
&\alpha_2(x,t) = \log(x + t + 2), && \beta_2(x,t) = \sin(x + t),\\
&\alpha_3(y,t) = y + t, && \beta_3(y,t) = e^y + t^2 + 3,\\
&\alpha_4(y,t) = 1 + t\sin y, && \beta_4(y,t) = 3 + t\cos y,\\
&\alpha_5(x,t) = \alpha_2(x,t), && \beta_5(x,t) = \beta_2(x,t),\\
&\alpha_6(y,t) = \alpha_4(y,t), && \beta_6(y,t) = \beta_4(y,t),
\end{aligned} \tag{5.2}$$

$$\begin{aligned}
p_1(x, y, t, v, w, z) &= (1 + x^2 + y^2 + t^2)/4 + \tan^{-1}(v^2 + 1) + \cos(w + z) + 2,\\
p_2(x, y, t, v, w, z) &= \sin(x + y) + (t + 4)/3 + \cos v + (1 + \sqrt{w^2 + z^2})^{-1} + 1,
\end{aligned}$$

and

$$f(x, y, t, v, w, z) = \tilde{f}(x, y, t) + v\sin(w) + z^2/(1 + z^2),$$

where

$$\tilde{f} = u_t - p_1(x, y, t, u, u_x, u_y)u_{xx} - p_2(x, y, t, u, u_x, u_y)u_{yy} - u\sin(u_x) - u_y^2/(1 + u_y^2).$$

In Tables 5.1 and 5.2, we give the L^∞ and L^2 errors and the corresponding rates for the rectangle and the L-shaped region, respectively. The boundary conditions are approximated using Gauss interpolants of $g_1, \ldots, g_6$. We select $\tau_i = h_i^{(r+1)/2}$ ($N_t^{(i)} = N_i^{(r+1)/2}$) to demonstrate numerically the expected second order accuracy in t and $r+1$ order accuracy in space. In Table 5.1, we also give CPU times (in seconds) which confirm the theoretical analysis of section 2.2, showing that the total cost of our scheme is $O(r^4 N_i^{2+(r+1)/2})$. The time results also indicate that to achieve a given accuracy, the scheme takes less time for a larger value of r.

In Tables 5.3 and 5.4, we give the L^∞ errors in u_x, u_y, H^1 errors, and the corresponding rates for the rectangle and the L-shaped region, respectively. The boundary conditions are approximated using Gauss interpolants of $g_1, \ldots, g_6$. We choose $\tau_i = h_i^{r/2}$ ($N_t^{(i)} = N_i^{r/2}$) to demonstrate numerically the expected second order accuracy in t and r order accuracy in space.

In Tables 5.5 and 5.6, we give the maximum absolute value errors in $u(x_k, y_l, d)$, $u_x(x_k, y_l, d)$, $u_y(x_k, y_l, d)$, $k, l = 0, \ldots, N_i$. We approximate the boundary conditions using Hermite interpolants of $g_1, \ldots, g_6$. We take $\tau_i = h_i^{r-1}$ ($N_t^{(i)} = N_i^{r-1}$) to demonstrate numerically the expected second order accuracy in t and $2r-2$ order accuracy in space. Such an order of accuracy in space indicates the phenomenon of superconvergence.

We point out that for the L-shaped region, the L^∞ rates for u_x and u_y are both approximately between $r-1/2$ and r (cf. Table 5.4). Also in the case of the L-shaped region, the phenomenon of superconvergence is observed for the maximum norm error in u at the nodes, whereas the rates of convergence for the maximum norm error in u_x and u_y at the nodes are both between $2r-5/2$ and $2r-2$ (cf. Table 5.6). These results are expected for the L-shaped region and are consistent with the observed results for elliptic problems [3].

In the last example, we use the modification of our scheme described in Remark 2.9 to solve an equation of the form (1.4). In fact, for the rectangle Ω with $a_1 = a_2 = 0$, $b_1 = b_2 = 1$, we solve problem (1.5), (1.2), (2.1), (2.2) with the exact solution (5.1), α_i and β_i, $i = 1, 2, 3, 4$, of (5.2),

$$q_1(x, y, t, u, u_x, u_y) = \tan^{-1}\left(1 + \sqrt{u_x^2 + u_y^2}\right) u_x,$$

$$q_2(x, y, t, u, u_x, u_y) = \tan^{-1}\left(1 + \sqrt{u_x^2 + u_y^2}\right) u_y,$$

and

$$f(x, y, t, v, w, z) = u_t - (q_1(x, y, t, u, u_x, u_y))_x - (q_2(x, y, t, u, u_x, u_y))_y.$$

TABLE 5.7
Rectangle; L^∞, L^2 errors in $u(\cdot,\cdot,d)$.

r	N_i	L^∞ error	Rate	L^2 error	Rate
3	4	0.731–03		0.516–03	
	16	0.290–05	3.988	0.205–05	3.987
	36	0.113–06	3.999	0.803–07	3.998
4	4	0.184–03		0.131–03	
	16	0.181–06	4.996	0.129–06	4.995
	36	0.314–08	4.999	0.224–08	4.999
5	4	0.462–04		0.330–04	
	16	0.113–07	5.998	0.809–08	5.997
	36	0.887–10	5.978	0.636–10	5.975

(The elliptic operator in this problem is $A_4 u$ on page 284 of [29].) In order to apply the modified scheme, (1.5) is first transformed, as discussed in section 1 (cf. (1.6)), into an equation of the form (1.4). The boundary conditions are approximated using Gauss interpolants of $g_1, \ldots, g_4$. In Table 5.7, for $\tau_i = h_i^{(r+1)/2}$ ($N_t^{(i)} = N_i^{(r+1)/2}$), we give the L^∞ and L^2 errors and the corresponding rates. The results confirm the expected second order accuracy in t and $r+1$ order accuracy in space.

SIMULTANEOUS PSEUDO-TIMESTEPPING FOR AERODYNAMIC SHAPE OPTIMIZATION PROBLEMS WITH STATE CONSTRAINTS*

S. B. HAZRA† AND V. SCHULZ†

Abstract. This paper presents a numerical method for constrained aerodynamic shape optimization problems. It is based on simultaneous pseudo-timestepping in which stationary states are obtained by solving the pseudo-stationary system of equations representing the state, costate, and design equations. The main advantages of this method are that it blends in nicely with a previously existing pseudo-timestepping method for the states only, and that a preconditioner can be used for convergence acceleration which stems from the reduced SQP methods. Design examples for drag reduction with constant lift and drag reduction with constant pitching moment for an RAE2822 airfoil are included. The overall cost of computation is 4–8 times that of the forward simulation runs depending on the grid size and the number of design parameters.

1. Introduction.

With the increase in efficiency of computer technology and availability of robust numerical methods, automated aerodynamic shape optimization is currently in practice. Using present-day computational fluid dynamics (CFD) methods, it is possible to compute the flow field very accurately around a complete aircraft in a few hours' time. Also, numerical algorithms for optimization methods are making significant improvements. Therefore, it is one of the goals of researchers in the field of aerodynamic design to combine both so that multidisciplinary design can be carried out in a reasonable amount of time using the current computational facilities. Considerable progress in this direction has been made in the past few years.

In control theory based design methods, as presented in [27, 28, 29, 30, 18], a control function (parameterized) is optimized to achieve the goal or objective subject to given constraints which relate the control function and the objective or cost function. Among various methods used for this purpose, gradient based optimization methods are used in most practical applications. In this method, the gradient information of the cost function with respect to the parameters, also known as sensitivities, is used to find a direction toward achieving the goal. Once the direction is found, a step, determined by some means which is known as line search or globalization strategy, toward this direction is taken in each optimization iteration. This process is continued until convergence.

The overall process is difficult due to various reasons. The constraints are nonlinear partial differential equations, known as state equations (e.g., Euler equations or Reynolds-averaged Navier–Stokes equations together with turbulence modeling). Currently available CFD is a remedy to this difficulty. Another difficulty lies in the

numerical optimization algorithm. If a gradient based iterative method, e.g., steepest descent, conjugate gradient, or quasi-Newton method, is used, then several requirements are to be fulfilled for convergence of the method. The sensitivity derivatives required for this method are computed using the continuous adjoint approach which has advantage over the finite difference approach. In this approach, another set of partial differential equations, known as adjoint or costate equations, are to be solved. In each iteration of this method one has to solve the state and costate equations sufficiently accurately. This has to be repeated several times until the convergence of the optimization algorithm. Therefore, in spite of using high fidelity CFD, the overall cost is quite high to get an optimal solution. Computational results based on these methodologies have been presented in [19, 20, 32, 33, 10, 12] on structured grids. An application of this method on unstructured grids has been presented in [1]. This approach with less accurate state and costate solutions has been performed in Iollo, Kuruvila, and Ta'asan [31].

In [15] we proposed a new method for solving such problems using simultaneous pseudo-timestepping. It is well known that there is a strong correlation between iterative methods and pseudo-timestepping [24, 7] which has been exploited for construction of a timestepping method in the spirit of reduced sequential quadratic programming (RSQP) methods. This formulation is advantageous since the steady-state flow is obtained by integrating the pseudo-unsteady Euler (or Navier–Stokes) equations in this problem class. Therefore, one can use the same timestepping scheme for the whole set of equations, and preconditioners can be used to accelerate the convergence. Certain preconditioners are equivalent to SQP methods, whose mathematical background is well studied. In [14, 16] we have implemented that method for the shape design example using Euler equations.

Practical shape design problems involve additional state constraints, e.g., shape optimization of aircraft for drag reduction with constant lift. Applications of traditional gradient methods to such problems are made in, among others, [5, 6, 12]. The computational effort required is about 40 forward simulation runs and 9 adjoint runs for each of the objective functions and of the additional constraints. The methods presented in [15, 14, 16] cannot be extended easily to this larger and more important problem class. Every aspect has to be revised, and additional ideas based on the concept of partially reduced SQP methods [35] come into play, as will be seen later. The basic solution idea is to project the unconstrained design velocity onto the tangent space of the state constraints by solving a quadratic programming (QP) problem involving the reduced Hessian and reduced gradients. Application examples for drag reduction with constant lift and drag reduction with constant pitching moment for an RAE2822 airfoil are included.

The number of iterations required for the full optimization problem is 4–8 times that of the analysis problem. This means a drastic reduction of the computational cost compared to usual gradient methods.

The preconditioner based on RSQP methods causes scaling or damping of the gradients which are used to find a direction. In the convergence histories of all the computations, one observes a linear convergence with respect to the objective; starting from an almost feasible initial guess, each iteration step in the primal, adjoint, and design space is so small that the process truly reflects a continuous behavior. Each integration step of the preconditioned pseudo-time formulation is contracting enough so that no additional globalization strategy is necessary. The preconditioning in the design space gives short enough integration steps that the iterates "surf" along

an almost feasible manifold toward optimality. We do not have theoretical proof of convergence of the method as yet. This will be taken up in the near future. Here we provide computational results for two different reduced Hessian approximations, showing evidence that a better approximation leads to faster convergence. Also, computational results are provided for different numbers of design parameters, different state constraints, and different grid sizes. The computational results show evidence of numerical convergence in all cases.

The paper is organized as follows. We explain the unconstrained simultaneous pseudo-timestepping method in the next section. Section 3 presents the problem with additional constraints and its reduction to preconditioned pseudo-unsteady optimization problems. In section 4, we present the state, costate, and design equations, their discretization, geometry parameterization, gradient computation, and grid perturbation methods. Numerical results are presented in section 5. We draw our conclusions in section 6.

2. Simultaneous pseudo-timestepping for optimization problems. The optimization problem that we are dealing with in this study is of the class of optimal control problems that also includes the subclass of shape design problems. These problems can be written in abstract form as

$$\begin{aligned} &\min\ I(w,q) \\ &\text{s.t.}\quad c(w,q)=0, \end{aligned} \tag{1}$$

where $(w,q) \in X \times P$ (X, P are appropriate Hilbert spaces), and where $I : X \times P \to \mathbb{R}$ and $c : X \times P \to Y$ are twice Frechet-differentiable (with Y an appropriate Banach space). The Jacobian, $J = \frac{\partial c}{\partial w}$, is assumed to be invertible. Here, the equation $c(w,q) = 0$ represents the steady-state flow equations (in our case, Euler equations) together with boundary conditions, w is the vector of state variables, and q is the vector of design variables. The objective $I(w,q)$ is the drag of an airfoil for the purposes of this paper. In what follows, we denote by the notation $()^\top$ the transpose of the vector or the operator. In an optimal control setting, adjoint variables are from the dual space, and the notation should reflect this. However, since ultimately we are dealing with discretized magnitudes, we do not distinguish between finite- and infinite-dimensional adjoints and always use the same notation.

The necessary optimality conditions can be formulated using the Lagrangian functional

$$L(w,q,\lambda) = I(w,q) - \lambda^\top c(w,q), \tag{2}$$

where λ is the Lagrange multiplier or the adjoint variable from the dual Hilbert space. If $\hat{z} = (\hat{w}, \hat{q})$ is a minimum, then there exists a $\hat{\lambda}$ such that

$$\nabla_z L(\hat{z}, \hat{\lambda}) = \nabla_z I(\hat{z}) - \hat{\lambda}^\top \nabla_z c(\hat{z}) = 0. \tag{3}$$

Hence, the necessary optimality conditions are

$$c(w,q) = 0 \quad \text{(state equation)}, \tag{4a}$$

$$\nabla_w L(w,q,\lambda) = 0 \quad \text{(costate equation)}, \tag{4b}$$

$$\nabla_q L(w,q,\lambda) = 0 \quad \text{(design equation)}. \tag{4c}$$

Traditional so-called black-box methods, such as the steepest descent method or the conjugate gradient method, involve the solution of the state and costate equations at

each update of the design variables. These methods act only in the design space and assume that the state and costate equations are solved sufficiently accurately. This leads to very high computational cost for these methods.

In order to determine the solution of this system by use of a simultaneous pseudo-timestepping method we look for steady-state solutions of the following pseudo-time embedded evolution equations:

$$\begin{aligned} \frac{dw}{dt} + c(w,q) &= 0, \\ \frac{d\lambda}{dt} + \nabla_w L(w,q,\lambda) &= 0, \\ \frac{dq}{dt} + \nabla_q L(w,q,\lambda) &= 0. \end{aligned} \tag{5}$$

This formulation is advantageous since the steady-state flow is obtained by integrating the pseudo-unsteady Euler (or Navier–Stokes) equations in this problem class. However, this pseudo-time embedded system is usually a stiff system of ODEs. Therefore explicit timestepping schemes (which are used in most applications of this problem class) may converge very slowly or may even diverge. In order to accelerate convergence, this system needs preconditioning. The preconditioner that we use stems from RSQP methods as discussed below.

2.1. Preconditioners. For the solution of problem (1), we recall a straightforward RSQP method. A detailed discussion of this approach can be found in [34, 35]. Here we present the outline of the method.

RSQP methods are related to projected Lagrangian methods (cf. [13]) and are most advantageous in cases where the number of degrees of freedom (here the design parameters) is small compared to the number of state variables. The variable steps in each iteration can be considered linear combinations of steps toward optimality and steps toward feasibility of the constraints. The constraints are linearized by a Taylor expansion up to first order terms, so that all steps toward optimality lie in the tangent space of c of the current approximation (w,q):

$$T_{(w,q)}c = \left\{ \begin{pmatrix} \Delta w \\ \Delta q \end{pmatrix} \middle| \, c(w,q) + J(w,q)\,\Delta w + \frac{\partial c}{\partial q}(w,q)\,\Delta q = 0 \right\}.$$

The optimization problem is projected to this tangent space and approximated by a quadratic problem with the projected Hessian of the Lagrangian given by (2).

In this method, the computationally expensive operation of computing the exact projected Hessian is typically avoided by using appropriate update formulas. It can be proved that under mild conditions the reduced SQP method with the update formulas for the reduced Hessian shows superlinear local convergence properties (see [34]).

In the above method, it is necessary to invert the Jacobian J of the constraints. In many cases, that is not a viable approach. The following considerations allow one to replace J with an approximate operator A which is invertible with comparatively low cost.

To this end, one employs an inexact RSQP method as introduced in [35]. Although it is not inverted, the Jacobian is still used for the computation of the correct adjoint variables and the correct state increments in the sense of defect correcting iterations. The algorithm of this method reads as follows.

ALGORITHM 1. The RSQP method with an approximate Jacobian.

(0) Set $k := 0$, $\lambda_0 = 0$; start at some initial guess w_0, q_0.
(1) Compute the increment of the adjoint variables from the linear system with the adjoint operator $A^\top$:
$A^\top(w_k, q_k)\,\Delta\lambda_k := \nabla_w I(w_k, q_k) - J^\top(w_k, q_k)\,\lambda_k$;
compute the reduced gradient
$\gamma_k := \nabla_q I(w_k, q_k) - (\frac{\partial c}{\partial q}(w_k, q_k))^\top(\lambda_k + \Delta\lambda_k)$;
determine some approximation B_k of the projected Hessian of the Lagrangian.
(2) Solve $B_k \Delta q_k = -\gamma_k$.
(3) Compute step on w from the linear system
$A(w_k, q_k)\,\Delta w_k := -\frac{\partial c}{\partial q}(w_k, q_k)\,\Delta q_k - c(w_k, q_k)$.
(4) Set $w_{k+1} := w_k + \Delta w_k$, $q_{k+1} := q_k + \Delta q_k$, and $\lambda_{k+1} = \lambda_k + \Delta\lambda_k$.
(5) $k := k + 1$; go to (1) until convergence.

A step of this method can also be interpreted as an approximate Newton step for the necessary conditions of finding the extremum of problem (1), since the updates of the variables are computed according to the linear system

$$\begin{pmatrix} 0 & 0 & A^\top \\ 0 & B & \left(\frac{\partial c}{\partial q}\right)^\top \\ A & \frac{\partial c}{\partial q} & 0 \end{pmatrix} \begin{pmatrix} \Delta w \\ \Delta q \\ \Delta\lambda \end{pmatrix} = \begin{pmatrix} -\nabla_w L \\ -\nabla_q L \\ -c \end{pmatrix}. \tag{6}$$

This is the basic formulation of the inexact RSQP methods that we use in the subsequent sections.

2.2. Preconditioned system for pseudo-timestepping in optimization problems. The necessary conditions (4a)–(4c) for optimization can be considered as an overall nonlinear equation,

$$F(w, \lambda, q) = \begin{pmatrix} \nabla_w L(w, \lambda, q) \\ \nabla_q L(w, \lambda, q) \\ c(w, \lambda, q) \end{pmatrix} = 0,$$

which must be solved. In this way, it would be possible to perform an optimization strategy in a consistent way with the timestepping method.

In our implementation, we use the inverse of the matrix in (6) as a preconditioner for the timestepping process. The pseudo-time embedded system of ODEs that we consider is

$$\begin{pmatrix} \dot{w} \\ \dot{q} \\ \dot{\lambda} \end{pmatrix} = K \begin{pmatrix} -\nabla_w L \\ -\nabla_q L \\ -c \end{pmatrix}, \tag{7}$$

where

$$K = \begin{bmatrix} 0 & 0 & A^\top \\ 0 & B & \left(\frac{\partial c}{\partial q}\right)^\top \\ A & \frac{\partial c}{\partial q} & 0 \end{bmatrix}^{-1} = \begin{bmatrix} A^{-1}\frac{\partial c}{\partial q}B^{-1}\left(\frac{\partial c}{\partial q}\right)^\top A^{-\top} & -A^{-1}\frac{\partial c}{\partial q}B^{-1} & A^{-1} \\ -B^{-1}\left(\frac{\partial c}{\partial q}\right)^\top A^{-\top} & B^{-1} & 0 \\ A^{-\top} & 0 & 0 \end{bmatrix}.$$

This seems natural since (6) can be considered as an explicit Euler discretization for the corresponding timestepping that we envision. Also, due to its block structure, it is computationally inexpensive. The preconditioner employed is similar to the preconditioners for KKT systems discussed in [3, 2] in the context of Krylov subspace methods and in [4] in the context of Lagrange–Newton–Krylov–Schur methods.

Within the inexact RSQP preconditioner, one has to look for an appropriate approximation of the reduced Hessian, B. In particular, when dealing with partial differential equations constituting the state equations, the reduced Hessian can often be expressed as a pseudo-differential operator, the symbol of which can be computed and exploited for preconditioning purposes as in [15]. Here we use an update formula involving second order information similar to BFGS updates, as explained in section 5.

3. Scalar state constraints. Adding a scalar state constraint to problem (1) results in

$$\begin{aligned} &\min\ I(w,q) \\ &\text{s.t.}\quad c(w,q)=0, \\ &\qquad h(w,q)=0,\ \in\mathbb{R}. \end{aligned} \tag{8}$$

Typically, in practical applications, the additional constraints are of the form

$$h(w,q)\geq 0$$

and represent the validity region of the model or the design construction. For the sake of simplicity in presentation we discuss only equality constraints, which is the case in our application. Inequality constraints can be handled by an active set strategy (see, for example, [8]), which is trivial for a scalar inequality. More difficult constraints, e.g., constraints in contact problems, which are not scalar valued, are beyond the scope of this paper.

One approximate Newton step for necessary conditions of problem (8) corresponding to an RSQP method is derived from the following system of equations:

$$\begin{pmatrix} 0 & 0 & \left(\dfrac{\partial h}{\partial w}\right)^{\top} & A^{\top} \\ 0 & B & \left(\dfrac{\partial h}{\partial q}\right)^{\top} & \left(\dfrac{\partial c}{\partial q}\right)^{\top} \\ \dfrac{\partial h}{\partial w} & \dfrac{\partial h}{\partial q} & 0 & 0 \\ A & \dfrac{\partial c}{\partial q} & 0 & 0 \end{pmatrix} \begin{pmatrix} \Delta w \\ \Delta q \\ \Delta\mu \\ \Delta\lambda \end{pmatrix} = \begin{pmatrix} -\nabla_w L \\ -\nabla_q L \\ -h \\ -c \end{pmatrix}, \tag{9}$$

where μ is the Lagrange multiplier corresponding to the additional state constraint $h(w,q)$. In the following we use Gaussian elimination for partial reduction of this system.

LEMMA 3.1.

$$\begin{pmatrix} B & g_h \\ g_h^{\top} & 0 \end{pmatrix} \begin{pmatrix} \Delta q \\ \Delta\mu \end{pmatrix} = \begin{pmatrix} -\nabla_q L + \left(\dfrac{\partial c}{\partial q}\right)^{\top} A^{-\top}\nabla_w L \\ -h + \dfrac{\partial h}{\partial w}A^{-1}c \end{pmatrix}, \tag{10}$$

[illegible] $g_h = (\frac{\partial h}{\partial q} - \frac{\partial h}{\partial w} A^{-1} \frac{\partial c}{\partial q})^\top$ [illegible] $h(w,q)$ [illegible]. We use simple elimination of the variables Δw and $\Delta\lambda$ from (9). The last equation gives

$$\Delta w = A^{-1}\left(-c(w,q) - \frac{\partial c}{\partial q}\Delta q\right).$$

Substitution of this for Δw in the third equation results in

$$\left(\frac{\partial h}{\partial q} - \frac{\partial h}{\partial w}A^{-1}\frac{\partial c}{\partial q}\right)\Delta q = -h + \frac{\partial h}{\partial w}A^{-1}c.$$

If we define

$$g_h := \left(\frac{\partial h}{\partial q} - \frac{\partial h}{\partial w}A^{-1}\frac{\partial c}{\partial q}\right)^\top = \begin{bmatrix} -A^{-1}\dfrac{\partial c}{\partial q} \\ I \end{bmatrix}^\top \begin{bmatrix} \nabla_w h \\ \nabla_q h \end{bmatrix}$$

as the reduced gradient of $h(w,q)$, one obtains

$$g_h^\top \Delta q = -h + \frac{\partial h}{\partial w}A^{-1}c. \tag{11}$$

From the first equation one gets

$$\Delta\lambda = A^{-\top}\left(-\nabla_w L - \left(\frac{\partial h}{\partial w}\right)^\top \Delta\mu\right).$$

Substitution in the second equation results in

$$B\Delta q + \left(\left(\frac{\partial h}{\partial q}\right)^\top - \left(\frac{\partial c}{\partial q}\right)^\top A^{-\top}\left(\frac{\partial h}{\partial w}\right)^\top\right)\Delta\mu = -\nabla_q L + \left(\frac{\partial c}{\partial q}\right)^\top A^{-\top}\nabla_w L.$$

This can be written in terms of the reduced gradient as

$$B\Delta q + g_h\Delta\mu = -\nabla_q L + \left(\frac{\partial c}{\partial q}\right)^\top A^{-\top}\nabla_w L. \tag{12}$$

Writing (11) and (12) in matrix vector notation results in the new system (10). ∎

We use this reduction strategy in the following to solve problem (8) using simultaneous pseudo-timestepping. The preconditioned pseudo-time embedded nonstationary system to be solved reads as

$$\begin{pmatrix} 0 & 0 & \left(\dfrac{\partial h}{\partial w}\right)^\top & A^\top \\ 0 & B & \left(\dfrac{\partial h}{\partial q}\right)^\top & \left(\dfrac{\partial c}{\partial q}\right)^\top \\ \dfrac{\partial h}{\partial w} & \dfrac{\partial h}{\partial q} & 0 & 0 \\ A & \dfrac{\partial c}{\partial q} & 0 & 0 \end{pmatrix} \begin{pmatrix} \dot w \\ \dot q \\ \dot\mu \\ \dot\lambda \end{pmatrix} = \begin{pmatrix} -\nabla_w L \\ -\nabla_q L \\ -h \\ -c \end{pmatrix}. \tag{13}$$

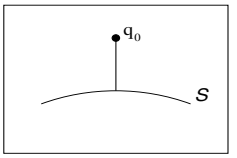

FIG. 1. *Projection.*

This problem is reduced to the QP problem (Lemma 3.1)

$$\begin{aligned} &\min \ \frac{1}{2}\dot{q}^\top B\dot{q} + g^\top \dot{q} \\ &\text{s.t.} \quad g_h^\top \dot{q} = -h(w,q) + \frac{\partial h}{\partial w} A^{-1} c, \end{aligned} \tag{14}$$

where $g = (\nabla_q L - (\frac{\partial c}{\partial q})^\top A^{-\top} \nabla_w L)$ is the reduced gradient of the objective function. For the construction of the reduced gradients g and g_h, one has to solve one adjoint problem (approximately) for g and one for g_h.

LEMMA 3.2. [illegible] (14) [illegible] (10) [illegible] $\dot{q}$ [illegible] $\dot{\mu}$ [illegible] (14)) [illegible]. Writing the Lagrangian of the system and a straightforward calculation of the first order necessary conditions will lead to the result. ∎

Therefore, this reduction can be interpreted as a projection of the design velocity from (7) toward the linearized lift constraint, thus resembling dynamic projection strategies onto invariants as in [36].

3.1. Back projection. Due to the nonlinearity of the problem there is some deviation from the additional state constraint. Therefore we use the following correction strategy in each optimization step to avoid this deviation. We minimize the distance between the point q_0 and the manifold $\mathcal{S}$ of constant lift $\mathcal{S} = \{q \,|\, h(w(q)) = l_0\}$ (Figure 1). That means we solve ideally the problem

$$\begin{aligned} &\min \ \tfrac{1}{2}||q - q_0||^2 \\ &\text{s.t.} \quad h(w(q)) - l_0 = 0. \end{aligned} \tag{15}$$

We use one step of a generalized Gauss–Newton method to solve this problem. Since the stiffness matrix of the flow equations is approximated by A when forming the reduced gradient g_h, we compute the step Δq from

$$\begin{aligned} &\min \ \frac{1}{2}||\Delta q||^2 \\ &\text{s.t.} \quad g_h^\top \Delta q = -h(w,q) + \frac{\partial h}{\partial w} A^{-1} c. \end{aligned} \tag{16}$$

The necessary optimality conditions will lead to the system of equations

$$\begin{pmatrix} I & g_h \\ g_h^\top & 0 \end{pmatrix} \begin{pmatrix} \Delta q \\ \nu \end{pmatrix} = \begin{pmatrix} 0 \\ -\left(h(w,q) - \dfrac{\partial h}{\partial w} A^{-1} c\right) \end{pmatrix},$$

where ν is the Lagrange multiplier for the system (16). Solving this system gives

$$\Delta q = \frac{-(h(w,q) - \frac{\partial h}{\partial w} A^{-1} c)}{g_h^\top g_h} g_h.$$

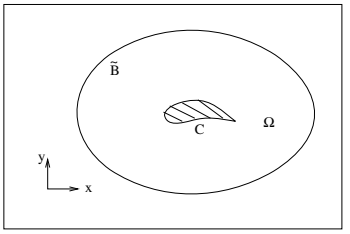

FIG. 2. *Physical domain of the problem.*

Hence, the corrected step is given by

$$q^{k+1} = q_0^{k+1} - \Delta q. \tag{17}$$

The overall algorithm reads as follows.

ALGORITHM 2. The simultaneous pseudo-timestepping for the preconditioned system.

(0) Set $k := 0$; start at some initial guess w_0, λ_0, and q_0.
(1) Compute λ^{k+1} marching one step in time for the adjoint equations.
(2) Compute sensitivities using state and adjoint solutions (using (28)).
(3) Determine some approximation B_k of the projected Hessian of the Lagrangian (for example, using (31)).
(4) Solve the quadratic subproblem (14) to get $\dot{q}$.
(5) March in time one step for the design equation as follows: $q_0^{k+1} = q^k + \Delta t \cdot \dot{q}$
(6) Use the correction step (17) for the new step.
(7) Compute w^{k+1} marching one step in time for the state equations.
(8) Set $k := k + 1$; go to (1) until convergence.

In the current implementation, $A^{-1}c$ in the right-hand side of the constraint in (14) is approximated by (scaled) $\dot{w}$ value from the previous iteration as it is updated only at step (7) of the above algorithm. The scaling factor depends on the accuracy of the state solution achieved in one time step as well as discretization of the parameter space. The size of the vector $\dot{w}$ is caused by the "orthogonal step" $A^{-1}c$ as well as by the tangential optimization step. Therefore it is only a crude measure for $A^{-1}c$. In our applications the scaling factor lies between 0.01 and 0.04. If we were to work with a sufficiently converged state solution, then c would be almost equal to 0. Since we do not work with a sufficiently converged solution, this approximation is necessary. Δt in step (5) of the algorithm is the minimum time step length of the forward solver. It is a "one-shot" method since we perform one time step for each design update.

4. Detailed equations of the aerodynamic shape optimization problem. In this section we explain briefly the state, costate, and design equations represented in equations (4a)–(4c) for the shape optimization problem.

State equations. Since we are interested in the steady flow, a proper approach for numerical modeling is to integrate the unsteady Euler equations in time until a steady state is reached. These equations in Cartesian coordinates (x, y) for two-dimensional flow can be written in integral form for the region Ω with boundaries $\partial\Omega$ $(= \tilde{B} \cup C)$ (see Figure 2) as

$$\frac{\partial}{\partial t} \int_\Omega w \, d\Omega + \int_{\partial\Omega} F \cdot \vec{n} \, ds = 0, \tag{18}$$

where $\vec{n}$ denotes the unit outward normal to $\partial\Omega$ and

$$w := \begin{pmatrix} \rho \\ \rho u \\ \rho v \\ \rho E \end{pmatrix}, \qquad F := [f, g], \qquad f := \begin{pmatrix} \rho u \\ \rho u^2 + p \\ \rho uv \\ \rho uH \end{pmatrix}, \quad \text{and} \quad g := \begin{pmatrix} \rho v \\ \rho uv \\ \rho v^2 + p \\ \rho vH \end{pmatrix},$$

where ρ, u, v, p, E, and H denote density, x- and y-components of velocity, pressure, total energy, and enthalpy, respectively. For a perfect gas the pressure and total enthalpy are given by

$$p = (\gamma - 1)\rho \left\{ E - \frac{1}{2}(u^2 + v^2) \right\}, \quad H = E + \frac{p}{\rho},$$

respectively, with γ denoting the ratio of specific heats. The boundary conditions used to solve these equations are the zero normal velocity on the solid wall, and the far field boundary is treated by considering the incoming and outgoing characteristics based on the one-dimensional Riemann invariants.

The cost function that we choose in the present optimization problem is drag reduction. Hence, the cost function reads as

$$I(w, q) := C_D = \frac{1}{C_{ref}} \int_C C_p \left(n_x \cos\alpha + n_y \sin\alpha \right) ds, \tag{19}$$

where C_{ref} denotes the chord length, α denotes the angle of attack, n_x and n_y denote the components of the unit outward normal, and the surface pressure coefficient is defined by

$$C_p := \frac{2(p - p_\infty)}{\gamma M_\infty^2 p_\infty}. \tag{20}$$

Here M denotes the Mach number, and the quantities with subscript $_\infty$ denote the values at free stream. The additional state constraint is constant lift; that is,

$$h(w, q) := C_L - C_{L0} = \frac{1}{C_{ref}} \int_C C_p \left(n_y \cos\alpha - n_x \sin\alpha \right) ds \; - \; C_{L0}, \tag{21}$$

where C_{L0} is a given constant value. Similarly, the additional state constraint of constant pitching moment is given by

$$h_1(w, q) := C_M - C_{M0} = \frac{1}{C_{ref}^2} \int_C C_p \left(n_y(x - x_m) - n_x(y - y_m) \right) ds \; - \; C_{M0}, \tag{22}$$

where (x_m, y_m) is the pitching moment's reference point and C_{M0} is a given constant value. The airfoil is decomposed into thickness and camber distributions. During the optimization only camberline is modified. This allows the thickness of the airfoil to remain constant (this geometric constraint is necessary; otherwise the optimization will result in a flat plate).

Costate equations. The costate or adjoint Euler equations are given by (see, for example, [11])

$$\frac{\partial}{\partial t} \int_\Omega \lambda \, d\Omega + \int_{\partial\Omega} \bar{F} \cdot \vec{n} \, ds = 0, \tag{23}$$

where the vector λ contains the components of the adjoint variable and $\bar{F}$ is the matrix of adjoint flux density, defined as

$$\lambda := \begin{pmatrix} \lambda_1 \\ \lambda_2 \\ \lambda_3 \\ \lambda_4 \end{pmatrix}, \qquad \bar{F} := \left[\left(\frac{\partial f}{\partial w} \right)^T \lambda \, , \left(\frac{\partial g}{\partial w} \right)^T \lambda \right].$$

The boundary conditions for the adjoint Euler equations on the solid body are of Neumann type, and for the above mentioned cost function they are given by

$$n_x \lambda_2 + n_y \lambda_3 = \text{RHS} \quad \text{on solid wall.} \tag{24}$$

For the above mentioned cost function the right-hand side (RHS) of (24) is

$$\text{RHS} = -\frac{2}{\gamma M_\infty^2 p_\infty C_{ref}} (n_x \cos\alpha + n_y \sin\alpha) \quad \text{on solid wall.} \tag{25}$$

For the lift constraint it is given by

$$\text{RHS} = -\frac{2}{\gamma M_\infty^2 p_\infty C_{ref}} (n_y \cos\alpha - n_x \sin\alpha) \quad \text{on solid wall,} \tag{26}$$

and for the pitching moment constraint it is given by

$$\text{RHS} = -\frac{2}{\gamma M_\infty^2 p_\infty C_{ref}^2} (n_y (x - x_m) - n_x (y - y_m)) \quad \text{on solid wall.} \tag{27}$$

The far field boundary conditions are based on incoming and outgoing characteristics, and free-stream conditions apply here as well. It is important to note that the adjoint Euler equations are linear in λ and the wall boundary conditions depend on the cost function.

Design equation. For the design equation (4c), we need an expression for the derivative of the Lagrangian with respect to the geometry of the airfoil. All the computations are carried out in a generalized coordinate system. Therefore, a transformation is used to transform the physical (x, y)-domain into the computational (ξ, η)-domain. In the computational domain, the components of the gradient $\frac{\partial L}{\partial q}$ can be determined by integrating the adjoint solutions multiplied by the metric sensitivities as follows:

$$\begin{aligned} \left(\frac{\partial L(q + \epsilon \tilde{q})}{\partial q} \right) \Big|_{\epsilon=0} &= -\int_C p(-\lambda_2 \tilde{q}_\xi^y + \lambda_3 \tilde{q}_\xi^x) ds \\ &\quad - \int_\Omega \left(\lambda_\xi^T \left(\tilde{q}_\eta^y f - \tilde{q}_\eta^x g \right) + \lambda_\eta^T \left(-\tilde{q}_\xi^y f + \tilde{q}_\xi^x g \right) \right) d\Omega + T1, \end{aligned} \tag{28}$$

where $\tilde{q}$ is the variation in the geometry of the airfoil and $\tilde{q}^x$, $\tilde{q}^y$ are its x- and y-components. For the sensitivities of the cost function the term $T1$ is given by

$$T1 = \frac{1}{C_{ref}} \int_C C_p \left((\tilde{q}^\perp)^x \cos\alpha + (\tilde{q}^\perp)^y \sin\alpha \right) ds, \tag{29}$$

and for the additional constraint of lift, it is given by

$$T1 = \frac{1}{C_{ref}} \int_C C_p \left((\tilde{q}^\perp)^y \cos\alpha - (\tilde{q}^\perp)^x \sin\alpha \right) ds, \tag{30}$$

where $\left((\tilde{q}^\perp)^x, (\tilde{q}^\perp)^y \right)$ are the components of the unit normal to $\tilde{q}$.

Discretization. The state and costate equations are discretized using a cell centered finite volume scheme. The semidiscrete equations are augmented with first and third order artificial dissipation and then solved using a 5-stage Runge–Kutta type timestepping scheme, as explained in detail in [22, 23].

Surface parameterization. The airfoil is decomposed into thickness and camber distributions. During the optimization only camber distributions are modified. This allows the thickness of the airfoil to remain constant (otherwise the drag reduction problem will result in a flat geometry). In this representation the y-coordinates of the surface are written in parametric form

$$y(\bar{r}) = \sum_{i=1}^{n} \tau_i \psi_i(\bar{r}),$$

where $\bar{r}$ is the coordinate along the airfoil chord, ψ_i are the base functions, and τ_i are the design parameters (here $q = (\tau_1, \tau_2, \ldots, \tau_n)^\top$). In the current study Hicks–Henne functions [17] are selected as base functions which are given by

$$\psi_i(r) = \sin\left(\pi r^{\frac{\ln(0.5)}{\ln(a)}}\right)^b,$$

where a and b control the center and thickness of the perturbations and r is the normalized coordinate along the chord.

Gradient computation. As an efficient method of calculating the gradient $(\delta I)_{m=1,\ldots,n} := \nabla_q I$, we use, as in [11], the so-called grid moving technique based on Reuther's approach (see [21]) for evaluating the integrals (28), which are dependent on the adjoint field vector λ and the metric sensitivities generated by the perturbation of the geometry (by the n design variables). The idea is to allow the geometry perturbation in the whole flow field (the whole grid) while keeping the far field boundary fixed. For this, one introduces a distance function $R(\xi, \eta) = 1 - \frac{\eta}{\eta_B(\xi)}$, where $\eta_B(\xi)$ denotes the values of η at the far field corresponding to the points $(\xi, 0)$ at the wall. Then it holds that

$$R(\xi, 0) = 1 \quad \text{at the wall} \quad \text{and} \quad R(\xi, \eta_B(\xi)) = 0 \quad \text{at the far field.}$$

The grid for the perturbed (new) geometry is defined by

$$x_{new} - x_{old} := R \cdot (x_{new_s} - x_{old_s}),$$

$$y_{new} - y_{old} := R \cdot (y_{new_s} - y_{old_s}),$$

where the index s refers to the values at the surface and x_{new}, y_{new} correspond to x_{new_s}, y_{new_s}, respectively. Thus, the perturbations are

$$\delta x = R \delta x_s, \qquad \delta y = R \delta y_s,$$

where $\tilde{q}^x = \delta x_s$, $\tilde{q}^y = \delta y_s$ in (28), and the metric sensitivities are

$$\delta x_\xi = R \cdot (\delta x_s)_\xi + R_\xi \delta x_s, \quad \delta y_\xi = R \cdot (\delta y_s)_\xi + R_\xi \delta y_s,$$

$$\delta x_\eta = R \cdot (\delta x_s)_\eta + R_\eta \delta x_s, \quad \delta y_\eta = R \cdot (\delta y_s)_\eta + R_\eta \delta y_s.$$

The second term of each of these equalities is very small and, therefore, could be omitted from the above expressions. The effect of this simplification has been studied and justified in [11]. In that case the metric sensitivities can be expressed as

$$\delta x_\xi \approx R \cdot (\delta x_s)_\xi, \quad \delta y_\xi \approx R \cdot (\delta y_s)_\xi,$$

$$\delta x_\eta \approx R \cdot (\delta x_s)_\eta, \quad \delta y_\eta \approx R \cdot (\delta y_s)_\eta,$$

and one obtains the components of the gradient (for the cost function (19)) as integrals along the geometry C:

$$\begin{aligned}\delta I = &- \int_C \left((\delta y_s)_\eta \int_\eta \frac{\partial \lambda^T}{\partial \xi} (R(\eta) \cdot f) d\eta \right) d\xi + \int_C \left((\delta x_s)_\eta \int_\eta \frac{\partial \lambda^T}{\partial \xi} (R(\eta) \cdot g) d\eta \right) d\xi \\ &+ \int_C \left((\delta y_s)_\xi \int_\eta \frac{\partial \lambda^T}{\partial \eta} (R(\eta) \cdot f) d\eta \right) d\xi - \int_C \left((\delta x_s)_\xi \int_\eta \frac{\partial \lambda^T}{\partial \eta} (R(\eta) \cdot g) d\eta \right) d\xi \\ &- \int_C p \left(-\lambda_2 (\delta y_s)_\xi + \lambda_3 (\delta x_s)_\xi \right) d\xi + \frac{1}{S_{ref}} \int_C C_p \left((\delta y_s)_\xi \cos\alpha - (\delta x_s)_\xi \sin\alpha \right) d\xi.\end{aligned}$$

The integrals in η have to be evaluated once. Then, for each design variable only the integration in ξ along C remains to be evaluated.

Grid-perturbation strategy. As the shape of the airfoil changes during the optimization process, the location of the grid nodes has to be adjusted. This can be done by generating a new grid after each design iteration or by using a grid-perturbation strategy (as explained in [16]) after each design iteration.

The discretization, surface parameterization, and grid-perturbation strategy are performed in a standard way (cf. [25, 26, 11]).

5. Numerical results and discussion. The optimization method is applied to test cases of the RAE2822 airfoil for drag reduction with constant lift and drag reduction with constant pitching moment. The physical domain is discretized using an algebraically generated (193×33) C-grid. The camberline representation of the airfoil is parameterized by 21 Hicks–Henne parameters. The complete optimization cycle is performed under the optimization platform SynapsPointerPro [9]. We start the optimization iteration with the solution obtained after 500 time steps of the state equations (w_0) and of the costate equations (λ_0). The FLOWer code [25, 26] of the German Aerospace Center (DLR) is used for solving the forward and adjoint equations. These codes are very robust and have been tested in many applications including flow computations for the company AIRBUS-Germany. Therefore, we made no modifications to this code by taking the block matrices A and $A^\top$ corresponding to the state and costate equations in the preconditioner. They are just identity matrices in the current implementation.

The design equation is integrated in time using an explicit Euler scheme, and the state and costate equations are integrated in time using a 5-stage Runge–Kutta scheme. Therefore the time steps used for the three sets of equations are not the same. In the current implementation of FLOWer the time steps are not the same even in each discretization cell as they are determined independently according to the local stability. However, this has no effect on the final solution at steady state.

One of the main issues in using this kind of preconditioned pseudo-timestepping is the approximation of the reduced Hessian. A better approximation leads to faster

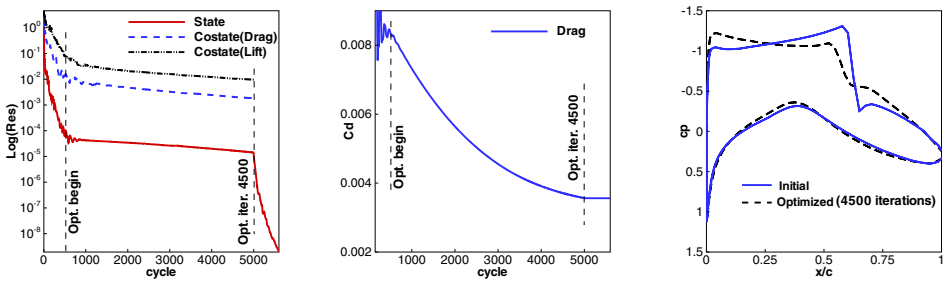

FIG. 3. *Convergence history of the optimization iterations and the comparison of surface pressure distributions.*

convergence of the optimization algorithm. We first take an approximation of the reduced Hessian as

$$B_k = \beta \delta_{ij},$$

where β ($>> 1$) is a constant which is chosen to scale the design updates and δ_{ij} is the Kronecker symbol representing the identity matrix. In the current computation the value of β is 15. The convergence history and the surface pressure distributions of 4500 optimization iterations are presented in Figure 3. As we see from the optimized surface pressure distribution, there is still a weak shock present there, which means that the solution has not yet reached the optimum after 4500 optimization iterations.

Next, we consider the reduced Hessian approximation based on the current gradient and parameter update information. We define $s_k := (q_{k+1} - q_k)$ and $z_k := (\nabla I_{k+1} - \nabla I_k)$, where k represents the iteration number. Then the reduced Hessian approximation is determined based on the sign of the product $(z_k^T s_k)$. If the sign is positive, the reduced Hessian is approximated by

$$B_k = \bar{\beta} \frac{z_k^T s_k}{z_k^T z_k} \delta_{ij}, \tag{31}$$

where $\bar{\beta}$ is a constant. Otherwise, it is approximated by $\beta \delta_{ij}$, where β is another constant. Additionally, we impose upper and lower limits on the factor so that

$$\beta_{min} < \bar{\beta} \frac{z_k^T s_k}{z_k^T z_k} < \beta_{max}.$$

This prevents the optimizer from taking too small or too large steps. The constants β_{min} and β_{max} can be chosen, e.g., depending on the accuracy achieved in one time step by the forward and adjoint solver. In the current computations the values of the constants $\bar{\beta}$, β_{max}, and β_{min} are 6, 15, and 2.5.

The optimization iteration is stopped when $||\Delta q||_\infty < 0.0005$. After the convergence of the optimization iteration, another 600 time steps are performed for the state equation on the optimized geometry to reduce its residual further so that the force coefficients and surface pressure distribution can be compared with those obtained by other methods.

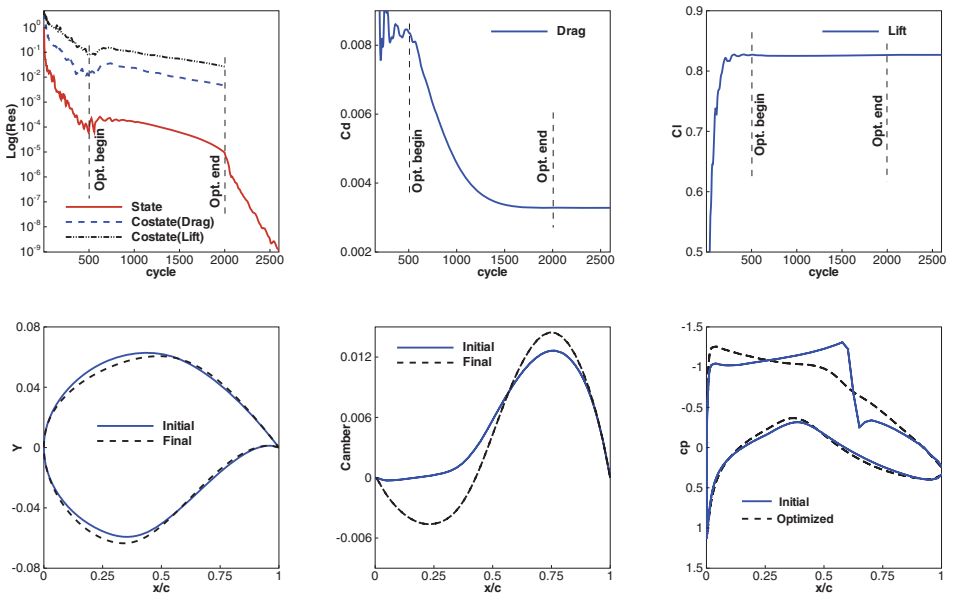

FIG. 4. *Convergence histories* (*top*) *and comparison of initial and final airfoils, camberlines, and surface pressure distributions* (*bottom*) *of the optimization of Case* 1.

TABLE 1

Comparison of number of iterations and force coefficients for baseline and optimized airfoils for different numbers of design parameters (*on* 193×33 *grid*).

Geometry	Iter	CD	ΔC_D	CL	ΔC_L
Baseline		0.849651E-02		0.826600E+00	
Opt.(Case 1, p=21)	1500	0.328198E-02	61.37%	0.826832E+00	-0.028%
Opt.(Case 2, p=40)	750	0.328765E-02	61.30%	0.826671E+00	-0.009%

[illegible] 1 [illegible] 21 [illegible]

The optimization problem requires 1500 iterations to converge. Figure 4 (top) presents the optimization convergence histories of this case. Figure 4 (bottom) presents the comparison of initial and final airfoils, camberlines, and surface pressure distributions. Since the major amount of drag in the transonic regime is caused by the shock, the optimization for drag reduction results in a shockless airfoil. A comparison of the force coefficients for baseline and optimized geometries is presented in Table 1. The drag reduction is 61.37%, and the lift is well maintained with an increase of only 0.028%.

Each forward run and each adjoint run requires approximately 1500 iterations in time to reach a steady state. The total number of time steps required in this case is $(500+1500+600)$ for a state solver, and 2 times $(500+1500)$ for adjoint solvers. This together is approximately 4.4 times that of the forward simulation run. The effort to solve the design equation is almost negligible compared to state or costate solutions. Also, in every optimization iteration the approximate gradients are to be computed twice (once for the drag and once for the lift). Since this is only a matrix-vector product with the current approximations of the adjoints, the time required for this is also negligible compared to that of the state or costate solutions. Additionally, the

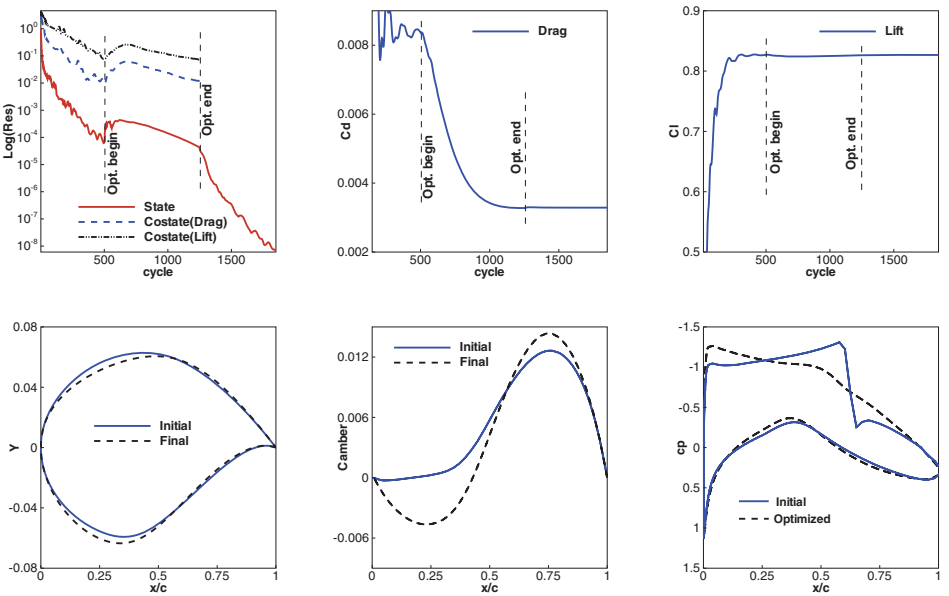

FIG. 5. *Convergence histories* (*top*) *and comparison of initial and final airfoils, camberlines, and surface pressure distributions* (*bottom*) *of the optimization of Case* 2.

simultaneous pseudo-time method needs a new grid, obtained by grid perturbation as discussed earlier, after each optimization iteration. Additional time is required to write the output after every iteration and read the same before each iteration, as the iterations start with solution values from the previous iteration. However, the total time required for this overhead is less than one complete forward run. If we add on everything, the total effort is less than 7 times that of forward simulation runs.

2 40

In this case we use finer parameterization of the design space with 40 design parameters. The optimization problem requires 750 iterations to converge. The faster convergence of the method can be explained from the physics of the problem. The optimization problem deals with drag reduction with additional state constraint. The major drag in the transonic regime is caused by the shock jump. Therefore, the optimizer tries to change the design parameters in such a way that the drag disappears. In a finer parameterization a small change in parameters has more effect on shock than in a coarser parameterization. To achieve the same effect in coarser parameterization one has to have large changes in design parameters, which causes constraint violation. That is why in this particular problem class finer parameterization leads to faster convergence.

Since we use adjoint gradients, the gradient computation is independent of the number of design variables. Therefore, it is advantageous to use finer design space. Figure 5 (top) presents the optimization convergence histories of this case. Figure 5 (bottom) presents the comparison of initial and final airfoils, camberlines, and surface pressure distributions. A comparison of the force coefficients for baseline and optimized geometries is presented in Table 1. The drag reduction is 61.30%, and the lift is increased by only 0.009%. The optimized force coefficients are almost the same

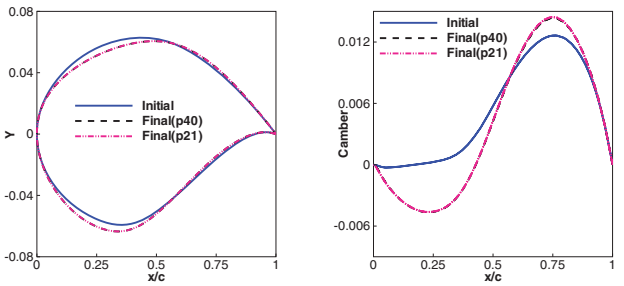

FIG. 6. *Comparison of initial and final airfoils and camberlines of Case* 1 *and Case* 2 *computations.*

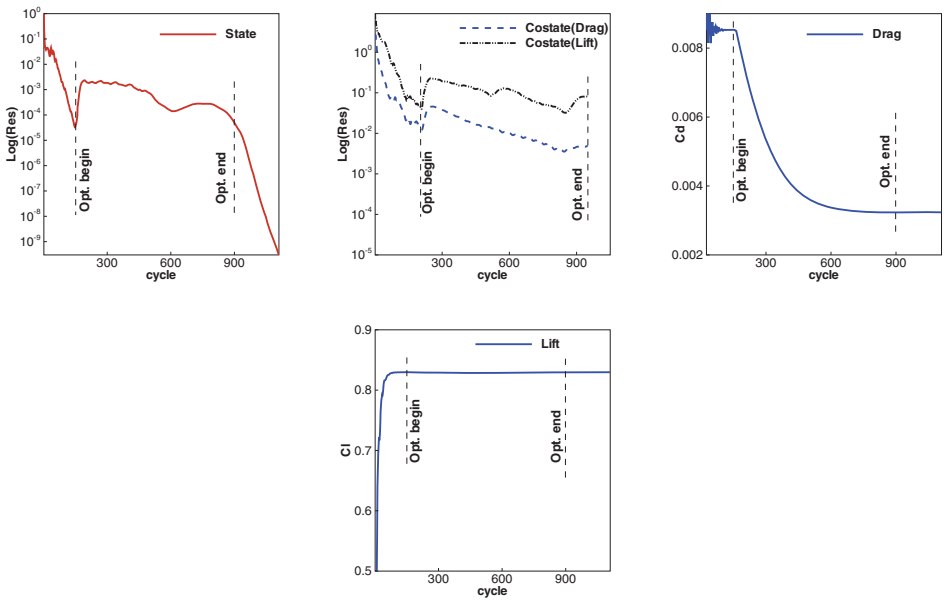

FIG. 7. *Convergence histories of the optimization iteration of Case* 3.

in both cases. Figure 6 presents the comparison of airfoils and camberlines obtained in Cases 1 and 2. Again, there is no noticeable difference. However, the number of optimization iterations is half that of Case 1, and the total effort in this case is less than 5 times that of forward simulation runs.

3 40 321×57

In this case the computational domain is discretized by a finer grid of size 321×57. The forward and adjoint solutions are computed using the multigrid solvers in FLOWer. The optimization is started with initial state solution (w_0) obtained after 150 time steps and costate solution (λ_0) obtained after 200 time steps. The optimization requires 750 iterations to converge. After the convergence of the optimization, another 200 time steps are carried out for the state solution to achieve sufficiently accurate force coefficients. Figure 7 presents the optimization convergence histories

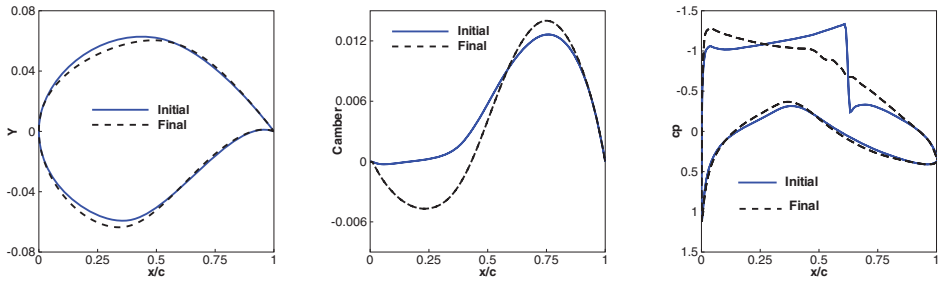

FIG. 8. *Comparison of initial and final airfoils, camberlines, and surface pressure distributions of Case* 3 *computations.*

TABLE 2
Comparison of force coefficients for baseline and optimized airfoils in Case 3 *computation* (*on* 321×57 *grid*).

Geometry	Iter	CD	ΔC_D	CL	ΔC_L
Baseline		0.852910E-02		0.829500E+00	
Opt.(Case 3, p=40)	750	0.323553E-02	62.06%	0.829657E+00	-0.02%

of this case. Figure 8 presents the comparison of initial and final airfoils, camberlines, and surface pressure distributions. A comparison of the force coefficients for baseline and optimized geometries is presented in Table 2. The drag reduction is 62.06% which is a bit more than the last two cases, and the lift is again well maintained by an increase of only 0.02%. In this case the steady-state forward solution is reached by 450 multigrid iterations and thus, if we add up everything, the total effort of the optimization problem is less than 8 forward simulation runs.

4 21

Computations for this case are carried out on a 193×33 grid as in Case 1 (and Case 2) with a different state constraint, namely, pitching moment. The design space is parameterized with 21 design parameters. The optimization problem requires 1400 iterations to converge in this case. Figure 9 (top) presents the optimization convergence histories of this case. Figure 9 (bottom) presents the comparison of initial and final airfoils, camberlines, and surface pressure distributions. Since the major amount of drag in this case also is caused by the shock, the optimization for drag reduction results in a shockless airfoil. A comparison of the force coefficients for baseline and optimized geometries is presented in Table 3. The drag reduction is 60.50% and the pitching moment is well maintained by a decrease of only 0.02%. In this case the total computational effort is approximately 6 times that of forward simulation runs.

5 40

Computations for this case are carried out as in the last case but with 40 design parameters. This requires 625 iterations for the convergence of the optimization problem. In this case also the convergence is faster than that of Case 3 due to finer parameterization of the design space. Figure 10 (top) presents the optimization convergence histories of this case. Figure 10 (bottom) presents the comparison of initial and final airfoils, camberlines, and surface pressure distributions. A comparison of the force coefficients for baseline and optimized geometries is presented in Table 3.

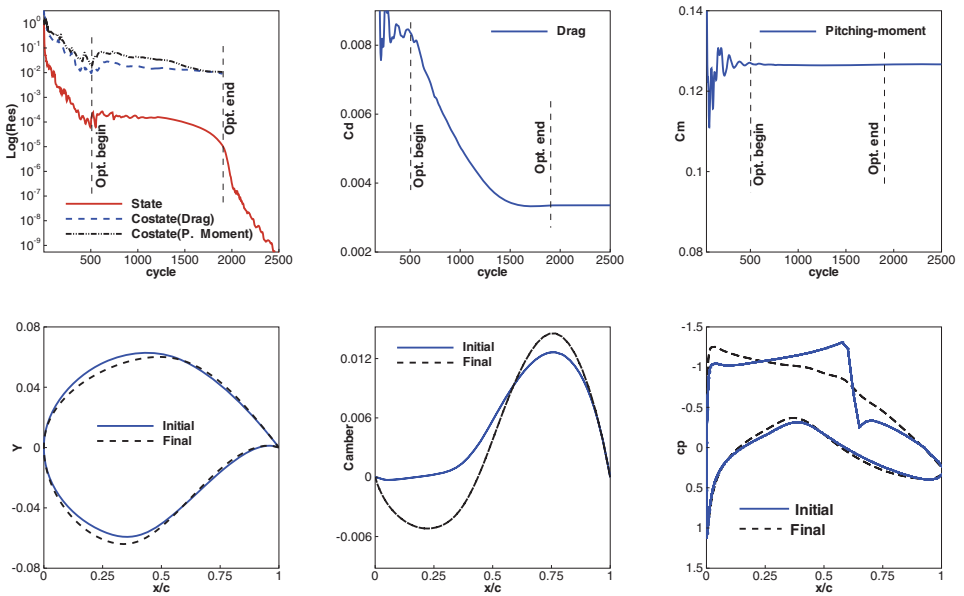

FIG. 9. *Convergence histories (top) and comparison of initial and final airfoils, camberlines, and surface pressure distributions (bottom) of the optimization of Case* 4.

TABLE 3

Comparison of number of iterations and force coefficients for baseline and optimized airfoils for different numbers of design parameters (on 193×33 *grid).*

Geometry	Iter	CD	ΔC_D	CM	ΔC_M
Baseline		0.849651E-02		0.126700E+00	
Opt.(Case 4, p=21)	1400	0.335566E-02	60.50%	0.126669E+00	0.02%
Opt.(Case 5, p=40)	625	0.340304E-02	59.95%	0.126731E+00	-0.02%

The drag reduction is 59.95%, and the pitching moment is well maintained with an increase of only 0.02%. The final force coefficients are almost the same as in Case 4. Figure 11 presents the comparison of initial and final airfoils and camberlines obtained in Cases 4 and 5. There is also no noticeable difference in the optimized airfoils and camberlines obtained in these two cases. Again, as in Case 2, the total computational effort in Case 5 is approximately 4 times that of forward simulation runs.

In the convergence histories of all the figures, one observes a linear convergence with respect to the objective; starting from an almost feasible initial guess (i.e., after 500 state iterations and 500 costate iterations independently (150 and 200 iterations, respectively, for Case 3)), each iteration step in the primal, adjoint, and design space is so small that the process truly reflects a continuous behavior. Each integration step of the preconditioned pseudo-time formulation is contracting enough so that no additional globalization strategy is necessary. The preconditioning in the design space gives short enough integration steps that the iterates "surf" along an almost feasible manifold toward optimality.

We have not made an explicit comparison of our results with those of other optimization methods. However, it is possible to obtain an impression of this comparison if one imagines what optimization progress could be achieved in 3 optimization iter-

ations (that is, 3 forward and 2×3 adjoint simulation runs) of any gradient based methods, since this takes more (9 forward simulation runs) computational effort than our one-shot approach. The CPU time required for the computations on a 193×33 grid is 8–16 minutes and on a 321×57 grid about 30 minutes on a Linux machine with an AMD Opteron processor, cpu 2405 MHz, and 16 MB RAM.

6. Conclusions. A new method has been proposed for aerodynamic shape optimization with state constraints which is based on simultaneous pseudo-timestepping. The preconditioned pseudo-stationary state, costate, and design equations are integrated simultaneously in time until a steady state is reached. The preconditioner used in this study is motivated by a continuous reinterpretation of RSQP methods. Reduced Hessian approximation based on quasi-Newton updates leads to faster convergence than that obtained by using a constant diagonal matrix. The overall cost of

computation is approximately 4–8 times that of forward simulation runs. Application to three-dimensional problems is our next goal.

Acknowledgments. We would like to thank N. Gauger and J. Brezillon for discussions on the FLOWer code and the gradient based optimization methods for FLOWer that currently exist. We also would like to thank the anonymous referees for their comments and suggestions which have substantially improved the exposition.

STRUCTURED TOTAL LEAST SQUARES FOR COLOR IMAGE RESTORATION*

HAOYING FU†, MICHAEL K. NG‡, AND JESSE L. BARLOW†

Abstract. The problem of 3×3 color mixing image restoration is considered. The blurring matrices, as well as the observed image, are contaminated by noise; therefore the total least squares (TLS) method is employed to restore the original image. Since the blurring matrices are also structured, we apply the structured total least squares (STLS) method [J. B. Rosen, H. Park, and J. Glick, *SIAM J. Matrix Anal. Appl.*, 17 (1996), pp. 110–126]. The blurring matrices are generally ill conditioned; thus Tikhonov's regularization is used to stabilize the solution. Since Neumann boundary conditions are used in the restoration process, the discrete cosine transform (DCT) based preconditioner is effective for the linear systems encountered in our STLS algorithm.

1. Introduction.

The color image restoration problem has attracted much research effort recently [2, 8, 9, 12, 15, 17, 22]. A color image may be regarded as a set of three images in the three color components, red, green, and blue. A more general term, multichannel images, is often used to denote color images where each color component is considered as a channel.

In most applications [2], the observed image is distorted by blur and additive noise. Let $f_r(x,y)$, $f_g(x,y)$, and $f_b(x,y)$ be the original red, green, and blue scenes. Let $u_r(x,y)$, $u_g(x,y)$, and $u_b(x,y)$ be the observed red, green, and blue scenes. Let $h_{ij}(x,y)$ (for $i,j \in \{r,g,b\}$) be the within-channel and cross-channel point spread functions, normalized such that each function integrates to 1. Let $n_r(x,y)$, $n_g(x,y)$, and $n_b(x,y)$ be the noise present in the observed image. The image formation process can be modeled as follows [8, 9]:

$$\begin{aligned} u_r &= w_{rr}h_{rr} \star f_r + w_{gr}h_{gr} \star f_g + w_{br}h_{br} \star f_b + n_r, \\ u_g &= w_{rg}h_{rg} \star f_r + w_{gg}h_{gg} \star f_g + w_{bg}h_{bg} \star f_b + n_g, \\ u_b &= w_{rb}h_{rb} \star f_r + w_{gb}h_{gb} \star f_g + w_{bb}h_{bb} \star f_b + n_b. \end{aligned} \tag{1.1}$$

Here w_{ij} (for $i,j \in \{r,g,b\}$) are nonnegative weights that measure the contribution of the original channels to each observed channel, and $\star$ denotes two-dimensional (2D) convolution. We note that at least one of w_{ri}, w_{gi}, and w_{bi} ($i \in \{r,g,b\}$) is nonzero.

Let $\mathbf{f}_i$, $\mathbf{u}_i$, and $\mathbf{n}_i$ (for $i \in \{r,g,b\}$) be the row by row ordering of the discretized original scene, observed scene, and additive noise, respectively. Let H_{ij} (for $i,j \in \{r,g,b\}$) be the blurring matrices of appropriate size built according to the discretized

point spread functions $\mathbf{h}_{ij}$. Then the discretized image formation process can be put into a matrix-vector form:

$$\begin{aligned} \mathbf{u}_r &= w_{rr}H_{rr}\mathbf{f}_r + w_{gr}H_{gr}\mathbf{f}_g + w_{br}H_{br}\mathbf{f}_b + \mathbf{n}_r, \\ \mathbf{u}_g &= w_{rg}H_{rg}\mathbf{f}_r + w_{gg}H_{gg}\mathbf{f}_g + w_{bg}H_{bg}\mathbf{f}_b + \mathbf{n}_g, \\ \mathbf{u}_b &= w_{rb}H_{rb}\mathbf{f}_r + w_{gb}H_{gb}\mathbf{f}_g + w_{bb}H_{bb}\mathbf{f}_b + \mathbf{n}_b. \end{aligned} \tag{1.2}$$

Let

$$\mathbf{f} = \begin{bmatrix} \mathbf{f}_r \\ \mathbf{f}_g \\ \mathbf{f}_b \end{bmatrix}, \quad \mathbf{u} = \begin{bmatrix} \mathbf{u}_r \\ \mathbf{u}_g \\ \mathbf{u}_b \end{bmatrix}, \quad \text{and} \quad \mathbf{n} = \begin{bmatrix} \mathbf{n}_r \\ \mathbf{n}_g \\ \mathbf{n}_b \end{bmatrix},$$

let

$$\mathbf{w} = [w_{rr} \quad w_{gr} \quad w_{br} \quad w_{rg} \quad w_{gg} \quad w_{bg} \quad w_{rb} \quad w_{gb} \quad w_{bb}]^T,$$

and define

$$H(\mathbf{w}) = \begin{bmatrix} w_{rr}H_{rr} & w_{gr}H_{gr} & w_{br}H_{br} \\ w_{rg}H_{rg} & w_{gg}H_{gg} & w_{bg}H_{bg} \\ w_{rb}H_{rb} & w_{gb}H_{gb} & w_{bb}H_{bb} \end{bmatrix}.$$

Equation (1.2) can be written as

$$\mathbf{u} = H(\mathbf{w})\mathbf{f} + \mathbf{n}. \tag{1.3}$$

Very often people use the observed image to recover the original image of the same domain. The observed image is not completely determined by the original image in the region of interest (ROI) because of the convolution. To determine the image, we make assumptions about the pixel values of the original image outside the ROI. The zero boundary condition assumes that the scene outside the ROI is totally dark. When the real scene outside the ROI does not satisfy this assumption well, ringing effects will appear at the boundaries of the restored image. Zero boundary conditions cause the blurring matrices H_{ij} to be block Toeplitz with Toeplitz blocks (BTTB). Neumann boundary conditions assume that the scene outside the ROI is a reflection of the scene inside. This reduces the ringing effects when the image is close to stationary at the boundaries. Using Neumann boundary conditions causes the blurring matrices H_{ij} to be block Toeplitz plus Hankel with Toeplitz plus Hankel blocks (BTHTHB), which in general gives better restoration results than those using zero boundary conditions [16].

Image restoration problems tend to be very ill conditioned. Directly solving (1.2) will yield a solution that is extremely sensitive to noise; therefore regularization methods are needed to stabilize the solution.

There is considerable work in the literature on least squares restoration of color images. Based on the assumption that the within-channel and cross-channel point spread functions are separable, Hunt and Kubler [12] derived a minimum mean squares error (MSE) multichannel restoration filter. Filters that utilize the cross-channel correlation without using the separability assumption can be found in [8] and [9]. More results can be found in [15, 17, 22].

The least squares solution assumes that exact information for the point spread functions, $\mathbf{h}_{ij}$, and the weights, w_{ij}, is available. For single channel image restoration problems, it has been demonstrated [14, 18, 19] that total least squares (TLS)

methods, in particular structured total least squares (STLS) [21] methods, yield better results than the ordinary least squares method when error exists in the blurring matrices. In this paper, we consider applying STLS for the multichannel image restoration problem. Our algorithm extends the basic algorithm presented in [19] and incorporates an efficient preconditioning technique.

The rest of this paper is organized as follows. In section 2, we give a description of the regularized STLS problem. In section 3, we derive our algorithm for solving the regularized STLS problem. In section 4, we propose an efficient way to precondition the linear systems encountered in section 3. Experimental results are shown in section 5, and section 6 concludes this paper.

2. Tikhonov's regularization of the STLS problem. In general the matrix H in (1.3) is ill conditioned. The method of regularization can be used to stabilize the solution. In the classical Tikhonov regularization [11], stability is attained by introducing a penalty term that measures the "irregularity" of the solution. One of the widely used regularization techniques for color image restoration is the one proposed by Galatsanos et al. in [9].

An important concept in the regularization technique of Galatsanos et al. is the "weighted three-dimensional (3D) Laplacian." Let

$$\boldsymbol{\beta} = [\beta_{rg} \quad \beta_{rb} \quad \beta_{gb}]^T = \left[\frac{\|\mathbf{f}_r\|_2}{\|\mathbf{f}_g\|_2} \quad \frac{\|\mathbf{f}_r\|_2}{\|\mathbf{f}_b\|_2} \quad \frac{\|\mathbf{f}_g\|_2}{\|\mathbf{f}_b\|_2} \right]^T, \tag{2.1}$$

and let L be the 2D Laplacian matrix of appropriate size. The "weighted 3D Laplacian" matrix is defined as follows:

$$R(\boldsymbol{\beta}) = \begin{bmatrix} 2I + L & -\beta_{rg} I & -\beta_{rb} I \\ -\frac{1}{\beta_{rg}} I & 2I + L & -\beta_{gb} I \\ -\frac{1}{\beta_{rb}} I & -\frac{1}{\beta_{gb}} I & 2I + L \end{bmatrix}.$$

Note that

$$R(\boldsymbol{\beta}) = D \hat{L} D^{-1},$$

where

$$D = \begin{bmatrix} \|\mathbf{f}_r\|_2 I & 0 & 0 \\ 0 & \|\mathbf{f}_g\|_2 I & 0 \\ 0 & 0 & \|\mathbf{f}_b\|_2 I \end{bmatrix}, \quad \hat{L} = \begin{bmatrix} 2I + L & -I & -I \\ -I & 2I + L & -I \\ -I & -I & 2I + L \end{bmatrix}.$$

Therefore, the operation $R(\boldsymbol{\beta})\mathbf{f}$ can be interpreted as applying the standard 3D Laplacian (with circulant boundary conditions imposed on the third dimension) on a scaled version of $\mathbf{f}$ with the results scaled back afterwards.

Let

$$\Omega = \begin{bmatrix} \alpha_r I & 0 & 0 \\ 0 & \alpha_g I & 0 \\ 0 & 0 & \alpha_b I \end{bmatrix},$$

where α_r, α_g, and α_b are positive constants, and I is the identity matrix of appropriate size.

Denote the elementwise square root of the matrix Ω by $\sqrt{\Omega}$ (note that Ω is a diagonal matrix with positive diagonal elements). The regularization technique of Galatsanos et al. takes the following form:

$$\min_{\mathbf{f}} \|\mathbf{u} - H\mathbf{f}\|_2^2 + \|\sqrt{\Omega}R(\beta)\mathbf{f}\|_2^2. \tag{2.2}$$

In this equation, Ω is used to control the degree of regularization. The constants α_r, α_g, and α_b are called the regularization parameters, and R is called the regularization operator. Notice that R depends on the vector $\boldsymbol{\beta}$, which further depends on the solution. In the literature, it is common practice to use an estimate of $\boldsymbol{\beta}$ rather than the exact $\boldsymbol{\beta}$. However, our algorithm will solve for $\boldsymbol{\beta}$ as part of the problem.

From a statistical point of view, if H is known exactly, the solution to (2.2) can be interpreted as the "maximum a posteriori estimator" of the original image. In this interpretation, the regularization term represents prior information on the original image, the regularization operator reflects the type of prior information, and the parameters α_r, α_g, and α_b indicate our level of confidence in the prior information.

As mentioned earlier, the least squares method assumes that exact information of the blurring matrix is available. In practice, the blurring matrix may also be contaminated by noise. The TLS method allows for the possibility of error in the elements of the blurring matrix H, so that the modified blurring matrix is given by $\tilde{H} = H + E$, where E is the error matrix to be determined. For image restoration problems, because H exhibits certain structures, it is more appropriate to apply STLS [21]. The STLS method requires that $\tilde{H}$ has the same structure as H.

In this paper, our focus is on cases where our knowledge of H_{ij}, for $i, j \in \{r, g, b\}$, is precise but that of $\mathbf{w}$ is inexact. However, the basic algorithms of this paper can be easily modified to handle the case in which our knowledge of H_{ij} is also inexact; see, for instance, [7, 19].

Let

$$\tilde{\mathbf{w}} = [\tilde{w}_{rr} \quad \tilde{w}_{gr} \quad \tilde{w}_{br} \quad \tilde{w}_{rg} \quad \tilde{w}_{gg} \quad \tilde{w}_{bg} \quad \tilde{w}_{rb} \quad \tilde{w}_{gb} \quad \tilde{w}_{bb} \quad]^T$$

be the modified $\mathbf{w}$. From our assumption, it follows that the modified blurring matrix is parameterized by $\tilde{\mathbf{w}}$. Therefore, the regularized STLS problem for color image restoration takes the following form:

$$\min_{\mathbf{f},\tilde{\mathbf{w}}} \|H(\tilde{\mathbf{w}})\mathbf{f} - \mathbf{u}\|_2^2 + \|\sqrt{\Omega}R(\boldsymbol{\beta})\mathbf{f}\|_2^2 + \alpha_h\|\mathbf{w} - \tilde{\mathbf{w}}\|_2^2. \tag{2.3}$$

The last term in this formula can be interpreted as a penalty term for the "irregularity" of the error in $\mathbf{w}$, and α_h can be interpreted as the regularization parameter used to control the degree of regularization on that error.

For simplicity, let

$$\begin{aligned}\mathbf{z} &= \tilde{\mathbf{w}} - \mathbf{w} \\ &= [z_{rr} \quad z_{gr} \quad z_{br} \quad z_{rg} \quad z_{gg} \quad z_{bg} \quad z_{rb} \quad z_{gb} \quad z_{bb}]^T;\end{aligned}$$

then (2.3) becomes

$$\min_{\mathbf{f},\mathbf{z}} \|H(\mathbf{w} + \mathbf{z})\mathbf{f} - \mathbf{u}\|_2^2 + \|\sqrt{\Omega}R(\boldsymbol{\beta})\mathbf{f}\|_2^2 + \alpha_h\|\mathbf{z}\|_2^2. \tag{2.4}$$

Experimental results showed that this formula tends to yield a darker version of the original image and a $\tilde{\mathbf{w}}$ whose elements are systematically larger than those of $\mathbf{w}$

(see Figure 5.8). This way it keeps the residual norm almost unchanged but reduces the "irregularity" of the solution.

To overcome this problem, we add the following constraints to (2.3):

$$\begin{aligned} z_{rr} + z_{gr} + z_{br} &= 0, \\ z_{rg} + z_{gg} + z_{bg} &= 0, \\ z_{rb} + z_{gb} + z_{bb} &= 0. \end{aligned} \tag{2.5}$$

That is, we require the sum of the modified weights for each observed channel to be the same as that of the original ones. Equation (2.5) is an expression of the conservation of intensity values in the color image.

This looks as if an unconstrained optimization problem has been turned into a constrained one. However, since

$$\begin{aligned} z_{br} &= -z_{rr} - z_{gr}, \\ z_{bg} &= -z_{rg} - z_{gg}, \\ z_{bb} &= -z_{rb} - z_{gb}, \end{aligned}$$

now the modified blurring matrix, $\tilde{H}$, is parameterized by only six variables, z_{rr}, z_{gr}, z_{rg}, z_{gg}, z_{rb}, and z_{gb}. Let

$$\hat{\mathbf{z}} = [z_{rr} \quad z_{gr} \quad z_{rg} \quad z_{gg} \quad z_{rb} \quad z_{gb}]^T;$$

then $\hat{\mathbf{z}}$ contains all the information in $\mathbf{z}$.

Note that if the constraints stated in (2.5) are satisfied, then $\mathbf{z} = \Gamma\hat{\mathbf{z}}$ with

$$\Gamma = \operatorname{diag}(\hat{\Gamma}, \hat{\Gamma}, \hat{\Gamma}), \quad \hat{\Gamma} = \begin{bmatrix} 1 & 0 \\ 0 & 1 \\ -1 & -1 \end{bmatrix}.$$

Therefore,

$$\|\mathbf{z}\|_2^2 = \hat{\mathbf{z}}^T \Gamma^T \Gamma \hat{\mathbf{z}}.$$

It is easy to check that the matrix S defined as follows is symmetric positive definite and satisfies $S^2 = \Gamma^T\Gamma$:

$$S = \operatorname{diag}(\hat{S}, \hat{S}, \hat{S}), \quad \text{where } \hat{S} = \begin{bmatrix} \frac{\sqrt{3}+1}{2} & \frac{\sqrt{3}-1}{2} \\ \frac{\sqrt{3}-1}{2} & \frac{\sqrt{3}+1}{2} \end{bmatrix}. \tag{2.6}$$

Therefore, $\|\mathbf{z}\|_2 = \|S\hat{\mathbf{z}}\|_2$.

It follows that our problem can be stated as

$$\min_{\mathbf{f},\hat{\mathbf{z}}} \|H(\mathbf{w} + \Gamma\hat{\mathbf{z}})\mathbf{f} - \mathbf{u}\|_2^2 + \|\sqrt{\Omega}R(\boldsymbol{\beta})\mathbf{f}\|_2^2 + \alpha_h\|S\hat{\mathbf{z}}\|_2^2. \tag{2.7}$$

An important issue in the regularization is the choice of the regularization parameters, α_r, α_g, α_b, and α_h. The optimal value for these parameters depends on the noise level of the observed image and estimated point spread functions. For the least squares solution, Ng and Bose proposed an efficient way to find the optimal $[\alpha_r \quad \alpha_g \quad \alpha_b]$ in [15]. Based on the statistical interpretation of the regularization term, $[\alpha_r \quad \alpha_g \quad \alpha_b]$ reflects our level of confidence in the prior information, which is

largely determined by the noise level on the right-hand side. Considering the TLS solution is also the least squares solution of a problem that has the same right-hand side but a different blurring matrix, we expect the optimal values for $[\alpha_r \quad \alpha_g \quad \alpha_b]$ in the TLS solution to be close to those in the least squares solution. Therefore, we simply use the optimal $[\alpha_r \quad \alpha_g \quad \alpha_b]$ computed by the least squares method for our TLS solution. In order to find the optimal α_h, we use an approach that is similar to the approach employed by Chan and Wong in [4]. That is, we start with a small value for α_h and increase it until a satisfactory solution is found by visually checking the recovered image. One can also use a more systematic approach such as the L-curve method [11], which tries to find a good balance between yielding small TLS residual and "regularity" of the recovered $\hat{\mathbf{z}}$ in (2.7).

3. Solving the regularized STLS problem. In [21], Rosen, Park, and Glick presented an iterative algorithm for structured total least norm in 1-, 2-, and infinity-norms. Pruessner and O'Leary extended the algorithm of Rosen, Park, and Glick to include regularization in all of these norms and demonstrated its use on single channel image deblurring in [19]. For the 2-norm case, the basic idea of the technique of Rosen, Park, and Glick is to approximate the cost function by a quadratic function and minimize that quadratic function at each iteration. Here we show that this technique can be extended to solve (2.7).

For convenience, let

$$\Psi(\mathbf{f}, \hat{\mathbf{z}}) = \|H(\mathbf{w} + \Gamma\hat{\mathbf{z}})\mathbf{f} - \mathbf{u}\|_2^2 + \|\sqrt{\Omega}R(\boldsymbol{\beta})\mathbf{f}\|_2^2 + \alpha_h\|S\hat{\mathbf{z}}\|_2^2;$$

then (2.7) becomes

$$\min_{\mathbf{f},\hat{\mathbf{z}}} \Psi(\mathbf{f}, \hat{\mathbf{z}}). \tag{3.1}$$

If the elements of $\boldsymbol{\beta}$ are constants, then this problem can be solved in a way similar to how Pruessner and O'Leary solved the single channel image deblurring problem in [19]. Taking into account that elements of $\boldsymbol{\beta}$ are not constants, we propose solving (2.7) as follows. At each iteration, we fix $\boldsymbol{\beta}$, approximate the cost function by a quadratic function, and minimize that function. At the end of each iteration, we use the new guess for $\mathbf{f}$ to update $\boldsymbol{\beta}$.

If $\boldsymbol{\beta}$ is fixed, then

$$\begin{aligned}\Psi(\mathbf{f} + \Delta\mathbf{f}, \hat{\mathbf{z}} + \Delta\hat{\mathbf{z}}) = {} & \|H(\mathbf{w} + \Gamma\hat{\mathbf{z}} + \Gamma\Delta\hat{\mathbf{z}})(\mathbf{f} + \Delta\mathbf{f}) - \mathbf{u}\|_2^2 \\ & + \|\sqrt{\Omega}R(\boldsymbol{\beta})(\mathbf{f} + \Delta\mathbf{f})\|_2^2 + \alpha_h\|S(\hat{\mathbf{z}} + \Delta\hat{\mathbf{z}})\|_2^2.\end{aligned} \tag{3.2}$$

Ignoring higher order terms, we get

$$\begin{aligned}\Psi(\mathbf{f} + \Delta\mathbf{f}, \hat{\mathbf{z}} + \Delta\hat{\mathbf{z}}) \approx {} & \|H(\mathbf{w} + \Gamma\hat{\mathbf{z}})(\mathbf{f} + \Delta\mathbf{f}) + H(\Gamma\Delta\hat{\mathbf{z}})\mathbf{f} - \mathbf{u}\|_2^2 \\ & + \|\sqrt{\Omega}R(\boldsymbol{\beta})(\mathbf{f} + \Delta\mathbf{f})\|_2^2 + \alpha_h\|S(\hat{\mathbf{z}} + \Delta\hat{\mathbf{z}})\|_2^2.\end{aligned} \tag{3.3}$$

Let

$$\begin{aligned}\hat{\Psi}(\Delta\mathbf{f}, \Delta\hat{\mathbf{z}}) = {} & \|H(\mathbf{w} + \Gamma\hat{\mathbf{z}})(\mathbf{f} + \Delta\mathbf{f}) + H(\Gamma\Delta\hat{\mathbf{z}})\mathbf{f} - \mathbf{u}\|_2^2 \\ & + \|\sqrt{\Omega}R(\boldsymbol{\beta})(\mathbf{f} + \Delta\mathbf{f})\|_2^2 + \alpha_h\|S(\hat{\mathbf{z}} + \Delta\hat{\mathbf{z}})\|_2^2.\end{aligned} \tag{3.4}$$

When $\boldsymbol{\beta}$ is fixed, minimizing $\hat{\Psi}$ is a Gauss–Newton step for minimizing Ψ.

Define the matrix Z as follows:

$$Z = \begin{bmatrix} Z_1 & 0 & 0 \\ 0 & Z_2 & 0 \\ 0 & 0 & Z_3 \end{bmatrix}, \tag{3.5}$$

where

$$\begin{aligned} Z_1 &= [H_{rr}\mathbf{f}_r - H_{br}\mathbf{f}_b \quad H_{gr}\mathbf{f}_g - H_{br}\mathbf{f}_b], \\ Z_2 &= [H_{rg}\mathbf{f}_r - H_{bg}\mathbf{f}_b \quad H_{gg}\mathbf{f}_g - H_{bg}\mathbf{f}_b], \\ Z_3 &= [H_{rb}\mathbf{f}_r - H_{bb}\mathbf{f}_b \quad H_{gb}\mathbf{f}_g - H_{bb}\mathbf{f}_b]. \end{aligned}$$

Then Z satisfies

$$H(\Gamma\Delta\hat{\mathbf{z}})\mathbf{f} = Z\Delta\hat{\mathbf{z}}. \tag{3.6}$$

Therefore, $\hat{\Psi}$ becomes

$$\begin{aligned} \hat{\Psi}(\Delta\mathbf{f}, \Delta\hat{\mathbf{z}}) &= \|H(\mathbf{w} + \Gamma\hat{\mathbf{z}})(\mathbf{f} + \Delta\mathbf{f}) + Z\Delta\hat{\mathbf{z}} - \mathbf{u}\|_2^2 \\ &\quad + \|\sqrt{\Omega}R(\boldsymbol{\beta})(\mathbf{f} + \Delta\mathbf{f})\|_2^2 + \alpha_h\|S(\hat{\mathbf{z}} + \Delta\hat{\mathbf{z}})\|_2^2. \end{aligned} \tag{3.7}$$

It follows that minimizing $\hat{\Psi}$ is equivalent to solving the following linear least squares system:

$$\min_{\Delta\mathbf{f}, \Delta\hat{\mathbf{z}}} \left\| \begin{bmatrix} H(\mathbf{w} + \Gamma\hat{\mathbf{z}}) & Z \\ \sqrt{\Omega}R(\boldsymbol{\beta}) & 0 \\ 0 & \sqrt{\alpha_h}S \end{bmatrix} \begin{bmatrix} \Delta\mathbf{f} \\ \Delta\hat{\mathbf{z}} \end{bmatrix} - \begin{bmatrix} \mathbf{u} - H(\mathbf{w} + \Gamma\hat{\mathbf{z}})\mathbf{f} \\ -\sqrt{\Omega}R(\boldsymbol{\beta})\mathbf{f} \\ -\sqrt{\alpha_h}S\hat{\mathbf{z}} \end{bmatrix} \right\|_2. \tag{3.8}$$

The STLS algorithm for color image restoration is summarized as follows.

ALGORITHM 3.1.
1. Set $\mathbf{f}$ to be the least squares solution, $\hat{\mathbf{z}} = 0$, construct Z according to (3.5)
2. Repeat
   (a) Solve (3.8) for $\Delta\mathbf{f}$, $\Delta\hat{\mathbf{z}}$.
   (b) Set $\mathbf{f} = \mathbf{f} + \Delta\mathbf{f}$, $\hat{\mathbf{z}} = \hat{\mathbf{z}} + \Delta\hat{\mathbf{z}}$,
   (c) construct Z according to (3.5),
   (d) update $\boldsymbol{\beta}$ according to (2.1).
   until $\|\Delta\mathbf{f}\|$, $\|\Delta\hat{\mathbf{z}}\| \leq \epsilon$.

We have no proof that this algorithm converges; however, experimental results indicate that this algorithm converges very quickly, provided that the regularization parameters are not too small. It is recommended that the least squares solution be used as the initial guess.

4. Solving the linear least squares systems efficiently. The main computational task of one iteration of Algorithm 3.1 is to solve the linear least squares system (3.8). The conjugte gradient least squares (CGLS) method [1] is often used to solve large sparse linear least squares systems in the form of

$$\min_{\mathbf{x}} \|\mathbf{b} - A\mathbf{x}\|_2.$$

The convergence of the CGLS method depends on the condition number of the coefficient matrix, A. When the condition number of A is large, the CGLS method may converge slowly; in that case, preconditioners [10, sect. 10.3] can be used to accelerate the convergence. The idea of preconditioning is to apply the regular CGLS to the transformed system

$$\min_{\tilde{\mathbf{x}}} \|\mathbf{b} - \tilde{A}\tilde{\mathbf{x}}\|_2,$$

where $\tilde{A} = AG^{-1}$ and $\tilde{\mathbf{x}} = G\mathbf{x}$. We need G to be such that $M = G^TG$ has a spectrum similar to A^TA and that the linear system $M\mathbf{x} = \mathbf{b}$ is easy to solve. We call G a preconditioner for A, or M a preconditioner for A^TA.

In [7], Fu and Barlow proposed a preconditioner for a linear system that is similar to (3.8). Unfortunately, the system here requires a different preconditioning strategy, because even though the submatrices of H are BTHTHB, the matrix H itself is not BTHTHB.

4.1. Symmetric blurring matrices. For (3.8), since

$$A = \begin{bmatrix} H(\mathbf{w}+\mathbf{z}) & Z \\ \sqrt{\Omega}R(\boldsymbol{\beta}) & 0 \\ 0 & \sqrt{\alpha_h}S \end{bmatrix}, \tag{4.1}$$

we have

$$A^TA = \begin{bmatrix} H(\mathbf{w}+\mathbf{z})^TH(\mathbf{w}+\mathbf{z}) + R(\boldsymbol{\beta})^T\Omega R(\boldsymbol{\beta}) & H(\mathbf{w}+\mathbf{z})^TZ \\ Z^TH(\mathbf{w}+\mathbf{z}) & Z^TZ + \alpha_h S^TS \end{bmatrix}.$$

Let $\hat{M}$ be the upper left block of A^TA, that is,

$$\hat{M} = H(\mathbf{w}+\mathbf{z})^TH(\mathbf{w}+\mathbf{z}) + R(\boldsymbol{\beta})^T\Omega R(\boldsymbol{\beta}).$$

We remark that the inverse of $\hat{M}$ can be easily computed if all the cross- and within-channel point spread functions are symmetric. By "symmetric" we mean that $h(x,y) = h(-x,y) = h(x,-y) = h(-x,-y)$. In fact, Ng and Bose efficiently computed the inverse of a matrix that is quite similar to $\hat{M}$ in [15].

Ng, Chan, and Tang [16] showed that if the point spread function h is symmetric, then the corresponding blurring matrix H with Neumann boundary conditions can be diagonalized by the 2D discrete cosine transform (DCT) [20] matrix C. Therefore,

$$H = \begin{bmatrix} C^T\Lambda_{rr}C & C^T\Lambda_{gr}C & C^T\Lambda_{br}C \\ C^T\Lambda_{rg}C & C^T\Lambda_{gg}C & C^T\Lambda_{bg}C \\ C^T\Lambda_{rb}C & C^T\Lambda_{gb}C & C^T\Lambda_{bb}C \end{bmatrix},$$

where Λ_{ij} (for $i,j \in \{r,g,b\}$) are real diagonal matrices.

The 2D Laplacian matrix with Neumann boundary conditions can also be diagonalized by the 2D DCT matrix. Let

$$L = C^T\Lambda_L C;$$

then

$$R = \begin{bmatrix} C^T(\Lambda_L + 2I)C & C^T(-\beta_{rg}I)C & C^T(-\beta_{rb}I)C \\ C^T(-\frac{1}{\beta_{rg}}I)C & C^T(\Lambda_L + 2I)C & C^T(-\beta_{gb}I)C \\ C^T(-\frac{1}{\beta_{br}}I)C & C^T(-\frac{1}{\beta_{gb}}I)C & C^T(\Lambda_L + 2I)C \end{bmatrix}.$$

It follows that the matrix $\hat{M}$ can be put into the following form:

$$\hat{M} = \begin{bmatrix} C^T\Lambda_{11}C & C^T\Lambda_{12}C & C^T\Lambda_{13}C \\ C^T\Lambda_{12}C & C^T\Lambda_{22}C & C^T\Lambda_{23}C \\ C^T\Lambda_{13}C & C^T\Lambda_{23}C & C^T\Lambda_{33}C \end{bmatrix} = (I \otimes C^T) \begin{bmatrix} \Lambda_{11} & \Lambda_{12} & \Lambda_{13} \\ \Lambda_{12} & \Lambda_{22} & \Lambda_{23} \\ \Lambda_{13} & \Lambda_{23} & \Lambda_{33} \end{bmatrix} (I \otimes C).$$

Here Λ_{ij} are real diagonal matrices. The matrix with diagonal blocks can be permuted into a block diagonal matrix so that $\hat{M}$ is expressed as

$$\hat{M} = \tilde{C}^T \operatorname{diag}(B_{1,1}, \ldots, B_{1,n}, B_{2,1}, \ldots, B_{2,n}, \ldots, B_{n,1}, \ldots, B_{n,n})\tilde{C}, \tag{4.2}$$

where

$$\tilde{C} = P(I \otimes C)$$

for the appropriate permutation matrix P. Here each $B_{k,\ell}$ $(1 \le k, \ell \le n)$ is a 3×3 symmetric matrix, and we consider an $n \times n$ image in each color channel. Next we show that $\hat{M}$ is symmetric and positive definite.

THEOREM 4.1. [illegible] $(\mathbf{w}+\mathbf{z})_{ij} \ge 0$ [illegible] $i, j \in \{r, g, b\}$ [illegible] $(\mathbf{w}+\mathbf{z})_{ri}$ $(\mathbf{w}+\mathbf{z})_{gi}$ [illegible] $(\mathbf{w}+\mathbf{z})_{bi}$ $i \in \{r, g, b\}$ [illegible] $\hat{M}$ [illegible]. It is clear that $\hat{M}$ is symmetric. According to (4.2), it suffices to show that $B_{k,\ell}$ are positive definite for $1 \le k, \ell \le n$. In fact, the matrices $B_{k,\ell}$ are given by

$$B_{k,\ell} = Q_{k,\ell}(\mathbf{w}+\mathbf{z})^T Q_{k,\ell}(\mathbf{w}+\mathbf{z}) + (U + [\Lambda_L]_{k\ell} I)^T \Phi^2 (U + [\Lambda_L]_{k\ell} I),$$

where

$$Q_{k,\ell}(\mathbf{w}+\mathbf{z}) = \begin{bmatrix} (\mathbf{w}+\mathbf{z})_{rr}[\Lambda_{rr}]_{k\ell} & (\mathbf{w}+\mathbf{z})_{gr}[\Lambda_{gr}]_{k\ell} & (\mathbf{w}+\mathbf{z})_{br}[\Lambda_{br}]_{k\ell} \\ (\mathbf{w}+\mathbf{z})_{rg}[\Lambda_{rg}]_{k\ell} & (\mathbf{w}+\mathbf{z})_{gg}[\Lambda_{gg}]_{k\ell} & (\mathbf{w}+\mathbf{z})_{bg}[\Lambda_{bg}]_{k\ell} \\ (\mathbf{w}+\mathbf{z})_{rb}[\Lambda_{rb}]_{k\ell} & (\mathbf{w}+\mathbf{z})_{gb}[\Lambda_{gb}]_{k\ell} & (\mathbf{w}+\mathbf{z})_{bb}[\Lambda_{bb}]_{k\ell} \end{bmatrix},$$

$$U = \begin{bmatrix} 2 & -\beta_{rg} & -\beta_{rb} \\ -\frac{1}{\beta_{rg}} & 2 & -\beta_{gb} \\ -\frac{1}{\beta_{rb}} & -\frac{1}{\beta_{gb}} & 2 \end{bmatrix}, \quad \text{and} \quad \Phi = \begin{bmatrix} \sqrt{\alpha_r} & 0 & 0 \\ 0 & \sqrt{\alpha_g} & 0 \\ 0 & 0 & \sqrt{\alpha_b} \end{bmatrix}.$$

Let

$$F_{k,\ell} = \begin{bmatrix} Q_{k,\ell}(\mathbf{w}+\mathbf{z}) \\ \Phi(U + [\Lambda_L]_{k,\ell} I) \end{bmatrix}. \tag{4.3}$$

It is clear that $B_{k,\ell}$ is positive definite if and only if $F_{k,\ell}$ has full column rank. We note that the eigenvalues of the discrete Laplacian with the Neumann boundary condition are given by

$$[\Lambda_L]_{k\ell} = 4\sin^2\left(\frac{(k-1)\pi}{2n}\right) + 4\sin^2\left(\frac{(\ell-1)\pi}{2n}\right), \quad 1 \le k, \ell \le n.$$

Therefore, we have, $[\Lambda_L]_{1,1} = 0$. It implies that $F_{k,\ell}$ has full column rank for k and ℓ, except when $k = \ell = 1$.

Next we show that $F_{1,1}$ also has full column rank. It is easy to check that the eigenvalues of U are 0, 3, and 3 and that their corresponding eigenvectors are

$$[\beta_{rb}, \beta_{gb}, 1]^T, \quad [-\beta_{rb}, 0, 1]^T, \quad \text{and } [-\beta_{rg}, 1, 0]^T,$$

respectively. Therefore $\Phi(U + [\Lambda_L]_{k,\ell} I)\mathbf{x} = \mathbf{0}$ if and only if $k = \ell = 1$ and $\mathbf{x}$ is proportional to the nonnegative vector $[\beta_{rb}, \beta_{gb}, 1]^T$. Since discrete point spread functions are normalized such that their sums are equal to 1, it is easy to show that $[\Lambda_{ij}]_{1,1} = 1$. By the assumption, it is clear that $Q_{1,1}(\mathbf{w} + \mathbf{z})$ is a positive matrix, and thus $Q_{1,1}(\mathbf{w} + \mathbf{z})\mathbf{x} = 0$. Thus there is no vector $\mathbf{x}$ such that $F_{1,1}\mathbf{x} = \mathbf{0}$. It follows that $F_{1,1}$ must have full column rank. The result follows. □

It follows that

$$\hat{M}^{-1} = (I \otimes C^T) P^T \operatorname{diag}(B_{1,1}^{-1}, \ldots, B_{1,n}^{-1}, B_{2,1}^{-1}, \ldots, B_{2,n}^{-1}, \ldots, B_{n,1}^{-1}, \ldots, B_{n,n}^{-1}) P (I \otimes C).$$

Therefore, the inverse of $\hat{M}$ can be computed by performing several 2D DCTs and computing the inverses of n^2 3×3 matrices. The preconditioner $\hat{M}$ can also be factored into $\hat{M} = \hat{G}^T \hat{G}$, where

$$G = \operatorname{diag}(G_{1,1}, \ldots, G_{1,n}, G_{2,1}, \ldots, G_{2,n}, \ldots, G_{n,1}, \ldots, G_{n,n}) P (I \otimes C),$$

and $B_{k,\ell} = G_{k,\ell}^T G_{k,\ell}, 1 \le k, \ell \le n$, are the result of either the Cholesky factorization of $B_{k,\ell}$ or the QR factorization of $F_{k,\ell}$ in (4.3).

When all the cross- and within-channel point spread functions are symmetric, we propose to precondition $A^T A$ by the matrix M defined as follows:

$$M = \begin{bmatrix} \hat{M} & 0 \\ 0 & Z^T Z + \alpha_h S^T S \end{bmatrix}.$$

Since the eigenvalues of S are 1 and $\sqrt{3}$ and $\alpha_h > 0$, the matrix $Z^T Z + \alpha_h S^T S$ is positive definite, and the preconditioner M is also positive definite. It is clear that $A^T A$, when preconditioned by M, is different from the identity matrix only at the last six rows and last six columns, which means it is the identity matrix plus a rank-12 change. Thus preconditioned CGLS is guaranteed to converge to the exact solution within 13 iterations.

4.2. Nonsymmetric blurring matrices. If not all the cross- and within-channel point spread functions are symmetric, we suggest constructing the preconditioner according to the symmetric part of the point spread functions. In [13], Kwan and Ng proved the following theorem and lemma.

THEOREM 4.2. $\mathbf{h}$ H_n $\mathbf{h}$ $c(H_n)$ H_n $\mathbf{h}_s$

$$\mathbf{h}_s(i,j) = (\mathbf{h}(i,j) + \mathbf{h}(i,-j) + \mathbf{h}(-i,j) + \mathbf{h}(-i,-j))/4$$

LEMMA 4.3. $\mathbf{h}$ H_n $\mathbf{h}$ $\mathbf{h}$ $\mathbf{h}_s$

$$\delta = \sum_{i,j} |\mathbf{h}(i,j) - \mathbf{h}_s(i,j)|.$$

$$\|H_n - c(H_n)\|_1, \|H_n - c(H_n)\|_\infty \leq 4\delta,$$

$c(H_n)$ H_n

Here we consider the preconditioner for A^TA to be given by

$$M_c = \begin{bmatrix} c(H(\mathbf{w}+\mathbf{z}))^T c(H(\mathbf{w}+\mathbf{z})) + R(\boldsymbol{\beta})^T \Omega R(\boldsymbol{\beta}) & 0 \\ 0 & Z^TZ + \alpha_h S^T S \end{bmatrix}, \tag{4.4}$$

where

$$c(H(\mathbf{w}+\mathbf{z})) = \begin{bmatrix} (\mathbf{w}+\mathbf{z})_{rr} c(H_{rr}) & (\mathbf{w}+\mathbf{z})_{gr} c(H_{gr}) & (\mathbf{w}+\mathbf{z})_{br} c(H_{br}) \\ (\mathbf{w}+\mathbf{z})_{rg} c(H_{rg}) & (\mathbf{w}+\mathbf{z})_{gg} c(H_{gg}) & (\mathbf{w}+\mathbf{z})_{bg} c(H_{bg}) \\ (\mathbf{w}+\mathbf{z})_{rb} c(H_{rb}) & (\mathbf{w}+\mathbf{z})_{gb} c(H_{gb}) & (\mathbf{w}+\mathbf{z})_{bb} c(H_{bb}) \end{bmatrix}.$$

Using the above lemma, we have the following result. First, recall that

$$\|\mathbf{w}+\mathbf{z}\|_\infty = \max_{i,j \in \{r,g,b\}} (\mathbf{w}+\mathbf{z})_{ij}. \tag{4.5}$$

LEMMA 4.4. A (4.1) M_c (4.4)

$$\max_{i,j \in \{r,g,b\}} \|H_{ij} - c(H_{ij})\|_{1,\infty} \leq 4\delta,$$

$$\|H(\mathbf{w}+\mathbf{z})^T H(\mathbf{w}+\mathbf{z}) - c(H(\mathbf{w}+\mathbf{z}))^T c(H(\mathbf{w}+\mathbf{z}))\|_2 \leq 8\delta \|\mathbf{w}+\mathbf{z}\|_\infty.$$

. We note that

$$\begin{aligned} \|H_{ij}^T H_{k\ell} - c(H_{ij})^T c(H_{k\ell})\| &\leq \|H_{ij}^T [H_{k\ell} - c(H_{k\ell})]\| + \|[H_{ij}^T - c(H_{ij})^T] c(H_{k\ell})\| \\ &\leq \|H_{ij}^T\| \|[H_{k\ell} - c(H_{k\ell})]\| + \|[H_{ij}^T - c(H_{ij})^T]\| \|c(H_{k\ell})\| \end{aligned}$$

with $i,j,k,\ell \in \{r,g,b\}$. Since the discrete point spread function is normalized such that its sum is equal to 1,

$$\|H_{ij}^T\|_1 = \|H_{ij}^T\|_\infty = \|c(H_{ij})\|_1 = \|c(H_{ij})\|_\infty = 1.$$

Using the above results and the statement (4.5), we can estimate

$$\|H(\mathbf{w}+\mathbf{z})^T H(\mathbf{w}+\mathbf{z}) - c(H(\mathbf{w}+\mathbf{z}))^T c(H(\mathbf{w}+\mathbf{z}))\|_{1,\infty} \leq 8\delta \|\mathbf{w}+\mathbf{z}\|_\infty.$$

Hence the result follows. □

According to Lemma 4.4, we see that if the point spread function is close to symmetric, then M_c will be a good approximation for A^TA. It follows that if we construct the matrix $\hat{M}$ according to the symmetric part of the point spread functions, then the matrix M_c defined as in (4.4) will be a good preconditioner for A^TA.

To show that the spectra of the preconditioned matrices are clustered around 1, we consider a sequence of blurring matrices and investigate the spectra of the sequence of the preconditioned blurring matrices. Therefore, we assume that the given blurring matrix H_{ij} comes from a fixed singly infinite matrix H_{ij}^∞. We associate with H_{ij}^∞ the function ϕ_{ij} where the entries of H_{ij} and H_{ij}^∞ are the Fourier coefficients of ϕ_{ij}. The

function ϕ_{ij} is called the [illegible] of the sequence of blurring matrices; see [3] for details. With the generating function ϕ_{ij} for the blurring matrix H_{ij}, it can be shown that the eigenvalues of the matrix $c(H_{ij})$ are given by

$$\phi_{ij}\left(\frac{(k-1)\pi}{2n}, \frac{(\ell-1)\pi}{2n}\right), \quad 1 \le k, \ell \le n, \quad i, j \in \{r, g, b\},$$

and the largest eigenvalue of $c(H_{ij})$ is given by $\phi_{ij}(0,0)$ when $\ell = k = 1$; see, for instance, [3, 13]. Since discrete point spread functions are normalized such that their sums are equal to 1, it is easy to show that $\phi_{ij}(0,0) = 1$. Next we show that the smallest eigenvalue of M_c is uniformly bounded below away from 0 by a positive constant independent of the size of M_c.

THEOREM 4.5. [illegible] $(\mathbf{w}+\mathbf{z})_{ij} \ge 0$ [illegible] $i, j \in \{r, g, b\}$ [illegible] $(\mathbf{w}+\mathbf{z})_{ri}$ $(\mathbf{w}+\mathbf{z})_{gi}$ [illegible] $(\mathbf{w}+\mathbf{z})_{bi}$ $(i \in \{r, g, b\})$ [illegible] γ_{min} [illegible] M_c [illegible] M_c [illegible] γ_{min}

[illegible]. We define for simplicity that

$$\xi(x, y) = \lambda_{\min}(F_{x,y}^T F_{x,y}),$$

where

$$F_{x,y} = \begin{bmatrix} Q_{x,y}(\mathbf{w}+\mathbf{z}) \\ \Phi(U + \psi(x,y)I) \end{bmatrix},$$

$$Q_{x,y}(\mathbf{w}+\mathbf{z}) = \begin{bmatrix} (\mathbf{w}+\mathbf{z})_{rr}\phi_{rr}(x,y) & (\mathbf{w}+\mathbf{z})_{gr}\phi_{gr}(x,y) & (\mathbf{w}+\mathbf{z})_{br}\phi_{br}(x,y) \\ (\mathbf{w}+\mathbf{z})_{rg}\phi_{rg}(x,y) & (\mathbf{w}+\mathbf{z})_{gg}\phi_{gg}(x,y) & (\mathbf{w}+\mathbf{z})_{bg}\phi_{bg}(x,y) \\ (\mathbf{w}+\mathbf{z})_{rb}\phi_{rb}(x,y) & (\mathbf{w}+\mathbf{z})_{gb}\phi_{gb}(x,y) & (\mathbf{w}+\mathbf{z})_{bb}\phi_{bb}(x,y) \end{bmatrix},$$

$$\psi(x, y) = 4\sin^2 x + 4\sin^2 y.$$

With this notation, we have shown in Theorem 4.1 that $F_{x,y}$ has full column rank, and hence the smallest eigenvalue of the matrix $F_{x,y}^T F_{x,y}$ is positive. Therefore, $\xi(x,y) > 0$ for all $(x,y) \in [0, \pi/2]^2$. Since $\xi(x,y)$ is a continuous function on $[0, \pi/2]^2$, there exists a constant γ_{min}, independent of the size of the matrix, such that $\xi(x,y) \ge \gamma_{min} > 0$ for all $(x,y) \in [0, \pi/2]^2$. Hence the result follows. □

By using Lemma 4.4 and Theorem 4.5, we can prove the following theorem.

THEOREM 4.6. [illegible] $(\mathbf{w}+\mathbf{z})_{ij} \ge 0$ [illegible] $i, j \in \{r, g, b\}$ [illegible] $(\mathbf{w}+\mathbf{z})_{ri}$ $(\mathbf{w}+\mathbf{z})_{gi}$ [illegible] $(\mathbf{w}+\mathbf{z})_{bi}$ $i \in \{r, g, b\}$ [illegible]

$$\max_{i,j \in \{r,g,b\}} \|H_{ij} - c(H_{ij})\|_{1,\infty} \le 4\delta.$$

[illegible]

$$M_c^{-1} A^T A = I + E_1 + E_2,$$

[illegible] E_1 [illegible] 12 [illegible] $\|E_2\|_2 \le 8\delta \|\mathbf{w}+\mathbf{z}\|_\infty / \gamma_{min}$ [illegible] γ_{min} [illegible] 4.5

[illegible]. We note that

$$\begin{aligned} & M_c^{-1} A^T A \\ &= I + M_c^{-1}(A^T A - M_c) \\ &= I + M_c^{-1} \begin{bmatrix} H(\mathbf{w}+\mathbf{z})^T H(\mathbf{w}+\mathbf{z}) - c(H(\mathbf{w}+\mathbf{z}))^T c(H(\mathbf{w}+\mathbf{z})) & H(\mathbf{w}+\mathbf{z})^T Z \\ Z^T H(\mathbf{w}+\mathbf{z}) & 0 \end{bmatrix}. \end{aligned}$$

The result follows by noting that the matrix

$$M_c^{-1}\begin{bmatrix} 0 & H(\mathbf{w}+\mathbf{z})^T Z \\ Z^T H(\mathbf{w}+\mathbf{z}) & 0 \end{bmatrix}$$

is a matrix of rank 12 and

$$\begin{aligned} &\left\| M_c^{-1}\begin{bmatrix} (H(\mathbf{w}+\mathbf{z})^T H(\mathbf{w}+\mathbf{z}) - c(H(\mathbf{w}+\mathbf{z}))^T c(H(\mathbf{w}+\mathbf{z}))) & 0 \\ 0 & 0 \end{bmatrix}\right\|_2 \\ &\le \|M_c^{-1}\|_2 \left\|\begin{bmatrix} H(\mathbf{w}+\mathbf{z})^T H(\mathbf{w}+\mathbf{z}) - c(H(\mathbf{w}+\mathbf{z}))^T c(H(\mathbf{w}+\mathbf{z})) & 0 \\ 0 & 0 \end{bmatrix}\right\|_2 \\ &\le 8\delta \|M_c^{-1}\|_2 \|\mathbf{w}+\mathbf{z}\|_\infty \le 8\delta \|\mathbf{w}+\mathbf{z}\|_\infty / \gamma_{min}. \qquad \square \end{aligned}$$

According to Theorem 4.6, if δ is sufficiently small (i.e., if the point spread function is quite symmetric), then the spectra of the preconditioned matrices $M_c^{-1}A^TA$ are clustered around 1, and therefore the preconditioned conjugate gradient method will converge very quickly. In the next section, this result is confirmed by our experimental results.

5. Experimental results. The image shown in Figure 5.1 is used for computer simulation.

5.1. The first test. The discretized point spread functions are as follows:

$$\mathbf{h}_{rr} = \mathbf{h}_{gr} = \mathbf{h}_{br} = \begin{bmatrix} \frac{1}{9} & \frac{1}{9} & \frac{1}{9} \\ \frac{1}{9} & \frac{1}{9} & \frac{1}{9} \\ \frac{1}{9} & \frac{1}{9} & \frac{1}{9} \end{bmatrix},$$

$$\mathbf{h}_{rg} = \mathbf{h}_{gg} = \mathbf{h}_{bg} = \begin{bmatrix} 0 & 0.125 & 0 \\ 0.125 & 0.5 & 0.125 \\ 0 & 0.125 & 0 \end{bmatrix},$$

$$\mathbf{h}_{rb} = \mathbf{h}_{gb} = \mathbf{h}_{bb} = \begin{bmatrix} 0.0625 & 0.125 & 0.0625 \\ 0.125 & 0.25 & 0.125 \\ 0.0625 & 0.125 & 0.0625 \end{bmatrix}.$$

FIG. 5.1. *The original image.*

FIG. 5.2. *The observed image.*

The weights used to generate the observed channels are as follows:

$$\mathbf{w} = [0.5 \quad 0.3 \quad 0.2 \quad 0.25 \quad 0.5 \quad 0.25 \quad 0.2 \quad 0.3 \quad 0.5]^T.$$

A noise returned by the MATLAB command "0.01*(rand-0.5)" [6] is added to the observed channels. Figure 5.2 shows the observed image.

