AN INFEASIBLE PRIMAL-DUAL ALGORITHM FOR TOTAL BOUNDED VARIATION–BASED INF-CONVOLUTION-TYPE IMAGE RESTORATION*

M. HINTERMÜLLER† AND G. STADLER‡

Abstract. In this paper, a primal-dual algorithm for total bounded variation (TV)–type image restoration is analyzed and tested. Analytically it turns out that employing a global $\boldsymbol{L}^s$-regularization, with $1 < s \leq 2$, in the dual problem results in a local smoothing of the TV-regularization term in the primal problem. The local smoothing can alternatively be obtained as the infimal convolution of the ℓ_r-norm, with $r^{-1} + s^{-1} = 1$, and a smooth function. In the case $r = s = 2$, this results in Gauss-TV–type image restoration. The globalized primal-dual algorithm introduced in this paper works with generalized derivatives, converges locally at a superlinear rate, and is stable with respect to noise in the data. In addition, it utilizes a projection technique which reduces the size of the linear system that has to be solved per iteration. A comprehensive numerical study ends the paper.

1. Introduction.

Image denoising based on total bounded variation regularization (TV regularization) was introduced in [26]. Since then it has received a considerable amount of attention and is widely accepted as a reliable tool in edge preserving image restoration; see the selected papers [1, 4, 5, 6, 9, 10, 14, 23, 29] and the recent monograph [32] for further references.

Compared to classical H^1-type regularization, such as $\int_\Omega |\nabla u|^2_{\ell^2}\, dx$ with u representing the reconstructed image, or other techniques based on smooth (at least C^1) functionals, the TV term $\int_\Omega |Du|$ is nondifferentiable in the Fréchet sense. This nondifferentiability is responsible for preserving edges in images, but at the same time, it poses significant numerical challenges. Early computational techniques employed global smoothing of the bounded variation (BV) seminorm to overcome the nondifferentiability [9, 33]; see also the more recent work [2]. In many cases a C^∞-function like $\int_\Omega (|\nabla u|^2_{\ell^2} + \epsilon)^{1/2}\, dx$, with $\epsilon > 0$ fixed, is used as a smooth approximation of the nondifferentiable TV term. For small smoothing parameter ϵ, this technique introduces severe ill-conditioning of second derivatives and adversely affects, e.g., Newton's method for solving the first order conditions associated with the smoothed TV-type problem. To remedy this ill-conditioning, in [6] a (dual) flux variable w is introduced together with the requirement that the iterates w^k stay in the interior of the unit ball (strict feasibility) in the pointwise almost everywhere sense. Another type of global regularization is introduced in the primal affine scaling technique in [21], where

the interior point treatment acts like a global regularization within a continuation framework.

As the above-mentioned smoothing of the BV seminorm introduces [illegible] global nonlinearity to the problem, several authors studied local smoothing [5, 10, 28]; see [31] for further references. The idea is to keep the original problem formulation to the largest possible extent. While the above remarks on ill-conditioning persist, in the local case the BV seminorm is changed only close to kinks. The utilized functionals are typically only once continuously differentiable as opposed to the C^∞-type global smoothing.

Yet another approach that avoids global smoothing is based on active set techniques; see [15, 17, 18] for closely related algorithms. Utilizing augmented Lagrangian formulations, these methods predict the set of points where the BV seminorm is nondifferentiable, fix the gradient of the primal variable on this set, and compute it on the complement set. It turns out that the original problem is approximated by a sequence of problems which are almost as difficult to solve as the original one. In [15] this drawback is overcome by using a penalization technique, which, to some extent, acts like an additional regularization. In [18] a heuristic lumping technique is applied for solving the auxiliary problems. In numerical practice these active set-type methods are significantly faster than the widely used gradient descent schemes [26] or fixed point–type iterations [9, 33].

In this paper, we adopt the Hilbert space perspective of [15, 17, 18]; i.e., we consider the problem

$$(\mathcal{P}) \qquad \min_{u\in H_0^1(\Omega)} \frac{\mu}{2}\int_\Omega |\nabla u|_2^2\,dx + \frac{1}{2}\int_\Omega |Ku-z|^2\,dx + \alpha\int_\Omega |\nabla u|_r\,dx,$$

where $\Omega\subset\mathbb{R}^2$ is an open, bounded (image) domain with Lipschitz-continuous boundary $\partial\Omega$, $K : L^2(\Omega)\to L^2(\Omega)$ is a continuous linear operator with K^* its adjoint, $z\in L^2(\Omega)$ represents given noisy data, $\mu,\alpha>0$, and $|\nabla u|_r = (|u_x|^r+|u_y|^r)^{1/r}$, with $1\le r<+\infty$. Typically $0<\mu\ll\alpha$ such that $(\mathcal{P})$ is a close approximation to the TV-regularized problem

$$(\mathcal{P}_{BV}) \qquad \min_{u\in \mathrm{BV}(\Omega)} \frac{1}{2}\int_\Omega |Ku-z|^2\,dx + \alpha\int_\Omega |Du|_r,$$

where $\mathrm{BV}(\Omega)$ denotes the space of functions of bounded variation; i.e., a function u is in $\mathrm{BV}(\Omega)$ if the BV seminorm

$$\int_\Omega |Du|_r = \sup\left\{\int_\Omega u\,\mathrm{div}\ \vec{v}\,dx : \vec{v}\in(C_0^\infty(\Omega))^2, |\vec{v}(x)|_s\le 1\right\},$$

with $r^{-1}+s^{-1}=1$, is finite. We recall that $\mathrm{BV}(\Omega)\subset L^2(\Omega)$ for $\Omega\subset\mathbb{R}^2$ [12]. For the discretized version of $(\mathcal{P})$ and as long as K^*K is invertible, we may even choose $\mu=0$ and obtain stable results; see section 5. A particular instance with K^*K invertible is given by image denoising where $K=\mathrm{id}$.

The aim of the present paper is to devise an implementable algorithm which is based on a primal-dual approach, overcomes the difficulties of the methods in [15, 17, 18], is locally rapidly convergent, and, in contrast to, e.g., [6], takes advantage of local regularization only. The primal-dual framework is obtained by considering the Fenchel dual to $(\mathcal{P})$, which turns out to be a bound-constrained concave quadratic maximization problem. The objective function of the dual problem involves the divergence operator, which is responsible for the solution set not to be a singleton.

To avoid this nonuniqueness property, we propose a simple $\boldsymbol{L}^s$-regularization, with $1 < s \leq 2$ and $\boldsymbol{L}^s(\Omega) = (L^s(\Omega))^2$, such that the resulting regularized dual problem admits a unique solution. Let $\gamma > 0$ denote the corresponding regularization parameter. Then, in the context of the primal problem, for $w \in \mathbb{R}^n$ this regularization is given by the inf-convolution

$$\phi_{r,\gamma}(w) = \inf\{|\hat{w}|_r + (r\gamma)^{-1}|w - \hat{w}|_r^r : \hat{w} \in \mathbb{R}^n\}.$$

As a consequence, the regularized version of $(\mathcal{P})$ involves the term $\int_\Omega \Phi_{r,\gamma}(\nabla u)\,dx$, with $\Phi_{r,\gamma}(\nabla u)(x) = \phi_{r,\gamma}(\nabla u(x))$, rather than $\int_\Omega |\nabla u|_r\,dx$. In the special case $s = 2$ we obtain Gauss-TV regularization [28], which was recently shown to be an excellent choice for medical imaging [20]. The latter statement is mainly based on the fact that the Gauss-TV regularization employs a local smoothing of $|\cdot|_2$ and allows avoidance of the adverse staircase or bulkiness effect well known in pure TV regularization; see, e.g., [3]. Similar effects are obtained for $1 < s < 2$. In our model, the choice of γ influences the amount of local smoothing. Indeed, for small γ one finds that $\Phi_{r,\gamma}$ is close to the BV seminorm, whereas for large γ, strong smoothing of $|\cdot|_r$ takes place. For further techniques to reduce the staircase effect we refer the reader to [19].

The rest of the paper is organized as follows. In section 2 we derive the Fenchel dual problem of $(\mathcal{P})$, introduce the dual regularization, and discuss some of its aspects. The primal-dual algorithm is defined in section 3, where we also provide a discussion of global as well as fast local convergence. In section 4 we consider aspects of the implementation, and in section 5 we report on our numerical experience with the new algorithm, validate the theoretical results, and we study the qualitative behavior of our dual regularization technique.

Throughout the paper we shall frequently use the following notation. For a vector $v \in \mathbb{R}^n$, and $r \in \mathbb{R}$ we define $|v|^r := (|v_1|^r, \ldots, |v_n|^r)^\top$ and $\sigma(v) \in \mathbb{R}^n$ with $\sigma(v) = (\operatorname{sign}(v_1), \ldots, \operatorname{sign}(v_n))^\top$. We use $|\cdot|_s$ for the ℓ_s-vector norm in $\mathbb{R}^n$. Further we denote by $\star$ the Hadamard product of vectors, i.e., $v \star w = (v_1 w_1, \ldots, v_n w_n)^\top$. For vector-valued functions we write $\vec{p}$ and $p(x) \in \mathbb{R}^n$ for its value at x. For a symmetric matrix $M \in \mathbb{R}^{m,m}$, $\lambda_{\min}(M)$ denotes its smallest eigenvalue. In the case when M is nonsymmetric, $\lambda_{\min}(M)$ is the smallest eigenvalue of $\frac{1}{2}(M + M^\top)$, the symmetrization of M.

2. The Fenchel dual of $(\mathcal{P})$ and its regularization. For the reader's convenience we now recall the Fenchel duality theorem in infinite-dimensional spaces; see, e.g., [11]. For this purpose let V and Y be Banach spaces with topological duals V^* and Y^*, respectively. Further, let $\Lambda \in \mathcal{L}(V, Y)$ be the space of continuous linear operators from V to Y, and let $\mathcal{F} : V \to \mathbb{R} \cup \{\infty\}$, $\mathcal{G} : Y \to \mathbb{R} \cup \{\infty\}$ be convex, proper, and lower semicontinuous such that there exists $v_0 \in V$ with $\mathcal{F}(v_0) < \infty$, $\mathcal{G}(\Lambda v_0) < \infty$, and $\mathcal{G}$ continuous at Λv_0. Then

$$\inf_{v \in V} \{\mathcal{F}(v) + \mathcal{G}(\Lambda v)\} = \sup_{q \in Y^*} \{-\mathcal{F}^*(\Lambda^* q) - \mathcal{G}^*(-q)\}, \tag{2.1}$$

where $\Lambda^* \in \mathcal{L}(Y^*, V^*)$ is the adjoint of Λ. The convex conjugates $\mathcal{F}^* : V^* \to \mathbb{R} \cup \{\infty\}$, $\mathcal{G}^* : Y^* \to \mathbb{R} \cup \{\infty\}$ of $\mathcal{F}$ and $\mathcal{G}$, respectively, are defined by

$$\mathcal{F}^*(v^*) = \sup_{v \in V} \{\langle v, v^* \rangle_{V,V^*} - \mathcal{F}(v)\},$$

and analogously for $\mathcal{G}^*$. The conditions imposed on $\mathcal{F}$ and $\mathcal{G}$ guarantee that the dual problem (which is the problem on the right-hand side of (2.1)) admits a solution.

Furthermore, the solutions $\bar v \in V$ and $\bar q \in Y^*$ are characterized by the optimality conditions

$$\begin{aligned} \Lambda^* \bar q &\in \partial \mathcal{F}(\bar v), \\ -\bar q &\in \partial \mathcal{G}(\Lambda \bar v), \end{aligned} \tag{2.2}$$

where ∂ denotes the subdifferential from convex analysis.

2.1. Fenchel dual of ($\mathcal{P}$). Now we apply the Fenchel calculus to

$$\begin{aligned} \mathcal{F}(u) &:= \frac{1}{2}\int_\Omega |Ku - z|^2\, dx + \frac{\mu}{2}\int_\Omega |\nabla u|_2^2 dx, \\ \mathcal{G}(\vec q) &:= \alpha \int_\Omega |\vec q|_r\, dx, \;\; \Lambda u := (u_x, u_y)^\top, \end{aligned}$$

with $V := H_0^1(\Omega)$, $Y := \boldsymbol{L}^2(\Omega)$, $1 \le r < +\infty$. As a result we obtain

$$\begin{aligned} \mathcal{F}^*(u^*) &:= \frac{1}{2}|||u^* + K^* z|||_{H^{-1}}^2 - \frac{1}{2}\|z\|_{L^2}^2, \\ \mathcal{G}^*(\vec q^*) &:= I_{\{\vec w \in \boldsymbol{L}^2(\Omega) : |\vec w|_s \le \alpha \text{ a.e. in } \Omega\}}(\vec q^*), \end{aligned}$$

where $r^{-1} + s^{-1} = 1$, I_S is the indicator function of the set $S \subset \boldsymbol{L}^2(\Omega)$, and $|||v|||_{H^{-1}} = \langle H_{\mu,K} v, v\rangle_{H_0^1, H^{-1}}$, $v \in H^{-1}(\Omega)$, with $H_{\mu,K} = (K^*K - \mu\Delta)^{-1}$. Here $\langle \cdot, \cdot \rangle_{H_0^1, H^{-1}}$ denotes the duality pairing between $H_0^1(\Omega)$ and its dual $H^{-1}(\Omega)$, and $\Delta : H_0^1(\Omega) \to H^{-1}(\Omega)$.

Setting $\vec p = -\vec q$, then, according to (2.1), the dual problem of ($\mathcal{P}$) is

$$\sup_{\substack{\vec p \in \boldsymbol{L}^2(\Omega), \\ |\vec p|_s \le \alpha \text{ a.e. in } \Omega}} \; -\frac{1}{2}|||\operatorname{div} \vec p + K^* z|||_{H^{-1}}^2 + \frac{1}{2}\|z\|_{L^2}^2. \tag{$\mathcal{P}^\star$}$$

Note that the Fenchel dual of ($\mathcal{P}$) is a bound constrained maximization problem with a concave quadratic objective function. Further observe that the solution to ($\mathcal{P}^\star$) is not unique since the divergence operator has a nontrivial kernel.

From (2.2) we obtain the following characterization of solutions $\bar u$ and $\bar{\vec p}$ of ($\mathcal{P}$) and ($\mathcal{P}^\star$), respectively:

$$-\mu\Delta \bar u + K^*K\bar u - \operatorname{div} \bar{\vec p} = K^* z \;\text{ in } H^{-1}(\Omega), \tag{2.3a}$$

$$\left.\begin{aligned} -\alpha(\sigma(\nabla \bar u) \star |\nabla \bar u|^{r-1}) + |\nabla \bar u|_r^{r-1}\bar{\vec p} &= 0 \quad \text{if} \quad |\bar{\vec p}|_s = \alpha, \\ \nabla \bar u &= 0 \quad \text{if} \quad |\bar{\vec p}|_s < \alpha \end{aligned}\right\} \;\text{ in } \boldsymbol{L}^2(\Omega). \tag{2.3b}$$

In (2.3a)–(2.3b) the expression $|\nabla \bar u|_r^{r-1}$ can be interpreted as a Lagrange multiplier for the inequality constraint in the dual problem ($\mathcal{P}^\star$). We summarize the above results in the following theorem.

THEOREM 2.1. [illegible] ($\mathcal{P}$) [illegible] ($\mathcal{P}^\star$) [illegible] (2.1) [illegible] $\bar u$ [illegible] ($\mathcal{P}$) [illegible] $\bar{\vec p}$ [illegible] ($\mathcal{P}^\star$) [illegible] (2.3a)–(2.3b) [illegible] ($\mathcal{P}$) [illegible] $\bar{\vec p}^1$ $\bar{\vec p}^2$ [illegible] ($\mathcal{P}^\star$) [illegible] $\operatorname{div}(\bar{\vec p}^1 - \bar{\vec p}^2) = 0$ [illegible] $\bar{\vec p}^1 = \bar{\vec p}^2$ [illegible] $\nabla \bar u \neq 0$

With respect to the special case $\mu = 0$ we point out that

- in [15, Remark 2.1], for $K = \mathrm{id}$, it is shown that the solution $\bar u = \bar u(\mu)$ satisfies $\bar u(\mu) \rightharpoonup \bar u_{\mathrm{BV}}$ weakly in $L^2(\Omega)$ as $\mu \to 0$, where $\bar u_{BV}$ denotes the unique solution to ($\mathcal{P}_{BV}$);

- for $\mu = 0$, in [14] the Fenchel predual problem of $(\mathcal{P})$ in an ℓ_1-vector-norm setting is derived. Surprisingly it turns out that the predual of the TV problem $(\mathcal{P}_{BV})$ is posed in a Hilbert space. Its structure is similar to $(\mathcal{P}^\star)$. The underlying function space is $H_0(\mathrm{div}) = \{\vec{v} \in \boldsymbol{L}^2(\Omega) : \mathrm{div}\, \vec{v} \in L^2(\Omega),\ \vec{v} \cdot \vec{n} = 0 \text{ on } \partial\Omega\}$, where $\vec{n}$ denotes the outward unit normal to $\partial\Omega$. For a convergence analysis of the proposed semismooth Newton method, however, an H^1-type regularization of the dual problem is necessary; for details see [14, section 3].

2.2. Regularization. Nonuniqueness of the solution to the dual problem may cause instabilities in a numerical scheme utilizing primal and dual variables. As a remedy we propose the following simple Tikhonov-type regularization of $(\mathcal{P}^\star)$:

$$(\mathcal{P}^\star_\gamma) \qquad \sup_{\substack{\vec{p} \in \boldsymbol{L}^2(\Omega),\\ |\vec{p}|_s \le \alpha \text{ a.e. in } \Omega}} -\frac{1}{2}|||\mathrm{div}\, \vec{p} + K^* z|||^2_{H^{-1}} + \frac{1}{2}\|z\|^2_{L^2} - \frac{\gamma^{s-1}}{s\alpha^{s-1}}\|\vec{p}\|^s_{\boldsymbol{L}^s},$$

where $\gamma > 0$ is the regularization parameter and $1 < s \le 2$. Subtracting the term $s^{-1}\alpha^{1-s}\gamma^{s-1}\|\vec{p}\|^s_{\boldsymbol{L}^s}$ from the objective functional of $(\mathcal{P}^\star)$ results in an $\boldsymbol{L}^s$-uniformly concave objective functional in $(\mathcal{P}^\star_\gamma)$. Thus, $(\mathcal{P}^\star_\gamma)$ admits a unique solution $\vec{p}_\gamma \in \boldsymbol{L}^2(\Omega)$ for every fixed $\gamma > 0$.

Due to the reflexivity of the involved function spaces, we compute the Fenchel dual of $(\mathcal{P}^\star_\gamma)$ and study the effect of the dual regularization in the primal problem. For the Fenchel calculus, we set $\vec{p} = -\vec{q}$ and

$$\begin{aligned}\mathcal{F}(\vec{q}) &:= I_{\{\vec{w} \in \boldsymbol{L}^2(\Omega) : |\vec{w}|_s \le \alpha\}}(\vec{q}) + \frac{\gamma^{s-1}}{s\alpha^{s-1}}\|\vec{q}\|^s_{\boldsymbol{L}^s},\\ \mathcal{G}(\Lambda\vec{q}) &:= \frac{1}{2}|||K^* z - \mathrm{div}\, \vec{q}|||^2_{H^{-1}} - \frac{1}{2}\|z\|^2_{L^2},\ \ \Lambda\vec{q} := \mathrm{div}\, \vec{q},\end{aligned}$$

with $Y := H^{-1}(\Omega)$, $V := \boldsymbol{L}^2(\Omega)$. The Fenchel dual problem of $(\mathcal{P}^\star_\gamma)$ is given by

$$(\mathcal{P}_\gamma) \qquad \min_{u \in H^1_0(\Omega)} \frac{\mu}{2}\int_\Omega |\nabla u|^2\, dx + \frac{1}{2}\int_\Omega |Ku - z|^2\, dx + \alpha \int_\Omega \Phi_{r,\gamma}(\nabla u)\, dx,$$

where $r^{-1} + s^{-1} = 1$ and, for $\vec{w} \in \boldsymbol{L}^2(\Omega)$,

$$\Phi_{r,\gamma}(\vec{w})(x) := \begin{cases} |w(x)|_r - \frac{r-1}{r}\gamma^{1/(r-1)} & \text{if } |w(x)|_r \ge \gamma^{1/(r-1)},\\ \frac{1}{r\gamma}|w(x)|^r_r & \text{if } |w(x)|_r < \gamma^{1/(r-1)}.\end{cases}$$

The function $\Phi_{r,\gamma}$ is continuously differentiable. Hence, the objective functional in $(\mathcal{P}_\gamma)$ is continuously differentiable and strictly convex. Thus, $(\mathcal{P}_\gamma)$ admits a unique solution $\bar{u}_\gamma \in H^1_0(\Omega)$. Further, $\Phi_{r,\gamma}(\nabla u)$ represents a local smoothing of $\int_\Omega |\nabla u|_r\, dx$ and, as our analysis shows, it is connected to a particular regularization of the Fenchel dual of $(\mathcal{P}^\star)$. In the case $r = 2$ we have

$$\Phi_{2,\gamma}(\vec{w})(x) := \begin{cases} |w(x)|_2 - \frac{\gamma}{2} & \text{if } |w(x)|_2 \ge \gamma,\\ \frac{1}{2\gamma}|w(x)|^2_2 & \text{if } |w(x)|_2 < \gamma.\end{cases}$$

This choice is related to results in [5, p. 186] and [28], and it is known as Gauss-TV regularization. In medical imaging it is in many cases superior to the Perona–Malik filter [24], edge-flat-gray filter [16], and pure TV filtering. Let us also mention that $\Phi_{2,\gamma}$ is sometimes referred to as Huber function; see [10, 32].

By (2.2), the solutions $\bar{u}_\gamma$ and $\bar{\vec{p}}_\gamma$ of the regularized problems $(\mathcal{P}_\gamma)$ and $(\mathcal{P}_\gamma^\star)$, respectively, satisfy

$$-\mu\Delta\bar{u}_\gamma + K^*K\bar{u}_\gamma - \operatorname{div}\bar{\vec{p}}_\gamma = K^*z \ \text{ in } H^{-1}(\Omega), \tag{2.4a}$$

$$\left.\begin{array}{rll} \gamma\bar{\vec{p}}_\gamma - \alpha(|\nabla\bar{u}_\gamma|^{r-1} \star \sigma(\nabla\bar{u}_\gamma)) &= 0 \quad \text{if} \quad |\bar{\vec{p}}_\gamma|_s < \alpha, \\ |\nabla\bar{u}_\gamma|_r^{r-1}\bar{\vec{p}}_\gamma - \alpha(|\nabla\bar{u}_\gamma|^{r-1} \star \sigma(\nabla\bar{u}_\gamma)) &= 0 \quad \text{if} \quad |\bar{\vec{p}}_\gamma|_s = \alpha \end{array}\right\} \ \text{in } \boldsymbol{L}^2(\Omega). \tag{2.4b}$$

One can easily verify that (2.4b) can be equivalently expressed as

$$\max(\gamma, |\nabla\bar{u}_\gamma|_r^{r-1})\bar{\vec{p}}_\gamma - \alpha(|\nabla\bar{u}_\gamma|^{r-1} \star \sigma(\nabla\bar{u}_\gamma)) = 0. \tag{2.5}$$

This reformulation is fundamental for the algorithm which we propose in the next section.

Comparing (2.4b) and (2.3b) one finds that our regularization changes the optimality conditions only on subsets of Ω where $|\nabla\bar{u}_\gamma|_r < \gamma^{1/(r-1)}$, i.e., on sets where the pointwise constraint $|\bar{\vec{p}}_\gamma|_s \le \alpha$ is inactive. At sharp edges in the image, $|\nabla\bar{u}_\gamma|_r$ is large and (2.4b) becomes

$$|\nabla\bar{u}_\gamma|_r^{r-1}\bar{\vec{p}}_\gamma = \alpha(|\nabla\bar{u}_\gamma|^{r-1} \star \sigma(\nabla\bar{u})),$$

as it would be the case for the original problem $(\mathcal{P})$. As a consequence, our regularization does not smear sharp edges in the image. In addition, our local smoothing prevents the adverse [illegible] or [illegible] effect which typically occurs in TV regularization [16, 20]; see the discussion in section 5.2.

The following convergence result for $(\bar{u}_\gamma, \bar{\vec{p}}_\gamma)$ as $\gamma \to 0$ justifies our dual regularization analytically. The proof is given in Appendix A.

THEOREM 2.2. [illegible] $\bar{u}_\gamma$ [illegible] $(\mathcal{P}_\gamma)$ [illegible] $\bar{u}$ [illegible] $(\mathcal{P})$ [illegible] $H_0^1(\Omega)$ [illegible] $\gamma \to 0$ [illegible] $\gamma \to 0$ [illegible] $\bar{\vec{p}}_\gamma$ [illegible] $(\mathcal{P}_\gamma^\star)$ [illegible] $\bar{\vec{p}}$ [illegible] $(\mathcal{P}^\star)$ [illegible] $\boldsymbol{L}^2(\Omega)$

We conclude this section by pointing out another interesting relation between the dual regularization, $\Phi_{r,\gamma}$, and inf-convolution. In fact, $\Phi_{r,\gamma}$ can be obtained in a purely primal fashion. For this purpose consider for $w \in \mathbb{R}^n$ the inf-convolution

$$\phi_{r,\gamma}(w) := \inf\{|\hat{w}|_r + (r\gamma)^{-1}|w - \hat{w}|_r^r : \hat{w} \in \mathbb{R}^n\}.$$

One finds

$$\phi_{r,\gamma}(w) = \begin{cases} |w|_r - \frac{r-1}{r}\gamma^{1/(r-1)} & \text{if } |w|_r > \gamma^{1/(r-1)}, \\ \frac{1}{r\gamma}|w|_r^r & \text{if } |w|_r \le \gamma^{1/(r-1)}. \end{cases}$$

Thus, $\Phi_{r,\gamma}(\vec{q})(x) = \phi_{r,\gamma}(q(x))$ for $x \in \Omega$.

REMARK 2.3. [illegible] $(\mathcal{P}_\gamma^\star)$ [illegible] $\gamma^{s-1}/(s\alpha^{s-1})$ [illegible] $\tilde{\gamma}/s$ $\tilde{\gamma} > 0$ [illegible] (2.5) [illegible]

$$\max(\alpha\tilde{\gamma}^{r-1}, |\nabla\bar{u}_{\tilde{\gamma}}|_r^{r-1})\bar{\vec{p}}_{\tilde{\gamma}} - \alpha(|\nabla\bar{u}_{\tilde{\gamma}}|^{r-1} \star \sigma(\nabla\bar{u}_{\tilde{\gamma}})) = 0. \tag{2.6}$$

[illegible] $\tilde{\gamma} = \gamma^{s-1}/\alpha^{s-1}$ (2.6) [illegible] (2.5)

3. Primal-dual algorithm and its convergence. As it turned out in recent work, primal-dual schemes are typically superior to purely primal methods; see [6, 14]. Thus, we take (2.4a) and (2.5) as the starting point for devising an algorithm for solving the discrete analogue of $(\mathcal{P}_\gamma)$. In this way we naturally involve the primal variable

u and the dual variable $\vec{p}$. Consequently, we compute the solutions to the discrete versions of $(\mathcal{P}_\gamma)$ and $(\mathcal{P}_\gamma^\star)$ simultaneously. The algorithm proposed here is related to semismooth Newton methods [13, 25, 30]. In what follows we denote discretized quantities by superscript h. For a vector $w \in \mathbb{R}^l$ we denote by $D(w) := \operatorname{diag}(w)$ the $l \times l$ diagonal matrix with diagonal entries w_i.

The discrete analogues of (2.4a) and (2.5) are

$$B_\mu^h \bar{u}_\gamma^h - \operatorname{div}^h \bar{p}_\gamma^h = (K^h)^\top z^h, \tag{3.1a}$$

$$\max(\gamma e^h, \eta_r(\nabla^h \bar{u}_\gamma^h)) \star \bar{p}_\gamma^h - \alpha\big(|\nabla^h \bar{u}_\gamma^h|^{r-1} \star \sigma(\nabla^h \bar{u}^h)\big) = 0, \tag{3.1b}$$

where $\bar{u}_\gamma^h \in \mathbb{R}^m$, $\bar{p}_\gamma^h \in \mathbb{R}^{2m}$, for some $m \in \mathbb{N}$ which depends on the image size, solve the discrete analogues of $(\mathcal{P}_\gamma)$ and $(\mathcal{P}_\gamma^\star)$. Further, $z^h \in \mathbb{R}^m$ and $\nabla^h \in \mathbb{R}^{2m\times m}$, and $e^h \in \mathbb{R}^{2m}$ is the vector of all ones. We use $B_\mu^h = -\mu\Delta^h + (K^h)^\top K^h$, with $\Delta^h, (K^h)^\top K^h \in \mathbb{R}^{m\times m}$. Throughout we assume that B_μ^h is symmetric and positive definite. Note that this allows $\mu = 0$ if $(K^h)^\top K^h$ is invertible. The function $\eta_r : \mathbb{R}^{2m} \to \mathbb{R}^{2m}$ is defined by

$$(\eta_r(v))_i = (\eta_r(v))_{i+m} = |(v_i, v_{i+m})^\top|_r^{r-1} \quad \text{for } v \in \mathbb{R}^{2m},\ 1 \le i \le m.$$

The discrete gradient operator is composed as

$$\nabla^h = \begin{pmatrix} \nabla_x^h \\ \nabla_y^h \end{pmatrix} \in \mathbb{R}^{2m\times m},$$

where $\nabla_x^h \in \mathbb{R}^{m\times m}$ corresponds to the discrete derivative in the x-direction and $\nabla_y^h \in \mathbb{R}^{m\times m}$ corresponds to the derivative in the y-direction. In our implementation we use

$$\operatorname{div}^h = -(\nabla^h)^\top$$

and the implied ordering for the components of $\bar{p}_\gamma^h$. Subsequently we will frequently use the mapping $\xi_t : \mathbb{R}^{2m} \to \mathbb{R}^{2m}$ defined by

$$\xi_t(v)_i = \xi_t(v)_{i+m} := |(v_i, v_{i+m})^\top|_t$$

for $v \in \mathbb{R}^{2m}$, $i = 1, \dots, m$, and $1 < t < +\infty$. Note that $|\xi_t(v)|^{t-1} = \eta_t(v)$.

3.1. Approximate generalized Newton step. In the following we present our algorithm for the solution of (3.1a)–(3.1b). We restrict our discussion to the case $2 \le r < +\infty$ (and thus $1 < s \le 2$). It is well known that the max-operator and the ℓ_r-norm involved in (3.1b) are generalized differentiable and semismooth [13, 22, 25]. This is also true for the composition of the semismooth functions occurring in (3.1b). A particular element of the generalized Jacobian (see [8, 13, 25]) of $\max : \mathbb{R}^l \to \mathbb{R}^l$ is the diagonal matrix $G_{\max} \in \mathbb{R}^{l\times l}$ with

$$(G_{\max}(w))_{ii} := \begin{cases} 1 & \text{if } w_i \ge 0, \\ 0 & \text{if } w_i < 0 \end{cases} \quad \text{for } 1 \le i \le l.$$

Given approximations u_k^h, p_k^h of $\bar{u}_\gamma^h$, $\bar{p}_\gamma^h$, the results on generalized differentiability and semismoothness alluded to above and our assumption that $r \ge 2$ justify the

application of a Newton step to (3.1a)–(3.1b) at (u_k^h, p_k^h):

$$\begin{pmatrix} B_\mu^h & (\nabla^h)^\top \\ \big(-\alpha(r-1)D(|\nabla^h u_k^h|^{r-2}) + \chi_{\mathcal{A}_{k+1}} D(p_k^h) N_r^h(\nabla^h u_k^h)\big)\nabla^h & D(m_k^h) \end{pmatrix} \begin{pmatrix} \delta_u \\ \delta_p \end{pmatrix} = \begin{pmatrix} -B_\mu^h u_k^h - (\nabla^h)^\top p_k^h + (K^h)^\top z^h \\ \alpha\big(|\nabla^h u_k^h|^{r-1} \star \sigma(\nabla^h u_k^h)\big) - D(m_k^h) p_k^h \end{pmatrix}, \tag{3.2}$$

where we use $m_k^h = \max(\gamma e^h, \eta_r(\nabla^h u_k^h)) \in \mathbb{R}^{2m}$ for convenience, and $\chi_{\mathcal{A}_{k+1}} = D(t_k^h) \in \mathbb{R}^{2m\times 2m}$ with

$$(t_k^h)_i := \begin{cases} 1 & \text{if } \eta_r(\nabla^h u_k^h)_i \geq \gamma, \\ 0 & \text{else.} \end{cases} \tag{3.3}$$

Further, N_r^h denotes the Jacobian of η_r; i.e., for $v = (v_x, v_y)^\top \in \mathbb{R}^{2m}$, with $v_x, v_y \in \mathbb{R}^m$, we have

$$N_r^h(v) = (r-1)\big(D(\xi_r(v))\big)^{-1} \begin{pmatrix} D(|v_x|^{r-1} \star \sigma(v_x)) & D(|v_y|^{r-1} \star \sigma(v_y)) \\ D(|v_x|^{r-1} \star \sigma(v_x)) & D(|v_y|^{r-1} \star \sigma(v_y)) \end{pmatrix}.$$

Since $D(m_k^h)$ is invertible, we can eliminate δ_p from the Newton system (3.2). The remaining equation for δ_u is written as

$$H_k \delta_u = f_k, \tag{3.4}$$

where the matrix H_k and the right-hand side f_k are defined by

$$H_k := B_\mu^h + (\nabla^h)^\top D(m_k^h)^{-1}\big(\alpha(r-1)D(|\nabla^h u_k^h|^{r-2}) - \chi_{\mathcal{A}_{k+1}} D(p_k^h) N_r^h(\nabla^h u_k^h)\big)\nabla^h,$$

$$f_k := -B_\mu^h u_k^h + (K^h)^\top z^h - \alpha \nabla^h D(m_k^h)^{-1}\big(|\nabla^h u_k^h|^{r-1} \star \sigma(\nabla^h u_k^h)\big).$$

Note that H_k is the Schur complement of $D(m_k^h)$ in the system matrix in (3.2). Further properties of H_k are addressed next.

First, note that H_k is in general not symmetric, since

$$C_k^h := \alpha(r-1)D(|\nabla^h u_k^h|^{r-2}) - \chi_{\mathcal{A}_{k+1}} D(p_k^h) N_r^h(\nabla^h u_k^h)$$

is not. However, in the solution, i.e., for $(u_k^h, p_k^h) = (\bar{u}_\gamma^h, \bar{p}_\gamma^h)$ we infer from (3.1b) that $(p_k^h)_i = \alpha(\eta_r \nabla^h u_k^h))_i^{-1} |\nabla^h u_k^h|_i^{r-2} \sigma(\nabla^h u_k^h)_i$ holds for all $i \in \{1, \dots, 2m\}$ with $\eta_r(\nabla^h u_k^h)_i \geq \gamma$. Thus,

$$\begin{aligned} &\chi_{\mathcal{A}^{k+1}} D(p_k^h) N_r^h(\nabla^h u_k^h) \\ &\quad = (r-1)\chi_{\mathcal{A}^{k+1}}\big(D(\xi_r(\nabla^h u_k^h))\big)^{-1} D(p_k^h) \\ &\qquad\qquad \cdot \begin{pmatrix} D(|\nabla_x^h u_k^h|^{r-1} \star \sigma(\nabla_x^h u_k^h)) & D(|\nabla_y^h u_k^h|^{r-1} \star \sigma(\nabla_y^h u_k^h)) \\ D(|\nabla_x^h u_k^h|^{r-1} \star \sigma(\nabla_x^h u_k^h)) & D(|\nabla_y^h u_k^h|^{r-1} \star \sigma(\nabla_y^h u_k^h)) \end{pmatrix} \\ &\quad = \alpha(r-1)\chi_{\mathcal{A}^{k+1}}\big(D(\xi_r(\nabla^h u_k^h))\big)^{-r} \begin{pmatrix} D_1 & D_2 \\ D_2 & D_3 \end{pmatrix}, \end{aligned}$$

where

$$\begin{aligned} D_1 &= D\big(|\nabla_x^h u_k^h|^{2r-2}\big), \\ D_2 &= D\big(|\nabla_x^h u_k^h|^{r-1} \star |\nabla_y^h u_k^h|^{r-1} \star \sigma(\nabla_x^h u_k^h) \star \sigma(\nabla_y^h u_k^h)\big), \\ D_3 &= D\big(|\nabla_y^h u_k^h|^{2r-2}\big). \end{aligned}$$

Hence, in the solution the matrix C_k^h—and thus the entire system matrix H_k—is symmetric.

In what follows we investigate definiteness properties of the matrix H_k. Whenever H_k is positive definite, these observations lead us to simple modifications to obtain a uniformly positive definite matrix. This guarantees that in each (approximate) Newton step a descent direction is computed.

We start by considering properties of C_k^h. Note that one can reorder the indices such that $D(p_k^h)N_r^h(\nabla^h u_k^h)$ becomes a block-diagonal matrix where every 2×2 diagonal block has the structure

$$(n_k^h)_i := \frac{r-1}{(\xi_r(\nabla^h u_k^h))_i}\begin{pmatrix} (p_k^h)_i|\nabla_x^h u_k^h|_i^{r-1}\sigma(\nabla_x^h u_k^h)_i & (p_k^h)_i|\nabla_y^h u_k^h|_i^{r-1}\sigma(\nabla_y^h u_k^h)_i \\ (p_k^h)_{i+m}|\nabla_x^h u_k^h|_i^{r-1}\sigma(\nabla_x^h u_k^h)_i & (p_k^h)_{i+m}|\nabla_y^h u_k^h|_i^{r-1}\sigma(\nabla_y^h u_k^h)_i \end{pmatrix}$$

for $1 \le i \le m$. By this reordering, C_k^h is transformed into a block-diagonal matrix with diagonal blocks

$$(c_k^h)_i := \alpha(r-1)\begin{pmatrix} |\nabla_x^h u_k^h|_i^{r-2} & 0 \\ 0 & |\nabla_y^h u_k^h|_i^{r-2} \end{pmatrix} - (t_k^h)_i(n_k^h)_i, \tag{3.5}$$

where $(t_k^h)_i \in \{0,1\}$ is defined in (3.3). Obviously, $(c_k^h)_i$ is positive semidefinite for all inactive indices, i.e., for all i with $(t_k^h)_i = 0$. It remains to find conditions which imply that $(c_k^h)_i$ is positive semidefinite whenever $(t_k^h)_i = 1$. It is well known that positive semidefiniteness of $(c_k^h)_i$ is characterized by nonnegativity of all eigenvalues of its symmetrization. Therefore, we compute the eigenvalues $\lambda((\hat{c}_h^k)_i)^+$ and $\lambda((\hat{c}_h^k)_i)^-$ of $(\hat{c}_k^h)_i := \big((c_k^h)_i + (c_k^h)_i^\top\big)/2$, where

$$(c_k^h)_i = (r-1)\begin{pmatrix} a_{k,i} & b_{k,i} \\ c_{k,i} & d_{k,i} \end{pmatrix}$$

with

$$\begin{aligned}
a_{k,i} &= \alpha|\nabla_x^h u_k^h|_i^{r-2} - (\xi_r(\nabla^h u_k^h))_i^{-1}(p_k^h)_i|\nabla_x^h u_k^h|_i^{r-1}\sigma(\nabla_x^h u_k^h)_i, \\
b_{k,i} &= -(\xi_r(\nabla^h u_k^h))_i^{-1}(p_k^h)_i|\nabla_y^h u_k^h|_i^{r-1}\sigma(\nabla_y^h u_k^h)_i, \\
c_{k,i} &= -(\xi_r(\nabla^h u_k^h))_i^{-1}(p_k^h)_{i+m}|\nabla_x^h u_k^h|_i^{r-1}\sigma(\nabla_x^h u_k^h)_i, \\
d_{k,i} &= \alpha|\nabla_y^h u_k^h|_i^{r-2} - (\xi_r(\nabla^h u_k^h))_i^{-1}(p_k^h)_{i+m}|\nabla_y^h u_k^h|_i^{r-1}\sigma(\nabla_y^h u_k^h)_i.
\end{aligned}$$

Since we are considering the case $(t_k^h)_i = 1$, from (3.3) it follows that $(\xi_r(\nabla^h u_k^h))_i > 0$ and thus the above expressions are well defined. For the eigenvalues of $(\hat{c}_k^h)_i$ we obtain

$$\lambda((\hat{c}_k^h)_i)^\pm = \frac{a_{k,i}+d_{k,i}}{2} \pm \sqrt{\left(\frac{a_{k,i}+d_{k,i}}{2}\right)^2 + \left(\frac{b_{k,i}+c_{k,i}}{2}\right)^2 - a_{k,i}d_{k,i}}. \tag{3.6}$$

Let us now assume that the following two conditions hold:

$$\text{(C)} \qquad \xi_s(p_k^h)_i \le \alpha \quad \text{and} \quad (b_{k,i}+c_{k,i})^2 \le 4a_{k,i}d_{k,i}.$$

The first condition implies that $a_{k,i} \ge 0$ and $d_{k,i} \ge 0$. The second condition yields that $(b_{k,i}+c_{k,i})^2/4 - a_{k,i}d_{k,i}$ is nonpositive. Comparing with (3.6) we obtain that both eigenvalues $\lambda((\hat{c}_k^h)_i)^\pm$ are nonnegative real numbers, and hence $(c_k^h)_i$ is positive semidefinite.

Let us briefly interpret the conditions in (C). The condition $\xi_s(p_k^h)_i \leq \alpha$ corresponds to feasibility of the dual variable. Assuming that this condition holds, the latter condition in (C) is more likely to be satisfied if the matrix $(c_k^h)_i$ is close to a symmetric matrix, which can be seen as follows: assuming $b_{k,i} = c_{k,i}$ we obtain

(3.7)
$$\begin{aligned}\frac{(b_{k,i}+c_{k,i})^2}{4} - a_{k,i}d_{k,i} &= b_{k,i}c_{k,i} - a_{k,i}d_{k,i}\\ &= -\alpha^2|\nabla_x^h u_k^h|_i^{r-2}|\nabla_y^h u_k^h|_i^{r-2} + \alpha(\xi_r(\nabla^h u_k^h))_i^{-1}\\ &\qquad \cdot |\nabla_x^h u_k^h|_i^{r-2}|\nabla_y^h u_k^h|_i^{r-2}\left((p_k^h)_{i+m}(\nabla_y^h u_k^h)_i + (p_k^h)_i(\nabla_x^h u_k^h)_i\right)\\ &\leq \alpha|\nabla_x^h u_k^h|_i^{r-2}|\nabla_y^h u_k^h|_i^{r-2}(-\alpha + (\xi_s(p_k^h))_i)\\ &\leq 0.\end{aligned}$$

Above, the Hölder inequality and the assumption that $\xi_s(p_k^h)_i \leq \alpha$ are used. We summarize our results in the following lemma.

LEMMA 3.1. [illegible] (C) [illegible] $i \in \{1,\dots,m\}$ [illegible] C_k^h [illegible]

An immediate corollary of Lemma 3.1 is stated next.

COROLLARY 3.2. [illegible] (C) [illegible] $i \in \{1,\dots,m\}$ [illegible] $k \in \mathbb{N}$ [illegible] $k \in \mathbb{N}$ [illegible] H_k [illegible] $\lambda_{\min}(H_k) \geq \lambda_{\min}(B_\mu^h) > 0$ [illegible] $\{H_k^{-1}\}_{k\in\mathbb{N}}$ [illegible]

[illegible]. The assertions follow from the fact that $B_\mu^h = -\mu\Delta^h + (K^h)^\top K^h$ is symmetric and positive definite by assumption and from Lemma 3.1. ∎

In the case $r = s = 2$ the second assumption in (C) is automatically satisfied, as can be seen from the next lemma.

LEMMA 3.3. [illegible] $r = s = 2$ [illegible] (C) [illegible] C_k^h [illegible]. Suppose that $r = s = 2$ and that the first condition in (C) is satisfied. Then, for $k \in \mathbb{N}$ and $i \in \{1,\dots,m\}$,

$$\begin{aligned}&(b_{k,i}+c_{k,i})^2/4 - a_{k,i}d_{k,i}\\ &\quad= (2\xi_2(\nabla^h u_k^h)_i)^{-2}\Big((p_k^h)_i^2(\nabla_y u_k^h)_i^2 + (p_k^h)_{i+m}^2(\nabla_x u_k^h)_i^2\\ &\qquad\qquad - 2(p_k^h)_i(p_k^h)_{i+m}(\nabla_x u_k^h)_i(\nabla_y u_k^h)_i\Big) - \alpha^2\\ &\qquad + \alpha\xi_2(\nabla^h u_k^h)_i^{-1}\left((p_k^h)_i(\nabla_x u_k^h)_i + (p_k^h)_{i+m}(\nabla_y u_k^h)_i\right)\\ &\quad= (2\xi_2(\nabla^h u_k^h)_i)^{-2}\Big(\left((p_k^h)_i^2 + (p_k^h)_{i+m}^2\right)\left((\nabla_x u_k^h)_i^2 + (\nabla_y u_k^h)_i^2\right)\\ &\qquad\qquad - \left((p_k^h)_i(\nabla_x u_k^h)_i + (p_k^h)_{i+m}(\nabla_y u_k^h)_i\right)^2\Big) - \alpha^2\\ &\qquad + \alpha\xi_2(\nabla^h u_k^h)_i^{-1}\left((p_k^h)_i(\nabla_x u_k^h)_i + (p_k^h)_{i+m}(\nabla_y u_k^h)_i\right)\\ &\quad= -\Big(\alpha - (2\xi_2(\nabla^h u_k^h)_i)^{-1}\left((p_k^h)_i(\nabla_x u_k^h)_i + (p_k^h)_{i+m}(\nabla_y u_k^h)_i\right)\Big)^2\\ &\qquad + \left((p_k^h)_i^2 + (p_k^h)_{i+m}^2\right)/4\\ &\quad\leq -\alpha^2/4 + \left((p_k^h)_i^2 + (p_k^h)_{i+m}^2\right)/4\\ &\quad\leq 0.\end{aligned}$$

Thus, for $r = s = 2$, the second condition in (C) follows from $\xi_s(p_k^h)_i \le \alpha$ as asserted in the lemma. ∎

Whenever (C) is satisfied, Lemma 3.1 and Corollary 3.2 guarantee that the solution of (3.4) exists for all k and that it is a descent direction for the objective function in $(\mathcal{P}_\gamma)$. In general, however, the assumptions in (C) are unlikely to hold for all $i \in \{1, \dots, m\}$ and $k \in \mathbb{N}$. To guarantee the positive definiteness of the system matrix in our Newton-type step, in the subsequent algorithm we modify the term involving $D(p_k^h)N_r^h(\nabla^h u_k^h)$ for indices i which violate (C).

As above, we work with the reordered system matrix and consider for $i \in \{1, \dots, m\}$ the 2×2 matrix $(c_k^h)_i$ as defined in (3.5). To enforce the first condition in (C) we replace $\big((p_k^h)_i, (p_k^h)_{i+m}\big)$ by $\alpha \max\big(\alpha, \xi_s(p_k^h)_i\big)^{-1}\big((p_k^h)_i, (p_k^h)_{i+m}\big)$ when assembling the system matrix; i.e., we project p_k^h onto the feasible set. The resulting 2×2 matrix is denoted by

$$(\tilde{c}_k^h)_i = \begin{pmatrix} \tilde{a}_{k,i} & \tilde{b}_{k,i} \\ \tilde{c}_{k,i} & \tilde{d}_{k,i} \end{pmatrix}.$$

Due to the projection step we have $\tilde{a}_{k,i} \ge 0$ and $\tilde{d}_{k,i} \ge 0$. Then we check whether $(\tilde{b}_{k,i} + \tilde{c}_{k,i})^2/4 - \tilde{a}_{k,i}\tilde{d}_{k,i} \le 0$ is satisfied. If this is not the case we dampen the off-diagonal elements by $\nu_{k,i} = 2\sqrt{\tilde{a}_{k,i}\tilde{d}_{k,i}}/|\tilde{b}_{k,i} + \tilde{c}_{k,i}|$. From this we obtain

$$(\tilde{\tilde{c}}_k^h)_i = \begin{pmatrix} \tilde{a}_{k,i} & \nu_{k,i}\tilde{b}_{k,i} \\ \nu_{k,i}\tilde{c}_{k,i} & \tilde{d}_{k,i} \end{pmatrix}.$$

The resulting 2×2 matrix is positive semidefinite; i.e., its symmetrization has nonnegative eigenvalues. Revoking the reordering of the indices results in a modified system matrix which we denote by H_k^+. It replaces H_k in (3.4). We have the following result (compare with Corollary 3.2, also for a proof).

LEMMA 3.4. [illegible] H_k^+ [illegible] $\lambda_{\min}(H_k^+) \ge \lambda_{\min}(B_\mu^h) > 0$ [illegible] $k \in \mathbb{N}$ [illegible] $\{(H_k^+)^{-1}\}_{k\in\mathbb{N}}$ [illegible]

3.2. Algorithm. Now we are prepared for defining our approximate generalized Newton method for solving (3.1a)–(3.1b). Whenever (C) is not satisfied, it operates with H_k^+; otherwise the true system matrix H_k is used. In the next section we show that the new algorithm converges at a locally superlinear rate. This convergence result parallels the one for generalized Newton methods; see, e.g., [13, 30].

We propose the following algorithm.

ALGORITHM.

1. Initialize $(u_0^h, p_0^h) \in \mathbb{R}^m \times \mathbb{R}^{2m}$ and set $k = 0$.
2. Estimate the active sets, i.e., determine $\chi_{\mathcal{A}_{k+1}} \in \mathbb{R}^{2m\times 2m}$.
3. Compute H_k^+ if (C) is not satisfied for all $i = \{1, \dots, m\}$; otherwise set $H_k^+ = H_k$. Solve
$$H_k^+ \delta_u = f_k$$
for δ_u.
4. Compute δ_p according to (3.2).
5. Update $u_{k+1}^h := u_k^h + \delta_u$, $p_{k+1} := p_k^h + \delta_p$.
6. Stop, or set $k := k + 1$ and go to step 2.

Note that during the iteration of our algorithm the dual variable p is allowed to become infeasible with respect to the discrete version of the Fenchel dual problem $(\mathcal{P}_\gamma^\star)$. This differs significantly from the method in [6], where the dual iterates are forced to stay in the interior of the feasible region. Such a restriction may lead to prohibitively small step sizes in Newton's method.

3.3. Convergence analysis. In this section we investigate convergence properties of the above algorithm.

LEMMA 3.5. [illegible] $\bar{u}_\gamma^h$ $\bar{p}_\gamma^h$ [illegible] $(\mathcal{P}_\gamma)$ [illegible] $(\mathcal{P}_\gamma^\star)$ [illegible] $p_k^h \to \bar{p}_\gamma^h$ [illegible] $u_k^h \to \bar{u}_\gamma^h$ [illegible] H_k^+ [illegible] H_k [illegible] $k \to \infty$

[illegible]. Our argumentation again utilizes the reordered system. As above we argue for each 2×2 block separately. For inactive indices, i.e., for i with $(t_k^h)_i = 0$, the original and the modified 2×2 blocks coincide.

Let us now turn to active indices, i.e., to indices where $(t_k^h)_i = 1$. First note that the assumption $p_k^h \to \bar{p}_\gamma^h$ implies that $(\xi_s(p_k^h))_i \to (\xi_s(\bar{p}_\gamma^h))_i \leq \alpha$. Hence, for the projected dual variables it holds that

$$\alpha \max\big(\alpha, \xi_s(p_k^h)\big)^{-1}\big((p_k^h)_i, (p_k^h)_{i+m}\big) \to \big((\bar{p}_\gamma^h)_i, (\bar{p}_\gamma^h)_{i+m}\big).$$

Moreover, the matrix $(c_k^h)_i$ converges to a symmetric matrix as $(u_k^h, p_k^h) \to (\bar{u}_\gamma^h, \bar{p}_\gamma^h)$ (recall the discussion on page 8). Hence, the estimate (3.7) implies that $e_{k,i} := (b_{k,i} + c_{k,i})^2/4 - a_{k,i}d_{k,i} \to e_{\gamma,i} \leq 0$ for all i. If $e_{\gamma,i} < 0$, then $e_{k,i} < 0$ for all $k \geq k_0$ with some $k_0 \in \mathbb{N}$. Thus, for all $k \geq k_0$ no dampening of the off-diagonal elements occurs. If $e_{\gamma,i} = 0$, it is easy to see that $\nu_{k,i} \to 1$ as $p_k^h \to \bar{p}_\gamma^h$ and $u_k^h \to \bar{u}_\gamma^h$. Hence, all modified 2×2 diagonal blocks converge to the original blocks as $k \to \infty$. Revoking the reordering of the indices ends the proof. ∎

The local convergence of the above algorithm is the subject of the next theorem.

THEOREM 3.6. [illegible] (u_k^h, p_k^h) [illegible] $(\bar{u}_\gamma^h, \bar{p}_\gamma^h)$ [illegible] (u_0^h, p_0^h) [illegible] $(\bar{u}_\gamma^h, \bar{p}_\gamma^h)$

[illegible]. Recall that (3.1a)–(3.1b) are semismooth. However, since we possibly modify our system matrix, we end up with an approximate semismooth Newton method, and fast local convergence does not follow from standard arguments.

Utilizing a technique similar to that in the proof of Lemma 3.5 we can show that for each $\Delta > 0$ there exists a radius $\rho > 0$ such that if (u_k^h, p_k^h) is in a ρ-ball around $(\bar{u}_\gamma^h, \bar{p}_\gamma^h)$, then there exists $C_2 > 0$ with

$$\|H_k - H_k^+\| \leq \Delta \quad \text{and} \quad \|H_k^+\| \leq C_2.$$

Thus, the assumptions of Theorem 4.1. in [30] are satisfied. Using this theorem we obtain that the iterates (u_k^h, p_k^h) converge to $(\bar{u}_\gamma^h, \bar{p}_\gamma^h)$ at a linear rate, provided that (u_0^h, p_0^h) is sufficiently close to $(\bar{u}_\gamma^h, \bar{p}_\gamma^h)$. Then, Lemma 3.5 implies that $H_k^+ \to H_k$. As a consequence, the assumptions of Theorem 4.2. in [30] are satisfied, which yields that the iterates converge locally superlinearly. ∎

As a globalization strategy for the above algorithm we use an Armijo linesearch technique with backtracking for the functional of the primal regularized problem $(\mathcal{P}_\gamma)$. Let us point out, however, that in our numerical experiments the step size is almost always equal to one; i.e., a full step of our generalized Newton algorithm leads to a sufficient decrease in the functional.

4. Aspects of the implementation. To illustrate the feasibility of our approach for large scale systems, our implementation utilizes an inexact solve of the linear system arising in step 3 of the algorithm.

In the case $r = 2$ (Gauss-TV regularization) the system matrix arising in our algorithm simplifies and no dampening of the off-diagonal elements is necessary to obtain positive definiteness of the system matrix (see Lemma 3.3). However, an immediate application of the preconditioned conjugate gradient (PCG) method for the solution of the linear system in each Newton step is not feasible since H_k^+ (like H_k) is in general not symmetric. Therefore, in our implementation we replace $N_r^h(\nabla^h u_k^h)$ by its symmetrization $\tilde{N}_k^h(\nabla^h u_k^h) := 1/2\big(N_r^h(\nabla^h u_k^h) + N_r^h(\nabla^h u_k^h)^\top\big)$. As a result, the system matrix $\tilde{H}_k^+$ is symmetric and the PCG method can be applied.

The symmetrization of H_k^+ is justified by the fact that in the solution the system matrix H_k (respectively, H_k^+) is symmetric and therefore coincides with its symmetrization $\tilde{H}_k$ (see page 8). Thus, using the symmetrization of H_k^+ in step 3 of our algorithm still results in a locally superlinearly convergent algorithm. Obviously, a similar observation holds true for the case $r > 2$. However, our numerical experience shows that proceeding with the nonsymmetric matrix gives slightly better results with respect to the number of primal-dual iterations (usually 0–3 fewer iterations are needed). Therefore, we utilize the biconjugate gradient stabilized (BICGSTAB) algorithm (see, e.g., [27]) to solve the nonsymmetric positive definite linear system arising in each Newton step. We point out that alternatively one may use specialized techniques such as the recently developed semiconjugate direction method; see [34].

Next we address the accuracy required when solving the Newton-type system in every iteration. For this purpose let res_k denote the residual of the nonlinear system. Motivated by the superlinear convergence rate we stop the PCG or the BICGSTAB iteration as soon as the norm of the residual of the linearized system drops below

$$\mathrm{tol}_{k+1} := 0.1 \min\left\{ \left(\frac{\mathrm{res}_k}{\mathrm{res}_0}\right)^{3/2}, \frac{\mathrm{res}_k}{\mathrm{res}_0} \right\}.$$

As a preconditioner for the system matrix we use an incomplete Choleski factor of the symmetrization of H_k^+. The algorithm is initialized with a Gaussian smoothing of the noisy image z and with $p_0^h = 0$. We stop the Newton iteration as soon as the initial residual is reduced by a factor of 10^{-6}.

5. Numerical results. In this section we present numerical results for the Gauss-TV case $r = 2$, as well as for the case $r > 2$. We discretize the Laplace operator with the standard five-point stencil with homogenous Dirichlet boundary conditions and use forward differences for the gradient and the corresponding discrete adjoint scheme for the divergence operator. Unless otherwise specified we concentrate on image denoising, i.e., $K = \mathrm{id}$. The choice of the parameters α and γ is based on the quality of the restored images, i.e., the parameters are adjusted manually.

5.1. Behavior of the algorithm. Here, we study the behavior of our proposed method with respect to its reconstruction ability, convergence properties such as speed of convergence, stability with respect to the noise level, the choice of r, and possible violations of the dual bound constraint during the iteration. In the following section we provide a qualitative study of the influence of the regularization parameter γ on, e.g., the staircase effect.

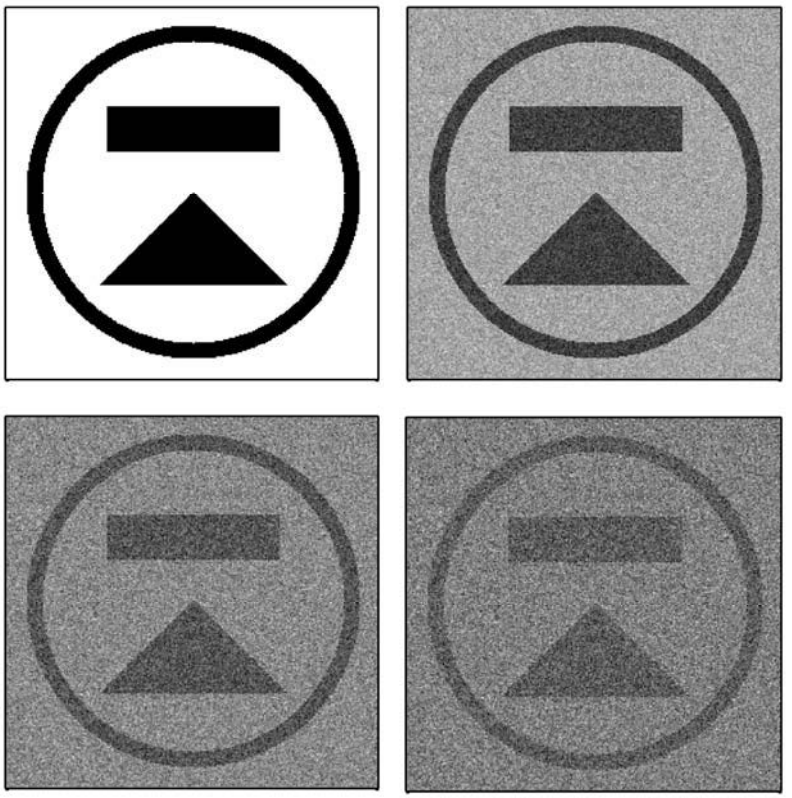

FIG. 5.1. *Example* 1: *Original image (*256 × 256 *pixels) and image with* 20% *Gaussian white noise (upper row), images containing* 50% *and* 80% *noise (lower row).*

TABLE 5.1
Example 1: *Number of primal-dual iterations (*#PD*) and overall number of CG iterations (*#CG*) for different noise levels.*

Noise	#PD	#CG
20%	11	48
50%	12	58
80%	13	61

5.1.1. Example 1. Our first test examples are displayed in Figure 5.1. On the upper left-hand side the original 256 × 256 image, which is similar to the ones used in [6, 14], is shown. A degraded image containing 20% of Gaussian white noise is given by the upper right plot. In the lower row images with a noise level of 50% respectively 80% are depicted. First we consider Gauss-TV regularization, i.e., $r = 2$ in $(\mathcal{P}_\gamma)$. We choose $\mu = 0$, $\gamma = 10^{-3}$, and $\alpha = 0.35$ for denoising the image with 20% noise. For the images containing 50% and 80% Gaussian white noise $\alpha = 0.90$ and $\alpha = 1.35$ are chosen, respectively. The numbers of primal-dual iterations of the algorithm for the three different noise levels are shown in Table 5.1, where we also provide the overall number of CG iterations. Note that our method behaves very stably with respect to the noise level. In our tests we also observe that the algorithm's performance is

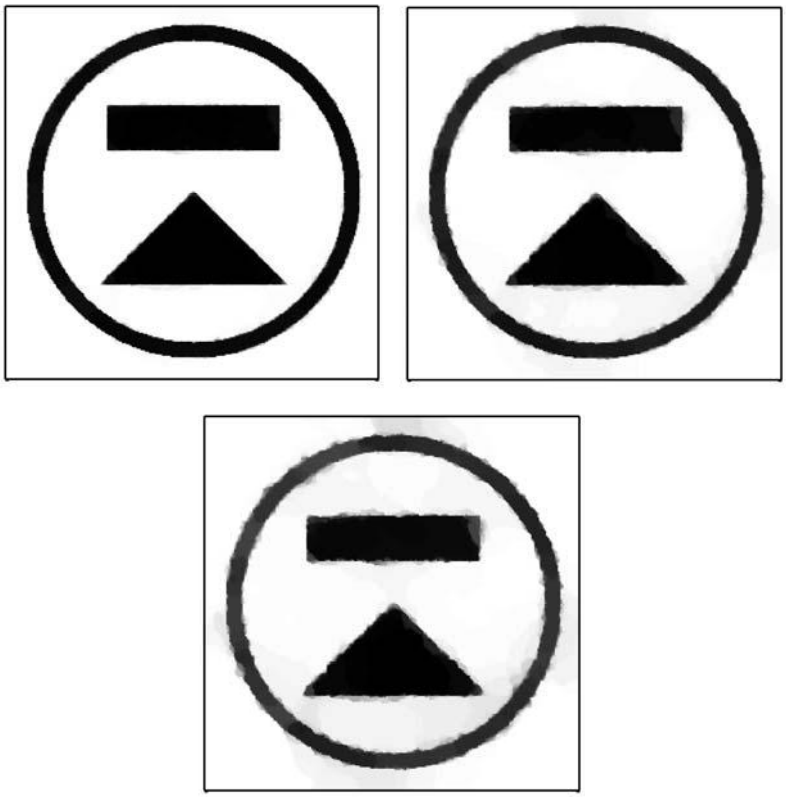

FIG. 5.2. *Example* 1: *Results of our algorithm with* $r = 2$ *for the image with* 20% *noise (upper row, left), with* 50% *noise (upper row, right), and with* 80% *noise (lower row).*

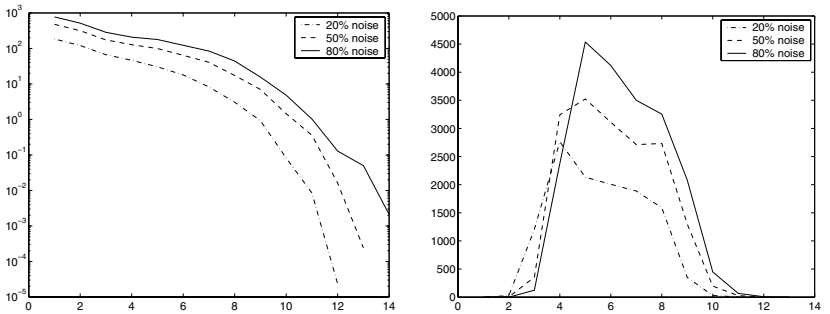

FIG. 5.3. *Example* 1: *Norm of the residual (left) and number of pixels where the dual variable is infeasible (right) versus iterations.*

rather independent of its initialization. Even for seemingly poor initializations u_0^h the algorithm converges and requires only two to three additional iterations when compared to a run initialized by the smoothed noisy image. The denoised images produced by our algorithm are shown in Figure 5.2. To document the convergence behavior we show the residual of the nonlinear system for the three noise levels in a logarithmic plot (Figure 5.3, left). We observe a fast decrease towards the end of

the iterations, which indicates a rapid local convergence of the method. To emphasize that our method, in contrast to the algorithm in, e.g., [6], allows violations of the dual constraints, in the right plot of Figure 5.3 we depict the number of points, where the iterates p_k^h are infeasible, i.e., where $|p_k^h|_s > (1+\varepsilon)\alpha$. Here $\varepsilon = 10^{-5}$ is introduced to compensate roundoff errors. Since the dual variable is initialized with $p_0^h = 0$, the number of infeasible points is small for the starting iterations, then it increases before it tends to zero as the algorithm approaches the solution.

[illegible] μ [illegible] γ. In our numerical tests we observe that the performance of the algorithm and the reconstructions are comparable for μ with $0 \le \mu \ll \alpha$. In particular, our choice $\mu = 0$ appears unproblematic. For large values of μ (i.e., $\mu \sim \alpha$ and larger), the quality of the reconstruction degrades (sharp edges are smoothed) and the number of overall PCG steps decreases. Concerning the influence of the parameter γ on the convergence behavior we observe that the method is not very sensitive with respect to γ. However, let us point out that large γ tends to decrease the iteration numbers.

[illegible]. We also tested our algorithm for images having different resolutions. For this purpose, the image containing 50% noise in Figure 5.1 was chosen, and reconstructions for analog images having 128×128 and 512×512 pixels were computed. Our algorithm stopped after 11, 12, and 11 iterations and overall 51, 58, and 57 PCG iterations for the resolutions 128×128, 256×256, and 512×512, respectively. This shows a remarkable stability with respect to the image size.

[illegible] $r > 2$. Next we test our algorithm with $r = 2.5$. For our test we use the image from Figure 5.1 containing 50% of Gaussian white noise and a rotated version of the same image. The parameters are set to $\mu = 0$, $\alpha = 0.9$, and $\gamma = 2.5 \cdot 10^{-5}$. We point out that for $r > 2$ the parameter γ must be chosen smaller as for $r = 2$ in order to obtain a reconstruction of comparable quality. This can be seen from the dual problem formulation $(\mathcal{P}_\gamma^\star)$, where s also influences the weight of the regularizing term; see the discussion in Remark 2.3. For both, the original and the rotated image, our algorithm terminates after 20 primal-dual iterations. Overall, 61 and 65 BICGSTAB iterations are needed, respectively. We observe local fast convergence of the iterates as expected from Theorem 3.6. Furthermore, during the iterations many components of the dual iterates violate the pointwise constraints. Since we are in the case $r > 2$, off-diagonal entries may be dampened in order to guarantee positive definiteness of the system matrix (see the discussion on page 11). In our computations, for the rotated image only in the first 10 iterations a few (at most 71) off-diagonal elements are scaled by dampening factors between 0.7 and 1. After iteration 10 no dampening is necessary. We contribute this behavior to the fact that the system matrix is already close to a symmetric matrix for which no dampening of off-diagonal elements is required (see the discussions on page 8 and (3.7)).

Results of our computations are shown in Figure 5.4. The reconstruction of the rotated image differs from the rotated reconstruction of the original image. This is partly due to the fact that the unit ball of the ℓ_r-norm is not invariant with respect to rotations for $r \neq 2$. Obviously, there are other reasons for the different reconstructions as well: rotating introduces errors to the image. Furthermore, one-sided differences for the gradients influence the flow of information in the reconstruction process.

[illegible]. Finally, we illustrate the restoration ability of our algorithm for blurred noisy images, i.e., for $K \neq \mathrm{id}$. We consider the image from Figure 5.1 without noise and choose a block Toeplitz matrix (see, e.g., [32]) for the discrete blurring operator K^h. Block Toeplitz matrices occur as

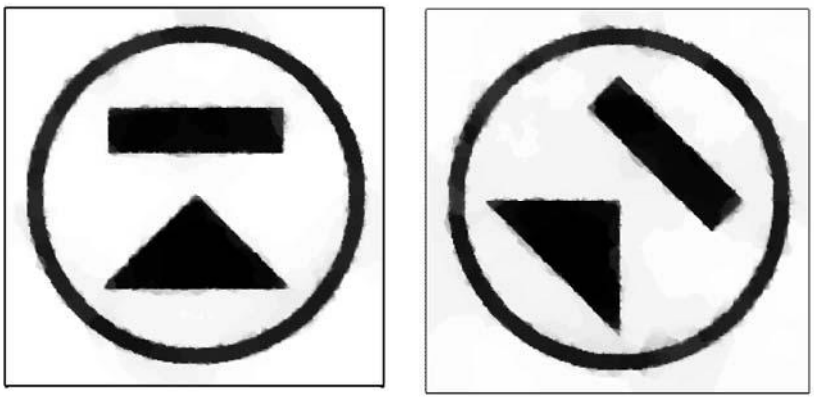

FIG. 5.4. *Example* 1: *Results of our calculations with* $r = 2.5$ *for the image from Figure* 5.1 *containing* 50% *of noise (left) and a rotated version of this image (right).*

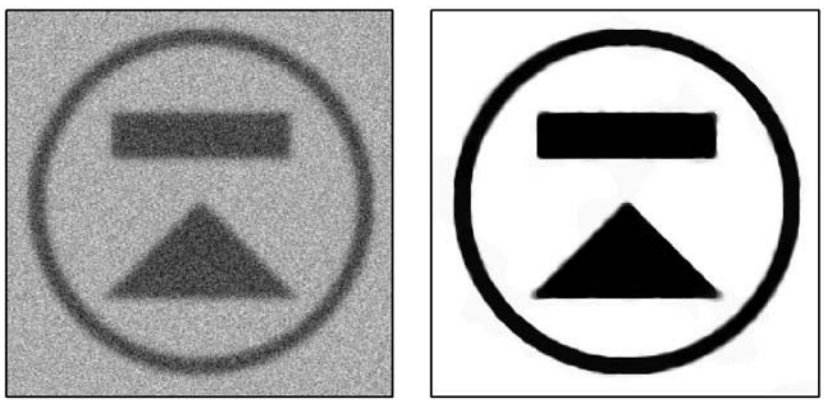

FIG. 5.5. *Example* 1: *Blurred noisy image (left) and reconstruction with* $r = 2$, $\alpha = 0.3$, *and* $\gamma = 10^{-3}$ *(right).*

matrix representations of discrete convolution operators, which represent a model for blurring of images. After applying K^h to the image, 20% of Gaussian white noise is added. The resulting degraded image can be seen on the left of Figure 5.5. For the reconstruction process we choose $r = 2$, $\alpha = 0.3$, $\gamma = 10^{-3}$, and $\mu = 0$. The result obtained after 16 primal-dual iterations can be seen on the right side of Figure 5.5.

5.1.2. Example 2 (validation of Theorem 3.6). In a second example we apply our method for enhancing the image shown in the left plot of Figure 5.6 that contains 10% of Gaussian white noise. Its resolution is 512×512 pixels. We apply Gauss-TV regularization, i.e., $r = 2$, with parameters $\mu = 0$, $\alpha = 0.08$, and $\gamma = 10^{-3}$. The result obtained after 11 iterations is shown in the right plot of Figure 5.6. To illustrate the convergence behavior of the method, in Table 5.2 we report on the norm of the nonlinear residual, the number of dually infeasible points, the step length, and the quotient

$$q_k = \frac{\|u_{k+1}^h - \bar{u}_\gamma^h\|}{\|u_k^h - \bar{u}_\gamma^h\|} \tag{5.1}$$

for each iteration. Above, $\bar{u}_\gamma^h$ denotes a beforehand calculated solution of the problem.

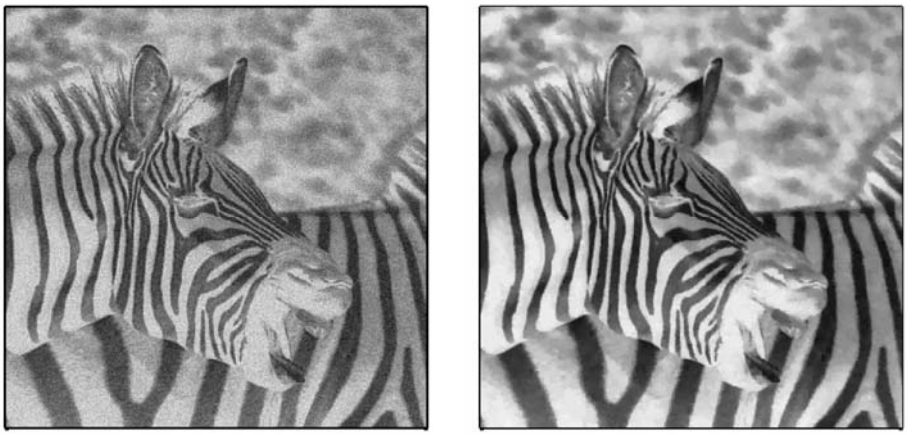

FIG. 5.6. *Example* 2: *Noisy* 512×512 *image (left) and results of our calculations with* $r = 2$, $\gamma = 10^{-3}$, *and* $\alpha = 0.08$ *(right).*

9	3.81e–1	2	878	1	0.143
10	6.12e–2	3	73	1	0.086
11	3.44e–3	2	6	1	0.009
12	1.42e–5	2	0	1	0.000

We observe a decrease of q^k (except for iteration 7) which implies a locally superlinear convergence of the iterates (compare with Theorem 3.6). Again, the algorithm makes use of iterates that heavily violate the inequality constraints imposed on the dual variable.

Numerical experiments show that a robust and fast convergence of the method is essentially based on the replacement of the system matrix H_k by H_k^+. In fact, due to our approximation technique based on (C), a positive definite matrix is obtained which guarantees that δ_u is a descent direction reducing the objective function of $(\mathcal{P}_\gamma)$. Indeed, our line search always accepts step size $\beta_k = 1$ for achieving a sufficient decrease.

5.2. Qualitative study of the dual regularization. The image restoration model $(\mathcal{P}_{BV})$ tends to produce piecewise constant, i.e., "blocky" images. This may be useful in some applications. However, for images containing affine regions with noise, the result will be an adverse "staircase" effect. To prevent the method from

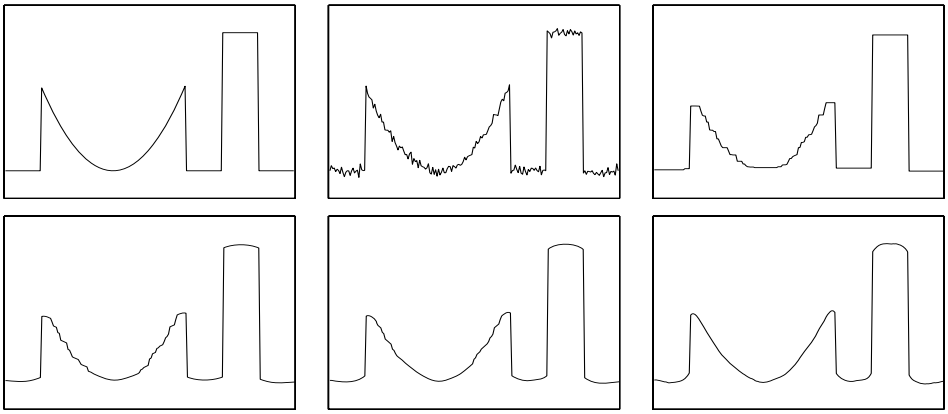

FIG. 5.7. *Upper row: Original one-dimensional image (left), noisy image (middle), and result of our calculations with* $\gamma = 10^{-10}$ *(right). Lower row: results obtained with* $\gamma = 0.1$ *(left),* $\gamma = 0.2$ *(middle), and* $\gamma = 0.5$ *(right).*

this oversharpening while preserving sharp edges, recently several strategies have been proposed and tested (see, e.g., [3, 7, 16]). In our approach, the parameter γ allows to control the BV model and the blocky structure in the image reconstruction. The regularization attached to γ induces a switch between a Gaussian-like regularization for small gradients and TV regularization for large gradients. To illustrate this influence of γ, a one-dimensional analogue to our algorithm was implemented. In Figure 5.7 the results for a one-dimensional image are shown, which were obtained by our algorithm with $\alpha = 10^{-2}$ and for various values of γ. The result for $\gamma = 0.5$ has exactly four active points at the solution. This implies that only at the four discontinuities of the original image TV regularization is applied, whereas all other regions are treated with a Gaussian regularization.

5.2.1. Example 3. Finally, we discuss the influence of γ on the two-dimensional noisy magnetic resonance (MR) image shown in Figure 5.8 (upper left). Its resolution is 256×256 pixels. A certain noise level in MR images is unavoidable due to background interference or other disturbances. Filters are used either to enhance the image quality without altering any image details or to prepare the image for a qualitative analysis, such as the segmentation of structures.

In [20] Gauss-TV denoising was shown to give good results for medical images. For this reason, we choose $r = 2$, the parameters $\mu = 0$ and $\alpha = 0.06$ and investigate the influence of the parameter γ on the reconstructed image. The result for $\gamma = 10^{-5}$ (see Figure 5.8, upper row, right) is obtained after 16 iterations. The reconstructions for $\gamma = 5 \cdot 10^{-3}$ and $\gamma = 5 \cdot 10^{-2}$ are obtained after 8 and 7 iterations of our algorithm, respectively. The corresponding results are shown in the lower row of Figure 5.8. Details of Figure 5.8 are shown in Figure 5.9. We observe that the reconstruction obtained with $\gamma = 10^{-5}$ is close to a piecewise constant image. This effect can be reduced by using larger γ values, e.g., $\gamma = 5 \cdot 10^{-3}$. However, depending on the noise level, if γ becomes too large, some of the noisy patterns may remain; see the result for $\gamma = 5 \cdot 10^{-2}$. In conclusion, this shows that the parameter γ can be useful in avoiding oversharpening of images while preserving sharp edges.

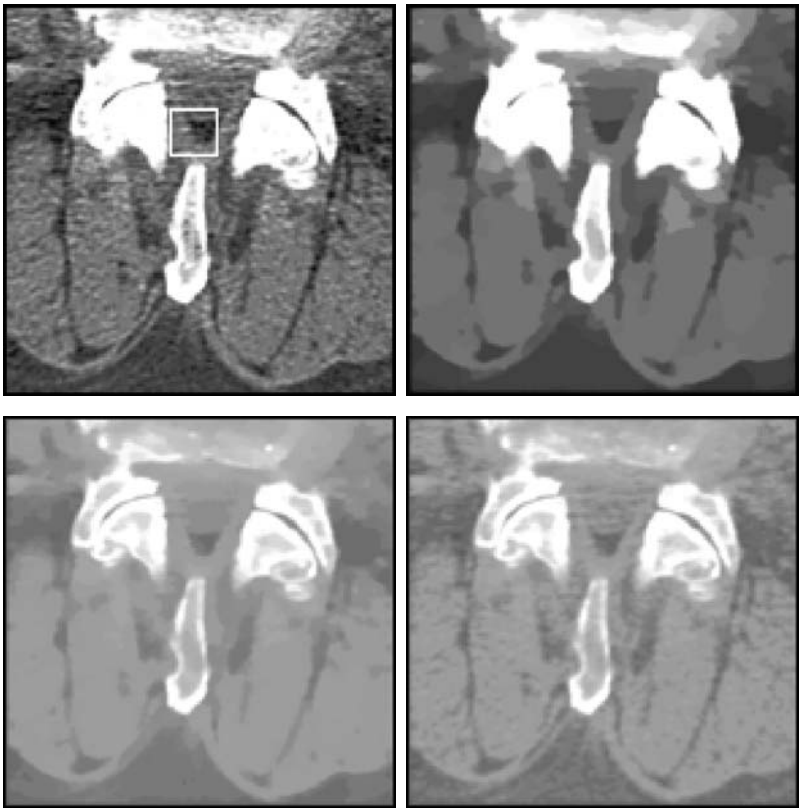

FIG. 5.8. *Example* 3: *Noisy magnetic resonance image (upper row, left, white box indicates the detail shown in Figure* 5.9*) and results of our calculations with* $r = 2$, $\mu = 0$, $\alpha = 0.06$ *and with* $\gamma = 10^{-5}$ *(upper row, right),* $\gamma = 5 \cdot 10^{-3}$ *(lower row, left), and* $\gamma = 5 \cdot 10^{-2}$ *(lower row, right).*

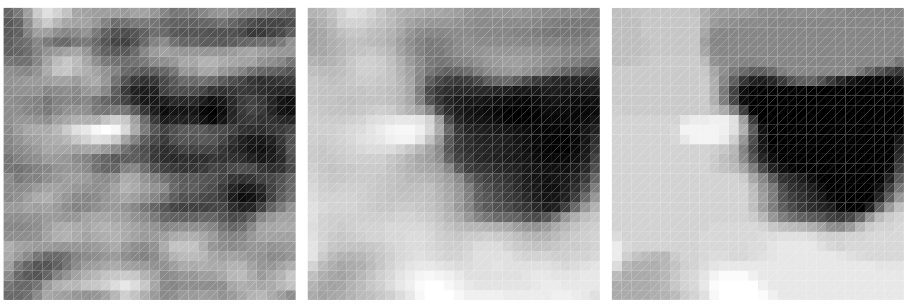

FIG. 5.9. *Example* 3: *Details of the images shown in Figure* 5.8. *Detail of the original image (right), reconstruction with* $\gamma = 5 \cdot 10^{-3}$ *(middle), and with* $\gamma = 10^{-5}$ *(right).*

Appendix A. Proof of Theorem 2.2. Subtracting the weak form of (2.4a) from the weak form of (2.3a) results in

$$\int_\Omega (\bar{u} - \bar{u}_\gamma) v \, dx + \mu \int_\Omega \nabla(\bar{u} - \bar{u}_\gamma)^\top \nabla v \, dx = \int_\Omega (\bar{\vec{p}}_\gamma - \bar{\vec{p}})^\top \nabla v \, dx \tag{A.1}$$

for all $v \in H_0^1(\Omega)$. Choosing $v := \bar{u} - \bar{u}_\gamma$ yields

$$\int_\Omega (\bar{u} - \bar{u}_\gamma)^2 \, dx + \mu \int_\Omega |\nabla(\bar{u} - \bar{u}_\gamma)|_2^2 \, dx = \int_\Omega (\bar{\vec{p}}_\gamma - \bar{\vec{p}})^\top \nabla(\bar{u} - \bar{u}_\gamma) \, dx. \tag{A.2}$$

Pointwise bounds for the term $(\bar{\vec{p}}_\gamma - \bar{\vec{p}})^\top \nabla(\bar{u} - \bar{u}_\gamma)$ are established as follows: First we split Ω into disjoint sets according to the complementarity conditions (2.3b) and (2.4b); namely, $\Omega = \mathcal{A}_\gamma \cup \mathcal{I}_\gamma = \mathcal{A} \cup \mathcal{I}$ with

$$\begin{aligned} \mathcal{A}_\gamma &= \{x \in \Omega : |\nabla \bar{u}_\gamma|_r^{r-1} > \gamma\}, \quad & \mathcal{I}_\gamma &= \Omega \setminus \mathcal{A}_\gamma, \\ \mathcal{A} &= \{x \in \Omega : |\nabla \bar{u}|_r^{r-1} > 0\}, & \mathcal{I} &= \Omega \setminus \mathcal{A}. \end{aligned} \tag{A.3}$$

Then we bound $(\bar{\vec{p}}_\gamma - \bar{\vec{p}})^\top \nabla(\bar{u} - \bar{u}_\gamma)$ separately on the four sets $\mathcal{A}_\gamma \cap \mathcal{A}$, $\mathcal{A}_\gamma \cap \mathcal{I}$, $\mathcal{I}_\gamma \cap \mathcal{A}$, and $\mathcal{I}_\gamma \cap \mathcal{I}$. Subsequently, we frequently dismiss the argument (x) when referring to function values at x. We start with $\mathcal{A}_\gamma \cap \mathcal{A}$, where we use the facts that $|\bar{\vec{p}}|_s = |\bar{\vec{p}}_\gamma|_s = \alpha$ and that $\bar{\vec{p}}_\gamma = \alpha\big(|\nabla \bar{u}_\gamma|^{r-1} \star (|\nabla \bar{u}_\gamma|)\big)/|\nabla \bar{u}_\gamma|_r^{r-1}$ and $\bar{\vec{p}} = \alpha\big(|\nabla \bar{u}|^{r-1} \star (|\nabla \bar{u}|)\big)/|\nabla \bar{u}|_r^{r-1}$:

$$\begin{aligned} (\bar{\vec{p}}_\gamma - \bar{\vec{p}})^\top \nabla(\bar{u} - \bar{u}_\gamma) &\le |\bar{\vec{p}}_\gamma|_s |\nabla \bar{u}|_r - \frac{\alpha}{|\nabla \bar{u}_\gamma|_r^{r-1}} |\nabla \bar{u}_\gamma|_r^r - \frac{\alpha}{|\nabla \bar{u}|_r^{r-1}} |\nabla \bar{u}|_r^r + |\bar{\vec{p}}|_s |\nabla \bar{u}_\gamma|_r \\ &= \alpha |\nabla \bar{u}|_r - \alpha |\nabla \bar{u}_\gamma|_r - \alpha |\nabla \bar{u}|_r + \alpha |\nabla \bar{u}_\gamma|_r = 0. \end{aligned} \tag{A.4}$$

Next we turn to the set $\mathcal{A}_\gamma \cap \mathcal{I}$, where we exploit the facts that $\nabla \bar{u} = 0$ and $|\bar{\vec{p}}_\gamma|_s = \alpha$:

$$\begin{aligned} (\bar{\vec{p}}_\gamma - \bar{\vec{p}})^\top \nabla(\bar{u} - \bar{u}_\gamma) &= (\bar{\vec{p}} - \bar{\vec{p}}_\gamma)^\top \nabla \bar{u}_\gamma \\ &\le |\bar{\vec{p}}|_s |\nabla \bar{u}_\gamma|_r - \frac{\alpha}{|\nabla \bar{u}_\gamma|_r^{r-1}} |\nabla \bar{u}_\gamma|_r^r \\ &= |\bar{\vec{p}}|_s |\nabla \bar{u}_\gamma|_r - \alpha |\nabla \bar{u}_\gamma|_r \le 0. \end{aligned} \tag{A.5}$$

On the set $\mathcal{I}_\gamma \cap \mathcal{A}$ one uses $|\bar{\vec{p}}_\gamma|_s \le \alpha$ and obtains similar to the above that

$$(\bar{\vec{p}}_\gamma - \bar{\vec{p}})^\top \nabla(\bar{u} - \bar{u}_\gamma) \le 0. \tag{A.6}$$

Finally, we turn to the set $\mathcal{I}_\gamma \cap \mathcal{I}$ where we have $\nabla \bar{u} = 0$, $|\nabla \bar{u}_\gamma|_r^{r-1} \le \gamma$, $|\bar{\vec{p}}|_s \le \alpha$, and $|\bar{\vec{p}}_\gamma|_s \le \alpha$. We obtain

$$\begin{aligned} (\bar{\vec{p}}_\gamma - \bar{\vec{p}})^\top \nabla(\bar{u} - \bar{u}_\gamma) &= (\bar{\vec{p}} - \bar{\vec{p}}_\gamma)^\top \nabla \bar{u}_\gamma \\ &\le |\bar{\vec{p}} - \bar{\vec{p}}_\gamma|_s |\nabla \bar{u}_\gamma|_r \\ &\le 2\alpha \gamma^{1/(r-1)}. \end{aligned} \tag{A.7}$$

Since $(\mathcal{A}_\gamma \cap \mathcal{A})$, $(\mathcal{A}_\gamma \cap \mathcal{I})$, $(\mathcal{I}_\gamma \cap \mathcal{A})$, $(\mathcal{I}_\gamma \cap \mathcal{I})$ provide a disjoint partitioning of Ω, the estimates (A.4)–(A.7) yield, together with (A.2),

$$\int_\Omega (\bar{u} - \bar{u}_\gamma)^2 \, dx + \mu \int_\Omega |\nabla(\bar{u} - \bar{u}_\gamma)|_2^2 \, dx \le \int_\Omega 2\alpha \gamma^{1/(r-1)} \, dx. \tag{A.8}$$

Hence, we infer that $\bar{u}_\gamma \to \bar{u}$ strongly in $H_0^1(\Omega)$ as $\gamma \to 0$. From (A.1) we obtain the weak convergence of $\bar{\vec{p}}_\gamma \to \bar{\vec{p}}$ in grad $H_0^1(\Omega) \subset \boldsymbol{L}^2(\Omega)$. This ends the proof. ∎

A MULTILEVEL NONLINEAR METHOD*

IRAD YAVNEH† AND GREGORY DARDYK†

Abstract. A multilevel nonlinear method (MNM) for the numerical solution of nonlinear partial differential equations is developed. The MNM algorithm is motivated and analyzed using a simplified model which retains the essential features of the new approach. It is thereby shown to combine the advantages of the two classical multigrid approaches to nonlinear problems. The analysis is supported by numerical tests for nonlinear differential equations in one and two dimensions.

Key words. multigrid, nonlinear partial differential equations, numerical methods for partial differential equations

1. Introduction.

Many problems in the sciences and engineering are modeled by nonlinear partial differential equations (PDEs), usually requiring numerical solution. Most commonly, the PDE is approximated by a finite difference, element, or volume discretization on a grid, which results in a large but sparse nonlinear algebraic system of equations. Reliable and computationally efficient solvers for such systems are essential for achieving relevant and accurate simulations.

One of the most efficient techniques for solving such large systems is the multigrid iterative method (see, for example, the classical [1, 14, 15], the expository [5], and the comprehensive [25]). In this approach, a sequence of progressively coarser grids is used to accelerate the convergence of some basic iterative process on the target grid. The basic iterative method is referred to as the "relaxation" or "smoothing" operator, as its objective is to smooth the error in the current approximation relative to the computational grid. There are two general approaches for solving discretized PDEs by multigrid methods. One is to perform a global linearization (GL), usually by Newton's method or some inexact variant thereof, and solve the resulting linear system approximately by a linear multigrid algorithm; this is then repeated iteratively. The second approach, represented by the full approximation scheme (FAS) of [1, 2] and the closely related nonlinear multigrid method (NLMG) of [14], is to perform only local linearization (LL)—in the error-smoothing process. Convergence acceleration is then provided by nonlinear coarse-grid operators.

Over the years, variants of these two general categories have been proposed and developed, usually in an ad hoc framework of a particular problem. Some recent examples of developments and implementations of GL multigrid solvers appear in [16, 17, 23, 27, 28], while LL applications can be found in, e.g., [4, 7, 11, 12, 13, 18, 19, 20, 21]. For "friendly" problems, both approaches work well and the difference in efficiency is usually not large (e.g., [25, section 5.3]). However, for more difficult problems, the two approaches often exhibit distinct behavior, with GL holding an advantage in some situations and LL in others. We are therefore motivated to develop

methods which will be at least as good as the more suitable of these two approaches, and often better than both.

The algorithm we propose is first motivated and analyzed in section 2, employing a simplified scalar analogy, and then presented in detail in section 3. The algorithm has been applied recently in [6] for the problem of two-dimensional phase unwrapping. However, this was an application-focused paper comparing different methods, with no analysis and just a very brief description of the algorithm.

Multigrid methods for [illegible] problems have been studied very extensively. For many problems, robust multigrid methods (such as the classical "algebraic" [3, 22], or "black-box" [8, 9] multigrid) are well known to be effective even in the presence of discontinuous coefficients and irregular domain boundaries. This represents an advantage for GL methods, where the problem solved per iteration is linear. LL approaches, on the other hand, generally require "direct" rediscretization of the nonlinear operator on the coarse grids, which is less robust. On the other hand, the [illegible] of efficient GL methods is usually small, which means that slow global search methods must often be applied before the fast GL method can be effective. This may represent a significant disadvantage.

1.1. Classical approaches. We first review two classical GL and LL methods. A two-grid framework is used, which is later generalized to a complete multigrid algorithm by recursion. Indices h and H denote fine- and coarse-grid operators and functions, respectively. The fine grid h is the target grid, while grid H is employed to accelerate convergence. We assume that, for [illegible] fine-grid operators, we can construct [illegible] coarse-grid approximations on grid H. By "robust" we mean that, given an appropriate smoother, the multigrid solver exhibits the typical fast and mesh-independent convergence.

Let the fine-grid problem be

$$N_h u_h = f_h, \tag{1}$$

where N_h is some discrete nonlinear matrix operator, u_h is the sought solution vector, and f_h is a given vector. Using iterative methods, it is assumed that we have some current approximation to the solution, denoted $\tilde{u}_h$, which we are trying to improve. It is convenient to subtract $N_h\tilde{u}_h$ from both sides of (1), obtaining the defect equation

$$N_h u_h - N_h\tilde{u}_h = f_h - N_h\tilde{u}_h \equiv r_h. \tag{2}$$

Let K_h denote a linearization of N_h. For example, using Newton's method we define K_h to be the Jacobian matrix of N_h, computed for the current approximation:

$$K_h = N_h'[\tilde{u}_h].$$

Then, Newton's method approximates (2) by

$$K_h(u_h - \tilde{u}_h) \approx r_h. \tag{3}$$

Let K_H denote the coarse-grid approximation to the linear operator K_h, which is obtained using a robust linear coarse-grid correction method. Indeed, in our simple analysis below, it is assumed that this coarse-grid operator provides a "perfect" approximation of the linear fine-grid operator (as would be the case if total reduction is used). That is, the two-grid algorithm, with suitable error-smoothing, solves the linear fine-grid problem exactly. Let I_h^H and I_H^h denote appropriate fine-to-coarse

(restriction) and coarse-to-fine (prolongation) operators, respectively. Then, after we smooth the error in (3) with a suitable relaxation, we solve the following coarse-grid problem:

$$K_H(u_H - \bar{I}_h^H \tilde{u}_h) = I_h^H r_h, \tag{4}$$

where $\bar{I}_h^H$ is some restriction operator[1] which may be different from I_h^H. Once u_H is computed, the correction is interpolated and added to $\tilde{u}_h$:

$$\tilde{u}_h^{new} = \tilde{u}_h + I_H^h(u_H - \bar{I}_h^H \tilde{u}_h). \tag{5}$$

We can optionally follow up with additional relaxation of (3), and this completes one Newton iteration.

Next, we review the classical FAS. First, the error in the fine-grid solution is smoothed using a suitable nonlinear relaxation method (which employs only local linearization). Let $\hat{N}_H$ denote a nonlinear coarse-grid approximation to N_h, obtained by rediscretizing the nonlinear problem on the coarse grid (normally using the same discretization as that of the fine grid; this is called direct discretization). The coarse-grid problem is then

$$\hat{N}_H u_H - \hat{N}_H \bar{I}_h^H \tilde{u}_h = I_h^H r_h. \tag{6}$$

The correction to the fine-grid approximation is added as in (5).

The two approaches are substantially distinct. In the GL method we approximate N_h by its linearization, which we then proceed to approximate on the coarse grid. Using suitable linear multigrid methods, the latter approximation is excellent, and the overall robustness of the method is therefore determined, loosely speaking, by the accuracy of the linearization, which depends in turn on the properties of the Jacobian and on the closeness of $\tilde{u}_h$ to u_h. In the LL approach, on the other hand, we use a nonlinear approximation to N_h on the coarse grid. If this approximation is sufficiently accurate, the LL algorithm can yield fast convergence even with a rather poor initial guess for the fine-grid solution, thus having an advantage over the GL approach. However, if $\hat{N}_H$ approximates N_h poorly, for example due to some nonsmoothness of the coefficients, then the method might not converge even if the initial error is very small and the nonlinearity very weak.

2. A scalar analogy. To motivate and analyze our approach, we present an analogy in the form of a simple scalar problem, which contains the essential elements we are studying. This analysis can be generalized to the multivariate vector-valued case, but this would increase the complication without yielding additional insight. Consider the problem of finding a real number u satisfying

$$N(u) = f, \tag{7}$$

where N is some twice continuously differentiable nonlinear real-valued function, and f is a constant which serves to help follow the analogy. For any given $\rho > 0$, denote $D_\rho = \{z : |u - z| < \rho\}$, and assume $|N'(z)| \geq K > 0$ for all $z \in D_\rho$.

[1] Since this is a linear problem, the coarse-grid correction is independent of this transfer operator; the usual choice for linear problems is $\bar{I}_h^H = 0$, which yields the so-called correction scheme.

2.1. FAS. Denote the current approximation to u by $u_n \in D_\rho$, and the error by $e_n = u_n - u$. Suppose that there exists some nonlinear function $\hat{N}$ which approximates N and which is easy to invert ($\hat{N}$ corresponds to $\hat{N}_H$ in our analogy). Then we can define an iteration process, which is analogous to FAS, by

$$\hat{N}(u_{n+1}) - \hat{N}(u_n) = f - N(u_n) \equiv r_n. \tag{8}$$

Suppose that $\hat{N}$ is an $O(\epsilon)$ approximation to N, where ϵ is a positive small parameter. That is,

$$\hat{N}(z) \equiv N(z) + \epsilon\phi(z), \tag{9}$$

for some twice continuously differentiable function ϕ. Substituting (9) into (8), we obtain after rearrangement

$$\epsilon[\phi(u_{n+1}) - \phi(u_n)] = f - N(u_{n+1}) \equiv r_{n+1}.$$

Using the mean-value theorem and the fact that $f = N(u)$, we get

$$\epsilon\phi'(\xi_1)(e_{n+1} - e_n) = -N'(\xi_2)e_{n+1},$$

for some $\xi_1 \in (u_n, u_{n+1})$ and $\xi_2 \in (u, u_{n+1})$. Assume $|\phi'| \le P < K/2\epsilon$ in D_ρ. Then

$$\left|\frac{e_{n+1}}{e_n}\right| = \left|\frac{\epsilon\phi'(\xi_1)}{N'(\xi_2) + \epsilon\phi'(\xi_1)}\right| \le \left|\frac{\epsilon P}{K - \epsilon P}\right| < 1. \tag{10}$$

Thus, the iteration converges to u, and the asymptotic convergence behavior is given by

$$\lim_{n\to\infty}\left|\frac{e_{n+1}}{e_n}\right| = \left|\frac{\epsilon\phi'(u)}{N'(u) + \epsilon\phi'(u)}\right| = \epsilon\left|\frac{\phi'(u)}{N'(u)}\right| + O\left(\epsilon^2\right) \quad \text{for } \epsilon \to 0. \tag{11}$$

2.2. Newton's method. The Newton iteration for this problem can be written as

$$N'(u_n)(u_{n+1} - u_n) = r_n. \tag{12}$$

For a sufficiently good initial approximation Newton's method converges. In particular, if $|N''| \le R$ in D_ρ, then

$$\left|\frac{e_{n+1}}{e_n}\right| \le \left|\frac{e_n R}{2K}\right|, \tag{13}$$

and the iteration converges to u if $|e_n| < 2K/R$. The well-known quadratic asymptotic convergence behavior is given by

$$\lim_{n\to\infty}\left|\frac{e_{n+1}}{e_n^2}\right| = \left|\frac{N''(u)}{2N'(u)}\right|. \tag{14}$$

2.3. Multilevel nonlinear method (MNM). Equations (10)–(11) and (13)–(14) demonstrate the advantage and disadvantage of each approach. Newton's method converges extremely fast when we have a good initial approximation ($|e_n|$ sufficiently small). FAS, on the other hand, will have a large attraction basin if $\hat{N}$ is a good

approximation to N, though it will not be useful when $\hat{N}$ approximates N poorly. It is generally far less dependent on a good initial approximation than Newton's method.

We now devise a method that has the advantages of both fast asymptotic convergence and a large attraction basin. First, we subtract $N(u_n)$ from both sides of (7) to obtain the defect equation,

$$N(u) - N(u_n) = r_n. \tag{15}$$

The key idea is to split the left side of (15) into a relatively large linear part and a small nonlinear part and use the $\hat{N}$ approximation only for the nonlinear part. Accordingly, we add and subtract $N'(u_n)(u - u_n)$ in the left side of (15). This yields

$$N'(u_n)(u - u_n) + F\,[\,N(u), N(u_n), N'(u_n), u, u_n\,] = r_n, \tag{16}$$

where

$$F\,[\,N(u), N(u_n), N'(u_n), u, u_n\,] = N(u) - N(u_n) - N'(u_n)(u - u_n). \tag{17}$$

Note that (16) is equivalent to the original problem (7), but the nonlinear term F (which is nothing but the remainder term of a truncated Taylor series) is only of size $O(|u - u_n|^2)$, while the first term and the right side are $O(|u - u_n|)$. We use the nonlinear approximation only for the small nonlinear part. That is, we define the iteration by

$$N'(u_n)(u_{n+1} - u_n) + F\big[\,\hat{N}(u_{n+1}), \hat{N}(u_n), \hat{N}'(u_n), u_{n+1}, u_n\,\big] = r_n. \tag{18}$$

Leaving only u_{n+1} terms on the left side we obtain

$$\begin{aligned} N'(u_n)u_{n+1} + \hat{N}(u_{n+1}) - \hat{N}'(u_n)u_{n+1} = r_n + N'(u_n)u_n \\ + \hat{N}(u_n) - \hat{N}'(u_n)u_n. \end{aligned} \tag{19}$$

Assume that we can easily invert the left side of (19) and solve for u_{n+1}. To analyze the convergence behavior of this iteration, we first use (9) to obtain, after rearrangement,

$$\epsilon\,\{\,[\phi(u_{n+1}) - \phi(u_n)] - \phi'(u_n)(u_{n+1} - u_n)\,\} = r_{n+1}. \tag{20}$$

Taylor series expansions now yield

$$\frac{\epsilon}{2}\phi''(\xi_1)(e_{n+1} - e_n)^2 = -e_{n+1}N'(\xi_2) \tag{21}$$

for some $\xi_1 \in (u_n, u_{n+1})$ and $\xi_2 \in (u_{n+1}, u)$. Denote

$$\mu = -\frac{N'(\xi_2)}{\epsilon e_n \phi''(\xi_1)}.$$

(If the denominator here is zero, then we have immediate convergence by (21), so we exclude this case.) Solving the quadratic equation (21) for the error reduction factor we obtain two solutions, the relevant one being

$$\frac{e_{n+1}}{e_n} = \mu + 1 - \mathrm{sign}(\mu)\,\sqrt{\mu^2 + 2\mu}. \tag{22}$$

TABLE 1
Comparison of convergence behavior for the scalar problem, under the assumptions $|N'| \geq K > 0$, $|N''| \leq R$, $|\phi'| \leq P$, $|\phi''| \leq Q$ *in* D_ρ.

Method	$\lim_{n\to\infty} \left\lvert \frac{e_{n+1}}{e_n^p} \right\rvert$	p	Sufficient for convergence
FAS	$\left\lvert \frac{\epsilon\phi'(u)}{N'(u)} \right\rvert$	1	$\left\lvert \frac{2\epsilon P}{K} \right\rvert < 1$
Newton	$\left\lvert \frac{N''(u)}{2N'(u)} \right\rvert$	2	$\left\lvert \frac{e_n R}{2K} \right\rvert < 1$
MNM	$\left\lvert \frac{\epsilon\phi''(u)}{2N'(u)} \right\rvert$	2	$\left\lvert \frac{2\epsilon e_n Q}{K} \right\rvert < 1$

(We assume here that we know how to choose the relevant solution when we solve (19) for u_{n+1}. In practice, this is not a problem when the iteration is relevant, since u_n provides a good initial approximation to the correct u_{n+1}.) A real solution to (22) exists if $\mu \notin (-2, 0)$. Furthermore, $|e_{n+1}/e_n| < 1$ for $\mu \notin [-2, 0]$. That is, the error is reduced by the iteration essentially whenever (19) has a real solution. In particular, if $|\phi''| \leq Q$ in D_ρ, then a sufficient condition for convergence of the new algorithm is

$$|\epsilon e_n| < \frac{K}{2Q}. \tag{23}$$

Furthermore, if the iteration converges to u, then the asymptotic convergence behavior is given by

$$\lim_{n\to\infty} \left\lvert \frac{e_{n+1}}{e_n^2} \right\rvert = \frac{\epsilon}{2} \left\lvert \frac{\phi''(u)}{N'(u)} \right\rvert + O\left(\epsilon^2\right) \quad \text{for } \epsilon \to 0. \tag{24}$$

We summarize the results of the scalar analysis in Table 1. These results are encouraging inasmuch as they show that the proposed method, which is analogous to the MNM described in detail below, enjoys both the quadratic convergence rate of Newton's method and the large attraction basin suggested by the ϵ coefficient. Indeed, the convergence rate of MNM is similar to the product of the convergence rates of FAS and Newton's method.

2.3.1. Backtracking. Although we expect to see a large attraction basin of the MNM, compared to Newton's method, there will be occasions where ϵ is not sufficiently small to yield convergence for a given initial guess. A well-known method for ensuring global convergence of Newton's method is backtracking [10]. While a Newton step does not ensure that the residual r_n will be reduced, the [illegible] of the Newton step is always one of descent. Thus, if we [illegible] the Newton correction by some sufficiently small positive scalar $0 < \lambda < 1$, we are assured that the residual will be reduced. Alternatively, instead of damping the correction step, we can damp the residual, by multiplying the right side of (12) by λ. Since this is a linear equation,

damping the right side is equivalent to damping the correction. We obtain from the damped-residual version of (12)

$$u_{n+1} - u_n = \frac{\lambda r_n}{N'(u_n)}. \tag{25}$$

Therefore we have, by the mean value theorem and (25),

$$\begin{aligned} r_{n+1} &= r_n - N'(\xi)(u_{n+1} - u_n) \\ &= r_n \left(1 - \lambda \frac{N'(\xi)}{N'(u_n)}\right) \end{aligned} \tag{26}$$

for some $\xi \in (u_n, u_{n+1})$. By (25), (26), and the continuity of N' (and the fact that it is bounded away from zero in D_ρ), there always exists a positive λ_{max} such that

$$\left|\frac{r_{n+1}}{r_n}\right| < 1 \quad \text{for every } \lambda \in (0, \lambda_{max}). \tag{27}$$

For MNM, damping the correction is no longer equivalent to damping the residual, since it is a nonlinear method. Indeed, as seen above, there might not even be a solution to the nonlinear iteration, hence no "direction" is defined. However, we show now that MNM also yields a "descent direction" if we backtrack using residual damping. This approach is in the spirit of the NLMG of [14], where residual damping is introduced in conjunction with a compensating overcorrection. Suppose that we multiply r_n in (16), (18), and (19) by $\lambda \in (0, 1)$. We then get from (19), denoting $\delta = u_{n+1} - u_n$ and using a Taylor series expansion,

$$\frac{1}{2}\hat{N}''(\xi_1)\delta^2 + N'(u_n)\delta = \lambda r_n \tag{28}$$

for some $\xi_1 \in (u_n, u_{n+1})$. If $\hat{N}''(\xi_1) = 0$, then (25)–(26) hold. Otherwise, δ is given by

$$\delta = \frac{N'(u_n)}{\hat{N}''(\xi_1)} \left(-1 \pm \sqrt{1 + 2\lambda r_n \hat{N}''(\xi_1)/N'(u_n)^2}\right). \tag{29}$$

Only the solution with the plus sign in front of the square root is relevant, and we assume that our nonlinear solver can find this solution. (In practice this is not a problem, as u_n provides an arbitrarily good initial guess for the correct u_{n+1} as λ is reduced.) We thus have

$$\delta = \frac{\lambda r_n}{N'(u_n)} + O\left(\lambda^2 r_n^2 \hat{N}''(\xi_1)/N'(u_n)^3\right), \quad \lambda r_n \to 0. \tag{30}$$

Now, similarly to (26),

$$\begin{aligned} r_{n+1} &= r_n - N'(\xi)(u_{n+1} - u_n) \\ &= r_n \left(1 - \lambda \frac{N'(\xi)}{N'(u_n)} + O\left(\lambda^2 r_n^2 \hat{N}''(\xi_1)/N'(u_n)^3\right)\right) \quad \text{for } \lambda r_n \to 0, \end{aligned} \tag{31}$$

so here too we can always choose some sufficiently small positive λ_{max} such that (27) holds. Indeed, the residual reduction factor of damped MNM tends to that of the damped Newton step as λ tends to zero. This is expected, as MNM can be viewed as a nonlinear correction to Newton's method, with the correction tending to zero with the damping parameter (cf. section 3.2).

3. MNM: A multilevel nonlinear method. We return now to the actual problem and the multigrid algorithm. Let $\hat{K}_H$ denote the linearization of $\hat{N}_H$. Then, analogously to (19), we define the coarse-grid problem as

$$N_H u_H = f_H, \tag{32}$$

with

$$N_H = K_H + \hat{N}_H - \hat{K}_H \tag{33}$$

and

$$f_H = I_h^H r_h + N_H \bar{I}_h^H \tilde{u}_h. \tag{34}$$

Note that K_H and $\hat{K}_H$ are analogous to $N'(u_n)$ and $\hat{N}'(u_n)$, respectively. That is, we are assuming that K_H is an excellent approximation to K_h, while $\hat{K}_H$ might not be as good. This makes sense because, as noted above, there are well-known methods that provide excellent coarse-grid approximations to linear fine-grid operators, whereas direct discretization often does not when coefficients are nonsmooth.

3.1. The MNM algorithm. The multigrid algorithm, which we describe next, is obtained from the two-grid algorithm by the usual recursion. Specific details, such as the relaxation method, intergrid transfers, and algorithmic parameters, can vary. In sections 4.1 and 4.2 we specify the particular choices used in our numerical tests.

A hierarchy of grids is defined and numbered 0 to M, where grid 0 is the target grid, which is the finest one, and grid M is the coarsest. On each level (grid) j we solve approximately a problem of the form

$$N_j u_j + L_j u_j = f_j, \tag{35}$$

where u_j is the vector of unknowns, f_j is a given vector, N_j—like $\hat{N}_H$ above—is a grid-j discretization of N (as in the classical FAS algorithm), and L_j is a linear correction operator (similar to $K_H - \hat{K}_H$ above). We specify the usual integer parameters, ν_1 and ν_2, which are the number of relaxation sweeps carried out before and after the coarse-grid correction, respectively, and the cycle index γ, which specifies the number of recursive calls (1 for a so-called V cycle, 2 for a W cycle, and so on.)

Initially, u_0 is set to some approximation (which is normally obtained using the so-called full multigrid (FMG) approach [1]), and L_0 is the zero matrix of appropriate size. Then, the MNM cycle, described below, is called repeatedly for $j = 0$, until some convergence criterion is met.

function $u_j = \mathrm{MNM}(u_j, N_j, L_j, f_j, j, \gamma, \nu_1, \nu_2, M)$

If $(j < M)$ ** On every grid but the coarsest **
{
Relax ν_1 times the equation,
$N_j u_j + L_j u_j = f_j$
Compute the residual,
$r_j = f_j - (N_j u_j + L_j u_j)$
Construct the linearized operator,
$K_j = L_j + N'_j[u_j]$
Initialize the coarse-grid solution,
$u_{j+1} = \bar{I}_j^{j+1} u_j$
Compute the robust coarsening of the linearized operator,
$K_{j+1} = I_j^{j+1} K_j I_{j+1}^j$
Compute L_{j+1} by subtracting off the linearization of N_{j+1},
$L_{j+1} = K_{j+1} - N'_{j+1}[u_{j+1}]$
Compute the coarse-grid right side,
$f_{j+1} = I_j^{j+1} r_j + N_{j+1} u_{j+1} + L_{j+1} u_{j+1}$
Call MNM recursively (repeat γ times),
$u_{j+1} = \mathrm{MNM}(u_{j+1}, N_{j+1}, L_{j+1}, f_{j+1}, j+1, \gamma, \nu_1, \nu_2, M)$
}
else ** On the coarsest grid **
{
Solve approximately the equation,
$N_M u_M + L_M u_M = f_M$
Return u_M
}
end if

Interpolate and add the correction,
$u_j = u_j + I_{j+1}^j (u_{j+1} - \bar{I}_j^{j+1} u_j)$
Relax ν_2 times the equation,
$N_j u_j + L_j u_j = f_j$
Return u_j

The restriction and prolongation operators, denoted here by I_j^{j+1} and I_{j+1}^j, respectively, are chosen so as to yield a robust coarse-grid approximation of the linear operator, K_j. These can be any of several matrix-dependent transfer operators that have been developed over the years. In our two-dimensional (2D) tests we use the black-box multigrid method of [8]. For the restriction of u_j we use the operator $\bar{I}_j^{j+1}$, which can be simple injection or some local averaging. Observe that the combined operator, $N_j + L_j$, is nothing but an approximation on level j of the fine-grid operator, N_0. Thus, the relaxation methods used in the classical FAS algorithm, such as Gauss–Newton, are suitable here as well. It is important to note that, since we are combining two different approximations to the fine-grid operator (for example, when computing the linear correction, L_j), they need to be scaled compatibly. We explain this issue and demonstrate the algorithm with an explicit simple example in the next subsection. (See also comments regarding scaling in section 4.1.)

3.1.1. A concrete example. By way of illustration, we now show an explicit example of the MNM cycle with two grids. Capital subscripts correspond to coarse-grid values and operators. Consider the one-dimensional (1D) nonlinear problem,

$$Nu = -u_{xx} - Ce^u = f, \tag{36}$$

with some appropriate boundary conditions, which are not important for this discussion. Here, C is a positive constant and $f(x)$ is given. (With $f = 0$ and zero Dirichlet boundary conditions, this is the classical Bratu problem.) Standard second-order finite-difference discretization on a grid of mesh size h produces a nonlinear system,

$$N_h u_h = f_h, \tag{37}$$

with the ith row of $N_h u_h$ given by

$$(N_h u_h)_i = h^{-2}\left[-u_{i-1} + 2u_i - h^2 Ce^{u_i} - u_{i+1}\right]. \tag{38}$$

Here and below, we omit the h subscript when using subscripts to denote row number (equivalently, mesh point). Let $\tilde{u}_h$ denote the current approximation to u_h. Employing Newton linearization, we obtain $K_h = N_h'(\tilde{u}_h)$, where the ith row of $K_h u_h$ can be written as

$$(K_h u_h)_i = h^{-2}\left[-u_{i-1} + u_i(2 - \sigma_i) - u_{i+1}\right], \tag{39}$$

with

$$\sigma_i = h^2 Ce^{\tilde{u}_i}.$$

Evidently, K_h approximates the linear operator,

$$K = -\partial_{xx} - Ce^{\tilde{u}}.$$

Assume standard coarsening, with coarse mesh point I coinciding with fine mesh point $i = 2I$. As in FAS, we need to transfer the current approximation, $\tilde{u}_h$, to the coarse grid and construct the nonlinear coarse-grid operator, $\hat{N}_H$, where $H = 2h$ denotes the coarse mesh interval. Assume we use injection for this transfer,

$$\tilde{U}_H = \bar{I}_h^H \tilde{u}_h,$$

with $\tilde{U}_I = \tilde{u}_i$. The operator $\hat{N}_H$ is obtained by rediscretization on the coarse grid. However, we introduce a multiplicative scaling, to be discussed below. The Ith row of $\hat{N}_H U_H$ is thus given by

$$\left(\hat{N}_H U_H\right)_I = B_I H^{-2}\left[-U_{I-1} + 2U_I - H^2 Ce^{U_I} - U_{I+1}\right], \tag{40}$$

where B_I is the scaling. The linearization of $\hat{N}_H$ is denoted by $\hat{K}_H$, with the Ith row of $\hat{K}_H U_H$ given by

$$\left(\hat{K}_H U_H\right)_I = B_I H^{-2}\left[-U_{I-1} + U_I(2 - \Sigma_I) - U_{I+1}\right], \tag{41}$$

with

$$\Sigma_I = H^2 Ce^{\tilde{U}_I} = 4\sigma_i.$$

Next, we turn to the construction of the robust coarse-grid approximation to K_h. The appropriate prolongation operator (see discussion in section 4) is such that the interpolated function, $v_h = I_H^h U_H$, satisfies the homogeneous equation, $(K_h v_h)_i = 0$, at odd i:

$$\left(I_H^h U_H\right)_i = \begin{cases} U_{i/2} & \text{if } i \text{ is even,} \\ \frac{U_{(i-1)/2}+U_{(i+1)/2}}{2-\sigma_i} & \text{if } i \text{ is odd.} \end{cases} \tag{42}$$

As the problem is symmetric, we choose the restriction to be the transpose of the prolongation. Therefore, the Galerkin coarsening rule yields the robust coarse-grid approximation to K_h:

$$K_H = \left(I_H^h\right)^T K_h I_H^h.$$

Observe that the restriction, I_H^h, appears as a factor both in K_H and in the right-hand side of the coarse-grid equation (since it is used to restrict the residuals). Hence, its scaling is unimportant with respect to K_H, since it cancels out. In contrast, when we construct $\hat{K}_H$ by direct discretization, we are implicitly assuming that the rows of the restriction sum up to one (hence, that a constant function remains invariant when restricted to the coarse grid). Since in MNM we combine the different operators, we must therefore scale K_H and N_H for consistency by multiplying them by the row-sums of the restriction operator. For $I = i/2$, this yields

$$B_I = 1 + \frac{1}{2-\sigma_{i-1}} + \frac{1}{2-\sigma_{i+1}} = \frac{2+\delta^- + \delta^+ - \sigma_i}{2-\sigma_i},$$

where

$$\delta^{\pm} = \frac{2-\sigma_i}{2-\sigma_{i\pm1}}.$$

For the Galerkin coarse-grid linear operator, an explicit computation yields

$$\begin{aligned}&(K_H U_H)_I \\ &\quad = B_I \left(\frac{4}{2+\delta^- + \delta^+ - \sigma_i}\right) H^{-2} \left\{-\delta^- U_{I-1} + \left[-\delta^- - \delta^+ + (2-\sigma_i)^2\right] U_I - \delta^+ U_{I+1}\right\}.\end{aligned} \tag{43}$$

The linear correction to $\hat{N}_H$ is given by $L_H = K_H - \hat{K}_H$, and the complete MNM coarse-grid operator is given by

$$N_H = \hat{N}_H + L_H = N_H + K_H - \hat{K}_H, \tag{44}$$

with $\hat{N}_H$, K_H, and $\hat{K}_H$ given by (40), (43), and (41), respectively.

To get an impression of the character of L_H, observe that if u_h is smooth (that is, undergoes a relative change of order h from one grid point to the next), then $\delta^{\pm} = 1 + O(h^3)$ (because σ_i itself is of order h^2). Substituting 1 for $\delta^{\pm}$, we obtain by a straightforward computation

$$(L_H U_H)_I = B_I H^{-2} \frac{\sigma_i}{4-\sigma_i} \left(-U_{I-1} + 2U_I - U_{I+1}\right).$$

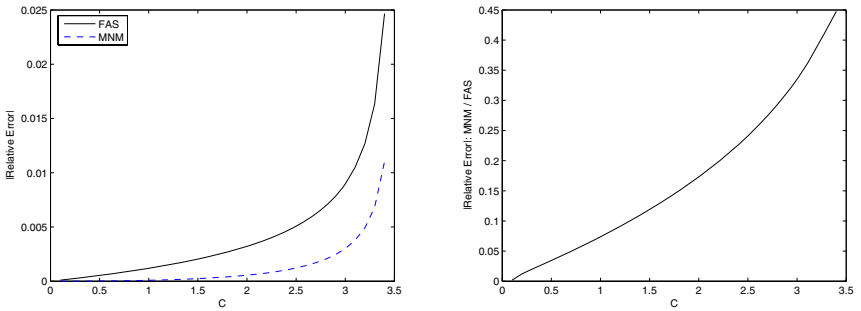

FIG. 1. *The maximal relative difference between the fine-grid solution to the* 1*D Bratu problem and two coarse-grid solutions, one using* $\hat{N}_H$ *(FAS) and the other using* N_H *(MNM). The relative differences appear on the left and their ratio on the right.*

Note that the correction L_H increases somewhat the relative size of the Laplacian in the nonlinear operator. This turns out to compensate for the slight extra "stiffness" of the coarse grid compared to the fine grid. Thus, it improves the nonlinear coarse-grid approximation to the fine-grid operator, as demonstrated below. Observe that the linear correction is normally very small, since K_H and $\hat{K}_H$ are both $O(h^2)$ approximations to the scaled K. It becomes large only when $\sigma_i \sim 1$. Furthermore, L_H is "very slightly" nonsymmetric due to the spatially varying scaling factor, B_I. This may become significant on coarse grids. We may choose to retain the symmetry by fixing the scaling factor to be some constant nominal value.

To demonstrate the effect of the linear correction, L_H, we perform a simple numerical test. We set f and the boundary conditions to zero, and the domain to $(0, 1)$, and solve the problem on a grid of 16 mesh intervals—our fine grid—for a range of positive C values. It is well known that solutions for the differential problem exist only for C that is below some critical value, and the problem becomes more and more difficult as C approaches this value. Next, we approximate and solve the same problem on a coarse grid of eight intervals, once using $\hat{N}_H$ (FAS) and once using N_H (MNM), employing the previously determined fine-grid solution to compute L_H. We compare in Figure 1 the maximal difference between the fine-grid solution and the two coarse-grid solutions. Evidently, the MNM coarse-grid operator provides a much better approximation. The relative gain in accuracy is very large when the parameter C is small (because the linearizations then yield excellent approximations), and it becomes smaller and smaller, but still quite significant, as the critical turning point is approached.

3.1.2. Computational cost. The number of operations per V cycle is proportional to the number of unknowns in all three algorithms—FAS, Newton, and MNM. The actual cost per cycle for each of the methods depends on the problem and on the implementation. FAS requires evaluating the nonlinear operator for every relaxation sweep and for residual computation. Newton's method requires only one linearization per cycle, which is comparable in cost to an evaluation of the nonlinear operator, and the resulting linear operator can then be stored. On the other hand, after each such linearization, a setup of the robust linear solver with its matrix-dependent intergrid transfers and (Petrov–)Galerkin coarse-grid operators needs to be applied. The MNM algorithm is essentially a combination of the two, starting from the second-finest grid. An MNM cycle is therefore more expensive than either an FAS or a Newton iteration,

but it is less expensive than the sum of the two. In particular, on the finest grid, where normally most of the work is performed, the MNM and FAS algorithms are identical because there is no linear correction term.

3.1.3. Backtracking. We introduce an optional backtracking procedure into the basic MNM algorithm, both for the local (scalar, as we use nonlinear pointwise Gauss–Seidel relaxation) nonlinear problems encountered in the relaxation, and for the coarse-grid correction. In the local problems we damp the Newton-step corrections in the classical manner, while for the coarse-grid corrections we backtrack via residual damping as described in subsection 2.3.1. We basically use the classical backtracking procedure of [10] with the following changes: (1) We do not compute the condition number and redefine the problem for poorly conditioned problems; (2) We limit the number of attempts to reduce the residual by backtracking; if unsuccessful, the correction is simply discarded. The reason for these changes is that we do not want to spend much effort to reduce the residual of coarse-grid problems when this is unlikely to contribute much to the convergence of the fine-grid problem. The greatest difficulties occur on the coarser grids (because, in our analogy, ϵ is larger there), and it is often not cost-effective to insist on residual reduction on the very coarse grids, where there might not even be a solution in some cases. As the fine-grid residual is reduced, the convergence on all the grids normally becomes much easier, consistent with our analysis.

The backtracking procedure naturally adds to the cost of the algorithm, but this increase is rarely substantial. In the relaxation, the main increase normally comes from the need to recompute the residuals of the local problems to check at which of the equations (if any) backtracking is required. Usually, there are few such locations, if any, and the backtracking procedure is implemented only for those equations. For the coarse-grid correction process (which backtracks by residual damping), there is a potential for a greater increase in cost, because if the coarse-grid correction fails to reduce the residual norm then we discard it and recompute the coarse-grid correction with a damped residual, etc. As we shall show, the actual increase in the operation count in our tests was small.

The measure we use to describe the actual complexity of the MNM algorithm with backtracking is the [illegible], $\bar{\gamma}$. Recall that the cycle index γ is the number of recursive calls to function MNM in the standard algorithm (with no backtracking). Hence, the number of visits to grid j is γ^j. Due to the backtracking, the number of visits may be larger, resulting in an effective cycle index that is larger than the nominal one. Suppose that the actual total number of relaxation sweeps performed on grid j in a particular computation, divided by the number of sweeps carried out on the finest grid, is k_j, and that the number of variables on grid j is n_j. Then the effective cycle index is naturally defined implicitly as the only positive solution of

$$\sum_{j=0}^{M} n_j \bar{\gamma}^j = \sum_{j=0}^{M} k_j n_j. \tag{45}$$

In particular, if $n_j/n_{j+1} \approx \tau > 1$, where the coarsening ratio τ is independent of j, then

$$\bar{\gamma} \approx \frac{\sum_{j=0}^{M-1} k_{j+1} \tau^{-j}}{\sum_{j=0}^{M} k_j \tau^{-j}}. \tag{46}$$

In this case, the bound (2.4.14) of [25, p. 51] for the total computational work per cycle holds approximately: if the fine-grid work is Cn_0, then the total work is approximately

$$W \approx \frac{\tau C n_0}{\tau - \bar{\gamma}} \quad \text{for } \bar{\gamma} < \tau. \tag{47}$$

In a parallel computing environment, the standard backtracking procedure is relatively more troubling, since it is done sequentially. In this case we would prefer to compute in parallel several coarse-grid solutions—with different residual-damping parameters ($\lambda = 1, 1/2, 1/4, \ldots$, for example)—and choose the correction with the largest damping parameter which still yields a reduction of the residual norm, discarding the rest.

3.2. Adaptive MNM. An interesting alternative (or addition) to backtracking, is a more general adaptive procedure. Consider the MNM coarse-grid operator N_H of (33). Two points of view suggest themselves: (a) The first term, K_H, is the main term, while the second and third terms comprise a nonlinear correction for the defect which results from approximating N_h by the usual Newton linearization; (b) The second term, $\hat{N}_H$, is the main term, while the first and third terms form a linearized correction for the defect resulting from the nonrobustness of the FAS approximation. Normally, these corrections improve the coarse-grid approximation. Suppose, however, that there is somewhere a discontinuity in a coefficient. This may show up as a large linear correction, $K_H - \hat{K}_H$, because $\hat{K}_H$ is no longer a good approximation to K_h. This indicates that $\hat{N}_H$ itself is a poor approximation to N_h, and therefore we might be better off not using the FAS contribution. We should then damp (perhaps completely) the [illegible] correction, reducing to Newton's method. On the other hand, suppose that due to some nonlinear near-singularity the linearization provides a poor approximation. This would show up as a large nonlinear correction. We might then be better off using FAS in this case, and we should damp the [illegible] correction. Accordingly, we introduce two nonnegative parameters, a and b, and redefine N_H as

$$N_H = aK_H + b\hat{N}_H + (1 - a - b)\hat{K}_H. \tag{48}$$

We thus obtain MNM for $a = b = 1$, Newton's method for $a = 1$, $b = 0$, and FAS for $a = 0$, $b = 1$. In fact, a and b can be diagonal matrices instead of scalars, so that the damping is chosen locally.

Although the details are quite different, this use of parameters to obtain favorable "compromises" between different types of coarse-grid operators is in the spirit of the nonlinear multigrid approach of [14]. There, the coarse-grid operator varies from that of FAS—when the (multiplicative) parameter is equal to one, to an operator that is linearized around the initial coarse-grid approximate solution—when it is equal to zero. This effect is somewhat similar to what we obtain in the present approach as we vary (a, b) from $(0, 1)$ to $(1, 0)$ if we use a fixed-point linearization.

We applied a version of adaptive MNM in [6], fixing $b = 1$ and optimizing $a \in [0, 1]$ over the convergence factor at very coarse grids. This approach proved quite useful, but we expect that a more refined analysis will allow us to yield still greater dividends from the adaptive approach. We do not pursue this further here; however, in section 4.2 we demonstrate the potential of this approach by manually selecting appropriate values of a and b for problems which prove to be difficult for the standard MNM, even with backtracking.

4. Numerical tests.

4.1. 1D tests. We first test our algorithm on the following nonlinear 1D diffusion problem:

$$
\begin{aligned}
Nu \equiv -\left[\, g(x,u,u_x)u_x \,\right]_x &= f(x), \quad x \in (0,1),\\
u(0) &= u_\ell,\\
u(1) &= u_r,
\end{aligned}
\tag{49}
$$

where u is the unknown function, and g, f, u_ℓ, u_r are given. Discretizing by second-order accurate finite differences on a uniform grid $x_h = \{x_i\}_{i=0}^n$, with mesh size $= 1/n$, we obtain the nonlinear system

$$
N_h u_h = f_h, \tag{50}
$$

where the ith equation in the system is given by

$$
-\frac{g_{i+1/2}(x_h, u_{i+1}, u_i)[u_{i+1} - u_i] - g_{i-1/2}(x_h, u_i, u_{i-1})[u_i - u_{i-1}]}{h^2} = f_i, \quad i = 1, \ldots, n-1. \tag{51}
$$

Here, u_i and f_i are the ith components of u_h and f_h, respectively, and $g_{i\pm1/2}$ is some discrete approximation to g midway between grid points i and $i \pm 1$. The boundary conditions yield $u_0 = u_\ell$ and $u_n = u_r$. In our test problems we define g to correspond to the so-called van Genuchten curve modeling hydraulic conductivity of unsaturated soils [26]. This problem, in two dimensions, has been studied extensively by Starke in [23, 24] employing a least-squares finite elements approach with, in the latter paper, a GL multilevel approach, and by Korsawe and Starke in [18], where three LL methods (variants of FAS) are compared.

Given constant parameters k_s, α, and p, we have

$$
g = g(u) = \begin{cases} 1, & u \geq 0,\\ k_s \psi(|u|), & u < 0, \end{cases} \tag{52}
$$

where

$$
\psi(\theta) = [1 + (\alpha\theta)^p]^{-\frac{q}{2}} \left(1 - \frac{(\alpha\theta)^{p-1}}{[1 + (\alpha\theta)^p]^q}\right)^2, \tag{53}
$$

with $q = 1 - 1/p$. To represent $g_{i\pm1/2}$ we compute $g(u_i)$ and $g(u_{i\pm1})$ and use simple averaging. For a given domain and boundary conditions, this problem generally becomes more difficult for smaller p and larger α. For $p < 2$, g' fails to satisfy a Lipschitz condition at $u = 0$, and $g(u)$ actually tends to a step function for $p \to 1^+$. For α that is not small compared to one, the solution exhibits a thin boundary layer near $x = 0$ (in our example), which narrows quickly as α grows. The boundary conditions are $u_\ell = -2$, $u_r = 1$, and we set $f = 0$. The initial guess for the fine-grid solution is the linear profile which satisfies the boundary conditions. We perform V cycles until the ℓ_2 residual norm is reduced to at most 10^{-8} times its initial value. We backtrack if the coarse-grid correction plus the (single) postrelaxation sweep has failed to reduce the ℓ_2 norm of the residual. In this case, we discard the coarse-grid correction, damp the residual according to the strategy of [10], and compute a new coarse-grid correction.

For error smoothing we use Gauss–Seidel relaxation in red-black ordering, whereby we first relax at the even-indexed points and then at the odd-indexed points. To

describe the prolongation operator, let the n_j by n_j matrix, K_j, denote the linearized operator on grid j. Then the prolongation operator is a matrix P (denoted I_{j+1}^j above) of size n_j by n_{j+1}, with

$$P_{i,k} = \begin{cases} 1 & \text{if } i = 2k, \\ -\frac{K_{i,i\mp1}}{K_{i,i}} & \text{if } i = 2k \pm 1, \\ 0 & \text{otherwise.} \end{cases} \tag{54}$$

The restriction operator (denoted I_j^{j+1} above) is a matrix R of size n_{j+1} by n_j, whose (j,i)th element is given by (54), with K_j replaced by its transpose. With these choices and the construction of the coarse-grid operator by Petrov–Galerkin coarsening, K_j remains a tridiagonal matrix on all the grids. Furthermore, for linear problems, the multigrid cycle is an exact solver (equivalent to total reduction), provided that ν_1 or ν_2 is nonzero and the problem on the coarsest grid is solved exactly. This is a well-known result of the fact that, after we relax on the fine grid at the odd-indexed points—leaving there zero residuals—the remaining error is in the range of the prolongation defined by (54).

As explained in subsection 3.1.1, it is important to scale the different coarse-grid approximations which are added/subtracted to be compatible. The usual FAS algorithm assumes that rows of the restriction matrix sum up to 1. Therefore, in the MNM algorithm of section 3.1, the correct scaling of N_{j+1} (hence also N'_{j+1}) is by left-multiplication by a diagonal matrix whose elements are the row-sums of the restriction matrix, I_j^{j+1}. Such a rescaling can result in the loss of symmetry. We choose to simply scale by the constant 2, which is correct for the standard full-weighting, and is an excellent approximation on all the grids for the actual restriction.

In all our tests the finest grid is 256 intervals. For the nonlinear algorithms (MNM and FAS) we use seven multigrid levels, coarsening down to a grid of three interior variables. On the coarsest grid we relax 10 times. We use $\gamma = 1$ (V cycle) and $\nu_1 = \nu_2 = 1$. The FAS algorithm is the standard one (except that we also allow backtracking), with injection for $\bar{I}_h^H$ (local averaging is sometimes better for FAS, but not dramatically so in our tests).

We show results for physical parameters $\alpha = 0.5, 1.0$, and $p = 2.5, 1.8$, in Figures 2, 3, 4, and 5, with NWT denoting Newton's method. In Figure 2, it is evident that MNM indeed behaves as predicted by the analysis. Its asymptotic convergence rate is similar to that of NWT, but it gets there much sooner. In the moderate case (top left), $\alpha = 0.5$, $p = 2.5$, all three methods perform well. For $\alpha = 1.0$, $p = 2.5$ (bottom left) there is a rather thin boundary layer near $x = 0$, as seen in Figure 3. This nonsmooth solution causes FAS convergence to slow down significantly, while the other two methods remain effective. For $\alpha = 0.5$, $p = 1.8$ (top right), on the other hand, the solution is rather smooth but there is a strong singularity in the derivative of g at $u = 0$ (see Figure 5). As a result, the linearization yields a very poor approximation at that point, and NWT stagnates, but FAS is hardly affected. MNM has a slower start, but soon regains its fast convergence. Here, it is evident that MNM could gain much from an adaptive procedure as outlined in section 3.2, and implemented in [6]. For $\alpha = 1.0$, $p = 1.8$ (bottom right), there is both a boundary layer in u and a singularity of g', hence both FAS and NWT suffer, yet MNM remains very effective. In more extremely singular cases (smaller p), FAS becomes better than MNM due to the extreme poorness of the linear approximation. In such cases, adaptive MNM would be highly advantageous.

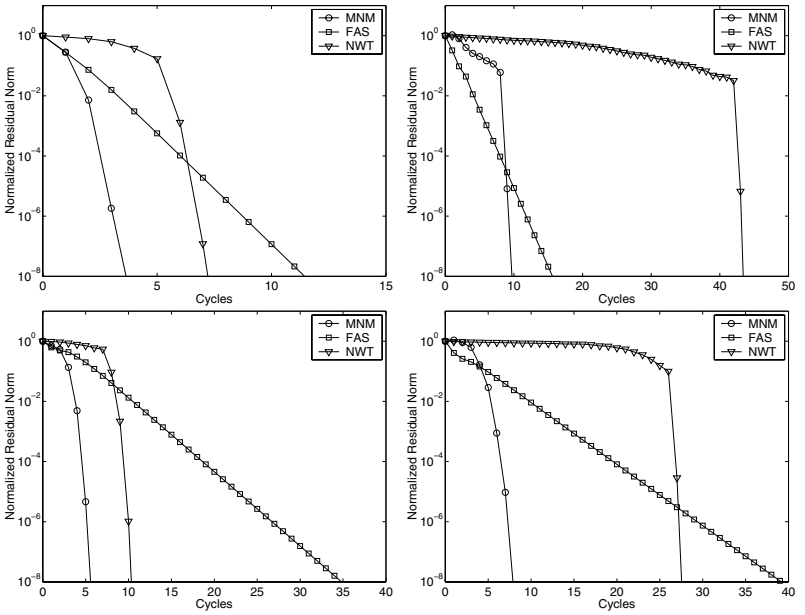

FIG. 2. *Residual norm convergence histories, normalized by the initial value, are shown for* $\alpha = 0.5$, $p = 2.5$ *(top left);* $\alpha = 0.5$, $p = 1.8$ *(top right);* $\alpha = 1.0$, $p = 2.5$ *(bottom left);* $\alpha = 1.0$, $p = 1.8$ *(bottom right).*

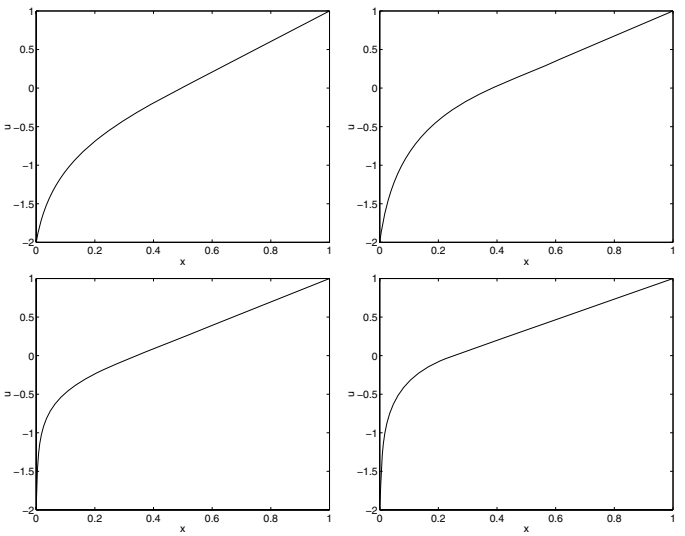

FIG. 3. *The numerical solution is shown for* $\alpha = 0.5$, $p = 2.5$ *(top left);* $\alpha = 0.5$, $p = 1.8$ *(top right);* $\alpha = 1.0$, $p = 2.5$ *(bottom left);* $\alpha = 1.0$, $p = 1.8$ *(bottom right).*

In the examples where $p = 2.5$, MNM used no backtracking, so $\bar{\gamma} = \gamma = 1$. For $\alpha = 1.0$, $p = 1.8$, we obtained $\bar{\gamma} = 1.11$, indicating an average increase of about 12% in the number of floating-point operations, compared to V cycles, by (47). For $\alpha = 0.5$, $p = 1.8$, we observed $\bar{\gamma} = 1.19$, implying a 23% average increase in computational cost, but there were also two cases of backtracking on the finest grid, so the overall work for MNM is about 35% more than is suggested by Figure 2.

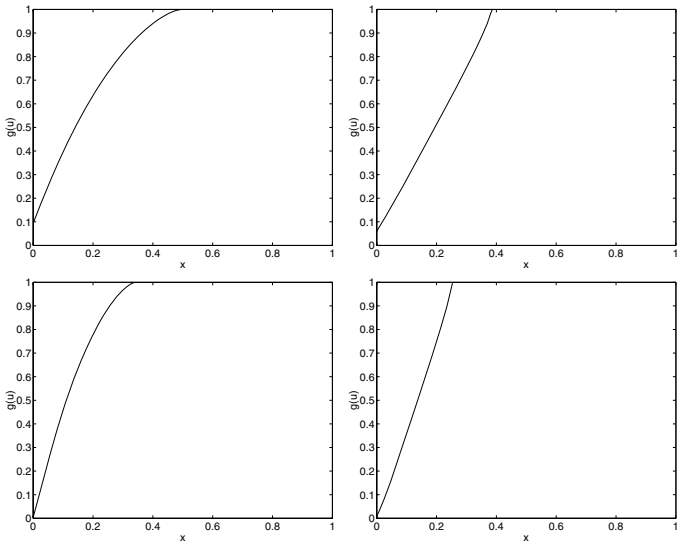

FIG. 4. *The diffusion coefficient g, computed for the numerical solutions at gridpoints, is shown for $\alpha = 0.5$, $p = 2.5$ (top left); $\alpha = 0.5$, $p = 1.8$ (top right); $\alpha = 1.0$, $p = 2.5$ (bottom left); $\alpha = 1.0$, $p = 1.8$ (bottom right).*

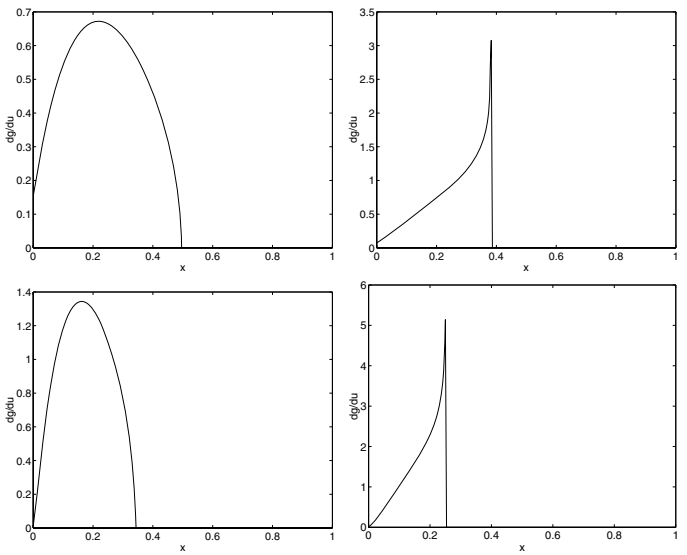

FIG. 5. *The derivative $g'(u)$, computed for the numerical solutions at gridpoints, is shown for $\alpha = 0.5$, $p = 2.5$ (top left); $\alpha = 0.5$, $p = 1.8$ (top right); $\alpha = 1.0$, $p = 2.5$ (bottom left); $\alpha = 1.0$, $p = 1.8$ (bottom right).*

4.2. 2D tests. We test the 2D version of the problem of section 4.1,[2]

$$N(u) \equiv -\nabla \cdot (g(u)\nabla u) = f(x,y), \quad x,y \in (0,1)\times(0,1), \tag{55}$$

again with Dirichlet boundary conditions, where u is the unknown function, g is given by (52), and f is a given function (zero in our tests). Discretizing by second-order

[2]See more 2D tests, including discontinuous coefficients, in [6].

accurate finite volumes on a uniform grid with mesh size h, we obtain the nonlinear system

$$N_h u_h = f_h, \tag{56}$$

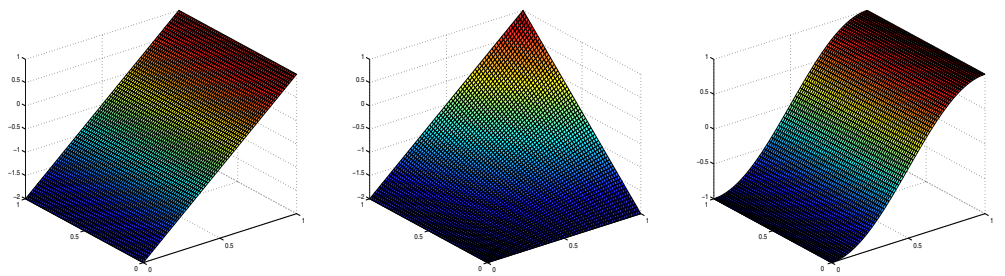
where the ith equation in the system is given by

$$\begin{aligned} &-\frac{g_{i+1/2,j}(u_{i+1,j},u_{i,j})[u_{i+1,j}-u_{i,j}]-g_{i-1/2,j}(u_{i,j},u_{i-1,j})[u_{i,j}-u_{i-1,j}]}{h^2} \\ &-\frac{g_{i,j+1/2}(u_{i,j+1},u_{i,j})[u_{i,j+1}-u_{i,j}]-g_{i,j-1/2}(u_{i,j},u_{i,j-1})[u_{i,j}-u_{i,j-1}]}{h^2} \\ &= f_{i,j} i = 1,\dots,n-1; j = 1,\dots,n-1. \end{aligned} \tag{57}$$

As in the 1D problem, $u_{i,j}$ and $f_{i,j}$ are the components of u_h and f_h, respectively, while $g_{i\pm1/2,j}$ and $g_{i,j\pm1/2}$ are averaged approximations to g midway between neighboring grid points: (i,j) and $(i\pm1,j)$ or (i,j) and $(i,j\pm1)$, respectively. The boundary conditions are described below.

The tests were performed with three cases of boundary conditions. The initial guesses for the three cases are shown in Figure 6. In the first case the boundary conditions were defined to be the boundaries of an inclined linear plane, with its upper side at $u=1$ and its lower side at $u=-2$. In the second case the boundary conditions were set to $u=-2$ along two adjacent sides, while the boundaries along the other two sides were set to linear profiles with $u=-2$ at their lower points and $u=1$ at their common top point. In the third case the boundary values were set to $u=-1$ and $u=1$ along two opposite sides, while along the other sides the values had the shape of a sine function, varying from -1 to 1. The right-hand side function was set to $f=0$ in all the examples.

We perform V cycles until the ℓ_2 residual norm is reduced by a factor of 10^{-8}. We backtrack if the coarse-grid correction plus the (single) postrelaxation sweep fails to reduce the ℓ_2 norm of the residual. In this case, we discard the coarse-grid correction, damp the residual according to the strategy of [10], and compute a new coarse-grid correction.



(a) Case 1: Inclined plane. (b) Case 2. (c) Case 3: Sine function.

FIG. 6. *Boundary conditions and initial guesses.*

TABLE 2

Test results for Case 1. *The* $*$ *superscript denotes that backtracking was required. For this case, setting* $a = 0.3$, $b = 0.5$ *yielded for MNM an average convergence factor of* 0.44 *with no backtracking.*

$P\backslash\alpha$	.5	.75	1

2	MNM = 0.13 FAS = 0.23 NLMG = 0.20 FP = 0.39	MNM = 0.25 FAS = 0.33 NLMG = 0.31 FP = 0.58	MNM = 0.38 FAS = 0.41 NLMG = 0.40 FP = 0.73
2.5	MNM = 0.12 FAS = 0.21 NLMG = 0.16 FP = 0.35	MNM = 0.25 FAS = 0.33 NLMG = 0.26 FP = 0.58	MNM = 0.41 FAS = 0.42 NLMG = 0.40 FP = 0.76

For error-smoothing we use a nonlinear Gauss–Seidel relaxation in red-black ordering. The local nonlinear problems of the relaxation are solved approximately by one Newton iteration. We use Dendy's classical black-box multigrid [8] to construct prolongation and restriction operators. Alternatives can of course be found in the literature, all essentially approximate generalizations of (54) to two dimensions.

In all our tests the finest grid has 64 intervals in each direction, while the coarsest grid has 4 intervals in each direction, yielding 5 multigrid levels, coarsening down to a grid of 3 by 3 interior variables. On the coarsest grid we relax 5 times. We use $\gamma = 1$ (V cycle) and $\nu_1 = \nu_2 = 1$. For the linearization in the GL and MNM algorithms, we use a fixed-point (FP) approach (sometimes called "lagged diffusion" or "principal-part linearization"), that is, the operator is linearized by freezing the diffusion coefficient, g. This approach was chosen rather than NWT, because the linear operators obtained using NWT are nonsymmetric and therefore require a robust solver for nonsymmetric linear problems. We will consider such solvers in the future.

In these tests we also compute results using the NLMG of Hackbusch [14], with the parameter optimized manually. These must of course be at least as good as those of FAS, since the latter is a special case where the parameter is set to 1. With a few exceptions, the results are not significantly superior to FAS, even though the parameter is optimized.

The results are presented in Tables 2, 3, and 4 for the three cases of boundary conditions. We show average convergence factors for physical parameters $\alpha = 0.5, 1.0, 1.5$, and $p = 1.5, 2.0, 2.5$, with FP denoting fixed-point GL. As in the 1D case, for a given domain and boundary conditions, the problem generally becomes more difficult for smaller p and larger α. The MNM algorithm yielded the fastest convergence in every case but two (the upper-right terms in Tables 2 and 4). In these cases (only), backtracking was required, and the results were still quite poor. (Recall that the analysis for backtracking was performed for Newton's linearization, not FP.) For these two cases where MNM failed, we recomputed the results using the "adaptive" approach

of section 3.2, with manually chosen parameters: $a = 0.3$, $b = 0.5$ yielded an average convergence factor of 0.44 for Case 1 with $p = 1.5$, $\alpha = 1$, while $a = 0.2$, $b = 0.4$ yielded an average convergence factor of 0.37 for Case 3 with the same values for p and α. This demonstrates the potential efficiency of adaptive MNM.

5. Discussion. MNM eliminates the compromise between global and local linearization, as we approximate the full nonlinear operator on the coarse grid, but we use a robust approximation for a large part of it. The new method exhibits better behavior than both its predecessors, consistent with the prediction of the scalar

analysis. The development of a two- (or higher-) dimensional solver employing Newton linearization is expected to yield better results, provided that a robust linear solver for nonsymmetric linear problems is used. The (partial) [illegible] MNM approach was used in [6], where it proved to be effective, but it can no doubt be improved significantly by deriving appropriate criteria to replace the generic optimization. In the tests above, we demonstrate that optimizing both parameters of the adaptive MNM may be quite efficient, while ensuring that MNM will be at least as good as the better of the two competitors, as they are each a special case of adaptive MNM.

INCORPORATING DIFFUSION IN COMPLEX GEOMETRIES INTO STOCHASTIC CHEMICAL KINETICS SIMULATIONS*

SAMUEL A. ISAACSON† AND CHARLES S. PESKIN‡

Abstract. A method is developed for incorporating diffusion of chemicals in complex geometries into stochastic chemical kinetics simulations. Systems are modeled using the reaction-diffusion master equation, with jump rates for diffusive motion between mesh cells calculated from the discretization weights of an embedded boundary method. Since diffusive jumps between cells are treated as first order reactions, individual realizations of the stochastic process can be created by the Gillespie method. Numerical convergence results for the underlying embedded boundary method, and for the stochastic reaction-diffusion method, are presented in two dimensions. A two-dimensional model of transcription, translation, and nuclear membrane transport in eukaryotic cells is presented to demonstrate the feasibility of the method in studying cell-wide biological processes.

Key words. reaction-diffusion, stochastic chemical kinetics, complex geometry, embedded boundary

1. Introduction.

Spatially homogeneous, deterministic mass-action kinetics is a standard model for the interactions of proteins, genes, and mRNAs within cellular networks. It assumes that the evolution of any chemical species can be represented by a continuously varying concentration representing the number of that species within the cell divided by the cell volume. Fundamentally, however, the numbers of protein and mRNA molecules within cells are discrete integer variables. The notion of a continuously varying concentration is only well defined for a sufficiently large number of the molecules. Moreover, for systems in which spatial effects are important the population number must not only be large within the cell but also locally within areas of interest. If the population number is sufficiently small, stochastic effects can have a noticeable impact on the behavior of the biological system.

The issue of stochasticity in gene expression was discussed in [3]. The authors subsequently demonstrated numerically that the variation of cell fates within a λ-phage infected population of bacterial cells can be explained as arising from a stochastically driven gene expression switch [4]. The presence of noise in prokaryotic transcription and translation was demonstrated experimentally in both [9] and [23]. More recently, experimental results demonstrating transcriptional noise in eukaryotic cells were presented in [6].

Spatial effects are present in many biological systems, and hence the spatially uniform, or well-mixed, assumption will not always hold. Systems in which spatial effects are known to play a role include Ash1 mRNA localization in budding yeast [1],

morphogen gradients across egg-polarity genes in Drosophila oocyte [1], and the synapse-specificity of long-term facilitation in Aplysia [20]. The exact processes by which proteins and mRNAs move between specific locations, and become localized, are not yet known definitively. Movement is believed to be composed of a mixture of diffusion and various forms of active transport. For example, in [10], mRNA movement within the cytoplasm was found to exhibit diffusive motion, "corralled" diffusive motion, and active, directionally specific, transport. A probabilistic switching between these three types of movement was observed in most cases. Moreover, the fraction of time spent in each of the types of motion was found to differ depending on whether the mRNA was destined to be localized or not.

Diffusion can be incorporated into deterministic mass-action kinetics through the use of reaction-diffusion partial differential equations. Molecular noise can be accounted for through the use of stochastic chemical kinetics, but the usual formulation of stochastic chemical kinetics assumes a spatially homogeneous cellular space. Methods for incorporating diffusion into stochastic chemical kinetics are presented in [25] and [12]. In both methods, space is divided into a collection of equally sized mesh cells. A reaction-diffusion master equation is then derived to give the probability of the system being in a given state. In [12] all transition rates between mesh cells are identical, and formulas for the transition rates are calculated in this case. In [25] a discussion of the continuum-limit for the first several moments of the model is given, but no method is given for calculating the cell-based transition rates.

We present a stochastic reaction-diffusion model for mesh cells of arbitrary volume and varying diffusive transition rates. In section 3, a method is developed for calculating diffusive transition rates between mesh cells within a domain containing multiple complex boundaries. The development of a convergent diffusive approximation within complex geometries is critical for use in individual (biological) cell models where the large number of organelles and membranes could have a significant effect on the overall dynamics of chemical systems. Transition rates are systematically calculated from terms in an embedded boundary discretization of the Fokker–Planck equation for a classically diffusing Brownian particle. We expect the reaction-diffusion master equation to be such a discretization in the case of no reactions and only one particle. The notion of the master equation as an approximation to a continuum equation was used in [26] to obtain approximations of the Fokker–Planck equation for a single particle moving in a one-dimensional potential. The master equation itself has a special structure, requiring a constraint on the weights of the discretization. Our method is found to conserve probability and satisfy detailed balance. The underlying embedded boundary discretization converges between first and second order in practice. As an application of the method, a model of transcription, translation, and nuclear transport within a two-dimensional eukaryotic cell is developed and simulated.

We note that the method we develop is an Eulerian method, using an underlying Cartesian mesh. Other models have been developed using Lagrangian methods that track the movement of each individual molecule within the system. For example, in [2] a Lagrangian method was developed for simulating stochastic reaction-diffusion systems within biological cells. These methods have the benefit of allowing exact local treatments of particle diffusion; however, they introduce other challenges in how to handle reactions between particles, detection of particle collisions, and resolving particle-geometry interactions. Lagrangian methods have been found very useful in the turbulent reactive flow literature. We point the reader interested in numerical methods for convection dominated reactive flows to [22] and [19].

2. Master equation formulation of reaction-diffusion. In section 2.1 the general abstract definition of the master equation is presented. Several properties of the transition rates, $W_{ij}(t)$, are pointed out. These properties constrain the form of the discretization of the Fokker–Planck equation used in generating the diffusive transition rates for the reaction-diffusion master equation. Sections 2.2 and 2.3 review the chemical master equation for a spatially homogeneous system, and the Gillespie method for creating realizations of it. In section 2.4 the reaction-diffusion master equation is presented, along with the motivation for thinking of its diffusive jump rates as weights in a spatial-only discretization of the Fokker–Planck equation.

2.1. General master equation. Let $X(t)$ denote an integer valued, continuous time Markov process. Let $Q_i(t) = \text{Prob}\{X(t) = i | X(0) = x_0\}$, and $W_{ij}(t)dt = \text{Prob}\{X(t + dt) = i | X(t) = j\}$. By definition, $W_{ij}(t)$ is the transition rate at time t to go into state i from state j, for $i \neq j$. Then

$$Q_i(t + dt) = \left(1 - \sum_{j \neq i} W_{ji}(t)dt\right) Q_i(t) + \sum_{j \neq i} W_{ij}(t)Q_j(t)dt + o(dt). \tag{2.1}$$

This says that the probability of being in state i a small time after time t is the probability of being there at time t and staying there added to the probability of being in another state at time t and transitioning to i. The master equation is the coupled set of ODEs obtained by rearranging and taking the limit $dt \to 0$ of (2.1):

$$\begin{aligned} \frac{dQ_i}{dt} &= \sum_{j:j\neq i} \left(W_{ij}(t)Q_j(t) - W_{ji}(t)Q_i(t)\right) \\ &= \left(\sum_{j:j\neq i} W_{ij}(t)Q_j(t)\right) - W_i(t)Q_i(t), \quad W_i(t) = \sum_{j\neq i} W_{ji}(t) \geqslant 0. \end{aligned} \tag{2.2}$$

There are several properties of the structure of (2.2) that we subsequently use. First, $W_{ij}(t) \geq 0$. Second, the term $W_{ij}(t)Q_j(t)$ appears twice with opposite sign: once in the equation for $\partial_t Q_i$ and once in the equation for $\partial_t Q_j$. This implies that the amount of probability that flows per unit time into state i due to transitions from state j to i is exactly the amount of probability that flows per unit time out of state j due to these same transitions. Finally, the only negative term in the equation for $Q_i(t)$ is given by $W_i(t)Q_i(t)$.

2.2. Review of stochastic chemical kinetics. Consider a well-mixed chemical system in a finite closed volume V; that is, the probability of a given particle of the system being in an arbitrary subregion of volume dV is dV/V. Further, let each individual particle's velocity be a Maxwell–Boltzmann distributed random variable. With these assumptions Gillespie showed in [16] that a chemical system can be represented as an integer valued, continuous time Markov process satisfying a master equation.

Let $\boldsymbol{M}(t) = (M^1(t), \ldots, M^L(t))$ denote the state vector of the chemical system. $M^l(t)$ will be the random variable representing the number of molecules of chemical species l at time t. Define $\boldsymbol{m} = (m^1, \ldots, m^L)$ to be a given value of $\boldsymbol{M}(t)$. Denote by S^l the [illegible] of the lth species. Assume there are K possible reactions, with the function $a^k(\boldsymbol{m})$ giving the probability per unit time of reaction k occurring when $\boldsymbol{M}(t) = \boldsymbol{m}$. For example, letting k label the unimolecular (first order) reaction

$S^i \to S^j$, then $a^k(\boldsymbol{m}) = \alpha\, m^i$, where α is the rate constant in units of number of occurrences of the reaction per molecule of S^i per unit time. Letting k' denote the index of the bimolecular reaction $S^i + S^j \to S^n$, where $i \neq j$, then $a^{k'}(\boldsymbol{m}) = \beta\, m^i m^j$. Here β is the rate constant in units of number of occurrences of the reaction per molecule of S^i and per molecule of S^j, per unit time. Note that if species i and j are the same, then $a^{k'}(\boldsymbol{m}) = (\beta/2)\, m^i(m^i - 1)$. Let $\boldsymbol{\nu}_k = (\nu_k^1, \ldots, \nu_k^L)$ be the change in $\boldsymbol{M}$ that results from one occurrence of reaction k (i.e., $\boldsymbol{M}(t) \to \boldsymbol{M}(t) + \boldsymbol{\nu}_k$). The integers $(\nu_k^1, \ldots, \nu_k^L)$ define the stoichiometry of the kth reaction. In the notation of section 2.1, $a^k(\boldsymbol{m}) = W_{\boldsymbol{m}+\boldsymbol{\nu}_k, \boldsymbol{m}}$, assuming $\boldsymbol{\nu}_i \neq \boldsymbol{\nu}_k$ for all $i \neq k$. (If two or more reactions have identical stoichiometry, their rates are added to obtain the corresponding transition rate W. Also, if there are no reactions leading from state $\boldsymbol{m}'$ to $\boldsymbol{m}$, then $W_{\boldsymbol{m},\boldsymbol{m}'}$ is zero.) Note that the ν_k^l may be positive or negative (or zero). Then if

$$P(\boldsymbol{m}, t) \equiv P(\boldsymbol{m}) \equiv \text{Prob}\{\boldsymbol{M}(t) = \boldsymbol{m} | \boldsymbol{M}(0) = \boldsymbol{m}_0\},$$

the master equation for the time evolution of the probability of the system will be

$$\frac{dP(\boldsymbol{m})}{dt} = \sum_{k=1}^{K} \left(a^k(\boldsymbol{m} - \boldsymbol{\nu}_k) P(\boldsymbol{m} - \boldsymbol{\nu}_k) - a^k(\boldsymbol{m}) P(\boldsymbol{m}) \right). \tag{2.3}$$

This is a coupled set of ODEs over all possible integer values of the components of the vector $\boldsymbol{m}$. We shall subsequently refer to (2.3) as the chemical master equation. Assuming all the $\boldsymbol{\nu}_k$ are distinct, in the notation of section 2.1 the master equation is

$$\frac{dP(\boldsymbol{m})}{dt} = \sum_{k=1}^{K} \left(W_{\boldsymbol{m}, \boldsymbol{m}-\boldsymbol{\nu}_k} P(\boldsymbol{m} - \boldsymbol{\nu}_k) - W_{\boldsymbol{m}+\boldsymbol{\nu}_k, \boldsymbol{m}} P(\boldsymbol{m}) \right). \tag{2.4}$$

In both (2.3) and (2.4) the first term in the sum corresponds to all possible transitions into state $\boldsymbol{m}$ from some prestate, $\boldsymbol{m} - \boldsymbol{\nu}_k$, while the second term corresponds to all possible transitions out of state $\boldsymbol{m}$ to $\boldsymbol{m} + \boldsymbol{\nu}_k$.

We now consider the relationship between the traditional macroscopic chemical kinetic equations to the master equation derived above. Define $\boldsymbol{C} \equiv \boldsymbol{M}/V$ to be the vector of random variables for the concentration of each species. Let $\tilde{a}^k$ denote the concentration dependent form of the rate a^k. $\tilde{a}^k$ and a^k are related by $\tilde{a}^k(\boldsymbol{c}) = a^k(V\boldsymbol{c})/V$, and vice versa $a^k(\boldsymbol{m}) = \tilde{a}^k(\boldsymbol{m}/V)V$. Note that $\tilde{a}^k(\boldsymbol{c})$ is the expected number of occurrences of reaction k [illegible] per unit time when the vector of concentrations is $\boldsymbol{c}$. From the master equation the mean of C^l, $\langle C^l \rangle$, satisfies

$$\frac{d\langle C^l \rangle}{dt} = \sum_{k=1}^{K} \nu_k^l \langle \tilde{a}^k(\boldsymbol{C}) \rangle.$$

If the averaging operation commutes with the functions $\tilde{a}^k$, then one obtains the equations for classical deterministic chemical kinetics,

$$\frac{d\langle C^l \rangle}{dt} = \sum_{k=1}^{K} \nu_k^l\, \tilde{a}^k(\langle \boldsymbol{C} \rangle);$$

however, in general $\langle \tilde{a}^k(\boldsymbol{C}) \rangle \neq \tilde{a}^k(\langle \boldsymbol{C} \rangle)$, unless $\tilde{a}^k$ is linear. One does expect that asymptotically, as the population sizes become very large, $\langle \tilde{a}^k(\boldsymbol{C}) \rangle \approx \tilde{a}^k(\langle \boldsymbol{C} \rangle)$. For a discussion of the validity of the deterministic approximation see [17].

2.3. Gillespie method. The number of the ODEs comprising the master equation are very large even for simple chemical systems. Direct solution methods become impractical, and thus Monte Carlo methods are used instead. These methods create realizations of the underlying stochastic process, $\boldsymbol{M}(t)$, governed by the master equation. Statistics from many realizations can be used to calculate moments of $\boldsymbol{M}(t)$ and the distribution, $P(\boldsymbol{m}, t)$. In [15] Gillespie presented two equivalent methods that produce exact realizations of $\boldsymbol{M}(t)$.

One of the two methods, the first reaction method, is based on calculating the time of occurrence of each reaction independently, as if no other reactions are present in the system. The reaction with the minimal time to its next occurrence is then executed, and the system state updated. This process is then repeated until the simulation reaches the desired final time. In detail, let

$$p\left(\tau, k|\boldsymbol{m}, t\right) d\tau \equiv \text{ Prob}\{\text{reaction } k \text{ occurs in the interval } [t+\tau, t+\tau+d\tau), \\ \text{ignoring that another reaction could occur first}\}.$$

Then in [15] it is shown that

$$p\left(\tau, k|\boldsymbol{m}, t\right) = a^k\left(\boldsymbol{m}\right) e^{-a^k(\boldsymbol{m})\tau}. \tag{2.5}$$

Knowing $\boldsymbol{m}$ at time t, for each reaction k, a time τ_k at which reaction k would occur can be generated by inverting the probability distribution corresponding to probability density (2.5). The time at which reaction k would occur is given by $t + \tau_k$, where

$$\tau_k = \frac{1}{a^k(\boldsymbol{m})} \ln \frac{1}{r_k},$$

r_k being a uniformly distributed random number in $[0, 1]$. The overall time-evolution algorithm is then the following:

1. Initialize $t = 0$, set initial molecule numbers $\boldsymbol{m} = \boldsymbol{m}_0$
2. Calculate $a^k(\boldsymbol{m})$ for all k
3. For each k, generate $\tau_k = \left(\ln\left(1/r_k\right)\right)/a^k(\boldsymbol{m})$
4. Execute the reaction, k', with the smallest τ_k, update $\boldsymbol{m} := \boldsymbol{m} + \boldsymbol{\nu}_{k'}$
5. Set the time to $t := t + \tau_{k'}$
6. Return to 2.

Optimized versions of Gillespie's algorithms that substantially decrease the computational work were developed by Gibson and Bruck [14]. Their next reaction method is equivalent to the first reaction method but requires only one random number per reaction event. By using a special data structure they reduce finding the reaction with the minimum τ_k to a constant work operation, and updating following a reaction to logarithmic work in the number of reactions, K. For all subsequent Monte Carlo simulations discussed we use the next reaction method.

2.4. Reaction-diffusion master equation. Let the domain of interest be a closed volume V. Divide the domain into a series of computational cells indexed by $i = 1, \ldots, N$. Assume that the size of each cell can be chosen such that within each cell, independently, the master equation formulation of chemical kinetics holds (see section 2.2). Transitions of particles [illegible] cells are then modeled as first order reactions.

Let $M_i^l(t)$ denote the random variable for the number of particles of species l in cell i, $l = 1, \ldots, L$. Define $\boldsymbol{M}^l(t) = (M_1^l, \ldots, M_N^l)^T$ to be the spatial vector of

species l, and $\boldsymbol{M}(t) = (\boldsymbol{M}^1, \ldots, \boldsymbol{M}^L)$ to be the state matrix of the system. As for the well-mixed case, let

$$P(\boldsymbol{m}, t) \equiv P(\boldsymbol{m}) \equiv \text{Prob}\{\boldsymbol{M}(t) = \boldsymbol{m} | \boldsymbol{M}(0) = \boldsymbol{m}_0\}.$$

Let $\boldsymbol{M}_i(t) = (M_i^1, \ldots, M_i^L)$, $\boldsymbol{e}_i^l$ be the matrix all of whose elements are zero except for the element (i, l), which is one, and let $\boldsymbol{e}_i$ be the column vector which has a 1 in its ith entry and is 0 elsewhere. $\boldsymbol{e}_i \boldsymbol{\nu}_k$ will denote the matrix formed by the product of the column vector $\boldsymbol{e}_i$ with the row vector $\boldsymbol{\nu}_k$. This matrix will be zero everywhere except for the ith row, which will be equal to $\boldsymbol{\nu}_k$. It corresponds to the change in $\boldsymbol{M}(t)$ due to one occurrence of reaction k at location i (i.e., $\boldsymbol{M}(t) \to \boldsymbol{M}(t) + \boldsymbol{e}_i \boldsymbol{\nu}_k$). Let k_{ij}^l denote the jump rate for each individual molecule of the lth chemical species into cell i from cell j, for $i \neq j$. Since diffusion is treated as a first order reaction, and since the molecules are assumed to diffuse independently, the total probability per unit time at time t for one molecule of species l to jump from cell j to cell i is $k_{ij}^l M_j^l(t)$.

The master equation for the time evolution of $P(\boldsymbol{m}, t)$ is then

$$\begin{aligned} \frac{dP(\boldsymbol{m})}{dt} =& \sum_{i=1}^{N} \sum_{j=1}^{N} \sum_{l=1}^{L} \left(k_{ij}^l \left(m_j^l + 1 \right) P(\boldsymbol{m} + \boldsymbol{e}_j^l - \boldsymbol{e}_i^l) - k_{ji}^l m_i^l P(\boldsymbol{m}) \right) \\ &+ \sum_{i=1}^{N} \sum_{k=1}^{K} \left(a_i^k(\boldsymbol{m}_i - \boldsymbol{\nu}_k) P(\boldsymbol{m} - \boldsymbol{e}_i \boldsymbol{\nu}_k) - a_i^k(\boldsymbol{m}_i) P(\boldsymbol{m}) \right). \end{aligned} \tag{2.6}$$

This is a coupled set of ODEs over all possible integer values of the matrix $\boldsymbol{m}$. Notice the important point that the reaction probabilities per unit time, $a_i^k(\boldsymbol{m})$, may now depend on spatial location. For example, in an eukaryotic cell some reactions may occur only in the nucleus and others may occur only in the cytoplasm.

Equation (2.6) is separated into two sums. The first term corresponds to diffusive motion between cells i and j of a given species, l. The second is just the components of the chemical master equation, but applied at each individual cell. At this point no specification has been made as to where the rates k_{ij}^l come from, or what their values should be.

For deterministic reaction-diffusion, let $C^l(\boldsymbol{x}, t)$ denote the concentration and D^l the diffusion constant of the lth species. Let $\tilde{a}^k(\boldsymbol{C}(\boldsymbol{x}, t), \boldsymbol{x})$ denote the spatially varying concentration dependent form of a_i^k (see section 2.2). Then

$$\frac{\partial C^l(\boldsymbol{x}, t)}{\partial t} = D^l \Delta C^l + \sum_{k=1}^{K} \nu_k^l \, \tilde{a}^k(\boldsymbol{C}(\boldsymbol{x}, t), \boldsymbol{x}).$$

To see the relation to the stochastic formulation let $C_i^l(t) = M_i^l(t)/V_i$ be the random variable for the chemical concentration of species l, in cell i. Let $\tilde{a}_i^k$ denote the concentration dependent form of a_i^k. $\tilde{a}_i^k$ and a_i^k are related by $\tilde{a}_i^k(\boldsymbol{c}) = a_i^k(V_i \boldsymbol{c})/V_i$, and vice versa $a_i^k(\boldsymbol{m}) = \tilde{a}_i^k(\boldsymbol{m}/V_i) V_i$. From the reaction-diffusion master equation the average of C_i^l then satisfies

$$\frac{d\langle C_i^l \rangle}{dt} = \sum_{j=1}^{N} \left(\frac{V_j}{V_i} k_{ij}^l \langle C_j^l \rangle - k_{ji}^l \langle C_i^l \rangle \right) + \sum_{k=1}^{K} \nu_k^l \langle \tilde{a}_i^k \left(C_i \right) \rangle.$$

Suppose the rates k_{ij}^l could be chosen so that the first term is a discretization of $D^l \Delta C^l$. The only difference between the deterministic and the means of the stochastic formulation in the continuum limit would then be the noncommutativity of the reaction terms with averaging; diffusion would be identical.

Returning to the reaction-diffusion master equation (2.6), we expect that the diffusive jump rates should be independent of the chemical reactions present within a given chemical system. As such, we now consider a chemical system consisting of no reactions. In this case, we expect each particle of each chemical species to independently undergo Brownian motion in the continuum limit as the computational cell size approaches zero. Since, by construction, the diffusive motion of each particle of each chemical species is independent in the reaction-diffusion master equation formulation, it is sufficient to further restrict ourselves to a system consisting of only one chemical species containing just one particle. With these choices, the reaction-diffusion master equation reduces to

$$\frac{dP(\boldsymbol{m})}{dt} = \sum_{i=1}^{N} \sum_{j=1}^{N} k_{ij} \, (m_j + 1) \, P(\boldsymbol{m} + \boldsymbol{e}_j - \boldsymbol{e}_i) - k_{ji} m_i P(\boldsymbol{m}). \tag{2.7}$$

Since $\boldsymbol{M}(t)$ is describing one particle, $M_i(t)$ will be zero for all i except the location the particle is currently at. Let $\boldsymbol{X}(t)$ be the Brownian motion process of the particle. Then define

$$Q_i(t) \equiv P(\boldsymbol{e}_i, t) \approx \text{Prob}\{\boldsymbol{X}(t) \in V_i | \boldsymbol{X}(0) = \boldsymbol{x}_0\},$$

where $\boldsymbol{e}_i$ denotes, as before, the unit vector along the ith Cartesian coordinate axis of $\mathbb{R}^N$. With this definition, $Q_i(t)$ is the probability that the particle is in the ith computational cell. Letting $\boldsymbol{m} = \boldsymbol{e}_i$, equation (2.7) implies

$$\frac{dQ_i}{dt} = \sum_{j=1}^{N} k_{ij} \, Q_j - k_{ji} \, Q_i. \tag{2.8}$$

Define a probability density for the particle's position by $p_i(t) \equiv Q_i(t)/V_i$. Then p_i satisfies

$$\frac{dp_i}{dt} = \sum_{j=1}^{N} \frac{V_j}{V_i} k_{ij} \, p_j - k_{ji} \, p_i. \tag{2.9}$$

Again, if the rates form a discretization of $D\Delta p$, for p the continuum single particle density, then the continuum limit as cell size goes to zero would be

$$\frac{\partial p(\boldsymbol{x}, t)}{\partial t} = D \Delta p. \tag{2.10}$$

This is the Fokker–Planck equation for a single classical Brownian particle.

With these continuum limits in mind, constructing an operator, L_h, of the form

$$(L_h p)_i = \sum_{j=1}^{N} \frac{V_j}{V_i} k_{ij} \, p_j - k_{ji} \, p_i,$$

where $L_h \to \Delta$ as $h \to 0$, will determine the k_{ij}. (Here h represents the maximum length scale associated with a computational cell.) The diffusion jump rates will then be k_{ij}, provided $k_{ij} \geq 0$ (see section 2.1).

3. Determining the jump rates. From the results of section 2.4, an appropriate spatial discretization of either the classical deterministic formulation of reaction-diffusion, or the Fokker–Planck equation for a single Brownian particle, would determine the jump rates in (2.6). We note that in choosing the jump rates to recover either one of these two formulations, the macroscopic diffusion of the mean concentration from the reaction-diffusion master equation, or the microscopic Brownian motion of independent particles, we will also recover the other formulation. Previous authors [12], [25] have used the requirement of obtaining macroscopic diffusion of the mean concentrations given by the reaction-diffusion master equation to derive diffusive jump rates in the special case of a uniform Cartesian mesh. In this case, it has been shown that the jump rates, with mesh width h, can be given by

$$\frac{D}{h^2}$$

for jumps between neighboring mesh cells, and are zero for jumps between non-neighboring cells. This result has been known from as far back as [11]. In this section, instead of focusing on recovering macroscopic diffusion of the mean concentrations, we focus on the mathematically equivalent requirement of reproducing single particle Brownian motion. We note that if we assume molecules are only moving by diffusion, then the requirement of recovering single particle Brownian motion in the continuum limit is a physical necessity for the reaction-diffusion master equation. With this choice we can derive valid jump rates for diffusion within complex geometries, allowing us to extend the existing methodology to handle arbitrary boundaries. This result is important since many problems of practical interest contain geometrically complex domains, such as the movement of molecules within biological cells where there are many barriers due to organelles and membranes.

To discretize the Laplacian, and hence obtain the diffusive jump rates, boundary conditions must be specified for the domain of interest; this is discussed in section 3.1. Section 3.2 derives the embedded boundary method to discretize the Fokker–Planck equation, and calculates the corresponding diffusive jump rates for the reaction-diffusion master equation. Some consequences of the specific discretization chosen are also presented. In section 3.3 the complete algorithm for solving the reaction-diffusion master equation is summarized. Convergence of the embedded boundary discretization is demonstrated for several examples in section 3.4, while section 3.5 discusses the convergence of the overall algorithm of section 3.3.

3.1. Boundary conditions. Since we are applying the overall method to simulations of biochemical networks in eukaryotic cells, which are cells with a nuclear membrane, we formulate our boundary conditions for this type of domain. Denote the entirety of the cell by Ω and the cell membrane (i.e., exterior boundary) as $\partial\Omega$. A eukaryotic cell will also have a nucleus, $\Omega_n \subset \Omega$, a closed volume contained completely within the interior of the cell. The nuclear membrane, $\partial\Omega_n$, encloses the nucleus, partitioning the cell's interior into two distinct compartments.

Passage through the cellular membrane will not be allowed, so that the exterior boundary will have a no-flux Neumann condition. This can, of course, be changed to a more general flux condition if necessary. The nuclear membrane will be impermeable to certain species, requiring again a no-flux Neumann condition, while allowing a passive flux for others. This second condition will be modeled in this paper by having the nuclear membrane flux proportional to the jump in probability density, or concentration, across the membrane. Note that this boundary condition assumes molecules

cross the nuclear membrane independently of each other. The boundary condition may be derived from a more detailed model of the nuclear membrane as containing channels, called nuclear pores, through which certain species may diffuse. The nuclear membrane is thin relative to the size of a eukaryotic cell, and hence the diffusive motion of molecules within the membrane will equilibrate rapidly. This implies that the diffusive flux within the membrane can be assumed spatially constant. In addition, the number of nuclear pores is large enough that we approximate them as a fixed background density within the membrane. Combining these two approximations, and idealizing the membrane as infinitely thin, implies that the flux through the nuclear membrane is proportional to the difference in probability density, or concentration, across the membrane. Note that in certain situations this boundary condition would need to be modified to a more physically detailed model. One such example would be if the number of molecules crossing the nuclear membrane can become large enough to saturate the nuclear pores.

Consider a single particle moving by classical Brownian motion within the cell. Let $p(\boldsymbol{x},t)$ denote the probability density for the position of the particle. Then within both the nucleus, Ω_n, and the cytoplasm, $\Omega \setminus \Omega_n$, $p(x,t)$ will satisfy (2.10). (Here $\Omega \setminus \Omega_n$ denotes the set of points within Ω that are not also contained in Ω_n.) Let $[p]_n$ denote the jump in $p(\boldsymbol{x},t)$ across the nuclear membrane. Define by ρ the nuclear membrane permeability, and by D the diffusion constant of the particle. Let $\boldsymbol{\eta}$ denote the outward pointing normal to a given surface. Then, incorporating the assumed boundary conditions, $p(\boldsymbol{x},t)$ satisfies

$$\begin{aligned} \frac{\partial p}{\partial t} &= D\Delta p \qquad && \text{in } \Omega, \\ \frac{\partial p}{\partial \boldsymbol{\eta}} &= 0 && \text{on } \partial\Omega, \\ -D\frac{\partial p}{\partial \boldsymbol{\eta}} &= -\rho\,[p]_n && \text{on } \partial\Omega_n, \end{aligned} \tag{3.1}$$

with the initial condition $p(\boldsymbol{x},0) = \delta(\boldsymbol{x}-\boldsymbol{x}_0)$, where $\boldsymbol{x}_0$ is the known initial position of the particle. A discretization of these equations that has the general form of (2.9) will determine the jump rates in the reaction-diffusion master equation.

The corresponding multiple species, deterministic reaction-diffusion model for the assumed boundary conditions follows. Let $[C^l]_n$ denote the jump in C^l across the nuclear membrane, ρ^l the nuclear membrane permeability, and D^l the diffusion constant of the lth species. Then

$$\begin{aligned} \frac{\partial C^l(\boldsymbol{x},t)}{\partial t} &= D^l\Delta C^l + \sum_{k=1}^{K} \nu_k^l\, \tilde{a}^k(\boldsymbol{C}(\boldsymbol{x},t),\boldsymbol{x}) && \text{in } \Omega, \\ \frac{\partial C^l(\boldsymbol{x},t)}{\partial \boldsymbol{\eta}} &= 0 && \text{on } \partial\Omega, \\ -D^l\frac{\partial C^l(\boldsymbol{x},t)}{\partial \boldsymbol{\eta}} &= -\rho^l\left[C^l\right]_n && \text{on } \partial\Omega_n, \end{aligned} \tag{3.2}$$

with the initial condition, $C^l(\boldsymbol{x},0) = C_0(\boldsymbol{x})$.

3.2. Numerical discretization. For simplicity, we discretize (3.1) instead of the deterministic reaction-diffusion formulation (3.2). We may do this because our purpose is not to obtain a numerical scheme for the deterministic equations but instead

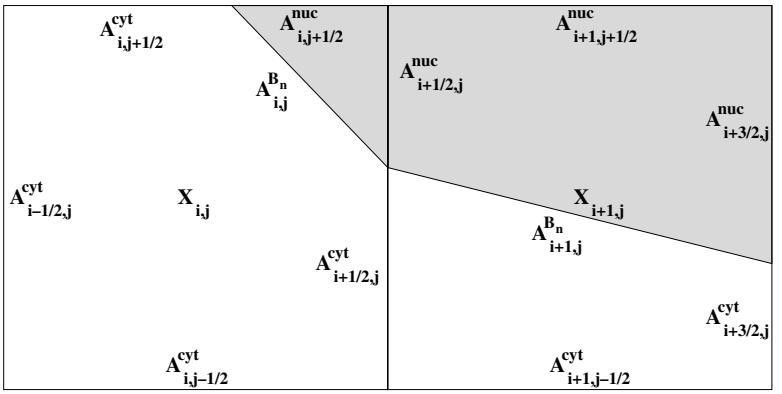

FIG. 1. *Two-dimensional Cartesian mesh cells cut by nuclear membrane. The darker region represents the portion of Ω_n, the nuclear space, within the mesh cells. The lighter region represents the portion of $\Omega \setminus \Omega_n$, the cytoplasm, within the mesh cells. $A^{\mathrm{cyt}}_{i+1/2,j}$ gives the length of the piece of the face connecting cells (i,j) and $(i+1,j)$ that is within the cytoplasmic domain. The remaining $A^{\alpha}_{i,j}$ values, for α a given domain, are defined similarly. $A^{B_n}_{i,j}$ is the length of the piece of the nuclear membrane within the cell (i,j). $X_{i,j}$ gives the center of the Cartesian cell at location (i,j). Also, $V^{\alpha}_{i,j}$ (not shown) gives the area of the portion of cell (i,j) within the domain α.*

to obtain the jump rates for use in our stochastic simulation, and, as was shown in section 2.4, the jump rates are the same whether we use (3.1) or the full deterministic reaction-diffusion system (3.2). For the remainder of this section, we use the word "cell" to refer to a cell of the Cartesian computational mesh, and we specify "biological cell" when that is what we mean. We embed Ω in a Cartesian mesh with cell centers $\boldsymbol{x_i}$ and mesh width h. There are three different domains contained in this description: the nuclear space, Ω_n, the cytoplasm, $\Omega \setminus \Omega_n$, and the space exterior to the biological cell. The total computational domain within which the biological cell is embedded is taken to be a square.

Define three separate solutions to (3.1), corresponding to each of the three domains: p^{nuc}, the value of $p(x,t)$ within Ω_n, p^{cyt}, the value of $p(x,t)$ within $\Omega \setminus \Omega_n$, and p^{ext}, the value of p outside the biological cell. Since the particle is assumed to never leave Ω, p^{ext} will be zero. Denote by p^{α} the value of the solution for domain α, where $\alpha \in \{\mathrm{nuc}, \mathrm{cyt}, \mathrm{ext}\}$. Each of these solutions is assumed to be smoothly extendable across the boundaries of its region of definition. Note that the actual solution $p(x,t)$ will not be smooth across either the nuclear or cellular membrane, but its value on either side of each of these membranes can be smoothly extended to the other side.

For spatial dimension d, let $\boldsymbol{i} \in \mathbb{Z}^d$ denote the index vector for mesh cells. With the smooth extension assumption, a cell-centered solution value, $p^{\alpha}_{\boldsymbol{i}}$, can always be defined within cells containing some portion of the domain α. For a cell completely within this domain only one solution value will be considered, $p^{\alpha}_{\boldsymbol{i}}$. If a cell is split by one of the membranes, then two cell-centered solution values will be stored for the cell. It is assumed that at most one boundary intersects a given cell. For example, in Figure 1, which shows the two-dimensional case for simplicity, cell $\boldsymbol{i} = (i,j)$ is split by the nuclear membrane; hence, there would be two solution values stored for this cell, $p^{\mathrm{nuc}}_{\boldsymbol{i}}$ and $p^{\mathrm{cyt}}_{\boldsymbol{i}}$. These two solution values are subsequently used to approximate the boundary condition on the membrane. They also allow, in the master equation formulation, separate probabilities of the particle being in either portion of the cell.

Again, as the particle cannot cross $\partial\Omega$, $p_{\boldsymbol{i}}^{\text{ext}} = 0$ for all $\boldsymbol{i}$. As we know $p_{\boldsymbol{i}}^{\text{ext}}$, multiple values need not be stored for cells cut by $\partial\Omega$. If the particle could cross the cellular membrane, then $p_{\boldsymbol{i}}^{\text{ext}}$ would not necessarily be zero, and multiple values would be needed in cells split by $\partial\Omega$.

Figure 1 defines several geometric quantities associated with cells that are used in the numerical discretization. Let $\boldsymbol{e}_k$ denote the unit vector along the kth coordinate axis of $\mathbb{R}^d$. Define by

$$\boldsymbol{F}(x,t) = -D\nabla p \tag{3.3}$$

the probability flux vector per unit area. Let $\boldsymbol{F}^\alpha$ be the flux vector of the domain α solution and $(F_k)^\alpha$ the kth component of $\boldsymbol{F}^\alpha$. $\boldsymbol{\eta}^\alpha$ will denote the outward pointing, with respect to domain α, normal to a given surface. Following the conservative discretization method in [21], for all cells, $\boldsymbol{i}$, in which $p_{\boldsymbol{i}}^\alpha$ is defined,

(3.4)

$$\begin{aligned}
\frac{dp_{\boldsymbol{i}}^\alpha}{dt} &= -(\nabla\cdot\boldsymbol{F}^{\boldsymbol{\alpha}})_i \\
&\approx -\frac{1}{V_{\boldsymbol{i}}^\alpha}\int_{V_{\boldsymbol{i}}^\alpha}\nabla\cdot\boldsymbol{F}^{\boldsymbol{\alpha}}\,dV = -\frac{1}{V_{\boldsymbol{i}}^\alpha}\int_{\partial V_{\boldsymbol{i}}^\alpha}\boldsymbol{F}^{\boldsymbol{\alpha}}\cdot\boldsymbol{\eta}^{\boldsymbol{\alpha}}\,dS \\
&= -\frac{1}{V_{\boldsymbol{i}}^\alpha}\left(\sum_{\pm}\sum_{k=1}^{d}\int_{A^\alpha_{\boldsymbol{i}\pm\boldsymbol{e}_k}}\boldsymbol{F}^{\boldsymbol{\alpha}}\cdot\boldsymbol{\eta}^{\boldsymbol{\alpha}},\ dS + \int_{B_n}\boldsymbol{F}^{\boldsymbol{\alpha}}\cdot\boldsymbol{\eta}^{\boldsymbol{\alpha}}\,dS + \int_{B_e}\boldsymbol{F}^{\boldsymbol{\alpha}}\cdot\boldsymbol{\eta}^{\boldsymbol{\alpha}}\,dS\right) \\
&\approx -\frac{1}{V_{\boldsymbol{i}}^\alpha}\left(\sum_{k=1}^{d}\left(A^\alpha_{\boldsymbol{i}+\frac{1}{2}\boldsymbol{e}_k}(F_k)^\alpha_{\boldsymbol{i}+\frac{1}{2}\boldsymbol{e}_k} - A^\alpha_{\boldsymbol{i}-\frac{1}{2}\boldsymbol{e}_k}(F_k)^\alpha_{\boldsymbol{i}-\frac{1}{2}\boldsymbol{e}_k}\right) + A_{\boldsymbol{i}}^{B_n}\boldsymbol{F}_{\boldsymbol{i}}^{B_n}\cdot\boldsymbol{\eta}_{\boldsymbol{i}}^{B_n}\right).
\end{aligned}$$

Here, $B_n = \partial\Omega_n \cap \partial V_{\boldsymbol{i}}^\alpha$ and $B_e = \partial\Omega \cap \partial V_{\boldsymbol{i}}^\alpha$. The surface integral over B_e is identically zero due to the no-flux boundary condition at $\partial\Omega$. If a nonzero flux boundary condition is specified instead, then the integral would contribute another term of the form

$$-\frac{1}{V_{\boldsymbol{i}}^\alpha}A_{\boldsymbol{i}}^{B_e}\boldsymbol{F}_{\boldsymbol{i}}^{B_e}\cdot\boldsymbol{\eta}_{\boldsymbol{i}}^{B_e}$$

in the last line of (3.4).

To give a valid reaction-diffusion master equation the fluxes are chosen as the standard full-face centered difference

$$(F_k)^\alpha_{\boldsymbol{i}\pm\frac{1}{2}\boldsymbol{e}_k} = \mp D\,\frac{p^\alpha_{\boldsymbol{i}\pm\boldsymbol{e}_k} - p^\alpha_{\boldsymbol{i}}}{h}.$$

From the nuclear membrane boundary condition

$$\boldsymbol{F}_{\boldsymbol{i}}^{B_n}\cdot\boldsymbol{\eta}_{\boldsymbol{i}}^{B_n} = -\rho\,[p]_{\boldsymbol{i}}^{B_n}.$$

To enforce this jump condition the cell-centered solution value for the domain on the other side of the nuclear membrane is used. For example, if $\alpha = \text{nuc}$, then $p_{\boldsymbol{i}}^{\alpha'}$ is used, where $\alpha' = \text{cyt}$. Vice versa, if $\alpha = \text{cyt}$, then $\alpha' = \text{nuc}$. Using this definition, the boundary condition is approximated by choosing

$$\rho\,[p]_{\boldsymbol{i}}^{B_n} \equiv \rho(p_{\boldsymbol{i}}^{\alpha'} - p_{\boldsymbol{i}}^\alpha).$$

With all the flux terms specified, the final discretization is then

$$\frac{dp_{\boldsymbol{i}}^{\alpha}}{dt} = \frac{D}{V_{\boldsymbol{i}}^{\alpha} h}\left(\sum_{\pm}\sum_{k=1}^{d} A_{\boldsymbol{i}\pm\frac{1}{2}\boldsymbol{e}_k}^{\alpha}\left(p_{\boldsymbol{i}\pm\boldsymbol{e}_k}^{\alpha} - p_{\boldsymbol{i}}^{\alpha}\right)\right) + \frac{A_{\boldsymbol{i}}^{B_n}\rho}{V_{\boldsymbol{i}}^{\alpha}}(p_{\boldsymbol{i}}^{\alpha'} - p_{\boldsymbol{i}}^{\alpha}). \tag{3.5}$$

For cells that do not intersect any boundary the discretization reduces to the standard five- (seven-) point discrete Laplacian in two dimensions (three dimensions).

Defining the probability of the particle being in the domain α portion of the $\boldsymbol{i}$th cell as

$$Q_{\boldsymbol{i}}^{\alpha}(t) = p_{\boldsymbol{i}}^{\alpha} V_{\boldsymbol{i}}^{\alpha} \approx \text{Prob}\{\boldsymbol{X}(t) \in V_{\boldsymbol{i}}^{\alpha} | \boldsymbol{X}(0) = \boldsymbol{x}_0\},$$

the discretization can be rewritten as

$$\frac{dQ_{\boldsymbol{i}}^{\alpha}}{dt} = \frac{D}{h}\left(\sum_{\pm}\sum_{k=1}^{d} \frac{A_{\boldsymbol{i}\pm\frac{1}{2}\boldsymbol{e}_k}^{\alpha}}{V_{\boldsymbol{i}\pm\boldsymbol{e}_k}^{\alpha}} Q_{\boldsymbol{i}\pm\boldsymbol{e}_k}^{\alpha} - \frac{A_{\boldsymbol{i}\pm\boldsymbol{e}_k}^{\alpha}}{V_{\boldsymbol{i}}^{\alpha}} Q_{\boldsymbol{i}}^{\alpha}\right) + A_{\boldsymbol{i}}^{B_n}\rho\left(\frac{Q_{\boldsymbol{i}}^{\alpha'}}{V_{\boldsymbol{i}}^{\alpha'}} - \frac{Q_{\boldsymbol{i}}^{\alpha}}{V_{\boldsymbol{i}}^{\alpha}}\right). \tag{3.6}$$

The first term in (3.6) represents diffusive motion between computational cells, while the second represents motion across the nuclear membrane within one computational cell. Let the two components of a split computational cell be represented as separate computational cells. In this form, all movement between computational cells within the same domain is by diffusive jumps, while movement between computational cells of different domains is by jumps determined by the membrane fluxes. Despite the appearance of the membrane flux terms, this equation, with an appropriate index relabeling to account for the multiple components of a split computational cell, still has the same form as (2.8). Hence, all motion is still represented as first order reactions, with jump rates given by the coefficients of the $Q_{\{\cdot\}}^{\{\cdot\}}$ terms.

Taking $A_{\boldsymbol{ij}}^{\alpha}$ to be the area of the domain α face shared by cells $\boldsymbol{i}$ and $\boldsymbol{j}$, the jump rate from the domain α component of cell $\boldsymbol{j}$ to the domain α component of cell $\boldsymbol{i}$ is

$$k_{\boldsymbol{ij}}^{\alpha} = \frac{D A_{\boldsymbol{ij}}^{\alpha}}{h V_{\boldsymbol{j}}^{\alpha}}. \tag{3.7}$$

For strictly interior cells this reduces to

$$k_{\boldsymbol{ij}}^{\alpha} = \frac{D}{h^2}.$$

The jump rate across the nuclear membrane in cell $\boldsymbol{i}$ from domain α' to domain α is

$$k_{\boldsymbol{i}}^{\alpha\alpha'} = \frac{A_{\boldsymbol{i}}^{B_n}\rho}{V_{\boldsymbol{i}}^{\alpha'}}. \tag{3.8}$$

A similar equation holds for the jump from domain α to domain α'. Note that $k_{\boldsymbol{ij}}^{\alpha}$ and $k_{\boldsymbol{ji}}^{\alpha}$ are unequal in general because $V_{\boldsymbol{i}}^{\alpha}$ may not be equal to $V_{\boldsymbol{j}}^{\alpha}$. Similarly, $k_{\boldsymbol{i}}^{\alpha\alpha'}$ and $k_{\boldsymbol{i}}^{\alpha'\alpha}$ will also differ as $V_{\boldsymbol{i}}^{\alpha}$ may not be equal to $V_{\boldsymbol{i}}^{\alpha'}$.

There is a fundamental difference in the scaling between (3.7), which scales like $1/h^2$, and (3.8), which scales like $1/h$. This difference arises because the flux for diffusive motion is proportional to the [illegible] of the density, while the flux across the

nuclear membrane is proportional to the $\boldsymbol{\prime\prime}$ $\ldots$ $\boldsymbol{\prime}$ in the density across the membrane.

A consequence of the conservative discretization form is that total probability is conserved:

$$\sum_{\alpha}\sum_{\boldsymbol{i}\in\alpha}\frac{dQ_{\boldsymbol{i}}^{\alpha}}{dt}=\sum_{\alpha}\sum_{\boldsymbol{i}\in\alpha}\frac{dp_{\boldsymbol{i}}^{\alpha}}{dt}V_{\boldsymbol{i}}^{\alpha}=0.$$

The master equation approximation will also satisfy the principle of detailed balance—the statement that at thermodynamic equilibrium the unidirectional probability flux from cell $\boldsymbol{i}$ to cell $\boldsymbol{j}$ is equal to the unidirectional probability flux from cell $\boldsymbol{j}$ to cell $\boldsymbol{i}$. We expect detailed balance to hold, as (3.1) forms a closed and isolated system due to the no-flux cellular membrane condition and passive nuclear membrane flux (no active transport). Letting $p^{eq}(x,t)=p^{eq}$ be the constant equilibrium solution to the continuous problem, $(Q^{eq})_{\boldsymbol{i}}^{\alpha}=p^{eq}V_{\boldsymbol{i}}^{\alpha}$ will be the equilibrium probability of the Brownian particle being in the domain α component of cell $\boldsymbol{i}$. For $A_{\boldsymbol{ij}}^{\alpha}$, the area of the domain α face between cells $\boldsymbol{i}$ and $\boldsymbol{j}$, the detailed balance condition is

$$\begin{aligned}
&k_{\boldsymbol{ji}}^{\alpha}(Q^{eq})_{\boldsymbol{i}}^{\alpha}=k_{\boldsymbol{ij}}^{\alpha}(Q^{eq})_{\boldsymbol{j}}^{\alpha}\\
\iff&\frac{DA_{\boldsymbol{ij}}^{\alpha}}{hV_{\boldsymbol{i}}^{\alpha}}(Q^{eq})_{\boldsymbol{i}}^{\alpha}=\frac{DA_{\boldsymbol{ij}}^{\alpha}}{hV_{\boldsymbol{j}}^{\alpha}}(Q^{eq})_{\boldsymbol{j}}^{\alpha}\\
\iff&\frac{(Q^{eq})_{\boldsymbol{i}}^{\alpha}}{V_{\boldsymbol{i}}^{\alpha}}=\frac{(Q^{eq})_{\boldsymbol{j}}^{\alpha}}{V_{\boldsymbol{j}}^{\alpha}},
\end{aligned}$$

which holds by the definitions of $(Q^{eq})_{\boldsymbol{i}}^{\alpha}$ and $(Q^{eq})_{\boldsymbol{j}}^{\alpha}$. For jumps across a membrane between domains α and α',

$$\begin{aligned}
&k_{\boldsymbol{i}}^{\alpha'\alpha}(Q^{eq})_{\boldsymbol{i}}^{\alpha}=k_{\boldsymbol{i}}^{\alpha\alpha'}(Q^{eq})_{\boldsymbol{i}}^{\alpha'}\\
\iff&\frac{A_{\boldsymbol{i}}^{B_n}\rho}{V_{\boldsymbol{i}}^{\alpha}}(Q^{eq})_{\boldsymbol{i}}^{\alpha}=\frac{A_{\boldsymbol{i}}^{B_n}\rho}{V_{\boldsymbol{i}}^{\alpha'}}(Q^{eq})_{\boldsymbol{i}}^{\alpha'}\\
\iff&\frac{(Q^{eq})_{\boldsymbol{i}}^{\alpha}}{V_{\boldsymbol{i}}^{\alpha}}=\frac{(Q^{eq})_{\boldsymbol{i}}^{\alpha'}}{V_{\boldsymbol{i}}^{\alpha'}},
\end{aligned}$$

which again holds by the definitions of $(Q^{eq})_{\boldsymbol{i}}^{\alpha}$ and $(Q^{eq})_{\boldsymbol{i}}^{\alpha'}$. Note that an active transport boundary condition at the cellular membrane could make the system open, in which case detailed balance would no longer be expected to hold. Moreover, an active transport mechanism at the nuclear membrane would also prevent the system from coming to thermodynamic equilibrium and would result in a steady state in which the above relationships across the nuclear membrane would be violated. This would not affect the rate constants for other (passive) processes, however, which would therefore still satisfy the conditions derived from the principle of detailed balance.

For comparison to our discretization, note that in [21] $(F_k)_{\boldsymbol{i}\pm\frac{1}{2}\boldsymbol{e}_k}$ is chosen to be the standard centered difference approximation when the kth face does not intersect a boundary. This leads to the five- (seven-) point Laplacian as the discretization for strictly interior cells. For faces cut by the boundary, [21] interpolates between the centered difference flux in neighboring cells to approximate the flux at the midpoint of the cut face. This method leads to a second order accurate approximation to the Laplacian, but does not give a valid master equation for the continuous time–discrete space discretization. To see why, note that the general form of the master equation

for the probability, Q_i, of being at site i with transition probability per unit time $W_{ji} \geqslant 0$ is given by (2.2). In general interpolation will introduce negative weights W_{ji} or W_{ij} into the ith equation. Furthermore, interpolation violates the condition that if the ith equation contains a term $W_{ij}Q_j$, then the jth equation should contain a term $-W_{ij}Q_j$.

An alternative discretization method is presented in [13] that accounts for the boundary by using the standard five- (seven-) point Laplacian at all locations and adding an extra forcing term. As the master equation has no forcing terms this method would not give an equation that could be realized by the Gillespie method.

3.3. Overall method. Using the discretization from the previous section, realizations of the stochastic process described by the reaction-diffusion master equation can be created using the Gillespie method. The overall simulation algorithm is as follows:

1. Initialization:
   (a) Given the membrane locations, calculate $A^{\alpha}_{\boldsymbol{i}\pm\boldsymbol{e}_k}$, $V^{\alpha}_{\boldsymbol{i}}$, and $A^{B_n}_{\boldsymbol{i}}$ for each location, $\boldsymbol{i}$, each direction, $\boldsymbol{e}_k$, and each domain, α.
   (b) From (3.7) and (3.8) calculate the jump rates for all species, within all Cartesian cells containing some part of Ω.
   (c) For each piece of a Cartesian cell, calculate the rates of all chemical reactions that can occur there. For reactions with volume dependent rates use $V^{\alpha}_{\boldsymbol{i}}$ to change the rate constants to units of reciprocal time.
2. Time Evolution:
   (a) Simulate individual realizations of the stochastic process described by the reaction-diffusion master equation using the Gillespie method. Diffusive and transmembrane solute motion are represented as first order reactions, using the jump rates calculated in step 1(b). Within each component of a cell, the rates from step 1(c) are used to simulate chemical reactions.
3. Output:
   (a) To estimate moments or distributions, use statistics from many simulations.

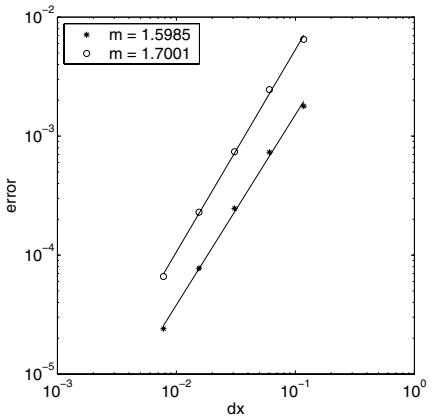
3.4. Convergence of the numerical discretization. The convergence of the discretization provided by (3.5) is illustrated in two dimensions for both the Poisson equation and diffusion equation with circular boundaries. The method was found to converge between first and second order spatially. Let $(\boldsymbol{u}_h)^{\alpha}_{\boldsymbol{i}}$ denote the numerical solution to the Poisson problem, and $\boldsymbol{u}_h$ the vector whose components are given by $(\boldsymbol{u}_h)^{\alpha}_{\boldsymbol{i}}$. Define the maximum norm, $\|\boldsymbol{u}_h\|_{\infty}$, as

$$\|\boldsymbol{u}_h\|_{\infty} = \max_{\alpha,\boldsymbol{i}\in\alpha} |(\boldsymbol{u}_h)^{\alpha}_{\boldsymbol{i}}|.$$

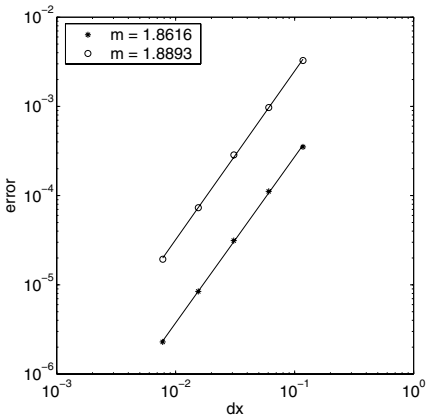
A volume weighted two norm, $\|\boldsymbol{u}_h\|^w_2$, is defined as

$$\|\boldsymbol{u}_h\|^w_2 = \left(\sum_{\alpha} \sum_{\boldsymbol{i}\in\alpha} \left((\boldsymbol{u}_h)^{\alpha}_{\boldsymbol{i}}\right)^2 V^{\alpha}_{\boldsymbol{i}} \right)^{\frac{1}{2}}.$$

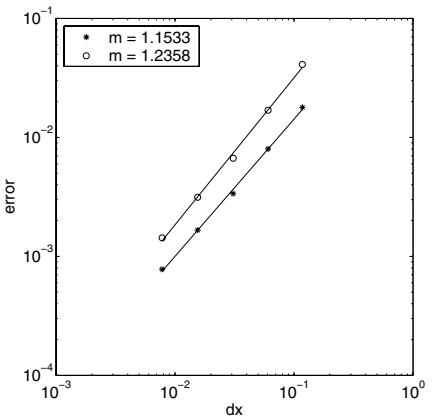
Let $(\boldsymbol{u}^n_h)^{\alpha}_{\boldsymbol{i}}$ denote the numerical solution to the diffusion equation at time t_n, $\boldsymbol{u}^n_h$ the solution vector at time t_n, and $\boldsymbol{u}_h$ the solution over all spatial locations, domains, and times. The maximum norm over all time is defined as $\max_n \|\boldsymbol{u}^n_h\|_{\infty}$. As in section 3.1,



(a) Error for (3.9), with exact solution (3.10).



(b) Error for (3.9), with exact solution (3.11).



(c) Error for (3.12), with exact solution (3.13).

FIG. 2. *Convergence results for Poisson equation solutions; star is two norm error and circle is maximum norm error. These errors are plotted against the mesh width dx on log-log plots. The empirical order of accuracy is m, which is the slope of the best fit straight line in each case.*

$\partial\Omega$ will denote the cell membrane, or outer boundary, while $\partial\Omega_n$ will denote the nuclear membrane, or inner boundary. In all of the examples considered in this section, the two boundaries are concentric circles with radii 1 and 1/2, respectively. The domain into which the circles are embedded is taken, for a given mesh width h, to be the square centered at the origin with sides of length $2 + 4h$. This provides a separation between the boundary of the computational domain and the embedded boundaries.

Figure 2(a) shows the convergence of the discretization for the Poisson equation

with just the outer boundary. The equations are

$$\begin{aligned} \Delta u &= f(\boldsymbol{x}) \quad \text{in } \Omega, \\ \frac{\partial u}{\partial \boldsymbol{\eta}} &= 0 \qquad \text{on } \partial\Omega, \end{aligned} \tag{3.9}$$

where $f(\boldsymbol{x})$ was chosen so that the exact solution was

$$u = \frac{r^4}{4} - \frac{r^3}{3}, \quad r \le 1, \tag{3.10}$$

with $u = 0$ for $r > 1$. The two norm error converged at order 1.6, while the maximum norm error converged at order 1.7.

An angular dependence was added to $f(\boldsymbol{x})$ to give the exact solution

$$u = \left(\frac{r^4}{4} - \frac{r^3}{3}\right)\cos\theta, \quad r \le 1, \tag{3.11}$$

with $u = 0$ for $r > 1$. Figure 2(b) shows the convergence of the errors for this problem. The θ dependence actually improves the convergence, so that the two norm error is order 1.86, while the maximum norm error now converges at order 1.89.

Figure 2(c) shows the convergence of the discretization for the Poisson equation with both boundaries. The equations are

$$\begin{aligned} \Delta u &= f(\boldsymbol{x}) \qquad \text{in } \Omega, \\ \frac{\partial u}{\partial \boldsymbol{\eta}} &= 0 \qquad \text{on } \partial\Omega, \\ -\frac{\partial u}{\partial \boldsymbol{\eta}} &= -\pi\,[u]_n \quad \text{on } \partial\Omega_n, \end{aligned} \tag{3.12}$$

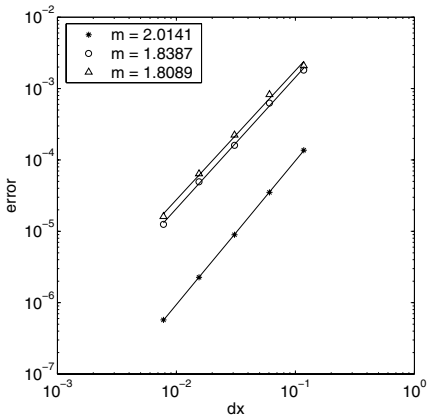
where $f(\boldsymbol{x})$ was chosen so that the exact solution was

$$u = \begin{cases} \cos \pi r + \sin \pi r & \text{in } \Omega_n, \\ \cos \pi r & \text{in } \Omega \setminus \Omega_n, \\ 0 & \text{outside } \Omega. \end{cases} \tag{3.13}$$

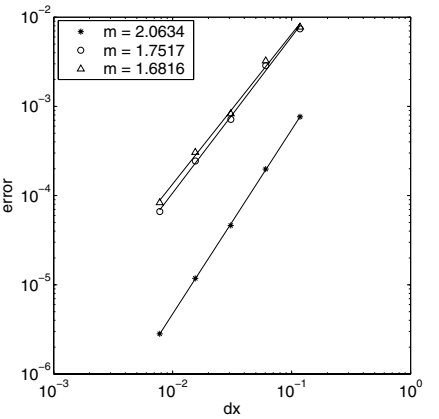
The jump condition at the interior boundary reduces the order of convergence to 1.15 in the two norm and 1.23 in the maximum norm.

Figure 3(a) shows the convergence of the discretization for the diffusion equation with just the exterior boundary. The final time, at which the two norm and maximum norm errors were measured, was taken to be $t_f = .025$. At this time the solution was still far from equilibrium. $\Delta t/h$ was fixed at about t_f/L, where L was the diameter of the outer boundary. For the examples in Figure 3, $\Delta t/h \approx .013$. The time integration was performed using the second order, L_0 stable, implicit Runge–Kutta method mentioned in [21]. Similar results were obtained for a Crank–Nicolson discretization. The equations are

$$\begin{aligned} \frac{\partial u}{\partial t} &= \Delta u + f(\boldsymbol{x}, t) \quad \text{in } \Omega, \\ \frac{\partial u}{\partial \boldsymbol{\eta}} &= 0 \qquad\qquad\quad \text{on } \partial\Omega, \end{aligned} \tag{3.14}$$



(a) Error for (3.14), with exact solution (3.15).



(b) Error for (3.16), with exact solution (3.17).

FIG. 3. *Convergence results for diffusion equation solutions; star is two norm error at t_f, circle is the maximum norm error at t_f, and diamond is the maximum of the maximum norm error over all time. These errors are plotted against the mesh width dx on log-log plots. The empirical order of accuracy is m, which is the slope of the best fit straight line in each case.*

where $f(\boldsymbol{x}, t)$ was chosen so that the exact solution was

$$u = \left(\frac{r^4}{4} - \frac{r^3}{3}\right) e^{-20t}, \quad r \leq 1, \tag{3.15}$$

with $u = 0$ for $r > 1$. At t_f, the two norm error converged at about order 2.01, and the maximum norm error converged at about order 1.84. The maximum over all time points of the maximum norm converged at about order 1.81.

Figure 3(b) shows the convergence of the discretization for the diffusion equation with both boundaries. Note that the same time discretization was used as above, again with $\Delta t/h \approx .013$. The equations are

$$\begin{aligned} \frac{\partial u}{\partial t} &= \Delta u + f(\boldsymbol{x}, t) && \text{in } \Omega, \\ \frac{\partial u}{\partial \boldsymbol{\eta}} &= 0 && \text{on } \partial\Omega, \\ -\frac{\partial u}{\partial \boldsymbol{\eta}} &= -\left[u\right]_n && \text{on } \partial\Omega_n, \end{aligned} \tag{3.16}$$

where $f(\boldsymbol{x}, t)$ was chosen so that the exact solution was

$$u = \begin{cases} \left(\frac{br^4}{4} + \frac{ar^3}{3} + \frac{ar^5}{5}\right) e^{-20t} & \text{in } \Omega_n, \\ \left(\frac{r^3}{3} - \frac{r^4}{4}\right) e^{-20t} & \text{in } \Omega \setminus \Omega_n, \\ 0 & \text{outside } \Omega. \end{cases} \tag{3.17}$$

a and b were chosen to satisfy the jump boundary condition at $r = 1/2$. At t_f the two norm error converged at about order 2.06, and the maximum norm error converged at

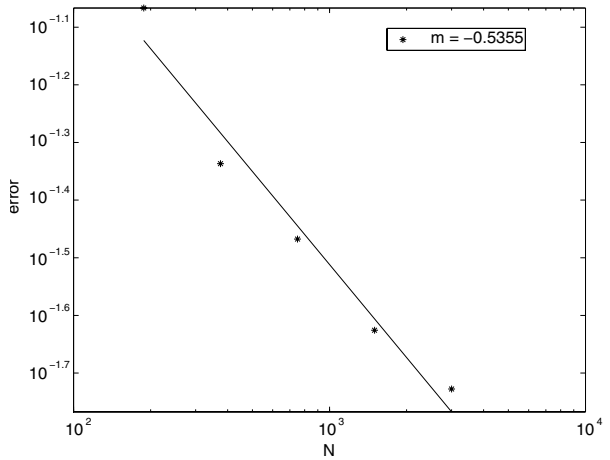


FIG. 4. *Convergence of the mean of Gillespie simulations to the numerical solution to* (3.1). *Here the error is given by the maximum absolute difference over all times and spatial locations between the Gillespie simulation estimate and the numerical solution. A* 37 *by* 37 *mesh was used with mesh width* 2/33, $D = 1$, *and* $\rho = 1$. *The particle was started at the center of the domain for all simulations. m gives the slope of the best fit line to the data.*

about order 1.75. The maximum over all time points of the maximum norm converged at about order 1.68.

3.5. Convergence of the overall method. The overall method presented in section 3.3 has two sources of error associated with it: sampling error and error due to the spatial discretization. The Gillespie method provides exact realizations of the stochastic process defined by the reaction-diffusion master equation, hence the error in any individual realization is due solely to the spatial discretization. From the central limit theorem, for a fixed mesh size, we expect the error between the mean population levels from N simulations and the means of the reaction-diffusion master equation to be approximately $O(1/\sqrt{N})$. Note that the constant in the $O(1/\sqrt{N})$ term will depend on the mesh size. With a sufficient number of samples the joint probability distribution, for a fixed mesh size, can be estimated to any desired accuracy, but the required number of samples might be very large.

As an example, consider a single particle moving within a two-dimensional biological cell. Assume the cell has a circular cellular membrane of radius 1, and a circular nuclear membrane of radius 1/2. The particle's dynamics are assumed to be given by (3.1), with $D = 1$ and $\rho = 1$. Since there is only one particle, the mean number of the particle in a given region is just the probability of the particle being in that region. As the reaction-diffusion master equation is in terms of the population levels of the particle at different locations, its mean should converge to the solution of (3.1) as h goes to zero. Figure 4 shows the maximum error over all times between the mean of N Gillespie simulations and the numerical solution to (3.1), as the number of samples is increased. Here h is fixed at 2/33, for a 37 by 37 mesh. Notice that the error decreases like $1/\sqrt{N}$.

Having obtained the distribution given by the reaction-diffusion master equation, there is still the question of how accurate a representation of the dynamics of the system it gives. It is not clear that the reaction-diffusion master equation has a well-defined continuum limit as h goes to zero. Instead, it is generally considered valid

only for a range of h values, and there are several simultaneous physical conditions which h should satisfy. First, h should be significantly larger than the mean free path, λ, between the elastic collisions driving diffusion. This condition ensures that the system can be considered in local equilibrium within a computational cell because of many nonreactive collisions. Note, however, that to ensure that the system is accurately resolving local behavior, and also that the approximation of diffusion as jumps between cells is reasonable, h should be significantly smaller than the length scale of the entire system, L. Summarizing these constraints,

$$L \gg h \gg \lambda.$$

As we now show, h also needs to be chosen large enough (!) that the system can be considered in local equilibrium and well mixed within each mesh cell on the time scale of the fastest bimolecular reactions. This assumption underlies the use of stochastic chemical kinetics independently within each mesh cell. For this to hold, the time scale for the particle to diffuse throughout a mesh cell should be much faster than the time scale for the fastest bimolecular chemical reaction. The time scale to diffuse throughout a region of length scale h is approximately h^2/D. For a bimolecular reaction, the time scale with rate constant k is h^3/k for a mesh cell of volume h^3. (Recall that the units of the rate constant of a bimolecular reaction are volume per unit time.) Hence, it is necessary that

$$\frac{h^3}{k} \gg \frac{h^2}{D},$$

which implies that

$$h \gg \frac{k}{D}.$$

Thus, the rate constant for a bimolecular reaction places a fundamental lower limit on the spatial size of mesh cells. Fortunately, for cellular processes and the molecules involved in them, k/D is generally not large enough to impose a significant restriction on h. In summary, letting k denote the rate constant of the fastest bimolecular reaction,

$$L \gg h \gg \max\left(\lambda, \frac{k}{D}\right).$$

In these inequalities D is the diffusion coefficient of a particular molecular species and k refers to the fastest bimolecular reaction in which that species participates. Such inequalities must hold simultaneously for all species under consideration. Note that a first order reaction does not restrict the mesh size in any manner since it generally represents an internal molecular event, and is not dependent on the system being well mixed locally.

As of yet, the reaction-diffusion master equation has not been derived from more microscopic physical models. Its validity has been verified numerically in [5] through comparison with microscopic hard sphere models that track individual particle positions and momenta. One might also hope that, for sufficiently fast diffusion, the results from the reaction-diffusion master equation applied to an initially well-mixed system would agree over a range of h values with the spatially homogeneous chemical master equation. For example, consider the simple chemical reaction $A + B \to C$,

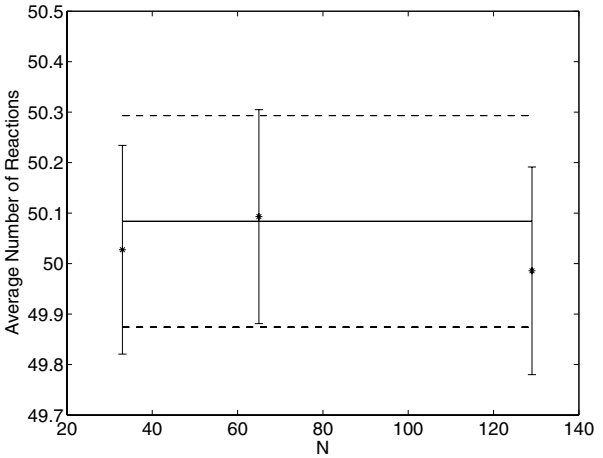

FIG. 5. *Average number of reactions in stochastic diffusion simulations, given by stars, compared to the exact solution for the expected number of reactions of the spatially homogeneous chemical master equation, given by the solid straight line. Error bars give* 99.7 *percent confidence intervals about the data points. The error bars are calculated using the sampled variance. N gives the number of mesh points in each direction. For each data point,* 3000 *sample realizations were used to calculate the average number of reactions. The dashed lines give the predicted* 99.7 *percent confidence interval, for* 3000 *samples, about the exact mean using the exact variance of the well-mixed master equation. Data is from* $t = .1$*, a time at which approximately half the A and half the B chemicals have been converted to C. Note the drastically expanded vertical scale.*

within a 1 unit by 1 unit square. The exact solution, at any time, for the average number of reactions in the spatially homogeneous chemical master equation is given in [18]. This reduces the statistical error in the problem to that in estimating the average number of reactions from the reaction-diffusion master equation. 100 molecules of A and 100 of B are each started randomly distributed throughout the domain. No-flux boundary conditions were assumed for the diffusion of chemicals, but periodic boundary conditions were also tested with no significant impact on the results. With bimolecular rate constant, .0001, and a diffusion constant of 100 for each species, $k/D = .000001$. Hence, by the preceding arguments h should only need to be greater than .000001 for the reaction-diffusion master equation to be valid. Figure 5 shows that as the number of mesh points, N, is increased, the average number of reactions from spatial simulations agrees with the exact number of reactions given by the spatially homogeneous chemical master equation to statistical error.

4. Transcription, translation, transport model. As an application of the method presented in section 3.3 we present a model of transcription, nuclear export, translation, and nuclear import in eukaryotes. While the model is simplified, and uses transcription and translation models that are more appropriate for a prokaryotes, it demonstrates the feasibility of the method in simulating biological networks. Section 4.1 describes the basic molecular cell biology necessary to understand the biochemical reaction model of section 4.2. Section 4.3 shows the time evolution of one realization of the model.

4.1. Background biology. The process by which a functional protein is produced from a segment of DNA that codes for it, called a gene, is a complex series of chemical events. In a coarsest description, the gene is first [illegible] to produce

a copy of itself called an mRNA. The mRNA is a linear sequence of nucleotides, every three of which comprise an element of a code representing an amino acid. The mRNA is then translated by special cellular machinery whereby the linear sequence of nucleotides is read, and the corresponding sequence of amino acids that the mRNA codes for is assembled. The polypeptide chain of amino acids typically undergoes further chemical and structural modifications to then form a functional protein.

For eukaryotes this situation is more complicated: transcription occurs in the nucleus and translation occurs in the cytoplasm of the cell. Between transcription and translation there is then an additional step that is required involving the movement of the mRNA out of the nucleus. This nuclear export process requires a series of chemical events; it cannot occur simply through diffusion of the mRNA. Similarly, those proteins that influence gene expression must be imported into the nucleus to be effective.

Large protein complexes form pores in the nuclear membrane through which all transmembrane traffic flows. These nuclear pore complexes are normally only wide enough for small molecules of less than 9 nanometers to pass through by free diffusion. Large molecules, such as mRNAs and most proteins, require the assistance of nuclear export and import receptors, which allow the pores effectively to dilate so that molecules of up to 26 nanometers can pass [1].

We shall be interested in the export of newly transcribed mRNA from the nucleus, and the import of the resulting protein product back into the nucleus. These two pathways are believed to be distinct in the nuclear receptors used, and in the biasing factors that confer directionality to the process (so that, for example, newly exported mRNA does not get reimported into the nucleus). Since the general mRNA export pathway is still unsettled, we shall use the same pathway for modeling mRNA export and protein import. This pathway is driven by a nuclear membrane RanGTP gradient that confers directionality to the movement of cargo across the membrane. A subset of the full RanGTP cycle model presented in [24] is used to account for the movement of receptors and their cargo. The RanGTP nuclear transport process is sometimes referred to as "active" because there is an energy expenditure in maintaining the gradient of RanGTP across the nuclear membrane. In contrast, the actual movement of cargo across the nuclear membrane is believed to be passive. Note that this pathway is used for the export of some mRNAs, for example, the export of incompletely spliced HIV mRNA encoding viral structural proteins [7].

The basic model presented in the next section is built on the pathway of transcription of one gene to produce mRNA, nuclear export of the mRNA, translation of the mRNA within the cytoplasm, and import of the resulting protein product back into the nucleus. Protein import plays an important role in many transcriptional networks, allowing the protein product of one gene to bind and regulate the expression of another. Several important steps in the transcription-translation cycle for eukaryotes are not modeled, including splicing, the opening of the chromatin to allow physical access to the gene, and the assembly of the transcription initiation complex.

4.2. Chemical model. The eukaryotic cell is modeled in two dimensions as two concentric circles, representing the plasma and nuclear membranes. The plasma membrane radius is taken to be 11.81 μm, while the nuclear membrane radius is 5 μm. The transcription and translation models used are based on those presented in [8]. Specifically, the gene of interest has several states. DNA denotes that the gene is free of RNA polymerase II, hereafter RNAP, the enzyme which reads the nucleotides comprising the gene and then incorporates the corresponding nucleoside triphospate

into the growing mRNA transcript. DNA^0 will denote that the RNAP is bound to the gene's promoter and ready to begin transcription. DNA^l will denote that the first l of the nucleotides forming the gene have been read and incorporated into the mRNA, with M giving the total number of nucleotides in the gene. Finally, the number of mRNA molecules within spatial computational cell i is given by $mRNA_i$. For simplicity, the gene is assumed to be localized in the center of the nucleus, which will have index i_{center}. The concentration of both RNAP and the nucleoside triphospates that are added to the mRNA transcript are assumed fixed so that transitions between the different DNA states are first order reactions. With these definitions, the transcriptional reactions, all defined solely at the cell center, are then

$$\begin{aligned} DNA &\to DNA^0, \\ DNA^{l-1} &\to DNA^l, \quad l = 1, \ldots, M-1, \\ DNA^{L-1} &\to mRNA_{i_{\text{center}}} + DNA. \end{aligned}$$

The rates for these reactions are, respectively, $.05\,\text{s}^{-1}$, $30\,\text{s}^{-1}$, and $30\,\text{s}^{-1}$. The number of nucleotides in the gene, M, is chosen to be 999.

Newly transcribed mRNA is assumed to diffuse freely throughout the nucleus until entering the export pathway. The mRNA export model is based on the RanGTP export system. Denote by NR the nuclear export receptor to which mRNA can bind; by Rt, RanGTP; by Rd, RanGDP; by Rb, RanBP1; and by NR–Rt the nuclear receptor complexed with RanGTP. All five are assumed to be at steady state concentrations, and uniformly distributed throughout the nucleus and cytoplasm. Note that the steady state concentrations are not assumed to be the same within the nucleus and cytoplasm, simply within each individually. Steady state concentrations and subsequent reaction rates were based on the data in [24]. The export process consists of three reactions, beginning with the binding of the export receptor-RanGTP complex to nuclear mRNA. Once this has occurred, the nuclear membrane is assumed to be permeable to the complex. At all locations within the cytoplasm the complex can then bind RanBP1, which subsequently induces the release of the mRNA from the complex. The reactions are

$$\begin{aligned} mRNA_i + NR\text{–}Rt_i &\to mRNA\text{–}NR\text{–}Rt_i && \text{within nucleus,} \\ mRNA\text{–}NR\text{–}Rt_i + Rb_i &\rightleftarrows mRNA\text{–}NR\text{–}Rt\text{–}Rb_i && \text{within cytoplasm,} \\ mRNA\text{–}NR\text{–}Rt\text{–}Rb_i &\to mRNA_i + NR_i + Rb_i + Rd_i && \text{within cytoplasm.} \end{aligned}$$

Using the assumption of constant concentrations, we can reduce these reactions to the following four:

$$\begin{aligned} mRNA_i &\to mRNA\text{–}NR\text{–}Rt_i && \text{within nucleus,} \\ mRNA\text{–}NR\text{–}Rt_i &\rightleftarrows mRNA\text{–}NR\text{–}Rt\text{–}Rb_i && \text{within cytoplasm,} \\ mRNA\text{–}NR\text{–}Rt\text{–}Rb_i &\to mRNA_i && \text{within cytoplasm.} \end{aligned}$$

The rates for these reactions are, respectively, $1184.5\,\text{s}^{-1}$, $298.93\,\text{s}^{-1}$ for the forward, $.5\,\text{s}^{-1}$ for the reverse, and $51.19\,\text{s}^{-1}$.

Once the mRNA is free within the cytoplasm, it can then associate with ribosomes, the molecular machines on which translation occurs. The ribosomes are assumed to be uniformly distributed throughout the cytoplasm as a constant background concentration. The translation process begins with the binding of an mRNA

to a ribosome to form a complex that is ready to translate, denoted by $mRNA_i^0$. As the ribosomes are very large, it is assumed that the translation process is immobile. Translation then consists of a series of elongation steps by which the mRNA is moved through the ribosome and read, and each set of three nucleotides is translated into the appropriate amino acid. This amino acid is then added to the growing polypeptide that will become the protein. Let $mRNA^l$ denote that l amino acids have been incorporated into the polypeptide chain, $l = 1, \ldots, N$, where $N = M/3$. Denote by P protein. Assuming all amino acid concentrations are spatially homogeneous and at steady state, the translation process reduces to the following set of reactions:

$$\begin{aligned} mRNA_i &\to mRNA_i^0 && \text{within cytoplasm,} \\ mRNA_i^{l-1} &\to mRNA_i^l, \quad l = 1, \ldots, N-1, && \text{within cytoplasm,} \\ mRNA_i^{N-1} &\to P_i + mRNA_i && \text{within cytoplasm.} \end{aligned}$$

The rates for these reactions are, respectively, $.5\,\mathrm{s}^{-1}$, $33\,\mathrm{s}^{-1}$, and $33\,\mathrm{s}^{-1}$.

Protein may freely diffuse within both the nucleus and the cytoplasm; however, it may not freely cross the nuclear membrane. Instead, it uses the RanGTP nuclear import process to enter the nucleus. This process consists of two reactions: protein binding to nuclear import receptor within the cytoplasm, and unbinding of protein from the receptor upon binding of RanGTP within the nucleus. The reactions are then

$$\begin{aligned} P_i + NR_i &\to P\text{–}NR_i && \text{within cytoplasm,} \\ P\text{–}NR_i + Rt_i &\to P_i + NR\text{–}Rt_i && \text{within nucleus.} \end{aligned}$$

Using the constant concentration assumption, these reactions can be reduced to the following first order reactions:

$$\begin{aligned} P_i &\to P\text{–}NR_i && \text{within cytoplasm,} \\ P\text{–}NR_i &\to P_i && \text{within nucleus.} \end{aligned}$$

The rates for these reactions are, respectively, $1218.25\,\mathrm{s}^{-1}$ and $1.23\,\mathrm{s}^{-1}$.

A feedback mechanism is incorporated into the model by allowing the protein to repress the expression of its own gene. Denoting by DNA_{rep} the repressed state of the gene, the reactions are

$$DNA + P_{i_{center}} \rightleftarrows DNA_{\mathrm{rep}}.$$

Here the forward reaction rate is $.01\,\mu\mathrm{m}^3\mathrm{s}^{-1}$ and the reverse rate is $.01\,\mathrm{s}^{-1}$.

Finally, mRNA is assumed to be degradable within the cytoplasm with rate $.2\,\mathrm{s}^{-1}$, and protein anywhere with rate $.0025\,\mathrm{s}^{-1}$. Table 4.1 gives the diffusion and nuclear membrane permeability rates for the different species in the model. Note that because of the finite diffusion coefficients, this model will give different statistics than the corresponding well-mixed model. For example, in the nuclear export model the time for an mRNA-nuclear export receptor complex to diffuse throughout the nucleus is approximately

$$\frac{r_{\mathrm{nuc}}^2}{D} = 250 \text{ s}.$$

TABLE 4.1
Diffusion constant, D, and nuclear membrane permeability, ρ, for each species.

Species	D $\mu\text{m}^2\,\text{s}^{-1}$	ρ $\mu\text{m}\,\text{s}^{-1}$
$mRNA$	.1	0
$mRNA^l$	0	0
$mRNA$–NR–Rt	.1	.17
$mRNA$–NR–Rt–Rb	.1	0
P	20.0	0
P–NR	20.0	1.87

In contrast, the time scale for that complex to leave the nucleus in the well-mixed model would be approximately

$$\frac{\frac{4}{3}\pi r_{\text{nuc}}^3}{4\pi r_{\text{nuc}}^2\,\rho} = 9.8 \text{ s}.$$

With the assumed biological constants the two step export process, finding the nuclear membrane and then passing through it, is strongly diffusion limited. Therefore, a well-mixed model with infinitely fast diffusion would ignore the long time scale for an export complex to find the nuclear membrane, much less to get through it. This would result in a substantially faster export process than biologically occurs.

4.3. Numerical results. Figures 6 and 7 show the time evolution of one realization of the model described in the previous section, using an underlying 37 by 37 Cartesian mesh with a mesh width of approximately .72 microns. Within the simulations we calculate the number of molecules of each chemical species within each mesh cell. We assume that each individual mesh cell particles are well mixed, and as such the marker for every molecule in each figure is placed randomly within the mesh cell containing that molecule. Initially there are no mRNAs or proteins within the system, and the DNA is in the unbound state. Figure 6 shows the evolution of the system over several minutes. By Figure 6(a) the first mRNA has been fully transcribed and, because of the fast binding rate, is bound to a nuclear export receptor. The DNA is unbound, waiting for the next transcription cycle to begin. After 160 seconds, a second mRNA has been transcribed and bound with a nuclear receptor. The DNA is again unbound. By 310 seconds several proteins have been translated. One is diffusing within the cytoplasm bound to a nuclear receptor, while the other has already undergone the nuclear import process and is diffusing freely within the nucleus. Notice there is only one visible mRNA, as the second is undergoing translation within the cytoplasm and hence not displayed. The DNA is also not visible as it is undergoing transcription. Finally, after 380 seconds, several proteins have accumulated within the nucleus, with one binding to and inhibiting the DNA. A free mRNA is diffusing within the cytoplasm, along with a nuclear receptor coupled protein.

By allowing the protein to feed back and inhibit the transcription of its gene, we create a system in which protein production occurs in bursts. Figure 7 shows that a large amount of protein is built up in the nucleus by 1160 seconds, and that the DNA is in the repressed state. The higher protein levels increase the probability of the gene becoming repressed, and because the on rate for binding is sufficiently fast, and the off rate sufficiently slow, by 1670 seconds the overall protein population has shrunk from 10 to just 2. This is due in part to the fast decay rates of the mRNA. As the DNA is repressed, no mRNAs are transcribed to replace those that quickly decay, and hence the protein population simply decays away over time. Once the protein

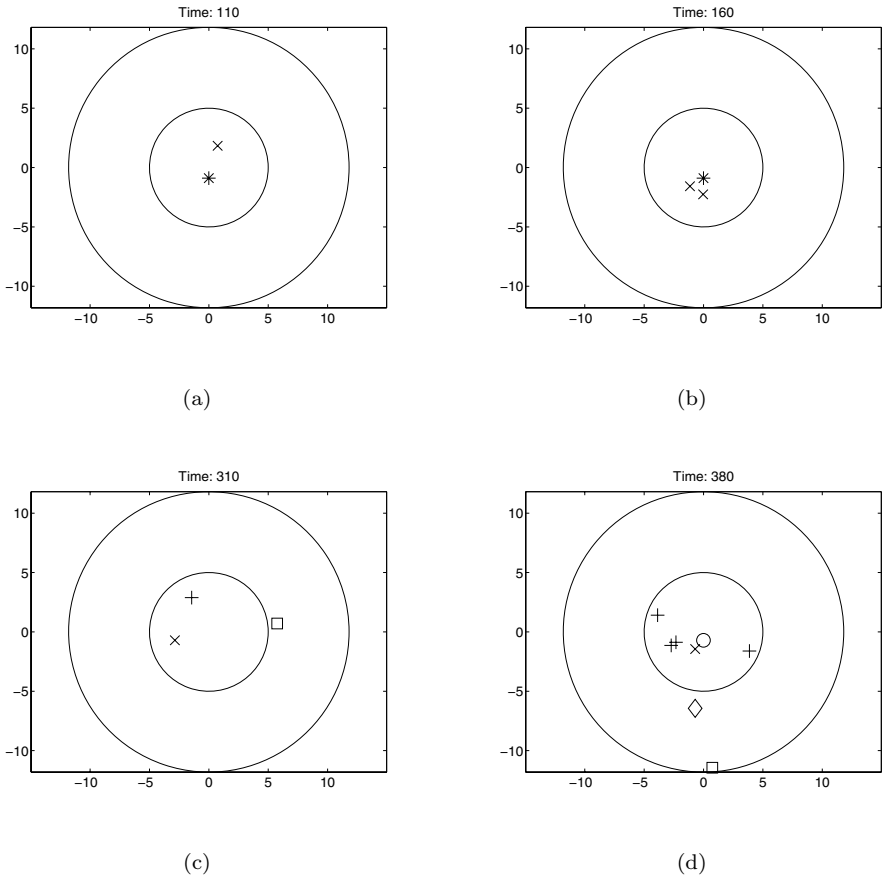

FIG. 6. *Evolution of one realization of the model from section* 4.2 *over several minutes. A star denotes the unbound DNA and a circle that the DNA is repressed. During transcriptional states the DNA is not displayed. A diamond denotes mRNA, and "×'s" denote mRNA bound to nuclear receptor and RanGTP. mRNAs coupled to nuclear receptors, RanGTP, and RanBP*1 *are not present in the images shown. During translation mRNAs are not displayed. A plus denotes a protein, and a box represents protein bound to nuclear receptor. Time is in seconds.*

population becomes sufficiently low, as in Figure 7(b), it becomes more unlikely that protein will find the DNA to bind and repress it, and hence the DNA is able to enter the transcription cycle. By 2010 seconds at least one mRNA has been transcribed and subsequently translated several times, as the nuclear protein level has increased. The production of mRNA followed by its subsequent translation produces new proteins, and consequently the nuclear protein population rises thereafter. By 2080 seconds, 10 protein molecules are within the nucleus.

Figure 8 shows the total number of nuclear proteins in one realization, over 30,000 seconds. The total number is given by the amount of free, receptor-bound, and DNA-bound proteins within the nucleus at a fixed time. Note that the number of proteins tends to quickly jump up to a given amount, and then more slowly decay to either one or zero proteins. When only one protein is present for large periods of time, it is usually bound to the DNA, thereby repressing the gene (data not shown).

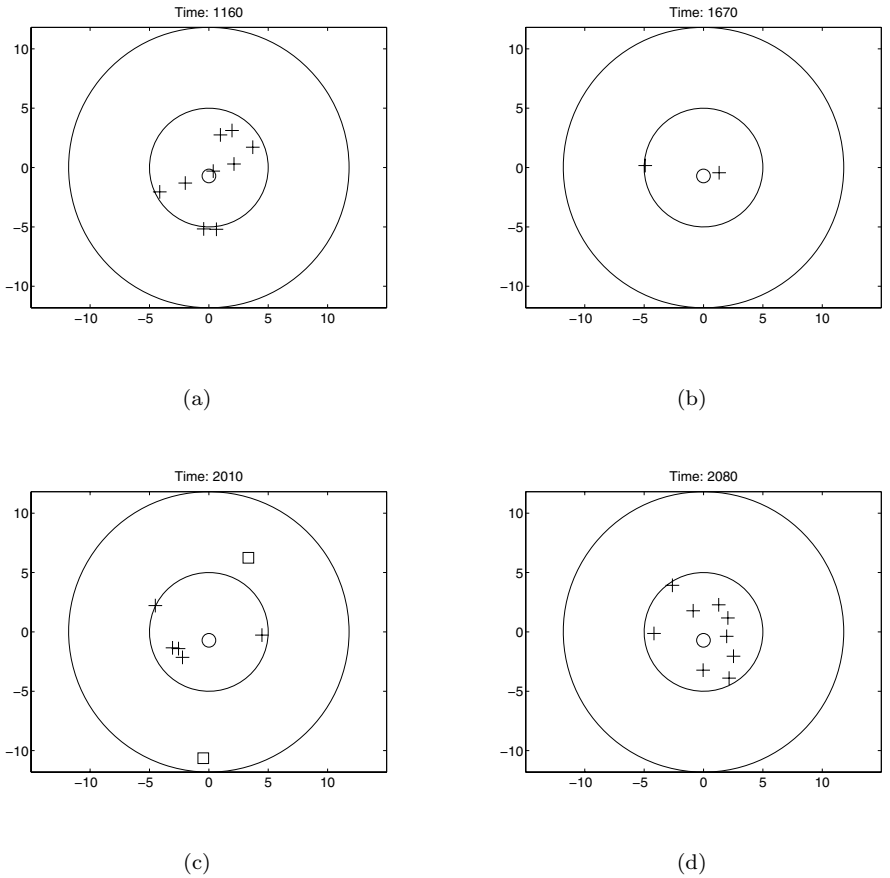

FIG. 7. *Evolution of one realization of the model from section* 4.2 *over a half hour. Symbols have the same codes as in Figure* 6.

5. Conclusions and future work. We have presented a method for calculating diffusive jump rates for the reaction-diffusion master equation within complex geometries. The method allows for multiple domains, and easily handles both jump and Neumann boundary conditions. The underlying discretization on which the method is based is found to converge between first and second order accuracy on both the Poisson equation and the diffusion equation. The discretization also conserves probability, and gives jump rates that satisfy the principle of detailed balance for diffusive motion and for passive boundary fluxes. With only one particle and no chemical reactions the method converges, as the mesh width goes to zero, to the solution to the Fokker–Planck equation for a classical Brownian particle. Further, when the system contains only first order reactions, the mean concentrations given by the method converge to the solution of the reaction-diffusion equations associated with the deterministic model of the chemical system. If the system contains bimolecular or higher order reactions, however, no such agreement with the solution of deterministic reaction-diffusion equations would be expected (except in the limit of large numbers of molecules), since averaging does not commute with multiplication. In such cases,

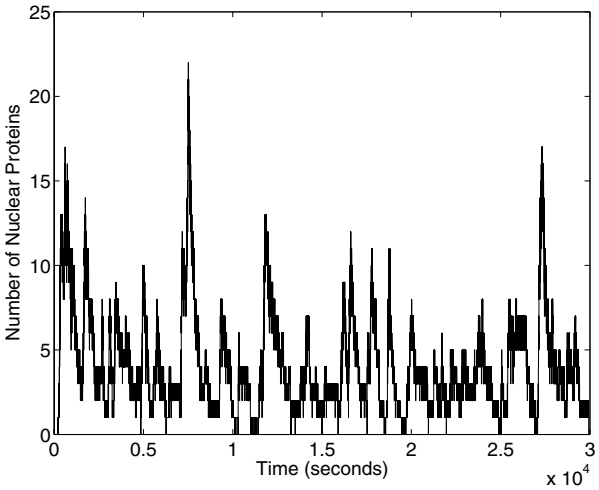

FIG. 8. *Total number of nuclear proteins in one realization of the model from section* 4.2. *Simulation occurred over* 30,000 *seconds, with data points at one second intervals.*

our method should give a more accurate representation of the stochastic dynamics of the spatially distributed chemical system.

As an illustrative application, we developed a model for eukaryotic transcription, nuclear export, translation, nuclear import, and gene regulation, and we simulated this model in a simplified two-dimensional representation of a eukaryotic cell. Spontaneous, but noisy, oscillations in nuclear protein levels were observed in this simple genetic network.

For future work, we plan to extend the current software implementation of the method to three dimensions, with the eventual goal of simulating cellular networks with realistic nuclear membrane and plasma membrane geometry. One interesting question is the interplay between reaction rates and diffusion rates in producing oscillatory nuclear protein levels. For different parameter regimes well-mixed stochastic, well-mixed deterministic, deterministic reaction-diffusion, and stochastic reaction-diffusion models could all show different qualitative behavior. We are also working on developing a more accurate biochemical model for the transcription and translation processes within eukaryotic cells.

Acknowledgments. The authors thank Ian G. Macara for helpful discussions regarding the model in [24]. We would also like to thank the referees for their careful reading of the paper and helpful comments and suggestions.

ON CONSTRAINT PRESERVATION IN NUMERICAL SIMULATIONS OF YANG–MILLS EQUATIONS*

SNORRE H. CHRISTIANSEN† AND RAGNAR WINTHER†

Abstract. The problem of constraint preservation for discretizations of nonlinear PDEs is addressed in the example of the hyperbolic Yang–Mills equations in temporal gauge. These equations preserve a nonlinear divergence field analogous to the electric charge for Maxwell's equations. We introduce and discuss several discretizations of these equations on finite element spaces of Lie algebra valued differential forms. Numerical experiments indicate that simply restricting the variational formulation to the Galerkin spaces yields substantial drift in the charge, contrary to the linear Maxwell case. We then propose a fully discrete method constrained with Lagrange multipliers, for which we prove discrete charge conservation and observe excellent energy conservation.

Key words. constraint preservation, finite elements, Yang–Mills equations

1. Introduction.

Many physical phenomena can be accurately described in terms of fields subject to a constrained evolution equation. For instance, Maxwell's equations describe an electric field in the vacuum as a divergence-free vector field satisfying a wave equation. The Navier–Stokes equations describe the velocity field of an incompressible fluid as a divergence-free vector field subject to a nonlinear evolution equation, involving the pressure which is a Lagrange multiplier for the divergence constraint. For both of these examples, discretization is today relatively well understood, leading to powerful simulation tools.

However, for other examples the situation is less satisfactory. In particular, in certain gauges, Einstein's equations of general relativity (GR) reduce to a hyperbolic evolution equation for a Riemannian metric on a space-slice, subject to nonlinear differential constraints (see, e.g., Wald [39]). The construction of good discretizations of these equations is an active research topic where much remains to be done. Lehner [26] mentions in particular the need to develop tools to help interpret data from gravitational wave detection experiments in the new field of "gravitational wave astronomy." It has been suggested that the problems encountered for simulating Einstein's equations are linked to difficulties for discretizations to preserve nonlinear differential constraints, since hyperbolicity might be lost outside the constraint manifold.

To gain insight into the generic problem of constraint preservation for nonlinear PDEs, we study in this paper the Yang–Mills equations in their hyperbolic form. These are evolution PDEs preserving a nonlinear constraint on the Cauchy data (initial values). However, in contrast to the initial value formulation of Einstein's equations, the Yang–Mills system remains stable even if the constraint is violated. The Yang–Mills equations appear relatively ripe for numerical analysis and could therefore serve as a stepping stone toward the successful simulation of more complicated equations. There are several reasons for this belief. First, concerning space discretization, when the Lie algebra is trivial, Yang–Mills equations reduce to Maxwell's equations

and the Galerkin discretization of these on edge element spaces is now relatively well understood (see section 3.1 for references). Second, concerning time discretization, recent years have seen a deeper understanding of geometric properties of time-stepping methods (see also section 3.1). These two points are of course not completely distinct as they can be seen as facets of space-time variational principles. A third reason for optimism is that contrary to many other nonlinear equations one has analysis tools for studying relatively rough solutions to Yang–Mills equations, perhaps enabling norm estimates on the nonsmooth functions that appear in finite element discretizations (see section 2.2).

Briefly put, Yang–Mills equations are Euler–Lagrange equations for a time dependent gauge potential, which can be deduced from a Lagrangian which is invariant under a certain group of transformations called gauge transformations. This invariance provides a conservation property similar to (electric) charge conservation for Maxwell's equations. However, the natural discretization space for gauge potentials appears not to be invariant under the natural candidate for a subgroup of gauge transformations, contrary to the linear case of Maxwell's equations. We study the effect of this noninvariance on charge conservation and observe numerically that indeed, by discretizing , we lose , -conservation of some significant quantities (even before time is discretized). We then discuss ways to impose charge conservation with Lagrange multipliers. Once a satisfactory way of doing this has been found, we turn to the time discretization.

The paper is organized as follows. A first part is devoted to introducing the equations and their setting. In section 2.1 we define Lie algebra valued differential forms and describe the basic operations on them that we will need. Then, in section 2.2, we introduce the Yang–Mills equations from a variational principle and relate these equations to Maxwell's equations. In section 2.3 we prove the charge conservation property we are interested in. In a second part we turn to discretizations and study first, in section 3.1, the (semi)discretizations obtained by restricting the Lagrangian to a finite dimensional space of gauge potentials. We show numerical results indicating that charge conservation is bad even though other parameters appear to be good. Motivated by this failure, we then, in section 3.2, discuss ways to impose charge conservation actively and show excellent numerical results for one of them. We have also included some remarks pertaining to the implementation of the proposed schemes in section 3.3. Finally, we conclude with some indications of possible directions in which to pursue the investigations.

2. Yang–Mills equations.

2.1. Lie algebra valued differential forms. In this section we introduce notation and collect some facts about Lie algebra valued differential forms. Short introductions to this topic can be found in Taylor [37, appendix C] and Donaldson and Kronheimer [13, chapter 2]. While we allow arbitrary base-manifolds, we restrict our attention to what are called trivial principal bundles, so in fact we shall not need the definition of a principal bundle at all. This leads to many simplifications in the presentation. Some of the global topological properties of the theory are thus lost, but we hope to convince the reader that even in this simplified setting many interesting problems remain. The discretizations we will introduce later will allow for general base-manifolds but are also restricted to trivial principal bundles.

We will define many objects in terms of tensor products. This is convenient not only for the exposition but also for implementing algorithms since tensor products of operators correspond to Kronecker products of matrices, providing a systematic way of

assembling complex objects from simpler constituents. A handy introduction to tensor products of vector spaces can be found in Ryan [33, chapter 1]. We will come back to issues of implementation later. Many tensor products are canonically isomorphic to spaces of (multi)linear maps. In particular, if E denotes a finite dimensional vector space, the space of p-linear forms on E can be identified with the p-fold tensor product $(\otimes^p E^\star)$. If $u : E^p \to \mathbb{R}$ is a p-linear form and $v : E^q \to \mathbb{R}$ is a q-linear form, their tensor product $u \otimes v$ is the $(p+q)$-linear form $E^{p+q} \to \mathbb{R}$ defined by

$$(u \otimes v)(\xi_1, \ldots, \xi_{p+q}) = u(\xi_1, \ldots, \xi_p) v(\xi_{p+1}, \ldots, \xi_{p+q}). \tag{2.1}$$

The antisymmetrization operator on the space of p-linear forms is the projector α_p defined by

$$(\alpha_p u)(\xi_1, \ldots, \xi_p) = \frac{1}{p!} \sum_{\sigma \in \mathfrak{S}(p)} \epsilon(\sigma) u(\xi_{\sigma(1)}, \ldots, \xi_{\sigma(p)}), \tag{2.2}$$

where $\mathfrak{S}(p)$ denotes the group of permutations of the set $\{1,\ 2, \ldots, p\}$ and ϵ is the signature morphism. Antisymmetric p-linear forms are also said to be alternating.

We will use freely the language of (real-valued) differential forms, as exposed, for instance, in Lang [25], but recall some basic facts. Let M be a finite dimensional real and smooth manifold. The tangent space of M at a point x is denoted $\mathrm{T}_x M$. For any integer p, a p-form on M is an object u which to any point $x \in M$ associates a p-linear alternating map $u_x : (\mathrm{T}_x M)^p \to \mathbb{R}$. We denote by Ω^p the space of (smooth) p-forms on M. When $p > \dim M$, Ω^p is reduced to 0. Ω^0 is the space of real-valued functions on M. The direct sum of the spaces Ω^p is denoted Ω. The wedge product is a bilinear associative map $\wedge : \Omega \times \Omega \to \Omega$ such that for each integer p and q

$$\wedge : \Omega^p \times \Omega^q \to \Omega^{p+q}. \tag{2.3}$$

For each $u \in \Omega^p$ and $v \in \Omega^q$, $u \wedge v$ is defined at $x \in M$ by

$$(u \wedge v)_x = \frac{(p+q)!}{p!\ q!} \alpha_p(u_x \otimes v_x). \tag{2.4}$$

We then have

$$v \wedge u = (-1)^{pq} u \wedge v. \tag{2.5}$$

The exterior derivative is a linear map $\mathrm{d} : \Omega \to \Omega$ such that for each integer p

$$\mathrm{d} : \Omega^p \to \Omega^{p+1}. \tag{2.6}$$

In charts it can be constructed by antisymmetrizing the full differential. It is also characterized by the following two properties: If $u \in \Omega^0$, then for each $x \in M$, $(\mathrm{d}u)_x = \mathrm{D}u(x) : \mathrm{T}_x M \to \mathbb{R}$ is the usual differential of u at x (also called derivative or tangent map). Moreover, for each $u \in \Omega^p$ and $v \in \Omega^q$ we have

$$\mathrm{d}(u \wedge v) = (\mathrm{d}u) \wedge v + (-1)^p u \wedge \mathrm{d}v. \tag{2.7}$$

Essentially because the full second order differential (say, in some chart) is symmetric (on $\mathbb{R}^n$ the partial derivatives ∂_i commute: $\partial_i \partial_j = \partial_j \partial_i$), the operator d satisfies

$\mathrm{d}^2 = 0$. This makes the sequence of spaces (Ω^p) what is called a complex (see, e.g., Gelfand and Manin [17, p. 8]):

$$0 \xrightarrow{\mathrm{d}} \Omega^0 \xrightarrow{\mathrm{d}} \Omega^1 \xrightarrow{\mathrm{d}} \Omega^2 \xrightarrow{\mathrm{d}} \cdots \tag{2.8}$$

We now fix a finite dimensional real Lie algebra $\mathfrak{g}$, that is, a finite dimensional real vector space equipped with a bilinear map $[\cdot,\cdot] : \mathfrak{g} \times \mathfrak{g} \to \mathfrak{g}$ called a Lie bracket, which is antisymmetric and satisfies the Jacobi identity: for all $a, b, c \in \mathfrak{g}$ we have

$$[a, b] + [b, a] = 0, \tag{2.9}$$

$$[a, [b, c]] + [b, [c, a]] + [c, [a, b]] = 0. \tag{2.10}$$

Under the condition that the other properties of the bracket are kept, the Jacobi identity is equivalent to the property that, for all $a, b, c \in \mathfrak{g}$,

$$[a, [b, c]] = [[a, b], c] + [b, [a, c]], \tag{2.11}$$

which expresses that for each $a \in \mathfrak{g}$, $[a, \cdot]$ acts as a derivation on $[\cdot,\cdot]$.

By a $\mathfrak{g}$-valued p-form (on M) we mean an object A which to any point $x \in M$ associates a p-linear alternating map $A_x : (\mathrm{T}_x M)^p \to \mathfrak{g}$. The space of $\mathfrak{g}$-valued p-forms is canonically isomorphic to the tensor product $\Omega^p \otimes \mathfrak{g}$. Explicitly, if $u \in \Omega^p$ and $a \in \mathfrak{g}$, $u \otimes a$ can be identified with the $\mathfrak{g}$-valued p-form defined at any $x \in M$ by

$$(\xi_1, \ldots, \xi_p) \mapsto u_x(\xi_1, \ldots, \xi_p)a, \tag{2.12}$$

and any $\mathfrak{g}$-valued p-form is a linear combination of (at most $\dim \mathfrak{g}$) such forms. The bracket of $\mathfrak{g}$-valued forms is a bilinear operator $(\Omega \otimes \mathfrak{g}) \times (\Omega \otimes \mathfrak{g}) \to \Omega \otimes \mathfrak{g}$ giving restrictions $(\Omega^p \otimes \mathfrak{g}) \times (\Omega^q \otimes \mathfrak{g}) \to \Omega^{p+q} \otimes \mathfrak{g}$. It is denoted $[\cdot,\cdot]$ and uniquely characterized by the property that for all $u \in \Omega^p$, $a \in \mathfrak{g}$, $v \in \Omega^q$, and $b \in \mathfrak{g}$

$$[u \otimes a, v \otimes b] = (u \wedge v) \otimes [a, b]. \tag{2.13}$$

In other words, we consider the tensor product of the standard wedge $\wedge$ defined on (real-valued) differential forms on M, with the Lie bracket $[\cdot,\cdot]$ on $\mathfrak{g}$. This gives $\Omega \otimes \mathfrak{g}$ the structure of a graded Lie algebra. That is, if we have $A \in \Omega^p \otimes \mathfrak{g}$, $B \in \Omega^q \otimes \mathfrak{g}$, and $C \in \Omega^r \otimes \mathfrak{g}$, then we deduce from (2.5), (2.9), and (2.11)

$$0 = [A, B] + (-1)^{pq}[B, A], \tag{2.14}$$

$$[A, [B, C]] = [[A, B], C] + (-1)^{pq}[B, [A, C]]. \tag{2.15}$$

The exterior derivative is extended to an operator $\mathrm{d} : \Omega \otimes \mathfrak{g} \to \Omega \otimes \mathfrak{g}$ inducing maps $\Omega^p \otimes \mathfrak{g} \to \Omega^{p+1} \otimes \mathfrak{g}$. It is uniquely characterized by the property that

$$\forall u \in \Omega^p,\ \forall a \in \mathfrak{g} \quad \mathrm{d}(u \otimes a) = (\mathrm{d}u) \otimes a. \tag{2.16}$$

If A is a [illegible], i.e., an element of $\Omega^1 \otimes \mathfrak{g}$, we associate with it a [illegible] denoted d_A defined by

$$\mathrm{d}_A : \begin{cases} \Omega^q \otimes \mathfrak{g} & \to \quad \Omega^{q+1} \otimes \mathfrak{g}, \\ B & \mapsto \quad \mathrm{d}B + [A, B]. \end{cases} \tag{2.17}$$

It is a derivation in the sense that if $B \in \Omega^q \otimes \mathfrak{g}$ and $C \in \Omega^r \otimes \mathfrak{g}$ we have (compare with (2.7) and (2.11))

$$\mathrm{d}_A[B, C] = [\mathrm{d}_A B, C] + (-1)^q [B, \mathrm{d}_A C]. \tag{2.18}$$

The [illegible] of a gauge potential A is the element $\mathcal{F}(A)$ of $\Omega^2 \otimes \mathfrak{g}$ defined by [illegible] as

$$\mathcal{F}(A) = \mathrm{d}A + (1/2)[A, A]. \tag{2.19}$$

This definition is motivated by the property that for all gauge potentials A and all $B \in \Omega^q \otimes \mathfrak{g}$ we have

$$\mathrm{d}_A \mathrm{d}_A B = [\mathcal{F}(A), B]. \tag{2.20}$$

We remark that the bilinear map $[\cdot, \cdot] : (\Omega^1 \otimes \mathfrak{g})^2 \to \Omega^2 \otimes \mathfrak{g}$ is symmetric. Therefore the differential $\mathrm{D}\mathcal{F}$ of the curvature map $\mathcal{F} : \Omega^1 \otimes \mathfrak{g} \to \Omega^2 \otimes \mathfrak{g}$ satisfies for all $A, A' \in \Omega^1 \otimes \mathfrak{g}$

$$\mathrm{D}\mathcal{F}(A)A' = \mathrm{d}_A A'. \tag{2.21}$$

We also have the [illegible]:

$$\mathrm{d}_A \mathcal{F}(A) = 0. \tag{2.22}$$

We suppose that $\mathfrak{g}$ is the Lie algebra associated with a Lie group G. For generalities on Lie groups we refer to, e.g., Duistermaat and Kolk [14]. For notational purposes we suppose that G is a matrix Lie group. Given a function $Q : M \to G$, the associated [illegible] $\mathcal{G}_Q$ is the map which transforms a gauge potential A into the gauge potential $A' = \mathcal{G}_Q(A)$ defined by

$$A' = QAQ^{-1} - (\mathrm{D}Q)Q^{-1}. \tag{2.23}$$

This notation calls for some comments. First, for a given $q \in G$, one shows that $\mathrm{Ad}(q) : a \mapsto qaq^{-1}$ maps $\mathfrak{g}$ into $\mathfrak{g}$ linearly so that the first term on the right-hand side of (2.23), interpreted pointwise, provides a gauge potential. For generalities about the adjoint representation $\mathrm{Ad} : G \to \mathrm{End}(\mathfrak{g})$ see [14, p. 2]. Second, also for a given $q \in G$, (right and left) multiplication by q^{-1} maps the tangent space $\mathrm{T}_q G$ of G at q linearly into $\mathfrak{g}$. And for any function $Q : M \to G$ the differential of Q gives rise to linear maps $\mathrm{D}Q(x) : \mathrm{T}_x M \to \mathrm{T}_{Q(x)} G$. Thus the second term on the right-hand side of (2.23), interpreted pointwise, also provides a gauge potential. Combining these observations shows that A' defined as above is indeed a gauge potential.

Gauge transformations behave nicely with covariant derivatives and curvature. With $A' = \mathcal{G}_Q(A)$ as before, we have

$$\mathrm{d}_{A'}(QBQ^{-1}) = Q(\mathrm{d}_A B)Q^{-1} \tag{2.24}$$

and

$$\mathcal{F}(A') = Q\mathcal{F}(A)Q^{-1}. \tag{2.25}$$

Moreover, $\mathcal{G}$ determines a group action in the sense that

$$\mathcal{G}_{Q'} \circ \mathcal{G}_Q = \mathcal{G}_{Q'Q}, \tag{2.26}$$

where on the right-hand side we use pointwise multiplication to define the product $Q'Q$.

We suppose that a Riemannian metric is given on M. That is, for any $x \in M$ we have a Euclidean scalar product on $\mathrm{T}_x M$, depending smoothly on x. It enables us to construct L^2-products on Ω as follows. First, for any Euclidean space E (we have in mind the tangent spaces $\mathrm{T}_x M$), whose scalar product we denote by $(\cdot|\cdot)$, we first obtain a Euclidean structure on the dual $E^\star$, whose scalar product we also denote by $(\cdot|\cdot)$, by requiring that $u \mapsto (u|\cdot)$ is an isometry $E \to E^\star$. Next, on the space of p-linear forms on E^p (not necessarily alternating), there is a unique scalar product such that, for any $u_1, \ldots, u_p$, $v_1, \ldots, v_p$ in $E^\star$,

$$(u_1 \otimes \cdots \otimes u_p | v_1 \otimes \cdots \otimes v_p) = (u_1|v_1) \cdots (u_p|v_p). \tag{2.27}$$

This scalar product can be restricted to the subspace of alternating p-linear forms on E^p. This construction provides for each $x \in M$ a Euclidean structure on the space of p-linear forms on $(\mathrm{T}_x M)^p$, denoted $(\cdot|\cdot)_x$. We then obtain a scalar product $\langle \cdot, \cdot \rangle$ on Ω defined by

$$\langle u, v \rangle = \int_M (u_x | v_x)_x \mathrm{d}x, \tag{2.28}$$

where we integrate using the measure on M provided by the Riemannian metric.

We suppose furthermore that the Lie group G is compact. Then on $\mathfrak{g}$ there is a scalar product denoted $(\cdot|\cdot)$ which is compatible in the sense that for all $q \in G$ the map $\mathrm{Ad}(q)$ is an isometry of $\mathfrak{g}$ (see, e.g., [14, p. 135]). This property implies that

$$\forall a, b, c \in \mathfrak{g} \quad ([a, b]|c) + (b|[a, c]) = 0. \tag{2.29}$$

With the help of this scalar product and a Riemannian metric on M we can construct L^2-products on $\Omega \otimes \mathfrak{g}$, as well as L^q-spaces, by slightly extending the preceding method. Given as before a Euclidean space E, one first shows that there is a unique scalar product on $(\otimes^p E^\star) \otimes \mathfrak{g}$ such that for $u, v \in \otimes^p E^\star$, and $a, b \in \mathfrak{g}$

$$(u \otimes a | v \otimes b) = (u|v)(a|b). \tag{2.30}$$

This provides scalar products on the spaces $(\otimes^p (\mathrm{T}_x M)^\star) \otimes \mathfrak{g}$ as before, as well as a scalar product on $\Omega \otimes \mathfrak{g}$ denoted $\langle \cdot, \cdot \rangle$. We also obtain L^q-norms defined by

$$\|A\|_{\mathrm{L}^q} = \left(\int_M |A_x|_x^q \mathrm{d}x \right)^{1/q}, \tag{2.31}$$

where $|\cdot|_x$ is the Euclidean norm on $(\otimes^p (\mathrm{T}_x M)^\star) \otimes \mathfrak{g}$ defined by the constructed scalar product. At least for our purposes these norms behave like standard L^q-norms on scalar functions, for which we refer to Folland [16]. We shall allow ourselves to speak about L^q-spaces of real and Lie algebra valued forms without burdening the notation with the precision of what kind of forms we will be considering at each time.

From (2.29) we deduce that for any $A \in \Omega^0 \otimes \mathfrak{g}$ and any $B, C \in \Omega^p \otimes \mathfrak{g}$ we have

$$\langle [A, B], C \rangle + \langle B, [A, C] \rangle = 0. \tag{2.32}$$

In particular, the case $B = C$ yields

$$\langle [A, B], B \rangle = 0. \tag{2.33}$$

2.2. Yang–Mills Lagrangian and equations. In accordance with notions introduced in the previous section we consider the following setting and notation: M is a compact Riemannian manifold (without boundary) and G is a compact Lie group with associated Lie algebra $\mathfrak{g}$. A compatible scalar product on $\mathfrak{g}$ is chosen. The L^2-duality on $\Omega \otimes \mathfrak{g}$ with respect to the Riemannian metric on M and the compatible scalar product on $\mathfrak{g}$ is denoted $\langle \cdot, \cdot \rangle$. The L^2-norm is denoted $\| \cdot \|$.

The hyperbolic Yang–Mills equation, in the temporal gauge, is an equation for gauge potentials on M that can be derived from the Lagrangian $\mathcal{L}$ defined on $(\Omega^1 \otimes \mathfrak{g})^2$ by

$$\mathcal{L}(A, A') = (1/2)\|A'\|^2 - (1/2)\|\mathcal{F}(A)\|^2. \tag{2.34}$$

We look for time dependent gauge potentials $A : t \mapsto A(t) \in \Omega^1 \otimes \mathfrak{g}$ satisfying the stationary action principle. That is, we look for trajectories A which, for any $t, t' \in \mathbb{R}$, are critical points of the action integral

$$B \mapsto \int_t^{t'} \mathcal{L}(B(s), \dot{B}(s)) \mathrm{d}s, \tag{2.35}$$

among trajectories B such that $B(t) = A(t)$ and $B(t') = A(t')$.

If we ignore for the time being some questions about the regularity of solutions and continuity properties of operators, the associated Euler–Lagrange equation for a time dependent gauge potential $A : t \mapsto A(t)$ is (at any time t)

$$\forall A' \in \Omega^1 \otimes \mathfrak{g} \quad \langle \ddot{A}, A' \rangle = -\langle \mathcal{F}(A), \mathrm{D}\mathcal{F}(A)A' \rangle, \tag{2.36}$$

$$= -\langle \mathcal{F}(A), \mathrm{d}_A A' \rangle. \tag{2.37}$$

The so-called strong formulation of this equation is obtained by introducing $\mathrm{d}_A^\star$, the formal adjoint of d_A, with respect to L^2-duality on M. Smooth solutions to (2.37) are those satisfying

$$\ddot{A} = -\mathrm{d}_A^\star \mathcal{F}(A). \tag{2.38}$$

To us the strong formulation is mainly a convenient notation. Discretizations are guided by the weak formulation or indeed the stationary action principle.

Various first order formulations are useful. With a time dependent gauge potential $A : t \mapsto A(t)$ we associate time dependent fields $E : t \mapsto E(t) \in \Omega^1 \otimes \mathfrak{g}$ and $B : t \mapsto B(t) \in \Omega^2 \otimes \mathfrak{g}$ defined by

$$E(t) = -\dot{A}(t), \tag{2.39}$$

$$B(t) = \quad \mathcal{F}(A(t)). \tag{2.40}$$

We remark that these two equations imply the following evolution equation for B:

$$\dot{B}(t) = \mathrm{D}\mathcal{F}(A(t))\dot{A}(t) = -\mathrm{d}_A E. \tag{2.41}$$

So we get (in strong form)

$$\dot{A} = -E, \tag{2.42}$$

$$\dot{E} = \quad \mathrm{d}_A^\star B, \tag{2.43}$$

$$\dot{B} = -\mathrm{d}_A E. \tag{2.44}$$

Conversely, if (A, E, B) satisfies the above system, and the initial condition $B(0) = \mathcal{F}(A(0))$, then for all times t, $B(t) = \mathcal{F}(A(t))$ and A satisfies the Euler–Lagrange equation (2.37).