The estimated weights are set to

$$\mathbf{w} = [0.45 \quad 0.33 \quad 0.22 \quad 0.275 \quad 0.45 \quad 0.275 \quad 0.22 \quad 0.33 \quad 0.55]^T.$$

The relative error on the estimated weights is 10%.

We use the peak signal to noise ratio (PSNR) to measure the quality of the recovered images. The PSNR of a discretized color image is defined as

$$PSNR(\mathbf{f}) = 20log_{10}\sqrt{\frac{1}{\|\mathbf{f} - \mathbf{f}_{true}\|_2^2/(3mn)}},$$

where $\mathbf{f}_{true}$ is the true image, and m and n are the size of the image.

Two least squares solutions are computed. One is obtained by using the $\boldsymbol{\beta}$ calculated from the observed image; the other is obtained by using the $\boldsymbol{\beta}$ calculated from the original image. Figures 5.3 and 5.4 show these two images. For both solutions, $[\alpha_r \quad \alpha_g \quad \alpha_b] = [0.0001 \quad 0.0001 \quad 0.0001]$ is used.

For the TLS solution, $\alpha_h = 9$ yields satisfactory results. The recovered weights are as follows:

$$\mathbf{w} = [0.4943 \quad 0.3137 \quad 0.1920 \quad 0.2555 \quad 0.4688 \quad 0.2757 \quad 0.1902 \quad 0.3292 \quad 0.4807]^T.$$

The relative error of the recovered weights is 5.4%, which is much smaller than that of the original estimates. Figure 5.5 shows the image recovered by the STLS method. The PSNRs of the recovered images indicate that the TLS solution is much better.

Figure 5.6 shows the error norm (measured as $\|[\Delta\mathbf{f}^T \Delta\hat{\mathbf{z}}^T]\|$) at each iteration of Algorithm 3.1. As can be seen, Algorithm 3.1 converged to an error level of 10^{-2} in

FIG. 5.3. *The image recovered by the least squares method. The observed image is used to calculate* $\boldsymbol{\beta}$. *PSNR* $= 27.79db$.

FIG. 5.4. *The image recovered by the least squares method. The original image is used to calculate* $\boldsymbol{\beta}$. *PSNR* $= 28.01db$.

12 iterations. More iterations will further reduce the error norm but will have very little effect on the recovered image.

Two variants of Algorithm 3.1 are also used to compute TLS solutions. One uses a fixed $\boldsymbol{\beta}$, which is calculated from the observed image. The image recovered by this variation is shown in Figure 5.7. The difference between the PSNRs of this image and the one shown in Figure 5.5 is 0.82db, which is not a small value. The difference can be larger if the $\boldsymbol{\beta}$ values based on the observed image are quite different from those based on the recovered image, which will occur if there is significant cross-channel blur and the original image has significantly different intensity levels in the three channels (for example, when the original image is dominated by the red channel). The other variant does not apply the constraints stated in (2.5). That is, the solution

FIG. 5.5. *The image recovered by Algorithm* 3.1. *PSNR* = 34.22*db*.

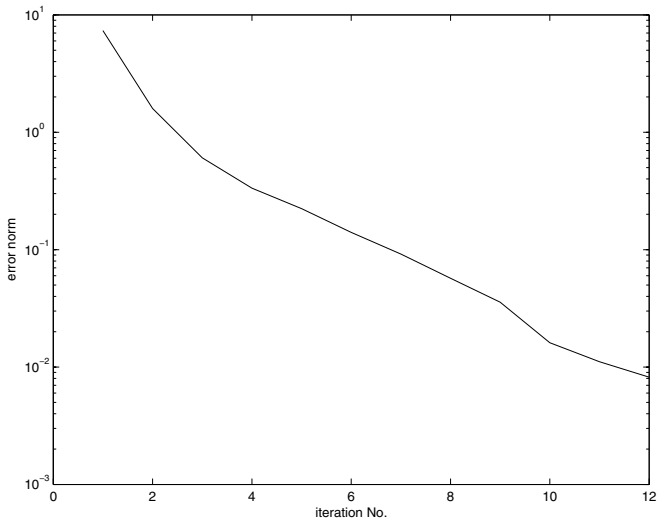

FIG. 5.6. *Error norm at each iteration of Algorithm* 3.1.

of (2.4) is computed. The image recovered by this variant, which has a much lower PSNR, is shown in Figure 5.8. Table 5.1 shows the relative error of each channel when different restoration methods are used, which also indicates that the solution returned by Algorithm 3.1 is the best.

5.2. The second test. We remark that in practice, it is quite possible that no information for the weights is available at all. In that situation, one can use an estimate of 1/3 for all the cross- and within-channel weights. Using the same observed image in Figure 5.2, the recovered weights are as follows:

$$\mathbf{w} = [0.4809 \quad 0.3054 \quad 0.2137 \quad 0.3018 \quad 0.3488 \quad 0.3494 \quad 0.2125 \quad 0.3465 \quad 0.4411]^T.$$

FIG. 5.7. *The image recovered by a variant of Algorithm* 3.1 *(a fixed* $\boldsymbol{\beta}$ *is used). PSNR* $= 33.40db$.

FIG. 5.8. *The image recovered by a variant of Algorithm* 3.1 *(without the constraints stated in* (2.5)). *PSNR* $= 29.47db$.

TABLE 5.1

Relative error of each channel when different restoration methods are used. TLS: total least squares restoration; Algorithm 3.1 *is used. TLS-*1*: total least squares restoration; a fixed* $\boldsymbol{\beta}$ *is used. TLS-*2*: total least squares restoration; the solution of* (2.4) *is computed. LS-*1*: least squares restoration; the observed image is used to calculate* $\boldsymbol{\beta}$*. LS-*2*: least squares restoration; the original image is used to calculate* $\boldsymbol{\beta}$*.*

	TLS	TLS-1	TLS-2	LS-1	LS-2
Red channel	0.0219	0.0224	0.0222	0.0857	0.0826
Green channel	0.0166	0.0251	0.0918	0.0522	0.0492
Blue channel	0.0238	0.0239	0.0674	0.0691	0.0684

The relative error on the estimated weights is 19.19%. The PSNRs of the images recovered by the least squares method are 24.55db and 21.00db when the β are calculated from the original image and the observed image, respectively. The PSNR of the

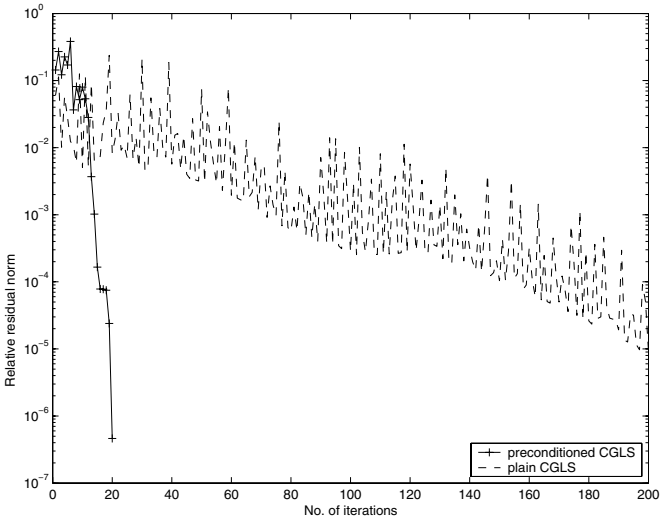

FIG. 5.9. *Relative residual norm at each CGLS iteration.*

image recovered by our proposed method is 29.74db, where the β is calculated from the observed image. Without a doubt, a less accurate estimate of the weights will worsen both the least squares and TLS solutions, but it also makes the TLS solution more likely to recover a better estimate of the weights and therefore outperform the least squares solution.

5.3. The third test. Experiments also showed that the preconditioning technique proposed in section 4 is very effective if the point spread functions are symmetric or close to symmetric. As predicted by theoretical analysis, preconditioned CGLS converges to the exact solution in 13 iterations when the point spread functions are symmetric. When the point spread functions are not symmetric, there is no guarantee that preconditioned CGLS will converge to the exact solution in 13 iterations, but the convergence rate is considerably accelerated if the functions are close to symmetric. This is shown in Figure 5.9. In this example, a noise returned by the MATLAB command "0.01*rand" is added to the elements of the original symmetric point spread functions. The point spread functions are then normalized such that they integrate to 1. As can be seen, preconditioned CGLS converges much faster.

Next we test the performance of the preconditioning techniques for nonsymmetric point spread functions. In the test, we set $H_{rr} = H_{rg} = H_{rb}$, $H_{gr} = H_{gg} = H_{gb}$, and $H_{br} = H_{bg} = H_{bb}$. Their corresponding point spread functions are examples of blurring that occurs in wavefront coding where a cubic phase filter is used to improve depth of field restoration in light efficient wide aperture optical systems [5]. An example of the point spread function for H_{rr} can be found in Figure 5.10. We find in Figure 5.11 that the performance of the preconditioner is poorer than in the previous case, but the convergence rate is considerably accelerated and is much better than the convergence rate of the method without using the preconditioner.

6. Conclusion. In conclusion, we have proposed a regularized STLS algorithm for color image restoration. In our problem setup, we assume that the blurring matrix, as well as the right-hand side, is contaminated by noise. The regularized STLS problem is stated as an unconstrained optimization problem. Our algorithm solves

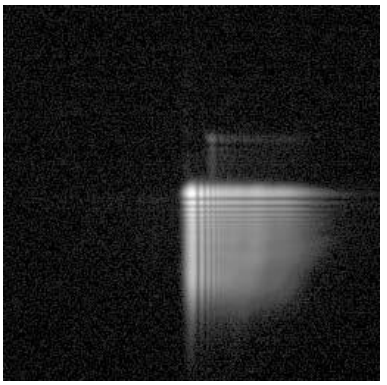

FIG. 5.10. *Image of the nonsymmetric point spread function.*

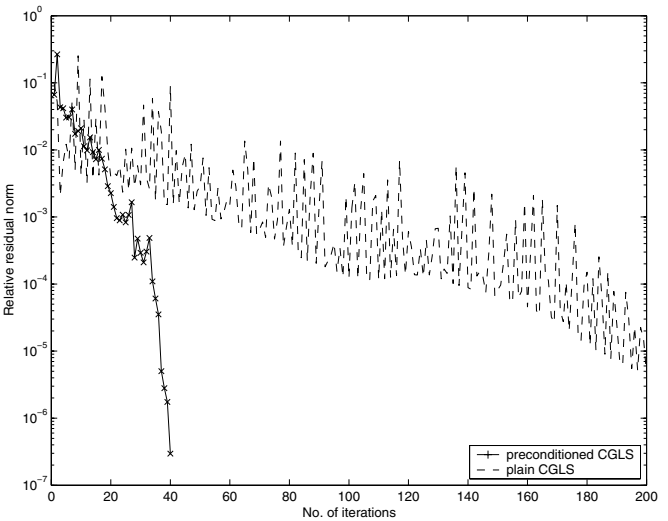

FIG. 5.11. *Relative residual norm at each CGLS iteration.*

the problem iteratively. At each iteration, the objective function is simplified by fixing certain parameters and ignoring high order terms. The simplified version of the objective function can be minimized by solving a linear least squares system. This system is solved by the preconditioned CGLS method. The main contribution of this paper includes solving for the weights of the weighted 3D Laplacian as part of the problem and proposing an efficient preconditioner for the linear systems encountered in the STLS algorithm. Experimental results showed that the STLS method recovers the error on the blurring matrix well, and it yields an image that is superior to the least squares solution.

A FINITE-DIFFERENCE APPROXIMATION OF A TWO-LAYER SYSTEM FOR GROWING SANDPILES*

MAURIZIO FALCONE† AND STEFANO FINZI VITA†

Abstract. We study from a numerical point of view a system of partial differential equations recently proposed in [K. P. Hadeler and C. Kuttler, *Granular Matter*, 2 (1999), pp. 9–18] to model the dynamics of growing sandpiles generated by a vertical source on a flat bounded table. In such a system, an eikonal equation for the standing layer of the pile is coupled to an advection equation for the rolling layer. We analyze a suitable explicit finite difference scheme in one dimension and discuss its properties. A comparison is made with respect to the variational approach of [L. Prigozhin, *European J. Appl. Math.*, 7 (1996), pp. 225–235], particularly in terms of steady-state solutions. Since the effective equilibrium configuration reached by the growing process is not completely clear for this model, we show experiments in one and two dimensions, which characterize the steady-state solutions for different source terms.

Key words. growing piles, granular matter, hyperbolic systems, finite difference schemes

AMS subject classifications. 65M06, 65M12, 70F45

DOI. 10.1137/050629410

1. Introduction.

In recent years several papers have been devoted to the mathematical study of granular matter, and different models have been proposed in the framework of kinetic [3, 4], cellular automata [2, 9, 17], or partial differential equations theories [6, 7, 1, 10, 14, 11, 13].

A typical prototype for granular matter is sand, and one of the simplest phenomena to describe is the following. Let us consider an initially empty table (a bounded open domain Ω of $\mathbb{R}^2$). The sand is poured on a subset of Ω according to the value of a nonnegative function $f(x,t)$ (the source). The pile grows in height with a slope which is always lower than a characteristic value (strongly depending on the physical properties of the granular matter). This means that the sand is added to the pile at every point where f is strictly positive while the slope of the pile profile u remains below the critical value α. When the slope becomes steeper than α the sand rolls down, enlarging the heap base. Physical experiments on real sandpiles show that, for f independent of t in the steady avalanching regime, the profile reaches a steady state in a finite time. The height of the pile stops growing when at some point its base reaches the boundary of the table. After that time the sand will fall down from the table at that point (the tip moves slightly in the opposite direction), so that the pile profile remains unchanged.

We will focus our attention on the numerical simulations based on differential models and in particular on a recent model proposed by Hadeler and Kuttler [13]. Their model is an improvement on the one proposed by de Gennes [10] as a simplification of the one-dimensional model studied by Bouchaud, Cates, Ravi Prakash, and Edwards (i.e., BCRE; see [6, 7]). All the above models use two interacting variables: the standing layer u and the rolling layer v. The interactions between u and v

are described in [13] by a system of nonlinear partial differential equations for which it is quite delicate to prove existence and uniqueness results. However, a partial characterization of its stationary solutions has been given recently by Cannarsa and Cardaliaguet [8] (see Theorem 2.1). We will construct an approximation scheme for that system and analyze its properties in the one-dimensional case, showing that the scheme mimics several characteristics of the continuous model (Theorem 3.1). Moreover, we propose a natural extension of the scheme to the two-dimensional model and test it in several experiments, comparing the solutions to those generated by a different model (always in the PDE framework). In particular, we will consider the general model for growing sandpiles on an infinite flat table introduced by Aronsson, Evans, and Wu [1] as the limit of fast/slow diffusion evolution equations for the p-Laplace operator when p tends to $+\infty$. Such a variational model, when restricted to a bounded domain, turns out to be analytically equivalent to the degenerate parabolic problem independently studied by Prigozhin [14] for the bounded table case. It is interesting to note that the two models considered in [13] and in [14] have theoretically the same set of admissible equilibria. The precise asymptotic behavior of solutions is well known for the second one and depends only on the geometry of the source support. In contrast, no rigorous mathematical characterization is known for the steady-state solution of the two-layer model. We are able to give a numerical description of this equilibrium configuration, showing that it has in general a larger support and also depends on the source intensity.

It is worth mentioning that a different approximation scheme (a finite difference semidiscretization in time) has been considered in [16] for the two-layer model.

The paper is organized as follows. Section 2 is devoted to the presentation of the three continuous models mentioned above and to a discussion of their asymptotic behavior. In section 3 we present our scheme and prove that it is consistent with the physics of the growing pile problem. Finally, in section 4 we present several numerical experiments and compare our results to those known for the other two models.

2. Three continuous models. In [1] the sequence of solutions $\{u_p\}_p$ of the parabolic equations for the p-Laplace operator in $\mathbb{R}^n \times (0,T)$ is proved to converge almost everywhere, for p tending to $+\infty$, to a solution of the evolutionary variational inequality

$$u(t) \in K: \ (u_t - f, \phi - u) \geq 0 \quad \forall \phi \in K, \ \forall t \in (0,T), \quad u(0) \equiv 0, \tag{1}$$

where

$$K := \{\phi \in W^{1,\infty}(\mathbb{R}^n): \ |\nabla \phi| \leq \alpha\}.$$

To simplify the presentation we hereafter set $\alpha = 1$, since this is not restrictive for the analysis of the models.

In a series of papers (see, e.g., [14]), Prigozhin independently obtained the same variational inequality for the case of a bounded domain Ω (that is, with $K \subset W_0^{1,\infty}(\Omega)$ and the same bound for $\nabla \phi$) as an equivalent formulation of the degenerate parabolic problem

$$u_t = \nabla \cdot (v \nabla u) + f \qquad \text{in } \Omega \times (0,T), \tag{2}$$

$$|\nabla u| \leq 1, \quad |\nabla u| < 1 \Rightarrow v = 0 \qquad \text{in } \Omega \times (0,T), \tag{3}$$

$$u(\cdot,t) = 0 \quad \text{on } \partial\Omega, \qquad u(\cdot,0) = 0 \quad \text{in } \Omega, \tag{4}$$

where $v(x,t) \geq 0$ is an auxiliary function, still unknown, whose positivity indicates that some matter, poured by the source, is rolling down along the surface of the pile in that point. Under suitable hypotheses, it was proved that in the bounded table case problem (1) has a unique solution u, which is a nondecreasing function of time and is also bounded from above by the maximal admissible profile, given by the distance function d from the boundary of Ω:

$$d(x) := \inf_{z \in \partial\Omega} |x - z|.$$

(The discontinuity set $\mathcal{R}$ of ∇d is usually called the [illegible] set or the [illegible] of Ω.) Then, if $f = f(x)$, the solution $u(\cdot,t)$ of (1) will evolve towards an equilibrium state $\overline{u} \in K$; from (2)–(4) we see that $\overline{u}$ solves, for a suitable v, the system

$$-\nabla \cdot (v \nabla u) = f, \quad (1 - |\nabla u|)v = 0 \quad \text{in } \Omega, \quad u|_{\partial\Omega} = 0. \tag{5}$$

As we already mentioned in the introduction, a different continuous model has been proposed by Bouchaud et al. in [6]. They introduced a system of two partial differential equations to govern the growth of a sandpile, seen as the superposition of two distinct layers, the standing and the rolling ones. More recently, following the fundamental works of de Gennes [10] on granular matter, Hadeler and Kuttler [13] have revisited that model, coupling an eikonal-type equation for the standing layer u (which forms heaps and slopes) to an advection-type equation for the small rolling layer v running down the slope. We will use their formulation, which corresponds to the system

$$v_t = \nabla \cdot (v \nabla u) - (1 - |\nabla u|)v + f \qquad \text{in } \Omega \times (0,T), \tag{6}$$

$$u_t = (1 - |\nabla u|)v \qquad \text{in } \Omega \times (0,T), \tag{7}$$

$$u(\cdot,t) = 0 \quad \text{on } \partial\Omega, \qquad u(\cdot,0) = v(\cdot,0) = 0 \quad \text{in } \Omega. \tag{8}$$

We see that the natural Dirichlet boundary condition for the open table is imposed to the standing layer u. In contrast, no condition is given for v at $\partial\Omega$. The reason can be seen by expanding (6):

$$v_t - \nabla u \cdot \nabla v = (\Delta u - (1 - |\nabla u|))v + f\ . \tag{9}$$

For a fixed u, (9) can be interpreted as a linear advection equation in v. Then, the sign of the vector field ∇u on $\partial\Omega$ implies that no boundary condition is needed in this case.

The model based on (6)–(8) is essentially different from the above-mentioned variational model, since now positive rolling layers are allowed during the evolution even before the corresponding standing layer becomes critical (see [15] for a detailed comparison of the two models). This feature can be useful in the modeling of some granular materials. Nevertheless, it is interesting to remark that this different dynamics exhibits the same equilibria of (6)–(8), given by solutions of system (5). In the framework of viscosity solutions theory, such equilibria have been recently characterized by Cannarsa and Cardaliaguet [8], as follows.

THEOREM 2.1. [illegible] $\Omega \subset \mathbb{R}^2$ [illegible] C^2 [illegible] $f \geq 0$ [illegible] Ω [illegible] (5) [illegible] (u,v) [illegible] $u = d$, Ω $v = 0$, $\mathcal{R}$

$$v(x) = \int_0^{\tau(x)} f(x + t\nabla d(x)) \frac{1 - (d(x) + t)k(x)}{1 - d(x)k(x)}\, dt \qquad \forall x \in \Omega \backslash \overline{\mathcal{R}}. \tag{10}$$

[illegible] (u', v') [illegible] $v' = v$ [illegible] Ω [illegible] $u' = d$ [illegible] $\{x \in \Omega : v > 0\}$

In the previous formula, for any point $x \in \Omega$, $k(x)$ denotes the curvature of $\partial\Omega$ at the projection of x onto it, while $\tau(x)$ indicates the so-called normal distance to $\overline{\mathcal{R}}$, defined as

$$\tau(x) = \min\{t \geq 0 : x + t\nabla d(x) \in \overline{\mathcal{R}}\}.$$

By the above result there exists a unique equilibrium solution v for any given source f, and an integral representation formula is given for it outside $\mathcal{R}$ (where $v = 0$). In contrast, for u there is no uniqueness, although every solution must coincide with d in the set where $v > 0$. Then, if we denote by D_f the set of positivity of a (constant in time) source term f in Ω, two distinct cases can occur:

(a) $\mathcal{R} \subset D_f$: the unique possible asymptotic equilibrium for both models is essentially given for the standing layer by the distance function d.

(b) $\mathcal{R}$ is not contained in D_f: the two models behave differently. The steady state for the first model can be proven to be, for the standing layer, the minimum (with respect to f) of the possible equilibria, that is, the union of all maximal circular cones centered in points of D_f. Namely,

$$u^*(x) = \max_{y \in D_f} (d(y) - |x - y|)^+. \tag{11}$$

In the two-layer system, as already remarked, the different dynamics of the rolling layer forces the solution to evolve towards a larger equilibrium configuration $\overline{u}$, which also depends on the source intensity (as clearly shown by the numerical experiments discussed in the last section) and for which a rigorous mathematical characterization is not known.

3. An approximation scheme for the two-layer model. Let us consider the one-dimensional version of (6)–(8). Let $\Omega = (0, 1)$; we want to solve numerically the system

$$v_t = (vu_x)_x - (1 - |u_x|)v + f = vu_{xx} + v_x u_x - (1 - |u_x|)v + f, \tag{12}$$

$$u_t = (1 - |u_x|)v, \tag{13}$$

$$u(0, t) = u(1, t) = 0, \qquad u(x, 0) = v(x, 0) = 0, \quad x \in \Omega\ . \tag{14}$$

Let $x_i = ih$, for $i = 0, 1, \ldots, N$ and $h = \Delta x = 1/N$, denote the nodes of a grid in Ω. We set by definition

$$D^+ u_i = \frac{u_{i+1} - u_i}{h}, \qquad D^- u_i = \frac{u_i - u_{i-1}}{h}. \tag{15}$$

Then we discretize the derivative of u at a node x_i by the difference with maximal absolute value, namely,

$$Du_i \equiv \text{maxmod}(D^- u_i, D^+ u_i), \tag{16}$$

whereas the corresponding derivative of v is approximated by the upwind (with respect to Du_i) finite difference, i.e.,

$$\overline{D} v_i \equiv \begin{cases} D^+ v_i & \text{if } Du_i > 0,\ D^+ u_i > 0, \\ D^- v_i & \text{if } Du_i < 0,\ D^- u_i < 0, \\ 0 & \text{otherwise.} \end{cases}$$

We discretize time by a fixed step Δt and use the standard notation, where z_i^n denotes the approximate value of a function $z(x,t)$ for $t = t_n \equiv n\Delta t$ and $x = x_i$. Using the forward Euler method for the time derivatives, we obtain our fully explicit scheme for the solution of (12)–(14):

$$v_i^{n+1} = v_i^n + \Delta t \left[v_i^n D^2 u_i^n + \overline{D} v_i^n D u_i^n - (1 - |D u_i^n|) v_i^n + f_i \right], \tag{17}$$

$$u_i^{n+1} = u_i^n + \Delta t (1 - |D u_i^n|) v_i^n, \tag{18}$$

$$u_1^n = u_N^n = 0 \quad \forall n, \quad u_i^0 = v_i^0 = 0 \quad \forall i, \tag{19}$$

where

$$D^2 u_i^n \equiv \frac{u_{i-1}^n - 2u_i^n + u_{i+1}^n}{h^2} \tag{20}$$

denotes the standard central finite difference scheme for the term u_{xx}, and (19) gives the natural discrete versions of boundary and initial conditions (14).

Let us briefly present some properties of the above scheme, which preserves the physical characteristics of the continuous model. Further details and complete proofs will be presented in a forthcoming paper [12].

THEOREM 3.1. [illegible] $f \geq 0$, [illegible] Ω [illegible]

$$\frac{\Delta t}{h} \leq \min\left(\frac{1}{2}, \frac{1}{C\|f\|_\infty}\right), \tag{21}$$

[illegible] u^n [illegible] v^n [illegible] (17)–(19) [illegible]:

(i) [illegible] u $0 \leq u^n \leq u^{n+1}$;

(ii) [illegible] v $v^n \geq 0$;

(iii) [illegible] u $|Du^n| \leq 1$

[illegible]. Let us remark that properties (i)–(iii) are trivially satisfied for $n = 0$, due to (19). Then, we prove the results by induction.

(i) This is a direct consequence of our assumptions and of (18).

(ii) From (17) we have

$$v_i^{n+1} = v_i^n + \Delta t G_i^n, \tag{22}$$

where

$$G_i^n \equiv v_i^n D^2 u_i^n + \overline{D} v_i^n D u_i^n - (1 - |D u_i^n|) v_i^n + f_i. \tag{23}$$

Since it can be proved that

$$G_i^n \geq -\frac{2}{h} v_i^n, \tag{24}$$

we can conclude from (21) that

$$v_i^{n+1} \geq \left(1 - \frac{2\Delta t}{h}\right) v_i^n \geq 0. \tag{25}$$

The proof of (24) is rather long since it must take into account all the possible cases with respect to the signs of first and second discrete derivatives. Let us just give here the proof for one of the cases, which leads to an upper bound for $\frac{\Delta t}{h}$. Assume

$D^2u_i < 0$, $Du_i = D^-u_i \geq D^+u_i > 0$, and $\overline{D}v_i = D^+v_i < 0$ (the index n has been dropped, since in this calculation it is fixed). By definition, we have

$$\begin{aligned} G_i &= v_i \frac{D^+u_i - Du_i}{h} + \frac{v_{i+1} - v_i}{h} Du_i - (1 - Du_i)v_i + f_i \\ &\geq -\frac{2}{h} v_i Du_i - (1 - Du_i)v_i = -v_i \left(1 + \left(\frac{2}{h} - 1\right) Du_i\right) \geq -\frac{2}{h} v_i. \end{aligned} \tag{26}$$

(iii) Let us start noting that, by (16), if $Du_i^n = D^+u_i^n$, then

$$|Du_i^n| \leq |Du_{i+1}^n|. \tag{27}$$

In fact, if $Du_{i+1} = D^-u_{i+1}$ and $Du_i = D^+u_i$, then $Du_{i+1} = Du_i$ (again n has been dropped). Otherwise, $Du_{i+1} = D^+u_{i+1}$, and we have $|D^+u_{i+1}| > |D^-u_{i+1}| = |Du_i|$. This also implies that if $|Du_i^n| \leq 1$ for any i, then

$$0 \leq (1 - |Du_{i+1}^n|) \leq (1 - |Du_i^n|). \tag{28}$$

We first prove property (iii) for $(n+1)$ under the additional assumption that for the index n

$$\frac{\Delta t}{h} v_i^n \leq 1 \quad \text{for any } i. \tag{29}$$

To simplify the presentation, we give the proof only for the case $0 < Du_i^n = D^+u_i^n < 1$ (the other cases can be treated in a similar way). Subtracting (18) for i from the same equation for $(i+1)$, we get

$$D^+u_i^{n+1} = D^+u_i^n + \Delta t \frac{(1 - |Du_{i+1}^n|)v_{i+1}^n - (1 - |Du_i^n|)v_i^n}{h}. \tag{30}$$

Then, (28) implies

$$D^+u_i^{n+1} \leq Du_i^n + \frac{\Delta t}{h}(1 - |Du_{i+1}^n|)v_{i+1}^n \leq Du_i^n + \frac{\Delta t}{h}(1 - |Du_i^n|)v_{i+1}^n. \tag{31}$$

From (29) we conclude

$$D^+u^{n+1} \leq Du_i^n + 1 - Du_i^n = 1. \tag{32}$$

In a similar way,

$$D^-u_i^{n+1} \leq D^-u_i^n + \frac{\Delta t}{h}(1 - |Du_i^n|)v_i^n \leq Du_i^n + \frac{\Delta t}{h}(1 - |Du_i^n|)v_i^n \leq 1, \tag{33}$$

so that we get $Du_i^{n+1} \leq 1$. Let us now prove that $Du_i^{n+1} \geq -1$. Again, by subtraction, assumption (29) implies

$$D^+u_i^{n+1} \geq -\frac{\Delta t}{h}(1 - |Du_i^n|)v_i^n \geq -\frac{\Delta t}{h} v_i^n \geq -1. \tag{34}$$

Moreover,

$$D^-u_i^{n+1} \geq D^-u_i^n - \frac{\Delta t}{h}(1 - |Du_{i-1}^n|)v_{i-1}^n \geq D^-u_i^n - (1 - |Du_{i-1}^n|), \tag{35}$$

and the lower bound follows if $(D^- u_i^n + |Du_{i-1}^n|) \geq 0$. Note that the previous inequality is always satisfied, since $Du_{i-1}^n = D^+ u_{i-1}^n$ implies $Du_{i-1}^n = D^- u_i^n$, and $Du_{i-1}^n = D^- u_{i-1}^n$ implies $|Du_{i-1}^n| \geq |D^+ u_{i-1}^n| = |Du_i^n|$.

Then, it should remain to prove only (29): here we do not give the rigorous proof, but we simply remark that it follows from (21) and from the natural bound

$$v_i^n \leq C\|f\|_\infty \quad \forall i,$$

which says that the amount of rolling sand in any point can be bounded from above by the source intensity. The stability condition (21) is therefore not very restrictive for small intensity source terms. □

By standard arguments one can show that the above scheme is consistent with the continuous system and that the local error is $O(\Delta x, \Delta t)$. We refer to [12] for a discussion of the stability of the scheme as well as for a proof of its convergence. Moreover, the stability conditions allow us to show that (u^n, v^n) converges, for n going to $+\infty$, to an equilibrium configuration $(\bar{u}, \bar{v})$ of the discrete system satisfying $(1 - |D\bar{u}|)\bar{v} = 0$.

The two-dimensional extension of the scheme is straightforward, and its main features are preserved. We introduce in the domain Ω (for simplicity, a rectangle) a uniform grid of nodes $x_{i,j}$, and, as usual, we denote by $(u_{i,j}^n, v_{i,j}^n)$ the components of the discrete solutions on node $x_{i,j}$ at time $t = t_n$. Then the scheme can be written as

$$v_{i,j}^{n+1} = v_{i,j}^n + \Delta t \left[v_{i,j}^n D^2 u_{i,j}^n + \overline{D} v_{i,j}^n \cdot Du_{i,j}^n - (1 - |Du_{i,j}^n|) v_{i,j}^n + f_{i,j} \right], \tag{36}$$

$$u_{i,j}^{n+1} = u_{i,j}^n + \Delta t (1 - |Du_{i,j}^n|) v_{i,j}^n, \tag{37}$$

$$u_{i,j}^0 = v_{i,j}^0 = 0 \quad \forall i,j, \quad u_{i,j}^n = 0 \quad \text{on } \partial\Omega \quad \forall n, \tag{38}$$

where now

$$D^2 u_{i,j} = \frac{u_{i,j-1} + u_{i,j+1} - 4u_{i,j} + u_{i-1,j} + u_{i+1,j}}{h^2}$$

is the standard five-point discretization of the Laplace operator, and the discrete gradient vectors $Du_{i,j}$ and $\overline{D} v_{i,j}$ are defined, component by component, as in the one-dimensional case. For example,

$$Du_{i,j} = (D_x u_{i,j}, D_y u_{i,j}),$$

where

$$D_x u_{i,j} = \text{maxmod}\left(\frac{u_{i,j} - u_{i-1,j}}{h}, \frac{u_{i+1,j} - u_{i,j}}{h} \right),$$

and $D_y u_{i,j}$ is defined in a similar way.

4. Numerical tests. All the tests refer to the Hadeler and Kuttler (HK) model. We have implemented the algorithm in one and two dimensions, testing different source terms, in cases (a) and (b).

In one dimension the ridge set $\mathcal{R}$ reduces to the middle point of the interval. Whenever the support of the source contains that point, we are in case (a), so that the final shape of the pile is given by the sum $(\overline{u} + \overline{v})$, where $\overline{u}$ is the distance function d and $\overline{v}$ is the rolling layer characterized by the explicit formula (10) (see Figure 1 (top)).

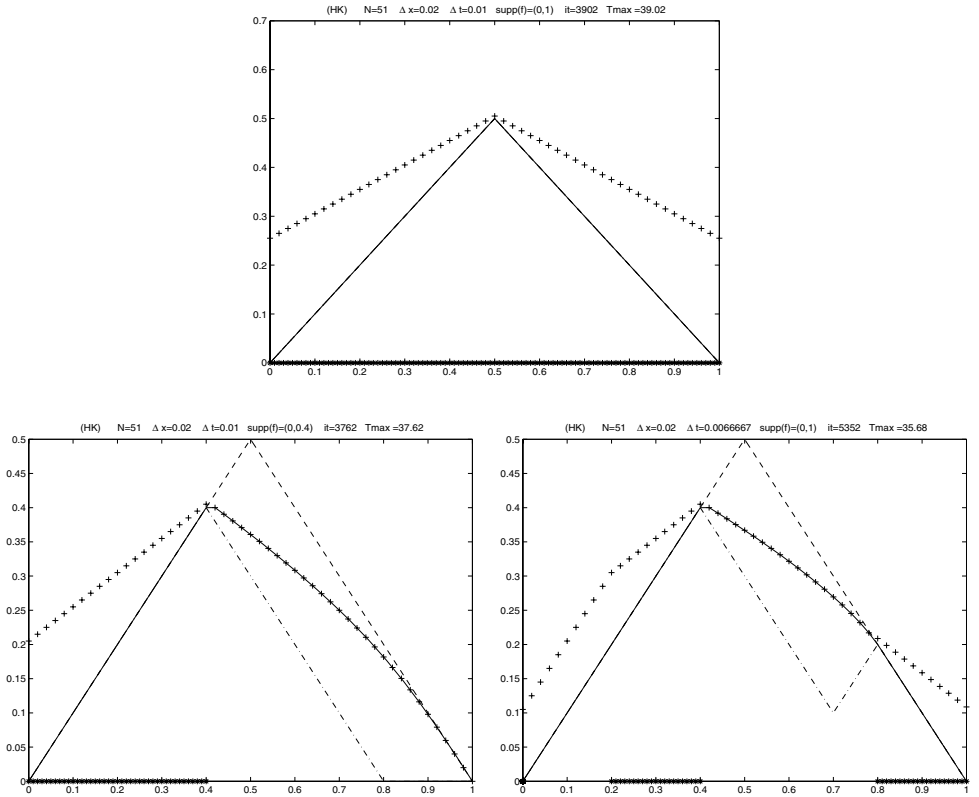

FIG. 1. *(HK-1D) $f \equiv 0.5$, plots of stationary u_h [—] and $(u_h + v_h)$ [++], compared with the distance function d [- -] and the minimal solution u^* [··-]: $D_f = [0, 1]$ (top), $D_f = [0, 0.4]$ (bottom left), $D_f = [0.2, 0.4] \cup [0.8, 1]$ (bottom right).*

In any other situation we fall into case (b), and the stable solution $\overline{u}$ in general does not coincide with the minimal solution (11) in all of Ω. More precisely, we get $u^* = \overline{u} = d$ in regions where the final rolling layer v is positive. In the complementary set the algorithm computes a larger function (see Figure 1 (bottom)). Such a function strongly depends on the source intensity, and a comparison principle holds:

$$0 \le f_1 \le f_2 \quad \text{in } D_f \quad \Rightarrow \quad u^* \le \overline{u}_1 \le \overline{u}_2 \le d \quad \text{in } \Omega.$$

This is clearly shown in Figure 2, where we plot the equilibria corresponding to different constant source terms sharing the same support D_f.

The growing process of the standing layer for different source terms is shown in Figure 3, where the pile profiles are plotted every 100 time iterations. It can be seen very well that the pile support expands before its slope becomes critical.

The stability bound (21) is confirmed by the experiments. In fact, Table 1 shows the following bound for the admissible Δt (asymptotically when $h \to 0$):

$$\Delta t \le C_f h,$$

which becomes more severe when the source intensity increases. As one can see looking at the first column ($f \equiv 1$) of Table 1, the ratio is always close to 0.5 and tends to 0.5 for N going to infinity. For bigger values of f (second and third columns) the

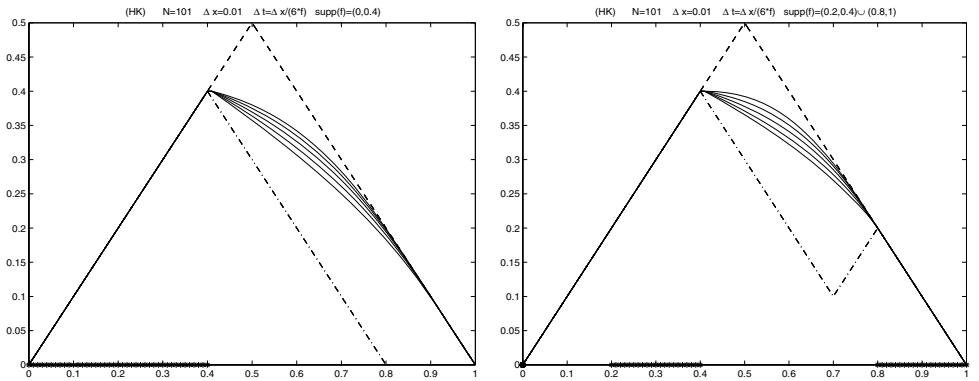

FIG. 2. *(HK-1D) $f \equiv 0.5/1/1.5/2/2.5$, plots of stationary u_h [—] compared with the distance function d [- -] and the minimal solution u^* [-·-]: $D_f = [0, 0.4]$ (left), $D_f = [0.2, 0.4] \cup [0.8, 1]$ (right).*

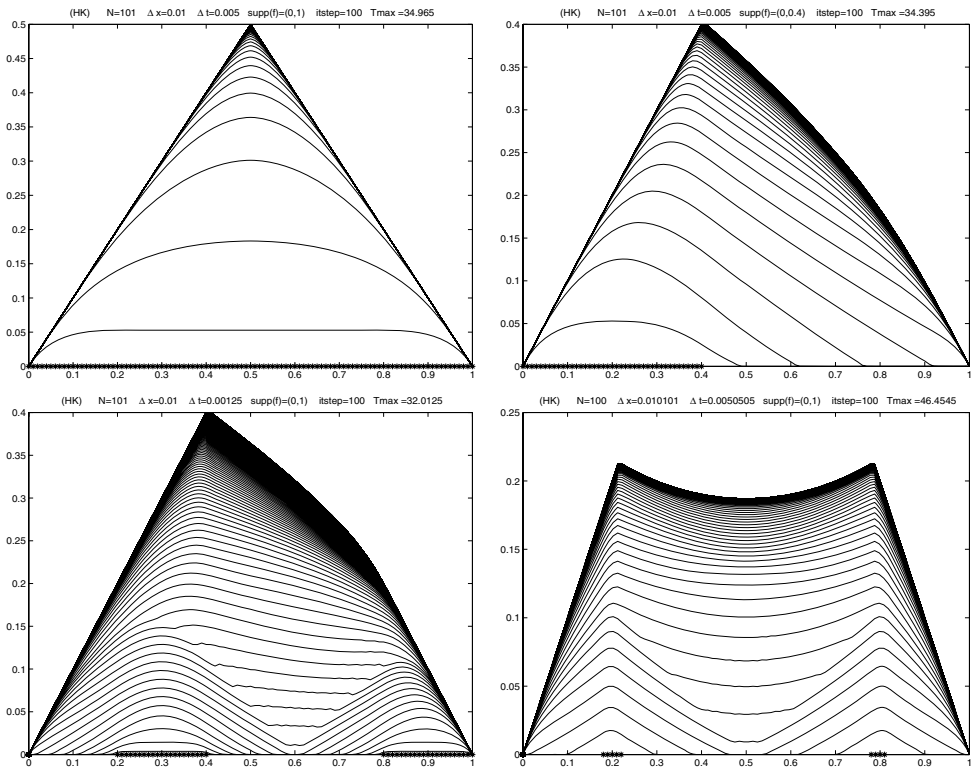

FIG. 3. *(HK-1D) $f \equiv 0.5$, plots of u_h every 100 time iterations: $D_f = [0, 1]$ (top left), $D_f = [0, 0.4]$ (top right), $D_f = [0.2, 0.4] \cup [0.8, 1]$ (bottom left), $D_f = [0.18, 0.22] \cup [0.78, 0.82]$ (bottom right).*

ratio which guarantees stability tends to a value strictly lower than 0.5. Moreover, as expected, the ratio $\Delta t/h$ always decreases along the rows of Table 1.

The two-dimensional experiments have been made in the case of a rectangular table. We used an $N \times M$ uniform grid of nodes $x_{i,j} = (ih, jh)$. Here the ridge set is no longer strictly contained in Ω, since it is the union of segments and reaches the

TABLE 1
Maximal ratio $\Delta t/h$ which yields stabilization in time of the discrete solutions when $D_f = [0,1]$ and f is constant.

N	$f \equiv 1$	$f \equiv 2$	$f \equiv 3$
201	0.6	0.52	0.46
401	0.552	0.476	0.424
601	0.528	0.45	0.41
801	0.512	0.44	0.392
1001	0.5	0.43	0.39

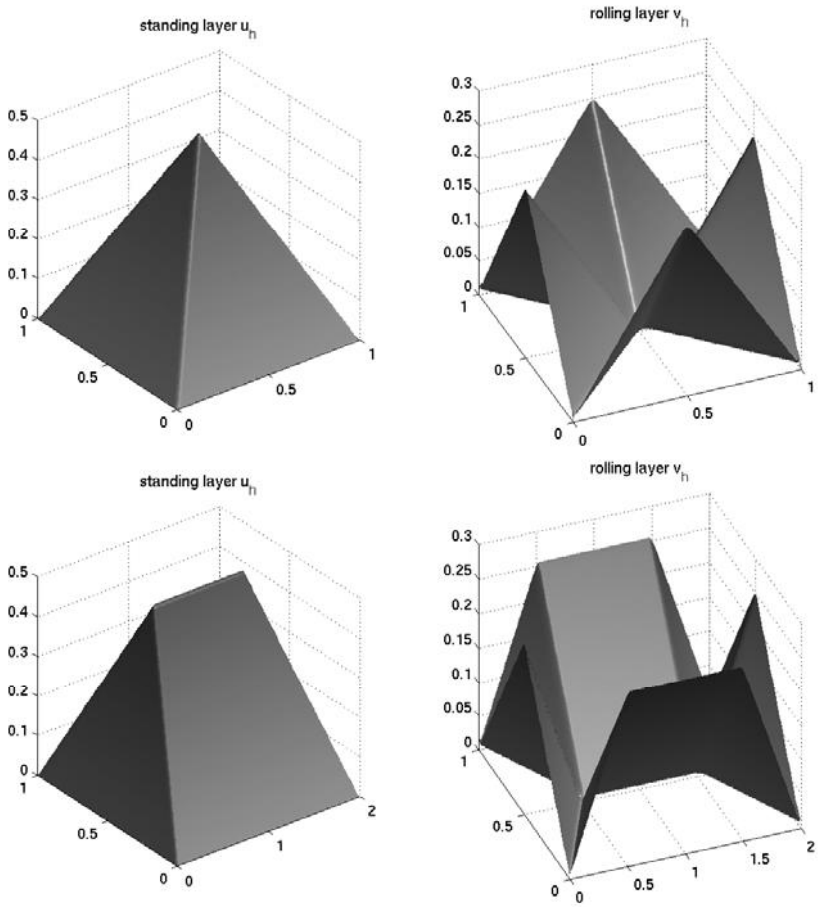

FIG. 4. *(HK-2D) $D_f = \Omega$, $f \equiv 0.5$: $\Omega = (0,1) \times (0,1)$, $N = M = 101$ (top); $\Omega = (0,1) \times (0,2)$, $N = 101$, $M = 201$ (bottom).*

boundary at the four vertices.

We are in case (a) if, for example, the source term is positive (e.g., constant) everywhere in Ω. In Figure 4 we see the stable configurations u and v for the square and the rectangular tables.

All the simulations of the growth process of sandpiles with source support in case

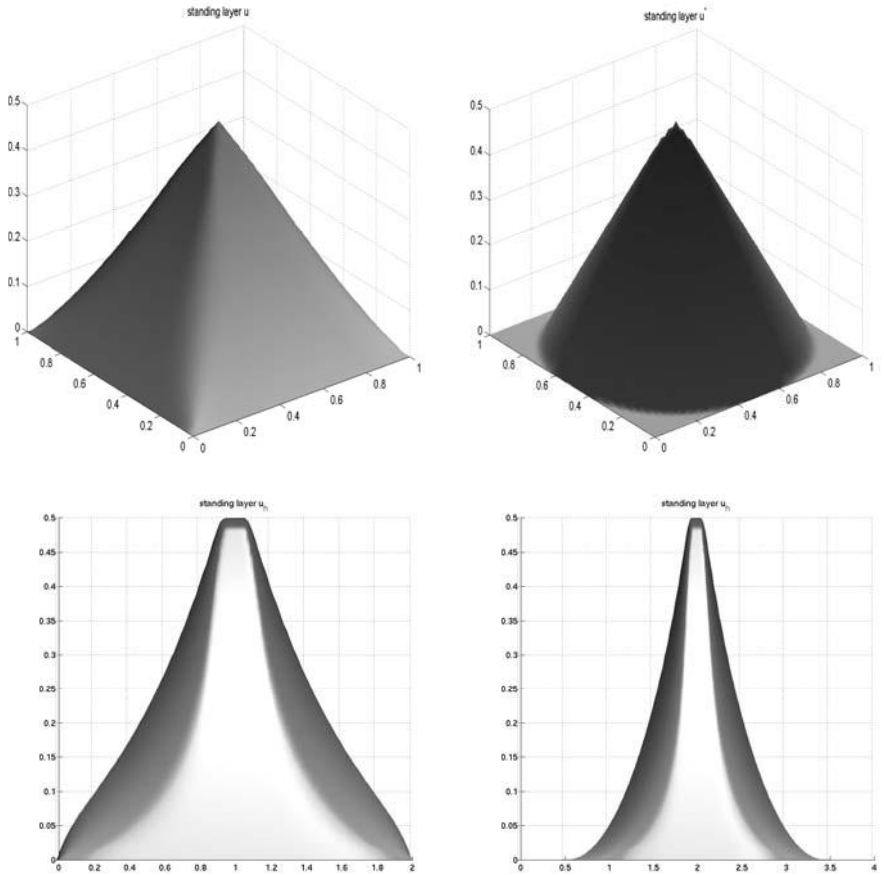

FIG. 5. *(HK-2D)* u_h *versus* u^* *for* $\Omega = (0,1) \times (0,1)$, $D_f = [0.45, 0.55]^2$, $f \equiv 0.5$, $N = M = 51$ *(top); asymptotic pile profiles when* $\Omega = (0,1) \times (0,2)$ *and* $\Omega = (0,1) \times (0,4)$ *(bottom).*

(b) show approximate equilibria that are always larger than the minimal ones. We are in case (b) if, for example, the source support is a small square at the center of the table. Then the stable equilibrium (11) has an almost conical shape, and sand is leaving the table only at the middle of the edges. The solution reached by the double-layer scheme instead fills the entire square table (Figure 5 (top)). We have to consider a much longer rectangular table in order to see also in this case a compact support solution. In Figure 5 (bottom) we see the different contact angles of the pile with the table when it touches the boundary and when it stays away from the boundary. Finally, we show a more general example, with a nonconstant source term $f(x,y) = \max\{0, \sin(2\pi x) + \cos(2\pi y) - \sin(2\pi xy)\}$ (its support is strictly contained in $\overline{\Omega}$). Note that the minimal stationary solution (11) in this case would be the union of cones of Figure 6 (top right), whereas the HK model evolves towards a relaxed equilibrium where sand partially fills the valleys among the heaps (top left). On the contrary, the corresponding rolling layers for the two equilibria are essentially the same (see Figure 6 (bottom)), in accordance with the partial uniqueness result of Theorem 2.1. As a final remark, it is interesting to note that the above experiments are in accordance with some real experiments reported in the literature; see, e.g., [1, 5, 15, 13, 17].

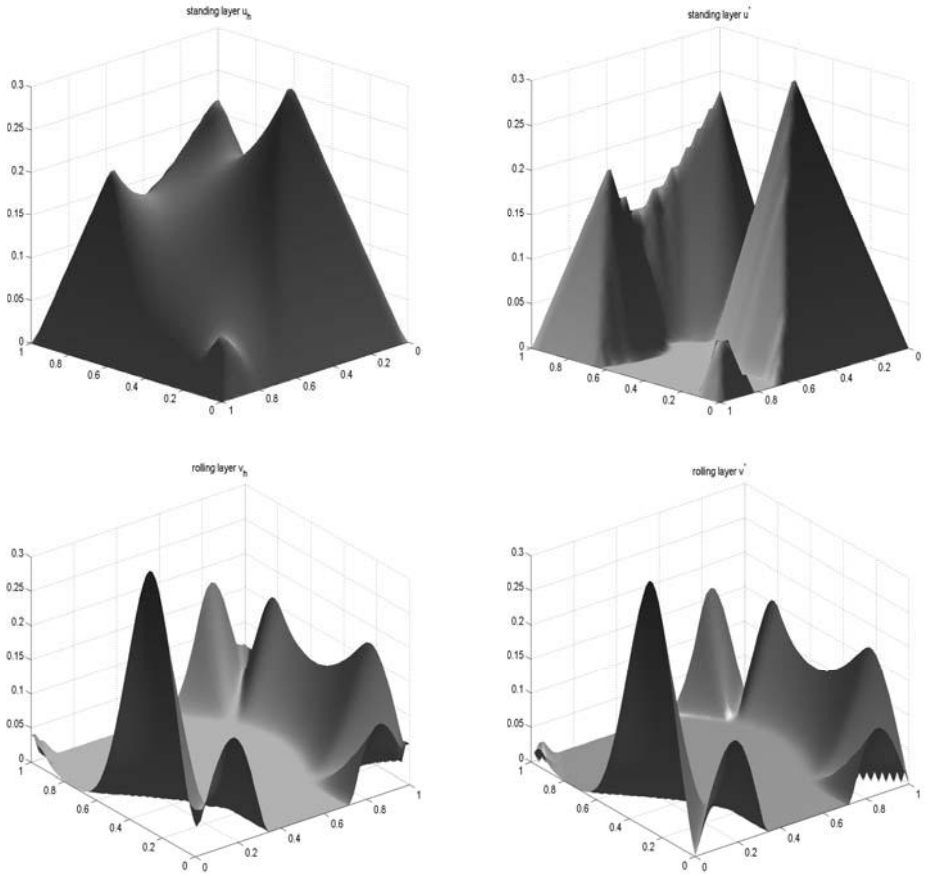

FIG. 6. *(HK-2D)* $\Omega = (0,1)\times(0,1)$, $D_f \subset \Omega$, $f(x,y) = \max\{0, \sin(2\pi x)+\cos(2\pi y)-\sin(2\pi xy)\}$, $N = M = 51$*:* u_h *versus* u^* *(top);* v_h *versus* v^* *(bottom).*

A NEUMANN–DIRICHLET PRECONDITIONER FOR A FETI-DP FORMULATION OF THE TWO-DIMENSIONAL STOKES PROBLEM WITH MORTAR METHODS*

HYEA HYUN KIM† AND CHANG-OCK LEE†

Abstract. A FETI-DP (dual-primal finite element tearing and interconnecting) formulation for the two-dimensional Stokes problem with mortar methods is considered. Separate sets of unknowns are used for velocity on interfaces, and the mortar constraints are enforced on the velocity unknowns by Lagrange multipliers. Average constraints on edges are further introduced as primal constraints to solve the Stokes problem correctly and to obtain a scalable FETI-DP algorithm. A Neumann–Dirichlet preconditioner is shown to give a condition number bound, $C \max_{i=1,\ldots,N}\{(1+\log(H_i/h_i))^2\}$, where H_i and h_i are the subdomain size and the mesh size, respectively, and the constant C is independent of the mesh parameters H_i and h_i.

Key words. FETI-DP, mortar methods, Neumann–Dirichlet preconditioner, Stokes problem

1. Introduction.

In this paper, an iterative substructuring method with Lagrange multipliers is studied for the two-dimensional Stokes problem with nonconforming discretizations. Nonconforming discretizations are important for multiphysics simulations, contact-impact problems, the generation of meshes and partitions aligned with jumps in diffusion coefficients, *hp*-adaptive methods, and special discretizations in the neighborhood of singularities. Of the many methods for nonconforming discretizations, including Galerkin methods [7], we consider the mortar methods [1, 3, 20, 21] originally introduced by Bernardi, Maday, and Patera.

Dual-primal FETI (FETI-DP) methods were introduced in [11] as a generalization of the FETI (finite element tearing and interconnecting) method [12]. Continuity of solutions at subdomain corners is enforced by primal variables to improve the convergence as well as to make local problems nonsingular. Later Mandel and Tezaur [17] proved that these algorithms give the condition number bound, $C\,(1+\log(H/h))^2$, for both second- and fourth-order elliptic problems in two dimensions. Here, H and h denote the subdomain size and mesh size, respectively. For three-dimensional elliptic problems with heterogeneous coefficients, Klawonn, Widlund, and Dryja [14] introduced averages over individual edges and/or faces as primal constraints to obtain a method as scalable as in two dimensions. Later FETI-DP algorithms were extended to the Stokes problem in both two and three dimensions by Li [15, 16]. Edge and/or face average constraints as well as vertex constraints are selected as a set of primal constraints to enhance the convergence of the FETI-DP algorithms.

Recently, FETI-DP methods have been applied to nonconforming discretizations [8, 9, 10, 13, 18]. For elliptic problems in two dimensions, Dryja and Widlund [9, 10] proposed several preconditioners and showed the condition number bound $C(1+\log(H/h))^2$. However, the constant C depends on the ratio of mesh sizes across

interfaces. Later, the current authors [13] proposed a Neumann–Dirichlet preconditioner, which gives the same condition number bound without the dependence of C upon the ratio of mesh sizes. The proposed preconditioner is similar to the previous FETI-DP preconditioners except that it solves local problems with Neumann boundary conditions on nonmortar interfaces and with a zero Dirichlet boundary condition on mortar interfaces.

The purpose of this paper is to extend the FETI-DP algorithm developed in [13] to the two-dimensional Stokes problem with mortar discretizations. The inf-sup stable $P_1(h)$-$P_0(2h)$ finite element space is considered in each subdomain. The triangulations are nonmatching across subdomain interfaces. To achieve the optimal approximation, we impose mortar matching conditions on the velocity functions. An optimal approximation of mortar methods for the Stokes problem was proved by Belgacem [2]. The inf-sup constant of the mortar finite element space is important in the analysis. If the constant is independent of mesh size and subdomain size, then the optimal order of approximation follows independent of the number of subdomains and mesh size, as in the case of elliptic problems. In [2], it was shown that the inf-sup constant is independent of mesh size for the Hood–Taylor finite element space, but this was not shown for the subdomain size. For the $P_1(h)$-$P_0(2h)$ mortar finite element space, we compute the inf-sup constant numerically by increasing the number of subdomains and decreasing mesh sizes, and we observe that the constant seems to be independent of these parameters.

We follow the FETI-DP formulation developed in [15]. The fundamental idea of the present paper is the same as one of [15], with additional technical complications caused by nonmatching grids across subdomain interfaces. Mortar matching constraints will be enforced on velocity unknowns across interfaces instead of pointwise matching constraints in conforming discretization. We introduce the primal constraints, i.e., edge average and vertex constraints, to solve the Stokes problem efficiently and correctly. We then propose a Neumann–Dirichlet preconditioner and analyze the condition number bound. The preconditioner consists of local Stokes problems with Neumann boundary conditions on nonmortar edges and a zero Dirichlet boundary condition on the remaining part of the subdomain boundary. The additional complication caused by mortar discretizations can be handled by using this preconditioner. In the analysis, the stability of the mortar projection in the $H_{00}^{1/2}$-norm is used. Our theory can be extended to Lagrange multiplier spaces with this property. Several such Lagrange multiplier spaces have been developed by Wohlmuth [20, 21].

This paper is organized as follows. Section 2 contains a brief introduction to Sobolev spaces and finite elements. In section 3, we derive a FETI-DP formulation of the Stokes problem. Section 4 is devoted to analyzing the condition number bound. Numerical results are included in section 5. Throughout this paper, C denotes a generic constant independent of mesh sizes and subdomain sizes. We will use H_i and h_i to denote the subdomain size and the typical mesh size of each subdomain Ω_i, respectively.

2. Sobolev spaces and finite elements.

2.1. A model problem. Let Ω be a bounded polygonal domain in $\mathbb{R}^2$, and let $L^2(\Omega)$ be the space of square integrable functions defined in Ω equipped with the norm

$$\|v\|_{0,\Omega}^2 := \int_\Omega v^2 \, dx.$$

The space $L^2_0(\Omega)$ contains functions in $L^2(\Omega)$ with zero average $\int_\Omega v\,dx = 0$. The space $H^1(\Omega)$ consists of functions that are square integrable up to the first weak derivatives with the norm

$$\|v\|^2_{1,\Omega} := \int \nabla v \cdot \nabla v\,dx + \int v^2\,dx.$$

The space $H^1_0(\Omega)$ is a subspace of $H^1(\Omega)$ with functions having zero trace on the boundary of Ω.

In this paper, we consider the following Stokes problem: For $\mathbf{f} \in [L^2(\Omega)]^2$, find $(\mathbf{u}, p) \in [H^1_0(\Omega)]^2 \times L^2_0(\Omega)$ satisfying

$$\begin{aligned} -\triangle \mathbf{u} + \nabla p &= \mathbf{f} \quad \text{in } \Omega, \\ -\nabla \cdot \mathbf{u} &= 0 \quad \text{in } \Omega, \\ \mathbf{u} &= \mathbf{0} \quad \text{on } \partial\Omega. \end{aligned} \tag{2.1}$$

We then partition Ω into nonoverlapping subdomains $\{\Omega_i\}_{i=1}^N$, which are geometrically conforming; a subdomain intersects its neighbors on a whole edge or at a vertex. For each subdomain, we introduce the space $H^1_D(\Omega_i)$ to be a subspace of $H^1(\Omega_i)$ with zero trace on $\partial\Omega_i \cap \partial\Omega$, the space $L^2_0(\Omega_i)$ to be a subspace of $L^2(\Omega_i)$ with zero average, and the space Π_0, which consists of functions that are constant in each subdomain and have zero average in Ω:

$$\begin{aligned} H^1_D(\Omega_i) &:= \left\{ v \in H^1(\Omega_i) \ : \ v = 0 \text{ on } \partial\Omega_i \cap \partial\Omega \right\}, \\ L^2_0(\Omega_i) &:= \left\{ q \in L^2(\Omega_i) \ : \ \int_{\Omega_i} q\,dx = 0 \right\}, \\ \Pi_0 &:= \left\{ q_0 \ : \ q_0|_{\Omega_i} \text{ is constant and } \int_\Omega q_0\,dx = 0 \right\}. \end{aligned} \tag{2.2}$$

The problem (2.1) is then written into an equivalent variational form: Find $(\mathbf{u}, p_I, p_0) \in \prod_{i=1}^N \left[H^1_D(\Omega_i)\right]^2 \times \prod_{i=1}^N L^2_0(\Omega_i) \times \Pi_0$ such that

$$\begin{aligned} \sum_{i=1}^N (\nabla \mathbf{u}, \nabla \mathbf{v})_{\Omega_i} - \sum_{i=1}^N (p_I + p_0, \nabla \cdot \mathbf{v})_{\Omega_i} &= \sum_{i=1}^N (\mathbf{f}, \mathbf{v})_{\Omega_i} \quad \forall\, \mathbf{v} \in \prod_{i=1}^N \left[H^1_D(\Omega_i)\right]^2, \\ -\sum_{i=1}^N (\nabla \cdot \mathbf{u}, q_I)_{\Omega_i} &= 0 \quad \forall\, q_I \in \prod_{i=1}^N L^2_0(\Omega_i), \\ -\sum_{i=1}^N (\nabla \cdot \mathbf{u}, q_0)_{\Omega_i} &= 0 \quad \forall\, q_0 \in \Pi_0, \\ \mathbf{u}|_{\Omega_i} - \mathbf{u}|_{\Omega_j} &= 0 \quad \forall\, \Gamma_{ij} = \partial\Omega_i \cap \partial\Omega_j. \end{aligned} \tag{2.3}$$

Here $(\cdot,\cdot)_{\Omega_i}$ denotes the inner product in $[L^2(\Omega_i)]^n$ for $n = 1, 2$. We now introduce a finite element space to approximate the above problem. Triangulations $\Omega_i^{2h_i}$ and $\Omega_i^{h_i}$ for pressure and velocity, respectively, are given in each subdomain. The finer triangulation $\Omega_i^{h_i}$ is obtained from $\Omega_i^{2h_i}$ by connecting midpoints of edges in the triangle $\tau \in \Omega_i^{2h_i}$ so that τ is divided into four triangles. We assume that these triangulations are quasi-uniform and may not match across subdomain interfaces. The finite element space $P_1(h_i) - P_0(2h_i)$ is then associated with each subdomain Ω_i;

we denote by X_i the space of conforming linear finite elements on the triangulation $\Omega_i^{h_i}$ and by Q_i the space of functions constant on each triangles in $\Omega_i^{2h_i}$ with zero average over Ω_i:

$$X_i := \left\{ \mathbf{v}_i \in \left[H_D^1(\Omega_i) \cap C(\Omega_i) \right]^2 \ : \ \mathbf{v}_i|_\tau \text{ is piecewise linear } \forall\, \tau \in \Omega_i^{h_i} \right\},$$
$$Q_i := \left\{ q_i \in L_0^2(\Omega_i) \ : \ q_i|_\tau \text{ is constant } \forall\, \tau \in \Omega_i^{2h_i} \right\}.$$

The inf-sup stability of the space $P_1(h_i) - P_0(2h_i)$ can be shown from the macro element technique in [19] or from the inf-sup stability of the space $P_2(2h_i) - P_0(2h_i)$ in [6]. The space $P_2(2h_i) - P_0(2h_i)$ consists of piecewise quadratic functions for velocity and piecewise constant functions for pressure in the same triangulation $\Omega_i^{2h_i}$. In the proof of the stability of $P_1(h_i) - P_0(2h_i)$, we may regard $P_2(2h_i) - P_0(2h_i)$ as identical to $P_1(h_i) - P_0(2h_i)$.

Our FETI-DP formulation will be described using the space X, an approximate space for velocity, which can be discontinuous across the interfaces except corners; the space Q_I for pressure, which has zero average in each subdomain; and the space W for velocity on the interfaces, which is continuous at corners and can be discontinuous on the remaining part:

$$\begin{aligned} X &:= \left\{ \mathbf{v} \in \prod_{i=1}^N X_i \ : \ \mathbf{v} \text{ is continuous at subdomain corners} \right\}, \\ Q_I &:= \prod_{i=1}^N Q_i, \\ W_i &:= X_i|_{\partial\Omega_i} \quad \text{for } i = 1, \dots, N, \\ W &:= \left\{ \mathbf{w} \in \prod_{i=1}^N W_i \ : \ \mathbf{w} \text{ is continuous at subdomain corners} \right\}. \end{aligned} \tag{2.4}$$

Throughout this paper, we will use the same notation for a finite element function and the nodal unknowns of the function. For example, $\mathbf{v}_i$ can be used to denote a finite element function or the corresponding nodal unknowns. The same holds for the notations W_i, X, W, etc.

We now introduce Sobolev spaces on the subdomain boundaries. The space $H^{1/2}(\partial\Omega_i)$ is the trace space of $H^1(\Omega_i)$ normed by

$$\|w_i\|_{1/2,\partial\Omega_i}^2 := |w_i|_{1/2,\partial\Omega_i}^2 + \frac{1}{H_i}\|w_i\|_{0,\partial\Omega_i}^2,$$

where

$$|w_i|_{1/2,\partial\Omega_i}^2 := \int_{\partial\Omega_i}\int_{\partial\Omega_i} \frac{|w_i(x) - w_i(y)|^2}{|x-y|^2}\, ds(x)\, ds(y).$$

For any $\Gamma_{ij} \subset \partial\Omega_i$, the space $H_{00}^{1/2}(\Gamma_{ij})$ is a set of functions in $L^2(\Gamma_{ij})$ of which zero extension to $\partial\Omega_i$ is contained in $H^{1/2}(\partial\Omega_i)$, and it is equipped with the norm

$$\|v\|_{H_{00}^{1/2}(\Gamma_{ij})}^2 := |v|_{H^{1/2}(\Gamma_{ij})}^2 + \int_{\Gamma_{ij}} \frac{v(x)^2}{\operatorname{dist}(x, \partial\Gamma_{ij})}\, ds.$$

From section 4.1 in [22], the following relation holds for $v \in H_{00}^{1/2}(\Gamma_{ij})$:

$$C_1 \|\widetilde{v}\|_{1/2,\partial\Omega_i} \le \|v\|_{H_{00}^{1/2}(\Gamma_{ij})} \le C_2 \|\widetilde{v}\|_{1/2,\partial\Omega_i}, \tag{2.5}$$

where $\widetilde{v}$ is the zero extension of v to $\partial\Omega_i$. The inequalities in (2.5) also hold for the product spaces $[H^{1/2}(\partial\Omega_i)]^2$ and $[H_{00}^{1/2}(\Gamma_{ij})]^2$ equipped with product norms.

2.2. Mortar methods. We consider the space X for velocity and the space $P = Q_I \times \Pi_0$ for pressure to approximate the Stokes problem (2.3); see (2.4) and (2.2) for the definitions of X, Q_I, and Π_0. We will impose the mortar matching condition on the velocity functions. On the interface $\Gamma_{ij} = \partial\Omega_i \cap \partial\Omega_j$, two different triangulations are given by the triangulations in Ω_i and Ω_j. We distinguish them by choosing one as a mortar side and the other as a nonmortar side. On each subdomain Ω_i, we define

$$m_i := \{j \ : \ \Omega_j \text{ is the mortar side of } \Gamma_{ij} \quad \forall\, \Gamma_{ij} \subset \partial\Omega_i\},$$

which is a set of subdomain indices j such that Ω_j intersects Ω_i on the interface Γ_{ij}, where Ω_j is chosen as the mortar side and Ω_i is chosen as the nonmortar side.

On each interface Γ_{ij}, we consider a trace space

$$X_{n(ij)}|_{\Gamma_{ij}}, \tag{2.6}$$

where $X_{n(ij)}$ is the finite element space on the nonmortar side of Γ_{ij}; i.e., $n(ij) = i$ if Ω_i is the nonmortar side of Γ_{ij}. The standard Lagrange multiplier space introduced in [3] is then given by

$$M_{ij} := \{\boldsymbol{\psi} \in X_{n(ij)}|_{\Gamma_{ij}} \ : \ \boldsymbol{\psi}|_\tau \text{ is constant on } \tau \text{ which intersects } \partial\Gamma_{ij}\}.$$

Here τ is the restriction of a triangle in the triangulation $\Omega_{n(ij)}^{h_{n(ij)}}$ to the interface Γ_{ij}. We then take the Lagrange multiplier space

$$M := \prod_{i=1}^{N} \prod_{j \in m_i} M_{ij}. \tag{2.7}$$

The mortar matching condition on $\mathbf{v} = (\mathbf{v}_1, \ldots, \mathbf{v}_N) \in X$ is

$$\int_{\Gamma_{ij}} (\mathbf{v}_i - \mathbf{v}_j) \cdot \boldsymbol{\lambda}_{ij}\, ds = 0 \quad \forall \boldsymbol{\lambda}_{ij} \in M_{ij},\ \forall\, i = 1, \ldots, N,\ \forall j \in m_i. \tag{2.8}$$

The mortar finite element space of velocity is then given by

$$V := \{\mathbf{v} \in X \ : \ \mathbf{v} \text{ satisfies the mortar matching condition (2.8)}\}. \tag{2.9}$$

It was shown in [2] that the best approximation property holds for the space $V \times P$, given by the Hood–Taylor finite element space for each subdomain, if it satisfies the inf-sup condition

$$\inf_{q \in P} \sup_{\mathbf{v} \in V} \frac{\int_\Omega \nabla \cdot \mathbf{v}\, q\, dx}{\|v\|_{1,\Omega}^* \|q\|_{0,\Omega}} \ge \beta,$$

where the constant β is independent of the mesh size and the subdomain size. Here $\|v\|^*_{1,\Omega}$ denotes the broken H^1-norm

$$\|v\|^*_{1,\Omega} = \left(\sum_{i=1}^{N} \|v\|^2_{1,\Omega_i} \right)^{1/2}.$$

To our best knowledge, there is no mathematical proof that shows that the constant β is independent of the subdomain size. We compute the inf-sup constant numerically and observe that the constant is independent of the subdomain size as well as the mesh size; see section 5. Therefore we can get a solution as accurate as that in conforming approximations.

3. FETI-DP formulation.

3.1. Notation. We will introduce several notations which will be used in the FETI-DP formulation. We recall X_i, the velocity finite element space in Ω_i; W_i, the trace space of X_i on $\partial\Omega_i$; and X, a subspace of the product space of X_i with functions that are continuous at subdomain corners. The space W is similarly defined as a subspace of the product space of W_i. The definitions of these spaces are given in (2.4).

The unknowns $\mathbf{v}_i \in X_i$ and $\mathbf{w}_i \in W_i$ are ordered into

$$\mathbf{v}_i = \begin{pmatrix} \mathbf{v}_I^i \\ \mathbf{v}_r^i \\ \mathbf{v}_c^i \end{pmatrix}, \quad \mathbf{w}_i = \begin{pmatrix} \mathbf{w}_r^i \\ \mathbf{w}_c^i \end{pmatrix},$$

where the subscripts I, r, and c represent the d.o.f. (degrees of freedom) corresponding to the interior, edges, and corners, respectively. We define the following spaces based on the splitting of unknowns: X_I, the space of velocity unknowns at the interior of each subdomain; W_r, the space of velocity unknowns at the interior of both mortar and nonmortar edges; W_c, the space of velocity unknowns at global corners; and W_c^i, the space of velocity unknowns at subdomain corners:

$$\begin{aligned} X_I &= \left\{ \mathbf{v}_I \ : \ \mathbf{v}_I|_{\Omega_i} = \mathbf{v}_I^i, \quad \forall i = 1, \ldots, N \right\}, \\ W_r &= \left\{ \mathbf{w}_r \ : \ \mathbf{w}_r|_{\partial\Omega_i} = \mathbf{w}_r^i, \quad \forall i = 1, \ldots, N \right\}, \\ W_c &= \left\{ \mathbf{w}_c \ : \ \mathbf{w}_c \text{ are velocity unknowns at global corners} \right\}, \\ W_c^i &= \left\{ \mathbf{w}_c^i \ : \ \mathbf{w}_c^i \text{ are velocity unknowns at corners in } \Omega_i \right\}. \end{aligned} \tag{3.1}$$

We further define the restriction map

$$L_c^i \ : \ W_c \to W_c^i$$

that gives

$$L_c^i \mathbf{w}_c = \mathbf{w}_c^i \quad \forall i = 1, \ldots, N, \text{ for } \mathbf{w}_c \in W_c.$$

We will now express the mortar matching condition (2.8) as a matrix form

$$B\mathbf{w} = \mathbf{0}, \tag{3.2}$$

where

$$\begin{aligned} B &= \begin{pmatrix} B_1 & \cdots & B_N \end{pmatrix}, \\ \mathbf{w} &= \begin{pmatrix} \mathbf{w}_1^t & \cdots & \mathbf{w}_N^t \end{pmatrix}^t, \qquad \mathbf{w}_i = \mathbf{v}_i|_{\partial\Omega_i}. \end{aligned}$$

Since $\mathbf{w}$ is continuous at global corners, the above equation can be written as a different form with unknowns $\mathbf{w}_r \in W_r$ and $\mathbf{w}_c \in W_c$:

$$B_r \mathbf{w}_r + B_c \mathbf{w}_c = \mathbf{0}, \tag{3.3}$$

where B_r and B_c are assembled by local matrices $B_{i,r}$ and $B_{i,c}$,

$$B_r = \begin{pmatrix} B_{1,r} & \cdots & B_{N,r} \end{pmatrix}, \qquad B_c = \sum_{i=1}^{N} B_{i,c} L_c^i.$$

These matrices $B_{i,r}$ and $B_{i,c}$ consist of the columns of B_i corresponding to the unknowns on edges and corners, respectively. We will use any of these two expressions (3.2) and (3.3) from place to place for the sake of convenience.

3.2. FETI-DP formulation with primal constraints. In this section, we formulate a FETI-DP operator with the mortar constraints (3.3). To solve the Stokes problem efficiently, we will consider the following primal constraints:

$$\int_{\Gamma_{ij}} (\mathbf{v}_i - \mathbf{v}_j)\, ds = \mathbf{0} \qquad \forall i = 1, \ldots, N,\ \forall j \in m_i. \tag{3.4}$$

Note that (3.4) holds by replacing $\boldsymbol{\lambda}_{ij} = \binom{1}{0}$ or $\binom{0}{1}$ in (2.8), because constant multipliers belong to the Lagrange multiplier space M_{ij}. These constraints are average matching conditions of each velocity component on subdomain interfaces. These primal constraints were introduced by Li [15, 16] to the Stokes problem with conforming discretization. The primal constraints enlarge the size of the coarse problem so that it may lead to a fast convergence of the FETI-DP iteration.

We write (3.4) as

$$R^t (B_r \mathbf{w}_r + B_c \mathbf{w}_c) = \mathbf{0}, \tag{3.5}$$

where the matrix R is a Boolean matrix that has the number of columns equal to twice the number of interfaces Γ_{ij}, and the number of rows equal to the d.o.f. of the space M. For $\boldsymbol{\lambda} \in M$, at each interior nodal point of Γ_{ij}, $\boldsymbol{\lambda}|_{\Gamma_{ij}}$ has two components corresponding to horizontal and vertical parts of velocity function, and $R^t \boldsymbol{\lambda} = \mathbf{0}$ means that sums of each $\boldsymbol{\lambda}|_{\Gamma_{ij}}$ corresponding to the horizontal and vertical parts of velocity function are zero.

Let U be the Lagrange multiplier space corresponding to the constraints (3.5); for $\boldsymbol{\mu} \in U$, $\boldsymbol{\mu}|_{\Gamma_{ij}}$ has two components that correspond to the constraints for each horizontal velocity and vertical velocity on the interface Γ_{ij}. By introducing Lagrange multipliers $\boldsymbol{\lambda}$ and $\boldsymbol{\mu}$ to enforce the constraints (3.3) and (3.5), we have the following mixed formulation of the problem (2.3): Find $(\mathbf{u}_I, p_I, \mathbf{u}_r, \mathbf{u}_c, p_0, \boldsymbol{\mu}, \boldsymbol{\lambda}) \in X_I \times Q_I \times W_r \times W_c \times \Pi_0 \times U \times M$ such that

$$\begin{pmatrix} A_{II} & G_{II} & A_{Ir} & A_{Ic} & G_{I0} & \mathbf{0} & \mathbf{0} \\ G_{II}^t & \mathbf{0} & G_{rI}^t & G_{cI}^t & \mathbf{0} & \mathbf{0} & \mathbf{0} \\ A_{rI} & G_{rI} & A_{rr} & A_{rc} & G_{r0} & B_r^t R & B_r^t \\ A_{cI} & G_{cI} & A_{cr} & A_{cc} & G_{c0} & B_c^t R & B_c^t \\ G_{I0}^t & \mathbf{0} & G_{r0}^t & G_{c0}^t & \mathbf{0} & \mathbf{0} & \mathbf{0} \\ \mathbf{0} & \mathbf{0} & R^t B_r & R^t B_c & \mathbf{0} & \mathbf{0} & \mathbf{0} \\ \mathbf{0} & \mathbf{0} & B_r & B_c & \mathbf{0} & \mathbf{0} & \mathbf{0} \end{pmatrix} \begin{pmatrix} \mathbf{u}_I \\ p_I \\ \mathbf{u}_r \\ \mathbf{u}_c \\ p_0 \\ \boldsymbol{\mu} \\ \boldsymbol{\lambda} \end{pmatrix} = \begin{pmatrix} \mathbf{f}_I \\ \mathbf{0} \\ \mathbf{f}_r \\ \mathbf{f}_c \\ \mathbf{0} \\ \mathbf{0} \\ \mathbf{0} \end{pmatrix}. \tag{3.6}$$

Here

$$\begin{pmatrix} A_{II} & A_{Ir} & A_{Ic} \\ A_{rI} & A_{rr} & A_{rc} \\ A_{cI} & A_{cr} & A_{cc} \end{pmatrix} \quad \text{is a stiffness matrix given by} \quad \sum_{i=1}^{N} (\nabla \mathbf{u}, \nabla \mathbf{v})_{\Omega_i},$$

$$\begin{pmatrix} G_{II}^t & G_{rI}^t & G_{cI}^t \end{pmatrix} \quad \text{is a matrix given by} \quad \sum_{i=1}^{N} (-\nabla \cdot \mathbf{v}, p_I)_{\Omega_i},$$

$$\begin{pmatrix} G_{I0}^t & G_{r0}^t & G_{c0}^t \end{pmatrix} \quad \text{is a matrix given by} \quad \sum_{i=1}^{N} (-\nabla \cdot \mathbf{v}, p_0)_{\Omega_i}.$$

The velocity spaces X_I, W_r, and W_c are defined in (3.1). For the definitions of spaces Q_I, Π_0, and M, see (2.4), (2.2), and (2.7), respectively. Since $p_0|_{\Omega_i}$ is constant and $\mathbf{v}_I|_{\partial\Omega_i} = \mathbf{0}$ for $\mathbf{v}_I \in X_I$, the divergence theorem gives $G_{I0} = \mathbf{0}$.

Let

$$\mathbf{z}_r = \begin{pmatrix} \mathbf{u}_I \\ p_I \\ \mathbf{u}_r \end{pmatrix}, \quad \mathbf{z}_c = \begin{pmatrix} \mathbf{u}_c \\ p_0 \\ \boldsymbol{\mu} \end{pmatrix}.$$

We regard $\mathbf{z}_c$ as a primal variable in the FETI-DP formulation and then write (3.6) into

$$\begin{pmatrix} K_{rr} & K_{rc} & \widetilde{B}_r^t \\ K_{rc}^t & K_{cc} & \widetilde{B}_c^t \\ \widetilde{B}_r & \widetilde{B}_c & \mathbf{0} \end{pmatrix} \begin{pmatrix} \mathbf{z}_r \\ \mathbf{z}_c \\ \boldsymbol{\lambda} \end{pmatrix} = \begin{pmatrix} \widetilde{\mathbf{f}}_r \\ \widetilde{\mathbf{f}}_c \\ \mathbf{0} \end{pmatrix}.$$

In section 4, we will show that the matrix K_{rr} is invertible; see Lemma 4.1. After eliminating $\mathbf{z}_r$, we obtain the following equation for $\mathbf{z}_c$ and $\boldsymbol{\lambda}$:

$$\begin{pmatrix} -F_{cc} & F_{cl} \\ F_{cl}^t & F_{ll} \end{pmatrix} \begin{pmatrix} \mathbf{z}_c \\ \boldsymbol{\lambda} \end{pmatrix} = \begin{pmatrix} -\mathbf{d}_c \\ \mathbf{d}_l \end{pmatrix},$$

where

$$\begin{aligned} F_{ll} &= \widetilde{B}_r K_{rr}^{-1} \widetilde{B}_r^t, \\ F_{cl} &= K_{rc}^t K_{rr}^{-1} \widetilde{B}_r^t - \widetilde{B}_c^t, \\ F_{cc} &= K_{cc} - K_{rc}^t K_{rr}^{-1} K_{rc}, \\ \mathbf{d}_l &= \widetilde{B}_r K_{rr}^{-1} \widetilde{\mathbf{f}}_r, \\ \mathbf{d}_c &= \widetilde{\mathbf{f}}_c - K_{rc}^t K_{rr}^{-1} \widetilde{f}_r. \end{aligned}$$

The matrix F_{cc}, a coarse problem in the FETI-DP formulation, is invertible; see Lemma 4.2. By eliminating $\mathbf{z}_c$, we then obtain the following equation for $\boldsymbol{\lambda}$:

$$F_{DP} \boldsymbol{\lambda} = \mathbf{d}_l - F_{cl}^t F_{cc}^{-1} \mathbf{d}_c, \tag{3.7}$$

where

$$F_{DP} = F_{ll} + F_{cl}^t F_{cc}^{-1} F_{cl}.$$

Since the primal constraints (3.4) are selected from the mortar matching condition, the solution $\boldsymbol{\lambda}$ is not uniquely determined in the space M. We define a subspace

$$\widetilde{M} = \left\{ \boldsymbol{\lambda} \in M \ : \ R^t \boldsymbol{\lambda} = \mathbf{0} \right\}, \tag{3.8}$$

where the matrix R is given in (3.5). The matrix F_{DP} is symmetric and positive definite on $\widetilde{M}$; see Remark 4.3. Hence the solution $\boldsymbol{\lambda}$ of (3.7) is uniquely determined in $\widetilde{M}$.

3.3. Preconditioner. We will define several norms of the finite element function spaces given on the interfaces and propose a preconditioner for the operator F_{DP}.

First, we define a norm for the velocity space W on the interfaces. For $\mathbf{w}_i \in W_i$, we define $S_i \mathbf{w}_i$ by

$$\begin{pmatrix} A_{II}^i & G_{II}^i & A_{Ir}^i & A_{Ic}^i \\ (G_{II}^i)^t & \mathbf{0} & (G_{rI}^i)^t & (G_{cI}^i)^t \\ A_{rI}^i & G_{rI}^i & A_{rr}^i & A_{rc}^i \\ A_{cI}^i & G_{cI}^i & A_{cr}^i & A_{cc}^i \end{pmatrix} \begin{pmatrix} \mathbf{u}_I^i \\ p_I^i \\ \mathbf{w}_r^i \\ \mathbf{w}_c^i \end{pmatrix} = \begin{pmatrix} \mathbf{0} \\ \mathbf{0} \\ S_i \begin{pmatrix} \mathbf{w}_r^i \\ \mathbf{w}_c^i \end{pmatrix} \end{pmatrix},$$

where the superscript i for a matrix denotes the submatrix corresponding to the subdomain Ω_i. Since the upper left 2×2 matrix

$$\begin{pmatrix} A_{II}^i & G_{II}^i \\ (G_{II}^i)^t & \mathbf{0} \end{pmatrix}$$

represents the local Stokes problem with a Dirichlet boundary condition, it is invertible so that the Schur complement S_i is well defined. We then assemble local Schur complement matrices and define

$$S := \operatorname{diag}(S_1, \ldots, S_N).$$

It can be seen easily that S is symmetric and positive definite on W.

We now introduce finite element spaces given on the nonmortar interfaces:

$$W_{ij} := \left\{ \mathbf{w}_{ij} \in X_{n(ij)}|_{\Gamma_{ij}} \ : \ \mathbf{w}_{ij} \text{ vanishes at the end points of } \Gamma_{ij} \right\},$$
$$W_n := \prod_{i=1}^{N} \prod_{j \in m_i} W_{ij}.$$

Here $n(ij)$ denotes the nonmortar subdomain of the interface Γ_{ij}. We define by $E(\mathbf{w}_n)$ the zero extension of the function $\mathbf{w}_n \in W_n$ to the all interfaces, i.e., mortar and nonmortar interfaces. We further define the following subspaces of W and W_n that satisfy a certain set of constraints:

$$\begin{aligned} \widetilde{W} &:= \left\{ \mathbf{w} \in W \ : \ \int_{\Gamma_{ij}} (\mathbf{w}_i - \mathbf{w}_j)\, ds = 0, \quad \forall\, \Gamma_{ij} \right\}, \\ \widetilde{\widetilde{W}} &:= \left\{ \mathbf{w} \in \widetilde{W} \ : \ \int_{\partial \Omega_i} \mathbf{w}_i \cdot \mathbf{n}_i = 0, \quad \forall i \right\}, \\ \widetilde{W}_n &:= \left\{ \mathbf{w}_n \in W_n \ : \ \int_{\Gamma_{ij}} \mathbf{w}\, ds = 0, \quad \forall\, \Gamma_{ij} \right\}, \end{aligned} \tag{3.9}$$

where $\mathbf{n}_i$ denotes the outward unit normal vector on the subdomain boundary $\partial \Omega_i$.

We now introduce the Neumann–Dirichlet preconditioner $\widehat{F}_{DP}^{-1}$ given by

$$\langle \widehat{F}_{DP}\boldsymbol{\lambda}, \boldsymbol{\lambda}\rangle = \max_{\mathbf{w}_n \in \widetilde{W}_n \setminus \{0\}} \frac{\langle BE(\mathbf{w}_n), \boldsymbol{\lambda}\rangle^2}{\langle SE(\mathbf{w}_n), E(\mathbf{w}_n)\rangle}. \tag{3.10}$$

In the following, we will provide an explicit form of $\widehat{F}_{DP}^{-1}$ in detail. We define the l^2-orthogonal projections P and P_n by

$$P \,:\, M \to \widetilde{M}, \qquad P_n \,:\, W_n \to \widetilde{W}_n.$$

Since the constraints on the spaces $\widetilde{M}$ and $\widetilde{W}_n$ are given locally on each nonmortar interface, these projections are composed of diagonal blocks of projections defined on each nonmortar interface,

$$P = \mathrm{diag}_{i=1,\dots,N}\left(\mathrm{diag}_{j\in m_i}\left(P^{ij}\right)\right), \quad P_n = \mathrm{diag}_{i=1,\dots,N}\left(\mathrm{diag}_{j\in m_i}\left(P_n^{ij}\right)\right), \tag{3.11}$$

where P^{ij} and P_n^{ij} are l^2-orthogonal projections given by

$$P^{ij} \,:\, M|_{\Gamma_{ij}} \to \widetilde{M}|_{\Gamma_{ij}}, \qquad P_n^{ij} \,:\, W_n|_{\Gamma_{ij}} \to \widetilde{W}_n|_{\Gamma_{ij}}.$$

We define the restriction R_{ij} and the extension E_{ij}^i by

$$R_{ij} \,:\, W_n \to W_{ij}, \quad E_{ij}^i \,:\, W_{ij} \to W_i,$$

and then express the zero extension $E(\mathbf{w}_n) = (\mathbf{w}_1, \dots, \mathbf{w}_N)$ as

$$\mathbf{w}_i = E_i \mathbf{w}_n \quad \text{with} \quad E_i = \sum_{j\in m_i} E_{ij}^i R_{ij}. \tag{3.12}$$

Using this notation, the formula (3.10) is written as

$$\langle \widehat{F}_{DP}\boldsymbol{\lambda}, \boldsymbol{\lambda}\rangle = \max_{\mathbf{w}_n \in \widetilde{W}_n \setminus \{0\}} \frac{\langle \widehat{B}\mathbf{w}_n, \boldsymbol{\lambda}\rangle^2}{\langle \widehat{S}\mathbf{w}_n, \mathbf{w}_n\rangle}, \tag{3.13}$$

where

$$\widehat{S} = \sum_{i=1}^{N} E_i^t S_i E_i, \qquad \widehat{B} = \mathrm{diag}_{i=1}^{N}\left(\mathrm{diag}_{j\in m_i}\left(B_{ij}\right)\right). \tag{3.14}$$

Here the matrix B_{ij} is a block of B_i corresponding to the unknowns of the nonmortar interface $\Gamma_{ij} \subset \partial\Omega_i$. It is easy to check that

$$\widehat{B} \,:\, \widetilde{W}_n \to \widetilde{M}$$

is one-to-one for $\dim(\widetilde{W}_n) = \dim(\widetilde{M})$ and $\widehat{B}(\widetilde{W}_n) \subset \widetilde{M}$, and that $\widehat{S}$ is symmetric and positive definite on $\widetilde{W}_n$; see (3.8) and (3.9). Let

$$\widehat{B}_p = P^t \widehat{B} P_n, \qquad \widehat{S}_p = P_n^t \widehat{S} P_n. \tag{3.15}$$

These operators are invertible, and their inverses are denoted by $\widehat{B}_p^{-1}$ and $\widehat{S}_p^{-1}$, respectively. The maximum in (3.13) occurs when $\mathbf{w}_n \in \widetilde{W}_n$ satisfies $\widehat{S}_p \mathbf{w}_n = \widehat{B}_p^t \boldsymbol{\lambda}$, and it gives

$$\langle \widehat{F}_{DP}\boldsymbol{\lambda}, \boldsymbol{\lambda}\rangle = \langle \widehat{B}_p \widehat{S}_p^{-1} \widehat{B}_p^t \boldsymbol{\lambda}, \boldsymbol{\lambda}\rangle.$$

Since $\widehat{B}_p$ is block diagonal, $\widehat{B}_p^{-1}$ can be written as

$$\widehat{B}_p^{-1} = \mathrm{diag}_{i=1}^{N}\left(\mathrm{diag}_{j\in m_i}\left((B_p^{ij})^{-1}\right)\right), \qquad B_p^{ij} = (P^{ij})^t B_{ij} P_n^{ij}. \tag{3.16}$$

By using the expressions in (3.11), (3.12), and (3.14)–(3.16), we obtain

$$\widehat{F}_{DP}^{-1} = (\widehat{B}_p^t)^{-1}\widehat{S}_p\widehat{B}_p^{-1} = \sum_{i=1}^{N} B_{i,n}^t S_i B_{i,n},$$

where $B_{i,n}$ is given by

$$B_{i,n} = \begin{pmatrix} \mathrm{diag}_{j\in m_i}\left(P_n^{ij}(B_p^{ij})^{-1}\right) \\ 0 \end{pmatrix} R_i.$$

Here $R_i : M \to \Pi_{j\in m_i} M_{ij}$ is the restriction, and the zero submatrix corresponds to the unknowns of the mortar edges and corners that belong to Ω_i. The matrix $B_{i,n}$ provides each subdomain problem with Neumann boundary conditions on the nonmortar edges and a zero Dirichlet boundary condition on the remaining part of the subdomain boundary. Hence we call it a Neumann–Dirichlet preconditioner.

4. Condition number estimation. In this section we analyze the condition number bound of the FETI-DP operator with the Neumann–Dirichlet preconditioner. In advance, we will provide the following two lemmas, which prove that the matrices K_{rr} and F_{cc} are invertible.

LEMMA 4.1. [illegible] K_{rr} [illegible] $X_I \times Q_I \times W_r$ [illegible]. Since the upper left 2×2 matrix of K_{rr} is invertible, it suffices to show that the Schur complement S_{rr} is invertible on W_r:

$$\begin{pmatrix} A_{II} & G_{II} & A_{Ir} \\ G_{II}^t & \mathbf{0} & G_{rI}^t \\ A_{rI} & G_{rI} & A_{rr} \end{pmatrix} \begin{pmatrix} \mathbf{u}_I \\ p_I \\ \mathbf{u}_r \end{pmatrix} = \begin{pmatrix} \mathbf{0} \\ \mathbf{0} \\ S_{rr}\mathbf{u}_r \end{pmatrix}. \tag{4.1}$$

For any $\mathbf{u}_r \in W_r$, we consider

$$\begin{aligned} \mathbf{u}_r^t S_{rr}\mathbf{u}_r &= \begin{pmatrix} \mathbf{u}_I \\ p_I \\ \mathbf{u}_r \end{pmatrix}^t \begin{pmatrix} A_{II} & G_{II} & A_{Ir} \\ G_{II}^t & \mathbf{0} & G_{rI}^t \\ A_{rI} & G_{rI} & A_{rr} \end{pmatrix} \begin{pmatrix} \mathbf{u}_I \\ p_I \\ \mathbf{u}_r \end{pmatrix} \\ &= \begin{pmatrix} \mathbf{u}_I \\ \mathbf{u}_r \end{pmatrix}^t \begin{pmatrix} A_{II} & A_{Ir} \\ A_{rI} & A_{rr} \end{pmatrix} \begin{pmatrix} \mathbf{u}_I \\ \mathbf{u}_r \end{pmatrix} + 2p_I^t \begin{pmatrix} G_{II}^t & G_{rI}^t \end{pmatrix} \begin{pmatrix} \mathbf{u}_I \\ \mathbf{u}_r \end{pmatrix} \\ &= \begin{pmatrix} \mathbf{u}_I \\ \mathbf{u}_r \end{pmatrix}^t \begin{pmatrix} A_{II} & A_{Ir} \\ A_{rI} & A_{rr} \end{pmatrix} \begin{pmatrix} \mathbf{u}_I \\ \mathbf{u}_r \end{pmatrix}. \end{aligned}$$

Here $\mathbf{u}_I$ and p_I are the solution of (4.1), and we have used that $G_{II}^t\mathbf{u}_I + G_{rI}^t\mathbf{u}_r = \mathbf{0}$. The last equality in the above equation gives that S_{rr} is symmetric and positive definite on W_r. ∎

LEMMA 4.2. [illegible] Ω [illegible]

$$-\sum_i (p_0, \nabla\cdot\mathbf{v}_r)_{\Omega_i} + \sum_{i,j} \boldsymbol{\mu}\cdot\int_{\Gamma_{ij}} (\mathbf{v}_r^i - \mathbf{v}_r^j)\,ds = 0 \quad \forall\ \mathbf{v}_r \in W_r,$$

$$-\sum_i (p_0, \nabla\cdot\mathbf{v}_c)_{\Omega_i} + \sum_{i,j} \boldsymbol{\mu}\cdot\int_{\Gamma_{ij}} (\mathbf{v}_c^i - \mathbf{v}_c^j)\,ds = 0 \quad \forall\ \mathbf{v}_c \in W_c$$

[illegible] $\begin{pmatrix} p_0 \\ \boldsymbol{\mu} \end{pmatrix}$ [illegible] F_{cc} [illegible]

. We define a Schur complement matrix

$$\begin{pmatrix} A_{II} & G_{II} & A_{Ir} & A_{Ic} \\ G_{II}^t & 0 & G_{rI}^t & G_{cI}^t \\ A_{rI} & G_{rI} & A_{rr} & A_{rc} \\ A_{cI} & G_{cI} & A_{cr} & A_{cc} \end{pmatrix} \begin{pmatrix} \mathbf{u}_I \\ p_I \\ \mathbf{u}_r \\ \mathbf{u}_c \end{pmatrix} = \begin{pmatrix} \mathbf{0} \\ \mathbf{0} \\ \begin{pmatrix} S_{rr} & S_{rc} \\ S_{cr} & S_{cc} \end{pmatrix} \begin{pmatrix} \mathbf{u}_r \\ \mathbf{u}_c \end{pmatrix} \end{pmatrix}.$$

As in the proof of the previous lemma, we can show that the Schur complement

$$\begin{pmatrix} S_{rr} & S_{rc} \\ S_{cr} & S_{cc} \end{pmatrix}$$

is symmetric and positive definite. The matrix F_{cc} is then given by

$$\begin{pmatrix} S_{rr} & S_{rc} & G_{r0} & B_r^t R \\ S_{cr} & S_{cc} & G_{c0} & B_c^t R \\ G_{r0}^t & G_{c0}^t & \mathbf{0} & \mathbf{0} \\ R^t B_r & R^t B_c & \mathbf{0} & \mathbf{0} \end{pmatrix} \begin{pmatrix} \mathbf{u}_r \\ \mathbf{u}_c \\ p_0 \\ \boldsymbol{\mu} \end{pmatrix} = \begin{pmatrix} \mathbf{0} \\ F_{cc} \begin{pmatrix} \mathbf{u}_c \\ p_0 \\ \boldsymbol{\mu} \end{pmatrix} \end{pmatrix}. \tag{4.2}$$

We assume that $\mathbf{u}_c$, p_0, and $\boldsymbol{\mu}$ give

$$F_{cc} \begin{pmatrix} \mathbf{u}_c \\ p_0 \\ \boldsymbol{\mu} \end{pmatrix} = 0,$$

and we will show that they are zero. Multiplying (4.2) by $\begin{pmatrix} \mathbf{u}_r^t & \mathbf{u}_c^t & -p_0^t & -\boldsymbol{\mu}^t \end{pmatrix}$, we obtain

$$\begin{pmatrix} \mathbf{u}_r \\ \mathbf{u}_c \end{pmatrix}^t \begin{pmatrix} S_{rr} & S_{rc} \\ S_{cr} & S_{cc} \end{pmatrix} \begin{pmatrix} \mathbf{u}_r \\ \mathbf{u}_c \end{pmatrix} + \begin{pmatrix} \mathbf{u}_r \\ \mathbf{u}_c \end{pmatrix}^t \begin{pmatrix} G_{r0} & B_r^t R \\ G_{c0} & B_c^t R \end{pmatrix} \begin{pmatrix} p_0 \\ \boldsymbol{\mu} \end{pmatrix} - \begin{pmatrix} p_0 \\ \boldsymbol{\mu} \end{pmatrix}^t \begin{pmatrix} G_{r0}^t & G_{c0}^t \\ R^t B_r & R^t B_c \end{pmatrix} \begin{pmatrix} \mathbf{u}_r \\ \mathbf{u}_c \end{pmatrix} = 0.$$

It follows that $\begin{pmatrix} \mathbf{u}_r \\ \mathbf{u}_c \end{pmatrix} = 0$ because the Schur complement matrix is symmetric and positive definite and the last two terms cancel each other. Equation (4.2) then reduces to

$$\begin{pmatrix} G_{r0} & B_r^t R \\ G_{c0} & B_c^t R \end{pmatrix} \begin{pmatrix} p_0 \\ \boldsymbol{\mu} \end{pmatrix} = 0.$$

This is equivalent to the equation in the assumption. Hence we have $\begin{pmatrix} p_0 \\ \boldsymbol{\mu} \end{pmatrix} = 0$. □

. . . . 4.1. Most triangulations of the domain Ω satisfy the assumption of Lemma 4.2 because the number of velocity unknowns $\mathbf{v}_r$ and $\mathbf{v}_c$ is usually grater than the number of unknowns p_0 and $\boldsymbol{\mu}$.

LEMMA 4.3. . .

$$B(\widetilde{\widetilde{W}}) = B(\widetilde{W}) = \widetilde{M}.$$

. . . . From $\widetilde{\widetilde{W}} \subset \widetilde{W}$, the inclusion $B(\widetilde{\widetilde{W}}) \subset B(\widetilde{W})$ is obvious.

We will show that

$$B(\widetilde{W}) \subset B(\widetilde{\widetilde{W}}).$$

Let $E(\mathbf{w}_n) = (\mathbf{w}_1, \ldots, \mathbf{w}_N) \in W$ be the zero extension of $\mathbf{w}_n \in W_n$. Since $\mathbf{w}_j|_{\Gamma_{ij}} = 0$ for $j \in m_i$, i.e., for functions on mortar interfaces, and $E(\mathbf{w}_n)$ has zero value at subdomain corners, the identity holds

$$B(E(\mathbf{w}_n)) = \widehat{B}\mathbf{w}_n, \tag{4.3}$$

where the matrix $\widehat{B}$ is defined in (3.14), and it is one-to-one from $\widetilde{W}_n$ onto $\widetilde{M}$,

$$\widehat{B}(\widetilde{W}_n) = \widetilde{M}. \tag{4.4}$$

For $\mathbf{w}_n \in \widetilde{W}_n$, the zero extension $E(\mathbf{w}_n) = (\mathbf{w}_1, \ldots, \mathbf{w}_N)$ satisfies

$$\int_{\Gamma_{ij}} \mathbf{w}_i \, ds = \mathbf{0} \qquad \forall\, i = 1, \ldots, N, \quad \forall \Gamma_{ij} \subset \partial\Omega_i,$$

and then the compatibility condition of the local Stokes problem holds:

$$\int_{\partial\Omega_i} \mathbf{w}_i \cdot \mathbf{n}_i \, ds = 0.$$

This implies that $E(\mathbf{w}_n)$, for $\mathbf{w}_n \in \widetilde{W}_n$, belongs to the space $\widetilde{\widetilde{W}}$. From this fact and (4.3) we obtain

$$\widehat{B}(\widetilde{W}_n) \subset B(\widetilde{\widetilde{W}}). \tag{4.5}$$

From the definition of $\widetilde{W}$ and $\widetilde{M}$, we have

$$B(\widetilde{W}) = \widetilde{M}. \tag{4.6}$$

Combining (4.6), (4.4), and (4.5), we prove $B(\widetilde{W}) \subset B(\widetilde{\widetilde{W}})$. ∎

REMARK 4.2. Lemma 4.3 says that the constraints

$$\int_{\partial\Omega_i} \mathbf{w}_i \cdot \mathbf{n}_i \, ds = 0$$

do not affect the range space $B(\widetilde{W})$.

We now provide the following well-known identity that is useful for the analysis of the condition number bound.

LEMMA 4.4. For $\boldsymbol{\lambda} \in \widetilde{M}$,

$$\langle F_{DP}\boldsymbol{\lambda}, \boldsymbol{\lambda}\rangle = \max_{\mathbf{w} \in \widetilde{\widetilde{W}} \setminus \{0\}} \frac{\langle B\mathbf{w}, \boldsymbol{\lambda}\rangle^2}{\langle S\mathbf{w}, \mathbf{w}\rangle}.$$

PROOF. The problem (3.6) is equivalent to the following min-max problem:

$$\max_{\boldsymbol{\lambda} \in B(\widetilde{\widetilde{W}})} \min_{\mathbf{w} \in \widetilde{\widetilde{W}}} \left\{ \frac{1}{2}\langle S\mathbf{w}, \mathbf{w}\rangle - \langle \mathbf{d}, \mathbf{w}\rangle + \langle B\mathbf{w}, \boldsymbol{\lambda}\rangle \right\}, \tag{4.7}$$

where $\mathbf{d}$ is the Schur complement forcing vector obtained from $\begin{pmatrix} \mathbf{f}_I^t & \mathbf{0}^t & \mathbf{f}_r^t & \mathbf{f}_c^t \end{pmatrix}^t$ after solving local Stokes problems.

Let P_W be the l^2-orthogonal projection

$$P_W : W \to \widetilde{\widetilde{W}}.$$

Note that $B(\widetilde{\widetilde{W}}) = \widetilde{M}$ from Lemma 4.3, and P is the projection from M onto $\widetilde{M}$ introduced in section 3. We consider

$$\mathbf{w} = (\mathbf{w}_1, \ldots, \mathbf{w}_N) \quad \text{such that} \quad \mathbf{w}_i = \begin{pmatrix} \mathbf{u}_r|_{\partial\Omega_i} \\ L_c^i \mathbf{u}_c \end{pmatrix},$$

where $(\mathbf{u}_r, \mathbf{u}_c)$ is from the solution of (3.6). The fifth and sixth rows in (3.6) give

$$\int_{\partial\Omega_i} \mathbf{w}_i \cdot \mathbf{n}_i \, ds = 0 \quad \forall i = 1, \ldots, N,$$
$$\int_{\Gamma_{ij}} (\mathbf{w}_i - \mathbf{w}_j) \, ds = 0 \quad \forall \, \Gamma_{ij}.$$

These equations imply that $\mathbf{w}$ belongs to $\widetilde{\widetilde{W}}$. By taking the Euler–Lagrangian in (4.7), we can see that $(\mathbf{w}, \boldsymbol{\lambda}) \in \widetilde{\widetilde{W}} \times \widetilde{M}$ from the solution of (3.6) satisfies

$$\begin{pmatrix} S_p & B_p^t \\ B_p & \mathbf{0} \end{pmatrix} \begin{pmatrix} \mathbf{w} \\ \boldsymbol{\lambda} \end{pmatrix} = \begin{pmatrix} P_W^t \mathbf{d} \\ \mathbf{0} \end{pmatrix}, \tag{4.8}$$

where

$$S_p = P_W^t S P_W, \qquad B_p = P^t B P_W.$$

Since S is symmetric and positive definite (s.p.d.) on $\widetilde{\widetilde{W}}$, the equation for $\boldsymbol{\lambda}$ follows by eliminating $\mathbf{w}$ in (4.8):

$$B_p S_p^{-1} B_p^t \boldsymbol{\lambda} = B_p S_p^{-1} \mathbf{d},$$

which is the same as (3.7). Therefore we have the identity

$$B_p S_p^{-1} B_p^t = F_{DP}. \tag{4.9}$$

For $\boldsymbol{\lambda} \in \widetilde{M}$, we consider

$$\max_{\mathbf{w} \in \widetilde{\widetilde{W}} \setminus \{0\}} \frac{\langle B\mathbf{w}, \boldsymbol{\lambda} \rangle^2}{\langle S\mathbf{w}, \mathbf{w} \rangle}. \tag{4.10}$$

Since S is s.p.d. on $\widetilde{\widetilde{W}}$, the maximum in (4.10) occurs when $S_p \mathbf{w} = B_p^t \boldsymbol{\lambda}$, and it gives

$$\max_{\mathbf{w} \in \widetilde{\widetilde{W}} \setminus \{0\}} \frac{\langle B\mathbf{w}, \boldsymbol{\lambda} \rangle^2}{\langle S\mathbf{w}, \mathbf{w} \rangle} = \langle B_p S_p^{-1} B_p^t \boldsymbol{\lambda}, \boldsymbol{\lambda} \rangle. \tag{4.11}$$

From (4.9) and (4.11), the required identity follows. □

4.3. From (4.9), we can see that F_{DP} is s.p.d. on $\widetilde{M}$.

4.4. From Lemma 4.4, $E(\mathbf{w}_n) \in \widetilde{\widetilde{W}}$ for $\mathbf{w}_n \in \widetilde{W}_n$, and (3.10), we obtain the following lower bound of the FETI-DP operator:

$$\begin{aligned}\langle F_{DP}\boldsymbol{\lambda},\boldsymbol{\lambda}\rangle &= \max_{\mathbf{w}\in\widetilde{\widetilde{W}}\setminus\{0\}} \frac{\langle B\mathbf{w},\boldsymbol{\lambda}\rangle^2}{\langle S\mathbf{w},\mathbf{w}\rangle} \\ &\geq \max_{\mathbf{w}_n\in\widetilde{W}_n\setminus\{0\}} \frac{\langle BE(\mathbf{w}_n),\boldsymbol{\lambda}\rangle^2}{\langle SE(\mathbf{w}_n),E(\mathbf{w}_n)\rangle} \\ &= \langle \widehat{F}_{DP}\boldsymbol{\lambda},\boldsymbol{\lambda}\rangle.\end{aligned}$$

The following lemma can be found in Bramble and Pasciak [5].

LEMMA 4.5. $\mathbf{w}_i \in W_i$

$$C_1\beta^2\langle S_i\mathbf{w}_i,\mathbf{w}_i\rangle \leq |\mathbf{w}_i|^2_{1/2,\partial\Omega_i} \leq C_2\langle S_i\mathbf{w}_i,\mathbf{w}_i\rangle,$$

β Ω_i C_1 C_2 h_i H_i

Since we have chosen the inf-sup stable $P_1(h) - P_0(2h)$ finite element space, the constant β is independent of h_i and H_i.

We also have the following result, which is derived in [17, Lemma 5.1].

LEMMA 4.6. $\mathbf{w} = (\mathbf{w}_1,\ldots,\mathbf{w}_N) \in W$

$$\|\mathbf{w}_i - \mathbf{w}_j\|^2_{H_{00}^{1/2}(\Gamma_{ij})} \leq C \max_{l\in\{i,j\}} \left\{\left(1+\log\frac{H_l}{h_l}\right)^2\right\}\left(|\mathbf{w}_i|^2_{1/2,\partial\Omega_i} + |\mathbf{w}_j|^2_{1/2,\partial\Omega_j}\right).$$

DEFINITION 4.7. $\pi_{ij} : [H_{00}^{1/2}(\Gamma_{ij})]^2 \to W_{ij}$

$$\int_{\Gamma_{ij}} (\mathbf{v} - \pi_{ij}\mathbf{v})\cdot\boldsymbol{\lambda}_{ij}\,ds = 0 \ \ \forall\boldsymbol{\lambda}_{ij} \in M_{ij}.$$

From Lemma 2.2 in [1], π_{ij} is continuous on $H_{00}^{1/2}(\Gamma_{ij})$; i.e., there exists a constant C such that

$$\|\pi_{ij}\mathbf{v}\|_{H_{00}^{1/2}(\Gamma_{ij})} \leq C\|\mathbf{v}\|_{H_{00}^{1/2}(\Gamma_{ij})} \qquad \forall\mathbf{v} \in [H_{00}^{1/2}(\Gamma_{ij})]^2. \tag{4.12}$$

We now provide an upper bound of the FETI-DP operator.

LEMMA 4.8. $\boldsymbol{\lambda} \in \widetilde{M}$

$$\max_{\mathbf{w}\in\widetilde{\widetilde{W}}\setminus\{0\}} \frac{\langle B\mathbf{w},\boldsymbol{\lambda}\rangle^2}{\langle S\mathbf{w},\mathbf{w}\rangle} \leq C\frac{1}{\beta^2}\max_{i=1,\ldots,N}\left\{\left(1+\log\frac{H_i}{h_i}\right)^2\right\}\langle \widehat{F}_{DP}\boldsymbol{\lambda},\boldsymbol{\lambda}\rangle.$$

From the definition of π_{ij}, we have

$$\langle B\mathbf{w},\boldsymbol{\lambda}\rangle = \sum_{i=1}^{N}\sum_{j\in m_i}\int_{\Gamma_{ij}}(\mathbf{w}_i-\mathbf{w}_j)\cdot\boldsymbol{\lambda}_{ij}\,ds = \sum_{i=1}^{N}\sum_{j\in m_i}\int_{\Gamma_{ij}}\pi_{ij}(\mathbf{w}_i-\mathbf{w}_j)\cdot\boldsymbol{\lambda}_{ij}\,ds. \tag{4.13}$$

Let $\mathbf{z}_n \in W_n$ be $\mathbf{z}_n|_{\Gamma_{ij}} = \pi_{ij}(\mathbf{w}_i - \mathbf{w}_j)$. Since $\binom{1}{0}, \binom{0}{1} \in M_{ij}$ and $\mathbf{w} \in \widetilde{\widetilde{W}}$, we have

$$\int_{\Gamma_{ij}} \mathbf{z}_n \, ds = \int_{\Gamma_{ij}} (\mathbf{w}_i - \mathbf{w}_j) \, ds = 0, \tag{4.14}$$

so that $\mathbf{z}_n \in \widetilde{W}_n$. From (3.10), the definition of $\widehat{F}_{DP}$, (4.13) can be bounded by

$$\langle B\mathbf{w}, \boldsymbol{\lambda}\rangle^2 = \langle BE(\mathbf{z}_n), \boldsymbol{\lambda}\rangle^2 \le \langle \widehat{F}_{DP}\boldsymbol{\lambda}, \boldsymbol{\lambda}\rangle \langle SE(\mathbf{z}_n), E(\mathbf{z}_n)\rangle, \tag{4.15}$$

where $E(\mathbf{z}_n) = (\mathbf{z}_1, \ldots, \mathbf{z}_N)$ is the zero extension of $\mathbf{z}_n$. From Lemma 4.5, (2.5), (4.12), and Lemma 4.6, we obtain

$$\begin{aligned}
\langle SE(\mathbf{z}_n), E(\mathbf{z}_n)\rangle &= \sum_{i=1}^{N} \langle S_i \mathbf{z}_i, \mathbf{z}_i\rangle \\
&\le C\frac{1}{\beta^2} \sum_{i=1}^{N} |\mathbf{z}_i|^2_{1/2,\partial\Omega_i} \\
&\le C\frac{1}{\beta^2} \sum_{i=1}^{N} \sum_{j\in m_i} \|\mathbf{w}_i - \mathbf{w}_j\|^2_{H_{00}^{1/2}(\Gamma_{ij})} \\
&\le C\frac{1}{\beta^2} \max_{i=1,\ldots,N} \left\{ \left(1 + \log \frac{H_i}{h_i}\right)^2 \right\} \sum_{i=1}^{N} |\mathbf{w}_i|^2_{1/2,\partial\Omega_i} \\
&\le C\frac{1}{\beta^2} \max_{i=1,\ldots,N} \left\{ \left(1 + \log \frac{H_i}{h_i}\right)^2 \right\} \langle S\mathbf{w}, \mathbf{w}\rangle.
\end{aligned} \tag{4.16}$$

The estimates (4.15) and (4.16) give the required bound. ∎

From Remark 4.4 and Lemmas 4.4 and 4.8, we obtain the condition number bound of our FETI-DP algorithm.

THEOREM 4.9. [illegible] (3.10) [illegible]

$$\kappa(\widehat{F}_{DP}^{-1} F_{DP}) \le C\frac{1}{\beta^2} \max_{i=1,\ldots,N} \left\{ \left(1 + \log \frac{H_i}{h_i}\right)^2 \right\}.$$

5. Numerical results. In this section, we provide numerical tests for the proposed FETI-DP algorithm. The following Stokes problem is considered:

$$\begin{aligned}
-\triangle \mathbf{u} + \nabla p &= \mathbf{f} \quad \text{in } \Omega, \\
-\nabla \cdot \mathbf{u} &= 0 \quad \text{in } \Omega, \\
\mathbf{u} &= \mathbf{0} \quad \text{on } \partial\Omega,
\end{aligned} \tag{5.1}$$

where Ω is a unit rectangle in $\mathbb{R}^2$ and $\mathbf{f}$ is given from the exact solution

$$\mathbf{u} = \begin{pmatrix} \sin^3(\pi x)\sin^2(\pi y)\cos(\pi y) \\ -\sin^2(\pi x)\sin^3(\pi y)\cos(\pi x) \end{pmatrix} \quad \text{and} \quad p = x^2 - y^2.$$

We consider only the uniform partition of Ω. The notation $N = 4 \times 4$ means that Ω is partitioned into 4×4 square subdomains. With this partition, we triangulate

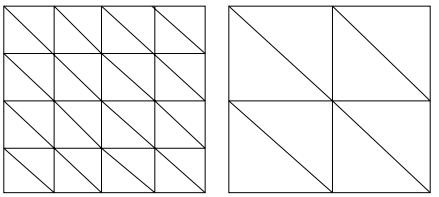

FIG. 1. *Triangulations for velocity (left) and for pressure (right) when* $n = 5$.

TABLE 1

CG iterations (condition number) when n *(the number of nodes) increases with a fixed* $N = 4 \times 4$ *(the number of subdomains):* $\widehat{F}_{DP}^{-1}F_{DP}$ *(with preconditioner),* F_{DP} *(without preconditioner).*

each subdomain in the following manner. Let $n = 4k + 1$ with k an integer. For matching triangulations, we take the same uniform triangulation in each subdomain with $(n-1)/2+1$ nodes, including end points on both horizontal and vertical edges. We denote it by $\Omega_i^{2h_i}$, a triangulation for the pressure. A triangulation for the velocity, $\Omega_i^{h_i}$, is then given by dividing each triangle in $\Omega_i^{2h_i}$ into four triangles, as in Figure 1. For nonmatching grids, we take randomly $(n-1)/2+1$ nodes on each horizontal and vertical edge and then generate a nonuniform structured triangulation $\Omega_i^{2h_i}$ from the nodes. A triangulation $\Omega_i^{h_i}$ is obtained from $\Omega_i^{2h_i}$, as before.

We solved the FETI-DP operator with and without preconditioner, varying N and n on both matching and nonmatching triangulations. The CG (conjugate gradient) iteration is terminated when the relative residual reduces by 10^{-6}.

In Tables 1 and 2, the number of CG iterations and the corresponding condition number are shown, varying N and n. Table 1 shows the numbers when $(n-1)$ increases two-fold with fixed $N = 4 \times 4$. The preconditioner performs well, and the condition numbers seem to exhibit $\log^2$-growth as n increases. The preconditioner is much more efficient for the nonmatching case. Table 2 shows the performance of the

preconditioner when N increases with $n = 5$ and 9. The CG iteration becomes stable as N increases.

We have further observed the convergent behaviors of the approximated solution. The H^1 and L^2-errors for velocity and pressure are examined. The errors and reduction factors are shown in Table 3 for various N and n on matching grids. Three cases are considered: when $n-1$ increases two-fold with a fixed $N = 4\times 4$ and when N increases two-fold in both horizontal and vertical edges of Ω with a fixed $n = 5$ or 9. For all cases, we can see that the H^1-error for velocity and the L^2-error for pressure reduce by half, and the L^2-error for velocity reduces by quarter. These factors are optimal for the $P_1(h) - P_0(2h)$ finite element space.

Tables 4–5 show errors and reduction factors for the nonmatching case. In Table 4, we observe the optimal convergence of errors as $(n-1)$ increases two-fold with a fixed $N = 4\times 4$. When $n = 5$ and 9, as N increases, the errors also show the optimal convergence in Table 5.

As mentioned in section 2, if the inf-sup constant of the space $V\times P$ is independent

65	0.5983	0.5983

of N and n, then the optimality of approximation can be shown for the space $V \times P$. Let β^* and β be the inf-sup constants for the space $V \times P$ and the $P_1(h) - P_0(2h)$ finite elements, respectively, and β_0 be the inf-sup constant for the space $V \times \Pi_0$; see (2.9) and (2.2) for the definition. The constant β^* depends on β and β_0 from the trick conceived by Boland and Nicolaides [4]. Hence, if the constant β_0 is independent of n and N, then the same holds for β^*. We showed that β_0 is independent of n and N numerically for various N and n. The results are given in Tables 6 and 7 for both matching and nonmatching cases. We observe that β_0 becomes stable as N or n increases.

AN EXIT PROBABILITY APPROACH TO SOLVING HIGH DIMENSIONAL DIRICHLET PROBLEMS*

FABIAN M. BUCHMANN† AND WESLEY P. PETERSEN†

Abstract. We present an approach to solving high dimensional Dirichlet problems in bounded domains which is based on a variant of the Feynman–Kac formula that connects solutions to elliptic partial differential equations and functional integration. We integrate the resulting system of stochastic differential equations numerically with the Euler scheme. To correct for possible intermediate excursions of the simulated paths and to find good approximations for first exit times, we extend to higher dimensions a strategy which we introduced in [F. M. Buchmann, *J. Comput. Phys.*, 202 (2005), pp. 446–462] for stopping problems in one dimension. In addition, for Dirichlet problems, good approximations of the first exit points are needed to evaluate the boundary condition. To this end, we sample a random point on the tangent hyperplane of the boundary of the domain once a first exit is estimated. To detect excursions and adequately compute first exit times, we apply the same local half-space approximation. We therefore assume that the domain is smooth enough such that these approximations are possible. Numerical experiments in dimensions up to 128 show that resulting approximations are of very high quality. In particular, we observe that first order convergence behavior of the Euler scheme can be maintained.

1. Introduction and notation.

In this work we present an approach to solve numerically Poisson's equation in high dimensional domains. Our approach is based on the stochastic representation of the solution which is given by some variant of the Feynman–Kac formula. Numerically, we have to integrate a system of stochastic differential equations (SDEs) and will approximate mathematical expectations by finite sum arithmetic means (Monte-Carlo approach). In the stochastic formulation, a Brownian path starting from a point (x) in the domain is simulated until it reaches the boundary for the first time, and the exit point must be estimated to compute the boundary contribution to an average of a functional. It is this special feature (stopping at the first exit) that makes the problem especially interesting from a numerical viewpoint. Namely, the numerical approximation of the first exit time and the first exit point is essential for good convergence properties of the resulting algorithm.

In more detail, we consider the following boundary value problem for $u : \mathbf{R}^n \to \mathbf{R}$:

$$\frac{1}{2}\triangle u(x) + g(x) = 0 \quad \text{for} \quad x \in D, \quad \text{and} \quad u(x) \to \psi(x) \quad \text{as} \quad x \to \partial D. \tag{1.1}$$

Here, D denotes a bounded domain in n-space. We will assume throughout this work that D, ∂D, the inhomogeneity g, and boundary condition ψ (both functions are $\mathbf{R}^n \to \mathbf{R}$) are such that a unique solution exists which is sufficiently smooth; see, for

example, [9]. Then $u(x)$ is given by the Feynman–Kac formula

$$u(x)=\mathbb{E}\left[\psi(X(\tau^D))+\int_0^{\tau^D} g(X(s))\,\mathrm{d}s\right]. \tag{1.2}$$

In (1.2) X is an n-dimensional Brownian motion starting at $x\in D$ when $t=0$, and τ^D is the first exit time of the process $X(t)$ from D (which by continuity is also the first passage time to ∂D):

$$\tau^D=\inf_{t>0}\{X(t)\notin D\}=\inf_{t>0}\{X(t)\in\partial D\},\quad x\in D. \tag{1.3}$$

Consequently, $X(\tau^D)$ is the first exit point of the process from D (the point where the boundary ∂D is hit for the first time).

Throughout this paper we will write $\xi\sim\mathcal{D}$ if a random number ξ (or a random variable) has the distribution (or density) $\mathcal{D}$. In particular we will make use of the distributions summarized in Table 1.1.

2. Weak approximation of stopped diffusions in dimension one. We have presented an algorithm to simulate stopped diffusions (in a weak sense) in [5, 3, 4]. In order to make this article self-contained we summarize it briefly here.

Let $D=(a,b)\subset\mathbf{R}$ be a bounded interval and suppose we wish to approximate $\mathbb{E}[f(\tau)]$, where

$$f(\tau)=\int_0^{\tau} g(X(s))\,\mathrm{d}s\quad\text{for some}\quad g:\mathbf{R}\to\mathbf{R}. \tag{2.1}$$

We again assume that the function g is such that the integral in (2.1) is well defined. In (2.1), $X(t)$, $t\geq 0$, is a one-dimensional Brownian motion starting at $x\in D$ and $\tau=\inf\{t>0:X(t)\notin D\}$.

The following formulation in terms of SDEs is equivalent:

$$\mathrm{d}X(t)=\mathrm{d}W(t)\quad\text{and}\quad \mathrm{d}f(t)=g(X(t))\,\mathrm{d}t,\quad 0\leq t<\tau, \tag{2.2}$$

with initial conditions $X(0)=x$ and $f(0)=0$. A weak approximate solution of system (2.2) is now standard (see, for example, [13, 17]).

Our algorithm is based on the simplest possible scheme to numerically integrate the system (2.2), the Euler–Maruyama scheme. We simply fix a step size h and iterate (2.3) for $k=0,\ldots$ until (1.3) applies, where $X_0=x$ and $f_0=0$:

$$X_{k+1}=X_k+\sqrt{h}\xi,\quad \xi\sim\mathcal{N}(0,1), \tag{2.3a}$$

$$f_{k+1}=f_k+hg(X_k). \tag{2.3b}$$

If we apply this strategy to approximate $\mathbb{E}[f(\tau)]$ (see (2.1)), the main difficulty presents itself immediately. In (2.1), stopping time τ is not known but must be

determined by (1.3). On the other hand, we are only interested in finding a good approximation of the expectation of $f(\tau)$ (as in (1.2)). Suppose that we can approximate $f(\tau)$ and denote corresponding realizations $f^{(i)} := f^{(i)}_{K^{(i)}}$ (the number of steps changes from realization to realization and will be made precise in what follows; see Algorithm 2.1). We then approximate the expectation by a finite mean over the N realizations as

$$\mathbb{E}[f(\tau)] \approx \frac{1}{N}\sum_{i=1}^{N} f(\tau^{(i)}). \tag{2.4}$$

Our algorithm takes advantage of the fact that we only want the mean of the approximation of f to be close to $\mathbb{E}[f(\tau)]$ but do not need pathwise convergence. In other words, we need good approximations in a weak and not strong (or pathwise) sense. The better the approximate distributions are, the better the approximation of $\mathbb{E}f$ will be.

To describe our method, consider the one-dimensional case $D = (-\infty, b)$ with $x < b$. Then τ is the first hitting time of level b of the process $X(t)$. Our algorithm extends a method to approximate killed diffusions [1, 10] in a natural way: For the weak approximation of killed diffusions it suffices to know $\tau < T$ where $T > 0$ is a fixed (deterministic) value. In that case a path is killed if $\tau < T$; i.e., it does not contribute to an expectation at T if it reached level b before T. For stopped diffusions, however, an approximation of τ is needed because we need to know exactly the first hitting of b actually occurred. Algorithm 2.1 gives this approximation, and we can add a last Euler step of appropriate length (either $\mathcal{T}_1$ or $\mathcal{T}_2$) to the approximation of the integral (2.1).

Clearly, we start for every path with $X_0 = x$ and $f_0 = 0$. For $k = 0, 1, \ldots$ we proceed as described in Algorithm 2.1.

Remark 2.1. In n-dimensional cases, locally we apply a half-space approximation of D close to the boundary, which permits us to reduce our problem to the one-dimensional situation [10].

ALGORITHM 2.1

Set $y \leftarrow X_k$, generate $\xi \sim \mathcal{N}(0, h)$ and set $z \leftarrow y + \xi$. {preliminary Euler step}
if $z < b$ **then** {depending on the value of z there are two possibilities}
  Generate $u \sim \mathcal{U}(0, 1)$ and set $\mathcal{T}_1 \leftarrow -2(b - y)(b - z)/\log u$
  if $\mathcal{T}_1 \le h$ **then** {compare with the step size h: test for excursion}
    Set $f(\tau) \leftarrow f_k + \mathcal{T}_1 g(y)$ {last Euler step of length $\mathcal{T}_1$}
    stop
  else
    Set $f_{k+1} \leftarrow f_k + hg(y)$, $X_{k+1} \leftarrow z$ and **goto** item 1 {continue integrating}
  end if
else {$z \ge b$ implying $\tau \le t_{k+1}$}
  Generate $s \sim \mathcal{IG}((b - y)^2/h, (b - y)/(z - b))$ and set $\mathcal{T}_2 \leftarrow hs/(1 + s)$
  Set $f(\tau) \leftarrow f_k + \mathcal{T}_2 g(y)$ {last Euler step of length $\mathcal{T}_2$}
  stop
end if

Algorithm 2.1 is executed for N independent sample paths (the sample size) and then the mathematical expectation is approximated by the finite mean; see (2.4) (for the Monte-Carlo method, see [15] and references therein).

Having stated our method, let us summarize briefly the formula on which it is based. This will motivate our approach in higher dimensional settings (section 3); see [5] for the derivation. Let $\mathbb{P}_{y,h,z}[\cdot]$ be the law of a Brownian bridge pinned at time-space coordinates (t_k, y) and (t_{k+1}, z) (where $t_{k+1} = t_k + h$). Recall that we set $y = X_k$ and $z = X_{k+1}$ and suppose $D = (-\infty, b)$ with $x < b$; i.e.,

$$\tau = H_b(x) := \inf_{t>0} \{X_x(t) = b\} \tag{2.5}$$

is the first hitting time of level b. We then have [14] the following:

- For $y, z < b$,

$$\mathbb{P}_{y,h,z}\left[H_b(y) \le t\right] = \exp\left(-\frac{2}{t}(b-y)(b-z)\right), \quad t > 0. \tag{2.6}$$

- For $y < b < z$,

$$\begin{aligned} &\mathbb{P}_{y,h,z}[\tau \in \mathrm{d}t] \\ &= \frac{b-y}{\sqrt{2\pi}}\sqrt{\frac{h}{t^3(h-t)}}\exp\left(-\frac{(h(b-y)-t(z-y))^2}{2ht(h-t)}\right)\mathbf{1}_{\{0<t<h\}}\,\mathrm{d}t \end{aligned} \tag{2.7}$$

and after the substitution $s = t/(1-t) \ge 0$ (hence $t = s/(1+s)$)

$$= \sqrt{\frac{\gamma}{2\pi s^3}}\exp\left(-\frac{\gamma(s-\delta)^2}{2\delta^2 s}\right)\mathbf{1}_{\{s>0\}}\,\mathrm{d}s, \tag{2.8}$$

where $\gamma = (b-y)^2/h$ and $\delta = (b-y)/(z-b)$. We recall that a random variable ξ [illegible] $\gamma, \delta > 0$ if it has the density (2.8). In this case, we write $\xi \sim \mathcal{IG}(\gamma, \delta)$. We refer to [8] for a review on this distribution and to [16] for an algorithm to generate random variables $\xi \sim \mathcal{IG}(\gamma, \delta)$. This allows us (using (2.8)) to generate a random variable with density (2.7).

[illegible] 2.2. In the case that $z = b$ (which has probability zero in theory but might occur in finite-precision arithmetic on a computer) we set $\tau \approx t_{k+1}$ and hence stop the integration as $f(\tau) \approx f_k + hg(X_k)$.

3. Higher dimensions. We now turn our attention to the approximation of the solution $u(x)$ of (1.1) with $x \in D \subset \mathbf{R}^n$ with $n \ge 2$. From (1.1) we see that we need approximations of both τ and $X(\tau)$. We first describe how to extend Algorithm 2.1 presented in section 2 to higher dimensions and then show how to find $X(\tau)$.

3.1. Reduction to one dimension: Half-space approximation. We assume that for any two points $y, z \in \mathbf{R}^n$ there is a unique point on the boundary ∂D which is "closest" to y and z in some sense (we make this statement precise later on). Denote this point by X_b and suppose further that ∂D is sufficiently smooth in a sufficiently large neighborhood of X_b, such that we can approximate ∂D locally by a tangent hyperplane. For a bounded domain $D \subset \mathbf{R}^n$, every point $X_b \in \partial D$ can be mapped by a simple scaling and rotation to $(b, 0, \ldots, 0)^T$ with $b > 0$ (see section 3.4 for an efficient implementation of these rotations using Givens transformations). To derive our algorithm, we therefore assume such a transformation has been done and that near ∂D, D is given by the half-space $\{v \in \mathbf{R}^n : v^1 < b\}$ with boundary (hyperplane) $\{v \in \mathbf{R}^n : v^1 = b\}$. Suppose $x^1 < b$. We then have (compare with (2.5))

$$\tau = H_b(x) := \inf_{t>0} \left\{X_x^1(t) = b\right\}.$$

3.2. Approximation of the first exit time. For $y, z \in \mathbf{R}^n$ with $y^1, z^1 < b$ we have (compare with (2.6))

$$\mathbb{P}_{y,h,z}\left[H_b(y) \le t\right] = \exp\left(-\frac{2}{t}(b-y^1)(b-z^1)\right), \quad t > 0,$$

while for $y^1 < b$ but $z^1 > b$ it holds that (compare with (2.7))

$$\mathbb{P}_{y,h,z}[H_b(y) \in \mathrm{d}t] = \frac{b-y^1}{\sqrt{2\pi}}\sqrt{\frac{h}{t^3(h-t)}}\exp\left(-\frac{\left(h(b-y^1)-t(z^1-y^1)\right)^2}{2ht(h-t)}\right)\mathbf{1}_{\{0<t<h\}}\,\mathrm{d}t.$$

The following observation is immediate.

Remark 3.1. In the case of a boundary connected to only one of the components of an n-dimensional Brownian motion (and assuming that the boundary is locally flat, i.e., (locally) a hyperplane), the fact that these individual components are n one-dimensional Brownian motions leads to formulae as simple as in the one-dimensional setting. Furthermore, only the components connected to the boundary show up in the equations.

Therefore, extension of Algorithm 2.1 to higher dimensions is evident and we shall skip the details. Only the exit point estimation requires further elaboration.

3.3. Approximation of the exit point. In the previous section we described how to approximate the first exit time $\tau = \tau_D$ of Brownian motion from a domain D in n-space. As noted earlier, in order to approximate the solution $u(x)$ of Poisson's equation (1.1) by its stochastic representation (1.2) $u(x) = \mathbb{E}[\psi(X(\tau)) + f(\tau)]$, an approximation of the exit point $X(\tau)$ is required as soon as the boundary condition ψ is no longer a constant.

Using the notation introduced earlier, we cite the result which is the starting point for the approximation of $X(\tau)$; see [14, Lemma 7]. We recall that $\tau = \inf_{t>0}\{X^1(t) \ge b\}$. Assume $z^1 > b$. Given $X^1(s)$, $s \in [0,\tau]$, the joint distribution of $X^i(\tau)$ conditioned on $X(t) = z$ is given by [14, Lemma 6] (with $X(0) = 0$)

$$z^i\frac{\tau}{t} + \sqrt{\tau\left(1-\frac{\tau}{t}\right)}\cdot\xi^i, \quad \text{where} \quad \xi^i \sim \mathcal{N}(0,1), \quad i = 2,\dots,n. \tag{3.1}$$

The assumption that $z^1 > b$ (or, equivalently, that $z^1 \ge b$) can be replaced by the assumption that $\tau < t$ (or $\tau \le t$, respectively). We can therefore apply (3.1) as soon as the integration process is stopped (as soon as an approximation of τ is found by the extension of Algorithm 2.1 to higher dimensions using locally half-space approximations of D). The extension to the general case with $y = X_k$ and $z = X_{k+1}$ with $\tau \le t_{k+1}$ is then straightforward and yields for the resulting joint distribution of $X^i(\tau)$

$$y^i + (z^i - y^i)\frac{\tau}{h} + \sqrt{\tau\left(1-\frac{\tau}{h}\right)}\cdot\xi^i, \quad \text{where} \quad \xi^i \sim \mathcal{N}(0,1), \quad i = 2,\dots,n. \tag{3.2}$$

It remains only to incorporate the rotation of the map $X_b \mapsto (\|X_b\|, 0, \dots, 0)^T$. This rotation can be described by multiplication with an orthogonal matrix R, but we used a more efficient implementation using Givens rotations, described below. We then have $\|\tilde{X}_b^1\| = \|X_b\|$ because R is orthogonal. The exit point of the transformed

vector $\tilde{X}_b$ can be found from (3.2) by replacing $x^i \to \tilde{x}^i$ and $y^i \to \tilde{y}^i$. With this formula for the $\tilde{x}, \tilde{y}$ coordinates, we can thus [illegible] an approximation for $\tilde{X}(\tau)$ on the tangent hyperplane through $(\|X_b\|, 0, \dots, 0)^T$. Once $\tilde{X}_b$ is generated, we project back to ∂D via (3.6).

Rotating back, $(\|X_b\|, 0, \dots, 0)^T \mapsto X_b$ is easily affected by the inverse $R^{-1} = R^T$, which gives us the approximation for the exit point as $X(\tau) \approx R^{-1}\tilde{X}_b$, where this inversion is applied by $n-1$ pairwise rotations of (3.6).

ALGORITHM 3.1 Simulate one path (with index (i)) to get an approximation $\overline{u}^{(i)}$ for $u^{(i)} = \psi(X^{(i)}(\tau^{(i)})) + f^{(i)}(\tau)$ with $u(x) = \mathbb{E}[u^{(i)}]$. We assume that D is the unit n-sphere and further omit the sample index (i) for better readability.

$y \leftarrow x$, $f \leftarrow 0$ {initialize with initial conditions of SDEs}
for $k = 0, 1, 2, \dots$ **do** {integrate until τ; see Algorithm 2.1}
  $z^i = y^i + \sqrt{h}\xi$, $\xi \sim \mathcal{N}(0,1)$ for $i = 1, \dots, n$
  $X_b \leftarrow$ a point on ∂D closest to y and z
  $\tilde{y} \leftarrow Ry$ and $\tilde{z} \leftarrow Rz$ via (3.5)
  if $\tilde{z}^1 \geq 1$ **then** {D was clearly left}
    Generate $\mathcal{T}_2$ according to (2.7), (2.8) with input variables $\tilde{y}^1$, $\tilde{z}^1$ and $b = 1$.
    $f(\tau) \leftarrow f + \mathcal{T}_2 g(y)$
    stop
  else {check for an intermediate excursion}
    Generate $\mathcal{T}_1$ (see (2.6) with input variables $\tilde{y}^1$, $\tilde{z}^1$ and $b = 1$)
    if $\mathcal{T}_1 \leq h$ **then** {excursion detected}
      $f(\tau) \leftarrow f + \mathcal{T}_1 g(y)$
      stop
    else {continue integration}
      $f \leftarrow f + hg(y)$ and $y \leftarrow z$
    end if
  end if
end for
$\tilde{X}^1 \leftarrow 1$ and for $i = 2, \dots, n$ generate $\tilde{X}^i$ according to (3.2)
$\tilde{X} \leftarrow \tilde{X}/|\tilde{X}|$ {project back on ∂D}
$X(\tau) \leftarrow R^{-1}\tilde{X}$ using (3.6)
$\overline{u} \leftarrow \psi(X(\tau)) + f(\tau)$

3.4. On the implementation of the rotations. Once a suitable $X_b \in \partial D$ is found, we have to map the situation to the case where $\tilde{X}_b = (\|X_b\|, 0, \dots, 0)^T$. Then, the above operation is a rotation in n-space which can be written as $RX_b = \tilde{X}_b$ with an orthogonal $(n \times n)$-matrix R. In particular, we need $\tilde{y} = Ry$ and $\tilde{z} = Rz$ to generate $\mathcal{T}_1$ and $\mathcal{T}_2$, respectively.

Of course, one could simply calculate R and perform two matrix-vector products, but this would result in an algorithm scaling like $\mathcal{O}(n^2)$. Because these rotations have to be done in every step, this is clearly expensive computationally, especially if the dimension n is large. Also, suppose that we have some point $\tilde{u}$ in the transformed system and we additionally need the "original" point u, $u = R^T\tilde{u}$. This would be another $\mathcal{O}(n^2)$-operation.

We therefore used a procedure which has $\mathcal{O}(n)$ operations. It uses Givens rotations [11, section 3.4] and is described below. Because Givens rotations are unitary, both forward and inverse mappings are norm preserving.

To illustrate, let $X_b = (X_b^1, \ldots, X_b^n) =: b_{(1)} \in \mathbf{R}^n$ and define updated versions of X_b by $b_{(k)}$ for $k \geq 2$. Subscripts (k) indicate that the kth element of the updated $b_{(k)}$ vector is zeroed. The kth rotation to compute the update $b_{(k)} = R_{(k)} b_{(k-1)}$, for $k = 2, \ldots, n$ having $\cos, \sin$ parameters in the 1st and kth rows, uses

$$R_{(k)} = \begin{pmatrix} \cos(\varphi_{(k)}) & & & -\sin(\varphi_{(k)}) & & \\ & 1 & & & & \\ & & \ddots & & & \\ & & & 1 & & \\ \sin(\varphi_{(k)}) & & & \cos(\varphi_{(k)}) & & \\ & & & & 1 & \\ & & & & & \ddots \\ & & & & & & 1 \end{pmatrix} \tag{3.3}$$

with

$$\cos(\varphi_{(k)}) = \frac{b_{(k-1)}^1}{w_{(k-1)}} \quad \text{and} \quad \sin(\varphi_{(k)}) = \frac{-b_{(k-1)}^k}{w_{(k-1)}}$$

and

$$w_{(k-1)} = ((b_{(k-1)}^1)^2 + (b_{(k-1)}^k)^2)^{\frac{1}{2}}. \tag{3.4}$$

Proceeding in the same way, after $n-1$ such rotations, we have

$$b_{(n)} = R_{(n)} R_{(n-1)} \cdots R_{(2)} X_b. \tag{3.5}$$

It is easy to see that each $R_{(k)}$ in (3.3) is unitary, i.e., $R_{(k)}^T R_{(k)} = \mathbb{I} = R_{(k)} R_{(k)}^T$, and thus the inverse transformation is performed in the reverse order:

$$R^{-1} = R^T = R_{(2)}^T R_{(3)}^T \cdots R_{(n)}^T. \tag{3.6}$$

The rotations $\tilde{y} = Ry$ and $\tilde{z} = Rz$, and likewise their inverses, can be computed simultaneously.

The calculated trigonometric tables $\cos(\varphi_{(i)}), \sin(\varphi_{(i)})$ from (3.5) are stored in two arrays of length $n-1$ for the connected inverse transformation ($R^{-1} = R^T$).

The procedure used in our experiments used Givens rotations, but Householder transformations [7] would do as well. Namely, X_b may be projected into direction $e_1 = (1, 0, \ldots, 0)^T$ by a rank-one update H:

$$HX_b = \begin{pmatrix} \|X_b\| \\ 0 \\ \vdots \\ 0 \end{pmatrix},$$

where

$$H = \mathbb{I} - 2\frac{vv^T}{\|v\|^2} \tag{3.7}$$

and vector $v = X_b - \|X_b\| e_1$. The Householder transformation is also unitary; in fact, $H = H^T$. This transformation, HX_b, again requires $\mathcal{O}(n)$ operations. Givens rotations have a slight advantage over distributed memory machines (such as our Beowulf) because inner products, which require global communications to get $\|v\|$ and $\|X_b\|$, are not required.

4. Numerical experiments. We show results from extensive tests performed with the method developed in the previous sections. We first show results from experiments performed when the boundary condition ψ is constant (without loss of generality we took $\psi \equiv 0$). Then, sampling of the exit point is unnecessary and we can concentrate on the approximation of $\mathbb{E}[\tau]$. We next show results from experiments with nonconstant boundary conditions, hence sampling $X(\tau)$ on the boundary.

4.1. Constant boundary condition. We concentrate on the [illegible], i.e., Poisson's equation (1.1) with $g \equiv 1$ and $\psi \equiv 0$. Then $u(x) = \mathbb{E}[\tau^D(x)]$ is the mean first exit time. Note that for this problem numerical integration using the Euler scheme is exact and any errors in numerical simulation (other than the statistical error) are due to the stopping at the first exit.

4.1.1. Two-dimensional square. Our first test is such that no error arising due to the (local) approximation of ∂D by its tangent hyperplane at the point X_b is present. The flatter ∂D is, the smaller this error will be. We therefore start with a simple two-dimensional domain without local curvature, i.e., a square.

We set $D = (-1,1) \times (-1,1)$ and consider $\triangle u = -2$ with a zero valued boundary condition. Expanding $u(x,y)$ in eigenfunctions, $\cos(\frac{2k+1}{2}\pi x)\cos(\frac{2l+1}{2}\pi y)$, we find

$$u(0) = \frac{128}{\pi^4} \sum_{k,l=0}^{\infty} \frac{(-1)^{k+l}}{(2k+1)(2l+1)\left((2k+1)^2+(2l+1)^2\right)} \approx 0.5893708\ldots.$$

to compare with our numerical approximations.

When computing the closest boundary point, we do not take into account more than one boundary segment for an excursion test in each step, even if two boundaries are equally far away:

If $z \in D$, we simply take (one of) the boundary segment(s) that minimize(s) the sum of the euclidean distance of y and z to ∂D.

If $z \notin D \cup \partial D$, we assume that $(X(t))_t$ crosses the boundary ∂D at the same point as a linear interpolated version of the discrete path $(X_k)_k$ would.

In doing so, we introduce an additional error. We neglect this error and do not try to correct for it; see [1] for a discussion and possible solutions to this problem. From our results it will be apparent that for sufficiently small h, these errors can indeed be neglected: Asymptotically we get (at least) the desired $\mathcal{O}(h)$-behavior of the error (see Figure 4.1 and the conclusions thereafter).

In this first test, we compare the following methods:

(T): This method stops only if $z \notin D$. In this case, it approximates $\tau \approx t_k$.

(K): This method applies a [illegible] test and stops always (if $z \notin D$ or if an intermediate excursion is detected) at t_k. In other words, this method is similar to ours, but it ignores the last integration step of length $\mathcal{T}_1$ or $\mathcal{T}_2$, respectively.

(SK): This method is a mixture of methods (K) and (S): In the case of an excursion, integration is stopped at $t_k + \mathcal{T}_1$ and at t_k if $z \notin D$ (the random variable $\mathcal{T}_2$ is not generated).

(S): This is the advocated method which samples both $\mathcal{T}_1$ and $\mathcal{T}_2$.

From the results shown in Figure 4.1 we draw the following conclusions:

- The trivial stopping procedure as applied by method (T) is clearly not satisfying. Integration stops much too late on average (as the true solution is approached from above; see the left-hand plot) and resulting convergence order is only $\frac{1}{2}$.

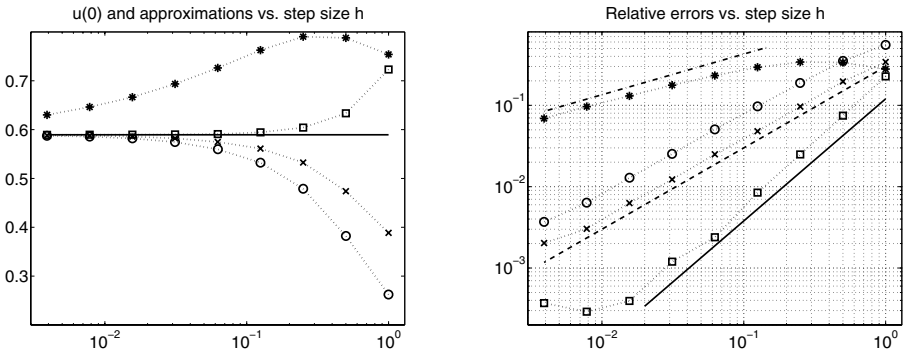

FIG. 4.1. *Results for two-dimensional square with $g \equiv 1$ and $\psi \equiv 0$. On the left, approximate solutions are shown versus step size h together with the exact solution (which is indicated by a solid line). On the right, corresponding relative errors are shown versus step size h. Three lines are added: a dash-dotted line with slope $\frac{1}{2}$, a dashed line with slope 1, and a solid line with slope $\frac{3}{2}$. In both plots, $\cdots * \cdots$ is method (T), $\cdots \circ \cdots$ is method (K), $\cdots \times \cdots$ is method (SK), and $\cdots \square \cdots$ is method (S).*

- Applying some sort of a posteriori test to detect intermediate excursions remedies the main difficulties. Convergence of all three methods (K), (SK), and (S) is much better.
- Method (K) stops integration too early on average (it always stops at the beginning of a time step). The same holds for method (SK), although applying a stopping test instead of a killing test to detect intermediate excursions reduces corresponding errors by approximately a factor of two.
- Method (S) is clearly superior to all the other methods tested: The approximation of $u(0)$ is very good, and connected errors converge with an order higher than 1 (approximately $\frac{3}{2}$).
- Method (S) stops integration for large step sizes (as did method (T)) too late on average. We speculate, that this is due to the fact that we always test only for an excursion across the boundary, even in situations when two boundary segments are close. This is, for example, the case when y and z are close to a corner.

4.1.2. Unit *n*-spheres. We next show simulations for unit n-spheres (unit n-balls); i.e., we set $D = B_1^n = \{x \in \mathbf{R}^n : |x| < 1\}$. The point on ∂D was chosen as follows (we denote it by X_b):

$z \in \partial D$: We set $X_b = z$.

$z \in D$: We set X_b to be the minimizer of the sum of the square of the distances to the boundary. For the unit n-sphere this yields $X_b \leftarrow (y+z)/|y+z|$, which is computationally very efficient and produces for h small enough adequate choices.

$z \notin D \cup \partial D$: We set X_b to the point where the line connecting y and z crosses ∂D.

We show results obtained with method (S) when applied to the exit problem in various dimensions. Results for dimensions $n = 2, 4, 8, 16$ are in Figure 4.2, and those for $n = 64, 128$ are in Figure 4.3. Sample size was always $N = 4 \times 10^6$, and confidence intervals were always smaller than the plot symbols.

From the results in Figures 4.2 and 4.3 we see that for the exit problem in unit n-spheres, asymptotically a convergence order of 1 can always be observed. This is

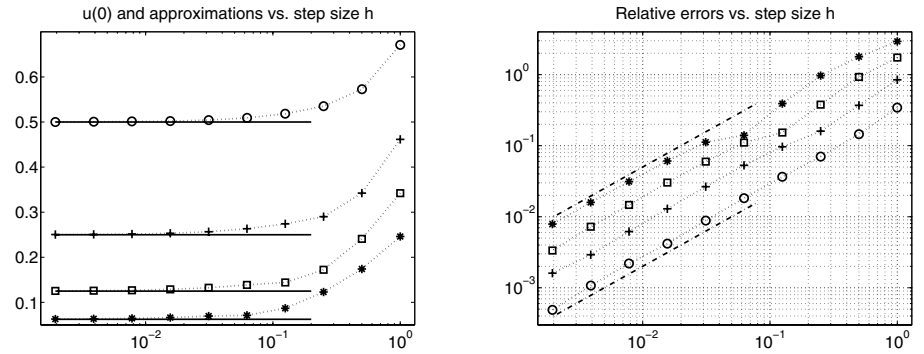

FIG. 4.2. *Results for the exit problem in unit n-spheres. On the left, approximate solutions are shown versus step size h together with corresponding exact solutions (which are indicated by a solid line). On the right, corresponding relative errors are shown versus step size h. Two dashed lines with slope* 1 *are added. In both plots,* $\cdots\circ\cdots$ *is* $n = 2$, $\cdots+\cdots$ *is* $n = 4$, $\cdots\square\cdots$ *is* $n = 8$, *and* $\cdots*\cdots$ *is* $n = 16$.

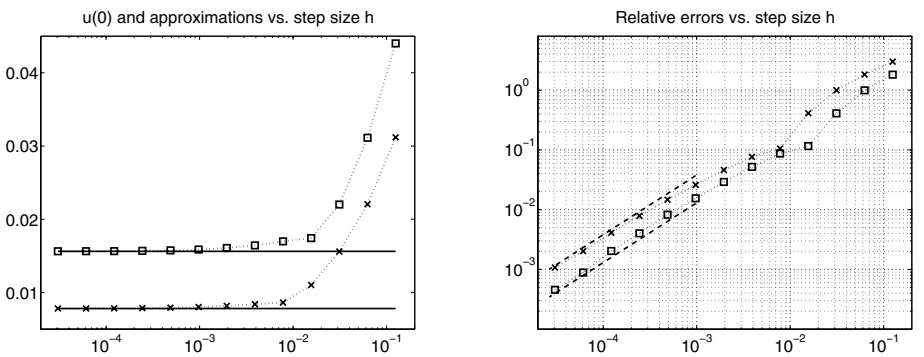

FIG. 4.3. *Results for the exit problem in unit n-spheres. On the left, approximate solutions are shown versus step size h together with corresponding exact solutions (which are indicated by a solid line). On the right, corresponding relative errors are shown versus step size h. Two dashed lines with slope* 1 *are added. In both plots,* $\cdots\square\cdots$ *is* $n = 64$ *and* $\cdots\times\cdots$ *is* $n = 128$.

encouraging, as it shows that the local approximation of ∂D by a tangent hyperplane seems to work, independent of the dimension. Note, however, that as dimension n is increased, a smaller step size h is needed to observe first order convergence.

4.2. Nonconstant boundary conditions. We now show some experiments with $n = 32$ dimensional unit spheres involving three different problems with one variant of the second problem. Explicit solutions are given in (4.1), (4.2a), (4.2b), and (4.3), respectively.

4.2.1. Constant inhomogeneity, linear boundary condition.

$$g(x) \equiv 1 \quad \text{and} \quad \psi(x) = \sum_{i=1}^{32} x^i \Longrightarrow u(x) = \frac{1}{32}\left(1 - |x|^2\right) + \sum_{i=1}^{32} x^i. \tag{4.1}$$

For this problem, integration is still exact (as again $g(x) \equiv 1$), but in contrast to the [illegible], an approximation for $X(\tau)$ is required in order to evaluate the boundary condition for every path as soon as $x \neq 0$. The boundary condition does not vary significantly and is linear.

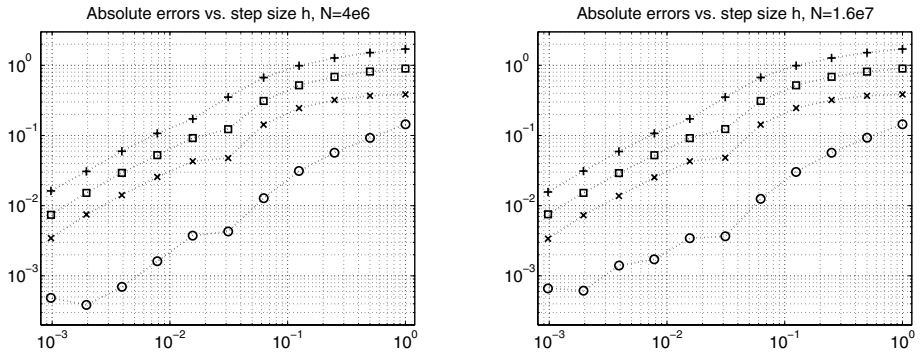

FIG. 4.4. *Results for test problem* (4.1). *Absolute errors versus step size h for two different sample sizes* $N = 4 \times 10^6$ *on the left and* $N = 1.6 \times 10^7$ *on the right. The solution is evaluated at* $x = (x^i)$ *with* $x^i = \alpha/32$ *for* $i = 1, \ldots, 32$. *In both plots,* $\cdots \circ \cdots$ *is* $\alpha = 0$, $\cdots \times \cdots$ *is* $\alpha = 1$, $\cdots \square \cdots$ *is* $\alpha = 2$, *and* $\cdots + \cdots$ *is* $\alpha = 4$.

For this problem we show results for $u(x)$ with $x = (\alpha/32)_{i=1,\ldots,32}$ with $\alpha = 0, 1, 2, 4$. Note that for higher α, x is closer to the boundary ∂D and therefore the probability that a point $X_b \in \partial D$ is the first exit point of a path starting at x is no longer uniformly distributed on ∂D (as is the case for $x = (0, \ldots, 0)^T$). To better distinguish the individual results for different values of α, we show plots of the absolute error; see Figure 4.4.

4.2.2. Quadratic inhomogeneity, quartic boundary condition. We make $g(x)$ harder to integrate and choose a nonlinear boundary condition. We show results of two variants of this problem:

$$g(x) = -\sum_{i=1}^{32} \left(x^i\right)^2 \quad \text{and} \quad \psi(x) = \frac{1}{6} \sum_{i=1}^{32} \left(x^i\right)^4 \implies u(x) = \psi(x). \tag{4.2a}$$

This problem still has an intrinsic symmetry: $g(\cdot)$ is constant on the spheres $|x| \equiv \|x\|_2 = r = \text{const}$, and $\psi(\cdot)$ is constant when $\|x\|_4^4 \equiv \sum_i (x^i)^4 = R = \text{const}$, respectively. We therefore consider the following extension:

$$g(x) = -\sum_{i=1}^{32} i \left(x^i\right)^2 \quad \text{and} \quad \psi(x) = \frac{1}{6} \sum_{i=1}^{32} i \left(x^i\right)^4 \implies u(x) = \psi(x). \tag{4.2b}$$

We show relative errors obtained versus step size h in Figure 4.5.

4.2.3. General (transcendental) inhomogeneity and boundary condition. The last example we use to test Algorithm 3.1 is defined as follows: We set for $k^i = 1, 2, \ldots$, with $k = (k^i)_{i=1,\ldots,32}$,

$$g(x) = \prod_{i=1}^{32} \cos(2\pi k^i x^i) \quad \text{and} \quad \psi(x) = \frac{g(x)}{2\pi^2 |k|^2}. \tag{4.3}$$

Then $u(x) = \psi(x)$, $x \in \partial D$. Results for $x^i = 0$, 5/100, and 1/10 are shown in Figures 4.6, 4.7, and 4.8, respectively.

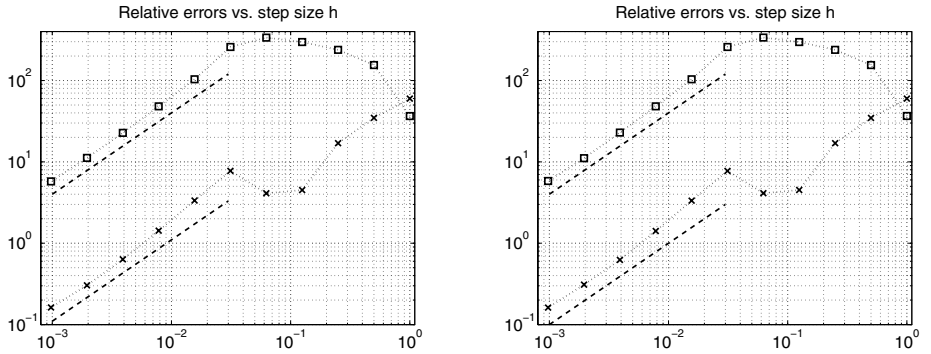

FIG. 4.5. *Results for test problems* (4.2a) *on the left and* (4.2b) *on the right. Shown are relative errors versus step size* h *for sample size* $N = 4 \times 10^6$. *The solution is evaluated at* $x = (x^i)$ *with* $x^i = 5/100$ *and* $x^i = 1/10$ *for* $i = 1, \ldots, 32$. *In both plots,* $\cdots \square \cdots$ *is* $x^i = 5/100$ *and* $\cdots \times \cdots$ *is* $x^i = 1/10$, *and two dashed lines with slope* 1 *are added.*

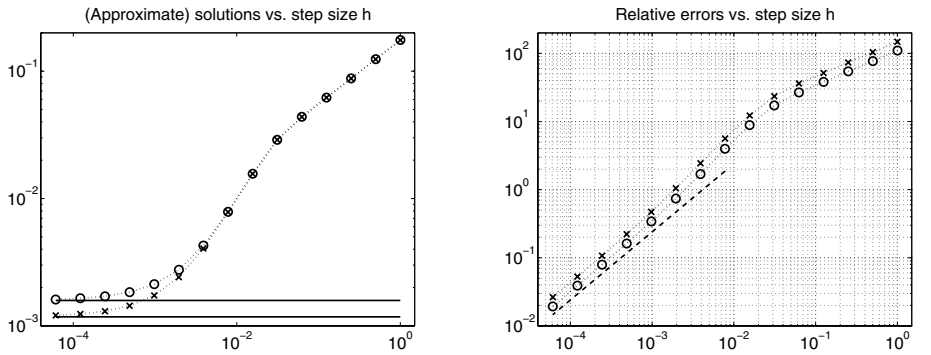

FIG. 4.6. *Results for test problem* (4.3) *when the solution is evaluated at* $x = (x^i)$ *with* $x^i = 0$ *for* $i = 1, \ldots, 32$ *for* $N = 10^6$ *paths. On the left, we show the approximate solutions versus step size* h *and indicate the exact solution with a solid line. On the right, we plot corresponding errors versus step size* h *and add a dashed line with slope* 1. *In both plots,* $\cdots \circ \cdots$ *is the result obtained for* $k = (1, \ldots, 1)$, *while* $\cdots \times \cdots$ *are those for* $k = (3, 2, 1, 1, \ldots, 1)$. *Compare with* $x^i = 5/100$ *in Figure* 4.7 *and* $x^i = 1/10$ *in Figure* 4.8.

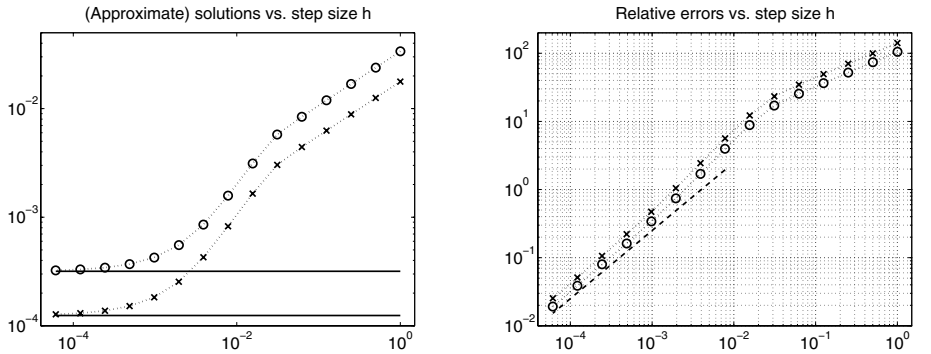

FIG. 4.7. *Results for test problem* (4.3) *when the solution is evaluated at* $x = (x^i)$ *with* $x^i = 5/100$ *for* $i = 1, \ldots, 32$ *for* $N = 10^6$ *paths. See Figures* 4.6 *and* 4.8 *for comparisons with* $x^i = 0$ *and* $x^i = 1/10$, *respectively.*

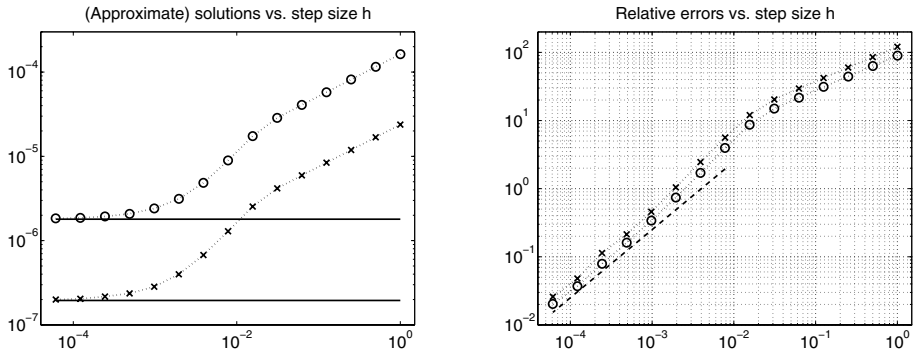

FIG. 4.8. *Results for test problem* (4.3) *when the solution is evaluated at* $x = (x^i)$ *with* $x^i = 1/10$ *for* $i = 1, \ldots, 32$ *for* $N = 10^6$ *paths. See Figures* 4.6 *and* 4.7 *to compare the results for* $x^i = 0$ *and* $x^i = 5/100$*, respectively.*

4.2.4. Discussion of the numerical results for 32-dimensional spheres. Problem (4.1) results show that there is some absolute error increase as the initial point moves out from the center. This is not surprising since the solution (4.1) increases approximately linearly as $|x| = r$ (the initial radius) increases. Thus the relative error is approximately constant in this range. Plots in Figure 4.5 of the relative error for problems (4.2a) and (4.2b) confirm this assessment. Additionally, the expected $\mathcal{O}(h)$-accuracy of our Euler method is evident.

5. Conclusions and final remarks. We have outlined a general procedure for estimating exit times and exit points for Monte-Carlo solutions of elliptic partial differential equations in n-dimensional spaces. Since the Feynman–Kac representation requires good estimates for these statistics, an accurate sampling method seems essential. In our procedure, two situations are evident: , , $X_k \in D$ and $X_{k+1} \in D$ both hold, but possible excursions are estimated as in (2.6); and , , $X_k \in D$ but $X_{k+1} \notin D$. In the latter situation, the sample path has clearly exited domain D; thus an estimate of τ^D, $t_k < \tau^D < t_{k+1}$, is required. Exit point $X(\tau^D)$ must be sampled only if an excursion was determined in the first case, and always in the second case (definite exit). For this exit point, a bridge process (3.2) is used. First, a transformation to a local tangent hyperplane coordinate system is made. This transformation makes it easier to estimate the exit point. This transformed exit point is then rotated back to the original coordinates to get $X(\tau^D)$. These local hyperplane $\leftrightarrow$ original coordinate transformations can be done with Givens rotations (3.5) or Householder reflections (3.7) in $\mathcal{O}(n)$ arithmetic operations.

Another procedure for estimating exit times is given in Jansons and Lythe [12]. Their method uses exponential timestepping and has the advantage that in one dimension, spatial sampling/step is a two-sided exponential distribution (see, for example, [2, equations (1.0.2) and (1.0.5), p. 153]). Tails of exponential distributions are obviously easier to sample than are normal distributions. In higher dimensions ($n > 1$), their situation is more complicated and yields a density proportional to $K_{n/2}(h^{-1/2}|x|)$, where $K_{n/2}$ is a modified Bessel function. It would be very interesting to see how their elegant procedure for estimating the exit times could be expanded to include sampling exit distributions. The walk-on-spheres method of Milstein and Tretyakov (see chapter 6 of [18]) provides another alternative. This procedure has an advantage over simple bounded increment methods [4, 6] in that the increments

are intrinsically isotropic in n-space, although the 3-point approach [4, 6] can be made isotropic with random orthogonal rotations [19]. However, their walk-on-spheres method becomes a 2-point formula in one dimension and appears to be of lower accuracy in our experiments [6].

What remains to be done, particularly for problems similar to our test in section 4.1.1, is a better analysis of corners or cusps. That will be a subject of future work, but data in Figure 4.1 show encouraging results by a crude procedure which simply chooses the nearest side, at least for near-center values of x.

NUMERICAL METHODS FOR DIFFERENTIAL EQUATIONS IN RANDOM DOMAINS*

DONGBIN XIU† AND DANIEL M. TARTAKOVSKY‡

Abstract. Physical phenomena in domains with rough boundaries play an important role in a variety of applications. Often the topology of such boundaries cannot be accurately described in all of its relevant detail due to either insufficient data or measurement errors or both. This topological uncertainty can be efficiently handled by treating rough boundaries as random fields, so that an underlying physical phenomenon is described by deterministic or stochastic differential equations in random domains. To deal with this class of problems, we propose a novel computational framework, which is based on using stochastic mappings to transform the original *deterministic/stochastic problem in a random domain* into a *stochastic problem in a deterministic domain*. The latter problem has been studied more extensively, and existing analytical/numerical techniques can be readily applied. In this paper, we employ both a stochastic Galerkin method and Monte Carlo simulations to solve the transformed stochastic problem. We demonstrate our approach by applying it to an elliptic problem in single- and double-connected random domains, and comment on the accuracy and convergence of the numerical methods.

Key words. random domain, stochastic inputs, differential equations, uncertainty quantification

1. Introduction.

Physical phenomena described by differential equations in domains with rough geometries are ubiquitous and include applications ranging from surface imaging [24] to manufacturing of nano-devices [5]. Indeed, given a proper spatial resolution, virtually any natural or manufactured surface becomes rough. Consequently, there is a growing interest in experimental, theoretical, and numerical studies of deterministic and probabilistic descriptions of such surfaces and of solutions of differential equations defined on the resulting domains.

The early attempts to represent surface roughness and to study its effects on system behavior were based on simplified, easily parameterizable, [illegible] surface inhomogeneities, such as symmetrical asperities to represent indentations [32, 26] and semispheres to represent protrusions [17]. More general representations of surface roughness, which nevertheless admit simple parameterizations, include sinusoidal corrugations [13] and periodic linear segments [6]. A recent trend in describing surface roughness is to use fractal and fractal-like representation. These include deterministic Von Koch's [10, 6, 8] and Minkowski's [6] fractals, as well as their random generalizations [29].

The work of this author was performed at Los Alamos National Laboratory (LA-UR 04-5497) under the auspices of the National Nuclear Security Agency of the U.S. Department of Energy under contract W-7405-ENG-36 and was supported in part by the U.S. Department of Energy under the DOE/BES Program in the Applied Mathematical Sciences, contract KC-07-01-01, and in part by the LDRD Program at Los Alamos National Laboratory.

Alternatively, one can use [illegible] fields to represent rough surfaces whose detailed topology cannot be ascertained due to the lack of sufficient information and/or measurement errors [15, 27]. In this paper, we adopt random representations of rough surfaces, because of their generality. Such an approach allows us not only to make predictions of the system behavior, but also to quantify the corresponding predictive uncertainties.

The presence of uncertainty in rough boundaries necessitates the development of new approaches for the analysis and numerical solution of differential equations defined on random domains. For example, classical variational formulations might not be suitable for such problems [1], and a finite difference approach [34] is shown to be accurate only for relatively simple rectangular irregularities. Most of the existing analyses deal with deterministic roughness and are very problem-specific. For example, the use of conformal mappings [7, 6] requires that a physical phenomenon be accurately described by Laplace's equation in two dimensions, while the use of the Liebmann method [8] requires a particular geometry configuration and Dirichlet boundary conditions on the rough surface.

Adoption of a probabilistic framework to describe rough surfaces renders even essentially deterministic problems stochastic; e.g., deterministic equations in random domains give rise to stochastic boundary-value problems. This necessitates the search for new stochastic analyses and algorithms. For example, rigorous bounds for elliptic problems on random domains have been derived for both Dirichlet [2] and Neumann [1] boundary conditions, and perturbation solutions of Laplace's equation in a domain bounded by a random fractal boundary with a small surface dimension have been obtained [29]. One of the very few existing numerical studies employed traditional Monte Carlo simulations [6], which turned out to be so computationally expensive as to become impractical.

In this paper, we present a computational framework that is applicable to a wide class of deterministic and stochastic differential equations defined on domains with random (rough) boundaries. A key component of this framework is the use of robust stochastic mappings to transform an original deterministic or stochastic differential equation defined on a [illegible] into a stochastic differential equation defined on a [illegible]. This allows us to employ the well-developed theoretical and numerical techniques for solving stochastic differential equations in deterministic domains. The idea of transforming irregular domains into their regular counterparts has been used in computational fluid dynamics [33] and optimization problems [4], among other applications. The proposed approach extends this idea to stochastic problems.

In section 2, we provide a general mathematical formulation of a random domain problem. A stochastic mapping technique, which is defined by a solution of an appropriate boundary value problem for Laplace's equation, is presented in section 3.2. A mathematical formulation of the transformed stochastic equations in deterministic domains is given in section 3.3. This section also contains the description of two numerical approaches, Monte Carlo simulations (section 3.3.1) and a stochastic Galerkin method (section 3.3.2), whose relative strengths are discussed in section 3.3.3. In section 4, we apply our computational approach to a two-dimensional elliptic problem defined on both single- and double-connected random domains. For moderately high random dimensions (up to 16-dimensional random space), the stochastic Galerkin method is shown to be more efficient than Monte Carlo simulations. We conclude by listing a few open issues in section 5.

2. Differential equations in random domains. Let $\omega \in \Omega$ be a random realization drawn from a complete probability space $(\Omega, \mathcal{A}, \mathcal{P})$, whose event space Ω generates its σ-algebra $\mathcal{A} \subset 2^{\Omega}$ and is characterized by a probability measure $\mathcal{P}$. For all $\omega \in \Omega$, let $D(\omega) \subset \mathbb{R}^d$ be a d-dimensional random domain ($d = 1, 2, 3$), bounded by boundary $\partial D(\omega)$, some or all of whose segments are random. We consider the following stochastic (linear or nonlinear) boundary value problem: for $\mathcal{P}$-almost everywhere (a.e.) in Ω, given $a : D(\omega) \to \mathbb{R}$ and $b : \partial D(\omega) \to \mathbb{R}$, find a stochastic solution $v : \bar{D}(\omega) \to \mathbb{R}$ such that

$$\begin{aligned} L(x; v) &= a(x) \quad \text{in } D(\omega), \\ B(x; v) &= b(x) \quad \text{on } \partial D(\omega). \end{aligned} \tag{2.1}$$

Here $x = (x_1, \ldots, x_d)$ is the coordinate in $\mathbb{R}^d$, L is a differential operator, and B is a boundary operator. The operator B can take various forms on different boundary segments, e.g., $B \equiv I$, where I is the identity operator, on Dirichlet segments and $B \equiv \mathbf{n} \cdot \nabla$ on Neumann segments whose outward unit normal vector is $\mathbf{n}$. The operators L and B, as well as the driving terms a and b, can be either deterministic or random. To simplify the presentation, we assume that the shape of the boundary $\partial D(\omega)$ is the only source of randomness. This is done without loss of generality, since incorporation of other sources of randomness is straightforward, and stochastic equations in deterministic domains have been studied extensively. Finally, we assume that the random boundary $\partial D(\omega)$ is sufficiently regular, and the boundary condition in (2.1) is properly posed, to guarantee the well-posedness a.e. $\omega \in \Omega$ of the stochastic boundary-value problem (SBVP) (2.1). We refer to this problem as a random domain problem or RDP.

Except for a few studies mentioned in section 1, and despite their practical and theoretical importance, RDPs have not been systematically analyzed. At the same time, the theory of stochastic partial differential equations in fixed deterministic domains is relatively mature. To take advantage of the existing methods for deterministic domains, we introduce a one-to-one mapping function and its inverse

$$\xi = \xi(x, \omega), \qquad x = x(\xi, \omega), \tag{2.2}$$

which transforms the random domain $D(\omega) \subset \mathbb{R}^d$ into a deterministic domain $E \subset \mathbb{R}^d$, whose coordinates are denoted as $\xi = (\xi_1, \ldots, \xi_d)$; i.e., for $\mathcal{P}$-a.e. $\omega \in \Omega$,

$$x \in D(\omega) \longleftrightarrow \xi \in E. \tag{2.3}$$

The stochastic mapping (2.3) transforms the deterministic differential operators L and B into their stochastic counterparts $\mathcal{L}$ and $\mathcal{B}$, respectively, and RDP (2.1) into the following SBVP. For $\mathcal{P}$-a.e. $\omega \in \Omega$, given $f : E \times \Omega \to \mathbb{R}$ and $g : \partial E \times \Omega \to \mathbb{R}$, find a stochastic solution $u : \bar{E} \times \Omega \to \mathbb{R}$ such that

$$\begin{aligned} \mathcal{L}(\xi, \omega; u) &= f(\xi, \omega) \quad \text{in } E, \\ \mathcal{B}(\xi, \omega; u) &= g(\xi, \omega) \quad \text{on } \partial E, \end{aligned} \tag{2.4}$$

where f and g are the transformed functions of a and b, respectively. Note that since the random mapping (2.3) depends on random $D(\omega)$, other possible sources of randomness, including coefficients of the differential operators in (2.1) and boundary and initial conditions, can be easily incorporated into the formulation of RDP (2.1) and do not change the following analysis.

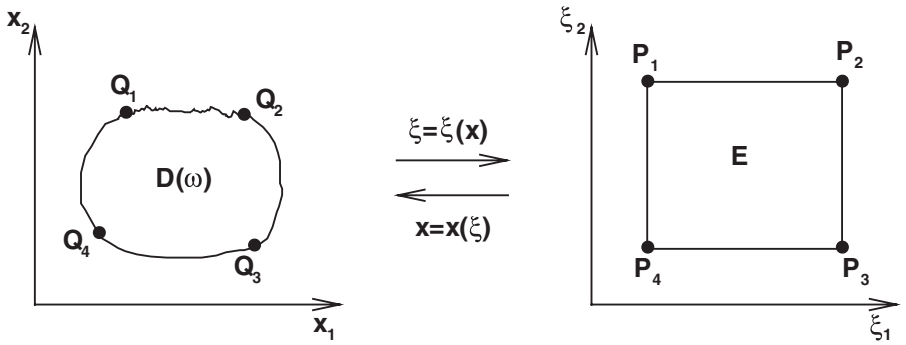

FIG. 2.1. *A schematic representation of a computational domain $D(\omega)$ with the random boundary segment $\widehat{Q_1Q_2}$ and its mapping onto a deterministic rectangular domain E, where four reference points Q_i are mapped onto P_i, $i = 1, 2, 3, 4$.*

The geometry of the deterministic domain E is to a large extent arbitrary and should be chosen in a way that simplifies the subsequent analysis and computation. Consider, for example, the domain $D(\omega)$ in Figure 2.1, whose boundary segment $\widehat{Q_1Q_2}(\omega)$ is random. Possible choices of the corresponding deterministic domain E include domains whose deterministic boundary segments remain unchanged, and the random boundary segment $\widehat{Q_1Q_2}(\omega)$ is replaced with (i) its ensemble mean $\mathbb{E}[\widehat{Q_1Q_2}(\omega)]$, where $\mathbb{E}$ denotes the expectation operator in the probability space, and (ii) its upper or lower bounds. (Depending on the problem, one can define such bounds based on either the total volume of $D(\omega)$ or the distance of $\partial D(\omega)$ to a certain location in the domain of interest, or in some other way.) Here, to facilitate numerical simulations in the transformed domain E, we choose it to have a canonical shape, such as the rectangle $\overline{P_1P_2P_3P_4}$ shown in Figure 2.1.

3. Computational framework. A computational framework that is applicable to a wide range of practical applications should provide (i) a general parameterization of the random boundary $\partial D(\omega)$, (ii) an effective way to obtain the stochastic mapping (2.2), and (iii) an efficient method for solving the subsequent SBVP (2.4) in deterministic domains. We construct such a framework by introducing a stochastic mapping based on solutions of Laplace's equations (section 3.2), and by employing two complementary numerical algorithms to solve the resulting SBVPs: a Monte Carlo method and a stochastic Galerkin method (section 3.3).

While the approach discussed in this section is applicable to one- and three-dimensional problems as well, here we consider the two-dimensional domain shown in Figure 2.1, to simplify the presentation. Without loss of generality, we assume that only the segment $\widehat{Q_1Q_2}$ of the overall boundary $\partial D(\omega)$ is random, and we represent it as $\widehat{Q_1Q_2}(\omega) = r(z, \omega)\mathbf{e}_1 + s(z, \omega)\mathbf{e}_2$, where $\mathbf{e}_1$ and $\mathbf{e}_2$ are unit vectors in the x_1 and x_2 directions, respectively; r and s are the parameterization functions for the segment; and z is the parameterization variable. We seek to map $D(\omega)$ onto a square $E = [0, 1] \times [0, 1]$.

3.1. Parameterization of random boundary. Parameterization of the random boundary $\widehat{Q_1Q_2}$ consists of the following steps. First, we use Reynolds decomposition to represent random functions, e.g., $A(\omega) = \langle A \rangle + A'(\omega)$, as the sums of

their ensemble means $\langle A\rangle \equiv \mathbb{E}[A(\omega)]$ and zero-mean fluctuations $A'(\omega)$. The latter term can be characterized by a variety of techniques, including its representation as a random field with a given point distribution and two-point correlation function. Here, following common practice, we approximate the fluctuation term by a finite number $K \geq 1$ of mutually uncorrelated random variables $Y_1(\omega), \ldots, Y_K(\omega)$ with zero mean and unit variance, so that $r(z,\omega)$ and $s(z,\omega)$ in (3.4) can be approximated as

$$r(z,\omega) \approx \langle r(z)\rangle + \sum_{k=1}^{K} \hat{r}_k(z) Y_k(\omega) \tag{3.1}$$

and

$$s(z,\omega) \approx \langle s(z)\rangle + \sum_{k=1}^{K} \hat{s}_k(z) Y_k(\omega). \tag{3.2}$$

The parameterization (3.1) and (3.2) is an approximation of the true processes, whose accuracy and robustness are the subject of ongoing research in the field of numerical generation of random processes. If these processes are non-Gaussian, this task becomes particularly challenging [16, 28, 30, 39]. (In such cases, the goal is often reduced to approximating pointwise marginal distribution functions and two-point covariance functions.) Analysis of the errors induced by the finite-term representations in (3.1) and (3.2), as well as of their efficiency, is beyond the scope of this paper. Instead we refer the interested reader to the references mentioned above.

The choice of a parameterization of the random boundary $\widehat{Q_1Q_2}$ defines the expansion coefficients $\{\hat{r}_k\}$ and $\{\hat{s}_k\}$. One popular choice is the Karhunen–Loève (KL) decomposition [23], which is an optimal decomposition in terms of the mean-square approximation error and has been used extensively to represent random inputs [3, 14, 36]. Other types of decomposition also can be employed. In section 4 of this paper, we explore both the KL expansion and a Fourier expansion.

3.2. Mapping of the random domain. We construct the stochastic mapping of $D(\omega)$ onto E via solutions of the Laplace equations

$$\frac{\partial^2 x_1}{\partial \xi_1^2} + \frac{\partial^2 x_1}{\partial \xi_2^2} = 0, \qquad \frac{\partial^2 x_2}{\partial \xi_1^2} + \frac{\partial^2 x_2}{\partial \xi_2^2} = 0 \quad \text{in } E, \tag{3.3}$$

subject to the boundary conditions

$$x_1(0,\xi_2) = x_1|_{\widehat{Q_4Q_1}}, \qquad x_1(1,\xi_2) = x_1|_{\widehat{Q_3Q_2}}, \tag{3.4a}$$

$$x_1(\xi_1,0) = x_1|_{\widehat{Q_4Q_3}}, \qquad x_1(\xi_1,1) = r(z,\omega) \tag{3.4b}$$

and

$$x_2(0,\xi_2) = x_2|_{\widehat{Q_4Q_1}}, \qquad x_2(1,\xi_2) = x_2|_{\widehat{Q_3Q_2}}, \tag{3.4c}$$

$$x_2(\xi_1,0) = x_2|_{\widehat{Q_4Q_3}}, \qquad x_2(\xi_1,1) = s(z,\omega), \tag{3.4d}$$

where $x_i|_{\widehat{Q_mQ_n}}$ denotes the x_i coordinate along the boundary segment $\widehat{Q_mQ_n}$. Similar mappings have been used extensively to solve numerically deterministic problems in structured body-fitted curvilinear coordinates [33], and more recently to analyze the interface dynamics in disordered media [19]. The properties and a more detailed

technical description of such mappings can be found in [33]. The stochastic mapping (3.3)–(3.4) can be viewed as a generalization of this idea to random domains. We also remark that the boundary conditions (3.4) are not expressed in a definitive manner. One can choose different distributions of boundary coordinates in x as boundary conditions in (3.4), in order to achieve better computational results by, e.g., clustering a mesh close to the regions of interests (see [33] for details).

As a result of (3.1) and (3.2), solutions of (3.3) can be expressed as

$$x_i(\xi,\omega) = \sum_{k=0}^{K} \hat{x}_{i,k} Y_k(\omega), \qquad i = 1, 2. \tag{3.5}$$

Then, denoting $\hat{r}_0 \equiv \langle r \rangle$ and $\hat{s}_0 \equiv \langle s \rangle$, substituting the expansions (3.1) and (3.5) into (3.3)–(3.4), and collecting the terms of each $\{Y_k(\omega)\}$, i.e., conducting a Galerkin projection (in the random space) of the resulting equations onto the basis spanned by $\{1, Y_1(\omega), \ldots, Y_K(\omega)\}$, we obtain $(K+1)$ equations for the expansion coefficients,

$$\frac{\partial^2 \hat{x}_{1,k}}{\partial \xi_1^2} + \frac{\partial^2 \hat{x}_{1,k}}{\partial \xi_2^2} = 0, \qquad \frac{\partial^2 \hat{x}_{2,k}}{\partial \xi_1^2} + \frac{\partial^2 \hat{x}_{2,k}}{\partial \xi_2^2} = 0, \quad k = 0, \ldots, K, \tag{3.6}$$

subject to the boundary conditions

$$\hat{x}_{1,k}(0,\xi_2) = x_1|_{\widehat{Q_4Q_1}} \cdot \delta_{k0}, \qquad \hat{x}_{1,k}(1,\xi_2) = x_1|_{\widehat{Q_3Q_2}} \cdot \delta_{k0}, \tag{3.7a}$$

$$\hat{x}_{1,k}(\xi_1,0) = x_1|_{\widehat{Q_4Q_3}} \cdot \delta_{k0}, \qquad \hat{x}_{1,k}(\xi_1,1) = \hat{r}_k(z) \tag{3.7b}$$

and

$$\hat{x}_{2,k}(0,\xi_2) = x_2|_{\widehat{Q_4Q_1}} \cdot \delta_{k0}, \qquad \hat{x}_{2,k}(1,\xi_2) = x_2|_{\widehat{Q_3Q_2}} \cdot \delta_{k0}, \tag{3.7c}$$

$$\hat{x}_{2,k}(\xi_1,0) = x_2|_{\widehat{Q_4Q_3}} \cdot \delta_{k0}, \qquad \hat{x}_{2,k}(\xi_1,1) = \hat{s}_k(z), \tag{3.7d}$$

where $\delta_{mn} = 0$ if $m \neq n$ and $\delta_{mn} = 1$ if $m = n$ is the Kronecker delta function. Solutions of the deterministic boundary value problems (3.6)–(3.7) give the stochastic mapping function $x_i(\xi,\omega)$ in (3.5), whose metrics terms and Jacobian can be readily evaluated.

3.3. Numerical solutions of the transformed equations. Since the stochastic mapping $x_i(\xi,\omega)$ in (2.2) is represented by (3.5) as a function of the random variables $\{Y_k(\omega)\}_{k=1}^K$, the metrics terms and the Jacobian corresponding to the coordinate transformation from x to ξ become functions of $\{Y_k(\omega)\}_{k=1}^K$ as well. In particular, the Jacobian takes the form

$$J(\xi,\omega) \equiv \frac{\partial(\xi_1,\ldots,\xi_d)}{\partial(x_1,\ldots,x_d)} = J(\xi, Y_1(\omega), \ldots, Y_K(\omega)). \tag{3.8}$$

Hence, according to the Doob–Dynkin lemma [25], a solution of the SBVP (2.4) can be described by a finite number of random variables $\{Y_k(\omega)\}_{k=1}^K$, i.e.,

$$u(x,\omega) = u(x, Y_1(\omega), \ldots, Y_K(\omega)). \tag{3.9}$$

The transformed SBVP (2.4) in the fixed domain E can be solved by a variety of techniques, including perturbation methods [18] and second-moment analyses [22]. In this paper, we use two complementary approaches, Monte Carlo simulations and stochastic Galerkin methods.

To facilitate numerical implementation, we further assume that the random variables $\{Y_k(\omega)\}_{k=1}^K$ are mutually independent, rather than just uncorrelated. (Such an assumption is not needed for Gaussian processes, for which independence and uncorrelation are equivalent.) While this assumption might introduce additional errors in the finite-term approximations (3.1) and (3.2) of target random processes, it enables one to define the corresponding Hilbert functional spaces via simple tensor product rules. In other words, the independence assumption is made for technical convenience, and has been employed in many applications in stochastic simulations, e.g., [3, 21, 36] and references therein. We also remark that similar assumptions are often made in sampling methods, where random number generators typically generate [illegible], not just uncorrelated, series of random numbers. It is worthwhile to point out that it is possible to construct multidimensional functional spaces based on a finite number of [illegible] random variables [31]. However, in its current form such a construction is not amenable to a straightforward numerical implementation.

3.3.1. Monte Carlo simulations. Monte Carlo simulations (MCS) are one of the most developed methods for solving stochastic differential equations. Although their convergence rate is relatively slow—a typical Monte Carlo simulation consisting of M realizations converges as $1/\sqrt{M}$ (see [11])—it is independent from the number of random variables $\{Y_k(\omega)\}_{k=1}^K$. We remark that the presence of random boundaries $\partial D(\omega)$ makes the direct use of MCS for solving the RDP (2.1) less than straightforward. Since each realization of the random domain $D(\omega_j), j = 1, \ldots, M$, is different, a remeshing procedure is needed to render the statistical averaging of a solution at any point x in the domain meaningful.

In our approach, we apply MCS to the transformed SBVP (2.4) instead. Since this SBVP is defined on the fixed deterministic domain E, the use of MCS becomes straightforward and consists of the following steps:

1. for a given number of realizations M, generate the independent random variables $\{Y_k(\omega_j)\}_{k=1}^K$, for $j = 1, \ldots, M$;
2. for each $j = 1, \ldots, M$, use (3.1) and (3.2) to construct realizations of the random boundary $\widehat{Q_1Q_2}(\omega_j) = r(\omega_j)\mathbf{e}_1 + s(\omega_j)\mathbf{e}_2$, and solve Laplace's equations (3.6)–(3.7) to obtain realizations of the stochastic mapping $x_i(\xi, \omega_j), i = 1, \ldots, d$;
3. for each $j = 1, \ldots, M$, evaluate the metrics terms and the Jacobian $J(\xi, \omega_j)$, and solve the SBVP (2.4) in the deterministic domain $\xi \in E \subset \mathbb{R}^d$;
4. postprocess the results to evaluate the solution's statistics, e.g., $\langle u(\xi) \rangle \equiv \mathbb{E}[u] = M^{-1} \sum_{j=1}^M u(\xi, \omega_j)$.

For each realization $j = 1, \ldots, M$, step 3 solves a deterministic problem on a deterministic domain E, which can be accomplished with any suitable spatial discretization scheme.

3.3.2. Stochastic Galerkin method. Stochastic Galerkin (SG) methods are polynomial-type expansions in the random space. In general, these methods exhibit fast convergence rates, provided that solutions are sufficiently smooth in the random space. The first SG methods employed polynomial chaos expansions [14], which are based on the Wiener–Hermite expansion. More recent developments of the generalized polynomial chaos employ non-Hermite polynomials to improve efficiency for a wide class of problems. Such generalizations include global polynomial expansions based on hypergeometrical polynomials [37, 36, 38], piecewise polynomial expansions [3, 9], and wavelet basis expansions [20, 21]. Here we briefly review the framework based on global polynomial expansions.

Let $\{Y_i\}_{i=1}^K$ be independent random variables with probability density functions $\rho_i : \Gamma_i \to \mathbb{R}^+$, and assume that their images $\Gamma_i \equiv Y_i(\Omega)$ are bounded intervals in $\mathbb{R}$ for $i = 1, \ldots, K$. Then

$$\rho(y) = \prod_{i=1}^{K} \rho_i(Y_i) \qquad \forall y \in \Gamma \tag{3.10}$$

is the joint probability density of $y = (Y_1, \ldots, Y_K)$ with the support

$$\Gamma \equiv \prod_{i=1}^{K} \Gamma_i \subset \mathbb{R}^K. \tag{3.11}$$

This allows one to rewrite (2.4) as a $(d + K)$-dimensional differential equation

$$\begin{aligned} \mathcal{L}(\xi, y; u) &= f(\xi, y), \quad (\xi, y) \in E \times \Gamma, \\ \mathcal{B}(\xi, y; u) &= g(\xi, y), \quad (\xi, y) \in \partial E \times \Gamma. \end{aligned} \tag{3.12}$$

Let us define a one-dimensional polynomial space in $L^2_{\rho_i}(\Gamma_i)$, the space for all square integrable functions in Γ_i with respect to measure $\rho_i dY_i$,

$$W_i^{p_i} \equiv \{v : \Gamma_i \to \mathbb{R} : v \in \operatorname{span}\{\phi_m(Y_i)\}_{m=0}^{p_i}\}, \qquad i = 1, \ldots, K, \tag{3.13}$$

where $\{\phi_m(Y_i)\}$ form a set of orthogonal polynomials satisfying the orthogonality conditions

$$\int_{\Gamma_i} \rho_i(Y_i)\phi_m(Y_i)\phi_n(Y_i)dY_i = h_m^2 \delta_{mn}, \tag{3.14}$$

with normalization factors $h_m^2 = \int_{\Gamma_i} \rho_i(Y_i)\phi_m^2(Y_i)dY_i$. Then, the corresponding K-dimensional polynomial space is defined by

$$W_{K,p} \equiv \bigotimes_{|\mathbf{p}| \le p} W_i^{p_i}, \tag{3.15}$$

where the tensor product is over all possible combinations of the multi-index $\mathbf{p} = (p_1, \ldots, p_K) \in \mathbb{N}_0^K$ such that the length of the multi-index satisfies $|\mathbf{p}| = \sum_{k=1}^K p_k \le p$. The total number of basis functions in (3.15) is $(K + p)!/(K!p!)$.

The type of orthogonal polynomials $\{\phi_m(Y_i)\}$ in (3.14) is determined by the probability density function of $Y_i(\omega)$, for $i = 1, \ldots, K$. For example, uniform distributions are best approximated with Legendre polynomials, while Hermite polynomials are most appropriate for Gaussian distributions. A detailed list of such correspondences and the rates of their convergence can be found in [37, 36].

Finally, an SG formulation of (3.12) is as follows. For all $\xi \in \bar{E}$, find $u_p(\xi, y) \in W_{K,p}$ such that

$$\int_\Gamma \rho(y)\mathcal{L}(\xi, y; u_p)\, v(y)dy = \int_\Gamma \rho(y) f(\xi, y)v(y)d\mathbf{y} \quad \forall v(y) \in W_{K,p},\ \xi \in E, \tag{3.16}$$

$$\int_\Gamma \rho(y)\mathcal{B}(\xi; u_p)v(y)dy = \int_\Gamma \rho(y) g(\xi, y)v(y)dy \quad \forall v(y) \in W_{K,p},\ \xi \in \partial E. \tag{3.17}$$

The weak formulation (3.16)–(3.17) results in a set of deterministic problems in the fixed domain E and can be further discretized by any standard discretization technique, including finite elements and finite volumes. Construction of stochastic Sobolev spaces for stochastic diffusion equations is discussed in detail in [3]. For more implementation details and numerical examples, see [37, 36].

3.3.3. Selection of a numerical method. The dimensionality of the problem (3.12) is $d+K$, although only d dimensions involve differentiations. The total number K of random variables $\{Y_i\}_{i=1}^K$ that is needed to represent the random boundary $\partial D(\omega)$ by (3.1) and (3.2) with a given accuracy depends on, among other factors, the correlation length of $\partial D(\omega)$. Although one may choose different decomposition methods in (3.1) and (3.2), in general, the value of K increases when the correlation length becomes smaller.

SG methods converge with increased order of p. In fact, an exponential convergence has been proved for stochastic diffusion equations in [3] and shown numerically for various stochastic equations in [36, 37, 38]. However, when $K \gg 1$ is very large, the total number of expansion terms $(K+p)!/K!p!$ increases quickly, and this effectively reduces the convergence rate with respect to the number of expansion terms. In this case, it may be necessary to resort to MCS, as their convergence rate, $1/\sqrt{M}$, albeit slower, is asymptotically independent of the value of K.

Thus, for low to moderate values of K (less than 10), SG methods are preferred, and for large values of $K \gg 1$, the Monte Carlo method is preferred. However, if high accuracy of a stochastic solution is required, then SG methods can be more efficient even for relatively large values of K. (For example, see [35] for computations with $K = 38$ for a three-dimensional time-dependent heat transfer problem.)

4. Applications to elliptic equations in random domains. In this section, we apply the computational framework described above to elliptic problems in single- and double-connected random domains.

4.1. Formulation. Consider a deterministic Poisson equation with homogeneous Dirichlet boundary conditions in a random domain: for $\mathcal{P}$-a.e. $\omega \in \Omega$, $c, a : D(\omega) \to \mathbb{R}$, find $v : \bar{D}(\omega) \to \mathbb{R}$ such that

$$\begin{aligned} \nabla \cdot [c(x)\nabla v(x,\omega)] &= a(x) \quad \text{in } D(\omega), \\ v(x,\omega) &= 0 \quad \text{on } \partial D(\omega). \end{aligned} \tag{4.1}$$

The stochastic mapping (2.2) transforms (4.1) into a stochastic Poisson equation on a deterministic domain E: for $\mathcal{P}$-a.e. $\omega \in \Omega$, $\kappa, f, \alpha_{ij} : E \times \Omega \to \mathbb{R}, 1 \le i, j \le d$, find $u : \bar{E} \times \Omega \to \mathbb{R}$ such that

$$\sum_{i=1}^{d} \frac{\partial}{\partial \xi_i} \left[\kappa(\xi,\omega) \sum_{j=1}^{d} \left(\alpha_{ij}(\xi,\omega) \frac{\partial u}{\partial \xi_j} \right) \right] = J^{-1} f(\xi,\omega) \quad \text{in } E, \tag{4.2}$$

$$u(\xi,\omega) = 0 \qquad \text{on } \partial E,$$

where the random fields κ and f are the transformations of c and a, respectively; J is the transformation Jacobian defined in (3.8); and

$$\alpha_{ij}(\xi,\omega) = J^{-1} \nabla \xi_i \cdot \nabla \xi_j, \qquad 1 \le i, j \le d. \tag{4.3}$$

The use of (3.1) and (3.2) to parameterize the random boundary $\partial D(\omega)$ with a finite number of random variables $\{Y_i(\omega)\}_{i=1}^K$ yields a strong form of (4.2),

$$\sum_{i=1}^{d} \frac{\partial}{\partial \xi_i} \left[\kappa(\xi,y) \sum_{j=1}^{d} \left(\alpha_{ij}(\xi,y) \frac{\partial u}{\partial \xi_j} \right) \right] = J^{-1} f(\xi,y) \qquad \text{in } E \times \Gamma, \tag{4.4}$$

subject to the boundary condition

$$u(\xi, y) = 0 \qquad \text{on } \partial E \times \Gamma. \tag{4.5}$$

In what follows, we solve the SBVP (4.4)–(4.5) by MCS and SG methods. Note that the left-hand side of (4.5) typically takes the form of a complicated function of the random vector y, even though the representation of the input, i.e., random boundary ∂D, is linear in y. Thus, in SG methods the projection of (4.5) onto the basis functions can be nontrivial. In this paper, we employ a typical approach that uses the quadrature/cubature rule with sufficient accuracy to ensure the accuracy of the projection (e.g., [37]).

4.2. Diffusion in a channel with a rough surface. Consider steady-state diffusion, described by (4.1) with $f \equiv 0$, in a two-dimensional channel $D(\omega) = \{(x_1, x_2) | 0 \le x_1 \le L_x, s(x_1, \omega) \le x_2 \le L_y\}$. To be specific, we set $L_x = 5$, $L_y = 1$, and treat the rough bottom boundary as a random field $s = s(x_1, \omega)$ with zero mean $\langle s(x_1, \omega) \rangle = 0$ and an exponential two-point covariance function

$$C_S(x_1, z_1) = \mathbb{E}\left[s(x_1, \omega) s(z_1, \omega)\right] = \exp\left(-\frac{|x_1 - z_1|}{b}\right), \tag{4.6}$$

where $b > 0$ is the correlation length. In the computational examples below, $b = L_x/5 = 1$, which corresponds to a boundary of moderate roughness. Finally, we prescribe Dirichlet boundary conditions $u = 1$ at $x_2 = L_y$ and $u = 0$ elsewhere.

We employ the finite-term KL-type expansion (3.2) to decompose the boundary process. The expansion coefficients $\{\hat{s}_k\}_{k=1}^K$ are given by $\hat{s}_k(x_1) = \sqrt{\lambda_k}\psi_k(x_1)$, where $\{\lambda_k, \psi_k(x_1)\}$ are the eigenvalues and eigenfunctions of the integral equations

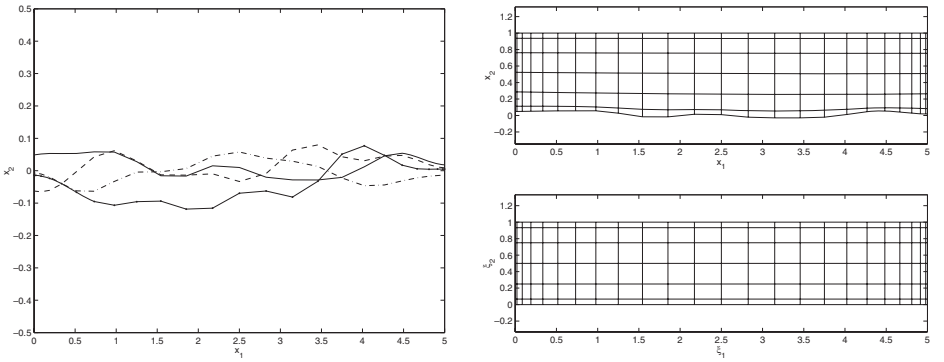
$$\int C_S(x_1, z_1)\psi_k(z_1) dz_1 = \lambda_k \psi_k(x_1), \qquad k = 1, \dots, K. \tag{4.7}$$

Then the decomposition (3.2) becomes

$$s(x_1, \omega) \approx \sigma \sum_{k=1}^{K} \hat{s}_k(x_1) Y_k(\omega) = \sigma \sum_{k=1}^{K} \sqrt{\lambda_k}\psi_k(x_1) Y_k(\omega). \tag{4.8}$$

We set $\{Y_i(\omega)\} \sim U(-1, 1)$ to be independent uniform random variables in $(-1, 1)$ and use the parameter $0 < \sigma < 1$ to control the maximum deviation of the rough surface. (In the computational examples in this section, we set $\sigma = 0.1$.) We employ Legendre polynomials as the basis functions (3.13) in the SG method, since they form the optimal basis corresponding to uniform random inputs [37].

It is worthwhile to stress again that the expansion (4.8) introduces two sources of errors—the errors due to the finite K-term truncation and the errors due to the assumption of independence of $\{Y_k(\omega)\}$. The truncation error is typically controlled by selecting the value of K to ensure that the eigenvalues $\{\lambda_k\}$ with $k > K$ are sufficiently small. For example, our numerical tests reveal that the expansion (4.8) with $K = 10$ captures 95% of the L_2 norm. Hence, we employ a ten-term KL expansion to represent the random boundary, and show some realizations of the boundary in Figure 4.1(a). Theoretical error estimates of such truncations can be found in [12]. Error analysis on the independence assumption is lacking and lies outside the scope of the present study.



(a) (b)

FIG. 4.1. *Channels with a rough wall generated with the ten-term ($K = 10$) KL expansion* (4.8). (a) *Four sample realizations of the bottom boundary $s(x_1, \omega_j)$ ($j = 1, \ldots, 4$).* (b) *A sample realization of the channel in the physical domain (x_1, x_2) and in the mapped domain in (ξ_1, ξ_2). Chebyshev meshes are used in both domains.*

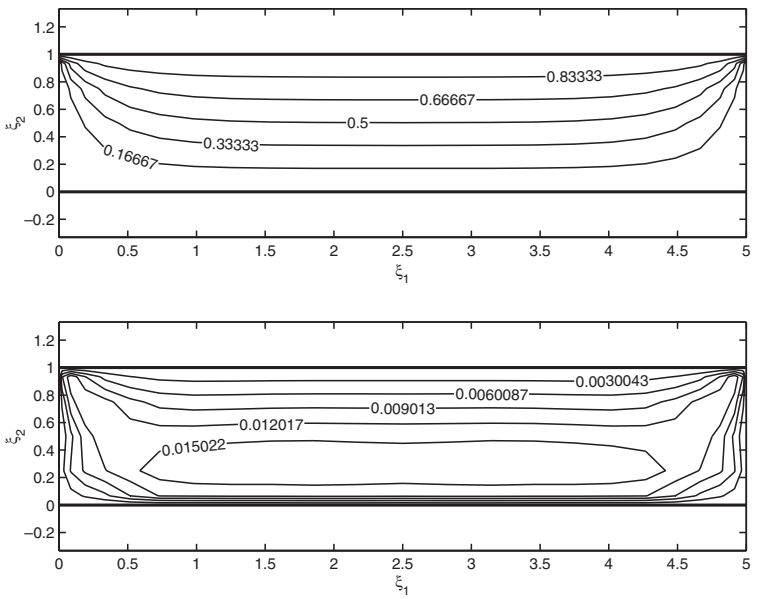


FIG. 4.2. *The mean and STD of the dependent variable u, computed with the SG method.*

Figure 4.1(b) shows a realization of the channel $D(\omega_j)$ mapped onto the corresponding rectangular domain $E = [0, L_x] \times [0, L_y]$. The mapping Laplace equations (3.3) are solved by the Chebyshev collocation method. Figure 4.1(b) also shows the Chebyshev collocation mesh points in both the physical domain D and the mapped domain E.

The stochastic elliptic problem (4.2) is solved in the mapped rectangular domain E with the SG method described in section 3.3.2. The Chebyshev collocation method is used in both ξ_1 and ξ_2 directions. Figure 4.2 shows the first two ensemble moments of the solution, i.e., its mean (top) and standard deviation (STD) (bottom). We

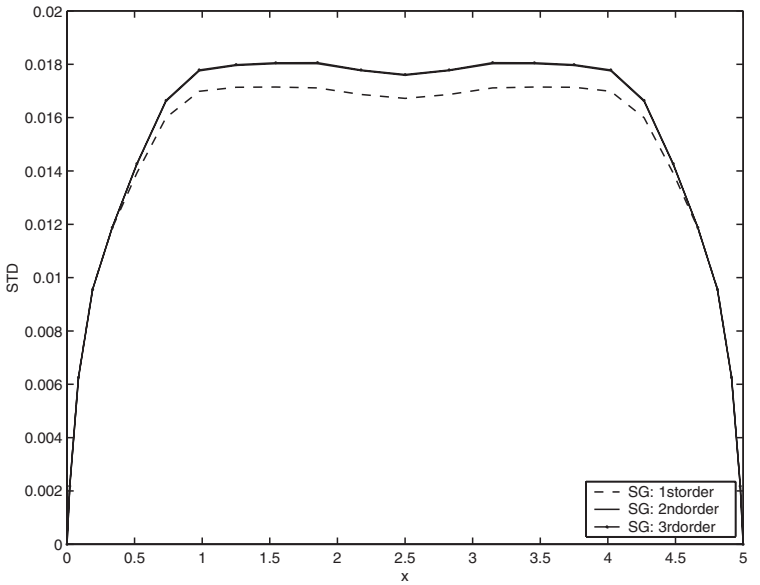

FIG. 4.3. *The STD profiles along the cross section $y = 0.25$, computed with the first-, second-, and third-degree Legendre polynomials.*

observe that the STD reaches its maximum close to, but not at, the random bottom boundary.

To ascertain the convergence of the polynomial chaos expansion, we examine the STD profile along the cross section $y = 0.25$, where the STD is close to its maximum. Figure 4.3 shows the STD profiles obtained with different orders of Legendre expansions. Once can see that the second order is sufficient for the Legendre expansion to converge. Although not shown here, the convergence of the mean solution is similar to that of the STD.

MCS are also conducted to verify the results obtained by the SG method. Figure 4.4 compares the STD profile along the cross section $y = 0.25$ computed via the second-order Legendre expansion with those obtained from MCS. We observe that as the number of realizations increases, the MCS results converge to the converged SG results. With about 2,000 realizations, the MCS results agree well with SG results. In this case, at second order ($p = 2$) and ten random dimensions ($K = 10$), the SG method requires $(K + p)!/K!p! = 66$ basis functions and is computationally more efficient than MCS. In CPU time, the second-order SG method is approximately 20 times faster than MCS with 2,000 realizations.

4.3. Diffusion in double-connected domains with rough exclusion. Consider steady-state diffusion, described by (4.1) with $f \equiv 0$, in a double-connected domain $D(\omega)$ consisting of the square $[-2, 2] \times [-2, 2]$ with a randomly perturbed unit circular exclusion. A sample realization of such a domain is shown in Figure 4.5(a), and several sample realizations of the surface of the random exclusion are depicted in Figure 4.5(b). The boundary conditions are $u = 1$ along the surface of the exclusion and $u = 0$ along the outer square.

The inner random boundary is constructed and parameterized by superimposing a zero-mean random perturbation process on the radius $R(\theta)$ of a unit circle centered

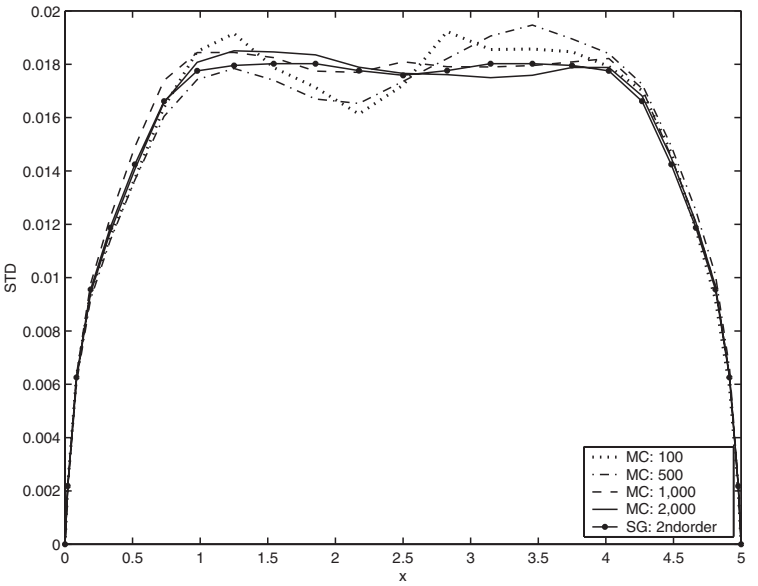

FIG. 4.4. *The STD profiles along the cross section* $y = 0.25$*, computed with the SG method (the second-order Legendre chaos) and the MCS consisting of* 100*,* 500*,* 1,000*, and* 2,000 *realizations.*

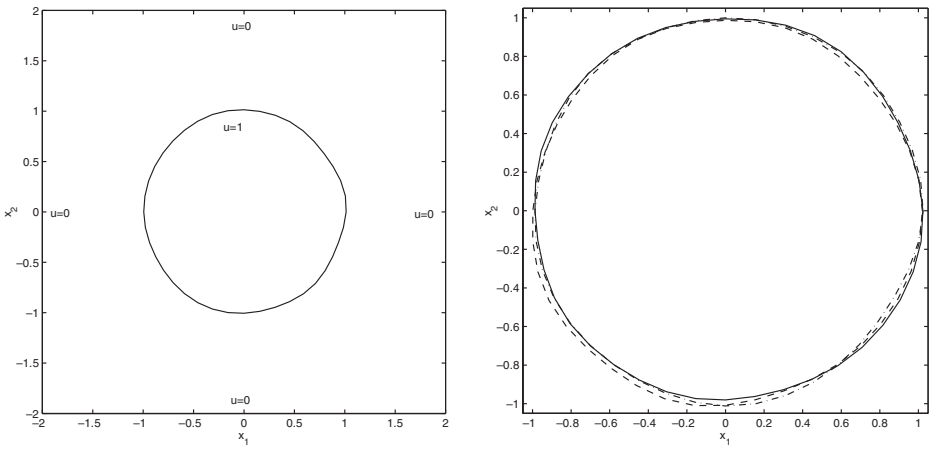
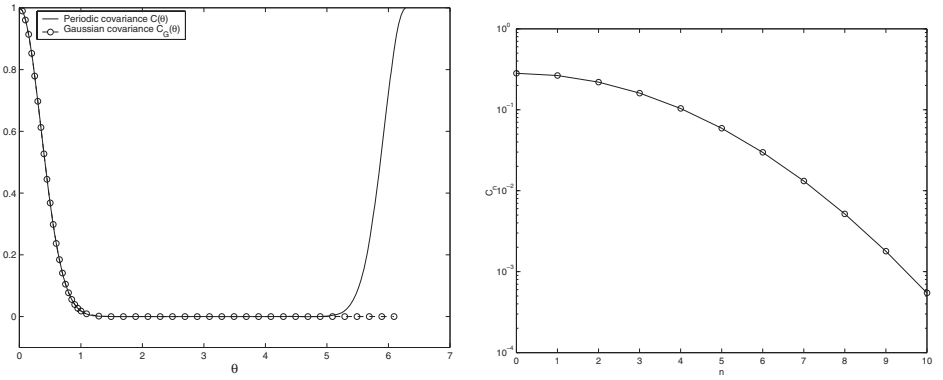


(a) (b)

FIG. 4.5. *A double-connected domain with a rough circular exclusion generated with the* 16*-term* $(N = 16)$ *Fourier expansion* (4.9). (a) *A sample realization of the random computational domain.* (b) *Three sample realizations of the circular exclusion* $R(\theta, \omega_j)$ $(j = 1, \ldots, 4)$.

at $(0, 0)$, where $0 \leq \theta \leq 2\pi$. In other words, the inner boundary is defined as $(x_1, x_2) = (R\cos\theta, R\sin\theta)$, for $0 \leq \theta \leq 2\pi$, where $R(\theta, \omega) = 1 + \sigma R'(\theta, \omega)$ is the radius. Here $0 < \sigma < 1$ is used to control the maximum deviation of the process. We require that both $\langle R' \rangle = 0$ and the statistics of $R(\theta, \omega)$ be [illegible] on the circle, i.e., that $\langle R'(\theta_1) R'(\theta_2) \rangle = C_R(|\theta_1 - \theta_2|)$.



(a) (b)

FIG. 4.6. (a) *Periodic covariance function $C(\theta)$ (solid line) based on the nonperiodic Gaussian function $C_G = \exp(-\theta^2/b^2)$ with $b = 0.5$ (dashed line with circles).* (b) *Decay of the Fourier cosine coefficients of the periodic covariance function.*

Since the random process $R'(\theta, \omega)$ is periodic, we use a Fourier-type expansion

$$R'(\theta, \omega) = \sum_{n=-N}^{N} R_n(\omega) e^{-in\theta} \tag{4.9}$$

for its decomposition into a finite number of random variables (see (3.1) and (3.2)). In this expansion, the coefficients $R_n(\omega) = R_n^r(\omega) + iR_n^i(\omega)$ are complex random variables. It is straightforward to show that if R_n^r and R_n^i are statistically independent for all n, and have zero mean and the variance of $C_n/4$, where $C_n = \frac{1}{\pi}\int_0^{2\pi} C_R \cos(n\theta) d\theta$ are the coefficients of the Fourier cosine series of the covariance function C_R, then the random field $R'(\theta, \omega)$ given by (4.9) has the prescribed covariance function C_R. (It is worth noting that in periodic domains, Fourier expansion is in fact the KL expansion.)

A periodic covariance function $C_R(|\theta_1 - \theta_2|)$ with the period of 2π is constructed by extending the standard Gaussian covariance function $C_G = \exp(-(\theta_1 - \theta_2)^2/b^2)$ to the periodic domain $(0, 2\pi)$, where b is the correlation length. Figure 4.6(a) shows such a periodic covariance function and contrasts it with the standard nonperiodic Gaussian covariance function. Figure 4.6(b) demonstrates the decay of the Fourier cosine coefficients $\{C_n\}$ for the periodic covariance function with the correlation length $b = 0.5$. Based on the decay of C_n, we choose $N = 8$ ($C_9 = 0.0052, C_1 = 0.2821, C_9/C_1 < 2\%$).

In the following examples, we set the coefficients $R_n^r, R_n^i, n = 1, \ldots, N$, in the expansion (4.9) to be independent uniform random variables of $U(-1, 1)$. This results in a 16-dimensional ($K = 2N = 16$) random space Γ for problem (4.2). In the computational examples below, we set $\sigma = 0.02$. We again use Legendre expansion in the SG method to represent the uniform random inputs.

To map the double-connected random domain $D(\omega)$ onto a single-connected deterministic domain E, we introduce an artificial cut in the domain D, as shown in Figure 4.7. This cut dissects the overall boundary into four segments: the inner boundary $\widehat{AB}$, the cut $\overline{BC}$, the outer boundary $\widehat{CD}$, and the cut $\overline{DA}$. Note that the segments $\overline{BC}$ and $\overline{AD}$ are at the same physical locations, although while solving the

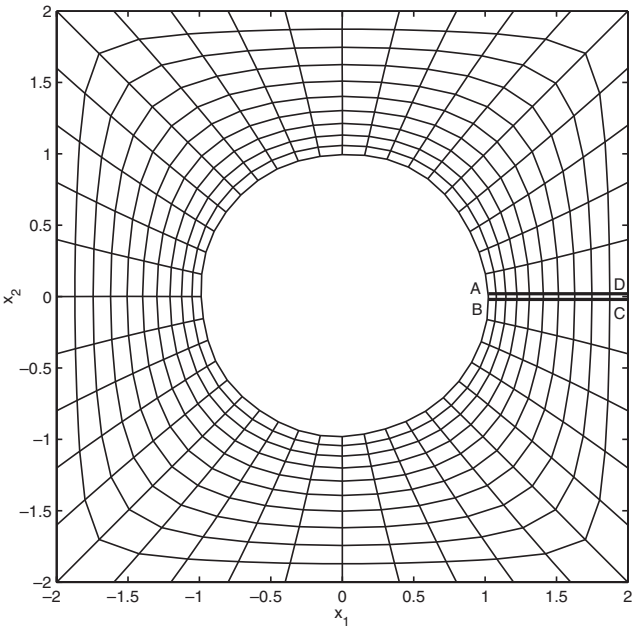


FIG. 4.7. *Random double-connected domain constructed with the* 16*-term* ($N = 2K = 16$) *Fourier expansion, and the corresponding computational mesh.*

Laplace equations (3.3) they are treated as two distinct boundaries. To emphasize this point, these two cuts are shown as two separate lines in Figure 4.7.

The mapped domain in (ξ_1, ξ_2) is a rectangle of $\overline{ABCD}$, whose length $\overline{AB}$ and $\overline{CD}$ is 2π and width $\overline{BC}$ and $\overline{DA}$ is 1. To solve (3.6), we use the Fourier collocation method in the ξ_1-direction (because of the periodicity) and the second-order finite difference method in the ξ_2-direction. Figure 4.7 shows a sample resulting mesh in (x_1, x_2).

The mapped stochastic Poisson equation (4.2) is solved with the 40-point Fourier collocation scheme in the ξ_1-direction, and the ten-point second-order finite difference scheme in the ξ_2-direction. (Numerical tests have been conducted to ensure resolution independence of the solutions in the physical domain.) The resulting mean and standard deviation of the solution are shown in Figure 4.8. Note that in the construction of the inner boundary, the dominating mode ($n = 1$) in the Fourier expansion (4.9) has a period of 2π (the $\sin\theta$ and $\cos\theta$ modes). This results in the two local extrema in the standard deviation field.

These numerical solutions are compared with those obtained from MCS. Figure 4.9 compares the STD profiles obtained with both methods along the radius of $R \approx 1.21$. Due to the smallness of the random input ($\sigma = 0.02$), both MCS and the SG method converge quickly. In fact, the solutions (mean and STD) obtained with the first- and second-order Legendre-chaos expansions almost completely coincide. Also, we observe the convergence of the Monte Carlo method as the number of realizations increases. This example has 16 dimensions in random space ($K = 16$). At first order ($p = 1$), the SG method needs $(K + p)!/K!p! = 17$ terms, and is more efficient than the Monte Carlo method.

5. Summary. We have proposed a computational framework for the computation of deterministic/stochastic differential equations defined on [illegible]. A key component of the proposed approach is the use of stochastic mappings to transform the original problem into a (better understood) problem of stochastic equations in [illegible]. While a variety of such stochastic mappings can be designed, here we have implemented a mapping defined by solutions of the Laplace equations. We have used numerical examples involving single-connected and double-connected random domains to demonstrate the versatility of the mapping technique.

This random mapping enables us to apply the existing analytical/numerical methods for the resulting transformed stochastic equations in fixed domains. In random spaces, we have presented methods based on Monte Carlo simulations and stochastic Galerkin methods, although we emphasize that other suitable techniques can be used. In physical spaces, we have used a variety of discretizational methods, including the Chebyshev collocation method, Fourier collocation method, and finite difference method. We applied our approach to the elliptic problems in the single- and double-connected random domains, and examined the convergence and efficiency of MCS and SG methods.

Several issues need to be addressed:

- [illegible] There are several sources of errors, in addition to the discretizational errors in solving the transformed SBVP (2.4). In particular, the errors in solving the mapping problems (3.3) and their effect on the Jacobian evaluation (3.8) and the solution of SBVP (2.4) are important. Also, the accurate approximation of the random processes defining rough boundaries by a finite number of random variables in (3.1) and (3.2) plays a key role in the proposed approach. This by itself is an active research area. Furthermore, the effect of the representation errors on the overall accuracy of the present approach is unclear. For example, for an elliptic equation, a small error in the approximation of the shape of a Neumann boundary may be magnified in the final solution [1]. Hence a complete error analysis of the proposed method is required, in addition to the error analysis of the boundary representation.
- [illegible] We have assumed that the random boundary $\partial D(\omega)$ is sufficiently regular for the RDP (2.1) to be well-posed. For example, for the elliptic problems considered in section 4, the [illegible] regularity requirements on the boundary $\partial D(\omega)$ to guarantee the well-posedness, e.g., coercivity, of the transformed stochastic elliptic equation (4.2) is unclear. We thus have restricted ourselves to domains with random boundaries of low to moderate roughness in the numerical examples. The rigorous regularity requirements of the boundary are problem-specific and remain an open issue for a wide class of important problems.
- [illegible] In many cases, the transformed stochastic equations are expected to be more complicated than their original counterparts (compare, for example, (4.1) and (4.2)). However, such transformed equations need to be solved only in the region close to the random boundary. Figure 5.1 shows a schematic of the decomposition of the computational domain into a "boundary region" and a "far-field region," in which the transformed and original equations, respectively, are to be solved. These two equations are coupled through random boundary conditions on the interface between the two domains.

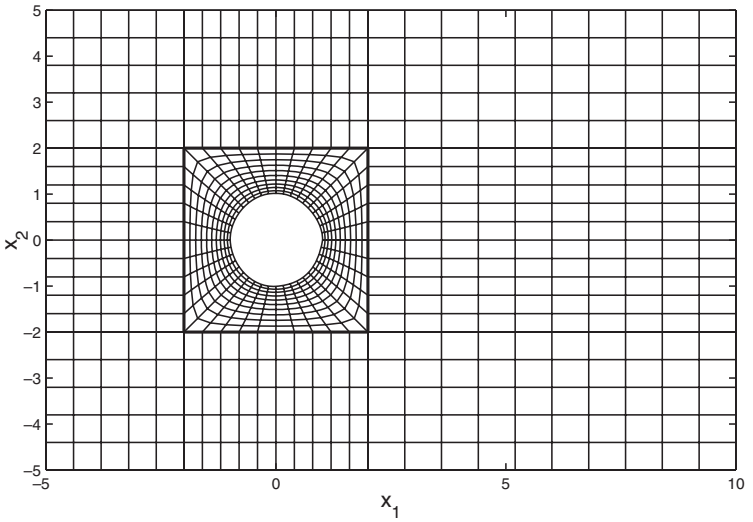

FIG. 5.1. *Schematic representation of a computational mesh for a double-connected domain with a random inclusion. The interface between the "boundary region" and "far-field region" is shown in bold.*

INTEGRATION PRECONDITIONING MATRIX FOR ULTRASPHERICAL PSEUDOSPECTRAL OPERATORS*

ELSAYED M. E. ELBARBARY†

Abstract. In this paper, we give an integration rectangular preconditioner for ultraspherical pseudospectral operators. We present an explicit solution of matrix equations with the structure provided by the pseudospectral discretization of the nth-order differential operator, subject to various types of boundary conditions. This occurs in two steps. In the first step we introduce an integration rectangular preconditioner. In the second step we use a new strategy to impose the boundary conditions, on the condition that the coefficients matrix has a known inverse. Computational examples are given.

Key words. ultraspherical polynomials, pseudospectral methods, differentiation matrix, integration matrix, pseudospectral preconditioner matrix

DOI. 10.1137/050630982

1. Introduction.

In recent decades, pseudospectral methods have proven efficient for obtaining accurate solutions to ordinary and partial differential equations. This leads to computations with full matrices that do not satisfy any good property. The pseudospectral discretization of the nth-order linear one dimensional differential equation, subject to appropriate boundary conditions, produces a badly conditioned linear system that is very difficult to solve. It is well known that the conditioning of the nth-order pseudospectral differentiation matrix scales at best as $O(N^{2n})$, where N is the order of the approximation [20]. The ill-conditioning of the pseudospectral matrices is particularly important since the associated algebraic systems are typically solved by iterative methods. Aspects of numerical stability and accuracy during the solution process for systems of linear equations arising from this method lead us to a modification of the solution path. It was already proposed in [9]: the prior integration of the differential equation. This is in contrast to the good condition number of the resulting linear equations.

The use of integration operators for the treatment of differential equations by orthogonal polynomials dates back to Clenshaw [3]. The integration form of differential equations was applied by Clenshaw and Curtis [4] in spectral space and by El-Gendi [8] in point space. El-Gendi [8] has argued, however, that it is better to directly compute the function values rather than the Chebyshev coefficients [24]. These methods do not extend to nonconstant coefficient problems, since we cannot determine the Green function analytically. Another alternative method, which does not require knowledge of the Green function, was suggested by Jeffreys and Jeffreys [21] and employed in [14, 15, 25, 26, 31] for similar purposes. This procedure is accomplished by starting with Chebyshev approximation for the highest-order derivative and generating approximations to the lower-order derivatives through integration of the highest-order derivative.

Pseudospectral methods have been developed by presenting suitable preconditioners. Previous works on preconditioners for pseudospectral operators resulted in the development of preconditioners based on a low-order approximation of the inverse operator. Orszag [27] suggested that one use a finite difference operator based on the collocation points as a preconditioner of the Chebyshev pseudospectral discretization of the Poisson equation. For the first-order problems, the corresponding strategy of using finite difference operators does not lead to analogous satisfactory results [10]. Some other preconditioners have been proposed and successfully tested in [2, 6, 7, 10, 22, 23, 28, 29].

Recent works using the integration preconditioning idea [5, 18] follow a different approach. Hesthaven [18] applies the boundary conditions by a penalty method, through appropriate adjusting coefficients in the spectral integrator, while Coutsias, Hagstrom, and Torres [5] choose a definite integral that introduces the first k expansion coefficients as arbitrary parameters, which are chosen to satisfy the boundary conditions after the equation has been integrated for the higher coefficients.

Recently, Ghoreishi and Hosseini [13] presented a pseudospectral preconditioner on arbitrary grids closely related to the idea of Hesthaven [18].

The aim of this paper is to present the optimal preconditioner (exact inverse) of the nth-order one dimensional differential operators, subject to various types of boundary conditions. This takes place in two steps. First, we introduce an integration rectangular preconditioner related to the idea of Hesthaven [18]. Second, we use a new strategy to impose the boundary conditions, on the condition that the coefficients matrix has a known inverse.

The remaining part of this paper is organized as follows. In section 2, we introduce the spectral and pseudospectral differentiation matrices based on ultraspherical polynomials and discuss the properties of ultraspherical polynomials. Here, we focus on the new property that results, a relation between the ultraspherical polynomials and their derivatives, which is used to define the nth-order integration operator. We also continue by briefly revising the Hesthaven work [18]. In section 3, we use the spectral integration matrix and its inverse (spectral differentiation matrix) in a restricted domain to define the well-known pseudospectral differentiation matrix. We will define rectangular pseudospectral preconditioners based on the spectral integration matrix in a restricted domain. Section 4 addresses the performance of the rectangular pseudospectral preconditioner for the advective operator. We suggest a new strategy to impose the boundary conditions to obtain an optimal preconditioner (exact inverse). In section 5, we present a similar analysis for the diffusion operator, subject to Dirichlet as well as Robin boundary conditions. Also, a similar treatment for the Helmholtz equation is presented in section 6. Numerical computations have been done on the Helmholtz equation and singular perturbation problem in section 7. Section 8 contains the conclusion of this paper.