We will also use the following first order formulation involving only the fields A and E:

$$\dot{A} = -E, \tag{2.45}$$

$$\dot{E} = \quad \mathrm{d}_A^\star \mathcal{F}(A). \tag{2.46}$$

It differs from the standard Hamiltonian reformulation of Euler–Lagrange equations by the sign appearing in (2.45). The choice of signs is motivated by the conventions used in electromagnetics, at which we shall arrive shortly.

We have stated most of the above results as if every field was smooth. For the purposes of numerical analysis it is useful however to keep in mind the following existence and uniqueness results for nonsmooth solutions of the Yang–Mills equations. Perhaps most importantly to us, Klainerman and Machedon [24] have proved global well-posedness in the Sobolev space H^1_{loc} for initial data with finite energy. An essential ingredient here is a compactness result of Uhlenbeck [38]. Tao [36] has obtained local results for norms weaker than H^1_{loc}. Earlier results include existence and uniqueness for high-order Sobolev norms by Segal [34]; see also Eardley and Moncrief [15].

Actually even the H^1_{loc} framework is somewhat inadequate for numerical analysis. It appears mainly because we have gauge potentials A, say, in L^2, with exterior derivative $\mathrm{d}A$ in L^2, for which we have , , , control over $\mathrm{d}^\star A$. Experience from Maxwell's equations (to which we devote the next paragraph) indicates that we should consider discretization spaces consisting of potentials $A \in \mathrm{L}^2$ such that $\mathrm{d}A \in \mathrm{L}^2$, but for which $\mathrm{d}^\star A$ is not necessarily integrable. This term should rather be controlled by the good behavior of $\langle A, \mathrm{d}P' \rangle$ for a large enough space of "test-functions" $P' \in \mathrm{L}^2$ satisfying $\mathrm{d}P' \in \mathrm{L}^2$.

The numerical analysis is as of today incomplete and we do not claim to have found the right framework for carrying it out.

Many of the results of this paper are motivated by analogies with Maxwell's equations and we now make this link explicit. In the context of electromagnetics, M is three-dimensional, E is the electric field, and B is the magnetic field. We choose G to be the group

$$\mathbb{U} = \{u \in \mathbb{C} \ : \ |u| = 1\}, \tag{2.47}$$

so that $\mathfrak{g}$ can be identified with $i\mathbb{R} \subset \mathbb{C}$. Since $\mathbb{U}$ is commutative the Lie bracket is trivial, leading to many simplifications. From (2.43), (2.44) we obtain the familiar (vacuum) Maxwell equations for E and B, given here in vector notation:

$$\dot{E} = \quad \operatorname{curl} B, \tag{2.48}$$

$$\dot{B} = -\operatorname{curl} E. \tag{2.49}$$

Equations (2.39), (2.40) express that the magnetic potential A is a solution of (also in vector notation)

$$\dot{A} = -E, \tag{2.50}$$

$$\operatorname{curl} A = \quad B. \tag{2.51}$$

The strong form of the Euler–Lagrange equation (2.38) for A is

$$\ddot{A} = -\operatorname{curl}\operatorname{curl} A. \tag{2.52}$$

All fields here are $\mathbb{R}$-proportional to the complex number i, so it is customary to cancel it out. Other choices of magnetic potentials are often used but in this paper we restrict our attention to the above choice of gauge, called temporal gauge (because A can be identified with a 1-form on time-space $\mathbb{R} \times M$ having no component along the time axis).

Maxwell's equations (2.48), (2.49) preserve the following constraints on the initial data:

$$\operatorname{div} E = 0, \tag{2.53}$$

$$\operatorname{div} B = 0. \tag{2.54}$$

This follows immediately from the identity $\operatorname{div} \operatorname{curl} = 0$. The Yang–Mills equations have similar constraints as we shall see in the next section.

In this presentation we have of course reversed the historical order, since Yang and Mills obtained their equations in an effort to generalize Maxwell's equations to the case where G is a noncommutative Lie group such as SU(2).

2.3. Conservation properties. For Maxwell's equations (2.48), (2.49) the two divergence constraints (2.53), (2.54) appear as completely symmetric. But once a magnetic potential is introduced as in (2.50), (2.51), these two constraints acquire rather different meanings. This will become even more apparent for the Yang–Mills equations, which have similar constraints. The generalization to Yang–Mills equations of the divergence constraint (2.54) on the magnetic field is the Bianchi identity (2.22). As we shall see, it is not a problem to handle numerically, at least for the discretizations we have chosen. On the other hand, the following identity, which is analogous to charge conservation (2.53), is numerically more challenging. We should have the constraint

$$\forall P' \in \Omega^0 \otimes \mathfrak{g} \quad \langle \dot{A}, \mathrm{d}_A P' \rangle = 0. \tag{2.55}$$

In general (not necessarily temporal) gauge, this equation is actually one of the Yang–Mills equations. In our setting, however, it appears as a constraint which is preserved by the flow , ′ which should be satisfied initially. We now check this in two (related) ways.

Pick $P' \in \Omega^0 \otimes \mathfrak{g}$, and regard it as a constant function of time. Putting $A' = \mathrm{d}_A P'$ in (2.37) we obtain (from (2.20) and (2.33))

$$\langle \ddot{A}, \mathrm{d}_A P' \rangle = -\langle \mathcal{F}(A), [\mathcal{F}(A), P'] \rangle = 0. \tag{2.56}$$

We also remark that

$$\langle \dot{A}, [\dot{A}, P'] \rangle = 0. \tag{2.57}$$

It follows that

$$\langle \dot{A}, \mathrm{d}_A P' \rangle^{\cdot} = \langle \ddot{A}, \mathrm{d}_A P' \rangle + \langle \dot{A}, [\dot{A}, P'] \rangle = 0. \tag{2.58}$$

In analogy with Maxwell's equations we will refer to this conservation property as charge conservation. As already mentioned, condition (2.55) should also be satisfied initially. Thus, with $\dot{A} = -E$, the couple $(A(t), E(t))$ should evolve on the (in general infinite dimensional, nonlinear, and perhaps singular) "manifold" with equation

$$\forall P' \in \Omega^0 \otimes \mathfrak{g} \quad \langle E, \mathrm{d}_A P' \rangle = 0. \tag{2.59}$$

We now show how this property can be obtained using Noether's theorem. First fix a map $Q : M \to G$, and consider the associated gauge transformation $\mathcal{G}_Q : \Omega^1 \otimes \mathfrak{g} \to \Omega^1 \otimes \mathfrak{g}$. For all gauge potentials $A, A' \in \Omega^1 \otimes \mathfrak{g}$ we have (using (2.25) and the compatibility of the scalar product)

$$\mathcal{L}(\mathcal{G}_Q(A), \mathrm{D}\mathcal{G}_Q(A)A') = (1/2)\|QA'Q^{-1}\|^2 - (1/2)\|Q\mathcal{F}(A)Q^{-1}\|^2 \tag{2.60}$$

$$= \mathcal{L}(A, A'). \tag{2.61}$$

In other words the Lagrangian $\mathcal{L}$ is invariant under gauge transformations $\mathcal{G}_Q$ associated with maps $Q : M \to G$. On the other hand, if we fix a gauge potential A and differentiate the map $Q \mapsto \mathcal{G}_Q(A)$ at the constant map $I : M \to G$ equal to the unit of G, we get the following linear map:

$$\Gamma(A) : \left\{ \begin{array}{rcl} \Omega^0 \otimes \mathfrak{g} & \to & \Omega^1 \otimes \mathfrak{g}, \\ P' & \mapsto & -\mathrm{d}_A P'. \end{array} \right. \tag{2.62}$$

Therefore, by Noether's theorem (see, e.g., Marsden and West [28, p. 369]), for each $P' \in \Omega^0 \otimes \mathfrak{g}$ the following function on $(\Omega^1 \otimes \mathfrak{g})^2$ is constant on trajectories $t \mapsto (A(t), \dot{A}(t))$:

$$(A, A') \mapsto \mathrm{D}_2\mathcal{L}(A, A')\Gamma(A)P' = -\langle A', \mathrm{d}_A P' \rangle. \tag{2.63}$$

This provides an interpretation of the charge conservation property.

3. Discretization.

3.1. Unconstrained schemes. For the discussion of numerical schemes we suppose that the spaces Ω^p do not consist solely of smooth fields but have been completed with respect to some norm of the form

$$u \mapsto \|u\|_{\mathrm{L}^q} + \|\mathrm{d}u\|_{\mathrm{L}^q}, \tag{3.1}$$

with $q < +\infty$. Then the exterior derivative extends to a continuous operator $\mathrm{d} : \Omega^p \to \Omega^{p+1}$. The exponent q should be chosen such that the brackets of forms yield sufficiently integrable forms.

For each integer p let X_h^p denote a finite dimensional subspace of Ω^p. We require that $\mathrm{d}X_h^p \subset X_h^{p+1}$. This provides a commuting diagram

$$\begin{array}{ccccccccc} 0 & \to & \Omega^0 & \to & \Omega^1 & \to & \Omega^2 & \to & \cdots \\ \uparrow & & \uparrow & & \uparrow & & \uparrow & & \\ 0 & \to & X_h^0 & \to & X_h^1 & \to & X_h^2 & \to & \cdots, \end{array} \tag{3.2}$$

where the vertical arrows are inclusion maps and the horizontal ones are instances of the exterior derivative. The following discussion of discretizations makes the most sense when X_h^{p+1} is small among the spaces containing $\mathrm{d}X_h^p$ (the precise statement would be that the vertical arrows in diagram (3.2) should induce isomorphisms in cohomology; see Gelfand and Manin [17]). Commuting diagrams are increasingly used to interpret or guide developments in numerical analysis; see Arnold [1].

The index h is there to remind us that we are in fact interested in sequences of spaces indexed by some parameter h and convergence results with respect to h.

For the numerical experiments we equip the domain M with a simplicial mesh $\mathcal{T}_h$ and take (X_h^p) to be the standard lowest-order finite element complex, where X_h^0 consists of continuous and piecewise affine functions, X_h^1 is a space of 1-forms called (lowest-order) Nédélec's edge elements (of the first family), and X_h^2 is a space of 2-forms referred to as Raviart–Thomas face elements. Similar constructions have been used in physics (see Sorkin [35]) and can be traced back at least to Weil [40] who used them for algebraic/topological purposes (see also Whitney [41]). The interpretation of mixed finite element methods in terms of such differential forms is due to Bossavit [6]. In this choice of spaces the dimension of X_h^p is exactly the number of p-dimensional simplexes in the mesh. The parameter h denotes the maximal diameter of the simplexes of $\mathcal{T}_h$.

The finite element point of view provides other choices of spaces as well—for instance, spaces built with polynomials of any degree; see Nédélec [30], [31]. For surveys on these spaces in the context of electromagnetics, we refer the reader to Hiptmair [21] and Monk [29]. So-called *hp* versions of these finite element spaces are also useful for simulating Maxwell's equations, and we refer the reader to Demkowicz [12] for an overview on this topic. For generalities about mixed finite element methods, see [8], [32], [18].

Given such a finite dimensional complex we will use the spaces $X_h^p \otimes \mathfrak{g}$ as discretization spaces for Lie algebra valued differential forms.

We consider time dependent gauge potentials of the form $A : t \mapsto A(t) \in X_h^1 \otimes \mathfrak{g}$. Restricting the Lagrangian (2.34) to $(X_h^1 \otimes \mathfrak{g})^2$, the corresponding stationary action principle yields the Euler–Lagrange equation

$$\forall A' \in X_h^1 \otimes \mathfrak{g} \quad \langle \ddot{A}, A' \rangle = -\langle \mathcal{F}(A), \mathrm{d}_A A' \rangle. \tag{3.3}$$

An equivalent first order formulation is the following system for time dependent A, E in $X_h^1 \otimes \mathfrak{g}$:

$$\dot{A} = -E, \tag{3.4}$$

$$\forall E' \in X_h^1 \otimes \mathfrak{g} \quad \langle \dot{E}, E' \rangle = \langle \mathcal{F}(A), \mathrm{d}_A E' \rangle. \tag{3.5}$$

For these semidiscrete equations we have energy conservation. For instance, for the second order formulation, along any trajectory A, the following quantity is constant:

$$\mathcal{E}(A, \dot{A}) = 1/2(\|\dot{A}\|^2 + \|\mathcal{F}(A)\|^2). \tag{3.6}$$

This can be checked directly by inserting $A' = \dot{A}$ in (3.3) and is of course a general property of Hamiltonian systems.

We remark furthermore that we have the Bianchi identity

$$\mathrm{d}_A \mathcal{F}(A) = 0, \tag{3.7}$$

corresponding to the absence of magnetic charges, since $\mathcal{F}(A)$ is represented exactly. That is, for any given time, $A(t)$ is an element of the finite element space $X_h^1 \otimes \mathfrak{g}$ and $\mathcal{F}(A(t))$ is in a corresponding higher-order finite element space specified in section 3.3. The Bianchi identity for the discretization is then just a particular case of the standard Bianchi identity. (The projection of $\mathcal{F}(A(t))$ down to $X_h^2 \otimes \mathfrak{g}$, on the other hand, would provide a field F not necessarily satisfying $\mathrm{d}_A F = 0$.)

The Bianchi identity corresponds to the constraint $\operatorname{div} B = 0$ in electromagnetics. For the analogue of $\operatorname{div} E = 0$ we have greater problems however. For discretizations

of Maxwell's equations this constraint is obtained in a weak form. We now detail this, as it is a source of inspiration for Yang–Mills equations.

The standard semidiscretization of the Euler–Lagrange equation (2.52) for Maxwell's equations would be to look for a magnetic potential of the form $A : t \mapsto A(t) \in X_h^1$ satisfying

$$\forall A' \in X_h^1 \quad \langle \ddot{A}, A' \rangle = -\langle \operatorname{curl} A, \operatorname{curl} A' \rangle. \tag{3.8}$$

Inserting $A' = \operatorname{grad} P'$ for $P' \in X_h^0$ into this equation gives

$$\langle \dot{A}, \operatorname{grad} P' \rangle^{\cdot} = 0, \tag{3.9}$$

when P' is considered as a constant function of time. In particular, if the equality $\langle \dot{A}, \operatorname{grad} P' \rangle = 0$ holds initially for some $P' \in X_h^0$, it will hold at all times.

If a magnetic potential $A \in X_h^1$ satisfies $\langle \dot{A}, \operatorname{grad} P' \rangle = 0$ for all $P' \in X_h^0$, one says that it is weakly (or Galerkin) divergence-free. Ideally one might want strong divergence freedom, and such divergence freedom appears to be necessary for many applications in electromagnetics. However there are indications that [illegible] weak divergence freedom might be just as good as strong divergence freedom. An important example is Kikuchi's compactness property [23]. It asserts that if we have a sequence (A_h) indexed by a mesh parameter $h \to 0$ of fields $A_h \in X_h^1$ such that A_h and $\operatorname{curl} A_h$ are L^2-bounded, and A_h is weakly divergence-free, one can extract a subsequence which is L^2-convergent. This property mimics the (Rellich) compactness of the injection $\mathrm{H}^1 \to \mathrm{L}^2$, since a vector field on a compact manifold which is in L^2 and has its curl and divergence in L^2 is actually in H^1. This property is an essential ingredient in the analysis of the numerical approximation of eigenvalues of the curl curl operator on edge element spaces (see Boffi et al. [4]) and essentially guarantees the absence of spurious modes. The link between spurious modes in eigenvalue computations and problems encountered in time-evolution simulations has been investigated; see, e.g., Hesthaven and Warburton [20], Boffi and Gastaldi [5], and Boffi, Buffa, and Gastaldi [3].

A refinement of Kikuchi's property which is useful for the convergence analysis of nonlinear terms and which was partly inspired by the present work is proved in Christiansen [10]. It indicates that with respect to the convergence of so-called div-curl expressions, if (A_h) is an L^2-bounded sequence of vector fields $A_h \in X_h^1$ which are Galerkin divergence-free, everything happens [illegible] $\operatorname{div} A_h \to 0$ in the H^{-1}-norm.

For noncommutative Lie groups G the simple trick used in (3.9) can no longer be carried out. One would like to be able to insert $A' = \mathrm{d}_A P'$ into (3.3) for $P' \in X_h^0 \otimes \mathfrak{g}$, but this is not legitimate since in general d_A maps $X_h^0 \otimes \mathfrak{g}$ out of $X_h^1 \otimes \mathfrak{g}$. From the point of view of Noether's theorem we remark that the gauge transformations associated with maps $Q : M \to G$ of the form

$$x \mapsto Q(x) = \exp(P(x)), \quad P \in X_h^0 \otimes \mathfrak{g}, \tag{3.10}$$

do not map $X_h^1 \otimes \mathfrak{g}$ into itself, contrary to the linear Maxwell case. We remark however that if Q is constant the associated gauge transformation does map $X_h^1 \otimes \mathfrak{g}$ into itself, since this space is stable under pointwise application of $\operatorname{Ad}(q) : \mathfrak{g} \to \mathfrak{g}$ for any q in G. Alternatively one can simply remark that if $P' \in X_h^0 \otimes \mathfrak{g}$ is a constant map, $A' = \mathrm{d}_A P' = [A, P']$ is indeed in $X_h^1 \otimes \mathfrak{g}$ providing a valid test-function in (3.3). This proves that the scheme conserves [illegible] charge.

One might hope that for any given $P' \in X_h^0 \otimes \mathfrak{g}$, considered as a constant function of time, the quantities $\langle \dot{A}, \mathrm{d}_A P' \rangle$ just oscillate around the initial value which is assumed to be small. We now present some numerical results to see if these hopes are answered.

We will show numerical results obtained with time discretizations according to the leap-frog scheme, which is by far the most popular time discretization of large scale Hamiltonian systems. For its use in the case of Maxwell's equations see Joly [22]. For additional points on the numerical analysis of time and space discretization of Maxwell's equations see Ciarlet and Zou [11]. This discretization scheme should be seen in the context of so-called symplectic integration methods; see, e.g., Berndt [2] for an introduction to symplectic geometry and Hairer, Lubich, and Wanner [19], Leimkuhler and Reich [27], and Marsden and West [28] for numerical aspects. We introduce a time step τ and consider approximations A^i of $A(i\tau)$ obtained by the recursion formula

$$\left\langle \frac{A^{i+1} - 2A^i + A^{i-1}}{\tau^2}, A' \right\rangle = -\langle \mathcal{F}(A^i), \mathrm{D}\mathcal{F}(A^i)A' \rangle. \tag{3.11}$$

Here and in the following all variables appearing with a "′" should be preceded by a "for all" statement referring to a certain space of the form $X_h^p \otimes \mathfrak{g}$, which should be clear from the context. This will ease the notational burden somewhat.

The leap-frog scheme is usually implemented using coupled one-term recurrences rather than a two-term recurrence. One introduces $E^{i+1/2}$ as an approximation of $E((i+1/2)\tau)$ in the following reformulation of (3.11):

$$\frac{A^i - A^{i-1}}{\tau} = -E^{i-1/2}, \tag{3.12}$$

$$\left\langle \frac{E^{i+1/2} - E^{i-1/2}}{\tau}, E' \right\rangle = \langle \mathcal{F}(A^i), \mathrm{D}\mathcal{F}(A^i)E' \rangle. \tag{3.13}$$

Since E and A are not seen at the same time this technique is often called time-staggering. To some extent time staggering is what lets us remain explicit in the time step, a huge advantage compared with implicit schemes for large scale computations.

In Figure 1 we show numerical results obtained for $\mathfrak{su}(2)$-valued gauge potentials on a two-dimensional sphere. Thus in our previous notation $\mathfrak{g} = \mathfrak{su}(2)$ and $M = \mathbb{S}^2$. Recall that $\mathfrak{su}(2)$ is the three-dimensional Lie algebra consisting of trace-free and skew-hermitian 2×2 complex matrices (see, e.g., [14, p. 10]). It is the Lie algebra associated with the compact Lie group SU(2) consisting of unitary 2×2 complex matrices with determinant 1. The finite element spaces were constructed from an unstructured mesh of the sphere (there is no particular reason for choosing a sphere rather than another surface, except that by using a rather symmetric one embedded in $\mathbb{R}^3$, we could visually check some predictions about symmetry properties of the waves).

We have plotted the L^2-norms squared of A^i, $\mathrm{d}A^i$, and $(1/2)[A_i, A_i]$ as a function of time in multiples of π. For the chosen initial values the L^2-norm of the quadratic term $(1/2)[A_i, A_i]$ is relatively small compared with the linear term $\mathrm{d}A^i$ in the curvature. Linearization of the equations indicates that the waves travel around the sphere with speed 1, which accounts some of the almost 2π-periodic features which can be seen in the graphs.

For Maxwell's equation (3.8) the leap-frog discretization is stable under a CFL condition (i.e., $\tau \leq Ch$). This is proved in Joly [22] using the conservation of a discrete

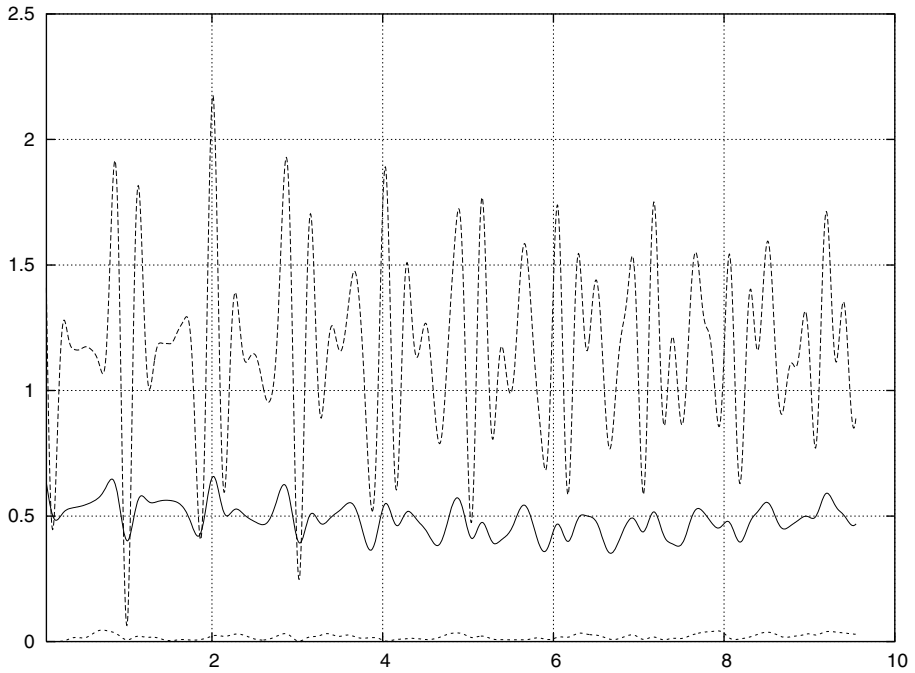

FIG. 1. L^2*-norms squared of* A^i *(plain),* $\mathrm{d}A^i$ *(dashed), and* $(1/2)[A_i, A_i]$ *(finely dashed).*

energy containing a negative term which is controlled by an inverse inequality. This discrete energy is defined as

(3.14)
$$(1/2)\left\|\frac{A^{i+1}-A^i}{\tau}\right\|^2+(1/2)\left(\left\|\operatorname{curl}\left(\frac{A^{i+1}+A^i}{2}\right)\right\|^2-\left\|\operatorname{curl}\left(\frac{A^{i+1}-A^i}{2}\right)\right\|^2\right).$$

For the general Yang–Mills equations we have not found a similar conserved discrete energy. However, at least for the numerical examples, the leap-frog scheme seems to be stable for roughly the same values of the time step τ as for the Maxwell case. For the numerical results presented here the time step is 0.01, which is a few times less than the stability limit. The graphs show 3000 time steps. It might be added that in the course of our simulations we found that there is a remarkably sharp value for τ (depending on initial conditions) above which the scheme was unstable but under which the numerical results appeared rather satisfactory. If we call τ_0 such a value, the interval of time steps for which the behavior was erratic but stable was less than $\tau_0/100$ wide.

In Figure 2 we have plotted some reasonable approximations of the energy as a function of time. These are

$$\mathcal{E}^{i+1/2}=(1/2)\left\|\frac{A^{i+1}-A^i}{\tau}\right\|^2+(1/4)(\|\mathcal{F}(A^i)\|^2+\|\mathcal{F}(A^{i+1})\|^2) \tag{3.15}$$

and

$$\mathcal{E}^{i}=(1/2)\left\|\frac{A^{i+1}-A^{i-1}}{2\tau}\right\|^2+(1/2)\|\mathcal{F}(A^i)\|^2. \tag{3.16}$$

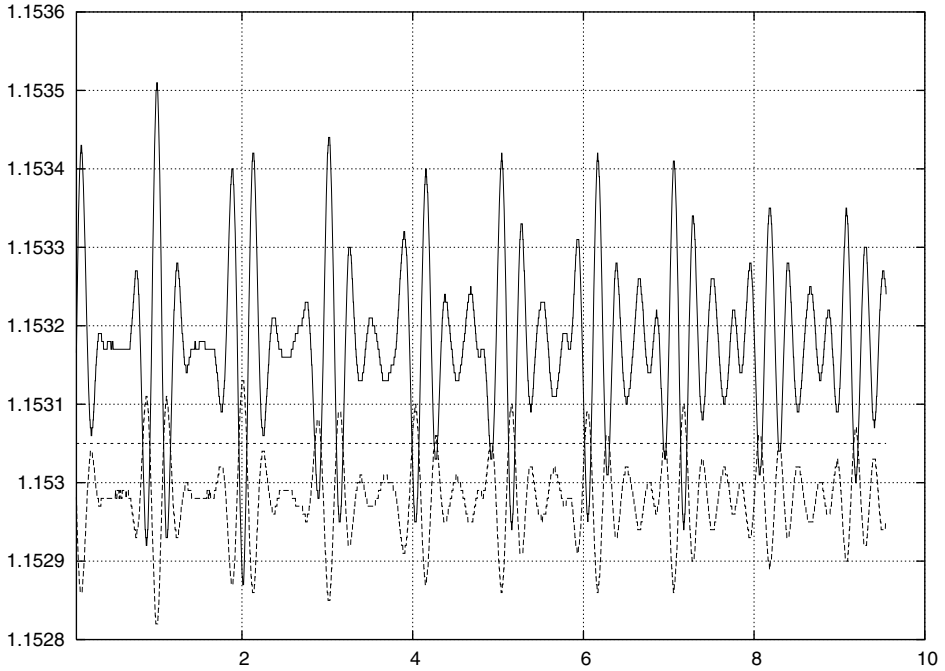

FIG. 2. *Energies* $\mathcal{E}^{i-1/2}$ *(plain),* $\mathcal{E}^i$ *(dashed), and* $(1/6)(\mathcal{E}^{i-1/2} + 4\mathcal{E}^i + \mathcal{E}^{i+1/2})$ *(finely dashed).*

We have also plotted a linear combination of these two energies which yielded very good conservation (the conservation cannot be exact however for convex combinations, since this would imply unconditional stability).

In Figure 3 we have plotted two graphs. One is the L^2-norm squared of a discrete divergence field $D^i \in X_h^0 \otimes \mathfrak{g}$ defined as the solution of (for all $D' \in X_h^0 \otimes \mathfrak{g}$)

$$\langle D^i, D' \rangle = \left\langle \frac{A^{i+1} - A^{i-1}}{2\tau}, \mathrm{d}D' \right\rangle. \tag{3.17}$$

The other graph is the L^2-norm squared of a field $C^i \in X_h^0 \otimes \mathfrak{g}$ measuring charge defined by (for all $C' \in X_h^0 \otimes \mathfrak{g}$)

$$\langle C^i, C' \rangle = \left\langle \frac{A^{i+1} - A^{i-1}}{2\tau}, \mathrm{d}_{A^i} C' \right\rangle. \tag{3.18}$$

Ideally the charge field C^i should remain small compared with D^i, but this appears not to be the case. This tends to indicate that the field D^i is unreliable. Direct visualization shows that it displays strongly mesh-dependent features, as if a smooth (ideal) field D had been perturbed by the noise C^i. As already remarked, total charge is conserved for the scheme, so that C^i must be oscillatory and visualization shows that oscillations are on the scale of the mesh-width h. We remark furthermore that, by energy conservation, the L^2-norm of $(A^{i+1} - A^{i-1})/2\tau$ is bounded so that the H^{-1}-norm of $\mathrm{d}^\star(A^{i+1} - A^{i-1}/2\tau)$ is also bounded. On the other hand Figure 3 shows that the L^2-norm of D^i tends to grow. Together these observations indicate that D^i develops high-frequency modes. We will come back to this observation for the constrained discretizations.

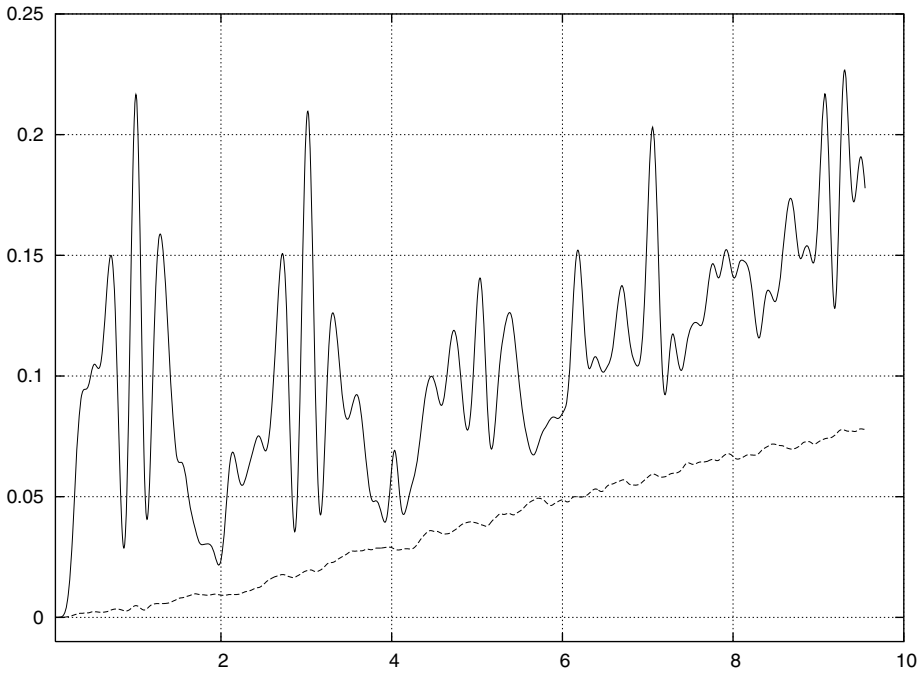

FIG. 3. L^2-*norms squared of divergence* D^i *(plain) and charge* C^i *(dashed).*

We believe this bad behavior with respect to charge conservation to be attributable to the semidiscretization (the space discretization) rather than the leap-frog scheme (the time discretization). That is, the leap-frog scheme just serves to illustrate that the semidiscretization does not provide adequate charge conservation. In this sense the semidiscretization (3.3) is inadequate for simulating Yang–Mills equations. Note that the stability indicated by Figures 1 and 2, together with the drift observed in Figure 3, illustrates the fact that the Yang–Mills system is stable also away from the constraint manifold. But if the Yang–Mills equations were to be coupled with other equations, the development of high frequency modes could be disastrous.

In this paper we will mostly use the leap-frog scheme. This is of course not the only possibility. As an example of an interesting implicit scheme we mention

(3.19)
$$\left\langle \frac{A^{i+1}-2A^i+A^{i-1}}{\tau^2}, A' \right\rangle$$

(3.20)
$$= -\frac{1}{2}\left\langle \mathcal{F}\left(\frac{A^{i-1}+A^i}{2}\right) + \mathcal{F}\left(\frac{A^i+A^{i+1}}{2}\right), \mathrm{D}\mathcal{F}\left(\frac{A^{i-1}}{4}+\frac{A^i}{2}+\frac{A^{i+1}}{4}\right)A' \right\rangle.$$

One of its charms is the following discrete energy conservation property.

PROPOSITION 3.1. [illegible] (3.19), (3.20) [illegible]

(3.21)
$$\frac{1}{2}\left(\left\|\frac{A^{i+1}-A^i}{\tau}\right\|^2 + \left\|\mathcal{F}\left(\frac{A^{i+1}+A^i}{2}\right)\right\|^2\right).$$

. . . . Inserting A' defined by

$$A' = \frac{A^{i+1} - A^{i-1}}{2\tau} = \frac{1}{2}\left(\frac{A^{i+1} - A^i}{\tau} + \frac{A^i - A^{i-1}}{\tau}\right) \tag{3.22}$$

into the left-hand side (3.19) gives

$$\frac{1}{2\tau}\left(\left\|\frac{A^{i+1} - A^i}{\tau}\right\|^2 - \left\|\frac{A^i - A^{i-1}}{\tau}\right\|^2\right). \tag{3.23}$$

Next we use the property that, since the curvature map $\mathcal{F}$ is a polynomial of degree 2, we have, for all gauge potentials A, B,

$$\mathcal{F}(B) = \mathcal{F}(A) + \mathrm{D}\mathcal{F}\left(\frac{A+B}{2}\right)(B - A). \tag{3.24}$$

Applying this identity to

$$A = \frac{A^{i-1} + A^i}{2} \quad \text{and} \quad B = \frac{A^i + A^{i+1}}{2} \tag{3.25}$$

shows that the right-hand side (3.20) with $A' = (1/\tau)(B - A)$ is equal to

$$-\frac{1}{2\tau}\left\langle \mathcal{F}\left(\frac{A^{i-1} + A^i}{2}\right) + \mathcal{F}\left(\frac{A^i + A^{i+1}}{2}\right), \mathcal{F}\left(\frac{A^i + A^{i+1}}{2}\right) - \mathcal{F}\left(\frac{A^{i-1} + A^i}{2}\right)\right\rangle. \tag{3.26}$$

From this the proposition follows. □

This conservation property implies unconditional stability of the scheme. This is useful in particular when the mesh contains strong local refinements.

3.2. Constrained schemes. Since unconstrained schemes have trouble with charge conservation we now examine ways to impose this as a constraint on the flow. This is easier to do on first order formulations such as (3.4), (3.5).

In analogy with the continuous case and standard discretizations of Maxwell's equations, we would like (A, E) to evolve on the subset of $(X_h^1 \otimes \mathfrak{g}) \times (X_h^1 \otimes \mathfrak{g})$ with

$$\forall P' \in X_h^0 \otimes \mathfrak{g} \quad \langle E, \mathrm{d}_A P' \rangle = 0. \tag{3.27}$$

One expects this set to be manifold-like, with singularities located where the kernel of d_A is nontrivial.

We first discuss constraint imposition in general. Suppose we have a system of the form

$$\dot{u} = f(u), \quad g(u) = 0, \tag{3.28}$$

which is compatible in the sense that the vector field f is tangent to the zero-set Z_g of g. One way of imposing constraints on this system is by introducing Lagrange multipliers v and imposing that for all u', v'

$$\langle \dot{u}, u' \rangle + \langle \mathrm{D}g(u)u', v \rangle = \langle f(u), u' \rangle, \tag{3.29}$$

$$\langle \mathrm{D}g(u)\dot{u}, v' \rangle = 0. \tag{3.30}$$

When Dg is onto at each point, the system has a unique solution for given initial values. If the constraint is satisfied initially, it produces trajectories on the zero-set Z_g of g, governed by the vector field defined as the orthogonal projection of f to the tangent spaces of Z_g, according to the duality products $\langle \cdot, \cdot \rangle$. More generally it produces trajectories on the level-sets of g.

When the constraint is compatible, this trajectory must be the one given by (3.28) and the Lagrange multiplier v remains equal to 0. But when the system (3.29), (3.30) is used for incompatible systems, the Lagrange multiplier v will vary, measuring in a sense how incompatible the original system was.

If we apply this method of imposing constraints to the first order system (3.4), (3.5) with the constraint (3.27), we get the following constrained first order system, with Lagrange multipliers $P : t \mapsto P(t) \in X_h^0 \otimes \mathfrak{g}$:

$$\langle \dot{A}, A' \rangle + \langle E, [A', P] \rangle = \langle -E, A' \rangle, \tag{3.31}$$

$$\langle \dot{E}, E' \rangle + \langle E', \mathrm{d}_A P \rangle = \langle \mathcal{F}(A), \mathrm{d}_A E' \rangle, \tag{3.32}$$

$$\langle E, [\dot{A}, P'] \rangle + \langle \dot{E}, \mathrm{d}_A P' \rangle = 0. \tag{3.33}$$

In this system (3.31) can be rewritten using (2.33):

$$\dot{A} = -E + \Pi_h [E, P], \tag{3.34}$$

where Π_h denotes L^2-orthogonal projection onto $X_h^1 \otimes \mathfrak{g}$. In this situation it is not clear what one should call energy of the system, let alone if it is conserved. This is a severe drawback. One could impose an additional constraint on the energy, but this seems cumbersome. Moreover, explicit time discretization of the constrained system (3.31)–(3.33) seems difficult to achieve since the constraint (3.33) appears to be unsuited for time-staggering as in (3.12), (3.13).

In the system (3.31)–(3.33) we see that the term $\langle E, [\dot{A}, P'] \rangle$ ought to be 0. As an alternative to that system we therefore consider the following nonstandard constrained system for fields $A(t), E(t) \in X_h^1 \otimes \mathfrak{g}$ and Lagrange multipliers $P(t) \in X_h^0 \otimes \mathfrak{g}$:

$$\dot{A} = -E, \tag{3.35}$$

$$\langle \dot{E}, E' \rangle + \langle E', \mathrm{d}_A P \rangle = \langle \mathcal{F}(A), \mathrm{d}_A E' \rangle, \tag{3.36}$$

$$\langle \dot{E}, \mathrm{d}_A P' \rangle = 0. \tag{3.37}$$

For the continuous analogue of this system, we remark that by the cancellation property (2.56) given in our first proof of charge conservation in section 2.3, it is equivalent to the unconstrained Yang–Mills equations (2.37) and should yield Lagrange multipliers equal to 0.

For the discrete case we obtain a system which is both energy and constraint preserving (in particular, it is not equivalent to the unconstrained semidiscretization).

PROPOSITION 3.2. [illegible] (3.35)–(3.37) [illegible] (3.27) [illegible]

$$1/2(\|E\|^2 + \|\mathcal{F}(A)\|^2)^{\cdot} = 0. \tag{3.38}$$

[illegible]. Indeed we have for constant P'

$$\langle E, \mathrm{d}_A P' \rangle^{\cdot} = \langle \dot{E}, \mathrm{d}_A P' \rangle + \langle E, [E, P'] \rangle = 0. \tag{3.39}$$

It follows that if the constraint (3.27) is satisfied initially it will be satisfied at all times. Inserting $E' = E$ in (3.36) then gives energy conservation. □

Next we turn to time discretizations of (3.35)–(3.37). Consider the following scheme:

$$\frac{A^i - A^{i-1}}{\tau} = -E^{i-1/2}, \tag{3.40}$$

$$\left\langle \frac{E^{i+1/2} - E^{i-1/2}}{\tau}, E' \right\rangle + \langle E', \mathrm{d}_{A^i} P^i \rangle = \langle \mathcal{F}(A^i), \mathrm{D}\mathcal{F}(A^i) E' \rangle, \tag{3.41}$$

$$\left\langle \frac{E^{i+1/2} - E^{i-1/2}}{\tau}, \mathrm{d}_{A^i} P' \right\rangle = 0. \tag{3.42}$$

Luckily this scheme turns out to be constraint preserving in the following sense.

PROPOSITION 3.3. [illegible] (3.40)–(3.42) [illegible]

$$\left\langle \frac{A^{i+1} - A^{i-1}}{2\tau}, \mathrm{d}_{A^i} P' \right\rangle. \tag{3.43}$$

[illegible] First we remark that

$$\left\langle \frac{A^{i+1} - A^{i-1}}{2\tau}, \mathrm{d}_{A^i} P' \right\rangle = \left\langle \frac{E^{i+1/2} + E^{i-1/2}}{2}, \mathrm{d}_{A^i} P' \right\rangle \tag{3.44}$$

$$= \langle E^{i+1/2}, \mathrm{d}_{A^i} P' \rangle = \langle E^{i-1/2}, \mathrm{d}_{A^i} P' \rangle. \tag{3.45}$$

Then we write

$$\langle E^{i+1/2}, \mathrm{d}_{A^i} P' \rangle - \langle E^{i-1/2}, \mathrm{d}_{A^{i-1}} P' \rangle = \langle E^{i-1/2}, [A^i - A^{i-1}, P'] \rangle \tag{3.46}$$

$$= \langle E^{i-1/2}, [-\tau E^{i-1/2}, P'] \rangle \tag{3.47}$$

$$= 0. \tag{3.48}$$

This gives the desired result. □

Next we show numerical results for the same mesh, time step, and initial values as for the unconstrained case. In Figure 4 we have plotted L^2-norms as in Figure 1 and obtained graphs which are very similar but not identical to the unconstrained case.

In Figure 5 we have plotted the same energies as in Figure 2. Here the similarity with the unconstrained case is surprising. Finally, in Figure 6 we have plotted the divergence and charge defined as for Figure 3. It appears that we have obtained charge conservation without destroying long-time energy conservation. This is somewhat surprising since for symplectic schemes such as the leap-frog scheme existing results on long-time approximate energy conservation are often based on fine properties of Hamiltonian ODEs (see, in particular, [19, chapter 13]) whose extension to constrained discretizations of a PDE are not clear. For the plot of the divergence we have rather large discrepancies with the unconstrained case. For the former discretization, we observed that H^{-1}-boundedness and L^2 growth of D^i indicate the development of high-frequency modes. Since for the constrained scheme, the L^2-norm of D^i grows less (if at all) over a relatively long time period, it appears that we have eliminated the high-frequency modes.

The above constraint preservation is not limited to the leap-frog scheme. The system (3.40)–(3.42) can be expressed as a second order recurrence relation. The discrete acceleration

$$B^i = \frac{A^{i+1} - 2A^i + A^{i-1}}{\tau^2} \tag{3.49}$$

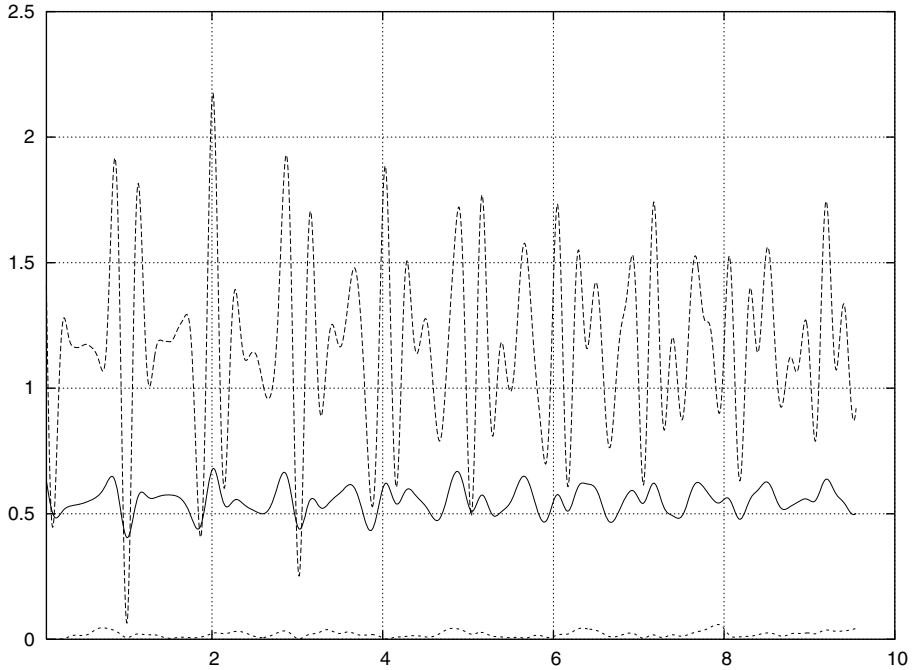

FIG. 4. L^2*-norms squared of* A^i *(plain),* $\mathrm{d}A^i$ *(dashed), and* $(1/2)[A_i, A_i]$ *(finely dashed). Constrained case.*

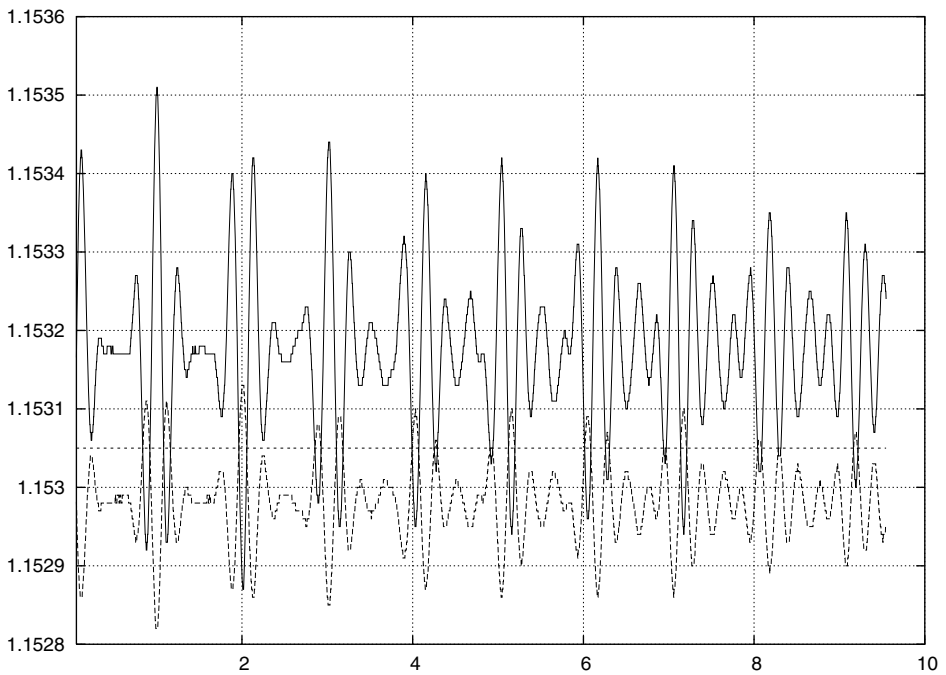

FIG. 5. *Energies* $\mathcal{E}^{i+1/2}$ *(plain),* $\mathcal{E}^i$ *(dashed), and* $(1/6)(\mathcal{E}^{i-1/2}+4\mathcal{E}^i+\mathcal{E}^{i+1/2})$ *(finely dashed). Constrained case.*

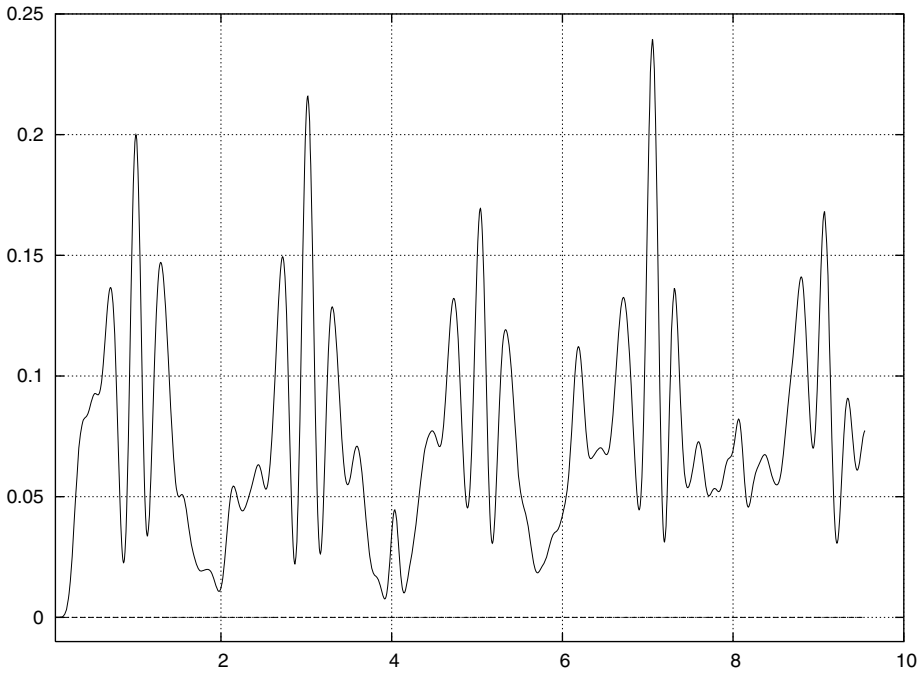

FIG. 6. L^2*-norms squared of divergence* D^i *(plain) and charge* C^i *(dashed). Constrained case.*

should be a solution of

$$\langle B^i, A' \rangle + \langle A', \mathrm{d}_{A^i} P^i \rangle = -\langle \mathcal{F}(A^i), \mathrm{D}\mathcal{F}(A^i) A' \rangle, \tag{3.50}$$

$$\langle B^i, \mathrm{d}_{A^i} P' \rangle = 0. \tag{3.51}$$

The proof of constraint preservation provided for Proposition 3.3 did not depend on the structure of the first term on the right-hand side of (3.40). Therefore we can also impose constraints on the implicit scheme (3.19)–(3.20) by replacing the first term in the right-hand side of (3.50) by the one in (3.20). For this scheme, if the constraint is satisfied initially it will be satisfied for all times, enabling us keep the discrete energy conservation property proved in Proposition 3.1.

3.3. Implementation questions. In this section we comment on some points relevant to the implementation of the above fully discrete algorithm: representation of bilinear maps and resolution of saddle point problems.

Several bilinear maps appear. In particular, we have the wedge of differential forms, the Lie bracket on the chosen Lie algebra, and the bracket of Lie algebra valued differential forms, which is the tensor product of the preceding two maps. Concerning the Lie algebra, a basis (e_i) is chosen and the bilinear map $[\cdot, \cdot]$ is expressed in this basis by the so-called structure constants β_{ij}^k defined by

$$[e_i, e_j] = \sum_k \beta_{ij}^k e_k. \tag{3.52}$$

A similar method can be used to represent the wedge of forms. We are interested in the case of the wedge on $X_h^0 \times X_h^1$ and $X_h^1 \times X_h^1$. From the first one, we can obtain the

bracket of Lie valued forms needed to define the constraint by taking the Kronecker product with the structure constants of the Lie algebra. From the second we obtain the bracket needed to define curvature.

Products of polynomials create polynomials of higher degree so in order to represent these wedge products we must introduce high-order finite element spaces. For simplicity we now skip the index h for the spaces and introduce a new one referring to polynomial degree. For the lowest-order finite element spaces already introduced we use $X^p = X_1^p$.

Denote by X_n^0 the space of continuous functions which are piecewise polynomials of degree at most n. We can also denote by X_0^0 the vector space consisting of the constant functions. The space X_n^0 can also be characterized as the vector space generated by products $u_1 \cdots u_n$, where $u_i \in X_1^0 = X^0$. Next we define the high-order finite element space X_{n+1}^p as the vector space generated by forms uv, where $u \in X_n^0$ and $v \in X_1^p$. Then one checks that

$$\wedge \ : \ X_n^p \times X_m^q \to X_{n+m}^{p+q}. \tag{3.53}$$

It can also be checked that in three dimensions, the family of spaces (X_n^p) corresponds—under the standard identification of differential forms with vector fields—to the first family of mixed finite element spaces as defined in [30], n being the maximum degree of the polynomials used to represent the fields in each tetrahedron (in this context one often says that one uses incomplete polynomials of degree n, since not all differential forms which can be represented piecewise by polynomials of degree n are used; witness the case $n = 1$ for $p \geq 1$).

As already mentioned, to implement our algorithm we are interested in the cases

$$\wedge \ : \ X_1^0 \times X_1^1 \to X_2^1 \quad \text{and} \quad \wedge \ : \ X_1^1 \times X_1^1 \to X_2^2. \tag{3.54}$$

Implementing a basis for high-order finite elements is notoriously cumbersome, since it involves noncanonical choices, which would make for acrobatic indexing exercises when implementing the above wedge products. As a simpler alternative, instead of bases we used generating families which might have linear dependencies. Generally speaking, given a bilinear map $\alpha : E \times F \to G$ between finite dimensional spaces E, F, and G equipped with finite generating families (e_i), (f_j), and (g_k), respectively, suppose we have some family (α_{ij}^k) such that

$$\alpha(e_i, f_j) = \sum_k \alpha_{ij}^k g_k. \tag{3.55}$$

Such a family exists but is in general not unique, but the action of α on vectors expressed as linear combinations of the families (e_i), (f_j) can still be recovered. Explicitly, if

$$u = \sum_i u^i e_i \quad \text{and} \quad v = \sum_j v^j f_j, \tag{3.56}$$

then we have, by simple bilinearity,

$$\alpha(u, v) = w = \sum_k w^k g_k, \quad \text{with} \quad w_k = \sum_{ij} \alpha_{ij}^k u^i v^j. \tag{3.57}$$

We now detail the choice of generating families for $\wedge \ : \ X_1^0 \times X_1^1 \to X_2^1$. For $E = X_1^0$ and $F = X_1^1$ we equip them with their standard (canonical) bases denoted

$(e_i)_{i\in I}$ and $(f_j)_{j\in J}$ indexed by nodes and edges, respectively. A generating family of X_2^1 is provided by the family $(e_i f_j)_{(i,j)\in I\times J}$ but most of these elements are 0. We therefore use the subfamily consisting of, on the one hand, for each edge $j \in J$ with extremities j_0 and j_1 (members of I) in some orientation of the edges, the two 1-forms

$$e_{j_0} f_j \quad \text{and} \quad e_{j_1} f_j, \tag{3.58}$$

and on the other hand, for each triangle k with vertices k_0, k_1, and k_2, if we denote by k_l' the edge opposite to the vertex k_l,

$$e_{k_l} f_{k_l'} \quad \text{with} \quad l = 0, 1, 2. \tag{3.59}$$

This last family is not linearly independent since for each triangle

$$\sum_l e_{k_l} f_{k_l'} = 0. \tag{3.60}$$

As already indicated, it turned out that it was easier to implement the algorithms in this framework rather than ejecting one of the three terms $e_{k_l} f_{k_l'}$ in each triangle (which is enough to ensure linear independence).

Working with tensors of the form (α_{ij}^k) requires routines for treating sparse tensors. For each k there is only a small number (independent of h) of nonzero coefficients. For each k we introduce sets I_k and J_k defined by

$$I_k = \{i \in I \ : \ \exists j \in J \quad \alpha_{ij}^k \neq 0\}, \tag{3.61}$$

$$J_k = \{j \in J \ : \ \exists i \in I \quad \alpha_{ij}^k \neq 0\}. \tag{3.62}$$

We number the elements of I_k and J_k consecutively with integers starting at 1 and store for each element of the $|I_k| \times |J_k|$ matrix thus obtained the corresponding coefficient α_{ij}^k.

While this is certainly not the sparsest representation of the family (α_{ij}^k) it makes the following contraction operation rather quick and easy. In order to assemble the constraint matrix appearing in the saddle point problem (3.41), (3.42) we need to assemble the sparse matrix obtained by contracting the bracket[1] $[\cdot,\cdot] : (X_1^0 \otimes \mathfrak{g}) \times (X_1^1 \otimes \mathfrak{g}) \to X_2^1 \otimes \mathfrak{g}$ with a gauge potential $A^i \in X_1^1 \otimes \mathfrak{g}$. In the above notation, if α is the bracket and v is the gauge potential we want to assemble the matrix of the operator $u \mapsto \alpha(u, v)$. The sparsity pattern of this matrix is determined by the sets I_k and assembling this matrix involves only summing the products

$$\sum_{j\in J_k} \alpha_{ij}^k v^j \tag{3.63}$$

for each k and each $i \in I_k$. This is a small number (independent of h) of operations for each k .

In order to treat the saddle point problem (3.41), (3.42) we need not only assemble the matrix but of course also solve the resulting system. To do this we used an Usawa algorithm. It is an iterative algorithm which requires preconditioning the Schur complement. Indeed, computing the Lagrange multiplier P^i is essentially equivalent to solving a problem of the form

$$\forall P' \in X_h^0 \otimes \mathfrak{g} \quad \langle \Pi_h \mathrm{d}_{A^i} P', \mathrm{d}_{A^i} P^i \rangle = L^i(P'), \tag{3.64}$$

[1]The L^2-duality should also be incorporated in the discussion through its Gram (or mass) matrix on $X_2^1 \otimes \mathfrak{g}$, but this is secondary for the point we want to make here.

where Π_h denotes L^2 projection $X_2^1 \otimes \mathfrak{g} \to X_1^1 \otimes \mathfrak{g}$, and L^i is some linear form on $X_1^0 \otimes \mathfrak{g}$ (this can be checked by directly inserting $E' = \Pi_h \mathrm{d}_{A^i} P'$ into the system). For the numerical results presented here we used as a preconditioner the exact inverse of the matrix of the bilinear form on $(X_1^0 \otimes \mathfrak{g})^2$ defined as

$$(P, P') \to \langle \mathrm{d}P, \mathrm{d}P' \rangle + \langle P, P' \rangle. \tag{3.65}$$

This inverse can be represented by factorization once the nodes have been optimally numbered. The number of times this matrix is used justifies the use of a factorization algorithm, as compared with iterative methods which are often preferred for large scale problems. The above choice of preconditioner was guided by the fact that lower-order terms are compact perturbations of the Laplacian, so that one expects spectral clustering around 1 for the preconditioned system. The Babuska–Brezzi compatibility condition (see Brezzi [7]) we will prove in the next section also proves that this preconditioner yields a condition number bounded uniformly in h.

We now prove a Babuska–Brezzi compatibility condition, ensuring that the above saddle point problem (3.41), (3.42) (or, equivalently, (3.64)) is well-posed. It is slightly more technical than usual since d_A might have a nontrivial kernel. Recall that a continuous operator is said to be left semi-Fredholm if it has closed range and finite dimensional kernel. The sum of a left semi-Fredholm operator and a compact operator is again left semi-Fredholm. In the following proposition we suppose that M is three-dimensional.

PROPOSITION 3.4. [illegible] $A \in \mathrm{L}^3$ [illegible] $\mathrm{d}_A : \mathrm{H}^1 \to \mathrm{L}^2$ [illegible] S [illegible] H^1 [illegible] $S \cap \ker \mathrm{d}_A = \{0\}$ [illegible] $\overline{h} > 0$ [illegible] $C > 0$ [illegible] $h < \overline{h}$ [illegible]

$$\inf_{P' \in X_h^0 \otimes \mathfrak{g} \cap S} \sup_{A' \in X_h^1 \otimes \mathfrak{g}} \frac{|\langle A', \mathrm{d}_A P' \rangle|}{\|A'\|_0 \|P'\|_1} \geq 1/C, \tag{3.66}$$

[illegible]. Since $\mathrm{d}^\star \mathrm{d} : \mathrm{H}^1 \to \mathrm{H}^{-1}$ is Fredholm, d is left semi-Fredholm $\mathrm{H}^1 \to \mathrm{L}^2$. Next we show that for A in L^3 the map $\mathrm{H}^1 \to \mathrm{L}^2$ given by $P \mapsto [A, P]$ is compact. This in turn immediately implies that d_A is left semi-Fredholm.

We have a continuous (but noncompact) Sobolev injection $\mathrm{H}^1 \to \mathrm{L}^6$. Moreover Hölder's inequality shows that $[\cdot, \cdot]$ is continuous $\mathrm{L}^3 \times \mathrm{L}^6 \to \mathrm{L}^2$. Thus $[\cdot, \cdot]$ is continuous $\mathrm{L}^3 \times \mathrm{H}^1 \to \mathrm{L}^2$.

Pick gauge potentials $A_n \in \mathrm{L}^\infty$ such that $(A_n) \to A$ in L^3. Then $[A_n, \cdot]$ converges in norm to $[A, \cdot]$ in the space of maps $\mathrm{H}^1 \to \mathrm{L}^2$. Moreover $[A_n, \cdot]$ is a compact map $\mathrm{H}^1 \to \mathrm{L}^2$ as follows from the (Rellich) compactness of the injection $\mathrm{H}^1 \to \mathrm{L}^2$. Thus $[A, \cdot]$ is a norm limit of compact operators $\mathrm{H}^1 \to \mathrm{L}^2$, and hence it is compact.

Since d maps X_h^0 into X_h^1 there is trivially $C > 0$ such that for all h we have

$$\inf_{P' \in X_h^0 \otimes \mathfrak{g},\ \int P' = 0} \sup_{A' \in X_h^1 \otimes \mathfrak{g}} \frac{|\langle A', \mathrm{d}P' \rangle|}{\|A'\|_0 \|P'\|_1} \geq 1/C. \tag{3.67}$$

Thus $\mathrm{d}_A = \mathrm{d} + [A, \cdot]$ is a compact perturbation of a map satisfying a (one-sided) uniform discrete Inf-Sup condition (up to a finite dimensional space). The proposition then follows from Corollaries 1.11 and 1.13 in Christiansen [9]. □

In geometric terms this proposition shows that the infinitesimal generators of the gauge transformations $\mathcal{G}_Q$ associated with Lie group valued maps $Q : M \to G$ of the

form

$$x \mapsto Q(x) = \exp(P(x)), \tag{3.68}$$

with $P \in X_h^0 \otimes \mathfrak{g}$, are far from orthogonal to $X_h^1 \otimes \mathfrak{g}$. This property should be compared to the case of a commutative Lie group G (e.g., Maxwell) for which $X_h^1 \otimes \mathfrak{g}$ is stable under such gauge transformations, which, as already mentioned, provides an interpretation of the conservation property (3.9) in terms of Noether's theorem.

Typically one would like to apply the Babuska–Brezzi compatibility property along trajectories $t \mapsto A(t) \in X_h^1 \otimes \mathfrak{g}$. For this purpose we mention that Corollary 1.17 in Christiansen [9] automatically extends certain estimates which follow from Proposition 3.4 to hold [illegible] for [illegible] of gauge potentials A that are compact in L^3.

4. Perspectives. We believe that Yang–Mills equations provide a test bench for many problems in the theory of discretizations of constrained PDEs and we mention in this conclusion directions for future investigations.

Extension to nontrivial principal bundles seems to be a challenging geometric problem and is under investigation.

Multiplying the Lie bracket on $\mathfrak{g}$ by a real parameter provides some freedom in tuning the strength of the nonlinearity. That is, we can introduce a coupling parameter $\gamma \in \mathbb{R}$ and consider the curvature

$$\mathcal{F}_\gamma(A) = \mathrm{d}A + (\gamma/2)[A, A]. \tag{4.1}$$

We are interested in trajectories obtained from the associated Lagrangian

$$\mathcal{L}_\gamma(A, A') = (1/2)\|A'\|^2 - (1/2)\|\mathcal{F}_\gamma(A)\|^2. \tag{4.2}$$

The limit $\gamma \to 0$ is often referred to as the weak coupling limit, while the case $\gamma = 0$ is equivalent to Maxwell's equations. Various series expansions, e.g., in powers of γ, around the "trivial" case $\gamma = 0$ are used in many circumstances (for instance, KAM theory) to provide information where other methods fail.

We mention also that, in physics, quantized versions of the Yang–Mills equations are the most important. Given a representation of the Lie group G on a vector space V, a gauge potential on M gives rise to a connection on the space of V-valued maps on M which is compatible with G, and vice versa. The lattice gauge theory due to Wilson consists in using a cubic lattice and attaching Lie group elements to each edge, representing the parallel transport of a connection. The curvature of the connection has degrees of freedom attached to each square of the lattice, called Wilson loops. This discretization appears to be linked to the presently proposed finite element method in much the same way as, for Maxwell's equations, the Yee scheme, which is a staggered finite difference scheme on cubic lattices, is related to variational mixed finite element methods.

Acknowledgments. This work was inspired by a discussion among Douglas N. Arnold, Alan D. Rendall, and the second author at an IMA "hot topics" workshop on Numerical Relativity in June 2002. We thank Geir Ellingsrud and Roman Kozlov for interesting discussions on connections and geometric integration. We also thank Per Christian Moan and Jan B. Thomassen for their remarks.

NEW NONOVERLAPPING DOMAIN DECOMPOSITION METHODS FOR THE HARMONIC MAXWELL SYSTEM*

ANA ALONSO RODRÍGUEZ† AND LUCA GERARDO-GIORDA†

Abstract. We study a nonoverlapping domain decomposition method for the harmonic Maxwell equations with a new kind of interface condition. Using Fourier analysis we derive suitable families of transmission conditions in $\mathbb{R}^3$ that involve second order tangential differential operators and that guarantee convergence for both propagative and evanescent modes. Such families depend upon parameters that are chosen to optimize the convergence rate of the corresponding iterative algorithm. We then propose iterative solvers for the Maxwell equations based on a domain decomposition procedure where such conditions are enforced on the interface. Some numerical results for a two-domain decomposition show the effectiveness of the optimized interface conditions.

Key words. domain decomposition methods, harmonic Maxwell system, optimized interface conditions

1. Introduction.

The numerical solution of the time-harmonic Maxwell system over a large three-dimensional domain is a difficult task. The linear system resulting from the finite element approximation is complex and the matrix is neither Hermitian nor definite. To construct an efficient iterative method to solve this system, domain decomposition can be used. We concentrate on nonoverlapping domain decomposition methods (see, for instance, [9]). The idea is to decompose the domain into several nonoverlapping subdomains and to solve in parallel the local problems. This procedure leads to an iterative method that converges to the solution of the original problem if the solutions in the subdomains are related by means of suitable boundary conditions at the interface. The performance of the method depends drastically on the choice of this interface conditions.

The earliest nonoverlapping domain decomposition method for the time-harmonic Maxwell system was introduced in [4] with an interface condition of Robin type. For this algorithm it is proved that the local solutions converge to the corresponding restrictions of the global solution weakly in the spaces of complex vector functions of L^2 with curl in L^2. In his Ph.D. thesis, Chevalier [2] proposed a modification of the Robin interface condition by adding a second order differential operator along the interface. For this new algorithm there is not an accurate convergence analysis. In [3] an interface condition involving a second order tangential operator is analyzed and some numerical results are given for a model problem with conditions of radiative type on the whole boundary. A Fourier analysis shows that, for the interface conditions used in these three algorithms, the iteration map is not a contraction in the presence of evanescent modes.

The use of a second order interface operator arises naturally since the Fourier analysis shows that the exact interface conditions involve a pseudodifferential operator and second order tangential derivatives. By approximating the pseudodifferential

†Dipartimento di Matematica, Università di Trento, Via Sommarive 14, I-38050 Povo (TN), Italy (alonso@science.unitn.it, gerardo@cmapx.polytechnique.fr).

operator we identify two families of interface conditions that lead to iteration maps that are contractive for both propagative and evanescent modes. The first family depends on a complex parameter $p \in \mathbb{C}$, while the second one depends on two parameters, one real ($r \in \mathbb{R}$) and one purely imaginary (iq, $q \in \mathbb{R}$). We will refer in what follows to the first family as [illegible] interface conditions and to the second as [illegible] interface conditions. The parameters $p \in \mathbb{C}$ and $r, q \in \mathbb{R}$ can then be optimized, namely, they can be chosen to optimize the convergence rate of the corresponding iterative procedure, as done by Gander, Magoulès, and Nataf for the Helmholtz equation (see [5]).

The paper is organized as follows. In section 2 the model problem in $\mathbb{R}^3$ is solved by means of an additive Schwarz method in a very general framework: using Fourier analysis, we derive two families of interface conditions which guarantee convergence for both propagative and evanescent modes. An optimization is then performed on the parameters describing such families. In section 3 the proposed domain decomposition algorithms are detailed for a two-domain decomposition at both the continuous and the discrete level. In section 4 the algorithms are validated by some numerical tests. Finally, in section 5, a survey of the nonoverlapping domain decomposition algorithms for the harmonic Maxwell system that previously appeared in literature is given: the interface conditions in these algorithms can be easily included in the general framework we introduce in section 2 and are compared numerically with the conditions we propose.

2. Optimized interface conditions for a model problem in $\mathbb{R}^3$. The harmonic solutions of Maxwell equations are complex valued fields $\mathbf{E}$ and $\mathbf{H}$ such that the fields

$$\mathcal{E}(\mathbf{x}, t) = \mathcal{R}e(\mathbf{E}(\mathbf{x})\exp(i\omega t)),$$
$$\mathcal{H}(\mathbf{x}, t) = \mathcal{R}e(\mathbf{H}(\mathbf{x})\exp(i\omega t))$$

satisfy the Maxwell system. The positive number ω is called the pulsation of the harmonic wave. $\mathbf{E}$ and $\mathbf{H}$ satisfy the time-harmonic equations

$$\begin{aligned} &\operatorname{curl} \mathbf{E} + i\omega\mu\mathbf{H} = \mathbf{0}, \\ &\operatorname{curl} \mathbf{H} - i\omega\varepsilon\mathbf{E} = \mathbf{J}, \end{aligned} \tag{1}$$

where $\mathbf{J}$ is the amplitude of the applied current density.

The model problem we consider is the second order time-harmonic Maxwell equation obtained from (1) by eliminating either the magnetic field $\mathbf{H}$ or the electric filed $\mathbf{E}$. It reads

$$\operatorname{curl}\operatorname{curl} \mathbf{u} - \omega^2\mathbf{u} = \mathbf{F} \quad \text{in } \Omega, \tag{2}$$

where, for the sake of simplicity in notations, we have normalized both the electric permittivity ε and the magnetic permeability μ (i.e., $\varepsilon = \mu = 1$). When $\mathbf{u}$ stands for the electric field, $\mathbf{F} := -i\omega\mathbf{J}$; on the other hand, if $\mathbf{u}$ is the magnetic field, $\mathbf{F} := \operatorname{curl} \mathbf{J}$.

We present the analysis in the domain $\Omega = \mathbb{R}^3$ with the radiation condition

$$\lim_{r\to\infty} r(\operatorname{curl} \mathbf{u} \times \mathbf{n} + i\omega\mathbf{u}) = \mathbf{0}, \tag{3}$$

where $r = |\mathbf{x}|$, $\mathbf{n} = \mathbf{x}/|\mathbf{x}|$.

We decompose the domain in two nonoverlapping subdomains $\Omega_B := \mathbb{R}^2 \times (-\infty, 0)$ and $\Omega_T := \mathbb{R}^2 \times (0, +\infty)$ and we set $\Gamma := \overline{\Omega_B} \cap \overline{\Omega_T}$. Since, as is well known in domain

decomposition literature, an iterative algorithm of Schwarz type without overlap does not converge when Dirichlet interface conditions are used, we consider the following iterative algorithm with more general interface conditions: given $\mathbf{u}_B^0$ and $\mathbf{u}_T^0$, for $j \geq 0$ solve

$$
\begin{cases} \operatorname{curl}\operatorname{curl}\mathbf{u}_B^{j+1} - \omega^2\mathbf{u}_B^{j+1} = \mathbf{F} & \text{in } \Omega_B, \\ \operatorname{curl}\mathbf{u}_B^{j+1}\times\mathbf{n}_B + S_B(\mathbf{u}_{B,\tau}^{j+1}) = \operatorname{curl}\mathbf{u}_T^{j}\times\mathbf{n}_B + S_B(\mathbf{u}_{T,\tau}^{j}) & \text{on } \Gamma, \end{cases}
$$

$$
\begin{cases} \operatorname{curl}\operatorname{curl}\mathbf{u}_T^{j+1} - \omega^2\mathbf{u}_T^{j+1} = \mathbf{F} & \text{in } \Omega_T, \\ \operatorname{curl}\mathbf{u}_T^{j+1}\times\mathbf{n}_T + S_T(\mathbf{u}_{T,\tau}^{j+1}) = \operatorname{curl}\mathbf{u}_B^{j}\times\mathbf{n}_T + S_T(\mathbf{u}_{B,\tau}^{j}) & \text{on } \Gamma. \end{cases} \tag{4}
$$

Here S_B and S_T are two linear operators acting in the tangential direction on the interface and $\mathbf{u}_{L,\tau}^j := \mathbf{n}_B \times \mathbf{u}_L^j \times \mathbf{n}_B = \mathbf{n}_T \times \mathbf{u}_L^j \times \mathbf{n}_T$ for $L = B, T$. It is then easy to see that if $\ker(S_B + S_T) = \{\mathbf{0}\}$, we recover at convergence the solution of the single domain problem.

Since the problems involved are linear, it is enough to analyze the convergence to the zero solution for the homogeneous system. Note that since $\operatorname{curl}\operatorname{curl}\mathbf{v} - \nabla\operatorname{div}\mathbf{v} = -\Delta\mathbf{v}$, the homogeneous equation $\operatorname{curl}\operatorname{curl}\mathbf{u}_L^{j+1} - \omega^2\mathbf{u}_L^{j+1} = \mathbf{0}$ is equivalent to

$$
\begin{aligned} -\Delta\mathbf{u}_L^{j+1} - \omega^2\mathbf{u}_L^{j+1} &= \mathbf{0} \quad \text{in } \Omega_L, \\ \operatorname{div}\mathbf{u}_L^{j+1} &= 0 \quad\;\; \text{in } \Omega_L, \qquad L = B, T. \end{aligned} \tag{5}
$$

We perform a partial Fourier transform in the x and y directions, which we denote with $\mathcal{F}$, and we call k_1 and k_2 the corresponding dual variables. The transform $\mathcal{F}$ is defined as

$$
\mathcal{F} : \mathbf{u}(x, y, z) \to \widehat{\mathbf{u}}(k_1, k_2, z) = \int\!\!\int_{\mathbb{R}^2} \mathbf{u}(x, y, z) e^{-i(k_1 x + k_2 y)}\, dx\, dy.
$$

Then we obtain

$$
\begin{cases} -\frac{\partial^2\widehat{\mathbf{u}}_B^{j+1}}{\partial z^2} + (k_1^2 + k_2^2 - \omega^2)\widehat{\mathbf{u}}_B^{j+1} = \mathbf{0}, & (k_1, k_2) \in \mathbb{R}^2,\ z < 0, \\ -ik_1\widehat{u}_{B,1}^{j+1} - ik_2\widehat{u}_{B,2}^{j+1} + \partial_z\widehat{u}_{B,3}^{j+1} = 0, & (k_1, k_2) \in \mathbb{R}^2,\ z < 0, \\ \mathcal{F}(\operatorname{curl}\mathbf{u}_B^{j+1})\times\mathbf{n}_B + \sigma_B(k_1, k_2)(\widehat{\mathbf{u}}_{B,\tau}^{j+1}) & \\ \qquad = \mathcal{F}(\operatorname{curl}\mathbf{u}_T^{j})\times\mathbf{n}_B + \sigma_B(k_1, k_2)(\widehat{\mathbf{u}}_{T,\tau}^{j}), & (k_1, k_2) \in \mathbb{R}^2,\ z = 0, \end{cases} \tag{6}
$$

$$
\begin{cases} -\frac{\partial^2\widehat{\mathbf{u}}_T^{j+1}}{\partial z^2} + (k_1^2 + k_2^2 - \omega^2)\widehat{\mathbf{u}}_T^{j+1} = \mathbf{0}, & (k_1, k_2) \in \mathbb{R}^2,\ z > 0, \\ -ik_1\widehat{u}_{T,1}^{j+1} - ik_2\widehat{u}_{T,2}^{j+1} + \partial_z\widehat{u}_{T,3}^{j+1} = 0, & (k_1, k_2) \in \mathbb{R}^2,\ z > 0, \\ \mathcal{F}(\operatorname{curl}\mathbf{u}_T^{j+1})\times\mathbf{n}_T + \sigma_T(k_1, k_2)(\widehat{\mathbf{u}}_{T,\tau}^{j+1}) & \\ \qquad = \mathcal{F}(\operatorname{curl}\mathbf{u}_B^{j})\times\mathbf{n}_T + \sigma_T(k_1, k_2)(\widehat{\mathbf{u}}_{B,\tau}^{j}), & (k_1, k_2) \in \mathbb{R}^2,\ z = 0, \end{cases}
$$

where σ_L denotes the symbol of the operator S_L.

The general solutions of $-\frac{\partial^2\widehat{\mathbf{u}}_L}{\partial z^2} + (k_1^2 + k_2^2 - \omega^2)\widehat{\mathbf{u}}_L = \mathbf{0}$, $(L = B, T)$ are

$$
\widehat{\mathbf{u}}_L(k_1, k_2, z) = \mathbf{a}_L(k_1, k_2)e^{\lambda z} + \mathbf{b}_L(k_1, k_2)e^{-\lambda z},
$$

where $\lambda = \lambda(k_1, k_2) = \sqrt{k_1^2 + k_2^2 - \omega^2}$ denotes the root of the characteristic equation which is either real and positive or purely imaginary. Since the radiation conditions exclude growing solutions as well as incoming modes at infinity we obtain that $\mathbf{b}_B(k_1, k_2) = \mathbf{a}_T(k_1, k_2) = \mathbf{0}$, hence

$$\widehat{\mathbf{u}}_B(k_1, k_2, z) = \mathbf{a}_B(k_1, k_2)e^{\lambda z},$$
$$\widehat{\mathbf{u}}_T(k_1, k_2, z) = \mathbf{b}_T(k_1, k_2)e^{-\lambda z}.$$

From the transformed divergence-free conditions $-ik_1\widehat{u}_{L,1} - ik_2\widehat{u}_{L,2} + \partial_z\widehat{u}_{L,3} = 0$ we get

$$\begin{aligned} \lambda\widehat{u}_{B,3} &= \partial_z\widehat{u}_{B,3} = i(k_1\widehat{u}_{B,1} + k_2\widehat{u}_{B,2}) \\ -\lambda\widehat{u}_{T,3} &= \partial_z\widehat{u}_{T,3} = i(k_1\widehat{u}_{T,1} + k_2\widehat{u}_{T,2}); \end{aligned}$$

thus, for $\lambda \neq 0$,

$$\widehat{u}_{B,3} = \frac{i}{\lambda}(k_1\widehat{u}_{B,1} + k_2\widehat{u}_{B,2}), \qquad \widehat{u}_{T,3} = -\frac{i}{\lambda}(k_1\widehat{u}_{T,1} + k_2\widehat{u}_{T,2}).$$

This means that we can write $\mathcal{F}(\operatorname{curl} \mathbf{u}_L) \times \mathbf{n}_L$ in terms of the tangential components on Γ, $(\widehat{u}_{L,1}, \widehat{u}_{L,2})$. In fact we can prove the following result.

LEMMA 1. [illegible] $\mathbf{u}_L$ $L = B, T$ [illegible]

$$\begin{aligned} &-\Delta\mathbf{u}_L - \omega^2\mathbf{u}_L = \mathbf{0} && \text{[illegible]}\ \Omega_L, \\ &\operatorname{div} \mathbf{u}_L = 0 && \text{[illegible]}\ \Omega_L, \\ &\lim_{r\to\infty} r(\operatorname{curl} \mathbf{u}_L \times \mathbf{n} + i\omega\mathbf{u}_L) = 0, \end{aligned}$$

[illegible] $\mathbf{U}_L := \begin{bmatrix} \widehat{u}_{L,1} \\ \widehat{u}_{L,2} \end{bmatrix}$ [illegible]

$$\lambda\,\mathcal{F}(\operatorname{curl} \mathbf{u}_L) \times \mathbf{n}_L = \begin{bmatrix} R\,\mathbf{U}_L - \omega^2\mathbf{U}_L \\ \mathbf{0} \end{bmatrix},$$

[illegible] $R = R(k_1, k_2)$ [illegible]

$$R := \begin{bmatrix} k_2^2 & -k_1k_2 \\ -k_1k_2 & k_1^2 \end{bmatrix}.$$

[illegible]. This result can be found in [2]. We include here the proof for completeness. We consider the case $L = B$ but the proof is analogous for $L = T$. Since

$$\mathcal{F}(\operatorname{curl} \mathbf{u}_B) = \begin{bmatrix} -ik_2\widehat{u}_{B,3} - \dfrac{\partial\widehat{u}_{B,2}}{\partial z} \\ \dfrac{\partial\widehat{u}_{B,1}}{\partial z} + ik_1\widehat{u}_{B,3} \\ -ik_1\widehat{u}_{B,2} + ik_2\widehat{u}_{B,1} \end{bmatrix} = \begin{bmatrix} \dfrac{k_2}{\lambda}(k_1\widehat{u}_{B,1} + k_2\widehat{u}_{B,2}) - \lambda\widehat{u}_{B,2} \\ \lambda\widehat{u}_{B,1} - \dfrac{k_1}{\lambda}(k_1\widehat{u}_{B,1} + k_2\widehat{u}_{B,2}) \\ -ik_1\widehat{u}_{B,2} + ik_2\widehat{u}_{B,1} \end{bmatrix}$$

we easily conclude

$$\lambda\mathcal{F}(\operatorname{curl}\mathbf{u}_B)\times\mathbf{n}_B=\begin{bmatrix}\lambda^2\widehat{u}_{B,1}-k_1(k_1\widehat{u}_{B,1}+k_2\widehat{u}_{B,2})\\ -k_2(k_1\widehat{u}_{B,1}+k_2\widehat{u}_{B,2})+\lambda^2\widehat{u}_{B,2}\\ 0\end{bmatrix}$$

$$=\begin{bmatrix}(k_2^2-\omega^2)\widehat{u}_{B,1}-k_1k_2\widehat{u}_{B,2}\\ -k_2k_1\widehat{u}_{B,1}+(k_1^2-\omega^2)\widehat{u}_{B,2}\\ 0\end{bmatrix}. \qquad \square$$

1. We recall that for a function $\mathbf{q}:\mathbb{R}^2\to\mathbb{R}^2$, $\operatorname{curl}\mathbf{q}=\frac{\partial q_2}{\partial x}-\frac{\partial q_1}{\partial y}$ and

$$\overrightarrow{\operatorname{curl}}_\Gamma\operatorname{curl}_\Gamma\mathbf{q}=\begin{bmatrix}\dfrac{\partial}{\partial y}\left(\dfrac{\partial q_2}{\partial x}-\dfrac{\partial q_1}{\partial y}\right)\\ -\dfrac{\partial}{\partial x}\left(\dfrac{\partial q_2}{\partial x}-\dfrac{\partial q_1}{\partial y}\right)\end{bmatrix}.$$

It is then easy to see that

$$R\,\mathbf{U}_L=\mathcal{F}(\overrightarrow{\operatorname{curl}}_\Gamma\operatorname{curl}_\Gamma\mathbf{u}_{L,\tau}).$$

Since the third components in the above expressions vanish identically, we can express the action of one iteration of the algorithm (6), in terms of $\mathbf{U}_B$ and $\mathbf{U}_T$, as

$$\tfrac{1}{\lambda}(R\,\mathbf{U}_B^{j+1}-\omega^2\mathbf{U}_B^{j+1})+\sigma_B\mathbf{U}_B^{j+1}=-\tfrac{1}{\lambda}(R\,\mathbf{U}_T^{j}-\omega^2\mathbf{U}_T^{j})+\sigma_B\mathbf{U}_T^{j},$$

$$\tfrac{1}{\lambda}(R\,\mathbf{U}_T^{j+1}-\omega^2\mathbf{U}_T^{j+1})+\sigma_T\mathbf{U}_T^{j+1}=-\tfrac{1}{\lambda}(R\,\mathbf{U}_B^{j}-\omega^2\mathbf{U}_B^{j})+\sigma_T\mathbf{U}_B^{j}.$$

If σ_B and σ_T are such that the matrix $(R-\omega^2I+\lambda\sigma_L)$ is invertible for $L=B$, T, we have

$$\mathbf{U}_B^{j+1}=(R-\omega^2I+\lambda\sigma_B)^{-1}(-R+\omega^2I+\lambda\sigma_B)\mathbf{U}_T^{j},$$

$$\mathbf{U}_T^{j+1}=(R-\omega^2I+\lambda\sigma_T)^{-1}(-R+\omega^2I+\lambda\sigma_T)\mathbf{U}_B^{j}.$$

If we let

$$M_B:=(R-\omega^2I+\lambda\sigma_B)^{-1}(-R+\omega^2I+\lambda\sigma_B)(R-\omega^2I+\lambda\sigma_T)^{-1}(-R+\omega^2I+\lambda\sigma_T)$$

and

$$M_T=(R-\omega^2I+\lambda\sigma_T)^{-1}(-R+\omega^2I+\lambda\sigma_T)(R-\omega^2I+\lambda\sigma_B)^{-1}(-R+\omega^2I+\lambda\sigma_B),$$

we can write $\mathbf{U}_B^{j+2}=M_B\mathbf{U}_B^{j}$, $\mathbf{U}_T^{j+2}=M_T\mathbf{U}_T^{j}$. Given $\mathbf{U}_B^0$ and $\mathbf{U}_T^0$, we get

$$\mathbf{U}_B^{2n}=M_B^n\mathbf{U}_B^0,\qquad\qquad \mathbf{U}_T^{2n}=M_T^n\mathbf{U}_T^0.$$

Since the matrices M_B and M_T share the same spectrum as a function of k_1 and k_2, we can define the convergence rate of the algorithm as being the spectral radius of M_B (or, equivalently, M_T), namely,

$$\rho(k_1,k_2):=\rho(M_T)=\rho(M_B).$$

Thus, the sequence $(\mathbf{U}_B^j,\mathbf{U}_T^j)$ converges to zero if and only if $\rho<1$.

Notice that choosing $\sigma_L = \frac{1}{\lambda_L}(R - \omega^2 I)$, for $L = B, T$, we can easily derive

$$M_B = M_T = \frac{-\lambda_B + \lambda}{\lambda_B + \lambda} \frac{-\lambda_T + \lambda}{\lambda_T + \lambda} I. \tag{7}$$

Choosing $\lambda_B = \lambda_T = \lambda(k)$ we have $\rho(M_T) = \rho(M_B) = 0$, and the algorithm converges in two iterations. Unfortunately, due to the presence of the square root in the symbol, this choice corresponds to nonlocal operators S_L which cannot be used in practice in the real domain where computations take place. To overcome this problem we approximate λ by the symbol of a local operator. The easiest solution to avoid an increase in the order of the interface operator is to replace λ with a constant. In other words, we take $\lambda_L = p_L \in \mathbb{C}$ independent of k_1 and k_2 for $L = B, T$. In this way S_L is the second order operator

$$S_L = \frac{1}{p_L}(\overrightarrow{\mathrm{curl}}_\Gamma \mathrm{curl}_\Gamma - \omega^2 I), \tag{8}$$

where curl_Γ is the surface scalar curl operator and $\overrightarrow{\mathrm{curl}}_\Gamma$ the surface vector curl operator. In the remaining part of the section we present two suitable choices for such parameters.

2. Another choice would be to approximate $\lambda(|k|)$ by means of a low order truncation of its Taylor expansion that is given by

$$\lambda(|k|) = i\omega - i\frac{|k|^2}{2\omega} - i\frac{|k|^4}{8\omega^3} + O(|k|^6).$$

Such expansion is a suitable approximation only for small values of $|k|$. Moreover, since $\lambda(|k|)$ takes positive real values for $|k| > \omega$, a purely imaginary approximation as the one provided by this expansion is not efficient: when $\lambda(|k|)$ is real the numerators and denominators in (7) are complex conjugated numbers and $\rho(M_B) = \rho(M_T) = 1$.

2.1. Symmetric interface conditions. The most natural choice is to take $p_B = p_T = p \in \mathbb{C}$, which amounts to use the same operator in the interface condition on both subdomains: we thus refer to this choice as [illegible]. With this assumption, owing to (7), the sequence $(\mathbf{U}_B^j, \mathbf{U}_T^j)$ converges if and only if

$$\rho(p, |k|) = \left|\frac{-p + \lambda}{p + \lambda}\right|^2 < 1.$$

On one hand, for evanescent modes ($|k|^2 > \omega^2$), we have that

$$\begin{aligned}\left|\frac{-p + \lambda}{p + \lambda}\right|^2 &= \frac{(-\mathcal{R}e\, p + \sqrt{|k|^2 - \omega^2})^2 + (\mathcal{I}m\ p)^2}{(\mathcal{R}e\, p + \sqrt{|k|^2 - \omega^2})^2 + (\mathcal{I}m\ p)^2} \\ &= \frac{|p|^2 + |k|^2 - \omega^2 - 2\,\mathcal{R}e\, p\sqrt{|k|^2 - \omega^2}}{|p|^2 + |k|^2 - \omega^2 + 2\,\mathcal{R}e\, p\sqrt{|k|^2 - \omega^2}} < 1\end{aligned}$$

if and only if $\mathcal{R}e\, p > 0$.

On the other hand, for propagative modes ($|k|^2 < \omega^2$), we similarly have

$$\begin{aligned}\left|\frac{-p + \lambda}{p + \lambda}\right|^2 &= \frac{(\mathcal{R}e\, p)^2 + (-\mathcal{I}m\, p + \sqrt{\omega^2 - |k|^2})^2}{(\mathcal{R}e\, p)^2 + (\mathcal{I}m\, p + \sqrt{\omega^2 - |k|^2})^2} \\ &= \frac{|p|^2 + \omega^2 - |k|^2 - 2\,\mathcal{I}m\, p\sqrt{\omega^2 - |k|^2}}{|p|^2 + \omega^2 - |k|^2 + 2\,\mathcal{I}m\, p\sqrt{\omega^2 - |k|^2}} < 1\end{aligned}$$

if and only if $\mathcal{I}m\, p > 0$.

Notice, however, that for $|k|^2 = \omega^2$ the convergence rate $\rho(p, |k|) = 1$ for all $p \in \mathbb{C}$.

This analysis leads us to consider algorithm (4) with the second order interface conditions

$$
(9) \quad \begin{cases} \operatorname{curl} \mathbf{u}_B^{j+1} \times \mathbf{n}_B + \frac{1}{p}(\overrightarrow{\operatorname{curl}}_\Gamma \operatorname{curl}_\Gamma - \omega^2 I)(\mathbf{u}_{B,\tau}^{j+1}) \\ \qquad\qquad = \operatorname{curl} \mathbf{u}_T^{j} \times \mathbf{n}_B + \frac{1}{p}(\overrightarrow{\operatorname{curl}}_\Gamma \operatorname{curl}_\Gamma - \omega^2 I)(\mathbf{u}_{T,\tau}^{j}), \\ \operatorname{curl} \mathbf{u}_T^{j+1} \times \mathbf{n}_T + \frac{1}{p}(\overrightarrow{\operatorname{curl}}_\Gamma \operatorname{curl}_\Gamma - \omega^2 I)(\mathbf{u}_{T,\tau}^{j+1}) \\ \qquad\qquad = \operatorname{curl} \mathbf{u}_B^{j} \times \mathbf{n}_T + \frac{1}{p}(\overrightarrow{\operatorname{curl}}_\Gamma \operatorname{curl}_\Gamma - \omega^2 I)(\mathbf{u}_{B,\tau}^{j}) \end{cases}
$$

on Γ. The complex parameter p is chosen with $\mathcal{R}e\, p, \mathcal{I}m\, p \in \mathbb{R}^+$. In the following we call

$$\mathbb{C}^+ := \{q \in \mathbb{C} \mid \mathcal{R}e\, q > 0, \mathcal{I}m\, q > 0\}.$$

The best choice of p is the one that gives a minimal spectral radius. As we have noted before, if $|k|^2 = \omega^2$, then $\rho(p, |k|) = 1$ for all $p \in \mathbb{C}^+$. However, following [5], we can restrict ourselves to consider spatial frequencies such that $|k| \in I := (m, \omega_-) \cup (\omega_+, M)$, where ω_- and ω_+ are parameters to be chosen such that $\omega_- < \omega < \omega_+$, where m denotes the smallest value of $|k|$ relevant to the subdomain and where M is the largest value of $|k|$ supported by the numerical grid. This largest frequency is of order π/h. Hence we choose p^{opt} as being the solution of the optimization problem

$$\rho_{\text{S}}^{\text{opt}} = \min_{p \in \mathbb{C}^+} \max_{|k| \in I} |\rho(p, |k|)|$$

that coincides with the one analyzed in [5], whose solution is given by

$$
(10) \qquad \mathcal{R}e\, p^{\text{opt}} = \mathcal{I}m\, p^{\text{opt}} = \frac{\left[(\omega^2 - \omega_-^2)(M^2 - \omega^2)\right]^{1/4}}{\sqrt{2}}
$$

and provides the convergence rate

$$\rho_{\text{S}}^{\text{opt}} = \frac{1 - \sqrt{2}\left(\frac{\omega^2 - \omega_-^2}{M^2 - \omega^2}\right)^{1/4} + \left(\frac{\omega^2 - \omega_-^2}{M^2 - \omega^2}\right)^{1/2}}{1 + \sqrt{2}\left(\frac{\omega^2 - \omega_-^2}{M^2 - \omega^2}\right)^{1/4} + \left(\frac{\omega^2 - \omega_-^2}{M^2 - \omega^2}\right)^{1/2}}.$$

2.2. Unsymmetric interface conditions. Another opportunity stems from the expression of matrices M_B and M_T in (7) and from the fact that λ is either real and positive or purely imaginary: choosing one parameter real and positive and the other one purely imaginary (with positive imaginary part), the reduction factor is strictly smaller than 1 for all modes. To fix the ideas, if we take, for instance, $p_B = r \in \mathbb{R}^+$, and $p_T = i\, q,\ q \in \mathbb{R}^+$, the reduction factor is given by

$$
(11) \qquad \rho(r, q, |k|) = \left| \frac{-r + \lambda}{r + \lambda} \, \frac{-iq + \lambda}{iq + \lambda} \right|
$$

(and we claim that the inverse choice provides the same result). We immediately have for propagative modes

$$
(12) \qquad \left| \frac{-r + \lambda}{r + \lambda} \right| = 1, \qquad \left| \frac{-iq + \lambda}{iq + \lambda} \right| < 1,
$$

as well as for evanescent modes

$$\left|\frac{-r+\lambda}{r+\lambda}\right| < 1, \qquad \left|\frac{-iq+\lambda}{iq+\lambda}\right| = 1. \tag{13}$$

The algorithm we are thus led to consider is based on the following interface conditions on Γ (recall that $(iq)^{-1} = -i/q$):

$$\begin{cases} \operatorname{curl} \mathbf{u}_B^{j+1} \times \mathbf{n}_B + \frac{1}{r}(\overrightarrow{\operatorname{curl}}_\Gamma \operatorname{curl}_\Gamma - \omega^2 I)(\mathbf{u}_{B,\tau}^{j+1}) \\ \qquad = \operatorname{curl} \mathbf{u}_T^{j} \times \mathbf{n}_B + \frac{1}{r}(\overrightarrow{\operatorname{curl}}_\Gamma \operatorname{curl}_\Gamma - \omega^2 I)(\mathbf{u}_{T,\tau}^{j}), \\ \operatorname{curl} \mathbf{u}_T^{j+1} \times \mathbf{n}_T - \frac{i}{q}(\overrightarrow{\operatorname{curl}}_\Gamma \operatorname{curl}_\Gamma - \omega^2 I)(\mathbf{u}_{T,\tau}^{j+1}) \\ \qquad = \operatorname{curl} \mathbf{u}_B^{j} \times \mathbf{n}_T - \frac{i}{q}(\overrightarrow{\operatorname{curl}}_\Gamma \operatorname{curl}_\Gamma - \omega^2 I)(\mathbf{u}_{B,\tau}^{j}). \end{cases} \tag{14}$$

As this choice entails the use of different operators in the construction of matching conditions on the two sides of the interface, we refer to it as [illegible].

Again, the best choice of the parameters $p_B = r$ and $p_T = iq$ is the one that gives a minimal convergence rate. Once again, if $|k|^2 = \omega^2$, then $\rho(r, q, |k|) = 1$ for each $r, q \in \mathbb{R}$. However, in this case, owing to (12) and (13), an optimization procedure for the parameters can be performed separately on the two intervals $I_1 = (m, \omega_-)$ and $I_2 = (\omega_+, M)$, where m, M, ω_-, and ω_+ are the ones introduced in the previous section. The min-max problem we are dealing with is thus decoupled and reads

$$\rho_{\mathrm{NS}}^{\mathrm{opt}} = \begin{cases} \min\limits_{q \in \mathbb{R}^+} \max\limits_{|k| \in I_1} \left|\dfrac{-iq+\lambda}{iq+\lambda}\right| & \text{for propagative modes,} \\ \min\limits_{r \in \mathbb{R}^+} \max\limits_{|k| \in I_2} \left|\dfrac{-r+\lambda}{r+\lambda}\right| & \text{for evanescent modes,} \end{cases} \tag{15}$$

which has an elegant analytical solution, given by the following lemma.

LEMMA 2. [illegible] (15) [illegible]

$$\begin{cases} q^{\mathrm{opt}} = \left[(\omega^2 - \omega_-^2)\,(\omega^2 - m^2)\right]^{1/4} & \text{for propagative modes,} \\ r^{\mathrm{opt}} = \left[(\omega_+^2 - \omega^2)\,(M^2 - \omega^2)\right]^{1/4} & \text{for evanescent modes,} \end{cases}$$

[illegible]

$$\rho_{\mathrm{NS}}^{\mathrm{opt}} = \begin{cases} \dfrac{(\omega^2 - \omega_-^2)^{1/4} - (\omega^2 - m^2)^{1/4}}{(\omega^2 - \omega_-^2)^{1/4} + (\omega^2 - m^2)^{1/4}} & \text{for propagative modes,} \\ \dfrac{(M^2 - \omega^2)^{1/4} - (\omega_+^2 - \omega^2)^{1/4}}{(M^2 - \omega^2)^{1/4} + (\omega_+^2 - \omega^2)^{1/4}} & \text{for evanescent modes.} \end{cases} \tag{16}$$

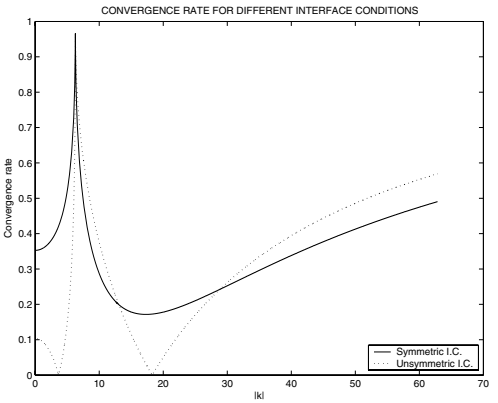

FIG. 1. *Convergence rate (as a function of $|k|$) in Fourier space of the optimized Schwarz algorithm with symmetric (solid line) and unsymmetric (dashed line) interface conditions.*

. We outline the solution for propagative modes, the solution for evanescent ones being similar. With the change of variables

$$x := \sqrt{\omega^2 - |k|^2}$$

we are led to study

$$\min_{q\in\mathbb{R}^+} \max_{x\in I^-} \left|\frac{x-q}{x+q}\right|,$$

where $I^- = (\sqrt{\omega^2-\omega_-^2}, \sqrt{\omega^2-m^2}) = (x_0, x_1)$. Since the function $\varphi(x,q) = \frac{x-q}{x+q}$ is monotone increasing for $x \in I^-$, $\varphi(0,q) = -1$, and $\lim_{x\to\infty}\varphi(x,q) = 1$, the maximum of the modulus is attained on the boundary of the interval. The min-max problem reduces thus to

$$\min_{q\in\mathbb{R}^+} \max \left\{ \left|\frac{x_0-q}{x_0+q}\right|, \left|\frac{x_1-q}{x_1+q}\right| \right\}.$$

We thus have that the optimal parameter for propagative modes belongs to the interval (x_0, x_1) and is given by

$$q^{\text{opt}} = \sqrt{x_0 x_1} = \left[(\omega^2-\omega_-^2)\,(\omega^2-m^2)\right]^{1/4}. \tag{17}$$

For evanescent modes, in a similar way, the change of variable $x := \sqrt{|k|^2-\omega^2}$ reduces to study the min-max problem on $\mathbb{R}^+ \times I^+$, where $I^+ = (\sqrt{\omega_+^2-\omega^2}, \sqrt{M^2-\omega^2})$, whose solution is given by

$$r^{\text{opt}} = \left[(\omega_+^2-\omega^2)\,(M^2-\omega^2)\right]^{1/4}. \tag{18}$$

So far, a simple algebra leads to the expression of the optimal reduction factor (16). □

We report in Figure 1 the convergence rates $\rho(p^{\text{opt}}, |k|)$ and $\rho(r^{\text{opt}}, q^{\text{opt}}, |k|)$ for $\omega = 2\pi$. In the solid line we show the convergence rate as a function of $|k|$ of the

symmetric algorithm for $p = p^{\text{opt}}$, and in the dashed line, the convergence rate of the unsymmetric algorithm for $r = r^{\text{opt}}$ and $q = q^{\text{opt}}$. Notice that in both cases it is less than or equal to one and it is equal to one only for $|k| = \omega$. We recall that the optimization has been done separately for the symmetric and the unsymmetric algorithm.

3. Two-domain decomposition. In the following we consider a bounded domain $\Omega \subset \mathbb{R}^3$ and the boundary value problem

$$\text{(19)} \qquad \begin{cases} \text{curl curl } \mathbf{u} - \omega^2 \mathbf{u} = \mathbf{F} & \text{in } \Omega, \\ \text{curl } \mathbf{u} \times \mathbf{n} + i\omega \mathbf{u}_\tau = \mathbf{0} & \text{on } \Gamma_R, \\ \mathbf{u} \times \mathbf{n} = \mathbf{0} & \text{on } \Gamma_D, \end{cases}$$

where Γ_R and Γ_D are two disjoint open subsets of $\partial\Omega$ such that $\overline{\Gamma_R} \cup \overline{\Gamma_D} = \partial\Omega$.

We decompose the domain Ω in two nonoverlapping subdomains Ω_l, $l = 1, 2$. We set $\Gamma = \overline{\Omega_1} \cap \overline{\Omega_2}$ and for simplicity we assume that $\overline{\Gamma} \cap \overline{\Gamma_R} = \emptyset$. Let us set $\Gamma_{R,l} = \Gamma_R \cap \partial\Omega_l$ and $\Gamma_{D,l} = \Gamma_D \cap \partial\Omega_l$. We denote $\mathbf{n}_l$ the unit normal outward vector on $\partial\Omega_l \cap \Gamma$.

We consider the following iterative procedure:

(20)

$$\begin{cases} \text{curl curl } \mathbf{u}_1^{j+1} - \omega^2 \mathbf{u}_1^{j+1} = \mathbf{F} & \text{in } \Omega_1, \\ \text{curl } \mathbf{u}_1^{j+1} \times \mathbf{n}_1 + i\omega \mathbf{u}_{1,\tau}^{j+1} = \mathbf{0} & \text{on } \Gamma_{R,1}, \\ \mathbf{u}_1^{j+1} \times \mathbf{n}_1 = \mathbf{0} & \text{on } \Gamma_{D,1}, \\ \text{curl } \mathbf{u}_1^{j+1} \times \mathbf{n}_1 + \frac{1}{p_1}(\overrightarrow{\text{curl}}_\Gamma \text{curl}_\Gamma - \omega^2 I)(\mathbf{u}_{1,\tau}^{j+1}) & \\ \qquad = \text{curl } \mathbf{u}_2^j \times \mathbf{n}_1 + \frac{1}{p_1}(\overrightarrow{\text{curl}}_\Gamma \text{curl}_\Gamma - \omega^2 I)(\mathbf{u}_{2,\tau}^j) & \text{on } \Gamma; \end{cases}$$

$$\begin{cases} \text{curl curl } \mathbf{u}_2^{j+1} - \omega^2 \mathbf{u}_2^{j+1} = \mathbf{F} & \text{in } \Omega_2, \\ \text{curl } \mathbf{u}_2^{j+1} \times \mathbf{n}_2 + i\omega \mathbf{u}_{2,\tau}^{j+1} = \mathbf{0} & \text{on } \Gamma_{R,2}, \\ \mathbf{u}_2^{j+1} \times \mathbf{n}_2 = \mathbf{0} & \text{on } \Gamma_{D,2}, \\ \text{curl } \mathbf{u}_2^{j+1} \times \mathbf{n}_2 + \frac{1}{p_2}(\overrightarrow{\text{curl}}_\Gamma \text{curl}_\Gamma - \omega^2 I)(\mathbf{u}_{2,\tau}^{j+1}) & \\ \qquad = \text{curl } \mathbf{u}_1^j \times \mathbf{n}_2 + \frac{1}{p_2}(\overrightarrow{\text{curl}}_\Gamma \text{curl}_\Gamma - \omega^2 I)(\mathbf{u}_{1,\tau}^j) & \text{on } \Gamma; \end{cases}$$

where either $p_1 = p_2 = p^{\text{opt}}$, or $p_1 = r^{\text{opt}}$, and $p_2 = iq^{\text{opt}}$, according to the choice of symmetric or unsymmetric interface conditions.

By introducing the new variables

$$\boldsymbol{\lambda}_1^j := -\text{curl } \mathbf{u}_2^j \times \mathbf{n}_2 + \frac{1}{p_1}(\overrightarrow{\text{curl}}_\Gamma \text{curl}_\Gamma - \omega^2 I)(\mathbf{u}_{2,\tau}^j)$$

and

$$\boldsymbol{\lambda}_2^j := -\text{curl } \mathbf{u}_1^j \times \mathbf{n}_1 + \frac{1}{p_2}(\overrightarrow{\text{curl}}_\Gamma \text{curl}_\Gamma - \omega^2 I)(\mathbf{u}_{1,\tau}^j)$$

the algorithm becomes

$$
\begin{cases}
\operatorname{curl}\operatorname{curl}\mathbf{u}_1^{j+1}-\omega^2\mathbf{u}_1^{j+1}=\mathbf{F} & \text{in } \Omega_1,\\
\operatorname{curl}\mathbf{u}_1^{j+1}\times\mathbf{n}_1+i\omega\mathbf{u}_{1,\tau}^{j+1}=\mathbf{0} & \text{on } \Gamma_{R,1},\\
\mathbf{u}_1^{j+1}\times\mathbf{n}_1=\mathbf{0} & \text{on } \Gamma_{D,1},\\
\operatorname{curl}\mathbf{u}_1^{j+1}\times\mathbf{n}_1+\frac{1}{p_1}(\overrightarrow{\operatorname{curl}}_\Gamma\operatorname{curl}_\Gamma-\omega^2 I)(\mathbf{u}_{1,\tau}^{j+1})=\boldsymbol{\lambda}_1^j & \text{on } \Gamma;
\end{cases}
$$

$$
\begin{cases}
\operatorname{curl}\operatorname{curl}\mathbf{u}_2^{j+1}-\omega^2\mathbf{u}_2^{j+1}=\mathbf{F} & \text{in } \Omega_2,\\
\operatorname{curl}\mathbf{u}_2^{j+1}\times\mathbf{n}_2+i\omega\mathbf{u}_{2,\tau}^{j+1}=\mathbf{0} & \text{on } \Gamma_{R,2},\\
\mathbf{u}_2^{j+1}\times\mathbf{n}_2=\mathbf{0} & \text{on } \Gamma_{D,2},\\
\operatorname{curl}\mathbf{u}_2^{j+1}\times\mathbf{n}_2+\frac{1}{p_2}(\overrightarrow{\operatorname{curl}}_\Gamma\operatorname{curl}_\Gamma-\omega^2 I)(\mathbf{u}_{2,\tau}^{j+1})=\boldsymbol{\lambda}_2^j & \text{on } \Gamma;
\end{cases}
\tag{21}
$$

$$
\boldsymbol{\lambda}_1^{j+1}=-\boldsymbol{\lambda}_2^j+\left(\frac{1}{p_1}+\frac{1}{p_2}\right)(\overrightarrow{\operatorname{curl}}_\Gamma\operatorname{curl}_\Gamma-\omega^2 I)(\mathbf{u}_{2,\tau}^{j+1}),
$$

$$
\boldsymbol{\lambda}_2^{j+1}=-\boldsymbol{\lambda}_1^j+\left(\frac{1}{p_1}+\frac{1}{p_2}\right)(\overrightarrow{\operatorname{curl}}_\Gamma\operatorname{curl}_\Gamma-\omega^2 I)(\mathbf{u}_{1,\tau}^{j+1}).
$$

3.1. Weak formulation. We are interested in the finite elements approximation of the bidomain problem (20), so we will consider its weak formulation. First we need to introduce some functional spaces.

Let Σ be a connected subset of $\partial\Omega$

$$
L^2_{\tan}(\Sigma):=\{\mathbf{v}\in L^2(\Sigma)^3\ :\ \mathbf{v}\cdot\mathbf{n}=0 \text{ on } \Sigma\},
$$

$$
H(\operatorname{curl}_\Gamma;\Sigma):=\{\mathbf{q}\in L^2_{\tan}(\Sigma)\ :\ \operatorname{curl}_\Gamma\mathbf{q}\in L^2_{\tan}(\Sigma)\},
$$

$$
H_0(\operatorname{curl}_\Gamma;\Sigma):=\{\mathbf{q}\in H(\operatorname{curl}_\Gamma;\Sigma)\ :\ \mathbf{q}\cdot\mathbf{t}=0 \text{ on } \partial\Sigma\},
$$

where $\mathbf{t}$ denotes a tangent vector to $\partial\Sigma$.

We consider the spaces

$$
H_{\mathrm{imp}}(\operatorname{curl};\Omega):=\{\mathbf{v}\in H(\operatorname{curl};\Omega)\ :\ \mathbf{v}_\tau\in L^2_{\tan}(\partial\Omega)\},
$$

$$
H_{0,\Sigma}(\operatorname{curl};\Omega):=\{\mathbf{v}\in H(\operatorname{curl};\Omega)\ :\ \mathbf{v}_\tau=0 \text{ on } \Sigma\},
$$

$$
H_{\mathrm{reg},\Sigma}(\operatorname{curl};\Omega):=\{\mathbf{v}\in H_{\mathrm{imp}}(\operatorname{curl};\Omega)\ :\ \mathbf{v}_{\tau|\Sigma}\in H(\operatorname{curl}_\Gamma;\Sigma)\}.
$$

The variational formulation of the boundary value problems will be set in the space

$$
V_l:=H_{0,\Gamma_{D,l}}(\operatorname{curl};\Omega_l)\cap H_{\mathrm{reg},\Gamma_{D,l}\cup\Gamma}(\operatorname{curl};\Omega_l)
$$

with $l=1,2$.

We also need the space

$$
V_l^0:=\{\mathbf{v}\in V_l\ :\ \mathbf{v}_\tau=\mathbf{0} \text{ on } \Gamma\}(=H_{0,\Gamma_{D,l}\cup\Gamma}(\operatorname{curl};\Omega_l)\cap H_{\mathrm{imp}}(\operatorname{curl};\Omega_l))\ .
$$

Notice that from the assumption $\overline{\Gamma}\cap\overline{\Gamma_R}=\emptyset$ it follows that $\partial\Gamma\subset\overline{\Gamma_{D,l}}$, hence for all $\mathbf{v}\in V_l$, $\mathbf{v}_{\tau|\Gamma}\in H_0(\operatorname{curl}_\Gamma;\Gamma)$. Moreover for all $\mathbf{p}\in H_0(\operatorname{curl}_\Gamma;\Gamma)$ there exists $\mathcal{E}_l(\mathbf{p})\in H_{0,\partial\Omega_l\setminus\Gamma}(\operatorname{curl};\Omega_l)$ such that $\mathcal{E}_l(\mathbf{p})_{\tau|\Gamma}=\mathbf{p}$. To give the variational formulation

of (20) we will decompose $\mathbf{v} \in V_l$ in the following way: $\mathbf{v} = \mathbf{v}^0 + \mathcal{E}_l(\mathbf{p})$, where $\mathbf{p} = \mathbf{v}_{\tau|\Gamma} \in H_0(\mathrm{curl}_\Gamma; \Gamma)$ and $\mathbf{v}^0 = \mathbf{v} - \mathcal{E}_l(\mathbf{p}) \in V_l^0$.

Owing to the Green formula,

$$\int_\Sigma \overrightarrow{\mathrm{curl}}_\Gamma \mathrm{curl}_\Gamma \mathbf{q} \cdot \mathbf{p} = \int_\Sigma \mathrm{curl}_\Gamma \mathbf{q}\, \mathrm{curl}_\Gamma \mathbf{p} + \int_{\partial\Sigma} \mathrm{curl}_\Gamma \mathbf{q}\, (\mathbf{p} \cdot \mathbf{t}),$$

we are led to consider the bilinear form in $H(\mathrm{curl}_\Gamma; \Gamma)$,

$$s(\mathbf{p}, \mathbf{q}) := \int_\Gamma (\mathrm{curl}_\Gamma \mathbf{p}\, \mathrm{curl}_\Gamma \overline{\mathbf{q}} - \omega^2 \mathbf{p} \cdot \overline{\mathbf{q}}),$$

the bilinear form in $H_{\mathrm{imp}}(\mathrm{curl}; \Omega_l)$,

$$a_l(\mathbf{w}, \mathbf{v}) := \int_{\Omega_l} (\mathrm{curl}\, \mathbf{w} \cdot \mathrm{curl}\, \overline{\mathbf{v}} - \omega^2 \mathbf{w} \cdot \overline{\mathbf{v}}) + i\omega \int_{\Gamma_{R,l}} \mathbf{w}_\tau \cdot \overline{\mathbf{v}}_\tau,$$

the bilinear form in V_l,

$$r_l(\mathbf{w}, \mathbf{v}) = a_l(\mathbf{w}, \mathbf{v}) + \frac{1}{p_l} s(\mathbf{w}_{\tau|\Gamma}, \mathbf{v}_{\tau|\Gamma}),$$

and the linear form

$$L_l(\mathbf{v}) = \int_{\Omega_l} \mathbf{F} \cdot \mathbf{v}.$$

The weak formulation of (20) reads

$$\begin{cases} \text{Find } \mathbf{u}_1^{j+1} \in V_1 : \\ r_1(\mathbf{u}_1^{j+1}, \mathbf{v}) = L_1(\mathbf{v}) & \forall\, \mathbf{v} \in V_1^0, \\ r_1(\mathbf{u}_1^{j+1}, \mathcal{E}_1\mathbf{q}) = L_1(\mathcal{E}_1\mathbf{q}) + L_2(\mathcal{E}_2\mathbf{q}) - r_2(\mathbf{u}_2^j, \mathcal{E}_2\mathbf{q}) & \\ \qquad\qquad + \left(\dfrac{1}{p_1} + \dfrac{1}{p_2}\right) s(\mathbf{u}_{2,\tau}^j, \mathbf{q}) & \forall\, \mathbf{q} \in H_0(\mathrm{curl}_\Gamma, \Gamma), \end{cases}$$

$$\begin{cases} \text{Find } \mathbf{u}_2^{j+1} \in V_2 : \\ r_2(\mathbf{u}_2^{j+1}, \mathbf{v}) = L_2(\mathbf{v}) & \forall\, \mathbf{v} \in V_2^0, \\ r_2(\mathbf{u}_2^{j+1}, \mathcal{E}_2\mathbf{q}) = L_2(\mathcal{E}_2\mathbf{q}) + L_1(\mathcal{E}_1\mathbf{q}) - r_1(\mathbf{u}_1^j, \mathcal{E}_1\mathbf{q}) & \\ \qquad\qquad + \left(\dfrac{1}{p_1} + \dfrac{1}{p_2}\right) s(\mathbf{u}_{1,\tau}^j, \mathbf{q}) & \forall\, \mathbf{q} \in H_0(\mathrm{curl}_\Gamma, \Gamma). \end{cases}$$

The new variables $\boldsymbol{\lambda}_l^j$ introduced in (21) must be intended in the following sense: $\boldsymbol{\lambda}_l^j \in (H_0(\mathrm{curl}_\Gamma; \Gamma))'$ such that for all $\mathbf{q} \in H_0(\mathrm{curl}_\Gamma; \Gamma)$

$$\begin{aligned} \langle \boldsymbol{\lambda}_l^j, \mathbf{q} \rangle_\Gamma &= -[a_m(\mathbf{u}_m^j, \mathcal{E}_m\mathbf{q}) - L_m(\mathcal{E}_m\mathbf{q})] + \frac{1}{p_l} s(\mathbf{u}_{m,\tau}^j, \mathbf{q}) \\ &= -[r_m(\mathbf{u}_m^j, \mathcal{E}_m\mathbf{q}) - L_m(\mathcal{E}_m\mathbf{q})] + \left(\frac{1}{p_1} + \frac{1}{p_2}\right) s(\mathbf{u}_{m,\tau}^j, \mathbf{q}), \end{aligned}$$

$l = 1, 2$, $m = 1, 2$, $l \neq m$.

Hence the weak formulation of (21) reads

$$\begin{cases} \text{Find } \mathbf{u}_1^{j+1} \in V_1 : \\ r_1(\mathbf{u}_1^{j+1}, \mathbf{v}) = L_1(\mathbf{v}) & \forall\, \mathbf{v} \in V_1^0, \\ r_1(\mathbf{u}_1^{j+1}, \mathcal{E}_1\mathbf{q}) = L_1(\mathcal{E}_1\mathbf{q}) + \langle \boldsymbol{\lambda}_1^j, \mathbf{q}\rangle_\Gamma & \forall\, \mathbf{q} \in H_0(\mathrm{curl}_\Gamma, \Gamma), \end{cases}$$

$$\begin{cases} \text{Find } \mathbf{u}_2^{j+1} \in V_2 : \\ r_2(\mathbf{u}_2^{j+1}, \mathbf{v}) = L_2(\mathbf{v}) & \forall\, \mathbf{v} \in V_2^0, \\ r_2(\mathbf{u}_2^{j+1}, \mathcal{E}_2\mathbf{q}) = L_2(\mathcal{E}_2\mathbf{q}) + \langle \boldsymbol{\lambda}_2^j, \mathbf{q}\rangle_\Gamma & \forall\, \mathbf{q} \in H_0(\mathrm{curl}_\Gamma, \Gamma), \end{cases} \tag{22}$$

$$\langle \boldsymbol{\lambda}_1^{j+1}, \mathbf{q}\rangle_\Gamma = -\langle \boldsymbol{\lambda}_2^j, \mathbf{q}\rangle_\Gamma + \left(\frac{1}{p_1} + \frac{1}{p_2}\right) s(\mathbf{u}_{2,\tau}^{j+1}, \mathbf{q}) \qquad \forall\, \mathbf{q} \in H_0(\mathrm{curl}_\Gamma, \Gamma),$$

$$\langle \boldsymbol{\lambda}_2^{j+1}, \mathbf{q}\rangle_\Gamma = -\langle \boldsymbol{\lambda}_1^j, \mathbf{q}\rangle_\Gamma + \left(\frac{1}{p_1} + \frac{1}{p_2}\right) s(\mathbf{u}_{1,\tau}^{j+1}, \mathbf{q}) \qquad \forall\, \mathbf{q} \in H_0(\mathrm{curl}_\Gamma, \Gamma).$$

3.2. Finite elements discretization. We will employ a curl-conforming finite element approximation of the problem. We can use the first family of Nédélec finite elements in a tetrahedral mesh or in a hexaedral mesh (see [7, 1, 6]). Other possibles choices are the finite element families introduced and analyzed by Nédélec in [8].

Let $\{\mathcal{T}_h\}_{h>0}$ be a regular family of finite element meshes of Ω of elements of maximum diameter h such that each $K \in \mathcal{T}_h$ is contained either in $\overline{\Omega_1}$ or in $\overline{\Omega_2}$. We denote $\mathcal{T}_{l,h}$ the restriction of $\mathcal{T}_h$ to Ω_l, $l = 1, 2$.

Let $\mathbf{P}_k$, $k \geq 1$, be the space of polynomials of degree less than or equal to k, and denote by $\mathbf{P}_k^*$ the space of homogeneous polynomials of degree k. We set

$$\Sigma_k := \{\mathbf{p} \in (\mathbf{P}_k^*)^3 |\ \mathbf{p}(\mathbf{x}) \cdot \mathbf{x} = 0\}, \quad R_k := (\mathbf{P}_{k-1})^3 \oplus \Sigma_k.$$

Notice that $(\mathbf{P}_{k-1})^3 \subset R_k \subset (\mathbf{P}_k)^3$. To discuss finite elements built on hexaedra, we also need the polynomial space

$$Q_{n_1,n_2,n_3} := \{\text{polyomials of maximum degree } n_1 \text{ in } x_1,\ n_2 \text{ in } x_2,\ \text{and } n_3 \text{ in } x_3\}.$$

If $\{\mathcal{T}_h\}_{h>0}$ is a family of tetrahedral meshes, we employ the finite element spaces

$$N_{l,h}^k := \{\mathbf{v}_h \in H(\mathrm{curl}; \Omega_l) \mid \mathbf{v}_{h|K} \in R_k \ \forall\ K \in \mathcal{T}_{l,h}\}.$$

On the other hand, if $\{\mathcal{T}_h\}_{h>0}$ is a family of hexaedral meshes, then the curl-conforming finite element space that we employ is given by

$$N_{l,h}^k := \{\mathbf{v}_h \in H(\mathrm{curl}; \Omega_l) \mid \mathbf{v}_{h|K} \in Q_{k-1,k,k} \times Q_{k,k-1,k} \times Q_{k,k,k-1} \ \forall\ K \in \mathcal{T}_{l,h}\}.$$

Now we consider the spaces

$$X_{l,h} = \{\mathbf{v}_h \in N_{l,h}^k \mid \mathbf{v}_h \times \mathbf{n}_l = \mathbf{0} \text{ in } \Gamma_{D,l}\}.$$

A mesh $\mathcal{T}_{l,h}$ of Ω_l induces a mesh on Γ in the sense that the faces of the elements in $\mathcal{T}_{l,h}$ that lie on Γ obey the usual finite elements meshing constraints. Since we have matching grids in the interface, $\mathcal{T}_{1,h}$ and $\mathcal{T}_{2,h}$ induce the same partition of Γ. Moreover the tangential component of an element of $N_{l,h}^k$ on Γ lies in the appropriate two-dimensional analogue of the set $N_{l,h}^k$. Let us denote Y_h the finite elements space induced on Γ by the tangential components of functions of $X_{l,h}$.

Let $\{\mathbf{w}_i^l\}_{i=1}^{N_l}$ be a basis of $X_{l,h}$ and $\{\mathbf{q}_i\}_{i=1}^{n}$ the corresponding basis of Y_h. For simplicity we assume that these bases are such that $\mathbf{q}_i = \mathbf{w}_{N_l-n+i,\tau}$ for $i = 1, \ldots, n$, $l = 1, 2$. We consider the matrices R_l, $l = 1, 2$, and S with entries

$$(R_l)_{i,j} = r_l(\mathbf{w}_j^l, \mathbf{w}_i^l), \quad 1 \le i, j \le N_l,$$

$$S_{i,j} = s(\mathbf{q}_j, \mathbf{q}_i), \quad 1 \le i, j \le n.$$

Moreover we consider the matrices

$$B_l \in \mathbb{R}^{n \times N_l} \quad B_l = [0 \quad I],$$

where 0 denotes the $n \times (N_l - n)$ matrix with all zero entries and I is the $n \times n$ identity matrix. B_1 and B_2 are the trace operators of domains Ω_1 and Ω_2 on the interface Γ.

Finally let us consider the vectors

$$(\mathbf{f}_l)_j = L_l(\mathbf{w}_j^l), \quad 1 \le j \le N_l.$$

Then, the discrete analogous of algorithm (22) reads as follows.

ALGORITHM 1. [illegible] $\Lambda_l^0 \in \mathbb{C}^n$ [illegible] $j \ge 0$ [illegible]

$$R_l \mathbf{U}_l^{j+1} = \mathbf{f}_l + B_l^T \Lambda_l^j,$$

[illegible] $l = 1, 2$ [illegible]

$$\Lambda_1^{j+1} = -\Lambda_2^j + \left(\frac{1}{p_1} + \frac{1}{p_2}\right) S B_2 \mathbf{U}_2^{j+1},$$

$$\Lambda_2^{j+1} = -\Lambda_1^j + \left(\frac{1}{p_1} + \frac{1}{p_2}\right) S B_1 \mathbf{U}_1^{j+1}.$$

Denoting $\mathbf{g}_l = R_l^{-1} \mathbf{f}_l$ this algorithm can be rewritten as

$$\begin{aligned} \Lambda_1^{j+1} &= -\Lambda_2^j + \left(\frac{1}{p_1} + \frac{1}{p_2}\right) S B_2 (\mathbf{g}_2 + R_2^{-1} B_2^T \Lambda_2^j), \\ \Lambda_2^{j+1} &= -\Lambda_1^j + \left(\frac{1}{p_1} + \frac{1}{p_2}\right) S B_1 (\mathbf{g}_1 + R_1^{-1} B_1^T \Lambda_1^j), \end{aligned} \tag{23}$$

which is a fixed-point iteration to solve the linear system

$$\begin{bmatrix} I & I - \left(\frac{1}{p_1} + \frac{1}{p_2}\right) S B_2 R_2^{-1} B_2^T \\ I - \left(\frac{1}{p_1} + \frac{1}{p_2}\right) S B_1 R_1^{-1} B_1^T & I \end{bmatrix} \begin{bmatrix} \Lambda_1 \\ \Lambda_2 \end{bmatrix} = \left(\frac{1}{p_1} + \frac{1}{p_2}\right) \begin{bmatrix} S B_2 \mathbf{g}_2 \\ S B_1 \mathbf{g}_1 \end{bmatrix}. \tag{24}$$

The linear system (24) can now be solved by a more efficient Krylov subspace method. This corresponds to use the optimized Schwarz method as a preconditioner for the Krylov subspace method.

ALGORITHM 2. [illegible] (24) [illegible]

Notice that when the GMRES method is applied to the linear system (24), each multiplication of the matrix

$$M := \begin{bmatrix} I & I - \left(\frac{1}{p_1} + \frac{1}{p_2}\right) SB_2 R_2^{-1} B_2^T \\ I - \left(\frac{1}{p_1} + \frac{1}{p_2}\right) SB_1 R_1^{-1} B_1^T & I \end{bmatrix}$$

by a vector requires the solution of two local problems of the type $R_l \mathbf{x} = \mathbf{b}$, $l = 1, 2$.

4. Numerical experiments. In this section we validate the interface conditions proposed in the previous sections by means of some numerical tests. For the implementation we have used MATLAB 6.5. We compare the performance of the two type of interface conditions for both Algorithm 1 and 2.

The computational domain throughout this section will be

$$\Omega = [0, 2] \times [0, 1] \times [0, 1],$$

in which we consider the following problem:

$$\begin{cases} \text{curl curl } \mathbf{u} - \omega^2 \mathbf{u} = \mathbf{F} & \text{in } [0,2] \times [0,1] \times [0,1], \\ \mathbf{u} \times \mathbf{n} = \mathbf{0} & \text{on } \{y = 0\},\ \{y = 1\},\ \{z = 0\},\ \{z = 1\}, \\ \text{curl } \mathbf{u} \times \mathbf{n} + i\,\omega \mathbf{u}_\tau = \mathbf{0} & \text{on } \{x = 0\},\ \{x = 2\}\,. \end{cases} \tag{25}$$

We take $\omega = 2\pi$. The function $\mathbf{F}$ is chosen such that the exact solution $\mathbf{u}$ is the gradient of the function $\Psi = x(2-x)y(1-y)z(1-z)e^{i\omega(y+z)/2}$.

We employ curl-conforming linear finite elements in a uniform hexahedral mesh and we perform the computations with the optimized parameters p^{opt}, r^{opt}, and q^{opt} as defined in the previous sections.

4.1. Influence of the mesh size. In this first series of tests we decompose Ω into two equal subdomains, $\Omega_1 = [0, 1] \times [0, 1] \times [0, 1]$ and $\Omega_2 = [1, 2] \times [0, 1] \times [0, 1]$.

In Table 1 we report the number of iterations required to achieve an increment vector (in the case of Algorithm 1) or a residual vector (in the case of Algorithm 2) of norm less than 10^{-8}. We compare the four algorithms for different mesh sizes. In Figure 2 we report the convergence histories of the four algorithms for a fixed mesh size, and in Figure 3 we report the convergence histories of each algorithm with respect to the mesh size.

The most efficient method is the Krylov one with symmetric interface condition. The speed-up of the Krylov accelerations is remarkable for both symmetric and unsymmetric interface conditions (no wonder in that).

TABLE 1
Iteration counts for different algorithms and different mesh sizes. Nonconstant initial data.

h	Iterative S	Iterative NS	Krylov S	Krylov NS
1/8	107	77	15	27
1/12	249	126	17	33
1/16	478	205	19	37
1/20	> 500	305	20	40

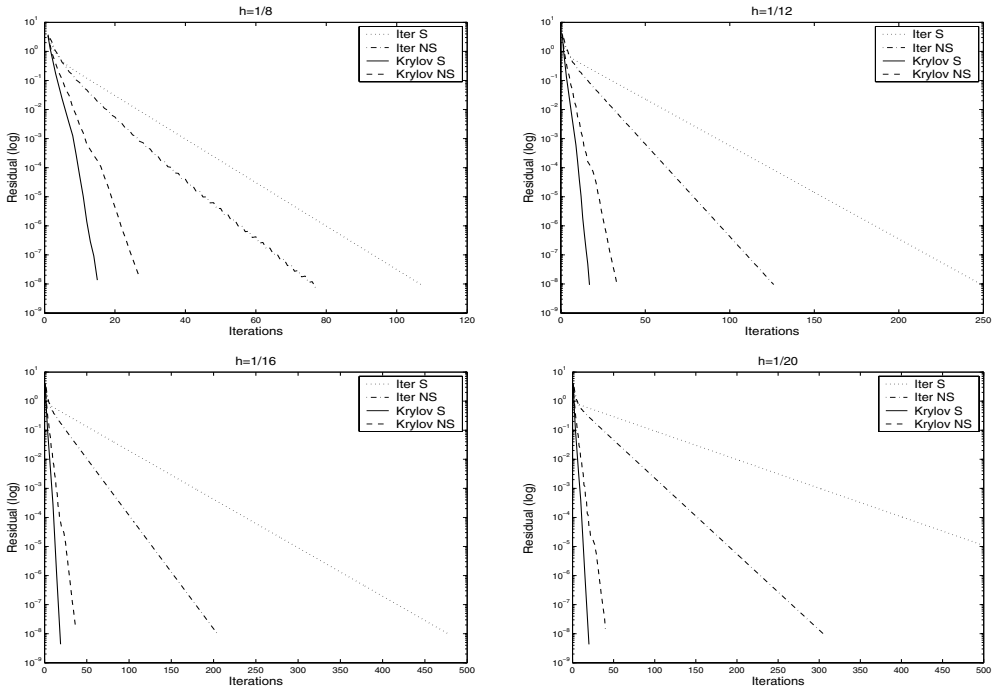

FIG. 2. *Convergence history of the different algorithms for different mesh sizes: from top left* $h = 1/8$, $h = 1/12$, $h = 1/16$, $h = 1/20$.

4.2. Influence of the position of the interface. In the previous tests the two subdomains were symmetric with respect to the interface. In the second series of tests we compare the performance of the four algorithms when the position of the interface changes. We choose $h = 1/12$, and we consider three different positions of the interface, at $x = 1/3$, $x = 2/3$, and $x = 4/3$, yielding the following decompositions:

$$\Omega_1 = [0, 1/3] \times [0, 1]^2, \qquad \Omega_2 = [1/3, 2] \times [0, 1]^2,$$

$$\Omega_1 = [0, 2/3] \times [0, 1]^2, \qquad \Omega_2 = [2/3, 2] \times [0, 1]^2,$$

and

$$\Omega_1 = [0, 4/3] \times [0, 1]^2, \qquad \Omega_2 = [4/3, 2] \times [0, 1]^2.$$

We report in Table 2 the iteration counts for the four algorithms. Only the Krylov algorithm with symmetric interface conditions shows a significative increase in the number of iterations.

5. Other interface conditions used in domain decomposition methods for the harmonic Maxwell system. In this section we give a brief survey of other interface conditions proposed in literature for the harmonic Maxwell system, always in the framework of nonoverlapping domain decomposition methods. We apply to these interface conditions the analysis we made in section 2 and we note that for all of them the iterative procedure (6) fails to converge, in the presence of evanescent modes. We will keep throughout this section the notation used in section 2.

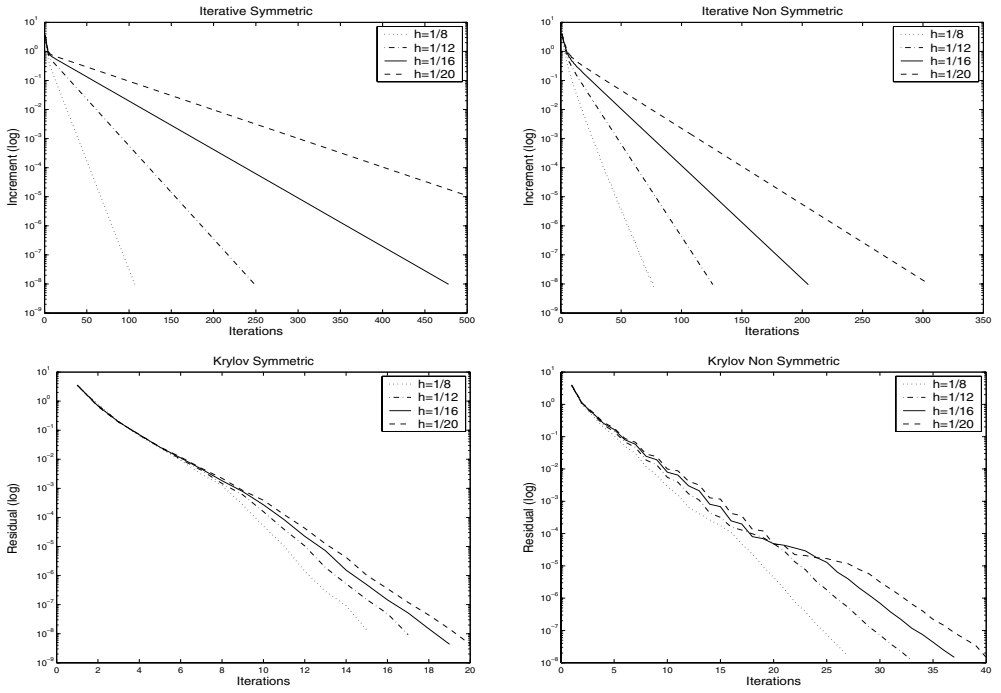

FIG. 3. *Convergence history of the different algorithms with respect to the mesh size: from top left, iterative symmetric, iterative nonsymmetric, Krylov symmetric, Krylov nonsymmetric.*

Despres–Joly–Roberts [4]. The earliest nonoverlapping domain decomposition algorithm for Maxwell system was proposed in [4], where the interface operator is given by

$$S_B = S_T = i\omega I. \tag{26}$$

In [4], the authors, considering a decomposition into an arbitrary number of subdomains and a boundary condition of radiative type at finite distance, show that the proposed algorithm converges weakly in $H(\mathrm{curl}, \Omega_j)$ $(j = 1, \ldots, N)$ to the solution of the single domain problem and that $\mathbf{u}_j^n$ and curl $\mathbf{u}_j^n \times \mathbf{n}$ converge to $\mathbf{u}_j$ and curl $\mathbf{u}_j \times \mathbf{n}$, respectively. The convergence properties of this algorithm depend heavily on the boundary condition, as it allows control of the energy on the outer boundaries by means of the energy on the inner ones.

For the interface operator (26) the Fourier analysis shows that the iterative procedure (6) converges only for propagative modes, while for the evanescent ones the convergence rate is exactly 1.

In fact, in this case we have $M_B = M_T = N^2$, where

$$N = \frac{1}{(\lambda + i\omega)^2} \begin{bmatrix} k_1^2 - k_2^2 & 2k_1k_2 \\ 2k_1k_2 & k_2^2 - k_1^2 \end{bmatrix},$$

and the eigenvalues of N are

$$\mu^{\pm} = \pm \frac{|k|^2}{(\lambda + i\omega)^2}.$$

If $|k|^2 < \omega^2$, then $\lambda = i\sqrt{\omega^2 - |k|^2}$ and

$$|\mu^{\pm}| = \frac{|k|^2}{(\sqrt{\omega^2 - |k|^2} + \omega)^2} < \frac{\omega^2}{(\sqrt{\omega^2 - |k|^2} + \omega)^2} < 1.$$

On the other hand, if $|k|^2 > \omega^2$, then λ is real and

$$|\mu^{\pm}| = \frac{|k|^2}{\lambda^2 + \omega^2} = 1.$$

Thus, the algorithm (4) with the interface conditions proposed in [4] does not converge for evanescent modes. However, the boundary condition (a radiation at finite distance) considered by the authors does not allow evenescent modes to come into the system: thus, the above result is not in contradiction with their work.

Chevalier [2]. To improve the convergence of the algorithm introduced in [4], Chevalier proposed in his thesis [2] the use of the interface operator

$$S_B = S_T = i\omega I + \zeta \overrightarrow{\text{curl}}_\Gamma \text{curl}_\Gamma, \tag{27}$$

$\zeta \in \mathbb{C}$ being a complex parameter to be tuned, which consists in adding to the previous interface conditions a space derivative of second order in the direction tangential to the interface, following what is done in the literature for Helmholtz equations (see, for instance, [2] and [5]).

In [2] there is neither an accurate analysis of the algorithm nor a clear tuning of the parameter ζ, and we show here that, different from the case of the Helmholtz equation, the use of the second order transmission condition does not guarantee convergence for evanescent modes. In fact, we have again $M_B = M_T = N^2$ with

$$\begin{aligned} N &= [R - \omega^2 I + \lambda(\zeta R + i\omega I)]^{-1}[-R + \omega^2 I + \lambda(\zeta R + i\omega I)] \\ &= [(\lambda\zeta + 1)R + (i\lambda\omega - \omega^2)I]^{-1}[(\lambda\zeta - 1)R + (i\lambda\omega + \omega^2)I]. \end{aligned}$$

If $\lambda\zeta \neq \pm 1$,

$$= \frac{\lambda\zeta - 1}{\lambda\zeta + 1} \left[R + \frac{i\lambda\omega - \omega^2}{\lambda\zeta + 1} I\right]^{-1} \left[R + \frac{i\lambda\omega + \omega^2}{\lambda\zeta - 1} I\right].$$

Setting $a = \frac{i\lambda\omega - \omega^2}{\lambda\zeta + 1}$ and $b = \frac{i\lambda\omega + \omega^2}{\lambda\zeta - 1}$,

$$\begin{aligned} N &= \frac{\lambda\zeta - 1}{\lambda\zeta + 1}(R + aI)^{-1}(R + bI) \\ &= \frac{\lambda\zeta - 1}{\lambda\zeta + 1} \frac{1}{a|k|^2 + a^2} \begin{bmatrix} k_1^2 + a & k_1k_2 \\ k_1k_2 & k_2^2 + a \end{bmatrix} \begin{bmatrix} k_2^2 + b & -k_1k_2 \\ -k_1k_2 & k_1^2 + b \end{bmatrix} \\ &= \frac{\lambda\zeta - 1}{\lambda\zeta + 1} \frac{1}{a|k|^2 + a^2} \begin{bmatrix} k_1^2 b + k_2^2 a + ab & -k_1k_2(a - b) \\ -k_1k_2(a - b) & k_1^2 a + k_2^2 b + ab \end{bmatrix}. \end{aligned}$$

The eigenvalues of the matrix

$$\begin{bmatrix} k_1^2 b + k_2^2 a + ab & -k_1 k_2 (a-b) \\ -k_1 k_2 (a-b) & k_1^2 a + k_2^2 b + ab \end{bmatrix}$$

are $\gamma^+ = a(|k|^2 + b)$ and $\gamma^- = b(|k|^2 + a)$; hence the eigenvalues of N are

$$\mu^+ = \frac{\lambda\zeta - 1}{\lambda\zeta + 1} \frac{|k|^2 + b}{|k|^2 + a}, \quad \mu^- = \frac{\lambda\zeta - 1}{\lambda\zeta + 1} \frac{b}{a} = \frac{i\lambda + \omega}{i\lambda - \omega}.$$

It is now easy to observe that when λ is real $|\mu^-| = 1$, and the algorithm does not converge for evanescent modes.

Collino–Delbue–Joly–Piacentini [3]. The Fourier analysis in section 2 (Lemma 1 and Remark 1) shows that the operator linking $\mathbf{n} \times \mathbf{u} \times \mathbf{n}$ to curl $\mathbf{u} \times \mathbf{n}$ is

$$\mathcal{T}(\text{curl } \mathbf{u} \times \mathbf{n}) + (\omega^2 - \overrightarrow{\text{curl}}_\Gamma \text{curl}_\Gamma)\, \mathbf{n} \times \mathbf{u} \times \mathbf{n} = 0, \tag{28}$$

where $\mathcal{T}$ is a pseudodifferential operator corresponding, in the Fourier space, to the multiplication by $\lambda(|k|) = \sqrt{|k|^2 - \omega^2}$: due to its nonlocality, this operator cannot be used in practice.

Another interface condition, based on a zeroth order Taylor expansion of the function $\lambda(|k|)$ in the neighborhood of $|k| = 0$, has then been proposed in [3], where the interface operators are given by

$$S_B = S_T = -i\omega\beta \left(I + \frac{\alpha}{\omega^2} \overrightarrow{\text{curl}}_\Gamma \text{curl}_\Gamma \right). \tag{29}$$

Taking $\alpha = -1$ this interface condition coincides with our symmetric interface conditions for $p = i\frac{\beta}{\omega}$. If $\beta \in \mathbb{R}$, then $\mathcal{R}e\, p = 0$ and we have from section 2.1 that $\rho = 1$ for evanescent modes.

Notice, however, that the authors assume $\sqrt{\omega^2 - |k|^2} \sim \omega$, which amounts to taking into account, at once, only propagative modes, and, among them, only the ones with very small space frequency. Our approach differs a fortiori from this latter one, since we do not impose any restriction on the spatial frequency $|k|^2$.

Numerical experiments. In Figure 4 we compare the convergence history of the iterative procedure with the following interface conditions: optimized symmetric (i.e., (8) with $p_T = p_B$ given by (10)), optimized unsymmetric (i.e., (8) with $p_B = r$ and $p_T = iq$, r given in (17) and q given in (18)), the interface condition (26), and the one introduced by Chevalier (27) with $\zeta = i/2\omega$. We apply them to the model problem (25) and also to a similar one with a radiation condition on the whole boundary

$$\begin{cases} \text{curl curl } \mathbf{u} - \omega^2 \mathbf{u} = \mathbf{F} & \text{in } \Omega = [0,2] \times [0,1] \times [0,1], \\ \text{curl } \mathbf{u} \times \mathbf{n} + i\,\omega \mathbf{u}_\tau = \mathbf{0} & \text{on } \partial\Omega\,. \end{cases} \tag{30}$$

Also in this case the data $\mathbf{F}$ is chosen such that the exact solution is $\mathbf{u} = \nabla[x(2-x)y(1-y)z(1-z)e^{i\omega(y+z)/2}]$.

We plot the norm of the increment for the first 100 iterations since its norm is greater that 10^{-8}. For the model problem (25) the interface conditions (26) and (27) do not converge. (Note that the boundary condition in (25) differs from the one considered in [4].) For the model problem (30) the convergence of the four algorithms

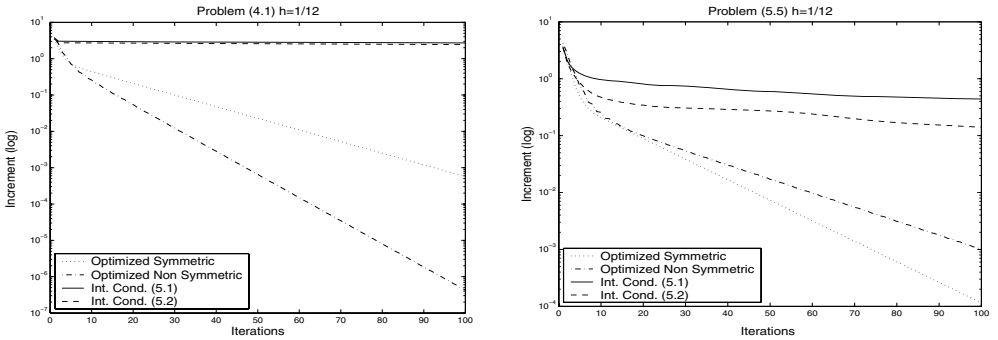

FIG. 4. *Convergence history for different interface conditions. Problem* (25) *(left) and problem* (30) *(right): iterative algorithm.*

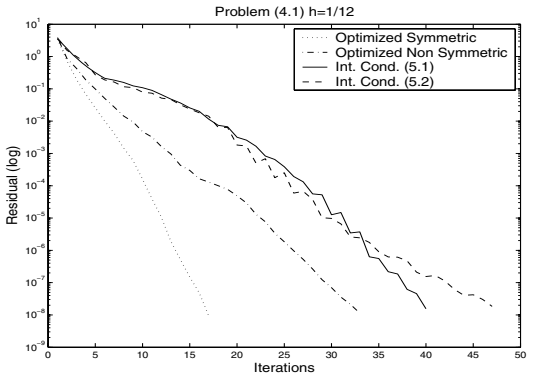

FIG. 5. *Convergence history for different interface conditions, Problem* (25)*: Krylov algorithm.*

is very slow. In this case the fastest one is the one that uses the optimized unsymmetric interface conditions.

Finally, in Figure 5 we compare the convergence histories for the different interface conditions when the Krylov algorithm is applied to problem (25). Notice that neither of the interface conditions (26) and (27) has been previously used in such a framework. All algorithms converge, and the ones with optimized conditions are faster. In this case the fastest one is the one that uses the optimized symmetric interface conditions.

6. Conclusions. We proposed and analyzed two families of second order interface conditions to be used in the framework of nonoverlapping domain decomposition methods for the time-harmonic Maxwell equations. These conditions have been derived by means of a Fourier analysis: the first family depends on a complex parameter, while the second family depends on two real parameters. These parameters have been chosen to optimize the convergence rate of the method. The resulting interface operators have been applied to two different algorithms in the case of a two-domain decomposition: the first algorithm is an iterative procedure of fixed point type and the second one is a Krylov subspace method. The numerical solution of some test problems has been addressed to validate the two algorithms: in both cases we obtained a convergent method. In particular, the Krylov subspace procedure, based on GMRES iterations, appears to be very efficient. Finally, we compared these optimized

interface conditions with other conditions proposed in literature: evidence is that the optimized conditions provide more efficient and robust algorithms.

A CLASS OF EXTENDED LIMITERS APPLIED TO PIECEWISE HYPERBOLIC METHODS*

SUSANA SERNA†

Abstract. Piecewise hyperbolic methods (PHMs) have been widely used for the approximation of hyperbolic conservation laws. In this paper we have studied the "power limiters" in order to analyze their suitable use in the design of PHMs. We formulate a new PHM, based on these limiters, improving the behavior of the PHM in [SIAM J. Sci. Comput., 15 (1994), pp. 892–915], at local extrema, jump discontinuities, and discontinuities in derivative. We show that this new hyperbolic reconstruction (we call it PowerPHM) is local total variation bounded and it behaves stably with a reduced numerical viscosity compared to PHM. We show numerical evidence of the above mentioned features by means of one- and two-dimensional numerical tests with the Euler equations of gas dynamics.

Key words. conservation laws, shock capturing schemes, high order accuracy, piecewise hyperbolic reconstructions, limiters, local total variation bounded

DOI. 10.1137/040611811

1. Introduction.

Our general goal consists in obtaining high order accurate numerical approximations to piecewise smooth real functions of a real variable with a finite number of jump discontinuities to approximate the solution of hyperbolic systems of conservation laws.

Our discussion here will focus on a fixed uniform grid and a fixed degree of local accuracy, trying to minimize the spurious information generated when dealing simultaneously with coarse and fine scales.

A first order approximation to a piecewise smooth function in a fixed grid can be defined as a piecewise constant function, with jump discontinuities located at the cell interfaces [4]. Van Leer considered second order approximations defined as piecewise linear functions, introducing for the first time the minmod limiter function applied on neighboring slopes to avoid the Gibbs phenomena near discontinuities when computing approximate solutions to hyperbolic conservation laws [21, 22, 10]. Total variation diminishing (TVD) schemes were introduced in [6] to get high order accurate nonoscillatory approximations of the solution of hyperbolic conservation laws, but the main drawback of these schemes was the degeneration to first order of accuracy at local extrema [13]. Essentially nonoscillatory (ENO) methods were introduced to get high order accurate reconstruction procedures of order larger than two, avoiding Gibbs phenomena and spurious oscillations, up to local truncation errors [7]. ENO procedures use the smoothest polynomial interpolation by means of choosing the divided differences of smallest size following a tree-like algorithm. The selection procedure of the ENO methods is a limiter function acting on the successive divided differences of the data. One of the important issues of the high order accurate reconstruction procedures is the size of the stencil, i.e., the number of data points needed to perform

the approximation. If the stencil is small the behavior of the procedure is robust when used in evolution problems where discontinuities are either moving or interacting, but the degree of accuracy is limited. By using a limiter function we may design reconstruction procedures with an optimal size of the stencil and good resolution of discontinuities.

The analysis and research of new classes of limiters has been a fruitful research field in investigating how to modify the Lax–Wendroff scheme to get useful, simple, second order in space and time, and one time stepping schemes. Limiters for this purpose have been introduced by van Leer, Roe, and other authors (see [6, 14, 21, 22, 10]). Our idea to explore new classes of limiters has been applied to methods of order larger than two.

In [17] a new class of limiters, the so-called power limiters, were introduced to be applied on neighboring second order differences to define new five point stencil ENO parabolic reconstruction procedures. The resulting third order PowerENO method and its fifth order accurate sequel Weighted PowerENO method showed better capability to resolve discontinuities and local extrema than ENO methods when combined with shock capturing schemes for the approximation of hyperbolic conservation laws.

In [11] a third order accurate piecewise hyperbolic procedure using three data points was proposed as a compact and robust scheme. The piecewise hyperbolic method (PHM) was designed using the harmonic mean as the basic average to limit the gradient of the local reconstruction. The piecewise hyperbolic reconstruction procedure works robustly combined with shock capturing schemes [2, 3, 11, 12, 19], relaxation schemes [1, 15], and moving mesh methods [9]. This good behavior is mainly due to the following:

1. Reduced stencil.
2. Hyperbolas are less oscillatory than parabolas.
3. The use of a limiter based on the harmonic mean.

A well-known drawback of the PHM reconstruction procedure is the loss of total variation at local extrema as a consequence of the strong effect of using the harmonic mean as a slope limiter.

In this research work we analyze the use of power limiters as slope limiters for the design of three point stencil piecewise hyperbolic reconstructions. To this end we need to perform a new analytical study of power limiters to know the qualitative properties required for a power limiter to define correctly a hyperbolic approximation with local variation bounded. As a result of this study we propose a new piecewise hyperbolic reconstruction procedure based on the power limiter that accomplishes the required conditions. The new PowerPHM procedure shares with the PHM the mentioned good properties, prescribes more total variation in cell, and improves the resolution of local extrema, jump discontinuities, and discontinuities in derivative in comparison with the PHM. We have presented a PowerPHM shock capturing scheme to approximate the solution of compressible fluid flow. We show evidence of the robustness and accuracy of our new scheme through a set of numerical experiments that include the evolution and interaction of strong shocks in one and two dimensions.

The paper is organized as follows. In section 2 we introduce the necessary notation and we review the basic facts on piecewise hyperbolic reconstructions. In section 3 we present a new analytical study of the power limiters, establishing the necessary conditions to obtain well-behaved hyperbolic reconstructions. Then we define the local hyperbolic power reconstruction and we show that it is well defined with local total variation bounded (LTVB). In section 4, we present a set of numerical tests showing numerical evidence of the features analyzed in section 3. We draw our conclusions in section 5.

2. Piecewise hyperbolic reconstruction. In this section we briefly review a number of basic constructions and analytical results on PHMs that we use later in section 3 in the development and analysis of our new reconstruction procedure based on power limiters. We analyze how oscillatory a hyperbolic reconstruction is compared to a parabolic one in terms of the local variation in cell.

In order to settle our notation and computational framework, we consider numerical approximations to the scalar initial value problem

$$u_t + f(u)_x = 0, \tag{2.1}$$

$$u(x,t) = u_0(x), \tag{2.2}$$

where u_0 is a periodic or compactly supported piecewise smooth function.

We consider the following computational grid: $x_j = jh$ (h being the spatial step), $t_n = n\Delta t$ is the time discretization (with Δt the time step), and $I_j = [x_{j-\frac{1}{2}}, x_{j+\frac{1}{2}}]$ is the spatial cell, where $x_{j+\frac{1}{2}} = x_j + \frac{h}{2}$ is the cell interface and $C_j^n = [x_{j-\frac{1}{2}}, x_{j+\frac{1}{2}}] \times [t_n, t_{n+1}]$ is the computational cell. Let u_j^n be an approximation of the mean value in I_j, $\frac{1}{h}\int_{x_{j-\frac{1}{2}}}^{x_{j+\frac{1}{2}}} u(x,t_n)dx$, of the exact solution $u(x,t_n)$ of the initial value problem (2.1) and (2.2), obtained from a finite volume scheme in conservation form:

$$u_j^{n+1} = u_j^n - \frac{\Delta t}{h}(\tilde{f}_{j+\frac{1}{2}} - \tilde{f}_{j-\frac{1}{2}}), \tag{2.3}$$

where the numerical flux, $\tilde{f}$, is a function of $k+l$ variables

$$\tilde{f}_{j+\frac{1}{2}} = \tilde{f}(u_{j-k+1}^n, \ldots, u_{j+l}^n), \tag{2.4}$$

which is consistent with the flux of (2.1),

$$\tilde{f}(u, \ldots, u) = f(u). \tag{2.5}$$

We will use the above basic framework to apply high order accurate reconstruction procedures in numerical tests. We want to find numerical approximations of a piecewise smooth function $g(x)$ from its cell averages, given for the cells of the above defined uniform grid of stepsize $h > 0$, $x_j = jh$,

$$v_j = \frac{1}{h}\int_{x_{j-\frac{1}{2}}}^{x_{j+\frac{1}{2}}} g(x,t_n)dx. \tag{2.6}$$

The specific uniform grid considered is the scale of computation chosen for our approximation. The idea is to capture subscales of the original chosen scale by means of a piecewise smooth function, R, such that the restriction to each computational cell, $[x_{j-\frac{1}{2}}, x_{j+\frac{1}{2}}]$, is a suitable elementary function, R_j, such that

$$v_j = \frac{1}{h}\int_{x_{j-\frac{1}{2}}}^{x_{j+\frac{1}{2}}} R_j(x,t_n)dx \tag{2.7}$$

and it approximates g up to a degree of accuracy.

We are going to analyze the behavior of R in terms of h, when h tends to zero. This behavior might be undesirable around jump discontinuities of g since the function R may develop either Gibbs phenomena or Runge oscillatory patterns. On the other hand, the order of accuracy may degenerate through smooth regions of g due to the presence of the above singularities. The mentioned computational problems are always present when using the described framework to approximate the solution of hyperbolic conservation laws, since those evolution equations may develop discontinuities (shocks) in finite time.

We focus on third order accurate piecewise smooth functions, R, such that each R_j is determined from condition (2.7) and two more conditions, usually obtained from divided differences of v_j. We denote

$$d_{j+\frac{1}{2}} = \frac{v_{j+1} - v_j}{h}, \tag{2.8}$$

$$d_j = \frac{d_{j+\frac{1}{2}} + d_{j-\frac{1}{2}}}{2}, \tag{2.9}$$

$$D_j = d_{j+\frac{1}{2}} - d_{j-\frac{1}{2}}, \tag{2.10}$$

$$\alpha_j = \frac{D_j}{2d_j}. \tag{2.11}$$

If we know the first derivatives of g at the cell interfaces, i.e., $g'(x_{j+\frac{1}{2}})$, we can use the following two interpolating conditions to ensure third order accuracy in smooth regions:

$$R'_j\left(x_j - \frac{h}{2}\right) = g'(x_{j-\frac{1}{2}}), \tag{2.12}$$

$$R'_j\left(x_j + \frac{h}{2}\right) = g'(x_{j+\frac{1}{2}}). \tag{2.13}$$

We use the first order divided differences $d_{j-\frac{1}{2}}$ and $d_{j+\frac{1}{2}}$ instead of $g'(x_{j-\frac{1}{2}})$ and $g'(x_{j+\frac{1}{2}})$, respectively, if the last values are not available. If we consider a local parabola of the form

$$p_j(x) = a_j + b_j(x - x_j) + \frac{c_j}{2}(x - x_j)^2, \tag{2.14}$$

there is a unique parabola such that conditions (2.7), (2.12), and (2.13) are satisfied; that is, a_j, b_j, and c_j are uniquely defined. Following [11], if we consider hyperbolas of the form

$$r_j = e_j + \frac{\lambda_j}{(x - x_j) + f_j}, \tag{2.15}$$

we can compute a unique hyperbola satisfying (2.7), (2.12), and (2.13) (λ_j, e_j and f_j are uniquely defined), assuming that $g'(x_{j-\frac{1}{2}}) \cdot g'(x_{j+\frac{1}{2}}) > 0$, since hyperbolas are monotone functions.

We want to study how oscillatory the approximation R of the function $g(x)$ is in terms of h. To the best of our knowledge, the total variation of R in each cell is a measure of how oscillatory our approximation is [6]. In order to get a coarse comparison between the parabolic and the hyperbolic reconstructions we may assume for the sake of simplicity the following notation. We consider the cell for $j = 0$, $[x_{-\frac{1}{2}}, x_{\frac{1}{2}}]$, and we use $d_l := d_{-\frac{1}{2}}$ and $d_r := d_{\frac{1}{2}}$.

If $d_l \cdot d_r > 0$, the total variation of the parabola p_0 (assuming p_0 is monotone) is

$$TV(p_0) = h\frac{|d_l| + |d_r|}{2} \tag{2.16}$$

and the total variation of the hyperbola r_0 is (see [11])

$$TV(r_0) = h\sqrt{|d_l| \cdot |d_r|}. \tag{2.17}$$

From the arithmetic-geometric inequality we conclude that the parabolic reconstruction prescribes more total variation than the hyperbolic one. Let us remark that formulas (2.16) and (2.17) are the product of h times an average of two positive numbers. If g is smooth on a region containing our computational cell $[-\frac{h}{2}, \frac{h}{2}]$, then d_l and d_r are bounded and therefore, $TV(p_0) = O(h)$ and $TV(r_0) = O(h)$. Thus, p_0 and r_0 are smooth enough to be nonoscillatory and those quantities tend to zero with h.

On the other hand, if g has a jump discontinuity at $x_0 = 0$, either d_l or d_r is $O(\frac{1}{h})$, and

$$TV(p_0) = O(1) \tag{2.18}$$

and

$$TV(r_0) = O\big(\sqrt{h}\big). \tag{2.19}$$

Thus, in the presence of discontinuities, hyperbolas are much less oscillatory than parabolas. One way to make a piecewise smooth approximation less oscillatory is by using slope limiters to preprocess first order derivatives in a way that the order of accuracy does not degenerate.

We can assert that hyperbolas have a natural mechanism to limit the gradient by means of an average. In fact, the first derivative of r_0 at $x_0 = 0$ is, from [11],

$$r_0'(x_0) = \operatorname{sgn}(d_l)\left(\frac{2\sqrt{|d_l|}\sqrt{|d_r|}}{\sqrt{|d_l|} + \sqrt{|d_r|}}\right)^2, \tag{2.20}$$

which is much smaller in size than the one of the parabola,

$$p_0'(x_0) = \operatorname{sgn}(d_l)\frac{|d_l| + |d_r|}{2}, \tag{2.21}$$

assuming $d_l \cdot d_r > 0$, (see Hardy, Littlewood, and Polya [5]).

Applying Marquina [11, p. 899] we can write any hyperbola $r_0(x)$ in terms of any d_0 and α (for $-2 < \alpha < 2$), and satisfying the conservation property (2.7) and $r_0'(x_0) = d_0$, in the form

$$r_0(x) = v_0 + d_0 h \frac{1}{\alpha^2}\left[\log\left(\frac{2-\alpha}{2+\alpha}\right) - \frac{\alpha h}{\alpha(x-x_0)-h}\right]. \tag{2.22}$$

An appropriate choice of d_0 and α gives a hyperbola that interpolates one of the lateral derivatives.

Two cases are relevant for this purpose:

(a) If $d_0 \cdot d_l > 0$ then $\alpha = 2(\sqrt{\frac{d_0}{d_l}} - 1)$ if and only if $d_l = r'(x_0 - \frac{h}{2})$.

(b) If $d_0 \cdot d_r > 0$ then $\alpha = 2(1 - \sqrt{\frac{d_0}{d_r}})$ if and only if $d_r = r'(x_0 + \frac{h}{2})$.

Another important issue for piecewise hyperbolic reconstructions is to control the total variation growth. The LTVB condition was introduced in [11] for this purpose.

DEFINITION 2.1. [illegible] R [illegible] $M > 0$ [illegible] h [illegible] j

$$TV(R_j) \le Mh. \tag{2.23}$$

To ensure that a hyperbolic reconstruction is LTVB, it is sufficient to restrict the range of values of α to an interval $[-K, K]$ such that $0 < K < 2$.

Marquina in [11] proposed an appropriate choice of d_0 to accomplish the above property. Indeed, the local hyperbolic harmonic reconstruction (LHHR) designed in [11] prescribes, in each computational cell, a hyperbola r_j that satisfies (2.7), interpolates the lateral derivative with the smallest absolute value, and assigns, as the central derivative (d_0), the harmonic mean of both lateral derivatives instead of (2.20). In this case, the range of values for α, independent of h, is confined to

$$-2(\sqrt{2}-1) < \alpha < 2(\sqrt{2}-1). \tag{2.24}$$

This inequality is essential to prove that the LHHR is LTVB [11].

The main drawback of the LHHR is the loss of accuracy at local extrema and, as a consequence, the loss of total variation at those points.

One way to increase locally the total variation of the reconstruction is to consider another choice of d_0 allowing a wider range of α values than the one prescribed by the d_0 of the LHHR in (2.24).

Next, we are going to analyze a class of slope limiters suitable for hyperbolic reconstructions that improves the behavior of the LHHR and satisfies the LTVB condition.

3. Power limiters and piecewise hyperbolic power reconstruction. In this section we present the main analytical results of our paper. After reviewing the definition and basic properties of the power limiters we examine the qualitative properties of the "power means" related to the classical means, appearing in hyperbolic reconstructions to design well-behaved PHM based on power limiters. Then, we introduce the PowerPHM reconstruction procedure showing that it is well defined and it is LTVB.

A limiter might be considered as a function of two or more variables based on an average of nonnegative numbers. As was pointed out in [17], we can define the most usual limiters in terms of classical averages.

The minmod, ENO, and harmonic limiters are based on classical means between two nonnegative numbers. In fact, if x and y are real numbers,

$$\text{minmod}(x,y) = \frac{(\text{sgn}(x)+\text{sgn}(y))}{2}\ \min(|x|,|y|), \tag{3.1}$$

$$\text{mineno}(x,y) = \text{minsign}(x,y)\ \min(|x|,|y|), \tag{3.2}$$

$$\text{harmod}(x,y) = \frac{(\text{sgn}(x)+\text{sgn}(y))}{2}\ \frac{2|x||y|}{|x|+|y|}, \tag{3.3}$$

$$\text{hareno}(x,y) = \text{minsign}(x,y)\ \frac{2|x||y|}{|x|+|y|}, \tag{3.4}$$

where $\text{sgn}(x)$ is the sign function, and

$$\text{minsign}(x,y) = \begin{cases} \text{sgn}(x), & |x| <= |y|, \\ \text{sgn}(y) & \text{otherwise.} \end{cases}$$

In [17], an extended class of limiters was introduced in order to design improved ENO reconstructions, including as particular cases the above mentioned limiters. The $\text{power}_p(x,y)$ mean for $x>0$, $y>0$, and p a positive integer is defined in [17] as

$$\text{power}_p(x,y) = \frac{(x+y)}{2}\ \left(1-\left|\frac{x-y}{x+y}\right|^p\right). \tag{3.5}$$

The corresponding limiters are defined for any x and y as

$$\text{powermod}_p(x,y) = \frac{(\text{sgn}(x)+\text{sgn}(y))}{2}\,\text{power}_p(|x|,|y|), \tag{3.6}$$

$$\text{powereno}_p(x,y) = \text{minsign}(x,y)\,\text{power}_p(|x|,|y|). \tag{3.7}$$

The following inequalities are satisfied for any $x>0$ and $y>0$:

$$\min(x,y) \le \text{power}_p(x,y) \le \text{power}_q(x,y) \le \frac{x+y}{2}$$

for $0<p<q$, and

$$\text{power}_1(x,y) = \min(x,y), \tag{3.8}$$

$$\text{power}_2(x,y) = \frac{2xy}{x+y}. \tag{3.9}$$

The power_3 mean can be written in terms of the min and max functions for $x\ge 0$ and $y\ge 0$, not simultaneously zero [17]:

$$\text{power}_3(x,y) = \min(x,y)\frac{x^2+y^2+2(\max(x,y))^2}{(x+y)^2}. \tag{3.10}$$

Our goal is to improve the resulting effect of applying the harmonic mean on lateral derivatives in the LHHR relaxing this limiting effect by using power_3 mean instead and, likewise, ensuring the existence of a positive number β satisfying $-2\beta \leq \alpha \leq 2\beta$ and $\sqrt{2}-1 < \beta < 1$, thus allowing more local variation in the cell.

To this end we have to compare the power_3 mean with the harmonic one and the natural mean for the hyperbola (2.20).

We use the following notation to settle the next propositions. If $x > 0$ and $y > 0$ then $\mathcal{M}(x,y) = \min(x,y)$, $\mathcal{A}(x,y) = \frac{x+y}{2}$, $\mathcal{G}(x,y) = \sqrt{xy}$, $\mathcal{H}(x,y) = \frac{2xy}{x+y}$, and $\mathcal{H}_4 = (\frac{2\sqrt{x}\sqrt{y}}{\sqrt{x}+\sqrt{y}})^2$. Let us remark that $\mathcal{H}_4$ appears in the expression (2.20) as the natural derivative of the hyperbola at the center.

In order to be more concise we will skip the dependence on x and y. We denote $\mathcal{P}_j = \text{power}_j(x,y)$.

Let us compare these averages.

PROPOSITION 3.1.

. . $x \geq 0$. , $y \geq 0$ . . . . $r = \frac{\mathcal{G}}{\mathcal{A}}$. , $R = |\frac{x-y}{x+y}|$ . . .

1. $R^2 + r^2 = 1$
2. $\mathcal{H} = \mathcal{A}(1-R^2)$
3. $\mathcal{H}_4 = \mathcal{H}(1+R^2\frac{1}{(1+r)^2})$
4. $\mathcal{P}_3 = \mathcal{H}(1+R^2\frac{1}{1+R})$
5. $\mathcal{P}_4 = \mathcal{H}(1+R^2)$
6. $\mathcal{H} \leq \mathcal{P}_3 \leq \mathcal{P}_4$
7. $\mathcal{H} \leq \mathcal{H}_4 \leq \mathcal{P}_4$

. . . . The proof is straightforward. □

PROPOSITION 3.2. . . . . $\mathcal{P}_3$. , $\mathcal{H}_4$ . . . .

Since $\mathcal{R}_3$ is a strictly decreasing function of λ in $[0,1]$ and $\mathcal{R}_3(0) = 3$, we have that $\mathcal{R}_3 \leq 3$. □

Following [17], we define $\text{powereno}(x,y) = \text{powereno}_3(x,y)$. We use this limiter for the design of the local hyperbolic power reconstruction.

The following algorithm defines a hyperbola in terms of d_0 and α according to (2.22).

LOCAL HYPERBOLIC POWER RECONSTRUCTION (LHPR) METHOD

Let define $tol = h^2$,

if $(|d_l| \leq tol)$ and $(|d_r| \leq tol)$ **then**

$d_0 = 0$ and $\alpha = 0$

else

$d_0 = \text{powereno}(d_l, d_r) = \text{minsign}(dl, dr)\min(|dl|, |dr|)\frac{dl^2+dr^2+2(\max(|dl|,|dr|))^2}{(|dl|+|dr|)^2}$

if $|d_l| \leq |d_r|$ **then**

$ratio = \frac{d_l^2+3d_r^2}{(|d_l|+|d_r|)^2}$ $(= \mathcal{R}_3)$

$\alpha = 2(\sqrt{ratio} - 1)$

else

$ratio = \frac{3d_l^2+d_r^2}{(|d_l|+|d_r|)^2}$ $(= \mathcal{R}_3)$

$\alpha = 2(1 - \sqrt{ratio})$

end

end

The following lemma shows that this algorithm gives a well-defined hyperbola.

LEMMA 3.4. [illegible] α [illegible]

$$-2(\sqrt{3} - 1) < \alpha < 2(\sqrt{3} - 1). \tag{3.12}$$

[illegible]. The proof follows easily from Lemma 3.3. □

Thus, we get the LTVB property for the LHPR method.

THEOREM 3.5. [illegible]

[illegible]. We can find a constant $M > 0$ such that for all j except for a finite number of isolated j's for which $d_{j+\frac{1}{2}} = O(\frac{1}{h})$, $|d_{j+\frac{1}{2}}| \leq M$.

If $|d_{j-\frac{1}{2}}| \leq |d_{j+\frac{1}{2}}|$, $d_{l_j} = d_{j-\frac{1}{2}}$ and

$$d_{r_j} = d_{j-\frac{1}{2}}\Big(\frac{2}{2-\alpha}\Big)^2. \tag{3.13}$$

Due to Lemma 3.4, we have that

$$TV(r_j) \leq (2 + \sqrt{3}) \cdot M \cdot h. \qquad \square$$

To illustrate our study we present in Figure 3.1 the harmonic piecewise hyperbolic, the power piecewise hyperbolic, and PowerENO parabolic [17] static reconstructions computed from a set of discrete data points representing the cell averages of some function containing a kink, a local extremum, and a jump discontinuity. Cell average values are represented by horizontal lines covering each computational cell. The dotted line represents PHM, the dash-dotted line the PowerPHM, and the solid line the PowerENO in each computational cell, respectively.

We observe that the local power hyperbolic reconstruction assigns hyperbolas with larger gradient than the ones for the PHM reconstruction.

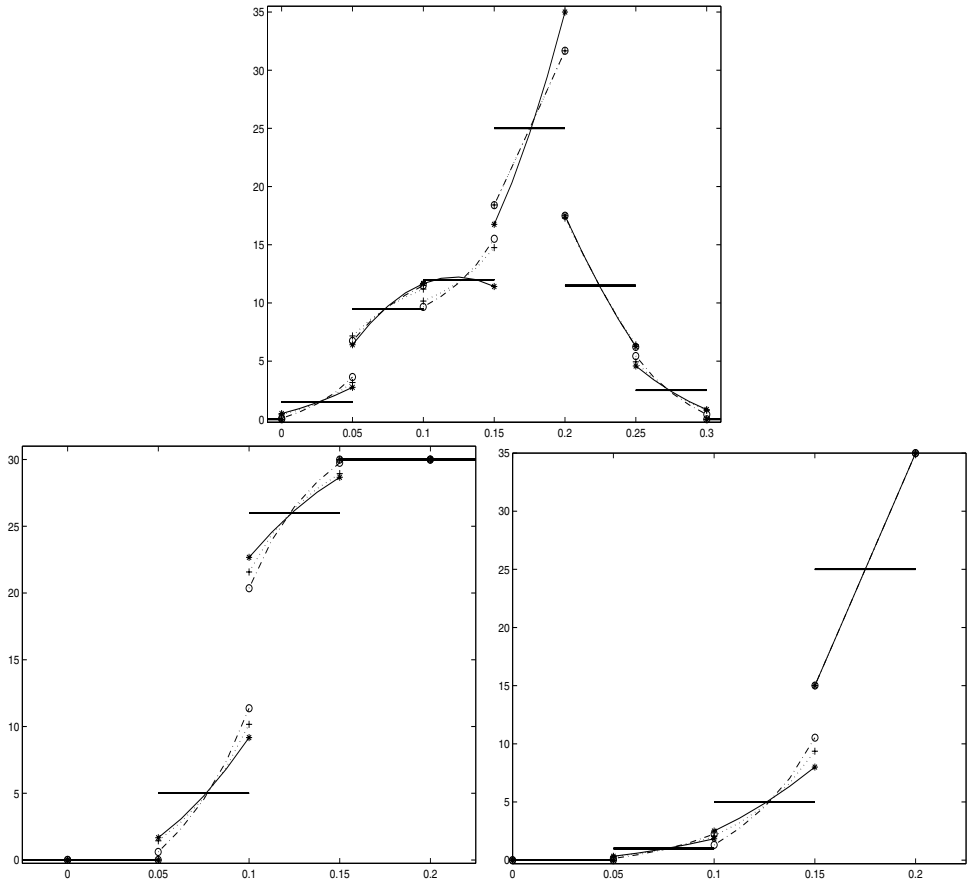

FIG. 3.1. *Piecewise smooth reconstructions: Local extrema (top), jump discontinuity (bottom left), discontinuity in derivative (bottom right). PHM, dotted line; PowerPHM, dash-dotted line; and PowerENO, solid line.*

4. Numerical experiments. The procedure to design a PowerPHM scheme for scalar hyperbolic conservation laws reads as follows. We start with an approximate Riemann solver that computes the numerical flux (in an explicit way) at every interface from neighboring cell averages, following Godunov's idea to get a spatial discretization in conservation form. In order to get high order accuracy in space we use the so-called *flux formulation* by Shu and Osher [20], based on the following simple lemma.

LEMMA 4.1. [illegible] $g(x)$ [illegible]

$$f(u(x)) = \frac{1}{h}\int_{x-\frac{h}{2}}^{x+\frac{h}{2}} g(\psi)d\psi, \tag{4.1}$$

[illegible]

$$f(u(x))_x = \frac{g(x+\frac{h}{2}) - g(x-\frac{h}{2})}{h}. \tag{4.2}$$

This lemma implies that for approximating the numerical flux $f_{j+\frac{1}{2}}$ with a high order of accuracy, it is enough to reconstruct $g_{j+\frac{1}{2}}$ up to the same order of accuracy.

TABLE 4.1
Errors and numerical orders of $u_t + u_x = 0$, $u_0(x) = \frac{1}{2}\left(\frac{1}{2} + \sin(2\pi x)\right)$, $0 \le x \le 1$ *at* $t = 1$.

	N	L_∞-error	L_∞ order	L_1-error	L_1 order
PHM	20	7.11E-02	-	2.98E-02	-
	40	2.56E-02	1.47	7.97E-03	1.90
	80	9.01E-03	1.51	1.80E-03	2.15
	160	2.96E-03	1.61	5.45E-04	1.72
PowerPHM	20	5.35E-02	-	1.92E-02	-
	40	1.63E-02	1.72	3.65E-03	2.40
	80	4.73E-03	1.78	9.56E-04	1.93
	160	1.25E-03	1.93	1.82E-04	2.39

In our case, we use our piecewise hyperbolic power reconstruction procedure to approximate $g_{j+\frac{1}{2}}$ up to third order of accuracy. We also use the third order accurate TVD Runge–Kutta method to evolve in time, introduced in [20], in order to be consistent with the spatial accuracy. The resulting scheme is a convex combination of three Euler explicit time-stepping schemes in conservation form. We call this scheme PowerPHM. This Euler explicit time-stepping procedure is total variation stable under a suitable CFL restriction $\lambda = \frac{\Delta t}{h} \le \lambda_0$, where λ_0 is inversely proportional to $\max|f'(u)|$ as usual.

4.1. Accuracy test. To study the accuracy of our method, we consider the scalar linear equation $u_t + u_x = 0$ with $u(x,0) = u_0(x)$ periodic in $0 \le x \le 1$,

$$u_0(x) = \frac{1}{2}\left(\frac{1}{2} + \sin(2\pi x)\right).$$

We have computed the solution at $t = 1$ with CFL $= 0.8$ and the mesh refinement sequence $N = 20, 40, 80, 160$ grid points for the PHM and the PowerPHM, respectively. We show in Table 4.1 the corresponding L_∞- and L_1-errors that compare with the exact solution. We observe smaller L_∞- and L_1-errors for the PowerPHM due to its better resolution of local extrema. The new method shows improved numerical orders of accuracy compared with the $O(h^{\frac{3}{2}})$ global accuracy of the PHM procedure.

4.2. Linear advection. For the linear advection test, PowerPHM has been based on Godunov's first order sheme for scalar conservation laws. We use the label PowerPHM-GOD to refer to this scheme.

We solve the linear equation $u_t + u_x = 0$ for two periodic initial data defined in $0 \le x \le 1$:

$$u_0(x) = \begin{cases} 1, & 0.25 \le x \le 0.75, \\ 0 & \text{otherwise} \end{cases} \quad \text{and} \quad u_1(x) = \begin{cases} \sin\left(\pi \frac{x-0.2}{0.6}\right), & 0.2 \le x \le 0.8, \\ 0 & \text{otherwise.} \end{cases}$$

We compute the approximate solution for PHM and PowerPHM using a grid of 100 points with a CFL factor of 0.8. We display in Figure 4.1 two output times that correspond to 10 and 200 periods of both signals. We observe a very dissipative behavior of both methods at large times.

We observe that PowerPHM smears jump discontinuities less and better resolves local extrema and discontinuities in the first derivative than PHM.

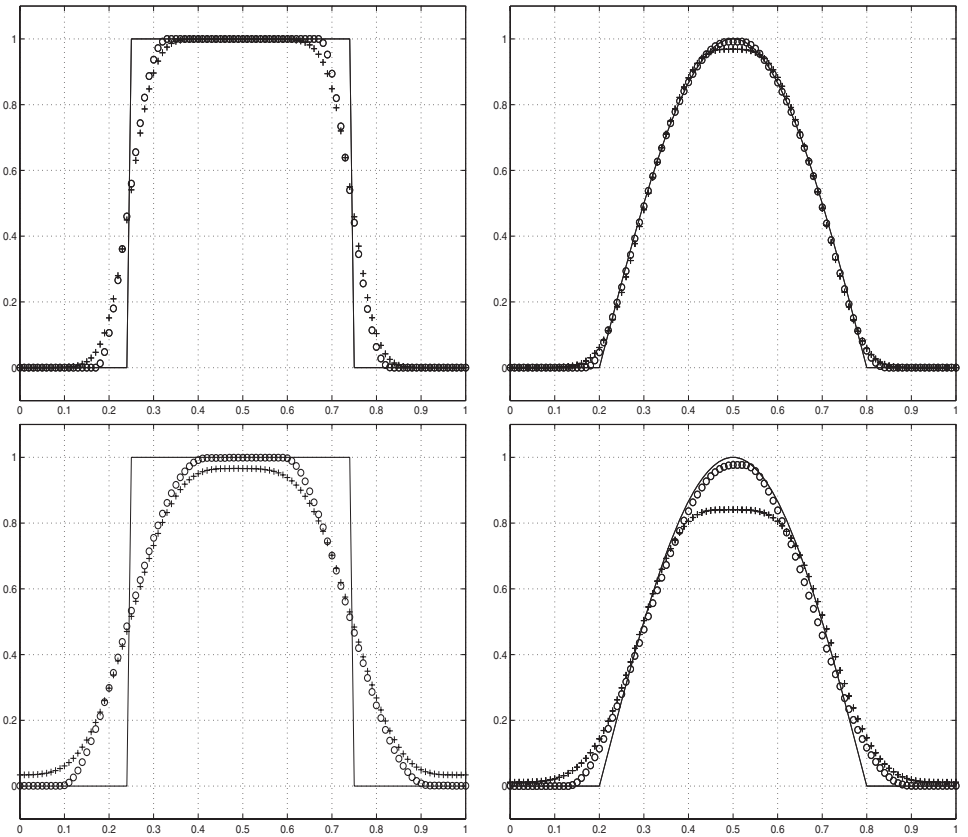

FIG. 4.1. *Numerical solution of linear advection with* 100 *grid points, CFL*=0.8 *until time* 10 *(top) and time* 200 *(bottom), for PHM-GOD scheme "+" and PowerPHM-GOD schemes "o."*

4.3. Euler equations. We consider the one-dimensional Euler equations of gas dynamics

$$\begin{aligned} \rho_t + (\rho u)_x &= 0, \\ (\rho u)_t + \left(P + \frac{(\rho u)^2}{\rho} \right)_x &= 0, \\ E_t + (u(E+P))_x &= 0, \end{aligned}$$

where ρ is the density, u is the velocity, P is the pressure, and $E = \frac{1}{2}\rho u^2 + \rho\epsilon$ is the total energy, ϵ being the specific internal energy per unit volume. We compute the pressure by means of the ideal gas equation of state $P = (\gamma - 1)\rho\epsilon$, where γ is the adiabatic exponent. We use $\gamma = 1.4$ in our experiments. We consider initial value problems by means of an initial profile of the density, velocity, and pressure defined through the domain.

We have chosen three significant test problems of compressible gas dynamics where strong dynamics are present. In order to get a more complete picture of the behavior of the new scheme we compare the results with the PHM scheme and the fifth order parabolic Weighted PowerENO method.

The PHM, PowerPHM, and Weighted PowerENO schemes we have implemented for systems of conservation laws are based on the first order Marquina's flux formula

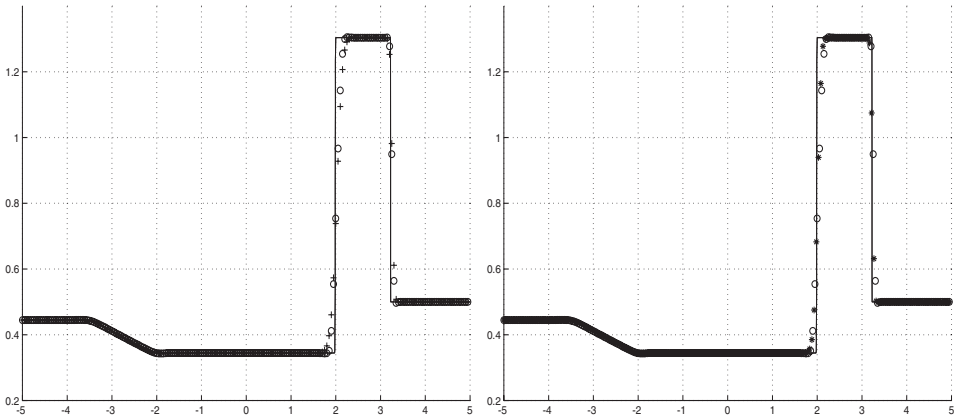

FIG. 4.2. *Numerical solution of the density profile for the Lax shock tube problem at* $t = 1.3$*,* $CFL = 0.8$*, 200 points. Left: The PHM-MFF scheme "+" and PowerPHM-MFF scheme "o." Right: PowerPHM-MFF scheme "o" and Weighted PowerENO "*."*

(MFF) [2], applying the corresponding reconstruction procedure to the local characteristic fluxes and variables, and using the third order accurate TVD Runge–Kutta method for the evolution in time.

We use the labels PHM-MFF, PowerPHM-MFF, and Weighted PowerENO-MFF to refer to these schemes.

4.3.1. Lax shock tube problem. We consider the following Riemann problem due to Lax [8]:

$$u_0(x) = \begin{cases} (0.445, 0.698, 3.528) & -5 \le x < 0, \\ (0.5, 0, 0.571) & 0 \le x \le 5. \end{cases}$$

We have displayed in Figures 4.2 and 4.3 the density profile of the Lax shock tube problem at time $t = 1.3$ and its zoomed regions, respectively. We obtain correct position and speed of discontinuities. We can observe a slight reduction in the smearing of the contact wave for our PowerPHM in comparison with PHM. Comparable results of PowerPHM with the Weighted PowerENO method are displayed. The interesting feature of our PowerPHM is the "sharpening" of jump discontinuities with the same order of spatial accuracy as the classical PHM.

4.3.2. Shock entropy wave interaction. We consider the one-dimensional wave interaction introduced in [20] for testing stability and accuracy of high order methods. The initial data are

$$u_0(x) = \begin{cases} (3.85714, 2.62936, 10.33333) & -5 \le x < -4, \\ (1 + 0.2\sin(5x), 0, 1) & -4 \le x \le 5. \end{cases}$$

We use a uniform grid with 400 points and we evolve until time 1.8, using PHM-MFF, PowerPHM-MFF, and Weighted PowerENO-MFF. We display in Figure 4.4 the zoomed area of the perturbed region behind the shock wave where we observe an improved resolution of our PowerPHM scheme compared with PHM.

The fifth order Weighted PowerENO method better resolves the smooth fine structure developed in this test.

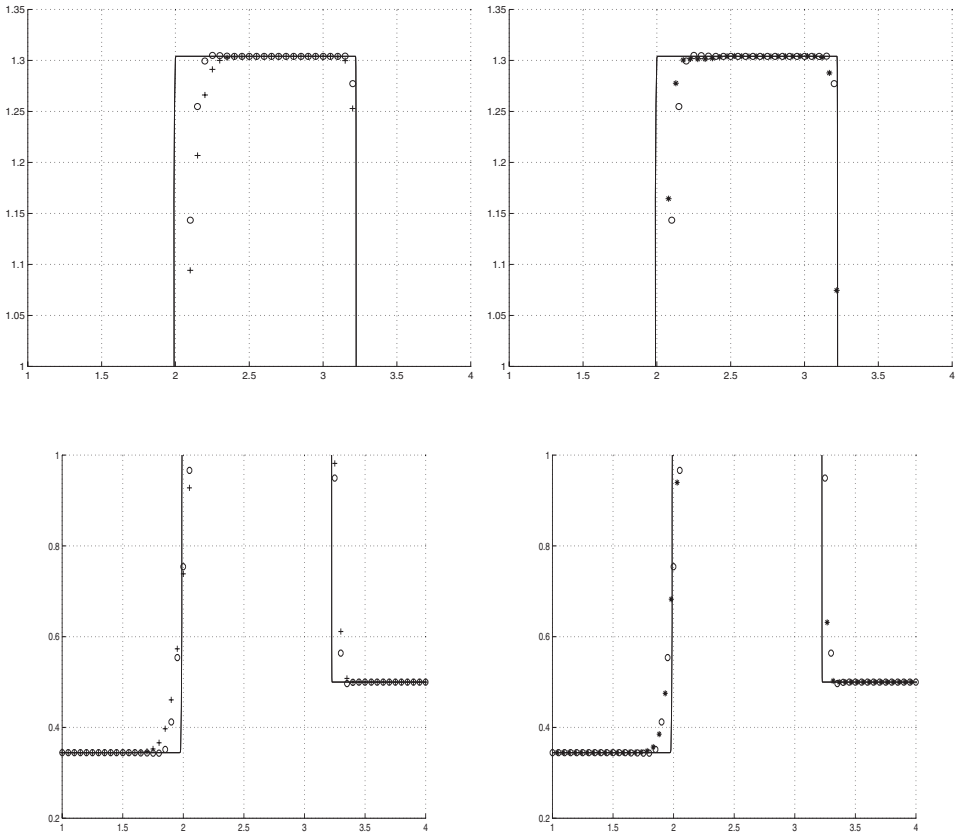

FIG. 4.3. *Zoomed regions of the density profile of Lax shock tube problem.*

4.3.3. Interaction of blast waves. This one-dimensional interacting shock wave problem was suggested in [23] as a very challenging numerical test.

The initial data to simulate the interaction of two blast waves consists in three constant states:

$$u_0(x) = \begin{cases} (\rho_L, v_L, P_L) = (1, 0, 10^3), & 0 \le x < 0.1, \\ (\rho_M, v_M, P_M) = (1, 0, 10^{-2}), & 0.1 \le x < 0.9, \\ (\rho_R, v_R, P_R) = (1, 0, 10^2), & 0.9 \le x \le 1. \end{cases}$$

Reflecting boundary conditions are applied on both ends of the interval. The density field of the solution to this problem after the collision contains interaction of rarefaction waves, contact discontinuities, and shocks.

Figures 4.5 and 4.6 show the density component computed with 400 grid points evolved until times 0.028 and 0.038, respectively, with CFL factor 0.5.

The three schemes behave robustly along the evolution of this strong test. The local extrema are better resolved for the fifth order accurate Weighted PowerENO scheme. We observe an improved result for the PowerPHM scheme compared with the PHM scheme.

4.3.4. Computational cost and efficiency. In this section we analyze the efficiency and computational cost of the reconstruction procedures under study for the one-dimensional shock test problems.

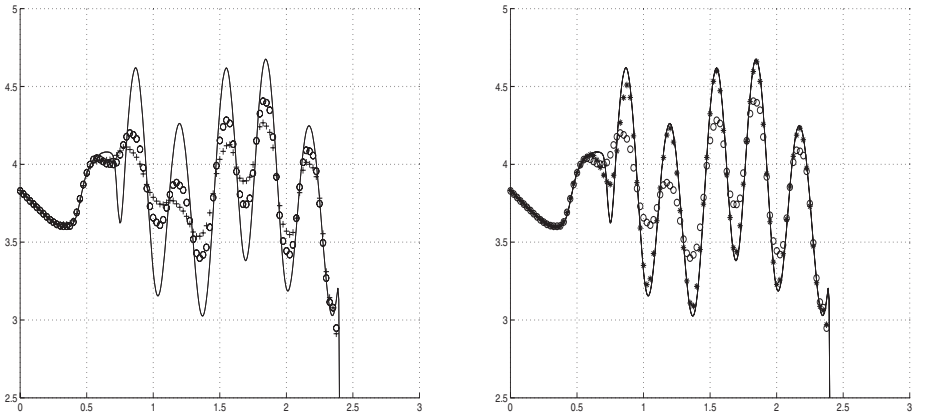

FIG. 4.4. *Zoomed region of the numerical solution of the density profile for the shock-entropy wave interaction with PHM-MFF "+" and PowerPHM-MFF "o" (left), PowerPHM-MFF and Weighted PowerENO-MFF (right) using a grid of* 400 *points with* $CFL = 0.8$ *until time* 1.8.

In Tables 4.2, 4.3, and 4.4 we display the L_1-error, as an overall error when discontinuities are present, of the solution computed with respect to a reference solution for a mesh refinement sequence together with the CPU time for each of the computations.

The reference solution for the Lax shock tube problem is the exact solution of the Riemann problem [18]. The reference solution for the shock entropy test and the two interacting blast waves problem were computed with the Weighted PowerENO scheme with 12800 grid points. The computing times are expressed in seconds and are obtained for a fixed number of iterations for the three schemes. The ratio $\frac{\Delta t}{\Delta x}$ is 0.1 for the Lax shock tube problem and the shock entropy interaction test and 0.01 for the interaction of blast waves.

For each of the test problems and schemes, the errors reduce under mesh refinement. The errors give a rough measure of the accuracy of the methods since the L_1-error gives the same weight to the points belonging to the smooth regions and the

points of the discontinuity regions. A more complete understanding of the accuracy of the methods can be obtained from direct observation of Figures 4.2, 4.3, 4.4, 4.5, and 4.6. The computational times are similar for both hyperbolic schemes and smaller than the corresponding times for the fifth order parabolic scheme.

4.4. Two-dimensional Riemann problem. We consider the Riemann problem corresponding to configuration 3 defined in [16] in the domain $[0,1] \times [0,1]$

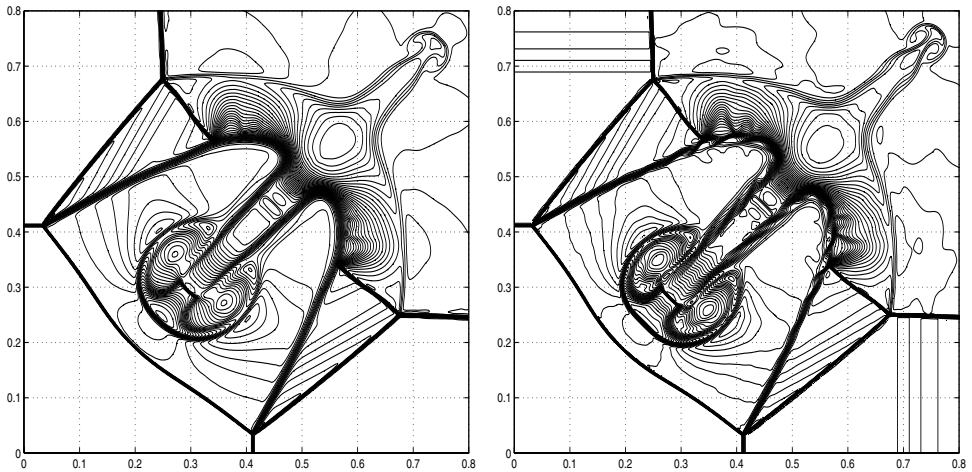

FIG. 4.7. *Zoomed region of the density contour lines of the numerical solution of the two-dimensional Riemann problem using* 400×400 *points,* $CFL = 0.8$*, at time* 0.8 *for the PHM-MFF scheme (left) and PowerPHM-MFF (right).*

localizing the contact point at $(0.75, 0.75)$ instead of the center of the square. We evolve in time until 0.8 with a CFL factor of 0.8 and a grid of 400×400 points. In Figure 4.7 we display the approximations of the density contour profile obtained with the PHM-MFF and PowerPHM-MFF schemes. We can observe a substantial improvement at the contact where the instability is manifest for the PowerPHM-MFF scheme. We also notice a better resolution of the structure appearing at the top right region for the PowerPHM-MFF scheme.

5. Conclusions. In this paper we have analyzed the power limiters to know their suitability to be used as slope-limiters for piecewise hyperbolic reconstructions. We have found that the powereno limiter has the desired qualities for the design of a piecewise hyperbolic reconstruction. We formulate a new PHM based on the powereno limiter (we call it PowerPHM) that behaves stably with reduced numerical viscosity compared to PHM. We show that this new method is LTVB and improves the behavior of PHM at local extrema, jump discontinuities, and discontinuities in derivative. We have shown numerical evidence of the above mentioned features by means of one- and two-dimensional numerical tests with the Euler equations of gas dynamics.

A MULTIGRID METHOD FOR INCOMPRESSIBLE FLOW PROBLEMS USING QUASI DIVERGENCE FREE FUNCTIONS*

GUNAR MATTHIES† AND FRIEDHELM SCHIEWECK‡

Abstract. We consider a finite element method of higher order on a quadrilateral or triangular, hexahedral or tetrahedral mesh for solving the linearized Navier–Stokes equations (Oseen equations) by means of discontinuous elements for the pressure and suitable conforming elements for the velocity such that the global and the local inf-sup condition are satisfied. Our goal is the construction of a coupled multigrid solver for the corresponding algebraic system of equations. The idea of this solver is to switch inside of the multigrid method to a new velocity basis which leads to a reduced system with a much lower number of unknowns as well as a very small number of couplings between them. We call this new basis quasi divergence free since most of the basis functions are discretely divergence free which implies that they do not have any coupling to the pressure. The quasi divergence free basis functions can be constructed locally during the assembling process of the stiffness matrix. We create a multigrid method for solving the reduced problem efficiently. Since most of the velocity basis functions are completely decoupled from the pressure we can construct a smoother with low computational costs. The efficiency of the new multigrid method compared with other known coupled multigrid solvers is demonstrated by numerical experiments for a Stokes problem, the driven cavity problem, and a benchmark problem.

Key words. higher order finite elements, quasi divergence free basis, incompressible flow, Oseen equations, Navier–Stokes equations, multigrid

1. Introduction.

Many processes in science and engineering include fluid flow coupled with other physical phenomena. For the numerical simulation of such complex applications, it is very important to have a fast solver for flow problems. In the last few years, higher order finite element methods turned out to be very efficient numerical methods concerning the number of unknowns in relation to the achieved accuracy. In this paper, we consider the numerical solution of an incompressible flow problem by means of a higher order finite element method and the construction of a multigrid solver for the corresponding algebraic system of equations.

For simplicity, we take as model problem the stationary d-dimensional , ($d = 2$ or 3) with Dirichlet boundary conditions, i.e., we want to find a velocity $u : \Omega \to \mathbb{R}^d$ and a pressure $p : \Omega \to \mathbb{R}$ such that

$$\begin{aligned} -\operatorname{div} \mathbb{T}(u,p) + (\beta \cdot \nabla)u &= f \quad \text{in } \Omega, \\ \operatorname{div} u &= 0 \quad \text{in } \Omega, \\ u &= g \quad \text{on } \Gamma, \end{aligned} \tag{1.1}$$

where $\mathbb{T}(u,p) \in \mathbb{R}^{d\times d}$ denotes the stress tensor defined via the deformation tensor

‡Institut für Analysis und Numerik, Otto-von-Guericke-Universität Magdeburg, Postfach 4120, D-39016 Magdeburg, Germany (friedhelm.schieweck@mathematik.uni-magdeburge.de, http://www-ian.math.uni-magdeburg.de/∼schiewec).

$\mathbb{D}(u) \in \mathbb{R}^{d\times d}$ for the velocity $u = (u_1, \dots, u_d)$ in the following way:

$$\mathbb{T}(u,p) := -p\mathbb{I} + 2\nu\mathbb{D}(u), \quad \mathbb{I} := (\delta_{i,j}), \quad \mathbb{D}(u) := \frac{1}{2}\left(\frac{\partial u_i}{\partial x_j} + \frac{\partial u_j}{\partial x_i}\right).$$

The vector function $\beta : \Omega \to \mathbb{R}^d$ is a given convection field with $\operatorname{div}\beta = 0$. Furthermore, $\Omega \subset \mathbb{R}^d$ is a connected, bounded domain with a polygonal ($d = 2$) or polyhedral ($d = 3$) boundary $\Gamma := \partial\Omega$, ν the viscosity, $f : \Omega \to \mathbb{R}^d$ a given body force and $g : \Gamma \to \mathbb{R}^d$ the prescribed boundary data satisfying the solvability condition $\int_\Gamma g \cdot n\, ds = 0$, where n denotes the outer normal unit vector on the boundary Γ. Problem (1.1) arises if a Picard iteration is applied to the stationary Navier–Stokes equations [25, 5] or it corresponds to the Stokes equations if $\beta \equiv 0$.

We use a higher order conforming finite element method on triangles and/or quadrilaterals ($d = 2$) and tetrahedra or hexahedra ($d = 3$), respectively. It is essential for our method to have a discontinuous pressure approximation and a finite element pair for velocity and pressure that satisfies the local (elementwise) and the global inf-sup condition. Let us emphasize that a discontinuous pressure is not a disadvantage. By means of a simple postprocessing procedure one can compute a continuous piecewise polynomial pressure function which maintains the optimal approximation order of the discontinuous pressure solution [21]. In order to get a method of order $r \geq 2$ in the energy norm, we approximate the pressure by discontinuous piecewise P_{r-1}-elements. On quadrilaterals and hexahedra a continuous piecewise Q_r-approximation for the velocity is used. For triangles and tetrahedra we approximate the velocity by continuous functions where the restriction to each element is contained in a suitable enrichment of the polynomial space P_r. Details are given in [4, 7]. For the sake of simplicity, we restrict ourselves to a fixed polynomial degree r for all elements. However, our method can be generalized easily to the case where the degree can vary from element to element.

In the literature, a lot of work has been devoted to the solution of the large algebraic system in saddle point form that corresponds to the discrete problem associated with (1.1). We refer to the overview paper [2] and to [5, 18, 25] for some recent work in the context of computational fluid dynamics. In this paper, we consider the category of so-called [illegible] where the unknown vectors for velocity and pressure are computed simultaneously. Here, our goal is to achieve an improvement for the coupled multigrid solvers in the case of higher order finite element discretizations of (1.1). The problem of the existing multigrid solvers in this category is that they use a block Gauss–Seidel smoother (Vanka smoother) with a relatively large block size which leads to high computational costs. Typically this block size is the number of all degrees of freedom for velocity and pressure that belong to one element. That means the block size becomes large for higher order elements, in particular, in the 3D case [14, 11, 12].

The new idea of this solver is to switch inside of the multigrid method to a new basis of a suitable velocity subspace which leads at the end to a highly reduced number of velocity and pressure unknowns as well as to a very small number of couplings between them. We call this new basis a [illegible] or, for convenience, a [illegible] since most of the basis functions are discretely divergence free. This implies that they do not have any coupling to the pressure. The QDF basis functions can be constructed locally during the assembling process of the stiffness matrix. The discrete Oseen problem is equivalent to a subspace formulation called [illegible] in the

following. This problem is further decomposed by an orthogonal splitting into two subproblems. The first one is a problem for the element bubble part u_b of the velocity solution $u_h = u_b + \widetilde{u}_s$. It can be solved independently from the remaining part $\widetilde{u}_s$ in an elementwise way during the assembling process of the stiffness matrix. The second problem of the decomposition is a [illegible] for the velocity part $\widetilde{u}_s$ and the piecewise constant part $\overline{p}_h$ of the pressure solution $p_h = \overline{p}_h + \widetilde{p}_h$. It has a much smaller dimension than the original discrete Oseen problem. The remaining pressure part $\widetilde{p}_h$ can be computed at the end by an elementwise postprocessing procedure.

In this paper, we create a multigrid method for solving the QDF formulation of the Oseen problem efficiently. The most important ingredient of this method is the construction of a suitable QDF velocity basis where almost all basis functions are discretely divergence free. Only those basis functions which are associated with so-called [illegible] are not discretely divergence free. The number of flux nodes is equal to the number of the $(d-1)$-dimensional faces of the grid, i.e., it is relatively small compared to the total number of velocity unknowns in the reduced Oseen problem. Since each discretely divergence free basis function is completely decoupled from the pressure, this, in principle, allows one to apply a point Gauss–Seidel smoothing to all nonflux nodes. Thus, switching inside of our multigrid method to the QDF velocity basis allows us to construct a smoothing procedure with very low computational costs compared to existing multigrid methods from the literature. For a bounded polynomial degree r, the computational overhead to work with the QDF basis is only proportional to the number of unknowns. The required memory for an efficient implementation of the QDF basis is less than the memory that will become free from the fact that a lot of nonzero matrix entries of the original finite element method are no longer used for our new multigrid method.

The idea to use a discretely divergence free basis for the velocity space is not new. For the 2D situation, we refer in case of continuous pressure elements to [27, 28] and in case of a discontinuous pressure approximation to [8, 9, 23, 4, 3, 24, 26] for elements up to second order and to [22] for higher order finite element approximations. Efficient multigrid solvers based on a discretely divergence free basis of the velocity space are constructed in [3, 24]. However, the main drawback of this approach is that the construction of such a basis in the 3D case is very complicated [10]. Therefore, it seems to be better to renounce a complete discretely divergence free basis and to work instead with a QDF basis which might be the right compromise.

The paper is organized as follows. We introduce some notation and define the finite element spaces in section 2. The construction of the QDF basis of the velocity space is presented in section 3. In section 4 we show how the saddle point problem created from the original basis is decomposed into local subproblems on each element and a global system with a highly reduced dimension. The aspects of an efficient implementation of our new method are discussed in section 5. In section 6 we describe the main components of our multigrid method and present a solution technique for the Navier–Stokes problem. The performance of the new multigrid method compared with other coupled multigrid solvers known from the literature is tested in section 7 by means of numerical experiments for a Stokes problem, the driven cavity problem, and a benchmark problem [20].

2. Preliminaries and notation. For a domain $G \subset \mathbb{R}^d$, the $L^2(G)$ inner product and norm are denoted by $(\cdot,\cdot)_G$ and $\|\cdot\|_{0,G}$, respectively, for scalar functions as well as for vector- or tensor-valued functions. For example, for tensor-valued

functions $A, B : G \to \mathbb{R}^{d\times d}$, we define the inner product as

$$(A,B)_G := \int_G \sum_{i,j=1}^{d} A_{i,j}(x)B_{i,j}(x)dx\,.$$

For a sufficiently smooth $(d-1)$-dimensional manifold $\gamma \subset \overline{\Omega}$, we denote by $\langle\cdot,\cdot\rangle_\gamma$ the inner product in $L^2(\gamma)$ or in $(L^2(\gamma))^d$, respectively. For a domain $G \subset \mathbb{R}^d$, the Sobolev spaces $H^k(G) = W^{k,2}(G)$ are defined in the usual way with the standard norm and semi-norm $\|\cdot\|_{k,G}$ and $|\cdot|_{k,G}$, respectively.

We define the spaces X, X_0 and M, M_0 for velocity and pressure, respectively, as

$$\begin{aligned} X &:= (H^1(\Omega))^d\,, & X_0 &:= (H_0^1(\Omega))^d\,,\\ M &:= L^2(\Omega), & M_0 &:= L_0^2(\Omega) := \{q \in L^2(\Omega) : (q,1)_\Omega = 0\}. \end{aligned}$$

Let $\widetilde{g} \in X$ be an extension of the boundary function $g : \Gamma \to \mathbb{R}^d$ of (1.1) into the domain Ω. Then, the weak formulation of problem (1.1) reads as follows:

$$(u,p) \in (\widetilde{g} + X_0) \times M_0\,,$$

$$\begin{aligned} a(u,v) + b(v,p) &= (f,v)_\Omega \qquad &&\forall\, v \in X_0,\\ b(u,q) &= 0 &&\forall\, q \in M_0, \end{aligned} \tag{2.1}$$

where

$$a(u,v) := 2\nu\,(\mathbb{D}(u),\mathbb{D}(v))_\Omega + ((\beta\cdot\nabla)u,v)_\Omega\,, \qquad b(v,p) := -(\operatorname{div} v,p)_\Omega\,. \tag{2.2}$$

For the discretization of this problem, we decompose the domain $\Omega \subset \mathbb{R}^d$ into elements $K \in \mathcal{T}_h$ which are allowed to be triangles and/or quadrilaterals in the case $d = 2$ and either tetrahedra or hexahedra in the case $d = 3$. We assume that the grid $\mathcal{T}_h$ is regular and shape-regular in the usual sense. The diameter of an element K is denoted by h_K and the global mesh-size of the grid $\mathcal{T}_h$ is defined as $h := \max_{K\in\mathcal{T}_h} h_K$. For an element $K \in \mathcal{T}_h$, we denote by $\mathcal{E}(K)$ the set of all $(d-1)$-dimensional faces of K, by $\mathcal{E}_h := \bigcup_{K\in\mathcal{T}_h} \mathcal{E}(K)$ the set of all faces of the grid $\mathcal{T}_h$, by $\mathcal{E}_h(\Gamma)$ the set of all boundary faces $E \subset \Gamma$ and by $\mathcal{E}_h^0 := \mathcal{E}_h \setminus \mathcal{E}_h(\Gamma)$ the set of all inner faces. Note that a $(d-1)$-dimensional face $E \in \mathcal{E}_h$ can belong to at most two different elements. For a given inner face $E \in \mathcal{E}_h^0$, let $K(E)$ and $K'(E)$ be those two elements of the grid $\mathcal{T}_h$ which have E as their common face. For a boundary face $E \in \mathcal{E}_h(\Gamma)$, let $K(E)$ denote that element such that $E \in \mathcal{E}(K(E))$. We will denote by n_E^K the unit normal vector of a face $E \in \mathcal{E}(K)$ which is directed outward with respect to the element K. To each face $E \in \mathcal{E}_h$ we assign the unit normal vector $n_E := n_E^{K(E)}$.

We denote by $\mathbb{P}_m(G)$ the space of all polynomials on the domain $G \subset \mathbb{R}^d$ with total degree less than or equal to m and by $\mathbb{Q}_m(G)$ the space of those polynomials where the maximum power in each coordinate is less than or equal to m. For an element K, let $F_K : \widehat{K} \to K$ be the one-to-one mapping between the reference element $\widehat{K}$ and K. For sufficient conditions that guarantee the bijectivity of nonaffine reference mappings F_K, we refer to [17].

It is essential for our approach that there are no continuity requirements for the pressure approximation.

The finite element spaces M_h and $M_{h,0}$ for the pressure with $M_h \subset M$ and $M_{h,0} \subset M_0$ are defined as

$$M_h := \{q \in L^2(\Omega) :\ q\big|_K \circ F_K \in \mathbb{P}_{r-1}(\widehat{K}) \quad \forall K \in \mathcal{T}_h\}\,, \qquad M_{h,0} := M_h \cap M_0\,. \tag{2.3}$$

The velocity spaces X and X_0 will be approximated by the finite element spaces $X_h \subset X$ and $X_{h,0} \subset X_0$ of order $r \geq 2$ which are defined as

$$X_h := (S_h)^d\,, \qquad X_{h,0} := X_h \cap X_0\,, \tag{2.4}$$

with the scalar finite element space

$$S_h := \{\varphi \in H^1(\Omega) :\ \varphi\big|_K \circ F_K \in \mathbb{U}_r(\widehat{K}) \quad \forall K \in \mathcal{T}_h\}. \tag{2.5}$$

The space $\mathbb{U}_r(\widehat{K})$ depends on the shape of element K. We assume that it is chosen such that the local inf-sup condition on K is fulfilled. This means that there is a constant $\beta_0 > 0$ which is independent on K such that

$$\inf_{q \in \widetilde{M}_h(K)} \sup_{v \in X_{h,0}(K)} \frac{(\operatorname{div} v, q)_K}{|v|_{1,K}\|q\|_{0,K}} \geq \beta_0 \tag{2.6}$$

holds true for all $K \in \mathcal{T}_h$, where

$$\begin{array}{rcl} \widetilde{M}_h(K) & := & \{q \in M_{h,0} :\ q = 0 \text{ on } \Omega \setminus K\}\,, \\ X_{h,0}(K) & := & \{v \in X_h :\ v = 0 \text{ on } \Omega \setminus K\}\,, \end{array} \tag{2.7}$$

are the local pressure and velocity spaces associated with the element K, respectively. As an example, the choice $\mathbb{U}_r(\widehat{K}) = \mathbb{Q}_r(\widehat{K})$ on quadrilaterals or hexahedra guarantees that assumption (2.6) is satisfied; see [17]. A possible choice for $\mathbb{U}_r(\widehat{K})$ on triangles and tetrahedra is a suitable bubble enrichment of $\mathbb{P}_r(\widehat{K})$. For details, see [4, 7].

We use the [illegible] version of the local spaces where their definition is done via the reference transformation for both the velocity and the pressure. Thus, for a nonaffine reference mapping, the pressure will be approximated by functions which may be no polynomials. Note that also the [illegible] version of the local space is possible where only the velocity is defined using the reference transformation while the pressure will be approximated by piecewise polynomials from $\mathbb{P}_{r-1}(K)$ [7]. Our method will work also for the unmapped pressure definition. In the case of nonaffine reference transformations the mapped and unmapped version differ, but on families of regularly refined meshes we obtain the same optimal error estimates for both versions; see [1, 16].

Let $\widetilde{g}_h \in X_h$ be a suitable approximative extension of the boundary function g in (1.1) with

$$\langle\, \widetilde{g}_h, n \,\rangle_\Gamma = \langle\, g, n \,\rangle_\Gamma = 0. \tag{2.8}$$

Details will be given later on. Then, the discrete Oseen problem reads as follows: [illegible] $(u_h, p_h) \in (\widetilde{g}_h + X_{h,0}) \times M_{h,0}$ [illegible]

$$\begin{array}{rcll} a_h(u_h, v_h) + b(v_h, p_h) & = & f_h(v_h) & \forall\, v_h \in X_{h,0}\,, \\ b(u_h, q_h) & = & 0 & \forall\, q_h \in M_{h,0}\,, \end{array} \tag{2.9}$$

where $a_h(\cdot,\cdot)$ is either the bilinear form $a(\cdot,\cdot)$ in case of the Galerkin discretization or a stabilized version of it (see section 6.4). f_h denotes a bounded linear functional which is $f_h(\cdot) = (f, \cdot)_\Omega$ for the Galerkin discretization or a modified version if a stabilization technique is used. Together with (2.6) we assume that the pair $(X_{h,0}, M_{h,0})$ satisfies also the global inf-sup condition uniformly with respect to the mesh-size h. For example, in the case of quadrilaterals or hexahedra, the choice $\mathbb{U}_r(\widehat{K}) = \mathbb{Q}_r(\widehat{K})$

ensures this condition; see [17] for mapped and [7] for unmapped pressure elements. Thus, for a coercive and continuous bilinear form $a_h(\cdot,\cdot)$, the existence of a unique and stable solution (u_h, p_h) of problem (2.9) is guaranteed (see [7] and Theorem 4.1).

Finally, let us introduce some general notation. We denote by $\mathrm{card}(J)$ the number of elements of a finite set J. The dual space of a given space X will be denoted by X'. For a set $G \subset \mathbb{R}^m$, we denote by $\mathrm{int}(G)$ and $\overline{G}$ the interior and closure of G, respectively.

3. Construction of a quasi divergence free basis. Let φ_j, $j \in J$, denote the usual vector-valued Lagrange basis functions of the finite element space X_h, i.e.,

$$X_h = \mathrm{span}\{\varphi_j : j \in J\}\,, \tag{3.1}$$

where the indices $j \in J$ will be called [illegible] in what follows. Each node $j \in J$ is associated with a nodal point $a_j \in \overline{\Omega}$ of the grid $\mathcal{T}_h$. Let $J(\Gamma)$ and J_0, defined as

$$J(\Gamma) := \{j \in J : a_j \in \Gamma\}\,, \qquad J_0 := J \setminus J(\Gamma)\,, \tag{3.2}$$

denote the set of the boundary nodes and the set of the interior nodes, respectively, such that $X_{h,0} = \mathrm{span}\{\varphi_j : j \in J_0\}$.

Our construction of QDF basis functions ψ_j, $j \in \widetilde{J}$, of $\widetilde{X}_h$ is based on two projection operators which are applied to a subset of the basis functions φ_j of X_h. The first operator P_b maps into the space of the element bubble functions and the second operator P_f maps into a space of specially chosen face bubble functions.

Let us start with the definition of QDF functions and discretely divergence free functions. To this end, we need the discrete pressure subspace $\widetilde{M}_h \subset M_{h,0}$ defined by

$$\widetilde{M}_h := \{q \in M_{h,0} :\ q\big|_K \in L^2_0(K)\ \ \forall K \in \mathcal{T}_h\}\,. \tag{3.3}$$

Definition 3.1. [illegible] $v_h \in X_h$ [illegible] **quasi divergence free function** [illegible] **QDF function** [illegible] $\widetilde{M}_h \subset M_{h,0}$ [illegible]

$$b(v_h, q_h) = 0 \qquad \forall q_h \in \widetilde{M}_h\,. \tag{3.4}$$

[illegible]

$$\widetilde{X}_h := \{v_h \in X_h :\ b(v_h, q_h) = 0\ \ \forall q_h \in \widetilde{M}_h\} \quad \text{[illegible]} \quad \widetilde{X}_{h,0} := \widetilde{X}_h \cap X_0 \tag{3.5}$$

[illegible] **subspaces of the QDF functions** [illegible] X_h [illegible] $X_{h,0}$ [illegible]

$$V_h := \{v_h \in X_h :\ b(v_h, q_h) = 0\ \ \forall q_h \in M_h\} \quad \text{[illegible]} \quad V_{h,0} := V_h \cap X_0 \tag{3.6}$$

[illegible] **subspaces of the discretely divergence free functions** [illegible] X_h [illegible] $X_{h,0}$ [illegible]

In order to clarify the relation between QDF functions and discretely divergence free functions it is useful to introduce the spaces of the piecewise constant pressure functions

$$\overline{M}_h := \{q \in L^2(\Omega) :\ q\big|_K \in \mathbb{P}_0(K)\ \ \forall K \in \mathcal{T}_h\} \quad \text{and} \quad \overline{M}_{h,0} := \overline{M}_h \cap M_0\,. \tag{3.7}$$

Now, from $\widetilde{M}_h \subset M_{h,0} \subset M_h$ it follows that $V_h \subset \widetilde{X}_h$. For the pressure spaces we have the L^2-orthogonal decompositions

$$M_h = \overline{M}_h \oplus \widetilde{M}_h\,, \qquad M_{h,0} = \overline{M}_{h,0} \oplus \widetilde{M}_h, \qquad \text{and} \qquad \widetilde{M}_h = \bigoplus_{K\in\mathcal{T}_h} \widetilde{M}_h(K). \tag{3.8}$$

This implies that a function $v_h \in X_h$ belongs to the discretely divergence free subspace V_h if and only if $v_h \in \widetilde{X}_h$ and

$$b(v_h, q_h) = 0 \qquad \forall q_h \in \overline{M}_h\,. \tag{3.9}$$

It is easy to see that the condition (3.9) is equivalent to the property that, for each element $K \in \mathcal{T}_h$, the integral of the normal flux of v_h across the element boundary ∂K is zero, i.e.,

$$\sum_{E\in\mathcal{E}(K)} \left\langle\, v_h, n_E^K \,\right\rangle_E = 0 \qquad \forall K \in \mathcal{T}_h\,. \tag{3.10}$$

Using the fact that $b(v_h, 1) = 0$ for all functions $v_h \in X_{h,0}$, we get that

$$v_h \in V_{h,0} \qquad \text{if and only if} \qquad v_h \in \widetilde{X}_{h,0} \ \text{ and (3.10) is satisfied.} \tag{3.11}$$

[illegible] 3.2. It is important to emphasize that an essential assumption of our approach is the fact that the pressure space is discontinuous which implies the property (3.8) and the above mentioned relation between the QDF functions and the discretely divergence free functions. Furthermore, the question whether a function $v_h \in X_h$ is a QDF function can be checked elementwise. Therefore, the construction of a QDF basis of $\widetilde{X}_h$ can be done in an elementwise fashion.

3.1. Correction by element bubble functions. For a given element $K \in \mathcal{T}_h$, let

$$J(K) := \{j \in J :\ K \subset \mathrm{supp}(\varphi_j)\} \tag{3.12}$$

be the set of the local velocity nodes associated with K. Then, the local velocity space $X_h(K) \subset X_h$ related to element K is defined as

$$X_h(K) := \mathrm{span}\{\varphi_j : j \in J(K)\}\,. \tag{3.13}$$

For each $K \in \mathcal{T}_h$, we split the set of nodes $J(K)$ into the set $J_b(K)$ of [illegible], where the associated basis functions φ_j are so-called [illegible], and the remaining set $J_s(K)$ of so-called [illegible] living on the [illegible] of the grid $\mathcal{T}_h$, i.e.,

$$J_b(K) := \left\{j \in J(K) :\ \mathrm{supp}(\varphi_j) \subset \overline{K}\right\} \qquad \text{and} \qquad J_s(K) := J(K) \setminus J_b(K). \tag{3.14}$$

The associated local velocity spaces are defined as

$$X_b(K) := \mathrm{span}\{\varphi_j :\ j \in J_b(K)\}\,, \qquad X_s(K) := \mathrm{span}\{\varphi_j :\ j \in J_s(K)\}\,, \tag{3.15}$$

such that $X_h(K) = X_b(K) \oplus X_s(K)$. Note that, due to the global continuity of the basis functions φ_j on Ω, we have $v_h\big|_K \in (H_0^1(K))^d$ for all element bubble functions

$v_h \in X_b(K)$. Moreover, the space $X_b(K)$ coincides with $X_{h,0}(K)$ in (2.7). The global set of nodes can be split as $J = J_b \cup J_s$ with

$$J_b := \bigcup_{K \in \mathcal{T}_h} J_b(K) \qquad \text{and} \qquad J_s := J \setminus J_b = \bigcup_{K \in \mathcal{T}_h} J_s(K) \tag{3.16}$$

and the global velocity space is decomposed into $X_h = X_b \oplus X_s$, where

$$X_b := \operatorname{span}\{\varphi_j : \ j \in J_b\} \qquad \text{and} \qquad X_s := \operatorname{span}\{\varphi_j : \ j \in J_s\}. \tag{3.17}$$

Note that, due to the local support of the basis functions φ_j, $j \in J_b$, we have the following decomposition:

$$X_b = \bigoplus_{K \in \mathcal{T}_h} X_b(K), \tag{3.18}$$

which is orthogonal in L^2 and H^1.

In the following, we will construct basis functions $\widetilde{\varphi}_j$, $j \in \widetilde{J}$, of the subspace of QDF functions $\widetilde{X}_h$. The idea for the construction of $\widetilde{\varphi}_j$ is to subtract from the original basis function φ_j a correction consisting of element bubble functions. To this end, we define the operators

$$P_b : X \to X_b \qquad \text{and} \qquad Q_b : X \to \widetilde{M}_h$$

as follows. For a given function $w \in X = (H^1(\Omega))^d$, the pair $(P_b w, Q_b w)$ is defined to be the solution of the problem:

$(P_b w, Q_b w) \in X_b \times \widetilde{M}_h$

$$\begin{aligned} a_h(P_b w, v_h) \, + \, b(v_h, Q_b w) &= a_h(w, v_h) && \forall \, v_h \in X_b \,, \\ b(P_b w, q_h) &= b(w, q_h) && \forall \, q_h \in \widetilde{M}_h \,. \end{aligned} \tag{3.19}$$

Using the orthogonal splittings (3.18) and (3.8), we see that problem (3.19) is equivalent to $\operatorname{card}(\mathcal{T}_h)$ many local problems, i.e., $(P_b w, Q_b w)$ can be written as a sum

$$(P_b w, Q_b w) = \sum_{K \in \mathcal{T}_h} (P_b^K w, Q_b^K w)$$

with local operators $P_b^K : X \to X_b(K)$ and $Q_b^K : X \to \widetilde{M}_h(K)$ associated with the element $K \in \mathcal{T}_h$ such that, for a given $w \in X$, the pair $(P_b^K w, Q_b^K w)$ is defined as the solution of the following local problem:

$(P_b^K w, Q_b^K w) \in X_b(K) \times \widetilde{M}_h(K)$

$$\begin{aligned} a_h(P_b^K w, v_h) \, + \, b(v_h, Q_b^K w) &= a_h(w, v_h) && \forall \, v_h \in X_b(K) \,, \\ b(P_b^K w, q_h) &= b(w, q_h) && \forall \, q_h \in \widetilde{M}_h(K) \,. \end{aligned} \tag{3.20}$$

Since $X_b(K)$ coincides with the space $X_{h,0}(K)$ from (2.7), the assumption (2.6) implies the inf-sup condition for problem (3.20). Thus, from the standard FEM-theory for mixed problems [4] we get that, for each $K \in \mathcal{T}_h$, the local problem (3.20) has a unique solution which continuously depends on the local norm $\|w\|_{1,K}$. Hence, the global problem (3.19) also has a unique solution which depends continuously on the global norm $\|w\|_{1,\Omega}$.

Now, using the operator P_b, we define the following functions $\widetilde{\varphi}_j$ for the index set J_s of all skeleton nodes:

$$\widetilde{\varphi}_j := (I - P_b)\varphi_j \qquad \forall j \in J_s, \tag{3.21}$$

where I denotes the identity operator. Since $(P_b\varphi_j)\big|_{\partial K} = 0$ for all $K \in \mathcal{T}_h$, we get that $\widetilde{\varphi}_j$ coincides with φ_j on the skeleton of the grid $\mathcal{T}_h$, i.e.,

$$\widetilde{\varphi}_j(x) := \varphi_j(x) \qquad \forall x \in \bigcup_{K\in\mathcal{T}_h} \partial K \quad \forall j \in J_s. \tag{3.22}$$

Therefore, all the $\widetilde{\varphi}_j$ with $j \in J_s$ are linearly independent functions in X_h. Moreover, from the second equation in (3.19), it follows that $\widetilde{\varphi}_j \in \widetilde{X}_h$. Thus, the functions $\widetilde{\varphi}_j$, $j \in J_s$, are the basis functions of a subspace $\widetilde{X}_s \subset \widetilde{X}_h$ defined by

$$\widetilde{X}_s := \operatorname{span}\{\widetilde{\varphi}_j : \ j \in J_s\}\,, \tag{3.23}$$

and the operator $I - P_b : X_s \to \widetilde{X}_s$ is an isomorphism.

However, for $j \in J_b$, the solution of problem (3.19) with $w = \varphi_j$ is $(P_b\varphi_j, Q_b\varphi_j) = (\varphi_j, 0) \in X_b \times \widetilde{M}_h$ such that $\widetilde{\varphi}_j$ defined by (3.21) would be zero. Therefore, in general, we have to construct for each element $K \in \mathcal{T}_h$ an additional set of basis functions $\widetilde{\varphi}_j$, $j \in \widetilde{J}_b(K)$, of the subspace $\widetilde{X}_b(K)$ of the quasi divergence free element bubble functions defined as

$$\widetilde{X}_b(K) := \{v_h \in X_b(K) : \ b(v_h, q_h) = 0 \ \ \forall q_h \in \widetilde{M}_h(K)\}. \tag{3.24}$$

Here "in general" means the case when the polynomial degree r of the velocity space is larger than 2. For example, in the case of quadrilateral elements with Q_2-elements for the velocity and discontinuous P_1-elements for the pressure we have for all elements K that $\dim(\widetilde{X}_b(K)) = \dim(X_b(K)) - \dim(\widetilde{M}_h(K)) = 0$, i.e., no basis functions have to be constructed. For a given element $K \in \mathcal{T}_h$, the problem to determine basis functions $\widetilde{\varphi}_j$ such that

$$\widetilde{X}_b(K) = \operatorname{span}\{\widetilde{\varphi}_j : \ j \in \widetilde{J}_b(K)\} \tag{3.25}$$

is equivalent to an algebraic problem of a small fixed size. This problem consists of the computation of basis vectors of the kernel of the matrix $B^K \in \mathbb{R}^{\dim(\widetilde{M}_h(K))\times\dim(X_b(K))}$ defined as

$$B^K_{i,j} := b(\varphi_j, \chi_i) \qquad \forall i \in \widetilde{I}(K), \ j \in J_b(K), \tag{3.26}$$

where the χ_i, $i \in \widetilde{I}(K)$, denote the basis functions of the local pressure space $\widetilde{M}_h(K)$. Basis vectors of $\ker(B^K)$ could be obtained, for instance, by means of a singular value decomposition of the matrix B^K. In the following, let us assume that the basis functions $\widetilde{\varphi}_j$, $j \in \widetilde{J}_b(K)$, are available for all elements $K \in \mathcal{T}_h$ in the sense that coefficients $c^K_{j,i} \in \mathbb{R}$ are known such that

$$\widetilde{\varphi}_j = \sum_{i\in J_b(K)} c^K_{j,i}\varphi_i \qquad \forall j \in \widetilde{J}_b(K)\,. \tag{3.27}$$

Then, the global space of the quasi divergence free element bubble functions $\widetilde{X}_b$ defined as

$$\widetilde{X}_b := \{v_h \in X_b : \ b(v_h, q_h) = 0 \ \ \forall q_h \in \widetilde{M}_h\}\,, \tag{3.28}$$

can be represented by means of basis functions $\widetilde{\varphi}_j$ as follows:

$$\widetilde{X}_b = \mathrm{span}\{\widetilde{\varphi}_j : \ j \in \widetilde{J}_b\}\,, \qquad \text{where} \qquad \widetilde{J}_b := \bigcup_{K\in\mathcal{T}_h} \widetilde{J}_b(K). \tag{3.29}$$

Since all functions $v_h \in \widetilde{X}_b$ vanish on the element boundaries, the condition (3.10) is satisfied which implies that

$$\widetilde{X}_b = V_b := V_h \cap X_b \qquad \text{and} \qquad \widetilde{X}_b(K) = V_b(K) := V_h \cap X_b(K) \quad \forall K \in \mathcal{T}_h\,, \tag{3.30}$$

i.e., all quasi divergence free element bubble functions are discretely divergence free.

Now we are in the position to give the basis representation of the subspace of the QDF functions $\widetilde{X}_h$:

$$\widetilde{X}_h = \mathrm{span}\{\widetilde{\varphi}_j : \ j \in \widetilde{J}\}, \qquad \text{where} \qquad \widetilde{J} := J_s \cup \widetilde{J}_b. \tag{3.31}$$

Using the space $\widetilde{X}_s$ defined in (3.23), we can decompose $\widetilde{X}_h$ in the direct sum

$$\widetilde{X}_h = \widetilde{X}_s \oplus V_b, \tag{3.32}$$

where $V_b = V_h \cap X_b$ is the space of the discretely divergence free element bubble functions. In fact, by construction it is clear that the space $\widetilde{X}_s \oplus V_b$ is a subspace of $\widetilde{X}_h$ and if we consider the dimensions we obtain

$$\begin{aligned} \dim(\widetilde{X}_s \oplus V_b) &= \mathrm{card}(J_s) + \sum_{K\in\mathcal{T}_h} \Big(\dim(X_b(K)) - \dim(\widetilde{M}_h(K))\Big) \\ &= \dim(X_s) + \dim(X_b) - \sum_{K\in\mathcal{T}_h} \dim(\widetilde{M}_h(K)) = \dim(\widetilde{X}_h). \end{aligned}$$

Similarly we can decompose X_h in the direct sum

$$X_h = \widetilde{X}_s \oplus X_b\,. \tag{3.33}$$

In fact, an arbitrary function $v_h \in X_h$ has a representation as $v_h = v_s + \widetilde{v}_b$ with $v_s \in X_s$ and $\widetilde{v}_b \in X_b$. Using $\widetilde{v}_s := (I - P_b)v_s \in \widetilde{X}_s$ we get the representation $v_h = \widetilde{v}_s + v_b$ with $v_b := \widetilde{v}_b + P_b v_s \in X_b$. This shows that $X_h \subset \widetilde{X}_s \oplus X_b$. By construction we have $\widetilde{X}_s \oplus X_b \subset X_h$.

3.2. Correction by face bubble functions. The aim of this subsection is to perform a further decomposition of the subspace $\widetilde{X}_s$ in the form

$$\widetilde{X}_s = V_s \oplus \widetilde{X}_f,$$

where $V_s \subset V_h$ is a subspace of discretely divergence free functions which should be as large as possible. An advantage of using V_h-subspaces is that velocity components lying in those subspaces do not have any couplings with the pressure in the discrete Oseen problem (2.9).

The property that a QDF basis function $\psi_j \in \widetilde{X}_s$ belongs to V_h is equivalent to the condition that ψ_j satisfies the condition (3.10). The idea to fulfill (3.10) for ψ_j is

to start from the already known QDF basis function $\widetilde{\varphi}_j$ and to modify it in such a way that on each $(d-1)$-dimensional face $E \in \mathcal{E}_h$ the normal flux $\langle \psi_j, n_E \rangle_E$ becomes zero. To this end we modify the normal flux of $\widetilde{\varphi}_j$ across E by subtracting a multiple of a properly chosen face bubble function associated with the face E. This does not change the normal fluxes for all other faces.

In the following, we will describe how to choose these face bubble functions. Recall that each node $j \in J$ is associated with a nodal point $a_j \in \overline{\Omega}$. Then, for each face $E \in \mathcal{E}_h$, the set

$$J_0(E) := \{j \in J_s : \ a_j \in \mathrm{int}(E)\} \tag{3.34}$$

denotes the set of all skeleton nodes that correspond to the interior of the $(d-1)$-dimensional face E. Among all the nodes $j \in J_0(E)$ we choose a special [illegible] E, denoted by $j_f(E)$, that realizes the maximum absolute normal flux of the corresponding basis functions, i.e.,

$$|\langle \varphi_{j_f(E)}, n_E \rangle_E| = \max_{j \in J_0(E)} |\langle \varphi_j, n_E \rangle_E|. \tag{3.35}$$

Note that, due to the fact that $P_b \varphi_j\big|_E = 0$ for all $j \in J_0(E)$, the analogous equation holds true for the QDF basis functions $\widetilde{\varphi}_{j_f(E)}$ and $\widetilde{\varphi}_j$, respectively. To simplify the notation we introduce the abbreviations

$$\varphi_E := \varphi_{j_f(E)}, \qquad \widetilde{\varphi}_E := \widetilde{\varphi}_{j_f(E)} \qquad \forall E \in \mathcal{E}_h. \tag{3.36}$$

The set $J_f(K)$ of all flux nodes of an element $K \in \mathcal{T}_h$ and the set $\widetilde{J}_s(K)$ of the remaining skeleton nodes are defined by

$$J_f(K) := \{j_f(E) : \ E \in \mathcal{E}(K)\} \qquad \text{and} \qquad \widetilde{J}_s(K) := J_s(K) \setminus J_f(K). \tag{3.37}$$

Let J_f and $\widetilde{J}_s$ denote the corresponding global sets of nodes given by

$$J_f := \bigcup_{K \in \mathcal{T}_h} J_f(K) \qquad \text{and} \qquad \widetilde{J}_s := \bigcup_{K \in \mathcal{T}_h} \widetilde{J}_s(K) = J_s \setminus J_f\,, \tag{3.38}$$

and $\widetilde{X}_f$ the subspace of $\widetilde{X}_s$ associated with the flux nodes, i.e.,

$$\widetilde{X}_f := \mathrm{span}\{\widetilde{\varphi}_j : \ j \in J_f\}. \tag{3.39}$$

Then, we introduce the operator $P_f : X \to \widetilde{X}_f$ such that for a vector-valued function $w \in X = (H^1(\Omega))^d$ the discrete function $P_f w \in \widetilde{X}_f$ is defined as

$$P_f w := \sum_{E \in \mathcal{E}_h} \frac{\langle w, n_E \rangle_E}{\langle \widetilde{\varphi}_E, n_E \rangle_E} \widetilde{\varphi}_E. \tag{3.40}$$

It is easy to see that this operator has the property

$$\langle P_f w, n_E \rangle_E = \langle w, n_E \rangle_E \qquad \forall E \in \mathcal{E}_h, \quad \forall w \in (H^1(\Omega))^d. \tag{3.41}$$

Now, starting from the basis functions $\widetilde{\varphi}_j$ of $\widetilde{X}_h$ with $j \in \widetilde{J} = (\widetilde{J}_s \cup J_f) \cup \widetilde{J}_b$, we define new basis functions ψ_j of $\widetilde{X}_h$ as

$$\psi_j := \begin{cases} \widetilde{\varphi}_j - P_f \widetilde{\varphi}_j, & j \in \widetilde{J}_s, \\ \widetilde{\varphi}_j, & j \in J_f \cup \widetilde{J}_b. \end{cases} \tag{3.42}$$

Note that the function $\psi_j = \widetilde{\varphi}_j - P_f\widetilde{\varphi}_j$ would be zero for $j \in J_f$ and it would be equal to $\widetilde{\varphi}_j$ for $j \in \widetilde{J}_b$. One easily verifies that the functions $\psi_j \in \widetilde{X}_s$ with $j \in \widetilde{J}_s$ are linearly independent. Moreover, the property (3.41) implies that $\psi_j \in V_h$ for all $j \in \widetilde{J}_s$. Thus, we get the desired decomposition $\widetilde{X}_s = V_s \oplus \widetilde{X}_f$ with the space

$$V_s := \operatorname{span}\{\psi_j : \ j \in \widetilde{J}_s\} \subset V_h.$$

Using (3.32) with $V_b = \operatorname{span}\{\widetilde{\varphi}_j; \ j \in \widetilde{J}_b\} = \operatorname{span}\{\psi_j; \ j \in \widetilde{J}_b\}$ we finally get the decomposition of the subspace $\widetilde{X}_h$ of the quasi divergence free functions

$$\widetilde{X}_h = \widetilde{X}_s \oplus V_b \qquad \text{with} \qquad \widetilde{X}_s = V_s \oplus \widetilde{X}_f = \operatorname{span}\{\psi_j : \ j \in J_s = \widetilde{J}_s \cup J_f\}\,, \tag{3.43}$$

where both spaces V_s and V_b are subspaces of the space V_h of the discretely divergence free functions. That means that all the basis functions ψ_j with $j \in \widetilde{J}_s \cup \widetilde{J}_b$ do not have any couplings with the pressure in the Oseen problem (2.9).

4. Decomposition of the saddle point problem. In this section, we show how the discrete Oseen problem (2.9) can be split into two subproblems using the decomposition (3.33) of the velocity space $X_h = \widetilde{X}_s \oplus X_b$. At first we explain how the discrete extension $\widetilde{g}_h \in X_h$ of the boundary function $g : \Gamma \to \mathbb{R}^d$ is chosen. Let

$$g_h = \sum_{j \in J(\Gamma)} g_j \varphi_j \in X_h \qquad \text{with} \qquad g_j \in \mathbb{R}$$

be an interpolate of g using only boundary nodes $j \in J(\Gamma)$ and satisfying the solvability condition $\langle\, g_h, n \,\rangle_\Gamma = \langle\, g, n \,\rangle_\Gamma = 0$. Then we choose

$$\widetilde{g}_h := \sum_{j \in J(\Gamma)} g_j \widetilde{\varphi}_j = (I - P_b) g_h \in \widetilde{X}_s, \tag{4.1}$$

where $\widetilde{g}_h \in \widetilde{X}_s$ follows from the fact that $J(\Gamma) \subset J_s$.

It is easy to see that the discrete solution u_h of (2.9) is a solution of the following [illegible] of the discrete Oseen problem:
[illegible] $(u_h, \overline{p}_h) \in (\widetilde{g}_h + \widetilde{X}_{h,0}) \times \overline{M}_{h,0}$ [illegible]

$$\begin{array}{lcll} a_h(u_h, \widetilde{v}_h) \,+\, b(\widetilde{v}_h, \overline{p}_h) & = & f_h(\widetilde{v}_h) & \forall\, \widetilde{v}_h \in \widetilde{X}_{h,0}, \\ b(u_h, \overline{q}_h) & = & 0 & \forall\, \overline{q}_h \in \overline{M}_{h,0}\,. \end{array} \tag{4.2}$$

Now, the splitting (3.32) of $\widetilde{X}_h$ as the direct sum $\widetilde{X}_h = \widetilde{X}_s \oplus V_b$ implies that the discrete solution $u_h \in \widetilde{g}_h + \widetilde{X}_{h,0}$ can be uniquely represented in the form

$$u_h = \widetilde{u}_s + u_b = (\widetilde{g}_h + \widetilde{u}_{s,0}) + u_b \tag{4.3}$$

with $\widetilde{u}_s \in \widetilde{X}_s$, $u_b \in V_b$ and $\widetilde{u}_{s,0} \in \widetilde{X}_{s,0} := \widetilde{X}_s \cap X_0$. From the definition of the operator $P_b : X \to X_b$ in (3.19), it follows by taking the test function $v_h = v_b \in V_b$ and using $b(v_b, p_h) = 0$ that

$$a_h(v_s - P_b v_s, v_b) = 0 \qquad \forall v_s \in X_s\,,\ v_b \in V_b\,.$$

Since the operator $I - P_b : X_s \to \widetilde{X}_s$ is an isomorphism we get the property

$$a_h(\widetilde{v}_s, v_b) = 0 \qquad \forall \widetilde{v}_s \in \widetilde{X}_s\,,\ v_b \in V_b\,, \tag{4.4}$$

which says that the subspaces $\widetilde{X}_s$ and V_b satisfy a certain orthogonality condition. This property is important for the decomposition of the Oseen problem (2.9) into smaller subproblems which will be described in the following.

If we insert the splitting $u_h = \widetilde{u}_s + u_b$ into the first equation of (2.9) and take the test function $v_h = v_b \in V_b \subset X_{h,0}$ we get, by means of $b(v_b, p_h) = 0$ and (4.4), the following problem for u_b:

$u_b \in V_b$:

$$a_h(u_b, v_b) = f_h(v_b) \qquad \forall v_b \in V_b\,. \tag{4.5}$$

That means that the element bubble part u_b of the solution u_h can be computed independently from the remaining part $\widetilde{u}_s$. Moreover, this computation can be done separately on each element $K \in \mathcal{T}_h$ inside of the assembling process of the stiffness matrix. If the basis functions $\psi_j = \widetilde{\varphi}_j$, $j \in \widetilde{J}_b(K)$, of V_b are available, the part of the u_b-problem (4.5) on element K can be calculated by solving the equivalent $\widetilde{n}_b(K) \times \widetilde{n}_b(K)$ linear system of equations where $\widetilde{n}_b(K) := \dim(X_b(K)) - \dim(\widetilde{M}_h(K))$. In the special case that the space X_h corresponds to conforming $\mathbb{Q}_2$-elements and M_h corresponds to discontinuous $\mathbb{P}_1$ elements, nothing is to do for solving (4.5) since $V_b = \{0\}$ and $u_b = 0$. If the basis functions ψ_j of V_b are not available, we can compute the part $u_b^K \in X_b(K)$ on an element K of $u_b = \sum_{K \in \mathcal{T}_h} u_b^K \in X_b$ corresponding to the splitting (3.18) by solving the mixed local problem associated to (4.5):

$(u_b^K, \theta^K) \in X_b(K) \times \widetilde{M}_h(K)$:

$$\begin{array}{lcll} a_h(u_b^K, v_h) + b(v_h, \theta^K) & = & f_h(v_h) & \forall\, v_h \in X_b(K)\,, \\ b(u_b^K, q_h) & = & 0 & \forall\, q_h \in \widetilde{M}_h(K)\,. \end{array} \tag{4.6}$$

Now, we want to derive the problem for the part $\widetilde{u}_s$ of the solution u_h. Due to the decomposition (3.8) of the pressure space $M_{h,0}$ the pressure solution p_h can be uniquely split in the form $p_h = \overline{p}_h + \widetilde{p}_h$ with $\overline{p}_h \in \overline{M}_{h,0}$ and $\widetilde{p}_h \in \widetilde{M}_h$. If we take in (2.9) the test functions $v_h = \widetilde{v}_s \in \widetilde{X}_{s,0} = \widetilde{X}_s \cap X_0 \subset X_{h,0}$ and $q_h = \overline{q}_h \in \overline{M}_{h,0} \subset M_{h,0}$ and if we use the properties $b(\widetilde{v}_s, \widetilde{p}_h) = 0$ and $b(u_b, \overline{q}_h) = 0$ we get the following for $\widetilde{u}_s$ and $\overline{p}_h$:

$(\widetilde{u}_s, \overline{p}_h) \in (\widetilde{g}_h + \widetilde{X}_{s,0}) \times \overline{M}_{h,0}$:

$$\begin{array}{lcll} a_h(\widetilde{u}_s, \widetilde{v}_s) + b(\widetilde{v}_s, \overline{p}_h) & = & f_h(\widetilde{v}_s) - a_h(u_b, \widetilde{v}_s) & \forall\, \widetilde{v}_s \in \widetilde{X}_{s,0}\,, \\ b(\widetilde{u}_s, \overline{q}_h) & = & 0 & \forall\, \overline{q}_h \in \overline{M}_{h,0}\,. \end{array} \tag{4.7}$$

THEOREM 4.1. $a_h(\cdot,\cdot)$ $C_1 = C_1(\nu, \beta)$ $C_2 = C_2(\nu, \beta)$

$$a_h(v_h, v_h) \geq C_1 |v_h|_{1,\Omega}^2 \qquad \forall\, v_h \in X_{h,0}\,, \tag{4.8}$$

$$a_h(v_h, w_h) \leq C_2 |v_h|_{1,\Omega} |w_h|_{1,\Omega} \qquad \forall\, v_h, w_h \in X_h. \tag{4.9}$$

(4.6) (4.7) $(u_b^K, \theta^K) \in X_b(K) \times \widetilde{M}_h(K)$ $K \in \mathcal{T}_h$ $(\widetilde{u}_s, \overline{p}_h) \in (\widetilde{g}_h + \widetilde{X}_{s,0}) \times \overline{M}_{h,0}$ $u_h \in \widetilde{g}_h + \widetilde{X}_{h,0}$ (2.9) (4.2)

$$u_h = \widetilde{u}_s + \sum_{K \in \mathcal{T}_h} u_b^K \in \widetilde{g}_h + X_{h,0}\,. \tag{4.10}$$

[illegible] $p_h \in M_{h,0}$ [illegible] (2.9) [illegible] $p_h = \overline{p}_h + \widetilde{p}_h$ [illegible] $\overline{p}_h \in \overline{M}_{h,0}$ [illegible] (4.7) [illegible] $\widetilde{p}_h = \sum_{K \in \mathcal{T}_h} \widetilde{p}_h^K \in \widetilde{M}_h$ [illegible] $\widetilde{p}_h^K \in \widetilde{M}_h(K)$ [illegible]

Find $\widetilde{p}_h^K \in \widetilde{M}_h(K)$ such that

$$b(v_b, \widetilde{p}_h^K) = f_h(v_b) - a_h(u_h, v_b) \qquad \forall\, v_b \in X_b(K)\,. \tag{4.11}$$

[illegible] $K \in \mathcal{T}_h$ [illegible] (4.11) [illegible] $\widetilde{p}_h^K \in \widetilde{M}_h(K)$ [illegible] $(u_h, \overline{p}_h)$ [illegible] (4.2) [illegible]

[illegible]. Due to the assumption (2.6) and the fact that $X_b(K) = X_{h,0}(K)$, the spaces $(X_b(K), \widetilde{M}_h(K))$ fulfill the inf-sup condition. Moreover, since $X_b(K) \subset X_{h,0}$, the bilinear form $a_h(\cdot,\cdot)$ is coercive on $X_b(K) \times X_b(K)$. Therefore, the mixed problem (4.6) has a unique solution (u_b^K, θ^K) for each $K \in \mathcal{T}_h$.

In the following, we will show that the pair $(\widetilde{X}_{s,0}, \overline{M}_{h,0})$ satisfies the inf-sup condition. We will restrict the presentation to the case of quadrilateral or hexahedral elements where the velocity space is defined by (2.5) with $\mathbb{U}_r(\widehat{K}) = \mathbb{Q}_r(\widehat{K})$. In [17, Lemma 7], it is proved that, for each $q_h \in \overline{M}_{h,0}$, there exists a $\bar{v}_h \in \bar{X}_h$ such that

$$b(\bar{v}_h, q_h) \geq \bar{\beta}_1 |\bar{v}_h|_{1,\Omega} \|q_h\|_{0,\Omega}\,, \tag{4.12}$$

where $\bar{\beta}_1$ is a positive h-independent constant and $\bar{X}_h \subset X_0$ is a space that consists of vector-valued Q_1-functions enriched with special Q_2-functions associated with the element faces. Since the space $\bar{X}_h$ does not contain any bubble functions of X_b we have, due to $r \geq 2$, that $\bar{X}_h \subset X_{s,0}$. Thus, it holds $\bar{v}_h \in X_{s,0}$ which implies that $v_h := \bar{v}_h - P_b \bar{v}_h \in \widetilde{X}_{s,0}$. Since $P_b \bar{v}_h \in X_b$, the functions $\bar{v}_h$ and v_h coincide on each element face $E \in \mathcal{E}_h$. Therefore, for each piecewise constant $q_h \in \overline{M}_{h,0}$, it holds that

$$b(\bar{v}_h, q_h) = -\sum_{K \in \mathcal{T}_h} \left\{ q_h\big|_K \sum_{E \in \mathcal{E}(K)} \left\langle\, \bar{v}_h, n_E^K \,\right\rangle_E \right\} = b(v_h, q_h)\,. \tag{4.13}$$

If we apply Proposition II.1.3 of [4] to the solution $P_b^K w = P_b w\big|_K$ of the mixed problem (3.20), we get by means of (4.8) and (4.9) the estimate

$$|P_b w|_{1,K} \leq C_3 |w|_{1,K} \qquad \forall\, w \in X_h\,,\ \forall\, K \in \mathcal{T}_h\,, \tag{4.14}$$

where $C_3 := (C_2/C_1 + 1)\sqrt{d}/\beta_0 + C_2/C_1$ is a constant independent of K and β_0 the local inf-sup-constant in (2.6). Now, we conclude from (4.14) that

$$|v_h|_{1,\Omega} = |\bar{v}_h - P_b \bar{v}_h|_{1,\Omega} \leq (1 + C_3) |\bar{v}_h|_{1,\Omega}\,,$$

which implies by means of (4.12) and (4.13)

$$b(v_h, q_h) = b(\bar{v}_h, q_h) \geq \bar{\beta}_1 |\bar{v}_h|_{1,\Omega} \|q_h\|_{0,\Omega} \geq \frac{\bar{\beta}_1}{1 + C_3} |v_h|_{1,\Omega} \|q_h\|_{0,\Omega}\,,$$

i.e., the spaces $(\widetilde{X}_{s,0}, \overline{M}_{h,0})$ satisfy the inf-sup condition. In the case of simplicial elements, where the local space $\mathbb{U}_r(\widehat{K})$ of the velocity is a suitable enrichment of the space $\mathbb{P}_r(\widehat{K})$, the inf-sup condition can be proved analogously with an auxiliary space

$\bar{X}_h$ that consists of P_1-functions and special face bubble functions (see (2.3) and (2.32) in sect. II.2 of [7]).

Due to assumptions (4.8) and (4.9), the bilinear form $a_h(\cdot,\cdot)$ is coercive and continuous also on $\widetilde{X}_{s,0} \times \widetilde{X}_{s,0}$. Thus, the inf-sup condition for the spaces $(\widetilde{X}_{s,0}, \overline{M}_{h,0})$ implies that the reduced Oseen problem (4.7) has a unique solution $(\widetilde{u}_s, \overline{p}_h)$.

Now, let $\widetilde{u}_s$ and $u_b = \sum_{K\in\mathcal{T}_h} u_b^K$ be the unique solutions of (4.7) and (4.5), respectively. Further, let $\overline{p}_h$ and $\widetilde{p}_h = \sum_{K\in\mathcal{T}_h} \widetilde{p}_h^K$ be the unique solutions of (4.7) and (4.11), respectively. Note that the unique solvability of (4.11) follows from the assumption (2.6) that the local spaces $X_b(K) = X_{h,0}(K)$ and $\widetilde{M}_h(K)$ fulfill the inf-sup condition. In the following, we will show that $u_h := \widetilde{u}_s + u_b$ and $p_h := \overline{p}_h + \widetilde{p}_h$ are the solutions of the original Oseen problem (2.9). Let v_b be an arbitrary element of V_b. Then, from $a_h(\widetilde{u}_s, v_b) = 0$, see (4.4), $b(v_b, p_h) = 0$ and (4.5) we get

$$a_h(u_h, v_b) + b(v_b, p_h) = f_h(v_b) \qquad \forall\, v_b \in V_b\,. \tag{4.15}$$

Using $a_h(\widetilde{v}_s, u_b) = 0$, $b(\widetilde{v}_s, \widetilde{p}_h) = 0$ and the first equation of (4.7) we obtain

$$a_h(u_h, \widetilde{v}_s) + b(\widetilde{v}_s, p_h) = f_h(\widetilde{v}_s) \qquad \forall\, \widetilde{v}_s \in \widetilde{X}_{s,0}\,. \tag{4.16}$$

The decomposition $\widetilde{X}_h = \widetilde{X}_s \oplus V_b$ and (4.15) and (4.16) yield

$$a_h(u_h, \widetilde{v}_h) + b(\widetilde{v}_h, p_h) = f_h(\widetilde{v}_h) \qquad \forall\, \widetilde{v}_h \in \widetilde{X}_{h,0}\,. \tag{4.17}$$

The equations (4.11) and $b(v_b, \overline{p}_h) = 0$ imply that

$$a_h(u_h, v_b) + b(v_b, p_h) = f_h(v_b) \qquad \forall\, v_b \in X_b(K)\,. \tag{4.18}$$

Due to the decomposition (3.18) of X_b, (4.18) also holds for an arbitrary $v_b \in X_b$. Thus, it follows that u_h and p_h satisfy the first equation of the Oseen problem (2.9). From the second equation of (4.7) we get with $b(u_b, \overline{q}_h) = 0$ the equation

$$b(u_h, \overline{q}_h) = 0 \qquad \forall \overline{q}_h \in \overline{M}_{h,0}\,.$$

By definition we have $\widetilde{u}_s \in \widetilde{X}_s \subset \widetilde{X}_h$ and $u_b \in V_b \subset \widetilde{X}_h$ which implies $u_h \in \widetilde{X}_h$, i.e.,

$$b(u_h, \widetilde{q}_h) = 0 \qquad \forall \widetilde{q}_h \in \widetilde{M}_h\,.$$

Thus, from the decomposition $M_{h,0} = \overline{M}_{h,0} \oplus \widetilde{M}_h$ it follows that u_h fulfills also the second equation of the Oseen problem (2.9). This proves the representations of u_h and p_h since problem (2.9) has a unique solution.

If we take in (2.9) the test functions $v_h \in \widetilde{X}_{h,0}$ and $q_h \in \overline{M}_{h,0}$ we easily see that $(u_h, \overline{p}_h)$ is a solution of (4.2). The inf-sup condition for the pair $(\widetilde{X}_{h,0}, \overline{M}_{h,0})$ follows immediately from the inf-sup condition for $(\widetilde{X}_{s,0}, \overline{M}_{h,0})$. This implies that the problem (4.2) has a unique solution which completes the proof of Theorem 4.1. □

REMARK 4.2. The assumptions (4.8) and (4.9) in Theorem 4.1 are satisfied if $\operatorname{div}\beta = 0$ and the Galerkin discretization is used, i.e., if the bilinear form $a_h(\cdot,\cdot)$ is identical to $a(\cdot,\cdot)$. In the case, where $a_h(\cdot,\cdot)$ is derived from a streamline diffusion stabilization method, these assumptions are discussed, e.g., in [6].

In the following, we analyze the structure of the QDF formulation (4.2) of the Oseen problem by exploiting the fact that the space $\widetilde{X}_h$ can be decomposed in the

direct sum $\widetilde{X}_h = V_b \oplus V_s \oplus \widetilde{X}_f$; see (3.43). The solution u_h of (4.2) can be decomposed as

$$u_h = \widetilde{g}_h + u_{h,0} \qquad \text{with} \qquad u_{h,0} \in \widetilde{X}_{h,0} = \operatorname{span}\{\psi_j : j \in \widetilde{J}_0\}, \quad \widetilde{J}_0 := \widetilde{J} \setminus J(\Gamma),$$

where $\widetilde{J} = \widetilde{J}_b \cup J_s$; see (3.31). By the disjoint decomposition (3.38) of the index set $J_s = \widetilde{J}_s \cup J_f$ the following disjoint decomposition of the index set $\widetilde{J}_0$ is induced:

$$\widetilde{J}_0 = \widetilde{J}_b \cup \widetilde{J}_{s,0} \cup J_{f,0} \qquad \text{with} \qquad \widetilde{J}_{s,0} := \widetilde{J}_s \setminus J(\Gamma) \quad J_{f,0} := J_f \setminus J(\Gamma).$$

Using this decomposition, the coefficient vector $\underline{u}^{h,0} = (u_j^{h,0})$ of $u_{h,0} = \sum_{j \in \mathcal{J}_0} u_j^{h,0} \psi_j$ can be partitioned into the two block vectors

$$\underline{u}^{h,0} = \begin{pmatrix} \underline{u}^{n,0} \\ \underline{u}^{f,0} \end{pmatrix} \qquad \text{with} \qquad \underline{u}^{n,0} := (u_j^{h,0})_{j \in \mathcal{J}_b \cup \mathcal{J}_{s,0}}, \quad \underline{u}^{f,0} := (u_j^{h,0})_{j \in J_{f,0}}.$$

Let $\overline{I}$ be the index set of the elements $K \in \mathcal{T}_h$ such that $\mathcal{T}_h = \{K_i : i \in \overline{I}\}$. Then, the piecewise constant pressure solution $\overline{p}_h$ of (4.7) corresponds to the coefficient vector $\underline{p}$ with

$$\underline{p} := (p_i)_{i \in \overline{I}} \in \mathbb{R}^{\operatorname{card}(\overline{I})}, \qquad \text{where} \qquad \overline{p}_h = \sum_{i \in \overline{I}} p_i \chi_0^{K_i}.$$

Here, $\chi_0^{K_i}$ denotes the function in $\overline{M}_h$ which is 1 on K_i and 0 otherwise. Due to the fact that $\psi_j \in V_h$ for all nonflux nodes $j \in \widetilde{J}_b \cup \widetilde{J}_{s,0}$, the QDF formulation (4.2) corresponds to a block system of the following structure:

$$\begin{pmatrix} A^{nn} & A^{nf} & 0 \\ A^{fn} & A^{ff} & (B^f)^T \\ 0 & B^f & 0 \end{pmatrix} \begin{pmatrix} \underline{u}^{n,0} \\ \underline{u}^{f,0} \\ \underline{p} \end{pmatrix} = \begin{pmatrix} \underline{r}^{n,0} \\ \underline{r}^{f,0} \\ \underline{s} \end{pmatrix}. \tag{4.19}$$

We see that only the QDF basis functions ψ_j for flux nodes $j \in J_{f,0}$ are coupled with the piecewise constant pressure. In contrast to the original basis functions, this is an important computational advantage for the construction of cheap block Gauss–Seidel smoothers since the structure of (4.19) allows, in principle, to apply a point Gauss–Seidel smoother for all nonflux nodes $j \in \widetilde{J}_0 \setminus J_{f,0}$. Moreover, the number of flux nodes is equal to the number of faces $E \in \mathcal{E}_h$ which is small compared to the total number of velocity unknowns in (4.19), in particular, in the case of higher order finite elements. That means that in the algebraic system (4.19) generated by means of the QDF basis functions most of the velocity unknowns are decoupled from the pressure unknowns.

5. Implementation aspects.

5.1. Generation of the QDF basis functions. Within a numerical code it is not necessary to have explicit formulas for the modified QDF basis functions ψ_j. It suffices to know how one can obtain these functions by linear combinations of standard Lagrange basis functions.

First we will have a look at the element bubble correction operator P_b which is defined locally by (3.20). Using the standard bases $\{\varphi_j : j \in J(K)\}$ and $\{\chi_i : i \in \widetilde{I}(K)\}$ for the local velocity and pressure spaces $X_h(K)$ and $\widetilde{M}_h(K)$, respectively,

problem (3.20) for $w = \varphi_j$, $j \in J_s(K)$, is equivalent to the following system of linear equations:

$$\begin{pmatrix} A^K & (B^K)^T \\ B^K & 0 \end{pmatrix} \begin{pmatrix} \underline{c}_j^K \\ \underline{d}_j^K \end{pmatrix} = \begin{pmatrix} \underline{r}_j^K \\ \underline{s}_j^K \end{pmatrix} \tag{5.1}$$

with

$$\begin{aligned} (A^K)_{i,k} &:= a_h(\varphi_k, \varphi_i), \quad i,k \in J_b(K), \qquad B^K \text{ defined by (3.26)}, \\ (\underline{r}_j)_i &:= a_h(\varphi_j, \varphi_i), \quad i \in J_b(K), \qquad (\underline{s}_j)_i := b(\varphi_j, \chi_i), \quad i \in \widetilde{I}(K). \end{aligned}$$

We see that everything which we need to generate the above system is computed during the usual local assembling process of element stiffness matrices. From the solution vector $\underline{c}_j^K = (c_{j,i}^K) \in \mathbb{R}^{\mathrm{card}(J_b(K))}$ of the linear system (5.1) we get the following representation of the local part $P_b^K \varphi_j$ of the projection $P_b \varphi_j$ on element K:

$$P_b^K \varphi_j = \sum_{i \in J_b(K)} c_{j,i}^K \varphi_i, \qquad j \in J_s(K). \tag{5.2}$$

In order to be able to reconstruct the modified local functions $\widetilde{\varphi}_j\big|_K = \varphi_j\big|_K - P_b^K \varphi_j$, $j \in J_s(K)$, we store the coefficients $c_{j,i}^K$. The required storage for this is less than the memory in the original finite element method for storing the matrix entries $a_h(\varphi_j, \varphi_i)$ with $j \in J_s(K)$, $i \in J_b(K)$, which are no longer needed in the new method using the QDF basis.

Now we will describe how the action of the operator P_f defined in (3.40) can be implemented. For a basis function φ_j, which corresponds to the nodal point a_j, we have that $\varphi_j|_E \equiv \widetilde{\varphi}_j|_E \equiv 0$ for all faces $E \in \mathcal{E}_h$ with $a_j \notin \overline{E}$. Hence, the sum in (3.40) for $w = \widetilde{\varphi}_j$ reduces to a small sum over those faces E with

$$E \in \mathcal{E}_h(j) := \{E \in \mathcal{E}_h : a_j \in \overline{E}\}. \tag{5.3}$$

Then, the function $\psi_j = \widetilde{\varphi}_j - P_f \widetilde{\varphi}_j$, $j \in J_s(K) \setminus J_f(K)$, defined in (3.42), can be written as

$$\psi_j = \widetilde{\varphi}_j - \sum_{E \in \mathcal{E}_h(j)} \alpha_{j,E}\, \widetilde{\varphi}_{j_f(E)} \quad \text{with} \quad \alpha_{j,E} := \frac{\langle \varphi_j, n_E \rangle_E}{\langle \varphi_E, n_E \rangle_E}, \tag{5.4}$$

where we have used that φ_j and $\widetilde{\varphi}_j$ coincide on all $E \in \mathcal{E}_h$. For each face $E \in \mathcal{E}_h$, we store the coefficients $\alpha_{j,E}$ for all nodes j belonging to the closure of E, i.e., for all $j \in J(E)$ with

$$J(E) := \{j \in J : a_j \in \overline{E}\}, \tag{5.5}$$

where $\alpha_{j,E}$ is defined by (5.4) if $j \in J_s \setminus J_f$ and by

$$\alpha_{j,E} := \langle \varphi_j, n_E \rangle_E \qquad \text{if} \qquad j = j_f(E) \in J(E) \cap J_f\,.$$

This is useful since for $j = j_f(E) \in J_f$ we have $\psi_j = \widetilde{\varphi}_j$ and

$$\alpha_{j,E} = \langle \varphi_j, n^{K(E)} \rangle_{\partial K(E)} = \langle \psi_j, n^{K(E)} \rangle_{\partial K(E)} = \begin{cases} -b(\psi_j, \chi_0^K) & \text{if} \quad K = K(E) \\ +b(\psi_j, \chi_0^K) & \text{if} \quad K = K'(E), \end{cases}$$

where $K(E)$ and $K'(E)$ denote the two elements associated with the face E (see section 2) and $\chi_0^K \in \overline{M}_h$ is the function which is 1 on K and 0 on $\Omega \setminus K$. In the algebraic system, which is equivalent to the reduced Oseen problem (4.7), we need, for each velocity node $j \in J_s$, the matrix entries $b(\psi_j, \chi_0^K)$ for all $K \in \mathcal{T}_h$. Note that it is a common practice that the functions χ_0^K, which are not in $\overline{M}_{h,0}$, are used as a basis of the larger pressure space $\overline{M}_h$ and that the condition $\overline{p}_h \in \overline{M}_{h,0} = \overline{M}_h \cap L_0^2(\Omega)$ is realized within the discrete solver by subtracting a suitable global constant from the pressure approximation. Now, using that $\psi_j \in V_h$ for all $j \in \widetilde{J}_s = J_s \setminus J_f$, we get

$$b(\psi_j, \chi_0^K) = 0 \qquad \forall j \in J_s \setminus J_f\,,\ K \in \mathcal{T}_h\,,$$

i.e., the matrix entry $b(\psi_j, \chi_0^K)$ can be nonzero only if $j \in J_f(K)$. Therefore, if we store the coefficients $\alpha_{j,E} = \pm b(\psi_j, \chi_0^K)$ for $j = j_f(E) \in J_f(K)$, $E \in \mathcal{E}(K)$, then it is no longer necessary to store any matrix entries associated with the bilinear form $b(\cdot,\cdot)$. The memory required for storing the $\alpha_{j,E}$ is approximately equal to the memory that becomes free from the matrix entries of the bilinear form $b(\cdot,\cdot)$.

Now we consider the linear algebraic system which corresponds to the reduced Oseen problem (4.7) by using the new QDF basis $\{\psi_j : j \in J_s\}$ for $\widetilde{X}_s$ and the basis $\{\chi_0^K : K \in \mathcal{T}_h\}$ for $\overline{M}_h$. Using the stored coefficients $\alpha_{j,E}$ and $c_{j,i}^K$, this system is easily generated by means of linear combinations of rows and columns of the element stiffness matrices of the original finite element method. For example, the entries of the global stiffness matrix $\overline{A} = (\overline{A}_{i,j})$ with $\overline{A}_{i,j} := a_h(\psi_j, \psi_i)$ are assembled in an elementwise fashion as

$$\overline{A}_{i,j} = \sum_{K \in \mathcal{T}_h} \overline{A}_{i,j}^K \qquad \text{with} \qquad \overline{A}_{i,j}^K := a_K(\psi_j, \psi_i)\,,$$

where $a_K(\cdot,\cdot)$ denotes the additive part of $a_h(\cdot,\cdot)$ associated with the element K. The modified element matrix entries $\overline{A}_{i,j}^K$ are computed from the original entries $A_{i,j}^K := a_K(\varphi_j, \varphi_i)$ in the following way. Using the representation (5.4) of the QDF basis functions ψ_j restricted to an element K, we have for nonflux nodes $i, j \in J_s \setminus J_f$,

$$\begin{aligned}\overline{A}_{i,j}^K = a_K(\widetilde{\varphi}_j, \widetilde{\varphi}_i) &- \sum_{E \in \mathcal{E}_h^K(j)} \alpha_{j,E}\, a_K(\widetilde{\varphi}_{j_f(E)}, \widetilde{\varphi}_i) - \sum_{F \in \mathcal{E}_h^K(i)} \alpha_{i,F}\, a_K(\widetilde{\varphi}_j, \widetilde{\varphi}_{j_f(F)}) \\ &+ \sum_{E \in \mathcal{E}_h^K(j)} \sum_{F \in \mathcal{E}_h^K(i)} \alpha_{j,E}\, \alpha_{i,F}\, a_K(\widetilde{\varphi}_{j_f(E)}, \widetilde{\varphi}_{j_f(F)}),\end{aligned}$$

where $\mathcal{E}_h^K(j) := \{E \in \mathcal{E}(K) : a_j \in \overline{E}\}$ denotes the set of those faces of element K that are associated with the nodal point a_j.

In a similar way, one can compute in a previous step the needed intermediate matrix entries $\widetilde{A}_{i,j}^K := a_K(\widetilde{\varphi}_j, \widetilde{\varphi}_i)$ by linear combinations of the entries $A_{i,j}^K = a_K(\varphi_j, \varphi_i)$ of the original element stiffness matrix using the stored coefficients $c_{j,i}^K$.

Remark 5.1. The memory for storing the nonzero matrix entries $\overline{A}_{i,j}$ is the same as for storing the nonzero entries $A_{i,j}$, $i, j \in J_s$, of the original global stiffness matrix which are no longer needed for solving the reduced Oseen problem (4.7). Moreover, the additional work to compute the element matrix entries $\overline{A}_{i,j}^K$ from the original entries $A_{i,j}^K$ is only proportional to the number of velocity unknowns due to the local support of the QDF basis functions.