2. Pseudospectral preconditioner matrix. We assume that $\{C_n^{(\lambda)}(x)\}_{n=0}^{\infty}$ is a family of ultraspherical polynomials in the finite domain $x \in [-1, 1]$, with the first two being

$$C_0^{(\lambda)}(x) = 1, \qquad C_1^{(\lambda)}(x) = (2\lambda + 1)x,$$

while the remaining polynomials are given through the recursion formula [1, 18, 30]

$$(2n + 2\lambda + 1)xC_n^{(\lambda)}(x) = (n + 1)C_{n+1}^{(\lambda)}(x) + (n + 2\lambda)C_{n-1}^{(\lambda)}(x).$$

If $u(x) \in C^{\infty}[-1,1]$, then we will write

$$u_N(x) = \sum_{k=0}^{N} \hat{u}_k^{(0)} C_k^{(\lambda)}(x),$$

where $\hat{u}_k^{(0)}$ represents the continuous expansion coefficients. Utilizing the orthogonality of the orthogonal polynomials in $L_w^2[-1,1]$ with weight function $w(x) = (1-x^2)^{\lambda}$, we have

$$\hat{u}_k^{(0)} = \frac{1}{\gamma_k^*} \int_{-1}^{1} u(x) C_k^{(\lambda)}(x) w(x) dx,$$

where the continuous normalization factor, γ_k^*, is defined as [18]

$$\gamma_k^* = 2^{2\lambda+1} \frac{\Gamma^2(\lambda+1)\Gamma(k+2\lambda+1)}{k!(2k+2\lambda+1)\Gamma^2(2\lambda+1)}, \quad k = 0,1,2,\ldots,N.$$

The ith derivative of $u(x)$ is approximated by series expansion in the form

$$u_N^{(i)}(x) = \sum_{k=0}^{N} \hat{u}_k^{(i)} C_k^{(\lambda)}(x),$$

and the ith order spectral differentiation matrix $D_s^{(i)}$ is introduced, providing that

$$\hat{\mathbf{u}}^{(i)} = D_s^{(i)} \hat{\mathbf{u}}^{(0)},$$

where $\hat{\mathbf{u}}^{(i)} = (\hat{u}_0^{(i)}, \hat{u}_1^{(i)}, \ldots, \hat{u}_N^{(i)})^T$.

The discrete expansion of $u(x)$ is given by [18],

$$u_N(x) = \sum_{k=0}^{N} \tilde{u}_k C_k^{(\lambda)}(x),$$

where

$$\tilde{u}_k = \frac{1}{\gamma_k} \sum_{i=0}^{N} \omega_i \; u(x_i) C_k^{(\lambda)}(x_i), \quad n = 0,1,\ldots,N. \tag{2.1}$$

The grid points (Gauss–Lobatto points) are ordered as

$$-1 = x_0 < x_1 < \cdots < x_{N-1} < x_N = 1,$$

where

$$\{x_i\}_{i=0}^{N} = \left\{ x \in [-1,1] \mid (1-x^2) \frac{dC_N^{(\lambda)}(x)}{dx} = 0 \right\}.$$

The discrete normalization factor, $\gamma_k = \gamma_k^*$, $k = 0,1,\ldots,N-1$, while

$$\gamma_N = 2^{2\lambda+1} \frac{\Gamma^2(\lambda+1)\Gamma(N+2\lambda+1)}{NN!\Gamma^2(2\lambda+1)}.$$

The Gauss–Lobatto weights, ω_i, are given through the following formula:

$$\omega_i = \begin{cases} 2^{2\lambda+1}\frac{(N-1)!\Gamma(\lambda+1)\Gamma(\lambda+2)}{\Gamma(N+2\lambda+2)}, & i=0,N, \\ -2^{2\lambda+1}\frac{\Gamma^2(\lambda+1)\Gamma(N+2\lambda+1)}{N!(N+2\lambda+1)\Gamma^2(2\lambda+1)}\left[C_N^{(\lambda)}(x_i)\frac{d}{dx}C_{N-1}^{(\lambda)}(x_i)\right]^{-1}, & i=1,2,\ldots,N-1. \end{cases}$$

Thus $u_N(x_i) = u(x_i)$, $i = 0, 1, \ldots, N$; in other words, the discrete projection is exact at the points $\{x_i\}_{i=0}^N$.

The kth-order pseudospectral differentiation matrix $D_p^{(k)}$ is introduced on the condition that

$$\mathbf{u}^{(k)} = D_p^{(k)}\mathbf{u}^{(0)},$$

where

$$\mathbf{u}^{(k)} = (u^{(k)}(x_0), u^{(k)}(x_1), \ldots, u^{(k)}(x_N))^T,$$

and the entries of the pseudospectral differentiation matrix, $D_p^{(k)}$, are given by

$$D_{ij}^{(k)} = \omega_j \sum_{n=k}^{N} \frac{1}{\gamma_n} C_n^{(\lambda)}(x_j)\frac{d^k}{dx^k}C_n^{(\lambda)}(x_i).$$

It is well known that $D_p^{(k)}$ is a centro-antisymmetric full matrix with a condition number proportional to N^{2k} [10].

The following theorem has fundamental importance in developing the integration operator. It gives a relation between the ultraspherical polynomials and their derivatives.

THEOREM 2.1. [illegible]

$$C_n^{(\lambda)}(x) = \sum_{m=0}^{k} \eta_{k,m,n}\frac{d^k}{dx^k}C_{n+k-2m}^{(\lambda)}(x), \qquad n > k,$$

[illegible]

$$\eta_{k,m,n} = \frac{(-1)^m\binom{k}{m}}{\prod_{\ell\neq m}^{k_{\ell=0}}(2k+2n+2\lambda-2\ell-2m+1)}.$$

As special cases, we have the following:

(1) $k = 1$,

$$C_n^{(\lambda)}(x) = \frac{\frac{d}{dx}C_{n+1}^{(\lambda)}(x)}{(2n+2\lambda+1)} - \frac{\frac{d}{dx}C_{n-1}^{(\lambda)}(x)}{(2n+2\lambda+1)}, \qquad n > 1; \tag{2.2}$$

(2) $k = 2$,

$$C_n^{(\lambda)}(x) = \frac{\frac{d^2}{dx^2}C_{n+2}^{(\lambda)}(x)}{(2n+2\lambda+1)(2n+2\lambda+3)} - \frac{2\frac{d^2}{dx^2}C_n^{(\lambda)}(x)}{(2n+2\lambda+3)(2n+2\lambda-1)}$$
$$+ \frac{\frac{d^2}{dx^2}C_{n-2}^{(\lambda)}(x)}{(2n+2\lambda+1)(2n+2\lambda-1)}, \qquad n > 2; \tag{2.3}$$

(3) $k = 3$,

$$\begin{aligned} C_n^{(\lambda)}(x) &= \frac{\frac{d^3}{dx^3}C_{n+3}^{(\lambda)}(x)}{(2n+2\lambda+1)(2n+2\lambda+3)(2n+2\lambda+5)} \\ &\quad - \frac{3\frac{d^3}{dx^3}C_{n+1}^{(\lambda)}(x)}{(2n+2\lambda+1)(2n+2\lambda+5)(2n+2\lambda-1)} \\ &\quad + \frac{3\frac{d^3}{dx^3}C_{n-1}^{(\lambda)}(x)}{(2n+2\lambda+1)(2n+2\lambda+3)(2n+2\lambda-3)} \\ &\quad - \frac{\frac{d^3}{dx^3}C_{n-3}^{(\lambda)}(x)}{(2n+2\lambda+1)(2n+2\lambda-1)(2n+2\lambda-3)}, \qquad n > 3. \end{aligned} \tag{2.4}$$

The recursions (2.2) and (2.3) are well-known recurrence formulas. Recurrence relations for higher-order derivatives may likewise be obtained by repeatedly combining the relations (2.2)–(2.3). The proof of this theorem can be easily seen by induction.

We now introduce the row vectors

$$\mathbf{C} = [C_0^{(\lambda)}(x), C_1^{(\lambda)}(x), \ldots, C_N^{(\lambda)}(x)]$$

and

$$\mathbf{C}_x = \left[\frac{d}{dx}C_0^{(\lambda)}(x), \frac{d}{dx}C_1^{(\lambda)}(x), \ldots, \frac{d}{dx}C_N^{(\lambda)}(x)\right].$$

Hesthaven [18] observed that the two row vectors $\mathbf{C}$ and $\mathbf{C}_x$ are related through the integral operator $B_{[1]}^{(-1)}$, as

$$\mathbf{C} = \mathbf{C}_x B_{[1]}^{(-1)}. \tag{2.5}$$

The notation $B_{[k]}$ denotes a matrix with its first k rows set to zero. The elements of the matrix $B_{[1]}^{(-1)}$ can be determined from the recursion relations (2.2). Consider that $\frac{d}{dx}C_0^{(\lambda)}(x) = 0$, so the first row of integral operator $B_{[1]}^{(-1)}$ can set to zero.

We note that, in the case of finite order expansion, (2.5) is correct except for the last elements in $\mathbf{C}$. For example, in the case of $N = 4$,

$$\mathbf{C} - \mathbf{C}_x B_{[1]}^{(-1)} = \left(0, 0, 0, 0, -\frac{5}{24} + \frac{35}{12}x^2 - \frac{35}{8}x^4\right).$$

Thus it happens that, in the more general case, the last k elements in $\mathbf{C}$ are not correct for the kth derivative. Also, we note that the matrix $B_{[1]}^{(-1)}$ is singular.

Let us introduce the spaces Q_m^n by

$$Q_m^n = \operatorname{span}\{C_k^{(\lambda)}(x) \mid m \le k \le n\}.$$

Hence, in the absence of the first row and last column of the matrix $B_{[1]}^{(-1)}$, the matrix $B_{[1]}^{(-1)}$ will be reduced to $B^{(-1)}$. The matrix $B^{(1)}$ is a uniquely defined inverse of the integration matrix $B^{(-1)}$ in the following restricted domain:

$$B^{(1)} : Q_1^N \longrightarrow Q_0^{N-1} \quad \text{and} \quad B^{(-1)} : Q_0^{N-1} \longrightarrow Q_1^N.$$

The spectral differentiation matrix $D_s^{(1)}$ is determined from $B^{(1)}$ by adding the first column and the last row, which must be identically zero.

Introducing the vectors

$$\mathbf{u} = (u(-1), u(x_1), \ldots, u(x_{N-1}), u(1))^T \quad \text{and} \quad \tilde{\mathbf{u}} = (\tilde{u}_0, \tilde{u}_1, \ldots, \tilde{u}_N)^T,$$

we see that the two vectors $\mathbf{u}$ and $\tilde{\mathbf{u}}$ are related through the similarity transformations [18]

$$\mathbf{u} = T^{-1}\tilde{\mathbf{u}}, \qquad \tilde{\mathbf{u}} = T\mathbf{u},$$

where the entries of the $(N+1) \times (N+1)$ orthogonal matrices, T^{-1} and T, are given as

$$T_{ij}^{-1} = C_j^{(\lambda)}(x_i), \qquad T_{ij} = \frac{\omega_j}{\gamma_i} C_i^{(\lambda)}(x_j), \qquad i, j = 0, 1, \ldots, N.$$

We observe that

$$(T^{-1}T)_{ij} = \omega_j \sum_{n=0}^{N} \frac{1}{\gamma_n} C_n^{(\lambda)}(x_i) C_n^{(\lambda)}(x_j) = \delta_{i,j}, \tag{2.6}$$

implying that

$$T^{-1}T = I,$$

where $\delta_{i,j}$ is the Kronecker symbol. Hesthaven [18] used the spectral differentiation matrix $D_s^{(1)}$ to define the pseudospectral differentiation matrix $D_p^{(1)}$ as follows:

$$D_p^{(1)} = T^{-1} D_s^{(1)} T.$$

Likewise, Hesthaven [18] made an analogous analysis for the higher derivatives.

He presented singular integration preconditioners of the first- and second-order pseudospectral differentiation matrices as

$$P^{(-1)} = T^{(-1)} B_{[1]}^{(-1)} T, \qquad P^{(-2)} = T^{(-1)} B_{[2]}^{(-2)} T,$$

and he has developed his preconditioners by overcoming the singularity problem by defining modified spectral integration matrices $\tilde{\mathrm{B}}_{[1]}^{(-1)}$ and $\tilde{\mathrm{B}}_{[2]}^{(-2)}$. For the first-order differentiation matrix he has replaced the last element in the first row by a certain parameter. For the second-order differentiation matrix, he has replaced the last two elements of the first and second rows by a certain four parameters. These parameters can be determined, providing that the matrices $\tilde{\mathrm{B}}_{[1]}^{(-1)}$ and $\tilde{\mathrm{B}}_{[2]}^{(-2)}$ are nonsingular, by properly choosing the parameters, a choice that allows for optimizing the preconditioner.

In the next section, we consider an alternative procedure to identify a rectangular preconditioner matrix for an nth-order linear differential operator.

3. Rectangular pseudospectral preconditioner matrix. Imposing the boundary conditions strongly would alter the appropriate rows and columns in the differentiation matrix. The delicate symmetries of the differentiation matrix are ruined, and the construction of the inverse is no longer clear. Funaro and Gottlieb [11] introduced a penalty method which enforced the boundary condition only weakly through

a boundary correction rather than modifying the coefficient matrix. Such a penalty method has been studied for the collocation formulation with preconditioning [11]. Further details on the penalty method can be found in, e.g., [12, 16, 17, 19, 20]. Now, let us consider the construction of a preconditioner in two steps. The first step is done in absence of the boundary conditions, and the obtained coefficients matrix is a rectangular matrix. In the second step, the enforcing of the boundary conditions is done by adding auxiliary equations, on the condition that the coefficients matrix becomes a square matrix and its inverse is known.

We next introduce the row vectors

$$\mathbf{C}^{(0)}_{0,N-k} = [C^{(\lambda)}_0(x), C^{(\lambda)}_1(x), \ldots, C^{(\lambda)}_{N-k}(x)]$$

and

$$\mathbf{C}^{(k)}_{k,N} = \left[\frac{d^k}{dx^k}C^{(\lambda)}_k(x), \frac{d^k}{dx^k}C^{(\lambda)}_{k+1}(x), \ldots, \frac{d^k}{dx^k}C^{(\lambda)}_N(x)\right],$$

The row vectors $\mathbf{C}^{(0)}_{0,N-k}, \mathbf{C}^{(k)}_{k,N}$ are related through the integration matrix $B^{(-k)}$ as follows:

$$\mathbf{C}^{(0)}_{0,N-k} = \mathbf{C}^{(k)}_{k,N} B^{(-k)},$$

where

$$B^{(-k)} = [b^k_{ij}], \quad i,j = 0,1,2,\ldots,N-k,$$

$$b^k_{ij} = \begin{cases} \eta_{k,\alpha,j}, & j = i+2\alpha,\ \alpha = 0,1,\ldots,k, \\ 0 & \text{otherwise.} \end{cases}$$

As special cases, we have the following:

(1) $k = 1$,

$$B^{(-1)} = [b^1_{ij}], \quad i,j = 0,1,2,\ldots,N-1,$$

$$b^1_{ij} = \begin{cases} \frac{-1}{(2j+2\lambda+1)}, & j = i+2, \\ \frac{1}{(2j+2\lambda+1)}, & j = i, \\ 0 & \text{otherwise.} \end{cases}$$

(2) $k = 2$,

$$B^{(-2)} = [b^2_{ij}], \quad i,j = 0,1,2,\ldots,N-2,$$

$$b^2_{ij} = \begin{cases} \frac{1}{(2j+2\lambda+1)(2j+2\lambda-1)}, & j = i+4, \\ \frac{-2}{(2j+2\lambda+3)(2j+2\lambda-1)}, & j = i+2, \\ \frac{1}{(2j+2\lambda+1)(2j+2\lambda+3)}, & j = i, \\ 0 & \text{otherwise.} \end{cases}$$

The eigenvalues of the matrix $B^{(-k)}$ are given by

$$\mu_i = \eta_{k,0,i}, \qquad i = 0,1,\ldots,N-k,$$

and the eigenvalues of the matrix $B^{(k)}$ are $\frac{1}{\mu_i}$, $i = 0, 1, \ldots, N-k$.

Define the following rectangular matrices:

$$E_k = [e_{ij}], \quad e_{ij} = \frac{\omega_j}{\gamma_i} C_i^{(\lambda)}(x_j), \quad i = 0, 1, 2, \ldots, N-k, \quad j = 0, 1, 2 \ldots, N,$$
$$H_k = [h_{ij}], \quad h_{ij} = C_j^{(\lambda)}(x_i), \quad i = 0, 1, 2, \ldots, N, \quad j = k, k+1, \ldots, N,$$
$$R^{(k)} = [r_{ij}^{(k)}], \quad r_{ij}^{(k)} = \frac{d^k}{dx^k} C_j^{(\lambda)}(x_i), \quad i = 0, 1, 2, \ldots, N, \quad j = k, k+1, \ldots, N,$$
$$S_k = [s_{ij}], \quad s_{ij} = \frac{\omega_j}{\gamma_i} C_i^{(\lambda)}(x_j), \quad i = k, k+1, \ldots, N, \quad j = 0, 1, 2 \ldots, N,$$
$$V_k = [v_{ij}], \quad v_{ij} = C_j^{(\lambda)}(x_i), \quad i = 0, 1, 2, \ldots, N, \quad j = 0, 1, 2, \ldots, N-k.$$

It is easy to verify the relations

$$D_p^{(k)} = R^{(k)} S_k,$$
$$V_k = R^{(k)} B^{(-k)},$$
$$R^{(k)} = V_k B^{(k)},$$
$$S_k H_k = I, \text{ while } H_k S_k \neq I,$$

which can be used to compute the pseudospectral differentiation matrix as follows:

$$D_p^{(k)} = V_k B^{(k)} S_k. \tag{3.1}$$

In view of the equation

$$E_k V_k = I, \quad \text{while } V_k E_k \neq I, \tag{3.2}$$

we introduce the rectangular $(N-k+1) \times (N+1)$ matrix

$$P^{(-k)} = B^{(-k)} E_k,$$

which represents the suggested rectangular integration preconditioner. Using $P^{(-k)}$ and (3.1) and (3.2), we will get

$$P^{(-k)} D_p^{(k)} = S_k.$$

The matrix S_k is a rectangular $(N-k+1) \times (N+1)$ matrix. Namely, the use of this rectangular preconditioner in the pseudospectral discretization makes the number of equations plus the number of boundary conditions equal the number of unknowns. Therefore, we do not delete equations corresponding to the boundary conditions. We note that the matrix S_k is a part of matrix T. Then by adding the first k rows of the matrix T to the matrix S_k, become identically. So, we will add k auxiliary equations as

$$\sum_{n=0}^{N} \frac{\omega_n}{\gamma_i} C_i^{(\lambda)}(x_n) u(x_n) = \beta_i, \qquad i = 1, 2, \ldots, k,$$

where β_i are parameters to be determined from the boundary conditions.

In view of (2.1), we see that the parameters β_i, $i = 1, 2, \ldots, k$, are exactly the coefficients of the k lowest modes in the expansion of the solution.

According to what we mentioned above, the matrix S_k becomes T, which has an inverse T^{-1}. We then provide the explicit solution to the system of algebraic equations that arise from the pseudospectral discretization.

In the next sections, we will apply the previous idea upon the advective and diffusive operators, subject to various types of boundary conditions.

4. Preconditioning of the advective operator. Let us consider the first-order problem

$$\frac{du(x)}{dx} = f(x), \qquad u(1) = u_0.$$

We seek a polynomial solution for using the discrete approximation

$$D_p^{(1)}\mathbf{u} = \mathbf{f}, \qquad u(x_0) = u_0.$$

Here $\mathbf{u}$ and $\mathbf{f}$ refer to the grid vectors of the two functions $u(x)$ and $f(x)$ at the Gauss–Lobatto collocation points associated with the polynomial basis $C_n^{(\lambda)}(x)$. Since the condition number of $D_p^{(1)}$ is proportional to N^2, this may be nontrivial for N large. Now we will keep the structure of $D_p^{(1)}$, use the rectangular preconditioners, and delay the use of the boundary conditions for a next step.

To proceed, we apply the rectangular preconditioner $P^{(-1)}$, as

$$S_1\ \mathbf{u} = B^{(-1)}E_1\ \mathbf{f} = P^{(-1)}\mathbf{f}. \tag{4.1}$$

Equation (4.1) consists of N equations in $(N+1)$ unknowns (in the absence of the boundary conditions).

By adding auxiliary equation

$$\sum_{n=0}^{N} \frac{\omega_n}{\gamma_0} C_0^{(\lambda)}(x_n)u(x_n) = \beta_1,$$

the matrices S_1 and T became identical.

From this one can write

$$\mathbf{u} = T^{-1}\begin{pmatrix} \beta_1 \\ P^{(-1)}\mathbf{f} \end{pmatrix}. \tag{4.2}$$

The value of parameter β_1 can be determined from the boundary condition as

$$\beta_1 = u(x_0) - \sum_{j=1}^{N} p_j^{(-1)} C_j^{(\lambda)}(x_0),$$

where $p_j^{(-1)}$, $j = 1, 2, \ldots, N$, are the elements of the vector $P^{(-1)}\mathbf{f}$. Therefore, we could obtain $\mathbf{u}$ directly from (4.2).

5. Preconditioning of the diffusive operator. In the next two subsections we shall show how the specification of boundary conditions allows us to determine the values of the added parameters.

5.1. Dirichlet boundary conditions. Let us consider the homogeneous elliptic problem

$$\frac{d^2u(x)}{dx^2} = f(x), \quad u(1) = u_0, \quad u(-1) = u_N, \tag{5.1}$$

and seek solutions of polynomial form leading to a discrete form of (5.1) as

$$D_p^{(2)}\mathbf{u} = \mathbf{f}, \quad u(x_0) = u_0, \quad u(x_N) = u_N,$$

where $\mathbf{u}$ and $\mathbf{f}$ refer to the vectors of $u(x)$ and $f(x)$ at the Gauss–Lobatto points. Following the development of the rectangular preconditioner for the advection operator, we apply the preconditioner $P^{(-2)}$ as

$$S_2\mathbf{u} = B^{(-2)}E_2\mathbf{f} = P^{(-2)}\mathbf{f}. \tag{5.2}$$

This equation consists of $N-1$ equations in $(N+1)$ unknowns (without boundary conditions).

By adding auxiliary equations

$$\sum_{n=0}^{N} \frac{\omega_n}{\gamma_0} C_0^{(\lambda)}(x_n)u(x_n) = \beta_1 \tag{5.3}$$

and

$$\sum_{n=0}^{N} \frac{\omega_n}{\gamma_1} C_1^{(\lambda)}(x_n)u(x_n) = \beta_2, \tag{5.4}$$

the matrices S_2 and T became identical. Therefore,

$$\mathbf{u} = T^{-1}\begin{pmatrix} \beta_1 \\ \beta_2 \\ P^{(-2)}\mathbf{f} \end{pmatrix}.$$

In other words,

$$u_k = \beta_1 + \beta_2 C_1^{(\lambda)}(x_k) + \varphi(x_k), \quad k = 0, 1, \ldots, N, \tag{5.5}$$

where $\varphi(x) = \sum_{j=2}^{N} p_j^{(-2)} C_j^{(\lambda)}(x)$, and $p_j^{(-2)}$, $j = 2, 3, \ldots, N$, are the elements of the vector $P^{(-2)}\mathbf{f}$.

The values of parameters β_1 and β_2 are determined from the boundary conditions as

$$\beta_1 = \frac{1}{2}(u(x_0) + u(x_N) - \varphi(x_0) - \varphi(x_N)),$$

$$\beta_2 = \frac{1}{2(2\lambda+1)}(u(x_0) - u(x_N) - \varphi(x_0) + \varphi(x_N)).$$

Therefore, we could obtain $\mathbf{u}$ directly from (5.5).

5.2. Robin boundary conditions. Consider the Poisson problem

$$\frac{d^2u(x)}{dx^2} = f(x),$$

subject to Robin boundary conditions

$$\gamma_0 u_x(1) + \gamma_1 u(1) = \gamma_2, \qquad \delta_0 u_x(-1) + \delta_1 u(-1) = \delta_2. \tag{5.6}$$

The analysis for the Robin problem follows the same route described for the Dirichlet problem until (5.5). When we apply the boundary conditions (5.6) in (5.5), the parameters β_1 and β_2 are determined as follows:

$$\beta_2 = \frac{\gamma_2\delta_1 - \gamma_1\delta_2 - \gamma_1\delta_1\varphi(x_0) - \gamma_0\delta_1\varphi'(x_0) + \gamma_1\delta_0\varphi'(x_N) + \gamma_1\delta_1\varphi(x_N)}{(2\lambda+1)(-\gamma_1\delta_0 + \gamma_0\delta_1 + \gamma_1\delta_1 + \gamma_1\delta_1)},$$

$$\beta_1 = \frac{\gamma_2 - \gamma_1\varphi(x_0) - \gamma_0\varphi'(x_0)}{\gamma_1} - \beta_2\frac{(2\lambda+1)(\gamma_0+\gamma_1)}{\gamma_1}.$$

We note that in the case of Neumann boundary conditions, $\gamma_1 = \delta_1 = 0$, the parameters are undetermined. Thus, the Neumann problems remain open, and we will stop at (5.2) to solve the resulting algebraic equations and the boundary conditions equations, while the Robin problems are solved on the condition that $\gamma_1 \neq 0$.

6. Preconditioning of the Helmholtz equation. In this section, we are interested in using the pseudospectral method with integration preconditioning to solve the Helmholtz equation

$$\alpha u(x) - u''(x) = f(x), \qquad u(1) = u_0, u(-1) = u_N, \tag{6.1}$$

and seek solutions of polynomial form leading to a discrete form of (6.1) as

$$\alpha \mathbf{u} - D_p^{(2)} \mathbf{u} = \mathbf{f}, \qquad u(x_0) = u_0, u(x_N) = u_N.$$

We apply the preconditioner $P^{(-2)}$ as

$$\alpha P^{(-2)} \mathbf{u} - S_2 \mathbf{u} = P^{(-2)} \mathbf{f}.$$

By adding the auxiliary equations (5.3) and (5.4), we will get

$$\alpha \begin{pmatrix} \mathbf{0} \\ \mathbf{0} \\ P^{(-2)} \end{pmatrix} \mathbf{u} - T\mathbf{u} = \begin{pmatrix} 0 \\ 0 \\ P^{(-2)} \mathbf{f} \end{pmatrix} - \begin{pmatrix} \beta_1 \\ \beta_2 \\ 0 \\ \vdots \\ 0 \end{pmatrix}.$$

Hence,

$$\tilde{\mathrm{A}} \mathbf{u} = \left(\alpha T^{-1} \begin{pmatrix} \mathbf{0} \\ \mathbf{0} \\ P^{(-2)} \end{pmatrix} - I \right) \mathbf{u} = T^{-1} \begin{pmatrix} 0 \\ 0 \\ P^{(-2)} \mathbf{f} \end{pmatrix} - \begin{pmatrix} \beta_1 + \beta_2 C_1^{(\lambda)}(x_0) \\ \beta_1 + \beta_2 C_1^{(\lambda)}(x_1) \\ \beta_1 + \beta_2 C_1^{(\lambda)}(x_2) \\ \vdots \\ \beta_1 + \beta_2 C_1^{(\lambda)}(x_N) \end{pmatrix}. \tag{6.2}$$

The elements of the coefficient matrix $\tilde{\mathrm{A}}$ are given by

$$a_{i,j} = \sum_{l=2}^{N} \alpha C_l^{(\lambda)}(x_i) \sum_{k=0}^{N-2} b_{l-2,k}^2 \frac{\omega_j}{\gamma_k} C_k^{(\lambda)}(x_j) - \delta_{i,j}, \qquad i, j = 0, 1, \ldots, N.$$

The unknowns in (6.2) are given by $\beta_1, \beta_2, u(x_1), u(x_2), \ldots, u(x_{N-1})$. Then we get

$$A\mathbf{v} = T^{-1} \begin{pmatrix} 0 \\ 0 \\ P^{(-2)} \mathbf{f} \end{pmatrix} - \begin{pmatrix} a_{0,0} u_0 + a_{0,N} u_N \\ a_{1,0} u_0 + a_{1,N} u_N \\ a_{2,0} u_0 + a_{2,N} u_N \\ \vdots \\ a_{N,0} u_0 + a_{N,N} u_N \end{pmatrix}, \tag{6.3}$$

where $\mathbf{v} = (\beta_1, u(x_1), u(x_2), \ldots, u(x_{N-1}), \beta_2)^T$ and

$$A = \begin{pmatrix} 1 & a_{0,1} & a_{0,2} & \cdots & a_{0,N-1} & C_1^{(\lambda)}(x_0) \\ 1 & a_{1,1} & a_{1,2} & \cdots & a_{1,N-1} & C_1^{(\lambda)}(x_1) \\ 1 & a_{2,1} & a_{2,2} & \cdots & a_{2,N-1} & C_1^{(\lambda)}(x_2) \\ \vdots & \vdots & \vdots & \ddots & \vdots & \vdots \\ 1 & a_{N,1} & N_{0,2} & \cdots & a_{N,N-1} & C_1^{(\lambda)}(x_N) \end{pmatrix}.$$

Hence, we get the solution by solving the system of equations in (6.3).

7. Numerical results. In this section, we present two numerical examples using the integration preconditioning pseudospectral Chebyshev ($PChP$) (Legendre (PLP)) method. The numerical results will be compared with those obtained by the standard pseudospectral Chebyshev (ChP) (Legendre (LP)) method. The following tables contain a "condition number," which can be estimated as follows:

$$Cond(A) = \sqrt{\frac{\text{Maximum eigenvalue of } (AA^T)}{\text{Minimum eigenvalue of } (AA^T)}}.$$

Calculations were performed on a PC running MATHEMATICA software.

7.1. Our first example is the Helmholtz equation

$$u(x) - u''(x) = -\frac{x+1}{2}, \qquad u(\pm 1) = 0, \tag{7.1}$$

with the exact solution

$$u(x) = \frac{\sinh(x+1)}{\sinh(2)} - \frac{x+1}{2}.$$

In the case of $\alpha = 1$, $u_0 = u_N = 0$, and $f(x) = -\frac{x+1}{2}$, we solve the system of equations (6.3). The numerical results are compared with those obtained by the classical pseudospectral method in Table 1.

TABLE 1
Numerical results for the Chebyshev basis.

	ChP		$PChP$	
N	Condition number	Maximal error	Condition number of the matrix A	Maximal error
16	9.40×10^{02}	3.05×10^{-16}	10.39	1.80×10^{-16}
32	1.48×10^{04}	1.39×10^{-16}	19.83	2.53×10^{-16}
64	2.35×10^{05}	1.79×10^{-16}	38.63	2.64×10^{-16}
128	3.76×10^{06}	1.37×10^{-16}	76.20	2.97×10^{-16}
256	6.01×10^{07}	4.62×10^{-14}	151.31	5.27×10^{-16}
512	9.62×10^{08}	7.10×10^{-13}	301.54	4.99×10^{-16}
1024	1.54×10^{10}	3.22×10^{-12}	601.98	1.08×10^{-15}

7.2. Our second example has variable coefficients, and the solution develops two boundary layers of width $O(\epsilon)$ near $x = \pm 1$. The equation is

$$\epsilon u''(x) - xu'(x) - u(x) = 0, \quad u(\pm 1) = 1, \tag{7.2}$$

and the exact solution is $u(x) = e^{\frac{x^2-1}{2\epsilon}}$.

Applying the preconditioner $P^{(-2)}$ to (7.2) and adding the auxiliary equations (5.3) and (5.4), we will get

$$\left(\epsilon I - T^{-1}\begin{pmatrix}\mathbf{0}\\ \mathbf{0}\\ P^{(-2)}(FD_p^{(-1)}+I)\end{pmatrix}\right)\mathbf{u} = \begin{pmatrix}\beta_1+\beta_2 C_1^{(\lambda)}(x_0)\\ \beta_1+\beta_2 C_1^{(\lambda)}(x_1)\\ \beta_1+\beta_2 C_1^{(\lambda)}(x_2)\\ \vdots\\ \beta_1+\beta_2 C_1^{(\lambda)}(x_N)\end{pmatrix}, \tag{7.3}$$

where F is the diagonal matrix with diagonal elements x_i, $i = 0, 1, \ldots, N$.

Re-sort the unknowns in (7.3) by the form $\beta_1, u(x_1), u(x_2), \ldots, u(x_{N-1}), \beta_2$ to get a coefficient matrix similar to that obtained from (7.3) after replacing the first and last columns with corresponding columns in the matrix A.

Tables 2, 4, and 6 contain the results of our experiments for the Chebyshev basis and $\epsilon = 1$, $\epsilon = 10^{-1}$, and $\epsilon = 10^{-2}$, respectively. Tables 3, 5, and 7 contain the results for the Legendre basis and $\epsilon = 1$, $\epsilon = 10^{-1}$, and $\epsilon = 10^{-2}$, respectively.

8. Conclusion. The method discussed in this article is quite useful for deriving efficient algorithms for treatment of one dimensional boundary value problems. The present approach is a point space analogue of the spectral method in [5]. It chooses a definite integral that fixes the arbitrary constants of integration by bringing in the lowest modes through adjustable parameters. Namely, the additional parameters are exactly the coefficients of the k lowest modes in the expansion of the solution. The differentiation nullifies the lowest terms in the expansion, and the additional equations

introduced are simply the leading lines in the transform matrix which produces these coefficients. These parameters are finally set to satisfy the boundary conditions. The method is shown to work well on a test problem involving a stiff ordinary differential equation. The higher dimensional problems require further study in order to establish the usefulness of the pseudospectral integration preconditioners within a more general context.

LAGRANGIAN NUMERICAL APPROXIMATIONS TO ONE-DIMENSIONAL CONVOLUTION-DIFFUSION EQUATIONS*

LAURENT GOSSE† AND GIUSEPPE TOSCANI‡

Abstract. This work focuses on the numerical analysis of one-dimensional nonlinear diffusion equations involving a convolution product. First, homogeneous friction equations are considered. Algorithms follow recent ideas on mass transportation methods and lead to simple schemes which can be proved to be stable, to decrease entropy, and to converge toward the unique solution of the continuous problem. In particular, for the first time, homogeneous cooling states are displayed numerically. Further, we present results on the more delicate fourth-order thin-film equation for which a nonnegativity-preserving scheme is derived. The dead core phenomenon is presented for the Hele–Shaw cell.

Key words. granular flows, friction equations, Lagrangian approximation, Wasserstein metric, homogeneous cooling states, Hele–Shaw cell

1. Introduction. One objective for the present paper is to study some constructive approximations for one-dimensional (1D) dissipative Boltzmann equations modeling granular flows; they read as

$$\partial_t f + v\partial_x f = Q(f,f) + R, \qquad t,x,v \in \mathbb{R}_*^+ \times \mathbb{R} \times \mathbb{R},$$

for kinetic densities $f(t,x,v) \geq 0$. Here $Q(f,f)$ stands for the term modeling the inelastic collisions [1, 2, 27, 30], whereas R renders the effects of, e.g., external heating processes, such as Brownian agitation, which leads to a diffusion term; see [11] for a large survey on granular materials. First, it is customary now to decouple the transport and collision steps relying on a time-splitting technique (see, e.g., [28, 26, 18]); thus it makes sense to restrict ourselves to homogeneous densities $f(t,v)$. We shall therefore concentrate on the following Cauchy problem for $t,v \in \mathbb{R}_*^+ \times \mathbb{R}$:

$$\partial_t f(t,v) = \partial_v \left\{ f(t,v) \int_{\mathbb{R}} \mathcal{I}'(v-\omega) f(t,\omega).d\omega \right\} + \mu\partial_v(vf(t,v)) + \sigma\partial_{vv} f(t,v), \tag{1.1}$$

where $\mathcal{I}$ stands for an interaction potential. Generally, it is taken as $\mathcal{I}(\xi) = |\xi|^{\gamma+2}/\gamma + 2$, $\gamma \geq 0$. Equation (1.1) rewrites as a convolution Fokker–Planck equation:

$$\partial_t f = \partial_v \big\{ f\partial_v \big(f *_v \mathcal{I}(v) \big) + \sigma\partial_v f \big\} + \mu\partial_v(vf).$$

Several particular cases of (1.1) are of interest; the first one corresponds to setting $\sigma = \mu = 0$ and models dissipative flows of granular media. This model was proposed by McNamara and Young [27] and then studied from a mathematical viewpoint in

[1, 2, 7, 13, 14]. Roughly speaking, it describes a huge number of particles that undergo inelastic collisions (see [30, 26]) which lead to a monotonic decay of the temperature. Steady states display a very elementary structure, namely a Dirac mass concentrated onto the null velocity; however, a rescaling process allows us to derive a particular class of intermediate asymptotics called [illegible] [2, 24, 30]. These states have been singled out mainly because they are minimizers of a "free energy functional" (which is to be intensively used in section 3.1)

$$\mathcal{J}(f) := \int_{\mathbb{R}^2} f(v)f(w)\mathcal{I}(v-w).dv.dw - \int_{\mathbb{R}} f(v)v^2.dv, \tag{1.2}$$

among probability measures on $\mathbb{R}$. However, although stability could be hoped for, it has recently been shown that these states are too poor to play a role of similar importance as Barenblatt–Pattle source solutions for porous media equations; detailed proofs are available in [10]. It will be one of our objectives to display numerically such homogeneous cooling states in section 3.2; to the authors' knowledge, this has not been performed before.

Another objective is to develop on the numerical analysis of the so-called lubrication approximation of the Navier–Stokes equations for the movement of thin films driven by surface tension (see [25]); such a derivation leads to a fourth-order Cauchy problem,

$$\partial_t u + \partial_x(a(u)\partial_{xxx}u) = 0, \qquad u(t=0,.) = u_0 \geq 0, \quad t,x \in \mathbb{R}_*^+ \times \mathbb{R}. \tag{1.3}$$

The theory for this equation is still sparse (see [3, 4, 5, 6, 16]); especially, little is known about uniqueness of strong, i.e., $H^2(\mathbb{R})$ nonnegative, solutions. A special and somewhat more tractable case of (1.3) corresponds to $a(u) = u$ and is generally referred to as the Hele–Shaw cell: we shall focus on it in section 5, where certain ideas proposed in [29] will be expanded. Let us first explain why this problem can fall inside the class of "convolutive diffusion equations." Our main trick is to consider, for a small number $0 < \varepsilon \ll 1$, a smoothered equation,

$$\partial_t u^\varepsilon + \partial_x\big(a(u^\varepsilon)\partial_{xxx}u^\varepsilon *_x \Gamma_\varepsilon(x)\big) = \partial_t u^\varepsilon + \partial_x\big(a(u^\varepsilon)u^\varepsilon *_x \Gamma_\varepsilon'''(x)\big) = 0,$$

where Γ_ε is a standard Friedrichs mollifier. At this point, one can derive an approximate problem for (1.3) written in the convenient form for $t,x \in \mathbb{R}_*^+ \times \mathbb{R}$,

$$\partial_t u^\varepsilon + \partial_x\big(a(u^\varepsilon)\partial_x(u^\varepsilon *_x \Gamma_\varepsilon''(x))\big) = 0, \qquad u(t=0,.) = u_0 \geq 0. \tag{1.4}$$

However, even if we share some features with the aforementioned models of granular flows (especially for $a(u) = u$), a major difficulty arises from the fact that $-\Gamma_\varepsilon''$ will never be a convex function; it is nonetheless possible to obtain a numerical process able to preserve nonnegativity of solutions, a property commonly considered important in practice [34, 21].

Going a bit deeper into the contents of this work, we aim at showing that modern Wasserstein techniques can be successful at producing simple numerical schemes for (1.1) which are positivity-preserving, stable, and consistent with the continuous problem. Indeed, it has been shown in [15], and we shall briefly recall in section 2.1 how one can pass by means of a Lagrangian-type change of variables from (1.1) to the much more tractable equation holding for $t, \varrho \in \mathbb{R}_*^+ \times (0,1)$,

$$\partial_t V(t,\varrho) + \sigma\partial_\varrho\left(\frac{1}{\partial_\varrho V(t,\varrho)}\right) + \mu V(t,\varrho) + \int_0^1 \mathcal{I}'\big(V(t,\varrho) - V(t,\varrho')\big).d\varrho' = 0, \tag{1.5}$$

which reduces, in the case $\sigma = \mu = 0$, to some sort of integro-differential equation. This trick is reminiscent of a previous work [19] and allows us to circumvent the issues which are connected to numerical approximation of probability measures with finite differences; see [9, 17, 26] for more in this direction. One feature of paramount importance for (1.5) is the easiness in proving contractivity in any p-Wasserstein metric for various numerical approximations, just relying on the standard Jensen's inequality. It is also not difficult to convert such an estimate into a BV bound, thus showing compactness for a sequence of approximations for the V variable. Such a program is to be realized in sections 2.2–2.3. The BV framework (functions of bounded variation) corresponds exactly to measure solutions for (1.1), and hence provides a convenient approach to the problem. Section 4 is concerned with the modifications brought by the immersion of such granular media inside a thermal fluid. Following [12], we are most of all interested in classical solutions even if we shall keep on using numerical schemes based on the "reciprocal equation" (1.5). Convergence is shown in section 4.1, whereas the "tails" of the solutions for large $|v|$ (see [2, 7, 8, 9, 13]) are to be studied numerically in section 4.2. Section 5 is entirely devoted to the study of the Hele–Shaw cell's equation for which we can propose a nonnegativity-preserving scheme based on similar ideas. An energy estimate is given in section 5.2, and some numerical results are shown in section 5.3; an extension to mobilities $a(u) \neq u$ is briefly discussed in Remark 2 and in more detail in section 6. Finally, concluding remarks are given in section 7, and Appendices A and B contain the proofs of two important contraction estimates. Appendix C deals with some special features of the Fourier scheme (6.2) for (1.3) with $a(u) = u$.

2. Lagrangian approximation of 1D friction equations; $\sigma = \mu = 0$. The object under the scope is now

$$\partial_t f(t,v) = \partial_v \left\{ f(t,v) \int_{\mathbb{R}} \mathcal{I}'(v-\omega) f(t,\omega).d\omega \right\}; \qquad t, v \in \mathbb{R}_*^+ \times \mathbb{R}, \tag{2.1}$$

as proposed in [27] from the Boltzmann equation in a so-called quasi-elastic limit in the case $\mathcal{I}(\xi) = |\xi|^3/3$, i.e., $\gamma = 1$. We use the notation $\mathbb{R}_*^+ = (0, +\infty)$ throughout the paper. Since (2.1) is known to admit Dirac-type similarity solutions, it is convenient to introduce the following functional framework for $p \geq 1$:

$$\mathcal{M}_p(\mathbb{R}) = \left\{ v \mapsto f(.,v) \text{ probability measure such that } \int_{\mathbb{R}} |v|^p f(.,v).dv < +\infty \right\},$$

equipped with the topology of weak convergence of measures. A distinguished class of metrics on $\mathcal{M}_p(\mathbb{R})$ is given by the so-called Wasserstein (or Monge–Kantorovitch) distance [19, 24, 32], which can be written as the usual L^p distance of the [illegible] (to be defined in section 2.1),

$$d_p(f,g) := \left(\int_0^1 |V(.,\varrho) - W(.,\varrho)|^p .d\varrho \right)^{1/p}, \qquad 1 \leq p < +\infty.$$

By a weak solution to the Cauchy problem for (2.1), we mean any $f \in C^1(\mathbb{R}_*^+; \mathcal{M}_p(\mathbb{R}))$ satisfying for all $\varphi \in C^1(\mathbb{R})$ and $t > 0$,

$$\begin{aligned} \frac{d}{dt} \int_{\mathbb{R}} \varphi(v) f(t,v).dv &= - \int_{\mathbb{R}^2} \mathcal{I}'(v-w) \varphi'(v) f(t,v) f(t,w).dv.dw \\ &= \frac{1}{2} \int_{\mathbb{R}^2} \mathcal{I}'(v-w)(\varphi'(w) - \varphi'(v)) f(t,v) f(t,w).dv.dw, \end{aligned} \tag{2.2}$$

and $f(t,.) \to f(t=0,.) = f_0 \in \mathcal{M}_p(\mathbb{R})$ weakly as a measure as $t \to 0$. The second equality holds because $\mathcal{I}'$ is an odd function. Obviously, choosing $\varphi(v) = 1, v$ in (2.2) yields conservation of mass and momentum; thus it makes sense to restrict ourselves to centered probability measures. Further, inserting $\varphi(v) = v^2$ leads to

$$\frac{d}{dt}\theta(t) := \frac{d}{dt}\int_{\mathbb{R}^2} v^2 f(t,v).dv = -\int_{\mathbb{R}^2} \mathcal{I}'(v-w)(v-w)f(t,v)f(t,w).dv.dw \leq 0.$$

Thus the temperature is meant to decrease monotonically in time (at most at an exponential rate; see [30] and Figure 1) because $\mathcal{I}'$ is monotone nondecreasing. We also deduce from [24] the following uniqueness theorem.

THEOREM 2.1. [illegible] $f_0 \in \mathcal{M}_p(\mathbb{R})$ [illegible] $p = 2$ [illegible] $\mathcal{I}$ [illegible] (2.1) [illegible]

The proof is given in Appendix A.

2.1. The reciprocal mapping. From [10], the decay towards stable similarity solutions (homogeneous cooling states) can be expected to be slow, and because of their singular structure, one cannot use high-order discretizations. This clearly constitutes a numerical difficulty we propose to overcome by means of the change of variable described as follows:

- Let us introduce the distribution function associated with the initial probability measure f_0,

$$\varrho_0(v) = \int_{-\infty}^{v} f_0(\omega).d\omega \in (0,1), \qquad \varrho_0 \in BV(\mathbb{R}),$$

which is obviously nondecreasing in the v variable. We can thus define a (nondecreasing) pseudoinverse:

$$\begin{aligned} v_0 : (0,1) &\to \mathbb{R}, \\ \bar{\varrho} &\mapsto v_0(\bar{\varrho}) := \inf\{\omega \in \mathbb{R} \text{ such that } \varrho_0(\omega) = \bar{\varrho}\}. \end{aligned} \tag{2.3}$$

- For any given value $\bar{\varrho} \in (0,1)$, we can define the [illegible]

$$\begin{aligned} V : \quad \mathbb{R}^+ &\to \mathbb{R}, \\ t &\mapsto V(t,\bar{\varrho}), \end{aligned}$$

by means of the implicit function theorem in case $\partial_v \varrho \neq 0$, such that

$$V(t=0,\bar{\varrho}) = v_0(\bar{\varrho}), \qquad \varrho(t, V(t,\bar{\varrho})) = \bar{\varrho}. \tag{2.4}$$

Integrating (2.1) in v,

$$\partial_t \varrho(t,v) = \partial_v \varrho(t,v)\int_{\mathbb{R}} \mathcal{I}'(v-\omega)\partial_v \varrho(t,\omega).d\omega, \qquad \partial_v \varrho(t,v) = f(t,v),$$

and differentiating the second equality of (2.4) with respect to time, one deduces easily the time evolution of $V(.,\varrho)$ (we drop the $\bar{}$ for ease of reading); see also [15, 24]:

$$\partial_t V(t,\varrho) + \int_0^1 \mathcal{I}'\big(V(t,\varrho) - V(t,\varrho')\big).d\varrho' = 0, \qquad t > 0, \tag{2.5}$$

and $V(t=0,\varrho) = v_0(\varrho)$ for any $\varrho \in (0,1)$.

We define a Cartesian computational grid by means of the two positive parameters $\Delta t, \Delta v$. From now on, let v_k and t^n stand for $k\Delta v$ and $n\Delta t$, respectively. Therefore our numerical approach to (2.1) with convenient (unit mass, centered) initial data is built on computing the pseudoinverse of ϱ_0, $V(t=0,.)$, evolving it in time by means

of an [illegible] marching scheme for (2.5) in order to deduce the values of $\varrho(t, X(t,.)) \in [0,1]$ thanks to (2.4). Working on this pseudoinverse $V(t,.)$ allows us to bypass the usual problems in approximating Dirac measures [9, 17]. This trick can be used mainly because (2.1) is [illegible]. It will prove useful to introduce the [illegible] definition of weak solution to (2.1) (see [24, p. 412]).

DEFINITION 1. [illegible] $f_0 \in \mathcal{M}_p(\mathbb{R})$. $f(t,v) \in C^1(\mathbb{R}_*^+; \mathcal{M}_p(\mathbb{R}))$ [illegible] (2.1), (2.5) [illegible] $\varphi \in C^1(\mathbb{R})$ [illegible] $t > 0$

$$\frac{d}{dt}\int_0^1 \varphi(V(t,\varrho)).d\varrho = -\int_{(0,1)^2} \mathcal{I}'(V(t,\varrho) - V(t,\varrho'))\varphi'(V(t,\varrho)).d\varrho.d\varrho'$$
$$= -\int_{(0,1)^2} \mathcal{I}'(V(t,\varrho) - V(t,\varrho'))\frac{\varphi'(V(t,\varrho) - \varphi'(V(t,\varrho')}{2}.d\varrho.d\varrho'.$$

[illegible] $f(t,.) \to f_0$ [illegible] $t \to 0$ [illegible]

We now discretize the ϱ and t axes and define

$$V_k^n \simeq V(t^n, \varrho_k); \qquad \varrho_k := \varrho_0(v_k),\ t^n = n\Delta t \quad \text{for } k \in \mathcal{K} \subset \mathbb{N},\ n \in \mathbb{N}. \tag{2.6}$$

A numerical scheme for (2.5) reads as

$$V_k^{n+1} = V_k^n - \Delta t \sum_{k' \in \mathcal{K}} |C_{k'}| \mathcal{I}'(V_k^n - V_{k'}^n), \tag{2.7}$$

where $|C_k| = \varrho_{k+\frac{1}{2}} - \varrho_{k-\frac{1}{2}}$ stands for the width of the control cell centered on ϱ_k with $\varrho_{k+\frac{1}{2}} = \varrho_0(x_{k+\frac{1}{2}})$. As ϱ_0 is at least of bounded variation (hence it makes sense to speak about left/right values at a given point), a convenient choice is given by linear interpolation, $\varrho_{k+\frac{1}{2}} = \frac{1}{2}(\varrho_k + \varrho_{k+1})$, which yields $|C_k| = \frac{1}{2}\big(\varrho_{k+1} - \varrho_{k-1}\big)$. Since no divided differences show up in (2.7), there is no need for boundary conditions. The scheme (2.7) is conservative [illegible]. This furthermore yields, since $\mathcal{I}$ is an even function,

$$\forall n \in \mathbb{N}, \qquad \sum_k |C_k| V_k^n = \sum_k |C_k| V_k^0 \simeq \int_0^1 V(t=0,\varrho).d\varrho = \int_{\mathbb{R}} v.f_0(x).dv.$$

We stress that the ϱ_k's do [illegible] depend on time. In order to reconstruct $\tilde{\varrho}(t^n,.)$, an approximation of $\varrho(t,.)$ at a given time $t \simeq t^n$, one has to interpolate the family of numerical values ϱ_k, X_k^n, t^n since

$$\tilde{\varrho}(t^n, V_k^n) \overset{def}{=} \varrho_k \simeq \varrho(t^n, V_k^n),$$

$\partial_v \varrho$ being the weak solution to (2.1), up to the numerical truncation errors on V_k^n coming from the discretization (2.7). Then one deduces $f(t^n,.)$ by, e.g., centered divided differences.

2.2. Wasserstein contraction estimate. The fundamental lemma reads as follows.

LEMMA 2.2. [illegible] f_0, g_0 [illegible] $\mathcal{M}_p(\mathbb{R})$ [illegible] (2.1) [illegible] V, W [illegible]

$$\Delta t \sup_{V_k^0, W_{k'}^0} \big(\mathcal{I}''\big) \le 1, \qquad k, k' \in \mathcal{K}^2, \tag{2.8}$$

[illegible] (2.7) [illegible] d_p [illegible]

$$\forall n \in \mathbb{N}, \qquad \sum_k |C_k| |V_k^{n+1} - W_k^{n+1}|^p \le \sum_k |C_k| |V_k^n - W_k^n|^p, \qquad p \ge 1. \tag{2.9}$$

In practice, for (2.8), the supremum can be taken on the convex hull of the given set of data.

. We readily substract the schemes (2.7) on each variable to derive

$$\forall n \in \mathbb{N}, \qquad V_k^{n+1} - W_k^{n+1} = V_k^n - W_k^n - \Delta t \sum_{k' \in \mathcal{K}} |C_{k'}| \Big(\mathcal{I}'(V_k^n - V_{k'}^n) - \mathcal{I}'(W_k^n - W_{k'}^n) \Big).$$

We apply the mean-value theorem for each k, k' to obtain

$$\mathcal{I}'(V_k^n - V_{k'}^n) - \mathcal{I}'(W_k^n - W_{k'}^n) = (\mathcal{I}'')_{k,k'}^n \Big((V_k^n - W_k^n) - (V_{k'}^n - W_{k'}^n) \Big),$$

where convexity manifests itself through

$$0 \leq (\mathcal{I}'')_{k,k'}^n := \mathcal{I}'' \Big(\lambda (V_k^n - V_{k'}^n) + (1-\lambda)(W_k^n - W_{k'}^n) \Big),$$

for some $\lambda \in [0,1]$. Hence rearranging terms, one finds out that $V_k^{n+1} - W_k^{n+1}$ is a convex combination of each $V_{k'}^n - W_{k'}^n$, $k' \in \mathcal{K}$, under the CFL condition (2.8) since $\mathcal{I}$ is convex:

$$V_k^{n+1} - W_k^{n+1} = (V_k^n - W_k^n) \Big(1 - \Delta t \sum_{k' \in \mathcal{K}} |C_{k'}| (\mathcal{I}'')_{k,k'}^n \Big) + \Delta t \sum_{k' \in \mathcal{K}} |C_{k'}| (\mathcal{I}'')_{k,k'}^n (V_{k'}^n - W_{k'}^n).$$

The result (2.9) follows from summing on $k \in \mathcal{K}$ and invoking Jensen's inequality. ∎

This result is but a numerical equivalent of Theorem 1 in [24]. As an immediate consequence of Lemma 2.2, one obtains the L^p stability of the method, just taking $W_k^0 \equiv 0$ (which implies $W_k^n \equiv 0$ since $\mathcal{I}'(0) = 0$).

PROPOSITION 2.3. 2.2,

$$\forall n \in \mathbb{N}, \qquad \sum_k |C_k| \Big(|V_k^{n+1}|^p - |V_k^n|^p \Big) \leq 0, \qquad p \geq 1.$$

This somehow highlights the solution's support decay proved in [24]. It shows in particular the constant decrease of the numerical solution's temperature since $\theta(t^n) \simeq \sum_k |C_k| |V_k^n|^2$. Clearly, more involved treatments of the integral term of (2.5) would yield an estimate of the same flavor. It would also be possible to consider higher-order Runge–Kutta methods in time; see, e.g., [20].

COROLLARY 2.4. 2.2, f_0

$$\forall k, n \in \mathcal{K} \times \mathbb{N}, \qquad |V_k^{n+1} - V_k^n| \leq \Delta t \sup_{V_k^0} |\mathcal{I}'|. \tag{2.10}$$

. From Proposition 2.3, the sequence V_k^n is bounded in $L^\infty(0,1)$. The estimate (2.10) follows from $\sum_{k \in \mathcal{K}} |C_k| = \|f_0\|_{L^1(\mathbb{R})} = 1$. ∎

2.3. Compactness and entropy consistency of the scheme. By analogy with (1.2), we can define an "entropy" functional for (2.1),

$$\forall t \geq 0, \qquad \mathcal{E}(t,f) = \int_{\mathbb{R}^2} \mathcal{I}(v - v') f(t,v) f(t,v') . dv . dv',$$

which is known to decrease as times grow at least for certain potentials. It can be easily checked that (2.7) keeps this property; this is the purpose of the next result.

PROPOSITION 2.5. $\mathcal{E}^n = \sum_{k,k'} |C_k||C_{k'}|\mathcal{I}(V_k^n - V_{k'}^n)|$, $\mathcal{I}(\xi) = |\xi|^{2+\gamma}/\gamma+2$ 2.2,

$$\forall n \in \mathbb{N}, \qquad \mathcal{E}^n \leq \Big(1 - \Delta t \inf_{V_k^0}(\mathcal{I}'')\Big)^{n(\gamma+2)} \mathcal{E}^0. \tag{2.11}$$

. The proof proceeds as in Lemma 2.2; substracting and linearizing (2.7) with $W_k^n = V_\ell^n$ for some $\ell \in \mathcal{K}$ gives

$$\begin{aligned}
|V_k^{n+1} - V_\ell^{n+1}| &= \Big|V_k^n - V_\ell^n - \Delta t \sum_{k' \in \mathcal{K}} \Big|C_{k'}\big|\big(\mathcal{I}'(V_k^n - V_{k'}^n) - \mathcal{I}'(V_\ell^n - V_{k'}^n)\big)\big| \\
&= \Big|V_k^n - V_\ell^n - \Delta t \sum_{k' \in \mathcal{K}} \Big|C_{k'}\big|(\mathcal{I}'')_{k,\ell,k'}^n\big((V_k^n - V_\ell^n) - (V_{k'}^n - V_{k'}^n)\big)\big| \\
&= |V_k^n - V_\ell^n|\Big(1 - \Delta t \sum_{k' \in \mathcal{K}} |C_{k'}|(\mathcal{I}'')_{k,\ell,k'}^n\Big),
\end{aligned}$$

where $(\mathcal{I}'')_{k,\ell,k'}^n = \mathcal{I}''(\lambda V_k^n + (1-\lambda)V_\ell^n - V_{k'}^n)$ and from which we deduce that $|V_k^{n+1} - V_\ell^{n+1}| \leq |V_k^n - V_\ell^n|(1 - \Delta t \inf_{V_k^n}(\mathcal{I}''))$ under the CFL condition (2.8). Summing leads to (2.11). Thus the proof is complete. □

Of course, if one lets $\Delta t \to 0$, (2.11) provides the exponential decay of the entropy; see [24]. Lemma 2.2 also implies a bound on the total variation of the scheme, as we show now.

COROLLARY 2.6. 2.2,

$$\forall n \in \mathbb{N}, \qquad \sum_{k \geq 1} |V_k^n - V_{k-1}^n| \leq \Big(1 - \Delta t \inf_{V_k^0}(\mathcal{I}'')\Big)^n \sum_{k \geq 1} |V_k^0 - V_{k-1}^0|. \tag{2.12}$$

(2.7)

. The proof is essentially the same as in Proposition 2.5; substracting and linearizing (2.7) with $\ell = k-1$ gives again $|V_k^{n+1} - V_{k-1}^{n+1}| \leq |V_k^n - V_{k-1}^n|\big(1 - \Delta t \inf_{V_k^n}(\mathcal{I}'')\big)$ using the CFL condition (2.8). This also implies monotonicity preservation. By summing for $k, k' \geq 1$, one obtains the decrease of the total variation which is initially bounded if f_0 has compact support. □

. 1. One clearly sees that the CFL (2.8) condition is indeed very mild in this case, since the values of Δt and $|C_k|$ are completely decorrelated. In particular, no implicit time integrator is needed to ensure stability, in sharp contrast with [9].

The decrease of the total variation was to be expected; one can imagine considering $V(t=0,\varrho)$ as an initial value and $W(t=0,\varrho) := V(t=0,\varrho-h)$, $0 < h \ll 1$. Thus the Wasserstein contraction (2.9) ensures that the corresponding numerical approximations (2.7) will get closer to each other as times grow. For $p = 1$, this is exactly what is meant by (2.12). Eventually, and at least for $\mathcal{I}(\xi) = |\xi|^{2+\gamma}/\gamma+2$, both V and W will get stuck onto a self-similar profile which depends only on the value of $\gamma \geq 0$. We shall return to this in section 3.

At this level, it is convenient to define a sequence of approximate "Lagrangian solutions" $V^{\Delta t} \in BV_{loc}(\mathbb{R}_*^+ \times (0,1))$ as for all $t, \varrho \in \mathbb{R}_*^+ \times (0,1)$,

$$V^{\Delta t}(t,\varrho) = V_k^n \text{ if } |t - t^n| \leq \frac{\Delta t}{2} \text{ and } |\varrho - \varrho_k| \leq \frac{|C_k|}{2}. \tag{2.13}$$

Obviously, this implies the existence of another sequence $\varrho^{\Delta t}(t,v)$ defined as follows: for all $t, v \in \mathbb{R}_*^+ \times \mathbb{R}$,

$$\varrho^{\Delta t}(t,v) = \varrho_k \text{ if } |t - t^n| \leq \frac{\Delta t}{2} \text{ and } \frac{V_{k-1}^n - V_k^n}{2} \leq v - V_k^n \leq \frac{V_{k+1}^n - V_k^n}{2}, \tag{2.14}$$

from which one can recover an approximation $f^{\Delta t}(t,v)$ to (2.1) by divided differences. As a consequence of the monotonicity of the sequence $(V_k^n)_{k\in\mathcal{K}}$ for all $n \in \mathbb{N}$, $f^{\Delta t} \geq 0$ as soon as $f_0 \geq 0$. We note in passing that the total variation of $\varrho^{\Delta t}$ in the v variable is constant by construction.

Thus it just remains to extract a subsequence still denoted $V^{\Delta t}$ converging strongly in $L^1_{loc}(\mathbb{R}_*^+ \times (0,1))$ by Helly's compactness principle. From (2.7), we can compute $\varphi(V_k^{n+1})$ for a smooth function φ; then applying the mean-value theorem leads to

$$\forall k, n, \qquad \frac{1}{\Delta t}\Big(\varphi(V_k^{n+1}) - \varphi(V_k^n)\Big) = -\sum_{k'\in\mathcal{K}} |C_{k'}| \mathcal{I}'(V_k^n - V_{k'}^n)\varphi'(V_k^n) + o(1).$$

It is now easy to deduce that $V^{\Delta t}$, (2.13) will satisfy the requirements of Definition 1 as $\Delta t, \Delta v \to 0$. Hence we deduce the following result.

THEOREM 2.7. *Let $f_0 \in \mathcal{M}_p(\mathbb{R})$ [illegible] $\mathcal{I}$ [illegible] (2.8), [illegible] $V^{\Delta t}$ [illegible] (2.13) [illegible] (2.7) [illegible] $L^1_{loc}(\mathbb{R}_*^+ \times (0,1))$ [illegible] $\Delta t, \Delta v \to 0$ [illegible] (2.1) [illegible] 1. [illegible] $\mathcal{E}$ [illegible] $\mathcal{I}(\xi) = |\xi|^{2+\gamma}/(\gamma+2)$*

3. Study of the solution's large-time behavior. From [10], we know that the so-called homogeneous cooling states cannot hope to play the role of paramount importance, as is the case for Barenblatt–Pattle similarity solutions for nonlinear diffusion equations. However, we are about to show that they still can be evidenced numerically by means of our approach.

3.1. Entropy dissipation properties and similarity variable. In this section, we must restrict ourselves to usual interaction potentials $\mathcal{I}(\xi) = |\xi|^{\gamma+2}/\gamma + 2$, $\gamma \geq 0$, because we shall use homogeneity properties. The plan is to change variables in order to make potential self-similar profiles stationary; this opens the way to the study of long-time asymptotics for (2.1). We proceed by considering the associated problem with an antidrift term (it corresponds to (1.1) with $\mu = -1$ and $\sigma = 0$):

$$\partial_t g(t,v) = \partial_v \left\{ g(t,v) \int_{\mathbb{R}} \mathcal{I}'(v-\omega) g(t,\omega).d\omega - v g(t,v) \right\}; \qquad t, v \in \mathbb{R}_*^+ \times \mathbb{R}. \tag{3.1}$$

Indeed, if $g_\infty(v)$ is a steady-state solution for (3.1), then we can deduce a similarity solution of (2.1) quite easily (see [31]):

$$f_s(t,v) = \frac{1}{\alpha(t)} g_\infty\left(\frac{v}{\alpha(t)}\right); \qquad \alpha'(t) + \alpha^{1+\gamma}(t) = 0,\ \alpha(0) = 1.$$

Let us now consider $g(\tau, v)$ solution of (3.1) for $\tau(t) = -\log(\alpha(t))$ in order to state one result from [1, 10, 24].

THEOREM 3.1. *Let $f_0 \in \mathcal{M}_p(\mathbb{R})$ [illegible] $p = 2$ [illegible] f [illegible] (2.1). [illegible] $g(\tau, v)$ [illegible] (3.1). [illegible]*

$$g \overset{\tau\to+\infty}{\longrightarrow} \frac{1}{2}\left(\delta\left(v - \frac{1}{2}\right) + \delta\left(v + \frac{1}{2}\right)\right)$$

(δ [illegible])

Notice that $\alpha(0) = 1$ implies that $\theta_s(0) = \int_{\mathbb{R}} f_s(t=0,v)v^2.dv = \int_{\mathbb{R}} v^2 g_\infty(v).dv = 1/4$. Following [1, 24], we recall the free energy functional (1.2) defined in the introduction. However, we rewrite it in terms of the reciprocal mapping,

$$\mathcal{J}(g,\tau) = \frac{1}{2+\gamma}\int_{(0,1)^2} |\tilde{V}(\tau,\varrho) - \tilde{V}(\tau,\varrho')|^{2+\gamma}.d\varrho.d\varrho' - \int_{\mathbb{R}} \tilde{V}(\tau,\varrho)^2.d\varrho,$$

where $\tilde{V}(\tau,\varrho)$ is the reciprocal mapping of $g(\tau,v)$. We can give at once the value of $\mathcal{J}(g_\infty)$:

$$\begin{aligned}\mathcal{J}(g_\infty) &= \frac{1}{2+\gamma}\int_{(0,1)^2} |\tilde{V}_\infty(\varrho) - \tilde{V}_\infty(\varrho')|^{\gamma+2}.d\varrho.d\varrho' - \frac{1}{4}\\ &= \frac{2}{2+\gamma}\int_0^{\frac{1}{2}}\int_{\frac{1}{2}}^1 |\tilde{V}_\infty(\varrho) - \tilde{V}_\infty(\varrho')|^{2+\gamma}.d\varrho.d\varrho' - \frac{1}{4}\\ &= \frac{1}{2(2+\gamma)} - \frac{1}{4} = -\frac{\gamma}{4(2+\gamma)} \le 0.\end{aligned}$$

In particular, there holds that

$$\tilde{V}(\tau,\varrho) = \frac{V(\tau,\varrho)}{\alpha(t)},$$

where V still stands for the reciprocal mapping of $f(t,v)$ solution of (2.1). Hence $\mathcal{J}(g,\tau)$ rewrites (at this level we use that $\mathcal{I}(V/\alpha) = \alpha^{-(2+\gamma)}\mathcal{I}(V)$) as

$$\mathcal{J}(f,t) = \frac{1}{2+\gamma}.\frac{1}{\alpha(t)^{(2+\gamma)}}\int_{(0,1)^2} |V(t,\varrho) - V(t,\varrho')|^{2+\gamma}.d\varrho.d\varrho' - \frac{\theta(t)}{\alpha(t)^2};$$

with the temperature $\theta(t)$ defined in section 2, $\theta(t) = \int_0^1 V(t,\varrho)^2.d\varrho$ can be shown to satisfy the following equation:

$$\begin{aligned}\frac{d\theta(t)}{dt} &= \int_0^1 \partial_t V(t,\varrho)V(t,\varrho).d\varrho\\ &= -2\int_{(0,1)^2} V(t,\varrho)\mathcal{I}'(V(t,\varrho) - V(t,\varrho')).d\varrho.d\varrho'\\ &= -\int_{(0,1)^2} \mathcal{I}(V(t,\varrho) - V(t,\varrho')).d\varrho.d\varrho' \le 0.\end{aligned}$$

In the last step we use explicitly that $\mathcal{I}(\xi)$ is a power function. It is now necessary to make an [illegible] concerning the speed of decay for $\mathcal{J}$; namely, we assume that

$$\exists z \text{ such that } 0 \le \mathcal{J}(g,\tau) - \mathcal{J}(g_\infty) \le \underbrace{[\mathcal{J}(g,\tau=0) - \mathcal{J}(g_\infty)]z(\tau)}_{Z(\tau(t))}, \tag{3.2}$$

upon which relies the following result.

PROPOSITION 3.2. [illegible] $V(t=0,\varrho)$ [illegible] $f_0(v) \in \mathcal{M}_p(\mathbb{R})$. [illegible] (3.2)

$$\lim_{t\to+\infty}\frac{1}{t}\int_0^t Z(\tau(s)).ds = 0 \Rightarrow \lim_{t\to+\infty}\frac{\theta(t)}{\alpha(t)^2} = \frac{1}{4}.$$

As an immediate consequence, this statement allows us to use the temperature as a way of rescaling the solution, as already done for nonlinear diffusion equations in [19] (except that here the task is to zoom out a Dirac measure); this might be of interest if considering more general interaction potentials $\mathcal{I}(\xi)$, in the spirit of [31], for which no similarity variable α is yet available.

. From the evolution of θ, we deduce that

$$\mathcal{J}(g,\tau) = -\frac{\alpha^{-(2+\gamma)}(t)}{\gamma(2+\gamma)}\frac{d\theta(t)}{dt} - \frac{\theta(t)}{\alpha^2(t)}.$$

Hence we compute

$$\begin{aligned}\frac{d}{dt}\big(\theta(t)\alpha^{-(2+\gamma)}(t)\big) &= \frac{d\theta(t)}{dt}\alpha^{-(2+\gamma)}(t) - (2+\gamma)\alpha^{-(3+\gamma)}(t)\alpha'(t)\theta(t)\\ &= \frac{d\theta(t)}{dt}\alpha^{-(2+\gamma)}(t) + (2+\gamma)\alpha^{-2}(t)\theta(t)\\ &= -(2+\gamma)\mathcal{J}(g,\tau).\end{aligned}$$

If (3.2) holds, then

$$-\mathcal{J}(g_\infty) \geq \frac{1}{2+\gamma}\frac{d\theta(t)}{dt}\big(\theta(t)\alpha^{-(2+\gamma)}(t)\big) \geq -\mathcal{J}(g_\infty) - Z(\tau(t)).$$

Thus we integrate in time and multiply by $\alpha^\gamma(t)$ to derive

$$-\mathcal{J}(g_\infty).t.\alpha^\gamma(t) \geq \frac{1}{2+\gamma}\frac{\theta(t)}{\alpha^2(t)} - \theta(0)\alpha^\gamma(t) \geq \alpha^\gamma(t)\left(-\mathcal{J}(g_\infty).t - \int_0^t Z(s).ds\right).$$

The final step is to notice that $\alpha^\gamma(t) = (1+\gamma t)^{-1}$ and that $-\mathcal{J}(g_\infty)(2+\gamma)/\gamma = \frac{1}{4}$. □

3.2. Numerical validation: Homogeneous cooling states. Proposition 3.2 provides us with a simple and systematic way to visualize approximate similarity solutions of (2.1) just computing

$$g_\infty^{\Delta t}(v) = f^{\Delta t}\Big(t, 2v\sqrt{\theta(t)}\Big)2\sqrt{\theta(t)}, \tag{3.3}$$

which can be easily obtained from (2.7). Indeed, Proposition 3.2 (relying on assumption (3.2)) ensures that (3.3) will behave asymptotically well. This is illustrated in Figure 1 for various values of $\gamma \geq 0$. To the authors' knowledge, this is the first time such intermediate asymptotics are displayed numerically. Clearly, as γ decreases, θ gets closer to the zero machine, and the accuracy in computing (3.3) is reduced. However, the correct shape is kept even with $\theta \simeq 10^{-10}$. The parameters we use are $\Delta v = 0.05$, and the time step is chosen adaptively. The initial data is a Gaussian distribution, $f_0(v) = \frac{1}{2\pi}\exp(-x^2/2)$.

4. Inclusion in a "thermal bath": the 1D friction-diffusion equation $\sigma > 0$. We now deal with the Cauchy problem for the equation:

$$\partial_t f(t,v) = \partial_v\left\{f(t,v)\int_{\mathbb{R}}\mathcal{I}'(v-\omega)f(t,\omega).d\omega\right\} + \sigma\partial_{vv}f; \qquad t,v \in \mathbb{R}_*^+ \times \mathbb{R}. \tag{4.1}$$

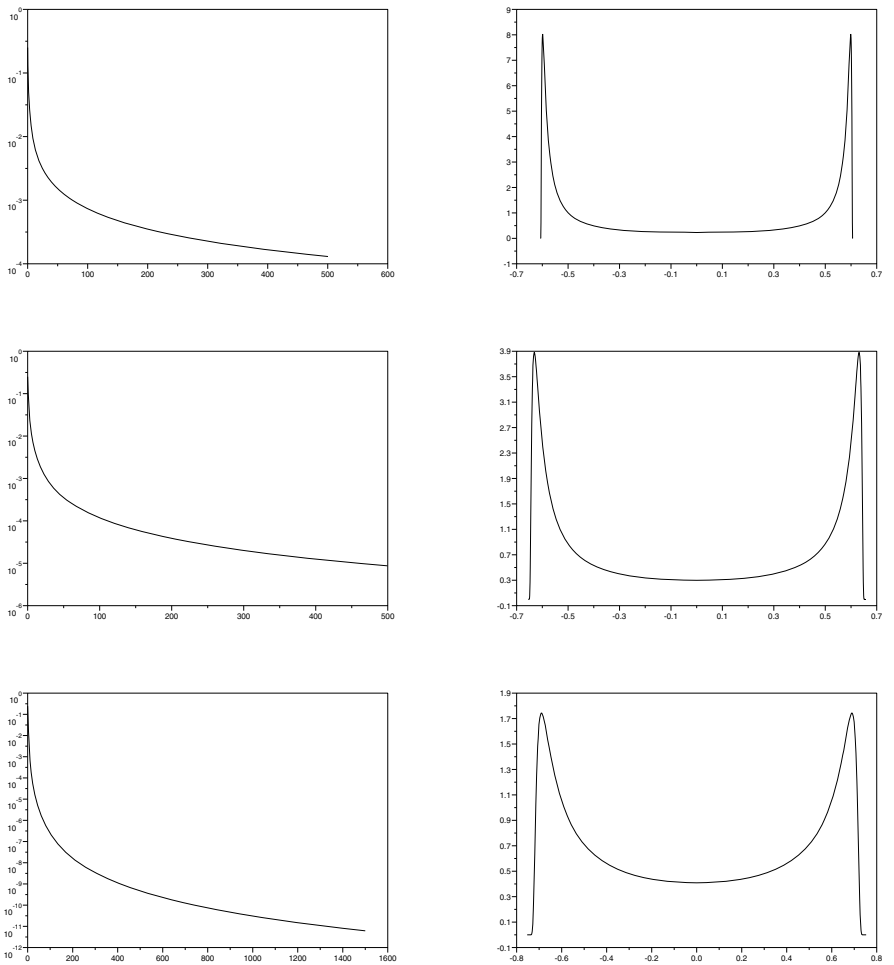

FIG. 1. *Decay of the temparatures* $t \mapsto \theta(t)$ (*left*) *and numerical similarity solutions* (*right*) *for* $\gamma = 1.8, 1.2, 0.5$ (*top to bottom*). *Notice the duration of stabilizing processes as* γ *is decreased.*

Existence and uniqueness have been shown in [12]. As in the preceding sections, we recall the weak solution to (4.1) as a distribution $f(t,v) \in C^1(\mathbb{R}_*^+; \mathcal{M}_p(\mathbb{R}))$ satisfying

$$\begin{aligned} \frac{d}{dt}\int_{\mathbb{R}} \varphi(v) f(t,v).dv &= -\int_{\mathbb{R}^2} \mathcal{I}'(v-w)\varphi'(v) f(t,v) f(t,w).dv.dw \\ &\quad + \sigma \int_{\mathbb{R}} \varphi''(v) f(t,v).dv \\ &= \frac{1}{2}\int_{\mathbb{R}^2} \mathcal{I}'(v-w)(\varphi'(w)-\varphi'(v)) f(t,v) f(t,w).dv.dw \\ &\quad + \sigma \int_{\mathbb{R}} \varphi''(v) f(t,v).dv, \end{aligned} \tag{4.2}$$

and $f(t,.) \to f(t=0,.) = f_0 \in \mathcal{M}_p(\mathbb{R})$ weakly as a measure as $t \to 0$. Clearly, from this definition, one deduces again the conservation of mass and momentum, which

corresponds to $\varphi(v) = 1, v$. However, the temperature is not meant to vanish as for the case $\sigma = 0$.

Uniqueness still holds for these measure solutions.

THEOREM 4.1. [illegible] $f_0 \in \mathcal{M}_p(\mathbb{R})$ [illegible] $p = 2$ [illegible] $\mathcal{I}$ [illegible] (4.1) [illegible]

The proof is given in Appendix B. The solution of (4.1) has been shown to converge weakly to the one of (2.1) as $\sigma \to 0$ in [26]. However, the results of [12] are more interesting at a computational level because they deal with smoother solutions. Let us recall the following result.

THEOREM 4.2. [illegible] $f_0 \in \mathcal{M}_p(\mathbb{R})$ [illegible] $\int_{\mathbb{R}}(1+v^4)f_0(v).dv$ [illegible] $\mathcal{I}$ [illegible] (4.1) [illegible] $(1+v^4)f(t,v) \in C^0(\mathbb{R}^+_*; L^1(\mathbb{R}))$ [illegible] $f_0 \in C^2(\mathbb{R})$ [illegible] f [illegible]

From this result, one sees immediately that the behavior of solutions is very different because of the diffusive term: global smooth solutions do exist.

4.1. Numerical scheme and Wasserstein contraction estimate. We do not recall the whole derivation of the equation satisfied by the reciprocal mapping (which can be easily derived from the considerations in section 2.1 and [19]): for all $t, \varrho \in \mathbb{R}^+_* \times (0,1)$,

$$\partial_t V(t,\varrho) + \sigma \partial_\varrho \left(\frac{1}{\partial_\varrho V(t,\varrho)} \right) + \int_0^1 \mathcal{I}'\Big(V(t,\varrho) - V(t,\varrho')\Big).d\varrho' = 0. \tag{4.3}$$

We shall also rely on the same type of discretization; hence we give at once the expression of the resulting scheme:

(4.4)

$$V_k^{n+1} = V_k^n - \Delta t \sum_{k' \in \mathcal{K}} |C_{k'}| \mathcal{I}'(V_k^n - V_{k'}^n) - \frac{\sigma \Delta t}{|C_k|} \left\{ \left(\frac{\varrho_{k+1} - \varrho_k}{V_{k+1}^n - V_k^n} \right) - \left(\frac{\varrho_k - \varrho_{k-1}}{V_k^n - V_{k-1}^n} \right) \right\}.$$

This scheme can be easily proven to be conservative and preserves momentum. It is also clearly asymptotic-preserving in the sense of Jin [22]. In contrast with section 2.1, (4.4) has to be completed by boundary conditions in $\varrho = 0, 1$; we observe that

$$\frac{1}{\partial_\varrho V(t,\varrho)} = f(t, V(t,\varrho)) = 0 \quad \text{for } \varrho = 0, 1,$$

at least for smooth functions vanishing at infinity. Hence in $\varrho = 0$, we have

$$V_0^{n+1} = V_0^n - \Delta t \sum_{k' \in \mathcal{K}} |C_{k'}| \mathcal{I}'(V_0^n - V_{k'}^n) - \frac{\Delta t \sigma}{|C_k|} \left(\frac{\varrho_1 - \varrho_0}{V_1^n - V_0^n} \right)$$

and a similar expression in $\varrho = 1$. In the spirit of Lemma 2.2, we can prove the following lemma.

LEMMA 4.3. [illegible] f_0, g_0 [illegible] $\mathcal{M}_p(\mathbb{R})$ [illegible] (4.1) [illegible] V, W [illegible]

$$\Delta t \sup_{V_k^n, W_{k'}^n} \left\{ \mathcal{I}'' + \sigma \left(\frac{\varrho_{k+1} - \varrho_k}{(V_{k+1}^n - V_k^n)^2} + \frac{\varrho_{k+1} - \varrho_k}{(W_{k'+1}^n - W_{k'}^n)^2} \right) \right\} \leq 1, \qquad k, k' \in \mathcal{K}^2, \tag{4.5}$$

[illegible] (4.4) [illegible] d_p [illegible]

$$\forall n \in \mathbb{N}, \qquad \sum_k |C_k| |V_k^{n+1} - W_k^{n+1}|^p \leq \sum_k |C_k| |V_k^n - W_k^n|^p, \qquad p \geq 1. \tag{4.6}$$

. We substract the schemes (4.4) and rearrange the terms corresponding to each variable. The integral term is linearized the same way and with the notation of Lemma 2.2; the diffusive part gives

$$\begin{aligned} V_k^{n+1} - W_k^{n+1} = (V_k^n - W_k^n)\Big(1 - \Delta t \sum_{k' \in \mathcal{K}} |C_{k'}| (\mathcal{I}'')_{k,k'}^n + \frac{\Delta t}{|C_k|}(\Phi'_{k+\frac{1}{2}} + \Phi'_{k-\frac{1}{2}})\Big) \\ + \Delta t \sum_{k' \in \mathcal{K}} |C_{k'}| (\mathcal{I}'')_{k,k'}^n (V_{k'}^n - W_{k'}^n) \\ - \frac{\Delta t}{|C_k|}\Phi'_{k+\frac{1}{2}}(V_{k+1}^n - W_{k+1}^n) - \frac{\Delta t}{|C_k|}\Phi'_{k-\frac{1}{2}}(V_{k-1}^n - W_{k-1}^n), \end{aligned}$$

with the following function:

$$\Phi_{k+\frac{1}{2}}(V) = \frac{\sigma(\varrho_{k+1} - \varrho_k)}{V}, \qquad \Phi'_{k+\frac{1}{2}}(V) = -\frac{\sigma(\varrho_{k+1} - \varrho_k)}{V^2} \leq 0.$$

Then $\Phi'_{k+\frac{1}{2}}$ stands for a midpoint value obtained through the mean-value theorem. From the CFL condition (4.5), the combination is convex; thus Jensen's inequality yields the announced result. □

We stress that Lemma 4.3 does not imply any L^p decay no more simply because initializing with $W_k^0 \equiv C^t \in (0,1)$ is forbidden by the CFL condition (4.5). Nevertheless, the order-preserving property still holds.

However, as said before, this result allows one to restrict attention to smooth C^2 initial data (which give rise to classical solutions as well) in order to take advantage of classical techniques in numerical analysis. Indeed, even in case the initial data is singular, one can argue that the error between the solutions emerging from its regularization and the genuine solution decay with time in any Wasserstein metric d_p.

So, going down this track, we first observe (by means of Taylor expansions) that the scheme (4.4) is clearly a first-order discretization of (4.1); hence its , is $e_k^n = O(\Delta t + |C_k|)$. Hence in order to establish convergence, we must study the evolution in time of its , $e^{\Delta t}(t,\varrho) \overset{def}{=} V^{\Delta t}(t,\varrho) - V(t,\varrho)$ for all $\varrho \in (0,1)$. It satisfies

$$\begin{aligned} \partial_t e^{\Delta t}(t,\varrho) + \sigma \partial_\varrho \left(\frac{1}{\partial_\varrho V^{\Delta t}(t,\varrho)} - \frac{1}{\partial_\varrho V(t,\varrho)} \right) \\ + \int_0^1 \mathcal{I}'\Big(V^{\Delta t}(t,\varrho) - V^{\Delta t}(t,p)\Big) - \mathcal{I}'\Big(V(t,\varrho) - V(t,p)\Big).dp = e_k^n \end{aligned}$$

for $t = t^n$ and $\varrho = \varrho_k$. At this point, one multiplies by $e^{\Delta t}(t,\varrho)$ and integrates in $\varrho \in (0,1)$. The integral term is positive by the uniqueness proof of Theorem 2.1 given in Appendix A. The diffusive term is handled thanks to a monotonicity argument, as in the proof of Theorem 4.1 given in Appendix B; indeed, an integration by parts yields

$$-\sigma \int_0^1 (\partial_\varrho V^{\Delta t} - \partial_\varrho V) \left(\frac{1}{\partial_\varrho V^{\Delta t}} - \frac{1}{\partial_\varrho V} \right)(t,\varrho).d\varrho \geq 0, \qquad \sigma \geq 0.$$

Thus it remains only that

$$\frac{1}{2}\partial_t \int_0^1 e^{\Delta t}(t,\varrho)^2.d\varrho \leq O(\Delta t + \sup_k |C_k|) \int_0^1 |e^{\Delta t}(t,\varrho)|.d\varrho,$$

and since $(0,1)$ is bounded, the L^2 norm dominates the L^1. Hence the error grows at most exponentially in time depending on the local truncation error of (4.4). We deduce the following result.

THEOREM 4.4. [illegible] $f_0 \in C^2(\mathbb{R})$ [illegible] $\mathcal{I}$ [illegible] (4.5), [illegible] $V^{\Delta t}$ [illegible] (2.13) [illegible] (4.4) [illegible] $\Delta t, \Delta v \to 0$ [illegible] [illegible] (4.3) [illegible] (4.1).

The equivalence of the two notions of solution to (4.1) has been used previously in [26]. It is easy to obtain a formal notion of consistency for the scheme (4.4) following the ideas presented in [19]; namely, one writes down the basic equality coming directly from (2.4),

$$\forall k, n \in \mathcal{K} \times \mathbb{N}, \qquad \varrho^{\Delta t}(t^n, V_k^n) = \varrho^{\Delta t}(t^{n+1}, V_k^{n+1}),$$

and then plugs into (4.4). A partly implicit finite-volume discretization of (4.1) is derived by means of Taylor expansions, assuming that $\varrho^{\Delta t}$ is at least C^1 in the v variable. We close this section mentioning that (4.4) is not the unique choice leading to the contraction property (4.6); a time-splitting strategy would behave equally well. In this last case, the proof would be the concatenation of the proof of Lemma 2.2 and [19] (the CFL would be slightly lighter though). The last situation emanating from (2.1) which has not yet been treated is $\sigma > 0$ and $\mu \neq 0$ and corresponds to a so-called [illegible] equation, as studied in [12]. However, when expressed by means of the reciprocal mapping, the confining term rewrites simply as $\mu V(t, \varrho)$, thus leading to a simple exponential term which can be integrated explicitly. Indeed, upon multiplying (1.5) by $\exp(\mu t)$, one derives the following equation:

$$\partial_t \tilde{V}(t,\varrho) + \exp(\mu t)\left\{\sigma \partial_\varrho\left(\frac{1}{\exp(-\mu t)\partial_\varrho \tilde{V}(t,\varrho)}\right) + \int_0^1 \mathcal{I}'\Big(\exp(-\mu t)(\tilde{V}(t,\varrho) - \tilde{V}(t,\varrho'))\Big).d\varrho'\right\} = 0, \tag{4.7}$$

where $\tilde{V}(t,.) = \exp(\mu t)V(t,.)$. The aforementioned techniques allow us to cover this case with minor changes.

4.2. Numerical results; study of the solution's "tails". Our first validation for (4.4) has been to look at the behavior of rescaled numerical solutions (3.3) as σ is decreased by several orders of magnitude. This has to do with checking the so-called asymptotic-preserving property in the sense of [22]. In this case, the decay of the approximate solution's temperature is interesting to look at since it should strengthen as $\sigma \to 0$. This is indeed the case as seen in Figure 2; the parameters used are $\Delta v = 0.27$ and $\gamma = 1.2$. The time step Δt is chosen adaptively according to (4.5).

It is a well-known fact that for great values of $|v|$, the solution of (4.1) with $\gamma = 1$ behaves like $\exp(-|v|^3)$; see [7, 8, 9]. We tried to check it out by iterating (4.4) with $\sigma = 1$ for quite a long time starting from a Gaussian initial datum. Results are shown in Figure 3. However, as the values of $f^{\Delta t}$ become very small (less than 10^{-50}), results could be slightly corrupted by spurious noise; it is nevertheless seeable that the behavior is qualitatively correct.

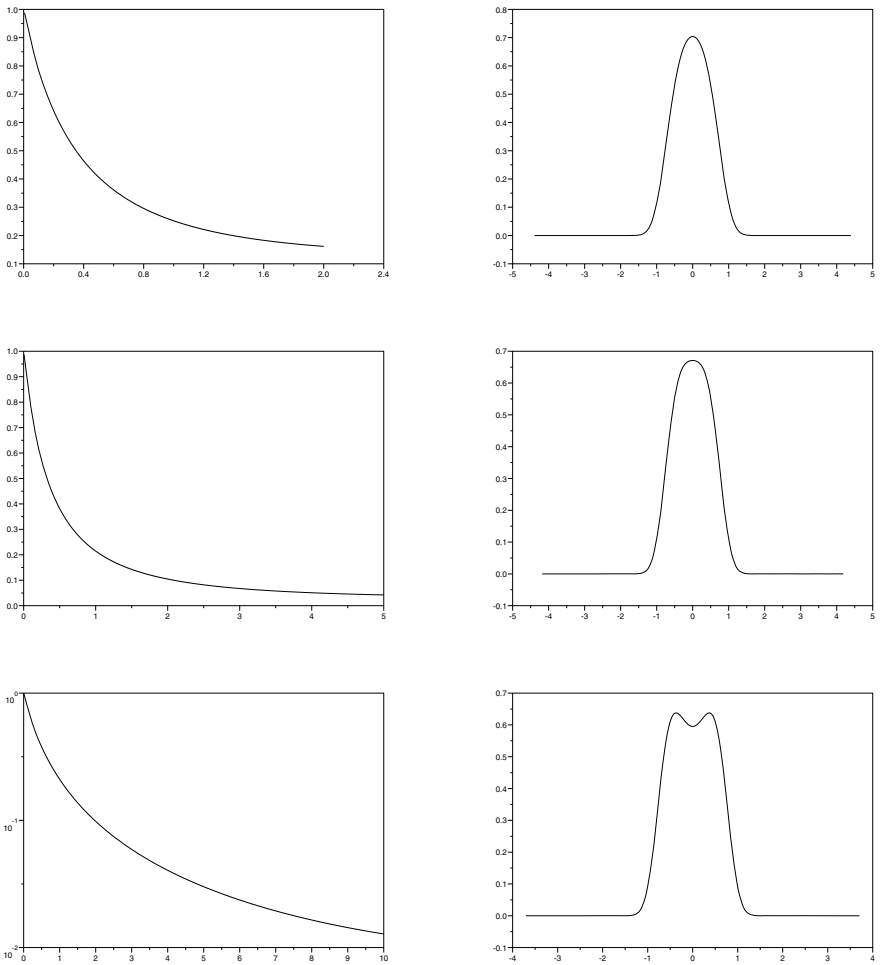

FIG. 2. *Decay of the temparatures* $t \mapsto \theta(t)$ (*left*) *and rescaled numerical solutions* (3.3) (*right*) *for* $\sigma = 0.1, 0.01, 0.001$ (*top to bottom*).

5. Numerical approximations of the Hele–Shaw cell.

5.1. Derivation of the numerical process. As announced in the introduction, we are about to concentrate mainly on a particular case of (1.4) corresponding to $a(u) = u$ (we drop the superscripts ε, as there is no ambiguity),

$$\partial_t u + \partial_x\big(u\partial_x(u *_x \Gamma_\varepsilon''(x))\big) = 0, \qquad 0 \le u_0 \in L^1 \cap H^1(\mathbb{R}).$$

The general case with mobility $a(u) \neq u$ is to be tackled in section 6 by means of quite different techniques. It is well known that (1.3) is mass-preserving; hence there is no loss of generality in considering only nonnegative initial data satisfying the additional requirement $\int_{\mathbb{R}} u_0(x).dx = 1$. One easily shows that it also dissipates energy, i.e.,

$$\frac{d}{dt}\int_{\mathbb{R}} |\partial_x u(t,x)|^2.dx \le 0, \qquad t \in \mathbb{R}^+.$$

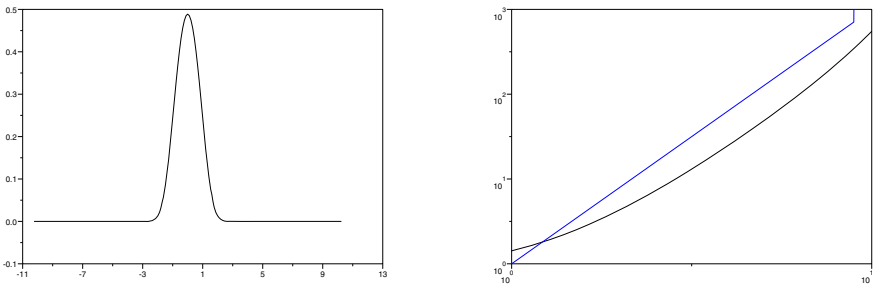

FIG. 3. *Large-time behavior for* (4.1) *at time* $t \simeq 33$ (*left*) *and comparison of its solution's tails with* $v \mapsto \exp(-|v|^3)$ (*right, where we plotted* $-\ln(f^{\Delta t})$ *and* $|v^3|$ *in logscale*).

Nonnegativity preservation has been proved to hold as a consequence of entropy dissipation [4, 5, 6]; however, in one space dimension, positive solutions to (1.3) are classical for $a(u) = u^p$, p big enough. As the solution vanishes, it typically suffers a loss of regularity and propagates at finite speed (it admits in particular source-type solutions [16]). This is strongly reminiscent of second-order degenerate parabolic equations already treated numerically in [19]. In this context, we first recall that approximations of the type (1.4) have been shown to be consistent with the original problem (1.3) for the special choice of Γ_ε being a Gaussian kernel,

$$\Gamma_\varepsilon(x) = \frac{1}{\sqrt{2\pi\varepsilon}} \exp\left(-\frac{x^2}{2\varepsilon}\right);$$

see Theorem 3.1 in [29]. Relying on this result, we shall pursue with this choice even if (many) other choices could be admissible too, as, for instance, the compactly supported Landau kernel given by ($m \in \mathbb{N}$)

$$\Gamma_{\varepsilon,m}(x) = \begin{cases} \frac{(\varepsilon^2 - x^2)^m}{\int_{-\varepsilon}^{\varepsilon} (\varepsilon^2 - y^2)^m . dy}, & |x| \leq \varepsilon, \\ 0, & |x| > \varepsilon. \end{cases}$$

For our purpose, one would get

$$\Gamma_{\varepsilon,4}(x) = \frac{315(\varepsilon^2 - x^2)^4}{128\varepsilon^9}, \qquad \Gamma'''_{\varepsilon,4}(x) = \frac{105}{2\varepsilon^6} x(9\varepsilon^2 - 21x^2)\Gamma_{\varepsilon,1}(x).$$

Other kernels can be found in, e.g., [33]. Anyway, following ideas from the preceding sections, one can derive a numerical scheme for (1.4): by integration,

$$\partial_t \varrho + (\partial_x \varrho)(\partial_x \varrho *_x \Gamma'''_\varepsilon) = 0, \qquad \varrho(t,x) = \int_{-\infty}^{x} u(t,y).dy,$$

and introducing $X(t,\varrho)$ as the reciprocal mapping of $u(t,x)$, ($\|u_0\|_{L^1(\mathbb{R})} = 1$)

$$\partial_t X(t,\varrho) - \int_0^1 \Gamma'''_\varepsilon(X(t,\varrho) - X(t,\varrho')).d\varrho' = 0, \qquad (t,\varrho) \in \mathbb{R}^+ \times (0,1). \tag{5.1}$$

For Γ_ε being Gaussian, the scheme is completely determined with

$$\Gamma_\varepsilon(x) = \frac{1}{\sqrt{2\pi\varepsilon}} \exp\left(-\frac{x^2}{2\varepsilon}\right), \qquad \Gamma'''_\varepsilon(x) = \left(\frac{3x}{\varepsilon^2} - \frac{x^3}{\varepsilon^3}\right)\Gamma_\varepsilon(x).$$

Hence, defining a Cartesian grid by means of two positive parameters $\Delta t, \Delta x$ and denoting $t^n = n\Delta t$, $x_k = k\Delta x$, $\varrho_k = \varrho_0(x_k)$, one obtains finally

$$X_k^{n+1} = X_k^n + \Delta t \sum_{k' \in \mathcal{K}} |C_{k'}| \Gamma_\varepsilon'''(X_k^n - X_{k'}^n). \tag{5.2}$$

Now the novelty lies in the fact that Γ_ε''' has no sign; this somehow reflects the high-order space derivative in (1.3). As in section 2, no boundary conditions are needed for (5.2).

5.2. Stability estimates for $\varepsilon > 0$. As in former papers [34, 21], we aim at establishing a nonnegativity-preserving property; however, our scheme is not contractive in any Wasserstein distance. What remains is only the monotonicity-preserving property.

PROPOSITION 5.1. [illegible] $u_0 \geq 0$ [illegible] $X(t, \varrho)$ [illegible] (5.1) [illegible] $X(t = 0, .)$ [illegible] $\varrho(t = 0, .)$ [illegible]

$$\Delta t \leq \frac{1}{6} \varepsilon^2 \sqrt{2\pi\varepsilon \exp(3)}, \tag{5.3}$$

[illegible] (5.2) [illegible]

[illegible]. The proof proceeds by substracting and linearizing (5.2); one gets

$$\begin{aligned} X_k^{n+1} - X_{k-1}^{n+1} &= X_k^n - X_{k-1}^n + \Delta t \sum_{k' \in \mathcal{K}} |C_{k'}| \Big(\Gamma_\varepsilon'''(X_k^n - X_{k'}^n) - \Gamma_\varepsilon'''(X_{k-1}^n - X_{k'}^n) \Big) \\ &= (X_k^n - X_{k-1}^n) \Big(1 + \Delta t \sum_{k' \in \mathcal{K}} |C_{k'}| (\Gamma_\varepsilon'''')_{k,k-1,k'}^n \Big), \end{aligned}$$

where $(\Gamma_\varepsilon'''')_{k,k-1,k'}^n = \Gamma_\varepsilon''''(\lambda X_k^n + (1-\lambda) X_{k-1}^n - X_{k'}^n)$. Now, for Γ_ε being Gaussian, its fourth derivative reads as

$$\Gamma_\varepsilon''''(x) = \frac{\Gamma_\varepsilon(x)}{\varepsilon^2} \big(y^2 - 6y + 3 \big), \qquad y = \frac{x^2}{\varepsilon}.$$

By elementary calculus, this polynomial has a minimum for $y = 3$, and the corresponding value is -6. It remains to observe that (5.3) ensures that $1 + \Delta t \inf \Gamma_\varepsilon'''' \geq 0$. □

As an immediate consequence, nonnegativity for the u variable holds under the same condition (5.3). At this point, we stress that our scheme (5.2) is endowed with a very light CFL restriction $\Delta t = O(\varepsilon^{5/2})$; indeed, the parameters Δt and Δx are completely decorrelated as in section 2.2. Clearly, the smaller the ε, the more precise the numerical approximation but the higher the computational cost. The choice of the Landau kernel would impose $\Delta t = O(\varepsilon^5)$.

We now move on to an energy estimate for the scheme (5.2); it is convenient to recall some shorthand notation from [19], namely,

$$\delta X_{k-\frac{1}{2}}^n := X_k^n - X_{k-1}^n, \qquad \delta \varrho_{k-\frac{1}{2}} := \varrho_k - \varrho_{k-1}.$$

PROPOSITION 5.2. [illegible] $\alpha = \frac{6}{\varepsilon^2 \sqrt{2\pi\varepsilon \exp(3)}}$ [illegible] 5.1, [illegible] (5.2):

$$\forall n \in \mathbb{N}, \quad \left| \frac{\delta \varrho_{k+\frac{1}{2}}}{\delta X_{k+\frac{1}{2}}^n} - \frac{\delta \varrho_{k-\frac{1}{2}}}{\delta X_{k-\frac{1}{2}}^n} \right| \leq \exp(\alpha t^n) \left\{ \left| \frac{\delta \varrho_{k+\frac{1}{2}}}{\delta X_{k+\frac{1}{2}}^0} - \frac{\delta \varrho_{k-\frac{1}{2}}}{\delta X_{k-\frac{1}{2}}^0} \right| + O(\varepsilon^2) \right\}. \tag{5.4}$$

. We observe that from the proof of Proposition 5.1, the divided difference satisfies

$$\left|\frac{\delta\varrho_{k-\frac12}}{\delta X^n_{k-\frac12}}\right| \le \left|\frac{\delta\varrho_{k-\frac12}}{\delta X^{n-1}_{k-\frac12}}\right| \frac{1}{1+\Delta t\inf\Gamma''''_\varepsilon} \le \left|\frac{\delta\varrho_{k-\frac12}}{\delta X^0_{k-\frac12}}\right| \exp(-t^n\inf(\Gamma''''_\varepsilon)),$$

since the CFL condition (5.3) ensures monotonicity preservation and $\inf(\Gamma''''_\varepsilon)\le 0$. For any choice of a,b,c,d in $\mathbb{R}^+$, there holds that $\left|\frac{a}{b}-\frac{c}{d}\right| \le \frac{|a-c|}{b} + c\left|\frac1b-\frac1d\right|$. Hence we get that

$$\left|\frac{\delta\varrho_{k+\frac12}}{\delta X^{n+1}_{k+\frac12}} - \frac{\delta\varrho_{k-\frac12}}{\delta X^{n+1}_{k-\frac12}}\right| \le \frac{\left|\frac{\delta\varrho_{k+\frac12}}{\delta X^{n}_{k+\frac12}} - \frac{\delta\varrho_{k-\frac12}}{\delta X^{n}_{k-\frac12}}\right|}{1+\Delta t\inf(\Gamma''''_\varepsilon)} + O(\Delta t)\left|\frac{\delta\varrho_{k-\frac12}}{\delta X^0_{k-\frac12}}\right| \exp(-t^n\inf(\Gamma''''_\varepsilon)).$$

By induction, this yields

$$\begin{aligned}\left|\frac{\delta\varrho_{k+\frac12}}{\delta X^{n+1}_{k+\frac12}} - \frac{\delta\varrho_{k-\frac12}}{\delta X^{n+1}_{k-\frac12}}\right| &\le \exp(-(n+1)\Delta t\inf(\Gamma''''_\varepsilon))\\ &\quad\times\left\{\left|\frac{\delta\varrho_{k+\frac12}}{\delta X^{0}_{k+\frac12}} - \frac{\delta\varrho_{k-\frac12}}{\delta X^{0}_{k-\frac12}}\right| + O(\Delta t)\left|\frac{\delta\varrho_{k-\frac12}}{\delta X^0_{k-\frac12}}\right| \frac{1+\Delta t\inf(\Gamma''''_\varepsilon)}{-\Delta t\inf(\Gamma''''_\varepsilon)}\right\}.\end{aligned}$$

It remains to plug into the value of $\inf(\Gamma''''_\varepsilon)\le 0$ and to observe that the last term is at least $O(\varepsilon^2)$. Thus (5.4) follows. □

Unfortunately, it does not seem easy to establish the equivalent of the energy decay which holds for the continuous problem (1.3) as a consequence of the nonnegativity of $a(u)$. However, (5.4) can be considered as a "cheap" estimate which ensures that approximate solutions generated by (5.2) will not blow up in finite time.

5.3. Numerical results: Dead core phenomenon and similarity solution. We finally aim at illustrating our approach's outcome on two test cases from the literature, each describing a typical phenomenon for (1.3): the first one is the appearance of the so-called dead core, which corresponds to film rupture (see section 9 in [34] and [21]); the second is the spreading of the source-type solution already studied in [16, 29].

We first consider the following initial data, taken from [6, 34]:

$$u_0(x) = 0.8 - \cos(\pi x) + 0.25\cos(2\pi x), \qquad x\in(-2,2). \tag{5.5}$$

Despite the fact that the authors of [34] consider $a(u)=\sqrt{u}$, we obtained dead core evidence around time $t\simeq 0.003$ as shown in Figure 4; initial data are plotted for comparison. The parameters used for this run are $\Delta x = 2^{-7}$ and $\varepsilon = 0.002$, and Δt is computed from (5.3). Observe in particular the loss of regularity when passing from $t=0.002$ to $t=0.0035$. There is no clear touchdown onto the x-axis, as our scheme is endowed with an error in $\varepsilon>0$ from the very beginning; left apart are the errors coming from the discretization in $\Delta t, \Delta x$.

The second case of interest is the simulation of a droplet's spreading, rendered through a similarity solution which is only $C^1(\mathbb{R})$; the following formula is (partially) taken from [29]:

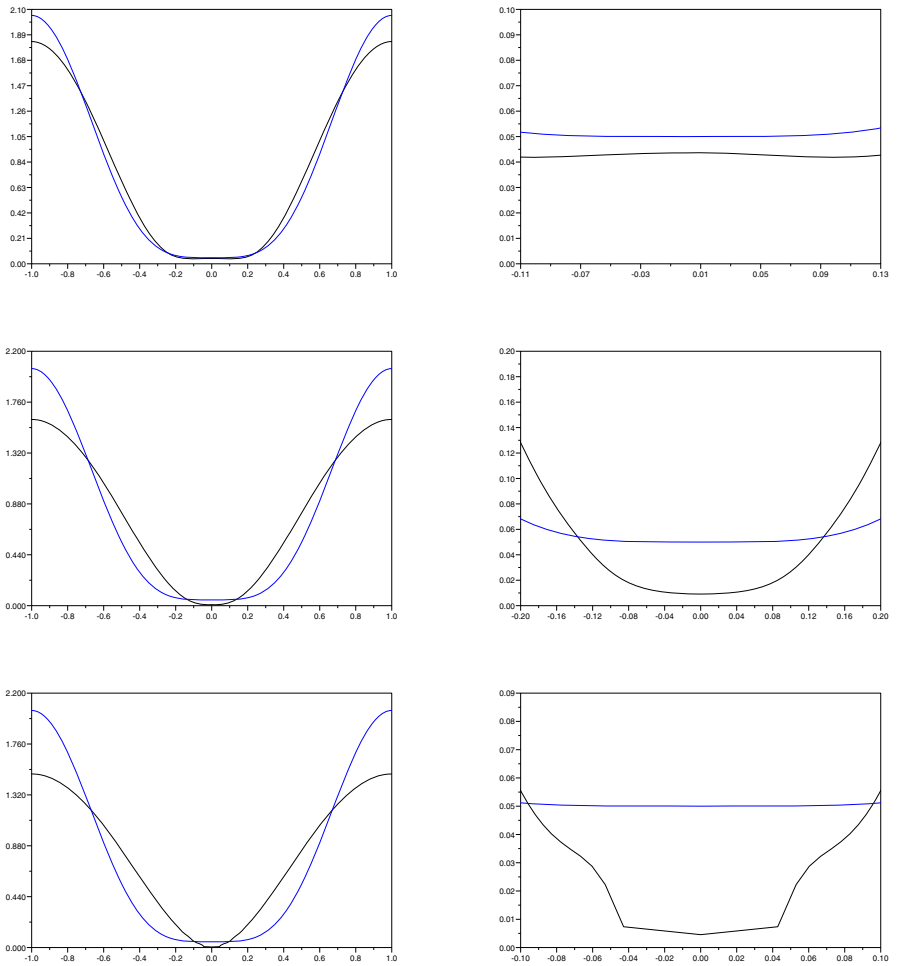

FIG. 4. *Evolution of the dead core for initial data* (5.5) *at times* $t = 0.001, 0.002, 0.0035$ (*top to bottom*).

(5.6)

$$S(t,x) = \frac{1}{24(5t+\tau)^{\frac{1}{5}}} \max\left[0, \left(\omega^2 - \frac{x^2}{(5t+\tau)^{\frac{2}{5}}}\right)^2\right], \qquad u_0(x) = \frac{S(0,x)}{\|S(0,.)\|_{L^1(\mathbb{R})}}.$$

The parameters used here are $\Delta x = 2^{-8}$, $\varepsilon = 0.03$, $\omega = 2$, and $\tau = 0.5$, and we iterate up to time $t = 0.11$; see Figure 5. The main difference with the preceding case is that the rendering of our scheme (5.2) shows oscillations (which decay with ε): this comes from the loss of regularity at the vanishing points of the approximate solution. We note in passing that oscillations occurred also for [29] and [34], where a postprocessing has been implemented to plot only selected points (see [34, p. 550]). From our CFL condition (5.3), there is clearly a tradeoff between quality of rendering and CPU time for such a simulation. We plotted the initial data and the exact value of the source-type profile for the sake of completeness; an evolution of the temperature is also shown.

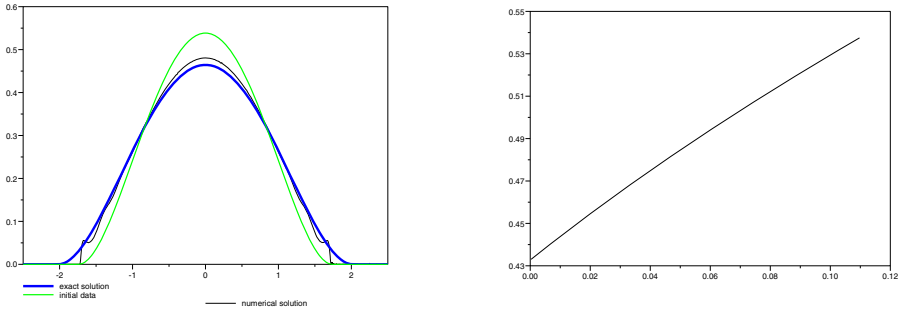

FIG. 5. *Spreading of the similarity solution* (5.6) *at time* $t = 0.11$ *with* $\tau = 0.5$ (*left*) *and evolution of its temperature* $t \mapsto \theta(t)$ (*right*).

. . . . 2. From the computations in section 5.1, one could formally extend the present approach to mobilities $a(u) \neq u$. In this direction, (5.1) would modify like

$$\partial_t X(t,\varrho) - a\left(\frac{1}{\partial_\varrho X}\right)\partial_\varrho X(t,\varrho)\int_0^1 \Gamma_\varepsilon'''(X(t,\varrho)-X(t,\varrho')).d\varrho' = 0$$

and the numerical scheme (5.2), with obvious notation, like

$$X_k^{n+1} = X_k^n + \tilde{a}\left(\frac{\delta\varrho_{k+\frac{1}{2}}}{\delta X^n_{k+\frac{1}{2}}}, \frac{\delta\varrho_{k-\frac{1}{2}}}{\delta X^n_{k-\frac{1}{2}}}\right)\Delta t \sum_{k'\in\mathcal{K}} |C_{k'}|\Gamma_\varepsilon'''(X_k^n - X_{k'}^n).$$

Hence the design of a discrete mobility $\tilde{a} \geq 0$ which could maintain monotonicity and energy estimates has to be tackled (as in [34]).

6. An efficient Fourier scheme for general thin-film equations. As pointed out in Remark 2, the preceding approach cannot be extended to general mobilities $a(u) = u^p$ in a straightforward manner. To partially fix this drawback, we wish to propose here a general way to build schemes for (1.3), based on repeated use of `fft` routines. However, we have been unable to establish any rigorous bound on this class of approximate solutions; thus we just mention it here. Future work might be dedicated to these matters.

We assume solutions of (1.3) endowed with a $H^1(\mathbb{R})$ regularity in the space variable (see [16]); hence we introduce their Fourier transform which we shall denote $\hat{u}(t,\xi)$ for $\xi \in \mathbb{R}$. Obviously, there holds that $\partial_t\hat{u}(t,\xi) = -i\xi\widehat{a(u)\partial_{xxx}u}$. Our strategy is based on the idea of computing correctly the nonlinear term relying on the unknown's smoothness. By repeated integrations by parts, one derives the following equality:

$$\widehat{a(u)\partial_{xxx}u}(t,\xi) = -i\xi\int_{\mathbb{R}}\left(A(\partial_x u) - 2\partial_x u\partial_x a(u) - \xi^2 A(u)\right)\exp(-ix\xi).dx,$$

where, for $a(u) = u^p$, $A(u) = \frac{u^{p+1}}{p+1}$. This leads to the general expression:

(6.1)
$$\partial_t\hat{u}(t,\xi) + \xi^2\left\{B\widehat{(u,\partial_x u)}(t,\xi) + \xi^2\widehat{A(u)}(t,\xi)\right\} = 0, \quad B(u,\partial_x u) = p(\partial_x u)^2u^{p-1} + A(\partial_x u).$$

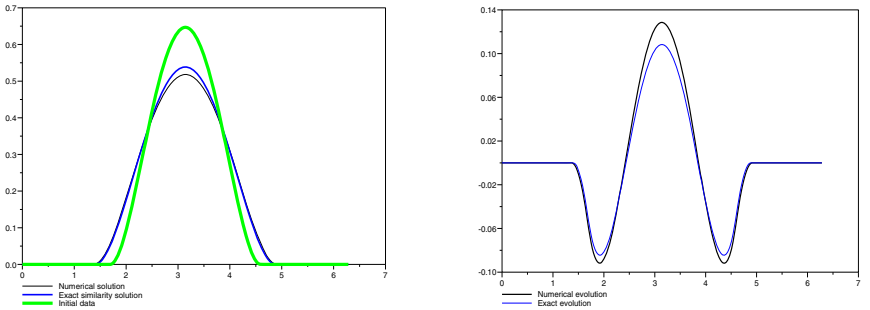

FIG. 6. *Similarity solution* (5.6) *at time* $t = 0.06$ *with* (6.2), $\tau = 0.2$ (*left*); *difference with initial data for exact solution and numerical* (*right*).

The Hele–Shaw cell corresponding to $p = 1$ is actually a quite particular case, as (6.1) simplifies and boils down to[1]

$$\partial_t \hat{u}(t,\xi) + \xi^2 \left\{ \frac{3}{2} \widehat{|\partial_x u|^2}(t,\xi) + \frac{\xi^2}{2} \widehat{|u|^2}(t,\xi) \right\} = 0. \tag{6.2}$$

It is easy to implement both (6.1) and (6.2) using, e.g., the SCILAB package. The derivative $|\partial_x u|^2$ is computed via Fourier transform, too; this has the advantage of suppressing the wide-stencil problem inherent to (1.3). Indeed, both approaches in [21, 34] suffer from it. Moreover, we observed that (6.2) does not ask for an implicit time integrator; like all the schemes proposed in this paper, it can be treated explicitly, thus keeping the computational cost very low. A last observation is that [illegible] that the CFL condition for (6.2) is linear, similar to $\Delta t \leq \Delta x/20^3$ instead of $\Delta t = O(\Delta x^4)$ for finite differences; the factor 20 has been found experimentally, and we cannot give any rigorous explanation of it. It is necessary to filter spurious oscillations when computing derivatives; a standard Gaussian filter has been used there.