5.2. Computation of $\widetilde{p}_h$. In the following, we want to discuss how the pressure part $\widetilde{p}_h \in \widetilde{M}_h$ of the pressure solution $p_h = \overline{p}_h + \widetilde{p}_h$ given in Theorem 4.1 can be determined in practice if the parts $\widetilde{u}_s$ and $u_b = \sum_{K\in\mathcal{T}_h} u_b^K$ of the velocity solution $u_h = \widetilde{u}_s + u_b$ have been already computed. From Theorem 4.1 we know that $\widetilde{p}_h$ can be decomposed elementwise as $\widetilde{p}_h = \sum_{K\in\mathcal{T}_h} \widetilde{p}_h^K$, where $\widetilde{p}_h^K \in \widetilde{M}_h(K)$ is the unique solution of the local problem (4.11). There are two ways to solve this problem. The first one is to solve for the coefficient vector $\underline{\widetilde{p}}^K$ of $\widetilde{p}_h^K$ the linear algebraic system that corresponds to (4.11). The structure of this system is

$$\left(B^K\right)^T \underline{\widetilde{p}}^K = \underline{z}^K, \tag{5.6}$$

where

$$\begin{aligned} &\left(B^K\right)^T \in \mathbb{R}^{\dim(X_b(K))\times\dim(\widetilde{M}_h(K))}, \quad \underline{\widetilde{p}}^K \in \mathbb{R}^{\dim(\widetilde{M}_h(K))}, \\ &\underline{z}^K = (z_j^K) \in \mathbb{R}^{\dim(X_b(K))} \quad \text{with} \qquad z_j^K := f_h(\varphi_j) - a_K(u_h,\varphi_j) \qquad \forall j \in J_b(K). \end{aligned}$$

For the definition of the matrix B^K, see (3.26). Since (4.11) has a unique solution (see Theorem 4.1) and (5.6) is equivalent to (4.11) it follows that $\ker((B^K)^T)=\{0\}$. Therefore, the symmetric matrix $B^K(B^K)^T$ is regular and $\underline{\widetilde{p}}^K$ can be computed by solving the linear system

$$B^K(B^K)^T\underline{\widetilde{p}}^K = B^K\underline{z}^K. \tag{5.7}$$

The disadvantage of this approach is that the local element matrices, which are needed to generate the systems (5.7) for all elements $K \in \mathcal{T}_h$, have to be assembled again since they are not stored inside of our new multigrid method for the reduced Oseen problem (4.7).

The second approach for computing $\widetilde{p}_h^K \in \widetilde{M}_h(K)$ uses the local pressure solutions $\theta^K \in \widetilde{M}_h(K)$ of the local Oseen problem (4.6) and $\theta_j^K := Q_b^K\varphi_j \in \widetilde{M}_h(K)$, $j \in J_s(K)$, of problem (3.20) with $w = \varphi_j$. The algebraic systems equivalent to these local Oseen problems have to be solved anyway by means of a direct solver in order to generate the QDF basis functions for the velocity. Thus, the coefficient vectors of θ^K and θ_j^K are available for free. For our second approach, we assume that these coefficient vectors will be stored. The required storage for this is less than the memory that becomes free from the matrix entries $b(\varphi_j,\chi_i)$, $j \in J_s(K)$, $i \in \widetilde{I}(K)$, and the right-hand side components $-b(\widetilde{g}_h,\chi_i)$, $i \in \widetilde{I}(K)$, which are no longer needed for our new method relying on QDF basis functions. Now, let us assume that the local representation of the computed solution $\widetilde{u}_s \in \widetilde{X}_s$ of the reduced Oseen problem (4.7) on an element $K \in \mathcal{T}_h$ is given by means of coefficients $\widetilde{u}_j \in \mathbb{R}$ as follows:

$$\widetilde{u}_s(x) = \sum_{j\in J_s(K)} \widetilde{u}_j\psi_j(x) \qquad \forall\, x \in K.$$

Applying the definition (3.42) of the ψ_j and (5.4), we can represent $\widetilde{u}_s$ in the form

$$\widetilde{u}_s(x) = \sum_{j\in J_s(K)} u_j\widetilde{\varphi}_j(x) \qquad \forall\, x \in K$$

using the basis functions $\widetilde{\varphi}_j \in \widetilde{X}_s$ defined by (3.21) and coefficients $u_j \in \mathbb{R}$ defined as $u_j := \widetilde{u}_j$ if $j \in J_s(K)\setminus J_f(K)$ and $u_j := \widetilde{u}_j - \sum_{i\in J(E)\setminus\{j\}} \alpha_{i,E}\widetilde{u}_i$ if $j = j_f(E) \in J_f(K)$.

From the definition of $\widetilde{\varphi}_j\big|_K = \varphi_j\big|_K - P_b^K\varphi_j$ and $\theta_j^K := Q_b^K\varphi_j$ in (3.20), it follows that

$$b(v_b, \theta_j^K) = a_h(\widetilde{\varphi}_j, v_b) \qquad \forall v_b \in X_b(K).$$

Using the definition of θ^K in (4.6) we obtain that the pressure function $\widetilde{p}_h^K$ defined by

$$\widetilde{p}_h^K := \theta^K - \sum_{j\in J_s(K)} u_j\theta_j^K \tag{5.8}$$

is the unique solution of (4.11). This shows that we can calculate $\widetilde{p}_h^K$ by the cheap computation of the coefficients u_j from the coefficients $\widetilde{u}_j$ of the QDF basis representation of $\widetilde{u}_s$ if we invest the memory to store the coefficients that represent the pressure functions θ^K and θ_j^K.

5.3. Transformation of basis representations. In this subsection, we will describe two operators which allow one to switch from the basis representation of a function in $\widetilde{X}_h = \operatorname{span}\{\psi_j : j \in \widetilde{J}\}$ to the one in $X_h = \operatorname{span}\{\varphi_j : j \in J\}$ and vice versa. Let $N := \operatorname{card}(J)$ and $\widetilde{N} := \operatorname{card}(\widetilde{J})$. By the finite element isomorphism a function $v_h \in \widetilde{X}_h \subset X_h$ is uniquely associated with a coefficient vector $\underline{\widetilde{v}} = (\widetilde{v}_j) \in \mathbb{R}^{\widetilde{\mathcal{N}}}$ such that $v_h = \sum_{j\in\widetilde{\mathcal{P}}} \widetilde{v}_j\psi_j$. Thus, using (3.42) and (5.4), we have

$$v_h = \sum_{j\in\widetilde{\mathcal{P}}_s} \widetilde{v}_j\big(\widetilde{\varphi}_j - P_f\varphi_j\big) + \sum_{j\in\widetilde{\mathcal{P}}_b\cup J_f} \widetilde{v}_j\widetilde{\varphi}_j = \sum_{j\in\mathcal{P}} v_j^*\widetilde{\varphi}_j$$

with coefficients v_j^* defined by

$$v_j^* := \begin{cases} \widetilde{v}_j & \text{if} \quad j \in \widetilde{J}_s \cup \widetilde{J}_b, \\ \widetilde{v}_j - \displaystyle\sum_{i\in J(E)\setminus\{j\}} \alpha_{i,E}\widetilde{v}_i & \text{if} \quad j = j_f(E) \in J_f. \end{cases} \tag{5.9}$$

Now, from $\widetilde{J} = J_s \cup \widetilde{J}_b$ and the representation (3.27) of $\widetilde{\varphi}_j$ for $j \in \widetilde{J}_b$ we get

$$v_h = \sum_{j\in\mathcal{P}} v_j^*\widetilde{\varphi}_j = \sum_{j\in J_s} v_j^*\big(\varphi_j - P_b\varphi_j\big) + \sum_{K\in\mathcal{T}_h} \sum_{j\in\tilde{J}_b(K)} v_j^* \sum_{i\in J_b(K)} c_{j,i}^K\varphi_i.$$

Using the local representation (5.2) of $P_b\varphi_j$ for $j \in J_s$, we obtain the following basis representation of $v_h = \sum_{j\in\widetilde{\mathcal{P}}} \widetilde{v}_j\psi_j \in \widetilde{X}_h$ by means of the original basis $\{\varphi_j : j \in J\}$ of X_h:

$$v_h = \sum_{j\in J} v_j\varphi_j \qquad \text{with} \qquad v_j := \begin{cases} v_j^* & \text{if} \quad j \in J_s, \\ \displaystyle\sum_{i\in\mathcal{P}_b(K)} c_{i,j}^K v_i^* - \sum_{i\in J_s(K)} c_{i,j}^K v_i^* & \text{if} \quad j \in J_b(K). \end{cases} \tag{5.10}$$

Obviously, the mapping that assigns the coefficient vector $\underline{v}$ of the original basis representation to the coefficient vector $\underline{\widetilde{v}}$ of the QDF basis representation of a function $v_h \in \widetilde{X}_h$ is linear, i.e., there is a linear operator $\Pi : \mathbb{R}^{\mathcal{N}} \to \mathbb{R}^N$ such that

$$v_h = \sum_{j\in\widetilde{\mathcal{P}}} (\underline{\widetilde{v}})_j\psi_j = \sum_{j\in J} (\Pi\underline{\widetilde{v}})_j\varphi_j \ \in \ \widetilde{X}_h \qquad \forall\, \underline{\widetilde{v}} \in \mathbb{R}^{\widetilde{\mathcal{N}}}. \tag{5.11}$$

At the end of this section we want to construct for a given function $v_h = \sum_{j\in J} v_j\varphi_j \in X_h$ a suitable QDF approximation $\widetilde{v}_h = \sum_{j\in\mathcal{F}} \widetilde{v}_j\psi_j \in \widetilde{X}_h \subset X_h$ which will be used later on during the prolongation in the multigrid method. Using the decomposition $X_h = X_s \oplus X_b$ we can write any function $v_h \in X_h$ uniquely in the form

$$v_h = v_s + v_b, \qquad \text{with} \qquad v_s = \sum_{j\in J_s} v_j\varphi_j \in X_s, \quad v_b = \sum_{j\in J_b} v_j\varphi_j \in X_b.$$

Since the projector $I - P_b$ maps from X_s into the space $\widetilde{X}_s \subset \widetilde{X}_h$, a natural approximation of the part v_s of v_h is the function $\widetilde{v}_s$ with

$$\widetilde{v}_s := (I - P_b)v_s = \sum_{j\in J_s} v_j\widetilde{\varphi}_j \in \widetilde{X}_s.$$

Therefore, we have

$$v_h = \widetilde{v}_s + w_b \qquad \text{with} \qquad w_b := v_b + P_b v_s \ \in \ X_b,$$

which is, due to the decomposition $X_h = \widetilde{X}_s \oplus X_b$ (see (3.33)), the unique splitting of v_h into a function $\widetilde{v}_s \in \widetilde{X}_s$ and a function $w_b \in X_b$. Thus, the decomposition $\widetilde{X}_h = \widetilde{X}_s \oplus V_b$ (see (3.32)) suggests to define the approximation $\widetilde{v}_h \in \widetilde{X}_h$ of v_h as

$$\widetilde{v}_h := \widetilde{v}_s + \widetilde{w}_b \qquad \text{with} \qquad \widetilde{w}_b := L_b w_b \in V_b\,, \tag{5.12}$$

where $L_b : X_b \to V_b$ is a suitable projection operator. Using the elementwise decomposition of X_b (see (3.18)), we have

$$w_b = \sum_{K\in\mathcal{T}_h} w_b^K \qquad \text{with} \qquad w_b^K = \sum_{j\in J_b(K)} v_j\varphi_j + \sum_{i\in J_s(K)} v_i P_b^K\varphi_i = \sum_{j\in J_b(K)} w_j^K\varphi_j,$$

where

$$w_j^K := v_j \ + \sum_{i\in J_s(K)} v_i c_{i,j}^K \qquad \forall\, j \in J_b(K)\,. \tag{5.13}$$

We define L_b locally as

$$L_b w_b = \sum_{K\in\mathcal{T}_h} L_b^K w_b^K,$$

where $L_b^K : X_b(K) \to V_b(K)$ is a suitable projection operator as, for example, the L^2 projection. The local coefficient vector $\underline{\widetilde{w}}^K := (\widetilde{w}_j^K)$ of the projection $\widetilde{w}_b^K = L_b^K w_b^K$ can be obtained from the coefficient vector $\underline{w}^K := (w_j^K)_{j\in J_b(K)}$ by matrix-vector multiplication with a small local matrix, say $D^K = (D_{i,j}^K) \in \mathbb{R}^{\mathrm{card}(\mathcal{F}_b(K))\times\mathrm{card}(J_b(K))}$, i.e.,

$$\widetilde{w}_b^K = \sum_{j\in\mathcal{F}_b(K)} \widetilde{w}_j^K\psi_j \qquad \text{with} \qquad \widetilde{w}_j^K = \sum_{i\in J_b(K)} D_{j,i}^K w_i^K\,.$$

In an efficient implementation, the matrices D^K should be computed and stored for each element $K \in \mathcal{T}_h$ during the assembling process of the element stiffness matrices

before starting the multigrid solver. The required memory is less than the one for storing the matrix entries of the bubble functions $a_h(\varphi_j, \varphi_i)$, $i, j \in J_b(K)$, in the original finite element method which is no longer needed in our new method.

Finally, a straightforward calculation yields the following basis representation for the approximation $\widetilde{v}_h \in \widetilde{X}_h$ of a given function $v_h = \sum_{j \in J} v_j \varphi_j \in X_h$:

(5.14)
$$\widetilde{v}_h = \sum_{j \in \mathcal{F}} \widetilde{v}_j \psi_j \qquad \text{with} \qquad \widetilde{v}_j := \begin{cases} v_j & \text{if} \quad j \in J_s \setminus J_f, \\ \displaystyle\sum_{i \in J_b(K)} D^K_{j,i} w^K_i & \text{if} \quad j \in \widetilde{J}_b(K), \\ \displaystyle v_j + \sum_{i \in J(E) \setminus \{j\}} v_i \, \alpha_{i,E} & \text{if} \quad j = j_f(E) \in J_f, \end{cases}$$

where the w^K_i are defined by (5.13).

Obviously, the resulting coefficient vector $\underline{\widetilde{v}} = (\widetilde{v}_j) \in \mathbb{R}^{\mathcal{F}}$ of $\widetilde{v}_h \in \widetilde{X}_h$ in the QDF basis depends linearly on the coefficient vector $\underline{v} = (v_j) \in \mathbb{R}^N$ of $v_h \in X_h$. Hence, there is a linear operator $\widetilde{\Pi} : \mathbb{R}^N \to \mathbb{R}^{\mathcal{F}}$ such that

$$\widetilde{v}_h = \sum_{j \in \mathcal{F}} (\widetilde{\Pi} \underline{v})_j \psi_j \ \in \ \widetilde{X}_h \qquad \forall \, \underline{v} \in \mathbb{R}^N, \tag{5.15}$$

is the projection of v_h into the subspace $\widetilde{X}_h$. It is easy to verify that a given $v_h \in \widetilde{X}_h$ implies $\widetilde{v}_h = v_h$.

As a summary we can say that both operators Π and $\widetilde{\Pi}$ as well as all other tools that are necessary to work with the QDF basis can be implemented efficiently with a computational work which is only proportional to the number of unknowns. This fact is important to ensure optimal computational costs for our proposed multigrid solver. The required memory to store the additionally needed coefficients $c^K_{j,i}$, $\alpha_{j,E}$, and $D^K_{i,j}$ is less than the memory that will become free from the fact that a lot of nonzero matrix entries of the original finite element method are no longer used in the new multigrid solver based on the QDF basis functions.

6. Multigrid method.

6.1. The multigrid cycle. In the following, we will describe the modifications of the usual multigrid cycle that are made in our approach. First we introduce some notations that use the grid level ℓ instead of the discretization parameter h. Let the final grid $\mathcal{T}_h$ be the finest grid $\mathcal{T}^{(L)} := \mathcal{T}_{h_L}$ of a sequence of uniformly refined grids $\mathcal{T}^{(\ell)} := \mathcal{T}_{h_\ell}$, $\ell = 0, 1, \ldots, L$, and let $X^{(\ell)}$, $\widetilde{X}^{(\ell)}$, $\widetilde{X}^{(\ell)}_s$, $X^{(\ell)}_b$, $V^{(\ell)}_b$, $\widetilde{M}^{(\ell)}$, and $\overline{M}^{(\ell)}$ denote the corresponding spaces $X_{h,0}$, $\widetilde{X}_{h,0}$, $\widetilde{X}_{s,0}$, X_b, V_b, $\widetilde{M}_h$, and $\overline{M}_{h,0}$ associated with the grid $\mathcal{T}_h = \mathcal{T}^{(\ell)}$.

The aim of one multigrid cycle on the finest level $\ell = L$ is to compute an improved approximation of the solution of the [illegible] ℓ:

[illegible] $(\widetilde{u}^{(\ell)}_s, \overline{p}^{(\ell)}) \in \widetilde{X}^{(\ell)}_s \times \overline{M}^{(\ell)}$ [illegible]

$$\begin{aligned} a_h(\widetilde{u}^{(\ell)}_s, \widetilde{v}_s) + b(\widetilde{v}_s, \overline{p}^{(\ell)}) &= \langle \, d^{(\ell)}, \widetilde{v}_s \, \rangle \qquad \forall \, \widetilde{v}_s \in \widetilde{X}^{(\ell)}_s \,, \\ b(\widetilde{u}^{(\ell)}_s, \overline{q}) &= \langle \, e^{(\ell)}, \overline{q} \, \rangle \qquad \forall \, \overline{q} \in \overline{M}^{(\ell)} \,. \end{aligned} \tag{6.1}$$

Here, $\widetilde{u}_s^{(L)}$ denotes the solution part $\widetilde{u}_{s,0}$ in the decomposition $u_h = (\widetilde{g}_h + \widetilde{u}_{s,0}) + u_b$, see (4.3) and (4.7), and the linear functionals are defined by

$$\begin{aligned} \langle\, d^{(L)}, \widetilde{v}_s \,\rangle &:= f_h(\widetilde{v}_s) - a_h(\widetilde{g}_h, \widetilde{v}_s) - a_h(u_b, \widetilde{v}_s)\,, \\ \langle\, e^{(L)}, \overline{q} \,\rangle &:= -b(\widetilde{g}_h, \overline{q})\,. \end{aligned} \tag{6.2}$$

The smoothing procedure applied to (6.1) will be described in section 6.2.

For the coarse grid correction, we consider two different approaches. The first one is a so-called [illegible] presented in [13, sect. 4.3]. Here, the coarse space correction is computed in a lowest order space based on the finest grid $\mathcal{T}^{(L)}$. This problem is then solved by a usual multigrid approach which uses the lowest order spaces on all grids $\mathcal{T}^{(\ell)}$, $\ell \le L$.

In the second approach, the coarse space corrections are computed in the spaces $\widetilde{X}^{(\ell)} \times \overline{M}^{(\ell)}$ with $\ell < L$. Here, our first modification compared to a usual multigrid cycle is that the coarse grid problems on levels $\ell < L$ are not reduced Oseen problems of type (6.1) but QDF-formulations of discrete Oseen problems of the type:

[illegible] $(\widetilde{u}^{(\ell)}, \overline{p}^{(\ell)}) \in \widetilde{X}^{(\ell)} \times \overline{M}^{(\ell)}$ [illegible]

$$\begin{aligned} a_h(\widetilde{u}^{(\ell)}, \widetilde{v}) \,+\, b(\widetilde{v}, \overline{p}^{(\ell)}) &= \langle\, \widetilde{d}^{(\ell)}, \widetilde{v} \,\rangle && \forall\, \widetilde{v} \in \widetilde{X}^{(\ell)}\,, \\ b(\widetilde{u}^{(\ell)}, \overline{q}) &= \langle\, e^{(\ell)}, \overline{q} \,\rangle && \forall\, \overline{q} \in \overline{M}^{(\ell)}\,, \end{aligned} \tag{6.3}$$

where the linear functionals $\langle\, \widetilde{d}^{(\ell)}, \cdot \,\rangle$ and $\langle\, e^{(\ell)}, \cdot \,\rangle$ are defined via defect restriction from the next finer grid level. The reason that we have to solve in the larger space $\widetilde{X}^{(\ell)} = \widetilde{X}_s^{(\ell)} \oplus V_b^{(\ell)}$ is that on one hand the restricted coarse grid defects $\langle\, \widetilde{d}^{(\ell)}, \widetilde{v} \,\rangle$ do not vanish for coarse quasi divergence free bubble functions $\widetilde{v} \in V_b^{(\ell)}$ and on the other hand that the subspaces $\widetilde{X}_s^{(\ell)}$, for $\ell = 0, 1, \ldots, L$, do not satisfy the approximation property in contrast to the spaces $\widetilde{X}^{(\ell)}$.

Problem (6.3) on a coarse grid level $\ell < L$ can be decomposed into two subproblems. Let $u_b^{(\ell)} \in V_b^{(\ell)}$ be the solution of the mixed problem:

[illegible] $(u_b^{(\ell)}, \theta^{(\ell)}) \in X_b^{(\ell)} \times \widetilde{M}^{(\ell)}$ [illegible]

$$\begin{aligned} a_h(u_b^{(\ell)}, v_b) \,+\, b(v_b, \theta^{(\ell)}) &= \langle\, \widetilde{d}^{(\ell)}, v_b \,\rangle && \forall\, v_b \in X_b^{(\ell)}\,, \\ b(u_b^{(\ell)}, \widetilde{q}) &= 0 && \forall\, \widetilde{q} \in \widetilde{M}^{(\ell)}\,. \end{aligned} \tag{6.4}$$

Due to the structure of the functions in $X_b^{(\ell)}$, this problem decomposes into local problems over each element of the grid. Instead of solving (6.4) on each newly entered coarser level $\ell < L$, one can compute and store during the assembling process of the stiffness matrix on level ℓ, for each element $K \in \mathcal{T}^{(\ell)}$, a local matrix that assigns to a given local vector of bubble defects $\langle\, \widetilde{d}^{(\ell)}, \varphi_i \,\rangle$ with $i \in J_b(K)$ the corresponding local vector of nodal values of the solution $u_b^{(\ell)}$ restricted on K.

Now, one can easily show that the solution $(\widetilde{u}^{(\ell)}, \overline{p}^{(\ell)})$ of (6.3) can be computed as

$$\widetilde{u}^{(\ell)} = \widetilde{u}_s^{(\ell)} + u_b^{(\ell)},$$

where $(\widetilde{u}_s^{(\ell)}, \overline{p}^{(\ell)}) \in \widetilde{X}_s^{(\ell)} \times \overline{M}^{(\ell)}$ is the solution of a reduced Oseen problem of type (6.1) with the linear functional

$$\langle\, d^{(\ell)}, \widetilde{v}_s \,\rangle := \langle\, \widetilde{d}^{(\ell)}, \widetilde{v}_s \,\rangle - a_h(u_b^{(\ell)}, \widetilde{v}_s) \qquad \forall\, \widetilde{v}_s \in \widetilde{X}_s^{(\ell)}\,. \tag{6.5}$$

6.1. In the case of a polynomial degree of $r = 2$, we have $V_b^{(\ell)} = \{0\}$, i.e., $u_b^{(\ell)} = 0$ and $\widetilde{X}^{(\ell)} = \widetilde{X}_s^{(\ell)}$ such that (6.3) is already a reduced Oseen problem of type (6.1).

Due to the decomposition of each coarse grid problem (6.3), we have to apply the smoothing procedure and the defect restriction only to each reduced Oseen problem of type (6.1). A further modification compared to a usual multigrid cycle concerns the choice of the fine grid correction. Let $(\widetilde{u}_s^{(\ell+1)}, \overline{p}^{(\ell+1)}) \in \widetilde{X}_s^{(\ell+1)} \times \overline{M}^{(\ell+1)}$ be a multigrid iterate after the smoothing step applied to the reduced Oseen problem (6.1) on level $\ell+1$. For the corresponding coarse grid problem (6.3), let $u_b^{(\ell)}$ denote the velocity solution of (6.4) and $(\widetilde{u}_s^{(\ell)}, \overline{p}^{(\ell)}) \in \widetilde{X}_s^{(\ell)} \times \overline{M}^{(\ell)}$ the corresponding coarse grid correction computed by applying some multigrid cycles to the reduced Oseen problem (6.1) on level ℓ. As fine grid correction for improving the iterate $\widetilde{u}_s^{(\ell+1)}$ we need a function $\widetilde{v}_s^{(\ell+1)} \in \widetilde{X}_s^{(\ell+1)}$. However, the corresponding coarse grid correction from (6.3), which is the function $\widetilde{u}^{(\ell)} = u_b^{(\ell)} + \widetilde{u}_s^{(\ell)}$, is contained in the space $\widetilde{X}^{(\ell)}$. That means, we need a prolongation operator $\widetilde{P}^{(\ell)} : \widetilde{X}^{(\ell)} \to \widetilde{X}^{(\ell+1)}$ such that the fine grid correction $\widetilde{v}_s^{(\ell+1)} = \widetilde{P}^{(\ell)} \widetilde{u}^{(\ell)}$ is in the subspace $\widetilde{X}_s^{(\ell+1)}$ with zero bubble part. This is realized if we choose simply the operator $L_b^K = 0$ in the definition of the operator $\widetilde{\Pi}$; see section 5.3. As the fine grid correction for the pressure approximation $\overline{p}^{(\ell+1)}$ we take the usual prolongation of $\overline{p}^{(\ell)}$.

6.2. Smoother. We apply the smoother on each grid level ℓ only to the corresponding reduced Oseen problem of type (6.1). One smoothing step consists essentially of a loop over all elements where some block solves are performed for each element $K \in \mathcal{T}^{(\ell)}$. In order to simplify the notation we omit the level ℓ and introduce, for a nodal point a_m at the boundary of an element $K \in \mathcal{T}_h = \mathcal{T}^{(\ell)}$, the set $J_n(a_m)$ of all nonflux nodes which are connected to a_m, i.e.,

$$J_n(a_m) := \{ j \in J \setminus J_f : a_j = a_m \}.$$

We use a block Gauss–Seidel smoother which can be regarded as a successive subspace correction method. Therefore, we define, for an arbitrary index set $I \subset \widetilde{J}$, the velocity subspace

$$\widetilde{X}_I := \operatorname{span}\{\psi_j : j \in I\} \cap \widetilde{X}_{h,0}$$

and the local pressure subspaces

$$\overline{M}_K := \operatorname{span}\{\chi_0^K\} \subset \overline{M}_h \qquad \forall K \in \mathcal{T}_h.$$

Let $(u^{\mathrm{old}}, p^{\mathrm{old}}) \in \widetilde{X}_s^{(\ell)} \times \overline{M}^{(\ell)}$ be an approximation of the solution $(\widetilde{u}_s^{(\ell)}, \overline{p}^{(\ell)})$ of the reduced Oseen problem of type (6.1) on some grid level ℓ with right-hand side functionals $\langle d, \cdot \rangle$ and $\langle e, \cdot \rangle$ defined by defect restriction and formula (6.5). Then, one smoothing step $(u^{\mathrm{old}}, p^{\mathrm{old}}) \mapsto (u, p)$ is defined as follows:

$(u, p) := (u^{\mathrm{old}}, p^{\mathrm{old}})$
for $K \in \mathcal{T}_h$ **do**
(i) Find $(v, q) \in \widetilde{X}_{J_f(K)} \times \overline{M}_K$ such that

(6.6)
$$\begin{aligned} a_h(v, w) + b(w, q) &= \langle d, w \rangle - a_h(u, w) - b(w, p) && \forall w \in \widetilde{X}_{J_f(K)}, \\ b(v, \mu) &= \langle e, \mu \rangle - b(u, \mu) && \forall \mu \in \overline{M}_K, \end{aligned}$$

update $(u, p) := (u, p) + (v, q)$

(ii) **for** all nodal points $a_m \in \partial K \setminus \Gamma$ **do**

Find $v \in \widetilde{X}_{J_n(a_m)}$ such that

$$a_h(v,w) = \langle\, d, w \,\rangle - a_h(u,w) \qquad \forall w \in \widetilde{X}_{J_n(a_m)} \tag{6.7}$$

update $u := u + v$

end do

end do

L_0^2 projection $p := p - |\Omega|^{-1}(p,1)_\Omega$.

In (6.6) we solve a system associated with all flux nodes of element K and the one node for the pressure constant. This is a small saddle-point problem of the dimension $\mathrm{card}\big(\mathcal{E}(K)\big) + 1$. For all nodal points $a_m \in \partial K$, we have $\widetilde{X}_{J_n(a_m)} \subset V_h$ due to $\widetilde{X}_s = V_s \oplus \widetilde{X}_f$, i.e., in the problem (6.1), the functions of the subspace $\widetilde{X}_{J_n(a_m)}$ are decoupled from the pressure. Therefore, the system (6.7) does not contain pressure terms. The size of the linear system associated with (6.7) is equal to $\mathrm{card}\,(J_n(a_m))$. It is either $(d-1)$, if a_m is connected to a flux node of K in the sense that a face $E \in \mathcal{E}(K)$ exists with $a_m = a_{j_f(E)}$, or it is d otherwise. For the special case of the Q_2-element in 2D, the different blocks of degrees of freedom associated with the systems (6.6) and (6.7) are shown in Figure 6.1. Since all local systems are of small size they can be solved very efficiently by means of a direct solver.

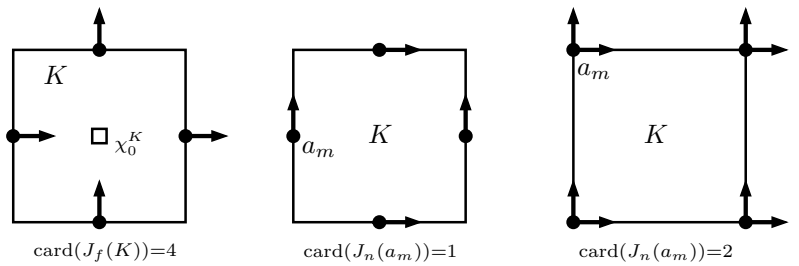

FIG. 6.1. *Blocks of degrees of freedom for the Q_2-element in 2D. Left: one 5×5-block from* (6.6)*, middle: four 1×1-blocks from* (6.7)*, right: four 2×2-blocks from* (6.7).

6.3. Prolongation and restriction. In the following, we describe the transfer operators between the fine and coarse grid velocity spaces. For the pressure spaces, the transfer operators are chosen in the usual way. Let the operators Π and $\widetilde{\Pi}$ of section 5.3 in the situation $X_h = X^{(\ell)}$ and $\widetilde{X}_h = \widetilde{X}^{(\ell)}$, $\ell = 0, \ldots, L$, be denoted by $\Pi^{(\ell)} : \mathbb{R}^{\widetilde{N}^{(\ell)}} \to \mathbb{R}^{N^{(\ell)}}$ and $\widetilde{\Pi}^{(\ell)} : \mathbb{R}^{N^{(\ell)}} \to \mathbb{R}^{\widetilde{N}^{(\ell)}}$, where $\widetilde{N}^{(\ell)} := \dim(\widetilde{X}^{(\ell)})$ and $N^{(\ell)} := \dim(X^{(\ell)})$. Moreover, let us assume that the local projection operator $L_b^K : X_b(K) \to V_b(K)$, used in the definition of the operator $\widetilde{\Pi}$, is defined by $L_b^K w := 0$ for all $w \in X_b(K)$. This is necessary since no prolongated correction may be added to the already computed fine grid bubble parts.

Now, we will define the prolongation operator $\widetilde{P}^{(\ell)} : \widetilde{X}^{(\ell)} \to \widetilde{X}^{(\ell+1)}$, i.e., we will describe how a fine grid QDF approximation $\widetilde{u}^{(\ell+1)} \in \widetilde{X}^{(\ell+1)}$ of a given coarse grid QDF function $\widetilde{u}^{(\ell)} \in \widetilde{X}^{(\ell)}$ is computed; schematically, this is shown in Figure 6.2. The function $\widetilde{u}^{(\ell)} \in \widetilde{X}^{(\ell)}$ is uniquely associated with the coefficient vector $\underline{\widetilde{u}}^{(\ell)} \in \mathbb{R}^{\widetilde{N}^{(\ell)}}$ in the QDF basis. From this vector we compute the coefficient vector $\underline{u}^{(\ell)} := \Pi^{(\ell)} \underline{\widetilde{u}}^{(\ell)}$

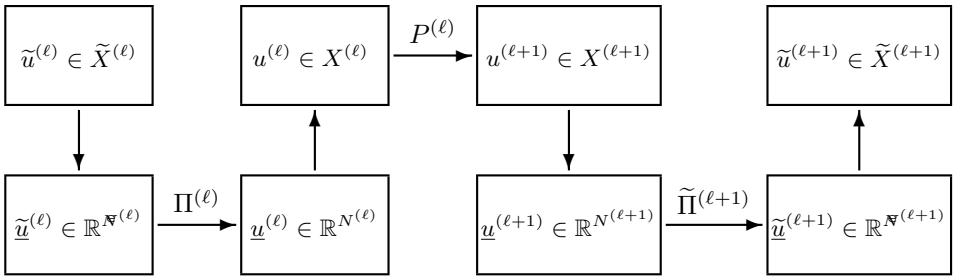

FIG. 6.2. *Computation of the prolongation $\widetilde{u}^{(\ell+1)}$ of a given coarse grid QDF function $\widetilde{u}^{(\ell)}$.*

that corresponds to the representation of $u^{(\ell)} = \widetilde{u}^{(\ell)}$ in the original finite element basis of $X^{(\ell)}$; see (5.11). Now, we apply the prolongation operator $P^{(\ell)} : X^{(\ell)} \to X^{(\ell+1)}$ that would be used for a multigrid method with the original spaces $X^{(\ell)}$, $\ell = 0, \dots, L$. This operator yields a fine grid approximation $u^{(\ell+1)} := P^{(\ell)} u^{(\ell)}$ of $\widetilde{u}^{(\ell)}$ in the original fine grid space $X^{(\ell+1)}$ which again corresponds to a coefficient vector $\underline{u}^{(\ell+1)} \in \mathbb{R}^{N^{(\ell+1)}}$. Finally, we apply our operator $\widetilde{\Pi}^{(\ell+1)}$ in order to compute the coefficient vector $\underline{\widetilde{u}}^{(\ell+1)} := \widetilde{\Pi}^{(\ell+1)} \underline{u}^{(\ell+1)}$ of the projection $\widetilde{u}^{(\ell+1)}$ of $u^{(\ell+1)}$ into the subspace $\widetilde{X}^{(\ell+1)}$ of the QDF functions in $X^{(\ell+1)}$. Thus, the definition of the prolongation $\widetilde{u}^{(\ell+1)} = \widetilde{P}^{(\ell)} \widetilde{u}^{(\ell)}$ of the coarse grid QDF function $\widetilde{u}^{(\ell)}$ is completed.

For the defect restriction operator $\widetilde{R}^{(\ell)} : (\widetilde{X}^{(\ell+1)})' \to (\widetilde{X}^{(\ell)})'$, we choose the adjoint of the above defined prolongation operator $\widetilde{P}^{(\ell)} : \widetilde{X}^{(\ell)} \to \widetilde{X}^{(\ell+1)}$. We will omit the technical details here.

6.4. Solving the Navier–Stokes problem. For solving the stationary Navier–Stokes equations, we have to find a velocity field u and pressure field p which solve the Oseen equations (1.1) with the convection field $\beta = u$. A finite element discretization on the finest mesh $\mathcal{T} = \mathcal{T}^{(L)}$ leads to a nonlinear system of equations for nodal vectors U and P of the following form:

$$\begin{pmatrix} A(U) & B_1(U)^T \\ B & 0 \end{pmatrix} \begin{pmatrix} U \\ P \end{pmatrix} = \begin{pmatrix} F(U) \\ G \end{pmatrix}. \tag{6.8}$$

Here, the matrix $A(U)$ is associated with the bilinear form a_h, matrix B with the bilinear form b, matrix $B_1(U)$ with a bilinear form b_1, and the vector $F(U)$ with the linear form f_h, where a_h, b_1, and f_h use a convection field β which is the finite element function related to the nodal vector U. For the Galerkin discretization, we have $a_h = a$, $b_1 = b$, and $f_h(\cdot) = (f, \cdot)_\Omega$. As a stabilized discretization in case of a high Reynolds number, we choose the reduced streamline diffusion method given in [6], i.e., we choose $a_h = a_{\mathrm{SD}}$, $b_1 = b_{\mathrm{SD}}$, and $f_h = f_{\mathrm{SD}}$ with

$$\begin{aligned} a_{\mathrm{SD}}(w, v) &:= a(w, v) + \textstyle\sum_{K \in \mathcal{T}} \delta_K \left(-2\nu \operatorname{div} \mathbb{D}(w) + (\beta \cdot \nabla) w, (\beta \cdot \nabla) v \right)_K, \\ b_{\mathrm{SD}}(v, q) &:= b(v, q) + \textstyle\sum_{K \in \mathcal{T}} \delta_K \left(\nabla q, (\beta \cdot \nabla) v \right)_K, \\ f_{\mathrm{SD}}(v) &:= (f, v)_\Omega + \textstyle\sum_{K \in \mathcal{T}} \delta_K \left(f, (\beta \cdot \nabla) v \right)_K. \end{aligned} \tag{6.9}$$

The parameter δ_K is chosen as $\delta_K = \delta_0 h_K^2$ with a constant δ_0; see [6].

For solving (6.8), we use a Picard-type linearization combined with a defect correction, i.e., a nonlinear iteration $(U^n, P^n) \to (U^{n+1}, P^{n+1})$ is defined as follows:

(i) solve approximately

$$\begin{pmatrix} A(U^n) & B^T \\ B & 0 \end{pmatrix} \begin{pmatrix} V^n \\ Q^n \end{pmatrix} = \begin{pmatrix} D^n \\ E^n \end{pmatrix}, \tag{6.10}$$

where

$$\begin{pmatrix} D^n \\ E^n \end{pmatrix} := \begin{pmatrix} F(U^n) \\ G \end{pmatrix} - \begin{pmatrix} A(U^n) & B_1(U^n)^T \\ B & 0 \end{pmatrix} \begin{pmatrix} U^n \\ P^n \end{pmatrix},$$

(ii) update $(U^{n+1}, P^{n+1}) := (U^n, P^n) + \omega\,(V^n, Q^n)\,,$

where ω is a relaxation parameter.

The main part of this iteration is the approximate solution of the discrete Oseen problem (6.10) which is done by applying several cycles of the previously described multigrid method. Numerical experiments have shown that it is sufficient to stop the multigrid iteration for solving (6.10) if the norm of the initial residual has been damped by a factor of 10.

7. Numerical tests. In this section, we compare by means of numerical tests the two new multigrid methods for the QDF basis described in section 6.1, which we denote by and , with the corresponding two multigrid methods using the Vanka smoother for the usual basis which we denote by and .

We consider three different 2D-problems: a Stokes problem, the driven cavity problem, and a benchmark flow problem.

All numerical computations were carried out on a Linux PC (Pentium IV, 2.8 GHz) using the code MooNMD [15]. The presented times are given in seconds.

If not mentioned otherwise, all multigrid approaches use an $F(1,1)$-cycle. The F-cycle combines the good convergence properties of a W-cycle with the low costs of a V-cycle. For all multigrid methods we choose a damping parameter of 0.9 within the smoother.

7.1. Stokes problem. We consider the Stokes problem in the unit square $\Omega = (0,1)^2$ with the prescribed solution

$$u(x,y) := \begin{pmatrix} \sin^2(k\pi x)\sin(2k\pi y) \\ \sin(2k\pi x)\sin^2(k\pi y) \end{pmatrix}, \qquad p(x,y) := \sin(k\pi x) - \sin(k\pi y), \qquad k = 5,$$

the data $f := -\operatorname{div} \mathbb{T}(u,p)$, $\nu = 1$, and $g \equiv 0$. Note that the given flow field describes an array of $k \times k$ vortices.

The coarsest grid $\mathcal{T}^{(0)}$ is a decomposition of the unit square into four congruent squares. Our results are presented for the finest grid $\mathcal{T}_h = \mathcal{T}^{(7)}$ generated by seven uniform refinement steps. This grid consists of 256×256 squares. We use Q_2-elements for the approximation of the velocity and discontinuous P_1-elements to approximate the pressure. On the grid $\mathcal{T}^{(7)}$, this leads in the case of using the usual finite element basis to $526,338$ degrees of freedom (d.o.f.) for the velocity and $196,608$ d.o.f. for the pressure while the QDF basis needs only $395,266$ d.o.f. for the velocity and $65,536$ d.o.f. for the piecewise constant pressure within the reduced Stokes problem.

In order to show the independence of the solution process from the starting vector, we made for each of the four multigrid methods 99 runs with randomly chosen starting vectors.

Table 7.1 gives for all considered multigrid methods the total run time (t_{total}), the time for solving the linear system (t_{solve}), the number of multigrid cycles needed

TABLE 7.1
Results for different multigrid approaches; minimum and maximum of the mentioned quantities are given.

	usual		MDML		QDF		QDF-MDML	
	min	max	min	max	min	max	min	max
t_{total}	104.8	105.8	83.0	92.1	44.9	45.8	64.1	69.3

# cycles	14	14	12	12	20	20	10	10
t_{cycle}	6.86	6.92	6.13	6.84	1.81	1.84	5.50	5.99
aver. rate	0.0833	0.0840	0.0578	0.0588	0.194	0.195	0.0319	0.0322
memory	330		326		292		296	

to achieve a residual less than 10^{-11} ( ), the averaged time per cycle (t_{cycle}), the average convergence rate per cycle ( ), and the needed memory in MByte ( ). Note that due to a better performance, a $F(2,2)$-cycle was used for QDF-MDML. Table 7.1 shows that the convergence of all considered multigrid methods is independent from the starting vector of the iterative solution process. Although the average convergence rate for the QDF method is the worst one, the very small cycle time results at the end in the shortest total run time. Compared to the QDF method, the QDF-MDML method needs more computation time since the local systems within the smoother for the lowest order element Q_1^{rot}/P_0 are larger than for the QDF basis. In contrast to this, the MDML method performs faster than the usual multigrid method because the local systems for the Q_1^{rot}/P_0-element are much smaller than for the Q_2/P_1-element.

7.2. Driven cavity problem. Our second example is the driven cavity problem in the unit square with $\nu = 1/3000$. Since the standard Galerkin discretization for this Reynolds number lacks of stability, we use the reduced streamline diffusion finite element method as a stabilization technique, [6]. Furthermore, we restrict our tests to the MDML and the QDF-MDML multigrid approaches since they have shown to be superior to the other approaches. For the underlying Q_1^{rot}/P_0-element on the lower multigrid levels, an upwind discretization is used which is very robust and stabilizes the whole multigrid method. All calculations were carried out on $\mathcal{T}^{(6)}$ as finest mesh which consists of 128×128 squares.

Instead of solving the linear systems themselves by multigrid methods we applied a preconditioned flexible GMRES method [19] as solver where we have chosen either the MDML or the QDF-MDML multigrid method as preconditioner.

In Table 7.2 we present the total run time t_{total}, the solver time t_{solve}, and the time t_{mod} which is needed to modify the matrices and right-hand sides according to the QDF basis. Moreover, we show the ratio between the corresponding times for

TABLE 7.2
Total time and solver time for the driven cavity problem.

FE pair	MDML		QDF-MDML	
	t_{total}	t_{solve}	t_{total}/ratio	$t_{\text{solve}} + t_{\text{mod}}$/ratio
Q_2/P_1	963	839	497/ 1.94	336 + 23/ 2.34
Q_3/P_2	3,205	2,803	1,139/ 2.81	555 + 121/ 4.15
Q_4/P_3	10,431	8,846	3,377/ 3.09	885 + 542/ 6.20

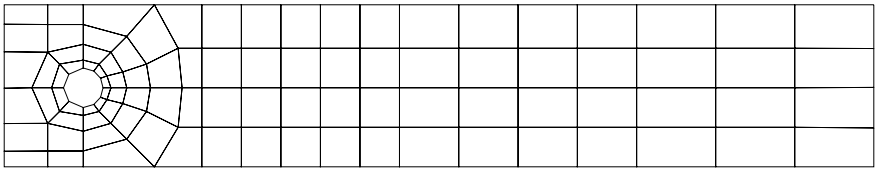

FIG. 7.1. *Coarsest mesh for the benchmark problem.*

the multigrid methods MDML and QDF-MDML. If we look at the solver time we see that the ratio increases from around 2 for the Q_2/P_1-element up to 6 for the Q_4/P_3-element. That means that the advantage of using the new multigrid method based on the QDF basis gets bigger with increasing polynomial degree of the finite elements. In contrast, the ratio of the total run time increases rather slowly for increasing polynomial degree. This is caused by the fact that the time used for assembling the matrices and right-hand sides, which does not belong to the solver time, is relatively large for higher order discretizations; see Table 7.2.

7.3. Flow around a circle. Our final example is the benchmark problem [illegible]; see [20]. We consider the Navier–Stokes equations with $\nu = 10^{-3}$. The coarsest mesh $\mathcal{T}_h^{(0)}$ for our computations is shown in Figure 7.1. A parabolic inflow and outflow profile is prescribed at the left and right boundary of the channel while $g \equiv 0$ on all other boundary parts.

A benchmark quantity to be computed is the lift coefficient c_l related to the circle; see [20] for a detailed definition. For the computation of c_l, we have used in our numerical tests the equivalent formula given, e.g., in [14].

We will now compare the performance of the preconditioned flexible GMRES method with the MDML and the QDF-MDML multigrid method as preconditioner for the Q_r/P_{r-1}-element with increasing r. Starting from the coarse mesh $\mathcal{T}_h^{(0)}$ shown in Figure 7.1, all finer meshes are obtained by uniform refinement with boundary adaption at the circle. In the discretization, the curved boundary of the circle was taken into account by means of isoparametric finite elements. Since the problem corresponds to a moderate physical Reynolds number of 20 we have used the standard Galerkin discretization which works well here.

TABLE 7.3
Total run time and error $e(c_l)$ of benchmark quantity c_l.

FE pair	level	total run time			$e(c_l)$
		MDML	QDF-MDML	ratio	
Q_2/P_1	2	20.0	8.9	2.25	8.71-06
Q_2/P_1	3	62.6	35.7	1.75	7.36-07
Q_2/P_1	4	252.7	185.6	1.36	6.81-08
Q_3/P_2	2	54.9	21.5	2.55	-8.76-08
Q_3/P_2	3	190.0	85.3	2.23	-1.17-08
Q_3/P_2	4	894.8	358.4	2.50	-4.84-10
Q_4/P_3	2	175.0	59.1	2.96	-2.50-08
Q_4/P_3	3	600.5	229.1	2.62	2.84-10
Q_4/P_3	4	2962.8	1015.6	2.92	1.02-10

Table 7.3 shows the error $e(c_l)$ of the calculated quantity c_l with respect to the reference parameter

$$c_{l,\mathrm{ref}} = 0.010618937712,$$

which was obtained in [14]. We see that higher order methods are able to produce more accurate results on coarser meshes in less time than lower order methods on even finer meshes. The ratio between the total run times needed for the MDML method and the QDF-MDML method ranges between 1.5 and 3. Note again that for higher order discretizations the time for assembling matrices and right-hand sides can't be neglected.

NUMERICAL MODELING OF ELASTIC WAVES ACROSS IMPERFECT CONTACTS.*

BRUNO LOMBARD† AND JOËL PIRAUX†

Abstract. A numerical method is described for studying how elastic waves interact with imperfect contacts such as fractures or glue layers existing between elastic solids. These contacts have been classicaly modeled by interfaces, using a simple rheological model consisting of a combination of normal and tangential linear springs and masses. The jump conditions satisfied by the elastic fields along the interfaces are called the "spring-mass conditions." By tuning the stiffness and mass values, it is possible to model various degrees of contact, from perfect bonding to stress-free surfaces. The conservation laws satisfied outside the interfaces are integrated using classical finite-difference schemes. The key problem arising here is how to discretize the spring-mass conditions and how to insert them into a finite-difference scheme: this was the aim of the present paper. For this purpose, we adapted an interface method previously developed for use with perfect contacts [*J. Comput. Phys.*, 195 (2004), pp. 90–116]. This numerical method also describes closely the geometry of arbitrarily shaped interfaces on a uniform Cartesian grid, at negligible extra computational cost. Comparisons with original analytical solutions show the efficiency of this approach.

Key words. elastic waves, interface methods, spring-mass jump conditions, discontinuous coefficients, imperfect contact, hyperbolic conservation laws.

1. Introduction.

Here we propose to study the propagation of mechanical waves in an elastic medium divided into several subdomains. The wavelengths are assumed to be much larger than the thickness of the contact zones between subdomains, or [illegible] [18]. Each interphase is replaced by a zero-thickness [illegible], where elastic fields satisfy jump conditions. In elastodynamics, the contacts between elastic media are usually assumed to be perfect [1]. They can therefore be modeled by perfect jump conditions, such as perfectly bonded, perfectly lubricated, or stress-free conditions. For example, perfectly bonded conditions will mean that both elastic displacements and normal elastic stresses are continuous across the interface at each time step.

In practice, contacts are often imperfect because of the presence of microcracks or interstitial media in the interphase. Take, for example, fractures in the earth, which are filled with air or liquid, and where jumps occur in the elastic displacements and elastic stresses. The simplest imperfect conditions are the [illegible] (which are sometimes called "linear slip displacements"): these conditions are realistic in the case of incident waves with very small amplitudes [17]. The spring-mass conditions have been extensively studied, both theoretically and experimentally [18, 20, 21]. This approach has been applied in various disciplines, such as nondestructive evaluation of materials [2, 22] and geophysics [17].

However, very few studies have dealt so far with the numerical simulation of wave propagation across imperfect contacts described by spring-mass conditions. To our knowledge, only three approaches have been proposed for this purpose. First, Gu, Nihei, and Myer developed a boundary integral method which can be applied to

arbitrarily shaped interfaces [7], but this method requires knowing the Green functions on both sides of the interface, which complicates the study of realistic heterogeneous media. Second, a finite-element method has been proposed by Haney and Sneider [8]. The jump conditions are incorporated automatically here into the numerical scheme, via the variational formulation, and attempts have been made to perform numerical analysis. The main drawback of this approach is that it requires adapting the mesh to the interface, which increases the computational effort. Third, other authors have approached this problem by implicitly accounting for the boundary conditions by using an equivalent medium and then deriving new finite-difference formulas [3, 4]. This approach can be applied to arbitrarily shaped interfaces on a uniform Cartesian grid, but the accuracy is low, and this method involves explicitly changing the numerical scheme near the interface. Note that the inertial effects were not investigated in any of these three cases, although they may be important factors [18].

The aim of this paper is to describe a procedure for incorporating the spring-mass conditions into existing finite-difference schemes, on a regular Cartesian grid. The geometry of arbitrarily shaped interfaces is properly taken into account, reducing the unwanted diffraction classically induced by the Cartesian grid. Last, the extra computational cost is low. For this purpose, we adapted the [illegible] (ESIM) previously developed for dealing with perfect contacts in one dimension [15] and two dimensions [12]. A study has also dealt with imperfect contacts in one dimension [11]. In the present study, this approach is extended to two-dimensional configurations. The focus here is on the description of imperfect contacts; to avoid additional complications, we take media with simple constitutive laws (elastic and isotropic media), but the procedure should be suitable for dealing with more realistic media. The inertial effects are taken into account.

This paper is organized as follows. In section 2, the problem is stated in terms of the configuration, the conservation laws, and the spring-mass conditions. In section 3, a numerical strategy is described for integrating the conservation laws on the whole computational domain: the same scheme is used throughout the domain, but near an interface [illegible] of the solution are used, which implicitly account for the spring-mass conditions. Section 4 is the core part of this paper: it describes in detail how to compute the modified values. Numerical experiments are described in section 5, and comparisons with original analytical solutions show the efficiency of the method. Note that although no rigorous mathematical proof of the validity of the algorithms was obtained, the results of the numerical experiments performed were extremely satisfactory.

2. Problem statement.

2.1. Configuration. Let us consider two isotropic elastic media Ω_0 and Ω_1 separated by a stationary interface Γ (Figure 2.1). We study a two-dimensional configuration with plane strains and adopt Cartesian coordinates x and y pointing rightward and upward, respectively. The interface is described by a parametric description $(x(\tau), y(\tau))$. The unit tangential vector $\boldsymbol{t}$ and the unit normal vector $\boldsymbol{n}$ are

$$\boldsymbol{t} = \frac{1}{\sqrt{x'^2 + y'^2}} \begin{pmatrix} x' \\ y' \end{pmatrix}, \qquad \boldsymbol{n} = \frac{1}{\sqrt{x'^2 + y'^2}} \begin{pmatrix} -y' \\ x' \end{pmatrix}, \tag{2.1}$$

where $x' = \frac{dx}{d\tau}$ and $y' = \frac{dy}{d\tau}$. Γ is assumed to be sufficiently smooth to ensure that $x(\tau)$, $y(\tau)$ and their successive spatial derivatives are continuous all along Γ, up to a given order of derivation.

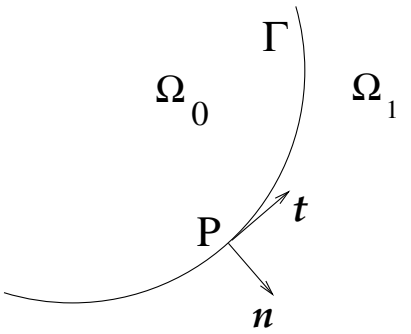

FIG. 2.1. *Interface* Γ *between two elastic media* Ω_0 *et* Ω_1.

The physical parameters are the density ρ, the elastic speed of the compressional P-waves c_p, and the elastic speed of the shear SV-waves c_s. For the sake of simplification, these parameters are taken to be piecewise constant; however, they may be discontinuous across Γ

$$(\rho,\, c_p,\, c_s) = \begin{cases} (\rho_0,\, c_{p0},\, c_{s0}) & \text{if} \quad (x,\, y) \in \Omega_0, \\ (\rho_1,\, c_{p1},\, c_{s1}) & \text{if} \quad (x,\, y) \in \Omega_1. \end{cases} \tag{2.2}$$

The elastic fields are the two components of the elastic velocity $\boldsymbol{v}(v_1, v_2)$ and the three independent components of the elastic stress tensor $\boldsymbol{\sigma}(\sigma_{11}, \sigma_{12}, \sigma_{22})$. The projections, normal and tangential to the interface, of the elastic displacement $\boldsymbol{u}(u_1, u_2)$, those of the velocity $\boldsymbol{v}$, and those of the normal stress $\boldsymbol{\sigma.n}$ are denoted by

$$\left| \begin{array}{l} u_N = \boldsymbol{u.n}, \\ u_T = \boldsymbol{u.t}, \end{array} \right. \quad \left| \begin{array}{l} v_N = \boldsymbol{v.n}, \\ v_T = \boldsymbol{v.t}, \end{array} \right. \quad \left| \begin{array}{l} \sigma_N = (\boldsymbol{\sigma.n}).\boldsymbol{n}, \\ \sigma_T = (\boldsymbol{\sigma.n}).\boldsymbol{t}. \end{array} \right. \tag{2.3}$$

Let P be a point on Γ (Figure 2.1), and t be the time. Given a function $f(x,\, y,\, t)$, the limit values of f at P on both sides of Γ are written

$$f_l(P,\, t) = \lim_{M \to P, M \in \Omega_l} f(M,\, t), \tag{2.4}$$

where $l = 0, 1$. The jump of f across Γ, from Ω_0 to Ω_1, is denoted by

$$[f(P,\, t)] = f_1(P,\, t) - f_0(P,\, t). \tag{2.5}$$

2.2. Conservation laws. To study the propagation of small perturbations in Ω_i $(i = 0, 1)$, we use a velocity-stress formulation of elastodynamic equations. Setting

$$\boldsymbol{U} = {}^T(v_1, v_2, \sigma_{11}, \sigma_{12}, \sigma_{22}), \tag{2.6}$$

the linearization of mechanics equations gives a first-order linear hyperbolic system in each subdomain

$$\frac{\partial}{\partial t}\boldsymbol{U} + \boldsymbol{A}_l \frac{\partial}{\partial x}\boldsymbol{U} + \boldsymbol{B}_l \frac{\partial}{\partial y}\boldsymbol{U} = \boldsymbol{0}, \qquad l = 0, 1, \tag{2.7}$$

which is satisfied outside Γ. The 5×5 piecewise-constant matrices $\boldsymbol{A}_l$ and $\boldsymbol{B}_l$ $(l=0,1)$ are [1]

$$\boldsymbol{A}_l = -\begin{pmatrix} 0 & 0 & \dfrac{1}{\rho} & 0 & 0 \\ 0 & 0 & 0 & \dfrac{1}{\rho} & 0 \\ \rho\, c_p^2 & 0 & 0 & 0 & 0 \\ 0 & \rho\, c_s^2 & 0 & 0 & 0 \\ \rho\left(c_p^2 - 2\, c_s^2\right) & 0 & 0 & 0 & 0 \end{pmatrix},$$

$$\boldsymbol{B}_l = -\begin{pmatrix} 0 & 0 & 0 & \dfrac{1}{\rho} & 0 \\ 0 & 0 & 0 & 0 & \dfrac{1}{\rho} \\ 0 & \rho\left(c_p^2 - 2\, c_s^2\right) & 0 & 0 & 0 \\ \rho\, c_s^2 & 0 & 0 & 0 & 0 \\ 0 & \rho\, c_p^2 & 0 & 0 & 0 \end{pmatrix}. \tag{2.8}$$

2.3. Spring-mass conditions. An incident wave at the interface generates four other waves: a reflected P-wave, a reflected SV-wave, a transmitted P-wave, and a transmitted SV-wave. To pose the problem suitably, it is necessary to define four independent jump conditions satisfied by the fields along Γ (Figure 2.1). [illegible] are generally used for this purpose, namely,

$$\begin{aligned} &[u_N(P,\,t)] = 0, \qquad [\sigma_N(P,\,t)] = 0, \\ &[u_T(P,\,t)] = 0, \qquad [\sigma_T(P,\,t)] = 0, \end{aligned} \tag{2.9}$$

corresponding to a perfectly bonded contact between the two solids in question.

To describe an imperfect contact, one can generalize (2.9) into [illegible]. With the notations defined in (2.4), the spring-mass conditions are

$$\boxed{\begin{aligned} &[u_N(P,\,t)] = \frac{1}{K_N}\,\sigma_{N0}(P,\,t), \qquad [\sigma_N(P,\,t)] = M_N\,\frac{\partial^2}{\partial\, t^2}\,u_{N0}(P,\,t), \\ &[u_T(P,\,t)] = \frac{1}{K_T}\,\sigma_{T0}(P,\,t), \qquad [\sigma_T(P,\,t)] = M_T\,\frac{\partial^2}{\partial\, t^2}\,u_{T0}(P,\,t), \end{aligned}} \tag{2.10}$$

where $K_N > 0$, $K_T > 0$, $M_N \geq 0$, $M_T \geq 0$ are called the normal stiffness, the tangential stiffness, the normal mass, and the tangential mass of the interface, respectively. The conditions (2.10) are called "spring-mass conditions" because of analogies with the equations governing the dynamics of a spring-mass system (Figure 2.2). One basic underlying assumption made here is that the elastic stresses do not affect the nature of the contact and hence that K_N, K_T, M_N, and M_T do not depend on t or on the fields. They can vary with space and hence with the parameter τ.

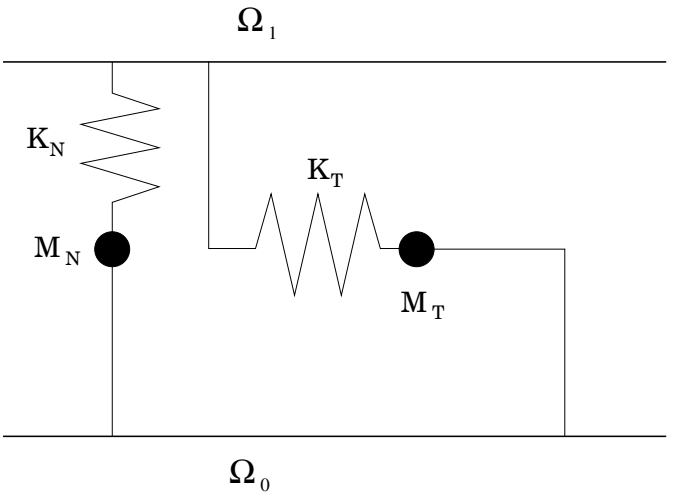

FIG. 2.2. *Spring-mass rheological model of the contact.*

The spring-mass conditions provide an easy way of describing a wide range of contacts between solids, from perfect contact to disconnected media. For $K_N \to +\infty$, $K_T \to +\infty$, $M_N = 0$, and $M_T = 0$, we obtain the perfectly bonded conditions (2.9). For $K_N \to +\infty$, $K_T \to 0$, $M_N = 0$, and $M_T = 0$, we obtain $\sigma_T(P, t) \to 0$, which amounts to a perfect slip with no friction. Lastly, for $K_N \to 0$, $K_T \to 0$, $M_N = 0$, and $M_T = 0$, we obtain $\sigma_N(P, t) \to 0$ and $\sigma_T(P, t) \to 0$, hence $\boldsymbol{\sigma}.\boldsymbol{n}(P, t) \to \mathbf{0}$: the media Ω_0 and Ω_1 tend to have stress-free boundaries, which means that no waves are transmitted from one medium to the other.

The spring-mass conditions entail an important property: the plane waves reflected and transmitted by a plane interface with conditions (2.10) are frequency dependent [21]. These waves therefore show a distorted profile that is quite different from the profile of the incident wave, even below the critical angle. In addition, even if the incident wave is spatially bounded in the direction of propagation, the reflected and transmitted waves are not spatially bounded: a "coda" follows each of these waves. Phenomena of this kind, which do not occur with perfect conditions, are observed experimentally (see, e.g., [17]).

By choosing appropriate values of K_N, K_T, M_N, and M_T, it is possible to model realistic configurations. The spring-mass conditions (2.10) can also be obtained quite rigorously in some cases; the values of K_N, K_T, M_N, and M_T will therefore depend on the physical and geometrical properties of the interphase. Take a plane elastic layer sandwiched between two homogeneous isotropic half-spaces. If the thickness of the intermediate layer is much smaller than the wavelength, the spring-mass conditions can be deduced from an asymptotic analysis of the wave propagation behavior inside the layer [18].

The spring-mass conditions model (2.10) has some limitations. First, if $K_N < +\infty$ and $M_N \neq 0$, or if $K_T < +\infty$ and $M_T \neq 0$, these conditions are asymmetrical. In Appendix A, we establish that the influence of this asymmetry is either null (in the case of reflected waves) or negligible (in that of transmitted waves) in the one-dimensional context. We have checked numerically that this is also the case in the two-dimensional context. Setting up symmetrical conditions would considerably complicate the jump conditions, in return for absolutely negligible effects.

The second drawback follows from the first equation given by (2.10): there is no reason why a negative jump of u_N should not occur, with an absolute value greater than the real thickness of the interphase. Since a penetration of both faces on the interphase is not physically realistic, the conditions (2.10) are valid only in the case of very small perturbations. With larger perturbations, finer modeling procedures are required, based on nonlinear contact laws [23]. Jump conditions of this kind, which are currently under study, require more complex numerical methods.

3. Time-marching.

3.1. Numerical scheme. To integrate the hyperbolic system (2.7), we introduce a uniform lattice of grid points: $(x_i, y_j, t_n) = (i\,\Delta x, j\,\Delta y, n\,\Delta t)$, where $\Delta x = \Delta y$ are the spatial mesh sizes and Δt is the time step. The approximation $\boldsymbol{U}_{i,j}^n$ of $\boldsymbol{U}(x_i, y_j, t_n)$ is computed using explicit two-step, spatially centered finite-difference schemes. The time-stepping of these schemes is written symbolically

$$\boldsymbol{U}_{i,j}^{n+1} = \boldsymbol{H}_{i,j}\left(\boldsymbol{U}_{i+\tilde{i},\,j+\tilde{j}}^{n},\ (\tilde{i},\,\tilde{j}) \in \Sigma\right). \tag{3.1}$$

$\boldsymbol{H}_{i,j}$ is a discrete operator and Σ is the stencil of the scheme. The subscripts in $\boldsymbol{H}_{i,j}$ refer to the physical parameters at $(x_i,\, y_j)$. See [9] for a review of the huge body of literature on numerical methods for conservation laws.

The interface Γ is immersed in the regular meshing, so that one can distinguish between two sets of grid points: the [illegible], where the stencil of the scheme involves a single medium, e.g., Ω_0 or Ω_1, and the [illegible], where the stencil of the scheme crosses Γ. The distribution of irregular points along Γ obviously depends on the geometry of Γ and on the stencil of the scheme. At regular points, the scheme (3.1) is applied classically, as in homogeneous media. At irregular points, however, the scheme (3.1) is modified to take the spring-mass conditions (2.10) into account. This modification is carried out using an interface method, and the main aim of the present article is to describe this procedure, which will be presented in detail in subsequent sections.

In the numerical experiments described in section 5, we use a second-order scheme: the wave propagation algorithm (WPALG), originally developed by LeVeque in the field of computational fluid dynamics [10]. Its stencil is ($\tilde{i} = -2 \ldots 2$, $\tilde{j} = -2 \ldots 2$) and $(\tilde{i},\, \tilde{j}) \neq (\pm 2, \pm 2)$. WPALG is a useful tool for dealing with linear elastic wave propagation, for at least three reasons. First, it involves the use of nonlinear flux limiters that prevent numerical dispersion. Second, this scheme reduces the numerical anisotropy introduced by the Cartesian grid. Third, WPALG is stable in two dimensions up to CFL = 1. For the convergence measurements performed in section 5 (test 1), we also used the standard second-order Lax–Wendroff scheme.

Note that other schemes can be used: in particular, we have successfully combined the interface method with staggered schemes, such as [19]. It should therefore be possible to adapt most solvers for use with the interface method described in the forthcoming discussion.

3.2. Interface method. From now on, we will focus on the time-stepping procedure near the interface. To take into account the spring-mass conditions satisfied along Γ, the scheme (3.1) is also applied at irregular points, but some of the numerical values used for the time-stepping procedure are changed. The use of so-called modified values deduced from the jump conditions is the key feature of the interface method developed in our previous studies: the "explicit simplified interface method"

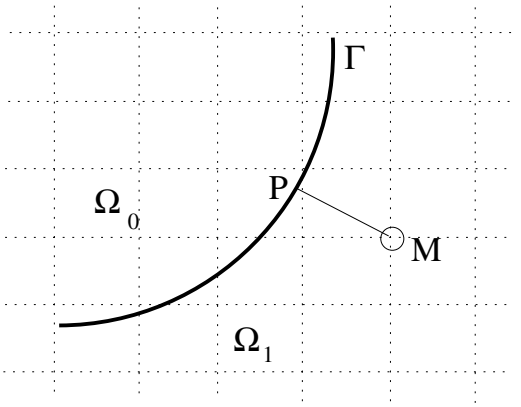

FIG. 3.1. *Zoom on an irregular point M; orthogonal projection P of M onto Γ.*

TABLE 3.1
n with indices used throughout the text ($l = 0, 1$).

	Value	Number of

n_c	$2(k+1)(k+2)$	jump conditions
n_m	$k(k-1)/2$	compatibility conditions
n_q	variable	grid points to estimate $\boldsymbol{U}_l^k$

(ESIM) [11, 12, 15]. At time t_n, the general method used to compute modified values is as follows. On each side of Γ, one defines a smooth extension $\boldsymbol{U}^*(x, y, t_n)$ of the exact solution on the other side. The extension $\boldsymbol{U}^*$ is built satisfying the same jump conditions as the exact solution $\boldsymbol{U}$. At any irregular point, the modified value is a numerical estimate of $\boldsymbol{U}^*$ at this point.

Let us introduce some notation. Take an irregular point M with coordinates (x_I, y_J), belonging to Ω_1. (The following discussion can easily be adapted to the case where $M(x_I, y_J) \in \Omega_0$.) Let $P(x_P, y_P)$ be a point on Γ near M, for example, the closest orthogonal projection of M onto Γ (Figure 3.1). The vector containing the limit values of the exact solution $\boldsymbol{U}(x, y, t_n)$ and those of its spatial derivatives at P up to the kth order is denoted by

$$\boldsymbol{U}_l^k = \lim_{M \to P, M \in \Omega_l} {}^T\left({}^T\boldsymbol{U}, \ldots, \frac{\partial^\alpha}{\partial x^{\alpha-\beta}\, \partial y^\beta}\, {}^T\boldsymbol{U}, \ldots, \frac{\partial^k}{\partial y^k}\, {}^T\boldsymbol{U} \right), \tag{3.2}$$

where $l = 0$ or 1, $\alpha = 0, \ldots, k$, and $\beta = 0, \ldots, \alpha$. This vector has $n_v = 5(k+1)(k+2)/2$ components. Throughout the text, many n with indices have been used; to avoid any confusion, they are summed up in Table 3.1. To obtain concise expressions for the

kth order Taylor expansions at P of quantities at $(x_i,\, y_j)$, we define the $5 \times n_v$ matrix

$$\mathbf{\Pi}^k_{i,j} = \left(\boldsymbol{I}_5, \ldots, \frac{1}{\beta\,!\,(\alpha-\beta)\,!}\,(x_i - x_P)^{\alpha-\beta}(y_j - y_P)^{\beta}\boldsymbol{I}_5, \ldots, \frac{(y_j - y_P)^k}{k\,!}\,\boldsymbol{I}_5 \right), \tag{3.3}$$

where $\boldsymbol{I}_5$ is the 5×5 identity matrix, $\alpha = 0, \ldots, k$, and $\beta = 0, \ldots, \alpha$. The modified value $\boldsymbol{U}^*_{I,J}$ is then defined as a numerical estimate of the smooth extension

$$\boldsymbol{U}^*(x_I, y_J, t_n) = \mathbf{\Pi}^k_{I,J}\,\boldsymbol{U}^k_0. \tag{3.4}$$

Note that $\boldsymbol{U}^k_0$ is the limit value of the solution and its spatial derivatives on the other side of Γ with respect to M.

The modified values at all the irregular points surrounding Γ are computed in a similar way at t_n. The time-stepping at an irregular point (i, j) is written symbolically

$$\boldsymbol{U}^{n+1}_{i,j} = \boldsymbol{H}_{i,j}\left(\hat{\boldsymbol{U}}^n_{i+\tilde{i},\, j+\tilde{j}},\, (\tilde{i},\, \tilde{j}) \in \Sigma \right), \tag{3.5}$$

where

$$\hat{\boldsymbol{U}}_{i+\tilde{i},\, j+\tilde{j}} = \begin{cases} \boldsymbol{U}^n_{i+\tilde{i},\, j+\tilde{j}} \text{ if } (x_{i+\tilde{i}},\, y_{j+\tilde{j}}) \in \Omega_1, \\ \\ \boldsymbol{U}^*_{i+\tilde{i},\, j+\tilde{j}} \text{ if } (x_{i+\tilde{i}},\, y_{j+\tilde{j}}) \in \Omega_0. \end{cases} \tag{3.6}$$

The time-stepping procedure is completed over the whole computational domain by applying (3.1) at the regular points. It only remains now to calculate $\boldsymbol{U}^*$'s, since $\boldsymbol{U}^k_0$ in (3.4) is unknown.

4. Calculating modified values.

4.1. Differentiation of the spring-mass conditions. In the first step toward calculating the modified value (3.4), we look for the jump conditions satisfied by $\boldsymbol{U}^k_l$ (3.2) for any k. These conditions are deduced from the spring-mass conditions (2.10) satisfied by $u_{N,T}$ and $\sigma_{N,T}$. Before describing the procedure, let us introduce a new notation. The vector containing the limit values of the $(k+1)$th spatial derivatives of $\boldsymbol{U}(x, y, t)$ at P is denoted by

$$\overline{\boldsymbol{U}}^{k+1}_l = \lim_{M \to P,\, M \in \Omega_l} {}^T\left(\frac{\partial^{k+1}}{\partial\, x^{k+1}}\,{}^T\boldsymbol{U}, \ldots, \frac{\partial^{k+1}}{\partial\, x^{k+1-\alpha}\,\partial\, y^{\alpha}}\,{}^T\boldsymbol{U}, \ldots, \frac{\partial^{k+1}}{\partial\, y^{k+1}}\,{}^T\boldsymbol{U} \right), \tag{4.1}$$

where $l = 0$ or 1, $\alpha = 0, \ldots, k+1$. This vector has $5(k+2)$ components. Once again, the point P considered and the instant t are omitted.

For $k = 0$, the two equations in (2.10) that deal with the jump in the elastic displacement are differentiated in terms of t. The geometry of Γ and stiffness and mass values do not depend on t; since $\boldsymbol{v} = \frac{\partial \boldsymbol{u}}{\partial\, t}$, we obtain

$$\begin{aligned} [v_N(P,\, t)] &= \frac{1}{K_N}\,\frac{\partial}{\partial\, t}\,\sigma_{N0}(P,\, t), \qquad [\sigma_N(P,\, t)] = M_N\,\frac{\partial}{\partial\, t}\,v_{N0}(P,\, t), \\ [v_T(P,\, t)] &= \frac{1}{K_T}\,\frac{\partial}{\partial\, t}\,\sigma_{T0}(P,\, t), \qquad [\sigma_T(P,\, t)] = M_T\,\frac{\partial}{\partial\, t}\,v_{T0}(P,\, t). \end{aligned} \tag{4.2}$$

The time derivatives in (4.2) are replaced by spatial derivatives thanks to the conservation laws (2.7). We sum up the relations thus obtained in matrix terms

$$\boldsymbol{C}_1^0\,\boldsymbol{U}_1^0 = \boldsymbol{C}_0^0\,\boldsymbol{U}_0^0 + \boldsymbol{E}_0^0\,\overline{\boldsymbol{U}}_0^1. \tag{4.3}$$

$\boldsymbol{C}_l^0$ $(l = 0, 1)$ are 4×5 matrices; $\boldsymbol{U}_l^0$ are the vectors (3.2) for $k = 0$ (i.e., the limit values of (2.6)); $\boldsymbol{E}_0^0$ is a 4×10 matrix; last, $\overline{\boldsymbol{U}}_0^1$ is the vector (4.1) for $l = 0$ and $k = 0$. Matrices $\boldsymbol{C}_l^0$ describe the perfectly bonded conditions (2.9). Matrix $\boldsymbol{E}_0^0$ describes the correction induced by the springs and masses in (2.10). Both matrices $\boldsymbol{C}_l^0$ and $\boldsymbol{E}_0^0$ depend on τ, but they are independent of t; they are dealt with in greater detail in Appendix B.

To compute the conditions satisfied up to $k = 1$, we differentiate (4.3) in terms of t and τ. First, the differentiation of (4.3) in terms of t yields

$$\boldsymbol{C}_1^0\,\frac{\partial}{\partial t}\,\boldsymbol{U}_1^0 = \boldsymbol{C}_0^0\,\frac{\partial}{\partial t}\,\boldsymbol{U}_0^0 + \boldsymbol{E}_0^0\,\frac{\partial}{\partial t}\,\overline{\boldsymbol{U}}_0^1. \tag{4.4}$$

The time derivatives in (4.4) are replaced by spatial derivatives, using the conservation laws (2.7); with the notations (3.2) and (4.1), one readily obtains $(l = 0, 1)$

$$\frac{\partial}{\partial t}\,\boldsymbol{U}_l^0 = \begin{pmatrix} \mathbf{0} & -\boldsymbol{A}_l & -\boldsymbol{B}_l \end{pmatrix} \boldsymbol{U}_l^1, \qquad \frac{\partial}{\partial t}\,\overline{\boldsymbol{U}}_0^1 = \begin{pmatrix} -\boldsymbol{A}_0 & -\boldsymbol{B}_0 & \mathbf{0} \\ \mathbf{0} & -\boldsymbol{A}_0 & -\boldsymbol{B}_0 \end{pmatrix} \overline{\boldsymbol{U}}_0^2,$$

which are injected into (4.4). Second, the differentiation of (4.3) in terms of τ yields

$$\left(\frac{d}{d\tau}\,\boldsymbol{C}_1^0\right) \boldsymbol{U}_1^0 + \boldsymbol{C}_1^0\,\frac{\partial}{\partial \tau}\,\boldsymbol{U}_1^0 = \left(\frac{d}{d\tau}\,\boldsymbol{C}_0^0\right) \boldsymbol{U}_0^0 + \boldsymbol{C}_0^0\,\frac{\partial}{\partial \tau}\,\boldsymbol{U}_0^0 + \left(\frac{d}{d\tau}\,\boldsymbol{E}_0^0\right) \overline{\boldsymbol{U}}_0^1 + \boldsymbol{E}_0^0\,\frac{\partial}{\partial \tau}\,\overline{\boldsymbol{U}}_0^1. \tag{4.5}$$

Since $\boldsymbol{U}_l^0$ $(l = 0, 1)$ and $\overline{\boldsymbol{U}}_0^1$ depend on $x(\tau)$ and $y(\tau)$, the chain-rule gives

$$\begin{aligned} l = 0, 1, \qquad \frac{\partial}{\partial \tau}\,\boldsymbol{U}_l^0 &= x'\,\frac{\partial}{\partial x}\,\boldsymbol{U}_l^0 + y'\,\frac{\partial}{\partial y}\,\boldsymbol{U}_l^0 \\ &= \begin{pmatrix} \mathbf{0} & x'\boldsymbol{I}_5 & y'\boldsymbol{I}_5 \end{pmatrix} \boldsymbol{U}_l^1 \end{aligned}$$

and

$$\frac{\partial}{\partial \tau}\,\overline{\boldsymbol{U}}_0^1 = \begin{pmatrix} x'\boldsymbol{I}_5 & y'\boldsymbol{I}_5 & \mathbf{0} \\ \mathbf{0} & x'\boldsymbol{I}_5 & y'\boldsymbol{I}_5 \end{pmatrix} \overline{\boldsymbol{U}}_0^2.$$

Due to the normalization of vectors $\boldsymbol{n}$ and $\boldsymbol{t}$ in (2.1) and (2.3), special care must be taken with the differentiation procedure $\frac{d}{d\tau}\,\boldsymbol{E}_0^0$ in (4.5) (see Appendix B). From the previous discussion, one builds three 12×15 matrices $\boldsymbol{C}_0^1$, $\boldsymbol{C}_1^1$ and $\boldsymbol{D}_0^1$, and one 12×15 matrix $\boldsymbol{E}_0^1$, so that

$$\boldsymbol{C}_1^1\,\boldsymbol{U}_1^1 = \left(\boldsymbol{C}_0^1 + \boldsymbol{D}_0^1\right) \boldsymbol{U}_0^1 + \boldsymbol{E}_0^1\,\overline{\boldsymbol{U}}_0^2. \tag{4.6}$$

Matrices $\boldsymbol{C}_l^1$ describe the influence of perfectly bonded conditions. Matrices $\boldsymbol{D}_0^1$ and $\boldsymbol{E}_0^1$ describe the changes introduced by the springs and masses.

By iterating a similar procedure $(k-1)$ times, one can find matrices such that

$$\boxed{\boldsymbol{C}_1^k\,\boldsymbol{U}_1^k = \left(\boldsymbol{C}_0^k + \boldsymbol{D}_0^k\right)\,\boldsymbol{U}_0^k + \boldsymbol{E}_0^k\,\overline{\boldsymbol{U}}_0^{k+1},} \tag{4.7}$$

where $\boldsymbol{C}_0^k$, $\boldsymbol{C}_1^k$, and $\boldsymbol{D}_0^k$ are $n_c \times n_v$ matrices with $n_c = 2(k+1)(k+2)$ and $n_v = 5(k+1)(k+2)/2$; $\boldsymbol{E}_0^k$ is a $n_c \times 5(k+2)$ matrix. (In practice and as shown in section 4.4, the last matrix is never computed.) This is a tedious procedure, however, even with low values of k (e.g., $k=1$). This task can be carried out automatically by developing appropriate formal calculus tools; the simulations shown in section 5 were obtained in this way.

4.2. Compatibility conditions. Some components of the spatial derivatives of $\boldsymbol{U}$ are not independent. We set

$$\alpha_1 = \frac{\lambda + 2\,\mu}{4\,(\lambda+\mu)} = \frac{c_p^2}{4\left(c_p^2 - c_s^2\right)}, \qquad \alpha_2 = \frac{-\lambda}{4\,(\lambda+\mu)} = \frac{2\,c_s^2 - c_p^2}{4\left(c_p^2 - c_s^2\right)}, \tag{4.8}$$

where λ and μ are the Lamé coefficients. Then, the standard plane elasticity [illegible] of Saint-Venant [6, 13] are, in terms of stresses,

$$\alpha_2\,\frac{\partial^2\,\sigma_{11}}{\partial\,x^2} + \alpha_1\,\frac{\partial^2\,\sigma_{22}}{\partial\,x^2} - \frac{\partial^2\,\sigma_{12}}{\partial\,x\,\partial\,y} + \alpha_1\,\frac{\partial^2\,\sigma_{11}}{\partial\,y^2} + \alpha_2\,\frac{\partial^2\,\sigma_{22}}{\partial\,y^2} = 0. \tag{4.9}$$

Equation (4.9) is differentiated $(k-2)$-times in terms of x and y, giving the $n_m = k(k-1)/2$ relations

$$\begin{aligned} &\alpha_2\,\frac{\partial^k\,\sigma_{11}}{\partial\,x^{k-j}\,\partial\,y^j} + \alpha_1\,\frac{\partial^k\,\sigma_{22}}{\partial\,x^{k-j}\,\partial\,y^j} - \frac{\partial^k\,\sigma_{12}}{\partial\,x^{k-j-1}\,\partial\,y^{j+1}} \\ &+ \alpha_1\,\frac{\partial^k\,\sigma_{11}}{\partial\,x^{k-j-2}\,\partial\,y^{j+2}} + \alpha_2\,\frac{\partial^k\,\sigma_{22}}{\partial\,x^{k-j-2}\,\partial\,y^{j+2}} = 0, \quad k \geq 2,\ j = 0, \ldots, k-2. \end{aligned} \tag{4.10}$$

Conditions (4.10) are satisfied at each point in Ω_l $(l = 0, 1)$, especially at P (see Figure 2.1). One can therefore express the limit values $\boldsymbol{U}_l^k$ in terms of a vector $\boldsymbol{V}_l^k$ with $n_v - n_m$ independent components

$$\boxed{\boldsymbol{U}_l^k = \boldsymbol{G}_l^k\,\boldsymbol{V}_l^k, \quad l = 0, 1,} \tag{4.11}$$

where $\boldsymbol{G}_l^k$ is a $n_v \times (n_v - n_m)$ matrix deduced from (4.10). The relation (4.11) is useful to reduce the number of components in (4.7), as seen in the next subsection. An algorithm has been proposed in [12] for computing the nonnull components of $\boldsymbol{G}_l^k$

but there was a mistake for $k \geq 3$. The correct algorithm is ($l = 0,\ 1$)

$$
\begin{array}{l}
\alpha = 0, \quad \beta = 0, \\
\text{for } \gamma = 0, \ldots, k, \text{ for } \delta = 0, \ldots, \gamma \\
\quad \text{if } \delta = 0 \text{ then for } \varepsilon = 1, \ldots, 5 \\
\quad\quad \alpha = \alpha + 1, \quad \beta = \beta + 1, \quad \boldsymbol{G}_l^k[\alpha, \beta] = 1 \\
\quad \text{if } \gamma \neq 0 \text{ and } \delta \neq 0 \text{ and } \gamma \neq \delta \text{ then} \\
\quad\quad \text{if } \gamma = 2 \text{ then } \nu = 0,\ \eta = 0, \\
\quad\quad \text{else if } \delta = 1 \text{ then } \nu = 0,\ \eta = 1, \\
\quad\quad \text{else if } \delta = \gamma - 1 \text{ then } \nu = 1,\ \eta = 0, \\
\quad\quad \text{else } \nu = 1,\ \eta = 1, \\
\quad\quad \alpha = \alpha + 1, \quad \beta = \beta + 1, \qquad \boldsymbol{G}_l^k[\alpha, \beta] = 1 \\
\quad\quad \alpha = \alpha + 1, \quad \beta = \beta + 1, \qquad \boldsymbol{G}_l^k[\alpha, \beta] = 1 \\
\quad\quad \alpha = \alpha + 1, \quad \beta = \beta + 1, \qquad \boldsymbol{G}_l^k[\alpha, \beta] = 1 \\
\quad\quad \alpha = \alpha + 1, \quad \beta = \beta - 5 + \nu, \quad \boldsymbol{G}_l^k[\alpha, \beta] = \alpha_2 \\
\quad\quad\quad\quad\quad\ \beta = \beta + 2 - \nu, \quad \boldsymbol{G}_l^k[\alpha, \beta] = \alpha_1 \\
\quad\quad\quad\quad\quad\ \beta = \beta + 7, \qquad \boldsymbol{G}_l^k[\alpha, \beta] = \alpha_1 \\
\quad\quad\quad\quad\quad\ \beta = \beta + 2 - \eta, \quad \boldsymbol{G}_l^k[\alpha, \beta] = \alpha_2 \\
\quad\quad \alpha = \alpha + 1, \quad \beta = \beta - 5 + \eta, \quad \boldsymbol{G}_l^k[\alpha, \beta] = 1 \\
\quad \text{if } \gamma \neq 0 \text{ and } \gamma = \delta \text{ then for } \varepsilon = 1, \ldots, 5 \\
\quad\quad \alpha = \alpha + 1, \quad \beta = \beta + 1, \quad \boldsymbol{G}_l^k[\alpha, \beta] = 1.
\end{array}
\tag{4.12}
$$

4.3. Solution of underdetermined systems. It is now required to express $\boldsymbol{V}_1^k$ in terms of $\boldsymbol{V}_0^k$. For this purpose, we inject the compatibility conditions (4.11) into the jump conditions (4.7). Setting

$$
\boldsymbol{S}_1^k = \boldsymbol{C}_1^k \, \boldsymbol{G}_1^k, \qquad \boldsymbol{S}_0^k = \left(\boldsymbol{C}_0^k + \boldsymbol{D}_0^k \right) \boldsymbol{G}_0^k,
\tag{4.13}
$$

we obtain the underdetermined system

$$
\boldsymbol{S}_1^k \, \boldsymbol{V}_1^k = \boldsymbol{S}_0^k \, \boldsymbol{V}_0^k + \boldsymbol{E}_0^k \, \overline{\boldsymbol{U}}_0^{k+1}.
\tag{4.14}
$$

To find the full range of solutions of (4.14), a singular value decomposition (SVD) of $\boldsymbol{S}_1^k$ [16] is computed. Setting $(\boldsymbol{S}_1^k)^{-1}$ to denote the $(n_v - n_m) \times n_c$ generalized inverse of $\boldsymbol{S}_1^k$ and $\boldsymbol{R}_{s_1}^k$ to denote the $(n_v - n_m) \times (n_v - n_m - n_c)$ matrix associated with the kernel of $\boldsymbol{S}_1^k$, we obtain

$$
\boxed{\boldsymbol{V}_1^k = \left(\left(\boldsymbol{S}_1^k \right)^{-1} \boldsymbol{S}_0^k \,|\, \boldsymbol{R}_{s_1}^k \right) \begin{pmatrix} \boldsymbol{V}_0^k \\ \\ \boldsymbol{\Lambda}^k \end{pmatrix} + \left(\boldsymbol{S}_1^k \right)^{-1} \boldsymbol{E}_0^k \, \overline{\boldsymbol{U}}_0^{k+1}},
\tag{4.15}
$$

where $\boldsymbol{\Lambda}_k$ is a $(n_v - n_m - n_c)$ vector of Lagrange multipliers. A similar procedure can be used to express $\boldsymbol{V}_0^k$ in terms of $\boldsymbol{V}_1^k$.

4.4. Numerical estimates of limit fields. Consider a set $\mathcal{B}$ of n_q grid points surrounding P; for practical purposes, we define $\mathcal{B}$ as the set of grid points whose distance from P is less than a given distance q. We successively examine each grid point in $\mathcal{B}$, writing the kth order Taylor expansions of $\boldsymbol{U}(x_i, y_j, t_n)$ at P. If $(x_i,\, y_j)$ is included in Ω_0, we deduce from (3.3) and (4.11) that

$$
\begin{aligned}
(x_i,\, y_j) \in \mathcal{B} \cap \Omega_0, \quad \boldsymbol{U}(x_i, y_j, t_n) &= \boldsymbol{\Pi}_{i,j}^k\, \boldsymbol{U}_0^k + \boldsymbol{O}(\Delta\, x^{k+1}) \\
&= \boldsymbol{\Pi}_{i,j}^k\, \boldsymbol{G}_0^k\, \boldsymbol{V}_0^k + \boldsymbol{O}(\Delta\, x^{k+1}) \\
&= \boldsymbol{\Pi}_{i,j}^k\, \boldsymbol{G}_0^k\, (\mathbf{1} \,|\, \mathbf{0}) \begin{pmatrix} \boldsymbol{V}_0^k \\ \\ \boldsymbol{\Lambda}^k \end{pmatrix} + \boldsymbol{O}(\Delta\, x^{k+1}),
\end{aligned}
\tag{4.16}
$$

where $\mathbf{1}$ is the identity matrix $(n_v - n_m) \times (n_v - n_m)$ and $\mathbf{0}$ is the null matrix $(n_v - n_m) \times (n_v - n_m - n_c)$. If $(x_i,\, y_j)$ is included in Ω_1, we deduce from (3.3), (4.11), and (4.15) that

$$
\begin{aligned}
(x_i,\, y_j) \in \mathcal{B} \cap \Omega_1, \quad \boldsymbol{U}(x_i, y_j, t_n) &= \boldsymbol{\Pi}_{i,j}^k\, \boldsymbol{U}_1^k + \boldsymbol{O}(\Delta\, x^{k+1}) \\
&= \boldsymbol{\Pi}_{i,j}^k\, \boldsymbol{G}_1^k\, \boldsymbol{V}_1^k + \boldsymbol{O}(\Delta\, x^{k+1}) \\
&= \boldsymbol{\Pi}_{i,j}^k\, \boldsymbol{G}_1^k \begin{pmatrix} \left(\boldsymbol{S}_1^k\right)^{-1} \boldsymbol{S}_0^k \,|\, \boldsymbol{R}_{s_1}^k \end{pmatrix} \begin{pmatrix} \boldsymbol{V}_0^k \\ \\ \boldsymbol{\Lambda}^k \end{pmatrix} \\
&\quad + \boldsymbol{\Pi}_{i,j}^k\, \boldsymbol{G}_1^k \left(\boldsymbol{S}_1^k\right)^{-1} \boldsymbol{E}_0^k\, \overline{\boldsymbol{U}}_0^{k+1} + \boldsymbol{O}(\Delta\, x^{k+1}).
\end{aligned}
\tag{4.17}
$$

Relations (4.16) and (4.17) are summed up in matrix terms as

$$
(\boldsymbol{\mathcal{U}}^n)_{\mathcal{B}} = \boldsymbol{M} \begin{pmatrix} \boldsymbol{V}_0^k \\ \\ \boldsymbol{\Lambda}^k \end{pmatrix} + \boldsymbol{N}\, \overline{\boldsymbol{U}}_0^{k+1} + \begin{pmatrix} \boldsymbol{O}(\Delta\, x^{k+1}) \\ \vdots \\ \boldsymbol{O}(\Delta\, x^{k+1}) \end{pmatrix},
\tag{4.18}
$$

where $(\boldsymbol{\mathcal{U}}^n)_{\mathcal{B}}$ refers to the set of exact values $\boldsymbol{U}(x_i, y_j, t_n)$ at the grid points of $\mathcal{B}$, $\boldsymbol{M}$ is a $5\, n_q \times (2\, n_v - 2\, n_m - n_c)$ matrix, and $\boldsymbol{N}$ is a $5\, n_q \times 5(k+2)$ matrix. The value of n_q depends on $\mathcal{B}$; this set is chosen so that (4.18) is overdetermined. In view of Table 3.1 and Table 4.1, this means that

$$
\begin{aligned}
n_q &\geq (2\, n_v - 2\, n_m - n_c)/5 \\
&\geq 2\left(k^2 + 5\, k + 3\right)/5.
\end{aligned}
$$

To ensure this inequality,

$$
q = (k + 0.2)\, \Delta\, x
\tag{4.19}
$$

can be used as a radius to obtain $\mathcal{B}$. From now on, numerical values and exact values are used indiscriminately in (4.18). We also remove $\boldsymbol{N}\, \overline{\boldsymbol{U}}_0^{k+1}$ and the remainder terms. The least-squares inverse $\boldsymbol{M}^{-1}$ of $\boldsymbol{M}$ is computed using classical techniques, such as

TABLE 4.1
Matrices used for computing the modified values ($l = 0, 1$).

Matrix	Size	Comment
$\boldsymbol{C}_l^k$	$n_c \times n_v$	jump conditions: perfect contact (4.7)
$\boldsymbol{D}_l^k$	$n_c \times n_v$	jump conditions: imperfect contact (4.7)
$\boldsymbol{G}_l^k$	$n_v \times (n_v - n_m)$	compatibility conditions (4.11)
$\boldsymbol{S}_l^k$	$n_c \times (n_v - n_m)$	(4.13)
$\boldsymbol{R}_{s_l}^k$	$(n_v - n_m) \times (n_v - n_c - n_m)$	kernel of $\boldsymbol{S}_l^k$ (4.15)
$\boldsymbol{\Pi}_{i,j}^k$	$5 \times n_v$	Taylor expansions (3.3)
$\mathbf{1}$	$(n_v - n_m) \times (n_v - n_m)$	identity (4.16)
$\mathbf{0}$	$(n_v - n_m) \times (n_v - n_c - n_m)$	null (4.16)
$\boldsymbol{M}$	$5\,n_q \times (2\,n_v - 2\,n_v - n_c)$	(4.18)
$\overline{\boldsymbol{M}^{-1}}$	$(n_v - n_q) \times 5\,n_q$	restriction of $\boldsymbol{M}^{-1}$ (4.21)

LU or SVD [16]. The set of Lagrange multipliers $\boldsymbol{\Lambda}^k$ is not useful for computing modified values; the restriction $\overline{\boldsymbol{M}^{-1}}$ of $\boldsymbol{M}^{-1}$ is therefore defined by keeping only the $(n_v - n_m)$ first lines of $\boldsymbol{M}^{-1}$. This gives the least-squares numerical estimate

$$\boldsymbol{V}_0^k = \overline{\boldsymbol{M}^{-1}}\,(\boldsymbol{\mathcal{U}}^n)_{\mathcal{B}}\,. \tag{4.20}$$

4.5. Modified value. We now have all the tools required to be able to compute the modified value at $M(x_I, y_J)$, as defined in section 3.2. The modified value at (x_I, y_J) is deduced from (3.4), (4.11), and (4.20),

$$\boxed{\boldsymbol{U}_{I,J}^* = \boldsymbol{\Pi}_{I,J}^k\,\boldsymbol{G}_0^k\,\overline{\boldsymbol{M}^{-1}}\,(\boldsymbol{\mathcal{U}}^n)_{\mathcal{B}}\,.} \tag{4.21}$$

A similar procedure is applied at each irregular point surrounding Γ. All the matrices required to compute the modified values are recalled in Table 4.1 with their sizes.

4.6. Comments about the algorithm. This algorithm can easily be adapted to existing codes without having to change the scheme. At each time step, one only needs to compute a few "modified values" (4.21), which do not depend on the scheme selected.

Since the interface is stationary and the nature of the contacts does not vary with time, most of the algorithm can be built up during a preprocessing step, consisting in determining irregular points, deriving interface conditions (4.7), solving underdetermined systems (4.15), and computing the matrices involved in (4.21). All these quantities are stored for future use. At each time step, we need only to carry out one matrix-vector multiplication (4.21) at each irregular point, before running time-stepping procedure. The matrices involved here are small: $5 \times 5\,n_q$ components, usually with $n_q \approx 20$. In addition, the number of irregular points is much smaller than the number of grid points. The extra computational cost is therefore very low. The CPU time measurements are likely to be approximately the same as those presented in [12].

The main aim of the interface method is to incorporate the jump conditions into finite-difference schemes. But it also gives a finer resolution of the geometries than the poor stair-step description induced by the Cartesian grid. The differentiations of spring-mass conditions involve successive derivatives of $x^{'}$ and $y^{'}$ (see section 4.1). In addition, the Taylor expansions in (4.16), (4.17), and (4.21) give information about the position of P inside the mesh.

In section 3.1, we stated that the interface method can be adapted to staggered grid schemes. This adaptation requires the algebra in sections 3 and 4 to be completely rewritten (although this is quite straightforward). To give an idea of the changes involved, let us focus on the staggered scheme [19] with a grid $(x_i,\, y_j,\, t_n)$ for stresses and a grid $(x_{i+\frac{1}{2}},\, y_{j+\frac{1}{2}},\, t_{n+\frac{1}{2}})$ for velocities. Two different sets of irregular points now need to be stored. The jump conditions for velocities and stresses are not correlated (see (4.3) and Appendix B); two independant systems of jump conditions (4.7) are therefore written. Since the jump conditions satisfied by the velocities yield as many equations as unknowns, they do not require an SVD. The compatibility conditions (4.10) are applied only to the jump conditions satisfied by the stresses, that constitute an underdetermined system. The modified values calculated in sections 4.4 and 4.5 are also split in two parts: at time $t_{n+\frac{1}{2}}$, the modified values of the stresses are computed (based on numerical values of $\boldsymbol{\sigma}$ at t_n) before being inserted into the time-marching procedure performed on the velocities. In the same way, at time t_{n+1}, the modified values of the velocities are computed (based on numerical values of $\boldsymbol{v}$ at $t_{n+\frac{1}{2}}$) before they are used to perform the time-marching procedure on the stresses.

4.7. Open questions. Four questions relating to numerical analysis remain to be solved. First, what are the effects of the term $\boldsymbol{N}\,\overline{\boldsymbol{U}}_0^{k+1}$ which was neglected in (4.18)? In one dimension [11], we established that this term is of the same order as the remainder terms. The proof in one dimension was based on performing explicit calculations on MAPLE; this approach seems difficult to apply in the two-dimensional context, because it depends on the geometry of Γ near P.

Second, what is the local truncation error at the irregular points obtained by combining the interface method with the scheme? In the one-dimensional context [11, 15], we established that the following was true: if r is the order of the scheme, the local truncation error at irregular points is still equal to r if $k \geq r$ (which means $k \geq 2$ in the case of second-order schemes such as WPALG), when this scheme is combined with the interface method. Extending this result to the two-dimensional context would require answering the previous question about $\boldsymbol{N}\,\overline{\boldsymbol{U}}_0^{k+1}$, and bounding the matrix $\overline{\boldsymbol{M}^{-1}}$. In practice, the convergence measurements indicate that this property is false in the two-dimensional context (at least for $r = 2$): we need $k = 3$ to ensure second-order accuracy (see section 5.2).

Third, what happens in the extreme case of a homogeneous medium (that is, $\rho_0 = \rho_1$, $c_{p0} = c_{p1}$, $c_{s0} = c_{s1}$, $K_N \to +\infty$, $K_T \to +\infty$, $M_N = 0$, and $M_T = 0$)? The ideal would obviously be that $\boldsymbol{U}_{i,j}^{*} = \boldsymbol{U}_{i,j}^{n}$, in order to recover the scheme in homogeneous medium. In one-dimensional configurations [11], we have shown that it is the case, given simple conditions about the set $\mathcal{B}$ used to estimate the modified values. In a two-dimensional context, these conditions cannot be satisfied because estimating the modified values requires least-squares computations. However, it would be interesting to estimate the difference between $\boldsymbol{U}_{i,j}^{*}$ and $\boldsymbol{U}_{i,j}^{n}$, which might lead to an optimal choice of $\mathcal{B}$.

Fourth and last, the stability analysis still remains to be performed. With a nonlinear scheme (such as WPALG), this seems out of reach so far, but an analysis could

perhaps be carried out with linear schemes (such as the Lax–Wendroff scheme). In the absence of theoretical rules, we have numerically considered many geometrical configurations, physical parameters values, stiffness, and mass values. With a wide range of parameters, no instabilities are usually observed up to the CFL limit, even after very long integration times (a few thousand time-steps). However, instabilities are observed in two cases. First, instabilities can increase when the physical parameters differ considerably between the two sides of an interface. This problem was previously mentioned in [12] in connection with perfect contacts. In practice, it is not too penalizing when dealing with realistic media: even quite large differences between the impedance values, such as those encountered in the case of Plexiglas-aluminium interfaces, yield stable computations. Second, the instabilities can increase at low values of $K_{N,T}$, when the two media tend to be disconnected. This may be due to the small denominators in (2.10). In this case, increasing the order k provides an efficient means of improving the stability limit (see subsection 5.4).

5. Numerical experiments.

5.1. Configurations. Five numerical experiments are performed here. Except for Test 3, the physical parameters are the same on both sides of Γ: this enables us to underscore both the effects of the spring-mass conditions and the accuracy of the interface method, since all wave reflections and changes observed will result from the spring-mass conditions, described numerically by the interface method.

Three geometrical configurations are studied: a plane interface, a circular interface, and a noncanonical object described by cubic splines. Analytical solutions can be obtained for the first two configurations when the spring-mass conditions are constant. The analytical solution of the problem with a plane wave impinging on a plane interface with spring-mass conditions can be quite easily calculated using Fourier analysis; this procedure will therefore not be described here. We have not found articles dealing with the more intricate case of a circular interface; since this analytical solution is useful to validate the algorithm, it has been described in Appendix C. Except for the convergence measurements in Test 1, all the computations were performed with the WPALG.

Apart from Test 5, the computations are all initialized by a plane right-going P-wave

$$\boldsymbol{U}(x,y,t_0) = \varepsilon \begin{pmatrix} -\dfrac{\cos\theta}{c_{p1}} \\ -\dfrac{\sin\theta}{c_{p1}} \\ \dfrac{\lambda_1 + 2\,\mu_1\,\cos^2\theta}{c_{p1}^2} \\ \dfrac{2\,\mu_1\,\sin\theta\,\cos\theta}{c_{p1}^2} \\ \dfrac{\lambda_1 + 2\,\mu_1\,\sin^2\theta}{c_{p1}^2} \end{pmatrix} f\left(t_0 - \frac{x\cos\theta + y\sin\theta}{c_{p1}}\right), \tag{5.1}$$

where ε is an amplitude factor, $\mu_1 = \rho_1\, c_{s1}^2$ and $\lambda_1 = \rho_1(c_{p1}^2 - 2\,c_{s1}^2)$ are the Lamé coefficients, θ is the angle between the direction of propagation and the x-axis, and

t_0 is the initial instant. Function f is a C^2 spatially bounded sinusoid

$$f(\xi) = \begin{cases} \sin(\omega_c\,\xi) - \dfrac{1}{2}\,\sin(2\,\omega_c\,\xi) & \text{if } 0 < \xi < \dfrac{1}{f_c}, \\ 0 \text{ else,} \end{cases} \tag{5.2}$$

where f_c is the central frequency, and $\omega_c = 2\,\pi\,f_c$.

We will conclude this section by making some comments on the figures. σ_{11} is shown with a green-red palette for P-waves and a magenta-yellow palette for SV-waves. (In the electronic version of this article, the plates are color.) The distinction between these waves depends on numerical estimates of div $\boldsymbol{v}$ and **curl** $\boldsymbol{v}$. Most of the snapshots shown are accompanied by a slice; the position of a slice is denoted by a horizontal line on the corresponding snapshot. On each slice, the exact solution and the numerical solution are indicated by a solid line and by points, respectively.

5.2. Test 1: Plane interface between identical media. Here we take the case of a $L_x \times L_y = 400 \times 400$ m^2 domain with a plane inclined interface Γ. The points ($x = 168$ m, $y = 17$ m) and ($x = 241$ m, $y = 253$ m) belong to Γ, and hence the angle between Γ and the x-axis is roughly equal to 72.8 degrees. The physical parameters are identical on both sides of Γ

$$\begin{cases} \rho_0 = \rho_1 = 1200 \text{ kg/m}^3, \\ c_{p0} = c_{p1} = 2800 \text{ m/s}, \\ c_{s0} = c_{s1} = 1400 \text{ m/s}, \end{cases}$$

which corresponds to realistic values in the case of Plexiglas. The spring-mass conditions are constant along Γ; the stiffness and mass values are

$$\begin{cases} K_N = 10^9 \text{ kg/s}^2, \quad K_T = 10^7 \text{ kg/s}^2, \\ M_N = 2000 \text{ kg/m}^2, \quad M_T = 1000 \text{ kg/m}^2. \end{cases}$$

The incident P-wave (5.1) is defined by $\theta = 40$ degrees, $f_c = 49.9$ Hz, $t_0 = 0.1$ s, and $\varepsilon = 2\,10^{-3}$. The numerical experiments are performed with $N_x \times N_y = 400 \times 400$ grid points, which amounts to 56 and 28 grid points per central wavelength for P-waves and SV-waves, respectively. We take CFL $= 0.9$, and $k = 2$ for the extrapolations involved in the interface method. To initialize the computation, one also needs to compute reflected and transmitted P- and SV-waves, via discrete Fourier transforms (DFT). To obtain the required level of accuracy, we perform the DFTs on 32768 points, with a sampling frequency of 0.018125 Hz. At each time step, the exact solution is imposed at the boundaries of the computational domain.

Figure 5.1 shows the solution at time steps $t_i = t_0 + 75\,i\,\Delta\,t$ $(i = 0, 1, 2)$. The slices are performed from

- $i = 0$: ($x = 70$ m, $y = 26$ m) to ($x = 360$ m, $y = 26$ m),
- $i = 1$: ($x = 156$ m, $y = 162$ m) to ($x = 207$ m, $y = 162$ m),
- $i = 2$: ($x = 246$ m, $y = 198$ m) to ($x = 282$ m, $y = 198$ m).

Looking from the left to the right on the first slice ($i = 0$), one can successively observe the reflected SV-wave, the transmitted SV-wave, and the transmitted P-wave. As mentioned in section 2.3, these waves do not have the same sinusoidal profile as the incident P-wave. A "coda" occurs after the reflected and transmitted P and SV-waves: as in [11], these fields are not spatially bounded in the direction of the propagation.

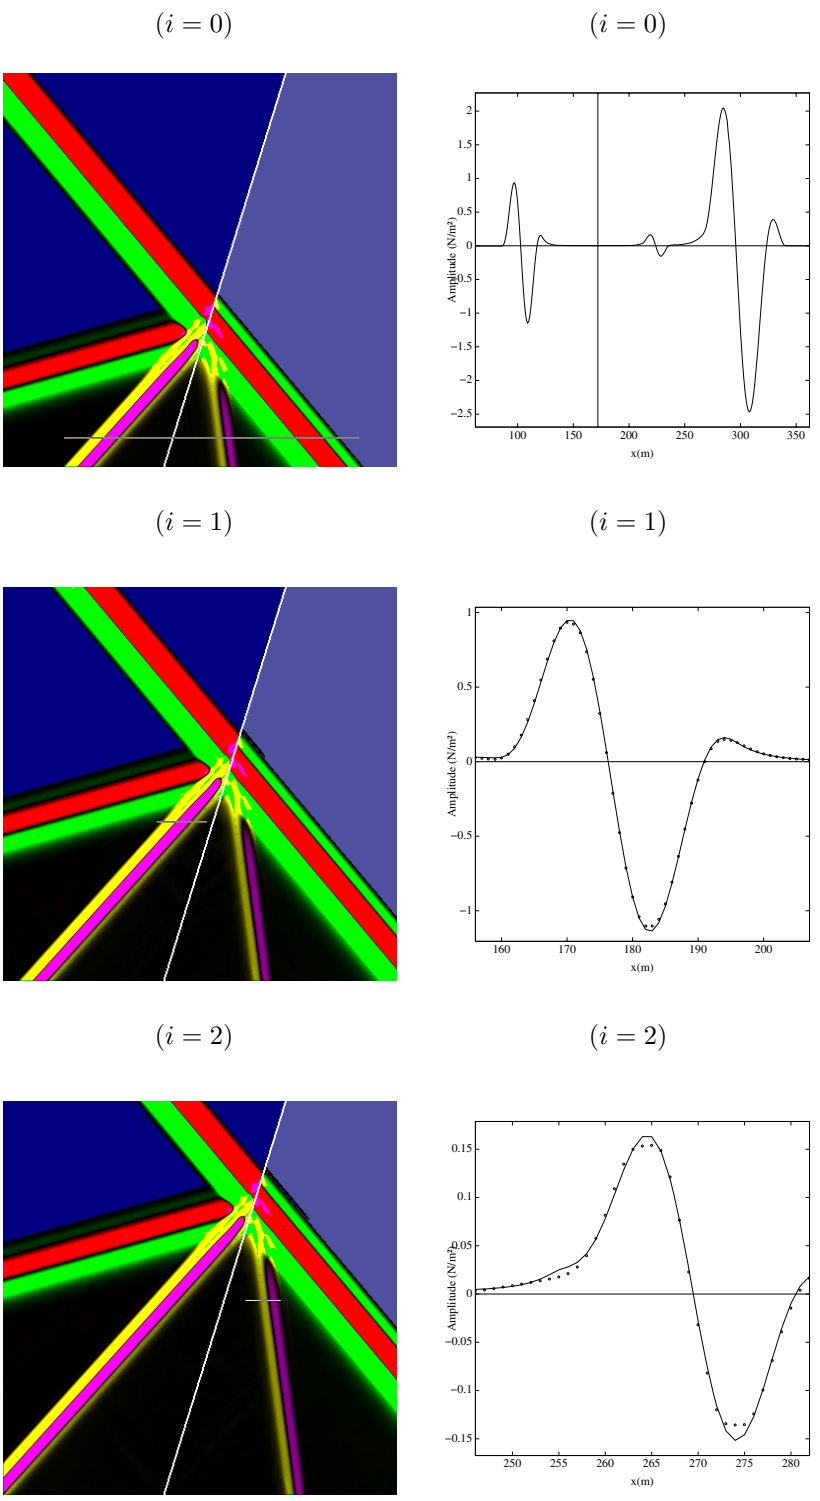

FIG. 5.1. *Test* 1: *plane interface between identical media at* $t = t_0 + 75\, i\, \Delta t$.

TABLE 5.1
Convergence measurements in Test 1.

Scheme	N_x	L_∞ error	L_∞ order	L_1 error	L_1 order
Lax–Wendroff	50	6.265e-1	-	4.676e3	-
	100	1.760e-1	**1.832**	1.336e3	**1.807**
+	200	4.755e-2	**1.888**	3.718e2	**1.845**
	400	1.228e-2	**1.953**	9.437e1	**1.978**
ESIM	800	3.164e-3	**1.956**	2.311e1	**2.030**
	1600	7.916e-4	**1.999**	5.667e0	**2.028**
WPALG	50	4.570e-1	-	6.259e2	-
	100	1.472e-1	**1.634**	1.504e2	**2.058**
+	200	4.260e-2	**1.789**	3.954e1	**1.926**
	400	1.398e-2	**1.607**	1.071e1	**1.884**
ESIM	800	4.464e-3	**1.647**	2.833e0	**1.919**
	1600	1.503e-3	**1.570**	7.369e-1	**1.943**

The second slice ($i = 1$) crosses the reflected SV-wave. The agreement between exact and numerical values is good; one only observes a small amount of numerical diffusion induced by WPALG. This is also so in the case of the last slice ($i = 2$) across the transmitted SV-wave.

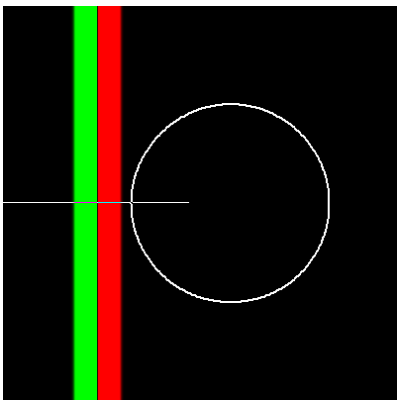
In Table 5.1, we show convergence measurements performed with the Lax–Wendroff scheme and with WPALG, by taking $k = 3$. This table was obtained by taking successively refined meshes with a constant CFL and measuring the differences between the analytical and numerical values. The orders of accuracy (2 for Lax–Wendroff, 1.5 in norm L_∞, and 2 in norm L_1 for WPALG) are the same as in homogeneous medium. Similar results can be obtained by increasing k. However, for $k = 2$, the convergence orders fall below 1.4. (We recall that $k = 2$ sufficies to ensure second-order accuracy for perfect contacts in two-dimensional contexts [12] and for imperfect contacts in one-dimensional contexts [11].)

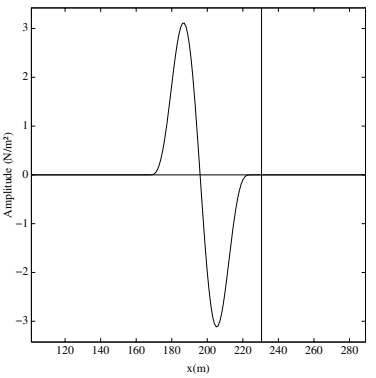
5.3. Test 2: Circular interface between identical media. As a second example, we take the case of a $L_x \times L_y = 600 \times 600$ m^2 domain and a circular interface (radius $a = 100$ m, centered at $x_0 = 330.5$ m, $y_0 = 300$ m). The numerical experiments are performed on $N_x \times N_y = 600 \times 600$ grid points. The physical parameters are the same as in the previous example. The spring-mass conditions are

$$\begin{cases} K_N = K_T = 10^9 \ \text{kg/s}^2, \\ M_N = M_T = 1000 \ \text{kg/m}^2. \end{cases}$$

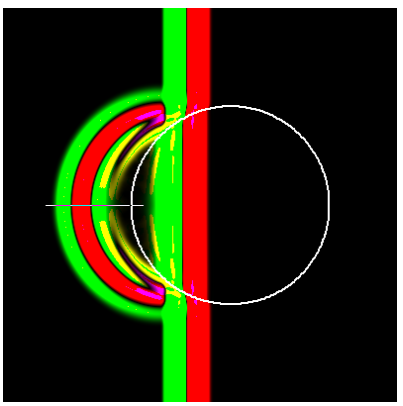
Figures 5.2 and 5.3 show the solution at the initial instant $t_0 = 0.08$ s, and at $t_i = t_0 + 100\, i\, \Delta t$ ($i = 1, \ldots, 5$) on a restricted domain $[100, 500] \times [100, 500]$ m^2 centered on the middle of the computational domain. No special treatment is applied to simulate the wave propagation in infinite medium (such as absorbing boundary conditions or perfectly matched layers), but the integration times are sufficiently short to prevent spurious waves reflected by the edges of the computational region from appearing

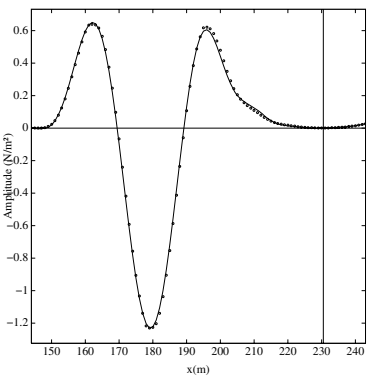
$(i = 0)$ $(i = 0)$



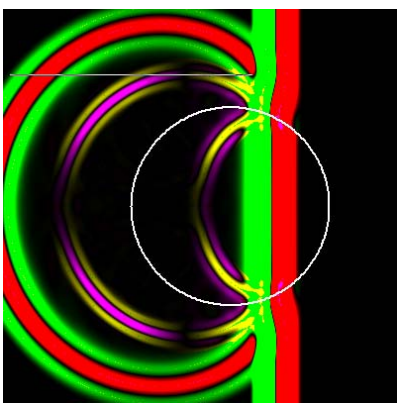


$(i = 1)$ $(i = 1)$





$(i = 2)$ $(i = 2)$



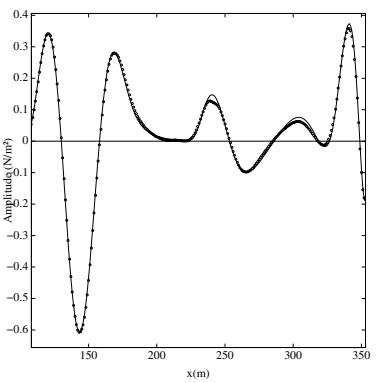


FIG. 5.2. *Test* 2-*a: cylindar between identical media,* $t = t_0 + 100\, i\, \Delta\, t$.

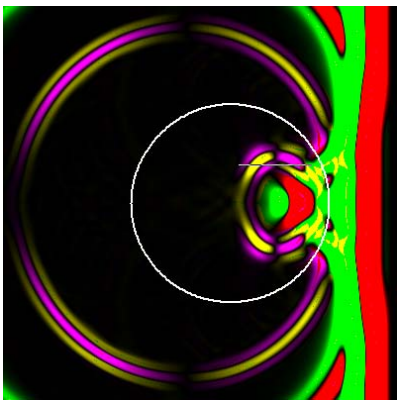
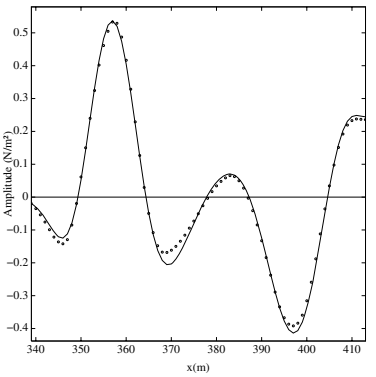
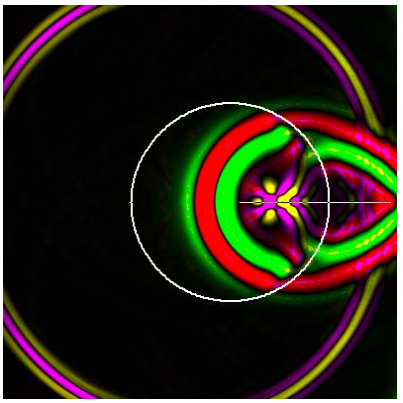
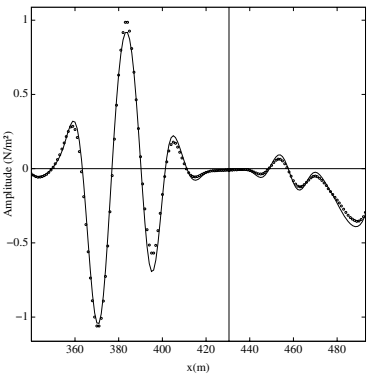
$(i = 3)$ $(i = 3)$



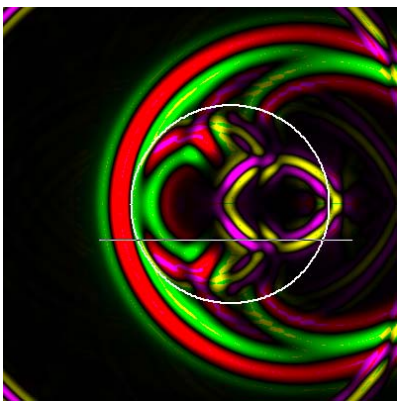


$(i = 4)$ $(i = 4)$





$(i = 5)$ $(i = 5)$



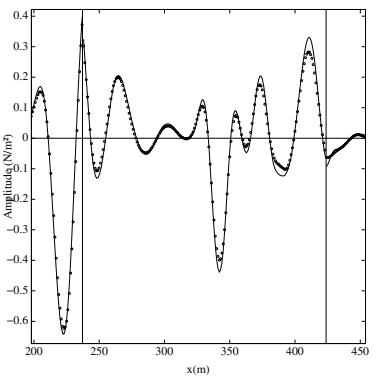


FIG. 5.3. *Test* 2-*b: cylindar between identical media at* $t = t_0 + 100\, i\, \Delta\, t$.

in the restricted domain (the same comment holds for the further figures). The slices are carried out from

- $i = 0$: ($x = 101$ m, $y = 301$ m) to ($x = 289$ m, $y = 301$ m),
- $i = 1$: ($x = 144$ m, $y = 300$ m) to ($x = 243$ m, $y = 300$ m),
- $i = 2$: ($x = 108$ m, $y = 433$ m) to ($x = 353$ m, $y = 433$ m),
- $i = 3$: ($x = 339$ m, $y = 339$ m) to ($x = 413$ m, $y = 339$ m),
- $i = 4$: ($x = 340$ m, $y = 300$ m) to ($x = 493$ m, $y = 300$ m),
- $i = 5$: ($x = 198$ m, $y = 264$ m) to ($x = 454$ m, $y = 264$ m).

The analytical solutions are computed on $N_{Bessel} = 90$ points (see (C.16) in Appendix C), 256 Fourier points, with 1-Hz sampling frequency.

The incident P-wave is converted into transmitted and reflected P- and SV-waves ($i = 1, 2$). A series of refraction-conversion events is then observed ($i = 3, 4, 5$). The agreement between the numerical and analytical values is excellent.

5.4. Test 3: Circular interface between different media. As a third example, we consider the same circular interface as in the previous test but take it to have different physical parameters on both each sides of Γ,

$$(\rho,\, c_p,\, c_s) = \begin{cases} \rho_0 = 2600 \text{ kg/m}^3,\, c_{p0} = 6400 \text{ m/s},\, c_{s0} = 3200 \text{ m/s}, \\ \rho_1 = 1200 \text{ kg/m}^3,\, c_{p1} = 2800 \text{ m/s},\, c_{s1} = 1400 \text{ m/s}. \end{cases}$$

These parameters are those of aluminium (inside Γ) and Plexiglas (outside Γ). Apart from these physical parameters, the values used for the computations are the same as in section 5.3. The initial values are the same as in Figure 5.2, $i = 0$.

Figure 5.4 gives the results of a parametric study in terms of the normal stiffness K_N: perfect contact ($i = 0$) which amounts to $K_N \to +\infty$, $K_N = 10^9$ kg/s^2 ($i = 1$), and $K_N = 10^8$ kg/s^2 ($i = 2$). The inertial effects and the tangential stiffness are not taken into account here,

$$\begin{cases} K_T \to +\infty, \\ M_N = M_T = 0 \text{ kg/m}^2. \end{cases}$$

The computations are shown in Figure 5.4 after 350 time steps. The slices are performed from $x = 100$ m to $x = 500$ m, at $y = 300$ m. Compared with the case of perfect contact ($i = 0$), one can see in ($i = 1, 2$) that the signs of the reflected waves are reversed. The waves that have entirely crossed the interface also differ greatly among the three cases. The case ($i = 2$) is much more difficult to handle than the cases ($i = 0, 1$) from the computational point of view. To obtain the good agreement shown in Figure 5.4 ($i = 2$), it is necessary to use $k = 4$ (for the numerical solution) and 32768 Fourier points with a sampling frequency of 0.018125 Hz (for the analytical solution).

Smaller values of K_N have also been investigated (figures not shown here). Below $K_N = 10^7$ kg/s^2, numerical instabilities have been observed when $k = 2$ (see subsection 4.7), whereas the computations remain stable when $k \geq 3$. Instabilities increase below $K_N = 10^5$ kg/s^2 if $k = 3$. Stable computations and excellent agreement with the analytical solutions are obtained down to $K_N = 10^4$ kg/s^2 if $k = 4$.

5.5. Test 4: Cubic spline between identical media. Up to now, we have dealt only with canonical objects with constant curvature. However, the use of the

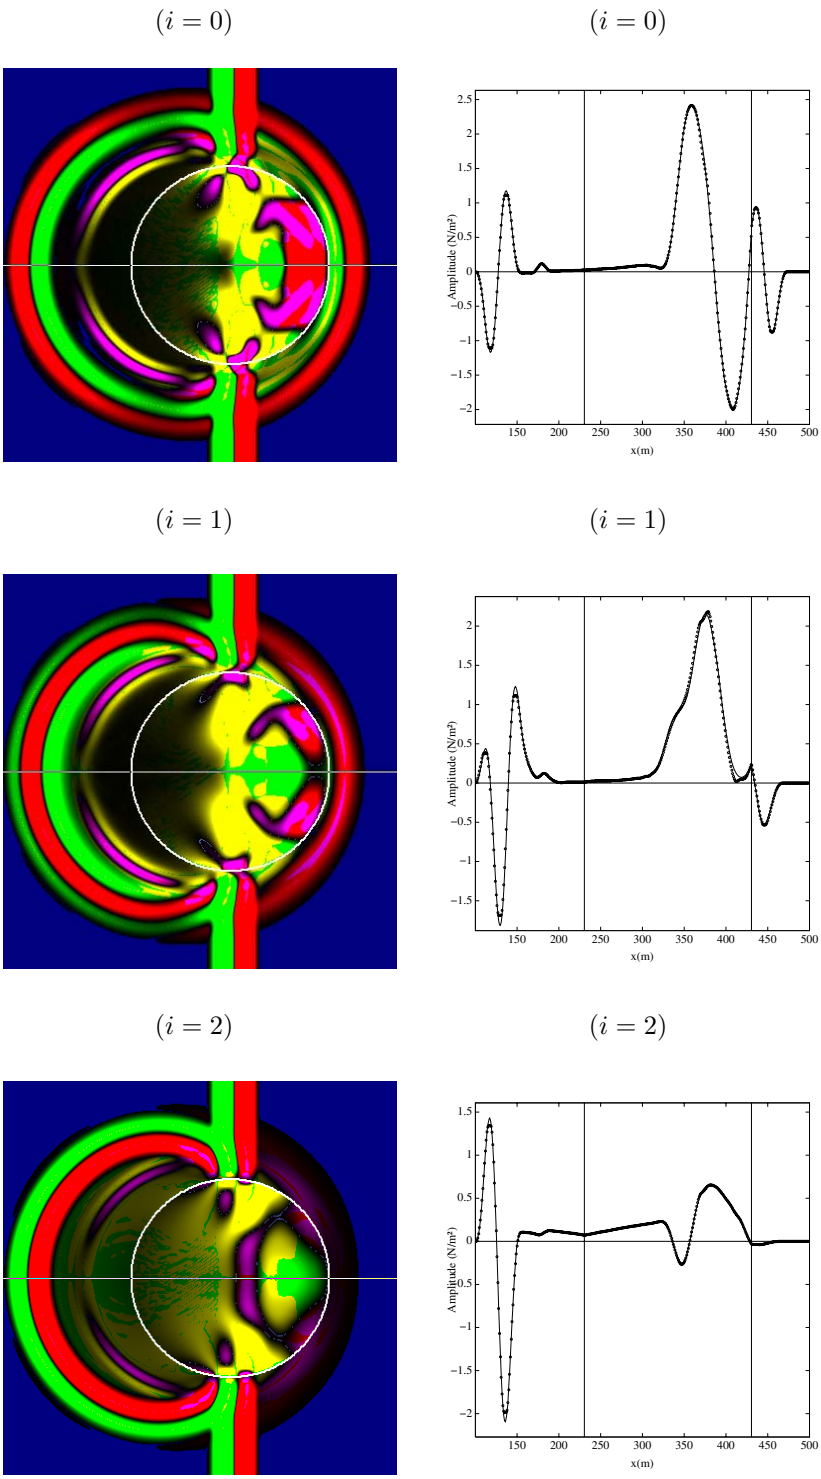

FIG. 5.4. *Test* 3: *cylindar between different media at* $t = t_0 + 360\,\Delta\,t$, *with various values of normal stifness.*

interface method is not restricted to such simple geometries. In this section, we study a more complex configuration corresponding to a cubic spline. The other parameters are the same as in section 5.3, except $t_0 = 0.07$ s.

Figure 5.5 shows snapshots of the solutions at times $t_i = t_0 + 150\, i\, \Delta t$ ($i = 0, 1, 2$). We obviously have no analytical solutions to compare with the numerical values. However, the computations remain stable, and the wave phenomena seem to be realistic.

5.6. Test 5: Plane interface with variable jump conditions. In the last experiment, we study the case of a plane interface with variable spring-mass conditions. The interface Γ is placed horizontally at $y = 130$ m on a $L_x \times L_y = 600 \times 400$ m^2 domain. The physical parameters have the same values as in section 5.2, and they are identical on both sides of Γ. The variable values of normal and tangential stiffness are

$$K_N = K_T = \begin{cases} 10^{12} \ \text{kg/s}^2 \ \text{ on } [x = 0 \text{ m} \ , \ x = 270 \text{ m}], \\ g(\tau) \ \text{ on } [x = 270 \text{ m} \ , \ x = 330 \text{ m}], \\ 10^{7} \ \text{kg/s}^2 \ \text{ on } [x = 330 \text{ m} \ , \ x = 600 \text{ m}], \end{cases} \tag{5.3}$$

where $g(\tau)$ is a cubic polynomial that ensures a C^1 continuity (τ is the abscissa along Γ). The stiffness values (5.3) are those of almost perfectly bonded media on the left part of the interface and almost perfectly disconnected media on the right part of the interface. The inertial effects are not taken into account: $M_N = M_T = 0$ kg/m^2.

The computations are initialized by a transient explosive P-wave centered at ($x_s = 300$ m, $y_s = 200$ m), with an elastic potential [14],

$$\Phi_{IP}(x,\, y,\, t) = \left(\tilde{\Phi}_{IP} * f\right)(x,\, y,\, t),$$

$$\tilde{\Phi}_{IP}(r,\, t) = \frac{1}{2\,\pi} \frac{H\left(t - \frac{r}{c_{p1}}\right)}{\sqrt{t^2 - \left(\frac{r}{c_{p1}}\right)^2}}, \qquad r = \sqrt{(x - x_s)^2 + (y - y_s)^2}, \tag{5.4}$$

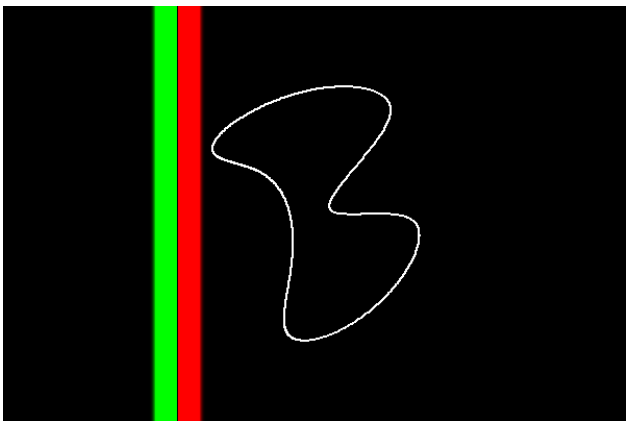
where H is the Heaviside function, $*$ denotes the time convolution, and f is the Ricker wavelet

$$f(t) = \frac{1}{2\,\pi^2\, f_c^2}\, e^{-\left(\pi\, f_c\, (t - t_c)\right)^2}. \tag{5.5}$$

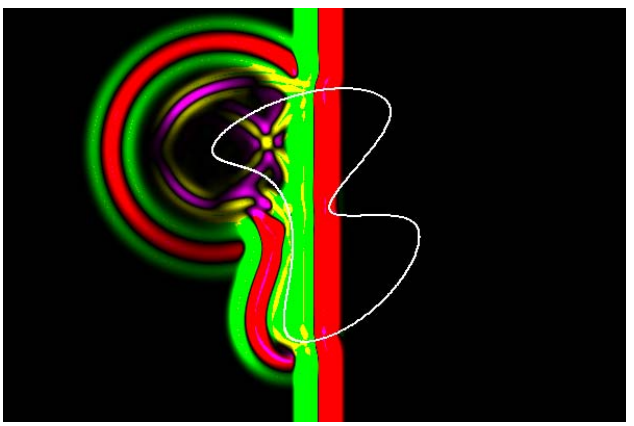
The velocities and stresses of the incident wave can be deduced from (5.4) thanks to classical elastodynamics relations [1]. The numerical experiments are performed on $N_x \times N_y = 600 \times 400$ grid points, with $f_c = 70$ Hz, $t_0 = 0.03$ s, $t_c = 0.01429$ s, CFL $= 0.9$, and $k = 3$.

Figure 5.6 shows snapshots of the numerical solution at $t = t_0 + 150\, i\, \Delta t$. The palettes are changed in each snapshot to maintain a constant range of colours despite the geometrical spreading of the waves. On the left part of the second snapshot ($i = 1$), the incident wave is totally transmitted; on the right part, the wave is almost totally reflected. The rapid change in the stiffness values occuring near $x = 300$ m acts as a point source for cylindrical P- and SV-waves. On the last snapshot, one can also observe a rightward-moving surface wave, denoted by a yellow-magenta zone.

$(i = 0)$



$(i = 1)$



$(i = 2)$

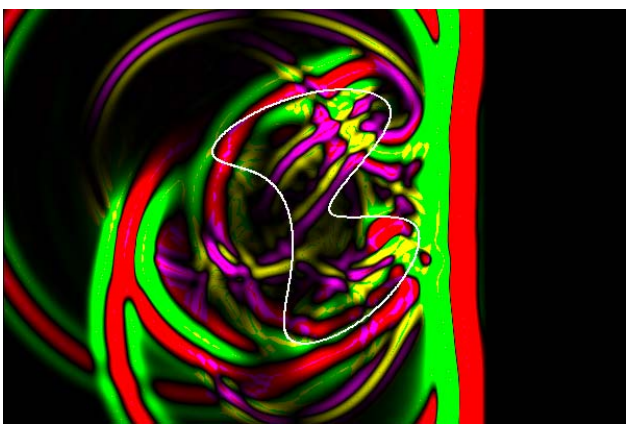


FIG. 5.5. *Test* 4: *cubic spline between identical media, at* $t = t_0 + 150\, i\, \Delta\, t$.

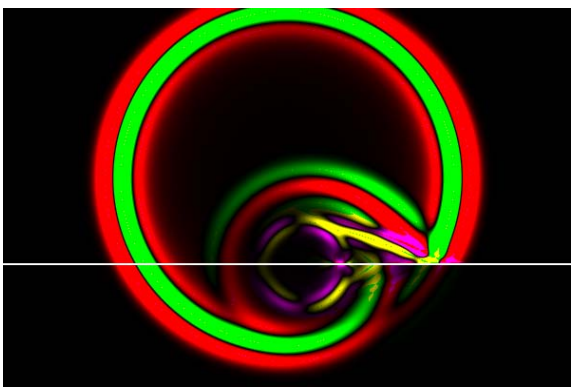
$(i = 1)$



$(i = 2)$

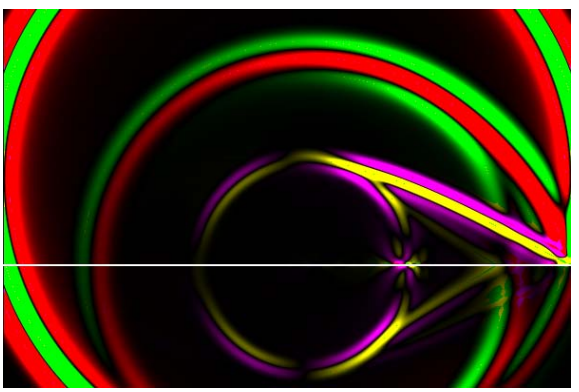


FIG. 5.6. *Test* 5: *plane interface with variable contact at* $t = t_0 + 150\, i\, \Delta t$.

Since both sides are almost stress-free surfaces in that place, this surface wave is a Rayleigh wave [1].

6. Conclusion. This paper deals with the numerical simulation of two-dimensional wave propagation in elastic solids separated by imperfect contacts. These contacts are modeled by interfaces with linear jump conditions: the [illegible] frequently used in geophysics [17] and nondestructive evaluation of materials [22]. The spring-mass conditions are incorporated into finite-difference time-domain schemes on a uniform Cartesian grid, via an [illegible]. This is an extension of previous studies on perfect contacts in one-dimensional [15] and two-dimensional [12] contexts and on imperfect contacts in a one-dimensional context [11]. The interface method also provides a fine description of the subcell geometry of the interfaces, at a negligible extra computational cost. Comparisons with original analytical solutions show the great accuracy of this approach.

Future paths of study might consist of taking into account numerically more realistic models for imperfect contact situations. A first improvement consists of describing the energy dissipation, as done, for example, in linear viscous bonding models [5]. A second improvement consists of extending the present approach for including nonlinear contact laws, which model realistic fractures and which prevent from interpenetration between the materials [23].

Appendix A. On the asymmetry of one-dimensional spring-mass conditions.

The aim of this section is to show that in some limit cases, the asymmetry of the jump conditions (2.10) has a negligible influence.

Consider the simplified case of a compressional plane wave propagating through Ω_0 normally to the plane interface Γ located at $x = \alpha$. Due to the symmetries involved in the problem, we have a one-dimensional configuration, with parameters $K = K_N$, $M = M_N$, $c_0 = c_{p0}$, and $c_1 = c_{p1}$. (A similar study could be performed with a shear plane wave and parameters $K = K_T$, $M = M_T$, $c_0 = c_{s0}$, and $c_1 = c_{s1}$.) The normalized harmonic components of the elastic displacement u and those of the elastic stress σ in medium Ω_0 (with $k_0 = \omega/c_0$) are

$$\hat{u}(x,\omega) = -i\,k_0\,e^{-ik_0x} + i\,k_0\,R^{\pm}\,e^{ik_0x},$$
$$\hat{\sigma}(x,\omega) = -\rho_0\,\omega^2\,e^{-ik_0x} - \rho_0\,\omega^2\,R^{\pm}\,e^{ik_0x},$$

and in medium Ω_1 (with $k_1 = \omega/c_1$), they are

$$\hat{u}(x,\omega) = -i\,k_1\,T^{\pm}\,e^{-ik_1x},$$
$$\hat{\sigma}(x,\omega) = -\rho_1\,\omega^2\,T^{\pm}\,e^{-ik_1x},$$

where ω is the angular frequency and $R^{\pm}$ and $T^{\pm}$ are the reflection and transmission coefficients it is required to determine (the superscripts $\pm$ are explained below). Under jump conditions shifted to the left (as in the present paper),

$$[\hat{u}(\alpha,\,\omega)] = \frac{1}{K}\,\hat{\sigma}(\alpha^-,\,\omega), \qquad [\hat{\sigma}(\alpha,\,\omega)] = -M\,\omega^2\,\hat{u}(\alpha^-,\,\omega),$$

a simple algebraic procedure gives

$$
\begin{aligned}
R^- &= \frac{\rho_1\, c_1 - \rho_0\, c_0 - i\,\omega\left(\dfrac{\rho_0\, c_0\, \rho_1\, c_1}{K} - M\right)}{\rho_0\, c_0 + \rho_1\, c_1 + i\,\omega\left(\dfrac{\rho_0\, c_0\, \rho_1\, c_1}{K} + M\right)}\, e^{-i\,\omega\frac{2\,\alpha}{c_0}}, \\
T^- &= \frac{2\,\rho_0\, c_1\left(1 + \dfrac{M\,\omega^2}{K}\right)}{\rho_0\, c_0 + \rho_1\, c_1 + i\,\omega\left(\dfrac{\rho_0\, c_0\, \rho_1\, c_1}{K} + M\right)}\, e^{i\,\omega\left(\frac{1}{c_1} - \frac{1}{c_0}\right)\alpha}.
\end{aligned}
\tag{A.1}
$$

Under jump conditions shifted to the right,

$$
[\hat{u}(\alpha,\,\omega)] = \frac{1}{K}\,\hat{\sigma}(\alpha^+,\,\omega), \qquad [\hat{\sigma}(\alpha,\,\omega)] = -M\,\omega^2\,\hat{u}(\alpha^+,\,\omega),
$$

we obtain in the same way

$$
\begin{aligned}
R^+ &= \frac{\rho_1\, c_1 - \rho_0\, c_0 - i\,\omega\left(\dfrac{\rho_0\, c_0\, \rho_1\, c_1}{K} - M\right)}{\rho_0\, c_0 + \rho_1\, c_1 + i\,\omega\left(\dfrac{\rho_0\, c_0\, \rho_1\, c_1}{K} + M\right)}\, e^{-i\,\omega\frac{2\,\alpha}{c_0}}, \\
T^+ &= \frac{2\,\rho_0\, c_1}{\rho_0\, c_0 + \rho_1\, c_1 + i\,\omega\left(\dfrac{\rho_0\, c_0\, \rho_1\, c_1}{K} + M\right)}\, e^{i\,\omega\left(\frac{1}{c_1} - \frac{1}{c_0}\right)\alpha}.
\end{aligned}
\tag{A.2}
$$

Comparisons between (A.1) and (A.2) show that [illegible] under both types of jump conditions and that

$$
\left|\frac{T^- - T^+}{T^-}\right| = \frac{M\,\omega^2}{K}.
$$

With realistic contacts [11, 18], the stiffness and mass satisfy $K \sim \rho\, c^2\,/\,h$ and $M \sim \rho\, h$, where ρ and c are the parameters of the intermediate medium (or [illegible]) and h is its thickness. Since $\omega = 2\,\pi\, c/\lambda$ (where λ is the wavelength) and $h \ll \lambda$ (a basic assumption underlying the spring-mass model), we obtain

$$
\left|\frac{T^- - T^+}{T^-}\right| \sim 4\,\pi^2\left(\frac{h}{\lambda}\right)^2 \ll 1.
$$

Hence, [illegible] under both types of jump conditions.

Appendix B. Zeroth order matrices of spring-mass conditions. The matrices $\boldsymbol{C}_l^0$ in (4.3) are ($l = 0, 1$)

$$
\boldsymbol{C}_l^0 = \begin{pmatrix}
-y' & x' & 0 & 0 & 0 \\
x' & y' & 0 & 0 & 0 \\
0 & 0 & y'^2 & -2\,x'\,y' & x'^2 \\
0 & 0 & -x'\,y' & x'^2 - y'^2 & x'\,y'
\end{pmatrix}.
$$

Setting

$$\beta_1 = \frac{\rho_0}{K_N}\,\frac{1}{\sqrt{x'^2+y'^2}}, \quad \beta_2 = \frac{\rho_0}{K_T}\,\frac{c_{s0}^2}{\sqrt{x'^2+y'^2}},$$

$$\beta_3 = \frac{M_N}{\rho_0}\,\sqrt{x'^2+y'^2}, \quad \beta_4 = \frac{M_T}{\rho_0}\,\sqrt{x'^2+y'^2},$$

the nonnull components of $\boldsymbol{E}_0^0$ in (4.3) are

$$\begin{aligned}
&\boldsymbol{E}_0^0[1,1] = \beta_1\left(y'^2 c_{p0}^2 + x'^2\left(c_{p0}^2 - 2\,c_{s0}^2\right)\right), && \boldsymbol{E}_0^0[3,3] = -\beta_3\,y',\\
&\boldsymbol{E}_0^0[1,2] = \beta_1\left(-2\,x'\,y'\,c_{s0}^2\right), && \boldsymbol{E}_0^0[3,4] = \beta_3\,x',\\
&\boldsymbol{E}_0^0[1,6] = \beta_1\left(-2\,x'\,y'\,c_{s0}^2\right), && \boldsymbol{E}_0^0[3,9] = -\beta_3\,y',\\
&\boldsymbol{E}_0^0[1,7] = \beta_1\left(x'^2 c_{p0}^2 + y'^2\left(c_{p0}^2 - 2\,c_{s0}^2\right)\right), && \boldsymbol{E}_0^0[3,10] = \beta_3\,x',\\
&\boldsymbol{E}_0^0[2,1] = \beta_2\left(-2\,x'\,y'\right), && \boldsymbol{E}_0^0[4,3] = \beta_4\,x',\\
&\boldsymbol{E}_0^0[2,2] = \beta_2\left(x'^2 - y'^2\right), && \boldsymbol{E}_0^0[4,4] = \beta_4\,y',\\
&\boldsymbol{E}_0^0[2,6] = \beta_2\left(x'^2 - y'^2\right), && \boldsymbol{E}_0^0[4,9] = \beta_4\,x',\\
&\boldsymbol{E}_0^0[2,7] = \beta_2\left(2\,x'\,y'\right), && \boldsymbol{E}_0^0[4,10] = \beta_4\,y'.
\end{aligned}$$

Appendix C. Exact solution for a plane wave on a circular interface with spring-mass conditions.

This analytical solution is obtained in six steps:

1. Fourier-transforming the incident wave (5.1);
2. writing the elastic potentials on the basis of circular functions;
3. expressing the elastic fields in terms of their potentials;
4. computing the reflection and transmission coefficients from (2.10);
5. returning to Cartesian coordinates;
6. inverting Fourier transform of the elastic fields (not described here).

Step 1. The Fourier transform $\mathcal{F}$ of a function $s(t)$, and its inverse Fourier transform $\mathcal{F}^{-1}$, are denoted by

$$\begin{aligned}
\hat{s}(\omega) &= \mathcal{F}(s(t)) = \frac{1}{2\,\pi}\int_{-\infty}^{+\infty} s(t)\,e^{-i\,\omega\,t}\,d\,t,\\
s(t) &= \mathcal{F}^{-1}(\hat{s}(\omega)) = \int_{-\infty}^{+\infty} \hat{s}(\omega)\,e^{i\,\omega\,t}\,d\,\omega,
\end{aligned} \tag{C.1}$$

where ω is the angular frequency. Applying a Fourier transform (C.1) to the part of the initial wave (5.1)

$$\Phi_{IP}(x,y,t) = f\left(t - \frac{x\cos\theta_1 + y\sin\theta_1}{c_{p1}}\right)$$

gives the harmonic potential of the incident P-wave

$$\hat{\Phi}_{IP}(x,y,\omega) = e^{-i\,\frac{\omega}{c_{p1}}(x\,\cos\theta_1 + y\,\sin\theta_1)}\,\hat{f}(\omega). \tag{C.2}$$

The Fourier transform of the bounded sinusoid (5.2) is

$$\hat{f}(\omega) = A = \frac{\omega_c}{2\,\pi}\left(\frac{1}{\omega^2-\omega_c^2}+\frac{1}{\omega^2-4\,\omega_c^2}\right)\left(e^{-i\,\frac{2\,\pi}{\omega_c}\omega}-1\right). \tag{C.3}$$

Step 2. The circular interface is centered on (x_0, y_0). A point $M(x, y) \in \Omega_1$ has polar coordinates $(x = x_0 + r\,\cos\phi, y = y_0 + r\,\sin\phi)$. We set $(l = 0,\ 1)$

$$k_{pl} = \frac{\omega}{c_{pl}}, \quad k_{sl} = \frac{\omega}{c_{sl}}, \quad S = e^{-i\,k_{p1}(x_0\,\cos\theta_1 + y_0\,\sin\theta_1)}, \quad \theta = \phi - \theta_1.$$

The first-kind Bessel functions J_n satisfy the classical property [14]

$$e^{-i\,r\,\cos\theta} = \sum_{n=0}^{+\infty} \varepsilon_n\, i^n\,(-1)^n\,\cos n\,\theta\, J_n(r), \tag{C.4}$$

with $\varepsilon_n = 1$ if $n = 0$, 2 else. From (C.2), (C.3), and (C.4), we can therefore express the harmonic potential of the incident P-wave as

$$\hat{\Phi}_{IP}(x, y, \omega) = A\,S \sum_{n=0}^{+\infty} \varepsilon_n\, i^n (-1)^n\,\cos n\,\theta\, J_n(k_{p1}\,r). \tag{C.5}$$

To satisfy the Sommerfeld condition, the harmonic elastic potential $\hat{\Phi}_{RP}$ of reflected P-waves and the harmonic pseudopotential $\hat{\boldsymbol{\Psi}}_{RS} = (0, 0, \hat{\Psi}_{RS})$ of reflected SV-waves are written on the basis of second-kind Hankel functions H_n. To prevent singularities from occuring at $r = 0$, the harmonic potential $\hat{\Phi}_{TP}$ of transmitted P-waves and the harmonic pseudopotential $\hat{\boldsymbol{\Psi}}_{TS} = (0, 0, \hat{\Psi}_{TS})$ of transmitted SV-waves are written on the basis of first-kind Bessel functions. Hence, we write

$$\begin{aligned}
&\hat{\Phi}_{RP} = \sum_{n=0}^{+\infty} R_n^p\,\cos n\,\theta\, H_n(k_{p1}\,r), \qquad \hat{\Psi}_{RS} = \sum_{n=0}^{+\infty} R_n^s\,\sin n\,\theta\, H_n(k_{s1}\,r),\\
&\hat{\Phi}_{TP} = \sum_{n=0}^{+\infty} T_n^p\,\cos n\,\theta\, J_n(k_{p0}\,r), \qquad \hat{\Psi}_{TS} = \sum_{n=0}^{+\infty} T_n^s\,\sin n\,\theta\, J_n(k_{s0}\,r),
\end{aligned} \tag{C.6}$$

where R_n^p, R_n^s, T_n^p, and T_n^s are the unknown coefficients of reflection and transmission, which still remain to be determined. Note that numerical routines [16] usually provide Y_n and $Y_n^{'}$ (with $Y_n = J_n$ or H_n). Later in the text, we will need $Y_n^{''}$; to determine this last value, we use the differential equation satisfied by the Bessel and Hankel functions

$$Y_n^{''}(x) + \frac{1}{x}\,Y_n^{'}(x) + \left(1 - \left(\frac{n}{x}\right)^2\right) Y_n(x) = 0.$$

Step 3. The elastic displacement $\boldsymbol{u} = {}^T(u_r, u_\theta)$ is deduced from Φ (for P-waves) or from $\boldsymbol{\Psi} = (0, 0, \Psi)$ (for SV-waves) by

$$\boldsymbol{u} = \mathbf{grad}\,\Phi \ \text{ for P-waves}, \qquad \boldsymbol{u} = \mathbf{curl}\,\boldsymbol{\Psi} \ \text{ for SV-waves}. \tag{C.7}$$

In cylindrical coordinates, the **grad** and **curl** operators are

$$\mathbf{grad}\,\Phi = \left(\frac{\partial\,\Phi}{\partial\,r},\ \frac{1}{r}\frac{\partial\,\Phi}{\partial\,\theta}\right), \qquad \mathbf{curl}\,\boldsymbol{\Psi}(0, 0, \Psi) = \left(\frac{1}{r}\frac{\partial\,\Psi}{\partial\,\theta},\ -\frac{\partial\,\Psi}{\partial\,r}\right). \tag{C.8}$$

In cylindrical coordinates, the three independent components of $\boldsymbol{\sigma}$ are [14]

$$\begin{aligned}
\sigma_{rr} &= (\lambda + 2\,\mu)\ \frac{\partial\, u_r}{\partial\, r} + \lambda \left(\frac{u_r}{r} + \frac{1}{r}\ \frac{\partial\, u_\theta}{\partial\, \theta} \right), \\
\sigma_{r\theta} &= \mu \left(\frac{\partial\, u_\theta}{\partial\, r} - \frac{u_\theta}{r} + \frac{1}{r}\ \frac{\partial\, u_r}{\partial\, \theta} \right), \\
\sigma_{\theta\theta} &= (\lambda + 2\,\mu)\ \left(\frac{1}{r}\ \frac{\partial\, u_\theta}{\partial\, \theta} + \frac{u_r}{r} \right) + \lambda\, \frac{\partial\, u_r}{\partial\, r},
\end{aligned} \tag{C.9}$$

where λ and μ are the Lamé coefficients. From (C.5), (C.6), (C.9), we easily deduce the harmonic fields over the whole domain. The components of the harmonic incident P-wave are

$$\begin{aligned}
\hat{u}_r^{ip} &= A\, S\, k_{p1} \sum_{n=0}^{+\infty} \varepsilon_n\, i^n (-1)^n \cos n\,\theta\, J_n^{'}(k_{p1}\, r), \\
\hat{u}_\theta^{ip} &= -\frac{A\, S}{r} \sum_{n=0}^{+\infty} \varepsilon_n\, i^n\, \frac{n\, \sin n\,\theta}{r}\, J_n(k_{p1}\, r), \\
\hat{\sigma}_{rr}^{ip} &= A\, S \sum_{n=0}^{+\infty} \varepsilon_n\, i^n (-1)^n \cos n\,\theta \Big((\lambda_1 + 2\,\mu_1)\, k_{p1}^2\, J_n^{''}(k_{p1}\, r) \\
&\qquad + \lambda_1 \frac{k_{p1}}{r}\, J_n^{'}(k_{p1}\, r) - \lambda_1 \left(\frac{n}{r}\right)^2\, J_n(k_{p1}\, r) \Big), \\
\hat{\sigma}_{r\theta}^{ip} &= A\, S\, 2\,\mu_1 \sum_{n=0}^{+\infty} \varepsilon_n\, i^n (-1)^n \sin n\,\theta \left(\frac{1}{r^2} J_n(k_{p1}\, r) - \frac{k_{p1}}{r}\, J_n^{'}(k_{p1}\, r) \right), \\
\hat{\sigma}_{\theta\theta}^{ip} &= A\, S \sum_{n=0}^{+\infty} \varepsilon_n\, i^n (-1)^n \cos n\,\theta \Big(\lambda_1\, k_{p1}^2\, J_n^{''}(k_{p1}\, r) \\
&\qquad + (\lambda_1 + 2\,\mu_1)\, \frac{k_{p1}}{r}\, J_n^{'}(k_{p1}\, r) - (\lambda_1 + 2\,\mu_1) \left(\frac{n}{r}\right)^2\, J_n(k_{p1}\, r) \Big).
\end{aligned} \tag{C.10}$$

The components of harmonic reflected P-waves are

(C.11)

$$\begin{aligned}
\hat{u}_r^{rp} &= k_{p1} \sum_{n=0}^{+\infty} R_n^p\, \cos n\,\theta\, H_n^{'}(k_{p1} r), \\
\hat{u}_\theta^{rp} &= -\frac{1}{r} \sum_{n=0}^{+\infty} R_n^p\, n\, \sin n\,\theta\, H_n(k_{p1} r), \\
\hat{\sigma}_{rr}^{rp} &= \sum_{n=0}^{+\infty} R_n^p \cos n\,\theta \left((\lambda_1 + 2\,\mu_1)\, k_{p1}^2\, H_n^{''}(k_{p1} r) + \lambda_1 \frac{k_{p1}}{r} H_n^{'}(k_{p1} r) - \lambda_1 \left(\frac{n}{r}\right)^2 H_n(k_{p1} r) \right), \\
\hat{\sigma}_{r\theta}^{rp} &= 2\,\mu_1 \sum_{n=0}^{+\infty} R_n^p\, n\, \sin n\,\theta \left(\frac{1}{r^2} H_n(k_{p1} r) - \frac{k_{p1}}{r} H_n^{'}(k_{p1} r) \right), \\
\hat{\sigma}_{\theta\theta}^{rp} &= \sum_{n=0}^{+\infty} R_n^p \cos n\,\theta \Big(\lambda_1\, k_{p1}^2\, H_n^{''}(k_{p1} r) + (\lambda_1 + 2\,\mu_1)\ \frac{k_{p1}}{r}\, H_n^{'}(k_{p1} r) \\
&\qquad - (\lambda_1 + 2\,\mu_1) \left(\frac{n}{r}\right)^2\, H_n(k_{p1} r) \Big).
\end{aligned}$$

The components of harmonic reflected SV-waves are

(C.12)
$$
\begin{aligned}
\hat{u}_r^{rs} &= \sum_{n=0}^{+\infty} R_n^s \, \frac{n \, \cos n\,\theta}{r} \, H_n(k_{s1} r), \\
\hat{u}_\theta^{rs} &= -k_{s1} \sum_{n=0}^{+\infty} R_n^s \, \sin n\,\theta \, H_n^{'}(k_{s1} r), \\
\hat{\sigma}_{rr}^{rs} &= -2\,\mu_1 \sum_{n=0}^{+\infty} R_n^s \, \cos n\,\theta \left(\frac{1}{r^2} \, H_n(k_{s1} r) - \frac{k_{s1}}{r} \, H_n^{'}(k_{s1} r) \right), \\
\hat{\sigma}_{r\theta}^{rs} &= -\mu_1 \sum_{n=0}^{+\infty} R_n^s \, \sin n\,\theta \left(k_{s1}^2 \, H_n^{''}(k_{s1} r) - \frac{k_{s1}}{r} \, H_n^{'}(k_{s1} r) + \left(\frac{n}{r} \right)^2 H_n(k_{s1} r) \right), \\
\hat{\sigma}_{\theta\theta}^{rs} &= -2\,\mu_1 \sum_{n=0}^{+\infty} R_n^s \, n \, \cos n\,\theta \left(\frac{k_{s1}}{r} \, H_n^{'}(k_{s1} r) - \frac{1}{r^2} \, H_n(k_{s1} r) \right).
\end{aligned}
$$

The components of harmonic transmitted P-waves are

(C.13)
$$
\begin{aligned}
\hat{u}_r^{tp} &= k_{p0} \sum_{n=0}^{+\infty} T_n^p \, \cos n\,\theta \, J_n^{'}(k_{p0} r), \\
\hat{u}_\theta^{tp} &= -\frac{1}{r} \sum_{n=0}^{+\infty} T_n^p \, n \, \sin n\,\theta \, J_n(k_{p0} r), \\
\hat{\sigma}_{rr}^{tp} &= \sum_{n=0}^{+\infty} T_n^p \cos n\,\theta \Big((\lambda_0 + 2\,\mu_0) \, k_{p0}^2 \, J_n^{''}(k_{p0} r) \\
&\qquad + \lambda_0 \, \frac{k_{p0}}{r} \, J_n^{'}(k_{p0} r) - \lambda_0 \left(\frac{n}{r} \right)^2 J_n(k_{p0} r) \Big), \\
\hat{\sigma}_{r\theta}^{tp} &= 2\,\mu_0 \sum_{n=0}^{+\infty} T_n^p \, n \, \sin n\,\theta \left(\frac{1}{r^2} J_n(k_{p0} r) - \frac{k_{p0}}{r} J_n^{'}(k_{p0} r) \right), \\
\hat{\sigma}_{\theta\theta}^{tp} &= \sum_{n=0}^{+\infty} T_n^p \cos n\,\theta \Big(\lambda_0 \, k_{p0}^2 \, J_n^{''}(k_{p0} r) + (\lambda_0 + 2\,\mu_0) \, \frac{k_{p0}}{r} \, J_n^{'}(k_{p0} r) \\
&\qquad - (\lambda_0 + 2\,\mu_0) \left(\frac{n}{r} \right)^2 J_n(k_{p0} r) \Big).
\end{aligned}
$$

Lastly, the components of harmonic transmitted SV-waves are

(C.14)
$$
\begin{aligned}
\hat{u}_r^{ts} &= \sum_{n=0}^{+\infty} T_n^s \, \frac{n \, \cos n\,\theta}{r} \, J_n(k_{s0} r), \\
\hat{u}_\theta^{ts} &= -k_{s0} \sum_{n=0}^{+\infty} T_n^s \, \sin n\,\theta \, J_n^{'}(k_{s0} r), \\
\hat{\sigma}_{rr}^{ts} &= -2\,\mu_0 \sum_{n=0}^{+\infty} T_n^s \, \cos n\,\theta \left(\frac{1}{r^2} \, J_n(k_{s0} r) - \frac{k_{s0}}{r} \, J_n^{'}(k_{s0} r) \right), \\
\hat{\sigma}_{r\theta}^{ts} &= -\mu_0 \sum_{n=0}^{+\infty} T_n^s \, \sin n\,\theta \left(k_{s0}^2 \, J_n^{''}(k_{s0} r) - \frac{k_{s0}}{r} \, J_n^{'}(k_{s0} r) + \left(\frac{n}{r} \right)^2 J_n(k_{s0} r) \right), \\
\hat{\sigma}_{\theta\theta}^{ts} &= -2\,\mu_0 \sum_{n=0}^{+\infty} T_n^s \, n \, \cos n\,\theta \left(\frac{k_{s0}}{r} \, J_n^{'}(k_{s0} r) - \frac{1}{r^2} \, J_n(k_{s0} r) \right).
\end{aligned}
$$

Step 4. We now compute the coefficients R_n^p, R_n^s, T_n^p, and T_n^s. For this purpose, we deduce from the spring-mass conditions (2.10) that

$$
\begin{aligned}
&\left(\hat{u}_r^{ip} + \hat{u}_r^{rp} + \hat{u}_r^{rs}\right)(a^+,\theta) = \left(\hat{u}_r^{tp} + \hat{u}_r^{ts} + \frac{1}{K_N}\left(\hat{\sigma}_{rr}^{tp} + \hat{\sigma}_{rr}^{ts}\right)\right)(a^-,\theta),\\
&\left(\hat{u}_\theta^{ip} + \hat{u}_\theta^{rp} + \hat{u}_\theta^{rs}\right)(a^+,\theta) = \left(\hat{u}_\theta^{tp} + \hat{u}_\theta^{ts} + \frac{1}{K_T}\left(\hat{\sigma}_{r\theta}^{tp} + \hat{\sigma}_{r\theta}^{ts}\right)\right)(a^-,\theta),\\
&\left(\hat{\sigma}_{rr}^{ip} + \hat{\sigma}_{rr}^{rp} + \hat{\sigma}_{rr}^{rs}\right)(a^+,\theta) = \left(\hat{\sigma}_{rr}^{tp} + \hat{\sigma}_{rr}^{ts} - M_N\,\omega^2\left(\hat{u}_r^{tp} + \hat{u}_r^{ts}\right)\right)(a^-,\theta),\\
&\left(\hat{\sigma}_{r\theta}^{ip} + \hat{\sigma}_{r\theta}^{rp} + \hat{\sigma}_{r\theta}^{rs}\right)(a^+,\theta) = \left(\hat{\sigma}_{r\theta}^{tp} + \hat{\sigma}_{r\theta}^{ts} - M_T\,\omega^2\left(\hat{u}_\theta^{tp} + \hat{u}_\theta^{ts}\right)\right)(a^-,\theta)
\end{aligned}
\tag{C.15}
$$

for all θ. Applying (C.15) to the fields (C.10)–(C.14) yields an infinite number of linear systems. For computational purpose, these systems are computed up to N_{Bessel} terms, giving the systems ($n = 0, 1, \ldots, N_{Bessel}$)

$$
\boldsymbol{Q}_n\,\boldsymbol{X}_n = \boldsymbol{Y}_n \qquad \text{with } \boldsymbol{X}_n = {}^T\left(R_n^p,\, R_n^s,\, T_n^p,\, T_n^s\right)
\tag{C.16}
$$

and

$$
\boldsymbol{Y}_n = -A\,S\,\varepsilon_n\,i^n(-1)^n
\begin{pmatrix}
J_n'(k_{p1}\,a)\\
\dfrac{n}{a}\,J_n(k_{p1}\,a)\\
(\lambda_1 + 2\,\mu_1)\,k_{p1}^2\,J_n''(k_{p1}\,a) + \dfrac{\lambda_1}{a}\,k_{p1}\,J_n'(k_{p1}\,a)\\
\qquad -\lambda_1\left(\dfrac{n}{a}\right)^2 J_n(k_{p1}\,a)\\
2\,\mu_1\,n\left(\dfrac{1}{a^2}\,J_n(k_{p1}\,a) - \dfrac{k_{p1}}{a}\,J_n'(k_{p1}\,a)\right)
\end{pmatrix}.
\tag{C.17}
$$

The coefficients of the matrices $\boldsymbol{Q}_n$ are

$$
\begin{aligned}
&\boldsymbol{Q}_n[1,1] = k_{p1}\,H_n'(k_{p1}\,a), \quad \boldsymbol{Q}_n[1,2] = \frac{n}{a}\,H_n(k_{s1}\,a),\\
&\boldsymbol{Q}_n[1,3] = -\left(k_{p0}\,J_n'(k_{p0}\,a) + \frac{1}{K_N}\left((\lambda_0 + 2\,\mu_0)\,k_{p0}^2\,J_n''(k_{p0}\,a)\right.\right.\\
&\qquad\left.\left. + \frac{\lambda_0}{a}\,k_{p0}\,J_n'(k_{p0}\,a) - \lambda_0\left(\frac{n}{a}\right)^2 J_n(k_{p0}\,a)\right)\right),\\
&\boldsymbol{Q}_n[1,4] = -\left(\frac{n}{a}\,J_n(k_{s0}\,a) - \frac{2\,\mu_0\,n}{K_N}\left(\frac{1}{a^2}\,J_n(k_{s0}\,a) - \frac{k_{s0}}{a}\,J_n'(k_{s0}\,a)\right)\right),\\
&\boldsymbol{Q}_n[2,1] = \frac{n}{a}H_n(k_{p1}\,a), \quad \boldsymbol{Q}_n[2,2] = k_{s1}\,H_n'(k_{s1}\,a),\\
&\boldsymbol{Q}_n[2,3] = -\left(\frac{n}{a}\,J_n(k_{p0}\,a) - \frac{2\,\mu_0\,n}{K_T}\left(\frac{1}{a^2}\,J_n(k_{p0}\,a) - \frac{k_{p0}}{a}\,J_n'(k_{p0}\,a)\right)\right),\\
&\boldsymbol{Q}_n[2,4] = -\left(k_{s0}\,J_n'(k_{s0}\,a) + \frac{\mu_0}{K_T}\left(k_{s0}^2\,J_n''(k_{s0}\,a)\right.\right.\\
&\qquad\left.\left. - \frac{k_{s0}}{a}\,k_{p0}\,J_n'(k_{s0}\,a) + \left(\frac{n}{a}\right)^2 J_n(k_{s0}\,a)\right)\right),
\end{aligned}
\tag{C.18}
$$

$$
\begin{aligned}
\boldsymbol{Q}_n[3,1] &= (\lambda_1 + 2\,\mu_1)\,k_{p1}^2\,H_n^{''}(k_{p1}\,a) + \frac{\lambda_1\,k_{p1}}{a}\,H_n^{'}(k_{p1}\,a) - \lambda_1\left(\frac{n}{a}\right)^2\,H_n(k_{p1}\,a),\\
\boldsymbol{Q}_n[3,2] &= -2\,\mu_1\,n\left(\frac{1}{a^2}\,H_n(k_{s1}\,a) - \frac{k_{s1}}{a}\,H_n^{'}(k_{s1}\,a)\right),\\
\boldsymbol{Q}_n[3,3] &= -\left((\lambda_0 + 2\,\mu_0)\,k_{p0}^2\,J_n^{''}(k_{p0}\,a) + \left(\frac{\lambda_1}{a} - M_N\,\omega^2\right)k_{p0}\,J_n^{'}(k_{p0}\,a)\right.\\
&\qquad \left. -\lambda_0\left(\frac{n}{a}\right)^2\,J_n(k_{p0}\,a)\right),\\
\boldsymbol{Q}_n[3,4] &= \left(\frac{2\,\mu_0\,n}{a^2} + M_N\,\omega^2\,\frac{n}{a}\right)\,J_n(k_{s0}\,a) - \frac{2\,\mu_0\,n\,k_{s0}}{a}\,J_n^{'}(k_{s0}\,a),\\
\boldsymbol{Q}_n[4,1] &= 2\,\mu_1\,n\left(\frac{1}{a^2}\,H_n(k_{p1}\,a) - \frac{k_{p1}}{a}\,H_n^{'}(k_{s1}\,a)\right),\\
\boldsymbol{Q}_n[4,2] &= -\mu_1\left(k_{s1}^2\,H_n^{''}(k_{s1}\,a) - \frac{k_{s1}}{a}\,H_n^{'}(k_{s1}\,a) + \left(\frac{n}{a}\right)^2\,H_n(k_{s1}\,a)\right),\\
\boldsymbol{Q}_n[4,3] &= -\left(\left(\frac{2\,\mu_0\,n}{a^2} + M_T\,\omega^2\,\frac{n}{a}\right)\,J_n(k_{p0}\,a) - \frac{2\,\mu_0\,n\,k_{p0}}{a}\,J_n^{'}(k_{p0}\,a)\right),\\
\boldsymbol{Q}_n[4,4] &= \mu_0\,k_{s0}^2\,J_n^{''}(k_{s0}\,a) - \left(\frac{\mu_0}{a} + M_T\,\omega^2\right)k_{s0}\,J_n^{'}(k_{s0}\,a) + \mu_0\left(\frac{n}{a}\right)^2\,J_n(k_{s0}\,a).
\end{aligned}
$$

Since the values of Hankel functions can be huge (typically 10^{60}), one must be careful when inverting (C.16). Normalization of $\boldsymbol{Q}_n$ and the use of extended arithmetic are required for this purpose.

Step 5. To return to Cartesian coordinates, we use the rotation formulas [6]

(C.19)
$$
\begin{pmatrix} v_1 \\ v_2 \\ \sigma_{11} \\ \sigma_{12} \\ \sigma_{22} \end{pmatrix} = \begin{pmatrix} \cos\phi & -\sin\phi & 0 & 0 & 0 \\ \sin\phi & \cos\phi & 0 & 0 & 0 \\ 0 & 0 & \cos^2\phi & -2\,\sin\phi\,\cos\phi & \sin^2\phi \\ 0 & 0 & \sin\phi\cos\phi & \cos^2\phi - \sin^2\phi & -\sin\phi\,\cos\phi \\ 0 & 0 & \sin^2\phi & 2\,\sin\phi\,\cos\phi & \cos^2\phi \end{pmatrix} \begin{pmatrix} v_r \\ v_\theta \\ \sigma_{rr} \\ \sigma_{r\theta} \\ \sigma_{\theta\theta} \end{pmatrix}.
$$

A LOCAL LEVEL SET METHOD FOR PARAXIAL GEOMETRICAL OPTICS*

JIANLIANG QIAN† AND SHINGYU LEUNG†

Abstract. We propose a local level set method for constructing the geometrical optics term in the paraxial formulation for the high frequency asymptotics of two-dimensional (2-D) acoustic wave equations. The geometrical optics term consists of two multivalued functions: a travel-time function satisfying the eikonal equation locally and an amplitude function solving a transport equation locally. The multivalued travel-times are obtained by solving a level set equation and a travel-time equation with a forcing term. The multivalued amplitudes are computed by a new Eulerian formula based on the gradients of travel-times and takeoff angles. As a byproduct the method is also able to capture the caustic locations. The proposed Eulerian method has complexity of $O(N^2 \mathrm{Log} N)$, rather than $O(N^4)$ as typically seen in the Lagrangian ray tracing method. Several examples including the well-known Marmousi synthetic model illustrate the accuracy and efficiency of the Eulerian method.

Key words. paraxial eikonal equations, level sets, multivalued geometrical optics, caustics

1. Introduction.

Geometrical optics is the branch of optics which is characterized by the neglect of the wavelength, i.e., that corresponding to the limiting case (wavelength) going to zero ([illegible]), or, equivalently, for the wave number near infinity ([illegible]), since in this approximation the optical laws may be formulated in the language of geometry [5]. This definition is based on short wavelength assumption of light and can be generalized to deal with other wave phenomena as well. The linear or nonlinear partial differential equations describing these wave propagations involve a parameter, such as the wavelength λ, which is small compared to all other lengths in the problem [48]. The asymptotic method is for the asymptotic solution of PDEs governing these wave propagations.

Consider the linear acoustic wave equation. According to the Debye procedure, inserting the high frequency asymptotic ansatz into the wave equation reduces the resolution of the PDE into the resolution for a sequence of ODEs. Among all the terms in the asymptotic ansatz, the most important term is the zeroth order term, the so-called geometrical optics term [25]. The geometrical optics term consists of two functions, a phase function satisfying the eikonal equation, a first-order nonlinear PDE, and an amplitude function solving a linear transport equation with the phase gradient as coefficients. Thus to construct the geometrical optics term the eikonal equation has to be solved first for the phase function; then the transport equation for amplitude might be integrated afterwards.

Conventionally, the eikonal equation was solved by the method of characteristics, aka. the ray tracing method in the seismology and optics; thus the method inherits the intrinsic shortcoming of the Lagrangian method, i.e., the nonuniform resolution in the desired computational domain [8]. In this setup, the amplitude function could be obtained by solving an ODE system as well, and it has the similar shortcoming

[8]. Certainly it is possible to overcome this drawback by introducing complicated interpolation and bookkeeping data structures [46]. However, in the late 80's Vidale [45], and van Trier and Symes [44] introduced direct discretizations of the eikonal equation based on finite difference schemes, which are Eulerian approaches and yield uniform resolutions of the solution in the computational domain. As pointed out in [44], the obtained solution should be understood as the minimum phase or the first-arrival travel-time in the viscosity solution sense for Hamilton–Jacobi equations [26, 11]. Once the travel-time is obtained, the transport equation for amplitude might be integrated [49, 42, 35]. Since the viscosity solution usually develops kinks, the gradient of the phase function is discontinuous. Therefore, the resulting solution for the transport equation has to be understood in the measure sense [15]. The difference between the ray tracing solution and the finite difference solution of the eikonal equation is that one is multiple-valued and the other single-valued [3, 13]. Although the viscosity concept and related numerical methods provide a natural Eulerian framework for geometrical optics, the drawback is that it provides only first arrivals while some applications may require all arrival times. Moreover, White [47] proved that there is a high probability for so-called transmission caustics to occur in an inhomogeneous medium. Beyond transmission caustics, more than one ray passes over each point in space so that the phase is multivalued. Therefore, it is important to design Eulerian methods for multivalued solutions of the eikonal equation, in general, the Hamilton–Jacobi equation.

In the last decade or so, there have been a lot of efforts in this direction: geometrical domain decomposition type methods [2], slowness matching method [40, 41], dynamic surface extension method [37, 36], segment projection method [14], level set method [29, 33, 24, 10, 34], and phase space method [17]. See [3, 13] for up-to-date reviews of the above methods and moment-based methods [12, 19, 23, 20].

In this work we present a local level set method for paraxial geometrical optics. By paraxial we mean that the wave propagation has a spatial orientation so that one of the spatial directions may be viewed as an evolution direction. This criterion may be quantified by assuming a subhorizontal condition for the eikonal equation [41]. In [34], we presented a global level set method for the paraxial eikonal equation in the two-dimensional (2-D) case, and the computed multivalued travel-time matched the ray tracing solution very well even in the difficult synthetic Marmousi model. Therefore we proceed along the same line and design a fast local level set method for both multivalued travel-times and amplitudes, thus constructing the geometrical optics term. This construction will be useful for modern high resolution seismic imaging [18, 21, 39, 7, 28]. Our formulation for computing multivalued amplitude is based upon a level set formulation and an extension of the Eulerian amplitude formulation used in [35], which is different from the one used in [29]. As a byproduct, our formulation also yields the cuspoid caustic curves (A_3 type) [43], which is related to the catastrophe theory; thus it suggests that the level set theory can be used to study the catastrophe development. See [4] for another Eulerian method for capturing caustics. The overall complexity of our level set method is $O(N^2 \mathrm{Log} N)$ rather than $O(N^4)$ as typically seen in the ray tracing formulation.

The rest of the paper is organized as follows: section 2 presents very briefly the paraxial formulation of the eikonal equation and the level set formulation for wavefront locations, travel-times, amplitudes and caustics; section 3 gives implementation details of the current formulation using the local level set method; section 4 shows some numerical examples to illustrate the efficiency and accuracy of the Eulerian method; and section 5 indicates some possible future works.

2. Governing equations.

2.1. Paraxial formulation for the eikonal equation. Consider a point source condition for the eikonal equation defined in an open, bounded domain

$$\Omega = \{(x,z) : x_{\min} \le x \le x_{\max}, 0 \le z \le z_{\max}\}. \tag{1}$$

To emphasize the point source condition the eikonal equation is written as follows,

$$|\nabla_{\mathbf{x}} \tau(\mathbf{x}, \mathbf{x}_s)| = \frac{1}{c(\mathbf{x})}. \tag{2}$$

$$\lim_{\mathbf{x}\to\mathbf{x}_s} \frac{\tau(\mathbf{x},\mathbf{x}_s)}{\|\mathbf{x}-\mathbf{x}_s\|} = \frac{1}{c(\mathbf{x}_s)}, \qquad \tau \ge 0, \tag{3}$$

where $\mathbf{x}_s$ is the given source point.

In some applications, for example, wave propagation in reflection seismics, the travel-times of interest are carried by the so-called subhorizontal rays [21, 39, 35], where subhorizontal means [illegible]. By the method of characteristics for the eikonal equation (2), the point source condition (3) and the subhorizontal condition, we use depth z as the running parameter so that we have a reduced system [34]

$$\frac{dx}{dz} = \tan\theta \tag{4}$$

$$\frac{d\theta}{dz} = \frac{1}{c}\left(\frac{\partial c}{\partial z}\tan\theta - \frac{\partial c}{\partial x}\right) \tag{5}$$

with

$$x|_{z=0} = x_s \tag{6}$$

$$\theta|_{z=0} = \theta_s, \tag{7}$$

where θ_s varies from $-\theta_{\max} \le \theta \le \theta_{\max} < \frac{\pi}{2}$. In addition, the travel-time is computed by integrating

$$\frac{dt}{dz} = \frac{1}{c\cos\theta} \tag{8}$$

with

$$t|_{z=0} = 0. \tag{9}$$

2.2. Level set equation for wavefronts. If we define $\phi = \phi(z,x,\theta)$ such that the zero level set, $\{(x(z),\theta(z)) : \phi(z,x(z),\theta(z)) = 0\}$, gives the location of the reduced bicharacteristic strip $(x(z),\theta(z))$ at z, then we may differentiate the zero level set equation with respect to z to obtain

$$\phi_z + u\phi_x + v\phi_\theta = 0 \tag{10}$$

with

$$u = \frac{dx}{dz} \text{ and } v = \frac{d\theta}{dz}, \tag{11}$$

which are given by the ray equations (4-5). In essence, we embed the ray tracing equations as the velocity field, $\mathbf{u} = (u, v)$, into the level set equation which governs the motion of the bicharacteristic strips in the phase space.

The initial condition for the level set motion equation (10) is taken to be

$$\phi|_{z=0} = \phi(0, x, \theta) = x - x_s \,, \tag{12}$$

which is obtained from initial conditions (6) and (7). This is a signed distance function, satisfying $|\nabla_{x,\theta}\phi| = 1$, to the initial phase space curve

$$\{(x, \theta) : x = x_s, -\theta_{\max} \le \theta \le \theta_{\max}\} \tag{13}$$

in the reduced phase space

$$\Omega_p = \{(x, \theta) : x_{\min} \le x \le x_{\max}, -\theta_{\max} \le \theta \le \theta_{\max}\}. \tag{14}$$

Using the same boundary condition as in [34], we have

$$\left.\frac{\partial \phi}{\partial \mathbf{n}}\right|_{\partial\Omega_p} = 0 \tag{15}$$

where $\mathbf{n}$ is the outward normal along the boundary of Ω_p.

2.3. Travel-time. To determine the travel-time of the ray from the above level set equation, we now derive a corresponding equation governing the evolution of travel-time. By the subhorizontal condition in the paraxial formulation and the ray equation (8), let $F_{\mathbf{u}}(x, \theta; z)$ be the flow generated by the velocity field $\mathbf{u}$ in the phase space (x, θ) along the z-direction. Thus we can write

$$\frac{dT}{dz}(z, F_{\mathbf{u}}(x, \theta; z)) = \frac{1}{c \cos\theta} \,. \tag{16}$$

Therefore, having $t = T(z, x, \theta)$, we get the following advection equation:

$$\frac{dt}{dz} = \frac{dT}{dz} = T_z + uT_x + vT_\theta = \frac{1}{c \cos\theta} \,. \tag{17}$$

The initial condition for T is specified according to the initial condition (9):

$$T|_{z=0} = T(0, x, \theta) = 0 \,, \tag{18}$$

which is consistent with the initial condition (12).

Following the same argument as in [34], we use the boundary condition

$$\frac{\partial T}{\partial x} = \frac{1}{c \sin\theta} \,, \tag{19}$$

on $x = x_{\min}$ and $x = x_{\max}$, and

$$\frac{\partial T}{\partial \theta} = \left(\sin\theta \frac{\partial c}{\partial z} - \cos\theta \frac{\partial c}{\partial x}\right)^{-1} \,, \tag{20}$$

on $\theta = -\theta_{\max}$ and $\theta = \theta_{\max}$.

2.4. Amplitude. The amplitude of a ray can be computed according to the formula given in [49, 35]:

$$\tilde{A}(x,z;x_s,z_s) = \frac{1}{2\pi}\sqrt{\frac{c}{2}}\sqrt{|\nabla\tilde{T}\times\nabla\tilde{\psi}|}\ , \tag{21}$$

where $\tilde{T}$ and $\tilde{\psi}$ are, respectively, the travel-time and the takeoff angle of a ray reaching (x,z) from (x_s,z_s). Travel-times and takeoff angles are well defined on each solution branch in the physical space (x,z). To compute this quantity in the reduced phase space, we consider T as the extension of $\tilde{T}$ to the phase space; furthermore, we may also extend $\tilde{\psi}$ and $\tilde{A}$ to ψ and A in the (z,x,θ) space, respectively. Since the takeoff angle is constant along a given ray in the phase space, we have

$$\psi_z + u\psi_x + v\psi_\theta = 0\,. \tag{22}$$

Moreover, we have

$$\begin{aligned}
\frac{\partial\tilde{T}}{\partial x} &= T_x + T_\theta\frac{\partial\theta}{\partial x}\,,\\
\frac{\partial\tilde{T}}{\partial z} &= T_z + T_\theta\frac{\partial\theta}{\partial z}\,,\\
\frac{\partial\tilde{\psi}}{\partial x} &= \psi_x + \psi_\theta\frac{\partial\theta}{\partial x}\,,\\
\frac{\partial\tilde{\psi}}{\partial z} &= \psi_x + \psi_\theta\frac{\partial\theta}{\partial z}\,.
\end{aligned} \tag{23}$$

It follows that

$$\left|\nabla\tilde{T}\times\nabla\tilde{\psi}\right| = \left|(T_x\psi_\theta - T_\theta\psi_x)\left(-v + u\frac{\partial\theta}{dx} + \frac{\partial\theta}{\partial z}\right) - \frac{1}{c\cos\theta}\left(\psi_x + \psi_\theta\frac{\partial\theta}{\partial x}\right)\right|\,. \tag{24}$$

Since $\phi(z,x,\theta(x,z)) = 0$ on the zero level set and equation (5), we have

$$\frac{\partial\theta}{\partial x} = -\frac{\partial\phi/\partial x}{\partial\phi/\partial\theta} \ \text{ and } \ \frac{\partial\theta}{\partial z} = v - u\frac{\partial\theta}{\partial x}\,. \tag{25}$$

Finally we have

$$A(z;x,\theta) = \frac{1}{2\pi}\sqrt{\frac{c}{2\cos\theta}}\sqrt{\left|\frac{\psi_x\phi_\theta - \psi_\theta\phi_x}{\phi_\theta}\right|}\,. \tag{26}$$

To compute the amplitude, we need the derivatives of the level set function at different z's. However, as illustrated in [34], reinitialization of the level set function is necessary and, unfortunately, this process would only keep the location of the zero level set unchanged. This means the derivatives of ϕ cannot be computed directly from the level set function by differentiating the function ϕ itself after the regularization procedure. Therefore, to compute the derivatives of the level set function on the zero level set, we need to advect those derivatives as well. We first let $\xi = \phi_x$ and $\eta = \phi_\theta$. Differentiating the advection equation for ϕ with respect to x and θ, respectively, we have

$$\begin{aligned}
&\xi_z + u\xi_x + v\xi_\theta + u_x\xi + v_x\eta = 0\,,\\
&\eta_z + u\eta_x + v\eta_\theta + u_\theta\xi + v_\theta\eta = 0\,.
\end{aligned} \tag{27}$$

We might apply the same idea to the advection equation for takeoff angles as well so that the derivatives of takeoff angles could be determined. Once those ingredients are in place, the amplitude could be obtained. However, we will not use this approach because this is not efficient computationally and it is difficult to reconcile the accuracies of four different derivatives numerically.

Instead, defining

$$\Delta = \psi_x \phi_\theta - \psi_\theta \phi_x \tag{28}$$

and differentiating it with respect to z, we have the advection equation

$$\Delta_z + \nabla_{x,\theta} \cdot (\mathbf{u}\Delta) = 0\,, \tag{29}$$

and the amplitude can then be computed by

$$A(z; x, \theta) = \frac{1}{2\pi} \sqrt{\left| \frac{c}{2\cos\theta} \frac{\Delta}{\phi_\theta} \right|}\,. \tag{30}$$

Therefore, we can simply solve the advection equations for ϕ_x, ϕ_θ and Δ in order to get the amplitude. We need the advection equation for ϕ_x because it is coupled with the one for ϕ_θ.

In general, Δ is a bounded quantity and ϕ_θ may approach zero. When ϕ_θ goes to zero, A goes to ∞ and we are approaching caustics.

Next we have to initialize the quantities that we are going to advect. At $z = 0$, we can set ϕ_x and ϕ_θ equal to 1 and 0, respectively. However, ψ_x is a singular function at the source and it is better to start computing ψ_x and ψ_θ at some $z = dz > 0$ close to zero. Assuming that the velocity c can be approximated by a constant near the source, we have

$$\begin{aligned} \psi_x(z, x, \theta)|_{z=dz} &= \frac{\cos^2\theta}{dz}\,, \\ \psi_\theta(z, x, \theta)|_{z=dz} &= 1\,. \end{aligned} \tag{31}$$

Thus at small $z = dz > 0$,

$$\phi(z, x, \theta)|_{z=dz} = x - dz \tan\theta\,, \tag{32}$$

and $\Delta(dz, x, \theta) \equiv -2$, which is independent of the dz as long as the velocity can be well approximated by a constant near the source. This makes the computation of amplitude stable.

2.5. Caustics. Mathematically, caustic surfaces are envelopes of the family of rays. In the geometrical optics, at a caustic the amplitude of the asymptotic expansion becomes infinite, so that the usual asymptotic expansion is no longer valid at caustics, and some special expansions have been introduced to construct wave fields near the caustics [27, 6].

In the current level set formulation, the caustic curves correspond to

$$\{(z, x) : \phi(z, x, \theta(x, z)) = 0 \text{ and } \phi_\theta(z, x, \theta(x, z)) = 0\}.$$

On the zero level set, when $\phi_\theta \neq 0$, there exists local unique projection onto the x-space; when $\phi_\theta = 0$, the corresponding singularities or catastrophes of the implicit function $\theta = \theta(z, x)$ for fixed z's are identified as caustics [43].

3. Implementation.

3.1. Local level set method. The computational complexity of the algorithm in [34] can be improved dramatically by implementing a narrow banding [1] or PDE-based version [32] of local level set method. In this work we adopt a version similar to the one proposed in [32].

Because we are interested only in the zero level set, all the updates can actually be done in a tube centered at $\phi = 0$. The radius of this tube, γ, is picked to be $5\Delta x$, due to the fact that five grid values are needed for the fifth order weighted essentially nonoscillatory (WENO) scheme when solving the advection equations. Therefore, by only considering the grid points within this tube, the complexity of the algorithm in [34] can be reduced by a factor of N from $O(N^3 \mathrm{Log} N)$ to $O(N^2 \mathrm{Log} N)$.

Reinitialization and orthogonalization are the two core ingredients in the local level set method as proposed in [32]. Reinitialization restores the equally spaced property for the level sets. The usual way is to make ϕ a signed distance function without moving the zero level set of ϕ appreciably. To achieve this, one can solve the following equation to steady state $\tilde{\phi}_\infty$ [38, 50, 9, 16, 32, 30]:

$$\frac{\partial \tilde{\phi}}{\partial \xi} + S(\phi)(|\nabla \tilde{\phi}| - 1) = 0 \tag{33}$$

$$\tilde{\phi}|_{\xi=0} = \phi(z, ., .)\,. \tag{34}$$

Here $S(\phi)$ could be the smoothed signum function [32]

$$S(\phi) = \frac{\phi}{\sqrt{\phi^2 + |\nabla \phi|^2 \Delta x \Delta \theta}}\,, \tag{35}$$

where Δx and $\Delta \theta$ are the mesh sizes along x- and θ-directions, respectively. However, we usually only need to evolve equation (33) for a few steps. How often we should invoke the reinitialization step is a subtle issue; see [32, 30] for some discussions. Because we are only interested in the value of T where $\phi = 0$, we apply the following orthogonalization procedure [9, 16, 32, 30]:

$$\frac{\partial \hat{T}}{\partial \xi} + \mathrm{sgn}(\phi)\left(\frac{\nabla \phi}{|\nabla \phi|} \cdot \nabla \hat{T}\right) = 0\,, \tag{36}$$

$$\hat{T}|_{\xi=0} = T(z, ., .) \tag{37}$$

which theoretically preserves the values of T where $\phi = 0$, but changes them elsewhere such that the new T does not vary too much near the desired region. At the steady state, $\nabla \phi \cdot \nabla \hat{T} = 0$.

3.2. Detecting caustics. Because passing through a caustic implies overturning of the zero level set in the x-θ space, the number of θ's such that $\phi(z, x, \theta(x)) = 0$ will increase or decrease by two when x varies monotonically. Therefore, a simple way to detect caustics is first enumerating the number of roots θ_k's for every x_i, then checking where those numbers have sudden jumps, and finally approximating locations of caustics by taking the midpoint of two adjacent x_i's which have different numbers of θ_k. The resulting approximation of the caustics locations is of first-order accuracy.

Let x_c^* be the exact location of a caustic at some fixed z^*. Assume that x_c is the computed caustic location obtained from the level set formulation, i.e., solving

$$\phi(z^*, x, \theta(x, z^*)) = 0, \tag{38}$$

$$\phi_\theta(z^*, x, \theta(x, z^*)) = 0. \tag{39}$$

Let x_c' be the approximate caustic location computed using our midpoint approximation. We have at least $x_c = x_c^* + O(\Delta x^2)$ which is delivered by the second-order scheme used here. Because the distance between x_c and x_c' is less than $\Delta x/2$, we have $x_c' = x_c + O(\Delta x)$ and, therefore, $x_c' = x^* + O(\Delta x)$.

In terms of multivalued travel-times, passing through a caustic implies that the number of travel-times increases or decreases by two as we will see in numerical examples.

3.3. Algorithm. Hence we have the following local level set algorithm for computing the geometrical optics terms.

I. Initialization.
   1. Given N_x and N_θ, determine
$$\Delta x = \frac{x_{\max} - x_{\min}}{N_z - 1} \text{ and } \Delta\theta = \frac{2\theta_{\max}}{N_\theta - 1}.$$
   2. Initialize ϕ, T, ϕ_x and ϕ_θ at $z = 0$.
   3. For each (x_i, θ_j), where $i = 1, \dots, N_x$ and $j = 1, \dots, N_\theta$, check if any of $|\phi(x_i, \theta_j)|$, $|\phi(x_{i-1}, \theta_j)|$, $|\phi(x_{i+1}, \theta_j)|$, $|\phi(x_i, \theta_{j-1})|$ or $|\phi(x_i, \theta_{j+1})|$ is less than γ. Collect all these points and call the set Γ.

II. March in z until $z = z_{\max}$.
   1. Determine Δz from the CFL condition.
   2. March one Δz step by solving the level set equation (10) in Γ.
   3. Reinitialize the level set function in Γ by solving (33).
   4. March one Δz step by solving the travel-time equation (17) in Γ.
   5. If $z \neq \Delta z$, update Δ by solving (29).
   6. Orthogonalize T, ϕ_x and ϕ_θ to ϕ respectively in Γ by solving (36).
   7. If $z \neq \Delta z$, orthogonalize Δ to ϕ in Γ. Otherwise, initialize Δ.
   8. Update the tube Γ.
   9. Detect caustics by checking if there is a change in the number of θ_k's which gives $\phi(z; x_i, \theta_k) = 0$ for two adjacent x_i's.

III. Output. For each x_i with $i = 1, \dots, N_x$,
   1. Determine all root θ_k such that $\phi(z_{\max}; x_i, \theta_k) = 0$ $(k = 1, \dots)$.
   2. Determine $T(z_{\max}; x_i, \theta_k)$ $(k = 1, \dots)$ by interpolation.
   3. Determine $\phi_x(z_{\max}, x_i, \theta_k)$, $\phi_\theta(z_{\max}; x_i, \theta_k)$ and $\Delta(z_{\max}; x_i, \theta_k)$ $(k = 1, \dots)$ by interpolation, and then compute $A(z_{\max}; x_i, \theta_k)$.

To determine Δz in step II.1, we only need to scan through the grid points in the computational tube Γ in order to determine the maxima of velocity fields u and v, and this takes $O(N\text{Log}N)$ steps.

In step II, the level set equation and the travel-time equation are decoupled and can be solved separately. The spacial derivatives are approximated by a fifth-order WENO-Godunov scheme [22] while a third-order total variation diminishing-Runge–Kutta (TVD-RK) method [31] is used for the time marching.

Unlike the global level set method, the reinitialization step in II.3 is used not only to regularize the level set function but also to ensure the location of the tube in step II.8 more accurate. This step is necessary here and the number of iterations is to be determined so that the information of the location of the zero level set is propagated by a distance larger than γ, the radius of the tube. Numerically, one or two steps per iteration in z would be enough to get a reasonably good solution. However, formally, let β be the CFL number used in the reinitialization and $m_{\min}$ be the minimum number of iterations of reinitialization; then we have

$$m_{\min} = \frac{\gamma}{\beta \min(\Delta x, \Delta\theta)} . \tag{40}$$

Because $\gamma = O(\Delta x)$, $m_{\min} = O(1)$. Overall the complexity of the reinitialization step for each Δz advancement would be equal to the number of grid points within the tube and is given by $O(N\mathrm{Log}N)$.

For the root-finding and the interpolation in step III, we can simply use any nonoscillatory interpolation scheme, for example, linear interpolation or ENO reconstruction.

The next issue is how to update the computational tube Γ. A simple way is to scan all grid points in the domain and to apply the same procedure as that in I.3. The complexity of the resulting method will be $O(N^2)$. However, because the motion of the zero level set is purely advective, zeros will not be generated outside the tube. We can, therefore, update the tube by only scanning through the boundary of Γ, and this requires only $O(N\mathrm{Log}N)$ operations.

As a result, for each iteration in z-direction, the complexity is $O(N\mathrm{Log}N)$. Because of the CFL condition, the number of iterations in z is of $O(N)$. Overall the complexity of this algorithm is only $O(N^2\mathrm{Log}N)$. Comparing to $O(N^4)$ as typically seen in the Lagrangian ray tracing method, this Eulerian method is highly efficient and attractive.

4. Numerical examples. For the first three examples, we put a point source at the origin and velocity functions $c(x, z)$ are all C^∞. The fourth example, the synthetic Marmousi model, is a very challenging one where the velocity function is given only as a gridded function. Unless specified, the computational domain we use in the following examples is chosen to be

$$\Omega_p = \{(x, \theta) : -1 \le x \le 1, \theta_{\max} \le \theta \le \theta_{\max}\} , \tag{41}$$

where $\theta_{\max} = 9\pi/20$. Accordingly, the Marmousi velocity will be rescaled to the above computational domain.

4.1. Constant model. The simplest case one can imagine is the constant velocity model with $c(x, z) = 1$. Figure 1 shows the exact and computed travel-times and amplitudes of the constant model. The solid lines are the exact solutions. The numerical solutions match well with the true values.

Tables 1 and 2 show the convergence results for this test case. Convergence history for travel-time solutions is shown in Table 1, while Table 2 contains that of the amplitudes. The results show second-order convergence for both travel-time solution and amplitude at $x = 1$.

In this simple case, we can also compute the solution where we assume the boundary $x = x_{\max}$ is reflective. When the zero level set hits the boundary $x = x_{\max}$ in the $x - \theta$ space, it will not leave the domain; instead, a new ray will be generated in the

computational space at the same $x = x_{\max}$ and with θ having opposite sign to the original ray.

For the travel-time, we have to determine boundary conditions for the incident and the reflected rays separately. We can use the same boundary condition as in the nonreflective case for the incident ray. The reflective ray has the same travel-time as the incident ray at the boundary $x = x_{\max}$.

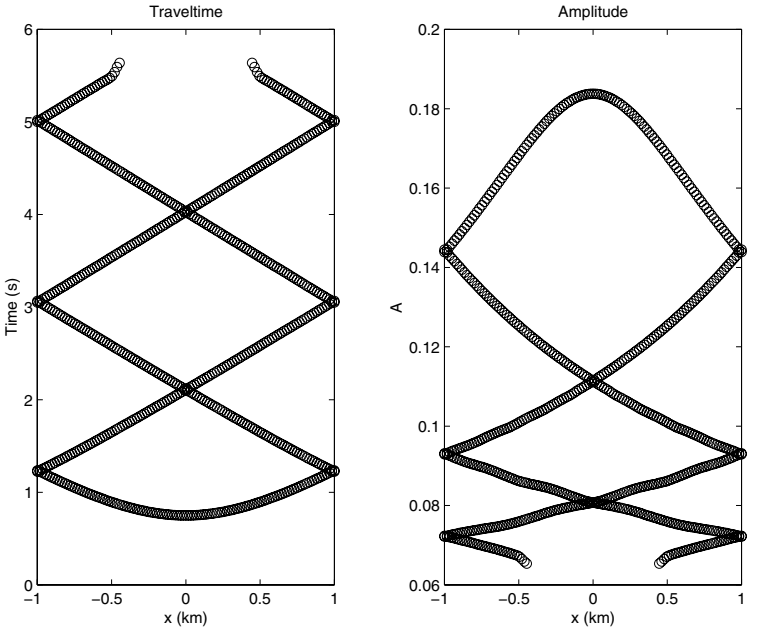

FIG. 2. *(Constant Model) Travel-time at $z = 0.75km$ with reflective boundary conditions.*

Therefore, we have the following boundary condition on $x = x_{\max}$:

$$
\begin{aligned}
\phi(x_{\max}, \theta) &= \phi(x_{\max}, -\theta) \\
\phi_x(x_{\max}, \theta) &= \phi_x(x_{\max}, -\theta) \\
\phi_\theta(x_{\max}, \theta) &= \phi_\theta(x_{\max}, -\theta) \\
\Delta(x_{\max}, \theta) &= \Delta(x_{\max}, -\theta) \\
T(x_{\max}, \theta) &= \begin{cases} \text{from (19)} & \text{if} \quad u(x_{\max}, \theta) > 0 \\ T(x_{\max}, -\theta) & \text{if} \quad u(x_{\max}, \theta) < 0 \end{cases}
\end{aligned} \tag{42}
$$

Similar boundary conditions can be used on the other side $x = x_{\min}$ and will not be fully discussed here. For the other two boundaries $\theta = \theta_{\max}$ and $\theta = -\theta_{\max}$, we can use the same boundary conditions as in the nonreflective case detailed in section 2.

Figure 2 shows the solutions obtained at $z = 1$km using the proposed method with reflective boundary conditions imposed on both boundaries $x = \pm 1$; multiple reflections are captured clearly as shown in travel-times and amplitudes using 120 grid points in both x- and θ-directions.

4.2. Waveguide model. The velocity function is given by

$$c(x, z) = 1.1 - \exp(-0.5x^2)\,. \tag{43}$$

The function is symmetric with respect to $x = 0$, and we also expect the same type of symmetry in both the travel-time and the amplitude.

Figure 3 shows travel-times, amplitudes and some intermediate quantities at $z =$1.6km using 240-by-240 grid points, respectively. The solid lines in the travel-time and amplitude plots are obtained using a ray tracing method. The solutions are symmetric as expected. Δ in this velocity model should be equal to -2 everywhere.

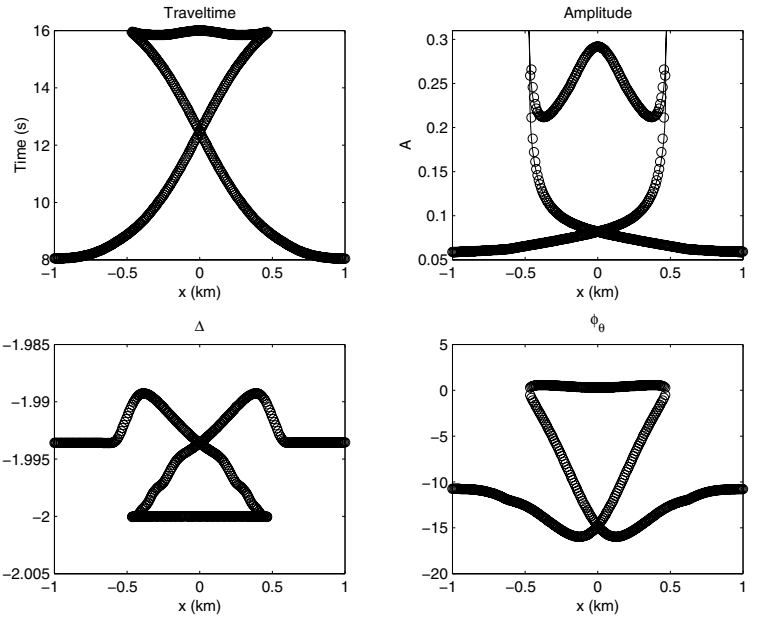

FIG. 3. *(Waveguide Model) Travel-time, amplitude,* Δ *and* ϕ_θ *at* $z = 1.6km$ *using a* 240*-by-*240 *grid.*

As we mentioned earlier, the velocity model is approximated by a constant near the source and this gives the initial condition $\Delta = -2$ at $z = dz$. For this waveguide model, because $u_x = v_\theta = 0$, the equation for Δ is purely advective; therefore the exact solution is $\Delta(z; x, \theta) = -2$, which is independent of z. The variations in the subplot of Δ in Figure 3 are due to numerical errors.

The singularities in the amplitudes, shown in the upper right subfigure in Figure 3, come from the vanishing of ϕ_θ on the zero level set of ϕ at around $x = \pm 0.45$km, shown in the lower right subfigure in Figure 3.

The caustic curves detected by the local level set method are shown in Figure 4: circles are computed locations of the caustics in the waveguide model, and the solid lines are the rays emanating from the source by a ray tracing method. The caustic locations are exactly those places where rays form an envelope as seen in the figure.

To demonstrate the improvement in the computational efficiency of the current formulation, we computed the solutions of this test case on a Pentium IV desktop with different sets of grid points and recorded the computational time. Table 3 shows the dramatic improvement delivered by the $O(N^2 \mathrm{Log} N)$ local level set method proposed here and the typical behavior of $O(N^3 \mathrm{Log} N)$ complexity offered by the global level set method.

4.3. Sinusoidal model. This example is adapted from the sinusoidal waveguide model used in [40, 41], and the velocity function is given by

$$c(x, z) = 1 + 0.2 \sin(0.5\pi z) \sin[3\pi(x + 0.55)] \,. \tag{44}$$

Figure 5 shows travel-times, amplitudes and some intermediate quantities at z =2.0km using 240-by-240 grid points. The subplot for travel-times in Figure 5 shows that the triplications in the travel-time developed at $z = 2.0$ are clearly captured by the level set Eulerian method. Singularities in the amplitude come from the

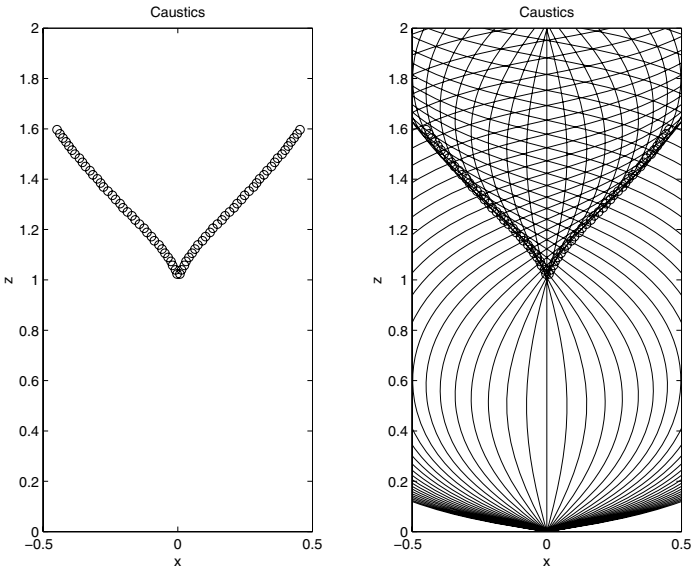

FIG. 4. *(Waveguide Model) Location of caustics and some rays from a ray tracing method. Caustics are determined by the local level set method with a* 360*-by-*360 *grid in the* x*-*θ *space.*

overturning of the zero level set in the phase space, i.e., $\phi_\theta = 0$, which is shown in the lower right subfigure in Figure 5.

Figure 6 shows locations of the caustics detected by the proposed method, and the results match those from the ray tracing method.

4.4. Synthetic Marmousi model. This example is the Marmousi model from the 1996 INRIA Workshop on Multi-arrival Travel-times. The calibration data used here were computed by Dr. Klimes and can be found at http://www.caam.rice.edu/~benamou/traveltimes.html. This is a synthetic model which will challenge the level set method used here.

The original Marmousi model is sampled on a 24m-by-24m grid, consisting of 384 samples in the x-direction and 122 samples in the z-direction; therefore the model dimension is 9.192km long in the x-direction and 2.904km deep in the z-direction. In the computational results presented here, we use a portion of Marmousi model, i.e., a window from 2.64km to 9.36km in the x-direction and from 0km to 2.904km in the z-direction. The source is located at x=6.0km and z=2.8km. The purpose is to compute (possibly multivalued) travel-times for those sampling points, i.e., the receivers from 160 to 340 on the surface z=0.0km. It should be emphasized that since we are using a local level set method, we can choose such a large window of the velocity model. In the example presented in [34], we were able to deal with a much smaller portion of the velocity model because we used a global level set method.

As illustrated in [34], to resolve a complicated wave front like the one generated by the Marmousi model, we have to use very fine computational meshes which need huge memory storage in the global level set setup. In the previous work [34], we applied up to 400 grid points in the x-direction to resolve the solutions between receiver 200 to 300. With the local level set method developed here, we are able to tackle a much

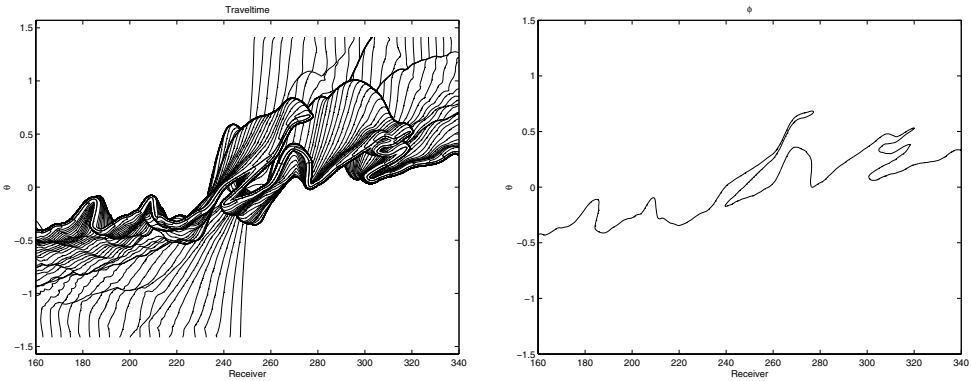

FIG. 7. *(Marmousi Model) Contours of the travel-time and the zero level set at* $z = 0.0km$.

larger portion of the original velocity and produce higher resolution travel-times with reasonable memory and computational cost. Figure 7 shows the zero level set and its overlay on the travel-time field by using a refinement of the original model with a refinement ratio = 8, i.e., we are using 1440 grid points in the x-direction to resolve the arrivals between receiver 160 to 340. As we can see from the plot, the zero level set has lots of overturnings and tiny tips. Therefore, there are lots of caustics developed in the wave propagation. The resulting travel-times at the surface along with the ray tracing solutions are shown in Figure 8; the two solutions match with each other reasonably well. Near receiver 340 we have captured five branches of travel-times as shown in Figure 9.

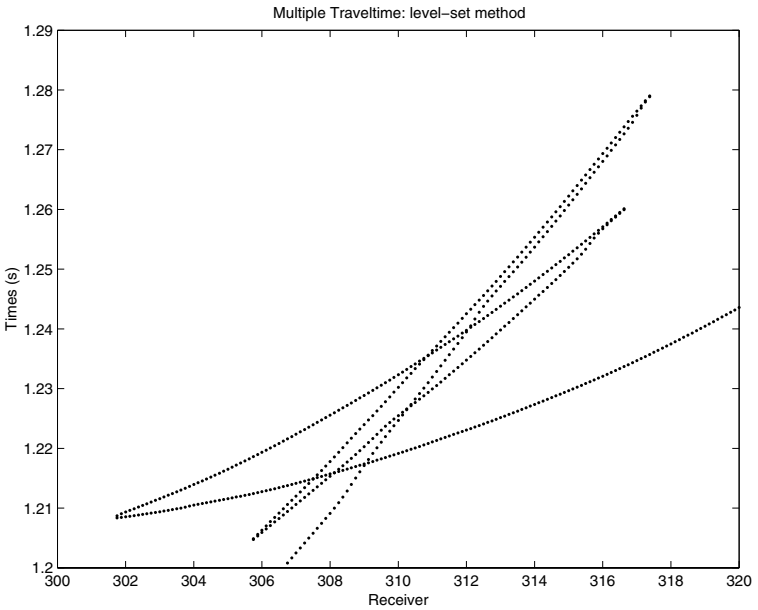

FIG. 9. *(Marmousi Model) Zoom-in at receiver* 310*: the local level set method at* $z = 0.0km$.

5. Conclusion. We have proposed a local level set method for paraxial geometrical optics, so that the multivalued travel-time and amplitude can be constructed with ease. The computational complexity of the algorithm is $O(N^2 \mathrm{Log} N)$, therefore it is highly efficient. Although the subhorizontal condition is required for the approach to work, it is suitable for many applications, such as reflection seismics, underwater acoustics and optics. The future work includes grafting this approach to high resolution seismic inversion [39] and computing the high frequency wave field using a time domain approach proposed in [6] rather than the usual frequency domain approach in [27].

TOPOLOGICAL OPTIMIZATION OF THE EVALUATION OF FINITE ELEMENT MATRICES*

ROBERT C. KIRBY†, ANDERS LOGG‡, L. RIDGWAY SCOTT§, AND ANDY R. TERREL†

Abstract. We present a topological framework for finding low-flop algorithms for evaluating element stiffness matrices associated with multilinear forms for finite element methods posed over straight-sided affine domains. This framework relies on phrasing the computation on each element as the contraction of each collection of reference element tensors with an element-specific geometric tensor. We then present a new concept of *complexity-reducing relations* that serve as distance relations between these reference element tensors. This notion sets up a graph-theoretic context in which we may find an optimized algorithm by computing a minimum spanning tree. We present experimental results for some common multilinear forms showing significant reductions in operation count and also discuss some efficient algorithms for building the graph we use for the optimization.

Key words. finite element, variational form, optimized algorithm, minimum spanning tree

1. Introduction.

Several ongoing projects have led to the development of tools for automating important aspects of the finite element method, with the potential for increasing code reliability and decreasing development time. By developing libraries for existing languages or new domain-specific languages, these software tools allow programmers to define variational forms and other parts of a finite element method with succinct, mathematical syntax. Existing C++ libraries for finite elements include DOLFIN [6, 7], Sundance [16, 17], and deal.II [2]. These rely on some combination of operator overloading and object orientation to present a high-level syntax to the user. Other projects have defined new languages with their own grammar and syntax, such as FreeFEM [20], GetDP [5], and Analysa [1]. Somewhere between these two approaches is the FEniCS Form Compiler, FFC [13, 15], developed primarily by the second author. This Python library relies on operator overloading to define variational forms, but rather than using the Python interpreter to evaluate the forms, FFC generates low-level code that can be compiled into other platforms such as DOLFIN.

While these tools are effective at exploiting modern software engineering to produce workable systems, we believe that additional mathematical insight will lead to even more powerful codes with more general approximating spaces and more powerful algorithms. To give one example, work by the first author [9, 10] shows how the Ciarlét definition of the finite element leads to a code for arbitrary order elements of general type. This code, FIAT, is used by FFC and is currently being integrated with Sundance. For further examples, we refer the reader to work by the first three authors and Knepley (see [11, 12]), which study how to efficiently (in the sense of

operation count) evaluate local stiffness matrices for finite element methods. For a given variational form, for each element e, there exists a "geometric tensor" G_e. Each entry of the $n \times n$ element stiffness matrix for e may be written as the contraction of a specific reference element tensor (depending only on the form, the polynomial basis, and the reference element) with G_e. We saw that there are relations between many of the reference element tensors (equality, colinearity, small Hamming distance) that may be exploited to find an algorithm with significantly fewer floating point operations than standard techniques.

In [11], we devised a crude algorithm that searched for and exploited these dependencies, generating simple Python code for evaluating the local stiffness matrix for the Laplacian on triangles given the geometric tensor. In this paper, we set the optimization process in a more abstract graph/topological context. In section 2, we express the calculation for some finite element operators as tensor contractions. These ideas are more fully developed in [13], where the first two authors show how this tensor structure may be used to implement a compiler capable of generating the reference tensors, and hence code, for building the stiffness matrices for general multilinear forms on affine elements. Further, a generalization to nonaffine mappings, including curvilinear elements, is suggested. In section 3, we introduce the idea of [illegible], which are a kind of distance relations among the tensors that serve to model the cost of complexity in computing the contractions. Using these ideas, we show how to derive an algorithm for performing the computation that is optimal in a certain sense. We demonstrate the reduction in operation count for several finite element operations in section 4. After this, we show how these efficient algorithms may be derived more efficiently through the use of certain search procedures in section 5. Finally, we state some conclusions and remarks about ongoing work in section 6.

2. Finite element formulation. The finite element method is a general methodology for the discretization of differential equations. A linear (or linearized) differential equation for the unknown function u is expressed in the form of a canonical variational problem, and the discrete approximation U of u is sought as the solution of a discrete version of the following variational problem [4, 3]: Find $U \in V$ such that

$$a(v, U) = L(v) \quad \forall v \in \hat{V}, \tag{1}$$

where $(\hat{V}, V)$ is a pair of suitable discrete (typically piecewise polynomial) function spaces, $a : \hat{V} \times V \to \mathbb{R}$ a bilinear form, and $L : \hat{V} \to \mathbb{R}$ a linear form.

The variational problem (1) corresponds to a linear system $A\xi = b$ for the expansion coefficients $\xi \in \mathbb{R}^M$ of the discrete function U in a basis $\{\varphi_i\}_{i=1}^M$ for V. If $\{\hat{\varphi}_i\}_{i=1}^M$ is the corresponding basis for $\hat{V}$, the entries of A and b are given by $A_{ij} = a(\hat{\varphi}_i, \varphi_j)$ and $b_i = L(\hat{\varphi}_i)$, respectively. When we consider general multilinear forms below, the multilinear form a is represented by a [illegible] A.

2.1. Multilinear forms. Let now $\{V_i\}_{i=1}^r$ be a given set of discrete function spaces defined on a triangulation $\mathcal{T} = \{e\}$ of $\Omega \subset \mathbb{R}^d$. We consider a general multilinear form a defined on the product space $V_1 \times V_2 \times \cdots \times V_r$:

$$a : V_1 \times V_2 \times \cdots \times V_r \to \mathbb{R}. \tag{2}$$

Typically, $r = 1$ (linear form) or $r = 2$ (bilinear form), but forms of higher arity appear frequently in applications and include variable coefficient diffusion and advection of momentum in the incompressible Navier–Stokes equations.

Let $\{\varphi_i^1\}_{i=1}^{M_1}, \{\varphi_i^2\}_{i=1}^{M_2}, \ldots, \{\varphi_i^r\}_{i=1}^{M_r}$ be bases of $V_1, V_2, \ldots, V_r$, and let $i = (i_1, i_2, \ldots, i_r)$ be a multi-index. The multilinear form a then defines a rank r tensor given by

$$A_i = a(\varphi_{i_1}^1, \varphi_{i_2}^2, \ldots, \varphi_{i_r}^r). \tag{3}$$

In the case of a bilinear form, the tensor A is a matrix (the stiffness matrix), and in the case of a linear form, the tensor A is a vector (the load vector).

To compute the tensor A by assembly, we need to compute the [illegible] A^e on each element e of the triangulation $\mathcal{T}$ of Ω [13]. Let $\{\varphi_i^{e,1}\}_{i=1}^{n_1}$ be the restriction to e of the subset of $\{\varphi_i^1\}_{i=1}^{M_1}$ supported on e, and define the local bases on e for $V_2, \ldots, V_r$ similarly. The rank r element tensor A^e is then given by

$$A_i^e = a_e(\varphi_{i_1}^{e,1}, \varphi_{i_2}^{e,2}, \ldots, \varphi_{i_r}^{e,r}). \tag{4}$$

2.2. Evaluation by tensor representation. The element tensor A^e can be efficiently computed by representing A^e as a special tensor product. If the multilinear form a is given by an integral over the domain Ω, then each entry A_i^e of A^e is given by an integral over the element e. By a change of variables and a series of linear transformations, we may rewrite this integral as an integral over a reference element E. In particular, when the map from the reference element E is affine, the linear transformations of derivatives can be moved outside of the integral to obtain a representation of the element tensor A^e as a tensor product of a constant tensor A^0 and a tensor G_e that varies over the set of elements,

$$A_i^e = A_{i\alpha}^0 G_e^\alpha, \tag{5}$$

or more generally a sum $A_i^e = A_{i\alpha}^{0,k} G_{e,k}^\alpha$ of such tensor products, where i and α are multi-indices and we use the convention that repetition of an index means summation over that index. We refer to A^0 as the [illegible] and to G_e as the [illegible]. The rank of the reference tensor is the sum of the rank $r = |i|$ of the element tensor and the rank $|\alpha|$ of the geometric tensor G_e. As we shall see, the rank of the geometric tensor depends on the specific form.

In [13], we present an algorithm that computes the tensor representation (5) for fairly general multilinear forms. This algorithm forms the foundation for FFC [15].

As an example, we consider here the tensor representation of the element tensor A^e for Poisson's equation $-\Delta u(x) = f(x)$ with homogeneous Dirichlet boundary conditions on a domain Ω. The bilinear form a is given here by $a(v,u) = \int_\Omega \nabla v(x) \cdot \nabla u(x)\,\mathrm{d}x$, and the linear form L is given by $L(v) = \int_\Omega v(x) f(x)\,\mathrm{d}x$. By a change of variables using an affine map $F_e : E \to e$, we obtain the following representation of the element tensor A^e:

$$\begin{aligned} A_i^e &= \int_e \nabla\varphi_{i_1}^{e,1}(x) \cdot \nabla\varphi_{i_2}^{e,2}(x)\,\mathrm{d}x \\ &= \det F_e' \frac{\partial X_{\alpha_1}}{\partial x_\beta} \frac{\partial X_{\alpha_2}}{\partial x_\beta} \int_E \frac{\partial \Phi_{i_1}^1(X)}{\partial X_{\alpha_1}} \frac{\partial \Phi_{i_2}^2(X)}{\partial X_{\alpha_2}}\,\mathrm{d}X = A_{i\alpha}^0 G_e^\alpha, \end{aligned} \tag{6}$$

where $A_{i\alpha}^0 = \int_E \frac{\partial \Phi_{i_1}^1(X)}{\partial X_{\alpha_1}} \frac{\partial \Phi_{i_2}^2(X)}{\partial X_{\alpha_2}}\,\mathrm{d}X$, $G_e^\alpha = \det F_e' \frac{\partial X_{\alpha_1}}{\partial x_\beta} \frac{\partial X_{\alpha_2}}{\partial x_\beta}$, and $\Phi_{i_j}^j = \varphi_{i_j}^{e,j} \circ F_e$ for $j = 1, 2$. We see that the reference tensor A^0 is here a rank four tensor and the geometric tensor G_e is a rank two tensor. In [11], we saw that dependencies frequently occur between A_i^0 and A_j^0 for many multi-indices i, j that can reduce the overall cost of computation.

3. Optimizing stiffness matrix evaluation.

3.1. An abstract optimization problem. Tensors of arbitrary rank may be rewritten as vectors, with contraction becoming the Euclidean inner product. So, we will deal only with vectors and inner products to formulate our abstract optimization problem. We let $Y = \{y^i\}_{i=1}^n$ be a collection of n vectors in $\mathbb{R}^m$. In the most general case, this is a collection rather than a set, as some of the items in Y may be identical. Corresponding to Y, we must find a process for computing for arbitrary $g \in \mathbb{R}^m$ the collection of items $\{(y^i)^t g\}_{i=1}^n$. Throughout this paper, we will measure the cost of this as the total number of multiply-add pairs (MAPs) required to complete all the dot products. This cost is always bounded by nm, but we hope to improve on that. This could be alternatively formalized as building an abstract control-flow graph for performing the dot products that is equivalent to the naive process but contains a minimal number of nodes. Our techniques, however, rely on structure that is not apparent to traditional optimizing compilers, so we prefer the present formulation.

We seek out ways of optimizing the local matrix evaluation that rely on notions of distance between a few of the underlying vectors. The Euclidean metric is not helpful here; we focus on other, discrete measures of distance such that if y and z are close together, then $y^t g$ is easy to compute once $z^t g$ is known (and vice versa). Many of the dependencies we considered in [11] were between pairs of vectors—equality, colinearity, and Hamming distance. Here we develop a theory for optimizing the evaluation of finite element matrices under binary relations between the members of the collection. This starts by introducing some notions of distance on the collection of vectors and finds an optimized computation with respect to those notions by means of a minimum spanning tree.

3.2. Complexity-reducing relations.

DEFINITION 1. [illegible] $\rho : Y \times Y \to [0, m]$ [illegible] ρ [illegible] complexity-reducing [illegible] $y, z \in Y$ [illegible] $\rho(y, z) \le k < m$ [illegible] $y^t g$ [illegible] $z^t g$ [illegible] k [illegible]

EXAMPLE 1. [illegible] $e^+(y, z) = d(1 - \delta_{y,z})$ [illegible] $\delta_{y,z}$ [illegible] e^+ [illegible] $e^+(y, z) = 0$ [illegible] $y^t g = z^t g$ [illegible] $g \in \mathbb{R}^m$ [illegible] $e^-(u, v) = e^+(u, -v)$ [illegible] $u = -v$ [illegible] $u^t g$ [illegible] $v^t g$ [illegible]

EXAMPLE 2. [illegible]

$$c(y, z) = \begin{cases} 0, & y = z, \\ 1, & y = \alpha z \text{ [illegible] } \alpha \in \mathbb{R}, \quad \alpha \neq 0, 1, \\ m & \text{otherwise.} \end{cases} \tag{7}$$

[illegible] c [illegible] $y^t g = (\alpha z)^t g = \alpha(z^t g)$ [illegible] $y^t g$ [illegible] $z^t g$ [illegible]

EXAMPLE 3. [illegible] $H^+(y, z)$ [illegible] y [illegible] z [illegible] H^+ [illegible] $H^+(y, z) = k$ [illegible] y [illegible] z [illegible] k [illegible] $y - z$ [illegible] k [illegible] $(y - z)^t g$ [illegible] k [illegible] $y^t g = (y - z)^t g + z^t g$ [illegible] $H^-(y, z) = H^+(y, -z)$

THEOREM 1. [illegible] ρ_1 [illegible] ρ_2 [illegible]

$$\rho(y, z) = \min(\rho_1(y, z), \rho_2(y, z)). \tag{8}$$

[illegible] ρ [illegible]

Pick $y, z \in Y$, let $1 \leq i \leq 2$ be such that $\rho(y, z) = \rho_i(y, z)$, and let $\rho_i(y, z) \equiv k$. But ρ_i is a complexity-reducing relation, so for any $g \in \mathbb{R}^m$, $y^t g$ may be computed in no more than $k = \rho(y, z)$ MAPs. Hence ρ is complexity-reducing. ∎

This simple result means that we may consider any finite collection of complexity-reducing relations (e.g., colinearity together with Hamming distance) as if they were a single relation for the purpose of finding an optimized computation in the later discussion.

DEFINITION 2. [illegible] composite [illegible] simple

To see that not all complexity-reducing relations are metrics, it is easy to find a composite complexity-reducing that violates the triangle inequality. Let $\rho(y, z) = \min(H^+(y, z), c(y, z))$. It is not hard to show that H^+ and c are both metrics. If we take $y = (1, 2, 2)^t$ and $z = (0, 4, 4)^t$, then $\rho(y, z) = 3$ since the vectors are neither colinear nor do they share any common entries. However, if we let $x = (0, 2, 2)^t$, then $\rho(y, x) = 1$ since the vectors share two entries and $\rho(x, z) = 1$ by colinearity. Hence, $\rho(y, z) > \rho(y, x) + \rho(x, z)$, and the triangle inequality fails.

REMARK 1. [illegible] Steiner points [illegible] $\{(1, 2, 2)^t, (0, 4, 4)^t\}$ [illegible] $(0, 2, 2)^t$ [illegible] g [illegible]

3.3. Finding an optimized computation. Having defined complexity-reducing relations and given several examples, we now show how they may be used to determine an optimized evaluation of the stiffness matrix. We shall work in the context of a single complexity-reducing relation ρ, which may be composite.

In order to compute $\{(y^i)^t g\}_{i=1}^n$, we would like to pick some $y^i \in Y$ and compute $(y^i)^t g$. Then we want to pick some y^j that is very close to y^i under ρ and then compute $(y^j)^t g$. Then we pick some y^k close to either y^i or y^j and compute that dot product. So, this process continues until all the dot products have been computed. Moreover, since the vectors Y depend only on the variational form and finite element space and not the mesh or parameters, it is possible to do this search once offline and generate low-level code that will exploit these relations. We first formalize the notion of finding the optimal computation and then how the code may be generated.

We introduce a weighted, undirected graph $G = (Y, E)$, where Y is our collection of vectors defined above. Our graph is completely connected; that is, every pair of vectors y^i, y^j are connected by an edge. The weight of this edge is defined to be $\rho(y^i, y^j)$. We may think of walking along the edge from y^i to y^j as using the dot product $(y^i)^t g$ to compute $(y^j)^t g$. If ρ is composite, it will be helpful to know later which underlying relation gave the minimum value used for ρ. So, suppose that $\rho(y, z) = \min\{\rho_i(y, z)\}_{i=1}^R$. For any fixed y, z, let $\varrho(y, z)$ be a in integer in $[1, R]$ such that $\rho_{\varrho(y,z)}(y, z) = \rho(y, z)$. In addition to weights, we thus associate with each edge $\{y^i, y^j\}$ the entity $\varrho(y^i, y^j)$.

A standard graph-theoretic object called a [illegible] is exactly what we need [14]. A spanning tree, which we shall denote (Y, E'), is a subgraph that satisfies certain properties. First, it contains all of the n nodes of the original graph. Second, (Y, E') is connected. Finally, E' has $n - 1$ edges, so that there are no cycles

(thus it is a tree). Now there are possibly many spanning trees for a given graph. Every spanning tree has a [illegible] associated with it that is the sum of the weights of its edges. A [illegible] spanning tree is a spanning tree such that the sum of the edge weights is as small as possible. Minimum spanning tree algorithms start with a particular node of the graph, called the [illegible]. Regardless of which root is chosen, minimum spanning tree algorithms will generate trees with exactly the same sum of edge weights.

While technically a minimum spanning tree is undirected, we can think of it as being a directed graph with all edges going away from the root. Such a notion tells us how to compute all of the dot products with minimal operations with respect to ρ. We start with the root node, which we assume is y^0, and compute $(y^0)^t g$. Then, for each of the children of y^0 in the tree, we compute the dot products with g using the result of $(y^0)^t g$. Then we use the dot products of the children to compute the dot products of each of the children's children, and so on. This is just a breadth-first traversal of the tree. A depth-first traversal of the tree would also generate a correct algorithm, but it would likely require more motion of the computed results in and out of registers at runtime.

The total number of MAPs in this process is m for computing $(y^0)^t g$ plus the sum of the edge weights of (Y, E'). As the sum of edge weights is as small as it can be, we have a minimum-cost algorithm for computing $\{(y^i)^t g\}_{i=1}^n$ with respect to ρ for any $g \in \mathbb{R}^m$. On the other hand, it is not a true optimal cost, as one could find a better ρ or else use relations between more than two vectors (say, three coplanar vectors). One other variation is in the choice of root vector. If, for example, some y^i has several elements that are zero, then it can be dotted with g with fewer than m MAPs. Hence, we pick some $\bar{y} \in Y$ such that the number of nonzero entries is minimal to be the root. We summarize these results in a theorem.

THEOREM 2. [illegible] $G = (Y, E)$ [illegible] $g \in \mathbb{R}^m$ [illegible] $\{(y^i)^t g\}_{i=1}^n$ [illegible] $m' + w$ [illegible] m' [illegible] Y [illegible] w [illegible] G

The overhead of walking through the tree at runtime would likely outweigh the benefits of reducing the floating point cost. We can instead traverse the tree and generate low-level code for computing all of the dot products—this function takes as an argument the vector g and computes all of the dot products of Y with g. An example of such code was presented in [11].

3.4. Comparison to spectral elements. Our approach is remarkably different from the spectral element method. In spectral element methods, one typically works with tensor products of Lagrange polynomials over logically rectangular domains. Efficient algorithms for evaluating the stiffness matrix or its action follow naturally by working dimension-by-dimension. While such decompositions are possible for unstructured shapes [8], these are restricted to specialized polynomial bases. On the other hand, our approach is blind to both the element shape and the kind of approximating spaces used. While spectral element techniques may ultimately prove more effective when available, our approach will enable some level of optimization in more general cases, such as Raviart–Thomas–Nedelec [21, 22, 18, 19] elements on tetrahedra.

4. Experimental results. Here we show that this optimization technique is successful at generating low-flop algorithms for computing the element stiffness matrices associated with some standard variational forms. First, we consider the bilinear

forms for the Laplacian and advection in one coordinate direction for tetrahedra. Second, we study the trilinear form for the weighted Laplacian. In all cases, we generated the element tensors using FFC [13, 15], which in turn relies on FIAT [9, 10] to generate the finite element basis functions and integration rules. Throughout this section, we let $d = 2, 3$ refer to the spatial dimension of Ω.

4.1. Laplacian. We consider first the standard Laplacian operator

$$a(v, u) = \int_\Omega \nabla v(x) \cdot \nabla u(x) \, \mathrm{d}x. \tag{9}$$

We gave a tensor product representation of the local stiffness matrix in (6). The indices of the local stiffness matrix and the associated tensors are shown in Table 1.

Because the element stiffness matrix is symmetric, we need to build only the triangular part. Even without any optimization techniques, this naturally leads from computing $|P|^2$ contractions at a cost of d^2 MAPs each to $\binom{|P|+1}{2}$ contractions, where $|P|$ is the dimension of the polynomial space P. Beyond this, symmetry opens up a further opportunity for optimization. For every element e, G_e is symmetric. The equality of its off-diagonal entries means that the contraction can be performed in $\binom{d+1}{2}$ rather than d^2 entries. This is readily illustrated in the two-dimensional case. We contract a symmetric 2×2 tensor G with an arbitrary 2×2 tensor K:

$$\begin{aligned} G : K &= \begin{pmatrix} G_{11} & G_{12} \\ G_{12} & G_{22} \end{pmatrix} : \begin{pmatrix} K_{11} & K_{12} \\ K_{21} & K_{22} \end{pmatrix} \\ &= G_{11}K_{11} + G_{12}(K_{12} + K_{21}) + G_{22}K_{22} \\ &= \tilde{G}^t \hat{K}, \end{aligned} \tag{10}$$

where $\tilde{G}^t = (G_{11}, G_{12}, G_{22})$ and $\hat{K}^t = (K_{11}, K_{12} + K_{21}, K_{22})$.

This simple calculation implies a linear transformation $\hat{\cdot}$ from $\mathbb{R}^{d \times d}$ into $\mathbb{R}^{\binom{d+1}{2}}$ obtained by taking the diagonal entries of the matrix together with the sum of the off-diagonal entries, that may be applied to each reference tensor, together with an associated mapping $\tilde{\cdot}$ on symmetric tensors that takes only the symmetric part and casts it as a vector. Hence, the overall cost of computing an element stiffness matrix before optimizations goes from $|P|^2 d^2$ to $\binom{|P|+1}{2}\binom{d+1}{2}$.

An interesting property of this transformation of the reference tensor is that it is [illegible] for the complexity-reducing relations we consider. The Hamming distance between two items under $\hat{\cdot}$ is bounded by the Hamming distance between the items. More precisely, $\rho(\hat{y}, \hat{z}) \leq \rho(y, z)$. Furthermore, if items are colinear before transformation, their images will be as well. So, for the optimizations we consider, we will not destroy any dependencies. Moreover, the transformation may introduce additional dependencies. For example, before applying the transformation, entries (0,1) and (1,5) are not closely related by Hamming distance or colinearity, as seen in Table 1. However, after the transformation, we see that the same items in Table 2 are colinear. Other examples can be readily found.

We optimized the evaluation of the Laplacian for Lagrange finite elements of degrees one through three on triangles and tetrahedra using a composite complexity-reducing relation with H^+, H^-, and c defined in Examples 2 and 3. We performed the optimization both with and without symmetry. The results are shown in Tables 3 and 4. Figure 1 shows a diagram of the minimum spanning tree computed by our code for the Laplacian on quadratic elements using symmetry. Each node of the graph is labeled with a pair (i, j) indicating the matrix entry (the vectors themselves are displayed in Table 2), and the edges are labeled with the associated weights. Simple inspection reveals that the sum of the edge weights is 14, which when added to 3 to compute the dot product for the root node agrees with the entry for quadratics in Table 4.

These techniques are successful in reducing the flop count, down to less than one operation per entry on triangles and less than two on tetrahedra for quadratic and cubic elements. We showed in [11] for low degree elements on triangles that going from standard numerical quadrature to tensor contractions led to a significant reduction

in actual runtime for matrix assembly. From the tensor contractions, we got another good speedup by simply omitting multiplication by zeros. From this, we gained only a modest additional speedup by using our additional optimizations. However, this is most likely due to the relative costs of memory access and floating point operations. We have to load the geometric tensor from memory, and we have to write every entry

of the matrix to memory. So then $n+m$ in the tables gives a lower bound on memory access for computing the stiffness matrix. Our optimizations lead to algorithms for which there are a comparable number of arithmetic and memory operations. Hence, our optimization has succeeded in reducing the cost of computing the local stiffness matrix to a small increment to the cost of writing it to memory.

4.2. Advection in one coordinate direction. Now we consider constant coefficient advection aligned with a coordinate direction

$$a(v,u) = \int_\Omega v(x) \frac{\partial u(x)}{\partial x_1} \,\mathrm{d}x. \tag{11}$$

This is part of the operator associated with constant coefficient advection in some arbitrary direction—optimizing the other coordinate directions would give similar results. These results are shown in Table 5. Again, our optimization generates algorithms for which the predominant cost of computing the element matrix is writing it down, as there is significantly less than one floating point cycle per matrix entry in every case.

4.3. Weighted Laplacian. Our final operator is the variable coefficient Laplacian

$$a_w(v,u) = \int_\Omega w(x) \nabla v(x) \cdot \nabla u(x) \,\mathrm{d}x. \tag{12}$$

This form may be viewed as a trilinear form $a(w,v,u)$ in which w is the projection of the coefficient into the finite element space. For many problems, this can be performed without a loss in order of convergence. For nonlinear problems, we will have to reassemble this form at each nonlinear iteration, so it is an important step to optimize. The reference tensor is

$$A^0_{i\alpha} = \int_E \Phi_{\alpha_1}(X) \frac{\partial \Phi_{i_1}(X)}{\partial X_{\alpha_2}} \frac{\partial \Phi_{i_2}(X)}{\partial X_{\alpha_3}} \,\mathrm{d}X \tag{13}$$

and the geometric tensor is

$$G^\alpha_e = w_{\alpha_1} \det F'_e \frac{\partial X_{\alpha_2}}{\partial x_\beta} \frac{\partial X_{\alpha_3}}{\partial x_\beta}. \tag{14}$$

Note that the geometric tensor is the outer product of the geometric tensor for the constant coefficient Laplacian, which we shall denote $(G^L)_e$, with the coefficients of the weight function. Unlike the constant coefficient case, the amount of arithmetic per entry in the element stiffness matrix grows with the polynomial degree.

3	210	120	25200	14334

We could simply proceed with the optimization as we did for other forms—the element tensor is only a collection of vectors that will have to be dotted into G_e for each element in the mesh, but now the dot products are more expensive since the vectors are longer. In this case, G_e must be explicitly formed for each element (this costs $|P|d^2$ once $(G^L)_e$ is formed). On the other hand, we could use the decomposition of G_e into $(G^L)_e$ and the coefficient vector w_k and do the contractions in stages. For example, we could organize the contraction as

$$A_i^e = \left(A^0_{i,(\alpha_1,\alpha_2,\alpha_3)} \left(G^L\right)_e^{(\alpha_2,\alpha_3)}\right) w_{\alpha_1}; \tag{15}$$

that is, for each of the $|P|^2$ entries of the stiffness matrix, we compute $|P|$ contractions of $d\times d$ tensors with $(G^L)_e$. This is a similar optimization problem as the Laplacian but with $|P|$ times more vectors to optimize over. After we do this set of computations, we must compute $|P|^2$ dot products with the coefficient vector w_k. Note that the contractions with $(G^L)_e$ may be optimized, but the resulting vectors to dot with w_k will not be known until runtime and must be computed at full cost. Hence, a lower bound for this approach is $|P|$ MAPs per entry (assuming that the contractions with G^L were absolutely free). On the other hand, one could contract with the coefficient first to give an array of $|P|^2$ tensors of size $d \times d$ and then contract each of these with $(G^L)_e$. As before, the first step can be optimized, but the second step cannot.

In any of these cases, we may use the same transformations to exploit symmetry as we did in the constant coefficient case. Since $G_e^{\alpha_1,\alpha_2,\alpha_3} = G_e^{\alpha_1,\alpha_3,\alpha_2}$, we may view each slice $A^0_{i\cdot}$ of the reference tensor as an array of $|P|$ tensors of size $d \times d$ and apply the transformation to each of these. If we fully form G_e, this reduces the cost from $|P|d^2$ to $|P|\binom{d+1}{2}$. In all of our experiments, we made use of this approach.

In Table 6, we see the cost of computing the weighted Laplacian by the first approach (optimizing directly the tensor product $A_i^e = A^0_{i\alpha} G_e^\alpha$). While the optimizations are not as successful as for the constant coefficient operators, we still get reductions of 30%–50% in the operation counts.

When we perform the contraction in stages, we find more dependencies (for example, the slices of two of the tensors could be colinear although the entire tensors are not). We show the cost of performing the optimized stage for contracting with $(G^L)_e$ first in Table 7 and for contracting with w_k first in Table 8.

In order to get a fair comparison between these approaches, we must factor in the additional costs of building G_e or performing the second stage of contraction. Once $(G^L)_e$ is built and symmetrized, it costs an additional $|P|\binom{d+1}{2}$ MAPs to construct G_e. If we optimize the computation of contracting with $(G^L)_e$ first, we do not have to build G_e, but we must perform a dot product with w_k for each entry of the matrix.

This costs $|P|$ per contraction with $\binom{|P|+1}{2}$ entries in the matrix. If we optimize the contraction with each w_k first, then we have an additional $\binom{|P|+1}{2}$ contractions with $(G^L)_e$ at a cost of $\binom{d+1}{2}$ each. We expect that which of these will be most effective must be determined (automatically) on a case-by-case basis. Table 9 shows the comparisons for the first approach (labeled G_e), the second approach (labeled $(G^L)_e$), and the third approach (labeled w_k) by indicating the cost of the optimized computation plus

the additional stages of computation. In most of these cases, contracting with the coefficient first leads to the lowest total cost.

5. Optimizing the optimization process. Since our graph (Y, E) is completely connected, we have $|E| = O(|Y|^2)$ and our optimization process requires complexity that is at least quadratic in the number of entries in the element stiffness matrix. In this section, we show how certain useful complexity-reducing relations may be evaluated over all of Y in better than quadratic time and then discuss how we may build a sparse graph (Y, E') with $|E| = O(|Y|)$ that will admit a much more efficient optimization process. Even though this process must be run only once per form and element (say, the Laplacian with quadratics on triangles), the quadratic algorithm can become very time consuming and challenge a single computer's resources for forms of high arity using high degree polynomials on tetrahedra.

5.1. Search algorithms. Before discussing how we may evaluate some of these complexity-reducing relations over the collection Y in better than quadratic time, we first describe some basic notation we will use for hash tables throughout this section and the next.

Hash tables are standard data structures [14] that associate each member of a set of $\cdot, \prime$ to some value, possibly drawn from another set of objects. The important point about hash tables is that the basic operations of setting and getting values are expected to be independent of the number of entries in the table (expected constant time access). Many higher-level programming languages have library support or built-in features supporting hash tables (many implementations of the standard template library in C++ include hash tables, and scripting languages such as Python and Perl have them built in as primitive types).

We begin by establishing some notation for the basic operations we use. If a is a key of table T, then we find the value associated with a by $T[a]$. If there is no value associated with a (that is, if a is not a key of T), we may update T by adding a key a associated with value b by the notation $T[a] \leftarrow b$. We use the same notation to indicate setting a new value to an existing key.

As before, we label the vectors y^i for $1 \le i \le n$. We want to partition the labels into a set of subsets $\mathcal{E}$ such that for each $E \in \mathcal{E}$, the vectors associated with each label in E are equal. Moreover, if two vectors are equal, then their labels must belong to the same E. This is easily accomplished by setting up a hash table whose keys are vectors and whose values are subsets of the integers $1 \le i \le n$. This process is described in Algorithm 1.