As a numerical validation, we selected again the similarity solution (5.6) with the same parameters, except a lower value of τ, and 256 discretization points in space (this asks for $\Delta t = 2.10^{-6}$). The results are displayed in Figure 6. One observes that despite a lower space resolution, the approximate solution is better than the one in Figure 5, as it does not show any oscillations at its tails. The speed of propagation is also correct. There is a particular structure associated with the differential equation (6.2); we present some computations on this in Appendix C. For the sake of completeness, we also include numerical results on a test case proposed in [21]: it is a Lipschitz initial datum, $u_0(x) = 0.1 \max(0, \pi - 2|\pi - x|)$, for $x \in [0, 2\pi]$. This highlights the great importance of the exponent p in the dynamics of (1.3) since, for $p = 1$, it develops instantaneously a zero-angle contact on each side, whereas for $p = 4$, the support does not spread [illegible], and convergence onto a parabolic profile is observed. Both features are successfully rendered by our Fourier approach (6.1), as can be seen in Figure 7. Similar parameters have been used, and the scheme is fully explicit in time.

7. Conclusion and outlook. We have proposed in this paper to work out a rather wide class of 1D nonlinear diffusion equations arising from physics modeling by using numerical techniques borrowed from mass transportation theory [32]. In cases it applies to, this approach generally allows for the derivation of simple schemes and

[1] This has to do with Theorem 1, Case 2 in [6].

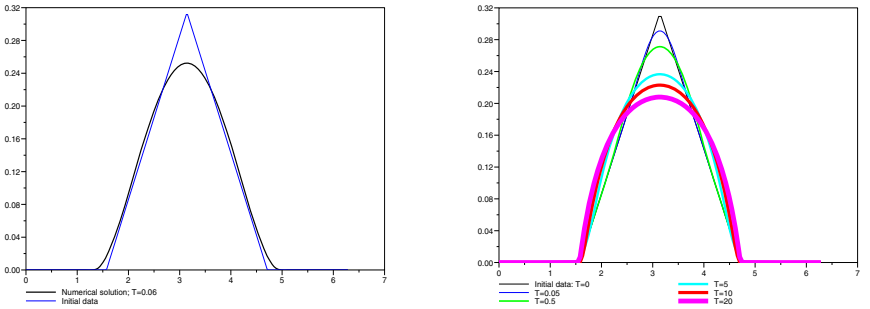

FIG. 7. *Evolution of Lipschitz initial data for $a(u) = |u|$ (left) and $a(u) = |u|^4$ (right).*

short proofs. Similar techniques could be applied in other areas of application, e.g., the so-called flashing ratchet [23]. However, several questions remain open; among them lies the design of an efficient strategy for the simulation of the full dissipative Boltzmann equation in the space t, x, v (see, however, [26]). The situation for the general thin-film equation is even more challenging; especially, the case $a(u) = u^3$ is very much of interest from the physics perspective (see again [25]). For this case, $p = 3$ and (6.1) reads as

$$\partial_t \hat{u}(t,\xi) + \xi^2 \left\{ \frac{3}{2} \widehat{|\partial_x u^2|^2}(t,\xi) + \frac{1}{4} \widehat{|\partial_x u|^4}(t,\xi) + \frac{\xi^2}{4} \widehat{|u|^4}(t,\xi) \right\} = 0.$$

Appendix A. Proof of Theorem 2.1. We consider two possible solutions f, g and assume that as densities they satisfy $\int_{\mathbb{R}} f(t,v).dv \equiv 1$ and $\int_{\mathbb{R}} vf(t,v).dv \equiv 0$. Then we insert (2.5) in the following expression to derive

$$\begin{aligned} \frac{d}{dt}\int_0^1 |V(t,\varrho)-W(t,\varrho)|^2.d\varrho &= 2\int_0^1 \partial_t (V(t,\varrho)-W(t,\varrho))(V(t,\varrho)-W(t,\varrho)).d\varrho \\ &= -2\int_{(0,1)^2} \big(\mathcal{I}'(V(t,\varrho)-V(t,p))-\mathcal{I}'(W(t,\varrho)-W(t,p))\big) \\ &\quad \times (V(t,\varrho)-W(t,\varrho)).dp.d\varrho. \end{aligned}$$

At this point, it is useful to recall from [24] that $\int_{\mathbb{R}} (v-w) d\mu(v,w) = 0$ for all density μ admitting f and g as marginals. This implies that $\int_0^1 V(t,\varrho) - W(t,\varrho).d\varrho = 0$; hence,

$$V(t,\varrho) - W(t,\varrho) = \int_0^1 (V(t,\varrho) - V(t,q)) - (W(t,\varrho) - W(t,q)).dq.$$

This is to be plugged into the previous equality in order to derive

$$\begin{aligned} &\frac{d}{dt}\int_0^1 |V(t,\varrho) - W(t,\varrho)|^2.d\varrho \\ &\quad = -2\int_0^1 \left(\int_0^1 \mathcal{I}'(V(t,\varrho) - V(t,p)) - \mathcal{I}'(W(t,\varrho) - W(t,p)).dp \right) \\ &\qquad \times \left(\int_0^1 (V(t,\varrho) - V(t,q)) - (W(t,\varrho) - W(t,q)).dq \right).d\varrho. \end{aligned}$$

Now the trick is to observe that the roles of p and ϱ are symmetric; thus we can exchange them in the second integral part. The integral rewrites as

$$\frac{d}{dt}\int_0^1 |V(t,\varrho)-W(t,\varrho)|^2.d\varrho = 2\int_{(0,1)^3} \big(\mathcal{I}'(V(t,p)-V(t,\varrho))-\mathcal{I}'(W(t,p)-W(t,\varrho))\big) \times\big((V(t,p)-V(t,q))-(W(t,p)-W(t,q))\big).d\varrho.dp.dq.$$

The sign changes because $\mathcal{I}'$ is odd. At this point, one computes half the difference of the preceding expressions in order to make the q terms disappear. All this boils down to

$$\frac{d}{dt}\int_0^1 |V(t,\varrho)-W(t,\varrho)|^2.d\varrho = -\int_{(0,1)^2} \big((V(t,\varrho)-V(t,p))-(W(t,\varrho)-W(t,p))\big) \times\big(\mathcal{I}'(V(t,\varrho)-V(t,p))-\mathcal{I}'(W(t,\varrho)-W(t,p))\big).dp.d\varrho \le 0,$$

since $\mathcal{I}'$ is nondecreasing. Finally, we reach the contraction estimate which has been first proved in [24] for special potentials.

Appendix B. Proof of Theorem 4.1. We follow the same idea while aiming at computing $\frac{d}{dt}\int_0^1 |V(t,\varrho)-W(t,\varrho)|^2.d\varrho$ as in Appendix A. Two terms appear on the right-hand side; the first one corresponds to the friction part and is to be treated exactly as in Appendix A. For the second one, it is enough to observe that

$$\begin{aligned} &-\int_0^1 (V(t,\varrho)-W(t,\varrho))\partial_\varrho\left(\frac{1}{\partial_\varrho V(t,\varrho}-\frac{1}{\partial_\varrho W(t,\varrho)}\right).d\varrho \\ &=\int_0^1 (\partial_\varrho V(t,\varrho)-\partial_\varrho W(t,\varrho))\left(\frac{1}{\partial_\varrho V(t,\varrho)}-\frac{1}{\partial_\varrho W(t,\varrho)}\right).d\varrho \le 0 \end{aligned}$$

by monotonicity of the function $v\mapsto 1/v$. The boundary terms are zero thanks to

$$\frac{1}{\partial_\varrho V(t,\varrho)} = f(t,V(t,\varrho)) = 0 \quad \text{for } \varrho = 0,1.$$

Appendix C. The structure of (6.2). It is interesting to rewrite in full detail (6.2):

$$\partial_t\hat{u}(t,\xi) = -\frac{\xi^2}{8\pi^2}\int_{\mathbb{R}} \exp(-ix\xi)\Big\{3\Big(\int_{\mathbb{R}} i\eta\hat{u}(t,\eta)\exp(ix\eta).d\eta\Big)^2 + \xi^2\Big(\int_{\mathbb{R}}\hat{u}(t,\eta)\exp(ix\eta).d\eta\Big)^2\Big\}.dx.$$

It trivially yields the conservation of mass since $\partial_t\hat{u}(t,0)=0$. The quantities between parentheses belong to $\mathbb{R}$. We use the fact that $a^2+b^2=(a+ib)(a-ib)$ and derive, after a simple change of variables,

$$\partial_t\hat{u}(t,\xi) = -\frac{3\xi^2}{8\pi^2}\int_{\mathbb{R}} \exp(-ix\xi)\Big(\int_{\mathbb{R}} i\eta\hat{u}\left(t,\eta-\frac{\xi}{\sqrt{3}}\right)\exp(ix\eta).d\eta\Big) \times\Big(\int_{\mathbb{R}} i\eta\hat{u}\left(t,\eta+\frac{\xi}{\sqrt{3}}\right)\exp(ix\eta).d\eta\Big).dx.$$

We can easily see that the terms between parentheses are now each other's complex conjugate since they read, e.g., as

$$M(x,\xi) \stackrel{def}{=} \int_{\mathbb{R}} i\eta\hat{u}\left(t,\eta+\frac{\xi}{\sqrt{3}}\right)\exp(ix\eta).d\eta$$
$$= \int_{\mathbb{R}^+} i\eta\left[\hat{u}\left(t,\eta+\frac{\xi}{\sqrt{3}}\right)\exp(ix\eta) - \overline{\hat{u}\left(t,\eta-\frac{\xi}{\sqrt{3}}\right)\exp(ix\eta)}\right].d\eta,$$

where we have used that u being real, $\hat{u}(t,-\xi) = \overline{\hat{u}(t,\xi)}$ for all ξ. Moreover, the quantity appearing in the expression of $\partial_t\hat{u}(t,\xi)$, $\xi \mapsto M(x,\xi)\overline{M(x,\xi)}$, is an even function for any value of x. Using this while performing a backward Fourier transform leads us to a simple expression for $\partial_t u(t,x)$,

$$\partial_t u(t,x) + \frac{1}{32\pi^3}\int_{\mathbb{R}^2}\xi^2\cos((y-x)\xi)M(x,\xi)\overline{M(x,\xi)}.dy.d\xi = 0,$$

which turns out to belong to $\mathbb{R}$. Hence the whole computation is coherent. This highlights a convolution structure inside the Hele–Shaw equation since one could rewrite it under the form

$$\partial_t u(t,x) + \frac{1}{32\pi^3}\int_{\mathbb{R}^2}\xi^2\big(M(.,\xi)\overline{M(.,\xi)} * \cos(\xi x)\big).d\xi = 0.$$

Acknowledgments. Part of this research was conducted in the Mathematics Department of the Università di Pavia, whose hospitality is acknowledged. The authors wish to thank Prof. J. A. Carrillo for having drawn their attention to the present problem.

ACCURACY PROPERTIES OF THE WAVE-RAY MULTIGRID ALGORITHM FOR HELMHOLTZ EQUATIONS*

IRENE LIVSHITS† AND ACHI BRANDT‡

Abstract. Helmholtz equations with their highly oscillatory solutions play an important role in physics and engineering. These equations present the main computational difficulties typical to acoustic, electromagnetic, and other wave problems. They are often accompanied by radiation boundary conditions and are considered on infinite domains. Solving them numerically using standard procedures, including multigrid, is too expensive. The wave-ray multigrid algorithm efficiently solves the Helmholtz equations and naturally incorporates the radiation boundary conditions. Important accuracy properties of the wave-ray solver are discussed in this paper.

Using various mode analyses, we show that, with the right choice of parameters, this algorithm can obtain an approximation to the differential solution with accuracy that equals the accuracy of the target grid discretization. Moreover, the boundary conditions can be introduced with any desired accuracy. Our theoretical conclusions are confirmed by numerical experiments.

Key words. Helmholtz equations, accuracy, multigrid, wave-ray

1. Introduction.

These studies are aimed at constructing fast and accurate numerical algorithms for the Helmholtz equation

$$\Delta u(x,y) + k^2 u(x,y) = f(x,y), \qquad (x,y) \in \mathbf{R}^2, \tag{1.1}$$

with the radiation boundary conditions. Our goal is to approximate the solution of (1.1) on a finite domain Ω of diameter d. We primarily consider domains with a d that satisfies $kd \gg 1$. This makes the problem highly indefinite and hard to solve.

Although the solution process we describe can solve more general problems, our analysis here is focused on the model problem (1.1) when the wave number k is constant, $f(x,y)$ has compact support $\Omega_f \subset \mathbf{R}^2$, and employed is the second-order discretization of (1.1),

$$(L^h u^h)_{i,j} = \frac{u^h_{i-1,j} + u^h_{i+1,j} + u^h_{i,j-1} + u^h_{i,j+1} - 4u^h_{i,j}}{h^2} + k^2 u^h_{i,j} = f_{i,j}, \tag{1.2}$$

where $u^h_{i,j}$ approximates $u(x_i, y_j)$ and $f_{i,j} \approx f(x_i, y_j)$, $i = 0, \ldots, N_x$, $j = 0, \ldots, N_y$, $\Omega_f \subset \Omega$. (Helmholtz equations (1.1) with radiation boundary conditions are usually considered on infinite domains. Therefore we assume, without a loss of generality, that Ω is considerably wider than Ω_f.)

For simplicity, Ω is chosen to be the square

$$\Omega = \{(x, y), -d/2 \le x \le d/2, -d/2 \le y \le d/2\}, \tag{1.3}$$

and hence $N_x = N_y = N$, $x_i = -d/2 + ih$, and $y_j = -d/2 + jh$.

For $kd \gg 1$, the cost of solving (1.2) can be overwhelming. To provide an accurate approximation to the differential solutions, discretization of (1.1) must employ many, actually more than $O(k^3d^3)$, grid points. Moreover, to converge to the numerical solution, a conventional solver should employ many, actually more than $O(k^6d^6)$, sweeps of a slow (e.g., Kaczmarz) relaxation scheme, since faster schemes diverge for some components. Thus the total work grows at least proportionally to $O(k^9d^9)$.

The above provides motivation for the use of multigrid methods [11], [13], [15], [17]. However, standard multigrid procedures are not efficient for the highly indefinite Helmholtz equations. This is because there is a range of Fourier error components $e^{i(\omega_1 x+\omega_2 y)}$ that the standard multigrid cycle cannot reduce efficiently. Those are the components with $\omega_1^2 + \omega_2^2 \approx k^2$; we call them [illegible]. On fine grids their amplitudes are much larger than the amplitudes of the corresponding normalized residuals, making them almost invisible to any local processing. Hence, they are only very slowly reduced by relaxation. On the other hand, unlike regular smooth components, these have poor approximations on coarse grids, which, therefore, cannot serve to correct the finer-grid solutions.

As a result, the characteristic components need a special multigrid treatment, and this is the basis of the wave-ray algorithm. Its fast convergence was the subject of [9]. There it was shown that the algorithm has high multigrid efficiency at a cost comparable to the cost of solving a Poisson equation with the standard cycle.

In the present paper we study the accuracy aspects of the wave-ray algorithm. The goal of this algorithm, employing the second-order discretization, is to provide accurate $O(h^2)$ approximation to the differential solution while costing only $O(h^{-2})$ computer operations. This is not as straightforward as for definite elliptic systems, both due to the phase errors and because the radiation boundary conditions need to be brought accurately from the coarsest level of the algorithm to the target level.

Obviously, by choosing a smaller finest grid mesh-size h, we would like to obtain a more accurate solution, i.e., one that is closer to the solution of differential equation (1.1). Moreover, since the second-order discretization scheme is employed in (1.2), the accuracy is expected to improve as $O(h^2)$. In the wave-ray algorithm, however, the following scenario is possible: after choosing a smaller h, the approximation error, the difference between the differential and the wave-ray solution, is almost unreduced. This property, not typical for the standard multigrid methods, occurs because of the extended role of the coarse grids in the wave-ray algorithm. This role is different because here the coarse grids do not produce just a correction to smooth error components, but the principal components of the solution itself. Moreover, these components are almost invisible on other grids (due to their small residuals) and therefore are not updated there. In addition, the radiation boundary conditions are introduced on the coarsest ray grid, and they are not corrected on any finer grids (carrying on interpolation errors). Therefore, processing on coarse ray grids can cause significant errors that overshadow the discretization error on the finest grid, governed by the finest mesh-size.

In this paper we discuss different factors and the errors they cause that can lead to such [illegible]. We then suggest ways to deal with them. The ultimate goal is to minimize the effect of these errors on the total error to the level

of becoming negligible compared to the finest grid discretization error, which then regains its principal error term status (as in traditional multigrid solvers).

In this study we do not assume any restriction on the finest grid mesh-size, and therefore we avoid the difficult task of dealing with the effect of pollution there (the work on fine grid pollution can be found, for example, in [4], [12], [14]). The problem of pollution in our algorithm appears on the coarse ray grids, where it is treated by properly choosing different parameters of the algorithm. These are discussed in detail.

The outline of the paper is as follows: We start with a description of the algorithm. Its efficiency is achieved by using two types of solution representation: wave and ray. (This gave the algorithm its name `wave-ray`. The grids on which the wave and the ray equations are discretized are called the [illegible] and the [illegible], respectively.) This technique can cause inaccuracies, unless the algorithmic parameters are properly chosen.

In section 2 we discuss discretization errors and their influence on the choice of the finest mesh-sizes in the wave and in the ray discretization. Unlike in standard multigrid procedures, coarse ray grids often (away from Ω_f) provide more accurate approximation to the differential solution than the finer ray or wave representations.

In section 3 our subject is the approximation of the differential problem on an infinite domain by a solver which employs finite domains on many levels. In particular, we deal with the question of how to impose the radiation boundary conditions.

We conclude the paper with numerical results and discuss their agreement with our theoretical conclusions.

1.1. Wave-ray algorithm for Helmholtz equations. First, we define the circle of [illegible] Fourier components to be the subset of characteristics components with frequencies $\omega_1^2 + \omega_2^2 = k^2$. They satisfy (1.1) with $f \equiv 0$ and have a significant role in the algorithm. Among all principal components we consider a finite set of [illegible] principal components uniformly spaced on the principal circle. We denote them (k_1^ℓ, k_2^ℓ), $\ell = 1, \ldots, L$; L is the number of lattice components. We use the word `lattice` to describe the discretization of the principal circle and to distinguish it from `grids` in the physical space. For the principal lattice component $e^{i(k_1^\ell x + k_2^\ell y)}$, we define a rotated Cartesian coordinate system (ξ^ℓ, η^ℓ), with ξ^ℓ being parallel to (k_1^ℓ, k_2^ℓ), the [illegible] direction.

Each characteristic component can be represented as a product of a lattice principal component and a smooth envelope function. Hence, a general representation of the error that cannot be efficiently reduced by a regular multigrid cycle can be given by

$$v(x,y) = \sum_{\ell=1}^{L} \hat{v}^\ell(x,y) e^{i(k_1^\ell x + k_2^\ell y)}, \tag{1.4}$$

where $\hat{v}^\ell(x,y)$ are smooth functions. Note that the functions $\hat{v}^\ell(x,y)$ are not uniquely defined: Fourier components of v with frequencies between two lattice points can be assigned to these points with arbitrary weights, yet still yielding the desired smoothness. Considered in the corresponding rotated coordinates, the scale of smoothness of $\hat{v}^\ell(x,y)$ is $O(L^2/k)$ in the propagation direction ξ^ℓ, and $O(L/k)$ in the η^ℓ direction. (In other words, the function $v(x,y)$ essentially consists of Fourier components with frequencies in a ring of width $O(k/L^2)$ around the principal circle.)

We call the functions $\hat{v}^\ell(x,y)$ the [illegible]; the equations we derive for them, the [illegible]. The residual ray equation for $\hat{v}^\ell(x,y)$ is

$$\Delta \hat{v}^\ell(x,y) + 2ik_1^\ell \frac{\partial}{\partial x}\hat{v}^\ell(x,y) + 2ik_2^\ell \frac{\partial}{\partial y}\hat{v}^\ell(x,y) = \hat{r}^\ell(x,y). \tag{1.5}$$

This results directly from the Helmholtz equation, with $\hat{r}^\ell(x,y)$ being the smooth weights in the ray representation of the wave residual function:

$$Lv(x,y) = r(x,y) = \sum_{\ell=1}^{L} \hat{r}^\ell(x,y) e^{i(k_1^\ell x + k_2^\ell y)}. \tag{1.6}$$

Each principal component $e^{i(k_1^\ell x + k_2^\ell y)}$ in its rotated coordinates has the form $e^{ik\xi^\ell}$, and thus (1.5) can be simplified there to

$$\Delta \hat{v}^\ell(\xi^\ell,\eta^\ell) + 2ik\frac{\partial}{\partial_{\xi^\ell}}\hat{v}^\ell(\xi^\ell,\eta^\ell) = \hat{r}^\ell(\xi^\ell,\eta^\ell), \quad (\xi^\ell,\eta^\ell) \in \hat{\Omega}^\ell. \tag{1.7}$$

Since the problem is defined over the entire space $(x,y) \in \mathbf{R^2}$, we have to define a large enough finite computational domain $\hat{\Omega}^\ell$ over which $\hat{v}^\ell$ will be computed. For convenience we choose $\hat{\Omega}^\ell$ to be rectangular,

$$\hat{\Omega}^\ell = \{(\xi^\ell,\eta^\ell) : \xi_0^\ell \le \xi^\ell \le \xi_1^\ell, -\eta_0^\ell \le \eta^\ell \le \eta_0^\ell\}, \tag{1.8}$$

where appropriate values for ξ_0^ℓ, ξ_1^ℓ, and η_0^ℓ will be a subject of the analysis below. We call the set of points (ξ^ℓ,η^ℓ) on the lines $\xi^\ell = \xi_0^\ell$, $\xi^\ell = \xi_1^\ell$, and $\eta^\ell = \pm\eta_0^\ell$ the `entrance`, the `exit`, and the `side` boundaries, respectively.

(Each equation (1.7) in the rotated coordinates allows the most aggressive coarsening ratio: by the factor of four (instead of two) in the propagation direction. The use of the standard Cartesian (x,y) coordinates is also possible. Moreover, it too allows a special coarsening for at least some components: for instance, for $L = 8$, one half of the components propagate in either x or y direction, and therefore for them the same coarsening can be applied. For a higher value of L, for most of the components their propagation direction is closer to either x or y, and therefore some stronger coarsening can be applied there, with the factors of three or four, depending on the component in question and the accuracy requirements.)

The error for which the usual multigrid cycle is not effective can efficiently be reduced by a multigrid procedure which on coarse grids represents the smooth ray functions $\hat{v}^\ell(x,y)$ rather than the nonsmooth function $v(x,y)$ itself. The coarser the grid, the larger the scale of smoothness of $\hat{v}^\ell(x,y)$ represented on it. This requires a larger L, i.e., a finer lattice of principal components.

Let the ray levels be enumerated by $n = 1,\dots,N$ so that $n = N$ is the level with the coarsest grid and the finest lattice. For the nth level, the principal lattice is then composed of the frequencies

$$(k_1^{n,\ell}, k_2^{n,\ell}) = (k\cos\theta^{n,\ell}, k\sin\theta^{n,\ell}), \qquad \ell = 1,\dots,L^n, \tag{1.9}$$

where $\theta^{n,\ell} = 2\pi\ell/L^n$; the corresponding ray functions are denoted $\hat{v}^{n,\ell}$. At each level n, each ray function $\hat{v}^{n,\ell}(x,y)$ in its rotated coordinates $(\xi^{n,\ell},\eta^{n,\ell})$ is discretized on a uniform grid with mesh-sizes $h_\xi^n = O((L^n)^2/k)$ and $h_\eta^n = O(L^n/k)$. Our actual choice of parameters, based on a careful mode analysis, has been

$$L^n = 2^{n+2}, \qquad h_\xi^n = C(L^n)^2/(32k), \qquad h_\eta^n = C(L^n)/(8k), \tag{1.10}$$

where typically $1.25 \le C \le 2.5$.

The wave-ray cycle is composed of two parts. The first part, the wave subcycle, is a standard multigrid cycle applied to (1.2). It proceeds from the finest wave grid to

the coarsest; there is actually no need to go to grids with mesh-size coarser than $4/k$ (this is because for such h the system (1.2) becomes so strongly diagonal dominant that the Gauss–Seidel relaxation converges very fast). Few Kaczmarz or Gauss–Seidel relaxation sweeps are performed on each wave level except for the ones with mesh-sizes $h \approx 2/k$. Relaxation on the coarsest grid reduces the smoothest part of the error, while relaxation on the fine levels reduce its high-frequency components. The wave subcycle does not change the characteristics components effectively, and consequently it leaves an error of the type (1.4). Also it does not treat the radiation boundary conditions, which are associated only with principal components and, therefore, ray representation. In this part of the algorithm the sole role of the coarse grids is to produce smooth noncharacteristic corrections to the finer grid approximations in the interior of the finer grid computational domains.

The second part of the algorithm starts with a ray subcycle, which is needed to reduce characteristic errors and to impose the radiation boundary conditions. First, the wave residual $r(x, y)$ is calculated on some sufficiently fine wave level with mesh-size $h = O(d^{-1/2}k^{-3/2})$—still fine enough to produce small phase errors throughout the computational domain. From this grid, the wave residual is transferred directly to the wave grid with $h \approx 1/k$. There, for each $1 \le \ell \le L^1$ this wave residual is multiplied by $e^{-i(k_1^\ell x + k_2^\ell y)}$, resulting in

$$r(x,y)e^{-i(k_1^\ell x+k_2^\ell y)} = \hat{r}^\ell(x,y) + \sum_{m\neq\ell} \hat{r}^m(x,y)e^{i(\Delta k_1^m x+\Delta k_2^m y)}, \tag{1.11}$$

where $k_j^m = k_j^{1,m}$, $\Delta k_j^m = k_j^m - k_j^\ell$, $j = 1, 2$. Notice that the first term on the right-hand side (RHS) of (1.11) is very smooth compared to each term of the sum. The next step is to approximate each $\hat{r}^\ell$ in the rotated coordinates $(\xi^\ell, \eta^\ell) = (\xi^{1,\ell}, \eta^{1,\ell})$. For this purpose a procedure called [illegible] is applied, denoted

$$\hat{r}^\ell = \hat{r}^{1,\ell} = W_{1,\ell}(r(x,y)e^{-i(k_1^\ell x+k_2^\ell y)}), \quad \ell = 1, \dots, L^1. \tag{1.12}$$

Here $W_{1,\ell}$ is a product of two weighting operators that accurately transfer smooth components from the wave grid with mesh-size $h \approx 1/k$ first to an intermediate ray grid with mesh-size $(h_\xi, h_\eta) \approx (2/k, 2/k)$, and then to the ray grid $(\xi^{1,\ell}, \eta^{1,\ell})$ with mesh-size $(h_\xi^1, h_\eta^1) \approx (4/k, 2/k)$. The operators are designed to almost annihilate components that are highly oscillatory on the current scale.

It is important to note here that the entire solver employs the full approximation scheme (FAS; see, e.g., [8]). This means that, although the equations at each level are basically equations for the correction $\hat{v}^{n,\ell}$, driven by the next-finer-level residuals, as in (1.7), they are modified (by adding an appropriate term to the RHS) so that their solution always represents the full approximation $\hat{u}^{n,\ell} = \hat{v}^{n,\ell} + \tilde{u}^{n,\ell}$, where $\tilde{u}^{n,\ell}$ is an approximation to $\hat{u}^{n,\ell}$. The algorithm employs the value of $\hat{u}^{n,\ell}$ at the end of the previous cycle, as the first approximation to $\tilde{u}^{n,\ell}$. Such approximation satisfies the radiation boundary condition, and it does not require an update from the wave part of the cycle, since characteristic components are not changed there. At the first cycle, $\tilde{u}^{n,\ell}$ satisfies the radiation boundary conditions at the entrance and side boundaries, and it is zero elsewhere.

The FAS RHS is calculated by

$$\hat{f}^{n,\ell} = \hat{r}^{n,\ell} + \hat{L}^n \tilde{u}^{n,\ell}. \tag{1.13}$$

The FAS is chosen to enable the imposition of the radiation boundary conditions at the coarsest ray level.

As the model boundary conditions, we have chosen the Dirichlet radiation boundary conditions, which can be formulated as follows: for each propagation direction ξ, the amplitude $\hat{u}_0$ of the principal component $e^{ik\xi}$ as it propagates from infinity into Ω is given. This amplitude, of course, gives the initial values of the corresponding ray function at the entering boundaries. These boundary conditions are very suitable for our investigation, since they allow explicit analysis of different error types on the ray grids. Similar to the Sommerfeld radiation boundary conditions, these Dirichlet boundary conditions control the size of entering principal components. No boundary conditions are imposed for the exiting waves, which are simply allowed to leave the domain (without causing any reflection). The rest of the solution is uniquely defined by the RHS.

After the discrete ray equations are relaxed on the finest ray level ($n = 1$) and the new solution approximations are calculated, the ray subcycle proceeds (if necessary) to increasingly coarser ray levels ($n = 2, \dots, N$). This includes recursive derivation of ray equations on increasingly coarser ray grids, having increasingly finer lattices (larger $L = L^n$). The equations on each grid have the ray form (1.7), discretized; they are the result of a separation process applied to the residuals of the next finer neighboring grids. Namely, to calculate $\hat{r}^{n,\ell}$ for odd ℓ, the corresponding ray residual function from the finer grid is used:

$$\hat{r}^{n,\ell} = W^{n,\ell}_{n-1,(\ell+1)/2} \hat{r}^{n-1,(\ell+1)/2}, \tag{1.14}$$

where here and below $W^{n,\ell}_{n-1,j}$ consists again of a product of two weighting operators, acting from the grid $(\xi^{n-1,j}, \eta^{n-1,j})$ to the target $(\xi^{n,\ell}, \eta^{n,\ell})$ designed to approximate the smooth components and annihilate high frequencies on the considered scale.

For even ℓ, $\hat{r}^{n,\ell}$ is calculated from two finer grid residuals:

$$\begin{aligned} \hat{r}^{n,\ell} = {} & W^{n,\ell}_{n-1,\ell/2} \big(\hat{r}^{n-1,\ell/2} e^{i((k_1^{n-1,\ell/2} - k_1^{n,\ell})x + (k_2^{n-1,\ell/2} - k_2^{n,\ell})y)} \big) \\ & + W^{n,\ell}_{n-1,\ell/2+1} \big(\hat{r}^{n-1,\ell/2+1} e^{i((k_1^{n-1,\ell/2+1} - k_1^{n,\ell})x + (k_2^{n-1,\ell/2+1} - k_2^{n,\ell})y)} \big). \end{aligned} \tag{1.15}$$

The lattice count should be taken modulo L; i.e., for $\ell = L^n$ take $\ell/2+1 = L^{n-1}+1 \equiv 1 (\mathrm{mod}\, L^{n-1})$.

On the coarsest grid, $n = N$, the radiation boundary conditions are imposed, facilitated by the nearly pure ray representation at that grid, in the following way. (For the sake of explanation, we define the [illegible] as follows: if a principal component in the (ξ, η) coordinates has a frequency $k(\cos\alpha, \sin\alpha)$, then α is its inclination angle on the corresponding grid.) The radiation boundary conditions for the ray domain associated with the principal direction $(\xi^{n,\ell}, \eta^{n,\ell})$ are the Dirichlet boundary conditions for the [illegible] and the [illegible] boundaries. Each principal lattice component represents a range of principal components with inclination angles $\alpha \in [-\Delta\theta^n, \Delta\theta^n]$, $\Delta\theta^n = 2\pi/2L^n$. The values of the entering rays for all such components are summed at the entrance $\xi = \xi_0$ and the side $\eta = \pm\eta_0$ boundaries. The boundary conditions are then defined as

$$\hat{u}^{n,\ell}(\xi_0, \eta) = \int_{-\Delta\theta^n}^{\Delta\theta^n} \hat{u}_{0,\alpha} e^{i(\theta_1^\alpha \xi_0 + \theta_2^\alpha \eta)}\, d\alpha$$

at the entrance boundary, and

$$\hat{u}^{n,\ell}(\xi, -\eta_0) = \int_{0}^{\Delta\theta^n} \hat{u}_{0,\alpha} e^{i(\theta_1^\alpha \xi - \theta_2^\alpha \eta_0)}\, d\alpha$$

and

$$\hat{u}^{n,\ell}(\xi,\eta_0)=\int_{-\Delta\theta^n}^{0}\hat{u}_{0,\alpha}e^{i(\theta_1^\alpha\xi+\theta_2^\alpha\eta_0)}\,d\alpha$$

at the side boundaries. Here $\hat{u}_{0,\alpha}$ is the amplitude of the entering principal components with the inclination angle α, and $(\theta_1^\alpha,\theta_2^\alpha)=k(\cos\alpha-1,\sin\alpha)$.

The ray equations are solved there quickly by a line Gauss–Seidel relaxation. Then the boundary conditions along with corrections are interpolated through the intermediate ray grids (without any relaxation) to the finest ray grid.

Interpolation from a coarser ray grid (with a finer lattice) to the next-finer ray grid (with coarser lattice) is performed differently on the boundary of the finer grid domain and in its interior. On the boundary $\hat{\Gamma}^{n,\ell}$ of the computational domain $\hat{\Omega}^{n,\ell}$ the solution values are interpolated directly from the three neighboring coarser grids:

$$\begin{aligned}\hat{u}^{n,\ell}=&\frac{1}{2}I^{n,\ell}_{n+1,2\ell-2}\big(\hat{u}^{n+1,2\ell-2}e^{i((k_1^{n+1,2\ell-2}-k_1^{n+1,2\ell-1})x+(k_2^{n+1,2\ell-2}-k_2^{n+1,2\ell-1})y)}\big)\\&+I^{n,\ell}_{n+1,2\ell-1}\hat{u}^{n+1,2\ell-1}\\&+\frac{1}{2}I^{n,\ell}_{n+1,2\ell}\big(\hat{u}^{n+1,2\ell}e^{i((k_1^{n+1,2\ell+1}-k_1^{n+1,2\ell-1})x+(k_2^{n+1,2\ell}-k_2^{n+1,2\ell-1})y)}\big),\end{aligned}$$

where the interpolation operator $I^{n,\ell}_{n+1,j}$ interpolates from the coarser grid $\hat{\Omega}^{n+1,j}$ to the finer grid $\hat{\Omega}^{n,l}$. This interpolation of the boundary conditions is the reason for using FAS, since it requires us to approximate solutions rather than corrections on all grids.

In the interior, the solution is only [illegible] by the coarse-grid approximations:

$$\begin{aligned}\hat{u}^{n,\ell}=\hat{u}^{n,\ell}&+\frac{1}{2}I^{n,\ell}_{n+1,2\ell-2}\big(\hat{v}^{n+1,2\ell-2}e^{i((k_1^{n+1,2\ell-2}-k_1^{n+1,2\ell-1})x+(k_2^{n+1,2\ell-2}-k_2^{n+1,2\ell-1})y)}\big)\\&+I^{n,\ell}_{n+1,2\ell}\hat{v}^{n+1,2\ell}+\frac{1}{2}I^{n,\ell}_{n+1,2\ell}\big(\hat{v}^{n+1,2\ell}e^{i((k_1^{n+1,2\ell}-k_1^{n+1,2\ell-1})x+(k_2^{n+1,2\ell}-k_2^{n+1,2\ell-1})y)}\big).\end{aligned}$$

Here corrections $\hat{v}^{n+1,j}$ are given by $\hat{v}^{n+1,j}=\hat{u}^{n+1,j}-\tilde{u}^{n+1,j}$, where $\tilde{u}^{n+1,j}$ again is the value of $\hat{u}^{n+1,j}$ at the end of the previous cycle.

No relaxation is performed on the way to the finest ray grid. From there, the ray solutions (for the boundary) and the ray corrections (for the interior) are interpolated to the wave grid with $h\approx 1/k$, where they are summed as in (1.4) and used to correct the previous wave solution. Similar to the ray-to-ray interpolation, the wave correction (at the interior) and the solution values (at the boundary) are interpolated to the finer wave grids, with a small number of relaxation sweeps performed on each grid.

See the appendix below for a formal description of the entire algorithm.

2. Discretization errors. In this section we discuss how to achieve an accurate approximation to the differential solutions in the interior of the finest computational domain. We examine the pointwise approximation to the differential solutions, analyze the influence of discretization errors, and conclude that the main source of inaccuracy is the phase errors, coming from both the wave and the ray representations. In our studies we measure only the errors eventually resulting in the interior of the target finest wave grid.

2.1. Phase errors. The [illegible] error is the difference in phases of the discrete and differential waves, accumulated along their propagation path due to their different wavelengths. This error can become very significant when the solution propagates along many wavelengths.

A peculiarity of our algorithm is that, unlike common discretization schemes, in the regions where the equation is homogeneous, the coarse ray grids provide more accurate approximations to the differential solution than the finer ray, and often are better than the wave grids. The ultimate role of the fine wave grids is to resolve the RHS f at scales smaller than or just comparable to the wavelength $2\pi/k$. The details are discussed in this section.

2.1.1. Wave phase error. We define a [illegible] $e^{i(k_1^h x + k_2^h y)}$ as any one that satisfies the discrete homogeneous equations (1.2),

$$L^h e^{i(k_1^h x + k_2^h y)} = 0. \tag{2.1}$$

By Taylor expansion in (1.2) it can be shown that, for $kh \ll 1$, the value of the corresponding discrete wave number $|k^h| = \sqrt{(k_1^h)^2 + (k_2^h)^2}$ can be approximated by

$$|k^h| \approx k\left(1 + \frac{k^2h^2}{\gamma}\right), \qquad 24 \le \gamma \le 48, \tag{2.2}$$

where the exact value of γ depends on the ratio $k_1^h : k_2^h$. The accumulated value of the relative phase error (the phase error over the period $2\pi/k$) propagating through the $kd/2\pi$ wavelengths of Ω can therefore be estimated as

$$E(kd, kh) \approx kd\frac{k^2h^2}{2\pi\gamma}. \tag{2.3}$$

To provide an accurate approximation to the differential solution on the target wave grid, the finest mesh-size h should be chosen so that $E(kd, kh)$ is small:

$$E(kd, kh) \ll 1. \tag{2.4}$$

2.1.2. Ray phase error. In standard multigrid procedures the accuracy of discretization on coarse grids influences the speed of convergence of the solver rather than the accuracy of the solution. In our algorithm the ray grids serve not only to correct the characteristic error components, but also to introduce the radiation boundary conditions and to approximate the principal components invisible on the finest wave grids. Hence, the quality of the solution approximation on the ray grids needs to be addressed. (Since the discussion below is relevant for any ℓth ray function and ray operator on any nth level, we omit the superscripts ℓ and n.)

We define a [illegible] $e^{i(\theta_\xi \xi + \theta_\eta \eta)}$ as any one which satisfies

$$\hat{L}^h e^{i(\theta_\xi \xi + \theta_\eta \eta)} = 0,$$

where $\hat{L}^h$ is a second-order discretization of (1.7), given in the (ξ, η) coordinates by

$$\begin{aligned}\hat{L}^h \hat{v}_{i,j} = {} & \frac{\hat{v}_{i-1/2,j-1} + \hat{v}_{i-1/2,j+1} - 2\hat{v}_{i-1/2,j}}{2h_\eta^2} + \frac{\hat{v}_{i+1/2,j-1} + \hat{v}_{i+1/2,j+1} - 2\hat{v}_{i+1/2,j}}{2h_\eta^2} \\ & + \frac{\hat{v}_{i-3/2,j} - \hat{v}_{i-1/2,j} - \hat{v}_{i+1/2,j} + \hat{v}_{i+3/2,j}}{2h_\xi^2} + 2ik\frac{\hat{v}_{i+1/2,j} - \hat{v}_{i-1/2,j}}{h_\xi}.\end{aligned} \tag{2.5}$$

On the scale of the employed grid, the term $2ikv_\xi$ is the principal term, and its accurate (second-order) discretization is the main factor in our choice of the discrete scheme. Our operator provides an accurate short central discretization for $2ikv_\xi$, and also a second-order accuracy for the remaining terms (it employs the Crank–Nicholson scheme for $v_{\eta\eta}$). On the other hand, the standard five-point stencil for the Laplace operator would come with the long central differences for the principal term leading to a weak diagonal term.

Discretization (2.5) also allows an efficient η-line relaxation (marching from entrance to exit, solving (2.5) simultaneously for all $\hat{v}_{i,j}$ with the same j; cf. section 3.2) on the ray grids. Substitution of $e^{i(\theta_\xi \xi + \theta_\eta \eta)}$ into (2.5) gives

$$\frac{2}{h_\eta^2}\cos\left(\frac{\phi_\xi}{2}\right)\left[\cos(\phi_\eta)-1\right]-\frac{4k}{h_\xi}\sin\left(\frac{\phi_\xi}{2}\right)+\frac{1}{h_\xi^2}\left[\cos\left(\frac{3\phi_\xi}{2}\right)-\cos\left(\frac{\phi_\xi}{2}\right)\right]=0,$$

where $\phi_\xi = \theta_\xi h_\xi$ and $\phi_\eta = \theta_\eta h_\eta$. Note that the highest frequency $(\theta_\xi, \theta_\eta)$, which must be represented on each ray grid (so that any principal and characteristic component has an accurate representation on at least one of the L ray grids), is given by

$$\theta_\xi \approx k\frac{\pi^2}{2L^2}, \quad \theta_\eta \approx k\frac{\pi}{L}. \tag{2.6}$$

This is the frequency associated with the principal component at the midpoint between two neighboring lattice points. With (1.10), the arguments of sines and cosines are sufficiently small for (2.6) to be replaced by its approximation:

$$-\theta_\eta^2+\frac{1}{8}\theta_\eta^2\phi_\xi^2-2k\theta_\xi+\frac{k}{12}\theta_\xi\phi_\xi^2-\theta_\xi^2\approx 0. \tag{2.7}$$

Using (2.7), we can approximate the size of a discrete ray wave number $\hat{k}_L = (\theta_\xi + k, \theta_\eta)$,

$$|\hat{k_L}|^2 = k^2+2k\theta_\xi+\theta_\xi^2+\theta_\eta^2 \approx k^2\left(1+\frac{\theta_\eta^2\phi_\xi^2}{8k^2}+\frac{\theta_\xi\phi_\xi^2}{12k}\right), \tag{2.8}$$

or, by (1.10) and (2.6),

$$|\hat{k}_L| \approx k\left(1+\frac{\beta}{L^2}\right), \tag{2.9}$$

with $\beta \approx 0.039C^2$ and $1.25 \le C \le 2.5$. The phase error arises from the propagation of principal components emanating from the radiation boundary conditions or from the RHS source. For instance, at a distance $\hat{d}$ from the entering boundary, the phase error can be estimated as

$$E(k\hat{d}, L) \approx k\hat{d}\frac{\beta}{2\pi L^2}. \tag{2.10}$$

2.2. RHS truncation errors. The phase error is the main discretization error in approximating the homogeneous equations. To estimate those truncation errors which arise in approximating the effect of a nonhomogeneous RHS, consider an RHS $f(x, y)$, a differential solution $u(x, y)$, and an approximate difference solution $u^h(x, y)$ in Ω of the form

$$f(x,y)=\int_{\mathbf{t}}\hat{f}(\mathbf{t})e^{i(t_1x+t_2y)}d\mathbf{t}, \qquad u(x,y)=\int_{\mathbf{t}}\hat{u}(\mathbf{t})e^{i(t_1x+t_2y)}d\mathbf{t},$$

and

$$u^h(x,y) = \int_{\mathbf{t}} \hat{u}^h(\mathbf{t}) e^{i(t_1 x + t_2 y)} d\mathbf{t}.$$

For any frequency $\mathbf{t} = (t_1, t_2),\ t = |\mathbf{t}|$, the following holds:

$$\hat{u}(\mathbf{t}) = \frac{\hat{f}(\mathbf{t})}{k^2 - t^2} \tag{2.11}$$

and

$$\hat{u}^h(\mathbf{t}) \approx \frac{\hat{f}(\mathbf{t})}{k^2 - t^2(1 - 2t^2h^2/\gamma)}, \tag{2.12}$$

where γ is defined in (2.2). The difference between (2.11) and (2.12) is $O(t^2h^2)$, meaning that the finest wave mesh-size should be fine enough to resolve the highest-frequency components of f that one cares to approximate. More precisely, for $|t - k|/k \geq O(1)$, the relative error

$$E(\mathbf{t}) = \frac{|\hat{u}(\mathbf{t}) - \hat{u}^h(\mathbf{t})|}{|\hat{u}(\mathbf{t})|} \tag{2.13}$$

is small when t^2h^2 is small.

The more severe requirements on the mesh-size arise, however, from the characteristic components, where t is close to k. For $|t - k|/k = \delta \ll 1$, using (2.11)–(2.12), one can show that

$$E(\mathbf{t}) = \frac{k^2h^2(1 + O(\delta)}{\gamma\delta + k^2h^2(1 + O(\delta))} \approx \frac{k^2h^2}{\gamma\delta}. \tag{2.14}$$

For this truncation error to be small, the target mesh-size h should satisfy

$$\frac{k^2h^2}{\gamma\delta_{\min}} \ll 1, \tag{2.15}$$

where $\delta_{\min} = \min_{t=|\mathbf{t}|, \hat{u}(\mathbf{t})\neq 0} \frac{|t-k|}{k}$. The problem (1.2) is considered on a computational domain of size d and a grid with mesh-size h. Only a finite number of Fourier components is distinguished on this grid. The minimal distance between such components, in the phase space, is $2\pi/d$. Therefore, $\delta_{min} = \frac{2\pi}{kd}$, and (2.15) can be replaced by

$$kd\frac{k^2h^2}{2\pi\gamma} \ll 1. \tag{2.16}$$

Note that requirement (2.16) is identical with the condition resulting from the wave phase error. Indeed,

$$E(t) = E(kd, kh)(1 + O(\delta)). \tag{2.17}$$

We have excluded from consideration the special case of resonance, when $\hat{f}/(k^2 - t^2)$ is not integrable, which would require a different formulation in the time domain.

3. Boundary conditions. One of the possible reasons for slowness of relaxation process is inefficient introduction of boundary conditions. If done on a sufficiently fine grid, it takes many (expensive) iterations until the boundary information propagates from the boundaries into the domain. The remedy from such slowness is to use coarse grids. This, however, is not a good solution for the standard multigrid solvers applied to the Helmholtz equation, since coarse wave grids are not suitable for representing accurate solutions. Instead, the wave-ray algorithm employs its ray grids to introduce the boundary conditions. These grids are very coarse but very accurately resolve the ray functions.

In this paper we consider the Dirichlet radiation boundary conditions given by the amplitudes of the waves incoming to the computational domain from infinity. These boundary conditions are actually formulated as Dirichlet boundary conditions for the ray functions: at the coarsest ray level each entering ray is represented on the grid (or divided between two grids) with the closest propagation direction, on which its boundary values are indeed very smooth. Let us note that all exiting-only rays (rays which do not enter the computational domain but are originated in Ω_f) can actually exit only through the exit boundaries of our rotated ray domains. Hence on all other boundaries of each of the ray domains we can impose as boundary conditions the incoming rays (or zero, if no incoming rays are assumed). No boundary conditions are needed at the exit boundaries since the discrete equations (2.5) and the order in which we relax them (from entrance to exit) ensure that information propagation in the negative ξ direction is effectively prohibited.

The wave-ray approach can also be used for an efficient introduction of other types of radiation boundary conditions (RBC), for instance, Sommerfeld-like boundary conditions (discussed, for instance, in [2], [3]). This can be done since near the boundaries (remote from Ω_f), any solution is nearly purely of a ray nature and can be represented in the ray form of type (1.4). Then, from the RBC formulated as differential equations for a wave function, it is easy to find a set of differential equations that describe boundary conditions for its ray functions. This set can be separated into conditions for individual components or, at most, for a pair of components with opposite propagation direction. In this case, these two components should be approximated together, still very efficiently since considered on coarse grids. The transition to these boundary conditions has not yet been done by the authors.

The RBC can be introduced by imposing the values of the ray functions $\hat{v}^\ell$ in (1.7) at the entrance and the side boundaries on the coarsest ray level as Dirichlet boundary conditions. Since $kh_\xi \gg 1$ on all ray levels (in fact, on the finest ray grid, the mesh-size in the propagation direction satisfies $kh_\xi \approx 4$; moreover, each time the algorithm proceeds to the next coarser ray grid with double L, the size of kh_ξ increases by a factor of four), the second derivative term $\hat{v}_{\xi\xi}$ in (1.7) is negligible on the scale (h_ξ, h_η), making (1.7) almost parabolic. Therefore, no condition is needed at the exit. There, instead of (2.5), the algorithm employs strictly upstream discretization, and the solution values are treated as the interior rather than the boundary. Treating the exit in this manner, as if there is no boundary at all, allows the exiting waves to leave the domain without reflection, somewhat similar to the effect of the Sommerfeld boundary conditions.

To guarantee an accurate introduction of the RBC, we have to avoid a possible influence of the interior solution on the boundary values, which can in its turn affect the solution in the domain of interest. First we discuss how an implementation of the wave-ray algorithm can pollute the boundary conditions, and how to introduce the RBC accurately—on finite domains and with a finite number of ray functions.

The second question is how to transfer these conditions to the finer ray, and then wave, grids. In our algorithm the wave solution on the boundary is evaluated by direct interpolation from the coarser (eventually, ray) grids. It means that some interpolation error is necessarily introduced on the boundaries and affects the solution accuracy there and in the interior. However, we will show that this influence decreases rapidly as the error propagates inside the computational domain. We analyze the interpolation from both wave and ray domains.

3.1. Side boundaries: Reflected rays. When imposing the RBC at the coarsest ray level, at the entrance these conditions are naturally defined as Dirichlet boundary conditions without having any negative effects. However, this is not so for the side boundaries, because on each ray grid there are principal components that actually exit through one or the other side boundary.

In the assignment of the RBC at the coarsest ray level, each principal component with inhomogeneous boundary conditions is distributed only between the two neighboring lattice components; hence on each of the two corresponding ray grids its inclination is less than $2\pi/L$. The distribution weights are proportional to the distances between the corresponding principal frequency and the lattice points in the phase space. Hence, on each ray grid only principal components with inclinations in the range $|\alpha| \le 2\pi/L$ are represented.

Let us consider, for example, the side boundary $\eta = -\eta_0$. This is an entrance boundary for all components with $\alpha \ge 0$. Therefore, we have to impose Dirichlet boundary conditions for the ray function there, as we do at the entrance. For the principal components with $\alpha < 0$, this boundary is obviously an exit. Since the boundary conditions are already imposed, upon reaching this boundary these components do not leave the ray domain. Instead, they turn into erroneous reflected rays. To avoid their influence, we choose the parameters of the algorithm so that these rays will not enter Ω as defined in (1.3). This can be achieved by moving ray side boundaries away from Ω. We thus define the ray domain $\hat{\Omega}^\ell$ by

$$\hat{\Omega}^\ell = \{(\xi^\ell, \eta^\ell) : \ -d^\ell/2 - \Delta d_\xi \le \xi^\ell \le d^\ell/2, \ \ -d^\ell/2 - \Delta d_\eta \le \eta^\ell \le d^\ell/2 + \Delta d_\eta\},$$

where $d^\ell = c^\ell d$ and c^ℓ is chosen so that the ray domain, even for $\Delta d_\eta = 0$, completely covers the wave domain ($1 \le c^\ell \le \sqrt{2}$, depending on the lattice point). Here Δd_η is how far the ray domains should be extended in the η direction, and Δd_ξ is how far they should be extended in the negative ξ direction (as discussed in the next section). On the finest ray level, with $L = 8$ and the maximum inclination angle $\alpha = \pi/4$, if Δd_η satisfies

$$\Delta d_\eta = \tan\left(\frac{\pi}{4}\right)\frac{d}{2} = \frac{d}{2}, \tag{3.1}$$

then no reflected rays enter the target domain Ω.

If the algorithm employs more than one ray grid, the coarser ray domains must meet two requirements. First, similar to the finest ray grids, they should be large enough not to allow the erroneous reflected rays into the target domain. Since the maximum inclination angle decreases as the algorithm proceeds to the coarser grids and the finer lattices, extension (3.1) is sufficient for all grids. More important, the coarser ray domains should cover neighboring finer ray domains, i.e., they should be of the size of the finer ray domains or larger (if the propagation directions are not aligned). The latter effect, however, diminishes as the difference between the propagation directions of neighboring principal components becomes smaller on the

finer lattices. Moreover, since the involved grids are coarser, this effect is negligible in terms of the overall computational work.

Let us notice that since the algorithm allows us to avoid the effect of reflected rays in the computational domain Ω, there is no need to impose artificial absorbing boundary conditions, such as perfect matching layers (PML; see, e.g., [5], [6], [1], [16]), which are actually used for the purpose of avoiding reflection.

3.2. Entrance: Backward residual influence. In the nearest neighborhood of the entrance boundary, on each ray grid we assume the solution to be purely of the ray form; i.e., it is governed only by the RBC. Ideally, there should be no impact of the interior solution on the upstream values. This would be true if we used a strictly upstream discretization for the ray equations. To provide an accurate ray discretization we have, however, chosen the discretization (2.5), which employs one downstream grid point. This implies upstream spread of changes in the solution from the region with nonzero residuals in the RHS of (1.7). The question then arises: how far back to place the entrance boundary from the region where residuals from the finer grids are defined, so that the entrance RBC is not polluted by the solution behavior in the interior?

An easy way to see the upstream impact of residuals is to analyze the changes in neighboring-line residuals introduced upon relaxing equations on one line, e.g., the line $\xi = \tilde{\xi}$. Such equations are relaxed using line Gauss–Seidel relaxation to change the solution values on the line $\xi = \tilde{\xi} + h_\xi/2$. Assuming that a Fourier component $r(\eta) = R_0 e^{i\omega\eta}$ of residuals exists on the line $\tilde{\xi}$, one line Gauss–Seidel relaxation sweep will change the solution on the line $\tilde{\xi} + h_\xi/2$ by $V_0 e^{i\omega\eta}$, where by (2.5)

$$\left(\frac{2ik}{h_\xi} - \frac{1}{2h_\xi^2} + \frac{\cos(\omega h_\eta) - 1}{h_\eta^2}\right) V_0 = -R_0. \tag{3.2}$$

Such a change will add $R_{-1}e^{i\omega\eta}, R_1 e^{i\omega\eta}$, and $R_2 e^{i\omega\eta}$ to the residuals on the lines $\xi = \tilde{\xi} - h_\xi$, $\xi = \tilde{\xi} + h_\xi$, and $\xi = \tilde{\xi} + 2h_\xi$, respectively, where by (2.5)

$$R_{-1} = R_2 = \frac{1}{2h_\xi^2} V_0 \tag{3.3}$$

and

$$R_1 = \left(-\frac{2ik}{h_\xi} - \frac{1}{2h_\xi^2} + \frac{\cos \omega h_\eta - 1}{h_\eta^2}\right) V_0. \tag{3.4}$$

Hence, and by (1.10),

$$\frac{|R_{-1}|}{|R_0|} < \frac{1}{4kh_\xi} = \frac{4}{L^2}. \tag{3.5}$$

Since the smallest value of L in our algorithm is 8, the ratio always satisfies

$$\frac{|R_{-1}|}{|R_0|} \le \frac{1}{16}. \tag{3.6}$$

If m_ξ relaxation sweeps are performed, the backward influence of the residual will continue to propagate and will reach the line $\xi = \tilde{\xi} - m_\xi h_\xi$. The size of the residual there, however, will not exceed $R_0 L^{-2m_\xi}$. Thus, at the distance of only few mesh-sizes the backward influence of the interior residuals becomes really negligible. It also

follows from (3.5) that on coarser ray grids the backward influence per unit length remains the same.

In our solver, for technical reasons, near the boundaries the solution is always defined by the ray formulation with the homogeneous RHS. Therefore, there is no need to extend the computational domain in the negative propagation direction.

3.3. Interpolation of boundary conditions. The subject of this section is how to diminish the influence of errors in boundary interpolation. Unlike many other boundary conditions, the RBC are defined on the coarsest (ray) grid. From there the boundary values are gradually interpolated into the finer ray grid, then to the intermediate wave grids, and, eventually, to the target wave grid.

Unlike the interior values, the boundary values are never changed (improved) on the finer grids, and therefore the errors that arise in the boundary interpolations are never corrected there. Therefore, to guarantee accurate solutions, it is necessary to be able to obtain for all [illegible] (those participating in the RBC) as small interpolation errors as needed. We show below that this is always possible by employing high enough interpolation orders along the boundaries. (No such high orders are needed in the interior of the fine grid.) Furthermore, we show that the effect of these boundary errors on the solution [illegible] the domain remains equally small.

3.3.1. Interpolation from a ray grid. In the coming discussion we need to distinguish between entrance and side boundaries.

Let us first consider a Fourier component of the error originated from interpolating a principal component on the [illegible], $\xi = \xi_0$, and thus having the form

$$v(\xi, \eta) = V(\xi) e^{i\omega_\eta \eta}. \tag{3.7}$$

Substitution of (3.7) into (1.7) leads to an ODE for $V(\xi)$:

$$V''(\xi) + 2ikV'(\xi) - \omega_\eta^2 V(\xi) = 0. \tag{3.8}$$

All principal components that should be approximated on a given ray grid have the frequencies that satisfy

$$(w_\xi, w_\eta) = k(\cos\theta - 1, \sin\theta), \quad -\pi/L \le \theta \le \pi/L. \tag{3.9}$$

This, in particular, means that $|\omega_\eta|$ is always less or equal to k, and therefore the error amplitude

$$V(\xi) = V(\xi_0) e^{-i(k \pm \sqrt{k^2 - \omega_\eta^2})\xi} \tag{3.10}$$

is oscillatory and neither decreases nor increases as the error propagates from the boundary into the domain. The initial amplitude $V(\xi_0)$ can be made arbitrarily small, because by (3.8) and (1.10), the ray functions represented on each grid are relatively smooth in the η direction:

$$|w_\eta h_\eta| \le 1, \tag{3.11}$$

where h_η is the mesh-size in the η direction of the coarse grid. Such functions can be interpolated from the coarse ray grids to the finer grids very accurately just by using an interpolation of a high enough order.

Let us next consider a [illegible], for definiteness the boundary $\eta = -\eta_0$. Substituting an interpolation error component of the form

$$\hat{v}(\xi, \eta) = \hat{V}(\eta) e^{i\omega_\xi \xi} \tag{3.12}$$

into the ray equation (1.7), we obtain an ODE for $V(\eta)$:

$$\hat{V}'' - (\omega_\xi^2 + 2k\omega_\xi)\hat{V} = 0. \tag{3.13}$$

By (3.9), $-2k < \omega_\xi < 0$, and therefore $\omega_\xi^2 + 2k\omega_\xi < 0$; any solution of (3.13) is again oscillatory, with an amplitude that neither decreases nor increases as it propagates into the computational domain. Fortunately, it too can be reduced as much as one wishes by increasing the interpolation order. This is because, by (1.10) and (3.9), for the highest principal frequency that still needs to be accurately represented on the fine ray grid there holds

$$|\omega_\xi| h_\xi < 0.4. \tag{3.14}$$

Comparison between (3.11) and (3.14) shows that the order of interpolation operators used along the side boundaries can be lower than that needed along the entrance.

3.3.2. Interpolation from a wave grid. We consider here two wave grids: a fine one, with a mesh-size h in both directions, and a coarse, with the mesh-size $2h$. We examine the propagation of a component of an interpolation error, resulting from interpolating a principal component $e^{i(k_1 x + k_2 y)}$, $k_1^2 + k_2^2 = k^2$, in the form

$$v(x, y) = V(y) e^{ik_1 x}, \tag{3.15}$$

introduced, for example, on the boundary $y = y_0 = -d/2$. Its amplitude, $V(y)$, satisfies the equation

$$V''(y) + (k^2 - k_1^2)V(y) = 0, \tag{3.16}$$

and hence

$$V(y) = V(y_0) e^{\pm ik_2^2 y}, \tag{3.17}$$

so $|V(y)| \le |V(y_0)|$. Using interpolation operators of a sufficiently high order, the initial amplitude $V(y_0)$ for such values of k_2 can be made as small as desired, since $|k_2|2h \le 2hk \le 1$; this is because for any wave grid to which the boundary conditions are interpolated, its mesh-size satisfies $kh \le 0.5$. These are grids finer than the reconstruction level scale h_b, where $kh_b \approx 1$; no boundary conditions are interpolated to the coarser levels.

All these results show that the boundary interpolation errors do not decay as they propagate into the computational domains; they can be diminished only by achieving small initial (on the boundaries) error amplitudes. To guarantee that, for the components of interest, the algorithm should employ interpolations of high orders (possibly higher than the typical, for standard multigrid solvers, second or fourth orders). Fortunately such high-order, and therefore expensive, interpolation procedures are needed only for interpolation to the ray entrance boundaries and to the boundaries of the wave grids with $kh \approx 1$ and $kh \approx 0.5$. (For the finer wave grids the principal components are smooth and can be accurately approximated by regular interpolation procedures.) Since this interpolation work is needed only on the boundaries and only on the coarse grid domains, its total cost is insignificant.

The results in Table 3.1 show how the increase of the interpolation order decreases the interpolation error.

TABLE 3.1
Error amplitudes obtained in interpolation of the Fourier component exp(iωx) from the grid with ωh ≈ 1 (the most oscillatory component that appears in the boundary interpolation) in the x direction. The parameter of the table is the interpolation order.

Order	2	4	6	8
Error	1.2e-01	2.1e-02	4.1e-03	8.4e-04

4. Numerical experiments. In all numerical experiments the wave-ray algorithm was applied to the model problem (1.1) considered on the computational domain

$$\Omega = \{(x, y) : -d/2 \le x, y \le d/2\} \tag{4.1}$$

and with the RHS support

$$\Omega_f = \{(x, y) | x^2 + y^2 \le 2^2\}. \tag{4.2}$$

In all experiments with the nonhomogeneous RHS, $f(x, y)$ is chosen to satisfy

$$f(x, y) = L\underline{u}(x, y), \tag{4.3}$$

where $\underline{u}(x, y)$ is a polynomial of $r = \sqrt{x^2 + y^2}$ for $|r| \le 2$, a Hankel function of r for $|r| > 2$, and in $\mathbf{C}^4(\mathbf{R^2})$. The RHS $f(x, y)$ is therefore a polynomial for $|r| \le 2$ and zero elsewhere. In most experiments we assume $k = 1$.

The size d of the target domain Ω varies for different tables. The algorithm employs only one ray level, with eight lattice components ($n = 1, L = L^1 = 8$). The RBC are either homogeneous, or inhomogeneous with just one principal component. This component is imposed on one ray grid that corresponds to the lattice principal component $(\cos(0), \sin(0))$. The algorithm employs (except in Tables 4.11–4.13 below) cubic interpolation. The number of extended mesh-sizes in the ξ direction for ray domains is usually $m_\xi = \Delta d_\xi / h_\xi = 2$, and in the η direction it is $m_\eta = \Delta d_\eta / h_\eta = 10$. The values of m_ξ and m_η become experimental parameters in Tables 4.5–4.7 below.

The errors, calculated in the L_2 norm, measure the difference between the discrete solution $u^h_{i,j}$ and the differential one $\underline{u}(x_i, y_j)$. In almost all experiments (unless stated otherwise) the errors are calculated in the domain

$$\Omega_e = \{(x, y) : \sqrt{x^2 + y^2} \le 15\}. \tag{4.4}$$

Note that Ω_e is located at the center of Ω. Therefore, the wave and the ray phase errors arising from the RHS do not depend on d. On the other hand, the phase errors caused by the nonhomogeneous RBC depend on d, since d defines the distance that the principal component travels before reaching Ω_e.

In all experiments, the error is measured after five wave-ray cycles; after that the error remains stable. The algorithm, however, continues to reduce the residual. (For numerical experiments on the residual convergence, see [9].)

The goal of our numerical experiments is to show the influence of different error terms and to confirm our theoretical conclusions.

4.1. Wave truncation errors. Since the RHS in Table 4.1 is not homogeneous, the error includes the wave truncation (nonphase) and the wave phase errors. For this model problem (with homogeneous RBC) and for the error measured in Ω_e, none of these errors depend on d, and both are proportional to h^2. The errors for $h = 0.25$ and $h = 0.5$ indeed exhibit these properties, and therefore we conclude that there

TABLE 4.1
Errors for different finest mesh-sizes h and computational domain sizes d; the results shown are for the model problems with the RHS defined by (4.3). *The RBC are homogeneous.*

$h = 0.5$	1.71e-01	3.30e-01	3.90e-01

TABLE 4.3
Errors for different finest mesh-sizes h and computational domain sizes d. The RHS is homogeneous. The RBC are nonhomogeneous for the nonlattice principal component $(\cos(\pi/8), \sin(\pi/8))$.

	$d = 32$	$d = 64$	$d = 128$
$h = 0.125$	5.51e-02	5.88e-02	7.41e-02
$h = 0.25$	7.61e-02	1.07e-01	1.73e-01
$h = 0.5$	1.70e-01	3.07e-01	5.71e-01

the wave errors are dominant. This, however, changes for $h = 0.125$, where the error decrease with h weakens, meaning that the resulting error is a combination of other errors, such as ray phase errors (the nonpolynomial part of the solution is of the ray nature, and consists of a variety of ray components) and interpolation errors. In the next experiments we will investigate the behavior of such errors and the ways to diminish them.

4.2. Phase errors. In Table 4.2, there are neither RHS-related errors (the RHS is homogeneous), nor RBC phase ray errors, since the solution ray functions are constant (because the RBC are defined at a lattice component). The errors depend linearly on the domain size d and quadratically on the target mesh-size h. These are the properties of the [illegible] (2.3), which is the main error source in these experiments.

In the experiments presented in Table 4.3, the RBC conditions are defined for a nonlattice principal component, and this introduces the RBC ray phase errors. Unlike the wave phase errors, they should not depend on the target mesh-size h but still depend on d.

The results show that the errors depend almost linearly on d, confirming their phase nature. Their dependence on h, however, is mixed: the error is a combination of the $O(h^2)$ wave and the $O(1)$ ray phase errors (by (2.3) and (2.10), respectively).

In Table 4.4 we compare the errors obtained for different values of the wave number, k. The range of k is chosen to allow the use of the same [illegible] wave and ray grids for all values of k. (For any pair of values $k = k_0$ and $k = 2k_0$, different grids should be chosen for separation ($kh \approx 1$) and for the ray representation (1.10). Therefore, in our experiments we consider k such that $k_0 = 0.8 \le k < 1.6 = 2k_0$.)

TABLE 4.4

Errors for different values of k; the RHS is homogeneous, the RBC are nonhomogeneous for the principal component $(\cos(\alpha), \sin(\alpha))$, $h = 0.125$, $d = 64$.

k	0.8	0.9	1.0	1.1	1.2	1.3	1.4	1.5
$\alpha = 0$	1.02e-02	1.43e-02	1.94e-02	2.60e-02	3.47e-02	4.66e-02	6.36e-02	8.73e-02
$\alpha = \pi/16$	1.30e-02	1.84e-02	2.27e-02	2.96e-02	3.78e-02	4.80e-02	6.50e-02	8.90e-02

TABLE 4.5

Errors for different values of $m_\eta = \Delta d_\eta / h_\eta$, the number of additional mesh-sizes in the positive (and negative) η direction for ray domains. The model problem is with the nonhomogeneous RHS defined by (4.3); *the RBC are homogeneous, $h = 0.125$.*

m_η	0	2	5	10
$d = 64$	3.34e-03	3.30e-03	3.25e-03	3.25e-03
$d = 32$	3.91e-03	3.26e-03	3.15e-03	3.15e-03

TABLE 4.6

Errors for different values of $m_\eta = \Delta d_\eta / h_\eta$, the number of additional mesh-sizes in the positive (and negative) η direction for ray domains. The model problem is with the homogeneous RHS; the RBC is nonhomogeneous for the principal component $(k_1, k_2) = (\cos(\alpha), \sin(\alpha))$, $d = 64$, $h = 0.125$.

m_η	0	2	5	10	20	40
$\alpha = \pi/16$	1.59e-01	1.38e-01	3.96e-02	2.27e-02	2.09e-02	2.09e-02
$\alpha = \pi/8$	2.28e-01	1.86e-01	6.99e-02	5.88e-02	5.73e-02	5.73e-02

TABLE 4.7

Errors for different values of $m_\xi = \Delta d_\xi / h_\xi$, the number of additional mesh-sizes in the negative ξ direction for ray domains. The model problem is with the nonhomogeneous RHS defined by (4.3); *the RBC are homogeneous, $d = 64$, $h = 0.125$.*

m_ξ	0	5	10
error	3.27e-03	3.25e-03	3.25e-03

For $\alpha = 0$, the error ratios are proportional to the cubic power of the wave number ratios, which is a characteristic of the wave phase error. For $\alpha = \pi/16$, instead of cubic dependence, the power is $2 + \epsilon$, $0 < \epsilon < 1$, reflecting the fact the error is a combination of the $O(k^3)$ wave and the $O(k)$ ray phase errors (by (2.3) and (2.10)).

4.3. Reflected rays. The results in Table 4.5 show almost no difference for different values of m_η for $d = 64$, and this is because of the character of the solution near the boundary: the solution decays as it propagates toward boundaries, and therefore the size of the reflected waves is small and does not affect the total error. The errors for $d = 32$ are slightly higher for small m_η, and this is because the size of the solution near the boundaries, and, consequently, the size of the reflected waves is higher. This, even more profoundly, can be seen when the solution amplitudes remain large near the boundary, as in Table 4.6.

Table 4.6 shows the influence of Δd_η (section 3.1) on the accuracy of the solution. The result confirm that in order to avoid influence of the reflected rays, the side boundaries of ray domains should be sufficiently extended.

4.4. Backward residual propagation. As discussed at the end of section 3.2, the results in Table 4.7 show no influence of the number of extra mesh-sizes in the direction opposite to the propagation direction ξ on the solution accuracy.

TABLE 4.8

Errors for the solver that employs ray discrete operators of second order (2.5); *the solver employs cubic interpolation, both in the interior and on the boundaries; the RHS is homogeneous, and the RBC are nonhomogeneous for the principal component* $(k_1, k_2) = (\cos(\alpha), \sin(\alpha))$.

h	d	$\alpha = 0.0$	$\alpha = \pi/16$	$\alpha = \pi/12$	$\alpha = \pi/8$
0.125	64	1.94e-02	2.27e-02	2.71e-02	5.88e-02
0.25	64	7.95e-02	7.84e-02	8.10e-02	1.07e-01

0.25	128	1.61e-01	1.55e-01	1.55e-01	1.73e-01

TABLE 4.9

Errors for the solver that employs ray discrete operators of fourth order; the solver employs cubic interpolation, both in the interior and on the boundaries; the RHS is homogeneous, and the RBC are nonhomogeneous for the principal component $(k_1, k_2) = (\cos(\alpha), \sin(\alpha))$.

h	d	$\alpha = \pi/16$	$\alpha = \pi/12$	$\alpha = \pi/8$
0.125	64	2.02e-02	2.02e-02	2.75e-02
0.25	64	7.79e-02	7.57e-02	7.74e-02
0.125	128	3.87e-02	3.79e-02	4.36e-02
0.25	128	1.54e-01	1.49e-01	1.43e-01

4.5. Ray phase errors. There are two ways to decrease ray phase errors. First, one can employ a high-order discretization for the ray equation (1.7). In the next two tables the accuracy of the solution obtained by the solver that employs the second- and the fourth-order discretization schemes for the ray equations are presented and compared.

Comparing the results in Tables 4.8 and 4.9 shows that the higher-order discretization does not much improve the accuracy for small α, i.e., $\alpha = \pi/16$, the expected results since very small discretization error is committed for nearly lattice component. The dominant error in this case, even for the second-order discretization scheme, is the wave phase error. For larger α, the improvement is significant (especially for the most oscillatory $\alpha = \pi/8$, the middle point between two lattice components): the dominant part of the remaining error is clearly of a wave nature; it depends almost quadratically on h and linearly on d. Such improvement is observed since the higher-order discretization diminishes all discretization errors, including the phase error—the main error source for larger α in Table 4.8.

To reduce the ray phase errors [illegible] increasing discretization orders, one needs to employ not one, as in the experiments discussed above, but several ray grids, with increasingly finer lattice discretization on the coarser grids. The finer the lattice discretization is, the smaller the ray phase errors (2.10) are. The goal of the intermediate (finer) ray grids is to reduce errors to the almost pure rays. The overall accuracy of the ray representation is then defined by the coarsest ray grid with the largest number of lattice components, $L = 2^{N+2}$, where N is the number of ray levels employed. There the radiation boundary conditions are imposed, facilitated by the nearly pure ray representation at that grid. With the right choice of N and, correspondingly, L, one can make the ray phase errors arbitrary small.

This approach is perfectly suitable for the problems considered on very large computational domains: it requires significant coarsening in space, as L grows (1.10), which makes the ray approximation very inexpensive even for large L and d.

Large L, however, cannot be used for the problems with not sufficiently large kd. This is because to allow effective separation and representation of the ray residuals, each ray grid should consist of at least a few points in each direction. Since the mesh-

TABLE 4.10

Errors for solutions of discrete ray equations with the choice of h_ξ, h_η, and the RBC for principal components that depends on the choice of $L = 8, 16$. The values of α in the top line are given for $L = 8$; the values of alpha for the same principal components for $L = 16$ is given in parentheses (for instance, $\alpha = \pi/8$ becomes a lattice component, i.e., its new value for $L = 16$ is $\alpha = 0$); the RHS is homogeneous, and the RBC are nonhomogeneous for the principal component $(k_1, k_2) = (\cos(\alpha), \sin(\alpha))$. The error is calculated in Ω_E.

L	(h_ξ, h_η)	d	0(0)	$\pi/32(\pi/32)$	$\pi/16(\pi/16)$	$\pi/12(\pi/24)$	$\pi/8(0)$
8	(4,2)	256	0.00	2.01e-04	3.20e-02	1.06e-01	5.50e-01
16	(16,4)	256	0.00	8.27e-03	1.42e-01	2.66e-02	0.00
16	(16,4)	512	0.00	1.64e-02	2.80e-01	5.20e-02	0.00

size in the ξ direction satisfies (for $L = 16$, for example) $kh_\xi \approx 16$, it is impossible to use larger L for $kd = 32, 64$, and technically tricky (employing more sophisticated separation) for $kd = 128$. Therefore, in all the numerical experiments presented here, the algorithm employs eight ray components. A higher number of ray functions, e.g., $L = 16, 32$, etc., should be used for values of kd larger than the ones presented here. For larger values of L the same kind of errors arise and same measures are taken as for $L = 8$.

In the next set of experiments we compare different discretization (with different mesh-sizes and different ranges of principal components) of the ray equation (2.5). The results allow us to compare the errors for different L. At each experiment, we employ only one ray grid (analogue of the coarsest ray grid for one lattice component) and solve there the discrete ray problem (1.7) with the homogeneous RHS and the nonhomogeneous boundary conditions for one principal component. (The choice of mesh-sizes and the range of components depends on L.) Such experiments are relevant to our discussion, since the obtained solutions (and their accuracy) would be barely changed on the finer (if any) ray grids (the ray solution is not even relaxed on the finer ray grids, after visiting the coarser ones) and on the wave grids as previously discussed. Indeed some error, such as from interpolation, is introduced on the way to the target grid, but this has already been analyzed and calculated. For Table 4.10 only the error is calculated in the larger (than Ω_e) domain Ω_E:

$$\Omega_E = \{(x, y) : \sqrt{x^2 + y^2} \le 50\}. \tag{4.5}$$

Clearly, the results in Table 4.10 are in agreement with (2.10): the maximal error (and this error is indeed of a phase nature, as it depends linearly on d) for $L = 8$ is observed for $\alpha = \pi/8$, the middle point between two lattice components for $L = 8$, and it is four times larger than the maximal error for $L = 16$ observed for $\alpha = \pi/16$, the middle point between two lattice components for $L = 16$.

4.6. Interpolation of boundary conditions. In Tables 4.11–4.13 the influence of the interpolation orders is tested. The difference between the tables is in the choice of the inclination angle α of the principal component for which the nonhomogeneous RBC are imposed. The influence of the interpolation orders on the accuracy of the solution is tested for different values of h and d, as well. Fourth-order discretization is employed for the ray operators in order to reduce phase ray errors, in this way making the influence of interpolation errors visible.

We start with the RBC nonhomogeneous for the lattice principal component with $\alpha = 0$. In this case the ray functions are constant, and therefore the accuracy of the ray interpolation does not matter, since interpolation of any order accurately interpolates

TABLE 4.11

Errors for interpolation operators of different orders. Here $(p_w(p_w^b), p_r(p_r^b))$ *are the order of wave and ray interpolation operators used in the algorithm, both in the interior and on the boundaries; the numbers in parentheses are the orders of the operators used to interpolate to the boundaries from the wave and the ray coarser grids, respectively, if they are different from the orders used for the interior interpolation; the RHS is homogeneous, and the RBC are nonhomogeneous for the principal component* $(\cos(0), \sin(0))$.

h	d	$(4,4)$	$(4,2)$	$(2,2)$	$(4(6),4)$	$(2(4),2)$

TABLE 4.13

Like Table 4.11*, except that the RBC are nonhomogeneous for the principal component* $(\cos(\pi/8), \sin(\pi/8))$.

h	d	$(4,4)$	$(2,2)$	$(4(6),4(6))$
0.125	64	5.88e-02	1.13e-01	5.84e-02
0.25	64	1.07e-01	1.41e-01	1.06e-01
0.5	128	1.73e-01	1.73e-01	1.73e-01

constant functions. In the wave representation, however, this e^{ix} component is the most oscillatory principal component that yields the highest truncation (phase) and boundary interpolation errors.

The results in Table 4.11 show that as long as the cubic interpolation ($p = 4$) is employed in the wave interpolation, the errors depend quadratically on h and linearly on d, meaning that the wave phase error is the main error source. The influence of the interpolation errors is insignificant (for instance, increasing the interpolation order on the boundary barely improves the accuracy). This, however, changes for $p = 2$ in the wave interpolation, for which the interpolation errors become visible. The ray interpolation order does not influence the accuracy of the solution for this α.

Next we consider the principal component with $\alpha = \pi/16$. Linear interpolation $p = 2$ from the ray grids sufficient for the previous example ($\alpha = 0$) introduces a significant error here. For $\alpha = \pi/16$, $|\omega_\eta h_\eta| \approx 0.4$ (section 3.3.1), and therefore interpolation from the ray grid can be accurately performed using cubic interpolation ($p = 4$). For the wave representation, however, on the reconstruction level $|wh| \approx 1$ (section 3.3.2), and the higher-order interpolation ($p = 4$ or $p = 6$) from the wave grids (especially on the boundaries) leads to a better accuracy.

In Table 4.13 the nonhomogeneous RBC are imposed for the principal component $(\cos(\pi/8), \sin(\pi/8))$, the midpoint between the neighboring lattice components $(\cos(0), \sin(0))$ and $(\cos(\pi/4), \sin(\pi/4))$. For this component, both the ray principal components ($|\omega_\eta h_\eta| \approx 0.8$) and the wave principal components ($|\omega h| \approx 1$ at the reconstruction level) are rather oscillatory, and it seems that the algorithm could benefit

from increasing interpolation orders, at least for the boundary interpolation. This, however, is not reflected in the results shown in Table 4.13.

The errors in Table 4.13 are almost independent of the interpolation accuracy. They, however, depend on the size of the computational domain, meaning that the ray phase errors discussed in section 4.5 are the main source of inaccurate approximations.

5. Conclusions and future application. For most multigrid procedures the accuracy of the solution is defined by the discretization accuracy at the finest grid. This is not always so for problems on unbounded domains, where it is computationally beneficial to use progressively extended coarse grid domains, so that in its outer part each coarse grid provides not a correction to the fine grid solution, but the solution itself. This feature is present in the wave-ray algorithm for solving indefinite Helmholtz equations with radiation boundary conditions. The developed solver shows a textbook multigrid efficiency for highly indefinite problems on unbounded domains. With the right choice of parameters (such as computational domains, wave and ray mesh-sizes, order of interpolation operators) the produced solution has the accuracy defined by the finest grid discretization. The analysis offered here can be applied to other problems given on infinite domains with boundary conditions defined at infinity. When restricted to finite computational domains, the numerical solvers for such problems have to deal with interpolation and other errors, similar to the ones discussed in this paper.

The wave-ray algorithm discussed in this paper is rather technical and employs several special features: rotated coordinate systems, special weighting operators, etc. Some of these technicalities, however, could be simplified (for example, the use of the (x, y) coordinates for all ray components and the standard full weighting for the residual separation), and the obtained simplified algorithm would still be an efficient (though less efficient) solver for the Helmholtz equation. One of the restrictions that cannot be lifted in this [illegible] multigrid solver is the requirement to represent principal components in their analytical form, which is available only for sufficiently smooth k. These principal components are used to obtain differential equations for the ray functions, which are then discretized and solved.

Our next step (currently in progress; see preliminary results in [10]) is to use the wave-ray approach in the [illegible] multigrid framework, where only numerical approximation to the principal components are needed and used to obtain discrete ray equations (skipping the differential equations step). This approach allows application of the wave-ray algorithm to problems with nonsmooth wave numbers. Moreover, similar ideas can be used in multigrid algorithms developed for other differential operators if some approximations to their algebraically smooth error components are known or can be inexpensively discovered (e.g., [7]) and then used as a part of the algebraic multigrid solver.

Appendix. Pseudocode. A brief pseudocode of the wave-ray algorithm is given next. It describes the solver that was used in all experiments presented in this paper.

Begin wave ray cycle
Wave subcycle: from the finest to the coarsest wave grid
`Finest wave grid` $m = M_t$
`Relaxation` $L^m u^m = f^m$
`Residual calculation by full weighting` $r^{m-1} = W_m^{m-1}(f^m - L^m u^m)$
`Solution initialization by injection` $u^{m-1} = I_m^{m-1} u^m$

for $m = M-1, \dots, 2$
  `FAS right-hand side` $f^m = r^m + L^m u^m$
  if $(kh_m \not\approx 2)$, `Relaxation` $L^m u^m = f^m$
  `Residual calculation by full weighting` $r^{m-1} = W_m^{m-1}(r^m - L^m u^m)$
  `Solution initialization by injection` $u^{m-1} = I_m^{m-1} u^m$
`Coarsest wave grid` $(m = 1)$ `Relaxation` $L^m u^m = f^m$
Wave subcycle: from the coarsest to some fine wave grid
for $m = 2, \dots, M_f$, $M_f \le M$ is the wave grid with a small phase error
  `Interpolation` $u^m = u^m + I_{m-1}^m v^{m-1}$
  if $(kh_m \not\approx 2)$, `Relaxation` $L^m u^m = f^m$
`Wave residual calculation for ray subcycle` $(m = M_f)$ $r^m = f^m - L^m u^m$
for $(m = M_f - 1, \dots, M_c)$, M_c is the wave grid with $kh_c \approx 1$
  `Residual transfer by full weighting` $r^m = W_{m+1}^m r^{m+1}$
Ray subcycle with N ray levels
`Finest ray grid` $n = 1$
for $(\ell = 1, \dots, L_1)$
  `Residual separation` $\hat{r}^{1,\ell} = W_{M_c}^{1,\ell}(r^{M_c}\overline{e}^{1,\ell})$,
  $\overline{e}^{1,\ell}$ is the complex conjugate of $e^{1,\ell}$, the ℓth component on the 1st lattice
  `Ray FAS right-hand side`
    $\hat{f}^{1,\ell} = \hat{r}^{1,\ell} + \hat{L}^1 \hat{u}^{1,\ell}$ `where` $(\hat{r}^{1,\ell} \ne 0)$ `and` $\hat{f}^{1,\ell} = 0$ `elsewhere`
for $(n = 2, \dots, N)$
  `Residual separation`
  for $(\ell = 1, \dots, N, \ell = \ell + 2)$ `for odd` ℓ
    $\hat{r}^{n,\ell} = W_{n-1,(\ell+1)/2}^{n,\ell}(\hat{r}^{n-1,(\ell+1)/2})$
  for $(\ell = 2, \dots, N, \ell = \ell + 2)$ `for even` ℓ
    $\hat{r}^{n,\ell} = W_{n-1,\ell/2}^{n,\ell}(\hat{r}^{n-1,\ell/2} e^{n-1,\ell/2} \overline{e}^{n,\ell}) + W_{n-1,\ell/2+1}^{n,\ell}(\hat{r}^{n-1,\ell/2+1} e^{n-1,\ell/2+1} \overline{e}^{n,\ell})$,
    `where` $e^{n,\ell}$ `is the` ℓ`th component on the` n`th lattice`
  for $(\ell = 1, \dots, L_n)$
    `Ray FAS right-hand side`
    $\hat{f}^{n,\ell} = \hat{r}^{n,\ell} + \hat{L}^n \hat{u}^{n,\ell}$ `where` $(\hat{r}^{n,\ell} \ne 0)$ `and` $\hat{f}^{n,\ell} = 0$ `elsewhere`
    if $(n \ne N)$, `Relaxation` $L^n u^{n,\ell} = f^{n,\ell}$
    else
      `Imposition of RBC at entrance and side boundaries`
      $\hat{u}^{n,\ell}(\xi, \eta) = \hat{u}_0(\eta)$ `for` $\xi = \xi_0$; $\hat{u}^{n,\ell}(\xi, \eta) = \hat{u}_\pm(\xi)$ `for` $\eta = \pm\eta_0$
      `Solving` $\hat{L}^n \hat{u}^{n,\ell} = \hat{f}^{n,\ell}$
for $(n = N - 1, \dots, 1)$
  `Interpolation to the next finer ray grid`
  for $(\ell = 1, \dots, L_n)$
    `Interior interpolation:` $\hat{u}^{n,\ell} = \hat{u}^{n,\ell} + I_{n+1,2\ell-1}^{n,\ell} \hat{v}^{n+1,2\ell-1} +$
    $\frac{1}{2} I_{n+1,2\ell-2}^{n,\ell}(\hat{v}^{n+1,2\ell-2} e^{n+1,2\ell-2}/e^{n,\ell}) + \frac{1}{2} I_{n+1,2\ell}^{n,\ell}(\hat{v}^{n+1,2\ell} e^{n+1,2\ell}/e^{n,\ell})$
    `Boundary interpolation:` $\hat{u}^{n,\ell} = 0$ on $\hat{\Gamma}^{n,\ell}$
    $\hat{u}^{n,\ell} = I_{n+1,2\ell-1}^{n,\ell} \hat{u}^{n+1,2\ell-1} + \frac{1}{2} I_{n+1,2\ell-2}^{n,\ell}(\hat{u}^{n+1,2\ell-2} e^{n+1,2\ell-2}/e^{n,\ell}) +$
    $\frac{1}{2} I_{n+1,2\ell}^{n,\ell}(\hat{u}^{n+1,2\ell} e^{n+1,2\ell}/e^{n,\ell})$
`Wave solution reconstruction` $m = M_c$:
`Zero initialization at boundaries` $u^m = 0$ on Γ_m
for $(\ell = 1, \dots, L^1)$
  `In interior` $u^m = u^m + e^\ell I_{1,\ell}^m \hat{v}^{1,\ell}$; `At boundaries` $u^m = u^m + e^\ell I_{1,\ell}^m \hat{u}^{1,\ell}$
`End wave reconstruction`
for $(m = M_c + 1, \dots, M)$
  `Zero initialization at boundaries` $u^m = 0$ on Γ_m
  `In interior` $u^m = u^m + I_{m-1}^m v^{m-1}$; `At boundaries` $u^m = u^m + I_{m-1}^m u^{m-1}$
  `Relaxation` $L^m u^m = f^m$

FAST COMPUTATION OF THE SLATER INTEGRALS*

L. GR. IXARU†, N. S. SCOTT‡, AND M. P. SCOTT§

Abstract. Slater integrals are two-dimensional radial integrals whose integrand is constructed from normalized eigenfunctions of the Schrödinger equation. These integrals occur in many atomic structure and scattering computations. However, in two-dimensional R-matrix propagation they represent a significant computational bottleneck. The problem involves two steps, that is, the numerical solution of the Schrödinger equation and the computation of the integrals, respectively. By exploiting the characteristic features of the problem we seek to devise a two-stage computational strategy, where the second stage is influenced and informed by the first. In particular, we focus on the development of extended frequency-dependent quadrature rules (EFDQRs) that improve the accuracy and significantly reduce the computation time of the integrals. The performance of these ad hoc rules is examined and compared to the currently used Newton–Cotes method in the construction of Hamiltonian matrices involving up to 300×10^6 integrals. A gain of two orders of magnitude in the CPU time is obtained.

Key words. computational atomic physics, CP methods, exponential fitting, frequency dependent weights, R-matrix, Slater integral

1. Introduction.

Electron collisions with atoms and ions have been the subject of international interest for many years. Data from these processes are essential in the analysis of important physical phenomena in many scientific and technological areas [5]. Despite the importance of these applications, relatively little accurate cross section data are known for many of the processes involved. For example, no accurate cross section data, involving high lying excited states, have been calculated for electron collisions with the simplest atomic target, hydrogen. Such data is essential, for example, to resolve discrepancies in the modeling of early-type stars [33]. The theoretical treatment of electron collisions at these [illegible] is difficult because of the need accurately to allow for excitation to Rydberg states and for ionization of the target. Recent theoretical and computational advances pioneered in Australia [6], Europe [12], [4], [8], and the USA [2] have, however, provided a new context within which to attack this problem.

A particularly promising technique is the two-dimensional R-matrix propagator [13], a variant of the general R-matrix approach [7], that enables the accurate study of electron collisions with hydrogen-like (H-like) and quasi-H-like atoms and ions at intermediate energies. As illustrated in Figure 1, the two-electron configuration space (x_1, x_2) is divided into square sectors. The two-electron wavefunction describing the motion of the target electron and the colliding electron is expanded within each sector

in terms of one-electron basis functions that are eigenfunctions of the Schrödinger equation, solved subject to certain fixed boundary conditions. The expansion coefficients are determined by diagonalizing the corresponding Hamiltonian matrix. The R-matrix may then be propagated across the sectors at each scattering energy and the scattering properties of interest determined.

An advantage of the technique is that the construction and diagonalization of each sector Hamiltonian matrix is independent. This renders the application suitable for exploiting both high performance computing (HPC) [34] and Grid architectures [10]. However, in large-scale simulations efficient exploitation is severely impeded by a significant load imbalance between the construction of the Hamiltonian matrix on diagonal and off-diagonal sectors. The root of the bottleneck is the large number of two-dimensional radial integrals, the so-called Slater integrals, that are required on each diagonal sector. Using standard "off the shelf" quadrature formula, Hamiltonian matrix construction on each diagonal sector, to approximately seven figures of accuracy, can take of the order of hours while each off-diagonal sector takes only tens of seconds.

We therefore pose the question, "Do the constituent components of the integrands have characteristics that can be exploited to enable the construction of a hand crafted quadrature formula that will both improve the accuracy and significantly reduce the computation time of the Slater integrals?" Answering this question is the focus of this paper. We begin in section 2 by specifying the problem; atomic units are used throughout the paper. In section 3 we investigate the solution of the Schrödinger equation and the computation of Slater integrals and outline a computational strategy that exploits the characteristic features of the problem. This strategy is further developed in section 4 and, in particular, in section 5 where we develop specialized sets of frequency-dependent quadrature rules that enable the Slater integrals to be computed to improved accuracy and at small computational cost. In section 6 we examine the efficiency of the quadrature rules when used to construct Hamiltonian matrices. Finally, in section 7 we present our concluding remarks.

2. The problem. Let $X_i = iH$, $i = 0, 1, \ldots, i_{max}$, be equidistant points on the half-axis $x \geq 0$. On each interval $I_i = (X_i, X_{i+1})$ we consider the eigenvalue problem

for the radial Schrödinger equation

$$y''_{nl} = (V(x) - E_{nl})y_{nl}(x), \quad x \in I_i, \tag{2.1}$$

in a Coulomb field,

$$V(x) = \frac{l(l+1)}{x^2} - \frac{2Z}{x}, \tag{2.2}$$

where l and Z represent the orbital angular momentum (a nonnegative integer) and the electric charge (a positive real number), respectively. The boundary conditions are as follows:

$$i = 0: \qquad y_{nl}(0) = 0, \qquad a_1 y_{nl}(X_1) + b_1 y'_{nl}(X_1) = 0,$$

$$i > 0: \ a_0 y_{nl}(X_i) + b_0 y'_{nl}(X_i) = 0, \ a_1 y_{nl}(X_{i+1}) + b_1 y'_{nl}(X_{i+1}) = 0,$$

where a_0, b_0, a_1, and b_1 are constants dictated by the physics of the problem but subject to the conditions $|a_0| + |b_0| \neq 0$ and $|a_1| + |b_1| \neq 0$. Throughout this paper we use $a_0 = a_1 = 0$ and $b_0 = b_1 = 1$.

The eigenfunctions, y_{nl}, normalized as

$$\int_{X_i}^{X_{i+1}} y_{nl}(x) y_{n'l}(x) dx = \delta_{nn'}, \tag{2.3}$$

are then used to compute two-dimensional radial integrals of the form

$$R = \int_{X_j}^{X_{j+1}} dx_2 \int_{X_i}^{X_{i+1}} dx_1 \, y_{n_3 l_3}(x_2) y_{n_4 l_4}(x_2) \Delta(x_1, x_2; \lambda) y_{n_1 l_1}(x_1) y_{n_2 l_2}(x_1), \tag{2.4}$$

where

$$\Delta(x_1, x_2; \lambda) := \begin{cases} \dfrac{x_1^\lambda}{x_2^{\lambda+1}} & \text{if } x_1 < x_2, \\ \dfrac{x_2^\lambda}{x_1^{\lambda+1}} & \text{if } x_1 \geq x_2. \end{cases}$$

Integrals of this form are sometimes called Slater integrals and have to be evaluated in each H by H square sector identified by the pair i, j, where $i = 0, 1, \ldots, i_{max}$ and $j = 0, \ldots, i$. An illustration for $i_{max} = 3$ is shown in Figure 1.

The following modest values give a lower limit for the computational effort involved in a realistic computation: $Z = 1$ (hydrogen atom), $H = 15$, $i_{max} \geq 10$, $1 \leq n \leq n_{max} = 20$, $0 \leq l \leq l_{max} = 9$, and $0 \leq \lambda \leq \lambda_{max} = 2l_{max} = 18$. Potentially, $n_{max}^4 \times (l_{max}+1)^4 \times (\lambda_{max}+1)$, i.e., 3.04×10^{10}, Slater integrals need to be computed in each sector. However, the invariance of R with respect to permutations $n_1 l_1 \rightleftarrows n_2 l_2$ or $n_3 l_3 \rightleftarrows n_4 l_4$, and the existence of physical selection rules based on correlations between λ and the orbital angular momenta l_1, l_2, l_3, l_4, reduce this number to a few hundred million integrals per sector. Nonetheless the computational effort remains substantial.

Not all Slater integrals exhibit the same computational complexity. Let us denote

$$J_1(a, z, \lambda, \phi) := \int_a^z dx \, x^\lambda \phi(x), \quad J_2(z, b, \lambda, \phi) := \int_z^b dx \, \frac{1}{x^{\lambda+1}} \phi(x). \tag{2.5}$$

If $i = j$, i.e., a diagonal sector of Figure 1, then

$$R = \int_{X_j}^{X_{j+1}} dz\, y_{n_3 l_3}(z) y_{n_4 l_4}(z) I(z, \lambda, \phi), \tag{2.6}$$

where

$$I(z, \lambda, \phi) = \left[\frac{1}{z^{\lambda+1}} J_1(X_j,\, z,\, \lambda, \phi) + z^{\lambda} J_2(z,\, X_{j+1},\, \lambda, \phi) \right], \tag{2.7}$$

and

$$\phi(x) = y_{n_1 l_1}(x) y_{n_2 l_2}(x).$$

This is a genuine double integral. However, if $i > j$, i.e., an off-diagonal sector, then R is simply a product of two one-dimensional integrals,

$$R = J_1(X_j,\, X_{j+1},\, \lambda, \phi_1) \times J_2(X_i,\, X_{i+1},\, \lambda, \phi_2), \tag{2.8}$$

where

$$\phi_1(x) = y_{n_3 l_3}(x) y_{n_4 l_4}(x), \quad \phi_2(x) = y_{n_1 l_1}(x) y_{n_2 l_2}(x).$$

It follows that the computation of an on-diagonal integral will take much longer than that of an off-diagonal integral and thus deserves special attention.

2.1. Graphical illustrations. To give a visual impression of the form of the Slater integral defined by (2.6) we present its constituent components on the diagonal sectors $I_0 \times I_0$ and $I_1 \times I_1$, denoted as 0, 0 and 1, 1, respectively, in Figure 1. We use the following typical, but randomly chosen, eigenfunctions $n_1 = 5$, $l_1 = 2$, $n_2 = 10$, $l_2 = 4$, $n_3 = 6$, $l_3 = 1$, $n_4 = 12$, $l_4 = 3$.

Figures 2 and 3 show the products of eigenfunctions, $\phi_1(x) = y_{n_1 l_1}(x) y_{n_2 l_2}(x)$ and $\phi_2(x) = y_{n_3 l_3}(x) y_{n_4 l_4}(x)$, that occur in the inner and outer integrals of (2.6), respectively. The behavior of (2.7), the inner integral $I(x, \lambda, \phi_1)$, for $\lambda = 2, 3, 4, 5, 6$ is displayed in Figures 4 and 5. Finally, Figures 6 and 7 show the complete Slater integrand again for $\lambda = 2, 3, 4, 5, 6$. These graphs illustrate the progressively complicated interference patterns among the constituent components of the double integral's integrand. Of particular note is the influence of λ on the amplitudes of the integrand.

3. Development of an ad-hoc computational strategy. The efficiency of the computation of the Slater integrals depends primarily on the number of points at which the values of the integrand are needed in order to achieve some predefined accuracy. For example, with a sector size of $H = 15$, the Newton–Cotes formulae typically require more than 1,000 mesh points to achieve about eight figures of accuracy. In this paper we target 10 figures of accuracy.

A significant reduction in the number of mesh points is possible but this requires an investigation of the two stages of the process, i.e., both the numerical solution of the Schrödinger equation and the actual computation of the Slater integrals. In fact, such an investigation should cover not only each separate stage but also the way in which the first is of assistance to the second. Our aim, therefore, is to design a sequence of numerical methods which advantageously exploits as many characteristic features of the problem as possible.

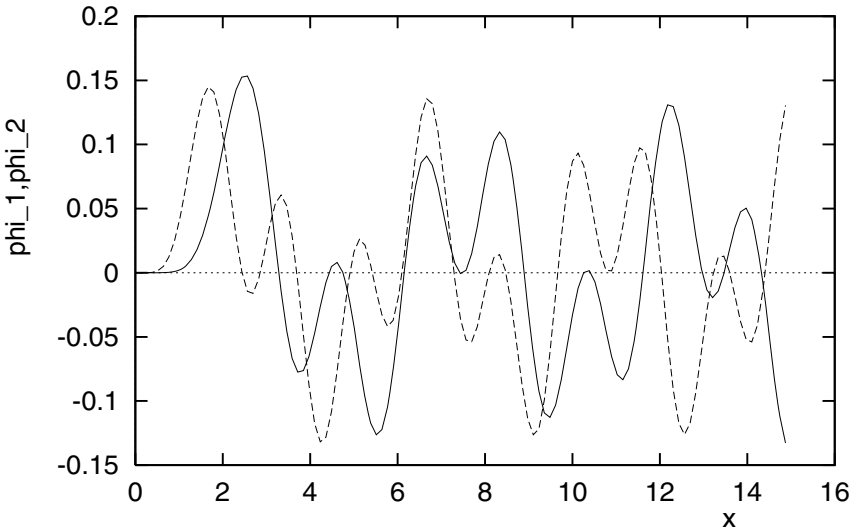

FIG. 2. *The functions* $\phi_1(x)$ (*solid lines*) *and* $\phi_2(x)$ (*broken lines*) *on interval* I_0.

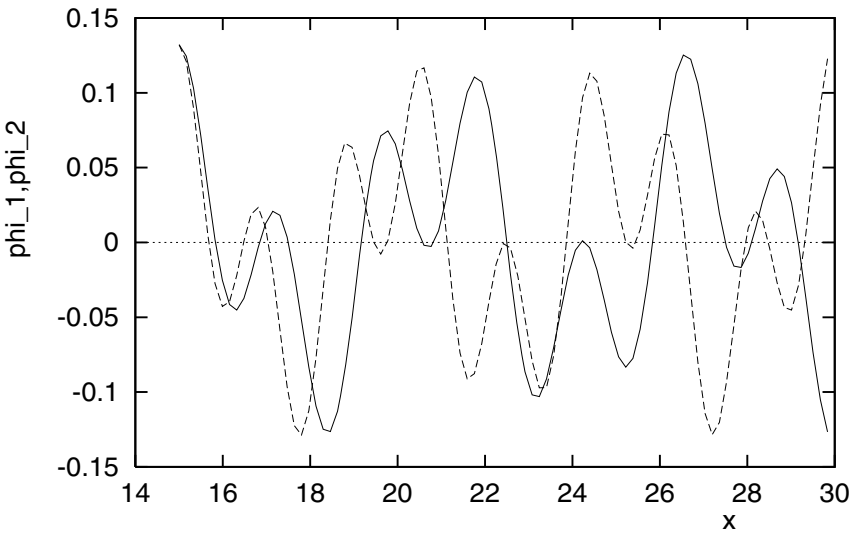

FIG. 3. *The functions* $\phi_1(x)$ (*solid lines*) *and* $\phi_2(x)$ (*broken lines*) *on interval on interval* I_1.

3.1. Solution of the Schrödinger equation. The potential function, $V(x)$, is singular at the origin, and therefore a tailored method is needed to compute a correct numerical solution in the vicinity of the origin. We specify the origin-enclosing interval by $(0,\, x_{cut}]$. To fix x_{cut} we have constructed and used the empirical formula

$$x_{cut} = \begin{cases} \min\{9(\exp(l)+1)/(\exp(l)+21),\, 3.75(l+0.5)/Z\} & \text{if } l \le 3, \\ 12(1+0.5/l)/Z & \text{if } l > 3. \end{cases}$$

For the solution on $(0,\, x_{cut}]$ we have opted for a piecewise perturbation version in which the centrifugal and Coulomb terms are taken as a reference and as a per-

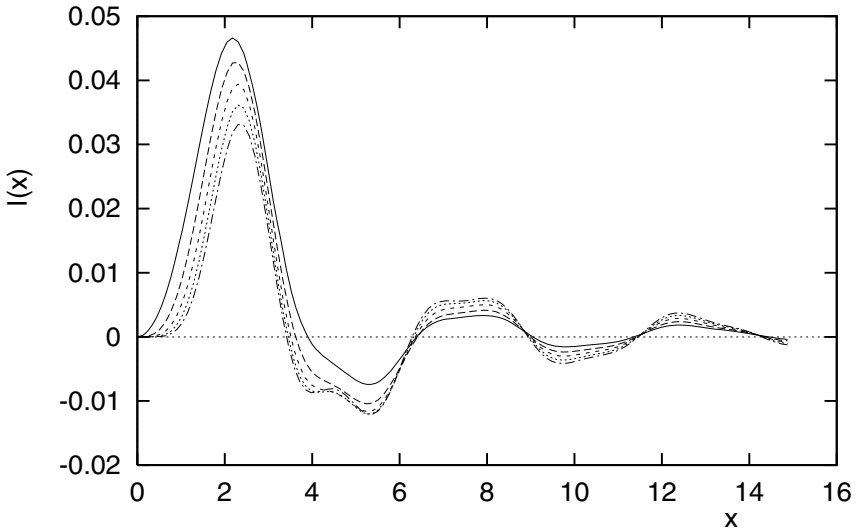

FIG. 4. *The inner integral* $I(x, \lambda, \phi_1)$ *on* I_0*:* $\lambda = 2$ (*solid lines*), $\lambda = 3$ (*long-dashed lines*), $\lambda = 4$ (*short-dashed lines*), $\lambda = 5$ (*dotted lines*), $\lambda = 6$ (*dashed-dotted lines*).

turbation potential, respectively. The procedure is described in [21], where another empirical formula for x_{cut} is described (see (3.28) of [21]). However, we have found the construction above to be slightly better in our context.

For $x > x_{cut}$ there are many options because, in principle, any numerical method for solving ODEs can be used; examples include multistep and Runge–Kutta methods. However, before making an informed choice we need to be cognizant of the following three conditions.

First, we note that eigenvalues and eigenfunctions for n up to 20 are required; higher values of n may also be needed in the future. Since the nth eigenfunction

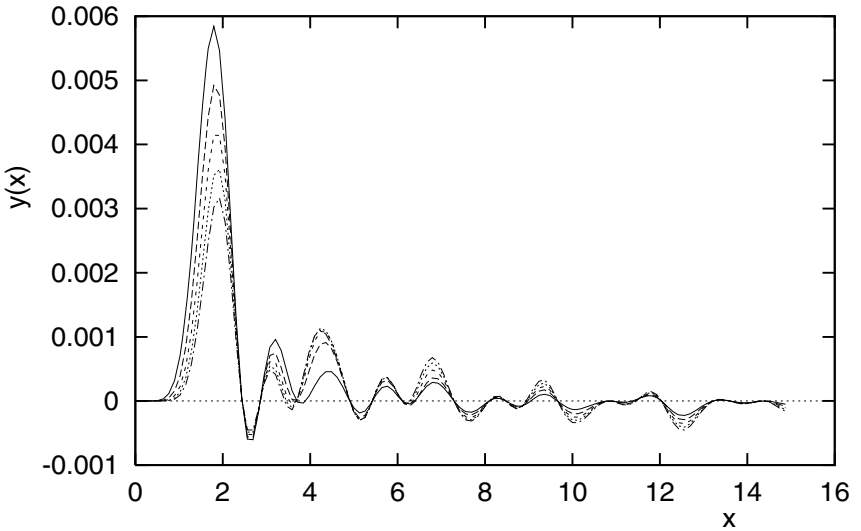

FIG. 6. *The full integrand* $y(x) = \phi_2(x)I(x, \lambda, \phi_1)$ *for the outer integral on* I_0*:* $\lambda = 2$ (*solid lines*), $\lambda = 3$ (*long-dashed lines*), $\lambda = 4$ (*short-dashed lines*), $\lambda = 5$ (*dotted lines*), $\lambda = 6$ (*dashed-dotted lines*).

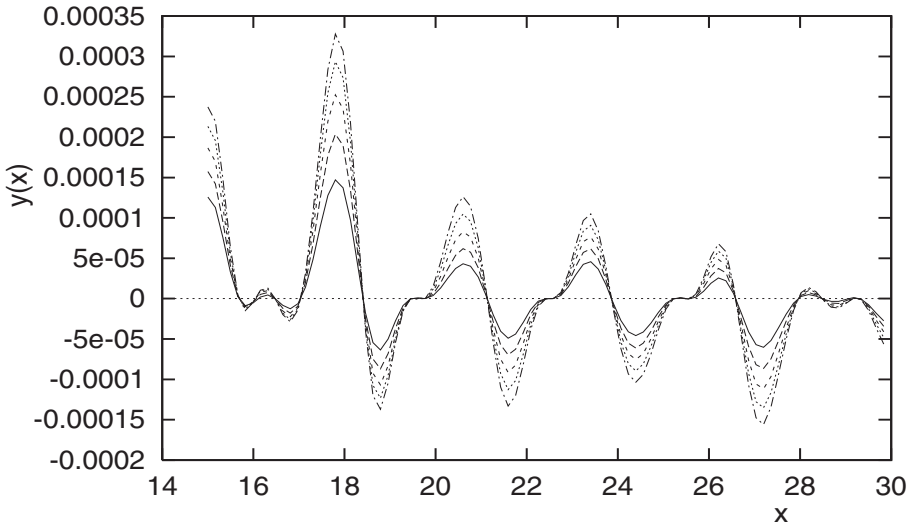

FIG. 7. *The full integrand* $y(x) = \phi_2(x)I(x, \lambda, \phi_1)$ *for the outer integral on* I_1*:* $\lambda = 2$ (*solid lines*), $\lambda = 3$ (*long-dashed lines*), $\lambda = 4$ (*short-dashed lines*), $\lambda = 5$ (*dotted lines*), $\lambda = 6$ (*dashed-dotted lines*).

has $n - 1$ nodes on the current interval, a convenient numerical method would be one in which, for a predetermined accuracy, the number of steps within the partition remains reasonably small, irrespective of n. Such a condition is not easily met because for most of the methods in current use the number of steps clearly increases with n. A second condition is the capacity of the method easily to allow for the evaluation of potentially valuable extra data. For example, a method which is able to furnish not only the eigenvalues and their eigenfunctions but also the first derivative of the

eigenfunctions should be preferred because the knowledge of the derivatives plays an important role in increasing the efficiency of the evaluation of the Slater integrals, as will be seen below. Finally, we require not only an ODE method but also a quadrature method. The latter is for the computation of the normalization integral, (2.3). The normalization should be sufficiently accurate using only the data provided by the ODE solver. For example, a pair of methods in which the ODE solver requires 100 steps while the quadrature rule needs data at 1,000 points is clearly unsuitable.

After a comparative examination of a number of possible candidates (methods written especially for Sturm–Liouville problems (see, e.g., [3], [29], [30], [31], and [32]) were considered with particular attention) we have opted for CPM{12, 10} of [19] which is a highly accurate version in the class of the constant (based) perturbation (CP) methods. A brief description of the method and of how it meets the aforementioned conditions is given in section 4. The theory of the CP methods is described in Chapter 3 of [16].

3.2. Computation of the Slater integrals. Only a few tens of steps are required for the CPM{12, 10} method to produce eigenvalues and eigenfunctions with a typical accuracy of 12 figures. However, the total number of the mesh points at which data are needed for an accurate computation of the Slater integrals by standard rules is generally much greater; as mentioned earlier, about 1,000 mesh points are required to achieve an accuracy of eight figures using Simpson's rule. Replacing the latter by a rule with more points, e.g., the Newton–Cote rule with five or six points, will indeed reduce the total number of mesh points, but such a reduction is still insufficient. Two other possible ways of improvement are available.

The first consists of using extended rules, i.e., rules in which the pointwise values of the integrand and of a number of its derivatives, if the latter are available, are involved. Rules of this type appear from time to time in the literature (see, e.g., [25]) but we are unaware of any systematic application of them.

Another way relies on a piece of information of a different nature. In addition to the pointwise values of the integrand and of its derivatives, this method also uses information on the global behavior of the integrand along the integration interval. In our case the integrand is a product of oscillatory functions whose frequencies are available. This opens up the possibility of formulating rules whose weights are no longer constant, as for the classical rules, but are frequency-dependent.

In section 5 a rule which combines all these possibilities will be described. It requires data between only 66 and 118 points.

3.3. Proposed procedure. In summary, the following main ingredients have been detected for a suitable two-stage computational strategy.

Stage 1: Solution of the Schrödinger equation using two different methods (one for $0 < x \leq x_{cut}$ and another for $x > x_{cut}$), each based on the piecewise perturbation theory.

Stage 2: Computation of Slater integrals using sets of extended frequency-dependent quadrature rules (EFDQRs).

These two stages are developed in section 4 and 5, respectively.

4. CP methods for the Schrödinger equation. These are methods for the initial value problem but they can also be used in a shooting scheme for solving the boundary value problem; see [16] for the general theory.

To illustrate the concept we consider the one-step Schrödinger equation,

$$y'' = (V(x) - E)y, \ X < x < X + h. \tag{4.1}$$

The solution is advanced from one end to the other by means of the propagation matrix algorithm:

$$\begin{bmatrix} y(X+h) \\ y'(X+h) \end{bmatrix} = \begin{bmatrix} u(h) & v(h) \\ u'(h) & v'(h) \end{bmatrix} \begin{bmatrix} y(X) \\ y'(X) \end{bmatrix}. \tag{4.2}$$

The problem then reduces to finding accurate values for the four elements of this matrix. We note that the algorithm automatically meets one of the previously stated conditions; i.e., it allows for the determination of both the solution and its first derivative.

The functions $u(\delta)$ and $v(\delta)$, with $\delta = x - X$, are called propagators and satisfy the local problem

$$y''(\delta) = (V(X+\delta) - E)y(\delta), \qquad \delta \in [0, h].$$

The initial values for u are

$$y(0) = 1,\ y'(0) = 0,$$

while those for v are

$$y(0) = 0,\ y'(0) = 1.$$

Evaluation, at $\delta = h$, of these propagators and of their derivatives with respect to δ provides the matrix elements required.

The computation of the four matrix elements involves three steps.

, , 1 The potential $V(X+\delta)$ is approximated by a sum over shifted Legendre polynomials $P_n^*(\delta/h)$ with a finite number N of terms:

$$V(X+\delta) \approx \tilde{V}(x+\delta) = \sum_{n=0}^{N} V_n h^n P_n^*(\delta/h).$$

The coefficient V_n is calculated by the quadrature:

$$V_n = \frac{2n+1}{h} \int_0^h V(X+\delta) P_i^* \left(\frac{\delta}{h}\right)\, d\delta.$$

For shifted Legendre polynomials, see [1]. The first three Legendre polynomials are $P_0^*(\gamma) = 1$, $P_1^*(\gamma) = -1 + 2\gamma$, and $P_2^*(\gamma) = 1 - 6\gamma + 6\gamma^2$ for $\gamma \in [0, 1]$.

, , 2 The potential $\tilde{V}(X+\delta)$ is separated into two parts: the constant reference potential

$$\overline{V} = V_0,$$

and the perturbation

$$\Delta V^{(N)}(\delta) = \sum_{n=1}^{N} V_n h^n P_n^*(\delta/h).$$

Indeed, the method's name is derived from this separation: as stated earlier, CP is an abbreviation for constant (based) perturbation. One way to identify the version

of a CP method[1] is to specify the values of N and Q; the latter is the number of perturbative corrections included in the algorithm. It should be noted that as the approximation concerns only the potential function, the accuracy of the solution should be practically independent of E. This expectation is confirmed by a theorem given in [19].

We have opted for version CPM{12, 10} of [19].[2] Numerical tests using this version and its comparison against some well-established codes are detailed in [19], [20], [21], and [22].

3 The four matrix elements are computed by means of some ready-to-use expressions which result from the perturbation treatment described above. These expressions become especially simple and transparent if written in terms of some ad-hoc functions. These functions were first introduced in [16] and are defined as follows:

$$\eta_{-1}(Z) = \begin{cases} \cos(|Z|^{1/2}) & \text{if } Z \le 0, \\ \cosh(Z^{1/2}) & \text{if } Z > 0, \end{cases}$$

$$\eta_0(Z) = \begin{cases} \sin(|Z|^{1/2})/|Z|^{1/2} & \text{if } Z < 0, \\ 1 & \text{if } Z = 0, \\ \sinh(Z^{1/2})/Z^{1/2} & \text{if } Z > 0, \end{cases}$$

$$\eta_m = [\eta_{m-2}(Z) - (2m-1)\eta_{m-1}(Z)]/Z, \qquad m = 1, 2, 3, \ldots.$$

Some useful properties are given below:

(i) Series expansion:

$$\eta_m(Z) = 2^m \sum_{q=0}^{\infty} \frac{g_{m\,q}\, Z^q}{(2q+2m+1)!},$$

with

$$g_{m\,q} = \begin{cases} 1 & \text{if } m = 0, \\ (q+1)(q+2)\cdots(q+m) & \text{if } m > 0. \end{cases}$$

In particular,

$$\eta_m(0) = \frac{1}{(2m+1)!!}.$$

(ii) Asymptotic behavior at large $|Z|$:

$$\eta_m(Z) \approx \begin{cases} \eta_{-1}(Z)/Z^{(m+1)/2} & \text{for odd } m, \\ \eta_0(Z)/Z^{m/2} & \text{for even } m. \end{cases}$$

[1] Other rules for identification are also available. Thus, the rule used in [19] is aimed at highlighting the accuracy properties. The version identified there as CPM$\{n_0, n_{as}\}$ is a method in which the number of terms in $\Delta V^{(N)}(\delta)$ which are used at each order of the perturbation theory varies with the order in such a way that the one-step error behaves as h^{n_0+1} when E is such that $|E - \bar{V}_0|h^2$ is small and as $h^{n_{as}+1}/\sqrt{E}$ when $E \to \infty$.

[2] Higher-order versions have recently became available; see [26], [27]. In fact, the perturbations can be calculated analytically to any order, but further progress in this direction will involve increasingly complex sets of symbolic computations.

(iii) Differentiation properties:

$$\eta'_m(Z) = \frac{1}{2}\eta_{m+1}(Z), \qquad m = -1, 0, 1, 2, \ldots.$$

Each propagator is expressed as a linear combination of such functions with perturbation-dependent coefficients. The argument of each of the η functions involved is $Z = (\bar{V} - E)h^2$; i.e., it accounts for the reference potential and for the energy.

For example, the first propagator of CPM{12, 10} is

$$u(h) = \eta_{-1}(Z) + \sum_{m=1}^{5} C_m \eta_m(Z). \tag{4.3}$$

With $\bar{V}_n = V_n h^{n+2}$, the first two coefficients are

$$C_1 = -\left[\bar{V}_1 + \bar{V}_3 + \bar{V}_5 + \bar{V}_7 + \bar{V}_9\right]/2,$$

which includes a set of first-order contributions, and

$$C_2 = \left[5\bar{V}_3 + 14\bar{V}_5 + 27\bar{V}_7 + 44\bar{V}_9\right]/2 - \left[105\bar{V}_1^2 + 63\bar{V}_2^2 + 45\bar{V}_3^2 + 35\bar{V}_4^2\right]/2520,$$

which collects some contributions from the first and second orders. The expressions of the other elements of the propagation matrix have a similar structure.

A practical advantage of any CP method with propagators expressed as linear combinations of the η functions is that the C coefficients can be calculated once, at the beginning of the whole computation. Any further computation of the propagation matrix at different E will require only the evaluation of the set of η values. This leads to a substantial reduction in CPU time.

4.1. Normalization of the solution. Differentiating (4.1) and (4.2) with respect to E gives the equation

$$y''_E = (V(x) - E)y_E - y, \; X < x < X + h, \tag{4.4}$$

and its one-step algorithm

$$\begin{bmatrix} y_E(X+h) \\ y'_E(X+h) \end{bmatrix} = \begin{bmatrix} u_E(h) & v_E(h) \\ u'_E(h) & v'_E(h) \end{bmatrix} \begin{bmatrix} y(X) \\ y'(X) \end{bmatrix} + \begin{bmatrix} u(h) & v(h) \\ u'(h) & v'(h) \end{bmatrix} \begin{bmatrix} y_E(X) \\ y'_E(X) \end{bmatrix}. \tag{4.5}$$

Calculation of the propagators with E suffixes requires only minimal extra effort. The case of $u_E(h)$ for CPM{12, 10} provides an illustration. Here $u_E(h)$ is the partial derivative of (4.3) with respect to E, an operation that involves only the η components. We have

$$u_E(h) = -\frac{1}{2}h^2\left[\eta_0(Z) + \sum_{m=1}^{5} C_m \eta_{m+1}(Z)\right], \tag{4.6}$$

where property (iii) of the η functions has been used. We see that no extra data are needed for the evaluation of $u_E(h)$.

The solution of this related equation is of direct importance in our context; see [17], [19]. First, it helps in constructing a Newton–Raphson recurrence scheme for fast localization of the eigenvalues. Second, it furnishes a simple way of evaluating the normalization constant, thus fulfilling one of the previously addressed conditions. By multiplying (4.1) by y_E, (4.4) by y, then subtracting and integrating over the current step, we get

$$\int_X^{X+h} dx\, y^2(x) = [y'(x)y_E(x) - y'_E(x)y(x)]|_X^{X+h}.$$

4.2. Determination of the frequency of the eigenfunctions. Each eigenfunction $y_{nl}(x)$, $x \in I_i$, has an oscillatory behavior, and the knowledge of its frequency, F_{nl}, will play an important role in the formulation of the frequency-dependent quadrature rules to be developed in section 5. There is no need for a highly accurate computation of the frequencies; an accuracy of up to 10% is sufficient.

The WKB approximation [28] provides a convenient method for such a purpose. Let x_{low} and x_{up} be the two ends of the so-called classically admissible interval, i.e., such that $E_{nl} - V(x) \geq 0$ for all $x \in [x_{low}, x_{up}]$. Then

$$F_{nl} = \frac{1}{x_{up} - x_{low}} \int_{x_{low}}^{x_{up}} dx \sqrt{E_{nl} - V(x)}. \tag{4.7}$$

On interval I_0 this formula must be slightly modified. The modification consists of the Langer correction, that is, using

$$V^L(x) = \frac{(l+1/2)^2}{x^2} - \frac{2Z}{x} \tag{4.8}$$

in place of $V(x)$.

A practical problem is that the resulting number of frequencies is $n_{max}^4 \times (l_{max} + 1)^4$, and this is too large for efficient computation and storage of the weights of the extended frequency-dependent quadrature rules. The following analysis shows that a reduction of this number to only n_{max}^4 is possible.

In Figure 8 we plot $V(x)$ for $l = 0, 1, 2, 3, 4$, and $Z = 1$. We see that the four curves differ visibly from each other only in the vicinity of the origin. As x is advanced they merge into each other and collectively tend to zero. Accordingly, it is expected that the l dependence of the eigenvalues E_{nl} (fixed n) and of the associated eigenfunctions $y_{nl}(x)$ on the interval I_i will be maximal for $i = 0$ and will gradually decline as i is increased. It is also expected that the shape of $y_{nl}(x)$ will tend to approach the pure trigonometric form corresponding to the free potential function $V(x) = 0$.

All these expectations are confirmed in Table 1 and Figures 9 and 10, where we have used $n = 5$. The consequence is that on any interval with $i \geq 1$ the frequencies can be accepted as being practically independent of l. This is less justified for $i = 0$. However, in what follows, this approximation is tacitly accepted on all intervals. On each interval, the values $f_n = F_{nl_{ref}}$ are retained for further use, where $l_{ref} = l_{max}/2$. The comparatively poorer quality of this approximation for $i = 0$ will be taken into account and compensated for.

5. EFDQRs. We begin this section by showing that by using information about the nature of integrand we can improve the accuracy of the integral. As an illustration we compute

$$I(\omega) = (\omega + 1) \int_0^1 dx \, \frac{1}{(1+x)^2} \cos[(\omega + 1)x] \tag{5.1}$$

by dividing the interval [0, 1] into 20 equal subranges and by applying a three-point quadrature rule on each subrange. The following three-point versions are used, where x_1, x_2, x_3 are equidistant points and $h = (x_3 - x_1)/2$:

• the standard Simpson rule,

$$\int_{x_1}^{x_3} dx \, y(x) \approx h[y(x_1) + 4y(x_2) + y(x_3)]/3\,; \tag{5.2}$$

• the extended version of it [25] which additionally uses the values of the derivatives,

$$\int_{x_1}^{x_3} dx \, y(x) \approx h[7y(x_1) + 16y(x_2) + 7y(x_3) + h(y'(x_3) - y'(x_1))]/15\,; \tag{5.3}$$

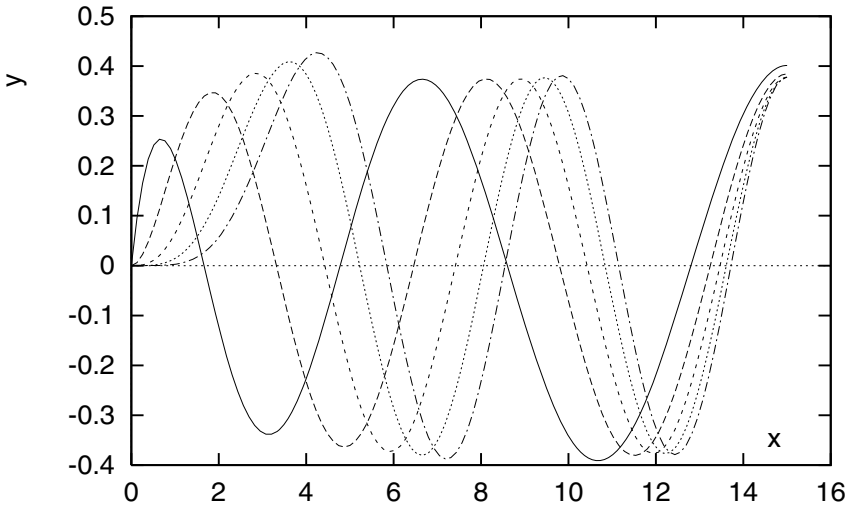

FIG. 9. *Eigenfunctions, $y_{nl}(x)$, on interval $I_0 = (0, 15]$ for $n = 5$ and various l: $l = 0$ (solid lines), $l = 1$ (long-dashed lines), $l = 2$ (short-dashed lines), $l = 3$ (dotted lines), $l = 4$ (dashed-dotted lines).*

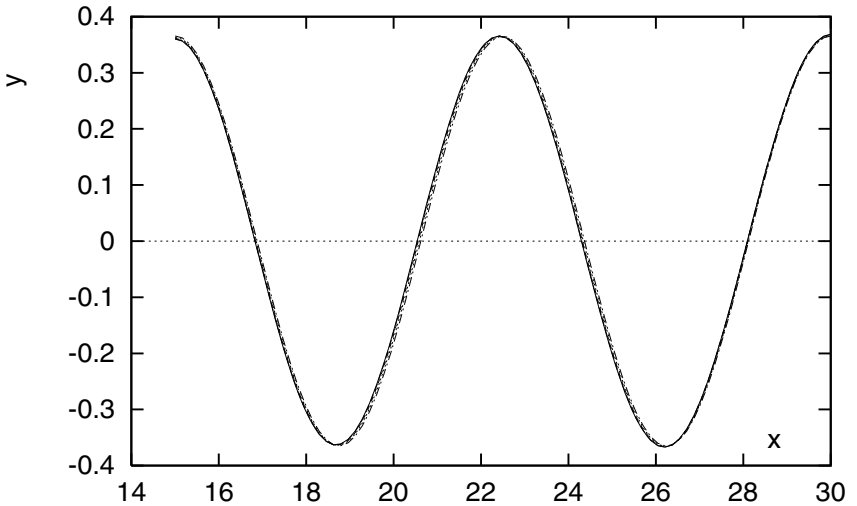

FIG. 10. *Eigenfunctions, $y_{nl}(x)$, on interval $I_1 = [15, 30]$, for $n = 5$ and various l: $l = 0$ (solid lines), $l = 1$ (long-dashed lines), $l = 2$ (short-dashed lines), $l = 3$ (dotted lines), $l = 4$ (dashed-dotted lines).*

- a version which uses the same set of input data on the integrand,

$$\int_{x_1}^{x_3} dx\, y(x) \approx h[a_1^{(0)}(y(x_1) + y(x_3)) + a_2^{(0)} y(x_2) + a_1^{(1)} h(y'(x_3) - y'(x_1))] \tag{5.4}$$

but where the coefficients $a_1^{(0)}$, $a_2^{(0)}$, and $a_1^{(1)}$ are chosen appropriately for integrands

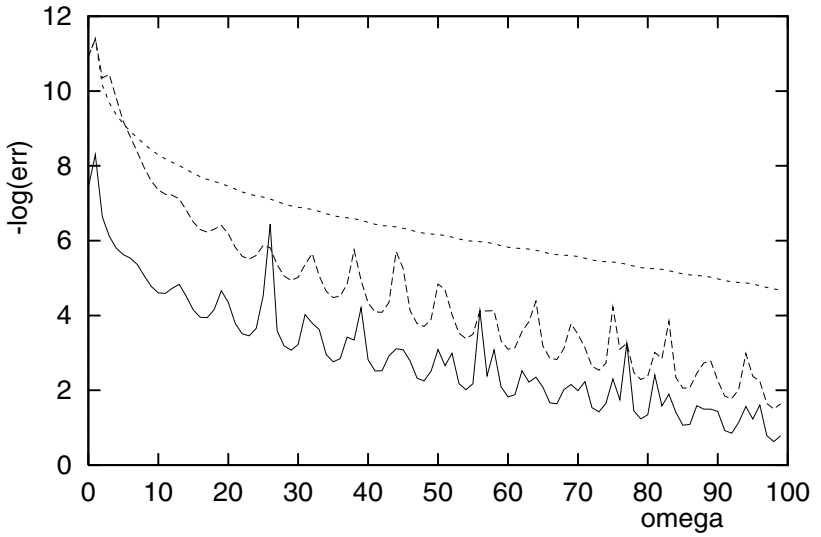

FIG. 11. *A comparison of the accuracies produced by the three quadrature rules for integral* (5.1): *Simpson* (*solid lines*), *extended Simpson* (*long-dashed lines*), *and extended Simpson with frequency dependent coefficients* (*short-dashed lines*).

of the form

$$y(x) = f_1(x)\sin(\omega x) + f_2(x)\cos(\omega x), \tag{5.5}$$

with smoothly varying $f_1(x)$ and $f_2(x)$. This case is covered by the exponential fitting procedure discussed in [23]; see also [18] for a succinct presentation. We do not enter into details about this general procedure but note that for the problem under discussion it consists of imposing the condition that (5.4) be exact if y is any of the three pairs of functions

$$x^p \exp(\pm i\omega x),\ p = 0,\ 1,\ 2. \tag{5.6}$$

The resulting system of linear equations for the three coefficients can be solved either analytically or numerically. We have opted for the numerical solution by means of the subroutine `efextqs` in the CD included with [23].

As to the quality of the three rules, the first two are exact when y is a polynomial of degree 3 and 5, respectively, while the third is exact if y is of the form (5.5), and $f_1(x)$ and $f_2(x)$ are second degree polynomials. The quantity

$$-\log[|I(\omega) - I^{comput}(\omega)|]$$

represents roughly the number of exact figures in $I(\omega)$ after the decimal point. This is displayed in Figure 11 for the three versions and for $0 < \omega < 100$. We see that all three are rather accurate for small ω. We also see that the accuracy exhibits a deterioration as ω is increased but at different rates, much in the favor of the last version, as expected.

The example clearly shows that, by exploiting the oscillatory nature of the integrand, we can significantly improve the accuracy of the result at little or no extra cost. This is the strategy adopted in the following section.

5.1. The quadrature rules. All quadrature rules involved in the calculation of the Slater integrals will be N-point extended frequency-dependent rules using equidistant mesh points, and will be of the form

$$\int_{x_1}^{x_N} dx\, y(x) \approx h \sum_{n=1}^{N} [a_n^{(0)} y(x_n) + h a_n^{(1)} y'(x_n)], \tag{5.7}$$

with $h = (x_N - x_1)/2$, where the coefficients satisfy the following symmetry/antisymmetry properties: $a_n^{(j)} = (-1)^j a_{N-n+1}^{(j)}$, $j = 0, 1$, $n = 1, 2, \ldots, N$. It follows that only N coefficients have to be calculated.

In principle, N may vary from one integral to another, but we adopted one and the same value, $N = 14$. A notable exception will be in the evaluation of the one-step inner integrals, where $N = 15$ will be used; see below.

5.1.1. Computation of the off-diagonal sector integrals J_1 and J_2. Here we are interested in the computation of $J_1(X_j, X_{j+1}, \lambda, \phi)$ and $J_2(X_j, X_{j+1}, \lambda, \phi)$ (see (2.5) and (2.8)) that occur in off-diagonal sectors. The integrand is

$$y(x) = u(x)\phi(x) = u(x) y_{n_1 l_1}(x) y_{n_2 l_2}(x), \tag{5.8}$$

where $u(x) = x^\lambda$, $1/x^{\lambda+1}$ for J_1 and J_2, respectively.

Normally, the interval $[X_j, X_{j+1}]$ is divided into n_{int} equidistant subranges and the $N = 14$ point rule (5.7) is used on each subrange with the coefficients fixed once for all subranges. The integration then requires the values of $y_{nl}(x)$ and $y'_{nl}(x)$ at $npnt = 13 n_{int} + 1$ equidistant points.

The cases $j \neq 0$ and $j = 0$ need separate treatment because some special features are present in the latter. In particular, the wavefunctions are definitely nonoscillatory in the vicinity of the origin (see also Figure 9), the frequencies exhibit a relatively important l dependence, and special care is required in J_2 at the origin because of the presence of the factor $1/x^{\lambda+1}$.

$j \neq 0$ Extensive tests have shown that $n_{int} = 5$ is sufficient for an accuracy of 10 figures in J_1 and J_2. Data is therefore required only at $npnt = 66$ points. The frequencies involved in the computation of the rule coefficients are not the eigenfunction frequencies f_{n_1} and f_{n_2}, but some linear combinations of these. This results from examination of the shape of the integrand of (5.8). Indeed, factor $u(x)$ is a smooth function on each subrange, but each of $y_{n_1 l_1}(x)$ and $y_{n_2 l_2}(x)$ is well described by the form (5.5) with the frequencies f_{n_1} and f_{n_2}, respectively. The product of the three is therefore a sum of two (5.5)-like forms, viz.,

$$y(x) = f_1^1(x)\sin(\omega_1 x) + f_2^1(x)\cos(\omega_1 x) + f_1^2(x)\sin(\omega_2 x) + f_2^2(x)\cos(\omega_2 x), \tag{5.9}$$

where $f_m^k(x)$, $m, k = 1, 2$, are smooth functions and $\omega_1 = f_{n_1} + f_{n_2}$, $\omega_2 = |f_{n_1} - f_{n_2}|$.

The 14 equations for the same number of coefficients are generated on this basis, that is, by imposing that (5.7) be exact for any of the following 14 pairs of functions:

$$x^p \exp[\pm \omega_k x],\ p = 0, 1 \ldots, 6,\ k = 1, 2, \tag{5.10}$$

and the rule with the coefficients obtained in this way will be exact when $y(x)$ is of form (5.9) and each $f_m^k(x)$ is a polynomial of at most degree 6.

$j = 0$ The coefficients are computed in the same way as for the previous case. However, since the input individual frequencies f_{n_1} and f_{n_2} now provide a less accurate representation of the actual behavior of the eigenfunctions, a narrower partition in subranges is used to compensate for the inaccuracy. Again, extensive tests have shown that $n_{int} = 9$ is satisfactory.

The computation of J_2 requires special consideration because the factor $1/x^{\lambda+1}$ is singular at the origin. As a matter of fact, an interesting property is that for the values of λ involved in the Slater integrals, that is, $|l_1 - l_2| \le \lambda \le l_1 + l_2$, the integral J_2 is finite. To see this it is sufficient to check that its integrand is finite at the origin. We rely on the well-known fact that the eigenfunction y_{nl} can be written as $y_{nl}(x) = x^{l+1} g_{nl}(x)$, where function $g_{nl}(x)$ is smooth and slowly varying near the origin and tends to a nonzero value when $x \to 0$. The integrand $y(x)$ of J_2 then reads

$$y(x) = x^{l_1+l_2+1-\lambda} g_{n_1 l_1}(x) g_{n_2 l_2}(x) \tag{5.11}$$

such that $y(0)$ is finite, and then J_2 is also finite.

Strictly speaking this result is irrelevant in the present context because the computation of J_2 is involved only for $j > 0$. However, formula (5.11) has its own importance in a different context which appears elsewhere in our computation. This is when overlap integrals of the coulomb and centrifugal behaviors $1/x$ and $1/x^2$ are required (this means that $\lambda = 0$, 1) but calculating $y(0)$ by direct use of $1/x^{\lambda+1}$ gives overflow. This can be easily avoided in the following way. Since $y'_{nl}(0) = \delta_{l\,0} g_{nl}(0)$ the evaluation at $x = 0$ of the first derivative of $y(x)$ given in (5.11) leads to the following expressions in which only the values of the first derivative of the eigenfunctions are involved:

$$\lambda = 0: \qquad y(0) = 0, \qquad y'(0) = y'_{n_1 l_1}(0) y'_{n_2 l_2}(0),$$

$$\lambda = 1: \qquad y(0) = y'_{n_1 l_1}(0) y'_{n_2 l_2}(0), \qquad y'(0) = 0.$$

5.1.2. Computation of the diagonal sector two-dimensional integral, (2.6).

The inner integral was defined earlier as

$$I(z, \lambda, \phi) = \left[\frac{1}{z^{\lambda+1}} J_1(X_i,\, z,\, \lambda, \phi) + z^{\lambda} J_2(z,\, X_{i+1},\, \lambda, \phi) \right], \tag{5.12}$$

with $\phi(x) = y_{n_1 l_1}(x) y_{n_2 l_2}(x)$. We are interested in the computation of the value of this integral and of its first derivative at the mesh points $z = x_1 (= X_i)$, $x_2, \ldots,$ $x_{npnt} (= X_{i+1})$ with $npnt = 13 n_{int} + 1$. We have used $n_{int} = 9$ on interval I_0 and $n_{int} = 7$ on all other intervals.

A convenient way to compute these integrals involves separate evaluations of the appropriate one-step integrals. We use the identities

$$\int_{x_k}^{x_{k+1}} dx\, y(x) = \int_{x_{k-m}}^{x_{k+1}} dx\, y(x) - \int_{x_{k-m}}^{x_k} dx\, y(x) \tag{5.13}$$

and

$$\int_{x_k}^{x_{k+1}} dx\, y(x) = \int_{x_k}^{x_{k+m}} dx\, y(x) - \int_{x_{k+1}}^{x_{k+m}} dx\, y(x) \tag{5.14}$$

for positive integer m. The advantage here is that the evaluation of the required one-step integral is based on the evaluation of the two integrals on the r.h.s., which can be made as accurate as needed by choosing m sufficiently large. An adverse effect is also present: the near-cancellation of similar sized numbers potentially leads to some accuracy loss. However, by using the round-off analysis tool CADNA [9] we have verified that with $m = 14$ this loss is insignificant.

We use this approach to obtain a single final (5.7)-like form for the numerical evaluation. For reasons of clarity let us take $k = 1$; obviously, in this case only the form of (5.14) can be considered. With $m = 14$ we use an $N = 15$ point rule for the first integral,

$$\int_{x_1}^{x_{15}} dx\, y(x) \approx h^* \sum_{n=1}^{15} [a_n^{*(0)} y(x_n) + h^* a_n^{*(1)} y'(x_n)], \tag{5.15}$$

where $h^* = (x_{15} - x_1)/2$, and a rule with $N - 1 = 14$ points for the second, viz.,

$$\int_{x_2}^{x_{15}} dx\, y(x) \approx h \sum_{n=2}^{15} [b_{n-1}^{(0)} y(x_n) + h b_{n-1}^{(1)} y'(x_n)], \tag{5.16}$$

where $h = (x_{15} - x_2)/2$. On subtracting we get

$$\int_{x_1}^{x_2} dx\, y(x) \approx \sum_{n=1}^{15} [c_n^{(0)} y(x_n) + c_n^{(1)} y'(x_n)], \tag{5.17}$$

where

$$c_1^{(j)} = (h^*)^{j+1} a_1^{*(j)}, \qquad j = 0,\, 1, \tag{5.18}$$

and

$$c_n^{(j)} = (h^*)^{j+1} a_n^{*(j)} + h^{j+1} b_{n-1}^{(j)}, \quad n = 2, 3, \ldots, 15, \quad j = 0,\, 1. \tag{5.19}$$

All one-step evaluations of J_1 and J_2 were made in this way, and $N = 15$ was used in all cases. Since the integrand is of the form of (5.8), its behavior is as in (5.9), and therefore the coefficients a^* of the $N = 15$ point rule are computed by imposing the conditions

$$x^{p_k} \exp[\pm \omega_k x],\ k = 1,\, 2,\ p_1 = 0,\, 1 \ldots, 7,\ p_2 = 0,\, 1 \ldots, 6 \tag{5.20}$$

(one new pair is added to conditions (5.10)) while the set (5.10) was used for the 14 coefficients b.

With the one-step values of J_1 and J_2, the integral $I(x_n,\, \lambda,\, \phi)$ is simply

$$I(x_n,\, \lambda,\, \phi) = \frac{1}{x_n^{\lambda+1}} \sum_{k=1}^{n-1} J_1(x_k,\, x_{k+1},\, \lambda,\, \phi) + x_n^{\lambda} \sum_{k=n}^{npnt-1} J_2(x_k,\, x_{k+1},\, \lambda,\, \phi).$$

As for the first derivative, the direct differentiation of (5.12) gives

$$I'(z,\, \lambda,\, \phi) = -\frac{\lambda+1}{z^{\lambda+2}} J_1(X_j,\, z,\, \lambda,\, \phi) + \lambda z^{\lambda-1} J_2(z,\, X_j,\, \lambda,\, \phi),$$

whence

$$I'(x_n,\, \lambda,\, \phi) = -\frac{\lambda+1}{x_n^{\lambda+1}} \sum_{k=1}^{n-1} J_1(x_k,\, x_{k+1},\, \lambda,\, \phi) + \lambda x_n^{\lambda-1} \sum_{k=n}^{npnt-1} J_2(x_k,\, x_{k+1},\, \lambda,\, \phi).$$

. On the interval I_0 the values to be used at $x_1 = 0$ are $I(0,\, \lambda,\, \phi) = I'(0,\, \lambda,\, \phi) = 0$, as follows from (5.8) with $y_{nl}(x) = x^{l+1} g_{nl}(x)$.

An $N = 14$ point frequency-dependent rule of form (5.7) is used to compute the outer integral, R, defined earlier as

$$R = \int_{X_j}^{X_{j+1}} dx\, y_{n_3 l_3}(x) y_{n_4 l_4}(x)\, I(x, \lambda, \phi).$$

However, the number of the frequencies is larger than before. Indeed, the x dependence of function $I(x, \lambda, \phi)$ on $x \in [X_j, X_{j+1}]$ is of the form (5.9) with $\omega_1 = f_{n_1} + f_{n_2}$ and $\omega_2 = |f_{n_1} - f_{n_2}|$. The other factor in the integrand, $y_{n_3 l_3}(x) y_{n_4 l_4}(x)$, is of the same form but with the frequencies $\omega_3 = f_{n_3} + f_{n_4}$ and $\omega_4 = |f_{n_3} - f_{n_4}|$. It follows that their product will be a function that is well described by a sum of eight functions of form (5.5) with the following eight possible frequencies: $|\omega_1 \pm \omega_3|$, $|\omega_1 \pm \omega_4|$, $|\omega_2 \pm \omega_3|$, and $|\omega_2 \pm \omega_4|$. Let these be Ω_k, $k = 1, \ldots, 8$, in descending order. The 14 coefficients are then constructed on the condition that the rule is exact for the set

$$\exp[\pm\Omega_k x],\ x \exp[\pm\Omega_k x] \text{ (for } k = 1, \ldots, 6), \exp[\pm\Omega_7 x] \text{ and } \exp[\pm\Omega_8 x]. \tag{5.21}$$

6. Hamiltonian matrix construction. Finally, we turn our attention to the efficiency of the extended frequency-dependent quadrature rules (EFDQRs) in constructing the Hamiltonian matrix in each sector. The Hamiltonian matrix in a given sector is defined by

$$(\Theta_k^{LS\Pi} | \mathcal{H} | \Theta_{k'}^{LS\Pi}), \tag{6.1}$$

where

$$\mathcal{H} = \sum_{i=1}^{2} \left(-\frac{1}{2}\nabla_i^2 - \frac{Z}{r_i} \right) + \frac{1}{r_{12}}. \tag{6.2}$$

Here, Z is the nuclear charge and $r_{12} = |\mathbf{r}_1 - \mathbf{r}_2|$, with $\mathbf{r}_1$ and $\mathbf{r}_2$ being the vector coordinates of the two electrons. L, S, and Π are the orbital, spin, and parity of the two-electron system, respectively.

The R-matrix basis states, $\Theta_k^{LS\Pi}(\mathbf{r}_1, \mathbf{r}_2)$, are expanded in each sector in terms of two-electron functions, $\Phi_{n_1 l_1 n_2 l_2}^{LS\Pi}(\mathbf{r}_1, \mathbf{r}_2)$, as follows:

$$\Theta_k^{LS\Pi}(\mathbf{r}_1, \mathbf{r}_2) = \sum_{n_1 l_1 n_2 l_2} \Phi_{n_1 l_1 n_2 l_2}^{LS\Pi}(\mathbf{r}_1, \mathbf{r}_2) \alpha_{n_1 l_1 n_2 l_2 k}^{LS\Pi}. \tag{6.3}$$

In a diagonal sector the normalized two-electron functions, $\Phi_{n_1 l_1 n_2 l_2}^{LS\Pi}(\mathbf{r}_1, \mathbf{r}_2)$, are given by

$$n_1 l_1 = n_2 l_2 : \quad \Phi_{nlnl}^{LS\Pi}(\mathbf{r}_1, \mathbf{r}_2) = x_1^{-1} y_{nl}(x_1) x_2^{-1} y_{nl}(x_2) \mathcal{Y}_{llLM_L}(\widehat{\mathbf{r}}_1, \widehat{\mathbf{r}}_2) \tag{6.4}$$

and

$$n_1 l_1 > n_2 l_2 :$$

$$\begin{aligned} \Phi_{n_1 l_1 n_2 l_2}^{LS\Pi}(\mathbf{r}_1, \mathbf{r}_2) = \frac{1}{\sqrt{2}} [& x_1^{-1} y_{n_1 l_1}(x_1) x_2^{-1} y_{n_2 l_2}(x_2) \mathcal{Y}_{l_1 l_2 LM_L}(\widehat{\mathbf{r}}_1, \widehat{\mathbf{r}}_2) \\ & + (-1)^{L+S+l_1+l_2} x_2^{-1} y_{n_1 l_1}(x_2) x_1^{-1} y_{n_2 l_2}(x_1) \mathcal{Y}_{l_2 l_1 LM_L}(\widehat{\mathbf{r}}_1, \widehat{\mathbf{r}}_2)]. \end{aligned} \tag{6.5}$$

In this latter case the sum over $n_1 l_1$ and $n_2 l_2$ in (6.2) is such that only terms in which $n_1 l_1 \geq n_2 l_2$ are included, i.e., $l_1 \geq l_2$ with the proviso that if $l_1 > l_2$, then there are no restrictions on n_1 and n_2 (except a specified maximum value, n_{max}), but if $l_1 = l_2$, then $n_1 > n_2$ if $L + S$ is odd and $n_1 \geq n_2$ if $L + S$ is even.

In (6.4) and (6.5) the angular function $\mathcal{Y}_{l_1 l_2 L M_L}$ is only nonzero if $|l_1 - l_2| \leq L \leq l_1 + l_2$. The expansion coefficients, $\alpha^{LS\Pi}_{n_1 l_1 n_2 l_2 k}$, are eventually obtained by diagonalizing the Hamiltonian matrix in each sector.

The time taken to construct a Hamiltonian matrix is dominated by the computation of the Slater integrals on diagonal sectors. In Tables 2, 3, and 4 we consider three typical cases with fixed n but increasing l that result in 8187600, 85741800, and 302869500 Slater integrals on the respective diagonal sectors.[3] We compare the EFDQR strategy developed in this paper against the Simpson Rule (SR) approach implemented in the current two-dimensional propagator [13]. We focus on the broad computational trends rather than a detailed performance analysis of the two implementations. For each case we present timings for the construction of the Hamiltonian matrix on the four diagonal sectors shown in Figure 1. The timings were performed on a single processing element on each of the following three installations.

The SR uses 1191 mesh points for each outer integral and scales consistently as expected across the three cases on each hardware platform. The resulting integrals are accurate to no better than seven significant figures. It should be noted that doubling the number of points in the SR points adds only one extra digit of accuracy. Since this rule converges linearly [24] it would require eight times as many points to achieve our targeted 10 figures of accuracy. However, the resulting computation time would be inordinately long.

The EFDQR strategy exhibits a more complicated, but equally consistent, behavior across the cases. The resulting integrals are accurate to no worse than 10 significant figures. Sector 0,0 always takes longer than sector 1,1 because of its special treatment of the origin. As mentioned in section 4.2 the frequency is only required to be accurate to within a few percent. This enables the frequency dependent weights computed in sector 1,1 to be reused in all subsequent sectors without significant loss of accuracy. This accounts for the improved performance on sectors 2,2 and 3,3. Indeed this setup time is independent of l and, within timing vagaries, can be seen to be constant on each platform.

The proportion of reusable inner integrals, $I(x_i, \lambda, \phi)$, increases progressively from Case 1 to Case 3. The EFDQR implementation exploits this characteristic by first computing and storing all possible inner integrals within a given sector. Such a strategy is practically impossible in SR because of the very large number of mesh points used. The benefit of this can be clearly seen in Table 5 which summarizes the average speedup of the EFDQR compared to SR.

7. Concluding remarks. In this paper we advocate the construction of handcrafted algorithms that exploit a problem's characteristics rather than the use of general "off the shelf" algorithms. The problem in this case is the computation of Slater integrals. We have focused on exploiting as many characteristics of the problem as possible to develop a two-stage strategy, where the first stage informs the second. In particular, we have focused on the l independence and n dependence of the frequencies of the oscillatory eigenfunctions that are solutions of the Schrödinger equation.

In the first stage the CP{12,10} method enables us to produce, to an accuracy of about 12 figures, eigenvalues, frequencies, normalized eigenfunctions, and the first derivative of the eigenfunctions in a few tens of steps using a fixed step size which is independent of n. By using this information and by exploiting the independence of the frequencies on l, we have been able to construct EFDQRs for the Slater integrals using the same mesh points. Further, the frequency-dependent weights calculated on a nonorigin diagonal sector can be used directly on any other nonorigin diagonal sector. The small number of mesh points enables storage and hence reuse of the inner integrals.

On realistic cases the resulting computational strategy is more accurate, giving an accuracy of 10 rather than 7 figures, and typically two orders of magnitude faster than the existing SR implementation. This new algorithm also improves the load balance

between diagonal and off-diagonal sectors, and it removes the bottleneck impeding current simulations involving high lying states of hydrogen.

Construction of the Hamiltonian matrix is an intermediate computation followed by parallel diagonalization. This is typically performed using multithreaded LAPACK or ScaLAPACK routines. Since each matrix element is independent there is considerable potential for parallel improvement. The next step is to exploit shared and distributed memory parallelism in the construction of the Hamiltonian matrix.

Acknowledgments. We are grateful to the UK EPSRC for the provision of computer time on the UK's two national supercomputing services. EFFICIENT DETECTION OF PERIODIC ORBITS IN CHAOTIC SYSTEMS BY STABILIZING TRANSFORMATIONS*

JONATHAN J. CROFTS† AND RUSLAN L. DAVIDCHACK†

Abstract. An algorithm for detecting periodic orbits in chaotic systems [R. L. Davidchack and Y.-C. Lai, *Phys. Rev. E* (3), 60 (1999), pp. 6172–6175], which combines the set of stabilizing transformations proposed by Schmelcher and Diakonos [*Phys. Rev. Lett.*, 78 (1997), pp. 4733–4736] with a modified semi-implicit Euler iterative scheme and seeding with periodic orbits of neighboring periods, has been shown to be highly efficient when applied to low-dimensional systems. The difficulty in applying the algorithm to higher-dimensional systems is mainly due to the fact that the number of the stabilizing transformations grows extremely fast with increasing system dimension. Here we analyze the properties of stabilizing transformations and propose an alternative approach for constructing a smaller set of transformations. The performance of the new approach is illustrated on the four-dimensional kicked double rotor map and the six-dimensional system of three coupled Hénon maps.

Key words. unstable periodic orbits, kicked double rotor map, coupled Hénon maps

DOI. 10.1137/050623401

1. Introduction.

Periodic orbits play an important role in the analysis of various types of dynamical systems. In systems with chaotic behavior, unstable periodic orbits (UPOs) form a "skeleton" for chaotic trajectories [3]. A well-regarded definition of chaos [7] requires the existence of an infinite number of UPOs that are dense in the chaotic set. Different geometric and dynamical properties of chaotic sets, such as natural measure, Lyapunov exponents, fractal dimensions, and entropies [19], can be determined from the location and stability properties of the embedded UPOs. Periodic orbits are central to the understanding of quantum-mechanical properties of nonseparable systems: The energy level density of such systems can be expressed in a semiclassical approximation as a sum over the UPOs of the corresponding classical system [9]. Topological description of a chaotic attractor also benefits from the knowledge of periodic orbits. For example, a large set of periodic orbits is highly constraining to the symbolic dynamics and can be used to extract the location of a generating partition [5, 22]. The significance of periodic orbits for the experimental study of dynamical systems has been demonstrated in a wide variety of systems [16], especially for the purpose of controlling chaotic dynamics [20] with possible application in communication [2].

It is therefore not surprising that much effort has been put into the development of methods for locating periodic solutions in different types of dynamical systems. In a limited number of cases, this can be achieved due to the special structure of the systems. Examples include the Biham–Wenzel method applicable to Hénon-like maps [1], or systems with known and well-ordered symbolic dynamics [11]. For generic systems, however, most methods described in the literature use some type of an

†Department of Mathematics, University of Leicester, Leicester LE1 7RH, UK (jc84@le.ac.uk, rld8@mcs.le.ac.uk).

iterative scheme that, given an initial condition (seed), converges to a periodic orbit of the chaotic system. In order to locate all UPOs with a given period p, the convergence basin of each orbit for the chosen iterative scheme must contain at least one seed. The seeds are often chosen either at random from within the region of interest, from a regular grid, or from a chaotic trajectory with or without close recurrences. Typically, the iterative scheme is chosen from one of the "globally" convergent methods of quasi-Newton or secant type. However, experience suggests that even the most sophisticated methods of this type suffer from a common problem: With increasing period, the basin size of the UPOs becomes so small that placing a seed within the basin with one of the above listed seeding schemes is practically impossible [18].

A different approach, which appears to effectively deal with the problem of reduced basin sizes, has been proposed by Schmelcher and Diakonos (SD) [25, 26]. The basic idea is to transform the dynamical system in such a way that the UPOs of the original system become stable and can be located by simply following the evolution of the transformed dynamical system. That is, to locate period-p orbits of a discrete dynamical system

$$U: \quad x_{j+1} = f(x_j), \quad f: \mathbb{R}^n \mapsto \mathbb{R}^n, \tag{1}$$

one considers an associated flow

$$\Sigma: \quad \frac{dx}{ds} = Cg(x), \tag{2}$$

where $g(x) = f^p(x) - x$ and C is an $n \times n$ constant orthogonal matrix. It is easy to see that map $f^p(x)$ and flow Σ have identical sets of fixed points for any C, while C can be chosen such that unstable period-p orbits of U become stable fixed points of Σ.

Since it is not generally possible to choose a single matrix C that would stabilize all UPOs of U, the idea is to find the smallest possible set of matrices $\mathcal{C} = \{C_k\}_{k=1}^{K}$ such that, for each UPO of U, there is at least one matrix $C \in \mathcal{C}$ that transforms the unstable orbit of U into a stable fixed point of Σ. To this end, Schmelcher and Diakonos have put forward the following conjecture [25].

CONJECTURE 1. $\mathcal{C}_{\mathrm{SD}}$ $n \times n$ ± 1 $n \times n$ G $C \in \mathcal{C}_{\mathrm{SD}}$ CG

OBSERVATION 1. $\mathcal{C}_{\mathrm{SD}}$ B_n [14] n $\mathcal{C}_{\mathrm{SD}}$ $K = 2^n n!$

The above conjecture has been verified for $n \leq 2$ and appears to be true for $n > 2$, but, thus far, no proof has been presented. According to this conjecture, any periodic orbit whose stability matrix does not have eigenvalues equal to one can be transformed into a stable fixed point of Σ with $C \in \mathcal{C}_{\mathrm{SD}}$. In practice, to locate periodic orbits of the map U, we try to integrate the flow Σ from a given initial condition (seed) using different matrices from the set $\mathcal{C}_{\mathrm{SD}}$. Some of the resulting trajectories will converge to fixed points, while others will fail to do so, either leaving the region of interest or failing to converge within a specified number of steps.

The main advantage of the SD approach is that the convergence basins of the stabilized UPOs appear to be much larger than the basins produced by other iterative schemes [26, 15, 6], making it much easier to select a useful seed. Moreover, depending on the choice of the stabilizing transformation, the SD method may converge to several different UPOs from the same seed.

The flow Σ can be integrated by any off-the-shelf numerical integrator. Schmelcher and Diakonos have enjoyed considerable success using a simple Euler method. However, the choice of the integrator for this problem is governed by considerations very different from those typically used to construct an ODE solver. Indeed, to locate a fixed point of the flow, it may not be very efficient to follow the flow with some prescribed accuracy. Therefore, local error considerations, for example, are not as important. Instead, the goal is to have a solver that can reach the fixed point in as few integration steps as possible. In fact, as shown by Davidchack and Lai [4], the efficiency of the method can be improved dramatically when the solver is constructed specifically with the above goal in mind. In particular, recognizing the typical stiffness of the flow Σ, Davidchack and Lai have proposed a modified semi-implicit Euler method:

$$x_{j+1} = x_j + [\beta s_j C^{\mathsf{T}} - G_j]^{-1} g(x_j), \tag{3}$$

where $\beta > 0$ is a scalar parameter, $s_j \equiv \|g(x_j)\|$ is an L_2 norm, $G_j \equiv Dg(x_j)$ is the Jacobian matrix, and "T" denotes transpose. Note that, away from the root of g, the above iterative scheme is a semi-implicit Euler method with step size $h = (\beta s_j)^{-1}$ and, therefore, it can follow the flow Σ with a much larger step size than an explicit integrator (e.g., Euler or Runge–Kutta). Close to the root, the proposed scheme can be shown to converge quadratically [15], analogous to the Newton–Raphson method.

Another important ingredient of the algorithm presented in [4] is the seeding with already detected periodic orbits of neighboring periods. This seeding scheme appears to be superior to the typically employed schemes and enables fast detection of plausibly all[1] periodic orbits of increasingly larger periods in generic low-dimensional chaotic systems. For example, for the Ikeda map at traditional parameter values, the algorithm presented in [4] was able to locate plausibly all periodic orbits up to period 22 for a total of more than 10^6 orbit points. Obtaining a comparable result with generally employed techniques requires an estimated 10^5 larger computational effort.

While the stabilization approach is straightforward for relatively low-dimensional systems, direct application to higher-dimensional systems is much less efficient due to the rapid growth of the number of matrices in $\mathcal{C}_{\mathrm{SD}}$. Even though it appears that, in practice, far fewer transformations are required to stabilize all periodic orbits of a given chaotic system [21], the sufficient subset of transformations is not known a priori. It is also clear that the route of constructing a universal set of transformations is unlikely to yield substantial reduction in the number of such transformations. For instance, a smaller set of universal transformations with $K = (n+1)!$, which is isomorphic to the Weyl group A_n, is sufficient to stabilize all types of periodic orbits for $n < 4$ but can be shown to fail for certain types of orbits when $n \geq 4$. Therefore, a more promising way of using stabilizing transformations for locating periodic orbits in high-dimensional systems is to design such transformations based on the information about the properties of the system under investigation.

[1] It is not possible to prove, within our approach, the completeness of the detected sets of UPOs. Rather, our assertion of completeness is based on the plausibility argument. The following three criteria are used for the validation of the argument:

(i) Methods based on rigorous numerics (e.g., in [8]) have located the same UPOs in cases where such comparison is possible (usually for low periods, since these methods are less efficient).

(ii) Our search strategy scales with the period p (see section 4 and [6]). If we can tune it to locate all UPOs for low periods (where we can verify the completeness using (i)), it is likely (but not provably) capable of locating all UPOs of higher periods as well.

(iii) For maps with symmetries, we test the completeness by verifying that all the symmetric partners for all detected UPOs have been found (see sections 4.1 and 4.2).

In this paper, we propose to construct stabilizing transformations based on the knowledge of the stability matrices of already detected periodic orbits (used as seeds). The advantage of our approach is in a substantial reduction of the number of transformations, which increases the efficiency of the detection algorithm, especially in the case of higher-dimensional systems. The layout of the paper is as follows. In section 2 we study the properties of the stabilizing transformations for $n = 2$ and their relationship to the properties of the stability matrix of a periodic orbit. In section 3 we extend the analysis to higher-dimensional systems and show how to construct stabilizing transformations using the knowledge of the stability matrices of already detected periodic orbit points. In particular, we argue that the stabilizing transformations depend essentially on the signs of unstable eigenvalues and the directions of the corresponding eigenvectors of the stability matrices. Section 4 illustrates the application of the new stabilizing transformations to the detection of periodic orbits in a four-dimensional kicked double rotor map and a six-dimensional system of three coupled Hénon maps. We conclude in section 5 with the summary and discussion of possible further developments of the stabilizing transformations approach.

2. Stabilizing transformations in two dimensions. The stability of a fixed point x^* of the flow Σ is determined by the real parts of the eigenvalues of the matrix CG, where $G \equiv Dg(x^*)$ is the Jacobian matrix of $g(x)$ evaluated at x^*. For x^* to be a stable fixed point of Σ, the matrix C has to be such that all the eigenvalues of CG have negative real parts. In order to understand what properties of G determine the choice of a particular stabilizing transformation C, we use the following parametrization for the general two-dimensional orthogonal matrices:

$$C_{s,\alpha} = \begin{pmatrix} s\cos\alpha & \sin\alpha \\ -s\sin\alpha & \cos\alpha \end{pmatrix}, \tag{4}$$

where $s = \pm 1$ and $-\pi < \alpha \le \pi$. When $\alpha = -\pi/2,\ 0,\ \pi/2$, or π, we obtain the set of matrices $\mathcal{C}_{\rm SD}$. For example, $C_{1,\pi/2} = \left(\begin{smallmatrix} 0 & 1 \\ -1 & 0 \end{smallmatrix}\right)$ and $C_{-1,\pi} = \left(\begin{smallmatrix} 1 & 0 \\ 0 & -1 \end{smallmatrix}\right)$.

If we write $G \equiv g_{ij}$ $(i, j = 1, 2)$, then the eigenvalues of $C_{s,\alpha}G$ are given by the following equations:

$$\sigma_{1,2} = -A\cos(\alpha - \theta) \pm \sqrt{A^2\cos^2(\alpha - \theta) - s\det G}, \tag{5}$$

where $\det G = g_{11}g_{22} - g_{12}g_{21}$, $A = \frac{1}{2}\sqrt{(sg_{11} + g_{22})^2 + (sg_{12} - g_{21})^2}$, and

$$\tan\theta = \frac{sg_{12} - g_{21}}{-sg_{11} - g_{22}}, \qquad -\pi < \theta \le \pi. \tag{6}$$

Note that the signs of the numerator and denominator are significant for defining the angle θ in the specified range and should not be canceled out. It is clear from (5) that both eigenvalues have negative real parts when

$$s = \bar{s} \equiv \operatorname{sgn}\det G \qquad \text{and} \qquad |\alpha - \theta| < \tfrac{\pi}{2}, \tag{7}$$

provided that $\det G \neq 0$. This result proves the validity of Conjecture 1 for $n = 2$. Moreover, it shows that there are typically two matrices in $\mathcal{C}_{\rm SD}$ that stabilize a given fixed point.

The parameter θ clearly plays an important role in the above analysis. The following theorems show its relationship to the eigenvalues and eigenvectors of the stability matrix of a fixed point.

THEOREM 1. x^* $f^p(x) : \mathbb{R}^2 \mapsto \mathbb{R}^2$ $Df^p(x^*)$ $\lambda_{1,2}$ $|\lambda_2| < 1 < |\lambda_1|$ $0 \le \phi_{1,2} < \pi$ $v_{1,2} = (\cos\phi_{1,2}, \sin\phi_{1,2})^\mathsf{T}$ θ (6):

1. $\lambda_1 < -1$:

$$\theta \in \left(-\tfrac{\pi}{2}, \tfrac{\pi}{2}\right). \tag{8}$$

$|\lambda_1| \gg 1$

$$\theta \approx (\phi_1 - \phi_2)(\mathrm{mod}\ \pi) - \tfrac{\pi}{2}. \tag{9}$$

2. $\lambda_1 > 1$:

$$\theta = \begin{cases} \frac{3\pi}{2} - \phi_1 - \phi_2, & 0 < \phi_1 - \phi_2 < \pi, \\ \frac{\pi}{2} - \phi_1 - \phi_2, & -\pi < \phi_1 - \phi_2 < 0. \end{cases} \tag{10}$$

. The matrix $G = Df^p(x^*) - I$, where I is the identity matrix, can be written as follows:

$$G \equiv \begin{pmatrix} g_{11} & g_{12} \\ g_{21} & g_{22} \end{pmatrix} = \begin{pmatrix} \cos\phi_1 & \cos\phi_2 \\ \sin\phi_1 & \sin\phi_2 \end{pmatrix} \begin{pmatrix} \lambda_1 - 1 & 0 \\ 0 & \lambda_2 - 1 \end{pmatrix} \begin{pmatrix} \cos\phi_1 & \cos\phi_2 \\ \sin\phi_1 & \sin\phi_2 \end{pmatrix}^{-1}. \tag{11}$$

1. Since $\det G = (\lambda_1 - 1)(\lambda_2 - 1) > 0$, we set $s = 1$ and obtain from (6)

$$\tan\theta = \frac{(\lambda_1 - \lambda_2)\cot(\phi_1 - \phi_2)}{2 - \lambda_1 - \lambda_2}, \tag{12}$$

where, just as in (6), as well as in (13) and (16) below, the signs of the numerator and denominator should not be canceled out. Since $2 - \lambda_1 - \lambda_2 > 0$, we have that $\cos\theta > 0$ or

$$\theta \in \left(-\tfrac{\pi}{2}, \tfrac{\pi}{2}\right).$$

For $|\lambda_1| \gg 1$, (12) yields

$$\tan\theta \approx -\cot(\phi_1 - \phi_2),$$

and, given (8), the result in (9) immediately follows.

2. In this case $\det G = (\lambda_1 - 1)(\lambda_2 - 1) < 0$; thus, from (6) with $s = -1$,

$$\begin{aligned} \tan\theta &= \frac{(\lambda_2 - \lambda_1)\cos(\phi_1 + \phi_2)/\sin(\phi_1 - \phi_2)}{(\lambda_2 - \lambda_1)\sin(\phi_1 + \phi_2)/\sin(\phi_1 - \phi_2)} \\ &= \frac{-\cos(\phi_1 + \phi_2)/\sin(\phi_1 - \phi_2)}{-\sin(\phi_1 + \phi_2)/\sin(\phi_1 - \phi_2)}, \end{aligned} \tag{13}$$

since $\lambda_2 - \lambda_1 < 0$. The result in (10) follows. □

THEOREM 2. x^* $f^p(x) : \mathbb{R}^2 \mapsto \mathbb{R}^2$ $Df^p(x^*)$ $\lambda_{1,2} = \lambda \pm \mathrm{i}\omega$

$$\begin{aligned} &\theta \in \left(-\tfrac{\pi}{2}, \tfrac{\pi}{2}\right) && \lambda < 1, \\ &\theta \in \left(-\pi, -\tfrac{\pi}{2}\right) \bigcup \left(\tfrac{\pi}{2}, \pi\right) && \lambda > 1. \end{aligned} \tag{14}$$

. The stability matrix can be decomposed as follows:

$$Df^p(x^*) = \begin{pmatrix} \cos\phi & \mathrm{e}^{\eta} \\ \sin\phi & 0 \end{pmatrix} \begin{pmatrix} \lambda & \omega \\ -\omega & \lambda \end{pmatrix} \begin{pmatrix} \cos\phi & \mathrm{e}^{\eta} \\ \sin\phi & 0 \end{pmatrix}^{-1}, \tag{15}$$

where $\eta \in \mathbb{R}$. Given that $G = Df^p(x^*) - I$, we have from (6) that

$$\tan\theta = \frac{-\omega \cosh\eta / \sin\phi}{1-\lambda}. \tag{16}$$

The result in (14) follows from the sign of the denominator. □

The key message of the above theorems is that the stabilizing transformation matrix depends mostly on the directions of the eigenvectors and the signs of the unstable[2] eigenvalues (or their real parts), and only marginally on the actual magnitudes of the eigenvalues. This means that a transformation that stabilizes a given fixed point x^* of f^p will also stabilize fixed points of all periods with similar directions of eigenvectors and signs of the unstable eigenvalues. In the next section, we will show how this observation can be used to construct stabilizing transformations for efficient detection of periodic orbits in systems with $n > 2$.

3. Extension to higher-dimensional systems. To extend the analysis of the preceding section to higher-dimensional systems, we note that the matrix $C_{\bar{s},\theta}$, as defined by (4), (6), and (7), is closely related to the orthogonal part of the of G [10]. Recall that any nonsingular $n \times n$ matrix can be uniquely represented as a product

$$G = QB, \tag{17}$$

where Q is an orthogonal matrix and B is a symmetric positive definite matrix. The following theorem provides the link between $C_{\bar{s},\theta}$ and Q for $n = 2$.

THEOREM 3. $G \in \mathbb{R}^{2\times 2}$ $G = QB$ Q B $C_{\bar{s},\theta}$ (4), (6), (7) Q

$$C_{\bar{s},\theta} = -Q^{\mathsf{T}}. \tag{18}$$

. Since $C_{\bar{s},\theta}$ is an orthogonal matrix by definition, it is sufficient to prove that $C_{\bar{s},\theta}G$ is symmetric negative definite. Then, by the uniqueness of the polar decomposition, it must be equal to $-B$.

Denote by b_{ij} the element in the ith row and jth column of $C_{\bar{s},\theta}G$. We must show that $b_{12} = b_{21}$. Using (6), we have that

$$\begin{aligned} b_{12} &= \bar{s}g_{12}\cos\theta + g_{22}\sin\theta \\ &= \left[\bar{s}g_{12} + g_{22}\frac{\bar{s}g_{12} - g_{21}}{-\bar{s}g_{11} - g_{22}}\right]\cos\theta \\ &= \left[\frac{g_{11}g_{12} + g_{21}g_{22}}{\bar{s}g_{11} + g_{22}}\right]\cos\theta \end{aligned} \tag{19}$$

[2]That is, eigenvalues whose magnitude is larger than one.

and, similarly,

$$b_{21} = g_{21}\cos\theta - \bar{s}g_{11}\sin\theta = \left[g_{21} - \bar{s}g_{11}\frac{\bar{s}g_{12} - g_{21}}{-\bar{s}g_{11} - g_{22}}\right]\cos\theta = \left[\frac{g_{11}g_{12} + g_{21}g_{22}}{\bar{s}g_{11} + g_{22}}\right]\cos\theta\,; \tag{20}$$

hence the matrix $C_{\bar{s},\theta}G$ is symmetric. Since, by definition, θ and $\bar{s}$ are chosen such that the eigenvalues of $C_{\bar{s},\theta}G$ are negative, the matrix $C_{\bar{s},\theta}G$ is negative definite. Finally, by the uniqueness of the polar decomposition,

$$C_{\bar{s},\theta}G = -B = -Q^{\mathsf{T}}G\,,$$

which completes the proof. □

For $n > 2$, we can always use the polar decomposition to construct a transformation that will stabilize a given fixed point. Indeed, if a fixed point x^* of an n-dimensional flow has a nonsingular matrix $G \equiv Dg(x^*)$, then we can calculate the polar decomposition $G = QB$ and use

$$C = -Q^{\mathsf{T}} \tag{21}$$

to stabilize x^*. Moreover, by analogy with the two-dimensional case, we can expect that the same matrix C will also stabilize fixed points $\tilde{x}$ with the matrix $\tilde{G} \equiv Dg(\tilde{x})$, as long as the orthogonal part $\tilde{Q}$ of the polar decomposition $\tilde{G} = \tilde{Q}\tilde{B}$ is sufficiently close to Q. More precisely, we have the following observation.

OBSERVATION 2. *C [illegible] $\tilde{x}$ [illegible] $Q\tilde{Q}^{\mathsf{T}}$ [illegible]*

We base this observation on the following corollary of Lyapunov's stability theorem [13].

COROLLARY 4. *[illegible] $B \in \mathbb{R}^{n\times n}$ [illegible] $Q \in \mathbb{R}^{n\times n}$ [illegible] QB [illegible]*. According to Lyapunov's theorem, a matrix $A \in \mathbb{R}^{n\times n}$ has all eigenvalues with positive real parts if and only if there exists a symmetric positive definite $G \in \mathbb{R}^{n\times n}$ such that $GA + A^{\mathsf{T}}G = H$ is positive definite.

Let $A = QB$ and let us choose G in the form $G = \frac{1}{2}QB^{-1}Q^{\mathsf{T}}$. Since B is positive definite, its inverse B^{-1} is also positive definite, and, since G and B^{-1} are related by a congruence transformation, according to Sylvester's inertia law [12], G is also positive definite. Now,

$$GQB + (QB)^{\mathsf{T}}G = \tfrac{1}{2}QB^{-1}Q^{\mathsf{T}}QB + \tfrac{1}{2}BQ^{\mathsf{T}}QB^{-1}Q^{\mathsf{T}} = \tfrac{1}{2}[Q + Q^{\mathsf{T}}].$$

Therefore, QB has eigenvalues with positive real parts if and only if $\frac{1}{2}[Q + Q^{\mathsf{T}}]$ is positive definite. The proof is completed by observing that, for orthogonal matrices, the eigenvalues of $\frac{1}{2}[Q + Q^{\mathsf{T}}]$ are equal to the real parts of the eigenvalues of Q. □

Note that Observation 2 is a direct generalization of conditions in (7) which are equivalent to requiring that the eigenvalues of $C_{s,\alpha}C_{\bar{s},\theta}^{\mathsf{T}}$ have positive real parts.

In the scheme where already detected periodic orbits are used as seeds to detect other orbits [4], we can use C in (21) as a stabilizing matrix for the seed x^*. Based on the analysis in section 2, this will allow us to locate a periodic orbit in the neighborhood of x^* with similar invariant directions and the same signs of the unstable

eigenvalues. Note, however, that the neighborhood of the seed x^* can also contain periodic orbits with the similar invariant directions but with some eigenvalues having the opposite sign (i.e., orbits with and without reflections). To construct transformations that would stabilize such periodic orbits, we can determine the eigenvalues and eigenvectors of the stability matrix of x^*,

$$Df^p(x^*) = V\Lambda V^{-1}, \tag{22}$$

where $\Lambda \equiv \mathrm{diag}(\lambda_1, \ldots, \lambda_n)$ is the diagonal matrix of eigenvalues of $Df^p(x^*)$ and V is the matrix of eigenvectors, and then calculate the polar decomposition of the matrix

$$\hat{G} = V(S\Lambda - I)V^{-1}, \tag{23}$$

where $S = \mathrm{diag}(\pm 1, \pm 1, \ldots, \pm 1)$. Note that, as follows from the analysis in section 2 for $n = 2$ and numerical evidence for $n > 2$, changing the sign of a stable eigenvalue will not result in a substantially different stabilizing transformation. Therefore, we restrict our attention to the following subset of S:

$$S_{ii} = \begin{cases} \pm 1, & |\lambda_i| > 1 \\ 1, & |\lambda_i| < 1 \end{cases} \quad \text{for} \quad i = 1, \ldots, n. \tag{24}$$

For a seed with k real unstable eigenvalues, this results in 2^k possible transformations. Note that, on the one hand, this set is much smaller than $\mathcal{C}_{\mathrm{SD}}$, while on the other hand, it allows us to target all possible types of periodic orbits that have invariant directions similar to those at the seed.

4. Numerical results. In this section we illustrate the performance of the new stabilizing transformations on a four-dimensional kicked double rotor map [24] and a six-dimensional system of three coupled Hénon maps [23]. Both systems are highly chaotic, and the number of UPOs is expected to grow rapidly with increasing period. The goal is to locate many UPOs of increasingly larger period. Of course, the completeness of the set of orbits for each period cannot be guaranteed, but it can be established with a high degree of certainty by using the plausibility criteria outlined in the introduction.

In order to start the detection process, we need to have a small set of periodic orbits (of period $p > 1$) that can be used as seeds. Such orbits can be located using, for example, random seeds and the standard Newton–Raphson method (or the scheme in (3) with $\beta = 0$). We can then use these periodic orbits as seeds to construct the stabilizing transformations and detect more UPOs with higher efficiency. The process can be iterated until we find no more orbits of a given period. In our previous work [4, 6] we showed that for two-dimensional maps such as Hénon and Ikeda it is sufficient to use period-$(p-1)$ orbits as seeds to locate plausibly all period-p orbits. For higher-dimensional systems, such as those considered in the present work, these seeds may not be sufficient. However, it is always possible to use more seeds by, for example, locating some of the period-$(p+1)$ orbits, which can then be used as seeds to complete the detection of period-p orbits. The following recipe can be used as a general guideline for developing a specific detection scheme for a given system:

1. Find a set of orbit points of low period using random seeds and the iterative scheme in (3) with $\beta = 0$ (i.e., the Newton–Raphson scheme).

2. To locate period-p orbits, first use period-$(p-1)$ orbits as seeds. For each seed x_0, construct 2^k stabilizing transformations C using (22)–(24), where k is the number of unstable eigenvalues of $Df^{p-1}(x_0)$.

3. Starting from x_0 and with a fixed value of $\beta > 0$, use the iteration scheme in (3) to construct a sequence $\{x_i\}$ for each of the 2^k stabilizing transformations. If a sequence converges to a point, check whether it is a new period-p orbit point and, if so, proceed to find a complete orbit by iterating the map f.

4. Repeat steps 2–3 for several β in order to determine the optimal value of this parameter (see explanation below).

5. Repeat steps 2–4 using newly found period-p points as seeds to search for period-$(p+1)$ orbits.

6. Repeat steps 2–4 using an incomplete set of period-$(p+1)$ orbits as seeds to find any missing period-p orbits.

Although we know that the action of β is to increase the basin size of the stabilized points, it is not known a priori what values of β to use for a given system and period. Monitoring the fraction of seeds that converge to periodic orbits, we observe that it grows with increasing β until it reaches saturation, indicating that the iterative scheme faithfully follows the flow Σ. On the other hand, larger β translates into smaller integration steps and, therefore, longer iteration sequences. Thus the optimal value of β is just before the saturation point. As demonstrated in our previous work [4] and observed in the numerical examples presented in the following sections, this value appears to scale exponentially with the period and can be estimated based on the information about the detection pattern at lower periods.

The stopping criteria in step 3, which we use in the numerical examples discussed below, are as follows. The search for UPOs is conducted within a rectangular region containing a chaotic invariant set. The sequence $\{x_i\}$ is terminated if (i) x_i leaves the region, (ii) i becomes larger than a predefined maximum number of iterations (we use $i > 100 + 5\beta$), (iii) the sequence converges, such that $\|g(x_i)\| <$, g. In cases (i) and (ii) a new sequence is generated from a different seed and/or with a different stabilizing matrix. In case (iii) five Newton iterations are applied to x_i to allow convergence to a fixed point to within the round-off error. A point x^* for which $\|g(x^*)\|$ is the smallest is identified with a fixed point of f^p. The maximum round-off error over the set $\mathcal{X}_p$ of all detected period-p orbit points,

$$\epsilon_{\max}(p) = \max\{\|g(x^*)\| : x^* \in \mathcal{X}_p\}, \tag{25}$$

is monitored in order to assess the accuracy of the detected orbits.

To check if the newly detected orbit is different from those already detected, its distance to other orbit points is calculated: If $\|x^* - y^*\|_\infty >$, x for all previously detected orbit points y^*, then x^* is a new orbit point. Even for a large number of already detected UPOs, this check can be done very quickly by presorting the detected orbit points along one of the system coordinates and performing a binary search for the points within , x of x^*. The infinity norm in the above expression is used for the computational efficiency of this check.

The minimum distance between orbit points,

$$d_{\min}(p) = \min\{\|x^* - y^*\|_\infty : x^*, y^* \in \mathcal{X}_p\}, \tag{26}$$

is monitored, and the algorithm is capable of locating all isolated UPOs of a given period p as long as $\epsilon_{\max}(p) <$, $g \lesssim$, $x < d_{\min}(p)$. Since typically $\epsilon_{\max}(p)$ increases and $d_{\min}(p)$ decreases with p (see Tables 1 and 2), the above conditions can be satisfied up to some period, after which higher-precision arithmetic needs to be used in the evaluation of the map. For the numerical examples presented in the following sections we use double-precision computation with , $g = 10^{-6}$ and , $x = 10^{-5}$.

TABLE 1

Number $n(p)$ of prime period-p UPOs, and the number $N(p)$ of fixed points of p-times iterated map for the kicked double rotor map. The asterisk for $p = 8$ indicates that this set of orbits is not complete. Parameters $\epsilon_{\max}(p)$ and $d_{\min}(p)$ are defined in (25) and (26).

p	$n(p)$	$N(p)$	$\epsilon_{\max}(p)$	$d_{\min}(p)$
1	12	12	$1.0 \cdot 10^{-14}$	$1.3 \cdot 10^{0}$
2	45	102	$5.9 \cdot 10^{-14}$	$3.4 \cdot 10^{-1}$
3	152	468	$5.8 \cdot 10^{-13}$	$6.2 \cdot 10^{-2}$
4	522	2190	$2.7 \cdot 10^{-12}$	$6.9 \cdot 10^{-3}$
5	2200	11 012	$2.6 \cdot 10^{-11}$	$1.1 \cdot 10^{-3}$
6	9824	59 502	$1.6 \cdot 10^{-10}$	$1.8 \cdot 10^{-4}$
7	46 900	328 312	$9.7 \cdot 10^{-10}$	$9.1 \cdot 10^{-5}$
8*	229 082	1 834 566	$1.2 \cdot 10^{-8}$	$5.5 \cdot 10^{-5}$

4.1. Kicked double rotor map. The kicked double rotor map describes the dynamics of a mechanical system known as the double rotor under the action of a periodic kick [24]. It is a four-dimensional map defined by

$$\begin{pmatrix} x_{n+1} \\ y_{n+1} \end{pmatrix} = \begin{pmatrix} My_n + x_n \pmod{2\pi} \\ Ly_n + c \sin x_{n+1} \end{pmatrix}, \tag{27}$$

where $x_n \in \mathbb{S}^2$ are the angle coordinates and $y_n \in \mathbb{R}^2$ are the angular velocities after each kick. Parameters L and M are constant 2×2 matrices that depend on the masses, lengths of rotor arms, and friction at the pivots, while $c \in \mathbb{R}^2$ is a constant vector whose magnitude is proportional to the kicking strength f_0. In our numerical tests we have used the same parameters as in [24], with the kicking strength $f_0 = 8.0$.

The following example illustrates the stabilizing properties of the transformations constructed on the basis of periodic orbits. Let us take a typical period-3 orbit point $x^* = (0.6767947, 5.8315697)$, $y^* = (0.9723920, -7.9998313)$ as a seed for locating period-4 orbits. The Jacobian matrix $Df^3(x^*, y^*)$ of the seed has eigenvalues $\Lambda = \mathrm{diag}(206.48, -13.102, -0.000373, 0.000122)$. Therefore, based on the scheme discussed in section 3, (22)–(24), we can construct four stabilizing transformations C corresponding to (S_{11}, S_{22}) in (24) being equal to $(+,+)$, $(-,+)$, $(+,-)$, and $(-,-)$. Of the total of 2190 orbit points of period 4 (see Table 1), the transformations C_1, C_2, C_3, and C_4 stabilize $\#(1) = 532$, $\#(2) = 544$, $\#(3) = 474$, and $\#(4) = 516$ orbit points, respectively, and these sets of orbits are almost completely nonoverlapping. That is, the number of orbits stabilized by both C_1 and C_2 is $\#(1 \cap 2) = 2$. Similarly, $\#(1 \cap 3) = 16$, $\#(1 \cap 4) = 0$, $\#(2 \cap 3) = 0$, $\#(2 \cap 4) = 14$, and $\#(3 \cap 4) = 0$. On the other hand, the number of period-4 orbits stabilized by at least one of the four transformations is $\#(1 \cup 2 \cup 3 \cup 4) = 2034$. This is a typical picture for other seeds of period 3 as well as other periods.

This example provides evidence for the validity of our approach to constructing the stabilizing transformations in high-dimensional systems based on periodic orbits. It also shows that, in the case of the double rotor map, a single seed is sufficient for constructing transformations that stabilize a majority of the UPOs. Of course, in order to locate the UPOs, we need to ensure that the seeds are in the convergence basins of the stabilized periodic orbits. That is why we need to use more seeds to locate plausibly all periodic orbits of a given period. Still, because of the enlarged basins of the stabilized orbits, the number of seeds is much smaller than that required with iterative schemes that do not use the stabilizing transformations.

Compared to the total of 384 matrices in $\mathcal{C}_{\mathrm{SD}}$, we use only two or four transformations for each seed, depending on the number of unstable directions of the seed

orbit points. Yet, the application of the detection scheme outlined in section 4 allows us to locate plausibly all periodic orbits of the double rotor map up to period 7. Table 1 also includes the number of detected period-8 orbits that were used as seeds to complete the detection of period 7.

The confidence with which we claim to have found plausibly complete sets of periodic orbits for each period is enhanced by the symmetry consideration. That is, since the double rotor map is invariant under the change of variables $(x, y) \mapsto (2\pi - x, -y)$, a necessary condition for the completeness of the set of orbits for each period is that for any orbit point (x^*, y^*) the set also contains an orbit point $(2\pi - x^*, -y^*)$. Even though this condition was not used in the detection scheme, we find that the detected sets of orbits (apart from period 8) satisfy this symmetry condition. Of course, this condition is not sufficient to prove the completeness of the detected sets of UPOs, but, combined with the exhaustive search procedure presented above, it provides a strong indication of the completeness.

4.2. Coupled Hénon maps. Another system we use to test the efficacy of our approach is a six-dimensional system of three coupled Hénon maps (CHM),

$$x_{n+1}^j = a - (\tilde{x}_n^j)^2 + b x_{n-1}^j \quad \text{for} \quad j = 1, 2, 3\,, \tag{28}$$

where $a = 1.4$ and $b = 0.3$ are the standard parameter values of the Hénon map and the coupling is given by

$$\tilde{x}_n^j = (1 - \epsilon) x_n^j + \frac{1}{2}\epsilon (x_n^{j+1} + x_n^{j-1}) \tag{29}$$

with $x_n^0 \equiv x_n^3$ and $x_n^4 \equiv x_n^1$. We have chosen the coupling parameter $\epsilon = 0.15$. Our choice of this system is motivated by the work of Politi and Torcini [23] in which they locate periodic orbits in CHM for a small coupling parameter by extending the method of Biham and Wenzel [1]. This makes the CHM an excellent test system, since we can compare our results against those for the Biham–Wenzel (BW) method. The BW method defines the following artificial dynamics:

$$\dot{x}_n^j(t) = (-1)^{s(n,j)} \{ x_{n+1}^j(t) - a + [\tilde{x}_n^j(t)]^2 - b x_{n-1}^j(t) \} \tag{30}$$

with $s(n, j) \in \{0, 1\}$. Given the boundary condition $x_{p+1}^j = x_1^j$, the equilibrium states of (30) are the period-p orbits for the CHM. The BW method is based on the property that every equilibrium state of (30) can be made stable by one of the 2^{3p} possible sequences of $s(n, j)$ and, therefore, can be located by simply integrating (30) to convergence starting from the same initial condition $x_n^j = 0.0$. It is also found that, for the vast majority of orbits, each orbit is stabilized by a unique sequence of $s(n, j)$.

In order to reduce the computational effort, Politi and Torcini suggest restricting the search to only those sequences $s(n, j)$ which are allowed in the uncoupled system, i.e., with $\epsilon = 0$. This reduction is possible because the introduction of coupling has the effect of pruning some of the orbits found in the uncoupled Hénon map without creating any new orbits.

We have implemented the BW method with both the full search and the reduced search (BW-r) up to as high a period as is computationally feasible (see Table 2). In the case of the full search we detect UPOs up to period 8 and in the case of the reduced search up to period 12. The seed $x_n^j = 0.0$ was used for all periods except for period 4, where it was found that with this seed both BW and BW-r located only 28 orbits. We found a maximum of 34 orbits using the seed $x_n^j = 0.5$. It is possible

TABLE 2

The number of prime UPOs for the system of CHM detected by three different methods: BW—full Biham–Wenzel, BW-r—reduced Biham–Wenzel, ST—our method based on stabilizing transformations. Max is the maximum number of detected UPOs obtained from all three methods and the system symmetry. See text for details.

11	-	272	277	278	$7.1 \cdot 10^{-9}$	$5.4 \cdot 10^{-4}$
12	-	1972	1999	1999	$2.5 \cdot 10^{-6}$	$4.3 \cdot 10^{-4}$
13*	-	-	1079	-	$8.6 \cdot 10^{-8}$	$4.0 \cdot 10^{-4}$
14*	-	-	6599	-	$2.3 \cdot 10^{-6}$	$3.5 \cdot 10^{-4}$
15*	-	-	5899	-	$7.0 \cdot 10^{-6}$	$1.5 \cdot 10^{-4}$

that more orbits can be found with different seeds for other periods as well, but we have not investigated this. The example of period 4 illustrates that, unlike for a single Hénon map, the Biham–Wenzel method fails to detect all orbits from a single seed.

Even though our approach (labeled "ST" in Table 2) is general and does not rely on the special structure of the Hénon map, its efficiency far surpasses the full BW method and is comparable to the BW-r method. Except for periods 6 and 10, the ST method locates the same or larger number of orbits.[3]

Unlike the double rotor map, the CHM possesses very few periodic orbits for small p, particularly for odd values of p. Therefore, we found that the direct application of the detection strategy outlined at the beginning of section 4 would not allow us to complete the detection of even period orbits. Therefore, for even periods p we also used $p + 2$ as seeds and, in case of period 12, a few remaining orbits were located with seeds of period 15. We did not attempt to locate a maximum possible number of UPOs for $p > 12$. The numbers of such orbits (labeled with asterisks) are listed in Table 2 for completeness.

As with the double rotor map, we used the symmetry of the CHM to test the completeness of the detected sets of orbits. It is clear from the definition of the CHM that all its UPOs are related by the permutation symmetry (i.e., six permutations of indices j). The column labeled "Max" in Table 2 lists the maximum number of UPOs that we were able to find using all three methods and applying the permutation symmetry to find any UPOs that might have been missed. As can be seen in Table 2, only a few orbits remained undetected by the ST method.

Concluding this section, we would like to point out that the high efficiency of the proposed method is primarily due to the fact that each stabilizing transformation constructed based on the stability properties of the seed orbit substantially increases the basins of convergence of orbits stabilized by this transformation. This is apparent in a typical increase of the fraction of converged seeds with the increasing value of

[3]The precise reason for the failure of the ST method to detect all period-6 and period-10 orbits needs further investigation. We believe that the orbits that were not detected have uncharacteristically small convergence basins with any of the applied stabilizing transformations.

parameter β in (3). For example, when detecting period-10 orbits of CHM using period-12 orbits as seeds, the fraction of seeds that converge to periodic orbits grows from 25–30% for small β (essentially the Newton–Raphson method) to about 70% for the optimal value of β.

5. Discussion and conclusions. We have presented a new scheme for constructing stabilizing transformations which can be used to locate periodic orbits in chaotic maps with the iterative scheme given by (3). The scheme is based on the understanding of the relationship between the stabilizing transformations and the properties of eigenvalues and eigenvectors of the stability matrices of the periodic orbits. Of particular significance is the observation that only the unstable eigenvalues are important for determining the stabilizing transformations. Therefore, unlike the original set of transformations proposed by Schmelcher and Diakonos, which grows with the system dimensionality as $2^n n!$, our set has the size of at most 2^k, where k is the maximum number of unstable eigenvalues (i.e., the maximum dimension of the unstable manifold). It is also apparent that, while the SD set contains a large fraction of transformations that do not stabilize any UPOs of a given system, all of our transformations stabilize a significant subset of UPOs. The dependence of the number of transformations on the dimensionality of the unstable manifold rather than on the system dimensionality is especially important in cases when we study low-dimensional chaotic dynamics embedded in a high-dimensional phase space. This is often the case in systems obtained from time-space discretization of nonlinear partial differential equations (e.g., the Kuramoto–Sivashinsky equation). Application of the stabilizing transformations approach to such high-dimensional chaotic systems will be the subject of our future work.

The new transformations were tested on two systems: a kicked double rotor map and three symmetrically coupled Hénon maps. We aimed to achieve a plausibly complete detection of periodic orbits of low periods up to as high a period as was computationally feasible. In both cases our algorithm was able to detect large numbers of UPOs with a high degree of certainty that the sets of UPOs for each period were complete. We have used the symmetry of the systems to test the completeness of the detected sets. On the other hand, when the aim is to detect as many UPOs as possible without verifying the completeness, the symmetry of the system could be used to increase the efficiency of the detection of UPOs: Once an orbit is detected, additional orbits can be located by applying the symmetry transformations.

One apparent drawback of the new scheme is that a small set of UPOs needs to be available for the construction of the stabilizing transformation at the start of the detection process. With the systems studied so far, we had no problem detecting UPOs of low period using the standard Newton–Raphson method by setting $\beta = 0$ in (3). However, in systems where it is hard to detect even a single periodic orbit, it would be useful to be able to determine stabilizing transformations without the knowledge of UPOs. Since the stabilizing transformations depend mostly on the properties of the unstable subspace, and since the decomposition into stable and unstable subspaces can be defined at any, not just periodic, point on the chaotic set, it should be possible to estimate such properties and construct the stabilizing transformations without the knowledge of the UPOs. The decomposition could be done, for example, in a process similar to that used in the subspace iteration algorithm [17], and a set of stabilizing transformations, for example, $\mathcal{C}_{\mathrm{SD}}$, could then be applied only within the unstable subspace. The feasibility of such a construction will be the topic for future investigation.

Acknowledgment. The authors would like to thank Alexander Gorban for useful discussion and numerous suggestions that helped improve the quality of the manuscript.

ENHANCING EIGENVALUE APPROXIMATION BY GRADIENT RECOVERY*

AHMED NAGA†, ZHIMIN ZHANG‡, AND AIHUI ZHOU§

Abstract. The polynomial preserving recovery (PPR) is used to enhance the finite element eigenvalue approximation. Remarkable fourth order convergence is observed for linear elements under structured meshes as well as unstructured initial meshes (produced by the Delaunay triangulation) with the conventional bisection refinement.

Key words. finite element method, recovery, superconvergence, eigenvalue

1. Introduction.

Recovery techniques such as the Zienkiewicz–Zhu superconvergence patch recovery (SPR) have been widely used in the finite element software industry for a posteriori error estimates and adaptive remeshing [1, 2, 14, 15]. Recently, we have discovered a new application for recovery techniques, which might have been overlooked in previous literature.

In this article, we report some remarkable enhancement results for the finite element eigenvalue approximation. The enhancement is based on gradient recovery techniques, especially the newly developed polynomial preserving recovery (PPR) [6, 7, 12, 13]. We know that the optimal convergence rate of the eigenvalue approximation by linear element for the Laplace operator is $O(h^2)$. Our numerical results indicate that the enhanced eigenvalue approximation converges at a rate of $O(h^4)$ for structured meshes as well as unstructured initial meshes (produced by the Delaunay triangulation) with regular refinement.

2. Eigenvalue enhancement.

On a domain $\Omega \subset \mathbb{R}^2$ with Lipschitz boundary, we consider a model eigenvalue problem: Find $(u, \lambda) \in H_0^1(\Omega) \times \mathbb{R}$ with $\|u\|_{0,\Omega} = 1$, such that

$$a(u, v) = \int_\Omega \nabla w \cdot \nabla v = \lambda(u, v) = \lambda \int_\Omega uv \quad \forall v \in H_0^1(\Omega). \tag{2.1}$$

We know that (2.1) has a countable sequence of real eigenvalues $0 < \lambda_1 \le \lambda_2 \le \cdots \to \infty$ and that their corresponding eigenfunctions are $u_1, u_2, \ldots$, which can be assumed to satisfy $(u_i, u_j) = \delta_{ij}$ for all $i, j \ge 1$.

The finite element approximation for (2.1) reads as follows: Find $(u_h, \lambda_h) \in S_0^h(\Omega) \times \mathbb{R}$ with $\|u_h\|_{0,\Omega} = 1$, such that

$$a(u_h, v_h) = \lambda_h(u_h, v_h) \quad \forall v_h \in S_0^h(\Omega) = S^h(\Omega) \cap H_0^1(\Omega), \tag{2.2}$$

where $S^h(\Omega)$ is the usual piecewise linear C^0 finite element space. It is well known that (2.2) has a finite sequence of eigenvalues $0 < \lambda_{1,h} \le \lambda_{2,h} \le \cdots \le \lambda_{n_h,h}$ and corresponding eigenfunctions $u_{1,h}, u_{2,h}, \ldots, u_{n_h,h}$, where $(u_{i,h}, u_{j,h}) = \delta_{ij}$ for all $(1 \le i, j \le n_h)$ and $n_h = \dim S_0^h(\Omega)$. In addition (see, e.g., [3, 4]),

$$\lambda_{i,h} \ge \lambda_i, \quad i = 1, 2, \ldots, n_h. \tag{2.3}$$

The following identity of eigenvalue and eigenfunction approximation (see, e.g., [3, 10]) is crucial for our method.

LEMMA 2.1. [illegible] (u, λ) [illegible] (2.1) [illegible] $w \in H_0^1(\Omega) \setminus \{0\}$ [illegible]

$$\frac{a(w,w)}{\|w\|_{0,\Omega}^2} - \lambda = \frac{a(w-u, w-u)}{\|w\|_{0,\Omega}^2} - \lambda \frac{\|w-u\|_{0,\Omega}^2}{\|w\|_{0,\Omega}^2}. \tag{2.4}$$

Setting $w = u_h$ in (2.4) yields

$$\lambda_h - \lambda = \|\nabla(u - u_h)\|_{0,\Omega}^2 - \lambda \|u - u_h\|_{0,\Omega}^2. \tag{2.5}$$

2.1. The polynomial preserving recovery (PPR). Following Zhang and Naga [13], we introduce a PPR operator $G_h : S^h \longrightarrow S^h \times S^h$, which produces a continuous piecewise linear gradient field and satisfies the following two properties:

(1) Polynomial preserving: There exists a constant C independent of u and h, such that

$$\|\nabla u - G_h u_I\|_{0,\Omega} \le C h^2 |u|_{3,\Omega},$$

where $u_I \in S^h$ is the piecewise linear interpolation of u.

(2) Boundedness: There exists a constant C independent of v and h, such that

$$\|G_h v\|_{0,\Omega} \le C |v|_{1,\Omega} \quad \forall v \in S^h.$$

We expect that the recovered gradient $\mathrm{G_h}\, u_h$ is "closer" to ∇u than ∇u_h is. Toward this end, we need some restriction on the mesh.

We say that two adjacent triangles (sharing a common edge) form an $O(h^{1+\alpha})$ $(\alpha > 0)$ approximate parallelogram if the lengths of any two opposite edges differ by only $O(h^{1+\alpha})$.

DEFINITION. [illegible] $\mathcal{T}_h$ [illegible] Condition α [illegible] $O(h^{1+\alpha})$ [illegible]

A common mesh refinement strategy is the [illegible], which decomposes one triangle into four congruent subtriangles by linking the three edge centers. An important property of the bisection is that it satisfies [illegible] α with $\alpha = \infty$.

We are able to establish the following theorem for the eigenfunction approximation. The proof will be omitted here since it is a straightforward mimic of proofs in [6, 9].

THEOREM 2.1. [illegible] $u \in W_\infty^3(\Omega) \cap H_0^1(\Omega)$ [illegible] $u_h \in S_0^h(\Omega)$ [illegible] (2.1) [illegible] (2.2) [illegible] G_h [illegible] $\mathcal{T}_h$ [illegible] Condition α [illegible] C [illegible] u [illegible] h [illegible]

$$\|\nabla u - G_h u_h\|_{0,\Omega} \le C h^{1+\beta} \|u\|_{3,\infty,\Omega}, \qquad \beta = \min(\alpha, 1). \tag{2.6}$$

. . . . . Although the theory needs some mesh condition, the recovery procedure itself can be applied to arbitrary meshes including anisotropic cases.

In what follows we also require that both u and a sequence of meshes $\mathcal{T}_h$ satisfy the following nondegeneracy property: There exists a constant $C > 0$ independent of h such that

$$\|\nabla(u - u_h)\|_{0,\Omega} \geq Ch. \tag{2.7}$$

As argued by Dörfler and Nochetto [5, sect. 4], this is not a very restrictive condition in practice; it is guaranteed, for instance, if $|D^2 u(x)| \geq C > 0$ for all x in a fixed region of Ω.

2.2. Asymptotically exact error estimates for $\lambda_h - \lambda$. An immediate benefit from the improved gradient based on the PPR is its accurate prediction of the error. We have the following theorem.

THEOREM 2.2. . . . . $\mathrm{G_h}\, u_h$ . . . . (2.6) . . . .

2.3. Eigenvalue enhancement. Now we propose an enhanced eigenvalue approximation based on the PPR-recovered gradient:

$$\lambda_h^* = \lambda_h - \eta_h^2. \tag{2.11}$$

Note that the cost of computing quantity $\eta_h = \|\mathrm{G_h}\, u_h - \nabla u_h\|_{0,\Omega}$ is very low. We refer to [8] for a general defect correction approach to improve the approximation accuracy of eigenvalues and [11] for other eigenvalue improvement techniques. The emphasis here is on the PPR under arbitrary initial meshes and superconvergence.

THEOREM 2.3. [illegible] $\mathrm{G_h}\, u_h$ [illegible] (2.6) [illegible] (2.7) [illegible]

$$|\lambda_h^* - \lambda| \le Ch^{2+\beta}. \tag{2.12}$$

[illegible]. From (2.8) and the definition of λ_h^*, we see that

$$-Ch^{\beta}\eta_h^2 \le \lambda_h^* - \lambda \le Ch^{\beta}\eta_h^2. \tag{2.13}$$

By the nondegeneracy condition (2.7) and the equivalence between η_h and $\|e_h\|_{0,\Omega}$ (2.9), we get $\eta_h = O(h)$. The conclusion follows by using $\eta_h = O(h)$ in (2.13). ∎

By (2.5), we see that the optimal rate for the linear finite element approximation of the eigenvalue is $O(h^2)$. Therefore, Theorem 2.3 is a superconvergence result.

Under uniform triangular mesh of the regular or chevron pattern, we can prove (2.6) with $\beta = 1$ for the linear finite element; see [13]. Then, by Theorem 2.3, we have

$$|\lambda_h^* - \lambda| \le Ch^3.$$

However, our numerical tests indicate

$$|\lambda_h^* - \lambda| \approx Ch^4$$

for all four patterns of uniform triangulation (see Figure 3.1) as well as uniform equilateral triangulation, and for unstructured initial meshes (generated by the Delaunay triangulation) with the bisection refinement. It seems that the error estimates in Theorems 2.2 and 2.3 are not optimal. Our conjecture is that instead of (2.9), we actually have

$$1 - Ch^{2\beta} \le \frac{\eta_h}{\|\nabla e_h\|_{0,\Omega}} \le 1 + Ch^{2\beta}. \tag{2.14}$$

As a consequence, we should have

$$\eta_h^2(1 - Ch^{2\beta}) \le \lambda_h - \lambda \le \eta_h^2(1 + Ch^{2\beta}) \tag{2.15}$$

in Theorem 2.2 and

$$|\lambda_h^* - \lambda| \le Ch^{2(1+\beta)} \tag{2.16}$$

in Theorem 2.3. With the bisection mesh refinement, we have $\alpha = \infty$, $\beta = 1$, and therefore, $|\lambda_h^* - \lambda| \le Ch^4$.

To better understand this ultraconvergence (superconvergence with degree 2) phenomenon, let us reexamine

$$\begin{aligned}\eta_h^2 &= \|\mathrm{G_h}\, u_h - \nabla u + \nabla e_h\|_{0,\Omega}^2 \\ &= \|\nabla e_h\|_{0,\Omega}^2 + \|\mathrm{G_h}\, u_h - \nabla u\|_{0,\Omega}^2 + 2(\nabla e_h, \mathrm{G_h}\, u_h - \nabla u).\end{aligned}$$

Note that

$$\|\nabla e_h\|_{0,\Omega}^2 \le Ch^4, \qquad \|\mathrm{G_h}\, u_h - \nabla u\|_{0,\Omega}^2 \le Ch^{2(1+\beta)}.$$

Using the Hölder inequality, we obtain only

$$\frac{|(\nabla e_h, \mathrm{G_h}\, u_h - \nabla u)|}{\|\nabla e_h\|_{0,\Omega}^2} \le Ch^{\beta},$$

which does not take into account the cancellation in the integral. The real bound should be

$$\frac{|(\nabla e_h, \mathrm{G_h}\, u_h - \nabla u)|}{\|\nabla e_h\|_{0,\Omega}^2} \le Ch^{2\beta}. \tag{2.17}$$

Unfortunately, we are not able to prove (2.17) even for uniform meshes. Nevertheless, we are able to verify it indirectly via numerical experience. Toward this end, we define a quantity

$$\omega_{1,h} = |(\mathrm{G_h}\, u_h - \nabla u, \mathrm{G_h}\, u_h - \nabla u_h)|\,. \tag{2.18}$$

Note that

$$\begin{aligned}(\nabla e_h, \mathrm{G_h}\, u_h - \nabla u) &= (\mathrm{G_h}\, u_h - \nabla u, \nabla u - \mathrm{G_h}\, u_h) + (\mathrm{G_h}\, u_h - \nabla u, \mathrm{G_h}\, u_h - \nabla u_h)\\ &= (\mathrm{G_h}\, u_h - \nabla u, \mathrm{G_h}\, u_h - \nabla u_h) + O(h^{2(1+\beta)}).\end{aligned}$$

We see that $\omega_{1,h}$ provides an indirect way to verify (2.17).

Another way to understand the role of $\omega_{1,h}$ in the ultraconvergence phenomenon of $\lambda_h^* - \lambda$ is via the identity

$$\begin{aligned}\lambda_h^* - \lambda &= \|\nabla u - \mathrm{G_h}\, u_h\|_{0,\Omega}^2 + 2(\nabla u - \mathrm{G_h}\, u_h, \mathrm{G_h}\, u_h - \nabla u_h) - \lambda\|e_h\|_{0,\Omega}^2\\ &= \|\nabla u - \mathrm{G_h}\, u_h\|_{0,\Omega}^2 \pm 2\omega_{1,h} - \lambda\|e_h\|_{0,\Omega}^2.\end{aligned} \tag{2.19}$$

If the recovered gradient enjoys superconvergence, then the term with the lowest convergence rate in (2.19) is the mixed dot product whose absolute value is $2\omega_{1,h}$. Indeed, this term controls the convergence rate of $\lambda_h^* - \lambda$, and sometimes, it cancels the first term $\|\nabla u - \mathrm{G_h}\, u_h\|_{0,\Omega}^2$ in a favorable way. We will see this in our numerical test examples.

In addition, we shall numerically examine another quantity,

$$\omega_{2,h} = \left|\|\nabla e_h\|_{0,\Omega} + \eta_h + \frac{\lambda\|e_h\|_{L_2(\Omega)}^2}{2\eta_h}\right| \left|\|\nabla e_h\|_{0,\Omega} - \eta_h - \frac{\lambda\|e_h\|_{L_2(\Omega)}^2}{2\eta_h}\right|. \tag{2.20}$$

Note that both $\|\nabla e_h\|_{0,\Omega}$ and η_h are of order $O(h)$. From our numerical test examples in the next section, we will see that η_h cancels the major part of $\|\nabla e_h\|_{0,\Omega}$. The role of $\omega_{2,h}$ can be seen from the following identity:

$$\begin{aligned}\lambda_h^* - \lambda &= \|\nabla e_h\|_{0,\Omega}^2 - \eta_h^2\left(1 + \frac{\lambda\|e_h\|_{0,\Omega}^2}{\eta_h^2}\right)\\ &= \left(\|\nabla e_h\|_{0,\Omega} + \eta_h\sqrt{1 + \frac{\lambda\|e_h\|_{0,\Omega}^2}{\eta_h^2}}\right)\left(\|\nabla e_h\|_{0,\Omega} - \eta_h\sqrt{1 + \frac{\lambda\|e_h\|_{0,\Omega}^2}{\eta_h^2}}\right).\end{aligned} \tag{2.21}$$

Using the first two terms of the asymptotic expansion

$$\sqrt{1+\frac{\lambda\|e_h\|_{0,\Omega}^2}{\eta_h^2}} = 1+\frac{\lambda\|e_h\|_{0,\Omega}^2}{2\eta_h^2} - \frac{\lambda^2\|e_h\|_{0,\Omega}^4}{4\eta_h^4} + \frac{3\lambda^3\|e_h\|_{0,\Omega}^6}{8\eta_h^6} + \cdots,$$

we have

$$\lambda_h^* - \lambda = \omega_{2,h} + \text{h.o.t.}$$

3. Numerical examples. In this section we numerically test the proposed eigenvalue enhancement procedure. The examples are based on the two-dimensional eigenvalue problem of (2.1). For comparison purposes, we compute the recovered gradient by both the PPR and Zienkiewicz–Zhu SPR [14].

Let λ denote the minimum eigenvalue and u the corresponding eigenfunction. As we mentioned before, if $\|\mathrm{G_h}\, u_h - \nabla u\|_{0,\Omega}$ has any superconvergence, then $\lambda_h^* - \lambda$ also has superconvergence. Indeed, this superconvergence is attributed to either $\omega_{1,h}$ or $\omega_{2,h}$ defined in (2.18) and (2.20), respectively.

Example 1. As our first example, we consider the eigenvalue problem (2.2) with $\Omega = (0,1)\times(0,1)$. In this case, $\lambda = 2\pi^2$, and its corresponding eigenfunction is $u = 2\sin(\pi x)\sin(\pi y)$. We consider both structured and unstructured meshes.

In order to generate structured meshes, we divide Ω into $m \times m$ subsquares and triangulate each subsquare to one of the patterns shown in Figure 3.1. In consecutive iterations, $m = 16, 32, 64, 128$ for the criss cross pattern, while $m = 8, 16, 32, 64$ for the other three patterns. The numerical results for each of the four patterns are shown in Figures 3.2–3.5.

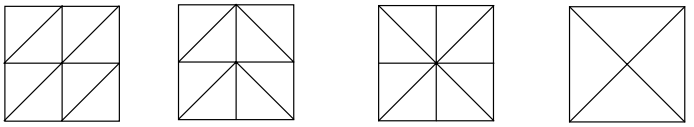
Let us have a closer look at Figure 3.2. First, the recovered gradient $\mathrm{G_h}\, u_h$ superconverges to ∇u. Accordingly, the convergence rate for $\omega_{1,h}$ is $O(h^3)$ if the Cauchy–Schwartz inequality is applied. However, this rate is $O(h^4)$ as depicted in Figure 3.2; i.e., $\omega_{1,h}$ is superconvergent. Consequently, all the terms in the identity for $\lambda_h^* - \lambda$ enjoy superconvergence. Hence, $\lambda_h^* - \lambda$ gets the ultraconvergence rate $O(h^4)$. Indeed, the same conclusion is true for the PPR in the other three cases.

As for the SPR, the situation is different. In the chevron pattern, the SPR-recovered gradient has no superconvergence [13]. Consequently, there is no superconvergence in $\lambda_h^* - \lambda$ although λ_h^* is more accurate than λ_h. In the Union Jack and the criss cross patterns, $\omega_{1,h}$ and consequently λ_h^*, do not gain from the superconvergence in the SPR-recovered gradient.

Next, we use the Delaunay triangulation (see Figure 3.6) to produce an unstructured initial mesh. In consecutive refinement, we construct a new mesh from the previous one by regular refinement, i.e., dividing each triangle into four congruent subtriangles by connecting its three edge centers. Figure 3.7 shows the convergence rates for various quantities of interest. Note that the recovered eigenvalue still has ultraconvergence. Surprisingly, the convergence rate is even better than the ones we have seen in the case of structured meshes, even though the recovered gradient does not have a full order recovery.

Example 2. So far, we have seen that $\omega_{1,h}$ and $\omega_{2,h}$ are almost the same. There are situations where the cancellations in $\omega_{2,h}$ are better, as we can see from the following example:

$$\begin{cases} -\triangle u = \lambda u & \text{in } \Omega = (0,1)^2, \\ u|_{x=0} = u|_{y=0} = u|_{y=1} = \partial_x u|_{x=1} = 0, \\ \|u\|_{L_2(\Omega)} = 1. \end{cases}$$



(a) The Regular pattern (b) The Chevron pattern (c) The Union Jack pattern (d) The Criss Cross pattern

FIG. 3.1. *The patterns used in constructing uniform meshes in* $\Omega = (0,1)^2$.

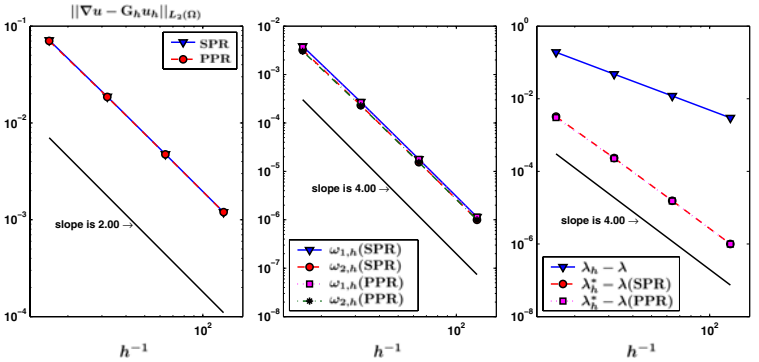


FIG. 3.2. *Example* 1 *results—the regular pattern case.*

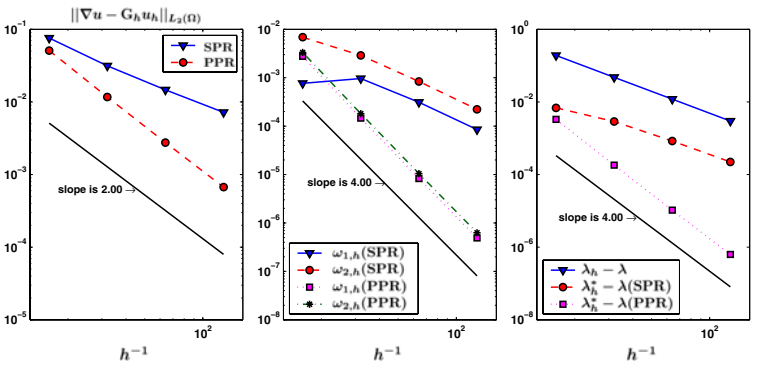

FIG. 3.3. *Example* 1 *results—the chevron pattern case.*

In this case,

$$\lambda = \frac{5\pi^2}{4}, \qquad u = 2\cos\left(\pi(x-1)/2\right)\sin \pi y.$$

Let us solve this problem using the sequence of meshes with an unstructured initial mesh employed in Example 1; see Figure 3.8 for the numerical results. As for the PPR, contrary to the SPR, the convergence rate of $\omega_{1,h}$ is less than the convergence rate of $\omega_{2,h}$ by at least 1. This means that η_h cancels not only the leading term in $\|\nabla e_h\|_{0,\Omega}$, but also the major part of $\frac{\lambda\|e_h\|_{0,\Omega}^2}{2\eta_h}$. This leads to a higher convergence rate in the recovered eigenvalue. Likewise, the dot product term in (2.19) cancels the first term in a favorable way since both terms are not as good as $O(h^4)$ and the enhanced eigenvalue converges at a rate $O(h^5)$!

3. In our previous two examples, the domain was a unit square. Let us

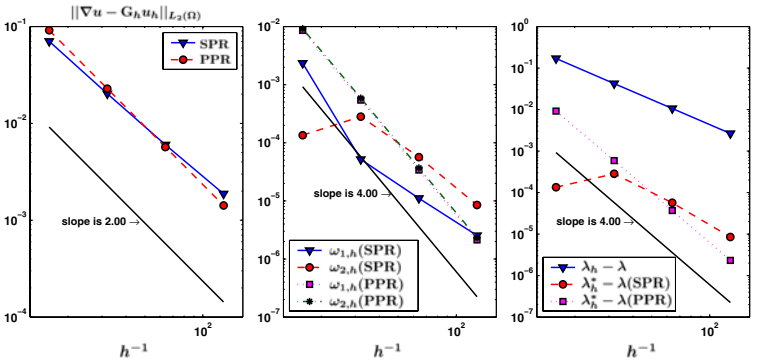

FIG. 3.4. *Example* 1 *results—the Union Jack pattern case.*

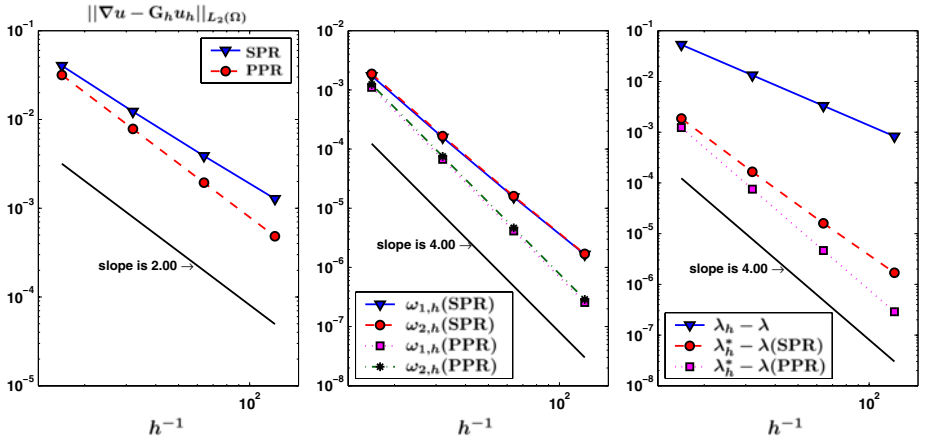

FIG. 3.5. *Example* 1 *results—the criss cross pattern case.*

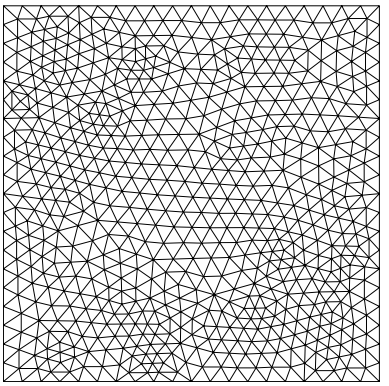

FIG. 3.6. *Example* 1*—the initial unstructured mesh case.*

change the domain to an equilateral triangle:

$$\Omega = (x, y) \in \mathbb{R}^2 : 0 < y < \sqrt{3}x, y > \sqrt{3}(1 - x).$$

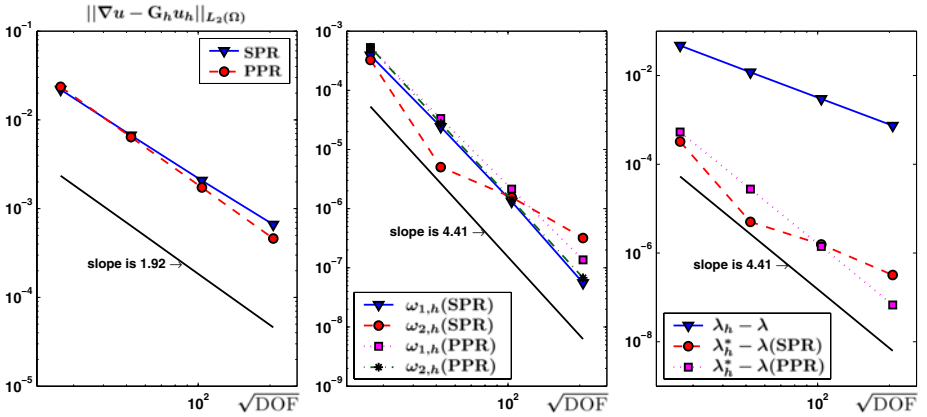

FIG. 3.7. *Example* 1 *results—the unstructured mesh case.*

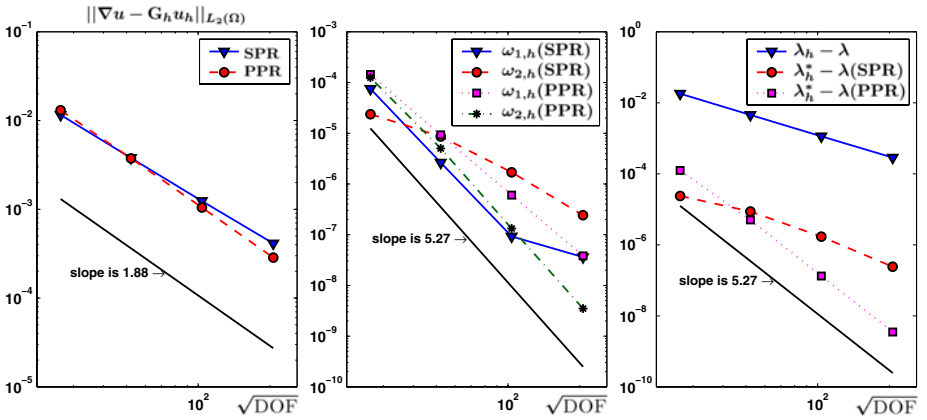

FIG. 3.8. *Example* 2 *results.*

With the zero boundary condition, $\lambda = 16\pi^2/3$ and

$$u = \frac{2\sqrt[4]{12}}{3}\left\{\sin\left(\frac{4\pi y}{\sqrt{3}}\right) + \sin\left(2\pi\left(x - \frac{y}{\sqrt{3}}\right)\right) + \sin\left(2\pi\left(1 - x - \frac{y}{\sqrt{3}}\right)\right)\right\}.$$

The structured meshes are generated by dividing Ω into $m(m+1)/2$ equilateral triangles with $m = 2^k$ for $k = 4, 5, 6, 7$. The initial mesh is shown in Figure 3.9. For unstructured initial mesh, we do as in Example 1 (see Figure 3.10.) The numerical results for both types of meshes are shown in Figures 3.11 and 3.12, respectively. Obviously, the results are similar to the ones in Example 1. Due to the high quality of the initially unstructured triangulation, there is not much difference between the convergence rates for uniform and unstructured meshes in this case.

EXAMPLE 4. In all previous examples, the eigenfunction u was analytic. Let us now consider the model problem (2.1) with

$$\Omega = \{(r, \theta) \in \mathbb{R}^2 : \ 0 < r < 1, \ \ 0 < \theta < 3\pi/2\},$$

in which case u has a corner singularity at $(0, 0)$. The smallest eigenvalue and its

eigenfunction for this problem are

$$u(r,\theta) = \frac{4J_{2/3}(\alpha r)}{\sqrt{6\pi}J_{5/3}(\alpha)}\sin(2\theta/3), \qquad \lambda_{\min} = \alpha^2, \qquad \alpha = \min\{x > 0 : J_{2/3}(x) = 0\},$$

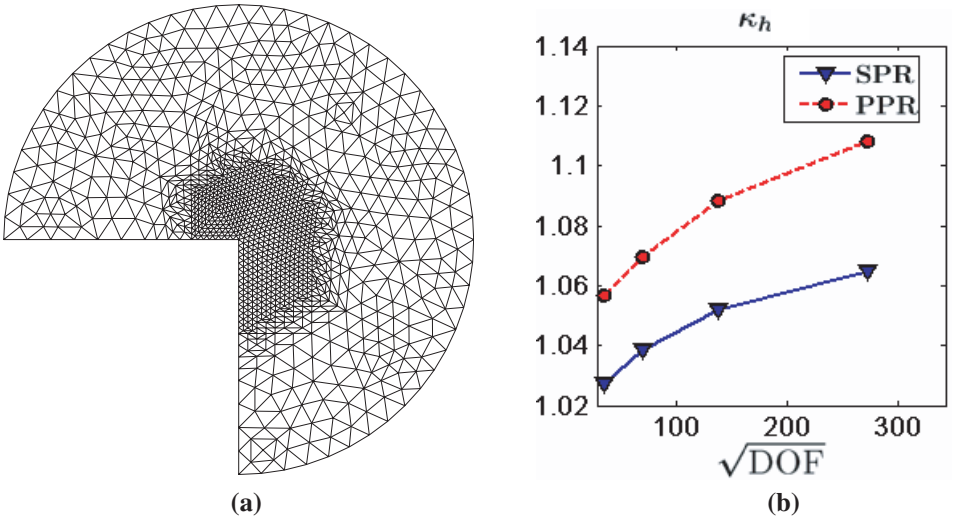

FIG. 3.13. *Example* 4*—the initial mesh* (a) *and the effectivity index* (b).

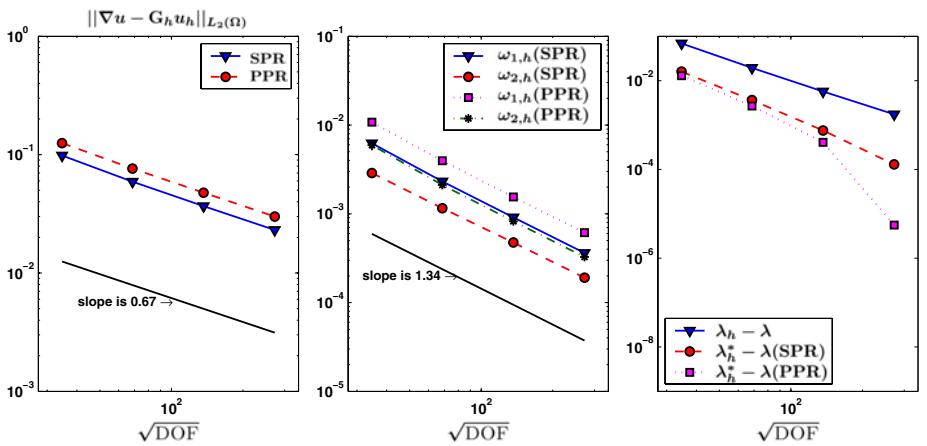

FIG. 3.14. *Example* 4 *results.*

where $J_{2/3}$ is the Bessel function of the first kind of order $2/3$. We start from an initial mesh shown in Figure 3.13(a). Note that this mesh is refined near $(0, 0)$ to avoid the pollution effect of the corner singularity. A sequence of meshes is produced by the regular refinement; i.e., by linking the three edge centers, each triangle is divided into four congruent subtriangles. From the numerical results in Figure 3.14, $\mathrm{G_h}\, u_h$ does not have superconvergence in both the PPR and the SPR. Nevertheless, η_h is still close to $\|\nabla e_h\|_{0,\Omega}$ (see the effectivity index $\kappa_h := \eta_h/\|\nabla e_h\|_{0,\Omega}$ in Figure 3.13(b)). From (2.10), the leading term in $\lambda_h^* - \lambda$ is $|\|\nabla e_h\|_{0,\Omega}^2 - \eta_h^2| = \|\nabla e_h\|_{0,\Omega}^2 |1 - \kappa_h^2|$. Since κ_h is very close to 1, the error in $\lambda_h^* - \lambda$ is a small fraction of the exact error $\lambda_h - \lambda$, which means that λ_h^* is more accurate than λ_h. This is true for both the PPR and the SPR.