Algorithm 1 Determining equality among vectors

    E[y^i] ← E[v^i] ∪ {i}
  else if −y^i is a key of E then
    E[−y^i] ← E[−y^i] ∪ {i}
  else
    E[y^i] ← {i}
  end if
end for
```

Floating point arithmetic presents a slight challenge to hashing. Numbers which are close together (within some tolerance) that should be treated as equal must be rounded to so that they are indeed equal. Hashing relies on a function that maps items into a set of integers (the "hash code"). These functions are discontinuous and sensitive to small perturbations. For most numerical algorithms in floating point arithmetic, we may define equality to be "near equality," but hash tables require us to round or use rational arithmetic before any comparisons are made. We have successfully implemented our algorithms in both cases.

As an alternative to hashing, one could form a binary search tree or sort the vectors by a lexicographic ordering. These would rely on a more standard "close to equal" comparison operation but run only in $O(mn \log(mn))$ time. So, for large enough data sets, hashing will be more efficient.

We may similarly partition the labels into a set of subsets $\mathcal{C}$ such that for each $C \in \mathcal{C}$, the vectors associated with the labels in C are colinear. Similarly, if two vectors are colinear, then their labels must belong to the same C. This process may be performed by constructing the collection of unit vectors $\hat{A}$, with $\hat{y}_i = \frac{y_i}{\|y_i\|}$ for each $1 \leq i \leq n$ for some norm $\|\cdot\|$ and using Algorithm 1 on $\hat{A}$.

Finding vectors that are close together in Hamming distance is more subtle. At worst, the cost is $O(mn^2)$, as we have to compare every entry of every pair of vectors. However, we may do this in expected linear time with some assumptions about Y. We first describe the algorithm and then state the conditions under which the algorithm performs in worse than linear time.

Our vectors each have m components. We start by forming m empty hash tables. Each H_i will map numbers that appear in the ith position of any vector to the labels of vectors that have that entry in that position. This is presented in Algorithm 2, in which y^i_j denotes the jth entry of y^i.

Algorithm 2 MAPPING UNIQUE ENTRIES AT EACH POSITION TO VECTORS CONTAINING THEM

```
for all 1 ≤ i ≤ d do
  H_i an empty table mapping numbers to sets of vector labels from {i}_{i=1}^n
end for
for all 1 ≤ i ≤ n do
  for all 1 ≤ j ≤ m do
    if y_j^i is a key of H_j then
      H_j[y_j^i] ← H_j[y_j^i] ∪ {i}
    else
      H_j[y_j^i] := {i}
    end if
  end for
end for
```

This process runs in expected $O(nm)$ time. From these tables, we can construct a table that gives the Hamming distance between any two vectors, as seen in Algorithm 3. This algorithm counts down from d each time it discovers an entry that two vectors share. Our algorithm reflects the symmetry of the Hamming distance.

On output, for $1 \leq i < j \leq n$, if $D[i][j]$ has no entry, the distance between v^i and v_j is m. Otherwise, the table contains the Hamming distance between the two vectors.

Algorithm 3 Computing Hamming distances efficiently

```
D an empty table
for all 1 ≤ i ≤ n do
  D[i] an empty table
end for
for all 1 ≤ i ≤ m do
  for all a in the keys of H_i do
    for all unique combinations k, ℓ of labels in H_i[a] do
      α := min(k, ℓ), β := max(k, ℓ)
      if D[α] has a key β then
        D[α][β] ← D[α][β] − 1
      else
        D[α][β] := m − 1
      end if
    end for
  end for
end for
```

Regarding complexity, there is a double loop over the entries of each H_i. Hence, the algorithm is quadratic in the maximum number of vectors that share the same entry at the same location. Presumably, this is considerably less than n on most data sets.

5.2. Using a sparse graph. If we create a graph $(Y, \tilde{E})$ with significantly fewer edges than (Y, E), we may be able to get most of the reduction in operation count while having a more efficient optimization process. For example, we might choose to put a cutoff on ρ, using only edges that have a large enough complexity reduction. So, we can define the set of edges being

$$E_k = \{\{y^i, y^j\} : \rho(y^i, y^j) \leq k\}. \tag{16}$$

For example, if we use Algorithms 2 and 3 to evaluate H^+ over all pairs from Y, then we are using $\rho = H^+$ and $k = m - 1$. Also, note that our structure D encodes a sparse graph. That is, the vectors of Y are the nodes of the graph, the neighbors of each y^i are simply the keys of $D[y^i]$, and the edge weight between some y^i and neighbor y^j is $D[y^i][j^j]$. It is not hard to move from this table into whatever data structure is used for graphs.

Then we could add colinearity or other complexity-reducing relations to this graph. If we use Algorithm 1 on the unit vectors to determine sets of colinear vectors, we can update the graph either by adding edges or updating the edge weights for each pair of colinear vectors.

If $|E_k| = O(|Y|)$, then computing a minimum spanning tree will require only $O(n \log n)$ time rather than $O(n^2 \log n)$. However, there is no guarantee that (Y, E_k) will be a connected graph. Some vectors might not have close neighbors, or else some subgraphs do not connect with each other. An optimized algorithm can still be obtained by finding the connected components of the (Y, E_k) and finding a minimum spanning tree for each component. Then the total cost of the computation is m times the number of connected components plus the sum of the weights of each of the minimum spanning trees.

6. Conclusion and ongoing work. We have developed a general optimization strategy for the evaluation of local stiffness matrices for finite elements. This is based on first formulating the computation as a sequence of tensor contractions and then introducing a new concept of complexity-reducing relations that allows us to set the optimization in a graph context. The optimization itself proceeds by computing a minimum spanning tree. These techniques worked very well at reducing the cost of evaluating finite element matrices for several forms using Lagrange elements of degrees one through three on triangles and tetrahedra. Finally, we discussed some efficient algorithms for detecting equality and colinearity and for evaluating the pairwise Hamming distance over the entire set of tensors.

We hope to extend our optimizations in several ways. First, we remarked that it may be possible to enrich the collection of tensors in such as way as to deliver a minimum spanning tree with lower total weight. We hope to explore such a process in the future. Also, we saw in [11] that frequently some of the tensors are linear combinations of two or more other tensors. However, both locating and making use of such relations in a more formal context have been difficult. We are working on geometric search algorithms to locate linear dependencies efficiently. However, once they are located, our optimization process must occur over a hypergraph rather than a graph. Finding a true minimum is also much more difficult, and we are working on heuristics that will allow us to combine these two approaches.

Finally, we plan to integrate our optimization strategy with FFC. While FFC currently generates very efficient code for evaluating variational forms, we will improve upon this generated code by piping the tensors through our optimization process before generating code to perform the contractions. This will lead to a domain-specific optimizing compiler for finite elements; by exploiting latent mathematical structure, we will automatically generate more efficient algorithms for finite elements than people write by hand.

SPHERICAL SPLINES FOR DATA INTERPOLATION AND FITTING*

V. BARAMIDZE†, M. J. LAI†, AND C. K. SHUM‡

Abstract. We study minimal energy interpolation and discrete and penalized least squares approximation problems on the unit sphere using nonhomogeneous spherical splines. Several numerical experiments are conducted to compare approximating properties of homogeneous and nonhomogeneous splines. Our numerical experiments show that nonhomogeneous splines have certain advantages over homogeneous splines.

Key words. spherical splines, data fitting

DOI. 10.1137/040620722

1. Introduction. Contemporary research in atmospheric sciences, geodesy, and geophysics requires the use of global data heterogeneously distributed in space around Earth. For spherical data interpolation/approximation, tensor products of univariate splines are not a good choice, since data locations are not usually spaced over a regular grid. Radial basis functions are not good candidates either, since the data values may have no rotational symmetry.

Spherical Bernstein–Bézier splines (introduced in [1] and studied in [2] and [7]) are well suited for scattered data interpolation/approximation problems. The spherical spline functions have many properties in common with classical polynomial splines over planar triangulations. Moreover, many spline interpolation and approximation methods for planar scattered data problems have analogues in spherical setting [2].

One of the disadvantages of using homogeneous spherical splines is that spline spaces of even and odd degrees have only zero function in common due to homogeneity of the basis. More explicitly, the spline space $S_d^r(\Delta)$ of degree d and smoothness r (defined in [2]) with d odd does not contain constant functions, and the spline space $S_d^r(\Delta)$ with d even does not contain linear functions. Therefore in the homogeneous spline spaces reproduction of polynomials of degree $m \leq d$ is not possible unless $m = d \bmod(2)$.

To overcome this disadvantage we propose a simultaneous employment of two spaces $S_d^r(\Delta)$ and $S_{d-1}^r(\Delta)$, with one degree even and the other odd. A direct sum of two spline spaces forms the larger nonhomogeneous spherical polynomial spline space proposed by [10]. A simple structure of the resulting spline space allows us to use methods developed for homogeneous splines in nonhomogeneous spline spaces. The spline solution obtained via minimization over the larger space has in general higher accuracy. In addition, spherical nonhomogeneous splines reproduce spherical nonhomogeneous polynomials.

In this paper we establish existence and uniqueness of homogeneous and nonhomogeneous spherical spline approximations. Moreover, we show how the use of a powerful iterative algorithm [4] solving special linear systems leads to efficient computation of spherical splines of arbitrary degree and smoothness.

The paper is organized as follows. In section 2 we discuss homogeneous spherical polynomials and then introduce nonhomogeneous spherical polynomials. We review properties necessary for the implementation of the computational algorithms which are presented in sections 3, 4, 5. In section 3 we describe a minimal energy (ME) interpolation method using both homogeneous and nonhomogeneous splines. We discuss discrete and penalized least squares spline approximation algorithms in sections 4 and 5. In each section we start with a description of the method, follow with a computational algorithm, and end with numerical examples. Some examples are designed to demonstrate advantages of nonhomogeneous splines over homogeneous. In addition, we solve real world data fitting problems and offer visual evaluation of the solutions. One potential application of the development of spherical splines is in the investigation of inverse problems arising in geophysics. Using heterogeneously distributed satellite measurements from new satellite gravity missions such as GRACE (Gravity Recovery and Climate Experiment) [14] we aim to obtain an alternative representation of Earth's gravity field and a more realistic description of the geopotential.

2. Preliminary. In this section we review several basic concepts, outline some properties of spherical splines, explain computational algorithms for scattered data interpolation and fitting, and present a numerical iterative technique for implementation of the algorithms. All the material in this preparatory section can be found either in [1] and [2] or in [4].

Let us define spherical Bernstein–Bézier polynomials first. We begin with a concept of homogeneity. A trivariate function $f(v)$ is homogeneous of degree d if

$$f(\alpha v) = \alpha^d f(v). \tag{2.1}$$

Let $\mathcal{H}_d$ denote the space of trivariate homogeneous polynomials of degree d. That is, $\mathcal{H}_d := \operatorname{span}\{x^i y^j z^k,\ i+j+k=d\}$.

Let $\tau = \langle v_1, v_2, v_3\rangle$ be a nondegenerate spherical triangle; i.e., assume that the area on the unit sphere bounded by the great circular arcs connecting v_1 and v_2, v_1 and v_3, and v_2 and v_3 is not zero. Let $b_1(v)$, $b_2(v)$, and $b_3(v)$ be the spherical barycentric coordinates of a point $v \in \mathbb{S}^2$, i.e.,

$$v = b_1(v)v_1 + b_2(v)v_2 + b_3(v)v_3.$$

Linear independence of vectors $v_1,\ v_2$, and $v_3 \in \mathbb{R}^3$ imply that the b_i's are uniquely determined. Clearly, the b_i's are linear functions of v. It was shown in [1] that the set

$$B^d_{ijk}(v) = \frac{d!}{i!j!k!} b_1(v)^i b_2(v)^j b_3(v)^k, \qquad i+j+k=d, \tag{2.2}$$

of Bernstein–Bézier basis polynomials of degree d forms a basis for $\mathcal{H}_d$. It is easy to see that $B^d_{ijk}(v)$ is a homogeneous polynomial of degree d. Thus, when restricted to $\mathbb{S}^2$,

$$p(v) = \sum_{i+j+k=d} c_{ijk} B^d_{ijk}(v) \tag{2.3}$$

is called a homogeneous spherical Bernstein–Bézier (SBB)- polynomial of degree d.

Due to this special representation, many properties of SBB polynomials are analogous to those of classical planar Bernstein–Bézier polynomials [1]. However, evaluating integrals of spherical polynomials is considerably more difficult than in the planar setting. All integrals needed for our algorithms have to be evaluated numerically.

Let us now define nonhomogeneous spherical polynomials. It was shown in [10] that $\mathcal{H}_d \oplus \mathcal{H}_{d-1}$ restricted to the unit sphere is identical to the space $\mathcal{P}_d$ of all trivariate polynomials of degree d restricted to the unit sphere. Therefore the set $\{B^d_{ijk},\, i+j+k=d\} \cup \{B^{d-1}_{ijk},\, i+j+k=d-1\}$ on $\mathbb{S}^2$ forms a basis for $\mathcal{P}_d|_{\mathbb{S}^2}$. We can express a nonhomogeneous spherical polynomial p in terms of SBB-basis functions as

$$p = \sum_{i+j+k=d} a_{ijk} B^d_{ijk}(v) + \sum_{i+j+k=d-1} c_{ijk} B^{d-1}_{ijk}(v).$$

With this definition it is easy to see that evaluating (de Casteljau's algorithm), taking derivatives, and computing integrals of homogeneous polynomials can be easily adapted for nonhomogeneous polynomials.

We are now ready to define spherical splines. Given a set $\mathcal{V}$ of points on the unit sphere $\mathbb{S}^2$ we can form a triangulation Δ, which may be a triangulation of a spherical domain on $\mathbb{S}^2$ or of the entire sphere. We will assume that Δ is regular in the sense that any two triangles either do not intersect each other or share their common vertex or their common edge. Let

$$S^r_d(\Delta) := \{s \in C^r(\mathbb{S}^2), s|_\tau \in \mathcal{H}_d, \tau \in \Delta\}$$

be the spherical spline space of degree d and smoothness $r \geq -1$. Here

$$s|_\tau = \sum_{i+j+k=d} c^\tau_{ijk} B^{d,\tau}_{ijk}(v).$$

The space of nonhomogeneous spherical splines is defined as

$$N^r_d(\Delta) := \{s \in C^r(\mathbb{S}^2), s|_\tau \in \mathcal{P}_d, \tau \in \Delta\}$$

with

$$s|_\tau = \sum_{i+j+k=d} a^\tau_{ijk} B^{d,\tau}_{ijk}(v) + \sum_{i+j+k=d-1} c^\tau_{ijk} B^{d-1,\tau}_{ijk}(v).$$

In general, we know neither the dimension of $S^r_d(\Delta)$ nor the construction of locally supported basis functions such as finite elements for arbitrary d and r. However, the lack of understanding of the dimension and construction of locally supported basis functions of general spline spaces does not prevent us from using them for scattered data interpolation and fitting. It is one of the purposes of this paper to show how to use spherical splines of arbitrary d and r with $d > r$ for scattered data interpolation and fitting. The crucial step in the process is to solve a singular linear system arising from the application of the Lagrange multipliers method [2] to the minimization. The linear system has a form which is explained later in detail:

$$\begin{bmatrix} A & L^T \\ L & 0 \end{bmatrix} \begin{bmatrix} \mathbf{c} \\ \lambda \end{bmatrix} = \begin{bmatrix} F \\ G \end{bmatrix}.$$

It is necessary to derive a computational algorithm to efficiently obtain the vector $\mathbf{c}$ containing coefficients of the spline solution. We use the following iterative method [4]:

$$\begin{bmatrix} A & L^T \\ L & -\epsilon I \end{bmatrix} \begin{bmatrix} \mathbf{c}^{(\ell+1)} \\ \lambda^{(\ell+1)} \end{bmatrix} = \begin{bmatrix} F \\ G - \epsilon\lambda^{(\ell)} \end{bmatrix},$$

for $\ell = 0, 1, \ldots$, where $\epsilon > 0$ is a fixed number, e.g., $\epsilon = 10^{-4}$, $\lambda^{(\ell)}$ is an iterative solution of a Lagrange multiplier coefficient vector with $\lambda^0 = 0$, and I is the identity matrix. The above matrix iterative steps can in fact be rewritten as follows:

$$\left(A + \frac{1}{\epsilon} L^T L\right) \mathbf{c}^{(\ell+1)} = AF\mathbf{c}^{(\ell)} + \frac{1}{\epsilon} L^T G$$

with $\mathbf{c}^{(0)} = 0$. Note that the size of the above linear system is much smaller than the original. The iterations converge very quickly as shown in the following theorem. In our numerical experiments, a few iterations (less than 10) often suffice. A general convergence theorem is proved in [4]. To state the convergence result, we need the following definition.

DEFINITION 2.1. [illegible] A [illegible] $n \times n$ [illegible] L [illegible] $m \times n$ [illegible] A [illegible] L [illegible] $\mathbf{c}^T A\mathbf{c} \geq 0$ [illegible] $A\mathbf{c} = 0$ $L\mathbf{c} = 0$ [illegible] $\mathbf{c} = 0$

THEOREM 2.2. [illegible] A [illegible] L [illegible] $A + \frac{1}{\epsilon} L^T L$ [illegible] $\epsilon > 0$ [illegible] C [illegible]

$$\|\mathbf{c}^{(\ell+1)} - \mathbf{c}\| \leq C\epsilon \|\mathbf{c}^{(\ell)} - \mathbf{c}\| \quad \text{[illegible]} \quad \ell \geq 0.$$

3. Minimal energy interpolation.

3.1. Energy functionals. Recall that $\mathcal{V} := \{v \in \mathbb{S}^2\}$ is a set of points on the unit sphere and $\{f(v), v \in \mathcal{V}\}$ is a set of spherical function values given at the locations $\mathcal{V}$. Let Δ be a regular spherical triangulation of $\mathbb{S}^2$ with vertices $\mathcal{V}$. For two integers d and r let $S_d^r(\Delta)$ be the spline space of spherical homogeneous polynomials of degree d and smoothness r.

We need to find a spline function $s \in S_d^r(\Delta)$ interpolating f at $\mathcal{V}$. In general such a spline is not unique. A typical way to use extra degrees of freedom is to minimize a functional $\mathcal{E}(s)$ measuring smoothness of s. In [2] the energy functional

$$\mathcal{E}(s) = \int_{\mathbb{S}^2} (\Delta^* s)^2 d\mu \tag{3.1}$$

was used, where Δ^* is the Laplace–Beltrami operator, μ is the Lebesgue measure on $\mathbb{S}^2$, and the integral in (3.1) is taken over the unit sphere. Note that the Laplace–Beltrami operator annihilates constants only. We propose an alternative functional motivated by Sobolev-type seminorms defined in [12]. Let

$$\mathcal{E}_\delta(s) = \int_{\mathbb{S}^2} \sum_{|\alpha|=2} (D^\alpha s_\delta)^2 d\mu. \tag{3.2}$$

In (3.2) s_δ is the unique homogeneous extension of s of degree δ to $\mathbb{R}^3 \setminus \{0\}$ defined by $s_\delta(v) = |v|^\delta s(\frac{v}{|v|})$. If the degree d of the homogeneous spline space is even, we take $\delta = 0$; if odd, we take $\delta = 1$. After evaluating second order partial derivatives, $D^\alpha s_\delta$ are restricted to $\mathbb{S}^2$ and are then integrated.

To establish existence and uniqueness of a spherical spline in $S_d^r(\Delta)$ interpolating f and minimizing (3.2), we need the following.

LEMMA 3.1. [illegible] Δ [illegible] $f \neq 0$ [illegible]

(1) $\mathcal{E}_0(f) = 0$ [illegible] f [illegible]

(2) $\mathcal{E}_1(f) = 0$ [illegible] f [illegible] $\mathbb{S}^2$

If $\mathcal{E}_\delta(f) = 0$, then by the definition, $D^\alpha f_\delta = 0$ on every triangle $\tau \in \Delta$. Consider $\delta = 1$. Since f_1 is linear homogeneous, $D^\alpha f_1$ is homogeneous of degree -1, and therefore, by the uniqueness of homogeneous extensions, $(D^\alpha f_1|_\tau)_{-1} = D^\alpha f_1$. On the other hand, by the definition, $(D^\alpha f_1|_\tau)_{-1}(v) = |v|^{-1}(D^\alpha f_1|_\tau)(\frac{v}{|v|})$. As we noted above, $D^\alpha f_1|_\tau = 0$, and therefore $D^\alpha f_1 = 0$ as well. Hence f_1 is a polynomial of degree at most 1. Since it is a homogeneous linear function, f_1 must be a homogeneous linear polynomial on $\mathbb{R}^3$. Therefore by the uniqueness of homogeneous extensions, f is a linear homogeneous polynomial on τ. A similar proof works for $\delta = 0$. The other direction follows trivially from definition (3.2). □

Let

$$\Gamma(f) := \{s \in S_d^r(\Delta) : s(v) = f(v) \text{ for all } v \in \mathcal{V}\}$$

be the set of all splines in $S_d^r(\Delta)$ interpolating f at the vertices of triangulation Δ. Let $s_f \in \Gamma(f)$ denote a spherical spline minimizing (3.2) over $\Gamma(f)$.

LEMMA 3.2. $\Gamma(f)$ $s_f \in S_d^r(\Delta)$ $f = 0$ (3.2) $\delta = d \bmod(2)$

Since $\mathcal{E}_\delta(s) \geq 0$ for all $s \in S_d^r(\Delta)$, $\mathcal{E}_\delta(s_f) = 0$ is the absolute minimum of $\mathcal{E}_\delta$ achieved at $s_f = 0$. To show the uniqueness, assume there is another $s \in \Gamma(0)$ with $\mathcal{E}_\delta(s) = 0$. We need to prove that $s = s_f$. By our assumption, $\mathcal{E}_\delta(s) = 0$ on every triangle $\tau \in \Delta$. By Lemma 3.1 s is either a linear homogeneous function (if d is odd) or s is a constant (if d is even) on every triangle $\tau \in \Delta$. Since s interpolates 0 at the vertices of each triangle, $s = 0$ on each triangle. Therefore $s = s_f$. □

THEOREM 3.3. Δ $\mathbb{S}^2$ $\mathcal{V}$ $\{f(v),\ v \in \mathcal{V}\}$ f d, r $d \geq 3r+2$ $s_f \in S_d^r(\Delta)$ f $\mathcal{E}_\delta$

Since $d \geq 3r + 2$, $\Gamma(f)$ is not empty [3]. There exists an ME spline s_f interpolating f since $\Gamma(f)$ is a nonempty closed convex set. To prove uniqueness suppose there exists $q_f \in \Gamma(f)$ minimizing $\mathcal{E}_\delta$, i.e., $\mathcal{E}_\delta(s_f) = \mathcal{E}_\delta(q_f)$. Since $\mathcal{E}_\delta(s_f + \nu s)$ achieves its minimal value at $\nu = 0$ over $s \in \Gamma(0)$, we have

$$\frac{d}{d\nu}\mathcal{E}_\delta(s_f + \nu s)|_{\nu=0} = 0,$$

which leads to

$$\sum_{|\alpha|=2} \int_{\mathbb{S}^2} (D^\alpha s_{f,\delta})(D^\alpha s_\delta) d\mu = 0$$

for $s \in \Gamma(0)$. In particular for $s = s_f - q_f$ we get

$$\sum_{|\alpha|=2} \int_{\mathbb{S}^2} (D^\alpha s_{f,\delta})^2 d\mu = \sum_{|\alpha|=2} \int_{\mathbb{S}^2} (D^\alpha s_{f,\delta})(D^\alpha q_{f,\delta}) d\mu.$$

Therefore,

$$\mathcal{E}_\delta(s_f - q_f) = 0,$$

and by Lemma 3.2 $s_f - q_f \equiv 0$. This completes the proof. □

To develop ME interpolation using nonhomogeneous splines, we fix integers $d \geq 1$ and $r \geq 0$ and recall that $N_d^r(\Delta) = S_d^r(\Delta) \oplus S_{d-1}^r(\Delta)$. To simplify our notation let us

assume that d is odd. We can present a spline function $s \in N_d^r(\Delta)$ as a sum $s_1 + s_0$, where the subscript 1 indicates that $s_1 \in S_d^r(\Delta)$ and that we use its linear extension to compute derivatives. Similarly, the subscript 0 indicates that $s_0 \in S_{d-1}^r(\Delta)$ and that we work with its constant extension.

We define an energy functional which annihilates nonhomogeneous linear polynomials as well as constants and homogeneous linear polynomials

$$\mathcal{E}(s) = \lambda \int_{\mathbb{S}^2} \sum_{|\alpha|=2} (D^\alpha s_1)^2 d\mu + (1-\lambda) \int_{\mathbb{S}^2} \sum_{|\alpha|=2} (D^\alpha s_0)^2 d\mu, \tag{3.3}$$

with $0 < \lambda < 1$.

LEMMA 3.4. [illegible] d [illegible] r [illegible] $N_d^r(\Delta)$ [illegible] f [illegible]

$$\widetilde{\Gamma}(f) := \{s \in N_d^r(\Delta) : s(v) = f(v) \text{ [illegible] } v \in \mathcal{V}\}$$

[illegible] $N_d^r(\Delta)$ [illegible] f [illegible] Δ [illegible] $s_f = 0 \in N_d^r(\Delta)$ [illegible] $f = 0$ [illegible] (3.3)

[illegible]. By the definition, $0 = s_f = s_1 + s_0$, where $s_1|_\tau$ is a homogeneous polynomial of degree d and $s_0|_\tau$ is a homogeneous polynomial of degree $d-1$. Since $S_d^r(\Delta) \cap S_{d-1}^r(\Delta) = 0$, $s_1 = 0$ and $s_0 = 0$. By definition (3.3), $\mathcal{E}(s_f) = 0$. Since $\mathcal{E}(s) \geq 0$ for all $s \in N_d^r(\Delta)$, $\mathcal{E}(0) = 0$ is the absolute minimum of $\mathcal{E}$. To show the uniqueness, assume there is $q_f \in \Gamma(0)$ with $\mathcal{E}(q_f) = 0$. We need to show that $q_f = s_f = 0$. As above, we know $q_f = q_1 + q_0$ for some $q_1 \in S_d^r(\Delta)$ and $q_0 \in S_{d-1}^r(\Delta)$. Then $\mathcal{E}_1(q_1) = 0$ and $\mathcal{E}_0(q_0) = 0$ on every triangle $\tau \in \Delta$. By Lemma 3.1 q_1 is a linear homogeneous polynomial and q_0 is a constant on $\mathbb{S}^2$. Therefore $q_1 + q_0$ is a trivariate linear polynomial satisfying zero interpolation conditions over points $v \in \mathcal{V}$, none of which is the origin. By the linear independence of x, y, z, and 1, $q_f = 0$ on every triangle. Therefore $q_f = s_f$. □

THEOREM 3.5. [illegible] Δ [illegible] $\mathbb{S}^2$ [illegible] $\mathcal{V}$ [illegible] $\{f(v), v \in \mathcal{V}\}$ [illegible] $d \geq 1$ $r \geq 0$ [illegible] $d \geq 3r + 2$ [illegible] $s_f \in N_d^r(\Delta)$ [illegible] f [illegible] $\mathcal{E}$

[illegible]. The proof follows from Lemma 3.4 as in the proof of Theorem 3.3. □

3.2. Computational algorithms. In this section we explain how to compute ME spherical interpolating splines. We use a coefficient vector $\mathbf{c} := (c_{ijk}^\tau, i+j+k = d, \tau \in \Delta)$ to represent each spline function in $S_d^r(\Delta)$. To simplify the data management we linearize the triple indices of SBB-coefficients c_{ijk} and correspondingly the indices of SBB-basis functions B_{ijk}^d. From the properties of SBB-polynomials, we have

$$c_{d00} = f(v_1), \quad c_{0d0} = f(v_2), \quad c_{00d} = f(v_3)$$

for the vertices of each triangle $\tau \in \Delta$. We assemble interpolation conditions into a matrix $\mathbf{K}$, according to the order of the coefficient vector $\mathbf{c}$. Then $\mathbf{Kc} = \mathbf{F}$ is the linear system of equations such that the coefficient vector $\mathbf{c}$ corresponds to a spline s interpolating f at the data sites $\mathcal{V}$.

To ensure the C^r continuity across each edge of Δ, we impose smoothness conditions which can be found in [1]. Let $\mathbf{M}$ denote the smoothness matrix such that $\mathbf{Mc} = 0$ if and only if $s \in S_d^r(\Delta)$.

Next fix $\delta = d \bmod(2)$. Define the energy matrix $\mathbf{E}$ by $\mathbf{E} = \operatorname{diag}(\mathbf{E}_\tau,\ \tau \in \Delta)$. Each block $\mathbf{E}_\tau$ is associated with a triangle τ and contains the entries

$$\mathbf{E}_{ij} := \int_\tau \sum_{|\alpha|=2} D^\alpha(B_i)_\delta D^\alpha(B_j)_\delta d\mu, \tag{3.4}$$

where B_i denotes a SBB-polynomial basis function (2.2) of degree d corresponding to the order of the linearized triple indices (i, j, k), $i + j + k = d$.

The problem of minimizing (3.2) over $S_d^r(\Delta)$ can be formulated as follows:

$$\text{Minimize } \mathbf{c}^T\mathbf{E}\mathbf{c} \text{ subject to } \mathbf{M}\mathbf{c} = 0 \text{ and } \mathbf{K}\mathbf{c} = \mathbf{F}.$$

Using the method of Lagrange multipliers, we must solve the linear system

$$\begin{bmatrix} \mathbf{E} & \mathbf{K}^T & \mathbf{M}^T \\ \mathbf{K} & 0 & 0 \\ \mathbf{M} & 0 & 0 \end{bmatrix} \begin{bmatrix} \mathbf{c} \\ \eta \\ \gamma \end{bmatrix} = \begin{bmatrix} 0 \\ \mathbf{F} \\ 0 \end{bmatrix}.$$

Here γ and η are vectors of Lagrange multiplier coefficients. We obtain the least square solution to the singular linear system above using the iterative method discussed in section 2. Lemma 3.2 implies that $\mathbf{E}$ is symmetric and positive definite with respect to

$$\begin{bmatrix} \mathbf{K} \\ \mathbf{M} \end{bmatrix}.$$

By Theorem 2.2, the iterative method converges to the vector $\mathbf{c}$, which is the coefficient vector of the unique interpolating spline minimizing (3.2). This furnishes a computational algorithm.

To solve the interpolation problem over $N_d^r(\Delta)$, we proceed similarly. Consider $s = s_1 + s_0$ with splines s_1 and s_0 of degrees d and $d-1$, respectively. Order the coefficients over each triangle τ as above and denote them by $\mathbf{c}_1^\tau$ and $\mathbf{c}_0^\tau$. Let $\tilde{\mathbf{c}} = (\mathbf{c}_1, \mathbf{c}_0)$, with $\mathbf{c}_1 := (\mathbf{c}_1^\tau,\ \tau \in \Delta)$ and $\mathbf{c}_0 := (\mathbf{c}_0^\tau,\ \tau \in \Delta)$. We denote interpolation, smoothness and energy matrices by $\mathbf{K}_1$, $\mathbf{K}_0$, $\mathbf{M}_1$, $\mathbf{M}_0$, $\mathbf{E}_1$, $\mathbf{E}_0$ correspondingly. Therefore interpolation conditions for s are

$$\tilde{\mathbf{K}}\tilde{\mathbf{c}} := \begin{bmatrix} \mathbf{K}_1 & \mathbf{K}_0 \end{bmatrix} \begin{bmatrix} \mathbf{c}_1 \\ \mathbf{c}_0 \end{bmatrix} = \mathbf{F}.$$

For s to be smooth we require both s_1 and s_0 to be smooth. The C^r smoothness conditions for s are

$$\tilde{\mathbf{M}}\tilde{\mathbf{c}} := \begin{bmatrix} \mathbf{M}_1 & 0 \\ 0 & \mathbf{M}_0 \end{bmatrix} \begin{bmatrix} \mathbf{c}_1 \\ \mathbf{c}_0 \end{bmatrix} = 0.$$

With definition (3.3) it is clear that the energy matrix in this case is defined by

$$\tilde{\mathbf{E}} = \begin{bmatrix} \lambda\mathbf{E}_1 & 0 \\ 0 & (1-\lambda)\mathbf{E}_0 \end{bmatrix}.$$

Therefore $s \in N_d^r(\Delta)$ minimizes (3.3), interpolates f at the vertices of Δ, and is C^r continuous if and only if the vector $\tilde{\mathbf{c}}$ of its coefficients satisfies the system of linear equations

$$\begin{bmatrix} \tilde{\mathbf{E}} & \tilde{\mathbf{K}}^T & \tilde{\mathbf{M}}^T \\ \tilde{\mathbf{K}} & 0 & 0 \\ \tilde{\mathbf{M}} & 0 & 0 \end{bmatrix} \begin{bmatrix} \tilde{\mathbf{c}} \\ \gamma \\ \eta \end{bmatrix} = \begin{bmatrix} 0 \\ \mathbf{F} \\ 0 \end{bmatrix}.$$

TABLE 3.1
Linear and constant polynomial reproduction on eight triangles.

$S_d^r(\Delta_1) \setminus f$	1	$x+z$	$z+1$
$S_3^1(\Delta_1)$	$4.2265e-01$	$1.1016e-15$	$2.1144e-01$
$S_4^1(\Delta_1)$	$4.6629e-15$	$2.5398e-01$	$9.1140e-02$
$N_4^1(\Delta_1)$	$6.4389e-15$	$1.4950e-15$	$1.5551e-15$

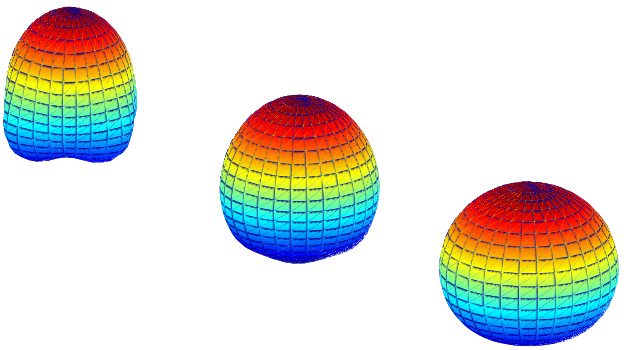

FIG. 3.1. *Interpolation of $z+1$ in S_3^1, S_4^1, and N_4^1 from left to right.*

As in the case of homogeneous splines, the linear system is singular. However, by Lemma 3.4 we have the following.

COROLLARY 3.6. $\tilde{\mathbf{E}}$ [illegible]

$$\begin{bmatrix} \tilde{\mathbf{K}} \\ \tilde{\mathbf{M}} \end{bmatrix}.$$

[illegible] Since $\mathcal{E}(s) = \tilde{\mathbf{c}}^T \tilde{\mathbf{E}} \tilde{\mathbf{c}} \geq 0$, $\tilde{\mathbf{c}}^T \tilde{\mathbf{E}} \tilde{\mathbf{c}} = 0$ implies that s is a linear polynomial. Zero side conditions force $s = 0$. By the linear independence of the basis functions, $\tilde{\mathbf{c}} = 0$. □

Thus by Theorem 2.2, the application of the iterative scheme allows us to successfully obtain its numerical solution.

3.3. Numerical experiments with ME splines. In this section we present several examples on scattered data interpolation using the ME method.

[illegible] 3.1. Let Δ_1 be the triangulation of the entire sphere based on six vertices $(1,0,0)$, $(0,1,0)$, $(0,0,1)$, $(-1,0,0)$, $(0,-1,0)$, and $(0,0,-1)$ and consisting of eight triangles. We sample 1, $x+z$ and $z+1$ at the six vertices, and compute ME spline interpolants in spherical spline spaces $S_3^1(\Delta)$, $S_4^1(\Delta)$, and $N_4^1(\Delta)$.

The maximal relative errors

$$\frac{\|s(w) - f(w)\|_\infty}{\|f(w)\|_\infty}$$

are computed based on the errors at 5120 points w almost evenly spaced over $\mathbb{S}^2$ and reported in Table 3.1. Note that not only linear and constant homogeneous polynomials are reproduced in $N_4^1(\Delta)$, but a nonhomogeneous polynomial $z+1$ is reproduced as well. In Figure 3.1 we present a visualization of the results of the last column of Table 3.1. It was shown in [1] that spherical linear functions are spheres through the origin. As expected from the table, the first two surfaces are not spheres.

TABLE 3.2

$N_4^1(\Delta)$	$9.3702e-02$	$2.0109e-02$	$1.7570e-03$	$2.0737e-04$

EXAMPLE 3.2. Next we investigate how the choice of λ affects the error in minimization over $N_d^r(\Delta)$. We interpolate $f(x,y,z) = 1 + 0.3x^8 + e^{0.2y^3}$ in $N_4^1(\Delta_i)$, $i = 1,\ldots,4$. The initial triangulation is Δ_1. The triangulation Δ_2 is obtained by bisecting the edges of Δ_1 and splitting each triangle into four subtriangles. Similarly we obtain uniform refinements Δ_3 and Δ_4. Each time, we evaluate the spline interpolant at 5120 almost evenly spaced points w and list maximal relative errors

$$e(\Delta_i) := \frac{\|s(w) - f(w)\|_\infty}{\|f(w)\|_\infty}$$

in Table 3.2. The results suggest that the errors on each Δ_i are almost the same for all the values of λ.

EXAMPLE 3.3. We compare the interpolation results for the function $f(x,y,z) = 1 + 0.3x^8 + e^{0.2y^3}$ in nonhomogeneous and homogeneous spaces. We use Table 3.2 as a guide for the choice of λ. The results in Table 3.3 demonstrate that on finer triangulations nonhomogeneous splines approximate the original function f better than homogeneous splines.

EXAMPLE 3.4. This is an example of scattered data spline interpolation. We are given 868 points in $\mathbb{R}^3$ (courtesy of Thomas Grandine at Boeing). We translate the point cloud so that its center coincides with the origin and project translated points onto the unit sphere. The projections give us locations on the sphere surface and the distances between the origin and translated points give us corresponding experimental function values. The locations on the sphere are triangulated, and the ME homogeneous cubic and quartic splines are computed as well as nonhomogeneous quartic splines. In Figure 3.2 we present one of the solutions together with the translated point cloud.

EXAMPLE 3.5. We present an example of scattered data interpolation over the Earth. We are given a satellite data set of simulated geopotential values (in m^2/s^2) observed by the gravity mission satellite, CHAMP [13], along its orbit for two days. The data collected amount to 5760 values. The CHAllenging Mini-satellite Payload (CHAMP) is a German geoscience satellite, launched on July 15, 2000, with a cir-

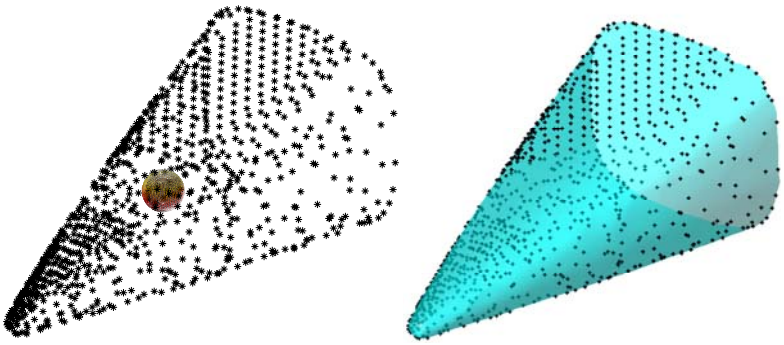

FIG. 3.2. *ME spherical spline interpolant of the point cloud.*

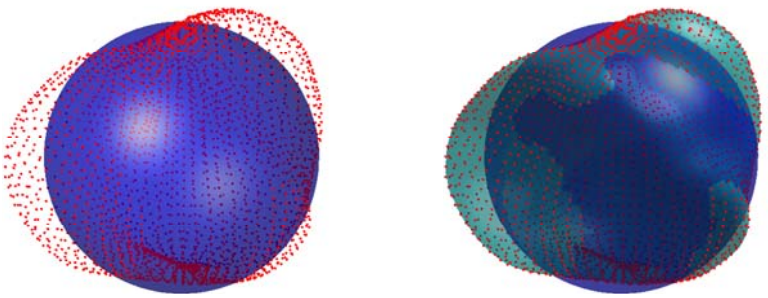

FIG. 3.3. *CHAMP geopotential data and ME spherical spline interpolant.*

cular orbit at an altitude of 450 km and orbital inclination of 87°. The simulated geopotential values are computed using a global geopotential model, EGM96 [11]. In Figure 3.3 we show the set of CHAMP scattered potential values which are normalized by the radius of the Earth and plotted over the unit sphere. The minimal energy homogeneous spherical interpolatory spline surface is shown in Figure 3.3 (right). It is clear that the spherical spline interpolates the given data and produces a reasonable fitting of the given geopotential values.

4. Discrete least squares fitting.

4.1. Existence and uniqueness. When the given data set is extremely large, e.g., $n \geq 10{,}000$, and highly redundant, it is suitable to find a discrete least squares (DLS) fitting to the given data instead of computing an interpolating spherical spline. The DLS approximation problem in $S_d^\tau(\Delta)$ can be described as follows. Let $\mathcal{V} = \{v_\ell, \ell = 1, \dots, n\}$ be the given data sites over $\mathbb{S}^2$ and Δ be a triangulation whose vertices may not relate to the data locations. For a given degree d, we assume that the data sites are rich enough in the following sense.

DEFINITION 4.1. [illegible] v_ℓ $\ell = 1, \dots, n$ [illegible] Δ [illegible] d [illegible]

$$\left[B_{ijk}^{d,\tau}(v_\ell)\right]_{i+j+k=d, v_\ell \in \tau}$$

[illegible] $\tau \in \Delta$

Suppose that the given data values are from a function f, i.e., $f(v_\ell) =: f_\ell$, $\ell = 1, \ldots, n$ are given. The least squares functional is defined by

$$\mathcal{L}(s) = \sum_{\ell=1}^{n} (s(v_\ell) - f_\ell)^2. \tag{4.1}$$

A DLS spherical spline $s_f \in S_d^r(\Delta)$ is the function minimizing $\mathcal{L}(s)$ over $S_d^r(\Delta)$, i.e.,

$$\mathcal{L}(s_f) = \min\{\mathcal{L}(s),\ s \in S_d^r(\Delta)\}.$$

THEOREM 4.2. [illegible] v_ℓ $\ell = 1, \ldots, n$ [illegible] Δ [illegible] d [illegible] s_f [illegible] d [illegible] r [illegible] (4.1) [illegible]. Recall that any $s \in S_d^r(\Delta)$ can be written as

$$s(v)|_\tau = \sum_{i+j+k=d} c_{ijk}^\tau B_{ijk}^{d,\tau}(v)$$

on a spherical triangle $\tau \in \Delta$. Let $\mathbf{c} = (c_{ijk}^\tau,\ i+j+k=d,\ \tau \in \Delta)$ be the coefficient vector of s. Note that

$$L(\mathbf{c}) := \mathcal{L}(s) = \sum_{\ell=1}^{n} |s(v_\ell) - f_\ell|^2 = \sum_{\tau \in \Delta} \sum_{v_\ell \in \tau} \left(\sum_{i+j+k=d} c_{ijk}^\tau B_{ijk}^{d,\tau}(v_\ell) - f_\ell \right)^2$$

is a continuous convex function of $\mathbf{c}$, $L(0) = \|\mathbf{f}\|_2^2$ with $\mathbf{f} = (f_\ell,\ \ell = 1, \ldots, n)$ the data value vector and $\|\mathbf{f}\|_2 := (\sum_{\ell=1}^n |f_\ell|^2)^{1/2}$ denoting the standard ℓ_2 norm of the vector $\mathbf{f}$. Consider $A = \{\mathbf{c},\ L(\mathbf{c}) \le \|\mathbf{f}\|_2^2\}$ and let us show that A is a bounded and closed set.

Fix any triangle $\tau \in \Delta$. For any $\mathbf{c} \in A$ we have

$$\left| \sum_{i+j+k=d} c_{ijk}^\tau B_{ijk}^{d,\tau}(v_\ell) - f_\ell \right|^2 \le \|\mathbf{f}\|_2^2 \quad \text{for all } v_\ell \in \tau.$$

It follows that

$$\left| \sum_{i+j+k=d} c_{ijk}^\tau B_{ijk}^{d,\tau}(v_\ell) \right| \le 2\|\mathbf{f}\|_2 \quad \text{for all } v_\ell \in \tau.$$

Since the data sites are evenly distributed with respect to d, the matrix

$$\left[B_{ijk}^{d,\tau}(v_\ell) \right]_{i+j+k=d, v_\ell \in \tau}$$

is of full rank and hence, there exists an index set $I_\tau \subset \{1, \ldots, n\}$ such that the square matrix $B^\tau = [B_{ijk}^{d,\tau}(v_\ell)]_{i+j+k=d, \ell \in I_\tau}$ is invertible. Therefore $\|(c_{ijk,i+j+k=d}^\tau)\|_2 \le C_\tau$, with C_τ a positive constant depending only on $\|\mathbf{f}\|_2$ and the norm of the inverse matrix of B^τ. Hence $\|\mathbf{c}\|_2$ is bounded above and A is bounded. It is easy to see that A is closed and that $A_s := \{\mathbf{c} : \mathbf{M}\mathbf{c} = 0\}$ is also closed. Here $\mathbf{M}\mathbf{c} = 0$ is the linear system representing the smoothness conditions for $S_d^r(\Delta)$. Hence, the set $A \cap A_s$ is compact, and there exists a $\mathbf{c}_f \in A \cap A_s$ minimizing $L(\mathbf{c})$.

To show uniqueness of the solution $\mathbf{c}_f$, we assume that there exist two solutions $\mathbf{c}_f$ and $\widehat{\mathbf{c}}_f$. The convexity of L implies that for any $0 \le \nu \le 1$ a convex combination $\mathbf{c}_f + \nu(\widehat{\mathbf{c}}_f - \mathbf{c}_f)$ also minimizes L. Thus

$$\begin{aligned}
&\frac{d}{d\nu} L(\mathbf{c}_f + \nu(\widehat{\mathbf{c}}_f - \mathbf{c}_f)) \\
&= \sum_{\tau\in\Delta}\sum_{v_\ell\in\tau}\left(\sum_{i+j+k=d}(\mathbf{c}^\tau_{ijk} + \nu(\widehat{\mathbf{c}}^\tau_{ijk} - \mathbf{c}^\tau_{ijk}))B^\tau_{ijk}(v_\ell) - f_\ell)(\widehat{\mathbf{c}}^\tau_{ijk} - \mathbf{c}^\tau_{ijk})B^\tau_{ijk}(v_\ell)\right) \\
&= \nu\sum_{\tau\in\Delta}\sum_{v_\ell\in\tau}\left(\sum_{i+j+k=d}(\widehat{\mathbf{c}}^\tau_{ijk} - \mathbf{c}^\tau_{ijk})^2 B^\tau_{ijk}(v_\ell)^2\right) \\
&+ \sum_{\tau\in\Delta}\sum_{v_\ell\in\tau}\left(\sum_{i+j+k=d}\mathbf{c}^\tau_{ijk}(\widehat{\mathbf{c}}^\tau_{ijk} - \mathbf{c}^\tau_{ijk})B^\tau_{ijk}(v_\ell)\right)^2 \\
&- \sum_{\tau\in\Delta}\sum_{v_\ell\in\tau}\left(\sum_{i+j+k=d} f_\ell(\widehat{\mathbf{c}}^\tau_{ijk} - \mathbf{c}^\tau_{ijk})B^\tau_{ijk}(v_\ell)\right) = 0
\end{aligned}$$

for any $0 \le \nu \le 1$. Since this expression is independent of ν, we have

$$\sum_{\tau\in\Delta}\sum_{v_\ell\in\tau}\left(\sum_{i+j+k=d}(\widehat{\mathbf{c}}^\tau_{ijk} - \mathbf{c}^\tau_{ijk})^2 B^\tau_{ijk}(v_\ell)\right)^2 = 0.$$

Since the data sites are evenly distributed over Δ, $\mathbf{c}_f = \widehat{\mathbf{c}}_f$. □

For nonhomogeneous spherical splines DLS approximation can be treated similarly. We seek a function $s = s_1 + s_0 \in N^r_d(\Delta)$ minimizing $\mathcal{L}(s)$.

For the nonhomogeneous case, Definition 4.1 has to be modified to take into account that the basis functions in $N^r_d(\Delta)$ consist of homogeneous SBB-basis polynomials of degrees d and $d-1$.

DEFINITION 4.3. [illegible] v_ℓ $\ell = 1, \dots, n$ [illegible] Δ [illegible] d [illegible]

$$\begin{bmatrix} B^{d,\tau}_{ijk}(v_\ell) \\ B^{d-1,\tau}_{i'j'k'}(v_\ell) \end{bmatrix}_{i+j+k=d, i'+j'+k'=d-1, v_\ell\in\tau}$$

[illegible] $\tau \in \Delta$

THEOREM 4.4. [illegible] v_ℓ $\ell = 1, \dots, n$ [illegible] d [illegible] $s_f \in N^r_d(\Delta)$ [illegible]
(4.1)

[illegible]. The proof is similar to the proof of Theorem 4.2. □

4.2. Computational algorithms. We first explain a computational algorithm for the DLS fit in $S^r_d(\Delta)$. The Lagrange multipliers method leads to the linear system

$$\begin{bmatrix} \mathbf{L}^T\mathbf{L} & \mathbf{M}^T \\ \mathbf{M} & 0 \end{bmatrix}\begin{bmatrix} \mathbf{c} \\ \eta \end{bmatrix} = \begin{bmatrix} \mathbf{L}^T\mathbf{F} \\ 0 \end{bmatrix},$$

where $\mathbf{L}$ is the observation matrix with entries $\mathbf{L}_{ij} = B_j(v_i)$, $i = 1, \dots, n$, and j runs from 1 to $\#\tau(d+1)(d+2)/2$, where $\#\tau$ denotes the number of triangles in Δ.

Here, $\mathbf{F}$ is a vector of function values ordered as the spherical points v_ℓ, $\ell = 1, \ldots, n$, $\mathbf{M}$ is the C^r smoothness matrix, and η is a vector of Lagrange multipliers. The least squares solution of this system is a vector $\mathbf{c}$ of coefficients of a homogeneous spline s of degree d and smoothness r defined with respect to the spherical triangulation Δ minimizing (4.1).

To find the DLS spline in $N_d^r(\Delta)$ we construct the observation matrix

$$\tilde{\mathbf{L}} = \begin{bmatrix} \mathbf{L}_1 & \mathbf{L}_0 \end{bmatrix}$$

and smoothness conditions $\tilde{\mathbf{M}}\tilde{\mathbf{c}} = 0$ as in the previous section. Here $\mathbf{L}_1$ and $\mathbf{L}_0$ are the observation matrices containing values of SBB-basis polynomials at the data sites for the spaces $S_d^{-1}(\Delta)$ and $S_{d-1}^{-1}(\Delta)$. We therefore solve the linear system

$$\begin{bmatrix} \tilde{\mathbf{L}}^T\tilde{\mathbf{L}} & \tilde{\mathbf{M}}^T \\ \tilde{\mathbf{M}} & 0 \end{bmatrix} \begin{bmatrix} c \\ \eta \end{bmatrix} = \begin{bmatrix} \tilde{\mathbf{L}}^T\mathbf{F} \\ 0 \end{bmatrix},$$

where $\mathbf{F}$ contains given data values and η is a vector of Lagrange multiplier coefficients.

THEOREM 4.5. [illegible] v_ℓ $\ell = 1, \ldots, n$ [illegible] Δ [illegible] d [illegible] $\tilde{\mathbf{L}}^T\tilde{\mathbf{L}}$ [illegible] $\tilde{\mathbf{M}}\tilde{\mathbf{c}} = 0$

[illegible] If $\tilde{\mathbf{c}}^T\tilde{\mathbf{L}}^T\tilde{\mathbf{L}}\tilde{\mathbf{c}} = 0$, then $\tilde{\mathbf{L}}\tilde{\mathbf{c}} = 0$. Then $\tilde{\mathbf{L}}\tilde{\mathbf{c}}|_\tau = 0$ for every $\tau \in \Delta$, where $\tilde{\mathbf{L}}|_\tau$ is of full rank and therefore $\tilde{\mathbf{c}} = 0$. □

Note that similar considerations apply to the homogeneous case; i.e. it is easy to see that the matrix $\mathbf{L}^T\mathbf{L}$ is positive definite with respect to $\mathbf{Mc} = 0$.

Hence Theorem 2.2 can be applied to find the DLS fittings in both homogeneous and nonhomogeneous spherical spline spaces.

4.3. Numerical experiments with DLS splines. The following are examples of DLS approximation on the sphere.

[illegible] 4.1. First we conduct experiments similar to the ones for ME splines in $S_3^1(\Delta_1)$, $S_4^1(\Delta_1)$, and $N_4^1(\Delta_1)$. The total number of scattered data points is 1006. Evaluation points and computation of errors are the same as in section 3.3. In addition we test higher degree polynomials to demonstrate the ability of $N_d^r(\Delta)$ to reproduce nonhomogeneous polynomials of degree d. Results are shown in Table 4.1.

[illegible] 4.2. We illustrate the convergence of DLS splines approximating $f(x, y, z) = 1 + 0.3x^8 + e^{0.2y^3}$ in Table 4.2.

[illegible] 4.3. We continue working with the data in Example 3.5. Recall Δ_1 is a triangulation based on six vertices and eight triangles as in Examples 3.1, 3.2, and 4.1.

TABLE 4.1
Polynomial reproduction over the unit sphere.

Then Δ_1 is refined uniformly twice to obtain Δ_2 and Δ_3. For each triangulation we compute DLS spline solutions in the spaces $S_3^1(\Delta_i)$, $S_4^1(\Delta_i)$, and $N_4^1(\Delta_i)$, $i = 1, 2, 3$. In Table 4.3 we list errors of

$$e(\Delta_i) := \frac{\max_{v\in\mathcal{V}}|s(v) - f(v)|}{\max_{v\in\mathcal{V}}|f(v)|}$$

for each of the computed splines over triangulation Δ_i. In Table 4.4 we list their relative standard deviation values

$$\mathrm{s}(\Delta_i) := \frac{\mathrm{std}|s(v) - f(v)|}{\max_{v\in\mathcal{V}}|f(v)|}.$$

5. Penalized least squares approximation.

5.1. Existence and uniqueness. Again we let $\mathcal{V} := \{v_\ell,\, \ell = 1, \ldots, n\}$ be a set of sites on $\mathbb{S}^2$ and $\{f_\ell,\, \ell = 1, \ldots, n\}$ be the corresponding values for some function f. We need to find a smooth surface resembling f. Another commonly used method in this situation is called a penalized least squares (PLS) fit.

Let Δ be a regular triangulation of $\mathbb{S}^2$ whose vertices $\mathcal{W}$ form a subset of the data sites $\mathcal{V}$. Consider the spline space $S_d^r(\Delta)$ of degree d and smoothness r. We look for a spline solution $s_f \in S_d^r(\Delta)$ satisfying

$$\mathcal{P}_\lambda(s_f) = \min\{\mathcal{P}_\lambda(s) : s \in S_d^r(\Delta)\}, \tag{5.1}$$

where λ is a positive weight and

$$\mathcal{P}_\lambda(s) := \mathcal{L}(s) + \lambda\mathcal{E}_\delta(s). \tag{5.2}$$

Here the DLS and ME functionals are as defined in (4.1) and (3.2), respectively. It is clear that for large $\lambda \gg 1$, s_f is close to ME splines, and for small $\lambda \ll 1$ the solution s_f is close to the DLS spline. One way to choose λ is by the cross validation method [15]. We choose a small value for λ to get a good approximation, such as that of the DLS fitting which in the planar setting has high approximation power [9].

THEOREM 5.1. [illegible] $\lambda > 0$ [illegible] $\mathcal{W}$ [illegible] Δ [illegible] $\mathcal{V}$ [illegible] $\leq 1/2$ [illegible] $|\tau|$ [illegible] 1 [illegible] $s_f \in S_d^r(\Delta)$ [illegible] (5.2)

[illegible]. Recall that any $s \in S_d^r(\Delta)$ can be written as

$$s(v)|_\tau = \sum_{i+j+k=d} c_{ijk}^\tau B_{ijk}^{d,\tau}(v)$$

on a spherical triangle $\tau \in \Delta$. Let $\mathbf{c} = (c_{ijk}^\tau,\ i+j+k=d,\ \tau \in \Delta)$ be the coefficient vector of s. Recall that the energy functional $\mathcal{E}(s)$ can be expressed in terms of $\mathbf{c}$ as

$$\mathcal{E}(s) = \mathbf{c}^T \mathbf{E} \mathbf{c}$$

with the entries of $\mathbf{E}$ defined in (3.4). The DLS functional $\mathcal{L}(s)$ is expressed as

$$\begin{aligned}\mathcal{L}(s) &= \sum_{\ell=1}^n |s(v_\ell) - f_\ell|^2 = \sum_{\tau\in\Delta} \sum_{v_\ell \in \tau} \left(\sum_{i+j+k=d} c_{ijk}^\tau B_{ijk}^\tau(v_\ell) - f_\ell \right)^2 \\ &= \mathbf{c}^T \mathbf{L}^T \mathbf{L} \mathbf{c} - 2\mathbf{f}^T \mathbf{L} \mathbf{c} + \|\mathbf{f}\|_2^2,\end{aligned}$$

with $\mathbf{f} = (f_\ell,\ \ell = 1, \ldots, n)$ being the vector of data values. Thus

$$\mathcal{P}_\lambda(s) = \lambda \mathbf{c}^T \mathbf{E} \mathbf{c} + \mathbf{c}^T \mathbf{L}^T \mathbf{L} \mathbf{c} - 2\mathbf{f}^T \mathbf{L} \mathbf{c} + \|\mathbf{f}\|_2^2.$$

Note that $\mathcal{P}_\lambda(0) = \|\mathbf{f}\|_2^2$. Consider $A = \{\mathbf{c}, \mathcal{P}_\lambda(s) \leq \|\mathbf{f}\|_2^2\}$. Let us show that A is a bounded and closed set so that the continuous function $\mathcal{P}_\lambda(s)$ has a minimum in A.

Fix $\mathbf{c} \in A$ and let s be the corresponding spline. Then $\mathcal{P}_\lambda(s) \leq \|\mathbf{f}\|_2^2$. By the definition of $\mathcal{P}_\lambda$ we must have $\lambda \mathcal{E}_\delta(s) \leq \|\mathbf{f}\|_2^2$. By Lemma 10 in [6] and Lemma 3.9 in [5] the energy of a spline is equivalent to the square of its second order Sobolev seminorm on every triangle of Δ and all norms of a spline on each triangle are equivalent; i.e., we have

$$|s|_{2,\infty,\tau} \leq \frac{C_1}{\sqrt{\lambda}} \|\mathbf{f}\|_2 \text{ and } |s|'_{2,\infty,\tau} \leq \frac{C_2}{\sqrt{\lambda}} \|\mathbf{f}\|_2$$

with C_1, C_2 depending on degree d of the spline space and the smallest angle in τ. Let r_τ denote the center of the smallest spherical cap containing τ. Let $\mathbf{T}_\tau$ be a plane tangent to τ at r_τ. Define $\bar{\tau}$ in this plane as a set of points $\{w : \frac{w}{|w|} \in \tau\}$. Define $s_\delta(w) = |w|^\delta s(\frac{w}{|w|})$ to be a homogeneous extension of s of degree δ and $\bar{s}_\delta$ to be its restriction to $\bar{\tau}$. Similarly define f_δ and $\bar{f}_\delta$. By Proposition 2.26 in [5]

$$|\bar{s}_1|_{2,\infty,\bar{\tau}} \leq C_3 |s|_{2,\infty,\tau} \text{ and } |\bar{s}_0|_{2,\infty,\bar{\tau}} \leq C_4 |s|'_{2,\infty,\tau}.$$

Therefore

$$|\bar{s}_\delta|_{2,\infty,\bar{\tau}} \leq \frac{C_5}{\sqrt{\lambda}} \|\mathbf{f}\|_2. \tag{5.3}$$

Since the vertices, say v_1, v_2, v_3, of τ belong to $\mathcal{W}$,

$$\begin{aligned}|\bar{s}_\delta(\bar{v}_i)| &\le |\bar{s}_\delta(\bar{v}_i) - \bar{f}_\delta(\bar{v}_i)| + |\bar{f}_\delta(\bar{v}_i)| \\ &\le |v_i|^\delta(|s(v_i) - f(v_i)| + |f(v_i)|) \\ &\le C_6((\mathcal{P}_\lambda(s))^{1/2} + \|\mathbf{f}\|_2) \le 2C_6\|\mathbf{f}\|_2,\end{aligned}$$

for $C_6 = \max\{|v_\ell|^\delta : v_\ell \in \tau\} \le 1/\cos(1/2)$ and $i = 1, 2, 3$. For any point $\bar{v}$ in $\bar{\tau}$ we need to show that $\bar{s}_\delta(\bar{v})$ is bounded. Use Taylor expansion to get

$$\bar{s}_\delta(\bar{v}_1) = \bar{s}_\delta(\bar{v}) + \nabla\bar{s}_\delta(\bar{v}) \cdot (\bar{v}_1 - \bar{v}) + O(|\bar{s}_\delta|_{2,\infty,\bar{\tau}}|\bar{\tau}|^2). \tag{5.4}$$

Using similar expressions for $\bar{v}_2$ and $\bar{v_3}$ we get

$$\begin{aligned}\bar{s}_\delta(\bar{v}_1) - \bar{s}_\delta(\bar{v}_2) &= \nabla\bar{s}_\delta(\bar{v}) \cdot (\bar{v}_1 - \bar{v}_2) + O(|\bar{s}_\delta|_{2,\infty,\bar{\tau}}|\bar{\tau}|^2), \\ \bar{s}_\delta(\bar{v}_2) - \bar{s}_\delta(\bar{v_3}) &= \nabla\bar{s}_\delta(\bar{v}) \cdot (\bar{v}_2 - \bar{v_3}) + O(|\bar{s}_\delta|_{2,\infty,\bar{\tau}}|\bar{\tau}|^2).\end{aligned}$$

Solving this linear system for $\nabla\bar{s}_\delta$, we get

$$\begin{aligned}D_x\bar{s}_\delta(\bar{v}) &= O(|\bar{\tau}|^3|\bar{s}_\delta|_{2,\infty,\bar{\tau}}/A_{\bar{\tau}}) + |\bar{s}_\delta(\bar{v}_1)| + |\bar{s}_\delta(\bar{v}_2)||\bar{\tau}|/A_{\bar{\tau}}, \\ D_y\bar{s}_\delta(\bar{v}) &= O(|\bar{\tau}|^3|\bar{s}_\delta|_{2,\infty,\bar{\tau}}/A_{\bar{\tau}}) + |\bar{s}_\delta(\bar{v}_1)| + |\bar{s}_\delta(\bar{v}_2)||\bar{\tau}|/A_{\bar{\tau}},\end{aligned}$$

where $A_{\bar{\tau}}$ denotes the area of $\bar{\tau}$. Using these estimates for $\nabla\bar{s}_\delta$ we get

$$|\bar{s}_\delta(\bar{v})| \le C_7((1 + |\bar{\tau}| + |\bar{\tau}|^2/A_{\bar{\tau}})\|\mathbf{f}\|_2 + |\bar{\tau}|^4|\bar{s}_\delta|_{2,\infty,\bar{\tau}}/A_{\bar{\tau}}).$$

Hence we use (5.3) and (5.4) to get

$$|\bar{s}_\delta(\bar{v})| \le C_8\|\mathbf{f}\|_2$$

with C_8 depending on the size of τ. By the definition,

$$|s(v)| = |\bar{v}|^{-\delta}|\bar{s}_\delta(\bar{v})| \le C_{\bar{\tau}}\|\mathbf{f}\|_2$$

is bounded since $|\bar{v}| \ge 1$ and $|\bar{\tau}|$ is bounded. By the stability of SBB-basis [12], $\mathbf{c}$ is bounded, and hence A is a bounded set. Since A is closed, it is compact. By the definition, $\mathcal{P}_\lambda(s)$ is a continuous function of $\mathbf{c}$ and therefore $\mathcal{P}_\lambda$ attains its minimum in A.

To show uniqueness of the minimizer s_f suppose there exists $\hat{s}_f$ with $\mathcal{P}_\lambda(s_f) = \mathcal{P}_\lambda(\hat{s}_f)$. Since $\mathcal{P}_\lambda$ is a convex functional for any $0 \le \nu \le 1$,

$$\mathcal{P}_\lambda(\nu s_f + (1-\nu)\hat{s}_f) \le \nu\mathcal{P}_\lambda(s_f) + (1-\nu)\mathcal{P}_\lambda(\hat{s}_f) = \mathcal{P}_\lambda(s_f).$$

On the other hand, since $\mathcal{P}_\lambda$ achieves minimum value at s_f,

$$\mathcal{P}_\lambda(s_f) \le \mathcal{P}_\lambda(\nu s_f + (1-\nu)\hat{s}_f).$$

Therefore $\mathcal{P}_\lambda(\hat{s}_f + \nu(s_f - \hat{s}_f))$ is a constant function of ν on $[0, 1]$. It follows that $\frac{d}{d\nu}\mathcal{P}_\lambda(\hat{s}_f + \nu(s_f - \hat{s}_f)) = 0$ for all $0 \le \nu \le 1$, i.e.,

$$\begin{aligned}0 &= \frac{d}{d\nu}\mathcal{P}_\lambda(\hat{s}_f + \nu(s_f - \hat{s}_f)) \\ &= 2\lambda(\hat{\mathbf{c}}_f + \nu(\mathbf{c}_f - \hat{\mathbf{c}}_f))^T\mathbf{E}(\mathbf{c}_f - \hat{\mathbf{c}}_f) \\ &\quad + 2(\hat{\mathbf{c}}_f + \nu(\mathbf{c}_f - \hat{\mathbf{c}}_f))^T\mathbf{L}^T\mathbf{L}(\mathbf{c}_f - \hat{\mathbf{c}}_f) - 2\mathbf{f}^T\mathbf{L}(\mathbf{c}_f - \hat{\mathbf{c}}_f).\end{aligned}$$

The above holds for any ν in $[0,1]$. It follows, as in Theorem 4.2, that

$$0 = 2\lambda(\mathbf{c}_f - \hat{\mathbf{c}}_f)^T\mathbf{E}(\mathbf{c}_f - \hat{\mathbf{c}}_f) + 2(\mathbf{c}_f - \hat{\mathbf{c}}_f)^T\mathbf{L}^T\mathbf{L}(\mathbf{c}_f - \hat{\mathbf{c}}_f).$$

Hence, we must have $(\mathbf{c}_f - \hat{\mathbf{c}}_f)^T\mathbf{E}(\mathbf{c}_f - \hat{\mathbf{c}}_f) = 0$ and $(\mathbf{c}_f - \hat{\mathbf{c}}_f)^T\mathbf{L}^T\mathbf{L}(\mathbf{c}_f - \hat{\mathbf{c}}_f) = 0$ since both $\mathbf{E}$ and $\mathbf{L}^T\mathbf{L}$ are nonnegative definite. Then $\mathcal{E}(s_f - \hat{s}_f) = 0$ and therefore $s_f - \hat{s}_f$ is a linear homogeneous polynomial, and $s_f(v_\ell) - \hat{s}_f(v_\ell) = 0$ at every vertex v_ℓ of Δ. Therefore $s_f = \hat{s}_f$. □

To solve the PLS problem using nonhomogeneous splines we work in $N_d^r(\Delta)$. We have to replace the energy functional (3.2) in (5.2) by (3.3). For a spherical spline function $s = s_1 + s_0$ define

$$\mathcal{P}_\lambda(s) = \mathcal{L}(s_1 + s_0) + \lambda_1 \int_{\mathbb{S}^2} \sum_{|\alpha|=2} (D^\alpha s_1)^2 d\mu + \lambda_0 \int_{\mathbb{S}^2} \sum_{|\alpha|=2} (D^\alpha s_0)^2 d\mu, \tag{5.5}$$

with $\lambda_1 > 0$, $\lambda_0 > 0$.

THEOREM 5.2. [illegible] $\lambda_1 > 0$ [illegible] $\lambda_0 > 0$ [illegible] $\mathcal{W}$ [illegible] Δ [illegible] $\mathcal{V}$ [illegible] $\max\{|\tau|, \tau \in \Delta\} =: |\Delta| \leq 1$ [illegible] $s_f \in N_d^r(\Delta)$ [illegible] (5.5)

[illegible]. The proof is similar to the proof of Theorem 5.1. □

5.2. Computational algorithms. We first consider PLS fitting in $S_d^r(\Delta)$. By the method of Lagrange multipliers, minimization of (5.2) over $S_d^{-1}(\Delta)$ subject to the smoothness C^r conditions in the matrix form $\mathbf{Mc} = 0$ results in a system of linear equations

$$\begin{bmatrix} \mathbf{P} & \mathbf{M}^T \\ \mathbf{M} & 0 \end{bmatrix} \begin{bmatrix} \mathbf{c} \\ \eta \end{bmatrix} = \begin{bmatrix} \mathbf{L}^T\mathbf{F} \\ 0 \end{bmatrix}.$$

Here $\mathbf{P} = \mathbf{L}^T\mathbf{L} + \lambda\mathbf{E}$ and $\mathbf{f}$ is a vector of function values ordered as the spherical points v_ℓ, $\ell = 1, \ldots, n$, $\mathbf{M}$ is a smoothness matrix, and η is a vector of Lagrange multiplier coefficients. The solution of this system is a vector $\mathbf{c}$ of coefficients of a homogeneous spline s of degree d and smoothness r defined over the spherical triangulation Δ minimizing (5.2). Note that the linear system is of the same form as the one in section 2. We use the iterative scheme to compute an approximation of $\mathbf{c}$.

To find the PLS spline in $N_d^r(\Delta)$ we construct the observation matrix $\tilde{\mathbf{L}}$ and smoothness conditions $\tilde{\mathbf{M}}\tilde{\mathbf{c}} = 0$ as in the setting of DLS splines. We also assemble the energy matrices $\mathbf{E}_1$ and $\mathbf{E}_0$ and solve the linear system

$$\begin{bmatrix} \tilde{\mathbf{P}} & \tilde{\mathbf{M}}^T \\ \tilde{\mathbf{M}} & 0 \end{bmatrix} \begin{bmatrix} \tilde{\mathbf{c}} \\ \eta \end{bmatrix} = \begin{bmatrix} \tilde{\mathbf{L}}^T\mathbf{f} \\ 0 \end{bmatrix},$$

where $\tilde{\mathbf{P}}$ in this case is

$$\tilde{\mathbf{L}}^T\tilde{\mathbf{L}} + \begin{bmatrix} \lambda_1\mathbf{E}_1 & 0 \\ 0 & \lambda_0\mathbf{E}_0 \end{bmatrix}.$$

COROLLARY 5.3. [illegible] $\tilde{\mathbf{P}}$ [illegible] $\tilde{\mathbf{M}}\tilde{\mathbf{c}} = 0$ [illegible] $\tilde{\mathbf{c}}^T\tilde{\mathbf{P}}\tilde{\mathbf{c}} = 0$ implies that $\tilde{\mathbf{c}}^T\tilde{\mathbf{E}}\tilde{\mathbf{c}} = 0$. Therefore $\mathcal{P}_\lambda(s) = 0$ implies that s is a linear polynomial. $\mathcal{L}(s) = 0$ as well, and therefore s interpolates $f = 0$ at every vertex of Δ. Hence $s = 0$ and so is $\tilde{\mathbf{c}} = 0$. □

Note that considerations of Corollary 5.3 apply to the homogeneous case, and therefore we can efficiently obtain homogeneous PLS spline solutions as well.

TABLE 5.1

5.3. Numerical experiments with PLS splines. In this section we present an example of a PLS fitting similar to Example 4.3.

Example 5.1. Note that for PLS fit we require the data at the vertices of a triangulation to be given. To deal with this requirement we modify the triangulation Δ_1 by replacing its vertices by points in $\mathcal{V}$ closest to them. Denote the new triangulation by $\bar{\Delta}_1$. After refining $\bar{\Delta}_1$ we again may not have the values of geopotential values available at the vertices of the refined triangulation. We replace these vertices by the points in $\mathcal{V}$ closest to them where values of geopotential are available. We call this new triangulation $\bar{\Delta}_2$. Similarly we obtain $\bar{\Delta}_3$. That is, $\bar{\Delta}_{i+1}$ is not exactly a uniform refinement of $\bar{\Delta}_i$. For each triangulation we compute PLS spline solutions in the spaces $S_3^1(\bar{\Delta}_i)$, $S_4^1(\bar{\Delta}_i)$, and $N_4^1(\bar{\Delta}_i)$, $i = 1, 2, 3$, with $\lambda = \lambda_1 = \lambda_2 = 10^{-6}$. In Table 5.1 we list relative error values

$$e(\bar{\Delta}_i) := \frac{\max_{v\in\mathcal{V}}|s(v) - f(v)|}{\max_{v\in\mathcal{V}}|f(v)|}$$

for each of the computed splines over triangulation Δ_i. In Table 5.2 we list their relative standard deviation values

$$\mathrm{s}(\bar{\Delta}_i) := \frac{\mathrm{std}|s(v) - f(v)|}{\max_{v\in\mathcal{V}}|f(v)|}.$$

LINEAR PDEs AND NUMERICAL METHODS THAT PRESERVE A MULTISYMPLECTIC CONSERVATION LAW*

JASON FRANK†, BRIAN E. MOORE‡, AND SEBASTIAN REICH§

Abstract. Multisymplectic methods have recently been proposed as a generalization of symplectic ODE methods to the case of Hamiltonian PDEs. Their excellent long time behavior for a variety of Hamiltonian wave equations has been demonstrated in a number of numerical studies. A theoretical investigation and justification of multisymplectic methods is still largely missing. In this paper, we study linear multisymplectic PDEs and their discretization by means of numerical dispersion relations. It is found that multisymplectic methods in the sense of Bridges and Reich [*Phys. Lett. A*, 284 (2001), pp. 184–193] and Reich [*J. Comput. Phys.*, 157 (2000), pp. 473–499], such as Gauss–Legendre Runge–Kutta methods, possess a number of desirable properties such as nonexistence of spurious roots and conservation of the sign of the group velocity. A certain CFL-type restriction on $\Delta t/\Delta x$ might be required for methods higher than second order in time. It is also demonstrated by means of the explicit midpoint method that multistep methods may exhibit spurious roots in the numerical dispersion relation for any value of $\Delta t/\Delta x$ despite being multisymplectic in the sense of discrete variational mechanics [J. E. Marsden, G. P. Patrick, and S. Shkoller, *Commun. Math. Phys.*, 199 (1999), pp. 351–395].

Key words. wave equations, dispersion relations, discretizations, multisymplectic methods, discrete conservation laws

1. Introduction.

The field of numerical analysis has experienced a recent, as well as growing, interest in geometric integration. When solving differential equations numerically it is important to preserve as much of the qualitative solution behavior as possible. In particular, it is advantageous to numerically preserve the symplectic structure of Hamiltonian systems.

The topic of symplectic integration for Hamiltonian ODEs has been thoroughly analyzed. The concept of symplectic time integration has also been extended to Hamiltonian PDEs (see, e.g., [16]). The concept of space-time multisymplectic integration is, however, much more recent and its development is still in the beginning stages. In some respects, even the proper definition of a multisymplectic integrator is still not clear. The original approach, presented by Marsden, Patrick, and Shkoller [15], defines a multisymplectic method as one which can be derived from a Lagrangian formulation using a discrete variational principle. The original approach was limited to first-order field theories (see [12] for an extension to second-order field theories). The discrete variational approach allows the systematic derivation of one-step and multistep multisymplectic methods.

The second approach, which was put forth by Bridges and Reich [7, 19], defines a multisymplectic integrator as a method which exactly preserves a multisymplectic conservation law by applying a symplectic one-step method such as Störmer–Verlet or implicit midpoint in space and time.

It is our intent to study multisymplectic integration methods in the context of linear multisymplectic PDEs. Based on a discussion of numerical dispersion relations, we will find that both conservation of a multisymplectic conservation law and discretization by one-step methods in space and time should be considered essential ingredients of a multisymplectic method.

According to Bridges [2, 3], a PDE of the general form

$$\mathbf{K}\mathbf{z}_t + \mathbf{L}\mathbf{z}_x = \nabla_{\mathbf{z}} S(\mathbf{z}) \tag{1.1}$$

is called multisymplectic provided $\mathbf{K}$ and $\mathbf{L}$ are (constant) $d \times d$ skew-symmetric matrices, and $S : \mathbb{R}^d \to \mathbb{R}$ is a smooth function. Here and throughout, subscripts are used to denote differentiation in the standard way, and we define $\mathbf{z} = \mathbf{z}(x,t)$ to be a d-dimensional vector of state variables. Many Hamiltonian PDEs can be formulated in this way, and the multisymplectic formulation has become useful for understanding these problems (cf. [2, 3, 4, 5, 6, 8]).

As one would expect, however, the nonlinearity of (1.1) makes the study of numerical solutions for the problem more difficult, and there is still much to understand with regard to multisymplectic discretization methods. Hence, the aim of this paper is to conduct an extensive analysis of multisymplectic discretization methods for the linear equation

$$\mathbf{K}\mathbf{z}_t + \mathbf{L}\mathbf{z}_x = \mathbf{A}\mathbf{z}, \tag{1.2}$$

where $\mathbf{A}$ is symmetric. This allows one to examine solutions and dispersion relations for both the continuous and discrete versions of this equation, providing a thorough understanding of the behavior of our numerical methods for linear problems.

We start by making the standard (complex-valued) separation of variables ansatz

$$\mathbf{z}(x,t) = u(t)v(x)\mathbf{a},$$

where $u(t)$ and $v(x)$ are complex-valued functions and $\mathbf{a}$ is a d-dimensional complex-valued vector. Substituting this ansatz into the linear PDE (1.2) leads to the linear system

$$\left(\frac{u'}{u}\mathbf{K} + \frac{v'}{v}\mathbf{L} - \mathbf{A}\right)\mathbf{a} = \mathbf{0}.$$

Solutions are found by setting

$$\lambda = \frac{u'}{u} \qquad \text{and} \qquad \mu = \frac{v'}{v}$$

with the complex numbers λ and μ satisfying

$$\det\left(\lambda\mathbf{K} + \mu\mathbf{L} - \mathbf{A}\right) = 0.$$

Since we are interested in wave-like solutions we furthermore seek (complex-valued) solutions with $\lambda = \mathtt{i}\omega$ and $\mu = \mathtt{i}k$, i.e.,

$$\mathbf{z}(x,t) = \mathrm{e}^{\mathtt{i}(kx+\omega t)}\mathbf{a}. \tag{1.3}$$

Here, k denotes the wave number and ω denotes the wave frequency, which must satisfy the dispersion relation [3]

$$\mathcal{D}(\omega, k) := \det\left(\mathtt{i}\omega\mathbf{K} + \mathtt{i}k\mathbf{L} - \mathbf{A}\right) = 0. \tag{1.4}$$

It is important to note that the matrix used in this calculation is self-adjoint, i.e., $\overline{\mathcal{D}(\omega, k)} = \mathcal{D}(\overline{\omega}, \overline{k})$, from which it is immediate that $0 = \mathcal{D}(\omega, k) = \mathcal{D}(\overline{\omega}, k)$ for real k. Hence, for any given real k, solutions ω of the dispersion relation are either real or come in complex-conjugate pairs meaning there is no diffusion [20, Chapter 11].

With the dispersion relation, one can write the frequency as a function of the wave number, such that

$$\mathcal{D}(\omega, k) = 0 \Longleftrightarrow \omega = \omega(k),$$

at least locally. Then, depending on the function $\mathcal{D}$, there may be multiple frequencies ω_i for every k, corresponding to different modes. One could also pose the reverse question and ask how many different wave numbers k can give rise to a given frequency ω.

It is worthwhile to note that taking the complex-conjugate in (1.3) also yields a solution and hence

$$\mathbf{z}(x,t) = \frac{1}{2}[\mathbf{a}\,\mathrm{e}^{\mathtt{i}(kx+\omega t)} + \overline{\mathbf{a}}\,\mathrm{e}^{-\mathtt{i}(kx+\omega t)}] \tag{1.5}$$

yields real-valued solutions. The dispersion relation is not restricted to single mode solutions (1.3). In fact, the most general oscillatory solution of the linear PDE (1.2) can be stated as a superposition of solutions

$$\begin{aligned}\mathbf{z}(x,t) = &\frac{1}{2}\sum_i \int_0^\infty \mathbf{a}_i(k)\,\mathrm{e}^{\mathtt{i}(kx-\omega_i(k)t)}\mathrm{d}k \\ &+ \frac{1}{2}\sum_i \int_0^\infty \overline{\mathbf{a}}_i(k)\,\mathrm{e}^{-\mathtt{i}(kx-\omega_i(k)t)}\mathrm{d}k, \qquad -\infty < x < \infty,\end{aligned}$$

which is obtained through Fourier analysis [20, Chapter 11]. Here the index i runs over all solution branches of the dispersion relation.

An important derived quantity is the group velocity defined by

$$v_g = \frac{d}{dk}\omega(k) = -\frac{\partial\mathcal{D}}{\partial k}\Big/\frac{\partial\mathcal{D}}{\partial\omega}.$$

The group velocity characterizes the speed of energy transport in wave packets [20, Chapter 11] and, hence, is fundamental to the understanding of linear waves. Following Whitham [20, Chapter 11], we introduce the Lagrangian density

$$\mathcal{L} = \frac{1}{2}\overline{\mathbf{a}}^T\left[\mathtt{i}\omega\mathbf{K} + \mathtt{i}k\mathbf{L} - \mathbf{A}\right]\mathbf{a} \tag{1.6}$$

and define the energy density

$$E = \omega\frac{\partial\mathcal{L}}{\partial\omega} = \frac{\mathtt{i}\omega}{2}\overline{\mathbf{a}}^T\mathbf{K}\mathbf{a}$$

and the energy flux

$$F = -\omega\frac{\partial\mathcal{L}}{\partial k} = -\frac{\mathtt{i}\omega}{2}\overline{\mathbf{a}}^T\mathbf{L}\mathbf{a}.$$

It holds that $F = v_g E$ since [2]

$$v_g = -\frac{\partial \mathcal{L}}{\partial k} \Big/ \frac{\partial \mathcal{L}}{\partial \omega} = -\frac{\bar{\mathbf{a}}^T \mathbf{L}\mathbf{a}}{\bar{\mathbf{a}}^T \mathbf{K}\mathbf{a}}.$$

We wish to extend the linear dispersion analysis to multisymplectic integration methods. As multisymplectic methods are obtained as a space-time concatenation of symplectic methods, we start the discussion with a review of results for symplectic ODE methods.

2. Symplectic integration of Hamiltonian ODEs. We recall some basic properties of symplectic integration methods for Hamiltonian ODEs of the form

$$\mathbf{K}\mathbf{z}_t = \nabla_{\mathbf{z}} S(\mathbf{z}), \tag{2.1}$$

where $\mathbf{K}$ is a (constant) $d \times d$ skew-symmetric matrix and $S : \mathbb{R}^d \to \mathbb{R}$ a smooth function. A numerical one-step method

$$\mathbf{z}^{n+1} = \Psi_{\Delta t}(\mathbf{z}^n) \tag{2.2}$$

is called symplectic if

$$\mathbf{d}\mathbf{z}^{n+1} \wedge \mathbf{K}\mathbf{d}\mathbf{z}^{n+1} = \mathbf{d}\mathbf{z}^n \wedge \mathbf{K}\mathbf{d}\mathbf{z}^n. \tag{2.3}$$

(See [13] for details and use of wedge product notation.) Let us discuss implications for the linearized equations

$$\mathbf{K}\mathbf{z}_t = \mathbf{A}\mathbf{z}, \tag{2.4}$$

where $\mathbf{A}$ is symmetric. We assume that the one-step method (2.2) is a Runge–Kutta (RK) method with stability function $R(z)$ [11]. Then the (complex-valued) numerical solution of (2.4) can be written in the form

$$\mathbf{z}^n = \sum_i R(\lambda_i \Delta t)^n \mathbf{a}_i,$$

where λ_i and $\mathbf{a}_i$ have to satisfy the generalized eigenvalue problem

$$[\lambda_i \mathbf{K} - \mathbf{A}]\, \mathbf{a}_i = 0 \tag{2.5}$$

associated with (2.4). Note that if λ is an eigenvalue of (2.5), then $-\lambda$ is also an eigenvalue. Furthermore, a symplectic RK method satisfies $R(\lambda)R(-\lambda) = 1$. The same property holds for all (not necessarily symplectic) symmetric RK methods [11].

If we now restrict the analysis to the symplectic Gauss–Legendre Runge–Kutta (GL RK) methods, then we conclude from $R(\lambda)R(-\lambda) = 1$ and A-stability of the method that $R(z)$ is on the unit circle for purely imaginary valued $\lambda = \mathtt{i}\omega$. We write this in the form

$$R(\mathtt{i}\omega\Delta t) = \mathrm{e}^{\mathtt{i}\phi},$$

with an appropriate phase function $\phi(\omega\Delta t)$ continuous in $\omega\Delta t$.

Let us explicitly derive the phase function ϕ for the implicit midpoint rule

$$\mathbf{K}\frac{\mathbf{z}^{n+1} - \mathbf{z}^n}{\Delta t} = \mathbf{A}\frac{\mathbf{z}^{n+1} + \mathbf{z}^n}{2}.$$

We write $\phi = \Omega\Delta t$ and obtain

$$\frac{\mathrm{e}^{\mathtt{i}\Omega\Delta t}-1}{\Delta t}\mathbf{K}\mathbf{a}_i = \frac{\mathrm{e}^{\mathtt{i}\Omega\Delta t}+1}{2}\mathbf{A}\mathbf{a}_i$$

for each solution mode and, using (2.5) with $\lambda_i = \mathtt{i}\omega_i$, this equation implies

$$\frac{\mathrm{e}^{\mathtt{i}\Omega\Delta t}-1}{\Delta t}\mathbf{K}\mathbf{a} = \mathtt{i}\omega_i\frac{\mathrm{e}^{\mathtt{i}\Omega\Delta t}+1}{2}\mathbf{K}\mathbf{a}.$$

Hence we must have

$$\frac{\mathrm{e}^{\mathtt{i}\Omega\Delta t}-1}{\Delta t} = \mathtt{i}\omega_i\frac{\mathrm{e}^{\mathtt{i}\Omega\Delta t}+1}{2},$$

which yields the definition for the stability function of the implicit midpoint method, i.e.,

$$\mathrm{e}^{\mathtt{i}\Omega\Delta t} = R(\mathtt{i}\omega\Delta t) = \frac{1+\mathtt{i}\omega\Delta t/2}{1-\mathtt{i}\omega\Delta t/2},$$

and

$$\phi(\omega\Delta t) = 2\tan^{-1}(\omega\Delta t/2) \in (-\pi, +\pi) \tag{2.6}$$

is a monotone function in $\omega\Delta t$.

The fourth-order GL RK method has stability function

$$R(z) = \frac{1+z/2+z^2/12}{1-z/2+z^2/12}.$$

Setting $z = \mathtt{i}\omega\Delta t$ and $R(\mathtt{i}\omega\Delta t) = e^{\mathtt{i}\phi}$ results in

$$\tan\frac{\phi}{2} = \frac{\omega\Delta t}{2-\frac{\omega^2\Delta t^2}{6}}.$$

For positive ω, the function $\phi(\omega\Delta t)$ can be chosen to increase monotonically from zero for $\omega = 0$ to $\phi(\omega\Delta t) = 2\pi$ for $\omega\Delta t \to \infty$. A similar statement holds for negative frequencies. Of course, from a sampling point of view, we have $\mathrm{e}^{\mathtt{i}\Omega\Delta t} = \mathrm{e}^{\mathtt{i}\phi}$ with

$$\Omega = \frac{1}{\Delta t}\left[\mathrm{mod}\left(\phi(\omega\Delta t)+\pi, 2\pi\right)-\pi\right] \in \left(\frac{-\pi}{\Delta t}, \frac{+\pi}{\Delta t}\right]. \tag{2.7}$$

Note that the implicit midpoint method simply yields

$$\Omega = \frac{1}{\Delta t}\phi(\omega\Delta t)$$

with phase function ϕ defined by (2.6).

For a general s-stage GL RK method of order $p = 2s$ it holds that $\phi(\omega\Delta t)$ is monotone with values in the interval $(-s\pi, +s\pi)$, $\phi(-y) = -\phi(y)$, and $\phi(y) < y$ for $y > 0$ [10]. Due to sampling on a discrete grid, i.e., (2.7), it can nevertheless happen that there are values of Δt for which $\Omega_i = \Omega_j$ even though $\omega_i \neq \omega_j$. These numerically induced 1-1 resonances can occur for $s \geq 2$ and

$$\max_i |\phi(\omega_i\Delta t)| > \pi.$$

Numerical resonance can lead to instabilities of the scheme under small perturbations [13]. Note that the implicit midpoint method and higher-order GL RK methods can be subject to other numerically induced resonance instabilities. See, e.g., Mandziuk and Schlick [14].

Our discussion of GL RK methods applied to (linear) Hamiltonian ODEs may be summarized as follows:

(i) Oscillatory solutions of (2.4) with frequency ω are represented numerically by an oscillatory solution with frequency Ω.
(ii) There is one-to-one correspondence between numerical and analytic[1] solutions modes (no spurious computational modes as for linear multistep methods).
(iii) The phase function ϕ is monotone. However, numerical resonances due to (2.7) are possible for GL RK methods with more than one stage.

It should be noted that the same statements would be true for any symmetric and A-stable implicit RK method such as Lobatto IIIA and Lobatto IIIB [11]. However, the family of Lobatto IIIA and IIIB methods is not symplectic in the sense of (2.3).

We will now investigate how these properties translate to multisymplectic discretization methods. We start with a discussion of the Preissman box scheme.

3. The Preissman box scheme. Applying the implicit midpoint rule to the PDE (1.1) in both space and time yields

$$\mathbf{K}\delta_t^+ \mathbf{z}^{n,m+1/2} + \mathbf{L}\delta_x^+ \mathbf{z}^{n+1/2,m} = \nabla S\big(z^{n+1/2,m+1/2}\big), \tag{3.1}$$

where we define the edge midpoint approximations

$$\mathbf{z}^{n+1/2,m} = \frac{1}{2}\left(\mathbf{z}^{n+1,m} + \mathbf{z}^{n,m}\right), \qquad \mathbf{z}^{n,m+1/2} = \frac{1}{2}\left(\mathbf{z}^{n,m+1} + \mathbf{z}^{n,m}\right),$$

the cell center approximation

$$\mathbf{z}^{n+1/2,m+1/2} = \frac{1}{4}\left(\mathbf{z}^{n+1,m+1} + \mathbf{z}^{n+1,m} + \mathbf{z}^{n,m+1} + \mathbf{z}^{n,m}\right),$$

and the finite difference approximations

$$\delta_t^+ \mathbf{z}^{n,m+1/2} = \frac{1}{\Delta t}\big(\mathbf{z}^{n+1,m+1/2} - \mathbf{z}^{n,m+1/2}\big),$$
$$\delta_x^+ \mathbf{z}^{n+1/2,m} = \frac{1}{\Delta x}\big(\mathbf{z}^{n+1/2,m+1} - \mathbf{z}^{n+1/2,m}\big).$$

In addition, define

$$\tau = \frac{\Delta t}{2} \qquad \text{and} \qquad \chi = \frac{\Delta x}{2}$$

through the remainder of the text.

PROPOSITION 1. [illegible] (3.1) [illegible]

$$\delta_t^+\big(\mathbf{dz}^{n,m+1/2} \wedge \mathbf{K}\mathbf{dz}^{n,m+1/2}\big) + \delta_x^+\big(\mathbf{dz}^{n+1/2,m} \wedge \mathbf{L}\mathbf{dz}^{n+1/2,m}\big) = \mathbf{0}.$$

[illegible] Proof of this result is due to Bridges and Reich [7]. □

[1]The qualifier *analytic* will be used throughout the paper to refer to a property of the given continuum equations (e.g., analytic solutions, analytic dispersion relation, and analytic group velocity) as opposed to properties of the numerical scheme (e.g., numerical solutions, numerical dispersion relation, and numerical group velocity).

Applying the Preissman box scheme to the linear PDE (1.2) yields

$$\mathbf{K}\delta_t^+ \mathbf{z}^{n,m+1/2} + \mathbf{L}\delta_x^+ \mathbf{z}^{n+1/2,m} = \mathbf{A}\mathbf{z}^{n+1/2,m+1/2}. \tag{3.2}$$

Based upon the results of [17, 18], the modified equation for the linear PDE (1.2) can be stated explicitly as

$$\mathbf{K}\left(\mathbf{z}_t - \frac{\tau^2}{3}\mathbf{z}_{ttt} + \frac{2\tau^4}{15}\mathbf{z}_{ttttt} - \cdots\right) + \mathbf{L}\left(\mathbf{z}_x - \frac{\chi^2}{3}\mathbf{z}_{xxx} + \frac{2\chi^4}{15}\mathbf{z}_{xxxxx} - \cdots\right) = \mathbf{A}\mathbf{z}. \tag{3.3}$$

This is a higher-order linear PDE and we may substitute a standard solution ansatz of the form

$$\mathbf{z}(x,t) = \mathrm{e}^{\mathtt{i}(\Omega t + Kx)}\mathbf{a}$$

into the equation. This yields

$$\left(\mathbf{K}\mathtt{i}\left(\Omega + \frac{\tau^2\Omega^3}{3} + \frac{2\tau^4\Omega^5}{15} + \cdots\right) + \mathbf{L}\mathtt{i}\left(K + \frac{\chi^2 K^3}{3} + \frac{2\chi^4 K^5}{15} + \cdots\right) - \mathbf{A}\right)\mathbf{a} = \mathbf{0}.$$

Then, due to the identity

$$\tan(\theta) = \theta + \frac{\theta^3}{3} + \frac{2\theta^5}{15} + \cdots,$$

we obtain

$$\left(\frac{\mathtt{i}}{\tau}\tan(\tau\Omega)\mathbf{K} + \frac{\mathtt{i}}{\chi}\tan(\chi K)\mathbf{L} - \mathbf{A}\right)\mathbf{a} = \mathbf{0}. \tag{3.4}$$

The modified equation can also be stated in closed form because the expansions in (3.3) converge; it is given by

$$\frac{1}{\tau}\mathbf{K}\tanh(\tau\partial_t)\mathbf{z} + \frac{1}{\chi}\mathbf{L}\tanh(\chi\partial_x)\mathbf{z} = \mathbf{A}\mathbf{z}.$$

Furthermore, the following theorem follows immediately from (3.4).

THEOREM 1. [illegible] (3.2) [illegible]

$$\mathcal{D}(\omega, k) = 0, \tag{3.5}$$

[illegible] $\mathcal{D}$ [illegible] (1.4) [illegible]

$$\omega = \frac{\tan(\tau\Omega)}{\tau} \qquad \textit{and} \qquad k = \frac{\tan(\chi K)}{\chi}, \tag{3.6}$$

[illegible] $-\frac{\pi}{2} < \tau\Omega < \frac{\pi}{2}$ [illegible] $-\frac{\pi}{2} < \chi K < \frac{\pi}{2}$ [illegible]

$$\mathcal{D}_N(\Omega, K) := \mathcal{D}\left(\frac{\tan(\tau\Omega)}{\tau}, \frac{\tan(\chi K)}{\chi}\right) = 0.$$

This result was first published by Ascher and McLachlan [1]; see also [17]. Three important conclusions are to be drawn. (i) The numerical group velocity V_g is defined by

$$V_g = \frac{d}{dK}\Omega(K) = -\frac{\partial \mathcal{D}}{\partial k}\frac{\partial k}{\partial K}\Big/\frac{\partial \mathcal{D}}{\partial \omega}\frac{\partial \omega}{\partial \Omega} = v_g\frac{\partial k}{\partial K}\Big/\frac{\partial \omega}{\partial \Omega}.$$

Since both

$$\frac{\partial \omega}{\partial \Omega} > 0 \qquad \text{and} \qquad \frac{\partial k}{\partial K} > 0,$$

we have derived the following.

COROLLARY 1. [illegible] v_g [illegible]

(ii) The monotonicity and invertibility of (3.6) implies the following corollary.

COROLLARY 2. [illegible] ω [illegible] k [illegible]

(iii) We consider the Lagrangian density (1.6) with ω and k now functions of Ω and K, respectively, and define the numerical energy density and flux for a single mode solution by

$$E_N = \frac{\mathtt{i}\Omega}{2}\frac{\partial \omega}{\partial \Omega}\bar{\mathbf{a}}^T\mathbf{K}\mathbf{a}, \qquad F_N = -\frac{\mathtt{i}\Omega}{2}\frac{\partial k}{\partial K}\bar{\mathbf{a}}^T\mathbf{L}\mathbf{a}. \tag{3.7}$$

COROLLARY 3. [illegible]

$$F_N = V_g E_N$$

[illegible] V_g [illegible]

[illegible]. The statement follows from the definitions (3.7) and the total derivative of

$$\bar{\mathbf{a}}^T\left(\frac{\mathtt{i}}{\tau}\tan(\tau\Omega)\mathbf{K} + \frac{\mathtt{i}}{\chi}\tan(\chi K)\mathbf{L} - \mathbf{A}\right)\mathbf{a} = 0$$

with respect to K. □

4. Numerical dispersion relation for multisymplectic GL RK methods. We now discuss the discretization of a linear multisymplectic PDE (1.2) using GL RK methods (possibly of different orders) in space and time. We apply an s^0-stage GL RK method in time with Butcher arrays $A^0 = (a^0_{ij})$, $b^0 = (b^0_i)$, $i, j = 1, \ldots, s^0$, and a similarly denoted s^1-stage GL RK method in space.

Reserve the indices m and n for the spatial and temporal meshes, respectively, and the indices i and j for spatial and temporal stage indices, respectively. The index k is a dummy index. Summation is implied by repeated indices in a product.

Let $\mathbf{Z} \approx \mathbf{z}$ at interior stages and $\boldsymbol{\zeta}, \boldsymbol{\sigma} \approx \mathbf{z}$ on horizontal and vertical edges, respectively. Let $\mathbf{T} \approx \mathbf{z}_t$ at interior stages and $\boldsymbol{\tau} \approx \mathbf{z}_t$ on edges. Let $\mathbf{X} \approx \mathbf{z}_x$ at interior stages and $\boldsymbol{\xi} \approx \mathbf{z}_x$ on edges. Let $\mathbf{U} \approx \mathbf{z}_{xt}$ at interior stages. (See Figure 1.)

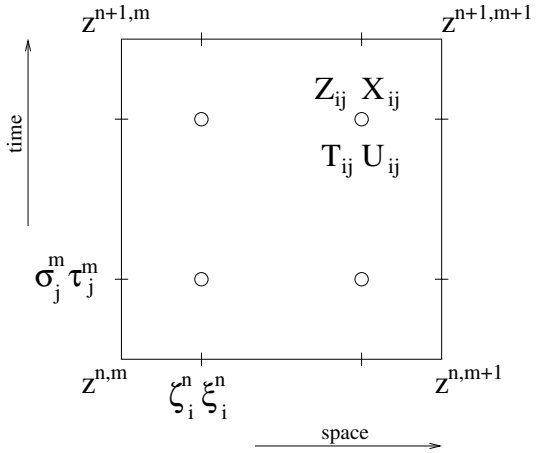

FIG. 1. *Arrangement of approximate quantities in* (4.1)–(4.11).

$$\mathbf{K}\mathbf{T}_{ij} + \mathbf{L}\mathbf{X}_{ij} = \mathbf{A}\mathbf{Z}_{ij}, \tag{4.1}$$

$$\mathbf{X}_{ij} = \boldsymbol{\xi}_i^n + \Delta t\, a_{jk}^0 \mathbf{U}_{ik}, \tag{4.2}$$

$$\mathbf{T}_{ij} = \boldsymbol{\tau}_j^m + \Delta x\, a_{ik}^1 \mathbf{U}_{kj}, \tag{4.3}$$

$$\mathbf{Z}_{ij} = \boldsymbol{\zeta}_i^n + \Delta t\, a_{jk}^0 \mathbf{T}_{ik}, \tag{4.4}$$

$$= \boldsymbol{\sigma}_j^m + \Delta x\, a_{ik}^1 \mathbf{X}_{kj}, \tag{4.5}$$

$$\boldsymbol{\xi}_i^{n+1} = \boldsymbol{\xi}_i^n + \Delta t\, b_j^0 \mathbf{U}_{ij}, \tag{4.6}$$

$$\boldsymbol{\zeta}_i^{n+1} = \boldsymbol{\zeta}_i^n + \Delta t\, b_j^0 \mathbf{T}_{ij}, \tag{4.7}$$

$$\boldsymbol{\tau}_j^{m+1} = \boldsymbol{\tau}_j^m + \Delta x\, b_i^1 \mathbf{U}_{ij}, \tag{4.8}$$

$$\boldsymbol{\sigma}_j^{m+1} = \boldsymbol{\sigma}_j^m + \Delta x\, b_i^1 \mathbf{X}_{ij}, \tag{4.9}$$

$$\mathbf{z}^{n+1,m+1} = \mathbf{z}^{n,m+1} + \Delta t\, b_j^0 \boldsymbol{\tau}_j^{m+1} \tag{4.10}$$

$$= \mathbf{z}^{n+1,m} + \Delta x\, b_i^1 \boldsymbol{\xi}_i^{n+1}. \tag{4.11}$$

Equations (4.1), (4.4), (4.5), (4.7), and (4.9) form a closed set (same number of equations as unknowns). To include the grid point data, either {(4.2), (4.6), and (4.11)} or {(4.3), (4.8), and (4.10)} should be added. The remaining relations are redundant.

We will concentrate on (4.1), (4.4), (4.5), (4.7), and (4.9) in the following. Let us assume that we have ω, k, and $\mathbf{a}$ satisfying the plane wave solution

$$[\mathtt{i}\omega\mathbf{K} + \mathtt{i}k\mathbf{L} - \mathbf{A}]\mathbf{a} = \mathbf{0}.$$

We look for a (complex-valued) numerical solution of the form

$$\mathbf{z}^{n,m} = \mathbf{a}^{nm} := \mathrm{e}^{\mathtt{i}\Omega n\Delta t}\mathrm{e}^{\mathtt{i}Km\Delta x}\mathbf{a}.$$

Let us therefore make the ansatz that all stage vectors are proportional to $\mathbf{a}^{nm}$:

$$\mathbf{Z}_{ij}^{nm} = \gamma_{ij}\mathbf{a}^{nm}, \quad \mathbf{X}_{ij}^{nm} = x_{ij}\mathbf{a}^{nm}, \quad \mathbf{T}_{ij}^{nm} = t_{ij}\mathbf{a}^{nm}, \quad \boldsymbol{\zeta}_i^n = \alpha_i\mathbf{a}^{nm}, \quad \boldsymbol{\sigma}_j^m = \beta_j\mathbf{a}^{nm}.$$

Substituting this solution into (4.1) gives

$$[t_{ij}\mathbf{K} + x_{ij}\mathbf{L} - \gamma_{ij}\mathbf{A}]\mathbf{a}^{nm} = 0,$$

for which the dispersion relation yields

$$\frac{t_{ij}}{\gamma_{ij}} = \mathtt{i}\omega, \qquad \frac{x_{ij}}{\gamma_{ij}} = \mathtt{i}k,$$

that is, $\mathbf{T}_{ij} = \mathtt{i}\omega\mathbf{Z}_{ij}$ and $\mathbf{X}_{ij} = \mathtt{i}k\mathbf{Z}_{ij}$.

Next, (4.4) yields

$$\gamma_{ij}\mathbf{a}^{nm} = \alpha_i\mathbf{a}^{nm} + \mathtt{i}\omega\Delta t\, a^0_{jk}\gamma_{ik}\mathbf{a}^{nm}.$$

For each i we obtain the solution

$$(I - \mathtt{i}\omega\Delta t\, A^0)\boldsymbol{\gamma}_{i:} = \alpha_i \mathbb{1}, \qquad \boldsymbol{\gamma}_{i:} = (\gamma_{i1}, \ldots, \gamma_{is^1})^T,$$

from which it follows that $\gamma_{ij} = \lambda_i\mu_j$ with

$$\boldsymbol{\mu} = (I - \mathtt{i}\omega\Delta t\, A^0)^{-1}\mathbb{1}, \qquad \boldsymbol{\alpha} = \boldsymbol{\lambda}.$$

Similarly, (4.5) yields

$$\boldsymbol{\lambda} = (I - \mathtt{i}k\Delta x\, A^1)^{-1}\mathbb{1}, \qquad \boldsymbol{\beta} = \boldsymbol{\mu}.$$

Finally, substitution into (4.7) gives

$$\lambda_i(\mathrm{e}^{\mathtt{i}\Omega\Delta t} - 1)\mathbf{a}^{nm} = \mathtt{i}\omega\Delta t b^0_j\lambda_i\mu_j\mathbf{a}^{nm},$$

or

$$(\mathrm{e}^{\mathtt{i}\Omega\Delta t} - 1) = \mathtt{i}\omega\Delta t\,(b^0)^T\boldsymbol{\mu} \Rightarrow e^{\mathtt{i}\Omega\Delta t} = 1 + \mathtt{i}\omega\Delta t\,(b^0)^T(I - \mathtt{i}\omega\Delta t\, A^0)^{-1}\mathbb{1} = R^0(\mathtt{i}\omega\Delta t). \tag{4.12}$$

Also, (4.9) similarly yields

$$\mathrm{e}^{\mathtt{i}K\Delta x} = R^1(\mathtt{i}k\Delta x). \tag{4.13}$$

We have effectively proven the following theorem.

THEOREM 2. [illegible] $R^0(z)$ [illegible] $R^1(z)$ [illegible] (1.2) [illegible] (1.3) [illegible] (1.2) [illegible]

$$\mathbf{z}^{n,m} = \mathrm{e}^{\mathtt{i}\Omega n\Delta t}\mathrm{e}^{\mathtt{i}Km\Delta x}\mathbf{a} = R^0(\mathtt{i}\omega\Delta t)^n\, R^1(\mathtt{i}k\Delta x)^m\mathbf{a},$$

[illegible] ω [illegible] k [illegible] $\mathcal{D}(\omega, k) = 0$ [illegible]

$$\mathcal{D}_N(\Omega, K) = 0$$

[illegible] $\omega(\Omega)$ [illegible] $k(K)$ [illegible] (4.12) [illegible] (4.13) [illegible]

$$\overline{\mathcal{D}_N(\Omega, K)} = \mathcal{D}_N(\overline{\Omega}, \overline{K}).$$

Since any symmetric and A-stable implicit RK method behaves like a symplectic method on the linear equation level, Theorem 2 also applies to those RK methods as well and to Lobatto IIIA and IIIB methods in particular.

We may write $R^0(\mathtt{i}y) = \mathrm{e}^{\mathtt{i}\phi(y)}$ and $R^1(\mathtt{i}y) = \mathrm{e}^{\mathtt{i}\theta(y)}$, where ϕ and θ are monotone phase functions as defined in section 2. Hence the practical computation of the numerical dispersion relation is as follows. Given a computational mode with wave number $K \in (-\pi/\Delta x, +\pi/\Delta x]$, one first finds the uniquely defined wave number k from $\mathrm{e}^{\mathtt{i}K\Delta x} = R^1(\mathtt{i}k\Delta x)$. The analytic dispersion relation $\mathcal{D}(\omega, k) = 0$ implies a corresponding frequency ω. One then uses $R^0(\mathtt{i}\omega\Delta t) = \mathrm{e}^{\mathtt{i}\phi}$ to determine the uniquely defined phase $\phi(\omega\Delta t)$. Finally, the modulo operation (2.7) gives the computational frequency Ω.

A number of important conclusions may be drawn. (i) Monotonicity of ϕ and θ implies $\phi' \geq 0$, $\theta' \geq 0$, and we obtain the following.

COROLLARY 4. [illegible]

$$V_g = -\frac{\partial \mathcal{D}_N}{\partial K} \Big/ \frac{\partial \mathcal{D}_N}{\partial \Omega}$$

[illegible] (K, Ω) [illegible]

$$v_g = -\frac{\partial \mathcal{D}}{\partial k} \Big/ \frac{\partial \mathcal{D}}{\partial \omega}$$

[illegible] (k, ω)

(ii) Monotonicity of ϕ and θ implies that we can define the inverses of ϕ and θ and the two explicit relations

$$\omega = \frac{1}{\Delta t}\phi^{-1}(\Delta t\Omega), \qquad k = \frac{1}{\Delta x}\theta^{-1}(\Delta x K).$$

Using these two relations, we find that a numerical single mode solution satisfies

$$\bar{\mathbf{a}}^T \left(\mathtt{i}\omega\mathbf{K} + \mathtt{i}k\mathbf{L} - \mathbf{A}\right)\mathbf{a} = 0.$$

Definition (3.7) for the energy density and flux implies now the following corollary.

COROLLARY 5. [illegible] (3.7) [illegible]

$$F_N = V_g E_N$$

[illegible] V_g [illegible]

(iii) Because of (2.7), nonintersecting branches of the analytic dispersion relation may intersect in the (K, Ω) plane unless either the implicit midpoint method is applied in time or Δt is chosen such that

$$\sup_{k \in S} |\phi(\omega(k)\Delta t)| \leq \pi,$$

where k is to be restricted to the proper domain S determined by the possible numerical wave numbers $-\pi < K\Delta x \leq \pi$. Intersecting branches (resonances) of the numerical dispersion relation may lead to instabilities of the method under small perturbations (see [2] for a discussion of the analytic case). Exclusion of intersecting branches leads to a CFL-type step-size restriction (except for an implicit midpoint time discretization). This will be discussed further in the following section.

5. An example: Fourth-order GL RK method in space and time. The linear wave equation

$$u_{tt} = u_{xx}$$

can be reformulated as a multisymplectic PDE of the form

$$-v_t - w_x = 0, \qquad u_t = v, \qquad u_x = -w \tag{5.1}$$

with $\mathbf{z} = (u, v, w)^T$,

$$\mathbf{K} = \begin{bmatrix} 0 & -1 & 0 \\ 1 & 0 & 0 \\ 0 & 0 & 0 \end{bmatrix}, \quad \mathbf{L} = \begin{bmatrix} 0 & 0 & -1 \\ 0 & 0 & 0 \\ 1 & 0 & 0 \end{bmatrix}, \quad \mathbf{A} = \begin{bmatrix} 0 & 0 & 0 \\ 0 & 1 & 0 \\ 0 & 0 & -1 \end{bmatrix}.$$

The analytic dispersion relation is $\omega^2 = k^2$. The application of the fourth-order GL RK method in space yields

$$\tan \frac{K\Delta x}{2} = \frac{k\Delta x}{2 - \frac{k^2 \Delta x^2}{6}},$$

and we find that $k\Delta x$ must be in the range of $0 \le k\Delta x < \sqrt{12}$ for computational wave numbers K satisfying $0 \le K\Delta x < \pi$. More specifically, we obtain

$$k\Delta x = -\frac{3}{b} + \sqrt{\frac{9}{b^2} + 12}, \qquad b = \tan \frac{K\Delta x}{2}.$$

Let us apply the same fourth-order method as the temporal discretization. Upon introducing the step-size mesh ratio $\beta = \Delta t/\Delta x$, one finds that $\omega\Delta t$ satisfies the inequalities

$$|\omega\Delta t| < \beta\sqrt{12}.$$

Branches of the numerical dispersion relation intersect whenever $\beta > 1$. However, $\phi' \ge 0$ (i.e., preservation of the sign of the group velocity) is guaranteed for any value of β. See Figure 2 for both cases $\beta < 1$ and $\beta > 1$.

Intersecting branches can be avoided altogether by an implicit midpoint discretization in time. Higher-order temporal discretization based upon the implicit midpoint method can be constructed using, e.g., Yoshida's fourth-order composition method [21]. The composed method still gives rise to a stability function of the form

$$R(i\omega\Delta t) = \mathrm{e}^{\mathrm{i}\phi}, \qquad \phi(\omega\Delta t) = 2\phi_{\mathrm{IM}}(\gamma\omega\Delta t) + \phi_{\mathrm{IM}}((1-2\gamma)\omega\Delta t),$$

where $\gamma = 1/(2-2^{1/3})$ and ϕ_{IM} is the phase function for the implicit midpoint method. It can be verified that $|\phi(\omega\Delta t)| \le \pi$ and that ϕ is a monotone function. See Figure 2 for numerical results.

6. The explicit midpoint scheme. This section discusses the effect of symplectic noncompact differencing methods by means of the explicit midpoint scheme.

Applying the explicit midpoint rule in both space and time yields a simple second-order two-step method. Introducing

$$\delta_t^{1/2}\mathbf{z}^{n,m} = \frac{1}{2\Delta t}\left(\mathbf{z}^{n+1,m} - \mathbf{z}^{n-1,m}\right) \quad \text{and} \quad \delta_x^{1/2}\mathbf{z}^{n,m} = \frac{1}{2\Delta x}\left(\mathbf{z}^{n,m+1} - \mathbf{z}^{n,m-1}\right),$$

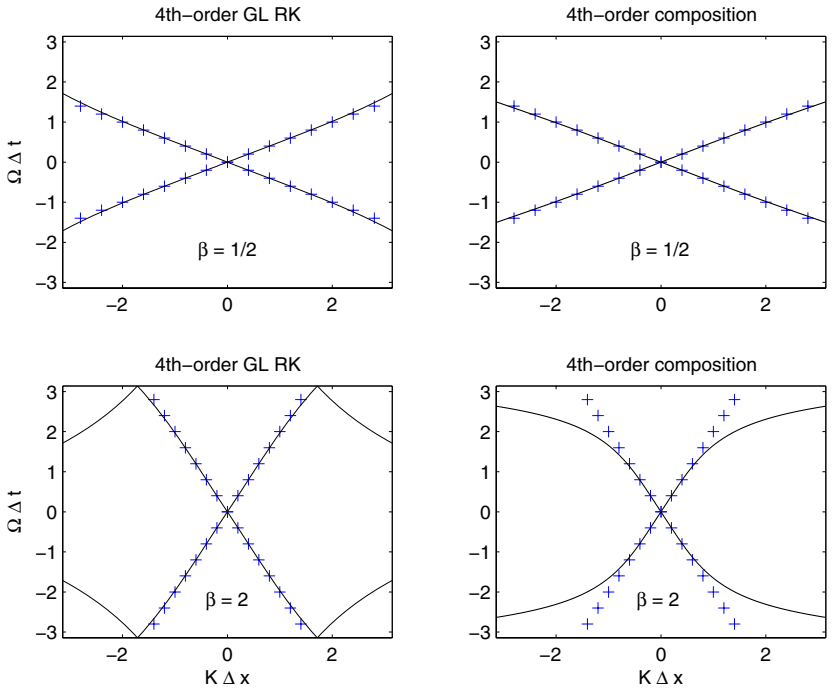

FIG. 2. *The numerical dispersion relations displayed in the left two plots are for a fourth-order GL RK space and time discretization for different values of* $\beta = \Delta t/\Delta x$. *The intersecting branches can clearly be seen for* $\beta = 2$. *These intersecting branches are no longer presented in a fourth-order space and time discretization with the time discretization now being a fourth-order composition method based on the implicit midpoint method. These results are displayed in the two plots to the right.*

in order to simplify notation, we present the explicit midpoint scheme in the following proposition.

PROPOSITION 2.

$$\mathbf{K}\delta_t^{1/2}\mathbf{z}^{n,m} + \mathbf{L}\delta_x^{1/2}\mathbf{z}^{n,m} = \nabla_{\mathbf{z}} S\left(\mathbf{z}^{n,m}\right)$$

$$\delta_t^+\left(\mathbf{dz}^{n,m} \wedge \mathbf{K}\mathbf{dz}^{n-1,m}\right) + \delta_x^+\left(\mathbf{dz}^{n,m} \wedge \mathbf{L}\mathbf{dz}^{n,m-1}\right) = 0.$$

The associated variational equation is given by

$$\mathbf{K}\delta_t^{1/2}\mathbf{dz}^{n,m} + \mathbf{L}\delta_x^{1/2}\mathbf{dz}^{n,m} = S_{zz}(\mathbf{z}^{n,m})\mathbf{dz}^{n,m}.$$

After taking the wedge product with $\mathbf{dz}^{n,m}$, we get

$$\mathbf{dz}^{n,m} \wedge \mathbf{K}\delta_t^{1/2}\mathbf{dz}^{n,m} + \mathbf{dz}^{n,m} \wedge \mathbf{L}\delta_x^{1/2}\mathbf{dz}^{n,m} = 0,$$

which is equivalent to

$$0 = \frac{1}{\Delta t}\left(\mathbf{dz}^{n,m} \wedge \mathbf{K}\left(\mathbf{dz}^{n+1,m} - \mathbf{dz}^{n-1,m}\right)\right) + \frac{1}{\Delta x}\left(\mathbf{dz}^{n,m} \wedge \mathbf{L}\left(\mathbf{dz}^{n,m+1} - \mathbf{dz}^{n,m-1}\right)\right).$$

Since

$$\begin{aligned}\mathbf{dz}^{n,m} \wedge \mathbf{K}\left(\mathbf{dz}^{n+1,m} - \mathbf{dz}^{n-1,m}\right) &= \mathbf{dz}^{n,m} \wedge \mathbf{K}\mathbf{dz}^{n+1,m} - \mathbf{dz}^{n,m} \wedge \mathbf{K}\mathbf{dz}^{n-1,m} \\ &= \mathbf{dz}^{n+1,m} \wedge \mathbf{K}\mathbf{dz}^{n,m} - \mathbf{dz}^{n,m} \wedge \mathbf{K}\mathbf{dz}^{n-1,m}\end{aligned}$$

and a similar result for the spatial discretization part, this gives the desired result. □

Applying this discretization to the linear equation yields

$$\mathbf{K}\delta_t^{1/2}\mathbf{z}^{n,m} + \mathbf{L}\delta_x^{1/2}\mathbf{z}^{n,m} = \mathbf{A}\mathbf{z}^{n,m}. \tag{6.1}$$

LEMMA 1. [illegible] (6.1) [illegible]

$$\mathcal{D}_{\mathbf{A}}(\omega, k) = 0$$

[illegible] $\mathcal{D}_{\mathbf{A}}$ [illegible] (1.4) [illegible]

$$\omega = \frac{\sin(\Omega\Delta t)}{\Delta t} \qquad \textit{and} \qquad k = \frac{\sin(K\Delta x)}{\Delta x}$$

[illegible] $-\pi < \Delta t\Omega \leq \pi$ [illegible] $-\pi < \Delta x K \leq \pi$
[illegible]. Substituting the (complex-valued) numerical solution ansatz

$$\mathbf{z}^{n,m} = \mathrm{e}^{\mathtt{i}(\Omega n\Delta t + Km\Delta x)}\mathbf{a}$$

into (6.1) gives

$$\left(\mathbf{K}\frac{\mathrm{e}^{\mathtt{i}\Omega\Delta t} - \mathrm{e}^{-\mathtt{i}\Omega\Delta t}}{2\Delta t} + \mathbf{L}\frac{\mathrm{e}^{\mathtt{i}K\Delta x} - \mathrm{e}^{-\mathtt{i}K\Delta x}}{2\Delta x} - \mathbf{A}\right)\mathbf{a} = 0.$$

Now, using the trigonometric identities

$$\mathrm{e}^{\mathtt{i}\Omega\Delta t} - \mathrm{e}^{-\mathtt{i}\Omega\Delta t} = 2\mathtt{i}\sin(\Delta t\Omega) \qquad \text{and} \qquad \mathrm{e}^{\mathtt{i}K\Delta x} - \mathrm{e}^{-\mathtt{i}K\Delta x} = 2\mathtt{i}\sin(\Delta x K),$$

the proof is completed. □

A first important conclusion is that the relation $R(\mathtt{i}\omega\Delta t) = \mathrm{e}^{\mathtt{i}\phi}$ implies that $\phi(\omega\Delta t)$, defined by

$$\sin\phi = \omega\Delta t,$$

is no longer monotone and is not defined for $|\omega\Delta t| > 1$ (instability of the method). Furthermore, the nonmonotonicity implies the existence of spurious roots in the numerical dispersion relation. A similar observation applies to the midpoint spatial discretization. Nonmonotonicity also implies that the sign of the numerical group velocity can be different from the sign of the analytic value for the corresponding (ω, k) pair.

We now investigate the behavior of the explicit midpoint space-time discretization for the linear wave equation (5.1). The discretization can be derived from the discrete Lagrangian

$$L = \frac{1}{2}\sum_{n,m}\left[\left(\frac{u^{n+1,m} - u^{n-1,m}}{2\Delta t}\right)^2 + \left(\frac{u^{n,m+1} - u^{n,m-1}}{2\Delta x}\right)^2\right]$$

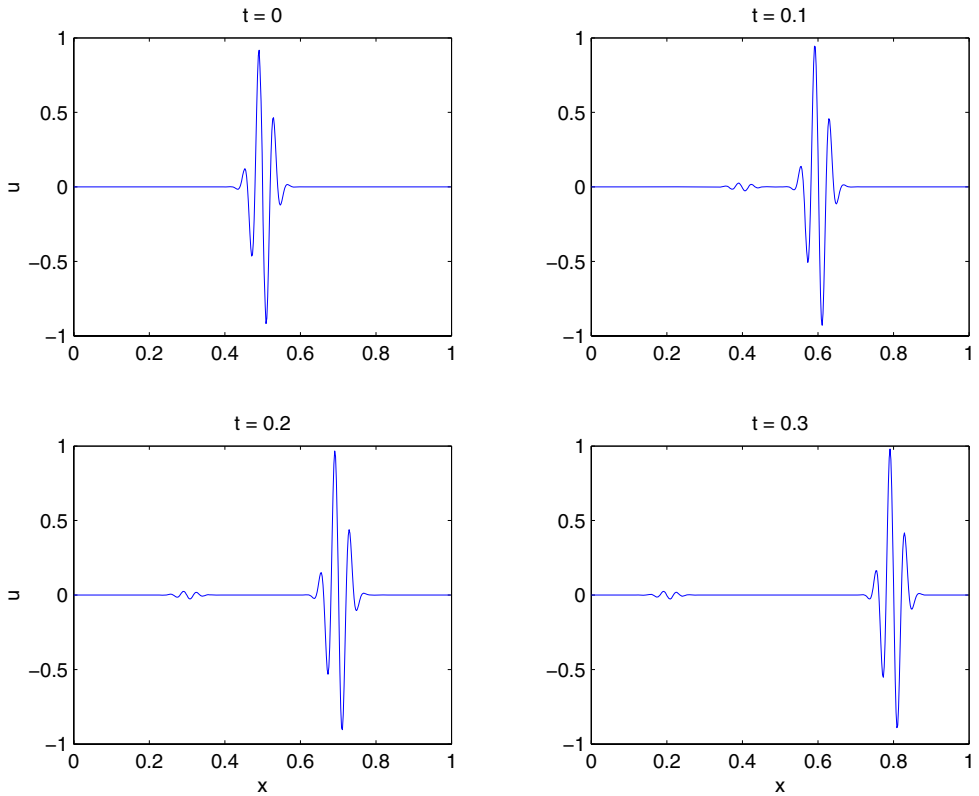

FIG. 3. *Numerical propagation of a wave packet under the space-time EMP method. The analytic solution consists of a wave packet moving entirely to the right. The displayed small perturbation moving towards the left is a numerical artifact due to the nonmonotone numerical dispersion relation of the EMP method.*

following the principle of discrete variational mechanics [15]. The numerical dispersion relation is given by

$$\sin^2(\Omega\Delta t) = \frac{\Delta t^2}{\Delta x^2}\sin^2(K\Delta x)$$

and is real-valued provided $\Delta t/\Delta x \leq 1$ (CFL condition). However, even for $\Delta t/\Delta x \leq 1$, the numerical dispersion relation has spurious roots for given K and Ω, respectively.

Let us first demonstrate the implication of the nonmonotone numerical dispersion relation for solutions of the linear wave equation (5.1). We solve the wave equation with the explicit midpoint (EMP) method in space and time over a spatial domain $x \in [0, 1)$ with periodic boundary conditions and initial data

$$u(x,0) = f(x), \quad v(x,0) = -f'(x), \quad f(x) = \exp(-30^2(x-1/2)^2)\sin(50\pi x).$$

The analytic solution consists of a wave packet moving to the right. The numerical solution for $\Delta x = 1/450$ and $\Delta t = 0.9\Delta x$ is displayed in Figure 3. The small perturbation moving towards the left is due to the nonmonotone numerical dispersion relation and would be absent for a GL RK discretization in space and time.

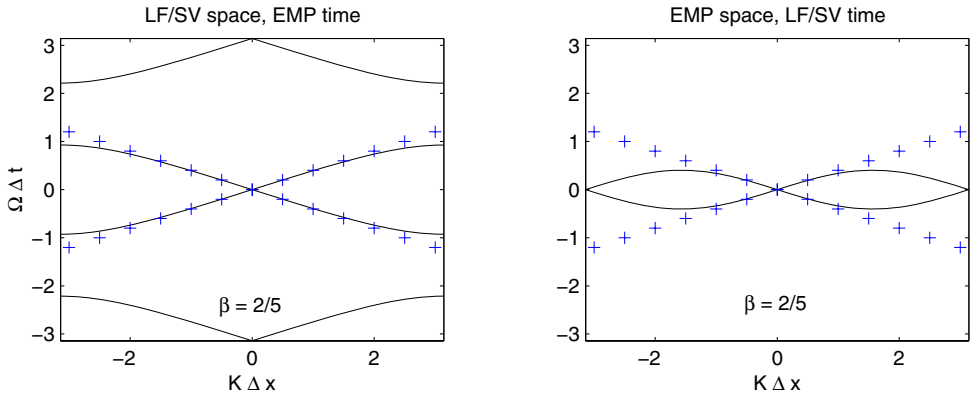

FIG. 4. *The numerical dispersion relations displayed on the left are for an EMP discretization in time and a Störmer–Verlet (LF/SV) discretization in space. The spurious branches (roots) in the numerical dispersion relation are due to the multistep EMP method. On the contrary, an LF/SV discretization in time combined with an EMP discretization in space yields a nonmonotone dispersion relation implying spurious roots.*

The spurious roots for K and/or Ω in the numerical dispersion relation of the space-time EMP discretization can be partially eliminated by substituting a symplectic one-step method in space or in time. As an example we consider the symplectic leapfrog/Störmer–Verlet (LF/SV) method. Applying the LF/SV method in space yields the numerical dispersion relation

$$\sin^2(\Omega\Delta t) = \frac{4\Delta t^2}{\Delta x^2}\sin^2\left(\frac{K\Delta x}{2}\right),$$

while application in time implies

$$\sin^2\left(\frac{\Omega\Delta t}{2}\right) = \frac{\Delta t^2}{4\Delta x^2}\sin^2(K\Delta x).$$

As shown in Figure 4 both combinations still imply spurious roots in their numerical dispersion relations. The same statement is true if the SV method is replaced in time by the implicit midpoint (IMP) method. The only difference is that there is no longer a stability restriction on β. See Figure 5.

It should be noted that there are spatial multistep discretizations with monotone phase function [9]. However, those methods do not seem to satisfy a discrete variational principle and, hence, do not give rise to multisymplectic discretization methods.

7. Summary: Towards a characterization of multisymplectic integration methods. There are a variety of numerical discretizations that satisfy a discrete multisymplectic conservation law. When applied to linear multisymplectic PDEs with wave-like solutions, all these methods yield real-valued numerical dispersion relations

$$\mathcal{D}_N(\Omega, K) = 0$$

provided the ratio $\Delta t/\Delta x$ satisfies a CFL-type condition $\Delta t/\Delta x \leq C$, where C is a positive number. This follows from the fact that $R(z)$, i.e., $\mathbf{z}^{n+1} = R(z)\mathbf{z}^n$, of a

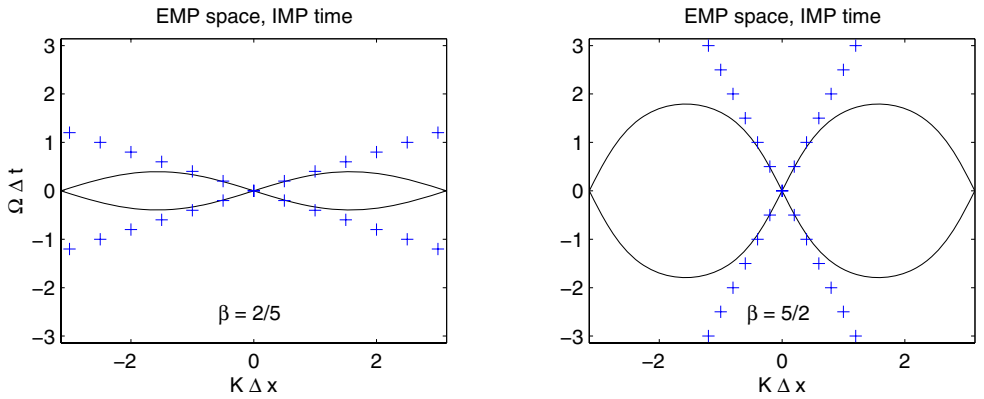

FIG. 5. *The displayed numerical dispersion relations are for an EMP discretization in space and an IMP discretization in time. Results are shown for $\beta < 1$ and $\beta > 1$.*

(stable and consistent) symplectic (one-step or multistep) method has to satisfy

$$|R(\mathtt{i}\sigma)| = 1$$

for sufficiently small $\sigma \geq 0$ because of conservation of volume.

One-step multisymplectic discretizations in space and time, such as GL RK, lead to (complex-valued) numerical approximations of the form

$$\mathbf{z}^{n,m} = R^0(\mathtt{i}\omega\Delta t)^n \, R^1(\mathtt{i}k\Delta x)^m \, \mathbf{a},$$

where $R^0(z)$ and $R^1(z)$ are the stability functions for the temporal and spatial discretization, respectively. It follows that multisymplectic GL RK discretizations in space and time are unconditionally stable, i.e., $C = \infty$.

Another key aspect of numerical methods is the existence or nonexistence of spurious roots in the numerical dispersion relation. The existence of spurious modes can be excluded provided (i)

$$R^0(\mathtt{i}y) = \mathrm{e}^{\mathtt{i}\phi(y)}, \qquad R^1(\mathtt{i}y) = \mathrm{e}^{\mathtt{i}\theta(y)}$$

for monotone phase functions ϕ, θ; and (ii) $\Delta t/\Delta x$ satisfies a CFL-type condition $\Delta t/\Delta x \leq c$. While all GL RK methods have monotone phase functions [10], the IMP time discretization is the only GL RK method for which $c = \infty$. Monotonicity of the phase function $\phi(\sigma)$ alone implies conservation of the sign of the group velocity under numerical discretization. Hence wave packets propagate numerically at a perturbed speed but in the correct direction. A multisymplectic discretization with

$$c < \frac{\Delta t}{\Delta x} \leq C$$

will, in general, lead to numerically induced 1-1 resonances (intersections of solution branches of the dispersion relation). Those spurious resonances can lead to instabilities of the method under small perturbations in the same manner as analytic resonances can give rise to instabilities [2]. It was found that higher-order time discretizations with $c = \infty$ can be constructed by proper composition of the IMP method. It should be noted that multisymplectic methods can be subject to additional numerically induced resonances. (Compare, e.g., Mandziuk and Schlick [14] for the case

of Hamiltonian ODEs.) This issue will be investigated in detail in a forthcoming publication.

Acknowledgment. The authors thank an anonymous referee for suggestions that led to a more thorough treatment of the energy transport under multisymplectic discretization methods.

A REAL GHOST FLUID METHOD FOR THE SIMULATION OF MULTIMEDIUM COMPRESSIBLE FLOW*

C. W. WANG†, T. G. LIU‡, AND B. C. KHOO§

Abstract. In the previous ghost fluid methods (GFMs) developed, the focus is on the definition of ghost fluid states while the pressure and velocity in the real fluid sides are taken for granted, except for the correction made to the density at the real fluid nodes next to the interface to overcome the possible problems related to overheating. It has been found that such GFMs encounter many difficulties when applied to shock impedance matching (-like) problems due to the inability of accurately imposing interfacial conditions. By predicting the flow states for the real fluid nodes just next to the interface and the ghost fluid nodes using the Riemann problem solver, a more accurate interface boundary condition can be imposed and the said difficulties are mitigated to a large extent. This leads to the development of a proposed real-GFM in this work. A simple yet efficient extension of the present method to multidimensions is also introduced. In order to overcome issues associated with the severe bunching of level set contours due to the large flow velocity gradient, an extension (artificial) velocity field is constructed in the computation of the level set function. The present method is applied to various one- and two-dimensional problems involving strong shock-interface interaction and complex flow physics.

Key words. Riemann problem, level set method, multimedium flow

1. Introduction.

Essentially nonoscillatory (ENO) schemes, first introduced by Harten and Osher [1] and Harten et al. [2], can achieve uniformly higher-order accuracy with sharp, essentially nonoscillatory shock transition. ENO schemes have shown their robustness and have worked very successfully in solving hyperbolic conservation laws [3, 4, 5] for single medium compressible flows. However, when such a scheme is used for simulating multimedium compressible flows, nonphysical oscillations occur or it may even fail to work. Additional work and techniques usually become necessary to somehow accommodate the change of the equation of state across the interface. One may refer to the conservative two-fluid capturing method developed for barotropic flows [6, 7], the nonconservative ghost fluid method (GFM) [8, 9] and its variants [10, 11], or others [12, 13, 14, 15, 16], to name some.

Of these methods, the GFM [8, 9] presented a fairly simple and flexible way to treat multimedium flows and is easily extended to multidimensions. The original GFM developed in [8] defines for the first medium the pressure and velocity at the ghost fluid nodes across the interface as the local pressure and velocity of the second medium, and the density is obtained via isobaric fixing. It has been found, however, that such a definition of ghost fluid status is not very robust when applied to gas-water flows [9]. Therefore, in [9], a new definition of the ghost fluid status was proposed

especially for treating gas-water flows. More specifically, to obtain the ghost fluid status for the gas medium, the ghost fluid velocity is directly duplicated from the water medium, while the ghost fluid pressure is extrapolated from the gas medium. In the definition of ghost fluid status for the water medium, the ghost fluid pressure is directly duplicated from the gas medium, while the ghost fluid velocity is extrapolated from the water medium. Hereafter, for ease of reference, we shall call the GFM developed in [9] the new GFM in this work. With the ghost nodes defined across the interface, computation is thereby carried out as if in a single medium without the necessity to change the numerical scheme employed and hence the method is of the great versatility. The original and new GFMs have been successfully applied to various areas such as the treatment of discontinuities in compressible and incompressible flows [17, 18, 19], flame and detonation fronts [20, 21], and fluid-structure coupling [9]. The success of the GFM depends on the implicit capture and imposition of boundary conditions at the moving interface. Since the flow states at the interface are usually material properties related, the boundary conditions at the interface are therefore usually nonlinearly affected by the flow material properties from both sides of the interface. This implies that the definition of ghost fluid states by simply duplicating from the real fluid is not strictly sufficient to take into account such effects arising from the different material properties present on both sides of the interface. This is one of the reasons why the GFM presented in [8] has some limitations in its applications and is found to be problem related [9].

A strong wave interaction can occur at the interface such as in the situation of a strong shock impacting on a material interface. As such, the pressure or the velocity can experience a large gradient or sudden jump across the interface. In such a situation, the ghost fluid states have to be predicted to take into consideration the influence of both wave interaction and material properties on the interfacial evolution as analyzed in [22]. In fact, because the GFM provides a solution via essentially solving two single medium GFM Riemann problems, some conditions (i.e., Conditions I and II as proposed in [23]) have to be satisfied in the definition of the ghost fluid states to ensure that the two GFM Riemann problems indeed give the correct solution in the respective real fluid sides. This has led to the development of a modified ghost fluid method (MGFM) proposed by in [22]. In the MGFM, a Riemann problem is defined and solved approximately to predict the interfacial status. The predicted interfacial status is then used to define the ghost fluid status at the ghost nodes across the interface. The MGFM has been shown to be robust and much less problem related and can be applied to various equations of state (EOS).

In the original GFM, the new GFM, and the MGFM, the focus is on defining the ghost fluid states while the pressure and velocity in the real fluid side are taken for granted, except for the correction made to the density at the real fluid nodes next to the interface to overcome the overheating. It has been found that such an approach adopted by the GFM algorithm is not very accurate when applied to those problems with a critical condition like the shock impedance matching (-like) problem [22, 23]. Because such a critical condition is usually related to the flow material properties on both sides of the interface, a single-medium computational method like the GFM can encounter many difficulties in enforcing and maintaining this critical condition. This will remain so unless this condition is equivalently imposed in advance before the computation is carried out as shown in [22]. Furthermore, the flow motion relative to the moving interface is subsonic. As a result, the influence of material properties from both fluids and the wave interaction at the interface can propagate both upward and downward simultaneously in relation to the interface motion. This implies

that a correction to the real fluid nodes next to the interface is deemed necessary to accurately take into account such influence (especially for those critical problems of shock impedance matching). On the other hand, in all the previously developed GFM algorithms, only the ghost fluid states are defined or modified to take into account such influence. This means that the consideration of such influence on the real fluid is artificially delayed by at least one time step. Therefore, one motivation of the present work is to develop a technique to consider the influence mentioned above on the fluids (lying on either side of the interface) simultaneously to better reflect the real/true flow physics. To do so, the real fluid states next to the interface instead of the ghost fluid states will be predicted by solving a Riemann problem and the ghost fluid states are then obtained by solving an advection equation. This will result in the complete modification and redefinition of the real fluid next to the interface. In doing so, one will find that the nonphysical reflection for the shock impedance matching problem can be greatly and further suppressed. At the same time, all the good features of the MGFM are still maintained. The algorithm based on the present implementation is called real ghost fluid method (rGFM) for ease of reference and discussion in this work. Furthermore, we will show theoretically that the rGFM indeed enables a better imposition of the boundary conditions at the interface and less conservative errors are incurred in comparison to the previous GFMs.

The paper is organized as follows. In section 2, the governing equations, EOS for gases and water, and the level set equation are provided. To avoid or prevent the appearance of hugely distorted level set contours caused by (potential) large flow velocity gradient, an extension artificial velocity field is constructed for solving the level set equation. In section 3, the detailed implementation of the present method based on the third-order ENO-LF scheme [3, 4] for one- and two-dimensional problems is presented. Some conclusions based on analysis for the rGFM are also obtained in this section. Tests on the accuracy, convergence, and conservation errors incurred for the rGFM are given in section 4. In section 5 extensive comparisons are made between the simulations and analytical results. A brief conclusion is given in section 6.

2. Equations.

2.1. Governing equations. The Euler equations governing two-dimensional compressible flows are written as

$$\frac{\partial U}{\partial t} + \frac{\partial F(U)}{\partial x} + \frac{\partial G(U)}{\partial y} = 0, \tag{2.1}$$

where $U = [\rho, \rho u, \rho v, E]^T$, $F(U) = [\rho u, \rho u^2 + p, \rho uv, (E+p)u]^T$, and $G(U) = [\rho v, \rho uv, \rho v^2 + p, (E+p)v]^T$. Here ρ is the density, u and v are the velocity components in the respective x and y directions, p is the pressure, and E is the total energy per unit volume. The total energy is the sum of internal energy and kinetic energy,

$$E = \rho e + \frac{1}{2}\rho(u^2 + v^2), \tag{2.2}$$

where e is the internal energy per unit mass.

2.2. Equations of state(EOS). For closure of (2.1), EOS is required. In the present work, our interest centered on the compressible gas and water media. The EOS for compressible gases and water can be expressed in the following consistent form as

$$p = (\gamma - 1)\rho e - \gamma B, \tag{2.3}$$

where γ and B are treated as constants. For the air,

$$\gamma = 1.4 \quad \text{and} \quad B = 0. \tag{2.4}$$

For the water medium (Tait's equation),

$$\gamma = 7.15 \quad \text{and} \quad B = 3309. \tag{2.5}$$

2.3. Level set equation. To track the moving interface, we employ the level set technique [24, 25, 26]. The level set equation for two-dimensional flows can be written as

$$\frac{\partial \phi}{\partial t} + u\frac{\partial \phi}{\partial x} + v\frac{\partial \phi}{\partial y} = 0. \tag{2.6}$$

In general $\phi(x, y, t)$ starts off as a signed distance function. For complex interface evolution, it has been found that a higher-order accurate discretization can better help to maintain the accurate position of the interface [8]. In this work, the fifth-order weighted ENO scheme [27, 28] is, thus, used to discretize the spatial derivatives together with the third-order Runge–Kutta time discretization [3] to advance the interface.

The possible disadvantage of using the level set technique is that solving equation (2.6) may lead to severely distorted contours when the velocity field experiences a large gradient in the vicinity of the interface. To remedy this situation, a redefinition of the velocity field is called forth via the extension velocity. There are several ways of constructing the extension velocity field in the literature. In [29], the velocity at the interface point, which is closest to the considered nodes, is taken as the extension velocity. In [30], the extension velocity is obtained by solving an equation, which ensures the level set function to be a signed distance function, and so the reinitialization step is obviated. In this work, a very simple yet efficient method for obtaining the extension velocity is proposed. In particular, the normal velocity at the interface, which is obtained from the Riemann problem solver, is extended to all the nodes in the fluid field as the extension velocity. As the Riemann problem solver provides the accurate interface moving velocity, the uniformly distributed level set contour and accurate interface position can be obtained without any need of reinitialization. The detail of implementation is discussed in the following section.

3. rGFM. In the rGFM, a Riemann problem is defined at the interface and solved for predicting the interfacial status. The predicted interfacial status is then used to redefine the flow states at the real fluid nodes next to the interface, and the ghost fluid states at the ghost nodes across the interface are obtained by solving an advection equation. In doing so, the isobaric fix which is used in the previous GFMs to overcome the overheating is not required. To show the method clearly, we first present the treatment of the interface boundary, where the Riemann problem is defined, and the implementation of the extension velocity for one-dimensional problems. Then we extend it to the two-dimensional problems. Finally, we carry out some analysis for the rGFM on the issue relating to the imposition of boundary conditions at the interface and on the conservation errors incurred by the algorithm. In the implementation of the present rGFM, the spatial discretization is either the first-order ENO-LF or the third-order ENO-LF [4, 5] (ENO scheme with Lax–Friedrichs flux) scheme; the resultant temporal ordinary differential equation (ODE) system is then solved using the third-order TVD Runge–Kutta discretization [3]. The former algorithm is termed the first-order ENO-LF while the latter is termed the third-order ENO-LF.

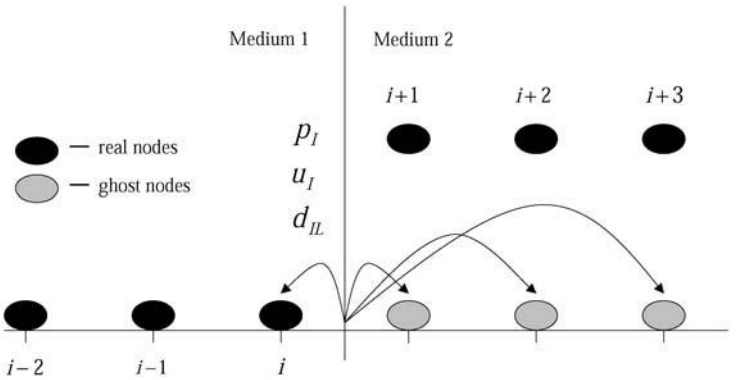

FIG. 1. *Updating the real and ghost nodes in the rGFM.* p_I*: interface pressure,* u_I*: interface velocity,* ρ_{IL}*: left interface density,* ρ_{IR}*: right interface density.*

3.1. For one-dimensional problems. Suppose that the interface lies between node i and node $i+1$ as depicted in Figure 1. To define the Riemann problem at the interface, the two initial constant states of the Riemann problem are simply given as U_L=U_i and U_R=U_{i+1} in the present paper. Such a simple definition works rather well due to the accurate imposition of boundary conditions at the interface (to be shown in section 3.4) and can be easily extended to two-dimensional cases on comparing to the previous GFMs. A better and perhaps simpler choice for U_L and U_R are U_{i-1} and U_{i+2}, respectively, which has been applied to the original GFM, the new GFM, and the MGFM due to employment of the isobaric fix (see [8] for more details). The latter has been found to also work equally well for the rGFM. Once the Riemann problem is defined, the Riemann problem solver [22, 26] can then be employed to provide intermediate interfacial states—p_I(pressure), u_I(velocity), and ρ_{IL} and ρ_{IR} representing the densities on the left and right sides of the interface, respectively. For the third-order ENO scheme [4], to update the states at the real fluid nodes next to the interface and the ghost fluid states at ghost nodes, we need to redefine the value for medium 1 at nodes from node i to node $i+3$. (Node i is a real fluid node, while $i+1$, $i+2$, and $i+3$ are ghost fluid nodes.) We take p_I, u_I, and ρ_{IL} as the pressure, velocity, and density at these said nodes. Likewise, for medium 2, we also take p_I, and u_I as the pressure and velocity at nodes $i+1$, i, $i-1$, and $i-2$. The density at these latter nodes is ρ_{IR}. Thus, the boundary conditions at the interface for medium 1 and medium 2 are imposed, and the solution can be advanced to the next time step.

The extension of the level set velocity field is very simple for one-dimensional problems. Essentially, one can just copy the velocity u_I from the Riemann problem solver to all the nodes in the fluid field. By solving for the one-dimensional equation (2.6), the level set function can be obtained at the new time step. Obviously, the signed distance function is maintained using the present extension velocity technique for the one-dimensional problems.

3.2. For two-dimensional problems. Defining the Riemann problem and obtaining the flow states at ghost nodes seems simple and straightforward for one-dimensional problems. However, for two-dimensional problems, it becomes much more involved because there is more than one velocity component to deal with. One has to construct the Riemann problem appropriately and then extrapolate the states to the associated ghost nodes accordingly. Using the level set function , we can define

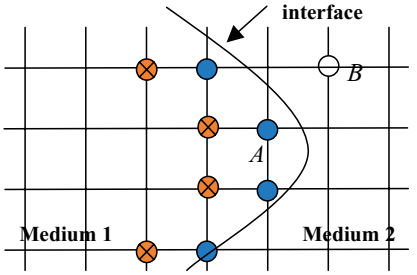

FIG. 2. *Construction of the Riemann problem.*

the unit normal at every grid node as

$$N = \frac{\nabla \phi}{|\nabla \phi|}. \tag{3.1}$$

The normal velocity at those nodes next to the interface is given by

$$u_N = (u, v) \cdot N. \tag{3.2}$$

First, we present the procedure of defining the Riemann problem and extrapolation for medium 1. Considering node A (see Figure 2), which is just bordering the interface, we have the normal velocity, u_N^A, the density, ρ^A, and the pressure, p^A. Next, we search for another node B also bordering the interface but on the other side of the medium such that the angle made by the respective normals at node A and node B is the minimum. In addition, we know the normal velocity, the density, and the pressure at node B, as denoted by u_N^B, ρ^B, and p^B, respectively. Therefore we can define a Riemann problem in the normal direction with the initial condition,

$$U_0 = \begin{cases} U_A, \\ U_B, \end{cases} \tag{3.3}$$

where $U_A = [\rho^A, u_N^A, p^A]^T$, $U_B = [\rho^B, u_N^B, p^B]^T$. We then solve for the Riemann problem to provide for an intermediate state ρ_L^I, ρ_R^I, u_N^I, and p^I.

The intermediate states are employed to redefine the flow states at those real fluid nodes next to the interface. After updating all the nodes bordering the interface in the real fluid, the ghost fluid states are then obtained by solving the following convection equation:

$$I_t \pm N \cdot \nabla I = 0 \tag{3.4}$$

(see also [8]). This is done by fixing the value of I in the real fluid region (where $\phi < 0$) and iterating (3.4) to steady state for all the ghost fluid nodes. Here I is a column vector comprising the normal velocity, tangential velocity, pressure, and density or entropy. A first-order ENO scheme is used to discretize the spatial derivatives. Likewise, for the calculation of medium 2, a node A in medium 1 can also be found corresponding to node B in medium 2 such that the angle made by the normal of node B and that of node A is the minimum. Therefore the Riemann problem can be constructed and then the ghost fluid states can be defined (in medium 1) by solving (3.4). The above procedure of defining and solving the Riemann problem gives the normal velocities for all the grid nodes next to the interface. By fixing the extension

velocity for all those nodes next to the interface and solving for (3.4) with a reverse convection direction to that for obtaining the ghost fluid states, the normal velocity field of the extension velocity is obtained. We use this normal velocity to define the extension velocity at any node C as

$$(u_1^C, v_1^C) = u_N^C \cdot N^C, \tag{3.5}$$

where u_N^C is the extended normal velocity and N^C is the normal vector at node C. We then advance the level set function to the next time step. The present technique is very simple and works rather efficiently, as the interface is predicted correctly. Unlike the one-dimensional implementation, the two-dimensional implementation of advancing the level set function theoretically does not guarantee that the level set function is maintained as a signed distance function. However, our applications have shown that the distance function is approximated and maintained quite well. The level set contours are almost uniformly distributed around the interface.

3.3. Summary of solution procedures. Here we briefly summarize the implementation procedures for the rGFM. The level set function is defined according to the initial condition of the problem at the first time step. Assuming that the flow states at $t = t^n$ have been obtained, the following steps are taken to calculate for the respective quantities at the next time step:

1. Construct the Riemann problem for medium 1, predict the interface states, and then redefine the flow states for those nodes next to the interface in the real fluid. Then obtain the ghost fluid states by solving (3.4).
2. After the boundary conditions are imposed, the third-order ENO-LF scheme is employed for discretizing the spatial derivatives of the governing equations. The solution in medium 1 is advanced to the next intermediate time level.
3. Repeat steps 1 and 2 for the next medium 2 until the solution in the whole domain is advanced to the next intermediate level.
4. Construct the extension velocity in the fluid field and solve for the level set equation to get the level set function at the next intermediate time step.
5. By repeating steps 1, 2, 3, and 4 at each intermediate time step of the third-order TVD Runge–Kutta method, the solution can be advanced from U^n to U^{n+1}.

3.4. Some conclusions on the rGFM. Numerical tests and applications to be given in sections 4 and 5 will show that the rGFM can give better numerical results even in comparison to the MGFM. In this subsection, analysis is carried out to better understand the underlying reasons; the analysis is based on one-dimensional flows. In the discussion below, the interface is supposed to lie between node i and node $i + 1$. We have the following findings.

THEOREM 1.

Physically, the initial singularity is instantly decomposed, and both flow states next to the interface change simultaneously to meet the interfacial conditions (the continuity of pressure and normal velocity). Numerically, this may not be captured faithfully by the previous GFM-based algorithms. As a result, numerical errors are introduced. This can happen as shown in [22] for the original GFM when applied to the strong shock impacting on the gas-water interface. Due to the usual employment of a high-resolution scheme, which is usually upwind based, the real fluid may not be affected if the initial flow state of this real fluid is supersonic. More specifically, for

illustration, the initial flow in medium 1 is supersonic as for a jet impact problem, and medium 2 is stationary and subject to low pressure. If the jet is of large magnitude, a full up-winded or Roe-type scheme will lead to numerical fluxes, $F_{i-\frac{1}{2}}=F_{i-1}$ and $F_{i+\frac{1}{2}}=F_i$. The fluid in medium 2 thereby exerts no influence on the flow at node i in the first step of computation for those one-step algorithms. Consequently, the decomposition of singularity in medium 1 will be at least one time step lagging behind that in medium 2, which results in numerical errors, while physically the decomposition of singularity at the interface occurs simultaneously in both the upstream and downstream directions. However, such nonsimultaneous decomposition does not occur for the rGFM. This is because the influence of fluid properties on the singularity decomposition is taken into account via solving an interfacial Riemann problem and the real fluids at the nodes next to the interface are also modified to consider such influence. Independent of the numerical scheme employed whether it be centered or up-winded, the numerical flux, $F_{i+\frac{1}{2}}$, will include the influence from medium 2 in updating the flow state at node i for medium 1. Therefore, the singularity is simultaneously decomposed in both fluids.

THEOREM 2.

There are easily two kinds of error arising from treatment of the interface using a previous GFM-based algorithm. One is that the interfacial location may not be captured accurately due to the nonconservative computation. The other is that the boundary conditions may not be enforced correctly. That is, the continuity of pressure and normal velocity across the interface may not be maintained. As pointed out in [22, 23], a GFM-based algorithm essentially consists of solving two GFM Riemann problems. If there is an initial singularity at the interface, neither the original GFM nor the new GFM can faithfully maintain the continuity of pressure and/or normal velocity across the interface in the very earlier stages of singularity decomposition. This is because there is no such mechanism for the pressure and/or normal velocity continuity initially using either GFMs, and the two GFM Riemann problems usually provide different flow status at the location of interface [22, 23]. On the other hand, the rGFM modifies the real fluid status at those nodes next to the interface via the predicted interfacial pressure and normal velocity and then extends to the ghost fluid nodes by solving equation (3.4) for each substep of the Runge–Kutta method. This ensures the pressure and normal velocity at the interfacial location are the same for the two GFM Riemann problems. In other words, the continuity of pressure and normal velocity at the interface is imposed. As for the MGFM, the ghost fluid status is directly defined using the predicted interfacial status, which is obtained via solving an interfacial Riemann problem. Because the interfacial location generally does not coincide with the ghost fluid nodes, the interfacial pressure and normal velocity in one GFM Riemann problem are not equal to the respective quantities in the other GFM Riemann problem, albeit they are quite close to each other, as shown in [22]. Consequently, the rGFM can better enforce the continuity of the interfacial pressure and normal velocity, while the other mentioned GFM algorithms do not strictly uphold such a property.

Because the present rGFM is nonconservative like all the other previous GFM algorithms, conservation errors are incurred. The occurrence of conservation errors is one of the causes for inaccurate results for some problems. Being so, the reduction of conservation errors is especially relevant and certainly critical in the construction of a viable method for treating the interface. For a GFM algorithm-based on the third-order TVD Runge–Kutta time discretization [3] (independent of the spatial discretization), we have the following findings.

THEOREM 3. [illegible] [3] [illegible] x_A, x_B [illegible]

$$TCE(t) = DETAT(t) + DETAS(t) + STEP1(t) + STEP2(t) + STEP3(t), \tag{3.6}$$

[illegible]

$$DETAT(t) = \frac{1}{\triangle x}\left(\int_{x_A}^{x_I^{n+1}} U_L^{n+1}dx - \int_{x_A}^{x_I^n} U_L^n dx + \int_{x_I^{n+1}}^{x_B} U_R^{n+1}dx - \int_{x_I^n}^{x_B} U_R^n dx\right),$$

$$DETAS(t) = \frac{1}{6\triangle x}\int_{t^n}^{t^{n+1}} \left[F_B^{(1)} - F_A^{(1)} + F_B^{(2)} - F_A^{(2)} + 4\left(F_B^{(3)} - F_A^{(3)}\right)\right] dt,$$

$$STEP1(t) = \frac{1}{6\triangle x}\int_{t^n}^{t^{n+1}} \left(F_{IL}^{(1)} - u_{IL}^{(1)}U_{IL}^{(1)} - F_{IR}^{(1)} + u_{IR}^{(1)}U_{IR}^{(1)}\right) dt,$$

$$STEP2(t) = \frac{1}{6\triangle x}\int_{t^n}^{t^{n+1}} \left(F_{IL}^{(2)} - u_{IL}^{(2)}U_{IL}^{(2)} - F_{IR}^{(2)} + u_{IR}^{(2)}U_{IR}^{(2)}\right) dt,$$

$$STEP3(t) = \frac{2}{3\triangle x}\int_{t^n}^{t^{n+1}} \left(F_{IL}^{(3)} - u_{IL}^{(3)}U_{IL}^{(3)} - F_{IR}^{(3)} + u_{IR}^{(3)}U_{IR}^{(3)}\right) dt.$$

Here $DETAT(t)$ denotes the increase within the fluid domain, $DETAS(t)$ is the flux out of the domain, while $STEP1(t)$, $STEP2(t)$, and $STEP3(t)$ are the errors associated with the interfacial treatment in the three intermediate time steps (or substeps) of the third-order TVD Runge–Kutta method, respectively. $F_{IL}^{(i)}$ and $F_{IR}^{(i)}$ are the fluxes on the left and right sides of the interface, and $U_{IL}^{(i)}$ and $U_{IR}^{(i)}$ are the value of the conservative variables on the left and right sides of the interface. $u_{IL}^{(i)}$ and $u_{IR}^{(i)}$ are the interfacial velocities provided by the respective GFM Riemann problems. Subscript L or R indicates the left or the right flow medium, while superscript i stands for the ith substep of the third-order Runge–Kutta method. We can obtain

$$\begin{aligned} F_{IL}^{(i)} - u_{IL}^{(i)}U_{IL}^{(i)} &= \left[0, p_{IL}^{(i)}, u_{IL}^{(i)}p_{IL}^{(i)}\right]^T, \\ F_{IR}^{(i)} - u_{IR}^{(i)}U_{IR}^{(i)} &= \left[0, p_{IR}^{(i)}, u_{IR}^{(i)}p_{IR}^{(i)}\right]^T, \end{aligned} \tag{3.7}$$

where $p_{IL}^{(i)}$ ($u_{IL}^{(i)}$) and $p_{IR}^{(i)}$ ($u_{IR}^{(i)}$) are the interfacial pressures (velocities) provided by the respective GFM Riemann problems. Theoretically, $u_{IL}^{(i)}$ should be equal to $u_{IR}^{(i)}$, and $p_{IL}^{(i)}$ should be equal to $p_{IR}^{(i)}$, and thus $STEP1(t)$, $STEP2(t)$, and $STEP3(t)$ should be equal to zero. However, because the GFM algorithm obtains solution essentially via computation in the single medium flow and both GFM Riemann problems are usually unable to provide identical pressure and normal velocity at the interface, $STEP1(t)$, $STEP2(t)$, and $STEP3(t)$ are not equal to zero. Consequently, there is strictly no conservation over the whole computation domain. Using the rGFM, however, $STEP1(t)$, $STEP2(t)$, or $STEP3(t)$ can be made to vanish. Thus, we have the following.

COROLLARY 1. [illegible]

$$TCE(t) = DETAT(t) + DETAS(t). \tag{3.8}$$

This is because the rGFM imposes the pressure and velocity boundary conditions at the interface in the process of defining the ghost fluid status as shown in Theorem 2. Therefore, Corollary 1 is obviously true.

To maintain conservation, the sum of $DETAT(t)$ and $DETAS(t)$ should be equal to zero. This is generally not true for the rGFM. The conservation errors incurred in the rGFM come primarily from the modification to the real fluid status at the nodes next to the interface. This is unlike the original GFM, the new GFM, and the MGFM, where besides the conservative errors associated with the isobaric fix imposed on the real fluid nodes, there are other conservative errors arising from the inaccurate imposition of boundary conditions at the interface (i.e., $STEP1(t)$, $STEP2(t)$, and are generally not equal to zero). Numerical tests in section 4 will show that the conservative errors arising from employing the rGFM are much less than those associated with using the original GFM, the new GFM, or even the MGFM.

4. Preliminary tests of the rGFM. To better understand the rGFM, some tests on accuracy and convergence of the rGFM will be done in this section.

4.1. On accuracy and convergence. We select a one-dimensional model of translating density profile first proposed by Davis [31] to test the accuracy and convergence of the rGFM. This is a linear model in which a specified density profile translates with a constant velocity and pressure. There are no reflection or transmission waves in this problem. The computation domain is $[-1, 1]$ and the CFL is equal to 0.5. The given initial density profile is

$$\rho(x,0) = \begin{cases} -0.8x^3 + 0.4, & x < 0, \\ -0.8x^3 + 2.0, & x > 0, \end{cases} \tag{4.1}$$

and the initial velocity and pressure are constant at $u = 1.0$ and $p = 2.0$. The heat conductivity ratio is $\gamma = 1.4$. The convergence and the accuracy of the density calculated with the rGFM-based third-order ENO-LF scheme are provided in Table 1 for different mesh sizes by doubly refining the mesh repeatedly. The numerical results show that the algorithm is third-order accurate in the L_∞ norm and even higher than third-order accurate in the L_1 norm. This means that the rGFM does not incur more errors that can lead to the degeneration of accuracy and convergence for this problem although the present method is not conservative. The density profile at $t = 0.2$ is given in Figure 3 when the interface has moved to $x = 0.2$ from the initial position of $x = 0.0$. The comparison to the theoretical solution shows that the rGFM captures the interface accurately for this problem.

4.2. The conservation errors. We shall use two cases to study the conservative errors of the rGFM. Case 1 is a high-speed air jet impacting on an air-water interface (i.e., Problem 4 in section 5). Case 2 is the oscillating water column problem proposed in [6]. In the discussion below, we again assume that the interface lies between node i and node $i + 1$.

TABLE 1
The convergence and the accuracy of density at $t = 0.2$.

Mesh size	L_∞ error	order	L_1 error	order
0.04	4.10E-04	-	5.27E-06	-
0.02	4.49E-05	3.19	4.04E-07	3.70
0.01	5.38E-06	3.06	3.46E-08	3.54
0.005	6.87E-07	2.97	3.17E-09	3.45
0.0025	8.65E-08	2.99	2.84E-10	3.48

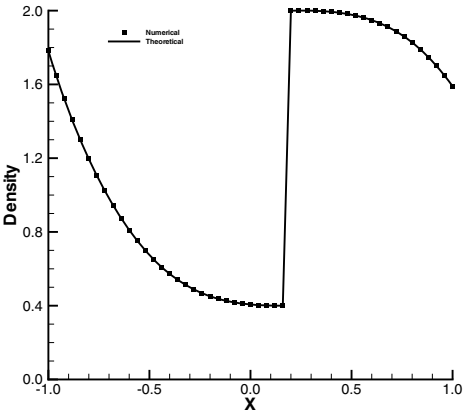

FIG. 3. *The density profile obtained at* $t = 0.2$.

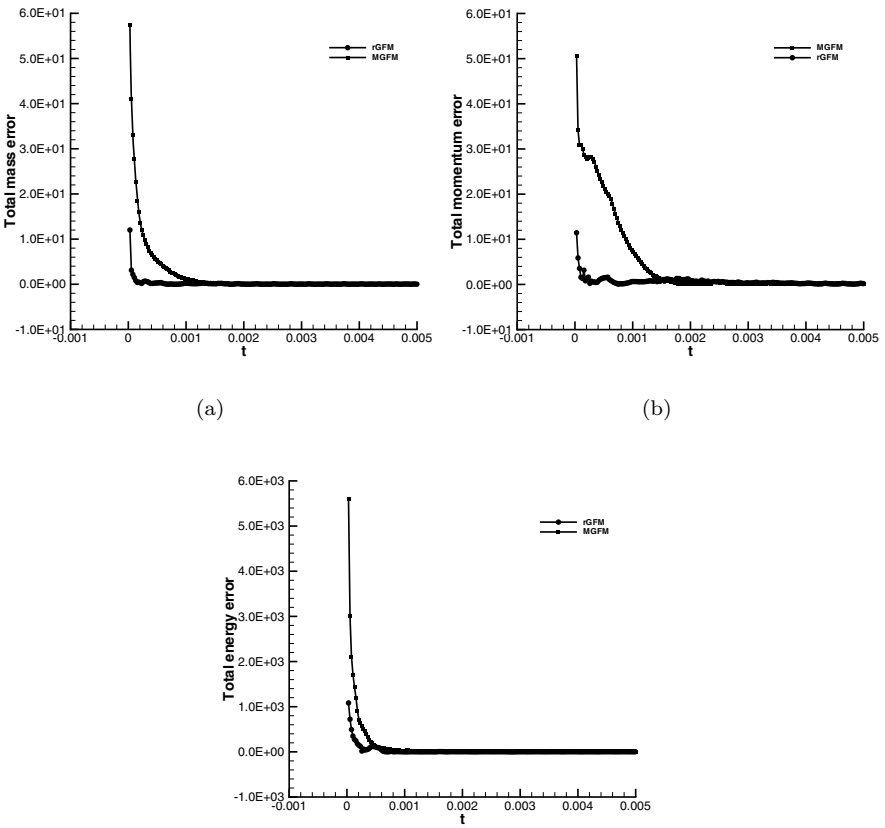

FIG. 4. *Comparison of conservation errors betwee the rGFM and the MGFM for Case* 1.

1. In this problem, the jet is supersonic. Figures 4(a), (b), and (c) shows the conservation errors for the total mass, momentum, and energy in the computational domain, respectively, for both the rGFM and the MGFM. The results are obtained

FIG. 5. *Initial status of the oscillating water column problem.*

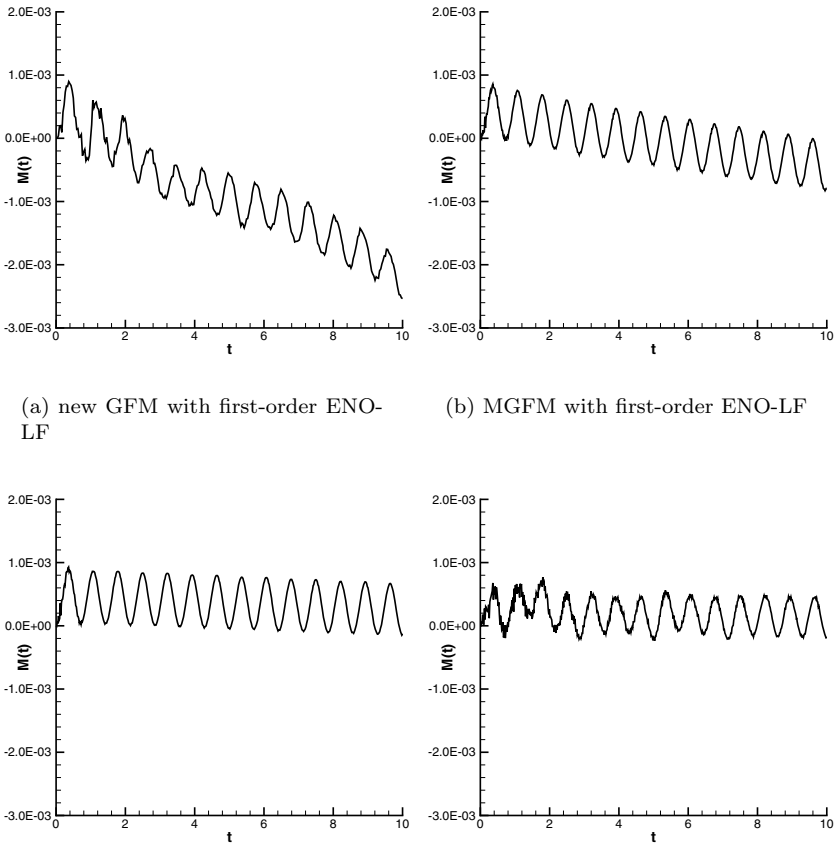
using formula (3.6). From these figures, it is apparent that large conservation errors are incurred in the first a few time steps of the computation via the MGFM. The errors, however, tend toward zero fairly quickly. The results also show that there are relatively much smaller errors incurred by the rGFM in the first several time steps of computation on comparing to the MGFM. These errors tend toward zero more quickly for the rGFM than for the MGFM. The results indicate that the conservative errors associated with the rGFM are even more contained and limited compared to the MGFM. It is clear that the redefinition of the real fluid states at the nodes bordering the interface and the accurate calculation of the numerical flux next to the interface are important at the beginning of the singularity decomposition. Since the flow states at the real fluid nodes in the rGFM are redefined with the Riemann problem solver rather than only for the ghost fluid nodes as carried out in the MGFM [22], the numerical flux $F_{i+\frac{1}{2}}$ is more accurately obtained and is independent of the numerical scheme selected as analyzed in Theorem 1. More important, according to Corollary 1, $STEP1(t)$, $STEP2(t)$, and $STEP3(t)$ are equal to zero in the rGFM, while these are not so in the very earlier stage of the singularity decomposition for the MGFM (or other previous GFMs). The far smaller conservation errors found support our analysis in section 3.4 that the rGFM imposes better and more accurate interfacial conditions than the previous GFMs mentioned. (Needless to say, the conservative errors pertaining to the previous GFMs in [8, 9] are even larger than the MGFM as already discussed and analyzed in [22, 23].)

EXAMPLE 2. This is a problem of a water column separated by the air and oscillating in the middle of a closed tube [6]. The problem is sketched in Figure 5. The initial status of the air and water are defined as $\gamma_a = 1.4$, $B_a = 0.0$, $\rho_a = 0.001$ and $\gamma_w = 7.0$, $B_w = 3000.0$, $\rho_w = 1.0$, respectively. The velocity is $u_a = u_w = u_0 = 1.0$, and the pressure is $p_a = p_w = p_0 = 1.0$. The two interfaces are located at $x_{IL} = -0.1$ and $x_{IR} = 0.1$.

With the fluids moving to the right, the air on the left of the water column expands while the air on the right of the water column is compressed. The pressure decreases at the former and increases at the latter; this leads to the deceleration and eventually stagnation of the fluids in the tube. Then the fluids move in the reverse direction due to the pressure gradient, and so on with the water column oscillating. Pressure waves are evident in the tube due to the impact of the air on the end boundaries and interaction with the water column. It is found and reported in [6] that the air mass has been erroneously converted into water. Figures 6(a) to (d) show the time evolution of the conservation errors of the air mass $M(t)$ computed with 80 grid points for the new GFM, the MGFM, and the rGFM. The said errors are given as

$$M(t) = \frac{m_a(t) - m_a(0)}{m_a(0)}, \tag{4.2}$$

where $m_a(t)$ is the total mass of the air in the tube at time t. It can indeed be observed that the conservation errors associated with the air mass appear to be oscillating similar to that observed in [6]. For the new GFM [9], which is especially formulated for the gas-water interface, the trend of the air mass loss looks large (see Figure 6(a)).



(a) new GFM with first-order ENO-LF

(b) MGFM with first-order ENO-LF

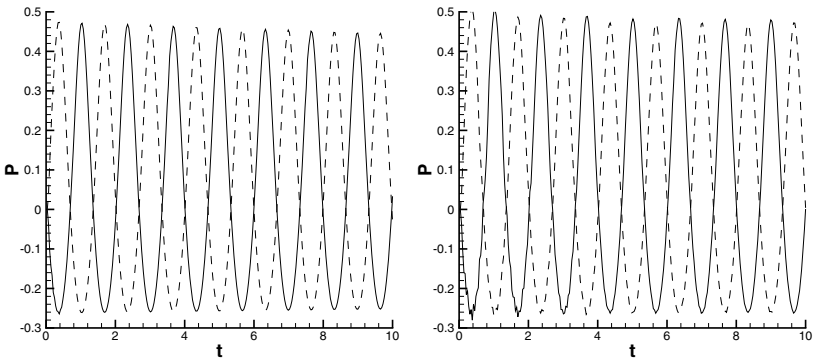
(c) rGFM with first-order ENO-LF

(d) rGFM with third-order ENO-LF

FIG. 6. *Comparison of conservation errors among the new GFM, the rGFM and the MGFM for Case* 2.

With employment of the MGFM, Figure 6(b) also depicts an oscillatory $M(t)$ but with a much gentler trend of net conversion of the air mass into water when compared to Figure 6(a). The results for the rGFM are shown in Figures 6(c) and 6(d) based on the first-order ENO-LF and the third-order ENO-LF, respectively. It is clear that while the amplitude of oscillations for Figure 6(b) is fairly comparable to Figure 6(c) the net conversion of the air mass with time as measured by the slope is obviously gentle for the latter. For Figure 6(d) computed with the third-order ENO-LF, the amplitude of oscillations is about the least and the rate of net conversion is the lowest; in fact, there is no considerable conversion of the air mass to water. The results further suggest that the conservative errors of the rGFM are limited and the rGFM espouses better characteristics than the previous GFMs in treating the interface. Figures 7(a) and (b) show the time evolution of the pressure coefficients at the wall boundaries calculated using the first-order ENO-LF and the third-order ENO-LF rGFM schemes, respectively. The wall pressure coefficients are given as

$$P(x=-1,t)=\frac{p(x=-1,t)-p_0}{p_0},\quad P(x=1,t)=\frac{p(x=1,t)-p_0}{p_0}. \tag{4.3}$$



(a) rGFM with first-order ENO-LF (b) rGFM with third-order ENO-LF

FIG. 7. *Time evolution of the pressure coefficients at boundaries. Solid line: at the left boundary; dashed line: at the right boundary.*

Both Figure 7(a) and Figure 7(b) show that there is a slight decrease of the pressure amplitude with time with the decrease in Figure 7(b) even smaller. It may be noted that an equivalent plot of P versus t in [6] also depicts a decrease of pressure amplitude of oscillations with time. Closer scrutiny suggests that the amplitude decrease for P is slightly smaller for the rGFM.

5. Applications to one- and two-dimensional problems. In this section, several problems are presented to test and further validate the present method and then applied to more challenging problems. In particular, Problem 1 is a gas-gas shock tube problem used previously in [8]. The next test carried out in Problem 2 is a gas shock impacting on a gas-water interface as also shown previously in [22]. Problems 3 and 4 with severe initial conditions are selected to show the ability of the rGFM to solve challenging cases. In Problem 3, the results obtained with the original GFM [8] and the MGFM [22] have been given for comparison. In the supersonic jet impacting case of Problem 4, the shock position as captured by the present method is identical to the theoretical solution. Problem 5, which is actually a one-dimensional axis-symmetric problem for single medium flow, is employed to validate the assembled two-dimensional rGFM code. Finally, the example on Problem 6 gives the interaction of two underwater high-pressure gas cylinders, which can be construed as two underwater explosions. All parameters in the problems are assumed to be nondimensional. It should be mentioned that although only four selected one-dimensional examples are presented below, the rGFM has been employed to test all other one-dimensional problems found in [8, 22], where analytical solutions are available. All results provided via the rGFM compared well to the respective analytical solutions (not shown here).

The approximate Riemann problem solver as detailed in [22, 26] is employed to supply the intermediate states. The calculations for the original GFM, the new GFM, the MGFM, and the present rGFM are carried out using the third-order ENO-LF. It is different from the schemes adopted in [8, 9] and [22], where the third-order ENO-LLF and MUSCL are adopted, respectively. The CFL number is taken as 0.5. For all the one-dimensional problems the computational domain is taken as [0, 1] with 201 nodes uniformly distributed unless stated otherwise.

Problem 1: Shock tube problem [8]. This is a gaseous shock tube problem taken from [8] and the initial condition is given as follows. The interface is set at the

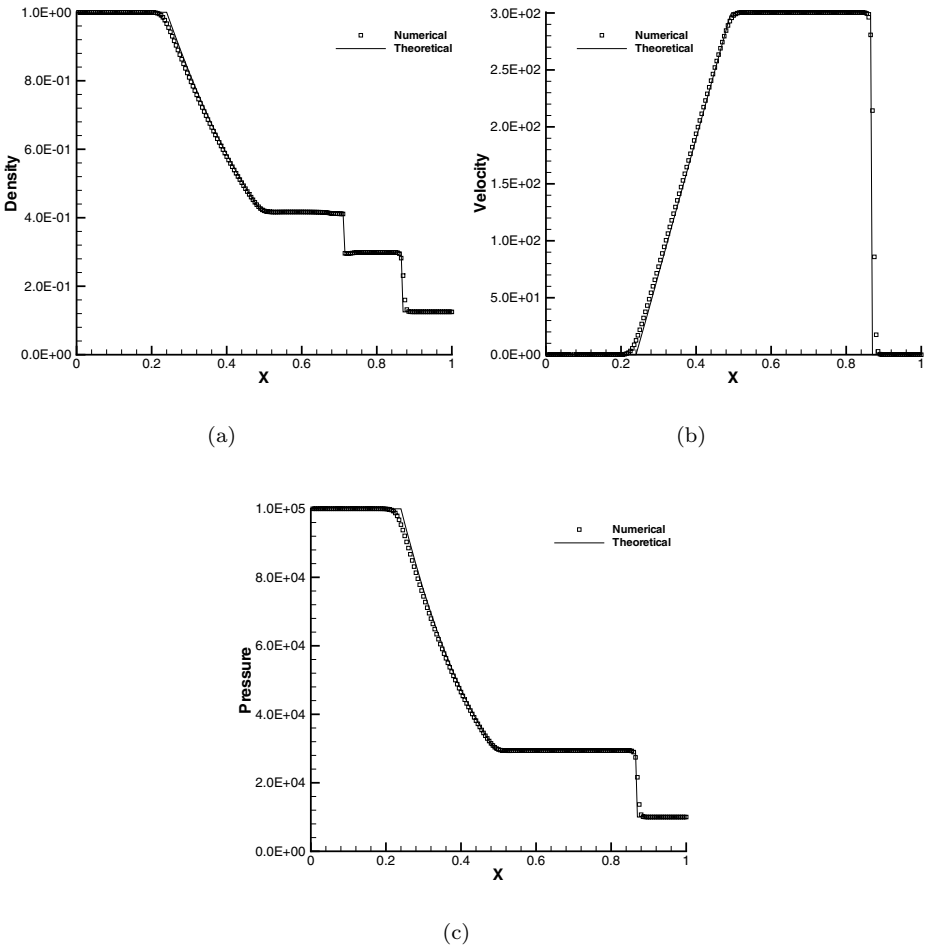


FIG. 8. *Problem* 1*: Comparison of the rGFM results with the theoretical solution at* $t = 0.0007$.

middle of the computational domain [0, 1], the left and the right states are defined respectively as $\gamma_L = 1.4$, $\gamma_R = 1.2$; $\rho_L = 1.0$, $\rho_R = 0.125$; $p_L = 10^5$, $p_R = 10^4$; $u_L = u_R = 0.0$ and $B_L = B_R = 0.0$. Figures 8(a), (b), and (c) show that the density, velocity, and pressure obtained by the rGFM compare reasonably to the theoretical results at time 0.0007. The position of the interface and the shock front are predicted accurately.

Problem 2: Strong shock impacting on a gas-water interface [22]. This is a case taken directly from Problem 7 in [22]. A shock is located at the same position as the interface, which lies between the 100th and 101th node points. The shock is defined as $\gamma_S = 1.4$, $\rho_S = 0.00596521$, $u_S = 911.8821$, $p_S = 1000$ and the states on the left and right sides of the interface are defined respectively as $\gamma_L = 1.4$, $\gamma_R = 7.15$; $\rho_L = 0.001$, $\rho_R = 1.0$; $p_L = 1.0$, $p_R = 1.0$; $u_L = u_R = 0.0$ and $B_L = 0.0$, $B_R = 3309.0$. Figures 9(a), (b), and (c) show that the numerical results obtained by the rGFM agree well with the theoretical results at time 0.0007. The locations of both the interface and the shock front are predicted accurately.

Problem 3: Gaseous shock in impedance-matching medium [22]. In this case a shock on the left side of the interface impacts on a gas-gas interface; this is

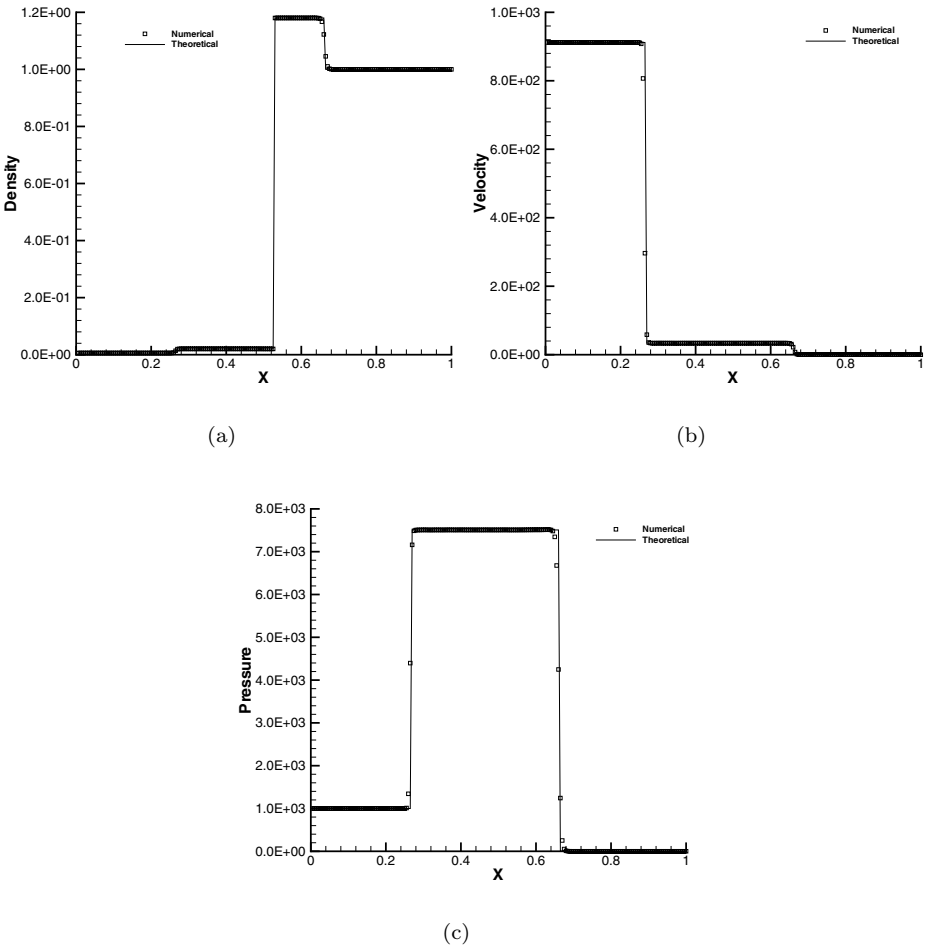

FIG. 9. *Problem 2: Comparison of the rGFM results with the theoretical solution at* $t = 0.0007$.

identical to Problem 6 in [22]. The shock strength is 100 and the initial position of the shock is same as the interface, which is located at $x_I = 0.2$ of the domain $[0, 1]$. The states on the left and right sides of the interface are defined respectively as $\gamma_L = 1.667$, $\gamma_R = 1.2$; $\rho_L = 0.82369077$, $\rho_R = 1.0$; $p_L = 1.0$, $p_R = 1.0$; $u_L = u_R = 0.0$ and $B_L = B_R = 0.0$. Based on the analysis on the interaction of the shock reflection at the interface, the shock is transmitted to the right side of the interface and there is no reflection of any kind. However, the calculation with the original GFM and the MGFM shows the obvious presence of nonphysical reflection, which occurs due to the inability of accurately imposing the shock impedance matching (-like) condition at the interface [22, 23]. Whether the nonphysical reflection is a rarefaction wave or compressive wave (shock) can be ascertained or determined beforehand for the original and new GFMs as discussed in [23]. Shown in Figures 10 and 11 are the respective results obtained by the original GFM and the MGFM at time $t = 0.06$. Already, there is marked improvement in the results of the MGFM where the nonphysical hump in the profile is greatly diminished compared to the original GFM [8]. For this same gas-gas problem, very severe nonphysical reflection occurs for the results using the new GFM [9] and is not presented here. Theoretically as discussed at length in [22],

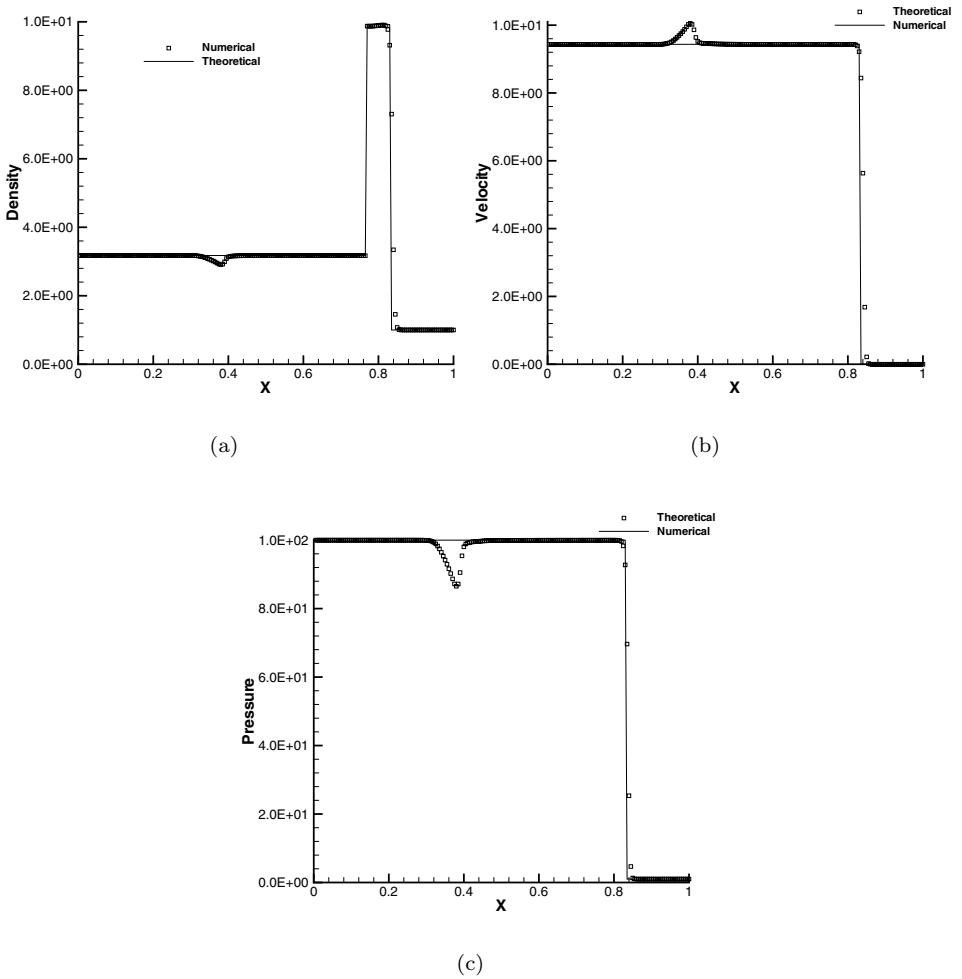

FIG. 10. *Problem 3: Comparison of the original GFM results with the theoretical solution at* $t = 0.06$.

such nonphysical reflection is indeed very difficult to remove completely. On the other hand, Figures 12(a), (b), and (c) show the density, velocity, and pressure obtained by the rGFM; these results clearly depict further improvement compared to the MGFM, although the reflection is still about perceptible.

Problem 4: Jet impact on the gas-water interface. This is an even more challenging problem. The initial conditions are given as follows: $\gamma_L = 1.4$, $\gamma_R = 7.15$; $\rho_L = 1.0$, $\rho_R = 1000.0$; $p_L = 1.0$, $p_R = 1.0$; $u_L = 90.0$, $u_R = 0.0$; and $B_L = 0.0$, $B_R = 3309$. The interface is located initially at $x_I = 0.6$. The results are obtained at time $t = 0.015$. Figure 13 shows the results calculated using the MGFM, while Figure 14 depicts the counterpart obtained via the rGFM. As analyzed in section 4.2, the not-so-perfect simultaneous decomposition of the singularity at the first few time steps of the shock interacting with the interface using the MGFM has resulted in a slightly faster left-moving shock wave, as can be observed in Figure 13(b) or (c). On the other hand, the computation with the present rGFM depicted in Figure 14 shows that the density, velocity, and pressure concur very well with the theoretical results.

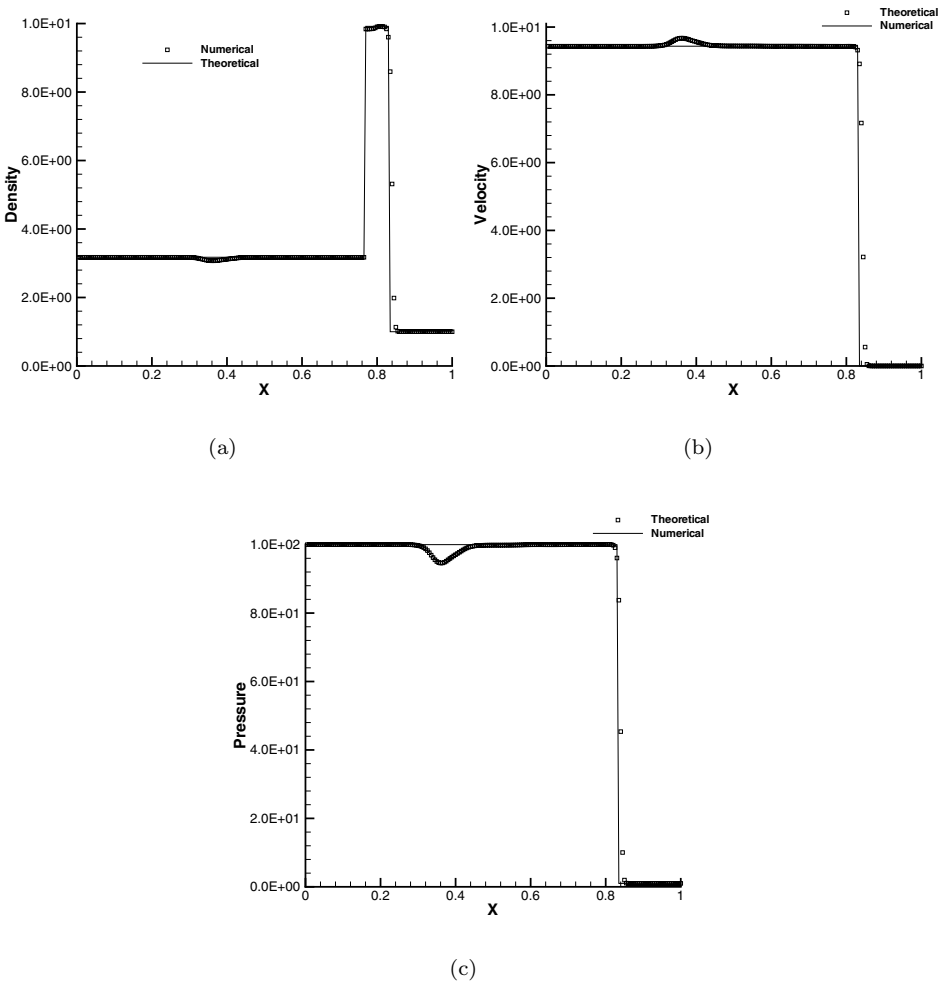

FIG. 11. *Problem 3: Comparison of the MGFM results with the theoretical solution at* $t = 0.06$.

Problem 5: A two-dimensional gaseous explosion in air. We consider a (pure air) single medium flow problem to test the assembled two-dimensional code for the rGFM. The computational domain is taken as $[0, 1] \times [0, 1]$. A gaseous bubble with a radius of 0.1 is located at the center of the domain. The state inside the bubble is $\gamma_1 = 1.4$, $\rho_1 = 1.0$, $u_1 = 0.0$, $v_1 = 0.0$, $p_1 = 100.0$; the state outside the bubble is $\gamma_2 = 1.4$, $\rho_2 = 1.0$, $u_R = 0.0$, $v_2 = 0.0$, $p_2 = 1.0$. This is actually a one-dimensional axis-symmetric problem for single medium flow. Hence we can simulate this problem using the third-order ENO-LF in conjunction with the third-order TVD Runge–Kutta method for the whole computational domain without involving any special treatment for the interface (the results are termed as ENO-LF in the plots) for comparison to the rGFM. The computational domain is divided uniformly by 201×201 nodes.

For this problem, once the diaphragm separating the high and low pressure sides is removed, a strong shock is generated and propagates radially outward. Simultaneously, a rarefaction wave is generated and traveling toward the center of the gas bubble, and a contact discontinuity (interface), across which a density jump occurs,

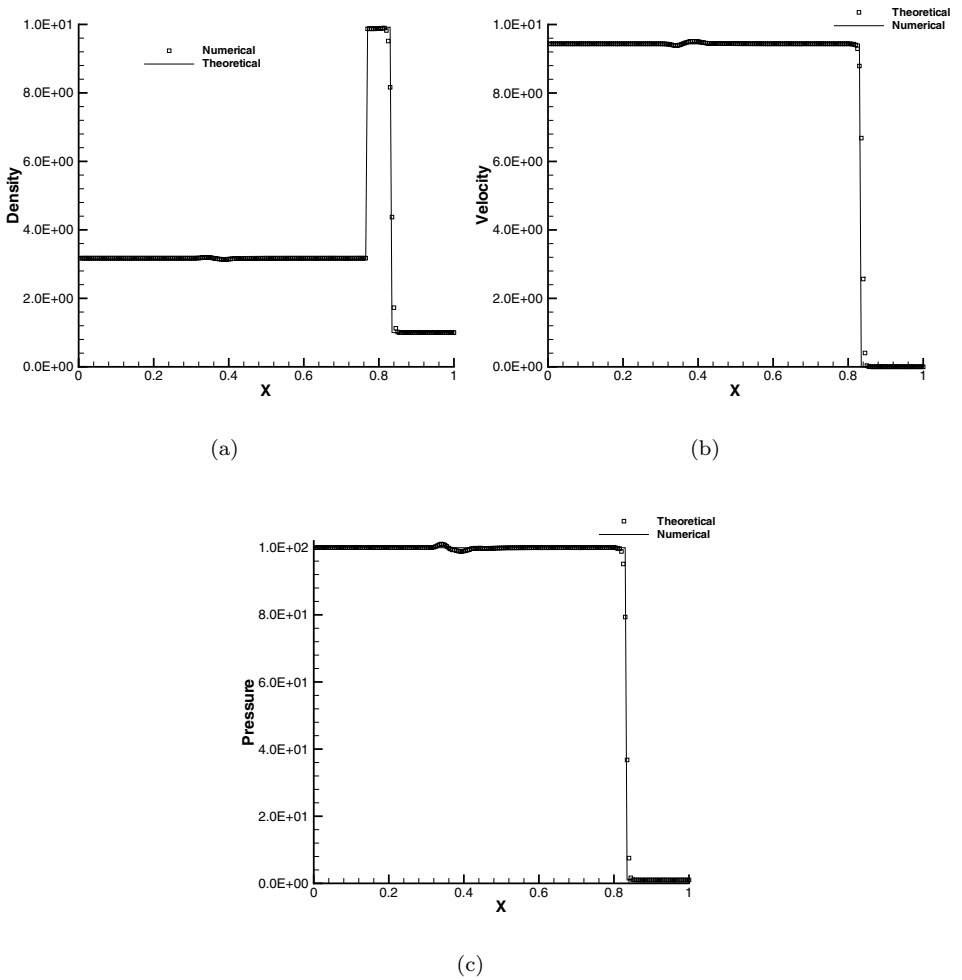

FIG. 12. *Problem 3: Comparison of the rGFM results with the theoretical solution at* $t = 0.06$.

is created. Due to overexpansion, a shock is generated inside the expanding gas bubble; this shock subsequently implodes and is reflected at the bubble center [32]. Figures 15(a), (b), and (c) show the results obtained by both methods at the time of $t = 0.04$. From the figure we can see that there is fair concurrence of results between the rGFM and the single medium ENO-LF except that the former provides a sharp interface while the latter indicates a rather smooth transition (see Figure 15(a)). One can also note that the velocity and pressure provided by the present rGFM is not so smooth across the interface as shown in Figures 15(b) and (c). Such phenomenon is physical and one should strictly detect in the flow a contact discontinuity in the density plot. In fact, the pressure gradient across a contact discontinuity should satisfy the following equality [33] for an axis-symmetric problem:

$$\frac{1}{\rho^-}\frac{\partial p^-}{\partial n} = \frac{1}{\rho^+}\frac{\partial p^+}{\partial n}, \tag{5.1}$$

where the superscript $+$ and $-$ indicate the flow states on each side of the interface, respectively, and n indicates the normal direction of the interface. Equation (5.1)

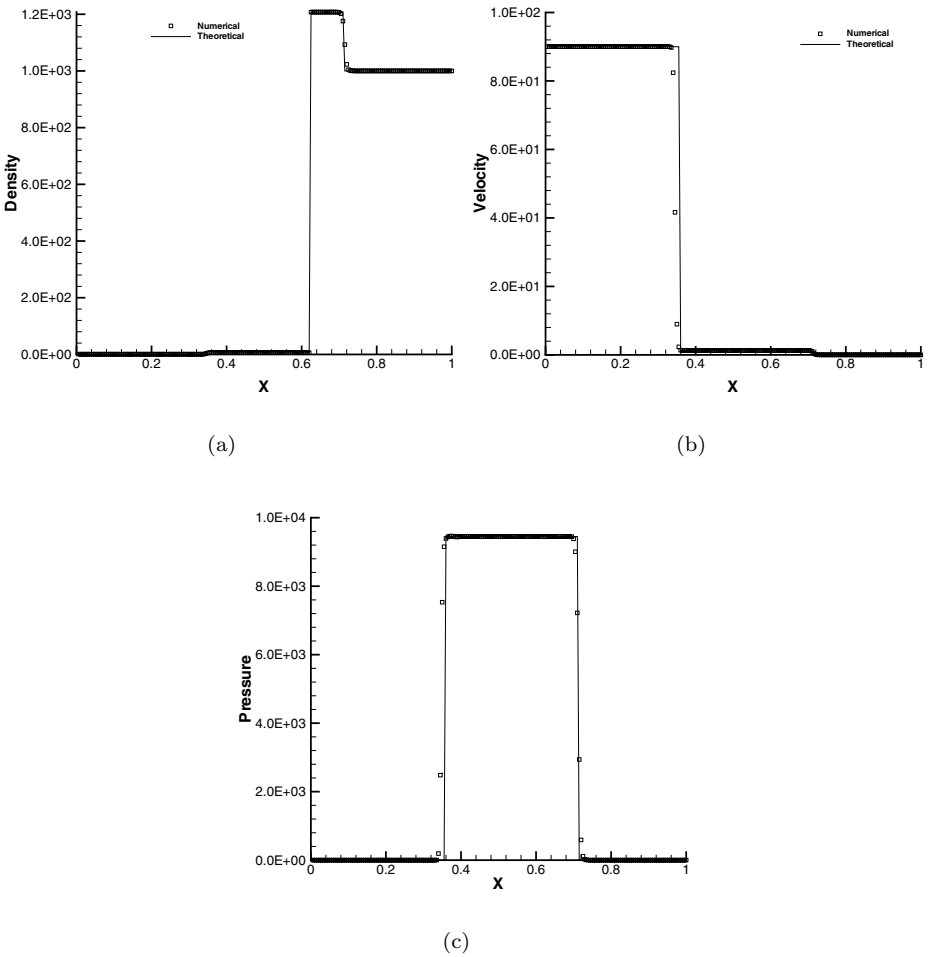

FIG. 13. *Problem 4: Comparison of the MGFM results with the theoretical solution at* $t = 0.015$.

reveals that the pressure gradient is discontinuous across the interface if the pressure gradient is not equal to zero (see Figure 15(c)) due to the density jump across the contact discontinuity. This in turn leads to the jump of the velocity gradient across the interface as shown in Figure 15(b). In Figure 15(c), it is clear that the pressure gradient is not quite equal to zero at the location of the interface.

Problem 6: A two-dimensional double underwater explosion. Two underwater explosions are initialized by two highly pressurized gas bubbles of equal dimensions. The computational domain measures $[0, 4] \times [0, 4]$ with 201×201 nodal points uniformly distributed, and the centers of two bubbles are located at $(1.4, 2)$ and $(2.6, 2)$ with an initial radius of 0.3 each. The flow state inside each bubble is defined as $\gamma_g = 1.4$, $\rho_g = 1000.0$, $p_g = 10^8$, $u_g = 0.0$, $v_g = 0.0$, and $B_g = 0.0$, and the region outside the two bubbles takes on the flow state $\gamma_w = 7.15$, $\rho_w = 1000.0$, $p_w = 10^5$, $u_w = 0.0$, $v_w = 0.0$, and $B_w = 3309.0$. A schematic of the problem is provided in Figure 16. Once the explosions are initiated, two main shock waves are generated and travel radially outward in the water. At time $t = 1.751 \times 10^{-4}$, the two main shock waves intersect and their subsequent interaction leads to two reflected shock waves traveling in the water but in the opposite directions. These two reflected

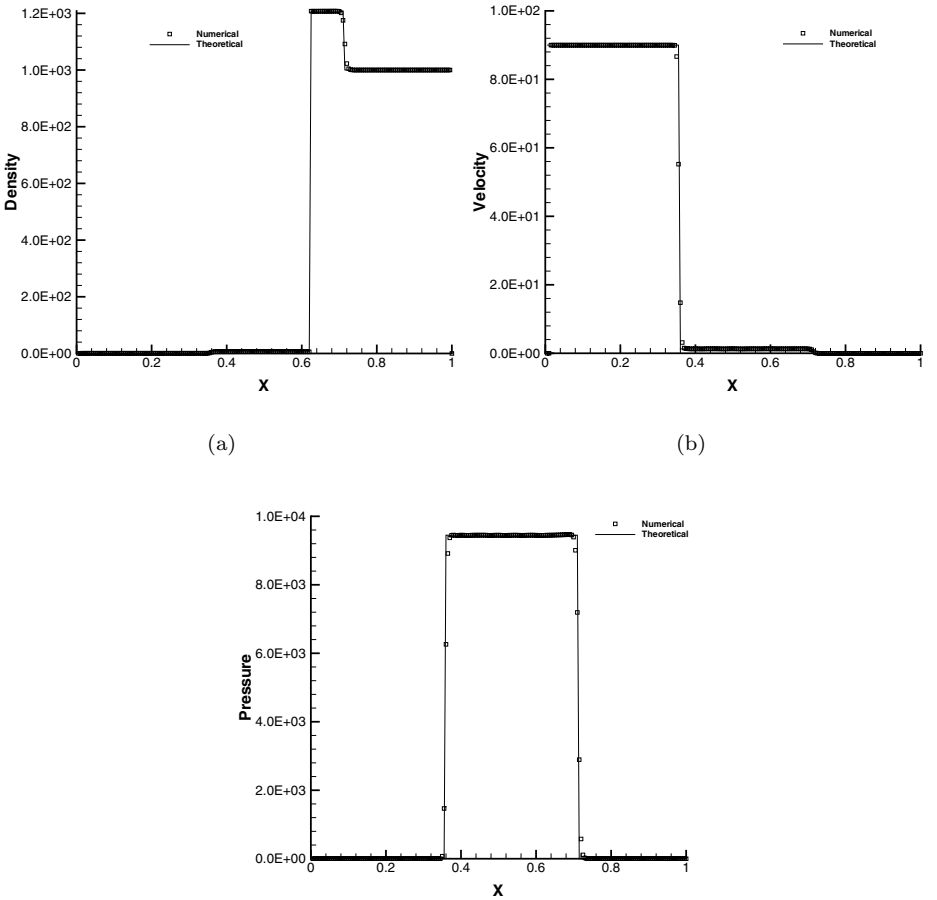

FIG. 14. *Problem 4: Comparison of the rGFM results with the theoretical solution at* $t = 0.015$.

shock waves reach the bubble interface at time $t = 3.450 \times 10^{-4}$. From [34] one may know that the reflection of the shock wave off each bubble surface is a rarefaction wave and the transmission into each gaseous bubble is a shock wave. A time sequence of pressure contours is presented in Figures 17(a), (b), and (c). Figure 17(a) (at $t = 1.172 \times 10^{-4}$) shows the two main shock waves traveling outward in the water before they intersect, and the two shock waves are reflected after their interaction as depicted in Figure 17(b) at $t = 2.888 \times 10^{-4}$. In Figure 17(c) the pressure contours at $t = 4.572 \times 10^{-4}$ indicate two rarefaction waves are reflected back into the water and two shock waves are transmitted inside each bubble due to the shock refraction at the bubble surfaces. Figure 18 is the plot of the level set contours at the same time as for Figure 17(c). One can notice that no contour distortion is found, and all the contour lines are nearly uniformly distributed; this demonstrates the efficiency of the present level set technique.

6. Conclusions. In this work, the rGFM algorithm has been presented. By predicting the flow states at the real fluid nodes next to the interface using the Rie-

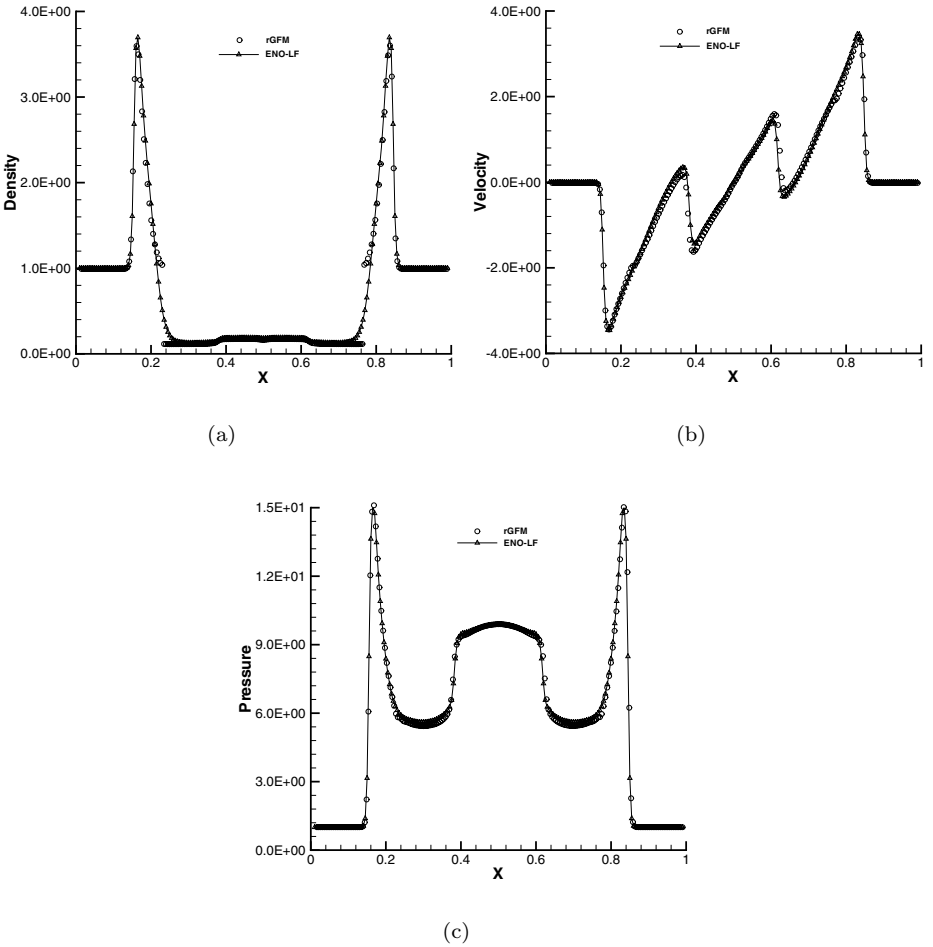

FIG. 15. *Problem 5: Comparison of the rGFM results with the ENO-LF results at* $t = 0.04$.

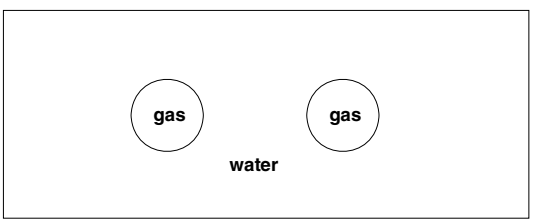

FIG. 16. *Schematics of the computational domain.*

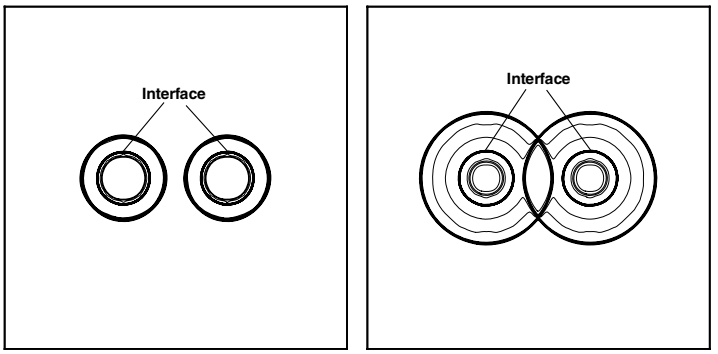
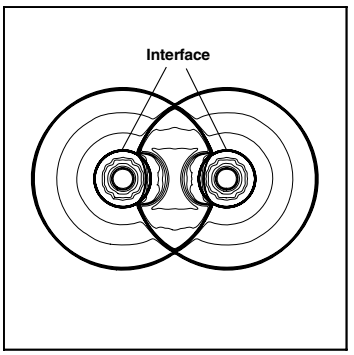
mann problem solver, a more accurate interface boundary condition can be provided for which has been supported by both theoretical analysis and numerical results. A simple yet efficient extension of the present rGFM to multidimensions has also been introduced. In order to overcome the difficulties associated with the severe distortion of the level set contours in the region of the material interface where the large flow velocity gradient may exist, an extension velocity field was constructed to advance



(a) $t = 1.172 \times 10^{-4}$ (b) $t = 2.888 \times 10^{-4}$



(c) $t = 4.572 \times 10^{-4}$

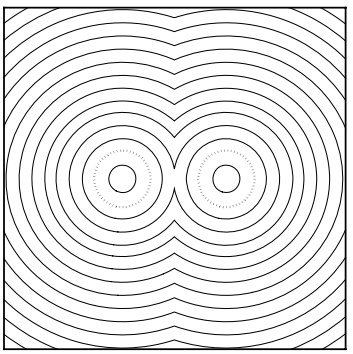

FIG. 18. *Problem 6: Level set contours at* $t = 4.572 \times 10^{-4}$. *The dotted line is the interface.*

the level set function. The present method has been applied to various problems involving strong shock-interface interaction and complex flow physics. The results obtained have clearly indicated that the present method is not problem related and can be employed to various equations of state.

DOI. 10.1137/040618953

Abstract. In this paper a new stochastic algorithm for the solution of population balance equations is presented. The population balance equations have the form of extended Smoluchowski equations which include linear and source terms. The new algorithm, called the linear process deferment algorithm (LPDA), is used for solving a detailed model describing the formation of soot in premixed laminar flames. A measure theoretic formulation of a stochastic jump process is developed and the corresponding generator presented. The numerical properties of the algorithm are studied in detail and compared to the direct simulation algorithm and various splitting techniques. LPDA is designed for all kinds of population balance problems where nonlinear processes cannot be neglected but are dominated in rate by linear ones. In those cases the LPDA is seen to reduce run times for a population balance simulation by a factor of up to 1000 with a negligible loss of accuracy.

1. Introduction.

The study of population balance problems for collections of particles that interact with each other via collisions has a long history—Bird [3] used this approach for gas dynamics in the 1970s. More recent applications include atmospheric aerosols (see, e.g., [4] and the references given there) and particle synthesis in flames [17].

In these later cases interactions between the particles and the surrounding gas which operate linearly on the particle population have to be considered in addition to particle-particle interactions which have nonlinear effects. Work by some of the authors of this present paper on the formation of soot in laminar premixed flames [2, 14] showed that a large amount of computer time was being devoted to the linear processes of particle-gas interactions.

The purpose of this paper is to present a new algorithm that we call the linear process deferment algorithm (LPDA) and which reduces the time required for simulations. We also compare this new method to the general numerical analysis technique of splitting. LPDA is applicable to population models of systems other than soot where nonlinear processes are important but dominated in rate by linear ones.

In this paper we first set out the population balance problem for soot formation and growth that we seek to solve. Then we give the structure of our original simulation procedures, the direct simulation algorithm (DSA). Detailed measurements of the

computer time used in different parts of this method motivate the introduction of operator splitting. The splitting provided accelerations and a framework to investigate methods for simulating linear processes which are then reused in our new algorithm. We present the LPDA and its stochastic basis and conclude with some comparisons between the algorithms considered in the paper.

2. Outline of general soot model. We assume

1. Individual soot particles may be completely described by elements of some type space E on which addition corresponding to coagulation is defined.

2. The soot population is described at time t by the number $n(t,x)$ per cm^3 of particles of type $x \in E$.

3. The function n evolves according to the discrete Smoluchowski coagulation equation:

$$\frac{\mathrm{d}}{\mathrm{d}t} n(t,x) = \left(\mathcal{K}_t(x) + \sum_{l \in \mathcal{U}} \mathcal{S}_t^{(l)}(x) \right) (n(t,\cdot)) + I(t,x). \tag{2.1}$$

In these definitions we make the implicit assumption that E is countable so that summations are meaningful. This assumption is common in the literature but not essential and later in this paper it will be removed by replacing the sums with integrals. The (time-dependent and nonlinear) coagulation operator $\mathcal{K}$ is then defined by

$$\begin{aligned} \mathcal{K}_t(x)(n(t,\cdot)) = {} & \frac{1}{2} \sum_{y,z \in E : y+z=x} K_t(y,z)\, n(t,y)\, n(t,z) \\ & - \sum_{y \in E} K_t(x,y)\, n(t,x)\, n(t,y). \end{aligned} \tag{2.2}$$

The first sum represents coagulation to form particles of type x and the second loss of particles of type x due to coagulation. $K_t(x,y)$ defines a map from the concentrations of particles of types x and y to their coagulation rate at time t given by $K_t(x,y)\, n(t,x)\, n(t,y)$. K is known as the coagulation kernel and we use the transition kernel given in [14].

Surface reactions which only involve one physical particle at a time are described by the linear operators $\mathcal{S}^{(l)}$ defined by

$$\mathcal{S}_t^{(l)}(x)(n(t,\cdot)) = \left(\sum_{y \in E} \beta_t^{(l)}(y)\, \mathbb{P}\left(g^{(l)}(y) = x \right) n(t,y) \right) - \beta_t^{(l)}(x)\, n(t,x) \tag{2.3}$$

for $l \in \mathcal{U}$, an index set for the surface reactions, according to our flame model we use, (see [1, 14]),

$$\mathcal{U} = \{ \mathrm{C_2H_2} \text{ addition}, \mathrm{OH} \text{ oxidation}, \mathrm{O_2} \text{ oxidation}, \text{pyrene condensation} \}.$$

$\beta_t^{(l)}(x)$ is the rate at which a particle of type x undergoes surface reaction l at time t.

$g^{(l)}(x)$ is the type of the result of a particle of type x undergoing surface reaction l or if the reaction removed the particle from the soot population the value will be $0 \in E$. We allow for $g^{(l)}$ to be a random function; in the deterministic case the probability in (2.3) is to be understood as an indicator function.

$I(t,x)$ is the rate at which particles of type x enter the system at time t; throughout our work we have assumed this is zero except when x describes a spherical particle of 32 carbon atoms (C atoms).

The gas phase chemistry (see [1]) needed to calculate I and the $\beta^{(l)}$ etc. is simulated separately with a method of moments approximation [7].

No boundary conditions are specified at this stage although in general we will use $n(0,x) = 0$ for all $x \in E$ since a small element of flow has no soot in it when it enters the flame.

We assume all particles to be spheres, all of the same density, so we take $E \subseteq \mathbb{R}_0^+$ and let x be the mass or the volume of the particle it describes.[1] It is then convenient to take $E = \mathbb{N}$, where $x \in E$ is the number of C atoms in a particle it describes. Addition is defined just as for the natural numbers: the result of the coagulation of two spheres is a new sphere with volume equal to the sum of the volumes of the initial spheres, i.e., coagulation is completely coalescent.

Different coagulation kernels are appropriate in different conditions; these are also used to model the pyrene condensation and inception processes. For details see [14]. All the work in this paper was carried out using the transition regime kernel. We have not found the use of more specific kernels to affect the results.

3. Direct simulation. The DSA [5] is the basic stochastic approach to solving equations like (2.1) and forms the starting point of our work. Our implementation is described in [8, 14]; however, we use a binary tree method for particle selection as this enables the use of more complex soot models. Various similar methods are discussed in [11], along with a detailed performance analysis. An essential assumption underlying much of the work in later sections of this paper is that DSA can be used to generate solutions of arbitrary precision for (2.1). Excellent reasons for accepting this assumption are provided by the mathematical proofs of a simplified version of it presented in [5, 6] and in the numerical tests reported in [13, 14].

3.1. Variation in number of particles. In a direct simulation on a computer of a chemical system where the number of particles may increase and decrease one has to limit the number of particles being tracked in the simulation. We do this by setting a maximum number of particles and when we wish to add a particle that would cause us to exceed this limit we rescale the volume for which soot formation is being simulated to reduce the number of particles by 1, the particle to exclude from the simulation is chosen uniformly at random from the entire ensemble. As coagulation or oxidation reduces the number of particles being simulated the accuracy of the simulation is also reduced. Therefore when the number of computational particles in the simulation drops below one half the maximum number we double the sample volume and duplicate each particle that is being simulated.

An introduction to this kind of issue is given in [15]. We tried a form of constant number algorithm by extending the method described above for use every time particles were removed from the simulation volume but found that for simulations of some artificial test cases this led to a much greater statistical uncertainty (around 1 order of magnitude in the first few moments of the distribution) in the results compared to using particle doubling. This is consistent with the results in [12]; therefore we use only particle doubling in our simulations.

3.2. Complexity of our implementation. For a binary tree with l levels (capacity 2^l particles) each event requires $O(l)$ operations. Selecting a particle involves reading one node on each level of the tree. Updating the tree when a particle has changed requires updating one node on each level of the tree (following the path to the root of the tree).

[1] The preceding formulation assumes the countability of E; this requirement is removed later.

TABLE 1
Illustrative results.

flame	tree depth	repetitions	m2 uncertainty	time / min
JW1.69	13	10	2.3%	50
JW1.69	10	30	6.8%	16.5
JW10.68	11	20	1.5%	4020
JW10.68	10	20	2.9%	1534

TABLE 2
Frequency of stochastic events.

	JW1.69	JW10.68
time steps	1.25×10^9	2.06×10^9
surface events (not pyrene)	1.20×10^9	2.05×10^9
pyrene condensation	4×10^7	1×10^7
coagulation	5×10^6	4×10^5
inception	4×10^6	2×10^5

The number of events scales linearly with the sample volume, V, as does the number of particles. Hence for reasonable choices of V and l (those for which the full capacity of the tree is used) a simulation will need a tree with $O(\log V)$ levels and will have a run time that is $O(V \log V)$.

3.3. DSA applied to flames. Most of the work in this paper focuses on simulating two premixed laminar flames studied in [10]—JW1.69 and JW10.68. The first is a 1-bar flame with equivalence ratio 0.69 and a peak soot volume fraction of approximately 2×10^{-8}, the second a 10-bar flame with equivalence ratio 0.68 and a peak soot volume fraction of approximately 2×10^{-6}. These soot volume fractions are at the extremes of the range studied in [10].

We performed simulations using different numbers of computational particles and varying numbers of repetitions getting some idea of systematic error in moments 0 to 3 of the final size distribution due to using a low number of computational particles (this error was generally small) and the number of repetitions needed to control the statistical noise. Some initial results follow in Table 1. "m2" refers to the second moment of the mass distribution, and the uncertainty is the half width, using a central limit theorem estimate, of the 95% confidence interval for the mean of the distribution being sampled (that of m2).

The run times for JW10.68 indicate that DSA as we have implemented it is not a very practical tool for investigating sooty flames on a desktop computer. In order to inform our attempts to reduce the run times we used the standard technique of profiling to find out what parts of the program consumed most of the execution time.

3.3.1. Profiling of DSA simulation. Table 2 shows the number of each type of event performed during 10 runs of a simulation of the premixed flame JW1.69 and 20 runs of JW10.68. JW1.69 was simulated with 16 tree levels and an initial sample volume of 2.8×10^{-7} cm^3, JW10.68 with a tree depth of 10 and an initial sample volume of 1.25×10^{-9} cm^3. Note that twice as many events are shown for the JW10.68 case as for the JW1.69 case although the sample volume is 200 times smaller. Pyrene condensation is reported separately from the other surface events because the physical model for the process is significantly different from that for the other surface reactions in $\mathcal{U}$ and the computational implementation is therefore different as well.

The main conclusion to be drawn from Table 2 is that essentially all the events are surface events and that there are not many pyrene events compared to the other

events. One may also note that coagulation events are even more rare than pyrene events.

To check exactly which parts of our program took longest to execute we used a profiler to measure the time spent in each function. The data were obtained over five runs simulating JW1.69 with a tree depth of 12 and an initial sample volume of 1.75×10^{-8} cm^3. We found that 64% of the execution time was consumed in functions that calculated the random time steps. These parts of the program are key to the simulation of a nonlinear coagulation process but are not fundamental for the surface processes since the surface growth for a single particle is simply a nonhomogeneous Poisson process until the time that particle is involved in a coagulation and which, conditional on the coagulation time, does not depend on the other particles. However, most of these time steps are simply concerned with the surface processes and not coagulation. A considerable amount of the 31% of time spent in functions that updated our computational particle ensemble to reflect the simulated surface events was also attributable to the binary tree structure necessary for simulating coagulation.

We profiled simulations of JW1.69 rather than JW10.68 because profiling leads to a very large increase in run times and so profiling JW10.68 was not feasible given the large run times for the basic simulations reported in Table 1.

3.3.2. Conclusions from DSA profiling. We note that

1. Almost all the computational time is spent simulating surface processes.
2. These surface processes are simulated in a framework designed for a different purpose.
3. In JW10.68 the preponderance of surface events is even greater (see Table 2) than for JW1.69, so an even greater proportion of time will be spent simulating surface processes.

We therefore looked at alternative ways of incorporating the surface processes into our simulations in the hope of reducing run times.

4. Operator splitting. In (2.1) we see the evolution of the particle distribution is driven by three kinds of process:

1. Coagulation—two particle events;
2. Single particle events,
   (a) Surface area processes,
   (b) Pyrene condensation;
3. Particle inception—involves no preexisting particles.

We know from the analysis above that most of the time taken in a simulation is spent updating the binary tree after events under 2(a). Operator splitting ([9] gives far more material than we use here) is an approach to numerically solving differential equations that allows us to introduce different methods to solve for the effects of single particle events.

4.1. Mathematical outline of splitting. Consider, for some operators $\mathcal{A}$ and $\mathcal{B}$, the ODE which we assume to have a unique, well-behaved solution

$$\begin{aligned} \frac{\mathrm{d}}{\mathrm{d}t} f &= (\mathcal{A} + \mathcal{B})(f), \\ f(0) &= f_0. \end{aligned} \tag{4.1}$$

The easiest way to numerically compute the solution over time is based on the idea that for small h

$$f(t+h) - f(t) \approx h(\mathcal{A} + \mathcal{B})(f)(t).$$

This is the basis of DSA where we simulate all the different processes simultaneously—the jump rate of every process depends on the current state of the particle ensemble.

However, at the cost of introducing a further approximation and by assuming that the resulting ODEs have well-behaved solutions, one can define auxiliary functions f_1, f_2 and advance the solution over a small time interval $[t_0, t_0 + \delta t]$ by solving with whatever numerical schemes one considers appropriate first,

$$\begin{aligned} \frac{\mathrm{d}}{\mathrm{d}t} f_1 =& \mathcal{A}(f_1), \\ f_1(t_0) =& f(t_0), \end{aligned} \tag{4.2}$$

and then

$$\begin{aligned} \frac{\mathrm{d}}{\mathrm{d}t} f_2 =& \mathcal{B}(f_2), \\ f_2(t_0) =& f_1(t_0 + \delta t). \end{aligned} \tag{4.3}$$

The key point is that completely different numerical methods may be used to solve (4.2) and (4.3).

4.2. Implementation of operator splitting. We split (2.1) into two parts by handling OH oxidation and C_2H_2 addition (sometimes also the insignificant process of O_2 oxidation) separately from all the other processes which are simulated in exactly the same way as in the DSA. We typically performed this splitting over time intervals of a length such that each particle would, on average, undergo r surface reactions during a splitting step where r was a positive but not necessarily integer valued parameter. The choice of r was the way we determined the length of the splitting step and so the accuracy and speed of the approximation.

The steps in advancing a simulation over times t from t_0 to t_1 are (t_2 and t_3 are auxiliary times):

1. $t \leftarrow t_0,\ t_2 \leftarrow t_0$
2. WHILE($t < t_1$)
   (a) Choose a step length $\triangle t$ and set $t_2 = t + \triangle t$. We choose $\triangle t$ as the time in which $n \times r$ events due to the split processes would be expected under DSA. n is the number of computational particles. Various conditions may lead to large values of $\triangle t$ being calculated—these must be reduced.
   (b) Perform the unsplit processes including coagulation from t to t_2 exactly as for DSA using the binary tree.
   (c) Extract a list of particles from the binary tree.
   (d) WHILE($t < t_2$)
      i. Choose a secondary time step length δt such that the chemical conditions vary only slightly over the time interval $[t, t + \delta t]$ and $t + \delta t \leqslant t_2$.
      ii. $t_3 \leftarrow t + \delta t$
      iii. Simulate the split processes up to t_3 for each particle. Methods for doing this are discussed below.
      iv. $t \leftarrow t_3$
      v. Return to top of the loop—2(d)
   (e) Put the updated computational particles back into the binary tree. (We should now have $t = t_2$)
   (f) Return to the top of the loop—2
3. Stop

4.2.1. Simulating split events for one particle. Exactly the same method as is used in DSA was applied to individual computational particles. We generated the inhomogeneous Poisson process referred to in section 3.3.1 by repeatedly calculating the exponentially distributed waiting times and performing events at their end points. We refer to this method as PP in later sections.

In order to further reduce the computational effort we introduced a second level of splitting. By dealing with the split processes one by one and making a further approximation we only have to generate one random variable per process per particle as follows:

1. Calculate the rate for the selected process at the start of the interval.
2. Assume this rate applies throughout the interval (e.g., ignoring the effects of the particle size changing) and so calculate the expected number of events λ.
3. Generate a random variable with the Poisson (λ) distribution as the number of events which actually occur and update the computational particle accordingly.

We refer to this method as PV (Poisson variable) in later sections.

4.2.2. Complexity. We perform the split surface processes without using the binary tree; this avoids the $O(\log n)$ update operations (n is the number of stochastic particles which should be roughly the same as the capacity of the binary tree) after each event that were slowing the simulations down. Instead, after performing surface reactions, an $O(1)$ operation, on each of the $n \sim O(V)$ particles individually for the full length of the splitting time step, we then completely rebuild the binary tree, which takes $O(n) \sim O(V)$ time.

Therefore the surface processes which previously had overall complexity $O(V \log V)$ in the sample volume V now have only complexity $O(V)$; contrast section 3.2. Since the surface processes dominate the simulation (see Table 2), this should reduce the apparent complexity of the simulation.

4.3. Numerical results.

4.3.1. Comparison of JW1.69 moments. We present some results for JW1.69 (one of the laminar premixed flames studied in [10]) generated using our implementations of operator splitting and compare to DSA results generated as described above. We used JW1.69 because it provides a realistic test case that can be simulated quickly and also for historic reasons.

Table 3 gives a summary of the simulations performed and the computer time they took. All timed simulations were performed using a binary tree of depth 13 and with an initial sample volume of $3.5 \times 10^{-8}\text{cm}^{-3}$. The simulations reported in this paper were generated using PCs with either 2.4 GHz Pentium 4 or 2 GHz Athlon CPUs. Both configurations were found to give almost identical performance on test cases.

TABLE 3
Detail of operator splitting runs for JW1.69.

algorithm	r	time for 10 repetitions / min
DSA	0	50
PV	1	30
PV	2	16
PV	5	8
PV	10	5.5
PP	5	12.5
PP	10	10

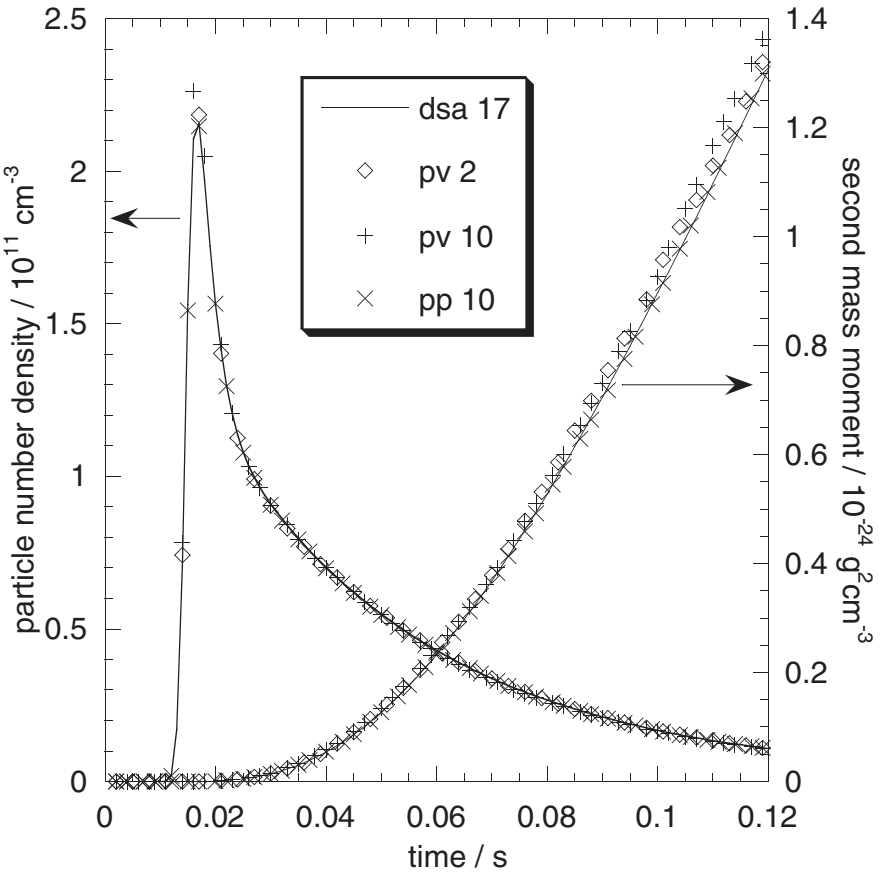

FIG. 1. *Operator splitting for* JW1.69.

With the PV algorithm we see a considerable speed increase as we move from $r = 0$ (DSA) to $r = 5$ with speed being almost linear in r but changing r from 5 to 10 makes very less difference to the execution time. We expect the bottleneck to be the inner loop of the algorithm set out in section 4.2. The PP splitting leads to longer run times than the PV because of the way each surface event is handled individually.

However, speed is not everything—one also has to consider the error introduced by the splitting approximation, so in Figure 1 we show the time evolution of the zeroth and second moments of the particle size distribution in a small volume element passing through the flame. To show the error introduced by the splitting we also plot results obtained using DSA with 30 repetitions, a binary tree depth of 17, and an initial sample volume of $5.6 \times 10^{-7}\text{cm}^{-3}$. We believe these results are indistinguishable from the true solution on the scale shown.

We see that the splitting only introduces a very modest error in the second moment of the distribution, at least for $r \leqslant 5$, compared to the high precision DSA. For the first moment the error will be smaller.

4.3.2. Particle distribution accuracy. One of the advantages of stochastic simulations is that one gets a complete description of the particle size distribution. We present details of this for the flame JW10.68 (see [10]). JW10.68 is a much sootier flame than JW1.69 and so provides a test in a situation where soot is significant. As

TABLE 4
Detail of operator splitting runs for JW10.68.

algorithm	r	time for 10 repetitions / min
DSA	0	2010
PV	5	134
PV	10	86
PP	20	250
PP	50	235

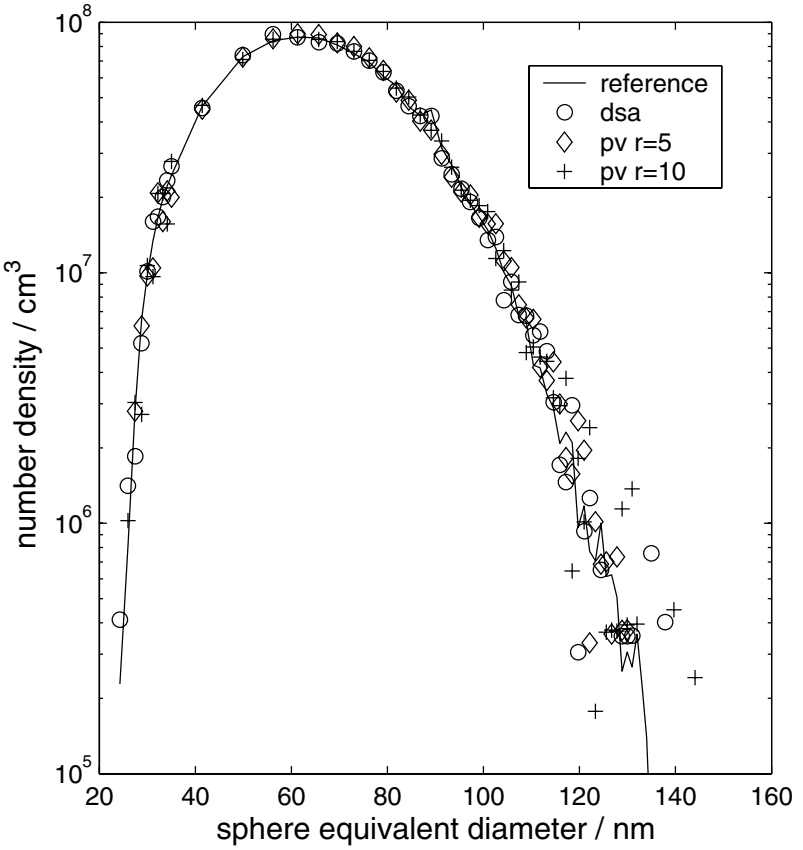

FIG. 2. *Final particle size distribution for* JW10.68.

can be seen, it is also far more computationally demanding. Table 4 gives details of the simulations we performed using a binary tree depth of 11 and an initial sample volume of $2.5 \times 10^{-9}\text{cm}^{-3}$ on the PCs described above.

The acceleration due to splitting is much larger for this flame than for JW1.69 (see Table 3)—a factor of 30 compared to one of 6 for DSA to PV $r = 5$. Further increases in r were found to offer much smaller speed gains with the PV algorithm while the PP algorithm times appear to have only a weak dependence on r, suggesting the time limiting step is the event-by-event simulation of the split processes.

Figure 2 shows the particle distributions obtained from the first three simulations described in Table 4. The distribution calculated from a set of 10 DSA runs using a binary tree depth of 14 is also shown as a reference curve; the simulations to generate this took 13 days of PC time! It can be seen that the factor of 8 ($= 2^{14-11}$) increase

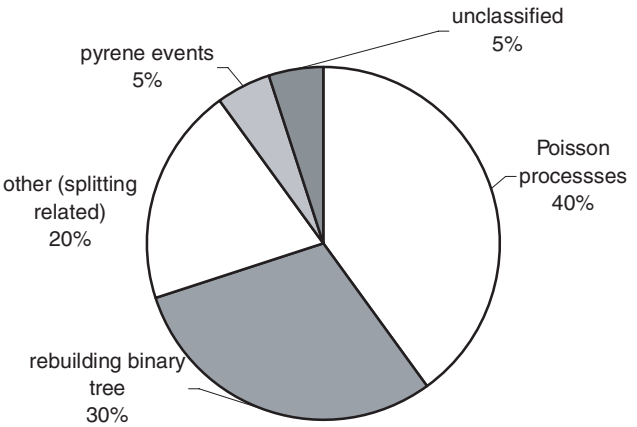

FIG. 3. *% of execution time spent on different tasks—op split.*

in the number of computational particles and hence the resolution of the reference solution simulations compared to those for the other results leads to less scatter in the distribution at large particle sizes in Figure 2. This is because the number of stochastic particles representing particles in a particular physical size range is proportional to the number density multiplied by the number of computational particles. If Figure 2 were extended in the bottom right-hand corner into the size range where no particles are predicted by the simulations using only 11 tree levels, greater scatter would be seen in the reference solution until it too dropped to 0.

4.4. Profiling of operator splitting. Operator splitting yields a considerable acceleration from DSA—see Table 4. The computational times are still substantial and would still be noticeable even with 1000 stochastic particles (tree depth of 10). Therefore it makes sense to repeat the analysis of section 3.3.1 and see if further improvements can be made. Figure 3 shows how the computational time is used during a PV algorithm run with the parameters used for the DSA profiling in section 3.3.1. "Poisson processes" refers to the approximation of the surface event Poisson processes by Poisson random variables for each particle during the splitting steps.

From this data we see that simulating the surface reactions is still by far the most computationally intensive task in the simulation—for JW1.69 a flame with relatively little surface growth compared to a sooty flame such as JW10.68. We also note that a substantial amount of time is spent approximating the Poisson processes that represent the surface reactions during splitting. We therefore try a further approximation in the next section.

4.5. Conclusions on operator splitting. Operator splitting using the PP and PV methods provides a substantial performance gain from DSA, in the most striking case reducing a run time by a factor of almost 10. The approximations made to achieve this acceleration have a small effect on the results; this error does not depend very strongly on the size of the time splitting steps. Compared to the uncertainties in the simulation of the gas phase chemistry (see, for example, [16]), the systematic error should not be a cause for concern.

5. Deferment of surface reactions. A new approach is to tag each stochastic particle with the time when it is added to the ensemble so particles are described by elements of the space $\tilde{E} = E \times [0, \infty)$. Some surface reactions (possibly now including

pyrene condensation) can be selected for "deferment"; such reactions are completely neglected as the simulation calculates time steps. Once a particle has been selected for an event the deferred events are simulated from the time recorded in the tag up to the current time. Only then does the nondeferred event take place. The tag is then reset to the current time so that the procedure can be repeated.

5.1. Measure theoretic formulation. To work toward the derivation of the generator for a stochastic jump process implementing this idea it is helpful to work in terms of measures, so we replace

$$n : [0, \infty) \times \tilde{E} \to [0, \infty)$$

by a family of measures giving the particle distribution on $\tilde{E}$ at each time.

To do this we endow $\tilde{E}$ with a σ-algebra $\mathcal{E}$ which makes the $g^{(l)}$, the $\beta_t^{(l)}$, K_t, $+$ and $I(t, \cdot)$ as defined below measurable. The $\mathbb{R}$ valued functions K_t and $\beta_t^{(l)}$ are extended to $\tilde{E}$ by simply ignoring the time stamp component, $g^{(l)}$ and $+$ (strictly $g_t^{(l)}$ and $+_t$) by defining the time stamp of the result to be the current time.

Let M be the space of measures on $\tilde{E}$ which we give the weak topology and the associated Borel σ-algebra $\mathcal{M}$. We describe the particle distribution by a function from time to M

$$\lambda : [0, \infty) \to M; \quad t \mapsto \lambda_t = \lambda(t, \cdot).$$

Thus for $A \in \mathcal{E}$ the number of particles per cm^3 described by elements of A at time t will be $\lambda_t(A)$.

The particle inflow rate will be given by a similar function,

$$I : [0, \infty) \to M; \quad t \mapsto I_t = I(t, \cdot).$$

The rate of inflow of particles with descriptions in A at time t is $I_t(A)$.

(2.1) can now be written for $A \in \tilde{E}$ as

(5.1)
$$\begin{aligned}\frac{\mathrm{d}}{\mathrm{d}t}\lambda_t(A) = &\int_{x\in A} I_t(dx)\\ &+ \sum_{l\in\mathcal{U}}\left[\int_{x\in\tilde{E}:g^{(l)}(x)\in A}\beta_t^{(l)}(x)\,\lambda_t(dx) - \int_{x\in A}\beta_t^{(l)}(x)\,\lambda_t(dx)\right]\\ &+ \frac{1}{2}\int_{y,z\in\tilde{E}:y+z\in A} K_t(y,z)\,\lambda_t(dy)\,\lambda_t(dz) - \int_{x\in A,y\in\tilde{E}} K_t(x,y)\,\lambda_t(dx)\,\lambda_t(dy).\end{aligned}$$

Hence for ϕ in a suitable class of test functions $\mathscr{C}$ we have a weak form (see, e.g., [6]),

(5.2)
$$\begin{aligned}\frac{\mathrm{d}}{\mathrm{d}t}\int_{x\in\tilde{E}}\phi(x)\,\lambda_t(dx) = &\int_{x\in\tilde{E}}\phi(x)\,I_t(dx)\\ &+ \sum_{l\in\mathcal{U}}\int_{x\in\tilde{E}}\beta_t^{(l)}(x)\left[\phi\left(g^{(l)}(x)\right) - \phi(x)\right]\lambda_t(dx)\\ &+ \frac{1}{2}\int_{x,y\in\tilde{E}}\left[\phi(x+y) - \phi(x) - \phi(y)\right]K_t(x,y)\,\lambda_t(dx)\,\lambda_t(dy).\end{aligned}$$

This includes the time stamp without really making use of it in λ, our representation of the particle population.

5.1.1. Deferred surface process operator. We now define a family of mappings $R_t : t \in [0, \infty)$ which map $x \in \tilde{E}$ to a random variable $R_t x \in E \times \{t\} \subseteq \tilde{E}$ with the distribution that a particle with description x would have at time t in the absence of deferrment. This only makes sense if t is later than the time stamp in x.

We also define an update operator

$$\mathcal{P}_t : M \to M$$

by

$$\mathcal{P}_t(\lambda)(A) = \int_{x \in \tilde{E}} \mathbb{P}(R_t x \in A)\, \lambda(dx). \tag{5.3}$$

Let $\mathcal{U}' \subseteq \mathcal{U}$ be the possibly empty set of surface reactions that are not deferred. We now want to define a "deferred solution" $\bar{\lambda}$ via an equation like (5.2) such that for any $\phi \in \mathscr{C}$

$$\Phi(\lambda_t) = \Phi\left(\mathcal{P}_t\left(\bar{\lambda}_t\right)\right), \tag{5.4}$$

where

$$\Phi(\nu) := \int_{x \in \tilde{E}} \phi(x)\, \nu(dx) \tag{5.5}$$

and λ solves (5.2).

A fairly obvious approach is

$$\begin{aligned}
\frac{\mathrm{d}}{\mathrm{d}t} \int_{x \in \tilde{E}} \phi(x)\, \bar{\lambda}_t(dx) &= \int_{x \in \tilde{E}} \phi(x)\, I_t(dx) \\
&+ \sum_{l \in \mathcal{U}'} \int_{x, \xi \in \tilde{E}} \left[\phi\left(g^{(l)}(\xi)\right) - \phi(x)\right] \beta_t^{(l)}(\xi)\, \mathbb{P}(R_t x \in d\xi)\, \bar{\lambda}_t(dx) \\
&+ \frac{1}{2} \int_{x,y,\xi,\zeta \in \tilde{E}} \left[\phi(\xi + \zeta) - \phi(x) - \phi(y)\right] K_t(\xi, \zeta) \\
&\qquad \mathbb{P}(R_t x \in d\xi)\, \mathbb{P}(R_t y \in d\zeta)\, \bar{\lambda}_t(dx)\, \bar{\lambda}_t(dy).
\end{aligned} \tag{5.6}$$

This defines a (or possibly some, since uniqueness is hard to establish) deterministic map from time to the soot population. However, while the resulting $\bar{\lambda}$ may satisfy (5.4) there are real problems using it as a basis for a simulation. First, we have the usual need to incorporate a majorant coagulation kernel (see, e.g., [8]). This then raises questions about the deferred processes for particles involved in fictitious jumps. Second, even when we have a majorant we still cannot handle individually the rates of the infinity of possible jumps given by R_t.

We developed an equation which allows for the use of deferred events generated for computational particles involved in events that prove to be fictitious and avoids considering individual values of $R_t x$. The basic idea is that if we can find $\hat{\beta}$ and $\hat{K}$ such that

$$\hat{\beta}_t^{(l)}\left(x; \bar{\lambda}_t\right) \geqslant \beta_t^{(l)}(R_t x) \tag{5.7a}$$

and

$$\hat{K}_t\left(x, y; \bar{\lambda}_t\right) \geqslant K_t(R_t x, R_t y) \tag{5.7b}$$

hold with probability 1, then it is sufficient to calculate rates for a particle using a majorant without knowing anything about deferred events. The deferred events can then be incorporated when another event is actually performed. In addition, if a particle is selected for a potential event which eventually turns out to be fictitious, postponed processes can be simulated on it anyway and the updated particle returned to the computational ensemble, thus reducing the deferment error.

Given the random nature of $R_t x$ it is likely to be hard to find $\hat{\beta}$ and $\hat{K}$ to satisfy (5.7) with probability 1 so we actually formulate our equation[2]

$$
\begin{aligned}
(5.8)\quad & \frac{\mathrm{d}}{\mathrm{d}t}\int_{x\in\tilde{E}}\phi(x)\,\bar{\lambda}_t(dx)=\int_{x\in\tilde{E}}\phi(x)\,I_t(dx)\\
&+\sum_{l\in U'}\int_{x,\xi\in\tilde{E}}\left[\phi\left(g^{(l)}(\xi)\right)-\phi(x)\right]\left[\beta_t^{(l)}(\xi)\wedge\hat{\beta}_t^{(l)}\left(x;\bar{\lambda}_t\right)\right]\mathbb{P}(R_t x\in d\xi)\,\bar{\lambda}_t(dx)\\
&\quad+\sum_{l\in U'}\int_{x,\xi\in\tilde{E}}[\phi(\xi)-\phi(x)]\left[\hat{\beta}_t^{(l)}\left(x;\bar{\lambda}_t\right)-\beta_t^{(l)}(\xi)\right]_+\mathbb{P}(R_t x\in d\xi)\,\bar{\lambda}_t(dx)\\
&\quad+\frac{1}{2}\int_{x,y,\xi,\zeta\in\tilde{E}}[\phi(\xi+\zeta)-\phi(x)-\phi(y)]\left[K_t(\xi,\zeta)\wedge\hat{K}_t\left(x,y;\bar{\lambda}_t\right)\right]\\
&\qquad\qquad\mathbb{P}(R_t x\in d\xi)\,\mathbb{P}(R_t y\in d\zeta)\,\bar{\lambda}_t(dx)\,\bar{\lambda}_t(dy)\\

\end{aligned}
$$

to make sense even if (5.7) are sometimes violated. Clearly (5.4) will not be satisfied if (5.7) do not hold, but provided this violation happens only with very small probability we can hope to recover a close approximation to (5.4).

5.1.2. Rate kernel. Define jump operators on the space of signed Borel measures on $\tilde{E}$ by

$$J^V_{x,y,z,w};\ \mu\mapsto\mu-V^{-1}(\delta_x+\delta_y-\delta_z-\delta_w)\ \ x,y,z,w\in\tilde{E}$$

and

$$J^V_{x,y,z};\ \mu\mapsto\mu-V^{-1}(\delta_x+\delta_y-\delta_z)\ \ x,y,z\in\tilde{E}$$

and

$$J^V_{x,y};\ \mu\mapsto\mu-V^{-1}(\delta_x-\delta_y)\ \ x,y\in\tilde{E}$$

and

$$J^V_x;\ \mu\mapsto\mu+V^{-1}\delta_x\ x\in\tilde{E}.$$

For $t\in[0,\infty)$ and $V\in(0,\infty)$ we define kernels

$$\alpha^V_t: M\times\mathcal{M}\to[0,\infty)$$

[2]Note that for $a,b\in\mathbb{R}$ we have $a_+\equiv\max(a,0)$ and $a\wedge b\equiv\min(a,b)$.

by specifying the value for $\mu \in M,\ C \in \mathcal{M}$

$$
\begin{aligned}
(5.9)\quad \alpha_t^V(\mu, C) &= \int_{x\in\tilde{E}} 1\left\{J_x^V \mu \in C\right\} V I_t(dx) \\
&+ \sum_{l\in\mathcal{U}'} \int_{x,\xi\in\tilde{E}} 1\left\{J_{x,g^{(l)}(\xi)}^V \mu \in C\right\} V \left[\beta_t^{(l)}(\xi) \wedge \hat{\beta}_t^{(l)}(x;\mu)\right] \mathbb{P}(R_t x \in d\xi)\, \mu(dx) \\
&+ \sum_{l\in\mathcal{U}'} \int_{x,\xi\in\tilde{E}} 1\left\{J_{x,\xi}^V \mu \in C\right\} V \left[\hat{\beta}_t^{(l)}(x;\mu) - \beta_t^{(l)}(\xi)\right]_+ \mathbb{P}(R_t x \in d\xi)\, \mu(dx) \\
&+ \frac{1}{2} \int_{x,y,\xi,\zeta\in\tilde{E}} 1\left\{J_{x,y,\xi+\zeta}^V \mu \in C\right\} V \left[K_t(\xi,\zeta) \wedge \hat{K}_t(x,y;\mu)\right] \\
&\qquad \mathbb{P}(R_t x \in d\xi)\, \mathbb{P}(R_t y \in d\zeta)\, \mu^{(2)}(dx, dy) \\
&+ \frac{1}{2} \int_{x,y,\xi,\zeta\in\tilde{E}} 1\left\{J_{x,y,\xi,\zeta}^V \mu \in C\right\} V \left[\hat{K}_t(x,y;\mu) - K_t(\xi,\zeta)\right]_+ \\
&\qquad \mathbb{P}(R_t x \in d\xi)\, \mathbb{P}(R_t y \in d\zeta)\, \mu^{(2)}(dx, dy),
\end{aligned}
$$

where for $A, B \in \tilde{E}$ we have $\mu^{(2)}(A \times B) = \mu(A)\,\mu(B) - \mu(A \cap B)$.

Using the kernels we define generators for stochastic processes on M by

$$
(5.10)\qquad \mathcal{G}_t^V(\Psi)(\mu) = \int_{\nu\in M} [\Psi(\nu) - \Psi(\mu)]\, \alpha_t^V(\mu, d\nu)
$$

for Ψ in a suitable class of test functions (not necessarily of the form given in (5.5)) and assuming (5.7) we can approximate (5.8) by

$$
(5.11)\qquad \frac{\mathrm{d}}{\mathrm{d}t}\Phi\left(\bar{\lambda}_t\right) = \mathcal{G}_t^V(\Phi)\left(\bar{\lambda}_t\right),
$$

which has an error that is $O\left(V^{-1}\right)$ as $V \to \infty$. By analogy with the work of Eibeck and Wagner (see [5] for a basic introduction and [6] for their latest generalization), we claim that the stochastic jump processes μ_t^V given by the generators $\mathcal{G}_t^V$ converge in distribution as $V \to \infty$ to a deterministic solution of (5.8) provided the initial conditions also converge. We then expect $\mathcal{P}_t\left(\bar{\lambda}_t\right)$ to converge in distribution to a deterministic solution, λ_t, of (5.2) in the same limit, i.e., to be a weak solution of our extended form of Smoluchowski's coagulation equation.

5.2. Implementation of deferment. Our implementation of this algorithm (LPDA) is essentially an application of DSA to the processes given in (5.10). We always used $\mathcal{U}' = \{\text{pyrene}\}$.

Some quantities (e.g., the moments plotted in Figure 4) are recorded frequently, in our case every millisecond. At these times we simulate all deferred growth due to all particles so that the size distribution is fully up to date before storing any data. This has the convenient effect of ensuring no stochastic particle is left for too long before its deferred surface growth is performed. One can therefore think of LPDA as a form of splitting but with a "just in time" feature to remove the main source of approximation error. However, with LPDA the number of times the entire ensemble has to be updated is orders of magnitude less than for ordinary operator splitting and so for practical purposes it is a completely different algorithm.

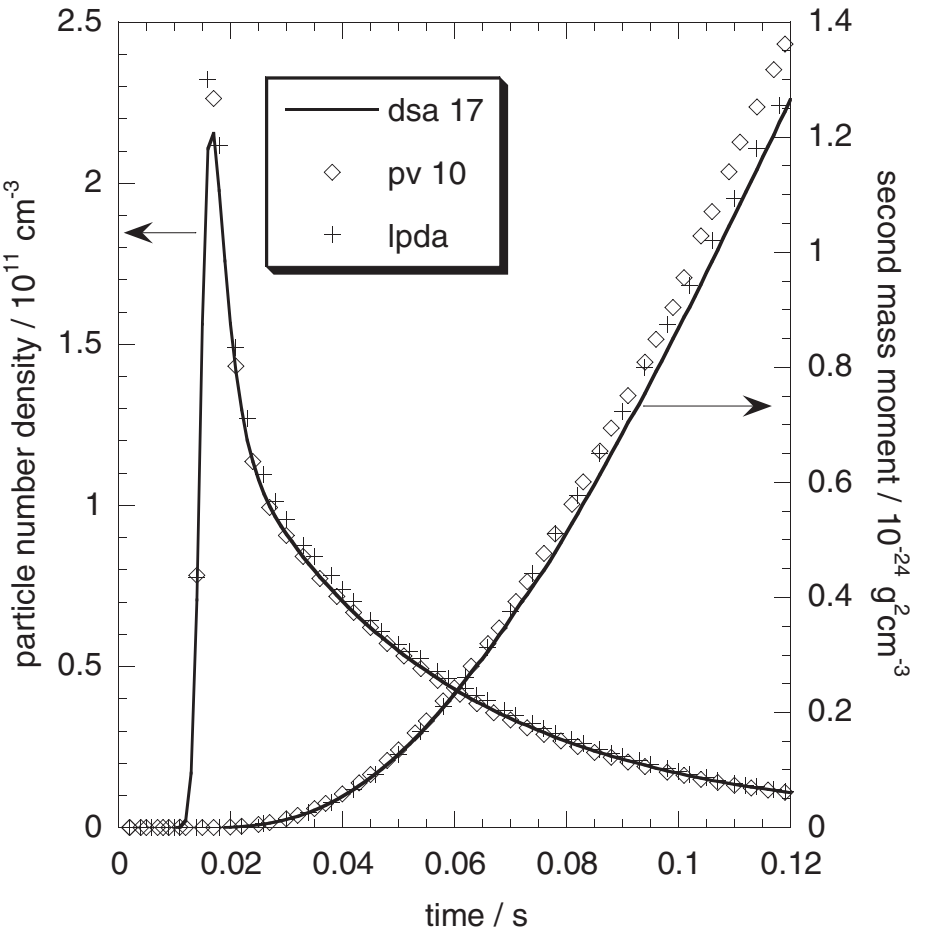

FIG. 4. *LPDA applied to* JW1.69.

5.2.1. Complexity. The (random) number of deferred events due to any particular particle is $O(1)$ in the sample volume V. There are $O(V)$ nondeferred events in a run and each of these requires use of the binary tree which takes $O(\log V)$ per event (see section 3.2). Hence the overall complexity is still $O(V \log V)$ in the (initial) sample volume for reasonable choices of tree depth. However, in section 4.2.2 we noted that most computational effort seemed to go on surface reactions and so if all these were deferred the complexity might not be observed in practice.

5.3. Numerical results.

5.3.1. Accuracy of moments. We used the same JW1.69 test case using a tree depth of 13 as in section 4.3.1. Ten runs took 250 seconds, an appreciable acceleration compared to the operator splitting cases. Figure 4 compares the zeroth and second moments of the mass distribution obtained with LPDA to the DSA precision run and to the PV splitting algorithm with $r = 10$ results. One can see that LPDA slightly overstates the number of particles compared to the other two methods at least until 0.08 s. Interestingly, with the second moment LPDA tracks the operator splitting solution until about 0.1 s and then moves much closer to the DSA solution. The first

TABLE 5
Detail of deferred suface growth runs for JW10.68.

	number of tree levels	time for 10 repetitions / min
DSA	13	8497
LPDA 15	15	22
LPDA 14	14	11
LPDA 13	13	5.25
LPDA 12	12	2.5

moment is not shown but here LPDA is virtually indistiguishable from DSA on the scale of the figures and noticeably better than the operator splitting results.

5.3.2. Particle distribution accuracy. As with operator splitting we investigate this topic for JW10.68; a summary of our runs is given in Table 5. The deferred surface growth runs were performed on the same machines used to generate results for section 4.3.1. We observe very considerable speed gains from using LPDA.

The LPDA run time with 13 tree levels is more than 3 orders of magnitude less than that for DSA, which is a very positive result. Figure 5 shows that the particle distribution is well reproduced using LPDA.

5.4. Conclusions on LPDA. This method is extremely attractive for further use in the simulation of laminar premixed flames because of the large speed gains possible without introducing large errors. The comments on the errors made in section 4.5 apply here as well.

The initial sample volume was scaled in direct proportion to the tree capacity for all the runs; for 13 tree levels we used an initial sample volume of 1×10^{-8} cm^{-3}. It is therefore interesting to see the run times showing $O(V)$ behavior, not $O(V \log V)$, as discussed in section 5.2.1.

6. Comparison of simulation methods.

6.1. Equal numbers of computational particles. A clear ordering in terms of speed can be seen in Table 6. In our view the differences in the particle distributions produced using the different methods are not material.

The ratios of run times between methods are very different for the two flames considered, as are the total run times. Unsurprisingly, the greatest accelerations were achieved for the problem that takes the most CPU time. We believe the reason JW10.68 takes so much longer to simulate than JW1.69 is that there are far more surface reactions.

6.2. Equal precision for JW1.69. In this section we consider the time required to get results of comparable quality using the three main algorithms discussed in this paper. We measure result quality using the second moment of the particle size distribution on exit from the flame. We take as our reference value the mean obtained from 30 runs using DSA, 17 tree levels, and an initial sample volume of 5.6×10^{-7} cm^3. Table 7 gives details of settings which lead to 99.9% confidence intervals for the second moment being entirely contained in an interval of $\pm 10\%$ around the reference value.

The parameters shown were selected as the least multiples of five runs that led to adequate results for the second moment. More runs or more tree levels were required for LPDA and operator splitting because these methods bias the mean value of the second moment and so tighter confidence intervals are needed to stay within the $\pm 10\%$ range.

7. Conclusion. We have explored the computational challenges of simulating the soot particle size distribution in laminar premixed flames using stochastic methods. We have tested a splitting technique that is well established in many fields of computation and give some indication of the optimum parameter values for this method. Finally we set out for the first time, in detail, a new stochastic algorithm for solving the population balance equations for soot particles in a laminar premixed flame. This algorithm is found to offer significant reductions in computational time and for one sooty, 10 bar flame, LPDA is 1000 times faster.

A DEFECT CORRECTION SCHEME FOR FINITE ELEMENT EIGENVALUES WITH APPLICATIONS TO QUANTUM CHEMISTRY*

LIHUA SHEN† AND AIHUI ZHOU†

Abstract. To produce highly accurate approximations for self-adjoint elliptic eigenvalues, we propose a finite element defect correction scheme. Its efficiency is proven by theoretical and numerical evidence. Very satisfying applications in computational quantum chemistry are also presented.

Key words. defect correction, eigenvalue, finite element, Hartree–Fock equation, highly accurate, quantum chemistry

1. Introduction.

It is known that the time independent Schrödinger equation models the behavior of a quantum molecular system. This equation deals with state functions $\psi(x)$, where x denotes the position of the particles (nuclei and electrons) and hence is a variable that lives in high dimensions. In quantum chemistry, it is significant to compute the total energy of the ground state of the system. However, this system is far too large to be directly tractable by numerical simulation for molecules larger than the hydrogen atom. Quantum chemists have thus introduced a series of simplified models. One of them is the so-called Hartree–Fock model [27, 28], which is a nonlinear eigenvalue system in three dimensions. In computation, approximations to the total energy of the ground state of the system require solving self-consistently a large number of linear eigenvalue problems. Namely, an iteration procedure for solving a large number of linear eigenvalue problems must be involved. Moreover, in order to obtain the numerical solution with satisfactory accuracy, the number of iterations is usually very large. Hence it is important to reduce the computational cost or improve the approximation accuracy in solving such linear eigenvalue problems (in three dimensions) at each iteration step. The purpose of this paper is to present a simple postprocessing approach to getting highly accurate approximations for a class of linear eigenvalue problems.

As the finite element method is one of the most effective numerical methods, we shall consider the use of finite element schemes to discretize eigenvalue problems. We first investigate a finite element postprocessing approach for the following model problem theoretically and numerically: Find $(u, \lambda) \in H_0^1(\Omega) \times R$ such that

$$\begin{cases} -\nabla(A\nabla u) + \beta u = \lambda u & \text{in } \Omega, \\ \|u\|_{0,\Omega} = 1, \end{cases} \tag{1.1}$$

where $\Omega \subset R^d (d = 2, 3)$ is a polygonal domain with boundary $\partial\Omega, A$ is a smooth positive definite symmetric matrix, and $0 \leq \beta \in L^\infty(\Omega)$. Then we turn to studying two Hartree–Fock problems and apply a similar numerical approach to achieve highly accurate approximations. One Hartree–Fock problem we will study is: Find $(u, E) \in H^1(R^3) \times R$, such that $\int_{R^3} |u|^2 dx = 1$ and

$$-\frac{1}{2}\Delta u - \frac{1}{|x|}u = Eu \quad \text{in } R^3, \tag{1.2}$$

while the other Hartree–Fock problem is: Find $(u, E) \in H^1(R^3) \times R$ such that $\int_{R^3} |u|^2 dx = 1$ and

$$-\frac{1}{2}\Delta u - \frac{2}{|x|}u + \int_{R^3} \frac{|u(y)|^2 dy}{|x - y|}u = Eu \quad \text{in } R^3. \tag{1.3}$$

Obviously, the Hartree–Fock equations are singular. For such singular problems, it is not so easy to construct highly accurate finite element approximations.

Highly accurate finite element approximations have been studied for decades [14, 17, 21, 23, 24, 32, 44]. In the context of solving boundary value problems, it is noted that most previous work focused on searching some superconvergent points when the associated data are smooth. For improving the accuracy of finite element eigenvalues, however, we need to study highly accurate approximations for eigenfunctions at all points of the underlying domain. It is now found that it is possible to get finite element approximations for eigenfunctions with higher accuracy by using some averaging techniques. As for highly accurate finite element approximations for eigenvalues, it is shown from our investigation that the averaging techniques need to be combined with some defect correction procedures.

It is observed from finite element discretizations that finite element solutions are usually oscillating even though the exact solutions are smooth. It is also seen that the finite element solutions can be reconstructed to be smooth if some averaging approaches are used and also that the smoothed finite element approximations would have better approximation accuracy, provided that the exact solutions are smooth. Historically, averaging approaches have indeed been applied in finite element computations. To our knowledge, the most popular averaging technique is the Zienkiewicz–Zhu (ZZ) gradient patch recovery [45, 46], which is based on a local discrete least-squares fitting. This technique has been widely used in engineering practices for its robustness in a posteriori error estimates and its efficiency in computer implementation. Superconvergence properties of the ZZ recovery for boundary value problems are studied by Zhang [39], Li and Zhang [25], and Zhang and Victory [41]. We refer to [2, 5, 6, 7, 12, 19, 20, 33, 36, 38, 40] for other investigations on superconvergence and a posteriori error control for boundary value problems by using various averaging techniques.

Based on the ZZ-averaging techniques, in this paper we will propose a defect correction scheme to produce highly accurate finite element eigenvalue approximations for (1.1), (1.2), and (1.3). Our defect correction scheme is nothing but a simple post-processing of the computed eigenvalue and eigenfunction. Further, it is shown that our defect correction scheme is efficient not only for smooth data problems but also for nonsmooth data problems. In particular, our defect scheme has been successfully applied to computational quantum chemistry and has obtained very satisfying results.

Note that it should be interesting to apply the approaches proposed in this paper to more complex quantum molecular systems. Indeed, it is our ongoing research to

solve the so-called Hartree–Fock–Slater equations (or X_α equations) and Kohn–Sham equations by the finite element method and to use the defect correction scheme to get highly accurate approximations for the eigenvalues and hence for the total energy for complex molecular systems.

The rest of this paper is organized as follows. In the next section, some preliminaries, including the finite element discretization and averaging operators, are presented. In section 3, a finite element defect correction scheme is proposed and analyzed. Examples of highly accurate finite element approximations for both eigenfunctions and eigenvalues are then constructed for (1.1) by using some averaging techniques, together with the defect correction procedure. Several numerical results that support our theory are also reported. In section 4, the finite element defect correction scheme, together with the averaging approaches, is applied to solving (1.2) and (1.3), which are two typical models in quantum chemistry. It is shown that our defect correction scheme is very efficient in such computations, too.

2. Preliminaries. We shall use the standard notation for Sobolev spaces $W^{s,p}(\Omega)$ and their associated norms and seminorms; see, e.g., [1, 15]. For $p = 2$, we denote $H^s(\Omega) = W^{s,2}(\Omega)$ and $H_0^1(\Omega) = \{v \in H^1(\Omega) : \ v|_{\partial\Omega} = 0\}$, where $v|_{\partial\Omega}$ is in the sense of trace, $\|\cdot\|_{s,\Omega} = \|\cdot\|_{s,2,\Omega}$, and $(\cdot,\cdot)$ is the standard L^2-inner product. Throughout this paper, we shall use C to denote a generic positive constant, which may stand for different values at its different occurrences and is independent of the mesh parameters.

Assume that $T^h = \{\tau\}$ is a triangulation of Ω with mesh size h, which consists of shape-regular simplices. Denote by ∂T^h the set of all edges of triangles for $d = 2$ or all surfaces of simplices for $d = 3$, by $\partial^2 T^h$ the set of all vertices of T^h, and let $\Lambda = \partial^2 T^h \setminus \partial\Omega$. We define finite element spaces

$$S^{h,r}(\Omega) = \{\ v \in H^1(\Omega) : \ v|_\tau \in P^r(\tau),\ \forall \tau \in T^h\}, \qquad S_0^{h,r}(\Omega) = S^{h,r}(\Omega) \cap H_0^1(\Omega),$$

where $P^r(\tau)$ is the space of polynomials of degree not greater than a positive integer r. In most of this paper we use $S^h(\Omega)$ and $S_0^h(\Omega)$ to denote $S^{h,1}(\Omega)$ and $S_0^{h,1}(\Omega)$, respectively. For a given $z \in \partial^2 T^h$, $l \in \partial T^h$, and $\tau \in T^h$, let ϕ_z be the nodal basis function of $S^h(\Omega)$ corresponding to z (i.e., the continuous piecewise linear function with respect to T^h, which takes the value 1 at z and which vanishes at all other vertices) and define

$$\omega_z = \bigcup_{z \in \bar{\tau}} \tau, \qquad \omega_l = \bigcup_{l \subset \bar{\tau}} \tau, \qquad \omega_\tau = \bigcup_{\bar{\tau}' \cap \tau \neq \emptyset} \tau'.$$

2.1. ρ-regular meshes. In discussing superconvergence of finite element approximations to boundary value problems, the finite element mesh T^h is usually required to be regular enough; for instance, it satisfies

$$\left| \int_\Omega A\nabla(u - u_I) \cdot \nabla v dx \right| \le Ch^{1+\rho} |u|_{2+\alpha,\Omega} |v|_{1,\Omega} \quad \forall v \in S_0^h(\Omega), \tag{2.1}$$

$$\left| \int_\Omega (u - u_I) \mathrm{div}(\varphi v) dx \right| \le Ch^{1+\rho} |u|_{2+\alpha,\Omega} |v|_{0,\Omega} \quad \forall v \in S^h(\Omega) \tag{2.2}$$

for $\varphi \in (W^{1,\infty}(\Omega))^d$ and $u \in H_0^1(\Omega) \cap H^{2+\alpha}(\Omega)$ with $\alpha > 0$. Here $\rho = \min(\alpha, 1/2)$, and u_I is the standard linear Lagrange interpolant of $u \in C(\bar{\Omega})$, namely

$$u_I \in S^h \ \text{ and } \ u_I = u \qquad \text{on } \partial^2 T^h.$$

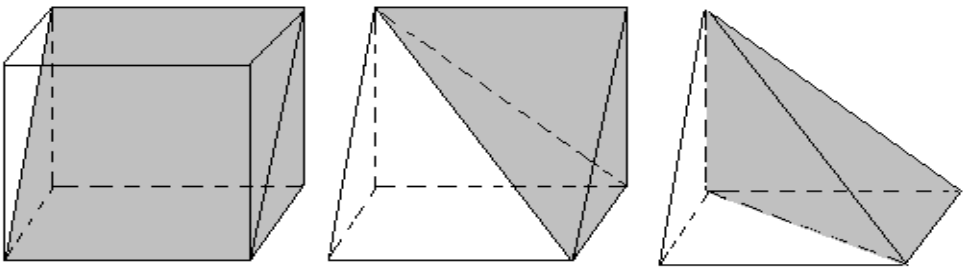

FIG. 1. *Kuhn's triangulation.*

It is known that (2.1) and (2.2) are satisfied for $\alpha = 1$ if T^h is piecewise uniform; see, e.g., [9, 14, 17, 21, 22, 23, 36, 42, 44] for (2.1) and [42, 43] for (2.2).

For a triangulation T^h in two dimensions, if the union of any two triangles (in T^h) that share an entire edge forms a parallelogram, then T^h is called uniform. A uniform triangulation T^h in three dimensions is induced from Kuhn's triangulation [9, 31]. Kuhn's triangulation T_0 (see Figure 1) is a partition of the cube $[0,1]^3$ consisting of six tetrahedra $\{\tau_\sigma : \sigma = (\sigma_1, \sigma_2, \sigma_3) \in \Sigma\}$ with Σ the group of permutations of the numbers $1, 2$, and 3, and each τ_σ is given by

$$\tau_\sigma = \{(x_1, x_2, x_3) \in [0,1]^3 : 0 \le x_{\sigma_1} \le x_{\sigma_2} \le x_{\sigma_3} \le 1\}.$$

Let $T = \{T_0 + z : z \in Z^3\}$ be the partition of R^3. Then a triangulation T^h in three dimensions is called uniform if there exist a nonsingular 3×3 matrix $\mathcal{B}$ and a point $w \in R^3$ such that $\tau \subset \bar{\Omega}$ or $\tau \subset \overline{R^3 \setminus \Omega}$ for all $\tau \in T_{\mathcal{B},w}$ and

$$T^h = \{\tau \in T_{\mathcal{B},w} : \tau \subset \bar{\Omega}\},$$

where $\mathcal{B}/h$ is independent of h, and

$$T_{\mathcal{B},w} = \{\mathcal{B}\tau + w : \tau \in T\}.$$

The partition $T_{\mathcal{B},w}$ is also called a uniform partition of R^3 for any given nonsingular 3×3 matrix $\mathcal{B}$ and $w \in R^3$. A shape-regular triangulation T^h is called piecewise uniform if there exist subdomains $\Omega_1, \Omega_2, \ldots, \Omega_m$ such that $\bar{\Omega} = \cup_{j=1}^m \bar{\Omega}_j$ and $T^h|_{\Omega_j}$ is a uniform triangulation of the subdomain Ω_j $(j = 1, 2, \ldots, m)$. One sees that any polygonal domain in two or three dimensions can be covered by a piecewise uniform triangulation.

We refer to [5, 36, 42] for other meshes that produce (2.1) and (2.2). For simplicity, we shall call a shape-regular mesh T^h ρ-regular if (2.1) and (2.2) are satisfied, and a shape-regular mesh T^h without any additional requirement irregular.

2.2. Averaging operators. In this subsection, we introduce global and local averaging operators: the L^2-projection operator and a Clément-type operator.

Associated with the finite element space $S^h(\Omega)$, the L^2-projection operator $Q_h : L^2(\Omega) \mapsto S^h(\Omega)$ is defined by

$$(Q_h w, v) = (w, v) \quad \forall v \in S^h(\Omega).$$

The following standard estimates for Q_h,

$$\|w - Q_h w\|_{l,\Omega} \le Ch^{s-l}|w|_{s,\Omega} \qquad \forall w \in H^s(\Omega),\ l \le s \le 2, l = 0, 1,$$

will be used in our analysis. Here and hereafter, we use the notation $Q_h(v_1, v_2) = (Q_h v_1, Q_h v_2)$ for $(v_1, v_2) \in L^2(\Omega) \times L^2(\Omega)$.

If T^h is ρ-regular, then the inequality

$$\|A\nabla u - Q_h A\nabla u_I\|_{0,\Omega} \le Ch^{1+\rho} \tag{2.3}$$

can be derived directly from (2.2) (cf. [5]). Note that a slightly different estimate from (2.3) can be found in [5], where a variant estimate of (2.2) was used.

Define a local averaging operator

$$C_h : A\nabla S_0^h(\Omega) \mapsto \underbrace{S^h(\Omega) \times \cdots \times S^h(\Omega)}_{d \text{ times}}$$

by (cf., e.g., [2, 26, 38, 45])

$$\mathcal{C}_h A\nabla v = \sum_{z \in \partial^2 T^h} (A\nabla v)_z \phi_z, \quad (A\nabla v)_z = \sum_{j=1}^{J_z} \alpha_z^j \big(A(z)\nabla v\big)_{\tau_z^j} \quad \forall v \in S_0^h(\Omega), \tag{2.4}$$

where $\bigcup_{j=1}^{J_z} \tau_z^j = \omega_z$, $\sum_{j=1}^{J_z} \alpha_z^j = 1$, and $\alpha_z^j \ge 0$. For instance, $\alpha_z^j = \frac{1}{J_z}$ or $\alpha_z^j = \frac{|\tau_z^j|}{|\omega_z|}$. One sees that $\mathcal{C}_h$ is a Clément-type operator. By the local averaging operator $\mathcal{C}_h$, a smoothened fluxfield $\mathcal{C}_h A\nabla v$ is then obtained from a fluxfield $A\nabla v$. Hence, the operator $\mathcal{C}_h$ may be called a flux recovery operator. Indeed, the operator $\mathcal{C}_h$ is nothing but a discretized L^2-projection. The so-called gradient recovery operator is discussed in [2, 11, 38, 45].

In contrast to [2, 11, 38, 45], here we are required to apply flux recovery operators to construct superconvergent approximations for $A^{1/2}\nabla u$, where u is some eigenfunction. We may also employ other types of local averaging operators, for instance, a local L^2-projection operator, a local discrete least-squares fitting operator, or Zhang's fitting operator (see, e.g., [12, 25, 40]). In this paper, we shall apply the local averaging operator C_h defined by (2.4). It is easy to see that

$$\|\mathcal{C}_h A\nabla v\|_{0,\Omega} \le \|v\|_{a,\Omega} \quad \forall v \in S_0^h(\Omega). \tag{2.5}$$

A direct calculation leads to (cf. [9, 36, 38])

$$\|(A\nabla u)_I - C_h A\nabla u_I\|_{0,\Omega} \le Ch^{1+\rho}\|u\|_{2+\alpha,\Omega} \tag{2.6}$$

if T^h is ρ-regular.

2.3. A model problem. Define a bilinear form $a(\cdot,\cdot) : H^1(\Omega) \times H^1(\Omega) \mapsto R$ by

$$a(w, v) = \int_\Omega (A\nabla w \cdot \nabla v + \beta w v)dx,$$

which obviously satisfies

$$a(w, v) \le C\|w\|_{1,\Omega}\|v\|_{1,\Omega} \quad \forall w, v \in H_0^1(\Omega).$$

It is noted that $a(\cdot,\cdot)$ can induce a norm $\|\cdot\|_{a,\Omega}$ on $H_0^1(\Omega)$ defined by

$$\|w\|_{a,\Omega}^2 = a(w,w) \quad \forall w \in H_0^1(\Omega).$$

The weak form of (1.1) is stated as follows: Find $(u,\lambda) \in H_0^1(\Omega) \times R$ such that

$$\begin{cases} a(u,v) &= \lambda(u,v) \quad \forall v \in H_0^1(\Omega), \\ \|u\|_{0,\Omega} &= 1. \end{cases} \tag{2.7}$$

It is known that (2.7) has a sequence of real eigenvalues $0 < \lambda_1 \le \lambda_2 \le \cdots$ and the corresponding eigenfunctions $u_1, u_2, \ldots$, which can be assumed to satisfy $(u_i, u_j) = \delta_{ij}$ $(i,j \ge 1)$.

The finite element discretization for (2.7) reads: Find $(u_h, \lambda_h) \in S_0^h(\Omega) \times R$ such that

$$\begin{cases} a(u_h, v_h) &= \lambda_h(u_h, v_h) \quad \forall v_h \in S_0^h(\Omega), \\ \|u_h\|_{0,\Omega} &= 1. \end{cases} \tag{2.8}$$

One sees that (2.8) has a finite sequence of eigenvalues $0 < \lambda_{1,h} \le \lambda_{2,h} \le \cdots \le \lambda_{n_h,h}$ and the corresponding eigenfunctions $u_{1,h}, u_{2,h}, \ldots, u_{n_h,h}$ with $(u_{i,h}, u_{j,h}) = \delta_{ij}$ $(1 \le i,j \le n_h)$, where $n_h = \dim S_0^h(\Omega)$. It is well known that (see, e.g., [3, 4, 13])

$$\lambda_{i,h} \ge \lambda_i, \quad i = 1,2,\ldots,n_h. \tag{2.9}$$

It is shown in [3, 4] (see also [37]) that

$$\|u - u_h\|_{0,\Omega} \le C\eta(h)\|u - u_h\|_{a,\Omega} \tag{2.10}$$

holds with $\eta(h) \to 0$ as $h \to 0$.

In our analysis, we will use the following property of eigenvalue and eigenfunction approximations (see, e.g., [3, 4, 37]).

LEMMA 2.1. [illegible] $(u,\lambda) \in H_0^1(\Omega) \times R$ [illegible] (2.7) [illegible] $w \in H_0^1(\Omega)$ [illegible]

$$\frac{a(w,w)}{\|w\|_{0,\Omega}^2} - \lambda = \frac{a(w-u, w-u)}{\|w\|_{0,\Omega}^2} - \lambda\frac{\|w-u\|_{0,\Omega}^2}{\|w\|_{0,\Omega}^2}. \tag{2.11}$$

The equality (2.11) is straightforward and useful. For instance, if $(u_h, \lambda_h) \in S_0^h(\Omega) \times R$ satisfies (2.8), then it is easy to obtain from (2.11) that

$$\lambda_h - \lambda = \frac{(A\nabla(u_h - u), \nabla(u_h - u)) + (\beta(u_h - u), u_h - u)}{\|u_h\|_{0,\Omega}^2} - \lambda\frac{(u_h - u, u_h - u)}{\|u_h\|_{0,\Omega}^2}$$

and hence

$$\lambda_h - \lambda = \|u_h - u\|_{a,\Omega}^2 + O(\|u_h - u\|_{0,\Omega}^2) = O(\|u_h - u\|_{a,\Omega}^2). \tag{2.12}$$

In this section, we assume that Ω is regular enough (for instance, Ω is a convex domain or a domain with a smooth boundary) so that for any $f \in L^2(\Omega)$ there exists a unique solution $u \in H_0^1(\Omega) \cap H^2(\Omega)$ satisfying

$$a(u,v) = (f,v) \quad \forall v \in H_0^1(\Omega).$$

As a result, the exact solution of (1.1) or (2.7) has the $H^2(\Omega)$-regularity, namely $M(\lambda_i) \subset H_0^1(\Omega) \cap H^2(\Omega)$, where

$$M(\lambda_i) = \{w \in H_0^1(\Omega) : w \text{ is an eigenfunction of } \lambda_i,\ \|w\|_{0,\Omega} = 1\}, \quad i = 1, 2, \ldots.$$

Thus, $\lambda_{i,h} - \lambda_i = O(h^2)\,(i = 1, 2, \ldots, n_h)$, and for $u_{i,h}$, there exists $\hat{u}_i \in M(\lambda_i)$ satisfying (see, e.g., [3, 4, 13])

$$h\|\hat{u}_i - u_{i,h}\|_{a,\Omega} + \|\hat{u}_i - u_{i,h}\|_{0,\Omega} \le Ch^2 \tag{2.13}$$

when $h \ll 1$.

In this paper we assume that (u, λ) and (u_h, λ_h) are solutions of (2.7) and (2.8), respectively, and satisfy

$$\lambda_h - \lambda + \|u - u_h\|_{0,\Omega} + h\|u - u_h\|_{a,\Omega} \le Ch^2. \tag{2.14}$$

Let $R_h : H_0^1(\Omega) \mapsto S_0^h(\Omega)$ be the Ritz–Galerkin projection operator, namely

$$a(R_h w, v) = a(w, v) \quad \forall v \in S_0^h(\Omega),\ \forall w \in H^1(\Omega).$$

Between the Ritz–Galerkin projection $R_h u$ of the eigenfunction and the finite element approximation u_h to the eigenfunction u, there is a super-close relationship (see [37]), as the next lemma shows.

LEMMA 2.2.

$$\|u_h - R_h u\|_{a,\Omega} \le C(\lambda_h - \lambda + \lambda\|u_h - u\|_{0,\Omega}). \tag{2.15}$$

To get approximations with higher accuracy, we require that the eigenfunction $u \in H_0^1(\Omega) \cap H^{2+\alpha}(\Omega)$ for some $\alpha \in (0, 1]$, which is reasonable (cf., e.g., [9, 17, 20, 23, 25, 32, 34, 44, 45, 46]). Consequently,

$$\|u_h - R_h u\|_{a,\Omega} \le Ch^2. \tag{2.16}$$

Note that (2.1) implies

$$\|R_h u - u_I\|_{a,\Omega} \le Ch^{1+\rho}, \tag{2.17}$$

which is well known in the superconvergence literature. Combining (2.16) and (2.17), we immediately obtain the following result.

LEMMA 2.3. [illegible] $u \in H_0^1(\Omega) \cap H^{2+\alpha}(\Omega)$ [illegible] T^h [illegible]

$$\|u_h - u_I\|_{a,\Omega} = O(h^{1+\rho}). \tag{2.18}$$

3. A defect correction scheme. Based on a recovery operator

$$\mathcal{F} : S_0^h(\Omega) \longrightarrow \underbrace{H^1(\Omega) \times \cdots \times H^1(\Omega)}_{d \text{ times}},$$

we construct a defect correction scheme for approximating eigenvalues as follows:

$$\lambda_h^{\mathcal{F}} = \lambda_h - \|\mathcal{F}u_h - A^{1/2}\nabla u_h\|_{0,\Omega}^2. \tag{3.1}$$

For the error analysis, we have the following estimation for $\lambda_h^{\mathcal{F}}$.

PROPOSITION 3.1. [illegible]

$$\mathcal{F} : S_0^h(\Omega) \longrightarrow \underbrace{H^1(\Omega) \times \cdots \times H^1(\Omega)}_{d \text{ times}},$$

[illegible]

$$\left|\lambda_h^{\mathcal{F}} - \lambda\right| \le C\|u - u_h\|_{a,\Omega}\|A^{1/2}\nabla u - \mathcal{F}u_h\|_{0,\Omega}$$

$$+ C(\|A^{1/2}\nabla u - \mathcal{F}u_h\|_{0,\Omega}^2 + \|u - u_h\|_{0,\Omega}^2). \tag{3.2}$$

[illegible] $\mathcal{F}$ [illegible]

$$\|\mathcal{F}v\|_{0,\Omega} \le C\|v\|_{a,\Omega} \quad \forall v \in S_0^h(\Omega), \tag{3.3}$$

[illegible]

$$\left|\lambda_h^{\mathcal{F}} - \lambda\right| \le C\|u - u_h\|_{a,\Omega} \inf_{v \in S_0^h(\Omega)} \left(\|v - u_h\|_{a,\Omega} + \|A^{1/2}\nabla u - \mathcal{F}v\|_{0,\Omega}\right)$$

$$+ C \inf_{v \in S_0^h(\Omega)} \left(\|v - u_h\|_{a,\Omega} + \|A^{1/2}\nabla u - \mathcal{F}v\|_{0,\Omega}\right)^2 + C\|u - u_h\|_{0,\Omega}^2. \tag{3.4}$$

[illegible] From the equality

$$A^{1/2}\nabla(u - u_h) = \mathcal{F}u_h - A^{1/2}\nabla u_h + A^{1/2}\nabla u - \mathcal{F}u_h, \tag{3.5}$$

we have

$$\left|\|\mathcal{F}u_h - A^{1/2}\nabla u_h\|_{0,\Omega} - \|u - u_h\|_{a,\Omega}\right| \le \|A^{1/2}\nabla u - \mathcal{F}u_h\|_{0,\Omega},$$

which implies

$$\left|\|\mathcal{F}u_h - A^{1/2}\nabla u_h\|_{0,\Omega}^2 - \|u - u_h\|_{a,\Omega}^2\right|$$

$$\le 2\|u - u_h\|_{a,\Omega}\|A^{1/2}\nabla u - \mathcal{F}u_h\|_{0,\Omega} + \|A^{1/2}\nabla u - \mathcal{F}u_h\|_{0,\Omega}^2. \tag{3.6}$$

Hence we obtain (3.2) from (2.12).

Using the boundedness of $\mathcal{F}$ and the estimation

$$\|A^{1/2}\nabla u - \mathcal{F}u_h\|_{0,\Omega} \le \|\mathcal{F}(v - u_h)\|_{0,\Omega} + \|A^{1/2}\nabla u - \mathcal{F}v\|_{0,\Omega} \quad \forall v \in S_0^h(\Omega),$$

we get

$$\|A^{1/2}\nabla u - \mathcal{F}u_h\|_{0,\Omega} \le C \inf_{v \in S_0^h(\Omega)} \left(\|v - u_h\|_{a,\Omega} + \|A^{1/2}\nabla u - \mathcal{F}v\|_{0,\Omega}\right), \tag{3.7}$$

which together with (3.2) produces (3.4). □

It is seen from (2.10) that $\lambda_h^{\mathcal{F}}$ is a highly accurate approximation to λ if

$$\inf_{v \in S_0^h(\Omega)} \left(\|v - u_h\|_{a,\Omega} + \|A^{1/2}\nabla u - \mathcal{F}v\|_{0,\Omega}\right) \ll \|u - u_h\|_{a,\Omega}, \tag{3.8}$$

as compared with λ_h. Hence, it is significant to construct a recovery operator $\mathcal{F}$ such that (3.8) is satisfied. Indeed, it is shown from our investigation that the general defect correction scheme (3.1) can produce highly accurate finite element eigenvalue approximations whether the data are smooth or not when some suitable recovery operators $\mathcal{F}$ are employed.

3.1. Averaging recovery on regular meshes. Applying the L^2-projection averaging, approximations for eigenvalues and eigenfunctions with higher accuracy are then constructed on ρ-regular meshes.

THEOREM 3.2. [illegible] $u \in H_0^1(\Omega) \cap H^{2+\alpha}(\Omega)$ [illegible] $T^h(\Omega)$, [illegible] $\mathcal{F} = A^{-1/2} Q_h A \nabla$, [illegible]

$$\|A^{1/2}\nabla u - \mathcal{F} u_h\|_{0,\Omega} \le C h^{1+\rho}, \tag{3.9}$$

$$|\lambda_h^{\mathcal{F}} - \lambda| \le C h^{2+\rho}. \tag{3.10}$$

[illegible] The estimation (3.10) can be directly derived from (3.2), (2.14), and (3.9). Hence we need only prove (3.9). From (2.3) and the equality

$$A^{1/2}\nabla u - A^{-1/2} Q_h A \nabla u_I = A^{-1/2}(A\nabla u - Q_h A \nabla u_I)$$

we get

$$\|A^{1/2}\nabla u - \mathcal{F} u_I\|_{0,\Omega} \le C h^{1+\rho}. \tag{3.11}$$

Since A is a smooth positive definite symmetric matrix and

$$\|Q_h v\|_{0,\Omega} \le \|v\|_{0,\Omega} \quad \forall v \in L^2(\Omega),$$

we see that (3.3) is satisfied, and hence (3.7) leads to

$$\|A^{1/2}\nabla u - \mathcal{F} u_h\|_{0,\Omega} \le C \left(\|u_I - u_h\|_{a,\Omega} + \|A^{1/2}\nabla u - \mathcal{F} u_I\|_{0,\Omega} \right), \tag{3.12}$$

which together with (2.18) and (3.11) yields (3.9). □

Note that (3.9) is an L^2-projection averaging–based superconvergence result. We should mention here that by using the L^2-projection averaging, a similar superconvergence estimate for a finite element solution to elliptic boundary value problems has been provided in [5].

We may also obtain highly accurate approximations on ρ-regular meshes by using the local averaging operator $\mathcal{C}_h$, which is a discretized L^2-projection (cf. also [26]). In fact, from (2.6) and

$$A^{1/2}\nabla u - A^{-1/2}\mathcal{C}_h A \nabla u_I = A^{-1/2}(A\nabla u - (A\nabla u)_I) + A^{-1/2}((A\nabla u)_I - \mathcal{C}_h A \nabla u_I)$$

we have

$$\|A^{1/2}\nabla u - A^{-1/2}\mathcal{C}_h A \nabla u_I\|_{0,\Omega} \le C h^{1+\rho} \tag{3.13}$$

when T^h is ρ-regular and $u \in H_0^1(\Omega) \cap H^{2+\alpha}(\Omega)$. Note that (3.3) is valid if $\mathcal{F} = A^{-1/2}\mathcal{C}_h A \nabla$; we then get

$$\|A^{1/2}\nabla u - \mathcal{F} u_h\|_{0,\Omega} \le C h^{1+\rho} \tag{3.14}$$

from (2.18), (3.13), and (3.12), and

$$|\lambda_h^{\mathcal{F}} - \lambda| \le C h^{2+\rho} \tag{3.15}$$

from (2.14), (3.14), and (3.2).

[illegible] It should be pointed out that if T^h is a piecewise uniform mesh obtained from T^{2h} by some refinements, it may be possible to produce highly accurate approximations to eigenvalues and eigenfunctions by applying some quadratic interpolation operator. Unfortunately, it is not so easy to construct quadratic interpolation operators on unstructured meshes.

3.2. Averaging recovery on irregular meshes. By using the averaging technique, we may also obtain highly accurate approximations on irregular meshes if we use other coarser meshes. More precisely, we may construct highly accurate approximations on shape-regular meshes if some L^2-projections on coarser meshes are applied.

For $H \gg h$, let $Q_H : L^2(\Omega) \longrightarrow S^H(\Omega)$ and $\tilde{Q}_H : L^2(\Omega) \longrightarrow S^{H,2}(\Omega)$ be the L^2-projection operators; namely,

$$(Q_H w - w, v) = 0 \qquad \forall v \in S^H(\Omega), \forall w \in L^2(\Omega),$$

$$(\tilde{Q}_H w - w, v) = 0 \qquad \forall v \in S_0^{H,2}(\Omega), \forall w \in L^2(\Omega).$$

By using the L^2-projections on the coarser mesh T^H, superconvergence for the gradient of finite element approximations to boundary value problems has been studied in [19, 33]. In the following, we shall apply this technique together with the defect correction to finite element approximations to eigenvalue problems.

THEOREM 3.3. Let $u \in H_0^1(\Omega) \cap H^{2+\alpha}(\Omega)$ and $\mathcal{F} = A^{-1/2} Q_H A \nabla$, then

$$\|A^{1/2}\nabla u - \mathcal{F} u_h\|_{0,\Omega} \le C(H^{1+\alpha} + h^2/H), \tag{3.16}$$

$$|\lambda_h^{\mathcal{F}} - \lambda| \le C(H^{1+\alpha} + h)(H^{1+\alpha} + h^2/H). \tag{3.17}$$

PROOF. For any $v \in (L^2(\Omega))^d$ we have

$$\begin{aligned} |(Q_H A\nabla(u - u_h), v)| &= |(A\nabla(u - u_h), Q_H v)| \\ &= |(u - u_h, \operatorname{div}(AQ_H v))| \le \|u - u_h\|_{0,\Omega} |AQ_H v|_{1,\Omega} \\ &\le C\|u - u_h\|_{0,\Omega} |Q_H v|_{1,\Omega}, \end{aligned}$$

which together with the inverse inequality and the estimate $\|Q_H v\|_{0,\Omega} \le C\|v\|_{0,\Omega}$ yields

$$|(Q_H A\nabla(u - u_h), v)| \le Ch^2 H^{-1} \|Q_H v\|_{0,\Omega} \le Ch^2 H^{-1} \|v\|_{0,\Omega} \tag{3.18}$$

and

$$\|Q_H A\nabla(u - u_h)\|_{0,\Omega} \le Ch^2/H. \tag{3.19}$$

Using the triangular inequality, (3.19), and

$$\|A\nabla u - Q_H A\nabla u\|_{0,\Omega} \le CH^{1+\alpha},$$

we then arrive at

$$\begin{aligned} &\|A^{1/2}\nabla u - \mathcal{F} u_h\|_{0,\Omega} \\ &= \|A^{1/2}\nabla u - A^{-1/2} Q_H A\nabla u_h\|_{0,\Omega} \le \|A^{-1/2}(A\nabla u - Q_H A\nabla u_h)\|_{0,\Omega} \\ &\le C\left(\|A^{-1/2}(A\nabla u - Q_H A\nabla u)\|_{0,\Omega} + \|A^{-1/2} Q_H A\nabla(u - u_h)\|_{0,\Omega}\right) \\ &\le C(H^{1+\alpha} + h^2/H), \end{aligned}$$

which is nothing but (3.16). Thus we obtain (3.17) from (3.2) and (3.16). □

REMARK 3.4. One sees that the optimal choice of size of the coarser mesh should be

$$H = O(h^{2/(2+\alpha)}).$$

If we take this choice, then we have approximations with higher accuracy, which are estimated as follows:

$$\|A\nabla u - Q_H A\nabla u_h\|_{0,\Omega} + \|A^{1/2}\nabla u - A^{-1/2}Q_H A\nabla u_h\|_{0,\Omega} \le Ch^{1+\alpha/(2+\alpha)}$$

and

$$|\lambda_h^{\mathcal{F}} - \lambda| \le Ch^{2+\alpha/(2+\alpha)}.$$

We may also get some highly accurate approximations from using the L^2-projection operator $\tilde{Q}_H$.

THEOREM 3.4. [illegible] $u \in H_0^1(\Omega) \cap H^{2+\alpha}(\Omega)$ [illegible] $\mathcal{F} = A^{1/2}\nabla\tilde{Q}_H$, [illegible]

$$\|A^{1/2}\nabla u - \mathcal{F}u_h\|_{0,\Omega} \le C(H^{1+\alpha} + h^2/H), \tag{3.20}$$

$$|\lambda_h^{\mathcal{F}} - \lambda| \le C(H^{1+\alpha} + h)(H^{1+\alpha} + h^2/H). \tag{3.21}$$

[illegible] Using the inverse inequality and the estimates

$$\|u - \tilde{Q}_H u\|_{a,\Omega} \le CH^{1+\alpha},$$
$$\|\tilde{Q}_H w\|_{0,\Omega} \le C\|w\|_{0,\Omega} \quad \forall w \in L^2(\Omega),$$

we obtain the following estimation:

$$\begin{aligned}\|u - \tilde{Q}_H u_h\|_{a,\Omega} &\le \|u - \tilde{Q}_H u\|_{a,\Omega} + \|\tilde{Q}_H(u - u_h)\|_{a,\Omega}\\ &\le CH^{1+\alpha} + CH^{-1}\|\tilde{Q}_H(u - u_h)\|_{0,\Omega}\\ &\le CH^{1+\alpha} + CH^{-1}\|u - u_h\|_{0,\Omega} \le C(H^{1+\alpha} + h^2/H),\end{aligned}$$

which is nothing but (3.20). Hence we obtain (3.21) from (3.2) and (3.20). □

[illegible] We may use another postprocess to construct highly accurate approximations for eigenvalues. If, for instance,

$$\tilde{\lambda}_h = \frac{\|\tilde{Q}_H u_h\|_{a,\Omega}^2}{\|\tilde{Q}_H u_h\|_{0,\Omega}^2},$$

then

$$0 < \tilde{\lambda}_h - \lambda \le C(H^{2(1+\alpha)} + h^4/H^2). \tag{3.22}$$

It should be pointed out that our defect correction schemes based on L^2-projection averaging techniques are different from that proposed in [37]. It is noted that the defect correction scheme on a shape-regular mesh proposed in this paper is first to solve the eigenvalue problem on the fine mesh and then to do some postprocessing through an L^2-projection averaging on some coarser mesh, while the scheme provided in [37] is first to solve the eigenvalue problem on some coarser mesh and then to correct the residual by solving some boundary value problem on the fine mesh.

3.3. Numerical experiments. In this subsection we will report several numerical results of highly accurate approximations of finite element eigenvalues constructed by using our averaging techniques and the defect correction procedures. Examples in two and three dimensions are provided. These results support our theory established above.

Let (u_h,λ_h) be an approximation to (u,λ) and define

$$\begin{aligned}
&\eta(Q_h,h) = \|A^{1/2}\nabla u_h - A^{-1/2}Q_hA\nabla u_h\|_{0,\Omega},\\
&\tilde{\lambda}_{h,Q_h} = \lambda_h - \|A^{1/2}\nabla u_h - A^{-1/2}Q_hA\nabla u_h\|^2_{0,\Omega},\\
&e(Q_h,h) = |\tilde{\lambda}_{h,Q_h} - \lambda|,\\
&\eta(G_h,h) = \|A^{1/2}\nabla u_h - A^{-1/2}\mathcal{C}_hAu_h\|_{0,\Omega},\\
&\tilde{\lambda}_{h,G_h} = \lambda_h - \|A^{1/2}\nabla u_h - A^{-1/2}\mathcal{C}_hAu_h\|^2_{0,\Omega},\\
&e(G_h,h) = |\tilde{\lambda}_{h,G} - \lambda|,\\
&\tilde{\lambda}_{h,Q_H} = \lambda_h - \|A^{1/2}\nabla u_h - A^{-1/2}Q_HA\nabla u_h\|^2_{0,\Omega},\\
&\tilde{\lambda}_{h,\tilde{Q}_H} = \frac{\|\tilde{Q}_Hu_h\|^2_{a,\Omega}}{\|\tilde{Q}_Hu_h\|^2_{0,\Omega}}.
\end{aligned}$$

EXAMPLE 3.1. Consider a model problem in two dimensions:

$$\begin{cases} -\Delta u &= \lambda u \quad \text{in } \Omega,\\ u &= 0 \quad \text{on } \partial\Omega, \end{cases} \tag{3.23}$$

where $\Omega = (0,1)\times(0,1)$. The eigenvalues of (3.23) are given by $\lambda_{k,l} = (k^2+l^2)\pi^2$, and the associated eigenfunctions are $u_{k,l} = \sin(k\pi(x-1))\sin(l\pi(y-1))$, $k,l = 1,2,\ldots$.

Here we address the first eigenvalue $\lambda \simeq 19.7392$ and its associated eigenfunction $u = \sin(\pi(x-1))\sin(\pi(y-1))$. Note that α in (2.13) or (2.14) is 1; the numerical results in Tables 1 and 2 coincide with our theory, while the numerical results in Tables 3 and 4 are better than those predicted by our theory.

Note that in Tables 3 and 4, the optimal choices of the mesh sizes are $H = O(h^{0.6667})$ (i.e., $\ln H/\ln h \simeq 0.6667$), and the theoretical convergence order in Tables 3 and 4 is 2.3333 and 2.6667, respectively.

TABLE 3

4.419417e-02	1.5622643e-02	7.6255081e-01	-1.622172e-05	3.755559e+00

TABLE 4
Example 3.1*: Global average on irregular meshes ($\tilde{Q}_H$ projection.)*

H	h	$\ln H/\ln h$	$\tilde{\lambda}_{h,\tilde{Q}_H}-\lambda$	order$(\tilde{\lambda}_{h,\tilde{Q}_H}-\lambda)$
3.535534e-01	1.767767e-01	6.000000e-01	2.159374e-01	
2.357023e-01	8.333333e-02	5.815856e-01	1.928435e-02	3.212194e+00
1.767767e-01	6.250000e-02	6.250000e-01	9.470608e-03	3.007341e+00
7.071068e-02	5.000000e-02	8.843109e-01	5.125633e-03	2.751319e+00

Example 3.2. Consider a model problem in three dimensions:

$$\begin{cases} -\sum_{i=1}^{3}\dfrac{\partial}{\partial x_i}\left(x_i^2\dfrac{\partial u}{\partial x_i}\right) = \lambda u & \text{in } \Omega, \\ u = 0 & \text{on } \partial\Omega, \end{cases} \tag{3.24}$$

where $\Omega=(1,3)\times(1,2)\times(1,2)$. The first eigenvalue is $\lambda=\frac{3}{4}+(\frac{2}{\ln^2 2}+\frac{1}{\ln^2 3})\pi^2\simeq 50.01212422$, and the associated eigenfunction is $u=\prod_{i=1}^{3}(x_i^{-\frac{1}{2}}\sin(\frac{\pi\ln x_i}{\ln\beta_i}))$, where $\beta_1=3$, $\beta_2=\beta_3=2$.

Some numerical results on uniform meshes are presented in Tables 5 and 6. In this example, the value α in (2.13) or (2.14) is 1. Hence our numerical results show a better order of convergence for eigenfunctions than those predicted by our theory. The numerical results on irregular meshes are presented in Tables 7 and 8. These results are comparable to those predicted by our theory. Note that the optimal choices of mesh sizes in Tables 7 and 8 are $H=O(h^{0.6667})$ (i.e., $\ln H/\ln h\simeq 0.6667$), and the theoretical convergence order in Tables 7 and 8 is 2.3333 and 2.6667, respectively.

4. Applications to quantum chemistry. For highly accurate finite element approximations to elliptic eigenvalue problems, theoretically we need to require that the exact solution and the coefficients are smooth. In practice, however, we have finite element approximations with higer accuracy even if the data are not so smooth. In this section, as illustrations, we shall apply the finite element defect correction scheme together with the averaging techniques to construct highly accurate approximations for two simplest Hartree–Fock equations in computational quantum chemistry: one Hartree–Fock equation is for hydrogen atoms and the other is for helium atoms. The data in such Hartree–Fock equations are not smooth. More precisely, the coefficients and the exact solutions of the Hartree–Fock equations are singular. However, it is shown by our numerical experiments that higher accuracy approximations for Hartree–Fock equations may be achieved. Particularly, approximations with much higher accuracy can be obtained if some adaptive finite element grids are employed. (As for the generalization of adaptive finite element grids for eigenvalue problems, we refer to [26] for details.) In our computation, the adaptive finite element grids that

will be used are constructed from the error indicator

$$\sum_{\tau\in T^h} \|A^{1/2}\nabla u_h - \mathcal{F}u_h\|_{0,\tau}^2$$

and the bisection approaches, where $\mathcal{F}$ is a recovery operator.

4.1. Hydrogen atoms. The Hartree–Fock equation for hydrogen atoms is written as

$$-\frac{1}{2}\Delta u - \frac{1}{|x|}u = Eu \qquad \text{in } R^3 \tag{4.1}$$

with $\int_{R^3}|u|^2dx = 1$. The total energy of the ground state for a hydrogen atom is the first eigenvalue E of (4.1). In the simulation, we solve (4.1) by using the finite element discretization (2.8) when

$$A = \begin{pmatrix} 1/2 & 0 & 0 \\ 0 & 1/2 & 0 \\ 0 & 0 & 1/2 \end{pmatrix}, \tag{4.2}$$

TABLE 9
H atoms, uniform meshes, and defect correction.

** Here the 5-order polynomial basis functions are used.*

$\beta = -1/|x|$, $\Omega = (-6.4, 6.4) \times (-6.4, 6.4) \times (-6.4, 6.4)$, and $\lambda = E$. Further, we apply $\mathcal{F} = \sqrt{1/2}Q_h\nabla$ and $\mathcal{F} = \sqrt{1/2}\mathcal{C}_h\nabla$ in our defect correction scheme, respectively. The numerical results are shown in Tables 9 and 10, where

$$\text{energy}(Q_h) = E_h - \|\sqrt{1/2}\nabla u_h - \sqrt{1/2}Q_h\nabla u_h\|^2_{0,\Omega}, \tag{4.3}$$

$$\text{energy}(G_h) = E_h - \|\sqrt{1/2}\nabla u_h - \sqrt{1/2}\mathcal{C}_h\nabla u_h\|^2_{0,\Omega}. \tag{4.4}$$

As compared with the results in the literature (see Table 11), one sees that our approaches are powerful.

4.2. Helium atoms. For the helium atom, the associated Hartree–Fock equation is

$$-\frac{1}{2}\Delta u - \frac{2}{|x|}u + \int_{R^3}\frac{|u(y)|^2dy}{|x-y|}u = Eu \ \text{ in } R^3 \tag{4.5}$$

with $\int_{R^3}|u|^2dx = 1$. In our computation for the total energy of the ground state, we solve the following nonlinear eigenvalue problem: Find $(u, E) \in H_0^1(\Omega) \times R$ such that $\int_\Omega |u|^2dx = 1$ and

$$\left\{\begin{array}{rcl} -\frac{1}{2}\Delta u - \frac{2}{|x|}u + \int_\Omega \frac{|u(y)|^2dy}{|x-y|}u &=& Eu \ \text{ in } \Omega, \\ u &=& 0 \ \text{ on } \partial\Omega, \end{array}\right. \tag{4.6}$$

where $\Omega = (-7.0, 7.0) \times (-7.0, 7.0) \times (-7.0, 7.0)$. The total energy of the ground state for the helium atom is

$$\mathcal{E} = 2E - \int_\Omega\int_\Omega \frac{|u(x)|^2|u(y)|^2dxdy}{|x-y|},$$

where E is the first eigenvalue of (4.5). Since it is nonlinear, we solve (4.6) self-consistently:

TABLE 14
He atoms, adaptive meshes, and defect correction.

Degree of freedom	Energy	energy(Q_h)	energy(G_h)
1341	-2.680944	-2.827951e+00	-2.847466e+00
2975	-2.752170	-2.841256e+00	-2.848725e+00
16691	-2.830592	-2.861307e+00	-2.862088e+00
49573	-2.847419	-2.864203e+00	-2.862788e+00

- Step 1. Given an initial data (u_0, E_0).
- Step 2. For any $n = 0, 1, 2, \ldots$, find $(u_{n+1}, E_{n+1}) \in H_0^1(\Omega) \times R$ such that $\int_\Omega |u_{n+1}|^2 dx = 1$ and

$$\text{(4.7)} \quad \begin{cases} -\dfrac{1}{2}\Delta u_{n+1} - \dfrac{2}{|x|}u_{n+1} + \displaystyle\int_\Omega \frac{|u_n(y)|^2 dy}{|x-y|}u_{n+1} = E_{n+1}u_{n+1} \ \text{ in } \Omega, \\ \qquad\qquad\qquad\qquad\qquad\qquad u_{n+1} = 0 \ \text{ on } \partial\Omega. \end{cases}$$

For $n = 1, 2, \ldots$, we solve (4.7) by using the finite element discretization (2.8) when A is given by (4.2),

$$\beta = \frac{-2}{|x|} + \int_\Omega \frac{|u_n(y)|^2 dy}{|x-y|},$$

$\Omega = (-7.0, 7.0) \times (-7.0, 7.0) \times (-7.0, 7.0)$, and $\lambda = E_{n+1}$. Similarly, we apply $\mathcal{F} = \sqrt{1/2}Q_h\nabla$ and $\mathcal{F} = \sqrt{1/2}\mathcal{C}_h\nabla$ in our defect correction scheme, respectively.

The relevant numerical results in the literature are provided in Table 12. The exact total energy may be viewed as -2.90 (cf. [10, 29]). Our numerical results are reported in Tables 13 and 14, where energy(Q_h) and energy(G_h) are defined by (4.3) and (4.4), respectively. It is shown again that our approaches are efficient. For instance, by using our defect correction scheme and the adaptive mesh, we may get an approximate total energy -2.849 with only 2975 degrees of freedom, which can be compared with results using the standard finite element method with special basis functions, whose number of degrees of freedom is 5×10^5.

Acknowledgments. The authors would like to thank Professor X. Gang and Mr. D. Zhang for their discussions of electronic structure computations that moti-

vated the application in section 4 above, and to thank the referees for their valuable comments and suggestions that improved the presentation of this paper.

ON EFFECTIVE METHODS FOR IMPLICIT PIECEWISE SMOOTH SURFACE RECOVERY*

U. M. ASCHER†, E. HABER‡, AND H. HUANG§

Abstract. This paper considers the problem of reconstructing a piecewise smooth model function from given, measured data. The data are compared to a field which is given as a possibly nonlinear function of the model. A regularization functional is added which incorporates the a priori knowledge that the model function is piecewise smooth and may contain jump discontinuities. Regularization operators related to total variation (TV) are therefore employed.

Two popular methods are modified TV and Huber's function. Both contain a parameter which must be selected. The Huber variant provides a more natural approach for selecting its parameter, and we use this to propose a scheme for both methods. Our selected parameter depends both on the resolution and on the model average roughness; thus, it is determined adaptively. Its variation from one iteration to the next yields additional information about the progress of the regularization process.

The modified TV operator has a smoother generating function; nonetheless we obtain a Huber variant with comparable, and occasionally better, performance.

For large problems (e.g., high resolution) the resulting reconstruction algorithms can be tediously slow. We propose two mechanisms to improve efficiency. The first is a multilevel continuation approach aimed mainly at obtaining a cheap yet good estimate for the regularization parameter and the solution. The second is a special multigrid preconditioner for the conjugate gradient algorithm used to solve the linearized systems encountered in the procedures for recovering the model function.

Key words. inverse problem, total variation, Huber regularization, lagged diffusivity, Gauss–Newton, multilevel continuation, multigrid preconditioner

1. Introduction.

We consider the problem of reconstructing a piecewise smooth model function in several dimensions from given, measured data. In general, the data are viewed as a nonlinear function of the model:

$$b = F(m) + \epsilon,$$

where F is the forward modeling operator, $m = m(\mathbf{x})$ is the model to be recovered, b is the data, and ϵ is measurement noise. We assume that the model is defined on a two-dimensional (2D) domain with unit volume, Ω, although extensions to 3D are possible and in principle straightforward.

The operators F under consideration vary considerably from an identity in simple denoising problems [34, 38, 35] through a linear, constant coefficient form in deblurring and tomography problems [38, 24, 23, 16] to the solution of a diffusive partial differential equation (PDE) system involving Poisson or Maxwell's differential equations

[10, 28, 5, 22]. Due to either ill-posedness of the problem or the presence of noise in the measured data (or both) the problem requires regularization. In a Tikhonov-type approach this leads to the optimization problem

$$\min_m T(m) \equiv \frac{1}{2}\|F(m) - b\|^2 + \beta R(m), \tag{1}$$

where $R(m)$ is the regularization operator which is the focus of attention in the present work, and $\beta \geq 0$ is the regularization parameter. We use the least squares norm for the data fitting term, although other norms are possible and may be more suitable depending on the noise statistics.

For simplicity of exposition we employ the following notational convention. The domain Ω is discretized by a uniform grid with N^2 square cells of length $h = 1/N$ each. With a slight abuse of notation the function $m(\mathbf{x})$ becomes an $(N+1)\times(N+1)$ grid function m which is occasionally further reshaped into a vector, $m \in \Re^K$, $K = (N+1)^2$. Likewise, the data b, given on a subset of the grid's nodes or cells, is occasionally rearranged as a vector, $b \in \Re^M$. Then $F\colon \Re^K \to \Re^M$ is a vector function, assumed continuously differentiable. And yet, we shall also denote the discretized gradient of m, say, simply as ∇m. Finally, we define the

$$J(m) = \frac{\partial F}{\partial m}.$$

Then the necessary conditions for optimum in (1) are written as a system of generally nonlinear algebraic equations,

$$J^T(F - b) + \beta R_m = 0. \tag{2}$$

For the regularization term, one typically considers a same-grid discretization of

$$R(m) = \int_\Omega \rho(|\nabla(m - m_{ref})|) + \hat{\alpha}(m - m_{ref})^2, \tag{3}$$

where $\hat{\alpha} \geq 0$ is a small parameter and m_{ref} is a given reference function. The selection of m_{ref} can be crucial, for instance in geophysical exploration, but here we set $\nabla m_{ref} = 0$ and concentrate on the choice of the function ρ. The latter relates directly to the a priori information we have about the smoothness of the model. Note that

$$R_m(m) = -\nabla \cdot (\sigma(|\nabla m|)\nabla m), \quad \text{where} \quad \sigma(\tau) = \frac{\rho'(\tau)}{\tau}.$$

For recovering smooth surfaces it is common to choose least squares, $\rho(\tau) = \frac{1}{2}\tau^2$, yielding $\sigma \equiv 1$. However, this choice is inadequate in the presence of discontinuities. The famous total variation (TV) choice (e.g. [11, 32, 38, 18]) uses the l_1-norm instead, $\rho(\tau) = \tau$, implying $\sigma(\tau) = 1/\tau$. Unfortunately, $\sigma(\tau) = 1/\tau$ is unbounded when τ shrinks, i.e., when $|\nabla m| \to 0$. Three remedies have been proposed in the literature to alleviate this. The first, and most recent, is to view $|\nabla m|$ as dual variables in a primal-dual approach. See [6] and references therein. This leads to some beautiful, more complex mathematical analysis. However, the other two possibilities to be explored below are so simple, [illegible], popular and effective in practice that the case for their replacement is necessarily not crucial. Moreover, the adaptive variants proposed in this article often yield better results than the pure TV would.

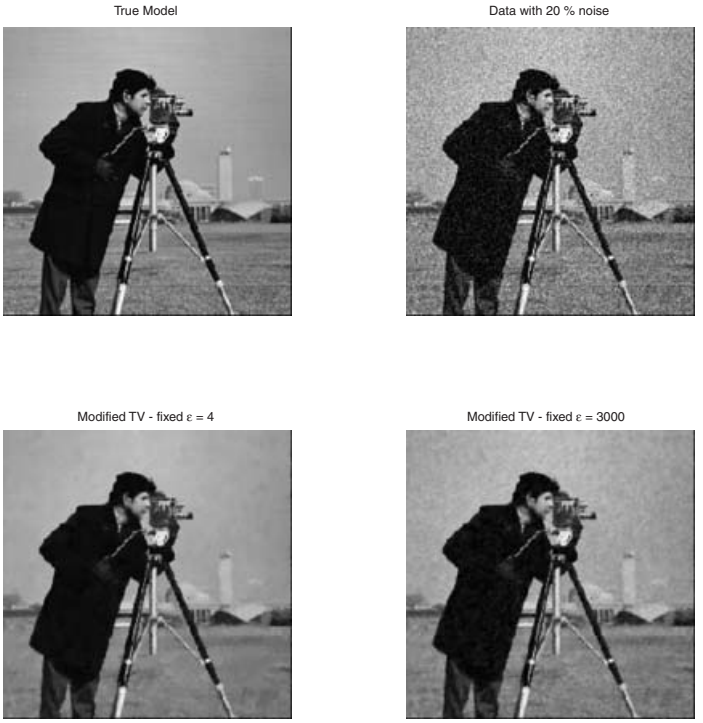

FIG. 1. *Denoising: The "true image" (upper left) is corrupted by adding* 20% *white noise (upper right) and the latter is fed as data b to a denoising program using the usual Tikhonov regularization with modified TV. The smaller value of switching parameter* ε *(lower left) produces a more pleasing result than the larger value (lower right). Taking* $\varepsilon = .01$ *or* $\varepsilon = 10^{-6}$ *yields results similar to those displayed in the lower left panel but at a higher cost.*

The [illegible] approach replaces $|\nabla m|$ in ρ and therefore in σ by

$$|\nabla m|_\varepsilon = \sqrt{m_x^2 + m_y^2 + \varepsilon^2}. \tag{4}$$

See, e.g., [9, 7, 38]. The parameter $\varepsilon \geq 0$ must be selected to be small enough so as to sharply preserve discontinuities and large enough so as not to cause undue numerical hardship, especially when iterative methods such as preconditioned conjugate gradients are used. We have found surprisingly little in the literature regarding the practical selection of this parameter.

Experiment 1. To see that there is an issue here, consider the popular example of denoising the picture given in the upper right panel of Figure 1 using a suitably modified TV regularization [32, 9]. For our grid function $m = \{m_{i,j}\}_{i,j=0}^{N}$ ($N = 256$, $h = 1/N$), denoting

$$D_{+,x} m_{i,j} = \frac{m_{i+1,j} - m_{i,j}}{h}$$

and similarly for $D_{+,y} m_{i,j}$, we define $|\nabla m_{i,j}|_h$, etc., by

$$|\nabla m|_\varepsilon = |\nabla m|_{h,\varepsilon} = \sqrt{(D_{+,x} m)^2 + (D_{+,y} m)^2 + \varepsilon^2}.$$

TABLE 1
Work units and CPU time vs the modification parameter ε.

ε	10^{-6}	10^{-2}	4	3000
Work units	37	30	12	10
CPU sec	127	115	50	42

This yields a symmetric term in the sum replacing the integral for $R(m)$ in (3) which appears in (1). We next vary ε and record work units and CPU times: the actual method used is described later, in sections 3 and 4; here we merely note that an increase in computing time relates directly to an increase in the total number of preconditioner calls in our procedure for solving the resulting linear systems.

Table 1 clearly indicates that more computational effort is required for smaller values of ε. Next, the results displayed in Figure 1 indicate that the choice $\varepsilon = 3000$ is not very good, especially for segmentation purposes; the other three values yield very similar, and satisfactory, results.

The combination of quality and cost therefore indicates not only that (i) as is well-known, values of ε which are too large or too small should be avoided, but also that (ii) the best value among those displayed, $\varepsilon = 4$, does not automatically leap to mind! It should be noted that the performance indicators in Table 1 do not change significantly in the range $4 \le \varepsilon \le 100$. Thus, the quest is not to find an optimal value of ε, but rather, to select it from "the right range." This parameter range, however, need not necessarily include values $\varepsilon \ll 1$ which are commonly used by practitioners. Unless one is content with a highly expensive trial and error approach, a procedure is required that would yield an effective, automatic selection of ε.

An alternative to modified TV uses the Huber switching function [25, 18, 34]

$$\rho(\tau) = \begin{cases} \tau, & \tau \ge \gamma, \\ \tau^2/(2\gamma) + \gamma/2, & \tau < \gamma \end{cases} \tag{5}$$

$$R_m(m) \leftarrow \nabla \cdot \left(\min\left\{ \frac{1}{\gamma}, \frac{1}{|\nabla m|} \right\} \nabla m \right).$$

Unlike for the smooth modified TV function, here ρ is not C^2, although its second derivative is bounded. Nonetheless we show in section 2 and Appendix A that the lagged diffusivity algorithm converges globally under the same assumptions as for the modified TV, extending the proof of [9]. The advantage of the choice (5) is that the selection of the parameter γ is much more transparent, and we capitalize on this in the present article.

Indeed, γ in (5) is viewed as answering the question, "what can be interpreted as a jump?" Thus, it is the minimal size of a local change in $|\nabla m|$ which is still interpreted by a TV functional and hence jumps will not be necessarily smeared. The TV interpretation is desirable, particularly if edges are to be respected, but it must be avoided in an $O(h)$ band, where the resolution limitation does not allow a true distinction between what may be zero and what is not.

With this in mind, we propose the following [illegible]:

$$\gamma = h \int_\Omega |\nabla m|. \tag{6}$$

The integral is of course replaced by a sum upon discretization. If the volume of Ω differs from unity then we divide by it to obtain the average of $|\nabla m|$. In (6), $\gamma = \gamma(m)$

depends on the solution, and indeed we adjust its value through the iteration in an obvious fashion. What this choice basically says is that we avoid the possibility of a jump [illegible] $|\nabla m|$ [illegible] h [illegible]; otherwise, a jump [illegible] happen.

Note that the average value of $|\nabla m|$ may well depend on the application, its scaling, and the amount of noise still present in a given iteration. Moreover, the rate of change in γ from one iteration to the next indicates to what extent the discontinuities have already been distinguished from the smooth parts of the surface m to be recovered.

Our choice of γ also leads to a selection of the parameter ε in (4), as elaborated upon in section 2.

Another, earlier choice uses so-called "robust statistics theory" where γ is interpreted as answering the question of how large the model's gradient can be before it is considered to be an outlier. One arrives at the formula (see, e.g., [34, p. 231] and references therein)

$$\gamma = c \cdot \text{median}[|\nabla m - \text{median}(|\nabla m|)|], \tag{7}$$

with $c \approx 1.5$. However, it is not entirely clear under what conditions the statistical arguments leading to (7) are valid, nor is it clear how this formula scales with h. In fact, the rationale leading to (7), unlike ours in deriving (6), does not favor TV whenever possible, in recognition of the tendency of TV regularization to flatten natural scenes.

While the selection of γ and ε is settled, that of the regularization parameter β, which is notoriously challenging in practical problems even for least squares regularization [38, 17], does not become easier here. Several systems must be solved in a search for a good β, each involving difficult nonlinear optimization and the solution of often ill-conditioned linear systems. For large problems (corresponding to high resolution) the resulting reconstruction algorithms can become tediously slow.

In section 3 we propose two mechanisms to improve efficiency. The first is a multilevel continuation approach [1]. While applying continuation also in a procedure to grow the model solution gradually this technique is aimed mainly at obtaining a cheap yet good estimate for the regularization parameter β. The key observation is that β should not vary much between different grids with our choice of γ.

The second item in section 3 is a special multigrid preconditioner for the conjugate gradient algorithm used to solve the linearized systems encountered in the procedures employed for recovering the model function. Because of jumps in the coefficient function σ a usual multigrid cycle can be ineffective [37].

We close this paper with numerical experiments demonstrating the proposed techniques on several inverse problems. These techniques work very well for problems such as denoising, deblurring and emission tomography. But for a problem such as electrical impedance tomography (EIT) [5] or electromagnetic geophysical prospecting [22] the reconstruction of a piecewise continuous model is fundamentally difficult. The conclusion section seals the paper.

2. Modified TV and Huber regularization. Let us consider first the Huber regularization (5) and the choice of the parameter γ given by (6). It is not difficult to see that, despite the appearance of the term $1/\gamma$ in (5), the regularization term $R(m)$ remains bounded as $h \to 0$. Indeed, on the continuous level fix γ and let

$$\Phi = \{\mathbf{x} : |\nabla m(\mathbf{x})| < \gamma\}. \tag{8a}$$

Then (1) is written as

$$\min_m \frac{1}{2}\|F(m)-b\|^2 + \beta\left[\frac{1}{2\gamma}\int_\Phi |\nabla m|^2 + \frac{\gamma}{2}\int_\Phi 1 + \int_{\Omega\setminus\Phi}|\nabla m|\right]. \tag{8b}$$

But by (8a),

$$\frac{1}{2\gamma}\int_\Phi |\nabla m|^2 + \frac{\gamma}{2}\int_\Phi 1 < \gamma\int_\Phi 1,$$

and also $\int_\Phi |\nabla m| < \gamma\int_\Phi 1$. Hence, letting $\gamma\to 0$ we get $R(m)\to\int_\Omega|\nabla m|$.

Now, the regularization term on a grid with mesh width h approximates the continuous $R(m)$ up to $O(h)$ by straightforward consistency. We summarize this in Lemma 1.

LEMMA 1. [illegible] (6) [illegible]

$$R(m) = \int_\Omega |\nabla m| \quad + O(h). \tag{9}$$

Next, consider the modified TV regularization (4). When $\varepsilon \gg |\nabla m|$ we obviously get approximately the least squares norm on $|\nabla m|$. Thus, the considerations for selecting ε should follow similar lines to those for γ. We choose

$$\varepsilon = 0.5\gamma, \tag{10}$$

which yields agreement with (5) at $\tau = 0$, where these formulae are most useful if considered as modifications of TV. It is important to note that while both forms of stabilizing the TV seminorm are roughly equivalent the choice of the stabilization parameter is natural in the Huber case but is less obvious for the modified TV. If edges are not to be emphasized then the choice of a larger γ again has a more obvious meaning in the Huber case.

Note that as $h\to 0$, $|\nabla m|_{h,\varepsilon}\to|\nabla m|$ in a well-defined manner.

2.1. Lagged diffusivity. Upon differentiating (1) with respect to m we obtain the following system of equations:

$$\beta[L(m)m]_{i,j} + [J^T(m)(F(m)-b)]_{i,j} = 0, \quad \text{where} \tag{11a}$$

$$(L(m)m)_{i,j} = \frac{1}{h^2}[\sigma_{i+1/2,j}(m_{i,j}-m_{i+1,j}) + \sigma_{i,j+1/2}(m_{i,j}-m_{i,j+1})$$

$$+ \sigma_{i-1/2,j}(m_{i,j}-m_{i-1,j}) + \sigma_{i,j-1/2}(m_{i,j}-m_{i,j-1})], \tag{11b}$$

$$\sigma_{i+1/2,j} = \min\left\{\frac{1}{\gamma}, \frac{h}{\sqrt{(m_{i,j}-m_{i+1,j})^2 + (m_{i,j}-m_{i,j+1})^2}}\right\}. \tag{11c}$$

Here, h is the step size of a uniform grid and $i,j = 1,\dots,N-1$. The five point discretization of the regularization term above can be thought of as a consistent finite volume discretization of the differential operator $-\beta\nabla\cdot(\min\{\frac{1}{\gamma},\frac{1}{|\nabla m|}\}\nabla m)$ with natural boundary conditions.

In order to solve the nonlinear system (11c) numerically, a fixed point iteration called [illegible] has been proposed and studied extensively (see, e.g., [38] and references therein). Given an initial iterate m^0, one repeatedly and approximately solves

$$\beta L(m^{s-1})m^s + J^T(m^s)(F(m^s)-b) = 0, \quad s = 1,2,\dots. \tag{12}$$

Thus, if F is linear, then for each s we solve a linear, anisotropic diffusion equation. This method works very well for low accuracy requirements (i.e., it converges rapidly at first but then slows down as its asymptotic convergence rate is only linear), especially if J^TJ is nonsingular.

Global convergence, i.e., from any starting point m^0, for the modified TV norm was shown in several references in the case that J^TJ is constant and bounded away from singularity; see [13] and references in Chapter 8 of [38], where it is also claimed that some proofs easily extend to Huber's function with γ fixed.

Here, for the sake of completeness, we extend the proof by Chan and Mulet [9] to the case where $F(m) = Jm$, J constant with a full column rank, using Huber's function (5) with γ adaptively defined by (6).

THEOREM 2. [illegible] $F(m) = Jm$ [illegible] J [illegible] (1) (2) [illegible] $\{m^s\}$ [illegible] (12) [illegible]

1. $T(m^s) \le T(m^{s-1})$ [illegible] $s \ge 1$
2. $\lim_{s\to\infty} |m^s - m^{s-1}| = 0$
3. [illegible] $\{m^s\}$ [illegible]

The proof is given in Appendix A.

Another possibility proposed by Chan, Golub and Mulet [7] and advocated in [38] is a primal-dual Newton method: dual variables corresponding to the flux (in (11c) these are the discretized $\mathbf{v} = \min\{\frac{1}{\gamma}, \frac{1}{|\nabla m|}\}\,\nabla m$) are considered as independent variables along with m and a Newton method is defined, observing maximum size constraints for $\mathbf{v}$. However, the typical number of iterations required using lagged diffusivity to reach the rough error tolerances which makes sense in the present context is so small that the improved convergence rate of the primal-dual method may kick in too late to be of practical interest.

Lagged diffusivity and damped Gauss–Newton. Returning to lagged diffusivity, in case that $F(m)$ is nonlinear it makes sense to also linearize the second term in (12) in a comparable manner. In particular, it makes sense to use a single Gauss–Newton iteration, linearizing $F(m^s)$ around m^{s-1}, which leads to the following linear system to be solved at each iteration:

$$\left(J^TJ \;+\; \beta L\right)\; \delta m \;= J^T(b - F(m^{s-1})) \;-\; \beta L m^{s-1}, \tag{13}$$

with $J = J(m^{s-1})$, and $L = L(m^{s-1})$ defined in (11c). In general global convergence is no longer guaranteed by simply setting $m^s = m^{s-1} + \delta m$, and a line search (i.e., setting $m^s = m^{s-1} + \eta\,\delta m$, $0 < \eta \le 1$; see, for instance, [30]) or a trust region method may be necessary to guarantee sufficient reduction of the objective function $T(m)$ of (1).

2.2. On choosing the regularization parameter. In general, the optimization problem (1) must be solved many times by the process described above for different regularization parameter values β. This contributes in a major way to the total cost of the solution process. A solution is accepted when some stopping criterion is satisfied. This is not our focus in the present article; however, leading to the next section we mention the simplest such criterion, namely, the discrepancy principle. Thus, one requires

$$\phi_d(m(\beta)) = \|F(m) - b\|^2 \le \text{tol} \tag{14}$$

for some specified tolerance level tol which depends on the noise level and is assumed given. A procedure of continuation in β is then developed, where previous values of ϕ_d are used to estimate the next value of β, e.g., by a secant iteration.

In practice the tolerance is derived from statistical arguments, such as χ^2 distribution, and it must be noted that one rarely has more than a rough estimate of what tol should be. This is true even for the case of a smooth model recovery.

3. Numerical techniques for large problems.

Multilevel continuation. Lemma 1 assures us that $R(m)$ does not vary much as the resolution is increased on the same domain. The same holds true, of course, for the data fitting term in (1). We therefore conclude that [illegible] (6) [illegible] β [illegible].

As in [1, 20] we develop a multilevel continuation methodology, aimed chiefly at exporting the value of β constructed on a coarse grid to finer grids.

Starting on the coarse grid and subsampling the data as needed, the algorithm calculates an approximate solution and an approximate regularization parameter. Next, we interpolate the solution to a finer grid using a piecewise linear interpolation (cf. [1]) and solve the optimization problem using the interpolated solution as a starting guess, with the regularization parameter obtained on the coarse grid possibly slightly adjusted. The process continues until we reach the finest grid.

The reason that we may need to adjust β as the grid is refined is that the discretization error may play a more major role on coarser grids, particularly when the forward problem also involves the inversion of a discretized differential equation. (That "the coarsest grid must be fine enough" is a well-known requirement in the multigrid literature; see [1] in our particular context.) Thus, a search for β commences as in section 2.2, so that a criterion such as (14) with a "soft tolerance" is respected before work starts on the next finer grid.

A multigrid preconditioner. Although multilevel continuation decreases the number of iterations needed to compute a solution on the finer grids, each iteration is still expensive because (13) is a large system of linear equations which corresponds to a differential or integro-differential equation with nonsmooth coefficients. Therefore, an essential component in any fast algorithm for the solution of the problem is a fast algorithm for the solution of the linear system.

To simplify notation we rewrite the system as

$$H\ \delta m \equiv (J^T J + \beta L)\ \delta m\ =\ \text{rhs}. \tag{15}$$

There are two cases to consider here. First, if $J^T J$ is sparse with a sparsity pattern similar to that of L (e.g. denoising, superresolution), then a preconditioned conjugate gradient (PCG) method with a multigrid cycle as a preconditioner can be directly applied to the system. If on the other hand $J^T J$ is dense, then one can approximate $J^T J$ either by a sparse matrix, for example, $\text{diag}\{J^T J\}$, or by a low rank matrix (see [20]) and obtain an approximate $\hat{J}^T \hat{J} + \beta L$ which is used as a preconditioner. We now briefly discuss how to obtain such an approximation. Obtaining an efficient approximation to J is a nontrivial matter see, for example, [19, 38, 3, 4], which is beyond the scope of the present paper.

We therefore apply a multigrid preconditioner based on the approximate inversion of L plus a positive definite sparse matrix. Note that since L is a discretization of a differential operator with nonsmooth coefficients standard multigrid methods are ineffective. One can resort to algebraic multigrid (AMG) (see, e.g., [36]); however, this may not be as efficient as geometric multigrid which utilizes the underlining grid that exists for our problem. We therefore turn to geometric multigrid methods which are developed for problems with nonsmooth coefficients [12, 26].

Let m_F be a grid function on the finest grid of $(N+1)^2$ points, or nodes. We set the next coarser grid function, m_C, to be the grid function on $(N/2+1)^2$ points chosen in the obvious manner. The difference from standard multigrid is in the use of [illegible]. This approach combines algebraic multigrid with geometric multigrid methods to obtain the interpolation operator. As common to algebraic multigrid methods we divide the fine grid points to coarse points (C) and fine points (F). The approximate Gauss–Newton step is reordered as

$$\begin{pmatrix} H_{FF} & H_{FC} \\ H_{FC}^T & H_{CC} \end{pmatrix} \begin{pmatrix} \delta m_F \\ \delta m_C \end{pmatrix} = \text{rhs}.$$

We next define the [illegible]

$$P = \begin{pmatrix} H_{FF}^{-1} H_{FC} \\ -I \end{pmatrix}$$

and, eliminating the fine grid points, obtain the [illegible]

$$P^T \begin{pmatrix} H_{FF} & H_{FC} \\ H_{FC}^T & H_{CC} \end{pmatrix} P \; \delta m_C = \text{rhs}_C.$$

The obvious problem with the exact interpolation and coarse grid operators is that the matrix H_{FF} does not have a sparse inverse. Different approximations for its inverse define different methods. For a survey and comparison of methods see [26]. Here we have chosen a similar approach to the one suggested by Dendy [12] to obtain sparse interpolation and coarse grid operators. The restriction operator is chosen to be the transpose of the interpolation and symmetric Gauss–Seidel is used as a smoother. Combining the above components into a V(3,1) cycle we have found that in most cases a single cycle is sufficient to reduce the residual norm below 10^{-2}.

4. Numerical experiments.

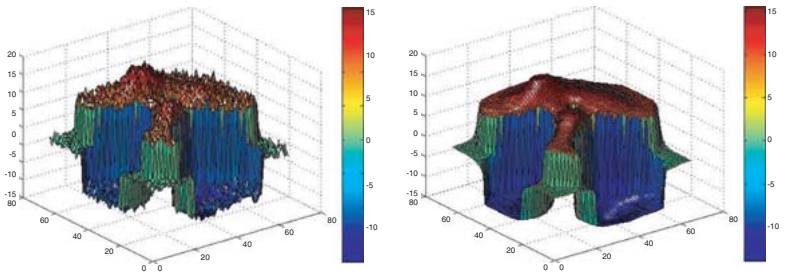
Experiment 1 (cont.). For simple denoising, $F(m) = m$ and hence $J = I$, the identity. We apply PCG iterations using our multigrid V-cycle preconditioner. The coarsest grid in all cases has $h_{coarsest} = 2^{-4}$.

For the example considered in section 1, $h = 2^{-8}$. Let us complete its details. The quality of the results strongly depends on β and some search was required before settling on $\beta = .07$ for a 20% noise. Using the Huber function with γ determined adaptively according to the formulas (6) and (7) we obtain after 10 lagged diffusivity iterations results which are very similar, indeed indistinguishable to the naked eye, to those displayed in the lower left and right panels, respectively, of Figure 1. The choice of 10 lagged diffusivity iterations has been made because that is when γ in (6) changes by less than 10% from one iteration to the next, but further iterations have not revealed significantly different results.

The respective final values of γ are 8.34 and 6.56×10^3, and this gives rise to the values of ε used in the experiment reported in section 1. There has been no notable difference in the performance of the Huber vs the modified TV variants in this case, and the results reported earlier therefore demonstrate both the general utility of the formula (6) and its superiority over (7). The (nonoptimized) CPU times reported in Table 1 correspond directly to the total number of PCG iterations required, and the latter count, for 10 nonlinear iterations in each case, is reported as "work units" in Table 1. The V-cycle preconditioner is therefore seen to perform rather effectively

TABLE 2
γ by (6) vs mesh width h.

h	2^{-4}	2^{-5}	2^{-6}	2^{-7}	2^{-8}
γ	4.05	2.03	1.04	0.518	0.255



(a) noisy data (b) denoised data

FIG. 2. *Denoising a surface with discontinuity.*

as well in our algorithm. The additional cost of carrying out the evaluation of the adaptive γ, by either formula (6) or (7), is negligible. In summary, then, our proposed algorithm performs very well indeed for this denoising problem.

Here is another denoising experiment. The "clean" data are synthesized from MATLAB's supplied function "peaks" modified as follows: $\forall\, |m_{i,j}| > 0.01$ $m_{i,j} = m_{i,j} + d\ sign(m_{i,j})$ We set $d = 10$. Adding 10% ($nlevel = 0.1$) Gaussian noise and setting $\beta = .06$ we run for different values of h and record in Table 2 the values of γ for the final m in each run. The value of γ is determined by (6). The linear dependence of γ on h clearly emerges. For the relative tolerance value of 10^{-2} on both the lagged diffusivity iteration and the PCG iteration, three lagged diffusivity iterations are required in all cases for both Huber and modified TV. A total of three PCG iterations (i.e., one for each lagged diffusivity iteration) are needed for modified TV while an additional PCG iteration is required for the Huber function. A typical result is depicted in Figure 2.

Note also that the same value of β has yielded quality results on all five grids, satisfying $\|F(m) - b\| < 2\|m\|nlevel$. On the other hand, when the coarsest grid was set coarser than $h = 2^{-4}$ it proved useless for the multilevel process.

A multilevel continuation process as described in section 3 has been set up as well. Bilinear interpolation from each grid to the next finer one proves more efficient than a similar piecewise constant interpolation. It cuts the iteration count on the finest grid to just one iteration and the overall elapsed time by a factor of more than two.

Repeating the above experiments with the lower noise level of 1% yields a faster convergence on the finest grid starting from the data (and requiring one or at most two iterations for convergence), so the multilevel continuation process is not useful. However, exporting the value of $\beta = .006$ determined on a coarse grid with the same $h_{coarsest}$ as before to finer grids does prove to work well here, too.

We have also made comparative runs choosing γ by the formula (7). The resulting value is significantly larger than γ of (6), especially on fine grids. Thus, the least squares norm is used more often in the regularization term R, typically resulting in

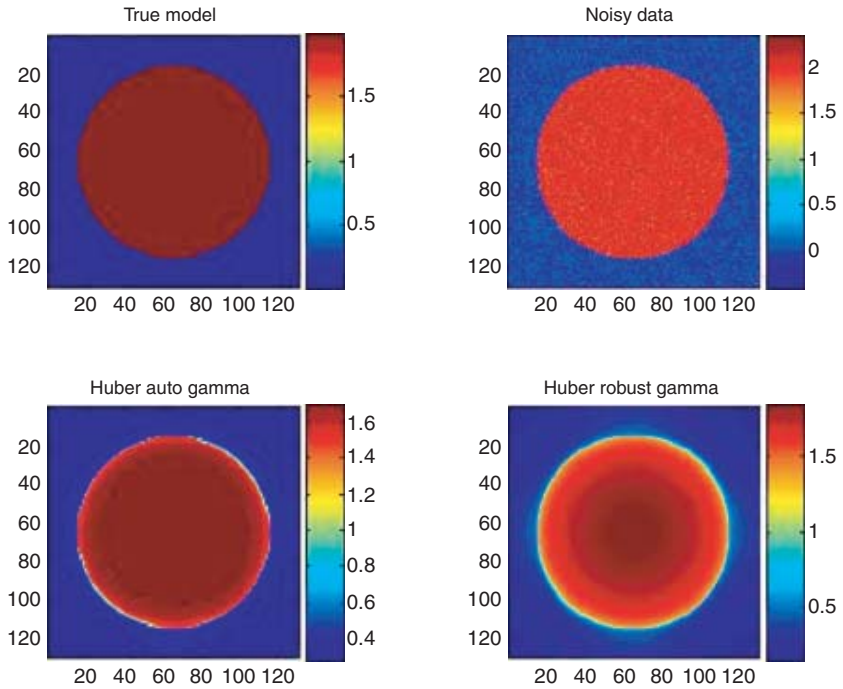


FIG. 3. *Denoising a piecewise constant surface: The true model takes the value* 2 *inside a circular pie subdomain (brown) and* 0 *in the background (blue). The run parameters are nlevel* $= .1$, $h = 2^{-7}$, $\beta = .06$. *The robust* $\gamma = 2.83$ *determined by* (7) *is much larger than the auto* $\gamma = .0276$ *determined by* (6). *Consequently, the discontinuity is more smeared in the lower right plot than in the lower left one.*

a possibly better approximation in smooth regions but in less sharp edges as well. An example of this sort is obtained here upon setting $d = 2$ in the above model. To make the point about the discontinuity smearing clearer to visualize, though, we plot in Figure 3 the results of a reconstruction of a piecewise constant surface.

Experiment 2. Next we consider the limited angle single photon emission tomography problem (SPECT). A brief description of the problem follows; see [23] for more detail. A chemical tracer is injected into a patient. This chemical emits photons in all directions. The chemical is targeted to bond to a specific functional area in the body (for example, it attaches itself to active muscles). As a result, a few minutes after the injection, some active parts of the body "glow" while others do not. In order to find these parts, the patient is put under a collimated camera. The camera can detect the glow only from a single direction. Mathematically, the number of photons that are detected at each collimator are

$$b_i = \int_{\text{ray}_i} m(x, y)\, dx\, dy. \tag{16}$$

The set of all the rays at the same direction forms a projection of the object onto this direction. The goal is to find m based on the projection data. In order to discretize the line integral (16) the model is divided into cells. We then trace each of the rays and obtain a matrix J. The entries of the matrix J_{ij} are the length of the ith ray in the jth cell. Since each ray usually passes through only a few cells, J is typically sparse.

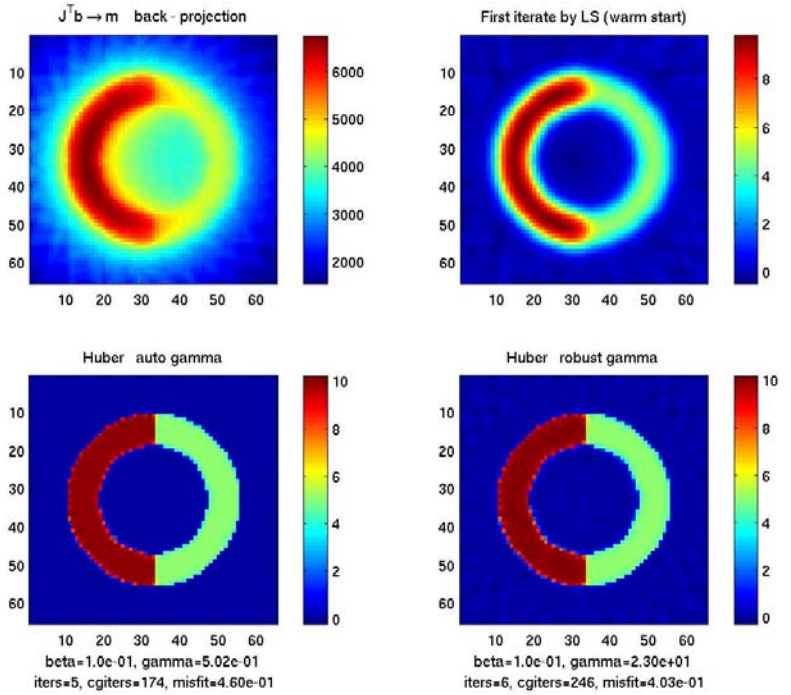

FIG. 4. *SPECT: noiseless data synthesized from two halves of a circular ring. Here* $\beta = .1$. *The back-projection image appears unfocused and the solution obtained by least squares regularization is useful as a starting iterate. The image obtained using Huber's function with* (6) *is excellent (lower left). The robust* γ (7) *gives somewhat poorer results.*

Here, the forward problem is linear,

$$F(m) = Jm.$$

The sensitivity matrix J is constant and has full row rank, but the problem is typically underdetermined and thus J^TJ is singular. For instance, one has to solve the problem (2) given by

$$J^TJm + \beta R_m = J^Tb,$$

where J is 2048×4225, for a 65×65 grid function m. So, we must have $\beta > 0$. Indeed, β may neither be too large nor too small. We have used a piecewise constant "true model" m_{true} which is well approximated in the lower left panel of Figure 4 to synthesize data b. At first we add no noise, so $b = Jm_{true}$. Results are pictured in Figure 4. Using the simple back-projection method, $m = J^Tb$, which is common in practice, leads to a blurred, out of scale image. We then set $\beta = 0.1$ and, keeping the same iteration tolerance values as in the previous experiment, apply our regularization techniques. (A significantly smaller β has led to an increased number of iterations due to the increased ill-conditioning of the linear system.) Using a least squares regularization ($\gamma = \infty$) yields blurred results which nonetheless prove useful as a starting iterate for a TV regularization. The Huber and modified TV regularizations produce excellent results with γ determined by (6). The TV regularization yields

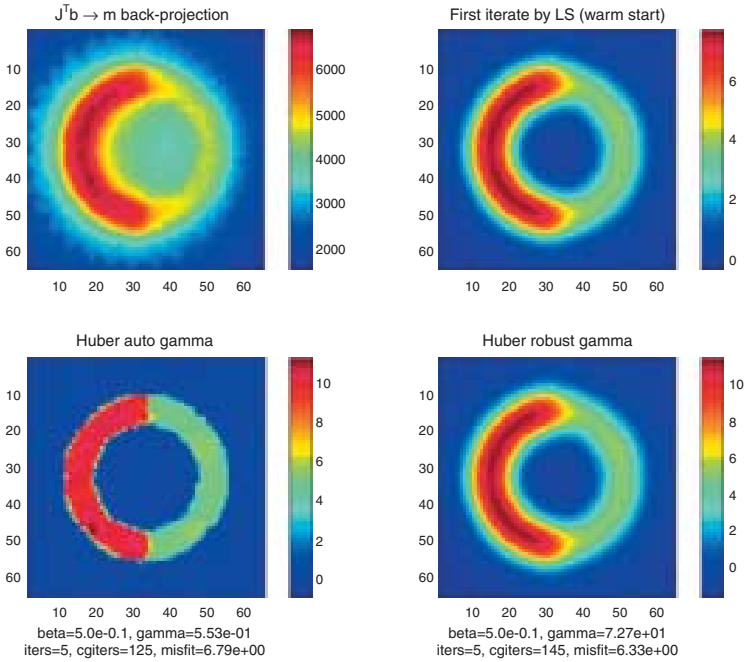

FIG. 5. *SPECT: data synthesized from two halves of a ring with* 10% *noise added on top. Here* $\beta = .5$. *The back-projection image appears unfocused and the solution obtained by least squares regularization is useful as a starting iterate. The image obtained using Huber's function with* (6) *is excellent (lower left). The robust* γ *gives inferior results.*

identical looking results and costs one additional work unit. The formula (7) for γ produces somewhat poorer results here; the difference can be more easily observed when reading an electronic copy of this article.

Next we add 10% normally distributed random noise to the data, set $\beta = .5$ and repeat the calculations. The results are gathered in Figure 5: the observations are similar to those in the noiseless case, except that now the performance of the "robust γ" is more clearly worse.

In Figure 6 we record the history of a continuation process with the same β. The total cost is only a fraction less than the one-grid process described above. The relative efficiency of multilevel continuation improves for larger values of β, though. Note how the dependence of γ of (6), not only on h but also on the smoothness of the surface, is expressed here.

We have also experimented with standard deblurring problems (e.g., [38, 24]) and found rather satisfactory results—and very close performance indicators—using either the modified TV or Huber's function with the switching parameter of (6). We do wish to repeat a general note of caution, though, that here too the TV regularization shines especially when recovering piecewise constant surfaces, although it does well also for a combination of rolling hills and steep canyons.

Experiment 3. The third experiment is conducted on problem (1) with $F(m) = Qu$, where u is the solution of the forward problem

$$A(m)u = q \tag{17}$$

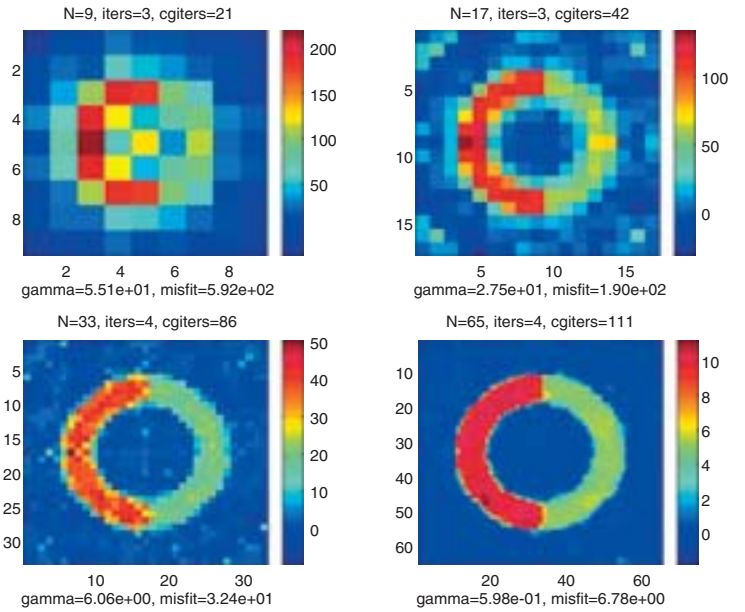

FIG. 6. *SPECT: data synthesized from two halves of a ring with* 10% *noise added on top. Here continuation with* $\beta = .5$ *is used. Note that* γ *get smaller faster than* h *because the surface becomes smoother.*

and Q indicates where in the domain the field u is being measured. Thus, $F(m) = QA(m)^{-1}q$. The matrix A discretizes an elliptic operator such as $\nabla \cdot (\sigma(\mathbf{x})\nabla)$, where $\sigma(\mathbf{x}) > 0$ is bounded away from 0, or Maxwell's equations in the frequency domain for a low frequency, and q are given sources. Both A and Q are typically large and sparse; see, e.g., [10, 5, 29, 21, 22, 2, 5, 8].

The discretized inverse problem in this case is much more ill-conditioned than in the previous problem instances. See [22] for realistic examples where the recovered field u approximates the unpolluted data b well while the quality of the reconstructed model is significantly poorer. Thus, one wonders in the context of piecewise continuous surfaces whether there is enough accurate data in applications to allow for an honest identification of discontinuities using such diffusive forward operators.

As a representative example we have considered the resistivity problem

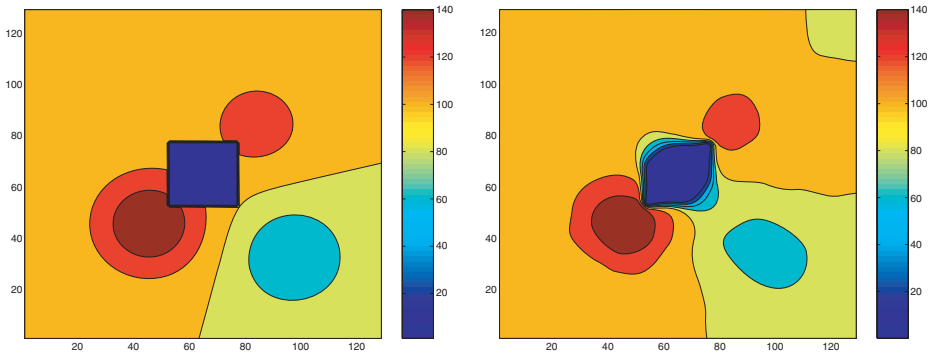
$$\nabla \cdot (m^{-1}\nabla u) = q \tag{18}$$

with natural boundary conditions on a unit domain in $2D$. The right-hand side is chosen with source and sink,

$$q = \exp(-10((x+0.6)^2 + (y+0.6)^2)) \\ - \exp(-10((x-0.6)^2 + (y-0.6)^2)),$$

and the "true model," depicted in Figure 7(a), contains discontinuities as well as smooth, nonconstant parts. We use this true model to generate a field on a 129×129 cell-centered grid and contaminate this with 1% white noise to yield the "observed data," b.

A standard finite volume discretization is applied to the forward problem, with harmonic averaging for m^{-1}.



(a) "True model" (b) Huber with $\beta = 10^{-5}$

FIG. 7. *The "true model" and the recovered model for Example* 1 *of Experiment* 3.

Figure 7(b) displays the recovered model using Huber's switching with $\beta = 10^{-5}$, which yields a final $\gamma = 4.6$ and an almost ideal misfit 1.01×10^{-2}. This is an excellent result.

However, the difference between a misfit of 1% and 2% is much too fine to define a cutting edge between a "good" and a "bad" model in more realistic situations, where we do not know the "true model" either. In fact, in most practical cases the noise level is unknown and one uses other statistical techniques such as GCV (e.g., [38]) to evaluate it. As it turns out one can vary the discontinuity locations significantly and still retain a misfit within 2%; see [2]. Unfortunately, therefore, in realistic experiments we may not know whether our recovered discontinuities are in the right place, not even approximately.

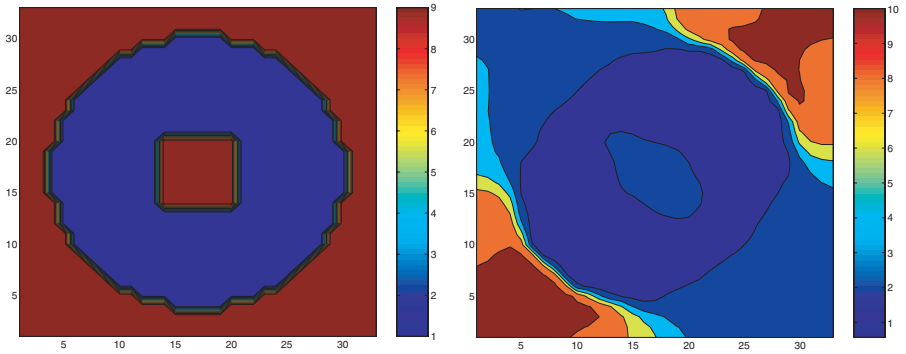
We then have considered a "true model" which only has two values and is given by the function

$$\mathrm{m}(x, y) = \begin{cases} 10, & -.2 < x, y < .2, \\ 10, & x^2 + y^2 > .8^2, \\ 1 & \text{otherwise.} \end{cases}$$

See Figure 8(a). The same setting as before is employed except that an exact solver is used for the linear equations encountered during the solution process and the grid size is 33×33.

The result using the Huber regularization with $\beta = 10^{-6}$ yielding $\gamma = 2.2$ is displayed in Figure 8(b). It is rather far from the "true" ring model. In particular, the cross diagonal symmetry is strongly violated, even though the misfit is an almost ideal 1.02×10^{-2}. Repeating the same experiment with a smaller $\gamma = .34$ yields a misfit of 8.7×10^{-3}, but the quality of the reconstructed model is not improved.

From these two examples it is clear that simply trusting the reconstruction because the misfit is "sufficiently small" cannot be advocated. Considering the maximum norm of the predicted minus the observed fields proves insufficient as well. It can then even be argued that displaying a smooth blob, such as obtained when using the least squares regularization with β small, is less committing than displaying a discontinuous solution, especially with only a few constant values, and as such is more commensurate with the actual information at hand.



(a) "True model" (b) Huber with $\beta = 10^{-6}$

FIG. 8. *The "true model" and the recovered model for Example* 2 *of Experiment* 3.

5. Conclusions and further comments. A new formula for selecting the Huber switching parameter γ, having selected β before, is proposed. This formula [illegible] what must be smooth and what can be a jump. The question of the automatic selection of γ (or ε for modified TV) is usually ignored among TV users, although it is important and has been considered by others who proposed a criterion based on robust statistics. However, we have demonstrated that our adaptive choice (6) is better, particularly for picking up edges.

Once γ has been determined, the constant ε in modified TV, if one insists on using this variant, is selected as $\varepsilon = 0.5\gamma$. We have shown this to be a good choice. The varying nature of either parameter provides further important information on the progress of the iteration process, and this together with the possibility of choosing larger values γ yield a method with capabilities beyond pure TV regularization.

A global convergence result for lagged diffusivity, similar to that known for modified TV, has been proved for the Huber variant. Moreover, with the above choice of ε numerical performance of the two variants has proved very close in many cases tried. This gives further reinforcement for our proposed formula.

Multilevel continuation has been proposed by keeping β fixed when refining the grid and by using bilinear interpolation of m for the next first iterate. The advantage in not having to calculate β from scratch on the fine grid can be huge.

Encouraging results are obtained for both the denoising and the SPECT problems. However, for diffusive forward problems the use of Huber or modified TV has tended to be unreliable. Note that in such problems it is possible to vary the discontinuity interface location significantly without violating the discrepancy principle for a given noise level.

Recent work has been carried out using level sets to recover the model under the assumption (which we do not utilize with the Huber and modified TV regularizations) that it is piecewise constant with known constant values (thus, it is a shape optimization problem [33, 27, 20, 14]). The stronger assumptions allow such methods to recover surfaces in situations where the Huber and TV regularizations fail, especially when the data are prescribed (more realistically) only in a ring next to the boundary, possibly in multiple sets. If the true model happens not to conform to these strong model assumptions, however, then there is no natural mode of recovery from determining a wrong model in this situation, especially when the data are sparse.

Both formulae (6) and (7) may fail, as will usual approaches for determining β, when processing an image with highly differing noise characteristics in different regions. A more local approach is then required.

We remark that in the image processing literature one often chooses to penalize even less through discontinuities than when using TV, e.g., using a Gaussian function or a Tukey biweight; see, e.g., [34, 31, 15]. However, this leads to nonconvex functionals and occasionally also to several local minima, which seems excessive in our more complex context where the forward problem operator is not simply the identity. We do not consider these more adventurous choices further here.

Appendix A. In this appendix we prove Theorem 2. To recall, we consider minimization of the functional $T(m)$ given by (1) where $F(m) = Jm$, J is a constant matrix with a full column rank. Set matrices $A_{ij}^T = \nabla_{i,j} \in \mathbb{R}^{N\times 2}, 1 \le i,j \le N$, so that the necessary conditions (2) can be written as

$$T_m(m) = \beta \sum_{i,j=1}^{N} \left(\frac{A_{ij}A_{ij}^T m}{|A_{ij}^T m|_\gamma} \right) + J^T(Jm - b) = 0,$$

where $|A_{ij}^T m|_\gamma = max\{\gamma, |A_{ij}^T m|\} > 0$. Then we have the following for T.

LEMMA 3. [illegible] T [illegible]

[illegible] Since $T(m) \ge \frac{1}{2}\|Jm - b\|^2$, T is coercive and bounded below by 0. Since T is twice *Fréchet* differentiable, we have for its Hessian

$$\begin{aligned} T_{mm} &= \beta \textstyle\sum_{i,j=1}^{N} A_{ij} \left(\frac{1}{|A_{ij}^T m|_\gamma} \left(I_2 - \frac{A_{ij}^T m \otimes A_{ij}^T m}{|A_{ij}^T m|_\gamma^2} \right) + \rho''(|A_{ij}^T m|) \frac{A_{ij}^T m \otimes A_{ij}^T m}{|A_{ij}^T m|_\gamma^2} \right) A_{ij}^T \\ &\quad + J^T J, \end{aligned}$$

where ρ is defined by (5) and $\bigotimes$ denotes the Kronecker product. By Cauchy–Schwarz, this yields

$$\begin{aligned} (A_{ij}^T m, A_{ij}^T v)^2 &\le (A_{ij}^T m, A_{ij}^T m)(A_{ij}^T v, A_{ij}^T v) \le |A_{ij}^T m|_\gamma^2 |A_{ij}^T v|^2 \\ &\Longrightarrow |A_{ij}^T v|^2 - \frac{(A_{ij}^T m, A_{ij}^T v)^2}{|A_{ij}^T m|_\gamma^2} \ge 0. \end{aligned}$$

Moreover, we have $\rho''(\tau) \ge 0$ if $\tau \ge 0$. So, the Hessian of T satisfies, $\forall\, v \ne 0$,

$$\begin{aligned} T_{mm}(v,v) &= \beta \textstyle\sum_{i,j=1}^{N} \left(\frac{1}{|A_{ij}^T m|_\gamma} \left(|A_{ij}^T v|^2 - \frac{(A_{ij}^T m, A_{ij}^T v)^2}{|A_{ij}^T m|_\gamma^2} \right) + \rho''(|A_{ij}^T m|) \frac{(A_{ij}^T m, A_{ij}^T v)^2}{|A_{ij}^T m|_\gamma^2} \right) \\ &\quad + v^T J^T J v > 0. \end{aligned}$$

Hence T is a strictly convex functional. ∎

Thus problem (1) has a unique solution. We then define

$$G(v,m) = T(m) + (v - m, T_m(m)) + \frac{1}{2}((v-m), C(m)(v-m))$$

and follow [9] almost verbatim in recognizing that the lagged diffusivity algorithm is an instance of the generalized Weiszfeld method, so that the following lemma holds.

LEMMA 4.

1. $C(m) = \beta \sum_{i,j=1}^{N} (A_{ij}A_{ij}^T/|A_{ij}^T m|_\gamma) + J^T J$ [illegible]
2. $\lambda_{min}(C(m)) \ge \mu = \lambda_{min}(J^T J) > 0\ \forall\, m$
3. $T(v) \le G(v,m)\ \forall\, v$

Using Lemmas 3 and 4 we can now establish the global convergence for the Huber switching function with γ adaptively defined by (6), as stated in Theorem 2. We address each item in turn:

1. From the above properties, we have $T(m^s) \leq G(m^s, m^{s-1})$. Moreover, the fixed point iteration equation is equivalent to the necessary condition for the generalized Weiszfeld method, which yields

$$m^s = \operatorname*{argmin}_v G(v, m^{s-1}) \Rightarrow G(m^s, m^{s-1}) \leq G(m^{s-1}, m^{s-1}) = T(m^{s-1}).$$

2. Recall that

$$\begin{aligned} T(m^s) &\leq G(m^s, m^{s-1}) \\ &= T(m^{s-1}) + (m^s - m^{s-1}, T_m(m^{s-1})) \\ &\quad + \tfrac{1}{2}((m^s - m^{s-1}), C(m^{s-1})(m^s - m^{s-1})) \\ &= T(m^{s-1}) - \tfrac{1}{2}((m^s - m^{s-1}), C(m^{s-1})(m^s - m^{s-1})). \end{aligned}$$

Then taking into account that $\lambda_{min}(C(m^{s-1})) \geq \mu > 0$, we have

$$\frac{1}{2}\mu|m^s - m^{s-1}|^2 \leq \frac{1}{2}((m^s - m^{s-1}), C(m^{s-1})(m^s - m^{s-1})) \leq T(m^{s-1}) - T(m^s).$$

It transpires that

$$0 \leq |m^s - m^{s-1}| \leq \sqrt{2\mu^{-1}(T(m^{s-1}) - T(m^s))}.$$

Note that T is bounded below and $\{T(m^s)\}$ is monotonically decreasing. Thus, $\{T(m^s)\}$ converges, implying that $\lim_{s\to\infty} |T(m^s) - T(m^{s-1})| = 0$; hence also $\lim_{s\to\infty} |m^s - m^{s-1}| = 0$.

3. Since $\{T(m^s)\}$ is monotonically decreasing, it is bounded above of course. The fact that T is coercive then guarantees that $\{m^s\}$ is bounded. By compactness, it suffices to show that the limit of every convergent subsequence of $\{m^s\}$ is the global minimum of (1). Let $\{m^{s_i}\}$ be a subsequence of $\{m^s\}$ that converges to m^*. Since $G_v(v, m) = T_m(m) + C(m)(v - m)$, T is continuously differentiable and C is continuous, we have that G_v is continuous. From the above $\lim_{s_i\to\infty} |m^{s_i} - m^{s_i-1}| = 0$, and we also have $\lim_{s_i\to\infty} m^{s_i} = \lim_{s_i\to\infty} m^{s_i-1} = m^*$. Then, taking limits for $G_{m^{s_i}}(m^{s_i}, m^{s_i-1})$, we deduce the following equation:

$$\begin{aligned} 0 &= \lim_{s_i\to\infty} G_{m^{s_i}}(m^{s_i}, m^{s_i-1}) = G_{m^{s_i}}(\lim_{s_i\to\infty} m^{s_i}, \lim_{s_i\to\infty} m^{s_i-1}) \\ &= G_{m^{s_i}}(m^*, m^*) = T_m(m^*) + C(m^*)(m^* - m^*) = T_m(m^*). \end{aligned}$$

Hence the sequence $\{m^s\}$ converges to the unique global minimum m^* of our problem (1).

LIMITER-FREE THIRD ORDER LOGARITHMIC RECONSTRUCTION*

ROBERT ARTEBRANT† AND H. JOACHIM SCHROLL†

Abstract. A third order conservative reconstruction, in the context of finite volume schemes for hyperbolic conservation laws, is constructed based on logarithmic functions. This logarithmic method reconstructs without the use of a limiter, any preprocessing of input data, special treatments for local extrema, or shock solutions. Also the method is local in the sense that data from only the nearest neighbors are required.

We test the new reconstruction method in several numerical experiments, including nonlinear systems in one and two space dimensions.

Key words. conservation law, finite volume method, high order reconstruction

1. Introduction.

In the present paper we develop a new reconstruction method for the computation of accurate numerical fluxes within the context of finite volume (FV) methods for conservation laws. These FV schemes are derived from the integro-differential formulation of the conservation law:

$$\frac{\mathrm{d}}{\mathrm{d}t}\int_\Omega u(x,t)\,\mathrm{d}x + \int_{\partial\Omega} f(u(x,t))\cdot n\,\mathrm{d}S = 0. \tag{1.1}$$

Within a spatial domain Ω the total amount of a certain quantity u is conserved; i.e., it does not change with time except by flow across the boundary $\partial\Omega$. The conserved quantity is the total amount or the [illegible] of u, while the dynamics of this average is determined by [illegible] of the flux $f(u(t,x))$ along the boundary. From given cell averages the [illegible] task is to accurately determine these point values along the boundary.

The very successful essentially nonoscillatory (ENO) reconstruction technique, developed in [3], uses polynomials and an adaptive selection of the stencil according to local smoothness. Solutions to hyperbolic conservation laws are generally only piecewise smooth, so the adaptive stencil procedure is a way to avoid interpolating discontinuous data. In [5], the weighted ENO (WENO) was developed, improving ENO in several ways and using a convex combination of all candidate stencils instead of just one. For recent developments of WENO, see [10] and references therein.

In this paper we are interested in a [illegible] reconstruction on a 3-point stencil. Further we would like to avoid any limiter affecting accuracy and costly modifications enforcing nonoscillatory properties. That is, in this setting the reconstruction problem essentially boils down to that of approximating functions. Then it is appropriate to consider a wider class of reconstructing functions, perhaps leading to a nonlinear approximation problem; as Rice puts it in [8] on the problem of approximating $f(x)$:

"The key to efficient approximation is to find an approximating function which can take on the same nature or behaviour as $f(x)$." This consideration makes it reasonable to try approximating functions other than polynomials; polynomials are unable to take on very large slopes followed by a flat region, which frequently occur in the piecewise smooth solutions to hyperbolic conservation laws.

In [6] Marquina proposes local reconstruction techniques (LHR and LHHR) based on the hyperbola as a reconstructing function. The hyperbola is more flexible than a polynomial; it is able to assume this shape with a large slope followed by a flatter part, making it possible to avoid discontinuities inside the cells and locating them at the cell boundaries. The hyperbola is, however, monotonic, and so the order reduces from three to one and a half at local extrema. Inspired by these reconstructions, a third order reconstruction for monotone data (LLR) and a fifth order (if existent) reconstruction (DLR) were developed in [1]. The [illegible] (LDLR) developed in the present paper improves over LLR and DLR in the following aspects: In contrast to LLR, the LDLR can reconstruct local extrema at full third order accuracy, and its variation within a cell is controlled. The capability to reconstruct local extrema may have a major impact on simulation results, as demonstrated in Example 12, section 3.4. In contrast to DLR, the LDLR exists for all input data, is defined on a 3-point stencil, and does not use any smoothness indicators.

In the next section the LDLR is constructed. Then in section 3 several numerical experiments are presented, testing the LDLR and comparing it to LHHR, ENO3, and WENO3. Higher order extension is presented in section 4, and concluding remarks follow (section 5). Finally in the appendix we present a possible extension of Marquina's LHHR, following the principle to obtain the LDLR.

2. Local double logarithmic reconstruction. In this section the piecewise reconstruction of an unknown smooth function using two logarithmic functions is described. The resulting reconstruction method uses data from only the central cell and its nearest neighbors and is therefore called local double logarithmic reconstruction (LDLR). The grid data are the cell averages and approximations to the lateral derivatives of the function to be reconstructed.

We are interested in a third order reconstruction of low variation without the use of a limiter. A simple Taylor expansion proves the principle used to obtain the third order of accuracy

LEMMA 2.1. [illegible] $f, g \in C^3[a,b]$ [illegible] $h = b - a$ [illegible]

$$\int_a^b f(x)dx = \int_a^b g(x)dx, \tag{2.1}$$

$$(f-g)'(a) = \mathcal{O}(h^2) = (f-g)'(b); \tag{2.2}$$

[illegible] $(f-g)(x) = \mathcal{O}(h^3)$ [illegible] $x \in [a,b]$

2.1. The ansatz function. We consider the computational grid $x_i = ih$, i integer and h a positive number, with cells $C_i = [x_{i-1/2}, x_{i+1/2}]$.

The reconstruction is piecewise defined in each cell; therefore we shall consider without restriction a reference cell C_0. The reconstructing function in this cell has the form

$$r_0(x) \sim A + B\log(x+C) + D\log(x+E).$$

We define for $x \in C_0$

$$\phi_0(x) = -\frac{ch}{a}\log\left[x - x_0 - \frac{h}{2}\left(\frac{2}{a} - 1\right)\right] - \frac{dh}{b}\log\left[x - x_0 - \frac{h}{2}\left(\frac{2}{b} - 1\right)\right], \tag{2.3}$$

where a, b, c, and d are parameters to be determined, and let

$$r_0(x) = v_0 + \phi_0(x) - \frac{1}{h}\int_{C_0}\phi_0(\xi)d\xi \tag{2.4}$$

be the reconstructing function.

For (2.4) to be a well-defined smooth function, we must pose some restrictions on the coefficients a and b. The lemma below gives the allowed range of these parameters.

LEMMA 2.2. [illegible] $\phi(x) = \frac{h}{\lambda}\log\left[x - x_0 - \frac{h}{2}\left(\frac{2}{\lambda} - 1\right)\right]$ [illegible] $\psi(x) = \phi(x) - \frac{1}{h}\int_{C_0}\phi(\xi)d\xi$ [illegible] $x \in C_0$ [illegible] ψ [illegible] $\lambda \in (-\infty, 1)$ [illegible]. Let $t(x) = x - x_0 + h/2 - h/\lambda$ be the argument of the log-function. The function ϕ has a singularity for $x \in C_0$ when $t(x) = 0$. Since t is linear in x and

$$\min_{x\in C_0} t(x) = -\frac{h}{\lambda} \quad \text{and} \quad \max_{x\in C_0} t(x) = h - \frac{h}{\lambda}, \tag{2.5}$$

t has a zero in C_0 for $\lambda \in [1, \infty)$. For $\lambda < 0$ we see that $t > 0$ and therefore ϕ, and hence ψ, is real and smooth for λ negative. Now consider $\lambda \in (0, 1)$. From (2.5) it follows that $t(x) < 0$ for $\lambda \in (0, 1)$; hence $\phi(x) = \frac{h}{\lambda}(\log|t(x)| + i\pi)$ and

$$\begin{aligned}\frac{\lambda}{h}\psi(x) &= \log|t(x)| + i\pi - \frac{1}{h}\int_{C_0}\log|t(x)| + i\pi dx \\ &= \log|t(x)| - \frac{1}{h}\int_{C_0}\log|t(x)|dx,\end{aligned}$$

and thus ψ is real and smooth for $\lambda \in (0, 1)$. Finally, ψ has a removable singularity at $\lambda = 0$ by setting $\psi(x)|_{\lambda=0} = x_0 - x$. □

2.2. Order conditions and symmetry. To reach third order we impose the conditions set in Lemma 2.1; given v_0, the cell average of the unknown function in C_0, and d_1 and d_2 second order approximations to the left and right derivatives, we require

$$\frac{1}{h}\int_{C_0} r_0(x)dx = v_0, \tag{2.6}$$

$$r_0'\left(x_0 - \frac{h}{2}\right) = d_1, \tag{2.7}$$

$$r_0'\left(x_0 + \frac{h}{2}\right) = d_2. \tag{2.8}$$

The reconstructing function (2.4) preserves the cell average v_0 by construction. Conditions (2.7)–(2.8) lead to the following pair of equations:

$$c + d = d_1, \tag{2.9}$$

$$-\frac{d(a-1) + c(b-1)}{(a-1)(b-1)} = d_2. \tag{2.10}$$

Thus we have four parameters to satisfy two equations. We solve for two parameters, leaving the others undetermined for later use. Simplicity and symmetry suggest solving for c and d, which appear linearly. We obtain

$$c = \frac{(a-1)(d_2(1-b)-d_1)}{b-a}, \tag{2.11}$$

$$d = d_1 - c. \tag{2.12}$$

Now the order conditions are satisfied, and we turn to considering other properties of the reconstruction that are feasible using the remaining parameters.

The reconstruction should be symmetric (to the extent allowed by the ansatz function) in the sense that if $r_0'(x_0 - h/2) = -r_0'(x_0 + h/2)$, then $r'(x_0) = 0$. This can be realized by setting $d_1 = -d_2$ and solving for b. We get

$$0 = r_0'(x_0)|_{d_1=-d_2} = 2d_2 \frac{ab - a - b}{(a-2)(a-1)},$$

that is,

$$b = \frac{a}{a-1}. \tag{2.13}$$

As shown by Lemma 2.2, the reconstructing function is well defined, provided $a < 1$ and $b < 1$. The parameter b in (2.13), seen as a function of a, has the range $(-\infty, 1)$ for $a \in (-\infty, 1)$. We also observe that $a = b$ (the reconstructing function degenerates to LLR [1]) is only possible for $a = b = 0$.

In the next section we use the remaining parameter a to control the variation of the reconstructing function.

2.3. Local variation boundedness. To construct a reconstruction procedure of sufficiently low variation we apply Marquina's concept of local variation boundedness [6].

DEFINITION 2.3 (local variation bounded). [illegible] local variation [illegible] f [illegible] C_i [illegible] $LV(f_i) = TV(f)|_{C_i}$ [illegible] local variation bounded [illegible] C_i [illegible] $LV(f_i) = \mathcal{O}(h)$ [illegible] h [illegible]

The interesting case is if a function f stays LVB in the case of a discontinuity within the cell, i.e., $f'(x_i - h/2) = \mathcal{O}(1/h)$ and $f'(x_i + h/2) = \mathcal{O}(1)$ or vice versa.

Assuming a [illegible], the local variation of the reconstructing function (2.4) can be expressed in terms of its parameters a, b, c, and d:

$$LV(r_0) = h \left| \frac{cb \log(1-a) + da \log(1-b)}{ab} \right|. \tag{2.14}$$

In the previous section we determined c, d, and b in (2.11)–(2.13) so that order and symmetry conditions were satisfied. We plug (2.11)–(2.13) into (2.14) to obtain an expression for the local variation containing the free parameter a:

$$LV(r_0) = h \frac{a-1}{a-2} \left| \frac{\log(1-a)(d_1 + d_2)}{a} \right|. \tag{2.15}$$

To set a variation condition on a we consider the case of a discontinuity within the cell, i.e., $d_1 = \mathcal{O}(1/h)$ and $d_2 = \mathcal{O}(1)$. Inspection of (2.15) leads us to the following variation lemma for r_0 (2.4) with coefficients c, d, and b from (2.11)–(2.13)

LEMMA 2.4. [illegible] $d_1 = \mathcal{O}(1/h)$ $d_2 = \mathcal{O}(1)$ [illegible] $d_1 d_2 > 0$ [illegible] $a = 1 - mh^q$ $0 < m \le \hat{m} < \infty$ [illegible] $LV(r_0) = \mathcal{O}(h^{|q|}|\log(h)|)$

[illegible]. Let us assume $q > 0$; the case $q < 0$ is similar. We compute (2.15) with $d_1 = M/h$ and $d_2 = N$ with $MN > 0$: $LV(r_0) = h\frac{mh^q}{1+mh^q}\left|\frac{\log(mh^q)(M/h+N)}{1-mh^q}\right| = \frac{mh^q}{|1-m^2h^{2q}|}|\log(m) + q\log h||M + Nh| = \mathcal{O}(h^q|\log h|)$. □

A special feature of LDLR is that [illegible] are reconstructed within a cell. Next we shall see that even in this case the local variation is under control. It turns out that the local variation of the reconstructing function in the case $d_1 d_2 < 0$ is not bigger than in the case of monotone data $|d_1|$ and $|d_2|$ (or $-|d_1|$ and $-|d_2|$).

The variation controlling parameter is assumed to be $a \in (0, 1)$, and its symmetric counterpart is $b = a/(a-1)$. Now let

$$k_0 = \frac{a-1}{b-a} = \frac{(a-1)^2}{a(2-a)} > 0,$$
$$k_1 = 1 - b = \frac{1}{1-a} > 0.$$

For $d_1 = M$, $d_2 = N$ with $MN > 0$ we write the linear coefficients from (2.11)–(2.12) as

$$c = k_0 k_1 N - k_0 M,$$
$$d = (1 + k_0)M - k_0 k_1 N.$$

Computing the coefficients for $N \to -N$, we obtain

$$\widetilde{c} = -k_0 k_1 N - k_0 M,$$
$$\widetilde{d} = (1 + k_0)M + k_0 k_1 N.$$

Define the functions

$$f(x) = \frac{2h}{2a(x_0 - x) + h(2-a)},$$

$$g(x) = \frac{2h(a-1)}{2a(x_0 - x) - h(2-a)}.$$

We can write the derivative of the reconstructing function (2.4) for the two cases as

$$r_0'(x) = cf(x) + dg(x) = k_0 k_1 N(f - g) - k_0 M(f - g) + Mg,$$
$$\widetilde{r_0}'(x) = \widetilde{c}f(x) + \widetilde{d}g(x) = -k_0 k_1 N(f - g) - k_0 M(f - g) + Mg.$$

Consider the functions $\sigma(x) = f(x) - g(x)$ and $\tau(x) = g(x) - k_0[f(x) - g(x)]$ such that $r_0'(x) = k_0 k_1 N\sigma(x) + M\tau(x)$:

$$\sigma(x) = \frac{2ha(2-a)(2(x_0 - x) - h)}{[2a(x_0 - x) + h(2-a)][2a(x_0 - x) - h(2-a)]},$$

$$\tau(x) = \frac{2h(2(x_0 - x) + h)(a-1)}{[2a(x_0 - x) + h(2-a)][2a(x_0 - x) - h(2-a)]}.$$

The denominator of σ and τ is

$$n(x) = [2a(x_0 - x)]^2 - [h(2-a)]^2.$$

For the spatial cell $C_0 = [x_0 - h/2, x_0 + h/2]$ we have $\max_{x \in C_0} n(x) = n(x_0 \pm h/2) = 4h^2(a-1)$. Since $a \in (0,1)$, it holds that $\max_{x \in C_0} n(x) < 0$, and thus $n(x) < 0$ for all $x \in C_0$. Now consider the numerator of σ,

$$t_\sigma(x) = 2ha(2-a)(2(x_0 - x) - h).$$

Here $t_\sigma(x)$ is linear in x and decreasing since $a \in (0,1)$. We have $\max_{x \in C_0} t_\sigma(x) = t_\sigma(x_0 - h/2) = 0$, and thus $t_\sigma(x) \le 0$, for all $x \in C_0$. The denominator is always negative, and the numerator always nonpositive, so we get

$$\sigma(x) = f(x) - g(x) \ge 0 \qquad \forall x \in C_0.$$

Now consider the numerator of τ,

$$t_\tau(x) = 2h(2(x_0 - x) + h)(a-1).$$

Here $t_\tau(x)$ is linear in x and increasing since $a \in (0,1)$. We have $\max_{x \in C_0} t_\tau(x) = t_\tau(x_0 + h/2) = 0$, and thus $t_\tau(x) \le 0$ for all $x \in C_0$. Therefore we find

$$\tau(x) = g(x) - k_0[f(x) - g(x)] \ge 0 \qquad \forall x \in C_0.$$

Let us assume $M > 0$ and $N > 0$; then

$$r_0'(x) = k_0 k_1 N \sigma(x) + M\tau(x) > 0$$

and

$$\begin{aligned} r_0'(x) + \widetilde{r_0}'(x) &= 2M\tau(x) \ge 0, \\ r_0'(x) - \widetilde{r_0}'(x) &= 2k_0 k_1 N \sigma(x) \ge 0, \end{aligned}$$

and so $|\widetilde{r_0}'(x)| \le |r_0'(x)|$ for all $x \in C_0$. The other cases follow by symmetry. In summary we have the following claim.

LEMMA 2.5. [illegible] $\widetilde{r_0}$ [illegible] $d_1 d_1 < 0$ [illegible] r_0 [illegible] $|d_1|$ [illegible] $|d_2|$ [illegible] $-|d_1|$ [illegible] $-|d_2|$ [illegible]

$$LV(\widetilde{r_0}) \le LV(r_0).$$

The following shows that Lemma 2.4 holds also in the nonmonotone case.

COROLLARY 2.6. [illegible] $d_1 = \mathcal{O}(1/h)$ $d_2 = \mathcal{O}(1)$ [illegible] $a = 1 - mh^q$ $0 < m \le \hat{m} < \infty$ [illegible] $LV(r_0) = \mathcal{O}(h^{|q|}|\log(h)|)$

In the following our goal is to find properties of $a(d_1, d_2)$ as a function of the lateral derivatives d_1 and d_2 yielding a limiter-free global third order local reconstruction.

The first condition is that the reconstructing function (2.4) be a well defined smooth function. As shown by Lemma 2.2, we must have

$$a(d_1, d_2) < 1 \qquad \forall d_1, d_2 \in \mathbb{R}. \tag{2.16}$$

Furthermore we shall require

$$a(\lambda, \lambda) = 0 \qquad \forall \lambda \in \mathbb{R}, \tag{2.17}$$

which ensures that in the case $d_1 \approx d_2$ the reconstructing function (2.4) is approximately the linear function; cf. the proof of Lemma 2.2 and the removable singularity.

Let us consider the ansatz

$$a(d_1, d_2) = 1 - 2\frac{|d_1|^q |d_2|^q}{|d_1|^{2q} + |d_2|^{2q}} \tag{2.18}$$

with $q > 0$. Condition (2.17) is trivially verified. Condition (2.16), however, is not satisfied since $a : \mathbb{R}^2 \to [0, 1]$, but we shall overlook this for the moment and turn to verifying the assumption on a in Corollary 2.6. We set $d_1 = M/h$ and $d_2 = N$ and evaluate a:

$$a\left(\frac{M}{h}, N\right) = 1 - 2\frac{|MN|^q}{|M|^{2q} + |N|^{2q} h^{2q}} h^q. \tag{2.19}$$

The bounds

$$\frac{|MN|^q}{|M|^{2q} + |N|^{2q}} \le \frac{|MN|^q}{|M|^{2q} + |N|^{2q} h^{2q}} \le \left|\frac{N}{M}\right|^q \tag{2.20}$$

show that the condition on a is satisfied with an m such that $2\frac{|MN|^q}{|M|^{2q}+|N|^{2q}} \le m \le 2\left|\frac{N}{M}\right|^q$. By Corollary 2.6 we have that in the interesting case $d_1 = \mathcal{O}(1/h)$ and $d_2 = \mathcal{O}(1)$ (or vice versa)

$$LV(r_0) = \mathcal{O}(h^q |\log h|). \tag{2.21}$$

By adjusting the exponent q large enough for the line Ch to lie above $-h^q \log h$, we can construct an LVB reconstruction. Thus we solve for q in

$$-h^q \log h = Ch, \quad C > 0, \tag{2.22}$$

to obtain

$$q = \frac{\log(Ch) - \log(-\log h)}{\log h}. \tag{2.23}$$

Now (2.23) is maximized for $h \in (0, 1)$, yielding

$$q^* = 1 + \frac{1}{C \exp(1)}. \tag{2.24}$$

2.4. The algorithm. In section 2.2 we found the coefficients c, d, and b of (2.11)–(2.13), and in the previous section an ansatz for the parameter a of (2.18) satisfying the assumption on a in Corollary 2.6. The condition (2.16), $a < 1$, was temporarily relaxed to $a \le 1$; the condition (2.17), $a(\lambda, \lambda) = 0$ for all λ, was satisfied ensuring that equal lateral derivatives give the linear function. Now since the coefficient c has the denominator $b - a$, which is zero if and only if $a = 0$, we will relax condition (2.17) in favor of satisfying (2.16). To this end we modify our ansatz (2.18) in the following simple way: Given the cell size h, we set $\text{TOL} = 0.1h^q$ and

$$a = (1 - \text{TOL})\left(1 + \text{TOL} - \frac{2|d_1|^q |d_2|^q + \text{TOL}}{|d_1|^{2q} + |d_2|^{2q} + \text{TOL}}\right). \tag{2.25}$$

The range of (2.25) is $[\text{TOL}(1 - \text{TOL}), 1 - \text{TOL}^2)$. Condition (2.16) is satisfied, and condition (2.17) is relaxed to $a(\lambda, \lambda) = \text{TOL}(1 - \text{TOL})$. Finally, to determine the exponent q we set $C = 1$ in (2.22); then (2.24) gives $q = 1.4$. Of course, using a smaller

C (a larger q) results in a reconstruction procedure of smaller local variation. There might be applications where a different q is preferred (see section 3.1, Example 4); in selecting q there is a trade-off between resolution and robustness. In general, however, changing the exponent from 1.4 is not recommended.

We are usually interested in the third order approximations of the point values at the cell boundaries. Instead of using the reconstructing function (2.4) directly we compute the lateral values conveniently by

$$r_0\left(x_0 \pm \frac{h}{2}\right) = v_0 + ch\eta^{\pm}(a) + dh\eta^{\pm}(b), \tag{2.26}$$

where

$$\eta^{+}(t) = -\frac{\log(1-t)+t}{t^2} \tag{2.27}$$

and

$$\eta^{-}(t) = \frac{(t-1)\log(1-t)-t}{t^2}. \tag{2.28}$$

To avoid two evaluations of each η-function one can exploit the fact that

$$\eta^{\pm}\left(b = \frac{a}{a-1}\right) = (a-1)\eta^{\mp}(a). \tag{2.29}$$

The functions $\eta^{\pm}$ have a removable singularity at zero by putting $\eta^{\pm}(0) = \pm\frac{1}{2}$. For numerical computations it is recommended that you interpolate the values around the removable singularity at zero.

For completeness we describe in quite some detail the use of LDLR in an FV scheme. The scalar conservation law

$$u_t + f(u)_x = 0 \tag{2.30}$$

in integrated form is given by (1.1), which holds for all spatial domains Ω. Leaving time continuous, the FV method discretizes (1.1) in space by requiring it to hold for all computational cells $C_i = [x_{i-1/2}, x_{i+1/2}]$:

$$\frac{\mathrm{d}}{\mathrm{d}t}\bar{u}_i(t) = -\frac{1}{h}\left(f(u(x_{i+1/2},t)) - f(u(x_{i-1/2},t))\right), \tag{2.31}$$

where

$$\bar{u}_i(t) = \frac{1}{h}\int_{x_{i-1/2}}^{x_{i+1/2}} u(x,t)dx$$

is the cell average. The flux $f(u(x_{i+1/2},t))$ is replaced by a numerical flux $\hat{f}_{i+1/2} = \hat{f}(u^-(x_{i+1/2},t), u^+(x_{i+1/2},t))$, with the superscripts $\pm$ indicating that the value is taken from the right or left, respectively. LDLR is not tied to any particular numerical flux function; for example, one can use the Lax–Friedrichs flux

$$\begin{aligned}\hat{f}_{i+1/2} = {} & 0.5\left[f(u^-(x_{i+1/2},t)) + f(u^+(x_{i+1/2},t))\right] \\ & -0.5\alpha\left[u^+(x_{i+1/2},t) - u^-(x_{i+1/2},t)\right],\end{aligned} \tag{2.32}$$

where α is an upper bound of the wave propagation speed. The semidiscrete FV scheme reads

$$\frac{\mathrm{d}}{\mathrm{d}t}\bar{u}_i(t) = -\frac{1}{h}\left(\hat{f}_{i+1/2} - \hat{f}_{i-1/2}\right). \tag{2.33}$$

The reconstruction task is now to obtain the arguments of the numerical flux function to higher order. LDLR determines $u^-(x_{i+1/2})$ by the following steps:

Compute the lateral derivatives $d_1 = (\bar{u}_i - \bar{u}_{i-1})/h$ and $d_2 = (\bar{u}_{i+1} - \bar{u}_i)/h$;
Compute the coefficient $a(d_1, d_2)$ of (2.25) and the coefficients c, d, b of (2.11)–(2.13);
Use (2.26) to find $u^-(x_{i+1/2}) = \bar{u}_i + ch\eta^+(a) + dh\eta^+(b)$.

Similarly the right-sided limit $u^+(x_{i+1/2})$ is computed as follows:

Compute the derivatives $d_1 = (\bar{u}_{i+1} - \bar{u}_i)/h$ and $d_2 = (\bar{u}_{i+2} - \bar{u}_{i+1})/h$;
Compute the coefficient $a(d_1, d_2)$ of (2.25) and the coefficients c, d, b of (2.11)–(2.13);
Use (2.26) to find $u^+(x_{i+1/2}) = \bar{u}_{i+1} + ch\eta^-(a) + dh\eta^-(b)$.

At this point we want to emphasize that LDLR requires only the evaluation of universal, fixed formulas (2.25), (2.11)–(2.13), and (2.26) regardless of the in-data, resulting in simple coding and efficiency (see section 3.3).

Finally, third order in time is accomplished by integrating the system (2.33) by the third order SSP-Runge–Kutta method from [2] under the stability condition

$$\lambda\frac{\Delta t}{h} = \mathrm{CFL} \le 1, \tag{2.34}$$

where λ is an upper bound of the maximal propagation speed.

For systems of conservation laws the reconstruction procedure is applied componentwise in this paper.

3. Numerical experiments. In this section we compute several numerical examples to test the local double logarithmic reconstruction and compare it to those of the LHHR, ENO3, and WENO3 techniques.

All LDLR computations except one in Example 4 in the next section are performed with the exponent $q = 1.4$; cf. section 2.3–2.4.

3.1. Convergence and accuracy tests.

Example 1. A convergence test. We test the rate of convergence for the LDLR with a [illegible] as the governing equation. Consider the Euler system

$$u_t + f(u)_x = 0$$

with

$$u = (\rho, \rho v, E), \quad f(u) = (\rho v, \rho v^2 + p, v(E + p)),$$

and

$$p = (\gamma - 1)\left(e - \rho\frac{u^2}{2}\right), \quad \gamma = 1.4.$$

With initial data $\rho(0, x) = 1 + 0.2\sin(x)$, $v \equiv 1$, and $p \equiv 1$ the Euler system has the solution $\rho(t, x) = 1 + 0.2\sin(x - t)$, $v \equiv 1$, and $p \equiv 1$ (see [7]). We compute approximations to the solution at $t = 1$, on the interval $-\pi \le x \le \pi$ with periodic boundary

TABLE 3.1
Euler convergence test: LDLR.

N	L_1-error	L_1-order	L_∞-error	L_∞-order

conditions, by local double logarithmic reconstruction of the conserved variables in the Van Leer upwind scheme [15]. The error in density is displayed in Table 3.1. Full third order convergence is clearly verified. Note that the third order is reached also at local extrema, as seen in the L_∞-norm. This is in contrast to monotone reconstructions like MUSCL [14], LHHR, and LLR, which suffer from clipping of extrema leading to reduced order of accuracy clearly visible in the L_∞-norm. We recomputed the convergence test with the LHHR reconstruction; the result is shown in Table 3.2.

EXAMPLE 2. Linear advection. The equation

$$u_t + u_x = 0, \quad -1 < x < 1,$$

is solved with periodic boundary condition and initial data as proposed in [4]. The signal consists of a smooth and narrow combination of Gaussians, a square wave, a triangle wave, and a half ellipse. We refer to [4] for the details. LDLR, LHHR, and ENO3 approximations at $t = 20$, obtained with 200 and 400 cells under CFL $= 0.6$, are shown in Figure 3.1. Considering the 200-cell computations, since LHHR does not reconstruct extrema, this approximation is far less resolved than the other two. The ENO3 approximation shows less symmetry than the other approximations, while the LDLR approximation clearly takes on negative values. Looking at the 400-cell computation, the LDLR shows the best resolution especially at corners, and the undershoots are negligible. The ENO3 is still not symmetric, and the LHHR is the most diffusive approximation.

EXAMPLE 3. Burgers' equation. The nonlinear equation

$$u_t + \left(\frac{u^2}{2}\right)_x = 0$$

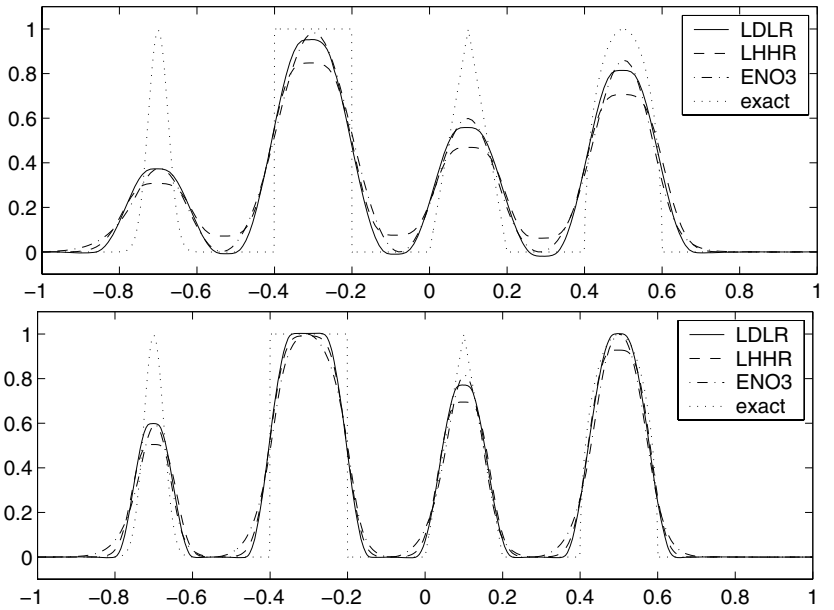

FIG. 3.1. *Advection. Upper row:* 200 *cells. Lower row:* 400 *cells.*

with initial data $u_0(x) = 1 + 1/2\sin(\pi(x-1))$ and 2-periodic boundary conditions is solved under CFL = 0.6. In Figure 3.2 the LDLR approximation at $t = 1.5$ and the computed total variation are depicted for 40, 80, and 160 cells. Despite the reconstruction of local extrema, we observe that the total variation is bounded by $\mathrm{TV}(u_0)$ for all times. Note that a monotone decreasing variation cannot be expected for a third order scheme [13]. Especially on the coarsest mesh we also observe a slight overshoot in two cells behind the right-moving shock wave. This effect is due to the bounded nonzero variation of the double logarithmic reconstruction. Recall that, in contrast to standard methods, unlimited reconstruction is applied across the discontinuity. The right column in Figure 3.2 shows that the overshoot vanishes as the mesh is refined and does not cause any instability. We conclude that the 40-point simulation is underresolved.

4. Buckley–Leverett equation. The nonlinear and nonconvex scalar Buckley–Leverett problem

$$u_t + \left(\frac{4u^2}{4u^2 + (1-u)^2}\right)_x = 0$$

is solved using local double logarithmic reconstruction of the conserved variable and the Lax–Friedrich flux (2.32). The initial data is $u = 1$ for $-\frac{1}{2} \le x \le 0$ and $u = 0$ elsewhere. Approximations using 120 and 360 cells with CFL = 0.7 are shown in Figure 3.3. We note that there is a slight "overshoot" in the compound wave where the rarefaction profile meets the shock. Such compound waves, which are typical for nonconvex problems, are numerically difficult to treat due to reduced stability properties. More diffusive schemes can compensate for this sensitivity in the problem and may give better results!

A higher value of the variation controlling exponent $q = 2$ in (2.25) decreases the total variation (increases the diffusion) of the LDLR scheme and in fact damps out the overshoot; see Figure 3.4.

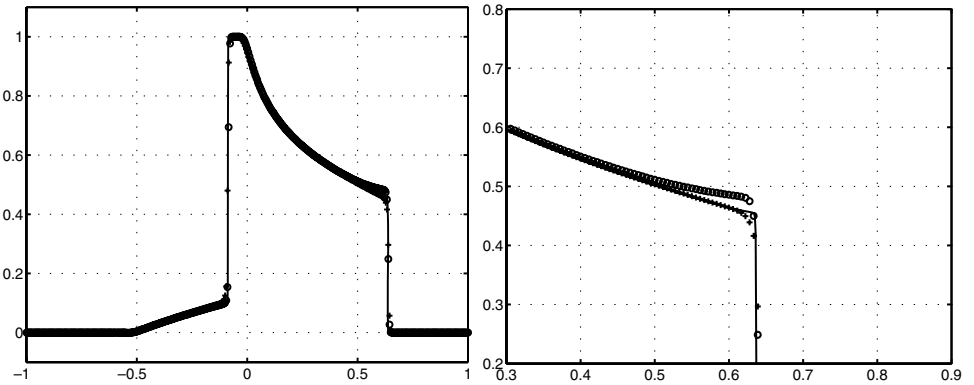

FIG. 3.4. *Buckley–Leverett: LDLR;* $q = 1.4$ (o), $q = 2.0$ (+).

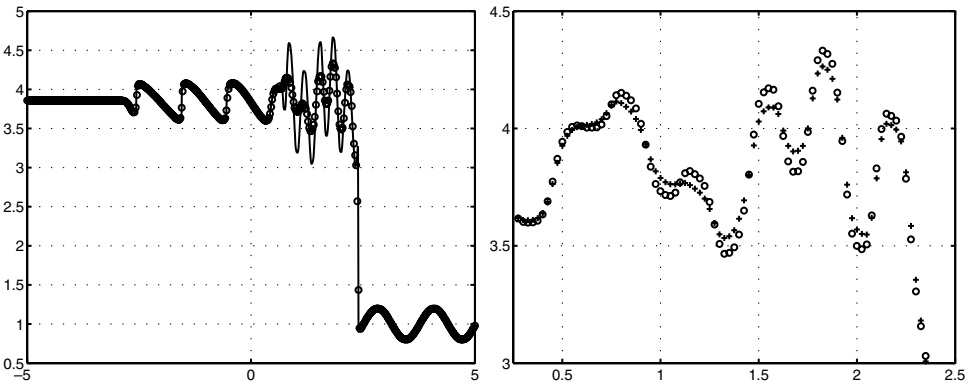

FIG. 3.5. *Shu–Osher shock-acoustic problem; LDLR* (o) *and LHHR* (+) .

3.2. One-dimensional Euler system.

EXAMPLE 5. Shu–Osher shock-acoustic problem. In this test problem, proposed by Shu and Osher [12], a supersonic shock wave moves into a smooth acoustic entropy wave. The initial data are

$$u(x,0) = (\rho, v, p) = \begin{cases} (3.857143, 2.629369, 10.333333), & -5 \le x < -5, \\ (1.0 + 0.2\sin(5x), 0.0, 1.0), & -4 \le x \le 5. \end{cases}$$

Behind the shock the acoustic wave is amplified. We run the experiment with componentwise reconstruction of the conserved variables in connection with Van Leer flux splitting. The number of cells is $N = 400$ and CFL $= 0.8$ for the computations. Depicted in Figure 3.5 are the LDLR approximation and a comparison between the LDLR and LHHR at $t = 1.8$. We observe that LDLR better resolves the waves behind the shock—especially near $x = 1.1$, where LHHR damps out two local extrema.

EXAMPLE 6. Sod problem. The initial data are

$$u(x,0) = (\rho, v, p) = \begin{cases} (1.0, 0.0, 1.0), & 0 \le x < 0.5, \\ (0.125, 0.0, 0.1), & 0.5 \le x \le 1. \end{cases}$$

We compute approximations using 200 cells with reconstructions of the conserved variables and the Lax–Friedrichs numerical flux. For ENO3 the constraint CFL $= 0.6$

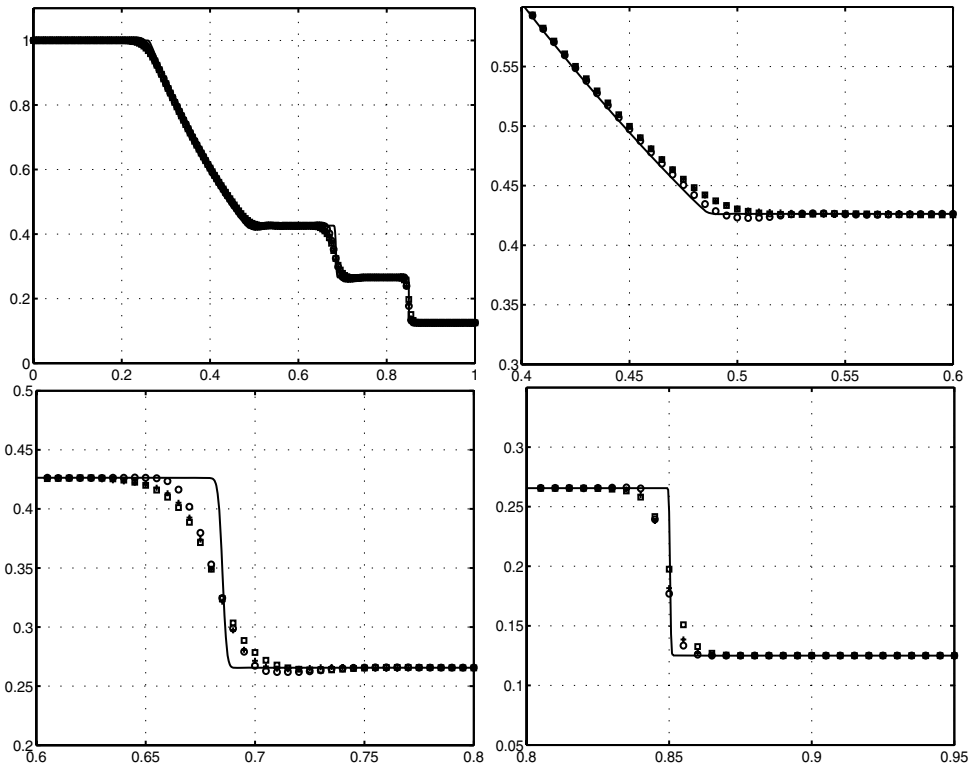

FIG. 3.6. *Sod problem; LDLR* (o) *, ENO*3 (+)*, and WENO*3 (□).

is used, and for LDLR and WENO3 we set CFL = 0.8. The approximations at $t = 0.2$ are shown in Figure 3.6. The local double logarithmic reconstruction introduces some very slight undershoots but on the other hand, resolves, the contact discontinuity in fewer cells than ENO and WENO; also the shock appears somewhat sharper.

EXAMPLE 7. Lax problem. The initial data are

$$u(x,0) = (\rho, v, p) = \begin{cases} (0.445, 0.698, 3.528), & 0 \le x < 0.5, \\ (0.5, 0.0, 0.571), & 0.5 \le x \le 1. \end{cases}$$

The computations with the Van Leer flux split and LDLR and ENO3 reconstructions of the conserved variables are on a 200 grid and subject to the constraint CFL = 0.8 for LDLR and WENO3 and CFL = 0.6 for ENO3. The approximations at $t = 0.13$ are displayed in Figure 3.7. We note that the LDLR approximation captures the discontinuities better than ENO3 and WENO3, especially the contact, and that no over- or undershoots are present.

EXAMPLE 8. Shockblast interaction. This experiment was proposed as a benchmark in [16]. The initial data are

$$u(x,0) = (\rho, v, p) = \begin{cases} (1.0, 0.0, 10^3), & 0 \le x < 0.1, \\ (1.0, 0.0, 10^{-2}), & 0.1 \le x < 0.9, \\ (1.0, 0.0, 10^2), & 0.9 \le x \le 1. \end{cases}$$

Reflective boundary conditions are used. Numerical solutions on 400 and 800 cell grid are computed with LDLR and LHHR applied on the Van Leer fluxes under CFL

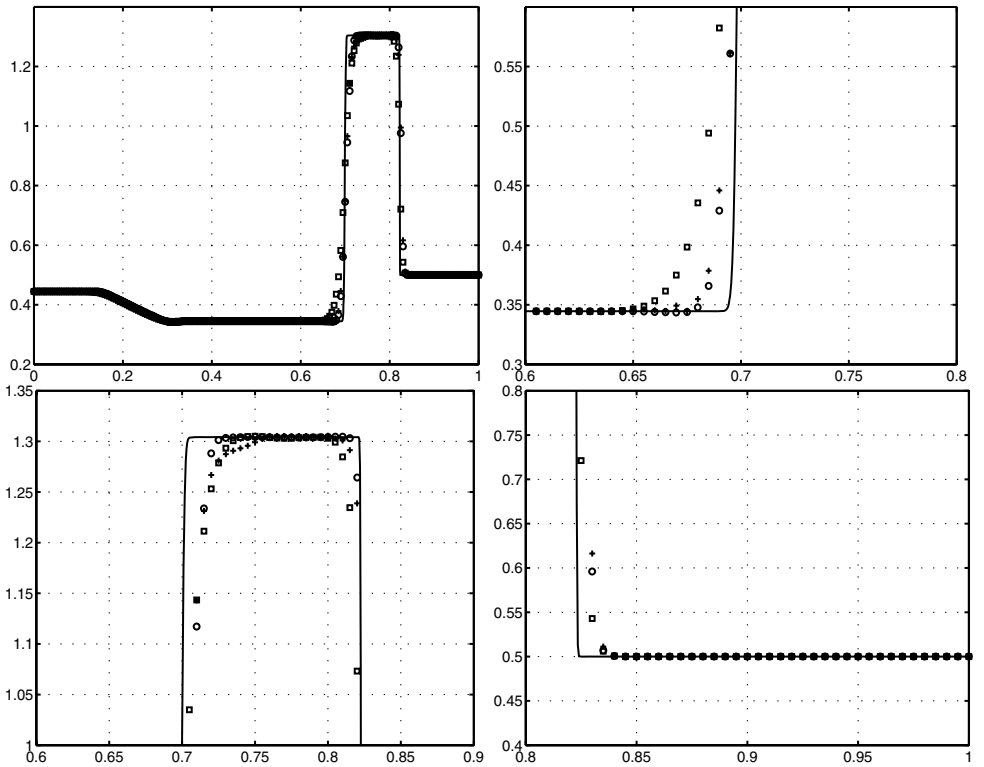

FIG. 3.7. *Lax problem; LDLR* (o)*, ENO3* (+)*, and WENO3.* (□)

$= 0.8$. In Figure 3.8 the approximations at $t = 0.038$ are displayed. For the 800-cell computations we observe that the lower peak is better resolved with LDLR; the LDLR approximations are, despite the full reconstruction of extrema, essentially free from over/undershoots and oscillations.

3.3. Computational cost. For a sound investigation of the efficiency of LDLR compared to other methods a large variety of problems should be tested; such tests are outside the scope of this paper. We are well aware that the performance of different methods depends on coding and hardware issues. Still we will need a "benchmark" method, LHHR, to set the LDLR results in perspective. In the present case things simplify a bit as both methods (LDLR and LHHR) rely on the same building principle and are of the same (formal) order. In fact, the basic FV code is exactly the same with only the reconstruction subroutine exchanged. Nevertheless the results presented below shall be taken as only a rough indication.

The tests were performed on a 500 MHz SunBlade 100 work station with 512 MB RAM using MATLAB Version 5.3.1.29215a (R11.1) on SOL2. The implementation avoids to a large extent for-loops and if-statements by extensive use of the dot and colon notation and by using logical arrays. The Sod and Lax problems are used as test problems with 200 cells and CFL $= 0.8$, as described in Examples 6 and 7 in section 3.2. Each example was run ten times in a row with LDLR and LHHR in sequence, and the average times were recorded as well as the number of flops used. The LDLR implementation exploited the symmetry in the η-functions as described in section 2.4. The same type of interpolation around the removable singularities in

the LDLR η-functions was used for the LHHR η-function. The LDLR was used in two ways: The results in the LDLR row in Table 3.3 were obtained by using LDLR also on constant states; the results in the LDLR* row were obtained as advised for LHHR in [6], that is, no reconstruction if both lateral derivatives are below the cell size squared. The results in Table 3.3 indicate that the computational cost for both schemes is comparable and that the LDLR, despite using two extra parameters, is not more expensive. For a comparison to ENO3 we refer to [6], where it is stated that the cost of LHHR is a bit higher than ENO3, but, on the other hand, LHHR is stable and accurate for high CFL numbers which reduce computational cost. The same stands true for LDLR.

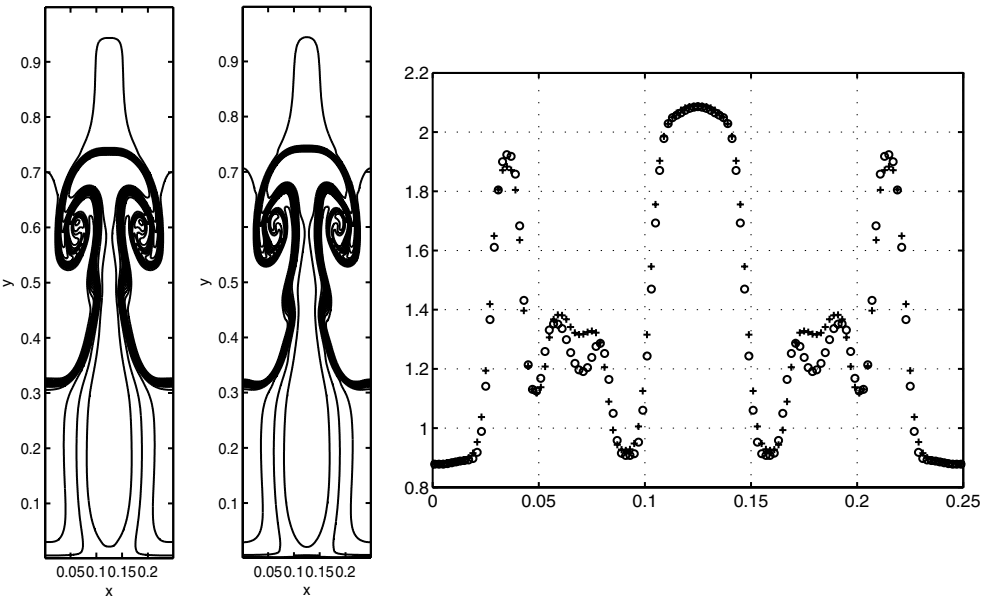

FIG. 3.9. *Rayleigh–Taylor instability. Density contours from* 0.952269 *to* 2.14589 *by step* 0.075. *From left to right: LHHR, LDLR, and vortex cut with LDLR* (o) *and LHHR* (+).

3.4. Two-dimensional (2d) Euler system. The 2d tests are computed using the dimension-by-dimension approach. We compute the numerical examples using the third order reconstructions on the conserved variables in Van Leer's upwind scheme.

[illegible] 9. Rayleigh–Taylor instability. See, for example, [11] and references therein for other simulations of this problem. The governing equations are the Euler equations with $\gamma = 5/3$ and source terms ρ and ρv added to the third and fourth equations, respectively. The computational domain is $[0, 1/4] \times [0, 1]$; the interface is located at $y = 0.5$ with initial data $\rho = 2$, $u = 0$, $p = 2y + 1$, and $v = -0.025c \cos 8\pi x$ for $0 \le y < 1/2$ and $\rho = 1$, $u = 0$, $p = y + 3/2$, and $v = -0.025c \cos 8\pi x$ for $1/2 \le y \le 1$. Reflective boundary conditions are imposed at the left and right boundary; at the top boundary we set $\rho = 1$, $u = 0$, $p = 2.5$, and $v = 0$, and on the bottom boundary $\rho = 2$, $u = 0$, $p = 1$, and $v = 0$. In Figure 3.9 LHHR and LDLR simulations on a 125×500 mesh under CFL $= 0.9$ at the final time $t = 1.95$ are depicted. A cut through the vortex at $y = 0.6$ shows that the local extrema are much better resolved for LDLR, especially near $x = 0.07$ and $x = 0.18$.

[illegible] 10. Double Mach reflection. For a detailed discussion of this problem, see [16]. Initially, on the computational domain $[0, 4] \times [0, 1]$, a Mach 10 shock is located at a 60° angle with the x-axis at $(x, y) = (1/6, 0)$. The boundary conditions are as follows: for $0 \le x \le 1/6$ exact postshock conditions are imposed, and for $1/6 < x \le 4$ reflective conditions are used; at the top boundary the flow values are set to describe the motion of the shock, and at the left and right boundaries inflow and outflow conditions, respectively, are used. To the right of the shock the fluid initially has a density of 1.4 and pressure of 1. We perform the computations with LDLR and LHHR on a 2000×500 grid under CFL $= 0.7$. Density contours at $t = 0.2$ are shown in Figure 3.10. We note the difference in resolution for LDLR and LHHR of the complex flow. In particular, the partially rolled up slip line and the local extrema at $(x = 2.62, y = 0.065)$ are sharper by the LDLR approximation.

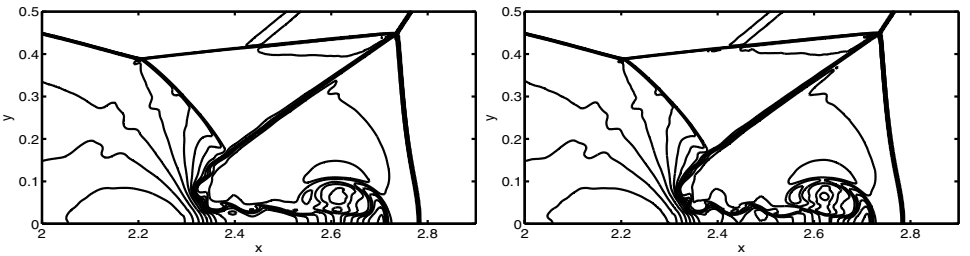

FIG. 3.10. *Double Mach reflection. Density contours from* 1.5 *to* 22.9705 *by step* 0.7156833. *Left: LHHR. Right: LDLR.*

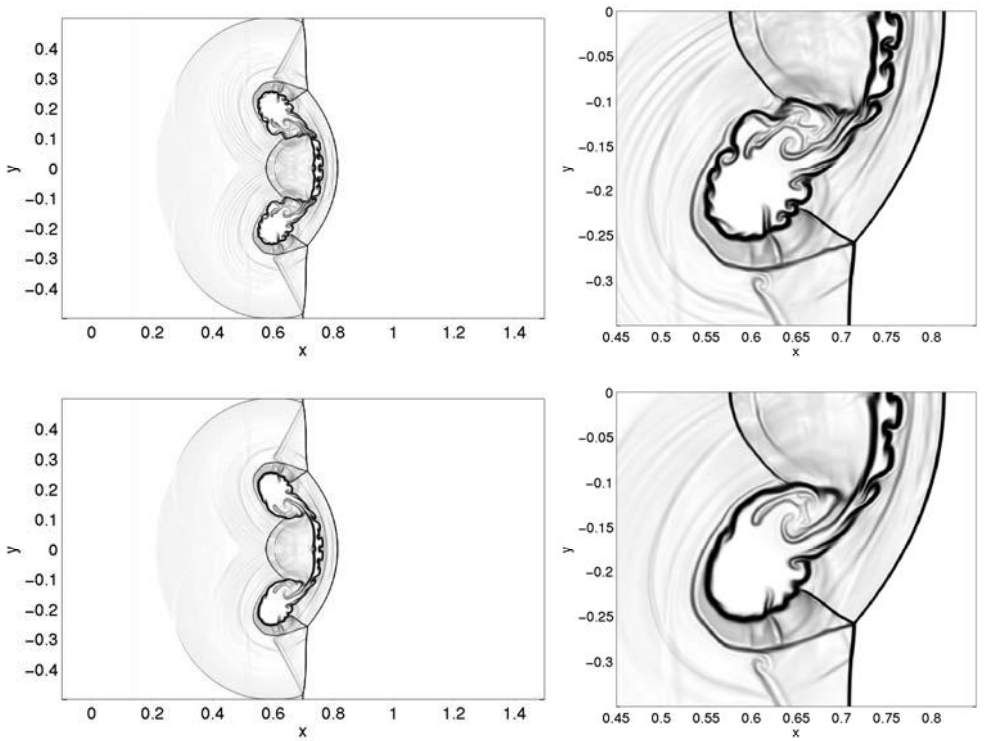

FIG. 3.11. *Shock-bubble, emulated Schlieren images at* $t = 0.2$. *Upper row: LDLR. Lower: LHHR.*

FIG. 3.11. Shock-bubble interaction. For a problem description and the precise data we refer to [9] and the web-page [17]. The LDLR and LHHR approximations are computed on a 1600×500 grid with reflective boundary condition at $y = 0$ under CFL $= 0.9$. In Figure 3.11 the results at $t = 0.2$ are displayed, and Figure 3.12 shows the approximations at $t = 0.4$. Comparing the LDLR and LHHR approximations, we observe more resolved contact discontinuities with the local double logarithmic method, resulting in considerably more vortex structure.

FIG. 3.12. A shock vortex interaction. In this experiment we simulate a shock wave in air diffracting down a step. The domain of interest is the unit square. On the bottom and the lower half of the left side a reflective boundary condition models a solid wall. The upper and right side are absorbing (artificial) boundaries. On the

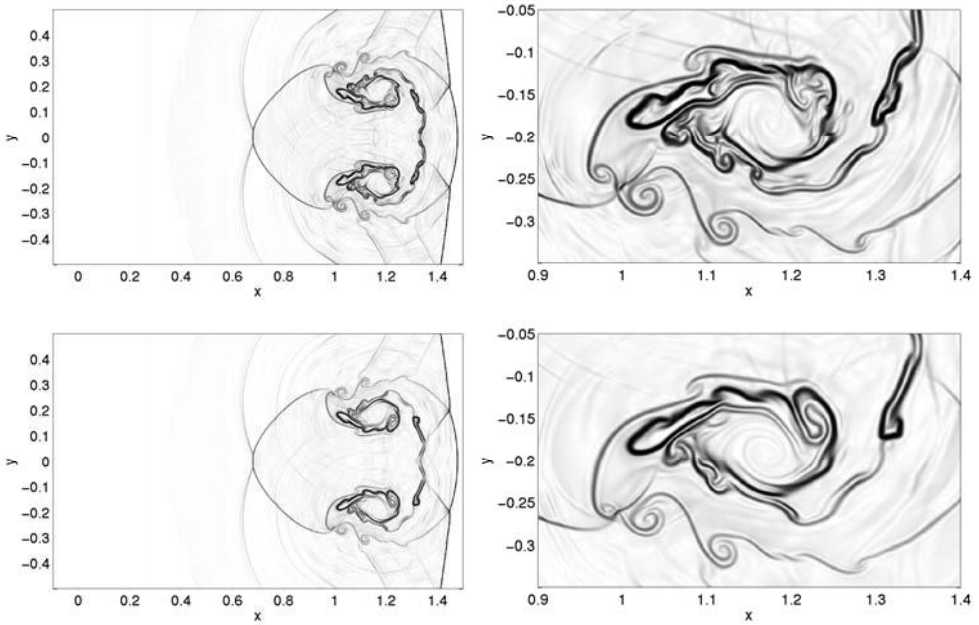

FIG. 3.12. *Shock-bubble, emulated Schlieren images at* $t = 0.4$. *Upper row: LDLR. Lower: LHHR.*

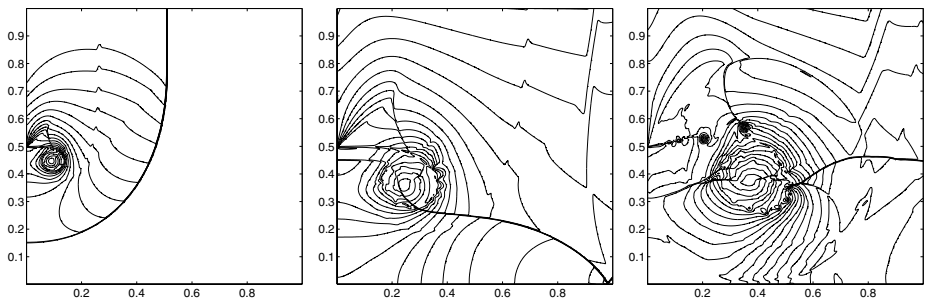

FIG. 3.13. *Shock-vortex. Density contours illustrating time evolution.*

upper half of the left side we put inflow conditions with $\rho = 1$, $p = 3$ and the flow speed at an angle of $\alpha = \pi/10$ connected to $\rho = 1$, $u = v = 0$, $p = 1$ inside the square by a single shock. The computation is run up to $t = 1$ on an 800×800 mesh under CFL $= 0.9$ with the reconstruction applied to Van Leer's partial fluxes. In Figure 3.13 the time evolution is illustrated. First we see the diffraction of the shock down the step and the formation of a large vortex in the wake. Next the shock is reflected on the bottom to pass through the vortex. A Schlieren animation of the flow is available on the web page [18]. The last movie frame is reproduced in Figure 3.14. Figure 3.15 shows enlarged details in the south-east part of the main vortex. Here the third order reconstruction of local extrema shows its effect: In the LDLR simulation we observe a sheet of several new vortices which are not resolved in the LLR simulation.

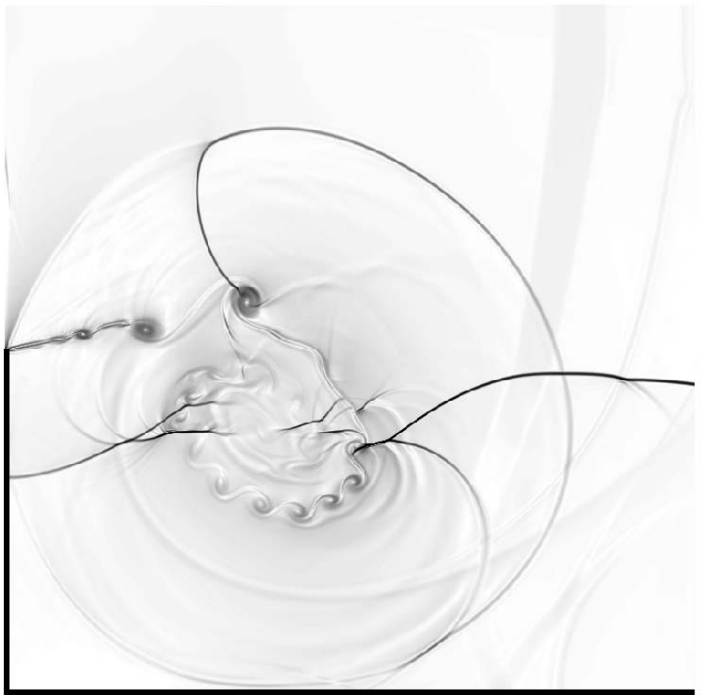

FIG. 3.14. *Shock-vortex. LDLR, emulated Schlieren image at* $t = 1.0$.

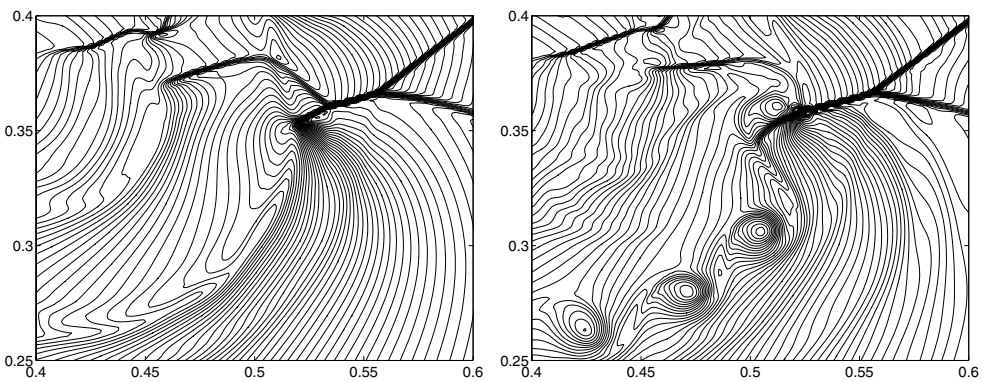

FIG. 3.15. *Shock-vortex, density contours. Left: LLR. Right: LDLR.*

4. Higher order extension. We are also interested in the local double logarithmic ansatz for use in a hybrid coupling to the fifth order DLR [1]. As described in [1], the DLR coefficients for fifth order do not always exist. In these cases we instead compute the LDLR coefficients for the third order. Note that the ansatz function is the same for the DLR and LDLR; the coefficients are, however, calculated with different objectives. The resulting scheme is applied to the test problem in Example 5 in section 3.2. The smoothness indicator in [1] is applied to the local characteristic projections of the required numerical derivatives of the conserved variables. We use

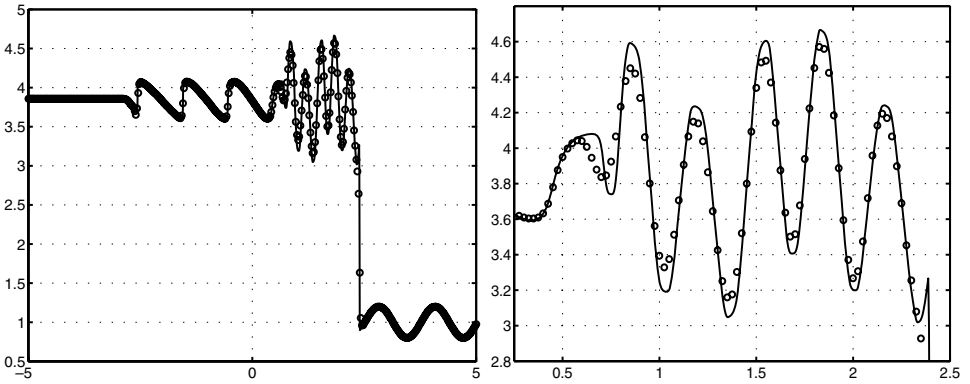

FIG. 4.1. *Shu–Osher shock-acoustic problem. DLR approximation.*

the Van Leer flux splitting with CFL = 0.8 and the same number of cells as in Example 5, section 3.2. The third order SSP–Runge Kutta method is used to advance in time. The result, displayed in Figure 4.1, shows that the waves behind the shock are much better resolved than with the third order schemes.

5. Concluding remarks. The developed reconstruction method uses an ansatz function of five parameters to get third order accuracy, leaving two parameters for symmetry and to control the variation of the reconstructing function. The numerical experiments conducted in this paper indicate that it is possible to obtain approximations to the solutions of hyperbolic conservation laws by a third order scheme on a 3-point spatial stencil without using explicit limiters on the slope information, provided that the local variation is controlled by other means. Moreover we have shown that the proposed reconstruction LDLR is not more expensive to compute, but is more accurate than, comparable third order methods.

Appendix A. LDHR—An extension of LHHR. The main reason for introducing the logarithmic ansatz is that the nonlinear system arising for a fifth order version is easily solvable in contrast to a hyperbolic ditto. However, for the third order version introduced in this paper the coefficients needed appear linearly. Therefore it is possible to extend the LHHR method [6] to reconstruct local extrema. In the following we present this local double hyperbolic reconstruction (LDHR).

The reconstructing function in the reference cell C_0 has the form

$$r_0(x) \sim A + \frac{B}{x+C} + \frac{D}{x+E}.$$

We define for $x \in C_0$

$$\phi_0(x) = -\frac{ch^2}{a^2}\frac{1}{\left[x - x_0 - \frac{h}{2}\left(\frac{2}{a} - 1\right)\right]} - \frac{dh^2}{b^2}\frac{1}{\left[x - x_0 - \frac{h}{2}\left(\frac{2}{b} - 1\right)\right]}, \tag{A.1}$$

where a, b, c, and d are the parameters, and let as for LDLR

$$r_0(x) = v_0 + \phi_0(x) - \frac{1}{h}\int_{C_0} \phi_0(\xi)d\xi \tag{A.2}$$

be the reconstructing function.

We satisfy the condition of Lemma 2.1 by solving for c and d, yielding

$$c = \frac{(a-1)^2(d_2(b-1)^2 - d_1)}{(a-2+b)(b-a)}, \tag{A.3}$$

$$d = d_1 - c. \tag{A.4}$$

Symmetry again implies $b = a/(a-1)$, and we get the expression for the local variation

$$LV(r_0) = h\frac{1-a}{(a-1)^2+1}|d_1 + d_2|. \tag{A.5}$$

The local variation in case of a discontinuity and with $a = 1 - h^q$ is of $\mathcal{O}(h^q)$. So we can, for example, use the parameter a given in (2.25) with $q = 1$ and TOL=$0.1h$ to get a LVB method. For computational purposes we use the lateral functions

$$\eta^+(t) = \frac{(t-1)\log(1-t) - t}{t^2(t-1)} \tag{A.6}$$

and

$$\eta^-(t) = \frac{\log(1-t) + t}{t^2} \tag{A.7}$$

and let

$$r_0\left(x_0 \pm \frac{h}{2}\right) = v_0 + ch\eta^{\pm}(a) + dh\eta^{\pm}(b). \tag{A.8}$$

Numerical tests show that this double hyperbolic reconstruction behaves essentially as the LDLR developed and tested in this paper.

AN ADAPTIVE HYBRID FEM/FDM METHOD FOR AN INVERSE SCATTERING PROBLEM IN SCANNING ACOUSTIC MICROSCOPY*

LARISA BEILINA† AND CHRISTIAN CLASON‡

Abstract. Scanning acoustic microscopy based on focused ultrasound waves is a promising new tool in medical imaging. In this work we apply an adaptive hybrid FEM/FDM (finite element methods/finite difference methods) method to an inverse scattering problem for the time-dependent acoustic wave equation, where one seeks to reconstruct an unknown sound velocity $c(x)$ from a single measurement of wave-reflection data on a small part of the boundary, e.g., to detect pathological defects in bone. Typically, this corresponds to identifying an unknown object (scatterer) in a surrounding homogeneous medium.

The inverse problem is formulated as an optimal control problem, where we use an adjoint method to solve the equations of optimality expressing stationarity of an associated augmented Lagrangian by a quasi-Newton method. To treat the problem of multiple minima of the objective function, the optimization procedure is first performed on a coarse grid to smooth the high frequency error, generating a starting point for optimization steps on successively refined meshes. Local refinement based on the results of previous steps will improve computational efficiency of the method.

As the main result then, an a posteriori error estimate is proved for the error in the Lagrangian, and a corresponding adaptive method is formulated, where the finite element mesh is refined from residual feedback. The performance of the adaptive hybrid method and the usefulness of the a posteriori error estimator for problems with limited boundary data are illustrated in three dimensional numerical examples.

1. Introduction.

Inverse scattering is a rapidly expanding area of computational mathematics with a wide range of applications including nondestructive testing of materials, shape reconstruction, nonmicroscopic ultrasound imaging, subsurface depth imaging of geological structures, and seismic prospection. The current work is devoted to an adaptive hybrid finite element/difference method (FEM/FDM) for an inverse scattering problem for the time-dependent three dimensional acoustic wave equation, with a special focus on the application of scanning acoustic microscopy (cf. [12]) in medical imaging. This problem takes the form of reconstructing a parameter from a single set of boundary displacement data measured using acoustic microscopy. Since the shear component of the elastic wave speed is much less than the longitudinal component in biological materials (by several orders of magnitude for soft tissue), an approximate common mathematical model for the displacement in water and sample is a scalar wave equation with (longitudinal) wave speed $c = \sqrt{(\lambda + 2\mu)/\rho}$, where ρ is the density and λ, μ are the Lamé constants of linear elasticity. More precisely, we will consider the problem of obtaining quantitative

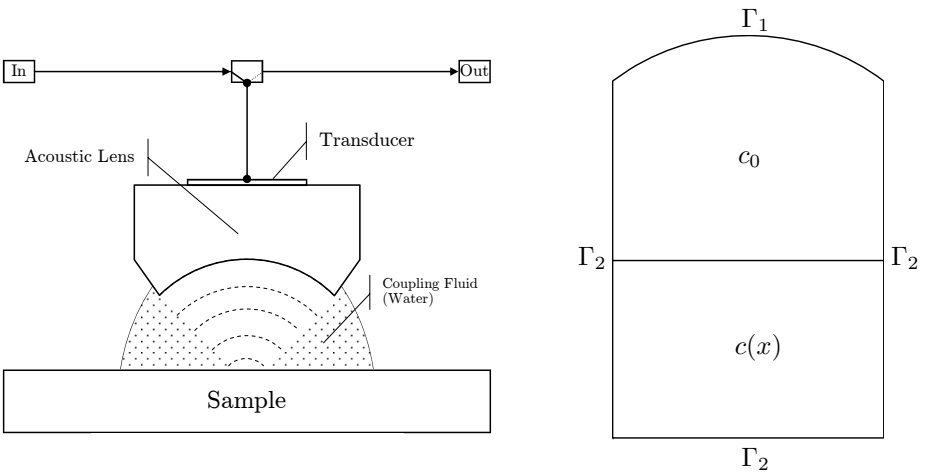

FIG. 1.1. *Sketch of a scanning acoustic microscope (left) and a cut of the corresponding three dimensional computational domain (right). Here,* c_0 *corresponds to the region filled with water,* $c(x)$ *to the sample, and* Γ_1 *to the lens boundary where a pulse is initiated and reflected echoes are measured.*

elasto-mechanical parameters of human bone by identifying the coefficient $c(x)$ in a bounded domain $\Omega \subset \mathbb{R}^3$, where short acoustic impulses are emitted on a part of the boundary $\Gamma_1 \subset \partial\Omega$, which are backscattered by material inhomogeneities and recorded again on Γ_1 (cf. Figure 1.1). In scanning acoustic microscopy, as in many other applications, Γ_1 is only a small part of the boundary, which introduces special difficulties for the reconstruction. Note that this problem differs significantly from another problem often considered in inverse scattering: that of reconstructing internal boundaries from far field measurements (cf. [16]).

Much research has been done to identify a coefficient in a three dimensional hyperbolic equation from boundary measurements. However, most previous papers treat the determination of the coefficient in the zeroth-order part of the hyperbolic operator—see, for example, Romanov [39] (using linearization), Imanuvilov and Yamamoto [25], Puel and Yamamoto [37], Feng et al. [22], and Rakesh [38] (requiring knowledge of the Dirichlet-to-Neumann map). The method of Carleman estimates introduced by Bukhgeim and Klibanov in [13] can prove the uniqueness and the conditional stability by a finite number of observations (cf. [26, 29] and the literature cited there). However, in the method of Carleman estimates it is necessary to assume that initial or external forces should satisfy positivity conditions, which restrict many practical applications.

Without such an assumption the problem of uniqueness and stability is still open. More generally, Bardos, Lebeau, and Rauch [2], using microlocal analysis, justified the rays of geometrical optics as tools for characterizing the stability of controllability for arbitrary domains. Their main result is the (nearly sharp) condition that every such ray must meet the controlled boundary in at least one nonglancing point.

There are different methods for computing the solution of the inverse problem for the acoustic wave equation in the time-domain—see, for example, [11, 40, 46]. Shirota [41] investigated a variational method for the reconstruction of the coefficient in an acoustic wave equation, which gave reasonable reconstruction for a set of given Cauchy data on most of the boundary. But the quality of the reconstruction deteriorated when

the measurement boundary was restricted, limiting the use for cases such as acoustic microscopy.

In order to reconstruct the parameter in a stable manner, we use an adjoint method with added Tikhonov regularization. Adjoint methods are well known in optimal control of partial differential equations [30]. They were also developed to solve inverse problems in different areas under the name of the propagation-backpropagation, time reversal, or phase conjugation method (cf. [32, 36, 42] and the literature cited there). The minimization problem is reformulated as the problem of finding a stationary point of a Lagrangian involving a forward wave equation (the state equation), a backward wave equation (the adjoint equation), and an equation expressing that the gradient with respect to the wave speed c vanishes. The optimum is sought in an iterative process solving in each step the forward and backward wave equations and updating the material coefficients by a quasi-Newton method. In Tikhonov regularization (cf. [18, 43, 45]), a small penalty term is added, stabilizing this ill-posed problem. To treat the problem of multiple local minima arising from the high frequency content of the data, we employ an adaptive approach, where we first solve the inverse problem on a coarse grid to smooth the high frequency components of the error, and then successively refine the mesh locally and use the results of previous iterations as an initial guess for a local optimization in order to capture finer details of the solution. Similar to multigrid methods (cf. [1, 14, 15, 35]), this will extend the basin of attraction of the global minimum, while at the same time improving the computational efficiency by the possibility of local refinement. Given the need for fast evaluation in applications like medical imaging and the high resolution possible with acoustic microscopy, the last point is of special importance.

The main contribution of this work therefore is to derive an a posteriori error estimate for the Lagrangian involving the residuals of the state equation, adjoint state equation, and the gradient with respect to the parameter (following [4, 5, 7, 8, 9, 20, 21, 27]) and employ this in an adaptive method where the spatial discretization is refined locally with feedback from the a posteriori error estimator. We present a numerical example showing the effectiveness of the computational inverse scattering in scanning acoustic microscopy using adaptive error control.

Additionally, often the surrounding body is homogeneous, and the material inhomogeneities occupy only a small portion of the body. In such cases the numerical solution of the wave equation is efficiently performed by a hybrid finite element/finite difference method developed in [6, 10], where the finite difference method is used in the structured part and finite elements are used in the unstructured part of the mesh. We exploit the flexibility of mesh refinement and adaptation of the finite element method in a domain including the object, and the efficiency of a structured mesh finite difference method in the surrounding homogeneous domain. The hybrid scheme can be viewed as a finite element scheme on a partially structured mesh which gives a stable coupling of the two methods.

An outline of the work is the following: in section 2 we formulate the inverse scattering problem and give the formulation of the adjoint method, in section 3 we introduce the finite element discretization, in section 4 we present a fully discrete version used in the computations, and in section 5 we describe the optimization by a quasi-Newton method. Section 6 contains the main result of this work: we prove an a posteriori error estimate and formulate an adaptive algorithm for the solution of the inverse problem. In section 7, we present computational results demonstrating the effectiveness of the adaptive finite element/difference method on an inverse scattering problem for scanning acoustic microscopy in three dimensions.

2. The inverse scattering problem. We consider the scalar wave equation in a bounded domain $\Omega \subset \mathbb{R}^3$, with boundary $\Gamma = \Gamma_1 \cup \Gamma_2$:

$$\begin{cases} \alpha \frac{\partial^2 v}{\partial t^2} - \triangle v &= 0, \quad \text{in } \Omega \times (0,T), \\ v(\cdot,0) &= 0, \quad \frac{\partial v}{\partial t}(\cdot,0) = 0, \text{ in } \Omega, \\ \partial_n v\big|_{\Gamma_1} &= v_1, \quad \text{on } \Gamma_1 \times (0,t_1], \\ \partial_n v\big|_{\Gamma_1} &= 0, \quad \text{on } \Gamma_1 \times (t_1,T], \\ \partial_n v\big|_{\Gamma_2} &= 0, \quad \text{on } \Gamma_2 \times [0,T], \end{cases} \tag{2.1}$$

where $v(x,t)$ is the scalar longitudinal displacement in an isotropic medium, t is the time variable, T is a final time, and $\alpha(x) = \frac{1}{c(x)^2}$ with $c(x) = \sqrt{(\lambda(x) + 2\mu(x))/\rho(x)}$ representing the wave speed depending on $x \in \Omega$. We assume that the density $\rho(x)$ and the Lamé coefficients $\lambda(x)$, $\mu(x)$ are strictly positive. The impulse wave $v_1(x,t)$ is initialized at the spherical boundary of the lens Γ_1 and propagated in time $(0,t_1]$ into Ω, which represents the region of investigation by the acoustic microscope (cf. 1.1).

Our goal is to find the coefficient function $\alpha(x)$ which minimizes the quantity

$$E(v,\alpha) = \frac{1}{2}\int_0^T \int_{\Gamma_1} (v - v_{obs})^2 \, dxdt + \frac{1}{2}\gamma \int_\Omega (\alpha - \alpha_0)^2 \, dx, \tag{2.2}$$

over the set $C_M = \{\alpha \in C(\overline{\Omega}) |\ M^{-1} \le \alpha(x) \le M\}$ for a fixed $M > 0$. Here v_{obs} is the observed data on Γ_1, and v (here understood as its trace on Γ) satisfies (2.1), thus depending on α. The second term involving α_0, an initial guess value for α, is a Tikhonov regularization. The choice of the regularization parameter γ is important in order to get a good reconstruction. This value will depend on the quality of the measured data, with poor data typically demanding more regularization. Several parameter choice rules exist if the noise level is known explicitly, which can be shown to be optimal (cf. [44] and literature cited there). The case of stochastic noise is discussed in [28]. Unfortunately, the noise level is hard to estimate a priori in our application, since it depends strongly on the operating conditions of the microscope and the specific sample to be measured. However, in [9], it was shown that γ can be chosen adaptively to get a best reconstruction by computing stability factors appearing in the solution to a dual linearized problem involving the Hessian of the Lagrangian. In our future research, we plan to study the behavior of the a posteriori error estimator connected to the Hessian problem for the application in scanning acoustic microscopy.

To solve this minimization problem with an adjoint method, we consider the augmented Lagrangian

$$L(u) = E(v,\alpha) + \int_0^T \int_\Omega \left(-\alpha \frac{\partial \lambda}{\partial t}\frac{\partial v}{\partial t} + \nabla\lambda\nabla v \right) \, dxdt - \int_0^{t_1} \int_{\Gamma_1} v_1 \lambda \, d\Gamma dt, \tag{2.3}$$

where $u = (v,\lambda,\alpha)$, and search for a stationary point with respect to u satisfying for all $\bar{u} = (\bar{v},\bar{\lambda},\bar{\alpha})$

$$L'(u)(\bar{u}) = 0, \tag{2.4}$$

where L' is the gradient of L. Equation (2.4) expresses that for all $\bar{u}$,

$$0 = \frac{\partial L}{\partial \lambda}(u)(\bar{\lambda}) = \int_0^T \int_\Omega \left(-\alpha \frac{\partial \bar{\lambda}}{\partial t}\frac{\partial v}{\partial t} + \nabla\bar{\lambda}\nabla v \right) \, dxdt - \int_0^{t_1} \int_{\Gamma_1} v_1 \bar{\lambda} \, d\Gamma dt, \tag{2.5}$$

(2.6)
$$0 = \frac{\partial L}{\partial v}(u)(\bar{v}) = \int_0^T \int_{\Gamma_1} (v - v_{obs})\ \bar{v}\ dxdt + \int_0^T \int_\Omega \left(-\alpha \frac{\partial \lambda}{\partial t} \frac{\partial \bar{v}}{\partial t} + \nabla \lambda \nabla \bar{v} \right)\ dxdt,$$

(2.7)
$$0 = \frac{\partial L}{\partial \alpha}(u)(\bar{\alpha}) = -\int_0^T \int_\Omega \frac{\partial \lambda(x,t)}{\partial t} \frac{\partial v(x,t)}{\partial t} \bar{\alpha}\ dxdt + \gamma \int_\Omega (\alpha - \alpha_0)\bar{\alpha}\ dx, \qquad x \in \Omega.$$

The equation (2.5) is a weak form of the state equation (2.1); (2.6) is a weak form of the adjoint state equation (which is solved backward in time)

(2.8)
$$\begin{cases} \alpha \frac{\partial^2 \lambda}{\partial t^2} - \triangle \lambda & = 0,\ x \in \Omega,\ 0 < t < T, \\ \lambda(\cdot, T) & = \frac{\partial \lambda(\cdot, T)}{\partial t} = 0, \\ \partial_n \lambda & = (v - v_{obs}) \quad \text{on } \Gamma \times [0, T], \end{cases}$$

and (2.7) expresses stationarity with respect to α. From standard results in optimal control theory (e.g., Chapter IV, Lemma 7.1 in [30]), we know that the solution of (2.8) exists and is unique.

The existence of minimizers of (2.2) can be proven using the techniques in [22]. Assuming compatibility conditions for v_1, one can prove a priori estimates in $H^1(\Omega \times [0,T])$ for the gradient of v (cf. [24,31]). Taking a minimizing sequence α_n of (2.2) in C_M with $\lim_{n\to\infty} E(v(\alpha_n), \alpha_n) = \inf_{\alpha \in C_M} E(v(\alpha), \alpha)$ and denoting $v_n = v(\alpha_n)$, we have from the strong convergence of ∇v_n in $L^2(\Omega \times [0,T])$ and the boundedness of α_n^{-1} the convergence of $\alpha_n^{-1} \nabla v_n$ in $L^2(\Omega \times [0,T])$. Passing to the limit in the weak formulation of (2.1) guarantees the existence of the limit v, and hence we conclude from the lower semicontinuity of the L^2 norm with respect to weak convergence that the limit (v, α) is a minimizer of (2.2).

To compute the solution of the minimization problem, we will use a quasi-Newton method with limited storage, which is described in section 5.

3. Finite element discretization. We now formulate a finite element method for (2.4) based on using continuous piecewise linear functions in space and time. We discretize $\Omega \times (0,T)$ in the usual way, denoting by $K_h = \{K\}$ a partition of the domain Ω into tetrahedra K ($h = h(x)$ being a mesh function representing the local diameter of the elements), and we let $J_k = \{J = J_1 \cup J_2\}$ be a partition of the time interval $(0,T)$ into time intervals $J = (t_{k-1}, t_k]$ of uniform length $\tau = t_k - t_{k-1}$, where $J_1 = (t_{k-1}, t_k],\ t \in (0, t_1]$, and $J_2 = (t_{k-1}, t_k],\ t \in (t_1, T]$. In fully discrete form, the resulting method corresponds to a centered finite difference approximation for the second-order time derivative and a usual finite element approximation of the Laplacian.

To formulate the finite element method for (2.4) we introduce the finite element spaces V_h, W_h^v, and W_h^λ defined by

$$\begin{aligned}
V_h &:= \{v \in L_2(\Omega) : v \in P_0(K), \forall K \in K_h\}, \\
W_1^v &:= \{v \in H^1(\Omega \times J_1) : v(\cdot, 0) = 0,\ \partial_n v|_{\Gamma_1} = v_1,\ \partial_n v|_{\Gamma_2} = 0\}, \\
W_2^v &:= \{v \in H^1(\Omega \times J_2) : v(\cdot, 0) = 0,\ \partial_n v|_{\Gamma} = 0\}, \\
W^\lambda &:= \{\lambda \in H^1(\Omega \times J) : \lambda(\cdot, T) = 0,\ \partial_n \lambda|_{\Gamma} = 0\}, \\
W_h^v &:= \{v \in W_1^v \cup W_2^v : v|_{K \times (J_1 \cup J_2)} \in P_1(K) \times (P_1(J_1) \cup P_1(J_2)), \forall K \in K_h, \forall J \in J_k\}, \\
W_h^\lambda &:= \{v \in W^\lambda : v|_{K \times J} \in P_1(K) \times P_1(J), \forall K \in K_h, \forall J \in J_k\},
\end{aligned}$$

where $P_1(K)$ and $P_1(J)$ are the sets of linear functions on K and J, respectively.

We define $U_h = W_h^v \times W_h^\lambda \times V_h$. The finite element method now reads: Find $u_h \in U_h$ such that

$$L'(u_h)(\bar{u}) = 0 \quad \forall \bar{u} \in U_h. \tag{3.1}$$

4. Fully discrete scheme. Expanding v, λ in terms of the standard continuous piecewise linear functions $\varphi_i(x)$ in space and $\psi_i(t)$ in time and substituting this into (2.5)–(2.6), we obtain the following system of linear equations:

$$M(\mathbf{v}^{k+1} - 2\mathbf{v}^k + \mathbf{v}^{k-1}) = \tau^2 P_1^k - \tau^2 K \left(\frac{1}{6}\mathbf{v}^{k-1} + \frac{2}{3}\mathbf{v}^k + \frac{1}{6}\mathbf{v}^{k+1} \right), \tag{4.1}$$

$$M(\boldsymbol{\lambda}^{k+1} - 2\boldsymbol{\lambda}^k + \boldsymbol{\lambda}^{k-1}) = -\tau^2 S^k - \tau^2 K \left(\frac{1}{6}\boldsymbol{\lambda}^{k-1} + \frac{2}{3}\boldsymbol{\lambda}^k + \frac{1}{6}\boldsymbol{\lambda}^{k+1} \right), \tag{4.2}$$

with initial conditions for both v and λ:

$$v(0) = \frac{\partial v}{\partial t}(0) = 0, \tag{4.3}$$

$$\lambda(T) = \frac{\partial \lambda}{\partial t}(T) = 0. \tag{4.4}$$

Here, M is the mass matrix in space, K is the stiffness matrix, $k = 1, 2, 3 \ldots$ denotes the time level, F^k, S^k are the load vectors, $\mathbf{v}$ is the unknown discrete field values of v, $\boldsymbol{\lambda}$ is the unknown discrete field values of λ, and τ is the time step.

The explicit formulas for the entries in system (4.1)–(4.2) at each element e can be given as

$$M_{i,j}^e = (\alpha\varphi_i, \varphi_j)_e, \tag{4.5}$$

$$K_{i,j}^e = (\bigtriangledown\varphi_i, \bigtriangledown\varphi_j)_e, \tag{4.6}$$

$$P_{1_{j,m}} = (v_1, \varphi_j\psi_m)_{\Gamma_1 \times J_1}, \tag{4.7}$$

$$S_{j,m}^e = (v - \tilde{v}, \varphi_j\psi_m)_{e \times J}, \tag{4.8}$$

where $(.,.)_e$ denotes the $L_2(e)$ scalar product. The matrix M_e is the contribution from element e to the global assembled matrix in space M, K^e is the contribution from element e to the global assembled matrix K, P_1 is the contribution of the boundary term on Γ_1, and S^e is the contribution from element e to the assembled source vector of the right-hand side of (2.8).

To obtain an explicit scheme we approximate M with the lumped mass matrix M^L, the diagonal approximation obtained by taking the row sum of M; see, e.g., [23]. By multiplying (4.1)–(4.2) with $(M^L)^{-1}$ and replacing the terms $\frac{1}{6}\mathbf{v}^{k-1} + \frac{2}{3}\mathbf{v}^k + \frac{1}{6}\mathbf{v}^{k+1}$ and $\frac{1}{6}\boldsymbol{\lambda}^{k-1} + \frac{2}{3}\boldsymbol{\lambda}^k + \frac{1}{6}\boldsymbol{\lambda}^{k+1}$ by $\mathbf{v}^k$ and $\boldsymbol{\lambda}^k$, respectively, we obtain an efficient explicit formulation:

$$\mathbf{v}^{k+1} = \tau^2 (M^L)^{-1} P_1^k + 2\mathbf{v}^k - \tau^2 (M^L)^{-1} K\mathbf{v}^k - \mathbf{v}^{k-1}, \tag{4.9}$$

$$\boldsymbol{\lambda}^{k-1} = -\tau^2 (M^L)^{-1} S^k + 2\boldsymbol{\lambda}^k - \tau^2 (M^L)^{-1} K\boldsymbol{\lambda}^k - \boldsymbol{\lambda}^{k+1}. \tag{4.10}$$

The discrete version of (2.7) takes the form

$$0 = -\int_0^T \int_\Omega \frac{\partial \lambda_h}{\partial t} \frac{\partial v_h}{\partial t} \bar{\alpha}\, dxdt + \gamma \int_\Omega (\alpha_h - \alpha_0)\bar{\alpha}\, dx, \qquad \forall \bar{\alpha} \in V_h. \tag{4.11}$$

5. Optimization by a quasi-Newton method. To solve the discrete problem (3.1), we use a quasi-Newton method with limited storage [33], where we compute a sequence α_h^k, $k = 0, 1, \dots$, of approximations of α_h with nodal values α_k given by

$$\alpha_{k+1} = \alpha_k - \rho^k H^k g_k. \tag{5.1}$$

Here, the step length ρ^n is computed with a line-search algorithm given in [34], and g_k are the nodal values of the gradient given by

$$g^k(x) = -\int_0^T \frac{\partial \lambda_h^k(x,t)}{\partial t} \frac{\partial v_h^k(x,t)}{\partial t} dt + \gamma(\alpha_k(x) - \alpha_0), \tag{5.2}$$

where v_h^k and λ_h^k solve the discrete analogues of (2.1) and (2.8).

H^k is given by the usual BFGS update formula of the Hessian (cf. [17])

$$H^{k+1} = (I - ds_k y_k^T) H^k (I - dy_k s_k^T) + \rho s_k s_k^T, \tag{5.3}$$

where $d = 1/(y_k^T s_k)$ and

$$s_k = \alpha_{k+1} - \alpha_k, \tag{5.4}$$

$$y_k = g_{k+1} - g_k. \tag{5.5}$$

Note that instead of explicitly computing the Hessian H^k in (5.1), we compute the product $H^{k+1} g^k$ from (5.3) to get

$$((I - ds_k y_k^T) H^k (I - dy_k s_k^T) + \rho s_k s_k^T) g^k = (I - ds_k y_k^T) H^k (g^k - dy_k s_k^T g^k) + \rho s_k s_k^T g^k, \tag{5.6}$$

involving only scalar products of vectors and computing $H^k g^k$ similarly. A modified version of H_k is stored implicitly, by using a certain number m of the vector pairs (s_i, y_i).

6. An a posteriori error estimate for the Lagrangian and an adaptive algorithm.

6.1. A posteriori error estimate. Following [8], we now present the main steps in the proof of an a posteriori error estimate for the Lagrangian. Let C denote various constants of moderate size. We start by writing an equation for the error e in the Lagrangian as

$$\begin{aligned} e = L(u) - L(u_h) &= \int_0^1 \frac{d}{d\epsilon} L(u\epsilon + (1-\epsilon)u_h) d\epsilon \\ &= \int_0^1 L'(u\epsilon + (1-\epsilon)u_h)(u - u_h) d\epsilon = L'(u_h)(u - u_h) + R, \end{aligned} \tag{6.1}$$

where R denotes (a small) second-order term. For full details of the arguments we refer the reader to [3] and [21].

Using the Galerkin orthogonality (3.1), the splitting $u - u_h = (u - u_h^I) + (u_h^I - u_h)$, where u_h^I denotes an interpolant of u, and neglecting the term R, we get the following error representation:

$$e \approx L'(u_h)(u - u_h^I) = (I_1 + I_2 + I_3), \tag{6.2}$$

where

$$I_1 = \int_0^T \int_\Omega \left(-\alpha_h \frac{\partial(\lambda - \lambda_h^I)}{\partial t} \frac{\partial v_h}{\partial t} + \nabla(\lambda - \lambda_h^I) \nabla v_h \right) \, dxdt - \int_0^{t_1} \int_{\Gamma_1} v_1 (\lambda - \lambda_h^I) \, d\Gamma dt, \tag{6.3}$$

$$I_2 = \int_0^T \int_\Omega (v_h - \tilde{v})(v - v_h^I) \, \delta_{obs} \, dxdt + \int_0^T \int_\Omega \left(-\alpha_h \frac{\partial \lambda_h}{\partial t} \frac{\partial (v - v_h^I)}{\partial t} + \nabla \lambda_h \nabla (v - v_h^I) \right) \, dxdt, \tag{6.4}$$

$$I_3 = -\int_0^T \int_\Omega \frac{\partial \lambda_h(x,t)}{\partial t} \frac{\partial v_h(x,t)}{\partial t} (\alpha - \alpha_h^I) \, dxdt + \gamma \int_\Omega (\alpha_h - \alpha_0)(\alpha - \alpha_h^I) dx. \tag{6.5}$$

To estimate (6.3) we integrate by parts in the first and second terms to get

$$\begin{aligned} \left| I_1 \right| = \Bigg| & \int_0^T \int_\Omega \left(\alpha_h \frac{\partial^2 v_h}{\partial t^2} (\lambda - \lambda_h^I) - \triangle v_h (\lambda - \lambda_h^I) \right) \, dxdt \\ & - \int_0^{t_1} \int_{\Gamma_1} v_1 (\lambda - \lambda_h^I) \, d\Gamma dt + \sum_K \int_0^T \int_{\partial K} \frac{\partial v_h}{\partial n_K} (\lambda - \lambda_h^I) \, dsdt \\ & - \sum_k \int_\Omega \alpha_h \left[\frac{\partial v_h}{\partial t}(t_k) \right] (\lambda - \lambda_h^I)(t_k) \, dx \Bigg|, \end{aligned} \tag{6.6}$$

where the terms $\frac{\partial v_h}{\partial n_K}$ and $\left[\frac{\partial v_h}{\partial t}\right]$ appear during the integration by parts and denote the derivative of v_h in the outward normal direction n_K of the boundary ∂K of element K and the jump of the derivative of v_h in time, respectively. In the third term of (6.6) we sum over the element boundaries, and each internal side $S \in S_h$ occurs twice. Denoting by $\partial_s v_h$ the derivative of a function v_h in one of the normal directions of each side S, we can write

$$\sum_K \int_{\partial K} \frac{\partial v_h}{\partial n_K} (\lambda - \lambda_h^I) \, ds = \sum_S \int_S \left[\partial_s v_h \right] (\lambda - \lambda_h^I) \, ds, \tag{6.7}$$

where $\left[\partial_s v_h\right]$ is the jump in the derivative $\partial_s v_h$ computed from the two elements sharing S. We distribute each jump equally to the two sharing triangles and return to a sum over element edges ∂K:

$$\sum_S \int_S \left[\partial_s v_h \right] (\lambda - \lambda_h^I) \, ds = \sum_K \frac{1}{2} h_K^{-1} \int_{\partial K} \left[\partial_s v_h \right] (\lambda - \lambda_h^I) \, h_K \, ds. \tag{6.8}$$

We formally set $dx = h_K ds$ and replace the integrals over the element boundaries ∂K by integrals over the elements K, to get

$$\left| \sum_K \frac{1}{2} h_K^{-1} \int_{\partial K} \left[\partial_s v_h \right] (\lambda - \lambda_h^I) \, h_K \, ds \right| \le C \max_{S \subset \partial K} h_K^{-1} \int_\Omega \left| \left[\partial_s v_h \right] \right| \cdot \left| (\lambda - \lambda_h^I) \right| \, dx, \tag{6.9}$$

where $\left[\partial_s v_h\right]\big|_K = \max_{S\subset\partial K}\left[\partial_s v_h\right]\big|_S$.

In a similar way we can estimate the fourth term in (6.6):

$$\begin{aligned}\left|\sum_k \int_\Omega \alpha_h \left[\frac{\partial v_h}{\partial t}(t_k)\right](\lambda-\lambda_h^I)(t_k)\,dx\right| &\le \sum_k \int_\Omega \alpha_h\tau^{-1}\cdot\left|\left[\frac{\partial v_h}{\partial t}(t_k)\right]\right|\cdot\left|(\lambda-\lambda_h^I)(t_k)\right|\,\tau dx\\ &\le C\sum_k\int_{J_k}\int_\Omega \alpha_h\tau^{-1}\cdot\left|\left[\partial v_{ht_k}\right]\right|\cdot\left|(\lambda-\lambda_h^I)\right|\,dxdt\\ &= C\int_0^T\int_\Omega \alpha_h\tau^{-1}\cdot\left|\left[\partial v_{ht}\right]\right|\cdot\left|(\lambda-\lambda_h^I)\right|\,dxdt,\end{aligned}\tag{6.10}$$

where

$$[\partial v_{ht_k}] = \max_{J_k}\left(\left[\frac{\partial v_h}{\partial t}(t_k)\right],\ \left[\frac{\partial v_h}{\partial t}(t_{k+1})\right]\right),\tag{6.11}$$

and $[\partial v_{ht}]$ is defined as the maximum of the two jumps in time on each time interval J_k appearing in (6.11):

$$[\partial v_{ht}] = [\partial v_{ht_k}] \quad \text{on } J_k.$$

Substituting both of the above expressions for the second and third terms in (6.6), we get

$$\begin{aligned}\left|I_1\right| \le &\left|\int_0^T\int_\Omega\left(\alpha_h\frac{\partial^2 v_h}{\partial t^2}-\triangle v_h\right)(\lambda-\lambda_h^I)\,dxdt\right|\\ &-\left|\int_0^{t_1}\int_{\Gamma_1} v_1(\lambda-\lambda_h^I)\,d\Gamma dt\right|\\ &+C\int_0^T\int_\Omega \max_{S\subset\partial K} h_k^{-1}\cdot\left|\left[\partial_s v_h\right]\right|\cdot\left|(\lambda-\lambda_h^I)\right|\,dxdt\\ &+C\int_0^T\int_\Omega \alpha_h\tau^{-1}\cdot\left|\left[\partial v_{ht}\right]\right|\cdot\left|(\lambda-\lambda_h^I)\right|\,dxdt.\end{aligned}\tag{6.12}$$

Next, we use a standard interpolation estimate for $\lambda-\lambda_h^I$ to get

$$\begin{aligned}\left|I_1\right| \le\ & C\int_0^T\int_\Omega\left|\alpha_h\frac{\partial^2 v_h}{\partial t^2}-\triangle v_h\right|\cdot\left(\tau^2\left|\frac{\partial^2\lambda}{\partial t^2}\right|+h^2\left|D_x^2\lambda\right|\right)\,dxdt\\ &-C\int_0^{t_1}\int_{\Gamma_1} v_1\cdot\left(\tau^2\left|\frac{\partial^2\lambda}{\partial t^2}\right|+h^2\left|D_x^2\lambda\right|\right)\,d\Gamma dt\\ &+C\int_0^T\int_\Omega \max_{S\subset\partial K} h_k^{-1}\cdot\left|\left[\partial_s v_h\right]\right|\cdot\left(\tau^2\left|\frac{\partial^2\lambda}{\partial t^2}\right|+h^2\left|D_x^2\lambda\right|\right)\,dxdt\\ &+C\int_0^T\int_\Omega \alpha_h\tau^{-1}\cdot\left|\left[\partial v_{ht}\right]\right|\cdot\left(\tau^2\left|\frac{\partial^2\lambda}{\partial t^2}\right|+h^2\left|D_x^2\lambda\right|\right)\,dxdt.\end{aligned}\tag{6.13}$$

Next, we note that the first integral in (6.13) disappears, since v_h is a continuous piecewise linear function. We then estimate $\frac{\partial^2\lambda}{\partial t^2} \approx \frac{[\partial\lambda_h/\partial t]}{\tau}$ and $D_x^2\lambda \approx \frac{[\partial\lambda_h/\partial n]}{h}$ to get

$$
\begin{aligned}
\left|I_1\right| &\le C\int_0^{t_1}\int_{\Gamma_1}\left|v_1\right|\cdot\left(\tau^2\left|\frac{\left[\frac{\partial\lambda_h}{\partial t}\right]}{\tau}\right|+h^2\left|\frac{\left[\frac{\partial\lambda_h}{\partial n}\right]}{h}\right|\right)\,d\Gamma dt\\
&+ C\int_0^T\int_\Omega \max_{S\subset\partial K} h_k^{-1}\left|\left[\partial_s v_h\right]\right|\cdot\left(\tau^2\left|\frac{\left[\frac{\partial\lambda_h}{\partial t}\right]}{\tau}\right|+h^2\left|\frac{\left[\frac{\partial\lambda_h}{\partial n}\right]}{h}\right|\right)\,dxdt \qquad (6.14)\\
&+ C\int_0^T\int_\Omega \alpha_h\tau^{-1}\left|\left[\partial v_{ht}\right]\right|\cdot\left(\tau^2\left|\frac{\left[\frac{\partial\lambda_h}{\partial t}\right]}{\tau}\right|+h^2\left|\frac{\left[\frac{\partial\lambda_h}{\partial n}\right]}{h}\right|\right)\,dxdt.
\end{aligned}
$$

We estimate I_2 similarly:

$$
\begin{aligned}
\left|I_2\right| &\le \int_0^T\int_\Omega\left|\left(\alpha_h\frac{\partial^2\lambda_h}{\partial t^2}(v-v_h^I)-\triangle\lambda_h(v-v_h^I)-(v_h-\tilde v)(v-v_h^I)\right)\right|\,dxdt\\
&+ C\int_0^T\int_\Omega \max_{S\subset\partial K} h_k^{-1}\cdot\left|\left[\partial_s\lambda_h\right]\right|\cdot\left|(v-v_h^I)\right|\,dxdt\\
&+ C\int_0^T\int_\Omega \alpha_h\tau^{-1}\cdot\left|\left[\partial\lambda_{ht}\right]\right|\cdot\left|(v-v_h^I)\right|\,dxdt\\
&\le C\int_0^T\int_\Omega\left|\left(\alpha_h\frac{\partial^2\lambda_h}{\partial t^2}-\triangle\lambda_h-(v_h-\tilde v)\right)\right|\cdot\left|(v-v_h^I)\right|\,dxdt\\
&+ C\int_0^T\int_\Omega \max_{S\subset\partial K} h_k^{-1}\cdot\left|\left[\partial_s\lambda_h\right]\right|\cdot\left|(v-v_h^I)\right|\,dxdt\\
&+ C\int_0^T\int_\Omega \alpha_h\tau^{-1}\cdot\left|\left[\partial\lambda_{ht}\right]\right|\cdot\left|(v-v_h^I)\right|\,dxdt\\
&\le C\int_0^T\int_\Omega\left|\left(\alpha_h\frac{\partial^2\lambda_h}{\partial t^2}-\triangle\lambda_h-(v_h-\tilde v)\right)\right|\left(\tau^2\left|\frac{\partial^2 v}{\partial t^2}\right|+h^2\left|D_x^2 v\right|\right)\,dxdt \qquad (6.15)\\
&+ C\int_0^T\int_\Omega \max_{S\subset\partial K} h_k^{-1}\cdot\left|\left[\partial_s\lambda_h\right]\right|\left(\tau^2\left|\frac{\partial^2 v}{\partial t^2}\right|+h^2\left|D_x^2 v\right|\right)\,dxdt\\
&+ C\int_0^T\int_\Omega \alpha_h\tau^{-1}\cdot\left|\left[\partial\lambda_{ht}\right]\right|\cdot\left(\tau^2\left|\frac{\partial^2 v}{\partial t^2}\right|+h^2\left|D_x^2 v\right|\right)\,dxdt\\
&\le C\int_0^T\int_\Omega\left|(v_h-\tilde v)\right|\cdot\left(\tau^2\left|\frac{\left[\frac{\partial v_h}{\partial t}\right]}{\tau}\right|+h^2\left|\frac{\left[\frac{\partial v_h}{\partial n}\right]}{h}\right|\right)\,dxdt\\
&+ C\int_0^T\int_\Omega \max_{S\subset\partial K} h_k^{-1}\left|\left[\partial_s\lambda_h\right]\right|\cdot\left(\tau^2\left|\frac{\left[\frac{\partial v_h}{\partial t}\right]}{\tau}\right|+h^2\left|\frac{\left[\frac{\partial v_h}{\partial n}\right]}{h}\right|\right)\,dxdt\\
&+ C\int_0^T\int_\Omega \alpha_h\tau^{-1}\cdot\left|\left[\partial\lambda_{ht}\right]\right|\cdot\left(\tau^2\left|\frac{\left[\frac{\partial v_h}{\partial t}\right]}{\tau}\right|+h^2\left|\frac{\left[\frac{\partial v_h}{\partial n}\right]}{h}\right|\right)\,dxdt.
\end{aligned}
$$

To estimate I_3 we use a standard approximation estimate of the form $\alpha - \alpha_h^I \approx hD_x\alpha$ to get

$$
\begin{aligned}
\big|I_3\big| &\le \int_0^T \int_\Omega \left|\frac{\partial \lambda_h(x,t)}{\partial t} \cdot \frac{\partial v_h(x,t)}{\partial t}\right| \cdot h \cdot \big|D_x\alpha\big| \, dxdt \\
&\quad + \gamma \int_\Omega (\alpha_h - \alpha_0) h \cdot \big|D_x\alpha\big| \, dx \\
&\le C \int_0^T \int_\Omega \left|\frac{\partial \lambda_h(x,t)}{\partial t} \cdot \frac{\partial v_h(x,t)}{\partial t}\right| \cdot h \cdot \left|\frac{[\alpha_h]}{h}\right| \, dxdt \\
&\quad + C\gamma \int_\Omega |\alpha_h - \alpha_0| \cdot h \cdot \left|\frac{[\alpha_h]}{h}\right| \, dx \\
&\le C \int_0^T \int_\Omega \left|\frac{\partial \lambda_h(x,t)}{\partial t} \cdot \frac{\partial v_h(x,t)}{\partial t}\right| \cdot \big|[\alpha_h]\big| \, dxdt \\
&\quad + C\gamma \int_\Omega |\alpha_h - \alpha_0| \cdot \big|[\alpha_h]\big| \, dx.
\end{aligned}
\tag{6.16}
$$

We therefore obtain the following result.

THEOREM 6.1. [illegible] $L(u) = L(v, \lambda, \alpha)$ [illegible] (2.3) [illegible] $L(u_h) = L(v_h, \lambda_h, \alpha_h)$ [illegible] $L(u)$ [illegible] e [illegible]

$$

$$
\sigma_\alpha = C\big|[\alpha_h]\big|. \tag{6.23}
$$

Note that R_{α_2} corresponds to the penalty term added in the Tikhonov regularization of (2.2). Indeed, as γ tends to zero, the error term R_{α_1} will dominate, and in the limit we arrive at the error estimator for the Lagrangian without regularization.

6.2. Adaptive algorithm. The main goal in adaptive error control for the Lagrangian is to find a mesh K_h with as few nodes as possible, such that $\|L(u) - L(u_h)\| < tol$. Instead of finding $L(u)$ analytically, we will use the a posteriori error estimate: We shall find a partition K_h such that the corresponding finite element approximation $L(u_h)$ satisfies

$$\begin{aligned}\Bigg(&\int_0^{t_1}\int_{\Gamma_1} R_{v_1}\sigma_\lambda \, d\Gamma dt + \int_0^T\int_\Omega R_{v_2}\sigma_\lambda \, dxdt + \int_0^T\int_\Omega R_{v_3}\sigma_\lambda \, dxdt \\ &+ \int_0^T\int_\Omega R_{\lambda_1}\sigma_v \, dxdt + \int_0^T\int_\Omega R_{\lambda_2}\sigma_v \, dxdt + \int_0^T\int_\Omega R_{\lambda_3}\sigma_v \, dxdt \\ &+ \int_0^T\int_\Omega R_{\alpha_1}\sigma_\alpha \, dxdt + \int_\Omega R_{\alpha_2}\sigma_\alpha \, dx\Bigg) < tol.\end{aligned} \tag{6.24}$$

The solution is found by an iterative process, where we start with a coarse mesh and successively refine the mesh by using the stopping criterion (6.24) with a view of using the minimal possible number of elements. More precisely, in the computations below we shall use the following adaptive algorithm:

1. Choose an initial mesh K_h and an initial time partition J_k of the time interval $(0, T)$.
2. Compute the solution v of the forward problem (2.1) on K_h and J_k with $\alpha = \alpha^{(n)}$.
3. Compute the solution λ of the adjoint problem (2.8) on K_h and J_k.
4. Update the velocity on K_h and J_k according to

$$\alpha^{(n+1)}(x) = \alpha^{(n)}(x) + \rho^{(n)}\left(\int_0^T \frac{\partial\lambda^n(x,t)}{\partial t}\frac{\partial v^n(x,t)}{\partial t}dt + \gamma(\alpha^{(n)}(x) - \alpha_0)\right).$$

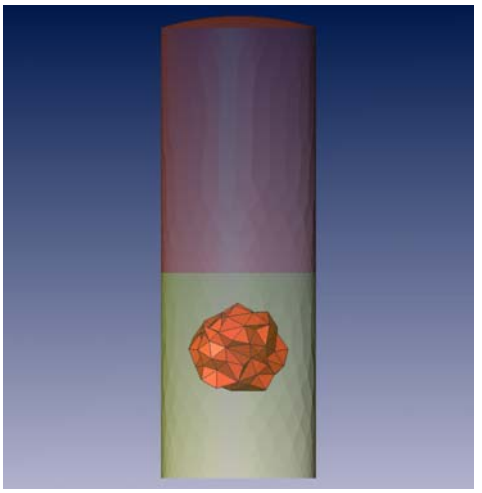
   Repeat steps 1–4 as long as the gradient quickly decreases.
5. Refine all elements where $(R_{\alpha_1} + R_{\alpha_2})\sigma_\alpha > tol$, and construct a new mesh K_h and a new time partition J_k. Here *tol* is a tolerance chosen by the user. Return to 1.

7. Numerical examples. We illustrate the efficiency and the performance of the hybrid FEM/FDM method on an inverse scattering problem for scanning acoustic microscopy in three dimensions. The geometry of the problem (see Figure 1.1) is taken from a specific microscope (WinSAM 2000, KSI Germany). The computational domain is set as $\Omega = [-10.0, 10.0] \times [-14.0, 16.0] \times [-10.0, 10.0]$, which is split into a finite element domain $\Omega_{FEM} = [-9.0, 9.0] \times [-10.0, -12.0] \times [-9.0, 9.0]$, with an unstructured mesh, and a surrounding domain Ω_{FDM}, with a structured mesh. The space mesh in Ω_{FEM} consists of tetrahedra and in Ω_{FDM} of hexahedra with mesh size $h = 1.0$. We apply the hybrid finite element/difference method presented in [10] with finite elements in Ω_{FEM} and finite differences in Ω_{FDM}. At all boundaries of Ω we use first-order absorbing boundary conditions [19].

The forced acoustic field consists of a wave $v = (v_1, v_2, v_3)$ given as

$$v_i(x, y, z, t)|_{y=0} = -\left(\frac{\sin(100t - \pi/2) + 1}{10}\right) \cdot n_i, \qquad 0 \le t \le \frac{2\pi}{100}, \tag{7.1}$$

which initiates at the spherical boundary Γ_1 of the lens in Ω_{FEM} and propagates in normal direction $n = (n_1, n_2, n_3)$ into Ω. This acoustic field is a simple model of the



(A) *Geometry of the microscope with inclusion to be reconstructed.*

FIG. 7.1. *Original mesh for computational domain* Ω_{FEM}.

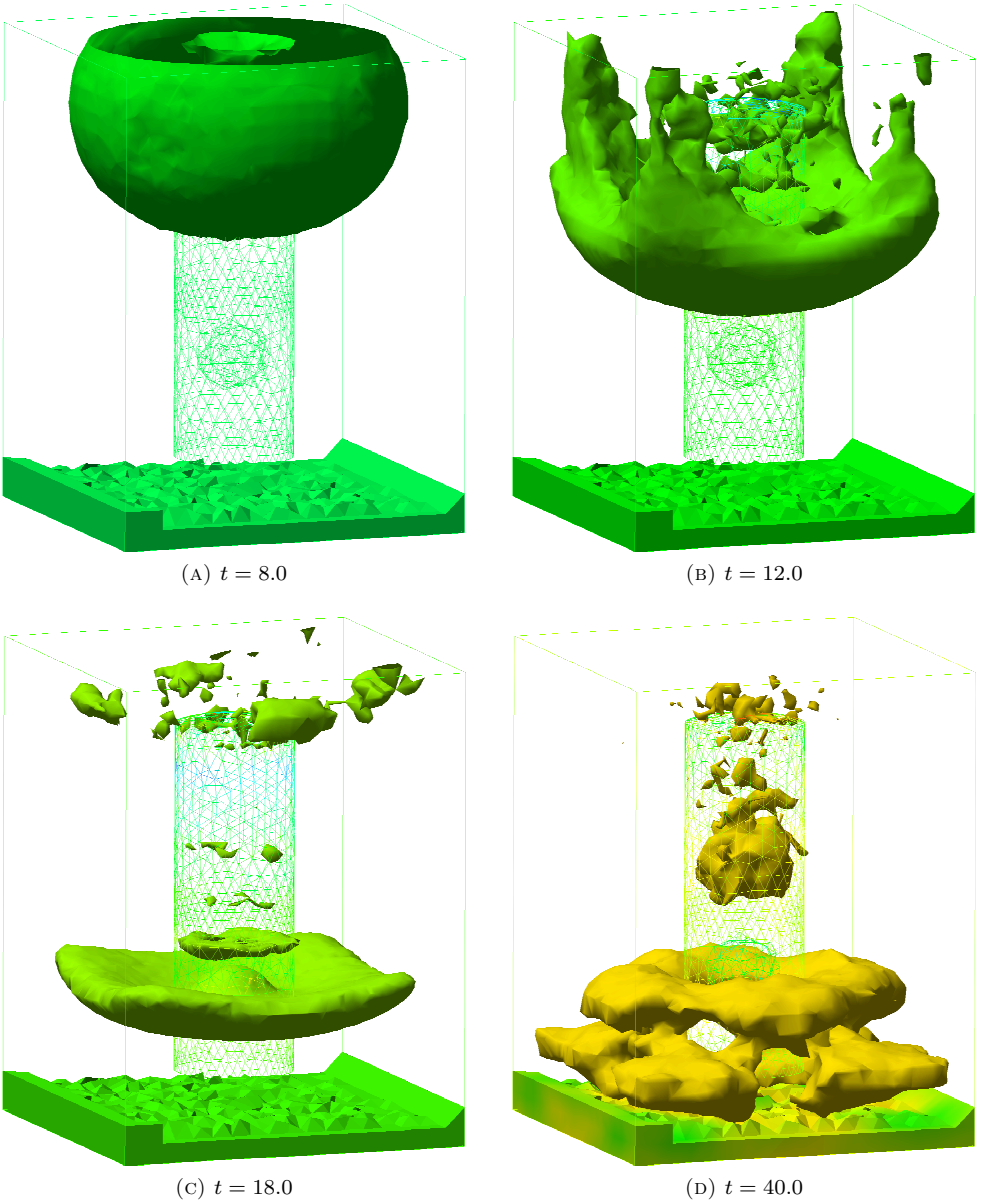
high-frequency excitation pulse generated by the transducer of the microscope. For real data, of course, it is advisable to take the source wavelet used in the specific microscope (which is known). As mentioned in the introduction, due to the multilevel strategy of our adaptive algorithm, we expect convergence for such multimodal sources as well. The observation points are also placed on Γ_1, corresponding to our application, where the same transducer records the reflected waves.

In all the computational tests we chose a time step τ according to the Courant–Friedrichs–Levy (CFL) stability condition

$$\tau \leq \frac{h}{ac_{\max}}, \tag{7.2}$$

where h is the minimal local mesh size, $c_{\max}$ is an a priori upper bound for the coefficient c, and a is a constant.

To improve the reconstruction and achieve better convergence we use the adaptive algorithm described in section 6.2. As we see from Theorem 6.1, the error in the Lagrangian consists of space-time integrals of different residuals multiplied by the interpolation errors. Thus, to estimate the error in the Lagrangian, we need to compute approximated values of $(v_h, \lambda_h, \alpha_h)$ together with residuals and interpolation errors. Since the residuals $R_{\alpha_1}, R_{\alpha_2}$ dominate, we neglect the terms $R_{v_2}, R_{v_3}, R_{\lambda_2}, R_{\lambda_3}$ in computation of the a posteriori error estimator. Further, we also neglect computation of the residuals R_{v_1}, R_{λ_1} since they indicate the error in the upper cylinder of the acoustic microscope, where we already know the value of $c(x) = c_0$. In the current work, the local refinement is based on the residuals since they already give good indications of where to adapt the mesh. The interpolation errors can be obtained following [9] by computing the Hessian of the Lagrangian, and will be included as part of a future work. Thus, the solution of the optimization problem is found in an iterative process, where we start with a coarse mesh shown in Figure 7.1 and evaluate the residuals by computing the Jacobian of the Lagrangian when the L^2 norm of $v - v_{obs}$ stops decreasing in the quasi-Newton iteration. Then we refine this mesh locally where the residuals are largest and construct a new time partition using



(A) $t = 8.0$ (B) $t = 12.0$

(C) $t = 18.0$ (D) $t = 40.0$

FIG. 7.2. *Solution of the forward problem* (4.9) *with exact value of the parameter* $c = 0.5$ *inside a spherical inclusion and* $c = 1.0$ *everywhere else in* Ω. *We show isosurfaces of the computed solution at different times inside* Ω_{FEM}.

(7.2). In all optimization steps, the number of stored corrections in the quasi-Newton method is $m = 5.0$.

To generate the data at the observation points, we solve the forward problem in the time interval $t = [0, 40.0]$ with the exact value of the parameter $c = 0.5$ inside a spherical inclusion and $c = 1.0$ everywhere else in Ω. In Figure 7.2 we present isosurfaces of the acoustic wavefield (i.e., the solution of the forward problem (4.9) with exact parameters) at different times inside Ω_{FEM}. The deformation of the wave

packet due to the presence of the inclusion leads to reflections traveling back to the observation points, carrying information about the obstacle.

We start the optimization algorithm with guess values of the parameter $c = 1.0$ at all points in the computational domain and a regularization parameter $\gamma = 0.1$. The computations were performed on the four adaptively refined meshes shown in Figure 7.3. Here, we solved the adjoint problem backward in time from $t = 40.0$ down to $t = 0.0$. In Figure 7.4 we display isosurfaces of the computed solution of the adjoint problem on different adaptively refined meshes at the time $t = 0.0$. We observe that the isosurfaces of the adjoint solution are concentrated around the interface between the two cylinders and in the inclusion. There we will also perform local refinement of the mesh, since the residual R_{α_1} in the a posteriori error estimator includes the term $\left|\frac{\partial \lambda_h}{\partial t}\right|$ involving solution of the adjoint problem. In Figure 7.5 we show a comparison

adaptively refined meshes. The norm of the adjoint solution decreases faster on finer meshes. Figure 7.6(F) shows a comparison of the L^2 norms in space of the adjoint solution λ_h on different meshes. Here, we present the smallest L^2 norm of λ_h on the corresponding meshes.

In Table 7.1 we give computed L^2 norms of $v - v_{obs}$ on different adaptively refined meshes at each optimization iteration while the norms decrease. The computational tests show that the best results are obtained on a four times adaptively refined mesh, where $||v - v_{obs}||$ is reduced approximately by a factor four between two optimization iterations. We note that the L^2 norms in space and time of $v - v_{obs}$ differ from coarser to finer meshes because of the increase in the number of observation points at the lens boundary during the refinement procedure. This also means that we capture higher and higher frequency content of the data with each refinement step.

The reconstructed parameter c on different adaptively refined meshes in the final optimization iteration is presented in Figure 7.7. We show isosurfaces of the parameter field $c(x)$, indicating domains with a given parameter value. We see that although the qualitative reconstruction on the coarse grid is already good enough to recover the shape of the inclusion even from limited boundary data, the quantitative reconstruction becomes acceptable only on the refined grids. Additionally, with successive refinement, the boundary of the reconstructed inclusion becomes sharper (compare the isosurface in Figure 7.7(A), (B) with those in Figure 7.7(D), (E)). On the grid with 33138 nodes (Figure 7.7(F)), the parameter in the inclusion is calculated as $c \approx 0.51$, compared to the exact value of $c = 0.5$.

However, since the quasi-Newton method is only locally convergent, the values of the identified parameters are very sensitive to the starting values of the parameters in the optimization algorithm and also to the values of the regularization parameter γ and step length ρ in the velocity upgrade. Therefore, to achieve more stable reconstruction, we enforce that the parameter c belongs to C_M by putting box constraints on the computed parameters and using a smoothness indicator to update values of c at the new optimization iteration by local averaging over the neighboring elements.

8. Conclusion. We present an explicit, adaptive, hybrid FEM/FDM method for an inverse scattering problem in scanning acoustic microscopy. The method is hybrid in the sense that different numerical methods, finite elements and finite differences, are used in different parts of the computational domain. The adaptivity is based on a posteriori error estimates for the associated Lagrangian in the form of space-time integrals of residuals multiplied by dual weights, which allows stable reconstruction of a parameter from data given on only a small part of the boundary. Their usefulness for adaptive error control is illustrated on an inverse scattering problem for scanning acoustic microscopy in three dimensions. Future work is concerned with choosing optimal regularization parameters for the functional to be minimized, and extending the adaptive algorithm to use an a posteriori error estimator for the parameter by solving an associated problem for the Hessian of the Lagrangian.

WEIGHTED MATCHINGS FOR PRECONDITIONING SYMMETRIC INDEFINITE LINEAR SYSTEMS*

MICHAEL HAGEMANN† AND OLAF SCHENK†

Abstract. Maximum weight matchings have become an important tool for solving highly indefinite unsymmetric linear systems, especially in direct solvers. In this study we investigate the benefit of reorderings and scalings based on symmetrized maximum weight matchings as a preprocessing step for incomplete $\mathrm{LDL}^{\mathrm{T}}$ factorizations. The reorderings are constructed such that the matched entries form 1×1 or 2×2 diagonal blocks in order to increase the diagonal dominance of the system. During the incomplete factorization only tridiagonal pivoting is used. We report results for this approach and comparisons with other solution methods for a diverse set of symmetric indefinite matrices, ranging from nonlinear elasticity to interior point optimization.

Key words. symmetric indefinite matrix, preconditioning, maximum weight matching, incomplete factorization, tridiagonal pivoting

1. Introduction.

We consider the iterative solution of symmetric and indefinite linear systems $A\boldsymbol{x} = \boldsymbol{b}$, where A is preconditioned by an incomplete $\mathrm{LDL}^{\mathrm{T}}$ factorization, which is also indefinite. We propose a preconditioning method based on a combination of symmetric weighted matchings and tridiagonal pivoting techniques, which significantly improves the robustness of the preconditioning for important classes of symmetric indefinite linear systems. The objective of this approach is to restrict the amount of pivoting during the incomplete factorization phase by obtaining a good initial pivoting order through a weighted matching in a preprocessing step. The tridiagonal pivoting strategy chooses either the 1×1 pivot on the diagonal or the 2×2 pivot from the current column and the immediately succeeding one, based on a simple factor growth criterion. The use of weighted matchings as an approximation of the pivoting order in the context of sparse direct solution methods for symmetric indefinite linear systems was introduced by Duff and Gilbert in [10]. This work was recently elaborated by Duff and Pralet [13] and Schenk and Gärtner [33]. While those previous works concentrated on sparse direct solution methods, we present approaches for the use of these techniques in preconditioning.

The matching is effective only if the diagonal entries of A are not consistently larger than the off-diagonal entries. Therefore it has no effect on many shifted systems like Helmholtz problems or matrices arising in shift-invert eigensolvers. This is reflected in the results, where especially saddle-point problems benefit from the preprocessing.

After preprocessing, the incomplete factorization preconditioner is applied to the reordered and scaled original system. A reordering Q, based on a symmetrized maximum weight matching of the matrix A, moves large off-diagonal entries into 2×2 diagonal blocks. An additional fill-reducing reordering P_Q, which maintains the

diagonal block structure, is applied to minimize the fill-in during the factorization phase. In the following, we call the combination of these two reorderings sym2x2block. Furthermore, the matrix is scaled by a symmetric scaling D_Q, which is also acquired through the weighted matching algorithm. Thus, the iterative method solves a linear system of the form

$$M^{-1}\hat{A}\hat{\boldsymbol{x}} = M^{-1}\hat{\boldsymbol{b}}, \tag{1.1}$$

where $\hat{A}$ is the scaled and reordered original linear system

$$\hat{A} = P_Q Q D_Q \; A \; D_Q Q^T P_Q^T. \tag{1.2}$$

The incomplete factorization preconditioner M consists of a lower triangular factor L and a block diagonal matrix D with 1×1 and 2×2 blocks.

Sparse symmetric indefinite linear systems arise in numerous areas ranging from incompressible flow computations to linear and nonlinear optimization, electromagnetic scattering, and finite element analysis, among others. Particularly for very large systems, efficient and scalable preconditioners are sought because the memory requirements and factorization costs of direct methods become increasingly prohibitive in this case.

1.1. Related work. The iterative solution of indefinite linear systems is an active research area, and a variety of approaches have been proposed. Many preconditioning approaches exploit the inherent block structure of the given problem type. Specifically for the preconditioning of saddle-point systems, a number of block preconditioning methods have been proposed, some of which are optimal in some sense. For a comprehensive survey of solution and preconditioning approaches, the reader is referred to [5]. Recent overviews of block preconditioning techniques include [2] and [38]. In the following we briefly review some of the algebraic approaches to solving symmetric indefinite linear systems.

Direct solvers are a common option for solving general indefinite problems. Since LU and LDL^T factorizations of indefinite matrices may break down or yield bad results due to small or zero diagonal entries, a number of techniques exist that try to avoid or alleviate these problems, some of which were specifically designed for symmetric matrices. There are basically three approaches, namely [illegible] techniques, [illegible] of the diagonal, and [illegible]. The classical pivoting approach for symmetric matrices is Bunch–Kaufman pivoting [8], which searches for 2×2 diagonal blocks during the factorization. An adaption to sparse matrices was introduced by Duff and Reid in [14] (see also [1]). In [20], Gould, Hu, and Scott performed a comprehensive study of current direct solvers for indefinite linear systems.

Fewer methods exist for symmetric incomplete factorizations. Gill et al. [19] propose using factors of MA27 with all negative diagonal entries in 2×2 blocks turned into positive ones, thus clustering the eigenvalues of the indefinite system around -1 and 1. Li and Saad [29] consider sparse incomplete LDL^T factorizations with Bunch–Kaufman pivoting. A number of unsymmetric methods have been proposed that are also applicable to symmetric systems. Chow and Saad in [9] conducted a comprehensive study of unsymmetric incomplete factorization techniques to solve indefinite systems. In [6], Benzi, Haws, and Tůma study unsymmetric permutations based on weighted matchings as a preprocessing step for various incomplete or approximate factorizations.

In [18] Freund and Jarre devise an indefinite block SSOR method that uses a greedy approximation of a maximum weight matching to find nonsingular 2×2

diagonal blocks in interior point optimization problems. Freund mentions a similar technique based on LDL^T factorizations in [17], but without giving further details.

1.2. Contributions. We conduct an experimental study on the use of weighted matchings in the preconditioning of symmetric indefinite linear systems with incomplete factorization techniques. We concentrate on simple approaches to leverage the information provided by the matchings. To the best of our knowledge, there are as yet no other studies that investigate the potential of these techniques in the context of preconditioning. Similar techniques have recently been explored for direct solvers [13, 33]. In order to assess the competitiveness of the approach, we conduct comparisons with several other relevant and comparable preconditioning methods and with a direct solver.

Section 2 introduces the matching algorithms used in this study. In section 3 we describe our approach to the problem of adapting the matchings to the preconditioning of symmetric matrices. The incomplete factorization is described in section 4. Numerical results and comparisons with other solution techniques are presented in section 5. In closing, we sketch some of the possible research directions we are currently considering.

2. Weighted matchings.

2.1. Introduction. The use of weighted matchings as a static approximation of the pivoting order in direct solvers was first proposed by Olschowka and Neumaier in 1996 [31]. The first implementations for sparse matrix problems were introduced by Duff and Koster [11] and Gupta and Ying [21]. The objective of this approach is to restrict the pivoting during the factorization phase, by obtaining a good pivoting order through a matching in a preprocessing step. Duff and Koster provide results of the effectiveness of this preprocessing step for both direct and iterative unsymmetric solvers [12]. Benzi, Haws, and Tůma [6] and Schenk, Röllin, and Gupta [35] conducted a more extensive analysis of these reorderings in the context of preconditioning. Up until recently, only unsymmetric permutations based directly on the matchings were considered. In 2002, Gilbert and Duff presented ideas on how to use matchings for the direct solution of symmetric systems while maintaining the symmetry [10]. Here, we build on some of their ideas and apply them in the context of preconditioning for symmetric indefinite systems.

2.2. Matching algorithms. The success of matchings as preprocessings in linear solvers is due in large part to the practical efficiency of the deployed matching algorithms. These algorithms work on associate graph representations of the matrices. In our case, the algorithms work on the [illegible] $G_A = (V_r, V_c, E)$, where V_r and V_c are vertex sets of cardinality n, representing the rows and columns, respectively, of the matrix and $E = \{(i,j) \mid a_{ij} \neq 0\}$ is the set of edges connecting the vertices in V_r and V_c.

Now we are looking for a subset $\mathcal{M} \subseteq E$ with the following properties: (a) for all vertices $v \in \{V_r, V_c\}$, exactly one edge $e \in \mathcal{M}$ is incident to v, and (b) the matched edges $e \in \mathcal{M}$ maximize a weight function $w(\cdot)$, with

$$w(\mathcal{M}) = \sum_{(i,j)\in\mathcal{M}} (C)_{ij}, \tag{2.1}$$

where C is a weight coefficient matrix for the edges of A, with $C = A$ as the simplest case. Such a subset $\mathcal{M}$ is called a [illegible] of G_A, and

the problem of finding it is known as the [illegible] or [illegible]. The first condition can always be satisfied if A is a structurally nonsingular matrix. The weight function (2.1) does not necessarily define a unique matching, however.

As of today, the most efficient algorithms for finding weighted matchings are based on [illegible]. Gupta and Ying state $\mathcal{O}(n(\tau + n \log n))$ as the upper bound for the time complexity of their implementation, where τ represents the number of nonzeros in A. Duff and Koster give an upper bound of $\mathcal{O}(n(\tau + n) \log n)$. For details of the implementations, see [12, 21]. An important feature of these algorithms in practice is that they typically behave much better than may be expected from the complexity analysis, which is also what we observed in our tests. Our implementation is based on [21].

2.3. Weight criteria. An important consideration for the matching is the choice of weighting. As the matching algorithms generally maximize (2.1), the criterion has to be formulated in terms of the weight coefficients c_{ij}. Typically, the coefficients c_{ij} are modified subsequently, either for better performance of the matching or to enforce the above conditions. See [21] for a survey of such techniques.

If we want to maximize the [illegible] A, the coefficient matrix C can simply be defined by $c_{ij} = |a_{ij}|$. The maximization of the [illegible] A can be acquired by using a simple logarithmic transformation:

$$c_{ij} = \begin{cases} \log |a_{ij}| & \text{if } a_{ij} \neq 0, \\ -\infty & \text{otherwise.} \end{cases} \tag{2.2}$$

Another criterion that is suggested in [12] is the maximization of the [illegible]. This requires a modified matching algorithm, called a "bottleneck matching." Since experimental results [6, 12, 35] suggest that the maximum product approach is generally the most beneficial, we use it exclusively.

2.4. Scalings. Perfect matchings of maximum weight have the property that dual variables u_i and v_i exist such that

$$\begin{cases} u_i + v_j = c_{ij} & \text{if } (i,j) \in \mathcal{M}, \\ u_i + v_j \leq c_{ij} & \text{otherwise.} \end{cases} \tag{2.3}$$

The augmenting path algorithms build these variables during the matching phase.

If the logarithmic transformation (i.e., (2.2)) was used as the weight matrix, the dual variables can be used to define row and column scalings D_r and D_c by setting $(D_r)_i = \exp(u_i)$ and $(D_c)_i = \exp(v_i)$, such that the following property holds:

$$|(A)_{ij}| = |(D_r A D_c)_{ij}| \quad \begin{cases} = 1 & \text{if } (i,j) \in \mathcal{M}, \\ \leq 1 & \text{otherwise.} \end{cases} \tag{2.4}$$

In theory, this scaling has two advantages. First, it provides a good [illegible] that is beneficial during the elimination process, especially for badly conditioned matrices. Second, the diagonal dominance of the permuted linear system may be increased. This is not always the case, however. Benzi, Haws, and Tůma [6] observed that the scaling can have a bad effect, probably because in some cases it weakens the diagonal dominance. We saw a similar behavior for some matrices, but the overall performance was better for the scaled systems.

Duff and Pralet show in [13] that for symmetric matrices the two scalings can be symmetrized by taking the componentwise square root of their product,

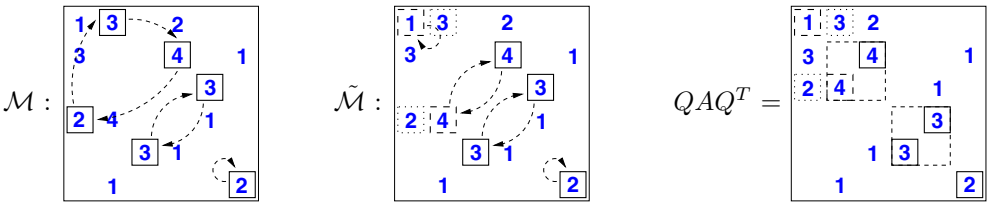

FIG. 3.1. *Illustration of the symmetric permutation Q, with $\mathcal{M} = (124)(35)(6)$ and $\tilde{\mathcal{M}} = (1)(24)(35)(6)$. The split matching $\tilde{\mathcal{M}}$ has two additional entries (indicated by dashed boxes), while two entries of the original matching were discarded (dotted boxes). The two 2-cycles are then permuted into 2×2 diagonal blocks.*

$D_Q = \sqrt{D_r \cdot D_c}$. Our tests show that the scaling is generally beneficial, although not for all matrices. This is in line with the observations in [6].

3. Construction of the sym2x2block reordering.

3.1. Symmetric matchings. In order to form diagonal 2×2 blocks out of the matched entries, we ideally want a [illegible] matching of maximum weight, i.e., a matching where $(i, j) \in \mathcal{M} \Rightarrow (j, i) \in \mathcal{M}$. Given such a matching, the entries (i, j) and (j, i) are readily reordered into 2×2 diagonal blocks. Duff and Pralet showed that the problem of finding symmetric maximum weight matchings in a symmetric matrix is equivalent to finding a matching in an undirected graph [13].

While these findings may be helpful in devising a special matching algorithm for this problem, to the best of our knowledge no method currently exists that is competitive with bipartite maximum weight matching algorithms. Therefore, we deploy the well-established matching algorithms and construct the desired reorderings in an additional postprocessing step. This additional step is of linear complexity and follows the approach presented by Duff and Gilbert [10], who note that in order to symmetrize a bipartite matching, one can [illegible] in the matchings such that only cycles of length one and two remain. The matching $\mathcal{M}$ in Figure 3.1, for example, contains three cycles, with the first cycle (124) being the only one longer than two. Interpreted as the associated row permutation, this cycle would permute row 1 into row 2, row 2 into row 4, and row 4 into row 1. To split this cycle, one can pick one of the corresponding diagonal entries (a_{11}, a_{22}, or a_{44}) as a singleton and pair the remaining entry with its symmetric counterpart. This procedure can be applied to larger cycles as well. Details of our implementation are given in section 3.3.

This approach, however, does not guarantee that we will find an optimal symmetric matching of maximum weight for the matrix. One can construct matrices whose maximum weight matching does not contain edges that appear in the symmetric maximum weight matching of the same matrix. Thus, a simple postprocessing step is in general not able to find the optimal symmetric matching. The implications and possible remedies of this problem are still an open research topic.

3.2. Overview. The construction of the preordering involves several steps. The splitting of cycles of length larger than two yields a set of 1- and 2-cycles, which can be used to build a reordering Q that moves the matched entries from the 2-cycles into 2×2 diagonal blocks. This part of the preprocessing is illustrated in Figure 3.1, and, as pseudocode, in lines 1–4 of Algorithm 3.1. Details are given in section 3.3.

After the block diagonal structure is established, an additional fill-reducing reordering is computed, which maintains the block diagonal structure. This is achieved through compression of the graph of QAQ^T by merging the 2×2 diagonal blocks

into simple vertices. The fill-reducing reordering P_Q can then be constructed from the reordering of the compressed graph and two helper arrays. This step is detailed in section 3.4 and reflected in lines 5–7 of the pseudocode.

ALGORITHM 3.1.

1. $\mathcal{M}$ D_r D_c =
2. =
3. $\tilde{\mathcal{M}}$ =
4. 1x1 = 22 $\tilde{\mathcal{M}}$
5. A_{comp} = 2x2 A Q 1, 1
6. P_{comp} = A_{comp}
7. P_Q = 2x2 P_{comp} 1, 1
8. D_Q = $\sqrt{D_r \cdot D_c}$
9. $\hat{A}$ = $P_Q Q$ $D_Q A D_Q$ $Q^T P_Q^T$

3.3. Splitting strategy. Starting from the cycle representation of the matching $\mathcal{M}$, a split version $\tilde{\mathcal{M}}$ is constructed. The splitting involves a number of considerations, as there are two possibilities for splitting an even cycle and m possibilities for splitting an m-cycle of odd length. An even cycle can be split starting from the first or the second entry, pairing the last and the first entry of the cycle. In an odd cycle, the choice of the first entry that will form the single 1-cycle determines the structure of the whole splitting.

Two criteria for the choice of the splitting have been proposed [10, 13]. One criterion focuses on the weight of the resulting transversal. In principle, this criterion can be applied to the scaled as well as to the original matrix. In [10], Duff and Gilbert consider only the scaled matrix, and show that the splitting of even cycles in that context always preserves the weight of the scaled original matching.

In [13], Duff and Pralet propose an alternative approach, referred to as "(relaxed) constrained orderings," which combines structural aspects of the splitting with criteria on the numerical values. The structural criterion focuses on the nonzero structure of the 2×2 block columns in the reordered matrix. Ideally, the two columns have the same nonzero structure, such that the combined block column does not introduce additional nonzero entries. Under certain conditions, some of the 2×2 blocks that have been determined based on the structural criterion are "relaxed," i.e., split into scalar pivots. The relaxation criteria depend on the numerical values in the 2×2 block. The objective of this approach is to acquire better reorderings from the subsequent fill-reducing method (see also section 3.4).

In our implementation, we just use the simple static splitting described below and do not split any of the 2×2 blocks found. The main reason for that approach is that we apply a numerical criterion for the choice of the pivot later during the factorization, when all relevant numerical information for the pivoting is available. Furthermore, our tests with relaxed approaches indicate that the split pivots can be a source of instability, while the benefit in terms of fill-in is marginal.

In splitting even cycles, we always begin with the first entry, whereas with odd cycles, we begin by choosing the largest diagonal entry in the cycle as the solitary entry. As most of the matchings consist mainly of 1- and 2-cycles, we did not investigate effects of other splitting strategies on the resulting fill-in.

After a set of 1- and 2-cycles has been acquired from the original matching, the function `build_diag22_reordering` constructs a reordering which yields the 2×2 diagonal block structure by moving both entries of each 2-cycle into adjacent rows and columns in the reordered matrix.

3.4. Combination with fill-reducing reorderings. In order to construct the factorization efficiently, care has to be taken that not too much fill-in is introduced during the elimination process. In order to combine the sym2x2block reordering with a fill-reducing reordering, we [illegible] the graph of the reordered system and apply a fill-reducing reordering to the compressed graph. In the compression step, the union of the structure of the two rows and columns corresponding to a 2×2 diagonal block are built and used as the structure of a single compressed row and column representing the union of the original ones. A fill-reducing reordering P_{comp} is then computed for the compressed graph. This reordering can then be expanded, so that it provides the reordering P_Q, which reduces the fill-in during the factorization, while maintaining the 2×2 block structure of the diagonal.

In Algorithm 3.1 this step is represented in lines 5–7. The graph of the reordered matrix is compressed, and the nodes that correspond to scalar pivots are marked in the [illegible]1x1 array. Furthermore, a reverse mapping [illegible] is constructed, which maps the nodes of the compressed graph back to their original index. Together with the permutation of the condensed system P_{comp}, these two arrays allow the construction of P_Q.

4. Incomplete LDL^T factorization with tridiagonal pivoting.

4.1. Algorithm. We use a symmetric variant of the Crout approach, which is also called a "left-looking" approach [15]. The implementation does not rely on BLAS routines, since the largest blocks we consider are the 2×2 block pivots. The L factor is constructed columnwise. To build the kth column of the factor, the nonzero entries[1] $A_{k:n,\,k}$ of the original matrix are copied, and updates from all factored columns from the left with couplings to k are added. Then a dropping strategy is applied in order to limit the amount of fill-in introduced by the updates. Finally, the remaining entries of the column are divided by the diagonal pivot entry. According to common practice, we refer to the updated, but not yet factored, part of the matrix as $A^{(k)}$, which is also called the "reduced matrix." As we are just updating one column at a time, we have access only to the part $A^{(k)}_{k:n,\,k}$ of the reduced matrix.

This approach has the nice property that in each step of the factorization we have all the values of a specific column of the factor at our disposal and can thus apply sophisticated dropping rules. After we have determined its favored entries, the column is used only for updates on later columns. Since we expect a preprocessed matrix with a "heavy" diagonal, we employ only a tridiagonal pivoting criterion due to Bunch [7], which chooses 1×1 or 2×2 pivots based solely on the diagonal and the subdiagonal entry in the column. If a 2×2 pivot is chosen, the two corresponding columns of the factor L are stored as a block column with identical sparsity pattern. The 2×2 pivots are explicitly inverted with a scaled inversion formula. Dropping in block columns is performed according to the ∞-norms of the 2×1 entries.

The following sections give a detailed description of the pivoting criterion and the dropping strategy.

4.2. Pivoting strategy. Symmetric pivoting strategies in general try to (a) find a suitable 1×1 or 2×2 diagonal pivot such that (b) the growth in the factors is bounded [1]. In the case of sparse matrices, an additional criterion to control the fill-in introduced by dynamic permutations is required [14]. Our experiments with the described preprocessing step indicated, however, that the preordering already

[1] We use MATLAB notation to indicate submatrices.

yields a good approximation to a feasible pivoting order. Only marginal benefits in terms of robustness could be achieved, almost regardless of the amount of work put into additional pivoting. While we could reproduce results similar to those found by Li and Saad [29], these Bunch–Kaufman-like techniques could not significantly improve the robustness and led to difficulties when the matrix contained dense rows or columns.

Thus we use a pivoting strategy that is as simple as possible. The choice of the pivot is based on a criterion introduced by Bunch [7]. Given a constant $\alpha := (\sqrt{5}-1)/2$, we choose a 2×2 pivot in step k if

$$|a_{kk}^{(k)}| \;\leq\; \alpha\, |a_{k+1,k}^{(k)}|^2, \tag{4.1}$$

where $a^{(k)}$ designates the entries in the reduced matrix after step k. The constant α is a weight that controls the choice of the pivot. It is obtained by equating the growth factor introduced by two consecutive 1×1 pivot factorization steps to the one introduced by a single factorization step with a 2×2 pivot. The original criterion includes a value σ, which reflects the largest entry in the reduced matrix. Since we calculate only one column of the reduced matrix and scale all the entries, we discarded this additional variable. See Higham [24] for a detailed derivation and for properties of this approach for the factorization of tridiagonal matrices.

The above pivoting rule does not cover the case of very small or zero pivots $a_{kk}^{(k)}$ with no suitable entry $a_{k+1,k}^{(k)}$. In order to avoid a breakdown of the algorithm, we use a simple [illegible] rule that prevents pivots from becoming smaller than ε_{piv} (see line 6 in Algorithm 4.1). We use a value of 10^{-8} for ε_{piv}, which is approximately the root of the machine precision and provided good overall results.

4.3. Dropping strategy. An important part of an incomplete factorization is the choice of an appropriate dropping strategy. This determines which entries will be kept in the factors, and should ideally strike a good balance between memory and computational savings and the quality of the preconditioning of the problem. Typical approaches include thresholds for minimal magnitudes in the factors, maximum fill-in of the factor [26, 32], and histogram-based approaches [3]. We base the dropping on the average number of entries per column of the matrix. Each column of the factor may contain at most γ_{col} entries, with $\gamma_{col} = \gamma \cdot \frac{nnz}{n}$, where nnz indicates the numbers of nonzeros in A. The entries in column k of $A^{(k)}$ are partially sorted, and the γ_{col} largest are inverted and taken across into the factor.

Another common criterion is to use a threshold criterion for the values in $A^{(k)}$. The choice of beneficial thresholds is, however, not well understood, and the benefits we saw in our experiments did not justify the added instabilities introduced by this approach. As suggested in earlier studies [26], we therefore chose the simpler strategy of using just γ as the only parameter controlling the amount of fill-in in the factors.

4.4. Summary of the incomplete factorization method. The following pseudocode provides a detailed overview of the incomplete factorization phase.

ALGORITHM 4.1. [illegible]

1. ***function:*** L D [illegible] ***ildlt-tp-factorization***
2. ***for*** [illegible] $1, \ldots, n$
3. [illegible] $a_{k:n,\,k}^{(k)}$ [illegible] $a_{k:n,\,1:k}^{(k)}$

5. Numerical experiments. We considered three sets of matrices that comprise a wide range of symmetric indefinite problems. The sets are described in sections 5.5 to 5.7. The tests were run on a double processor Pentium III 1.3 GHz system with 2 GB of memory under a Linux distribution based on the 2.6.9 kernel version. Only one processor was used for the testing. In order to provide realistic measurements, the timings were determined using the `gettimeofday` standard C library function, which provides a high accuracy wall clock time. To compensate for the variations, we list the best times out of three runs for each measurement.

In the comparison we concentrate on two properties of the methods, namely the amount of `fill`-in they introduce, and on the `total` time the solution takes to solve the system for one right-hand side. The fill-in is a major indicator for the method's memory usage and is a viable metric in this comparison, since all of the methods in some way rely on factorizations. The total solution time includes the computation of the matching, the fill-in reduction, the incomplete factorization, and the time for the iterative solution.

5.1. Iterative solution and termination criterion. We used the simplified symmetric QMR method (SQMR) as the standard Krylov-subspace solver (without look-ahead, as described in [17]). Since both the original system and the preconditioner are indefinite, we cannot use methods like SYMMLQ or MINRES, which require a positive definite preconditioner. We also considered GMRES(50) for the iterative solution. While GMRES provided slightly better convergence for some problems, it was generally slower and incurs a considerable memory overhead.

The iterative methods used the following . The current iterate $\hat{\boldsymbol{x}}_n$ was considered good enough if its residual referring to the preconditioned system $\hat{A}$ was less than 10^{-8}:

$$\|M^{-1}\boldsymbol{b} - M^{-1}\hat{A}\hat{\boldsymbol{x}}_n\| \leq 10^{-8}\|M^{-1}\boldsymbol{b}\|. \tag{5.1}$$

The maximum number of iterations was limited to 400. Failure of this limit is indicated by a dash ("–") in the tables that follow. Since we compare direct and iterative solvers in this paper, we also include another . The relative residuals of the results provided by the solvers were checked against the original system:

$$\|\boldsymbol{b} - A\boldsymbol{x_n}\| \leq 10^{-4}\|\boldsymbol{b}\|. \tag{5.2}$$

If they failed to be smaller than 10^{-4}, the systems were counted as incorrectly solved. In the tables, this is indicated by a dagger (†). If the residual turned out to be good enough although the iterative method did not stop before the maximum number of iterations, we counted the system as solved and indicate this by an asterisk (*).

All matrices were solved with an artificial right-hand side $\boldsymbol{b}$, with $\boldsymbol{b} = A \cdot \mathbf{1}$. The iterations were started with a zero initial guess.

5.2. Tested solution methods. In addition to results for the proposed approach, we provide comparisons with four other methods. To show the effects of the preprocessing and the pivoting, we compare the proposed method to a simple scalar incomplete $\mathrm{LDL}^{\mathrm{T}}$ factorization with a METIS reordering, and to the same factorization but with the sym2x2block reordering. Furthermore, for reference to other current methods, we provide comparisons with two additional preconditioned iterative methods and a direct solver.

We use the direct solver PARDISO [33, 34], which was shown to be competitive among current state-of-the-art direct solvers in a recent comparative study by Gould, Hu, and Scott [20]. Direct solvers are commonly used to solve general indefinite systems. In our tests we use the default setting of PARDISO, which uses supernodal Bunch–Kaufman pivoting and two steps of iterative refinement. This setting provides very fast results for symmetric indefinite systems [20]. However, some of the augmented sparse indefinite matrices used in this paper are very ill-conditioned and could not be solved using the default options.

A popular form of block preconditioners are the so-called [illegible] approaches, which are tailored for augmented systems of the form

$$\begin{pmatrix} H & B \\ B^T & 0 \end{pmatrix} \tag{5.3}$$

and need information about the dimension of the constraint block B in the system. The idea is to solve for the constraints B exactly and to use an approximation $\tilde{H}$ for block H. The simplest strategy to build M, which already has favorable properties, is to approximate H by its diagonal and to factorize M with a sparse direct solver (see, e.g., [16, 28, 30]), but various approaches are currently under active investigation (see [5, section 10.2] for a recent overview). We implemented the simple diagonal strategy and factorized M with PARDISO.

To provide comparisons with unsymmetric permutations, we include the ILUC-MPS method in our tests. See [6, 23] for earlier studies of this preconditioning method. The method is based on an incomplete LU factorization of the row-permuted and scaled matrix A,

$$M = LU = P_{\mathcal{M}} D_r A D_c - E. \tag{5.4}$$

For the tests, a Crout variant with no additional pivoting is used. The dropping criterion is the same as in the symmetric factorization. GMRES(50) is used in place of SQMR for the iterative solution, since the permuted systems are no longer symmetric.

Table 5.1 gives a short summary of the preconditioning methods and the abbreviations used. All factorization methods use the METIS nested dissection reordering by Karypis and Kumar [27].

5.3. Parameter selection. The only parameter for the incomplete factorizations is the fill-in bound γ. Unless otherwise noted, we used $\gamma = 6$, which provided good overall performance while keeping the fill-in moderate. Table 5.2 provides a comparison of the method for different values of γ for the first set of test problems.

5.4. Codes. All the preconditioned methods are implemented in the `sagg` solver library [22]. The incomplete factorizations are based on the same code base, in order to ensure meaningful comparisons. Specifically, the dropping criteria are implemented in exactly the same way in each implementation. The implementations of the iterative

solvers are either adapted from [4] or implemented from the original reference. The weighted matching code is based on [21] and performs comparably to the `mc64` code from the HSL library [25]. All codes were compiled using the GNU C compiler version 3.4.4, using `-O3` and processor specific optimizations.

5.5. Set 1: KKT systems. This set contains matrices that were used in recent papers by Keller, Gould, and Wathen [28] and Haws and Meyer [23]. It is comprised of a number of KKT systems from structural engineering and optimal control. As the names indicate, the `mass-` and `stiff-` matrices are mass and stiffness matrices of the form (5.3). The other matrices are from the Boeing sparse optimal control software SOCS [36]; see [23] for further details.

Looking at Table 5.3 it is of note that the proposed method is the only one which solved all of the problems. The `lnts` and `mass06` problems could not be solved with the default setting of PARDISO; hence the constraint preconditioner could not solve `lnts` either. It also only hardly solved the `stiff` problems, which have only a few constraint equations. With the same dropping threshold, the ILUC preconditioner used 50–90% of additional fill-in on average, but did not solve two systems.

Table 5.2 gives a comparison for smaller values of γ. With $\gamma = 6$, some of the incomplete factors contain more fill-in than the direct solver, because the fill-reducing reordering is not as good (see Figure 5.2 below). This is especially pronounced for the `traj*` and `lnts09` examples. These matrices contain very dense rows, but are otherwise very sparse. Thus the fill-in is increased, but few entries per column are dropped. It is remarkable, however, that the incomplete factorization is still faster than the direct solver in these cases.

TABLE 5.3
Comparison of various solvers for the KKT set. Smallest fill-in factors (within 5% of the smallest) are underlined; best times (within 5% of the fastest) are bolded; see the text for additional explanation.

5.6. Set 2: Matrices from interior point optimization. As a case study, we examine a series of interior point optimization matrices[2] from IPOPT [37]. The core step of the optimization algorithm is a damped Newton iteration, where in each step a modified symmetrized linear system of the form

$$\begin{pmatrix} W + \Sigma + \delta_w I & B \\ B^T & -\delta_c I \end{pmatrix} \tag{5.5}$$

is solved. In our examples, the upper left block of (5.5) is diagonal and $\delta_c = 10^{-8}$. The whole set consists of 57 matrices of increasing size. We show a subset of 12 matrices, which was selected to include the hard-to-solve examples (specifically `c-54`) as well as to give an impression of the scalability of the methods. Therefore matrices from the whole range were picked, with a bias toward the large ones. See Table 5.4 for a

[2]The matrices are available at http://www.computational.unibas.ch/cs/scicomp/matrices.

summary of the results, and Table 5.5 for more detailed timings and statistics of the individual solver components..

Surprisingly, the ILDL$^{\mathrm{T}}$-TP-S22B method scales almost perfectly with the dimension of the matrices. This is due to the fact that the fill-in is always bounded to a factor of at most five. The only significant outliers in terms of iterations are the matrices `c-41`, `c-54`, and `c-56`, whose B^T blocks do not have full rank. Because of these rank deficiencies, small diagonal entries from the (2,2) block are matched, which gives rise to small scalar pivots during the factorization. We are currently investigating ways to handle these rank deficiencies more effectively.

The ILUC-MPS method is obviously not well suited for these problems and solved less than half of the test problems when the fill-in was strictly bounded. In many cases the factorization failed because of floating-point exceptions caused by exceeding growth in the factors. Results for the CP-DIRECT method are not shown, because the upper left block of the matrix is already diagonal, and the results are thus similar to those for PARDISO.

5.7. Set 3: Selection of problems from HSL collection. The last set of test problems is taken from an extensive survey of direct solvers for indefinite problems[3] [20]. This set is rather challenging, and several of the matrices could not be solved by direct solvers under the constraints imposed in the report. The matrices come from a variety of application areas. From the 61 original matrices, we excluded 10 `c-*` matrices which are in the separate IPOPT set. Of the 51 remaining matrices, 34 are KKT matrices. We report the results separately for both parts. The tables are slightly abridged, but with examples of all failures included.

A selection of results for the KKT subset is given in Tables 5.6 and 5.7. The augmented systems `AUG*` and the nonconvex quadratic problems `NCVX*` are singular or nearly singular, so the significance of the residual norm is at least questionable. Most direct solvers tested in [20] were unable to solve these systems either. The other failure, `olesnik0`, is highly indefinite and also caused problems for the direct solvers. Between the two preconditioners there is no clear winner for this set. The incomplete

[3]The matrices can be found at ftp://ftp.numerical.rl.ac.uk/pub/matrices/symmetric/indef.

factorization preconditioner seems to have advantages for the linear complementarity and the quadratic programming problems, while the constraint preconditioner works well for most of the mine models and the `stokes*` problems.

From the general indefinite matrices, only few could be solved by the iterative method (see Table 5.8). Among these were a Dixon–Maany problem, a matrix inverse

approximation problem, a vibro-acoustic model, and the `bcsstk*` stiffness matrices. The last are diagonally dominant, so the matching had no influence on the solution. Many of these matrices were also challenging for the direct solvers [20].

5.8. Effects of preprocessing and pivoting. Table 5.9 illustrates the effects of the preprocessing step and the additional 2×2 pivoting in relation to a simple scalar incomplete LDL^T factorization. Both methods combined increase the number of solved problems by about 24%. The major part of this margin is due to the sym2x2block preprocessing. The 2×2 pivoting increases the stability by a small but critical margin. With the pivoting, all systems from the first two sets were reliably solved in less than 200 iterations. Without it, not all problems could be solved, and five problems took more than 300 iterations to converge.

5.9. Costs of preprocessing. There are two kind of costs involved in the preprocessing step. One is the time required to find a maximum weight matching for the matrix. This cost is, however, partly neutralized by the fact that the subsequent fill-reduction reordering is run on a compressed graph and is therefore of reduced complexity. Figure 5.1 relates the combined times of the matching and the fill-reducing reordering to a run of the fill-reducing reordering alone. Often the preprocessing step is even faster than METIS alone.

The other cost incurred by the preprocessing step is an increase of fill-in. This is due to the fact that the fill-reduction method works on a compressed matrix, and has

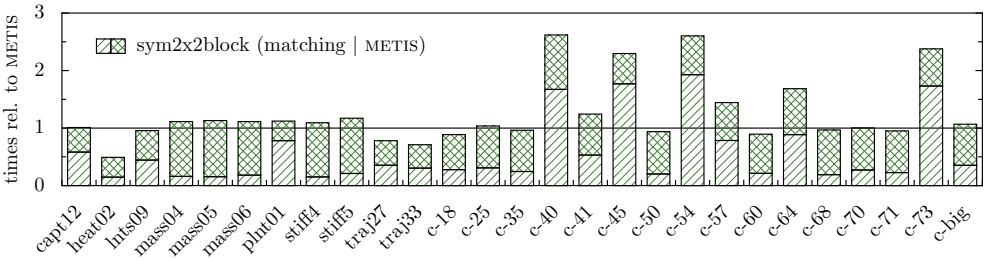

FIG. 5.1. *Times for the preprocessing step (matching + METIS) relative to METIS alone.*

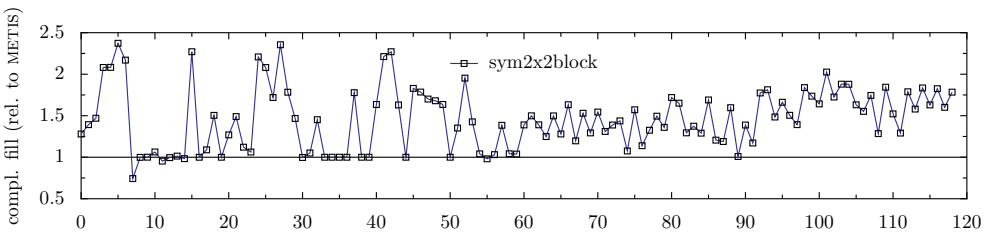

FIG. 5.2. *Fill-in for a complete symbolic factorization after the preprocessing step relative to fill-in for a factorization after METIS, for all matrices.*

thus a less accurate picture of the actual associated graph. Furthermore, the blocking often introduces additional fill-in on its own. Figure 5.2 shows the increase of fill-in for a complete symbolic factorization after the sym2x2block reordering, compared to the fill-in after a METIS reordering. The mean increase is 46%. This also illustrates why the fill-in of the incomplete factorizations can be higher than the fill-in for the direct factorization in some cases.

6. Conclusions and future work. We present a combination of a symmetric permutation and an incomplete LDL^T factorization that makes up a purely algebraic preconditioner for symmetric indefinite linear systems. It is particularly effective for sparse saddle-point problems, where the sym2x2block reordering is capable of providing a feasible pivoting order for the factorization while the cost of this preprocessing step remains relatively small. The incomplete factorization with tridiagonal pivoting is very fast, since it can be performed without pivot searching and possibly costly dynamic reorderings. By controlling the fill-in, it is possible to adjust the convergence and the memory demand over a wide range of values.

By developing a competitive implementation, we show that the relatively simple approach can compete with a fast direct solver both in terms of stability and performance. In comparison to the other preconditioners we tested, only the constraint preconditioners yielded similar results. In the simple form used here, however, our method strongly depends on the performance of the solution method for M.

The method is not well suited for many general indefinite problems like Helmholtz problems, which are highly indefinite but still have a strong diagonal. In these cases the matching yields the identity permutation, and the method falls back to a simple incomplete factorization.

Our results warrant further research into specialized, symmetric matching algorithms. Although only marginal benefits in terms of speedup are to be expected, optimal symmetric maximum weight matchings may further enhance the stability of

the method. We also experimented with approximate methods, with limited success thus far. This is, however, also a promising area of research.

Furthermore we plan to leverage the structural information that the matchings provide. In particular, information about structurally rank deficient blocks could be used to avoid numerical difficulties and might also be useful for higher level solvers like nonlinear optimization packages.

Acknowledgments. The authors thank Stefan Röllin for providing the original maximum matching implementation, Jennifer Scott for providing the HSL matrices, Andreas Wächter for providing the `c-*` matrices, and John Haws for providing the matrices from the first set. We would also like to thank the three referees for providing constructive criticism which improved both presentation and content of the paper.

FAST AND OBLIVIOUS CONVOLUTION QUADRATURE*

ACHIM SCHÄDLE†, MARÍA LÓPEZ-FERNÁNDEZ‡, AND CHRISTIAN LUBICH§

Abstract. We give an algorithm to compute N steps of a convolution quadrature approximation to a continuous temporal convolution using only $O(N \log N)$ multiplications and $O(\log N)$ active memory. The method does not require evaluations of the convolution kernel but instead uses $O(\log N)$ evaluations of its Laplace transform, which is assumed sectorial. The algorithm can be used for the stable numerical solution with quasi-optimal complexity of linear and nonlinear integral and integro-differential equations of convolution type. In a numerical example we apply it to solve a subdiffusion equation with transparent boundary conditions.

Key words. convolution, numerical integration, Runge–Kutta methods, Volterra integral equation, anomalous diffusion

AMS subject classification. 65R20

DOI. 10.1137/050623139

1. Introduction. In this paper we give a fast and memory-saving algorithm for computing the approximation of a continuous convolution (possibly matrix × vector)

$$\int_0^t f(t-\tau)\, g(\tau)\, d\tau\ , \qquad 0 \le t \le T, \tag{1.1}$$

by a convolution quadrature with a step size $h > 0$,

$$\sum_{j=0}^{n} \omega_{n-j}\, g(jh)\ , \qquad n = 1, \dots, N. \tag{1.2}$$

Here, the convolution quadrature weights ω_n are the coefficients of the generating power series (see [12])

$$\sum_{n=0}^{\infty} \omega_n \zeta^n = F\Big(\frac{\delta(\zeta)}{h}\Big), \tag{1.3}$$

where $F(s)$ is the Laplace transform of the (possibly matrix-valued) convolution kernel $f(t)$, and $\delta(\zeta) = 1 - \zeta$ or $\delta(\zeta) = (1-\zeta) + \frac{1}{2}(1-\zeta)^2$ for the methods based on the first- or second-order backward difference formula, respectively. We will also consider closely related convolution quadrature formulas that are based on implicit Runge–Kutta methods, such as the Radau IIA schemes [13].

Convolution quadratures (1.2)–(1.3) were introduced in [10, 11] and have since been used in a variety of applications. A recent review is given in [12], which contains an extensive, annotated bibliography. Attractive features of these convolution quadratures are that they work well for singular kernels $f(t)$, for kernels with multiple time

scales, and in the common situation where the Laplace transform $F(s)$ (the transfer function) but not the convolution kernel $f(t)$ (the impulse response) is known analytically. Perhaps most important, these convolution quadratures enjoy excellent stability properties in the discretization of integral equations or integrodifferential equations of convolution type, in a way often strikingly opposed to discretizations with more straightforward quadrature formulas. This comes about because the stability of a discrete convolution equation depends on the range of the generating function of the weights for $|\zeta| < 1$. In (1.3), the generating function is directly related to the Laplace transform $F(s)$ which determines the stability properties of the continuous convolution equation.

The direct way to compute (1.2) is to first compute and store the (possibly matrix-valued) weights $\omega_0, \dots, \omega_N$, which can be done accurately with $O(N)$ evaluations of the Laplace transform $F(s)$ [11], and then to compute the discrete convolution. Done naively, this requires $O(N^2)$ multiplications (possibly matrix $\times$ vector) and $O(N)$ active memory for the values $g(jh)$ and for the weights. Using FFT, the number of multiplications can be reduced to $O(N \log N)$ and to $O(N (\log N)^2)$ in the case of integral equations where the values of $g(t)$ are not known beforehand, but where $g(nh)$ is computed only in the nth time step [3]. However, that approach does not reduce the number of F-evaluations and the memory requirements.

Here we give an algorithm, also applicable in the case of linear and nonlinear integral equations, which computes (1.2) in a way that requires

- $O(N \log N)$ multiplications,
- $O(\log N)$ evaluations of the Laplace transform $F(s)$, and
- $O(\log N)$ active memory.

The history $g(jh)$ for $j = 0, \dots, N$ is forgotten in this algorithm, and only logarithmically few linear combinations of the g-values are kept in memory. These are obtained by solving numerically, with step size h, initial value problems of the form $y' = \lambda y + g$ with complex λ. The weights ω_n ($n \le N$) are not computed explicitly, except the first few, e.g., the first 10 weights.

The algorithm presented here takes up ideas of the fast convolution algorithm of [14], which instead of (1.2)–(1.3) makes a different approximation to the continuous convolution. The stability properties of the second-order method of [14] in integro-partial differential equations such as those of section 5 are, however, extremely difficult to analyze (cf. also [17]) and remain entirely unclear for higher-order extensions, whereas the stability of convolution quadratures (1.2)–(1.3) for such problems is well understood; see [1]. Here we show how the convolution quadratures (1.2)–(1.3) with all their known favorable properties can be implemented in an equally fast and memory-saving way as the method in [14].

Following the error analysis of [7, 8] we give exponentially convergent error bounds for the contour integral approximations that are employed in this algorithm. They ensure that the constants hidden in the O-symbols of the above work estimates depend only logarithmically on the error tolerance for these contour integral approximations.

We assume a [illegible] Laplace transform $F(s)$:

(1.4)

$F(s)$ is analytic in a sector $|\arg(s - \sigma)| < \pi - \varphi$ with $\varphi < \frac{1}{2}\pi$, and in this sector

$$|F(s)| \le M\,|s|^{-\nu} \quad \text{for some real } M \text{ and } \nu > 0.$$

The inverse Laplace transform is then given by

$$f(t) = \frac{1}{2\pi i} \int_\Gamma e^{t\lambda} F(\lambda)\, d\lambda, \qquad t > 0, \tag{1.5}$$

with Γ a contour in the sector of analyticity, going to infinity with an acute angle to the negative real half-axis and oriented with increasing imaginary part. The function $f(t)$ is analytic in $t > 0$ and satisfies

$$|f(t)| \le C\, t^{\nu-1}\, e^{ct}, \qquad t > 0, \tag{1.6}$$

and is therefore locally integrable. (The absolute values on the left-hand sides of the bounds (1.4) and (1.6) are to be interpreted as matrix norms for matrix-valued convolution kernels.) A prototypical example, which will actually be used in our numerical experiments, is the fractional-power kernel $f(t) = t^{\nu-1}/\Gamma(\nu)$ with $\nu > 0$, which has the Laplace transform $F(s) = s^{-\nu}$.

In section 2 we review convolution quadrature based on multistep and Runge–Kutta methods. We give a contour integral representation of the convolution quadrature weights whose discretization along hyperbolas or Talbot contours is discussed in section 3. The fast and oblivious convolution algorithm is formulated in section 4. Finally, in section 5 we give the results of numerical experiments with integral and integrodifferential equations originating from regular and anomalous diffusion problems.

2. Convolution quadrature. In this section we review briefly convolution quadrature and give a contour integral representation of the convolution quadrature weights on which the fast algorithm of this paper is based.

2.1. Convolution quadrature based on multistep methods. We consider the convolution quadrature (1.2) with weights (1.3). By (1.4) and Cauchy's integral formula we have, with a contour Γ as in (1.5),

$$\sum_{n=0}^{\infty} \omega_n \zeta^n = F\Big(\frac{\delta(\zeta)}{h}\Big) = \frac{1}{2\pi i} \int_\Gamma \Big(\frac{\delta(\zeta)}{h} - \lambda\Big)^{-1} F(\lambda)\, d\lambda.$$

Hence, with $e_n(z)$ defined by

$$(\delta(\zeta) - z)^{-1} = \sum_{n=0}^{\infty} e_n(z)\, \zeta^n, \tag{2.1}$$

we have the integral formula

$$\omega_n = \frac{h}{2\pi i} \int_\Gamma e_n(h\lambda)\, F(\lambda)\, d\lambda, \tag{2.2}$$

which can be viewed as the discrete analogue of (1.5). For the backward Euler discretization $\delta(\zeta) = 1 - \zeta$ we note the explicit formula

$$e_n(z) = (1 - z)^{-n-1}, \tag{2.3}$$

which is of the form $e_n(z) = q(z)r(z)^n$ with $r(z) = \frac{1}{1-z}$ and $q(z) = \frac{1}{1-z}$.

For the second-order backward differentiation formula (BDF), where $\delta(\zeta) = \sum_{k=1}^{p} \frac{1}{k}(1-\zeta)^k$ with $p = 2$, we obtain from a partial fraction decomposition of $(\delta(\zeta) - z)^{-1}$ that

$$e_n(z) = \frac{1}{\sqrt{1+2z}} \Big((2 - \sqrt{1+2z})^{-n-1} - (2 + \sqrt{1+2z})^{-n-1} \Big), \tag{2.4}$$

which is of the form $e_n(z) = q_1(z)r_1(z)^n + q_2(z)r_2(z)^n$. Connoisseurs of Cardano's formulas find analogous formulas to (2.4) also for the BDF methods of orders 3 and 4.

2.2. Convolution quadrature based on Runge–Kutta methods. We consider an implicit Runge–Kutta method with coefficients a_{ij}, b_j, c_i for $i, j = 1, \dots, m$. We denote the Runge–Kutta matrix by $\mathcal{A} = (a_{ij})$, the row vector of the weights by $b^T = (b_j)$, and the stability function by

$$r(z) = 1 + zb^T(I - z\mathcal{A})^{-1}\mathbb{1},$$

where $\mathbb{1} = (1, \dots, 1)^T$. We assume that all eigenvalues of the Runge–Kutta matrix $\mathcal{A}$ have positive real part and that the method is A-stable and the row vector of the weights equals the last line of the Runge–Kutta matrix,

$$b_j = a_{mj} \quad \text{for} \quad j = 1, \dots, m,$$

and correspondingly $c_m = 1$. Notice that this implies that the method is L-stable, i.e.,

$$|r(z)| \le 1 \text{ for } \mathrm{Re} z \le 0 \qquad \text{and} \quad r(\infty) = 0.$$

These conditions are in particular satisfied by the Radau IIA family of Runge–Kutta methods [4]. From such a Runge–Kutta method, a convolution quadrature is constructed as follows [13]: let

$$\Delta(\zeta) = \Big(\mathcal{A} + \frac{\zeta}{1-\zeta}\mathbb{1}b^T\Big)^{-1} \tag{2.5}$$

and define weight matrices W_n by

$$\sum_{n=0}^{\infty} W_n \zeta^n = F\Big(\frac{\Delta(\zeta)}{h}\Big). \tag{2.6}$$

Let $\omega_n = (\omega_n^1, \dots, \omega_n^m)$ denote the last row of W_n. Then an approximation to the convolution integral (1.1) at time $t_{n+1} = (n+1)h$ is given by

$$u_{n+1} = \sum_{j=0}^{n} \sum_{i=1}^{m} \omega_{n-j}^i \, g(t_j + c_i h) = \sum_{j=0}^{n} \omega_{n-j} \, g_j \tag{2.7}$$

with the column vector $g_j = \big(g(t_j + c_i h)\big)_{i=1}^m$. For a Runge–Kutta method of classical order p and stage order q, this approximation is known to be convergent of the order $\min(p, q+1+\nu)$ with ν of (1.4) [13, Theorem 2.2].

With the row vector $e_n(z) = (e_n^1(z), \dots, e_n^m(z))$ defined as the last row of the $m \times m$ matrix $E_n(z)$ given by

$$(\Delta(\zeta) - zI_m)^{-1} = \sum_{n=0}^{\infty} E_n(z) \, \zeta^n, \tag{2.8}$$

we obtain an integral formula like in (2.2),

$$\omega_n = \frac{h}{2\pi i} \int_\Gamma e_n(h\lambda) \otimes F(\lambda) \, d\lambda. \tag{2.9}$$

For $n \geq 0$, $e_n(z)$ is given as

$$e_n(z) = r(z)^n q(z) \tag{2.10}$$

with the row vector $q(z) = b^T(I - z\mathcal{A})^{-1}$; cf. [13, Lemma 2.4]. We note that

$$y_{n+1}^{(\lambda)} = h \sum_{j=0}^{n} e_{n-j}(h\lambda)\, g_j \tag{2.11}$$

is the Runge–Kutta approximation at time t_{n+1} of the linear initial value problem

$$y' = \lambda y + g(t), \quad y(0) = 0\,. \tag{2.12}$$

The convolution quadrature (2.7) is thus interpreted as

$$u_{n+1} = \frac{1}{2\pi i} \int_\Gamma F(\lambda)\, y_{n+1}^{(\lambda)}\, d\lambda\,;$$

see [13, Proposition 2.1].

3. Approximation of the contour integrals. The fast convolution algorithm will be based on discretizing the integrals in (2.2) and (2.9) along suitable complex contours. This approximation is discussed in the present section.

3.1. Quadrature on hyperbolas and Talbot contours. The fast algorithm approximates the quadrature weights ω_n by linear combinations of the exponential approximations $e_n(h\lambda)$, locally on a sequence of fast-growing time intervals $nh \in I_\ell$:

$$I_\ell = [B^{\ell-1}h, 2B^\ell h), \tag{3.1}$$

where the base $B > 1$ is an integer. For example, $B = 10$ was found a good choice in our numerical experiments. The approximation on I_ℓ results from applying the trapezoidal rule to a parametrization of the contour integral for the convolution quadrature weights,

$$\omega_n = \frac{h}{2\pi i} \int_{\Gamma_\ell} e_n(h\lambda) \otimes F(\lambda)\, d\lambda \approx h \sum_{k=-K}^{K} w_k^{(\ell)} e_n(h\lambda_k^{(\ell)}) \otimes F(\lambda_k^{(\ell)})\,, \qquad nh \in I_\ell, \tag{3.2}$$

with an appropriately chosen complex contour Γ_ℓ. The number of quadrature points on Γ_ℓ, $2K+1$, is chosen independent of ℓ. It is much smaller than what would be required for a uniform approximation of the contour integral on the whole interval $[0, T]$. The integration contour is chosen as a hyperbola [8] or a Talbot contour [20, 16].

The hyperbola is given by

$$\mathbb{R} \to \Gamma : \theta \mapsto \gamma(\theta) = \mu(1 - \sin(\alpha + i\theta)) + \sigma \tag{3.3}$$

with a positive scale parameter μ, a positive angle $\alpha < \pi/2 - \varphi$, and the shift σ of (1.4). The contour thus remains in the sector (1.4) of analyticity of $F(s)$. Additionally the contour is chosen such that the singularities of $e_n(hs)$ lie to the right of the contour. See the left part of Figure 3.1 for $\alpha = \pi/2 - 1/2$. The parameter μ will depend on ℓ, which yields a contour Γ_ℓ depending on the approximation interval I_ℓ. The weights and quadrature points in (3.2) are given by (omitting ℓ in the notation)

$$w_k = \frac{i\tau}{2\pi}\, \gamma'(\theta_k)\,, \quad \lambda_k = \gamma(\theta_k) \qquad \text{with} \qquad \theta_k = k\tau\,,$$

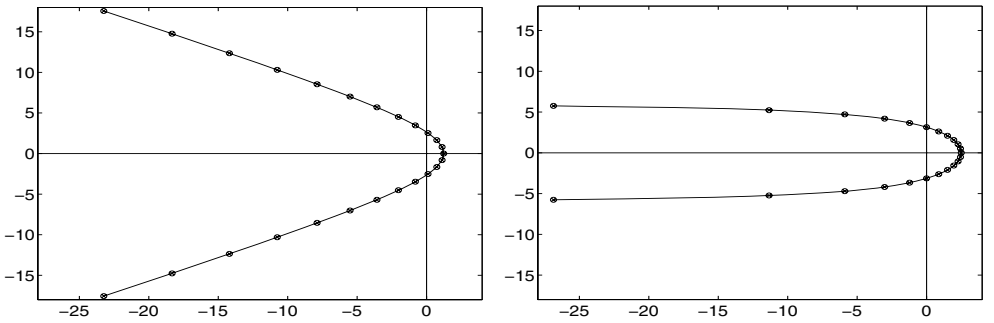

FIG. 3.1. *Hyperbola (left) and Talbot contour (right).*

where τ is a step length parameter.

Alternatively, the Talbot contour is given by

$$(-\pi,\pi) \to \Gamma : \theta \mapsto \gamma(\theta) = \mu\,(\theta\cot(\theta) + i\kappa\theta) + \sigma \tag{3.4}$$

where the parameters μ, κ, and σ are such that the singularities of $F(s)$ lie to the left of the contour and that the singularities of $e_n(hs)$ lie to the right of the contour. The parameter μ will again depend on ℓ. See the right part of Figure 3.1 for $\sigma = 0$. The weights and quadrature points in (3.2) are given by (omitting ℓ in the notation)

$$w_k = -\frac{i}{2(K+1)}\,\gamma'(\theta_k)\,, \qquad \lambda_k = \gamma(\theta_k) \qquad \text{with} \qquad \theta_k = \frac{k\pi}{K+1}\,.$$

3.2. Theoretical error bounds of the contour integral approximations. For the case of the hyperbola, we obtain with the proof of [7, Theorem 3] the following error bound, which shows exponential convergence.

THEOREM 3.1. [illegible] C, d $c_0, \dots, c_4$ [illegible] c [illegible] $t = nh \le T$ [illegible] (3.2) [illegible] (3.3) [illegible] $1 \le c\mu t \le n$ [illegible]

$$\|E(\tau,K,h,n)\| \le C\,h\,t^{\nu-1}\,(\mu t)^{1-\nu}\left(\frac{e^{c_0\mu t}}{e^{2\pi d/\tau}-1} + e^{(c_1-c_2\cosh(K\tau))\mu t} + e^{c_3\mu t}\Big(1+\frac{c_4\cosh(K\tau)\mu t}{n/2}\Big)^{-n/2}\right),$$

[illegible] ν [illegible] (1.4)

The first summand in this estimate corresponds to the error in the discretization of the integral (3.2), parametrized over the real line with an integrand holomorphic in a strip $|\mathrm{Im}\,\theta| < d$, with step size τ and with the infinite quadrature sum over all integers k [18, 19]. The other two terms result from truncating the infinite sum to the terms $-K \le k \le K$, using the strong decay of the integrand along the integration contour.

Given an error tolerance ε, the first term in the error bound becomes $O(\varepsilon\,h\,t^{\nu-1})$ if τ is chosen so small that $c_0\mu t - 2\pi d/\tau \le \log\varepsilon$, which requires an asymptotic proportionality $\frac{1}{\tau} \sim \log\frac{1}{\varepsilon} + \mu t$. For μ chosen such that $\frac{a_1}{B}\log\frac{1}{\varepsilon} \le \mu t \le a_1\log\frac{1}{\varepsilon}$ with an arbitrary positive constant a_1 and with $B > 1$, we obtain that the second term is $O(\varepsilon\,h\,t^{\nu-1})$ if $c_1 - c_2\cosh(K\tau) \le -B/a_1$, i.e., with $\cosh(K\tau) = a_2$ for a sufficiently

large constant a_2. With the above choice of τ, this yields $K \sim \log \frac{1}{\varepsilon}$. The third term then becomes smaller than $\varepsilon\, h\, t^{\nu-1}$ for $n \geq c \log \frac{1}{\varepsilon}$ with a sufficiently large constant c. In summary, this gives the following bound for the required number of quadrature points on the hyperbola.

THEOREM 3.2. (3.2) $\varepsilon\, h\, t^{\nu-1}$ $nh \in I_\ell$ $K = O(\log \frac{1}{\varepsilon})$ $n \geq c \log \frac{1}{\varepsilon}$ $c > 0$ K ℓ n h $nh \leq T$

No small error bound is, however, obtained for the first few $n < c \log \frac{1}{\varepsilon}$. The approximation is indeed poor for small n, as will be seen in the numerical experiments in section 3.4. Therefore the first few ω_n are not computed using the integral representation (3.2) but are computed using the method of section 3.5.

We expect that a similar result to Theorem 3.2 holds also for the Talbot contours, if the Laplace transform has an analytic continuation beyond the negative real axis from above and below, as is the case for the fractional powers considered below.

3.3. Choice of parameters for the hyperbolas. The estimate in Theorem 3.1 is valid for the discretization of contour integrals of the type considered in (3.2), where $e_n(h\lambda)$ is an approximation to $\exp(nh\lambda)$. Replacing $e_n(h\lambda)$ by $\exp(nh\lambda)$ in (3.2) we obtain the inverse Laplace transform at nh of F. For the numerical inversion of the Laplace transform there is a spectral order method developed in [9], where the error estimate is explicit in all constants involved. Getting an estimate explicit in all constants for the discretization of (3.2) is much more difficult and, in practice, we choose the parameters following the strategy proposed in [9] for the numerical inversion of the Laplace transform. This makes sense as for large n and small h with $nh \leq T$ the estimate in Theorem 3.1 tends to an expression of the same type as the error estimate for the approximation of the inverse Laplace transform in [9].

Given the approximation interval $[B^{\ell-1}h, (2B^\ell - 2)h]$ and K the number of nodes on the hyperbola, the strategy for choosing the parameters is as follows:

1. Choose $\alpha = d = (\pi/2 - \varphi)/2$, with φ of (1.4).
2. Minimize for $0 < \rho < 1$ the expression

$$\operatorname{eps}\, \epsilon_K(\rho)^{\rho-1} + \epsilon_K(\rho)^\rho,$$

   where

$$\epsilon_K(\rho) = \exp\Big(-\frac{2\pi d}{a(\rho)} K\Big), \qquad a(\rho) = \operatorname{acosh}\Big(\frac{2B}{(1-\rho)\sin\alpha}\Big)$$

   and eps is the machine precision.
3. Take

$$\tau = \frac{1}{K} a(\rho_{opt}), \qquad \mu = \frac{2\pi d K (1-\rho_{opt})}{(2B^\ell - 2) h\, a(\rho_{opt})}.$$

This strategy for choosing the hyperbola contours is used in the numerical experiments below.

3.4. Numerical experiments. In view of the examples of section 5 we present here numerical experiments with

$$f(t) = \frac{1}{\sqrt{\pi t}} \quad \text{for which} \quad F(s) = s^{-1/2}.$$

The error is calculated with respect to a reference solution, obtained for a discretization of the contour integral with a large number of integration points. For the

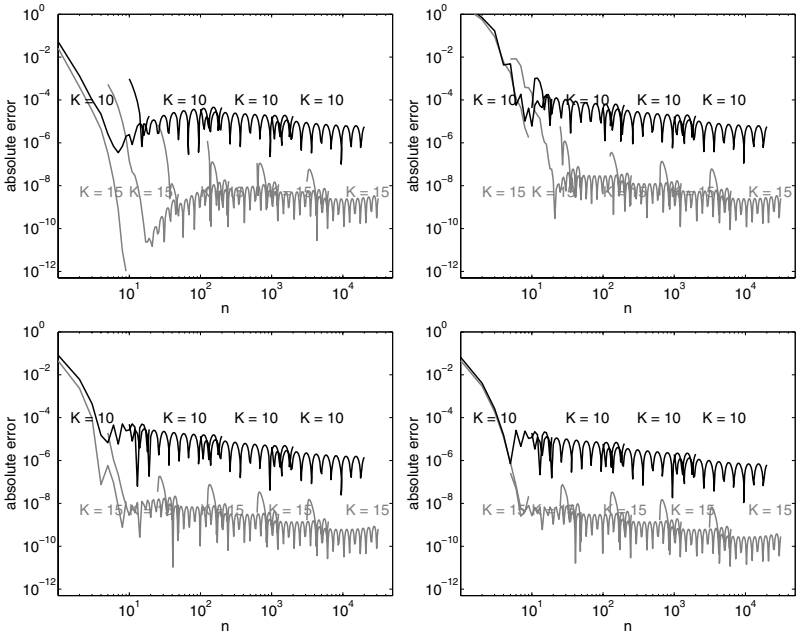

FIG. 3.2. *Hyperbola quadrature errors versus time in logarithmic scale for $K = 15$, $B = 5$ and $K = 10$, $B = 10$ for different Integrators. (Implicit Euler, BDF(2), RadauIIA(3), and RadauIIA(5) in clockwise order starting from the upper left).*

Radau IIA methods of order 3 and 5, where the ω_n are row vectors of dimension 2 and 3, respectively, we plot the error of the last entry.

Using the hyperbola contours, for $B = 10$ and $K = 10$ we obtain an absolute error of about 10^{-4} on the interval I_ℓ for $\ell \geq 2$ taking $\alpha = 1$, μ and τ as described above. For an absolute approximation error of $3 \cdot 10^{-8}$, we take $B = 5$, $K = 15$, and the other parameters as before; cf. Figure 3.2. For $n > 20$ there is no substantial difference between the quadrature errors corresponding to the different Runge–Kutta methods.

Using the Talbot contours, the following choices of parameters were experimentally found to give good results. An absolute accuracy of about 10^{-3} on the interval I_ℓ for $\ell \geq 2$ with right end-point T_ℓ is obtained with $B = 10$, $K = 10$, $\mu = 8/T_\ell$, $\kappa = 0.6$. For an absolute approximation error of 10^{-6}, take $B = 5$, $K = 15$, and the other parameters as before; cf. Figure 3.3. For $n > 20$ there is again no essential difference between the different Runge–Kutta methods.

As we commented after Theorem 3.2, the approximations to the first few convolution quadrature weights are poor and so they will not be used in the algorithm.

Figure 3.4 shows the absolute errors on the interval $[10, 20000]$ (similar for any interval $[a, 2000a]$ with $a > 10$) for the RadauIIA(3) method with $K = 10, 20, 40, 80, 160, 320, 640$. For the implicit Euler, the BDF(2), and the RadauIIA(5) methods these error plots look similar. This behavior of the errors clearly demonstrates the advantage of using local approximations. With $B = 10$, we need three approximation intervals to cover the interval $[10, 20000]$, so that for a work of $3 \cdot K$ with $K = 10$ we obtain better accuracy than with $K = 640$ over the whole interval.

In this example the maximum quadrature errors using the hyperbolas are smaller than those for the Talbot contours. Moreover, the hyperbolas allow us to choose larger

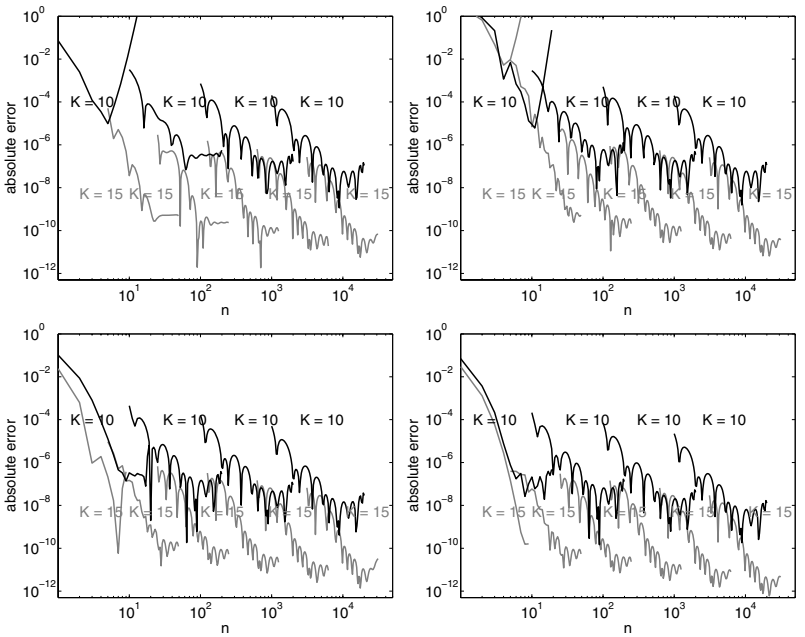

FIG. 3.3. *Talbot quadrature errors versus time in logarithmic scale for* $K = 15$, $B = 5$ *and* $K = 10$, $B = 10$ *for different Integrators. (Implicit Euler, BDF*(2)*, Radau*IIA(3)*, and Radau*IIA(5) *in clockwise order starting from the upper left).*

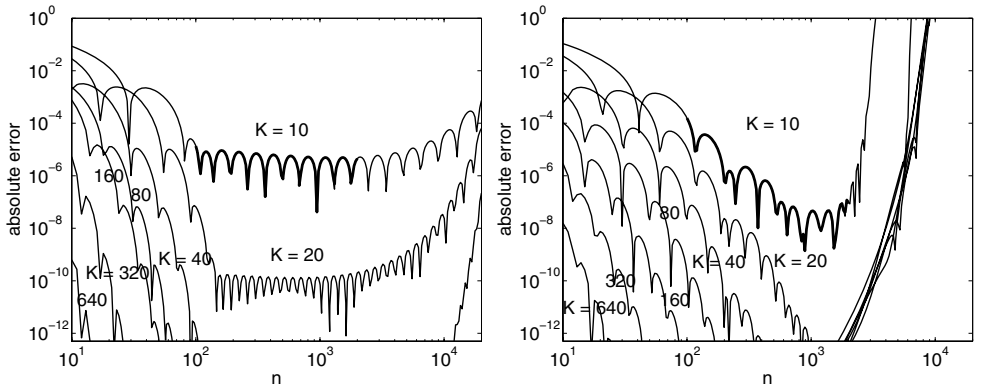

FIG. 3.4. *Hyperbola (left) and Talbot (right) quadrature error versus* n *in logarithmic scale for the Radau*IIA(3) *method with* $K = 10, 20, 40, 80, 160, 320, 640$. *The bold parts of the error curve correspond to the lower left parts of Figures* 3.3 *and* 3.2.

intervals. On the other hand, the Talbot contours turned out to be less sensitive to the choice of parameters and the Laplace transform functions than the hyperbolas.

3.5. Computation of the first few convolution quadrature weights. In view of the poor approximation properties of the discretized contour integral for the first few ω_n, the first N_0 (e.g., $N_0 = 10$ or 20, and asymptotically $N_0 = c \log \frac{1}{\varepsilon}$) convolution quadrature weights are approximated differently, using their representation

as an integral over a circle:

$$\omega_n = \text{ last row of } \frac{1}{2\pi i}\int_{|\zeta|=\rho} \zeta^{-n-1} F\Big(\frac{\Delta(\zeta)}{h}\Big)\, d\zeta, \qquad n \le N_0. \tag{3.5}$$

This is approximated by the trapezoidal rule,

$$\omega_n \approx \text{ last row of } \frac{\rho^{-n}}{J}\sum_{j=1}^{J} F\Big(\frac{\Delta(\zeta_j)}{h}\Big)\, e^{-2\pi i n j/J}, \qquad n \le N_0, \tag{3.6}$$

with $\zeta_j = \rho e^{-2\pi i j/J}$. The choice of the parameters ρ and J follows [11]: assuming that the values of F are computed with precision $\widehat{\epsilon}$, the error in ω_n $(0 \le n \le N_0)$ is $O(\widehat{\epsilon}^{1/2})$ if $J = N_0 + 1$ and $\rho^J = \widehat{\epsilon}^{1/2}$, and the error is $O(\widehat{\epsilon})$ if $J \ge N_0 \log(1/\widehat{\epsilon})$ and $\rho = e^{-\gamma h}$, with $\gamma > \sigma$ of (1.4).

4. The fast and oblivious algorithm. We now describe the convolution algorithm, concentrating on Runge–Kutta-based convolution quadrature. The algorithm differs slightly depending on whether we want to compute a convolution or to solve an integral or integrodifferential equation of convolution type.

4.1. The algorithm for computing convolutions. The algorithm presented here uses the organization scheme of the fast convolution algorithm described in a step-by-step manner in [14]. A pseudocode for the algorithm developed in [14] can be found in [5]. We now describe the fast and memory-saving algorithm for computing (2.7) for $n \le N$.

For fixed integer $n \le N$ and a given base B we split the discrete convolution (1.2) or (2.7) into L sums, where L is the smallest integer such that $n < 2B^L$:

$$u_{n+1} = \sum_{j=0}^{n} \omega_{n-j}\, g_j = u_{n+1}^{(0)} + \cdots + u_{n+1}^{(L)}$$

$$\text{with} \quad u_{n+1}^{(0)} = \omega_0\, g_n \quad \text{and} \quad u_{n+1}^{(\ell)} = \sum_{j=b_\ell}^{b_{\ell-1}-1} \omega_{n-j}\, g_j$$

for suitable $n = b_0 > b_1 > \cdots > b_{L-1} > b_L = 0$. In view of the approximation intervals (3.1), the splitting is done in such a way that for fixed ℓ in each sum from b_ℓ to $b_{\ell-1} - 1$, we have $n - j \in [B^{\ell-1}, 2B^\ell - 2]$. The $b_\ell = \mathtt{b}(\ell)$, $\ell = 1, \ldots, L-1$ are determined recursively by the following pseudocode:

```
L = 1; q = 0;
for n = 1 to N do
   if (2*B^L == n+1) then L = L+1; endif
   k = 1;
   while ((mod(n+1,B^k) == 0) & (k < L))
      q(k) = q(k)+1;
      k = k+1;
   endwhile
   for k = 1 to L-1 do b(k) = q(k)*B^k; endfor
endfor
```

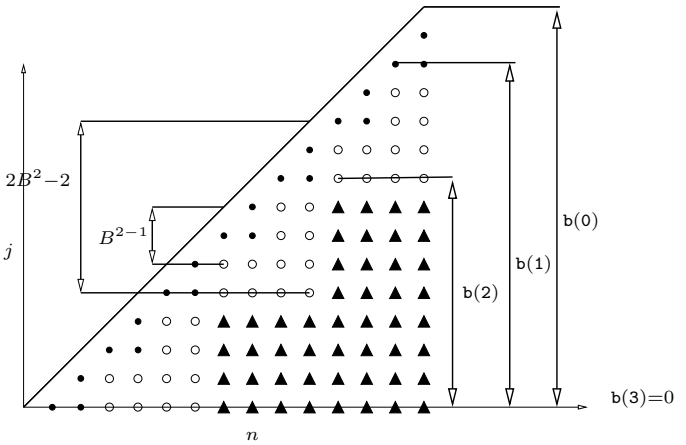

FIG. 4.1. *Visualization of the scheme for $B = 2$ to determine the values* `b(l)`. *For $n = 14$, $L = 3$ and* `b` $= [14\ 12\ 8\ 0]$. *Additionally the approximation interval for $\ell = 2$ is indicated.*

Note that for growing n, b_ℓ is augmented by B^ℓ every B^ℓ steps. The procedure is illustrated for $B = 2$ in Figure 4.1.

On inserting the integral representation (2.9) of the Runge–Kutta quadrature weights and the relation (2.10), i.e., $e_{n-j}(h\lambda) = r(h\lambda)^{n-j} q(h\lambda)$, we obtain

$$
\begin{aligned}
u_{n+1}^{(\ell)} &= \sum_{j=b_\ell}^{b_{\ell-1}-1} \omega_{n-j}\, g_j = \sum_{j=b_\ell}^{b_{\ell-1}-1} \frac{h}{2\pi i} \int_{\Gamma_\ell} e_{n-j}(h\lambda) \otimes F(\lambda)\, d\lambda\, g_j \\
&= \frac{1}{2\pi i} \int_{\Gamma_\ell} r(h\lambda)^{n-(b_{\ell-1}-1)}\, F(\lambda)\, y^{(\ell)}(h\lambda)\, d\lambda
\end{aligned}
\tag{4.1}
$$

with

$$
y^{(\ell)}(h\lambda) = h \sum_{j=b_\ell}^{b_{\ell-1}-1} e_{(b_{\ell-1}-1)-j}(h\lambda)\, g_j\,.
$$

Comparing this formula with (2.11), we see that $y^{(\ell)}(h\lambda)$ is the Runge–Kutta approximation $y(b_{\ell-1}h, b_\ell h, \lambda)$ to the solution at $t = b_{\ell-1}h$ of the linear initial-value problem

$$
y' = \lambda y + g(t), \quad y(b_\ell h) = 0, \tag{4.2}
$$

and hence $y^{(\ell)}(h\lambda)$ is computed as such, by Runge–Kutta time stepping. The integrals are discretized with the quadrature formula discussed in section 3:

$$
u_{n+1}^{(\ell)} \doteq \sum_{k=-K}^{K} w_k^{(\ell)}\, r(h\lambda_k^{(\ell)})^{n-b_{\ell-1}+1}\, F(\lambda_k^{(\ell)})\, y^{(\ell)}(h\lambda_k^{(\ell)}). \tag{4.3}
$$

In the nth time step, we thus compute $u_{n+1}^{(\ell)}$ and for subsequent use we update the Runge–Kutta solutions to the $(2K+1)L$ initial value problems (4.2) for the integration points $\lambda_k^{(\ell)}$ on the contours Γ_ℓ for $\ell = 1, \ldots, L$, doing one time step from t_n to t_{n+1} in each of these differential equations.

This algorithm does not keep the history g_j $(j = 0, \dots, n)$ in memory. Instead, for each $\ell = 1, \dots, L$, it stores the Runge–Kutta approximation `yRK(l)` to (4.2) at the current time step, the values $w_k^{(\ell)}$, $\lambda_k^{(\ell)}$, $r(h\lambda_k^{(\ell)})$, $F(\lambda_k^{(\ell)})$, the vector `y(l)` $= \big(y^{(\ell)}(h\lambda_k^{(\ell)})\big)$, and two auxiliary vectors `yA(l)` and `yM(l)` of the same dimension as `yRK(l)` and `y(l)` $((2K+1) \times (\text{size}\, g))$ needed for bookkeeping purposes.

Proceeding from t_n to t_{n+1} the Runge–Kutta solutions `yRK(l)` of (4.2) are advanced from $y(t_{b_\ell}, t_n, \lambda_k^{(\ell)})$ to $y(t_{b_\ell}, t_{n+1}, \lambda_k^{(\ell)})$ for $\ell = 2, \dots, L$ and all $k = -K \dots, K$.

The bookkeeping for the `yA` and `yM` is done using the following pseudocode:

```
l = 2;
while ((mod(n+1,Basis^(l-1)) == 0) & (l <= L))
  if (mod(n+1, Basis^l) == 0) then
    yA(l) = yRK(l);
    yM(l) = yRK(l);
    restart yRK(l);
  else
    yM(l) = yRK(l));
  endif
  l = l+1;
endwhile
```

Here "`restart yRK(l)`" means that `yRK(l)` is set to $y(t_{b_\ell}, t_{b_\ell}, \lambda_k^{(\ell)}) = 0$. This way the scheme in Figure 4.1 is build bottom up.

To retrieve the values `y(l)` $= y^{(\ell)}(h\lambda_k^{(\ell)})$ required at the current time from the `yA` and `yM` we use the `b(l)`. Again we give the pseudocode:

```
tvek = h*b;  % b is the vector of b(l); l = 0 , ... , L
for l = 2 to  length(tvek)-1 do
  y(l) = r(l) * y(l);
  if (tvek(l) == final time of yM(l)) then
    y(l) = yM(l);
    if (l == 2) then g = g(1:B-1);  endif
  endif
  if (tvek(l+1) ~= initial time of yM(l)) then
    y(l) = y(l) + yA(l)*r(l)^(B^(l-1));
  endif
endfor
```

Here `r(l)` denotes the stability function given in (2.10) and `g` is the vector containing the values $g_n, \dots, g_{b_1}$.

There are only $(2K+1)L$ evaluations of the Laplace transform $F(s)$. In the case of real functions $f(t)$ and $g(t)$ only the real parts of the above sums are used, since the imaginary ones cancel out, and hence the factor $2K+1$ can be replaced by $K+1$, since the quadrature points lie symmetric with respect to the real axis. We recall $L \le \log_B N$ and $K = O(\log \frac{1}{\varepsilon})$, where ε is the accuracy requirement in the discretization of the contour integrals.

In view of the poor approximation of the first convolution quadrature weights by the discretization of the contour integral, we evaluate $u_{n+1}^{(\ell)}$ directly for a few of the first ℓ, e.g., for $\ell = 0, 1$ with $B = 10$. For this we need to keep the $n - b_1 + 1 \le 2B$

values $g_{b_1}, \dots, g_n$ in memory, but none of the earlier history g_j for $j \le n - 2B$. We also need the few convolution quadrature weights $\omega_0, \dots, \omega_{2B-1}$, which are computed from (3.6) with $J = 2B$ evaluations of the Laplace transform $F(s)$, as described in section 3.5.

For the convolution quadrature based on the second-order BDF method a similar fast algorithm is obtained by inserting the formula (2.4) for $e_{n-j}(h\lambda)$ in (4.1).

4.2. The algorithm for solving integral equations. Consider now a Volterra integral equation

$$u(t) = a(t) + \int_0^t f(t-\tau)\, g(\tau, u(\tau))\, d\tau\,, \qquad t \ge 0, \tag{4.4}$$

with a kernel $f(t)$ whose Laplace transform satisfies the sectorial condition (1.4), with a smooth nonlinearity $g(t,u)$ and inhomogeneity $a(t)$. The adaptation of the above algorithm to such convolution equations is straightforward for the case of the convolution quadrature based on the implicit Euler method and the second-order BDF method, which use solution approximations only on the grid $t = nh$. The extension of the Runge–Kutta-based algorithm is, however, less immediate, because the integral approximation uses the internal stages of the Runge–Kutta method. Consider a Runge–Kutta-based convolution quadrature under the assumptions of section 2.2. With the column vector of internal stages $v_n = (v_{ni})_{i=1}^m$, the discretization of (4.4) reads

$$v_n = a_n + \sum_{j=0}^{n} W_{n-j}\, g_j\,, \qquad n \ge 0, \tag{4.5}$$

with $a_n = \big(a(t_n + c_i h)\big)_{i=1}^m$, with weight matrices W_n defined by (2.6), and with $g_j = \big(g(t_j + c_i h, v_{ji})\big)_{i=1}^m$ depending on the stages v_{ji}. The scheme is implicit in v_n. The solution at t_{n+1} is approximated by the last component of the stage vector v_n,

$$u_{n+1} = v_{nm}\,.$$

With the proof of [13, Theorem 4.1] we obtain that the error of this approximation over bounded time intervals is bounded by $O(h^k)$ with $k = \min(p, q+1)$, where p and q are the classical order and stage order, respectively, of the underlying Runge–Kutta method. This estimate holds under the assumption that the solution is sufficiently smooth. It gives orders 3 and 4 for the two- and three-stage Radau IIA methods, respectively. The precise approximation order for the three-stage method (of classical order 5) may become larger under appropriate conditions on the nonlinearity and the convolution kernel; cf. [13, Theorem 4.2].

The weight matrix W_n has the integral representation (cf. (2.9))

$$W_n = \frac{h}{2\pi i} \int_\Gamma E_n(h\lambda) \otimes F(\lambda)\, d\lambda\,,$$

where the $m \times m$ matrix $E_n(z)$ is defined by (2.8). By [13, Lemma 2.4], for $n \ge 1$, $E_n(z)$ is the rank-1 matrix given by

$$\begin{aligned} E_n(z) &= r(z)^{n-1} (I - z\mathcal{A})^{-1} \mathbb{1} b^T (I - z\mathcal{A})^{-1} \\ &= r(z)^{-1}\, (I - z\mathcal{A})^{-1} \mathbb{1}\, e_n(z). \end{aligned}$$

These relations permit us to proceed for the history term of (4.5) as we did for (2.7). We split the stage vector v_n as

$$v_n = a_n + v_n^{(0)} + \cdots + v_n^{(L)} \qquad \text{with} \qquad v_n^{(\ell)} = \sum_{j=b_\ell}^{b_{\ell-1}-1} W_{n-j}\, g_j$$

and obtain, like in (4.1),

$$v_n^{(\ell)} = \frac{1}{2\pi i} \int_{\Gamma_\ell} r(h\lambda)^{n-b_{\ell-1}} \, (I - h\lambda \mathcal{A})^{-1} \mathbb{1} \otimes F(\lambda)\, y^{(\ell)}(h\lambda)\, d\lambda \,,$$

where $y^{(\ell)}(h\lambda)$ is again the Runge–Kutta approximation at $t = b_{\ell-1}h$ to the initial-value problem (4.2), now for the inhomogeneity values $g_j = \big(g(t_j + c_i h, v_{ji})\big)_{i=1}^m$ in place of $g_j = \big(g(t_j + c_i h)\big)_{i=1}^m$. For $\ell \geq 2$ or 3, we thus approximate $v_n^{(\ell)}$ as

$$v_n^{(\ell)} \doteq \sum_{k=-K}^{K} w_k^{(\ell)}\, r(h\lambda_k^{(\ell)})^{n-b_{\ell-1}} \, (I - h\lambda_k^{(\ell)} \mathcal{A})^{-1} \mathbb{1} \otimes F(\lambda_k^{(\ell)})\, y^{(\ell)}(h\lambda_k^{(\ell)}) \,.$$

The algorithm stores the same values as before. The memory requirements for the algorithm are thus independent of the number of stages m and remain essentially the same as in the pure convolution case.

The effect of the (exponentially small in K) quadrature error of the contour integrals on the convolution quadrature approximation of the integral equation can be estimated using a discrete Gronwall inequality or by stability estimates of the convolution quadrature as, e.g., in [1]. Since the emphasis of the present paper is on the algorithmic aspects, we do not work out details of such estimates here.

5. Numerical experiments. We give two examples to illustrate the application and behavior of the fast convolution algorithm.

5.1. A nonlinear Volterra equation. We consider a nonlinear Volterra integral equation with weakly singular kernel from [6],

$$u(t) = -\int_0^t \frac{\big(u(\tau) - \sin(\tau)\big)^3}{\sqrt{\pi(t-\tau)}}\, d\tau \,. \tag{5.1}$$

The convolution quadrature based on the backward Euler method gives the implicit discretization

$$u_{n+1} = \sum_{j=0}^{n} \omega_{n-j} \big(u_{j+1} - \sin((j+1)h)\big)^3,$$

where ω_n is given by (1.3) with $F(s) = s^{-1/2}$ and $\delta(\zeta) = 1 - \zeta$. To solve the nonlinear equation in each time step we use Newton iterations. The history term is computed by the fast algorithm of the previous section.

We consider also the discretizations based on the backward differentiation method of order 2 (cf. section 2.1) and on the two- and three-stage Radau IIA implicit Runge–Kutta methods of orders 3 and 5, respectively; see sections 2.2 and 4.2.

In the numerical experiment we use the base $B = 5$ and the Talbot contours with $K = 15$ and $K = 30$ and the further parameters as in section 3.4. We choose

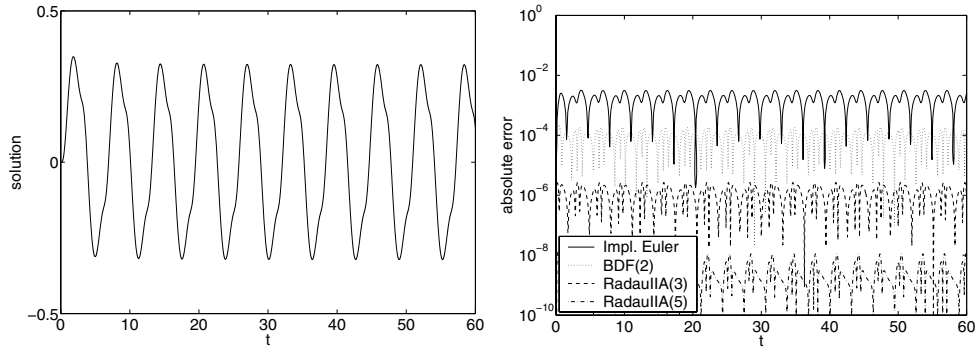

FIG. 5.1. *Evolution of the solution over the interval* $[0, 60]$ *(left) and logarithm of absolute error for different time integration methods (right) for* $h = 0.05$ *and* $K = 30$.

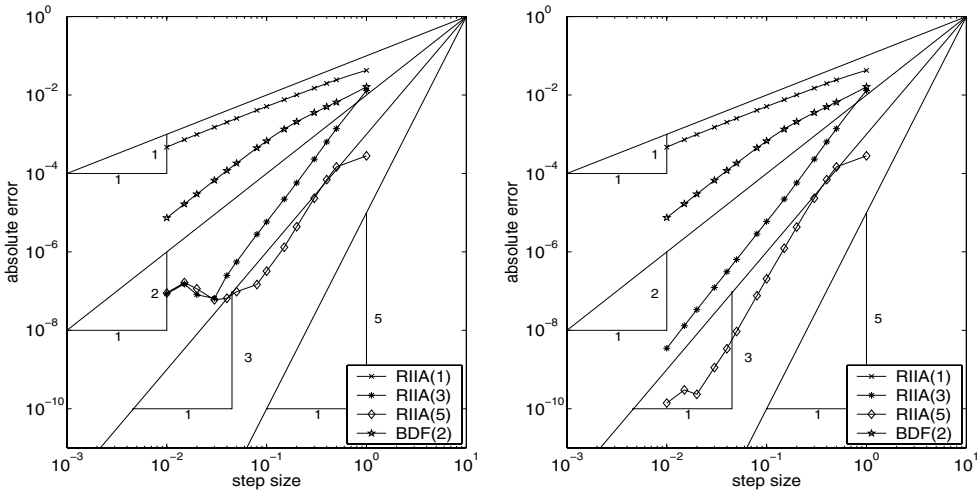

FIG. 5.2. *Absolute error versus step size* h *in logarithmic scale, for different integration methods, with* $K = 15$ *(left) and* $K = 30$ *(right).*

a tolerance of 10^{-12} in the Newton method. The error is calculated with respect to a reference solution, obtained with $h = 0.001$. Figure 5.1 shows the evolution of the absolute error and the oscillating solution u.

Figure 5.2 shows the errors $u_n - u(t_n)$ versus the step size h at time $t_n = 60$ for $K = 15$ and $K = 30$.

Figure 5.3 plots the cpu time versus the number of integration steps, up to 10^6 time steps. The near-linear growth of the computational work is clearly visible.

5.2. Fractional diffusion with transparent boundary conditions. Here we consider a fractional diffusion equation on the real line; see, e.g., [15] for applications of such equations in physics and for numerous references. The equation can be formulated as

$$u(x,t) - u_0(x) = \int_0^t \frac{(t-\tau)^{\alpha-1}}{\Gamma(\alpha)}\, \partial_{xx} u(x,\tau)\, d\tau + g(x,t) \quad \text{for } x \in \ , \quad t > 0, \tag{5.2}$$

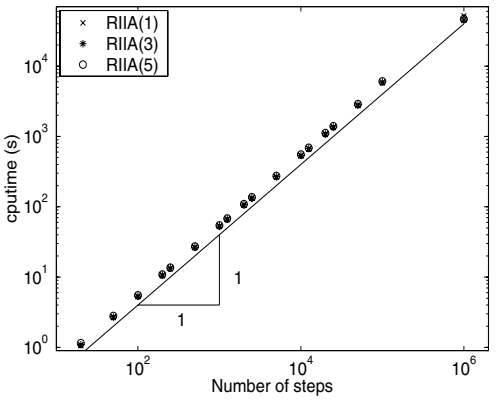

FIG. 5.3. *Cpu time in seconds versus the number of integration steps.*

with the asymptotic condition $u(x,t) \to 0$ for $x \to \pm\infty$, for an inhomogeneity g with $g(x,0) = 0$. To reduce the computation to a finite domain $x \in [-a,a]$ for initial data u_0 and inhomogeneity g with support in $[-a,a]$, we impose transparent boundary conditions at $x = \pm a$, which read

$$u(\pm a,t) = -\int_0^t \frac{(t-\tau)^{\alpha/2-1}}{\Gamma(\alpha/2)}\, \partial_\nu u(\pm a,\tau)\, d\tau, \tag{5.3}$$

with the outward derivative $\partial_\nu = \pm\partial_x$ at $x = \pm a$. These boundary conditions are derived with Laplace transform techniques in the same way as for the wave or the Schrödinger equation; see, e.g., [2]. Space discretization of (5.2) is done using second-order finite differences and a central finite difference to approximate the normal derivative. With the notation

$$\delta_{xx} u_l^n = \frac{1}{\Delta x^2}\big(u_{l-1}^n - 2u_l^n + u_{l+1}^n\big)\ , \quad \delta_\nu u_{\pm(M-1)}^n = \frac{1}{2\Delta x}\big(u_{\pm M}^n - u_{\pm(M-2)}^n\big)$$

for $a = M\Delta x$, the discrete equation approximating (5.2) is

$$\begin{aligned} u_l^{n+1} - u_l^0 &= \sum_{j=0}^{n} \omega_{n-j}^{(\alpha)}\, \delta_{xx} u_l^{j+1} + g_l^n \quad \text{for } l = -(M-1),\dots,M-1\ ;\ n>0, \\ u_{\pm(M-1)}^{n+1} &= -\sum_{j=0}^{n} \omega_{n-j}^{(\alpha/2)}\, \delta_\nu u_{\pm(M-1)}^{j+1}\ , \end{aligned} \tag{5.4}$$

where the weights $\omega_n^{(\beta)}$ are the convolution quadrature weights of the backward Euler method for the kernel $f(t) = t^{\beta-1}/\Gamma(\beta)$ with Laplace transform $F(s) = s^{-\beta}$. In this case $g_l^n = g(x_l, t_n + h)$.

In the numerical example we set $a = 5$ and $M = 450$. We consider the problem with $\alpha = 2/3$ and no inhomogeneity, i.e., $g \equiv 0$. The initial value is $u(x,0) = \exp(-x^2)$. Figure 5.4 shows the errors at $t = 2$ and $t = 10$ in dependence on the step size for the convolution quadratures based on the Radau IIA methods of orders 1, 3, 5, obtained with $B = 5$ and $K = 15$ in the fast convolution algorithm, by using the hyperbola contours. The reference solution is obtained with the convolution quadrature based on the Radau IIA method of order 5, with a small step size $h = 0.0002$

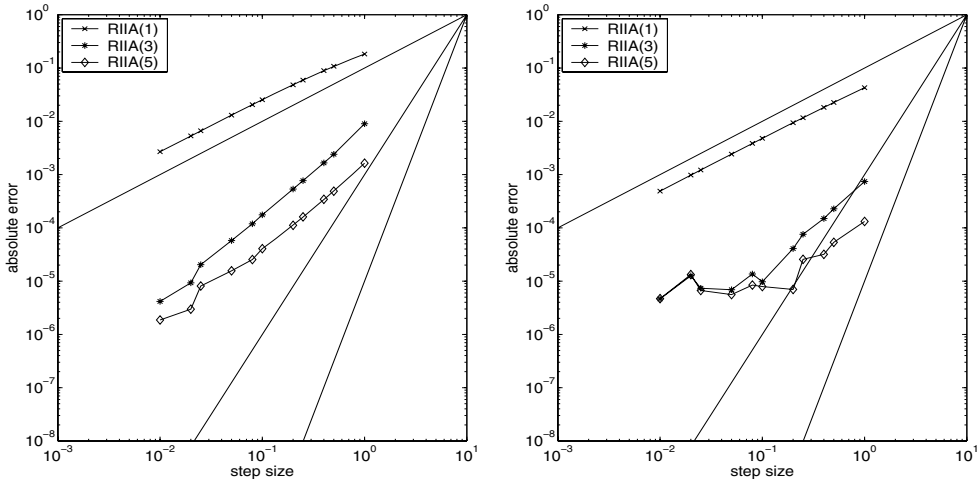

FIG. 5.4. *Absolute error versus time step in logarithmic scale, for different integration methods, with* $K = 15$. *Left* $t = 2$, *right* $t = 10$.

and large number $K = 40$ of nodes on the integration contour. We observe an order reduction for the higher-order methods, which is due to the temporal nonsmoothness of the solution at $t = 0$; cf. [1, sect. 8]. Nevertheless, the higher-order methods give much better accuracy.

The work diagram looks almost identical to Figure 5.3, showing practically linear dependence of the computational work on the number of time steps. The required memory is less than 200 entries per spatial grid point for up to $N \leq 10^4$ steps and less than 300 entries per grid point for $N \leq 10^6$ steps. These numbers are halved if we run the algorithm with $B = 10$, $K = 10$ instead of $B = 5$, $K = 15$, as is sufficient for less stringent accuracy requirements ($\sim 10^{-3}$).

Acknowledgment. We thank Cesar Palencia for helpful discussions during the preparation of this paper.

TWO-LEVEL TOEPLITZ PRECONDITIONING: APPROXIMATION RESULTS FOR MATRICES AND FUNCTIONS*

D. NOUTSOS†, S. SERRA CAPIZZANO‡, AND P. VASSALOS†

Abstract. Large 2-level Toeplitz systems arise in a variety of applications (see, e.g., [R. H. Chan and M. Ng, *SIAM Rev.*, 38 (1996), pp. 427–482]) for which efficient numerical methods for their solution are required. Some successful numerical techniques need the explicit knowledge of the generating function f of the considered system $T_n(f)\mathrm{x} = b$, an assumption that usually is not fulfilled in real applications. In this paper we analyze and complete the procedure proposed in [D. Noutsas, S. Serra Capizzano, and P. Vassalos, *Numer. Linear Algebra Appl.*, 12 (2005), pp. 231–239] for the 2-level case. In such a way, from the knowledge of the coefficients of $T_n(f)$, we determine optimal preconditioning strategies for the solution of our systems. Finally, some numerical experiments are performed and discussed in connection with our theoretical analysis.

Key words. 2-level Toeplitz matrix, conjugate gradient, preconditioning, preconditioned conjugate gradient

1. Introduction.

In this paper we consider the preconditioning of 2-level Toeplitz systems of the form $T_n(f)\mathrm{x} = b$, where $n = (n_1, n_2)$ have large components, the symbol f is assumed to be defined on $\mathbf{R}$, real-valued, 2π-periodic, and continuous, $(T_n(f))_{(j,k)(p,q)} = t_{k-j,q-p}$ with $t_{r,s}$ being the Fourier coefficients of f, i.e.,

$$t_{r,s} = \frac{1}{4\pi^2}\int_{-\pi}^{\pi}\int_{-\pi}^{\pi} f(x,y)\exp(-\mathbf{i}(rx+sy))dxdy, \quad \mathbf{i}^2 = -1.$$

Here the 2-index notation $(T_n(f))_{(j,k)(p,q)}$, $n = (n_1, n_2)$, indicates that we are selecting the block (j,k) of size n_2 with $j,k \in \{1,\ldots,n_1\}$ and, in that block, we are selecting the entry (p,q), $p,q \in \{1,\ldots,n_2\}$.

Such matrices (often also called block Toeplitz with Toeplitz blocks) arise in several applications (see, e.g., [6, 11, 13]), such as Markov chains, integral equations, in the solution of certain partial differential equations (PDEs), and image restoration. In some contexts the generating function f is explicitly given or can be easily obtained, but in many others, like image processing, Markov chains, and tomography, the analytic expression of the symbol is not available and, as a consequence, we do not know crucial properties such as the presence of zeros, their localization, or their multiplicities. We recall that the considered information is essential to understand the spectral properties (extreme eigenvalues, ill-conditioning, ill-posedness) of the matrices and therefore to select the most suitable preconditioning methods (see [19, 12]). The 1-level case has been treated in [23] using band Toeplitz preconditioners and in

[18] using circulant-like preconditioners constructed by positive reproducing kernels. These circulant preconditioners, as well as those belonging to more general matrix algebras, possess a natural extension in the 2-level setting. However, a quite general theory shows that it is impossible to find any of these 2-level extensions preserving either the superlinear or the optimal behavior: see [31, 25, 32] for negative results regarding the notion of superlinearity and [14, 15] for negative results regarding the notion of optimality.

We recall that the spectral properties of the Toeplitz matrices are described very precisely by the symbol (see, e.g., [3, 16]). For instance, if zero belongs to the range of f, then the sequence $\{T_n(f)\}_n$ is asymptotically ill-conditioned (for $n \to \infty$, $n = (n_1, n_2)$, i.e., for $n_1, n_2 \to \infty$): more precisely, the problem will be ill-posed in a discrete sense if f has a nondefinite sign while we have invertibility but asymptotical ill-conditioning if f is nonnegative (or equivalently nonpositive). In the latter we need preconditioning and an optimal technique consists in using $T_n(g)$ as a preconditioner where g is a nonnegative trigonometric polynomial which has the same zeros as f with the same orders. Any system related to $T_n(g)$ is banded and can be solved, under suitable assumptions, by multigrid methods [9] or cyclic reduction techniques [4, 5] in linear time; moreover, the preconditioning sequence is optimal so that only a fixed number of preconditioned conjugate gradient (PCG) iterations (independent of n_1 and of n_2) has to be performed in order to reach the solution within a preassigned accuracy. In conclusion, we need algorithms for determining analytical information on the zeros of f. In [17], by extending the proposal in [23], the 2-level case is considered for generating functions only known through the matrix coefficients (i.e., the Fourier coefficients of f): the main idea is to approximate f over the grid

$$\mathcal{S}_n = \left\{ \left(-\pi + \frac{2k\pi}{n_1} \ , \ -\pi + \frac{2j\pi}{n_2} \right), k = 1, 2, \ldots, n_1 \ , \ j = 1, 2, \ldots, n_2 \right\} \tag{1.1}$$

on the square $Q = (-\pi, \pi]^2$, and then we proceed by looking for the roots of f, by estimating their multiplicities, by characterizing the problem (well-conditioned, ill-conditioned, ill-posed), by choosing the appropriate method, and finally by constructing the chosen preconditioner. Since the zeros cannot be computed exactly in general, we also need to check the robustness of the preconditioning technique with regard to numerical/approximation errors in the computation of the position of the zeros. The contribution of this paper relies in giving a theoretical support to the heuristic proposal given in [17], by using and extending new tools developed in [29], and in giving a numerical procedure for approximating the polynomial factors of the symbol in the case of curves of zeros.

The paper is organized as follows. In section 2 we report basic results from the quoted literature, and in section 3 the proposed approach is theoretically analyzed and some numerical results are given.

2. Basic theory.

2.1. Results from the literature. In the following when we write inf and sup we mean the essential infimum and the essential supremum, i.e., up to zero measure sets (with respect to the Lebesgue measure); when we write $f \sim g$ we mean that there exist positive real constants r and R such that $rg(x, y) \leq f(x, y) \leq Rg(x, y)$ for almost every (x, y) in the definition set of f and g. Moreover, when we write $a_n \sim b_n$ and $\{a_n\}$ and $\{b_n\}$ are sequences, we understand that there exist positive real constants r and R such that $rb_n \leq a_n \leq Rb_n$ for every n. (Notice that in both

the instances, the case $R = +\infty$ is excluded.) A nonnegative function f has a zero at (x_0, y_0) if for every neighborhood I of (x_0, y_0) we have $\inf_{(x,y)\in I} f(x, y) = 0$. A set $\mathcal{S}$ of zeros of $f \geq 0$ is isolated if there exists a neighborhood J of $\mathcal{S}$ such that for every neighborhood $I \subset J, I \neq J$ of $\mathcal{S}$ we have $\inf_{(x,y)\in J\setminus I} f(x, y) > 0$. Furthermore, we write that a nonnegative function f has a zero of order at least $\alpha \geq 0$ at (x_0, y_0) if and only if there exist a positive constant c such that $f(x, y) \leq c\|(x, y) - (x_0, y_0)\|^\alpha$ in a suitable neighborhood of (x_0, y_0) and for some norm $\|\cdot\|$. We write that its order is $+\infty$ if it is of order at least α for every $\alpha > 0$ or in other words if

$$\lim_{(x,y)\to(x_0,y_0)} \frac{f(x, y)}{\|(x, y) - (x_0, y_0)\|^\alpha} = 0 \quad \forall \alpha > 0.$$

For our purpose, we will consider the following general definition for a zero of order $\alpha > 0$.

DEFINITION 1. [illegible] f [illegible] $L^1(Q)$ [illegible] (x_0, y_0) [illegible] $\alpha \in (0, \infty)$ [illegible] p [illegible] $\mathcal{C}_i$ $i = 1, \ldots, p$ [illegible] $l_i(x, y) = 0$ [illegible] (x_0, y_0) [illegible] $f \sim \breve{f}$ [illegible]

$$\breve{f}(x, y) = \sum_{i=1}^{p} |l_i(x, y)|^\alpha + g(x, y),$$

[illegible] g [illegible] (x_0, y_0) [illegible] $\beta > \alpha$

The above definition is quite general and includes many different cases, such as $f(x, y) = |x - x_0|^4 + |y - y_0|^3$ ($f = \breve{f}$, isolated zero at (x_0, y_0), $p = 1$, $\alpha = 3$, $\beta = 4$, $l_1(x, y) = y - y_0$, $g(x, y) = |x - x_0|^4$); $f(x, y) = |1 - x^2 - y^2|^2 + h(x, y)\exp(-1/(1 - x^2 - y^2))$, $h(x, y) \in L^\infty(Q)$ with positive essential range ($f = \breve{f}$, isolated curve of zeros represented by the circle centered at zero with radius 1, $p = 1$, $\alpha = 2$, $\beta = \infty$, $l_1(x, y) = 1 - x^2 - y^2$, $g(x, y) = h(x, y)\exp(-1/(1 - x^2 - y^2))$); $f(x, y) = |\sin(x^2+y^4+(x-y)^2)|+(x^2+y^2)^4$ ($\breve{f}(x, y) = x^2+y^4+(x-y)^2+(x^2+y^2)^4$, isolated zero at $(0, 0)$, $p = 2$, $\alpha = 2$, $\beta = 4$, $l_1(x, y) = x$, $l_2(x, y) = x - y$, $g(x, y) = y^4 + (x^2 + y^2)^4$).

LEMMA 1 (see [21, 16]). [illegible] f [illegible] $L^1(Q)$ [illegible] $\alpha < \infty$ [illegible] 1 [illegible] $T_n(f)$ $n = (n_1, n_2)$ [illegible] $\lambda_{\min}(T_n(f))$ [illegible] $\lambda_{\min}(T_n(f)) \sim \nu^{-\alpha}$ [illegible] $n_1 \sim n_2 \sim \nu$ [illegible] $f = f_n$ [illegible] n [illegible] n [illegible] 1

For a generic n-by-n matrix X with complex entries we define

$$\|X\|_p = \begin{cases} \left(\frac{\sum_{j=1}^n \sigma_j^p}{n}\right)^{1/p} & \text{if } p \in [1, \infty), \\ \sigma_1 & \text{if } p = \infty \end{cases}$$

with $\sigma_1 \geq \sigma_2 \geq \cdots \geq \sigma_n$ denoting the singular values of X. Furthermore, indicating by $m\{\cdot\}$ the Lebesgue measure (on Q in the present case), for $f \in L^p(Q)$ and $p \in [1, \infty)$, we define $\|f\|_p = \left[\frac{1}{m\{Q\}} \int_Q |f(x)|^p \, dx\right]^{1/p}$ and $\|f\|_\infty = \sup_{x\in Q} |f(x)|$ for $f \in L^\infty(Q)$, $p = \infty$, and sup denoting the essential supremum, i.e., up to zero measure sets.

LEMMA 2 (see [30, 26]). [illegible] f [illegible] $L^p(Q)$ [illegible] $\|T_n(f)\|_p \leq \|f\|_p$ [illegible] $\lim_{n\to\infty} \|T_n(f)\|_p = \|f\|_p \ \forall p \in [1, \infty]$

Finally, for θ Lebesgue measurable over $D \subset \mathbf{R}^k$, with k positive integer and $0 < m\{D\} < \infty$, the expression "$\{A_n\}$ is distributed as the measurable function θ" with A_n of size $N(n)$ is equivalent to writing that for any $F \in \mathcal{C}_0$ (continuous with bounded support) it holds

$$\lim_{n\to\infty} \frac{1}{N(n)} \sum_{j=1}^{N(n)} F\left(\lambda_j\left(A_n\right)\right) = \frac{1}{m\{D\}} \int_D F\left(\theta(x)\right)\, dx,$$

where $\{\lambda_j\left(A_n\right) : \ j = 1, \ldots, N(n)\}$ denotes the complete set of the eigenvalues of A_n and where n could be either a positive integer or a positive multi-index. Often the considered distribution results for the eigenvalues hold for Hermitian sequences, but there exist many noteworthy exceptions in the complex field (concerning non-Hermitian sequences): the case of Toeplitz sequences generated by complex-valued symbols whose range has nonempty interior and for which the complement of the range is a connected set in the complex field (see [33]), the case of quasi-Hermitian discretizations of finite difference differential operators (see [10]), and the case of the preconditioned sequences considered in Lemma 3. In our context we have $D = Q$, $k = 2$, and the matrices A_n are either Hermitian Toeplitz or preconditioned matrices (see Lemma 3) which can be turned into Hermitian ones by similarity transformations.

Now we recall a basic result which is the foundation of the band Toeplitz preconditioning.

LEMMA 3 (see [8, 27]). [illegible] f [illegible] g [illegible] $L^1(Q)$ [illegible] f/g [illegible]

$$\inf f/g < \lambda(T_n^{-1}(g)T_n(f)) < \sup f/g$$

[illegible] $\{T_n^{-1}(g)T_n(f)\}$ [illegible] f/g

We explain the band Toeplitz preconditioning approach with an example. Consider the function $f(x, y) = x^2 + y^2$ which has a unique zero of order two at $z_0 = (0, 0)$. The matrix $T_n(f)$ is full but can be optimally preconditioned by the simple band Toeplitz matrix

$$T_n(g) = \begin{bmatrix} B & -I & & & \\ -I & \ddots & \ddots & & \\ & \ddots & & \ddots & \\ & & \ddots & \ddots & -I \\ & & & -I & B \end{bmatrix}_{n_1 \times n_1}, \quad B = \begin{bmatrix} 4 & -1 & & & \\ -1 & \ddots & \ddots & & \\ & \ddots & & \ddots & \\ & & \ddots & \ddots & -1 \\ & & & -1 & 4 \end{bmatrix}_{n_2 \times n_2}$$

with I denoting the $n_2 \times n_2$ identity matrix and with $g(x, y) = 4 - 2\cos(x) - 2\cos(y) = 4\sin^2(x/2) + 4\sin^2(y/2)$. By Lemma 3 we deduce that the eigenvalues of the preconditioned matrix $T_n^{-1}(g)T_n(f)$ are

1. contained in the interval $(1, \pi^2/4)$, $1 = \min f/g$, $\pi^2/4 = \max f/g$, and
2. globally distributed as the function f/g.

Therefore, irrespectively of the 2-index $n = (n_1, n_2)$ and of the size $N(n) = n_1 n_2$ of the considered linear system, the number of PCG iterations for which we need to find the solution within a fixed accuracy $\epsilon > 0$ can be bounded by a universal constant independent of n (which can be estimated as a function of ϵ [1]). Moreover, for the solution of a system with matrix $T_n(g)$, we can use solvers based on fast sine transforms (see, e.g., [34]) costing $\mathcal{O}(N(n) \log N(n))$ arithmetic operations (flops),

multigrid methods [9], or just classical Poisson solvers (based on the cyclic reduction idea; see, e.g., [4, 5]) with cost of $\mathcal{O}(N(n))$ flops. In conclusion the associated PCG method is optimal (in the sense of Axelsson and Neytcheva [2]) since

1. the cost of each iteration is $\mathcal{O}(N(n)\log N(n))$ flops, $N(n) = n_1 n_2$, that is of the same order as the cost of a matrix vector product, and
2. the number of iterations does not depend on n.

We observe that the main point for deriving such a result does not rely on the regularity of the function f. Actually, if $f(x,y) = x^2 + y^2$ is replaced by $f(x,y) = (x^2+y^2)h(x,y)$, where $h(x,y)$ is any function in $L^\infty(Q)$ with positive essential range, then the same $T_n(g)$ is still an optimal preconditioner.

Therefore, the crucial points are the number of the zeros or curves of zeros of f, which should be finite, and their order, which should be even (for the case where the order of the zeros is not even, to our knowledge, the best idea is the use of multigrid strategies [9, 28]).

However, in many practical situations we possess the coefficients $\{t_{r,s}\}$, in some cases we know the positive definiteness of the matrix $T_n(f)$ or even the fact that $T_n(f)$ is asymptotically ill-conditioned, but very often we do not have an explicit expression for f. In that cases we have to recover the minimal information for devising an optimal preconditioning technique, i.e., the position and the order of the zeros of f.

In [23] an economic strategy was devised for the numerical evaluation of the order and the position of the zeros in the 1-dimensional case. The technique has been heuristically extended to two dimensions in [17]: in [29] the theoretical explanation of the goodness of the procedure for the 1-dimensional case was given. Here we complete the picture by giving theoretical results in the 2-dimensional setting and giving a numerical procedure for approximating the polynomial factors of the symbol in the case of curves of zeros. In actuality, under the assumption that the zeros are even, we can determine exactly the order of the zeros but the position of these zeros is affected by an error for which we can provide a rough a priori bound.

In conclusion, we would like to study the spectral behavior of

$$T_n^{-1}(\tilde{g})T_n(f),$$

where $f \sim g$, g is a trigonometric polynomial of fixed degrees and the zeros of $\tilde{g}$ are an approximation of those of g. A simple example is given by the situation

$$g(x,y) = \prod_{j=0}^{k}(4 - 2\cos(x - x_j) - 2\cos(y - y_j))^{\alpha_j},$$
$$\tilde{g}(x,y) = \prod_{j=0}^{k}(4 - 2\cos(x - \tilde{x}_j) - 2\cos(y - \tilde{y}_j))^{\alpha_j}$$

and $(\tilde{x}_j, \tilde{y}_j)$ is an approximation of (x_j, y_j) $\forall j = 0, \ldots, k$, even if the most challenging case is the one where the zeros form a curve: in this respect there is the problem of approximating such a curve by using the zeros of a trigonometric polynomial; since the symbol f is known only through the set of its Fourier coefficients, a direct fast solution (requiring only FFTs) can be obtained by considering the zeros of approximations of f such as the Fourier polynomial of degree n or its Cesaro sum of the same degree.

In the following subsection we furnish some mathematical tools with which to answer this question and in the subsequent subsection we analyze the spectral features of (approximate) preconditioned matrix sequences.

2.2. Theoretical results. We read the first part of Lemma 3 in the following way: if f and g are two essentially nonnegative functions (not identically zero) such that f/g is not constant and $f \sim g$, then

$$\kappa_p\left(T_n^{-1/2}(g)T_n(f)T_n^{-1/2}(g)\right) < C := (\sup f/g)(\inf f/g)^{-1} < \infty$$

for any $p \in [1,\infty]$ and with $\kappa_p(X) = \|X\|_p\|X^{-1}\|_p$ being the condition number of an invertible matrix X with respect to the (scaled) Schatten norm $\|\cdot\|_p$, $p \in [1,\infty]$. In the following we suppose to have a perturbed g, let us say g_n, such that g_n is not equivalent to f but it is close in norm to g. We try to see what happens to the condition numbers of the perturbed symmetrized preconditioned matrix

$$T_n^{-1/2}(g_n)T_n(f)T_n^{-1/2}(g_n).$$

THEOREM 1. [illegible] $f \sim g$ [illegible] $f_n \sim g_n$ [illegible] $n = (n_1, n_2)$ [illegible] $f, f_n, g, g_n \in L^p(Q)$ $p \in [1,\infty]$ [illegible] f [illegible] $\alpha < \infty$ [illegible] 1 [illegible] f_n [illegible] $\beta < \infty$ [illegible] 1 [illegible] C_1, C_2, q_1, q_2 [illegible] n [illegible]

$$\kappa_p\left(T_n^{-1/2}(g_n)T_n(f)T_n^{-1/2}(g_n)\right) \le \left[C_1 + q_1\nu^{\alpha}\|g_n - g\|_p\right]\left[C_2 + q_2\nu^{\beta}\|f_n - f\|_p\right]$$

[illegible] $n_1 \sim n_2 \sim \nu$ [illegible]. From the equivalence relationships $f_n \sim g_n$ and $f \sim g$, we infer that there exists constants C_1 and C_2, independent of n, such that

$$\sup g/f \le C_1, \quad \sup f_n/g_n \le C_2. \tag{2.1}$$

Moreover, from the nonnegativity of f and g_n and from the assumption on the maximal order of their zeros, by applying Lemma 1, we deduce that $\lambda_{\min}(T_n(f)) \sim \nu^{-\alpha}$ and that $\lambda_{\min}(T_n(g_n)) \sim \nu^{-\beta}$. Therefore, there exist absolute constants q_1 and q_2 independent of n for which we have

$$\|T_n^{-1}(f)\|_\infty \le q_1\nu^{\alpha}, \quad \|T_n^{-1}(g_n)\|_\infty \le q_2\nu^{\beta}. \tag{2.2}$$

Then, by the plain definition of the condition number, we have

$$\kappa_p\left(T_n^{-1/2}(g_n)T_n(f)T_n^{-1/2}(g_n)\right) = X_nY_n,$$

where

$$X_n = \|T_n^{-1/2}(g_n)T_n(f)T_n^{-1/2}(g_n)\|_p, \quad Y_n = \|T_n^{1/2}(g_n)T_n^{-1}(f)T_n^{1/2}(g_n)\|_p.$$

Moreover, since $\sigma_j(XY) \le \|X\|_\infty\sigma_j(Y)$, by definition of $\|\cdot\|_p$ norm, it follows that

$$\|XY\|_p \le \|X\|_\infty\|Y\|_p, \tag{2.3}$$

which corresponds to the submultiplicative property if $p = \infty$. Since $f_n \sim g_n$ with equivalence constants independent of n, by Lemma 3 we deduce that the spectrum of $T_n^{-1/2}(g_n)T_n(f_n)T_n^{-1/2}(g_n)$ is uniformly bounded away from zero and infinity (refer

to the constant C_2 in (2.1)). By invoking Lemma 2, we know that $\|T_n(f-f_n)\|_p \le \|f_n - f\|_p$ and by (2.2) we know that $\|T_n^{-1}(g_n)\|_\infty \le q_2\nu^\beta$. Therefore, by invoking the triangle inequality and (2.3) applied twice, we have

$$\begin{aligned} X_n &\le \|T_n^{-1/2}(g_n)T_n(f_n)T_n^{-1/2}(g_n)\|_p + \|T_n^{-1/2}(g_n)T_n(f-f_n)T_n^{-1/2}(g_n)\|_p \\ &\le C_2 + q_2\nu^\beta\|f_n - f\|_p. \end{aligned}$$

Moreover, since $T_n^{1/2}(g_n)T_n^{-1}(f)T_n^{1/2}(g_n)$ is positive definite, its spectral norm Y_n coincides with its maximal eigenvalue and since $T_n^{1/2}(g_n)T_n^{-1}(f)T_n^{1/2}(g_n)$ is similar to $T_n(g_n)T_n^{-1}(f)$ and the latter is similar to $T_n^{-1/2}(f)T_n(g_n)T_n^{-1/2}(f)$ which is positive definite, it follows that

$$\begin{aligned} Y_n &= \|T_n^{-1/2}(f)T_n(g_n)T_n^{-1/2}(f)\|_p \\ &\le \|T_n^{-1/2}(f)T_n(g)T_n^{-1/2}(f)\|_p + \|T_n^{-1/2}(f)T_n(g_n-g)T_n^{-1/2}(f)\|_p \\ &\le C_1 + q_1\nu^\alpha\|g_n - g\|_p, \end{aligned}$$

where in last inequality we have made recourse to Lemma 3 with the constant C_1 in (2.1), to Lemma 2, and to relations (2.2) and (2.3).

Finally we conclude that

$$\kappa_p\left(T_n^{-1/2}(g_n)T_n(f)T_n^{-1/2}(g_n)\right) \le [C_1 + q_1\nu^\alpha\|g_n - g\|_p]\left[C_2 + q_2\nu^\beta\|f_n - f\|_p\right]$$

and the proof is over. □

2.3. The robustness of the inexact band Toeplitz preconditioning. First we show that the error that we make in the evaluation of the zeros must be infinitesimal: if this is not the case, then the associated "inexact" band Toeplitz preconditioning is no longer optimal.

For the sake of simplicity, let us take a nonnegative essentially bounded function f with a unique zero of order 2α (α positive integer) at (x_0, y_0) and suppose that $g(x,y) = (2-2\cos(x-x_0))^\alpha + (2-2\cos(y-y_0))^\alpha$ and $\tilde g(x,y) = (2-2\cos(x-\tilde x_0))^\alpha + (2-2\cos(y-\tilde y_0))^\alpha$ with $(\tilde x_0, \tilde y_0) = (x_0, y_0) + (\delta_1, \delta_2)$. Here δ_1, δ_2 are fixed quantities independent of $n = (n_1, n_2)$ with $\|(\delta_1, \delta_2)\|_\infty \ne 0$. The following facts hold:

1. $\lim_{n\to\infty} \lambda_{\min}(T_n(f)) = 0$, $\lambda_{\max}(T_n(f)) \le \|f\|_\infty < \infty$;
2. $\lim_{n\to\infty} \lambda_{\min}(T_n^{-1}(\tilde g)T_n(f)) = 0$, $\lim_{n\to\infty} \lambda_{\max}(T_n^{-1}(\tilde g)T_n(f)) = \infty$,

where the claim in 1 is a consequence of Lemma 1 and the claim in 2 follows from the second part of Lemma 3. In actuality, by Lemma 3, the sequence $\{T_n^{-1}(\tilde g)T_n(f)\}$ is distributed as $h = f/\tilde g$ where h has a zero at (x_0, y_0) which is responsible for the relation $\lim_{n\to\infty} \lambda_{\min}(T_n^{-1}(\tilde g)T_n(f)) = 0$ and has a pole at $(\tilde x_0, \tilde y_0) = (x_0, y_0) + (\delta_1, \delta_2)$ which is responsible for the relation $\lim_{n\to\infty} \lambda_{\max}(T_n^{-1}(\tilde g)T_n(f)) = \infty$. In conclusion, it is self-evident that the associated PCG algorithm cannot be optimal and therefore we have to determine the root (x_0, y_0) within an error infinitesimal as n goes to infinity.

2.3.1. Isolated zeros. We proceed as follows. In full generality, let us suppose that f has $k+1$ zeros of even order $2\alpha_0, 2\alpha_1, \ldots, 2\alpha_k$ at $(x_0, y_0), (x_1, y_1), \ldots, (x_k, y_k)$ and let us take

$$g_n(x,y) = \prod_{j=0}^{k} [(2-2\cos(x-x_{j,n}))^{\alpha_j} + (2-2\cos(y-y_{j,n}))^{\alpha_j}]$$

with $\|(x_j, y_j) - (x_{j,n}, y_{j,n})\|_\infty \le \epsilon_\nu$, $n = (n_1, n_2)$, $n_1 \sim n_2 \sim \nu$. We wish to determine ϵ_ν such that

$$\kappa_\infty \left(T_n^{-1/2}(g_n) T_n(f) T_n^{-1/2}(g_n) \right) \le K, \tag{2.4}$$

where K is a universal constant independent of $n = (n_1, n_2)$.

By reading Theorem 1 with $p = \infty$ in our specific case, we obtain that

$$\begin{aligned} \kappa_\infty \left(T_n^{-1/2}(g_n) T_n(f) T_n^{-1/2}(g_n) \right) \le & \left[C_1 + q_1 \nu^{2\alpha_{\max}} \|g_n - g\|_\infty \right] \\ & \left[C_2 + q_2 \nu^{2\alpha_{\max}} \|f_n - f\|_\infty \right] \end{aligned} \tag{2.5}$$

with $n_1 \sim n_2 \sim \nu$. In the above equation the functions g and f_n have to be chosen in order to minimize $\|g_n - g\|_\infty$ and $\|f_n - f\|_\infty$ but with the constraint that $g \sim f$ and $f_n \sim g_n$. In such a way we hope to obtain a bound like the one in (2.4). An obvious proposal is represented by

$$\begin{aligned} g(x, y) &= g_n(x + (x_{j,n} - x_j), y + (y_{j,n} - y_j)), \\ f_n(x, y) &= f(x + (x_j - x_{j,n}), y + (y_j - y_{j,n})). \end{aligned} \tag{2.6}$$

It is evident that

$$g(x, y) = \prod_{j=0}^{k} [(2 - 2\cos(x - x_j))^{\alpha_j} + (2 - 2\cos(y - y_j))^{\alpha_j}],$$

$g \sim f$, and $f_n \sim g_n$; moreover a simple manipulation shows that

$$\|g - g_n\|_\infty \le \|\nabla g\|_\infty \epsilon_\nu \quad \text{and} \quad \|f - f_n\|_\infty \le L \epsilon_\nu^\gamma$$

if f is Hölder continuous with parameter $\gamma \in (0, 1]$ and constant $L > 0$. (In the regular case, e.g., if f is continuously differentiable, then f is Lipschitz continuous and therefore $L = \|\nabla f\|_\infty$ and $\gamma = 1$.) Here when we write $\|\nabla g\|_\infty$ and $\|\nabla f\|_\infty$, we mean the 1-norm of the vector composed by the infinity norms of the two components.

However, we can obtain a better estimate by choosing

$$g(x, y) = \begin{cases} g_n(x, y) & \text{if } \mathcal{A} \text{ holds true,} \\ g_n(x + (x_{j,n} - x_j), y + (y_{j,n} - y_j)) & \text{if } \mathcal{B} \text{ holds true,} \end{cases}$$

$$f_n(x, y) = \begin{cases} f(x) & \text{if } \mathcal{A} \text{ holds true,} \\ f(x + (x_j - x_{j,n}), y + (y_j - y_{j,n})) & \text{if } \mathcal{B} \text{ holds true} \end{cases} \tag{2.7}$$

with $\delta = 2\epsilon_\nu$, condition $\mathcal{A}$ being $\|(x, y) - (x_{j,n}, y_{j,n})\|_\infty > \delta \; \forall j = 0, \ldots, k$ and condition $\mathcal{B}$ being $\exists j \in \{0, \ldots, k\}$ such that $\|(x, y) - (x_{j,n}, y_{j,n})\|_\infty \le \delta$. In this way, due to the definition of order of zero, we have $\|g_n - g\|_\infty \le z_1 \epsilon_\nu^{2\alpha_{\min}}$ and $\|f_n - f\|_\infty \le z_2 \epsilon_\nu^{2\alpha_{\min}}$ for suitable absolute constants z_1 and z_2: beside the better approximation estimate, a surprising further advantage, when compared with the proposal in (2.6), is that we do not have to require any regularity to the function f. Furthermore, to apply the crucial relation (2.5) we have to verify that $f \sim g$ and $f_n \sim g_n$. This result is contained in the following theorem.

THEOREM 2. [illegible] f [illegible] $k + 1$ [illegible] $2\alpha_0, 2\alpha_1, \ldots, 2\alpha_k$ [illegible] $(x_0, y_0), (x_1, y_1), \ldots, (x_k, y_k)$ [illegible]

$$g_n(x, y) = \prod_{j=0}^{k} [(2 - 2\cos(x - x_{j,n}))^{\alpha_j} + (2 - 2\cos(y - y_{j,n}))^{\alpha_j}]$$

... $\|(x_j, y_j) - (x_{j,n}, y_{j,n})\|_\infty \le \epsilon_\nu$ $n = (n_1, n_2)$ $n_1 \sim n_2 \sim \nu$ ... f_n ... g ... (2.7) ... $f \sim g$ ... $f_n \sim g_n$ ... The proof of $f \sim g$ is equivalent to writing that $\frac{f}{g}$ and $\frac{g}{f}$ are uniformly bounded. Setting

$$g^*(x,y) = \prod_{j=0}^{k} \left[(2 - 2\cos(x - x_j))^{\alpha_j} + (2 - 2\cos(y - y_j))^{\alpha_j}\right],$$

by the assumptions on f, we have $\max\{\sup \frac{f(x,y)}{g^*(x,y)}, \sup \frac{g^*(x,y)}{f(x,y)}\} = C^* < \infty$. Therefore

$$\begin{aligned}
\sup \frac{f(x,y)}{g(x,y)} &= \max\left\{ \sup_{(x,y):\ \mathcal{A} \text{ holds}} \frac{f(x,y)}{g(x,y)}, \sup_{(x,y):\ \mathcal{B} \text{ holds}} \frac{f(x,y)}{g(x,y)} \right\} \\
&= \max\left\{ \sup_{(x,y):\ \mathcal{A} \text{ holds}} \frac{f(x,y)}{g(x,y)}, \sup_{(x,y):\ \mathcal{B} \text{ holds}} \frac{f(x,y)}{g^*(x,y)} \right\} \\
&\le \max\left\{ \sup_{(x,y):\ \mathcal{A} \text{ holds}} \frac{f(x,y)}{g(x,y)}, \sup \frac{f(x,y)}{g^*(x,y)} \right\} \\
&\le \max\left\{ \sup_{(x,y):\ \|(x,y)-(x_{j,n},y_{j,n})\|_\infty > 2\epsilon_\nu} \frac{f(x,y)}{g(x,y)}, C^* \right\}.
\end{aligned}$$

Now, by exploiting the asymptotical behavior of f and g in a neighborhood of the roots, we obtain

$$\sup \frac{f(x,y)}{g(x,y)} \le \sup_{(x,y):\ \|(x,y)-(x_{j,n},y_{j,n})\|_\infty > 2\epsilon_\nu} \hat{C} \frac{\|(x,y) - (x_j,y_j)\|_\infty^{2\alpha_{\max}}}{\|(x,y) - (x_{j,n},y_{j,n})\|_\infty^{2\alpha_{\max}}} + C^*$$

with $\hat{C}$ absolute constant independent of n. Hence by triangle inequality we deduce

$$\begin{aligned}
\sup \frac{f(x,y)}{g(x,y)} &\le \sup_{(x,y):\ \|(x,y)-(x_{j,n},y_{j,n})\|_\infty > 2\epsilon_\nu} \hat{C} \left[1 + \frac{\|(x_{j,n},y_{j,n}) - (x_j,y_j)\|_\infty}{\|(x,y) - (x_{j,n},y_{j,n})\|_\infty}\right]^{2\alpha_{\max}} + C^* \\
&\le \hat{C}(1.5)^{2\alpha_{\max}} + C^*,
\end{aligned}$$

where in the last inequality we have made recourse to the relations $\|(x_j, y_j) - (x_{j,n}, y_{j,n})\|_\infty \le \epsilon_\nu$ and $\|(x,y) - (x_{j,n}, y_{j,n})\|_\infty > 2\epsilon_\nu$.

A uniform bound (independent of n) is found along the same reasoning lines also for $\sup \frac{g(x,y)}{f(x,y)}$, $\sup \frac{f_n(x,y)}{g_n(x,y)}$ and $\sup \frac{g_n(x,y)}{f_n(x,y)}$ and therefore the theorem is proven. □

Finally, taking into account (2.5), the optimality is maintained i.e. (2.4) is satisfied if $\epsilon_\nu^{2\alpha_{\min}} \nu^{2\alpha_{\max}} = \mathcal{O}(1)$ which is equivalent to the relation $\epsilon_\nu = \mathcal{O}(\nu^{-\frac{\alpha_{\max}}{\alpha_{\min}}})$.

2.3.2. Curves of zeros. In the case of curves of zeros we suppose that f has $k+1$ regular curves of zeros of even order $2\alpha_0, 2\alpha_1, \ldots, 2\alpha_k$ at $(x_0(t), y_0(t)), (x_1(t), y_1(t)), \ldots, (x_k(t), y_k(t))$, $t \in [0,1]$, where $(x_j(t), y_j(t))$, $j = 0, \ldots, k$, is the solution of the implicit equation $l_j(x,y) = 0$. Let us take

$$g_n(x,y) = \prod_{j=0}^{k} (2 - 2\cos(l_{j,n}(x,y)))^{\alpha_j}$$

with $(x_{j,n}(t), y_{j,n}(t))$, $j = 0, \ldots, k$, being solution of the (approximate) implicit equation $l_{j,n}(x, y) = 0$, $\|(x_j(t), y_j(t)) - (x_{j,n}(t), y_{j,n}(t))\|_\infty \le \epsilon_\nu$, $n = (n_1, n_2)$, $n_1 \sim n_2 \sim \nu$. As in the case of isolated zeros the goal is to determine ϵ_ν such that

$$\kappa_\infty \left(T_n^{-1/2}(g_n) T_n(f) T_n^{-1/2}(g_n) \right) \le K, \tag{2.8}$$

where K is a universal constant independent of $n = (n_1, n_2)$. We consider Theorem 1 with $p = \infty$ in the latter context and then we have (2.5) with $n_1 \sim n_2 \sim \nu$ and where the functions g and f_n have to be chosen in order to minimize $\|g_n - g\|_\infty$ and $\|f_n - f\|_\infty$ but with the constraint that $g \sim f$ and $f_n \sim g_n$. In such a way, as in the case of the isolated zeros, we wish to obtain a bound as in (2.8). We consider the proposal described by

$$g(x, y) = \begin{cases} g_n(x, y) & \text{if } \mathcal{A} \text{ holds true,} \\ g_n(x + (x_{j,n} - x_j), y + (y_{j,n} - y_j)) & \text{if } \mathcal{B} \text{ holds true,} \end{cases} \tag{2.9}$$

$$f_n(x, y) = \begin{cases} f(x) & \text{if } \mathcal{A} \text{ holds true,} \\ f(x + (x_j - x_{j,n}), y + (y_j - y_{j,n})) & \text{if } \mathcal{B} \text{ holds true} \end{cases}$$

with $\delta = 2\epsilon_\nu$, condition $\mathcal{A}$ being $\|(x, y) - (x_{j,n}(t), y_{j,n}(t))\|_\infty > \delta \ \forall j = 0, \ldots, k$ and condition $\mathcal{B}$ being $\exists j \in \{0, \ldots, k\}$, $\exists \bar{t} \in [0, 1]$ such that $\|(x, y) - (x_{j,n}(\bar{t}), y_{j,n}(\bar{t}))\|_\infty \le \delta$. In this way, due to the definition of order of zero, we have $\|g_n - g\|_\infty \le z_1 \epsilon_\nu^{2\alpha_{\min}}$ and $\|f_n - f\|_\infty \le z_2 \epsilon_\nu^{2\alpha_{\min}}$ for suitable absolute constants z_1 and z_2: we stress that no regularity of the function f is explicitly required. Furthermore, to apply the crucial relation (2.5) we have to verify that $f \sim g$ and $f_n \sim g_n$. This result is contained in the following theorem.

THEOREM 3. [illegible] f [illegible] $k+1$ [illegible] $2\alpha_0, 2\alpha_1, \ldots, 2\alpha_k$ [illegible] $(x_0(t), y_0(t)), (x_1(t), y_1(t)), \ldots, (x_k(t), y_k(t))$ $t \in [0, 1]$ [illegible] $(x_j(t), y_j(t))$ $j = 0, \ldots, k$ [illegible] $l_j(x, y) = 0$ [illegible]

$$g_n(x, y) = \prod_{j=0}^{k} (2 - 2\cos(l_{j,n}(x, y)))^{\alpha_j}$$

[illegible] $(x_{j,n}(t), y_{j,n}(t))$ $j = 0, \ldots, k$ [illegible] $l_{j,n}(x, y) = 0$ $\|(x_j(t), y_j(t)) - (x_{j,n}(t), y_{j,n}(t))\|_\infty \le \epsilon_\nu$ $n = (n_1, n_2)$ $n_1 \sim n_2 \sim \nu$ [illegible] f_n [illegible] g [illegible] (2.9) [illegible] $f \sim g$ [illegible] $f_n \sim g_n$ [illegible] 2)

[illegible]. The proof is similar to that of Theorem 2. □

In view of (2.5), the optimality of the related PCG method is maintained, i.e., (2.4) is satisfied if $\epsilon_\nu^{2\alpha_{\min}} \nu^{2\alpha_{\max}} = \mathcal{O}(1)$ which is equivalent to the relation $\epsilon_\nu = \mathcal{O}(\nu^{-\frac{\alpha_{\max}}{\alpha_{\min}}})$. We remark that a trivial combination of Theorems 2 and 3 implies that the same conclusions hold in the case of combinations of isolated zeros and (regular) curves of zeros. Finally we have to emphasize a practical (and serious) difficulty which arises when curves of zeros are present: indeed, in that case, given the approximate curves of zeros, the proposed function $g_n(x, y)$ is not necessarily a trigonometric polynomial. Therefore the corresponding matrix $T_n(g_n)$ is dense as $T_n(f)$ and a possible but tricky solution is to approximate g_n by a polynomial of fixed degree: in some cases this idea can be followed but we believe that the answer in the general case is in the negative since, when we force ϵ_ν to be small enough, the degree of the polynomial g_n cannot be controlled in general by an absolute constant independent of $n = (n_1, n_2)$, $n_1 \sim n_2 \sim \nu$.

2.4. Comments on the use of the results. In the case where the zero is unique or in the case where all the zeros have the same order, it is sufficient to choose $\epsilon_n = \nu^{-1}$: this is a very reasonable requirement from a practical point of view. When the ratio $\frac{\alpha_{\max}}{\alpha_{\min}}$ is high (case of unbalanced zeros), the required precision on the computation of the zeros becomes very high. We can meet the requirement with an effort of $\mathcal{O}(N(n)\log(N(n)))$ flops by evaluating f as the nth Fourier sum, $n = (n_1, n_2)$. However, we must emphasize that we are guaranteed to be successful only if f is regular enough: we recall that the sup norm error of the Fourier sum is, up to a $\log \nu$ factor, $n_1 \sim n_2 \sim \nu$, of the same order of the best approximation error and the latter is $o(\nu^{-K})$ if f is K times continuously differentiable. Therefore in the case of just continuous functions and in the case where we desire that the approximation of f maintain the sign of function, then we can use the Rayleigh quotient approach considered in detail in Theorem 4.

THEOREM 4. [illegible] f [illegible] 2π [illegible] 2 [illegible] $\theta_x = \exp(\mathbf{i}x), \theta_y = \exp(\mathbf{i}y)$ [illegible]

$$\Theta_x^T = \frac{1}{\sqrt{n_1}}(1\ \theta_x\ \theta_x^2\ \cdots\ \theta_x^{n_1-1}) \qquad \Theta_y^T = \frac{1}{\sqrt{n_2}}(1\ \theta_y\ \theta_y^2\ \cdots\ \theta_y^{n_2-1}).$$

[illegible] $\Theta_{xy} = \Theta_x \otimes \Theta_y$ [illegible] $n = (n_1, n_2)$ [illegible]

$$r_n[f](x,y) := \frac{\Theta_{xy}^H T_n(f)\Theta_{xy}}{\Theta_{xy}^H\Theta_{xy}} = f(x,y) + \mathcal{O}\left(\max\left\{\frac{1}{n_1}, \frac{1}{n_2}\right\}\right). \tag{2.10}$$

[illegible] $f \in L^1(Q)$, $f \geq 0$ [illegible]

$$r_n[f](x,y) \geq 0 \qquad \forall\ (x,y) \in Q$$

[illegible] $r_n[f]$ [illegible] f [illegible]

[illegible]. Since $\Theta_{xy}^H\Theta_{xy} = 1$ by definition of Θ_{xy}, it follows that $r_n[f](x,y) = \Theta_{xy}^H T_n(f)\Theta_{xy}$. Moreover the map $r_n[\cdot]$, as an operator from $L^1(Q)$ into the space of the trigonometric bivariate polynomials, is linear and positive: indeed the linearity is evident since $T_n(\alpha g_1 + \beta g_2) = \alpha T_n(g_1) + \beta T_n(g_2)$ by the linearity of the Fourier coefficients; moreover if f is real valued, then $T_n(f)$ is Hermitian (see, e.g., [19]) and if f is nonnegative, then $T_n(f)$ is nonnegative definite (see, e.g., [19]). As a consequence, since Θ_{xy} has unit length, we infer that $r_n[f](x,y)$ is real valued if f is and is nonnegative if f is. Finally (see again [19]), if f is nonnegative and not identically zero (essential supremum of f strictly positive), then $T_n(f)$ is positive definite and $r_n[f](x,y)$ is a strictly positive function. (In the terminology of [24] the latter property means that the operator is linear and strongly positive.)

Now we prove relation (2.10). In what follows it is important to note that (x,y) is generic but fixed and (s,t) is the pair of dummy variables internal to the operator r_n. For instance, $r_n[f(s,t)](x,y)$ is the operator r_n applied to the function f and then evaluated at the point (x,y), while $r_n[f(x,y)](x,y) = f(x,y)\cdot r_n[1](x,y) = f(x,y)$ since $f(x,y)$ is a fixed constant and r_n is linear. Having this point in mind, we proceed with the proof.

From the regularity assumptions we know that

$$f(s,t) = f(x,y) + [\nabla f]^T(x,y)\begin{pmatrix} \sin(s-x) \\ \sin(t-y) \end{pmatrix} + C(s,t,x,y),$$

where $|C(s,t,x,y)| \leq K\left[\sin^2((s-x)/2)+\sin^2((t-y)/2)\right]$ with K pure constant only depending on the infinity norms of ∇f and H_f and with H_f denoting the Hessian of f. (For this kind of Taylor-style theorem in the periodic setting see [7] and references therein.) Now we perform the main step for proving the desired result which makes use (1) of the linearity and positivity of the operator, (2) of the above Taylor style representation, (3) of the simple identities (related to the Korovkin test; see subsection 4.1.1 in [22]) $r_n[1](x,y) \equiv 1$, $r_n[\sin(s)](x,y) \equiv \sin(x)+\mathcal{O}(\frac{1}{n_1})$, $r_n[\sin(t)](x,y) \equiv \sin(y)+\mathcal{O}(\frac{1}{n_2})$, $r_n[\cos(s)](x,y) \equiv \cos(x)+\mathcal{O}(\frac{1}{n_1})$, $r_n[\cos(t)](x,y) \equiv \cos(y)+\mathcal{O}(\frac{1}{n_2})$, and (4) of the boundedness of the second derivative H_f: indeed calling $E_{n,f}(x,y) = |r_n[f(s,t)](x,y)-f(x,y)|$ the approximation error, we have

$$\begin{aligned}
E_{n,f}(x,y) &=_{(3)} |r_n[f(s,t)](x,y)-r_n[f(x,y)](x,y)| \\
&=_{\text{linearity}} |r_n[f(s,t)-f(x,y)](x,y)| \\
&=_{(2)} \left| r_n\left[[\nabla f]^T(x,y)\begin{pmatrix}\sin(s-x)\\ \sin(t-y)\end{pmatrix}+C(s,t,x,y)\right](x,y)\right| \\
&=_{\text{linearity}} \left|\frac{\partial f}{\partial x}(x,y) r_n[\sin(s-x)](x,y)+\frac{\partial f}{\partial y}(x,y) r_n[\sin(t-y)](x,y)\right. \\
&\quad \left. + r_n\left[C(s,t,x,y)\right](x,y)\right| \\
&\leq_{\text{positivity}} \left|\frac{\partial f}{\partial x}(x,y)\right| |r_n[\sin(s-x)](x,y)|+\left|\frac{\partial f}{\partial y}(x,y)\right| |r_n[\sin(t-y)](x,y)| \\
&\quad + r_n\left[|C(s,t,x,y)|\right](x,y) \\
&\leq_{\text{regularity}} \|\nabla f\|_\infty \left[|r_n[\sin(s-x)](x,y)|+|r_n[\sin(t-y)](x,y)|\right] \\
&\quad + K r_n\left[\sin^2((s-x)/2)+\sin^2((t-y)/2))\right](x,y).
\end{aligned}$$

Finally the claimed thesis is equivalent to proving that

$$\begin{aligned}
&|r_n[\sin(s-x)](x,y)|+|r_n[\sin(t-y)](x,y)| \\
&\quad + r_n\left[\sin^2((s-x)/2)+\sin^2((t-y)/2))\right](x,y) = \mathcal{O}\left(\max\left\{\frac{1}{n_1},\frac{1}{n_2}\right\}\right)
\end{aligned}$$

and, taking into account the identities $\sin^2((s-x)/2) = (1-\cos(s-x))/2$, $\sin^2((t-y)/2)) = (1-\cos(t-y))/2$, the latter is proven if we prove that

$$|r_n[\sin(s-x)](x,y)| = \mathcal{O}\left(\max\left\{\frac{1}{n_1},\frac{1}{n_2}\right\}\right), \tag{2.11}$$

$$|r_n[\sin(t-y)](x,y)| = \mathcal{O}\left(\max\left\{\frac{1}{n_1},\frac{1}{n_2}\right\}\right), \tag{2.12}$$

$$r_n[1-\cos(s-x)](x,y) = \mathcal{O}\left(\max\left\{\frac{1}{n_1},\frac{1}{n_2}\right\}\right), \tag{2.13}$$

$$r_n[1-\cos(t-y)](x,y) = \mathcal{O}\left(\max\left\{\frac{1}{n_1},\frac{1}{n_2}\right\}\right). \tag{2.14}$$

By the explicit computation in the banded case (taking into account that $r_n[f]$ is the Césaro sum of f [23, 22]), it is easy to verify that relationships (2.11)–(2.14) hold.

Here, for the sake of completeness, we just give a detailed look at the last one:

$$\begin{aligned} r_n[1-\cos(t-y)](x,y) &=_{\text{trigonometric identity}} r_n[1-\cos(t)\cos(y)-\sin(t)\sin(y)](x,y)\\ &=_{\text{linearity}} r_n[1](x,y)-\cos(y)r_n[\cos(t)](x,y)\\ &\quad -\sin(y)r_n[\sin(t)](x,y)\\ &=_{(3)} 1-\cos(y)\left[\cos(y)+\mathcal{O}\left(\frac{1}{n_2}\right)\right]\\ &\quad -\sin(y)\left[\sin(y)+\mathcal{O}\left(\frac{1}{n_2}\right)\right]=\mathcal{O}\left(\frac{1}{n_2}\right). \quad \square \end{aligned}$$

Regarding the Fourier expansion $F_{n_1-1,n_2-1}(f)$ of f of degree n_1-1 and n_2-1, we observe that the latter approximation is much faster when f is very smooth (due to its Lebesgue constant of order $\log(n_1)+\log(n_2)$), but may fail to converge when f is only continuous. On the other hand, thanks to the Korovkin theory, the Rayleigh quotient approximation always converges when f is continuous and preserves the sign of f, but its order of approximation is not sensitive to the regularity of f. We point out that these two types of approximation have been the main theoretical tools for the construction of our banded preconditioners (see [17]).

3. Numerical examples and related discussions. As a preliminary step, we consider two numerical examples which give evidence of the main ideas described in Theorem 2 and Theorem 3 (whose result was essentially conjectured in Proposition 1 of [17]): a good approximation of the "exact" trigonometric polynomial $g(x,y)$ leads to a controlled number of spectral outliers laying outside the main clustering mass described by the range of $\frac{f}{g}$.

1. We consider the Toeplitz matrix $T_n(f)$ produced by the generating function $f(x,y)=(1+x^2+y^2)(2\cos(x)-\sin(x+2y))^2$. It is obvious that the trigonometric polynomial $g(x,y)=(2\cos(x)-\sin(x+2y))^2$ has an infinite number of roots which form a curve of roots. For the solution of the system $T_n(f)\mathrm{x}=b$ by a PCG iteration we use as preconditioner the 2-level band Toeplitz matrix $T_n(\tilde{g})$ instead of $T_n(g)$, where $\tilde{g}(x,y)=(2\cos(x-\epsilon)-\sin(x+2y+\epsilon))^2$ is an approximation of $g(x,y)$. In Table 3.1 we show the strict relation existing between the approximation error and the number of outlying eigenvalues. It is observed that, only when $n_1\epsilon=n_2\epsilon$ exceeds 1, there exist eigenvalues of the preconditioned matrix that lie outside the range of $\frac{f}{g}$.

2. We consider the Toeplitz matrix $T_n(f)$ generated by $f(x,y)=(3+\cos(x))(4-2\cos(x)-2\cos(y))(2-2\cos(x-\pi))^2$. It is obvious that it has a zero of order 2 at $(0,0)$ and a line of zeros at $x=\pi$ of order 4. We make a theoretical check on the use of the preconditioner $T_n(\tilde{g})$, where $\tilde{g}(x,y)=((4-2\cos(x+\epsilon)-2\cos(y+\epsilon))(2-2\cos(x-\pi-\epsilon))^2$ is an approximation of $g(x,y)$ with $g(x,y)=(4-2\cos(x)-2\cos(y))(2-2\cos(x-\pi))^2$. In Table 3.2 we report the tight relationship between the approximation error and the number of outlying

eigenvalues. It can be noted that, only if $n_1^2\epsilon = n_2^2\epsilon$ exceeds 1, then there exist eigenvalues of the preconditioned matrix that lie outside the range of $\frac{f}{g}$: we stress that this case falls into the one of nonbalanced zeros for which we should expect $\epsilon_\nu \sim \nu^{-2}$, $\nu = n_1 = n_2$ since $\frac{\alpha_{\max}}{\alpha_{\min}} = 2$. Therefore the suggestion from this example is that the bounds found in Theorems 2 and 3 cannot be improved in general. (Possibly, a local analysis of the Toeplitz operators could help refine the analysis in the case of special sets of symbols with nonbalanced zeros.)

In the rest of the section we follow a procedure proposed in [17] which, starting from the knowledge of the entries of $T_n(f)$, is able to determine an approximation of the generating function f (with its zeros and related orders) and consequently gives all the necessary information for determining the appropriate preconditioner. We first present and complete a sketch of this procedure and then we discuss various numerical experiments to test the effectiveness of the proposed method.

The outline of the procedure in [17] (which was based on a general scheme proposed and analyzed in [23, 29], respectively) is given in the following steps:

- Step 1: Approximate the function f from the coefficients of the matrix.
- Step 2: Search for the possible roots of f.
- Step 3: Estimate the multiplicities of each root.
- Step 4: Categorize the roots and choose the appropriate preconditioner.

We observe that these steps can be regarded as a collection of ideas that eventually have the potential to lead to a real black-box procedure for the analysis, the detection and the effective preconditioning of ill-conditioned 2-level Toeplitz systems. Here we go in this direction by describing in detail a part of Step 4 concerning the case of curves of zeros, i.e., how to construct a polynomial factor having approximately the same zeros of f (curves of zeros and isolated zeros). We stress that this subroutine (i.e., Algorithm 1 reported on the next page) is essential for the effectiveness of the whole procedure and has been ignored so far in the relevant literature. Indeed, looking at Theorem 3, we see that the approximation of the curves of the zeros is not sufficient for determining the symbol of the precondition since what we really need is the approximation $l_{j,n}(x,y)$ of every implicit function $l_j(x,y)$, $j = 0,\dots,k$, which (implicitly) defines the right curve of zeros $(x_j(t), y_j(t))$, $t \in [0,1]$, $j = 0,\dots,k$.

However, as emphasized in the remarks following Theorem 3, the approximate factor $2 - 2\cos(l_{j,n}(x,y))$ and even the theoretical one $2 - 2\cos(l_j(x,y))$ in general are not trigonometric polynomials. Therefore, that nontrigonometric symbol $2 - 2\cos(l_{j,n}(x,y))$ or $2 - 2\cos(l_j(x,y))$ would correspond to a useless preconditioner owing to the denseness of preconditioner itself (which would make the method not optimal according to Axelsson and Neytcheva [2], since the cost of every iteration would be much higher than the cost of a matrix-vector product). As a consequence, in Algorithm 1, we follow a computational approach described in the following pseudocode (written in a pseudo high-level language) for the direct computation of the (approximate) polynomial factor (if any) containing all the zeros of f. To estimate

the polynomial factor we use least-square approximation (LSA). Since we want to have good approximation on the selected roots, we choose the information of all the points of the set

$$\mathcal{G}_n = \left\{ (x_j^{(n_1)}, y_j^{(n_2)}) \in \mathcal{S}_n, \text{ computed roots of } f \text{ on } \mathcal{S}_n, \ j = 1, \ldots, \tilde{\theta}_n \right\},$$

$\mathcal{S}_n$ being a $n_1 \times n_2$ uniform gridding on $Q = (-\pi, \pi]^2$ (see (1.1)). It is well known from the above theory that the computed values of f on these points, by Rayleigh quotient, are $\mathcal{O}(\max\{\frac{1}{n_1}, \frac{1}{n_2}\})$ instead of 0. So, these values contain a significant error. We could correct those by putting 0 but then the LSA procedure would give us a polynomial which takes negative values. To avoid this, we give positive values for f of order $\mathcal{O}(\max\{\frac{1}{n_1}, \frac{1}{n_2}\})$ (the same values for all points are acceptable). In addition, it is not sufficient to apply LSA only on the points of $\mathcal{G}_n$. It is necessary to choose some points which give enough information for the reconstruction of the shape of f. For this we choose a coarse grid $\mathcal{S}_{\hat{n}}$, $\hat{n} = (\hat{n}_1, \hat{n}_2)$, where $\hat{n}_1 << n_1$ and $\hat{n}_2 << n_2$ ($\hat{n}_1 \approx \sqrt{n_1}$, $\hat{n}_2 \approx \sqrt{n_2}$ are enough), and create all the points of $\mathcal{S}_{\hat{n}}$ which are added to the points of $\mathcal{G}_n$ for the LSA method. Let θ_n be the number of the selected points ($\theta_n = |\mathcal{G}_n| + |\mathcal{S}_{\hat{n}}|$) and $\hat{f}$ be the θ_n-dimensional vector of the approximated values of f, as these are described before. Let also $q = (q_1, q_2)$, $q_1, q_2 \geq 0$, $q_1 + q_2 \geq 1$ be the pair of orders of the trigonometric polynomial that we have to approximate in each direction. Then, we have to solve the LSA problem $\min_{\mathbf{t}} \|\hat{f} - V_q \mathbf{t}\|_2^2$, where V_q is the rectangular Vandermonde matrix defined by

$$((V_q)_{j,k})_{j=1,\ldots,\theta_n, k=1,\ldots,(2q_1+1)(2q_2+1)}$$

with $(V_q)_{j,k} = \psi_k(x_j^{(n_1)}, y_j^{(n_2)})$ and $\psi_k(x, y) = \exp(\mathbf{i}\alpha x + \mathbf{i}\beta y)$. Here the relation between the index $k \in \{1, \ldots, (2q_1+1)(2q_2+1)\}$ and the 2-index $(\alpha, \beta) \in \{-q_1, \ldots, q_1\} \times \{-q_2, \ldots, q_2\}$ is defined through the bijection $k := k(\alpha, \beta, q) = (\alpha + q_1)(2q_2 + 1) + \beta + q_2 + 1$, $q = (q_1, q_2)$. To apply LSA it is necessary to have $\theta_n \geq (2q_1 + 1)(2q_2 + 1)$; otherwise we choose additional points on the fine grid, near the estimated roots, in order to have more information about the roots, until the above inequality is satisfied.

ALGORITHM 1. APPROXIMATING FACTOR.

```
b :=false;
for q_1 = 1 : q_1^max do
    for q_2 = 1 : q_2^max do
        Minimize ||f̂ − V_q t||_2^2;
        construct the polynomial p_t(x, y) = Σ_k t_k ψ_k(x, y);
        if max_{(x,y)∈G_n} |p_t(x, y)| < ε_ν then
            b :=true;
        end if
    end for
end for
if b =true then
    write: "The approximating factor is optimal";
else
    write: "The approximating factor does not insure optimality";
end if
factor: p_t(x, y);
```

Here given $q_1^{\max} > 0$, $q_2^{\max} > 0$, the procedure will compute a mask $\mathbf{t} = \mathbf{t}(q)$ of Fourier coefficients with $q = (q_1, q_2)$, $0 \le q_1 \le q_1^{\max}$, $0 \le q_2 \le q_2^{\max}$, $q_1 + q_2 \ge 1$.

EXAMPLE 3. In order to test our procedure we solve

$$T_n(f)\mathrm{x} = b,$$

where the generating function is $f(x,y) = (x^2+y^2+1/4)(\cos(x+y)+\sin(2x))^2$ and has five curves of roots in the domain $Q = (-\pi, \pi]^2$ as is shown clearly in Figure 3.1(a). The knowledge of the generating function has been used only for the computation of the coefficients of $T_n(f)$. In what follows we calculate the grid $\mathcal{G}_n$ and we estimate the possible roots of f as well as their multiplicities. According to the reasoning in the previous sections, we set ϵ_ν as $.06, .03, .015, 7.5 * 10^{-3}, 3.75 * 10^{-3}$ for $\nu = n_1 = n_2 = 16, 32, 64, 128, 256$, respectively. For $\nu = 8$ we do not have enough information (points) to set up a reasonable good LSA scheme. We mention here that the cost of LSA is dominated by that of PCG since the number of columns of the overdetermined problem depends on the partial degrees q_1, q_2 of the desired trigonometric polynomial rather the dimensions n_1, n_2 of the original problem. The maximum permitted order of the approximated trigonometric polynomial is restricted by the dimension of the problem. More specifically, knowing that the cost of the solution of a band block Toeplitz system of size ν^2 $(n_1 = n_2 = \nu)$ and total bandwidth l can be done in $O(\nu^2 l^2)$ arithmetic operations, the total degree, which roughly speaking coincides with the total bandwidth, cannot exceed $\mathcal{O}(\log \nu)$. The stopping criterion of our algorithm is $p_t(x_i, y_i) < \epsilon_\nu$, where (x_i, y_i) are the estimated roots and $\epsilon_\nu = \mathcal{O}(\frac{1}{\nu})$ or the degree of the approximated polynomial is larger than $c \log \nu$ with suitable c. In practice, and for various examples, the second condition happens more often. This occurrence may lead to some eigenvalues which lay outside the range of $\frac{f}{g}$, where g is the trigonometric polynomial of minimal order which just raises the roots of f. On the other hand, by using LSA not only in the points that have been estimated as roots, we obtain a global approximation of the unknown function f and therefore we can gain a better clustering of the preconditioned system than that achieved by g. This observation is confirmed in Table 3.3, where we denote by I the unpreconditioned CG method, by $\hat{P}$ the PCG method derived from our procedure, and by P the optimal PCG method. Although the algorithm stopped because the second criterion was satisfied, the required iterations by the optimal preconditioner and the ones needed by our proposal are almost the same, and for some dimensions the global behavior is even better. We mention that the comparison with the optimal preconditioner has only theoretical meaning since, in the practical situation, we do not know the generating function and, as a consequence, the generating function of the exact preconditioner is not available. For the PCG method we used as an initial guess the null vector, as b the vector of all ones, and $\frac{\|r_k\|_2}{\|r_0\|_2} \le 10^{-5}$ as a stopping criterion, where r_k is the residual vector after k iterations.

TABLE 3.3
Iterations of the PCG method for $f(x,y) = (x^2 + y^2 + 1/4)(\cos(x+y) + \sin(2x))^2$.

FIG. 3.1. *The function f and its approximated trigonometric polynomial in* $[0,2]$ *and* $[0,20]$.

In Figure 3.1 we give two snapshots of the graphs of the unknown generating function f and the trigonometric polynomial $\hat{p}$ that we have estimated using our algorithm when $\nu = 32$ and the order of $p_{\mathbf{t}}$ is $(5,5)$. More precisely, in Figures 3.1(a) and 3.1(b) we observe the global approximation features of our scheme, while in 3.1(c) and 3.1(d) we concentrate our attention on comparing the exact generating function f and the approximate polynomial $p_{\mathbf{t}}$ in the domains where they attain small values: we recall that is the good approximation in such domains, which is crucial for a good performance of the associated preconditioner. In both cases, it is clear that a very good approximation has been achieved by the procedure.

. . . . 1. For functions like $x^2 + (y-1)^4$ that need different treatment in each variable, our four-step algorithm can estimate very accurately the root $(0,1)$ as well as the multiplicities 2 in the x direction and 4 in the y direction (see Example 3 in [17]).

. . . . 2. Furthermore, it is worth commenting on the case where f has zeros of not even orders (not integer as well): in that case even the exact band Toeplitz

preconditioning (error free with respect to the position of the zeros) is no longer optimal. However, in the 1-dimensional setting, it has been proved that in the worst case (refer to [20]) the number of PCG iterations can grow at most as $\nu^{1/2}$, ν being the size of the 1-level Toeplitz matrix, which can be reasonably good for very ill-conditioned positive definite Toeplitz systems. It is remarked here that the proof of the 1-level case can be extended in the 2-level case. The obtained result is that in the worst case the number of PCG iterations can grow at most as $\nu^{1/2}$, $\nu \sim n_1 \sim n_2$. To show this we consider $f(x,y) = |x|^3 + |y|^5$ which has the isolated zero $(0,0)$ with multiplicities $(3,5)$. By applying our four-step algorithm we will get an isolated zero $(x_0, y_0) \approx (0,0)$ with the associated multiplicities $(k_1, k_2) \approx (3,5)$. If we approximate k_1 and k_2 by the closest even integers we could get four possible choices: $(2,4)$, $(2,6)$, $(4,4)$, or $(4,6)$. We describe in detail the first possibility $(2,4)$. The associated trigonometric polynomial is $2 - 2\cos(x) + (2 - 2\cos(y))^2$ and the condition number of the preconditioned matrix can be estimated by studying the limit of $\frac{|x|^3+|y|^5}{2-2\cos(x)+(2-2\cos(y))^2}$ as $(x,y) \to (0,0)$. In this case a simple analysis in polar coordinates implies that $\kappa(T_n^{-1}(g)T_n(f)) = \mathcal{O}(\nu)$. By using the tools introduced in this paper, we get $\kappa(T_n^{-1}(\tilde{g})T_n(f)) = \mathcal{O}(\nu)$, where $\tilde{g} = 2-2\cos(x+\epsilon_1)+(2-2\cos(y+\epsilon_2))^2$, $\epsilon_1 \sim \epsilon_2 \sim \frac{1}{\nu}$. Hence the number of PCG iterations grows as $\nu^{1/2}$. This is shown in Table 3.4, where we consider the above four choices. We can observe in this table that the choice $(4,6)$ is better than the one of $(4,4)$; then $(2,6)$ follows and the worst choice is $(2,4)$. An explanation of the aforementioned phenomenon is contained in the classical PCG convergence theory due to Axelsson and Lindskög [1]. In the overestimated choices, the eigenvalues of the preconditioned matrix are far away from zero but some of them grow to infinity since $\frac{f}{g}$ is far away from zero but unbounded while in the underestimated ones, they are uniformly bounded but some of them tend to zero since $\frac{f}{g}$ is bounded but has a zero at $(0,0)$. Now, from [1], it is well known that small eigenvalues disturb the PCG convergence more than big eigenvalues and, as a consequence, it is a general recommendation to overestimate the multiplicities of the roots rather than underestimate them when the involved numbers are not even integers.

3. As a conclusion, we remark here that the above theory could be extended in the d-dimensional case where $d \geq 3$. The difference is that we may have isolated roots, curves of roots, surfaces of roots, or hypersurfaces of roots. It is possible to state and prove spectral properties for the d-dimensional case analogous to the ones given in this paper for the 2-dimensional case. The difficulty is on the practical side. It is more complicated to construct an efficient algorithm which would recognize the roots, their nature (isolated, curves, surfaces, or hypersurfaces), and

their multiplicities. On the other hand, concerning the applications, d-level ($d \geq 3$) Toeplitz systems arise from several discretization schemes for elliptic d-dimensional PDEs. In that case, the symbol f is known (or at least the position and the order of the zeros is known) and therefore the exact trigonometric polynomial which deletes the roots can be determined analytically.

CENTROIDAL VORONOI TESSELLATION-BASED REDUCED-ORDER MODELING OF COMPLEX SYSTEMS*

JOHN BURKARDT†, MAX GUNZBURGER†, AND HYUNG-CHUN LEE‡

Abstract. A reduced-order modeling methodology based on centroidal Voronoi tessellations (CVTs) is introduced. CVTs are special Voronoi tessellations for which the generators of the Voronoi diagram are also the centers of mass (means) of the corresponding Voronoi cells. For discrete data sets, CVTs are closely related to the h-means and k-means clustering techniques. A discussion of reduced-order modeling for complex systems such as fluid flows is given to provide a context for the application of reduced-order bases. Then, detailed descriptions of CVT-based reduced-order bases and how they can be constructed from snapshot sets and how they can be applied to the low-cost simulation of complex systems are given. Subsequently, some concrete incompressible flow examples are used to illustrate the construction and use of CVT-based reduced-order bases. The CVT-based reduced-order modeling methodology is shown to be effective for these examples.

Key words. reduced-order modeling, Voronoi diagrams, incompressible flows, clustering

1. Introduction.

Even with the use of good mesh generators, discretization schemes, and solution algorithms, the computational simulation of complex, turbulent, or chaotic systems still remains a formidable endeavor. For example, typical finite element codes may require many thousands of degrees of freedom for the accurate simulation of fluid flows. The situation is even worse for optimization problems for which multiple solutions of the complex state system are usually required or in feedback control problems for which real-time solutions of the complex state system are needed. The need for so many degrees of freedom results from two causes. First, phenomena occurring over very small spatial and temporal scales have to be resolved. For example, flows at even moderate values of the Reynolds number are usually turbulent. In a direct computational simulation, very small eddies have to be accurately resolved, even if one is only interested in the large-scale features of the flow. Second, the functions or grid stencils used to effect approximation have no direct relation to the solution of the complex state system. For example, the standard, locally supported, piecewise polynomial basis functions used to define a finite element approximation of the flow solution are not specially designed for a particular flow or for flows in general. Thus, in a typical finite element calculation for a turbulent flow, many thousands of degrees of freedom are needed in order to properly resolve the small eddies.

The natural question to ask is whether or not it is really necessary to have thousands of degrees of freedom in order to produce accurate approximations to solutions of complex systems. For example, for turbulent flows, one would like to identify highly persistent spatio-temporal structures using relatively inexpensive, low-dimensional approaches instead of using expensive standard techniques in the numerical solution

of partial differential equations.[1] The feedback control of complex systems provides another example; in this setting, low-dimensional state models are needed so that actuation can be determined quickly from sensed data. As a result, there have been many studies devoted to the development, testing, and use of reduced-order models for complex systems such as unsteady fluid flows.

The types of reduced-order models that we study are those that attempt to determine accurate approximate solutions of a complex system using very few degrees of freedom. To do so, such models have to use basis functions that are in some way intimately connected to the problem being approximated. Once a very low-dimensional reduced basis has been determined, one can employ it to solve the complex system by applying, e.g., a Galerkin method. In general, reduced bases are globally supported so that the discrete systems are dense; however, if the reduced basis is of very low dimension, one does not care about the lack of sparsity in the discrete system. Of course, the first natural question to ask is: How does one determine a reduced basis of very low dimension?

There have been many reduced-order modeling techniques proposed. In the structural and fluid mechanics communities, Taylor polynomial and Lagrange polynomial based methods were studied in, e.g., [23, 31] and were shown to be effective for some specific problems. In the Lagrange polynomial approach, one determines a low-dimensional basis by solving the complex system for several values of the parameters that appear in the specification of the system or at several instants in time during the evolution of the system. In the Taylor polynomial approach, the low-dimensional basis consists of the solution of the complex system and of its derivatives with respect to the parameters evaluated at fixed values of the parameters. In both cases, one uses the reduced basis to determine the solution of the complex system at other values of the parameters and, in both cases, the reduced basis is determined by employing high-dimensional discretizations that are, of course, very costly. In simulation settings, that cost is hopefully amortized over subsequent calculations for many other parameter values using the low-cost reduced basis approach. Likewise, in control settings, the cost is amortized over the many state solves necessary to determine the controls.

Today, the most popular reduced-order modeling approach for complex systems is based on proper orthogonal decomposition (POD) analysis. POD begins with a set of $\widetilde{m}$ snapshots; these could be generated by evaluating the computational solution of a transient problem at several instants of time or by evaluating the computational solution for several values of the parameters appearing in the problem description or by a combination of the two. The snapshot set can even be determined, in principle, from experiments. The computational solutions that are used to determine the snapshot set are determined using costly, large-scale, high-fidelity, e.g., finite element, codes. The $\widetilde{d}$-dimensional POD basis is then determined from the $\widetilde{d}$ eigenvectors corresponding to the $\widetilde{d}$ most dominant eigenvalues of the correlation matrix for the snapshots.[2] The POD basis is then used, usually by applying a projection procedure,

[1] The whole field of turbulence modeling, e.g., k-ϵ and large-eddy simulation (LES) models, is an attempt at reduced-order modeling. However, these approaches still result in complex systems of partial differential equations that are usually solved by employing very high-dimensional approximation schemes. The approaches to reduced-order modeling considered here are different and result in very low-dimensional models for complex systems.

[2] Perhaps more simply, a totally equivalent definition of the $\widetilde{d}$-dimensional POD basis is the first $\widetilde{d}$ left singular vectors of the matrix whose columns are the snapshot vectors. In statistical analyses, POD is known as the Karhunen–Loève analysis or the method of empirical orthogonal eigenfunctions or principal component analysis.

to determine an approximate solution for different values of the system parameters. For example, in an optimal control or optimization setting, one would generate the POD basis from snapshots that correspond to several sets of values of the optimization or control parameters. These snapshots are determined using expensive, e.g., finite element, codes having many thousands of degrees of freedom. However, the snapshots can be generated "off-line" and their costs can be hopefully amortized over several optimization calculations. When one performs the optimization or control of the system, one uses the small-dimensional POD basis to determine the multiple state solutions and any sensitivity or adjoint equations solutions needed by the optimizer or by the controller. The POD basis possesses a well-known optimization characteristic. POD-based model reduction has been applied with some success to several problems, most notably in fluid mechanics settings. For detailed discussions, one may consult [1, 2, 3, 4, 5, 15, 17, 18, 20, 21, 22, 25, 26, 27, 28, 29, 30, 32, 33, 34, 35, 36, 37, 38, 41, 42]. A few more details about how snapshots are generated and how a POD basis is used for model reduction are also given in section 1.1.

Now that we have discussed two approaches for generating reduced bases, another natural question to ask is when can one expect a reduced-order model to "work," i.e., to produce accurate, very low-dimensional approximations to a solution of a complex system. Clearly, they can work only when the low-dimensional basis "contains" all of the information needed to produce an accurate approximation, i.e., in an interpolatory setting or in the very limited settings where extrapolation can work. In the POD setting, the snapshots used to define the POD basis must contain all the information, e.g., the dynamic behavior, of the solution one is trying to obtain. The beauty of POD, when it works, is that it can reduce a set of hundreds of snapshots to a set of just a handful of POD basis vectors that contain essentially the same information. However, when the snapshot set does not contain the needed information, one has to generate new snapshots and then generate a new POD basis, often in an adaptive manner. This can happen when one uses a reduced-basis method in an optimization or control setting. Initially, the snapshots, and therefore the POD basis, can be constructed to contain the needed information, but as the optimizer or controller changes the parameters in the problem, it is often the case that the original snapshot set does not contain enough information to accurately approximate the solution at the new values of the parameters, and thus the snapshot set has to be augmented with new snapshots that reflect the new behavior. Even worse, it may be the case that the POD basis, which included most of the information contained in the snapshot set for the parameters used to generate the snapshots, ignored information in the snapshot set that may be useful for other values of the parameters. Furthermore, redoing the POD basis when the snapshot set changes requires the solution of a new eigenvalue or singular value problem which is of the size of the cardinality of the snapshot set.

Centroidal Voronoi tessellations (CVTs) have been successfully used in several data compression settings, e.g., in image processing and the clustering of data.[3] Reduced-order modeling of complex systems is another data compression setting, i.e., replacing high-dimensional approximations with low-dimensional ones. Thus, one can

[3]CVTs are useful in many other settings, e.g., just to name some, optimal quadrature rules, optimal representation and quantization, cell division, data compression, optimal distribution of resources, territorial behavior of animals, optimal placement of sensors and actuators, grid generation in two and three dimensions and on surfaces, and meshfree methods. For further discussions about the applications of CVTs, see, e.g., [6, 7, 8, 9, 10, 11, 12, 13, 14, 19, 24]. Also, like POD, CVT is closely related to well-known statistical techniques; in fact, for discrete data sets, CVT can be identified with the h-means and k-means clustering methods.

ask if CVTs can be used for the reduced-order modeling of complex systems. In CVT-reduced order modeling, we start with a snapshot set just as is done in a POD-based setting. However, instead of determining a POD basis from the snapshot set, we apply our CVT methodologies to determine the generators of a CVT of the snapshot set; these generators constitute the reduced-order basis. We then use the CVT-based basis in just the same way as one uses a POD-based basis to determine a very low-dimensional approximation to the solution of a complex system. CVT also possesses an optimality property, although it is different from that possessed by POD bases.

The efficiency of CVT- and POD-based reduced bases depends on the their dimension, i.e., if a CVT- or POD-based basis is low-dimensional and can still approximate the state well, then approximations of the state of a complex system can be inexpensively determined. However, the ability of a CVT- or POD-based basis to approximate the state of a system is totally dependent on the information contained in the snapshot set used to generate the basis. Certainly, a CVT- or POD-based basis cannot contain more information than that contained in the snapshot set.[4] Thus, crucial to the success of both the CVT- and POD-based approaches to model reduction is the generation of "good" snapshot sets.

Unfortunately, at this time, the generation of snapshot sets is an art and not a science; it is, in fact, a rather primitive art. One recognizes that the generation of snapshot sets is an exercise in the design of experiments. For example, for stationary systems, how does one choose the sets of parameters at which the state and perhaps sensitivities are calculated using expensive, high-fidelity computations in order to generate the snapshot set? Clearly, some a priori knowledge about the types of states to be simulated or optimized using the reduced-order model is very useful in this regard. The large body of statistics literature on the design of experiments has not been used in a systematic manner. For time-dependent systems, many ad hoc measures have been invoked in the hope that they will lead to good snapshot sets. Time-dependent parameters, e.g., appearing in boundary conditions, are used to generate states that are "rich" in transients, even if the state of interest depends only on time-independent parameters. Moreover, in order to generate even "richer" dynamics, impulsive forcing is commonly used, e.g., starting the evolution impulsively with different strength impulses or introducing impulses in the midst of a simulation. In section 3, we adopt some of these strategies for the generation of snapshot sets in the concrete examples we consider. However, generating snapshot sets is not a main focus of this paper. It is clear, though, that in the future, a great deal of effort needs to be directed towards developing and justifying methodologies for generating good snapshot sets. After all, a POD or CVT basis can only be as good as the snapshot set used to generate it.

1.1. Schematic of POD- or CVT-based model reduction for simulation problems. For the sake of concreteness, we suppose that we wish to solve the problem:

$$\text{given } \theta \in \Theta, \text{ find } u(t,x) \in U \text{ such that } N(u;\theta;v) = 0 \ \forall\, v \in U, \ \text{a.e. } t \in (0,T)\,, \tag{1.1}$$

where U and Θ are given solution[5] and parameter function spaces, respectively, and

[4] Recall that the goal of invoking POD or CVT is merely to determine a low-dimensional basis that "contains" almost all the information contained in the snapshot set.

[5] In general, the spaces of test and trial functions are not the same, i.e., in (1.1) the test functions v do not, in general, belong to the same space as do the trial functions u. For the sake of simplicity of exposition, we here assume that they are the same.

$(0,T)$ is a specified time interval.[6] If (1.1) represents a time-dependent problem, then it should be supplemented with initial conditions.[7] The mapping $N : U \times \Theta \times V$ is linear in its third argument and is generally nonlinear in its first two arguments; $N(\cdot;\cdot;\cdot)$ in general involves space and time derivatives and integrals of combinations of its arguments. In (1.1), θ denotes a set of parameters that serve to specify the problem, u denotes the desired solution, and v denotes a suitable test function. Thus, (1.1) implicitly defines a solution mapping $u(\theta) : \Theta \to U$. The object of a computational simulation is to find approximations of this mapping.

For the sake of even further concreteness, we consider finite element methods for the approximation of solutions of (1.1). To this end, one chooses a finite-dimensional subspace[8] $U^h \subset U$ parameterized by a parameter h tending to zero (e.g., the grid size) and then one poses the approximate problem:

$$\begin{aligned} &\text{given } \theta \in \Theta, \text{ find } u^h(t,x) \in U^h \text{ such that} \\ &N(u^h;\theta;v^h) = 0 \quad \forall\, v^h \in U^h, \text{ a.e. } t \in (0,T)\,. \end{aligned} \tag{1.2}$$

The approximate solution is computed by choosing a basis $\{\phi_k(x)\}_{k=1}^{\widetilde{j}}$, then writing $u^h(t,x) = \sum_{k=1}^{\widetilde{j}} U_k(t)\phi_k(x)$, and then solving the problem:[9]

$$\begin{aligned} &\text{given } \theta \in \Theta, \text{ find } U_k(t),\ k = 1\ldots,\widetilde{j}, \text{ such that} \\ &N\left(\textstyle\sum_{k=1}^{\widetilde{j}} U_k\phi_k;\theta;\phi_j\right) = 0 \quad \text{for } j = 1,2,\ldots,\widetilde{j},\ t \in (0,T)\,. \end{aligned} \tag{1.3}$$

In general, for complex systems of practical interest, the dimension $\widetilde{j}$ of the approximating space U^h may be in the many thousands. As a result, it may be very expensive to solve (1.3) for a single set θ of parameter values and it may be prohibitively expensive to solve (1.3) for many sets of parameter values. The latter is exactly the situation which causes the interest in reduced-order modeling so that we assume that we want to find approximations of the solutions of (1.1) for many sets of parameter values. We now describe the steps that go into defining and using POD- or CVT-type reduced-order models for finding approximations to the solutions of (1.1).

1.1.1. Generating snapshots. We begin by choosing several parameter sets $\theta_1, \theta_2, \ldots, \theta_{\widetilde{\ell}}$ and then solving (1.3) for each set, i.e., we solve the $\widetilde{\ell}$ problems:

$$\begin{aligned} &\text{for } \ell = 1,\ldots,\widetilde{\ell},\ \text{find } U_k^\ell,\ k = 1\ldots,\widetilde{j}, \text{ such that} \\ &N\left(\textstyle\sum_{k=1}^{\widetilde{j}} U_k^\ell\phi_k;\theta_\ell;\phi_j\right) = 0 \quad \text{for } j = 1,2,\ldots,\widetilde{j}\,. \end{aligned} \tag{1.4}$$

Note that, in general, for each ℓ, (1.4) represents the solution of a large nonlinear system of ordinary differential equations, or in the stationary case, a large system of

[6] Using (1.1) as our prototype complex system prejudices our discussion towards Galerkin-finite element and Galerkin-spectral methods. However, one could easily extend our discussion to other methods, including finite difference and finite volume methods.

[7] If (1.1) represents a stationary problem, we simply suppress all dependencies on t; for the sake of concreteness, we will assume that (1.1) represents a time-dependent problem.

[8] One may also need to approximate the parameter space in which case one also has to choose an approximating parameter subspace $\Theta^h \subset \Theta$. However, for the sake of simplicity of the exposition, we assume that this is not necessary for the problem we consider. It is also possible that the mapping N has to be replaced by an approximate mapping N^h, but we ignore that possibility as well. We note that there is no difficulty extending our discussion to the more general cases.

[9] So far, we have only effected spatial discretization. If the mapping N involves time derivatives of u, then the problem (1.3) is a system of nonlinear ordinary differential equations (ordinary differential equations) for $U_k(t),\ k = 1\ldots,\widetilde{j}$. Thus, further discretization in time is usually needed to solve (1.3).

discrete nonlinear equations. Therefore, generating snapshots is an expensive proposition.

Next, we choose several time values $t_1, t_2, \ldots, t_{\widetilde{q}}$ within the interval $[0, T]$ and we evaluate the coefficients $U_k^\ell(t)$, $k = 1 \ldots, \widetilde{j}$ and $\ell = 1, \ldots, \widetilde{\ell}$, at these time values. Using this information, we define the $\widetilde{m} = \widetilde{q}\widetilde{\ell}$

$$\vec{U}_m = \begin{pmatrix} U_1^\ell(t_q) \\ U_2^\ell(t_q) \\ \vdots \\ U_{\widetilde{j}}^\ell(t_q) \end{pmatrix}, \quad m = (\ell - 1)\widetilde{q} + q, \quad q = 1 \ldots, \widetilde{q}, \text{ and } \ell = 1, \ldots, \widetilde{\ell}. \tag{1.5}$$

Note that the snapshot vectors $\vec{U}_m \in \mathbb{R}^{\widetilde{j}}$, where $\widetilde{j}$ is the dimension of the finite element space being employed which may be in the many thousands. On the other hand, the number of snapshots $\widetilde{m} = \widetilde{q}\widetilde{\ell}$ is usually taken to be of the order of hundreds.

The process just described for generating snapshots is a well defined recipe except that it requires the choosing of $\widetilde{\ell}$ parameter sets $\theta_1, \ldots, \theta_{\widetilde{\ell}}$ and $\widetilde{q}$ values of time $t_1, \ldots, t_{\widetilde{q}}$. As has already been mentioned, how these choices are made is not something that is a systematic science. In section 3, we provide some examples of how these choices are made.

There are definitions other than (1.5) that have been used to define snapshot sets. For example, one could add to the snapshots in (1.5) approximations to the time derivatives of the coefficients $U_k^\ell(t)$, i.e., in addition to (1.5), we have the snapshot vectors

$$\vec{U}_m \approx \begin{pmatrix} \left.\frac{dU_1^\ell}{dt}\right|_{t_q} \\ \vdots \\ \left.\frac{dU_{\widetilde{j}}^\ell}{dt}\right|_{t_q} \end{pmatrix}, \quad m = \widetilde{\ell}\widetilde{q} + (\ell - 1)\widetilde{q} + q, \quad q = 1 \ldots, \widetilde{q}, \text{ and } \ell = 1, \ldots, \widetilde{\ell}$$

so that now we have a set of snapshots of cardinality $\widetilde{m} = 2\widetilde{\ell}\widetilde{q}$. The approximation to the time derivatives may be effected, e.g., by using finite difference quotients.

1.1.2. Generating reduced bases from the snapshot set. Snapshot sets by themselves are not always directly useful for reduced-order modeling. First, in order to include "enough" useful information about solutions of complex systems, one usually has on the order of hundreds of snapshot vectors which is too high a number for practicality. Second, snapshot sets may be linearly dependent or may be poorly conditioned as a basis so that, again, they may not be practical. On the other hand, snapshot sets often contain much redundant information so that it should be possible to define smaller basis sets of much lower cardinality that are well conditioned and that have nearly the same information content as the snapshot set. POD and CVT analyses can be applied for this purpose.

Before applying POD or CVT analyses, the snapshot set is usually modified. For example, one usually subtracts the mean of the snapshot set before further processing, e.g., instead of using (1.5), one uses the modified snapshots in which the mean of the snapshots is subtracted from every snapshot:

$$\vec{V}_m = \vec{U}_m - \overline{U} \quad \text{for } m = 1, \ldots, \widetilde{m}, \qquad \text{where} \qquad \overline{U} = \frac{1}{\widetilde{m}} \sum_{m=1}^{\widetilde{m}} \vec{U}_m \,.$$

In addition, snapshot vectors are sometimes manipulated so as to efficiently account for inhomogeneous boundary conditions. In any case, we assume that we now have in hand a satisfactory snapshot set $\mathcal{V} = \{\vec{V}_m\}_{m=1}^{\widetilde{m}}$ from which we want to define a low-dimensional reduced basis.

Let us briefly consider POD-based reduced bases. There are many equivalent ways to define POD bases corresponding to a given snapshot set. Perhaps the simplest definition is as follows. First, we form the snapshot matrix

$$S = (\vec{V}_1, \vec{V}_2, \cdots, \vec{V}_{\widetilde{m}}),$$

i.e., the matrix whose columns are the snapshot vectors; the ordering does not matter. Note that S is a $\widetilde{j} \times \widetilde{m}$ matrix so that, in practice, it has many more rows than columns. Then, the $\widetilde{d}$-dimensional POD basis consists of the first $\widetilde{d}$ left singular vectors of S. Note that the POD basis vectors belong to $\mathbb{R}^{\widetilde{j}}$ and that the POD basis is perfectly conditioned since, by definition, it is an orthonormal basis. It has also been found in many settings that POD bases of low dimension, i.e., of the order of ten or so, contain almost all the information present in snapshot sets consisting of hundreds of vectors.

Instead of POD, in this paper we consider using CVT analyses to generate a low-dimensional reduced basis from a given set of snapshots. This process is described in detail in section 2.

1.1.3. Using a reduced basis to solve a simulation problem. Suppose now that we have in hand a $\widetilde{d}$-dimensional reduced basis $\mathcal{Z} = \{\vec{Z}_i\}_{i=1}^{\widetilde{d}}$, be it POD-based or CVT-based. The basis vectors $\vec{Z}_i$ belong to $\mathbb{R}^{\widetilde{j}}$ and consist of the coefficients of particular (globally supported) functions belonging to the finite element trial space U^h. In fact, if we write

$$\vec{Z}_i = \begin{pmatrix} Z_{i,1} \\ Z_{i,2} \\ \vdots \\ Z_{i,\widetilde{j}} \end{pmatrix} \qquad \text{for } i = 1, \ldots, \widetilde{d},$$

the corresponding finite element functions are given by

$$z_i(x) = \sum_{j=1}^{\widetilde{j}} Z_{i,j}\phi_j(x) \qquad \text{for } i = 1, \ldots, \widetilde{d}, \tag{1.6}$$

where $\{\phi_j(x)\}_{j=1}^{\widetilde{j}}$ is the basis for the finite element space U^h, and the $\widetilde{d}$-dimensional reduced basis can be written in the form $\{z_i(x)\}_{i=1}^{\widetilde{d}}$. The reduced-order space $Z^h = \text{span}\,\{z_1(x), \ldots, z_{\widetilde{d}}(s)\} \subset U^h$. Note that $\dim Z^h = \widetilde{d}$ which is very small compared to the dimension $\widetilde{j}$ of the finite element space used to define the discrete problem (1.2).

Having obtained a reduced basis, we now want to use it to determine an approximate solution of (1.1) for new parameter sets θ. We use exactly the same process that led to (1.2) and (1.3). Since we now seek an approximate solution $u_{ro}^h(t,x)$ belonging to the reduced-order space Z^h for all $t \in (0,T)$, we solve the problem:

$$\begin{aligned} &\text{given } \theta \in \Theta, \text{ find } u_{ro}^h(t,x) \in Z^h \text{ such that} \\ &N(u_{ro}^h; \theta; v^h) = 0 \quad \forall\, v^h \in Z^h, \text{ a.e. } t \in (0,T). \end{aligned} \tag{1.7}$$

Since $u^h_{ro}(t,x) \in Z^h$, we can write $u^h_{ro}(t,x) = \sum_{i=1}^{\widetilde{d}} c_i(t) z_i(x)$ for some time-dependent coefficients c_i, $i = 1, \ldots, \widetilde{d}$. Then, (1.7) is equivalent to the problem of finding the coefficients $c_i(t)$, $i = 1, \ldots, \widetilde{d}$, from the nonlinear system of ordinary differential equations:

$$\begin{array}{l} \text{given } \theta \in \Theta, \text{ find } c_i(t),\ i = 1 \ldots, \widetilde{d}, \text{ such that} \\ N\left(\sum_{i=1}^{\widetilde{d}} c_i z_i; \theta; z_j\right) = 0 \quad \text{for } j = 1, 2, \ldots, \widetilde{d},\ t \in (0,T)\,. \end{array} \tag{1.8}$$

The reduction in size between (1.3) and (1.8) is now explicitly evident. The former is a system of $\widetilde{j}$ nonlinear ordinary differential equations for the $\widetilde{j}$ unknowns $U_k(t)$, $k = 1, \ldots, \widetilde{j}$, while (1.8) is a system of $\widetilde{d}$ ordinary differential equations for the $\widetilde{d}$ unknowns $c_i(t)$, $i = 1, \ldots, \widetilde{d}$. Thus, having produced the reduced basis $\{z_i(x)\}_{i=1}^{\widetilde{d}}$, we can now solve (1.8) for any given parameter set θ much more cheaply than if we resorted to solving (1.3).

Using (1.6), we see that the solution of (1.7) or, equivalently, of (1.8) can be written as

$$u^h_{ro}(t,x) = \sum_{k=1}^{\widetilde{j}} \left(\sum_{i=1}^{\widetilde{d}} c_i(t) Z_{i,k} \right) \phi_k(x) \tag{1.9}$$

so that clearly $u^h_{ro} \in U^h$, i.e., the solution of (1.7) lives in the finite element space. However, only $\widetilde{d}$ degrees of freedom (the c_i's) completely determine $u^h_{ro} \in U^h$. If we substitute (1.9) into (1.7) or, equivalently, if we substitute (1.6) into (1.8), we arrive at another equivalent form for the reduced-order problem:

$$\begin{array}{l} \text{given } \theta \in \Theta, \text{ find } c_i(t),\ i = 1 \ldots, \widetilde{d}, \text{ such that} \\ N\left(\sum_{k=1}^{\widetilde{j}} \left(\sum_{i=1}^{\widetilde{d}} c_i Z_{i,k}\right) \phi_k(x); \theta; \sum_{j=1}^{\widetilde{j}} Z_{m,j} \phi_j(x)\right) = 0 \\ \text{for } m = 1, 2, \ldots, \widetilde{d},\ t \in (0,T)\,. \end{array} \tag{1.10}$$

This form of the reduced-order problem is written in terms of the standard finite element functions ϕ_j and the components of the reduced basis vectors $Z_{i,j}$; it is the form that is actually used in practice to assemble the $\widetilde{d}$ ordinary differential equations corresponding to the reduced-order problem.

To complete the definition of the reduced-order problem, one must choose a solution method for the system of ordinary differential equations (1.10).

We have now given an almost complete recipe for how a reduced basis is determined and used to find low-order approximations of complex systems; the missing step is how a reduced basis is determined from the snapshot set. We briefly described how this step is carried out in the POD setting, and in the next section, we describe how it is done in the CVT setting.

2. Centroidal Voronoi tessellation-based reduced bases. The generation of a CVT-based reduced-order basis is the intermediate step of the model reduction algorithm. It follows the generation of the snapshot set, creating a set of basis vectors which are used in the subsequent step to determine approximations of the solution of the complex system for new physical states, i.e., new sets of parameters. We now provide a definition of a CVT-based reduced basis and then discuss how they are constructed.

2.1. Definition of centroidal Voronoi tessellations for discrete data sets. The definition of centroidal Voronoi tessellations (CVTs) for discrete data sets begins with a set $\mathcal{V} = \{\vec{V}_m\}_{m=1}^{\widetilde{m}}$ consisting of $\widetilde{m}$ vectors belonging to $\mathbb{R}^{\widetilde{j}}$. Of course, $\mathcal{V}$ can also be viewed as a set of $\widetilde{m}$ points in $\mathbb{R}^{\widetilde{j}}$. The definition also requires us to introduce the notion of clustering or tessellation, which in our context is defined to be a subdivision of the set $\mathcal{V}$ into $\widetilde{d} \le \widetilde{m}$ subsets $\mathcal{V}_i$, $i = 1, \dots \widetilde{d}$, such that $\mathcal{V}_i \cap \mathcal{V}_j = \emptyset$ for $i \neq j$ and $\cup_{i=1}^{\widetilde{d}} \mathcal{V}_i = \mathcal{V}$. The set of subsets $\{\mathcal{V}_i\}_{i=1}^{\widetilde{d}}$ is called a [illegible] or a [illegible] of the set $\mathcal{V}$. One way to determine a clustering is to first choose a set $\mathcal{Z} = \{\vec{Z}_i\}_{i=1}^{\widetilde{d}}$ consisting of $\widetilde{d} \le \widetilde{m}$ distinct vectors,[10] also belonging to $\mathbb{R}^{\widetilde{j}}$, and then choose a function $C(\vec{V}) = \vec{Z}$ that assigns each $\vec{V}_m \in \mathcal{V}$ to a particular $\vec{Z}_i \in \mathcal{Z}$, and then letting $\mathcal{V}_i = \{\vec{V}_m \in \mathcal{V} \text{ such that } C(\vec{V}_m) = \vec{Z}_i\}$ for $i = 1, \dots, \widetilde{d}$. We call the collection $(\mathcal{V}, C, \mathcal{Z})$ a [illegible]. The vectors $\vec{Z}_i$ are called [illegible] and the subsets $\mathcal{V}_i$ are called [illegible]. The cardinality of cluster $\mathcal{V}_i$ is denoted by $\overline{m}_i$; clearly, $\sum_{i=1}^{\widetilde{d}} \overline{m}_i = \widetilde{m}$, the cardinality of the set $\mathcal{V}$. The vectors

$$\overline{Z}_i = \frac{1}{\overline{m}_i} \sum_{\vec{V}_m \in \mathcal{V}_i} \vec{V}_m \qquad \text{for } i = 1, \dots, \widetilde{d}$$

are called the [illegible] or [illegible].

For a given set $\mathcal{V}$, a [illegible] or [illegible] of $\mathcal{V}$ is a particular type of cluster configuration for which the cluster generators $\{\vec{Z}_i\}_{i=1}^{\widetilde{d}}$ may be chosen arbitrarily and for which the clustering rule C assigns each $\vec{V}_m \in \mathcal{V}$ to the nearest[11] $\vec{Z}_i \in \mathcal{Z}$:

$$C(\vec{V}_m) = \vec{Z}_i \quad \Longrightarrow \quad |\vec{V}_m - \vec{Z}_i| = \min_{\vec{Z}_j \in \mathcal{Z}} |\vec{V}_m - \vec{Z}_j| \,. \tag{2.1}$$

Given a given set $\mathcal{V}$ of $\widetilde{m}$ vectors in $\mathbb{R}^{\widetilde{j}}$ and a positive integer $\widetilde{d} \le \widetilde{m}$, a [illegible] (CVT) or [illegible] of $\mathcal{V}$ is a special Voronoi tessellation satisfying

$$\vec{Z}_i = \overline{Z}_i \,, \tag{2.2}$$

i.e., the generators of the Voronoi tessellation coincide with the centroids of the corresponding Voronoi clusters. It is important to note that general Voronoi tessellations do not satisfy the CVT property (2.2) so that, for given a set $\mathcal{V}$ and positive integer $\widetilde{d}$, a CVT must be constructed. Algorithms for this purpose are discussed in section 2.2.

CVTs possess an optimization property that can be used as a basis for an alternate definition. Given a given set $\mathcal{V}$ of $\widetilde{m}$ vectors in $\mathbb{R}^{\widetilde{j}}$, a positive integer $\widetilde{d} \le \widetilde{j}$, and a clustering configuration $(\mathcal{V}, C, \mathcal{Z})$, let

$$E(\mathcal{V}, C, \mathcal{Z}) \equiv \sum_{m=1}^{\widetilde{m}} |\vec{V}_m - C(\vec{V}_m)|^2 = \sum_{m=1}^{\widetilde{d}} \sum_{\vec{V}_m \in \mathcal{V}_i} |\vec{V}_m - \vec{Z}_i|^2 \tag{2.3}$$

[10] The vectors in the data set $\mathcal{V}$ need not be distinct.

[11] Of course, there may be more than one vector in $\mathcal{Z}$ that is nearest a $\vec{V}_m$ so that a tie-breaking rule has to be appended to (2.1). For example, among all vectors in $\mathcal{Z}$ that satisfy (2.1), we could choose the one with the smallest index value.

denote [illegible]" Then, it can be shown (see [6]) that among all possible assignment rules $C(\cdot)$ and all possible cluster generators $\{\vec{Z}_i\}_{i=1}^{\widetilde{d}}$, i.e., among all possible cluster configurations, cluster energy minimizers are CVT cluster configurations.

One easily recognizes that (2.3) defines the variance of the clustering so that, as described here, CVTs are minimum variance clusterings of discrete point sets. Thus, in the context discussed here, CVTs are well known in the statistical literature under names like k-means clustering. However, CVTs can be generalized in many ways, e.g., to continuous sets, to other metrics, to weighted energy functionals, etc. Since the latter generalization can be useful in the model reduction setting, we will briefly discuss it in section 4.

The connection between CVTs and reduced bases is now easily made. The set $\mathcal{V}$ is obviously the set of (possibly modified) snapshots. Then, the CVT reduced basis set is the set of generators $\mathcal{Z} = \{\vec{Z}_i\}_{i=1}^{\widetilde{d}}$ of a CVT of $\mathcal{V}$.

2.2. Algorithms for constructing discrete CVTs. Even for moderate values of $\widetilde{m}$ and $\widetilde{d}$, the number of possible clusterings of the data is enormous, meaning that an exhaustive search for minimizers of the cluster energy cannot be carried out. Fortunately, there do exist good algorithms for determining CVTs of discrete point sets. We use the h-means and k-means methods (see, e.g., [16, 39, 40]) which are described in section 2.2.1. The h-means method is cheaper to use than k-means, but does not minimize the cluster energy function directly, and so it is not completely reliable. Since the two methods are compatible, an efficient hybrid technique consists of applying h-means until it can achieve no further energy reduction, followed by (presumably few) steps of k-means to drive the energy down.

The h-means and k-means algorithms have the attractive property of being [illegible] with respect to the cluster energy. Given any cluster configuration $(\mathcal{V}, C, \mathcal{Z})$, both algorithms consider a series of modifications to the cluster assignment function C. However, a modification is only made if it is guaranteed to reduce the cluster energy $E(\mathcal{V}, C, \mathcal{Z})$. Thus, an algorithm based on taking h-means or k-means steps cannot diverge or produce a final clustering having higher energy than the initial clustering. Also, since the set $\mathcal{V}$ is finite dimensional, the algorithms are guaranteed to terminate in finitely many steps. By virtue of the nearest neighbor and centroidal generator features, the resulting clusters will be discretely convex and will tend to correspond to natural clusterings of the data.

The single step approach of the h-means and k-means methods, i.e., the fact that the methods consider one member of the data set $\mathcal{V}$ at a time, has the disadvantage of making the methods vulnerable to "local minima."[12] The k-means algorithm will never allow a one-point modification that increases the cluster energy, and so it is guaranteed to halt if it reaches a local minimum. However, for a given problem, there can be many local minima that are not global minimizers of the cluster energy. To deal with the problem of local minima, one can simply apply the CVT construction algorithm several times, using different initial configurations, and then take the final configuration having the lowest cluster energy to be the best estimate of the optimal configuration. One should also note that in other applications of CVT it has been found the local minima determined by, say, the k-means method yield very good

[12]Given a nearest-neighbor, i.e., a Voronoi, cluster configuration $(\mathcal{V}, C, \mathcal{Z})$, define a *one point change* as a change, for a single data point $\vec{V}_m$, in the value of the cluster assignment function from $C(\vec{V}_m) = \vec{Z}_i$ to $C(\vec{V}_m) = \vec{Z}_j$, followed by the replacement of $\vec{Z}_i$ and $\vec{Z}_j$ by the centroids of their new associated clusters. A *local minimum* is then a cluster configuration $(\mathcal{V}, C, \mathcal{Z})$ with the property that every one-point change results in an increase in the cluster energy.

results; this is borne out by the computational results of this paper which show that CVT reduced-order modeling can provide effective low-dimensional approximations.

2.2.1. The h-means and k-means algorithms. The h-means algorithm begins with an initial cluster configuration $(\mathcal{V}, C, \mathcal{Z})$. Then, for each point $\vec{V}_m \in \mathcal{V}$, the algorithm finds the nearest cluster generator $\vec{Z}_i \in \mathcal{Z}$; if that is not the cluster to which the data point is currently assigned, the data point is "transferred" to the cluster associated with its nearest generator. When all data points have been considered, the cluster generators $\vec{Z}$ are replaced by the centroids of the newly formed clusters. If at least one point was transferred during this process, a new sweep of all the points is carried out, and this continues until a sweep is made in which no point is transferred.

Recall that:

$\mathcal{V} = \{\vec{V}_m\}_{m=1}^{\widetilde{m}}$ denotes the fixed set of points to be clustered into a CVT consisting of $\widetilde{d}$ clusters, where $\widetilde{d}$ is also fixed;

$\mathcal{Z} = \{\vec{Z}_i\}_{i=1}^{\widetilde{d}}$ denotes the cluster generators which can possibly change at each step of the algorithm;

$\{\mathcal{V}_i\}_{i=1}^{\widetilde{d}}$ denotes the clustering of $\mathcal{V}$ which can also possibly change at each step of the algorithm; and

$\overline{d}_i$ denotes the cardinality of the cluster $\mathcal{V}_i$ which can also possibly change at each step of the algorithm.

Then, the h-means algorithm may be formalized as follows:

```
do
    for each V_m ∈ V
        determine Z_i ∈ Z that minimizes |V_m − Z_j|
        if V_m ∉ V_i, then
            reassign V_m to V_i
        end if
    end for
    if no transfers occurred, exit the loop
    for each i = 1, ..., d̃
        Z_i = (1/d̄_i) Σ_{V_m ∈ Z_i} V_m
    end for
end do
```

The k-means algorithm is a sophisticated version of h-means. The h-means transfer test is based on the distance from a point to a cluster center. However, if a point is transferred to a new cluster, the cluster center, when it is recomputed, will move closer to the point, something that h-means misses until the step is complete, i.e., until all points in $\mathcal{V}$ are treated. Within each iteration, the k-means algorithm works with a transfer test that directly measures the change in energy that occurs when a point moves from one cluster to another and then immediately redetermines the cluster centroids before moving to the next point in $\mathcal{V}$. A single k-means sweep is computationally more expensive than a single h-means sweep. This added expense is the reason why the h-means algorithm is employed first to perform the "easy" transfers.[13] The k-means algorithm may be formalized as follows:

[13] How much more expensive is k-mean compared to h-mean depends on exactly how one carries out the steps in the two methods, e.g., how one calculates nearest neighbors. Our limited experience has indicated that it is more efficient to use k-means, especially near the end of the CVT construction process.

```
do
    for each V_m ∈ 𝒱
        evaluate the cluster energy for all possible transfers of V_m from its
          current cluster 𝒱_i to any of the other clusters 𝒱_j, j = 1, ..., d̃,
          j ≠ i
        if moving V_m from its current cluster 𝒱_i to the cluster 𝒱_k will most
          reduce the cluster energy, then
            reassign V_m to cluster 𝒱_k
            replace the cluster generators Z_i and Z_k by the centroids of
            the newly modified clusters 𝒱_i and 𝒱_k, respectively
        end if
    end for
    if no transfers occurred, exit the loop
end do
```

The main lines of a hybrid algorithm can now be made clear. Starting with a randomly initialized cluster configuration, one applies the h-means iteration (presumably many times) and the k-means iteration (hopefully a few times) to produce a locally optimal cluster configuration. One repeats the process several times, each time starting with a different random initial cluster configuration. The generators of the locally optimal configuration having the lowest cluster energy are then output as the approximation to the desired CVT reduced-order basis.

We note that there are several ancillary processing issues that arise in the implementation of CVT construction algorithms. For example, one may wish to thin, shift, or scale the snapshots so that clustering patterns are more readily exposed. One may also want to use, instead of the Euclidean one, metrics that do not differentiate between snapshot vectors which point in nearly the same direction but which have different magnitudes. Additionally, the choice of the initial set of generators can affect the efficiency of a CVT construction algorithm.

3. Computational experiments. To demonstrate the use, efficiency, and accuracy of the CVT-based reduced-order modeling technique, two examples are considered, which we denote the [illegible] and [illegible] problems. Both are incompressible flow problems having boundary conditions that include an inflow shape function containing a multiplicative parameter α that controls the strength of the inflow.

3.1. In/Out problem. The governing equations of two-dimensional incompressible viscous flow in a square region $\Omega = (0,1) \times (0,1)$ are the Navier–Stokes system

$$\frac{\partial \mathbf{u}}{\partial t} - \nu \, \Delta \mathbf{u} + \mathbf{u} \cdot \nabla \mathbf{u} + \nabla p = \mathbf{0} \quad \text{in} \quad (0,T) \times \Omega, \tag{3.1}$$

$$\nabla \cdot \mathbf{u} = 0 \quad \text{in} \quad (0,T) \times \Omega \tag{3.2}$$

along with, for the specific problem we considered here, the initial and boundary conditions

$$\mathbf{u}(0,\mathbf{x}) = \mathbf{u}_0(\mathbf{x}) \quad \text{in} \quad \Omega, \tag{3.3}$$

$$\mathbf{u} = 100 \, \alpha(t) \, y \, (0.2 - y) \quad \text{on} \quad (0,T) \times \Gamma_i, \tag{3.4}$$

$$(\mathbf{n} \cdot \nabla) \, \mathbf{u} = 0 \quad \text{on} \quad (0,T) \times \Gamma_o, \tag{3.5}$$

$$\mathbf{u} = 0 \quad \text{on} \quad (0,T) \times \Gamma_d, \tag{3.6}$$

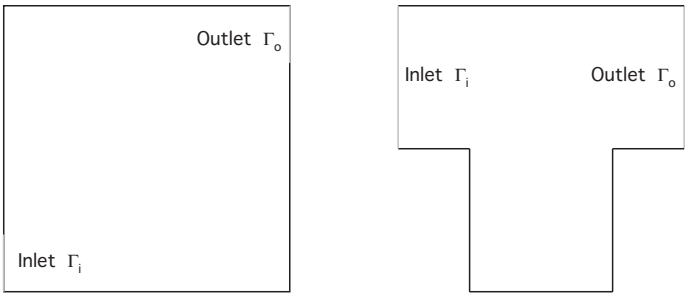

FIG. 3.1. *The flow regions for the In/Out (left) and T-cell (right) examples.*

where $\mathbf{x} = (x, y)$, $\Gamma_i = \{x = 0\,;\, 0 < y < 0.2\}$, and $\Gamma_o = \{x = 1\,;\, 0.8 < y < 1\}$ are the inflow and outflow parts of the boundary, respectively, and $\Gamma_d = \partial\Omega\backslash(\overline{\Gamma}_i \cup \overline{\Gamma}_o)$. See Figure 3.1. In (3.4), $\alpha(t)$ is a parameter that determines the strength of the parabolic inflow velocity profile. We choose $\nu = 1$ and $T = 0.08$.

Accurate Galerkin-mixed method finite element approximations of the solutions of (3.1)–(3.6) are obtained using the $P2$–$P1$ Taylor–Hood finite element pair on a grid of 1681 nodes. Finite element solutions are used for the generation of snapshots and later for comparison with CVT-based reduced-order solutions.

For the generation of snapshots, we will also solve, by the finite element method, stationary versions of (3.1)–(3.6) for which the time derivative term in (3.1) and the initial condition (3.3) are omitted and α in (3.4) is chosen independent of t.

3.1.1. Generating snapshots. We use the procedure given in section 1.1.1 to determine a set of snapshot vectors. First, the finite element approximation to the stationary version of (3.1)–(3.6) with $\alpha = 1$ is obtained. Using that steady-state solution as the initial data $\mathbf{u}_0$ in (3.3) and using $\alpha = 5$ for $0 < t < T/2 = 0.04$ and $\alpha = 1$ for $0.04 < t < T = 0.08$ in the boundary condition (3.4), we then determine a finite element approximation $\sum_{k=1}^{\widetilde{j}} U_k(t)\phi_k(\mathbf{x})$ of the solution of (3.1)–(3.6), where $\widetilde{j}$ denotes the dimension of the finite element space used for the velocity and ϕ_x denotes the basis functions for that space. This is the flow we use to generate the snapshots; it can be viewed as one for which the steady-state solution for $\alpha = 1$ is suddenly jolted, at $t = 0$, by increasing the value of α to five, and jolted again at $t = T/2 = 0.04$ by decreasing the value of α back to one. The 800 snapshot vectors

$$\vec{U}_m = \begin{pmatrix} U_1(t_m) \\ U_2(t_m) \\ \vdots \\ U_{\widetilde{j}}(t_m) \end{pmatrix}, \quad m = 1, \ldots, 800$$

are then determined by evaluating the solution of this impulsively started problem at 800 equally spaced time values t_m, $m = 1, \ldots, 800$, ranging from $t = 0$ to $t = T = 0.08$.

For subsequent use, it is convenient to modify the 800 snapshots so that they satisfy homogeneous boundary conditions. To this end, we first obtain the reference finite element approximation $\mathbf{v}(\mathbf{x}) = \sum_{k=1}^{\widetilde{j}} V_k\phi_k(\mathbf{x})$ of the stationary version of (3.1)–(3.6) with $\alpha = 3$. We then modify the first 400 snapshots by

$$\vec{U}_m \leftarrow \left(\vec{U}_m - \frac{5}{3}\vec{V}\right) \quad \text{for } m = 1, \ldots, 400$$

and, in the same way, the second 250 snapshots are modified

$$\vec{U}_m \leftarrow \left(\vec{U}_m - \frac{1}{3}\vec{V} \right) \quad \text{for } m = 401, \ldots, 800,$$

where

$$\vec{V} = \begin{pmatrix} V_1 \\ V_2 \\ \vdots \\ V_{\widetilde{j}} \end{pmatrix}.$$

In this way, all the snapshots satisfy homogeneous boundary conditions.

The snapshots we have generated by the above processes we will refer to as the [illegible] This is to contrast them with a second set of snapshots we will use, referred to as the [illegible] which are obtained from the nonnormalized snapshots by dividing by their respective length, i.e., the normalized snapshots are given by

$$\vec{U}_m \leftarrow \frac{\vec{U}_m}{|\vec{U}_m|}.$$

We will also used a [illegible] that is determined from the nonnormalized snapshots by deleting every other snapshot from the latter, i.e., the 250 reduced snapshots are given by

$$\vec{U}_m \quad \text{for } m = 2, 4, 6, \ldots, 800.$$

3.1.2. Generating CVT reduced basis. We next apply the algorithms of section 2.2 to determine the generators of a CVT of each of the snapshot sets; a set of generators is to be used as a reduced basis. CVTs having $\widetilde{d} = 4$, 8, and 16 generators are determined. Figure 3.2 displays, for the 4-generator case, the CVT basis computed from the normalized snapshots. Note that since the original boundary conditions have been "subtracted away," each basis function satisfies a zero Dirichlet boundary condition at the inlet, and a zero Neumann condition at the outlet. In the interior of the region, each basis function satisfies (discretized) continuity equation.

Figure 3.3 displays the system of 8 CVT basis functions computed from the same data. It is important to note that the set of size 8 is not built by augmenting the set of size 4; most of the elements of the larger set seem significantly different from any of those of the smaller set.

Each generator $\vec{Z}_i \in \mathbb{R}^{\widetilde{j}}$ of a CVT defines a finite element function, i.e., if

$$\vec{Z}_i = \begin{pmatrix} Z_1^i \\ Z_2^i \\ \vdots \\ Z_{\widetilde{j}}^i \end{pmatrix} \quad \text{for } i = 1, \ldots, \widetilde{d},$$

we then have the corresponding finite element functions

$$\mathbf{z}_i = \sum_{k=1}^{\widetilde{j}} Z_1^i \phi_j(\mathbf{x}) \quad \text{for } i = 1, \ldots, \widetilde{d}.$$

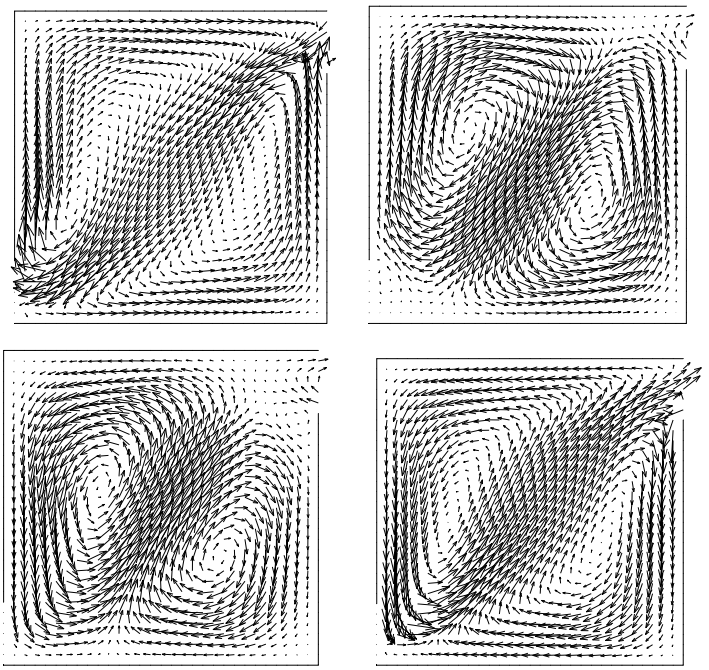

FIG. 3.2. *The CVT basis of dimension* 4 *determined from normalized snapshots.*

3.1.3. Determining CVT-based reduced-order approximations. We now use the Galerkin procedure discussed in section 1.1.3 to determine a CVT-based reduced-order approximation of the velocity field. The approximate velocity field $\mathbf{u}(\mathbf{x}, t)$ is represented as a linear combination of the CVT basis functions as follows:

$$\mathbf{u}_{cvt} = \beta(t)\mathbf{v} + \sum_{i=1}^{\widetilde{d}} a_i(t)\mathbf{z}_i(\mathbf{x}), \tag{3.7}$$

where $\mathbf{z}_i$ denotes the ith CVT basis function, $a_i(t)$ is the corresponding coefficient, $\mathbf{v}$ is the reference solution defined in section 3.1.1, $\beta(t) \equiv \alpha(t)/\alpha_r$, $\alpha_r = 3$, and $\widetilde{d}$ is the total number of CVT basis functions. In our computations, $\widetilde{d} = 4$, 8, or 16. The first term in (3.7) is included so that $\mathbf{u}$ satisfies the boundary conditions in (3.1)–(3.6).

Applying the Galerkin principle which forces the residual to be orthogonal to each of the basis functions, we obtain

$$\begin{aligned} \int_\Omega \frac{\partial}{\partial t}\mathbf{u}_{cvt} \cdot \mathbf{z}_j \, d\Omega + \nu \int_\Omega \nabla \mathbf{u}_{cvt} : \nabla \mathbf{z}_j \, d\Omega \\ + \int_\Omega (\mathbf{u}_{cvt} \cdot \nabla)\mathbf{u}_{cvt} \cdot \mathbf{z}_j \, d\Omega = 0 \qquad \text{for } j = 1, \ldots, \widetilde{d}. \end{aligned} \tag{3.8}$$

Note that due to the fact that the CVT basis functions $\mathbf{z}_j$, $j = 1, \ldots, \widetilde{d}$, are discretely solenoidal, the pressure does not appear in this system. Using (3.7), it is easy to see

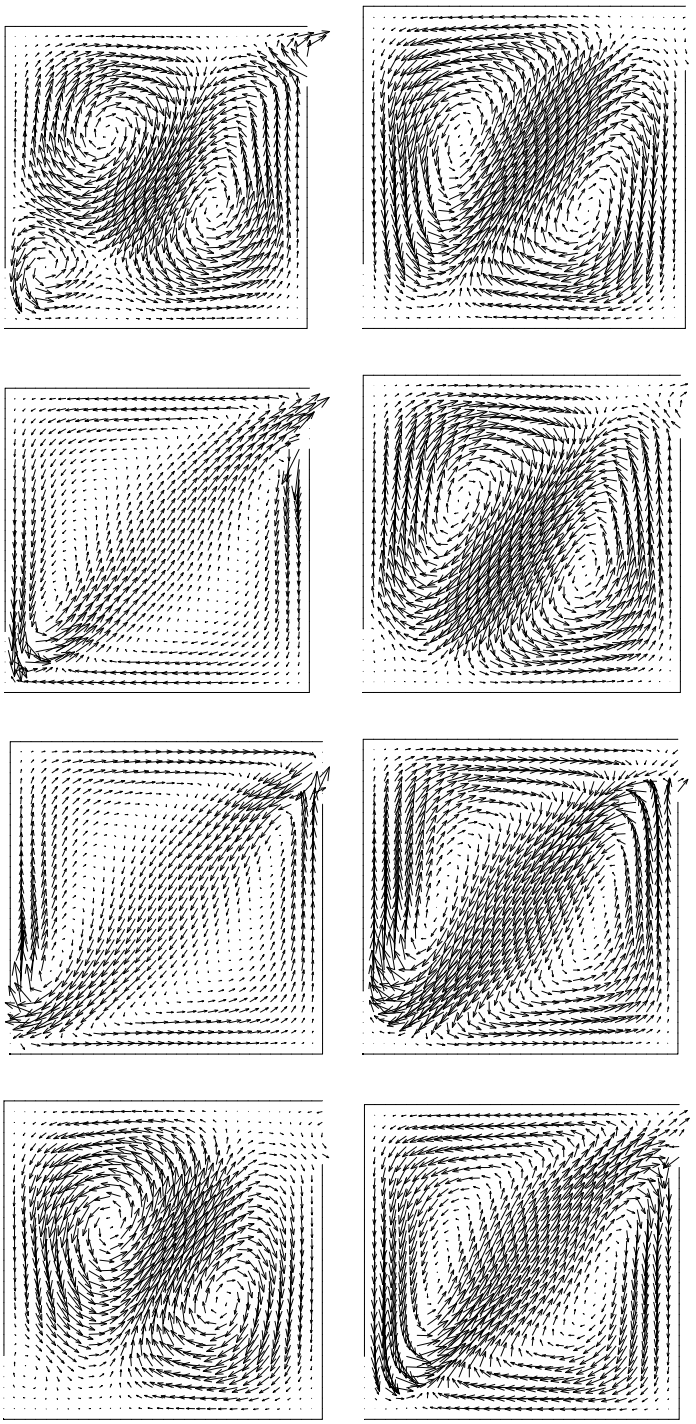

FIG. 3.3. *The CVT basis of dimension 8 function determined from normalized snapshots.*

that (3.8) is equivalent to the system of nonlinear ordinary differential equations

$$
\begin{aligned}
&\sum_{i=1}^{\widetilde{d}} \frac{d}{dt} a_i(t)\Big(\mathbf{z}_i, \mathbf{z}_j\Big) + \nu \sum_{i=1}^{\widetilde{d}} a_i(t)\Big(\nabla \mathbf{z}_i, \nabla \mathbf{z}_j\Big) \\
&+ \left(\sum_{i=1}^{\widetilde{d}} a_i(t)\mathbf{z}_i \cdot \nabla \sum_{k=1}^{\widetilde{d}} a_k(t)\mathbf{z}_k, \mathbf{z}_j\right) + \beta(t) \sum_{i=1}^{\widetilde{d}} a_i(t)\Big(\mathbf{z}_i \cdot \nabla \mathbf{v} + \mathbf{v} \cdot \nabla \mathbf{z}_i, \mathbf{z}_j\Big) \\
&+ \frac{d}{dt}\beta(t)\Big(\mathbf{v}, \mathbf{z}_j\Big) + \beta(t)\Big(\beta(t) - 1\Big)\Big(\mathbf{v} \cdot \nabla \mathbf{v}, \mathbf{z}_j\Big) = 0, \quad j = 1, \ldots, \widetilde{d},
\end{aligned}
\tag{3.9}
$$

along with the initial conditions

$$
\sum_{i=1}^{\widetilde{d}} a_i(0)\big(\mathbf{z}_i, \mathbf{z}_j\big) = \big(\mathbf{u}_0 - \beta(0)\mathbf{v}, \mathbf{z}_j\big), \tag{3.10}
$$

where $(\cdot, \cdot)$ denotes the $L^2(\Omega)$ inner product. The set of ordinary differential equations (3.9)–(3.10) is solved by using a 4th order Runge–Kutta method.

To demonstrate robustness, the low-dimensional, CVT-based dynamic model was solved using several shapes for the inlet velocity factor $\alpha(t)$ and several different choices for the CVT basis set. The two choices for the inlet velocity function for which we present results are given by:

- [illegible] 1: a hat function with respect to time (see Figure 3.4);
- [illegible] 2: a sinusoid with respect to time (see Figure 3.5).

Nine different CVT bases were used: for $\widetilde{d} = 4$, 8, and 16,

- a set of $\widetilde{d}$ CVT basis functions derived from the nonnormalized snapshot set;
- a set of $\widetilde{d}$ CVT basis functions derived from the normalized snapshot set;
- a set of $\widetilde{d}$ CVT basis functions derived from the reduced snapshot set.

In addition, for both Cases 1 and 2, solutions of the system (3.1)–(3.6) were also approximated using the full finite element discretization employing thousands of unknowns.

Computing the CVT-based reduced-order solution for basis function sets of size $\widetilde{d} = 4$, 8, and 16 allowed for some study of the approximation error behavior. The CVT-based solutions are compared to the corresponding solutions of the full finite element system. The relative L^2 error was computed at each time step, based on the difference between the full finite element and CVT-based reduced-order solutions. The plots of these L^2 errors versus time are displayed in Figures 3.4 and 3.5 for Cases 1 and 2, respectively. Note that, for each case and for every time step, the overall L^2 error decreases as the size of the CVT basis set is increased.

Further comparisons are provided in Figures 3.6 and 3.7 where we display, side by side, the full finite element and CVT-based reduced-order solutions using 8 basis functions at selected time steps. Visually, the two solutions seem indistinguishable; however, the CVT-based solution was constructed from a system of 8 ordinary differential equations, while the corresponding finite element solution is derived by solving 1681 ordinary differential equations. The total running time was reduced by a factor of several thousand.

3.2. The T-cell problem. The CVT-based reduced-order modeling methodology was also applied to a second example of flow in a t-shaped region; see Figure 3.1. The flow enters from the left and exits on the right. We choose $\nu = 1$ and $T = 0.05$. A

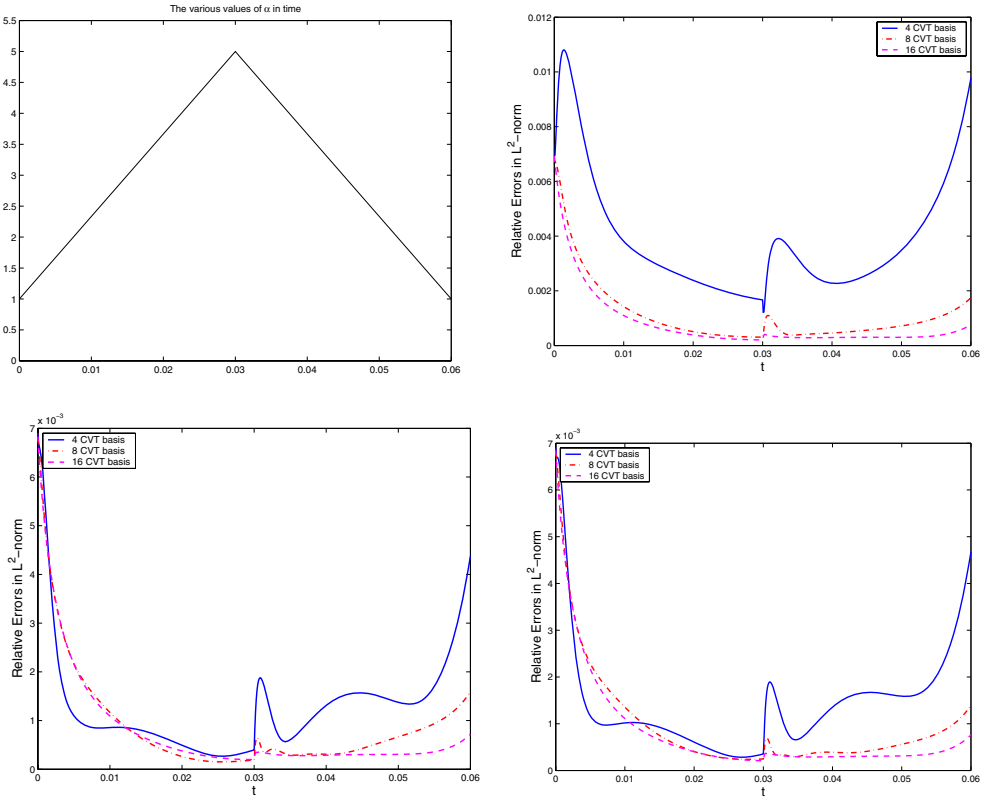

FIG. 3.4. *Multiplicative inflow strength parameter α for Case* 1 *(top left) and L^2-norm of difference between CVT-based reduced-order solutions and a full finite element simulation vs. time for the In/Out problem based on the normalized snapshot set (top right), the nonnormalized snapshot set (bottom left), and the reduced snapshot set (bottom right).*

grid of 4961 nodes was used for all finite element computations. Again, a multiplicative parameter α controls the strength of the inflow. For $0 < t < 0.025$, $\alpha = 5$ was used which represents an abrupt change at $t = 0$ from the value 1 used to generate the steady-state initial condition. For $0.025 < t < 0.05$, $\alpha = 1$ was used which represents another abrupt change at $t = 0.025$. The abrupt changes in the value of α cause sharp transient effects. This single finite element solution of (3.1)–(3.6) was sampled at 500 equally spaced time intervals to generate 500 snapshot vectors.

As for the In/Out problem, computations were performed for CVT bases of size 4 (displayed in Figure 3.8), 8 (displayed in Figure 3.9), and 16. Also, nonnormalized, normalized, and reduced snapshot sets were considered. The nine basis sets were then used to approximate the solution of a time-dependent flow in the T-shaped region. The multiplicative flow strength factor $\alpha(t)$ was chosen to be

$$\alpha(t) = \begin{cases} 160t + 1 & (0 \le t \le 0.025) \\ -160(t - 0.05) + 1 & (0.025 \le t \le 0.05). \end{cases}$$

A finite element solution of the same problem (using 4961 nodes) was also computed for comparison purposes. In Figure 3.10, the time histories of the differences between the CVT-based reduced-order solutions and the full finite element solutions, measured in the $L^2(\Omega)$-norm, are provided for the nine basis sets.

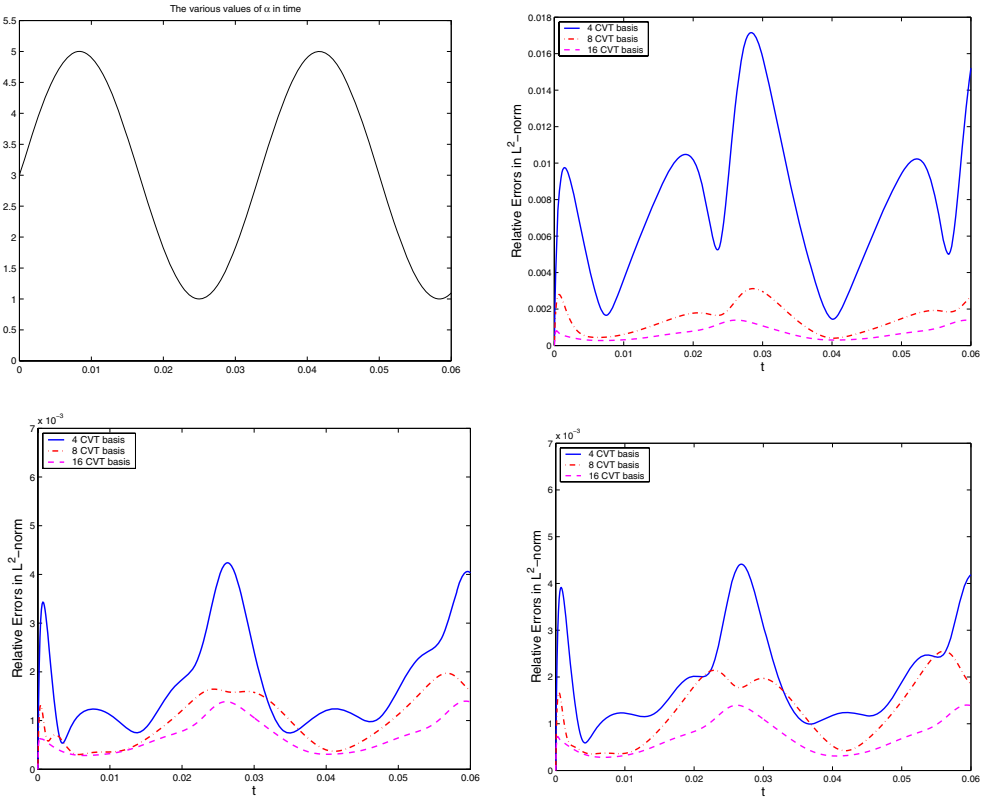

FIG. 3.5. *Multiplicative inflow strength parameter α for Case 2 (top left) and L^2-norm of difference between CVT-based reduced-order solutions and a full finite element simulation vs. time for the In/Out problem based on the normalized snapshot set (top right), the nonnormalized snapshot set (bottom left), and the reduced snapshot set (bottom right).*

3.3. Some information about CVT bases. It is of interest to mention some details about the CVT basis generation process; this discussion will consider the case of 8 CVT generators, based on nonnormalized snapshots, for the T-cell problem.

The basis generation algorithm preprocessed the data by subtracting an appropriate multiple of a steady-state solution that satisfies the boundary conditions and which had been computed with the parameter value $\alpha = 1$. The overall computation was repeated with 15 random initial generator configurations. The inner h-means and k-means algorithms were limited to a maximum of 30 iterations but always concluded before that limit was reached. The initial cluster energy of the random configurations was generally about 50,000; the final cluster energy of the 15 cases varied from 2,879.5 to 3,212.5.

For a "typical" random initial configuration, Table 3.1 shows how the cluster energy drops. Of course, the huge energy at the initial random configuration is slightly misleading. It drops tremendously after the first h-means step, as each data point is assigned to its nearest cluster center.

There was an interesting feature observed about the final cluster generators. For each cluster, the cluster elements tended to comprise all the solutions in a single time interval. In particular, for the case discussed here, the 8 cluster generators had components as listed in Table 3.2. In the interest of clarity, we've renumbered the cluster indices.

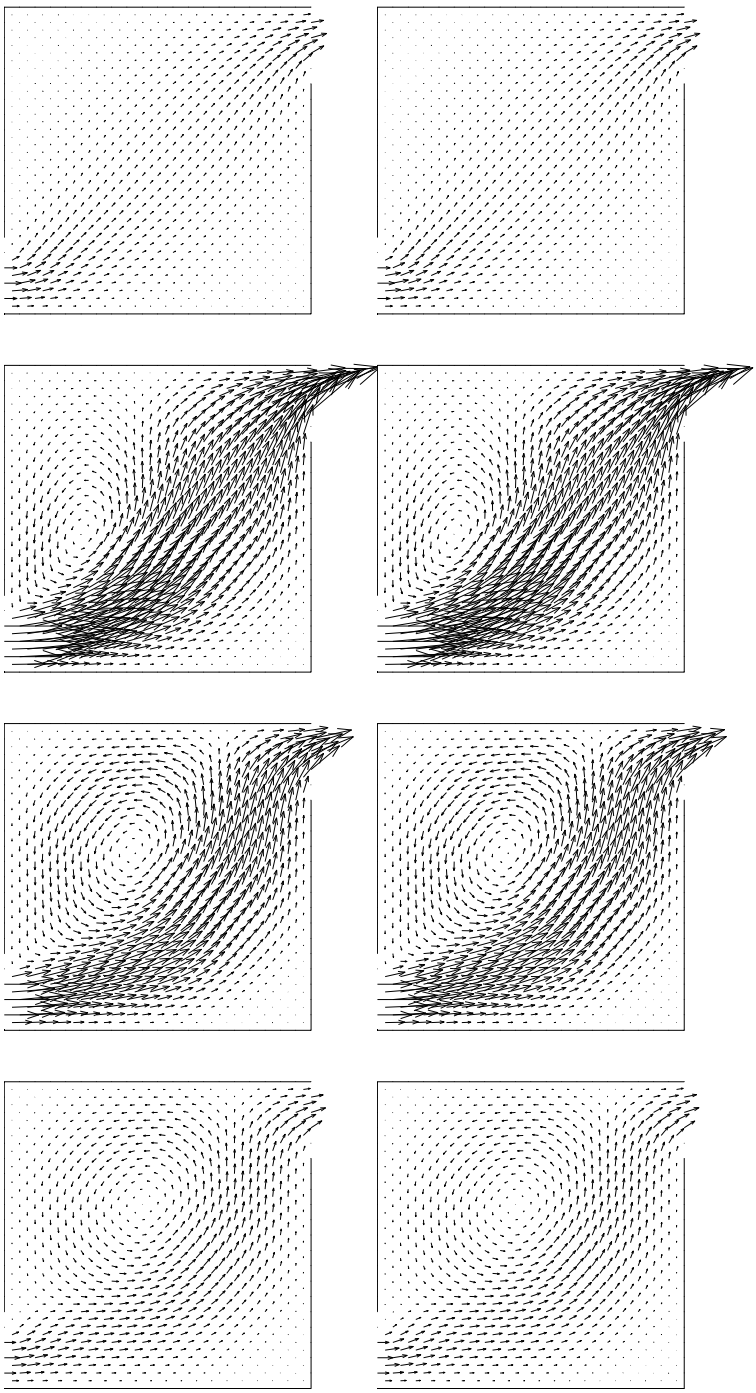

FIG. 3.6. *Full finite element approximation (left) and CVT-based reduced-order approximation of size 8 based on nonnormalized snapshots (right) for* $t = 0.1$ *(top),* $t = 1.0$ *(second),* $t = 1.5$ *(third),* $t = 2.0$ *(bottom).*

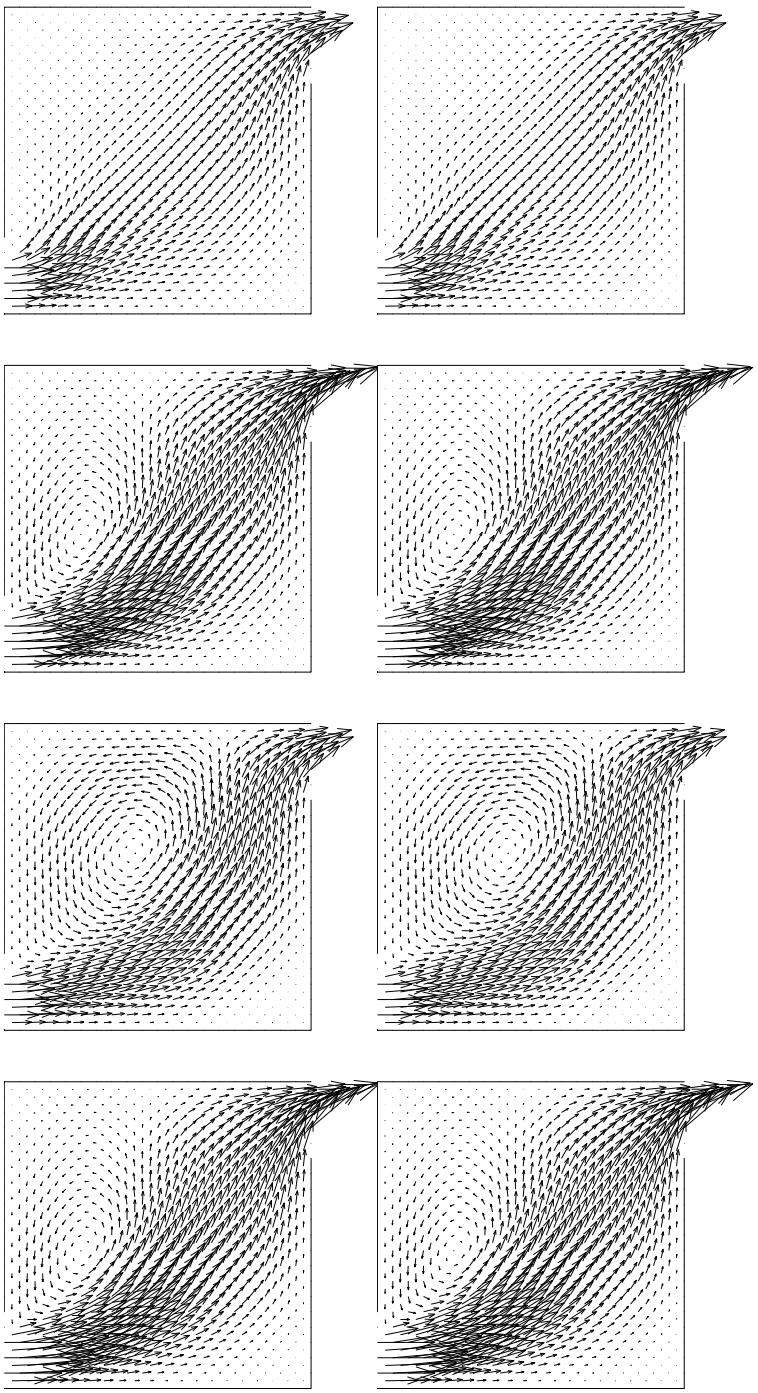

FIG. 3.7. *Full finite element approximation (left) and CVT-based reduced-order approximation of size 8 based on nonnormalized snapshots (right) for* $t = 2.5$ *(top),* $t = 3.0$ *(second),* $t = 3.5$ *(third),* $t = 5.0$ *(bottom).*

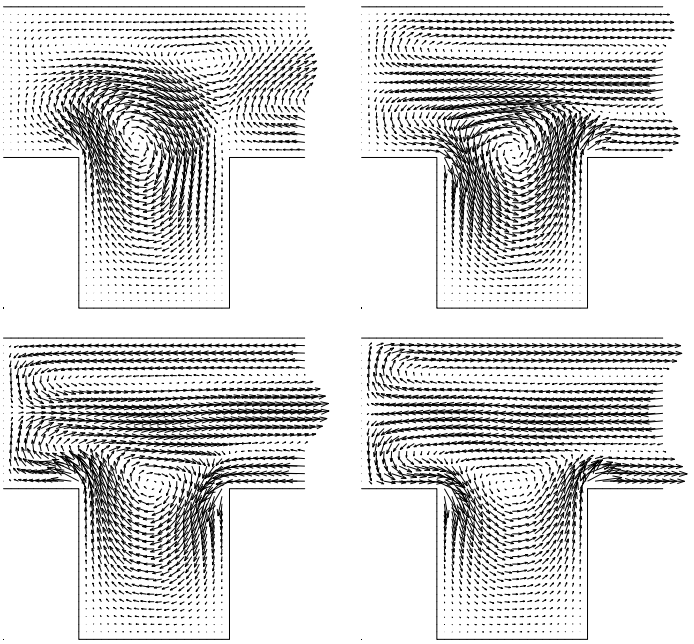

FIG. 3.8. *The CVT basis of dimension 4 determined from nonnormalized snapshots.*

Note that, except for cluster 5, the clusters are formed exactly from a sequence of data points at neighboring times. The two smallest clusters, number 1 and number 6, correspond to the initial transient and the "shock" to the system that occurs after step 250, when the system parameter α is changed. Since the solution is changing rapidly at those times, it makes sense that the clusters are small, and yet still comprise a sizable portion of the total cluster energy. Also, the one exceptional cluster, number 5, corresponds to the relatively quiescent "tails" of the two evolution processes, since it contains the solutions for steps [75, 250] and [308, 500]. This near "sequential" arrangement of snapshots within the clusters may be useful in some settings, e.g., for adapting a CVT basis.

4. Concluding remarks. We have introduced and discussed a centroidal Voronoi tessellation based reduced-order modeling methodology and have shown that it is effective, i.e., accurate and inexpensive, on some example problems. The CVT-based approach is based on data clustering concepts. Compared to POD-based reduced-order modeling approaches, which are the ones in most common use today, the CVT-based approach is potentially less expensive, i.e., for the same number of snapshots and the same number of basis vectors, the CVT-based approach is usually less costly than POD-based approaches which require the solution of a dense eigenvalue of singular value decomposition problem. Although no direct comparisons of POD- and CVT-based results were made, the computational results provided in this paper indicate that the latter approach provides accurate results for the same type of problems for which the former approach works.

There are several avenues for the further development of CVT-based reduced-order modeling methodologies which we are currently considering. First, in [9], a discussion was given of how the CVT- and POD-based reduced-order modeling approaches can be combined to produce a hybrid method (called CVOD in that paper)

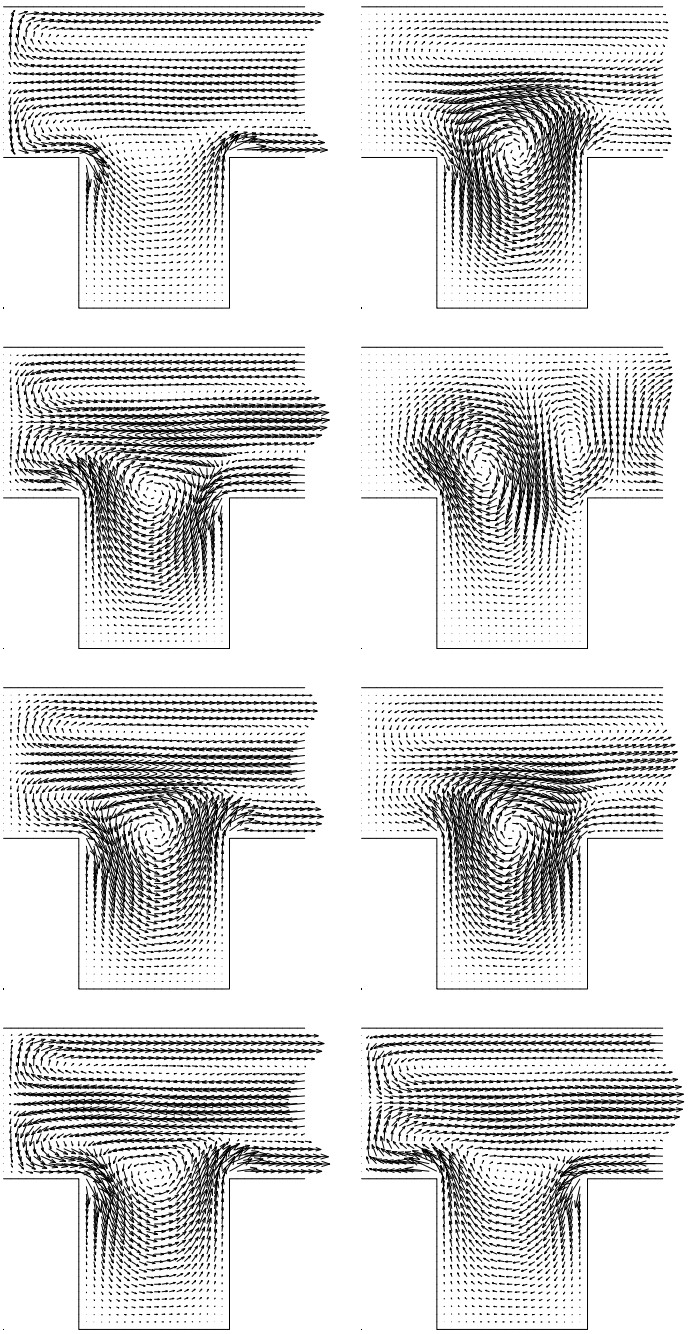

FIG. 3.9. *The CVT basis of dimension 8 determined from nonnormalized snapshots.*

that possesses the good features of both. The implementation of CVOD and experimentation with the various hybridization possibilities is a subject that is certainly deserving of attention.

Another important avenue we are pursuing is the application of CVT- and CVOD-based reduced-order modeling methodologies to control and optimization problems for

complex systems. Many approaches to such problems require multiple or real-time state simulations so that reducing the cost of those simulations is a necessity. Indeed, much of the current interest in the reduced-order modeling of complex systems is motivated by control and optimization problems. One issue that is sure to enter these considerations is the adaptation of reduced-order bases. Adaptation is likely to be needed since, during a control or optimization process, the snapshot set that was used to generate the reduced basis my not remain adequate to represent the dynamic behavior of the system. The "sequential" aspect of CVT clustering of the snapshots may turn out to be a useful feature in this context.

A third avenue is to use the flexibility provided by CVT methodologies to advantage in the reduced-order modeling setting. For example, it is often the case that one wants a certain snapshot or a group of snapshots to have greater influence on the reduced basis than do the others. This can be easily accomplished by simply scaling the important snapshots, or equivalently, by introducing a density function defined over the snapshot set; important snapshots would have high associated densities. CVT construction algorithms would then automatically prejudice some of the generators towards the important snapshots. Furthermore, constrained CVTs can be applied which enable one to include important snapshot vectors in the reduced basis.

RAPID PROLATE PSEUDOSPECTRAL DIFFERENTIATION AND INTERPOLATION WITH THE FAST MULTIPOLE METHOD*

NARAYAN KOVVALI†, WENBIN LIN†, ZHIQIN ZHAO†, LUISE COUCHMAN‡, AND LAWRENCE CARIN§

Abstract. Pseudospectral methods utilizing prolate spheroidal wave functions as basis functions have been shown to possess advantages over the conventional pseudospectral methods based on trigonometric and orthogonal polynomials. However, the spectral differentiation and interpolation steps of the prolate pseudospectral method involve matrix-vector products, which, if evaluated directly, entail $O(N^2)$ memory requirement and computational complexity (where N is the number of unknowns utilized for discretization and interpolation). In this work we show that the fast multipole method (FMM) can be used to reduce the memory requirement and computational complexity of the prolate pseudospectral method to $O(N)$. Example simulation results demonstrate the speed and accuracy of the resulting fast prolate pseudospectral solver.

Key words. prolate spheroidal wave functions, pseudospectral method, differentiation, interpolation, fast multipole method

DOI. 10.1137/050635961

1. Introduction. Pseudospectral methods [5, 10, 11, 26, 27] are some of the most powerful numerical approaches known for solving ordinary and partial differential equations. The strength of pseudospectral methods is derived from the approximation theory of the basis functions used in the discretization procedure. Traditionally, the basis functions have been chosen from families of trigonometric and orthogonal polynomials and related functions. When the functions involved in the problem are sufficiently smooth, pseudospectral methods require very few unknowns to yield solutions with , , ... accuracy, and have consequently found widespread application in many areas, such as fluid dynamics, quantum mechanics, and electromagnetics.

Recently, prolate spheroidal wave functions [3, 18, 24, 25, 29] of order zero have also been used as basis functions in pseudospectral methods [2, 6, 7, 8, 17]. It has been shown that the prolate basis possesses significant advantages over its polynomial counterparts. The prolate expansion, which is the natural tool for effectively representing bandlimited functions on an interval, seems to be more suitable than the orthogonal polynomials for describing wave phenomena encountered in real-world physics and engineering applications. The prolate pseudospectral method yields spectrally accurate results using even fewer unknowns than conventional pseudospectral methods. In addition, the prolate pseudospectral method utilizes a more uniform spatial grid, which has the advantages of (a) achieving better resolution in the center of the domain and (b) allowing for a larger stable time step in the solution of time-dependent problems. It is also easy to modify an existing pseudospectral code to use the prolate spheroidal wave functions.

Regardless of the basis in use, the spectral differentiation and interpolation steps of pseudospectral methods involve matrix-vector products, which, if evaluated directly, entail $O(N^2)$ memory requirement and computational complexity (where N is the number of unknowns utilized for discretization and interpolation). For the pseudospectral methods based on Fourier and Chebyshev polynomial series, the fast Fourier transform (FFT) and the fast cosine/sine transforms, respectively, can be employed to reduce the aforementioned costs to $O(N \log N)$, provided that all computations are restricted to standard grid positions. When the grid is nonstandard, or the pseudospectral methods are based on Legendre and other orthogonal polynomials and related functions, it has been shown [4, 5, 9] that the fast multipole method (FMM) [12, 13, 15] can be used to reduce the costs to $O(N)$.[1] In this work we show that as for the conventional pseudospectral methods, the FMM can also be used to reduce the memory requirement and computational complexity of the prolate pseudospectral method to $O(N)$. The resulting fast prolate pseudospectral solver is ideally suited for the large-scale problems of physics and engineering applications.

The remainder of the paper is organized as follows. Section 2 reviews the pseudospectral method based on prolate spheroidal wave functions. Section 3 describes the fast prolate pseudospectral differentiation and interpolation with the FMM. Example simulation results are presented in section 4, which is followed by conclusion in section 5.

2. Pseudospectral method based on prolate spheroidal wave functions. In this section, we briefly review the framework of the pseudospectral method based on prolate spheroidal wave functions. For a more detailed discussion, the reader is referred to [6, 7, 8, 17].

2.1. Prolate spheroidal wave functions. Prolate spheroidal wave functions [3, 18, 24, 25, 29] of order zero are the eigenfunctions $\psi_j(x)$ of the Helmholtz equation in prolate spheroidal coordinates

$$\left[(x^2-1)\frac{d^2}{dx^2} + 2x\frac{d}{dx} + c^2x^2\right]\psi_j(x) = \chi_j\psi_j(x), \tag{2.1}$$

where $j = 0, 1, \ldots$ denotes the mode number, χ_j are the associated eigenvalues, and the constant c is known as the "bandwidth parameter."

For any positive real c, the prolate spheroidal wave functions are orthonormal on $[-1, 1]$ with respect to the unit weight function. They form a complete basis of $\mathbf{L^2}[-1, 1]$ and a Chebyshev system [29] on this interval. The wave function $\psi_j(x)$ is symmetric for even j and antisymmetric for odd j, and has exactly j zeros in $[-1, 1]$. When $c = 0$, the prolate spheroidal wave functions are the normalized Legendre functions, i.e., $\psi_j(x)|_{c=0} = \overline{P}_j(x)$. The most efficient procedure known for computing the prolate spheroidal wave functions is a Legendre–Galerkin method [3, 29].

Prolate spheroidal wave functions are the natural tool for representing bandlimited functions on the interval. In [6, 8] it was shown that in the representation of a bandlimited function $f(x)$ of bandwidth W (Fourier transform identically zero for frequency $|\omega| > W$), the expansion coefficients decay exponentially as $j \to \infty$, for $j > W$ when a Chebyshev or Legendre basis is used, and for $j > 2W/\pi$ when the

[1] Optionally, the fast eigenfunction transform of [21] can be used, but this is restricted to the case of basis functions which satisfy three-term recurrence relations (like the orthogonal polynomials, for example).

prolate basis with $c = W$ is used.[2] This means that the error in the representation of $f(x)$ using $N > O(W)$ terms of a truncated series of Chebyshev, Legendre, or prolate functions (with parameter c chosen as the bandwidth W) falls [illegible] with increasing N. More important, the prolate expansion is [illegible] to Chebyshev and Legendre polynomial series in that it requires a factor $\pi/2$ fewer unknowns to achieve spectral accuracy.

The parameter c plays an important role in the approximation theory of the prolate spheroidal wave functions. For a bandlimited function of bandwidth W, the value $c = W$ usually seems to be the best choice for the parameter. For functions which are not bandlimited, the optimum value of c is in general not fixed but can be a function of N. Regardless of whether the function being represented is bandlimited or not, all the useful choices of c must satisfy [6]

$$0 \le c < c_*(N) = (\pi/2)(N + 1/2). \tag{2.2}$$

If c does not satisfy (2.2), all the prolate functions in the truncated series vanish near the end points of the interval and are therefore incapable of representing arbitrary functions. Empirical studies for representative prototype functions in [6] show that c can be chosen about one-half to two-thirds of $c_*(N)$ for moderate N, approaching the limit as N increases. Guidelines on the suitable choice of c can also be found in [2]. A simple procedure for obtaining a good approximation to the optimum value of c in practical applications of the prolate pseudospectral method has been given in [20].

2.2. Prolate pseudospectral method. Owing to their promising approximation properties, prolate spheroidal wave functions of order zero have recently been applied as basis functions in the pseudospectral method [6, 7, 8, 17].

Consider the representative equation

$$Lf(x) = g(x) \tag{2.3}$$

on the domain $x \in [-1, 1]$, where L is a linear differential operator, g is a known function, and f is the unknown function to be determined.[3] Boundary conditions accompany the original equation, and it is assumed that the problem is well-posed.

In order to solve (2.3) numerically, the prolate pseudospectral method effects the following discretization procedure. First, the function f is approximated using the semidiscrete representation

$$f(x) = \sum_{j=0}^{N-1} f_j \, C_j(x), \tag{2.4}$$

where $\{f_j, j = 0, \ldots, N-1\}$ are the expansion coefficients and $\{C_j, j = 0, \ldots, N-1\}$ are "cardinal " [5] functions, which are simply a linear combination of the zero-order prolate spheroidal wave functions $\{\psi_j, j = 0, \ldots, N-1\}$. The cardinal functions are designed to satisfy the interpolation property

$$C_j(x_k) = \delta_{j,k}, \quad j, k = 0, \ldots, N-1, \tag{2.5}$$

[2] Even if the function being represented is not bandlimited, under conditions of sufficient smoothness, spectral accuracy can be achieved in the representation.

[3] For simplicity, we have considered functions of only a single variable. The discussion, however, also applies to functions of many variables.

where δ denotes the Kronecker delta symbol and $\{x_k, k = 0, \ldots, N-1\}$ are appropriately chosen "collocation" [5] positions. The advantage of using the cardinal basis is that the expansion coefficients directly provide us the samples of the function f at the collocation positions, i.e.,

$$f_j = f(x_j), \quad j = 0, \ldots, N-1. \tag{2.6}$$

The spatial grid positions used for collocation in pseudospectral methods are usually chosen as the nodes of a Gaussian quadrature associated with the basis functions being employed. In the prolate pseudospectral method, two important choices for the collocation grid points are the prolate Gauss–Lobatto grid and the prolate-Lobatto grid (sometimes also called the "roots" grid) [6]. Both grids include the end points $x_0 = -1$ and $x_{N-1} = 1$ and have been reported to yield similar performance when used in the pseudospectral method. The prolate pseudospectral solver of this paper utilizes the prolate-Lobatto grid defined as follows.

DEFINITION 2.1 (prolate-Lobatto positions). Let ψ_{N-1} be the $N-1$ [illegible] $x_0, \ldots, x_{N-1} \in [-1, 1]$ [illegible] N [illegible] $s(x) = (1-x^2)\psi'_{N-1}(x)$ [illegible] $x_0 = -1$ $x_{N-1} = 1$

We refer the reader to [17] for details on the efficient computation of this grid.

Substituting the expansion (2.4) into (2.3), we get

$$\sum_{j=0}^{N-1} f_j \, LC_j(x) = g(x). \tag{2.7}$$

This is followed by pseudospectral collocation, leading to the prolate pseudospectral discretization of the original equation (2.3) given by

$$\sum_{j=0}^{N-1} f_j \, LC_j(x_k) = g(x_k), \quad k = 0, \ldots, N-1. \tag{2.8}$$

Writing (2.8) concisely in matrix form, we have

$$\mathbf{L}\mathbf{f} = \mathbf{g}, \tag{2.9}$$

where the vector $\mathbf{f}$ comprises the expansion coefficients $\{f_j, j = 0, \ldots, N-1\}$, the vector $\mathbf{g}$ comprises $\{g(x_k), k = 0, \ldots, N-1\}$, and the matrix $\mathbf{L}$ is a representation of the operator L in the prolate basis with elements given by

$$\mathbf{L}(i, j) = LC_j(x_i), \quad i, j = 0, \ldots, N-1. \tag{2.10}$$

The linear system of equations in (2.9) is solved (in conjunction with any boundary conditions) for the expansion coefficients, and the function f is known using (2.4).

3. Fast prolate pseudospectral differentiation and interpolation with the FMM. In the model problem of the previous section, the storage requirement for the dense matrix $\mathbf{L}$ is $O(N^2)$. Moreover, the direct solution of (2.9) requires computational effort proportional to $O(N^3)$, which quickly becomes prohibitive for large N. It is therefore common to use an iterative solver, which only requires the repeated evaluation of matrix-vector products involving $\mathbf{L}$. Unfortunately, the direct computation of these matrix-vector products is still $O(N^2)$ and, given the fact that

the matrix-vector products must be computed repeatedly, even the cost involved in the iterative solution strategy remains challenging.

The situation is even worse for eigenvalue and time-dependent problems. At each iteration of an eigenvalue solver, a linear system similar in form to the one above must be solved. In time-dependent problems, matrix-vector products involving the dense matrix $\mathbf{L}$ have to be evaluated at each of a usually very large number of time steps.

In [4, 5, 9] it has been shown that, when the expansions are based on orthogonal polynomials and related functions, the structure of the pseudospectral discretization matrix is such that the one-dimensional FMM can be used to accelerate computation of the aforementioned matrix-vector products. In this section we show that the structure of the pseudospectral discretization matrix $\mathbf{L}$ can similarly be exploited to evaluate the matrix-vector products efficiently in $O(N)$ operations via the FMM in one dimension. Without loss of generality, we assume in the following that $\mathbf{L}$ is the matrix representation of a first-derivative operator L in the prolate basis.

The matrix-vector products which appear in the prolate pseudospectral method are of two kinds: (a) differentiation on the prolate-Lobatto grid and (b) interpolation onto a different grid. The prolate pseudospectral differentiation on the prolate-Lobatto grid is given by the matrix-vector product

$$f'(x_k) = \sum_{j=0}^{N-1} f_j \, \mathbf{L}(k,j) = \sum_{j=0}^{N-1} f(x_j) \, C_j'(x_k), \quad k = 0, \ldots, N-1, \tag{3.1}$$

and the prolate pseudospectral interpolation onto a different grid $y_0, \ldots, y_{M-1} \in [-1, 1]$ is represented by the matrix-vector product

$$f(y_i) = \sum_{j=0}^{N-1} f(x_j) \, C_j(y_i), \quad i = 0, \ldots, M-1. \tag{3.2}$$

The cost of evaluating (3.1) and (3.2) using direct matrix-vector multiplication is $O(N^2)$ and $O(MN)$, respectively.

The following set of theorems, which can be thought of as prolate analogues of the observations in [4, 5, 9], provide the analytical framework for accelerating the prolate pseudospectral differentiation and interpolation steps to $O(N)$ and $O(M+N)$, respectively, using the FMM in one dimension.

LEMMA 3.1 (prolate cardinal functions). [illegible] $\{C_j, j = 0, \ldots, N-1\}$ [illegible] (2.5) [illegible] $\{x_k, k = 0, \ldots, N-1\}$ [illegible]

$$C_j(x) = \frac{s(x)}{s'(x_j)(x - x_j)}, \quad j = 0, \ldots, N-1, \tag{3.3}$$

[illegible] $s(x) = (1-x^2)\psi'_{N-1}(x)$ [illegible]. First, $C_j(x_k) = 0$ for $j, k = 0, \ldots, N-1$ and $k \neq j$ because by definition the prolate-Lobatto collocation positions satisfy $\{s(x_k) = 0, k = 0, \ldots, N-1\}$. Moreover, $C_j(x_j) = 1$ for $j = 0, \ldots, N-1$ because $\lim_{x \to x_j} s(x)/(x - x_j) = s'(x_j)$. □

[illegible] 3.2. The cardinal functions in (3.3) are [illegible] linear combinations of the prolate spheroidal wave functions; however, numerical experiments [19] indicate that they yield representations for bandlimited functions which are just as good.

THEOREM 3.3 (prolate pseudospectral differentiation). [illegible] (3.1) [illegible] $\{x_k, k = 0, \ldots,$

$N-1\}$

$$f'(x_k) = \frac{f(x_k)s''(x_k)}{2s'(x_k)} + s'(x_k)\sum_{\substack{j=0\\ j\neq k}}^{N-1} \frac{f(x_j)}{s'(x_j)(x_k-x_j)}, \quad k = 0,\ldots,N-1, \tag{3.4}$$

$s(x) = (1-x^2)\psi'_{N-1}(x)$

. Differentiating (3.3), we note that

$$C_j'(x) = -\frac{C_j(x)}{(x-x_j)} + \frac{s'(x)}{s'(x_j)(x-x_j)},$$

which, combined with the fact that $C_j(x_k) = 0$ for $k \neq j$, readily gives us the second term on the right-hand side of (3.4) upon substitution into (3.1) and pulling $s'(x_k)$ out of the summation over j. For the first term on the right-hand side of (3.4), rewrite the differentiation of (3.3) in the form

$$C_j'(x) = \frac{1}{s'(x_j)}\left[\frac{s'(x)(x-x_j) - s(x)}{(x-x_j)^2}\right],$$

take the limit $x \to x_j$, and finally substitute into (3.1). □

THEOREM 3.4 (prolate pseudospectral interpolation).

(3.2)

$y_0,\ldots,y_{M-1} \in [-1,1]$

$\{x_k, k = 0,\ldots,N-1\}$

$$f(y_i) = s(y_i)\sum_{j=0}^{N-1} \frac{f(x_j)}{s'(x_j)(y_i-x_j)}, \quad i = 0,\ldots,M-1, \tag{3.5}$$

$s(x) = (1-x^2)\psi'_{N-1}(x)$

. Use (3.3) for the cardinal functions in (3.2) and pull $s(y_i)$ out of the summation over j. □

3.5. It is well known [9] that numerical pseudospectral differentiation is an ill-conditioned procedure. In fact, for the pseudospectral method based on Chebyshev polynomials, the condition number has been shown [14] to be proportional to N^2 (where N is the size of the differentiation matrix). The prolate pseudospectral method may well suffer from the same problem; however, preliminary experiments [2, 7, 19, 29] seem to indicate that the conditioning may be better than that of Chebyshev differentiation. While this is an important issue and needs further examination, a careful analysis is beyond the scope of this article.

The fast algorithms of this section exploit the form of the expressions in (3.4) and (3.5) for evaluating them efficiently using the FMM in one dimension. A formal description of the algorithms for fast prolate pseudospectral differentiation and interpolation now follows. It is assumed below that the vectors $\{x_k, s'(x_k), s''(x_k), \alpha_k = s''(x_k)/(2s'(x_k)), k = 0,\ldots,N-1\}$ and $\{s(y_i), i = 0,\ldots,M-1\}$ have been precomputed and stored.

ALGORITHM 3.1 (fast prolate pseudospectral differentiation with the FMM).

Input: Function values at prolate-Lobatto points $\{f(x_k), k = 0,\ldots,N-1\}$.
Output: Function derivative at prolate-Lobatto points $\{f'(x_k), k = 0,\ldots,N-1\}$.

Step 1

Comment[Initialization.]
Initialize FMM (all calculations independent of $f(x_k)$ performed here).
Complexity: $O(N)$

Step 2

Comment[Compute charge strengths for the FMM.]
do $j = 0, \ldots, N-1$
  Compute $\beta_j = f(x_j)/s'(x_j)$.
end do
Complexity: $O(N)$

Step 3

Comment[Compute contributions from off-diagonal entries of the differentiation matrix efficiently using the FMM in one dimension.]
Compute $\gamma_k = \sum_{j=0, j\neq k}^{N-1} \frac{\beta_j}{(x_k - x_j)}$, $k = 0, \ldots, N-1$, using the FMM.
Complexity: $O(N)$

Step 4

Comment[Add contribution from the diagonal entries of the differentiation matrix to finish the calculation.]
do $k = 0, \ldots, N-1$
  Compute $f'(x_k) = f(x_k) \cdot \alpha_k + s'(x_k) \cdot \gamma_k$.
end do
Complexity: $O(N)$

ALGORITHM 3.2 (fast prolate pseudospectral interpolation with the FMM).

Input: Function values at prolate-Lobatto points $\{f(x_k),\ k = 0, \ldots, N-1\}$.
Output: Prolate interpolant $\{f(y_i),\ i = 0, \ldots, M-1\}$.

Step 1

Comment[Initialization.]
Initialize FMM (all calculations independent of $f(x_k)$ performed here).
Complexity: $O(M+N)$

Step 2

Comment[Compute charge strengths for the FMM.]
do $j = 0, \ldots, N-1$
  Compute $\beta_j = f(x_j)/s'(x_j)$.
end do
Complexity: $O(N)$

Step 3

Comment[Compute the interpolation matrix contributions efficiently using the FMM in one dimension.]
Compute $\gamma_i = \sum_{j=0}^{N-1} \frac{\beta_j}{(y_i - x_j)}$, $i = 0, \ldots, M-1$, using the FMM.
Complexity: $O(M+N)$

Step 4
Comment[Scale contributions to finish the calculation.]
do $i = 0, \ldots, M-1$
Compute $f(y_i) = s(y_i) \cdot \gamma_i$.
end do
Complexity: $O(M)$

The running times (and storage requirements) of Algorithms 3.1 and 3.2 are $O(N)$ and $O(M+N)$, respectively. The reader will note that the differentiation and interpolation matrices were never explicitly constructed; instead, the interactions have been evaluated efficiently using the FMM. Also, when the prolate pseudospectral differentiation or interpolation is required for many different sets of function values $\{f(x_j),\, j = 0, \ldots, N-1\}$ on the prolate-Lobatto grid positions $\{x_j,\, j = 0, \ldots, N-1\}$, the initialization steps have to be performed only once.

4. Simulation results. In this section, we present numerical simulation results. We first show results of experiments with the FMM and follow this with the solution of an example problem using the FMM-accelerated prolate pseudospectral method. All calculations were carried out in double-precision on a 3.06 GHz Intel Xeon processor.

4.1. Numerical experiments with the FMM. We consider the problem of computing the summations

$$f(x_j) = \sum_{\substack{k=1 \\ k \neq j}}^{N} \frac{q_k}{x_j - x_k}, \quad j = 1, \ldots, N,$$

with $\{x_k, k = 1, \ldots, N\}$ chosen as the Chebyshev Gauss–Lobatto positions

$$x_k = -\cos\left(\frac{k-1}{N-1} \cdot \pi\right), \quad k = 1, \ldots, N,$$

and $\{q_k, k = 1, \ldots, N\}$ being uniform random numbers in $[0, 1]$. Tables 4.1 and 4.2 show comparisons of the CPU-time expended in the computation by the FMM of Algorithm 3.1 in [9] and the direct calculation, for different values of N. The timing for the FMM has been split into two parts: the initialization step and the evaluation step.[4] The relative error in the results (in the l^∞ and l^2 norms) is also listed in the tables. We see that the CPU-time for the FMM computation grows only linearly, as opposed to the quadratic growth of that for the direct calculation. Moreover, if we consider only the CPU-time for the evaluation step, the FMM is almost always more efficient than the direct calculation. We also note that $p = 16$ terms in the Chebyshev expansions of the FMM seem to be sufficient for achieving near double-precision accuracy in the result, with $p = 7$ yielding near single-precision accuracy.

4.1. While the FMM and direct matrix-vector multiplication are, respectively, $O(N)$ and $O(N^2)$ in complexity, the proportionality constants of these costs are somewhat implementation-dependent. It is possible, for example, to decrease the constants (for both methods) by exploiting in the computations involved [5].

[4]The reason for doing this is that in the applications of interest here the summations must usually be computed many times, with $\{x_k, k = 1, \ldots, N\}$ remaining the same but $\{q_k, k = 1, \ldots, N\}$ changing between successive computations. The computations which depend only on $\{x_k, k = 1, \ldots, N\}$ have been collected into the initialization step which therefore needs to be carried out only *once*, while the evaluation step has to be repeated for every different $\{q_k, k = 1, \ldots, N\}$. The point is that it is often the evaluation step of the FMM which governs the total time complexity.

4.2. FMM-accelerated prolate pseudospectral method for the scalar wave equation. Consider the first-order hyperbolic initial boundary value problem

$$\begin{aligned} &u_t = c_0 u_x, && x \in [-1,1], \quad t > 0, \\ &u(x,0) = f(x), && x \in [-1,1], \\ &u(1,t) = g(t), && t \geq 0. \end{aligned} \tag{4.1}$$

The inflow function $g(t)$ is chosen as $f(1 + c_0 t)$, and the exact solution is given by $u(x,t) = f(x + c_0 t)$. We choose $f(x) = \cos^2(\frac{251\pi}{2}x)$ and the wave velocity as $c_0 = 0.05$. Note the high value of the wave number, selected to mimic the situation in large problems.

We solve (4.1) numerically using prolate pseudospectral differentiation in space and the third-order Adams–Bashforth (AB-3) formula [26] in time:

$$\mathbf{v}^{n+1} = \mathbf{v}^n + \frac{1}{12} c_0 \Delta t D_N^P (23\mathbf{v}^n - 16\mathbf{v}^{n-1} + 5\mathbf{v}^{n-2}), \tag{4.2}$$

where $\mathbf{v}^n$ denotes the numerical solution at the nth time step, Δt is the size of the time step, and D_N^P represents the prolate pseudospectral differentiation matrix of size N. The exact solution is used for the three initial AB-3 time steps. For the prolate differentiation matrix, we use bandwidth parameter $c = 790$, which is close to the bandwidth 251π of the bandlimited function $f(x)$, and size $N = 575$ to achieve a relative error of about 10^{-11} in the spatial derivatives. The inflow boundary condition at $x = 1$ is imposed strongly. For the FMM-accelerated prolate pseudospectral method, $p = 16$ terms were used in the Chebyshev expansions of the FMM to retain near double-precision accuracy.

Tables 4.3 and 4.4 show the number of time steps N_{tstep}, running times, and errors in the computed solutions at the grid positions at final time $t_f = 2$ from the direct and FMM-accelerated prolate pseudospectral methods, as a function of Δt. For each row, Δt is decreased by a factor of 5. The following observations can be made:

TABLE 4.3
Direct prolate pseudospectral method for the scalar wave equation (4.1).

- Since N_{tstep} increases by the same factor, the running times (for both methods) also increase fivefold along each row.
- The extremely large errors in the first row are explained by the fact that the discretization (4.2) is unstable for $\Delta t = 5 \times 10^{-3}$. Figure 4.1 confirms this with plots of the stability region for AB-3 time stepping and eigenvalues of the modified prolate differentiation matrix (scaled by $c_0 \Delta t$) for pseudospectral collocation with the strongly imposed boundary condition.[5] As seen from Figure 4.1, for the choice $\Delta t = 5 \times 10^{-3}$ some of the eigenvalues lie outside the stability region and the numerical methods are consequently unstable. Even though the differentiation matrix is not explicitly constructed in the FMM-accelerated method, the "eigenvalues" have their effect. The situation is remedied by choosing $\Delta t = 1 \times 10^{-3}$ in the second row for which the eigenvalues lie inside the stability region and the methods are now stable.[6] For the smaller values of Δt in the remaining rows, stability is retained.
- The errors decrease by factors of 125 along the rows, which is attributed to the third-order accuracy of the AB-3 time stepping (reduction in Δt by a factor of 5 reduces the errors $5^3 = 125$ times). This indicates that it is the error due to temporal discretization which is dominating in these results; the spatial derivatives are very accurate. This pattern is followed until $\Delta t = 1.6 \times 10^{-6}$ in the last row for which the time discretization error is now of the same order as the error in the spatial derivatives. For the FMM-accelerated prolate pseudospectral method, the additional errors introduced by the FMM start becoming important.

[5] It is worth noting here that the eigenvalues of the modified prolate differentiation matrix are known to have negative real parts [8].

[6] It has been shown that eigenvalue analysis only provides necessary conditions for Lax-stability; the necessary and sufficient conditions are obtained using ε-pseudoeigenvalues [16, 22, 23].

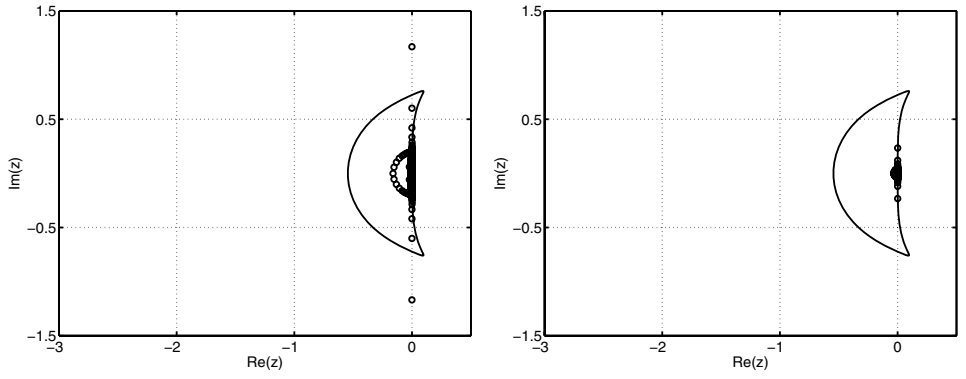

FIG. 4.1. *Stability region for AB-3 time stepping and eigenvalues of the modified prolate differentiation matrix* D_N^P *in* (4.2) *(scaled by* $c_0\Delta t$*) for pseudospectral collocation with a strongly imposed boundary condition.* (a) $\Delta t = 5 \times 10^{-3}$ *(unstable);* (b) $\Delta t = 1 \times 10^{-3}$ *(stable).*

- Finally, the point of this exercise. The FMM-accelerated prolate pseudospectral solver is nearly 3 times faster than the direct prolate pseudospectral method. This figure is consistent with the savings afforded by FMM over direct matrix-vector multiplications for the choice of $N = 575$ (see Table 4.1). Importantly, as opposed to the $O(N^2)$ direct prolate pseudospectral method, the FMM-accelerated prolate pseudospectral solver is an $O(N)$ method. The factor of 3 savings in running time is for our example problem with $N = 575$ unknowns. [illegible] N [illegible]

In the results shown in Table 4.4 for the FMM-accelerated prolate pseudospectral method, the number of terms used in the Chebyshev expansions of the FMM was kept fixed at $p = 16$, ensuring approximately double-precision accuracy. However, as seen from the values of the errors in Tables 4.3 and 4.4, the large errors due to temporal discretization are dominating the accuracy of the results. It therefore seems to be unnecessary to carry out the FMM computations to such high precision. Table 4.5 shows the results of repeating the above experiment for the FMM-based prolate pseudospectral method with p now being varied as a function of the time step Δt. In each case, the value of p is selected according to the accuracy allowed by Δt.

From the results in Table 4.5 we see that, as expected, the errors in the solutions are only slightly affected by this decrease in the precision of the FMM. Note that if p were to be decreased further, the error in the FMM would dominate. The increase in running times along the rows is now more than fivefold. This is because even though N_{tstep} increases only by factors of 5, p is also increasing along the rows. However, with number of terms p used in the FMM expansions changing with Δt, the FMM-accelerated prolate pseudospectral solver is now nearly 3 to 5 times faster than the direct prolate pseudospectral method, with the savings being highest for larger Δt (smaller p). This speedup will increase with the number of unknowns.

[illegible] 4.2. A note on the stability of the AB-3 time stepping in the FMM-accelerated prolate pseudospectral solver for the choice $p = 7$. It is well known that the

stability limit for explicit time stepping in pseudospectral solvers based on Chebyshev and Legendre polynomials is sensitive to the precision with which the computations are carried out [28].[7] The relevant question now is: How are the eigenvalues of the FMM-based (implicit) prolate pseudospectral differentiation matrix D_N^P affected by single-precision accuracy in its representation? The answer is that the eigenvalues are undoubtedly affected by the lower accuracy of the differentiation matrix, but not significantly enough to change the trend in Figure 4.1. This has been verified by examination of its spectrum (not shown here) and is confirmed by the results in Table 4.5.

5. Conclusion. In this paper we have presented fast algorithms for differentiation and interpolation in the pseudospectral method based on prolate spheroidal wave functions. Our approach is motivated by [4, 5, 9], where similar schemes have been developed for conventional pseudospectral methods based on orthogonal polynomials and related functions. Numerical results show that, as compared to the direct prolate pseudospectral method, the FMM-accelerated prolate pseudospectral solver shows significant improvement in running times. For large-scale problems where the number of unknowns is high, the savings are expected to be significant.

Several open questions remain. First, what is the conditioning of prolate pseudospectral differentiation? Our experiments indicate that the conditioning may be better than that of Chebyshev pseudospectral differentiation (which has a condition number proportional to N^2, where N is the size of the differentiation matrix). Second, the FFT is known to improve the numerical stability of Chebyshev differentiation [1]; it is not yet clear what role the FMM-based fast algorithm has to play in this context. A related observation is that, unlike the eigenvalues of the Chebyshev and Legendre differentiation matrices, those of the prolate differentiation matrix do not seem to be highly precision-sensitive. These issues are currently under investigation and results will be reported at a later date.

Acknowledgments. The authors thank Professor Leslie Greengard for several pointers to the FMM literature and Dr. Qian-Yong Chen for useful discussions. The authors are also grateful to the anonymous reviewers for their valuable comments.

[7] The differentiation matrices involved in these methods tend to be ill-conditioned and have eigenvalues which are strongly affected by the working precision. This has led to the concept of "precision-dependent stability" in explicit time stepping schemes used with these methods (see [28] for more details).

AN INTERFACE-STRIP DOMAIN DECOMPOSITION PRECONDITIONER*

ALFIO QUARTERONI†, MARZIO SALA‡, AND ALBERTO VALLI§

Abstract. In this paper we consider domain decomposition preconditioners based on a vertex-oriented (VO) decomposition of the computational domain. In element-oriented (EO) decompositions, each element of the grid belongs to a different domain, while in VO decompositions each vertex belongs to a different subdomain. Based on VO decompositions, we present some preconditioners for the solution of the original system, as well as for that of the Schur complement system. Theoretical properties are investigated for a finite element approximation of an elliptic problem. Numerical results and comparison with state-of-the-art preconditioners are also reported. The numerical results presented here show the effectiveness of the proposed preconditioners and their good scalability properties.

Key words. parallel preconditioner, domain decomposition, Schur complement system

1. Introduction. We consider the iterative solution by Krylov methods of sparse linear systems of type

$$A\mathbf{u} = \mathbf{f}, \tag{1.1}$$

where $A \in \mathbb{R}^{n\times n}$ is a nonsingular matrix, arising from the discretization of a boundary value problem for partial differential equations (PDEs), $\mathbf{u} \in \mathbb{R}^n$ is the solution vector, and $\mathbf{f} \in \mathbb{R}^n$ is the right-hand side of the known terms.

The convergence rate of the adopted Krylov method typically depends on the spectral properties of A, mainly on its condition number $\kappa(A)$. The latter is defined as $|||A|||\cdot|||A^{-1}|||$ (for a suitable matrix norm $|||\cdot|||$), or simply as $\lambda_{\max}(A)/\lambda_{min}(A)$ if the matrix is symmetric and positive definite. Since the matrix A in (1.1) is typically ill-conditioned (see, e.g., [21]), one most often resorts to solving the preconditioned system

$$P^{-1}A\mathbf{u} = P^{-1}\mathbf{f}, \tag{1.2}$$

where P is a nonsingular matrix called the [illegible]. The operator P should approximate A^{-1} as closely as possible so that $\kappa(P^{-1}A) \ll \kappa(A)$, while still being reasonably cheap to invert. Ideally, P should be [illegible]; i.e., $\kappa(P^{-1}A)$ ought not depend on the mesh size, and, when considering parallel preconditioners, a further requirement for P is that it is [illegible]; i.e., $\kappa(P^{-1}A)$ should not depend on the number of processors used in the computations.

In this paper, we address parallel preconditioners issuing from domain decomposition (DD) ideas [27, 22]. DD is currently a very active area of research in the

field of numerical approximation of boundary value problems for PDEs. The key idea of (homogeneous) DD techniques is to split the original computational domain, say Ω, into smaller components $\Omega_i, i = 1, \ldots, M$ (which may or may not overlap), called subdomains, and then solve the boundary value problem on each subdomain. Clearly, additional interface conditions have to be imposed on $\partial\Omega_i \setminus \partial\Omega$. Usually, the original global problem is reformulated as an iterative procedure on the subdomains.

Two approaches can be followed to define DD preconditioners. In [illegible], local Dirichlet-type problems are solved on each Ω_i. Here the communication between the solutions on the different subdomains is guaranteed by the overlapping regions. This procedure, often referred to as the one-level Schwarz method, is not scalable. In fact, the information exchange among the subdomains is only through the overlapping regions. A good scalability may be recovered by the addition of a coarse correction, whose role is to spread out information among distant subdomains. On the other side, [illegible] are usually reformulated in terms of the so-called Schur complement (SC) system. The idea is to partition the set of nodes assigned to each subdomain into the sets of boundary nodes and internal nodes. This latter set can be "condensed." Thus, instead of solving a linear system with matrix A, one can solve a linear system with the SC matrix S. If A is a symmetric and positive definite matrix, it is possible to show that $\kappa(S) \leq \kappa(A)$; see [1].

The very first step in both overlapping and nonoverlapping DD approaches is the decomposition of the computational domain Ω into the subdomains. Here, we analyze two different strategies that can be used to define this decomposition. Let $\Omega \subset \mathbb{R}^d$, $d = 2, 3$, be a polygonal domain, let $\mathcal{T}_h$ be a triangulation made of polygons or polyhedra, and, for the sake of simplicity, assume that the boundary of Ω coincides with that of the triangulation.

We consider the following two cases. In the first approach, $\mathcal{T}_h$ is partitioned into M nonoverlapping parts, namely $\mathcal{T}_{h,1}$, $\mathcal{T}_{h,2}, \ldots, \mathcal{T}_{h,M}$. For each $i = 1, \ldots, M$ we associate to $\mathcal{T}_{h,i}$ a subdomain Ω_i, formed by the interior of the union of the elements of $\mathcal{T}_{h,i}$, while Ω_Γ is composed of a finite number of $d-1$ manifolds; see the left-hand side of Figure 1.1 for an example in the case $M = 2$. This situation represents the common case where Ω_Γ is the union of the part of the boundary of Ω_i that is internal to Ω. This type of decomposition is called [illegible] (EO) because each element of $\mathcal{T}_h$ belongs exclusively to one of the M subdomains Ω_i.

An alternative approach consists of partitioning Ω into $M + 1$ nonoverlapping parts $\mathcal{T}_{h,1}$, $\mathcal{T}_{h,2}, \ldots, \mathcal{T}_{h,M}$, and $\mathcal{T}_{h,\Gamma}$. By construction, the portion of space Ω_Γ of which $\mathcal{T}_{h,\Gamma}$ is a triangulation is now formed by the union of a finite number of "strips" lying between the Ω_i. This decomposition is called [illegible] (VO) because each vertex belongs exclusively to one of the M subdomains Ω_i. This time Ω_Γ is a d-dimensional domain as well (see the right-hand side of Figure 1.1).

Note that, by construction, in an EO decomposition all the vertices on Ω_Γ are shared by two or more subdomains Ω_i, while in a VO decomposition they belong to exactly two subdomains: Ω_Γ and one of the Ω_i.

In this paper we deal with VO decompositions. Indeed, VO decompositions are adopted by several state-of-the-art parallel linear algebra packages. From the point of view of parallel computing, a distinguishing feature of VO decompositions is that the transition region Ω_Γ can be replicated among the processors which hold the Ω_i, which provides a way for data communication. In addition, using a VO approach one may derive the global SC operator from the assembled global matrix A, while adopting

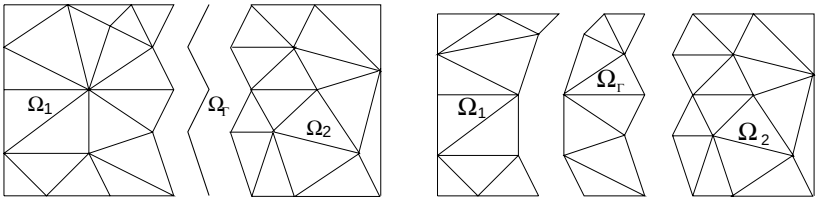

FIG. 1.1. *Example of EO (left) and VO (right) decomposition.*

an EO decomposition would require working at the level of the subdomain assembly process.

In this paper we are concerned with the determination of efficient preconditioners for VO decompositions. Our contribution is twofold. First, we detail how to derive from a VO decomposition a two-level overlapping DD preconditioner that does not require a coarse space. Indeed, for problems arising from PDEs, a typical choice for defining the coarse correction is to solve the original PDE problem on a coarse grid. However, the construction of a coarse grid and that of the corresponding restriction and extension operators may be difficult or computationally expensive on general unstructured grids and arbitrary geometries. In addition, for a general, possibly nonconvex domain it is difficult to ensure that the boundary conditions are correctly represented on the coarse level.

To overcome these difficulties, we show how the VO decomposition easily allows the definition of a coarse operator based on aggregation procedures. The latter have been introduced and analyzed in [29] and [3], and then used for the shallow water equations and two-dimensional (2D) potential flows [20], for three-dimensional (3D) potential flow computations [9], for groundwater flows [13], for multiphase flows [15], for discontinuous Galerkin approximation of advection-diffusion problems [16], and for 3D compressible Euler equations on unstructured tetrahedral grids [24, 10], to mention some uses.

The second, most important, contribution of this paper is the definition of a novel preconditioner, which reformulates classical EO schemes in the VO framework. We detail a new Dirichlet–Neumann DD preconditioner that we call , based on a VO decomposition like that presented in the right-hand side of Figure 2.1. The Dirichlet step is performed in parallel in the domains Ω_i, while the Neumann step is performed in the domain Ω_Γ. When considering the stiffness matrix derived by the finite element approximation of the Laplace operator in two or three dimensions, the condition number of the preconditioned SC turns out to be $O(H/h)$, H being a bound for the diameter of Ω_i and h being the mesh size (therefore, the condition number gets better as the number of subdomains becomes larger, a property that is interesting for parallel numerical computation).

A similar asymptotic behavior of the condition number is proved to hold for other diagonal or diagonal-like preconditioners, as in the case of the SC after condensation [2], the Schwarz method with minimum overlap [6], and the FETI method with lumping [8]. We point out that this estimate is less favorable than others, such as those obtained for the balancing Neumann–Neumann method or the FETI method. However, our algorithm is (it does not necessarily require the introduction of an explicit coarse space), and our preconditioner is , as only one Neumann solver in the domain Ω_Γ (which contains very few mesh nodes) is needed. This last problem is global and, to some extent, is a surrogate for coarse correction. For these reasons,

it turns out that the performance of our method is comparable to that realized by more sophisticated two-level methods in which the coarse space is indeed explicitly introduced, and some presented numerical results confirm this claim.

Finally, another important feature of our algorithm is that the condition number of the preconditioned Schur complement is [illegible] in the coefficients of the elliptic operator.

The paper is organized as follows. In section 2 we introduce the algebraic formalism for EO and VO decompositions. Linear system (1.1) is reformulated for both the EO and the VO approach, pointing out the main differences. The EO approach has been extensively investigated in the literature (see, for instance, [4, 18, 27, 22]); hence, in section 3 we present several preconditioners for the VO decomposition. The solutions of both the original system and the SC system are considered. For the latter, an $O(H/h)$ theoretical estimate of the condition number is obtained. Numerical results are presented in section 4, while in section 5 we draw some conclusions.

2. Element-oriented and vertex-oriented decompositions. The difference between EO and VO decompositions can be easily appreciated in the case of two subdomains. Therefore, unless otherwise stated, in the following discussion we consider a decomposition in two subdomains Ω_1 and Ω_2, so that $\overline{\Omega} = \overline{\Omega_1} \cup \overline{\Omega_2} \cup \overline{\Omega_\Gamma}$.

We need to introduce some notation. The nodes on $\overline{\Omega_\Gamma}$ will be called [illegible] nodes, and in particular those on $\overline{\Omega_i} \cap \overline{\Omega_\Gamma}$ are the border nodes of the domain Ω_i. A node of $\overline{\Omega_i}$ which is not a border node is called [illegible] to Ω_i, $i = 1, \ldots, M$.

For vectors, we will consistently use the subscripts I and B to indicate internal and border, respectively, while the superscript (i) will denote the domain to which we are referring. Thus, $\mathbf{u}_I^{(i)}$ will indicate the vector of unknowns associated to nodes internal to Ω_i, while $\mathbf{u}_B^{(i)}$ is associated to the border nodes. The dimensions of these vectors will be denoted $n_I^{(i)}$ and $n_B^{(i)}$, respectively. Unless otherwise specified, for matrices we will use the superscript (i) to indicate the subdomain to which we are referring.

2.1. Element-oriented decompositions. In the case of two subdomains, one can rewrite (1.1) so that the nodes associated to Ω_1 are ordered first, followed by the nodes internal to Ω_2, and finally by those on Ω_Γ. Therefore,

$$\begin{pmatrix} A_{II}^{(1)} & 0 & A_{IB}^{(1)} \\ 0 & A_{II}^{(2)} & A_{IB}^{(2)} \\ A_{BI}^{(1)} & A_{BI}^{(2)} & A_{BB}^{(1)} + A_{BB}^{(2)} \end{pmatrix} \begin{pmatrix} \mathbf{u}_I^{(1)} \\ \mathbf{u}_I^{(2)} \\ \mathbf{u}_B \end{pmatrix} = \begin{pmatrix} \mathbf{f}_I^{(1)} \\ \mathbf{f}_I^{(2)} \\ \mathbf{f}_B \end{pmatrix}. \tag{2.1}$$

If A is symmetric, then $A_{BI}^{(i)} = (A_{IB}^{(i)})^T$. $A_{BB}^{(i)}$ represents the mutual influence of the border nodes of Ω_i. For example, in the case of a finite element discretization, one has

$$[A_{BB}^{(i)}]_{kj} = a(\varphi_j|_{\Omega_i}, \varphi_k|_{\Omega_i}),$$

where φ_k, φ_j are the finite element shape functions associated to border nodes k and j, respectively, restricted to the subdomain Ω_i. The two null blocks arise because of the local support of the shape functions.

Eliminating the internal nodes from system (2.1) gives

$$S_{EO}\mathbf{u}_B = \mathbf{g}, \tag{2.2}$$

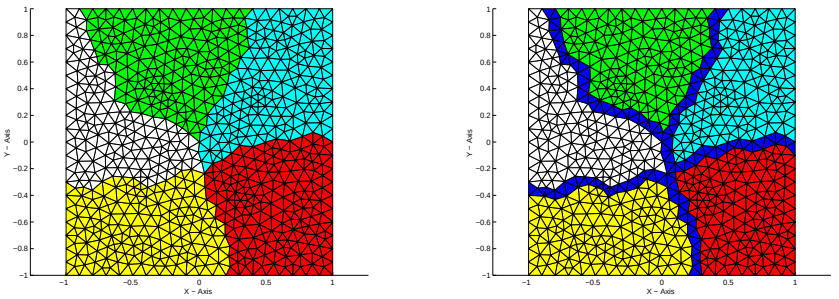

FIG. 2.1. *On the left, EO decomposition: Each element is assigned to a different subdomain* $\Omega_i, i = 1, \dots, M$. *On the right, VO decomposition: Each vertex is assigned to a different subdomain. The blue domain is called* Ω_Γ.

where $S_{EO} = S_1 + S_2$ and $\mathbf{g} = \mathbf{g}^{(1)} + \mathbf{g}^{(2)}$, with

$$S_i = A_{BB}^{(i)} - A_{BI}^{(i)} {A_{II}^{(i)}}^{-1} A_{IB}^{(i)}, \tag{2.3}$$

$$\mathbf{g}^{(i)} = \mathbf{f}_B^{(i)} - A_{BI}^{(i)} {A_{II}^{(i)}}^{-1} \mathbf{f}_I^{(i)}. \tag{2.4}$$

The generalization to an arbitrary number of subdomains (see the left-hand side of Figure 2.1) is straightforward. We introduce the restriction matrix $\bar{R}_i \in \mathbb{R}^{n_B^{(i)} \times n_B}$ which from a global vector $\mathbf{u}_B \in \mathbb{R}^{n_B}$ extracts the entries corresponding to the border nodes of Ω_i, i.e., $\mathbf{u}_B^{(i)} = \bar{R}_i \mathbf{u}_B$. Its transpose $\bar{R}_i^T$ is the prolongation matrix relative to the subdomain Ω_i which extends by zero a vector of border values. Then,

$$S_{EO} = \left(\sum_{i=1}^{M} \bar{R}_i^T S_i \bar{R}_i \right), \quad \mathbf{g} = \mathbf{f}_B - \sum_{i=1}^{M} \bar{R}_i^T A_{BI}^{(i)} {A_{II}^{(i)}}^{-1} \mathbf{f}_I^{(i)}.$$

2.2. Vertex-oriented decompositions. The strategy of section 2.1 can be followed for VO decompositions. In this case, (1.1) can be rewritten as

$$A\mathbf{u} = \begin{pmatrix} A_{II}^{(1)} & A_{IB}^{(1)} & 0 & 0 \\ A_{BI}^{(1)} & A_{BB}^{(1)} + A_\Gamma^{(1,1)} & 0 & A_\Gamma^{(1,2)} \\ 0 & 0 & A_{II}^{(2)} & A_{IB}^{(2)} \\ 0 & A_\Gamma^{(2,1)} & A_{BI}^{(2)} & A_{BB}^{(2)} + A_\Gamma^{(2,2)} \end{pmatrix} \begin{pmatrix} \mathbf{u}_I^{(1)} \\ \mathbf{u}_B^{(1)} \\ \mathbf{u}_I^{(2)} \\ \mathbf{u}_B^{(2)} \end{pmatrix} = \begin{pmatrix} \mathbf{f}_I^{(1)} \\ \mathbf{f}_B^{(1)} \\ \mathbf{f}_I^{(2)} \\ \mathbf{f}_B^{(2)} \end{pmatrix}. \tag{2.5}$$

The border nodes are split into two subsets, one belonging to $\overline{\Omega_1}$ and the other to $\overline{\Omega_2}$. A_Γ represents the mutual influence of border nodes, considering only the contribution from the subdomain Ω_Γ. For instance, in the case of a finite element discretization, one has

$$[A_\Gamma^{(l,m)}]_{ij} = a(\varphi_j|_{\Omega_\Gamma}, \varphi_i|_{\Omega_\Gamma})$$

for $i \in \overline{\Omega_l} \cap \overline{\Omega_\Gamma}$ and $j \in \overline{\Omega_m} \cap \overline{\Omega_\Gamma}$.

The elimination of the vector associated to the internal nodes leads to the system

$$S_{VO}\mathbf{u}_B = \begin{pmatrix} S_1 + A_\Gamma^{(1,1)} & A_\Gamma^{(1,2)} \\ A_\Gamma^{(2,1)} & S_2 + A_\Gamma^{(2,2)} \end{pmatrix} \begin{pmatrix} \mathbf{u}_B^{(1)} \\ \mathbf{u}_B^{(2)} \end{pmatrix} = \begin{pmatrix} \mathbf{g}^{(1)} \\ \mathbf{g}^{(2)} \end{pmatrix}, \tag{2.6}$$

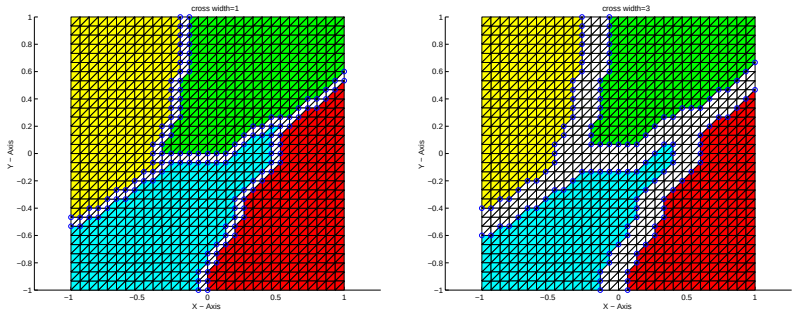

FIG. 2.2. *Two VO unstructured decompositions, with $M = 4$ and cross width $\delta = 1$ (left) and $\delta = 3$ (right).*

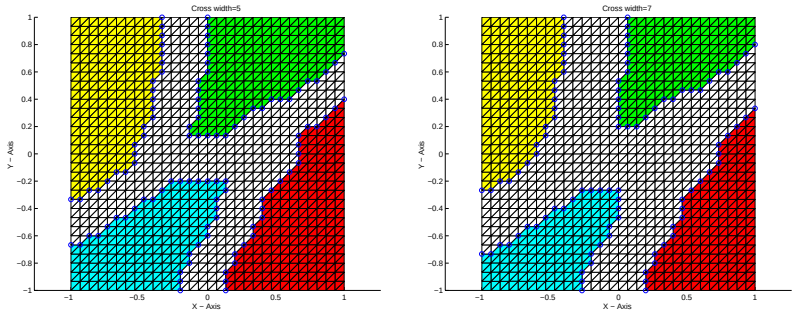

FIG. 2.3. *Two VO unstructured decompositions, with $M = 4$ and cross width $\delta = 5$ (left) and $\delta = 7$ (right).*

with S_i and $\mathbf{g}^{(i)}$ defined by (2.3) and (2.4). Its generalization to the case of M subdomains gives

(2.7)
$$\begin{pmatrix} S_1 + A_\Gamma^{(1,1)} & A_\Gamma^{(1,2)} & \dots & A_\Gamma^{(1,M)} \\ A_\Gamma^{(2,1)} & S_2 + A_\Gamma^{(2,2)} & \dots & A_\Gamma^{(2,M)} \\ \vdots & \vdots & \ddots & \vdots \\ A_\Gamma^{(M,1)} & A_\Gamma^{(M,2)} & \dots & S_M + A_\Gamma^{(M,M)} \end{pmatrix} \begin{pmatrix} \mathbf{u}_B^{(1)} \\ \mathbf{u}_B^{(2)} \\ \vdots \\ \mathbf{u}_B^{(M)} \end{pmatrix} = \begin{pmatrix} \mathbf{g}^{(1)} \\ \mathbf{g}^{(2)} \\ \vdots \\ \mathbf{g}^{(M)} \end{pmatrix}.$$

Some of the blocks $A_\Gamma^{(i,j)}$ may in fact be empty. This happens when no element in the triangulation contains nodes belonging to both $\overline{\Omega_i}$ and $\overline{\Omega_j}$.

The subdomain Ω_Γ can be characterized by its , that is, the minimum number of elements that one has to cross moving from a subdomain Ω_i to an $\Omega_j, i \neq j$. Formally, this width can be defined as follows. Let us indicate with Δ_{ij} the minimum number of edges that one has to cross when moving from an arbitrary node belonging to Ω_i to a node of Ω_j, $i, j = 1, \dots, M, i \neq j$; then

$$\delta = \min_{i,j} \Delta_{ij}$$

represents the width of Ω_Γ. In the VO decomposition described so far, we have $\delta = 1$, while an EO decomposition has $\delta = 0$. Examples of VO decomposition for $M = 4$ and $\delta = 1, 3, 5, 7$ are given in Figures 2.2 and 2.3. The algorithm reported in Figure 2.4 can be used to increment the width of a given decomposition.