4. Conclusion. We have shown that the PPR-recovered gradient $\mathrm{G_h}\, u_h$ can enhance the accuracy of λ_h if $\mathrm{G_h}\, u_h$ superconverges to ∇u (as we have seen in Examples 1, 2, and 3) or if the effectivity index of η_h is close to 1 (as we have seen in Example 4). Although the numerical results in this work are solely for the two-dimensional Poisson equation and the linear finite element method, the idea is nevertheless applicable to more general eigenvalue problems in the form

$$a(u, v) = \lambda b(u, v). \tag{4.1}$$

Here $a(\cdot, \cdot)$ and $b(\cdot, \cdot)$ are symmetric bilinear forms on some Hilbert space H and satisfy certain strong ellipticity and positivity conditions such that the following basic identity is valid (see [3, Lemma 9.1]):

$$\tilde{\lambda} - \lambda = \|u - w\|_a^2 - \lambda \|u - w\|_b^2,$$

where (u, λ) is an eigenpair of (4.1) with $\|u\|_b = 1$, $w \in H$ with $\|w\|_b = 1$, and $\tilde{\lambda} = a(w, w)$. In this setting, let $(\tilde{\lambda}, w) = (\lambda_h, u_h)$ be the finite element approximation of (u, λ). If we are able to improve the quantity involving u in the $\|\cdot\|_a$-norm via a recovery procedure, then $\|u - u_h\|_a^2$ may be substituted by a computable value to enhance the eigenvalue approximation. Further investigation along this line for the linear and the nonlinear problems is under way.

CONTINUATION OF BIFURCATIONS IN PERIODIC DELAY-DIFFERENTIAL EQUATIONS USING CHARACTERISTIC MATRICES*

RÓBERT SZALAI†, GÁBOR STÉPÁN†, AND S. JOHN HOGAN‡

Abstract. In this paper we describe a method for continuing periodic solution bifurcations in periodic delay-differential equations. First, the notion of characteristic matrices of periodic orbits is introduced and equivalence with the monodromy operator is demonstrated. An alternative formulation of the characteristic matrix is given, which can be computed efficiently. Defining systems of bifurcations are constructed in a standard way, including the characteristic matrix and its derivatives. For following bifurcation curves in two parameters, the pseudo-arclength method is used combined with Newton iteration. Two test examples (an interrupted machining model and a traffic model with driver reaction time) conclude the paper. The algorithm has been implemented in the software tool PDDE-CONT.

Key words. delay-differential equations, periodic solutions, bifurcations, continuation

DOI. 10.1137/040618709

1. Introduction.

Continuation methods have widespread use in scientific applications described by ordinary differential equations (ODEs)(see, e.g., [6, 9, 21]). These methods are used to investigate invariant structures, such as fixed points and periodic orbits of dynamical systems over a range of parameter values. Usually only special or trivial solutions are available analytically and direct simulations only converge to stable (or unstable, if time reversed) solutions. Numerical continuation methods provide an ideal tool to find bifurcations of these solutions even after they become of saddle type. Similarly, bifurcations can also be continued by allowing additional parameters to vary.

However, when delay-differential equations (DDEs) [7, 17, 18] are considered, the resulting infinite-dimensional system presents far greater numerical challenges. Available continuation methods for bifurcations in DDEs are essentially limited to fixed points. The software DDE-BIFTOOL, developed by Engelborghs, Luzyania, and Roose [13], is capable of continuing bifurcations of fixed points. It can also continue periodic orbits, but not their bifurcations. To compute fixed point bifurcations, Engelborghs, Luzyania, and Roose [13] used the characteristic matrix [17], which can be computed analytically when the partial derivatives of the vector field are known. They exploited the fact that this matrix is singular at bifurcation points. In this paper we use a similar approach, but for periodic orbits.

The paper is organized as follows. In section 2, we introduce the characteristic matrix for periodic orbits. We derive its equivalence with the monodromy operator

and show how its computational cost can be reduced to that of the solution of one system of linear equations. In section 3, continuation of periodic orbits is discussed using the pseudo-arclength method. Continuation of bifurcations is discussed in section 4. In section 5, we give implementation details of the algorithm. In section 6, two examples, an interrupted machining model and a traffic model, are analyzed.

2. Characteristic matrices. It is well known [7, 18] that linear autonomous delay equations admit the construction of a characteristic matrix. Thus, the task of finding the spectra of the infinite-dimensional problem is reduced to finding the roots of a nonlinear function, which is just the determinant of the characteristic matrix. Jordan chains [7] of the characteristic matrix at a spectral point can be used to obtain (generalized) eigenvectors of the infinitesimal generator.

For periodic DDEs, there is no such general characteristic matrix, except for special cases. For example, where the delay is an integer multiple of the period length and the partial derivatives of the vector field with respect to the delayed arguments are invertible, Verduyn Lunel [22] constructed a characteristic matrix. This case can also be found in [18], where an equivalence with the monodromy operator is derived (as in the autonomous case) based on the theory presented in [20].

Unfortunately, many important practical problems, such as our first test example of interrupted machining (see section 6.1), have noninvertible partial derivatives, so the case in [22] is not applicable. This difficulty can be overcome using Floquet theory [17], and a characteristic matrix can be constructed for integer delays [25]. Although this latter problem does not give equivalence with the monodromy operator, it serves as a starting point of our more general case.

In what follows, we generalize the results of Kaashoek and Verduyn Lunel [20] to periodic delay equations. Let x be a continuous function $x : I \subset \mathbb{R} \to \mathbb{R}^n$ and let $h > 0$ be a real number. Define $x_t \in C([-h, 0], \mathbb{R}^n)$ by $x_t(\theta) = x(t + \theta)$ and consider the following DDE:

$$x'(t) = f(t, x_t), \tag{2.1}$$

where $f : \mathbb{R}^n \times C([-h, 0], \mathbb{R}^n) \to \mathbb{R}^n$ is of class C^N, $N \geq 2$ in the second variable, and the prime denotes time-derivative. Further, assume that f is periodic in the first variable; thus $f(t, .) = f(t + \omega, .)$ with $\omega \geq h$. Consider a ω-periodic solution $v(t)$ of (2.1). Since f is smooth, we can linearize (2.1) at v in the form

$$x'(t) = \int_0^h d_\theta \eta^v(t, \theta) x(t - \theta), \tag{2.2}$$

where η^v is a matrix-valued function that is of bounded variation in θ and is associated with the periodic solution v. We can represent η uniquely if we take the space NBV, which consists of functions of bounded variations normalized such that $\eta(\theta) = 0$ for $\theta \in (-\infty, 0]$, right continuous on $(0, h)$ and constant on $[h, \infty)$. According to the basic theory of delay equations, (2.2) has a unique (forward) solution if we specify an initial function with $x_s = \phi$, $s \in \mathbb{R}$ fixed. The linearized equation can be written equivalently as

$$x'(t) = \int_0^{t-s} d_\theta \eta^v(t, \theta) x(t - \theta) + \int_{t-s}^{\infty} d_\theta \eta^v(t, \theta) \phi(t - s - \theta), \tag{2.3}$$

where the first term includes merely the unknown function, and the second term includes the initial function. Since the initial function is in the equation now, we can solve it uniquely by specifying an initial value $x(s) = \phi(0)$ only.

In what follows, we will consider a bigger space $X = L^\infty([-\omega, 0], \mathbb{R}^n)$, where $C([-\omega, 0], \mathbb{R}^n)$ is a closed subspace in X. This choice of X guarantees that there is a one-to-one relationship between solutions of (2.2) and the solutions given by our extended monodromy operator (defined below) by maintaining the compatibility with the duality framework for delay equations developed by Clement et al. [2, 3] (see also Diekmann et al. [7]). Let us define the operator

$$(\mathcal{A}(v,s)\varphi)(\theta) = \varphi'(\theta) - \int_0^{\omega+\theta} d_\vartheta \eta^v(s+\theta,\vartheta)\varphi(\theta-\vartheta) \tag{2.4}$$

with domain of definition $D(\mathcal{A}(v,s)) = \mathrm{Lip}([-\omega, 0], \mathbb{R}^n)$ and

$$(\mathcal{B}(v,s)\varphi)(\theta) = \int_{\omega+\theta}^{\omega} d_\vartheta \eta^v(s+\theta,\vartheta)\varphi(\omega+\theta-\vartheta) \tag{2.5}$$

on X. Note that $\overline{D(\mathcal{A}(v,s))} = C([-\omega, 0], \mathbb{R}^n)$ and $\mathcal{A}(v,s)$ has an n-dimensional kernel since, as we mentioned, we can solve $\mathcal{A}(v,s)\varphi = 0$ by specifying $\varphi(-\omega) = c$ for any $c \in \mathbb{R}^n$. To obtain the monodromy operator, we solve the equation $\mathcal{A}(v,s)\psi = \mathcal{B}(v,s)\varphi$ (which is just a reformulation of (2.3)) with the boundary condition $\psi(-\omega) = \varphi(0)$. Thus the monodromy operator becomes

$$U(s+\omega, s)\varphi = \psi. \tag{2.6}$$

The boundary condition can be eliminated by introducing the (even) bigger space $\hat{X} = \mathbb{R}^n \times X$, which includes the initial function ϕ and its initial value $\phi(0)$ as well. For ease of notation we use the following boundary value operators:

$$L : X \to \mathbb{R}^n,\ L\varphi = \varphi(-\omega),$$

$$M : X \to \mathbb{R}^n,\ M\varphi = \varphi(0).$$

These definitions make sense, since we consider only functions in the domain of $\mathcal{A}(v,s)$. Let

$$\hat{\mathcal{A}}(v,s) = \begin{pmatrix} 0 & L \\ 0 & \mathcal{A}(v,s) \end{pmatrix}$$

and

$$D(\hat{\mathcal{A}}(v,s)) = \{(c,\varphi) \in \hat{X} \mid \varphi \in D(\mathcal{A}(v,s)),\ c = M\varphi\}.$$

With this definition, it is easy to check that $\hat{\mathcal{A}}(v,s)$ is one-to-one and onto. $\hat{\mathcal{B}}(v,s)$ is defined similarly as

$$\hat{\mathcal{B}}(v,s) = \begin{pmatrix} I & 0 \\ 0 & \mathcal{B}(v,s) \end{pmatrix}.$$

The extended monodromy operator becomes $\hat{U}(s+\omega, s) = \hat{\mathcal{A}}^{-1}(v,s)\hat{\mathcal{B}}(v,s)$. Note that

$$\hat{\mathcal{A}}(v,s)\begin{pmatrix} \psi(0) \\ \psi \end{pmatrix} = \hat{\mathcal{B}}(v,s)\begin{pmatrix} \varphi(0) \\ \varphi \end{pmatrix} \Leftrightarrow \psi(-\omega) = \varphi(0), \quad \mathcal{A}\psi = \mathcal{B}\varphi$$

gives (2.6).

It can easily be proved that the eigenvalues of $\hat{U}(s+\omega,s)$ and $U(s+\omega,s)$ are the same (see [20, Proposition 1.1.]). Therefore we can equivalently analyze the spectrum

$$\sigma(\hat{U}(s+\omega,s)) := \mathbb{C}\backslash\{\lambda\in\mathbb{C}\,|\,(\lambda I-\hat{U}(s+\omega,s))^{-1}\text{ is a bounded linear operator}\}.$$

In case of delay equations, $\hat{U}(s+\omega,s)$ is compact: Thus, its spectrum consists of eigenvalues which have a cluster point at 0. Since we are not interested in 0, we can define $\mu=1/\lambda$ and analyze the equivalent problem

$$\lambda I-\hat{U}(s+\omega,s)=\frac{1}{\mu}\hat{\mathcal{A}}^{-1}(v,s)(\hat{\mathcal{A}}(v,s)-\mu\hat{\mathcal{B}}(v,s))$$

or, for the sake of simplicity, $\hat{\mathcal{A}}(v,s)-\mu\hat{\mathcal{B}}(v,s)$. In this latter case,

$$\sigma(\hat{U}(s+\omega,s))=\mathbb{C}\backslash\left\{\frac{1}{\mu}\in\mathbb{C}\,|\,(\hat{\mathcal{A}}(v,s)-\mu\hat{\mathcal{B}}(v,s))^{-1}\text{ is a bounded linear operator}\right\}.$$

From now on, we suppress the initial time s, the periodic solution v, or both in the notation of $\mathcal{A}(v,s)$, $\hat{\mathcal{A}}(v,s)$, $\mathcal{B}(v,s)$, and $\hat{\mathcal{B}}(v,s)$.

2.1. Equivalence. Kaashoek and Verduyn Lunel [20] derived the equivalence of unbounded linear operators, including infinitesimal generators of evolutionary systems and a characteristic matrix $\Delta(z)$, with some spectral parameter z under quite general assumptions. Here, we show how general periodic DDEs can fit into their framework, and extend the characteristic matrix constructions for equations with integer delays in [18, section 8.3].

In accordance with the previous section, we infer that operator $\mathcal{A}$ has the following properties:

1. $\mathcal{N}:=\ker(\mathcal{A})$ is finite-dimensional, $\dim(\mathcal{N})=n$, and $\mathcal{N}\neq\{0\}$.
2. The operator $\mathcal{A}$ has a restriction $\mathcal{A}_0: X\to X$ such that
   (a) $D(\mathcal{A})=\mathcal{N}\oplus D(\mathcal{A}_0)$,
   (b) $\Omega:=\{\mu\in\mathbb{C}\,|\,(\mu\mathcal{B}-\mathcal{A}_0)^{-1}\text{ is a bounded operator on }X\}\neq\emptyset$.

Also, denote the isomorphism from $\mathbb{R}^n$ onto $\mathcal{N}$ by $\jmath$. In what follows, we will use the graph norm $\|x\|_{\hat{\mathcal{A}}}=\|x\|+\|\hat{\mathcal{A}}x\|$ on $D(\hat{\mathcal{A}})$. Using this norm, $\hat{\mathcal{A}}$ becomes bounded and $\hat{X}_A:=D(\hat{\mathcal{A}})$ becomes a closed space (see Hille and Phillips [19]).

THEOREM 2.1.

$$F(\mu)(\hat{\mathcal{A}}-\mu\hat{\mathcal{B}})E(\mu)=\begin{pmatrix}\Delta(\mu)&0\\0&I_X\end{pmatrix},\quad \mu\in\Omega, \tag{2.7}$$

$E:\Omega\to\mathcal{L}(\hat{X},\hat{X}_A)$ $F:\Omega\to\mathcal{L}(\hat{X}_A,\hat{X})$

$$\Delta(\mu)=(\mu M-L)\left(I-(\mu\mathcal{B}-\mathcal{A}_0)^{-1}\mu\mathcal{B}\right)\jmath,\qquad \mu\in\Omega. \tag{2.8}$$

$$\begin{aligned}
E(\mu)\begin{pmatrix}c\\ \varphi\end{pmatrix}&=\begin{pmatrix}M(Q(\mu)\jmath c+(\mu\mathcal{B}-\mathcal{A}_0)^{-1}\varphi)\\ Q(\mu)\jmath c+(\mu\mathcal{B}-\mathcal{A}_0)^{-1}\varphi\end{pmatrix},\\
E^{-1}(\mu)\begin{pmatrix}M\psi\\ \psi\end{pmatrix}&=\begin{pmatrix}\jmath^{-1}Q(0)\psi\\ (\mu\mathcal{B}-\mathcal{A})\psi\end{pmatrix},\\
F(\mu)\begin{pmatrix}c\\ \varphi\end{pmatrix}&=\begin{pmatrix}c-(\mu M-L)(\mu\mathcal{B}-\mathcal{A}_0)^{-1}\varphi\\ \varphi\end{pmatrix},\\
F^{-1}(\mu)\begin{pmatrix}c\\ \varphi\end{pmatrix}&=\begin{pmatrix}c+(\mu M-L)(\mu\mathcal{B}-\mathcal{A}_0)^{-1}\varphi\\ \varphi\end{pmatrix},
\end{aligned}$$

$$Q(\mu)\varphi = \varphi - (\mu\mathcal{B} - \mathcal{A}_0)^{-1}(\mu\mathcal{B} - \mathcal{A})\varphi.$$

. The proof is similar to the one in [20, Theorem 3.1.], and therefore it is omitted. □

The proof is based on the observation that for all $\mu \in \Omega$, $(\mu\mathcal{B}-\mathcal{A})$ has an n-dimensional kernel and that the projection onto $\ker(\mu\mathcal{B}-\mathcal{A})$ is $Q(\mu)$. Since $\ker Q(\mu)$ is independent of μ, $Q(\mu_1) = Q(\mu_1)Q(\mu_2)$ and therefore $Q(\mu)\jmath$ is an isomorphism from $\mathbb{R}^n$ to $\ker(\mu\mathcal{B}-\mathcal{A})$. Applying $(MQ(\mu), Q(\mu))^T$ to $\mu\hat{\mathcal{B}} - \hat{\mathcal{A}}$, we find that the first equation is the characteristic matrix and the second equation is identically zero.

We need a characteristic matrix around geometrically simple inverse characteristic multipliers, so we make the following conjecture.

CONJECTURE 2.2. $(\mathcal{A}_0 - \mu\mathcal{B})$

(i) μ^{-1}

(ii) μ^{-1} ”

In continuation the inverse of $\mathcal{A}_0 - \mu\mathcal{B}$ is numerically computed using LU decomposition, so that the above conjecture can be checked by monitoring the smallest diagonal element of the U factor. In our examples in section 6 this minimal diagonal element always stayed away from zero.

First we expand $(\mathcal{A} - \mu\mathcal{B})\varphi = \psi$, $L\varphi = c$ using (2.4) and (2.5) into

$$\dot\varphi(\theta) = \int_0^{\omega+\theta} \mathrm{d}_\vartheta\eta(s+\theta,\vartheta)\varphi(\theta-\vartheta) + \mu\int_{\omega+\theta}^{\omega} \mathrm{d}_\vartheta\eta(s+\theta,\vartheta)\varphi(\omega+\theta-\vartheta) - \psi(\theta),$$

which contains our problem, when $L\varphi = 0$. After integration by parts and changing integration limits, we get that

$$\dot\varphi(\theta) = \eta(s+\theta,\omega+\theta)c + \int_{-\omega}^{\theta} \eta(s+\theta,\theta-\vartheta)\dot\varphi(\vartheta)\mathrm{d}\vartheta$$
$$+ \mu\left(\eta(s+\theta,\omega)\varphi(\theta) - \eta(s+\theta,\omega+\theta)\varphi(0) + \int_{\theta}^{0} \eta(s+\theta,\omega+\theta-\vartheta)\dot\varphi(\vartheta)\mathrm{d}\vartheta\right) - \psi(\theta).$$

Denote $\phi = \dot\varphi$; then the equation becomes

(2.9)
$$\phi(\theta) = \int_{-\omega}^{\theta} h_{s,\mu}(\theta,\vartheta)\phi(\vartheta)\mathrm{d}\vartheta + \int_{\theta}^{0} k_{s,\mu}(\theta,\vartheta)\phi(\vartheta)\mathrm{d}\vartheta + (\eta(s+\theta,\omega+\theta)+\eta(s-\omega,\omega))c - \psi(\theta),$$

where

$$h_{s,\mu}(\theta,\vartheta) = \eta(s+\theta,\theta-\vartheta) + \mu\eta(s+\theta,\omega) - \mu\eta(s+\theta,\omega+\theta),$$

$$k_{s,\mu}(\theta,\vartheta) = \mu\eta(s+\theta,\omega+\theta-\vartheta) - \mu\eta(s+\theta,\omega+\theta).$$

For the sake of simplicity define

$$(S\phi)(\theta) = \int_{-\omega}^{\theta} h_{s,\mu}(\theta,\vartheta)\phi(\vartheta)\mathrm{d}\vartheta + \int_{\theta}^{0} k_{s,\mu}(\theta,\vartheta)\phi(\vartheta)\mathrm{d}\vartheta,$$

which is a Fredholm operator. Hence $\ker(I-S)$ has the same dimension as $\ker(I-S)^*$, which implies that $(I-S)$ is onto if and only if it is one-to-one. From (2.9) it is clear that $(\mathcal{A}-\mu\mathcal{B})$ has at least an n-dimensional kernel. It is also clear that if the kernel has exactly n dimensions, then there is a unique ϕ satisfying (2.9) for $c=0$, which implies that

$$\varphi(\theta)=\int_{-\omega}^{\theta}\phi(\vartheta)\mathrm{d}\vartheta.$$

Hence it is enough to prove that $\dim\ker(\mathcal{A}-\mu\mathcal{B})=n$ under our assumptions.

When μ is not a spectrum point of $(\hat{\mathcal{A}}-\mu\hat{\mathcal{B}})$ we prove that $(\mathcal{A}_0-\mu\mathcal{B})$ is one-to-one by contradiction. Assume that $\dim\ker(\mathcal{A}-\mu\mathcal{B})=m$, $m>n$. This implies the existence of an isomorphism $p:\mathbb{R}^m\to\ker(\mathcal{A}-\mu\mathcal{B})$. In this case $(L-\mu M)p$ has an at least $(m-n)$-dimensional kernel, which contradicts our assumption that $(\hat{\mathcal{A}}-\mu\hat{\mathcal{B}})$ is one-to-one and proves that $\dim\ker(\mathcal{A}-\mu\mathcal{B})=n$.

At a geometrically simple inverse characteristic multiplier μ, by definition, $(\hat{\mathcal{A}}-\mu\hat{\mathcal{B}})$ has a one-dimensional kernel spanned by $(M\varphi_0,\varphi_0)$. In this case we either have $\dim\ker(\mathcal{A}-\mu\mathcal{B})=n$ or $n+1$ by a similar argument as above. We have to prove that the latter case does not occur generically. If $\dim\ker(\mathcal{A}-\mu\mathcal{B})=n+1$, we then have the isomorphism $p:\mathbb{R}^{n+1}\to\ker(\mathcal{A}-\mu\mathcal{B})$ so that $\dim\ker(L-\mu M)p=1$. However, this is not generic, because for any operator, say $F:X\to\mathbb{R}^n$, $\dim\ker Fp\geqslant 1$. In order to fix this we need $\dim\ker(\mathcal{A}-\mu\mathcal{B})=n$ and this must hold for almost every periodic orbit with a geometrically simple singularity of a parameter-dependent system within a parameter interval. If it is true, the same reasoning applies as above, and we infer that $(\mathcal{A}_0-\mu\mathcal{B})$ is one-to-one and onto.

In numerical applications, computing (2.8) is not efficient. Instead, we use the isomorphism $R(\mu):\mathbb{R}^n\to\ker(\mu\mathcal{B}-\mathcal{A})$,

$$R(\mu)c=\begin{pmatrix}0 & I\end{pmatrix}\begin{pmatrix}0 & -L\\ 0 & \mu\mathcal{B}-\mathcal{A}\end{pmatrix}^{-1}\begin{pmatrix}c\\ 0\end{pmatrix},$$

which is well defined if

$$D\left(\begin{pmatrix}0 & -L\\ 0 & \mu\mathcal{B}-\mathcal{A}\end{pmatrix}\right)=D(\hat{\mathcal{A}})$$

in light of Conjecture 2.2. In this case, the equivalent characteristic matrix becomes

$$\tilde{\Delta}(\mu)=(\mu M-L)R(\mu).$$

3. Continuation of periodic orbits. Define the following nonlinear operator:

$$G:\ X\times\mathbb{R}^p\to X,\quad G(\varphi,\lambda)(\theta)=x'(\theta)-f(\theta,\imath_\theta(\varphi),\lambda),$$

where $t\in[-T,0]$, $(\imath_t(\varphi))(\theta)=\varphi((t+\theta)\bmod\omega)$. The domain of G is $D(G(.,\lambda))=\{\varphi\in\mathrm{Lip}([-\omega,0],\mathbb{R}^n)|\,\varphi(-\omega)=\varphi(0)\}$. We can extend this operator in the same way as in the previous section:

$$\hat{G}((c,\varphi),\lambda)=\begin{pmatrix}L\varphi-c\\ G(\varphi,\lambda)\end{pmatrix},\quad(c,\varphi)\in D(\hat{G}(.,\lambda))=D(\hat{\mathcal{A}}).$$

Now we have the nonlinear equation for the periodic solutions of (2.1) in the form

$$\hat{G}((c,\varphi),\lambda)=\begin{pmatrix}0\\ 0\end{pmatrix}. \tag{3.1}$$

Let $(c_0, \varphi_0) = u_0$ be a solution of (3.1) at λ_0. Then the Frechet derivative of (3.1) is $\hat{\mathcal{A}}(\varphi_0) - \hat{\mathcal{B}}(\varphi_0)$. By the equivalence (2.7) we infer that $\hat{\mathcal{A}}(\varphi_0) - \hat{\mathcal{B}}(\varphi_0)$ is one-to-one and onto at a regular solution, when there is no $+1$ multiplier of the monodromy operator ($\det \Delta(1) \neq 0$). In this case, the solution u_0 can be continued according to the implicit function theorem.

3.1. Pseudo-arclength continuation. In our computations, we use the pseudo-arclength method to continue branches beyond limit points [10]. Here, we will use the following bilinear form:

$$\langle\, ,\, \rangle : \hat{X}_A \times \hat{X}_A \to \mathbb{R}, \quad \langle u, v\rangle = (Mv)^* Mu + \frac{1}{\omega}\int_{-\omega}^{0} u^*(\theta)v(\theta)d\theta,$$

where the * denotes the (conjugate) transpose. Let us denote a branch of solutions by $(u, \lambda) : I \subset \mathbb{R} \to \hat{X} \times \mathbb{R}$ parametrized with the arclength γ with respect to the norm $\|(u,\lambda)\| = \sqrt{\langle u, u\rangle} + |\lambda|$. Consider a solution $(u_0, \lambda_0) = (u(0), \lambda(0))$, which we want to continue in λ. Since u_0 is a regular solution, we can obtain the tangents $\dot{u}_0$, $\dot{\lambda}_0$ from the equation

$$(\hat{\mathcal{A}}(u_0) - \hat{\mathcal{B}}(u_0))\dot{u}_0 + D_\lambda \hat{G}(u_0, \lambda)\dot{\lambda}_0 = 0.$$

Further, we normalize the tangents such that $\|(\dot{u}_0, \dot{\lambda}_0)\| = 1$. With these tangents we predict the next solution point on the branch of solutions $u_1^{(0)} = d\gamma\, \dot{u}_0$, $\lambda_1^{(0)} = d\gamma\, \dot{\lambda}_0$, where $d\gamma$ is the step size. Newton iteration of the correction step proceeds by solving

$$\begin{pmatrix} \hat{\mathcal{A}}(u_1^{(\nu)}) - \hat{\mathcal{B}}(u_1^{(\nu)}) & D_\lambda \hat{G}(u_1^{(\nu)}, \lambda_1^{(\nu)}) \\ \langle \dot{u}_0, \, . \, \rangle & \dot{\lambda}_0 \end{pmatrix} \begin{pmatrix} \Delta u \\ \Delta\lambda \end{pmatrix} = \begin{pmatrix} -\hat{G}(u_1^{(\nu)}, \lambda_1^{(\nu)}) \\ d\gamma - \langle \dot{u}_0, u_1^{(\nu)} - u_0\rangle - (\lambda_1^{(\nu)} - \lambda_0)\dot{\lambda}_0 \end{pmatrix} \tag{3.2}$$

and updating $u_1^{(\nu+1)} = u_1^{(\nu)} + \Delta u$, $\lambda_1^{(\nu+1)} = \lambda_1^{(\nu)} + \Delta\lambda$. According to bordering theorems (see, e.g., [10]), the coefficient operator in (3.2) is also one-to-one and onto, since $\hat{\mathcal{A}}(u_0) - \hat{\mathcal{B}}(u_0)$ is one-to-one and onto and $\dot{\lambda}_0 \neq 0$ at a regular solution. The same is true in the case of a quadratic fold when $D_\lambda \hat{G}(u_0, \lambda_0) \notin \mathcal{R}(\hat{\mathcal{A}}(u_0) - \hat{\mathcal{B}}(u_0))$.

4. Continuation of bifurcations. In this section we reformulate classical continuation theorems of codimension-one bifurcations for periodic DDEs. Since we have the equivalence with the finite-dimensional characteristic matrix, these classical theorems can be applied almost directly. In order to compute the Jacobians, we will need derivatives of the characteristic matrix with respect to u, λ, and the spectral parameter μ. For the sake of simplicity (and computational efficiency) we use $\tilde{\Delta}(\mu)$. In general, the derivative of the inverse of an operator-valued function A is

$$(D_x A^{-1}(x))(y) = -A^{-1}(x)(D_x A(x))(A^{-1}(x), y). \tag{4.1}$$

Using this relation

$$\begin{aligned} D_u\tilde{\Delta}(\mu)c = &-(\mu M - L)\begin{pmatrix} 0 & -L \\ 0 & \mu\mathcal{B} - \mathcal{A} \end{pmatrix}^{-1} \\ &\times D_u \begin{pmatrix} 0 & -L \\ 0 & \mu\mathcal{B}(u) - \mathcal{A}(u) \end{pmatrix} \left(\begin{pmatrix} 0 & -L \\ 0 & \mu\mathcal{B} - \mathcal{A} \end{pmatrix}^{-1} \begin{pmatrix} c \\ 0 \end{pmatrix}, \, . \, \right), \end{aligned}$$

$$D_\lambda\tilde{\Delta}(\mu)c = -(\mu M - L)\begin{pmatrix} 0 & -L \\ 0 & \mu\mathcal{B}-\mathcal{A}\end{pmatrix}^{-1} \times D_\lambda\begin{pmatrix} 0 & -L \\ 0 & \mu\mathcal{B}(u)-\mathcal{A}(u)\end{pmatrix}\begin{pmatrix} 0 & -L \\ 0 & \mu\mathcal{B}-\mathcal{A}\end{pmatrix}^{-1}\begin{pmatrix} c \\ 0\end{pmatrix},$$

and

$$D_\mu\tilde{\Delta}(\mu)c = M\,R(\mu)c - (\mu M - L)\begin{pmatrix} 0 & -L \\ 0 & \mu\mathcal{B}-\mathcal{A}\end{pmatrix}^{-1} \times \begin{pmatrix} 0 & 0 \\ 0 & \mathcal{B}(u)\end{pmatrix}\begin{pmatrix} 0 & -L \\ 0 & \mu\mathcal{B}-\mathcal{A}\end{pmatrix}^{-1}\begin{pmatrix} c \\ 0\end{pmatrix}. \tag{4.2}$$

Note that in the above formulas, it is always the same operator that is inverted.

4.1. Fold bifurcation. In case of a fold bifurcation there is a $+1$ eigenvalue of the monodromy operator, which is equivalent to $\det\Delta(1) = 0$. This implies that we have unit vectors p and q, ($p^*p = 1$, $q^*q = 1$) such that $p^*\Delta(1) = 0$ and $\Delta(1)q = 0$. The kernel of $\hat{\mathcal{A}}-\hat{\mathcal{B}}$ and $(\hat{\mathcal{A}}-\hat{\mathcal{B}})^*$ is spanned by $\varphi = E(1)(q,0)^T$ and $\psi = F^*(1)(p,0)^T$, respectively. The defining system is (see, e.g., Beyn et al. [1])

$$\begin{aligned}\hat{G}(u,\lambda) &= 0,\\ \tilde{\Delta}(1)q &= 0,\\ q_0^*q - 1 &= 0.\end{aligned}$$

The Jacobian with respect to (u,q,λ) is

$$\begin{pmatrix} \hat{\mathcal{A}}(u_0)-\hat{\mathcal{B}}(u_0) & 0 & D_\lambda\hat{G}(u_0,\lambda_0) \\ D_u\tilde{\Delta}(1)q_0 & \tilde{\Delta}(1) & D_\lambda\tilde{\Delta}(1)q_0 \\ 0 & q_0^* & 0\end{pmatrix}. \tag{4.3}$$

PROPOSITION 4.1. [illegible] (4.3) [illegible]. The proof is the same as for algebraic systems and is therefore omitted (see Doedel, Keller, and Kernévez [10, section 2.3.]). □

4.2. Period doubling. Similarly, the defining system is

$$\begin{aligned}\hat{G}(u,\lambda) &= 0,\\ \tilde{\Delta}(-1)q &= 0,\\ q_0^*q - 1 &= 0,\end{aligned}$$

and the Jacobian with respect to (u,q,λ) yields

$$\begin{pmatrix} \hat{\mathcal{A}}(u_0)-\hat{\mathcal{B}}(u_0) & 0 & D_\lambda\hat{G}(u_0,\lambda_0) \\ D_u\tilde{\Delta}(-1)q_0 & \tilde{\Delta}(-1) & D_\lambda\tilde{\Delta}(-1)q_0 \\ 0 & q_0^* & 0\end{pmatrix}. \tag{4.4}$$

4.3. Neimark–Sacker bifurcation. The defining system is

$$\begin{aligned}\hat{G}(u,\lambda) &= 0,\\ \tilde{\Delta}(e^{i\alpha})q &= 0,\\ q_0^*q - 1 &= 0,\end{aligned}$$

and its Jacobian with respect to (u, q, α, λ) becomes

$$\begin{pmatrix} \hat{\mathcal{A}}(u_0) - \hat{\mathcal{B}}(u_0) & 0 & 0 & D_\lambda \hat{G}(u_0, \lambda_0) \\ D_u \tilde{\Delta}(e^{i\alpha_0}) q_0 & \tilde{\Delta}(e^{i\alpha_0}) & D_\alpha \tilde{\Delta}(e^{i\alpha_0}) q_0 & D_\lambda \tilde{\Delta}(e^{i\alpha_0}) q_0 \\ 0 & q_0^* & 0 & 0 \end{pmatrix}. \tag{4.5}$$

Here we use complex values in the last two rows of the Jacobian, which can be expanded to reals, and then use the same argument to prove the regularity as in [10, section 2.3.].

4.4. Remark on the autonomous case. The presented method can easily be extended for autonomous equations by adding a phase condition to the defining systems and the period to the list of unknown variables [12]. In the case of a fold bifurcation in autonomous systems, the characteristic multiplier $+1$ has algebraic multiplicity two; therefore, it is not sufficient to use $\Delta(1)q$, but by the equivalence of Jordan chains [20],

$$\begin{aligned} \tilde{\Delta}(1) q_1 &= 0, \\ D_\mu \tilde{\Delta}(1) q_1 + \tilde{\Delta}(1) q_2 &= 0. \end{aligned} \tag{4.6}$$

The size of this system of equations can be reduced by computing q_1 and $D_\mu \Delta(1) q_1$. The eigenfunction ϕ_1 of the trivial multiplier 1 is always the derivative of the solution, which equals the right-hand side of the equation $\phi_1(\theta) = f(\iota_\theta(u_0), \lambda)$. Further, from the analysis above, we infer that $q_1 = M\phi_1 = f(\iota_{(0)}(u_0), \lambda)$. On the other hand, $D_\mu \Delta(1) q_1$ can be computed according to (4.2) as

$$D_\mu \tilde{\Delta}(\mu) q_1 = f(i_{(0)}(u), \lambda) - M \begin{pmatrix} 0 & -L \\ 0 & \mathcal{B} - \mathcal{A} \end{pmatrix}^{-1} \begin{pmatrix} 0 \\ \mathcal{B} f(i_{(.)}(u), \lambda) \end{pmatrix}.$$

In general, (4.6) defines a one-dimensional kernel space at a regular solution, which corresponds to q_1. However, if there is an algebraically double $+1$ multiplier, our system (4.6) has a two-dimensional kernel space. To eliminate the trivial kernel we use bordering, which reduces (4.6) to

$$\begin{pmatrix} D_\mu \tilde{\Delta}(\mu) q_1 & \tilde{\Delta}(\mu) \\ 0 & q_1^* \end{pmatrix} \tilde{q}_2 = 0,$$

where $\tilde{q}_2$ is a new variable, which contains q_2 from its second element. We remark that in [8], test functionals for folds in ODEs are constructed in a similar way.

5. Implementation. In this section, we summarize the numerical methods used in our continuation software that uses orthogonal collocation [5] to discretize the operators $\mathcal{A}$ and $\mathcal{B}$ of equations with discrete fixed delays. Thus, (2.1) can be written as

$$x'(\tilde{t}) = \tilde{f}(\tilde{t}, x(\tilde{t} - \tilde{\tau}_1), \ldots, x(\tilde{t} - \tilde{\tau}_m)),$$

where $\tilde{f} : \mathbb{T}^1 \times \mathbb{R}^n \times \cdots \times \mathbb{R}^n \to \mathbb{R}^n$ and $0 \le \tilde{\tau}_1 < \tilde{\tau}_2 < \cdots < \tilde{\tau}_m \le \omega$. By rescaling the time with $\tilde{t} = \omega t$ and defining $f(t, x_1, \ldots, x_m) = \tilde{f}(\omega t, x_1, \ldots, x_m)$, our equation becomes

$$x'(t) = \omega f(t, x(t - \tau_1), \ldots, x(t - \tau_m)).$$

Its variational system at v is

$$x'(t) = \sum_{i=1}^{m} D_{x_i} f(t, v(t-\tau_1), \dots, v(t-\tau_m)) x(t-\tau_i).$$

Also, assume that the initial time $s = 0$. Let A_i, $B_i : X \times [-1,0] \to \mathbb{R}^{n\times n}$ be defined by

$$A_i(v,\theta) = \omega H(1+\theta-\tau_i) D_{x_i} f(\theta, v((\theta-\tau_1) \bmod 1), \dots, v((\theta-\tau_m) \bmod 1)),$$
$$B_i(v,\theta) = \omega H(\tau_i-1-\theta) D_{x_i} f(\theta, v((\theta-\tau_1) \bmod 1), \dots, v((\theta-\tau_m) \bmod 1)),$$

where mod maps to $[-1,0]$ and H is the Heaviside function. Then (2.4) and (2.5) become

$$(\mathcal{A}(v)\varphi)(\theta) = \varphi'(\theta) - \sum_{i=1}^{m} A_i(\theta)\varphi(\theta-\tau_i),$$
$$(\mathcal{B}(v)\varphi)(\theta) = \sum_{i=1}^{m} B_i(\theta)\varphi(1+\theta-\tau_i).$$

5.1. Collocation. Here, we summarize the main steps of the method; its detailed discussion can be found in [12]. We approximate the solution φ on $\mathfrak{n}$ intervals by degree $\mathfrak{m}$ polynomials. The method requires the space X to be $C^{\mathfrak{m}}([-1,0],\mathbb{R}^n)$, and consequently $D(\mathcal{A}(v)) = C^{\mathfrak{m}+1}([-1,0],\mathbb{R}^n)$ and f is also $C^{\mathfrak{m}}$-smooth in t. The mesh is represented by the intervals $[\theta_i, \theta_{i+1}]$, $i = 0, \dots, \mathfrak{n}-1$ with $-1 = \theta_0 < \theta_1 < \cdots < \theta_{\mathfrak{n}} = 0$. Also denote the length of an interval by $h_i := \theta_{i+1} - \theta_i$. The approximate solution can be written on the ith subinterval as

$$\tilde{\varphi}(\theta) = \sum_{j=0}^{\mathfrak{m}} \varphi(\theta_{i+\frac{j}{\mathfrak{m}}}) P_{i,j}(\theta),$$

where

$$P_{i,j}(\theta) = \prod_{r=0, r\neq j}^{\mathfrak{m}} \frac{\theta - \theta_{i+\frac{r}{\mathfrak{m}}}}{\theta_{i+\frac{j}{\mathfrak{m}}} - \theta_{i+\frac{r}{\mathfrak{m}}}}$$

and $\theta_{i+\frac{j}{\mathfrak{m}}} := \theta_i + j\frac{h_i}{\mathfrak{m}}$. Let c_i, $i = 1, \dots, \mathfrak{m}-1$, be the roots of the degree $\mathfrak{m}$ Legendre polynomial scaled from $[-1,1]$ to $[0,1]$. Then define the collocation points by $c_{j,i} = \theta_j + h_j c_i$. The discretized version of operator $\mathcal{A}$ becomes

$$(\mathcal{A}_d(v)\tilde{\varphi})(c_{j,i}) = \tilde{\varphi}'(c_{j,i}) - \sum_{i=1}^{m} A_i(c_{j,i})\tilde{\varphi}(c_{j,i}-\tau_i). \tag{5.1}$$

Operator $\mathcal{B}$ is discretized similarly. Note that (5.1) is an operator from $\mathbb{R}^{(\mathfrak{m}\times\mathfrak{n}-1)\times n}$ to $\mathbb{R}^{\mathfrak{m}\times\mathfrak{n}\times n}$, so it has (at least) an n-dimesional kernel just as its abstract counterpart (2.4) has. The discretized version of $\hat{\mathcal{A}}$ acting on $(M\varphi, \varphi)$ can be represented by a square matrix by placing the $-L\varphi$ vector into the first n rows, which is of full rank at a regular solution v according to [11, Theorem 3.1] when $|h| = \max_{i=0}^{n-1} h_i$ is sufficiently small. Moreover, if we choose the space $X = C^{\mathfrak{m}}([-1,0],\mathbb{R}^n)$ as described above, then there exist a $\delta > 0$ and $C > 0$ such that the solutions of $\hat{\mathcal{A}}\psi = \hat{\mathcal{B}}\varphi$ and $\hat{\mathcal{A}}_d\tilde{\psi} = \hat{\mathcal{B}}_d\tilde{\varphi}$ satisfy

$$\max_{\theta\in[-1,0]} |\psi(\theta) - \tilde{\psi}(\theta)| \leq C|h|^{\mathfrak{m}} \tag{5.2}$$

if $|h| \in (0, \delta]$ (see Engelborghs and Doedel [11, Theorem 3.3]). Although superconvergence is lost for delay equations, some improvement can be achieved over (5.2) by using modified collocation schemes (see [11, section 4] and [12]).

5.2. Solving bordered linear systems. Equations (3.2), (4.3), (4.4), and (4.5) contain the operator $\hat{\mathcal{A}} - \hat{\mathcal{B}}$, functionals such as $\langle \dot{u}_0, . \rangle$ on $\hat{X}$, vectors such as $D_\lambda \hat{G}(u_0, \lambda_0)$ in $\hat{X}$, and also the finite-dimensional characteristic matrix. From a computational point of view, it is better to factorize the discretized counterparts of these components separately rather than copying them into one big matrix. Usually, the discretized infinite-dimensional part has a special sparsity structure, which can be exploited in computations. Other reasons for bordering methods might be the reuse of code and avoiding the frequent copying of large data structures. In our code, we used methods developed by Govaerts [14, 15] and Govaerts and Pryce [16]. These methods have the advantage over classical bordering methods [10, 1] in that they do not require the calculation of the kernel of singular matrices for the computation and can be used with arbitrary stable solvers. This feature makes it possible to use the same routine for sparse (e.g., $\hat{\mathcal{A}}_d - \hat{\mathcal{B}}_d$ with discrete delays) and dense (e.g., $\hat{\mathcal{A}}_d - \hat{\mathcal{B}}_d$ with distributed delays) matrices, leaving space for future improvements.

The method of mixed block elimination (BEM) [14] is used in factorizing the discretized counterpart of the Jacobian in (3.2). For solving equations of the form

$$\begin{pmatrix} A & b \\ c^* & d \end{pmatrix} \begin{pmatrix} x \\ y \end{pmatrix} = \begin{pmatrix} \alpha \\ \beta \end{pmatrix},$$

the method requires a solution with A and one with A^*. Note that for this solution A is factorized only once. For the bigger problem

$$\begin{pmatrix} A & 0 & b \\ C & D & e \\ f^* & g^* & h \end{pmatrix} \begin{pmatrix} x \\ y \\ z \end{pmatrix} = \begin{pmatrix} \alpha \\ \beta \\ \delta \end{pmatrix},$$

which appears in (4.3) and (4.4), we apply the generalized mixed block elimination (GMBE) [14] technique, which requires one solution with D^T and two BEM steps with A and D, respectively. In case of systems augmented with wider borders, BEMW [14] is used, which is the iterative form of the recursive version of BEM. The wider borders occur in (4.5) and (4.3), and also in (4.4) when they are further augmented with derivatives and tangent vectors in the two-parameter continuation context similarly to (3.2). These kinds of equations can be solved using GMBE, but BEM must be replaced with BEMW.

Factorization of sparse matrices was carried out using UMFPACK,[1] which implements the unsymmetric multifrontal method of direct LU factorization (see Davies [4]). For (nearly) optimal performance we construct the matrices $\hat{\mathcal{A}}_d - \hat{\mathcal{B}}_d$ directly in compressed row form instead of the default compressed column form. After factorization, we interchange the solution methods for the matrix and its transpose to get the correct results. For dense matrices, we use the standard LAPACK routine GESVX.

6. Examples. Our first example is a forced system which models an interrupted machining process. In this example, when considering period-one solutions, the delay equals the period. However, this is not the case for period-two solutions, where

[1] We remark that this package is incorporated into MATLAB as well.

there are two delays, the smallest being half of the period length; thus the characteristic matrix definition of Verduyn Lunel [22] is not applicable and we need our general construction. The second example is a traffic model, which demonstrates that our algorithm can handle arbitrary (varying) delays. This second example, being autonomous, also demonstrates the fold continuation in our remark in section 4.4.

6.1. Interrupted machining. Here, we analyze bifurcations of period-two orbits in an interrupted machining model. To this end, we consider an extended version of the equation of motion in [25] in the form

(6.1)
$$\begin{aligned} x''(t)+2\zeta x'(t)+x(t) = {} & wg(t)H\left(1+x(t-2T)-x(t-T)\right)F_c\left(1+x(t-T)-x(t)\right) \\ & + wg(t)H\left(1+x(t-T)-x(t-2T)\right)F_c\left(2+x(t-2T)-x(t)\right), \end{aligned}$$

where H is the Heaviside function,

$$g(t) = \begin{cases} 0 & \text{if } \exists\, k:\ kT \le t < (k+1-\rho)T \\ 1 & \text{if } \exists\, k:\ (k-\rho)T \le t < kT \end{cases}, \quad k \in \mathbb{Z},$$

and

$$F_c(x) = H(x)\left(\frac{120}{59}x - \frac{48}{59}x^2 + \frac{35}{177}x^3\right).$$

This cutting force function F_c is a polynomial approximation of the common three-quarter rule $F_c(x) \approx 4/3\, x^{3/4}$ (see [27]). Also, $\zeta = 0.015$ is the relative damping, and $\rho = 0.1$ is the ratio between the period length T and the time spent with cutting. Equation (6.1) has a unique T-periodic solution, which is described by the ODE

$$x''(t) + 2\zeta x'(t) + x(t) = wg(t)F_c(1).$$

In a quite large neighborhood of this periodic solution, (6.1) simplifies to

$$x''(t) + 2\zeta x'(t) + x(t) = wg(t)F_c\left(1+x(t-T)-x(t)\right), \tag{6.2}$$

while the second line of (6.1) is turned on if the tool did not cut the workpiece in the previous period. Its variational equation around the T-periodic solution is

$$x''(t) + 2\zeta x'(t) + x(t) = wg(t)\left(x(t-T)-x(t)\right).$$

The stability of the above equation was analyzed analytically in [25] in great detail. The stability chart is shown in Figure 1. We analyze the lowest lens at $T \approx 15$. The bifurcation diagram at $T = 14.75$ can be seen in Figure 2. The first period doubling bifurcation at $w \approx 0.6629$ is subcritical. The arising unstable period-two orbit folds back and then loses its stability through a torus bifurcation. The other period doubling bifurcation is supercritical. On the stable branch there is a torus bifurcation window. This branch folds back, too, and becomes unstable.

The bifurcations in Figure 2 are continued in two parameters using our method. First, the stability boundaries of (6.2) are obtained, which coincides with the semi-analytical results of [25]. The period-T orbits are also checked analytically. In order to avoid difficulties arising from the nonsmoothness of (6.1), we substitute the Heaviside function $H(x)$ by $(1+\tanh(C\,x))/2$ with $C = 30$. Choosing bigger values for C is not reasonable because it only improves the results within the line thickness but makes

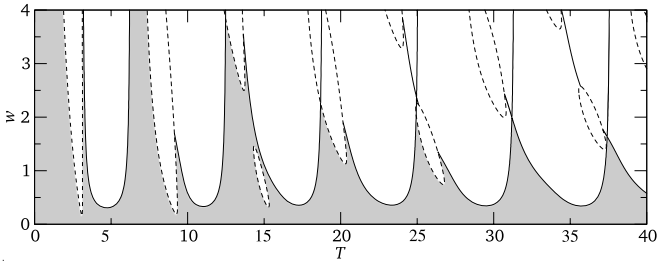

FIG. 1. *Stability chart for the interrupted machining model showing period doubling boundaries (dashed lines) and Neimark–Sacker boundaries (continuous lines). In the gray region the T-periodic solution is stable ($\zeta = 0.015$).*

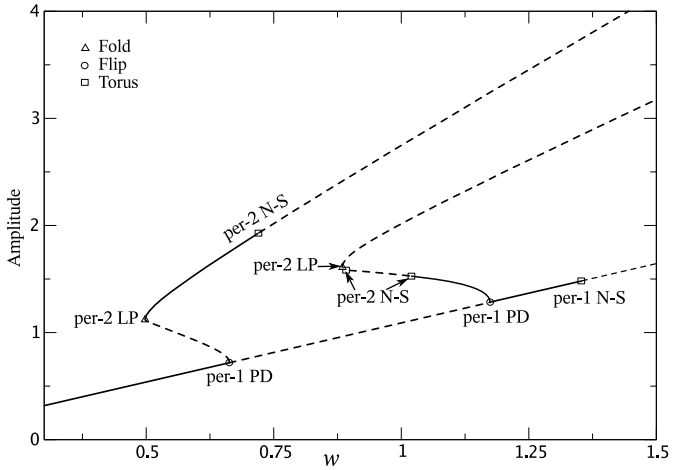

FIG. 2. *This bifurcation diagram shows the period-two orbits emanating from the period-one solution at the stability boundary in the vertical cross section of a lens at $T = 14.75$ in Figure 1. Continuous lines denote stable solutions, while dashed lines correspond to unstable solutions.*

the computation more difficult due to derivatives tending to infinity. The period-two orbits arising at the lens in the space of two parameters extended with the solution amplitude form a highly distorted tube-like object. Figure 3 shows the computed bifurcation curves. The lower continuous curve corresponds to the fold bifurcation of orbits arising at the lower part of the lens. The other continuous curve shows the fold of the upper solution branch in Figure 2. It can be seen that there are two cusp points on the bifurcation curve which, in addition, connects to the period doubling boundary of period-one solutions separating sub- and supercritical period doubling bifurcations. The dash-dot lens near to the upper fold curve is an unstable island on the supercritically bifurcated family of period-two solutions, while the other dash-dot line corresponds to the stability loss of motion on the other branch of orbits.

6.2. Traffic model with driver reaction time. Here, we focus on the fold bifurcations of periodic orbits in the autonomous traffic model described in Orosz, Wilson, and Krauskopf [23]. We consider N_c cars on a circular track of length L, so

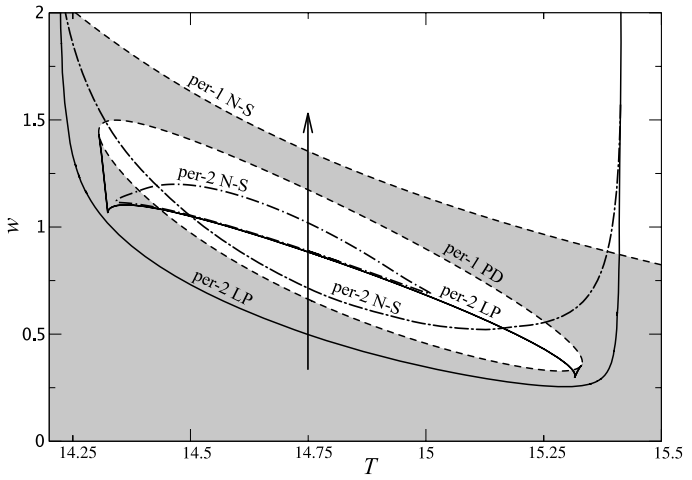

FIG. 3. *Bifurcations of period-two orbits. Dashed lines correspond to the stability of period-two solutions (see Figure 1). Continuous lines are fold bifurcation curves, and dash-dot lines are Neimark–Sacker stability curves of period-two solutions.*

that the distances between the cars (h_i) add up to L:

$$\sum_i h_i(t) = L. \tag{6.3}$$

In addition, these distances vary with the speed difference between two adjacent cars:

$$\dot{h}_i(t) = v_{i+1}(t) - v_i(t), \tag{6.4}$$

where v_i denotes the speed of the ith car. The drivers increase or decrease their speed according to their current speed and the headway before them. However, they cannot react immediately; thus a delayed value of the headway is considered in the model:

$$\dot{v}_i(t) = \beta[V(h_i(t-\tau)) - v_i(t)], \tag{6.5}$$

where β is the sensitivity of the drivers and V is the so-called optimal velocity function defined as

$$V(h) = \begin{cases} 0, & 0 \le h \le 1, \\ v^0 \frac{(h-1)^3}{1+(h-1)^3}, & h > 1. \end{cases}$$

The steady state solution of the model corresponds to equal headways and equal car velocities; that is,

$$h_i^* = L/N, \quad v_i^* = V(h_i^*),$$

where N_c is the number of cars on the track.

From now on we focus on the case $N_c = 3$; thus our equations become

$$\begin{aligned}
\dot{h}_1(t) &= v_2(t) - v_1(t), \\
\dot{h}_2(t) &= v_3(t) - v_2(t), \\
\dot{v}_1(t) &= \beta[V(h_1(t-\tau)) - v_1(t)], \\
\dot{v}_2(t) &= \beta[V(h_2(t-\tau)) - v_2(t)], \\
\dot{v}_3(t) &= \beta[V(L - h_1(t-\tau) - h_2(t-\tau)) - v_3(t)],
\end{aligned}$$

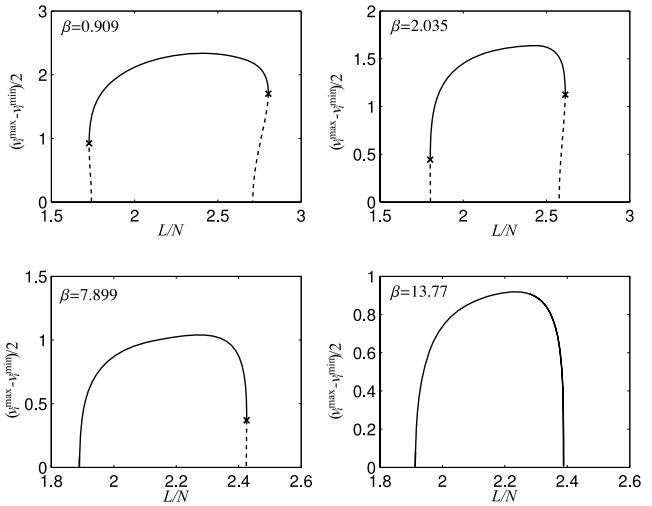

FIG. 4. *Branches of periodic orbits in the traffic model. Dashed curves represent unstable solutions, while continuous curves denote stable solutions. The parameters are* $v^0 = 0.8$ *and* $\tau = 1.0$.

using (6.3). The fixed points can undergo a Hopf bifurcation. Although it is not computationally efficient, we computed the Hopf bifurcation curve using our method, considering the fixed point as a periodic solution (see Figure 5). After computing the critical eigenvectors of the characteristic matrix we constructed a linearly approximate periodic solution around the fixed point

$$h_i(t) = \epsilon \mathrm{Re}(\mathrm{e}^{i\alpha t} h_i^q),$$
$$v_i(t) = \epsilon \mathrm{Re}(\mathrm{e}^{i\alpha t} v_i^q),$$

where ϵ is a sufficiently small real number, α is in the argument of the critical characteristic multiplier (see (4.5)), and h_i^q, v_i^q are the respective components of the kernel vector q of $\Delta(\mathrm{e}^{i\alpha})$. The computed branches of periodic solutions for different values of β can be seen in Figure 4. These periodic orbits undergo fold bifurcations, whose locations can be continued in two parameters using our method. These fold curves are represented by continuous lines in Figure 5, while the Hopf bifurcation of the fixed point is denoted by the dashed lines. It can be seen that the two types of bifurcations meet in a degenerate Hopf point, where the monodromy operator has triple $+1$ eigenvalues including the trivial one.

7. Discussion. In our presentation the characteristic matrix definition was given for equations with delays smaller than or equal to the period. However, our definition can be easily extended to any bounded delays such as the special case of integer delays in [22]. This extended algorithm is already implemented in the software PDDE-CONT [24].

Although the full equivalence of a characteristic matrix and the monodromy operator at spectral points remains to be proven, the correctness of our conjecture can be checked numerically with minimal effort. For discrete delays τ_i that are rationally related to the period, e.g., $\tau_i = r_i/p$, $r_i, p \in \mathbb{N}$, one can construct an $(n \times p)$-dimensional characteristic matrix that is equivalent to the monodromy operator, since the operator in Conjecture 2.2 can be inverted by solving ODEs. Hence for discrete delays that are sufficiently close to rational delays, a characteristic matrix can be constructed,

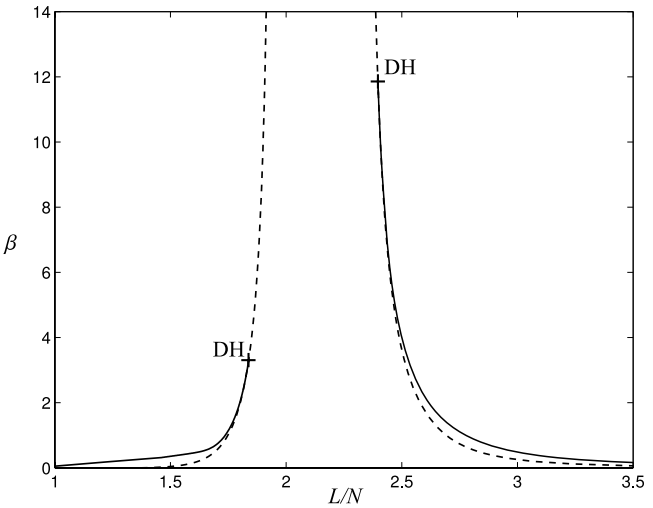

FIG. 5. *Stability chart. Between the two dashed curves denoting Hopf bifurcations, the fixed point is unstable. The arising periodic orbits fold back along the continuous curve. The fold curves meet the Hopf bifurcation curve in the degenerate Hopf points denoted by "+" signs ($v^0 = 0.8$, $\tau = 1.0$).*

because the resolvent set of an operator is open and the operator is norm continuous with respect to the delays.

The equivalence with the monodromy operator also gives the opportunity to compute center manifolds and normal forms for periodic equations in special cases where the characteristic matrix is analytically available as was demonstrated in [26].

8. Conclusions. Periodic DDEs frequently arise in applications that describe phenomena in engineering, biology, and other disciplines. In this paper we have constructed a characteristic matrix for general periodic DDEs in order to use it in the numerical continuation of bifurcations. We also have presented the equivalence of the characteristic matrix with the monodromy operator, which makes regularity proofs of defining systems of equations similar to the proofs in the case of finite-dimensional algebraic systems. We have implemented the algorithm in software written in C++ [24], which uses collocation to discretize the infinite-dimensional operators. Bordering techniques were also used in the solution of linear systems extended with the characteristic matrix, some derivatives, and tangent vectors. Finally, two examples, an interrupted machining model and a traffic model, were analyzed.

Acknowledgments. The authors thank Bernd Krauskopf, Kirk Green, Gábor Orosz, and Barnabás Garay for helpful discussions.

PARALLEL SUPPORT SET SEARCHES FOR MESHFREE METHODS*

C. CARTWRIGHT†, S. OLIVEIRA‡, AND D. E. STEWART§

Abstract. We describe the implementation of a parallel algorithm that solves a computational geometry problem arising in meshfree methods. We solve the following problem: Given a collection of N d-rectangles S_i and Q points x_k in $\mathbb{R}^d$, compute $I_k = \{i \mid x_k \in S_i\}$. This task is necessary for computing values of the meshfree basis functions $\Psi_i(x_k)$ and can be used to efficiently compute the mass and stiffness matrices for the meshfree Galerkin method.

Key words. meshfree methods, computational geometry, quadtrees

1. Introduction.

Recently there has been a growing interest in developing meshfree methods for solving partial differential equations (PDEs) as an alternative to finite element methods (FEMs). Meshfree methods in general require more complicated geometric tasks than are associated with FEMs. Efficient computational geometry algorithms are necessary if meshfree methods are to be viable.

In this article we look at the solution of a particular computational geometry problem arising from meshfree Galerkin methods, a class of meshfree methods. In section 2 we introduce meshfree methods and the geometric task that they require for efficient implementation. In section 3 we discuss quadtree data structures and how we use them to solve our particular problem. Then in section 4 we discuss how to parallelize the sequential algorithm described in section 3, considering the issues of data distribution which can be rather irregular in applications. Parallel performance estimates are derived in section 5, followed in section 6 by a discussion of a partitioning algorithm we use to balance the computational load. Finally in section 8 we give numerical results that illustrate the scalability of our algorithm and improvements we are able to achieve through attempting to control the load balance among processors.

We use standard asymptotic notation: $f(n) = O(g(n))$ means that there is a C and an n_0 where $n \geq n_0$ implies $|f(n)| \leq C\,|g(n)|$. Furthermore, $f(n) = \Omega(g(n))$ means that $g(n) = O(f(n))$; $f(n) = \Theta(g(n))$ means that $f(n) = O(g(n))$ and $g(n) = O(f(n))$.

2. Geometric problems arising in meshfree methods.

Some of the limitations of the traditional FEMs for solving PDEs are the computationally intensive tasks of generating meshes with good quality and of regenerating meshes when necessary. Recently there have been several methods, known as meshfree methods, that do not require constructions of grids (meshes) and are being developed as an alternative

to FEMs that for large deformation problems may perform better than traditional FEMs. There are a number of types of meshfree methods, such as [illegible] (PUFEMs), [illegible] (RKPMs), [illegible] (EFG), [illegible], and [illegible] (MLS). [illegible]. An overview of meshfree methods can be found in [1] and more recently in [5]. In this article we will focus on computational geometry techniques that are applicable to meshfree Galerkin methods.

In meshfree Galerkin methods, a set of basis functions Ψ_i, $i = 1, 2, \ldots, N$, is defined, and we seek an approximate solution $u^h = \sum_{i=1}^{N} u_i^h \Psi_i(x)$. To solve a PDE such as

$$-\nabla \cdot A(x)\nabla u + c(x)u = f$$

in Ω with Neumann boundary conditions, we construct a linear system of equations to solve for the u_i's, $\sum_{j=1}^{N} K_{ij} u_j^h = f_i$ for $i = 1, 2, \ldots, N$, where

$$K_{ij} = \int_{\Omega} (\nabla \Psi_i(x)^T A(x) \nabla \Psi_j(x) + c(x)\Psi_i(x)\Psi_j(x)) dV(x). \tag{2.1}$$

In all meshfree methods, one starts with an a priori given set of [illegible] Φ_i on Ω, which are typically smooth and nonnegative and have compact support. Usually these kernel functions are obtained from a single reference function using "centers" x_i and "radii" a_i: $\Phi_i(x) = \Phi((x - x_i)/a_i)$. The reference function $\Phi(z)$ is commonly a tensor product of B-spline functions $\Phi(z) = B(z_1)\, B(z_2) \cdots B(z_d)$, where B is a standard cubic spline function with nodes at -1, $-1/2$, 0, $+1/2$, $+1$, with support $[-1, +1]$. Alternative choices include $\Phi(z) = B(\|z\|_2)$ and radial basis functions.

From these kernel functions, meshfree methods construct basis functions that have better approximation properties. Partition of unity methods (PUMs) usually set

$$\Psi_i(x) = \frac{\Phi_i(x)}{\sum_{j=1}^{N} \Phi_j(x)},$$

which are called Shepard functions in the meshfree literature [10]. These basis functions are then "enriched" by adding additional basis functions $\Psi_i(x)\, v_j(x - x_i)$, where v_j belongs to a small set of functions, typically polynomials. For example, $v_j(z) = z_j$, $j = 1, 2, \ldots, d$, so that any linear function can be exactly represented by basis functions. Alternatively, RKPMs construct basis functions in order to be able to reproduce a certain space of functions, typically low order polynomials. Suppose we wish to reproduce all affine functions so that if f is an affine function, $f(x) = \sum_{i=1}^{N} \Psi_i(x)\, f(x_i)$. Then we set $H(z) = [1, z_1, \ldots, z_d]^T$ and construct the RKPM basis functions by the rule

$$\Psi_i(x) = H(0)^T M(x)^{-1} H(x - x_i)\, \Phi_i(x),$$

where $M(x) = \sum_{i=1}^{N} H(x - x_i) H(x - x_i)^T\, \Phi_i(x)$.

It should be noted that unless there is some kind of cancellation, the supports of the basis functions are exactly the supports of the kernel functions, which are typically rectangles or balls in $\mathbb{R}^d$. An illustration of how some of the support sets might appear is shown in Figure 1. Also note that in order to compute $\Psi_i(x)$ in either the PUMs or

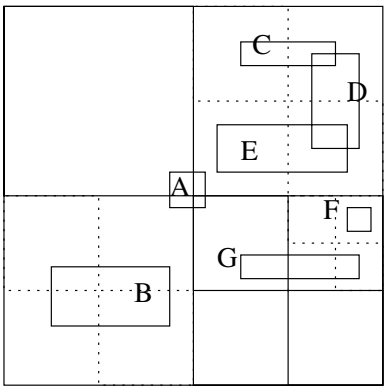

FIG. 1. *Sample collection of rectangles. For clarity we show only a few rectangles; normally the rectangles cover* Ω.

RKPMs it is necessary to compute the values of $\Phi_j(x)$ for ,, j. In practice, for fixed x, $\Phi_j(x) \neq 0$ for only a small set of values of j. Thus, in order to be computationally efficient, given x, we would like to know the set $I(x) = \{\, j \mid x \in \operatorname{supp} \Phi_j \,\}$ in order to compute $\Psi_i(x)$ for any and all i. Derivatives can be obtained by simply differentiating the formulas given for Ψ_i and substituting the values and derivatives of the kernel functions.

The only meshfree methods presented in the literature which do not require finding $\{\, i \mid x \in \operatorname{supp} \Phi_i \,\}$ are the methods of Klaas and Shephard [6] and Griebel and Schweitzer [3] which construct the basis functions in a way based on quadtrees or octrees where the support sets covering a given point can be determined by looking at neighboring rectangles in the octree. This can be done using pointers in the quadtree/octree nodes to neighboring nodes and ensuring that the levels of these neighboring nodes differ by at most one. To make this technique work, however, Klaas and Shephard make some restrictive assumptions about the "radii" a_i of the support sets used. The width of a support set, assuming that the center is exactly a center of a quadtree or octree rectangle, must be between the width of that octree rectangle and $1\frac{1}{2}$ times the width of that octree rectangle. Modifications of their algorithm could increase this ratio to any number less than 2 with a potentially large increase in the methods complexity, but a ratio of 2 or higher renders their method inapplicable. This could become a serious obstacle to adaptive methods. The method of Griebel and Schweitzer is more flexible, but it too restricts the placement of support sets in order to enable fast neighborhood searches. Even so, for a general set of quadrature points, the method of Griebel and Schweitzer still requires a search of the quadrature points for each nonzero entry of the stiffness matrix. By contrast, the method described below has no such restrictions.

Not only can we use our algorithm for the task of computing $\Psi_i(x)$ for a given $x \in \Omega$, but we can also use it to efficiently assemble stiffness matrices using quadratures:

$$K_{ij} \approx \sum_{i=1}^{Q} [\nabla \Psi_i(y_k)^T A(y_k) \nabla \Psi_j(y_k) + c(y_k) \Psi_i(y_k) \Psi_j(y_k)]\, \omega_k.$$

This can be done via the following algorithm that loops first over the quadrature points. Note that $S_i = \operatorname{supp} \Psi_i$:

for $k = 1, \ldots, Q$

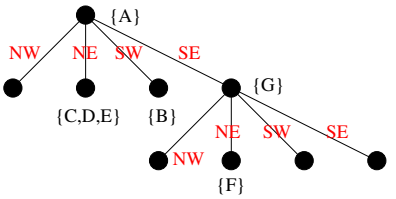

FIG. 2. *MX-CIF quadtree for rectangles in Figure* 1.

$$
\begin{aligned}
&I_k \leftarrow \{\, i \mid y_k \in S_i \,\} \\
&\text{for } i,\, j \in I_k \\
&\qquad K_{ij} \leftarrow K_{ij} + [\nabla \Psi_i(y_k)^T A(y_k) \nabla \Psi_j(y_k) + c(y_k)\Psi_i(y_k)\Psi_j(y_k)]\, \omega_k.
\end{aligned}
$$

The task of computing I_k may of course be solved by exhaustively testing each y_k with every S_i to see which S_i cover y_k. This would be an inefficient strategy, since there would be many "wasted tests" where a support set did not contain a certain point. The use of quadtrees is effective in reducing the number of wasted tests and thus producing an efficient algorithm. The sequential algorithm of Han, Oliveira, and Stewart [4], which uses quadtrees to compute I_k, is discussed in section 3. The remainder of the article is devoted to the parallelization of that algorithm and issues of parallel performance, especially speedup and load balancing.

3. Quadtrees. A quadtree is a tree data structure where each node has four children. An octree is a tree in which each node has eight children. Each of these structures is a generalization of binary trees. They may be further generalized to trees in R^d in which each node has 2^d children. For solving 2-dimensional problems, we use region-based quadtrees, in which each node of the quadtree is a rectangle. The root of the quadtree is the entire domain (or enclosing rectangle) over which the PDE is solved, and the children of a node are the 4 subrectangles which form the parent rectangle.

3.1. MX-CIF quadtrees. In the sequential algorithm of Han, Oliveira, and Stewart, the expanded MX-CIF quadtree data structure (developed by Abel and Smith, and named by Samet) is used [9]. An MX-CIF quadtree is an area-based quadtree in which each set S (circle or rectangle) is associated with the quadtree node corresponding to the smallest block (rectangle) that contains S in its entirety. For the support sets shown in Figure 1, the MX-CIF quadtree is shown in Figure 2. For this application, each point must be tested against all sets linked to the nodes in the path from the root node to the leaf node containing the point. The farther down the tree we go, the fewer candidate points there will be to test. To reduce the number of tests necessary, we would like to link the sets down as far in the quadtree as possible. For our application, the MX-CIF quadtree would not handle appropriately small rectangles that do not fit nicely inside blocks, e.g., the set A in Figure 1. These sets would be tested against a larger number of points than is really necessary. To help fix this problem, the [illegible] MX-CIF quadtree is used. For each set S, instead of linking it to the smallest enclosing block B, if $diam(S) < \frac{1}{2} width(B)$ we look at the children of B, B_i and split S into the parts $S'_i = S \cap B_i$. We then find the smallest enclosing blocks, D_i, of S'_i, repeating the procedure for all D_i where $diam(S'_i) < \frac{1}{2} width(D_i)$. Use of the [illegible] quadtree will ensure that the smaller the set is, the further down the quadtree it will be stored, and fewer tests will be

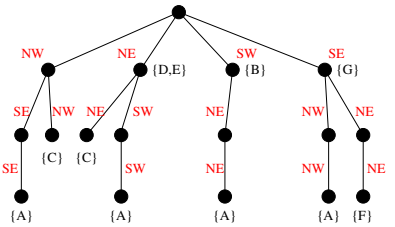

FIG. 3. *Expanded MX-CIF quadtree for rectangles in Figure* 1.

required. For the support sets shown in Figure 1, the expanded MX-CIF quadtree is shown in Figure 3.

The sequential algorithm of Han, Oliveira, and Stewart works in two stages. Stage 1 consists of building the expanded MX-CIF quadtree, which for this application the authors describe as a "splitting" algorithm (since sets that overlap blocks will be split into smaller sets). In stage 2, each point is tested to find which sets cover that point using the quadtree structure.

Note that for any additional quadrature points that are determined later, we merely need to rerun stage 2 with the new quadrature points. Thus this method is also applicable to adaptive quadrature methods.

3.2. Adaptive methods and the quadtree algorithm. While handling adaptivity is not the main purpose of this paper, we would like to make some comments about how the quadtree algorithm can handle adaptive changes in the collection of support sets $\{ S_i \mid i = 1, 2, \ldots, N \}$ and the set of quadrature points $\{ x_k \mid k = 1, 2, \ldots, Q \}$. Typically, adaptive algorithms change a small number of support sets, perhaps replacing one support set S_i with a small number of new support sets $S'_{i_1}, S'_{i_2}, \ldots, S'_{i_p}$. Similarly, an adaptive algorithm would remove a small subset of the set of quadrature points and add a set of new quadrature points.

The process of adding a new support set S'_j to an MX-CIF quadtree is the same as that used for building the initial MX-CIF quadtree. Deletion of a support set S_i can also be accomplished easily by removing any links to S_i and then deallocating any "dead" subtrees of the quadtree that contain no links to support sets. Alternatively, the two operations could be separated: The removal of links could be done as a "batch" operation, and then a "pruning" operation could be applied to the entire tree to remove all "dead" subtrees. To make this more efficient, each node of the quadtree can have a "modified" bit to indicate if it, or any descendant of it, has been modified. This can be done efficiently by setting the "modified" bit of any node accessed by an addition operation; the deletion of a support set would involve unlinking the support set, then setting the "modified" bits of the linking quadtree node and its ancestor nodes. These bits would be reset after a pruning operation or after updates have been completed.

Adjusting the sets $I_k = I(x_k)$ could be done by reprocessing all of the quadrature nodes. This expense can be reduced by using a "modified" bit as described in the previous paragraph: For each quadrature point x_k, go down the tree as required by the standard algorithm, checking the linked support sets, but stop when the "modified" bit is not set. The new list of support sets I'_k then consists of all the support sets found before reaching the unmodified subtree, plus all support sets in the original list I_k linked at a depth greater than or equal to the depth of the root of the unmodified subtree. New quadrature points will have to be processed using the standard algorithm.

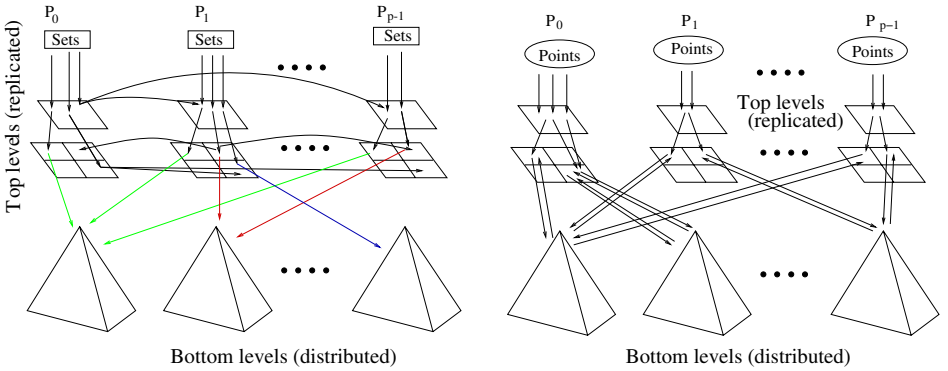
4. Parallelizing the algorithm. We assume that there is an algorithm which takes a collection of support sets and a data structure defining the region of integration, and computes the set of quadrature points and weights. These algorithms typically generate quadrature points that depend locally on the collection of support sets nearby. For parallel implementations, this often translates into quadrature points being generated on processors that are close to the processors that "own" support sets that contain them.

However, in the development of our algorithm, we do not assume such locality. First, this gives our algorithm greater flexibility. Different algorithms may well result in different levels or kinds of locality, or may occasionally violate a specific condition on how near quadrature points are to the support sets that contain them in the network of processors. Second, our algorithm can make use of this locality, as long as the all-to-all communication routines can make use of the locality of the communication pattern (such as avoiding communication altogether when source and destination processors are the same).

4.1. Problem of data distribution. A simple approach to parallelizing the algorithm for finding sets which cover a point would be to evenly distribute the set data. Then the sets on local processors could be linked to nodes in the quadtree. While this approach requires little space on each processor (only part of the quadtree structure is stored on each processor), this has a disadvantage in that $\frac{n-1}{n}$ of the points would have to be located on all the processors, meaning that there is parallelism only in regard to set data but not to point data. Alternatively, it is possible to create an algorithm which would distribute all of the points but would require that all of the sets and the quadtree structure be duplicated on all of the processors. This would require a lot of space on each processor and would also lack any degree of parallelism with respect to set data. Achieving parallelism in both the set and point data, while also distributing the quadtree structure as much as possible, requires a more complicated parallel algorithm.

4.2. Solution: Use *two-level* quadtree structures. Our solution was to divide the quadtree into two parts: one for the top levels, levels 0 (the root) up to level L (the user chooses L), and another structure for the bottom levels (all nodes at level L or lower in the tree). Each processor contains the entire top level structure, while the bottom level structure is distributed among all processors. Each processor is assigned a branch (one or more) of the tree, i.e., a node(s) at level L and all descendant nodes. This algorithm balances the costs and benefits of the simpler approaches mentioned in the previous section. The benefit is that both the set and point data may be initially evenly distributed, increasing parallelism, while the cost of the data overhead required may be minimized by choosing L appropriately, since only the top L levels of the quadtree need to replicated among all processors. This is illustrated in Figure 4.

4.3. Description of the steps in our parallel algorithm. In parallelizing stage 1 of the sequential algorithm, we use the splitting algorithm to process the support sets. After the sets have been evenly distributed among all processors, each processor calls the splitting algorithm on its collection of sets. If a set is to be linked into nodes at the top L levels of the quadtree, this set's data will need to be broadcast to all other processors and must be linked to the top quadtree structure in all processors. This is necessary to allow the equal distribution of points, since any processor may have a point that is located within some rectangle at a node in any



(a) Constructing the quadtree

(b) Testing the quadrature points

FIG. 4. *Two-level parallel quadtree data structures.*

level of the quadtree. If a set is to be linked to a rectangle in the bottom levels of the quadtree, the set data is sent to the appropriate processor assigned that rectangle, and is then linked in at the appropriate node(s). Recall that it is possible for a set to be linked to more than one subrectangle in possibly different levels, so that a support set may be linked to both the top and bottom levels, and thus a set's data may be contained on more than one processor. This is illustrated by Figure 4(a).

For stage 2 to run in parallel, each processor first checks all of its sets linked to the top level against all of its assigned points (which are initially evenly distributed among processors) to see which sets cover which points. Then an exchange of points is made so that all points are sent to the processor which contains the rectangles (the "roots" of the bottom level quadtrees) in which those points are located. Finally the received points are checked against the sets linked to the bottom levels of the quadtree to see which sets cover which points. This is illustrated by Figure 4(b).

Locality of support sets and quadrature nodes can be utilized by solving the stable marriage problem for matching bottom-level quadtrees and processors, where the desirability of a match of a bottom-level quadtree and a processor is given by the number of support sets in the bottom-level quadtree that are "owned" by the given processor. Cheaper alternatives to solving the full stable marriage problem can include assigning bottom-level quadtrees to the (unmatched) processor that owns the largest number of support sets in the bottom-level quadtree. Note that either of these techniques can be applied [illegible]. Note that solving the full stable marriage problem would take $O(p^2)$ in the worst case, but only $O(p \log p)$ in the average case. The cheaper methods require only $O(p)$ time.

5. Theoretical estimates. For the following estimates the following notation is used: d is the dimension of the problem (usually $d = 2$ or 3), $\epsilon = \min_i \operatorname{diam}(S_i)$, N is the number of support sets, p is the number of processors, Q is the number of (quadrature) points, n_t is the number of S_i's linked to top levels in the quadtree, and n_b is the number of S_i's linked to the bottom levels of the quadtree. Note that $n_b + n_t = N$.

5.1. Parallel computation time. The average computation time for stage 1 of the algorithm (to process the support sets, assuming they are uniformly distributed) may be estimated as follows.

The computations should scale for the sets linked to the bottom level of the quadtree. Since the quadtree structure has depth $O(\log(1/\epsilon))$, the computation time should be

$$O\left(\left(\frac{n_b}{p}\right)\log(1/\epsilon)\right).$$

There will be some overhead for the top level sets since all must be on each processor. However, if the sets are fairly small, most sets should be linked to the lower levels and not to the top levels, and so the algorithm should be fairly scalable for sets in which there are not too many large sets.

The total computation time from stage 1 is then

$$O\left(\left(\frac{n_b}{p}\right)\log(1/\epsilon) + n_t\right).$$

The average computation time required for stage 2 (to test which points are covered by which sets) can be computed as follows: Since the points should be evenly distributed and the quadtree has depth $O(\log(1/\epsilon))$, the points should be tested on average

$$O\left(\frac{Q}{p}\left[\log\left(\frac{1}{\epsilon}\right) + \mathbb{E}(\mathit{covering\#})\right]\right)$$

times, where $\mathbb{E}(\mathit{covering\#})$ is the expected number of sets covering each point. Stage 2 should be completely scalable, except for some small $O(1)$ space overhead.

5.2. Communication time. The average case communication time (under the case of uniformly generated sets and points) may be estimated as follows: There are a fixed number of communications, 14, each with a start-up time of t_s.

Assuming that t_{all} is the time to send one word (or byte) of information via an all-to-all exchange (the only type used in this algorithm), the 14 communications have roughly the following totals of information exchanged:

- 2 `Allreduce`s of total length 2^{dL} each,
- 4 `Alltoall`s of total length p each,
- 7 `Alltoallv`s, 4 of length n_b and 3 of length Q,
- 1 `Allgatherv` of length n_t.

Combining these we get a total (average case) estimate of the communication time of

$$14t_s + t_{all}[2(2^{dL}) + 4p + 3Q + 4n_b + n_t].$$

In most cases Q will be much larger than the other variables affecting the communication, so the number of points should be what affects the communication time the greatest.

Finally, there will be some time due to latency. Since we decided on synchronous communication and using only all-to-all communication, for each of the 14 communications, all processors fill the entire buffers with data before sending any data. So the waiting time between computations and communication is directly proportional to the load imbalance. Thus load balancing is important for controlling both computation costs and latency.

6. Partitioning for load balance. For applications over regular domains with uniform distributions of support sets and quadrature points, the computational load should already be approximately balanced. Each branch of the bottom-level quadtrees should require roughly the same amount of work, and the best approach is to assign the same number of branches to each processor; i.e., p should divide evenly into 2^{dL}. For irregularly shaped domains or where the distribution of points is not uniform, the work required on each branch of the bottom level may vary significantly. Our a priori estimate for the amount of work done on each processor is the number of sets linked to the bottom-level branches. This is a good predictor for the actual load since the work depends on the area of the sets, and the splitting algorithm helps to ensure that sets in the same level of the tree have similar size areas. We seek to partition the branches among the processors such that the number of sets assigned to each processor is roughly equal.

We do this by minimizing the sum of the number of sets linked to the branches assigned to any single processor (i.e., we minimize the maximum load on any single processor).

Specifically, the problem we seek a solution for may be stated as follows: Given a sequence of N nonnegative integers $a_1, a_2, \ldots, a_N$, let $\mathcal{B} := \{1, 2, \ldots, N\}$:

$$\text{minimize } \max_k \sum_{i \in B_k} a_i \quad \text{such that} \quad \{ B_k \mid k = 1, \ldots, p \} \text{ is a partition of } \mathcal{B}.$$

Here a_i is the number of sets assigned to the bottom levels of branch i, and B_k consists of the branches assigned to processor k.

Note that this problem is the minimum makespan scheduling problem described by Vazirani [12] and is known to be NP-hard. We need only an approximate solution to this discrete optimization problem since this problem is based only on an estimate of the amount of computational work. We implemented the following heuristic algorithm of Graham [2]:

Sort the elements so that (after relabeling) $a_1 \geq a_2 \geq \cdots \geq a_N$
$B_k \leftarrow \emptyset$ for $k = 1, 2, \ldots, p$
$m_k \leftarrow 0$ for $k = 1, 2, \ldots, p$
For $i = 1$ to N
    $k \leftarrow \text{argmin}_l \, m_l$
    $m_k \leftarrow m_k + a_i$
    $B_k \leftarrow B_k \cup \{i\}$.

Graham was able to prove that this algorithm produces a value of $\max_k \sum_{i \in B_k} a_i$ within a factor of 4/3 of the optimum [2].

Upon termination of the algorithm we will have a partition of the set $S = \cup_{k=1}^{p} B_k$, and $m_k = \sum_{i \in B_k} a_i$ are the loads on each processor. A list of branches to be assigned to each processor is also produced in the algorithm implemented for this application.

Increasing L increases the number of possible processors, since if there are L levels in the top level, there are 2^{dL} leaf rectangles of the top level, and each leaf may be assigned to only one processor; i.e., the number of processors is limited by 2^{dL}. Without load balancing, exactly one branch is assigned to each processor, and so we must have exactly $p = 2^{dL}$. Load balancing allows us to choose the number of processors flexibly, allowing any $p \leq 2^{dL}$.

Increasing L will improve load balancing up to a point. Since the number of branches to be assigned is 2^{dL}, exponentially more branches are created as L is increased. Even using our heuristic, finding a solution to the discrete optimization

problem may outweigh the savings gained by increasing L further. Increasing L also will increase the number of sets linked to the top level, which will reduce some of the parallelism in regard to the set data.

Locality of support sets and quadrature points can also be exploited in the load-balancing step. A simple approach is to first use the above load-balancing heuristic to obtain balanced groups of bottom-level quadtrees and then match the groups to processors using the same criteria as described at the end of section 4.3. An alternative would be to combine load balancing (the number of support sets on each processor should be roughly the same) and locality (bottom-level quadtrees should be assigned to processors which contain the majority of their support sets) into a single objective function and then apply a greedy algorithm to assign the bottom-level quadtrees to processors. Note that the optimal way to assign bottom-level quadtrees will depend on the ratio of speed of computation to speed of communication: Relatively large communication times would make locality more important than balancing. The objective function used to assign bottom-level quadtrees to processors would need to take this into account.

7. Adaptivity in parallel. As noted in section 3.2, we would like to make some comments regarding how to handle adaptive methods efficiently, although this is not a main purpose of this paper. The "modified" bit can be incorporated into quadtree nodes in the parallel case as for the sequential case. Parallel additions of support sets can be done as for constructing the original quadtree, except that quadtree nodes traversed in the addition algorithm would have the "modified" bit set. Parallel deletions of support sets should be initiated by the processor "owning" the support set. Provided each processor keeps a record of which bottom-level quadtree(s) is linked to the deleted support set, nodes in the top-level quadtree can be marked as "modified." Then a message would need to be sent to the processor owning the corresponding bottom-level quadtree, indicating that this support set should be deleted. The processor containing the bottom-level quadtree can then apply the sequential deletion algorithm: Remove the link and set the "modified" bits of the linking node and its ancestors in the bottom-level quadtree. Collections of these operations can be combined to reduce overhead. Top-level nodes which have the modified bit set must be communicated to all processors. Since finding all modified top-level quadtree nodes is essentially a union operation, it can be performed in $O(\log p)$ communication steps with $\leq 2^{dL}$ items to communicate in each step. Since adaptation typically occurs in small regions, the amount of data that needs to be communicated could be considerably less than this, although 2^{dL} is typically modest (say, $d = 2$ and $L = 3$ gives $2^{dL} = 64$).

Rebalancing may eventually prove necessary. This would require the broadcast of 2^{dL} data items in order to determine a new assignment of data items. The algorithm to do this should take into account the current assignment of bottom-level quadtrees to processors in order to minimize unnecessary communication.

Processing the old set of quadrature points can be done using the modified bits of the quadtree nodes as noted in section 3.2. In particular, note that if traversing the top-level quadtree for a given quadrature point stops at a node where the "modified" bit is not set, that quadrature point does not need to be communicated to the processor containing the associated bottom-level quadtree. This, combined with the techniques for using locality, can greatly reduce the amount of communication needed. New quadrature points would have to be processed as normal.

8. Numerical results. We implemented our algorithm in parallel in C using MPI, the Message Passing Interface. Helpful references are the texts of Pacheco [8] and Snir et al. [11]. We ran the test cases on the Xeon cluster (Tungsten) at the National Center for Supercomputing Applications at the University of Illinois, Urbana-Champaign. This is a distributed memory cluster-type parallel computer.

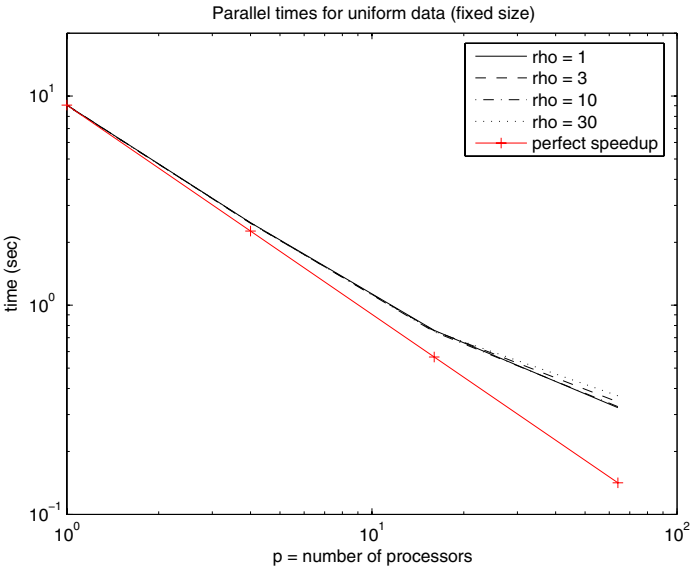
The test data we used was randomly generated. There were two main ways in which this data was generated. The first was uniform generation on support sets and test points on the unit square $[0,1] \times [0,1]$. The second had support sets and test points generated over a circle with a wedge removed from it, creating a reentrant corner. The density of support sets and points was chosen to have an $r^{-\alpha}$ distribution where r is the distance from the reentrant corner. This nonuniform distribution was chosen to have no support sets or points in the southeast quadrant of the unit square.

Two kinds of tests were carried out with this data. One was with a fixed problem size to test speedup. The other consisted of scalability tests where the number of support sets and the number of test points increased proportionally to the number of processors. In keeping with the application to meshfree methods, the support sets generated became smaller as the number of support sets increased so as to keep the average covering number ρ_0 (the expected number of support sets covering a random point) approximately constant. Tests were done with different values for ρ_0. Since the data generation was done using pseudorandom number generators, we repeated the problems with different seed values in order to estimate the effect of randomness on the results. Parallel times were obtained using the MPI routine `MPI_Wtime`. This avoided including the program loading and setup overhead.

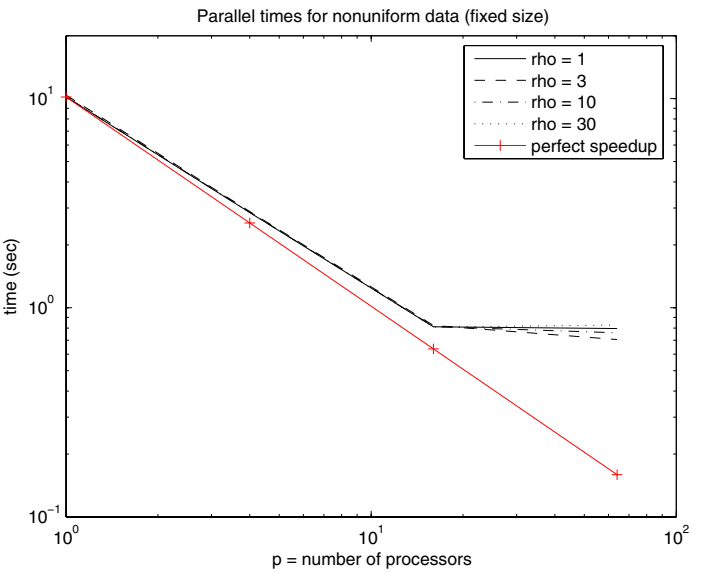
8.1. Data generation. For the uniform data generation, center points for the support sets and test points were generated uniformly on the unit square $[0,1] \times [0,1]$. All the generated support sets were square but with a width W that was chosen uniformly from an interval $[0, w_0]$, with w_0 chosen to give the desired average covering number ρ_0. To do this we ensured that $N\,\mathbb{E}(A) = \rho_0\,A_0$, where A is the (random) area of the generated support set, $\mathbb{E}$ is the expectation operator, and A_0 is the area of the region covered (that is, the unit square; thus $A_0 = 1$). Since $A = 4W^2$, some simple calculations give the parameter $w_0 = \sqrt{3\rho_0/(4N)}$ needed for the generation of the support sets. The Unix pseudorandom number generator `drand48` was used for data generation.

For the nonuniform data generation, an exponent $\alpha > 0$ is chosen where the probability density for the support set centers and the test points were both $\rho(r) := C_\alpha\, r^{-\alpha}$, where $0 < r \le 1$ is the radius from the reentrant corner. The constant C_α is chosen so that the total probability is one; that is, $\int_0^{r_{\max}} (3\pi/2)\, r\, \rho(r)\, dr = 1$. Again the support sets generated are squares with width W; thus the area is $A = 4W^2$. The distribution of W is chosen to depend on r so that $N\,\mathbb{E}(4W^2)\,\rho(r) = \rho_0$. The corner is set to be at (0.45, 0.55); the value of $r_{\max} = 0.4$. Unlike the uniform case, W is determined directly from r, instead of involving yet another (pseudo)random number. Since r is already a random quantity, we did not think that there was any need to have additional randomness in the size of the support set.

Note that nearby support sets and quadrature points generated by this procedure are usually not generated on the same or nearby processors. That is, there is no locality of support sets and quadrature points to exploit. In a meshfree system which does generate nearby support sets and quadrature points on the same or nearby processors, the techniques for exploiting locality described at the end of sections 4.3 and 6 should improve the performance beyond what is presented here.



(a)



(b)

FIG. 5. *Parallel times for fixed problem size (speed-up tests):* (a) *uniform data,* (b) *nonuniform data.*

8.2. Speed-up tests. The simplest tests we performed were speed-up tests. In these tests we fix the size of the problem and increase the number of processors up to some upper limit. For our tests, we used 1, 4, 16, and 64 processors. We used 1.28×10^6 support sets and 1.92×10^6 test points.

The times for these runs are shown in Figure 5.

As can be seen in Figure 5(a) and (b), the speedup is good up to about 16 proces-

sors, but there is reduced improvement in going to 64 processors with uniform data and no improvement in going to 64 processors with nonuniform data. For any problem with a fixed data size there is a limit to how much improvement can be gained from parallelism.

The best speedup for nonuniform data is about 13.2 for 16 processors, giving a parallel efficiency of about 82%. For uniform data the best speedup obtained is about 26.5 for 64 processors, giving a parallel efficiency of only about 41%. If we stopped at 16 processors with the uniform data we would get a speedup of 12.0, giving a parallel efficiency of 75%.

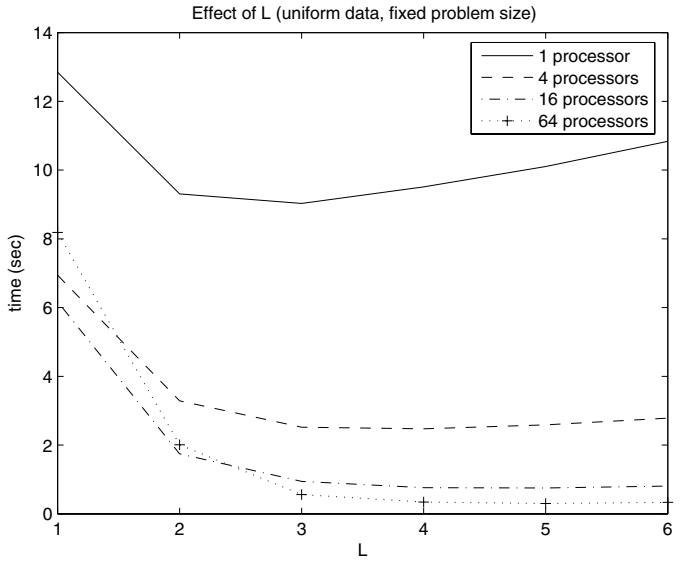
These speedups were obtained using the times for the optimum value of L. A question that naturally arises is how the choice of L affects the times; theoretically this should depend solely on the size of the support sets, and does not depend on the size of the problem or the number of processors. This can be seen in the times for all the values of L used ($L = 1, 2, \ldots, 6$) as shown in Figure 6.

Indeed, we see that for $L \geq 3$ for uniform data ($L \geq 4$ for nonuniform data) with $p \geq 4$ the difference in the times is negligible. Note that $L = 3$ means that the top-level tree has $4^3 = 64$ leaves, which is sufficient for good load balance for uniform data even for 64 processors. For nonuniform data with 64 processors we need more leaves than processors for good load balance; thus $L = 4$ giving $4^4 = 256$ leaves is sufficient for good load balance.

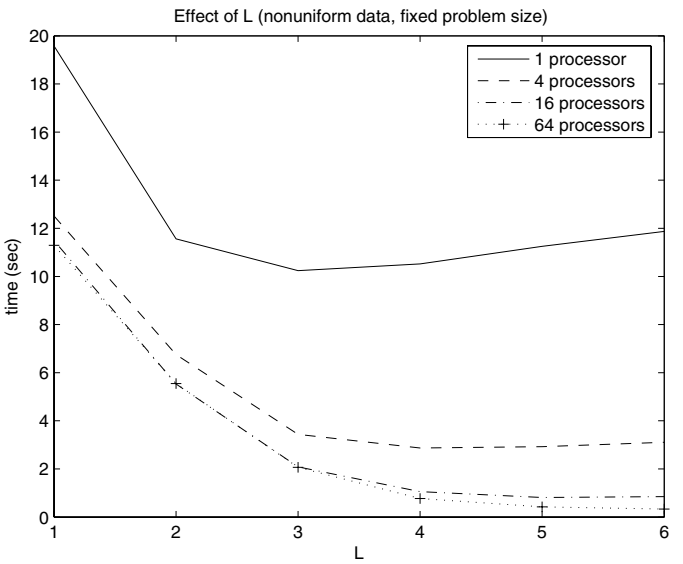
To more clearly demonstrate the effect of L on the load balance, see Figure 7, which shows the ratio of the maximum load to the average load per processor in terms of the number of support sets handled by each processor. Note that for 64 processors with $L = 3$ (which gives 64 leaves for the top-level tree) the ratio is still about five for nonuniform data; this means that without load balancing the algorithm would take roughly five times as long on 64 processors.

8.3. Scalability tests. The main reason for using parallel computers is not for solving a fixed problem faster but for solving larger problems in a short time. To test our algorithm for this, we carried out scalability tests, where the size of the data set increased proportionally to the number of processors, starting with 20,000 support sets and 30,000 test points for one processor. Since the size of the support sets decreases as the problem size becomes larger, the depth of the expanded MX-CIF quadtree must increase along with it. As a result, the time for the sequential algorithm is approximately $O(N \log N)$, where N is the number of support sets. This means that if the number of processors p is proportional to N, ideally the time for the parallel computation should go like $\beta_1 + \beta_2 \log(p)$, ignoring nonscalable communications and computations.

MPI supports sparse communication through `MPI_AlltoAllv`; however, the receiver must know in advance how many items to receive from each originating processor to use this routine. The time for each processor to get this information is $\Theta(p)$ because these numbers must be transmitted by `MPI_AlltoAll`, which assumes a communication pattern. The $\Theta(p)$ time per processor implies a total parallel cost of at least $\Omega(p^2)$ for this step. To be scalable the total parallel cost would have to be $O(p \log(p))$, since the sequential cost is $O(N \log(N))$, and the efficiency would not go to zero as $p \to \infty$. Note that this is an MPI implementation restriction. For large p, and most pairs of processors, the numbers of items to transmit would be zero; if MPI had a version of `MPI_AlltoAllv` that only required specifying the nonzero numbers to be transmitted and received, then this nonscalable communication step would be avoided.



(a)



(b)

FIG. 6. *Dependence of parallel times on L:* (a) *uniform data,* (b) *nonuniform data.*

In this sense the MPI model is at a disadvantage relative to the shared-memory framework (even if it is implemented on a distributed memory machine): In the shared-memory framework a processor can request an individual data item from a remote processor, without the remote processor knowing in advance that it has to receive a request from that processor. In the MPI framework the remote processor has to know in advance that it has to send the data item to the original processor.

It might be useful to have [illegible] all-to-all communication routines whereby sparse

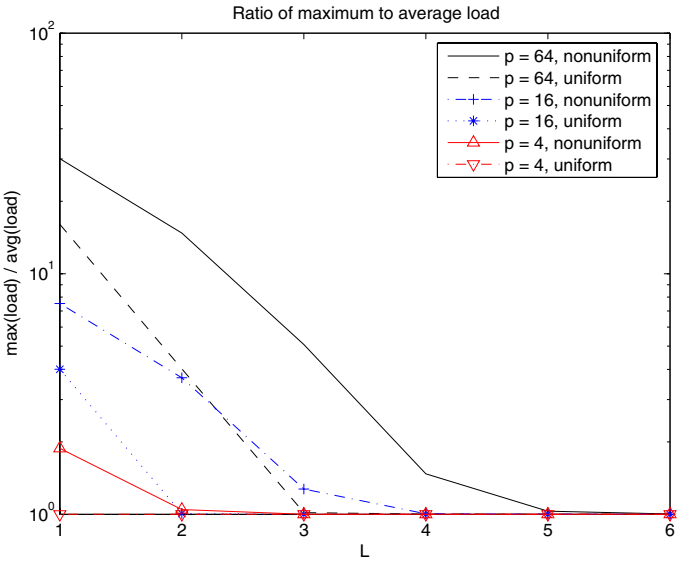


FIG. 7. *Effect of L on ratio of maximum load to average load.*

communication patterns can be efficiently handled. The MPI-2 standard [7] includes the concept of [illegible] and [illegible] of processors, which can be used to communicate between prespecified groups of processors. This can provide some similar functionality. However, these do not provide ad hoc sparse communication patterns. Such a communication routine is conceivable and should be efficiently implementable.

In spite of this nonscalability, the algorithm performs well in practice up to 64 or even 128 processors, as can be seen in Figure 8. In these tests we used $L = \log_4(p) + 2$ to ensure good load balance. The graph in Figure 8 looks a little odd with the times for 128 processors being greater than the times for 256 processors. This is because 128 not being a power of 4, we used $L = 6$, the same value as for 256 processors. The additional overhead in this case appears to have contributed to larger than expected times for 128 processors with nonuniform data.

Also note that alongside the plots of the actual times, there are also plots of the form $\beta_1 + \beta_2 \log(p)$ obtained by linear regression on the minimum times for 1, 4, and 16 processors.

9. Conclusions. We have presented a parallel algorithm for dealing with a problem in computational geometry which is relevant for meshfree methods in PDEs. While this algorithm is not scalable as $p \to \infty$, the bottlenecks preventing scalability could be avoided by allowing true sparse all-to-all communication in message passing libraries. In spite of this difficulty, the algorithm appears to work in a scalable fashion with up to 64 processors.

Acknowledgments. We would like to thank the National Center for Supercomputing Applications (NCSA) at the University of Illinois at Urbana-Champaign for providing access, CPU time, and assistance on the Xeon cluster which was used for the computations reported here. A previous draft of this paper included results from Origin2000 machines at NCSA. We would also like to thank the referees for their suggestions for improvements to the paper.

HIGH-RESOLUTION FINITE VOLUME METHODS FOR DUSTY GAS JETS AND PLUMES*

MARICA PELANTI† AND RANDALL J. LEVEQUE†

Abstract. We consider a model for dusty gas flow that consists of the compressible Euler equations for the gas coupled to a similar (but pressureless) system of equations for the mass, momentum, and energy of the dust. These sets of equations are coupled via drag terms and heat transfer. A high-resolution wave-propagation algorithm is used to solve the equations numerically. The one-dimensional algorithm is shown to give agreement with a shock tube test problem in the literature. The two-dimensional algorithm has been applied to model explosive volcanic eruptions in which an axisymmetric jet of hot dusty gas is injected into the atmosphere and the expected behavior is observed at two different vent velocities. The methodology described here, with extensions to three dimensions and adaptive mesh refinement, is being used for more detailed studies of volcanic jet processes.

1. Introduction.

We study compressible gas dynamics coupled with a suspended particulate phase having small volume fraction but possibly large density per unit volume relative to the gas. We refer to the particulate phase as "dust" (though in some contexts it could represent liquid droplets) and to the mixture as a "dusty gas." Dusty gas flows arise in many applications, from industrial processes to geophysical flows. One particular application, which was the original motivation for our work, is the study of volcanic ash plumes and pyroclastic flows. The numerical approach developed and tested here should be directly applicable in other contexts as well.

We ignore viscosity in the present work and use the compressible Euler equations to model the conservation of mass, momentum, and energy in the gas phase, using an ideal gas equation of state. The particulate phase is modeled by a similar system of equations for the conservation of mass, momentum, and energy of the dust. We ignore interparticle collisions and assume there is no pressure component in the momentum equations, using the so-called pressureless dust or sticky particle equations for this flow (see section 2). These two sets of conservation laws are coupled together through source terms that model drag and heat transfer between the phases.

In the absence of coupling terms, we would have two decoupled sets of hyperbolic conservation laws. The pressureless dust equations are nonstrictly hyperbolic (since the sound speed is zero in the absence of pressure) and have a degenerate structure in which delta shocks can arise, shocks at which delta function singularities form in this mathematical idealization. The source term coupling smooths out singularities in the solution. The speed of sound in the dusty gas is lower than the sound speed of the pure gas phase and can be substantially lower at high dust densities if there

is sufficient coupling, i.e., if the relaxation times of the momentum and heat transfer processes are sufficiently fast (see section 2.2). One effect of this is that dusty gas jets can be supersonic at relatively low velocities, and thus the shock wave structures typically seen in supersonic jets are often observed at lower velocities than might be expected. In particular, jets of ash in volcanic eruptions can exhibit such structures; see, e.g., [22].

The effect of gravity on both the gas and dust phases can also be included in the model when needed, as, for example, in the case of volcanic plumes, where gravity plays a substantial role. One question of particular interest in this context is whether an eruption column rises high into the atmosphere as a "Plinian column" and slowly disperses downwind, or whether the column collapses with the heavier dust phase flowing along the surface. This depends on the balance between the downward force of gravity and the upward momentum and buoyancy of the hot dense jet.

Applications to volcanic jets will be explored in more detail in a forthcoming paper [13] in which numerical results obtained with our approach will be compared with results from a similar model and different numerical method developed in the work of Neri, Esposti Ongaro, and co-workers [34, 36]. In the present paper we present the details of our numerical algorithm and several test problems.

The model is presented in more detail in section 2 and the numerical algorithm is developed in section 3. We use the wave-propagation algorithm as implemented in the CLAWPACK software [26]. This is a high-resolution finite volume algorithm for the hyperbolic conservation law portion of the equations, based on solving Riemann problems at each cell interface at every time step. We use the "f-wave formulation" [2, 29] of the algorithm in which the flux difference between neighboring cells is decomposed into waves that are then used to update the cell averages in each cell. This formulation is preferable for the pressureless dust portion of the hyperbolic system, where we use the algorithm developed in [30]. This formulation also allows us to incorporate the source term due to gravity in the gas dynamics portion of the hyperbolic system into the Riemann solver in such a way that hydrostatic balance in the atmosphere is well maintained in the absence of flow or dust (with the pressure gradient balancing the gravitational force on the gas). This is discussed in more detail in section 6, where gravity is introduced. The gravitational force in the dust equations and the source terms modeling interphase drag and heat transfer are all handled by a fractional step procedure, as described in section 5.

Our goal is to keep the physical model as simple as possible while still allowing simulation of some fundamental features of hot dilute dusty flows in the presence of gravity. In particular, we ignore viscosity within the gas phase and the effects of turbulence. In modeling the structure of dusty gas jets as considered here, this is a reasonable approximation.

Ultimately we hope that this approach will also be useful for modeling some aspects of volcanic eruptions in three dimensions over large domains to better understand hazards associated with active volcanos. For this it is desirable to have a simple model that is applicable on mapped grids that follow realistic terrain and to which adaptive mesh refinement can also be applied. The present model has been implemented on quadrilateral and hexahedral grids, and adaptive mesh refinement has been applied using both the AMRCLAW package included in CLAWPACK and the recently developed CHOMBO-CLAW package [5].

Extensive work has been done on dusty gas and related flows. The formulation that we adopt to describe the dynamics of this two-phase flow under the above assumptions follows especially the work of Harlow and Amsden [17], Sainsaulieu

[40, 42, 41], and Saito [43]. In particular, the physical and numerical model in [17] has been widely used in the field of geophysics to study the particle-laden flows ejected during volcanic eruptions, e.g., [46, 44, 10, 32, 36, 9]. A technique to obtain the macroscopic system of the presented model is the procedure described, e.g., in [19, 11], and applied by Sainsaulieu in [40], which consists in averaging the equations governing each single phase at the microscopic scale.

2. The equations for a dusty gas. We consider a two-phase flow composed of a gaseous carrier phase and a dispersed phase that can consist of either solid particles (dust) or liquid droplets, though we concentrate on the case of dust. In the following, the subscripts g and d will refer to the gas and the dust (or droplets), respectively. Each phase is modeled as a continuum described by macroscopic quantities, with the gas phase being compressible and the dispersed phase incompressible at a microscopic level (with microscopic density $\rho_d =$ constant within each particle or droplet). Moreover, we assume the carried phase is dilute; that is, its volume fraction $\vartheta_d \ll 1$.

2.1. One-dimensional equations. We first consider the one-dimensional equations in slightly more generality than we ultimately use computationally in order to discuss some of the physical and mathematical issues. In section 3 we discuss the numerical algorithms used in the context of the one-dimensional equations. In section 4 we present the relevant portion of these equations in three dimensions and discuss the multidimensional generalization of the numerical algorithm. Initially we ignore gravity and consider one-dimensional flow in the x-direction. In section 6 we discuss the manner in which gravity is incorporated into the algorithm.

In one space dimension the equations take the form

$$\frac{\partial}{\partial t}(\vartheta_g \rho_g) + \frac{\partial}{\partial x}(\vartheta_g \rho_g u_g) = 0, \tag{1a}$$

$$\frac{\partial}{\partial t}(\vartheta_g \rho_g u_g) + \frac{\partial}{\partial x}\left(\vartheta_g \rho_g u_g^2 + \vartheta_g p_g\right) = p_g \frac{\partial \vartheta_g}{\partial x} - D(u_g - u_d), \tag{1b}$$

$$\begin{aligned}\frac{\partial}{\partial t}(\vartheta_g \rho_g e_g) + \frac{\partial}{\partial x}((\vartheta_g \rho_g e_g + \vartheta_g p_g) u_g) \\ = -p_g \frac{\partial}{\partial x}((1-\vartheta_g) u_d) - D(u_g - u_d) u_d - \mathcal{Q}(T_g - T_d),\end{aligned} \tag{1c}$$

$$\frac{\partial}{\partial t}(\vartheta_d \rho_d) + \frac{\partial}{\partial x}(\vartheta_d \rho_d u_d) = 0, \tag{1d}$$

$$\frac{\partial}{\partial t}(\vartheta_d \rho_d u_d) + \frac{\partial}{\partial x}\left(\vartheta_d \rho_d u_d^2 + \varphi\right) = -\vartheta_d \frac{\partial p_g}{\partial x} + D(u_g - u_d), \tag{1e}$$

$$\begin{aligned}\frac{\partial}{\partial t}(\vartheta_d \rho_d e_d) + \frac{\partial}{\partial x}((\vartheta_d \rho_d e_d + \varphi) u_d) \\ = -\vartheta_d u_d \frac{\partial p_g}{\partial x} + D(u_g - u_d) u_d + \mathcal{Q}(T_g - T_d).\end{aligned} \tag{1f}$$

Here ρ_g, ρ_d are the microscopic material densities, ϑ_g, ϑ_d the volume fractions, u_g, u_d the velocities along the x-axis, e_g, e_d the specific total energies, and T_g, T_d the temperatures. Moreover, p_g denotes the gas pressure and φ denotes a pressure correction

for the dispersed phase that will be set to zero below. Finally, D and $\mathcal{Q}$ express a drag and heat transfer function, respectively. To complete the description we need closure relations and specific expressions for D and $\mathcal{Q}$.

The specific total energies are related to the specific internal energies ε_g, ε_d through

$$e_g = \varepsilon_g + \frac{1}{2}|u_g|^2 \quad \text{and} \quad e_d = \varepsilon_d + \frac{1}{2}|u_d|^2. \tag{2}$$

The gaseous phase is assumed to follow the ideal polytropic gas thermodynamic relations

$$p_g = (\gamma - 1)\rho_g \varepsilon_g, \quad \gamma = \text{constant}, \tag{3a}$$

$$\varepsilon_g = c_{vg} T_g, \quad c_{vg} = \text{constant}. \tag{3b}$$

The pressure φ associated to the dispersed phase is small in comparison to the gas pressure p_g, and considering negligible interaction between particles (droplets), it can be assumed to be zero, as in [17, 43]. However, a nonzero φ plays an important role from a mathematical point of view, since the homogeneous equations of the dispersed phase lose strict hyperbolicity under the hypothesis $\varphi \equiv 0$. Following [41], here a nonzero φ is viewed as a pressure correction that allows one to maintain the strict hyperbolicity of the dispersed phase system. We will consider φ a function of the macroscopic density only:

$$\varphi = \varphi(\beta), \quad \beta \equiv \vartheta_d \rho_d. \tag{4}$$

For instance, we can define φ based on the pressure law of the isothermal flow equations:

$$\varphi(\beta) = a_d^2 \beta, \tag{5}$$

with a_d small. In [40, 41], where in particular the suspended phase is considered made of droplets, φ is expressed in the form

$$\varphi = \varphi_0 \vartheta_d^{\,\delta} = \varphi_0 \left(\frac{\beta}{\rho_d}\right)^{\delta}, \tag{6}$$

where φ_0 is a constant proportional to the rest pressure of the gas flow on the droplets and $\delta = \frac{4}{3}$. Note that mathematically we recover (5) from (6) taking $\varphi_0 = \rho_d a_d^2$ and $\delta = 1$.