```
1  For k = 1, ..., N Do
2      For every element j of T_{h,i}, i = 1, ..., M Do:
3          If k is a border node, assign the element j to T_{h,Γ}
4      End For
5      Update the set of internal and border nodes
6  End For
```

FIG. 2.4. *Algorithmic procedure to increment δ for a given VO decomposition.*

3. Preconditioners for vertex-oriented decompositions. We now focus on the definition of overlapping and nonoverlapping Schwarz preconditioners for VO decompositions. First, in section 3.1 we revisit aggregation techniques and illustrate how to take advantage of VO decompositions to define a two-level Schwarz preconditioner for the original system (1.1). Then, in section 3.2 we introduce a novel preconditioner, based on the application of Dirichlet–Neumann algorithms to the VO decomposition, and present a bound on the condition number of the resulting system.

3.1. Preconditioners for the original system. Let $A_i = R_i A R_i^T$, $i = 1, \ldots, M$, where R_i is the rectangular (restriction) matrix which, when applied to a vector corresponding to $\overline{\Omega}$, returns its components in $\overline{\Omega_i}$. The matrix A_i can also be defined as

$$A_i = \begin{pmatrix} A_{II}^{(i)} & A_{IB}^{(i)} \\ A_{BI}^{(i)} & A_{BB}^{(i)} + A_{\Gamma}^{(i,i)} \end{pmatrix}.$$

Given the A_i's, a two-level Schwarz preconditioner $P_{S,C,add}$ can be expressed as

$$P_{S,C,add}^{-1} = \sum_{i=0}^{M} R_i^T A_i^{-1} R_i. \tag{3.1}$$

A_0 is the so-called [illegible], whose role is to spread out information among the distant subdomains. The construction of A_0 involves the discretization of the PDE problem on a coarser grid, whose number of elements n_0 is much lower than that of the original fine grid.

This procedure may be difficult or computationally expensive on general unstructured grids and arbitrary geometries. In addition, for a general, possibly nonconvex domain, it is difficult to ensure that the boundary conditions are correctly represented on the coarse level.

In VO decompositions, however, the definition of a coarse operator can be based on aggregation procedures. Precisely, on each subdomain Ω_i we build $n_{0,i}$ [illegible] $\vartheta_{i,s}$, $i = 1, \ldots, M$, $s = 1, \ldots, n_{0,i}$, each of them representing a set of contiguous vertices; see Figure 3.1 for an example in two dimensions. Then on every Ω_i, each aggregate is associated to a vector $\boldsymbol{\eta}_{s,i}$, $s = 1, \ldots, n_{0,i}$, whose elements are built following the rule

$$\boldsymbol{\eta}_{s,i}(k) = \begin{cases} 1 & \text{if } k \text{ belongs to } \vartheta_{s,i}, \\ 0 & \text{otherwise.} \end{cases}$$

At this stage, the construction of R_0, called the smoothed aggregation (SA) procedure, is made in two steps: coarsening and grid transfer construction. The former corresponds to building a nonsmoothed restriction operator $\tilde{R}_0$ so that each fine

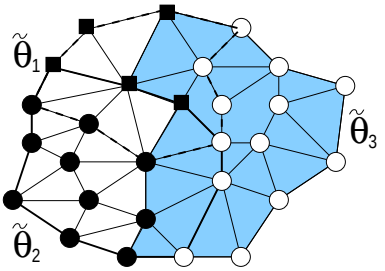

FIG. 3.1. *Examples of aggregates for a 2D domain. The nodes marked with ■, ○, and • belong to $\tilde{\vartheta}_1$, $\tilde{\vartheta}_2$, and $\tilde{\vartheta}_3$, respectively.*

grid node is included in just one aggregate. This decomposition can be obtained using a graph partitioning algorithm (VO decomposition of the grid). The value $n_0 = \sum_{i=1}^{M} n_{0,i}$ represents the dimension of the coarse space, since each aggregate will be given a coarse grid basis function. We will indicate with $\tilde{\vartheta}_i$ the set of nodes that form the nonsmoothed aggregate i. The entries of $\tilde{R}_0$ are

$$\tilde{R}_0(i,j) = \begin{cases} 1 & \text{if } j \in \tilde{\vartheta}_i, \\ 0 & \text{otherwise.} \end{cases} \tag{3.2}$$

$\tilde{R}_0$ can be viewed as a simple grid transfer operator corresponding to piecewise constant interpolation. A 2D example is reported in Figure 3.1. The second step (which may actually be avoided) consists of applying a prolongation smoother $\tilde{S}_0$ to produce the final prolongation operator $R_0^T = \tilde{R}_0^T \tilde{S}_0$. For more details, the reader is referred to [29, 3].

3.2. Preconditioners for the SC system. Equation (2.7) may be reinterpreted as a two-subdomain formulation, the subdomains being given by Ω_Γ and $\Omega_\star = \cup_{i=1}^{M} \Omega_i$. Clearly one has $\overline{\Omega} = \overline{\Omega_\star} \cup \overline{\Omega_\Gamma}$, and

$$S_{VO} = S_\star + A_\Gamma, \tag{3.3}$$

with $S_\star = \text{blockdiag}\{S_i, i = 1, \ldots, M\}$. In (3.3), $S_\star$ is the SC obtained by eliminating the internal nodes of $\Omega_\star$, while the SC of domain Ω_Γ, usually indicated by S_Γ, coincides with A_Γ, since no internal nodes have been included in Ω_Γ.

Note that $S_\star$ has a (dense) diagonal block form, while A_Γ is sparse and, in general, features many zero-blocks.

For the matrix (3.3) we propose three preconditioners:

$$P_\star = S_\star, \quad P_\Gamma = A_\Gamma, \quad P_{NN} = (S_\star^{-1} + A_\Gamma^{-1})^{-1}. \tag{3.4}$$

$P_\star$ and P_Γ are formally equivalent to Dirichlet–Neumann (DN) preconditioners [22, section 3.2]. The inversion of $P_\star$ involves M Neumann solves (one in every Ω_i), whereas only one Neumann solve in Ω_Γ is required to invert P_Γ. The latter solve is somehow unusual since all the nodes of Ω_Γ stand on the border of the domain Ω_Γ. P_{NN} is the two-subdomain Neumann–Neumann (NN) preconditioner.

1. The DN and NN preconditioners are optimal for the two-subdomain case. However, the analysis requires the subdomains to have a measure independent of h. This condition is not verified when we use as preconditioner $P_\star$, P_Γ, or P_{NN}, since

the width of Ω_Γ is of order h. Clearly, if the subdivision is modified so that Ω_Γ has a measure independent of h, then $P_\star$, P_Γ, and P_{NN} become optimal preconditioners.

The preconditioner P_Γ behaves better (both theoretically and numerically) than $P_\star$ (see the theoretical results in Proposition 1, which we have been able to prove only for the P_Γ preconditioner; see, moreover, the numerical results in Table 6). On the other hand, though the condition number of $P_{NN}^{-1}S_{VO}$ is in general slightly lower than that of $P_\Gamma^{-1}S_{VO}$ (see Table 6), the computational complexity of P_{NN} is higher than that of P_Γ, as it requires $M+1$ solves. Moreover, in the "floating" subdomains Ω_i (those internal to Ω), the solution of a pure Neumann problem can demand compatibility conditions on the data. For this reason, in what follows we will focus almost exclusively on the preconditioner P_Γ.

We now derive a convergence estimate for the interface-strip preconditioner. For the sake of simplicity, the estimate of the condition number of the preconditioned Schur complement $P_\Gamma^{-1}S$ will be presented only in a case of simple geometry for the Laplace operator with homogeneous boundary conditions. However, using similar arguments, the interested reader could easily extend the result to more general situations: For instance, the result is true for any second-order elliptic operator (without zero-order terms and being associated to a symmetric and coercive bilinear form), and also for the two-dimensional elasticity system; however, other boundary conditions and domains are allowed as well. In particular, in Remark 2 we consider the important case of a diffusion coefficient with jumps, showing that the condition number of the preconditioned Schur complement is independent of the jumps.

Let us consider the square $\Omega = (0,1)\times(0,1)$ and a family of uniform triangulations $\mathcal{T}_h$ of it. We assume that Ω is subdivided into the union of the disjoint squares Ω_j, $j = 1,\dots,M$, with side-length H such that $\sqrt{M}(H+h) = 1+h$, and of the domain Ω_Γ, which is connected and consists of the union of $2(\sqrt{M}-1)$ nondisjoint strips of length 1 and width h. Let us also set

$$\Omega_\star = \cup_{j=1}^{M}\Omega_j, \quad \Omega_\Gamma = \Omega \setminus \overline{\Omega_\star}, \quad \Gamma = \overline{\Omega_\star}\cap\overline{\Omega_\Gamma}. \tag{3.5}$$

We denote by η_h the trace on Γ of the piecewise [illegible] functions v_h defined in Ω. Then, we indicate by $E_{h,\star}\eta_h$ the discrete harmonic extension of η_h in $\Omega_\star$ and by $E_{h,\Gamma}\eta_h$ the discrete harmonic extension of η_h in Ω_Γ. Since in Ω_Γ there are no internal nodes (the width of Ω_Γ is equal to h), the function $E_{h,\Gamma}\eta_h$ is simply the interpolant of η_h in $\overline{\Omega_\Gamma}$.

The action of both the Schur complement S and P_Γ can be expressed through the local bilinear forms in the following way (here $\boldsymbol{\eta}$ and $\boldsymbol{\mu}$ denote the vector of the nodal values of η_h and μ_h, respectively) (see, e.g., [22, p. 22]):

$$S\boldsymbol{\eta}\cdot\boldsymbol{\mu} = \int_{\Omega_\star}\nabla E_{h,\star}\eta_h\cdot\nabla E_{h,\star}\mu_h + \int_{\Omega_\Gamma}\nabla E_{h,\Gamma}\eta_h\cdot\nabla E_{h,\Gamma}\mu_h,$$

$$P_\Gamma\boldsymbol{\eta}\cdot\boldsymbol{\mu} = \int_{\Omega_\Gamma}\nabla E_{h,\Gamma}\eta_h\cdot\nabla E_{h,\Gamma}\mu_h.$$

We can prove the following proposition.

PROPOSITION 1. [illegible] C_1 [illegible] h [illegible] H [illegible]

$$P_\Gamma\boldsymbol{\eta}\cdot\boldsymbol{\eta} \le S\boldsymbol{\eta}\cdot\boldsymbol{\eta} \le C_1\,\frac{H}{h}\,P_\Gamma\boldsymbol{\eta}\cdot\boldsymbol{\eta} \quad \forall\boldsymbol{\eta}\in\mathbb{R}^{n_B}.$$

[illegible] $P_\Gamma^{-1}S$ [illegible] $\kappa(P_\Gamma^{-1}S) \le C_1 H/h$

$\int_{\Omega_\star}|\nabla E_{h,\star}\eta_h|^2$, and this can be done by adding the contributions to the integral from each square Ω_j. The first inequality is obvious. To prove the second one, we need to bound

By means of a translation, instead of Ω_j we can consider the square Q_H centered in $(0,0)$ and with sides of length H. Then by the change of variable $(\widehat{x},\widehat{y}) = T(x,y) = (x/H, y/H)$, we map Q_H over the unit square $\widehat{Q}$. The triangulation over Q_H is transformed into a triangulation onto $\widehat{Q}$; the correspondent mesh size is given by h/H. Introducing, for each function g defined in Q_H, the function $\widehat{g} = g \circ T^{-1}$ defined in $\widehat{Q}$, and denoting by $\widehat{E}_{h/H}\widehat{\eta_h}$ the discrete harmonic extension of $\widehat{\eta_h}$ with respect to the triangulation in $\widehat{Q}$, it is easily verified that $\widehat{E}_{h/H}\widehat{\eta_h} = \widehat{E_{h,\star}\eta_h}$ and that

$$\int_{Q_H}|\nabla E_{h,\star}\eta_h|^2 = \int_{\widehat{Q}}|\widehat{\nabla}\widehat{E}_{h/H}\widehat{\eta_h}|^2. \tag{3.6}$$

The uniform extension theorem for finite elements (see, e.g., [30, sect. 4.2.2]) gives that

$$\int_{\widehat{Q}}|\widehat{\nabla}\widehat{E}_{h/H}\widehat{\eta_h}|^2 \le C_0|\widehat{\eta}_h|^2_{1/2,\partial\widehat{Q}}\ , \tag{3.7}$$

where the constant C_0 does not depend on h and H and $|\cdot|_{1/2,\partial\widehat{Q}}$ denotes the seminorm of $H^{1/2}(\partial\widehat{Q})$.

Let us now observe that the set Ω_Γ is the union of $F_j \cap \Omega$, where the "frames" F_j are the sets of width h around Ω_j.

Note that these sets are not disjoint, but any possible intersection concerns at most four of them. Moreover, by means of a translation, we can think that each set F_j is the frame $F_{H,h}$ of the square Q_H.

Let us consider now the set $\widehat{F}_{1,1/2}$, that is, the frame of width $1/2$ around $\widehat{Q}$. We want to construct a function in $\widehat{F}_{1,1/2}$ such that its value on the internal boundary of $\widehat{F}_{1,1/2}$ (that is, on $\partial\widehat{Q}$) is equal to $\widehat{\eta}_h$. The natural idea is to start from $E_{h,\Gamma}\eta_h$, that is, from the interpolant of η_h in $\overline{\Omega_\Gamma}$. For simplicity, we will write $\psi_h = E_{h,\Gamma}\eta_h$, and we recall that $\psi_{h|\Gamma} = \eta_h$.

Now we have to pass from the domain F_j (or, equivalently, from $F_{H,h}$) onto $\widehat{F}_{1,1/2}$. First of all, note that the transformation T maps $F_{H,h}$ onto the set $\widehat{F}_{1,h/H}$. Moreover, we define

$$t(\xi) := \begin{cases} \xi & \text{if } |\xi| \le 1/2, \\ 1/2[1 + h^{-1}H(|\xi| - 1/2)]\xi/|\xi| & \text{if } 1/2 \le |\xi| \le 1/2 + h/H; \end{cases}$$

then we introduce the transformation

$$K(\widehat{x},\widehat{y}) := (t(\widehat{x}), t(\widehat{y})),$$

which maps $\widehat{F}_{1,h/H}$ onto $\widehat{F}_{1,1/2}$, leaving the internal boundary $\partial\widehat{Q}$ unchanged. We are now in a position to set

$$\psi^\sharp : \widehat{F}_{1,1/2} \to \mathbb{R}, \quad \psi^\sharp := \psi_{h|F_{H,h}} \circ T^{-1} \circ K^{-1},$$

and we easily verify that $\psi^\sharp_{|\partial\widehat{Q}} = \widehat{\eta}_h$.

We can thus use the trace theorem to obtain

$$|\widehat{\eta}_h|^2_{1/2,\partial\widehat{Q}} \leq C_1 ||\nabla\psi^\sharp||^2_{0,\widehat{F}_{1,1/2}} \tag{3.8}$$

(see [30, Theorem 4.1]). To estimate the right-hand side, taking into consideration the explicit expression of the transformations T and K, we can prove

$$||\nabla\psi^\sharp||^2_{0,\widehat{F}_{1,1/2}} \leq C_2 h^{-1} H \int_{F_{H,h}} |\nabla\psi_h|^2 \ . \tag{3.9}$$

By collecting (3.6), (3.7), (3.8), and (3.9) we have thus obtained

$$\begin{aligned} \textstyle\int_{\Omega_j} |\nabla E_{h,\star}\eta_h|^2 &\leq C_3 h^{-1} H \textstyle\int_{F_j} |\nabla E_{h,\Gamma}\eta_h|^2 \\ &= C_3 h^{-1} H \textstyle\int_{F_j\cap\Omega} |\nabla E_{h,\Gamma}\eta_h|^2. \end{aligned} \tag{3.10}$$

The last equality holds true as, for those squares Ω_j having at least one side on $\partial\Omega$, the function η_h has been extended by 0 on $\partial\Omega_j \cap \partial\Omega$ and on the boundary of F_j external to Ω, so that $E_{h,\Gamma}\eta_h = 0$ on $F_j \setminus (F_j \cap \Omega)$.

Bearing in mind the geometry of Ω_Γ we easily obtain the estimate

$$4 \int_{\Omega_\Gamma} |\nabla E_{h,\Gamma}\eta_h|^2 \geq \sum_j \int_{F_j\cap\Omega} |\nabla E_{h,\Gamma}\eta_h|^2.$$

The thesis now follows by summing up the contribution from all the domains Ω_j and the frames F_j. □

. . . . 2. The same result also holds for the elliptic operator

$$Lu := -\sum_i D_i[\rho(\mathbf{x}) D_i u],$$

where $\rho(x)$ is a positive and bounded function in Ω.

A more precise conclusion can be reached for a piecewise constant elliptic coefficient, that is, when $\rho(\mathbf{x}) = \rho_j > 0$ in $\Omega_j \cup (F_j^{1/2} \cap \Omega)$, $j = 1, \ldots, M$, where $F_j^{1/2}$ is the frame of width $h/2$ around Ω_j: In this case the constant C_1 in Proposition 1 does not depend on the jumps of the coefficients ρ_j.

In fact, in each domain Ω_j the extension operator with respect to the operator L coincides with the harmonic extension, therefore (3.7) holds. Moreover, proceeding as before we obtain (3.10) (with $F_j^{1/2}$ instead of F_j) and therefore

$$\begin{aligned} S_\star \boldsymbol{\eta}\cdot\boldsymbol{\eta} &= \sum_{j=1}^M \rho_j \int_{\Omega_j} |\nabla E_{h,\star}\eta_h|^2 \\ &\leq C_3 h^{-1} H \sum_{j=1}^M \rho_j \int_{F_j^{1/2}\cap\Omega} |\nabla E_{h,\Gamma}\eta_h|^2 \\ &= C_3 h^{-1} H P_\Gamma \boldsymbol{\eta}\cdot\boldsymbol{\eta}, \end{aligned}$$

where the constant C_3 does not depend on the jumps of the coefficients ρ_j.

TABLE 1
2D model problem. Condition number of $P_S^{-1}A$ using the one-level Schwarz preconditioner P_S with minimal overlap ($\delta = h$).

$\kappa(P_S^{-1}A)$	$H = 1/4$	$H = 1/8$	$H = 1/16$	$H = 1/32$
$h = 1/15$	24.29	45.92	-	-
$h = 1/31$	51.66	98.63	194.97	-
$h = 1/63$	106.31	203.80	403.31	804.48
$h = 1/127$	215.58	414.03	819.73	1635.34

4. Numerical experiments. We consider a piecewise linear finite element approximation of the problem

$$\begin{cases} -\sum_i D_i[\rho(x) D_i u] = f & \text{in } \Omega, \\ u = g & \text{on } \partial\Omega, \end{cases} \tag{4.1}$$

to numerically validate the preconditioners proposed in section 3 and compare them with other popular DD preconditioners.

For 2D problems, $\Omega = (0,1)\times(0,1)$ and the mesh is built by dividing Ω into $(1/h)^2$ uniform squares, which are then subdivided into two triangles. For 3D problems, $\Omega = (0,1) \times (0,1) \times (0,1)$ and the mesh is divided into $(1/h)^3$ uniform hexahedra, subdivided into 5 tetrahedra. Unless otherwise stated, $\rho(x,y) = 1$ and $f(x,y)$ and $g(x,y)$ are chosen so that $u(x,y) = \sin x \sin y$ in 2D and $u(x,y,z) = \sin x \sin y \sin z$ in 3D.

As regards the decomposition into subdomains, we consider overlapping squares (for 2D problems) or hexahedra (for 3D problems) Ω_i, of equal area H^2 or volume H^3, plus the subdomain Ω_Γ in the case of a VO decomposition. Unless otherwise specified, the width of Ω_Γ is of one element, and the linear systems (1.1), (2.2), and (2.7) are solved by a preconditioned conjugate gradient (PCG) method [12, 23]. The estimated condition number (ECN) reported in some of the tables is computed according to the algorithm given in [11, pp. 128–130].

4.1. Solution of the original system. We start by considering the solution of the system (1.1), using a one-level Schwarz preconditioner on a VO decomposition of the grid. In this case, Ω_Γ represents the union of the overlapping regions among the subdomains Ω_i. In Table 1 we report the ECN of the preconditioned system. Table 2 reports the ECN for two-level Schwarz preconditioners, using, respectively, a coarse grid and the aggregation procedure with nonsmoothed aggregation. The latter approach yields a preconditioned matrix that, for any given H and h, has a condition number asymptotically equivalent but larger than that obtained using a classical coarse grid. Nonetheless, this drawback is somehow compensated for by the ease of generating nonsmoothed aggregation. For further results on this subject, see [17, 25, 26].

4.2. Interface-strip preconditioners. We now focus on the solution of system (2.7). For regular decompositions such as those presented in Proposition 1, the Schur matrix S_{VO} is (as expected) badly conditioned: From Table 3 one sees that $\kappa(S_{VO})$ is slightly more than linear with h^{-1}; therefore preconditioning this matrix is mandatory. The preconditioner P_Γ proposed in section 3.2 is also studied in Table 3. The results of Table 3 confirm the theoretical estimates of Proposition 1, while Table 4 suggests that a similar estimate may hold for 3D domains as well.

1/16	1/64	2.91	3.08	3.09	3.09

Table 5 is related to a model problem with discontinuous coefficients. The computational domain $\Omega = (0,1)\times(0,1)$ is subdivided into nonoverlapping squares of side H. Using this checkerboard distribution, the coefficient ρ of problem (4.1) is set to 1 in all the white squares and to ρ_1 in the black squares. Ω_Γ is constructed as follows: Let us indicate the interface between the squares with Γ. Then, Ω_Γ contains all the elements that share at least one edge with Γ. Note that, by construction, $\delta = 2$. The results reported in the table confirm that the condition number of $P_\Gamma^{-1}S_{VO}$ does not depend on the jumps in the coefficient ρ of (4.1); see Remark 2 for more details.

The results for the other preconditioners proposed in section 3.2 are reported in Table 6. For a given h, we have first constructed a VO decomposition in 4 subdomains,

TABLE 6
2D model problem. Condition number for the VO SC matrix, with no preconditioning and using the preconditioners proposed in section 3. The domain is partitioned into 4 subdomains, and the influence of the cross width is reported. (Note that $S_\Gamma = A_\Gamma$ if $\delta = 1$ but not if $\delta \geq 2$.)

	δ	$\kappa(S_{VO})$	$\kappa(S_\Gamma^{-1}S_{VO})$	$\kappa(S_\star^{-1}S_{VO})$	$\kappa(P_{NN}^{-1}S_{VO})$

TABLE 7
2D model problem. Condition number of S_{VO} (in parentheses: that of $P_\Gamma^{-1}S_{VO}$). Unstructured decomposition into M subdomains (obtained using METIS).

	$M = 12$	$M = 20$	$M = 32$
$h = 1/15$	80.54 (11.67)	85.62 (15.69)	90.42 (7.65)
$h = 1/31$	150.22 (47.16)	184.14 (35.76)	219.02 (17.93)
$h = 1/47$	235.24 (20.60)	286.27 (40.57)	330.72 (24.84)
$h = 1/63$	300.47 (45.93)	382.03 (48.63)	464.09 (34.27)

as described in section 2 (that is, $\delta = 1$). Then, our algorithm (see Figure 2.4) was used to increase the width. In the table, $P_{NN}^{-1} = S_\star^{-1} + A_\Gamma^{-1}$. All the tested preconditioners share the same asymptotic behavior; however, $P_\star$ results in a consistently larger condition number than P_{NN} and P_Γ. As M additional Neumann problems have to be solved to invert P_{NN}, in the following we will focus only on P_Γ.

In Table 7 the ECN of S_{VO} and $P_\Gamma^{-1}S_{VO}$ is again reported, this time for 2D decompositions into M subdomains; the subdomain partition has been obtained by using the software METIS (see [14]). The analogous results for the 3D case are reported in Table 8. These examples again show the good performance of the interface-strip preconditioner, especially in the 3D case, where the ECN appears essentially independent of the mesh size and the number of subdomains and always remains quite small.

4.3. Comparisons between interface-strip and balancing Neumann–Neumann preconditioners. In order to compare P_Γ with more standard preconditioners, we have used one of the state-of-the-art preconditioners for nonoverlapping decompositions, namely, the balancing Neumann–Neumann (BNN). The BNN preconditioner is based on the NN preconditioner for EO decompositions

$$P_{NN}^{-1} = \sum_{i=1}^{M} \bar{R}_i D_i {S_i}^{-1} D_i \bar{R}_i. \tag{4.2}$$

The scaling diagonal matrices D_i allow us to preserve good conditioning even when the subdomains have different characteristics, for instance, because of the different values of the coefficients of the differential operator.

It is possible to prove that the preconditioner (4.2) satisfies the estimate

$$\kappa\left(P_{NN}^{-1}S\right) \leq \frac{C}{H^2}\left(1 + \log(H/h)\right)^2.$$

Despite the term $1/H^2$, the convergence of the NN algorithm is quite good for a small number of subdomains, as noted in [5, 18]. The BNN preconditioner, proposed by Mandel [19], adds a coarse correction to (4.2), constructed by using piecewise constant coarse grid space. The corresponding coarse operator involves one unknown per subdomain in the scalar case. It can be proved that the resulting preconditioner satisfies

$$\kappa(P_{BNN}^{-1}A) \leq C\left(1 + \log\frac{H}{h}\right)^2. \tag{4.3}$$

For numerical results, we refer the reader to [19, 7] or [22, sect. 3.2.2]; see also Table 9.

A comparison between BNN (with an EO decomposition) and P_Γ (with a VO decomposition) is shown in Table 10. The 2D grid has been partitioned, by means of

the software METIS, into M subdomains using a VO decomposition. Then, in order to obtain an EO decomposition, each of the elements in Ω_Γ has been assigned to one of the neighboring subdomains. The SC system has been solved with a tolerance of 10^{-10}.

In Table 10, `it_`Γ and `it_BNN` indicate the number of iterations needed to converge using P_Γ and P_{BNN}, respectively. `flops_`Γ and `flops_BNN` refer to the flops required to solve the problem, as indicated by the MATLAB command `flops`. We have not included in the flop count the operations required to explicitly form the SC matrix and the coarse matrix of BNN. The Neumann problems have been solved using an LU decomposition. The operations needed to compute the LU factors have not been included in the flop count.

Since the interface-strip preconditioner is suboptimal, in terms of iterations it is always outperformed by BNN, whose asymptotic behavior (4.3) is more favorable than that presented in Proposition 1, especially for large values of H/h. However, each application of BNN requires the solution of M Neumann problems; hence, when M is large (i.e., H is small), the BNN method is much more expensive than one application of P_Γ, which requires only the solution of a very sparse Neumann problem on Ω_Γ. In fact, the results presented in this section show that the proposed interface-strip preconditioner can be the right choice for the presented values of h and H, and therefore it should be preferred to BNN in these cases.

4.4. Parallel computations. We now report some preliminary numerical results for assessing the scalability of the interface-strip preconditioner. In a parallel environment, the strip Ω_Γ is replicated among the processors and therefore the preconditioning step

$$P_\Gamma \mathbf{z} = \mathbf{r} \tag{4.4}$$

must be solved in a distributed way. One can either adopt a parallel direct solver or solve the Neumann problem on Ω_Γ iteratively, using a nested iterative solver. Some numerical results (not reported here) suggested that we focus on the iterative solver. We have considered two variants. In the first one, indicated in the tables by $P_{\Gamma,J}$, two steps of the Jacobi method are applied to (4.4) with initial guess $\mathbf{z}_0 = \mathbf{0}$. The second one, indicated by $P_{\Gamma,CG}$, uses a nested conjugate gradient, iterated up to the fulfillment of the criterion

$$\frac{\|\mathbf{r} - P_\Gamma \mathbf{z}_i\|_2}{\|\mathbf{r}\|_2} \leq 10^{-2}.$$

Note that this latter approach may result in a nonconstant preconditioner, leading PCG to diverge (unless the linear system with P_Γ is solved up to machine precision). For this reason, in the numerical experiments using a nested Krylov solver, we have resorted to GMRESR [28], which allows variable preconditioning.

Tables 11 and 12 report the iterations required to solve up to a tolerance of $\|\mathbf{r}_k\|/\|\mathbf{r}_0\| \leq 10^{-5}$ our model problem on $(0,1) \times (0,1)$ and on $(0,1) \times (0,1) \times (0,1)$, respectively, while Table 13 reports the CPU times, obtained on a LINUX cluster with 12 nodes, each one composed by a biprocessor Pentium IV. Although simple to implement, $P_{\Gamma,J}$ has some effects only for 2D problems, while in 3D the reduction is only marginal. For example, in 2D with $h = 1/512$ and $H = 1/4$, the iterations are reduced from 428 in the nonpreconditioned system to 186 (see Table 11), while in 3D with $h = 1/64$ and $H = 1/4$ the iterations are reduced from 70 to 40 (see Table 12).

TABLE 11
Iterations required for convergence for the 2D model problem.

h	H	S_{VO}	$P_{\Gamma,J}^{-1}S_{VO}$	$P_{\Gamma,CG}^{-1}S_{VO}$
1/16	1/2	26	16	11
	1/4	33	21	12
1/32	1/2	51	24	14
	1/4	57	29	15
1/64	1/2	65	34	15
	1/4	70	40	17

TABLE 13
CPU time for the 2D model problem, obtained on a LINUX cluster with a tolerance $\|\mathbf{r}_k\|/\|\mathbf{r}_0\| \leq 10^{-5}$.

h	H	S_{VO}	$P_{\Gamma,J}^{-1}S_{VO}$	$P_{\Gamma,CG}^{-1}S_{VO}$
1/128	1/2	3.29	2.92	1.27
	1/3	1.42	1.65	0.60
	1/4	0.99	0.75	0.45
1/256	1/2	24.09	16.51	6.41
	1/3	12.93	6.75	2.92
	1/4	8.80	3.68	1.78
1/512	1/2	208.75	184.36	75.39
	1/3	150.32	65.69	22.34
	1/4	80.89	35.84	12.71

$P_{\Gamma,CG}$ behaves better in both 2D and 3D. However, both $P_{\Gamma,J}$ and $P_{\Gamma,CG}$ converge much faster than the nonpreconditioned system in terms of CPU time, as Table 13 shows.

5. Conclusions. For the numerical solution of large linear systems arising from the discretization of elliptic partial differential equations, we have presented a new approach for the iterative solution of the SC system with many subdomains. The presented method does not need the explicit definition of a coarse space and it is based on the decomposition of the original computational domain in two subdomains, in such a way that one of the two subdomains, say, Ω_Γ, is connected to all the others. This subdomain can be seen as an interface-strip, whose width is of one or more elements.

Among the available preconditioners for nonoverlapping two-subdomain decompositions, we have investigated a DN preconditioner, where a Neumann problem is

solved in Ω_Γ. This (global) Neumann problem acts as a coarse solver: This becomes apparent when considering the problem on the interface-strip solved by eliminating the edges first. The remaining problem on substructure vertices has the same connectivity as the usual vertex-based coarse problem. The strip on the edges of the subdomain interfaces acts basically as a diagonal preconditioner.

As presented in section 3, the condition number of the preconditioned system is of order H/h (therefore getting better as the number of subdomains becomes larger, a property that is interesting for parallel numerical computation). This makes the proposed preconditioner asymptotically equivalent to other methods, such as, for instance, the two-level Schwarz preconditioner with small overlap [6]. Although other two-level preconditioners with a better asymptotic behavior are available in the literature (for example, BNN or FETI), the presented numerical results show that, from the point of view of computational cost, the advocated approach can be competitive. In fact, on one hand it does not require an explicit coarse space and, on the other hand, the preconditioning step needs only the solution of one Neumann problem on a (small) subdomain of special shape, with limited computational cost per iteration.

As shown in Remark 2 and Table 5, another interesting feature of the proposed method is that the condition number of the preconditioned Schur complement does not depend on the jumps of the coefficients.

For a scalar implementation one can factorize and store P_Γ, while on a parallel computer a strategy for solving the global problem associated to P_Γ is necessary. Note also that this linear system does not need to be solved exactly.

Acknowledgment. The authors wish to thank the referees, whose remarks have helped improve the presentation of the paper.

A SINGULAR FUNCTION BOUNDARY INTEGRAL METHOD FOR LAPLACIAN PROBLEMS WITH BOUNDARY SINGULARITIES*

CHRISTOS XENOPHONTOS†, MILTIADES ELLIOTIS‡, AND GEORGIOS GEORGIOU‡

Abstract. A singular function boundary integral method for Laplacian problems with boundary singularities is analyzed. In this method, the solution is approximated by the truncated asymptotic expansion for the solution near the singular point and the Dirichlet boundary conditions are weakly enforced by means of Lagrange multiplier functions. The resulting discrete problem is posed and solved on the boundary of the domain, away from the point of singularity. The main result of this paper is the proof of convergence of the method; in particular, we show that the method approximates the generalized stress intensity factors, i.e., the coefficients in the asymptotic expansion, at an exponential rate. A numerical example illustrating the convergence of the method is also presented.

Key words. boundary singularities, boundary approximation methods, Lagrange multipliers, stress intensity factors

1. Introduction.

In many engineering problems (e.g., fracture mechanics applications) governed by elliptic partial differential equations (PDEs), boundary singularities arise when there is a sudden change in the boundary conditions and/or on the boundary itself. Singularities are known to affect adversely the accuracy and the convergence of standard numerical methods, such as finite element, boundary element, finite difference, and spectral methods. Grid refinement and high-order discretizations are common strategies aimed at improving the convergence rate and accuracy of the above-mentioned standard methods. If, however, the form of the singularity is taken into account and is properly incorporated into the numerical scheme, then a more effective method may be constructed (see, e.g., [10, 15]). (For a recent survey of treatment of singularities in elliptic boundary value problems see [17] and the references therein.)

In the case of the two-dimensional Laplace equation, for example, the form of the singularity is visible through the asymptotic expansion for the solution u near the singular point. When the boundaries sharing the singular point are not curved, u is given by [12]

$$u(r,\theta) = \sum_{j=1}^{\infty} \alpha_j r^{\beta_j} \phi_j(\theta), \tag{1.1}$$

where (r,θ) are polar coordinates centered at the singular point, $\alpha_j \in \mathbb{R}$ are the unknown singular coefficients, and $\beta_j \in \mathbb{R}, \phi_j(\theta)$ are the eigenvalues and eigenfunctions of the problem, respectively, which are uniquely determined by the geometry and the boundary conditions along the boundaries sharing the singular point. The constants

α_j are often called [illegible] (GSIFs) or flux intensity factors. In the case of elasticity problems with cracks, these constants are called stress intensity factors (SIFs) and serve as a measure of the stress at which failure occurs. In most commonly used methods, such as the finite element method (FEM), the SIFs are calculated as a postsolution operation (see, e.g., [4, 26, 27]). If, however, the goal of the computation is the calculation of the SIFs, then methods which calculate these quantities [illegible] may be preferable. The singular function boundary integral method (SFBIM), which we will analyze in this article, falls in the latter category. (See also [19, 20, 22, 23] and the references therein for additional information on the determination and importance of the aforementioned coefficients.)

The SFBIM was originally developed by Georgiou and coworkers [10, 11] and was subsequently refined and expanded by Elliotis, Georgiou, and Xenophontos [6, 7, 8, 9]. The method uses the leading terms in the local asymptotic expansion for the solution near the singular point as an approximation, while any Dirichlet boundary conditions are weakly enforced by means of Lagrange multiplier functions. The resulting problem is posed on the boundary of the domain; hence the dimension of the problem is reduced by one, leading to considerable computational cost reduction. We should also mention here the works of Li et al. [14, 15, 16] and Arad et al. [1], who also developed similar methods. (See also [21] for a review of SIF evaluation and modeling of singularities in boundary integral methods.)

The SFBIM has been successfully applied to a number of problems in solid and fluid mechanics and excellent numerical results have been obtained thus far [6, 7, 8, 9]. In particular, it was observed that the method (i) approximates the SIFs at an exponential rate of convergence, (ii) is very efficient, and (iii) compares extremely well with other accurate methods found in the literature. Our main goal in this article is to prove the observed convergence rates of the method.

The rest of the paper is organized as follows: In section 2 we present the formulation of the method for a two-dimensional Laplacian problem with a boundary singularity. In section 3 we present the convergence analysis, and in section 4 we comment on how the method can be efficiently implemented. Finally, section 5 includes the results of some numerical computations illustrating the convergence of the method. Throughout the paper the usual notation $H^k(\Omega)$ will be used for spaces containing functions on the domain $\Omega \subset \mathbb{R}^2$ with boundary $\partial\Omega$, having k generalized derivatives in $L^2(\Omega)$; the norm and seminorm on $H^k(\Omega)$ will be denoted by $\|\cdot\|_{k,\Omega}$ and $|\cdot|_{k,\Omega}$, respectively. Also, the letters C and c will be used to denote generic positive constants independent of any discretization parameters and possibly having different values in each occurrence.

2. The model problem and its formulation. For simplicity we consider the Laplacian problem stated below and depicted graphically in Figure 2.1. Find u such that

$$\Delta u = 0 \text{ in } \Omega, \tag{2.1}$$

$$\frac{\partial u}{\partial n} = 0 \text{ on } S_1, \tag{2.2}$$

$$u = 0 \text{ on } S_2, \tag{2.3}$$

$$u = f(r,\theta) \text{ on } S_3, \tag{2.4}$$

$$\frac{\partial u}{\partial n} = g(r,\theta) \text{ on } S_4, \tag{2.5}$$

where $\partial\Omega = \bigcup_{i=1}^{4} S_i$.

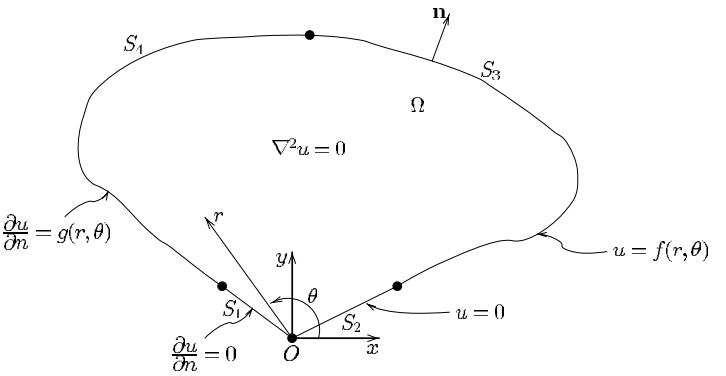

FIG. 2.1. *A two-dimensional Laplace equation problem with one boundary singularity.*

In (2.1)–(2.5), Δ denotes the Laplacian operator, the variables (r, θ) denote polar coordinates centered at O, and the functions f and g are known. It is assumed that f, g, and the boundary $\partial\Omega$ are such that there is only one boundary singularity at O. The local solution near O is given by an asymptotic expansion of the form (1.1) [12].

Even though the presentation and analysis of the method will be restricted to the type of boundary singularity shown in Figure 2.1, any type of boundary singularity for which an asymptotic expansion (1.1) exists can be treated.

Multiplying (2.1) by a test function $v \in V_1$ (to be specified shortly) and integrating over Ω, we get

$$\iint_{\Omega} v\Delta u = 0,$$

and then, by means of Green's theorem, we obtain

$$-\iint_{\Omega} \nabla v \cdot \nabla u + \int_{\partial\Omega} v\frac{\partial u}{\partial n} = 0.$$

Since $\frac{\partial u}{\partial n} = 0$ on S_1 and $\frac{\partial u}{\partial n} = g(r,\theta)$ on S_4, we further have

$$\iint_{\Omega} \nabla v \cdot \nabla u - \int_{S_2} v\frac{\partial u}{\partial n} - \int_{S_3} v\frac{\partial u}{\partial n} = \int_{S_4} vg. \tag{2.6}$$

Suppose v is chosen to satisfy

$$\Delta v = 0 \text{ in } \Omega,\ v = 0 \text{ on } S_2,\ \frac{\partial v}{\partial n} = 0 \text{ on } S_1, \tag{2.7}$$

one such choice being $v \equiv r^{\beta_j}\phi_j(\theta)$ (see (1.1)). Then (2.6) becomes

$$\iint_{\Omega} \nabla v \cdot \nabla u - \int_{S_3} v\frac{\partial u}{\partial n} = \int_{S_4} vg. \tag{2.8}$$

Now, since $u = f$ on S_3 we have

$$-\int_{S_3} \frac{\partial v}{\partial n}(u - f) = 0,$$

so adding this to (2.8), we get

$$\iint_{\Omega} \nabla v \cdot \nabla u - \int_{S_3} v \frac{\partial u}{\partial n} - \int_{S_3} \frac{\partial v}{\partial n}(u - f) = \int_{S_4} vg$$

or, equivalently,

$$\iint_{\Omega} \nabla v \cdot \nabla u - \int_{S_3} v \frac{\partial u}{\partial n} - \int_{S_3} \frac{\partial v}{\partial n} u = \int_{S_4} vg - \int_{S_3} \frac{\partial v}{\partial n} f.$$

Letting

$$\lambda = \left.\frac{\partial u}{\partial n}\right|_{S_3}, \ \mu = \left.\frac{\partial v}{\partial n}\right|_{S_3}, \tag{2.9}$$

the above equation becomes

$$\iint_{\Omega} \nabla v \cdot \nabla u - \int_{S_3} v\lambda - \int_{S_3} \mu u = \int_{S_4} vg - \int_{S_3} \mu f.$$

Hence, the [illegible] to be solved reads as follows: Find $(u, \lambda) \in V_1 \times V_2$ such that

$$B(u, v) + b(u, v; \lambda, \mu) = F(v, \mu) \quad \forall \ (v, \mu) \in V_1 \times V_2, \tag{2.10}$$

where

$$B(u, v) = \iint_{\Omega} \nabla v \cdot \nabla u, \tag{2.11}$$

$$b(u, v; \lambda, \mu) = -\int_{S_3} v\lambda - \int_{S_3} \mu u, \tag{2.12}$$

$$F(v, \mu) = \int_{S_4} vg - \int_{S_3} \mu f. \tag{2.13}$$

The spaces V_1 and V_2 are chosen as follows. Let the [illegible] of functions in $H^1(\Omega)$ be denoted by

$$H^{1/2}(\partial\Omega) = \left\{ u \in H^1(\Omega) : u|_{\partial\Omega} \in L^2(\partial\Omega) \right\}. \tag{2.14}$$

With $T : H^1(\Omega) \to H^{1/2}(\partial\Omega)$ denoting the trace operator, the norm of $H^{1/2}(\partial\Omega)$ is defined as

$$\|\psi\|_{1/2,\partial\Omega} = \inf_{u \in H^1(\Omega)} \left\{ \|u\|_{1,\Omega} : Tu = \psi \right\}. \tag{2.15}$$

Then, we define $H^{-1/2}(\partial\Omega)$ as the [illegible] of $H^0(\partial\Omega) \equiv L^2(\partial\Omega)$ with respect to the norm

$$\|\varphi\|_{-1/2,\partial\Omega} = \sup_{\psi \in H^{1/2}(\partial\Omega)} \frac{\int_{\partial\Omega} \varphi\psi}{\|\psi\|_{1/2,\partial\Omega}}. \tag{2.16}$$

(See, e.g., [24] for more details.) We then define

$$H_*^1(\Omega) = \left\{u \in H^1(\Omega) : u|_{S_2} = 0\right\}, \tag{2.17}$$

and we take

$$V_1 = H_*^1(\Omega),\ V_2 = H^{-1/2}(S_3). \tag{2.18}$$

The discrete problem corresponding to (2.10) then reads as follows: Find $(u_N, \lambda_h) \in [V_1^N \times V_2^h] \subset [H_*^1(\Omega) \times H^{-1/2}(S_3)]$ such that

$$B(u_N, v) + b(u_N, v; \lambda_h, \mu) = F(v, \mu)\ \ \forall\ (v, \mu) \in V_1^N \times V_2^h, \tag{2.19}$$

with $B(u,v), b(u,v;\lambda,\mu)$, and $F(v,\mu)$ given by (2.11)–(2.13), and with V_1^N, V_2^h finite dimensional spaces to be chosen shortly.

[illegible] 1. The above formulation will be used in the analysis of the method; for the implementation, we will use an equivalent boundary integral formulation in which all integrations will be one-dimensional and carried out away from the point causing the singularity. Details will be given in section 4.

3. Error analysis. We begin by defining the finite dimensional spaces V_1^N and V_2^h which will be used in the approximate problem (2.19). First, with

$$v_i \equiv r^{\beta_i}\phi_i(\theta) \tag{3.1}$$

denoting the singular functions, we define the finite dimensional space

$$V_1^N = span\left\{v_i\right\}_{i=1}^N. \tag{3.2}$$

Next, let S_3 be divided into quasiuniform sections $\Gamma_i, i = 1, \ldots, n$, such that $S_3 = \bigcup_{i=1}^n \Gamma_i$. Let $h_i = |\Gamma_i|$ and set $h = \max_{1\le i\le n} h_i$. We assume that for each segment Γ_i, there exists an invertible mapping $\mathcal{F}_i : I \to \Gamma_i$ which maps the interval $I = [-1, 1]$ to Γ_i, and we define the space

$$V_2^h = \left\{\lambda_h : \lambda_h|_{\Gamma_i} \circ \mathcal{F}_i^{-1} \in \mathcal{P}_p(I), i = 1, \ldots, n\right\}, \tag{3.3}$$

where $\mathcal{P}_p(I)$ is the set of polynomials of degree $\le p$ on $I = [-1, 1]$. In practice, the representation of the boundary S_3 determines the mappings $\mathcal{F}_i$; i.e., if S_3 is represented by a polynomial, then an isoparametric mapping may be used, and if S_3 has some (general) parametric representation, then the [illegible] technique may be used (see Ch. 6 in [25]).

We have the following theorem.

THEOREM 3.1. [illegible] (u, λ) [illegible] (u_N, λ_h) [illegible] (2.10) [illegible] (2.19) [illegible] c_0, c, β [illegible] γ [illegible] N [illegible] h [illegible]

$$B(v,v) \ge c_0 \|v\|_{1,\Omega}^2 \quad |B(u,v)| \le c\|u\|_{1,\Omega}\|v\|_{1,\Omega}\ \forall v \in V_1^N, \tag{3.4}$$

$$\exists\, 0 \ne v_N \in V_1^N \quad \left|\int_{S_3} \mu_h v_N\right| \ge \beta \|\mu_h\|_{-1/2,S_3}\|v_N\|_{1,\Omega}\ \forall \mu_h \in V_2^h, \tag{3.5}$$

$$\left|\int_{S_3} \lambda v\right| \le \gamma \|\lambda\|_{-1/2,S_3}\|v\|_{1,\Omega}\ \forall v \in V_1^N. \tag{3.6}$$

(3.7)
$$\|u-u_N\|_{1,\Omega}+\|\lambda-\lambda_h\|_{-1/2,S_3}\leq C\left\{\inf_{v\in V_1^N}\|u-v\|_{1,\Omega}+\inf_{\eta\in V_2^h}\|\lambda-\eta\|_{-1/2,S_3}\right\},$$

$C\in\mathbb{R}^+$ N h

This is similar to the classical result for saddle point problems (cf. [5]), and its proof for our problem appears in the appendix; see also Theorem 6.1 in [14].

Before verifying that (3.4)–(3.6) hold for the problem under consideration, we will make certain assumptions that will aid in the analysis. First, we note that for any function w which can be expressed in the form given by (1.1), we can always write

$$w=w_N+r_N,$$

where

$$w_N=\sum_{j=1}^{N}\alpha_j v_j\in V_1^N,\ r_N=\sum_{j=N+1}^{\infty}\alpha_j v_j. \tag{3.8}$$

We will assume that there exists $a\in(0,1)$ such that

$$|r_N|\leq Ca^N \tag{A1}$$

and

$$\left|\frac{\partial r_N}{\partial r}\right|\leq CNa^N. \tag{A2}$$

If $r<1$ in (1.1), assumptions (A1), (A2) may be replaced with the assumption that $|\alpha_j|<\infty\ \forall\, j$, since then, by (3.1) and the fact that ϕ_j is harmonic,

$$|r_N|\leq\sum_{j=N+1}^{\infty}|\alpha_j|\,r^{\beta_j}\leq C\frac{r^{\beta_{N+1}}}{1-r}\leq Ca^N,$$

with $r<a<1$, and $C\in\mathbb{R}^+$ independent of a and N. Similarly,

$$\begin{aligned}\left|\frac{\partial r_N}{\partial r}\right|&\leq\sum_{j=N+1}^{\infty}|\alpha_j|\,r^{\beta_j-1}=\sum_{j=N+1}^{\infty}|\alpha_j|\left\{\frac{d}{dr}\int_0^r\rho^{\beta_j-1}d\rho\right\}=\frac{d}{dr}\sum_{j=N+1}^{\infty}|\alpha_j|\left\{\int_0^r\rho^{\beta_j-1}d\rho\right\}\\&\leq\frac{d}{dr}\sum_{j=N+1}^{\infty}|\alpha_j|\,r^{\beta_j}\leq C\frac{d}{dr}\left(\frac{r^{\beta_{N+1}}}{1-r}\right)\leq CNa^N.\end{aligned}$$

If $r\geq 1$, one may partition the domain Ω into subdomains in which separate approximations may be obtained, including one near O which is valid for $r<1$. The solution over the entire domain can then be composed by combining the solutions from each subdomain and properly dealing with their interactions across the interfaces separating them (see, e.g., [18]).

Let us now verify that (3.4)–(3.6) hold for the problem given by (2.19). First, note that $B(v,v)=|v|_{1,\Omega}^2$ so that, by Poincaré's inequality,

$$B(v,v)\geq c_0\|v\|_{1,\Omega}^2\ \forall v\in H_*^1(\Omega). \tag{3.9}$$

By the Cauchy–Schwarz inequality,

$$B(u,v) \le c\,\|u\|_{1,\Omega}\,\|v\|_{1,\Omega}\ \forall u,v \in H^1_*(\Omega), \tag{3.10}$$

so that (3.9) and (3.10) give (3.4). To verify (3.5), consider the following auxiliary problem (for which a unique solution exists): Find w such that

$$\Delta w = 0 \text{ in } \Omega, \tag{3.11}$$

$$\frac{\partial w}{\partial n} = \mu_h \text{ on } S_3, \tag{3.12}$$

$$w = 0 \text{ on } S_2, \tag{3.13}$$

$$\frac{\partial w}{\partial n} = 0 \text{ on } S_1 \cup S_4, \tag{3.14}$$

where $\mu_h \in V_2^h$ in (3.12). From (3.11) and (3.12) we obtain (using Green's formula and Poincaré's inequality)

$$\int_{S_3} \mu_h w = \int_{S_3} w\frac{\partial w}{\partial n} = \iint_{\Omega} w\Delta w + \iint_{\Omega} |\nabla w|^2 = |w|^2_{1,\Omega} \ge c_0\,\|w\|^2_{1,\Omega}\,, \tag{3.15}$$

with $c_0 \in \mathbb{R}^+$. Also (cf. [2])

$$\|\mu_h\|_{-1/2,S_3} = \left\|\frac{\partial w}{\partial n}\right\|_{-1/2,S_3} \le C\,\|w\|_{1,\Omega}\,, \tag{3.16}$$

so that by (3.15) and (3.16)

$$\int_{S_3} \mu_h w \ge c_0\,\|w\|^2_{1,\Omega} \ge \beta\,\|w\|_{1,\Omega}\,\|\mu_h\|_{-1/2,S_3}, \tag{3.17}$$

with $\beta \in \mathbb{R}^+$ independent of w and h. Now, let $w_N \in V_1^N$ be such that $w = w_N + r_N$, as given by (3.8). We have

$$\int_{S_3} \mu_h w_N = \int_{S_3} \mu_h w - \int_{S_3} \mu_h r_N, \tag{3.18}$$

and also

$$\int_{S_3} \mu_h r_N \le \|\mu_h\|_{-1/2,S_3}\,\|r_N\|_{1/2,S_3} \le C_1\,\|\mu_h\|_{-1/2,S_3}\,\|r_N\|_{1,\Omega}, \tag{3.19}$$

so that, combining (3.17)–(3.19), we get

$$\int_{S_3} \mu_h w_N \ge \beta\,\|w\|_{1,\Omega}\,\|\mu_h\|_{-1/2,S_3} - C_1\,\|\mu_h\|_{-1/2,S_3}\,\|r_N\|_{1,\Omega}. \tag{3.20}$$

Now, using the reverse triangle inequality, we have

$$\|w\|_{1,\Omega} = \|w_N + r_N\|_{1,\Omega} \ge \|w_N\|_{1,\Omega} - \|r_N\|_{1,\Omega}\,,$$

which along with (3.20) gives

$$\begin{aligned}\int_{S_3} \mu_h w_N &\geq \beta \left(\|w_N\|_{1,\Omega} - \|r_N\|_{1,\Omega} \right) \|\mu_h\|_{-1/2,S_3} - C_1 \|\mu_h\|_{-1/2,S_3} \|r_N\|_{1,\Omega} \\ &\geq \beta \|w_N\|_{1,\Omega} \|\mu_h\|_{-1/2,S_3} - (C_1+\beta) \|\mu_h\|_{-1/2,S_3} \|r_N\|_{1,\Omega} . \end{aligned} \tag{3.21}$$

Since by assumption (A1), r_N converges to 0 exponentially (or, equivalently, w_N converges to w exponentially), we have

$$\lim_{N\to\infty} \frac{\|r_N\|_{1,\Omega}}{\|w_N\|_{1,\Omega}} = 0,$$

which means that for any $\varepsilon > 0$ there exists N^* such that

$$\frac{\|r_N\|_{1,\Omega}}{\|w_N\|_{1,\Omega}} < \varepsilon$$

whenever $N > N^*$. Hence, for N sufficiently large we may write

$$\frac{\|r_N\|_{1,\Omega}}{\|w_N\|_{1,\Omega}} < \frac{\beta}{2\,(C_1+\beta)}, \tag{3.22}$$

where C_1 and β are the constants from above. Combining (3.21) and (3.22) leads to

$$\int_{S_3} \mu_h w_N \geq \frac{\beta}{2} \|\mu_h\|_{-1/2,S_3} \|w_N\|_{1,\Omega} ,$$

which in turn gives (3.5) once we replace w_N by v_N and $\beta/2$ by β. Condition (3.6) follows directly from the definition of the $H^{-1/2}$-norm (see also (3.19)). The preceding discussion leads to the following theorem.

THEOREM 3.2. [illegible] (u,λ) [illegible] (u_N,λ_h) [illegible] (2.10) [illegible] (2.19) [illegible] $\lambda \in H^k(S_3)$ [illegible] $k \geq 1$ [illegible] C [illegible] N, h [illegible] $a \in (0,1)$ [illegible]

$$\|u-u_N\|_{1,\Omega} + \|\lambda-\lambda_h\|_{-1/2,S_3} \leq C \left\{ \sqrt{N} a^N + h^m p^{-k} \right\}, \tag{3.23}$$

[illegible] $m = \min\{k, p+1\}$.

[illegible]. From Theorem 3.1 we have

$$\|u-u_N\|_{1,\Omega} + \|\lambda-\lambda_h\|_{-1/2,S_3} \leq C \left\{ \inf_{v\in V_1^N} \|u-v\|_{1,\Omega} + \inf_{\eta\in V_2^h} \|\lambda-\eta\|_{-1/2,S_3} \right\}.$$

Now,

$$\inf_{v\in V_1^N} \|u-v\|_{1,\Omega} \leq \|u-w_N\|_{1,\Omega} = \|r_N\|_{1,\Omega} ,$$

with w_N, r_N given by (3.8). Using (A1) and (A2) we get

$$\inf_{v\in V_1^N} \|u-v\|_{1,\Omega} \leq \|r_N\|_{0,\Omega} + |r_N|_{1,\Omega} \leq C \left\{ a^N + \sqrt{N} a^N \right\} \leq C\sqrt{N} a^N, \tag{3.24}$$

with $C \in \mathbb{R}^+$ independent of N. Next, let λ_I be the pth-order interpolant of λ on the partition $\{\Gamma_i\}_{i=1}^n$ of S_3. We have (cf. [3])

$$\|\lambda - \lambda_I\|_{0,S_3} \leq Ch^m p^{-k} \|\lambda\|_{k,S_3}, \tag{3.25}$$

where $m = \min\{k, p+1\}$, and $C > 0$ a constant independent of h and p. Now,

$$\inf_{\eta \in V_2^h} \|\lambda - \eta\|_{-1/2,S_3} \leq \|\lambda - \lambda_I\|_{-1/2,S_3} \leq \|\lambda - \lambda_I\|_{0,S_3}, \tag{3.26}$$

so that, since $\lambda \in H^k(S_3)$, (3.24)–(3.26) give the desired result. □

REMARK 2. The above theorem shows that if the number of singular functions N is increased then u_N converges to u at an exponential rate. The theorem also shows that the convergence of λ_h to λ can occur in one of three ways: (i) by keeping p fixed and reducing h, (ii) by keeping h fixed and increasing p, or (iii) by doing both. These three "options" loosely correspond to the three versions of the FEM, namely, the h, p, and hp versions (cf. [3]).

REMARK 3. Based on the above theorem, one may obtain the "optimal" matching between N and h, i.e., the relationship between the number of singular functions and the number of Lagrange multipliers used in the method, by choosing them in such a way so that the error in (3.23) is balanced. For example, in the case when p is kept fixed and $h \to 0$, we take $h^{p+1} \approx \sqrt{N} a^N$. This leads to the following approximate expression for N:

$$N \approx (p+1) \left| \frac{\ln h}{\ln a} \right|. \tag{3.27}$$

The approximation of the GSIFs is given by the following corollary.

COROLLARY 3.3.

$$u = \sum_{j=1}^{\infty} \alpha_j r^{\beta_j} \phi_j(\theta)$$

$$u_N = \sum_{j=1}^{N} \alpha_j^N r^{\beta_j} \phi_j(\theta)$$

(2.10) (2.19) α_j, α_j^N C N $a \in (0,1)$

$$\left|\alpha_j - \alpha_j^N\right| \leq Ca^N. \tag{3.28}$$

. This is a direct consequence of (A1) and the fact that

$$\left|\alpha_j - \alpha_j^N\right| \leq C \|u - u_N\|_{0,\Omega}.$$

(See also (3.24).) □

4. Implementation. We now give a description of the implementation in order to emphasize the properties of the method. As mentioned in Remark 1, the discretized equation will be solved on the boundary of the domain; here we describe how this is done. Recall the discrete version of the problem given by (2.19), which may be rewritten in the form as follows: Find $(u_N, \lambda_h) \in [V_1^N \times V_2^h]$ such that

$$\iint_\Omega \nabla v \cdot \nabla u_N - \int_{S_3} v\lambda_h = \int_{S_4} vg \;\forall\; v \in V_1^N, \tag{4.1}$$

$$\int_{S_3} \mu\,(u_N - f) = 0 \;\forall\; \mu \in V_2^h. \tag{4.2}$$

We wish to reduce the double integral in (4.1) to a boundary one. To this end, using Green's theorem, we have

$$\iint_\Omega \nabla v \cdot \nabla u_N = \int_{\partial\Omega} \frac{\partial v}{\partial n} u_N - \iint_\Omega u_N \Delta v = \int_{\partial\Omega} \frac{\partial v}{\partial n} u_N$$

by (2.7). Moreover, since $\frac{\partial v}{\partial n}\big|_{S_1} = 0$ by (2.7), and $u_N|_{S_2} = 0$ by (2.17), we get

$$\int_{\partial\Omega} \frac{\partial v}{\partial n} u_N = \int_{S_3} \frac{\partial v}{\partial n} u_N + \int_{S_4} \frac{\partial v}{\partial n} u_N,$$

and (4.1)–(4.2) may be written as follows: Find $(u_N, \lambda_h) \in [V_1^N \times V_2^h]$ such that

$$\int_{S_3} \frac{\partial v}{\partial n} u_N + \int_{S_4} \frac{\partial v}{\partial n} u_N - \int_{S_3} v\lambda_h = \int_{S_4} vg \;\forall\; v \in V_1^N, \tag{4.3}$$

$$\int_{S_3} \mu\,(u_N - f) = 0 \;\forall\; \mu \in V_2^h. \tag{4.4}$$

Obviously if $(u_N, \lambda_h) \in [V_1^N \times V_2^h]$ solves (2.19) (or (4.1)–(4.2)), then it also solves (4.3)–(4.4); it is straightforward to reverse the above steps and see that the two-dimensional formulation analyzed in the previous section is in fact equivalent to the one-dimensional formulation given by (4.3)–(4.4). The latter are the equations which we discretize, since they are posed on the boundary of the domain Ω. This reduces the dimension of the problem by one and leads to significant computational savings. Now, to obtain the linear system of equations corresponding to (4.3)–(4.4), we write

$$u_N = \sum_{j=1}^{N} \alpha_j^N v_j \in V_1^N, \tag{4.5}$$

and

$$\lambda_h = \sum_{i=1}^{M} \gamma_i \psi_i \in V_2^h, \tag{4.6}$$

with α_j^N and γ_k the unknowns in the system, and $V_1^N = span\,\{v_j\}_{j=1}^N$, $V_2^h = span\,\{\psi_i\}_{i=1}^N$. Upon inserting these into (4.3)–(4.4), we obtain the $(N+M)\times(N+M)$ linear system

$$\begin{bmatrix} K_1 & K_2 \\ K_2^T & 0 \end{bmatrix} \begin{bmatrix} \overrightarrow{\alpha} \\ \overrightarrow{\gamma} \end{bmatrix} = \begin{bmatrix} \overrightarrow{G} \\ \overrightarrow{F} \end{bmatrix}, \tag{4.7}$$

where $\overrightarrow{\alpha} = \left[\alpha_1^N, \ldots, \alpha_N^N\right]^T$, $\overrightarrow{\gamma} = [\gamma_1, \ldots, \gamma_M]^T$, and

$$[K_1]_{j,k} = \int_{S_3} v_k \frac{\partial v_j}{\partial n} + \int_{S_4} v_k \frac{\partial v_j}{\partial n}\ ,\ j = 1, \ldots, N,\ k = 1, \ldots, N,$$

$$[K_2]_{j,i} = -\int_{S_3} v_j \psi_i\ ,\ j = 1, \ldots, N,\ i = 1, \ldots, M,$$

$$\left[\overrightarrow{G}\right]_j = \int_{S_4} v_j g,\ j = 1, \ldots, N,$$

$$\left[\overrightarrow{F}\right]_i = \int_{S_3} f\psi_i,\ i = 1, \ldots, M.$$

It is easily shown that the coefficient matrix in (4.7) is symmetric. This matrix, however, is singular if $N < M$. Hence, we should choose N larger than M, but not too large since for excessively large values of N the linear system (4.7) becomes ill conditioned and the results obtained are unreliable. The relationship between N and h (hence M) described in Remark 2 should be our guide in deciding how large to choose these values; see also section 5. As a final remark in this section, we should point out that all integrals involved in the determination of the coefficient matrix (and right-hand side) in (4.7) are along the sides of the domain that [illegible]. Moreover, they are one-dimensional and can be approximated by standard techniques, such as Gaussian quadrature.

5. Numerical results. Even though the analysis of the method was carried out for the rather general case of a domain having curved boundaries (except the ones intersecting at the singular point), and the nonhomogeneous boundary conditions can be given by any smooth function, we will consider for simplicity the model problem depicted in Figure 5.1, originally studied in [13]. The numerical results presented here correspond to the following choices of all relevant parameters: The Lagrange multiplier function λ_h used to impose the Dirichlet condition along S_3 is expanded in terms of [illegible] basis functions ψ_i (see (4.6)), and boundary S_3 is divided into $2n$ quadratic elements of equal size. For the integration, boundary S_4 is also subdivided into n intervals of equal size. All integrals involved are calculated numerically by subdividing each interval above into 10 subintervals and using a 15-point Gauss–Legendre quadrature over each one. In computing the coefficient matrix in (4.7), its symmetry is taken into account.

To determine the relationship between the number of singular functions N and the number of Lagrange multipliers M, we proceed as follows: Since for λ_h we are using $p = 2$ and $h = 2/n$, we have $M = 2n + 1$. For the moment, we fix $n = 8$ (say), which amounts to $M = 17$, and solve the linear system (4.7) for various values of $N > M$ (e.g., $N = 19, 21, 23, \ldots$). We concentrate only on the calculation of the first GSIF α_1^N and record our results in Table 5.1. From the table we see that, for this choice for M, the value of α_1^N is converged up to 14 significant digits once $N = 35$. Moreover, from (3.27) we have

$$N \approx (p+1)\frac{\ln h}{\ln a} = (p+1)\frac{\ln(2/n)}{\ln a} = (p+1)\frac{\ln\left(\frac{2p}{M-1}\right)}{\ln a}$$

$$\Rightarrow \ln a \approx \frac{p+1}{N} \ln\left(\frac{2p}{M-1}\right) \Rightarrow a \approx \left(\frac{2p}{M-1}\right)^{\frac{p+1}{N}};$$

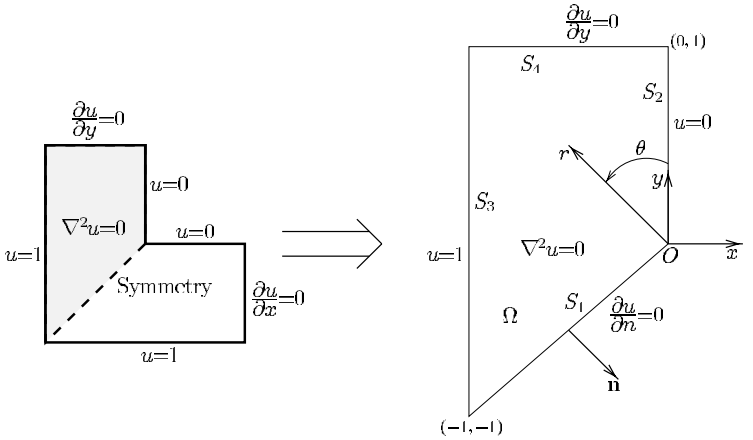

FIG. 5.1. *Geometry and boundary conditions for the model problem.*

TABLE 5.1
Approximate GSIF α_1^N *with* $M = 17$.

N	α_1^N

33	1.12798040105939
35	1.12798040105939

TABLE 5.2
Approximate GSIFs α_j^N, $j = 1, \ldots, 5$.

j	α_j^N (SFBIM)	α_j^N (*hp*-FEM)	α_j^N (Ref. [13])
1	1.12798040105939	1.12798010	1.1280
2	0.16993386650225	0.16993387	0.1699
3	−0.02304097399348	−0.0230419	−0.0230
4	0.0034711966582	0.0034755	0.0035
5	0.0009151570991	0.0009126	0.0009

hence, using $M = 17$ and $N = 35$, we find that $a \approx 0.89$. With a known, we may now compute the rest of the GSIFs and/or any other quantities of interest by choosing N and M via (3.27). For example, for $M = 41$ (i.e., $h = 1/10$), we find that $N \approx 60$.

Table 5.2 above shows the converged approximate values for the first five GSIFs obtained using the SFBIM (with $M = 41$ and $N = 60$), as well as the *hp* version of the FEM, which is considered to be the state-of-the-art method for problems with singularities [25]; the values from reference [13] are also included for comparison.

These results suggest that the SFBIM can be an attractive (and often preferable) method for problems in which the GSIFs are the main goal of the computation. Figure 5.2 shows the convergence of the leading GSIFs with N; in particular, the figure shows a semilog plot of the estimated percentage relative error in α_j^N, $j = 1, \ldots, 5$; since no

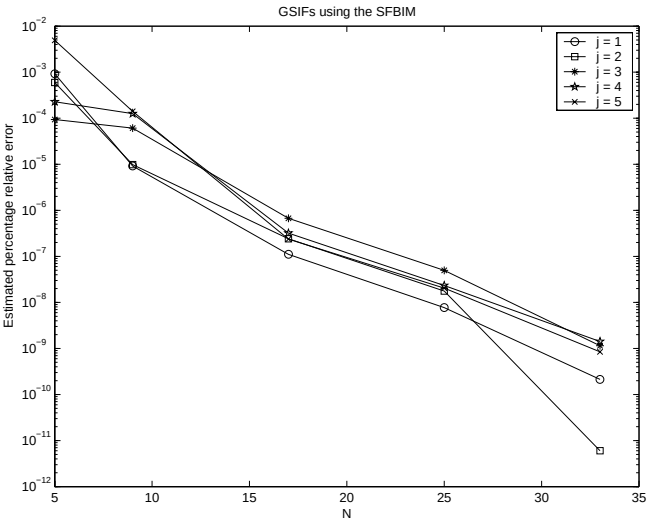

FIG. 5.2. *Convergence of* α_j^N, $j = 1, \ldots, 5$, *using the SFBIM.*

exact values exist for the true GSIFs, we use α_j^{60} as our reference/"exact" value. Since each error curve is essentially straight, this illustrates the exponential convergence of the method, as predicted by Corollary 3.3.

Appendix. Proof of Theorem 3.1. Here, for completeness, we give a proof of Theorem 3.1. First, we note that since (u, λ) also satisfy (2.19), we have $\forall\ (v, \mu) \in V_1^N \times V_2^h$

$$B(u - u_N, v) = -b(u - u_N, v; \lambda - \lambda_h, \mu) = \int_{S_3} v(\lambda - \lambda_h) + \int_{S_3} \mu(u - u_N). \tag{A.1}$$

Since $u = f$ on S_3 and $\int_{S_3} \mu(u_N - f) = 0\ \forall\ \mu \in V_2^h$, we have

$$\int_{S_3} \mu u_N = \int_{S_3} \mu u\ \forall \mu \in V_2^h, \tag{A.2}$$

and thus the last integral in (A.1) is zero. Hence,

$$B(u - u_N, v) = \int_{S_3} v(\lambda - \lambda_h). \tag{A.3}$$

Letting $w = u_N - v, v \in V_1^N$, we get

$$B(u_N - v, w) = B(u_N - u, w) + B(u - v, w) = B(u - v, w) - \int_{S_3} w(\lambda - \lambda_h)$$

$$= B(u - v, w) - \int_{S_3} w(\lambda - \eta) - \int_{S_3} w(\eta - \lambda_h).$$

By means of (A.2), the above equation becomes

$$B(u_N - v, w) = B(u - v, w) - \int_{S_3} w(\lambda - \eta) - \int_{S_3} (\lambda_h - \eta)(u - v). \tag{A.4}$$

Now, from (3.4), (3.6), and (A.4) we get

$$\begin{aligned} c_0 \|u_N - u\|_{1,\Omega}^2 &= c_0 \|w\|_{1,\Omega}^2 \\ &\le \|u - v\|_{1,\Omega} \|w\|_{1,\Omega} + \gamma \|w\|_{1,\Omega} \|\lambda - \eta\|_{-1/2,S_3} + \gamma \|u - v\|_{1,\Omega} \|\lambda_h - \eta\|_{-1/2,S_3} \\ &\le C\big\{(\|u - v\|_{1,\Omega} + \|\lambda - \eta\|_{-1/2,S_3}) \|w\|_{1,\Omega} + \|u - v\|_{1,\Omega} \|\lambda_h - \eta\|_{-1/2,S_3}\big\}. \end{aligned}$$

This is an inequality of order 2:

$$c_0 x^2 \le bx + d\ ,\ b, d > 0,$$

where

$$x = \|w\|_{1,\Omega}\ ,\ b = C(\|u - v\|_{1,\Omega} + \|\lambda - \eta\|_{-1/2,S_3}),$$

$$d = C \|u - v\|_{1,\Omega} \|\lambda_h - \eta\|_{-1/2,S_3} \le \frac{C}{2} \left(\varepsilon \|\lambda_h - \eta\|_{-1/2,S_3} + \frac{1}{\varepsilon} \|u - v\|_{1,\Omega} \right)^2,\ \varepsilon > 0.$$

Therefore, we obtain the bound

$$x \le \frac{b + \sqrt{b^2 + 4c_0 d}}{2c_0}$$

or, equivalently,

(A.5)
$$\|w\|_{1,\Omega} \le C \left\{ \|u - v\|_{1,\Omega} + \|\lambda - \eta\|_{-1/2,S_3} + \frac{1}{\varepsilon} \|u - v\|_{1,\Omega} \right\} + C\varepsilon \|\lambda_h - \eta\|_{-1/2,S_3}.$$

Next, using (3.5) with $\mu_h = \lambda_h - \eta$, we find that there exists $0 \neq v_N \in V_1^N$ such that

$$\|\lambda_h - \eta\|_{-1/2,S_3} \le \beta \frac{\left| \int_{S_3} (\lambda_h - \eta) v_N \right|}{\|v_N\|_{1,\Omega}}. \tag{A.6}$$

Also, it follows from (A.3) that

$$\begin{aligned} \int_{S_3} (\lambda_h - \eta) v_N &= \int_{S_3} (\lambda_h - \lambda) v_N + \int_{S_3} (\lambda - \eta) v_N = B(u - u_N, v_N) + \int_{S_3} (\lambda - \eta) v_N \\ &\le c \|u - u_N\|_{1,\Omega} \|v_N\|_{1,\Omega} + \gamma \|v_N\|_{1,\Omega} \|\lambda - \eta\|_{-1/2,S_3}, \end{aligned} \tag{A.7}$$

so that by (A.6) and (A.7),

$$\begin{aligned} \|\lambda_h - \eta\|_{-1/2,S_3} &\le C \left\{ \|u - u_N\|_{1,\Omega} + \|\lambda - \eta\|_{-1/2,S_3} \right\} \\ &\le C \left\{ \|u - v\|_{1,\Omega} + \|v - u_N\|_{1,\Omega} + \|\lambda - \eta\|_{-1/2,S_3} \right\}. \end{aligned}$$

Since $\|v - u_N\|_{1,\Omega} = \|w\|_{1,\Omega}$, we have from (A.5)

$$\begin{aligned} \|\lambda_h - \eta\|_{-1/2,S_3} \le C_1 \Big\{ &\|u - v\|_{1,\Omega} + \|\lambda - \eta\|_{-1/2,S_3} + \varepsilon^{-1} \|u - v\|_{1,\Omega} \Big\} \\ &+ \varepsilon \|\lambda_h - \eta\|_{-1/2,S_3} \end{aligned}$$

with $C_1 \in \mathbb{R}^+$ independent of v, η, and ε. Letting $C_1\varepsilon \leq 1/2$ we get

$$\|\lambda_h - \eta\|_{-1/2,S_3} \leq C\left\{\|u - v\|_{1,\Omega} + \|\lambda - \eta\|_{-1/2,S_3}\right\}. \tag{A.8}$$

Using the triangle inequality, we immediately get

$$\begin{aligned}\|\lambda - \lambda_h\|_{-1/2,S_3} &\leq \|\lambda - \eta\|_{-1/2,S_3} + \|\lambda_h - \eta\|_{-1/2,S_3} \\ &\leq C\left\{\|u - v\|_{1,\Omega} + \|\lambda - \eta\|_{-1/2,S_3}\right\}.\end{aligned} \tag{A.9}$$

Similarly, using (A.5) and (A.9), we get

$$\begin{aligned}\|u - u_N\|_{1,\Omega} &\leq \|u - v\|_{1,\Omega} + \|v - u_N\|_{1,\Omega} = \|u - v\|_{1,\Omega} + \|w\|_{1,\Omega} \\ &\leq C\left\{\|u - v\|_{1,\Omega} + \|\lambda - \eta\|_{-1/2,S_3}\right\},\end{aligned}$$

which gives the desired result.

Acknowledgments. The authors would like to thank the anonymous referees for the valuable comments which led to an improved manuscript.

NONOSCILLATORY CENTRAL SCHEMES FOR ONE- AND TWO-DIMENSIONAL MAGNETOHYDRODYNAMICS EQUATIONS. II: HIGH-ORDER SEMIDISCRETE SCHEMES*

JORGE BALBÁS† AND EITAN TADMOR‡

Abstract. We present a new family of high-resolution, nonoscillatory semidiscrete central schemes for the approximate solution of the ideal magnetohydrodynamics (MHD) equations. This is the second part of our work, where we are passing from the fully discrete staggered schemes in [J. Balbás, E. Tadmor, and C.-C. Wu, *J. Comput. Phys.*, 201 (2004), pp. 261–285] to the semidiscrete formulation advocated in [A. Kurganov and E. Tadmor, *J. Comput. Phys.*, 160 (2000), pp. 241–282]. This semidiscrete formulation retains the simplicity of fully discrete central schemes while enhancing efficiency and adding versatility. The semidiscrete algorithm offers a wider range of options to implement its two key steps: nonoscillatory reconstruction of point values followed by the evolution of the corresponding point valued fluxes. We present the solution of several prototype MHD problems. Solutions of one-dimensional Brio–Wu shock-tube problems and the two-dimensional Kelvin–Helmholtz instability, Orszag–Tang vortex system, and the disruption of a high density cloud by a strong shock are carried out using third- and fourth-order central schemes based on the central WENO reconstructions. These results complement those presented in our earlier work and confirm the remarkable versatility and simplicity of central schemes as black-box, Jacobian-free MHD solvers. Furthermore, our numerical experiments demonstrate that this family of semidiscrete central schemes preserves the $\nabla \cdot \mathbf{B} = 0$-constraint within machine round-off error; happily, no constrained-transport enforcement is needed.

Key words. multidimensional conservation laws, ideal magnetohydrodynamics (MHD) equations, high-resolution central schemes, nonoscillatory reconstructions, Jacobian-free form, semi-discrete schemes

1. Introduction.

In this paper we present third- and fourth-order accurate, nonoscillatory semidiscrete central schemes for the approximate solution of the equations of ideal magnetohydrodynamics,

$$\rho_t = -\nabla \cdot (\rho \mathbf{v}), \tag{1.1}$$

$$(\rho \mathbf{v})_t = -\nabla \cdot \left[\rho \mathbf{v}\mathbf{v}^\top + \left(p + \frac{1}{2} B^2 \right) I_{3\times 3} - \mathbf{B}\mathbf{B}^\top \right], \tag{1.2}$$

$$\mathbf{B}_t = \nabla \times (\mathbf{v} \times \mathbf{B}), \tag{1.3}$$

$$e_t = -\nabla \cdot \left[\left(\frac{\gamma}{\gamma - 1} p + \frac{1}{2} \rho v^2 \right) \mathbf{v} - (\mathbf{v} \times \mathbf{B}) \times \mathbf{B} \right]. \tag{1.4}$$

Here, ρ and e are scalar quantities representing, respectively, the mass density and the total internal energy, $\mathbf{v} = (v_x, v_y, v_z)^\top$ is the velocity field with , , norm

$v^2 := \|\mathbf{v}\|^2$, and $\mathbf{B} = (B_x, B_y, B_z)^\top$ and $B^2 := \|\mathbf{B}\|^2$ represent the magnetic field and its norm. The pressure, p, is coupled to the internal energy, $e = \frac{1}{2}\rho v^2 + \frac{1}{2}B^2 + p/(\gamma - 1)$, where γ is the (fixed) ratio of specific heats. The system is augmented by the solenoidal constraint,

$$\nabla \cdot \mathbf{B} = 0; \tag{1.5}$$

that is, if the condition $\nabla \cdot \mathbf{B} = 0$ is satisfied initially at $t = 0$, then by (1.3) it remains invariant in time.

Our work [2] demonstrated the capability of central schemes to accurately and efficiently detect and resolve the steep gradients that characterize the solutions of (1.1)–(1.4); it suggested further development of higher-order, black-box-type central schemes for these equations. In this paper, we present a family of third- and fourth-order accurate, nonoscillatory semidiscrete central schemes which remain stable without any further explicit enforcement of the constraint (1.5). This semidiscrete formulation [14] retains the main advantages of central schemes over the upwind ones, namely, simplicity and efficiency resulting from the minimal amount of characteristic information required when evolving the solution over staggered grids, allowing for Jacobian-free formulations and avoiding dimensional splitting in multidimensional models. Moreover, semidiscrete schemes allow more flexibility in the calculation of the time step, Δt, than their fully discrete counterparts: on the one hand, they are implemented over nonstaggered grids, and thus the CFL stability condition allows for the use of larger time steps, and on the other hand, for rth-order methods, the numerical dissipation of the semidiscrete formulation is of order $\mathcal{O}((\Delta x)^{2r-1})$ versus that of the corresponding fully discrete version of order $\mathcal{O}((\Delta x)^{2r}/\Delta t)$, which allows the use of smaller time steps with considerably less smearing of discontinuities. Finally, the semidiscrete formulation also enjoys a remarkable adaptability to a wide range of nonoscillatory reconstruction techniques and evolution routines developed independently of the methods.

In addition to the five magnetohydrodynamics (MHD) prototype problems discussed in [2]—two one-dimensional Brio and Wu shock tube models originally proposed in [3], two different configurations (periodic and convective models) of the two-dimensional transverse Kelvin–Helmholtz instability problem, and the two-dimensional MHD vortex system of Orszag and Tang—we implement these new schemes to simulate the disruption of a high density cloud by a strong shock. The evolution of the Orszag–Tang vortex system involves the interaction between several shock waves traveling at various speed regimes, and the interaction between the high-density cloud and the strong shock describes a highly superfast flow, making both of these very suitable problems to test the robustness of numerical algorithms.

The paper is structured as follows. In section 2, we extend the derivation of the second- and third-order, central semidiscrete schemes presented in [14, 13, 12] to schemes of arbitrary order r. Starting with the staggered discretization that led to the fully discrete central schemes [20, 19, 10, 17], we evolve separately the smooth and nonsmooth parts of the solution and project the resulting cell averages back onto the original grid. We then pass to the $\Delta t \downarrow 0$-limit, yielding the rth-order semidiscrete formulation of central schemes. This rather general formulation of central schemes entertains a broad range of options to implement the two main steps of the algorithm: nonoscillatory [illegible] of point values from cell averages, followed by the [illegible] of the corresponding point valued fluxes. In section 3 we discuss the nonoscillatory reconstruction techniques and evolution routines that we implement to approximate

the semidiscrete formulation of (1.1)–(1.4). For the reconstruction of point values, we propose an extension of the third-order central WENO (CWENO) reconstruction of Kurganov and Levy [12] and the two-dimensional fourth-order CWENO reconstruction of Levy, Puppo, and Russo [18], developed originally in the context of fully discrete central schemes. For the evolution step, we use third- and fourth-order strong stability preserving (SSP) Runge–Kutta schemes [23, 25, 5]. In sections 4 and 5 we describe the prototype MHD problems mentioned above and present the numerical solutions obtained with our new family of high-resolution semidiscrete central schemes. In section 4 we report on the one-dimensional shock tube problems of Brio and Wu [3] and discuss the improved resolution and better control of spurious oscillations provided by the new schemes. The two-dimensional test problems and the corresponding numerical results are presented and discussed in section 5. These results confirm the efficiency of central schemes to accurately compute the solution of MHD equations. The combination of simplicity and high resolution allows us to obtain solutions comparable to those obtained with high-order upwind schemes, e.g., [3, 4, 11, 22, 21], without having to refine the computational mesh as in [2]. We therefore retain the simplicity of central schemes—they eliminate the need for a detailed knowledge of the eigen-structure of the Jacobian matrices and avoid dimensional splitting and the costly use of (approximate) Riemann solvers that serve as building blocks for upwind schemes; at the same time, this simplicity is achieved without an increase in the computational work that was enforced by the finer meshes required with the lower-order methods and/or any explicit enforcement of the solenoidal constraint $\nabla \cdot \mathbf{B} = 0$.

2. Semidiscrete central schemes. In [2] we demonstrated the robustness of black-box-type central schemes to calculate the approximate solutions of (1.1)–(1.4) and discussed the advantages of these methods over those based on upwind differencing. We also pointed out, however, that the efficiency resulting from a minimal amount of characteristic information required by central schemes may be compromised by the low-order accuracy of the schemes, since the latter often require finer meshes to resolve steep gradients. In order to circumvent this limitation and gain full advantage of the simplicity, ease of implementation, and efficiency of central schemes, we seek higher-order methods. Although it is possible to carry out a higher-order extension of the fully discrete central schemes discussed in [2] (see, e.g., [16, 18]), we find the semidiscrete formulation of Kurganov and Tadmor [14] more advantageous: its implementation over nonstaggered grids allows the use of larger time steps, it enjoys a reduced numerical dissipation (of order $\mathcal{O}((\Delta x)^{2r-1})$) in comparison to that of fully discrete schemes ($\sim \mathcal{O}((\Delta x)^{2r}/\Delta t)$), and it is derived independently of any reconstruction or evolution algorithm. Indeed, many of the existing high-order, nonoscillatory reconstruction algorithms and evolution routines can be easily incorporated into the semidiscrete central formulation, making the simplicity and ease of implementation of central schemes an attractive alternative.

2.1. One-dimensional schemes. The solutions of nonlinear hyperbolic systems of conservation laws,

$$u_t + f(u)_x = 0, \tag{2.1}$$

and in particular those of (1.1)–(1.4), are characterized by the onset and propagation of discontinuities. The higher-order extensions of the first-order Lax–Friedrichs central scheme [15] that have been developed over the past two decades (see, e.g., [20, 19,

10, 14]) provide a rather general approach for solving this type of problem with only a minimal amount of information on the eigen structure of the Jacobian matrix of $f(u)$. (Indeed, Jacobian-free formulations of central schemes completely avoid the computation of $\frac{\partial f}{\partial u}$.) These schemes are based on the evolution of the cell averages (we use the usual $\fint_I$ to denote the average, $1/|I| \cdot \int_I$),

$$\bar{u}_\alpha^n := \fint_{I_\alpha} u(\xi, t^n) d\xi, \qquad I_\alpha := \left[x_\alpha - \frac{\Delta x}{2}, x_\alpha + \frac{\Delta x}{2} \right],$$

while alternating over staggered grids, $\{I_j\} \times t^n$ and $\{I_{j+\frac{1}{2}}\} \times t^{n+1}$. Dividing (2.1) by Δx and integrating over the control volume $I_{j+\frac{1}{2}} \times [t^n, t^{n+1}]$ yields an exact discrete statement of the conservation law in terms of these cell averages,

$$\bar{u}_{j+\frac{1}{2}}^{n+1} = \bar{u}_{j+\frac{1}{2}}^n - \frac{1}{\Delta x} \left[\int_{t^n}^{t^{n+1}} f(u(x_{j+1}, \tau)) d\tau - \int_{t^n}^{t^{n+1}} f(u(x_j, \tau)) d\tau \right]. \tag{2.2}$$

The evaluation of the expressions on the right of (2.2) proceeds in two steps. First, the cell averages $\{\bar{u}_{j+\frac{1}{2}}^n\}$ are recovered by integrating a piecewise nonoscillatory polynomial reconstruction of the point-values of $u(x, t^n)$ from their cell averages $\{\bar{u}_j^n\}$ that we denote by

$$u(x, t^n) = R\,(x; \bar{u}^n) := \sum_j p_j^n(x) \cdot \mathbf{1}_{I_j}. \tag{2.3}$$

This reconstruction procedure is at the heart of high-resolution, nonoscillatory central schemes and requires the coefficients of the polynomials $\{p_j^n(x)\}$ to be determined so that $R(x; \bar{u}^n)$ satisfies the following three essential properties:

- $\mathcal{P}_1$—conservation of cell averages: $\bar{p}_j^n(x) = \bar{u}_j^n$.
- $\mathcal{P}_2$—accuracy: $R\,(x; \bar{u}^n) = u(x, t^n) + \mathcal{O}((\Delta x)^r)$ for rth-order accurate scheme, wherever $u(\cdot, t^n)$ is sufficiently smooth.
- $\mathcal{P}_3$—nonoscillatory behavior of $\sum_j p_j(x) \cdot \mathbf{1}_{I_j}$ which is characterized in different ways for different reconstructions. Examples include TVD reconstructions initiated by van Leer [27] and Harten [7], number of extrema diminishing (NED) and shape-preserving properties of the Liu–Tadmor third-order scheme [19], and the higher-order nonoscillatory extensions offered by the essentially nonoscillatory (ENO) reconstructions of Harten et al. [6] or their weighted versions (WENO), e.g., [24, 9], and their implementation within the central differencing framework, e.g., [12, 16, 18].

Equipped with the reconstructed point values $u(\cdot, t^n)$, the second step evaluates the two time integrals of $f(u(\cdot, \tau))$. Since the solution of (2.2) remains smooth along the lines $\{x = x_j\} \times [t^n, t^{n+1}]$, a simple quadrature rule suffices to approximate those integrals. This requires the intermediate values, $\{\bar{u}_j^{n+\beta}\}$, which are predicted either by a Taylor expansion or alternatively by Runge–Kutta solvers of the ODE $u_\tau = \hat{f}_x|_{x=x_j}$, $u(x_j, 0) = u_j^n$, $\tau > t^n$, where $\hat{f}_x$ stands for the numerical derivative of $f(u)$. This type of evolution over staggered grids based on cells with uniform width Δx does not admit a semidiscrete limit as $\Delta t \downarrow 0$. Instead, a modified approach proposed by Kurganov and Tadmor in [14] and based on variable size cells (depicted in Figure 2.1) yields the desired semidiscrete limit. Here, we extend the derivation of second- and third-order semidiscrete schemes of [14, 12, 13] to schemes of arbitrary order of accuracy r [1]. The first step passing from a fully discrete to a semidiscrete formulation consists of

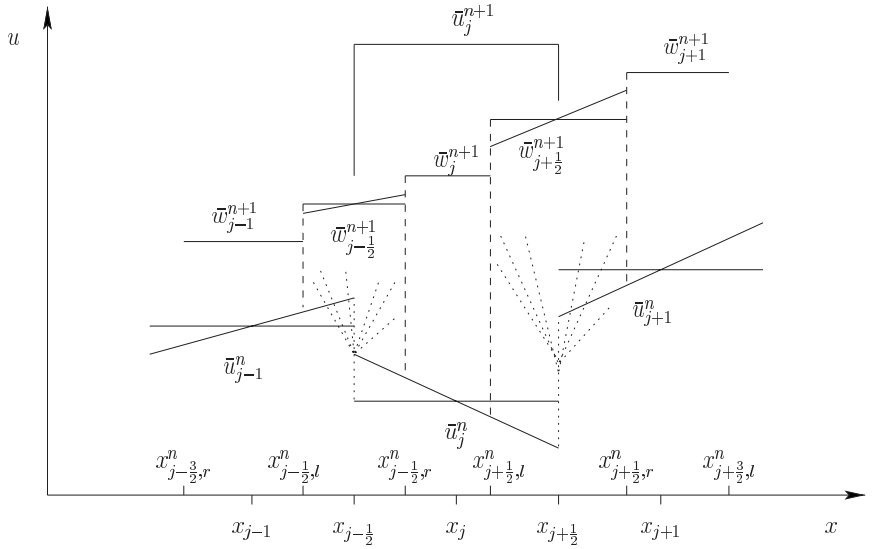

FIG. 2.1. *Modified central differencing of Kurganov and Tadmor.*

reducing the size of the staggered cells covering the Riemann fans. Instead of cells with uniform width Δx, we use cells with variable width of order $\mathcal{O}(\Delta t)$, by incorporating the maximal local speed of propagation,

$$a_{j+\frac{1}{2}}^n = \max_{u\in\mathcal{C}\left(u_{j+\frac{1}{2}}^-,u_{j+\frac{1}{2}}^+\right)} \rho\left(\frac{\partial f}{\partial u}(u)\right); \tag{2.4}$$

here $u_{j+\frac{1}{2}}^-$ and $u_{j+\frac{1}{2}}^+$ stand for, respectively, the reconstructed values of u to the left and right of the interfacing breakpoints, $u_{j+\frac{1}{2}}^{\pm} := R(x_{j+\frac{1}{2}}\pm, \bar{u}^n)$, and $\mathcal{C}$ is the phase curve connecting these two states through the Riemann fan. For practical purposes, we choose

$$a_{j+\frac{1}{2}}^n := \max\left\{\rho\left(\frac{\partial f}{\partial u}(u_{j+\frac{1}{2}}^-)\right), \rho\left(\frac{\partial f}{\partial u}(u_{j+\frac{1}{2}}^+)\right)\right\},$$

which is exact for genuinely nonlinear and linearly degenerate fields.

This information allows us to repartition the original grid so as to distinguish between subcells of width $2a_{j+\frac{1}{2}}^n\Delta t^n$, where the solution is dictated by the nonsmooth Riemann fan,

$$\widetilde{I}_{j+\frac{1}{2}} = \left[x_{j+\frac{1}{2},l}^n,\ x_{j+\frac{1}{2},r}^n\right] := \left[x_{j+\frac{1}{2}} - a_{j+\frac{1}{2}}^n\Delta t^n,\ x_{j+\frac{1}{2}} + a_{j+\frac{1}{2}}^n\Delta t^n\right],$$

and the other cells of width $\Delta x_j := \Delta x - \Delta t^n(a_{j-\frac{1}{2}}^n + a_{j+\frac{1}{2}}^n)$, which are beyond the influence of the Riemann fans so that the solution remains smooth,

$$\widetilde{I}_j = \left[x_{j-\frac{1}{2},r}^n,\ x_{j+\frac{1}{2},l}^n\right] := \left[x_{j-\frac{1}{2}} + a_{j-\frac{1}{2}}^n\Delta t^n,\ x_{j+\frac{1}{2}} - a_{j+\frac{1}{2}}^n\Delta t^n\right].$$

In nonsmooth regions, the cell averages $\{\bar{w}^{n+1}_{j+\frac{1}{2}}\}$ are computed via staggered evolution over the (narrower, $\mathcal{O}(\Delta t)$) cells covering the Riemann fans,

$$\begin{aligned}\bar{w}^{n+1}_{j+\frac{1}{2}} &:= \fint_{x^n_{j+\frac{1}{2},l}}^{x^n_{j+\frac{1}{2},r}} u(x,t^{n+1})dx \\ &= \fint_{x^n_{j+\frac{1}{2},l}}^{x^n_{j+\frac{1}{2},r}} R\,(x;\bar{u}^n)dx - \frac{1}{2a^n_{j+\frac{1}{2}}}\int_{t^n}^{t^{n+1}} \big[f(u(x^n_{j+\frac{1}{2},r},\tau)) - f(u(x^n_{j+\frac{1}{2},l},\tau))\big]d\tau, \end{aligned} \tag{2.5}$$

and in the smooth regions, direct integration of (2.1) yields the cell averages $\{\bar{w}^n_j\}$

$$\begin{aligned}\bar{w}^{n+1}_{j} &:= \fint_{x^n_{j-\frac{1}{2},r}}^{x^n_{j+\frac{1}{2},l}} u(x,t^{n+1})dx \\ &= \fint_{x^n_{j-\frac{1}{2},r}}^{x^n_{j+\frac{1}{2},l}} R\,(x;\bar{u}^n)dx - \frac{1}{\Delta x_j}\int_{t^n}^{t^{n+1}} \big[f(u(x^n_{j+\frac{1}{2},l},\tau)) - f(u(x^n_{j-\frac{1}{2},r},\tau))\big]d\tau. \end{aligned} \tag{2.6}$$

The [illegible] cell averages, $\{\bar{u}^{n+1}_j\}$, are then recovered via a new nonoscillatory piecewise polynomial reconstruction of the point values of $u(x,t^{n+1})$ from the new cell averages (2.5) and (2.6),

$$R\,(x;\bar{w}^{n+1}) = \sum_j q^{n+1}_j(x)\cdot \mathbf{1}_{\widetilde{I}_j} + q^{n+1}_{j+\frac{1}{2}}(x)\cdot \mathbf{1}_{\widetilde{I}_{j+\frac{1}{2}}}. \tag{2.7}$$

Projection onto the original grid, $\{I_j\}$, (2.7) yields

$$\begin{aligned}\bar{u}^{n+1}_j &:= \fint_{x_{j-\frac{1}{2}}}^{x_{j+\frac{1}{2}}} R\,(x;\bar{w}^{n+1})dx \\ &= \frac{1}{\Delta x}\left[\int_{x_{j-\frac{1}{2}}}^{x_{j-\frac{1}{2},r}} q^{n+1}_{j-\frac{1}{2}}(x)\,dx + \int_{x_{j-\frac{1}{2},r}}^{x_{j+\frac{1}{2},l}} q^{n+1}_{j}(x)\,dx + \int_{x_{j+\frac{1}{2},l}}^{x_{j+\frac{1}{2}}} q^{n+1}_{j+\frac{1}{2}}(x)\,dx\right]. \end{aligned} \tag{2.8}$$

The explicit calculation of the polynomials $q^{n+1}_j(x)$ and $q^{n+1}_{j+1/2}(x)$ will, in fact, prove to be irrelevant for the semidiscrete formulation that we seek. As we shall see below, only the [illegible] of these q's matter, and in the $\Delta t \downarrow 0$-limit, these averages are further reduced to the original point values reconstructed at the interfaces, $p(x_{j\pm\frac{1}{2}},t^n)$. We turn to the details. Without loss of generality, we assume that the q^{n+1} are polynomials of degree $r-1$ (required to preserve the underlying rth-order accuracy) and satisfy properties $\mathcal{P}_1$ – $\mathcal{P}_3$ for the cell averages (2.5) and (2.6) in the corresponding cells $\widetilde{I}_j$ and $\widetilde{I}_{j+\frac{1}{2}}$. We express these polynomials as $q^{n+1}_{j\pm\frac{1}{2}}(x) = \sum_{k=0}^{r-1} A^{(k)}_{j\pm\frac{1}{2}}(x - x_{j\pm\frac{1}{2}})^k/k!$; their coefficients can be uniquely determined by imposing the conservation constraints,[1]

$$\fint_{\widetilde{I}_{j+p}} q^{n+1}_{j+s}(x)dx = \bar{w}^n_{j+p}, \qquad p = 0, \pm\frac{1}{2}, \pm 1, \ldots, \pm\frac{r-1}{2}, \qquad s = -\frac{1}{2}, 0, \frac{1}{2}. \tag{2.9}$$

[1]The choice of symmetric intervals around $\tilde{I}_j$ yields methods of odd order. For methods of even order, it suffices to sacrifice one of the side constraints, $p = \pm\frac{r-1}{2}$.

Equipped with this notation, the first and last integrals on the right of (2.8) read

$$\begin{aligned}\int_{x_{j-\frac{1}{2}}}^{x_{j-\frac{1}{2},r}} q_{j-\frac{1}{2}}^{n+1}(x)\,dx &= \sum_{k=0}^{r-1}\left[\frac{A_{j-\frac{1}{2}}^{(k)}}{(k+1)!}(x-x_{j-\frac{1}{2}})^{k+1}\right]_{x_{j-\frac{1}{2}}}^{x_{j-\frac{1}{2}}+a_{j-\frac{1}{2}}^{n}\Delta t}\\ &= \sum_{k=0}^{r-1}\frac{(\Delta t)^{k+1}}{(k+1)!}(a_{j-\frac{1}{2}}^{n})^{k+1}A_{j-\frac{1}{2}}^{(k)}\end{aligned} \tag{2.10}$$

and

$$\begin{aligned}\int_{x_{j+\frac{1}{2},l}}^{x_{j+\frac{1}{2}}} q_{j+\frac{1}{2}}^{n+1}(x)\,dx &= \sum_{k=0}^{r-1}\left[\frac{A_{j+\frac{1}{2}}^{(k)}}{(k+1)!}(x-x_{j+\frac{1}{2}})^{k+1}\right]_{x_{j+\frac{1}{2}}-a_{j+\frac{1}{2}}^{n}\Delta t}^{x_{j+\frac{1}{2}}}\\ &= \sum_{k=0}^{r-1}(-1)^{k}\frac{(\Delta t)^{k+1}}{(k+1)!}(a_{j+\frac{1}{2}}^{n})^{k+1}A_{j+\frac{1}{2}}^{(k)}.\end{aligned} \tag{2.11}$$

For the second integral in (2.8), we observe that by property $\mathcal{P}_1$ the polynomial $q_j^{n+1}(x)$ must satisfy

$$\int_{x_{j-\frac{1}{2},r}}^{x_{j+\frac{1}{2}},l} q_j^{n+1}(x)\,dx = \Delta x_j \bar{w}_j^{n+1} = \left[\Delta x - \Delta t(a_{j-\frac{1}{2}}^{n} + a_{j+\frac{1}{2}}^{n})\right]\bar{w}_j^{n+1}. \tag{2.12}$$

Substituting (2.10)–(2.12) into (2.8), we arrive at a fully discrete, nonstaggered approximation (of arbitrary order of accuracy r) of the cell averages in (2.2),

$$\begin{aligned}\bar{u}_j^{n+1} = &\sum_{k=0}^{r-1}\frac{\lambda(\Delta t)^k}{(k+1)!}\left[(a_{j-\frac{1}{2}}^{n})^{k+1}A_{j-\frac{1}{2}}^{(k)} + (-1)^k(a_{j+\frac{1}{2}}^{n})^{k+1}A_{j+\frac{1}{2}}^{(k)}\right]\\ &+ \left[1-\lambda(a_{j-\frac{1}{2}}^{n} + a_{j+\frac{1}{2}}^{n})\right]\bar{w}_j^{n+1}, \quad \lambda := \frac{\Delta t}{\Delta x}.\end{aligned} \tag{2.13}$$

Given the appropriate reconstructions $R(x;\bar{u}^n)$, $R(x;\bar{w}^n)$ and quadrature rules to evaluate the flux integrals in (2.5) and (2.6), then (2.13) constitutes a family of fully discrete nonoscillatory central schemes, e.g., [8, 14]. This type of scheme admits a considerably simpler and more versatile semidiscrete limit, $d\bar{u}_j/dt := \lim_{\Delta t\to 0}(\bar{u}_j(t^n+\Delta t) - \bar{u}_j(t^n))/\Delta t$.

To this end, we rewrite (2.13) as

$$\begin{aligned}\frac{d\bar{u}_j}{dt} = &\lim_{\Delta t\to 0}\left\{\frac{1}{\Delta x}\left(a_{j-\frac{1}{2}}^{n}A_{j-\frac{1}{2}}^{(0)} + a_{j+\frac{1}{2}}^{n}A_{j+\frac{1}{2}}^{(0)}\right) + \frac{1}{\Delta t}(\bar{w}_j^{n+1} - \bar{u}_j^{n})\right.\\ &- \frac{1}{\Delta x}\left(a_{j-\frac{1}{2}}^{n} + a_{j+\frac{1}{2}}^{n}\right)\bar{w}_j^{n+1} + \sum_{k=1}^{r-1}\frac{\lambda(\Delta t)^{k-1}}{(k+1)!}\left[\left(a_{j-\frac{1}{2}}^{n}\right)^{k+1}A_{j-\frac{1}{2}}^{(k)}\right.\\ &\left.\left.+ (-1)^k\left(a_{j+\frac{1}{2}}^{n}\right)^{k+1}A_{j+\frac{1}{2}}^{(k)}\right]\right\}\\ = &\lim_{\Delta t\to 0}\left\{\frac{1}{\Delta x}\left(a_{j-\frac{1}{2}}^{n}A_{j-\frac{1}{2}}^{(0)} + a_{j+\frac{1}{2}}^{n}A_{j+\frac{1}{2}}^{(0)}\right) + \frac{1}{\Delta t}(\bar{w}_j^{n+1} - \bar{u}_j^{n})\right.\\ &\left.- \frac{1}{\Delta x}\left(a_{j-\frac{1}{2}}^{n} + a_{j+\frac{1}{2}}^{n}\right)\bar{w}_j^{n+1}\right\}.\end{aligned} \tag{2.14}$$

Since the width of the local Riemann fans approaches zero in the $\Delta t \downarrow 0$-limit, i.e., $x^n_{j+\frac{1}{2},l}, x^n_{j+\frac{1}{2},r} \to x_{j+\frac{1}{2}}$, we obtain by conservation of cell averages property $\mathcal{P}_1$, $A^{(0)}_{j\pm\frac{1}{2}} = \bar{w}^{n+1}_{j\pm\frac{1}{2}}$ so that (2.14) yields

$$\begin{aligned}\frac{d\bar{u}_j}{dt} = \lim_{\Delta t\to 0}\Bigg\{ &\frac{1}{\Delta x}\left(a^n_{j-\frac{1}{2}}\bar{w}^{n+1}_{j-\frac{1}{2}} + a^n_{j+\frac{1}{2}}\bar{w}^{n+1}_{j+\frac{1}{2}}\right) + \frac{1}{\Delta t}(\bar{w}^{n+1}_j - \bar{u}^n_j)\\ &- \frac{1}{\Delta x}\left(a^n_{j-\frac{1}{2}} + a^n_{j+\frac{1}{2}}\right)\bar{w}^{n+1}_j\Bigg\}.\end{aligned} \tag{2.15}$$

As $\Delta t \downarrow 0$ we end up with limiting values which depend solely on the reconstructed values $R(x,u)$ on both sides of the interfacing breakpoints, $x_{j\pm\frac{1}{2}}$, given by

$$\begin{aligned}u(x^n_{j+\frac{1}{2},l},t) &\to p^n_j(x_{j+\frac{1}{2}}) =: u^-_{j+\frac{1}{2}}(t),\\ u(x^n_{j+\frac{1}{2},r},t) &\to p^n_{j+1}(x_{j+\frac{1}{2}}) =: u^+_{j+\frac{1}{2}}(t);\end{aligned} \tag{2.16}$$

here $p^n_j(x)$ and $p^n_{j+1}(x)$ are the polynomial reconstructions of $R(x;\bar{u}^n)$ at the original time step t^n introduced in (2.3). The corresponding averages in (2.5) approach $\bar{w}^{n+1}_{j+\frac{1}{2}} \sim (\Delta f)_{j+\frac{1}{2}}/2a^n_{j+\frac{1}{2}}$, where $(\Delta f)_{j+\frac{1}{2}} := f(u^+_{j+\frac{1}{2}}) - f(u^-_{j+\frac{1}{2}})$, while the smoother averages in (2.6) are of order $\bar{w}^{n+1}_j \sim \bar{u}^n_j - \Delta t(\Delta f)_{j+\frac{1}{2}}$. Inserted into (2.15), we end up with a semidiscrete limit which can be written in its final conservative form,

$$\frac{d\bar{u}_j}{dt} = -\frac{H_{j+\frac{1}{2}}(t) - H_{j-\frac{1}{2}}(t)}{\Delta x}; \tag{2.17}$$

here $H_{j\pm\frac{1}{2}}(t)$ are the numerical fluxes given by

$$H_{j+\frac{1}{2}}(t) := \frac{f(u^+_{j+\frac{1}{2}}(t)) + f(u^-_{j+\frac{1}{2}}(t))}{2} - \frac{a_{j+\frac{1}{2}}(t)}{2}\left[u^+_{j+\frac{1}{2}}(t) - u^-_{j+\frac{1}{2}}(t)\right]. \tag{2.18}$$

Once again, we emphasize that among its several advantages, the versatility of this semidiscrete formulation is the independence of the specific reconstruction, (2.3), and evolution algorithms which are utilized to recover the interface values $u^-_{j+\frac{1}{2}}$ and $u^+_{j+\frac{1}{2}}$ and to evolve the cell averages in (2.17). A description of our particular choices for these algorithms is provided in section 3.

2.2. Two-dimensional schemes. Starting with a general hyperbolic conservation law in two space dimensions,

$$u_t + f(u)_x + g(u)_z = 0, \tag{2.19}$$

we proceed as in section 2.1 and consider the sliding averages of u over the cells $I_{j,k} := [x_{j-1/2}, x_{j+1/2}] \times [z_{k-1/2}, z_{k+1/2}]$,

$$\bar{u}^n_{j,k} := \fint_{I_{j,k}} u(x,z,t^n)\,dx\,dz,$$

where Δx and Δz represent the space scales in the x- and the z-direction, respectively.

As in the one-dimensional case, we seek a semidiscrete formulation for the evolution of the cell averages of the conservation law (2.19). We begin by incorporating

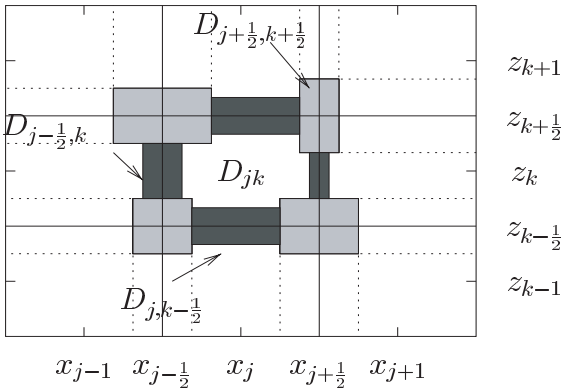

FIG. 2.2. *Floor plan for modified central differencing in two space dimensions.*

the information provided by the local speeds of propagation, which we approximate by

$$
\begin{aligned}
a^n_{j+\frac{1}{2},k} &:= \max\left\{\rho\left(\frac{\partial f}{\partial u}\left(u^W_{j+1,k}\right)\right), \rho\left(\frac{\partial f}{\partial u}\left(u^E_{j,k}\right)\right)\right\}, \quad b^n_{j,k+\frac{1}{2}}, \\
&:= \max\left\{\rho\left(\frac{\partial g}{\partial u}\left(u^S_{j,k+1}\right)\right), \rho\left(\frac{\partial g}{\partial u}\left(u^N_{j,k}\right)\right)\right\},
\end{aligned} \tag{2.20}
$$

where the cell interface values in the z- and x-directions,

$$
\begin{aligned}
u^N_{j,k} &:= p^n_{j,k}(x_j, z_{k+\frac{1}{2}}), \quad u^S_{j,k} := p^n_{j,k}(x_j, z_{k-\frac{1}{2}}), \\
u^E_{j,k} &:= p^n_{j,k}(x_{j+\frac{1}{2}}, z_k), \quad u^W_{j,k} := p^n_{j,k}(x_{j-\frac{1}{2}}, z_k),
\end{aligned} \tag{2.21}
$$

are calculated via a nonoscillatory piecewise polynomial reconstruction,

$$
R(x, z; \bar{u}^n) = \sum_{j,k} p^n_{j,k}(x, z)\mathbf{1}_{I_{j,k}}; \tag{2.22}
$$

the polynomials $\{p^n_{j,k}(x, z)\}$ are determined so that $R(x, z; \bar{u}^n)$ satisfies properties analogous to $\mathcal{P}_1$ – $\mathcal{P}_3$ above. This information allows us to separate between regions of smoothness, depicted as $D_{j,k}$ in Figure 2.2, and regions of nonsmoothness, depicted as the shaded regions. Nine sets of cell averages are calculated as follows:

- In the clear shaded regions, $D_{j\pm\frac{1}{2},k\pm\frac{1}{2}}$, the solution is not smooth in both directions; staggered evolution over the control volumes $D_{j\pm\frac{1}{2},k\pm\frac{1}{2}} \times [t^n, t^{n+1}]$ is used to obtain the new cell averages $\{\bar{w}^{n+1}_{j\pm\frac{1}{2},k\pm\frac{1}{2}}\}$,
- In the dark shaded regions, $D_{j\pm\frac{1}{2},k}$ and $D_{j,k\pm\frac{1}{2}}$, the solution is smooth only in one direction; staggered evolution is used along the nonsmooth interfaces to obtain, respectively, the cell averages $\{\bar{w}^{n+1}_{j\pm\frac{1}{2},k}\}$ and $\{\bar{w}^{n+1}_{j,k\pm\frac{1}{2}}\}$,
- To evolve the smooth part of the solution, we integrate the polynomial $p^n_{j,k}(x, z)$ and the corresponding fluxes over the nonrectangular control volume $D_{j,k} \times [t^n, t^{n+1}]$; these cell averages are denoted by $\{\bar{w}^{n+1}_{j,k}\}$.

This approach allows us to form a new polynomial, denoted $R(x, z; \bar{w}^{n+1})$, which is reconstructed from these smooth and nonsmooth portions of the solution, and to

reproject it back onto the original grid-cells,

$$\bar{u}_{j,k}^{n+1} = \fint_{I_{j,k}} R\,(x,z;\bar{w}^{n+1})\,dx\,dz. \tag{2.23}$$

The resulting nonstaggered fully discrete scheme admits a more versatile semidiscrete limit as $\Delta t \to 0$,

$$\frac{d}{dt}\bar{u}_{j,k}(t) = -\frac{H^x_{j+\frac{1}{2},k}(t) - H^x_{j-\frac{1}{2},k}(t)}{\Delta x} - \frac{H^z_{j,k+\frac{1}{2}}(t) - H^z_{j,k-\frac{1}{2}}(t)}{\Delta z}, \tag{2.24}$$

with numerical fluxes

$$\begin{aligned} H^x_{j+\frac{1}{2},k}(t) = {} & \frac{1}{12}\Big[f\left(u^{NW}_{j+1,k}(t)\right) + f\left(u^{NE}_{j,k}(t)\right) + 4\Big(f\left(u^{W}_{j+1,k}(t)\right) \\ & + f\left(u^{E}_{j,k}(t)\right)\Big) + f\left(u^{SW}_{j+1,k}(t)\right) + f\left(u^{SE}_{j,k}(t)\right)\Big] \\ & - \frac{a_{j+\frac{1}{2},k}(t)}{12}\Big(u^{NW}_{j+1,k}(t) - u^{NE}_{j,k}(t) + 4\Big(u^{W}_{j+1,k}(t) \\ & - u^{E}_{j,k}(t)\Big) + u^{SW}_{j+1,k}(t) - u^{SE}_{j,k}(t)\Big), \end{aligned} \tag{2.25}$$

$$\begin{aligned} H^z_{j,k+\frac{1}{2}}(t) = {} & \frac{1}{12}\Big[g\left(u^{SW}_{j,k+1}(t)\right) + g\left(u^{NW}_{j,k}(t)\right) + 4\Big(g\left(u^{S}_{j,k+1}(t)\right) \\ & + g\left(u^{N}_{j,k}(t)\right)\Big) + g\left(u^{SE}_{j,k+1}(t)\right) + g\left(u^{NE}_{j,k}(t)\right)\Big] \\ & - \frac{b_{j,k+\frac{1}{2}}(t)}{12}\Big(u^{SW}_{j,k+1}(t) - u^{NW}_{j,k}(t) + 4\Big(u^{S}_{j,k+1}(t) \\ & - u^{N}_{j,k}(t)\Big) + u^{SE}_{j,k+1}(t) - u^{NE}_{j,k}(t)\Big). \end{aligned} \tag{2.26}$$

This particular version of the numerical fluxes results from using Simpson's quadrature rule to approximate the integrals of the fluxes f and g along the cell boundaries $[z_{k-\frac{1}{2}}, z_{k+\frac{1}{2}}]$ and $[x_{j-\frac{1}{2}}, x_{j+\frac{1}{2}}]$, respectively, and it incorporates information from the [illegible] interface values,

$$\begin{aligned} u^{NE}_{j,k} &:= \hat{p}^n_{j,k}(x_{j+\frac{1}{2}}, z_{k+\frac{1}{2}}), \quad u^{SW}_{j,k} := \hat{p}^n_{j,k}(x_{j-\frac{1}{2}}, z_{k-\frac{1}{2}}), \\ u^{SE}_{j,k} &:= \hat{p}^n_{j,k}(x_{j+\frac{1}{2}}, z_{k-\frac{1}{2}}), \quad u^{NW}_{j,k} := \hat{p}^n_{j,k}(x_{j-\frac{1}{2}}, z_{k+\frac{1}{2}}), \end{aligned} \tag{2.27}$$

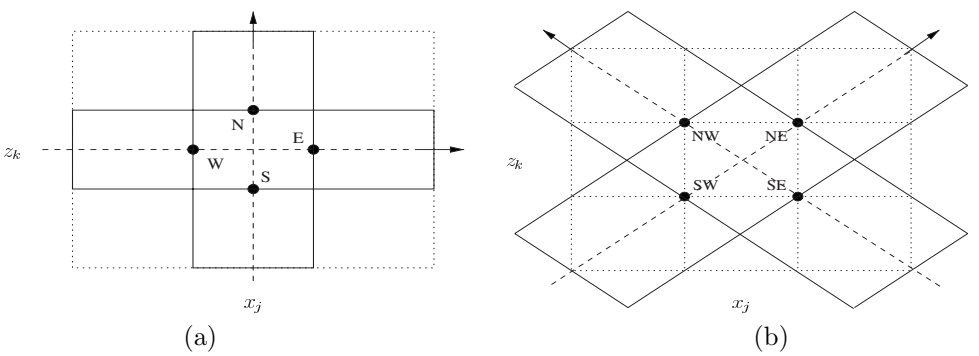

FIG. 2.3. (a) *Reconstruction in x- and z-directions.* (b) *Diagonal axes for reconstruction.*

into the scheme. These corner values are recovered via the nonoscillatory reconstruction $\hat{R}(x,z;\bar{u}^n) = \sum \hat{p}^n_{j,k}(x,z)\cdot \mathbf{1}_{I_{j,k}}$, which may coincide with the original reconstruction, $R(x,z;\bar{u}^n)$, or, alternatively, interpolate the cell values along the diagonal directions shown in Figure 2.3(b) so as to prevent the onset of spurious oscillations along those axes.

3. Implementation of semidiscrete central schemes. The framework of the semidiscrete scheme described above entertains a wide range of options for the implementation of their two main ingredients: nonoscillatory reconstruction and evolution. In this section we provide some examples of nonoscillatory reconstructions and evolution routines that we implemented for computing the solutions of the system (1.1)–(1.4) presented in sections 4 and 5.

3.1. Third-order CWENO reconstruction. Our first choice for the reconstruction of the point values of u is the third-order CWENO polynomial reconstruction of Kurganov and Levy [12]. A piecewise quadratic polynomial that satisfies the essential properties $\mathcal{P}_1$, $\mathcal{P}_2$, and $\mathcal{P}_3$ above is formed as follows: in each cell $I_j = [x_{j-\frac{1}{2}}, x_{j+\frac{1}{2}}]$, the polynomials $\{p^n_j(x)\}$ in (2.3) are written as a convex combination of three polynomials $P_{\rm L}(x)$, $P_{\rm C}(x)$, and $P_{\rm R}(x)$,

$$p^n_j(x) = w_{\rm L}P_{\rm L}(x) + w_{\rm C}P_{\rm C}(x) + w_{\rm R}P_{\rm R}(x), \qquad \sum_{i\in\{{\rm L},{\rm C},{\rm R}\}} w_i = 1, \tag{3.1}$$

where the linear polynomials

$$P_{\rm L}(x) = \bar{u}^n_j + \frac{\bar{u}^n_j - \bar{u}^n_{j-1}}{\Delta x}(x - x_j) \quad \text{and} \quad P_{\rm R}(x) = \bar{u}^n_j + \frac{\bar{u}^n_{j+1} - \bar{u}^n_j}{\Delta x}(x - x_j), \tag{3.2}$$

conserve the pair of cell averages $\bar{u}^n_{j-1}$, $\bar{u}^n_j$ and $\bar{u}^n_j$, $\bar{u}^n_{j+1}$, respectively, and the parabola centered around x_j,

$$\begin{aligned} P_{\rm C}(x) = \bar{u}^n_j &- \frac{1}{12}(\bar{u}^n_{j-1} - 2\bar{u}^n_j + \bar{u}^n_{j+1}) \\ &+ \frac{\bar{u}^n_{j+1} - \bar{u}^n_{j-1}}{2\Delta x}(x - x_j) + \frac{\bar{u}^n_{j-1} - 2\bar{u}^n_j + \bar{u}^n_{j+1}}{\Delta x^2}(x - x_j)^2, \end{aligned} \tag{3.3}$$

is determined so as to satisfy

$$c_{\rm L}P_{\rm L}(x) + c_{\rm R}P_{\rm R}(x) + (1 - c_{\rm L} - c_{\rm R})P_{\rm C}(x) = u^n_j + u'_j(x - x_j) + \frac{1}{2}u''_j(x - x_j)^2,$$

where u^n_j, u'_j, and u''_j approximate the point values $u(x_j,t^n)$, $u_x(x_j,t^n)$, and $u_{xx}(x_j,t^n)$ given respectively by

$$\begin{aligned} u^n_j &:= \bar{u}^n_j - \frac{1}{24}(\bar{u}^n_{j-1} - 2\bar{u}^n_j + \bar{u}^n_{j+1}), \\ u'_j &:= \frac{\bar{u}^n_{j+1} - \bar{u}^n_{j-1}}{2\Delta x}, \quad \text{and} \quad u''_j := \frac{\bar{u}^n_{j-1} - 2\bar{u}^n_j + \bar{u}^n_{j+1}}{\Delta x^2}. \end{aligned} \tag{3.4}$$

We guarantee the conservation of the cell averages $\bar{u}^n_{j-1}$, $\bar{u}^n_j$, and $\bar{u}^n_{j+1}$ by any symmetric choice of the weights c_i (e.g., $c_{\rm L} = c_{\rm R} = 1/4$, $c_{\rm C} = 1/2$) and the accuracy property, $\mathcal{P}_2$, in smooth regions [17],

$$p^n_j(x) = u(x,t^n) + \mathcal{O}((\Delta x)^3), \quad x \in [x_{j-\frac{1}{2}}, x_{j+\frac{1}{2}}].$$

Property $\mathcal{P}_3$—the nonoscillatory behavior of $\{p_j^n(x)\}$ is attained with the nonlinear weights

$$w_i = \frac{\alpha_i}{\sum_m \alpha_m} \quad \text{with} \quad \alpha_i = \frac{c_i}{(\epsilon + IS_i)^2}, \quad i, m \in \{\text{L}, \text{C}, \text{R}\}, \tag{3.5}$$

where $\epsilon \ll 1$ prevents the denominator from vanishing (for the calculations in sections 4 and 5 we choose $\epsilon = 10^{-6}$), and the smoothness indicators, IS_i, provide a local measure of the derivatives of $P_i(x)$,

$$IS_i = \sum_{l=1}^{2} \int_{I_j} (\Delta x)^{2l-1} (P_i^{(l)}(x))^2 dx, \quad i \in \{\text{L}, \text{C}, \text{R}\}, \tag{3.6}$$

switching automatically to the second-order reconstructions P_{L} and P_{R} in the presence of steep gradients and avoiding the onset of spurious oscillations [9, 12, 17]. In this case, they read

$$\begin{aligned} IS_{\text{L}} &= (\bar{u}_j^n - \bar{u}_{j-1}^n)^2, \qquad IS_{\text{R}} = (\bar{u}_{j+1}^n - \bar{u}_j^n)^2, \\ IS_{\text{C}} &= \frac{13}{3}(\bar{u}_{j+1}^n - 2\bar{u}_j^n + \bar{u}_{j-1}^n)^2 + \frac{1}{4}(\bar{u}_{j+1}^n - \bar{u}_{j-1}^n)^2. \end{aligned} \tag{3.7}$$

1. For this particular reconstruction, the one-dimensional interface values, $u^-_{j+\frac{1}{2}}(t)$ and $u^+_{j+\frac{1}{2}}(t)$, required in the numerical flux (2.18) take the explicit form

$$\begin{aligned} u^-_{j+\frac{1}{2}}(t^n) := p_j^n(x_{j+\frac{1}{2}}) &= \frac{1}{2} w_{\text{L}}(3\bar{u}_j^n - \bar{u}_{j-1}^n) \\ &\quad + \frac{1}{12} w_{\text{C}}(-5\bar{u}_{j+1}^n + 8\bar{u}_j^n - \bar{u}_{j-1}^n) + \frac{1}{2} w_{\text{R}}(\bar{u}_{j+1}^n + \bar{u}_j^n), \\ u^+_{j+\frac{1}{2}}(t^n) := p_{j+1}^n(x_{j+\frac{1}{2}}) &= \frac{1}{2} w_{\text{L}}(\bar{u}_{j+1}^n + \bar{u}_j^n) \\ &\quad + \frac{1}{12} w_{\text{C}}(-\bar{u}_{j+2}^n + 8\bar{u}_{j+1}^n - 5\bar{u}_j^n) + \frac{1}{2} w_{\text{R}}(-\bar{u}_{j+2}^n + 3\bar{u}_{j+1}^n). \end{aligned}$$

2. In the case of systems of equations, the choice of these smoothness indicators is, indeed, nontrivial. The different conserved quantities involved in any particular system (density, momentum, etc.) may very well develop discontinuities at different points throughout the solution domain that do not affect every other quantity in the system. Hence, choosing the smoothness indicators individually for each quantity may cause the scheme to use different stencils for different quantities during the same evolution step. This can be avoided by either using [illegible] smoothness indicators, e.g., an (norm-scaled) average of the individual ones, or by identifying those that are physically relevant, such as, e.g., the density near a contact discontinuity. (See section 4 for our particular choices in the one-dimensional case and [16] for an in-depth discussion about the selection of smoothness indicators for systems of equations.)

In two and higher space dimensions, a possibility for calculating the interface values in (2.21) and (2.27) in a rather straightforward way is to apply this one-dimensional third-order reconstruction [illegible] in the x- and z-directions (Figure 2.3(a)) and, if so desired, in the two diagonal directions of the coordinate frame displayed in Figure 2.3(b). In two dimensions, however, we note that the constant

term in the x-direction parabola, (3.3), requires an additional correction (in the transverse direction of the reconstruction) in order to guarantee third-order accuracy when the point value $u(x_j, z_k, t^n)$ is recovered from the neighboring cell averages,

$$u(x_j, z_k, t^n) = \bar{u}^n_{j,k} - \frac{1}{12}(\bar{u}^n_{j-1,k} - 2\bar{u}^n_{j,k} + \bar{u}^n_{j+1,k}) - \frac{1}{12}(\bar{u}^n_{j,k-1} - 2\bar{u}^n_{j,k} + \bar{u}^n_{j,k+1}) + \mathcal{O}((\max\{\Delta x, \Delta z\})^3).$$

That is, along the line $z = z_k$, the reconstruction in the x-direction is carried out using the linear polynomials $P_{\mathrm{L}}(x, z_k)$ and $P_{\mathrm{R}}(x, z_k)$ as in (3.2), and the parabola $P_{\mathrm{C}}(x, z_k)$, given by

$$P_{\mathrm{C}}(x, z_k) = \bar{u}^n_{j,k} - \frac{1}{12}(\bar{u}^n_{j-1,k} - 2\bar{u}^n_{j,k} + \bar{u}^n_{j+1,k}) - \frac{1}{12}(\bar{u}^n_{j,k-1} - 2\bar{u}^n_{j,k} + \bar{u}^n_{j,k+1}) + \frac{\bar{u}^n_{j+1,k} - \bar{u}^n_{j-1,k}}{2\Delta x}(x - x_j) + \frac{\bar{u}^n_{j-1,k} - 2\bar{u}^n_{j} + \bar{u}^n_{j+1,k}}{\Delta x^2}(x - x_j)^2. \tag{3.8}$$

The same reconstruction is carried out in the z-direction, holding $x = x_j$ fixed. And, should one choose to implement the reconstruction along the diagonal directions, the corresponding polynomials are given by (consult [13] for additional details)

$$\hat{p}^n_{j,k}(x, z) = \hat{w}_{\mathrm{L}}\hat{P}_{\mathrm{L}}(x, z) + \hat{w}_{\mathrm{C}}\hat{P}_{\mathrm{C}}(x, z) + \hat{w}_{\mathrm{R}}\hat{P}_{\mathrm{R}}(x, z) \tag{3.9}$$

with

$$\hat{P}_{\mathrm{L}}(x, z) = \bar{u}^n_{j,k} + \frac{\bar{u}^n_{j,k} - \bar{u}^n_{j-1,k-1}}{\Delta}\left(\frac{\Delta}{2\Delta z}(z - z_k) + \frac{\Delta}{2\Delta x}(x - x_j)\right),$$

$$\begin{aligned}\hat{P}_{\mathrm{C}}(x, z) = \bar{u}^n_{j,k} &- \frac{1}{12}(\bar{u}^n_{j+1,k+1} - 2\bar{u}^n_{j,k} + \bar{u}^n_{j-1,k-1}) \\ &- \frac{1}{12}(\bar{u}^n_{j-1,k+1} - 2\bar{u}^n_{j,k} + \bar{u}^n_{j+1,k-1}) \\ &+ \frac{\bar{u}^n_{j+1,k+1} - \bar{u}^n_{j-1,k-1}}{2\Delta}\left(\frac{\Delta}{2\Delta z}(z - z_k) + \frac{\Delta}{2\Delta x}(x - x_j)\right) \\ &+ \frac{\bar{u}^n_{j+1,k+1} - 2\bar{u}^n_{j,k} + \bar{u}^n_{j-1,k-1}}{\Delta^2}\left(\frac{\Delta}{2\Delta z}(z - z_k) + \frac{\Delta}{2\Delta x}(x - x_j)\right)^2,\end{aligned}$$

$$\hat{P}_{\mathrm{R}}(x, z) = \bar{u}^n_{j,k} + \frac{\bar{u}^n_{j+1,k+1} - \bar{u}^n_{j,k}}{\Delta}\left(\frac{\Delta}{2\Delta z}(z - z_k) + \frac{\Delta}{2\Delta x}(x - x_j)\right) \tag{3.10}$$

along the SW–NE axis and

$$\hat{P}_{\mathrm{L}}(x, z) = \bar{u}^n_{j,k} + \frac{\bar{u}^n_{j,k} - \bar{u}^n_{j+1,k-1}}{\Delta}\left(\frac{\Delta}{2\Delta z}(z - z_k) - \frac{\Delta}{2\Delta x}(x - x_j)\right),$$

$$\begin{aligned}\hat{P}_{\mathrm{C}}(x, z) = \bar{u}^n_{j,k} &- \frac{1}{12}(\bar{u}^n_{j+1,k+1} - 2\bar{u}^n_{j,k} + \bar{u}^n_{j-1,k-1}) \\ &- \frac{1}{12}(\bar{u}^n_{j-1,k+1} - 2\bar{u}^n_{j,k} + \bar{u}^n_{j+1,k-1}) \\ &+ \frac{\bar{u}^n_{j-1,k+1} - \bar{u}^n_{j+1,k-1}}{2\Delta}\left(\frac{\Delta}{2\Delta z}(z - z_k) - \frac{\Delta}{2\Delta x}(x - x_j)\right) \\ &+ \frac{\bar{u}^n_{j-1,k+1} - 2\bar{u}^n_{j,k} + \bar{u}^n_{j+1,k-1}}{\Delta^2}\left(\frac{\Delta}{2\Delta z}(z - z_k) - \frac{\Delta}{2\Delta x}(x - x_j)\right)^2,\end{aligned}$$

$$\hat{P}_{\mathrm{R}}(x, z) = \bar{u}^n_{j,k} + \frac{\bar{u}^n_{j+1,k+1} - \bar{u}^n_{j,k}}{\Delta}\left(\frac{\Delta}{2\Delta z}(z - z_k) - \frac{\Delta}{2\Delta x}(x - x_j)\right) \tag{3.11}$$

along the SE–NW axis, where $\Delta = \sqrt{(\Delta x)^2 + (\Delta z)^2}$. The nonlinear weights, $\hat{w}_i$, are also calculated direction by direction according to the one-dimensional recipe (3.5) with the smoothness indicators given by the [illegible] average of the componentwise indicators, $IS_i^{(m)}$, calculated as in (3.7),

$$IS_i = \frac{1}{d}\sum_{m=1}^{d} \frac{1}{\|u^{(m)}\|_2 + \epsilon}\, IS_i^{(m)}, \quad i \in \{\text{L}, \text{C}, \text{R}\}, \tag{3.12}$$

where $u^{(m)}$ stands for the mth component of u, and $\|u^{(m)}\|_2^2 = \sum_{j,k} |u_{j,k}^{(m)}|^2 \Delta x \Delta z$ represents its ℓ_2 norm over the discretized solution domain.

3.2. CWENO fourth-order reconstruction. In section 5 we demonstrate the versatility of the central semidiscrete scheme (2.24)–(2.26) by implementing the dimension-by-dimension third-order reconstruction described above and the [illegible] fourth-order CWENO reconstruction of Levy, Puppo, and Russo [18] and Balbás [1] that recovers the interface point values in (2.21) and (2.27) via a biquadratic polynomial interpolant satisfying the desired conservation, accuracy, and nonoscillatory properties in two-space dimensions. Following is an outline of this fourth-order reconstruction, originally developed by Levy and others within the central, fully discrete, staggered framework. In each cell $I_{j,k}$, the piecewise polynomial interpolants in (2.22), $p_{j,k}^n(x,z)$, are written as a convex combination of nine biquadratic polynomials, $P_{j+p,k+q}(x,z)$, that conserve the cell averages $\{\bar{u}_{j+p,k+q}^n\}_{p,q=-1}^{1}$ and approximate the point values of $u(x,z,t^n)$ within fourth-order accuracy,

$$p_{j,k}^n(x,z) = \sum_{p,q=-1}^{1} w_{j,k}^{p,q} P_{j+p,k+q}(x,z), \qquad \sum_{p,q=-1}^{1} w_{j,k}^{p,q} = 1, \quad w_{j,k}^{p,q} \geq 0, \tag{3.13}$$

where the polynomials $P_{j,k}(x,z)$ have the form (omitting, for simplicity, the j and k indices in the coefficients $\{b_m\}$),

$$\begin{aligned} P_{j,k}^n(x,z) = {} & b_0 + b_1(x-x_j) + b_2(z-z_k) + b_3(x-x_j)(z-z_k) \\ & + b_4(x-x_j)^2 + b_5(z-z_k)^2 + b_6(x-x_j)^2(z-z_k) \\ & + b_7(x-x_j)(z-z_k)^2 + b_8(x-x_j)^2(z-z_k)^2. \end{aligned} \tag{3.14}$$

The nine conservation constraints,

$$\fint_{x_{j-\frac{1}{2}}+p\Delta x}^{x_{j+\frac{1}{2}}+p\Delta x} \fint_{z_{k-\frac{1}{2}}+q\Delta z}^{z_{k+\frac{1}{2}}+q\Delta z} P_{j,k}(x,z)dz\, dx = \bar{u}_{j+p,k+q}^n, \quad p,q = -1,0,1, \tag{3.15}$$

uniquely determine the nine coefficients $\{b_m\}$,

$$\begin{aligned} b_0 &= \bar{u}^n - \frac{\Delta x^2}{24}\hat{u}_{xx} - \frac{\Delta z^2}{24}\hat{u}_{zz} + \frac{\Delta x^2 \Delta z^2}{24^2}\hat{u}_{xxzz}, \\ b_1 &= \hat{u}_x - \frac{\Delta z^2}{24}\hat{u}_{xzz}, & b_2 &= \hat{u}_z - \frac{\Delta x^2}{24}\hat{u}_{xxz}, \\ b_3 &= \hat{u}_{xz}, & b_4 &= \frac{1}{2}\hat{u}_{xx} - \frac{\Delta z^2}{48}\hat{u}_{xxzz}, \\ b_5 &= \frac{1}{2}\hat{u}_{zz} - \frac{\Delta x^2}{48}\hat{u}_{xxzz}, & b_6 &= \frac{1}{2}\hat{u}_{xxz}, \\ b_7 &= \frac{1}{2}\hat{u}_{xzz}, & b_8 &= \frac{1}{4}\hat{u}_{xxzz}, \end{aligned}$$

where the divided differences

$$\hat{u}_{x_{j,k}} = \frac{\bar{u}^n_{j+1,k} - \bar{u}^n_{j-1,k}}{2\Delta x}, \qquad \hat{u}_{z_{j,k}} = \frac{\bar{u}^n_{j,k+1} - \bar{u}^n_{j,k-1}}{2\Delta z},$$

$$\hat{u}_{xx_{j,k}} = \frac{\bar{u}^n_{j+1,k} - 2\bar{u}^n_{j,k} + \bar{u}^n_{j-1,k}}{\Delta x^2}, \qquad \hat{u}_{zz_{j,k}} = \frac{\bar{u}^n_{j,k+1} - 2\bar{u}^n_{j,k} + \bar{u}^n_{j,k-1}}{\Delta z^2},$$

$$\hat{u}_{xz_{j,k}} = \frac{\bar{u}^n_{j+1,k+1} - \bar{u}^n_{j+1,k-1} - \bar{u}^n_{j-1,k+1} + \bar{u}^n_{j-1,k-1}}{4\Delta x \Delta z},$$

$$\hat{u}_{xxz_{j,k}} = \frac{(\bar{u}^n_{j+1,k+1} - 2\bar{u}^n_{j,k+1} + \bar{u}^n_{j-1,k+1}) - (\bar{u}^n_{j+1,k-1} - 2\bar{u}^n_{j,k-1} + \bar{u}^n_{j-1,k-1})}{2\Delta x^2 \Delta z},$$

$$\hat{u}_{xzz_{j,k}} = \frac{(\bar{u}^n_{j+1,k+1} - 2\bar{u}^n_{j+1,k} + \bar{u}^n_{j+1,k-1}) - (\bar{u}^n_{j-1,k+1} - 2\bar{u}^n_{j-1,k} + \bar{u}^n_{j-1,k-1})}{2\Delta x \Delta z^2},$$

$$\hat{u}_{xxzz_{j,k}} = \frac{1}{\Delta x^2 \Delta z^2}\big[(\bar{u}^n_{j+1,k+1} - 2\bar{u}^n_{j+1,k} + \bar{u}^n_{j+1,k-1}) - 2(\bar{u}^n_{j,k+1} - 2\bar{u}^n_{j,k} + \bar{u}^n_{j,k-1}) + (\bar{u}^n_{j-1,k+1} - 2\bar{u}^n_{j-1,k} + \bar{u}^n_{j-1,k-1})\big]$$

serve to approximate the values of u and its partial derivatives at the points (x_j, z_k) within the fourth-order accuracy constraints of the method.

As in the third-order reconstruction, the nonlinear weights in (3.13), $w^{p,q}_{l,k}$, are computed so as to provide maximum accuracy in smooth regions and prevent oscillations in the nonsmooth regions by eliminating the contribution of polynomials with steep gradients across the cell interfaces. For each cell nine weights are calculated,

$$w^{p,q}_{j,k} = \frac{\alpha^{p,q}_{j,k}}{\sum_{m,n} \alpha^{m,n}_{j,k}} \quad \text{with} \quad \alpha^{p,q}_{j,k} = \frac{c^{p,q}_{j,k}}{(\epsilon + IS^{p,q}_{j,k})^2}, \quad m,n,p,q = -1,0,1, \tag{3.16}$$

and the linear coefficients, $c^{p,q}_{j,k}$, chosen so that symmetry guarantees fourth-order accuracy,

$$c^{0,0}_{j,k} = \frac{1}{2} \qquad \text{and} \qquad c^{p,q}_{j,k} = \frac{1}{16} \quad \forall\ p,q \neq 0;$$

convexity, $\sum^{1}_{p,q=-1} c^{p,q}_{j,k} = 1$, $c^{p,q}_{j,k} \geq 0$, guarantees conservation.

Global smoothness indicators are chosen according to (3.12). Unlike the third-order reconstruction where the exact calculation of the individual smoothness indicators is trivial and renders simple formulas, i.e., (3.7), in this fourth-order case, the exact calculation of the local L^2-norm of the partial derivatives of the polynomials $P^{p,q}_{j,k}$ is impractical. Instead, a Gaussian quadrature formula is used to approximate the integrals

$$IS^{p,q}_{j,k} = \int_{I_{j,k}} (|\partial_x P_{j+p,k+q}|^2 + |\partial_z P_{j+p,k+q}|^2 + (\Delta x)^2 |\partial_{xx} P_{j+p,k+q}|^2 + (\Delta z)^2 |\partial_{zz} P_{j+p,k+q}|^2)\, dx\, dz.$$

This approach still serves the purpose of automatically detecting and redirecting the numerical stencils in the direction of smoothness, thus preventing the onset of oscillations, [18].

3.3. Time evolution: Strong stability-preserving Runge–Kutta solvers. With the interface values (2.16), (2.21), and (2.27) computed with either of the above

CWENO reconstructions, we denote, for any grid function $w = \{w_j(t)\}$, the numerical fluxes on the right of (2.17) and (2.24) by

$$C[w(t)] = -\frac{H_{j+\frac{1}{2}}(w(t)) - H_{j-\frac{1}{2}}(w(t))}{\Delta x} \tag{3.17}$$

and

$$C[w(t)] = -\frac{H^x_{j+\frac{1}{2},k}(w(t)) - H^x_{j-\frac{1}{2},k}(w(t))}{\Delta x} - \frac{H^z_{j,k+\frac{1}{2}}(w(t)) - H^z_{j,k-\frac{1}{2}}(w(t))}{\Delta z}, \tag{3.18}$$

respectively, and evolve the solution $u^{(0)} := \bar{u}^n_j$ from t^n, to t^{n+1} with an appropriate ODE solver. For the numerical calculations reported in sections 4 and 5, we choose the strong stability-preserving (SSP) Runge–Kutta discretizations [23, 5]. In particular, for the third-order results, we employ

$$\begin{aligned} u^{(1)} &= u^{(0)} + \Delta t C[u^{(0)}], \\ u^{(2)} &= u^{(1)} + \frac{\Delta t}{4}(-3C[u^{(0)}] + C[u^{(1)}]), \\ u^{n+1} := u^{(3)} &= u^{(2)} + \frac{\Delta t}{12}(-C[u^{(0)}] - C[u^{(1)}] + 8\ C[u^{(2)}]), \end{aligned} \tag{3.19}$$

and for the fourth-order results of section 5.3,

$$\begin{aligned} u^{(1)} &= u^{(0)} + \frac{\Delta t}{2} C[u^{(0)}], \\ u^{(2)} &= u^{(1)} + \frac{\Delta t}{2}(-C[u^{(0)}] + C[u^{(1)}]), \\ u^{(3)} &= u^{(2)} + \frac{\Delta t}{2}(-C[u^{(1)}] + 2\ C[u^{(2)}]), \\ u^{n+1} := u^{(4)} &= u^{(3)} + \frac{\Delta t}{6}(C[u^{(0)}] + 2C[u^{(1)}] - 4C[u^{(2)}] + C[u^{(3)}]) \end{aligned} \tag{3.20}$$

is used to evolve the values reconstructed via the fourth-order CWENO interpolation algorithm of Levy and others of section 3.2.

4. One-dimensional numerical results. In one space dimension, equations (1.1)–(1.4) admit the conservative form (2.1) with

$$u = (\rho, \rho v_x, \rho v_y, \rho v_z, B_y, B_z, e)^\top, \tag{4.1}$$

$$\begin{aligned} f(u) = (&\rho v_x, \rho v_x^2 + p^* - B_x^2, \rho v_x v_y - B_x B_y, \rho v_x v_z - B_x B_z, B_y v_x - B_x v_y, \\ &B_z v_x - B_x v_z, (e + p^*) v_x - B_x (B_x v_x + B_y v_y + B_z v_z))^\top, \end{aligned} \tag{4.2}$$

where $p^* = p + \frac{1}{2}B^2$ stands for the total pressure (static plus magnetic).

In this section we present numerical simulations of the one-dimensional MHD equations, (2.1)–(4.2). The results were obtained using the semidiscrete central scheme (2.17)–(2.18) with the pointvalues $u^+_{j+\frac{1}{2}}(t)$ and $u^-_{j+\frac{1}{2}}(t)$, (2.16), computed via the CWENO third-order reconstruction of section 3.1, and evolved according to Shu's third-order SSP Runge–Kutta scheme as outlined in section 3.3. The schemes are implemented for computing the approximate solution of two coplanar shock tube MHD models described by Brio and Wu in [3]. We use a uniform grid in the space

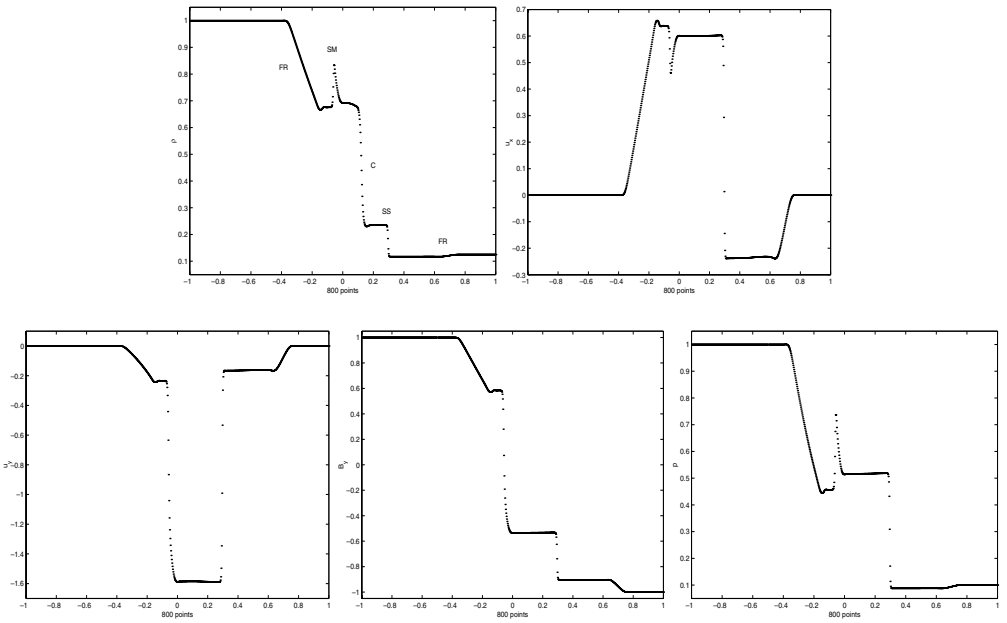

FIG. 4.1. *Results of Brio–Wu shock tube problem at* $t = 0.2$ *computed with* 800 *grid points using third-order CWENO reconstruction,* (3.1)*, and Shu's SSP Runge–Kutta solver,* (3.19).

discretization, and in both cases we choose the time step dynamically with CFL restriction

$$\Delta t = \frac{0.9\ \Delta x}{\max_k |a_k(u)|}, \tag{4.3}$$

where $\{a_k(u)\}_k$ are the eigenvalues of the Jacobian matrix of $f(u)$.

4.1. Brio–Wu shock tube problem. The first one-dimensional Riemann problem we consider consists of a shock tube with two initial equilibrium states, u_l and u_r, given by

$$(\rho, v_x, v_y, v_z, B_y, B_z, p)^\top = \begin{cases} (1.0, 0, 0, 0, 1.0, 0, 1.0)^\top & \text{for } x < 0, \\ (0.125, 0, 0, 0, -1.0, 0, 0.1)^\top & \text{for } x > 0, \end{cases} \tag{4.4}$$

and complemented with the constant values of $B_x \equiv 0.75$ and $\gamma = 2$. The problem is solved for $x \in [-1, 1]$ with 800 grid points, and numerical results are presented at $t = 0.2$. Figure 4.1 shows the density, the x- and y-velocity components, the y-magnetic field, and pressure profiles. The hydrodynamical data of this problem is the same as that in Sod's shock tube problem of gas dynamics. The variety of MHD waves, however, poses a considerable challenge for high resolution such as the [illegible] central schemes described in this paper. The solution of this problem consists of a left-moving fast rarefaction wave (FR), a slow compound wave (SM) which results from an intermediate shock that changes B_y from 0.58 to -0.31 and a slow rarefaction that changes B_y from -0.31 -0.53, a contact discontinuity (C), a right-moving slow shock (SS), and a right-moving fast rarefaction wave (FR). Note that the solution to this problem is not unique if B_z and v_z are not identically zero. The results in Figure 4.1 are in agreement with those previously reported in [2] and are comparable with

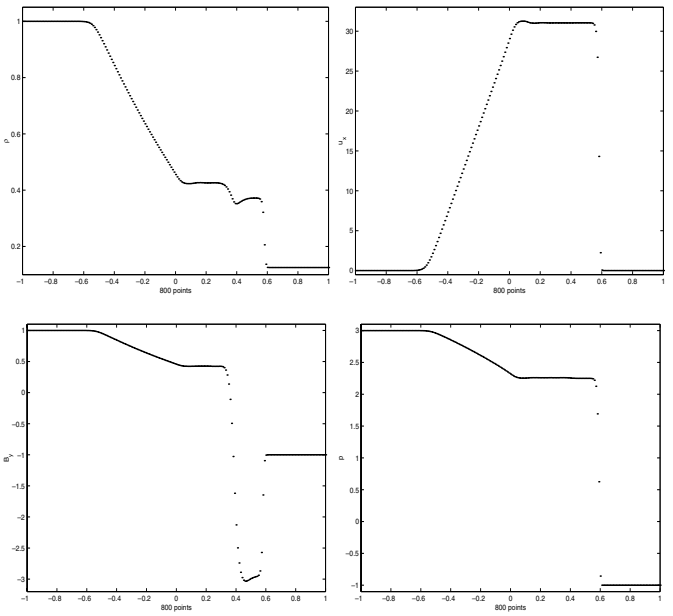

FIG. 4.2. *Results of Brio–Wu high Mach problem at* $t = 0.012$ *computed with* 200 *grid points using third-order CWENO reconstruction,* (3.1)*, and Shu's SSP Runge–Kutta solver,* (3.19).

the second-order upwind computations of Brio and Wu in [3] and with the fifth-order WENO computations presented by Jiang and Wu in [11]. In fact, the present results show a better control of the oscillations that typically appear at the trailing edge of the right-moving fast rarefaction wave when high-resolution schemes are employed. This better control is due to our choice of smoothness indicators. Our various numerical experiments show that in the absence of characteristic information, the average of the smoothness indicators of the density, ρ, and transverse magnetic field, B_y, scaled by their ℓ_2 norm, is the best combination for selecting a single stencil for reconstruction and evolution of all the conserved quantities in the system. Our numerical results confirm the ability of central schemes, whether in their fully discrete or semidiscrete formulations, to capture the main features of the discontinuous MHD solutions, while avoiding any characteristic information other than an estimate of the maximal speed of propagation, $\max_k |a_k(u)|$.

4.2. Brio–Wu high Mach shock tube problem. The following shock tube model proposed by Brio and Wu in [3] is commonly used to check the robustness of the numerical schemes for high Mach number problems. The initial equilibrium states, u_l and u_r, are given by

$$(\rho, v_x, v_y, v_z, B_y, B_z, p)^\top = \begin{cases} (1.0, 0, 0, 0, 1.0, 0, 1000)^\top & \text{for } x < 0, \\ (0.125, 0, 0, 0, -1.0, 0, 0.1)^\top & \text{for } x > 0 \end{cases} \tag{4.5}$$

and complemented with the values of $B_x \equiv 0$ and $\gamma = 2$. The Mach number of the right-moving shock wave is 15.5. If the plasma pressure is replaced by the sum of the static and magnetic pressures, denoted by p^* above, this model becomes a standard hydrodynamical Riemann problem. The solution is presented at $t = .012$, $x \in [-1, 1]$, with 200 grid points and with CFL number 0.9; consult (4.3).

The solution of this second Riemann problem consists of a left-moving fast rarefaction wave (FR), followed by a tangential discontinuity (TD), and a right-moving fast shock (FS) with Mach number 15.5. Across the tangential discontinuity, the density, the magnetic field, and the pressure can change, but both the fluid velocity and the total pressure, $p + \frac{B^2}{2}$, are continuous.

As in the previous problem, our results in Figure 4.2 are comparable to those reported in [2], [3], and [11] with second-order central and second- and fifth-order upwind schemes and demonstrate the robustness of the schemes described in section 2.

5. Two-dimensional numerical results. In two space dimensions, equations (1.1)–(1.4) admit the conservative form (2.19) with

$$u = (\rho, \rho v_x, \rho v_y, \rho v_z, B_x, B_y, B_z, e)^\top, \tag{5.1}$$

$$f(u) = (\rho v_x, \rho v_x^2 + p^* - B_x^2, \rho v_x v_y - B_x B_y, \rho v_x v_z - B_x B_z, 0, B_y v_x - B_x v_y, B_z v_x - B_x v_z, (e + p^*)v_x - B_x(B_x v_x + B_y v_y + B_z v_z))^\top, \tag{5.2}$$

$$g(u) = (\rho v_z, \rho v_z v_x - B_z B_x, \rho v_z v_y - B_z B_y, \rho v_z^2 + p^* - B_z^2, B_x v_z - B_z v_x, B_y v_z - B_z v_y, 0, (e + p^*)v_z - B_z(B_x v_x + B_y v_y + B_z v_z))^\top. \tag{5.3}$$

In this section we present the solution of four prototype problems for two-dimensional MHD equations. We begin testing our two-dimensional numerical schemes by solving the one-dimensional Brio–Wu shock tube problem described in section 4.1 on a two-dimensional domain with the flow rotated 45°. For the second problem—the Kelvin–Helmholtz instability with transverse magnetic field configuration—we consider two different sets of boundary conditions in the x-direction: periodic in the first case and a free outflow boundary in the second convective setup. The third problem was introduced by Orszag and Tang in [21] as a simple model to study MHD turbulence. The last problem that we present simulates the interaction between a strong shock and a high-density cloud. These four problems appear extensively in the literature as they have become—in the absence of a rigorous stability condition for numerical schemes for MHD equations—standard tests to validate numerical algorithms. In all cases, the time scale Δt is determined dynamically according to the CFL restriction

$$\Delta t = \frac{c}{\sqrt{(\max_k |a_k(u)|/\Delta x)^2 + (\max_k |b_k(u)|/\Delta z)^2}}, \tag{5.4}$$

where $c < 1$ is a positive constant and $\{a_k(u)\}_k$ and $\{b_k(u)\}_k$ represent the eigenvalues of the Jacobian matrices of $f(u)$ and $g(u)$, respectively.

It should be emphasized that the results presented below were obtained with the original formulation of semidiscrete central schemes in section 2, namely, they were implemented "as is," without any enforcement of the solenoidal constraint (1.5). The $\nabla \cdot \mathbf{B} = 0$-constraint was [illegible] preserved to machine round-off error. In fact, the same test problems displayed below were first solved using the (global) projection method as a way to enforce the $\nabla \cdot \mathbf{B} = 0$-constraint. We observed that the divergence-free results displayed below avoid undesirable effects such as loss of conservation and monotonicity, often induced by global projection solvers.

5.1. Brio–Wu rotated flow. The initial conditions described by (4.4) are extended to the two-dimensional domain $[-1, 1] \times [-1, 1]$ and rotated 45° so that the fluid does not flow in the direction of the grid axis. Our results are displayed in

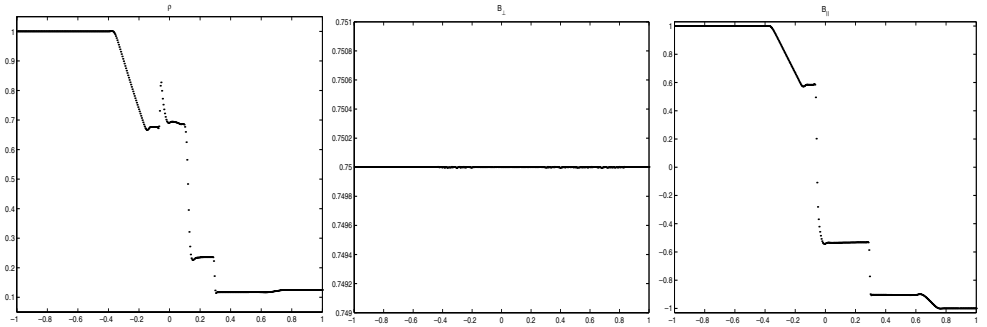

FIG. 5.1. *Results of rotated Brio–Wu shock tube problem at* $t = 0.2$ *computed over a* 600×600 *mesh using third-order dimension-by-dimension CWENO reconstruction,* (3.1)*, and Shu's SSP Runge–Kutta solver,* (3.19)*. From left to right: density, transverse, and parallel components of magnetic field (bottom)*

Figure 5.1, and they confirm the ability of central schemes to simulate discontinuous flows independently of the mesh orientation.

We observe that the small deviations from the constant value of the transverse component of the magnetic that can be observed in Figure 5.1 are well within the order of the scheme, and the numerical value of $\nabla \cdot \mathbf{B}$ is in the order of 10^{-13}.

5.2. Transverse Kelvin–Helmholtz instability. The Kelvin–Helmholtz instability arises when two superposed fluids flow one over the other with a relative velocity. It models, for example, the important mechanism for the momentum transfer at the Earth's magnetopause boundary, which separates the solar wind from the Earth's magnetosphere [11]. We approximate the solution of the two-dimensional periodic and convective models with transverse magnetic field configuration with the semidiscrete scheme of Kurganov and Tadmor, (2.24)–(2.26), implemented along with the reconstruction of section 3.1 and the SSP Runge–Kutta solver (3.19). In both cases, the governing equations are (5.1)–(5.3) are subject to initial conditions

$$(\rho, v_x, v_y, v_z, B_x, B_y, B_z, p)^\top = (1.0, v_{x0} + \tilde{v}_{x0}, 0, 0, 0, 1.0, 0, 0.5)^\top, \tag{5.5}$$

where

$$v_{x0} = \frac{v_0}{2} \tanh\left(\frac{z}{a}\right) \quad \text{and} \tag{5.6}$$

$$\tilde{v}_{x0} = \begin{cases} -\tilde{v}_0 \sin\left(\frac{2\pi x}{\lambda}\right) \frac{1}{1+z^2} & \text{if } -\frac{\lambda}{2} < x < \frac{\lambda}{2} \\ 0 & \text{otherwise} \end{cases}, \tag{5.7}$$

with $v_0 = 2$, $\tilde{v}_0 = -0.008$, $\lambda = 5\pi$, and $a = 1$. Also, the grids are stretched in the z-direction with a Roberts transformation [11],

$$z \leftarrow \frac{H \sinh(\tau z/2H)}{\sinh(\tau/2)}, \quad \tau = 6, \tag{5.8}$$

which renders a denser grid near $z = 0$, where the effect of the small initial perturbation $\tilde{v}_{x0}$ is more noticeable, and a coarser grid near $z = \pm H$, where little action takes place. The time step, Δt, is determined according to (5.4) with $c = 0.9$.

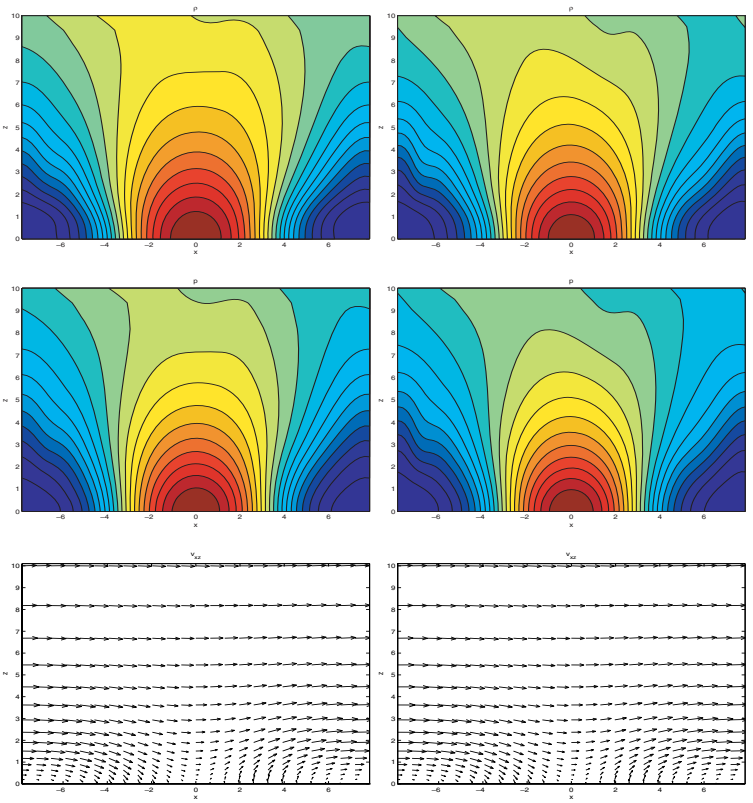

FIG. 5.2. *Results of transverse Kelvin–Helmholtz instability with periodic x-boundary conditions computed with third-order scheme. Left column uses 72×45 points and right column uses 96×60 grids, respectively. There are 20 contours for density and pressure, where darker colors indicate higher values. The density ranges from 0.79 to 1.2, the pressure ranges from 0.32 to 0.71, and the maximum value for the velocity is 1.25.*

In the periodic case, the computational domain is $[-\frac{L}{2}, \frac{L}{2}] \times [0, H]$, with $L = 5\pi$ and $H = 10$. The free outflow condition is applied at the top boundary, $z = H$, and the bottom boundary values are recovered by symmetry, since ρ, p, and B_y are symmetric, and v_x and v_z are antisymmetric under the transformation $(x, z) \to (-x, -z)$. In Figure 5.2, we present solutions at $t = 144$ with 72×45 and 96×60 grid points. The resolution and accuracy of our results are comparable to those reported in [2] obtained over two grids of sizes 96×96 and a 192×192, respectively, with the second-order staggered central scheme of Jiang and Tadmor; the gas kinetic scheme of Tang and Xu, [26], using a 200×200 uniform grid; and to those obtained with Jiang and Wu's fifth-order WENO scheme [11] over two grids of sizes 48×30 and 96×60, respectively. The higher computational cost of the third-order reconstruction as compared to that of the fully discrete second-order scheme we used in [2] is compensated by the smaller number of grid points needed to resolve accurately the steep gradients that characterize the solution.

In the convective setup, the initial conditions and perturbation are the same as in the periodic setup, (5.5)–(5.7). In this case, the free outflow condition is applied also in the x-direction over the computational domain $[-\frac{L}{2}, \frac{L}{2}] \times [0, H]$, where $H = 20$ and $L = 55\pi$ with $L >> \lambda$—so chosen to allow the excitation to convect freely without disturbing the x-boundaries. The values of the bottom boundary of the computational

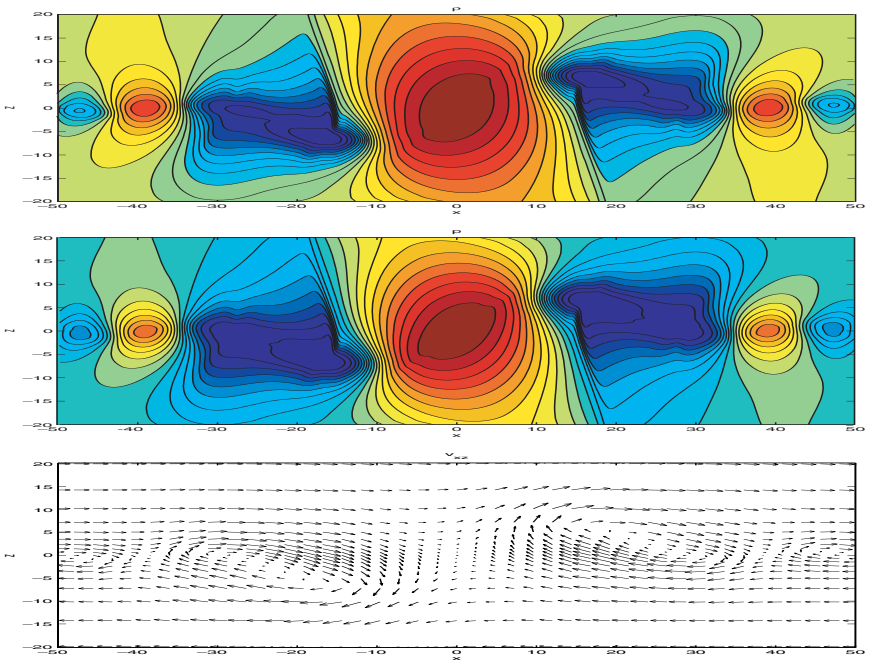

FIG. 5.3. *Solution of convective Kelvin–Helmholtz instability at* $t = 120$*, computed with third-order scheme on a* 792×72 *grid with* $c = 0.9$*. domain, $z = 0$, are recovered by symmetry as in the periodic configuration. Figures 5.3 and 5.4 display the solution over the region $[-50, 50] \times [-20, 20]$ computed with 792×92 grid points over computational domain at $t = 120$ and $t = 145$, respectively. The values of the bottom half of the solution domain are recovered using the same symmetry conditions as used to reconstruct the bottom boundary.

5.3. Orszag–Tang MHD turbulence problem. This model considers the evolution of a compressible Orszag–Tang vortex system. The evolution of the vortex system involves the interaction between several shock waves traveling at various speed regimes [11, 28], which makes the problem useful to validate the robustness of numerical schemes. The initial data is given by

$$\rho(x, z, 0) = \gamma^2, v_x(x, z, 0) = -\sin z,\ v_z(x, z, 0) = \sin x,$$
$$p(x, z, 0) = \gamma, B_x(x, z, 0) = -\sin z,\ B_z(x, z, 0) = \sin 2x,$$

where $\gamma = 5/3$. With these data, the RMS values of the velocity and magnetic fields are both 1; the initial average Mach number is 1; and the average plasma beta is $10/3$. We solve the problem in $[0, 2\pi] \times [0, 2\pi]$ with periodic boundary conditions in both x- and z-directions. For this problem we implement the fourth-order reconstruction of section 3.2 and the SSP Runge–Kutta fourth-order ODE solver (3.20) using a uniform grid with 192×192 points and $c = 0.9$ in (5.4).

Figures 5.6, 5.7, and 5.8 display the solution of the Orszag–Tang vortex system at $t = 0.5, t = 2$, and $t = 3$, respectively. These simulations were performed with 192×192 grid points using the fourth-order, genuinely multidimensional, CWENO reconstruction of section 3.2 SSP Runge–Kutta solver (3.18)–(3.20). These results

demonstrate the ability of higher-order central schemes to resolve the shocks that the vortex system develops while maintaining the simplicity and ease of implementation typical of this [illegible] type of finite-difference schemes. We also note that similar results were obtained with the dimension-by-dimension third-order reconstruction and the Runge–Kutta solver (3.19) using a 288×288 mesh. The improved resolution of the fourth-order scheme allows us to compute accurate approximations using coarser grids than those required by lower-order schemes—consult Figures 5.5 and 5.9, for

example, thus reducing the computational cost of this type of simulation, an advantage that is more evident in higher space dimensions.

5.4. Interaction between a strong shock and a high-density cloud. This problem, introduced in [4], describes the disruption of a high-density cloud by a strong shock wave. The flow is simulated over the computational domain $[0, 1] \times [0, 1]$ with 256×256 cells and open boundary conditions. The ratio of specific heats is $\gamma = 5/3$

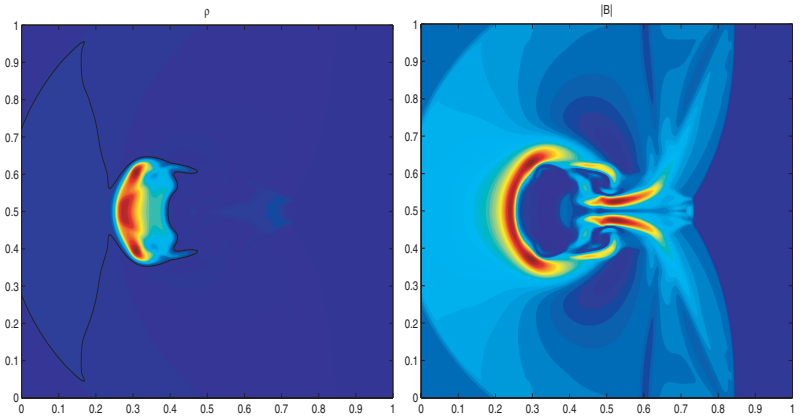

FIG. 5.10. *Third-order solution of the interaction between a strong shock and a high-density cloud obtained with a* 256×256 *uniform grid at* $t = 0.06$, $c = 0.5$. *Left: density; right: magnetic field,* $|B|$.

and the initial conditions are given by the two states,

(5.9)
$$(\rho, v_x, v_y, v_z, B_x, B_y, B_z, p)^\top = \begin{cases} (3.86859, 0, 0, 0, 0, -2.1826182, 2.1826182, 167.34)^\top & \text{for } x < 0.6, \\ (1, -11.2536, 0, 0, 0, 0.56418958, 0.56418958, 1)^\top & \text{for } x > 0.6, \end{cases}$$

separated by a discontinuity parallel to the z-axis at $x = 0.6$. To the right of the discontinuity there is a circular cloud of radius 0.15, centered at $x = 0.8$ and $z = 0.5$ with density $\rho = 10$ and $p = 1$. The solution we present in Figure 5.10 at $t = 0.06$ confirms the robustness of central schemes for highly superfast flows.

As in the case of the shock tube problem, the presence of discontinuities that affect only a particular component of the system—in this case a rotational discontinuity in the y component of the magnetic field—requires the careful choice of the smoothness indicators used in the calculation of the weights of the nonoscillatory reconstruction so as to prevent oscillations. Our numerical experiments suggest the use of the average of the smoothness indicators corresponding to the y-magnetic field and the density to determine the least oscillatory stencil for the evolution of all the conserved quantities.

6. Conclusions. The numerical schemes presented in this work and the results obtained with them complement those introduced in [2] and references therein and confirm the ability of this type of black-box solver to approximate the discontinuous solutions of ideal MHD equations accurately. The high-order semidiscrete schemes described in sections 2 and 3 retain the simplicity and ease of implementation of the fully discrete [illegible] methods while adding further advantages. As the limit of the reprojection of the staggered evolution of the cell averages, the semidiscrete formulation (2.17) requires only an estimate of the maximum local speeds of propagation to evolve the solution, avoiding any detailed knowledge of the eigen structure of (1.1)–(1.4) and, therefore, eliminating the need for Riemann solvers. The efficiency of the semidiscrete formulation is further enhanced by the larger time step that the implementation over nonstaggered grids yields and the wide range of reconstruction algorithms and ODE solvers available for its implementation. The use of these higher-order routines offers advantages that extend beyond the work presented here, in particular, the ability of

these schemes to compute accurate solutions over coarser grids and the possibility of applying the reconstruction algorithm dimension by dimension suggest these as an attractive alternative for schemes in higher space dimensions.

Our results also suggest a remarkable ability of central schemes to avoid any instability caused by the failure to satisfy the constraint $\nabla \cdot \mathbf{B} = 0$. All the results reported here have been calculated without any additional treatment for this constraint. Indeed, it can be shown that the magnetic field computed with the second-order staggered fully discrete schemes that lead to the semidiscrete formulation presented here satisfy the condition

$$\nabla \cdot \overline{\mathbf{B}}^{\,n+1}_{j+\frac{1}{2},k+\frac{1}{2}} = \nabla \cdot \overline{\mathbf{B}}^{\,n}_{j+\frac{1}{2},k+\frac{1}{2}}, \tag{6.1}$$

where $\overline{\mathbf{B}}^{\,n}_{j+\frac{1}{2},k+\frac{1}{2}}$ represents the cell average of the nonoscillatory polynomial reconstruction of the cell averages $\{\overline{\mathbf{B}}^{\,n}_{j+p,k+q}\}_{p,q=0,1}$.

Animations of the simulations presented in sections 4 and 5 and sample MHD codes are available online at http://www.math.lsa.umich.edu/∼jbalbas/MHD.

NUMERICAL ALGORITHMS FOR FORWARD-BACKWARD STOCHASTIC DIFFERENTIAL EQUATIONS*

G. N. MILSTEIN† AND M. V. TRETYAKOV‡

Abstract. Efficient numerical algorithms are proposed for a class of forward-backward stochastic differential equations (FBSDEs) connected with semilinear parabolic partial differential equations. As in [J. Douglas, Jr., J. Ma, and P. Protter, *Ann. Appl. Probab.*, 6 (1996), pp. 940–968], the algorithms are based on the known four-step scheme for solving FBSDEs. The corresponding semilinear parabolic equation is solved by layer methods which are constructed by means of a probabilistic approach. The derivatives of the solution u of the semilinear equation are found by finite differences. The forward equation is simulated by mean-square methods of order 1/2 and 1. Corresponding convergence theorems are proved. Along with the algorithms for FBSDEs on a fixed finite time interval, we also construct algorithms for FBSDEs with random terminal time. The results obtained are supported by numerical experiments.

1. Introduction.

Forward-backward stochastic differential equations (FBSDEs) have numerous applications in stochastic control theory and mathematical finance (see, e.g., [7, 5, 9, 25, 12] and references therein). Consider an FBSDE of the form

$$dX = a(t,X,Y)dt + \sigma(t,X,Y)dw(t), \quad X(t_0) = x, \tag{1.1}$$

$$dY = -g(t,X,Y)dt - f^{\intercal}(t,X,Y)Zdt + Z^{\intercal}dw(t), \quad Y(T) = \varphi(X(T)). \tag{1.2}$$

Here $X = X(t)$ and $a = a(t,x,y)$ are d-dimensional vectors; $\sigma = \sigma(t,x,y)$ is a $d \times n$-matrix; $Y = Y(t)$, $g = g(t,x,y)$, and $\varphi = \varphi(x)$ are scalars; $Z = Z(t)$ and $f = f(t,x,y)$ are n-dimensional vectors; and $w(t)$ is an n-dimensional $\{\mathcal{F}_t\}_{t\ge 0}$-adapted Wiener process, where $(\Omega, \mathcal{F}, \mathcal{F}_t, P)$, $t_0 \le t \le T$, is a filtered probability space. It is known (see, e.g., [1, 11, 19, 25, 12] and also references therein) that there exists a unique $\{\mathcal{F}_t\}_{t\ge 0}$-adapted solution $(X(t), Y(t), Z(t))$ of the system (1.1)–(1.2) under some appropriate smoothness and boundedness conditions on its coefficients.

Due to the four-step scheme from [11] (we recall it in the next section), the solution of (1.1)–(1.2) is connected with the Cauchy problem for the semilinear partial

differential equation (PDE):

$$\frac{\partial u}{\partial t}+\sum_{i=1}^{d}a^i(t,x,u)\frac{\partial u}{\partial x^i}+\frac{1}{2}\sum_{i,j=1}^{d}a^{ij}(t,x,u)\frac{\partial^2 u}{\partial x^i\partial x^j} \tag{1.3}$$

$$=-g(t,x,u)-\sum_{k=1}^{n}f^k(t,x,u)\sum_{i=1}^{d}\sigma^{ik}(t,x,u)\frac{\partial u}{\partial x^i},\quad t<T,\quad x\in\mathbf{R}^d,$$

$$u(T,x)=\varphi(x), \tag{1.4}$$

where

$$a^{ij}:=\sum_{k=1}^{d}\sigma^{ik}\sigma^{jk}.$$

In turn the corresponding solution of the semilinear PDE has a probabilistic representation using the FBSDE (1.1)–(1.2), which is a generalization of the Feynman–Kac formula (see, e.g., [22, 20, 19, 21, 25, 12]).

Our aim is to find an effective numerical algorithm for solving (1.1)–(1.2) in the mean-square sense. Not many works have been devoted to numerical integration of FBSDEs, but let us mention [4, 6, 2, 3]. Among these works, the present paper is most closely connected with [6]. As in [6], we exploit the four-step scheme for numerical solution of (1.1)–(1.2). Unlike [6], we use another approach for numerical solution of the corresponding semilinear PDE (1.3)–(1.4), which is developed in [14] (see also [16, 17, 18]).

The most significant distinction between our paper and [6] consists of numerical evaluation of Z. According to the four-step scheme, Z is expressed through first derivatives of the solution $u(t,x)$ to (1.3)–(1.4) with respect to x^i, $i=1,\dots,d$, while finding X and Y of (1.1)–(1.2) requires knowledge of u only. In [6] the authors write a system of semilinear PDEs for u and $\partial u/\partial x^i$, $i=1,\dots,d$, and solve it numerically in order to simulate then X, Y, and Z. This approach is rather expensive from the computational point of view. We approximate the derivatives by finite differences; thus we need to simulate u only. As it is proved in section 3, this approximation gives quite accurate results.

Along with the algorithms for FBSDEs on a fixed finite time interval, we also construct algorithms for FBSDEs with random terminal time. To the authors' best knowledge, numerical solution of FBSDEs with random terminal time is considered for the first time. Let us note that in this case the approach of [6] leads to a complicated system of boundary value problems whose numerical solution is less effective than the algorithms proposed here.

For clarity of exposition, we state and prove our results for the one-dimensional case ($d=1$, $n=1$) although it is not difficult to generalize them to any dimension. However, since the obtained algorithms require simulation of nonlinear PDEs, they can realistically be used in practice for solving FBSDEs with forward equation of dimension three or lower ($d\le 3$). At the same time, the variable Y can be of a high dimension; in such a case we shall deal with a system of semilinear parabolic PDEs instead of (1.3)–(1.4).

Let us note that in [6] a more general FBSDE than (1.1)–(1.2) is considered; it is connected with quasi-linear parabolic equations. We will consider this case in a separate publication.

In section 2 we recall the four-step scheme due to [11] and the probabilistic approach to numerical solution of the Cauchy problem (1.3)–(1.4) from [14] (see also [18]). In section 3 we obtain some results concerning accuracy of approximating derivatives $\partial u/\partial x^i$ by finite differences. In section 4 we prove the mean-square convergence of the Euler method for FBSDEs when using the approximations of u and $\partial u/\partial x$ given in the previous two sections. Sections 5 and 6 are devoted to FBSDEs with random terminal time (see e.g., [19, 25] and references therein). In these sections we have to consider the Dirichlet boundary value problem for semilinear parabolic PDEs instead of (1.3)–(1.4). For solving the Dirichlet problem we use the probabilistic approach again [16, 18], and for simulating solutions of FBSDEs with random terminal time we use the approximations of SDEs in space-time bounded domains [15, 18]. We also consider the case of unbounded random terminal time, which is connected with the Dirichlet boundary value problem for semilinear elliptic PDEs. The results obtained are supported by numerical experiments which are presented in section 7.

2. Preliminaries.

2.1. Four-step scheme for solving FBSDEs. First we recall the four-step scheme for solving FBSDE (1.1)–(1.2) [11]. Assume that the solution $u(t,x)$ of the Cauchy problem (1.3)–(1.4) is known. Consider the following SDE:

$$dX = a(t,X,u(t,X))dt + \sigma(t,X,u(t,X))dw(t), \quad X(t_0) = x. \tag{2.1}$$

Let $X(t) = X_{t_0,x}(t)$ be a solution of the Cauchy problem (2.1). Introduce

$$\begin{aligned} Y(t) &= u(t, X_{t_0,x}(t)), \\ Z^j(t) &= \sum_{i=1}^{d} \sigma^{ij}(t, X_{t_0,x}(t), Y(t)) \frac{\partial u}{\partial x^i}(t, X_{t_0,x}(t)), \qquad j = 1, \dots, n. \end{aligned} \tag{2.2}$$

It turns out that $(X(t), Y(t), Z(t))$ defined by (2.1)–(2.2) is the solution of the FBSDE (1.1)–(1.2). Indeed, it is $\{\mathcal{F}_t\}_{t\geq 0}$-adapted and (1.1) is evidently satisfied. To verify (1.2), it suffices to apply Ito's formula to $Y(t) = u(t, X_{t_0,x}(t))$.

2.2. Layer methods for PDEs. Now we recall layer methods for solving the problem (1.3)–(1.4) due to [14] (see also [18]). For simplicity in writing, we restrict ourselves to a one-dimensional version of the problem ($d = 1$, $n = 1$). Introducing

$$b(t,x,y) := a(t,x,y) + f(t,x,y)\sigma(t,x,y),$$

we get

$$\frac{\partial u}{\partial t} + b(t,x,u)\frac{\partial u}{\partial x} + \frac{1}{2}\sigma^2(t,x,u)\frac{\partial^2 u}{\partial x^2} + g(t,x,u) = 0, \quad t < T,\ x \in \mathbf{R}, \tag{2.3}$$

$$u(T,x) = \varphi(x)\,. \tag{2.4}$$

The solution to this problem is supposed to exist, be unique, be sufficiently smooth, and satisfy some conditions on boundedness. One can find theoretical results on this topic in [10, 23, 8, 24] (see also references therein). For convenience, we shall assume throughout the paper that the standing assumptions of [6] are fulfilled. We prefer to state them here in a less specific way since different numerical methods will require, e.g., different levels of smoothness of the coefficients.

ASSUMPTION 2.1. [illegible] b, σ, g [illegible] φ [illegible] $[t_0, T] \times \mathbf{R} \times \mathbf{R}$. [illegible] σ [illegible] $\sigma \geq \sigma_0$, [illegible] σ_0 [illegible]

Assumption 2.1 ensures the existence of a unique bounded solution $u(t, x)$ with bounded derivatives up to some order. We note that these assumptions are more than necessary (for instance, other types of assumptions are given in [14] (see also [18, pp. 419, 422])), and the methods constructed in this paper can be used under broader conditions.

We introduce a time discretization; to be definite let us take the equidistant one:

$$T = t_N > t_{N-1} > \cdots > t_0, \quad h := \frac{T - t_0}{N}.$$

Layer methods proposed in [14] (see also [18]) give an approximation $\bar{u}(t_k, x)$ of the solution $u(t_k, x)$, $k = N, \ldots, 0$, to (2.3)–(2.4). These methods are based on the local probabilistic representation of the solution to (2.3)–(2.4):

$$u(t_k, x) = E\left(u(t_{k+1}, X_{t_k,x}(t_{k+1})) + \int_{t_k}^{t_{k+1}} g(s, X_{t_k,x}(s), u(s, X_{t_k,x}(s)))ds\right), \tag{2.5}$$

where $X_{t_k,x}(s)$ is the solution of the Cauchy problem for the SDE

$$dX = b(s, X, u(s, X))ds + \sigma(s, X, u(s, X))dw(s), \quad X(t_k) = x. \tag{2.6}$$

Exploiting the weak Euler scheme, the following layer method is constructed [14, 18]:

$$\tilde{u}(t_N, x) = \varphi(x), \tag{2.7}$$

$$\begin{aligned}\tilde{u}(t_k, x) = {} & \frac{1}{2}\tilde{u}(t_{k+1}, x + hb(t_k, x, \tilde{u}(t_{k+1}, x)) - \sqrt{h}\sigma(t_k, x, \tilde{u}(t_{k+1}, x))) \\ & + \frac{1}{2}\tilde{u}(t_{k+1}, x + hb(t_k, x, \tilde{u}(t_{k+1}, x)) + \sqrt{h}\sigma(t_k, x, \tilde{u}(t_{k+1}, x))) \\ & + hg(t_k, x, \tilde{u}(t_{k+1}, x)), \quad k = N-1, \ldots, 1, 0.\end{aligned}$$

It is proved (see either [14] or [18, p. 420]) that this method is of order one; i.e.,

$$|\tilde{u}(t_k, x) - u(t_k, x)| \leq Kh, \tag{2.8}$$

where K does not depend on x, h, k.

To obtain a numerical algorithm, we need to discretize (2.7) in the variable x. Consider the equidistant space discretization

$$x_j = x_0 + j\varkappa h, \quad j = 0, \pm 1, \pm 2, \ldots,$$

where x_0 is a point on $\mathbf{R}$ and $\varkappa$ is a positive number; i.e., the step h_x of space discretization is equal to $\varkappa h$, where $h = h_t$ is the step of time discretization. Using, for instance, linear interpolation, we construct the following algorithm on the basis of the layer method (2.7).

ALGORITHM 2.2.

$$\bar{u}(t_N, x) = \varphi(x), \tag{2.9}$$

$$\bar{u}(t_k,x_j)=\frac{1}{2}\bar{u}(t_{k+1},x_j+hb(t_k,x_j,\bar{u}(t_{k+1},x_j))-\sqrt{h}\sigma(t_k,x_j,\bar{u}(t_{k+1},x_j)))$$
$$+\frac{1}{2}\bar{u}(t_{k+1},x_j+hb(t_k,x_j,\bar{u}(t_{k+1},x_j))+\sqrt{h}\sigma(t_k,x_j,\bar{u}(t_{k+1},x_j)))$$
$$+hg(t_k,x_j,\bar{u}(t_{k+1},x_j)),\quad j=0,\pm1,\pm2,\dots,$$

$$\bar{u}(t_k,x)=\frac{x_{j+1}-x}{\varkappa h}\bar{u}(t_k,x_j)+\frac{x-x_j}{\varkappa h}\bar{u}(t_k,x_{j+1}),\quad x_j\le x\le x_{j+1}, \tag{2.10}$$

$$k=N-1,\dots,1,0.$$

Algorithm 2.2 is of order one; i.e.,

$$|\bar{u}(t_k,x)-u(t_k,x)|\le Kh\,, \tag{2.11}$$

where K does not depend on x, h, k (see either [14] or [18, p. 423] for a proof).

Along with linear interpolation, a spline approximation is also considered and the cubic interpolation with step $h_x=\varkappa\sqrt{h}$ is used to reduce the number of nodes x_j (see [14, 18]). Clearly, both the method and algorithm can be considered with variable time and space steps. Algorithms for the multidimensional parabolic problems (such as (1.3)–(1.4) with $d>1$) are available in [14, 18] as well.

3. Approximation of the derivative $\partial u/\partial x$ by finite differences. Consider the solution $u(t,x)$ of the Cauchy problem for semilinear parabolic equation (2.3)–(2.4) and its approximations $\tilde{u}(t_k,x)$ by the layer method (2.7) and $\bar{u}(t_k,x)$ by Algorithm 2.2.

PROPOSITION 3.1. [illegible]

$$\frac{\partial u}{\partial x}(t_k,x)=\frac{\bar{u}(t_k,x+\gamma\sqrt{h})-\bar{u}(t_k,x-\gamma\sqrt{h})}{2\gamma\sqrt{h}}+O(h^{1/2}), \tag{3.1}$$

[illegible] (2.9) (2.10) [illegible] $\bar{u}$ [illegible] $\tilde{u}$.

[illegible]. Since the solution u has bounded third derivatives with respect to x (we assume that the functions from Assumption 2.1 have continuous bounded first derivative with respect to t and second derivatives with respect to x and u including the mixed ones), we have

$$\frac{\partial u}{\partial x}(t_k,x)=\frac{u(t_k,x+\gamma\sqrt{h})-u(t_k,x-\gamma\sqrt{h})}{2\gamma\sqrt{h}}+O(h).$$

Now (3.1) immediately follows from the inequality (2.11). □

[illegible] 3.2. Analogous to (3.1), we also get

$$\frac{\partial u}{\partial x}(t_k,x)=\frac{\bar{u}(t_k,x+\gamma h^{1/3})-\bar{u}(t_k,x-\gamma h^{1/3})}{2\gamma h^{1/3}}+O(h^{2/3}). \tag{3.2}$$

In fact, it is possible to prove a more accurate result than (3.1) or (3.2) for the layer approximation $\tilde{u}$ from (2.7).

THEOREM 3.3. [illegible]

$$\frac{\partial u}{\partial x}(t_k,x)=\frac{\tilde{u}(t_k,x+\gamma\sqrt{h})-\tilde{u}(t_k,x-\gamma\sqrt{h})}{2\gamma\sqrt{h}}+O(h), \tag{3.3}$$

[illegible] γ [illegible] h [illegible] (2.7) [illegible]. Clearly, the pair of functions $u(t,x)$ and $v(t,x):=\frac{\partial u}{\partial x}(t,x)$ satisfy the Cauchy problem for two parabolic equations consisting of (2.3)–(2.4) and

$$\begin{aligned}\frac{\partial v}{\partial t}+b(t,x,u)\frac{\partial v}{\partial x}+\frac{1}{2}\sigma^2(t,x,u)\frac{\partial^2 v}{\partial x^2}+\left(\sigma\frac{\partial\sigma}{\partial x}+\sigma\frac{\partial\sigma}{\partial u}v\right)\frac{\partial v}{\partial x}\\ +\left(\frac{\partial b}{\partial x}+\frac{\partial b}{\partial u}v\right)v+\frac{\partial g}{\partial x}+\frac{\partial g}{\partial u}v=0,\quad t<T,\ x\in\mathbf{R},\end{aligned} \tag{3.4}$$

$$v(T,x)=\varphi'(x)\,. \tag{3.5}$$

To solve the problem (2.3)–(2.4), (3.4)–(3.5), we use a layer method based on a local probabilistic representation. To this aim, introduce the system of SDEs with respect to X and scalars P, Q, R:

$$\begin{aligned}&dX=b(s,X,u(s,X))ds+\sigma(s,X,u(s,X))dw(s),\quad X(t_k)=x,\\ &dP=g(s,X,u(s,X))ds,\quad P(t_k)=0,\\ &dQ=\left(\frac{\partial b}{\partial x}+\frac{\partial b}{\partial u}v(s,X)\right)Qds+\left(\frac{\partial\sigma}{\partial x}+\frac{\partial\sigma}{\partial u}v(s,X)\right)Qdw(s),\quad Q(t_k)=1,\\ &dR=\left(\frac{\partial g}{\partial x}+\frac{\partial g}{\partial u}v(s,X)\right)Qds,\quad R(t_k)=0,\end{aligned} \tag{3.6}$$

where $\partial b/\partial x$, $\partial b/\partial u$, and the other derivatives are known functions of s, X, $u(s,X)$. One can verify that the following local probabilistic representation holds (cf. (2.5)–(2.6)):

$$\begin{aligned}u(t_k,x)&=E\left[u(t_{k+1},X_{t_k,x}(t_{k+1}))+P_{t_k,x,0}(t_{k+1})\right],\\ v(t_k,x)&=E\left[v(t_{k+1},X_{t_k,x}(t_{k+1}))Q_{t_k,x,1}(t_{k+1})+R_{t_k,x,1,0}(t_{k+1})\right].\end{aligned} \tag{3.7}$$

The corresponding layer method $\tilde{u}(t_k,x)$, $\tilde{v}(t_k,x)$ is given by the formulas (2.7) for $\tilde{u}$ while $\tilde{v}$ is found from

$$\tilde{v}(t_N,x)=\varphi'(x), \tag{3.8}$$

$$\begin{aligned}\tilde{v}(t_k,x)=&\frac{1}{2}\tilde{v}(t_{k+1},x+h\tilde{b}_k-\sqrt{h}\tilde{\sigma}_k)\\ &\times\left[1+h\left(\frac{\partial\tilde{b}_k}{\partial x}+\frac{\partial\tilde{b}_k}{\partial u}\tilde{v}(t_{k+1},x)\right)-h^{1/2}\left(\frac{\partial\tilde{\sigma}_k}{\partial x}+\frac{\partial\tilde{\sigma}_k}{\partial u}\tilde{v}(t_{k+1},x)\right)\right]\\ &+\frac{1}{2}\tilde{v}(t_{k+1},x+h\tilde{b}_k+\sqrt{h}\tilde{\sigma}_k)\\ &\times\left[1+h\left(\frac{\partial\tilde{b}_k}{\partial x}+\frac{\partial\tilde{b}_k}{\partial u}\tilde{v}(t_{k+1},x)\right)+h^{1/2}\left(\frac{\partial\tilde{\sigma}_k}{\partial x}+\frac{\partial\tilde{\sigma}_k}{\partial u}\tilde{v}(t_{k+1},x)\right)\right]\\ &+h\left(\frac{\partial\tilde{g}_k}{\partial x}+\frac{\partial\tilde{g}_k}{\partial u}\tilde{v}(t_{k+1},x)\right),\quad k=N-1,\dots,1,0,\end{aligned}$$

where $\tilde{b}_k := b(t_k, x, \tilde{u}(t_{k+1}, x))$, $\tilde{\sigma}_k := \sigma(t_k, x, \tilde{u}(t_{k+1}, x))$, and the notation $\partial\tilde{b}_k/\partial x$ means $\frac{\partial\tilde{b}_k}{\partial x} := \frac{\partial b}{\partial x}(t_k, x, \tilde{u}(t_{k+1}, x))$ and so on. The layer method (2.7), (3.8) for the system (2.3)–(2.4), (3.4)–(3.5) is of order one. The order of convergence can be proved due to [18] if we assume that the functions from Assumption 2.1 have continuous bounded second mixed derivatives with respect to t, x and t, u and third derivatives with respect to x and u including the mixed ones. This also implies that $\tilde{u}(t_k, x)$ has, in particular, a continuous bounded third derivative with respect to x.

Further, it is straightforward to verify

$$\frac{\partial\tilde{u}}{\partial x}(t_k, x) = \tilde{v}(t_k, x).$$

Thus we get

$$\frac{\partial u}{\partial x}(t_k, x) = v(t_k, x) = \tilde{v}(t_k, x) + O(h) = \frac{\partial\tilde{u}}{\partial x}(t_k, x) + O(h). \tag{3.9}$$

Since $\tilde{u}(t_k, x)$ has a bounded third derivative with respect to x, we obtain

$$\frac{\partial\tilde{u}}{\partial x}(t_k, x) = \frac{\tilde{u}(t_k, x + \gamma\sqrt{h}) - \tilde{u}(t_k, x - \gamma\sqrt{h})}{2\gamma\sqrt{h}} + O(h). \tag{3.10}$$

The formulas (3.9) and (3.10) imply (3.3). □

REMARK 3.4. We have not succeeded in a rigorous proof of the relation

$$\frac{\partial u}{\partial x}(t_k, x) = \frac{\bar{u}(t_k, x + \gamma\sqrt{h}) - \bar{u}(t_k, x - \gamma\sqrt{h})}{2\gamma\sqrt{h}} + O(h) \tag{3.11}$$

for $\bar{u}(t_k, x)$ from Algorithm 2.2. At the same time, we have some heuristic arguments justifying (3.11). It is possible to obtain the following representation for $\bar{u}(t_0, x)$:

$$\bar{u}(t_0, x) = \tilde{u}(t_0, x) + R(x, h)h + \sum_{k=1}^{N} \zeta_k h^2 + O(h^{3/2}). \tag{3.12}$$

Moreover, it is reasonable to consider $R(x, h)$ a function which changes in x slowly or, more exactly, that R satisfies the inequality

$$R(x + \gamma\sqrt{h}, h) - R(x - \gamma\sqrt{h}, h) = O(\sqrt{h}). \tag{3.13}$$

In (3.12) ζ_k are related to the distances between $x_j + hb(t_k, x_j, \bar{u}(t_{k+1}, x_j)) \pm \sqrt{h}\sigma(t_k, x_j, \bar{u}(t_{k+1}, x_j))$ and the nearest node x_i. These distances are random, in a sense, and it is natural to assume that ζ_k are independent and identically distributed (i.i.d.) uniformly bounded random variables with zero mean and variance $Var\zeta$. Then, due to the central limit theorem, we get

$$\sum_{k=1}^{N} \zeta_k h^2 \doteq \eta \sqrt{Var\zeta} \cdot \sqrt{N}\, h^2, \tag{3.14}$$

where η is a standard Gaussian random variable. The relation (3.11) follows from (3.12)–(3.14). We also note here in passing that if in Algorithm 2.2 we would put $h_x = \varkappa h^{5/4}$ instead of $h_x = \varkappa h$, then it would not be difficult to prove (3.11) rigorously.

In the multidimensional case ((1.3)–(1.4) with $d > 1$) we use the approximation

(3.15)
$$\frac{\partial u}{\partial x^i}(t_k, x) \approx \frac{\bar{u}(t_k, x^1, \dots, x^i + \gamma\sqrt{h}, \dots, x^d) - \bar{u}(t_k, x^1, \dots, x^i - \gamma\sqrt{h}, \dots, x^d)}{2\gamma\sqrt{h}},$$
$$i = 1, \dots, d,$$

where $\bar{u}$ is found by a multidimensional algorithm analogous to Algorithm 2.2 [14, 18]. Proposition 3.1 and Remark 3.4 are valid for (3.15) as well.

4. Numerical integration of FBSDEs. Let $\bar{u}(t_k, x)$ be defined by Algorithm 2.2 and introduce the notation

$$\frac{\Delta\bar{u}}{\Delta x}(t_k, x) := \frac{\bar{u}(t_k, x + \gamma\sqrt{h}) - \bar{u}(t_k, x - \gamma\sqrt{h})}{2\gamma\sqrt{h}} \quad \text{for some } \gamma > 0 \tag{4.1}$$

and also $\Delta_k w := w(t_k + h) - w(t_k)$. In practice it is advisable to choose the parameter γ close to the diffusion σ at the point (t_k, x).

Consider two numerical schemes for the FBSDE (1.1)–(1.2) with $d = n = 1$:

(4.2)
$$X_0 = x,$$
$$X_{k+1} = X_k + a(t_k, X_k, \bar{u}(t_k, X_k))h + \sigma(t_k, X_k, \bar{u}(t_k, X_k))\Delta_k w, \quad k = 0, \dots, N-1,$$

and

(4.3)
$$X_0 = x,$$
$$X_{k+1} = X_k + a(t_k, X_k, \bar{u}(t_k, X_k))h + \sigma(t_k, X_k, \bar{u}(t_k, X_k))\Delta_k w$$
$$+ \frac{1}{2}\sigma(t_k, X_k, \bar{u}(t_k, X_k)) \left(\frac{\partial\sigma}{\partial x}(t_k, X_k, \bar{u}(t_k, X_k)) \right.$$
$$\left. + \frac{\partial\sigma}{\partial u}(t_k, X_k, \bar{u}(t_k, X_k)) \frac{\Delta\bar{u}}{\Delta x}(t_k, X_k) \right) \times \left(\Delta_k^2 w - h\right), \quad k = 0, \dots, N-1;$$

Y and Z of the solution to (1.1)–(1.2) are approximated as

$$Y_k = \bar{u}(t_k, X_k), \quad Z_k = \sigma(t_k, X_k, Y_k) \frac{\Delta\bar{u}}{\Delta x}(t_k, X_k), \tag{4.4}$$

where X_k is either from (4.2) or (4.3).

Let us note that the first-order scheme (4.3) becomes the Euler scheme in the case of additive noise in (1.1).

THEOREM 4.1. (i) (4.2) (4.4) 1/2.

(4.5)
$$\left[E \left[(X(t_k) - X_k)^2 + (Y(t_k) - Y_k)^2 + (Z(t_k) - Z_k)^2 \right] \right]^{1/2} \le K (1 + x^2)^{1/2} h^{1/2},$$

K x, k, h

(ii) (4.3) (4.4) X Y.

$$\left[E \left[(X(t_k) - X_k)^2 + (Y(t_k) - Y_k)^2 \right] \right]^{1/2} \le K (1 + x^2)^{1/2} h, \tag{4.6}$$

$$\left|\frac{\Delta \bar{u}}{\Delta x}(t_k, x) - \frac{\partial u}{\partial x}(t_k, x)\right| \le Ch, \tag{4.7}$$

$$\left[E\left(Z(t_k) - Z_k\right)^2\right]^{1/2} \le K\left(1 + x^2\right)^{1/2} h, \tag{4.8}$$

K x, k, h

With respect to the assumption (4.7), see Remark 3.4.

(i) Let us prove that the Euler scheme satisfies

$$\left[E\left(X(t_k) - X_k\right)^2\right]^{1/2} \le K\left(1 + x^2\right)^{1/2} h^{1/2}. \tag{4.9}$$

Assume for a while that the solution $u(t, x)$ to (1.3)–(1.4) is known exactly. Then the coefficients in (1.1) are known functions of t and x and we can apply the standard mean-square Euler scheme

$$\hat{X}_{k+1} = \hat{X}_k + a(t_k, \hat{X}_k, u(t_k, \hat{X}_k))h + \sigma(t_k, \hat{X}_k, u(t_k, \hat{X}_k))\Delta_k w, \quad k = 0, \ldots, N-1, \tag{4.10}$$

which is of mean-square order $1/2$; i.e., $\hat{X}_k$ from (4.10) satisfies a relation like (4.9).

Now we compare X_k and $\hat{X}_k$. To this end, we exploit the (see [13] or [18, p. 4]). It states that if a one-step approximation $\bar{X}_{t,x}(t+h)$ of the solution $X_{t,x}(t+h)$ satisfies the conditions

$$|E(X_{t,x}(t+h) - \bar{X}_{t,x}(t+h))| \le K(1 + |x|^2)^{1/2} h^{p_1}, \tag{4.11}$$

$$\left[E|X_{t,x}(t+h) - \bar{X}_{t,x}(t+h)|^2\right]^{1/2} \le K(1 + |x|^2)^{1/2} h^{p_2} \tag{4.12}$$

with $p_2 > 1/2$ and $p_1 \ge p_2 + 1/2$, then the corresponding mean-square method X_k has order of convergence $p_2 - 1/2$; i.e.,

$$\left[E\left(X(t_k) - X_k\right)^2\right]^{1/2} \le K\left(1 + x^2\right)^{1/2} h^{p_2 - 1/2}.$$

Introduce the one-step approximations corresponding to X_k and $\hat{X}_k$:

$$X(t+h) \approx \bar{X} = x + a(t, x, \bar{u}(t, x))h + \sigma(t, x, \bar{u}(t, x))\Delta w \tag{4.13}$$

and

$$X(t+h) \approx \hat{X} = x + a(t, x, u(t, x))h + \sigma(t, x, u(t, x))\Delta w. \tag{4.14}$$

It is known [13, 18] that $\hat{X}$ from (4.14) satisfies (4.11) with $p_1 = 2$ and (4.12) with $p_2 = 1$. Due to Assumption 2.1 and the relation (2.11), we get

$$E(\hat{X} - \bar{X}) = a(t, x, u(t, x))h - a(t, x, \bar{u}(t, x))h = O(h^2)$$

and

$$E(\hat{X}-\bar{X})^2 = \left[a(t,x,u(t,x)) - a(t,x,\bar{u}(t,x))\right]^2 h^2 + \left[\sigma(t,x,u(t,x)) - \sigma(t,x,\bar{u}(t,x))\right]^2 h = O(h^3),$$

whence it follows that $\bar{X}$ from (4.13) also satisfies (4.11) with $p_1 = 2$ and (4.12) with $p_2 = 1$. Then, applying the fundamental convergence theorem, we prove (4.9). Now the rest of (4.5) follows from (2.2), (4.9), (2.11), and (3.1).

(ii) To prove (4.6), we just repeat all the arguments as above. The only difference is that this time we compare the one-step approximation corresponding to (4.3) with the one corresponding to the standard first-order mean-square scheme [18] applied to (1.1), assuming again that $u(t,x)$ is known exactly. We note that the estimate (3.1) is enough to obtain (4.6) but it would imply the mean-square order 1/2 for Z instead of (4.8). At the same time, it is clear that by (2.2), (4.6) together with (4.7) we obtain (4.8). □

Remark 4.2. Theorem 4.1 is also valid for other Euler-type methods (e.g., for the implicit Euler method) as well as for other first-order mean-square methods. Further, in the case of additive noise this theorem can be extended to constructive mean-square methods of order 3/2 [18] using second-order methods from [14, 18] for the semilinear parabolic problem (2.3)–(2.4).

Remark 4.3. Let us consider the weak Euler scheme

$$X_0 = x,$$
$$X_{k+1} = X_k + a(t_k, X_k, \bar{u}(t_k, X_k))h + \sigma(t_k, X_k, \bar{u}(t_k, X_k))\xi_k, \quad k = 0, \dots, N-1, \tag{4.15}$$

where ξ_k, $k = 0, \dots, N-1$, are i.i.d. random variables with the distribution $P(\xi = \pm 1) = 1/2$ and $\bar{u}(t_k, x)$ is defined by Algorithm 2.2. It is possible to prove that for a sufficiently smooth function $F(x,y)$ satisfying some boundedness conditions, the Euler method (4.15) and (4.4) is of weak order one; i.e.,

$$EF(X(t_k), Y(t_k)) - EF(X_k, Y_k) = O(h).$$

The proof is based on the main theorem on convergence of weak approximations [18, p. 100].

Remark 4.4. It is not difficult to generalize both the numerical algorithm considered and Theorem 4.1 to the case $d > 1$ using the multidimensional version of the Euler method (4.2) and (4.4), a multidimensional algorithm analogous to Algorithm 2.2 (see [14, 18]) to solve (1.3)–(1.4), and (3.15) to approximate the derivatives.

5. FBSDEs with random terminal time.

5.1. The parabolic case. Let G be a bounded domain in $\mathbf{R}^d$, let $Q = [t_0, T) \times G$ be a cylinder in $\mathbf{R}^{d+1}$, and let $\Gamma = \overline{Q} \setminus Q$. The set Γ is a part of the boundary of the cylinder Q consisting of the upper base and the lateral surface. Let $\varphi(t,x)$ be a function defined on Γ.

Consider the FBSDE with random terminal time (see e.g., [19, 25]):

$$dX = a(t,X,Y)dt + \sigma(t,X,Y)dw(t), \quad X(t_0) = x \in G, \tag{5.1}$$
$$dY = -g(t,X,Y)dt - f^{\intercal}(t,X,Y)Zdt + Z^{\intercal}dw(t), \quad Y(\tau) = \varphi(\tau, X(\tau)), \tag{5.2}$$

where $\tau = \tau_{t_0,x}$ is the first exit time of the trajectory $(t, X_{t_0,x}(t))$ from the domain Q; i.e., the point $(\tau, X(\tau))$ belongs to Γ. A solution to (5.1)–(5.2) is defined as an $\{\mathcal{F}_t\}_{t\geq 0}$-adapted vector $(X(t), Y(t), Z(t))$ together with the Markov moment τ, which satisfy

(5.1)–(5.2). This solution is connected with the Dirichlet boundary value problem for the semilinear parabolic equation

$$\frac{\partial u}{\partial t} + \sum_{i=1}^{d} a^i(t,x,u)\frac{\partial u}{\partial x^i} + \frac{1}{2}\sum_{i,j=1}^{d} a^{ij}(t,x,u)\frac{\partial^2 u}{\partial x^i \partial x^j} = -g(t,x,u) - \sum_{k=1}^{n} f^k(t,x,u)\sum_{i=1}^{d}\sigma^{ik}(t,x,u)\frac{\partial u}{\partial x^i}, \quad (t,x)\in Q, \tag{5.3}$$

$$u(t,x)|_{\Gamma} = \varphi(t,x). \tag{5.4}$$

Let $u(t,x)$ be the solution of (5.3)-(5.4), which is supposed to exist, be unique, and be sufficiently smooth. One can find many theoretical results on this topic in [10] (see also references therein and in [16, 18]). To be definite, we assume here that the conditions like Assumption 2.1 together with sufficient smoothness of the boundary ∂G and of the function φ are fulfilled.

Consider the following SDE in Q:

$$dX = a(t,X,u(t,X))dt + \sigma(t,X,u(t,X))dw(t), \quad X(t_0) = x, \tag{5.5}$$

with random terminal time τ which is defined as the first exit time of the trajectory $(t, X_{t_0,x}(t))$ of (5.5) from the domain Q. Introduce

$$\begin{aligned} Y(t) &= u(t, X_{t_0,x}(t)), \quad t_0 \le t \le \tau, \\ Z^j(t) &= \sum_{i=1}^{d}\sigma^{ij}(t, X_{t_0,x}(t), Y(t))\frac{\partial u}{\partial x^i}(t, X_{t_0,x}(t)), \quad j = 1,\dots,n, \quad t_0 \le t \le \tau. \end{aligned} \tag{5.6}$$

Clearly, the four-tuple $(X_{t_0,x}(t), Y(t), Z(t), \tau)$ is a solution of (5.1)–(5.2).

In what follows we restrict ourselves to the one-dimensional version of (5.1)–(5.2) ($d = 1$, $n = 1$). Introducing

$$b(t,x,y) := a(t,x,y) + f(t,x,y)\sigma(t,x,y),$$

we get

$$\frac{\partial u}{\partial t} + b(t,x,u)\frac{\partial u}{\partial x} + \frac{1}{2}\sigma^2(t,x,u)\frac{\partial^2 u}{\partial x^2} + g(t,x,u) = 0, \quad (t,x)\in Q, \tag{5.7}$$

$$u(t,x)|_{\Gamma} = \varphi(t,x). \tag{5.8}$$

In this case Q is the partly open rectangle $Q = [t_0, T)\times(\alpha,\beta)$, and Γ consists of the upper base $\{T\}\times[\alpha,\beta]$ and two vertical intervals, $[t_0,T)\times\{\alpha\}$ and $[t_0,T)\times\{\beta\}$.

In [16] (see also [18]) we propose a number of algorithms for solving the problem (5.7)–(5.8). As an example, let us recall one of them. Consider an equidistant space discretization with a space step h_x (recall that the notation for time step is h): $x_j = \alpha + jh_x$, $j = 0,1,2,\dots,M$, $h_x = (\beta-\alpha)/M$. The algorithm has the following form.

ALGORITHM 5.1.

$$\bar{u}(t_N, x) = \varphi(t_N, x), \quad x\in[\alpha,\beta], \tag{5.9}$$

$$\bar{u}(t_k, x_j) = \frac{1}{2}\bar{u}(t_{k+1}, x_j + \bar{b}_{k,j} \cdot h - \bar{\sigma}_{k,j} \cdot \sqrt{h}) + \frac{1}{2}\bar{u}(t_{k+1}, x_j + \bar{b}_{k,j} \cdot h + \bar{\sigma}_{k,j} \cdot \sqrt{h})$$
$$+ \bar{g}_{k,j} \cdot h \quad \text{if } x_j + \bar{b}_{k,j} \cdot h \pm \bar{\sigma}_{k,j} \cdot \sqrt{h} \in [\alpha, \beta];$$

$$\bar{u}(t_k, x_j) = \frac{1}{1 + \sqrt{\bar{\lambda}_{k,j}}}\varphi(t_{k+\bar{\lambda}_{k,j}}, \alpha) + \frac{\sqrt{\bar{\lambda}_{k,j}}}{1 + \sqrt{\bar{\lambda}_{k,j}}}\bar{u}(t_{k+1}, x_j + \bar{b}_{k,j} \cdot h + \bar{\sigma}_{k,j} \cdot \sqrt{h})$$
$$+ \bar{g}_{k,j} \cdot \sqrt{\bar{\lambda}_{k,j}} h \quad \text{if } x_j + \bar{b}_{k,j} \cdot h - \bar{\sigma}_{k,j} \cdot \sqrt{h} < \alpha;$$

$$\bar{u}(t_k, x_j) = \frac{1}{1 + \sqrt{\bar{\mu}_{k,j}}}\varphi(t_{k+\bar{\mu}_{k,j}}, \beta) + \frac{\sqrt{\bar{\mu}_{k,j}}}{1 + \sqrt{\bar{\mu}_{k,j}}}\bar{u}(t_{k+1}, x_j + \bar{b}_{k,j} \cdot h - \bar{\sigma}_{k,j} \cdot \sqrt{h})$$
$$+ \bar{g}_{k,j} \cdot \sqrt{\bar{\mu}_{k,j}} h, \text{ if } x_j + \bar{b}_{k,j} \cdot h + \bar{\sigma}_{k,j} \cdot \sqrt{h} > \beta,$$
$$j = 1, 2, \ldots, M-1;$$

$$\bar{u}(t_k, x) = \frac{x_{j+1} - x}{h_x}\,\bar{u}(t_k, x_j) + \frac{x - x_j}{h_x}\,\bar{u}(t_k, x_{j+1}), \quad x_j < x < x_{j+1}, \tag{5.10}$$
$$j = 0, 1, 2, \ldots, M-1, \; k = N-1, \ldots, 1, 0,$$

$\bar{b}_{k,j}$, $\bar{\sigma}_{k,j}$, $\bar{g}_{k,j}$ [illegible] $b(t,x,u)$, $\sigma(t,x,u)$, $g(t,x,u)$ [illegible] $(t_k, x_j, \bar{u}(t_{k+1}, x_j))$, $t_{k+\bar{\lambda}_{k,j}} := t_k + h\bar{\lambda}_{k,j}$, $t_{k+\bar{\mu}_{k,j}} := t_k + h\bar{\mu}_{k,j}$, [illegible] $0 < \bar{\lambda}_{k,j}, \bar{\mu}_{k,j} \le 1$ [illegible]

$$\alpha = x_j + \bar{b}_{k,j} \cdot \bar{\lambda}_{k,j} h - \bar{\sigma}_{k,j} \cdot \sqrt{\bar{\lambda}_{k,j} h}, \qquad \beta = x_j + \bar{b}_{k,j} \cdot \bar{\mu}_{k,j} h + \bar{\sigma}_{k,j} \cdot \sqrt{\bar{\mu}_{k,j} h}.$$

It is proved in [16] (see also [18, p. 475]) that if the value of h_x is taken equal to $\varkappa h$ with $\varkappa$ being a positive constant, then

$$|\bar{u}(t_k, x) - u(t_k, x)| \le Kh\,, \tag{5.11}$$

where K does not depend on x, h, k.

To construct Z due to (5.6), we need an approximation of $\partial u/\partial x$. To this end, we propose to use the formulas (cf. (3.1))

$$\frac{\partial u}{\partial x}(t_k, x) = \frac{\bar{u}(t_k, x + \gamma\sqrt{h}) - \bar{u}(t_k, x - \gamma\sqrt{h})}{2\gamma\sqrt{h}} + O(h^{1/2}) := \frac{\Delta\bar{u}}{\Delta x}(t_k, x) + O(h^{1/2}) \tag{5.12}$$
$$\text{if } x \pm \gamma\sqrt{h} \in [\alpha, \beta],$$

$$\frac{\partial u}{\partial x}(t_k,x)=\frac{4\bar u(t_k,x+\gamma\sqrt{h})-3\bar u(t_k,x)-\bar u(t_k,x+2\gamma\sqrt{h})}{2\gamma\sqrt{h}}+O(h^{1/2}) \tag{5.13}$$
$$:=\frac{\Delta\bar u}{\Delta x}(t_k,x)+O(h^{1/2})$$
$$\text{if } x-\gamma\sqrt{h}<\alpha,$$

and

$$\frac{\partial u}{\partial x}(t_k,x)=\frac{\bar u(t_k,x-2\gamma\sqrt{h})-4\bar u(t_k,x-\gamma\sqrt{h})+3\bar u(t_k,x)}{2\gamma\sqrt{h}}+O(h^{1/2}) \tag{5.14}$$
$$:=\frac{\Delta\bar u}{\Delta x}(t_k,x)+O(h^{1/2})$$
$$\text{if } x+\gamma\sqrt{h}>\beta.$$

Most probably, the accuracy in (5.12)–(5.14) is $O(h)$ rather than $O(h^{1/2})$, but we have not investigated this issue in detail.

Let us note that if we apply the method of differentiation to the boundary value problem (5.7)–(5.8), we obtain (3.4) for $v=\partial u/\partial x$ in Q and the Neumann boundary condition. Namely, this boundary condition is of the form

$$\text{on the upper base of } Q\text{: } v(T,x)=\frac{\partial\varphi}{\partial x}(T,x)$$

and, for example, on the vertical interval $[t_0,T]\times\{\alpha\}$:

$$b(t,\alpha,\varphi(t,\alpha))v(t,\alpha)+\frac{1}{2}\sigma^2(t,\alpha,\varphi(t,\alpha))\frac{\partial v}{\partial x}(t,\alpha)=-\frac{\partial\varphi}{\partial t}(t,\alpha)-g(t,\alpha,\varphi(t,\alpha)).$$

Thus, in the case of FBSDEs with random terminal time the approach of [6] leads to a complicated system of boundary value problems.

5.2. The elliptic case. The random terminal time in FBSDE (5.1)–(5.2) is bounded by the time T. Now we consider FBSDEs with unbounded random terminal time. Let G be a bounded domain in $\mathbf{R}^d$ and $Q=[0,\infty)\times G$ be a cylinder in $\mathbf{R}^{d+1}$.

Consider the FBSDE with random terminal time (see e.g., [19, 25]):

$$dX=a(X,Y)dt+\sigma(X,Y)dw(t),\quad X(0)=x\in G, \tag{5.15}$$
$$dY=-g(X,Y)dt-f^{\intercal}(X,Y)Zdt+Z^{\intercal}dw(t),\quad Y(\tau)=\varphi(X(\tau)), \tag{5.16}$$

where $\tau=\tau_x$ is the first exit time of the trajectory $X_x(t)$ from the domain G; i.e., the point $X(\tau)$ belongs to the boundary ∂G of G. A solution to (5.15)–(5.16) is defined as an $\{\mathcal{F}_t\}_{t\ge0}$-adapted vector $(X(t),Y(t),Z(t))$ together with the Markov moment τ, which satisfy (5.15)–(5.16). This solution is connected with the Dirichlet boundary value problem for the semilinear elliptic equation

$$\sum_{i=1}^{d}a^i(x,u)\frac{\partial u}{\partial x^i}+\frac{1}{2}\sum_{i,j=1}^{d}a^{ij}(x,u)\frac{\partial^2u}{\partial x^i\partial x^j} \tag{5.17}$$
$$=-g(x,u)-\sum_{k=1}^{n}f^k(x,u)\sum_{i=1}^{d}\sigma^{ik}(x,u)\frac{\partial u}{\partial x^i},\quad x\in G,$$

$$u(x)|_{\partial G}=\varphi(x). \tag{5.18}$$

Let $u(x)$ be the solution of (5.17)–(5.18), which is supposed to exist, be unique, and be sufficiently smooth. Consider the following SDE in G:

$$dX = a(X, u(X))dt + \sigma(X, u(X))dw(t), \quad X(0) = x, \tag{5.19}$$

with random terminal time τ which is defined as the first exit time of the trajectory $X_x(t)$ of (5.19) from the domain G. Introduce

$$Y(t) = u(X_x(t)), \quad 0 \le t \le \tau, \tag{5.20}$$
$$Z^j(t) = \sum_{i=1}^{d} \sigma^{ij}(X_x(t), Y(t)) \frac{\partial u}{\partial x^i}(X_x(t)), \quad j = 1, \dots, n, \ 0 \le t \le \tau.$$

Clearly, the four-tuple $(X_x(t), Y(t), Z(t), \tau)$ is a solution of (5.15)–(5.16). Note that in the one-dimensional case the problem (5.17)–(5.18) is the boundary value problem just for a second-order ordinary differential equation whose numerical solution does not cause any problem. To solve (5.17)–(5.18) for $d > 1$, one can use finite-difference methods or apply a multidimensional layer method analogous to (5.9)–(5.10) (see [16, 18]) using ideas of the relaxation method.

6. Numerical integration of FBSDEs with random terminal time. Trajectories $(t, X(t))$ of the SDE (5.1) belong to the space-time bounded domain $\bar{Q}$, and a corresponding approximation (ϑ_k, X_k) should possess the same property. It is obvious that, e.g., the standard Euler scheme (4.2) does not satisfy this requirement and specific methods are needed. Such approximations were proposed in [15] (see also [18]). In the one-dimensional case they take a simpler form, which is presented below. We note that here the notation differs partly from that used in [15, 18].

Consider the one-dimensional SDE

$$dX = \chi_{\tau_{t,x}>s} b(s, X)ds + \chi_{\tau_{t,x}>s}\sigma(s, X)dw(s), \quad X(t) = X_{t,x}(t) = x, \tag{6.1}$$

in a space-time bounded domain $Q = [t_0, T) \times (\alpha, \beta)$; the Markov moment $\tau_{t,x}$ is the first-passage time of the process $(s, X_{t,x}(s))$, $s \ge t$, to $\Gamma = \bar{Q} \setminus Q$.

Let $I_r := [-r, r]$, $r > 0$, $\Pi := [0, l) \times I_1$ for some $l > 0$, and $\Pi_h := [0, lh) \times I_{\sqrt{h}}$. Take a point $(s, y) \in Q$ and introduce another interval $I(s, y; h) := [x + hb(s, y) - \sigma(s, y)\sqrt{h}, x + hb(s, y) + \sigma(s, y)\sqrt{h}]$ and also the space-time rectangle $\Pi(s, y; h) = [s, s + lh) \times I(s, y; h)$. Let Γ_δ be an intersection of a δ-neighborhood of the set Γ with the domain Q. Below we take δ equal to $\lambda h^{(1-\varepsilon)/2}$ with $0 < \varepsilon \le 1$ and $\lambda = 2 \max\limits_{(s,y)\in\bar{Q}} |\sigma(s, y)|$. Now we construct a random walk over small space-time rectangles.

Algorithm 6.1 (random walk over small space-time rectangles). Choose a time step $h > 0$ and numbers $0 < \varepsilon \le 1$ and $L > 0$.

Step 0. $X_0 = x$, $\vartheta_0 = t$, $(t, x) \in Q$, $k = 0$.

Step 1. If $(\vartheta_k, X_k) \in \Gamma_{\lambda h^{(1-\varepsilon)/2}}$ or $k \ge L/h$, then Stop and
(i) put $\nu = k$, $(\vartheta_\nu, X_\nu) = (\vartheta_k, X_k)$;
(ii) if $\vartheta_\nu \ge T - \lambda h^{(1-\varepsilon)/2}$, then $\bar{\tau}_{t,x} = T$ and $\xi_{t,x} = X_\nu \in (\alpha, \beta)$; otherwise $\bar{\tau}_{t,x} = \vartheta_\nu$ and $\xi_{t,x}$ is the end of the interval $[\alpha, \beta]$ nearest to X_ν.

Step 2. Put $k := k + 1$. Simulate the first exit point $(\theta_k, w(\vartheta_{k-1} + \theta_k) - w(\vartheta_{k-1}))$ of the process $(s - \vartheta_{k-1}, w(s) - w(\vartheta_{k-1}))$, $s > \vartheta_{k-1}$, from the rectangle Π_h. Put

$$\vartheta_k = \vartheta_{k-1} + \theta_k, \tag{6.2}$$
$$X_k = X_{k-1} + b(\vartheta_{k-1}, X_{k-1})\theta_k + \sigma(\vartheta_{k-1}, X_{k-1})(w(\vartheta_k) - w(\vartheta_{k-1})). \tag{6.3}$$

Go to Step 1.

The sequence (ϑ_k, X_k) obtained by Algorithm 6.1 is a Markov chain stopping at the Markov moment ν in the neighborhood $\Gamma_{\lambda h^{(1-\varepsilon)/2}}$ of the boundary Γ. At each step $(\vartheta_k, X_k) \in \partial\Pi(\vartheta_{k-1}, X_{k-1}; h)$ and $\overline{\Pi}(\vartheta_{k-1}, X_{k-1}; h) \subset Q$; i.e., the chain belongs to the space-time bounded domain Q with probability one. The simulated points (ϑ_k, X_k) are close in the mean-square sense to $(\vartheta_k, X(\vartheta_k))$, and the point $(\bar{\tau}_{t,x}, \xi_{t,x})$ is close to $(\tau_{t,x}, X(\tau_{t,x}))$. It is proved in [15, 18] that

$$\left(E\,|X(\vartheta_k) - X_k|^2\right)^{1/2} \le K\ (\sqrt{h} + e^{-c_h L}), \quad k = 1, \dots, \nu, \tag{6.4}$$

$$E|\tau_{t,x} - \bar{\tau}_{t,x}| \le K\ (h^{(1-\varepsilon)/2} + e^{-c_h L}),$$

$$\left(E\left|X_{t,x}(\tau_{t,x}) - \xi_{t,x}\right|^2\right)^{1/2} \le K\ (\,h^{(1-\varepsilon)/4} + e^{-c_h L/2}),$$

where the constant K is independent of h, k, t, x and c_h tends to a positive constant independent of L as $h \to 0$. We note that the accuracy of the algorithm depends on the choice of h, ε, and L. Clearly, we reach higher accuracy by decreasing h and/or ε and increasing L.

Algorithm 6.1 in its turn requires an algorithm, which is considered below, for simulating the first exit point $(\theta, w(\theta))$ of the process $(s, w(s))$, $s > 0$, from the rectangle Π_h.

Let $W(s)$ be a one-dimensional standard Wiener process and let τ be the first exit time of $W(s)$ from the interval $I_1 = [-1, 1]$. Then the following formulas for the distribution and density of τ take place:

$$\mathcal{P}(t) = 1 - \frac{4}{\pi}\sum_{k=0}^{\infty}\frac{(-1)^k}{2k+1}\cdot\exp\left(-\frac{1}{8}\pi^2(2k+1)^2 t\right), \quad t > 0, \tag{6.5}$$

and

$$\mathcal{P}(t) = 2\sum_{k=0}^{\infty}(-1)^k \operatorname{erfc}\frac{2k+1}{\sqrt{2t}}, \quad t > 0, \qquad \operatorname{erfc} x = \frac{2}{\sqrt{\pi}}\int_x^{\infty}\exp(-y^2)dy\,; \tag{6.6}$$

$$\mathcal{P}'(t) = \frac{\pi}{2}\sum_{k=0}^{\infty}(-1)^k(2k+1)\exp\left(-\frac{1}{8}\pi^2(2k+1)^2 t\right), \quad t > 0, \tag{6.7}$$

and

$$\mathcal{P}'(t) = \frac{2}{\sqrt{2\pi t^3}}\sum_{k=0}^{\infty}(-1)^k(2k+1)\exp\left(-\frac{1}{2t}(2k+1)^2\right), \quad t > 0. \tag{6.8}$$

The formulas (6.5) and (6.7) are suitable for calculations under big t, and the formulas (6.6) and (6.8) are suitable for small t. See further computational details in [15, 18].

For the conditional probability

$$\mathcal{Q}(\mu; t) := P(W(t) < \mu \,/\, |W(s)| < 1,\ 0 < s < t)\,,$$

where $-1 < \mu \le 1$, the following equalities hold [15, 18]:

$$\mathcal{Q}(\mu; t) = \frac{P(W(t) < \mu\,,\ \tau \ge t)}{P(\tau \ge t)} \tag{6.9}$$

$$= \frac{1}{1 - \mathcal{P}(t)}\cdot\frac{2}{\pi}\sum_{k=0}^{\infty}\frac{1}{2k+1}\left((-1)^k + \sin\frac{\pi(2k+1)\mu}{2}\right)\exp\left(-\frac{1}{8}\pi^2(2k+1)^2 t\right)$$

and

$$\mathcal{Q}(\mu;t)=\frac{1}{1-\mathcal{P}(t)} \times\sum_{k=0}^{\infty}\frac{(-1)^k}{2}\left(\operatorname{erfc}\frac{2k-1}{\sqrt{2t}}-\operatorname{erfc}\frac{2k+\mu}{\sqrt{2t}}-\operatorname{erfc}\frac{2k+2-\mu}{\sqrt{2t}}+\operatorname{erfc}\frac{2k+3}{\sqrt{2t}}\right). \tag{6.10}$$

Note that the series (6.9) and (6.10) are of the Leibniz type, the formula (6.9) is convenient for calculations under big t, and the formula (6.10) is convenient for small t. We draw attention to the denominator $(1-\mathcal{P}(t))$ in (6.9) which is close to zero for $t\gg 1$. But it is not difficult to transform (6.9) to a form suitable for calculations. See further computational details in [15, 18].

Algorithm 6.2 (simulating exit point of $(t,W(t))$ from space-time rectangle Π [15, 18]). Let ι, ν, and γ be independent random variables. Let ι be simulated by the law $P(\iota=-1)=\mathcal{P}(l)$, $P(\iota=1)=1-\mathcal{P}(l)$, let ν be simulated by the law $P(\nu=\pm 1)=\frac{1}{2}$, and let γ be uniformly distributed on $[0,1]$.

Then a random point (τ,ξ), distributed as the exit point $(\tau,W(\tau))$, is simulated as follows. If the simulated value of ι is equal to -1, then the point (τ,ξ) belongs to the lateral sides of Π and

$$\tau=\mathcal{P}^{-1}(\gamma\mathcal{P}(l)),\quad \xi=\nu;$$

otherwise, when $\iota=1$, the point (τ,ξ) belongs to the upper base of Π and

$$\tau=l,\quad \xi=\mathcal{Q}^{-1}(\gamma;l).$$

Corollary 6.3. [illegible] θ [illegible] $(s,w(s))$, $s>0$, [illegible] $\partial\Pi_h$. [illegible]

$$(\theta,w)=(h\tau,\sqrt{h}\,\xi),$$

[illegible] (τ,ξ) [illegible] 6.2 [illegible] $(\theta,w(\theta))$.

Algorithm 6.1 together with Algorithm 6.2 and Corollary 6.3 gives the constructive procedure for modeling the Markov chain (ϑ_k,X_k) which approximates trajectories $(t,X(t))$ of the SDE (6.1) in the space-time bounded domain Q.

[illegible] 6.4. In the one-dimensional case one can construct a random walk which terminates on the boundary Γ rather than in a boundary layer. Indeed, fix a sufficiently small $h>0$ and define the function $\rho(t,x;h)$, $(t,x)\in Q$, in the following way. If $\Pi(t,x;h)\in Q$, set $\rho\equiv\rho(t,x;h)=h$. Otherwise, find $\rho(t,x;h)<h$ such that $\Pi(t,x;\rho)$ touches the boundary Γ; i.e., either $t+\rho=T$ or one of the ends of the interval $I(t,x;\rho)$ coincides with α or β. At each iteration of the algorithm we find $h_k=\rho(\vartheta_{k-1},X_{k-1};h)$ and simulate the first exit point $(\theta_k,w(\vartheta_{k-1}+\theta_k)-w(\vartheta_{k-1}))$ of the process $(s-\vartheta_{k-1},w(s)-w(\vartheta_{k-1}))$, $s>\vartheta_{k-1}$, from the rectangle Π_{h_k}. Then we evaluate (ϑ_k,X_k) due to (6.2)–(6.3). We stop the algorithm when $(\vartheta_k,X_k)\in\Gamma$ and put $\nu=k$, $(\vartheta_\nu,X_\nu)=(\vartheta_k,X_k)$, $\bar\tau_{t,x}=\vartheta_\nu$, $\xi_{t,x}=X_\nu$. In comparison with Algorithm 6.1, the algorithm of this remark allows us to simulate a one-dimensional space-time Brownian motion $(s,w(s))$ exactly. We note that this algorithm cannot be generalized even to the two-dimensional case, while Algorithm 6.1 is available for any dimension [15, 18].

Now we are in position to propose a numerical algorithm for solving the FBSDE with random terminal time (5.1)–(5.2). Let $\bar u(t_k,x)$ be defined by Algorithm 5.1 and

$\frac{\Delta\bar{u}}{\Delta x}(t_k, x)$ by (5.12)–(5.14). Further, we define $\bar{u}(t, x)$ by linear interpolation as

$$\bar{u}(t,x) = \frac{t_k - t}{h}\bar{u}(t_{k-1}, x) + \frac{t - t_{k-1}}{h}\bar{u}(t_k, x), \quad t_{k-1} \le x \le t_k, \tag{6.11}$$

and analogously we define $\frac{\Delta\bar{u}}{\Delta x}(t, x)$. It is clear (see (5.11) and (5.12)–(5.14)) that

$$|u(t,x) - \bar{u}(t,x)| \le Kh \tag{6.12}$$

and

$$\left|\frac{\partial u}{\partial x}(t,x) - \frac{\Delta\bar{u}}{\Delta x}(t,x)\right| \le K\sqrt{h}\,. \tag{6.13}$$

We approximate $X(t)$ from (5.1)–(5.2) by Algorithm 6.1 in which (6.3) is replaced by

$$\begin{aligned} X_k = X_{k-1} &+ b(\vartheta_{k-1}, X_{k-1}, \bar{u}(\vartheta_{k-1}, X_{k-1}))\theta_k \\ &+ \sigma(\vartheta_{k-1}, X_{k-1}, \bar{u}(\vartheta_{k-1}, X_{k-1}))(w(\vartheta_k) - w(\vartheta_{k-1})). \end{aligned} \tag{6.14}$$

The algorithm also gives us the approximation $(\bar{\tau}_{t,x}, \xi_{t,x})$ for the first exit point $(\tau_{t,x}, X_{t,x}(\tau_{t,x}))$ of the trajectory $(s, X_{t,x}(s))$ from Q. Further, we compute the components Y and Z as

$$\begin{aligned} &Y_k = \bar{u}(\vartheta_k, X_k), \quad Z_k = \sigma(\vartheta_k, X_k, Y_k)\,\frac{\Delta\bar{u}}{\Delta x}(t_k, X_k), \quad k = 1, \dots, \nu, \\ &\bar{Y}_\nu = \bar{u}(\bar{\tau}_{t,x}, \xi_{t,x}), \quad \bar{Z}_\nu = \sigma(\bar{\tau}_{t,x}, \xi_{t,x}, \bar{Y}_\nu)\,\frac{\Delta\bar{u}}{\Delta x}(\bar{\tau}_{t,x}, \xi_{t,x})\,. \end{aligned} \tag{6.15}$$

It is possible to prove (cf. (6.4) and (6.12)–(6.13)) that

(6.16)

$$\Big[E\left[(X(\vartheta_k) - X_k)^2 + (Y(\vartheta_k) - Y_k)^2 + (Z(\vartheta_k) - Z_k)^2\right]\Big]^{1/2} \le K\ (\sqrt{h} + e^{-c_h L}),$$

$$k = 1, \dots, \nu,$$

$$\Big[E\left[\big(X_{t,x}(\tau_{t,x}) - \xi_{t,x}\big)^2 + \big(Y(\tau_{t,x}) - \bar{Y}_\nu\big)^2 + \big(Z(\tau_{t,x}) - \bar{Z}_\nu\big)^2\right]\Big]^{1/2}$$

$$\le K\ (h^{(1-\varepsilon)/4} + e^{-c_h L/2}),$$

$$E|\tau_{t,x} - \bar{\tau}_{t,x}| \le K\ (h^{(1-\varepsilon)/2} + e^{-c_h L}).$$

Using Algorithm 6.1, we can also simulate the FBSDE with unbounded terminal time (5.15)–(5.16) analogously to the approximation of the FBSDE (5.1)–(5.2) considered in this section.

7. Numerical tests.

7.1. Description of the test problems.

Consider the FBSDE

$$dX = \frac{X\left(1 + X^2\right)}{\left(2 + X^2\right)^3}dt + \frac{1 + X^2}{2 + X^2}\sqrt{\frac{1 + 2Y^2}{1 + Y^2 + \exp\left(-\dfrac{2X^2}{t+1}\right)}}\,dw(t), \tag{7.1}$$

$$X(0) = x,$$

$$dY = -g(t, X, Y)dt - f(t, X, Y)Z dt + Z\,dw(t), \tag{7.2}$$

$$Y(T) = \exp\left(-\frac{X^2(T)}{T+1}\right),$$

where

$$g(t,x,u) = \frac{1}{t+1}\exp\left(-\frac{x^2}{t+1}\right) \times \left[\frac{4x^2\left(1+x^2\right)}{\left(2+x^2\right)^3} + \left(\frac{1+x^2}{2+x^2}\right)^2\left(1-\frac{2x^2}{t+1}\right) - \frac{x^2}{t+1}\right], \tag{7.3}$$

$$f(t,x,u) = \frac{x}{\left(2+x^2\right)^2}\sqrt{\frac{1+u^2+\exp\left(-\frac{2x^2}{t+1}\right)}{1+2u^2}}.$$

Note that Assumption 2.1 is satisfied.

The corresponding Cauchy problem (see (2.3)–(2.4)) has the form

$$\frac{\partial u}{\partial t} + \frac{1}{2}\left(\frac{1+x^2}{2+x^2}\right)^2 \frac{1+2u^2}{1+u^2+\exp\left(-\frac{2x^2}{t+1}\right)}\frac{\partial^2 u}{\partial x^2} + \frac{2x\left(1+x^2\right)}{\left(2+x^2\right)^3}\frac{\partial u}{\partial x} \tag{7.4}$$

$$= \frac{1}{t+1}\exp\left(-\frac{x^2}{t+1}\right)\left[\frac{x^2}{t+1} - \frac{4x^2\left(1+x^2\right)}{\left(2+x^2\right)^3} - \left(\frac{1+x^2}{2+x^2}\right)^2\left(1-\frac{2x^2}{t+1}\right)\right],$$

$$t < T,\ x \in \mathbf{R},$$

$$u(T,x) = \exp\left(-\frac{x^2}{T+1}\right). \tag{7.5}$$

We use the problem (7.1)–(7.2) to test the numerical algorithms proposed in section 4. To this end, we need to know the exact solution of this problem. First, it can easily be verified that the solution of the problem (7.4)–(7.5) is the function

$$u(t,x) = \exp\left(-\frac{x^2}{t+1}\right). \tag{7.6}$$

Now we find the solution of (7.1)–(7.2). Substituting

$$Y(t) = u(t,X(t)) = \exp\left(-\frac{X(t)^2}{t+1}\right)$$

in (7.1), we get

$$dX = \frac{X\left(1+X^2\right)}{\left(2+X^2\right)^3}dt + \frac{1+X^2}{2+X^2}\,dw(t), \quad X(0) = x, \tag{7.7}$$

whose solution can be expressed by the formula

$$X(t) = \Lambda(x + \arctan x + w(t)), \tag{7.8}$$

where the function $\Lambda(z)$ is defined by the equation

$$\Lambda + \arctan\Lambda = z\,. \tag{7.9}$$

Indeed, $X(0) = \Lambda(x + \arctan x) = x$. Further, due to the Ito formula, we have

$$dX = \Lambda'(x + \arctan x + w(t))\,dw + \frac{1}{2}\Lambda''(x + \arctan x + w(t))\,dt$$

and by (7.9) we get

$$\Lambda' = \frac{1+\Lambda^2}{2+\Lambda^2}, \quad \Lambda'' = \frac{2\Lambda(1+\Lambda^2)}{(2+\Lambda^2)^3},$$

whence it follows that (7.8) satisfies (7.7).

Thus, the solution of (7.1)–(7.2) is

$$X(t) = \Lambda(x + \arctan x + w(t)), \quad Y(t) = \exp\left(-\frac{X(t)^2}{t+1}\right), \tag{7.10}$$

$$Z(t) = -\frac{2X(t)\left(1+X^2(t)\right)}{(t+1)\left(2+X^2(t)\right)} \exp\left(-\frac{X(t)^2}{t+1}\right),$$

where $\Lambda(z)$ is defined by (7.9).

Now consider the test problem for numerical algorithms for FBSDEs with random terminal time (cf. (7.1)–(7.2)):

$$dX = \frac{X\left(1+X^2\right)}{\left(2+X^2\right)^3}dt + \frac{1+X^2}{2+X^2}\sqrt{\frac{1+2Y^2}{1+Y^2+\exp\left(-\frac{2X^2}{t+1}\right)}}\,dw(t), \tag{7.11}$$

$$X(t_0) = x \in (0,\beta),$$

$$dY = -g(t,X,Y)dt - f(t,X,Y)Z dt + Z\,dw(t), \tag{7.12}$$

$$Y(\tau_x) = \exp\left(-\frac{X^2(\tau_{t_0,x})}{\tau_{t_0,x}+1}\right),$$

where $g(t,x,y)$ and $f(t,x,y)$ are from (7.3) and $\tau_{t_0,x}$ is the first exit time of the trajectory $(t, X_{t_0,x}(t))$, $t > t_0 > -1$, from the space-time rectangle $[t_0,T)\times(0,\beta)$; i.e., either $\tau_{t_0,x} = T$ or $X(\tau_{t_0,x})$ is equal to 0 or β. The corresponding Dirichlet problem (see (5.3)–(5.4) and also (7.4)–(7.5)) has the form

$$\frac{\partial u}{\partial t} + \frac{1}{2}\left(\frac{1+x^2}{2+x^2}\right)^2 \frac{1+2u^2}{1+u^2+\exp\left(-\frac{2x^2}{t+1}\right)}\frac{\partial^2 u}{\partial x^2} + \frac{2x\left(1+x^2\right)}{\left(2+x^2\right)^3}\frac{\partial u}{\partial x} \tag{7.13}$$

$$= \frac{1}{t+1}\exp\left(-\frac{x^2}{t+1}\right)\left[\frac{x^2}{t+1} - \frac{4x^2\left(1+x^2\right)}{\left(2+x^2\right)^3} - \left(\frac{1+x^2}{2+x^2}\right)^2\left(1-\frac{2x^2}{t+1}\right)\right],$$

$$t < T,\ x \in (0,\beta),$$

$$u(t,0) = 1, \quad u(t,\beta) = \exp\left(-\frac{\beta^2}{T+1}\right), \tag{7.14}$$

$$u(T,x) = \exp\left(-\frac{x^2}{T+1}\right). \tag{7.15}$$

Obviously, the solution of this problem is given by (7.6) again. The exact solution of (7.11)–(7.12) can be simulated using formulas (7.10).

7.2. Numerical experiments. We simulate (7.1)–(7.2) using the Euler scheme (4.2) and (4.4), where the solution u of (7.4)–(7.5) is approximated by Algorithm 2.2. Of course, practical realization of such algorithms always requires a truncation of the infinite space domain using the knowledge of behavior of solutions at infinity. In

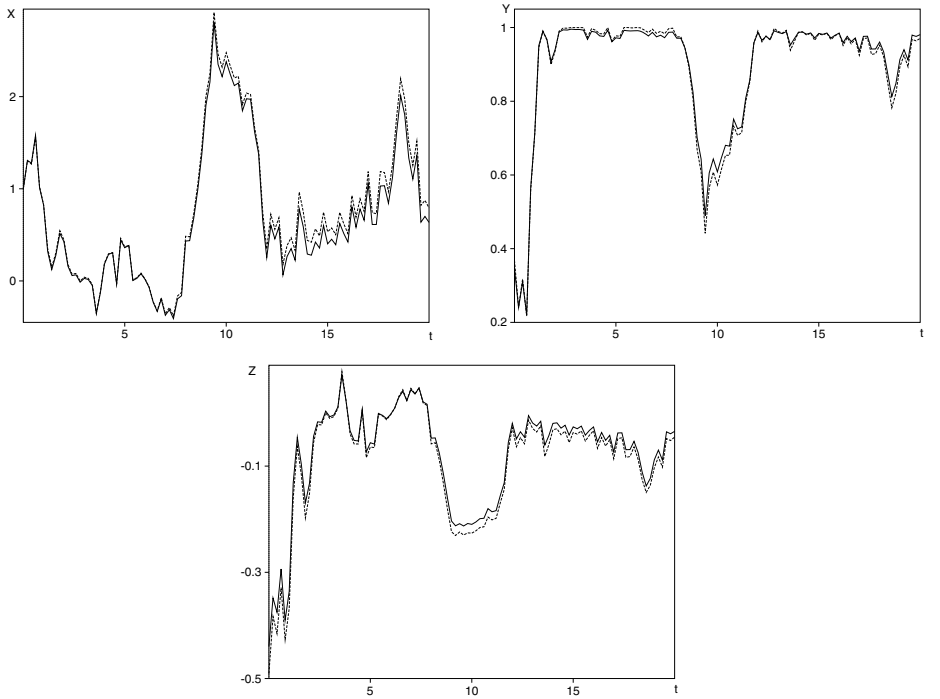

FIG. 1. *Simulation of the FBSDE* (7.1)–(7.2) *using the layer method from Algorithm* 2.2 *and the Euler scheme* (4.2) *and* (4.4) *(solid lines) with* $h = 0.2$, $\varkappa = 1$, *and* $x = 1$. *The corresponding exact trajectory (dashed lines) is found due to* (7.10). *The upper left figure gives the sample trajectories for* $X(t)$, *the upper right figure for* $Y(t)$, *and the lower figure for* $Z(t)$.

this example we restrict simulation to the space interval $[-20, 20]$. To check that this truncation does not affect accuracy, we performed control simulation for the interval $[-30, 30]$.

Figure 1 presents a comparison of the exact sample trajectories $X(t)$, $Y(t)$, $Z(t)$ found due to (7.10) and the approximate trajectories obtained by the Euler scheme (4.2) and (4.4). Table 1 gives errors in simulation of the test problem (7.1)–(7.2) by the Euler scheme (4.2) and (4.4). The "±" reflects the Monte Carlo error only; it does not reflect the error of the method. More precisely, the averages presented in the table are computed in the following way:

$$E\left(X(T) - X_N\right)^2 \doteq \frac{1}{M}\sum_{m=1}^{M}\left(X^{(m)}(T) - X_N^{(m)}\right)^2 \pm 2\sqrt{\frac{\bar{D}_M}{M}},$$

where

$$\bar{D}_M = \frac{1}{M}\sum_{m=1}^{M}\left(X^{(m)}(T) - X_N^{(m)}\right)^4 - \left[\frac{1}{M}\sum_{m=1}^{M}\left(X^{(m)}(T) - X_N^{(m)}\right)^2\right]^2$$

and $X^{(m)}(T)$ and $X_N^{(m)}$ are independent realizations of $X(T)$ and X_N, respectively. The numerical results are in good agreement with the theoretical ones proved for the Euler method: Convergence of X_N, Y_N, Z_N is of mean-square order $1/2$. We also see that $\bar{u}$ has the first-order convergence.

TABLE 1

OPTIMAL PARAMETER IN HERMITIAN AND SKEW-HERMITIAN SPLITTING METHOD FOR CERTAIN TWO-BY-TWO BLOCK MATRICES*

ZHONG-ZHI BAI†, GENE H. GOLUB‡, AND CHI-KWONG LI§

Abstract. The optimal parameter of the Hermitian/skew-Hermitian splitting (HSS) iteration method for a real two-by-two linear system is obtained. The result is used to determine the optimal parameters for linear systems associated with certain two-by-two block matrices and to estimate the optimal parameters of the HSS iteration method for linear systems with n-by-n real coefficient matrices. Numerical examples are given to illustrate the results.

Key words. non-Hermitian matrix, Hermitian matrix, skew-Hermitian matrix, splitting iteration method, optimal iteration parameter

1. Introduction.

To solve the large sparse non-Hermitian and positive definite system of linear equations

$$Ax = f,\ A \in \mathbb{C}^{n\times n} \text{ positive definite},\ A \neq A^*,\ \text{and } x, f \in \mathbb{C}^n, \tag{1.1}$$

Bai, Golub, and Ng [2] recently proposed the [illegible] (HSS) iteration method based on the fact that the coefficient matrix A naturally possesses the [illegible] (HS) splitting [10, 19]

$$A = H + S,$$

where

$$H = \frac{1}{2}(A + A^*) \quad \text{and} \quad S = \frac{1}{2}(A - A^*),$$

with A^* being the conjugate transpose of the matrix A. They showed that this HSS iteration converges unconditionally to the exact solution of the system of linear

equations (1.1), with the upper bound on convergence speed about the same as that of the conjugate gradient method when applied to Hermitian matrices. Moreover, the upper bound of the contraction factor is dependent on the spectrum of the Hermitian part H but is independent of the spectrum of the skew-Hermitian part S as well as the eigenvalues of the matrices H, S, and A. Numerical experiments have shown that the HSS iteration method is very efficient and robust both as a solver and as a preconditioner (to Krylov subspace methods such as GMRES and BiCGSTAB; see [15, 18]) for solving non-Hermitian and positive definite linear systems.

To further improve the efficiency of the method, it is desirable to determine or find a good estimate for the optimal parameter α^*. Unfortunately, there is no good method for doing that. In this paper, we analyze two-by-two real matrices in detail and obtain the optimal parameter α^* that minimizes the spectral radius of the iteration matrix of the corresponding HSS method. We then use the results to determine the optimal parameters for linear systems associated with certain two-by-two block matrices and to estimate the optimal parameter α^* of the HSS method for general n-by-n nonsymmetric positive definite system of linear equations (1.1). Numerical examples are given to show that our estimations improve previous results and are close to the values of the optimal parameters.

Unless specified otherwise, we assume throughout the paper that the non-Hermitian matrix $A \in \mathbb{C}^{n\times n}$ is positive definite, i.e., $A \neq A^*$, and its Hermitian part $H = \frac{1}{2}(A + A^*)$ is Hermitian positive definite.

2. The HSS iteration. Let us first review the HSS iteration method presented in Bai, Golub, and Ng [2].

The HSS iteration method. [illegible] $x^{(0)} \in \mathbb{C}^n$ [illegible] $x^{(k)}$ [illegible] $k = 0, 1, 2, \ldots$ [illegible] $\{x^{(k)}\}$ [illegible]

$$\begin{cases} (\alpha I + H)x^{(k+\frac{1}{2})} = (\alpha I - S)x^{(k)} + f, \\ (\alpha I + S)x^{(k+1)} = (\alpha I - H)x^{(k+\frac{1}{2})} + f, \end{cases}$$

[illegible] α [illegible]

In matrix-vector form, the above HSS iteration method can be equivalently rewritten as

$$x^{(k+1)} = \mathcal{M}(\alpha)x^{(k)} + \mathcal{G}(\alpha)f, \qquad k = 0, 1, 2, \ldots, \tag{2.1}$$

where

$$\mathcal{M}(\alpha) = (\alpha I + S)^{-1}(\alpha I - H)(\alpha I + H)^{-1}(\alpha I - S) \tag{2.2}$$

and

$$\mathcal{G}(\alpha) = 2\alpha(\alpha I + S)^{-1}(\alpha I + H)^{-1}.$$

Here, $\mathcal{M}(\alpha)$ is the iteration matrix of the HSS method. In fact, (2.1) may also result from the splitting

$$A = B(\alpha) - C(\alpha)$$

of the coefficient matrix A, with

$$\begin{cases} B(\alpha) = \dfrac{1}{2\alpha}(\alpha I + H)(\alpha I + S), \\ C(\alpha) = \dfrac{1}{2\alpha}(\alpha I - H)(\alpha I - S). \end{cases}$$

The following theorem established in [2] describes the convergence property of the HSS iteration.

THEOREM 2.1. $A \in \mathbb{C}^{n\times n}$ $H = \frac{1}{2}(A + A^*)$ $S = \frac{1}{2}(A - A^*)$ α $\rho(\mathcal{M}(\alpha))$ $\mathcal{M}(\alpha)$ (2.2)

$$\sigma(\alpha) = \max_{\lambda_j \in \lambda(H)} \frac{|\alpha - \lambda_j|}{|\alpha + \lambda_j|},$$

$\lambda(\cdot)$

$$\rho(\mathcal{M}(\alpha)) \le \sigma(\alpha) < 1 \qquad \alpha > 0;$$

$x^* \in \mathbb{C}^n$ (1.1)

$\gamma_{\min}$ $\gamma_{\max}$ H

$$\tilde{\alpha} \equiv \arg\min_{\alpha} \left\{ \max_{\gamma_{\min} \le \lambda \le \gamma_{\max}} \left| \frac{\alpha - \lambda}{\alpha + \lambda} \right| \right\} = \sqrt{\gamma_{\min}\gamma_{\max}}$$

$$\sigma(\tilde{\alpha}) = \frac{\sqrt{\gamma_{\max}} - \sqrt{\gamma_{\min}}}{\sqrt{\gamma_{\max}} + \sqrt{\gamma_{\min}}} = \frac{\sqrt{\kappa(H)} - 1}{\sqrt{\kappa(H)} + 1},$$

$\kappa(H)$ H

Of course, $\tilde{\alpha}$ is usually different from the optimal parameter

$$\alpha^* = \arg\min_{\alpha} \rho(\mathcal{M}(\alpha)),$$

and it always holds that

$$\rho(\mathcal{M}(\alpha^*)) \le \sigma(\tilde{\alpha}).$$

Numerical experiments in [2] have confirmed that in most situations, $\rho(\mathcal{M}(\alpha^*)) \ll \sigma(\tilde{\alpha})$. See [3, 12, 6, 16, 1, 13, 8, 14, 11, 7] for further applications and generalizations of the HSS iteration method.

3. The real two-by-two case. In this section, we study linear systems associated with a real two-by-two matrix A with positive definite symmetric part. We first determine the eigenvalues of $\mathcal{M}(\alpha)$ defined in (2.2). The following theorem is stated in general terms so that it can be used more conveniently for future discussion.

THEOREM 3.1. $A = H + S \in \mathbb{R}^{2\times 2}$ H S H $\lambda_1 \ge \lambda_2 > 0$ $\det(S) = q^2$ $q \in \mathbb{R}$ $\mathcal{M}(\alpha)$ (2.2)

$$\lambda_\pm = \frac{(\alpha^2 - \lambda_1\lambda_2)(\alpha^2 - q^2) \pm \sqrt{(\alpha^2 - \lambda_1\lambda_2)^2(\alpha^2 - q^2)^2 - (\alpha^2 - \lambda_1^2)(\alpha^2 - \lambda_2^2)(\alpha^2 + q^2)^2}}{(\alpha + \lambda_1)(\alpha + \lambda_2)(\alpha^2 + q^2)}.$$

[illegible]

$$(\alpha^2-\lambda_1\lambda_2)^2(\alpha^2-q^2)^2 \geq (\alpha^2-\lambda_1^2)(\alpha^2-\lambda_2^2)(\alpha^2+q^2)^2,$$

[illegible] $\rho(\mathcal{M}(\alpha))$ [illegible]

$$\frac{|\alpha^2-\lambda_1\lambda_2||\alpha^2-q^2|+\sqrt{(\alpha^2-\lambda_1\lambda_2)^2(\alpha^2-q^2)^2-(\alpha^2-\lambda_1^2)(\alpha^2-\lambda_2^2)(\alpha^2+q^2)^2}}{(\alpha+\lambda_1)(\alpha+\lambda_2)(\alpha^2+q^2)};$$

[illegible]

$$(\alpha^2-\lambda_1\lambda_2)^2(\alpha^2-q^2)^2 < (\alpha^2-\lambda_1^2)(\alpha^2-\lambda_2^2)(\alpha^2+q^2)^2,$$

[illegible] $\rho(\mathcal{M}(\alpha))$ [illegible]

$$\sqrt{\frac{(\alpha-\lambda_1)(\alpha-\lambda_2)}{(\alpha+\lambda_1)(\alpha+\lambda_2)}}.$$

[illegible]. Let $A = H + S \in \mathbb{R}^{2\times 2}$, where H is symmetric positive definite, and S is skew-symmetric. Then there is an orthogonal matrix $Q \in \mathbb{R}^{2\times 2}$ such that Q^tHQ is a diagonal matrix with diagonal entries λ_1 and λ_2, where Q^t denotes the transpose matrix of Q. We may replace A by Q^tAQ without changing the assumptions and conclusions of our theorem. So, assume that

$$H = \begin{bmatrix} \lambda_1 & 0 \\ 0 & \lambda_2 \end{bmatrix} \quad \text{and} \quad S = \begin{bmatrix} 0 & q \\ -q & 0 \end{bmatrix} \qquad \text{with } q \in \mathbb{R}.$$

Then $(\alpha I + H)^{-1}(\alpha I - H)(\alpha I + S)^{-1}(\alpha I - S)$ equals

$$\frac{1}{\alpha^2+q^2} \cdot \begin{bmatrix} \dfrac{(\alpha^2-q^2)(\alpha-\lambda_1)}{\alpha+\lambda_1} & -\dfrac{2q\alpha(\alpha-\lambda_1)}{\alpha+\lambda_1} \\ \dfrac{2q\alpha(\alpha-\lambda_2)}{\alpha+\lambda_2} & \dfrac{(\alpha^2-q^2)(\alpha-\lambda_2)}{\alpha+\lambda_2} \end{bmatrix}.$$

The formula for $\lambda_\pm$ and the assertion on $\rho(\mathcal{M}(\alpha))$ follow. □

One may want to use the formula of $\rho(\mathcal{M}(\alpha))$ in Theorem 3.1 to determine the optimal choice of α. It turns out that the analysis is very complicated and not productive. The main difficulty is the expression

$$\sqrt{(\alpha^2-\lambda_1\lambda_2)^2(\alpha^2-q^2)^2-(\alpha^2-\lambda_1^2)(\alpha^2-\lambda_2^2)(\alpha^2+q^2)^2} \tag{3.1}$$

in the formula of $\rho(\mathcal{M}(\alpha))$. For example, one may see [5] for the analysis of a similar and simpler problem. Here, we use a different approach that allows us to avoid the complicated expression (3.1).

For notational simplicity, we write

$$\rho(\alpha) = \rho(\mathcal{M}(\alpha)).$$

Define

$$\phi(\alpha) = \left\{\frac{\operatorname{trace}(\mathcal{M}(\alpha))}{2}\right\}^2 = \left\{\frac{(\alpha^2-q^2)(\alpha^2-\lambda_1\lambda_2)}{(\alpha^2+q^2)(\alpha+\lambda_1)(\alpha+\lambda_2)}\right\}^2,$$

$$\psi(\alpha) = \det(\mathcal{M}(\alpha)) = \frac{(\alpha-\lambda_1)(\alpha-\lambda_2)}{(\alpha+\lambda_1)(\alpha+\lambda_2)},$$

and

$$\omega(\alpha) = \max\{\phi(\alpha),\ |\psi(\alpha)|\}.$$

Evidently,

$$\rho(\alpha)^2 \geq \omega(\alpha).$$

Moreover,

$$1 = \phi(0) = \lim_{\alpha\to+\infty} \phi(\alpha) \quad \text{and} \quad 1 = \psi(0) = \lim_{\alpha\to+\infty} \psi(\alpha).$$

Thus,

$$\lim_{\alpha\to+\infty} \omega(\alpha) = \omega(0) = 1 > \omega(\xi) \quad \text{for all } \xi > 0.$$

Since $\omega(\alpha)$ is continuous and nonnegative, there exists $\alpha^* > 0$ such that

$$\omega(\alpha^*) = \min\{\omega(\alpha) \mid \alpha > 0\}.$$

We will show that

$$\phi(\alpha^*) = |\psi(\alpha^*)|. \tag{3.2}$$

As a result, the eigenvalues of $\mathcal{M}(\alpha^*)$ have the same modulus, and thus

$$\rho(\alpha)^2 \geq \omega(\alpha) \geq \omega(\alpha^*) = \rho(\alpha^*)^2 \quad \text{for all } \alpha > 0.$$

By the above discussion, establishing (3.2) will lead to the following theorem.

THEOREM 3.2. [illegible] 3.1 [illegible] ϕ [illegible] ψ [illegible] $\alpha^* > 0$ [illegible]

$$\rho(\mathcal{M}(\alpha^*)) = \min\{\rho(\mathcal{M}(\alpha)) \mid \alpha > 0\}$$

[illegible]

$$\mathbf{S} = \{\alpha > 0 \mid \phi(\alpha) = |\psi(\alpha)|\},$$

[illegible] $\alpha > 0$ [illegible]

$$(\alpha^2 + q^2)^2(\alpha^2 - \lambda_1^2)(\alpha^2 - \lambda_2^2) = (\alpha^2 - q^2)^2(\alpha^2 - \lambda_1\lambda_2)^2 \tag{3.3}$$

[illegible]

$$(\alpha^2 + q^2)^2(\lambda_1^2 - \alpha^2)(\alpha^2 - \lambda_2^2) = (\alpha^2 - q^2)^2(\alpha^2 - \lambda_1\lambda_2)^2. \tag{3.4}$$

[illegible]. We need only demonstrate the validity of (3.2), i.e.,

$$\phi(\alpha^*) = |\psi(\alpha^*)|.$$

Note that $\phi(\alpha)$ is continuously differentiable for $\alpha > 0$, and $|\psi(\alpha)|$ is continuous for $\alpha > 0$ and differentiable except for $\alpha = \lambda_1$ and λ_2. Since $\omega(\alpha) = \max\{\phi(\alpha),\ |\psi(\alpha)|\}$, if α^* satisfies

$$\omega(\alpha^*) = \min\{\omega(\alpha) \mid \alpha > 0\},$$

then one of the following holds:

(i) $\phi(\alpha^*) = |\psi(\alpha^*)|$;

(ii) $\phi(\alpha^*) > |\psi(\alpha^*)|$ and $\phi(\alpha^*)$ is a local minimum of $\phi(\alpha)$;

(iii) $|\psi(\alpha^*)| > \phi(\alpha^*)$ and $|\psi(\alpha^*)|$ is a local minimum of $|\psi(\alpha)|$.

First, we claim that (iii) cannot happen. To see this, note that

$$\psi'(\alpha) = \frac{2(\lambda_1+\lambda_2)(\alpha^2-\lambda_1\lambda_2)}{[(\alpha+\lambda_1)(\alpha+\lambda_2)]^2},$$

which is positive or negative according to $\alpha > \sqrt{\lambda_1\lambda_2}$ or $\alpha < \sqrt{\lambda_1\lambda_2}$, respectively, and $\psi'\left(\sqrt{\lambda_1\lambda_2}\right) = 0$. Because $\lambda_1 \geq \sqrt{\lambda_1\lambda_2} \geq \lambda_2$, we see that $|\psi(\alpha)| = \psi(\alpha)$ is differentiable and decreasing on $(0, \lambda_2)$, and $|\psi(\alpha)| = \psi(\alpha)$ is differentiable and increasing on $(\lambda_1, +\infty)$. Thus, there cannot be α^* in $(0, \lambda_2) \cup (\lambda_1, +\infty)$ satisfying (iii). Furthermore, $|\psi(\lambda_j)| = 0$ for $j = 1, 2$; so, it is impossible to have $\alpha^* = \lambda_j$ satisfying (iii). Finally, $|\psi(\alpha)| = -\psi(\alpha)$ is differentiable on (λ_2, λ_1) with a local maximum at $\sqrt{\lambda_1\lambda_2}$. Thus, there cannot be α^* in (λ_2, λ_1) satisfying (iii).

Next, we show that (ii) cannot happen. The analysis is more involved. Instead of $\phi(\alpha)$, we consider its square root

$$F(\alpha) = \frac{(\alpha^2-q^2)(\alpha^2-\lambda_1\lambda_2)}{(\alpha^2+q^2)(\alpha+\lambda_1)(\alpha+\lambda_2)} = \left(1 - \frac{2q^2}{\alpha^2+q^2}\right)\left(1 - \frac{\lambda_1}{\alpha+\lambda_1} - \frac{\lambda_2}{\alpha+\lambda_2}\right).$$

Then

$$\begin{aligned} F'(\alpha) &= \frac{4q^2\alpha}{(\alpha^2+q^2)^2}\frac{(\alpha^2-\lambda_1\lambda_2)}{(\alpha+\lambda_1)(\alpha+\lambda_2)} + \frac{(\alpha^2-q^2)}{(\alpha^2+q^2)}\left(\frac{\lambda_1}{(\alpha+\lambda_1)^2} + \frac{\lambda_2}{(\alpha+\lambda_2)^2}\right) \\ &= \frac{\lambda_1+\lambda_2}{(\alpha^2+q^2)^2(\alpha+\lambda_1)^2(\alpha+\lambda_2)^2} \cdot P(\alpha), \end{aligned}$$

where

$$\begin{aligned} P(\alpha) = \alpha^6 &+ \frac{4(\lambda_1\lambda_2+q^2)}{\lambda_1+\lambda_2}\alpha^5 + (\lambda_1\lambda_2+4q^2)\alpha^4 \\ &- q^2(q^2+4\lambda_1\lambda_2)\alpha^2 - \frac{4q^2\lambda_1\lambda_2(q^2+\lambda_1\lambda_2)}{\lambda_1+\lambda_2}\alpha - \lambda_1\lambda_2q^4. \end{aligned}$$

Suppose $q \leq \sqrt{\lambda_1\lambda_2}$. Then $F'(\alpha) < 0$ for $\alpha \in (0, q)$, and $F'(\alpha) > 0$ for $\alpha \in (\sqrt{\lambda_1\lambda_2}, +\infty)$. So, $F(\alpha)$ is decreasing on $(0, q)$ and increasing on $[\sqrt{\lambda_1\lambda_2}, +\infty)$. Hence, $\phi(\alpha) = F(\alpha)^2$ cannot have a local minimum in these two intervals. Thus, there cannot be an α^* in these intervals satisfying (ii). Because $\phi(q) = \phi\left(\sqrt{\lambda_1\lambda_2}\right) = 0$, we cannot have $\alpha^* = q$ or $\sqrt{\lambda_1\lambda_2}$ satisfying (ii).

Next, we [illegible] that $F(\alpha)$ has only one critical point in $\left(q, \sqrt{\lambda_1\lambda_2}\right)$, which is a local minimum. This point will be the unique critical point for $\phi(\alpha) = F(\alpha)^2$ on $\left(q, \sqrt{\lambda_1\lambda_2}\right)$, which is a local maximum. Thus, there cannot be an α^* in this interval satisfying (ii).

To prove our claim, note that $\alpha > 0$ is a critical point of $F(\alpha)$ if and only if α is a zero of $P(\alpha)$. So, it suffices to show that $P(\alpha)$ has only one positive zero. Now

$$P''(\alpha) = 30\alpha^4 + \frac{80(\lambda_1\lambda_2+q^2)}{\lambda_1+\lambda_2}\alpha^3 + 12(\lambda_1\lambda_2+4q^2)\alpha^2 - 2q^2(q^2+4\lambda_1\lambda_2).$$

Since $P''(0) < 0$ and $\lim_{\alpha\to+\infty} P''(\alpha) = +\infty$, we see that $P''(\alpha)$ has a positive zero. However, $P''(\alpha)$ cannot have two or more positive zeros (counting multiplicity). Otherwise,

$$P'''(\alpha) = 120\alpha^3 + \frac{240(\lambda_1\lambda_2 + q^2)}{\lambda_1 + \lambda_2}\alpha^2 + 24(\lambda_1\lambda_2 + 4q^2)\alpha$$

has a positive zero, which is impossible. Next, we argue that

$$P'(\alpha) = 6\alpha^5 + \frac{20(\lambda_1\lambda_2 + q^2)}{\lambda_1 + \lambda_2}\alpha^4 + 4(\lambda_1\lambda_2 + 4q^2)\alpha^3$$

$$- 2q^2(q^2 + 4\lambda_1\lambda_2)\alpha - \frac{4q^2\lambda_1\lambda_2(q^2 + \lambda_1\lambda_2)}{\lambda_1 + \lambda_2}$$

has exactly one positive zero. Since $P'(0) < 0$ and $\lim_{\alpha\to+\infty} P'(\alpha) = +\infty$, we see that $P'(\alpha)$ has a positive zero. Since $P''(0) < 0$ and $P''(\alpha)$ has only one positive zero α_1, we see that $P'(\alpha)$ is decreasing on $(0, \alpha_1)$ and increasing on $(\alpha_1, +\infty)$. So, $P'(\alpha)$ can have only one positive zero $\alpha_2 > \alpha_1$.

We can apply the same argument to $P(\alpha)$. Since $P(0) < 0$ and $\lim_{\alpha\to+\infty} P(\alpha) = +\infty$, we see that $P(\alpha)$ has a positive zero. Since $P'(0) < 0$ and $P'(\alpha)$ has only one positive zero α_2, we see that $P(\alpha)$ is decreasing on $(0, \alpha_2)$ and increasing on $(\alpha_2, +\infty)$. So, $P(\alpha)$ can have only one positive zero $\alpha_3 > \alpha_2$, and our claim is proved.

One can use a similar argument to get the desired conclusion if $q > \sqrt{\lambda_1\lambda_2}$. We omit the discussion. □

Remark 3.3. Using the absolute value function, we can combine (3.3) and (3.4) to a single equation

$$|(\alpha^2 + q^2)^2(\lambda_1^2 - \alpha^2)(\alpha^2 - \lambda_2^2)| = [(\alpha^2 - q^2)(\alpha^2 - \lambda_1\lambda_2)]^2.$$

Nonetheless, the polynomial equations are easier to solve and use. In fact, if $\lambda_1 = \lambda_2 = \lambda^*$, then (3.3) and (3.4) have only one positive solution, namely, $\alpha = \lambda^*$. Suppose $\lambda_1 > \lambda_2$. If we use the substitution $\beta = \alpha^2$, then (3.3) reduces to the quadratic equation

$$[(\lambda_1 - \lambda_2)^2 - 4q^2]\beta^2 + 2q^2(\lambda_1 + \lambda_2)^2\beta + q^2[q^2(\lambda_1 - \lambda_2)^2 - 4\lambda_1^2\lambda_2^2] = 0,$$

which has solutions

$$\frac{q(2\lambda_1\lambda_2 - q\lambda_1 + q\lambda_2)}{\lambda_1 - \lambda_2 + 2q} \quad \text{and} \quad \frac{-q(2\lambda_1\lambda_2 + q\lambda_1 - q\lambda_2)}{\lambda_1 - \lambda_2 - 2q}$$

if $|\lambda_1 - \lambda_2| \neq 2q$. Otherwise, the equation is linear and has a solution

$$\beta = \frac{2(q^4 - \lambda_1^2\lambda_2^2)}{(\lambda_1 + \lambda_2)^2} = \frac{2(q^2 + \lambda_1\lambda_2)(q^2 - \lambda_1\lambda_2)}{(\lambda_1 + \lambda_2)^2}$$

$$= \frac{(\lambda_1 + \lambda_2)^2(q^2 - \lambda_1\lambda_2)}{2(\lambda_1 + \lambda_2)^2} = \frac{1}{2}(q^2 - \lambda_1\lambda_2).$$

Of course, these solutions will be useful only if they are positive and lie outside the interval $[\lambda_2^2, \lambda_1^2]$. Similarly, by the substitution $\beta = \alpha^2$, (3.4) reduces to the

quartic equation

$$\begin{aligned} &2\beta^4 - (\lambda_1+\lambda_2)^2\beta^3 + 2[\lambda_1^2\lambda_2^2 - q^2(\lambda_1-\lambda_2)^2 + q^4]\beta^2 \\ &\quad - q^4(\lambda_1+\lambda_2)^2\beta + 2q^4\lambda_1^2\lambda_2^2 = 0, \end{aligned} \tag{3.5}$$

which has exactly two solutions μ_1 and μ_2 with $\mu_1 \in [\lambda_2^2, \lambda_1\lambda_2)$ and $\mu_2 \in ((\lambda_1^2 + \lambda_2^2)/2, \lambda_1^2]$. Furthermore, if $q^2 \in [\lambda_2^2, \lambda_1^2]$, then $\mu_1 \le q^2$ and $\mu_2 \ge q^2$. In particular, if $q = \lambda_i$ for $i \in \{1, 2\}$, then $\beta = \lambda_i^2$ is a solution. The verification of the above statements will be given in the last section.

As an illustration of Theorems 3.1 and 3.2 as well as Remark 3.3, we consider a simple example for which $\lambda_1 = 2$, $\lambda_2 = 1$, and $q = 1$. By straightforward computations, we know that the only positive roots of (3.3) are $\alpha_1^* = 1$ and $\alpha_2^* = \sqrt{5}$, and those of (3.4) are $\alpha_3^* = 1$ and

$$\alpha_4^* = \frac{\sqrt{6}}{6}\sqrt{\left(7 + \sqrt[3]{712 + 9\sqrt{5277}} + \frac{43}{\sqrt[3]{712 + 9\sqrt{5277}}}\right)} \approx 1.914.$$

We remark that now (3.4) is equivalent to $(\beta - 1)(2\beta^3 - 7\beta^2 + \beta - 8) = 0$. Based on Theorem 3.1, from direct calculations we have

$$\rho(\mathcal{M}(\alpha_1^*)) = \rho(\mathcal{M}(\alpha_3^*)) = 0, \quad \rho(\mathcal{M}(\alpha_2^*)) = \frac{\sqrt{3}(7 - 3\sqrt{5})}{6} \approx 0.0842$$

and

$$\rho(\mathcal{M}(\alpha_4^*)) \approx 0.201.$$

Therefore, for the HSS iteration method, the optimal parameter is $\alpha^* = 1$ and the corresponding optimal convergence factor is $\rho(\mathcal{M}(\alpha^*)) = 0$. On the other hand, from Theorem 2.1 we can easily obtain

$$\tilde{\alpha} = \sqrt{2} \approx 1.414 \quad \text{and} \quad \sigma(\tilde{\alpha}) = 3 - 2\sqrt{2} \approx 0.172.$$

Obviously, it holds that $\rho(\mathcal{M}(\alpha^*)) < \sigma(\tilde{\alpha})$.

Remark 3.4. Note that in our proof of Theorem 3.2, we get much information for the function $\omega(\alpha) = \max\{\phi(\alpha), |\psi(\alpha)|\}$ with $\alpha > 0$. In particular, we show that all the local minima of $\omega(\alpha)$ satisfy

$$\phi(\alpha) = |\psi(\alpha)|,$$

and they are the roots of (3.3) and (3.4). Moreover, the local minima of $\omega(\alpha)$ are also local minima of $\rho(\alpha)$, and the global minimum of $\rho(\alpha)$ and $\omega(\alpha)$ occurs at the same α^*. If one can prove independently that the local minima $\rho(\alpha)$ always occur when the eigenvalues of $\mathcal{M}(\alpha)$ have the same magnitude, then one can conclude that the functions $\omega(\alpha)$ and $\rho(\alpha)$ have the same local and global minima. Once again, this is difficult to do because of the expression (3.1) in $\rho(\alpha) = \rho(\mathcal{M}(\alpha))$.

Using the notation defined in Theorem 3.1, we immediately get the following conclusion from Theorem 3.2.

COROLLARY 3.5. 3.1 $\alpha^* > 0$

$$\rho(\mathcal{M}(\alpha^*)) = \min\{\rho(\mathcal{M}(\alpha)) \mid \alpha > 0\}$$

$$(\alpha^2 + q^2)^2(\alpha^2 - \lambda_1^2)(\alpha^2 - \lambda_2^2) = (\alpha^2 - q^2)^2(\alpha^2 - \lambda_1\lambda_2)^2$$

$$(\alpha^2 + q^2)^2(\lambda_1^2 - \alpha^2)(\alpha^2 - \lambda_2^2) = (\alpha^2 - q^2)^2(\alpha^2 - \lambda_1\lambda_2)^2.$$

3.6. The first equation in Corollary 3.5 can be reduced to a quadratic equation and the second one can be reduced to a quartic equation with respect to $\beta = \alpha^2$, respectively, analogously to those in Remark 3.3.

3.7. Note that the results in this section are also valid if $\lambda_1 > 0 = \lambda_2$ and $q \neq 0$.

3.8. We should point out again that Theorem 3.2 has been established only for real matrices. For complex matrices, how to determine the optimal iteration parameter of the HSS iteration method is still an open problem.

4. Two-by-two block matrices. In this section, we determine the optimal parameter α^* for a two-by-two block matrix of the form

$$A = \begin{bmatrix} \lambda_1 I_r & E \\ -E^* & \lambda_2 I_s \end{bmatrix}, \tag{4.1}$$

where $\lambda_1 > \lambda_2 > 0$. Note that the case when $\lambda_1 = \lambda_2$ is trivial.[1] Systems of linear equations with the two-by-two block matrices (4.1) arise in many applications; for details we refer the readers to [17, Chapter 6], [9, Chapters 4, 5, and 10], [20, 10, 4, 5], and the references therein. According to Young [20] and Varga [17], the matrix A in (4.1) is called a 2-cyclic matrix and is connected with property A.

THEOREM 4.1. $A \in \mathbb{C}^{n\times n}$ (4.1) $\lambda_1 > \lambda_2 > 0$ $E \in \mathbb{C}^{r\times s}$ $q_1 \geq q_2 \geq \cdots \geq q_k$

$$H = \frac{1}{2}(A + A^*) = \begin{bmatrix} \lambda_1 I_r & 0 \\ 0 & \lambda_2 I_s \end{bmatrix} \qquad S = \frac{1}{2}(A - A^*) = \begin{bmatrix} 0 & E \\ -E^* & 0 \end{bmatrix}$$

A $\rho(\mathcal{M}(\alpha))$ $\mathcal{M}(\alpha)$ (2.2) α^*

[1] If $\lambda_1 = \lambda_2 \equiv \lambda^*$, then the iteration matrix of the HSS iteration method is given by $\mathcal{M}(\alpha) = \frac{\alpha-\lambda^*}{\alpha+\lambda^*}Q(\alpha)$, where $Q(\alpha) := (\alpha I + S)^{-1}(\alpha I - S)$ is a Cayley transform of S and is, thus, unitary, and $S = \left[\begin{smallmatrix} 0 & E \\ -E^* & 0 \end{smallmatrix}\right]$; see (2.2). Obviously, it holds that $\rho(\mathcal{M}(\alpha)) = \frac{|\alpha-\lambda^*|}{\alpha+\lambda^*}$. Therefore, for the HSS iteration method applied to this special linear system, the optimal parameter is $\alpha^* = \lambda^*$ and the corresponding optimal convergence factor is $\rho(\mathcal{M}(\alpha^*)) = 0$.

$$(\alpha - \sqrt{\lambda_1\lambda_2})(\alpha - \sqrt{q_1 q_k}) = 0,$$

$$(\alpha^2 + q_j^2)^2(\alpha^2 - \lambda_1^2)(\alpha^2 - \lambda_2^2) = (\alpha^2 - q_j^2)^2(\alpha^2 - \lambda_1\lambda_2)^2$$

$$(\alpha^2 + q_j^2)^2(\lambda_1^2 - \alpha^2)(\alpha^2 - \lambda_2^2) = (\alpha^2 - q_j^2)^2(\alpha^2 - \lambda_1\lambda_2)^2,$$

$j = 1, k$

. Suppose A satisfies the hypotheses of the theorem. Then A is unitarily similar to $A_1 \oplus \cdots \oplus A_k \oplus \lambda_1 I_u \oplus \lambda_2 I_v$, where $\oplus$ denotes the matrix direct sum, $A_j = \left[\begin{smallmatrix} \lambda_1 & q_j \\ -q_j & \lambda_2 \end{smallmatrix}\right]$, $u = r - k$, and $v = s - k$. For $\alpha > 0$, define

$$\rho(\alpha) = \rho(\mathcal{M}(\alpha)) \quad \text{and} \quad \rho_j(\alpha) = \rho(\mathcal{M}_j(\alpha)),$$

where $\mathcal{M}(\alpha)$ is unitarily similar to $\mathcal{M}_1(\alpha) \oplus \cdots \oplus \mathcal{M}_k(\alpha) \oplus \frac{\alpha-\lambda_1}{\alpha+\lambda_1} I_u \oplus \frac{\alpha-\lambda_2}{\alpha+\lambda_2} I_v$, with $\mathcal{M}_j(\alpha)$ being the HSS iteration matrix associated with A_j for $j = 1, 2, \ldots, k$. Furthermore, define

$$f_j(\alpha) = |\alpha - \lambda_j|/|\alpha + \lambda_j| \quad \text{for } j = 1, 2.$$

Consider four cases.

1. If $r > k$ and $s > k$, then $f_1(\alpha)$ and $f_2(\alpha)$ are eigenvalues of $\mathcal{M}(\alpha)$ and

$$\rho(\alpha) = \max\{|f_1(\alpha)|,\ |f_2(\alpha)|\}$$

is the largest singular value of $\mathcal{M}(\alpha)$. Thus,

$$\rho(\alpha^*) = \rho\left(\sqrt{\lambda_1\lambda_2}\right) = \frac{\sqrt{\lambda_1} - \sqrt{\lambda_2}}{\sqrt{\lambda_1} + \sqrt{\lambda_2}}.$$

2. Suppose $r > k$ and $s = k$. Let $\rho_0(\alpha) = f_1(\alpha)$. Then

$$\rho(\alpha) = \max\{\rho_j(\alpha) \mid 0 \le j \le k\}.$$

For $\alpha \in \left(0, \sqrt{\lambda_1\lambda_2}\right]$,

$$\rho(\alpha) = \rho_0(\alpha) = f_1(\alpha)$$

is the largest singular value of $\mathcal{M}(\alpha)$. If $\alpha \ge (\lambda_1^3/\lambda_2)^{1/2}$, then

$$f_1(\alpha) = \left|\frac{\alpha - \lambda_1}{\alpha + \lambda_1}\right| = \left|1 - \frac{2\lambda_1}{\alpha + \lambda_1}\right| \ge \left|1 - \frac{2\lambda_1}{\sqrt{\lambda_1\lambda_2} + \lambda_1}\right| = \rho\left(\sqrt{\lambda_1\lambda_2}\right).$$

Thus, $\rho(\alpha) \ge \rho\left(\sqrt{\lambda_1\lambda_2}\right)$ if $\alpha \in \left[0, (\lambda_1\lambda_2)^{1/2}\right] \cup \left[(\lambda_1^3/\lambda_2)^{1/2}, +\infty\right)$. So, we focus on the interval

$$J = \left((\lambda_1\lambda_2)^{1/2},\ (\lambda_1^3/\lambda_2)^{1/2}\right).$$

For $\alpha \in J$, let

$$\phi_j(\alpha) = \left\{\frac{\operatorname{trace}(\mathcal{M}_j(\alpha))}{2}\right\}^2 = \left\{\frac{(\alpha^2 - q_j^2)(\alpha^2 - \lambda_1\lambda_2)}{(\alpha^2 + q_j^2)(\alpha + \lambda_1)(\alpha + \lambda_2)}\right\}^2$$

and

$$\psi(\alpha) = \det\left(\mathcal{M}_j(\alpha)\right) = \frac{(\alpha-\lambda_1)(\alpha-\lambda_2)}{(\alpha+\lambda_1)(\alpha+\lambda_2)}, \qquad j = 1, 2, \ldots, k.$$

Clearly, $\psi(\alpha)$ is independent of the index j. By Theorem 3.1, if $\phi_j(\alpha) \geq \psi(\alpha)$, then

$$\rho_j(\alpha) = \sqrt{\phi_j(\alpha)} + \sqrt{\phi_j(\alpha) - \psi(\alpha)};$$

otherwise,

$$\rho_j(\alpha) = \sqrt{\frac{(\alpha-\lambda_1)(\alpha-\lambda_2)}{(\alpha+\lambda_1)(\alpha+\lambda_2)}}.$$

We claim that

$$\max\{\rho_j(\alpha) : 1 \leq j \leq k\} = \max\{\rho_1(\alpha),\ \rho_k(\alpha)\}, \qquad \alpha \in J.$$

Suppose $1 < j < k$. If $\phi_j(\alpha) < \psi(\alpha)$, then

$$\rho_j(\alpha) = \sqrt{\frac{(\alpha-\lambda_1)(\alpha-\lambda_2)}{(\alpha+\lambda_1)(\alpha+\lambda_2)}},$$

and $\min\{\phi_1(\alpha), \phi_k(\alpha)\} \leq \phi_j(\alpha) < \psi(\alpha)$. It follows that $\rho_1(\alpha) = \rho_j(\alpha)$ or $\rho_k(\alpha) = \rho_j(\alpha)$. If $\phi_j(\alpha) \geq \psi(\alpha)$ and $\alpha \geq q_j^2$, then

$$0 \leq \phi_j(\alpha) \leq \phi_k(\alpha),$$

and hence

$$\rho_j(\alpha) = \sqrt{\phi_j(\alpha)} + \sqrt{\phi_j(\alpha) - \psi(\alpha)} \leq \sqrt{\phi_k(\alpha)} + \sqrt{\phi_k(\alpha) - \psi(\alpha)} = \rho_k(\alpha);$$

if $\phi_j(\alpha) \geq \psi(\alpha)$ and $\alpha < q_j^2$, then

$$0 < \phi_j(\alpha) \leq \phi_1(\alpha),$$

and hence

$$\rho_j(\alpha) = \sqrt{\phi_j(\alpha)} + \sqrt{\phi_j(\alpha) - \psi(\alpha)} \leq \sqrt{\phi_1(\alpha)} + \sqrt{\phi_1(\alpha) - \psi(\alpha)} = \rho_1(\alpha).$$

Thus, our claim is proved.

For each $\alpha \in J$, we have

$$\sqrt{|\alpha-\lambda_1|/|\alpha+\lambda_1|} \leq \sqrt{|\alpha-\lambda_2|/|\alpha+\lambda_2|},$$

and hence

$$\rho_0(\alpha) = \left|\frac{\alpha-\lambda_1}{\alpha+\lambda_1}\right| \leq \sqrt{\left|\frac{(\alpha-\lambda_1)(\alpha-\lambda_2)}{(\alpha+\lambda_1)(\alpha+\lambda_2)}\right|} \leq \max\{\rho_1(\alpha),\ \rho_k(\alpha)\}.$$

Combining the above, we see that

$$\rho(\alpha) = \max\{\rho_1(\alpha),\ \rho_k(\alpha)\}, \qquad \alpha \in J.$$

Let

$$\Omega(\alpha) = \max\{\phi_1(\alpha),\ \phi_k(\alpha),\ |\psi(\alpha)|\}.$$

Then

$$\Omega(\alpha) \le \max\{\rho_1(\alpha)^2,\ \rho_k(\alpha)^2\}.$$

If $\alpha^* \in J$ is such that $\Omega(\alpha^*) \le \Omega(\alpha)$ for all $\alpha \in J$, then one of the following holds:

(1) $\phi_1(\alpha^*) = \phi_k(\alpha^*) = |\psi(\alpha^*)|$;
(2.a) $\phi_1(\alpha^*) = \phi_k(\alpha^*) > |\psi(\alpha^*)|$, α^* is a local minimum of the function $\max\{\phi_1(\alpha),\ \phi_k(\alpha)\}$,
(2.b) $\phi_1(\alpha^*) = |\psi(\alpha^*)| > \phi_k(\alpha^*)$, α^* is a local minimum of the function $\max\{\phi_1(\alpha),\ |\psi(\alpha)|\}$,
(2.c) $\phi_k(\alpha^*) = |\psi(\alpha^*)| > \phi_1(\alpha^*)$, α^* is a local minimum of the function $\max\{\phi_k(\alpha),\ |\psi(\alpha)|\}$;
(3.a) $\max\{\phi_1(\alpha^*),\ \phi_k(\alpha^*)\} < |\psi(\alpha^*)|$ and α^* is a local minimum of the function $|\psi(\alpha^*)|$,
(3.b) $\max\{\phi_1(\alpha^*),\ |\psi(\alpha^*)|\} < \phi_k(\alpha^*)$ and α^* is a local minimum of the function $\phi_k(\alpha^*)$,
(3.c) $\max\{\phi_k(\alpha^*),\ |\psi(\alpha^*)|\} < \phi_1(\alpha^*)$ and α^* is a local minimum of the function $\phi_1(\alpha^*)$.

By the proof of Theorem 3.2, we see that the function $|\psi(\alpha)|$ has a differentiable local maximum at $\alpha > 0$ and two nondifferentiable local minima at λ_2 and λ_1, where $\psi(\lambda_1) = \psi(\lambda_2) = 0$. Thus, condition (3.a) cannot hold. Similarly, for $j = 1, k$, the proof of Theorem 3.2 shows that the function $\phi_j(\alpha)$ has a local maximum at $\alpha > 0$ and two local minima at $|q_j|$ and $\sqrt{\lambda_1\lambda_2}$, where $\phi_j(|q_j|) = \phi_j(\sqrt{\lambda_1\lambda_2}) = 0$. Thus, neither condition (3.b) nor (3.c) holds.

Now suppose that (1) or (2.a) holds. Then $\phi_1(\alpha^*) = \phi_k(\alpha^*)$ implies that $\alpha^* = \sqrt{q_1 q_k}$. In both cases, we have

$$\rho_1(\alpha^*) = \sqrt{\phi_1(\alpha^*)} + \sqrt{\phi_1(\alpha^*) - \psi(\alpha^*)} = \sqrt{\phi_k(\alpha^*)} + \sqrt{\phi_k(\alpha^*) - \psi(\alpha^*)} = \rho_k(\alpha^*),$$

and $\Omega(\alpha^*) = \max\{\rho_1(\alpha^*)^2,\ \rho_k(\alpha^*)^2\}$.

Suppose that (2.b) holds. If $\phi_k(\alpha^*) \ge \psi(\alpha^*)$, then

$$\rho_k(\alpha^*) = \sqrt{\phi_k(\alpha^*)} + \sqrt{\phi_k(\alpha^*) - \psi(\alpha^*)} < \sqrt{\phi_1(\alpha^*)} + \sqrt{\phi_1(\alpha^*) - \psi(\alpha^*)} = \rho_1(\alpha^*);$$

otherwise,

$$\rho_k(\alpha^*) = \sqrt{\frac{(\alpha^* - \lambda_1)(\alpha^* - \lambda_2)}{(\alpha^* + \lambda_1)(\alpha^* + \lambda_2)}} \le \rho_1(\alpha^*).$$

Thus, $\Omega(\alpha^*) = \rho_1(\alpha^*)^2 = \max\{\rho_1(\alpha^*)^2,\ \rho_k(\alpha^*)^2\}$. Moreover, since α^* is a local minimum of the function $\max\{\phi_1(\alpha),\ |\psi(\phi)|\}$, by Remark 3.4 we see that α^* is a root of the equation

$$(\alpha^2 + q_1^2)^2(\alpha^2 - \lambda_1^2)(\alpha^2 - \lambda_2^2) = (\alpha^2 - q_1^2)^2(\alpha^2 - \lambda_1\lambda_2)^2$$

or

$$(\alpha^2 + q_1^2)^2(\lambda_1^2 - \alpha^2)(\alpha^2 - \lambda_2^2) = (\alpha^2 - q_1^2)^2(\alpha^2 - \lambda_1\lambda_2)^2.$$

Suppose that (2.c) holds. We can use an argument similar to the case of (2.b) to conclude that $\Omega(\alpha^*) = \rho_k(\alpha^*)^2 = \max\{\rho_1(\alpha^*)^2,\ \rho_k(\alpha^*)^2\}$ and that α^* is a root of the equation

$$(\alpha^2 + q_k^2)^2(\alpha^2 - \lambda_1^2)(\alpha^2 - \lambda_2^2) = (\alpha^2 - q_k^2)^2(\alpha^2 - \lambda_1\lambda_2)^2$$

or

$$(\alpha^2 + q_k^2)^2(\lambda_1^2 - \alpha^2)(\alpha^2 - \lambda_2^2) = (\alpha^2 - q_k^2)^2(\alpha^2 - \lambda_1\lambda_2)^2.$$

Note that in all the cases (1), (2.a), (2.b), and (2.c), we have

$$\Omega(\alpha^*) = \max\{\rho_1(\alpha^*)^2,\ \rho_k(\alpha^*)^2\}.$$

Consequently, if $\alpha^* \in J$ yields the smallest $\Omega(\alpha)$, then

$$\rho(\alpha)^2 = \max\{\rho_1(\alpha)^2,\ \rho_k(\alpha)^2\} \geq \Omega(\alpha) \geq \Omega(\alpha^*) = \max\{\rho_1(\alpha^*)^2,\ \rho_k(\alpha^*)^2\} = \rho(\alpha^*)^2.$$

So, we need only consider those α satisfying the specified equations in the theorem to determine the optimal parameter α^*.

3. Suppose $r = k$ and $s > k$. Let $\rho_0(\alpha) = f_2(\alpha)$. Then

$$\rho(\alpha) = \max\{\rho_j(\alpha) \mid 0 \leq j \leq k\}.$$

Similarly to the proof of Case 2, we can show that

$$\rho(\alpha) \geq \rho(\sqrt{\lambda_1\lambda_2})$$

if α is positive and lies outside the interval

$$J = \left((\lambda_2^3/\lambda_1)^{1/2},\ (\lambda_1\lambda_2)^{1/2}\right).$$

So, we can focus on the interval J.

For $\alpha \in J$, we have

$$\rho(\alpha) = \max\{\rho_1(\alpha),\ \rho_k(\alpha)\}.$$

Note that in this case, for each $\alpha \in J$, we have

$$\sqrt{|\alpha - \lambda_2|/|\alpha + \lambda_2|} \leq \sqrt{|\alpha - \lambda_1|/|\alpha + \lambda_1|},$$

and hence

$$\rho_0(\alpha) = \left|\frac{\alpha - \lambda_2}{\alpha + \lambda_2}\right| \leq \sqrt{\left|\frac{(\alpha - \lambda_1)(\alpha - \lambda_2)}{(\alpha + \lambda_1)(\alpha + \lambda_2)}\right|} \leq \max\{\rho_1(\alpha),\ \rho_k(\alpha)\}.$$

Finally, if $\alpha^* \in J$ is such that $\rho(\alpha^*) < \rho(\sqrt{\lambda_1\lambda_2})$, we can show that α^* must satisfy one of the three specified equations using an argument similar to the one in Case 2.

4. Suppose $r = s = k$. Then

$$\rho(\alpha) = \max\{\rho_j(\alpha) \mid 1 \leq j \leq k\}.$$

Note that if α is positive and lies outside the interval

$$J = \left((\lambda_2^3/\lambda_1)^{1/2},\ (\lambda_1^3/\lambda_2)^{1/2}\right),$$

then each of the singular values of $\mathcal{M}(\alpha)$, which is equal to $|\alpha-\lambda_1|/|\alpha+\lambda_1|$ or $|\alpha-\lambda_2|/|\alpha+\lambda_2|$, has magnitude larger than $\rho(\sqrt{\lambda_1\lambda_2})$. Thus

$$\rho(\alpha) \geq |\det(\mathcal{M}(\alpha))|^{1/n} \geq \rho(\sqrt{\lambda_1\lambda_2}).$$

So, we can focus on those $\alpha \in J$. For each $\alpha \in J$, we can show that

$$\rho(\alpha) = \max\{\rho_1(\alpha),\ \rho_k(\alpha)\}.$$

Moreover, if $\alpha^* \in J$ is such that $\rho(\alpha^*) < \rho(\sqrt{\lambda_1\lambda_2})$, we can show that α^* must satisfy one of the three specified equations. □

REMARK 4.2. The second group of equations in Theorem 4.1 can be reduced to a group of quadratic equations and the last one can be reduced to a group of quartic equations with respect to $\beta = \alpha^2$, respectively, analogously to those in Remark 3.3.

As an illustration of Theorem 4.1 and Remark 4.2, we consider a simple example for which $\lambda_1 = 2$, $\lambda_2 = 1$, $q_1 = 1$, and $q_k = 2$. Obviously, $\alpha_0^* = \sqrt{2} \approx 1.414$ is the root of the first equation in Theorem 4.1. In addition, by straightforward computations, we know that the only positive roots of the group of the equations with respect to $q_1 = 1$ in Theorem 4.1 are

$$\alpha_1^* = 1, \quad \alpha_2^* = \sqrt{5} \approx 2.236$$

and

$$\alpha_3^* = \frac{\sqrt{6}}{6}\sqrt{\left(7 + \sqrt[3]{712+9\sqrt{5277}} + \frac{43}{\sqrt[3]{712+9\sqrt{5277}}}\right)} \approx 1.914,$$

and those with respect to $q_k = 2$ in Theorem 4.1 are

$$\alpha_4^* = 2, \quad \alpha_5^* = \frac{\sqrt{20}}{5} \approx 0.894$$

and

$$\alpha_6^* = \frac{\sqrt{6}}{6}\sqrt{\left(1 + \sqrt[3]{1477+36\sqrt{5277}} - \frac{167}{\sqrt[3]{1477+36\sqrt{5277}}}\right)} \approx 1.045.$$

We remark that now the second one in the group of equations with respect to $q_1 = 1$ is equivalent to $(\beta-1)(2\beta^3-7\beta^2+\beta-8) = 0$, and the second one in the group of equations with respect to $q_k = 2$ is equivalent to $(\beta-4)(2\beta^3-\beta^2+28\beta-32) = 0$. Based on Theorem 3.1, from direct calculations we have

$$\rho(\mathcal{M}(\alpha_0^*)) = 3-2\sqrt{2} \approx 0.172, \quad \rho(\mathcal{M}(\alpha_1^*)) = 0, \quad \rho(\mathcal{M}(\alpha_2^*)) = \frac{\sqrt{3}(7-3\sqrt{5})}{6} \approx 0.0842$$

and

$$\rho(\mathcal{M}(\alpha_3^*)) \approx 0.201, \quad \rho(\mathcal{M}(\alpha_4^*)) = 0, \quad \rho(\mathcal{M}(\alpha_5^*)) \approx 0.146, \quad \rho(\mathcal{M}(\alpha_6^*)) \approx 0.0899.$$

Therefore, for the HSS iteration method, the optimal parameter is $\alpha^* = 1$ or $\alpha^* = 2$ and the corresponding optimal convergence factor is $\rho(\mathcal{M}(\alpha^*)) = 0$. On the other hand, from Theorem 2.1 we can easily obtain

$$\tilde{\alpha} = \sqrt{2} \quad \text{and} \quad \sigma(\tilde{\alpha}) = 3-2\sqrt{2} \approx 0.172.$$

Obviously, it holds that $\rho(\mathcal{M}(\alpha^*)) < \sigma(\tilde{\alpha})$.

4.3. Our proof techniques can be used to handle the case when $\lambda_2 = 0$, which also occurs in applications; see [4] and the references therein. In such a case, we may normalize $\lambda_1 = 1$, and we always assume that $s = k$ to ensure that A is invertible. In such a case, we can use the analysis of Cases 2 and 4 in our proof of Theorem 4.1. Note that in this case, we have

$$\psi(\alpha) = \frac{\alpha - 1}{\alpha + 1}, \qquad \phi_j(\alpha) = \left\{ \frac{(\alpha^2 - q_j^2)\alpha}{(\alpha^2 + q_j^2)(\alpha + \lambda_1)} \right\}^2 \quad \text{for} \quad j = 1, k.$$

If $q_1 = q_k$, then A is unitarily similar to

$$A_1 \oplus \cdots \oplus A_k \oplus I_u$$

with

$$A_j = \begin{bmatrix} 1 & q_1 \\ -q_1 & 0 \end{bmatrix}, \qquad j = 1, 2, \ldots, k.$$

So, the analysis reduces to the two-by-two case, and Theorem 3.2 applies.

Suppose $q_1 > q_k > 0$. Then the optimal value α^* can be easily determined by checking whether $\rho_1(\alpha)$ and $\rho_k(\alpha)$ intersect at a point α^* such that

$$\phi_1(\alpha^*) - \psi(\alpha^*) = \phi_k(\alpha^*) - \psi(\alpha^*) \geq 0.$$

This happens if and only if $q_1 q_k \leq \frac{1}{2}(q_1 + q_k)$. In this case, $\alpha^* = \sqrt{q_1 q_k}$ is the optimal parameter, and

$$\rho(\mathcal{M}(\alpha^*)) = \frac{q_1 - q_k}{q_1 + q_k} \left(\frac{\sqrt{q_1 q_k}}{\sqrt{q_1 q_k} + 1} + \frac{\sqrt{(q_1 + q_k)^2 - 4q_1^2 q_k^2}}{(\sqrt{q_1 q_k} + 1)(q_1 - q_k)} \right).$$

Otherwise, $\alpha^* = \frac{q_1}{\sqrt{2q_1 - 1}}$ is the optimal parameter such that $\phi_1(\alpha^*) = \psi(\alpha^*) > \phi_k(\alpha^*)$ and

$$\rho(\mathcal{M}(\alpha^*)) = \frac{|q_1 - 1|}{q_1 + \sqrt{2q_1 - 1}}.$$

Note that the second case rarely appears in applications and its discussion was not included in [4]. Also, note that there were some typos in the formula of $\rho(\mathcal{M}(\alpha^*))$ for the first case in [4].

5. Estimation of optimal parameters for n-by-n matrices and numerical examples. In general, for a nonsymmetric and positive definite system of linear equations (1.1), the eigenvalues of its coefficient matrix A are evidently contained in the complex domain $\mathcal{D}_A := [\lambda_{\min}, \lambda_{\max}] \times \imath[-q, q]$, where $\imath$ is the imaginary unit, $\lambda_{\min}$ and $\lambda_{\max}$ are, respectively, the smallest and the largest eigenvalues of the Hermitian part H, and q is the largest module of the eigenvalues of the skew-Hermitian part S, of the coefficient matrix A. If a reduced (simpler and lower-dimensional) matrix A_R whose eigenvalues possess the same contour as the domain $\mathcal{D}_A$ is used to approximate the matrix A, then we may expect that the main mathematical and numerical properties of the HSS iteration method for the original linear system with the coefficient matrix A can be roughly preserved by the HSS iteration method applied to the linear

system with the reduced coefficient matrix A_R. A simple choice of the reduced matrix is given by

$$A_R = \begin{bmatrix} \lambda_{\max} & q \\ -q & \lambda_{\min} \end{bmatrix}$$

with $q = \|S\|$ or $q = \rho(H^{-1}S)\sqrt{\lambda_{\min}\lambda_{\max}}$. We can then use Theorem 3.2 and Corollary 3.5 to estimate the optimal parameter α^* of the HSS iteration method as follows.

ESTIMATION 5.1. [illegible] $A \in \mathbb{R}^{n\times n}$ [illegible] $H, S \in \mathbb{R}^{n\times n}$ [illegible] $\lambda_{\min} = \min\{\lambda \mid \lambda \in \lambda(H)\}$ $\lambda_{\max} = \max\{\lambda \mid \lambda \in \lambda(H)\}$ [illegible]

$$q = \|S\| \quad [\text{illegible}] \quad q = \rho(H^{-1}S)\sqrt{\lambda_{\min}\lambda_{\max}}.$$

[illegible]

$$(\alpha^2 + q^2)^2(\alpha^2 - \lambda_{\max}^2)(\alpha^2 - \lambda_{\min}^2) = (\alpha^2 - q^2)^2(\alpha^2 - \lambda_{\min}\lambda_{\max})^2$$

[illegible]

$$(\alpha^2 + q^2)^2(\lambda_{\max}^2 - \alpha^2)(\alpha^2 - \lambda_{\min}^2) = (\alpha^2 - q^2)^2(\alpha^2 - \lambda_{\min}\lambda_{\max})^2$$

[illegible] $\alpha^* > 0$ [illegible]

$$\rho(\mathcal{M}(\alpha^*)) = \min\{\rho(\mathcal{M}(\alpha)) \mid \alpha > 0\}.$$

[illegible] $\mathcal{M}(\alpha)$ [illegible] (2.2)

We first illustrate our estimates with the following example of a general nonsymmetric positive definite system of linear equations; see [2].

Consider the two-dimensional convection-diffusion equation

$$-(u_{xx} + u_{yy}) + \delta(u_x + u_y) = g(x, y)$$

on the unit square $[0, 1]\times[0, 1]$, with constant coefficient δ and subject to Dirichlet-type boundary conditions. When the five-point centered finite difference discretization is applied to it, we get the system of linear equations (1.1) with the coefficient matrix

$$A = T \otimes I + I \otimes T, \tag{5.1}$$

where the equidistant stepsize $h = \frac{1}{m+1}$ is used in the discretization on both directions and the natural lexicographic ordering is employed to the unknowns. In addition, $\otimes$ denotes the Kronecker product, T is a tridiagonal matrix given by

$$T = \text{tridiag}(-1 - R_e, 2, -1 + R_e),$$

and

$$R_e = \frac{\delta h}{2}$$

is the mesh Reynolds number. We remark that here the first-order derivatives are also approximated by the centered difference scheme.

From Lemma A.1 in [2, Appendix], we know that

$$\begin{cases} \gamma_{\min} \equiv \lambda_{\min} = \min\limits_{1\le j,k\le m} \lambda_{j,k}(H) = 4(1-\cos(\pi h)), \\ \gamma_{\max} \equiv \lambda_{\max} = \max\limits_{1\le j,k\le m} \lambda_{j,k}(H) = 4(1+\cos(\pi h)) \end{cases}$$

and

$$\min_{1\le j,k\le m} |\lambda_{j,k}(S)| = 0, \quad \max_{1\le j,k\le m} |\lambda_{j,k}(S)| = 4R_e\cos(\pi h).$$

Therefore, the optimal parameter $\tilde{\alpha}$ that minimizes the upper bound $\sigma(\alpha)$ of the convergence factor $\rho(\mathcal{M}(\alpha))$ of the HSS iteration method is given by

$$\tilde{\alpha} \equiv \sqrt{\gamma_{\min}\gamma_{\max}} = \sqrt{\lambda_{\min}\lambda_{\max}} = 4\sin(\pi h);$$

see Theorem 2.1.

In Table 1 we list the experimental optimal parameter α (denoted by $\alpha_{\exp}$), the estimated optimal parameter α (denoted by $\alpha_{\rm est}$) determined by Estimation 5.1, the upper-bound minimizer $\tilde{\alpha}$, and the corresponding spectral radii $\rho(\mathcal{M}(\alpha))$ of the HSS iteration matrix $\mathcal{M}(\alpha)$ for $\alpha = \alpha_{\exp}, \alpha_{\rm est}$, and $\tilde{\alpha}$. From this table we see that $\tilde{\alpha}$ always overestimates $\rho(\mathcal{M}(\alpha))$ when compared with $\alpha_{\rm est}$ and that $\alpha_{\rm est}$ yields quite a good approximation to $\alpha_{\exp}$.

TABLE 1
α versus $\rho(\mathcal{M}(\alpha))$ when $m = 32$.

δ	10	50	100	500	1000
$\alpha_{\exp}$	0.5195	2.2129	3.5606	12.0063	17.6346
$\rho(\mathcal{M}(\alpha_{\exp}))$	0.7794	0.4414	0.4635	0.6357	0.7161
α_{est}	0.5967	2.7084	5.1536	10.2948	15.0075
$\rho(\mathcal{M}(\alpha_{est}))$	0.8055	0.4582	0.4771	0.6374	0.7179
$\tilde{\alpha}$	0.3802	0.3802	0.3802	0.3802	0.3802
$\rho(\mathcal{M}(\tilde{\alpha}))$	0.8312	0.8702	0.8839	0.8999	0.9030

TABLE 2
IT and CPU when $m = 32$ and $\varepsilon = 10^{-6}$.

δ		10	50	100	500	1000
$\alpha_{\exp}$	IT	70	38	36	58	79
	CPU	0.7414	0.3905	0.6986	1.1147	1.5510
α_{est}	IT	66	44	45	55	72
	CPU	0.6842	0.4568	0.9238	1.0780	1.3991

In Table 2 we list the number of iterations (denoted by "IT") and the elapsed CPU time in seconds (denoted by "CPU") of the HSS iteration method when it is applied to the nonsymmetric positive definite system of linear equations (1.1) with coefficient matrix (5.1). From this table we see that the numerical results produced with $\alpha_{\rm est}$ coincide with those using $\alpha_{\exp}$, and the match is quite pertinent.

Here and in the next example, we choose the right-hand side vector f such that the exact solution of the system of linear equations is $(1, 1, \ldots, 1)^T \in \mathbb{R}^n$. In addition,

all runs are initiated from the initial vector $x^{(0)} = 0$ and terminated if the current iteration satisfies

$$\frac{\|f - Ax^{(k)}\|_2}{\|f - Ax^{(0)}\|_2} \leq \varepsilon.$$

The experiments are run in MATLAB (version 6.1) with a machine precision 10^{-16}. The machine used is a Pentium-III 500 personal computer with 256M memory.

Then we use the following example of two-by-two block system of linear equations to further confirm the above observations.

Consider the system of linear equations (1.1) with the coefficient matrix

$$A = \begin{bmatrix} B & E \\ -E^T & 0.5I \end{bmatrix}, \tag{5.2}$$

where

$$B = \begin{bmatrix} I \otimes T_H + T_H \otimes I & 0 \\ 0 & I \otimes T_H + T_H \otimes I \end{bmatrix} \in \mathbb{R}^{2m^2 \times 2m^2}, \tag{5.3}$$

$$E = \begin{bmatrix} I \otimes F \\ F \otimes I \end{bmatrix} \in \mathbb{R}^{2m^2 \times m^2}, \tag{5.4}$$

and

$$T_H = \text{tridiag}(-1, 2, -1) \in \mathbb{R}^{m \times m}, \qquad F = \delta h \cdot \text{tridiag}(-1, 1, 0) \in \mathbb{R}^{m \times m}, \tag{5.5}$$

with $h = \frac{1}{m+1}$ the discretization meshsize; see [4].

For this example, we have $r = 2m^2$ and $s = m^2$. Hence, the total number of variables is $r + s = 3m^2$.

In Table 3 we list the experimental optimal parameter α_{exp}, the estimated optimal parameter α_{est} determined by Estimation 5.1, and the corresponding spectral radii $\rho(\mathcal{M}(\alpha))$ of the HSS iteration matrix $\mathcal{M}(\alpha)$ for $\alpha = \alpha_{\text{exp}}$ and α_{est}. Here, considering Theorem 4.1 and the two-by-two block structure of the matrix A in (5.2), we may apply the equations in Estimation 5.1 to the q which is either the largest or the smallest singular value (denoted, respectively, by q_1 or q_k) of the matrix E, and consider the two points $\alpha = \sqrt{\lambda_{\min}\lambda_{\max}}$ and $\alpha = \sqrt{q_1 q_k}$, to obtain a more accurate estimate to the optimal iteration parameter for the HSS iteration method. From this table we can see that α_{est} yields quite a good approximation to α_{exp}.

TABLE 3
α versus $\rho(\mathcal{M}(\alpha))$.

δ	10			100		
m	16	24	32	16	24	32
α_{exp}	0.7457	0.5087	0.3849	1.0340	0.6553	0.4639
$\rho(\mathcal{M}(\alpha_{\text{exp}}))$	0.8291	0.8812	0.9090	0.7700	0.8490	0.8912
α_{est}	0.7350	0.5013	0.3802	0.7350	0.5013	0.3802
$\rho(\mathcal{M}(\alpha_{est}))$	0.8304	0.8816	0.9091	0.8304	0.8816	0.9091

In Table 4 we list the number of iterations and the elapsed CPU time of the HSS iteration method when it is applied to the two-by-two block system of linear equations (1.1) with the coefficient matrix (5.2)–(5.5). From this table we can see that the numerical results produced with α_{est} coincide with those using α_{exp}, and the match is quite pertinent.

6. Proof of Remark 3.3. The assertion concerning $\lambda_1 = \lambda_2$ and the assertion concerning (3.3) can be readily verified. We consider (3.4) and the reduced equation (3.5). Note that for $\alpha > 0$, the right-hand side of (3.4) is nonnegative, and the left-hand side is nonnegative on the interval $[\lambda_2, \lambda_1]$ only. So, all the positive solutions $\beta = \alpha^2$ of (3.5) lie in $[\lambda_2^2, \lambda_1^2]$. Define