The specific internal energy of the dispersed phase is related to the temperature through a constant specific heat c_{vd}:

$$\varepsilon_d = c_{vd} T_d, \quad c_{vd} = \text{constant}. \tag{7}$$

System (1) is closed by the equations (2), (3), (4), (7), together with the algebraic constraint $\vartheta_g + \vartheta_d = 1$, and definitions for the drag and heat transfer functions D and $\mathcal{Q}$.

The drag function D has the form (e.g., [31])

$$D = \frac{3}{4} C_{\mathrm{d}} \frac{\beta \rho}{\rho_d d} |u_g - u_d|, \tag{8}$$

where d is the dust particle diameter and $C_{\rm d}$ is the drag coefficient, which we express as in [10]:

$$C_{\rm d} = \begin{cases} \frac{24}{Re}\left(1 + 0.15Re^{0.687}\right) & \text{if } Re < 1000, \\ 0.44 & \text{if } Re \geq 1000. \end{cases} \tag{9}$$

Above $Re = \frac{\rho\, d|u_g - u_d|}{\mu}$ is the Reynolds number and μ the dynamic viscosity of the gas.

The heat transfer function is (see, e.g., [23])

$$\mathcal{Q} = \frac{Nu\, 6\kappa_g \beta}{\rho_d d^2}, \tag{10}$$

where $Nu = 2 + 0.65Re^{1/2}Pr^{1/3}$ is the Nusselt number. Here $Pr = \frac{c_{pg}\mu}{\kappa_g}$ is the Prandtl number, κ_g the gas thermal conductivity, and c_{pg} the gas specific heat at constant pressure. In general, μ and κ_g will be assumed constant.

The momentum equations (1b), (1e) and the energy equations (1c), (1f) include nonconservative terms modeling exchange of momentum and energy related to the gas pressure gradient, namely $p_g \frac{\partial \vartheta_g}{\partial x}$, $p_g \frac{\partial}{\partial x}\left((1-\vartheta_g)u_d\right)$, $\vartheta_d \frac{\partial p_g}{\partial x}$, and $\vartheta_d \frac{\partial p_g}{\partial x} u_d$. Under the hypothesis $\vartheta_d \ll 1$, these are small and give a weak coupling. They can be neglected, as in [43]. These nonconservative terms pose a mathematical difficulty when we wish to allow for discontinuous solutions of the two-phase system. An extensive mathematical analysis of the nonconservative system (1) without drag and heat transfer terms has been performed in [42, 41] by Sainsaulieu, who gives a definition of shock wave solutions for the two-phase nonconservative system and derives explicit approximate jump conditions for these discontinuous solutions, showing that they are perturbations of order $\varepsilon = \frac{1}{\rho_d} \ll 1$ of the decoupled jump conditions of the homogeneous system. Other work on nonconservative terms in nonlinear problems can be found, for example, in [1, 4, 8, 25].

In this work we drop these nonconservative terms, so that only drag and heat conduction source terms appear on the right-hand side of equations (1). We can then simplify the notation by introducing

$$\rho = \vartheta_g \rho_g, \quad p = \vartheta_g p_g, \quad E = \vartheta_g \rho_g e_g, \quad \beta = \vartheta_d \rho_d, \quad \Omega = \vartheta_d \rho_d e_d. \tag{11}$$

The reduced equations can then be written as

$$q_t + f(q)_x = \psi(q), \tag{12}$$

where q is the solution vector, which we partition into q_g, containing the mass, momentum, and energy of the gas, and q_d, containing these quantities for the dust. Then (12) is partitioned as

$$\frac{\partial}{\partial t}\begin{bmatrix} q_g \\ q_d \end{bmatrix} + \frac{\partial}{\partial x}\begin{bmatrix} f_g(q_g) \\ f_d(q_d) \end{bmatrix} = \begin{bmatrix} \psi_g(q) \\ \psi_d(q) \end{bmatrix}, \tag{13}$$

with

$$q_g = \begin{bmatrix} \rho \\ \rho u_g \\ E \end{bmatrix}, \quad f_g(q_g) = \begin{bmatrix} \rho u_g \\ \rho u_g^2 + p \\ (E+p)u_g \end{bmatrix}, \quad \psi_g = \begin{bmatrix} 0 \\ -D(u_g - u_d) \\ -D(u_g - u_d)u_d - \mathcal{Q}(T_g - T_d) \end{bmatrix}, \tag{14a}$$

(14b)
$$q_d = \begin{bmatrix} \beta \\ \beta u_d \\ \Omega \end{bmatrix}, \quad f_d(q_d) = \begin{bmatrix} \beta u_d \\ \beta u_d^2 + \varphi \\ (\Omega + \varphi) u_g \end{bmatrix}, \quad \psi_d = \begin{bmatrix} 0 \\ D(u_g - u_d) \\ D(u_g - u_d) u_d + \mathcal{Q}(T_g - T_d) \end{bmatrix}.$$

Numerically we solve system (13) using a fractional step procedure in which we alternate between a time step on the homogeneous hyperbolic system $q_t + f(q)_x = 0$ and a time step on the source terms, the system of ODEs $q_t = \psi(q)$ in each grid cell. (The source term for gravity in the gas will be treated differently in section 6.)

Notice that q_g and q_d are coupled only through the source terms and so the hyperbolic part decouples into two smaller systems for the gas and dust separately. For the gas phase,

$$\frac{\partial q_g}{\partial t} + \frac{\partial f_g(q_g)}{\partial x} = 0, \tag{15}$$

we have the standard Euler equations for gas dynamics for an ideal gas. This system has three distinct characteristic speeds u_g and $u_g \pm c_g$ given by the eigenvalues of the Jacobian matrix $f_g'(q_g)$, where c_g is the sound speed of the gas, and $c_g = \sqrt{\gamma p_g/\rho}$ for an ideal gas.

The equations for the dust phase are similar:

$$\frac{\partial q_d}{\partial t} + \frac{\partial f_d(q_d)}{\partial x} = 0. \tag{16}$$

If we assume that the pressure correction φ depends only on β (e.g., (5)), then the energy equation simply models advection of energy at velocity u_d. This equation is coupled to the rest of the system, however, when the source terms are added due to energy transfer between the phases.

Dropping the energy equation from the hyperbolic system for the dust, we obtain the reduced system

$$\frac{\partial}{\partial t} \begin{bmatrix} \beta \\ \beta u_d \end{bmatrix} + \frac{\partial}{\partial x} \begin{bmatrix} \beta u_d \\ \beta u_d^2 + \varphi \end{bmatrix} = \begin{bmatrix} 0 \\ 0 \end{bmatrix}. \tag{17}$$

The Jacobian matrix for this sytem has eigenvalues $u_d \pm c_d$, where $c_d = \sqrt{\varphi'(\beta)}$. For example, if we use the isothermal relation (5), $\varphi(\beta) = a_d^2 \beta$, then $c_d = a_d$. If we ignore interparticle collisions, then we want to consider the "pressureless" limit $a_d \to 0$, in which case the system (17) becomes nonstrictly hyperbolic with both eigenvalues equal to u_d, and the system (16) has all three eigenvalues equal to u_d. The Jacobian matrix lacks a complete set of eigenvectors in this case, and weak solutions to the equations can contain delta shocks—shock waves at which a delta function singularity of accumulated dust also arises [30].

The term "pressureless" is something of a misnomer when the limiting process described above is really intended, as we are considering the limit where interparticle collision effects play a role, but only when the density becomes very large. When the particulate phase is sufficiently dilute, the details of this interaction are unimportant and we can set $a_d = 0$. The drag coupling of these equations to the gas dynamics equations might be expected to yield a regularization effect preventing the formation of delta function singularities in the coupled system. We do not know of any theoretical work in this direction and believe that it would be an interesting topic to pursue.

Numerically we do not observe delta shocks in the coupled system, although numerical viscosity is also playing a role, and at any rate exact singularities could not arise in the numerical solution. More importantly, in practice the dust densities do not grow to levels that cause any difficulties near shocks.

2.2. The mixture speed of sound. Gas flows carrying a particulate phase may exhibit a sound speed that is much lower than the sound speed of the pure gas. Here we informally derive an expression for the speed of sound of the mixture of gas and particles, based on the model (1) with $\varphi \equiv 0$, under the assumption that momentum and energy exchange between the gas and dust occurs rapidly enough so that they are in mechanical and thermal equilibrium (*instantaneous relaxation* hypothesis). For example, this is often approximately satisfied in vast regions of the physical domain where volcanic processes occur. Note that we will not assume in general equilibrium between the two phases in our numerical method, but the expression of the mixture sound speed derived in this special case can be useful to estimate a posteriori the flow regime (subsonic/supersonic). Moreover we employ this expression in [38] to show that solving the coupled system handling the source terms by a fractional step approach is successful even in this equilibrium limit.

We consider the propagation of small-amplitude pressure waves (acoustic waves) against a steady background with constant velocities $u_{g0} = u_{d0} = 0$, constant densities $\rho_0 = \vartheta_{g0}\rho_{g0}$, $\beta_0 = \vartheta_{d0}\rho_d = (1 - \vartheta_{g0})\rho_d$ (recall that $\rho_d = \text{const.}$), and constant gas pressure. We also assume that $c_{vd}\beta_0 \gg c_{vg}\rho_0$ so that the dust contains much more thermal energy than the gas. Since we are assuming the temperature equilibrates rapidly between the gas and dust and we are considering small perturbations about a constant state, it is then reasonable to assume that the dust acts as a heat reservoir that keeps the gas at a constant temperature as the acoustic wave propagates. We can then drop the corresponding source term and simply consider isothermal behavior. The effective equation of state is then

$$p_g = a_g^2 \rho_g, \quad a_g^2 = R\bar{T}_g, \tag{18}$$

where a_g represents the isothermal sound speed of the pure gaseous phase and $\bar{T}_g$ denotes the constant temperature of the two-phase mixture. Under the above assumption of isothermal flow, and using (18), equations (1) give the reduced system

$$\frac{\partial}{\partial t}(\vartheta_g \rho_g) + \frac{\partial}{\partial x}(\vartheta_g \rho_g u_g) = 0, \tag{19a}$$

$$\frac{\partial}{\partial t}(\vartheta_g \rho_g u_g) + \frac{\partial}{\partial x}\left(\vartheta_g \rho_g u_g^2\right) + a_g^2 \vartheta_g \frac{\partial \rho_g}{\partial x} = -D(u_g - u_d), \tag{19b}$$

$$\frac{\partial}{\partial t}((1 - \vartheta_g)\rho_d) + \frac{\partial}{\partial x}((1 - \vartheta_g)\rho_d u_d) = 0, \tag{19c}$$

$$\frac{\partial}{\partial t}((1 - \vartheta_g)\rho_d u_d) + \frac{\partial}{\partial x}\left((1 - \vartheta_g)\rho_d u_d^2\right) + a_g^2(1 - \vartheta_g)\frac{\partial \rho_g}{\partial x} + D(u_g - u_d), \tag{19d}$$

where we have also used the algebraic constraint $\vartheta_g + \vartheta_d = 1$. Considering small perturbations with respect to background variables, we write

$$\rho_g = \rho_{g0} + \tilde{\rho_g} \qquad \text{and} \qquad \vartheta_g = \vartheta_{g0} + \tilde{\vartheta_g}. \tag{20}$$

Linearizing (19), and dividing the resulting continuity equations of the two phases by the corresponding background microscopic densities, we obtain

$$\frac{\vartheta_{g0}}{\rho_{g0}}\frac{\partial\tilde{\rho_g}}{\partial t}+\frac{\partial\tilde{\vartheta_g}}{\partial t}+\vartheta_{g0}\frac{\partial u_g}{\partial x}=0, \tag{21a}$$

$$\vartheta_{g0}\rho_{g0}\frac{\partial u_g}{\partial t}+a_g^2\vartheta_{g0}\frac{\partial\tilde{\rho_g}}{\partial x}=-D(u_g-u_d), \tag{21b}$$

$$-\frac{\partial\tilde{\vartheta_g}}{\partial t}+(1-\vartheta_{g0})\frac{\partial u_d}{\partial x}=0, \tag{21c}$$

$$(1-\vartheta_{g0})\rho_d\frac{\partial u_d}{\partial t}+a_g^2(1-\vartheta_{g0})\frac{\partial\tilde{\rho_g}}{\partial x}=D(u_g-u_d). \tag{21d}$$

Adding now (21b) and (21d) eliminates the drag source term, and if we assume that this acts sufficiently fast that velocity perturbations satisfy $u_g = u_d \equiv u$, then the resulting equation along with the sum of (21a) and (21c) gives a reduced system of two equations for $\tilde{\rho}_g$ and u:

$$\frac{\vartheta_{g0}}{\rho_{g0}}\frac{\partial\tilde{\rho_g}}{\partial t}+\frac{\partial u}{\partial x}=0, \tag{22a}$$

$$(\vartheta_{g0}\rho_{g0}+(1-\vartheta_{g0})\rho_d)\frac{\partial u}{\partial t}+a_g^2\frac{\partial\tilde{\rho_g}}{\partial x}=0. \tag{22b}$$

This system has wave speeds $\pm c_{\mathrm{m}}$, where

$$c_{\mathrm{m}}=a_g\sqrt{\frac{\rho_{g0}}{\vartheta_{g0}(\vartheta_{g0}\rho_{g0}+\vartheta_{d0}\rho_d)}} \tag{23}$$

is the mixture sound speed in the considered case of equilibrium flow. This expression can be derived more generally for the case in which the suspended phase is also compressible and governed by a nonzero pressure law, see, for example, [45, 11].

Under the assumption of a dilute dust phase, we can approximate $\vartheta_{g0} \approx 1$, and hence $\rho_{g0} \approx \rho_0$. Therefore, $c_{\mathrm{m}} \approx a_g\sqrt{\frac{\rho_0}{\rho_0+\beta_0}}$. This expression can also be obtained directly with a procedure analogous to that described above by neglecting in (1) the terms modeling momentum exchange due to the gas pressure gradient, which is again valid if $\vartheta_{g0} \approx 1$. This in particular suggests that neglecting pressure gradient terms in the hypothesis $\vartheta_d \ll 1$ still allows us to correctly model the propagation of acoustic waves.

Note that $c_{\mathrm{m}} < a_g < c_g = (\gamma R\bar{T}_g)^{1/2}$, where c_g is the isentropic pure gas sound speed (at same T_g) and, moreover, c_{m} can be significantly lower than a_g and c_g if β_0 is large compared to ρ_0.

It is interesting that this mixture sound speed arises only from the source terms coupling the gas and dust equations and can be significantly lower than the wave speeds given by the hyperbolic part of the system of equations. Numerical results presented in [38] show that using a fractional step approach in which the source terms are decoupled from the hyperbolic system, as described below, does give the correct behavior of the coupled system and the correct sound speed.

3. The numerical algorithm for the hyperbolic portion. To solve the homogeneous hyperbolic portion of the system (1) we use the wave-propagation algorithm described in [27, 29]. This is a Godunov-type finite volume method in which we first solve the Riemann problem at each interface between grid cells, i.e., the conservation law with piecewise constant initial data given by the current cell averages Q^n_{i-1} and Q^n_i at time t_n. The waves arising from this Riemann solution are used to update the cell average on either side. These waves are also used to define second-order correction terms based on Taylor series expansion. Near discontinuities such as shocks, however, these corrections do not improve the accuracy but instead lead to nonphysical oscillations in the numerical approximation. Hence limiters must be applied to the waves before using them in the correction terms in order to avoid oscillations and obtain high-resolution results. We use the "f-wave" formulation of these methods discussed in [2, 29]. With this approach the Riemann solution is represented by a decomposition of the flux difference $f(Q_i) - f(Q_{i-1})$ as a linear combination of eigenvectors of an approximate Jacobian matrix. Both the first-order Godunov updates and the second-order correction terms can be defined in terms of these f-waves, and the limiters are now applied to these f-waves before computing the correction terms. This formulation of the algorithm for the gas phase will be advantageous when we add gravity in section 6. For the dust phase it helps to simplify the treatment of the nonstrictly hyperbolic Riemann solution.

Recall that the hyperbolic equations decouple into separate systems (15) for the gas phase and (16) for the dust phase. To approximately solve the Riemann problem in the gas phase between states Q^{L}_g and Q^{R}_g in adjacent grid cells, we use the Roe linearization [29, 39] to define eigenvectors r^1, r^2, r^3 based on Roe averages of the solution quantities. We decompose

$$f(Q^{\text{R}}_g) - f(Q^{\text{L}}_g) = \sum_{p=1}^{3} \mathcal{Z}^p_g, \tag{24}$$

where each f-wave $\mathcal{Z}^p_g$ is a scalar multiple of r^p.

For the dust phase we use the algorithm presented in [30]. For the pressureless dust equations the solution to the Riemann problem consists of either a single delta shock if $u^{\text{L}}_d > u^{\text{R}}_d$ or a pair of waves with a vacuum between them if $u^{\text{L}}_d < u^{\text{R}}_d$. With the f-wave formulation we generally use only a single wave in either case with magnitude $\mathcal{Z}_d = f(Q^{\text{R}}_d) - f(Q^{\text{L}}_d)$ and speed

$$\hat{u}_d = \frac{\sqrt{\beta^{\text{L}}}\, u^{\text{L}}_d + \sqrt{\beta^{\text{R}}}\, u^{\text{R}}_d}{\sqrt{\beta^{\text{L}}} + \sqrt{\beta^{\text{R}}}}. \tag{25}$$

This is the usual Roe average for the dust velocity, based on the dust density, and it can also be shown to be the correct delta-shock propagation speed in the pressureless equations [30]. The only time we use two waves is if $u^{\text{L}}_d < 0 < u^{\text{R}}_d$, in which case they are spreading out with a vacuum state at the interface. Then we take

$$\begin{aligned} \mathcal{Z}^1_d &= -f_d(Q^{\text{L}}_d), \qquad s^1 = u^{\text{L}}_d, \\ \mathcal{Z}^2_d &= f_d(Q^{\text{R}}_d), \qquad s^2 = u^{\text{R}}_d, \end{aligned} \tag{26}$$

as the waves and speeds. For more details, see [30].

TABLE 1
Nomenclature.

ϑ_g, ϑ_d = volume fractions, $\vartheta_g + \vartheta_d = 1$, $\vartheta_d \ll 1$;
ρ_g, ρ_d = material microscopic mass densities (ρ_d = constant);
$\rho = \vartheta_g \rho_g$ = gas macroscopic density;
$\beta = \vartheta_d \rho_d$ = dust macroscopic density (concentration);
p_g = gas pressure, $p = \vartheta_g p_g$;
$\mathcal{V}_g = (u_g, v_g, w_g)^{\mathrm{T}}$, $\mathcal{V}_d = (u_d, v_d, w_d)^{\mathrm{T}}$ = vectorial velocities;
ε_g, ε_d = specific internal energies;
$e_g = \varepsilon_g + \frac{1}{2}\lvert\mathcal{V}_g\rvert^2$, $e_d = \varepsilon_d + \frac{1}{2}\lvert\mathcal{V}_d\rvert^2$ = specific total energies;
$E = \vartheta_g \rho_g e_g$, $\Omega = \vartheta_d \rho_d e_d$ = total energies per unit volume;
T_g, T_d = temperatures;
R = gas constant;
$\gamma = c_{pg}/c_{vg}$ = ratio of specific heats for gas;
c_{vd} = dust specific heat;
μ = gas dynamic viscosity;
κ_g = gas thermal conductivity;
$\mathfrak{g} = (0, 0, -g)^{\mathrm{T}}$ = gravity acceleration (z-direction);
D = drag function;
d = dust particle diameter;
C_{d} = drag coefficient;
$\mathcal{Q}$ = heat transfer function;
Re = Reynolds number;
Nu = Nusselt number;
Pr = Prandtl number.

4. The multidimensional equations and algorithm. The multidmensional equations we use have the form

$$\frac{\partial \rho}{\partial t} + \nabla \cdot (\rho \mathcal{V}_g) = 0, \tag{27a}$$

$$\frac{\partial}{\partial t}(\rho \mathcal{V}_g) + \nabla \cdot (\rho \mathcal{V}_g \otimes \mathcal{V}_g + pI) = -D(\mathcal{V}_g - \mathcal{V}_d), \tag{27b}$$

$$\frac{\partial E}{\partial t} + \nabla \cdot ((E + p)\mathcal{V}_g) = -D(\mathcal{V}_g - \mathcal{V}_d) \cdot \mathcal{V}_d - \mathcal{Q}(T_g - T_d), \tag{27c}$$

$$\frac{\partial \beta}{\partial t} + \nabla \cdot (\beta \mathcal{V}_d) = 0, \tag{27d}$$

$$\frac{\partial}{\partial t}(\beta \mathcal{V}_d) + \nabla \cdot (\beta \mathcal{V}_d \otimes \mathcal{V}_d) = D(\mathcal{V}_g - \mathcal{V}_d), \tag{27e}$$

$$\frac{\partial \Omega}{\partial t} + \nabla \cdot (\Omega \mathcal{V}_d) = D(\mathcal{V}_g - \mathcal{V}_d) \cdot \mathcal{V}_d + \mathcal{Q}(T_g - T_d). \tag{27f}$$

Here $\mathcal{V}_g = (u_g, v_g, w_g)^{\mathrm{T}}$ and $\mathcal{V}_d = (u_d, v_d, w_d)^{\mathrm{T}}$ are the velocity vectors (in the three-dimensional case). The closure relations are the same as those presented in section 2, and the drag and heat transfer terms are also unchanged except that now

$$D = \frac{3}{4} C_{\mathrm{d}} \frac{\beta \rho}{\rho_d d} |\mathcal{V}_g - \mathcal{V}_d| \tag{28}$$

depends on the Euclidean norm of the velocity difference, as does the Reynolds number $Re = (\rho\, d|\mathcal{V}_g - \mathcal{V}_d|)/\mu$. See Table 1 for a summary of the nomenclature used.

The finite volume method is extended to multidimensions using the wave-propagation approach described in [24, 27, 29] and implemented in CLAWPACK. We assume

the grid is logically rectangular, but a grid mapping can be incorporated so that a general quadrilateral (in two dimensions) or hexahedral (in three dimensions) grid is used. The two-dimensional case is discussed in detail in [29].

In each time step, one-dimensional Riemann problems are solved normal to each cell interface and the resulting waves are used to update the cell averages on either side. For the dusty gas equations, the one-dimensional Riemann problem in an arbitrary direction takes the same form as the Riemann problem in the x-direction discussed in section 3, using the normal components of the gas and dust velocities in each grid cell to define the data. Jumps in transverse velocities advect with the flow, at the velocity of the contact discontinuity in the gas equations or of the delta shock in the dust phase. The waves resulting from these normal Riemann solutions are also used in second-order correction terms, just as in one dimension after suitable limiters have been applied to avoid nonphysical oscillations.

A "transverse Riemann solver" is also incorporated that takes the information propagating into each grid cell and splits this into eigenvectors of the flux Jacobian matrix (evaluated in the cell) in the direction orthogonal to each of the adjacent cell faces (for a nonorthogonal mapped grid this must be done separately for each adjacent face). Use of these transverse Riemann solvers increases the accuracy of the multidimensional method by modeling cross-derivative terms needed in the Taylor series expansion, and also improves stability so that a Courant number close to 1 can typically be used (see [24] for a detailed discussion of accuracy and stability issues in three dimensions).

5. Source terms for drag and heat transfer. We also use a fractional step approach in applying the source terms for drag and heat transfer, first solving the ODEs arising from the drag terms over a time step Δt and then solving the ODEs for heat transfer. For the drag terms we have the system of ODEs

$$\frac{\partial \rho}{\partial t} = 0, \tag{29a}$$

$$\frac{\partial}{\partial t}(\rho \mathcal{V}_g) = -A|\mathcal{V}_g - \mathcal{V}_d|(\mathcal{V}_g - \mathcal{V}_d), \tag{29b}$$

$$\frac{\partial E}{\partial t} = -A|\mathcal{V}_g - \mathcal{V}_d|(\mathcal{V}_g - \mathcal{V}_d)\cdot \mathcal{V}_d, \tag{29c}$$

$$\frac{\partial \beta}{\partial t} = 0, \tag{29d}$$

$$\frac{\partial}{\partial t}(\beta \mathcal{V}_d) = A|\mathcal{V}_g - \mathcal{V}_d|(\mathcal{V}_g - \mathcal{V}_d), \tag{29e}$$

$$\frac{\partial \Omega}{\partial t} = A|\mathcal{V}_g - \mathcal{V}_d|(\mathcal{V}_g - \mathcal{V}_d)\cdot \mathcal{V}_d, \tag{29f}$$

with initial data ρ^0, $(\rho\mathcal{V}_g)^0$, E^0, β^0, $(\beta\mathcal{V}_d)^0$, Ω^0 at the beginning of the time step that come from the hyperbolic solver.

The densities ρ and β are constant in this step. We also assume that the Reynolds number is constant in time, so that the drag coefficient is equal to its initial value, $C_{\mathrm{d}} = C_{\mathrm{d}}^0$. Then A is constant in time and equal to

$$A^0 = \frac{3}{4} C_{\mathrm{d}}^0 \frac{\beta^0 \rho^0}{\rho_d d}. \tag{30}$$

Then we can write (29b), (29e) for the momentum of the two phases as

$$\frac{\partial \rho^0 \mathcal{V}_g}{\partial t} = -A^0 |\mathcal{V}_g - \mathcal{V}_d|(\mathcal{V}_g - \mathcal{V}_d), \tag{31a}$$

$$\frac{\partial \beta^0 \mathcal{V}_d}{\partial t} = A^0 |\mathcal{V}_g - \mathcal{V}_d|(\mathcal{V}_g - \mathcal{V}_d). \tag{31b}$$

These equations can be solved exactly to obtain

$$(\rho \mathcal{V}_g)(\Delta t) = (\rho \mathcal{V}_g)^0 + \frac{\mathcal{V}_g^0 - \mathcal{V}_d^0}{\xi_D^0} \left[\frac{1}{A^0 \xi_D^0 |\mathcal{V}_g^0 - \mathcal{V}_d^0| \Delta t + 1} - 1 \right], \tag{32a}$$

$$(\beta \mathcal{V}_d)(\Delta t) = (\beta \mathcal{V}_d)^0 - \frac{\mathcal{V}_g^0 - \mathcal{V}_d^0}{\xi_D^0} \left[\frac{1}{A^0 \xi_D^0 |\mathcal{V}_g^0 - \mathcal{V}_d^0| \Delta t + 1} - 1 \right], \tag{32b}$$

where we have introduced

$$\xi_D = \frac{1}{\rho} + \frac{1}{\beta}. \tag{33}$$

Once the momentum equations have been solved, we can use the form of the energy equations to calculate the corresponding changes in energy of each phase. The right-hand side of (29f) corresponds exactly to the change in kinetic energy of the dust corresponding to the change in momentum, and hence the internal energy of the dust remains constant in this step. The dust energy Ω is simply updated by the change in kinetic energy resulting from the momentum update.

The right-hand side of the gas energy equation (29c) is just the negative of the right-hand side of (29f), as required by conservation of total energy. Hence the gas energy E is updated by the negative of the update to Ω calculated above in order to leave the total energy unchanged. This energy change models both the change in kinetic energy in the gas and also a change in internal energy due to drag dissipation and the resulting heating of the gas.

Note that if the time step is large relative to the drag relaxation time, then the gas and dust velocities determined by the momentum updates (32) both approach the common equilibrium value

$$\mathcal{V}_{\text{eq}} = \frac{\rho^0 \mathcal{V}_g^0 + \mathcal{V}_d^0 \beta^0}{\rho^0 + \beta^0}. \tag{34}$$

The source terms for heat transfer have the form

$$\frac{\partial \rho}{\partial t} = 0, \tag{35a}$$

$$\frac{\partial}{\partial t}(\rho \mathcal{V}_g) = 0, \tag{35b}$$

$$\frac{\partial E}{\partial t} = -\mathcal{Q}(T_g - T_d), \tag{35c}$$

$$\frac{\partial \beta}{\partial t} = 0, \tag{35d}$$

$$\frac{\partial}{\partial t}(\beta \mathcal{V}_d) = 0, \tag{35e}$$

$$\frac{\partial \Omega}{\partial t} = \mathcal{Q}(T_g - T_d), \tag{35f}$$

with initial data ρ^0, β^0, $(\rho\mathcal{V}_g)^0$, $(\rho\mathcal{V}_d)^0$, E^0, Ω^0 coming from the result of applying the drag terms, as described above. In this step the densities and momenta remain constant and only the energies change due to heat transfer between the dust and gas. It follows that the Reynolds and Nusselt numbers are constant; hence $\mathcal{Q}$ is constant and equal to its initial value $\mathcal{Q}^0$:

$$\mathcal{Q}^0 = \frac{Nu^0\, 6\kappa_g \beta^0}{\rho_d d^2}. \tag{36}$$

By using $\varepsilon_g = c_{vg} T_g$, $\varepsilon_d = c_{vd} T_d$, where c_{vg}, c_{vd} are the specific heats at constant volume, we obtain a system of two ODEs for the temperature of each phase,

$$\frac{\partial T_g}{\partial t} = -\frac{1}{\rho^0 c_{vg}} \mathcal{Q}^0 (T_g - T_d), \tag{37a}$$

$$\frac{\partial T_d}{\partial t} = \frac{1}{\beta^0 c_{vd}} \mathcal{Q}^0 (T_g - T_d). \tag{37b}$$

These can be solved and used to compute the energy updates:

$$E(\Delta t) = E^0 + \frac{T_g^0 - T_d^0}{\xi_{\mathcal{Q}}^0} \left[e^{-\mathcal{Q}^0 \xi_{\mathcal{Q}}^0 \Delta t} - 1 \right], \tag{38a}$$

$$\Omega(\Delta t) = \Omega^0 - \frac{T_g^0 - T_d^0}{\xi_{\mathcal{Q}}^0} \left[e^{-\mathcal{Q}^0 \xi_{\mathcal{Q}}^0 \Delta t} - 1 \right], \tag{38b}$$

where

$$\xi_{\mathcal{Q}} = \frac{1}{\rho c_{vg}} + \frac{1}{\beta c_{vd}}. \tag{39}$$

If the time step is long compared to the relaxation time for heat transfer, the two gases reach the common equilibrium temperature

$$T_{\text{eq}} = \frac{\rho^0 c_{vg} T_g^0 + \beta^0 c_{vd} T_d^0}{\rho^0 c_{vg} + \beta^0 c_{vd}}. \tag{40}$$

6. Source terms for gravity. With gravity, the equations (27) take the form

$$\frac{\partial \rho}{\partial t} + \nabla \cdot (\rho \mathcal{V}_g) = 0, \tag{41a}$$

$$\frac{\partial}{\partial t} (\rho \mathcal{V}_g) + \nabla \cdot (\rho \mathcal{V}_g \otimes \mathcal{V}_g + pI) = \rho \mathfrak{g} - D(\mathcal{V}_g - \mathcal{V}_d), \tag{41b}$$

$$\frac{\partial E}{\partial t} + \nabla \cdot ((E + p)\mathcal{V}_g) = \rho \mathcal{V}_g \cdot \mathfrak{g} - D(\mathcal{V}_g - \mathcal{V}_d) \cdot \mathcal{V}_d - \mathcal{Q}(T_g - T_d), \tag{41c}$$

$$\frac{\partial \beta}{\partial t} + \nabla \cdot (\beta \mathcal{V}_d) = 0, \tag{41d}$$

$$\frac{\partial}{\partial t} (\beta \mathcal{V}_d) + \nabla \cdot (\beta \mathcal{V}_d \otimes \mathcal{V}_d) = \beta \mathfrak{g} + D(\mathcal{V}_g - \mathcal{V}_d), \tag{41e}$$

$$\frac{\partial \Omega}{\partial t} + \nabla \cdot (\Omega \mathcal{V}_d) = \beta \mathcal{V}_d \cdot \mathfrak{g} + D(\mathcal{V}_g - \mathcal{V}_d) \cdot \mathcal{V}_d + \mathcal{Q}(T_g - T_d), \tag{41f}$$

where $\mathfrak{g} = (0, 0, -g)^{\mathrm{T}}$ is the gravitational acceleration in the vertical direction. The gravity term for the dust equations is handled in the fractional step procedure along with the source terms for drag and heat transfer. Since the mass is constant over a time step in solving these ODEs, the equation for momentum is easily solved by modifying the vertical velocity by $-g\beta\Delta t$ and then adjusting the energy to reflect this change in kinetic energy.

The gravity source term for the gas could be handled in the same way. However, the gas also has pressure. In hydrostatic equilibrium (as in a stationary atmosphere) there is a pressure gradient that exactly balances the gravity source term. With a fractional step approach, the jump in pressure leads to nontrivial waves in the Riemann solution computed across each cell interface, which in turn causes a change in the cell averages during the hyperbolic step. The gravitational source term then leads to a compensating change in the cell averages that ideally would exactly cancel out the changes generated by the Riemann solution. In practice this will not happen and the numerical algorithm will not maintain a steady state. In fact the errors generated can be quite significant.

Instead we use an approach that does a much better job of maintaining hydrostatic balance and that applies the second-order correction terms and limiters in the hyperbolic solver to deviations from the steady state rather than to waves that arise artificially from the pressure gradient.

We take advantage of the f-wave formulation described in section 3 and incorporate an appropriate component of the gravity source term into the jump in flux across each interface before splitting this jump into waves. In place of (24), we split

$$f_g(Q_g^{\mathrm{R}}) - f_g(Q_g^{\mathrm{L}}) - \Psi = \sum_{p=1}^{3} \mathcal{Z}^p \tag{42}$$

into f-waves $\mathcal{Z}^p$. In solving this Riemann problem we have left and right states given by the cell averages in the cells on the two sides of the interface, with the velocities u_g^{L} and u_g^{R} taken to be the gas velocity normal to the interface from each side. On the left side, for example, we have

$$Q_g^{\mathrm{L}} = \begin{bmatrix} \rho^{\mathrm{L}} \\ \rho^{\mathrm{L}} u_g^{\mathrm{L}} \\ E^{\mathrm{L}} \end{bmatrix}, \qquad f(Q_g^{\mathrm{L}}) = \begin{bmatrix} \rho^{\mathrm{L}} u_g^{\mathrm{L}} \\ \rho^{\mathrm{L}} (u_g^{\mathrm{L}})^2 + p^{\mathrm{L}} \\ u^{\mathrm{L}}(E^{\mathrm{L}} + p^{\mathrm{L}}) \end{bmatrix}. \tag{43}$$

The source term for this Riemann problem that we use in (42) is then

$$\Psi = \Delta z \begin{bmatrix} 0 \\ -g(\rho^{\mathrm{L}} + \rho^{\mathrm{R}})/2 \\ -g(\rho^{\mathrm{L}} u_g^{\mathrm{L}} + \rho^{\mathrm{R}} u_g^{\mathrm{R}})/2 \end{bmatrix}. \tag{44}$$

Here $\Delta z = z^{\mathrm{R}} - z^{\mathrm{L}}$ is the difference in the vertical coordinate of the centroids of the two cells adjacent to this interface. In the hydrostatic case $u^{\mathrm{L}} = u^{\mathrm{R}} = 0$, and we expect the jump in pressure between the cell averages to approximately equal $-\Delta z\, g(\rho^{\mathrm{L}} + \rho^{\mathrm{R}})/2$, with this cancellation occurring before the waves are generated for use in the hyperbolic solver.

This approach to incorporating the gravitational source term into the Riemann solver is related to other so-called well-balanced methods for solving conservation laws with source terms in which the source terms balance the divergence of the flux in a

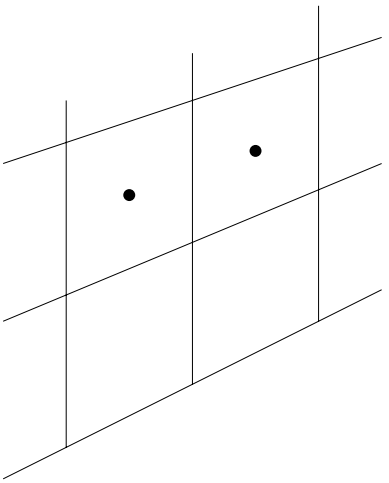

FIG. 1. *A two-dimensional mapped grid fitted to surface topography.*

nontrivial steady state. See, for example, [3, 6, 14, 15, 16, 20, 21, 28] for some other approaches. We note that the other source terms in our equations (drag, heat transfer, and the geometric source terms for axisymmetry) are nonzero only in transient regions of the flow and thus we do not need to worry about maintaining steady states and the fractional step approach we have adopted for these terms seems to work well in general. (In other applications there can exist steady states with nonzero velocities and then balancing these against the drag and heat transfer sources may be important as well.)

For applications to volcanic flows we will use a mapped grid that conforms to the ground surface, of the type shown in Figure 1 in two dimensions (blown up near the surface). A quadrilateral logically rectangular grid is used in which the horizontal grid lines are interpolated between the surface topography and a fixed upper elevation, while the vertical grid lines are still vertical. It is important to note that the gravitational source term will generally come into every Riemann solve on such a grid, even those in the x-direction that are normal to a vertical cell interface (e.g., between the two cells whose centroids are marked by dots in the figure). Since gravity does not act normal to this interface, one might be tempted to drop the source term in this normal Riemann solve. However, the difference in elevation of the cell centroids means that there will be a pressure difference in the steady state solution that must be cancelled by the source term. The expression (44) can be more formally justified by noting that the gravitational source is the gradient of the gravitational potential and hence is a covariant tensor. The directional derivative of this tensor in the coordinate direction comes into the Riemann problem across this interface, along with the normal components of the contravariant velocity.

7. Numerical experiments. We present numerical results of some test problems obtained by applying the presented dusty gas model. Second order corrections are performed in the solution of the hyperbolic portion of the system by using the monotonized centered (MC) limiter for the gas equations, and the minmod limiter for the dust equations.

In section 7.1 we consider a one-dimensional test with no gravity taken from [43].

In section 7.2 we report results of two-dimensional computations including gravity effects in the context of simulation of volcanic processes. Results on different bottom

topography and preliminary three-dimensional computations can be found in [38].

7.1. Shock tube experiment. We simulate a shock tube experiment that has been studied numerically by Saito in [43] and was originally considered in [31]. It involves high-pressure and high-density pure air ($\gamma = 1.4$) in the driver section and air laden with solid particles at room conditions in the driven section. As in [43], an extremely small amount of dust is assumed here in the driver section for numerical reasons. Dimensionless initial data are reported in Table 2. Flow variables are normalized by using as reference density ρ_{ref}, reference pressure p_{ref}, and reference temperature T_{ref} the values for air at room conditions. Moreover, the reference velocity is defined as $u_{\text{ref}} = \sqrt{\frac{p_{\text{ref}}}{\rho_{\text{ref}}}}$.

For this experiment only we adopt the constitutive relations for drag and heat transfer that are used in [43]. These slightly differ from the relations reported in section 2.1 that we normally employ. Here, instead of (9),

$$C_{\text{d}} = 0.46 + 28\, Re^{-0.85}. \tag{45}$$

Moreover, in (10) κ_g is computed as $\kappa_g = \mu c_{pg} Pr^{-1}$, where the Prandtl number is assumed to be a constant, $Pr = 0.75$, while the gas dynamic viscosity μ varies with the temperature T (see [7]):

$$\mu = 1.71 \times 10^{-5} \left(\frac{T}{273}\right)^{0.77}. \tag{46}$$

The algorithm for the source terms described in section 5 is adapted to allow for this temperature dependent expression of μ by assuming this variable frozen at each time step in the ODE solution.

Finally, the dust particle diameter needed to compute the Reynolds number is $d = 10\,\mu$m, and the dust and gas heat coefficients at constant volume are assumed to be equal, with a dimensionless value given by $1/(\gamma - 1)$.

Following [43], we solve dimensionless equations, which are normalized by using $\ell = \frac{4\rho_d d}{3\rho_{\text{ref}}}$ as a characteristic length and $\tau = \frac{\ell}{u_{\text{ref}}}$ as a characteristic time. The computational domain is the interval $[0, 100]$, and the diaphragm is located at $x = 50$ units. We use 1000 cells (as in [43]) and CFL = 0.9.

Results of the computations at normalized time units = 5, 10, and 30 are displayed in Figures 2, 3, and 4, respectively, together with results corresponding to the case of pure gas in both the driver and driven sections for comparison.

The structure of the solution of this shock tube problem involves a left-going rarefaction wave, a contact discontinuity, and a right-going shock wave. In particular,

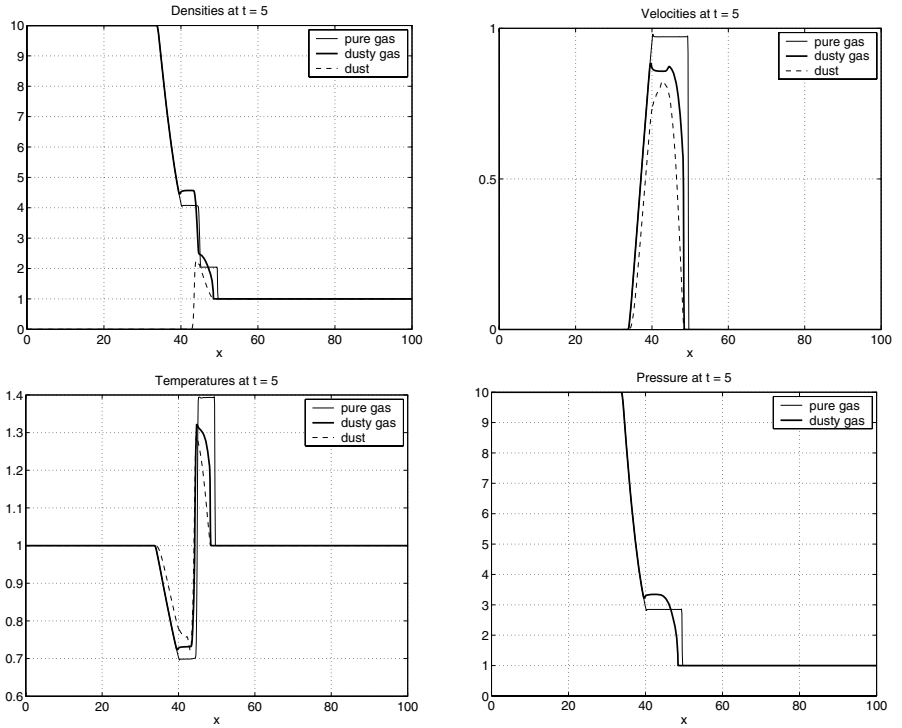

FIG. 2. *Saito's experiment. Densities, velocities, temperatures, and pressure at* $t = 5$.

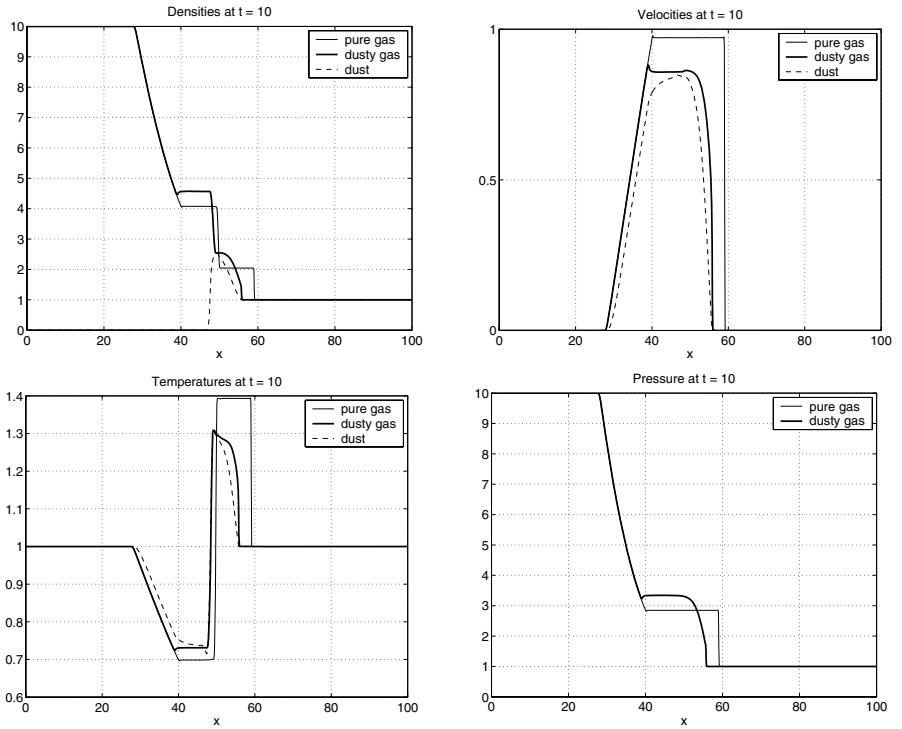

FIG. 3. *Saito's experiment. Densities, velocities, temperatures, and pressure at* $t = 10$.

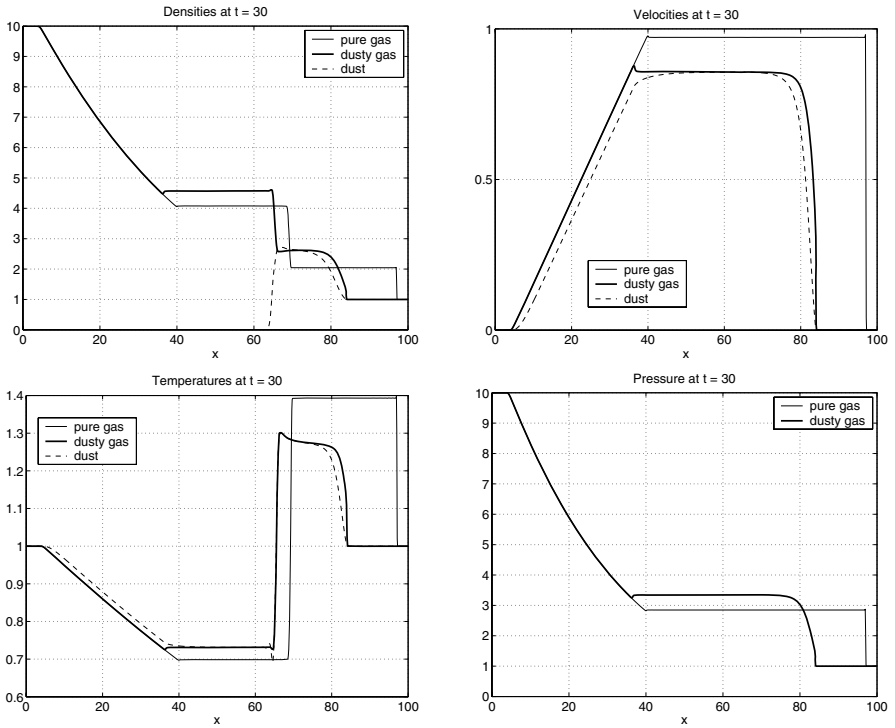

FIG. 4. *Saito's experiment. Densities, velocities, temperatures, and pressure at* $t = 30$.

the presence of the particulate phase leads to the development of a partially dispersed shock wave, characterized by a frozen shock in the gas followed by a relaxation region. This is formed since dust particles cannot follow any abrupt change in the gas due to their large inertia. With respect to the pure gas case, as described in [43], the dusty gas solution exhibits a deceleration of the shock front and a consequent higher compression behind it.

As time progresses, the structure of the solution tends to a stationary configuration characterized by an equilibrium region around the contact surface, and relaxation regions of constant width behind the rarefaction and shock wave. This stationary state can be observed in Figure 4, where in particular we can notice the equilibrium zones from the velocity and temperature profiles.

The results presented here agree well with those reported by Saito in [43], which are validated by the author by comparison with pseudostationary solutions obtained through numerical integration of the steady conservation equations. The numerical method of Saito is based on an operator splitting technique that uses the Harten [18] and Yee [48] scheme for the gas phase and a semianalytical approach for the dust phase. An inaccuracy in our results, not observed in [43], is the appearance of oscillations in the computed dust temperature in the neighborhood of the contact surface. These arise only when second-order corrections are performed, and they decrease with mesh refinement. We remark that oscillations are generated in the process of deriving the dust temperature from the internal energy per unit volume and dividing this by the computed dust density. No oscillations appear in the dust energy (or in other conserved variables), as shown in Figure 5. Note also that this

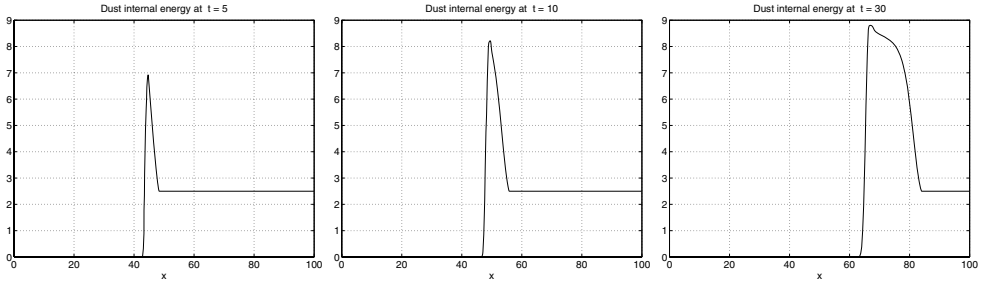

FIG. 5. *Saito's experiment. Dust internal energy per unit volume at* $t = 5$, 10, 30.

TABLE 3
Physical parameters for the two phases.

Quantity	Value	Unit
R	287.0	J/(kg K)
γ	1.4	
c_{vd}	$1.3 \cdot 10^3$	J/(kg K)
μ	$\mu = 10^{-5}$	Pa s
κ_g	0.05	W/(m K)

type of inaccuracy does not affect the computation process in our algorithm described in section 5. In fact, in the updating of the energies through (38) we actually do not need the dust temperature itself, but the product βT_d, as we can see by rewriting the term $\frac{T_g^0 - T_d^0}{\xi_{\mathcal{Q}}^0}$ as $\frac{\rho c_{vg} c_{vd}}{\rho c_{vg} + \beta c_{vd}} (\beta T_g^0 - \beta T_d^0)$. This is also consistent with the form of the heat transfer source term, which can be rewritten as $\mathcal{Q}(T_g - T_d) = \mathcal{Q}'(\beta T_g - \beta T_d)$, where $\mathcal{Q}' = \frac{Nu\, 6\kappa_g}{\rho_d d^2}$. The fact that in the results of Saito this difficulty does not arise can be explained by considering that his algorithm for the dust phase uses the dust temperature as a primary variable, whereas in our case the dust temperature is derived from the conserved variables.

7.2. Explosive volcanic eruptions. We employ the dusty gas flow model presented above to simulate some of the processes that characterize explosive volcanic events. Indeed, as mentioned in the introduction, the original motivation for the development of the two-phase flow model (27) was the numerical study of volcanic phenomena. The eruption mixture in this framework is described as a two-phase flow made of gas and solid particles of a single size. In particular, the gas phase is assumed to be dry air (no water vapor content). Some of the physical parameters adopted for the two phases are reported in Table 3.

We report results of two problems from a set of simulations that we have performed with data taken from the work of Neri and Dobran [32]. The aim was to test the performance of our model in describing the dynamics of pyroclastic dispersion in the atmosphere and pyroclastic flows on the ground, and the sensitivity to the variation of some eruption parameters that influence such processes.

The physical model assumed in [32] is more complex than ours and takes into account several effects that we neglect. Among these are viscosity of the gas, turbulence, water vapor content, exchange of momentum and energy between the two phases related to the gas pressure gradient, and the dense regime for the particulate phase. Despite the simplifications of our model, we observe that we are able to capture some of the relevant features of the various eruption styles that have been described in [32], at least in the first stages of the eruption that we study here.

TABLE 4
Vent conditions for the two numerical experiments.

Simulation	D_v [m]	v_v [m/s]	$p_{g,v}$ [MPa]	T_v [K]	$\vartheta_{d,v}$	d [μm]	ρ_d [kg/m^3]
A2	100	80	0.1	1200	0.01	10	2300
A6	100	200	0.1	1200	0.01	10	2300

Additional results on the simulation of volcanic processes, including modeling of overpressured jets on different crater morphology, can be found in [38].

Initial and boundary conditions. We consider the injection of a hot supersonic particle-laden gas from a volcanic vent into a cooler atmosphere (e.g., [47, 10, 32, 33, 35, 37, 36]). Initially, a standard atmosphere vertically stratified in pressure and temperature is set all over the domain. At the vent, the gas pressure, the velocities and temperatures of the two phases, and the dust volumetric fraction are assumed to be fixed and constant.

The ground boundary is modeled as a free-slip reflector. For two-dimensional experiments, an axisymmetric configuration of the flow is used, and system (41) is rewritten in cylindrical coordinates. We obtain a new set of equations with the same form of (41) on the left-hand side, but with an additional geometric source term on the right-hand side. This additional source term is treated numerically with an operator splitting technique and by employing a Runge–Kutta solver for the corresponding system of ODEs to be solved in time. In this two-dimensional axisymmetric configuration, half of the volcanic vent, of diameter D_v, is located in the lower left-hand corner of the computational domain and the symmetry axis is modeled as a free-slip reflector, while the upper and right-hand edges of the domain are free flow boundaries and all the variables gradients are set to zero.

Vent conditions. The gas and dust phase are assumed to be in thermal and mechanical equilibrium at the vent; that is, they have the same temperature T_v and the same exit velocity v_v. Data for the two numerical tests are summarized in Table 4 (subscript v refers to the vent), together with the physical properties assumed for the dust. The nomenclature of the two simulations is borrowed from [32]. The only difference with the set of data of this work is that we do not consider the water vapor content.

Note that the data sets of these two simulations differ only in the values of the vent velocities v_v, while the other variables describing the vent conditions are the same. The results for these data presented in [32] show that the eruption column evolves with a different style depending on the exit velocity: It is collapsing for $v_v = 80$ m/s, and transitional/Plinian for $v_v = 200$ m/s. As discussed below, the same behavior is described by our simulations. In these two experiments, omitting the water vapor content does not seem to influence the column style, at least in the first minutes of the process. However, some difference can be seen; see [38] for related discussion.

Note finally that for this set of experiments the vent pressure is balanced with the atmospheric pressure at the vent exit. Vent conditions are supersonic relative to the eruptive mixture, as can be verified by using the expression of the mixture sound speed in (23), and they are representative of jet conditions after decompression in the volcanic crater [32].

7.2.1. Simulation A2: Stationary collapsing column. Figure 6 shows the evolution of the eruptive mixture as computed for simulation A2, characterized by

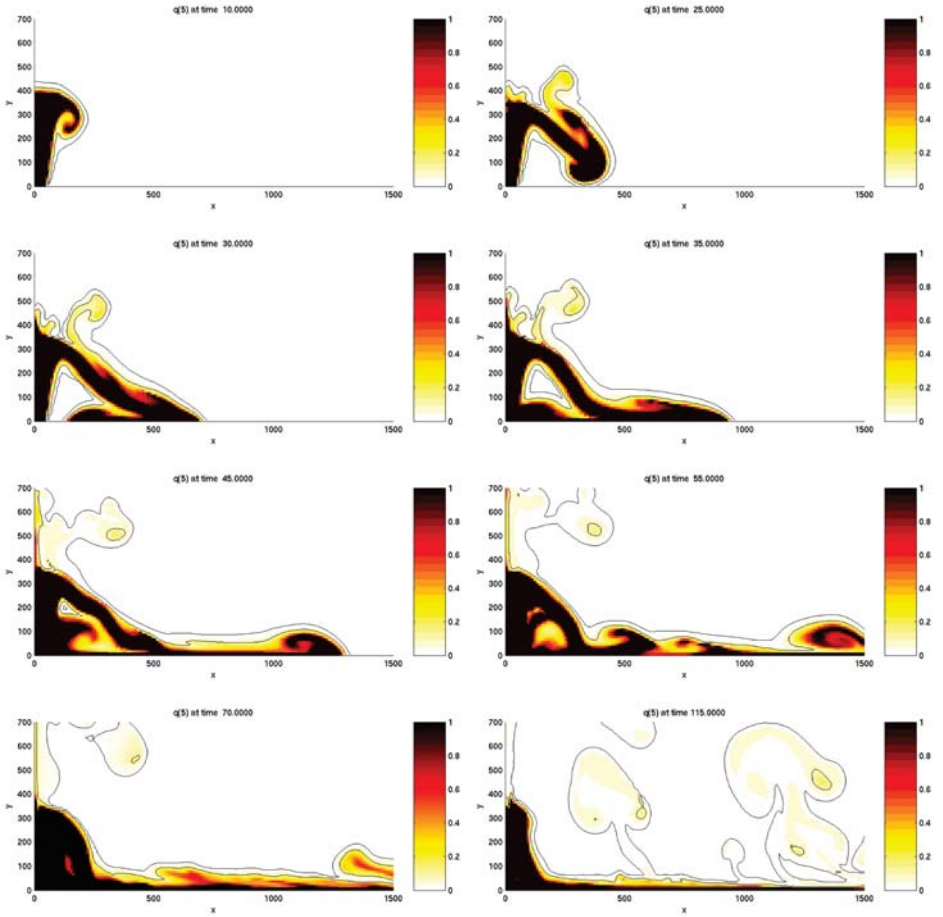

FIG. 6. *Simulation* A2. *Collapsing column. Dust density at time* $t = 10, 25, 30, 35, 45, 55, 70, 115$ *s. Computational domain:* $3000\ m \times 3000\ m$. *Cell size* $= 10\ m$ $(300 \times 300$ *cells*). *Contour values* $= 10^{[-4:1:0]}$ $[\mathrm{kg/m^3}]$.

$D_v = 100\,\mathrm{m}$ and $v_v = 80\,\mathrm{m/s}$. In agreement with [32], we can recognize the typical features of a collapsing volcanic column, that is, fountain building above the volcanic vent, radially spreading pyroclastic flow, material recycling from the collapsed column back into the fountain, and rising of ash plumes from the pyroclastic flow. At about 10 s and 400 m above the vent the two-phase flow jet loses its vertical thrust and begins to form a collapsing column. After the collapsed column has hit the ground, material starts being recycled into the fountain. As the time evolves, the impact distance from the vent decreases and the column tends to stabilize with a steady narrow shape (as observed in [32]).

In Figure 7 we display results computed on two different grid resolutions (cell size = 10 m on the left and cell size = 5 m on the right). We can see that a smaller cell size produces a longer runout of the pyroclastic flow and a smaller thickness, but there is no notable difference in the fountain height and in the dynamics of the collapse. The significant difference in the location of the flow head on the ground can be in part related to the type of free-slip boundary condition used, though the same effect of the

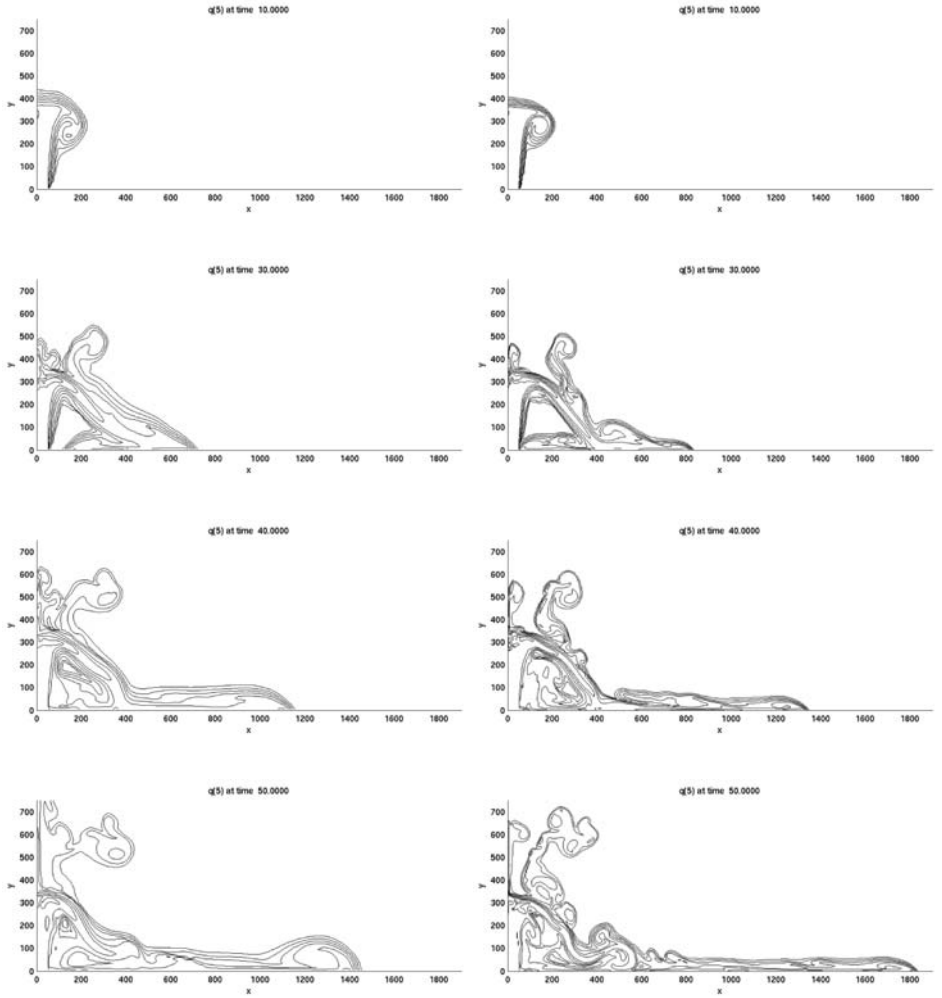

FIG. 7. *Simulation* A2. *Comparison between two different grid resolutions. Dust density at time* $t = 10, 30, 40, 50$ *s. Left:* $\Delta x = 10\,m$*; right:* $\Delta x = 5\,m$*. Contour values* $= 10^{[-5:.5:2]}$ [kg/m^3].

grid resolution has also been observed in [10], where a no-slip boundary condition is employed.

In Figure 8 we highlight the features of the recirculation region displaying a contour plot of the dust density together with the gas velocity vector field, as computed on the finest grid.

Relating our results with those in [32], we see good agreement between plots of physical quantities. In particular, the column height and the column impact distance are comparable. There is a difference in the length of the runout of the pyroclastic flow, which is larger in our computations. This is not surprising, since we use a free-slip boundary condition on the ground, whereas in [32] a no-slip condition is used (consistent with the fact that their model contains viscous terms).

7.2.2. Simulation A6: Transitional/Plinian column. Figure 9 shows the results for simulation A6, which has the same vent diameter $D_v = 100\,\text{m}$ as A2, but

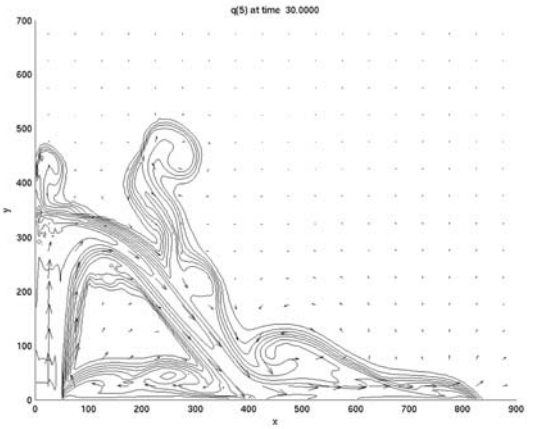

FIG. 8. *Simulation* A2. *Dust density contours and gas velocity vector field at* $t = 30$ *s. Contour values* $= 10^{[-5:.4:2]}$ [kg/m^3]. *Computational domain:* 2000 *m* $\times$ 1000 *m. Cell size* = 5 *m* (400 $\times$ 200 *cells*).

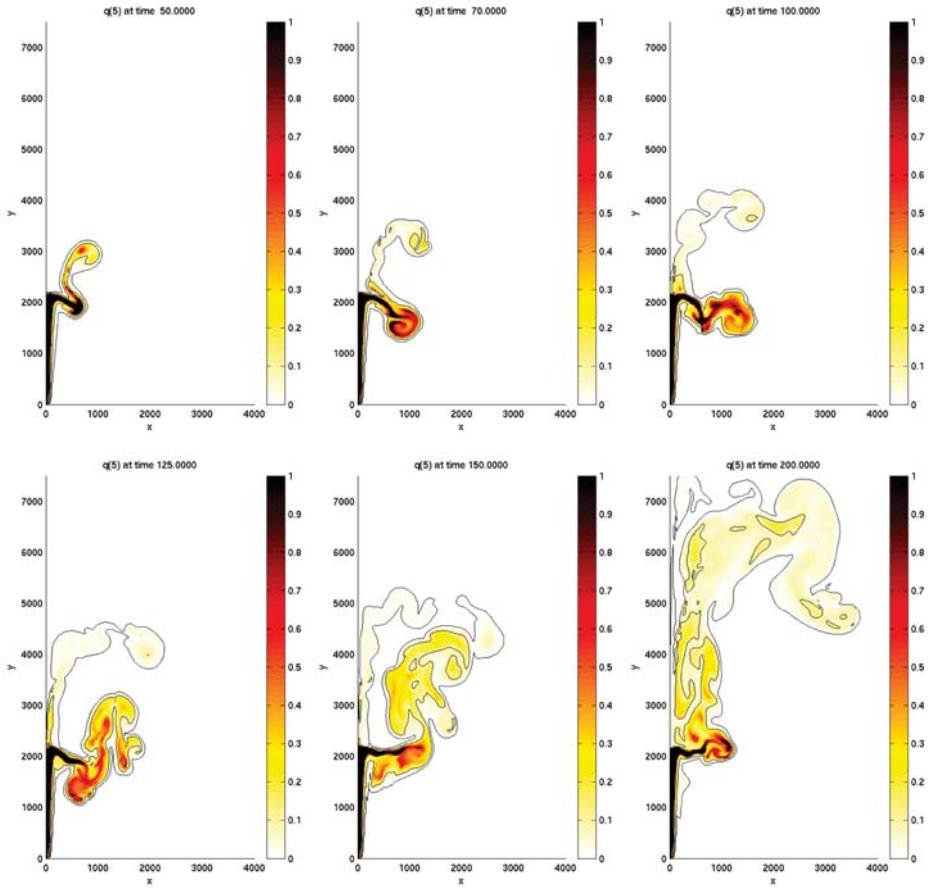

FIG. 9. *Simulation* A6. *Dust density at time* $t = 50, 70, 100, 125, 150, 170$ *s. Contour values* $= 10^{[-5:1:0]}$ [kg/m^3]. *Computational domain:* 5000 *m* $\times$ 9000 *m. Cell size* = 25 *m* (200 $\times$ 360 *cells*).

a greater exit velocity, $v_v = 200\,\mathrm{m/s}$. The increase in the jet velocity (keeping D_v fixed) generates a much more buoyant column, which in this case appears of transitional/Plinian type, consistent with the observations in [32]. This column reaches a height of about 2200 m and then begins to form a radially suspended flow with some material rising buoyantly on the top, and other material attempting instead to collapse. The eruptive mixture later develops as a buoyant column. Our plots show qualitative agreement with those displayed in [32], and in particular the column height is about the same.

8. Conclusions and extensions. We have considered a model for dusty gas flow that consists of the compressible Euler equations for the gas coupled to a similar (but pressureless) system of equations for the mass, momentum, and energy of the dust. These sets of equations are coupled via drag terms (depending on the velocity difference between dust and gas) and heat transfer (depending on the temperature difference). A high-resolution wave-propagation algorithm has been used to solve the equations numerically. This finite volume method is based on solving Riemann problems at cell interfaces. The source term modeling the effect of gravity on the gas is incorporated into the Riemann solver in order to minimize numerical artifacts that could arise from splitting this source term from the pressure gradient. Other source terms (drag, heat transfer, and the gravitational force on the dust) are handled with a fractional step approach.

The one-dimensional algorithm has been shown to give agreement with results presented by Saito [43]. The two-dimensional algorithm has been applied to model explosive volcanic eruptions in which an axisymmetric jet of hot dusty gas is injected into the atmosphere. Two test cases have been presented, one in which the jet collapses into a flow along the surface, and a second, at higher velocity, where the jet rises as a Plinian column. The expected behavior is observed in each case, based on results of other researchers.

Additional test cases are presented in [38], where it is also demonstrated that adaptive mesh refinement can be successfully applied to this problem using the AMRCLAW software in CLAWPACK [26]. Some preliminary computations in three space dimensions are also presented in [38] and compared to the two-dimensional axisymmetric results. Three-dimensional modeling over realistic topography such as Mount St. Helens is currently being investigated with an extension of this code.

Because the speed of sound in a dusty gas is much lower than in a pure gas (see section 2.2), volcanic jets can easily be supersonic and hence the jet can exhibit complex internal shock structures [22]. Some numerical study of this structure is presented in [38] and compared with some examples considered in the work of Esposti Ongaro and Neri [12]. In a joint research project with these researchers, we are continuing our study of volcanic jets using the methodology described in this paper. Further results will be presented elsewhere [13].

DISTRIBUTED IMMERSED BOUNDARY SIMULATION IN TITANIUM*

E. GIVELBERG† AND K. YELICK‡

Abstract. The immersed boundary method is a general numerical method for modeling elastic boundaries immersed within a viscous, incompressible fluid. It has been applied to several biological and engineering systems, including large-scale models of the heart and cochlea. These simulations have the potential to improve our basic understanding of the biological systems they model and aid in the development of surgical treatments and prosthetic devices. Despite the popularity of the immersed boundary method and the desire to scale the problems to accurately capture the details of the physical systems, parallelization for large-scale distributed memory machines has proved challenging. The primary difficulty is in achieving a load-balanced computation, while maintaining low communication costs when modeling the interactions between the fluid and the moving immersed boundary. In this paper we describe a parallelized algorithm for the immersed boundary method that is designed for scalability on distributed memory multiprocessors and clusters of SMPs. It is implemented using the Titanium language, a Java-based language designed for high performance scientific computing. Our software package, called `IB`, takes advantage of the object-oriented features of Titanium to provide a framework for simulating immersed boundaries that separates the generic immersed boundary method code from the specific application features that define the immersed boundary structure and the forces that arise from those structures. Our results demonstrate the scalability of our design and the feasibility of large-scale immersed boundary computations with the `IB` package.

Key words. fluid-structure interactions, immersed boundary method, distributed algorithm, large-scale computation

1. Introduction.

The immersed boundary method is a general numerical method for computational modeling of systems involving fluid-structure interactions. Complex systems where elastic (and possibly active) tissue is immersed in a viscous, incompressible fluid arise naturally in biology and engineering. The immersed boundary method was developed by Peskin and McQueen to study the patterns of the blood flow in the heart [17, 15]. It has subsequently been applied to a variety of problems, such as platelet aggregation during blood clotting [6], the deformation of red blood cells in a shear flow [5], the flow in collapsible thin-walled vessels [22], the swimming of eels, sperm, and bacteria [7, 4], the flow past a cylinder [14], two-dimensional [3] and three-dimensional models of the cochlea [10], valveless pumping [13], and flexible filament flapping in a flowing soap film [26]. For a recent review of the research in immersed boundary computations and further applications, see [18].

Realistic immersed boundary simulations of complex systems, such as the heart and the cochlea, require very large computing resources: The heart model experiments were carried out on the Cray T90 [19, 16], and the cochlea was constructed on the HP Superdome at Caltech [11]. Large computational grids are necessary to reduce the numerical error and to incorporate the finer details of the simulated system into

the model. For example, higher resolution in the heart model reveals the patterns of the turbulent flow around the valves. Similarly, in the cochlea the microstructure of the organ of Corti is of crucial importance to the dynamics of the whole system. Consequently, numerical experiments with both systems often required days of dedicated computing. Both the Superdome and the Cray T90 are shared memory machines; thus the parallelization of the serial immersed boundary code was achieved mainly (but not exclusively) with the help of compiler directives. Yet, the use of finer grids in simulations of complex systems eventually leads to computations that exceed the capabilities of the available shared memory systems. Large-scale simulations involving hundreds, and perhaps thousands, of processors must be carried out on machines with distributed architecture, which require the development of algorithms such as the one presented in this paper.

The main challenge in designing distributed algorithms consists of the need to balance the cost of communicating information among the available processors with the need to efficiently utilize these processors. On most distributed architecture multiprocessor machines, communication between processors consists of an initial phase, required to establish the connection, followed by the actual transfer of the data. The cost of the initial phase, called latency, is typically quite high. For example, on one of the most commonly available machines, the IBM SP RS/6000, the measured latency is 7.6 microseconds, while the bandwidth is about 240 MB/sec (see [2]), making small message transfer prohibitively expensive. It is therefore necessary to impose the additional constraint of bulk communication on the design of distributed algorithms.

The immersed boundary method uses a mixed Lagrangian–Eulerian formulation and has the important property that virtually any complex model of the immersed boundary force generation can be easily incorporated. The design of the distributed algorithm should preserve this property. The fluid and the immersed material are naturally described by separate computational grids. The fluid is modeled by a three-dimensional rectangular grid, while the immersed material is typically modeled as a collection of elastic fibers (one-dimensional grids) or as an elastic shell (a two-dimensional grid). Simulation proceeds in a series of time steps, where during each time step the elastic forces are computed on the material grids and then spread to the fluid grid. The fluid equations are solved yielding a new fluid velocity, which is then interpolated to the material grids and is finally used to update their position relative to the fluid.

Distributed memory implementations of the immersed boundary method have proved quite challenging. The interaction between the fluid and immersed boundaries is the primary source of difficulties in the design of a distributed algorithm. Typically, the immersed boundary structures are not evenly distributed throughout the fluid domain and, furthermore, their position may change significantly with time. The resulting system may therefore exhibit a significant amount of irregular communication. The first step toward distributed immersed boundary computations was taken by Sabbagh, who constructed a distributed Navier–Stokes solver in his doctoral dissertation [23]. Previous attempts to design a distributed algorithm for the whole immersed boundary method included a Split-C version on the Thinking Machine CM5 and an earlier Titanium version [24] on the Cray T3E, both machines having support for lightweight (i.e., low latency) communication. Despite the great need, so far no distributed memory implementation has been used in any immersed boundary model.

The heart and the cochlea are the two examples motivating our present work in developing the algorithm and the software package `IB` for immersed boundary com-

putations in Titanium. Titanium is an explicitly parallel dialect of Java developed at the University of California-Berkeley to support high-performance scientific computing on large-scale multiprocessors, including massively parallel supercomputers and distributed-memory clusters with one or more processors per node. Other language goals include safety, portability, and support for building complex data structures. Titanium is open-source software available from the UC Berkeley Computer Science Department [1].

The complexity of an immersed boundary computation is determined by the sizes of the fluid and the immersed boundary grids, and by the size of the time step. The heart model uses a 128^3-point fluid grid, with the heart muscle and the valves modeled by a collection of elastic fibers, totaling approximately 600,000 points. The cochlea model, on the other hand, uses a 256^3-point fluid grid, with the immersed material modeled as a set of elastic shells and bony walls, totaling approximately 750,000 points. Extensive numerical experiments with the cochlea have shown that the 256^3-point fluid grid is not sufficient for many numerical experiments (see [10]). The `IB` package has already been used to construct a 128^3-point heart model and a 512^3-point cochlea model, and a 256^3-point heart model is presently under construction. This work will be described in future publications.

The rest of the paper is organized as follows. In the next section we introduce the immersed boundary equations. These equations form the basis of the numerical method, which is described in section 3. The algorithm and the data structures utilized in our implementation are outlined in section 4. Sections 5 and 6 make the case for a wider adoption of the Titanium programming language for large-scale scientific computing: section 5 surveys the main features of the Titanium programming language, and section 6 briefly surveys some features of the `IB` software package. In the following section we demonstrate the feasibility of large-scale immersed boundary computations using our software. We conclude with a summary and a discussion of our plans for further research.

2. The immersed boundary equations. The immersed boundary method is based on a mixed Eulerian–Lagrangian formulation of the fluid-immersed material system. The fluid is described in the standard Cartesian coordinates on $\mathbb{R}^3$, while the immersed material is described in a different curvilinear coordinate system. Let ρ and μ denote the density and the viscosity of the fluid, and let $\mathbf{u}(\mathbf{x},t)$ and $p(\mathbf{x},t)$ denote its velocity and pressure, respectively. The Navier–Stokes equations of a viscous incompressible fluid are

$$\rho\left(\frac{\partial \mathbf{u}}{\partial t}+\mathbf{u}\cdot\nabla\mathbf{u}\right)=-\nabla p+\mu\nabla^2\mathbf{u}+\mathbf{F}, \tag{2.1}$$

$$\nabla\cdot\mathbf{u}=0, \tag{2.2}$$

where $\mathbf{F}$ denotes the density of the body force acting on the fluid. For example, if the immersed material is modeled as a thin shell, then $\mathbf{F}$ is a singular vector field, which is zero everywhere, except possibly on the surface representing the shell. While the immersed boundary equations are valid in any domain in $\mathbb{R}^3$, we will assume that the domain is rectangular and the boundary conditions are periodic. This enables us to use fast Fourier methods for the solution of the Navier–Stokes equations (2.1) and (2.2).

Let $\mathbf{X}(\mathbf{q},t)$ denote the position of the immersed material in $\mathbb{R}^3$. For a shell, $\mathbf{q}$ takes values in a domain $\Omega\subset\mathbb{R}^2$, and $\mathbf{X}(\mathbf{q},t)$ is a 1-parameter family of surfaces

indexed by t; i.e., $\mathbf{X}(\mathbf{q},t)$ is the middle surface of the shell at time t. Let $\mathbf{f}(\mathbf{q},t)$ denote the force density that the immersed material applies on the fluid. Then

$$\mathbf{F}(\mathbf{x},t) = \int \mathbf{f}(\mathbf{q},t)\delta(\mathbf{x}-\mathbf{X}(\mathbf{q},t))\,d\mathbf{q}, \tag{2.3}$$

where δ is the Dirac delta function on $\mathbb{R}^3$. This equation merely says that the fluid feels the force that the immersed material exerts on it, but it is important in the numerical method, where it is one of the equations determining fluid-material interaction. The other interaction equation is the no-slip condition for a viscous fluid:

$$\begin{aligned}\frac{\partial \mathbf{X}}{\partial t} &= \mathbf{u}(\mathbf{X}(\mathbf{q},t),t)\\ &= \int \mathbf{u}(\mathbf{x},t)\delta(\mathbf{x}-\mathbf{X}(\mathbf{q},t))\,d\mathbf{x}.\end{aligned} \tag{2.4}$$

The system has to be completed by specifying the force $\mathbf{f}(\mathbf{q},t)$ of the immersed material. In a complicated system such as the cochlea, the immersed material consists of many different components: membranes, bony walls, an elastic shell representing the basilar membrane, and various cells of the organ of Corti, including outer hair cells, which may actively generate forces. For each such component it is necessary to specify its own computation grid and an algorithm to compute its force $\mathbf{f}$. It is in the specification of these forces that models for various system components integrate into the macromechanical model.

3. The first-order immersed boundary numerical method. We describe here a first-order immersed boundary numerical scheme, which is the easiest to implement. The main algorithmic ideas developed in section 4 apply also to other versions of the immersed boundary method, such as the formally second-order immersed boundary method [14]. The fluid equations are discretized on a periodic rectangular lattice of mesh width h. The immersed material is described by a collection of one-, two- or three-dimensional computational grids, whose mesh width is typically approximately $h/2$. Some of the computational grids used in the cochlea model are shown in Figure 3.1.

The computation proceeds in time steps of duration Δt. It will be convenient to denote the time step by the superscript. For example, $\mathbf{u}^n(\mathbf{x}) = \mathbf{u}(\mathbf{x}, n\Delta t)$. At the beginning of the nth time step, $\mathbf{X}^n$ and $\mathbf{u}^n$ are known. Each time step consists of four parts, as shown in Procedure 1 (see [18] for more details).

PROCEDURE 1. The time step of the first-order immersed boundary method.

1: Compute $\mathbf{f}^n$, the force that the immersed boundary applies to the fluid.
2: Compute $\mathbf{F}^n$, the external force on the fluid.
3: Compute $\mathbf{u}^{n+1}$, the new fluid velocity.
4: Compute $\mathbf{X}^{n+1}$, the new position of the immersed boundary.

In part 1 the force $\mathbf{f}^n$ that the immersed boundary applies to the fluid is computed. For simple materials, such as fibers, this is a straightforward computation (see [20]). More complex material models may be considered. For a detailed description of an elastic shell immersed boundary force computation, see [9]. In part 2 the interpolation equation (2.3) is used to compute the external force on the fluid $\mathbf{F}^n$ from the force $\mathbf{f}^n$ applied by the immersed boundary. The force $\mathbf{F}^n$ is used in the Navier–Stokes solver

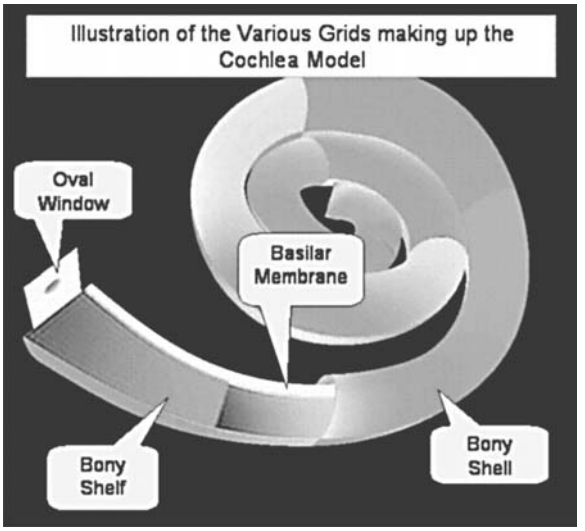

FIG. 3.1. *The immersed material grids of the cochlea model.*

in part 3 to compute the new fluid velocity $\mathbf{u}^{n+1}$. In part 4 this velocity is used in the interpolation equations (2.4) to compute the new position $\mathbf{X}^{n+1}$ of the immersed material.

We shall now describe the computations in steps 2–4 in detail, beginning with the Navier–Stokes equations. We will make use of the following difference operators which act on functions defined on the fluid lattice:

$$D_i^+\phi(\mathbf{x}) = \frac{\phi(\mathbf{x}+h\mathbf{e}_i)-\phi(\mathbf{x})}{h}, \tag{3.1}$$

$$D_i^-\phi(\mathbf{x}) = \frac{\phi(\mathbf{x})-\phi(\mathbf{x}-h\mathbf{e}_i)}{h}, \tag{3.2}$$

$$D_i^0\phi(\mathbf{x}) = \frac{\phi(\mathbf{x}+h\mathbf{e}_i)-\phi(\mathbf{x}-h\mathbf{e}_i)}{2h}, \tag{3.3}$$

$$\mathbf{D^0} = (D_1^0, D_2^0, D_3^0), \tag{3.4}$$

where $i = 1, 2, 3$ and $\mathbf{e}_1$, $\mathbf{e}_2$, $\mathbf{e}_3$ form an orthonormal basis of $\mathbb{R}^3$.

In step 3 we use the already known $\mathbf{u}^n$ and $\mathbf{F}^n$ to compute $\mathbf{u}^{n+1}$ and p^{n+1} by solving the following linear system of equations:

$$\rho\left(\frac{\mathbf{u}^{n+1}-\mathbf{u}^n}{\Delta t} + \sum_{k=1}^{3} u_k^n D_k^{\pm}\mathbf{u}^n\right) = -\mathbf{D}^0 p^{n+1} + \mu\sum_{k=1}^{3} D_k^+ D_k^-\mathbf{u}^{n+1} + \mathbf{F}^n, \tag{3.5}$$

$$\mathbf{D}^0\cdot\mathbf{u}^{n+1} = 0. \tag{3.6}$$

Here $u_k^n D_k^{\pm}$ stands for upwind differencing:

$$u_k^n D_k^{\pm} = \begin{cases} u_k^n D_k^-, & u_k^n > 0, \\ u_k^n D_k^+, & u_k^n < 0. \end{cases}$$

Equations (3.5) and (3.6) are linear constant coefficient difference equations and, therefore, can be solved efficiently with the use of the fast Fourier transform (FFT) algorithm.

We now turn to the discretization of (2.3), (2.4). Let us assume, for simplicity, that $\Omega \subset \mathbb{R}^2$ is a rectangular domain over which all of the quantities related to the shell are defined. We will assume that this domain is discretized with mesh widths Δq_1, Δq_2 and that the computational lattice for Ω is the set

$$\mathbf{Q} = \{(i_1 \Delta q_1, i_2 \Delta q_2) \mid i_1 = 1, \ldots, n_1, \quad i_2 = 1, \ldots, n_2\}.$$

In step 2 the force $\mathbf{F}^n$ is computed using the following equation:

$$\mathbf{F}^n(\mathbf{x}) = \sum_{\mathbf{q} \in \mathbf{Q}} \mathbf{f}^n(\mathbf{q}) \delta_h(\mathbf{x} - \mathbf{X}^n(\mathbf{q})) \Delta \mathbf{q}, \tag{3.7}$$

where $\Delta \mathbf{q} = \Delta q_1 \Delta q_2$ and δ_h is a smoothed approximation to the Dirac delta function on $\mathbb{R}^3$ described below.

Similarly, in step 4 the update of the position of the immersed material $\mathbf{X}^{n+1}$ is done using the equation

$$\mathbf{X}^{n+1}(\mathbf{q}) = \mathbf{X}^n(\mathbf{q}) + \Delta t \sum_{\mathbf{x}} \mathbf{u}^{n+1}(\mathbf{x}) \delta_h(\mathbf{x} - \mathbf{X}^n(\mathbf{q})) h^3, \tag{3.8}$$

where the summation is over the lattice $\mathbf{x} = (hi, hj, hk)$, where i, j, and k are integers.

The function δ_h, which is used in (3.7) and (3.8), is an approximation to the Dirac delta function. It is constructed to have compact support in order to reduce the complexity of the computation. The most commonly used δ_h spreads the force (in phase 2) of a single material point to a $4 \times 4 \times 4$ cube within the fluid grid. Similarly, in step 4 of the algorithm the fluid velocity of a $4 \times 4 \times 4$ cube within the fluid grid is needed to determine the fluid velocity of an immersed material point. This function is defined by the following equation:

$$\delta_h(\mathbf{x}) = h^{-3} \phi\left(\frac{x_1}{h}\right) \phi\left(\frac{x_2}{h}\right) \phi\left(\frac{x_3}{h}\right),$$

where

$$\phi(r) = \begin{cases} \frac{1}{8}(3 - 2|r| + \sqrt{1 + 4|r| - 4r^2}), & |r| \le 1, \\ \frac{1}{2} - \phi(2 - |r|), & 1 \le |r| \le 2, \\ 0, & 2 \le |r|. \end{cases}$$

For an explanation of the construction of δ_h, see [20].

4. The distributed algorithm. As a consequence of the mixed Eulerian–Lagrangian formulation of the immersed boundary method, the fluid and the immersed material are described by different data structures, all of which must be distributed among available processors. The main challenge in the design of the distributed algorithm lies in achieving a load-balanced computation while keeping the communication costs low. Furthermore, there are several natural design requirements that we impose on the algorithm. The algorithm must perform well for systems with sparse one- or two-dimensional immersed boundaries, as well as for systems with thick three-dimensional immersed structures. The immersed boundary may or may not move much during the simulation, and the performance of the algorithm should not depend on the mobility of the immersed boundary. In practice, the ability to easily integrate complex models of immersed material structures into the simulation model is very important. We would like to maintain this property of the immersed boundary method in distributed computations.

We begin the description of the algorithm by listing several basic design choices:

- The fluid is partitioned into a number of domains, which are assigned to all available processors.
- The immersed boundary is described by a collection of grids, each of which is wholly assigned to one of the available processors.
- The assignment of the data structures to processors is constant throughout the computation: Neither fluid points, nor material points migrate between processors.

Previous attempts to develop a distributed immersed boundary algorithm were based on different design choices, for example, splitting immersed boundary structures among processors. Our assumptions significantly simplify the development of the distributed algorithm, and while they appear to be somewhat restrictive, the resulting algorithm is nevertheless efficient, flexible, and scalable.

4.1. Interprocessor communication. As mentioned in the introduction, the interprocessor communication on most available distributed computers must be carried out in bulk, in order to avoid the penalty of high latency. Fine-grain communication is the main reason for the difficulties with scalability encountered in previous attempts to develop a distributed immersed boundary algorithm. All interprocessor communications in our algorithm use the following simple mailbox model: Each processor maintains a mailbox for incoming mail and a mailbox for outgoing mail for every processor, including itself. The act of sending mail from processor i to processor j means that the jth outgoing mailbox of processor i is copied onto the ith incoming mailbox of processor j.

4.2. Force computation. The force computation phase is the only part of the immersed boundary time step which depends on the specific structure of the immersed material. In phases 2 and 4 of the time step the material is treated simply as an unordered collection of points. In most applications force computation is by far the cheapest part of the immersed boundary time step.

The assumption that all data structures related to a given piece of the immersed boundary are completely contained in the memory of some processor implies that the computation of the force in phase 1 is entirely local, i.e., requires no communication, and is very efficient. However, we will see that in order to carry out the remaining, more expensive, phases of the immersed boundary time step efficiently, it is necessary to distribute the immersed material structures as evenly as possible among all available processors. In practice, certain portions of the immersed boundary may be quite large, leading to load imbalance in the computation. Our experience has shown that it is generally possible to subdivide such large structures among processors in an efficient way. For example, the basilar membrane in the cochlea model is a relatively large structure, modeled as an elastic shell. In order to achieve a load balanced computation we have partitioned the shell into a number of components assigned to different processors. As a result, the computation of the elastic force of the shell requires a preliminary communication phase in which boundary data for each component are exchanged between processors that own neighboring shell components. Each processor bundles the data it communicates, sending a single message to each of its neighbors. The total amount of data exchanged in this phase is typically very small, and the force computation phase remains significantly cheaper than the other phases of the immersed boundary time step. In order to simplify the discussion, in the remainder of this paper we assume that

4.3. The fluid solver. The solution of the discretized Navier–Stokes equations (3.5)–(3.6) is the central and most expensive part among the four parts that compose each time step of the first-order immersed boundary numerical method. The general framework of the immersed boundary method allows the use of fluid solvers different from the one described in section 3. Our design ensures that this remains true in the distributed case as well. It will be convenient, however, to describe the approach in the case of the specific fluid solver we have implemented.

Our fluid solver is perhaps the simplest possible distributed solver. It depends on the availability of efficient distributed three-dimensional FFT functions. We assume that the transform data is partitioned into slabs. When a transform of an $N_1 \times N_2 \times N_3$-point array $A[i_1, i_2, i_3]$ is computed using p processors (where N_1 is divisible by p), processor q stores the data slab

$$A[i_1, i_2, i_3]: \quad i_1 = \frac{N_1}{p}q, \ldots, \frac{N_1}{p}(q+1)-1, \quad i_2 = 0, \ldots, N_2-1, \quad i_3 = 0, \ldots, N_3-1.$$

Accordingly, fluid variables, such as velocity, pressure, and body force, are stored in such slabs: U_1, U_2, U_3, P and F_1, F_2, F_3. The application of the upwind differencing operator in (3.5) makes it necessary, however, to pad each such slab with two ghost planes corresponding to $i_1 = \frac{N_1}{p}q - 1$ and $i_1 = \frac{N_1}{p}(q+1)$. (Notice that because of the periodicity of the domain the calculation of the index i_1 is carried out modulo N_1.) In addition to the fluid variables mentioned above, we will also require three global fluid variables C_1, C_2, and C_3 for temporary storage, each occupying one slab per processor. The variables C_1, C_2, and C_3 store complex data on which a complex-to-complex Fourier transform is performed. The pressure variable is not required for time-stepping, but the pressure can be computed, if necessary, using additional storage, C_4, and one additional inverse Fourier transform computation. We require all three dimensions of the fluid slabs to be divisible by 4 (not counting the ghost planes in the first dimension), in order to facilitate the fluid cache implementation (see below).

We rewrite the Navier–Stokes equations (3.5)–(3.6) in the following form:

$$\rho\frac{\mathbf{u}^{n+1}}{\Delta t} + \mathbf{D}^0 p^{n+1} - \mu\sum_{k=1}^{3} D_k^+ D_k^- \mathbf{u}^{n+1} = \mathbf{C^n}, \tag{4.1}$$

$$\mathbf{D}^0 \cdot \mathbf{u}^{n+1} = 0, \tag{4.2}$$

where

$$\mathbf{C^n} = \rho\frac{\mathbf{u}^n}{\Delta t} - \rho\sum_{k=1}^{3} u_k^n D_k^{\pm}\mathbf{u}^n + \mathbf{F}^n. \tag{4.3}$$

The Navier–Stokes solver is shown in Procedure 2. At the beginning of this computation the slabs of U_1, U_2, and U_3 contain the values of the fluid velocity computed at the end of the nth time step. The first step is a preliminary communication phase where the ghost planes of the slabs corresponding to the three velocity components are exchanged. This can be done efficiently, with each processor sending a single message to each of its two neighbors. The barrier command synchronizes the processors, ensuring that all of the processors have completed their work before the next step can begin. At the end of the communication phase every processor has all the necessary data to compute the values stored in the slabs C_1, C_2, C_3 using (4.3). Notice that the right-hand side of (4.3) is complex data, while the left-hand side is real. The

PROCEDURE 2. The Navier–Stokes solver.

1: Exchange ghost planes for U_1, U_2, U_3;
2: *barrier*;
3: Compute C_1, C_2, C_3 using (4.3);
4: *barrier*;
5: Compute forward FFT of C_1, C_2, C_3;
6: *barrier*;
7: Solve transformed equations in C_1, C_2, C_3;
8: *barrier*;
9: Compute inverse FFT of C_1, C_2, C_3 and store the result in U_1, U_2, U_3.

Navier–Stokes equations (4.1)–(4.2) can now be solved using the distributed FFT. We assume that the FFT functions perform the transform "in place," so that the solution of the transformed equations is again a local computation requiring no communication. After the inverse Fourier transform has been completed, we copy the new fluid velocity from the complex C_1, C_2, C_3 into the real slabs U_1, U_2, U_3.

4.4. Fluid-structure interactions. The main difficulty in the design of the distributed immersed boundary algorithm lies in efficiently carrying out phases 2 and 4 of the immersed boundary time step. These phases require communication of information between the fluid grid and the immersed boundary grids. Computationally, these phases are expensive: On a single processor, depending on the immersed boundary system being simulated, each of these two phases may account for as much as 20–30% of the computing time.

In phase 2 immersed boundary forces must be communicated to the processors that own the appropriate portions of the fluid grid. In many applications, however, the immersed boundary interacts with only a small portion of the fluid grid, which may be owned by a fraction of all available processors. Communicating the immersed boundary forces to these processors will lead to a load imbalance in the computation. Furthermore, since each immersed boundary point interacts with a $4 \times 4 \times 4$ cube within the fluid grid, it is not easy to describe the set of fluid points that a given immersed boundary grid interacts with. To solve this problem we break up phase 2 into several stages and introduce a specialized cache-like data structure in each processor. We shall refer to this data structure simply as [illegible].

The force-spreading phase of the immersed boundary method is described in Procedure 3. First, each processor spreads the force of every immersed boundary grid point it owns into its fluid cache. At the end of this phase the processor fluid cache contains the representation of the forces applied to the portion of the fluid grid in the vicinity of the material grids possessed by that processor. It contains, however, only the forces contributed by the grids of that processor and not the forces due to grids owned by other processors. Next, every processor sends the contents of its cache to the processors that own the corresponding portions of the fluid force array. This communication is carried out in bulk: All information intended for a given recipient is bundled into the mailbox intended for that recipient and then sent as a single message. In the worst case, in this stage every processor sends a single large message to every other processor, including itself. Finally, when the communication has been completed every processor scans the messages it received and updates the portion of the fluid force array that it owns. At the end of this stage each force slab contains contributions from forces of [illegible] immersed material grids.

PROCEDURE 3. Force spreading for processor i $(1 \leq i \leq p)$.

```
1: for each immersed boundary grid do
2:   if the grid is owned by processor i then
3:     for every grid point do
4:       spread the grid point force f^n into the fluid cache;
5:     end for
6:   end if
7: end for
8: Pack the cache into mailboxes.
9: Send mail to each processor.
10: barrier;
11: for j = 1, ..., p do
12:   add the force data received from processor j to the force slab F_1, F_2, F_3;
13: end for
```

The first, local stage of force spreading is by far the most time-consuming part of the distributed procedure. Under most circumstances, the assignment of immersed boundary grids to processors at the start of the simulation can ensure that the total number of immersed boundary grid points owned by each processor is approximately the same. This will ensure a nearly perfect load balance distribution in the local force-spreading part of the computation. The communication stage depends on the total number of immersed boundary grid points and on their relative position. Significant savings can be achieved when portions of the immersed boundary that remain in proximity throughout the simulation are assigned to the same processor. In practice, this is usually known to the designer of the simulation experiment, who can carry out this assignment at the start of the simulation.

The final phase of the immersed boundary time step involves computing the new position of the immersed boundary by interpolating the new fluid velocity from the fluid grid to the immersed boundary grids. This phase is similar to the force-spreading phase, except that the fluid velocity data, instead of the fluid force data, is now communicated, and the information is propagating in the opposite direction: from the fluid grid to the immersed material grids. It is important to notice that the fluid portion that interacts with a given immersed boundary point in stage 2 is exactly the same as in stage 4. This information is stored in the fluid cache (see below) and is used in line 2 of Procedure 4.

4.5. The fluid cache. To finish the description of the computation we now provide the details of the fluid cache construction. We imagine the rectangular fluid grid as partitioned by a lattice into a collection of small $4 \times 4 \times 4$ cubes. Since we require the fluid slab dimensions to be divisible by 4, each fluid cube is completely contained in one slab. The fluid cache data structure in every processor consists of an $(N_1/4) \times (N_2/4) \times (N_3/4)$ array of pointers to cubes.

Initially this structure is empty, and a cube is allocated only when a point inside the cube is referenced. The fluid cache is easy to update, yet it does not contain an excessive amount of information. In addition to the pointer array, a linked list containing all the indices of the cubes that have already been allocated is maintained. Thus, at the end of the force-spreading phase each processor will have a list of all fluid cubes that interact with the portions of the immersed boundary that it owns. In effect, the data in the fluid cache describes within the fluid a narrow neighborhood of the

PROCEDURE 4. Move for processor i ($1 \le i \le p$).

```
1: for j = 1, ..., p do
2:    copy the appropriate portions of U_1, U_2, U_3 into the mailbox of processor j;
3: end for
4: Send mail to every processor.
5: barrier;
6: Unpack the mailboxes into the fluid cache.
7: for each immersed boundary grid do
8:    if the grid is owned by processor i then
9:       for every grid point do
10:         advance grid point coordinates using the velocity data in the fluid cache;
11:      end for
12:   end if
13: end for
```

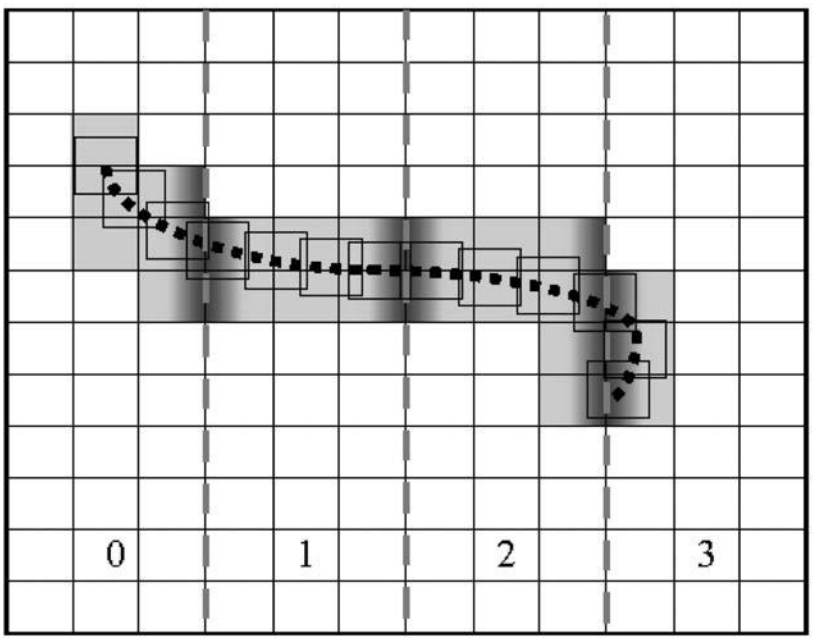

FIG. 4.1. *An illustration of the fluid cache: each point of the immersed boundary interacts with a* $4 \times 4 \times 4$ *cube of fluid around it; the shaded region describes the union of the fluid cache structures of all four processors. The cache of processor i is the intersection of slab i with the shaded region.*

immersed boundary owned by that processor as a collection of cubes (see Figure 4.1). The processor will then send cubes of fluid containing force data to processors that own these cubes. (Recall our assumption that fluid slab dimensions are divisible by 4, which ensures that each fluid cube is owned by exactly one processor.) Each recipient of a list of cubes containing fluid force data will record the cube indices and in the last stage of the algorithm it will return these cubes containing fluid velocity data to the sender.

Several issues related to cache management require further research. At present, we do not deallocate the cubes in the cache at the end of each time step. At the beginning of each time step we use the list of the cube indices to initialize all the allocated cubes to zero. This works well for portions of immersed boundary that do not move much during the simulation. For a highly mobile immersed boundary it may be necessary to implement a garbage collection mechanism in the fluid cache. While the size of the fluid cache in each processor is proportional to the total size of the fluid, our construction is practical because many of the currently available multiprocessor systems possess large amounts of memory (up to 32 GB per processor). Memory requirements for the fluid cache can be significantly reduced by implementing the cache using more complex data structures, but in such an implementation cache access may be slower. The $4 \times 4 \times 4$ size of the fluid cache cubes is not necessarily optimal. Good results have also been obtained with $4 \times 4 \times 1$ blocks. The choice of the block size in the fluid cache is not directly related to the width of support of the discrete delta function δ_h. With smaller cache blocks the total size of the cache in every processor is larger, while potentially less information needs to be communicated during the fluid-structure interaction phases.

5. The Titanium programming language. We have built a software package, called `IB`, implementing the distributed immersed boundary algorithm described above using the Titanium programming language. This section describes some of the features of the language that make it particularly suitable for large-scale scientific computing projects.

While much of scientific computing is still carried out in Fortran, the complexity of the simulated systems naturally leads to complex data structures. Modern multiprocessor computers require language-level tools to develop distributed algorithms, and programming languages have evolved to support object-oriented programming and to provide mechanisms for distributed programming. These tools have proved to be very successful in many fields, but they have rarely been used in the context of high-performance scientific computing because they often carry with them a performance penalty.

The Titanium programming language was developed with the goal of providing a modern language to meet the needs of scientific supercomputing. It is an explicitly parallel Java-based language designed to support high-performance scientific computing on large-scale multiprocessors, including massively parallel supercomputers and distributed-memory clusters with one or more processors per node [12, 25].

Titanium is a global address space language, closely related to UPC, Co-Array Fortran, and several older research languages based on C and C++. It combines the parallelism model commonly found in message passing modes with the shared address space found in shared memory models. In particular, Titanium uses a static parallelism (SPMD) model in which the number of parallel threads is determined at program startup time. It provides a global address space abstraction through which one thread may directly read or write to the memory of another thread, although the address space is logically partitioned so that each thread has a portion of the address space that is nearby. Programmers have control over data layout, synchronization, and load balancing for high performance, while the global address space simplifies programming but allows for direct expression of distributed data structures.

In spite of the global address space, the Titanium implementation runs on essentially any parallel machine, including shared memory multiprocessors, clusters of uniprocessors, and clusters of SMPs. On machines with hardware support for shared

memory, the compiler generates conventional load and store instructions to access memory that is associated with another thread. On a distributed memory platform, lightweight communication calls are inserted automatically when the accessed data structures reside on a remote processor. Titanium programs can run unmodified on uniprocessors, shared memory machines, and distributed memory machines—performance tuning may be necessary to arrange an application's data structures for distributed memory, but the functional portability allows for development on shared memory machines and uniprocessors.

Titanium preserves the safety properties of Java, which prevent accessing data that is unallocated through array bounds checking, strong typing, and automatic memory management. In addition to the parallelism model, which replaces conventional Java threads, Titanium adds support to improve programming for scientific applications. These include the following:

- user-defined immutable classes (often called "lightweight" or "value" classes);
- flexible and efficient multidimensional arrays with a rich set of operations for defining and manipulating the index set of an array;
- zone-based memory management, in addition to standard garbage collection;
- a type system for expressing and inferring locality and sharing properties of distributed data structures;
- compile-time prevention of deadlocks on barrier synchronization;
- a library of useful parallel collective operations such as barriers, broadcasts, and reductions;
- operator overloading;
- parameterized classes similar to a C++ style template.

6. The `IB` software package. The `IB` software package provides a collection of general-purpose classes necessary for the construction of immersed boundary simulations. This section briefly mentions some of the features of the package as an illustration of the importance of object-oriented programming in construction of large-scale computational models.

The fluid solver uses the FFTW software [8] to compute three-dimensional, distributed Fourier transforms. The fluid solver is contained in the `Fluid` class, which is defined by specifying fluid dimensions, mesh width, density, and viscosity:

```
Fluid fluid = new Fluid(N1, N2, N3, dx, rho, mu);
```

More complicated fluid models can be created using class inheritance. For example, the fluid in the heart model contains sources and sinks. Such a class can be defined as an extension of `IB.Fluid`. The new class will inherit many useful methods for manipulating fluid data structures, while overriding several methods, such as the fluid solver.

The specification of material grids and their type depends on the particular application. The `IB` package provides a number of classes for this purpose. Local properties of the material must be specified in a user-defined class derived from `IB.GridPoint`, and its global properties in a user-defined class derived from `IB.Grid`. For example, an elastic shell material type can be defined by deriving a class `Shell` and a class `ShellPoint`. The class `ShellPoint` naturally contains local elastic parameters of the material. On the other hand, the elastic force of the shell must be specified by defining a `ComputeForce` method within the `Shell` class.

The `IB` package also provides a `GridArray` class that enables handling hierarchical collections of material structures. In the cochlea model several surfaces are further subdivided into collections of grids; in the heart model the muscle fibers are arranged in groups, which are further arranged in layers.

Finally, the IB package provides a collection of methods to control the simulation and collect and analyze its output.

7. Software performance. Realistic immersed boundary models, such as the heart or the cochlea, require a significant amount of work to construct. We have therefore constructed a number of simple test models for the purpose of testing the distributed algorithm and tuning the performance of the IB software. Each such test model consists of a number of rectangular plates immersed in fluid. The precise nature of the elastic material is not important for the complexity of the immersed boundary computations because the elastic force calculation phase is negligible in time with respect to the other phases of the algorithm. The complexity of the computation is affected only by the total number of immersed boundary points and by their motion relative to the fluid. We have partitioned the immersed material into a number of grids, distributing an equal number of grids and an equal number of points among the processors. We expect to be able to achieve such a distribution in a realistic simulation. The heart, for example, is modeled by thousands of distinct fibers, which can be easily assigned to processors to achieve an even balancing of the load.

In immersed boundary computations, refining the fluid grid necessitates refining the immersed material grids accordingly. This is required to prevent the fluid leaking through the immersed boundary (for volume conservation in immersed boundary computations, see [21]). The cochlea model consists of a number of surfaces and, assuming the fluid grid is of size N^3, its total number of immersed boundary points is proportional to N^2. The heart muscle, on the other hand, though being modeled by a collection of one-dimensional fibers, occupies a three-dimensional volume, and therefore the total number of immersed boundary points in the heart model is proportional to N^3. Accordingly, we have tested the performance of the software on several models with varying numbers of immersed boundary points. Each of our test models contained a number of identical $N \times N$-point plates. We considered models with fluid grid of size N^3, where $N = 256$ and $N = 512$, and the number of plates $n = 1, 16$, and $N/8$. Accordingly, in the discussion below we refer to a model with n plates of size $N \times N$ as an (N, n) model. The models with $n = 1$ possess very little immersed material and therefore provide an insight into the performance of the fluid solver part of the algorithm. The $n = 16$ models resemble the cochlea in the size of their immersed material, while the $n = N/8$ models resemble the heart. The flow in each test model was generated by a periodic sinusoidal force of small amplitude applied to each of the plates. After a short initial phase the performance of the algorithm for each subsequent time step was essentially the same.

Our experiments were carried out on the IBM SP RS/6000 at the National Energy Research Scientific Computing Center (NERSC). This is a distributed memory computer possessing a large number of 16-processor nodes (currently 380 nodes), where each node has between 16 and 64 GB of memory. All of our tests were carried out on either 1, 2, 4, or 8 nodes, with the total number of processors used being 16, 32, 64, or 128. Figure 7.1 demonstrates the scaling of our software when a varying number of processors is used to compute two test problems. For the $(256, 1)$ we also present the data from experiments with 1, 2, 4, and 8 processors, all within a single node. Because our present algorithm requires the width of the fluid slabs (without the ghost planes) to be divisible by 4, we can utilize at most 64 processors on 256^3-fluid problems, and at most 128 processors on 512^3-fluid problems. Table 7.1 summarizes the wall-clock time per time step results for a number of test models, as well as the total number of floating point operations performed (in billions). The computations with

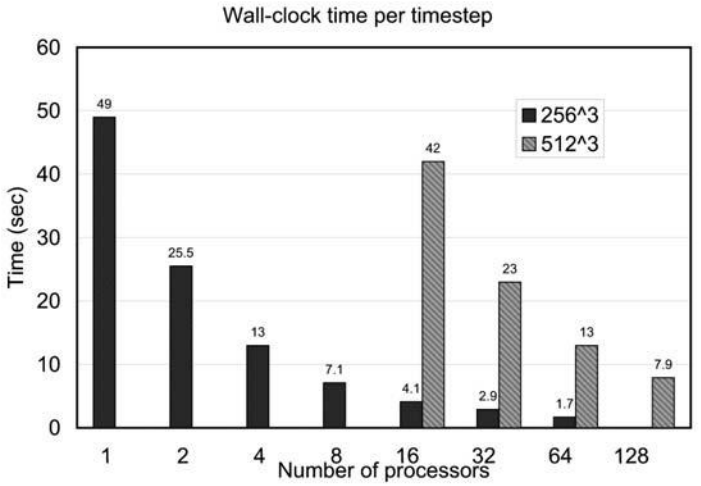

FIG. 7.1. *Execution wall-clock time (in seconds) per time step for the* $(256, 1)$ *and* $(512, 1)$ *models as a function of the number of processors.*

TABLE 7.1
Wall-clock time per time step for various test models.

Model name	Fluid grid size	Total immersed boundary size	Number of processors	Total GFLOPs	Wall-clock time
(256, 1)	256^3	$256^2 = 64$K points	64	4.34	1.7 sec
(256, 16)	256^3	$16 \times 256^2 = 1$M points	64	5.5	2.4 sec
(256, 32)	256^3	$32 \times 256^2 = 2$M points	64	6.78	3.1 sec
(512, 1)	512^3	$512^2 = 256$K points	128	38.4	7.9 sec
(512, 16)	512^3	$16 \times 512^2 = 4$M points	128	43.2	9.6 sec
(512, 64)	512^3	$64 \times 512^2 = 16$M points	128	58.1	15.2 sec

the 256^3-point fluid grid were performed on 64 processors, while the 512^3-point fluid grid computations used 128 processors.

Finally, Table 7.2 shows the timings of the main phases of each time step. The second row refers to the spreading of the forces from the immersed boundary into the local fluid cache structure. Rows 6–10 detail the performance of the fluid solver: "Upwind" refers to the initial step of the fluid solver which uses the slabs F_1, F_2, F_3 and applies the upwind differencing operator to U_1, U_2, U_3. Three Fourier transforms are applied to the components of the result of this computation. The fluid equations are then solved in the Fourier space, and the solution is obtained by means of inverse Fourier transforms. The total time devoted to the fluid solver is recorded in row 11. The last phase of the time step, named "move material," involves both the interpolation of the fluid velocity from cubes to immersed boundary grids and the updating of the immersed boundary position.

The results presented in Table 7.2 enable us to assess the scalability of the individual phases of the computation. The lines labeled with "spread force" and "move material" involve local computations with the fluid cache and show excellent scalability. It is interesting that a significant amount of time is necessary to perform local copy operations ("pack" and "unpack") to and from the fluid cache. No floating point operations are performed in these phases. The communication phases show excellent scaling: Because only fluid information is communicated, doubling the number of

immersed boundary points may require much less than double the amount of fluid information to be communicated.

8. Summary and conclusions. We have developed an efficient algorithm for immersed boundary simulations on distributed memory multiprocessor systems. The main difficulty in the design of the algorithm arises because of the need to communicate information between the fluid and the immersed boundary data structures, which are distributed across multiple processors. The difficulty of achieving load balance and maintaining low communication cost in the fluid-structure interaction is exacerbated by the hardware-imposed restriction that the interprocessor communication be carried out in bulk. We resolve this problem with the help of a specialized cache-like data structure, the fluid cache, to communicate information between processors. The fluid cache enables an efficient implementation of the fluid-structure interaction portion of the immersed boundary time step.

We have implemented the algorithm in the software package `IB` using the Titanium programming language. In our implementation the fluid solver uses the FFTW functions for efficient distributed FFT computations.

The `IB` package utilizes the object-oriented features of Titanium and its built-in facilities for generating efficient code, and provides the user with a set of versatile classes and utilities to build large-scale immersed boundary applications. A 512^3 cochlea model based on the `IB` package has been tested, and Peskin and McQueen's 128^3 heart model has already been reconstructed using the `IB` package. A 256^3 heart model is currently being built. This work will be reported in future publications. In this paper we described the development of the basic algorithm and the software performance results that enable such large-scale immersed boundary computations.

At present, these are the largest models that are practical. Indeed, since a single typical experiment with the cochlea model may require more than 10,000 time steps, we estimate that in the case of a 512^3-point fluid grid it will take more than 3 days to complete. Simulating a single beat of the heart, on the other hand, requires on the order of 100,000 time steps. Such an experiment with a 256^3 model could be completed in fewer than 3 days.