$$f(\beta) = (\lambda_1^2 - \beta)(\beta - \lambda_2^2), \quad g_1(\beta) = (\beta - \lambda_1\lambda_2)^2, \quad g_2(\beta) = \frac{(\beta - q^2)^2}{(\beta + q^2)^2},$$

$$g(\beta) = g_1(\beta)g_2(\beta) \quad \text{and} \quad h(\beta) = f(\beta) - g(\beta)$$

for $\beta > 0$. Then β is a positive solution of (3.5) if and only if β is a positive solution of

$$h(\beta) = 0.$$

Obviously, the graph of $f(\beta)$ is a concave parabola which intersects the β-axis at $\beta = \lambda_2^2$ and λ_1^2, while the graph of $g_1(\beta)$ is a convex parabola touching the β-axis at $\beta = \lambda_1\lambda_2$. Note that $f(\beta) = g_1(\beta)$ has two solutions in the intervals $[\lambda_2^2, \lambda_1\lambda_2)$ and $((\lambda_1^2 + \lambda_2^2)/2, \lambda_1^2]$. The graph of $g(\beta)$ can be obtained from that of $g_1(\beta)$ by reducing the vertical height of each point by the factor $g_2(\beta) \in (0, 1)$. Thus, the solution of $f(\beta) = g_1(\beta)$ closer to λ_2^2 will move further left to a solution of $f(\beta) = g(\beta)$; the solution of $f(\beta) = g_1(\beta)$ closer to λ_1^2 will move further right to a solution of $f(\beta) = g(\beta)$.

We claim that $h(\beta)$ cannot have more than 2 positive solutions in $[\lambda_2^2, \lambda_1^2]$; equivalently, (3.5) cannot have more than 2 positive solutions in $[\lambda_2^2, \lambda_1^2]$.

First, we prove the claim if $q^2 < \lambda_2^2$ or $q^2 > \lambda_1^2$. Let $p(\beta)$ be the polynomial on the left-hand side of (3.5) divided by 2. Then the product of the roots of (3.5) is the constant term of $p(\beta)$ and equals the positive number $q^4\lambda_1^2\lambda_2^2$. So, if (3.5) has more than 2 positive roots, then it must have 4 positive roots, say, $\beta_1 \le \beta_2 \le \beta_3 \le \beta_4$. Suppose $p'(\beta)$ has zeros $\beta_1' \le \beta_2' \le \beta_3'$, $p''(\beta)$ has zeros $\beta_1'' \le \beta_2''$, and $p'''(\beta)$ has zero ${\beta_1}'''$. We have $\beta_1' \le \beta_1'' \le \beta_2' \le \beta_2'' \le \beta_3'$ and $\beta_1'' \le {\beta_1}''' \le \beta_2''$. Thus,

$$\beta_1' \le {\beta_1}''' \le \beta_3'.$$

Now, examining the constant terms of the polynomials $p'(\beta)/4$ and $p'''(\beta)/24$, we see that

$$\beta_1'\beta_2'\beta_3' = q^4(\lambda_1 + \lambda_2)^2/8 \tag{6.1}$$

and ${\beta_1}''' = (\lambda_1 + \lambda_2)^2/8$. If $q^2 < \lambda_2^2$, then $q^2 < \beta_1 \le \beta_1' \le \beta_2'$, and hence

$$\beta_1'\beta_2'\beta_3' > (q^2)(q^2)({\beta_1}''') = q^4(\lambda_1 + \lambda_2)^2/8,$$

which contradicts (6.1). Similarly, if $q^2 > \lambda_1^2$, then $q^2 > \beta_4 \geq \beta_3' \geq \beta_2'$, and hence

$$\beta_1'\beta_2'\beta_3' < \beta_1'''(q^2)(q^2) = q^4(\lambda_1 + \lambda_2)^2/8,$$

which again contradicts (6.1). Thus, our claim is proved in these cases.

Next, we assume that $q^2 \in [\lambda_2^2, \lambda_1^2]$. Then

$$g(\beta) = \frac{(\beta - q^2)^2(\beta - \lambda_1\lambda_2)^2}{(\lambda_1^2 - \beta)(\beta - \lambda_2^2)}$$

has two zeros in $[\lambda_2^2, \lambda_1^2]$, namely, $\beta = q^2$ and $\beta = \lambda_1\lambda_2$.

If $\lambda_2^2 \leq q^2 \leq \lambda_1\lambda_2$, then f is increasing on $[\lambda_2^2, (\lambda_1^2 + \lambda_2^2)/2]$ and $q^2 \leq \lambda_1\lambda_2 \leq (\lambda_1^2 + \lambda_2^2)/2$. So, f is increasing on $[\lambda_2^2, q^2]$. Since $g(\beta)$ is decreasing on $[\lambda_2^2, q^2]$ and the function $h(\beta)$ has different signs at λ_2^2 and q^2, it follows that $h(\beta) = 0$ has a root in $[\lambda_2\lambda_1, q^2]$. On $(q^2, (\lambda_1^2 + \lambda_2^2)/2]$, we have $f(\beta) > g_1(\beta) \geq g_1(\beta)g_2(\beta)$. Thus, $f(\beta) = g_1(\beta)g_2(\beta)$ has no root in this interval. Finally, on the interval $[(\lambda_1^2+\lambda_2^2)/2, \lambda_1^2]$, f is decreasing and $g(\beta)$ is increasing, and the function $h(\beta)$ assumes nonzero values with different signs at the end points. Thus, $f(\beta) = g_1(\beta)g_2(\beta)$ has a root in $((\lambda_1^2 + \lambda_2^2)/2, \lambda_1^2)$.

Suppose $\lambda_1\lambda_2 < q^2 \leq \lambda_1^2$. On $[\lambda_2^2, \lambda_1\lambda_2]$, f is increasing and $g(\beta)$ is decreasing. Moreover, since the function $h(\beta)$ assumes nonzero values with different signs at λ_2^2 and $\lambda_1\lambda_2$, it follows that $h(\beta) = 0$ has a root in $(\lambda_2^2, \lambda_1\lambda_2)$.

Suppose $q^2 < (\lambda_1^2 + \lambda_2^2)/2$. On $(\lambda_1\lambda_2, (\lambda_1^2 + \lambda_2^2)/2]$, we have $f(\beta) > g_1(\beta) \geq g_1(\beta)g_2(\beta)$. Thus, $f(\beta) = g_1(\beta)g_2(\beta)$ has no root in this interval. On the interval $[(\lambda_1^2+\lambda_2^2)/2, \lambda_1^2]$, f is decreasing and $g(\beta)$ is increasing, and the function $h(\beta)$ assumes nonzero values with different signs at the end points. Thus, $f(\beta) = g(\beta)$ has a root in $((\lambda_1^2 + \lambda_2^2)/2, \lambda_1^2)$.

Finally, if $q^2 \in [(\lambda_1^2 + \lambda_2^2)/2, \lambda_1^2]$, then for $\beta \in (\lambda_1\lambda_2, q^2)$ we have

$$(\beta - \lambda_1\lambda_2)^2/(\beta + q)^2 \in (0, 1),$$

and hence

$$f(\beta) > (\beta - q)^2 > g(\beta).$$

Thus, $f(\beta) = g(\beta)$ has no solution in $[(\lambda_1^2 + \lambda_2^2)/2, q^2)$. Now, on the interval $[q^2, \lambda_1^2]$, f is decreasing and $g(\beta)$ is increasing, and the function $h(\beta)$ assumes values with different signs at the end points. Thus, $f(\beta) = g(\beta)$ has a root in $[q^2, \lambda_1^2]$.

STEPSIZE CONTROL FOR MEAN-SQUARE NUMERICAL METHODS FOR STOCHASTIC DIFFERENTIAL EQUATIONS WITH SMALL NOISE*

WERNER RÖMISCH† AND RENATE WINKLER†

Abstract. A strategy for controlling the stepsize in the numerical integration of stochastic differential equations (SDEs) is presented. It is based on estimating the pth mean of local errors. The strategy leads to stepsize sequences that are identical for all computed paths. For the family of Euler schemes for SDEs with small noise, we derive computable estimates for the dominating term of the pth mean of local errors and show that the strategy becomes efficient for reasonable stepsizes. Numerical experience is reported for test examples including scalar SDEs and a stochastic circuit model.

Key words. stepsize control, stochastic differential equations, small noise, mean-square numerical methods

1. Introduction.

We consider Itô stochastic differential equations (SDEs) of the type

$$x(t) = x_0 + \int_{t_0}^{t} f(x(s), s)ds + \int_{t_0}^{t} G(x(s), s)dw(s), \quad t \in \mathcal{J}, \tag{1.1}$$

where $\mathcal{J} = [t_0, T]$, $f : \mathbb{R}^n \times \mathcal{J} \to \mathbb{R}^n$, $G : \mathbb{R}^n \times \mathcal{J} \to \mathbb{R}^{n\times m}$ are continuous functions, and, moreover, f has continuous derivatives with respect to x. w is an m-dimensional Wiener process on a given probability space $(\Omega, \mathcal{F}, P)$ with filtration $(\mathcal{F}_t)_{t\in\mathcal{J}}$, and x_0 is a given $\mathcal{F}_{t_0}$-measurable initial value, independent of the Wiener process. It is assumed that there exists a pathwise unique, strong solution $x(\cdot)$.

We study mean-square and, more generally, pth mean convergent numerical methods for solving (1.1) based on time discretization. Our work is motivated by practical SDE models in circuit simulation [24, 27, 28] that do not satisfy the commutativity condition for G and are large scale with respect to n and m. As function calls are costly, we look at variable stepsize methods of low order and propose a new strategy for selecting stepsizes.

Several variable stepsize strategies for SDEs were developed during the last few years. Most of them are based on pathwise arguments and lead to pathwise different stepsize sequences. Such approaches often require a separate convergence analysis, as the available convergence theory for SDEs (e.g., in the mean-square or weak sense) is based on properties of certain expectations rather than paths which are typically nonsmooth objects. The strategies for pathwise controlling stepsizes differ for each approach. The classical paper [7] proposes a pathwise strategy by comparing results

of a given integration scheme with those of a higher order method. Hence, at least the higher order method requires the (approximate) computation of multiple Itô-integrals. The approaches in [18, 19, 4] are also based on a comparison of two Runge–Kutta schemes of different order. In [15] conditions are provided that imply mean-square convergence of the Euler–Maruyama scheme with pathwise different stepsize sequences. A different approach was developed in [12, 13, 23], where the authors obtain stepsize sequences that are (mean-square and pth mean, respectively) optimal for asymptotically small stepsizes.

In contrast to the above approaches we present a stepsize control that is based on estimates of the mean square or the pth mean of the local discretization error. This is justified by the fact that pth mean global errors can be estimated by the corresponding local ones provided that the method is stable and the exact initial value is given. In particular, we analyze the errors for the family of Euler–Maruyama schemes in the case of small noise. The local errors are represented in terms of stochastic integrals. The terms containing multiple stochastic integrals become so small that they are negligible for realistic stepsizes, and the low asymptotic order of convergence $1/2$ of the Euler–Maruyama schemes is observed only for stepsizes that are far too small to be used. We provide estimates for the mean square or pth mean of the dominating local error term that does not cost additional evaluations of the coefficients of the SDE or their derivatives.

Implementing a numerical scheme for the approximate integration of SDEs requires also a discretization of the sample space. One can compute only a finite number of paths. To implement the stepsize control we used a heuristic approach, where the mean square of the local terms was approximated by the information available from an ensemble of approximate solution paths that is computed simultaneously. This way our approach leads to stepsize sequences that are identical for all computed paths.

The stepsize strategy was implemented for the drift-implicit Euler method and extensively tested on a set of test examples. The choice of this drift-implicit method allows us to study the effects of the stepsize selection on the accuracy, i.e., the global discretization error, and on the convergence behavior of Newton's method for solving the implicit nonlinear equations simultaneously. In the case of step rejections, the method described in [19] is used to ensure that the correct Wiener paths are followed. Our numerical experience of the stepsize strategy confirms its usefulness and potential for SDEs with small noise, and also provides some information on its limitations. As expected by the analysis, it turns out that the stepsize control works successfully for ranges of stepsizes that lead to reasonably accurate results but that are still not so small that the asymptotic order of convergence $\mathcal{O}(h^{\frac{1}{2}})$ dominates the error. The latter phenomenon for SDEs with small noise was experimentally observed in [1, 6]. In the test examples we have used deterministic initial values. In general we think of applications in which the initial value has at least small variance. For deterministic differential equations with random initial values a pathwise stepsize control should be more efficient.

Our paper is organized as follows. In section 2 we introduce the class of discretization schemes that will be considered in this paper. We recall basic pth mean stability results and conditions for pth mean convergence stated in terms of the pth mean of the local discretization error and of its rate of convergence as the stepsize tends to zero. Starting from this observation we present, in section 3, a strategy for selecting pathwise identical stepsize sequences by estimating the pth mean of the local error. For the special case of integrating SDEs with small noise by the family of Euler

schemes, we provide computable estimates for the local errors in section 4. Finally, in section 5 we report on numerical experience of test runs of an implementation of the stepsize control for the implicit Euler scheme.

2. Numerical stability, consistency, and convergence of discretization methods for SDEs. We consider the drift-implicit discretization scheme of the form

$$x_\ell = x_{\ell-1} + \varphi(x_{\ell-1}, x_\ell; t_{\ell-1}, h_\ell) + \psi(x_{\ell-1}; t_{\ell-1}, h_\ell, I_{t_{\ell-1},h_\ell}), \quad \ell = 1, \dots, N, \tag{2.1}$$

for solving (1.1) on the deterministic grid $t_0 < t_1 < \cdots < t_N = T$ with stepsizes $h_\ell := t_\ell - t_{\ell-1}$, $\ell = 1, \dots, N$. Here, φ and ψ are functions defined on $\mathbb{R}^n \times \mathbb{R}^n \times \mathcal{T}$ and $\mathbb{R}^n \times \mathcal{T} \times \mathbb{R}^{m_I}$ with $\mathcal{T} := \{(t,h) : t, t+h \in \mathcal{J},\ h \in \mathbb{R}_+\}$, respectively, and mapping to $\mathbb{R}^n$. By $I_{t,h}$ we denote a vector of m_I multiple stochastic integrals of the form

$$I_{i_1 \dots i_k; t,h} = \int_t^{t+h} \int_t^{s_1} \cdots \int_t^{s_{k-1}} dw_{i_1}(s_k) dw_{i_2}(s_{k-1}) \cdots dw_{i_k}(s_1),$$

where the indices $i_1, \dots, i_k$ are in $\{0, 1, \dots, m\}$, k is bounded by a certain finite order k_{max}, and $dw_0(s)$ corresponds to ds.

For example, the family of drift-implicit Euler schemes, sometimes also called stochastic θ-methods, is of the form

$$x_\ell := x_{\ell-1} + h_\ell(\theta f(x_\ell, t_\ell) + (1-\theta) f(x_{\ell-1}, t_{\ell-1})) + G(x_{\ell-1}, t_{\ell-1}) \Delta w_\ell, \quad \ell = 1, \dots, N, \tag{2.2}$$

where $\theta \in [0,1]$, and $\Delta w_\ell := w(t_\ell) - w(t_{\ell-1}) = (I_{i;t_{\ell-1},h_\ell})_{i=1}^m$. Hence, one has $k_{max} := 1$, $m_I := m$, and

$$\varphi(z, x; t, h) := h(\theta f(x, t+h) + (1-\theta) f(z, t)),$$
$$\psi(z; t, h, I_{t,h}) := G(z,t)(w(t+h) - w(t)) = \sum_{j=1}^m g_j(z,t) \int_t^{t+h} dw_j(s),$$

where $g_j(z,t)$, $j = 1, \dots, m$, are the columns of the matrix $G(z,t)$.

The family of drift-implicit Milstein schemes differs from the Euler schemes by an additional correction term for the stochastic part. The Milstein schemes are described by the same function φ, and $k_{max} := 2$, $m_I := m + m^2$, and

$$\psi(z; t, h, I_{t,h}) := G(z,t) \Delta w_{t,h} + \sum_{j=1}^m (g_{j_x} G)(z,t) I_{(j);t,h}, \tag{2.3}$$

where $\Delta w_{t,h} := w(t+h) - w(t) = (I_{i;t,h})_{i=1}^m$, and $I_{(j);t,h} := (I_{j,i;t,h})_{i=1}^m$.

For measuring errors in the discretization scheme we use the norm for pth order integrable random variables $z \in L_p(\Omega, \mathbb{R}^n)$, i.e., $\|z\|_{L_p} := (\mathbb{E}|z|^p)^{1/p}$, where the exponent $p \geq 1$ is properly chosen in the sense that the initial value x_0 has a pth order moment and in that it fits into the unknown statistical parameters of $x(\cdot)$, which have to be computed approximately. We start our analysis by stating a result concerning the pth mean stability of (2.1), which extends the fundamental result of Milstein [20, 21]. Its proof is given in [24, 27].

THEOREM 2.1. [illegible] $p \geq 1$ [illegible] x_0 [illegible] p [illegible]

- [illegible] h^1, L_1, L_2
- [illegible] $(t,h) \in \mathcal{T}$ $h \le h^1$ [illegible] $\mathcal{F}_t$ [illegible] $y, \tilde{y}$ [illegible]

  (A2) $$\mathbb{E}(\psi(y;t,h,I_{t,h}) - \psi(\tilde{y};t,h,I_{t,h})|\mathcal{F}_t) = 0,$$

  (A3) $$\mathbb{E}(|\psi(y;t,h,I_{t,h}) - \psi(\tilde{y};t,h,I_{t,h})|^p|\mathcal{F}_t) \le h^{\frac{p}{2}} L_3^p |y-\tilde{y}|^p,$$

  (A4) $$\mathbb{E}|\psi(0;t,h,I_{t,h})|^p < \infty$$

[illegible] $L_3 > 0$
[illegible] $a \ge 1$ [illegible] $h^0 > 0$ [illegible]
$S > 0$ [illegible] $\{t_0, t_1, \dots, t_N\}$ [illegible]
$h := \max_{\ell=1,\dots,N} h_\ell \le h^0$ [illegible] $h \cdot N \le a \cdot (T - t_0)$:
[illegible] $\mathcal{F}_{t_0}$ [illegible] $x_0^*, \tilde{x}_0$ [illegible] p [illegible]
[illegible] $\ell \in \{1, \dots, N\}$ [illegible] $\mathcal{F}_{t_\ell}$ [illegible] $d_\ell^*, \tilde{d}_\ell$ [illegible] p [illegible]

(2.4)
$$\tilde{x}_\ell = \tilde{x}_{\ell-1} + \varphi(\tilde{x}_{\ell-1}, \tilde{x}_\ell; t_{\ell-1}, h_\ell) + \psi(\tilde{x}_{\ell-1}; t_{\ell-1}, h_\ell, I_{t_{\ell-1},h_\ell}) + \tilde{d}_\ell, \quad \ell = 1, \dots, N,$$

[illegible] $\{\tilde{x}_\ell\}_{\ell=0}^N$ [illegible]
[illegible] $\{x_\ell^*\}_{\ell=1}^N$ $\{\tilde{x}_\ell\}_{\ell=0}^N$ [illegible]
$\{d_\ell^*\}_{\ell=1}^N$ $\{\tilde{d}_\ell\}_{\ell=1}^N$ [illegible] $d_\ell := d_\ell^* - \tilde{d}_\ell$ [illegible] $d_\ell = s_\ell + r_\ell$ [illegible]
$\mathbb{E}(s_\ell|\mathcal{F}_{t_{\ell-1}}) = 0$:

$$\mathbb{E} \max_{\ell=1,\dots,N} |x_\ell^* - \tilde{x}_\ell|^p \le S^p \left(\mathbb{E}|x_0^* - \tilde{x}_0|^p + \frac{\max\limits_{\ell=1,\dots,N} \mathbb{E}|s_\ell|^p}{h^{\frac{p}{2}}} + \frac{\mathbb{E} \max\limits_{\ell=1,\dots,N} |r_\ell|^p}{h^p} \right), \tag{2.5}$$

$$\max_{\ell=1,\dots,N} \mathbb{E}|x_\ell^* - \tilde{x}_\ell|^p \le S^p \left(\mathbb{E}|x_0^* - \tilde{x}_0|^p + \frac{\max\limits_{\ell=1,\dots,N} \mathbb{E}|s_\ell|^p}{h^{\frac{p}{2}}} + \frac{\max\limits_{\ell=1,\dots,N} \mathbb{E}|r_\ell|^p}{h^p} \right). \tag{2.6}$$

Extracting the pth root from (2.6) yields the stability inequality

(2.7)
$$\max_{\ell=1,\dots,N} \|x_\ell^* - \tilde{x}_\ell\|_{L_p} \le S \left(\|x_0^* - \tilde{x}_0\|_{L_p} + \max_{\ell=1,\dots,N} \|s_\ell\|_{L_p}/h^{\frac{1}{2}} + \max_{\ell=1,\dots,N} \|r_\ell\|_{L_p}/h \right).$$

The scheme (2.1) is called p[illegible] if it satisfies properties (2.5) and (2.6), respectively, in the above result. Furthermore, it is called p[illegible] of order $\gamma > 0$ if the [illegible] l_ℓ at step ℓ, i.e.,

(2.8)
$$l_\ell := x(t_\ell) - x(t_{\ell-1}) - \varphi(x(t_{\ell-1}), x(t_\ell); t_{\ell-1}, h_\ell) - \psi(x(t_{\ell-1}); t_{\ell-1}, h_\ell, I_{t_{\ell-1},h_\ell}),$$

satisfies the properties

$$\|l_\ell\|_{L_p} \le c \cdot h_\ell^{\gamma+\frac{1}{2}} \quad \text{and} \quad \|\mathbb{E}(l_\ell|\mathcal{F}_{t_{\ell-1}})\|_{L_p} \le \bar{c} \cdot h_\ell^{\gamma+1}, \quad \ell = 1, \dots, N,$$

with constants $c, \bar{c} > 0$ depending only on the SDE and its solution. Clearly, the local discretization error arises by inserting the exact solution $x(\cdot)$ into the numerical scheme.

By the global errors e_ℓ we denote the difference

$$e_\ell := x(t_\ell) - x_\ell$$

of the exact and approximate solution at time t_ℓ. The discretization scheme (2.1) for (1.1) is called p... of order $\gamma > 0$ if the global error $e_\ell := x(t_\ell) - x_\ell$ satisfies the property

$$\max_{\ell=1,\dots,N} \|e_\ell\|_{L_p} \le C \cdot h^\gamma, \quad \text{where } h := \max_{\ell=1,\dots,N} h_\ell,$$

with a grid-independent constant $C > 0$.

THEOREM 2.2. ... (2.1) ... (1.1) ... p... ... $\gamma > 0$ ... 2.1 ... (2.1) ... p... ... γ ... $x(t_\ell)$ ... $\tilde{x}_\ell$ ... (2.4) ...

$$\max_{\ell=1,\dots,N} \|x(t_\ell) - \tilde{x}_\ell\|_{L_p} \le S\left((c+\bar{c})h^\gamma + \max_{\ell=1,\dots,N} \delta_\ell/h^{1/2} + \max_{\ell=1,\dots,N} \bar{\delta}_\ell/h\right), \tag{2.9}$$

... $\delta_\ell := \|\tilde{d}_\ell\|_{L_p}$, $\bar{\delta}_\ell := \|\mathbb{E}(\tilde{d}_\ell|\mathcal{F}_{t_{\ell-1}})\|_{L_p}$, ... $\tilde{d}_\ell$ ... (2.4).

... The assertion follows by applying the triangle inequality

$$\max_{\ell=1,\dots,N} \|x(t_\ell) - \tilde{x}_\ell\|_{L_p} \le \max_{\ell=1,\dots,N} \|x(t_\ell) - x_\ell\|_{L_p} + \max_{\ell=1,\dots,N} \|x_\ell - \tilde{x}_\ell\|_{L_p}$$

and the stability estimate (2.5) once to $x(t_\ell)$ related to the perturbations l_ℓ and once again to $\tilde{x}_\ell$ related to the perturbations $\tilde{d}_\ell$. The pth mean convergence follows as a special case of (2.9) for $d_\ell^* = l_\ell$, $\tilde{d}_\ell = 0$. By means of $r_\ell = \mathbb{E}(l_\ell|\mathcal{F}_{t_{\ell-1}})$, a suitable splitting $d_\ell = l_\ell = s_\ell + r_\ell$ is realized. □

The general results immediately apply to well-known schemes for SDEs. We illustrate this for the families of drift-implicit Euler and Milstein schemes. Both schemes fit into the framework of (2.1). By checking the assumptions of Theorem 2.1 we observe that both are pth mean stable: (A1) follows from the Lipschitz continuity of the drift coefficient f, (A2) is satisfied due to the explicit, nonanticipative discretization of the diffusion term, (A3) follows from the Lipschitz continuity of the diffusion coefficient G (and in the case of the Milstein scheme of the functions $g_{j_x}G$), and (A4) is a more technical assumption, which is satisfied since the function $G(0,\cdot)$ (and the functions $(g_{j_x}G)(0,\cdot)$) are bounded on the compact interval $\mathcal{J}$. Summarizing we have the following.

PROPOSITION 2.3. ... f ... G ... x ... (2.2) ... p... ... g_{j_x} $j = 1, \dots, m$ ... $g_{j_x} \cdot G$ ... x ... (2.3) ... p...

From the literature (see, e.g., [21]) it is known that the Euler schemes (2.2) are mean-square consistent of order 1/2 if, in addition, the coefficients are Hölder continuous with exponent 1/2 with respect to t. The Milstein schemes are mean-square consistent of order 1 if the functions f and G are sufficiently smooth. Appealing to Theorem 2.2 then provides the known mean-square convergence of the Euler schemes of order 1/2 and of the Milstein schemes of order 1.

3. Stepsize control based on the *p*th mean of local errors. For the efficient numerical integration of applied nonlinear SDEs, a reasonable stepsize control is indispensable. The problem was addressed in a number of recent papers, e.g., [3, 4, 7, 16, 18, 19]. Most of them suggest individual stepsize sequences for every path. Our approach is rigorously based on the stability and convergence results presented in the previous section. It leads to adaptive stepsize sequences that are uniform for all computed paths.

By means of the stability inequality (2.7) we know that the pth mean of the global errors $e_\ell := x(t_\ell) - x_\ell$ can be estimated by a term that is proportional to the pth mean of the local errors l_ℓ. Here, we assume that the initial value x_0 is given exactly. Therefore, a natural approach consists of controlling the local error term

$$\eta_\ell := \max\{\|s_\ell\|_{L_p}/h_\ell^{1/2}\,, \|r_\ell\|_{L_p}/h_\ell\}, \text{ where } l_\ell = s_\ell + r_\ell,\ \mathbb{E}(s_\ell|\mathcal{F}_{t_{\ell-1}}) = 0, \tag{3.1}$$

according to a given tolerance. Controlling this term requires some insight into its behavior. Clearly, we have $\eta_\ell = \mathcal{O}(h_\ell^\gamma)$ for a method that is pth mean convergent of order γ. However, for problems with small noise and stepsizes that cannot be considered asymptotically small and are of interest, η_ℓ may even be dominated by a term $\kappa_\ell \cdot h_\ell^{\bar\gamma}$, where $\bar\gamma \geq \gamma$ and κ_ℓ is a slowly varying factor (cf. section 4). The insight into the behavior of η_ℓ should lead to expressions for the error constant in the form $\kappa_\ell = \|k_\ell\|_{L_p}$ with $k_\ell = \chi(x_{\ell-1}, x_\ell, t_{\ell-1}, t_\ell)$.

Given that, for an interesting range of stepsizes h_ℓ, the local error term η_ℓ is dominated by

$$\eta_\ell \leq \kappa_\ell \cdot h_\ell^{\bar\gamma}, \quad \kappa_\ell = \|k_\ell\|_{L_p} = \|\chi(x_{\ell-1}, x_\ell, t_{\ell-1}, t_\ell)\|_{L_p}; \tag{3.2}$$

the stepsizes should be chosen according to the following conceptual algorithm.

ALGORITHM 3.1. Given the initial value $x_0 \in L_p(\Omega)$ at t_0, an initial stepsize h_1 and a tolerance tol, set $\ell := 1$.

(1) Solve the system

$$x_\ell = x_{\ell-1} + \varphi(x_{\ell-1}, x_\ell; t_{\ell-1}, h_\ell) + \psi(x_{\ell-1}; t_{\ell-1}, h_\ell, I_{t_{\ell-1},h_\ell})$$

for $x_\ell \in L_p(\Omega)$.

(2) Set

$$\bar\eta_\ell := h_\ell^{\bar\gamma}\|\chi(x_{\ell-1}, x_\ell, t_{\ell-1}, t_\ell)\|_{L_p}. \tag{3.3}$$

(3) Apply a control strategy that aims at matching the tolerance multiplied by a safety factor, say 0.8, with the proposed new stepsize. For example, the elementary control leads to

$$\frac{h_{new}}{h_\ell} := \left(\frac{0.8 \cdot \text{tol}}{\bar\eta_\ell}\right)^{1/\bar\gamma} \tag{3.4}$$

for $\ell \geq 2$; the proportional integral control PI34 (cf. [10, 25]) leads to

$$\frac{h_{new}}{h_\ell} := \left(\frac{0.8 \cdot \text{tol}}{\bar\eta_\ell}\right)^{0.3/\bar\gamma} \left(\frac{\bar\eta_{\ell-1}}{\bar\eta_\ell}\right)^{0.4/\bar\gamma}. \tag{3.5}$$

(4) If $\bar\eta_\ell \leq$ tol, accept the step.
If $t_\ell \geq T$, stop, else set $\ell := \ell + 1$, $h_\ell := h_{new}$ and go to (1).
If $\bar\eta_\ell >$ tol, reject the step and repeat it with the smaller stepsize $h_\ell := h_{new}$ that results from (3.4).

We emphasize that a stepsize sequence generated by Algorithm 3.1 is deterministic, since $\|\chi(x_{\ell-1}, x_\ell, t_{\ell-1}, t_\ell)\|_{L_p}$ is deterministic, though $x_{\ell-1}, x_\ell$ are random variables. Hence, Theorems 2.1 and 2.2 apply. If Algorithm 3.1 is realized and the computed quantities $\bar\eta_\ell$ are really dominating the local error term η_ℓ, say, e.g., $\eta_\ell \le 1.2\,\bar\eta_\ell$, then we have

$$\max_{\ell=1,\dots,N} \|x(t_\ell) - x_\ell\|_{L_p} \le 2.4\, S \cdot \mathrm{tol}$$

by the pth mean stability inequality (2.7) following Theorem 2.1. Even if the actual errors η_ℓ show a smaller order than the quantities $\bar\eta_\ell$ used, and only a relation like $\eta_\ell \le \mathrm{const} \cdot \bar\eta_\ell^{\,\beta}$, $\beta \in (0,1)$, is true, we still have

$$\max_{\ell=1,\dots,N} \|x(t_\ell) - x_\ell\|_{L_p} \le 2\,\mathrm{const} \cdot S \cdot \mathrm{tol}^{\beta}\,.$$

Intending to make use of this theoretical result for practical implementations, one faces several questions.

First, how large is the stability constant S? Of course, it is problem dependent. A more detailed look into the proof of Theorem 2.1, together with Proposition 2.3, shows that S behaves essentially as $e^{L(T-t_0)}$, where L is a Lipschitz constant for the drift and diffusion coefficients f and G (and of $(g_j)'_x \cdot G$ for the Milstein schemes) of the problem. By analogy with deterministic ODEs one may consider the problem as nonstiff and numerically well-posed, as long as $e^{L(T-t_0)}$ is moderate. Modifications for stiff problems are desirable, but go beyond the scope of this paper.

Second, how can the observed order $\bar\gamma$ and the error function χ be determined, and what conditions guarantee an estimate like $\eta_\ell \le 1.2\,\bar\eta_\ell$? These questions are discussed for the family of Euler–Maruyama schemes in the next section.

Finally, we discuss implementation issues of the conceptual algorithm, Algorithm 3.1. Of course, any implementation requires a finite number of realizations of the random variables. Here, we consider an ensemble of M paths starting from M samples $x_0^1, \dots, x_0^M$ of the initial value. Starting from $\ell = 1$, the next elements $x_\ell^1, \dots, x_\ell^M$ of the M paths are computed by solving the nonlinear equations

$$x_\ell^i = x_{\ell-1}^i + \varphi(x_{\ell-1}^i, x_\ell^i; t_{\ell-1}, h_\ell) + \psi(x_{\ell-1}^i; t_{\ell-1}, h_\ell, I^i_{t_{\ell-1},h_\ell}), \quad i = 1, \dots, M,$$

where $I^i_{t_{\ell-1},h_\ell}$ are samples of the corresponding stochastic integrals.

Next, the L_p-norm $\|\chi(x_{\ell-1}, t_{\ell-1}, x_\ell, t_\ell)\|_{L_p}$ in step (2) of Algorithm 3.1 is estimated by using the M samples of $x_{\ell-1}$ and x_ℓ, namely, by

$$\bar\kappa_\ell := \left(\frac{1}{M} \sum_{i=1}^{M} |\chi(x_{\ell-1}^i, x_\ell^i, t_{\ell-1}, t_\ell)|^p \right)^{\frac{1}{p}}. \tag{3.6}$$

Set

$$\hat\eta_\ell := h_\ell^{\bar\gamma} \bar\kappa_\ell \tag{3.7}$$

and perform steps (3) and (4) of Algorithm 3.1 with $\bar\eta_\ell$ replaced by $\hat\eta_\ell$. In the case of step rejections, the information computed so far is stored and used to compute intermediate values according to the strategy in [18, 19]. For a scheme (2.1), which uses only the Wiener increments $\Delta w_\ell = w(t_\ell) - w(t_{\ell-1})$, the computation of the intermediate values of the Wiener process is done as follows: Given $\Delta w_h := w(t+h) -$

$w(t)$ for some $t \in \mathbb{R}_+$ and $h > 0$, and $h = h_1 + h_2$, $h_1 > 0$, $h_2 > 0$, the Wiener increments

$$\Delta w_{h_1} = w(t + h_1) - w(t) \quad \text{and} \quad \Delta w_{h_2} = w(t + h_1 + h_2) - w(t + h_1)$$

are simulated according to the formulas

$$\Delta w_{h_1} = \frac{h_1}{h}\Delta w_h + \sqrt{\frac{h_1 h_2}{h}}\nu, \quad \Delta w_{h_2} = \frac{h_2}{h}\Delta w_h - \sqrt{\frac{h_1 h_2}{h}}\nu, \quad \nu \sim N(0, I_m).$$

In this way, the estimate (3.7) of (3.3) leads to estimates of the next stepsize and, hence, of the whole grid $t_0, t_1, \ldots, t_N$. Though all computed paths $(x_0^i, x_1^i, \ldots, x_N^i)$, $i = 1, \ldots, M$, are determined by using the same stepsizes $h_1, \ldots, h_N$, the stepsize sequence is no longer deterministic and, due to possible step rejections, the computed grid-points do not need to be stopping times. The estimate of the grid depends on the M paths, and its quality clearly depends on the sample size M as well as on the smallness of the noise. The resulting implementable algorithm represents a theory-based heuristic stepsize control.

The numerical results in section 5 show that a relatively small number $M = 100$ already provides good results for SDEs with small noise.

4. Local error estimates for the family of Euler schemes for SDEs with small noise. There are important applications of SDEs with small noise, where the diffusion coefficients are orders of magnitude smaller than the drift coefficients. For such problems the asymptotic order of convergence is too pessimistic for a reasonable range of stepsizes. Special numerical methods are constructed in [22], taking into account the smallness of the stochastic parts in such systems. Here, we will deal with the family of Euler schemes and present an efficient stepsize control based on the pth mean of local errors.

Following along the lines of [22] we let the SDE with small noise be of the form

$$x(t) = x_0 + \int_{t_0}^{t} f(x(s), s)ds + \int_{t_0}^{t} \epsilon\tilde{G}(x(s), s)dw(s), \quad t \in \mathcal{J}, \tag{4.1}$$

where $f : \mathbb{R}^n \times \mathcal{J} \to \mathbb{R}^n$, $\tilde{G} : \mathbb{R}^n \times \mathcal{J} \to \mathbb{R}^{n\times m}$ are functions satisfying the assumptions introduced in section 1 for f and G, and ϵ is a small parameter.

The family of drift-implicit Euler schemes with parameter $\theta \in [0, 1]$ for solving (4.1) on the deterministic grid $t_0 < t_1 < \cdots < t_N = T$ with stepsizes $h_\ell := t_\ell - t_{\ell-1}$, $\ell = 1, \ldots, N$, has the form

$$x_\ell = x_{\ell-1} + h_\ell\big(\theta f(x_\ell, t_\ell) + (1 - \theta)f(x_{\ell-1}, t_{\ell-1})\big) + \epsilon\tilde{G}(x_{\ell-1}, t_{\ell-1})\Delta w_\ell, \quad \ell = 1, \ldots, N, \tag{4.2}$$

where $\Delta w_\ell = w(t_\ell) - w(t_{\ell-1}) \sim N(0, h_\ell I_m)$.

In order to derive estimates for the local discretization error l_ℓ of (4.2), we first establish, similarly to [22], a representation of l_ℓ in terms of certain multiple stochastic integrals obtained by the Itô–Taylor expansion. The L_p-norm of these stochastic integrals is then characterized in terms of $\mathcal{O}(h_\ell^{k/2}\epsilon^q)$ for some $k, q \in \mathbb{N} \cup \{0\}$. Finally, we discuss which terms are dominating for interesting ranges of stepsizes and present computable estimates for the dominating terms.

4.1. Estimating local errors by Itô–Taylor expansion. In order to characterize the conditions on f and $\tilde{G}$ that are needed in the following, we introduce the classes C_L and $C^{s,s-1}$, $s \in \mathbb{N}$, of functions from $\mathbb{R}^n \times \mathcal{J}$ to $\mathbb{R}^n$. The class C_L contains all continuous functions that are Lipschitz continuous with a uniform constant with respect to the first variable. $C^{s,s-1}$ is the class of all functions having continuous partial derivatives up to order $s-1$ and, in addition, continuous partial derivatives of order s with respect to the first variable.

Let $x(\cdot)$ be a solution of the SDE (4.1) and y be a function in $C^{2,1}$. Then Itô's formula provides the expansion

$$y(x(t),t) - y(x_0,t_0) = \int_{t_0}^{t} \left(y_t + y_x f + \epsilon^2 \frac{1}{2} \sum_{r=1}^{m} \sum_{i,j=1}^{n} y_{x_i x_j} \tilde{g}_{ri} \tilde{g}_{rj} \right)(x(s),s)ds + \epsilon \sum_{r=1}^{m} \int_{t_0}^{t} (y_x \tilde{g}_r)(x(s),s) dw_r(s), \quad t \in \mathcal{J}. \tag{4.3}$$

Following [22] we introduce $m+1$ operators Λ_0 and Λ_r, $r = 1, \dots, m$, defined on $C^{2,1}$ and $C^{1,0}$, respectively, by

$$\Lambda_0 y = y_t + y_x f + \epsilon^2 \frac{1}{2} \sum_{r=1}^{m} \sum_{i,j=1}^{n} y_{x_i x_j} \tilde{g}_{ri} \tilde{g}_{rj}, \quad \Lambda_r y = y_x \tilde{g}_r, \quad r = 1, \dots, m.$$

Then the Itô formula (4.3) reads

$$y(x(t),t) - y(x_0,t_0) = \int_{t_0}^{t} \Lambda_0 y(x(s),s) ds + \epsilon \sum_{r=1}^{m} \int_{t_0}^{t} \Lambda_r y(x(s),s) dw_r(s), \quad t \in \mathcal{J}. \tag{4.4}$$

For $y \in C_L$, and similarly to section 2, we denote multiple stochastic integrals over intervals $[t, t+h] \subseteq \mathcal{J}$ by

$$I_{i_1 \dots i_j;t,h}(y) = \int_t^{t+h} \int_t^{s_1} \cdots \int_t^{s_{j-1}} y(x(s_j), s_j) dw_{i_1}(s_j) \cdots dw_{i_{j-1}}(s_2) dw_{i_j}(s_1),$$

where $i_1, \dots, i_j$ take values in $\{0, \dots, m\}$, and $dw_0(s)$ is understood to mean ds. As the function y has linear growth with respect to the first variable, the stochastic integrals are well defined.

LEMMA 4.1. [illegible] $p \geq 1$ [illegible] x_0 [illegible] p [illegible] $(t,h) \in \mathcal{T}$ [illegible] $i_j \in \{1, \dots, m\}$ $j = 1, \dots, k$ [illegible] $y \in C_L$ [illegible]

$$\mathbb{E}(I_{i_1 \dots i_k;t,h}(y) | \mathcal{F}_t) = 0 \quad \text{if } i_j \neq 0 \text{ for } j \in \{1, \dots, k\},$$

$$\|\mathbb{E}(I_{i_1 \dots i_k;t,h}(y) | \mathcal{F}_t)\|_{L_p} \leq \|I_{i_1 \dots i_k;t,h}(y)\|_{L_p} = \mathcal{O}(h^{\sum_{j=1}^{k} \nu_j}), \quad \nu_j = \begin{cases} 1, & i_j = 0, \\ \frac{1}{2}, & i_j \neq 0. \end{cases}$$

[illegible]. The first property is well known. The first estimate in the second assertion is due to properties of the conditional expectation. For $p = 2$ the second part is proved in [21, Lemma 2.1]. For $1 \leq p < 2$ it is a consequence of the estimate $\|\cdot\|_{L_p} \leq \|\cdot\|_{L_2}$.

Now, let $p > 2$. For $i_1 = 0$ we obtain by Hölder's inequality that

$$\|I_{0,i_2 \dots i_k;t,h}(y)\|_{L_p}^p = \mathbb{E}(|I_{0,i_2 \dots i_k,0;t,h}(y)|^p) \leq \left(\mathbb{E} \int_t^{t+h} |I_{i_2 \dots i_k;t,s_1-t}(y)| ds_1 \right)^p$$

$$\leq h^{\frac{p}{q}} \int_t^{t+h} \mathbb{E}(|I_{i_2 \dots i_k;t,s_1-t}(y)|^p) ds_1,$$

where $\frac{1}{q}+\frac{1}{p}=1$. Hence, for $\|I_{0,i_2\dots i_k;t,h}(y)\|^p_{L_p}$ we obtain the order $\mathcal{O}(h^{\frac{p}{q}+1})=\mathcal{O}(h^p)$.

For $i_1\neq 0$ we make use of estimates for the pth mean of stochastic integrals (see [8, section 1.4, Theorem 6], [17, section 1.7, Theorem 7.1]) and have

$$\|I_{i_1\dots i_k;t,h}(y)\|^p_{L_p}\leq\left(\frac{1}{2}p(p-1)\right)^{\frac{p}{2}}h^{\frac{p-2}{2}}\int_t^{t+h}\mathbb{E}(|I_{i_2\dots i_k;t,t-s_1}(y)|^p)ds_1.$$

Hence, in this case we obtain the order $\mathcal{O}(h^{\frac{p-2}{2}+1})=\mathcal{O}(h^{\frac{p}{2}})$.

Repeating these arguments successively, and using that the function y has linear growth and, thus, that $y(x(\cdot),\cdot)$ has a finite pth mean, completes the proof. □

PROPOSITION 4.2. [illegible] $f\in C^{4,3}$ [illegible] $\tilde g_r\in C^{2,1}$ $r=1,\dots,m$ [illegible] $\Lambda_0\Lambda_0 f$ $\Lambda_0\tilde g_r$ $\Lambda_r\Lambda_0 f$ $\Lambda_r f$ [illegible] $\Lambda_k\tilde g_r$ $k,r=1,\dots,m$ [illegible] C_L [illegible] l_ℓ ([illegible] (2.8)) [illegible] (4.2) [illegible] ℓ [illegible]

$$l_\ell=s_\ell+r_\ell \quad [illegible] \quad \mathbb{E}(s_\ell|\mathcal{F}_{t_{\ell-1}})=0$$

[illegible]

$$\|r_\ell\|_{L_p}/h_\ell=h_\ell\left|\theta-\frac{1}{2}\right|\|(\Lambda_0 f)_{t_{\ell-1}}\|_{L_p}+\mathcal{O}(h_\ell^2),$$
$$\|s_\ell\|_{L_p}/h_\ell^{1/2}=\epsilon\mathcal{O}(h_\ell)+\epsilon^2\mathcal{O}(h_\ell^{1/2}).$$

[illegible]. For $y\in C_L$ we make use of the following abbreviations:

$$y_s:=y(x(s),s),\quad I_{i_1\dots i_j}(y)=I_{i_1\dots i_j;t_{\ell-1},h_\ell}(y).$$

By reformulating the local error and by expanding all of its components at the pair $(x(t_{\ell-1}),t_{\ell-1})$ using (4.4) and the smoothness properties $f,\tilde g_r\in C^{2,1}$, $r=1,\dots,m$, we obtain

$$\begin{aligned}
l_\ell &= x(t_\ell)-x(t_{\ell-1})-h_\ell\big(\theta f(x(t_\ell),t_\ell)+(1-\theta)f(x(t_{\ell-1}),t_{\ell-1})\big)-\epsilon\tilde G(x(t_{\ell-1}),t_{\ell-1})\Delta w_\ell\\
&=\int_{t_{\ell-1}}^{t_\ell}f_s ds-h_\ell\big(\theta f_{t_\ell}+(1-\theta)f_{t_{\ell-1}}\big)+\int_{t_{\ell-1}}^{t_\ell}\epsilon\tilde G_s dw(s)-\epsilon\tilde G_{t_{\ell-1}}\Delta w_\ell\\
&=\int_{t_{\ell-1}}^{t_\ell}\left\{f_{t_{\ell-1}}+\int_{t_{\ell-1}}^{s}(\Lambda_0 f)_\tau d\tau+\epsilon\sum_{r=1}^m\int_{t_{\ell-1}}^{s}(\Lambda_r f)_\tau dw_r(\tau)\right\}ds\\
&\quad-\theta h_\ell\left\{f_{t_{\ell-1}}+\int_{t_{\ell-1}}^{t_\ell}(\Lambda_0 f)_\tau d\tau+\epsilon\sum_{r=1}^m\int_{t_{\ell-1}}^{t_\ell}(\Lambda_r f)_\tau dw_r(\tau)\right\}-(1-\theta)h_\ell f_{t_{\ell-1}}\\
&\quad+\epsilon\sum_{r=1}^m\int_{t_{\ell-1}}^{t_\ell}\left\{\int_{t_{\ell-1}}^{s}(\Lambda_0\tilde g_r)_\tau d\tau+\epsilon\sum_{k=1}^m\int_{t_{\ell-1}}^{s}(\Lambda_k\tilde g_r)_\tau dw_k(\tau)\right\}dw_r(s)\\
&=I_{00}(\Lambda_0 f)-\theta h_\ell I_0(\Lambda_0 f)+\epsilon\sum_{r=1}^m\big(I_{0r}(\Lambda_r f)-\theta h_\ell I_r(\Lambda_r f)I_{r0}(\Lambda_0\tilde g_r)\big)+\epsilon^2\sum_{r,k=1}^m I_{rk}(\Lambda_k\tilde g_r),
\end{aligned}$$

and, hence, a representation of the local error in terms of (multiple) stochastic integrals.

Next, we study the leading term $I_{00}(\Lambda_0 f) - \theta h_\ell I_0(\Lambda_0 f)$ of this representation. Since $\Lambda_0 f$ belongs to $C^{2,1}$, we may use the Itô formula (4.4) again and obtain

(4.5)
$$\Lambda_0 f_\tau = \Lambda_0 f_{t_{\ell-1}} + \int_{t_{\ell-1}}^{\tau} (\Lambda_0\Lambda_0 f)_s ds + \epsilon \sum_{r=1}^{m} \int_{t_{\ell-1}}^{\tau} (\Lambda_r \Lambda_0 f)_s dw_r(s)), \quad \tau \in [t_{\ell-1}, t_\ell],$$

which is taken to compute the desired (multiple) stochastic integrals and the whole leading term, respectively, i.e.,

$$I_{00}(\Lambda_0 f) = \frac{1}{2} h_\ell^2 (\Lambda_0 f)_{t_{\ell-1}} + I_{000}(\Lambda_0\Lambda_0 f) + \epsilon \sum_{r=1}^{m} I_{00r}(\Lambda_r\Lambda_0 f),$$

$$I_0(\Lambda_0 f) = h_\ell (\Lambda_0 f)_{t_{\ell-1}} + I_{00}(\Lambda_0\Lambda_0 f) + \epsilon \sum_{r=1}^{m} I_{0r}(\Lambda_r\Lambda_0 f),$$

$$\begin{aligned} I_{00}(\Lambda_0 f) - \theta h_\ell I_0(\Lambda_0 f) = h_\ell^2 \left(\frac{1}{2} - \theta\right) (\Lambda_0 f)_{t_{\ell-1}} + I_{000}(\Lambda_0\Lambda_0 f) - \theta h_\ell I_{00}(\Lambda_0\Lambda_0 f) \\ + \epsilon \sum_{r=1}^{m} \big(I_{00r}(\Lambda_r\Lambda_0 f) - \theta h_\ell I_{0r}(\Lambda_r\Lambda_0 f)\big). \end{aligned}$$

Now, we split $l_\ell = s_\ell + r_\ell$, where s_ℓ is composed of all integral terms with at least one nonzero index. Then we have $\mathbb{E}(s_\ell | \mathcal{F}_{t_{\ell-1}}) = 0$, and

$$\begin{aligned} r_\ell &= h_\ell^2 \left(\frac{1}{2} - \theta\right) (\Lambda_0 f)_{t_{\ell-1}} + I_{000}(\Lambda_0\Lambda_0 f) - \theta h_\ell I_{00}(\Lambda_0\Lambda_0 f), \\ s_\ell &= \epsilon \sum_{r=1}^{m} \big(I_{00r}(\Lambda_r\Lambda_0 f) - \theta h_\ell I_{0r}(\Lambda_r\Lambda_0 f)\big) \\ &\quad + \epsilon \sum_{r=1}^{m} \big(I_{0r}(\Lambda_r f) - \theta h_\ell I_r(\Lambda_r f) + I_{r0}(\Lambda_0 \tilde{g}_r)\big) + \epsilon^2 \sum_{r,k=1}^{m} I_{rk}(\Lambda_k \tilde{g}_r). \end{aligned}$$

Since all the functions $\Lambda_0\Lambda_0 f$, $\Lambda_0 \tilde{g}_r$, $\Lambda_r\Lambda_0 f$, $\Lambda_r f$, and $\Lambda_k \tilde{g}_r$, $k, r = 1, \ldots, m$, appearing as integrands of multiple stochastic integrals, satisfy the assumptions of Lemma 4.1, we may use the lemma repeatedly to obtain the assertion. □

4.2. Suggestions for local error estimates. The previous result enables us to study the local error term η_ℓ for special relations between ϵ and the stepsizes h_ℓ. Unless $\theta = 1/2$ for the trapezoidal rule, the dominating term of $\|r_\ell\|_{L_p}/h_\ell$ is

$$h_\ell \left|\theta - \frac{1}{2}\right| \|(\Lambda_0 f)_{t_{\ell-1}}\|_{L_p} = h_\ell \left|\theta - \frac{1}{2}\right| \|(f_t + f_x f)_{t_{\ell-1}}\|_{L_p} + \epsilon^2 \mathcal{O}(h_\ell),$$

and hence,

(4.6)
$$\eta_\ell = \bar{\eta}_\ell^* + \mathcal{O}(\epsilon^2 h_\ell^{1/2} + \epsilon h_\ell + h_\ell^2), \quad \bar{\eta}_\ell^* := h_\ell \left|\theta - \frac{1}{2}\right| \|(f_t + f_x f)(x(t_{\ell-1}), t_{\ell-1})\|_{L_p}.$$

Substituting the exact solution value $x(t_{\ell-1})$ with its numerical approximation $x_{\ell-1}$ does not lead to perturbations that are larger than $\mathcal{O}(\epsilon^2 h^{1/2} + \epsilon h + h^2)$. This motivates

the choice of $\bar{\gamma} = 1$ and $\chi(z, x, s, t) := |\theta - \frac{1}{2}|(f_t + f_x f)(z, s)$ for the definition of $\bar{\eta}_\ell$ in (3.3). We assume now that $\theta \neq \frac{1}{2}$ and that the relation of the small parameter ϵ and the applied stepsize h_ℓ is such that the global error term of order $\mathcal{O}(h_\ell)$ dominates the error term of order $\mathcal{O}(\epsilon^2 h_\ell^{1/2})$. This is realized if h_ℓ is much larger than $\epsilon^2 h_\ell^{1/2}$, which we express by

$$\epsilon^2 h_\ell^{1/2} \ll h_\ell, \quad \text{i.e.,} \quad \epsilon^4 \ll h_\ell. \tag{4.7}$$

More precisely, we need that

$$\epsilon^2 \left\| \sum_{r,k=1}^{m} I_{rk}(\Lambda_k \tilde{g}_r) \right\|_{L_p} \Big/ h_\ell^{1/2} < h_\ell \left| \theta - \frac{1}{2} \right| \|(f_t + f_x f)_{t_{\ell-1}}\|_{L_p}, \tag{4.8}$$

which follows from (4.7) provided that the values of the functions $\tilde{g}_{rx}\tilde{g}_k$, $r, k = 1, \ldots, m$, and $f_t + f_x f$ are moderate. Then, the local error term η_ℓ is indeed dominated by $\bar{\eta}_\ell^*$ from (4.6). Note that the corresponding choice of $\bar{\eta}_\ell$ leads to an a priori known estimate of the local error, since $\bar{\eta}_\ell$ involves only the knowledge of $x_{\ell-1}$, not of x_ℓ. That way, step rejections do not occur.

One drawback of the choice of (4.6) is its explicit use of the derivatives of the drift function f, which may not be available in practical problems. Therefore, we look for a derivative-free estimate of η_ℓ. We use

$$h_\ell \|(\Lambda_0 f)_{t_{\ell-1}}\|_{L_p} = \|f_{t_\ell} - f_{t_{\ell-1}}\|_{L_p} + \mathcal{O}(h_\ell^2 + \epsilon h_\ell^{3/2} + \epsilon h_\ell^{1/2}),$$

which follows from the expansion

$$f_{t_\ell} - f_{t_{\ell-1}} = h_\ell (\Lambda_0 f)_{t_{\ell-1}} + I_{00}(\Lambda_0 \Lambda_0 f) + \epsilon \sum_{r=1}^{m} I_{r0}(\Lambda_r \Lambda_0 f) + \epsilon \sum_{r=1}^{m} I_r(\Lambda_r f)$$

that is valid under the assumptions of Proposition 4.2 and is obtained by inserting (4.5) into Itô's formula (4.4) for $y = f$. Hence,

$$\eta_\ell = \bar{\bar{\eta}}_\ell^* + \mathcal{O}(h_\ell^2 + \epsilon h_\ell + \epsilon h_\ell^{1/2}), \quad \bar{\bar{\eta}}_\ell^* := \left| \theta - \frac{1}{2} \right| \|f(x(t_\ell), t_\ell) - f(x(t_{\ell-1}), t_{\ell-1})\|_{L_p}. \tag{4.9}$$

The estimate $\bar{\bar{\eta}}_\ell^*$ is dominating the local error term η_ℓ under the more restrictive assumption

$$\epsilon h_\ell^{1/2} \ll h_\ell, \quad \text{i.e.,} \quad \epsilon^2 \ll h_\ell, \tag{4.10}$$

or, more precisely,

$$\epsilon \left\| \sum_{r=1}^{m} I_r(\Lambda_r f) \right\|_{L_p} < h_\ell \|(\Lambda_0 f)_{t_{\ell-1}}\|_{L_p}. \tag{4.11}$$

Then, the term $\bar{\bar{\eta}}_\ell^*$ behaves like an order 1 term. Hence, we represent this choice by $\bar{\gamma} = 1$ and $\chi(z, x, s, t) := |\theta - \frac{1}{2}|\,(f(x, t) - f(z, s))/(t - s)$. In Algorithm 3.1 this is realized by the choice

$$\bar{\gamma} := 1, \quad \bar{\eta}_\ell := \left| \theta - \frac{1}{2} \right| \|f(x_\ell, t_\ell) - f(x_{\ell-1}, t_{\ell-1})\|_{L_p}. \tag{4.12}$$

REMARK 4.3. Note that $\bar{\eta}_\ell^*$ defined by (4.6), as well as $\bar{\bar{\eta}}_\ell^*$ defined by (4.9), vanishes for the trapezoidal rule. Here a more detailed discussion of the remaining terms is necessary. Then the part $\|r_\ell\|_{L_p}/h_\ell$ of the local error is of order 2 and is dominated by $\|(\Lambda_0\Lambda_0 f)_{t_{\ell-1}}\|_{L_p} \cdot h_\ell^2/12$. This term dominates the local error term η_ℓ as long as $\epsilon \ll h_\ell$, which is more restrictive than (4.10). Details will be given in a separate paper.

REMARK 4.4. If the length $T - t_0$ of the considered time interval differs considerably from 1, the more detailed stability estimate

$$\begin{aligned}&\max_{\ell=1,\dots,N} \|x_\ell^* - \tilde{x}_\ell\|_{L_p} \\ &\le \tilde{S}\left(\|x_0^* - \tilde{x}_0\|_{L_p} + \max_{\ell=1,\dots,N}\|s_\ell\|_{L_p}\left(\frac{T-t_0}{h}\right)^{\frac{1}{2}} + \max_{\ell=1,\dots,N}\|r_\ell\|_{L_p}\frac{T-t_0}{h}\right)\end{aligned} \tag{4.13}$$

(cf. [24]) should be used as a starting point. Since the length of the interval affects the local error terms differently, condition (4.8) modifies to

$$\epsilon^2\left\|\sum_{r,k=1}^m I_{rk}(\Lambda_k\tilde{g}_r)\right\|_{L_p}\left(\frac{T-t_0}{h_\ell}\right)^{\frac{1}{2}} < (T-t_0)h_\ell\left|\theta-\frac{1}{2}\right|\|(f_t+f_xf)_{t_{\ell-1}}\|_{L_p}, \tag{4.14}$$

which is true for

$$\epsilon^2((T-t_0)h_\ell)^{\frac{1}{2}} \ll (T-t_0)h_\ell, \quad \text{i.e.,} \quad \epsilon^4 \ll (T-t_0)h_\ell, \tag{4.15}$$

and moderate coefficients $\tilde{g}_{rx}\tilde{g}_k$, $r,k = 1,\dots,m$, and $(f_t + f_x f)$.

REMARK 4.5. The conditions (4.14), (4.15), (4.11), (4.10) are independent of the used time scale.

REMARK. A transformation of the time scale $t \in [t_0, T]$ to $\tau \in [0,1]$ via

$$\begin{aligned}&\tau = (t-t_0)/(T-t_0), \qquad t(\tau) = t_0 + (T-t_0)\tau, \\ &y(\tau) := x(t(\tau)), \qquad \hat{w}(\tau) := (T-t_0)^{-\frac{1}{2}}w(t(\tau))\end{aligned}$$

leads to the transformed SDE

$$y(s)\Big|_0^\tau = (T-t_0)\int_0^\tau f(y(s),t(s))ds + \epsilon(T-t_0)^{\frac{1}{2}}\int_{t_0}^\tau \tilde{G}(y(s),t(s))d\hat{w}(s), \quad \tau\in[0,1].$$

The conditions (4.14), (4.15), (4.11), (4.10) in terms of the transformed functions and variables

$$\hat{f}(y,\tau) = (T-t_0)f(y,t(\tau)), \quad \hat{\tilde{G}}(y,\tau) = (T-t_0)^{\frac{1}{2}}\tilde{G}(y,t(\tau)), \quad \hat{h} = h/(T-t_0), \quad \hat{T} = 1,$$

coincide with the original conditions.

REMARK 4.6. The simple conditions (4.7), (4.15), and (4.10), together with the condition of moderate function values, describe rules of thumb for the used stepsizes. We specify them for $p = 2$, a scalar Wiener process, and the diffusion coefficient $G = (g)$. Neglecting higher order terms in (4.8), (4.14), and (4.11), we then obtain the conditions

$$h_\ell > \frac{\|(g_xg)_{t_{\ell-1}}\|_{L_2}^2}{2|\theta-\frac{1}{2}|\,\|(f_t+f_xf)_{t_{\ell-1}}\|_{L_2}^2}, \tag{4.16}$$

$$(T-t_0)h_\ell > \frac{\|(g_xg)_{t_{\ell-1}}\|_{L_2}^2}{2|\theta-\frac{1}{2}|\,\|(f_t+f_xf)_{t_{\ell-1}}\|_{L_2}^2}, \tag{4.17}$$

and

$$h_\ell > \frac{\|(f_x g)_{t_{\ell-1}}\|_{L_2}^2}{\|(f_t + f_x f + \frac{1}{2} f_{xx} gg)_{t_{\ell-1}}\|_{L_2}^2} \tag{4.18}$$

in terms of the ratio of the coefficients.

For $m = 1$ condition (4.8) simplifies to

$$h_\ell^{-\frac{1}{2}} \|I_{11}(g_x g)\|_{L_p} < h_\ell \left|\theta - \frac{1}{2}\right| \|(f_t + f_x f)_{t_{\ell-1}}\|_{L_p}.$$

Choosing $p = 2$ and neglecting higher order terms, one obtains

$$h_\ell^{-\frac{1}{2}} h_\ell 2^{-\frac{1}{2}} \|(g_x g)_{t_{\ell-1}}\|_{L_2} < h_\ell \left|\theta - \frac{1}{2}\right| \|(f_t + f_x f)_{t_{\ell-1}}\|_{L_2},$$

i.e., (4.16). Analogous arguments apply to (4.14) and (4.11).

5. Test results. We implemented the stepsize strategy proposed in section 3 for the drift-implicit Euler scheme (i.e., (4.2) with $\theta = 1$). The error estimate (3.3) has been realized by the derivative-free choice of (4.12), and the control has been realized by (3.4) for $\ell = 1$ and (3.5) for $\ell \geq 2$. We tested the resulting algorithm extensively for $p = 2$ on a set of SDEs with small noise. First, we report results for two scalar SDEs with known analytic solutions, where we can access the actual errors. The accuracy is measured by the empirical error quantity

$$\max_{\ell=1,\ldots,N} \left(\frac{1}{M} \sum_{j=1}^{M} |x^j(t_\ell) - x_\ell^j|^2 \right)^{1/2} \tag{5.1}$$

that is considered as an estimate of the maximum L_2-norm of the global errors in the considered time interval. Here N denotes the number of steps, M the number of computed paths, and x_ℓ^j the computed approximation of the jth path at time t_ℓ, while $x^j(t_\ell)$ denotes the corresponding exact solution value.

Finally, we present results for a low-dimensional electronic circuit model. We draw some conclusions on the potential and on the limitations of the strategy.

Example 5.1 (linear homogeneous SDE with constant coefficients). We consider the linear scalar SDE in complex arithmetic

$$x(t) = x_0 + \int_0^t \alpha x(s) ds + \int_0^t i\beta x(s) dw(s), \quad t \in [0, 1], \tag{5.2}$$

with coefficients $f(x,t) := \alpha x$, $G(x,t) = (g(x,t)) = (i\beta x)$, initial value x_0, parameters $\alpha, \beta \in \mathbb{R}$, and a scalar Wiener process w. It was implemented as a two-dimensional system in real arithmetic. Its solution is given by the geometric Brownian motion $x(t) = x_0 \exp\big((\alpha + \frac{1}{2}\beta^2)t + i\beta w(t)\big)$. Conditions (4.16) and (4.18) are equivalent to

$$\frac{\beta^4}{2\alpha^4} \ll h_\ell \quad \text{and} \quad \frac{\beta^2}{\alpha^2} \ll h_\ell,$$

respectively. Here, the ratio $|\beta/\alpha|$ plays the role of the small parameter ϵ. As long as stepsizes with $\beta^4/(2\alpha^4) \ll h_\ell$ are used, the Euler scheme shows order 1 of convergence.

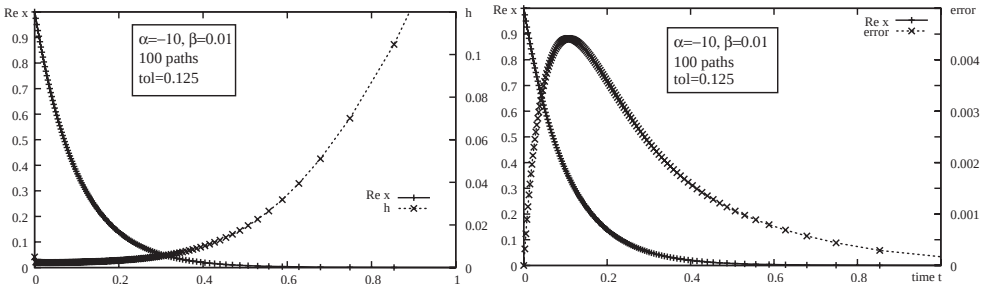

FIG. 5.1. *A computed solution path and stepsizes (left) or global errors (right) for the SDE* (5.2).

As long as even $\beta^2/\alpha^2 \ll h_\ell$ is satisfied, the proposed stepsize control should act properly.

In regions where the first condition is satisfied but the second one is violated, the controlled quantity $\|f_\ell - f_{\ell-1}\|_{L_2}$ is dominated by

$$\left\| \int_{t_{\ell-1}}^{t_\ell} f_x g(x(s), s) dw(s) \right\|_{L_2} \approx |\alpha\beta| h^{\frac{1}{2}} \, \|x_{\ell-1}\|_{L_2}$$

instead of

$$\left\| \int_{t_{\ell-1}}^{t_\ell} f_x f(x(s), s) ds \right\|_{L_2} \approx \alpha^2 h \|x_{\ell-1}\|_{L_2}.$$

The proposed control leads to stepsizes that match

$$\alpha^2 \|x_{\ell-1}\|_{L_2} h \approx \mathrm{tol}^2 / (|\beta| \, \|x_{\ell-1}\|_{L_2}).$$

In the following we present results for different values of the parameters α, β. The initial value was chosen to be $x_0 = 1$. We start with results for the parameters $\alpha = -10$, $\beta = 10^{-2}$ with ratio $|\beta/\alpha| = 10^{-3}$. The solution shows an exponential decrease with the steepest gradients at the beginning of the integration interval. In Figure 5.1 we give the real part of the solution (+) together with the adaptively chosen stepsizes (left picture, ×) and the observed global errors (right picture, ×) for the relative tolerance tol = 0.125 in Algorithm 3.1. The total number of steps was 129 corresponding to an average stepsize of $7.75 \cdot 10^{-3}$, whereas the minimal stepsize was $2.33 \cdot 10^{-3}$.

One hundred paths are computed simultaneously. Figure 5.2 gives the tolerance and accuracy (5.1) versus the number of steps. We plot the relative tolerance (△) and the accuracy with adaptively chosen stepsizes (+) and with constant stepsizes (×) versus the number of steps in logarithmic scale with base 10. Lines with slopes -1 and -0.5 are provided to enable comparisons with convergence of order 1 or 1/2.

To see how much the results are influenced by the statistical error due to only 100 randomly chosen paths, we repeated the computations 100 times for selected values of the relative tolerance. In Table 5.1 the mean value and standard deviation (in percentages) of the observed grid-points of the rejected steps and of the accuracy (5.1) are reported.

Let us add some observations. The global errors do not increase over the whole time interval, but show an exponential decrease after a shorter phase of increase at

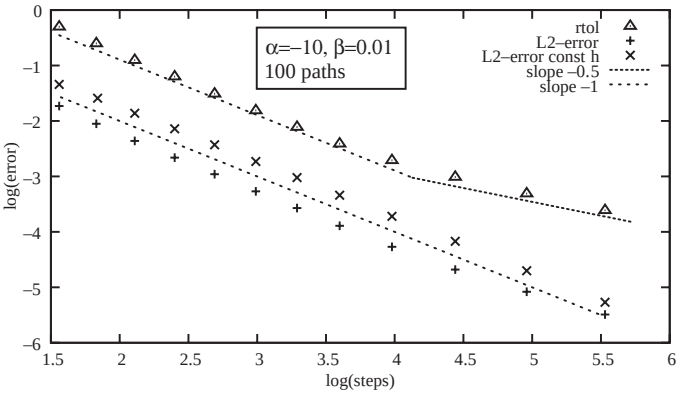

FIG. 5.2. *Tolerance and accuracy versus steps for the SDE* (5.2) *for* $\alpha = -10$ *and* $\beta = 10^{-2}$.

TABLE 5.1

	Successful steps		Rejected steps		Accuracy	
Tolerance	Mean	Deviation	Mean	Deviation	Mean	Deviation
2^{-5}	494	0%	0	0%	$1.08 \cdot 10^{-3}$	0.073%
2^{-10}	27426.25	0.11%	17.96	21.43%	$2.11 \cdot 10^{-5}$	0.077%

the beginning. Therefore, the maximum of the global errors over the integration steps is more meaningful than just the global error at the end of the interval. Furthermore, the error estimates are too pessimistic. Both effects are due to the damping of the solution by $\alpha = -10$, since the errors are damped as well. Further, in the case of the small noise parameter $|\beta/\alpha| = 10^{-3}$, the stepsize control works well up to average stepsizes of 10^{-4} and provides more accurate results than solving the SDE with the same number of constant steps. For higher numbers of steps, the smaller stepsizes at the beginning of the integration interval already lie below the threshold $\beta^2/\alpha^2 \ll h_\ell$. The results in Table 5.1 show that the proposed stepsize control works very well for stepsizes above this threshold and is still quite reasonable for stepsizes slightly below the threshold. The achieved accuracy differs only by less than 0.1% from one repetition of the simulation to another.

Next, we present results for the parameters $\alpha = -0.5$ and $\beta = 0.01$, i.e., $|\beta/\alpha| = 0.02$. Here, the decrease of the solution is much slower, and constant stepsizes are nearly optimal. Compared to the problem with $\alpha = -10$, the noise intensity is larger. In Figures 5.3 and 5.4 and Table 5.2 we present results of experiments that correspond to those described for $\alpha = -10$.

Due to less small noise, the range of accuracy, where the stepsize selection strategy works as intended, decreases to average stepsizes below 10^{-2}. In this range one can see a good correspondence of the tolerance to the accuracy. For very low accuracy (see the far left side of Figure 5.4), constant stepsizes seem to perform even better. Here, one has to see that the adaptive stepsize control first had to find the suitable stepsizes that correspond to the tolerance. Further, Table 5.2 shows that the simulations for $|\beta/\alpha| = 0.02$ and average stepsizes below 10^{-2} are slightly more affected by the randomly chosen 100 paths than the simulations for $|\beta/\alpha| = 0.001$ above. However, the differences from one repetition of the experiment to another still lie below 1%.

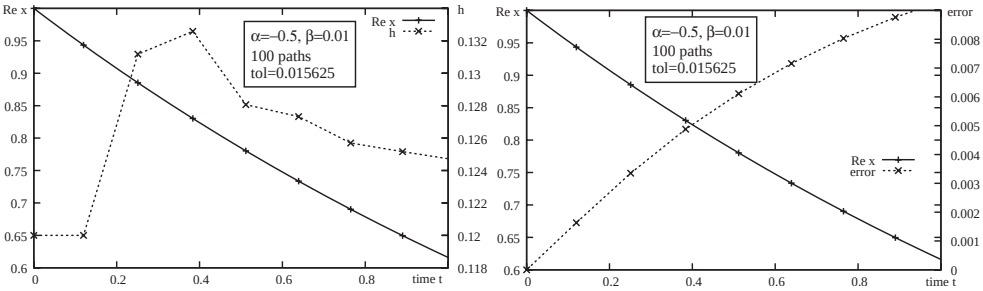

FIG. 5.3. *A computed solution path and stepsizes (left) or global errors (right) for the SDE* (5.2).

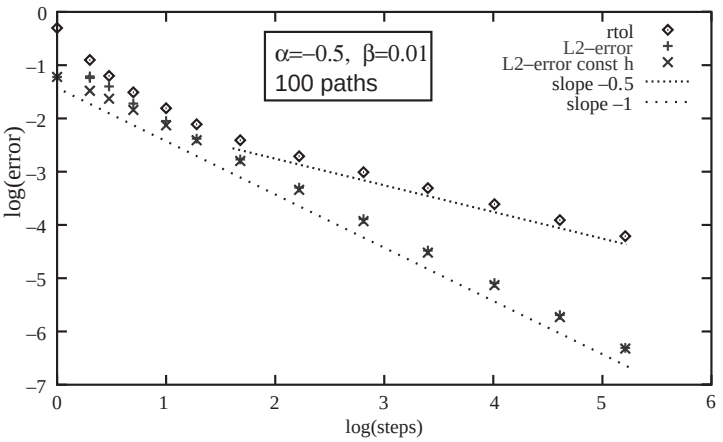

FIG. 5.4. *Tolerance and accuracy versus steps for the SDE* (5.2) *for* $\alpha = -0.5$ *and* $\beta = 10^{-2}$.

TABLE 5.2

	Successful steps		Rejected steps		Accuracy	
Tolerance	Mean	Deviation	Mean	Deviation	Mean	Deviation
2^{-6}	8	0%	0	0%	$9.37 \cdot 10^{-3}$	0.018%
2^{-11}	2537.64	0.57%	9.64	34.53%	$3.26 \cdot 10^{-5}$	0.62%

Finally, we report results for $\alpha = -0.5$, $\beta = 0.1$, i.e., $|\beta/\alpha| = 0.2$, where one can hardly speak of small noise. To obtain reasonable approximations of the $\|\cdot\|_{L_2}$-norm of the local error estimates, we increased the number of simultaneously computed paths to M = 1000. Nevertheless, we are in a situation for which the stepsize control proposed in this paper is not tailored. We present corresponding results in Figures 5.5 and 5.6 and in Table 5.3.

Here one can already observe the asymptotic order 1/2 of convergence for medium accuracy. In this region the local error term η_ℓ is dominated by $\|I_{11}(\Lambda_1 g_1)_{\ell-1}\|_{L_2} = \beta^2 h^{1/2} \|x_{\ell-1}\|_{L_2}$, and the stepsize control leads to stepsizes that match

$$\beta^2 h^{1/2} \|x_{\ell-1}\|_{L_2} \approx \mathrm{tol}\, |\beta/\alpha|.$$

Though we have increased the number of simultaneously computed paths to 1000, the results are influenced more by the randomness than in the previous simulations for

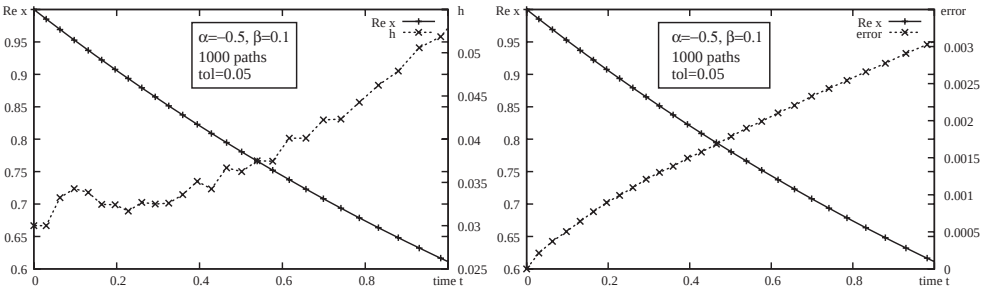

FIG. 5.5. *A computed solution path and stepsizes (left) or global errors (right) for the SDE* (5.2).

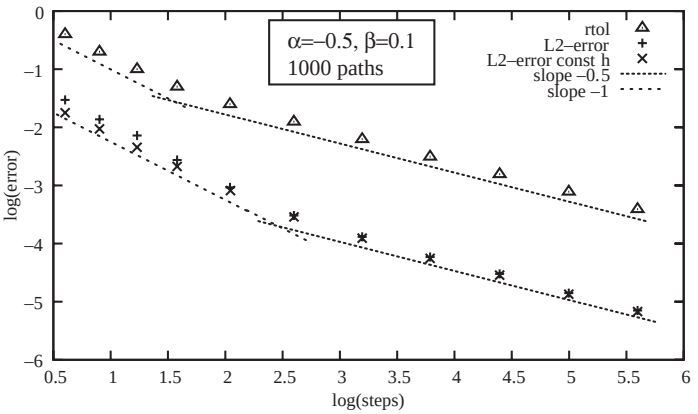

FIG. 5.6. *Tolerance and accuracy versus steps for the SDE* (5.2) *for* $\alpha = -0.5$ *and* $\beta = 0.1$.

smaller noise. We emphasize that the stepsize selection algorithm relies on a sufficient approximation of the norm of the local error terms by the simultaneously computed paths.

Example 5.2 (SDE with polynomial drift and diffusion). Here we consider a nonlinear scalar SDE with known solution and drift and diffusion coefficients $f(x,t) := -(\alpha + \beta^2 x)(1 - x^2)$, $G(x,t) = (g(x,t)) = (\beta(1 - x^2))$ that are tunable by real parameters α, β:

$$x(t) = \int_0^t -(\alpha + \beta^2 x(s))(1 - x(s)^2)ds + \int_0^t \beta(1 - x(s)^2)dw(s), \quad t \in [0,T], \tag{5.3}$$

where w denotes a scalar Wiener process. The solution is given by (cf. [14, eq. (4.46)])

$$x(t) = \frac{\exp(-2\alpha t + 2\beta w(t)) - 1}{\exp(-2\alpha t + 2\beta w(t)) + 1}.$$

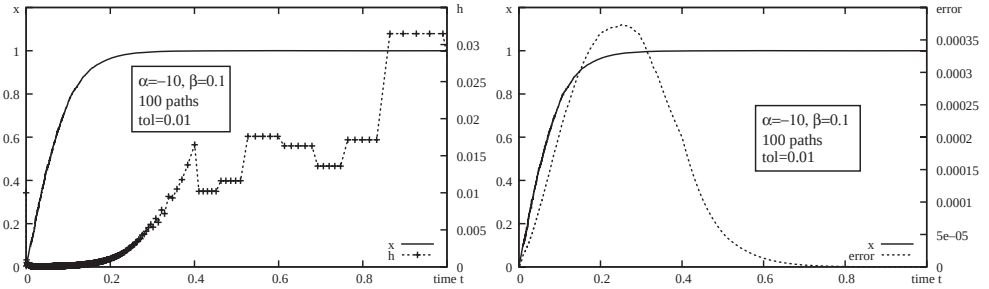

FIG. 5.7. *A computed solution path and stepsizes (left) or global errors (right) for the SDE* (5.3).

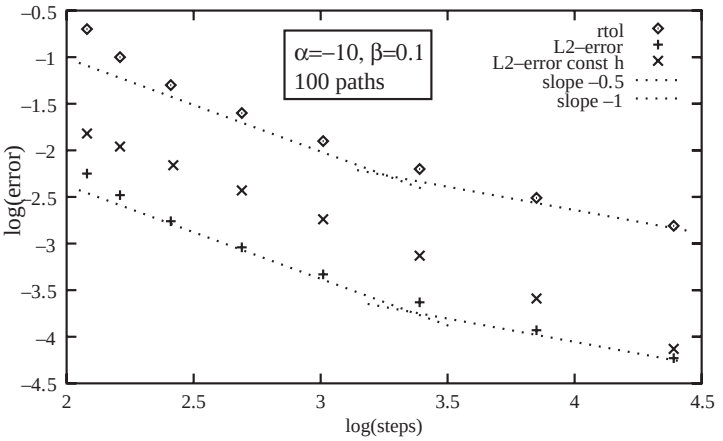

FIG. 5.8. *Tolerance and accuracy versus steps for the SDE* (5.3) *for* $\alpha = -10$, $\beta = 0.1$.

TABLE 5.4

0.005	3399.4	0.22%	8.45	23.56%	15.63	12.78%	$1.88 \cdot 10^{-4}$	0.71%

Due to the nonlinearity of the coefficients, the conditions (4.16), (4.17), (4.18) are solution dependent. Another effect of the nonlinearity is that restrictions of the stepsize are necessary to ensure the convergence of Newton's method for solving the nonlinear equations of the drift-implicit Euler scheme in every step. As in the deterministic setting, failures of Newton's method may also cause step rejections, especially for larger stepsizes, where the quality of the starting point for Newton's method may be worse. In such a case we halved the unsuccessful stepsize and forbade stepsize enlargements for the next five steps.

Though the problem is nonlinear, the principal observations we made were the same as for the linear example, Example 5.1. Here, we restrict our presentation to simulation results for one set of parameters, $\alpha = -10$ and $\beta = 0.1$, where 100 paths were computed simultaneously. In Figures 5.7 and 5.8 and Table 5.4 we present results

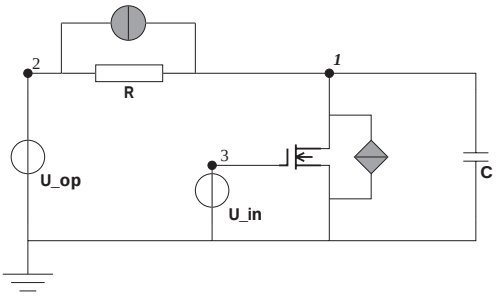

FIG. 5.9. *Thermal noise sources in a MOSFET inverter circuit.*

of experiments that correspond to those described for Example 5.1.

The solution shows a transient behavior at the beginning of the time interval. At the end of the time interval the stepsizes are bounded by the convergence behavior of Newton's method. Failures of Newton's methods also prevented simulation results for larger stepsizes in the case of larger noise. In Table 5.4 additional columns report the number of step rejections due to failures of Newton's method. In Figure 5.8 we observe order 1 behavior up to accuracies of 10^{-3}. The parameter $\alpha = -10$ causes a damping in the solution and a prediction of the global error that is much too pessimistic. The use of adaptive stepsizes provides considerably more accurate results than the computation with the same number of constant steps.

Example 5.3 (electronic circuit). We consider a model of an inverter circuit with a metal oxide semiconductor field effect transistor (MOSFET) under the influence of thermal noise. The equivalent circuit diagram is given in Figure 5.9.

The MOSFET is modeled as a current source from source to drain that is controlled by the nodal potentials at gate, source, and drain: $j_D = f_{mosfet}(e_{gate}, e_{drain}, e_{source})$. In our example the current j_D through the MOSFET is controlled by the input voltage U_{in} and the nodal potential e_1 at node 1: $j_D(U_{in}, e_1) := f_{mosfet}(U_{in}, e_1, 0)$. Often the models of MOSFETs are very sophisticated and involve hundreds of parameters. A first order model for MOSFETs is described in [9], where also further references are given. We simply used

$$j_D = K \cdot \big(\max(U_{GS} - V_{th}, 0)^2 - \max(U_{GD} - V_{th}, 0)^2\big),$$

where $U_{GS} = e_{gate} - e_{source}$, $U_{GD} = e_{gate} - e_{drain}$, and the threshold voltage V_{th} and the current amplification factor K are given parameters. The thermal noise of the resistor and of the MOSFET is modeled by additional white noise current sources that are shunt in parallel to the original, noise-free elements. The noise intensity is given by Nyquist's rule (cf. [2, 5, 26]):

$$I_{th} = \sigma_R \cdot \xi(t) = \sqrt{\tfrac{2k\mathrm{Temp}}{R}} \cdot \xi(t),$$

where $\xi(t)$ is a standard Gaussian white noise process, $k = 1.38066 \cdot 10^{-23}$ $[JK^{-1}]$ is Boltzmann's constant, Temp is the absolute temperature, and R is the resistance. For the thermal noise source of the MOSFET, this formula is modified by considering a solution-dependent conductance $g_D = g_{mosfet}(e_{gate}, e_{drain}, e_{source})$ instead of $g = 1/R$. We used

$$\begin{aligned} g_D &= 0 && \text{if} \quad U_{GS} \le V_{th}, \\ g_D &= \beta \cdot (U_{GS} - V_{th}) \cdot (1 + \lambda U_{DS}) && \text{if} \quad 0 < U_{GS} - V_{th} \le U_{DS}, \end{aligned}$$

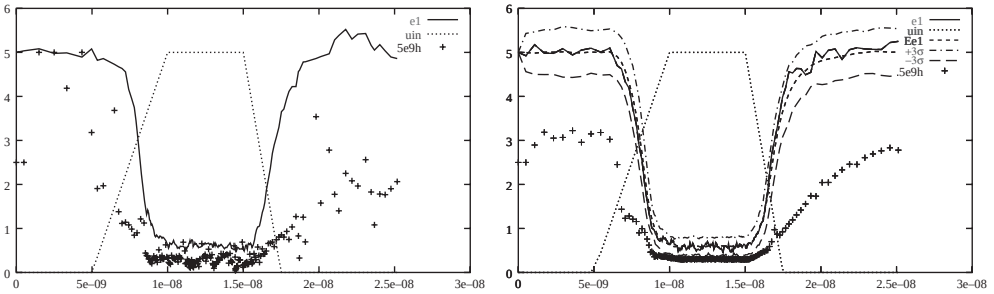

FIG. 5.10. *Simulation results for the noisy inverter circuit. Left:* 1 *path,* 188 (+ 46 *rejected*) *steps. Right:* 100 *paths,* 166 (+ 9 *rejected*) *steps.*

$$g_D = \beta \cdot (U_{DS}) \cdot (1 + \lambda U_{DS}) \qquad \text{if} \quad 0 < U_{GS} - V_{th} > U_{DS},$$

where $U_{DS} = e_{drain} - e_{source}$, and β, λ are parameters. Applying Kirchhoff's current law gives a model for the output voltage e_1 at node 1:

$$Ce_1' - (U_{op} - e_1)/R + j_D(U_{in}, e_1) - \sigma_R \xi_1 + \sigma_D(U_{in}, e_1)\xi_2 = 0, \tag{5.4}$$

where ξ_1, ξ_2 are independent standard Gaussian white noise processes. We treat this system as an Itô SDE with $n = 1$, $m = 2$, $f(x,t) = (U_{op} - x)/(C \cdot R) - j_D(U_{in}, x)/C$, $g_1(x,t) = \sigma_R/C$, $g_2(x,t) = -\sigma_D(U_{in}, x)/C$.

In this simple model, nearly no differences between the solutions of the noisy and the deterministic problem could be seen. Therefore, we dealt with a system where the diffusion coefficients had been scaled by a factor of 1000. In Figure 5.10 we present simulation results for the parameters $C = 2 \cdot 10^{-13}$ $[F]$, $R = 5 \cdot 10^3$ $[\Omega]$, $U_{op} = 5$ $[V]$, Temp $= 300$ $[K]$ on the time interval $[0, 2.5 \cdot 10^{-8}]$ $[s]$. In the MOSFET model we chose $V_{th} = 1$, $K = 10^{-3}$, $\beta = 0.\overline{3} \cdot 10^{-4}$, $\lambda = 0.02$, and the tolerance was 10^{-2}. In solid lines we plotted the values of the nodal potential e_1 and the given input voltage U_{in} versus time. Moreover, the applied stepsizes, suitably scaled, are shown by means of single crosses. We compare simulation results for the computation of a single path (in the left picture of Figure 5.10) with those for the computation of 100 simultaneously computed solution paths (in the right picture of Figure 5.10), where we additionally plotted the mean μ ($E\,e_1$ in the figure) and the lines $\mu \pm 3\sigma$ ($+3\sigma, -3\sigma$ in the figure), where σ was computed as the empirical estimate of the standard deviation for the output voltage. Using the information of an ensemble of simultaneously computed solution paths smoothes the stepsize sequence and considerably reduces the number of rejected steps (from 46 to 9). Even the number of needed successful steps is reduced from 188 to 166.

Acknowledgments. The authors thank Uwe Feldmann and Georg Denk (Infineon Technologies) for invaluable discussions and excellent cooperation and thank two anonymous referees for remarks and suggestions which led to an improved presentation of the material.

ADAPTIVE TIMESTEPPING FOR ELASTOHYDRODYNAMIC LUBRICATION SOLVERS*

C. E. GOODYER† AND M. BERZINS‡

Abstract. The application of variable-step time-integration techniques in a method of lines approach for the numerical solution of transient elastohydrodynamic lubrication calculations is described. Spatial discretization of the coupled integro-differential equations leads to a system of differential-algebraic equations in time. At each timestep a large system of nonlinear equations of 10^4–10^7 variables is solved by using multigrid methods and multilevel multi-integration. The application of temporal error control methods is considered with reference to both the differential-algebraic formulation of the system to be solved and the multigrid-based nonlinear equation solver to be used. The error control method used takes account of the magnitude of the spatial error present by using a local time error control based on the magnitude of this error. This approach is shown to be beneficial in reducing the computational work required. Experimental results on a variety of lubrication problems, including a challenging rough surface problem, are used to display the effectiveness of the methods.

Key words. elastohydrodynamic lubrication, method of lines, differential-algebraic equations, variable timestepping, error balancing

1. Introduction.

Elastohydrodynamic lubrication (EHL) problems arise in the mathematical modeling of highly loaded components undergoing deformation when lubricated by fluids such as oil. In particular, EHL may occur in journal bearings and gears where a load is applied on a very small contact area. This load causes pressures of up to 3 GPa and hence elastic deformation of the solid metal contact. Under these extreme conditions lubricating oil may have a glass-like consistency. EHL problems are most often modeled by nonlinear coupled integro-differential equations which require the use of numerical methods. Such EHL problems are of practical industrial interest but as the demand is for fast and robust solvers for increasingly more complicated problems, the ability to reduce the work needed for individual problems is thus paramount. A thorough background of EHL models and computations is provided by [38].

Numerical solutions have been computed since Petrusevich in 1951 [28], and finite difference, and to a lesser extent finite elements (see, e.g., [41]), have been used since then. The biggest advances have come from Lubrecht et al. with the application of multigrid in 1986 [24, 25, 36, 38] and multilevel multi-integration in 1990 [2, 38]. Since then the emphasis has largely been on solving more realistic and hence more physically challenging problems rather than further algorithmic developments. Most of the results are still computed by using a fixed regular grid and a fixed timestep with multilevel methods.

The need to move EHL simulations closer to the design process for both oils and components requires ever more complex problems to be formulated and solved;

see, e.g., [14]. These problems vary from transient cases, with variable loading and contact speeds, through complicated rheological behavior, to solutions incorporating surface features and, ultimately, true roughness. This requires that the solvers being used must be designed to be extensible to meshes of tens or hundreds of thousands of points in each direction and that the solutions can be obtained sufficiently quickly and reliably for problems with the order of 10^7–10^8 variables. Part of the need for large meshes is that, even in one dimension, mesh spacings as small as 10^{-5} are needed to obtain converged solution values of a pressure spike [17]. The industrial requirement is to be able to make accurate predictions of friction and for this in the case of measured surface roughness large meshes are needed.

EHL problems possess three very different characteristics in different areas of the domain. The cavitation region is the area of the solution beyond the free boundary where the Reynolds equation is not valid. In the center of the domain is the [illegible], where the pressure rises sharply to reach its maximum peak in a near Hertzian shape. EHL pressure profiles differ significantly from those in hydrodynamic cases with no surface deformation in that there is a ridge on the outflow side of the pressure peak. This can be seen in Figure 1.1 where a three-dimensional representation of the pressure profile is shown. Finally, in the noncontact region the pressure is very small compared to the contact region.

The deformation of the surface can be seen in Figure 1.2 which shows the shape of the contact along the centerline. The deformation of the original surface geometry is clearly visible. It can be seen that there is a constriction in the contact toward the outflow, which coincides with a position between the pressure spike and the cavitation boundary. At the outflow boundary a free boundary is formed representing the presence of a cavitation region where bubbles have formed in the lubricant film. The cases considered here always use a thin film approximation and are for the two-dimensional point contact case. In this work we shall restrict our discussion to the time dependent

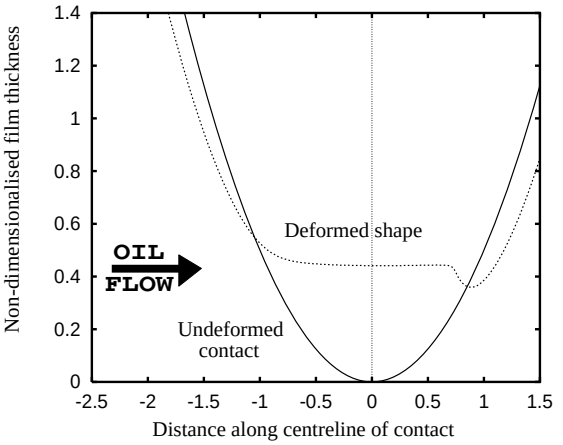

FIG. 1.2. *Typical solution for film thickness along the centerline of an EHL point contact.*

circular point contact cases and consider how to vary the timestep within the context of the multilevel multigrid solver, taking account of the spatial error present. The first results for adaptive timestepping in EHL solutions were presented by Goodyer et al. [13, 16]. More recently Watremetz et al. [39] have presented an alternative method of timestepping based on considering the physical situation rather than any measure of the truncation error.

As larger and larger EHL problems are solved or greater spatial accuracy is used it becomes more important to use a timestepping approach that reflects the spatial error present. This is particularly true for problems with very large numbers of points.

For example, in a benchmark parallel EHL calculation 250 million mesh points have been used by extending the techniques used in [18]. In this paper we thus look at the issue of developing an appropriate timestepping solver and error control method. In resolving this issue it is important to cast the discretized equations as a differential-algebraic system. This allows error estimation procedures from differential-algebraic equation (DAE) theory to be combined with both the multilevel multigrid solver and an estimate of the spatial error to obtain an efficient timesteping scheme. DAE theory also provides insight regarding which variables should be used in a local error test and which should be excluded. The DAE framework also makes it easier to understand how to choose the appropriate classes of time-integration methods and thus makes it easier to understand how to extend the approach described below to use high or variable order methods. In developing the approach described below we are aware of the tremendous advances made in the global error control of ODEs (see, e.g., [5, 9, 23, 26]) and think that such methods offer tremendous potential for the future. At present such methods are still sufficiently expensive that we will explore simpler methods based on attempting to keep the temporal error on a smaller scale than the spatial error [1, 22].

The rest of this paper is laid out as follows. In section 3 the equation system describing the problem is explained and the problem is reformulated as a DAE system. In section 4 a brief explanation of the spatial discretization and time-integration errors is supplied while section 5 describes the nonlinear equations solver employed. Section 6 describes the general approach we are using for the variable timestep approach, based on considering the DAE nature of the system. Section 7 describes in detail the error control mechanism employed in controlling the temporal error given the spatial error

present. Various examples of the use of variable timestepping are shown in section 8 where results for three very different cases, typical of the situations found in real transient EHL contacts, are presented, including consideration of the reduction in solution times.

2. Notation. The following notation of EHL variables will be used throughout the rest of the paper.

$\mathcal{A}$	surface roughness amplitude	a	halfwidth of Hertzian contact
$\mathcal{G}$	undeformed surface geometry	H	nondimensional film thickness
H_{00}	film thickness central offset	K	film thickness kernel matrix
P	nondimensional pressure	p_h	maximum Hertzian pressure
p_0	viscosity parameter	R_x	reduced radius of curvature
T	dimensionless time	u_s	sum of velocities of contacts
$\mathcal{W}$	surface roughness wavelength	X_d	surface roughness pattern center
X, Y	dimensionless coordinates	z	viscosity index
α	pressure viscosity index	ϵ	coefficient in Reynolds eqn.
λ	coefficient in Reynolds eqn.	η_0	viscosity at ambient pressure
$\bar{\eta}$	nondimensional viscosity	Φ	variable load factor
ψ	convergence test parameter	ρ_0	density at ambient pressure
$\bar{\rho}$	nondimensional density		

3. PDE system. The equations governing the EHL point contact are given, in nondimensional form, by the following six equations which are derived in standard texts such as [12, Chapter 4] and [38, Chapters 5 and 6]. The first is the Reynolds equation, which is based on fluid mass conservation and a thin film fluid flow approximation:

$$\frac{\partial}{\partial X}\left(\frac{\overline{\rho}\,H^3}{\overline{\eta}\lambda u_s(0)}\frac{\partial P}{\partial X}\right)+\frac{\partial}{\partial Y}\left(\frac{\overline{\rho}\,H^3}{\overline{\eta}\lambda u_s(0)}\frac{\partial P}{\partial Y}\right)-\frac{u_s(T)}{u_s(0)}\frac{\partial(\overline{\rho}\,H)}{\partial X}-\frac{\partial(\overline{\rho}\,H)}{\partial T}=0, \tag{3.1}$$

where λ is given by

$$\lambda=\frac{6\,\eta_0\,R_x^2}{a^3\,p_h}, \tag{3.2}$$

and where the other symbols are defined in section 2. The two rightmost terms of (3.1) are known as the wedge and squeeze terms, respectively. The boundary conditions are that the pressure is zero at all boundaries and at the outflow of the free boundary there are zero pressure derivatives; see [12, Chapter 11].

Second, the film thickness equation,

$$H(X,Y)=H_{00}+\mathcal{G}(X,Y,T)+\frac{2}{\pi^2}\int_{-\infty}^{\infty}\int_{-\infty}^{\infty}\frac{P(X',Y')\,\mathrm{d}X'\,\mathrm{d}Y'}{\sqrt{(X-X')^2+(Y-Y')^2}}, \tag{3.3}$$

may be used to compute the contact shape for a known applied pressure distribution. This equation consists of three parts: the offset film thickness or mutual approach, H_{00}, which is the separation of the solids assuming zero deformation; given undeformed geometry $\mathcal{G}(X,Y,T)$, which is generally parabolic, although will also include any roughness features on the surfaces; and the deformation term. The deformation integral is derived by assuming linear, elastic deformation of the two semi-infinite half spaces.

Finally, the force balance equation,

$$\int_{-\infty}^{\infty}\int_{-\infty}^{\infty} P(X,Y)\,\mathrm{d}X\,\mathrm{d}Y = \frac{2\,\pi}{3}\,, \tag{3.4}$$

is the constraint equation through which the applied force is implemented in non-dimensional form, as in (1.36)–(1.38) of [38]. By satisfying this conservation equation, the applied load of the case in question is guaranteed to be the calculated total pressure across the numerical solution.

The role of the force balance equation is quite complex in that without this extra equation there is one more degree of freedom than there are equations. The unknown variable is H_{00} which does not, however, appear directly in (3.4). A standard approach in EHL calculations (see, e.g., [38, equation (6.53)]) is to define an iteration for H_{00} using the residual of the discrete approximation to (3.4). This iteration is defined in (5.1) below, for example. A full explanation of how this iteration may be justified is given below in section 5. A brief explanation is that the discrete pressure integral in a discrete version of (3.4) is identical to an integral involving H_{00} and the film thicknesses. This identity may be seen by using the inverse of the discrete film thickness and pressure relationship defined by the discrete version of (3.3); see section 5 below.

A slightly modified form of this equation will be used in section 8.3 in conjunction with time varying loads.

The lubricant model used is that of a generalized Newtonian fluid. The viscosity model is the Roelands equation [29],

$$\overline{\eta}(P) = \exp\left\{\frac{\alpha\,p_0}{z}\left[-1+\left(1+\frac{Pp_h}{p_0}\right)^{z}\right]\right\}. \tag{3.5}$$

The density is defined using the Dowson and Higginson relation [6]:

$$\overline{\rho}(P) = \left(1+\frac{5.8\times10^{-10}\,Pp_h}{1+1.7\times10^{-9}\,Pp_h}\right). \tag{3.6}$$

It is worth remarking that the theoretical properties of the solution to these equations are not well understood. One notable exception is the finite element analysis of Wu and Oden [41, 42, 43] who considered lightly loaded EHL cases. One theoretical issue, addressed by Stenger, for example [33, 34], is that the film thickness $H(x,y)$ is uniquely defined by the pressure $P(x,y)$ via (3.3).

These equations are also precursors of equations involving rough surface geometries and/or non-Newtonian thermal effects; see, e.g., [10, 17].

3.1. Example reversal of entrainment. A typical example of a time dependent EHL problem is the test case of reversal of entrainment described in [30]. This situation corresponds to flow in one direction changing to the corresponding flow in the opposite direction over a short time period. This change is represented as a linear decrease in velocity. For the example from [30] it corresponds to oil entrainment changing from $0.05\mathrm{ms}^{-1}$ to $-0.05\mathrm{ms}^{-1}$ in 0.2s.

A key feature of this example is the saucer of viscous fluid that forms at the point of reversal (0.1s) and proceeds across the domain (toward the new outflow) before the deformation pattern readopts its characteristic horseshoe shape. All physical parameters are as given in [30], with the standard nondimensionalized quantities as given in Table 3.1. Figure 3.1 shows the central and minimum film thicknesses during this

TABLE 3.1
Nondimensionalized parameters for reversal example.

Parameter	Value
Viscosity index, α	2.1×10^{-8} Pa^{-1}
Maximum Hertzian pressure, p_h	0.45GPa
Initial sum of rolling speeds, $u_s(0)$	0.1ms^{-1}
Nondimensional coefficient, λ	0.056
Material parameter, G	2961
Load parameter, W	6.58×10^{8}
Speed parameter, U	1.47×10^{9}
Moes parameter, M	52.2
Moes parameter, L	6.9

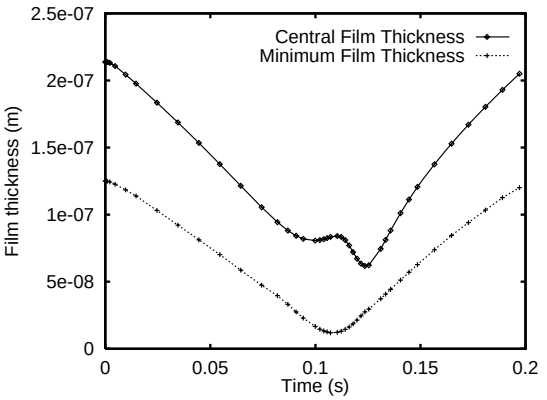

FIG. 3.1. *Central and minimum film thicknesses for reversal of entrainment.*

example. The points on the line indicate where timesteps have been taken. This test case will be used to demonstrate the issues that arise during the development of the timestepping algorithms. Comparisons of numerical solutions against experimental results are given by Goodyer [13].

4. Spatial and temporal discretization. Spatial discretization of the EHL system defined by (3.1)–(3.6) leads to a system of DAEs [3]. Defining the vector of film thicknesses across the whole domain, $\underline{H}$, and its multiple by the density $\underline{\rho}$ in a pointwise manner by

$$\begin{aligned} [\underline{H}]_k &= H_{i,j} \text{ for } k = i + (j-1)\times N_X, \\ \left[\underline{\rho H}\right]_k &= \rho_{i,j} H_{i,j}, \qquad i = 1,\ldots,N_X, \\ &\qquad\qquad\quad j = 1,\ldots,N_Y, \end{aligned} \tag{4.1}$$

with the vector of pressures, $\underline{P}$, likewise, then the first order upwind finite difference in space, implicit Euler in time, discretization of the Reynolds equation (3.1) is given by

$$\begin{aligned} &\frac{(\epsilon^n_{i-1,j}+\epsilon^n_{i,j})(P^n_{i-1,j}-P^n_{i,j}) + (\epsilon^n_{i+1,j}+\epsilon^n_{i,j})(P^n_{i+1,j}-P^n_{i,j})}{2(\Delta X)^2} \\ &+ \frac{(\epsilon^n_{i,j-1}+\epsilon^n_{i,j})(P^n_{i,j-1}-P^n_{i,j}) + (\epsilon^n_{i,j+1}+\epsilon^n_{i,j})(P^n_{i,j+1}-P^n_{i,j})}{2(\Delta Y)^2} \end{aligned}$$

$$-\frac{u_s(T)}{u_{ref}}\frac{\rho^n_{i,j}H^n_{i,j}-\rho^n_{i-1,j}H^n_{i-1,j}}{\Delta X}-\frac{\rho^n_{i,j}H^n_{i,j}-\rho^{n-1}_{i,j}H^{n-1}_{i,j}}{\Delta T}=0, \tag{4.2}$$

where the superscript n denotes values at time t_n. The boundary conditions are that all exterior boundaries have $P = 0$ and the line $j = 1$ is a symmetry condition in the Y direction. It is important to remark that once the entrainment direction has been reversed, the upwind direction of the discretization of the wedge term $\frac{\partial(\overline{\rho}H)}{\partial X}$ needs to be changed to reflect the changing flow direction.

The discretized forms of (3.3)–(3.6) are

$$H_{i,j} = H_{00} + \mathcal{G}_{i,j} + \sum_{k=1}^{N_X}\sum_{l=1}^{N_Y} K_{i,j,k,l}P_{k,l}, \tag{4.3}$$

$$\frac{2\pi}{3} = \Delta X \Delta Y \sum_{i=1}^{N_X}\sum_{j=1}^{N_Y} P_{i,j}, \tag{4.4}$$

$$\overline{\rho}_{i,j} = \frac{0.59\times 10^9 + 1.34 p_h P_{i,j}}{0.59\times 10^9 + p_h P_{i,j}}, \tag{4.5}$$

$$\text{and} \quad \overline{\eta}_{i,j} = \mathrm{e}^{\left\{\frac{\alpha p_0}{z}\left[-1+\left(1+\frac{p_h P_{i,j}}{p_0}\right)^z\right]\right\}}, \tag{4.6}$$

with all symbols as defined previously.

It is important to stress that the dependence of the film thickness $H_{i,j}$ at any point on the pressure values at every mesh point $P_{k,l}$ means that the sparsity pattern of the discrete nonlinear equations is dense in every case. When this dependence is combined with the nonlinear nature of the viscosity and density the result is a computationally challenging problem.

In (4.2) a first order upwind discretization of both first order derivatives is shown. Alternative schemes have been used by Venner and Lubrecht [38] and Wijnant [40]. Both methods again require the leading coefficients of both the wedge and squeeze terms to be one. Optimal use of these second order schemes rely on having a fixed relationship between the spatial and temporal timestep sizes, which, in an adaptive time-integration code, is no longer the case. These second order schemes are, in our experience, somewhat less stable when applied across a wide variety of cases.

4.1. DAE formulation. In order to apply DAE algorithms, theory, and error indicators it is helpful to recast the discretized EHL equations as DAEs. This is important as the form of the DAEs makes a significant difference to the algorithms that can be employed both for solution and for error estimation.

The differential-algebraic form of the discretized EHL equations may be written as

$$\underline{F}_1(\underline{P}, \underline{\overline{\rho}H}) - \left[\overline{\rho}H\right]' = 0, \tag{4.7}$$

the film thickness equation, (3.3), by

$$\underline{F}_2(\underline{P}, \underline{H}) = 0, \tag{4.8}$$

and the density equation, (3.6), by

$$\underline{F}_3(\underline{P}, \underline{\overline{\rho}}) = 0, \tag{4.9}$$

where $'$ denotes differentiation in time. These can then be combined to define a DAE system for $\underline{U}^{\mathrm{T}} = (\underline{P}^{\mathrm{T}}, \underline{H}^{\mathrm{T}})$ by

$$\underline{F}(\underline{U}, \underline{U}', t) = 0. \tag{4.10}$$

In the above case the DAE aspect arises from the lack of a temporal derivative of pressure in (4.7)–(4.9). Issues affecting the differences between solving ODE and DAE systems are discussed in detail in [3]. The authors have computational evidence that the EHL system is index one for regular meshes but need to show that $\frac{\partial \underline{F}_2}{\partial \underline{P}}$ is nonsingular in general.

The index of a DAE is defined as the minimum number of times that all or part of (4.10) must be differentiated with respect to T in order to determine U' as a continuous function of U and T [3]. Thus to find the index of the EHL DAE system given by (4.10), it is necessary to first differentiate (4.8) with respect to T to get

$$\frac{\partial \underline{F}_2}{\partial \underline{P}} \frac{\mathrm{d}\underline{P}}{\mathrm{d}T} + \frac{\partial \underline{F}_2}{\partial \underline{H}} \frac{\mathrm{d}\underline{H}}{\mathrm{d}T} = 0. \tag{4.11}$$

Hence, if $(\frac{\partial \underline{F}_2}{\partial \underline{H}})^{-1}$ exists, this gives an expression for $\frac{\mathrm{d}H}{\mathrm{d}T}$. Similarly, differentiating (4.9) gives

$$\frac{\partial \underline{F}_3}{\partial \underline{P}} \frac{\mathrm{d}\underline{P}}{\mathrm{d}T} + \frac{\partial \underline{F}_3}{\partial \underline{\overline{\rho}}} \frac{\mathrm{d}\underline{\overline{\rho}}}{\mathrm{d}T} = 0, \tag{4.12}$$

which gives an explicit expression for $\frac{\mathrm{d}\overline{\rho}}{\mathrm{d}T}$ if $\frac{\partial \underline{F}_3}{\partial \underline{\overline{\rho}}}$ is nonsingular.

Note that (4.7) may also be written as

$$\frac{\mathrm{d}\underline{\overline{\rho} H}}{\mathrm{d}T} = \underline{H} \frac{\mathrm{d}\underline{\overline{\rho}}}{\mathrm{d}T} + \underline{\overline{\rho}} \frac{\mathrm{d}\underline{H}}{\mathrm{d}T} = \underline{F}_1(\underline{P}, \underline{\overline{\rho} H}); \tag{4.13}$$

then expressions for P', H', and $\overline{\rho}'$ have been obtained in one differentiation step. Hence, the index of the transient EHL problem is one, provided both the aforementioned inverses exist.

The calculation of the density, $\overline{\rho}$, is entirely local, leading to a diagonal Jacobian matrix, $\frac{\partial \underline{F}_3}{\partial \underline{P}} \frac{\mathrm{d}\underline{P}}{\mathrm{d}T}$. This matrix is nonsingular provided that none of the diagonal entries given by

$$\frac{\partial \overline{\rho}_{i,j}}{\partial P_{i,j}} = \frac{\partial}{\partial P_{i,j}} \left(\frac{0.59 \times 10^9 + 1.34 p_h P_{i,j}}{0.59 \times 10^9 + p_h P_{i,j}} \right) \tag{4.14}$$

$$= \frac{0.2006 \times 10^9 p_h}{(0.59 \times 10^9 + p_h P_{i,j})^2} \tag{4.15}$$

are nonzero. For physical, nonnegative pressures, P, this matrix is invertible.

The invertibility of $\frac{\partial F_2}{\partial P}$ is much harder to establish. This is because the kernel matrix K is dense, and hence simple analysis is not possible. A computational investigation into the properties of this matrix showed that it was numerically nonsingular. Unfortunately, due to the very large size of the matrices involved, it was only possible to numerically investigate cases up to grid size 33×33, which remains far short of the fine mesh cases, with more than 1000×1000 points.

5. Nonlinear equations solution method. The methods used for solving for the pressure, the film thickness, and the lubricant properties are now described in turn. In order to obtain solutions to EHL problems quickly it has proved necessary [36, 38] to use multilevel and multigrid methods. Standard texts such as Briggs [4] and Trottenberg, Oosterlee, and Schüller [35] provide descriptions of multigrid methods.

In solving the Reynolds equation it is important to make use of different numerical schemes to reflect the different physical situation in each of the three different regions [13]. In the noncontact region a Gauss–Seidel line relaxation scheme is used; in the contact region a Jacobi line scheme is employed (see Nurgat, Berzins, and Scales [27]) rather than the distributed scheme of Venner [36]. In the cavitation region the Christopherson approach is used [7] to set all calculated negative pressures to zero.

The film thickness calculation, (3.3) once discretized, has the form given in (4.3). Hence for every mesh point, (i, j), the deformation term is a multi-summation of the pressures at all the other points in the computational domain. This calculation is therefore extremely expensive to compute exactly as it is $\mathcal{O}(N_X^2 N_Y^2)$ operations. We therefore use the multilevel multi-integration technique of Brandt and Lubrecht [2], which is described fully by Venner and Lubrecht [38], to reduce this calculation to $\mathcal{O}(N_X N_Y \ln N_X \ln N_Y)$ operations.

The calculation of H_{00} in (4.3) is accomplished by relaxation of the force balance equation (3.4), according to

$$H_{00} \leftarrow H_{00} - c\left(\frac{2\pi}{3} - \Delta X \Delta Y \sum_{i=1}^{N_X}\sum_{j=1}^{N_Y} P_{i,j}\right), \tag{5.1}$$

for all mesh points (i, j), where c is a small relaxation parameter; see [38, p. 148] and [12, p. 365].

At first sight it is unclear exactly how this equation may be justified. Write (4.3) and (4.4) in vector form as

$$\underline{H} = H_{00}\ \underline{e} + \underline{G} + K\underline{P}, \tag{5.2}$$

$$\frac{2\pi}{3} = \Delta X \Delta Y \underline{e}^T \underline{P}, \tag{5.3}$$

where $\underline{e}$ is the vector whose components are all one, $\underline{G}$ is the vector whose components are $\mathcal{G}_{i,j}$, and K is the matrix whose entries are composed of the elements $K_{i,j,k,l}$. Define the vector $\underline{y}$ as the solution of the system of equations

$$K\underline{y} = \underline{e}. \tag{5.4}$$

Hence

$$\underline{y}^T = \underline{e}^T\ K^{-1}. \tag{5.5}$$

It is worth remarking that although we do not know if K has an inverse we can easily attempt to compute $\underline{y}$ numerically. It then follows that the constraint equation (5.3) may be written by using (5.2) and (5.5) as

$$\frac{2\pi}{3} = \Delta X \Delta Y\ \underline{y}^T(\underline{H} - H_{00}\ \underline{e} - \underline{G}). \tag{5.6}$$

Although it would be possible to store and save $\underline{y}^T$ and $\underline{e}$, it is easier to use an iterative method. Applying a standard Newton–Jacobi-type procedure to calculate H_{00} from this equation with relaxation factor λ then gives

$$H_{00} \leftarrow H_{00} - c\left(\frac{2\pi}{3} - \Delta X \Delta Y \underline{y}^T(\underline{H} - H_{00}\underline{e} - \underline{G})\right), \tag{5.7}$$

where

$$c = \frac{\lambda}{\Delta X \Delta Y \underline{y}^T \underline{e}}. \tag{5.8}$$

Equations (5.1) and (5.7) are easily seen to be equivalent using (5.2). Computational experience suggests that c must be small and be chosen with some care.

One smoothing cycle is said to be the sequence of updating all the pressures, $P_{i,j}$, and film thickness values, $H_{i,j}$, along with the corresponding density and viscosity values.

In any implicit time-integration process it is important to ensure that the starting guess on a timestep is a good prediction. We therefore use linear extrapolation of the pressure, film thickness, and H_{00} solutions from the previous two steps. This prediction typically brings the root mean square residual at the start of the timestep down by an order of magnitude and possibly suggests that higher order methods might make an impact in time integration. Although it is possible to calculate $\underline{H}^{(0)}(t_n)$ directly from the predicted pressure solution, $\underline{P}^{(0)}(t_n)$, this does not lead to any noticeable improvements.

The solution method employed, described in [27] and [13], iteratively solves for pressure before updating the film thickness. One addition for the time dependent case is that the method for testing for convergence of the nonlinear iteration is the well-known (see, e.g., [3]) convergence test of [31]. In this test the iteration cycle on a timestep is continued until

$$\frac{\psi}{1-\psi}\left\|\underline{H}^{(m+1)}(t_n) - \underline{H}^{(m)}(t_n)\right\| < 0.33tol, \tag{5.9}$$

where tol is the time-integration error tolerance, and m is the iteration number. This also requires the definition of an estimate for the rate of convergence, ψ,

$$\psi = \left(\frac{\left\|\underline{H}^{(m+1)}(t_n) - \underline{H}^{(m)}(t_n)\right\|}{\left\|\underline{H}^{(1)}(t_n) - \underline{H}^{(0)}(t_n)\right\|}\right)^{\frac{1}{m}}, \tag{5.10}$$

with a suitable norm, $\|\cdot\|$, which we define below. An additional source of difficulty for EHL solvers is that it is often necessary to solve a steady state problem to calculate the initial conditions.

6. Local error estimation. For transient EHL calculations the choice of correct timestep size is critical. If the timestep is too large then important physical features may be missed should they fall between successive steps. Equally, choosing a very small stepsize may, at best, lead to a large amount of computational work for very small changes in the solution and, at worst, result in solutions diverging, for example, due to the magnification of temporal gradients. This is due not to the stability of the problem but to the convergence properties of the nonlinear solver described in detail in [13]. The strategy used here comes from [13] but a similar approach has been

used by Gaskell et al. [11] more recently. There are also issues unique to EHL-based multigrid solvers. For example, should the timestep become very small, then any corrections made may amplify, rather than reduce, the errors in the solution unless very small underrelaxation parameters are used in the multigrid solver.

6.1. Choice of variables. One of the central issues in the numerical solution of DAEs is the proper estimation of the error and which variables to include or exclude in the error test [3]. In this case there is a choice as to whether it is the errors in $\underline{P}$ or in $\underline{H}$ which are controlled. Intuitively, because the system given by (4.7) is solved for $\underline{P}$ and (4.8) is solved for $\underline{H}$ using this $\underline{P}$, it seems sensible to control the errors in $\underline{P}$. However, it is the contact region where the most change is taking place, and this is dominated by the wedge and squeeze terms in (3.1) which involve derivatives of $\underline{H}$. Experiments have confirmed that controlling these errors requires significantly less work per timestep and fewer timesteps are required. The error tests will therefore be formulated for variable $\underline{H}$. The difference between the magnitudes of the local errors in H and P is shown in the next subsection.

6.2. Calculating the local error estimate. Once the convergence test of (5.9) has been satisfied, a local error calculation is undertaken to establish a new timestep size. The size and nonlinearity of the systems of nonlinear equations to be solved at each timestep preclude the use of LU linear equation solvers to estimate the DAE local error by means of an extra backsolve [3, p. 147]. Instead, a multigrid-based iterative approach will be used to estimate the local error over the step. In estimating the local error we rely on the types of methods used by Brenan et al. [3] in our software, while recognizing that there are many alternatives.

First let us consider the Reynolds equation (4.7). Following the derivation given in [3, section 5.4], the system given by (4.7) can be considered, for the implicit Euler scheme used here, as

$$\frac{\overline{\rho_M}(\underline{P}_{n+1})\underline{H}_{n+1} - \overline{\rho_M}\,(\underline{P}_n)\,\underline{H}_n}{\Delta T} - \underline{F}_1(\underline{P}_{n+1}, \underline{H}_{n+1}) = 0, \tag{6.1}$$

where $\overline{\rho_M}\,(\underline{P})$ is a diagonal matrix with the ith diagonal entry consisting of the function $\overline{\rho}(.)$ evaluated using the ith pressure value. The true solution at timestep $n+1$ satisfies

$$\frac{\overline{\rho_M}\,(\underline{P}(t_{n+1}))\,\underline{H}\,(t_{n+1}) - \overline{\rho_M}\,(\underline{P}(t_n))\,\underline{H}(t_n) - \underline{TE}}{\Delta T} - \underline{F}_1(\underline{P}(t_{n+1}), \underline{H}(t_{n+1})) = 0, \tag{6.2}$$

where $\underline{TE}$ is the local truncation error, defined by

$$\underline{TE} = [\overline{\rho_M}\,(\underline{P})\,\underline{H}]''\,\frac{(\Delta T)^2}{2}. \tag{6.3}$$

In estimating the truncation error, $\underline{TE}$, our experiments have shown that the variation of the density is not as important as that of the film thickness. One may therefore consider treating the truncation error simply as $\overline{\rho_M}\underline{H}''$ and estimate it using the usual difference between predicted and corrected values; see [3]. Thus the estimated value denoted by $\underline{TE_a}$ is

$$\underline{TE_a} = \frac{\overline{\rho_M}(\underline{P_{n+1}})}{2}(\underline{H}_{n+1} - \underline{H}^{(0)}_{n+1}). \tag{6.4}$$

In estimating the growth in local error from t_n to t_{n+1} we assume that the error at t_n is zero and consequently that $\underline{P}_n = \underline{P}(t_n)$ and that $\underline{H}_n = \underline{H}(t_n)$. The local errors in pressure and film thickness are defined by $\underline{le\,H}$ and $\underline{le\,P}$ as

$$\begin{aligned} \underline{le\,P} &= \underline{P}_{n+1} - \tilde{\underline{P}}_{n+1}, \\ \underline{le\,H} &= \underline{H}_{n+1} - \tilde{\underline{H}}_{n+1}, \end{aligned} \tag{6.5}$$

where $\tilde{\underline{P}}_{n+1}$ and $\tilde{\underline{H}}_{n+1}$ are the values of the local solution to the equations with the computed values at t_n as the initial values.

This therefore leads to the following equation for the local errors $\underline{le\,H}$ and $\underline{le\,P}$:

$$\begin{aligned} \frac{\overline{\rho_M}(\tilde{\underline{P}}(t_{n+1}))\tilde{\underline{H}}\,(t_{n+1}) - \overline{\rho_M}(\tilde{\underline{P}}(t_n))\tilde{\underline{H}}(t_n)}{\Delta T} - \underline{F}_1(\tilde{\underline{P}}(t_{n+1}), \tilde{\underline{H}}(t_{n+1})) &= \underline{TE_a}, \\ \underline{F}_2(\tilde{\underline{P}}(t_{n+1}), \tilde{\underline{H}}(t_{n+1})) &= 0. \end{aligned} \tag{6.6}$$

This equation may then be solved for $\tilde{\underline{P}}$ and $\tilde{\underline{H}}$ using the standard EHL multigrid algorithm with right-hand side $\frac{\overline{\rho}}{2\Delta T}(\underline{H}_{n+1} - \underline{H}^{(0)}_{n+1})$.

In the case of the film thickness equation (4.3) since there is no transient term present, it can easily shown that neither the geometry nor H_{00} is present in the local error calculation, hence giving

$$\underline{le\,H} - K\underline{le\,P} = 0. \tag{6.7}$$

This gives us a relationship between the local errors in $\underline{H}$ and $\underline{P}$, where K is the film thickness integration kernel matrix.

The cost of this local error calculation on a timestep is that two or three more multigrid V-cycles are carried out to obtain solutions, $\tilde{\underline{P}}$ and $\tilde{\underline{H}}$, to the local error problem. This number of additional cycles is about one fifth of the total number of multigrid cycles.

Once these new solutions are calculated, an estimate of the total local error in $\underline{H}$ may be defined as

$$\|\underline{le\,H}\|_\omega = \|\tilde{\underline{H}}_{n+1} - \underline{H}_{n+1}\|_\omega. \tag{6.8}$$

The chosen norm, $\|\cdot\|_\omega$, is a weighted root mean square L_2-norm, as used in the software package DASSL, described in [3], defined by

$$\|\underline{H}\|_\omega = \sqrt{\frac{1}{N_X N_Y}\sum_{i=1}^{N_X}\sum_{j=1}^{N_y}\left(\frac{H_{i,j}}{\omega_{i,j}}\right)^2}, \tag{6.9}$$

with weights $\omega_{i,j}$ defined by

$$\omega_{i,j} = ATOL + H^{(0)}_{i,j} RTOL. \tag{6.10}$$

These weights are themselves, therefore, given in terms of the predicted solution at that mesh point on that timestep, $H^{(0)}_{i,j}$, and the absolute and relative error tolerances, $ATOL$ and $RTOL$, which will be defined in the next section.

Returning to the relationship between the local errors in P and H given in (6.7) and taking norms give

$$\|\underline{le\,H}\|_\omega \le \|K\|\,\|\underline{le\,P}\|_\omega \tag{6.11}$$

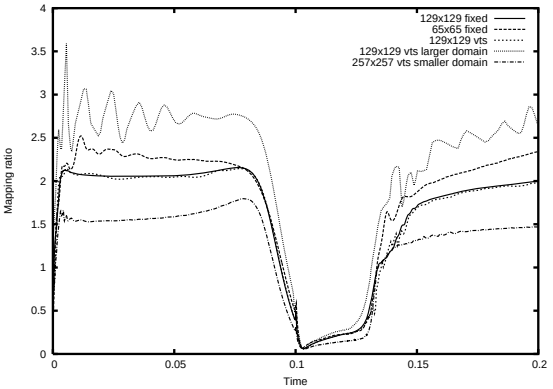

FIG. 6.1. *Ratio of* $\|\underline{le\, H}\|_\omega / \|\underline{le\, P}\|_\omega$.

for an appropriate matrix norm $\|.\|$. Examples of estimates of the values of this norm are shown below for the problem described in section 3.1. Figure 6.1 shows that the ratio of these errors satisfies

$$\|\underline{le\, H}\|_\omega / \|\underline{le\, P}\|_\omega \leq 4 \tag{6.12}$$

for calculations such as those in section 8. It is straightforward to monitor the ratio defined by the left-hand side of (6.12) during the calculation.

The local error test employed is then

$$\|\tilde{\underline{H}}_{n+1} - \underline{H}_{n+1}\|_\omega \leq 1. \tag{6.13}$$

Once this is true the stepsize change ratio is calculated by

$$r = (2\|\underline{le\, H}\|_\omega)^{\frac{-1}{k+1}}\,, \tag{6.14}$$

with k being the order of the method [32]. The new stepsize should then be chosen to be

$$\Delta T_{n+1} = r\Delta T_n, \tag{6.15}$$

subject to some standard limitations concerning maximum permissible stepsize. For example, if the error is small, e.g., $r > 1.5$ in (6.14), then the stepsize may be increased for the next timestep. If $r < 0.9$, then either the stepsize is reduced for the following step or, if the current step is considered to have failed, the current timestep may be retaken with a new stepsize. In between these extremes the stepsize is left unchanged. Stepsize increases are allowed only every two steps, but decreases are allowed on every step as is common in a number of time-integration codes. The main issue now is how to choose $RTOL$ and $ATOL$ so that they reflect the underlying spatial discretization errors.

7. Space and time error estimation and balancing. The general issue of controlling the global error in time dependent PDE calculations remains problematic despite many recent successful algorithms based upon adjoint methods; see [5, 26]. Adjoint methods are also important for EHL problems in that they provide a means of controlling the error in quantities of interest such as friction [20]. The key issue

for large scale engineering calculations is the cost of the estimation algorithms. The counterargument is that without incurring this cost there is no sure way of understanding the accuracy of the solution. Nevertheless for problems for which even computing any solution is a formidable challenge and an expensive use of computer time the option of using the adjoint-based error control algorithms cost is unattractive. For example, the algorithm of [5] requires one preliminary integration with a coarse tolerance, storage of solution values and then two adjoint integration techniques before the main integration is started.

In this section we consider less expensive options which take into account the magnitude of the spatial error based on the approach of [1, 22] but modified still further to reduce computational costs.

Let the continuous equation system, defined by (3.1)–(3.6), have an exact solution $u(x, y, t)$ together with a vector of values of this solution at spatial grid points at time t $\underline{u}(t)$, and the discretized equation system, defined by (4.10), have exact solution $\underline{U}(t)$. If, at time t, the numerical approximation to the solution of the system is $\tilde{\underline{U}}(t)$, then the total error, $E(t)$, is defined by

$$\begin{aligned} \underline{E}(t) &= \underline{u}(t) - \tilde{\underline{U}}(t) \\ &= (\underline{u}(t) - \underline{U}(t)) + (\underline{U}(t) - \tilde{\underline{U}}(t)) \\ &= \underline{e}(t) + \underline{g}(t), \end{aligned} \tag{7.1}$$

where $\underline{e}(t) = \underline{u} - \underline{U}$ represents the vector of spatial discretization errors on the mesh points, and $\underline{g}(t) = \underline{U} - \tilde{\underline{U}}$ is the global error in the time integration. Given that a solution has been discretized in space to a particular degree of accuracy, $\underline{e}(t)$, it is not worth solving the transient part to a much higher degree of accuracy, but equally this transient error $\underline{g}(t)$ must not degrade the spatial accuracy.

The control of the global error using adjoint methods is an active area; see [5, 9, 23, 26]. The optimal choice of timestep is governed by successfully relating the spatial error of the solution, with the time error. It has been shown (see, e.g., [1, 22]) that controlling the local (temporal) error per step, so that the local growth in time of the spatial error dominates, provides a practical reliable algorithm for balancing these errors. The disadvantage is that the strong theoretical basis of the adjoint methods is lacking. This form of error control, in all the experiments we have conducted, has done a good job of balancing the spatial and temporal errors. However, in common with the results of [1], it is the case that it is relatively expensive in terms of the number of timesteps taken.

In order to reduce computation times a modified approach is thus taken so that instead of controlling the local error in time so that it is a fraction of the growth in the spatial error we control the local error so that it is a fraction of the spatial discretization error. The approach used is like the extrapolation approach of section 3.1 of [22] in that the fine mesh solution is used to estimate the error in a coarser mesh and then extrapolation is used to estimate the error on the fine mesh. Using the approach in these papers yields a simple extrapolation-based estimate of the first order spatial error in the fine mesh solution given by

$$e_{i,j}(t) \approx \tilde{H}_{i,j}(t) - \tilde{H}_{I,J}(t), \tag{7.2}$$

where (i,j) is the fine grid point coincident with the coarse grid point (I,J).

The error control algorithm of [22, equation (3.10)] is then given by defining

$$\|\underline{le\, H}\|_\omega < \varepsilon \left\|\underline{e}_{n+1} - \underline{e}_n\right\|_\omega, \tag{7.3}$$

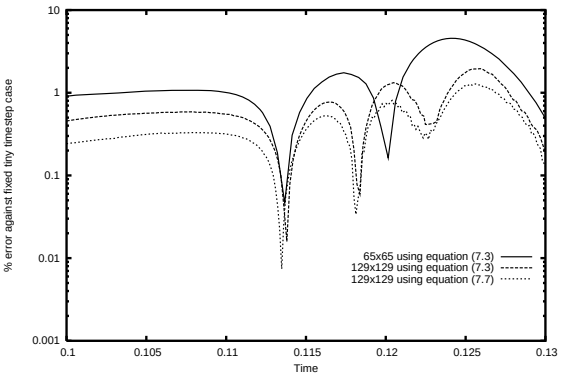

FIG. 7.1. *Comparison of errors in the minimum film thickness through reversal using different error control strategies.*

where $\|\cdot\|_\omega$ is a weighted root mean square L_2-norm, as used in (6.9). Using the approximation

$$\|\underline{e}_{n+1} - \underline{e}_n\|_\omega \approx \Delta t \left\| \frac{\partial \underline{e}}{\partial t} \right\|_\omega \tag{7.4}$$

allows the error control approximation to be written as a local error per unit step. Assuming that the spatial error may be expanded in powers of Δx and that $\Delta x{=}\Delta y$,

$$\left\| \frac{\partial \underline{e}}{\partial t} \right\|_\omega \approx \Delta x^p \left\| \frac{\partial \underline{\tilde{E}}}{\partial t} \right\|_\omega , \tag{7.5}$$

where $p = 1$ is the power of Δx in the spatial error; thus the error control can be approximated, as in [1, 22], by

$$\|\underline{le\, H}\|_\omega < \varepsilon_0 \, \Delta x^p \, \Delta t \left\| \frac{\partial \underline{\tilde{E}}}{\partial t} \right\|_\omega , \tag{7.6}$$

where $\varepsilon_0 = 0.1$ or 0.3. Although the efficiency could be increased by using a larger value of ε_0, a possible alternative to (7.3) is then given by

$$\|\underline{le\, H}\|_\omega < \varepsilon_1 \, \Delta x^p \, \|\underline{\tilde{E}}\|_\omega . \tag{7.7}$$

This approach adapts the timestep so that the local time error is a fraction of the spatial error estimate defined as in (7.7).

In order to assess the effectiveness of this approach an experiment was conducted using the two error controls on the test problem described in section 3.1. In this experiment a high-accuracy solution is computed using meshes of both 65×65 and 129×129 points and a small uniform timestep of $\Delta X^f/32$, where ΔX^f is from the finer resolution case. In comparing the methods the values of $\varepsilon_0 = 0.1$ and $\varepsilon_1 = 0.1$ were used on the 129×129 case. A comparison solution with the 65×65 point case is also included as this shows the effect of increasing mesh resolution. Figure 7.1 shows the percentage "errors" against this high accuracy solution in the key quantity of H_{cen}, the minimum film thickness, as the contact goes through the nonlinear reversal

TABLE 7.1
Computational performance comparison between different error control methods.

Grid dimension	Error control method	Timesteps taken	Iterations required
129×129	Fixed - small ΔT	36998	324065
129×129	Variable - using (7.7)	36628	111580
129×129	Variable - using (7.3)	140	2640

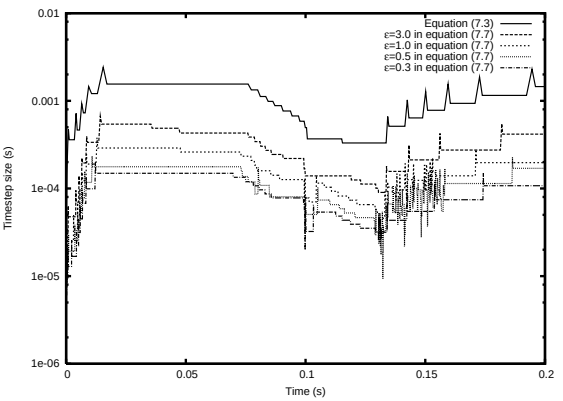

FIG. 7.2. *Comparison of timestep sizes for reversal of entrainment.*

phase of the calculation. The results show that in the first half of the simulation the errors using (7.7) are about 50% smaller than those using (7.3) relative to the tiny timestep case, but in the second half they are comparable. The figure concentrates on the important region around reversal. The computational cost of the three methods is demonstrated in Table 7.1. This table shows that the modified error control defined by (7.3) is a fraction of the cost of the approach defined by (7.7). This cost differential is reflected by the timesteps used by the two approaches as is shown in Figure 7.2. This figure compares the timestep sizes for the method of (7.3) (denoted as our method) with $\varepsilon = 0.1$ with the method of (7.7) with values of ε between 0.3 and 3. These values of ε are slightly larger than those used in the error balancing experiments of [1, 22]. The significant feature of these comparison experiments is that the error in a key quantity of interest, the central film thickness, is computed equally accurately in all cases, showing that the temporal error has been kept small. It is interesting to also see the variation in the timestep as the parameter ε in (7.3) is modified. This is shown in Figure 7.3 where it can be seen that the proposed method of step selection gives similar patterns of change. We have seen that sometimes using (7.7) may result in periods of relatively small steps without gaining additional accuracy. This seems to be related to the interplay between spatial and temporal error resulting in convergence difficulties for the multigrid solver.

The error control algorithm is implemented in the choice of the tolerances $RTOL$ and $ATOL$ being chosen at time t to be dynamically defined by

$$ATOL = \frac{1}{10}\sqrt{\frac{1}{N_X^C N_Y^C}\sum_{I=1}^{N_X^C}\sum_{J=1}^{N_Y^C}\left[\tilde{H}_{i,j}(t) - \tilde{H}_{I,J}(t)\right]^2} \tag{7.8}$$

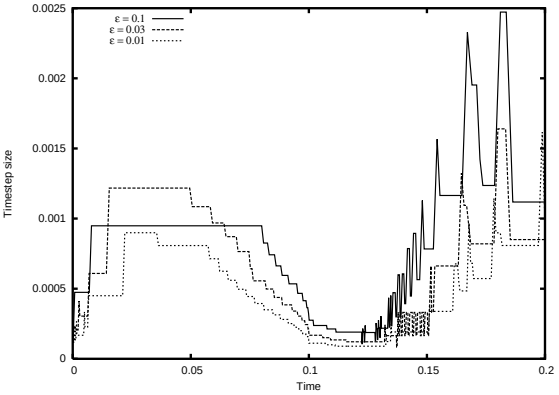

FIG. 7.3. *Comparison of timestep sizes when changing ε in* (7.3).

and

$$RTOL = ATOL \tag{7.9}$$

for fine mesh points (i, j) with coincident coarse points (I, J).

8. Examples. In this section we present examples of some typical, challenging, transient EHL cases. The first example in section 8.1 is that of reversal of entrainment. Second in section 8.2 is the overrolling of a single surface roughness feature. In section 8.3 we consider the situation where the load is varying. Finally, in section 8.4 the presence of a measured surface roughness pattern is simulated.

8.1. Reversal of entrainment. A clear example of the benefits of using variable timesteps can be seen in the case of the reversal of entrainment problem defined in section 3.1. In Figure 8.1(a) the points on the line indicate where timesteps have been taken. It can be seen that these are clustered around reversal and just after, as was desired. The actual timestep sizes can be seen in Figure 8.1(b) alongside the values of r, the stepsize change ratio. It was explained above that there can be advantages in not changing the stepsize too often. Choosing the new stepsize based on an a priori error test cannot guarantee that the new stepsize will be valid for more than one timestep. Thus having the range of values for r in (6.14) where the stepsize

129×129	variable	2.52	9.33	1.99	9.95

remains unchanged is important. The size of this region also governs how often the stepsize can change because if it is too small then the stepsize may be successively increased and decreased. This "chattering" effect, well known in the ODE community, may cause instabilities in the solution. This region is considered, for example, by Shampine and Gordon [32] and Hairer, Nørsett, and Wanner [19]. It is the range of values calculated for r in the error test, for which r should be set to 1 in (6.15).

The use of variable timestepping may require more cycles per timestep, but through the larger stepsizes these are being done considerably less often. It is also possible to limit the number of iterations per timestep if the convergence of individual steps is failing to satisfy the convergence test (5.9) quickly enough.

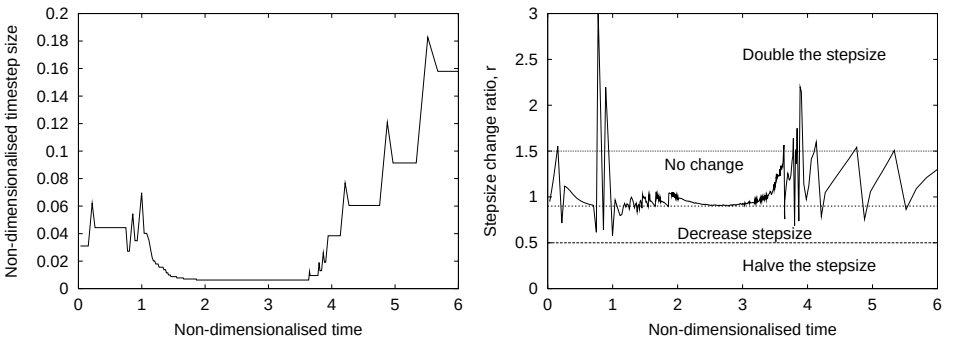
One of the stated aims for the use of variable timestepping was a reduction in the required computational time. Table 8.1 shows the computational time comparison between run times for fixed step ($\Delta T = \Delta X$) and variable timestep sizes. To confirm the validity of the results obtained, central and minimum film thicknesses are compared in Table 8.2 at two reference times: the point of reversal ($t = 0.1$ s) and the time that the minimum film thickness is achieved ($t = t_{min} \approx 0.108$ s). At these times the minimum film thickness is an order of magnitude less than the initial steady state. It is clear that the significant saving in computational work described produces results of similar accuracy.

8.2. Surface features. Following the experimental work of Kaneta, Sakai, and Nishikawa [21], Venner and Lubrecht [37] solved this transient example of a transverse ridge proceeding from left to right through the domain. For the local error control method to be considered effective it should be able to capture periods of rapid change in surface roughness cases where the relative importance of the asperity changes as it progresses through the contact. The undeformed geometry is given by

$$\mathcal{G}(X,Y,T) = \frac{X^2}{2} + \frac{Y^2}{2} - \mathcal{A} \times 10^{-10\left(\frac{X-X_d}{\mathcal{W}}\right)^2} \cos\left(2\pi \frac{X - X_d}{\mathcal{W}}\right), \tag{8.1}$$

TABLE 8.3
Parameters used for transverse ridge example, after Venner and Lubrecht [37].

Parameter	Value	Parameter	Value
E'	1.17×10^{11} Pa	Moes parameter, M	233
α	2.2×10^{-8} Pa^{-1}	Moes parameter, L	5.42
η_0	1.22 Pa s	material parameter, G	2.62×10^{3}
u_s	0.0215 m s^{-1}	speed parameter, U	8.8×10^{-12}
R_x	0.0127 m	load parameter, W	2.0×10^{-6}
a	1.84×10^{-4} m	ridge amplitude, $\mathcal{A}$	0.075
p_h	0.54×10^{9} Pa	ridge wavelength, $\mathcal{W}$	0.7



(a) Timestep size *(b) Stepsize change ratio, r*

FIG. 8.2. *Timestep sizes and stepsize change ratio during overrolling of a transverse ridge using variable timestepping.*

where $\mathcal{A}$ is the dimensionless amplitude of the ridge, $\mathcal{W}$ is the dimensionless wavelength of the ridge, and $X_d(T)$ is the dimensionless position of the ridge given by

$$X_d(T) = X_d(0) + \frac{2u_2T}{u_s}. \tag{8.2}$$

The parameters are as given in Table 8.3 with the ridge entering from the left-hand side of the domain, with $X_d(0) = -2.5$, and then progressing through the domain. They correspond to a ridge of height 0.2 μm and a width of 0.07 mm, approximately what was used by Kaneta, Sakai, and Nishikawa, and precisely what was used by Venner and Lubrecht. Initially the ridge is outside the area of influence on the solution, and the timestep is expected to be larger than the optimal timestep as the ridge passes through the contact region. Once the ridge has entered the cavitation region no further transient effects should be present, and hence the solutions should return to the steady state conditions, and the timestep size should increase.

The physical solutions obtained were as shown by Venner and Lubrecht [37], and hence the only part of interest is the timestep information. In Figure 8.2(a) the timestep size is shown. As expected it does rise to a maximum which then falls as the ridge enters the contact area at $T = 1.5$. This remains fairly constant until the ridge enters the cavitation region just after $T = 3.5$. Once out of the contact area the solution returns to steady state conditions and the timestep size increases dramatically. Consideration of the stepsize change parameter, r, in Figure 8.2(b) reveals how satisfactory the selected timestep size is, as the ridge passes through the contact area. The desire to increase the stepsize both initially and after overrolling is contrasted against the reduction in timestep size between $T = 1$ and $T = 2$.

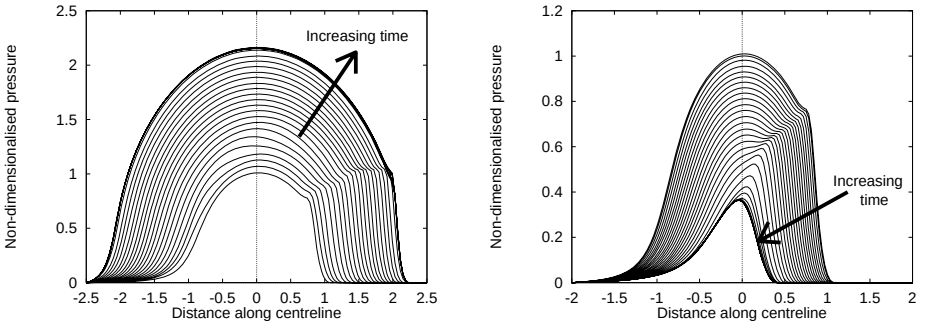


FIG. 8.3. (i) *Shock loading from* 0.45 *to* 0.90 *GPa in* 0.02 *s and* (ii) *unloading from* 0.45 *to* 0.22 *GPa in* 0.02 *s.*

8.3. Shock loading. The example of shock loading models the kind of change to the physical conditions experienced by the teeth on gears during meshing. Two kinds will be demonstrated in this section: shock loading and shock unloading. The load changes are of much greater amplitude than the oscillating loads investigated by Wijnant [40], and the timescale is very short.

The examples to be considered here both start from the initial conditions of the reversal example, shown in Table 3.1. The loading will take place by increasing the maximum Hertzian pressure to double its initial value for loading, or by halving it for the unloading case. Since this calculation is done using nondimensionalized versions of the equations as explained in section 3, it is the initial load against which the parameters are defined. In the nondimensionalization process the applied load is normally assumed to be constant, and thus, in the case of a varying load, a change to the conservation equation, (3.4), is necessary. This entails a modified right-hand side, hence changing the target sum of pressures. Thus (3.4) becomes

$$\frac{2\pi}{3}\Phi = \int_{-\infty}^{\infty}\int_{-\infty}^{\infty} P(X,Y)\,\mathrm{d}X\mathrm{d}Y, \tag{8.3}$$

where the variable load, Φ, is given by

$$\Phi = \left\{ \begin{array}{ll} 1, & t \le 0\text{s}, \\ 1 + 450t, & 0 \le t \le 0.02\text{s}, \\ 10, & t > 0.02\text{s}, \end{array} \right\} \text{for increasing loading,} \tag{8.4}$$

$$\Phi = \left\{ \begin{array}{ll} 1, & t \le 0\text{s}, \\ 1 - 45t, & 0 \le t \le 0.02\text{s}, \\ \frac{1}{10}, & t > 0.02\text{s}, \end{array} \right\} \text{for decreasing loading.} \tag{8.5}$$

Pressure solutions for the two cases are very different. The centerline pressure is shown at selected timesteps in Figure 8.3, with the arrow indicating the direction of increasing time of solution plots. The increase in both the size of the contact area and maximum pressure is evident.

The unloading example has a very different behavior, as shown in the right side of Figure 8.3, because the problem has dropped out of the EHL regime to just being hydrodynamically lubricated instead. This means that the pressure spike has completely disappeared, and the deformation is now minimal, with no sidelobes present at all.

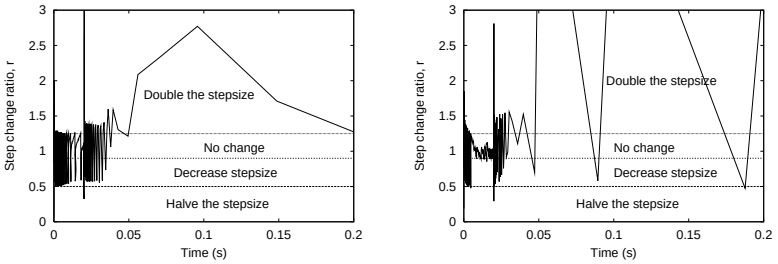

FIG. 8.4. *Shock loading and unloading: Stepsize change ratios.*

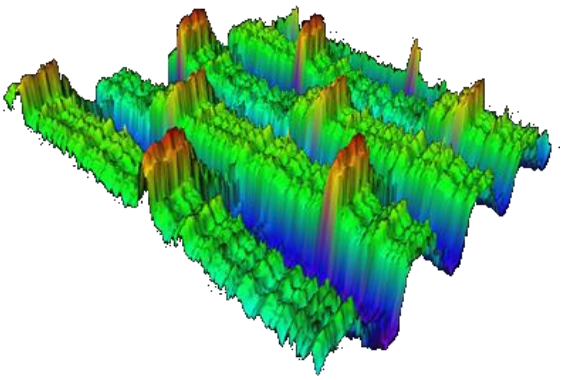

FIG. 8.5. *Roughness pattern applied across contact.*

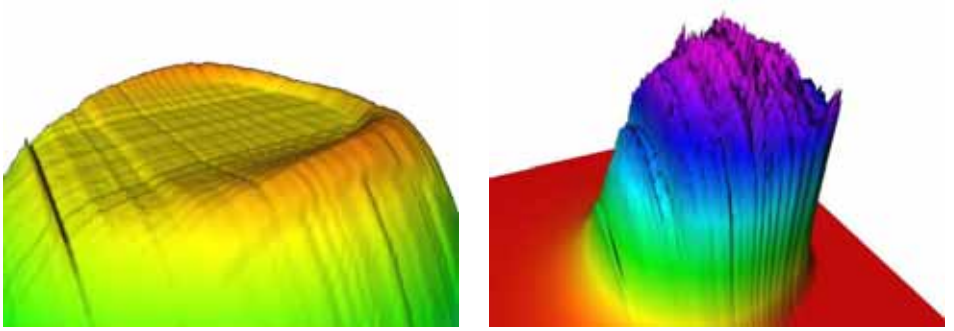
The timestep size is chosen based on the local error estimate which in turn depends on derivatives of the solution. It is therefore expected that when the system has reached the final steady state solution beyond 0.02 s the timestep should be much larger than in the initial stages. For the shock loading example the stepsize change ratio, r, is shown on the left of Figure 8.4. It can be clearly seen that the timestep does not increase until after the end of the loading period.

The stepsize change ratios for the shock unloading example is shown on the right side of Figure 8.4. Similar behavior to the shock loading case can be observed, although with a significantly less smooth increase in the timestep size.

8.4. Real surface roughness. A recent facet of EHL research has been the solution of problems with real surface roughness by a number of research groups; see, e.g., [8]. On a microscopic scale real surfaces of contacts are not defined by parabolas, nor are any features, such as bumps and dents, perfectly geometric shapes. In fact the surface is covered in small asperities. In an EHL contact the deformation of the solid will seek to smooth out these irregularities, and hence the pressure profile will be related to the local surface geometry. In fact for each individual asperity being flattened it is possible to see that it has its own EHL contact problem—just on a much smaller physical scale.

For this example we have imposed the measured roughness pattern shown in Figure 8.5 onto one of the surfaces. This therefore rolls through the contact over time, in the same manner as the surface feature simulated in section 8.2. An example, with the amplitude of the roughness applied at a nominal 25%, is shown in Figure 8.6.



(a) Contact shape (b) Pressure profile

FIG. 8.6. *Roughness pattern applied across contact.*

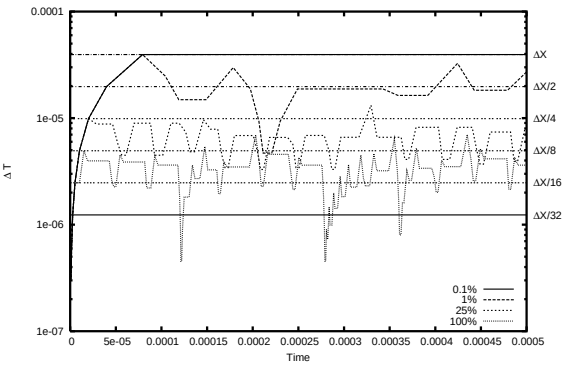


FIG. 8.7. *Timestep size for different amplitudes of roughness.*

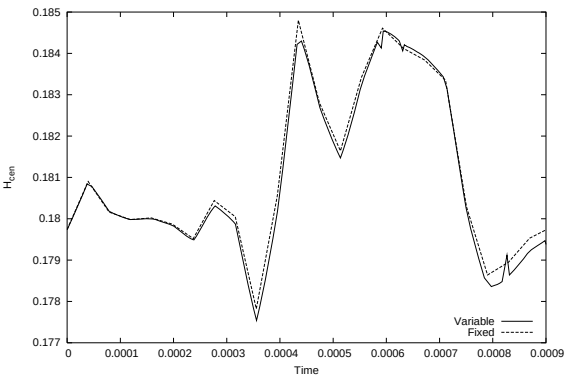

FIG. 8.8. *Central film thickness using fixed and variable timestepping approaches.*

In the previous examples it has been shown how the use of variable timestepping increases the efficiency of the solver without damaging the accuracy. For surface roughness cases the situation is slightly different in that variable timestepping will allow the tracking of the progression of each asperity through the domain. This is shown well in Figure 8.7 where the timestep size is monitored for increasing roughness

amplitudes. It can be seen how the selected timestep size diminishes as the contacts become less smooth, as we would expect.

The increase in accuracy that may be attained through the use of temporal adaptivity is shown in Figure 8.8, which shows the contrast in film thickness solution values at the center of the contact region. It is clearly seen how the fixed timestep approach both diverges from the variable timestepping solution and also misses out on the subtimestep scale features.

9. Conclusions. In this paper we have shown how a variable timestep approach has been used to provide an efficient method for solving transient EHL problems. It has been explained how the adaptive methods proposed fit into the standard multilevel schemes used for numerical solutions to EHL problems.

Variable timestepping has been shown, by experiments, to substantially reduce the required work while maintaining the same level of solution accuracy. The overhead in calculating new stepsizes is small, relative to the increase in performance. Changing the stepsize away from ΔT, within predefined limits, has been seen to pose no problems for the solver.

Examples of representative transient EHL situations have been considered, covering three different physical changes. The problem of reversal of entrainment was showcased and compared against the experimental results of Scales et al. [30]. The progression of the disc of highly viscous lubricant through the center of the contact just after reversal was automatically picked up by the variable timestep approach, and the results were shown to be just as accurate as for fixed timesteps.

The problem of surface roughness has been considered. It was seen how the overrolling of a single surface feature required small steps while the asperity passes through the center of the contact. One conclusion to be drawn from this example could be that for cases with real surface roughness, the timestep could be expected to be constant throughout. In the example of a full surface roughness pattern it has been seen how this level of constant timestep is related to the amplitude of the roughness pattern and may be much smaller than the mesh size. It is in cases like this where grid adaptation [15, 17] will be very beneficial.

The other case considered was that of shock loading, where the loading on the contact changed dramatically over a very short length of time. Again it was seen how the timesteps were very small as the major changes in the loading changed, but as the system reached a steady state the allowable timestep size increased.

The grid adaptation techniques shown to be beneficial in [15, 17] have not been included, hence allowing the advantages of the variable timestepping methods to be considered independently of other factors. Similarly the advantages of parallelism [14, 18] have also been neglected since they have no impact on the accuracy of the solution obtained.

Future work in this area should consider the use of adjoint-based approaches with regard to the direct estimation and control of errors in quantities such as the central and minimum film thicknesses, or other quantities of interest such as the friction [17, 20].

THE RIEMANN PROBLEM FOR THE EULER EQUATIONS WITH NONCONVEX AND NONSMOOTH EQUATION OF STATE: CONSTRUCTION OF WAVE CURVES*

SIEGFRIED MÜLLER† AND ALEXANDER VOß†

Abstract. The Riemann problem is considered for the investigation of nonclassical wave phenomena in Bethe–Zel'dovich–Thompson (BZT)-fluids and fluids which undergo a phase transition, i.e., the isentropes suffer kinks at the saturation boundaries. These fluids are modeled by a general equation of state that also takes into account regions of negative nonlinearity where the isentropes are nonconvex in the pressure-volume plane. Here the physical model is based on thermodynamical equilibrium. Both nonsmoothness as well as nonconvexity significantly influence the composition of the wave curves which are crucial for determining the solution for the Riemann problem for the Euler equations. This work gives explicit criteria for the composition of these wave curves by elementary wave types such as shocks, simple waves, and composite waves. Numerous examples for different wave curve compositions are presented.

Key words. Riemann problem, Euler equations, phase transition, negative nonlinearity, BZT-fluids

DOI. 10.1137/040619909

1. Introduction.

The dynamics of compressible flows has a strong influence on the design of aircraft and turbomachinery. In many applications the fluid is modeled by a perfect gas. In the range of perfect gas theory only two types of waves are possible and allowed by the entropy inequality—the [illegible] and the [illegible]. A compression shock is a discontinuity where the pressure of the fluid increases while the shock is passing, whereas in an expansion wave the pressure decreases.

However, the perfect gas model is no longer appropriate when dealing with so-called BZT-fluids, named after Bethe, Zel'dovich, and Thompson. These fluids, e.g., high molecular fluorcarbons and hydrocarbons, are characterized by a large heat capacity and are considered a subgroup of so-called retrograde fluids. BZT-fluids exhibit a region of negative nonlinearity near the curve of saturated vapor in phase space. This region is characterized by the nonconvexity of the isentropes in the pressure-volume plane where the fundamental derivative of gas dynamics Γ becomes negative due to the negative curvature of the isentropes; see Figure 1. From experiments, e.g., [BBKN83], it is known that there may occur nonclassical effects such as [illegible] and [illegible], as well as waves composed of adjacent shocks and simple waves. Here an expansion shock is a discontinuity where the pressure of the fluid decreases while the shock is passing, whereas in a compression wave the pressure increases. In short, most of the classical inequalities and effects are reversed in this area.

Below the critical point in phase space (see again Figure 1), liquid and vapor coexist in a so-called mixture region. Due to the involved phase changes new phe-

nomena such as [illegible] and [illegible] have been observed; cf. [DTMS79, TK83, TCK86, TCM$^+$87].

The aforementioned phenomena can be analytically investigated by the exact solution of a Riemann problem for compressible fluid flow where a general equation of state (EOS) is employed, capable of reflecting the negative nonlinearity of BZT-fluids as well as phase transitions and mixture states, respectively. Moreover, such an exact Riemann solver is helpful in many other respects. For instance, it may serve as a validation tool for numerical schemes since it is known that some of them do not catch all effects. Additionally, it can be used to determine initial conditions for experiments exhibiting the aforementioned phenomena.

The crucial point in solving the Riemann problem for compressible fluids is the construction of the wave curves. So far it has been an open problem how to [illegible] a practical method for the computation of the wave curves from the known theoretical construction, and thus to determine the exact Riemann solution in the general setting [illegible] phase transition. For this purpose we extend here the well-known concept of wave curve composition and construction (cf. [Wen72a, Wen72b]) to the [illegible] case for the first time. Following Liu's concept [Liu75] to characterize the admissibility of wave types by the monotonicity of the corresponding wave speeds, we additionally have to take into account that the wave curves may suffer kinks and therefore wave speeds may jump. Here we present a complete set of conditions characterizing those states on a wave curve where the wave type changes. Then these conditions are employed to compose a wave curve out of different elementary waves such as shock waves, simple waves, and composite waves in a [illegible] way. The construction is supplemented by numerous examples for different compositions. Details can be found at length in [Voß05]. Note that this paper is primarily concerned with the design of an algorithm for the computation of the wave curves. In particular, no convergence result is claimed. The existence, uniqueness, and regularity have been investigated in full detail in earlier works by Liu [Liu75] as well as Iguchi and LeFloch [IL03] for general systems of hyperbolic conservation laws.

Finally, we remark that the construction is based on certain assumptions. Since these assumptions are properly addressed in different parts of the paper we will summarize them here for the convenience of the reader: (1) We assume that the underlying system of conservation laws, namely, the Euler equations, modeling inviscid,

compressible fluid flow, is hyperbolic. Because of this assumption the different wave families do not coincide in the space-time continuum. Consequently, we exclude states corresponding to three-phase mixtures. (2) The nonlinear wave families are assumed to linearly degenerate only at isolated points. The flux functions also exhibit discontinuous derivatives at isolated points. This implies that the wave curves corresponding to the nonlinear fields are transversal to the submanifolds of degeneration points and kinks where the curvature of the isentropes vanishes or suffers a kink. (3) The presented construction of the wave curves is only admissible if the isentropes do not cross each other in the pressure-volume plane. This is guaranteed provided that the Grüneisen coefficient is positive, i.e., the material expands upon heating at constant pressure. A well-known exception is water that contracts upon heating near 0° C and 1 bar. (4) According to the above assumptions the solution of the Riemann problem may be reduced to constructing wave curves and determining an intersection point of the wave curves corresponding to the nonlinear fields in the pressure-velocity plane. To ensure uniqueness of the intersection point the wave curves have to be monotone. This holds true provided that the introduced by Smith [Smi79] on the EOS is satisfied; see [MP89]. (5) The wave curves need to be parameterized. Here we employ the pressure because this quantity varies monotonically along the wave curves as long as the introduced by Smith [Smi79] on the EOS is satisfied; see [MP89]. So far there is no evidence that the weak condition is ever violated. (6) The phase transition is assumed to take place instantaneously; i.e., the system is in equilibrium. Therefore, nonequilibrium phenomena such as metastable states are not considered here. Taking these effects into account would spoil the self-similarity of the Riemann solution. (7) Throughout the construction the will be imposed. Therefore, nonclassical shocks will not be included; cf. [HL00, Flo02].

1.1. Physical background. We first recall the modification of a cubic EOS, for instance, the EOS, in order to take into account the aformentioned physical regions. We remark that this approach is not restricted to the van der Waals EOS but can be applied, for instance, to more appropriate cubic EOSs such as the Redlich–Kwong or Peng–Robinson EOSs.

The van der Waals EOS is one of the simplest model equations. It is given by

$$\mathtt{p}(\mathtt{v},\mathtt{T}) = \frac{\mathcal{R}\,\mathtt{T}}{\mathtt{v}-\mathtt{b}} - \frac{\mathtt{a}}{\mathtt{v}^2}, \tag{1.1}$$

with pressure $\mathtt{p}$, specific volume $\mathtt{v}$, temperature $\mathtt{T}$, specific gas constant $\mathcal{R}$, internal pressure $\mathtt{a}/\mathtt{v}^2$, and covolume $\mathtt{b}$. This is an incomplete EOS and has to be completed by a caloric EOS for the internal energy $\mathtt{e}$ and the entropy $\mathtt{s}$,

$$\mathtt{e}(\mathtt{v},\mathtt{T}) = \mathtt{e}_0 + \int_{\mathtt{T}_0}^{\mathtt{T}} \mathtt{c}_\mathtt{v}(\mathtt{T})\ \mathtt{dT} - \frac{\mathtt{a}}{\mathtt{v}}, \qquad \mathtt{s}(\mathtt{v},\mathtt{T}) = \mathtt{s}_0 + \int_{\mathtt{T}_0}^{\mathtt{T}} \frac{1}{\mathtt{T}}\,\mathtt{c}_\mathtt{v}(\mathtt{T})\ \mathtt{dT},$$

such that the thermodynamic relation

$$\mathtt{de} = -\mathtt{p}\ \mathtt{dv} + \mathtt{T}\ \mathtt{ds} \tag{1.2}$$

holds. Here $\mathtt{c}_\mathtt{v}$ denotes the heat capacity at constant volume, $\mathtt{e}$ the internal energy, and $\mathtt{e}_0$ the heat of formation. Note that a BZT-fluid is characterized by a large heat capacity, i.e., $\mathcal{R}/\mathtt{c}_\mathtt{v} \ll 1$.

The pressure equation (1.1) shows an unphysical inclination in the mixture area. If we consider an isotherm for a temperature below the critical one (see Figure 1(b) for a BZT-fluid), we observe two local extrema, called spinodal points. They correspond to the endpoints of supersaturated vapor (maximum) and overexpanded liquid (minimum), respectively. Between these two points the derivative $\mathtt{p_v}(\mathtt{v},\mathtt{T})$ is positive and, hence, physically excluded. In order to provide physically meaningful data, we calculate the equilibrium or vapor pressure $\bar{\mathtt{p}}$, as a function of the temperature using the well-known Maxwell's construction principle. Summarized, for every temperature below the critical one, two volumes $\bar{\mathtt{v}}_1$ and $\bar{\mathtt{v}}_2$ and the equilibrium pressure $\bar{\mathtt{p}}$ are computed such that the equal-area-rule

$$\int_{\bar{\mathtt{v}}_1}^{\bar{\mathtt{v}}_2} \mathtt{p}(\mathtt{v},\mathtt{T})\ \mathtt{dv} = \bar{\mathtt{p}}\,(\bar{\mathtt{v}}_2 - \bar{\mathtt{v}}_1), \qquad\qquad \mathtt{p}(\bar{\mathtt{v}}_1,\mathtt{T}) = \mathtt{p}(\bar{\mathtt{v}}_2,\mathtt{T}) = \bar{\mathtt{p}},$$

holds. Performing this for all $\mathtt{T} < \mathtt{T_c}$ yields the saturated liquid and vapor curves, i.e., the phase boundaries, and hence the mixture area according to the underlying EOS. Then we compose a new pressure EOS by taking the equilibrium pressure for parameters $(\mathtt{v},\mathtt{T})$ inside the mixture region and the original (1.1) otherwise.

In the same manner we modify the corresponding caloric EOS and the entropy $\mathtt{s}$. Inside the mixture region these quantities are calculated as convex combinations of the equilibrium states at the phase boundary, i.e.,

$$\bar{\mathtt{e}} = (1-\nu)\,\bar{\mathtt{e}}_1 + \nu\,\bar{\mathtt{e}}_2, \qquad \bar{\mathtt{s}} = (1-\nu)\,\bar{\mathtt{s}}_1 + \nu\,\bar{\mathtt{s}}_2, \qquad \nu = \frac{\bar{\mathtt{v}} - \bar{\mathtt{v}}_1}{\bar{\mathtt{v}}_2 - \bar{\mathtt{v}}_1},$$

where ν is the steam mass fraction. For simplicity, we choose $\mathtt{c_v}$ above to be constant. In particular, these linear combinations also satisfy the thermodynamic relation (1.2).

For an extensive discussion concerning the physical properties of retrograde and BZT-fluids we refer to [Cra91, Tho91]. The treatment of the mixture regions and the derivation of the Maxwell construction from evaluating the Gibbs-function at the saturation curves can be found in [Bae88].

In the present paper we restrict our attention to systems being in equilibrium, which is tantamount to assuming instantaneous phase transitions. Following [MP89], such an equilibrium model is reasonable if the time for transition is short relative to the time scale of the flow. When this is not the case, then nonequilibrium phenomena such as the metastable state play a role.

1.2. Mathematical background. We now briefly summarize the fundamental concepts and notions for treating systems of hyperbolic conservation laws in one spatial dimension. Among them is a discussion on strict hyperbolicity and genuine nonlinearity in a generalized sense; i.e., we take into account smooth as well as Lipschitz continuous flux functions.

We remark that recent mathematically oriented literature, e.g., [Daf00] or [Flo02], tends to use "well-known" terms like [illegible] or [illegible] in a more general sense which is thus detached from their original, physical meaning. This makes allowance for the ongoing research in the field of hyperbolic conservation laws, for instance, in the case of nonclassical shock waves or retrograde fluids used in gas dynamics, leading to formerly thought "impossible" physical effects [Tho91].

A system of conservation laws

$$\mathtt{q}_t + \mathtt{f}(\mathtt{q})_x = 0, \quad \mathtt{q}(t,x) \in V,\ x \in \mathbb{R},\ t > 0, \tag{1.3}$$

with state vector $\mathtt{q} : \mathbb{R}_+ \times \mathbb{R} \to V \subset \mathbb{R}^m$ and flux function $\mathtt{f} : V \to \mathbb{R}^m$ is said to be a strictly hyperbolic system if the Jacobian $\partial_{\mathtt{q}}\mathtt{f}$ of a [illegible] flux $\mathtt{f}$ admits m real and distinct eigenvalues

$$\lambda_1(\mathtt{q}) < \cdots < \lambda_m(\mathtt{q}) \quad \forall \mathtt{q} \in V.$$

They are referred to as characteristic speeds, associated to the basis of right eigenvectors $\{\mathtt{r}_k(\mathtt{q})\}_{k=1,\dots,m}$. Additionally, they are supposed to be normalized; i.e., $\mathtt{l}_l^T \mathtt{r}_k = \delta_{l,k}$, where $\{\mathtt{l}_l\}_{l=1,\dots,m}$ denote the corresponding left eigenvectors. We emphasize that the assumption of strict hyperbolicity is crucial for solving the Riemann problem by determining the intersection of wave curves. However, there are physical applications where nonstrictly hyperbolic PDEs are involved; see, for instance, [IMPT88]. If initial data at time $t = 0$ is prescribed by a given function $\mathring{\mathtt{q}}$ consisting of piecewise constant data

$$\mathring{\mathtt{q}}(x) = \begin{cases} \mathtt{q}_l, & x < 0, \\ \mathtt{q}_r, & x > 0, \end{cases} \tag{1.4}$$

the initial value problem is referred to as the Riemann problem. As will be seen later, the solution of a Riemann problem, i.e., the type of occurring waves patterns, their compositions, and speeds, heavily depends on the [illegible] of the characteristic speeds λ_k along trajectories tangent to $\mathtt{r}_k$.

The pair $(\lambda_k, \mathtt{r}_k)$ is called the k-characteristic field. It is called genuinely nonlinear if the quantity

$$\zeta_k(\mathtt{q}) = [\nabla_{\mathtt{q}} \lambda_k \cdot \mathtt{r}_k](\mathtt{q})$$

does not vanish, i.e., $\zeta_k \not\equiv 0$. It is said to be linearly degenerated when $\zeta_k \equiv 0$. With this in mind, the definition of genuine nonlinearity can be read as a directional derivative of λ_k along an integral curve defined by the eigenvector $\mathtt{r}_k$.

In general, the flux function is assumed to be either smooth or Lipschitz continuous. Concerning the Euler equations and a cubic EOS we have a C^1-function away from phase boundaries which is just continuous on the saturation lines. At these states the derivatives suffer from kinks. In order to speak of hyperbolic systems and genuinely nonlinear characteristic fields even in the case of Lipschitz continuous flux functions, one has to adapt the notions above. This has been done in [CLT01], based on the definition of generalized derivatives and related important analytical results still valid for Lipschitz functions, which can be found in [Cla83] and [Fil88].

One can show that the initial data of a Cauchy or Riemann problem is propagated along straight (characteristic) lines in the x-t plane. Hence, it admits self-similar (weak) solutions of the form $\mathtt{q} = \mathtt{q}(\tilde{\xi})$ with $\tilde{\xi} = \frac{x}{t}$ and the solution additionally satisfies the boundary conditions $\mathtt{q}(-\infty) = \mathtt{q}_l$ and $\mathtt{q}(\infty) = \mathtt{q}_r$. According to [Daf00] such a self-similar weak solution, $\mathtt{q} = \mathtt{q}(\tilde{\xi})$, is a bounded and measurable function $\mathtt{q} \in \mathtt{BV}_{\mathrm{loc}}$. In particular, it is differentiable on $(-\infty, +\infty)$ almost everywhere and one-sided limits $\mathtt{q}(\tilde{\xi}) = \mathtt{q}(\tilde{\xi}-) = \mathtt{q}(\tilde{\xi}+)$ exist, except possibly on a countable set of $\tilde{\xi}$. Furthermore, it solves the ordinary differential equation

$$[-\tilde{\xi}\, I + [\partial_{\mathtt{q}}\mathtt{f}](\mathtt{q})]\,(\mathtt{d}_{\tilde{\xi}}\mathtt{q}) = 0, \tag{1.5}$$

in the sense of measures. We again refer to [Daf00] for details on the correlation of $\mathtt{BV}$ and the space of measures. The interval $(-\infty, +\infty)$ can be decomposed into

three disjoint sets $\mathcal{N}, \mathcal{H}$, and $\mathcal{R}$, where $\mathcal{N}$ denotes the set on which $\mathtt{q}$ is constant, i.e., $\mathtt{d}_{\tilde{\xi}}\mathtt{q} = 0$, on (at most) a countable union of disjoint open intervals. $\mathcal{H}$ is the (at most) countable set of points of jump discontinuities of $\mathtt{q}$ and for each $\tilde{\xi} \in \mathcal{H}$ the Rankine–Hugoniot condition holds. At least, the (possibly empty) set $\mathcal{R}$ consists of points of continuity of $\mathtt{q}$, where at each $\tilde{\xi} \in \mathcal{R}$ we have

$$\lambda_k(\mathtt{q}(\tilde{\xi})) = \tilde{\xi} \quad \text{for some } k \in \{1, \dots, m\}. \tag{1.6}$$

If $\mathtt{q}$ is also differentiable at $\tilde{\xi} \in \mathcal{R}$, (1.5) implies

$$\mathtt{d}_{\tilde{\xi}}\mathtt{q} = \tilde{c}\,\mathtt{r}_k(\mathtt{q}), \tag{1.7}$$

with some function $\tilde{c} = \tilde{c}(\tilde{\xi})$, satisfying

$$[\nabla_{\mathtt{q}}\lambda_k \cdot \mathtt{r}_k](\mathtt{q})\,\tilde{c} = \zeta_k(\mathtt{q})\,\tilde{c} = 1. \tag{1.8}$$

The latter directly follows from differentiation of (1.6) and indicates that $\mathtt{q}(\tilde{\xi})$ is a point of genuine nonlinearity of the k-characteristic family.

Finally, the above discussion shows that a self-similar solution is composed of constant states, shocks, and simple waves.

1.3. Outline of the paper. We first address the Riemann problem of gas dynamics in section 2. Here, the general structure of a solution in terms of wave curves is given, providing the basis for introducing the specific wave parts, i.e., rarefaction, shock, and composite curves. They are discussed in the context of genuinely nonlinear, nongenuinely nonlinear, and nonsmooth characteristic fields. Then, section 3 contains the construction of wave curves—our main focus. This is basically a discussion on the termination of wave curves if certain criteria are violated, for instance, admissibility criteria, and the problem of continuation. We specify 20 possible termination conditions and provide an example for each case. Section 4 describes how to map the constructed solution from phase space onto the x-t plane. This is not obvious as not every part of the wave curve induces a wave profile visible in the x-t plane. We end with a conclusion in section 5 and a collection of figures in section 6, corresponding to the previously discussed examples.

2. The Riemann problem of gas dynamics. By now, the Riemann problem is well understood for the Euler equations that model equilibrium hydrodynamics. For an overview we refer to the review article by Menikoff and Plohr [MP89].

In Lagrangian coordinates the vector $\mathtt{q}$ and the flux function $\mathtt{f}(\mathtt{q})$ are given by

$$\mathtt{q} = (\mathtt{v}, \mathtt{u}, \epsilon)^T, \qquad \mathtt{f}(\mathtt{q}) = (-\mathtt{u}, \mathtt{p}, \mathtt{pu})^T,$$

with the velocity $\mathtt{u}$ and the total energy $\epsilon = \mathtt{e} + \mathtt{u}^2/2$. This system is closed by a general EOS satisfying the relations

$$\mathtt{p} = \mathtt{p}(\mathtt{v}, \mathtt{s}), \quad \mathtt{p}_{\mathtt{v}}(\mathtt{v}, \mathtt{s}) < 0.$$

We assume that the isentrope is a strictly monotone function in order to ensure strict hyperbolicity of the underlying system of equations. By this assumption we exclude states corresponding to three-phase mixtures. In the phase diagram in the $\mathtt{p}$-$\mathtt{T}$ plane these states are characterized by the triple point. There the sound speed vanishes and therefore we lose strict hyperbolicity. According to Menikoff and Plohr [MP89, p. 82],

"however, this loss of strict hyperbolicity does not have the important consequences for the topology of wave curves in compressible fluid flow as it has for other nonstrictly-hyperbolic systems." For systems with more degenerate wave families we refer, for instance, to [Mil03, Tor03].

Furthermore we assume that the isentropes do not cross each other in the pressure-volume plane. This is guaranteed provided that the Grüneisen coefficient

$$\mathcal{G} = -\frac{\mathtt{v}}{\mathtt{T}}\,\mathtt{e}_{\mathtt{sv}}(\mathtt{v},\mathtt{s})$$

is positive.

The characteristic speeds $\lambda_k(\mathtt{q})$, $k = 1, 2, 3$, the corresponding right eigenvectors, and the speed of sound turn out to be

$$\begin{aligned}
\lambda_1 &= -\sqrt{-\mathtt{p}_{\mathtt{v}}(\mathtt{v},\mathtt{s})} = -\mathtt{c}/\mathtt{v} < \lambda_2 = 0 < \lambda_3 = +\sqrt{-\mathtt{p}_{\mathtt{v}}(\mathtt{v},\mathtt{s})} = \mathtt{c}/\mathtt{v},\\
\mathtt{r}_{1,3} &= \frac{1}{\lambda_{1,3}}\,(-1, \lambda_{1,3}, \mathtt{p} + \lambda_{1,3}\mathtt{u})^T, \quad \mathtt{r}_2 = (-\mathtt{p}_{\mathtt{e}}(\mathtt{v}\,\mathtt{e}), 0, \mathtt{p}_{\mathtt{v}}(\mathtt{v},\mathtt{e}))^T,\\
\mathtt{c}^2 &= -\mathtt{v}^2\,\mathtt{p}_{\mathtt{v}}(\mathtt{v},\mathtt{s}),
\end{aligned}$$

respectively. The properties of the corresponding characteristic k-fields are determined by

$$\zeta_{1,3} = \Gamma/\mathtt{v}, \qquad\qquad \zeta_2 = 0,$$

where Γ denotes the fundamental derivative of gas dynamics. This quantity is a measure for the curvature of the isentropes and is defined by

$$\Gamma = \frac{\mathtt{v}^3}{2\mathtt{c}^2}\,\mathtt{p}_{\mathtt{vv}}(\mathtt{v},\mathtt{s}) = -\frac{\mathtt{v}}{2}\frac{\mathtt{p}_{\mathtt{vv}}(\mathtt{v},\mathtt{s})}{\mathtt{p}_{\mathtt{v}}(\mathtt{v},\mathtt{s})};$$

cf. Figure 1. Since the term $\mathtt{p}_{\mathtt{v}}$ is assumed to be negative, the sign of Γ coincides with the convexity properties of the isentropes. Hence, for a convex EOS, i.e., $\Gamma > 0$, the nonlinear fields are genuinely nonlinear, whereas in the case of a nonconvex EOS they may locally degenerate and there exist states $\bar{\mathtt{q}}$ in phase space such that $\zeta_k(\bar{\mathtt{q}}) = 0$.

Obviously, the Euler equations have only two linearly nondegenerated wave families, namely, $k = 1, 3$. This fact is crucially exploited in the construction of the Riemann solution; see section 2.2.

Note that, according to standard assumptions of equilibrium thermodynamics, we may equivalently express the pressure also in terms of specific volume and internal energy. For an extensive discussion on complete and incomplete EOSs see again [MP89].

2.1. The general structure of a Riemann solution. As is generally known there is a one-to-one correlation between a Riemann solution considered in the space-time plane and a set of parameterized, one-dimensional (wave) curves in phase space. Hence, solving the Riemann problem in space-time can be shifted to the construction of wave curves in such a way that there is a path along these curves connecting the initial states $\mathtt{q}_l$ and $\mathtt{q}_r$. The basic idea of this construction principle is to consider curves corresponding to the k-characteristic fields, $k = 1, \ldots, m$, which are connected at points called intermediate states; i.e., these states connect a k-wave pattern with a $k+1$-wave pattern. To be more precise, we introduce the notation $\mathtt{W}_k = \mathtt{W}_k(\mathtt{q}, \xi)$ denoting the wave curve corresponding to the k-characteristic field emanating from

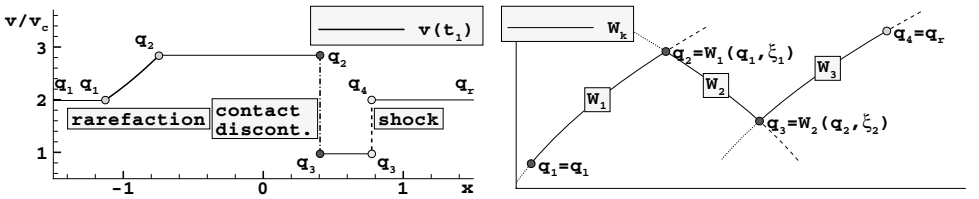
the state $\mathtt{q} \in \mathbb{R}^m$ and parameterized by $\xi \in \mathbb{R}$. These curves are composed of all states which can be connected to their origins with some specific wave type in space-time. Then we are looking for a unique set of parameter values ξ_k, $k = 1, \ldots, m$, characterizing the intermediate states $\mathtt{q}_{k+1} \in \mathbb{R}^m$ in phase space such that the conditions

$$\begin{aligned} \mathtt{q}_l &= \mathtt{W}_1(\mathtt{q}_l, 0) \equiv \mathtt{q}_1, \\ \mathtt{q}_{k+1} &= \mathtt{W}_k(\mathtt{q}_k, \xi_k), \quad k = 1, \ldots, m-1, \\ \mathtt{q}_r &= \mathtt{W}_m(\mathtt{q}_m, \xi_m) \equiv \mathtt{q}_{m+1}, \end{aligned}$$

or, equivalently,

$$\mathtt{W}_m(\mathtt{W}_{m-1}(\ldots(\mathtt{W}_1(\mathtt{q}_l, \xi_1), \xi_2), \ldots, \xi_{m-2}), \xi_{m-1}), \xi_m) = \mathtt{q}_r, \tag{2.1}$$

hold. Then the existence of a solution of the Riemann problem is tantamount to the existence of a set of parameters. [illegible] implies that there is exactly [illegible] parameter set. [illegible]



(a) Specific volume $\mathtt{v}(\cdot, t)$. (b) Wave curves.

FIG. 2. *Riemann solution in time-space and in phase space.*

The general procedure is illustrated by Figure 2 showing a classical solution of a Riemann problem for the Euler equation corresponding to a convex EOS.

The wave curve intersection in phase space is sketched in Figure 2(b) and the corresponding wave profiles in the x-t plane are shown in Figure 2(a). There are three elementary waves: (i) a simple wave connecting the states $\mathtt{q}_1 = \mathtt{q}_l$ and $\mathtt{q}_2$; (ii) a contact discontinuity from $\mathtt{q}_2$ to $\mathtt{q}_3$; and (iii) a shock between $\mathtt{q}_3$ and $\mathtt{q}_4 = \mathtt{q}_r$. The parameterized wave curves $\mathtt{W}_k = \mathtt{W}_k(\mathtt{q}_k, \xi)$ for $k \in \{1, 2, 3\}$ in this situation are sketched in Figure 2(b). For instance, one branch of wave curve $\mathtt{W}_1$ consists of all states which can be connected to $\mathtt{q}_1$ by a simple wave. As the first wave profile of the solution is a simple wave, the state $\mathtt{q}_2$ must be contained in the rarefaction branch of $\mathtt{W}_1$. Regarding this example we have

$$\mathtt{q}_1 = \mathtt{q}_l, \qquad \mathtt{q}_2 = \mathtt{W}_1(\mathtt{q}_1, \xi_1), \qquad \mathtt{q}_3 = \mathtt{W}_2(\mathtt{q}_2, \xi_2), \qquad \mathtt{q}_4 = \mathtt{W}_3(\mathtt{q}_3, \xi_3) = \mathtt{q}_r,$$

i.e., each intermediate state ($k = 2, 3$) and the right state are elements of the previous wave curve and ξ_k denotes the respective curve parameter. Note that states may coincide ($\mathtt{q}_k = \mathtt{q}_{k+1}$) and that this results in a wave that cannot be observed in the x-t plane.

Considered in the x-t space, a wave profile is just a composition of elementary wave profiles, i.e., a sequence of separated elementary waves (as in the example above), or sonic shocks adjoining simple waves (composite waves), or split waves when wave speeds are such that waves separate in the x-t space. Note that without knowledge of the [illegible] the latter split wave patterns cannot be distinguished from separated

elementary waves. Note also that the composition of a wave curve can be much more complex than the wave profile in x-t.

The construction of the wave curve $\mathtt{W}_k$ is subject to the properties of the k-characteristic fields. If it is linearly degenerated, the wave curve $\mathtt{W}_k$ is composed of one wave type only, namely, contact discontinuities. Otherwise, if it is nonlinear, the wave curve may be composed of several wave types which we here call [illegible]. Each wave part is a shock wave part, a simple wave part, or a composite wave part in the sense of Liu. For instance, a sonic shock wave profile with an adjacent continuous simple wave in x-t corresponds to a simple wave part with a following composite wave part embedded in the whole wave curve. The composition of wave curves out of wave parts and their corresponding wave profile in the x-t space is the main idea described in the following.

To account for the different parts of the wave curve $\mathtt{W}_k$ we first split it into two [illegible] $\mathtt{W}_{k+}$ and $\mathtt{W}_{k-}$ corresponding to positive and negative parameter direction relative to the origin of the wave curve. Then each wave branch is composed of [illegible] $\mathtt{W}_{k\pm}^{[j]}$ that might be an elementary wave or an elementary wave part corresponding to a composite wave. Then the wave curve can be written as the composition

$$\mathtt{W}_k = \mathtt{W}_{k+}^{[j]} \cup \mathtt{W}_{k-}^{[j]} = \{\mathtt{W}_{k+}^{[j]} \mid j \in J_{k+}\} \cup \{\mathtt{W}_{k-}^{[j]} \mid j \in J_{k-}\}.$$

Here the sets $J_{k\pm} = \{1, \dots, j_{k\pm,\max}\}$ denote index sets according to the number of involved wave parts of each branch. The associated intermediate states are referred to by $\mathtt{q}_{k\pm}^{[j]}$ and should satisfy

$$\mathtt{q}_{k\pm}^{[j]} = \mathtt{W}_{k\pm}^{[j]}(\mathtt{q}_{k\pm}, \xi_{k\pm}^{[j]}) = \mathtt{W}_{k\pm}(\mathtt{q}_{k\pm}, \xi_{k\pm}^{[j]}) \tag{2.2}$$

with appropriate parameters $\xi_{k\pm}^{[j]}$. In case of the Euler equations this parameterization is given by the pressure but it is not restricted to that.

The imposed equality concerning the right-hand side expression in (2.2) synchronizes the parameterization of $\mathtt{W}_{k\pm}$ and $\mathtt{W}_{k\pm}^{[j]}$. The various wave notions are sketched in Figure 3.

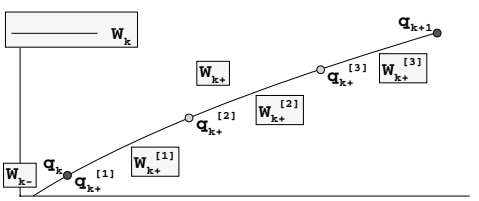


FIG. 3. *Wave curves, branches, and parts.*

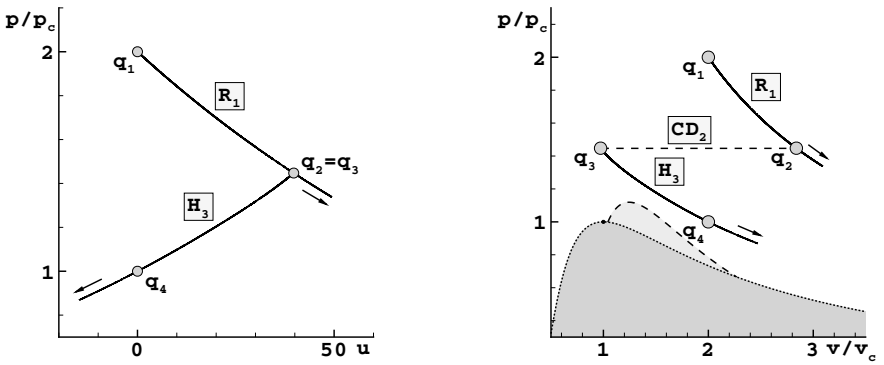
The monotonicity properties of the characteristic speed or shock speed along the wave curves is important for their composition. If we speak of wave speed along some wave curve, wave branch, or wave part, we always address the speed corresponding to the respective wave type.

2.2. Existence and uniqueness of solutions. As is well known, the 2-characteristic family of the Euler equations is linearly degenerated and the 2-wave is always a contact discontinuity. The Rankine–Hugoniot condition implies that the pressure $\mathtt{p}$ and the velocity $\mathtt{u}$ have to be constant along the curve $\mathtt{W}_2$; i.e., the pressure and

the velocity do not jump on contact discontinuities. Hence, projecting the wave curves onto the p-u plane reveals all information concerning existence and uniqueness of a Riemann solution, since existence means the intersection of the 1- and 3-wave curves and uniqueness means that there is exactly one intersection point. Figures 4(a) and 4(b) sketch wave curves projected onto the p-u and p-v planes, taken from the example shown in Figure 2. Here the solution consists of a 1-rarefaction, a 2-contact discontinuity, and a 3-shock.



(a) p-u-plane. (b) p-v-plane.

FIG. 4. *Wave curve projection onto* p-u *and* p-v *planes.*

In general the question of existence can be answered by looking at the asymptotic properties of the EOS, while uniqueness of a solution depends on the monotonicity properties of the wave curves in the p-u plane. Furthermore, the transversality of the wave curves is required to solve the Riemann problem. In [MP89] the authors discuss in greater detail asymptotic and monotonicity properties while taking into account regions where $\Gamma < 0$ and where phase transition occurs. They concluded that a solution for any Riemann problem exists and that it has standard structure, except that the 1- and 3-waves may be composite or split waves.

2.3. Wave curve structure. The composition of the wave curves is strongly correlated to the genuine nonlinearity of the characteristic fields. The different cases are subsequently listed and illustrated by Figure 5. At this time, we focus on characteristic fields which are not linearly degenerated.

(C) The "convex" case: Characteristic fields are genuinely nonlinear at all states. Then each wave curve consists of a rarefaction branch in one parameter direction and a shock branch in the other direction; i.e., each branch consists of exactly one wave part. In this situation a solution of the Riemann problem is composed of simple waves and shocks (besides contact discontinuities).

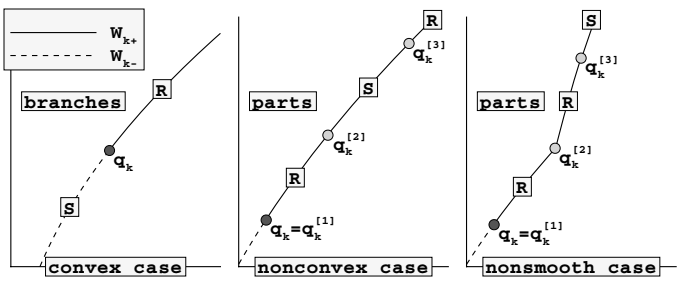
(NC) The "nonconvex" case: The genuine nonlinearity of the characteristic fields is violated at isolated states along wave curves, or precisely, along rarefaction curves. Then a wave branch may be composed of different wave parts. Figure 5 shows a typical k-wave, where a rarefaction is connected to a shock part, and the shock is connected to another rarefaction part. Notice, that the different waves are adjacent in the x-t plane; i.e., the wave speeds are equal at the states belonging to the two wave parts.

In case of the Euler equations this situation may occur for a real gas EOS such as van der Waals and a BZT-fluid in order to obtain states, where the

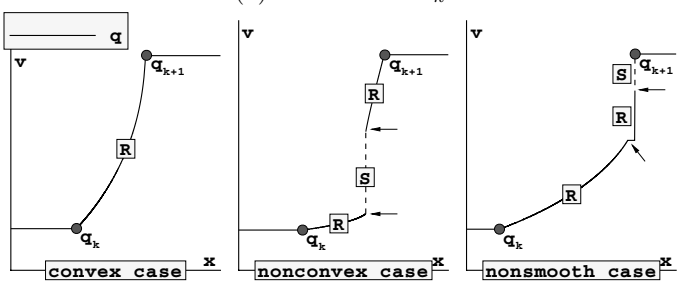
fundamental derivative Γ vanishes and the characteristic field degenerates.

(NS) The "nonsmooth" (and possibly nonconvex) case: Similar to the nonconvex case, there exist isolated states along the wave curves at which the differentiability property fails. At those states the curves are just continuous. This leads to wave curves which may also be composed of different wave parts, but due to the possible kinks the wave speeds jump between two wave parts. Concerning a solution in the x-t plane this may result in additional constant intermediate states, filling the gaps caused by the discontinuities in wave speeds. Figure 5 sketches a k-wave where a rarefaction curve is split into two parts and an adjacent shock is attached to the second rarefaction part.
Regarding the Euler equations we obtain such wave curves if we take into account phase transitions. They cause a jump in the characteristic speeds.

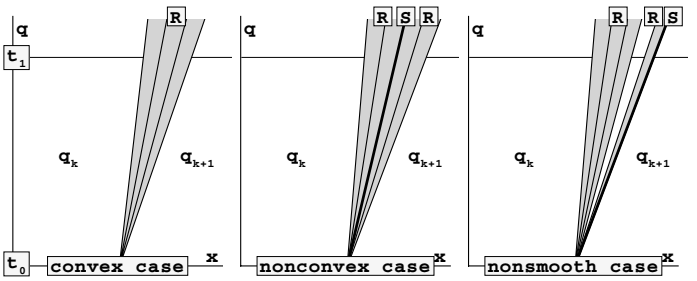
In the end all ingredients are available in order to explicitly construct a solution of the Riemann problem by composing admissible wave parts and we will obtain, in particular, the wave structures sketched in Figure 5.



(a) Wave curve $\mathtt{W}_k$.



(b) Solution of a Riemann problem, k-wave.



(c) Characteristics, k-wave.

FIG. 5. *Solution structure of Riemann problems corresponding to genuinely nonlinear, nongenuinely nonlinear, and nonsmooth nonlinear characteristic fields.*

2.4. Wave curves. In the following we summarize classical existence results involving [illegible] flux functions for the different wave curves, which can be found in [Flo02] and [Daf00]. In [CLT01] the authors prove the existence of rarefaction and shock curves for genuinely nonlinear systems and Lipschitz continuous flux functions. Their results are mainly based on the work of Filippov [Fil88] concerning ordinary differential equations with discontinuous coefficients and results from the theory of nonsmooth analysis given by Clarke [Cla83].

2.4.1. Simple waves. We have discussed before that for differentiable, self-similar solutions $\mathtt{q} = \mathtt{q}(\tilde{\xi})$, with $\tilde{\xi} = x/t$, the relations (1.7) and (1.8) hold. Now, we fix one genuinely nonlinear state $\mathtt{q}_0 \in V$, i.e., $\zeta_k(\mathtt{q}_0) \neq 0$, and consider the ordinary differential equation in the [illegible] $\mathtt{q}$

$$\mathtt{q}_{\tilde{\xi}} = \zeta_k(\mathtt{q})^{-1}\, \mathtt{r}_k(\mathtt{q}), \quad \mathtt{q}(\tilde{\xi}_0) = \mathtt{q}_0, \quad \tilde{\xi}_0 = \lambda_k(\mathtt{q}_0), \tag{2.3}$$

for one fixed but arbitrary $k \in \{1, \dots, m\}$. Then there exists a smooth solution $\mathtt{q}(\tilde{\xi})$ as long as the characteristic field is genuinely nonlinear (along this curve). Furthermore, integration of $\mathtt{d}_{\tilde{\xi}}\lambda_k$ together with the initial conditions yields $\lambda_k(\mathtt{q}(\tilde{\xi})) = \tilde{\xi}$. Note that the singularity in the term $\zeta_k(\mathtt{q})^{-1}$ for points of linear degeneracy stems from the special parameter choice of $\tilde{\xi}$.

Conversely, there exists a unique k-rarefaction wave curve $\mathtt{q}_k^{\mathtt{R}}(\xi)$ through $\mathtt{q}_0$, defined by

$$\mathtt{d}_\xi \mathtt{q}_k^{\mathtt{R}} = c\, \mathtt{r}_k(\mathtt{q}_k^{\mathtt{R}}), \quad \mathtt{q}_k^{\mathtt{R}}(\xi_0) = \mathtt{q}_0,$$

where $c \neq 0$ is an arbitrary Lipschitz continuous function. As long as the k-characteristic field remains genuinely nonlinear along $\mathtt{q}_k^{\mathtt{R}}$, the curve also solves (2.3) with the parameterization $\tilde{\xi}(\xi) = \lambda_k(\mathtt{q}_k^{\mathtt{R}}(\xi))$. For later use, we introduce the slightly more complicated notion $\mathtt{q}_k^{\mathtt{R}}(\xi, \mathtt{q}_0)$, when we need to emphasize the origin $\mathtt{q}_0$ of the wave curve.

A k-simple wave, connecting two states $\mathtt{q}_0$ and $\mathtt{q}_1 = \mathtt{q}_k^{\mathtt{R}}(\xi_1, \mathtt{q}_0)$ with a fixed parameter ξ_1, is then given by

$$\mathtt{q}(t,x) = \begin{cases} \mathtt{q}_0, & x \leq t\,\lambda_k(\mathtt{q}_0), \\ \mathtt{q}_k^{\mathtt{R}}(\xi(\tilde{\xi}), \mathtt{q}_0), & t\,\lambda_k(\mathtt{q}_0) < x < t\,\lambda_k(\mathtt{q}_1), \\ \mathtt{q}_1, & x \leq t\,\lambda_k(\mathtt{q}_1), \end{cases}$$

where the curve $\mathtt{q}_k^{\mathtt{R}}$ and the function $\xi(\tilde{\xi}) = \xi(x/t)$ are understood in the sense above. Moreover, if we have $\zeta(\mathtt{q}_0) \gtrless 0$ and choose $c > 0$, then $\lambda_k(\mathtt{q}_k^{\mathtt{R}}(\xi)) \gtrless \lambda_k(\mathtt{q}_0)$ locally if and only if $\xi \gtrless \xi_0$.

2.4.2. Shock waves. In the spirit of the last section, we fix one state $\mathtt{q}_0 \in V$ and collect all states $\mathtt{q} \in V$ that may be connected to $\mathtt{q}_0$ by a weak k-shock; i.e., the Rankine–Hugoniot jump condition holds,

$$\mathtt{f}(\mathtt{q}) - \mathtt{f}(\mathtt{q}_0) = \sigma\, (\mathtt{q} - \mathtt{q}_0), \tag{2.4}$$

with speed $\sigma = \sigma(\mathtt{q}, \mathtt{q}_0)$. Here a shock is called weak if limitations on the shock strength $|\mathtt{q} - \mathtt{q}_0| < \delta$ have to be imposed, where δ depends on $\partial\mathtt{f}(\mathtt{q}_0)$, $\partial^2\mathtt{f}(\mathtt{q}_0)$, and the modulus of continuity of $\partial^2\mathtt{f}$. In the following we always consider weak shocks. The set of shocks is called the Hugoniot locus of $\mathtt{q}_0$ and it represents the union of m shock curves. For each state $\mathtt{q}_0 \in V$ there is a unique C^2-curve $\mathtt{q}_k^{\mathtt{H}}(\xi)$ in the state

space V, called the k-shock curve through $\mathtt{q}_0$, and a C^2-function $\sigma_k(\xi)$, both defined for ξ in some neighborhood of ξ_0, with the following property: A state $\mathtt{q}$ can be connected to $\mathtt{q}_0$ by a k-shock of speed σ if and only if $\mathtt{q} = \mathtt{q}_k^{\mathtt{H}}(\xi)$, $\sigma = \sigma_k(\xi)$ for some ξ. Furthermore, we have $\mathtt{q}_k^{\mathtt{H}}(\xi_0) = \mathtt{q}_0$ and $\sigma_k(\xi_0) = \lambda_k(\mathtt{q}_0)$.

Again, the extended notion $\mathtt{q}_k^{\mathtt{H}}(\xi, \mathtt{q}_0)$, $\sigma_k(\xi, \mathtt{q}_0)$ shall be employed in the future when we want to point out the origin $\mathtt{q}_0$ of this shock curve.

At a state with $\zeta(\mathtt{q}_0) \gtrless 0$, a k-shock that connects $\mathtt{q}_0$ to a state $\mathtt{q}_1 = \mathtt{q}_k^{\mathtt{H}}(\xi, \mathtt{q}_0)$ satisfies the Lax entropy condition

$$\begin{aligned} \lambda_k(\mathtt{q}_0) > \sigma > \lambda_k(\mathtt{q}_1), \\ \lambda_{k+1}(\mathtt{q}_1) > \sigma > \lambda_{k-1}(\mathtt{q}_0) \end{aligned} \tag{2.5}$$

if and only if $\xi \lessgtr \xi_0$.

2.4.3. Composite waves. So far, we have constructed rarefaction and shock curves in case of genuinely nonlinear characteristic fields. In case of a linear degenerated state we cannot necessarily continue a rarefaction curve, since the solution may fold in the x-t plane. Analogously, a shock curve violates the Lax entropy condition if the shock speed drops below the characteristic speed. One can show that in the latter case the shock curve must have crossed at least one linear degenerated state. Hence, all phenomena are related to the existence of linear degenerated states and it is natural to extend the general situation to genuinely nonlinear characteristic fields, which are linearly degenerated on an $(m-1)$-dimensional hyperplane. This was first done by Gelfand [Gel59], [Gel63], for the scalar case and was generalized to hyperbolic systems in m dimensions by Wendroff [Wen72a], [Wen72b] and by Liu [Liu74], [Liu75]. In fact, they introduce a new type of wave curve, namely, the composite wave curve, which allows continuation of a wave curve.

We consider the situation where we have [illegible], i.e., where $\zeta_k = \nabla_{\mathtt{q}} \lambda_k \cdot \mathtt{r}_k$ vanishes locally at certain points of the phase space. To be precise, we assume that there is an $(m-1)$-dimensional hypersurface $\mathcal{M} \subset V$, where $\zeta_k|_{\mathcal{M}} = 0$ and the trajectories $\mathtt{q}_k^{\mathtt{R}}$ intersect $\mathcal{M}$ only at isolated points; i.e., $\mathtt{d}_\xi^2 \lambda_k(\mathtt{q}_k^{\mathtt{R}}(\xi)) \neq 0$ for all $\mathtt{q} \in \mathcal{M}$. Then we can continue a rarefaction curve if we consider the composite locus consisting of all roots $\mathtt{q} \in \mathcal{B}(\bar{\mathtt{q}})$ of

$$\Phi(\mathtt{q}, \xi^{\mathtt{R}}) = \mathtt{f}(\mathtt{q}) - \mathtt{f}(\mathtt{q}_k^{\mathtt{R}}(\xi^{\mathtt{R}})) - \lambda_k(\mathtt{q}_k^{\mathtt{R}}(\xi^{\mathtt{R}}))\,(\mathtt{q} - \mathtt{q}_k^{\mathtt{R}}(\xi^{\mathtt{R}})), \tag{2.6}$$

where $\mathtt{q}_k^{\mathtt{R}} = \mathtt{q}_k^{\mathtt{R}}(\xi^{\mathtt{R}}, \mathtt{q}_0)$ is a rarefaction curve, which degenerates at $\bar{\mathtt{q}} = \mathtt{q}_k^{\mathtt{R}}(\bar{\xi}, \mathtt{q}_0) \in \mathcal{M}$, i.e., $\zeta(\bar{\mathtt{q}}) = 0$.

At this stage it is not clear, however, that the composite locus is a [illegible]. It simply collects all states near the degeneration point that can be connected to any state on the rarefaction curve by a k-shock with a particular shock speed. Notice that (2.6) is actually the Rankine–Hugoniot condition where the shock speed equals the characteristic speed (sonic shock) and that, in particular, the composite locus contains the trivial solution $\mathtt{q} = \mathtt{q}_k^{\mathtt{R}}(\xi^{\mathtt{R}})$, i.e., the rarefaction curve itself.

Liu [Liu75] constructs the composite curve starting from $\bar{\mathtt{q}}$ by collecting all [illegible] states on Hugoniot curves, starting at states on the associated rarefaction curve. This way, the rarefaction curve is not part of the composite curve, but it is not clear that Liu's construction principle results in a unique curve, which additionally continues the rarefaction curve.

For this purpose the authors show in [MV05] the existence of a parameterizable composite curve $\mathtt{q}_k^{\mathtt{C}}$ in a local neighborhood of $\bar{\mathtt{q}}$ as being part of the composite locus. In particular, if one locally approaches $\bar{\mathtt{q}}$ on the rarefaction curve, then

the corresponding state on the composite curve approaches $\bar{\mathtt{q}}$ as well and the wave curve can be continued. Moreover, for any shock pair $[\mathtt{q}, \mathtt{q}^*]$ with $\mathtt{q} \in \mathtt{q}_k^{\mathtt{C}}$ and the associated state $\mathtt{q}^* \in \mathtt{q}_k^{\mathtt{R}}$ the curve $\mathtt{q}_k^{\mathtt{C}}$ is tangent to $\mathtt{q}^{\mathtt{H}}(\mathtt{q}^*)$ at $\mathtt{q}$. In particular, if $\sigma(\mathtt{q}, \mathtt{q}^*) = \lambda_k(\mathtt{q}^*) = \lambda_k(\mathtt{q})$, then $\mathtt{q}_k^{\mathtt{C}}$ is tangent to $\mathtt{q}_k^{\mathtt{R}}$ at $\mathtt{q}$; cf. [Liu75].

The composite curve provides the possibility to continue a rarefaction part of a wave curve beyond a state of linear degeneracy. It collects shock states which can be connected to some associated state, commonly denoted by $\mathtt{q}^*$, from the rarefaction curve. Now two questions arise: (i) In which sense are shocks collected in a composite curve admissible? (ii) How should we proceed, if there is no further corresponding rarefaction state?

The first question is answered within the frame of the [illegible] introduced below. The second issue addresses the fact that the associated rarefaction states run toward the origin of the rarefaction curve if we follow the composite curve. There might be the situation where we reach the origin of the rarefaction curve. In this case the solution is a simple shock and the wave curve is continued with a Hugoniot curve; we will come to this case later.

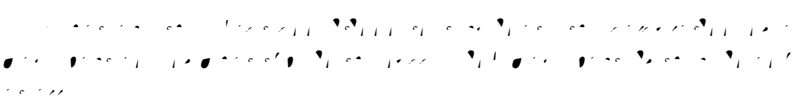
2.4.4. The Liu entropy criterion. The Liu entropy criterion was first presented in [Liu75] and concerns shock states, which may be connected by shock curves. Here a k-shock of speed $\sigma_k(\xi)$, connecting a state $\mathtt{q}_0$ to a state $\mathtt{q} = \mathtt{q}_k^{\mathtt{H}}(\xi, \mathtt{q}_0)$ for some ξ, is said to satisfy the Liu entropy condition if

$$\sigma_k(\xi) \leq \sigma_k(\hat{\xi}) \quad \forall \hat{\xi} \text{ between } \xi_0 \text{ and } \xi. \tag{2.7}$$

A k-shock connecting the states $\mathtt{q}_0$ and $\mathtt{q} = \mathtt{q}_k^{\mathtt{H}}(\xi, \mathtt{q}_0)$ and satisfying the Liu criterion (2.7) also satisfies the Lax criterion (2.5) if we suppose $\mathtt{l}^T(\mathtt{q})\,[\mathtt{d}_\xi \mathtt{q}_k^{\mathtt{H}}](\mathtt{q}) > 0$ to hold at ξ. If the k-characteristic family is genuinely nonlinear, then k-shocks satisfy the Liu criterion if and only if they satisfy the Lax criterion. Actually, the Liu condition is stronger than the Lax condition.

3. Construction of wave curves. The main goal of this chapter is to introduce a general construction principle for each wave branch that is part of an entropy solution to the Riemann problem. The idea of composing wave curves by curves of different types can be found in the work of Wendroff [Wen72b] and Liu [Liu75], and it holds for the nongenuinely nonlinear case. Here, we modify the EOS taking into account the mixture region and thus phase boundaries to the EOS and extend the construction to wave curves containing countable kinks; see [Voß05].

Since a wave branch is assembled from wave parts this basically means providing a set of conditions which successively determines the types of the wave parts and their parameter range. In particular, for a numerical implementation, the construction becomes an iterative and discrete process and the wave curve is assembled part by part and each part state by state. Seen from this point of view, the governing question reads as follows:



The answer is given in section 3.1, where we discuss all possible terminating conditions and derive the continuation of the wave branch. We will see that the monotonicity properties of the wave speeds are the crucial ingredients. We illustrate each case by an appropriate Riemann problem.

3.1. Terminating conditions for wave parts. Regarding this section the working frame is as follows:

- We always consider one specific wave branch $\mathtt{W}_k(\mathtt{q}_k, \xi)$ from its origin $\mathtt{q}_k$ to the final state $\mathtt{q}_{k+1}$, $k \in \{1, \dots, m\}$, and write $(\cdot)_k$ instead of the more complicated notation $(\cdot)_{k^\pm}$.
- This branch is composed of wave parts $\mathtt{W}_k^{[j]}$—at least of one. Refer to Figure 5 for a comparison of the possible cases.
- All wave parts are admissible, namely, shock speeds are decreasing and characteristic speeds are increasing, [illegible] the respective curve parts.
- The speeds of all wave profiles, reconstructed from the wave curve, are increasing; i.e., $\mathtt{q}(\cdot, t)$ is still a function.

Assume $\mathtt{q} = \mathtt{W}_k^{[j]}(\mathtt{q}_k, \xi)$ denotes a state belonging to the jth part of one branch of the wave curve $\mathtt{W}_k$. Then, in the first step toward a complete description of all possibilities, we have to distinguish four main cases characterizing states where the wave part starts to be no longer admissible:

$(\cdot)_{\mathtt{[m]}}$: The monotonicity `[m]` of the corresponding wave speed is violated from state $\mathtt{q}$; i.e., in case of a positive parameterized branch, the monotonicity is broken for all states $\mathtt{W}_k^{[j]}(\mathtt{q}_k, \xi + \varepsilon)$, $\varepsilon > 0$.

$(\cdot)_{\mathtt{[p]}}$: The wave part hits a phase boundary. Then $\mathtt{q}$ is assumed to be a state of the wave part in the old phase; i.e., the phase of all states with increasing parameter value is different. Subsequently, we break this case down into two (respectively, four) single cases and replace the marker `[p]` by one or two signs, related to the sign of the characteristic speed derivative along the curve and the sign of the jump in the wave speed.

$(\cdot)_{\mathtt{[W]}}$: The wave profile in the x-t plane corresponding to the state $\mathtt{q}$ is slower than the wave profile belonging to some previous wave part characterized by a smaller parameter value; i.e., the wave is [illegible] by a previous part. We write `[R]`, `[H]`, or `[C]` instead of `[W]`, depending on specific details of the overtaking process, such as the type of the previous or next wave part.

$(\cdot)_{\mathtt{[e]}}$: We reach the final state of the wave curve $\mathtt{W}_k$, i.e., $\mathtt{q} = \mathtt{q}_{k+1}$ and $\xi = \xi_{k+1}$. In this case the construction ends `[e]` and the wave curve is complete.

Some remarks concerning the conditions and the construction may be helpful. In general, if a wave part reaches a phase boundary or crosses the manifold of linear degenerated states $\mathcal{M}$, say, at parameter $\bar{\xi}$, we refer to a quantity a (along the curve) before and behind, respectively, by

$$a_- = \lim_{\xi \to \bar{\xi}_-} a(\xi), \qquad a_+ = \lim_{\xi \to \bar{\xi}_+} a(\xi).$$

In this sense, if the wave part is terminated at $\mathtt{q}_-$ and the curve is continued with a new wave part, the state $\mathtt{q}_+$ must be the origin of this succeeding wave part to ensure that the whole wave curve is continuous; see Figure 6.

Conditions $(\cdot)_{\mathtt{[p]}}$ and $(\cdot)_{\mathtt{[m]}}$ may coincide; i.e., there is a phase transition [illegible] the wave speed is not monotone. In that case we speak only of condition $(\cdot)_{\mathtt{[p]}}$. Conversely,

FIG. 6. *Discontinuous quantities along wave curves.*

if $(\cdot)_{\texttt{[m]}}$ is addressed, the wave curve is smooth and there is no phase transition.

Both conditions, $(\cdot)_{\texttt{[p]}}$ and $(\cdot)_{\texttt{[m]}}$ affect the admissibility of the wave part. In a certain sense this a local information and each state from a wave part can be checked without knowing information of previous wave parts. This is in contrast to the global condition $(\cdot)_{\texttt{[W]}}$, where the whole of the wave curve up to this state plays a role. On account of this fact one has to keep a record of previous wave parts such that the wave speed of all occurring wave profiles is increasing. To handle these speeds appropriately the idea of a stack is helpful. Such a stack works like a book pile. One can put some books on top of it ("push") or remove some books from the top ("pop"). Furthermore, only the book on the top level is available.

In our situation this reads as follows: some conditions push a wave speed on the stack, and others pop a wave speed. Checking whether the wave part is overtaken by a previous wave part means comparing the wave speed against the top level speed on the stack.

In the subsequent discussion we refer to a list of figure sets collected in section 6. Each set corresponds to a Riemann problem for the Euler equations. Here we use the van der Waals EOS with the BZT-fluid PP10 (pf-perhydrofluorene $C_{13}F_{22}$). We always choose the origin $\mathtt{q}_k$ and the last state $\mathtt{q}_{k+1}$ of a wave branch as initial conditions and show

(a) the solution $\mathtt{q}$ in space for some fixed time t,
(b) the wave speed along the wave branch,
(c) the entropy along the wave branch, and
(d) the wave curve projected onto p-v plane.

According to section 2.1, each wave part is superscripted by $(\cdot)^{[j]}$ and its type is denoted by R, H, or C. In case of composite parts and overtaking shock parts we add the index of the associated rarefaction part, respectively, the index of the second shock state (which is different from the origin of the wave part). For instance, we write $\mathtt{C}^{[4,2]}$ as an indication that rarefaction part $\mathtt{R}^{[2]}$ is associated to the composite part $\mathtt{C}^{[4]}$, which is the fourth wave part.

As we always consider only one branch of the k-characteristic family, we omit the wave index k and replace it, if necessary, by the terminating condition.

Note that in case of $\Gamma \gtrless 0$ the Bethe–Weyl theorem implies that the entropy $\mathtt{s}$ and the shock speed σ are monotone along a shock curve. The entropy always increases across a shock. If Γ may vanish, i.e., the characteristic field is nongenuinely nonlinear, the entropy is an extremum if and only if the shock speed is an extremum. This ensures that no shock states are embodied in the (Liu-admissible) shock curves at which the entropy decreases. Liu additionally shows that the entropy also increases at composite shock states; cf. [Liu75].

Because the entropy jumps are very small in the presented examples, we scale the shown curves by a factor corresponding to the entropy at state $\mathtt{q}^{[1]}$. In most cases we consider the 1-wave curve; i.e., a shock runs to the left and the entropy increases from state $\mathtt{q}^{[i]}$ to $\mathtt{q}^{[i+1]}$. If $k = 3$, then a shock runs to the right and the shock state $\mathtt{q}^{[i]}$ the shock is $\mathtt{q}^{[i+1]}$. Thus, the entropy must decrease along the wave curve; cf. case $\mathtt{H}_{\texttt{[+]}}$, Figure 17.

We remark that the observation of positive entropy increments across shocks is not surprising in the case of smooth flux functions. However, the construction principle reflects this property even in the occurrence of phase transitions.

3.2. Rarefaction curve parts. A rarefaction part is constructed as long as the characteristic speed is increasing and the wave part is smooth.

$\mathtt{R}_{\mathtt{[e]}}$: In the simplest case the wave branch is composed of exactly one wave part. Hence we terminate the rarefaction part $\mathtt{R}^{[1]}$ when it reaches the right state $\mathtt{q}_r = \mathtt{q}^{[2]}$, as shown in Figure 7 (see the appendix). In particular, no succeeding wave part is needed, as the wave curve is complete.
Notice that the bump near $\mathtt{q}^{[1]}$ in the characteristic speed diagram is caused by the nearby region of negative nonlinearity. Approaching this area with the wave curve leads to a local maximum in the wave speed; see the next case $\mathtt{R}_{\mathtt{[m]}}$.

$\mathtt{R}_{\mathtt{[m]}}$: The rarefaction curve $\mathtt{R}^{[1]}$ crosses the manifold of linear degenerated states $\mathcal{M}$ at state $\mathtt{q}^{[2]}$ and the characteristic speed reaches a maximum. In this case, the wave curve is continued with a composite curve, here $\mathtt{C}^{[2,1]}$. Figure 8 shows this situation. In particular, the speed diagrams clearly indicate the adjacent shock state $\mathtt{q}^*$ on the rarefaction part.

$\mathtt{R}_{\mathtt{[p]}}$: When the rarefaction part crosses a phase boundary the situation becomes more complicated, since we have to determine the monotonicity behavior of the characteristic speed in the new phase , the sign of the jump in the wave speed. In order to distinguish the different cases we replace our abbreviation [p] by a pair of signs: the first refers to the sign of λ' in the new phase and the second to the sign of the jump $\lambda_+ - \lambda_-$.
Obviously, there are four phase boundary situations possible.

$\mathtt{R}_{\mathtt{[++]}}$: The easiest case is given when the first rarefaction part $\mathtt{R}^{[1]}$ reaches a phase boundary, here at state $\mathtt{q}^{[2]}$, and we find that the characteristic speed λ is increasing in the new phase (first plus) and the jump in speed is positive (second plus); see Figure 9. Then we start a new rarefaction part $\mathtt{R}^{[2]}$ from $\mathtt{q}^{[2]}$ since the characteristic speed is still increasing. The solution consists of a split rarefaction fan with a constant state in between, namely, the state $\mathtt{q}^{[2]} = \mathtt{q}_-^{[2]} = \mathtt{q}_+^{[2]}$ at the phase boundary.
Technically, we have the choice to continue the current wave part $\mathtt{R}^{[1]}$ or terminate it and start a second rarefaction part in the new phase. As we will see later, e.g., in case $\mathtt{H}_{\mathtt{[R]}}$, the last characteristic speed of $\mathtt{R}^{[1]}$ must be kept in mind (push $\lambda_-^{[2]}$), and for that reason we choose the second alternative and continue the wave curve with the new rarefaction part $\mathtt{R}^{[2]}$, starting at the phase boundary. Accordingly, a simple wave part never embodies a kink state.

$\mathtt{R}_{\mathtt{[-+]}}$: We next treat the case where the characteristic speed is not increasing behind the phase boundary, but the jump in speed is positive; cf. Figure 10, state $\mathtt{q}^{[2]}$. Due to $\lambda'_+ < 0$ we cannot continue with a rarefaction part but it is possible to consider a shock curve with the boundary state as origin. Then the shock speed also decreases and thus the wave part is admissible in the sense of Liu. The jump in speed is positive and because of this the new wave profile, the shock, is faster than the rarefaction fan. Hence $\mathtt{q}(\cdot, t)$ is indeed a function. As before, we also have to push $\lambda_-^{[2]}$.
Note that the wave curve starts inside the region of negative nonlinearity and grows with increasing pressure; i.e., the simple wave is , , .

$\mathtt{R}_{\mathtt{[+-]}}$, $\mathtt{R}_{\mathtt{[--]}}$: The remaining cases $\mathtt{R}_{\mathtt{[+-]}}$ and $\mathtt{R}_{\mathtt{[--]}}$ (Figures 11 and 12) are very similar. Both have in common that the jump in characteristic speeds at state $\mathtt{q}^{[2]}$ is negative. Thus neither a rarefaction part nor a shock part starting at this (boundary) state may continue the wave curve, because the second wave profile would be slower than the last rarefaction state and $\mathtt{q}(\cdot, t)$ would become

multivalued. In order to overcome this problem we are looking for shocks whose shock speeds equal the speed of some state from the rarefaction part; i.e., we continue the wave curve by a composite part. The shock is adjacent to the rarefaction fan in the x-t plane by construction and the speed graph is continuous.

Note that the wave curves from Figures 11 and 12 differ by the fact that they leave the mixture phase at regions with different nonlinearity.

3.3. Shock and composite curve parts. Regarding the terminating conditions, shock and composite curves are very similar. This follows from the fact that, by construction, each composite state is also an element of a Hugoniot curve being tangential to the composite curve. This implies that if a condition holds at some composite state associated to the rarefaction state $\mathtt{q}^*$, an analogous condition must hold for shock curves if we start the wave branch at $\mathtt{q}^*$, and vice versa.

We assumed that shock and composite curves locally exist. They are admissible in the sense of Liu as long as the shock speed is decreasing along the curve.

$\mathtt{H}_{[e]}$: A single shock is shown in Figure 13. The shock speed is decreasing along the shock part $\mathtt{H}^{[1]}$ and thus it is Liu-admissible. Note that the shock curve crosses the region of negative nonlinearity but without causing a local minimum in shock speed. This is a qualitative difference between rarefaction and shock curves.

$\mathtt{C}_{[e]}$: The situation of a simple composite part is already treated in case $\mathtt{R}_{[m]}$; see Figure 8.

$\mathtt{H}_{[m]}$: If the shock speed equals the characteristic speed, here at $\mathtt{q}^{[2]}$, then we call it a [illegible]; see Figure 14. Thus, the solution considered in the x-t plane is composed of a shock with an adjacent rarefaction fan. In a way this is the reverse case of a composite wave. Here, the shock speed reaches a local minimum at the sonic state, i.e., $\sigma' = 0$, and continuing the shock curve $\mathtt{H}^{[1]}$ would lead to nonadmissible shock states. Therefore we continue the wave curve with a rarefaction part, that is, $\mathtt{R}^{[2]}$.

Note that the shock part may contain linearly degenerated and phase boundary states without getting nonadmissible.

$\mathtt{C}_{[m]}$: Similar to the previous case, the shock speed along a composite part may also coincide with the characteristic speed and reach a minimum. In this case the resulting shock is adjacent to a rarefaction fan on each side; cf. Figure 15, state $\mathtt{q}^{[3]}$. As in case $\mathtt{H}_{[m]}$ the composite part may contain linearly degenerated and phase boundary states.

$\mathtt{C}_{[b]}$: It may happen that the state on the associated rarefaction part of a composite part coincides with the origin of the rarefaction. Figure 16 shows an instance where we have $\mathtt{q}^* = \mathtt{q}^{[1]}$. In this situation the composite part ends and the wave curve is continued with a shock curve from $\mathtt{q}^{[3]}$. Recall that we already have $\mathtt{q}^{[3]} \in \mathtt{q}^{\mathtt{H}}(\mathtt{q}^*)$ and we just continue this shock curve. In order to indicate that this new shock part contains shock states related to $\mathtt{q}^{[1]}$, we add a second index referring to this state, i.e., we speak of the part $\mathtt{H}^{[3,1]}$.

Note, that this situation can easily be constructed if we consider the case $\mathtt{C}_{[m]}$, and start the wave curve construction on a state on the first rarefaction part $\mathtt{R}^{[1]}$ [illegible] the last associated state $\mathtt{q}^*$; this is between states $\mathtt{q}^*$ and $\mathtt{q}^{[2]}$.

$\mathtt{H}_{[+]}$, $\mathtt{H}_{[-]}$: In contrast to the characteristic speed along a simple wave the shock speed along a shock curve crossing a phase boundary is continuous. We do not terminate the shock part as long as the shock speed is decreasing, i.e.,

as long as the shock is Liu-admissible. Thus a shock part crossing a phase boundary is only terminated at the boundary if $\sigma_+ > \sigma_-$. On account of this we just have the two cases $\mathtt{H}_{[+]}$ and $\mathtt{H}_{[-]}$, referring to the monotonicity properties of λ at $\mathtt{q}_+$. In both cases we start a new wave part at state $\mathtt{q}_+$, either a rarefaction part ($\lambda'_+ > 0$), or a shock part otherwise ($\lambda'_+ < 0$). Examples are shown in Figures 17 and 18. Each second wave part creates a wave profile moving faster than the first shock due to the discontinuity in wave speed with positive jump. As before, the intermediate state is the state at the phase boundary, here $\mathtt{q}^{[2]}$.

In analogy to the cases $\mathtt{R}_{[++]}$ and $\mathtt{R}_{[-+]}$ we have to push the wave speed $\sigma_-^{[2]}$, since the jump in speed is positive.

$\mathtt{C}_{[+]}$, $\mathtt{C}_{[-]}$: We treat these conditions implicitly in case $\mathtt{H}_{[C]}$.

$\mathtt{H}_{[R]}$: This is the first case where we require the speed on the stack. In order to establish a situation where we use the top level speed we first have to push this speed at some earlier instant in the wave curve construction. The configuration is sketched in Figure 19.

We start with a rarefaction part $\mathtt{R}^{[1]}$ which reaches a phase boundary at state $\mathtt{q}^{[2]}$. At this state we determine the case $\mathtt{R}_{[-+]}$, such that we have to continue with a shock part, here $\mathtt{H}^{[2]}$. Before we do this we push speed $\lambda_-^{[2]}$ as we have explained before. The shock part crosses the phase boundary causing the kink in the speed diagram, but as the speed decreases we continue the shock curve. At some state $\mathtt{q}^{[3]}$ the shock speed equals the last characteristic speed of the rarefaction state $\mathtt{q}_-^{[2]}$, which is the top level speed on the stack. Continuing the shock curve would lead to shocks being slower than the rarefaction states, as we discussed before. Because the speed on the stack is caused by the first rarefaction part (and we chose to separate the two rarefaction parts) we can continue with a composite part $\mathtt{C}^{[3,1]}$ from $\mathtt{q}^{[3]}$, associated to $\mathtt{R}^{[1]}$. Finally, we have to remove the speed from the stack, and the case $\mathtt{H}_{[R]}$ is complete.

$\mathtt{H}_{[H]}$: This case can be handled similarly to the previous one. Figure 20 and, in particular, the speed diagram show the takeover of the second shock part $\mathtt{H}^{[2]}$ by the first part $\mathtt{H}^{[1]}$. Indeed, a short calculation shows that if $\sigma(\mathtt{q}^{[1]}, \mathtt{q}^{[2]}) = \sigma(\mathtt{q}^{[2]}, \mathtt{q}^{[3]})$, $\mathtt{q}^{[2]} \in \mathtt{q}^{\mathtt{H}}(\mathtt{q}^{[1]})$, and $\mathtt{q}^{[3]} \in \mathtt{q}^{\mathtt{H}}(\mathtt{q}^{[2]})$, we also have $\mathtt{q}^{[3]} \in \mathtt{q}^{\mathtt{H}}(\mathtt{q}^{[1]})$. In other words, the shock curves intersect at $\mathtt{q}^{[3]}$ and we continue the wave curve with a further shock part, labeled $\mathtt{H}^{[3,1]}$, which is part of the Hugoniot curve emanating from $\mathtt{q}^{[1]}$. This example shows a so-called [illegible], where the fluid condenses behind the shock.

$\mathtt{H}_{[C]}$, $\mathtt{C}_{[+]}$, $\mathtt{C}_{[-]}$: The final situation concerning shock curves is the takeover of a shock part by a composite part; cf. Figure 21. The given example is more complicated by nature as we need to establish (i) a configuration with a discontinuity in wave speed in order to push the speed, (ii) a rarefaction part in order to construct the composite part, and (iii) a shock curve which will be overtaken.

This case possibly provides the most complicated wave curve in this setting, as it incorporates two composite parts. We start again in the liquid phase with the rarefaction part $\mathtt{R}^{[1]}$ up to the phase boundary at $\mathtt{q}^{[2]}$ where we establish the second rarefaction part $\mathtt{R}^{[2]}$. The characteristic speed $\lambda_-^{[2]}$ is pushed. As part $\mathtt{R}^{[2]}$ reaches the saturated vapor boundary at state $\mathtt{q}^{[3]}$ we continue with a very small composite part $\mathtt{C}^{[3,2]}$. This part ends due to reaching the origin $\mathtt{q}^{[2]} = \mathtt{q}^*(\mathtt{q}^{[4]})$ of the associated rarefaction part $\mathtt{R}^{[2]}$ and the shock curve $\mathtt{H}^{[4,2]}$

follows. Then the shock speed equals the pushed speed at $\mathtt{q}^{[5]}$ and the shock curve is overtaken by a second composite part $\mathtt{C}^{[5,1]}$ corresponding to the first rarefaction part $\mathtt{R}^{[1]}$. The shock speed along the composite part reaches a minimum at state $\mathtt{q}^{[6]}$ and we end the wave curve with the rarefaction part $\mathtt{R}^{[6]}$. In the x-t plane the solution consists of a shock adjacent to a fan on either side. Note that we have one wave profile where only the parts $\mathtt{R}^{[1]}$, $\mathtt{C}^{[5,1]}$, and $\mathtt{R}^{[6]}$ play a role.

$\mathtt{C}_{[\mathtt{H}]}$, $\mathtt{C}_{[\mathtt{C}]}$: These situations are similar to the ones treated in $\mathtt{H}_{[\mathtt{H}]}$ and $\mathtt{H}_{[\mathtt{C}]}$, and we just have to start with a rarefaction and a composite part instead of a shock part.

The case $\mathtt{C}_{[\mathtt{H}]}$ is treated in Figure 22. On first glance this situation is covered by case $\mathtt{C}_{[\mathtt{b}]}$, but if we look at the suggested continuation, i.e., a shock curve with the first state of the simple wave as origin, we observe that this new shock part would be overtaken instantaneously by the first shock part. Hence we continue the first shock part directly, here denoted by $\mathtt{H}^{[4,1]}$.

We could not construct the case $\mathtt{C}_{[\mathtt{C}]}$ for the Euler equations equipped with a cubic EOS and one for the BZT-fluids provided in [Cra91], though we do not know if it may be possible for some combination of artificial EOS and/or BZT-fluid. Note that one needs at least two rarefaction parts and two composite parts in order to obtain the , , , , configuration

$$\mathtt{R}^{[1]}, \mathtt{C}^{[2,1]}, \mathtt{R}^{[3]}, \mathtt{C}^{[4,3]}, \mathtt{C}^{[5,1]}.$$

This involves at least two regions with negative nonlinearity or one region with negative nonlinearity and an appropriate phase change such as the one involved in the case $\mathtt{R}_{[\mathtt{+-}]}$. None of the situations we came across possess either of these properties.

Table 1 summarizes the discussion above and provides all derived terminating conditions and subsequent wave part types.

4. Mapping of solutions from phase space to space-time. The previous section describes in detail how to compose a wave curve such that all requirements concerning admissible Riemann solutions are met. It remains to show in which way the function $\mathtt{q}(t, x)$, living in the x-t plane, is obtained from the wave curves. As such a solution is scale-invariant it is sufficient to provide the solution in the form $\mathtt{q}(\tilde{\xi})$ with $\tilde{\xi} = \frac{x}{t}$. Moreover, $\mathtt{q}(\tilde{\xi})$ is composed of k-wave profiles, $k = 1, \ldots, m$, where each wave profile corresponds to one wave branch of the k-characteristic family. Hence we need to consider only one k-wave branch in order to do the transformation.

We approach the underlying idea by means of an example. Assume a wave branch is given by the sequence from the example shown in Figure 19,

$$\mathtt{W}_k = \mathtt{R}^{[1]}_{[\mathtt{-+}]} \cup \mathtt{H}^{[2]}_{[\mathtt{R}]} \cup \mathtt{C}^{[3,1]}_{[\mathtt{e}]};$$

then the solution consists of a rarefaction fan with an adjacent shock. The second wave part $\mathtt{H}^{[2]}_{[\mathtt{R}]}$ does not play any role because all states between $\mathtt{q}^{[4]}$ and the last associated state $\mathtt{q}^*$ from $\mathtt{R}^{[1]}$ are bridged by the shock stemming from the composite part $\mathtt{C}^{[3,1]}$.

We equipped the composite notation with an additional index referring to the associated rarefaction part, where, in particular, the state $\mathtt{q}^*$ lives. This linkage helps us figure out the skipped and the involved wave parts, namely, index 2 and indices

TABLE 1
Terminating conditions.

Types of wave parts and conditions in effect			
R	$\lambda' > 0$, curve is smooth

1 and 3, respectively. In short, the overtaking of waves always means skipping wave parts in between!

If we consider the wave construction backwards, i.e., from the fastest waves to the slowest ones, which is the parameter range $\tilde{\xi} = +\infty \to -\infty$, we can take advantage of this linkage information. The fastest wave profile is caused by the last involved wave part $\mathtt{C}^{[3,1]}$. As shock and composite curves collect possible shocks, only the last shock state, or last shock pair $[\mathtt{q}, \mathtt{q}_0]$, respectively, is important. In this case it is the shock between $\mathtt{q}^{[4]}$ and the associated state $\mathtt{q}^*$. We assign a (single valued) parameter range to this wave part, namely, the shock speed

$$\Xi^{[3]} = \{\sigma(\mathtt{q}^{[3]}, \mathtt{q}^*)\}.$$

The definition of a simple wave relates the states along a rarefaction part to their wave speed and thus each rarefaction part belongs to some nonsingular range in the variable $\tilde{\xi}$. As we skip wave part 2 due to the linkage of parts 3 and 1, we continue with part $\mathtt{R}^{[1]}$. This part connects states $\mathtt{q}^{[1]}$ and $\mathtt{q}^{[2]}$, but all occurring states in the fan must be slower than the composite shock between $\mathtt{q}^{[4]}$ and $\mathtt{q}^*$. Hence we take into account only the range of the rarefaction part between $\mathtt{q}^*$ and $\mathtt{q}^{[1]}$, i.e.,

$$\Xi^{[1]} = [\tilde{\xi}^{[1]}, \tilde{\xi}^*].$$

At this point we define two ranges $\Xi^{[i]}$, each corresponding to some wave part. In the nonconvex but smooth situation of the Riemann problem the union of ranges

$$\Xi = \bigcup_{j=1,3} \Xi^{[j]}$$

is a continuous interval, since the wave speed along the whole wave branch is continuous. The nonsmooth case causes jumps in wave speed and as a consequence we obtain gaps in Ξ. But as the wave curve is still continuous, the corresponding state on each side of this gap is the same and we have found the constant intermediate state to fill in the blank between the split wave profiles.

In a nutshell, the general strategy to obtain a function $\mathtt{q}(\tilde{\xi})$ can be described as follows:

- Collect the indices j of all involved wave parts $\mathtt{W}^{[j]}$ in a set J; let $\#J$ denote the number of elements in J. If we have a nonempty wave curve the set J contains at least one index.
- For this purpose iterate backward and use the linkage information to skip single indices.
- Define the corresponding parameter ranges $\Xi^{[j]}$ and add

$$\Xi^{[0]} = \{-\infty\} \quad \text{and} \quad \Xi^{[\#J+1]} = \{+\infty\}.$$

Then, skipping some details, the main point is to decide whether a given parameter $\tilde{\xi}$ lies [illegible] some $\Xi^{[j]}$, or [illegible] some ranges $\Xi^{[j]}$ and $\Xi^{[j+1]}$. In the first case we have a rarefaction part and the value is obtained by means of its definition. In the other case we use the corresponding boundary states of $\Xi^{[j]}$ and $\Xi^{[j+1]}$ (which should be equal) in order to obtain an intermediate state.

5. Conclusion. In this paper we are concerned with the construction of an entropy solution (in the sense of Liu) to the Riemann problem of gas dynamics. Here we take into account EOSs exhibiting regions of negative nonlinearity and phase transition assuming thermodynamical equilibrium. This setting applies to BZT-fluids, which play an important role in the design of turbomachinery. The wave curves corresponding to the nonlinear fields consist of various wave parts which are connected according to a set of rules, based on admissibility criteria for shock and rarefaction curves. The construction principle extends the methods used in the smooth, nongenuinely nonlinear case, first given by Wendroff and Liu. We present an algorithm for computing these wave curves, but we claim no convergence.

We emphasize that the construction can be applied to any hyperbolic system with properties comparable to the Euler equations regarding the characteristic fields and the existence of solutions. In particular, it works in the scalar case, where it yields the Riemann solution based on the convex hull of the flux function.

In addition to the theoretical work, a software library has been implemented containing all necessary modules to provide

- the k-wave curves in phase space;
- the wave profile in the x-t plane;
- various EOSs (among them are the well-known van der Waals, the Redlich–Kwong, and the Peng–Robinson EOSs; all cubic EOSs can be equipped with the Maxwell construction modeling the mixture region and phase boundaries) and
- the BZT-fluids.

The library can be used within a batch tool in order to generate plots like the ones we used in this paper, or it can be used as a fluid library, for instance, in the flow solver Quadflow; see [BLM04].

The exact Riemann solution has been used as a validation tool for numerical solvers. We have considered several standard schemes, e.g., the Lax–Friedrich and Lax–Wendroff schemes, the Roe scheme, a second order ENO scheme, the HLLC

and HLLE schemes, or the WAF scheme with MinBee and SuperBee limiters (see [Toro99]). The computations have been performed for various spatial resolutions and CFL numbers.

Finally, we remark that our construction is based on the entropy concept of Liu. By this the existence of so-called nonclassical shocks is excluded; see, for instance, [HL00], [Flo02], and the references therein. In the future it would be interesting to extend our construction taking into account these effects.

SPECTRUM OF THE VOLUME INTEGRAL OPERATOR OF ELECTROMAGNETIC SCATTERING*

NEIL V. BUDKO† AND ALEXANDER B. SAMOKHIN‡

Abstract. The spectrum of the volume integral operator of three-dimensional electromagnetic scattering is analyzed. The operator has both continuous essential spectrum, which dominates at lower frequencies, and discrete eigenvalues, which spread out at higher ones. The explicit expression of the operator's symbol provides an exact outline of the essential spectrum for any inhomogeneous anisotropic scatterer with Hölder continuous constitutive parameters. Geometrical bounds on the location of discrete eigenvalues are derived for various physical scenarios. Numerical experiments demonstrate good agreement between the predicted spectrum of the operator and the eigenvalues of its discretized version.

Key words. electromagnetics, singular integral operators, symbol, spectrum, eigenvalues

DOI. 10.1137/050630660

1. Introduction.

Knowledge of the spectrum of an integral operator is important for the efficient numerical solution of integral equations. For example, it may help to choose an iterative algorithm, estimate its convergence rate, and construct a proper preconditioner. The spectra of electromagnetic integral operators may also find direct applications in physics and engineering such as plasma studies, effective medium theories, and target identification.

Numerical estimation of the operator's spectrum after discretization is not too practical as it requires even more computational resources than the complete numerical solution of a scattering problem—not to mention that such a spectrum will be that of a matrix, which only approximates the original operator. In these circumstances any useful analytical prediction is extremely valuable.

In the pioneering papers [1] and [2] by Kleinman et al. the one-, two-, and (acoustical) three-dimensional cases and the (boundary) integral equations were considered. Here we look at the integral equation arising in vectorial three-dimensional electromagnetic scattering on penetrable objects known as or integral equation.

The first results concerning the spectrum of the three-dimensional electromagnetic scattering problems were derived from the analytical Mie solution for a spherical scatterer. This case was analyzed in considerable detail in [3], [4], [5], and the so-called were identified as eigenvalues. In [6] Rahola compared the theory of the Mie resonances with the numerical spectrum of the volume integral operator. Numerical experiments indicated, though, that apart from the expected discrete Mie

resonances, the spectrum of the discretized volume integral operator contained eigenvalues clustered along distinct line segments in the complex plane. However, the ad hoc explanation of this phenomenon presented in [6] cannot be extended to the case of a general inhomogeneous scatterer. The latter requires a different and more rigorous approach.

Our goal is to establish the connection between the operator's spectrum and the physical properties of a scatterer. Using the symbol of the electromagnetic volume integral operator we show that in addition to discrete eigenvalues the spectrum has an essential continuous part as well. Fortunately, the symbol can be derived explicitly allowing for exact predictions of the essential spectrum for any Hölder continuous anisotropic scatterer. In the isotropic case the essential spectrum is just the set of values admitted by the constitutive parameters of the object in $\mathbb{R}^3$. The approximate location of the discrete eigenvalues is estimated in the spirit of Kleinman et al. and depends mostly on the extent and shape of the object.

The paper is organized as follows. In the next two sections we recall several more or less well-known facts from the theory of Fredholm operators with pointwise multipliers and simple singular integral operators. Driven by the electromagnetic problem at hand in section 4 we consider "combined" operators consisting of both pointwise multiplication operators and simple singular integral operators. The theory of such combined operators was developed by Mikhlin and Prössdorf [7], [8], and we hope that our brief introduction will help to popularize their approach. The main purpose of these three sections is to introduce the concept of a symbol of a combined operator, which helps to establish the essential part of the operator's spectrum. Having mastered this tool we move on to the electromagnetic case where we construct the symbol of the volume integral operator, analyze the essential spectrum, and provide geometrical bounds on the distribution of discrete eigenvalues. Finally, we present some numerical experiments with the matrix version of the operator and try to comprehend similarities and differences between the continuous and the discrete worlds.

2. Spectrum of Fredholm operators with pointwise multipliers. The volume scattering in one and two dimensions is described by integral equations with manifestly Fredholm operators, i.e., an identity operator plus a compact integral operator. This is also the case in the acoustic three-dimensional scattering and has to do with the fact that the singularity in the kernel of all these integral operators is weak, i.e., its order is smaller than three (dimension of the spatial manifold), whereas the support of the scatterer is finite. For integral equations with Fredholm operators the questions of existence and uniqueness are linked, so that it is sufficient to establish the uniqueness of the solution only.

With operators which are not of the form "identity plus compact" the Fredholm property is established by proving the existence of a regularizer—an operator which, when applied to the operator in question, reduces it to the form "identity plus compact." There may be a left and a right regularizer, naturally. First, we clarify one important thing: the spectra of the original Fredholm operator and its regularized version are, in general, different. Indeed, consider the Fredholm integral equation

$$a(\mathbf{x})u(\mathbf{x}) + \int_{\mathbf{x},\mathbf{x}'\in D} K(\mathbf{x},\mathbf{x}')u(\mathbf{x}')\,\mathrm{d}\mathbf{x}' = v(\mathbf{x}), \tag{2.1}$$

where instead of the identity operator we have a (pointwise) multiplication with some continuous function $a(\mathbf{x}) \neq 0$, $\mathbf{x} \in D$. The integral operator is presumed to be

compact. In operator notation we shall write

$$[\mathrm{d}(a) + K]\, u = v, \tag{2.2}$$

where $\mathrm{d}(a)$ indicates that we have a multiplication operator, analogous to a diagonal matrix. The regularized Fredholm equation is obtained from (2.1) by a trivial operation of (pointwise) multiplication by $a(\mathbf{x})^{-1}$, i.e.,

$$u(\mathbf{x}) + a(\mathbf{x})^{-1} \int_{\mathbf{x},\mathbf{x}' \in D} K(\mathbf{x}, \mathbf{x}') u(\mathbf{x}')\, \mathrm{d}\mathbf{x}' = a(\mathbf{x})^{-1} v(\mathbf{x}). \tag{2.3}$$

Hence, the regularizer in this case is simply $\mathrm{d}(a)^{-1}$, as it gives the "identity plus compact" form

$$\mathrm{d}(a)^{-1}\, [\mathrm{d}(a) + K] = I + \mathrm{d}(a)^{-1} K = I + K', \tag{2.4}$$

where K' is a compact operator. The spectra of the two (original and regularized) operators are quite different though. Indeed, consider operator

$$\mathrm{d}(a) - \lambda I + K, \tag{2.5}$$

and let $\lambda = a(\mathbf{x}_0)$ for some arbitrary $\mathbf{x}_0 \in D$. If λ does not belong to the spectrum, then there exists a bounded inverse of (2.5) for that particular λ. This means that if we consider equality

$$[\mathrm{d}(a) - \lambda I + K]\, u = v, \tag{2.6}$$

then for all possible perturbations Δv of the right-hand side and the corresponding perturbations Δu of the solution there exists a constant $C < \infty$ such that

$$\|\Delta u\| \leq C \|\Delta v\|. \tag{2.7}$$

Due to the continuity of $a(\mathbf{x})$ in D we can always choose a neighborhood of $\mathbf{x}_0$, say, $\delta(\mathbf{x}_0)$, such that $|a(\mathbf{x}) - a(\mathbf{x}_0)| < \epsilon$ for $\mathbf{x} \in \delta(\mathbf{x}_0)$. Consider perturbations $\Delta u(\mathbf{x})$ which are zero outside $\delta(\mathbf{x}_0)$ and have a fixed norm $\|\Delta u\| = R$, independent of $\delta(\mathbf{x}_0)$. This can be a function of the type

$$\Delta u(\mathbf{x}) \sim e^{i\mathbf{x}\cdot\mathbf{k}(\delta,\epsilon)}, \quad \mathbf{x} \in \delta(\mathbf{x}_0), \tag{2.8}$$

or a similar oscillating function with varying spatial frequency $\mathbf{k}(\delta, \epsilon)$. Moreover, since K is compact, we may assume that our perturbations give $\|K\Delta u\| \leq \kappa\epsilon$ for all sufficiently small $\delta(\mathbf{x}_0)$. Further, we have $\|[a(\mathbf{x}) - a(\mathbf{x}_0)]\Delta u\| \leq R\epsilon$. Hence, for the perturbation of the right-hand side we obtain

$$\|\Delta v\| \leq \|(a - \lambda)\Delta u\| + \|K\Delta u\| \leq (R + \kappa)\epsilon\,, \tag{2.9}$$

whereas $\|\Delta u\| = R$ for all Δu. For the condition (2.7) to hold we must be able to provide $C < \infty$ such that

$$R \leq C(R + \kappa)\epsilon \tag{2.10}$$

for all ϵ, and this is obviously not possible, since we can make ϵ as small as we like by reducing $\delta(\mathbf{x}_0)$, while keeping R constant. Hence, the inverse of operator (2.5) is unbounded and $\lambda = a(\mathbf{x}_0)$ belongs to the spectrum of operator $[\mathrm{d}(a) + K]$.

If continuous function $a(\mathbf{x})$ is not constant on D, then the set of its values is an extended dense subset of the complex plane. The spectrum generated by such a function is called continuous as opposed to the usual discrete eigenvalues. In addition to continuous spectrum, operator $[\mathrm{d}(a) + K]$ may have discrete eigenvalues as well. The regularized operator $[I + K']$, however, is known to have a discrete spectrum only. This follows from the fact that the spectrum of K' is purely discrete [9]. Thus, regularization destroys the continuous spectrum. Finally, we notice that operator (2.5) cannot be regularized at the points of the continuous spectrum.

3. Spectrum of simple singular integral operators. The operator of three-dimensional electromagnetic scattering has the form

$$Au = \mathrm{d}(a)u + A^{\mathrm{s}}\mathrm{d}(b)u + Ku\,, \tag{3.1}$$

where K is compact and

$$A^{\mathrm{s}}\mathrm{d}(b)u = \lim_{\epsilon\to 0}\int_{\mathbf{x}'\in\mathbb{R}^3\setminus\delta(\epsilon)} \frac{f(\Theta)}{r^3} b(\mathbf{x}')u(\mathbf{x}')\,\mathrm{d}\mathbf{x}', \tag{3.2}$$

with $r = |\mathbf{x}' - \mathbf{x}|$, and $\Theta = (\mathbf{x}' - \mathbf{x})/r$. The principal-value integral (*p.v.*-integral) above is understood as an integral over the entire $\mathbb{R}^3$ excluding a ball around $\mathbf{x}$ whose radius tends to zero in the limit. This integral exists under certain assumptions on $b(\mathbf{x})u(\mathbf{x})$ and $f(\Theta)$. The necessary condition is

$$\int_{\Theta\in\mathbb{S}} f(\Theta)\mathrm{d}S = 0, \tag{3.3}$$

where integration is performed over a unit sphere $\mathbb{S}$. The Hölder continuity of $b(\mathbf{x})u(\mathbf{x})$ in $\mathbb{R}^3$ is another (sufficient) condition. Operator A^{s} in (3.2) is called the [illegible]. Its kernel is not an integrable function, and the best way to comprehend the meaning of such a *p.v.*-integral is to take the three-dimensional Fourier transform of $A^{\mathrm{s}}u$, i.e.,

$$\begin{aligned}
\tilde{v}(\mathbf{k}) &= \lim_{\epsilon\to 0}\int_{\mathbf{x}\in\mathbb{R}^3}\int_{\mathbf{x}'\in\mathbb{R}^3\setminus\delta(\epsilon)} \frac{f(\Theta)}{r^3} u(\mathbf{x}')e^{-i\mathbf{k}\cdot\mathbf{x}}\mathrm{d}\mathbf{x}'\mathrm{d}\mathbf{x} \\
&= \lim_{\epsilon\to 0}\int_{\mathbf{x}\in\mathbb{R}^3}\int_{\mathbf{x}'\in\mathbb{R}^3\setminus\delta(\epsilon)} \frac{f(\Theta)}{r^3} u(\mathbf{x}')e^{-i\mathbf{k}\cdot(\mathbf{x}-\mathbf{x}')}e^{-i\mathbf{k}\cdot\mathbf{x}'}\mathrm{d}\mathbf{x}'\mathrm{d}\mathbf{x} \\
&= \lim_{\epsilon\to 0}\int_{\mathbf{y}\in\mathbb{R}^3\setminus\delta(\epsilon)} \frac{f(-\Theta)}{r^3} e^{-i\mathbf{k}\cdot\mathbf{y}}\mathrm{d}\mathbf{y}\int_{\mathbf{x}'\in\mathbb{R}^3} u(\mathbf{x}')e^{-i\mathbf{k}\cdot\mathbf{x}'}\mathrm{d}\mathbf{x}' \\
&= F(\mathbf{k})\tilde{u}(\mathbf{k})\,.
\end{aligned} \tag{3.4}$$

In other words, we have arrived at a familiar $\mathbf{k}$-domain expression for the Fourier transform of a convolution. The function $F(\mathbf{k})$ can only be found if one knows the explicit form of $f(\Theta)$. However, there is something to say even in the general case.

Consider this:

$$
\begin{aligned}
F(\mathbf{k}) &= \lim_{\epsilon\to 0}\int_{\mathbf{y}\in\mathbb{R}^3\setminus\delta(\epsilon)} \frac{f(-\Theta)}{r^3}e^{-i\mathbf{k}\cdot\mathbf{y}}\mathrm{d}\mathbf{y} \\
&= \lim_{\epsilon\to 0}\int_{\epsilon}^{\infty}\int_S \frac{f(-\Theta)}{r}e^{-ir\rho\cos\gamma}\mathrm{d}S\mathrm{d}r = \lim_{\epsilon\to 0}\int_{\rho\epsilon}^{\infty}\int_S f(-\Theta)\frac{e^{-it\cos\gamma}}{t}\mathrm{d}S\mathrm{d}t \\
&= \lim_{\epsilon\to 0}\int_{\rho\epsilon}^{1}\int_S f(-\Theta)\frac{e^{-it\cos\gamma}}{t}\mathrm{d}S\mathrm{d}t + \int_1^{\infty}\int_S f(-\Theta)\frac{e^{-it\cos\gamma}}{t}\mathrm{d}S\mathrm{d}t \\
&= \int_1^{\infty}\int_S f(-\Theta)\frac{e^{-it\cos\gamma}}{t}\mathrm{d}S\mathrm{d}t + \lim_{\epsilon\to 0}\int_{\rho\epsilon}^{1}\int_S f(-\Theta)\frac{1}{t}\left[e^{-it\cos\gamma}-1\right]\mathrm{d}S\mathrm{d}t \\
&\quad + \lim_{\epsilon\to 0}\int_{\rho\epsilon}^{1}\frac{1}{t}\mathrm{d}t\int_S f(-\Theta)\mathrm{d}S \\
&= \int_1^{\infty}\int_S f(-\Theta)\frac{e^{-it\cos\gamma}}{t}\mathrm{d}S\mathrm{d}t + \int_0^{1}\int_S f(-\Theta)\frac{1}{t}\left[e^{-it\cos\gamma}-1\right]\mathrm{d}S\mathrm{d}t.
\end{aligned}
\tag{3.5}
$$

Above we have introduced spherical coordinate systems for both $\mathbf{y}$ and $\mathbf{k}$, where $\rho = |\mathbf{k}|$, and used condition (3.3). As one can see, since $\epsilon \to 0$ tends to zero independently of ρ, $F(\mathbf{k})$ does not depend on ρ, and, hence, it is independent of $|\mathbf{k}|$. In other words, if $F(\mathbf{k})$ depends on $\mathbf{k}$ at all, then it is only the direction of $\mathbf{k}$, not its magnitude, i.e.,

$$
F(\mathbf{k}) = F\left(\frac{\mathbf{k}}{|\mathbf{k}|}\right) = F(\tilde{\Theta})\,. \tag{3.6}
$$

Note that this is only true if the order of singularity in (3.2) is exactly three. If we had a weakly singular integral, then $F(\mathbf{k})$ would depend on $|\mathbf{k}|$ explicitly.

Let us now construct a regularizer for a simple singular operator A^{s}. Denoting by $\mathcal{F}$ and $\mathcal{F}^{-1}$, correspondingly, the forward and the inverse Fourier transforms, and by $F(\tilde{\Theta})^{-1}$ the inverse of $F(\tilde{\Theta})$, we can do, for example, the following:

$$
\mathcal{F}^{-1}F(\tilde{\Theta})^{-1}\mathcal{F}A^{\mathrm{s}}u = \mathcal{F}^{-1}F(\tilde{\Theta})^{-1}F(\tilde{\Theta})\mathcal{F}u = \mathcal{F}^{-1}\mathcal{F}u = u\,. \tag{3.7}
$$

In this way the original operator A^{s} is reduced by the regularizer $\mathcal{F}^{-1}F(\tilde{\Theta})^{-1}\mathcal{F}$ to an identity operator; i.e., the regularizer is also an inverse of the operator.

To recover the spectrum of a simple singular operator we need to consider

$$
\left[A^{\mathrm{s}} - \lambda I\right]u = \lim_{\epsilon\to 0}\int_{\mathbf{x}'\in\mathbb{R}^3\setminus\delta(\epsilon)}\frac{f(\Theta)}{r^3}u(\mathbf{x}')\,\mathrm{d}\mathbf{x}' - \lambda u(\mathbf{x})\,. \tag{3.8}
$$

Repeating calculations (3.4) we arrive at the following equivalent version of the spectral problem:

$$
F(\tilde{\Theta})\tilde{u}(\mathbf{k}) = \lambda\tilde{u}(\mathbf{k}). \tag{3.9}
$$

Hence, generalizing this to matrix-valued $F(\tilde{\Theta})$, we conclude that the domain $s(\lambda)$ in the complex plane consisting of all eigenvalues λ of matrix $F(\tilde{\Theta})$ for all $\tilde{\Theta}$ on the unit sphere belongs to the spectrum of the simple singular integral operator A^{s}. Note that, although matrix eigenvalues are always discrete, they may vary continuously with $\tilde{\Theta}$, thus creating a continuous spectrum. Again, the operator of (3.8) cannot be regularized for $\lambda \in s(\lambda)$.

4. Essential spectrum of combined operators. In the previous two sections we saw that the spectrum and the regularization of operators are tightly linked. Namely, operators of the spectral problems (2.5) and (3.8) could not be regularized for $\lambda \in s(\lambda)$. This is also true if we consider the spectral problem for operator (3.1), and, perhaps, for any operator. However, a rigorous proof of this link for a general case is too abstract, and we shall not provide it here. Taking it for granted we shall instead concentrate on the construction of a general regularizer.

We have shown that the Fredholm operator with free term $\mathrm{d}(a)$ could be regularized by $\mathrm{d}(a)^{-1}$, whereas a simple singular integral operator is regularized by $\mathcal{F}^{-1}F(\tilde{\Theta})^{-1}\mathcal{F}$. However, neither of these approaches works with the general operator (3.1) arising in the electromagnetic scattering problem. Since this general operator is a combination of multiplication and simple singular operators (further—a [illegible] operator) we expect that a proper combination of the two approaches may work.

The technique presented below is a simplified version of the approach suggested by Mikhlin [7], [8]. The first thing to note is that, while searching for a regularizer, the actual form of the compact operator in the resulting "identity plus compact" expression is not important. Second, a regularizer cannot be a compact operator, as the product of a compact operator with any other bounded linear operator is a compact operator. Finally, the product of any two combined operators is also a combined operator (plus a compact one, in general). For example, the product of two operators of type (3.1) will look like

$$\begin{aligned} A_1A_2 &= [\mathrm{d}(a_1) + A_1^{\mathrm{s}}\mathrm{d}(b_1) + K_1]\,[\mathrm{d}(a_2) + A_2^{\mathrm{s}}\mathrm{d}(b_2) + K_2] \\ &= \mathrm{d}(a_1)\mathrm{d}(a_2) + \mathrm{d}(a_1)A_2^{\mathrm{s}}\mathrm{d}(b_2) + A_1^{\mathrm{s}}\mathrm{d}(b_1)\mathrm{d}(a_2) + A_1^{\mathrm{s}}\mathrm{d}(b_1)A_2^{\mathrm{s}}\mathrm{d}(b_2) + K, \end{aligned} \tag{4.1}$$

where all compact operators are hidden in the generic compact operator K.

To every combined operator there corresponds a function called a [illegible] constructed in accordance with the following set of rules.

DEFINITION 4.1.

1. [illegible]
2. [illegible]
3. [illegible]
4. [illegible]

For the last property to hold it is sufficient to ensure that the multipliers are Hölder continuous functions in $\mathbb{R}^3$, so that the products of simple singular integral operators and multiplication operators and the products of their symbols are well defined. According to Definition 4.1, the symbol of the combined operator (3.1) is just the function

$$\mathrm{Symb}\,[A] = \Phi(\mathbf{x}, \tilde{\Theta}) = a(\mathbf{x}) + F(\tilde{\Theta})b(\mathbf{x})\,, \tag{4.2}$$

and the symbol of the product (4.1) of two combined operators is

$$\begin{aligned} \mathrm{Symb}\,[A_1A_2] &= a_1(\mathbf{x})a_2(\mathbf{x}) + a_1(\mathbf{x})F_2(\tilde{\Theta})b_2(\mathbf{x}) + F_1(\tilde{\Theta})b_1(\mathbf{x})a_2(\mathbf{x}) \\ &\quad + F_1(\tilde{\Theta})b_1(\mathbf{x})F_2(\tilde{\Theta})b_2(\mathbf{x}) = \Phi_1(\mathbf{x}, \tilde{\Theta})\Phi_2(\mathbf{x}, \tilde{\Theta}) \\ &= \mathrm{Symb}\,[A_1]\,\mathrm{Symb}\,[A_2]\,. \end{aligned} \tag{4.3}$$

For our purposes the most important property of a symbol is that the correspondence between a combined operator and its symbol is one-to-one up to a compact operator. This means that to each combined operator there corresponds only one symbol, whereas to each symbol there may correspond more than one operator, but their difference would be a compact operator.

Suppose now that we want to find a regularizer A^{r} of a combined operator A, i.e.,

$$A^{\mathrm{r}}A = A^{\mathrm{r}}\left[\mathrm{d}(a) + A^{\mathrm{s}}\mathrm{d}(b) + K\right] = I + K'. \tag{4.4}$$

The symbol of this product can be constructed using Definition 4.1 and is given by

$$\mathrm{Symb}\left[A^{\mathrm{r}}A\right] = \mathrm{Symb}\left[A^{\mathrm{r}}\right]\left[a(\mathbf{x}) + F(\tilde{\Theta})b(\mathbf{x})\right] = 1. \tag{4.5}$$

To this symbol there corresponds an operator of the form "identity plus compact"; i.e., should we succeed in obtaining such a unit symbol, the regularization is accomplished. Therefore, the symbol of a regularizer, say, $\Phi_{\mathrm{r}}(\mathbf{x}, \tilde{\Theta})$, must be an inverse of the symbol of the combined operator in question. Since the latter symbol may be a matrix-valued function, one may have to find an inverse of a matrix.

In this simplified version of Mikhlin's approach summarized in Definition 4.1 we have limited ourselves to combined operators. Therefore, in order to be able to apply the multiplication property in (4.5) we have to be sure that the regularizer, if it exists, belongs to the class of combined operators as well. This would be the case if the inverse of the symbol of a combined operator, $[a(\mathbf{x}) + F(\tilde{\Theta})b(\mathbf{x})]^{-1}$, had the form of a symbol of a combined operator itself, i.e., contained only multipliers and Fourier transforms of simple singular integral operators. Fortunately, it follows from the Cayley–Hamilton theorem for matrices that the inverse of a nonsingular matrix can always be represented as a polynomial of this matrix. Obviously, any such polynomial contains only the products of the multipliers and the Fourier transforms mentioned above.

Conditions on the existence of a regularizer thus become conditions on the existence and boundedness of the inverse of the symbol of a combined operator for all $\mathbf{x} \in \mathbb{R}^3$ and all $\tilde{\Theta}$ on a unit sphere.

The symbol will help us to recover the essential spectrum of combined operator A given by (3.1). Since operator $A - \lambda I$ is also a combined operator, its symbol is given by

$$\Phi(\mathbf{x}, \tilde{\Theta}, \lambda) = a(\mathbf{x}) + F(\tilde{\Theta})b(\mathbf{x}) - \lambda\mathbb{I} = \Phi(\mathbf{x}, \tilde{\Theta}) - \lambda\mathbb{I}\,, \tag{4.6}$$

where $\mathbb{I}$ is an identity matrix of the corresponding dimensions. This symbol is a parametric function of λ as well as $\mathbf{x}$ and $\tilde{\Theta}$. Suppose that λ coincides with the eigenvalue of the symbol matrix $\Phi(\mathbf{x}, \tilde{\Theta})$ for some $\mathbf{x}$ and $\tilde{\Theta}$. Then, operator $A - \lambda I$ cannot be regularized and, hence, does not have a bounded inverse. In summary (generalizing to matrix-valued symbols), the domain $s(\lambda)$ in the complex plane consisting of all eigenvalues of symbol $\Phi(\mathbf{x}, \tilde{\Theta})$ for all $\mathbf{x} \in \mathbb{R}^3$ and all $\tilde{\Theta} \in \mathbb{S}$ belongs to the (essential) spectrum of the corresponding combined operator A. If the eigenvalues of $\Phi(\mathbf{x}, \tilde{\Theta})$ vary continuously in the complex plane with $\mathbf{x}$ and $\tilde{\Theta}$ varying correspondingly in $\mathbb{R}^3$ and on $\mathbb{S}$, then the essential spectrum is continuous.

5. The electromagnetic case. Now we turn to the electromagnetic three-dimensional case. In the frequency domain with time-factor $\exp(-i\omega t)$ the total

electric field $\mathbf{E}$ in the presence of an inhomogeneous anisotropic electric-type scatterer satisfies the singular integral equation (see, e.g., [12])

$$\begin{aligned}\mathbf{E}^{\mathrm{in}}(\mathbf{x},\omega) = &\left[\mathbb{I} + \frac{1}{3}\chi(\mathbf{x},\omega)\right]\mathbf{E}(\mathbf{x},\omega)\\ &- \lim_{\epsilon\to 0}\int_{\mathbf{x}'\in\mathbb{R}^3\setminus|\mathbf{x}-\mathbf{x}'|<\epsilon} \mathbb{G}_0(\mathbf{x}-\mathbf{x}')\chi(\mathbf{x}',\omega)\mathbf{E}(\mathbf{x}',\omega)\,\mathrm{d}\mathbf{x}'\\ &- \int_{\mathbf{x}'\in\mathbb{R}^3} \mathbb{G}_1(\mathbf{x}-\mathbf{x}',\omega)\chi(\mathbf{x}',\omega)\mathbf{E}(\mathbf{x}',\omega)\,\mathrm{d}\mathbf{x}',\end{aligned} \tag{5.1}$$

where $\mathbf{E}^{\mathrm{in}}$ is a given incident electric field, and χ is the tensor of relative electric contrast of the object with respect to a homogeneous isotropic background. Explicitly it is given by

$$\chi(\mathbf{x},\omega) = \frac{1}{\eta_{\mathrm{b}}(\omega)}\eta(\mathbf{x},\omega) - \mathbb{I}, \tag{5.2}$$

where $\mathbb{I}$ denotes the 3×3 identity matrix and the constitutive parameters of the scatterer are described by the tensor of the transverse medium admittance (per length), which in its turn contains the more familiar tensors of conductivity $\sigma(\mathbf{x},\omega)$ and dielectric permittivity $\varepsilon(\mathbf{x},\omega)$, namely,

$$\eta(\mathbf{x},\omega) = \sigma(\mathbf{x},\omega) - i\omega\varepsilon(\mathbf{x},\omega). \tag{5.3}$$

The background medium has parameters $\eta_{\mathrm{b}}(\omega) = \sigma_{\mathrm{b}}(\omega) - i\omega\varepsilon_{\mathrm{b}}(\omega)$ and $\zeta_{\mathrm{b}}(\omega) = -i\omega\mu_{\mathrm{b}}(\omega)$, where μ_{b} is the magnetic permeability. The so-called wavenumber $k_{\mathrm{b}}(\omega)$ of this medium can be found from $k_{\mathrm{b}}^2(\omega) = -\eta(\omega)\zeta(\omega)$ by taking a proper branch of a square root. Although the contrast function is different from zero only within a finite spatial domain D, we have extended the limits of integration in (5.1) to the whole of $\mathbb{R}^3$. This formal extension allows direct application of the results of the previous section.

The kernels of the intregal operators in (5.1) contain tensors $\mathbb{G}_0$ and $\mathbb{G}_1$, the first of which is given by

$$\mathbb{G}_0(\mathbf{x}) = \frac{1}{4\pi|\mathbf{x}|^3}\left[3\,\mathbb{Q} - \mathbb{I}\right], \tag{5.4}$$

where tensor $\mathbb{Q} = \Theta(\Theta\cdot\,)$ can also be written in matrix notation as $\mathbb{Q} = \Theta\Theta^T$. This tensor is an orthogonal projector, i.e., $\mathbb{Q}^2 = \Theta\Theta^T\Theta\Theta^T = \mathbb{Q}$. The second kernel contains tensor

$$\begin{aligned}\mathbb{G}_1(\mathbf{x},\omega) = &\left[-\alpha(\mathbf{x},\omega) - 3\beta(\mathbf{x},\omega) + 3\gamma(\mathbf{x},\omega)\right]\mathbb{Q}\\ &+ \left[\alpha(\mathbf{x},\omega) + \beta(\mathbf{x},\omega) - \gamma(\mathbf{x},\omega)\right]\mathbb{I},\end{aligned} \tag{5.5}$$

with

$$\begin{aligned}&\alpha(\mathbf{x},\omega) = k_{\mathrm{b}}^2(\omega)\frac{e^{ik_{\mathrm{b}}(\omega)|\mathbf{x}|}}{4\pi|\mathbf{x}|}, \quad \beta(\mathbf{x},\omega) = i\,k_{\mathrm{b}}(\omega)\frac{e^{ik_{\mathrm{b}}(\omega)|\mathbf{x}|}}{4\pi|\mathbf{x}|^2},\\ &\gamma(\mathbf{x},\omega) = \frac{e^{ik_{\mathrm{b}}(\omega)|\mathbf{x}|}-1}{4\pi|\mathbf{x}|^3}.\end{aligned} \tag{5.6}$$

In the operator notation of the previous section our equation is written as

$$\left[\mathrm{d}\left(\mathbb{I}+\frac{1}{3}\chi\right)-A^{\mathrm{s}}\mathrm{d}(\chi)+K\right]u=u^{\mathrm{in}}. \tag{5.7}$$

The operator of this equation acts in the Hilbert space $L^2_{(3)}(\mathbb{R}^3)$ of square-integrable vector-valued functions. This choice of the functional space is physically motivated by the energy considerations. All components of the matrix-valued function $\chi(\mathbf{x},\omega)$ are presumed to be Hölder continuous in $\mathbb{R}^3$, i.e., not only inside the object, but also across its outer boundary. As previously K denotes a compact operator, which in this case is the last integral operator in (5.1) with weakly singular tensors (5.5)–(5.6) in its kernel. Although, in general, weakly singular integral operators are not compact on $\mathbb{R}^3$, the kernel of the last operator in (5.1) contains the contrast function as well, which effectively restricts the spatial support of the domain of the integral operator to D. Therefore, the total operator is compact.

There exist other formulations of this problem. For example, for isotropic scatterers with differentiable constitutive parameters the regularization of the integral equation can be carried out explicitly; see [10], [11]. However, from the discussion of the previous sections we know that the spectra of the original and the regularized operator may be very different.

To find the spectrum of our operator we first need to derive its symbol. The most laborious task here is, obviously, the Fourier transform of the simple singular integral operator. The function $f(\Theta)$ required in (3.5) is in our case

$$f(\Theta)=\frac{1}{4\pi}\left[3\mathbb{Q}-\mathbb{I}\right]. \tag{5.8}$$

It is a matrix-valued function and therefore its Fourier image $F(\tilde{\Theta})$ is also a matrix-valued function. The complete symbol of the electromagnetic volume integral operator was first obtained in [12] using the technique suggested in [8], where $f(\Theta)$ is expanded in terms of spherical harmonics. Comparing the result of [12] with the present formulation we find that

$$F(\tilde{\Theta})=\frac{1}{3}\mathbb{I}-\tilde{\mathbb{Q}}, \tag{5.9}$$

where $\tilde{\mathbb{Q}}=\tilde{\Theta}(\tilde{\Theta}\cdot\,)$, or in matrix notation $\tilde{\mathbb{Q}}=\tilde{\Theta}\tilde{\Theta}^T$. Now using Definition 4.1 and expression (5.2) we obtain the symbol of the electromagnetic volume integral operator for an anisotropic scatterer as

$$\Phi(\mathbf{x},\tilde{\Theta})=\mathbb{I}+\tilde{\mathbb{Q}}\chi(\mathbf{x},\omega)=\mathbb{I}-\tilde{\mathbb{Q}}+\tilde{\mathbb{Q}}\,\eta_{\mathrm{r}}(\mathbf{x},\omega), \tag{5.10}$$

where both χ and $\eta_{\mathrm{r}}=\eta/\eta_{\mathrm{b}}$ are matrix-valued functions and in general do not commute with matrix $\tilde{\mathbb{Q}}$. The inverse of this symbol can be found explicitly as

$$\Phi^{-1}(\mathbf{x},\tilde{\Theta})=\mathbb{I}+\xi^{-1}\tilde{\mathbb{Q}}-\xi^{-1}\tilde{\mathbb{Q}}\,\eta_{\mathrm{r}}(\mathbf{x},\omega), \tag{5.11}$$

where

$$\xi(\mathbf{x},\tilde{\Theta})=\tilde{\Theta}^T\eta_{\mathrm{r}}(\mathbf{x},\omega)\tilde{\Theta}. \tag{5.12}$$

In the isotropic case, where $\eta(\mathbf{x},\omega)$ is a scalar, the inverse of the symbol looks even simpler:

$$\Phi^{-1}_{\mathrm{isotropic}}(\mathbf{x},\tilde{\Theta})=\mathbb{I}-\tilde{\mathbb{Q}}+\tilde{\mathbb{Q}}\,\eta_{\mathrm{r}}^{-1}(\mathbf{x},\omega)=\mathbb{I}+\tilde{\mathbb{Q}}\chi'(\mathbf{x},\omega), \tag{5.13}$$

with χ' given by

$$\chi'(\mathbf{x},\omega) = \frac{\eta_{\mathrm{b}}(\omega)}{\eta(\mathbf{x},\omega)} - 1. \tag{5.14}$$
